Starting Materials. Alkyl halomethyl ether were prepared by Vousi,[18] Lapkina,[19] and Marvel's[20] methods.

*Methoxymethyltriphenylphosphonium Chloride, $[(C_6H_5)_3PCH_2O\text{-}CH_3]Cl$ (**1a**), Methoxymethyltriphenylphosphonium Bromide (**1b**), Methoxymethyltriphenyl phosphonium Iodide $[(C_6H_5)_3PCH_2OCH_3]I$ (**1c**), Ethoxymethyltriphenylphosphonium Bromide (**1d**), and Isopropoxymethyltriphenylphosphonium Bromide (**1e**)*: The correspond-

ing alkyl halomethyl ether (7.55 g (95 mmol dm^{-3}) for **1a**. 39.0 g (314 mmol dm^{-3}) for **1b**, 1.83 g (10.7 mmol dm^{-3}) for **1c**, 14.00 g (101 mmol dm^{-3}) for **1d**, and 18.00 g (118 mmol dm^{-3}) for **1e**) was added to a benzene solution of triphenylphosphine (25 g (95 mmol dm^{-3}) for **1a**, 82.1 g (312 mmol dm^{-3}) for **1b**, 2.8 g (10.7 mmol dm^{-3}) for **1c**, 26.4 g (101 mmol dm^{-3}) for **1d** and 31.0 g (118 mmol dm^{-3}) for **1e**). The solution was then stirred for 24 h at room temperature. The white salt thus precipitated was filtered off, washed with benzene, and dried under vacuum. The crude products were recrystallized from chloroform and ethyl acetate. Yield: 30.0 g (92.1%) for **1a**, 106.0 g (87.7%) for **1b**, 3.47 g (74.7%) for **1c**, 37.1 g (91.5%) for **1d**, and 41.0 g (83.7%) for **1e**. Found: C, 69.89; H, 5.80% for **1a**, C, 61.84; H, 5.06% for **1b**, C, 55.40; H, 4.50% for **1c**, C, 62.73; H, 5.83% for **1d**, and C, 63.54; H, 5.70% for **1e**. Calcd for $C_{20}H_{20}OClP$ (MW 342.81) C, 70.07; H, 5.88 for **1a**, $C_{20}H_{20}OBrP$ (MW 387.26) C, 62.03; H, 5.21 for **1b**, $C_{20}H_{20}OIP$ (MW 434.26) C, 55.32; H, 4.64 for **1c**, $C_{21}H_{22}OBrP$ (MW 401.28) C, 62.87; H, 5.53 for **1d**, and $C_{22}H_{24}OBrP$ (MW 415.33) C, 63.62; H, 5.82% for **1e**. Mp: 198—199 for **1a**, 208—210 for **1b**, 189—190 for **1c**, 227—229 for **1d**, and 190—191 °C for **1e**.

Methoxymethyltriphenylphosphonium Dicyanoargentate (I) (2a), Ethoxymethyltriphenylphosphonium Dicyanoargentate (I) (2b), and Isopropoxymethyltriphenylphosphonium Dicyanoargentate (I) (2c): **1b** (0.387 g, 1.0 mmol dm^{-3}), **1d** (0.40 g, 1.0 mmol dm^{3}), and **1e** (0.415 g, 1.0 mmol dm^{-3}) were dissolved in 1 cm^3 of methanol. Potassium dicyanoargentate (I) (0.2 g, 1.0 mmol dm^{-3}) was dissolved in 0.7 cm^3 of water. The methanol solution was added to an aqueous solution, and the new mixture was stirred; the white complex thus precipitated was filtered, washed with cooled water, and dried. Yield: 0.38 g (81.4%) for **2a**, 0.40 g (83.2%) for **2b**, and 0.40 g (80.8%) for **2c**. Found: C, 56.54; H, 4.52 for **2a**, C, 57.26; H, 4.59 for **2b**, and C, 58.32; H, 4.88% for **2c**. Calcd for $C_{22}H_{20}N_2OAgP$ (MW 467.28) C, 56.55; H, 4.31 for **2a**, $C_{23}H_{22}N_2OAgP$ (MW 481.31) C, 57.40; H, 4.01 for **2b**, and $C_{24}H_{24}N_2OAgP$ (MW 495.33) C, 58.20; H, 4.88% for **2c**. Mp: 122—124 for **2a**, 133—135 for **2b** and 126—127 °C for **2c**.

Methoxymethyltriphenylphosphonium Dicyanoaurate (I) (3a), Ethoxymethyltriphenylphosphonium Dicyanoaurate (I) (3b), and Isopropoxymethyltriphenylphonium Dicyanoaurate (I) (3c): 0.194 g (0.5 mmol dm^{-3}) of **1b**, 0.20 g (0.5 mmol dm^{-3}) of **1c**, and 0.207 g (0.5 mmol dm^{-3}) of **1d** was soluble in 0.5 cm^3 methanol. Potassium dicyanoaurate (I) (0.15 g, 0.5 mmol dm^{-3}) was soluble in water of 0.7 cm^3. The above methanol solution was added to an aqueous solution, the mixture was stirred; the white complex thus precipitated was filtered, washed with cooled water, and dried. Yield: 0.2 g (71.9%) for **3a**, 0.2 g (70.1%) for **3b** and 0.23 g (78.7%) for **3c**. Found: C, 47.52; H, 3.84 for **3a**, C, 48.44; H, 3.99 for **3b**, and C, 49.76; H, 4.30% for **3c**. Calcd for $C_{22}H_{20}N_2OAuP$ (MW 556.38) C, 47.49; H, 3.62 for **3a**, $C_{23}H_{22}N_2OAuP$ (MW 570.41) C, 48.43; H, 3.89 for **3b**, and $C_{24}H_{24}N_2OAuP$ (MW 584.43) C, 49.32; H, 4.14% for **3c**. Mp: 143—145 for **3a**, 150—152 for **3b**, and 143—146 °C for **3c**.

Methyltrihpenylphosphonium Bromide[21] *(5a), Ethyltriphenylphosphonium Bromide*[21a,22] *(5b), and Isobuthyltriphenylphosphonium Bromide*[23] *(5c)*: They were prepared from triphenylphosphine and the corresponding alkyl bromide.

The Reaction of 1b and Base: **1b** (4.20 g, 10.8 mmol dm^{-3}) and sodium amide (0.42 g, 10.8 mmol dm^{-3}) were suspended in dry THF (12 ml) at room temperature, and the mixture was stirred for approximately 1 h. The orange solution[11] was filtered under nitrogen. Dry pentane was added to the solution and cooled. The yellow crystal was filtered under nitrogen and dried. The ^{1}H-NMR spectrum of that crystal in benzene-d_6 did not show the expected signal of the ylide carbanion at room temperature. ^{1}H-NMR spectrum of yellow crystals: δ 3.07 (s, 3H, OCH_3), 4.0 (d, 2H, J=6, PCH_2), 7.2—8.1 (m, 15H, C_6H_5), in C_6D_6.

A solution of 0.13 g of phLi (1.15 mmol dm^{-3}) in toluene-d_8 (5 ml) was slowly added to a suspension of **1b** (0.95 g, 2.45 mmol dm^{-3}) in 2 ml of toluene-d_8 at −70 °C under helium. The orange solution was filtered after 4 h at −70 °C under helium. The orange filtrate did not show the signal of the ylide carbanion from the ^{1}H-NMR spectrum.

The orange solutions from NaH and **1b** in solvents (THF or toluene) at the present temperatures (r.t. or −70 °C) did not show the signals of the ylide carbanion from the ^{1}H-NMR spectra.

A Contribution to the Theory of Pulse Polarography. I. Theory of Current-Potential Curves

Hiroaki MATSUDA

Department of Electronic Chemistry, Graduate School at Nagatsuta, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received May 19, 1980)

A general theory of pulse polarographic current-potential curves is developed for a simple electrode reaction proceeding at the expanding plane electrode. It is shown that when the ratio of the sampling time to the pre-electrolysis time is smaller than 1/30, this condition being satisfied in usual pulse polarographic practice, the equation of current-potential curves can be greatly simplified. The theory developed is applied to the three modes of pulse polarography nowadays practically employed, *i.e.*, normal pulse, scan-reversal pulse and differential pulse polarography. For each mode, the dependence of current-potential curves on the kinetic parameters of electrode reaction as well as on the experimental variables is discussed.

Pulse polarography, originally devised by Barker[1] as an outcome of his work on square wave polarography, has become one of the most powerful and widely used electroanalytical techniques. Nowadays, this technique is successfully employed in routine works for chemical analysis of both inorganic and organic compounds, especially for trace analysis because of its high sensitivity.

A great potentiality of pulse polarography has been recognized also for the characterization of the mechanism of electrode reactions. Thus, the theoretical studies have been made extensively by Los and coworkers[2] and Galvez and Serna[3] for various types of limiting currents, *i.e.*, the diffusion-controlled, kinetic and catalytic currents. However, the theory of current-potential curves has not yet made significant progress and so pulse polarography seems not to realize sufficiently its great potentiality for the study of electrode kinetics. Oldham[4] reported a general theory of the potential pulse electrolysis for the stationary plane electrode and thus his results can not be applied quantitatively to the pulse polarographic conditions using the dropping mercury electrode (DME). Recently, Ruzic[5] has developed a general theory of pulse polarography, but the explicit equations derived by him hold only for the case, in which the pulse duration is short enough so that the d.c. component does not change appreciably during the pulse application. Birke[6] also published a theory of differential pulse polarography, in which he made, however, some simplifying assumption which were not well justified.

In view of the great potentiality of pulse polarography in studies of electrode kinetics, it is desirable to complete the theory of pulse polarographic waves, *i.e.*, to derive the explicit general equation of current-potential curves. In the present paper, we shall attempt such an approach and present explicit equations for several modes of pulse polarography nowadays practically used.

General Equation of Current-Potential Curves

Consider a simple electrode reaction, designated by

$$\mathrm{Ox} + ne \rightleftharpoons \mathrm{Red} \tag{1}$$

where both reactants Ox and Red are assumed to be soluble in solution or in DME. It is also assumed that (a) the electrode reaction (1) proceeds at the expanding plane electrode, which has been recognized as a good mathematical model of DME, and (b) the bulk of the solution contains only the reactant Ox. Then, the concentrations of Ox and Red at the electrode surface, C_O^s and C_R^s, can be expressed by[7]

$$C_O^s = C_O^\circ - \sqrt{\frac{7}{3\pi}}\frac{1}{\sqrt{D_O}}\int_0^t \frac{(i/nFq)u^{2/3}}{\sqrt{t^{7/3}-u^{7/3}}}\mathrm{d}u \tag{2}$$

$$C_R^s = \sqrt{\frac{7}{3\pi}}\frac{1}{\sqrt{D_R}}\int_0^t \frac{(i/nFq)u^{2/3}}{\sqrt{t^{7/3}-u^{7/3}}}\mathrm{d}u \tag{3}$$

where C_O° is the bulk concentration of Ox, D_O, and D_R denote the diffusion coefficients of Ox and Red, respectively, t is the time elapsed after the drop growth has begun, i the instantaneous faradaic current and q the surface area of DME. The faradaic current density is expressed as a function of the electrode potential and of the concentrations of Ox and Red at the electrode surface. According to the usual kinetic theory of electrode processes,[8] we have

$$i = nFq\{\vec{k}C_O^s - \overleftarrow{k}C_R^s\} \tag{4}$$

with

$$\begin{aligned}\vec{k} &= k_0 \exp\left[-(\alpha nF/RT)(E-E^\circ)\right]\\ \overleftarrow{k} &= k_0 \exp\left[\{(1-\alpha)nF/RT\}(E-E^\circ)\right]\end{aligned} \tag{5}$$

where E is the electrode potential, E° the formal standard potential of the reaction (1), α the cathodic transfer coefficient, k_0 the standard rate constant and F, R and T have their usual significance. Introducing Eqs. 2 and 3 into Eq. 4 yields

$$(i/nFq) = \vec{k}C_O^\circ - \sqrt{\frac{7}{3\pi}}\lambda\int_0^t \frac{(i/nFq)u^{2/3}}{\sqrt{t^{7/3}-u^{7/3}}}\mathrm{d}u \tag{6}$$

with

$$\lambda = (\vec{k}/\sqrt{D_O}) + (\overleftarrow{k}/\sqrt{D_R}) = (k_0/\sqrt{D})[\exp(-\alpha\zeta) + \exp\{(1-\alpha)\zeta\}] \tag{7}$$

$$\zeta = (nF/RT)(E - E_{1/2}^r) \tag{8}$$

$$E_{1/2}^r = E^\circ - (RT/nF)\ln\sqrt{D_O/D_R} \tag{9}$$

$$D = D_O^{1-\alpha}D_R^{\alpha} \tag{10}$$

where $E_{1/2}^r$ denotes the polarographic reversible half-wave potential. Equation 6 is the Volterra integral equation of second kind with respect to (i/nFq), whose solution gives the general expression for the current-

potential-time relationship of the potential-controlled electrolysis.

In the pulse polarographic conditions, the potential of DME is set on a constant value E_1 from the beginning of the drop growth to some time τ, and at $t=\tau$ it is stepped up from E_1 to the other constant value E_2. Therefore, if we write the current intensities during the periods $0<t<\tau$ and $\tau<t$ as i_1 and i_2, respectively, the electrolysis condition can be expressed as

$$0<t<\tau: E=E_1,\ i=i_1(t) \tag{11a}$$

$$\tau<t \quad : E=E_2,\ i=i_2(t) \tag{11b}$$

First, consider the electrolysis during the period $0<t<\tau$. Introducing Eq. 11a into Eqs. 6—8 yields

$$(i_1/nFq)=\vec{k}_1C_0^\circ-\sqrt{\frac{7}{3\pi}}\lambda_1\int_0^t\frac{(i_1/nFq)u^{2/3}}{\sqrt{t^{7/3}-u^{7/3}}}du \tag{12}$$

with

$$\lambda_1=(\vec{k}_1/\sqrt{D_O})+(\overleftarrow{k}_1/\sqrt{D_R})$$
$$=(k_0/\sqrt{D})[\exp(-\alpha\zeta_1)+\exp\{(1-\alpha)\zeta_1\}] \tag{13}$$

$$\zeta_1=(nF/RT)(E_1-E_{1/2}^r) \tag{14}$$

The solution of the Volterra integral Eq. 12 was already obtained in a previous paper.[9] We have

$$i_1=\frac{(i_d^c)_{Ilk}}{1+\exp(\zeta_1)}\sqrt{3\pi/7}(\lambda_1\sqrt{t})\psi(\lambda_1\sqrt{t}) \tag{15}$$

where

$$\psi(\lambda_1\sqrt{t})=\sum_{\nu=0}^{\infty}(-1)^\nu a_\nu(\sqrt{3/7}\ \lambda_1\sqrt{t})^\nu \tag{16a}$$

with

$$a_0=1,\ a_\nu=\prod_{\mu=1}^{\nu}\left\{\Gamma\left(\frac{3\mu+7}{14}\right)\Big/\Gamma\left(\frac{3\mu+14}{14}\right)\right\} \tag{16b}$$

and

$$(i_d^c)_{Ilk}=\sqrt{7/3}nFq\sqrt{D_O}C_0^\circ/\sqrt{\pi t} \tag{17}$$

In the above equations, Γ denotes Euler's Gamma function and $(i_d^c)_{Ilk}$ the instantaneous diffusion current of d.c. polarography given by the Ilkovic equation. For numerical calculations of the function $\psi(\lambda_1\sqrt{t})$, it is convenient to use the following approximate equation derived previously,[10] which holds in the whole range of the argument within an error of 0.2%:

$$\psi(\lambda_1\sqrt{t})=\sqrt{\frac{7}{3\pi}}\frac{g(\lambda_1\sqrt{t})/(\lambda_1\sqrt{t})}{1+g(\lambda_1\sqrt{t})} \tag{18}$$

with

$$g(\lambda_1\sqrt{t})=0.293(\lambda_1\sqrt{t})$$
$$\times[\tanh\{1.3\log(\lambda_1\sqrt{t}/1.61)\}+4.96] \tag{19}$$

Next, we shall obtain the solution of the Volterra integral Eq. 6 for the period $t>\tau$. We write, thereafter, $\tau+\theta$ instead of t. Then, introducing Eqs. 11a and 11b into Eq. 6, we have

$$(i_2/nFq)=\vec{k}_2C_0^\circ-\sqrt{7/3\pi}\ \lambda_2(I_1+I_2) \tag{20}$$

with

$$I_1=\int_0^\tau\frac{(i_1/nFq)u^{2/3}}{\sqrt{(\tau+\theta)^{7/3}-u^{7/3}}}du \tag{21}$$

$$I_2=\int_\tau^{\tau+\theta}\frac{(i_2/nFq)u^{2/3}}{\sqrt{(\tau+\theta)^{7/3}-u^{7/3}}}du \tag{22}$$

where

$$\lambda_2=(\vec{k}_2/\sqrt{D_O})+(\overleftarrow{k}_2/\sqrt{D_R})$$
$$=(k_0/\sqrt{D})[\exp(-\alpha\zeta_2)+\exp\{(1-\alpha)\zeta_2\}] \tag{23}$$

$$\zeta_2=(nF/RT)(E_2-E_{1/2}^r) \tag{24}$$

In appendix, the integrals I_1 and I_2 will be evaluated as a power series of $\sqrt{\theta/\tau}$ under the assumption that $\theta/\tau<1$. Thus, introducing Eqs. A-8 and A-9 into Eq. 20, we obtain, after some rearrangements,

$$(i_2/nFq)=\sqrt{D_O}C_O^\circ\left[\frac{1}{1+\exp(\zeta_2)}-\frac{1}{1+\exp(\zeta_1)}\right]\lambda_2$$
$$+\left[\frac{i_1(\tau)}{nFq(\tau)}\right]\left[\frac{\lambda_2}{\lambda_1}\right]\left\{1+\left[\frac{d\ln\psi}{d\ln\tau}\right]\left[\frac{\theta}{\tau}\right]+O([\theta/\tau]^2)\right\}$$
$$+\left[\frac{i_1(\tau)}{nFq(\tau)}\right]\frac{2}{\sqrt{\pi}}(\lambda_2\sqrt{\theta})$$
$$\times\left\{1-\frac{2}{3}\left[\frac{1}{6}-\frac{d\ln\psi}{d\ln\tau}\right]\left[\frac{\theta}{\tau}\right]+O([\theta/\tau]^2)\right\}$$
$$-\frac{\lambda_2}{\sqrt{\pi}}\int_0^\theta\frac{(i_2/nFq)}{\sqrt{\theta-u}}\left\{1-\frac{1}{3}\left[\frac{\theta-u}{\tau}\right]+O([\theta/\tau]^2)\right\}du \tag{25}$$

where $O([\theta/\tau]^2)$ denotes the sum of the second and higher order terms with respect to (θ/τ). Now, we expand (i_2/nFq) into a power series of $\sqrt{\theta/\tau}$. Thus

$$(i_2/nFq)=\phi_0+\phi_1+\phi_2+\phi_3+\cdots\cdots \tag{26}$$

where the function ϕ_j (j=0, 1, 2, 3, ···) corresponds to the order of $(\theta/\tau)^{j/2}$. Substituting Eq. 26 into Eq. 25 and equating the coefficients of like powers of $\sqrt{\theta/\tau}$ yields the following set of integral equations:

$$\phi_0=\sqrt{D_0}\,C_0^\circ\left[\frac{1}{1+\exp(\zeta_2)}-\frac{1}{1+\exp(\zeta_1)}\right]\lambda_2$$
$$+\left[\frac{i_1}{nFq}\right]\left[\frac{\lambda_2}{\lambda_1}\right]-\frac{\lambda_2}{\sqrt{\pi}}\int_0^\theta\frac{\phi_0(u)}{\sqrt{\theta-u}}du \tag{27}$$

$$\phi_1=\frac{2}{\sqrt{\pi}}\left[\frac{i_1}{nFq}\right](\lambda_2\sqrt{\tau})\sqrt{\theta/\tau}-\frac{\lambda_2}{\sqrt{\pi}}\int_0^\theta\frac{\phi_1(u)}{\sqrt{\theta-u}}du \tag{28}$$

$$\phi_2=\left[\frac{\lambda_2}{\lambda_1}\right]\left[\frac{i_1}{nFq}\right]\left[\frac{d\ln\psi}{d\ln\tau}\right]\left[\frac{\theta}{\tau}\right]+\frac{1}{3\tau}\frac{\lambda_2}{\sqrt{\pi}}$$
$$\times\int_0^\theta\sqrt{\theta-u}\,\phi_0(u)du-\frac{\lambda_2}{\sqrt{\pi}}\int_0^\theta\frac{\phi_2(u)}{\sqrt{\theta-u}}du \tag{29}$$

$$\phi_3=-\frac{4}{3\sqrt{\pi}}\left[\frac{i_1}{nFq}\right](\lambda_2\sqrt{\tau})\left[\frac{1}{6}-\frac{d\ln\psi}{d\ln\tau}\right](\theta/\tau)^{3/2}$$
$$+\frac{1}{3\pi}\frac{2}{\sqrt{\pi}}\int_0^\theta\sqrt{\theta-u}\,\phi_1(u)du$$
$$-\frac{\lambda_2}{\sqrt{\pi}}\int_0^\theta\frac{\phi_3(u)}{\sqrt{\theta-u}}du \tag{30}$$

This set of integral equations can easily be solved by applying the method of Laplace transformation.[11] Thus, we obtain for (i_2/nFq), after performing some calculations,

$$(i_2/nFq)=\frac{(i_d^c)_{Cott}}{nFq}\left[\frac{1}{1+\exp(\zeta_2)}-\frac{1}{1+\exp(\zeta_1)}\right]\Phi(\lambda_2\sqrt{\theta})$$
$$\times\left\{1-\frac{1}{3}\left(\frac{\theta}{\tau}\right)\left[1+\frac{F_2(\lambda_2\sqrt{\theta})}{F_0(\lambda_2\sqrt{\theta})}\right]+O([\theta/\tau]^2)\right\}$$
$$+\left[\frac{i_1(\tau)}{nFq(\tau)}\right]\{(\lambda_2/\lambda_1)-1\}F_0(\lambda_2\sqrt{\theta})$$
$$\times\left\{1-\frac{1}{3}\left(\frac{\theta}{\tau}\right)\left[1+\frac{F_2(\lambda_2\sqrt{\theta})}{F_0(\lambda_2\sqrt{\theta})}\left(1+3\frac{d\ln\psi}{d\ln\tau}\right)\right]\right.$$
$$\left.+O([\theta/\tau]^2)\right\}$$
$$+\left[\frac{i_1(\tau)}{nFq(\tau)}\right]\left\{1+\left(\frac{\theta}{\tau}\right)\left[\frac{d\ln\psi}{d\ln\tau}\right]+O([\theta/\tau]^2)\right\} \tag{31}$$

with

$$(i_d^c)_{Cott} = nFq(\tau+\theta)\sqrt{D_0}C_0^\circ/\sqrt{\pi\theta} \quad (32)$$

$$F_0(\xi) = \exp(\xi^2)\,\mathrm{erfc}(\xi) \quad (33)$$

$$F_2(\xi) = \xi^{-2}[1-(2/\sqrt{\pi})\,\xi - \exp(\xi^2)\mathrm{erfc}(\xi] \quad (34)$$

$$\Phi(\xi) = \sqrt{\pi}\,\xi\,F_0(\xi) = \sqrt{\pi}\,\xi\exp(\xi^2)\,\mathrm{erfc}(\xi) \quad (35)$$

where $(i_d^c)_{cott}$ denotes the diffusion current at the stationary plane electrode given by the Cottrell equation and erfc the complementary error function. The pulse polarographic current is in general measured as a difference between i_2 at $t=\tau+\theta_s$ (θ_s: sampling time) and i_1 at $t=\tau$. Therefore, taking into account the fact that the ratio of the surface area of DME at $t=\tau+\theta_s$ to that of $t=\tau$ can be expanded into the following power series of (θ_s/τ):

$$q(\tau+\theta_s)/q(\tau) = 1 + (2/3)(\theta_s/\tau) + O([\theta_s/\tau]^2), \quad (36)$$

we obtain for the pulse polarographic current, i_{pulse},

$$\begin{aligned} i_{pulse} &= i_2(\tau+\theta_s) - i_1(\tau) \\ &= (i_d^c)_{Cott}\left[\frac{1}{1+\exp(\zeta_2)} - \frac{1}{1+\exp(\zeta_1)}\right]\Phi(\lambda_2\sqrt{\theta_s}) \\ &\quad\times\left\{1-\frac{1}{3}\left[\frac{\theta_s}{\tau}\right]\left[1+\frac{F_2(\lambda_2\sqrt{\theta_s})}{F_0(\lambda_2\sqrt{\theta_s})}\right] + O([\theta_s/\tau]^2)\right\} \\ &\quad + i_1(\tau)\{(\lambda_2/\lambda_1) - 1\}F_0(\lambda_2\sqrt{\theta_s}) \\ &\quad\times\left\{1+\frac{1}{3}\left[\frac{\theta_s}{\tau}\right]\left[1-\frac{F_2(\lambda_2\sqrt{\theta_s})}{F_0(\lambda_2\sqrt{\theta_s})}\left(1+3\frac{\mathrm{d}\ln\phi}{\mathrm{d}\ln\tau}\right)\right]\right. \\ &\quad\left. + O([\theta_s/\tau]^2)\right\} \\ &\quad + i_1(\tau)\left\{\left[\frac{\theta_s}{\tau}\right]\left[\frac{2}{3}+\frac{\mathrm{d}\ln\phi}{\mathrm{d}\ln\tau}\right] + O([\theta_s/\tau]^2)\right\} \end{aligned} \quad (37)$$

In usual pulse polarographic practice, the values of τ and θ_s employed are of the orders of second and millisecond, respectively, *i.e.*, $\tau\simeq$ 1—6 s and $\theta_s\simeq$ 1—100 ms. Furthermore, the following relations hold in the whole range of the corresponding arguments:

$$-1 \geqq \frac{F_2(\lambda_2\sqrt{\theta_s})}{F_0(\lambda_2\sqrt{\theta_s})} \geqq -2 \text{ and } 0 \geqq \frac{\mathrm{d}\ln\phi(\lambda_1\sqrt{\tau})}{\mathrm{d}\ln\tau} \geqq -\frac{1}{2}.$$

Therefore, for $(\theta_s/\tau)\leqq 1/30$, which may be satisfied in usual experimental conditions, Eq. 37 can be greatly simplified, as follows:

$$\begin{aligned} i_{pulse} &= (i_d^c)_{Cott}\left[\frac{1}{1+\exp(\zeta_2)} - \frac{1}{1+\exp(\zeta_1)}\right]\Phi(\lambda_2\sqrt{\theta_s}) \\ &\quad + i_1(\tau)\{(\lambda_2/\lambda_1) - 1\}F_0(\lambda_2\sqrt{\theta_s}) \end{aligned} \quad (38)$$

This equation provides a general expression of the current-potential profiles for pulse polarography. Several modes of pulse polarography, nowadays practically used, are incorporated in this general equation. In the following, we shall further simplify Eq. 38 by introducing the experimental conditions corresponding to the mode employed.

Normal Pulse Polarography

In normal pulse polarography, the initial potential E_1 is anodic of the reduction wave and the scan of the potential E_2 is made to the cathodic direction. Therefore, we have E_1→sufficiently more anodic potential than $E_{1/2}^r$. Thus

$$\zeta_1 \longrightarrow +\infty,\ \lambda_1 \longrightarrow +\infty \text{ and } i_1(\tau) \longrightarrow 0.$$

Introducing the above conditions into Eq. 38 yields

$$i_{n\text{-}pulse}^c = \frac{(i_d^c)_{Cott}}{1+\exp(\zeta_2)}\Phi(\lambda_2\sqrt{\theta_s}) \quad (39)$$

where $i_{n\text{-}pulse}^c$ denotes the normal pulse polarographic current. This is the general equation of current-potential curves for normal pulse polarography. For the variations of current-potential curves with the kinetic parameters of electrode reaction, see Fig. 1. Equation 39 is exactly the same as derived by a number of authors[12] for the potentiostatic experiments at the stationary plane electrode. In the potentiostatic method, the variation of faradaic current with time at a constant potential is examined, whereas in pulse polarography the faradaic current at a given time θ_s is measured as a function of the electrode potential. Therefore, in order to examine the behavior of pulse polarographic waves, it is convenient to derive the expression similar to the log-plot in d.c. polarography.

First, consider the limiting case of reversible waves. The function $\Phi(\xi)$ is equal to unity within an error of 2%, when $\xi\geqq 5$. Therefore, if the condition

$$(k_0\sqrt{\theta_s}/\sqrt{D}) \geqq 5\times\alpha^\alpha(1-\alpha)^{1-\alpha} \quad (40)$$

is satisfied, Eq. 39 can be simplified into

$$i_{n\text{-}pulse}^c = (i_d^c)_{Cott}/[1+\exp(\zeta_2)] \quad (41a)$$

or solving the above equation with respect to E_2 yields

$$E_2 = E_{1/2}^r - (RT/nF)\ln[x/(1-x)] \quad (41b)$$

with

$$x = i_{n\text{-}pulse}^c/(i_d^c)_{Cott} \quad (42)$$

This is the equation for the log-plot of reversible waves, which is of the same form as for d.c. polarography.

Next, consider the case, $(k_0\sqrt{\theta_s}/\sqrt{D})\leqq 5\times\alpha^\alpha(1-\alpha)^{1-\alpha}$, in which the irreversibility appears in the pulse polarograms. Fortunately, Oldham and Parry[13] derived the convenient approximate equation for the inverse function of $\Phi(\xi)$, as follows:

$$\xi = \frac{\sqrt{3}}{4}\left\{\frac{1.75+\Phi^2}{1-\Phi}\right\}^{1/2}\Phi \quad (43)$$

Therefore, after combining Eq. 39 with Eq. 43 and performing some rearrangements, we obtain

$$E_2 = E^* - \frac{RT}{\alpha nF}\ln\left\{x\left[\frac{1.75+x^2(1+\exp\zeta_2)^2}{1-x(1+\exp\zeta_2)}\right]^{1/2}\right\} \quad (44)$$

with

$$E^* = E_{1/2}^r + \frac{RT}{\alpha nF}\ln\left[\frac{4}{\sqrt{3}}\frac{k_0\sqrt{\theta_s}}{\sqrt{D}}\right] \quad (45)$$

Equation 44 suggests a new log-plot for the normal pulse polarographic waves.

Now consider the pulse-polarographically quasi-reversible waves, for which the condition

$$5\times\alpha^\alpha(1-\alpha)^{1-\alpha} \geqq (k_0\sqrt{\theta_s}/\sqrt{D}) \geqq \exp[-4(1+\alpha)] \quad (46)$$

is satisfied. In general, the d.c. polarographic wave exhibits higher reversibility than the corresponding pulse polarographic wave does, because of the difference in electrolysis time scales employed in two methods. Therefore, from the analysis of d.c. polarographic wave corresponding to the pulse-polarographically quasi-

reversible wave, we can determine the reversible half-wave potential $E^{r}_{1/2}$ by using the extrapolation methods.[14,15] Then, the log-term in Eq. 44 becomes the experimentally accessible quantity. Thus, if we plot $\log (x[\{1.75+x^2(1+\exp\zeta_2)^2\}/\{1-x(1+\exp\zeta_2)\}]^{1/2})$ against E_2, we obtain a straight line, which has the reciprocal slope of $(2.3RT/\alpha nF)$ and intersects with the zero-line at $E_2=E^*$, provided that the transfer coefficient α may be regarded as constant in the potential region concerned. Therefore, we can determine the kinetic parameters of electrode reaction from the values of the reciprocal slope and of the potential E^*.

For the irreversible waves, which satisfy the condition

$$(k_0\sqrt{\theta_s}/\sqrt{D}) \leqq \exp[-4(1+\alpha)], \tag{47}$$

the term $\exp(\zeta_2)$ in Eq. 44 can be neglected compared with unity in the whole potential region concerned. Therefore, Eq. 44 can be reduced to

$$E_2 = E^* - \frac{RT}{\alpha nF} \ln\left\{x\left(\frac{1.75+x^2}{1-x}\right)^{1/2}\right\} \tag{48}$$

where E^* is the half-wave potential of irreversible wave. This is the same equation as that previously proposed by Oldham and Parry[13] for totally irreversible waves. Equation 48 indicates that the plot of $\log [x\{(1.75+x^2)/(1-x)\}^{1/2}]$ *vs.* E_2 can be made without any knowledge of $E^{r}_{1/2}$ and thus the kinetic parameters of electrode reaction can be determined from this plot in the same way as described above.

According to the modern theory of electron transfer at electrodes,[16] it is shown that the transfer coefficient may depend on the electrode potential. In such cases, it is better to rewrite Eq. 44 as

$$\ln \vec{k}_2 = -\ln\left[\frac{4}{\sqrt{3}}\frac{\sqrt{\theta_s}}{\sqrt{D_0}}\right] + \ln\left\{x\left[\frac{1.75+x^2(1+\exp\zeta_2)^2}{1-x(1+\exp\zeta_2)}\right]^{1/2}\right\} \tag{49}$$

which can be derived from Eq. 44 by taking into account the relations given by Eqs. 5, 9, and 10. Equation 49 indicates that the plot of $\log (x[\{1.75+x^2(1+\exp\zeta_2)^2\}/\{1-x(1+\exp\zeta_2)\}]^{1/2})$ *vs.* E_2 manifests the potential dependence of the cathodic rate constant $\vec{k}_2$. Thus, this log-plot may appear as bent toward the potential axis, if the transfer coefficient shows such a potential dependence as predicted by the modern theory of electron transfer at electrodes.[17]

Scan-reversal Pulse Polarography

In order to examine the reversibility of electrode reactions, Oldham and Parry[18] presented the scan-reversal pulse polarographic technique and discussed two limiting cases, *i.e.*, the behavior of reversible and totally irreversible waves. Since the general case is incorporated in Eq. 38, we shall derive a general equation for the scan-reversal pulse polarographic current, $i^{a}_{r\text{-pulse}}$.

In scan-reversal pulse polarography, the initial potential E_1 is set on the cathodic diffusion current plateau and the potential E_2 is scanned from the cathodic plateau to the anodic direction. Hence we have

$E_1 \longrightarrow$ sufficiently more cathodic potential than $E^{r}_{1/2}$.

Thus

$$\zeta_1 \longrightarrow -\infty,\ \lambda_1 \longrightarrow +\infty \text{ and } i_1(\tau) \longrightarrow (i^{c}_{d})_{IIk}.$$

Substituting the above conditions into Eq. 38 yields

$$i^{a}_{r\text{-pulsd}} = -\frac{(i^{c}_{d})_{Cott}}{1+\exp(-\zeta_2)}\Phi(\lambda_2\sqrt{\theta_s}) - (i^{c}_{d})_{IIk}F_0(\lambda_2\sqrt{\theta_s}) \tag{50}$$

This is the general expression of current-potential curves in scan-reversal pulse polarography. The first term on the right hand side of Eq. 50 manifests the anodic normal pulse polarographic wave, as can readily be seen from the comparison with Eq. 39, whereas the second term indicates the effects of the pre-electrolysis at the potential corresponding to the cathodic diffusion current plateau during the period 0—τ.

In order to visualize the variations of wave-shapes in dependence of the kinetic parameters of electrode reaction, the normalized current-potential curves, *i.e.*, $i^{a}_{r\text{-pulse}}/(i^{c}_{d})_{Cott}$ *vs.* E_2 curves, were calculated numerically for a series of values of $(k_0\sqrt{\theta_s}/\sqrt{D})$ under the assumption that $n=2$, $\alpha=0.5$, $\theta_s/\tau=0.01$ and $T=25$ °C. The results obtained are shown in Fig. 1, in which the cathodic normal pulse polarographic waves are also given for comparison.

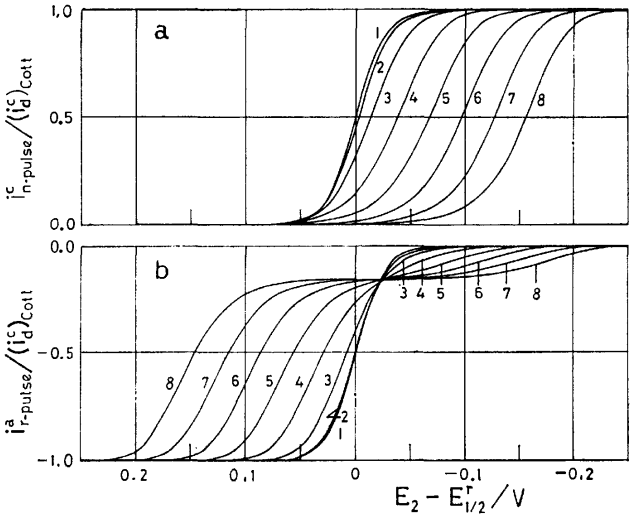

Fig. 1. Current-potential curves of normal pulse and scan-reversal pulse polarography.
(a) Normal, (b) scan-reversal. Values of $\log(k_0\sqrt{\theta_0}/\sqrt{D})$: (1)$\geqq$0.5 (reversible), (2) 0.0, (3) −0.5, (4) −1.0, (5) −1.5, (6) −2.0, (7) −2.5, (8) −3.0.

In the following, we shall examine the general Eq. 50. First, consider the reversible case, in which the condition (40) is fulfilled. In this case, the function $\Phi(\lambda_2\sqrt{\theta_s})$ in the first term on the right hand side of Eq. 50 is reduced to unity and the second term can be neglected within an error of *ca.* 3%. Hence we have for the reversible waves of scan-reversal pulse polarography

$$i^{a}_{r\text{-pulse}} = -(i^{c}_{d})_{Cott}/[1+\exp(-\zeta_2)] \tag{51}$$

Equation 51 indicates that the reversible scan-reversal pulse polarographic wave has the same wave-height

and the same half-wave potential as the reversible normal pulse polarographic wave does.

When values of the parameter $(k_0\sqrt{\theta_s}/\sqrt{D})$ are decreased, both the irreversibility and the effect of the second term on the right hand side of Eq. 50 appear and hence the portions of the wave, which are lower than or higher than $(i_d^c)_{Ilk}$, shift toward the more cathodic or the more anodic potential, respectively, as can readily be seen from Fig. 1. Thus the wave appears to have a drawn-out shape. Finally, when values of $(k_0\sqrt{\theta_s}/\sqrt{D})$ become so small that the condition (47) is fulfilled, the wave splits definitely into two waves. This behavior of the wave can readily be understood if recalling the fact that the pulse polarographic current is measured as the difference between the currents before and after the pulse application. Thus, the first wave does not correspond to the true anodic process but to the cathodic one, and in the potential region of the second wave occurs the anodic process.

Now such irreversible cases will be examined in some detail. The first and second waves appear at the potentials sufficiently more cathodic and more anodic than $E_{1/2}^r$, respectively, so that in the potential region corresponding to the first wave Eq. 50 can be reduced to

$$i_{r\text{-pulse}}^a = -(i_d^c)_{Ilk} F_0(\lambda_2\sqrt{\theta_s}) \tag{52}$$

This is the equation for the current-potential curve of the first wave. When the potential E_2 is placed near $E_{1/2}^r$, the values of $(\lambda_2\sqrt{\theta_s})$ become very small and thus the function $F_0(\lambda_2\sqrt{\theta_s})$ approarches to unity. Hence the limiting current of the first wave, $(i_1^a)_{1st}$, can be given by

$$(i_1^a)_{1st} = -(i_d^c)_{Ilk}. \tag{53}$$

This equation indicates that the height of the first wave is equal to that of d.c. polarographic wave, expressed by the Ilkovic equation. The half-wave potential of the first wave $(E_{1/2}^r)_{1st}$, can be obtained by equating $i_{r\text{-pulse}}^a$ to $-(1/2)(i_d^c)_{Ilk}$. Thus, by recalling the facts that the function $F_0(\xi)$ is equal to 1/2 at $\xi=0.770$ and that in this potential region $(\lambda_2\sqrt{\theta_s})$ can be written as $(k_0\sqrt{\theta_s}/\sqrt{D})\exp[-(\alpha nF/RT)(E_2-E_{1/2}^r)]$, we have

$$(E_{1/2}^a)_{1st} = E_{1/2}^r + \frac{RT}{\alpha nF}\ln[1.30\,(k_0\sqrt{\theta_s}/\sqrt{D})] \tag{54}$$

Hence the half-wave potential of the first wave shifts toward the cathodic direction with decreasing values of $(k_0\sqrt{\theta_s}/\sqrt{D})$. On the other hand, the potential region corresponding to the second wave is sufficiently more anodic than $E_{1/2}^r$, so that Eq. 50 can be reduced to

$$i_{r\text{-pulse}}^a = -(i_d^c)_{Cott}\Phi(\lambda_2'\sqrt{\theta_s}) - (i_d^c)_{Ilk}F_0(\lambda_2'\sqrt{\theta_s}) \tag{55}$$

with

$$\lambda_2'\sqrt{\theta_s} = (k_0\sqrt{\theta_s}/\sqrt{D}) \times \exp[\{(1-\alpha)\,nF/RT\}(E_2-E_{1/2}^r)] \tag{56}$$

where it should be kept in mind that $i_{r\text{-pulse}}^a$ in Eq. 50 denotes the total anodic current measured from the zero-line. If the current of the second wave is measured from the limiting current plateau of the first wave, we may write the equation for the current-potential curves of the second wave, as follows:

$$(i_{r\text{-pulse}}^a)_{2nd} = -(i_d^c)_{Cott}\Phi(\lambda_2'\sqrt{\theta_s}) + (i_d^c)_{Ilk}[1-F_0(\lambda_2'\sqrt{\theta_s})] \tag{57}$$

The limiting current of the second wave, $(i_1^a)_{2nd}$, can be derived by inserting the condition $(nF/RT)(E_2-E_r^{1/2})\to+\infty$ into Eq. 57. Hence

$$(i_1^a)_{2nd} = -[(i_d^c)_{Cott} - (i_d^c)_{Ilk}]. \tag{58}$$

The half-wave potential of the second wave, $(E_{1/2}^a)_{2nd}$, may be obtained by substituting the condition $(i_{r\text{-pulse}}^a)_{2nd}=(1/2)(i_1^a)_{2nd}$ into Eq. 57. Thus, we have, after performing some rearrangements,

$$[1-2\,\Phi(\gamma)]/[2F_0(\gamma)-1] = (i_d^c)_{Ilk}/(i_d^c)_{Cott} \tag{59}$$

with

$$\gamma = (k_0\sqrt{\theta_s}/\sqrt{D})\exp[\{(1-\alpha)nF/RT\} \times \{(E_{1/2}^a)_{2nd} - E_{1/2}^r\}] \tag{60}$$

The values of γ, which satisfy Eq. 59, may be calculated numerically as a function of $[(i_d^c)_{Ilk}/(i_d^c)_{Cott}]$. Since $(\theta_s/\tau)<1/30$ for usual pulse polarographic conditions, numerical calculations were performed for the range:

$$0 < (i_d^c)_{Ilk}/(i_d^c)_{Cott} < 0.3$$

The results obtained indicates that γ can be expressed by the following equation within errors of ±0.001 in the absolute values of γ:

$$\gamma = 0.433 - 0.205\,[(i_d^c)_{Ilk}/(i_d^c)_{Cott}] - 0.16\,[(i_d^c)_{Ilk}/(i_d^c)_{Cott}]^2 \tag{61}$$

Taking the logarithms of both sides of Eq. 60 yields for the half-wave potential of the second wave

$$(E_{1/2}^a)_{2nd} = E_{1/2}^r - \frac{RT}{(1-\alpha)nF}\ln[(1/\gamma)(k_0\sqrt{\theta_s}/\sqrt{D})], \tag{62}$$

where γ is given by Eq. 61. Hence, the half-wave potential of the second wave shifts toward the anodic direction with decreasing values of $(k_0\sqrt{\theta_s}/\sqrt{D})$.

Comparison of Eq. 58 with Eq. 53 yields for the ratio of the height of the first wave to that of the second wave

$$(i_1^a)_{1st}/(i_1^a)_{2nd} = (i_d^c)_{Ilk}/[(i_d^c)_{Cott} - (i_d^c)_{Ilk}] = 1/[\sqrt{(3/7)(\tau/\theta_s)}-1] \tag{63}$$

Thus, for usual pulse polarographic conditions, *i.e.*, $(\tau/\theta_s)\sim100$, we have $(i_1^a)_{1st} : (i_1^a)_{2nd}\approx1 : 6$. Further, the difference between the half-wave potentials of the first and second waves can be obtained from Eqs. 54 and 62, as follows:

$$(E_{1/2}^a)_{2nd} - (E_{1/2}^a)_{1st} = -\frac{RT}{\alpha(1-\alpha)nF}\ln\left[\frac{1.30^{1-\alpha}}{\gamma^\alpha}\,\frac{k_0\sqrt{\theta_s}}{\sqrt{D}}\right] \tag{64}$$

Equation 64 indicates that the difference between two half-wave potentials is increased with decreasing values of $(k_0\sqrt{\theta_s}/\sqrt{D})$ and thus it can be employed as an index indicating the degree of irreversibility of the electrode reaction concerned.

Differential Pulse Polarography

In differential pulse polarography, both the potentials E_1 and E_2 are scanned simultaneously toward the cathodic direction with their difference, $E_1-E_2\equiv\Delta E$, being kept constant. Hence, after performing some calculations by taking into account Eqs. 15, 17, 32, and 35, Eq. 38 can be transformed into

$$i_{\text{dif-pulse}} = (i_d^c)_{\text{Cott}} \frac{\sinh(\Delta\zeta/2)}{\cosh(\zeta_m)+\cosh(\Delta\zeta/2)} F_{\text{dcp}}\,\Phi(\lambda_2\sqrt{\theta_s}) \tag{65}$$

with

$$F_{\text{dcp}} = 1 + \frac{\exp(-\zeta_m)\sinh(\alpha\Delta\zeta/2)-\sinh([1-\alpha]\Delta\zeta/2)}{\exp(\alpha\Delta\zeta/2)\sinh(\Delta\zeta/2)} \times \psi(\lambda_1\sqrt{\tau}) \tag{66}$$

$$\Delta\zeta = \zeta_1 - \zeta_2 = (nF/RT)(E_1 - E_2) = (nF/RT)\Delta E \tag{67}$$

$$\zeta_m = (\zeta_1 + \zeta_2)/2 = (nF/RT)(E_m - E^r_{1/2}) \tag{68}$$

$$E_m = (E_1 + E_2)/2 = E_1 - (\Delta E/2) \tag{69}$$

where $\psi(\lambda_1\sqrt{\tau})$ is defined by Eq. 16 and can be evaluated with sufficient accuracy by using the approximate Eq. 18. Further it should be noticed that the potential E_m defined by Eq. 69 is by $(\Delta E/2)$ more negative than the potential E_1 which is frequently employed as the potential axis of differential pulse polarograms. Equation 65 is the general expression for the differential pulse polarographic waves, which holds for any values of the pulse height ΔE. If ΔE is smaller than *ca.* $5/n$ mV, Eq. 65 can be simplified into

$$i_{\text{dif-pulse}} = \frac{(i_d^c)_{\text{Cott}}\Delta\zeta}{4\cosh^2(\zeta_m/2)} F_{\text{dcp}}\Phi(\lambda_m\sqrt{\theta_s}) \tag{70}$$

with

$$F_{\text{dcp}} = 1 + [\alpha\exp(-\zeta_m) - (1-\alpha)]\psi(\lambda_m\sqrt{\tau}) \tag{71}$$

$$\lambda_m = (k_0/\sqrt{D})[\exp(-\alpha\zeta_m) + \exp\{(1-\alpha)\zeta_m\}] \tag{72}$$

In order to visualize the behavior of differential pulse polarographic waves in dependence of the kinetic parameters of electrode reaction, numerical calculations using the general Eq. 65 were performed for a series of values of $(k_0\sqrt{\theta_s}/\sqrt{D})$ and α under the assumption that $n=2$, $\Delta E=10$ mV, $\theta_s/\tau=0.01$ and $T=25$ °C. In Fig. 2, the normalized differential pulse polarographic currents obtained for $\alpha=0.5$ and 0.3 are plotted against the potential E_m. It can be seen from Fig. 2 that the $i_{\text{dif-pulse}}$—E_m curves have generally one peak, but when $\alpha<0.5$ and $(k_0\sqrt{\theta_s}/\sqrt{D})\approx 0.1-0.02$, they show some anomaly, *i.e.*, they have a shoulder or two peaks, as can be seen from the curves 4, 5, and 6 in Fig. 2(b). Further, we can see that the peak currents decrease at first very rapidly with decreasing the value of $(k_0\sqrt{\theta_s}/\sqrt{D})$ and then approach to a limiting value which does not depend on the standard rate constant k_0 (see Eq. 88). This behavior of differential pulse polarographic waves in dependence of the kinetic parameters is quite similar to that of square wave polarographic waves, which are given in Fig. 3 of Ref. 19.

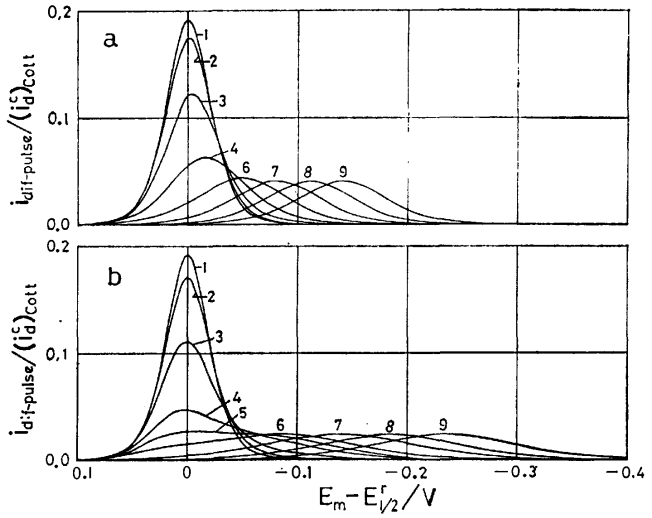

Fig. 2. Current-potential curves of differential pulse polarography.
(a) $\alpha=0.5$, (b) $\alpha=0.3$. Values of log $(k_0\sqrt{\theta_s}/\sqrt{D})$: (1)$\geqq$0.5 (reversible), (2) 0.0, (3) −0.5, (4) −1.0, (5) −1.25, (6) −1.5, (7) −2.0, (8) −2.5, (9) −3.0.

In the following, we shall examine the two limiting cases in some detail. First, consider the reversible limiting case, in which the condition (40) is fulfilled. In this case, the functions F_{dcp} and $\Phi(\lambda_2\sqrt{\theta_s})$ both approarch to unity. Hence Eq. 65 can be reduced to

$$i_{\text{dif-pulse}} = (i_d^c)_{\text{Cott}} \frac{\sinh(\Delta\zeta/2)}{\cosh(\zeta_m)+\cosh(\Delta\zeta/2)}. \tag{73}$$

This is the equation for the reversible waves of differential pulse polarography, which should be compared with Eq. 75 or 76 of Ref. 7 for the reversible square wave polarographic waves. Now we determine the three parameters which characterize the wave-shape, *i.e.*, the peak potential $(E_m)_p$, the peak current $(i_{\text{dif-pulse}})_p$ and the half-peak width $\Delta(E_m)_{p/2}$. As can easily be seen from Eq. 73, a maximum appears at $\zeta_m=0$. Hence, the peak potential can be given by

$$(E_m)_p = E^r_{1/2}. \tag{74}$$

Thus the peak potential coinsides with the reversible half-wave potential. The peak current can be derived by inserting Eq. 74 into Eq. 73, as follows:

$$(i_{\text{dif-pulse}})_p = (i_d^c)_{\text{Cott}}\tanh(\Delta\zeta/4) = (i_d^c)_{\text{Cott}}\tanh(nF\Delta E/4RT) \tag{75}$$

Equation 75 reveals that the normalized peak current, $(i_{\text{dif-pulse}})_p/(i_d^c)_{\text{Coff}}$, is increased in proportion to the pulse height ΔE for $(nF\Delta E/RT)<1$ and it approarches to the limiting value of unity when $(nF\Delta E/RT)>10$. The half-peak width can be defined as the difference between two potentials which satisfy the condition:

$$i_{\text{dif-pulse}} = (1/2)(i_{\text{dif-pulse}})_p.$$

Thus, introducing Eqs. 73 and 75 into the above condition and performing some calculations yields for such potentials

$$(E_m)_{p/2} = E^r_{1/2} \pm (RT/nF) \times \cosh^{-1}[2 + \cosh(nF\Delta E/2RT)]. \tag{76}$$

Hence the half-peak width $\Delta(E_m)_{p/2}$ can be expressed as

$$\Delta(E_m)_{p/2} = (2RT/nF) \times \cosh^{-1}[2 + \cosh(nF\Delta E/2RT)]. \tag{77}$$

For $(nF\Delta E/RT)<0.8$, Eq. 77 can be reduced to

$$\Delta(E_m)_{p/2} = 3.53(RT/nF), \tag{78}$$

On the other hand, when $(nF\Delta E/RT)>8$, we have

$$\Delta(E_m)_{p/2} = \Delta E \tag{79}$$

Equations 78 and 79 indicate that the half-peak width has the constant value of $90/n$ mV at 25 °C when $\Delta E<20/n$ mV, whereas it becomes to be equal to the pulse height ΔE for $\Delta E>200/n$ mV.

Next, consider another limiting case, in which the condition:

$$(k_0\sqrt{\tau}/\sqrt{D}) \leqq \exp[-4(1+\alpha)] \tag{80}$$

is fulfilled. In this case, the electrode process becomes d.c. polarographically irreversible[9] and thus, of course, pulse-polarographically irreversible. Then the corresponding wave appears in the potential region sufficiently more cathodic than $E^{r}_{1/2}$. Therefore, the general Eq. 65 can be transformed into

$$i_{\text{dif-pulse}} = (i^{c}_{d})_{\text{Cott}}[1-\exp(-\alpha\Delta\zeta)]\psi(\kappa^{-1}\chi)\Phi(\kappa\chi) \tag{81}$$

where κ and χ are defined as

$$\kappa = \sqrt[4]{\theta_s/\tau}\,\exp(\alpha\Delta\zeta/2) \tag{82}$$

$$\chi = (k_0\sqrt[4]{\theta_s\tau}/\sqrt{D})\exp(-\alpha\zeta_m) \tag{83}$$

Equation 81 provides the expression of irreversible waves. We shall now derive the equations for the peak potential, the peak current and the half-peak width of irreversible waves. As can be seen from Eqs. 81—83, the dependence of $i_{\text{dif-pulse}}$ on E_m can be given by $\psi(\kappa^{-1}\chi)\Phi(\kappa\chi)$ *vs.* $\ln\chi$ curves. Thus, the values of $\psi(\kappa^{-1}\chi)\Phi(\kappa\chi)$ in dependence of $\ln\chi$ were numerically calculated for a series of values of κ. The results obtained for the range of $0.1<\kappa<30$ are summarized as follows:

(1) The values of $\ln\chi_p$, at which $\psi(\kappa^{-1}\chi)\Phi(\kappa\chi)$ shows a maximum, can be given by

$$\ln\chi_p = -0.27 - 0.40\,\mathrm{sech}(2.2-0.8\ln\kappa) \tag{84}$$

(2) The maximum values of $\psi\Phi$, *i.e.*, $\psi(\kappa^{-1}\chi_p)\Phi(\kappa\chi_p)$, can be given by

$$\psi(\kappa^{-1}\chi_p)\Phi(\kappa\chi_p) = \frac{(\ln\kappa)^{1.62}}{1.50+(\ln\kappa)^{1.62}} \tag{85}$$

(3) The difference between the two values of $\ln\chi$, $\ln\chi'_{p/2}$ and $\ln\chi''_{p/2}$, which satisfy the algebraic equation:

$$\psi(\kappa^{-1}\chi)\Phi(\kappa\chi) = (1/2)\psi(\kappa^{-1}\chi_p)\Phi(\kappa\chi_p),$$

can be given by

$$\Delta\ln\chi_{p/2} = \ln\chi'_{p/2} - \ln\chi''_{p/2} = 3.21+0.522\,|\ln\kappa|^{1.77} \tag{86}$$

Equations 84—86 hold with errors of less than 2%. Therefore, by taking into account Eqs. 81—86, we obtain the following equations for the peak potential, the peak current and the half-peak width of the irreversible wave:

$$\begin{aligned}(E_m)_p = E^{r}_{1/2} + (RT/\alpha nF)\{&\ln(k_0\sqrt[4]{\theta_s\tau}/\sqrt{D}) + 0.27\\ &+ 0.40\,\mathrm{sech}[2.2-0.2\ln(\theta_s/\tau)\\ &- 0.4(\alpha nF/RT)\Delta E]\}\end{aligned} \tag{87}$$

$$\begin{aligned}(i_{\text{dif-pulse}})_p = (i^{c}_{d})_{\text{Cott}}&[1-\exp\{-(\alpha nF/RT)\Delta E\}]\\ &\times \frac{[(\alpha nF/2RT)\Delta E+(1/4)\ln(\theta_s/\tau)]^{1.62}}{1.50+[(\alpha nF/2RT)\Delta E+(1/4)\ln(\theta_s/\tau)]^{1.62}}\end{aligned} \tag{88}$$

$$\begin{aligned}\Delta(E_m)_{p/2} = (RT/\alpha nF)\{&3.21\\ &+0.522|(\alpha nF/2RT)\Delta E+(1/4)\ln(\theta_s/\tau)|^{1.77}\}\end{aligned} \tag{89}$$

From Eqs. 87—89 we can readily see how the shape of irreversible waves varys in dependence of the kinetic parameters of electrode reaction. The standard rate constant k_0 is not contained in the equations of the peak current and the half-peak width and hence it has no influence on the shape of irreversible waves, while the peak potential shifts in proportion to $\ln k_0$. On the other hand, the transfer coefficient α has a great influence both on the wave-shape and the peak potential in somewhat complicated ways, as can be seen from Eqs. 87—89.

Remark for Applying the Theory to Analysis of Experimental Data

In the pulse polarographic practice, in order to increase the S/N ratio, the pulse polarographic current is frequently integrated over some short period, $\Delta\theta$, at the end of the pulse duration, and it is expressed as the value averaged over $\Delta\theta$. In the theoretical considerations developed above, however, it is the instantaneous value at $\theta=\theta_s$. Thus, one problem may arise: what magnitude of error is introduced when the instantaneous value at $\theta=\theta_s$ is replaced by the value averaged over the time-duration from $\theta_s-(1/2)\Delta\theta$ to $\theta_s+(1/2)\Delta\theta$? If the current may vary linearly with time, the average current is precisely equal to the instantaneous one at the middle point of the time duration concerned. The case, in which the variation of current with time most greatly deviates from the linearity, is that of reversible waves. As can be seen from Eqs. 32, 41a, 51, and 73, the pulse polarographic current of reversible waves is proportional to $1/\sqrt{\theta}$. Therefore, the current, $\bar{i}_{\text{pulse}}$, averaged over the time-duration from $\theta_s-(\Delta\theta/2)$ to $\theta_s+(\Delta\theta/2)$ is given by

$$\begin{aligned}\bar{i}_{\text{pulse}} &= \text{const.}\frac{1}{\Delta\theta}\int_{\theta_s-\Delta\theta/2}^{\theta_s+\Delta\theta/2} d\theta/\sqrt{\theta}\\ &= \text{const.}\frac{2\sqrt{\theta_s}}{\Delta\theta}\left\{\left[1+\frac{\Delta\theta}{2\theta_s}\right]^{1/2}-\left[1-\frac{\Delta\theta}{2\theta_s}\right]^{1/2}\right\}\end{aligned}$$

For $\Delta\theta/2\theta_s<1$, we have

$$\bar{i}_{\text{pulse}} = \text{const.}\frac{1}{\sqrt{\theta_s}}\left\{1+\frac{1}{8}\left[\frac{\Delta\theta}{2\theta_s}\right]^2+\frac{7}{128}\left[\frac{\Delta\theta}{2\theta_s}\right]^4+\cdots\right\}$$

On the other hand, the instantaneous value of the pulse polarographic current at $\theta=\theta_s$ is given by

$$i_{\text{pulse}}(\theta=\theta_s) = \text{const.}\,(1/\sqrt{\theta_s})$$

Hence

$$\left|\frac{i_{\text{pulse}}(\theta=\theta_s)-\bar{i}_{\text{pulse}}}{i_{\text{pulse}}(\theta=\theta_s)}\right| = \frac{1}{8}\left[\frac{\Delta\theta}{2\theta_s}\right]^2\left\{1+\frac{7}{16}\left[\frac{\Delta\theta}{2\theta_s}\right]^2+\cdots\right\} \tag{90}$$

Equation 90 reveals that when the condition:

$$\Delta\theta/\theta_s \leqq 1/2 \tag{91}$$

is satisfied, the average current is equal to the instantaneous one at the middle point of the integration range with errors of less than 1%. This statement holds well also for the quasi-reversible and irreversible waves. Hence, we can derive the following conclusion: Let the current be integrated over the time-duration from θ_1 to $\theta_1+\Delta\theta$. Then θ_1 should be selected to be larger than $(3/2)\Delta\theta$, and in such a case the average value may be replaced by the instantaneous one at $\theta=\theta_1+(\Delta\theta/2)$.

Appendix

In this appendix, the integrals I_1 and I_2 will be evaluated. Introducing Eq. 15 with Eq. 16a into Eq. 21 yields

$$I_1 = \frac{\sqrt{D_0}C_0^\circ}{1+\exp(\zeta_1)}\lambda_1\sum_{\nu=0}^{\infty}(-1)^\nu a_\nu(\sqrt{3/7}\,\lambda_1)^\nu \times\int_0^\tau \frac{u^{(3\nu+4)/6}\mathrm{d}u}{\sqrt{(\tau+\theta)^{7/3}-u^{7/3}}} \quad \text{(A-1)}$$

Substituting $u=(\tau+\theta)\,v^{3/7}$ into the above equation and performing the indicated integration, we obtain

$$I_1 = \sqrt{\frac{3}{7}}\,\frac{\sqrt{D_0}C_0^\circ}{1+\exp(\zeta_1)}\sum_{\nu=0}^{\infty}(-1)^\nu a_\nu(\sqrt{3/7}\,\lambda_1\sqrt{\tau+\theta})^{\nu+1} \times\left\{\frac{\sqrt{\pi}\,\Gamma([3\nu+10]/14)}{\Gamma([3\nu+17]/14)} - B\left[1-(1+[\theta/\tau])^{-7/3};\ \frac{1}{2},\frac{3\nu+10}{14}\right]\right\} \quad \text{(A-2)}$$

where $B\,(\xi;\,a,\,b)$ is the incomplete beta function, defined by

$$B(\xi;a,b) = \int_0^\xi \xi^{a-1}(1-\xi)^{b-1}\mathrm{d}\xi$$

Taking into account Eqs. 16a, 16b, and 17, we obtain

$$I_1 = \sqrt{\frac{3\pi}{7}}\,\frac{\sqrt{D_0}C_0^\circ}{1+\exp(\zeta_1)}\left\{1-\psi(\lambda_1\sqrt{\tau+\theta}) - \frac{1}{\sqrt{\pi}}\sum_{\nu=0}^{\infty}(-1)^\nu a_\nu\,(\sqrt{3/7}\,\lambda_1\sqrt{\tau+\theta})^{\nu+1} \times B\left[1-(1+[\theta/\tau])^{-7/3};\ \frac{1}{2},\frac{3\nu+10}{14}\right]\right\} \quad \text{(A-3)}$$

For $(\theta/\tau)<1$, the functions B, ψ and $(\tau+\theta)^{(\nu+1)/2}$ can be expanded into the power series of (θ/τ), as follows:

$$B\left[1-(1+[\theta/\tau])^{-7/3};\ \frac{1}{2},\frac{3\nu+10}{14}\right] = 2\sqrt{\frac{7\theta}{3\tau}} \times\left\{1-\frac{3\nu+11}{18}\left(\frac{\theta}{\tau}\right)+O\left(\left[\frac{\theta}{\tau}\right]^2\right)\right\} \quad \text{(A-4)}$$

$$\psi(\lambda_1\sqrt{\tau+\theta}) = \psi(\lambda_1\sqrt{\tau}) + \frac{\mathrm{d}\psi(\lambda_1\sqrt{\tau}}{\mathrm{d}\ln\tau}\left(\frac{\theta}{\tau}\right)+O\left(\left[\frac{\theta}{\tau}\right]^2\right) \quad \text{(A-5)}$$

$$(\tau+\theta)^{(\nu+1)/2} = \tau^{(\nu+1)/2}\left\{1+\frac{\nu+1}{2}\left[\frac{\theta}{\tau}\right]+O([\theta/\tau]^2)\right\} \quad \text{(A-6)}$$

Further, from Eq. 16a we obtain the following relation:

$$\frac{\mathrm{d}\psi(\lambda_1\sqrt{\tau})}{\mathrm{d}\ln\tau} = \frac{1}{2}\sum_{\nu=0}^{\infty}(-1)^\nu\nu a_\nu(\sqrt{3/7}\,\lambda_1\sqrt{\tau})^\nu \quad \text{(A-7)}$$

Therefore, taking into account Eqs. A-4—A-7, the integral I_1 can be expanded into the following power series of $\sqrt{\theta/\tau}$:

$$I_1 = \sqrt{\frac{3\pi}{7}}\,\frac{\sqrt{D_0}C_0^\circ}{1+\exp(\zeta_1)}\left\{[1-\psi(\lambda_1\sqrt{\tau})] - \frac{2}{\sqrt{\pi}}[(\lambda_1\sqrt{\tau})\psi(\lambda_1\sqrt{\tau})]\sqrt{\theta/\tau} - \left[\frac{\mathrm{d}\psi}{\mathrm{d}\ln\tau}\right](\theta/\tau) + \frac{4}{3\sqrt{\pi}}[(\lambda_1\sqrt{\tau})\,\psi(\lambda_1\sqrt{\tau})]\left[\frac{1}{6}-\frac{\mathrm{d}\ln\psi}{\mathrm{d}\ln\tau}\right](\theta/\tau)^{3/2} + O([\theta/\tau]^2)\right\} \quad \text{(A-8)}$$

On the other hand, the integral I_2 can be evaluated as follows: Rewriting $\tau+u$ insted of u in Eq. 22 yields

$$I_2 = \frac{1}{\sqrt{\tau}}\int_0^\theta \frac{(i_2/nFq)(1+[u/\tau])^{2/3}\mathrm{d}u}{\sqrt{(1+[\theta/\tau])^{7/3}-(1+[u/\tau])^{7/3}}} = \sqrt{\frac{3}{7}}\int_0^\theta \frac{(i_2/nFq)}{\sqrt{\theta-u}}\left\{1-\frac{1}{3}\left[\frac{\theta-u}{\tau}\right]+O([\theta/\tau]^2)\right\}\mathrm{d}u. \quad \text{(A-9)}$$

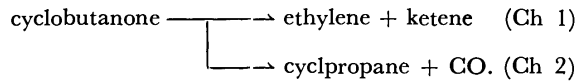
(Received May 21, 1980)

The multiple photon dissociation of cyclobutanone was discussed on the basis of the observed relative significance of two reaction channels. Cyclobutanone was irradiated by a TEA CO_2 laser beam of 9.6 μm R(14) line in a parallel and a focussed geometry. The detected products were ethylene, ketene, and cyclopropane under parallel geometry irradiation. Propylene and acetylene were also produced in focussed geometry irradiation. The kind of the products as well as the effects of reaction conditions on their yields led to the conclusion that the dissociation proceeds along two channels, in one of which ethylene and ketene are produced and in the other cyclopropane and CO. The experimental results agreed almost with the result simulated by a statistical model calculation based on the hypothesis that the energy absorbed in cyclobutanone molecules is statistically distributed among all vibrational degrees-of-freedom.

During the last decade, there has been a lot of interest in the mechanism of chemical reactions induced by a strong infrared laser field through multiple photon excitation.[1] A variety of polyatomic molecules are found to dissociate *via* the infrared multiple photon dissociation (MPD) even under a collisionless condition. The mechanism of MPD, at least its outline, is now well established, particularly for several pet molecules such as SF_6.[2,3] In MPD of relatively simple polyatomic molecules, the energy pumped into a molecule by a laser field is more or less randomly distributed in all vibrational degrees-of-freedom before decomposition, and most of the excited molecules decompose along the lowest possible thermal decomposition channel. Sometimes, however, apparently unexpected processes from the hypothesis of energy randomization are reported, such as a direct formation of C_2 fragment from ethylene.[4] Thus, more studies on variety of molecules are needed for full understanding of the MPD mechanism.

The events associated with MPD might be complex, particularly when the process is to be studied by means of conventional product analyses. The chemical reactions subsequent to MPD would be simplest for the case that the expected mode of dissociation involves only stable molecular products, thereby minimizing the possibilities of post-pulse chemical reactions. The thermal unimolecular dissociation process[5-9] as well as single photon photochemistry[10] is relatively well known for cyclobutanone. The thermal decomposition of this molecule occurs along two channels; the major one yields ethylene and ketene, and the minor one, cyclopropane and CO; *i.e.*,



These two channels seem to proceed in a concerted molecular elimination manner, though the detailed mechanism of the minor process is still open to debate. Provided that the decomposition of this molecule in MPD occurs along the above thermal channels, the dependency of the branching ratio as well as the yield of each channel on the laser energy would help understanding the inter- and intramolecular energy distributions of the excited molecules through multiple photon absorption. The branching ratio of the MPD reaction was studied very recently by Back and Back[11] and also by Harrison *et al.*[12] mainly as a function of pressure. Though these two data are quite contradictory to each other, both of them found that the branching ratio remained constant at pressures above 3 Torr, and concluded that the MPD at higher pressures was essentially the same as the thermal decomposition reaction. In the present paper, we will describe our experimental determination of the reaction yield as well as the branching ratio mainly against laser fluence at around 1 Torr. The result will be compared with calculations by a stochatic model for the excitation and reaction. Similar discussions on branching ratios were reported for several other molecules such as 1-bromo-2-fluoroethane,[13] ethylchloride-2d_1,[14] and 1-chloro-2-fluoroethylene.[15]

Experimental

A grating tuned TEA laser (Lumonics Research Ltd. Type 102, multimode) was employed as the irradiation source. The laser medium was the mixture of He and CO_2 without adding N_2 and the ouput pulse was about 80 ns fwhm with no appreciable longer tail as measured with a photon drag detector (Rofin Ltd., Model 7425/7400). Shot-to-shot fluctuations in the pulse energy were within ±5%. The laser energy was selectively attenuated by polyethylene sheets and was monitored by an energy meter (Gentic, ED-500).

Two different ways of irradiation were adopted. (1) A cylindrical (2.6 cm inner diameter × 10 cm length) Pyrex cell sealed with NaCl windows at both ends was used for the following focussed gemetry irradiation. The CO_2 laser beam was focussed inside the cell by use of a Ge lens of a 25 cm focal length. The radial distribution of the laser intensity at the focal point was determined by scanning a pin hole (90 μm dia.) to be a near Gaussian with an effective diameter of 0.1 cm; thus the effective irradiation area at the focus was estimated to be 8×10^{-3} cm^2. (2) A disc type (2.6 cm inner diameter × 1 cm length) Pyrex cylinder sealed with two NaCl windows was employed for the following parallel geometry irradiation. The cell was placed between a 25 cm focal length Ge lens and its focal point, around 19 cm distant from the lens. The effective irradiation area was determined to be 0.36 cm^2 on the basis of the burnt area measurement on thermal paper by

the laser irradiation. Within this area, the laser intensity was assumed to be constant. The field intensity or the fluence varied over 1.4 times between the two NaCl windows along the laser beam according to the geometric consideration. In both of the above geometries, precise determination of the effective area was difficult due to the multimode laser pattern. Errors introduced by the overall procedure might give a 40% uncertainty in the absolute value of the laser fluence, but much less than this for relative values.

Commercially obtained cyclobutanone of extra pure grade from Nakarai Kagaku Co. Ltd. was used after several freeze-thaw cycles. It proved to contain no detectable impurities identical to the irradiation products by gas-chromatography and infrared spectroscopy.

The gaseous materials were treated in a conventional vacuum line equipped with a MKS baratron pressure meter (170-6B/310BHS). Cyclobutanone was introduced into the irradiation cell manometrically. After the irradiation of a necessary number of laser shots (repetition rate was less than 0.3 Hz), the resultant gas mixture, or sometimes, a part of it, was transferred into a gas-sampler for a gas-chromatographic analysis. The products were analysed by use of a Shimadzu GC-4C gas-chromatograph with a flame ionization detector. The products (ethylene, acetylene, cyclopropane, and propylene) were identified in terms of their retention times by use of a Porapak Q and activated charcoal columns. Authentic samples were commercially obtained. Quantitative analyses were carried out with an activated charcoal column. Whether the products were totally recovered or not was checked with model mixture gases. The quantitative analyses were reliable within 10% for C_2 and C_3 hydrocarbons. Sometimes, the 10 cm irradiation cell itself was used as a sample cell for the double beam infrared spectrometer (Japan Spectroscopic Co. Ltd., IRA-1). The infrared spectra of cyclobutanone and the reaction mixture were thus obtained.

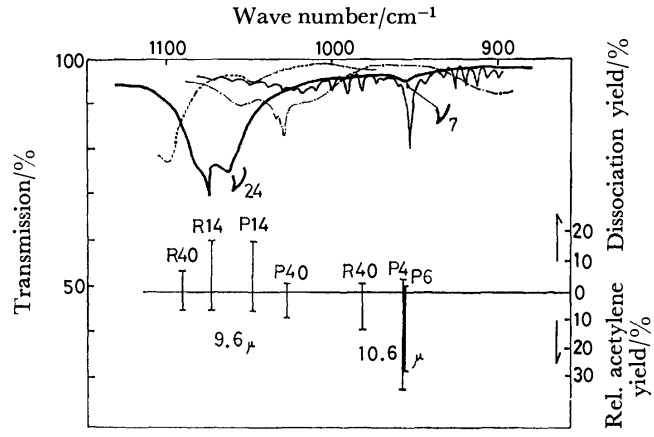


Fig. 1. Dissociation yield and relative acetylene yield with various laser lines, and the IR absorption spectra of cyclobutanone, ethylene, cyclopropane, and ketene. The dissociation yield is the consumed cyclobutanone per 100 shots divided by the initial cyclobutanone, and the relative acetylene yield is the fraction of acetylene among the summed yield of ethylene, acetylene, cyclopropane, and propylene. The irradiation was carried out in focussed gemoetry with 0.37—0.52 J incident laser pulses. The pressure of cyclobutanone was 1 Torr. The conventional IR absorption spectra were measured at 5 Torr (10 cm optical length) in the present work except for ketene. Its spectrum is from the Ref. 17.
Cyclobutanone (——), ethylene (——), cyclopropane (·—·—·), ketene (------).

Results

Product Analyses. The 9.6 μm R(14) line of the TEA CO_2 laser at 1075 cm^{-1} was usually employed in the present work. This line is approximately resonant with the Q branch of the cyclobutanone ν_{24} band (A type, rocking mode of the CH_2 groups, see Fig. 1),[16] which is the strongest absorption band in accord with the CO_2 laser lines. The linear absorption cross section was measured to be 3×10^{-19} cm^2 $molecule^{-1}$ by means of a conventional infrared spectrometer with a 2 cm^{-1} slit width.

The identified products in focussed geometry irradiation were ethylene, cyclopropane, propylene, acetylene, and ketene. The products except ketene were quantitatively analysed gas-chromatographically. In the gas chromatograms with an activated charcoal column, three other peaks were found at the retention times corresponding to methane, ethane, and propane. One unidentified peak was also observed between the cyclopropane and the propylene peak. These products were, however, found to be very minor, less than 1% of the total products even under the strongest irradiation conditions. No other gas chromatographic peaks were recognized before the effusion of cyclobutanone. Ketene gave no gas chromatographic peak, probably because of its reaction with column materials. Thus it was identified by its characteristic infrared absorption peak at 2150 cm^{-1}.[17] Furthermore, the identification was confirmed by the fact that the infrared peaks disappeared when the reaction mixture was kept with 50 Torr methanol for 30 min,[18] and that the resultant production of methyl acetate was proved gas chromatographically.

In parallel geometry irradiation, ethylene and cyclopropane were almost the exclusive products found by gas chromatographic analyses; acetylene, propylene, and other minor products gave only trace gas chromatographic peaks if any.

If the MPD proceeds *via* the two reaction channels similar to the thermal decomposition, ethylene, cyclopropane, and ketene are the expected products. We did not try to detect one other expected product, CO, because of its low sensitivity for the gas chromatographic and infrared analyses. In agreement with the assumption that the major channel is Ch 1, the observed amount of ethylene was 80% or more of the decomposed cyclobutanone under various irradiation conditions. At the same time, the infrared peak intensity of the band assigned to ketene were found to be approximately proportional to the peak intensity at 950 cm^{-1} of the product ethylene. Cyclopropane must not be produced by a secondary reaction such as CH_2+ethylene→ cyclopropane, in which CH_2 is supplied by MPD of ketene or other primary products, because the cyclopropane formed *via* the insertion of CH_2 to ethylene possesses too large internal energy to be stabilized under the present low pressure.[19] Acetylene and propylene,

which are not primary products of the above two channels, were found only in focussed geometry irradiation. As will be discussed later, acetylene is formed through MPD of a primary product and propylene through isomerization of the energy-excess cyclopropane. Thus, we will assume that the MPD of cyclobutanone proceeds *via* the two dissociation channels which are the same as those in the thermal decomposition. The product ethylene or ethylene+acetylene represents an extent of the Ch 1 decomposition, while cyclopropane or cyclopropane+propylene does that of the Ch 2. The products and the reaction mechanism coincide with the results of Back and Back[11] and of Harrison *et al.*,[12] who irradiated cyclobutanone with the laser light of 1047 cm^{-1} P(20) and 1073 cm^{-1} R(12) lines, respectively.

Effect of Irradiation Wavelength. Several preliminary experimental runs were carried out with various laser lines in focussed geometry. The kind of products did not change, but the dissociation yield and the relative yield of acetylene varied considerably as shown in Fig. 1. The dissociation yield is the highest at the 9.6 μm R(14) line among the examined laser lines, and decreases towards both sides of this line being approximately proportional to the linear absorption of cyclobutanone. The relatively high yield compared with the linear absorption at the 9.6 μm P(14) line may be reasonable, because the multiple photon absorption has the tendency to extend to the red compared with the single photon absorption.[1]

Ethylene[4,20,21] and cyclopropane[22] are known to give acetylene in high yields *via* CO_2 laser MPD. The high yield of acetylene in irradiation with the laser line of smaller wavenumber is understandable, because the primary products could absorb the laser lights of these wavenumber lines effectively. The absence of dissociation of ketene with 1080 cm^{-1} CO_2 laser irradiation is reported at a ketene pressure lower than 5 Torr. Only H_2 and CO with trace amount of acetylene is reported as gas phase products at higher ketene pressures.[23]

Thus we selected the 9.6 μm R(14) line as the most adequate for the present purpose to find out the dependence of the ratio of the two different channels on the irradiation conditions, because the dissociation yields were high and the interference by possible undesirable secondary reactions was small with this line. We confirmed, however, almost the same mechanism in the primary dissociation with other laser lines, including the 10.6 μm P(4) and P(6) lines which are resonant to the ν_7 ring mode band[16] of cyclobutanone.

Effect of the Number of Laser Shots. Figure 2 shows the dissociation yield as a function of the laser shot number in focussed geometry irradiation. Let $P_{CB(0)}$ mean the initial pressure of cyclobutanone and $P_{CB(N)}$, the pressure after N repetitive shots. log $[P_{CB(N)}/P_{CB(0)}]$ is plotted against the number of laser shots in Fig. 2 to show that a good proportionality exists between the two variables. The proportionality relation is readily derived, if the dissociation yield per one laser shot $W(=[P_{CB(N)}-P_{CB(N-1)}]/P_{CB(N-1)})$, is independent of the consumption of cyclobutanone and the gas mixture becomes uniform before the subsequent laser shot. The following proportionality relation is equated,

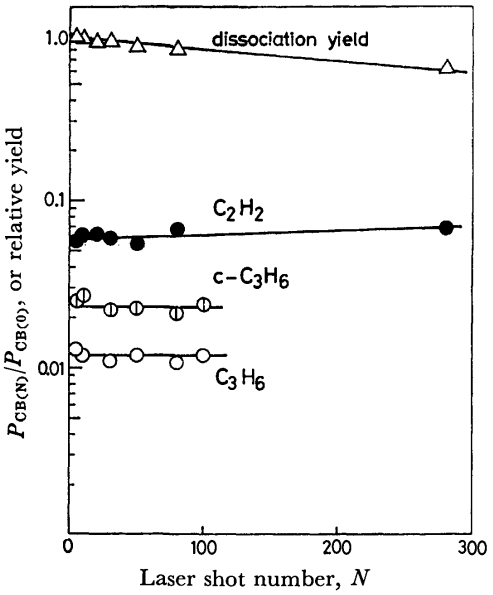

Fig. 2. Variations of dissociation yield and relative yields of acetylene, cyclopropane, and propylene with laser shot numbers. Cyclobutanone of 1.0—1.7 Torr was irradiated in focussed geometry with 0.46—0.47 J incident energy pulses.
△: $P_{CB(N)}/P_{CB(0)}$, ●: relative yield of acetylene, ①: relative yield of cyclopropane, ○: relative yield of propylene.

$$\log(P_{CB(N)}/P_{CB(0)}) = N\cdot\log(1-W). \quad (1)$$

When the dissociation yield is kept small enough (for example less than 10%), Eq. 1 is approximated by the equation,

$$W = [(P_{CB(0)} - P_{CB(N)})/P_{CB(0)}]/N, \quad (2)$$

which makes it possible to obtain W by dividing the yield after N shots by number N.

The relative yields of acetylene, cyclopropane, and propylene against the number of laser shots are also shown in Fig. 2. The relative yields of cyclopropane and propylene are independent of the laser shot number as is expected from the proposed reaction mechanism if no appreciable secondary dissociation of these products occurs. The yield of acetylene shows a slight increase with the laser shot number. Most of acetylene is considered to be produced *via* some secondary dissociation of the primary products, probably ethylene, as will be described in the next section. The fact that the observed dependence of the acetylene yield on shot numbers is small implies that the secondary dissociation proceeds mainly during the same laser pulse when the primary products are still vibrationally hot.

Effect of Laser Energy in Focussed Geometry Irradiation. Figure 3 shows the effect of laser energy (which is proportional to laser fluence in the present work) upon the product yields. The total yield is proportional to the 3/2 power of the laser energy. In focussed geometry irradiation, the 3/2 power dependence could be explained based on a conical geometry of the laser beam incorporating saturation effects.[24] In this treatment, the volume inside of which the laser intensity exceeds a

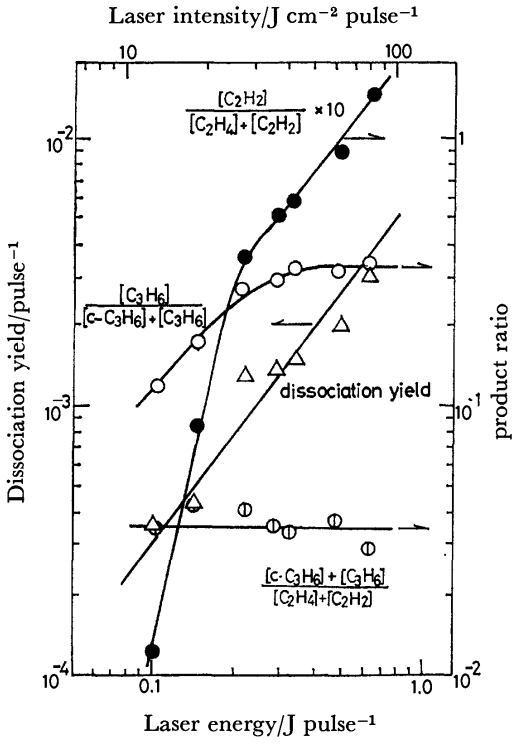

Fig. 3. The dependence of the dissociation yield, the fraction of acetylene, the branching ratio, and the degree of isomerization of the cyclopropane on the laser pulse energy in focussed geometry irradiation.
The laser energy (along the *absissa*) means the incident laser energy per pulse and the laser intensity means the field intensity which is defined as the energy of one pulse divided by the effectively irradiated area normal to the laser beam in the focal region.
△: Dissociation yield per pulse. The straight line shows the 3/2 power law, ●: ratio of acetylene *vs.* ethylene+acetylene (multiplied by 10), ⦶: ratio of cyclopropane+propylene *vs.* ethylene+acetylene, ○: ratio of propylene *vs.* cyclopropane+propylene.

certain value increases proportional to the 3/2 power of the incident laser energy. If the dissociation yield is effectively described by the relation $W=\alpha(I/I_{th})^n$ with a large n when $I<I_{th}$ and is constant α when $I\geq I_{th}$, the 3/2 power law holds over a broad intensity range, masking the effect of the order n of the process. The experimental finding in Fig. 3 is understandable in this context.

The ratio of acetylene *vs.* the sum of ethylene and acetylene increases proportional to the power of 3/2 or higher of the laser energy. This fact shows that acetylene is not a primary reaction product from cyclobutanone. Most of acetylene must be produced through MPD of some primary products during the same laser pulse. A theoretical model calculation will show in Discussion that the dissociation of cyclobutanone is complete far before the end of the laser pulse of a large power, and thus it is possible that the primary products absorb enough laser energy within the same laser pulse to dissociate. Under stronger irradiation conditions with a focussed geometry, visible luminescence was observed at the focal region. This suggests that radicals such as C_2 and CH_x are produced *via* some secondary MPD of primary products and may be intermediates for production of acetylene and other minor hydrocarbon species. Most of the acetylene should come from ethylene and/or ketene, which are the primary products capable of yielding a considerable amount of acetylene *via* the subsequent multiple photon absorption. The yield of acetylene under irradiation of a stronger laser pulse exceeds considerably the yield of C_3 hydrocarbons, which is almost independent of the laser energy. This shows that the C_3 hydrocarbons could not be the main primary product to yield acetylene. It is not determined conclusively which is the main primary product to produce acetylene, ethylene or ketene. Though ketene is reported not to produce acetylene through the MPD at 1080 cm^{-1},[23] the possibility may not be denied that the primary ketene, when it is still hot, could be the starting material for some secondary MPD. In spite of this, we prefer a view that the primary hot ethylene is the main precursor, judging from the fact that the relative acetylene yield decreased with increasing the irradiation wavenumber, roughly in agreement with the change of the linear absorption of ethylene, but reverse to that of ketene (see Fig. 1). The possibility that the primarily produced ethylene dissociates directly to yield acetylene without absorbing subsequent laser photons is considered to be very small on the basis of energetics.

It is important to note that the ratio of the sum of cyclopropane and propylene *vs.* that of ethylene and acetylene is independent of the laser energy. This is probably caused by the fact that, in focussed geometry irradiation, most of the dissociation occurs in the region where the laser intensity is equal to or slightly exceeds I_{th} in the context of the previous explanation of the geometric effect. Moreover, the later theoretical model calculation shows that the branching ratio does not strongly depend on the laser intensity so long as it is strong enough. The slight decrease in the experimental plots with increasing laser energy may mean some occurrence of secondary dissociations of the C_3 hydrocarbons.

The ratio of propylene *vs.* the sum of cyclopropane and propylene increases with the laser energy to a certain plateau value as shown in Fig. 3. This behaviour is consistent with the hypothesis that most of propylene is produced *via* unimolecular isomerization of the primary product cyclopropane.[25] The energetical threshold for the isomerization is much higher than those for Ch 1 and Ch 2 (see Discussion, Fig. 8). Thus the increase of the ratio until a certain plateau value does not conflict with the observed constancy in the branching ratio over the examined laser energy range. The fact that the certain plateau value is reached indicates that most of propylene is not produced *via* secondary MPD of primary products. If so, the ratio should increase with the laser energy similarly to the yield of acetylene.

Pressure Effects in Focussed and in Parallel Geometry Irradiations. Figure 4 shows the effect of the cyclobutanone pressure on the dissociation yield, the branching ratio, and also the degree of the isomerization of the primary product cyclopropane. The yield is pressure dependent, which may mean that the dissocia-

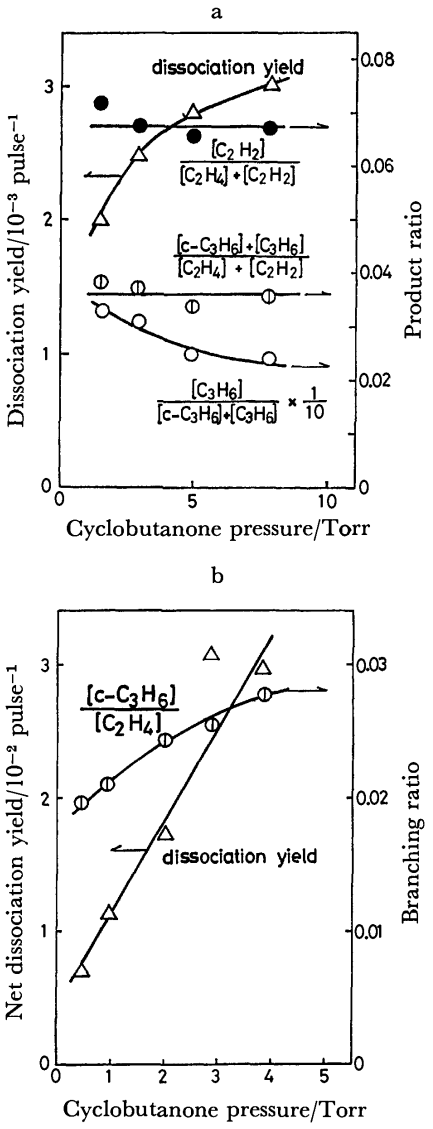

Fig. 4. The dependences of dissociation yield, the branching ratio, and the degree of isomerization of the cyclopropane on the pressure of cyclobutanone in focussed (4a) and in parallel (4b) geometry irradiations.
4a) △: Dissociation yield per pulse, ●: ratio of acetylene *vs.* ethylene+acetylene, ⓘ: ratio of cyclopropane +propylene *vs.* ethylene+acetylene, ○: ratio of propylene *vs.* cyclopropane+propylene (multiplied by 1/10). The incident energy per pulse was 0.47 J.

tion partly proceeds collision free and is partly supported by a certain kind of collisional events. It is difficult to extrapolate the dissociation yield to zero pressure to find out the percentage of the contribution of collision free dissociation without doubt, but it seems to be less than 50% even under 1 Torr of cyclobutanone. The branching ratio is pressure dependent in the parallel geometry irradiations. The dependence in the present experiments are in agreement with the observation by Harrison *et al.*,[12] but reverse to the result by Back and Back.[11] The increase in the branching ratio with increasing the pressure suggests that the collisional events result in producing cyclobutanone molecules with a relatively larger internal energy. In focussed geometry irradiation, the pressure effects are rather small, as is expected from the geometric consideration explained in the previous section. The fraction of propylene among C_3 products decreases with increasing pressure. This is due to the collisional stabilization of the primary hot cyclopropane.

In practice, full analysis of collisional effects is very difficult.[26] There must be many factors to be discussed such as rotational relaxation, redistribution of the energies of laser excited molecules, retardation of the diffusion loss of active species, collisional deactivation, and so forth. The data under lower pressures are thus desirable in order to elucidate the MPD mechanism, so long as a detection technique allows. However, our subsequent discussions are limited to the data taken at around 1 Torr due to the detectivity of the present analytical method.

Laser Intensity Effect on Product Yields in Parallel Geometry Irradiation. As has been already described, the exclusive products in parallel geometry irradiation are ethylene (Ch 1) and cyclopropane (Ch 2). The laser intensity dependence of the ethylene yield is plotted in Fig. 5. In these experiments, the yield is corrected for the fact that the effectively irradiated volume

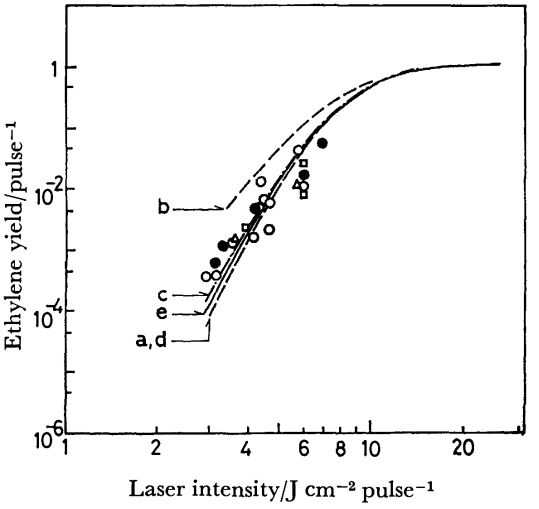

Fig. 5. Yield of ethylene *vs.* laser intensity in parallel geometry irradiation. Experimental data were from experiments with 2 (●), 1 (○), 0.5 (□), and 0.25 Torr (△) cyclobutanone. The yield means the yield per pulse in the effectively irradiated volume. The laser intensity means the incident energy of one pulse divided by the effectively irradiated area. The curves show model calculation results.
a: Calculations with $s=27$ for 1 Torr cyclobutanone. The effective dissociation threshold is at $n=18$ for Ch 1, and $n=21$ for Ch 2, b: calculations with $s=6$. The other conditions are the same as a, c: calculations for 0.25 Torr cyclobutanone. Other conditions are the same as a, d: calculations with $s=27$ for 1 Torr cyclobutanone. The effective dissociation threshold is at $n=18$ for Ch 1, and at $n=20$ for Ch2, e: revised relationship calculated by incorporating the inhomogeneity effect of the field intensity along the laser beam. The data are from curve a.

($0.36\ cm^3$) is much smaller than the total cell volume ($6.77\ cm^3$). The yield increases apparently proportional to around 7 power of the laser intensity. This trend is qualitatively in agreement with that observed by Back and Back[11] at 9.5 Torr pressure. The dissociation yield in the present experiment is, however, considerably smaller comparing at the same fluence. This is partly because of the pressure difference between the two experiments. At the same time, the P(20) line might be more efficient than the present R(14) line.

The ratio of the yield of cyclopropane over that of ethylene, which is the branching ratio of the two channels, is plotted against the laser intensity in Fig. 6. The range of the branching ratio (=[cyclopropane+propylene]/[ethylene+acetylene]) from focussed geometry irradiation is also indicated in the figure by hatching.

The experimental results in Figs. 5 and 6 are open to theoretical discussions on the basis of statistics in Discussion. The curves drawn in the figures show such theoretically predicted relationships.

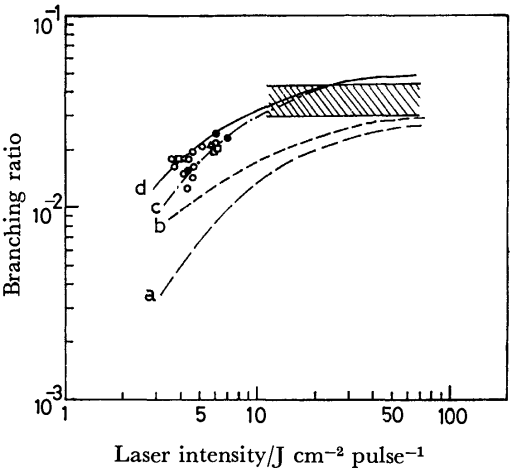

Fig. 6. The branching ratio *vs.* laser intensity. The branching ratio is the ratio of cyclopropane+propylene *vs.* ethylene+acetylene. The experimental results are plotted for 2 (●), 1 (○), 0.5 (□), and 0.25 Torr (△) cyclobutanone pressures. The hatching shows the range from focussed geometry irradiation. In this case, the laser intensity is that one at focal point. The curves show model calculation results. a, b, c, and d have the same meaning as those described in the figure caption of Fig. 5.

Discussion

Model Calculation of MPD Process. There have been reported a lot of theoretical treatments of multiple photon absorption and dissociation of polyatomic molecules. This complex process is analysed[2,3,27-34] based on a rather phenomenological view point by classifying the process into three regions: the first one is a coherent interaction region until some photons are absorbed, the second is an incoherent quasicontinuum region, and the third is a region where dissociation competes with absorption of laser photons. In the first region, the laser power is the deciding factor, and in the second, the laser fluence. In most polyatomic molecules, the dissociation yield as well as other observed phenomena are found to be dependent on the laser fluence, not on the laser power.[31] Thus the absorption of the laser photons in the second quasicontinuum region and the dissociation mechanism are considered to determine almost completely the total MPD process.

In this paper, the MPD process of cyclobutanone will be simulated on the method described by Black *et al.*,[31] whose validity has been proved in the analysis of the MPD of SF_6. We will expand their way to the case of the present two channels dissociation. The first coherent absorption region is neglected. In the quasicontinuum region, the energy pumped into a molecule by the laser field is assumed to be randomly distributed among all available internal degrees-of-freedom, owing to a very fast intramolecular energy migration. Molecules above the threshold of dissociation decompose at RRKM rates. The formulation is as follows.

The probability W_n of being in the state having the energy $n\hbar\omega$ above the starting level is described by use of the following rate equations,

$$dW_n/dt = K_n^a I W_{n-1} + K_n^e I W_{n+1} - (K_{n+1}^a + K_{n-1}^e) I W_n - K_n^{d1} W_n - K_n^{d2} W_n, \quad (3)$$

where K_n^a and K_n^e are absorption and stimulated-emission coefficients into that group, K_n^{d1} and K_n^{d2} are the dissociation rate constants along the two dissociation channels, and I is the laser intensity. The absorption and stimulated-emission coefficients in Eq. 3 represent up and down transitions. Assuming that the transition rates are governed by Fermi's Golden rule, the ratio of transition rates is given by the ratio of density of final states,

$$K_n^e/K_{n+1}^a = \rho_n/\rho_{n+1}, \quad (4)$$

where ρ_n is the density of vibrational states at a vibrational energy of $n\hbar\omega$ above the starting state. The net absorption cross section σ_n is equated as,

$$\sigma_n = (K_{n+1}^a - K_{n-1}^e)\hbar\omega. \quad (5)$$

In this treatment, the possible collisional effect on the distribution is neglected. In fact under stronger irradiation, the dissociation proceeds very rapidly and may not be interfered by collisional events seriously. But in weak irradiation, the dissociation occurs mainly after the laser pulse with a relatively slow rate. Dissociation must compete with some sort of collisional deactivation, and not every molecule with an energy in excess of the dissociation energy may react. The fractional dissociation from level n after the laser pulse is assumed to be written as,

$$f_n^i = K_n^{di}/(\sum_i K_n^{di} + D) \quad (i = 1, 2), \quad (6)$$

where D is the collisional deactivation rate constant with which K_n^{di} competes. The total fraction yield F^i after the laser pulse is the convolution of the fractional deactivation with the distribution function $W_{n(f)}$ at the end of the laser pulse,

$$F^i = \sum_n f_n^i W_{n(f)}. \quad (7)$$

These values should be added to the dissociation yields during the laser pulse.

According to the above procedure, the calculation was carried out with a Gear package for ordinary differential equations.[35] The necessary factors are selected as follows. (1) The time profile for the laser pulse was assumed to be an isoscales triangle of 80 ns fwhm. (2) The internal energy was quantized by $\hbar\omega$ of the adopted laser line, which is 3.07 kcal mol^{-1}. (3) ρ_n was calculated mostly by a RRK formula with $s=27$, the total number of the degrees-of-freedom of internal motion. Sometimes different s values were adopted. The density was once calculated according to the Whitten-Rabinovitch method[36] by adopting the internal vibrational frequencies summarized by E. K. C. Lee *et al.*[37] The result fairly agreed with calculations based on a RRK formula with $s=27$. (4) The net absorption cross section σ_n was assumed to be a constant independent of the internal energy. The value was selected so as to result in a fair agreement between the calculated and experimental results. The selected value was 4.5×10^{-20} cm^2 molecule^{-1}, which was about an order of magnitude smaller than the linear absorption cross section. Because the MPD process is described by the product $\sigma_n\times I$ as the first approximation, but not by the individual σ_n or I, the possible experimental error in the estimation of the laser intensity up to 40% may result in the estimation error in σ_n up to the same amount. (5) The RRKM dissociation rates were taken from the work of E. K. C. Lee *et al.*[37] The values were from their OSA and MP models respectively. No serious differences were expected by selecting other models. In accordance with the artificial quantization of the internal energy of cyclobutanone, the effective threshold for the two channels were selected at $n=18$ ($K_{18}^{d1}=3\times10^6$ s^{-1}), and $n=21$ ($K_{21}^{d2}=3\times10^5$ s^{-1}), respectively. (6) The collisional stabilization rate constant D was selected as 1.1×10^7 s^{-1} based on the collision diameter of 5.07 A for cyclobutanone.[38]

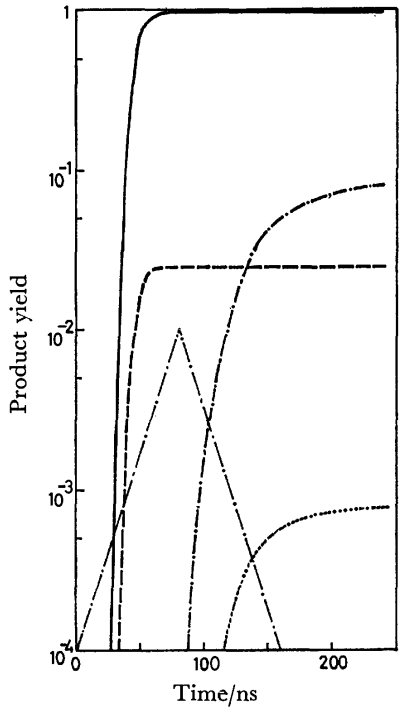

Fig. 7. Calculated time evolution of products of Ch 1 and Ch 2 under irradiations of several laser intensity. The isoscales triangle shows the time evolution of the model laser pulse (linear scale). Calculations were carried out by assuming $s=27$, and the absorption cross section$=4.5\times10^{-20}$ cm^2 molecule^{-1}, and by using the RRKM specific rates. The effective dissociation threshold is at $n=18$ (Ch 1) and at $n=21$ (Ch 2). Laser intensity, 67 J cm^{-2} pulse^{-1} (——; Ch 1, ——; Ch 2), or 6.7 J cm^{-2} pulse^{-1} (·—·—·; Ch 1, ------; Ch 2).

Comparison between the Calculated and Experimental Results. Figure 7 shows the time evolution of the dissociation yields. In this figure, no collision effect is taken into account even after the laser pulse. One important fact is that almost all molecules are dissociated shortly after the beginning of the laser pulse under a such intense irradiation as is met in focussed geometry irradiation. It is then understandable that the secondary multiple photon dissociation of the primary product occurs. Another fact to note is that the dissociation continues long after the end of the laser pulse, particularly under weaker irradiations.

Figure 8 shows the calculated dissociation yields from various levels above the dissociation energy during the laser pulse and also after the laser pulse. The average energy of the distribution of the yield is about 65 kcal mol^{-1} for Ch 1 dissociation under 4.7 J cm^{-2} pulse^{-1} irradiation, and is high as 85 kcal mol^{-1} for Ch 1 under 67 J cm^{-2} pulse^{-1} irradiation.

As has been already described in Results, the yield of Ch 1 as well as the branching ratio depend somewhat on the cyclobutanone pressure even at 1 Torr or less.

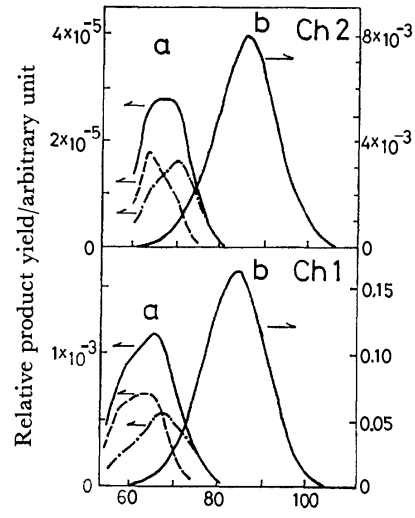

Fig. 8. The calculated dissociation yields from various levels above the dissociation energy.
a shows the results under a 4.7 J cm^{-2} pulse^{-1} irradiation. ·—·—·: The yields during the pulse, ——; the yields after the pulse, ——: the summation.
b shows the results under a 67 J cm^{-2} pulse^{-1} irradiation. In this case, dissociation is complete dur ing the laser pulse.
The pressure of cyclobutanone was 1 Torr. $s=27$, and the RRKM specific rates with the threshold for Ch 1 at $n=18$, and that for Ch 2 at $n=20$ were adopted.

This might correspond to the gradual change from the intrinsic MPD at a lower pressure to the thermal reaction at a higher pressure as are suggested by previous researchers.[11,12] The present model calculation does not take into account the collisional events rigorously. It is worthy to note that Eq. 3 is originally derived for collision-free MPD, and the vibrational-translational energy transfer is disregarded. When the absorption cross section σ_n is assumed to be independent of n, the analytic solution of Eq. 3 with neglecting the dissociation process turns out to be a thermal distribution,

$$W_n = (1/Q)\exp(-n\hbar\omega/kT)(n + s - 1)!/[n!(s - 1)!]. \quad (8)$$

Here, the state density is estimated by a RRK type calculation, and Q is an appropriate partition function. In the actual MPD, the distribution may be somewhat different from the one in Eq. 8 because of the effect of the dissociation process. Anyhow in this case of the constant σ_n, collisions are expected not to affect the distribution seriously. When the cross section σ_n is different in each energy state, the distribution reached by the absorption of laser photons might be quite different from the thermal one, and may change to a large extent through collisions towards the thermal distribution. That is, the collisional events play an important role. We have not any information about the individual σ_n values, and assumed a constant cross section. We consider that the treatment on the basis of Eq. 3 with the constant σ_n is valid as a zeroth approximation, and the following comparison between the present experimental results at around 1 Torr and the model calculations should be taken rather qualitatively.

The curves drawn in Fig. 5 show the yield of Ch 1 *vs.* the laser intensity. Curve b shows the result with $s=6$ for the state density calculation. As has been stated in Experimental, the field intensity varies over 1.4 times along the laser beam between the two NaCl windows even in parallel geometry irradiation. The curve e is estimated from the data in the curve a with taking into account the inhomogeneous distribution of the field intensity. This curve should be compared with the experimental results directly. The agreement between the experimental and calculated results is good, though the theoretically predicted pressure effect is overwhelmed by the data scattering. Unfortunately, we could explain the experimental results by an alternative choice of a larger absorption cross section with a smaller s value. Thus it is impossible to decide whether the vibrational freedom is all available or not by the analysis of this kind, unless the absorption cross section is exactly known.

The curves in Fig. 6 show the dependence of the branching ratio on the laser intensity. The inhomogeneity in the field intensity does not affect the theoretical curves to any appreciable extent. The calculation could not reproduce the experimental results, even by selecting a very small s value. Thus a faster dissociation along Ch 2 than that is predicted by the previous model must be assumed in order to reproduce the experimental results. This was achieved by lowering the effective threshold energy of Ch 2 by one unit, thus from $n=21$ to $n=20$. The results are shown in the figure. The experimental results both from parallel and focussed geometry irradiations seem to be relatively well reproduced. The change in the effective threshold must not be taken so serious, because of the unrealistic, but unavoidable, quantization of energy in the present model calculation, and also because of some ambiguity in the set of the RRKM calculation. The latter is caused by the fact that the thermal decomposition experiments of cyclobutanone by previous researchers are limited to a rather small temperature range with a very small yield of Ch 2 (about 0.5%).[5-9] At the same time, the theoretical curves are affected by the way of estimation of the collisional deactivation rate constant, D, under weaker irradiation. The change of the energy threshold of Ch 2 does not affect the curves in Fig. 5 to any appreciable extent.

Isomerization of the Primarily Produced Cyclopropane. If the cyclopropane possesses an excess internal energy of more than 63 kcal mol^{-1} immediately after its production, the unimolecular process to form propylene starts to compete with the collisional stabilization.[25] The energy content of the cyclopropane may be estimated by the following relation on the assumption that the excess energy along the dissociation is equally divided to all degrees-of-freedom,

$$\varepsilon_{CP} = (\varepsilon_{CB} - Q_{endo}) \times (3M - 6)/(3N - 6), \quad (9)$$

where ε_{CB} is the internal energy of cyclobutanone dissociating along Ch 2 and Q_{endo}, the endothermisity of Ch 2 (6.8 kcal mol^{-1} at 298 K[25]). N and M are the number of atoms in cyclobutanone and cyclopropane, respectively. The specific isomerization rates were taken from the work of Lin and Laidler,[39] and the strong collision was assumed with adopting the collisional deactivation rate constant as 1.1×10^7 s^{-1} Torr^{-1} from the collision diameters, 5.07 Å for cyclobutanone[38] and 4.17 Å for cyclopropane.[39]

The calculated fraction of isomerization is plotted

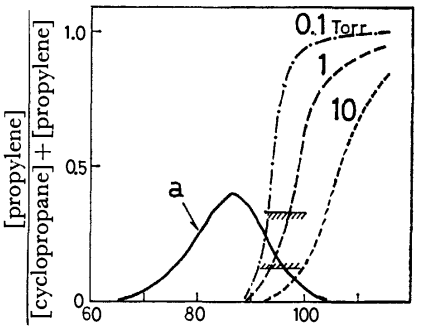

Fig. 9. The calculated degree of isomerization of the primary cyclopropane against the interanal energy of the dissociating cyclobutanone along Ch 2.
The cyclobutanone pressures of 0.1 (-·-·-), 1 (——), and 10 Torr (------) were employed. The hatching shows the range of the experimental results. The bold line of a mountain shape is the dissociation yield distribution against the internal energy of the dissociating cyclobutanone under 67 J cm^{-2} pulse^{-1} irradiation. This is taken from Fig. 8.

against the internal energy of cyclobutanone in Fig. 9. The experimental fraction is about 0.3 in focussed geometry irradiation, which leads to the conclusion that the average internal energy of the dissociating cyclobutanone is around 95 kcal mol^{-1}, with the aid of the curve in Fig. 9. This average values seems to be somewhat higher than the average energy content of the dissociating cyclobutanone obtained in the previous model calculation under 67 J cm^{-2} $pulse^{-1}$ irradiation, but the difference is not so large. It is also understandable that no propylene is observed in parallel geometry irradiation, where the energy of the dissociating cyclobutanone along Ch 2 is estimated to be lower than 80 kcal mol^{-1} as is shown in Fig. 8. Thus the degree of the cyclopropane isomerization does not contradict the hypothesis of the statistical molecular energy distribution in the MPD process.

The possibility of the unimolecular formation of acetylene from the primary hot ethylene without absorbing any subsequent laser photon is denied, because the process requires more than an excess energy of 70 kcal mol^{-1} [40,41] in ethylene. As an average, the ethylene possesses only a 36 kcal mol^{-1} excess energy after its formation from the cyclobutanone of 100 kcal mol^{-1} internal energy, according to the analogous estimation procedure to Eq. 9. No thermal unimolecular dissociation is known for ketene.

The Branching Ratio under a Variety of Excitation Procedures. The ratio of Ch 2/Ch 1 under various excitation methods are summarized in Table 1. In the photochemistry of cyclobutanone, it was established[10,42] that the triplet state (T_1, about 80 kcal mol^{-1} above S_0) of cyclobutanone decomposes exclusively to cyclopropane and CO. It was also established[10,43] that the singlet excited state (S_1, about 87 kcal mol^{-1} above S_0) undergoes $S_1 \rightarrow T_1$ intersystem crossing at a low photoexcitation energy and $S_1 \rightarrow S_0$ internal conversion at a high photoexcitation energy. The resulting hot ground state decomposes unimolecularly along the thermal dissociation channels. A molecular predissociation is also supposed to set on below 313 nm. The observed branching ratios in the photochemistry of cyclobutanone are understood according to the above scheme.

If a certain inverse intersystem crossing (or internal conversion) proceeds following the multiple photon absorption, a relatively large branching ratio is expected according to the above discussion. The observed small branching ratio in the MPD experiments denies the possibility. The fast intramolecular energy randomization and the very large difference in state densities between the ground and excited electronic states do not allow the excitation of the upper electronic states. Until now, the observation of the inverse intersystem crossing seems to be limited to the relatively simple molecule, F_2CO.[44]

Conclusion

(1) Multiple photon dissociation of cyclobutanone with 9.6 μm R(14) TEA CO_2 laser line proceeds along the same two channels as those observed in the thermal decomposition; the major one yields ethylene and ketene, and the minor one, cyclopropane and CO. Under stronger irradiations, the primary produced cyclopropane partly isomerizes to propylene, and some subsequent multiple photon absorptions of the primary products result in the formation of secondary products, particularly acetylene.

(2) From the comparison between the experimental results and a statistical model calculation concerning the laser energy effect on the product yields, the branching ratio, and the degrees of the subsequent isomerization from the primary produced cyclopropane, no sound evidence is found to reject the hypothesis that, during the laser pulse, the cyclobutanone molecules remain in external and also internal equilibria and dissociates at rates which are predicted from the unimolecular rates observed in conventional thermal experiments.

The Fraction of Bound Segments and the Chain Motion of Adsorbed Poly(methyl methacrylate) at the Solution-Solid Interface as Studied by Electron Spin Resonance

Harutoshi SAKAI,* Toshihiko FUJIMORI, and Yoshio IMAMURA

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received May 23, 1980)

The configuration of poly(methyl methacrylate) adsorbed on silica from dilute solution (CCl_4, benzene, and $CHCl_3$) was studied from the point of view of the chain motion by a spin-labeling technique. The ESR spectrum of the adsorbed polymer was found to be composed of three portions, which had considerably different degrees of the motional freedom of the local chain segments. The rotational correlation times corresponding to the three portions were estimated by the line shape analysis and the rapid passage technique. These times were 1×10^{-9}, 5×10^{-9}, and longer than 10^{-6} s, and were attributed to the motions in the long loop, short loop, and train, respectively. The large fractions of the bound segments, obtained in all the cases of low surface coverage, showed highly flattened structures of the adsorbed chain molecules. In the adsorption from a poor solvent (CCl_4), a strongly compressed structure with a large number of the short loops was found. The adsorbed layer thickness, indicated by the fraction of the segments in the three states, became much smaller with an increase in the solvent power and a decrease in the surface coverage.

In recent years, the configurational properties of chain polymer molecules adsorbed at the solution-solid interface have attracted the interest of many investigators. From the experimental results as well as the theoretical treatments, it is commonly accepted that an adsorbed molecule consists of sequences of segments restrained in the surface layer (train) and of other sequences that extend into the bulk solution phase (loop or tail).

More recently, experimental techniques such as IR, ESR, NMR, ellipsometry, *etc.*, have been applied to estimate the train and loop contents and the thickness of the adsorbed polymer layer.[1-6] However, each technique was thought to result in uncertainties both in the evaluating methods and in the data interpretation. For example, Robb and Smith pointed out the advantageous and disadvantageous aspects inherent in the ESR technique, by comparing their ESR results with the published data obtained by IR and NMR techniques.[3] In our previous study, we made a direct comparison of the ESR method with the IR method using an identical solution–adsorbent system (PMMA–CCl_4–silica).[4] Based on the experimental results, we pointed out a disagreement: the ESR method gave much larger values of p (fraction of the train segments of the adsorbed polymer) than the IR values.

In the same paper, we reported the new finding that the ESR spectrum of the adsorbed PMMA (nitroxide-labeled) was composed of three portions which were easily distinguishable by the degrees of the motional freedom of the segments. The three spectral components were assigned to the signals from the train, short loop, and long loop segments. These assignments in the previous study, however, had been qualitatively performed by the comparison of the observed line shape with those of three model spectra, obtained from a free polymer solution of low viscosity, a cooled solution to the frozen state, and a highly viscous polymer in the molten state.

In the present study, the rotational correlation times of the three components of the adsorbed PMMA and the model systems were quantitatively estimated. A rapid passage technique was used to examine the very slow motion of the bound segments. The detailed behavior of the train and loop segments is discussed in relation to the solvent effects and the degree of adsorption.

Experimental

The spin-labeled PMMA was prepared by an anionic polymerization, as described in a previous paper.[4] The procedure basically followed the method of Goode, *et al.*[7] A single fraction of the polymer used was obtained by the fractional precipitation from an acetone–water system. M_n/M_w was determined to be about 1.3 by GPC analysis, and M_n was 1.2×10^5 by membrane osmometry. The spin concentration was three labels per polymer molecule. The polymer was essentially isotactic, which gave the IR J-value of 26, and was more soluble in CCl_4 than the atactic PMMA.

Cabosil M-5 (Cabot) with a specified surface area of 220 m^2/g for nitrogen adsorption was used as the adsorbent. The silica was essentially nonporous and had an average particle size of 14 nm.

The polymer solution was added to silica, and the mixture was stirred for 4 h with a magnetic stirrer. The adsorption isotherms, shown in Fig. 1, were determined as follows. The silica dispersions were centrifuged, and the polymer concentrations in the supernatant solutions were determined by means of the infrared spectroscopy at the normal carbonyl stretching band near 1740 cm^{-1}. In the case of the benzene solutions, the concentrations were determined by using a calibration curve obtained with the plots of the solution viscosity *vs.* the concn. The amount of adsorption was calculated from the changes in the concn before and after the adsorption.

The ESR spectra were recorded on a JEOL JES FE 3-X spectrometer utilizing 100 kHz field modulation and X-band microwaves. Temperature was controlled by a cooled and rewarmed nitrogen-gas-flow system. To detect the spectrum of the adsorbed polymer itself, the silica was washed before the measurements with pure solvent to eliminate the free polymer. In the regions of unsaturated adsorption, the measurements were made without the washing, since the contribution from the unadsorbed polymer into the spectrum was negligible.

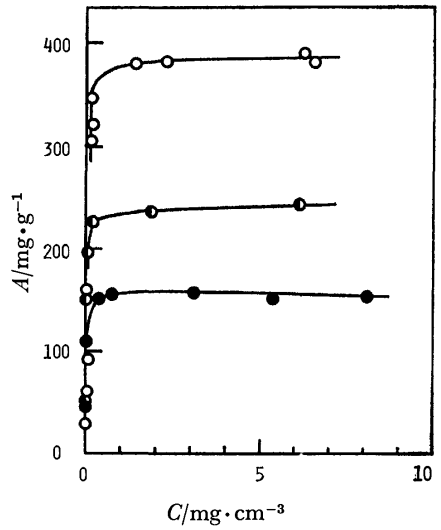

Fig. 1. Adsorption isotherms of PMMA at 25 °C.
From ○: CCl_4 solution, ◐: benzene, ●: $CHCl_3$.

An adiabatic rapid passage technique, developed by Hyde, *et al.*,[8] was also applied to the examination of the very slow tumbling motion of the adsorbed chain segments. The first harmonic of the dispersion signal was detected at 90° out-of-phase with respect to the Zeeman modulation. The saturation-transfer spectra were observed under the conditions of moderately saturating microwave field.

Calculation of Rotational Correlation Times. For the region of motionally narrowed line shape, 10^{-9} to 10^{-11} s, the correlation times (τ_c) were calculated by the equation:[9,10]

$$\tau_c = c\,\Delta H_{msl}[(h_0/h_{-1})^{1/2} - (h_0/h_{+1})^{1/2}]. \quad (1)$$

Here, ΔH_{msl} is the maximum slope width of the center field line, and h_{-1}, h_0, and h_{+1} are the signal heights of high, center and low field lines, respectively. The constant c is a parameter depending on the anisotropies of the hyperfine interaction and the g-factor.

In the region of relatively slow motion from 10^{-7} to 10^{-9} s, τ_c was estimated by the expression of Goldman, *et al.*:[11]

$$\tau_c = a(1 - S)^b, \quad (2)$$

where $S=A'_z/A_z$, A'_z is one-half the separation width of the hyperfine extrema (W), and A_z corresponds to the rigid limit value (W_{max}). The parameters, a and b, are dependent on the rotational diffusion model and the intrinsic line width in the spectrum. In this work, the values for the moderate jump diffusion model, $a=1.1\times10^{-9}$ and $b=-1.01$, was used for the calculation.

Results and Discussion

ESR Spectra. Figure 2 shows the ESR spectra of PMMA adsorbed on silica from CCl_4 solution. The line shapes indicate the diverse motion of the adsorbed chain. The ESR signals from the nitroxide labels attached to the polymer chain reflect sensitively the changes in the motion of the adsorbed chain segments arising from the differences in the configurational states, whether in the loop or the train. The spectral intensity ratio of the wings (marked with * in Fig. 2) to the inner parts (**) decreased with an increase in the surface coverage: the amount of adsorption relative to the saturated adsorption. This shows an increase in the

content of the mobile segments. These ESR spectra are composed of three portions which have different mobilities of the local chain, as described in a previous publication.[4] In conclusion, the three portions were attributed to the signals from train, short loop, and long loop parts of the adsorbed chain. As shown in Fig. 3 for an example, an ESR spectrum of the adsorbed PMMA could be synthesized by superposing three reference spectra, obtained from the following model systems in which each polymer chain had different degrees of the motional freedom. The spectrum A was observed in the unadsorbed polymer in CCl_4 solution at 10 °C, and consisted of three motional-narrowing lines due to the rapid rotational motion of the segments in the low viscosity medium. The spectrum B was obtained from the cooled polymer solution in the frozen state at −120 °C, and showed a typical powder pattern due to a rigid immobilization. The solid polymer in the molten state at 146 °C gave an incompletely averaged pattern due to an intermediate restriction of the chain motion (spectrum C). These three model spectra were superimposed upon one another on a computer to match the observed spectrum of the adsorbed polymer. As a result of the repeated runs, spectrum D gave a good fit to the line shape of the observed spectrum E. Thus, it was decided that the adsorbed polymer chain was constructed with three portions.

The Motion of the Adsorbed Chain Segments. The rotational motion of the loop segments is somewhat restricted by the fixing of the two loop ends by the surface, and will strongly depend on the length and the distance from the surface. The value of τ_c of the most mobile component was 1×10^{-9} s, while that of the intermediate portion was approximately 5×10^{-9} s. Therefore, resonable assignments for the relatively mobile components are as follows: the most freely

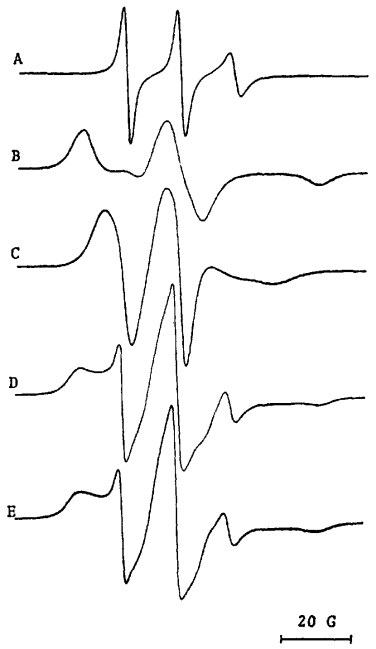

Fig. 3. ESR spectra of the spin-labeled PMMA.

rotating segments are in long loops, while the intermediately restricted segments are in short loops. The value of τ_c of the long loop segments was about twice as long as the unadsorbed polymer in solution at the same temperature, 25 °C. The sequences of the detached segments were considered to be long enough to allow the rapid tumbling motion, although each segment behaves in a less mobile way than does the free polymer in solution. The intermediate restriction of the short loop segments, 5×10^{-9} s, should be caused by a close neighboring with the train segments. Robb and Smith demonstrated the presence of short loops of about 2 or 3 segments, from a comparison of their ESR results with the IR.[3] They thought that the ESR counted the short loops as the train. However, we suggest that the intermediately restricted portion of the adsorbed chain corresponds to the short loops of a few segments.

On the other hand, the most immobilized portion could be attributed to the train segments. Their motion was examined by the dependence of the extreme separation width (W) upon the temperature and the rapid-passage experiments. In Fig. 4, the values of W in various systems are plotted *vs.* the temperature. In the case of the adsorbed polymer, W values remained constant over the wide temperature range of −120 to 70 °C. The value of 68.5 G is in good agreement with the rigid limit (W_{max}) of the unadsorbed polymer in CCl_4 or benzene in the frozen states at −120 °C. These results mean that τ_c of the most immobilized component is at least longer than 10^{-7} s, since this time is the useful rigid limit for the motion of the nitroxide-spin labels to be detected by normal ESR measurements. In addition, W_{max} values of the adsorbed systems were significantly smaller than those in hydrogen-bonding

media.[12] For example, the polymer solutions containing methanol or phenol gave the values of 73 and 76 G, respectively. Therefore, in the case of the adsorbed polymer phase, the direct H-bonding between the nitroxide labels and the surface silanol groups was negligible, and any specific adsorption through the nitroxide labels was not predominant over that between the original polymer segments and the surface. From the adsorption experiments using the unlabeled PMMA and the monomeric species (MMA and the labeled MMA), the same conclusion was obtained.

When the first harmonics of the dispersion mode were detected at 90° out-of-phase with respect to the field modulation under the conditions of a moderately saturating-microwave field, the rapid passage spectra could be observed. The spectrum A shown in Fig. 5 was obtained from the unadsorbed polymer in benzene solution in the frozen state at −50 °C. The spectrum B was obtained from the adsorbed polymer in benzene solution at 25 °C, and showed a slight effect of the saturation transfer. These spectra were quite similar

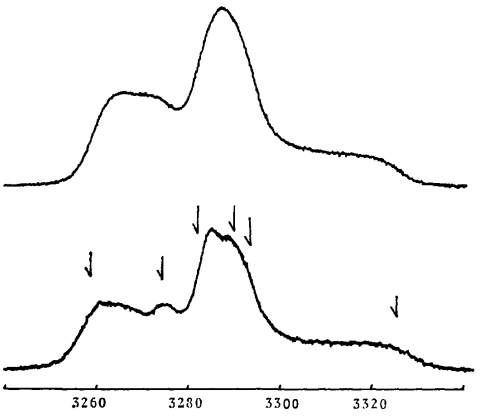

Fig. 5. Rapid passage dispersion spectra detected at 90° out-of-phase with respect to the field modulation of 5 G. Top: Unadsorbed in benzene at −50 °C, bottom: adsorbed on silica in benzene at 25 °C. The arrows show the turning points. Full scale is an interval of 100 G.

to the undifferentiated absorption spectra in the shape of the actual spectral distribution of spins. When τ_c is close to the reciprocal of the modulation frequency, approximately 10^{-6} s in this case, the spectral response is most sensitive to changes in τ_c.[8] The signal intensity would remarkably reduce with decreasing τ_c, in the regions between the turning points shown with arrows in Fig. 5. These turning points are the resonance fields where the magnetic principal axis of the nitroxide is oriented parallel or perpendicular to the applied field direction. The observed line shapes showed a very strong immobilization of the adsorbed polymer chain. If one neglects any contribution from a small amount of the mobile components on the spectrum, τ_c of the most immobile portion can be taken as longer than 10^{-6} s. Such a strong restriction demonstrates a rigid binding of the train segments by the surface sites. The motion was considerably slower than in the case of adsorbed monomeric species (labeled MMA) on silica. In general the rearrangements of the conformation of adsorbed polymeric molecules requires a relatively long period.[13] Such a strong restriction, due to the strict binding by the surface as described above, would disturb the rearrangement and consequently prevent the desorption process.

Miyamoto and Cantow studied the adsorption of isotactic PMMA onto silica from $CHCl_3$ solution using high-resolution NMR spectroscopy.[5] Since all of the signals from the adsorbed PMMA on the solid surface could not be detected, they concluded that the chain motion was strongly restricted at most of the segments, and the adsorbed molecule had an uniform and relatively compressed structure. In the present case of the ESR method, however, the spectrum seems to be composite, because the monitor attached to the polymer chain reflects sensitively the changes in the local segment motion over the wide range of τ_c from 10^{-7} to 10^{-11} s. The slow motional region in the long time scale is important in the case of the adsorbed chain. The considerable change in the motion arising from the differences in the configurational states of the adsorbed polymer segments, whether they are in train or loop, can be detected individually. The presence of three portions in the ESR spectrum was revealed by the line shape analysis in our study.

Effects of Solvent and Surface Coverage. The segment fractions in the three states were estimated from the integrated intensities of the signal components divided into three parts. Figures 6 and 7 show the fractions of the train, short loops and long loops as a function of the surface coverage (θ). At relatively low θ, most of the segments were highly localized near the surface. Consequently, the adsorbed polymer was flattened and formed a thin adsorbed layer. All of the theoretical treatments predict that a flexible chain polymer molecule will be strongly attracted by a solid surface and have an appreciably flat structure with a large fraction of train segments, in the case of a high level of the adsorption energy between the segments and the surface. In the present case, the adsorption is regarded to be caused by a strong attractive force much above 1 kT; the solvents used would not seriously perturb the adsorption energy, since H-bonding is the predominant interaction between the polymer and the surface. The revealed structures roughly agree with the theoretical prediction.

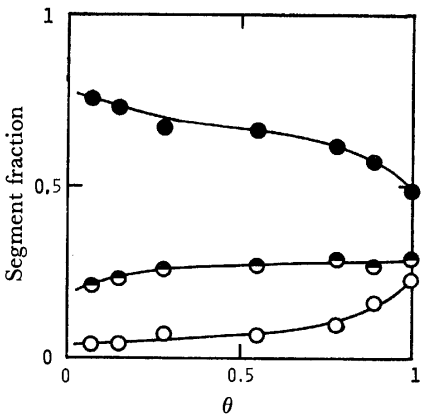

Fig. 6. The segment fractions of adsorbed PMMA in CCl_4 at 25 °C as a function of the surface coverage (θ).

The thickness of the adsorbed layer increased moderately with an increase in θ. The intermolecular interactions such as the adsorption competition among the molecules were encountered at the high concentration of the adsorbed polymer, and would cause the thickening. However, even at the saturation adsorption, a flat configuration still remained. In a previous publication, we reported that one adsorbed PMMA molecule had 24% of the H-bonded carbonyls. The surface area occupied by one molecule was estimated to be approximately 1.2×10^2 nm^2 at the saturation. This value is much smaller than the cross section of the random coil in solution estimated from the unperturbed dimension of PMMA.[14] Therefore, the adsorbed molecule seems to have a "compressed structure" at the CCl_4-silica interface.

The thickness was smaller in the good solvents (benzene and $CHCl_3$) than in the poor solvent (CCl_4). On the other hand, the maximum amount of adsorption (A_s) was appreciably decreased with increasing solvent

power, in the order of CCl_4, benzene, and $CHCl_3$. The decrease in A_s can be explained by the fact that a randomly coiled polymer is so extended in a good solvent that it occupies a larger surface area than in a poor solvent. The extension results in the decrease in the thickness under a strongly attractive force field. Particularly, there was a higher tendency of the short loop formation in the case of adsorption from CCl_4. In a poor solvent, such as CCl_4, the polymer molecule coiled and tended to form a large number of short loops. This tendency is consistent with the results from the computational statistical study by Clark *et al.*[15]

^{1}H NMR Study of Interaction of Probe Molecules with the Phosphate Ion on the Iron Core of Horse Spleen Ferritin

Noboru IMAI,* Yoji ARATA, and Shizuo FUJIWARA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received June 10, 1980)

The surface of the iron core of ferritin was investigated by ^{1}H NMR using small probe molecules which have different sizes and charges. It was shown that the parameter k, which is the linewidth for each NMR probe normalized by the total concentration of iron in ferritin, is dependent on the content of phosphorus in ferritin. At pH 7.4, the k values are 1—10 for positively charged probes, 2×10^{-2}—8×10^{-2} for negatively charged probes and 0.1—0.2 for neutral probes. Above pH 7, the k values for positively charged probes increase with an increase in pH, whereas those for negatively charged probes decrease. By contrast, the k values for neutral probes remain constant over the entire pH range. It was concluded that the k values reflect the mode of interactions of small molecules with the phosphate which exists on the surface on the iron core of ferritin, and that these interactions are determined primarily by the electrostatic force between the small molecules and the negative charge of the phosphate of ferritin. Furthermore, it was shown by using t-butylamine as a probe that K^+ ion binds strongly to ferritin and that chelating agents interact with ferritin in a wide concentration range.

Ferritin is an iron storage protein consisting of a shell of protein subunits surrounding the iron core which contains up to approximately 4000 iron atoms.[1,2] It has been shown that the iron core contains about 1 to 1.5% phosphate[3] and the concentration is much higher on the surface than in the inner part of the iron core.[4,5] It has also been reported that the ratio of phosphate to iron decreases with an increase in the iron content of ferritin.[5] Treffry and Harrison showed that ferritin, which had been reconstituted from iron(II) ion and apoferritin followed by incubation of the product in the presence of phosphate, resembles native ferritin with respect to the concentrations of phosphate incorporated per molecule or per Fe atom, and suggested that in the native ferritin most of the phosphate is adsorbed on the surface of the ferritin iron core after it is formed in the absence of phosphate.[6] May and Fish reported that the diffusion of acetic acid into apoferritin is much slower than that of methanol, glucose, and methylammonium ion.[7] Jones *et al.* showed that iron release from ferritin by polyanionic dihydroflavins is much slower than that by other dihydroflavins.[8]

In a previous paper, we have reported an NMR probe method where small molecules such as solvent water, tetramethylammonium ion and glycylglycylglycylglycine were used to study magnetic properties of the iron core of ferritin and to determine the pK_a values of the phosphate group on the surface of the iron core.[10] Because of the large size of the protein (molecular weight of the protein part, 445000),[1,2] any NMR signal from the protein shell of the native ferritin cannot be detected. It has been confirmed that the linewidth of the NMR probe examined is not influenced even if a high concentration of apoferritin (10 mg/ml) is present, indicating that the probe molecules are little influenced, if any, by the protein part of ferritin. It is unlikely that the paramagnetism of the ferritin iron can contribute to the line broadening of the probe molecules which exist outside the ferritin molecule; the effect of the iron core would decrease with the inverse of the sixth power of the distance.[9] Therefore only a direct interaction between ferritin iron core and the probe molecules, which contact with the iron core inside the protein shell, can be observed by the NMR method.

In the present experiment, the charge and size of the probe molecules were changed systematically. From these results, the state of the phosphate in the iron core will be discussed in detail. The interaction between ferritin and chelating agents, which are known to play an improtant role in the release of iron from ferritin, was also studied by the NMR probe method; the concentration range in which the chelating agents strongly interact with ferritin will be determined.

Experimental

Horse spleen ferritin was purchased from Nutritional Biochemicals Corporation (crystallized twice, Cd free, lot No. 4871, 4493). All chemicals used were of reagent grade. The concentration of iron in ferritin solutions were determined by atomic absorption.[10] Protein concentrations were measured by the Lowry method[11] and phosphorus concentrations were measured by a colorimetric method using ammonium molybdate and ascorbic acid.[12] The pH and concentration of ferritin in sample solutions were adjusted as follows: A stock solution of ferritin was prepared at concentrations of 0.2—0.4 M (as iron), and the pH of the solution was adjusted by dialyzing it against a buffer solution at a desired pH. The buffer solutions used were 10 mM glycine–HCl below pH 3.5; 0.1 M acetate in the pH range 3.5—6.2; 0.1 M Tris–HCl above pH 6.8. The stock solution thus prepared was added to a 10 mM probe solution just before each measurement. Before and after this treatment, very little pH change was observed; precipitation did not occur either. The pH of ferritin solutions was varied from 2 to 10. ^{1}H NMR spectra were recorded using a JEOL PS-100 spectrometer operating at 100 MHz in the conventional cw mode.

Results

Figure 1A shows how the linewidths of the methyl protons of methylamine and acetic acid are influenced differently with increasing concentrations of ferritin. At pH 7.4, the linewidth for methylamine is broadened 4—5 times at a concentration of 0.36 mM (as iron), whereas that for acetic acid remained almost unchanged even in the presence of 3.6 mM ferritin. Figure 1B

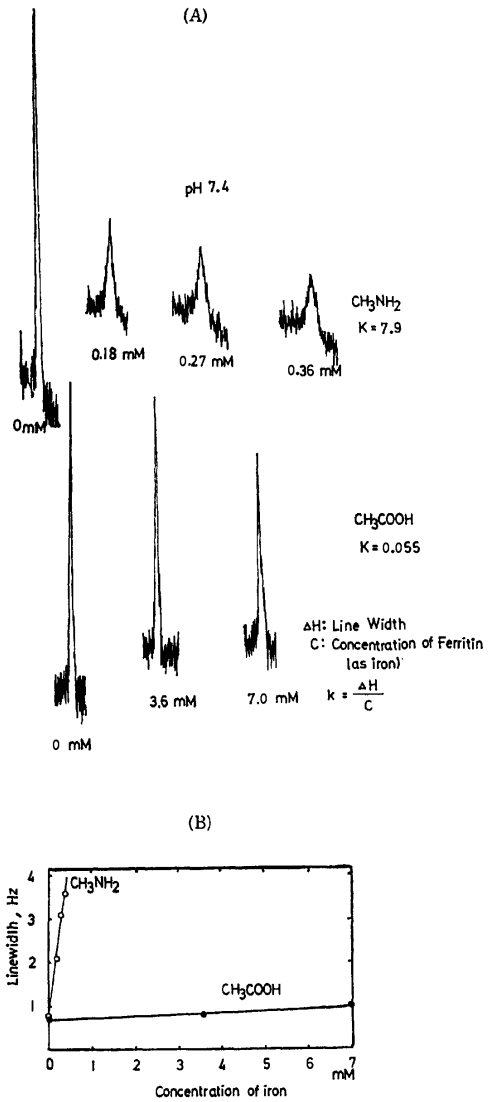

Fig. 1. (A) ^1H NMR spectra of methylamine (10 mM) and acetic acid (10 mM) at pH 7.4 in the presence of ferritin. The concentration (as iron) of ferritin added is shown in the figure. (B) The linewidths of the methyl peaks of methylamine and acetic acid as a function of the concentration of ferritin added.
○: Methylamine, ●: acetic acid.

shows the plots of the iron added *vs.* the linewidth of the peak. As shown in this figure, the slope for methylamine obtained from the plot is much larger than that for acetic acid.

We define the k value which is the linewidth normalized by the concentration of ferritin added and represents the line broadening of each peak. The observed linewidth ΔH_{obs} may be given as

$$\Delta H_{obsd} = \Delta H_0 + \Delta H_p \quad (1)$$

where ΔH_0 is the linewidth observed in the absence of ferritin and ΔH_p is a contribution from ferritin. When exchange between molecules which are under the influence of the iron core and those which are free in solution is fast enough, ΔH_p should increase linearly with the ferritin concentration (C) added. Therefore, $k(=\Delta H_p/C)$ should be constant, and

$$\Delta H_{obsd} = \Delta H_0 + kC. \quad (2)$$

The k value for methylamine is 8, whereas that for acetic acid is 6×10^{-2}; the former is two orders of magnitude larger than the latter. In view of the fact that at pH 7.4 methylamine and acetic acid exist as cation and anion, respectively, it appears that this large difference is caused by the difference in interaction between each of these probes and the negative charge of the phosphate group on the surface of iron core.[10] In fact, when ferritin containing less phosphate (phosphate : iron ratio (P/Fe) 0.08) is used, the k value of methylamine is 2.2, which is one fourth of that for ferritin with a larger P/Fe ratio of 0.10. This suggests that the k value is a sensitive parameter for the difference of the content of the phosphate of ferritin, and that the NMR probe method is useful to investigate the phosphate of ferritin.

The k *Values for Various Probes. Effects of the Charge and Size of the Probes*: The interaction of various probes with ferritin were investigated systematically. The probes which have the amino, hydroxyl, and carboxyl groups were used as representatives of positively charged, neutral and negatively charged probes, respectively. In addition, probe molecules which have the methyl and *t*-butyl groups were compared to study effects of the size of the probes. Probes with aromatic rings were also used to investigate the effect of the aromatic ring. Results are shown at two different pH values, 7.4 and 3.2 in Figs. 2A and 2B, respectively, where abscissa

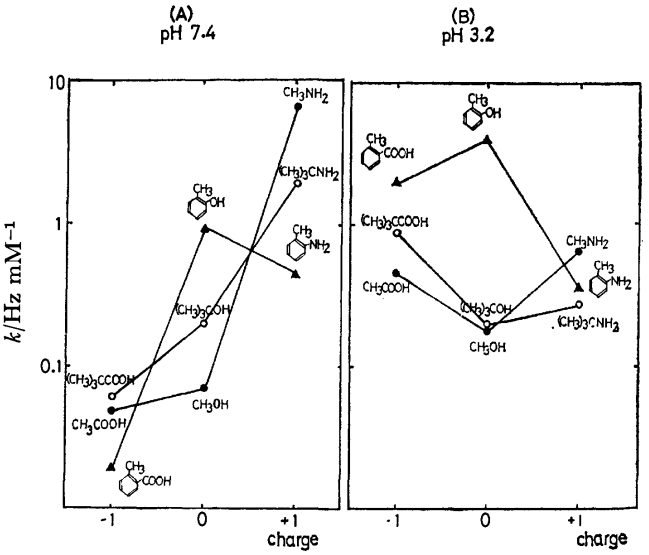

Fig. 2. The k values for probes with the amino, hydroxyl, and carboxyl groups. (A): pH 7.4, (B): pH 3.2.

represents the number of the charge of the probes used. The k values for neutral probes having the hydroxyl groups were about 0.1. The results for probes with the aromatic ring is quite different from those with the amino or carboxyl groups. It should also be noted that the k value for *o*-cresol is abnormally large and that *o*-toluidine is small compared with those of methylamine and *t*-butylamine.

At pH 3.2, the pattern of each curve in Fig. 2B

becomes quite different from that observed at pH 7.4; the k values for probes with the carboxyl group are much larger, whereas those for methylamine and t-butylamine are much smaller. By contrast, the k values for the neutral probes with the hydroxyl group remain constant. When the carboxyl groups of the probes lose their charges at low pH, electrostatic repulsion should decrease. Since the neutral probe has no charge, it is quite conceivable that the k value is not influenced by the change of pH.

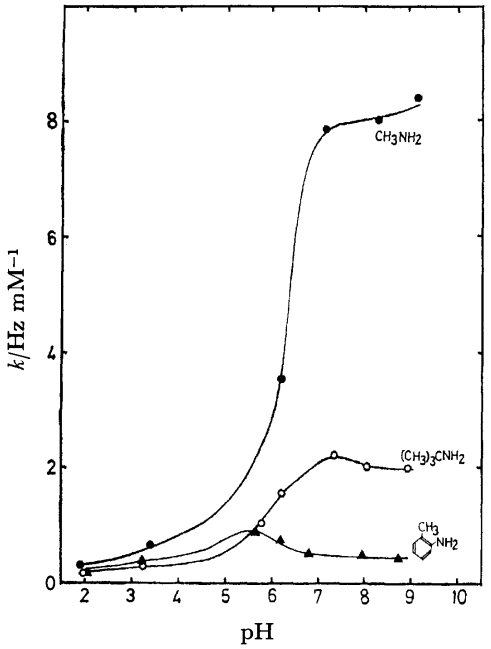

Fig. 3. The pH dependence of the k values for probes with the amino groups.
●: Methylamine, ○: t-butylamine, ▲: o-toluidine.

The pH *Dependence of the* k *Values. Positively Charged Probes with the Amino Group*: The pH dependence of the k values for various probes was investigated over a wide pH range in order to discuss in detail the results obtained above. The pH dependence of the k values for probes with the amino group is shown in Fig. 3. The pK_a of the phosphate in the iron core may be estimated from this curve.[10] It is seen in Fig. 3 that the k value for t-butylamine is one fourth of that for methylamine. The curve for o-toluidine has a maximum at pH 5—6. The charge of the amino group of o-toluidine with a pK_a of the amino group of 4.5 is lost at high pH; at the same time, the phosphate dissociates from the monoanion to the dianion in this pH range, suggesting that the maximum is due to a superposition of these two effects.

Neutral Probes with the Hydroxyl Groups: The pH dependence of the k values for methanol, t-butyl alcohol, and o-cresol is shown in Fig. 4. The k values for methanol and t-butyl alcohol are independent of pH. By contrast, the k value for o-cresol is much larger than those for methanol and t-butyl alcohol and has a maximum at low pH.

The affinity of Li^+, Na^+, and K^+ with Ferritin. Silk and Breslow[13] reported the effect of KCl and NaCl on the pH at which ferritin or apoferritin have no net charge, and suggested that K^+ ion binds with ferritin strongly. In the following we will show the usefulness of the NMR probe method in investigating interactions

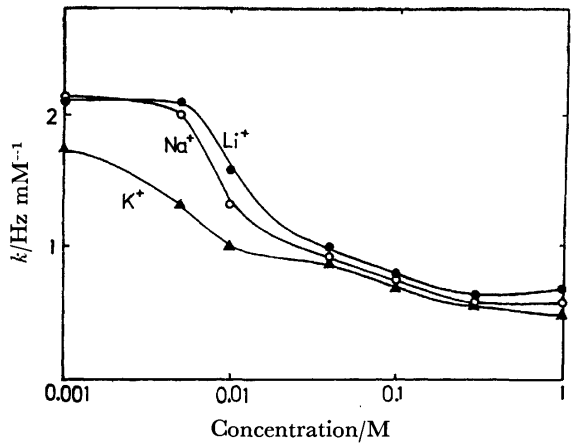

Fig. 6. The k values of t-butylamine as a function of the logarithmic concentration of Li^+, Na^+, and K^+ ions.

between ferritin and various kinds of ions, alkali cations being taken as an example. In Fig. 6, the k values for t-butylamine were plotted against the logarithmic concentration of each of the alkali ions. From a decrease in the k value for t-butylamine, it may be concluded that the interaction of t-butylamine with ferritin becomes weak with the increasing concentration of the cations added. When the concentration of the cations is high, there is little difference among k values for the three kinds of cations. In the concentration range below 10 mM, the k values for Na^+ and Li^+ become identical and equal to those observed in the absence of these ions (k=2.1). This result suggests that, in this concentration range of the cations, the broadening of linewidth is not affected by these ions. However, in the case of K^+ ion, the k value was still small even at a quite low concentration of 1 mM. This appears to indicate that the affinity of K^+ to ferritin is much stronger than those of Na^+ and Li^+.

The Interaction of Chelating Agents with Ferritin. It is well-known that chelating agents, as well as reducing agents, are capable of releasing iron from ferritin.[1,2] It has been reported that the rate, at which iron is released from ferritin by chelating agents, is generally quite slow; for example, only a small amount of iron can be released from ferritin by EDTA.[14] The NMR probe method may be used to investigate whether or not the poor iron releasing ability of EDTA is due to a weak interaction between EDTA and ferritin. In the present experiment, we use EDTA, citric acid, and acetic acid with four (pK_1 2.0, pK_2 2.67, pK_3 6.16, pK_4 10.26), three (pK_1 3.09, pK_2 5.49, pK_3 6.15), and one (pK 4.67) carboxyl groups, respectively. As expected from the negative charges which all these molecules have, the k values are quite small. Therefore, the interaction between the chelating agents and ferritin was investigated by using more sensitive second probes such as t-butylamine as described previously. The results are shown in Fig. 7. The k values for t-butylamine are plotted against the logarithmic concentrations of the chelating agents. The k value for acetic acid remains almost constant in the whole concentration range examined, whereas the curve for citric acid has a maximum at about a concentration of 3 mM and the curve for EDTA has a large value in a wide concentration range 0.03 to 10 mM. These results suggest that acetic acid which has no chelating ability does not interact with ferritin, whereas citric acid interacts with ferritin strongly in the narrow concentration range 1 to 10 mM and EDTA interacts more strongly in a much wider concentration range.

Discussion

Interaction of the Probe Molecules with the Phosphate on the Iron core of Ferritin. In the previous paper[10] we have suggested that the probe molecules interact with ferritin through the phosphate on the iron core. In order to confirm this, we compare interaction on the probe molecules with two types of ferritin, ferritin I (Fe/protein ratio 0.20; P/Fe ratio 0.10) and ferritin II (Fe/protein ratio 0.30; P/Fe ratio 0.08). Ferritin II contains more iron and less phosphate than ferritin I.

We first consider the broadening of neutral probes (for example, solvent water) in a solution which contains each of these two types of ferritin. The k values for ferritins I and II are designated as k_I and k_{II}, respectively. It was observed that at the same iron concentrations, the ratio k_I/k_{II} for neutral probes is 1.1, whereas k_I/k_{II} for positively charged probes is 3—5.

The broadening of the linewidths may be assumed to be proportional to the exposed area of the iron core which probe molecules can freely contact with. This area may be calculated as follows: The size and surface area of iron core are estimated using Fe/protein ratio (the number of iron atoms per molecule) and X-ray data (the size of unit cell)[15] on the basis of the assumption that each ferritin molecule contains one spherical iron core. At a given amount of iron, *i.e.*, at the same iron concentration, the number of iron core contained in a solution increases and the product of the number and the surface area of one iron core (total surface area) increases as the particle size decreases. Therefore, the surface area increases as the size of iron core (iron content of ferritin) decreases. Figure 8 shows the calculated surface area of iron core as a function of the

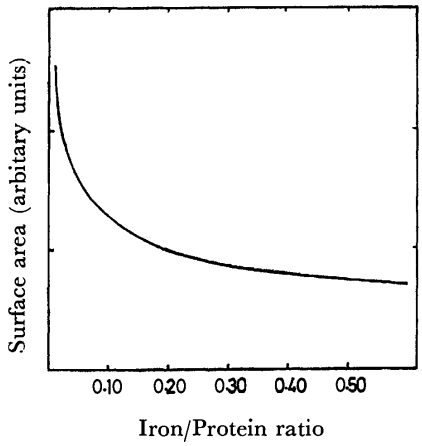

Fig. 8. The surface area of iron core as a function of the iron content of ferritin.

iron content of ferritin. This means that the linewidth should decrease as the iron content increases. This result is consistent with the report by Hoy *et al.*,[16,17] who reported that the rate of iron release from ferritin is closely related to the iron content.

In the above model, the ratio of the surface area of the iron core of ferritin I to that of ferritin II is about 1.1. This is consistent with the observation for the k values of the neutral probes. In view of these results, it may be concluded that the linewidth of the neutral probes is influenced only by the size of the iron core and not by the presence of the phosphate.

However, the line broadening for the positively charged probes in a ferritin I solution is quite different from that in a ferritin II solution. As mentioned above, the k_I/k_{II} ratio for the two solutions is 3—5. The large difference in k for the charged probes appears to be caused by the difference of the phosphate content. If the phosphate exists exclusively on the surface of the iron core,[4,5] the surface charge density of the phosphate for ferritin I should be larger than that for ferritin II. This would mean that the positively charged probe in the ferritin I solution is attracted to the iron core more strongly than in a ferritin II solution, and the k value for the ferritin I solution becomes larger than that for the ferritin II solutions. Since the protein part of ferritin I is presumably the same as that of ferritin II, it is likely that these differences are caused most probably by the phosphate on the iron core.

The Affinity of Li^+, Na^+, and K^+ with the Phosphate of Ferritin. The reason that the k values for t-butylamine decrease when the concentration of alkali ions becomes higher than 10 mM in Fig. 6 may be considered as follows: The alkali ions as well as t-butylamine have positive charges at pH$<$10 and presumably attracted to the negative charge of the phosphate of the iron core of ferritin. When the concentrations of the Li^+, Na^+, and K^+ ions are higher than that of t-butylamine (10 mM), it is probable that the alkali ions neutralize the negative charge of the phosphate; this would weaken the interaction of t-butylamine with ferritin and result in the narrowing of the linewidth of t-butylamine. On the other hand, when the concentration of alkali ions is lower than that of t-butylamine, the interaction of t-butylamine with the phosphate of ferritin would dominate and the linewidth of t-butylamine remain unchanged.

Interaction between Chelating Agents and Ferritin. Several chelating agents with the carboxyl groups were used to investigate how these molecules interact with ferritin. As mentioned previously, these molecules are subject to strong repulsing force from the negative charge of the phosphate on the core of ferritin and therefore should be insensitive as NMR probe. Thus, t-butylamine which is a sensitive NMR probe is added to the solutions, and the interaction between chelating agents and ferritin was investigated through the linewidth of t-butylamine. In this experiment, the linewidth of t-butylamine in a ferritin solution increases when the chelating agents are added. Possible reasons for the broadening of the linewidth of t-butylamine are as follows: 1) As mentioned previously, when the concentration of alkali ions increases, the negative charge of the phosphate of the iron core of ferritin is neutralized and the linewidth of t-butylamine decreases at a high concentration range of alkali ions as shown in Fig. 6. In the present experiment, this seems to be one of the reasons that each k value of EDTA, citric acid and acetic acid decreases in a high concentration range as shown in Fig. 7. 2) The negative charge of the chelating agents would cancel the positive charge of t-butylamine, resulting in a decrease in the k value of t-butylamine. 3) It is possible that the chelating agents strongly interact with ferritin and bind to the iron core of ferritin. The number of negative charges per ferritin molecule increases when the negatively charged chelating agents bind to the iron core of ferritin. This would also increase the k value of t-butylamine.

Conclusion

It has been shown that the NMR probe method is useful in obtaining information about ferritin and, in particular, the mode of interaction between the small molecules and ferritin. It was suggested that this interaction was determined primarily by the electrostatic repulsion and attraction which arise from the negative charge of the phosphate on the iron core of ferritin. It was also concluded that K^+ ion interacts strongly with the phosphate of the iron core even below a concentration of 1 mM and that EDTA binds strongly with ferritin in a wide concentration range 0.1—10 mM.

Fluorescence Decay Studies of 9-Aminoacridine Bound to Polyriboadenylic Acid

Yukio KUBOTA* and Yuko MOTODA

Department of Chemistry, Faculty of Science, Yamaguchi University, Yamaguchi 753

(Received June 16, 1980)

The interaction of the mutagenic dye 9-aminoacridine (9AA) with polyriboadenylic acid (poly rA) was studied by both steady-state and transient fluorescence measurements. It was found that the fluorescence decay of 9AA bound to poly d(A-T) follows a single-exponential decay law but that the decay data of 9AA bound to poly rA can be well described as a sum of two-exponential functions. The fact that nanosecond time-resolved fluorescence spectra are independent of time suggests that the double-exponential decay may be attributed to different microenvironments at the binding sites. The decay parameters, fluorescence emission maxima, and fluorescence quantum yields obtained at acid pH differ from those obtained at neutral pH. The fluorescence behavior of 9AA is discussed in connection with the conformational change of poly rA.

The dye 9-aminoacridine (9AA) is one of a number of acridines that are mutagenic[1] and that interact with DNA *in vitro*.[2] In previous work,[3,4] we have reported that guanine–cytosine base pairs completely quench the fluorescence of 9AA, upon binding to DNA, while adenine–thymine base pairs are responsible for its fluorescence and that the emitting sites of 9AA on DNA exhibit fluorescence decay curves which can be resolved into three-exponential components. The result has been attributed to the heterogeneity of the emitting sites.[4]

Studies on binding interactions between the dye and DNA are considerably complicated due to the content and the stereochemical arrangement of DNA bases.[2] Two approaches have been shown to be very useful in understanding the nature of interactions between the dye and DNA; one is to study using synthetic polynucleotides which contain simple types of binding sites, compared with DNA[3-6] and the other is to study complex formation between the dye and mononucleotides.[7-9] We have found that, upon binding to poly d(A-T) which contains only one type of site, the fluorescence quantum yield of 9AA is not substantially altered and its fluorescence decay follows a single-exponential decay law.[4] We have also found that the fluorescence of 9AA is markedly quenched by purine mononucleotides and that the weak fluorescence arises from 9AA complexed with adenosine 5′-monophosphate (AMP).[7,9] These findings suggest that the fluorescence behavior of 9AA may depend on whether the 6-amino group of adenine is hydrogen-bonded or free.

It is well established that the conformation of polyriboadenylic acid (poly rA) in solution changes from the hydrogen-bonded double-strand helix at low pH to the ordered single-strand structure of stacked bases at neutral pH.[10] Therefore, it is of great interest to study the fluorescence behavior of 9AA bound to poly rA in connection with its conformational change. Such a study may give a clue to the nature of interactions between 9AA and adenine residues.

In the present study, we investigated the fluorescence of 9AA bound to poly rA at various pH's by both steady-state and transient decay measurements. The decay behavior was found to be rather complex and possible interpretations are discussed.

Experimental

Materials. All chemicals were of reagent-grade purity or better. Poly rA was obtained from Miles, and, according to the manufacturer, had a molecular weight greater than 10^5. Poly d(A-T) was purchased from Miles. 9AA was the same sample as used before.[3,4] Poly rA solutions were prepared by first dissolving the required amounts of poly rA in 0.005 M† phosphate buffer (pH=6.9) and then dialyzing against the buffer solution to yield the desired pH. Concentrations of poly rA solutions were determined spectrophotometrically.[10] All measurements were carried out in 0.005 M phosphate buffer (pH=6.9) or 0.01 M acetate buffer (pH=4.1—5.9) solutions at (25±0.1)°C.

Absorption and Flow Dichroism Measurements. Absorption spectra were recorded using a Shimadzu UV-200S spectrophotometer. Flow dichroism measurements were made as described elsewhere.[11]

Steady-state Fluorescence Measurements. Steady-state fluorescence spectra were measured with a Hitachi MPF-2A spectrophotofluorometer. Correction was applied for the unequal quantum response of the detector system. The fluorescence quantum yield of the poly rA–9AA complex was determined by comparing the area under the fluorescence spectrum of the complex with the corresponding area of 9AA and by taking the quantum yield of 9AA to be 0.96.[3] For quantum yield measurements, the excitation monochromator was set at 408 nm with a 2—3 nm band pass, and the emission was recorded with a 2 nm band pass.

Transient Fluorescence Measurements. Transient fluorescence decay curves and time-resolved fluorescence spectra were measured with an Ortec nanosecond spectrophotofluorometer.[4,8,9] All decay measurements were performed under single photon counting conditions. The flash lamp was thyratron-triggered, air-filled (0.5 atm), and operated at 5.5 kV with a repetition rate of 25 kHz. The excitation wavelength at 375 nm was selected with an interference filter (Japan Vacuum Optics). The emission was observed by an RCA 8850 photomultiplier tube through a grating monochromator (Applied Photophysics Ltd.) whose bandpasses were varied from 2 to 10 nm according to the fluorescence intensity of the sample. Care was taken to eliminate anisotropic contributions to the observed decay according to the method described elsewhere.[4]

The observed decay curve $i(t)$ is represented by the convolution integral:

† 1 M=1 mol dm^{-3}.

$$i(t) = \int_0^t g(u)I(t-u)\mathrm{d}u \quad (1)$$

where $g(t)$ is the apparatus response function and $I(t)$ is the fluorescence decay which would be obtained with the δ-pulse excitation. It has been shown that the response function $g(t)$ depends on the energy of the photon impinging on the photocathode.[12] According to the method of Wahl *et al.*,[12] the true $g(t)$ was determined from the fluorescence decay curve of 1,1,4,4-tetraphenyl-1,3-butadiene in deaerated cyclohexane ($\tau = 1.72 \pm 0.02$ ns at 25 °C).

Deconvolution of Eq. 1 was achieved by the methods of Laplace transformation[13] and nonlinear least-squares[14] on the assumption that the fluorescence decay $I(t)$ is given by a sum of exponential functions:

$$I(t) = \sum_{i=1}^{n} \alpha_i \exp(-t/\tau_i) \quad (2)$$

where the α_i's and τ_i's are the amplitudes and lifetimes, respectively, of the ith component. Both methods yielded very similar results. The parameters obtained by analyses were convolved with the apparatus response function $g(t)$ and goodness of the fit between the observed and calculated decay curves was judged by inspection of the reduced χ^2, the weighed residuals, and the autocorrelation function of the residuals.[13,14] Data analysis was accomplished using a PDP 11/04 minicomputer (Digital Equipment Corp.) interfaced with an Ortec 6240B multichannel analyzer.

Results

Absorption and Steady-state Fluorescence Spectra. It is well established that the conformation of poly rA in solution changes from the double-strand helix at acid pH to the ordered single-strand structure of stacked bases at neutral pH.[10] The conformational transition depends on pH, temperature, and ionic strength.[10,15] Under the present conditions (ionic strength of 0.01 and 25 °C), the transition pH was found to be 6.0 in agreement with the previous finding.[10,15]

Since little is known about the optical properties of acridine dyes bound to poly rA,[16,17] absorption and steady-state fluorescence spectra at various pH's were first examined in order to obtain information on the

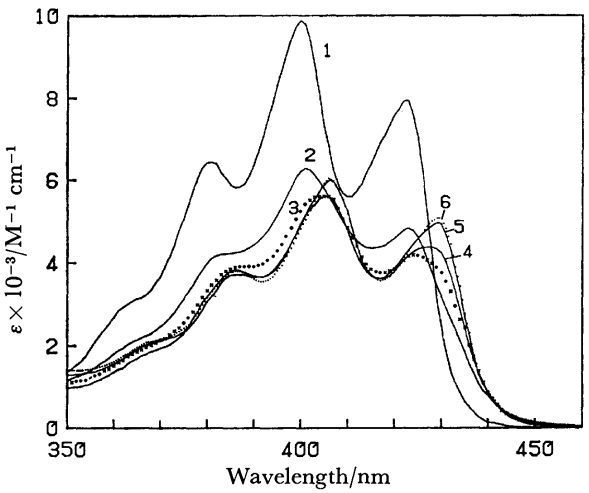

Fig. 1. Absorption spectra of poly rA–9AA complexes in 0.01 M acetate buffer (pH=4.9). 9AA: 3.8×10^{-5} M. P/D: (1) 0; (2) 4; (3) 10; (4) 20; (5) 150; (6) 193.

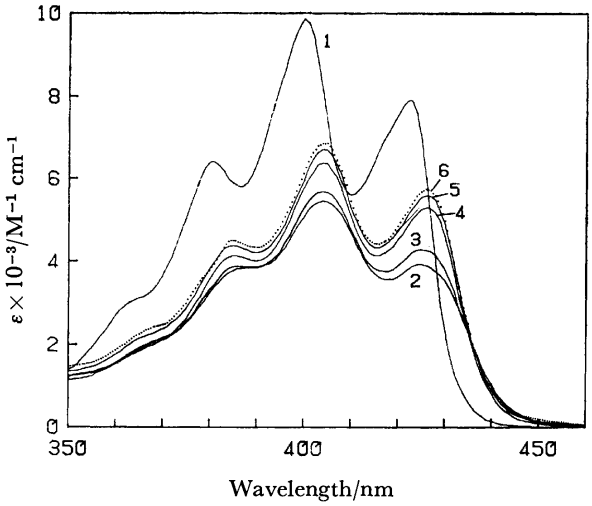

Fig. 2. Absorption spectra of poly rA–9AA complexes in 0.005 M phosphate buffer (pH=6.9). 9AA: 3.8×10^{-5} M. P/D: (1) 0; (2) 4; (3) 10; (4) 50; (5) 150; (6) 200.

binding state of 9AA. Figures 1 and 2 show absorption spectra of 9AA in the presence of poly rA, respectively, at pH=4.9 and pH=6.9. Absorption changes at low P/D** values ($P/D<4$), although spectra are not shown in Figs. 1 and 2 to avoid the complication due to overlaping, were found to result from the contributions of the bound and free 9AA. With increasing P/D, isosbestic points (425 nm at pH=4.9 ($P/D>20$) and 435 nm at pH=6.9 ($P/D>4$)) appear in the absorption spectra, and absorption bands can be seen to shift progressively toward a limit at high P/D values ($P/D>200$) (Figs. 1 and 2.) This finding suggests that the bound 9AA is transformed gradually from one type of complex (complex I) to a different type of complex (complex II). The limiting spectra at pH=4.9 and pH=6.9 ($P/D>200$), respectively, resemble closely the spectra of 9AA intercalated into DNA[4] and of 9AA complexed with AMP;[7] both spectra show hypochromicity and red shift, compared with the spectrum of the free dye. As Dourlent *et al.*[17] first inferred from absorption spectra of proflavine bound to poly rA and their similarity to its spectra upon binding to DNA, complex I may be attributed to electrostatic interactions of the 9AA cation with the phosphate group, followed by cooperative binding along the phosphate backbone of poly rA, whereas complex II may be ascribed to stacking interactions between 9AA and adenine residues.

In order to avoid the complication due to the presence of different binding processes, the following fluorescence studies were performed at sufficiently high P/D values ($P/D>400$) where complex II predominates and the concentration of the free dye is negligible.

Figure 3 shows steady-state fluorescence spectra of the poly rA–9AA complexes obtained at acid and neutral pH's and also shows their comparison with spectra of 9AA complexed with AMP or poly d(A-T). As can be seen from Fig. 3, the spectrum at pH=6.9 is very similar to that of the AMP–9AA complex, and the

** Molar ratio of DNA Phosphate to Dye.

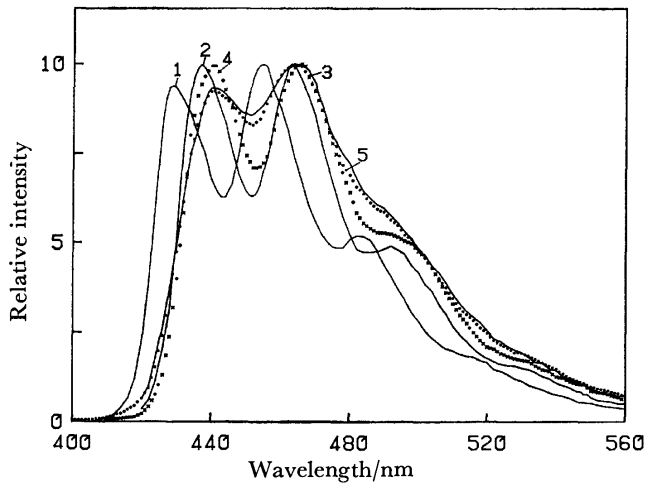

Fig. 3. Normalized fluorescence quantum spectra of 9AA in: (1) 0.005 M phoshpate buffer (pH=6.9); (2) poly rA (P/D=502, pH=4.9); (3) poly rA (P/D=503, pH=6.9); (4) poly d(A-T) (P/D=132, pH=4.9); (5) AMP (0.1 M, pH=6.9). The excitation wavelength was 390 nm, and the dye concentration was $7.4—12\times10^{-6}$ M.

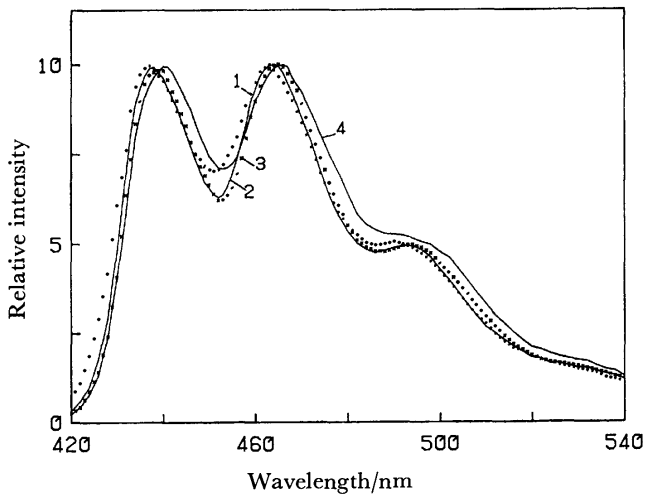

Fig. 4. Normalized fluorescence quantum spectra of poly rA–9AA complexes as a function of pH: (1) P/D=512, pH=4.1; (2) P/D=524, pH=5.3; (3) P/D=533, pH=5.9; (4) poly d(A-T)–9AA complex (P/D=132, pH=4.9). The excitation wavelength was 408 nm, and dye concentration was 1.2×10^{-5} M.

spectra at pH=4.9 and of the poly d(A-T)–9AA complex are similar in shapes except that the fluorescence bands of the poly d(A-T)–9AA complex are shifted toward longer wavelengths compared to those of the poly rA–9AA complex. Figure 4 indicates fluorescence spectra obtained at other acid pH's; a gradual red shift of the spectra can be seen upon going from pH=4.1 to pH=5.9. On the other hand, the fluorescence quantum yield (Φ_F) in this pH region (pH=4.1—5.9) was almost constant, while the Φ_F value at neutral pH was smaller than that at acid pH (Table 1).

Flow Dichroism. The poly rA–9AA complexes at acid pH showed negative flow dichroism in both the visible and ultraviolet regions; the reduced flow dichroism at a velocity gradient of 3200 s^{-1} was found to be −0.23 at 260 nm and −0.18 at 400 nm under conditions of P/D=20, [9AA]=5×10^{-5} M, and pH=5.0. This finding suggests that the acridine ring is oriented rather perpendicularly to the helix axis of poly rA like adenine residues.[11,18]

Fluorescence Decay Curves. Since fluorescence spectra of 9AA bound to poly rA depended on pH, fluorescence decay studies were undertaken to investigate further the nature of interactions between the dye and the binding sites. Decay curve measurements were made at high P/D values (P/D>400) and at low ionic strength (0.01). Under these conditions, the contribution of the free dye and energy transfer between bound dye molecules were negligibly small.

Figures 5 and 6 display typical decay data obtained at pH=4.9 and pH=6.9, respectively; the fit between the observed and theoretical convolved decay curves for a double-exponential decay law can be seen to be excellent. Sets of decay parameters obtained at various pH's are summarized in Table 1. In all cases, the χ^2, the weighed

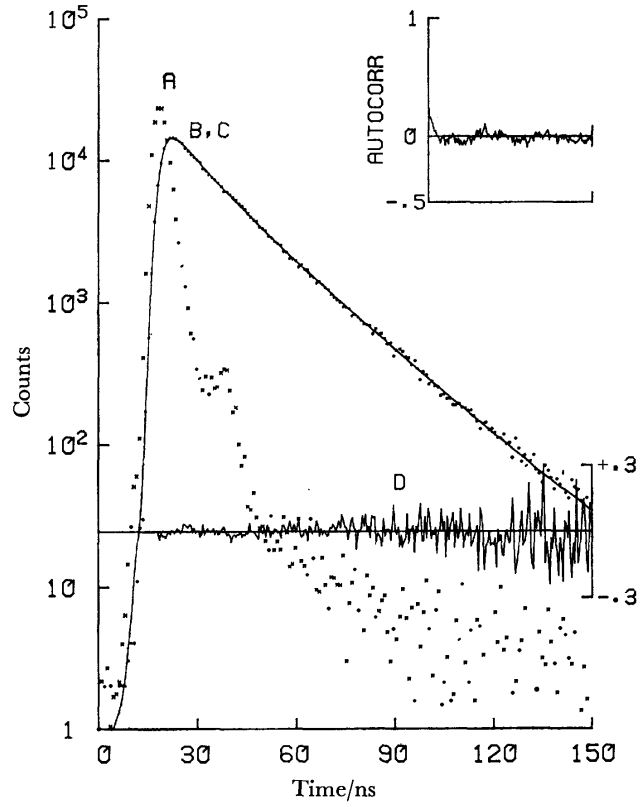

Fig. 5. Experimental decay curves and the results of a two-component analysis for poly rA–9AA complex (P/D=502) in 0.01 M acetate buffer (pH=4.9). 9AA: 7.4×10^{-6} M. The excitation and emission wavelengths were 375 and 455 nm, respectively. A: Apparatus response function. B: Observed decay curve. C: Best theoretical decay curve (smooth curve). D: Weighed residuals. The inset is the autocorrelation function of the residuals. Parameters obtained: τ_1=21.2 ns, τ_2=8.4 ns, α_1=0.088, α_2=0.077, and χ^2=1.71. The amplitudes normalized to unity are α_1=0.54 and α_2=0.46.

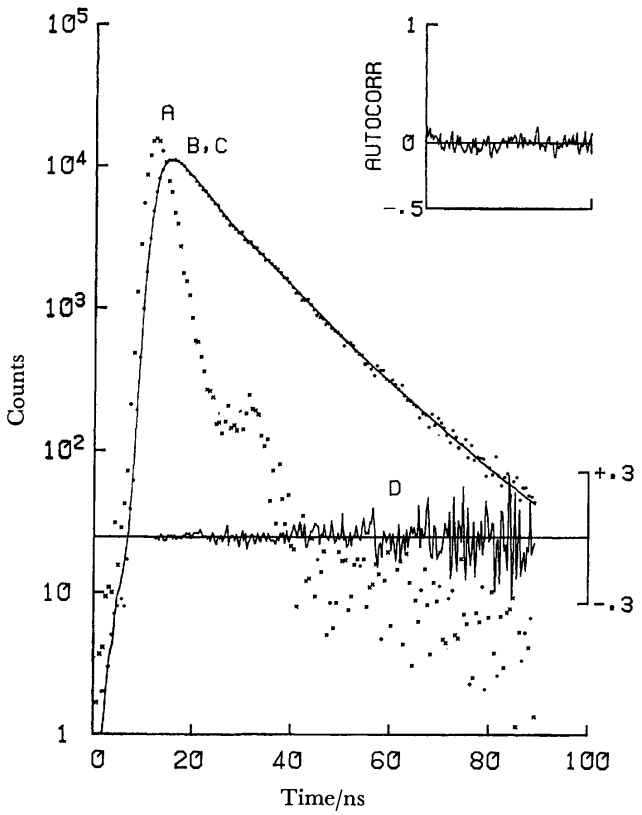

Fig. 6. Experimental decay curves and the results of a two-component analysis for poly rA–9AA complex (P/D=503) in 0.005 M phosphate buffer (pH=6.9). 9AA: 7.4×10^{-6} M. The excitation and emission wavelengths were 375 and 460 nm, respectively. Legends to each curve are as described for Fig. 5. The theoretical curve is based on the following parameters: τ_1=12.9 ns, τ_2=5.1 ns, α_1=0.111, α_2=0.123, and χ^2=1.19. The amplitudes normalized to unity are α_1=0.47 and α_2=0.53.

residuals, and the autocorrelation function of the residuals indicated that the data cannot be explained in terms of a single-exponential decay law but can be explained in terms of a double-exponential decay law. However, it must be emphasized that other more complex decay laws are not precluded because it is hard to analyze decay data in which two decay times are very close or one of amplitudes is very small.[13,19]

The decay parameters at acid pH differ from those at neutral pH, reflecting the differences in fluorescence spectra (Fig. 3) and quantum yields (Table 1). It should be noted that, at acid pH (pH=4.1—5.9), the value of τ_1 (long lifetime) increases with increasing pH, whereas that of τ_2 (short lifetime) is nearly constant in this pH range (Table 1). The implications of this finding are discussed below.

In contrast, the fluorescence decay of 9AA upon binding to poly d(A-T) at both acid and neutral pH's followed a single-exponential decay law (Table 1) in agreement with our previous finding.[4]

Nanosecond Time-resolved Fluorescence Spectra. Time-resolved fluorescence spectra in the nanosecond scale were measured in order to study any time-dependent interactions between the dye and its environments at the binding sites. The spectra were taken at time intervals ranging from 0 to 70 ns after the peak of exciting pulse. It was found that spectra showed no time dependence and were nearly identical with the steady-state fluorescence spectra. In agreement with this finding, there were no significant changes in the decay parameters when the decay was observed at emission wavelengths ranging from 430 to 510 nm.

Discussion

It is found in the present study that, at both acid and neutral pH's, the fluorescence decay of 9AA bound to poly d(A-T) obeys a single-exponential decay law, while that of 9AA bound to poly rA does not. The fluorescence decay curves of 9AA upon binding to poly rA can be well resolved into two-exponential components corresponding to the long (τ_1) and short (τ_2) lifetimes (Table 1).

Energy transfer between bound dye molecules might be possible as an explanation for the deviation of decay curves from single exponentiality.[6] On the basis of the Förster critical transfer distance (23±1 Å),[20] however, this appears unlikely at high P/D values. It is well

Table 1. Fluorescence decay parameters and quantum yields for 9AA bound to poly rA and poly d(A-T)[a]

System	pH	P/D	τ_1	α_1	τ_2	α_2	χ^2	Φ_F

	6.90	136	31.3	1.00			1.11	0.73

a) The dye concentration was $7.4—12\times10^{-6}$ M. The decay was observed at 455 or 460 nm; the results obtained here are not dependent on the emission wavelength. τ is given in nanoseconds, and the amplitudes (α's) are normalized to unity. Uncertainties in τ's and α's are within ±0.15 ns and ±1%, respectively.

established that the photophysics of excited-state reactions such as excimer or exciplex formation can easily lead to double-exponential decay kinetics.[21] If we focus our attention on such an excited-state system, the double-exponential decay of the poly rA–9AA complexes might be attributed to two distinct emitting species. This is unlikely, however, since the decay parameters do not show a significant dependence on the emission wavelength. The decay parameters obtained at acid and neutral pH's are seen to be quite different (Table 1). A conformational change at the binding sites may play an important role in the decay behavior of the bound 9AA. We suggest here that two lifetimes are related to different microenvironments at the binding sites.

If we assume that bound 9AA molecules are all fluorescent and that the radiative lifetime of the bound dye (τ_r) is independent of the nature of the binding sites, we obtain

$$\Phi_F = \frac{1}{\tau_r}(\alpha_1\tau_1 + \alpha_2\tau_2). \quad (3)$$

We observe that the absorption and fluorescence spectral behavior of the poly rA–9AA complexes at pH=4.9 and pH=6.9, respectively, is very similar to that of the poly d(A-T)–9AA and AMP–9AA complexes (Fig. 3).[4,7] It therefore seems reasonable to assume that the τ_r value of the poly rA–9AA complex at pH=4.9 or pH=6.9 is approximately equal to that of the poly d(A-T)–9AA or AMP–9AA complex. Using the observed lifetimes and quantum yields for the poly d(A-T)–9AA (Table 1) and AMP–9AA complexes (τ=1.45 ns and Φ_F=0.058),[9] the τ_r values for the poly d(A-T)–9AA and AMP–9AA complexes are evaluated to be 42.7 and 25.0 ns, respectively. Substituting the decay parameters given in Table 1 into Eq. 3 yields the following Φ_F values; $\Phi_F \approx 0.36$ at pH=4.9 and $\Phi_F \approx 0.35$ at pH=6.9. Taking into account the experimental error, both observed and calculated Φ_F values seem to be in reasonable agreement. This result and the double-exponential decay imply that there are at least two different microenvironments at the binding sites.

From the absorption and fluorescence spectral behavior at neutral pH and its similarity to that of the AMP-9AA complex, it seems likely that complex II at pH=6.9 results from stacking interactions between 9AA and adenine residues in a way very similar to the partial intercalation which predominantly occurs in single-strand denatured DNA;[22] the positive ring nitrogen of the dye is closely associated with the polynucleotide phosphate group and the dye lies between successive nucleotide bases. In such binding, greater contact between the acridine and adenine rings is expected to cause more effective quenching interactions.[9] Thus we propose that it is the mutual orientation or the extent of overlap between the dye and adenine residue which is responsible for the decay behavior. We attribute the component τ_1 (long lifetime) or τ_2 (short lifetime) to stacking interactions resulting in less or greater contact between the dye and adenine rings. It should be noted, however, that the actual decay law might be more complex since there would be many possibilities for the geometry of the bound dye; unfortunately more detailed decay analysis is beyond the present method.[13,19]

At acid pH, complex II shows the fluorescence spectrum similar to that of the poly d(A-T)–9AA complex and also shows negative flow dichroism. Furthermore, we observed that the decay of fluorescence anisotropy of the poly rA–9AA complex is very similar to that of ethidium bromide[23] or acridine dyes[24] intercalated between adjacent DNA base pairs. From these results it may be reasonably thought that the bound 9AA lies between hydrogen-bonded adenine-adenine pairs in a way similar to the intercalation into double-helical DNA.[25] We postulate that the above binding is responsible for the component τ_1 (long lifetime). Due to hydrogen bonding between the 6-amino group of adenine and the phosphate group and due to the protonation of 1-nitrogen (N_1) of adenine,[10,18,26] some steric hindrance may occur for the intercalation of 9AA. It is likely that 9AA binds rather outside the helix. In such binding sites (less hydrophobic ones), a part of the acridine ring would be exposed to solvent molecules, and hence the possibility of radiationless transition would be increased by collisions with the surrounding solvent. This explains why the τ_1 value is smaller than the lifetime of the poly d(A-T)–9AA complex (Table 1). The fraction of protonated N_1 is gradually decreased with increasing pH.[26] This allows 9AA to bind more interior areas of the helix, that is, more hydrophobic areas. This interpretation is consistent with a red shift of the fluorescence spectra (Fig. 4) and the increase of τ_1 with an increase in pH (Table 1).

Surprisingly there is an additional component τ_2 (short lifetime), in contrast with the poly d(A-T)–9AA complex (Table 1). The results in Table 1 show that the values of τ_2 and α_2 are almost independent of pH (pH=4.1—5.9). This means that the protonation of N_1 may not be so significant for the component τ_2. One possible explanation would assume that this component results from 9AA bound in the vicinity of discontinuities or ends of the helix,[10] in which adenine residues free from hydrogen bonding may cause some quenching of the 9AA fluorescence. However, the proportion of this component (α_2) seems to be rather high (Table 1). It is unlikely that there are a degree of strand discontinuities. Perhaps both sites corresponding to the components τ_1 and τ_2 may possess unequal binding affinity for 9AA owing to a conformational difference.

In conclusion, the results obtained here indicate that the decay behavior of 9AA bound to poly rA is rather complex. It is apparent that the 6-amino group of adenine free from hydrogen bonding plays a role in the quenching of the 9AA fluorescence. At present, however, there is no convincing evidence for the quenching mechanism. Indeed the study of transient intermediates by laser photolysis may answer the problem.

Laser Induced Biphotonic Dissociation of Nitrobenzene Derivatives in Solution

Kenji YOKOYAMA, Junko NAKAMURA, Takayoshi KOBAYASHI, and Saburo NAGAKURA*
The Institute of Physical and Chemical Research, Wako, Saitama 351
(Received June 20, 1980)

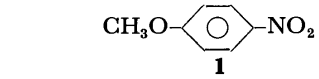
By irradiation with a focused laser beam, *p*-nitroanisole and *N*-[2-(*p*-nitrophenoxy)ethyl]aniline (**2**) in acetonitrile were found to show new reactions yielding nitroso compounds different from the case of the defocused laser beam irradiation. The laser intensity dependence of the product yield shows that the new reaction of **2** proceeds *via* a biphotonic process. The quenching effects of oxygen and *cis*-1,3-pentadiene upon the reaction rate indicate that the intermediate state is an excited singlet state.

Recently, laser induced chemical reactions have been studied by many authors, importance being attached to such multiphoton processes in the gas phase as unimolecular dissociation, ionization and sequential reactions.[1] However, reports on laser induced multiphoton reactions in the solution (at room temperature) are limited to the process with unstable products.[2]

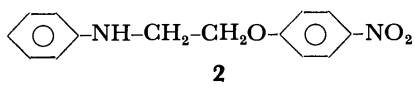
In the present study, we have found a new phenomenon that two different kinds of stable products are obtained with the photochemical reaction of nitrobenzene derivatives in acetonitrile by changing the focusing degree of laser beam for excitation. The result seems to be a typical example of switching of laser photoreactions to yield different kinds of stable products in the solution.

Experimental

Acetonitrile (Wako, Spectroscopic grade) was used as solvent without further purification. *p*-Nitroanisole (compound **1**) (Tokyo Kasei, Extra pure) was used after recrystallization from ethanol. *N*-[2-(*p*-nitrophenoxy)ethyl]aniline (compound **2**) was offered by Prof. K. Mutai, The University of Tokyo.



1



2

p-Nitrosoanisole was prepared by the method of Mijs *et al.*[3]

An N_2 laser (Molectron UV-24, peak power 900 kW, pulse duration 10 ns) was used as a source of irradiation. When a laser beam is defocused, the minimum cross section of beam, S, is about 1.0×0.3 cm^2 and $S\leq0.5\times0.1$ cm^2 when the laser beam is focused inside a sample cell. The incident energy per pulse was kept constant (10^{16} photons) for both cases. The repetition rate (20 Hz) and peak intensity of the exciting laser pulse were monitored with a photodiode throughout the reaction. Calibrated neutral density filters were used to attenuate the laser intensity.

Absorption spectra were measured with a Hitachi 320 spectrophotometer. Transient absorptions were measured by the apparatus reported previously.[4] Experiments were carried out at room temperature. Dielectric break down in the sample solution was not observed even for the maximum laser intensity.

Results and Discussion

The spectral change of **1** in acetonitrile by irradiation with defocused and focused beams of the N_2 laser were measured with the spectrophotometer and the results are shown in Figs. 1a) and 1b), respectively. The absorption intensity of **1** at 305 nm shows a slight decrease by the irradiation with a defocused beam, while the irradiation with a focused beam results in a large decrease of the absorption intensity and growing up of a new absorption band around 335 nm. These results show that the reactivity of **1** depends on the focusing degree of laser beam.

Similar experiments were made for **2** and the results are shown in Figs. 2a) and 2b). Mutai *et al.* concluded that a photo-Smiles rearrangement reaction occurs when **2** is irradiated with a defocused beam.[4,5] The absorption band of the photo-Smiles reaction product grows up at 390 nm (Fig. 2a)). By focusing the laser beam, however, a new band turns out to appear at 335 nm as is shown in Fig. 2b). This implies that a high density excitation induces a new reaction and produces a photoproduct other than that of the photo-Smiles rearrangement.

Both products from **1** and **2** by the irradiation with the focused laser beam have the band at 335 nm. This suggests that both products are similar to each other

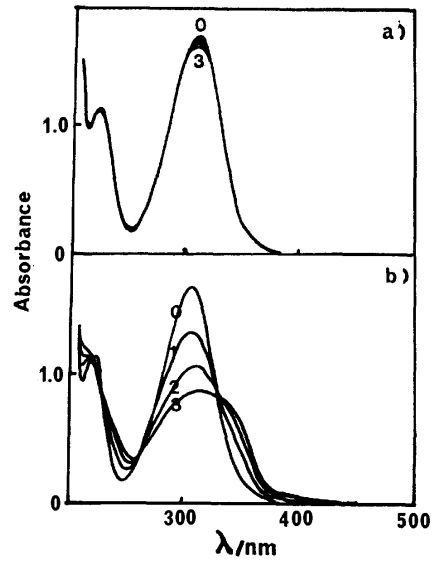


Fig. 1. Absorption spectra of **1** in acetonitrile after the irradiation with a) a defocused beam and b) a focused beam. Curves 0, 1, 2, and 3 represent the spectra after the irradiation for 0, 20, 40, and 60 min, respectively.

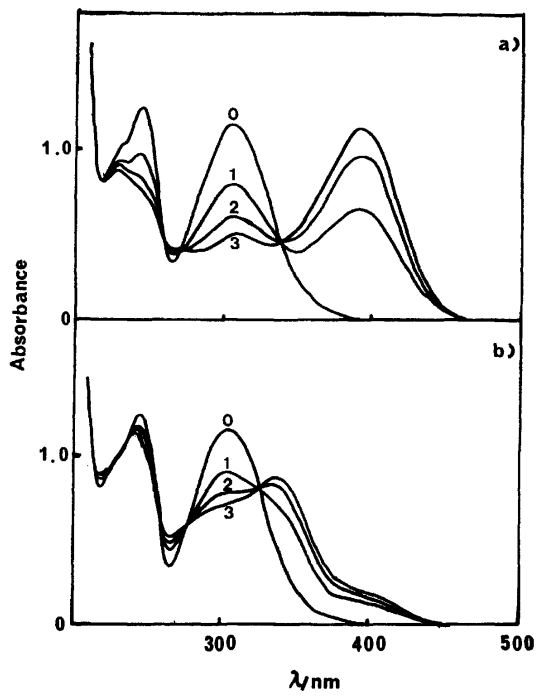

Fig. 2. Absorption spectra of **2** in acetonitrile after the irradiation with a) a defocused beam and b) a focused beam. Curves 0, 1, 2, and 3 represent the spectra after the irradiation for 0, 10, 20, and 30 min, respectively.

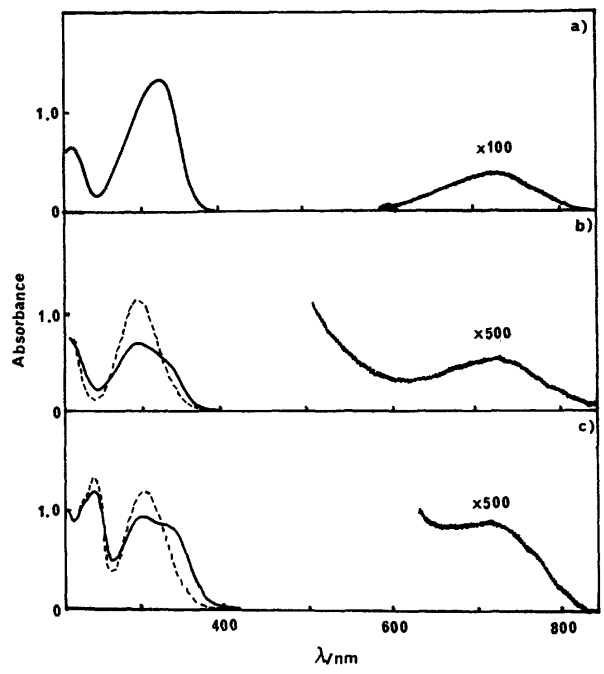

Fig. 3. Absorption spectra of *p*-nitrosoanisole and the new photoproducts from **1** and **2**. Cell thickness; 1 mm for the range of 200—500 nm and 100 mm for the range of 500—800 nm. a) The spectrum of *p*-nitrosoanisole. b) The spectrum of **1** after the irradiation. c) The spectrum of **2** after the irradiation. (Broken lines; the spectra before the irradiation.)

in their electronic structures. Since the 335 nm bands remain unchanged by addition of O_2 to the sample solutions or storing them in air for a few days, the new products responsible for the 335 nm bands are stable compounds. The process is unimolecular because the relative rate of the reaction is independent of the concentrations of the parent molecules.

In order to identify the new products which have the band at 335 nm, their spectra were measured in the wavelength region of 850—200 nm and a weak band was observed at 730 nm (Fig. 3). This finding suggests that the new products are nitroso compounds. For the purpose of comparison, the absorption spectrum of *p*-nitrosoanisole chemically prepared was measured and the result is shown in Fig. 3a). The spectrum is similar to the spectra of the products from **1** and **2** by the irradiation with the focused laser beam. This leads us to the conclusion that nitroso compounds are produced by the dissociation of an oxygen from the nitro group. Similarity of the absorption spectrum of the nitroso compound produced from **2** to that of *p*-nitrosoanisole is explained by the fact that conjugation between the ON-⟨○⟩-O-CH_2- and -HN-⟨○⟩ moieties is prohibited by the alkyl bridge.

The laser intensity dependence of the yield of the nitroso compound produced from **2** was studied. The

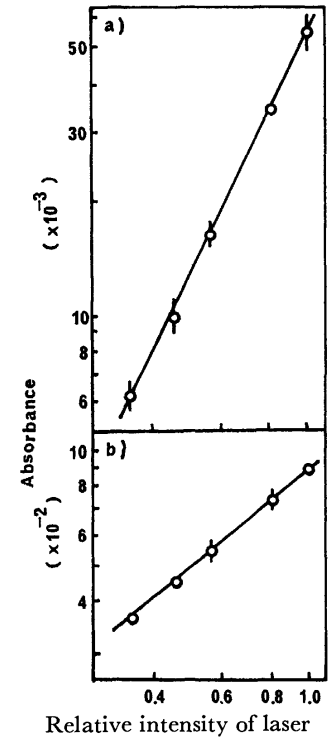

Fig. 4. The dependence of the yield of the photoproducts from **2** on the laser intensities. a) A plot of the logarithm of the absorbance of the nitroso compound at 335 nm *vs.* the laser intensity. The acetonitrile solution of **2** was irradiated with a focused beam for 5 min after bubbling with O_2 gas for 30 min. b) A plot of the logarithm of the absorbance of the final product of the photo-Smiles reaction at 390 nm *vs.* the laser intensity. The acetonitrile solution of **2** was irradiated with a defocused beam for 3 min.

logarithmic plot of the absorbance at 335 nm against the laser beam intensity shows a straight line with a slope of 2.0 (Fig. 4a)). This shows that the reaction proceeds *via* a biphotonic process. On the other hand, the laser intensity dependence of the yield of the final product in the photo-Smiles reaction shows a straight line with a slope of about 0.8, indicating that the reaction proceeds *via* a one photon process.

Considering the fact that the molar extinction coefficients of the nitroso compound at 335 nm and the final product of the photo-Smiles reaction at 390 nm are nearly equal, comparison between Figs. 2a) and 2b) induces the conclusion that the relative yield for the biphotonic process exceeds that for the one photon process when the laser beam is focused. This indicates that the new reaction proceeds *via* a consecutive two step process rather than a simultaneous two-photon process, since the transition probability of simultaneous two-photon absorption is much smaller than that of one photon absorption even in the resonance condition.[6]

The rate of reaction by the irradiation with a focused laser beam was not affected markedly by the addition of triplet quenchers (O_2 gas bubbled for 30 min or *cis*-1,3-pentadiene (0.1 mol dm^{-3})). This indicates that the intermediate state for the two step process is not the lowest triplet state with the lifetime of about 70 ns,[7] but an excited singlet state.

The biphotonic dissociation caused by the irradiation of the 337 nm laser beam indicates that an excited state existing at 6—7 eV above the ground state is responsible for the reaction. According to the calculation based on the CNDO/S-CI method[8] or the composite molecule method,[9] a state locally excited within the NO_2 group is located at 6.6 eV for nitrobenzene. This state has large transition component from a nonbonding MO to an antibonding MO on the NO bond as is shown in Fig. 5.

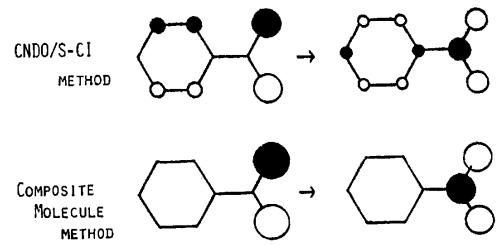

Fig. 5. The lower and upper MO corresponding to the local excitation within the nitro group.

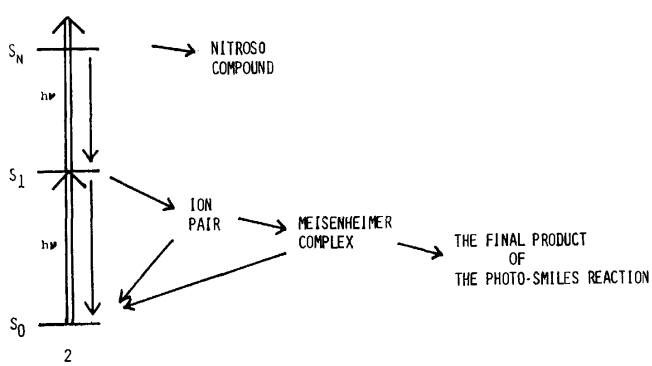

Fig. 6. The reaction scheme of **2**.

The antibonding character of the NO bond is expected to result in the cleavage of the bond.

Figure 6 shows the most probable scheme of photoreaction of **2**. The photo-Smiles reaction initiated with a defocused beam starts from the S_1 state and proceeds *via* an ion pair and a Meisenheimer complex to the final product.[4] This conclusion is confirmed by the fact that the yields of the two intermediates show linear dependences on laser intensity. By the irradiation with a focused laser beam, an effective excitation from S_1 to S_n state competes with the process of the photo-Smiles reaction and results in the production of the nitroso compound.

Nitrobenzene derivatives are known to have a large decay rate of the excited singlet state resulting in a nonfluorescent character. Thus, the focusing of laser beam seems to be necessary for the occurrence of the second absorption in a very short time of picosecond order. In turn, the short lifetime of intermediate state is consistent with the fact that the observed dependence of the amount of the produced nitroso compound on the laser intensity is quadratic, because a long lifetime of intermediate state would bring an approximately linear dependence on laser intensity.

Hasting and Matsen reported that nitrobenzene was converted into nitrosobenzene in the vapor phase by the irradiation of d.c. arcs with metal electrodes.[10] The detailed experimental conditions including the wavelength distribution of the irradiating source are not shown in their paper and the reaction mechanism is not clear. The present study has confirmed that nitro compounds can be converted into relating nitroso compounds *via* a two step process by the irradiation with light at 337 nm with the photon density of about 10^{17} photon cm^{-2} $pulse^{-1}$ and has presented a typical example of switching between different chemical reactions in solution by changing the focusing degree of a laser beam.

The authors express their sincere thanks to Prof. Kiyoshi Mutai, The University of Tokyo, for favorable offering of compound **2**.

5) K. Mutai, S. Kanno, and K. Kobayashi, *Tetrahedron Lett.*, **1978**, 1273.

6) According to a rough numerical estimation, when laser intensity is about 10^{17} photon cm^{-2} $pulse^{-1}$, the number of photons absorbed by a sample molecule at an ordinary simultaneous two-photon absoption band is about 10^{-10} photon $pulse^{-1}$, but that at a one photon absorption band is about

one photon pulse^{-1} (I. Webman and J. Jortner, *J. Chem. Phys.*, **50**, 2706 (1969)). Thus, the transition probability of two-photon process is much smaller than that of one photon process, although the former becomes about 7 orders larger when excitation energy coincides with a transition energy of one photon absorption band (J. E. Bjorkholm and P. F. Liao, *Phys. Rev. Lett.*, **33**, 128 (1974)).

Proton Magnetic Resonance Study of Interaction between Penicillin G and Hen Egg White Lysozyme

Fumiyuki MITSUMORI,*,† Yoji ARATA, and Shizuo FUJIWARA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received July 14, 1980)

Interaction between penicillin G and hen egg white lysozyme has been studied using NMR and gel chromatography. It has been demonstrated that the stoichiometry of the interaction is one to one with an association constant of approximately 1.9×10^2 M^{-1} (1M=1mol dm^{-3}). It has also been shown that the phenacyl side chain of penicillin G is interacting with the tryptophan-123 residue of the lysozyme molecule.

Study of interaction of penicillin with proteins is important in order to elucidate the behavior of penicillin in biological systems such as its transportation, antibacterial activity and allergy. Proteins such as serum albumin are known to function as a transport carrier of drugs in the blood circulation.[1] The antibacterial activity of penicillin is closely related to the fact that penicillin becomes an inhibitor of enzymes which synthesize the cell wall of bacteria.[2] As for the allergy, penicillin conjugates with proteins as a hapten, acquires immunogenicity, and at the antibody-antigen reaction penicillin interacts with its antibody protein selectively with high sensitivity, causing anaphylactic shock.[3] In each case, penicillin-protein interaction plays a decisive role.

Penicillin-serum albumin interaction has been examined using NMR.[4] However, very little is known about the binding site of albumin. It was also reported that in the complex between penicillin and carboxypeptidase, the C2-H proton of one of histidine residues of the protein shows a downfield shift.[5]

In the present paper, interaction between penicillin and lysozyme, one of the best characterized proteins, will be discussed on the basis of NMR measurements. Several studies have already been published on the penicillin-lysozyme interaction by means of X-ray diffraction,[6] inhibition of lysozyme activity,[7] equilibrium dialysis,[8] radioisotope labeling[9], and pulse radiolysis.[10] It has been reported that penicillin V binds to lysozyme in the ratio of one to one in the crystalline state,[6] and that hydrolytic action of lysozyme is inhibited 50% by the presence of 24 mM penicillin G.[7] It has been reported that an irreversible binding of penicillin G with lysine-116 of lysozyme occurs when a mixture of penicillin G and lysozyme is incubated for 48 h at 37 °C.[9] It has also been reported that no complex formation between penicillin G and lysozyme can be detected by means of equilibrium dialysis, whereas naphthylazopenicillin strongly interacts with lysozyme.[8]

In the present work, stoichiometry and the binding constant of the interaction between penicillin G and lysozyme are determined, and the binding sites on both sides will be discussed on the basis of NMR and gel chromatography results.

† Present address: National Institute for Environmental Studies, Yatabe, Tsukuba, Ibaraki 305.

Experimental

Penicillin G potassium salt (Sigma, Lot No. 24C-2130) and hen egg white lysozyme (Seikagaku Kogyo, Lot No. E5210) were used without further purification. All other reagents were of analytical grade.

For NMR measurements of the NH proton of tryptophan residues, lysozyme were dissolved in H_2O (5 mM in 0.1 M NaCl, pH 5.5), to which penicillin G was added. For other NMR measurements, penicillin G and lysozyme were dissolved in 0.3 M deuterated acetate buffer in D_2O (pH 5.5). NMR measurements at 100 MHz were performed using a JEOL PS-100 spectrometer operating in the correlation[11] and in the CW mode, and 360 MHz spectra were recorded on a Bruker HXS-360 in the correlation and in the FT mode. Chemical shift values are from either external DSS or internal HDO in D_2O.[12]

Gel chromatography was performed at 25 °C on a column (1×25 cm) of Sephadex G-25 by following the procedure described by Hummel and Dreyer.[13,14] Before use, the column was equilibrated with 0.1 M acetate buffer solution (pH 5.5) containing penicillin G (0.8—8.3 mM). About 50 mg of lysozyme was dissolved in 0.5 ml of the same eluting solution, and elution was performed at flow rate of 0.25 ml/min. The effluent was collected in 2.0-ml fractions and diluted to fit the concentration of penicillin G for UV measurements. The concentration of penicillin G was determined by the color development at 325 nm.[15]

Results and Discussion

Stoichiometry and Binding Constant of the Interaction between Penicillin G and Lysozyme. Figure 1 shows a typical elution profile at 325 nm. The amount of penicillin G bound to lysozyme is estimated from the area of trough displayed in the elution profile. The extent of binding of penicillin G to lysozyme was also measured at varying concentrations of penicillin G and the result is shown as a Scatchard plot in Fig. 2. This result clearly indicates that the stoichiometry of interaction between penicillin and lysozyme is one to one. The binding constant obtained from the plot is approximately 1.9×10^2 M^{-1}.

Binding Site in Penicillin G. Fischer and Jardetzky used the broadening of the phenyl and methylene peaks of penicillin G in the presence of albumin and concluded that the phenyl part of the penicillin molecule is involved in the interaction between penicillin G and albumin.[4] The phenyl and methylene peaks, which they treated as single peaks, are actually of AB and A_2B_2C spin systems, and are no longer singlet at 360 MHz. They

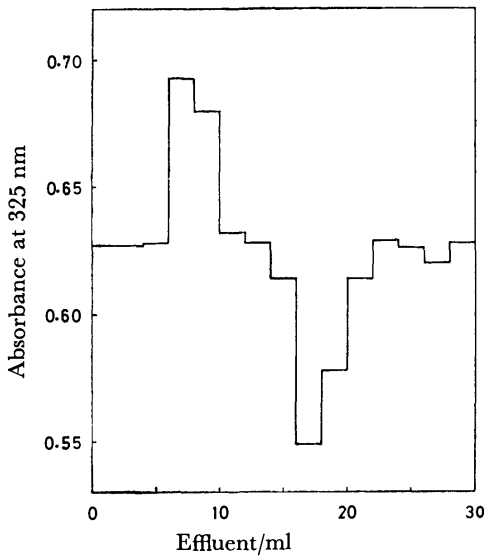

Fig. 1. Elution profile of the 325 nm absorbance accompanying the passage of lysozyme (50 mg) through a column of Sephadex G-25 which was equilibrated with 1.73 mM penicillin G at 25 °C. The collected effluent was diluted by 12.5-fold before the color development.

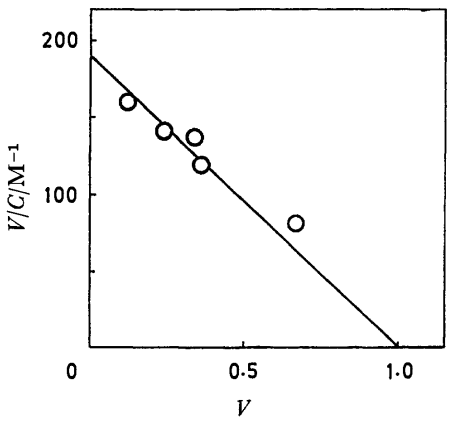

Fig. 2. Scatchard plot for the binding of penicillin G and lysozyme. C: The concentration of penicillin G in the eluting buffer, V: moles of penicillin G bound per mole of lysozyme.

have also shown that the chemical shift values of these peaks are dependent on the concentration of penicillin G. Thakkar and Wilham concluded that this concentration dependence of chemical shift values was caused by the self association of penicillin G.[16]

In the present experiment, the concentration of penicillin G is fixed at 32 mM, whereas that of lysozyme is varied from 0 to 10 mM. The change in spectrum of penicillin G under these conditions are shown in Fig. 3. With an increase in concentration of lysozyme from 0 to 10 mM, the phenyl peak shows an upfield shift of 0.098 ppm, the methylene peak an upfield shift of 0.079 ppm, and the β-CH_3 and 6-H peaks small upfield shifts of 0.035 ppm and 0.022 ppm, respectively. On the other hand, very little shift is observed in the α-CH_3, 3-H and 5-H protons. The result that 3-H is not affected by the presence of lysozyme suggests that no electrostatic

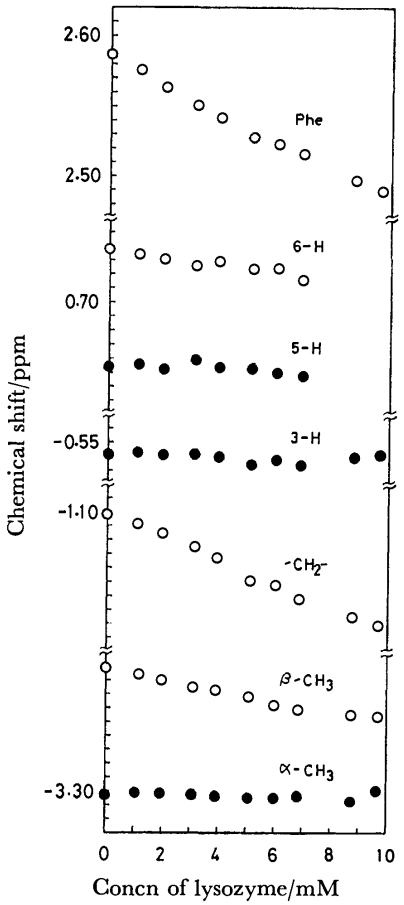

Fig. 3. A change in chemical shift values of penicillin G at varying concentrations of lysozyme in 0.3 M deuterated acetate buffer (pH 5.5). 28 °C. The concentration of penicillin G: 32 mM. Chemical shift values are in ppm from internal HDO whose chemical shifts are independent of the concentration of lysozyme within experimental error.

interaction involving the carboxyl group at C-3 of penicillin G occurs between penicillin G and lysozyme.

Among the groups of protons affected by the addition of lysozyme, the shifts observed for the phenyl and methylene peaks in the side chain are probably caused by the interaction with lysozyme; small shift in the β-CH_3 protons appears to be due to a change in intramolecular interaction of penicillin G molecule caused by interaction with lysozyme. This is supported by the experiments of the temperature dependence of the chemical shifts of penicillin G. As shown in Fig. 4, the β-CH_3 signal shows large temperature dependent shift. In contrast to this, 6-aminopenicillanic acid (6-APA), which has no side chain, does not show any such temperature dependent shift. Therefore, it may be concluded that the temperature dependent shift of β-CH_3 of penicillin G is primarily caused by the phenacyl side chain. Furthermore, the temperature dependent shift is much larger in the β-CH_3 group as compared to the α-CH_3 group. This result suggests that in an aqueous solution the penicillin G molecule tends to be less extended in shape, with the phenacyl side chain approaching from the side of the β-CH_3 group to the heterocyclic ring.

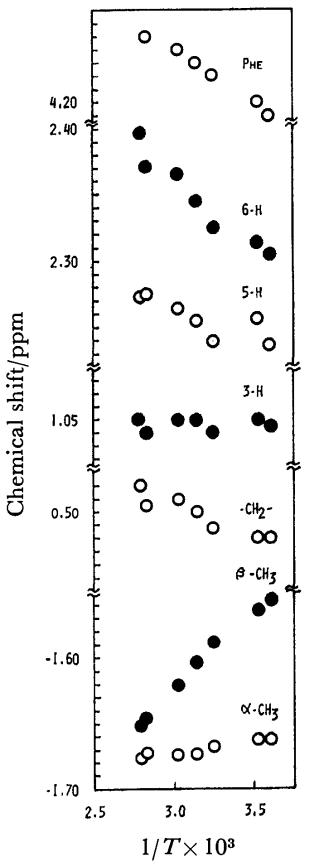

Fig. 4. Temperature dependence of chemical shift values of penicillin G in 0.3 M deuterated phosphate buffer (pH 7.0). Chemical shift values are in ppm from internal tetramethylammonium.

We assume that the shift caused by the addition of lysozyme is due to the fast exchange between the free and bound penicillin molecules. Then, the binding constant (K) and the chemical shift difference between the two states can be estimated by a least-squares method;[17] K was estimated to be in the range 10—250 M^{-1}, and the chemical shift differences for the phenyl and methylene groups in the ranges 0.4—1.3 ppm and 0.3—1.1 ppm, respectively.

In the presence of lysozyme, broadening of the methylene peak of penicillin G is observed at 100 MHz as Fischer and Jardetzky have already reported.[4] This peak is observed as an AB quartet at 360 MHz. Therefore, the broadening observed at 100 MHz is not quite helpful in obtaining information about the interaction of penicillin G with lysozyme.

Binding Site in Lysozyme. The result that the aromatic side chain of penicillin G molecule is the binding site suggests that aromatic amino acid residues of lysozyme may be involved in this interaction. Even in a relatively small protein such as lysozyme (M.W. 14300), proton signals observed separately are limited at the present resolving power of an NMR spectrometer.[18] Among those, C2-H proton of histidine-15 and NH protons of the indole ring of tryptophan residues can be used as probes for the investigation of the interaction site of lysozyme. The C2-H proton of His-15 does not show any change in chemical shift in the presence and absence of penicillin G, indicating that this histidine residue is not responsible for the interaction of penicillin G with lysozyme.

Correlation NMR technique is employed to observe exchangeable NH protons in H_2O. As shown in Fig. 5, the indole NH protons of five among six tryptophan residues are resolved. Peak I which is at the lowest field shows an upfield shift in the presence of penicillin G. Figure 6 gives chemical shift values of these five NH protons at varying concentrations of penicillin G. Only peak I shows an upfield shift with an increasing concentration of penicillin G. This result indicates that the tryptophan residue giving rise to peak I is involved in the interaction with penicillin G. Glickson, Phillips, and Rupley have reported that peaks III and V show a large shift in the presence of N-acetylglucosamine (NAG), an inhibitor of lysozyme.[19] The result of the present experiment suggests that penicillin G is different from NAG in its way of interaction with lysozyme.

On the basis of experiments such as chemical modification, binding of paramagnetic ions, inhibitors, and spin labels and solvent exchange, Cassels, Dobson, Poulsen, and Williams assigned the NH proton peaks from downfield as Trp-123, Trp-111 (or Trp-28), Trp-63, Trp-62, and Trp-108. In addition to this, they found the sixth peak in the upper field and assigned it as Trp-28 (or Trp-111).[20-22] Lenkinski, Dallas, and Glickson independently reported the assignments which agree with one of the two possibilities reported by Cassels *et al.*[23] Following the above assignments, Trp-123 is

the one which is involved in the interaction with penicillin G. Measurements of solvent exchange rates and X-ray structure studies have shown that Trp-123 is exposed to solvent;[20,24] penicillin G is presumably interacting with the Trp-123 residue on the surface of the lysozyme molecule.

Felsenfeld and Handschumacher have suggested that penicillin G binds to all tryptophan residues.[7] On the contrary, the present experiment indicates that penicillin G-lysozyme binding is more specific. Corran and Waley have reported that penicillin G is irreversibly bound to Lys-116 of lysozyme at its ε-amino group. However, this irreversible binding was observed after incubation of both substances for 48 h at pH 7.4 and 37 °C,[9] under which condition penicillin G is known to degrade forming various products.[25] In the present experiments, NMR measurements were performed immediately after penicillin G and lysozyme were mixed, so that it is quite unlikely that the covalent bond is formed.

The binding constant of $1.9\times10^2\,M^{-1}$ obtained for penicillin G is larger than that for NAG ($K=39\,M^{-1}$) and other saccharide monomers; however, it is smaller than those for dimers and trimers such as $(NAG)_2$ and $(NAG)_3$.[26] It is known that various pigments such as Biebrich scarlet, which have aromatic rings in the molecular structure, bind to lysozyme with high affinity.[27] Our result that the aromatic side chain of penicillin G is interacting with lysozyme with higher affinity than monosaccharides is consistent with these facts.

On the basis of an X-ray structural study of lysozyme which is diffused by penicillin V, Johnson has concluded that penicillin V binds specifically to the cleft on the surface of lysozyme. He has also shown that the penicillin binding site is apart $\approx$12 Å from the binding site of NAG and suggested that the binding is weaker than in the case of NAG.[6] Our results are not consistent with the conclusion reached by Johnson; *i.e.*, Trp-123 is not in the cleft of lysozyme molecule and the binding of penicillin G is stronger than that of NAG. There are two possibilities for this discrepancy. One is the difference in the molecular structure of penicillin G and penicillin V; in the penicillin V molecule the phenoxymethyl side chain is substituted for the benzyl side chain of penicillin G. All of our experiments were carried out in solution, whereas the X-ray structure was obtained in the crystalline state. This difference is another possibility for the above discrepancy. It is likely that in the crystalline state, where the lysozyme molecules are presumably more closely packed than in the case of solution, the penicilline molecule is hindered from approaching to Trp-123, which is in the dominant binding site of lysozyme.

In conclusion, interaction between penicillin G and lysozyme is one to one with a binding constant of approximately $1.9\times10^2\,M^{-1}$, and the phenacyl side chain of penicillin G and tryptophan-123 in lysozyme are involved in the binding.

The authors gratefully acknowledge a support from the Ministry of Health and Welfare (Special Research Grant #160). 360 MHz spectra were measured at Stanford Magnetic Resonance Laboratory which is supported by NIH grant #RR00711 and NSF grant #GP23633.

(Received April 26, 1979)

The crystal and molecular structure of the red compound, $[(NH_4)Cu_3Cl_4(C_6H_4O_2)_{1.5}\cdot H_2O]$, has been determined from 2115 X-ray diffraction data collected on an automated four-circle diffractometer. The crystals are monoclinic, with space group $P2_1/c$, and with four formula units in a unit cell of dimensions; $a=7.308(5)$, $b=11.593(7)$, $c=18.359(9)$ Å, and $\beta=90.16(3)°$. The structure was solved by direct methods, and block-diagonal least-squares refinements led to a final discrepancy index, R, of 0.035. The crystal structure is characterized by polymeric, beehive-like layers composed of $Cu_3Cl_4^-$ anions, and centro- and pseudocentrosymmetric *p*-benzoquinone molecules. Each of the *p*-benzoquinone molecules acts as a bridging ligand to the two *trans* $Cu_3Cl_4^-$ anions, with the Cu–C closest distances falling in the range from 2.047(5) to 2.086(5) Å. The NH_4^+ cations and the water molecules are accommodated by a roughly coplanar arrangement within the tunnel-like holes of the beehives, and the NH_4^+ cations are joined to the layers by intra- and interlayer hydrogen bonds of the N–H···O type. The $Cu_3Cl_4^-$ has a distorted cubane-type structure with one corner missing, and each Cu atom has a distorted tetrahedral coordination.

Yamaguchi *et al.* have synthesized a new compound with the composition of $[(NH_4)Cu_3Cl_4(C_6H_4O_2)_{1.5}\cdot H_2O]$ (hereafter abbreviated as BQ-Red), from $CuCl_2$, hydroquinone, and NH_4Cl in an aqueous solution. They have found, on the basis of spectroscopic studies, that this compound in the solid state is a polynuclear π-complex between $Cu_3Cl_4^-$ and *p*-benzoquinone (*p*-BQ).[1] It seems to have been reported few X-ray structural studies of metallic complexes containing *p*-BQ molecules as ligands, and so BQ-Red was expected to be a *p*-BQ complex of Cu(I) chloride of a novel type. The study of the crystal structure of BQ-Red has been carried out by the X-ray diffraction method to reveal the interactions between the $Cu_3Cl_4^-$ anions and the *p*-BQ molecules.

Experimental

Single crystals of this compound were prepared by one of the authors. Preliminary Weissenberg photographs showed the systematic absences of $0k0$, k odd and $h0l$, l odd, indicating the space group $P2_1/c$. The unit-cell parameters were obtained by a least-squares procedure using the 2θ values of 15 reflections measured on a Syntex $P\bar{1}$ four-circle diffractometer with Mo $K\alpha$ radiation. The density was measured by flotation in a methyl-iodide solution. The crystal used for X-ray work was ground to a sphere of 0.38 mm in diameter. The crystal data are given in Table 1.

TABLE 1. CRYSTAL DATA[a]

Formula unit	$Cu_3C_9H_{12}NO_4Cl_4$
Formula weight	530.65
Space group	$P2_1/c$
Density:	
D_m	2.27 g cm^{-3}
D_x	2.266 g cm^{-3}
Cell parameters:	
$a=7.308(5)$ Å	
$b=11.593(7)$ Å	
$c=18.359(9)$ Å	
$\beta=90.16(3)°$	
$V=1555.4(16)$ Å^3	
Number of formula units per unit cell:	$Z=4$
Linear absorption coefficient: (for Mo $K\alpha$ Radiation)	$\mu=49.1$ cm^{-1}

a) The numbers in parentheses, here and elsewhere in this paper, are the e.s.d.'s in the last significant digits.

Intensity data were collected by the θ-2θ scan technique at rates varying from 5.0 to 12.0° min^{-1} and with Mo $K\alpha$ radiation monochromated by a graphite crystal. 2115 independent reflections with 2θ values less than 45° were collected. Of these, 155 reflections with $I<0.7\sigma(I)$ were assigned values of $I=0.7\sigma(I)$ and were given zero weight in the initial refinement. The intensity data were corrected for Lorentz-polarization and absorption effects. The over-all temperature factor and the initial scale factor were obtained by the method of Wilson and were then used to compute the normalized structure factors, $|E|$.

Structure Determination and Refinement

The structure was solved by direct methods using the automatic phasing program MULTAN.[2] An E map calculated using 289 reflections with $|E|>1.5$ revealed the positions of all the Cu and Cl atoms. The other non-hydrogen atoms were obtained from a subsequent Fourier synthesis. Refinement was carried out by block-diagonal least-squares calculations in which the function minimized was $\Sigma\omega(|F_o|-|F_c|)^2$, initially with the unit weight and later with Cruickshank's weighting schemes for all reflections.[3] After refinement with anisotropic temperature factors, the H-atom positions were deduced from the difference Fourier syntheses, and the 35 most intense low-order reflections affected by the second extinction were corrected according to the method described by Stout and Jensen.[4] Refinement including the H atoms was terminated when the shifts of the parameters for the non-hydrogen atoms became less than a quarter of their estimated standard deviations. The final discrepancy index, R, was 0.035 for all reflections. A list of observed and calculated structure factors has been deposited with the office of the Chemical

Society of Japan as a Document No. 8036. The atomic scattering factors for Cu^+, Cl^-, O, N, and C_{cov}, and also the anomalous dispersion factors for the first two atoms, were taken from International Tables for X-ray Crystallography,[5] and those for H atom, from Stewart, Davidson, and Simpson.[6] All the calculations were carried out on a FACOM 230-75 computer in the Computer Center of Kyushu University, mainly by the use of the UNICS-II program system.[7] The figures were drawn by the use of the *ORTEP* program.[8] The final atomic parameters are listed in Table 2, along with their estimated standard deviations.

Results and Discussion

Crystal Structure. A projection of the crystal structure down the c axis is shown in Fig. 1, along with the atomic nomenclature scheme, while a stereoscopic illustration viewed along the a axis is shown in Fig. 2. The crystal structure consists of $Cu_3Cl_4^-$ anions, *p*-BQ molecules, NH_4^+ cations, and water molecules. The bond distances(l) and angles(θ) are listed in Table 3.

The $Cu_3Cl_4^-$ anions are arranged with an approximate $\bar{3}$ symmetry around the axis parallel to the a axis and passing through the inversion center at (1/2,1/2,0). Each of the *p*-BQ molecules is sandwiched between these anions in such a mode that the molecular plane is tilted about 99° in relation to the planes defined by the two C atoms and the one Cu atom, as shown in Fig. 3. These *p*-BQ molecules are also in an approximately threefold symmetric arrangement around each anion, with the Cu–C closest distances ranging from 2.047(5) to 2.086(5) Å. Inspection of these Cu–C distances and dihedral angles suggests that π-complexing occurs in BQ-Red. These Cu–C closest distances are shorter than the sum of the relevant Pauling's covalent radii, 2.12 Å.[9] This is indicative of strong interaction between the Cu atoms and the *p*-BQ molecules. It appears that this interaction plays an important role in the stability of the crystal. The distances from the Cu atoms to the centers of their nearest C–C bonds were found to be in the range from 1.953(5) to 1.960(5) Å, with an average value of 1.957 Å. BQ-Red is, to the best of our knowledge, the first reported π-complex

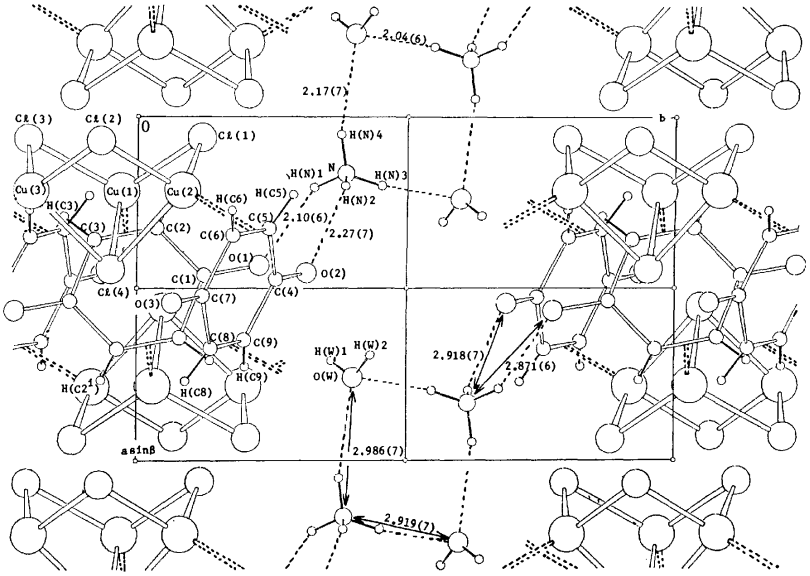

Fig. 1. Crystal structure projected down the c axis. Dashed and double-dashed lines indicate hydrogen bonds and Cu(I)-olefin bonds respectively, and distances in Å. The atoms in (1−x, 1/2+y, 1/2−z) and (x, 1/2−y, 1/2+z) have been omitted for clarity.

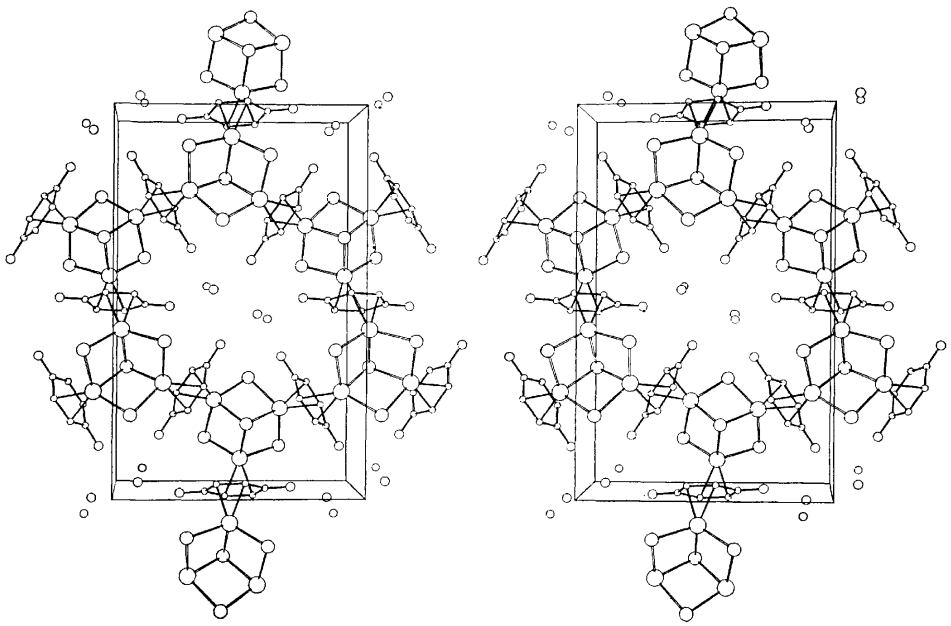

Fig. 2. Stereoscopic view of the crystal structure along the a axis. The center of the cell outline is at the inversion point (1/2, 1/2, 0). The b axis is horizontal, left to right, and the c axis points upward. The H atoms have been omitted for clarity.

where the *p*-BQ molecule bridges two *trans* Cu(I) cations as a di-olefinic ligand, although similar π-complexing has been found in $C_6H_6 \cdot (CuOSO_2CF_3)_2$, where the benzene molecule acts as a bridging ligand to two *trans* Cu(I) cations, with the Cu–C closest distances ranging from 2.09(2) to 2.30(2) Å.[10]

As shown in Fig. 2, each of the $Cu_3Cl_4^-$ anions is surrounded by three *p*-BQ molecules acting as bridging ligands, and these anions and molecules form a polymeric, two-dimensional, beehive-like network extended all over the bc plane. The beehive-like layers are stacked along the a axis, and the holes of the beehive look like tunnels running almost normal to the bc plane.

As shown in Fig. 1, the NH_4^+ cations and the water molecules are accommodated with a roughly coplanar arrangement within the tunnel-like holes of the beehive. The NH_4^+ is linked by hydrogen bonds to two *p*-BQ molecules and one water molecule within a layer, and the NH_4^+ cations and the water molecules in pairs bridge the layers with the hydrogen bonds across the centers of symmetry.

The crystal structure, thus, consists of polymeric,

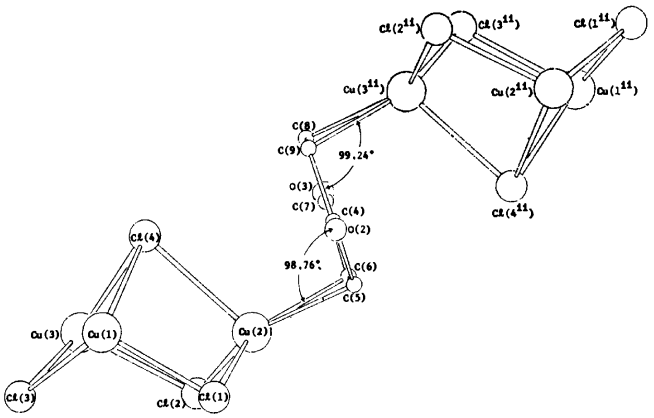

Fig. 3. Edge-on view of the p-BQ molecule lying at the general position. Similarly, the p-BQ molecule lying at the center of symmetry is coordinated to Cu(1) and Cu(1^{i}) so that its molecular plane makes an angle of 98.31° with the plane defined by C(2), C(3), and Cu(1).

beehive-like layers formed by $Cu_3Cl_4^-$ anions and p-BQ molecules, and of intra- and interlayer hydrogen bonds of the N–H···O type within the tunnel-like holes of the beehives.

Molecular Structure. The Cu_3Cl_4 moiety has a cap-like structure with an approximate threefold symmetry axis passing through the apex, Cl(4), and the midpoint of the three Cu atoms. The bond distances in the ring of the six-membered zigzag Cu–Cl chain range from 2.271(2) to 2.363(2) Å, while the three Cu–Cl(4) bonds bridging to the ring have distances ranging from 2.491(1) to 2.520(1) Å. The former and latter values are comparable respectively to the distances of the bidentate- and tridentate-chlorine-to-copper bonds found in other Cu(I) chloride complexes.[11,12] The bond angles within the Cu_3Cl_4 moiety fall into three groups; angles of about 109° between the ring Cl atoms subtended at each Cu atom, angles of about 80° at Cl(4), and the other angles of about 90°. Inspection

of these bond distances and angles suggests that the geometry of the Cu_3Cl_4 moiety may be described also as a distorted cubane-type with one corner missing. It has been found that the Cu_4Cl_4 core of $(P\cdot Ph_3CuCl)_4$ has a cubane-type structure in which each of the four Cu atoms has a distorted tetrahedral coordination, with Cu–Cl bond distances ranging from 2.362(2) to 2.505(2) Å.[13] In BQ-Red, each of the three Cu atoms has a distorted tetrahedral geometry coordinated by three Cl atoms and one *p*-BQ molecule, and the angles at the Cu atoms between the centers of their nearest C–C bonds and Cl atoms vary from 110.6(2) to 124.4(2)°. Such an environment around the Cu atom has also been found in $C_6H_6\cdot CuAlCl_4$, where the Cu atom has a distorted tetrahedral geometry coordinated by three Cl atoms and one benzene molecule acting as a mono-olefinic ligand.[14]

There are two crystallographically independent *p*-BQ molecules, one lying at an inversion center and the other at a general position. The latter has an approximate center of symmetry, though O(3) is the only oxygen atom not involved in hydrogen-bond formation. None of the bond distances or angles in either molecule is significantly different from the values obtained by gaseous electron diffraction.[15] Both molecules are also substantially planar, within the maximum deviations of 0.015 and 0.024 Å from their best-fit planes, despite that each of these molecules bridges two $Cu_3Cl_4^-$ anions with strong interactions.

The thermal-motion analysis has been applied to the three moieties of the $Cu_3Cl_4^-$ and the two independent *p*-BQ molecules in terms of the rigid-body model of translation and libration. The results suggest that both the *p*-BQ molecules behave as non-rigid bodies, in contrast with the Cu_3Cl_4 moiety, which behaves as a rigid body. This may be attributable to the polymeric structure. The thermal-motion corrections of the bond distances and angles were not applied in this work.

The authors are grateful to Professor Kawasaki at the Faculty of Pharmaceutical Sciences of Kyushu University for allowing them to use the automated diffractometer, and to Asst. Professor Kawano at the College of General Education of this university for his advice on the computation process.

The Kinetics of the Polymerization of Silicic Acid

Kanichi SHIMADA and Toshikazu TARUTANI*

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received July 16, 1979)

The process of the polymerization of silicic acid can be divided into three steps: (1) a reaction between monosilicic acids, (2) a reaction between monosilicic and polysilicic acids, and (3) a reaction between polysilicic acids. The rates of the reactions between monomer-monomer, monomer-polymer and polymer-polymer are most rapid at pH values around 9.3, 8.5, and 6.8 respectively. It is concluded that, above about pH 4, the polymerization due to Reactions 1, 2, and 3 proceeds mainly by a reaction between ionized and un-ionized silanol groups.

The rate of the polymerization of silicic acid differs with the pH values of the solution.[1-4] The polymerization of silicic acid is rapid in weakly alkaline and strongly acidic solutions, but very slow in the pH range of 1—3. The kinetics of polymerization of silicic acid have been studied by colorimetry,[1,4] because monosilicic acid reacts with a molybdate reagent in an acidic solution to give a yellow color, whereas polysilicic acid does not react with a molybdate reagent. However, no information is available on the change in particle size of the polymers with time. From a gel chromatographic study of the polymerization of silicic acid, it has been suggested that the mechanism of the growth of particles of polysilicic acid differs with the pH.[5]

The process of the polymerization of silicic acid may be divided into three steps.

(1): A reaction between monosilicic acids.
(2): A reaction between monosilicic and polysilicic acids.
(3): A reaction between polysilicic acids.

The first step of the polymerization of monosilicic acid is to form disilicic acid by the Reaction 1. If it can be assumed that, in the early stage of polymerization, the decrease in the concentration of monosilicic acid in solutions of various pH values is due mainly to Reaction 1, it may be possible to obtain the relationship between the rate of Reaction 1 and the pH.

When the concentration of monosilicic acid is higher than the solubility of amorphous silica at a given pH, monosilicic acid generally polymerizes, but the rate of polymerization depends on the concentration of monosilicic acid. In a solution with an adequate concentration of monosilicic acid, Reaction 1 does not occur within a certain period of time. Therefore, when monosilicic acid solution in which Reaction 1 does not occur within a certain period of time is mixed with a polysilicic acid solution and the concentration of monosilicic acid decreases with time from the moment of mixing the solutions, it is concluded that the decrease in the concentration of monosilicic acid is due mainly to Reaction 2.

When the concentration of monosilicic acid is close to the solubility of amorphous silica at a given pH, Reactions 1 and 2 virtually do not occur. As Reaction 3 proceeds regardless of the presence of monosilicic acid, the effect of the pH on the reaction between polysilicic acids can be measured by gel chromatography from the change in elution curves for silicic acid in the solutions of various pH values.

The present paper describes the effect of the pH on the rate of Reactions 1, 2, and 3. The term "monosilicic acid" here indicates the total sum of monosilicic acid (H_4SiO_4) and its conjugate base ($H_3SiO_4^-$), unless otherwise specified, while the term "polysilicic acid" indicates the dimer and larger polymer species.

Experimental

Sample Solution and Reagents. All the reagents used were of an analytical reagent grade. The monosilicic acid stock solution was prepared by fusing 0.500 g of anhydrous silica with 2.5 g of sodium carbonate, dissolving the melt in distilled water, and diluting the solution to 500 cm^3. A solution of Blue Dextran 2000 (Pharmacia Fine Chemicals, 0.4%) was used for the measurement of the void volume of gel bed in gel chromatography. The eluent for elution of silicic acid and Blue Dextran 2000 was a 0.1 mol/dm^3 sodium chloride solution of pH 2.

Preparation of Sephadex Column. Sephadex G-100 (Pharmacia Fine Chemicals) was suspended in the solution to be used as an eluent and was allowed to swell for three days. The column was a 1.0×45 cm or 1.5×45 cm glass tube with a porous polystyrene disc at the bottom. The Sephadex G-100 column was prepared as has been described in the literature.[6]

Procedure for Determination of Reaction 1. The monosilicic acid solution (500 ppm SiO_2) was adjusted to the desired pH with hydrochloric acid. After 5, 10, and 15 min, the concentration of monosilicic acid was measured by colorimetry.

Procedure for Determination of Reaction 2. The pH of the monosilicic acid solution (500 ppm) was adjusted to 8.3 with hydrochloric acid. After the solution had stood for 5 h, the pH of this solution was adjusted to 2 with hydrochloric acid, because polymerization and depolymerization do not occur for a short period at pH 2.[4] The concentration of monosilicic acid in this solution (Solution A) was 205 ppm, with the remainder being polysilicic acid. Several sample solutions containing 314 ppm of monosilicic acid and 187 ppm of polysilicic acid were prepared by mixing aliquots of Solution A and a 1000 ppm monosilicic acid solution. At the same time, the sample solutions were adjusted to the pH range of 6.9—9.6. After the solution had stood for 30 min, the concentration of monosilicic acid was measured by colorimetry and the silicic acid was chromatographed on Sephadex G-100 column. Elution was performed with a procedure similar to one previously reported.[5]

Procedure for Determination of Reaction 3. The pH of the monosilicic acid solution (500 ppm) was adjusted to 8 with hydrochloric acid. After the solution had stood for 5 h, the pH of this solution was adjusted to 2 with hydrochloric acid. The polysilicic acid was concentrated by the addition of dried Sephadex G-25 gel to the solution. After this treatment, the concentrations of monosilicic acid and polysilicic acid in

Table 1. The concentrations of monosilicic acid in initial sample solutions of various pH values

pH	SiO_2(ppm)	pH	SiO_2(ppm)
1	150	6	115
2	190	7	110
3	190	8	120
4	140	9.5	210
5	120	10	320

the solution (Solution B) were 179 and 536 ppm respectively. Ten sample solutions of various pH values containing 350 ppm polysilicic acid and monosilicic acid, in concentrations of various pH values shown in Table 1, were prepared by mixing solution B, a 1000 ppm monosilicic acid solution, distilled water, and a sodium hydroxide solution or hydrochloric acid. After the solutions had stood for 48 h, the pHs of these sample solutions were adjusted to 2 and the silicic acid was chromatographed.

All the experiments were carried out at 20 ± 1 °C.

Results

Effect of pH *on the Reaction between Monosilicic Acids.* The kinetics of polymer formation obtained by monitoring the concentration of monosilicic acid as functions of time and the pH is shown in Fig. 1. As it can be assumed that the decrease in the concentration of monosilicic acid is due mainly to the formation of disilicic acid by a Reaction 1 in an early stage of the polymerization, it is considered that the pH of the maximum of the decrease in the concentration of monosilicic acid after a few minutes may close to the pH at which the rate of the formation of disilicic acid is maximal. The pH giving the maximum rate of decrease in the concentration of monosilicic acid slightly shifted to a lower pH with lapse of time. This may be due to the effect of polymer formation by Reaction 2 as will be discussed later. The results indicate that the reaction between monosilicic acids is most rapid at a pH value around 9.3.

Effect of pH *on the Reaction between Monosilicic and Polysilicic Acids.* When the pHs of 330 ppm monosilicic acid solutions were adjusted to 8.6 and 9.0, the concentration of monosilicic acid in these solutions did not decrease within 30 min. That is, the monosilicic acid does not polymerize within this short period of time under these conditions. If the concentration of monosilicic acid decreases from the moment of mixing after polysilicic acid is introduced into the monosilicic acid solution of about 300 ppm, it may be concluded that the decrease in monosilicic acid is caused by the reaction between monosilicic and polysilicic acids. The procedure for the determination of Reaction 2 has been done under these conditions. The results are shown in Fig. 2. The decrease in the concentration of monosilicic acid was maximal at a pH value around 8.5.

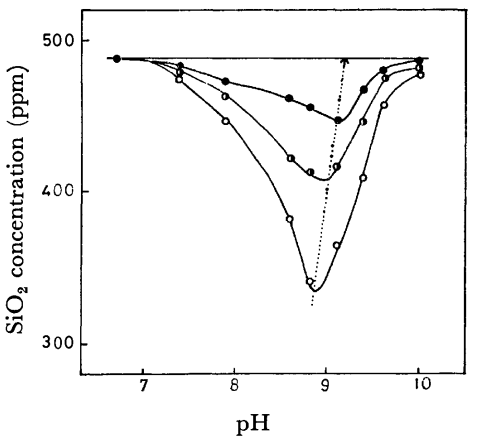

Fig. 1. Variation of the concentration of monosilicic acid as a function of pH. Time after ajusting pH: 5 min (—●—), 10 min (—◑—), 15 min (—○—).

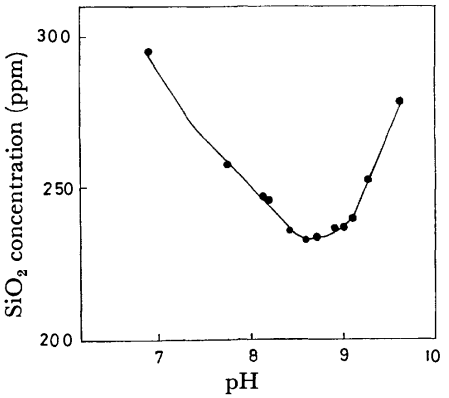

Fig. 2. Change in the concentration of monosilicic acid with pH after 30 min when polysilicic acid was added in monosilicic acid solutions.

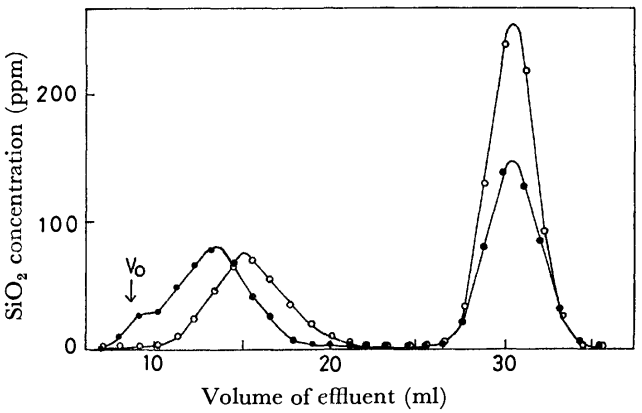

Fig. 3. Variation of elution curves for silicic acid in the solution of pH 8.9 with time. (Column, 1×45 cm). Initial solution: (—○—), solution after 30 min: (—●—).

The variation in elution curves for silicic acid with time is shown in Fig. 3. The position shown as V_0 is the elution volume of Blue Dextran 2000, which is considered not to be able to diffuse in the gel phase. It can be assumed that the elution volume of Blue Dextran is equal to the void volume of the bed. The peaks on the right are due to monosilicic acid, while the peaks on the left are due to polysilicic acid. The elution curve for silicic acid in the initial solution is symmetrical. The elution curve for the polysilicic acid in the solution shifts to the left after 30 min, but the shape of the elution curve, except shoulder at the V_0 position, is almost the same as that obtained from the initial solution. The shoulder of the elution curve at the V_0

position means that polysilicic acids larger in size than the possible separation range of the gel are eluted together at the V_0 position. If the growth of particles of polymers is due mainly to polymerization between monomer and polymer, the elution curves for polysilicic acid are symmetrical, and this symmetry is maintained in spite of the lapse of time.[5] The results shown in Fig. 3 reveal that the growth of the particles of the polymers is due mainly to the polymerization between monomer and polymer. From the results shown in Figs. 2 and 3, it is concluded that the polymerization between monomer and polymer is most rapid at a pH value around 8.5.

Effect of pH *on the Reaction between Polysilicic Acids.*

The concentrations of monosilicic acid shown in Table 1 are close to the solubility of amorphous silica at a given pH.[1,7,18] Reactions 1 and 2 did not occur in 1.0—10.0 pH range within 48 h. As the reaction between polymers proceeds regardless of the presence of monosilicic acid, the results obtained by the procedure used for the determination of Reaction 3 give the relationship between Reaction 3 and the pH. The elution curves for silicic acid in solutions of various pH values after they have stood for 48 h are shown in Fig. 4. The elution curve for silicic acid in the solution of pH 2 did not change within 48 h. This elution curve represents the distribution of particle sizes of silicic acids in initial solutions of various pH values. In the solutions above pH 4, the elution curves due to polymers shifted to the left after 48 h compared with that at pH 2. This means that the particle sizes of polymers became larger than in the initial solutions. The elution curve for silicic acid in the solution of pH 3 after 48 h was identical with that in the initial solution.

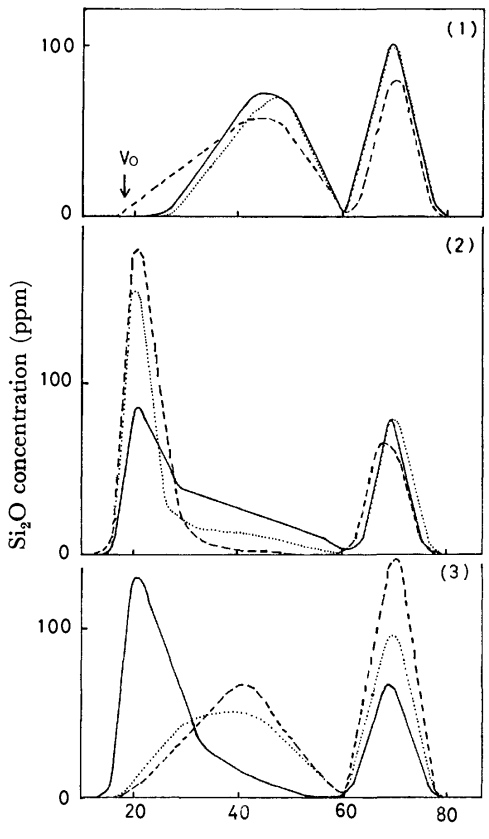

Fig. 4. Variation of elution curves for silicic acid in the solutions of various pH. (Column, 1.5×45 cm).
(1): pH 1 (——), pH 2 (·····), pH 4 (– – –), (2): pH 5 (——), pH 6 (·····), pH 7 (– – –), (3): pH 8 (——), pH 9.5 (·····), pH 10 (– – –).

Laurent and Killander[8] defined a constant, K_{av}, for a given gel in gel chromatography:

$$K_{av} = \frac{V_e - V_o}{V_t - V_o}$$

where V_0 is the void volume; V_t, the total bed volume, and V_e, the elution volume. Here, V_0, V_t, and V_e are easily measured. As the K_{av} value is correlated to V_e, it is a measure of the particle size and decreases with an increase in the particle size. As the elution volumes of polymers can not be obtained directly from the elution curves shown in Fig. 4, the mean elution volumes must be calculated using the following relationship;

$$V_e = \sum C_i V_i / \sum C_i$$

where V_e is the mean elution volume, C_i is the concentration in the i-th fraction, and V_i is the volume of the i-th fraction. The relationship between the pH and the K_{av} values of polysilicic acids in the solutions of various pHs after 48 h is shown in Fig. 5. It appears that the K_{av} value of polysilicic acid is at its minimum at a pH around 6.8. The results show that the rate of reaction between polysilicic acids is most rapid at a pH around 6.8.

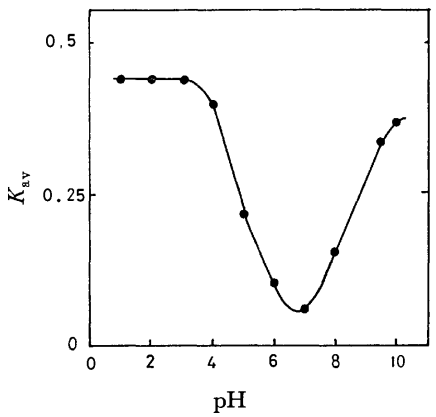

Fig. 5. Plot of K_{av} against pH.

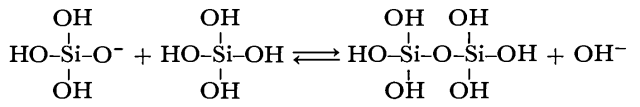
Discussion

The rates of the reactions between monomer-monomer, monomer-polymer, and polymer-polymer are most rapid at pH values around 9.3, 8.5, and 6.8 respectively. From the variation in ammonium molybdate reactive monosilicic acid, Richardson and Waddams[9] found that the polymerization is most rapid between pH 8—9. Merrill and Spencer[10] reported that the pH at the minimum gel time is about 7; Ray and Gangly[11] obtained similar results for gelation reactions. This discrepancy in the pH at which the maximum polymerization takes place can be explained by the facts that Richardson and Waddams measured the rate of polymerization caused by Reactions 1 and 2,

while, on the other hand, Merrill and Spencer measured the rate of Reaction 3.

As singly ionized monosilicic acid forms in a basic solution, the concentration of the singly ionized form becomes higher with an increase in the pH. Ashley and Innes[12] proposed that the polymerization of silicic acid proceeds by a reaction between singly ionized and un-ionized silicic acids. Reaction 1 does have its maximum



rate at a pH around 9.3 (Fig. 1). At this pH the concentration of un-ionized silicic acid and the singly ionized form is reasonably high; Greenberg and Sinclair[13] calculated the $(H_3SiO_4^-)/(H_4SiO_4)$ ratio based on the reported ionization constant of silicic acid and obtained the ratio of 1/1 at pH 9.5. As the pH giving the maximum rate of Reaction 1 is almost the same as that giving the $(H_3SiO_4^-)/(H_4SiO_4)$ ratio of 1/1, it is concluded that Reaction 1 mainly proceeds by the reaction of singly ionized silicic acid and un-ionized silicic acid, and that the rate of the formation of disilicic acid reaches its maximum at the pH at which the $(H_3SiO_4^-)/(H_4SiO_4)$ ratio is unity.

Komura *et al.*[15] have reported that the point of the zero charge of colloidal silica is pH 3.5 and that the negative charge of colloidal silica increases with an increase in the pH. If it can be assumed that the reaction between monosilicic acid and polysilicic acid is a reaction between a negatively charged site on the surface of polysilicic acid and un-ionized monosilicic acid, the rate of the polymerization due to Reaction 2 will reach its maximum at the pH at which the concentration of the negative ionic charge of polysilicic acids and un-ionized monosilicic acid is reasonably high. It is expected that the pH giving the maximum rate of polymerization by Reaction 2 is lower than that giving that by Reaction 1 because of the high concentration of un-ionized monosilicic acid at low pHs. The results show that the rate of polymerization due to Reaction 2 is most rapid at a pH around 8.5 (Fig. 2). At pH 8.5, the concentration of the negative charge of polysilicic acids is high and monosilicic acid mainly exists as an un-ionized form. Above pH 8.5, the concentration of the negative charge of polysilicic acids increases, and the concentration of un-ionized monosilicic acid decreases, with an increase in the pH. Below pH 8.5, the concentration of the negative charge of polysilicic acids decreases, and the concentration of un-ionized monosilicic acid increases, with a decrease in the pH. As is shown in Fig. 2, the rate of Reaction 2 becomes slow below and above pH 8.5. This means that Reaction 2 mainly proceeds by the reaction between an ionized silanol group of polysilicic acids and un-ionized monosilicic acid.

The isoelectric point of colloidal silica is between pH 1 and 2,[14] while the point of the zero charge of colloidal silica is pH 3.5.[15] However, below pH 3.5, the stability of polysilicic acid is very high in spite of these being no charge of polysilicic acids (Fig. 5). The DLVO theory can not be applied to this system. As negative ionic charges of silica particles increase with an increase in the pH, and as, above pH 9, a sufficient concentration of the negative charge is developed on the surface of the particles, causing mutual repulsion, the rate of Reaction 3 becomes very slow.[5] When it can be assumed that the growth of polymer particles due to Reaction 3 is mainly caused by the formation of Si–O–Si bonds by the reaction of $Si–O^-$ and Si–OH, and that the concentrations of Si–OH and $Si–O^-$ on the surface of polymer particles are suitable, there may be an optimum pH at which the rate of growth of particles is at its maximum. The rate of Reaction 3 is maximal at a pH around 6.8 (Fig. 5), for at this pH polysilicic acids have a negative charge and there may be a repulsive force between polymers. However, as Reaction 3 is most rapid at pH 6.8, it is suggested that repulsive force between polymers is weak at this pH and that polymers can collide. As the value of the acidity constant of the silanol group, Si–OH, on the surface of colloidal silica is around $pK_a=7$,[14–16] the ratio of Si–OH and $Si–O^-$ on the surface of polymers may be unity at a pH of about 7. As the rate of Reaction 3 is at its maximum at pH 6.8, it is concluded that the rate of Reaction 3 is controlled by the concentrations of ionized and un-ionized silanol groups in the same manner as in Reaction 1. From the experimental evidence of this study, it is concluded that, above about pH 4, the polymerization due to Reactions 1, 2, and 3 mainly proceeds by a reaction between ionized and un-ionized silanol groups.

Mass Spectrometric Studies of Some Carboxylic Acid Dimers Produced by a Nozzle Beam: HCO_2H, CH_3CO_2H, $C_2H_5CO_2H$, and n-$C_3H_7CO_2H$

Yoshihiro MORI,* Taiji KITAGAWA, Tomoki YAMAMOTO, Kazuo YANADA, and Shigeru NAGAHARA

Department of Pharmaceutical Sciences, Toyama Medical and Pharmaceutical University, Sugitani, Toyama 930-01

(Received December 10, 1979)

Characteristic ions $(M+1)^+$ and $(M+45)^+$, assigned to be the protonated monomer ion MH^+ and $(M\cdot CO_2H)^+$ respectively, have been detected in the mass spectrometric measurements of the dimer molecules M_2 and the higher clusters M_n of some carboxylic acids produced in their nozzle beams. It has been shown from the dependences of their relative intensities on the stagnation conditions that these ions are mainly formed through the fragmentation of the dimer ions. The MH^+ ion plays the most important role in these fragmentation processes of the dimers, while no dimer ion M_2^+ was observed. These results are discussed in terms of the enthalpy changes for the unimolecular decomposition reactions of M_2^+.

Protonated cluster ions $M_{n-1}H^+$ as well as $M_n^+(n\geq 2)$ have been observed in some hydrogeneous molecules, such as H_2O,[1] NH_3,[2] hydrogen halides,[3] and alcohols,[4] through electron or photon impact ionization of their cluster molecules produced using supersonic nozzle beams. The reactions to form these protonated ions have been explained by the unimolecular decomposition reaction of M_n^+.[5] However the detailed mechanisms vary with different molecules[3b] and the degree of their association,[5] and also depend on the impact energy of the electron or photon.[2]

A variety of new fragment ions other than the protonated ones have been observed in the ionization of van der Waals clusters of butane[6] and ethylene.[7] Some of them have been regarded as the key species in the ion-molecule reactions. These findings on the electron or photon impact induced fragmentations of the weakly bound clusters have enabled us to discuss the mechanisms of ion-molecule reactions[5,7] and the solvation of ions in the gas phase[1,2,5] from some different viewpoints. So it is of great interest to make clear such fragmentation processes of these cluster molecules and ions.

In this paper we report several common features observed in the electron impact induced fragmentations of the dimers of some aliphatic carboxylic acids produced in their nozzle beams. These acids have been well known to form a stable cyclic dimer through intermolecular hydrogen bonds even in the usual vapor phase.[8]

Experimental

The nozzle beam system in this experiment is shown in Fig. 1. A 60° conical nozzle source which has a 0.015 cm diameter orifice at the apex of this cone was used. The nozzle was fastened to the reservoir with a thin teflon gasket. No skimmer was used. Some copper plates with a circular opening of 1 cm diameter for the beam, cooled by liquid nitrogen, were used as a cryopump. This nozzle source has previously been employed in the optical measurements of naphthalene beams and has been compared with other nozzles having different shapes and orifice diameters.[9] Using this source, we could observe reasonable cooling effects and mach numbers, accompanied by the adiabatic expansion of pure naphthalene vapor.

The temperature T_0 at the nozzle throat was measured with a Fe-Constantan thermocouple mounted on the external face of the nozzle plate. The stagnation pressure P_0 behind the nozzle was determined by adjusting the temperature of the liquid carboxylic acid in the reservoir F according to the published data of vapor pressure.[10] Within the range of T_0 and P_0 in this work, the dimer fraction evaluated from the observed equilibrium constant[11] could be covered over the wide range from 0.1 to 0.6 in the stagnation conditions.

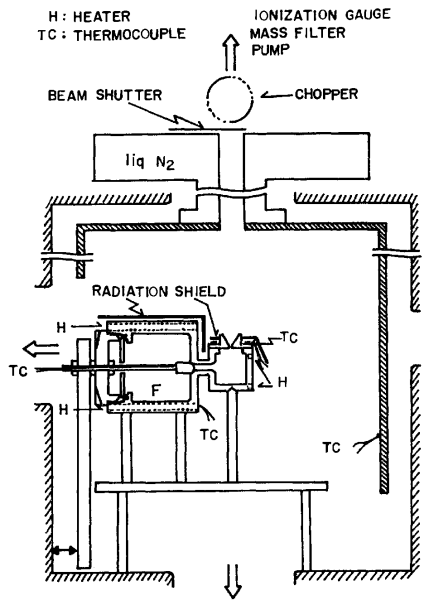

Fig. 1. Experimental apparatus for the measurements of mass spectra in the nozzle beam.

The beams were mechanically modulated at a frequency of 20—100 Hz and then directed into the ionizer of a quadrupole mass filter (Nichiden Varian model 531) equipped with a Bayard-Alpert gauge-type ionizer. Most measurements were carried out at the electron energy of 30 eV and the emission current of 1.0 mA. No marked dependences of mass spectra on the electron energy were observed in the range of 20 eV to 100 eV. To get the corrected intensities for the relative sensitivity of the secondary electron multiplier, the observed intensities of the ions with $m/e\geq 28$ were multiplied by the dimensionless factor $(m/28)^{1/2}$.[12]

Commercially available extra pure CH_3CO_2H, $C_2H_5CO_2H$, n-$C_3H_7CO_2H$, and HCO_2H were used after a distillation *in vacuo*. Deuterated CH_3CO_2D and CD_3CO_2D enriched more than 97—98% were commercially supplied.

Results and Discussion

Mass spectra of the four carboxylic acids RCO_2H (R=H, CH_3, C_2H_5, and n-C_3H_7) were measured in the nozzle beams as a function of T_0 and P_0 in stagnation conditions in the mass range from 1 up to 310. Two peaks, corresponding to the mass numbers of $(M+1)^+$ and $(M+45)^+$, were observed for all the acids, in addition to the previously reported mass spectrum of each monomer acid (M).[13]

Table 1. Mass shifts of MH^+ and $(M\cdot CO_2H)^+$ fragment ions in the deuterated acetic acid beams

Beam		CH_3CO_2H	CH_3CO_2D	CD_3CO_2D
T_0/K		374	369	381
P_0/Torr		100	120	160
Ion	m/e	Relative intensity

	108		0.0002	
	109		0.0001	0.0002
	110			0.0054
	111			0.0002

In order to assign these ions, mass spectra were measured in the nozzle beams of deuterated acetic acid, CD_3CO_2D and CH_3CO_2D. According to the results of the corresponding mass shift, these ions were assigned to the protonated monomer ion MH^+ and the adduct ion $(M\cdot CO_2H)^+$ ions, respectively. Table 1 summarizes the results of the mass shift and their relative intensities around the mass ranges of MH^+ and $(M\cdot CO_2H)^+$ ions in CH_3CO_2H, CH_3CO_2D, and CD_3CO_2D beams.

Figure 2 shows the temperature dependences of the relative intensities of MH^+ and $(M\cdot CO_2H)^+$ ions. It is clearly shown in the figure that MH^+ ion as well as $(M\cdot CO_2H)^+$ ion increases with decreasing T_0. From Fig. 2 the intensity ratios between MH^+ and $(M\cdot CO_2H)^+$ ions were obtained to be about 100, 2000, and 5000 for CH_3CO_2H, $C_2H_5CO_2H$, and n-$C_3H_7CO_2H$, respectively. In the case of the formic acid beam, it is difficult to obtain quantitative results for a long period of experimental runs because of a gradual corrosive reaction inside the nozzle source. But the results were qualtatively in accord with those obtained in the other acids and the intensity ratio $I_{MH^+}/I_{(M\cdot CO_2H)^+}$ was about 500.

Similar behaviors were observed in their pressure P_0

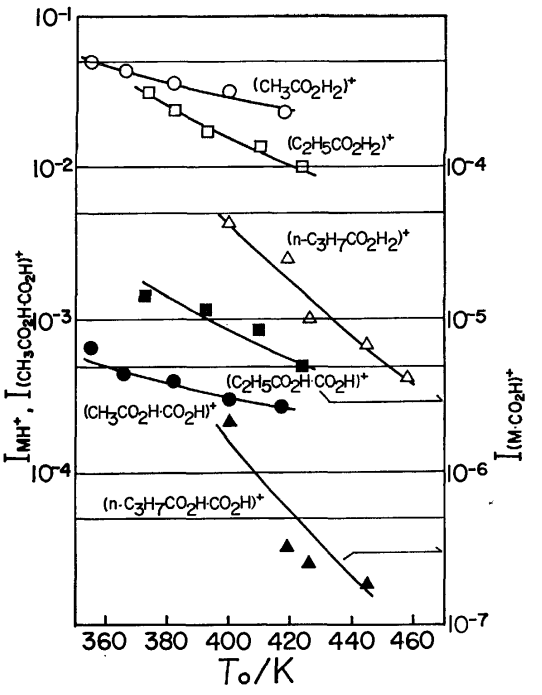

Fig. 2. Temperature dependences of the relative intensities of MH^+ and $(M\cdot CO_2H)^+$, I_{MH^+} and $I_{(M\cdot CO_2H)^+}$, normalized to the sum of each ion intensity, in CH_3CO_2H, $C_2H_5CO_2H$, and n-$C_3H_7CO_2H$ nozzle beams. The stagnation pressures were kept at about 140, 100, and 110 Torr, respectively. Open and full symbols represent MH^+ and $(M\cdot CO_2H)^+$, respectively. (1 Torr=133.322 Pa)

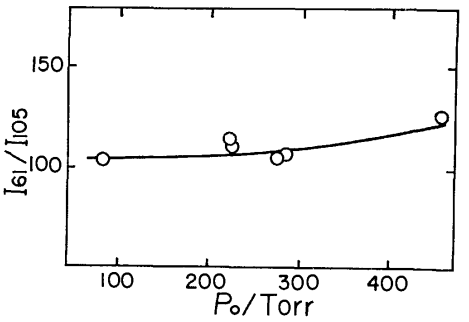

Fig. 3. Pressure dependence of intensity ratio between MH^+ and $(M\cdot CO_2H)^+$, I_{61}/I_{105}, at T_0=410 K for acetic acid. (1 Torr=133.322 Pa)

dependences. For acetic acid, this intensity ratio I_{61}/I_{105} was found to be nearly constant or slightly increasing with increasing P_0 as shown in Fig. 3.

Other fragment ions than MH^+ and $(M\cdot CO_2H)^+$ did not show such marked T_0 dependences within the range of T_0 in this study. Only RCO^+ ions (R=CH_3, C_2H_5, and n-C_3H_7) were found to slightly increase with decreasing T_0. Some portion of these acyl ion intensities might be ascribed to the dehydration reaction of MH^+ ion with excess energy.[14]

From such similar dependences of MH^+ and $(M\cdot CO_2H)^+$ ions on the stagnation conditions, both ions are considered to be formed by the electron impact fragmentation of the same molecular species, namely

the cluster molecules $M_n(n\geq 2)$, produced in their nozzle beams. However no traces of the dimer ion M_2^+ or of $M_n^+(n=3,4,5)$ were observed within the limit of the detection sensitivity, 10^{-6} of M^+. For these carboxylic acids, M_2H^+ ions with very weak intensities (10^{-4}—10^{-6} of M^+) were observed. But we could not definitely ascribe them to the fragmentation from $M_n^+(n\geq 3)$ because of the nearly equal contribution of ion-molecule addition reaction which presumably occurred in the ionizer. Only a small contribution of the higher clusters is suggested by the slight increase of MH^+ ion relative to $(M\cdot CO_2H)^+$ when P_0 increases, as can be seen in Fig. 3. This could be explained by the result that MH^+ fragment, not $M_{n-1}H^+$, is predominantly formed in the fragmentation processes of the parent cluster ion M_n^+.[15] Another reason for such an apparent small contribution of the higher clusters to these mass spectra is that some portion of the higher clusters and the dimer could be decomposed down to the dimer or the monomer on the electrode surface of the ionizer.

Thus we can conclude in this study that the observed MH^+ and also $(M\cdot CO_2H)^+$ ions are mainly formed through spontaneous decomposition of the dimer ions M_2^+, which can initially be generated in their vibrationally or electronically excited states by the electron impacts at 20—100 eV. The fragmentation to the protonated monomer ion is characteristic for these carboxylic acid dimer ions. These fragmentation behaviors resemble the case in $(HF)_2$,[3a] but are quite different from those in $(CH_3OH)_2$ and $(CH_3NH_2)_2$, where the intensity ratios $I_{M_2^+}/I_{MH^+}$ have been observed to be about 0.5.[4] Such differences can qualitatively be interpreted from some thermodynamical considerations about reaction (1):

$$M_2^+ \longrightarrow NH^+ + (M\text{-}H). \qquad (1)$$

The enthalpy change ΔH_2 for this unimolecular decomposition reaction can be estimated using the binding energy of M_2^+ ion, $-\Delta H_s(M_2^+)$, or the solvation energy of MH^+ by M, $-\Delta H_s(M_2H^+)$, and several thermodynamical parameters for a monomer molecule. The values of $\Delta H_s(M_2^+)$ have recently been obtained from the ionization potential measurements of the dimers by means of photoionization ($(H_2O)_2$[1c] and $(NH_3)_2$[2b]) and photoelectron spectroscopy ($(CH_3CO_2H)_2$[16]). The calculated values of ΔH_2 are shown in Table 2. It is shown that $(HF)_2^+$ ion spontaneously decomposes into H_2F^+ and F, while the decompositions of $(H_2O)_2^+$, $(NH_3)_2^+$, and $(CH_3OH)_2^+$ are rather endothermic. These trends are consistent with the observations of their M_2^+ ions in the eletron or photon impact ionization.[1-5] The decomposition of acetic acid dimer ion seems to be more endothermic, although this endothermicity may be reduced by the contribution of the entropy terms $T\Delta S_2$ for this reaction (1).[17] Nevertheless, no dimer ions of acetic acid nor of the other carboxylic acids were observed in this study. This fact suggests that there exist very effective channels to promote proton transfer along the hydrogen bond in the excited states of the dimer ions which strongly couple with MH^+ ion formation. At the present stage we can't explore these channels further, because we lack the experimental evidence about the state selected ionization or fragmentation. But these channels must greatly depend upon the cyclic structure of the dimer ion, which includes two hydrogen bonds.

Furthermore, we note that the dominant fragmentation is to $(M\cdot CO_2H)^+$ rather than to the $(M\cdot RCO)^+$ in the dimer ions. Indeed the observed intensity of $(M\cdot CH_3CO)^+$ ion for acetic acid was so weak (0.1 of $(M\cdot CO_2H)^+$) that the origins of this adduct ion were undecided for the same reasons as in M_2H^+. For propionic and butyric acids, no $(M\cdot RCO)^+$ ions could be detected. This trend contrasts with the observations in ion-molecule reactions, in which the $(M\cdot RCO)^+$ adduct ions have often been observed.[14,18]

Concerning $(M\cdot CO_2H)^+$ ions, the hydrogen bonded cyclic ion $(HCO_2H\cdot CO_2H)^+$ has been theoretically predicted from the β^- decay processes of monotritiated formic acid dimer $(HCO_2H\cdot {}^3HCO_2H)$.[19] It has been shown that in this ion the proton transfer occurs along the hydrogen bond with no activation energy to produce $HCO_2H_2^+$ and CO_2. This process could not be confirmed

Table 2. Estimated enthalpy changes ΔH_2 at 298 K for the reaction $M_2^+ \longrightarrow MH^+ + (M\text{-}H)$ (in kcal/mol) (1 kcal = 4.184 kJ)

ΔH_2[a]	$(H_2O)_2$	$(NH_3)_2$	$(CH_3OH)_2$	$(CH_3CO_2H)_2$	$(HF)_2$

as the main channel of MH^+ ion formation in the present study, but our results suggest that the $(M \cdot CO_2H)^+$ ions are stable species.

Another point shown in this work is that the transferable proton in an M_2^+ ion to yield MH^+ fragment ion is the hydroxyl proton, not the alkyl ones. The proofs are given by comparing the amounts of $CH_3CO_2DH^+$ ion in the CH_3CO_2D beam. The relative intensity of $CH_3CO_2DH^+$ ion ($m/e=62$) to M^+ ($m/e=61$) was obtained to be 0.044 in Table 1. This value never exceeds the value estimated from the natural abundances of the isotopes (0.024) and the contribution of $CH_3CO_2DH^+$ ion produced from an impurity of CH_3CO_2H (0.025). Thus, no proton transfer can occur from those of acetyl group to the other M in a dimer ion in the fragmentation processes from the M_2^+. This result does not contradict the fact that $(M \cdot CH_3CO)^+$ ion has rarely been observed *via* fragmentation of M_2^+ ion, as mentioned above.

The present work was partially supported by Grants-in-Aid for Scientific Research No. 354134 and also No. 247004 from the Ministry of Education, Science and Culture. The authors gratefully thank Dr. K. Nomoto for helpful discussions.

Is $O_2^*(a^1\Delta_g)$ Formed in the $O+O_3$, $H+O_3$, and $NO+O_3$ Reactions?

Nobuaki WASHIDA,* Hajime AKIMOTO, and Michio OKUDA
The National Institute for Environmental Studies, P.O. Tsukuba-gakuen, Tsukuba, Ibaraki 305
(Received March 11, 1980)

An attempt was made to detect $O_2^*(a^1\Delta_g)$ in the reactions of $O+O_3$, $H+O_3$, and $NO+O_3$ using a photoionization mass spectrometer. No significant signals for $O_2^*(a^1\Delta_g)$ were observed in these reactions. From the results, it is concluded that less than 0.06, 0.001, and 0.002 of the reactive collisions result in the production of $O_2^*(a^1\Delta_g)$ in the reactions of $O+O_3$, $H+O_3$ and $NO+O_3$ respectively, all at 298 K. The failure to observed $O_2^*(a^1\Delta_g)$ in these reactions was discussed by means of correlation diagrams and GVB model representations.

Recently, the observation of the singlet oxygen formed in the reaction of hydrogen atoms with molecular oxygen was reported in our laboratory.[1] In this system it was determined that the singlet oxygen was produced by the reaction of hydrogen atoms with hydroperoxyl radicals, which had themselves been formed by the recombination reaction of hydrogen atoms with molecular oxygen:

$$H + O_2 + M \rightarrow HO_2 + M \quad (1)$$

$$HO_2 + H \rightarrow H_2 + O_2^*(a^1\Delta_g) \quad (2)$$

A photoionization mass spectrometer was used to detect the singlet oxygen. When an argon lamp with a LiF window is used as a light source to photoionize the molecules, singlet oxygen can be photoionized by the argon resonance lines (11.83 and 11.62 eV), but ground-state molecular oxygen can not be ionized by these lines,[1,2] since the ionization potential for ground-state molecular oxygen is 12.06 eV, and the $O_2^*(a^1\Delta_g)$ and $O_2^*(b^1\Sigma_g^+)$ states are 0.98 and 1.63 eV higher than the ground-state respectively. The detection sensitivity of the photoionization mass spectrometer to singlet oxygen is quite high in comparison with the photometric detection by means of the forbidden $O_2^*(a^1\Delta_g) \rightarrow O_2(X^3\Sigma_g^-)$ transition. The detection limit is about 10^9—10^{10} molecules cm^{-3} for singlet oxygen in the reactor under good conditions (very low background signals and in the absence of the large signals around mass 32). Further, when photoionization mass spectrometry was used to detect singlet oxygen, the interference by the chemiluminescence in the reaction system was eliminated. For example, in the $H+O_2$ reaction system, singlet oxygen in the $a^1\Delta_g$ state could not be observed by the photometric method,[3] since the emission from $O_2^*(a^1\Delta_g)$ was overlapped by the strong chemiluminescence by HO_2. Therefore, photoionization mass spectrometry is a useful method to detect singlet oxygen in the chemiluminescent reaction system.

The reactions of $O+O_3$, $H+O_3$ and $NO+O_3$ can produce singlet oxygen according to the exothermicity and the spin correlation of the reactions. Nevertheless, this possibility has been ignored.[4] In this work, the fractions for the formation of singlet oxygen in the above reactions were determined by the use of the photoionization mass spectrometer; it seemed that this would be useful because strong chemiluminescence by OH and NO_2 has been observed in the near-IR region in all the above reactions except the $O+O_3$ reaction. After that, the reaction processes will be discussed using correlation diagrams and GVB model representations.

Experimental

The experimental set-up of the fast-flow reactor is shown in Fig. 1. The photoionization mass spectrometer coupled to the fast-flow reactor is as has been described previously.[5] The inner diameter of the cylindrical Pyrex reactor tube is 12.6 mm, and the length of the reaction zone can be varied from 10 to 200 mm by sliding the inlet tube (4 mm o.d.) in an O-ring seal. Ozone enters the main flow through six radially directed holes at the end of the inlet tube.

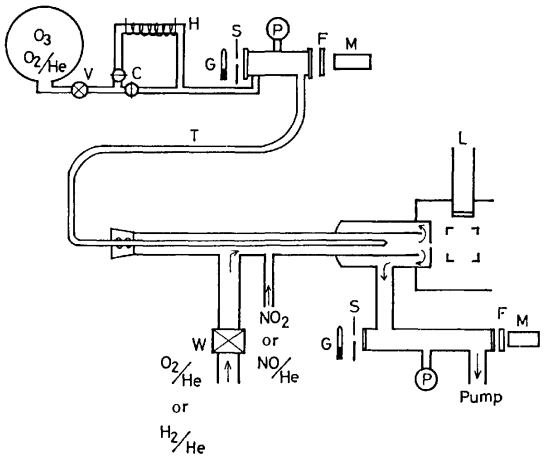

Fig. 1. Schematic diagram of the fast-flow reactor for the reactions of O, H, and NO with O_3.
V: Variable leak, C: Teflon stopcock, H: heater, G: Hg lamp, S: slit P: MKS baratron gauge, F: filter M: photomultiplier L: Ar lamp, T: Teflon tube, W: microwave cavity.

Hydrogen and oxygen atoms were produced in a microwave discharge (2450 MHz) in a helium mixture. The concentrations of both atoms were determined by titration with NO_2 according to the $H+NO_2 \rightarrow OH+NO$, and $O+NO_2 \rightarrow NO+O_2$ reactions, using the signals for NO at mass 30 as an indicator of the titration endpoint. NO_2 was added at a point 200 mm upstream from the sampling pinhole (the reaction time is about 10 ms under total pressure of 4 Torr (1 Torr = 133.3 Pa)). The method of determining the hydrogen-atom concentration is as has been described previously.[5] The known partial pressures of NO were added to calibrate the instrument sensitivity, typically about 2×10^4 counts/s for 1 mTorr of NO when two new argon lamps were used. Since the intensity of the argon lamps decreased slowly as a result of the origination of a color center in the LiF windows, the lamps were changed every 20 h. The measurements were then done between 10 to 20 h after the start of the discharge

of the new lamps, because in this period the intensity of the lamp was fairly stable.

The total and partial pressures of the gases were measured with an MKS Baratron gauge and were corrected to the values at the pinhole, considering the effect of the small pressure drop down the reactor tube.[5] Furthermore, the partial pressures of each component gas were corrected by means of the flow equation.[5] The linear-flow velocity, as measured with a bubble meter, was 16.5 m s^{-1} at 2 Torr, 19.9 m s^{-1} at 4 Torr, and 21.4 m s^{-1} at 6 Torr at 298 K. In this case, the flow in the flow tube, F (Torr l s^{-1}), as a function of the total pressure, P (Torr), was given by this equation: $F(P)=0.192+2.001P+0.0919P^2$. In this study, experiments were done under a total pressure of about 4 Torr.

The gases, H_2 (Nippon Sanso, 99.9999%), O_2 (Nippon Sanso, 99.99%), He (Nippon Sanso, 99.9999%), and NO_2 (Matheson, 99.5%), were used without further purification. The NO (Matheson, 99.0%) was purified by passing it through a column of Ascarite and was then distilled bulb-to-bulb using liquid nitrogen traps. After this purification, the amount of NO_2 present in this purified NO was less than 0.01%.[5] The ozone was prepared from a commercial ozonizer and was trapped on 500 grams of liquid nitrogen-cooled silica gel (5—10 mesh). After pumping, the adsorbed mixture of O_3 and O_2 on silica gel was heated up to room temperature and stored in a 50-l flask with a helium diluent. The mixture obtained usually consisted of 2—10% ozone and 10—20% oxygen in helium. The concentration of ozone was measured by absorption photometry at positions upstream and downstream of the flow reactor using a quartz cell, a Hg lamp coupled with a 2540 Å filter, and a photomultiplier.

The ozone was added to the reactor through a movable inlet. The measurements were done in both the presence and absence of ozone. In the case without O_3, the mixture of O_3–O_2–He was passed through a heated quartz tube (about 800 °C). In this case, the ozone was decomposed completely and converted to O_2 (no O atoms or no O_3 were detected by mass spectrometry and UV absorption). Switching the conditions with ozone and without ozone by means of Teflon stopcocks, the change in the signal at mass 32 was measured. The concentration of O_2 which was contained initially in the O_3–O_2–He mixture, $[O_2]_I$, was determined as follows. The O_3–O_2–He mixture was passed through the heated quartz tube. Under the condition without ozone, molecular oxygen was reacted with hydrogen atoms, and the singlet oxygen was produced as has been described before. Since the fraction of Reaction 2 in the total reaction of HO_2+H was determined[1] to be 0.015 ± 0.003, the concentration of O_2,

$$[O_2] = [O_2]_I + 3/2[O_3], \quad \text{(I)}$$

could be calculated using the rate constant for Reaction 1, the concentration of the hydrogen atoms, the total pressure, the reaction time, and the concentration of the singlet oxygen produced:

$$[O_2] = \frac{[O_2^*(a^1\Delta_g)]}{0.015\,k_1[H]t}, \quad \text{(II)}$$

where it is assumed that the rate for Reaction 2 is very rapid and that the concentration of HO_2 is in a steady-state concentration.[1] When the value for $[O_2]$ is determined, the $[O_2]_I$ can be calculated by means of Eq. I.

The flowing gases were sprayed through a conical Pyrex pinhole (0.2 mm in diameter) into the ionization region of a quadrupole mass spectrometer, where a collimated light beam from a microwave-powerd discharge lamp was intersected. In this work, an argon lamp with a LiF window was used photoionize the molecules. The concentration of singlet oxygen was calculated from the relative ionization cross section for NO and $O_2^*(a^1\Delta_g)$ by means of argon-resonance lines,[6] *i.e.*, $\sigma_{O_2^*}/\sigma_{NO}=0.5$. Since the sensitivity of NO to this instrument is 2×10^4 counts/s for 1 mTorr of NO, 10^{-4} m Torr of $O_2^*(a^1\Delta_g)$ could theoretically be detected.

The ions formed by photoionization were accelerated and focused into a quadrupole mass filter (UTi Model 100C). After mass selection, the ions were counted by means of a Daly-type detector[7] operated at −20 kV, a thin aluminum-coated plastic scintillator, and pulse-counting electronics (Canberra, Multichannel Analyzer, Omega-1). A working pressure of 2×10^{-5} Torr or less was maintained in the vacuum can by means of a 1200-l s^{-1} oil-diffusion pump with a liquid nitrogen trap. All the measurements were done at room temperature, 298±3K.

Results and Discussion

1) $O+O_3$ Reaction. The reaction of atomic oxygen with ozone is known to produce two ground-state oxygen molecules:

$$O(^3P) + O_3(X^1A_1) \rightarrow 2O_2(X^3\textstyle\sum_g^-) \quad \text{(3a)}$$
$$\Delta H = -93.7 \text{ kcal/mol.}$$

The vibrational excitation of ground-state oxygen[7] has been observed in levels up to $v=20$ or up to $v=25$ due to the exothermicity of Reaction 3a. However, the existence of singlet oxygen ($a^1\Delta_g$ and $b^1\textstyle\sum_g^+$) has never been observed, although the processes to form $O_2(X^3\textstyle\sum_g^-)+O_2^*(a^1\Delta_g)$ or $O_2^*(b^1\textstyle\sum_g^+)$ are accessible energetically and spin-allowed:

$$O(^3P) + O_3(X^1A_1) \rightarrow O_2(X^3\textstyle\sum_g^-) + O_2^*(a^1\Delta_g) \quad \text{(3b)}$$
$$\rightarrow O_2(X_3\textstyle\sum_g^-) + O_2^*(b^1\textstyle\sum_g^+). \quad \text{(3c)}$$

Measurements of the signals at mass number 32 were made by the addition of ozone to the oxygen atoms/He flow, which was produced in the microwave discharge of the O_2/He mixture. In this case, singlet oxygen was produced initially through the microwave discharge of the O_2/He mixture. This singlet oxygen initially produced disturbs the measurement of the signals at $m/e=32$ as a background. Therefore, measurements under the conditions of a high concentration of oxygen atoms and a low singlet-oxygen concentration in the

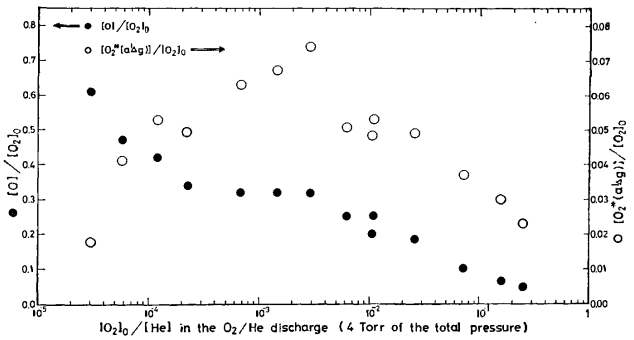

Fig. 2. The ratio of oxygen atoms produced to the initial concentration of O_2 in the O_2/He discharge, $[O]/[O_2]_0$ (●), and the ratio of singlet oxygen produced to the initial concentration of O_2 in the O_2/He discharge, $[O_2^*(a^1\Delta g)]/[O_2]_0$ (○), are plotted against the $[O_2]_0$/[He] in the O_2/He mixture. Discharge was done at total pressure of 4 Torr.

O_2/He discharge were desired. The concentrations of the oxygen atoms and singlet oxygen produced in the discharge were measured under a variety of ratios of O_2 to He in the O_2/H_2 discharge. Figure 2 shows that the absolute concentrations of both the oxygen atoms and the singlet oxygen increased at higher values of $[O_2]_0/[He]$, but the ratio of the concentration of the oxygen atoms produced to the initial concentration of O_2 is larger at lower values of $[O_2]_0/[He]$ (*i.e.*, oxygen atoms were produced effectively at a low "initial concentration of O_2," $[O_2]_0$). On the other hand, the ratio of the concentration of the singlet oxygen produced to the initial concentration of O_2 is smaller at lower values of $[O_2]_0/[He]$. The value of $[O_2^*]/[O_2]_0$ then passed through a maximum and, after that, decreased as the value of $[O_2]_0/[He]$ in increased. This decrease can be explained by the quenching of the singlet oxygen by oxygen atoms and ozone because the mixture of O_2 and He is discharged very far upstream of the reactor and the contact time of the discharged gases is about 50 ms. According to the results shown in Fig. 2, the condition of a low $[O_2]_0/[He]$ ratio should be good for measurement because the ratio of the atomic oxygen to the singlet oxygen formed is the largest.

The mass spectra measured in the $O+O_3$ reaction system are shown in Fig. 3. As is shown in Fig. 3, the singlet oxygen was produced in the O_2/He discharge and the increment of the signal at $m/e=32$ was not clear when ozone was added. The signal observed at $m/e=30$ may be the signal for NO, which is produced by the nitrogen present in the O_2/He mixture as an impurity. The small signal at $m/e=32$ when only the O_3–O_2–He mixture was introduced ((d) in Fig. 3) can be explained by the surface ionization in the ionization chamber. The mass spectrometer was fixed at $m/e=32$, and the signals at $m/e=32$ were accumulated. The results are shown in Table 1. In this case, measurements were

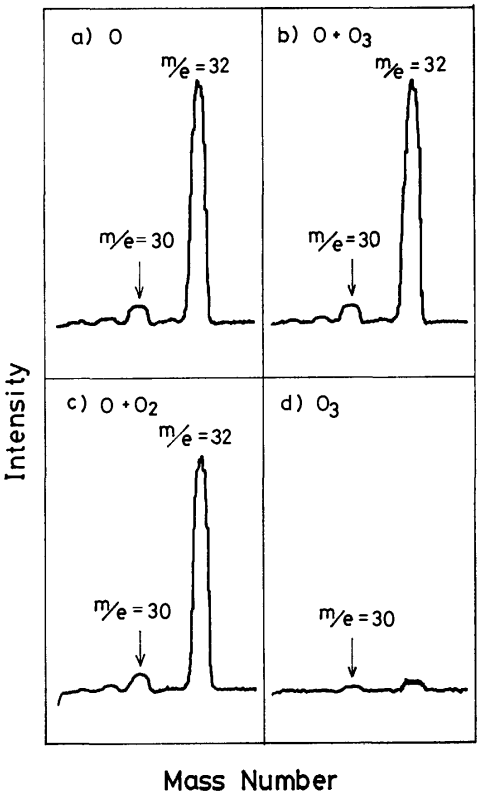

Fig. 3. Mass spectra in the $O+O_3$ reaction system. a): Only O_2/He discharge. b): O_3–O_2–He mixture was added to the O_2/He discharge. c): O_3–O_2–He mixture was passed through the heated quartz tube. Ozone was converted to O_2. d): Discharge was turned off. Only O_3–O_2–He mixture flowed Conditions: total pressure=4.032 Torr, $[O]_0$=4.6 m Torr $[O_3]$= 28.6 mTorr, reaction time =10.05 ms.

TABLE 1. RESULTS IN THE MEASUREMENT OF THE SIGNALS AT $m/e=32$ IN THE $O+O_3$ REACTION

Conditions				Signals at $m/e=32$ counts/5 s ($\pm$ was derived from the standard deviation in the 50 measurements)		
O_2/He discharge	Sensitivity of NO for 1 mTorr of NO	Reaction time (ms)	O_3–O_2–He Mixture added	O_2/He Discharge	Addition of O_3 (O_3–O_2–He mixture)	O_3 converted to O_2 (O_2–He mixture)
[a] Total pressure, 4.043 Torr $[O_2]_0$ 0.16 mTorr $[O]_0$ 0.095 mTorr $O_2^*(a^1\Delta_g)$ 0.003 mTorr	18326 counts/s	10.05	Total: 338 mTorr $[O_3]$ 29.4 mTorr $[O_2]_I$ 62.5 mTorr	d. 207.3±18.1 nd. 69.7±10.0 d.—nd. 137.6±12.4	d. 216.3±19.4 nd. 84.2± 9.7 d.—nd. 132.1±11.9	d. 216.7±16.2 nd. 74.9± 8.4 d.—nd. 141.8±10.6
[b] Total pressure, 4.032 Torr $[O_2]_0$ 13.8 mTorr $[O]_0$ 4.6 mTorr $O_2^*(a^1\Delta_g)$ 0.86 mTorr	17458 counts/s	10.05	Total: 329 mTorr $[O_3]$ 28.6 mTorr $[O_2]_I$ 60.9 mTorr	d. 37638.9±390.6 nd. 103.3±9.9 d.—nd. 37535.6±389.5	d. 37496.2±370.3 nd. 135.1±11.1 d.—nd. 37361.1±369.0	d. 37594.4±353.5 nd. 111.3±8.5 d.—nd. 37483.1±352.3

done under two different conditions: the $[O_2]_0/[He]$ ratios in the O_2/He discharge were 4.0×10^{-5} and 3.4×10^{-3}. As is shown in Fig. 2, the former is the case when the value for the ratio of the singlet oxygen to the oxygen atoms produced in the O_2/He discharge is small, while the latter is the case when the ratio of the singlet oxygen to the atomic oxygen has its maximum value. All the experimental conditions and signals at $m/e=32$ (counts/5 s) in the presence and absence of ozone are listed in Table 1. All the signals at $m/e=32$ were accumulated for 5 s per channel, and 50 channels were used for one measurement. The error limits ($\pm$) were derived from the standard deviation in these 50 signals. The signals at mass 32 were measured with the discharge on (d.) and off (nd.), (*i.e.*, in the presence and absence of oxygen atoms) and the difference (d. $-$nd.) used as the real signal for each measurement. The concentration of the singlet oxygen formed initially in the O_2/He discharge, listed in the first column in Table 1, was calculated from the signals at $m/e=32$ in the O_2/He discharge and the sensitivity of the instrument to NO. The small increment in the background (signals for nd.) when the O_3–O_2–He mixture was added can be explained by the effect of the field emission from the -20 kV stainless-steel target. As is shown in Table 1, the increase in the signals at $m/e=32$ could not be observed when the O_3–O_2–He mixture was added to the O_2/He discharged gases.

The rate constants for the reactions of $O+O_3$, k_3, have been reported to be 7.5, 8.3, and 10.6×10^{-15} cm^3 $molecule^{-1}$ s^{-1} at 300 K.[8-10] If the reaction proceeds only to produce singlet oxygen (Reactions 3b or 3c), the singlet oxygen produced should be given by $k_3[O][O_3]t$. The values for $k_3[O][O_3]t$ calculated are 2.5×10^{11} and 1.2×10^{13} molecule/cm^3 in the (a) and (b) measurements respectively in Table 1. In this case, 8.3×10^{-15} cm^3 $molecule^{-1}$ s^{-1} was used at the value for k_3. The detectable limit, if the increment of the signals occurred in the addition of the O_3–O_2–He mixture, can be estimated to be 20 counts/5 s for the (a) measurement and 1000 counts/5 s for the (b) measurement. These values (counts/5 s) correspond to 1.4×10^{10} molecule/cm^3 and 7.6×10^{11} molecule/cm^3 respectively. The value for the detectable $O_2^*(a^1\Delta_g)$, divided by the value for $k_3[O]_0[O]_3t$, gives the upper limit of the fraction for the formation of singlet oxygen, Reactions 3b or 3c, in the total reaction of $O+O_3$. The fractions were calculated to be less than 0.06 in both measurements, (a) and (b). No advantage was obtained in the accuracy of the value of the fraction in the (a) measurement (with the small initial signal of $O_2^*(a^1\Delta_g)$), because the ratio of the counting error to the signal was larger in the smaller signal in this equipment.

The deactivation rate constants of $O_2^*(a^1\Delta_g)$ by $O(^3P)$, O_2 and O_3 previously reported are $\leq1.3\times10^{-16}$,[11] 0.4—2.2×10^{-18},[12] and 4.4×10^{-15} cm^3 $molecule^{-1}$ s^{-1} [13] respectively. These deactivation rates are quite slow. The quenching of $O_2^*(a^1\Delta_g)$ by $O(^3P)$ and O_2 is negligibly small, and that by O_3 is less than 5% of the $O_2^*(a^1\Delta_g)$ supposed to be formed in Reaction 3b. Therefore, it was concluded that the fraction for the formation of $O_2^*(a^1\Delta_g)$, Reaction 3b, in the total reaction of $O+O_3$ is less than 0.06. The deactivation rate constant of $O_2^*(b^1\Sigma_g^+)$ by O_3 was been reported to be fast, 7×10^{-12} cm^3 $molecule^{-1}$ s^{-1},[14] This rate shows that the $O_2^*(b^1\Sigma_g^+)$ should be quenched completely under our experimental conditions if the $O_2(b^1\Sigma_g^+)$ is produced *via* Reaction 3c. Therefore, the conclusion is given only for the formation of $O_2^*(a^1\Delta_g)$, and only $O_2^*(a^1\Delta_g)$ will be dealt with in the following experiments and discussions.

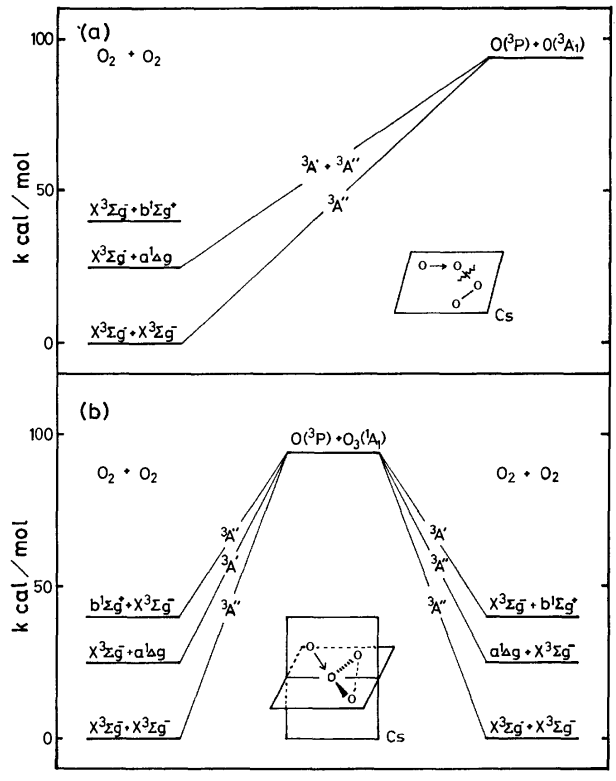

Fig. 4. Minimal state correlation diagrams in the $O+O_3$ reaction system when all atoms lie in a plane (a) and when $O(^3P)$ approaches O_3 in the plane which bisects the O_3 bond angle (b).

As has been mentioned before, vibrationally excited ground-state oxygen molecules were observed in the flash-photolysis absorption experiment.[7] According to the measurement by McGrath and Norrish,[7] the maximum in the population distribution of vibrationally excited O_2 is when $v=12$, 13, or 14, and both higher and lower levels have progressively lower populations. However, since the absorption cross-section in the Schumann-Runge band system in O_2 is smaller at lower v levels, population distributions lower than $v=11$ could not be measured in their observation. The energy for $v=12$, 13, or 14 is about a half of the exothermic energy for the $O+O_3$ reaction, 3a, that is about 4 eV. Therefore, the formation of singlet oxygen is energetically acceptable except when the two oxygen molecules formed in Reaction 3a are equally vibrationally excited. The minimal-state correlation diagrams when all atoms lie on a plane (Cs symmetry), and when $O(^3P)$ approaches O_3 on the plane which bisects the O_3 bond angle, are shown in Fig. 4. In these cases, the correla-

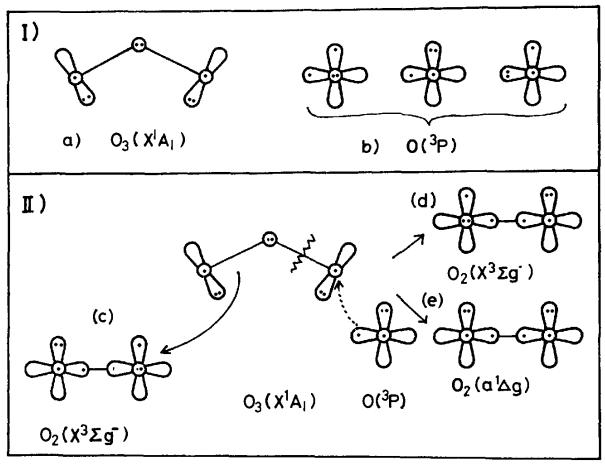

Fig. 5. GVB model representation in the $O+O_3$ reaction system.

tions with other upper states are abridged. As is shown in Fig. 4, the formation of the $a^1\Delta_g$-state molecular oxygen is possible in both the coplanar and bisecting plane models.

According to the valence-bond model which was explained by Goddard,[15] ground-state ozone and atomic oxygen are represented by (a) and (b) respectively in Fig. 5 (I). Figure 5 (II) shows the case in which an $O(^3P)$ approaches the side oxygen atom of ozone perpendicular to the ozone plane and in which each p-orbital having one electron makes a σ-bond. According to Goddard, this mechanism probably occurs in the lowest energy. In this case, O_4 in the transition state has no symmetry (C_1). When this O_4 complex is cleaved into two oxygen molecules, the electronic state of the O_2 on the left-hand side is in the ground state ($^3\Sigma_g^-$), while the O_2 in the right-hand side is the ground state (d) or the $a^1\Delta_g$ state (e). However, the O–O bond distance is expected to be shorter for the states with three oxygen π electrons than for those with four π electrons. This means that the energy of O_4 of the state of three π electrons is lower than that of four electrons. Therefore, (d) in Case (II), the formation of the ground-state O_2, should give the lowest energy to the O_4 complex. It can be considered that the energy of the transition-state complex of O_4 is lowest in the case of the formation of two ground-state molecular oxygens (probably vibrationally excited) after cleavage.

2) $H+O_3$ Reaction. This reaction is wellknown as the source of the vibrationally excited OH radicals. Recent work[16] has shown that the OH-product vibrational distribution peaks strongly in the highest accessible vibrational level, $v=9$, and that the mean fractions of the total energy entering the vibration and rotation in the OH are $\langle f'v\rangle \approx 0.90$ and $\langle f'r\rangle \approx 0.03$.

$$H(^2S) + O_3(X^1A_1) \rightarrow OH(^2\pi) + O_2(X^3\Sigma_g^-) \quad (4a)$$

$$\Delta H = -76.9 \text{ kcal/mol}$$

However, OH is distributed in the lower levels, although it has progressively lower populations. Therefore, it is possible that singlet oxygen can be formed due to the exothermicity:

$$H(^2S) + O_3(X^1A_1) \rightarrow OH(^2\pi) + O_2{}^*(a^1\Delta_g) \quad (4b)$$

$$\rightarrow OH(^2\pi) + O_2{}^*(b^1\Sigma_g^+). \quad (4c)$$

There have been no reports on the singlet oxygen produced in the reaction of $H+O_3$. Measurements of the signals at mass number 32 were attempted by the method described above. The mass spectra measured in the $H+O_3$ reaction system are shown in Fig. 6. As is shown in Fig. 6, the signals at mass 32 are not changed in the $H+O_3+O_2$ and $H+O_2$ systems (O_3/O_2 was passed through the heater). The signals at mass 32 measured under a variety of O_3/O_2 concentrations are shown in Fig. 7. As is shown in Fig. 7, the signals for mass 32 did not increase in the presence of ozone. In this case, 4.6% of an O_3/O_2 mixture (without He as a diluent) was added. The concentration of ozone in the O_3/O_2 mixture and the absolute concentration of

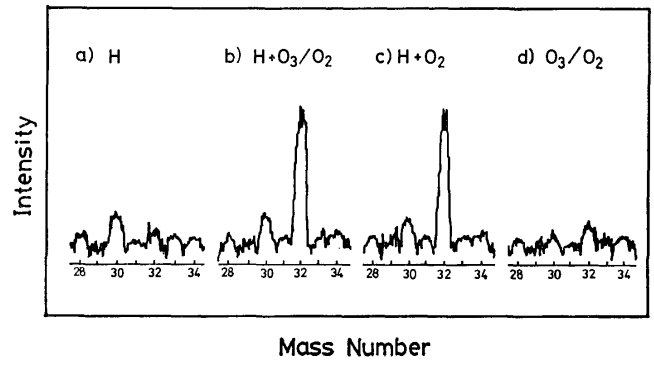

Fig. 6. Mass spectra in the $H+O_3$ reaction system. a): Only H_2/He discharge. b): O_3/O_2 mixture was added to the H_2/He discharge. c): O_3/O_2 mixture was passed through the heated quartz tube. Ozone was converted to O_2. d): Discharge was turned off. Only O_3/O_2 mixture flowed. Conditions: total pressure=4.6 Torr, [H]=8.69 mTorr, O_3+O_2=52 mTorr, O_3/O_2=7.5%, reaction time=6.1 ms.

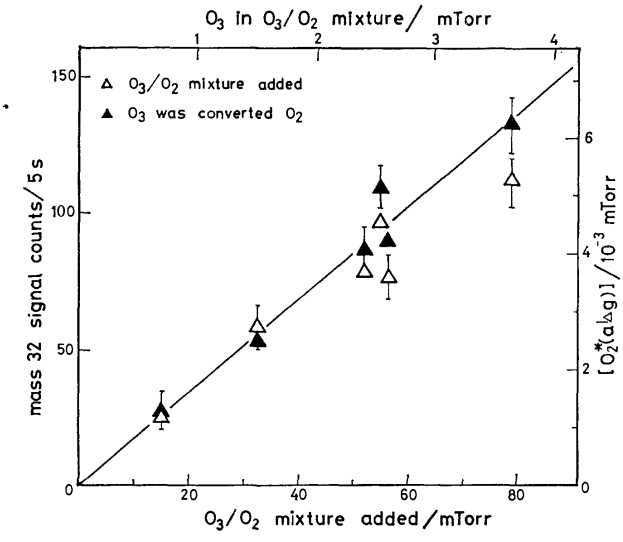

Fig. 7. Signals at $m/e=32$ *vs.* O_3/O_2 mixture added. △: Signals when O_3/O_2 mixture was added, ▲: signals when O_3/O_2 mixture was passed through the heated quartz tube. Conditions: total pressure=4.44 Torr, [H]=11.95 mTorr, reaction time=6.08 ms.

$O_2^*(a^1\Delta_g)$, as calculated from the sensitivity of NO, are shown in Fig. 7. When O_3 was converted to O_2 through the heater, the increase in the pressure of the O_3/O_2 mixture was about 2% ($O_3 \rightarrow 3/2O_2$). This is negligibly small compared with the counting error. The lack of increase in the signals for $O_2^*(a^1\Delta_g)$ in the presence of ozone showed that the $O_2^*(a^1\Delta_g)$ was formed only by Reactions 1 and 2. The absolute value for $O_2^*(a^1\Delta_g)$ agreed well with that of a previous work,[1] in which the fraction of Reaction 2 was about 0.015 of the total reaction of HO_2+H.

The deactivation of $O_2^*(a^1\Delta_g)$ by O_2 and O_3 can be neglected during the contact time of this work, 6.08 ms. The deactivation rate constant of $O_2^*(a^1\Delta_g)$ by hydrogen atoms has been reported to be 2.5×10^{-14} cm^3 molecule^{-1} s^{-1} [17]. This rate was also slow enough to neglect under those conditions, [H]=11.95 mTorr. The deactivation rate of $O_2^*(a^1\Delta_g)$ by OH is unknown. However, the nearly linear increase in the $O_2^*(a^1\Delta_g)$ signal in the presence of O_3 in Fig. 7 shows that the deactivation of $O_2^*(a^1\Delta_g)$ by OH does not affect the $O_2^*(a^1\Delta_g)$ signals.

The rate constant for Reaction 1 previously reported[18] is 1.57×10^{-32} cm^6 molecule^{-2} s^{-1} (M=He). This means that the second-order rate for Reaction 1 is 2.3×10^{-15} cm^3 molecule^{-1} s^{-1} under 4.44 Torr of He. On the other hand, the rate for Reaction 4 is very rapid. The rate constant for Reaction 4 was reported most recently[19] to be 2.8×10^{-11} cm^3 molecule^{-1} s^{-1} at 300 K. Therefore, the ozone should be consumed completely in the reactor under these experimental conditions, and the concentration of hydrogen atoms to react with O_2 might decrease with the addition of O_3. This effect is evident in Fig. 7. As is shown in Fig. 7, since the increment in the 1×10^{-3} mTorr of $O_2^*(a^1\Delta_g)$ should be detectable in both the presence and absence of O_3, it was concluded that the fraction of the formation of $O_2^*(a^1\Delta_g)$, Reaction 4b, in the total reaction of $H+O_3$ must be less than 0.001.

The reaction of OH with O_3 produces HO_2:

$$OH + O_3 \rightarrow HO_2 + O_2. \quad (5)$$

The rate constant for Reaction 5 reported most recently[20] is 8.2×10^{-14} cm^3 molecule^{-1} s^{-1} at 298 K. Three possible reaction paths have been suggested[21] for the reaction of vibrationally excited OH with O_3:

$$OH^* + O_3 \rightarrow HO_2 + O_2 \quad (6a)$$
$$\rightarrow H + 2O_2 \quad (6b)$$
$$\rightarrow OH + O + O_2. \quad (6c)$$

The reactions of OH^* (v=2—9) with O_3 have been shown to proceed with rate constants of $(2—11)\times10^{-12}$ cm^3 molecule^{-1} s^{-1} [21]. These rates for Reaction 5 and 6 are not fast enough to compete with Reaction 4 under these experimental conditions ($[H]\gg[O_3]$).

In the correlation in the reaction of $H(^2S)+O_3(X^1A_1)$, the ground states $OH(X^2\pi)+O_2(X^3\Sigma_g^-)$, can be correlated through the $^2A'$-state HO_3 complex (in both Cs planar and Cs bisecting complex) to the $H(^2S)+O_3(X^1A_1)$. However the $OH(X^2\pi)+O_2^*(a^1\Delta_g)$ or $O_2^*(b^1\Sigma_g^+)$ can not be correlated to it. This fact is consistent with the finding of this experiment in which the production of singlet oxygen can not be observed and is a result of the production of highly vibrationally excited OH radicals.[16]

3) $NO+O_3$ Reaction. The reaction of $NO+O_3$ is well known to emit the so-called "air afterglow" by means of the NO_2 formed, and this chemiluminescent reaction has been used by the chemiluminescent NO_x analyzer:

$$NO(X^2\pi) + O_3(X^1A_1) \rightarrow NO_2(X^2A_1) + O_2(X^3\Sigma_g^-) \quad (7)$$
$$\Delta H = -47.74 \text{ kcal/mol.}$$

In this case, the reaction produces visible and infrared emissions from electronically ($^2B_2$, $^2A_2$) and vibrationally excited ground-state NO_2.[22] Recent works using seeded beams[23,24] suggest that the cross-section of this chemiluminescent reaction increases very rapidly with an increase in the collision energy and is influenced by the electronic fine-structure states of NO ($\pi_{1/2}$, $\pi_{3/2}$). The enhancement of the reaction rate and chemiluminescence in this reaction by selective vibrational excitation with IR lasers has also been investigated.[25]

A puzzling feature of the reaction is the failure to observe excited $O_2^*(a^1\Delta_g)$ and $O_2^*(b^1\Sigma_g^+)$, energetically accessible and favored by the correlation diagram, since $O_2^*(a^1\Delta_g)$ lies lower than any other excited states of NO_2. The failure to observe $O_2^*(a^1\Delta_g)$ has also been reported by Gauthier and Snelling[26] in the reaction of O_3 with NO, where no $a^1\Delta_g$ emission was detected, and places an upper limit of 0.003 on the fraction of reactive collisions. A re-examination to observe

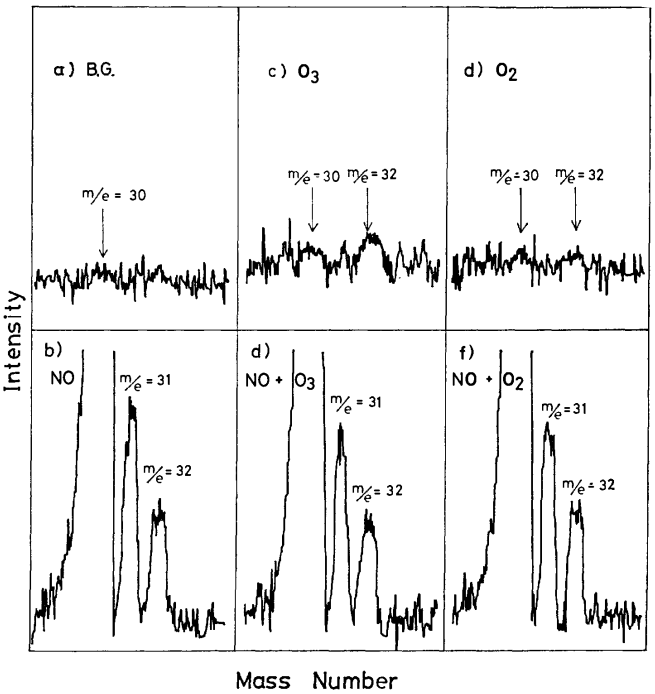

Fig. 8. Mass spectra in the $NO+O_3$ reaction system. a) Background. b) Only NO flowed. c) Only O_3–O_2–He mixture flowed. d) $NO+O_3$–O_2–He mixture. e) O_3–O_2–He mixture passed through the heated quartz tube. f) $NO+O_3$–O_2–He mixture passed through the heated quartz tube. Conditions: total pressure=3.8 Torr, $[O_3]$=18.2 mTorr, [NO]=2.3 mTorr, $[O_2]_1$=56.31 mTorr, reaction time=10.05 ms.

TABLE 2. SIGNALS AT $m/e=32$ IN THE O_3+NO REACTION SYSTEM UNDER THESE CONDITIONS TOTAL PRESSURES=3.782 Torr, $[O_3]=18.23$ mTorr, $[NO]=2.30$ mTorr, $[O_2]_I=56.31$ mTorr, REACTION TIME=10.05 ms

Run	Condition	Mass 32 signal, counts/5 s averaged over 128 measurements	
A	Background	28.9± 8.9	
B	Only O_3	31.7± 9.1	
C	Only O_2 (through heater)	30.2± 9.8	
D	Only NO	615.5±27.8	
E	O_3+NO	561.2±21.7	E−B=529.5±20.5
F	O_2+NO (through heater)	566.2±25.7	F−C=535.9±24.3

$O_2^*(a^1\Delta_g)$ was undertaken in the reaction of O_3+NO by means of the photoionization mass spectrometer used in this study.

The mass spectra measured in the $NO+O_3$ reaction system are shown in Fig. 8. The signals at $m/e=32$ are overlapped by the isotope signals of NO. The signals accumulated at $m/e=32$ are shown in Table 2. The difference between the signals in the O_3+NO (E—B) and O_2+NO (F—C) reactions is −6.44 counts/5 s, which means that the increment in the signal at $m/e=32$ can not be observed in the O_3+NO reaction. The rate constant for Reaction 7 reported most recently[27] is 1.80×10^{-14} cm^3 molecule^{-1} s^{-1} at 298 K. Therefore, the O_2 formed in Reaction 7 can be calculated to be $k_7[NO][O_3]t=0.250$ mTorr under the conditions listed in Table 2. On the other hand, 30 counts/5 s of the increment of the signal should be detectable under the conditions listed in Table 2 if $O_2^*(a^1\Delta_g)$ is produced. The 30 counts/5 s of the $O_2^*(a^1\Delta_g)$ signal can be calculated to be 4.8×10^{-4} mTorr because of the sensitivity of NO, 2.5×10^4 counts/s for 1 mTorr. Therefore, the fraction for the formation of $O_2^*(a^1\Delta_g)$ in the total reaction of O_3+NO should be less than 0.002.

The deactivation of $O_2^*(a^1\Delta_g)$ by NO and NO_2 have been reported[14] to be very slow, 4.5×10^{-17} and 5.0×10^{-18} cm^3 molecule^{-1} s^{-1} respectively. Therefore, the quenching of $O_2^*(a^1\Delta_g)$ by the reacting gases can be neglected. It has been suggested[2,28] that $O_2^*(a^1\Delta_g)$ can be formed in the energy-transfer reaction by electronically excited NO_2 with O_2.

$$NO_2^* + O_2 \rightarrow NO_2 + O_2^*(a^1\Delta_g). \quad (8)$$

According to a report by Clough and Thrush,[22] the formation of electronically excited NO_2 emitting light shorter than 875 nm is 6.5% of the total reaction of $NO+O_3$ at 300 K. Jones and Bayes[2] have determined the efficiency for Reaction 8, which decreases from 3.5 to 0.5% as the NO_2 excitation wavelength increases from 420 to 620 nm. Therefore, if NO_2^* is quenched completely only by O_2, the amount of $O_2^*(a^1\Delta_g)$ formed by Reaction 8 should be less than 0.002 of the total reaction of $NO+O_3$. Therefore, it is reasonable that the $O_2^*(a^1\Delta_g)$ produced in Reaction 8 could not be detected in this study. The above finding that less than 0.002 of the $NO+O_3$ reactive collisions result in the production of $O_2^*(a^1\Delta_g)$ is in good agreement with the result by Gauthier and Snelling.[26]

Redpath, Menzinger, and Carrington[23] preferred

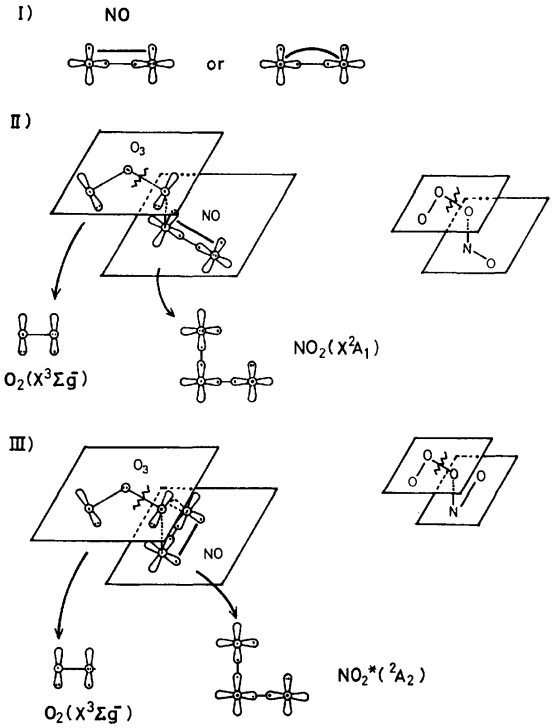

Fig. 9. GVB model representation in the $NO+O_3$ reaction system.

the bisecting-plane model in the $NO+O_3$ reaction, in which the NO approaches O_3 on the plane bisecting the O_3-bond angle (Cs symmetry); the formation of electronically excited NO_2 rather than the energetically preferred $O_2^*(a^1\Delta_g)$ can be explained by this model. However, the reaction on such a bisecting plane requires a very high energy, since ozone has the form of Ia) in Fig. 5.

According to the GVB-model representation, the NO molecule is shown by I) in Fig. 9. The cases in which O_3 reacts with NO with the lowest energy are Cases (II) and (III) in Fig. 9. In these cases, NO approaches the side oxygen atom of O_3 parallel to the ozone plane and makes a N–O σ-bond perpendicular to the ozone plane. After this stage, the NO_4 complex cleavages to O_2 and NO_2. Two types of NO_2 are produced: NO_2 with 4π electrons, Case (II), corresponds to $NO_2(X^2A_1)$ and $NO_2^*(^2B_2)$, and that having 3π electrons, Case (III), corresponds to $NO_2^*(^2A_2)$ and $NO_2^*(^2B_1)$. Since it can be expected that molecules with a lower energy are predominantly produced, the

NO_2 formed in Case (II) should be in the ground state ($^2A_1$) while that in Case (III) should be in the $^2A_2$ state. On the other hand, the O_2 formed is in the ground state in both cases.

The formation of electronically excited NO_2^* rather than the energetically preferred $O_2^*(a^1\Delta_g)$ can be explained by the GVB-model representation. However, the formation of the $^2B_1$ and the $^2B_2$ states of NO_2 can not be explained thus. It might be possible that the $^2B_1$ and the $^2B_2$ states of NO_2 are populated by vibronic interaction[29] with the $^2A_1$ and the $^2A_2$ states of the NO_2 produced initially after the O_2 has departed.

Further exact theoretical calculations are needed in order to clarify these reactions.

The authors wish to thank Professor Shigeru Nagase of Yokohama National University for his helpful discussions.

Phase Transitions in *N*-Propylpyridinium-TCNQ Ion-radical Complex Salts

Mutsuaki MURAKAMI* and Susumu YOSHIMURA
Matsushita Research Institute Tokyo, Inc., Ikuta, Tama-ku, Kawasaki 214
(Received March 27, 1980)

N-Propylpyridinium $(TCNQ)_x$ crystallized in two complex salts ($x=2$, 2.5), both of which displayed initial irreversible and subsequent reversible first-order phase transitions with a sharp discontinuity in the electrical conductivity. The reversible transitions of both salts are essentially the same in spite of their differences in stoichiometry. The transitions were accompanied by crystal structure changes; the changes in the physical properties were ascribed to the crystalline distortion in both the one-dimensional TCNQ chain and the motion of the cation molecules. The high-temperature phase was metallic, with a zero activation energy for conduction; the source of the metallic behavior was also discussed. The electronic and infrared absorption spectra suggest that the high-temperature modification has a less distorted stacking of TCNQ molecules in the column.

The phase transitions and metallic conductivity in a quasi-one-dimensional system based on 7.7.8.8-tetracyanoquinodimethane (TCNQ) ion-radical salts have been the subject of extensive investigation. The highly conducting salts of TCNQ with *N*-methylphenazinium (NMP(TCNQ)),[1,2] quinolinium $(Q(TCNQ)_2)$[3,4] and acridinium $(Ad(TCNQ)_2)$[5] display a metal-insulator (M-I) transition characterized by a smooth maximum in the conductivity. The metallic behavior of these salts has been explained in various manners: a mobility model in which the conductivity is defined as the product of the concentration of charge carriers and the mobility of the carriers,[6] diffusion through the localized state by means of a disorder effect,[7-9] inter-strand hopping due to the finite length of the conducting chains,[10,11] and an M-I transition with a single particle gap going to zero.[1]

On the other hand, there are some examples of first-order phase transitions which display a discrete change in the electrical conductivity. Reversible transitions are found in alkali-metal (TCNQ),[12,13] methyltriphenylphosphonium $(TCNQ)_2$,[14] and *N*-ethyl·*N*·methylmorpholinium $(TCNQ)_2$,[15,16] $(MEM(TCNQ)_2)$, while monotropic transitions are found in *N*-methylquinolinium $(TCNQ)_x$[17] and methyldiethylcyclohexylammonium $(TCNQ)_2$.[18] They have been understood on the basis of crystallographic change, Adler-Brooks transition,[19,20] spin Peierls transition, or transition from a metastable to a stable form.[21]

In a previous paper, we reported that substituted pyridinium and picolinium–TCNQ complex salts exhibited a variety of first-order phase transitions.[22] The irreversible transition was correlated to the appearance of multiple forms, while the reversible one manifested itself for specific cations. *N*-propylpyridinium $(TCNQ)_x$, $(NPPy(TCNQ)_x)$ complex salts crystallized in two forms ($x=2.5$ and 2.0) displayed two kinds of first-order phase transitions, *viz.*, an initial irreversible transition, and subsequent reversible transitions. In this paper, we will report on the electrical, optical, and magnetic properties of the transitions, and will discuss the transition mechanism and the source of the metallic behavior in the high-temperature phase.

Experimental

Preparation of NPPy(TCNQ)$_x$ Complex Salts. NPPy-$(TCNQ)_x$ complex Salt II was synthesized from *N*-propylpyridinium iodide and three-halves molar excess of TCNQ using one of the methods generally described by Melby *et al.*[23] After the salt had been synthesized, recrystallization was done in highly purified acetone at 0 °C. The formation of the two salts was controlled by the crystallization conditions: the Salt I was obtained from a concentrated solution (50 mmol dm^{-3}) with rapid crystallization as a fine needle form, while the Salt II was recrystallized by slow crystallization from a dilute solution (30 mmol dm^{-3}) as a rod or triclinic prism form.

The cation-to-TCNQ ratio of the complex salts was estimated by the spectral analysis from a simple salt of NPPy-(TCNQ) and neutral TCNQ.[21] The value of the molar excitation coefficient for TCNQ in highly purified acetonitrile was 67000 mol^{-1} dm^3 cm^{-1} at the wavelength of 395 nm, while the coefficients of $TCNQ^-$ were 26300 and 46100 mol^{-1} dm^3 cm^{-1} at 420 and 842 nm respectively; the coefficient at 395 nm was 21200 mol^{-1} dm^3 cm^{-1}. From the analysis, the cation-to-TCNQ ratio of I is estimated to be 2.48, and that of II, to be 1.94. The elemental analysis values for I were; Found: C, 72.32; H, 3.43; N, 24.43%, calcd for $(C_8H_{12}N)_2(C_{12}H_4N_4)_5$: C, 72.15; H, 3.48; N, 24.36%, while those for II were; Found: C, 72.62; H, 3.70; N, 23.48%, calcd for $(C_8H_2N)(C_{12}H_4N_4)_2$: C, 72.45; H, 3.77; N, 23.77%. From these results, considering the experimental error, we decided the cation-to-TCNQ ration to be 2.5 for I and 2.0 for II.

Electrical Measurements. The specific resistivities of compactions were determined with a resistivity measuring apparatus, Kokusai Electric Co., Ltd., Model VR4. The temperature dependence of the electrical resistivity along three crystallographic directions of a single crystal was measured with an ordinary four-point method with gold wires (0.05 mmϕ) and silver paste (duPont conductive silver coating material No. 4929). The sample was mounted in an evacuated glass cell sealed with a hermetic seal (NEC No. S110). The temperature was regulated with thermostat equipment (Sigma Electric Co., Ltd., Model TE-307S) and a temperature sweeper (Model SP-9D) at the sweep rate of 0.1—2.0 °C/min in the temperature range of 210—430K.

Other Measurements. The infrared absorption spectra were measured at various temperature with a Hitachi grating infrared spectrometer Model No. 215, in the wave number range between 4000 and 650 cm^{-1}. The solid state electronic absorption spectra were measured in the range between 5000 and 44000 cm^{-1} with a Cary spectrometer, Model No. 14. Samples were fully ground and carefully rubbed on a substrate; a quartz plate for measurements in the electronic region or a sodium chloride plate, for those in the infrared region.

Measurements of differential scanning calorimetry (DSC) were made with a Shimadzu thermoflex apparatus, SC-20, in a nitrogen atomosphere at the sweeping rate of 0.5—2.0 °C/

min in the temperature range of 293—430K. The data employed were an average value of ten measurements.

The powder X-ray diffraction patterns were measured with a Philips PW-1051 X-ray diffractometer by the use of the Cu·$K\alpha$ line.

The magnetic susceptibility was measured on a magnetic balance using Faraday's method in the temperature range of 100—430K. The sample, a pressed pellet about 100 mg, was placed in a quartz cell, and measurement was made under a vaccum. The absolute value of the susceptibility was estimated from gadrinium oxide ($\chi = 135 \times 10^{-6}$ emu/g) placed in the same quartz cell. The paramagnetic contribution (χ_{para}) to the susceptibility was determined from the difference of $\chi - \chi_{dia}$, while the diamagnetic contribution, χ_{dia}, was estimated from Pascal's rule.

Results and Discussion

Electrical Properties of NPPy(TCNQ)$_x$ Salts. The most typical difference between the two salts, besides stoichiometry and morphology, is the resistivity at room temperature; the specific resistivity of the powder smaple I (x=2.5) was 1.4 Ω cm, while that of the II (x=2.0) was 2000 Ω cm. In the Salt II, the lowest resistivity is found in the direction of the a-axis (1000 Ω cm), and the resistivity anisotropy ratio of the a, b, and c axes was 1 : 24 : 4.5. On the other hand, the lowest resistivity of I was found in the long axis (0.12 Ω cm) and its anisotropy ratio is expected to be larger than that of II.

The Temperature Dependence of the Resistivity of II. The temperature dependence of the electrical resistivity along each crystallographic direction of II was measured; the results are shown in Fig. 1. The resistivity abruptly changed at three temperatures; the resistivity jump observed at 383 K by initial heating was irreversible, while the other two jumps, at 370 K and 376 K, were the portions of a hysteresis loop of a reversible transition. We recognized two kinds of phase transitions and three distinct phases; it will be convenient to identify the phases as α_{II}, β', β as is indicated in the figure.

For example, in the c-direction, the inclination of the log ρ-T^{-1} curve in the semiconducting α_{II} phase increased with the temperature, from 0.18 eV in the temperature range of 200—230 K to 0.42 eV in the range of 330—370 K. On the other hand, the β' phase was metallic in the sense that it had a zero temperature coefficient of resistivity. The β phase was semiconducting, with an activation energy of 0.54 eV between 320 and 350 K, which was larger than that of the α_{II} phase in the same temperature range. A decrease in the activation energy was also observed at lower temperatures; the value was 0.16 eV in the temperature range of 200—230 K.

The features of the ρ-T characteristic for the three crystallographic directions closely resembled each other. Some quantitative differences between these crystal axes are summarized as follows: 1) The magnitudes of the resistivity jumps at the irreversible transitions were factors of 23, 140, and 45 for the a, b, and c axes respectively. 2) In the high-temperature β' phase, the resistivities were 2, 8, and 4 Ω cm for the a, b, and c axes respectively. The maximal anisotropy ratio in this phase was only 4, which is to be compared with that of the α_{II} phase, 24. 3) The a- and c-axis conductivity in the β' phase had a zero activation energy, while the b-axis one had a small positive value of 0.09 eV. 4) The magnitudes of the resistivity jumps in the reversible transition at 376 K were factors of about 12, 20, and 8 for the a, b, and c axes respectively. The maximal anisotropy ratio in the β phase at 293 K was reduced to about 20.

Crystal Structure Change of II. The very sharp resistivity change shown in Fig. 1 suggests a first-order phase transition, and, in fact, latent heat was observed at three temperatures with the DSC experiment. The results for ΔH were +13.81, −9.83, and +10.13 kJ mol^{-1} for the $\alpha_{II} \rightarrow \beta'$, $\beta' \rightarrow \beta$, and $\beta \rightarrow \beta'$ transitions respectively, and the corresponding entropy changes (ΔS) were +35.98, −26.57, and +26.69 J K^{-1} mol^{-1}.

Powder X-ray experiments were made at three temperatures corresponding to the three phases: the α_{II}

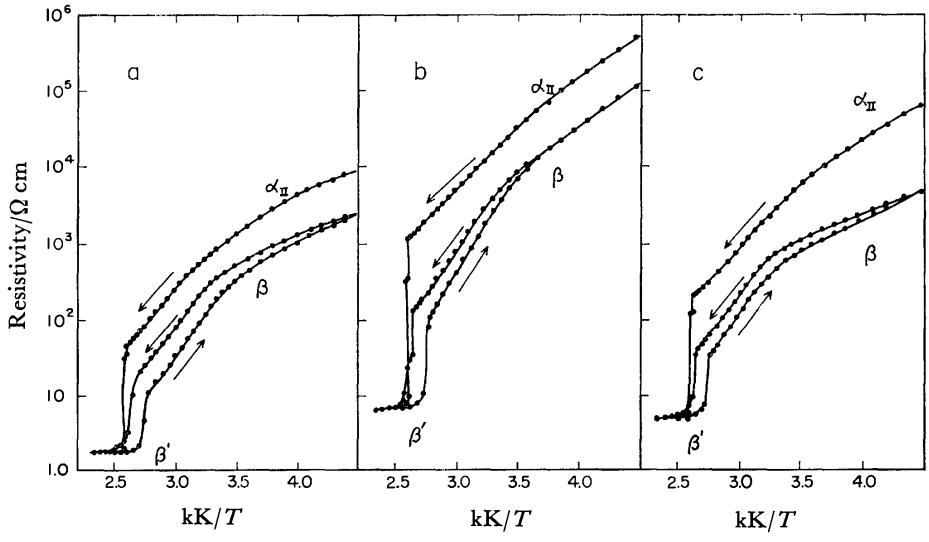

Fig. 1. Temperature dependence of the electrical resistivity of Salt-II along the a, b, c-directions.

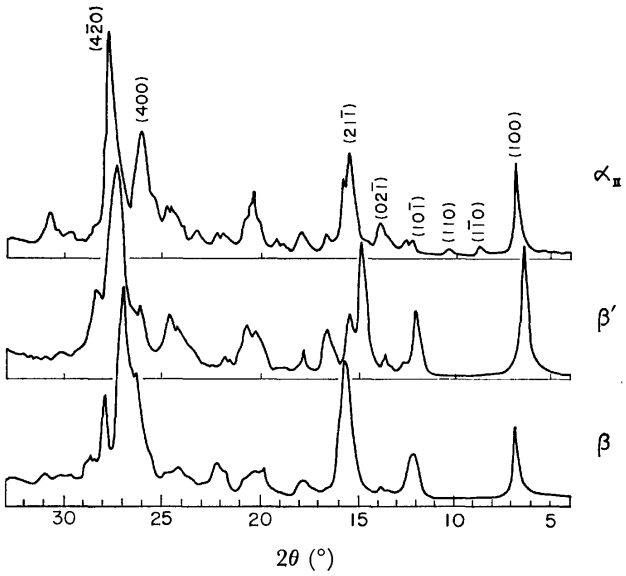

Fig. 2. Powder X-ray diagrams of α_{II} (293 K), β' (393 K), and β (293 K) modifications of Salt-II.

phase, 293 K, the β' phase, 399 K, and the β phase, 293 K. The results are shown in Fig. 2. The three X-ray diagrams of the α_{II}, β', and β phases were entirely different form each other, which confirms that the transitions are crystallographic phase transitions. Though a detail discussion of the crystal structure change must await a full crystal structure analysis of the β' and β phases, we can provide a rough view of the structure change as inferred from the shifts of the characteristic lines on the powder X-ray patterns. The most remarkable change at the $\alpha_{II}\rightarrow\beta'$ transition is observed in the lower angle region than 10°. From the crystal structure analysis of the α_{II} phase,[24] the relation between the lines and the reflection plane was calculated. The α_{II} belongs to the triclinic system with the space group P1 or P$\bar{1}$ and the lattice constants $a=$ 14.542, $b=13.723$, $c=7.802$ Å, $\alpha=104.06°$, $\beta=110.72°$, $\gamma=94.08°$ and $z=2$. The intense line at the lowest angle, 6.60°, is a (100) reflection, while the lines at 8.6° and 10.2° are reflections from (1$\bar{1}$0) and (110) respectively. In the β' phase, the lines corresponding to (1$\bar{1}$0) and (110) reflections disappeared, and only an intense line at 6.08° was observed in this region. The results indicate the change in the crystal symmetry: from a triclinic crystal (α_{II} phase) to a monoclinic crystal (β' phase). On the contrary, the crystal symmetry did not change at the $\beta'\leftrightarrows\beta$ transition, because the β phase had only a new line appearing at 6.55°. If these lines correspond to the (100) reflection, it means that the β' phase has the largest (100) spacing. The average inter-TCNQ column distance increased during the $\alpha_{II}\rightarrow\beta'$ transition and decreased during the $\beta'\rightarrow\beta$ transition. The large change in the interchain distance suggests that the rotation of cation molecules plays an important role at these transitions.

The most intense line in the α_{II} phase at 27.7° or the distance of about 3.2 Å originates from a spacing or paired TCNQ[24] in the TCNQ column. If the most intense reflection in the β' phase at 27.2° also comes from a plane nearly parallel to the TCNQ planes, the shift of this line with the $\alpha_{II}\rightarrow\beta'$ transition corresponds to a 1.8% increase in the inter-planar spacing of paired TCNQ molecules. Therefore the resistivity change at the $\alpha_{II}\rightarrow\beta'$ transition can be explained by the change in the stacking mode of TCNQ molecules from diadic to monadic configurations. In the β phase, the reflection appears at 27.0°; it undergoes an increase of about 0.7% in the spacing at the $\beta'\rightarrow\beta$ transition. The change in the interplanar spacing of TCNQ molecules at the reversible transition well explains the resistivity change.

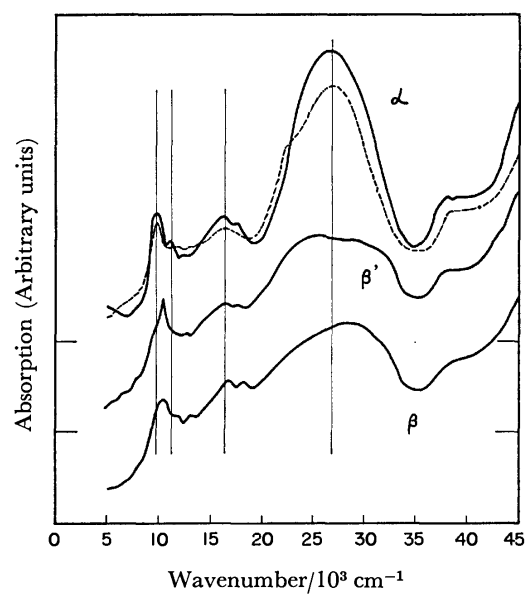

Fig. 3. Electronic absorption spectra of α (293 K), β' (393 K), and β (293 K) modifications of Salt-II (——) and Salt-I (-----).

Change in TCNQ Column Structure of II. Figure 3 shows the electronic absorption spectra of a powder film rubbed over a quartz plate at three temperatures corresponding to the α_{II}, β', and β phases. The spectrum of the α_{II} phase was characterized by a strong intramolecular absorption centered at 26800 cm^{-1} (local excitation band, LE_2)[25] and a relatively strong absorption at about 16000 cm^{-1}. The latter may be interpreted as an intramolecular transition of a TCNQ molecule (LE_1) and/or an absorption of associated TCNQ molecules.[26] In general, the absorption band at around 10000 cm^{-1} has been interpreted in various manners: as an intermolecular charge transfer transition of $TCNQ^-$ to $TCNQ^-$,[27] as a transition to an upper band distinguished from a near infrared absorption which is due to an intraband transition, or as an interaction between LE_1 and CT_1. The doubly splitting band at 10000 cm^{-1} and 11300 cm^{-1} may be due to an interaction of LE_1 and CT_1 by analogy of the electronic spectra of $TEA(TCNQ)_2$; the band splitting suggests the crystallographic inequivalence of the TCNQ molecules in the column.

The absorption spectrum of the β' phase differed from those of the α phase, in which it had a weaker absorption in the intramolecular excitation regions at around 25000

cm^{-1} and in which the absorption located at around 10000 cm^{-1} had a single sharp peak at 10400 cm^{-1}. The remarkable change in the intramolecular absorption may explain the increase in the conductivity in the β' phase. The change of the spectrum around 10000 cm^{-1} shows the change of the TCNQ column, namely, the structure at the β' phase is almost equivalent which implies that the negative charge may delocalize throughout the TCNQ column. In the case of such a column structure, the CT_1 absorption band does not appear; in fact, $Q(TCNQ)_2$ and NMP(TCNQ) show only a single LE_1 peak at around 10000 cm^{-1}. The spectrum of the β phase was characterized by an intramolecular absorption band at 28000 cm^{-1} and splitting bands at 10100 cm^{-1} and 11400 cm^{-1} (shoulder). The latter bands indicate the presence of crystallographic inequivalency in the TCNQ column.

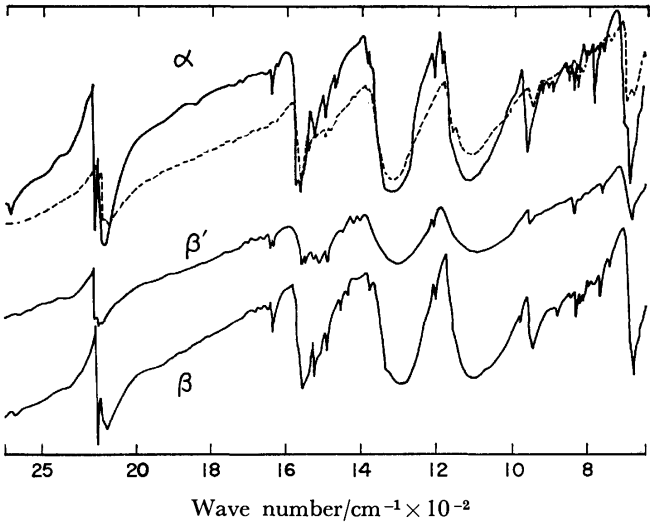

Fig. 4. Infrared absorption spectra of α (293 K), β' (393 K), and β (293 K) modifications of Salt-II (——) and Salt-I (------).

Similar results for the arrangement of TCNQ molecules were obtained from the infrared measurement.[28,29] The results are shown in Fig. 4. The α_{II} and β phases had sharp molecular absorption bands of TCNQ in the C≡N stretching regions around 2200 cm^{-1}, which indicates the presence of localized TCNQ molecules in the column. In the β' phase, sharp C≡N stretching absorptions were absent and the C–H bending band centered at 1290 cm^{-1} and the C–CN stretching band (1100 cm^{-1}) were broader and located at lower energies as compared with the α_{II} and β phases. The shift of the bands shows the decreased intermolecular repulsion or contraction of the electronic band gap, while the broadening of the bands may be due to the increased electronic band, which broadened to the infrared region. Thus, we concluded that the α_{II} and β phases have a disordered arrangement of TCNQ molecules, whereas the β' phase has an almost ordered stack of TCNQ molecules.

Metallic Nature of II in the β' Phase. The results of the ρ-T characteristics for the reversible $\beta \rightleftarrows \beta'$ transition are similar to those found in VO_2, which has offered a good example of a crystalline distortion or Adler-Brooks model.[30,31] The optical data which have suggested a pairing of TCNQ molecules at low temperatures are consistent with the increased resistivity of the β phase, because such a pairing opens an energy gap, as in the case of VO_2. The rough coincidence in both the transition temperature, T_0, and the activation energy for conduction just below, T_0, is noteworthy: II, 376 K and 0.51 eV, and VO_2 339 K and 0.50 eV.[32] However, a more exact examination may lead to the conclusion that the phase transition of our salt cannot be described by this mode. The Adler-Brooks model predicts that the energy gap, E_{g0}, due to a crystalline distortion is proportional to T_0, provided that the band widths are not very different. If we take $E_{g0}/kT_0=10$ as a rough estimate, the measured T_0 (376 K) gives an energy gap of 0.32 eV. Note that the observed activation energy, 0.51 eV (c-axis), is considerably larger than the predicted one, 0.16 eV. This discrepancy indicates the inapplicability of the Adler-Brooks model.

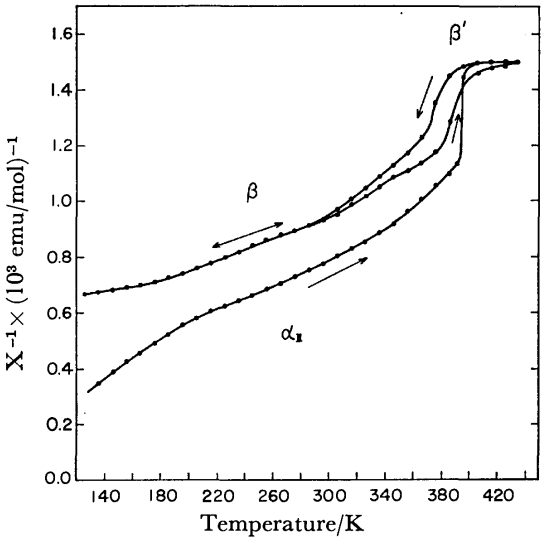

Fig. 5. Temperature dependence of the inverse paramagnetic susceptibility of Salt-II.

Figure 5 shows the temperature dependence of the paramagnetic susceptibility for the temperature range of 100—430 K. The results show discrete changes in χ which correspond to the resistivity jumps found in Fig. 1. The β' phase had a temperature independent susceptibility of about 5.0×10^{-4} emu/mol. The low-temperature α_{II} and β phases, on the other hand, exhibited Curie-Weiss like behavior, with a marked increase in the paramagnetic susceptibility at low temperatures.

The observed magnetic behavior cannot be described by ferromagnetic impurities, for the low-temperature α_{II} and β phases did not have the same magnitude of susceptibility. Indeed, the effective Curie-Weiss behavior may be explained by an array of disordered paramagnetic moments. The reason for this speculation is that the hopping motion of a localized electron is suggested by the fact that the activation energy around

370—300 K is considerably larger than that predicted by the Adler-Brooks model. Other reasons are that the NPPy cation is assymmetric and II was crystallized as a metastable crystal. The decrease in the magnitude of χ with the $\alpha_{II} \rightarrow \beta$ transition indicated that the crystal structure was made less ordered with the irreversible transition, which is consistent with the crystallographic and optical data.

The observed behavior of the paramagnetic susceptibility of the β' phase is likely to be connected with the Pauli spin susceptibility of the free electron system, and this seems to provide evidence that the β' phase is indeed metallic. However, the weak temperature dependence of the paramagnetic susceptibility of highly conducting TCNQ salts can also be described by the properties of a one-dimensional Mott insulator[33] or by those of a tight binding band.[34] In these cases, the electronic states have been thought to be localized at a lattice point in the one-dimensional TCNQ chain. Moreover, the disorder model can explain the observed behavior with an expression in the form of $\chi = \chi_{para} + \chi_{curie\text{-}weiss}$. Several data presented above suggest that the β' phase may also be described by a localized electronic model. For example, the intramolecular absorption band at 16000 cm^{-1} (Fig. 3) has a doublet peak, which indicates that the β' phase does not have a completely uniform stacking of the TCNQ molecule. This may be understood on the basis of the highly asymmetric structure of the cation molecule, which makes a major contrast to the case of MEM-$(TCNQ)_2$.[15,16] At this stage, we surmise that the β' phase is described by the phonon-assisted hopping between localized states. The relatively high and temperature-independent conductivity agrees well with the expected values of the minimum resistivity by hopping (order of 1 Ω cm) and the small temperature slope of the resistivity ($(\partial\rho/\partial T = 1.2 \times 10^{-3}$ Ω cm K^{-1}).[5]

Phase Transitions of I. The temperature dependence of the electrical resistivity of a powder sample of I ($x=2.5$) is shown in Fig. 6. An irreversible transition appeared in a broad temperature range starting at about 390 K, where the resistivity increased by a factor of about 5. Since the transition temperature was varied by the rate of the rise in the temperature or by the crystal perfection, the transition is a polymorphic transition from an unstable to a stable form. After the irreversible transition was completed, the salt displayed a reversible transition similar to that of II. We can also recognize three phases, so we indicates the phases as α_I, β', and β, as is indicated in the figure.

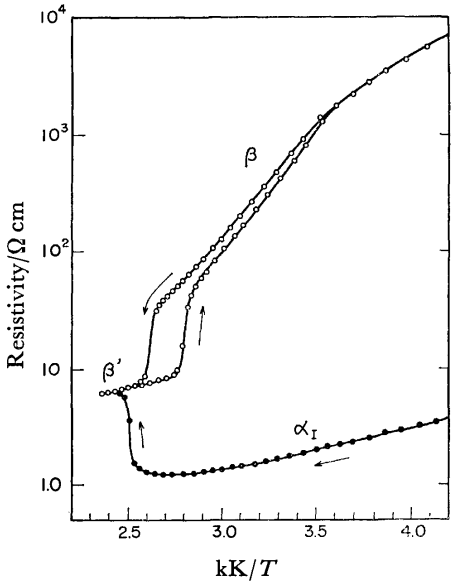

Fig. 6. Temperature dependence of the electrical resistivity of Salt-I (pressed rod), irreversible change (-●-●-), reversible change (-○-○-).

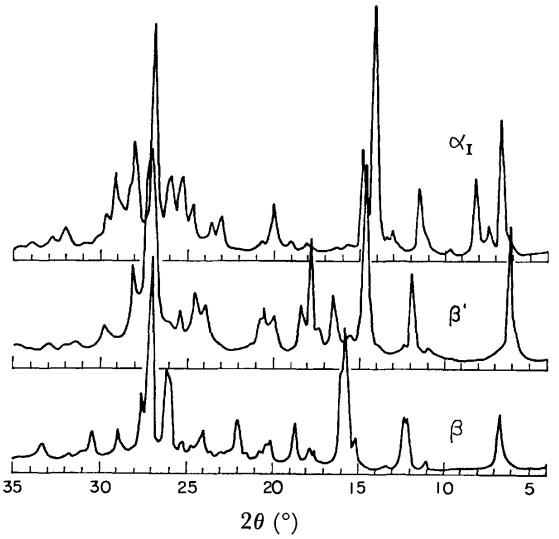

Fig. 7. Powder X-ray diagrams of α_I (293 K), β' (393 K), and β (293 K) modifications of Salt-I.

The powder X-ray diffraction patterns of I are shown in Fig. 7. The pattern of the α_I phase is quite different from that of the α_{II} phase, but the patterns of the β' or β phase of I and II are identical. During the $\alpha_I \rightarrow \beta'$ transition, a distinct change was observed at the most intense line around 26.8°, which implies that the average distance between TCNQ molecules expanded at the $\alpha_I \rightarrow \beta'$ transition. The electronic and infrared absorption spectra of I are shown by dotted lines in Figs. 3 and 4 respectively. The infrared spectrum of the α_I phase was characterized by broader bands located at a lower energy region as compared with the characteristic bands of TCNQ of the α_{II} phase. The electronic spectrum of the α_I phase was characterized by an absorption located at around 10000 cm^{-1}, in which the band splitting was not clear and the second peak was shouldered. The results indicate that the TCNQ column at the α_I phase is less distorted than that of the α_{II} phase and that TCNQ molecules are stacked almost uniformly. The conductivity change of the $\alpha_I \rightarrow \beta'$ transition is well explained by these results.

A difference in the ρ-T characteristic of I from that of II was the activation energy for conduction in the β' phase: 0 eV for II and 0.10 eV for I. Although I has quite a different stoichiometry from that of II, the same crystal structure may be realized by discarding one cation out of the five cation molecules from the structure of II.

If the crystal structure of I is characterized by such large defects in the cation column, the difference in the activation energies in the β' phase may be explained by such defects.

The authors offer their thanks to Dr. Ichimin Shirotani of Tokyo University and to Prof. Hayao Kobayashi of Tōhō University for their stimulating discussions. They are also indebted to Dr. Michiko Konno of Tokyo University for providing them with the details of the crystal structure of NPPy(TCNQ)$_x$, II.

The Heats of Solution of Optically Active Compounds and the Corresponding Racemic Compounds

Masayuki MATSUMOTO† and Kazuo AMAYA*

National Chemical Laboratory for Industry, 1-1, Azuma, Yatabe-Machi, Tsukuba-Gun, Ibaragi 305

(Received March 31, 1980)

The heats of solution of crystalline amino acids and hydroxy acid in water at 298.15 K were measured with a twin isoperibol calorimeter. It was found, as was expected from the theory, that the difference in the heat of solution between optically active compounds and their corresponding racemic compounds was appreciably large compared with the heat of mixing of concentrated aqueous solutions of *d*- and *l*-optical isomers.

According to the statistical thermodynamic theory for solutions containing *d*- and *l*-optical isomers, it was previously found by one of the present authors that first term of the excess enthalpy of the system was proportional to the inverse of the absolute temperature, $1/T$.[1,2] Takagi *et al.* measured the heat of mixing of aqueous solutions of *d*- and *l*-optical isomers at 298.75 K, but the values they obtained were too small to test the relation.[3] This may be attributed to the free rotation of optical isomers in solution, resulting in an averaging out, of the difference in interaction energy for each configuration.

However, in the solid state each molecule is confined in the cage formed by the surrounding molecules and is fixed to the most favorable configuration, and difference in configuration energy between an optically active compound and the corresponding racemic compound can be expected to be appreciably large.

In order to test this experimentally, the heats of solution of crystalline optically active compounds and the corresponding racemic compounds were measured.

Experimental

Materials. The alanine, D-glutamic acid, histidine, threonine, and L-valine were purchased from the Takara Kohsan Co., Ltd., the DL-glutamic acid, DL-valine and tartaric acid were also purchased, but from the Tokyo Kasei Co., Ltd. Their purities were certified by these makers and were guaranteed to be more than 99%.

These samples were dried over silica gels in a desiccator at room temperature for at least 3 d before use and were then used without further purification.

Apparatus and Procedures. The calorimeter used in this experiment was a Model TIC-2D twin isoperibol calorimeter manufactured by the Tokyo Riko Co., Ltd.; it is shown in Fig. 1.

It consists of two identical transparent Dewar vessels, about 0.15 dm³ in inner volume and equipped with a pair of thermistors with equal temperature coefficients, a pair of identical calibrating heaters, a pair of ampoule-breaking devices, and a pair of stirres driven by outside, rotating, permanent magnets. All these parts are installed in an aluminum block, which can be thermostatted within ±0.004 °C at any desired arbitrary temperature between −10 °C and 80 °C. Precise results can easily obtained by the employment of this twin system. During the experiment, the calorimeter was kept

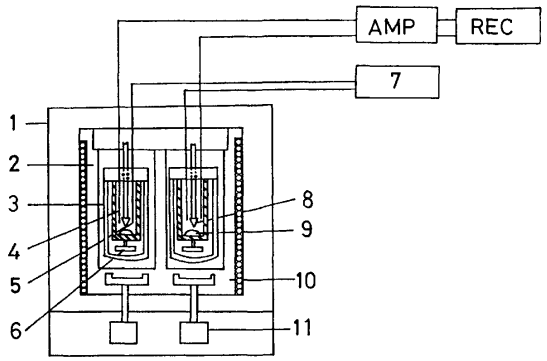

Fig. 1. Twin isoperibol calorimeter.
1): Case, 2): aluminum block, 3): Dewar vessel, 4): thermistor, 5): heater, 6): magnetic stirrer, 7): heater power source, 8) ampoule breaking device, 9): ampoule, 10): temperature controller, 11): motor for stirring, AMP: d.c.-amplifier, REC: recorder.

at 298.15±0.004 K. In each measurement, from 50 to 100 mg of the sample were sealed in a glass ampoule, and the sample and the blank ampoule were, respectively, set in the measurering and reference Dewar vessels, filled with 0.1 dm³ of distilled water.

The calorimeter was left for 24 h to reach thermal equilibrium, after which the sample and the blank ampoule were broken simultaneously with the ampoule-breaking devices. The dissolution was complete within 3 to 20 min, according to the sample. The difference in temperature between the two Dewar vessels was recorded on a chart recorder. The temperature change on dissolution was obtained by extrapolating the fore and after linear parts of the calorimetric curves (Challoner Method).[4] Electrical calibration was also made after the solution experiment, while the temperature change was obtained by the same procedure. The heat of solution, q_s, was derived by means of the following equation:

$$q_s = q_c \frac{\Delta t_s}{\Delta t_c}$$

where q_c is the heat quantity for electrical calibration, and where Δt_s and Δt_c are the temperature changes in solution and in the calibration experiment respectively.

Calibration of the Calorimeter. The calorimeter was calibrated with the NBS standard reference material 724a, tris(hydroxymethyl)aminomethane (THAM), and a 0.1 N (f=1.008) hydrochloric acid solution at 298.15 K.

Before use, THAM was dried *in vacuo* at room temperature for 1 h.

About 500 mg of THAM was sealed in a glass ampoule and set in the Dewar vessel filled with a 0.1 dm³ hydrochloric acid solution, and then the heat of solution was measured by the procedure described above. The mean value of the molar

† Present address: Department of Nutrition, Sagami Women's University, Bunkyo, Sagamihara, Kanagawa 228.

enthalpy of solution obtained by 3 runs was -29.32 ± 0.09 kJ/mol.

The value recommended by Hill *et al.* was -29.744 ± 0.003 kJ/mol.[5] Accordingly, the systematic error of our calorimeter was 1.4%, and the precision was 0.34%.

Results and Discussion

The values of the heat of solution of crystalline optically active compounds and their corresponding racemic compounds, and the difference between the two, are shown in Tables 1 and 2 respectively. This experiment was carried out under the conditions described above, so that these relative amounts gave final concentrations of about 0.01 mol/kg. Therefore, the heat of solution is considered to be the value at infinite dilution obtained by Spink and Auker.[6]

Table 1. Heats of solution of amino acids and tartaric acid in water at 298.15 K

Substance	Sample weight (g)	Observed heats of solution (J)	Heats of solution (kJ/mol)

Table 2. Differences in the heat of solution between optically active compounds and their corresponding racemic compounds

Substance	Differences in the heat of solution at 298.15 K (kJ/mol)
Alanine	2.00±0.21
Glutamic acid	4.1±0.2
Histidine	1.5±0.2
Threonine	0.17±0.13
Valine	2.29±0.01
Tartaric acid	9.4±0.3

It may be seen from Table 2 that the difference in the heat of solution between optically active compounds and their corresponding racemic compounds, which corresponds to the heat of mixing of optical isomers and their optical antipodes in the solid state, is appreciably large.[7]

On the other hand, the heat of mixing of optical isomers and their optical antipodes in the liquid state was nearly zero.[3]

This fact may be explained qualitatively as follows by employing simplified model of optical isomers.[1,8]

We assume that the optically active molecule is a cylindrical rod with circular planes at both ends, and that the circular planes are composed of three different elements a, b, and c.

For the *d*-isomer, the arrangement of these three elements is in the order a, b, and c clockwise as viewed from the top, while for its antipode, the *l*-isomer, it is a, b, and c anticlockwise, the peripheral part is composed of a uniform element, n, as is shown in Fig. 2.

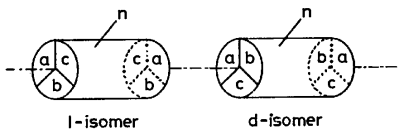

Fig. 2. A model of optical isomers.

Two neighboring molecules on the same axis can take three different states, which are obtained by rotating one of the molecules around the axis, with interacting pairs of elements $\begin{bmatrix} a & b & c \\ a & c & b \end{bmatrix}$, $\begin{bmatrix} a & b & c \\ c & b & a \end{bmatrix}$, and $\begin{bmatrix} a & b & c \\ b & a & c \end{bmatrix}$, whose interaction energies are $U_{aa}+2U_{bc}$, $U_{bb}+2U_{ac}$, and $U_{cc}+2U_{ab}$ respectively.

For the give of simplicity, we further assume that, in a system consisting of a large number of molecules, these molecules are arranged in such a way that their cylindrical axes lie on a straight line, and that each axis is surrounded by z nearest axes, as is shown in Fig. 3.

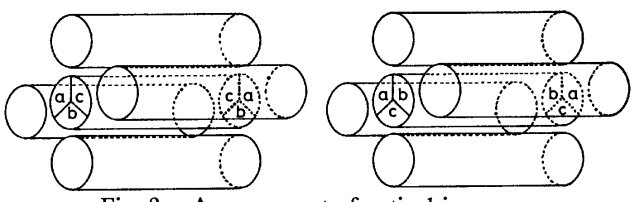

Fig. 3. Arrangement of optical isomers.

In the solid state, the relative angular positions of two neighboring molecules which lie on the same axis, are fixed and take the most stable position among the three states.

In the system of a pure *d*- or *l*-isomer, the interaction energy of the pair of circular planes for each of the three states takes such values as:

$$U_{aa} + 2U_{bc},\ U_{bb} + 2U_{ac},\ \text{and}\ U_{cc} + 2U_{ab}$$

respectively, where U_{ij} denotes the interaction energy of a pair of i and j elements.

The total configurational energy of the system consisting of N molecules of the pure isomer, U^{s}_{TA}, is expressed as:

$$U^{s}_{TA} = \frac{z}{2} NU_{nn} + NU_{Amax}$$

where U_{nn} and U_{Amax} denote the interaction energy between peripheral elements, n, and the interaction energy of the most stable position, respectively.

For a racemic system which consists of $N/2$ molecules of the *l*-isomer and $N/2$ molecules of the *d*-isomer, we may assume that the *l*-isomer and *d*-isomer lie alternately along the axis. Therefore, the interaction energy of pair of circular planes for each of the three states takes these values:

$$U_{aa} + U_{bb} + U_{cc},\ U_{ab} + U_{ac} + U_{bc},\ \text{and}$$
$$U_{ab} + U_{ac} + U_{bc}.$$

Two of them have equal values.

In the solid state, the relative angular position around the axes of two neighboring molecules is fixed. The total configurational energy of the system is, then expressed as:

$$U^{s}_{TR} = \frac{z}{2} NU_{nn} + NU_{Rmax}$$

where U_{Rmax} denotes the interaction energy of the most stable state among the three.

Therefore, the heat of mixing of *l*- and *d*-optical isomers in the solid state, ΔH^{s}_{m}, is expressed as: $\Delta H^{s}_{m} = N(U_{Rmax} - U_{Amax})$.

In general, U_{Rmax} and U_{Amax} have different values, and the heat of mixing has a finite value. However, in the liquid state each molecule can rotate freely around the axis. The average interaction energy is, then the mean of three states, and the total configurational energy of N pure optical isomers, U^{l}_{TA}, may be expressed as:

$$\begin{aligned} U^{l}_{TA} &= \frac{z}{2} NU_{nn} + \frac{N}{3}\{(U_{aa} + 2U_{bc}) + (U_{bb} + 2U_{ac}) \\ &\quad + (U_{cc} + 2U_{ab})\} \\ &= \frac{z}{2} NU_{nn} + \frac{N}{3}\{(U_{aa} + U_{bb} + U_{cc}) \\ &\quad + 2(U_{ab} + U_{ac} + U_{bc})\}. \end{aligned}$$

Similarly, for racemic systems, the total configurational energy, U^{l}_{TR}, may be expressed as:

$$\begin{aligned} U^{l}_{TR} &= \frac{z}{2} NU_{nn} + \frac{N}{3}\{(U_{aa} + U_{bb} + U_{cc}) \\ &\quad + 2(U_{ab} + U_{ac} + U_{bc})\}. \end{aligned}$$

Accordingly, the heat of mixing in the liquid state, $(U^{l}_{TR} - U^{l}_{TA})$ becomes zero in this approximation.

(Received December 11, 1979)

Copper(II) chloride and crown ethers (12-crown-4, 15-crown-5 and 18-crown-6) formed orange or orange-yellow complexes in dry chloroform. We found that the ESR g-anisotropy of the complexes was greatly dependent on the numbers of donor oxygens and the ring-numbers. The complexes obtained from 12-crown-4 and 18-crown-6 showed g-anisotropy ($g_{//}>g_{\perp}$); these are well characterized by the $3d_{x^2-y^2}$ or $3d_{xy}$ ground state. On the other hand, the complexes of 15-crown-5 and its benzo derivatives exhibited the reverse g-anisotropy ($g_{//}<g_{\perp}$); these are characterized by the $3d_{z^2}$ ground state with $S=1/2$. The electron nuclear dipolar term and the Fermi's isotropic term were estimated from the ESR parameters based on Bleaney's calculation. The chlorine superhyperfine splittings were observed in the $g_{//}$- component. The MO bonding parameters were estimated by assuming the compressed octahedral, the trigonal bipyramidal, and pentagonal bipyramidal geometry at the paramagnetic site. The bonding nature was studied on the basis of the observed ligand spin densities.

Many synthetic macrocyclic polyethers, polyamines, and other related molecules have been known to possess very interesting and unusual binding properties. They show a pronounced ability to bind a wide variety of cations and anions with marked conformational changes during binding. In addition, their hydrophobic exterior allows them to solubilized ionic substances in nonaqueous solvents.[1] These novel properties of crown ethers and polyamines resulted in their use as model ligands for ion transport systems, biological macrocycles, and the active chromophore of enzyme systems. It has been shown that the spectroscopic parameters of various model Cu(II)–polyamine or –macrocyclic complexes are useful in studying the paramagnetic active sites of Cu(II)–enzyme systems.

The ESR parameters of some cyclic polyamine–Cu(II) complexes have already been compared with those of the type (II)-Cu(II) protein.[2] Some model studies of the type (I)-Cu(II) protein have been performed using some thioether macrocyclic ligands.[3] Several investigators have also extensively studied the Cu(II)–proteins with model ligands such as nitrogen heterocyclics,[4] histidine and cystein containing oligo peptide.[5,6] In fact, the ESR parameters as well as the optical absorption character of these model complexes showed the excellent agreement with those of the square planar ($3d_{x^2-y^2}$ ground state) and of the tetrahedral type ($3d_{xy}$ ground state) paramagnetic active sites in copper proteins, where the g-anisotropy has been shown to be $g_{//}>g_{\perp}$ everywhere.

The possibility of the trigonal bipyramidal active site has also been proposed; the importance of the model studies with the $3d_{z^2}$ ground state in solution has been pointed out by Miskowski.[7] Several ESR studies of copper complexes with the $3d_{z^2}$ ground state have been reported for the compressed tetragonal, compressed trigonal bipyramidal, and *cis*-distorted octahedral site doped in solid matrices.[8] In solutions, however, formations of copper complexes with an axially compressed coordination require quite exceptional conditions, because the coordination geometries are usually fixed by the strong equatorial coordination of the polar functional groups and of the solvent molecules. In order to reveal unusual coordinations, we have chosen the crown ethers as the ligand. ESR investigations have been made for several Cu(II)–crown ether ligands with 12, 15, and 18 ring members in dry chloroform solutions (shown in Fig. 1).

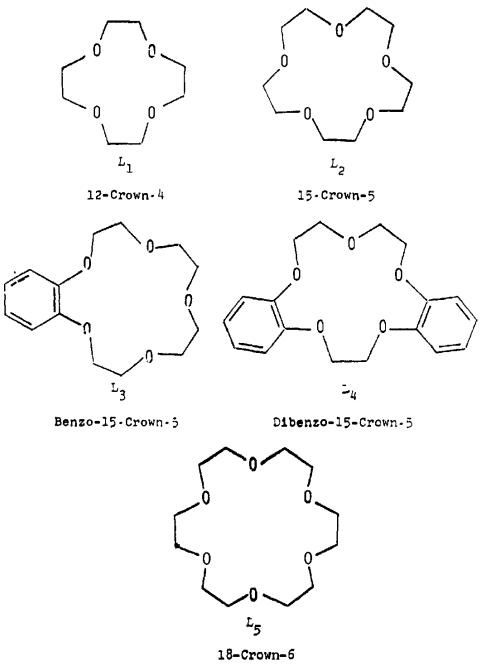

Fig. 1.

We found that the g-anisotropy of the crown ether Cu(II) complexes is strictly dependent on the numbers of ligand oxygen atoms. Cu(II) complexes with the L_2, L_3, and L_4 ligands reveal the inverted g-anisotropy ($g_{//}<g_{\perp}$), while the L_1 and L_5 complexes show the usual g-anisotropy ($g_{//}>g_{\perp}$). The bonding parameters in the copper-ligand bond of the L_2, L_3, and L_4 complexes were determined from the g and A tensors as well as

from the superhyperfine couplings of the chlorine atoms which are axially coordinated. The analysis of the ESR spectra confirmed that the L_2, L_3, and L_4 complexes are in the $3d_{z^2}$ ground state doublet. The electron nuclear dipolar term P and the Fermi isotropic term were determined based on Bleaney's calculation. The MO bonding parameters were estimated assuming the compressed octahedral, the trigonal, and the pentagonal bipyramidal geometry at the paramagnetic site. The bonding nature was characterized on the basis of the ligand spin densities.

Experimental

Benzo-15-crown-5 (L_3) and dibenzo-15-crown-5 (L_4) were synthesized according to Pedersen's procedure.[9] The pure materials were obtained by recrystallization in hexane; L_3: mp 80—82 °C (uncorrected). Found: C, 62.48; H, 7.46%. Calcd for $C_{14}H_{20}O_5$: C, 62.69; H, 7.46%. L_4: mp 114—115 °C (uncorrected). Found: C, 67.95; H, 6.33%. Calcd for $C_{18}H_{20}O_5$: C, 68.34; H, 6.37%. 12-Crown-4 (L_1), 15-crown-5 (L_2), and 18-crown-6 (L_5) purchased from Aldrich Chemicals were used without further purification.

Sample solutions were prepared as follows: commercial anhydrous cupric chloride, dried by heating the material at 110 °C for 6 h (0.04 mmol), and crown ether (0.4 mmol) were mixed with dry $CHCl_3$ (4 ml) under vacuum. The ESR spectra of the orange-to-yellow colored solutions were measured at 77 K. The details of the preparation and the ESR operating conditions were described in the previous paper.[10]

Results and Discussion

ESR Spectra. ESR spectra (Fig. 2) measured at 77 K for the L_1 and L_5 complexes showed the usual g-anisotropy with axial symmetry ($g_{//}>g_{\perp}$), whereas those of the L_2 and L_3 complexes[10] contained a typical line shape for nonoriented systems ($S=1/2$, $g_{//}>g_{\perp}$) (Fig. 3). The ligand superhyperfine splittings due to the two equivalent chlorine atoms can be clearly detected in the g_z component of the ESR spectra of the L_2, L_3, and L_4 complexes. The ESR parameters

determined are summarized in Table 1. The X-ray analysis of the L_1–$CuCl_2$ complex has already been performed. In this case, the copper atom binds with the two equatorial chlorine atoms and takes a distorted octahedral geometry, with the apical Cu–O (2.343 and 2.403 Å) distance much longer than the equatorial bond length (Cu–Cl=2.214, Cu–O=2.128 and 2.113 Å).[11] The ESR parameters of the L_1 and L_5 complexes shown in Table 1 suggest that the unpaired electron occupies either $d_{x^2-y^2}$ or d_{xy} type orbitals in the axially elongated octahedral ligand field. In fact, this conclusion is consistent with the results of the X-ray analysis of the L_1-complex. The structure of the L_5-complex has not been determined yet, but an analogous coordination scheme can be assumed based on the similarity in the observed ESR parameters.[12] In both cases, one will see that the equatorial chlorine atoms play an important role in stabilizing the in-plane bonding ($d_{x^2-y^2}$ or d_{xy}) in the octahedral geometry. The inverted g-anisotropy observed for the L_2, L_3, and L_4 complexes indicates that the unpaired electrons mainly occupy the $3d_{z^2}$ orbital of the metal in the ground state, because their Δg_z-value (g_z-g_e) has a small negative value (see Table 2).[13] The ultimate value of Δg_z is −0.02 for the pure $3d_{z^2}$ ground state, according to the theory.[14] The L_3 and L_4-complexes showed g-anisotropy with nearly axial symmetry. The L_2-complex had rhombic symmetry, which is supposedly due to the distortion arising from some steric requirement

in coordinating the metal ions with crown ether.[15] The ligand hyperfine splitting due to the chlorine atoms associated with the g_z-component suggests an apical perturbation on the Cu ions due to the two chlorine atoms coordinated above and below the pentagonal crown ring (Fig. 4).

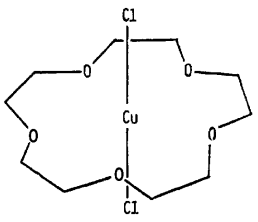

Fig. 4. The structure of $CuCl_2$-15-crown-5.

Characterization of the Bonding Parameters of L_2, L_3, and L_4 Complexes. The observed ESR spectra can be fitted by the spin Hamiltonian:

$$\hat{H} = \sum_{i=x,y,z} (g_i \beta H_i S_i + A_i \hat{S}_i \hat{I}_i) \quad (1)$$

if we neglect the copper nuclear Zeeman effect and the quadrupole interactions. A detailed discussion of the hyperfine tensor and its relation to the g-factors of the Cu(II) with the $3d_{z^2}$ ground state has already been given in the work of Bleaney.[14] For rhombic symmetry of the paramagnetic site, the relations between the g and the hyperfine tensor elements are given as follows:

$$A_x = P[-K + \Delta g_x + \frac{1}{14}\Delta g_y - \frac{2}{7}] \quad (2)$$

$$A_y = P[-K + \Delta g_y + \frac{1}{14}\Delta g_x - \frac{2}{7}] \quad (3)$$

$$A_z = P[-K + \Delta g_z - \frac{1}{14}(\Delta g_x + \Delta g_y) + \frac{4}{7}] \quad (4)$$

$$\Delta g_z = g_z - g_e,\ \Delta g_x = g_x - g_e,\ \Delta g_y = g_y - g_e$$

where K is the Fermi isotropic term and P defines the dipolar interaction of the copper nucleus with the unpaired electron, which is proportional to the average value of the inverse cubic power of the metal-unpaired electron distance. In the previous paper, P and K values were evaluated for the L_3 complex based on Swalen's calculation:[16]

$$P = 319 \times 10^{-4}\ cm^{-1} \text{ and } K = 0.127.^{10}$$

With the tentative use of these P and K values, the hyperfine tensor elements of the copper nucleus (A_x, A_y, and A_z) were calculated by using Bleaney's simple treatment; this gave satisfactory agreement between the observed and the calculated values for the L_2 and L_3 complexes, provided that $A_z > 0$ and A_x, $A_y < 0$ (see Table 1).

The considerable discrepancy between the observed and the calculated A_z values seen for the L_4 complex would be attributed to the overestimation of the K value; this will be revised in the following section. For nearly axially symmetry (L_3 and L_4) $\Delta g_\perp (g_\perp - g_e)$ can be expressed as a function of the ^2A-^2E, d-d transition energy $\Delta E_{xz,yz}$ and of the effective spin-orbital interaction parameter λ', which gives a measure of the extent of the electron delocalization into the ligand; $\lambda' = \alpha^2 \lambda_0$, $\Delta g_\perp = 6\lambda'/\Delta E_{xz,yz}$, where α^2 is the spin density on the copper $3d_{z^2}$ orbital. The effective value of spin-orbit interaction $\lambda'(-733.7\ cm^{-1})$ can be obtained based on the assumption that $\lambda' = (P/P_0)\lambda_0$,[17] where $P_0(360 \times 10^{-4}\ cm^{-1})$ and $\lambda_0(-828\ cm^{-1})$ are the dipolar-term and the spin-orbit interaction parameter of a Cu(II) free ion, respectively.

The value of α^2 was ≈ 0.89, and the corresponding d-d band transition energy $\Delta E_{xz,yz}$ was roughly 13800 cm^{-1} for the L_3 and the L_4 complex. A more rigorous value of α^2 was estimated from the ligand superhyperfine structures.

MO Scheme of the Bonding Parameters. According to ligand field theory, the unpaired electron occupies the molecular orbital involving the metal ion $3d_{z^2}$ and the ligand orbital.

The appropriate σ-unpaired orbital, ψ_{z^2}, can be expressed as follows:

$$\psi_{z^2} = \alpha d_{3z^2} - \frac{\alpha'}{2\sqrt{3}}(2Z_1 + 2Z_2 - Z_3 - Z_4 - Z_5 - Z_6) \quad (5)$$

$$\psi_{z^2} = \alpha d_{3z^2} - \frac{\alpha'}{2\sqrt{6}}(\sqrt{6}Z_1 + \sqrt{6}Z_2 - 2Z_3 - 2Z_4 - 2Z_5) \quad (6)$$

$$\psi_{z^2} = \alpha d_{3z^2} - \frac{\alpha'}{2\sqrt{10}}(\sqrt{10}Z_1 + \sqrt{10}Z_2 - 2Z_3 - 2Z_4 - 2Z_5 - 2Z_6 - 2Z_7) \quad (7)$$

for the octahedral (5), the trigonal bipyramidal (6), and the pentagonal bipyramidal (7) geometry, where Z_1 and Z_2 denote the AO's in the axial ligands, and Z_3—Z_6 and Z_7 are those in the equatorial ligands.[18]

The detailed structures of the L_2, L_3, and L_4 complexes are unknown. In order to obtain a qualitative view of the structure, however, some idealized calculations were carried out based on the chlorine hyperfine splitting. We used the assumption that the atomic orbitals of the two axially coordinated chlorine atoms can be described in term of the hybridization expressed as $Z_i = np \pm \sqrt{1-n^2}\,S$. For the maximum bonding of the ligand, the ideal sp hybridization may be assumed for

Table 2. Bonding parameters of 15-crown-5 copper complexes

	Octahedral				Pentagonal bipyramidal / Trigonal bipyramidal					A_z^{Cl}
	α^2	P	K	β^2	α^2	P	K	β^2	Δg_z

L_3	0.936	337	0.1328	0.0984	0.914	329	0.1235	0.0995	−0.0073	16.9
L_4	0.937	337	0.1082	0.1078	0.916	330	0.0995	0.1085	−0.0103	16.5

A_z^{Cl} and P in $10^{-4}\ cm^{-1}$.

the chlorine atoms ($n^2=1/2$). The hyperfine tensor of the chlorine atoms ($A_{//}$) for unit spin density is thus given as follows:

$$A_{//} = (1 - n^2)[A_f + 2A_p],\ n^2 = \frac{1}{2} \text{ for sp chlorine atoms}$$

$$A_f = g_N\beta_N g\beta[\frac{8}{9}\pi|\psi_{3s}(0)|^2],\ A_p = \frac{2}{5}g_N\beta_N g\beta < r^{-3} >_{3p} \quad (8)$$

where A_f and A_p are isotropic and anisotopic hyperfine constants, respectively. The effective values of A_f (1490×10^{-4} cm^{-1}) and A_p (44×10^{-4} cm^{-1}) were obtained from the parameters of ^{35}Cl and ^{37}Cl based on their natural abundance ratio.[19] The net spin densities ($\rho_{Cl}=0.011$) on the chlorine atoms are determined from the superhyperfine splittings due to the chlorine atoms listed in Table 1. The total ligand spin densities thus obtained are 0.066 for the octahedral ligand geometry and 0.088 for the trigonal and pentagonal bipyramidal geometry. The magnitudes of the spin density on the 3d orbital ($\alpha^2\simeq0.912$—0.934) were estimated by neglecting the overlap integral between the copper and ligand orbitals. Based on the α^2 values thus determined, the electron-nuclear dipolar term P and the Fermi contact term K were calculated from the A_z values using Bleaney's equation (4). The calculated bonding parameters are given in Table 2. Both P and K values evaluated from the ligand spin densities are in excellent accord with the previous assumption; $P=319\times10^{-4}$ cm^{-1} and $K=0.127$. Of interest is the anomalously small K value estimated for the Cu(II)–crown complexes in the $3d_{z^2}$ ground state, which is of the correct symmetry to mix with the 4s orbital.[20]

The isotropic interaction term measures the sum of the spin polarization due to 3d and 4s electrons, as is expressed below; $-PK=A_{3d}\alpha^2+A_{4s}\beta^2$, where $A_{3d}=-142\times10^{-4}$ cm^{-1} and $A_{4s}=+896\times10^{-4}$ cm^{-1}.[21] The β^2 values thus obtained are cited in Table 2. One will see that contribution of about 10% from 4s reduces the K value to a large extent in the present complexes. From the inspection of the bonding parameters listed in Table 2, several important aspects of the bonding nature of the L_2, L_3, and L_4 complexes can be clarified. The α^2-values assumed here are more or less qualitative, but at least it may be concluded that the natures of the copper-ligand bonds are rather ionic and that the unpaired electron weakly delocalizes into the ligand orbitals in these complexes. The Δg_z value, a measure of the admixture of $d_{x^2-y^2}$ into the ground state, decreases with increasing numbers of the fused benzene rings.

This means that the planar fused benzene restricts a conformational change in the crown ring during the optimum binding at the equatorial positions. The A_z value also shows a concomitant change with the Δg_z-value. The lower g_z value gives a larger A_z value, which is reflected in the K value. The smallest K-value can be calculated for the L_4-complex, where the 4s admixture parameter increases with increasing z character due to the octahedral Jahn-Teller distortion.

The ^{1}H, ^{14}N, and ^{63,64}Cu ENDOR spectra of stellacyanin have been measured recently. The unusual copper hyperfine tensor was explained by assuming a flattened tetrahedral geometry.[22] To our knowledge, the Cu(II)–chromophors or the complexes with the $3d_{z^2}$ ground state have not been clearly characterized in the biological systems. Nevertheless, the present work will present some fundamental knowledge for the ESR studies of Cu(II)-complexes with the $3d_{z^2}$ ground state as studied in solutions.

Paramagnetic Cobalt(III) Complexes with Organic Ligands. V. The Isolation and Properties of Salts of the Paramagnetic Bis(2,2'-bipyridine)(5-nitrosalicylato)cobalt(III) and of the Paramagnetic "β_1 and β_2"-Isomers of the 5-Nitrosalicylato(triethylenetetramine)-cobalt(III) and Their Derivatives[1]

Yoshihisa YAMAMOTO,* Eiko TOYOTA, and Naoto MITSUDERA
Faculty of Pharmaceutical Sciences, Higashi Nippon Gakuen University, Ishikari-Tobetsu, Hokkaido 061-02
(Received February 4, 1980)

The picrate of the paramagnetic, $[Co(5\text{-}NO_2sal)(bpy)_2]^{2+}$, has been isolated from a reaction mixture of picric acid, 60% nitric acid, and bis(2,2'-bipyridine)(salicylato)cobalt(III) chloride trihydrate, $[Co(sal)(bpy)_2]Cl\cdot 3H_2O$, which had been prepared from salicylic acid and *cis*-bis(2,2'-bipyridine)dichlorocobalt(III) chloride dihydrate. The absorption spectrum and the stability of an aqueous solution of the picrate of the paramagnetic, $[Co(5\text{-}NO_2sal)(bpy)_2]^{2+}$, were somewhat different from those of complexes of the paramagnetic, $[Co(5\text{-}NO_2sal\text{-}R)(NH_3)_4]^{2+}$ (R: H, CH_3). Several complexes of the paramagnetic, β_1-5-nitrosalicylato-, β_2-5-nitrosalicylato-, and β_2-3-methyl (and 4-methyl)-5-nitrosalicylato(triethylenetetramine)cobalt(III) have, analogously, been isolated from reaction mixtures of 60% nitric acid and β_1-salicylato-, β_2-salicylato, or β_2-methylsalicylato(triethylenetetramine)cobalt(III) chloride hydrate respectively. Their β_1 and β_2-isomeric forms were proved by a study of their IR and ^{1}H-NMR spectra. From the IR, NMR, and the magnetic susceptibility measurement results, these compounds are considered to have the paramagnetic complex, $[Co(5\text{-}NO_2sal)L]^{2+}$ (L: $(NH_3)_4$, $(en)_2$, $(bpy)_2$, and trien), and the electron hole is considered to delocalize over the chelate ring containing the cobalt atom and the 5-nitrosalicylato ligand.

Previously we have reported on several green paramagnetic cobalt(III) complexes with organic ligands, which are formally tetravalent. Various physicochemical measurements have showed, however, that the compounds contain radical cations and that the cobalt is trivalent.[2] In the paramagnetic cobalt(III) complexes, the paramagnetic cobalt(III) complex of an aromatic amine ligand such as bipyridine and the isomers of the paramagnetic cobalt(III) complex such as the triethylenetetramine ligand have not yet been described.

The present paper deals with the isolation and properties of complexes of the paramagnetic bis(2,2'-bipyridine)(5-nitrosalicylato)cobalt(III) and of the isomers of the paramagnetic β_1 and β_2-5-nitrosalicylato-(triethylenetetramine)cobalt(III); also, their properties are compared with those of 5-nitrosalicylato(tetraammine)cobalt(III) complexes.[2]

Results and Discussion

*Bis(2,2'-bipyridine)(salicylato)cobalt(III) Chloride Trihydrate, $[Co(sal)(bpy)_2]Cl\cdot 3H_2O$ (**1**) and Paramagnetic Bis(2,2'-bipyridine)(5-nitrosalicylato)cobalt(III) Picrate, $[Co(5\text{-}NO_2sal)(bpy)_2](pic)_2$ (**2**).* Although many studies of bis(2,2'-bipyridine)cobalt(III) complexes with aliphatic organic ligands[3-6] or inorganic ligands[5-8] have already been reported, the bis(2,2'-bipyridine)-cobalt(III) complex with an aromatic organic ligand has never been described. Complex **1** was prepared by the reaction of the salicylic acid and *cis*-$[CoCl_2(bpy)_2]Cl\cdot 2H_2O$. Complex **1** can also be prepared from the corresponding *trans* dichloro complex. It is soluble in water, methanol, or dimethyl sulfoxide and is insoluble in most organic solvents. The color of an aqueous solution of **1** is reddish brown, while that of a methanolic solution is green. This color change is reversible.[9] Complex **1** decomposes in an aqueous solution. Complex **2** has been isolated from the reaction mixture of Complex **1**, 60% nitric acid, and picric acid. In an aqueous solution, **2** is much more unstable than paramagnetic 5-nitrosalicylato(tetraammine)cobalt(III) complexes, $[Co(5\text{-}NO_2sal\text{-}R)(NH_3)_4]^{2+}$ (R: H, CH_3) (**3**).

The absorption spectrum of **1** in methanol has three absorption bands at 301, 313, and 587 nm. The absorption bands at 301 and 313 nm are the specific absorption bands[3c] of **1**. The absorption band at 587 nm is based on the d-d transition ($^1T_{1g}\leftarrow{}^1A_{1g}$) of the cobalt ion. The absorption spectrum of **2** in 65% nitric acid has two absorption bands, at 577 and 645 nm, in the 450—700 nm region. The ε at 645 nm of **2** is much weaker than that[10] at 660 nm of **3**, while the peak at 577 nm is stronger than that at 587 nm of **1**.

In the ^{1}H-NMR spectra, the signals (6.1—7.5 ppm) of the salicylato protons of the coordinated salicylato ligand of **1** were observed in dimethyl-d_6 sulfoxide, but those of **2** were not observed.[2] The signals (7.3—9.1 ppm) of the bipyridine protons of the coordinated bipyridine ligand of **1** and **2** were observed. In the ^{13}C-NMR spectrum of **1** in heavy water we observed fifteen signals for the bis(2,2'-bipyridine) ligand and seven signals for the salicylato ligand, which were assigned on the basis of the chemical shifts of salicylato-(tetraammine)cobalt(III) chloride monohydrate,[2] $[Co(sal)(NH_3)_4]Cl\cdot H_2O$ (**4**). The spectrum of **2** did not show the expected signals because of paramagnetism.[2]

The effective magnetic moment was 1.6 B.M., and the Curie-Weiss constant was -10 K for **2**.

In the IR spectra, the rocking deformation vibration was observed at 764 cm^{-1} for **1** and at 766 cm^{-1} for **2**. The cobalt atom of these complexes is considered to contain trivalent cobalt.[2]

From the IR, ^{1}H- and ^{13}C-NMR spectra and the magnetic susceptibility, an aromatic amine complex (**2**) was found to show the same properties as those of the

aliphatic amine complexes (**3**) except for the absorption spectra and the stability of the aqueous solutions.

β-Salicylato(triethylenetetramine)cobalt(III) Complexes and Paramagnetic β-5-Nitrosalicylato(triethylenetetramine)cobalt-(III) Complexes. The paramagnetic properties of these isomers have been the subject of little research. We expect that the delocalization of a radical cation of these isomers will differs from that of **3**. Three isomeric forms and the abbreviations of the salicylato (triethylenetetramine)cobalt(III) complexes studied in this paper are listed in Table 1. The color and solubility of **5**—**8** are similar to those of **9**[11] and **10**.[11] Complexes **14**—**19** are insoluble in most organic solvents, but are soluble in nitric acid, hydrochloric acid, and dimethyl sulfoxide. Aqueous solutions of the **14**—**19** complexes are somewhat more unstable than that of **3**, while that of **14** is more unstable than that of **15**.

The IR spectra of the **5**—**7** and **11**—**17** complexes have four strong peaks in the 990—1100 and 3000—3300 cm^{-1} regions respectively, as is shown in Table 2;

Solvent: D_2O. Standard: internal dioxane (δ=67.4 ppm).

therefore, they are assigned the β-form.[12] The rocking deformation vibrations[2] of these complexes were observed at 830—860 cm^{-1}.

The absorption spectra of the **14**—**17** complexes in 60% nitric acid showed three absorption bands at about 345, 460, and 660 nm. In the **14** and **15** complexes, although these spectra show similar forms, the second absorption band of **14** is shorter than that of **15**. The ε at 660 nm of these complexes is similar to that[10a] at 660 nm of **3**. In the **15**—**17** complexes, the second absorption band of **16** is shorter than that of **15**, while the ε at 667 nm of **16** and that at 633 nm of **17** are

weaker than that at 663 nm of **15**. These properties seem to be due to the substituent effect of the methyl group.[10b] In the **11**—**13** complexes, the second absorption bands are longer than those of **7**, **8**, and **10** respectively, while the ε's of those bands of the **11**—**13** complexes are much stronger than those of **7**, **8**, and **10** respectively. Those properties seem to be due to the substituent effect of the nitro group. The first absorption bands of **7**, **8**, and **10** shift to a shorter wavelength area than those of **5**, **6**, and **9** respectively. The absorption spectra of **18** and **19** could not be obtained because they turned dark green in 35% hydrochloric acid.

In the ^{1}H-NMR spectra, the protons of the coordinated triethylenetetramine and methylsalicylato ligands of these complexes were assigned on the basis of the results in earlier papers,[11,13] as is shown in Table 3. The signals of the 5-nitrosalicylato protons of the coordinated 5-nitrosalicylato ligands of **14** and **15**—**17** were not observed, either. The spectra of **5**, **6**, and **14** are similar to that of β_1-complex[11] (**9**) while those of **7**, **8**, and **15**—**17** are similar to that of the β_2-complex[11] (**10**). They are assigned the β_1 and β_2-forms respectively. The chemical shifts of the NH and NH_2 protons of coordinated trien in **11**, **14**, and **15** shifted to a lower field than those of **9** and **10**. This could be due to the nitro group in the coordinated 5-nitrosalicylato ligand. In the ^{13}C-NMR spectra of **5**—**8** and **11** in heavy water, we observed eight signals for the methylsalicylato ligand and six signals for the triethylenetetramine ligand. The chemical shifts of the methylsalicylato ligand are assigned on the basis of the chemical shift of **4**.[2] Those of the trien ligand are difficult to assign to the individual carbon atom. The ^{13}C-NMR spectra of **14**—**19** did not show the expected signals because of paramagnetism.

The effective magnetic moments of the **14**—**19** complexes were 1.7 B.M.

The above data show that the paramagnetic properties of the **14** and **15** isomers are little different from each other, while their properties are in agreement with those of **3**. The properties of **16** and **17** are only a little different from those of **15**. They can thus be grouped together as paramagnetic 5-nitrosalicylato-(amine)cobalt(III) complexes, $[Co(5\text{-}NO_2sal)L]^{2+}$ (L: $(NH_3)_4$, $(en)_2$, $(bpy)_2$, trien), with a radical cation delocalized over the chelate ring containing the cobalt atom and the 5-nitrosalicylato ligand, from the results of the IR spectra,[2] ^{1}H-, and ^{13}C-NMR spectra,[2] the magnetic susceptibility,[14] and the electric resistivity.[14] The properties of these complexes are collected in Tables 2—4.

Experimental

Measurements. The NMR spectra were recorded with an FX-60 apparatus (JEOL) for ^{13}C-NMR and an R-40 apparatus (Hitachi) for ^{1}H-NMR. The IR spectra were recorded on potassium bromide disks with a IR-27G apparatus (Shimadzu). The visible absorption spectra were recorded with a Shimadzu MPS-5000 recording spectrophotometer. The magnetic susceptibilities were measured by the Gouy method using a magnetic balance (Shimadzu) from liq.N_2 to r.t. The pH was measured with a Corning pH-meter M-125. The electro conductivity of an aqueous solution was determined by the use of a conductometer, CM-30 (Shimadzu) at room temperature.

Preparation of Complexes. Bis(2,2'-bipyridine)(salicylato)cobalt(III) Chloride Trihydrate (1): *cis*-Bis(2,2'-bipyridine)-dichlorocobalt(III) chloride dihydrate[15] (2.0 g, 3.89 mmol dm^{-3}) was added to AgOH, which had been made from silver nitrate (1.33 g, 7.83 mmol dm^{-3}) and potassium hydroxide. The mixture was stirred for about 30 min at 60 °C and then filtered. To the filtrate we then added salicylic acid (0.53 g, 3.84 mmol dm^{-3}) in a 10% ammonia solution of 5 ml. The mixture was concentrated at 60 °C. The black complex thus precipitated was filtered off, washed with a 3% ammonia solution, dried, and recrystallized from a 2—3% ammonia solution. Complex **1** was dried in a desiccator over diphosphorus pentaoxide. Yield: 1.70 g (73.2%). Found: C, 54.56; H, 4.07; N, 9.82; Cl, 5.23%. Calcd for $CoC_{27}H_{26}N_4O_6Cl$ (MW 596.91) C, 54.33; H, 4.39; N, 9.39; Cl, 5.94%. mp 240—243 °C. IR spectrum: $\rho_r(Co\text{–}N)_r$: 764 cm^{-1}. Absorption bands: 301 (ε=25600), 313 (ε=24200), and 587 nm (ε=330) in MeOH.

Paramagnetic Bis(2,2'-bipyridine)(5-nitrosalicylato)cobalt(III) Dipicrate (2): About 1 cm^3 of 60% nitric acid was added to **1** of 1.0 g (1.68 mmol dm^{-3}). The color of the solution was thus changed to green. Then several cm^3 of 60% nitric acid were added to it. An aqueous solution of picric acid (0.77 g, 3.36 mmol dm^{-3}) was added to the green solution, and it was stirred. The yellowish-green complex (**2**) thus precipitated was filtered off, washed with ice water, and dried. Yield: 1.34 g (79.1%). Found: C, 46.82; H, 2.40; N, 14.94%. Calcd for $CoC_{39}H_{23}N_{11}O_{19}$ (MW 1008.61) C, 46.44; H, 2.30; N, 15.28%. Dec 163—167 °C. IR spectrum: $\rho_r(Co\text{–}N)_r$: 766 cm^{-1}. Absorption bands: 577 (ε=867) and 645 nm (ε=675) in 65% DNO_3.

β-Salicylato(triethylenetetramine)cobalt(III) Chloride Monohydrate, β-3-Methylsalicylato(triethylenetetramine)cobalt(III) Chloride Monohydrate, and β-4-Methylsalicylato(triethylenetetramine)-cobalt(III) Chloride Monohydrate: These complexes were prepared by the reaction of the α-dichloro(triethylenetetramine)-cobalt(III) chloride[16] and salicylic acid, 3-methylsalicylic acid, or 4-methylsalicylic acid at pH 10—11 by Morgan's method.[17] Yields: 3-methylsalicylato(triethylenetetramine)-cobalt(III) chloride monohydrate, 64.4%; 4-methylsalicylato-(triethylenetetramine)cobalt(III) chloride monohydrate, 67.1%.

Separation of β_1-3-Methylsalicylato(triethylenetetramine)cobalt(III) Chloride Dihydrate (5), β_1-4-Methylsalicylato(triethylenetetramine)-cobalt(III) Chloride Dihydrate (6), β_2-3-Methylsalicylato(triethylenetetramine)cobalt(III) Chloride Monohydrate (7), and β_2-4-Methylsalicylato(triethylenetetramine)cobalt(III) Chliorde Monohydrate (8): The separation of β_1 and β_2 complexes was achieved by the use of ion-exchange resin.[18] Complexes **5** and **6** are changed to the corresponding β_2-complexes in an alkali solution. Yields: 0.033 g (6.6%) for **5**; 0.028 g (5.6%) for **6**; 0.43 g (86%) for **7**; 0.42 g (84%) for **8**. Found **5**: C, 39.88; H, 6.66; N, 13.48; Cl, 9.08%. **6**: C, 39.10; H, 6.39; N, 12.89; Cl, 8.95%. **7**: C, 41.35; H, 6.68; N, 13.59; Cl, 9.16%. **8**: C, 40.81; H, 6.14; N, 13.80; Cl, 9.39%. Calcd for **5** and **6**: $CoC_{14}H_{28}N_4O_5Cl$ (MW 426.79) C, 39.40; H, 6.61; N, 13.13; Cl, 8.31%. **7** and **8**: $CoC_{14}H_{26}N_4O_4Cl$ (MW 408.78) C, 41.14; H, 6.41; N, 13.71; Cl, 8.67%.

β_2-5-Nitrosalicylato(triethylenetetramine)cobalt(III) Nitrate Trihydrate (11): Complex **11** was prepared according to the procedure of a previous paper.[2] An orange-colored solution of **11**, acetone, and 60% nitric acid was set aside to crystallize at room temperature for several days. The orange complex thus separated was filtered off, washed with ice-water, and

dried. It was recrystallized several times from water, while it did not turn green in the 60% nitric acid. Yield: 0.54 g (14.1%). Found: C, 30.87; H, 5.07; N, 17.16%. Calcd for $CoC_{13}H_{27}N_6O_{11}$ (MW 502.33) C, 31.08; H, 5.42; N, 16.73%.

β_2-3-Methyl-5-Nitrosalicylato(triethylenetetramine)cobalt(III) Nitrate Dihydrate (12) and β_2-4-Methyl-5-Nitrosalicylato(triethylenetetramine)cobalt(III) Nitrate Dihydrate (13): Complexes **12** and **13** were prepared according to the procedure used for Complex **11**. Yields: 0.26 g (21.3%) for **12**; 0.20 g (16.4%) for **13**. Found **12**: C, 33.54; H, 5.22; N, 17.26%. **13**: C, 33.47; H, 5.26; N, 16.86%. Calcd for $CoC_{14}H_{27}N_6O_{10}$ (MW 498.34) C, 33.74; H, 5.46; N, 16.86%.

Paramagnetic β_1-5-Nitrosalicylato(triethylenetetramine)cobalt(III) Chloride Nitrate Dihydrate (14): Three cm^3 of 60% nitric acid were added to **9** (1.0 g, 2.53 mmol dm^{-3}). After the reaction,[16b] the solution was filtered using a glass filter (G-4), and the green filtrate was added to acetone. The green complex thus precipitated was filtered off, washed with acetone, and dried. It was then reprecipitated twice more by dissolution in 60% nitric acid and by the addition of acetone. Yield: 0.46 g (35.5%). Found: C, 30.64; H, 5.18; N, 15.90; Cl, 6.86%. Calcd for $CoC_{13}H_{25}N_6O_{10}Cl$ (MW 519.77) C, 30.04; H, 4.85; N, 16.17; Cl, 6.82%.

Paramagnetic β_2-5-Nitrosalicylato(triethylenetetramine)cobalt(III) Chloride Nitrate Dihydrate (15): Complex **15** was prepared from **10** (3.0 g, 7.60 mmol dm^{-3}) and 60% nitric acid (9 cm^3), according to the procedure used for Complex **14**. Yield: 1.87 g (47.3%). Found: C, 30.23; H, 5.03; N, 16.02, Cl, 7.25%. Calcd for $CoC_{13}H_{25}N_6O_{10}Cl$ (MW 519.77) C, 30.04; H, 4.85; N, 16.17; Cl, 6.82%.

Paramagnetic β_2-3-Methyl-5-Nitrosalicylato(triethylenetetramine)-cobalt(III) Chloride Nitrate Dihydrate (16) and Paramagnetic β_2-4-Methyl-5-Nitrosalicylato(triethylenetetramine)cobalt(III) Chloride Nitrate Dihydrate (17): Complexes **16** and **17** were prepared from **7** (1 g, 2.45 mmol dm^{-3}) or **8** (1 g, 2.45 mmol dm^{-3}) and 60% nitric acid (3 cm^3), according to the procedure used for Complex **14**. Yields: 0.56 g (42.8%) for **16**; 0.44 g (33.6%) for **17**. Found **16**: C, 31.11; H, 5.40; N, 16.01; Cl, 6.19%. **17**: C, 31.82; H, 5.15; N, 16.09; Cl, 6.70%. Calcd for **16** and **17** $CoC_{14}H_{27}N_6O_{10}Cl$ (MW 533.80) C, 31.50; H, 5.10; N, 15.74; Cl, 6.64%.

Paramagnetic β_1-5-Nitrosalicylato(triethylenetetramine)cobalt(III) Chloride Trihydrate (18) and Paramagnetic β_2-5-Nitrosalicylato-(triethylenetetramine)cobalt(III) Chloride Trihydrate (19): Complexes **18** and **19** were prepared from **14** (0.30 g, 0.52 mmol dm^{-3}) or **15** (0.50 g, 0.96 mmol dm^{-3}) and 35% hydrochloric acid (1 cm^3 for **14** and 1.5 cm^3 for **15**) respectively. Yields: 0.17 g (62.9%) for **18**; 0.31 g (63.1%) for **19**. Found **18**: C, 30.56; H, 5.52; N, 13.50; Cl, 13.10%. **19**: C, 29.97; H, 5.27; N, 13.42; Cl, 13.46%. Calcd for $CoC_{13}H_{27}N_5O_8Cl_2$ (MW 511.23) C, 30.54; H, 5.32; N, 13.70; Cl, 13.87%. Magnetic moments, μ_{eff}: 1.66 for **18**, 1.70 B.M. for **19**.

The authors wish to express their gratitude to Professor Masayasu Mori of Osaka City University for his discussions.

The *trans-cis* Isomerization of the Diaquabis(malonato)chromate(III) Ion in Various Organic Solvent-Water Mixtures

Kengo UCHIDA* and Yoshinobu TAKINAMI

Department of Chemistry, Faculty of Science, Hirosaki University, Bunkyo-cho, Hirosaki 036

(Received March 7, 1980)

The kinetics of the *trans-cis* isomerization of $[Cr(mal)_2(H_2O)_2]^-$ have been investigated in binary mixed solvents, including methanol–, ethanol–, dioxane–, and acetone–water mixtures. The first-order rate constant increases with a decrease in the volume percentage of the water, but is independent of the kind of organic solvent. The rate is not affected by the addition of any cation to an aqueous solution. These results are in contrast to those for the analogous oxalato complex, and are interpreted in terms of a dissociation mechanism in which the rate-determining step is the dissociation of the coordinating water molecule.

Many studies[1-14] have been made of various reactions of potassium diaquabis(oxalato)chromate(III), $K[Cr(ox)_2(H_2O)_2]$. Much less information is, though, available on the analogous complex of diaquabis(malonato)chromate(III). Some aquation,[15,16] anation,[17] and isomerization[8,18,19] have been investigated, though, and the behavior of the malonato complex seems to be rather different from that of the oxalato complex. For example, the isomerization of the malonato complex is much slower, but the aquation takes place more easily than that of the oxalato complex in an acid solution. With respect to the isomerization mechanism, Frank and Huchital[19] suggested a ring-opening mechanism and Casula *et al.*[8] proposed a primary dissociation of the water molecule.

In this work, we have studied the effects of mixed aqueous solvents, the addition of some kinds of salts, and the pH value of the solution on the *trans-cis* isomerization, and have proposed an aqua-ligand dissociation mechanism.

Experimental

Materials. Potassium *trans*-diaquabis(malonato)chromate(III), *trans*-$K[Cr(mal)_2(H_2O)_2]$, was prepared in a manner similar to that described by Chang.[20] The product was recrystallized twice from water. The other inorganic salts were of a guaranteed reagent grade and were recrystallized from water. Redistilled water and organic solvents of an ultraspecial grade or a guaranteed reagent grade were used as the solvents.

Procedures. The rates of the reactions were determined spectrophotometrically[8] at the wavelength of 565 nm using a Shimadzu double-beam spectrophotometer, UV 200S, with a temperature-controlled cell holder. The first-order rate constants, k, were obtained from the slopes of the plots of $\ln(A_\infty - A)$ *vs.* t, where A is the absorbance at time t and where A_∞ is the absorbance after the reaction is complete. These plots were straight, with very little scatter, in every case. The reaction cell was a quartz cell ($1 \times 1 \times 4.5$ cm) for a spectrophotometer with a branch. The concentration of the complex was 1.50×10^{-2} mol dm^{-3} in all cases. Most of the kinetic experiments were performed at 50 °C.

The pH values of the solution, which were not adjusted unless otherwise noted, were 4.4—4.6. When the pH value was varied, 0.1 mol dm^{-3} of NaOH or 0.05 mol dm^{-3} of HCl was added. The pH values were measured by means of a Hitachi-Horiba pH meter, M5, before and after the reaction. The pH values did not change during the reactions.

Results

Absorption Spectra. The wavelengths and the molar absorption coefficients, ε, of the absorption maxima of the complexes are collected in Table 1, where the subscript "eq" indicates the equilibrated mixture of the *trans*- and the *cis*-isomer after the reaction has stopped.

TABLE 1. SPECTRAL DATA FOR SOME COMPLEX IONS

Complex	λ_{1max}/nm[a]	λ_{2max}/nm[a]
trans-$[Cr(mal)_2(H_2O)_2]^-$	402(23.0)	556(18.6)
	401(20.3)[b]	555(17.6)[b]
	405(22)[c]	560(21)[c]
$[Cr(mal)_2(H_2O)_2]^-_{eq}$	418(40)	565(45.6)
cis-$[Cr(mal)_2(H_2O)_2]^-$	418(42.1)[b]	565(50.8)[b]
	415(41)[c]	565(51)[c]
trans-$[Cr(mal)_2(OH)(H_2O)]^{2-}$	414(38)	570(26)
	420(41)[c]	570(26)[c]
cis-$[Cr(mal)_2(OH)(H_2O)]^{2-}$	416(44)	574(39)
	425(48)[c]	575(43)[c]

a) Values in parentheses are the molar absorption coefficients (dm^3 mol^{-1} cm^{-1}). b) Ref. 19. c) Ref. 8.

Kinetics. When the *trans*-isomer is dissolved in water, *trans-cis* isomerization occurs and the reaction comes to an end at an equilibrium. The equilibrium lies close to the *cis*-form, and it has been reported[18] that 95% is of the *cis*-form at the equilibrium. The isomerization obeys good first-order kinetics even after 90% reaction, and a constant A_∞ value is always obtained. Aquation can be neglected in this work.

As the complex does not dissolve in such organic solvents as methanol, ethanol, dioxane, and acetone, mixtures of the organic solvent and water were used as the solvents. In such mixtures, the kinetic behavior was very similar to that in an aqueous solution which contained no organic solvent. The k values increased with an increase in the concentration of the organic solvent in every case, as is shown in Fig. 1. The values at higher concentrations of the organic solvent could not be obtained because of the low solubility of the complex. It may be clear that the specificity of the solvents is very small, and the variation in k values can not be elucidated individually by the mole fraction of the organic solvents, the relative permittivity, or the

viscosity of the solution. The k values seem to depend on only the volume percentage of the water, namely, the molarity of water, and to increase with a decrease in the molar concentration of the water. For example, the k values at 40 v/v% remain approximately constant ($(2.6—3.2)\times10^{-4}\ s^{-1}$) in every solvent. Some deviations do, however, occur near the limits of the solubility in the systems of alcohol and water. In these solvents, some structural effect due to a hydrogen bond between solvent molecules might play a special role.[21]

Effect of Added Salts on the k *Values. In an Aqueous Solution*: The effect of added salts on the k values was investigated. At first, several chlorides were added in order to examine the cationic effect. As the rate depends on the ionic strength, I, the concentration of the salts was adjusted to $I=1.0$. The k values were 2.5×10^{-4}, 2.6×10^{-4}, 2.8×10^{-4}, and $2.4\times10^{-4}\ s^{-1}$ for NaCl, $CaCl_2$, $SrCl_2$, and $LaCl_3$ respectively. Also, it is obvious that the values are approximately constant and independent of the kind of cation, in contrast to the case of the analogous oxalato complex, $[Cr(ox)_2(H_2O)_2]^-$.[4,11] As the reaction was not accelerated by the addition of a bivalent or tervalent cation, which has a great effect in the case of $[Cr(ox)_2(H_2O)_2]^-$, it is concluded that cations have no catalytic effect on the isomerization of the malonato complex.

On the other hand, Frank and Huchital[19] have found the accelerating effect of the nitrate ion. However, we found that this effect is general for the other anions and that the bivalent anion seems to be more effective. The effects of the concentration of the anions on the rate constants are shown in Fig. 2, where sodium salts are used. The sulfate ion has the greatest effect, and the order of the k values seems to be as follows:

$$SO_4^{2-} \gg I^- > NO_3^- > ClO_4^- \approx Br^- \geqslant Cl^-.$$

In Organic Solvent–Water Mixtures: A similar anionic effect was investigated in organic solvent–water mixtures. Ethanol of a protic solvent and acetone and dioxane of an aprotic solvent were used. The volume percentage of the organic solvent was adjusted to 50%, and sodium salts were used. As has been mentioned above, no solvent effect was observed in the absence of added salts, but a distinct solvent effect appeared in the presence of the added salts. The results are listed in Table 2. The order of k values is as follows:

$$\text{dioxane–}H_2O > \text{acetone–}H_2O > \text{ethanol–}H_2O.$$

Although the effect is not great, evidently some interaction between the anions and the organic solvents is present. The order of the catalytic effect by the anions also seems to change to $Cl^- > I^- > Br^-$, whereas the order is $Cl^- \leqslant Br^- < I^-$ in an aqueous solution containing no organic solvent.

pH Effect. The k values measured at various pH values are shown in Fig. 3. The rate increases rapidly above pH 5. All the spectra after the equilibrium is reached are very similar in the pH region of 3—6.

Table 2. Effect of added anion on k values in organic solvent–water mixtures
(50 v/v%, [anion] = 1.0 mol dm^{-3})

Solvent	$10^4\ k/s^{-1}$		
	Cl^-	Br^-	I^-
H_2O	2.5	2.7	3.7
Ethanol–H_2O	4.9	3.9	5.1
Acetone–H_2O	5.9	4.4	5.2
Dioxane–H_2O	6.1	4.9	6.1

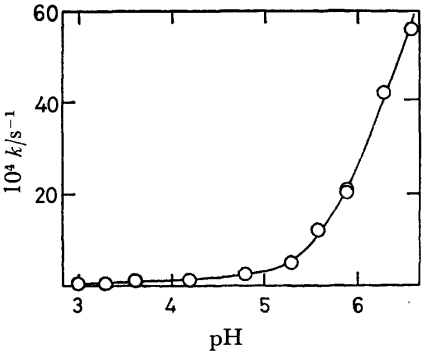

Fig. 3. Effect of pH on the rate constant.

Slight shifts of the absorption maxima can be seen above pH 6, but the molar absorption coefficients do not change so much. The spectral changes are probably due to the formation of a hydroxo complex of $[Cr(mal)_2(OH)(H_2O)]^{2-}$, spectral data of which are also shown in Table 1.

In the higher pH region, k values were obtained at 25.0 °C and $I=0.015$, because the rates were too fast to measure at 50.0 °C. The k values are 14.8×10^{-4} s^{-1} at pH 8.3 and 15.9×10^{-4} s^{-1} at pH 10.5.

Effect of the Temperature. The k values were measured at five different temperatures over the range from 307.2 K to 323.2 K. The activation parameters, listed in Table 3, were calculated from plots of $\ln k$ *vs.* $1/T$.

TABLE 3. ACTIVATION PARAMETERS

Solution	ΔH^*/kJmol^{-1}	ΔS^*/J mol^{-1}
Aqueous solution	116	42
Aqueous solution at pH 5.7	103	20
Aqueous solution containing Na_2SO_4	135	114
60%methanol-H_2O	163	195

Discussion

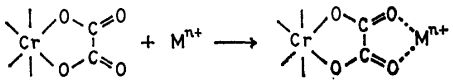
The rate of the isomerization of the malonato complex is much slower than that of the analogous oxalato complex. The orders of magnitude of the k values of the malonato and the oxalato complex are 10^{-6} and 10^{-4} s^{-1} respectively at 25 °C; the difference is about 100 times. The mechanism of the reaction has been studied for the oxalato complex,[6,8,22] and two main mechanisms have been proposed. At first, the added cation, such as Na^+, Ca^{2+}, or La^{3+}, forms an ion-pair, and a bond rupture takes place at a Cr–oxalato bond; then, the isomerization proceeds *via* a five-coordinated trigonal bipyramidal intermediate. Next is the twist mechanism, in which the rate is not affected by the cations and a proton.

In the malonato complex, the next four mechanisms could be considered in general: (a) a water-association mechanism, (b) a twist mechanism, (c) a ring-opening mechanism, and (d) an aqua-ligand dissociation mechanism.

Of these mechanisms, (a) can be eliminated because the k values increase with a decrease in the concentration of water and are independent of the kind of organic solvent, and it would be more difficult for solvent water to enter the complex when the concentration of the water decreases. Moreover, a seven-coordinated intermediate could hardly be considered, since the entropy of activation, ΔS^*, is positive. If a water molecule coordinates to the Cr atom, ΔS^* would be negative because of the decrease in the degree of freedom.

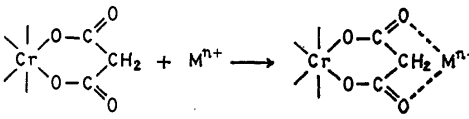
The twist mechanism (b) is also not reasonable, because the positive and great ΔS^* value, the anionic effect, and the increase in the k value with an increase in the volume percentage of the organic solvents could not be explained by this mechanism. Although the viscosity of the solvent may affect the twist, there is no close relation between the k value and the viscosity. However, it seems impossible to deny the possibility of this mechanism, since the oxalato complex may isomerize *via* a twist mechanism in the absence of any added salts.[22] A malonato chelate is larger and might be more easily distorted. Thus, the twist intermediate might be stabilized.

Mechanism (c) could be removed since the isomerization is not catalyzed by cations in the case of the malonato complex. On the other hand, in the oxalato complex the apparent rate constants are 5.5×10^{-4} s^{-1} and 1.3×10^{-2} s^{-1} in the presence of Na^+ and La^{3+} respectively,[11] these values differ by about 24 times. From these results, it seems that the cation may not play an important part in breaking the Cr–malonato bond, contrary to the case of the oxalato complex. Frank and Huchital[19] suggested the ring-opening mechanism because of the positive ΔS^*, the analogy to the oxalato complex, and the stability of the malonato complex referred to the second formation constants of the *cis*-oxalato and the *cis*-malonato complexes. However, they did not neglect the dissociation mechanism and proposed a combination of the ring-opening and water-dissociation mechanisms. However, Banerjea and Chatterjee[15] reported that the rate of the dissociation (aquation) of the *cis*-malonato complex in an aqueous acidic solution is about 70 times faster than that of the oxalato complex, and that the former is much more labile. If the malonato chelate is labile, the other mechanism should be proposed because the k value of the malonato is about 100 times smaller than that of the oxalato complex. An ion-pair formation would be important in the catalytic effect by cations in the oxalato complex, which is given by:



(1)

In the malonato complex, however, the methylene group seems to prevent the ion-pair formation, as given by:



(2)

Mechanism (d) seems to be most plausible. In the mechanism accompanying a dissociation of a ligand water molecule, ΔS^* would have a large positive value. Then, a five-coordinated intermediate may be formed after the dissociation. Moreover, the k value may increase with the decrease in the concentration of water, since the ligand water molecule could be removed more easily when the concentration of the water decreases. After the release of the water molecule, the chance of the recombination of the intermediate complex and a water molecule may decrease, while the possibility of the isomerization may increase as the concentration of the organic solvent increases. Although the organic solvent molecule may coordinate to the intermediate,

the bond may be weak, and so the isomerization would take place easily. Consequently, the isomerization could be accelerated. A catalytic effect by a nitrate ion has been found,[19] but a sulfate ion has an even more remarkable effect. A bivalent anion coming close to the ligand water molecule may assist the release of the water molecule effectively. The effects of univalent anions are less significant, and the difference in the effects in organic solvents could not be elucidated clearly. Hunt *et al.*[23] reported that the rate constant of the exchange of a water molecule, k_{ex}, is 7×10^{-7} s^{-1} and that the activation energy, E_a, is 112 kJ mol^{-1} [24] for $[Cr(H_2O)_6]^{3+}$ at 25 °C, while k_{ex} is less than 10^{-6} s^{-1} for *cis*-$[Cr(ox)_2(H_2O)_2]^-$.[3] It may tentatively be assumed from these values that the k_{ex} is 10^{-6}—10^{-7} s^{-1} for $[Cr(mal)_2(H_2O)_2]^-$. The observed k is 1.5×10^{-6} s^{-1}, and E_a is 119 kJ mol^{-1}, for the malonato complex in an aqueous solution. The similarity of these values may also support the theory that the rate-determining step is the dissociation of the ligand water molecule.

In the higher pH region, $[Cr(mal)_2(OH)(H_2O)]^{2-}$ is formed and the k values become larger. These values at 25 °C, which are very close to the values obtained by Casula *et al.*,[8] can be reduced to $k=0.040$ s^{-1} at pH 8.3 and $k=0.043$ s^{-1} at pH 10.5 at 50 °C by using the activation parameters. The two values are approximately the same as the rate constant for the hydroxo complex. In general, a hydroxo complex is more labile than a conjugate acid complex, as well as a cobalt(III) complex, since the charge of the central metal atom decreases partially upon the addition of a negative OH group and the bond of $Cr–OH_2$ becomes weak. The rate constant of the *trans-cis* isomerization of $[CrCl(en)_2(H_2O)]^{2+}$ is less than 6×10^{-6} s^{-1} at 35.0 °C.[25] If the isomerization occurs *via* water exchange, the rate might be expected to be similar for the malonato complex. The isomerization rate constant of the conjugate base, $[CrCl(OH)(en)_2]^+$, is less than 6×10^{-5} s^{-1}.[26] This value is not large, but it may be a little larger than that of $[CrCl(en)_2(H_2O)]^{2+}$.

The authors are sincerely grateful to Professor Taro Isobe for his continuing interest and encouragement.

A Kinetic Study on the Proton-transfer Reactions of Bis(dimethylglyoximato)cobalt(III) Complex Ions in Dioxane-Water Media†

Noboru Yoshida and Masatoshi Fujimoto*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received March 15, 1980)

The proton-transfer reactions of bis(dimethylglyoximato)cobalt(III) complex ions, $[Co^{III}(dmgH)_2X_2]^n$, with hydroxide ion, OH^-, were studied in dioxane–water media by means of a temperature-jump method. The rate constant, k_f, for the direct proton-transfer from $[Co^{III}(dmgH)_2X_2]^n$ to OH^- was found to be 1.6×10^5—2.9×10^6 mol^{-1} dm^3 s^{-1} in aqueous solution. The value of k_f for $[Co^{III}(dmgH)_2(CN)_2]^-$ anion decreased gradually from 1.6×10^5 to 4.0×10^4 mol^{-1} dm^3 s^{-1} for the change in the mole fraction of dioxane, x_{diox}, from 0 to 0.174. On the other hand, with increase in x_{diox}, the value of k_f for $[Co^{III}(dmgH)_2(NH_3)_2]^+$ cation gradually decreased from 2.9×10^6 to 1.1×10^6 mol^{-1} dm^3 s^{-1} in a region of lower x_{diox}, and then increased from 1.1×10^6 to 1.6×10^7 mol^{-1} dm^3 s^{-1} in a region of higher x_{diox}. The dependence of k_f on x_{diox} is interpreted in connection with reaction mechanism.

A large number of fast proton-transfer reactions in aqueous solutions have been investigated by relaxation techniques,[1] but only a few measurements have been reported for the reactions in non-aqueous media such as dioxane–water,[2-5] DMSO–water,[6] chlorobenzene,[7] and acetonitrile.[8]

We have studied the proton-transfer reactions of the univalent[4] and bivalent[5] anions of *o*-hydroxy azo compounds with hydroxide ion in dioxane–water media using a temperature-jump method. From the change in k_f of these Brønsted acids with increasing x_{diox} the dependency of k_f on x_{diox} was explained by both the change of the dielectric constant of medium and the solute-solvent interactions.

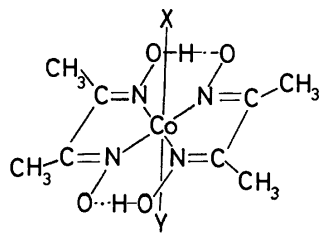

Fig. 1. Structural formulae of $[Co^{III}(dmgH)_2XY]^n$.

It has been established that dimethylglyoxime ($dmgH_2$) forms a stable square planar complex, $[Co^{III}(dmgH)_2X_2]Y$, on the basis of NMR[9] and IR[10] spectroscopic studies, chemical characteristics,[11] and syntheses,[12] where dmgH, X, and Y denote the coordinated univalent dimethylglyoximate anion, the axial ligand, and the counter ion, respectively. The structure of complexes having axial ligands is shown in Fig. 1. They constitute a series which enables us to design systematic variations in acid-dissociation constant and charge type of complexes. The acid-dissociation of bis(dimethylglyoximato)cobalt(III) complex ions can generally be represented by

$$[Co^{III}(dmgH)_2X_2]^n \rightleftharpoons [Co^{III}(dmg)(dmgH)X_2]^{n-1} + H^+, \quad (1)$$

where dmg denotes the coordinated bivalent dimethylglyoximate anion.[13,14] The values of pK_a of these weak Brønsted acids are in the order of magnitude 10—12 due to the strong intramolecular hydrogen-bond, OH···O⁻.

In the present paper, we report a kinetic study on the proton-transfer reactions in dioxane–water media of diamminebis(dimethylglyoximato)cobalt(III) cation ($[Co^{III}(dmgH)_2(NH_3)_2]^+$; DGA cation) and dicyanobis(dimethylglyoximato)cobaltate(III) anion ($[Co^{III}(dmgH)_2(CN)_2]^-$; CDG anion). DGA cation and CDG anion are relatively stable in both aqueous and dioxane–water media. The values of pK_a were determined spectrophotometrically ($pK_a^c(s)$) and kinetically ($pK_a^c(k)$), the $pK_a^c(s)$ and $pK_a^c(k)$ values being in good agreement with each other at each dioxane content. The rate constants, k_f and k_r, for the reaction

$$[Co^{III}(dmgH)_2X_2]^n + OH^- \underset{k_r}{\overset{k_f}{\rightleftharpoons}} [Co^{III}(dmg)(dmgH)X_2]^{n-1} + H_2O \quad (2)$$

were measured by the temperature-jump method. The dependency of the value of k_f on x_{diox} was found to differ considerably from each other due to the difference in the signs of their charge and the solute-solvent interactions. The dependency is discussed in connection with reaction mechanism.

Experimental

Materials. Water was deionized and distilled. Guaranteed grade dioxane (Wako) was distilled over sodium.

Bis(dimethylglyoximato)diamminecobalt(III) chloride, $[Co^{III}(dmgH)_2(NH_3)_2]Cl\cdot5H_2O$, was prepared from purpureo salt, $[Co^{III}Cl(NH_3)_5]Cl_2$, and dimethylglyoxime in the presence of ammonium acetate, and recrystallized from hot water.[15] Found: C, 21.28; H, 6.78; N, 18.90; Cl, 7.77%. Calcd for $C_8H_{30}N_6O_9CoCl$: C, 21.41; H, 6.74; N, 18.73; Cl, 7.90%.

Potassium dicyanobis(dimethylglyoximato)cobaltate(III), $K[Co^{III}(dmgH)_2(CN)_2]\cdot3/2\cdot H_2O$, was prepared from $[Co^{III}(dmgH)_2(NH_3)_2]Cl\cdot5H_2O$ and potassium cyanide.[16] Found: C, 28.30; H, 3.97; N, 19.86%. Calcd for $K[Co(C_8H_{14}O_4N_4)(CN)_2]\cdot3/2\cdot H_2O$: C, 29.49; H, 3.96; N, 20.63%.

† Presented in part at the 37th National Meeting of the Chemical Society of Japan, Tokyo, April 1, 1978, Abstracts Vol. 1, p. 275 and the 28th Annual Meeting on Coordination Chemistry, Matsuyama, October 11, 1978, Abstract, p. 337.

The metal complex $[Co^{III}(dmgH)_2(NH_3)_2]Cl$ at pH 4.3—9.5 was strongly adsorbed on the cation-exchange resin (Dowex 50W-X8) but not on the anion-exchange resin (Dowex 1-X4), indicating that the metal complex exists in a cationic form at pH 4—9. In the pH region higher than 10.17, the pK_a^c of the complex, a neutral species, $[Co^{III}(dmg)(dmgH)(NH_3)_2]$ is formed. On the other hand, the metal complex $K[Co^{III}(dmgH)_2(CN)_2]$ at pH 4.0—8.0 was strongly adsorbed on the anion-exchange resin but not on the cation-exchange resin.

Measurements. Measurements of pH in dioxane–water media were reported in a previous paper.[2] The acid-dissociation constants were determined spectrophotometrically with a Hitachi recording spectrophotometer Model EPS-3T. Kinetic measurements were carried out with a Union Giken co-axial-cable temperature-jump apparatus Model RA-105. The reactions were followed on the screen of an oscilloscope Tektronix Type 545B at a wavelength in the range 400—500 nm. All the measurements were carried out at 25.0±0.1 °C and at a constant ionic strength 0.10 adjusted with potassium nitrate.

Results and Discussion

The metal complex ions (Fig. 1) have two equivalent strong intramolecular hydrogen-bonds, OH···O⁻. An infrared absorption band around 1775 cm^{-1} for Ni(dmgH)$_2$ complex has been assigned to an intramolecular hydrogen bonding.[17] The absorption band for O–H stretching appears at 3170 cm^{-1} in the free ligand dimethylglyoxime. The bond length of the intramolecular hydrogen-bond, OH···O⁻, was reported to be 2.44 Å from the data of X-ray crystallography.[18] In some $[Co^{III}(dmgH)_2XY]$ complexes the O–H stretching frequency lies in the range 1770—1680 cm^{-1}.[19] As regards the complexes with X, Y=NH_3, a planar chelate structure was confirmed based on the data of X-ray crystallography.[20]

The absorption spectra of an aqueous solution of the cationic complex DGA at various pH values, at 25 °C, and at I=0.1 mol dm^{-3} ($NaClO_4$),[21] gave an isosbestic point at 246 nm (Fig. 2), indicating that the presence of only two absorbing species involved. In the pH region studied only one proton is dissociated from the Co(III) complex ion. The first acid-dissociation constant, K_a^c(s), of the reaction for DGA cation

$$[Co^{III}(dmgH)_2(NH_3)_2]^+ \rightleftarrows [Co^{III}(dmg)(dmgH)(NH_3)_2]^0 + H^+, \quad (3)$$

and that for CDG anion

$$[Co^{III}(dmgH)_2(CN)_2]^- \rightleftarrows [Co^{III}(dmg)(dmgH)(CN)_2]^{2-} + H^+, \quad (4)$$

are determined by the change in absorbance at 285 nm, ΔA_{285}, the equilibrium concentration of proton, $\bar{C}_H$, and the total concentration of the complex ion, C.[5] The plot of $C/\Delta A_{285}$ against $\bar{C}_H$ gives a straight line at each solvent composition. The values of K_a^c(s) determined spectrally at various dioxane contents are summarized in Table 1. The value of pK_a^c(s) increases with the increase in x_{dlox} irrespective of the difference in the sign of the charge of DGA cation and CDG anion (Fig. 3). The values of pK_a^c(s) of CDG anion at x_{dlox}=0 and 0.174 are 1.53 and 2.79 larger than those of DGA cation, respectively. These differences in pK_a^c(s) are attributed to the difference in the basicity of the axial ligands, NH_3 and CN^-.

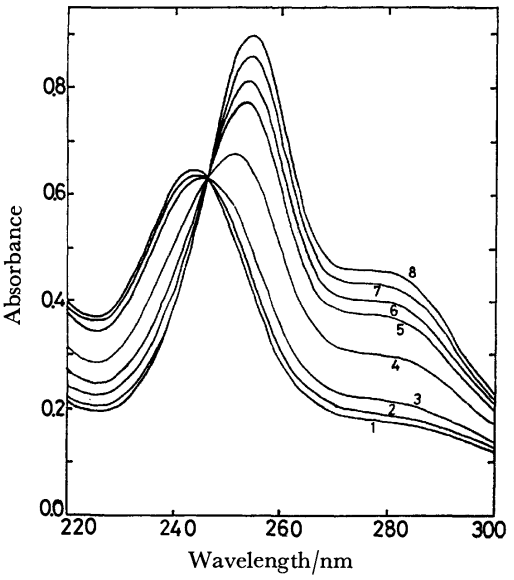

Fig. 2. Absorption spectra of the solution containing 2.59×10^{-5} mol dm^{-3} $[Co^{III}(dmgH)_2(NH_3)_2]^+$ ion at 25 °C and I=0.1 mol dm^{-3} ($NaClO_4$).
pH: (1) 5.85; 6.70, (2) 9.02, (3) 9.33, (4) 10.07, (5) 10.45, (6) 10.75, (7) 10.96, and (8) 11.11.

a, b) See Ref. 28.

For the proton-transfer reactions in the dioxane–water media of DGA cation,[22]

$$[Co^{III}(dmgH)_2(NH_3)_2]^+ + OH^- \rightleftharpoons [Co^{III}(dmg)(dmgH)(NH_3)_2]^0 + H_2O \quad (6)$$

and those of CDG anion,[23]

$$[Co^{III}(dmgH)_2(CN)_2]^- + OH^- \rightleftharpoons [Co^{III}(dmg)(dmgH)(CN)_2]^{2-} + H_2O, \quad (8)$$

the observed relaxation time, τ, is expressed by

$$\tau^{-1} = k_f(\bar{C}_{H_2A} + \bar{C}_{OH}) + k'_r, \quad (8)$$

where $\bar{C}$, suffix H_2A, and k'_r denote the equilibrium concentration, the acid form of Co(III) complex ions, and $k_r[H_2O]$, respectively. The plot of τ^{-1} against the sum of equilibrium concentrations gives a straight line at each dioxane content (Fig. 4). The values of k_f and

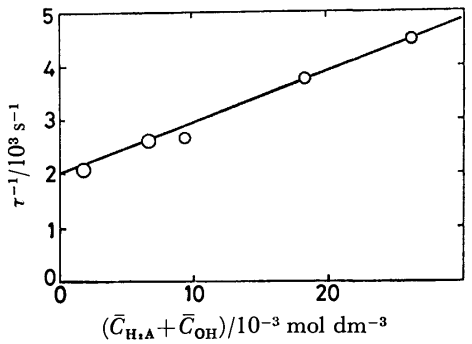

Fig. 4. Plot of the reciprocal relaxation time *vs.* $\bar{C}_{H_2A}+\bar{C}_{OH}$ at x_{diox}=0.050, 25 °C, and I=0.1 mol dm^{-3} (KNO_3). $[Co^{III}(dmgH)_2(CN)_2]^-$–$OH^-$ system.

k_r thus obtained are summarized in Table 2. The values of k_f are several orders of magnitude smaller than those for the diffusion-controlled proton-transfer reactions due to the strong intramolecular hydrogen-bond, OH···O$^-$. The values of log k_f of DGA cation are 1.26 and 2.60 larger than those of CDG anion at x_{diox}=0 and 0.174, respectively. The rate constant for the recombination of CDG anion with OH^- ion, k_f, decreases linearly with the increase in x_{diox}, *viz.*, from 1.6×10^5 to 4.0×10^4 mol^{-1} dm^3 s^{-1} for the change in x_{diox} from 0 to 0.174, similar to the changes observed in the univalent anions of *o*-hydroxy azo compounds.[4] However, the value of k_f of DGA cation decreases in a region of lower x_{diox} from 2.9×10^6 to 1.1×10^6 mol^{-1} dm^3 s^{-1} and increases in a region of higher x_{diox} from 1.1×10^6 to 1.6×10^7 mol^{-1} dm^3 s^{-1}.

The value of pK^c_a(k) was evaluated by the relationship, $K^c_a(k)=(k_f/k'_r)\cdot K^c_w=K^c_b\cdot K^c_w$, where K^c_w denotes the apparent ionic product of water.[5] The values of pK^c_a(k) are summarized in Table 2.

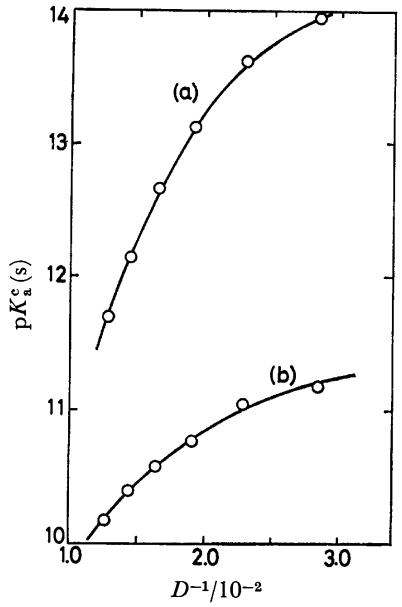

Fig. 5. Dependence of pK^c_a(s) on the inverse dielectric constant of the medium, D^{-1}.
(a): $[Co^{III}(dmgH)_2(CN)_2]^-$ anion. (b): $[Co^{III}(dmgH)_2(NH_3)_2]^+$ cation.

In Fig. 5 the values of pK^c_a(s) are plotted against D^{-1}, the inverse macroscopic dielectric constant of the medium. The dependence is not linear. A simple Born-type electrostatic effect is not observed. According to the Born theory[24] the change in pK^c_a of a Brønsted acid, H_2A, is expressed as

$$\Delta pK^c_a = pK^c_a(\text{in dioxane-water}) - pK^c_a(\text{in aqueous solution}) = (0.215Ne^2/RT)(1/r_H + Z^2_{HA}/r_{HA} - Z^2_{H_2A}/r_{H_2A})(1/D_{II} - 1/D_I), \quad (9)$$

where Z_{HA} and Z_{H_2A} denote the charge of the base (HA) and the acid form (H_2A), D is the macroscopic dielectric constant of the medium, r the radius of the species, R the gas constant, T the absolute temperature, e the elementary charge, and N the Avogadro number. From

Eq. 9 ΔpK_a^c of the univalent cation ($Z_{H_2A}=+1$ and $Z_{HA}=0$) is expected to be small. However, in the case of DGA cation the value of $\Delta pK_a^c(s)$ is as large as 1.00 for the change in x_{diox} from 0 to 0.174. The corresponding value of $\Delta pK_a^c(s)$ of CDG anion is 2.26. The value of $\Delta pK_a^c(s)$ of univalent anions of *o*-hydroxy azo compounds, 4-(2-hydroxy-5-ethylphenylazo)benzenesulfonic acid (HEB) and 4-(2-pyridylazo)resorcinol (PAR), were reported to be +1.77 and +1.83[5] and bivalent anions of *o*-hydroxy azo compounds, 4-(2,4-dihydroxyphenylazo)benzenesulfonic acid (TPO) and 7-hydroxy-8-phenylazo-1,3-naphthalenedisulfonic acid (HPN), +2.27 and +2.31.[4]

A reaction mechanism

$$H_2A \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} H_2A^* \quad (10)$$

$$H_2A^* + OH^- \underset{k_{32}}{\overset{k_{23}}{\rightleftharpoons}} H_2A^*\cdots(H_2O)_n\cdots OH^- \quad (11)$$

$$H_2A^*\cdots(H_2O)_n\cdots OH^- \underset{k_{43}}{\overset{k_{34}}{\rightleftharpoons}} HA + H_2O, \quad (12)$$

postulated previously[5] for the proton-transfer reactions of *o*-hydroxy azo compounds in dioxane–water media might be applied also to those of DGA cation and CDG anion. Equation 10 denotes the equilibrium between two isomeric Co(III) complex ions, *viz.*, an H_2A species having an intramolecular hydrogen-bond and an intermediate species H_2A^* having no intramolecular hydrogen-bond. The rate constant for the recombination of Brønsted acid with OH^-, k_f, is expressed as the product of the rate constant, k_{23}, for the diffusion-controlled encounter between H_2A^* and OH^-, and the equilibrium constant, $K_{12}=[H_2A^*]/[H_2A]$, for the breaking of the intramolecular hydrogen-bond and the interaction with the surrounding water molecules.[5]

$$k_f = K_{12}k_{23} = (k_{12}/k_{21})k_{23} \quad (13)$$

As regards the ion-ion reactions the Christiansen-Scatchard equation is proposed[25]

$$\ln(k_f/k_f^\circ) = -z_1z_je^2/kTr^*D, \quad (14)$$

where k is the Boltzmann's constant, r^* the reaction distance, and k_f° the rate constant at infinite dielectric constant.

Since the proton-transfer reaction of CDG anion and OH^- ion is a reaction between the same charge-type ions, the negative slope is expected in the plot of log k_f against D^{-1} (Fig. 6). From the slope the value of r^* is calculated to be 4.6 Å. This value is the intermediate one between the values for the slightly water-soluble Brønsted acid, (4-(*p*-nitrophenylazo)resorcinol; $r^*=2.9$ Å)[3] and a water-soluble Brønsted acid (4-(2-hydroxy-5-ethylphenylazo)benzenesulfonic acid; $r^*=7.2$ Å).[4] In the case of CDG anion having hydrophobic groups (four methyl groups) as in 4-(*p*-nitrophenylazo)-resorcinol (one nitro group), the inflection is observed in the plot as shown in Fig. 6.

The following reaction mechanism is proposed for the case of intramolecularly hydrogen-bonded dicarboxylic acid monoanions, AH^-, in aqueous solution.[26]

$$AH^- + OH^- \rightleftharpoons A^-\cdots H\cdots OH^- \rightleftharpoons A^{2-} + H_2O, \quad (15)$$

where $A^-\cdots H\cdots OH^-$ denotes an encounter complex with a weakened intramolecular hydrogen-bond. The mechanism shown in Eqs. 10—12 would be reasonable for the explanation of the solvent effects. From Eq. 14 the slope in Fig. 6 is expected to be positive in the case of DGA cation. However, with increasing D^{-1} the value of log k_f decreases at higher value of D (78—52) and then increases at lower value of D (52—35). This behavior is explained by the solute-solvent interactions and not by the simple electrostatic law (Eq. 14) nor by the reaction mechanism (Eq. 15). The rate constant, k_f, is equal to $K_{12}k_{23}$ (Eq. 13). The equilibrium constant, K_{12}, is a parameter which denotes the solute-solvent interactions, *viz.*, interactions with the surrounding water molecules. Thus the value of K_{12} gradually decreases with the increase in x_{diox}, *viz.*, decrease in D. If the contribution of the decrease of K_{12} to the value of k_f is larger than that of the increase of k_{23}, the rate constant k_f decreases at higher D where solute-solvent interaction is predominant, and then increases at lower D where the electrostatic effect is predominant.

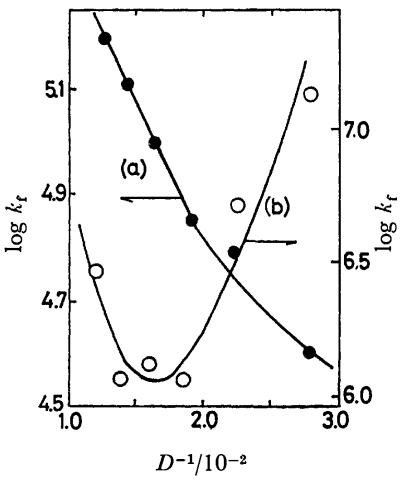

Fig. 6. Dependence of log k_f on the inverse dielectric constant of the medium, D^{-1}.
(a): $[Co^{III}(dmgH)_2(CN)_2]^-$ anion. (b): $[Co^{III}(dmgH)_2(NH_3)_2]^+$ cation.

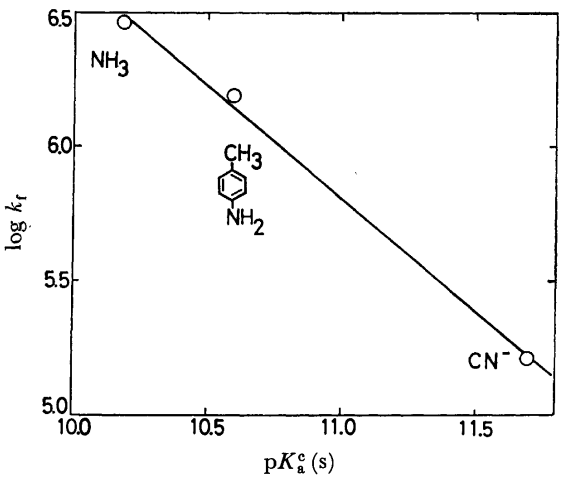

Fig. 7. Plot of log k_f *vs.* pK_a^c(s) in bis(dimethylglyoximato)cobalt(III) complex–OH^- system.

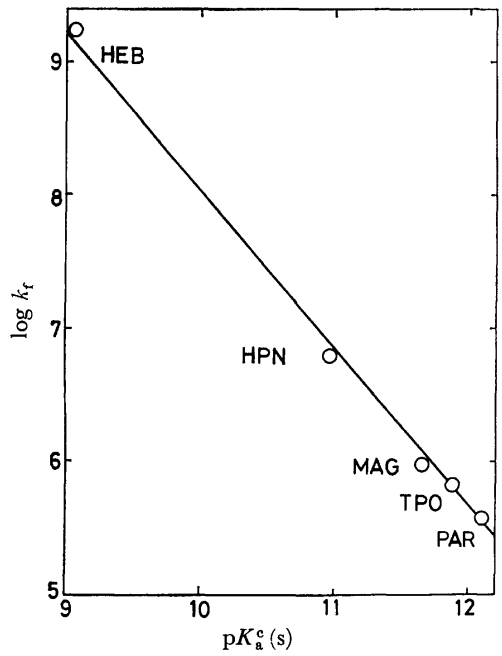

Fig. 8. Plot of log k_f *vs.* pK_a^c(s) in *o*-hydroxy azo compound–OH^- system.

Figure 7 shows the Brønsted plot with the slope −0.85 in aqueous solution,

$$\log k_f = -0.85\,pK_a^c(s) + 15.15. \quad (16)$$

The value is the intermediate one between −0.5 for the substituted malonic acids[27] and −1.2 for *o*-hydroxy azo compounds (log $k_f = -1.2$ pK_a^c(s)+20.05) (Fig. 8).[1-5] Masuda *et al.* reported the relationship of pK_a^c(s) and the basicity of an axial ligand and pointed out the importance of the transmittance of an electronic effect of the axial ligand to the oximato radical.[13] The rate constant k_f does reflect the thermodynamic stability of the intramolecular hydrogen-bond, namely the values of pK_a^c. This fact indicates that the axial ligand with larger electronic effect on the increase in the proton-dissociation of the in-plane oximato group tends to accelerate the dissociation of proton in the intramolecular hydrogen-bond of the Co(III) complex ion.

21) Sodium perchlorate was used for the adjustment of ionic strength in equilibrium measurements in order to avoid the disturbance by the intense absorption of KNO_3 in 280—340 nm.
22) The absorption in the range 400—500 nm of the base form of DGA cation rapidly increases in the time region of 2 μs div^{-1}. The reciprocal relaxation time of this fast step does not depend on the sum of the equilibrium concentrations of H_2A^+ and OH^- ions at each dioxane content. The signal-amplitude of the fast step depends only on the equilibrium concentration of the base form, HA^0. This indicates that the fast step would be an intramolecular structural change in the base form. The sum of the rate constants, k_1+k_{-1}, for this fast step is determined to be 4.5×10^4—2.3×10^5 s^{-1}. Since the concentration of the intermediate species accompanied by this fast step is very low, the value of K_a^c(s) is in good agreement with that of K_a^c(k) at each dioxane content.
23) Three relaxation phenomena were observed in the CDG anion–OH^- system. The signal amplitude of a very fast step is small as compared with that of DGA cation. The values of k_1+k_{-1} are found to be 1.3×10^5—2.0×10^5 s^{-1}. The very slow step would be the intramolecular step accompanied by the motion of axial ligands, since the value of τ^{-1} (3—5 s^{-1}) does not depend on the equilibrium concentrations. The values of k_2+k_{-2} for this slow step are found to be in the range 3.0—5.5 s^{-1}.

The Hydrothermal Preparation and Characterization of Platinum Metal Complexes with Ethylenediaminetetraacetic Acid and Propylenediaminetetraacetic Acid

Masami SAITO, Takashi UEHIRO,** and Yukichi YOSHINO*

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153

(Received March 19, 1980)

A new method for hydrothermal syntheses of osmium(III), ruthenium(III), iridium(III), and rhodium(III) complexes with ethylenediaminetetraacetic acid (EDTA) and propylenediaminetetraacetic acid (PDTA) has been developed. More than ten new complexes have been obtained in good yields and characterized by measuring their magnetic susceptibilities, infrared and electronic spectra, and acid-base properties. The stereochemical behavior of the iridium(III) and rhodium(III) complexes has also been described.

It is well known that most of the platinum metal ions are kinetically inert in aqueous solution,[1] that the preparation of their complexes with ethylenediaminetetraacetic acid and propylenediaminetetraacetic acid is not always reproducible, and that the yields are generally low. In order to improve this, the present authors have tried to prepare these complexes at temperatures higher than 100 °C using a Teflon bucket with a stainless-steel holder.[2]

In the present study attention was focused on the complexes of the less familiar platinum metals, *i.e.*, osmium, ruthenium, iridium, and rhodium, and efficient methods of the hydrothermal preparation of their EDTA and PDTA complexes involving some new complexes have been developed. The complexes thus obtained were characterized by measurements of their magnetic susceptibilities, infrared and electronic spectra, and acid-base properties.

Experimental

Materials. Osmium(VIII) oxide from Degussa, ruthenium(IV) oxide from the Japan Engelhard Co., iridium(IV) chloride from the Tanaka Noble Metals Co. and rhodium(III) chloride trihydrate from the Koso Chemicals Co. were employed. The other chemicals were of a reagent grade from the Wako Pure Chemicals Co. and were purified by recrystallization or distillation when necessary. Twice-distilled water was used throughout the experiment. For the hydrothermal preparation, a "Uniseal" with capacity of 23 ml from Uniseal Decomposition Vessels, Ltd., was used.

Physical Measurements. The infrared spectra were recorded on a JASCO Model 403G spectrophotometer, using the nujol or hexachlorobutadiene mull technique. The electronic spectra were obtained on a Hitachi Model 124 spectrophotometer, and the CD spectra, on a JASCO Model J-20 recording spectropolarimeter. The optical rotations were measured by means of a Yanaco Model OR-50 photoelectric polarimeter, and the NMR spectra, on a JEOL JUN-MH-100 spectrometer (100 MHz) at an ambient temperature (*ca.* 20 °C). The magnetic measurements were carried out with a Gouy balance at room temperature. Toa Dempa Digital pH-meters, Types HM-8 and HM-20B, were used for the acid-base titrations.

Preparation of Complexes. The general scheme of hydrothermal syntheses was as follows: the platinum metal halide or halogeno complex (1—4 mmol) and EDTA or PDTA (free acid or disodium salt) were mixed in a ratio of 1 : 1.05 in a bucket. To the mixture we then added 15 ml of water, and the resulting mixture was stirred for a while. Then, the bucket and the sealing lid were set in a stainless-steel holder, and the assembly was heated in an electric oven at temperatures from 100 to 150 °C for several hours or overnight. After the vessel has been cooled, a small amount of insoluble matter was filtered off, and the filtrate was evaporated to a small volume on a water bath. The addition of ethanol is often effective for crystallization.

*$NH_4[OsCl_2(H_2edta)]$ (**1a**).* The starting material, $(NH_4)_2[OsCl_6]$ was prepared by the reduction of OsO_4 with iron(II) in a methanol–HCl solution.[3] A mixture of 1.8 g of $(NH_4)_2[OsCl_6]$ (4 mmol) and 1.2 g of H_4edta (4.1 mmol) was suspended in 15 ml of water in a Teflon bucket, and the apparatus was heated at 150 °C for 5 h. Then, the filtrate was evaporated to a smaller volume. The crystals thus deposited were washed with ethanol and air-dried. Yield, 1.5 g.

*$H[OsCl_2(H_2edta)]\cdot 2.5H_2O$ (**1b**).* The filtrate obtained by the hydrothermal reaction in **1a** was directly passed through a column of cation-exchange resin in the hydrogen form (Dowex 50W, X8, 50—100 mesh). The effluent was concentrated by evaporation on a water bath, and the deposited crystals were washed with cold ethanol. Yield, 1.7 g.

*$NH_4[OsBr_2(H_2edta)]$ (**2a**).* OsO_4 was converted to $(NH_4)_2[OsBr_6]$ by Dwyer's method.[4] Then, a suspension of 2.8 g of $(NH_4)_2[OsBr_6]$ (4 mmol) and 1.2 g of H_4edta (4.1 mmol) in 15 ml of water was heated at 150 °C for 5 h. From the filtrate, yellowish brown crystals were obtained. Yield, 1.0 g.

*$H[OsBr_2(H_2edta)]$ (**2b**).* The above-mentioned filtrate containing **2a** was passed through a column of cation-exchange resin (H^+-form). Yield, 1.0 g.

*$H[RuCl_2(H_2edta)]\cdot 3.5H_2O$ (**3**).* One gram of $RuO_2\cdot nH_2O$ ($n=3$—4) was dissolved in 20 ml of concd HCl by heating. After repeated heating to dryness, the residue was dissolved in 15 ml of water. To this we added 1.7 g of H_4edta (5.7 mmol), after which the mixture was heated on a water bath to give a clear solution. The resulting solution was heated at 120 °C for 5 h. The filtrate was cooled in an ice bath to give yellow crystals. The crystals were washed with a small amount of cold ethanol and acetone successively. Yield, 2.5 g.

*$Na[RuCl(Hpdta)]\cdot 3H_2O$ (**4**).* To a $RuCl_3$ solution (5.5 mmol) obtained from $RuO_2\cdot nH_2O$ and concd HCl, 5.8 mmol of NaH_3pdta was added. The mixture was heated at 120 °C for 10 h. The filtrate from the reaction mixture was then concentrated to *ca.* 10 ml, and twice the volume of ethanol was added. The fine crystals thus obtained were

** Present address: National Institute for Environmental Studies, Yatabe, Tsukuba-gun, Ibaraki 305.

washed with ethanol. Yield, 1.5 g.

Na[IrCl(Hedta)]·2H$_2$O (5). A suspension of 0.68 g of $IrCl_4$ (2 mmol) and 0.75 g of Na_2H_2edta·2H$_2$O (2 mmol) in 15 ml of water was heated at 150 °C for 24 h. The filtrate from the reaction mixture was evaporated to *ca.* 5 ml. When the solution was cooled, yellow crystals separated out. Yield, 0.7 g.

Na[IrCl(Hpdta)]·3H$_2$O (6). A procedure similar to that described in **5** was applied, using Na_2H_2pdta in place of Na_2H_2edta. Yield, 0.7 g.

NH$_4$[RhCl$_2$(H$_2$edta)] (7). An aqueous suspension of 1.3 g of $RhCl_3·3H_2O$ (5 mmol) and 2.0 g of Na_2H_2edta·2H$_2$O (5.4 mmol) was heated at 120 °C for 5 h. To the filtrate we then added 8 ml of concd HCl, and the solution was evaporated to 10 ml. In this solution, 0.5 g of NH_4Cl was dissolved, after which the solution was cooled in an ice bath. Yellowish brown crystals were collected and washed with 50% ethanol and diethyl ether successively. Yield, 2.1 g.

[Os(edta)(H$_2$O)]·H$_2$O (8). An aqueous solution (20 ml) containing 1.5 g of H[OsCl$_2$(H$_2$edta)]·2.5H$_2$O (**1b**) was aerated for 20 h. The black, lustrous crystals thus deposited were collected and washed with water until free from chloride ions, and then with diethyl ether. Yield, 1.1 g.

H[OsI(Hedta)]·2.5H$_2$O (9a). One gram of **8** was added to 10 ml of concd HI (7.5 mol dm^{-3}), after which the mixture was stirred for 1 h. The I_2 liberated during the procedure was removed by extraction with diethyl ether. The crystals thus deposited were filtered and washed with a small amount of ethanol. Yield, 1.0 g.

NH$_4$[OsI(Hedta)] (9b). One gram of **9a** (1.5 mmol) was dissolved in 10 ml of warm water (*ca.* 40 °C). To this we then added 1.5 g of NH_4I. The crystals thus obtained were washed with a small amount of cold water and with ethanol successively. Yield, 0.9 g.

[Ir(Hedta)(H$_2$O)]·1.5H$_2$O (10). To an aqueous solution containing 3 mmol of **5** (10 ml) we added 3.1 mmol of $AgNO_3$ dissolved in 10 ml of water; the excess Ag^+ in the filtrate was removed by passing the solution through a column of hydrogen-form cation-exchange resin. After the effluent had been concentrated by evaporation, ethanol was added to give a precipitate. The precipitate was washed with ethanol and diethyl ether. Yield, 1.4 g.

(−)$_{589}$- and (+)$_{589}$-Na[IrCl(Hedta)]·2H$_2$O (11a). One millimole of **5** was dissolved in 10 ml of a warm solution containing 0.5 mmol of (+)$_{589}$-*cis*-[Co(NO$_2$)$_2$(en)$_2$]Cl. When the solution was cooled, yellowish brown crystals of the diastereoisomer separated out, the molar rotion being $[M]_{589}=-84°$. The diastereoisomer was mixed with 1 g of NaI paste and then minimum amount of water was added and filtration was done. The addition of ethanol led to the crystallization of (−)$_{589}$-Na[IrCl(Hedta)]·2H$_2$O; $[M]_{589}=-350°$. The (+)$_{589}$-isomer was obtained similarly by using (−)$_{589}$-*cis*-[Co(NO$_2$)$_2$(en)$_2$]Cl; $[M]_{589}=+350°$.

(+)$_{589}$- and (−)$_{589}$-Na[Ir(Hedta)(H$_2$O)]·1.5H$_2$O (11b). These were prepared by treating **11a** with $AgNO_3$ in the way described earlier for **10**. $[M]_{589}=\pm526°$.

(+)$_{589}$- and (−)$_{589}$-Na[IrCl((S)-Hpdta)]·3H$_2$O (12). These complexes were obtained in the same way as in the case of the active Na[IrCl(Hedta)]·2H$_2$O (**11a**) except that the molar ratio of the racemate to the resolving agent was 1 : 1. $[M]_{589}=\pm380°$. The optically active complex (−)$_{589}$-Na[IrCl((*R*)-pdta)]·3H$_2$O could be prepared directly by using (*R*)-PDTA under somewhat milder conditions, *i.e.*, 120 °C and 20 h. $[M]_{589}=-380°$.

(−)$_{589}$-[Rh(Hedta)(H$_2$O)] (13). The reacmic Na[RhCl(Hedta)]·2H$_2$O was resolved by using (+)$_{589}$-*cis*-[Co(NO$_2$)$_2$(en)$_2$]Br; the resulting (−)$_{589}$-[RhCl(Hedta)]$^-$ was converted into (−)$_{589}$-[Rh(Hedta)(H$_2$O)] by treating it with $AgNO_3$. $[M]_{589}=-260°$.

Results and Discussion

Hydrothermal Preparation. The analytical data for the complexes are presented in Table 1. In Table 2, the results of the hydrothermal preparation of the EDTA and PDTA complexes of osmium(III), ruthenium(III), iridium(III), and rhodium(III) are summarized. Of these, the osmium(III) complexes of EDTA were synthesized for the first time.[5] As may be seen from the table, the yields of the known complexes increased remarkably; for example, the yield of the iridium(III) complex (**5**) increased from 35% to 60%.[6] In the case of rhodium(III), both EDTA and PDTA complexes were obtained nearly quantitatively. As for ruthenium(III), the PDTA complex was obtained for the first time. It is noteworthy that, in the case of the iridium(III)-PDTA complex, (−)$_{589}$-Na[IrCl((*R*)-Hpdta)]·3H$_2$O can be prepared hydrothermally using optically active (*R*)-PDTA as a ligand, without any accompanying

racemization.

Osmium(III), (IV), and Ruthenium(III) Complexes. All the osmium complexes except **8** were found to be paramagnetic, with magnetic moments ranging from 1.73 to 1.82 B.M. which is to be expected for a spin-only atom with one unpaired electron spin. Hence, together with the analytical data in Table 1, the oxidation state of the osmium was presumed to be +3 with a low-spin $5d^5$ configuration. Some typical examples of the infrared spectra of the osmium-EDTA complexes in the region from 1200 to 1800 cm^{-1} are shown in Fig. 1. In the trivalent osmium complexes, there appear two characteristic CO stretching bands, one in the region of 1600 cm^{-1} and the other in the region higher than 1700 cm^{-1}. The former is assigned to the carboxylate coordinated to the metal, and the latter, to the free carboxylic acid. The frequencies of these bands are tabulated in Table 3. The appearance of these two bands indicates that, in all the complexes of osmium(III), the EDTA is bonded to the octahedral sites as a quinque- or quadridentate ligand. Such an interpretation may be supported by the examination of the pH-titration curves of the complexes with an alkali solution (Fig. 2). In the case of dihalogeno complex acid (**1b** or **2b**), 3 mol of alkali were consumed for 1 mol of osmium(III), indicating the presence of two carboxylic acid radicals. On the other hand, in the case of monohalogeno complex acid (**9a**), 2 mol of alkali were required for 1 mol of osmium(III), indicating the presence of one carboxylic acid radical.

Figure 3 presents some typical examples of the electronic spectra of the osmium(III) complexes. Strong and broad absorption bands are seen in the ultraviolet region.

The **8** complex was found to react with potassium

$Na[RuCl(Hpdta)]\cdot 3H_2O$	1.90	1635	1750	2.3[a]

a) The value for H[RuCl(Hpdta)] obtained by cation exchange.

iodide to give **1** equivalent of iodine per mole of osmium; this supports the idea that the oxidation state of the osmium atom is +4. As may be seen from Table 3 and Figs. 1, 2, and 3, the behavior of the tetravalent osmium complex is very different from that of the osmium(III) complexes described above. In the IR spectrum, a strong band was observed at 1675 cm^{-1}, too low to attribute it to a free COOH. In the acid-base titration (Fig. 2), the complex behaves as a rather strong monobasic acid, and deprotonation from a coordinated water molecule can be expected to take place. Furthermore, the magnetic susceptibility of the tetravalent osmium complex was determined to be -140×10^{-6} emu mol^{-1}. This observation seems rather unexpected because, in general, the tetravalent osmium complexes have been known to be paramagnetic, the magnetic moments ranging from 1.2 to 1.8 B.M. at room temperature.[7]

The question was finally solved by the X-ray structure analysis of a single crystal of the complex. The results revealed that the osmium(IV) complex is seven-coordinate (one edta^{4-} and one water molecule), and so the diamagnetism of the complex could be interpreted in terms of the 18-electron rule.[8]

The EDTA complexes of ruthenium(III) were prepared for the first time by Mukaida *et al.* in 1965;[9] since they have been well characterized by other workers as well.[10,11] In our study, we have attempted the hydrothermal preparation of other ruthenium complexes with EDTA and PDTA; two new complexes, $H[RuCl_2(H_2edta)]\cdot 3.5H_2O$ and $Na[RuCl(Hpdta)]\cdot 3H_2O$ were obtained in good yields. The characteristic properties of these complexes are shown in Table 3.

Iridium(III) and Rhodium(III) Complexes. The iridium complexes, **5**, **6**, and **10** were found to be diamagnetic. With reference to the analytical data (Table 1), the oxidation state of iridium was assumed as +3. In the IR spectra, besides ν_{asym}(COO$^-$) at 1650 cm^{-1}, ν_{asym}(COOH) in the region higher than 1700 cm^{-1} was observed in all the complexes. Therefore, in the solid states of these complexes, EDTA and PDTA may act as quinquedentate ligand, and one Cl$^-$ ion or H_2O molecule may occupy the sixth coordination site.

However, for the monochloro or monoaqua complex, two geometrical isomers are possible; the Cl$^-$ ion or the H_2O molecule may be *trans* to either a nitrogen or oxygen atom. In order to determine the structure, the deuteration of the acetate protons of $[IrCl(Hpdta)]^-$ in D_2O was studied by ^{1}H-NMR. It was observed that the only one AB-pattern with J=16.5 Hz survived after the other acetate signals had diminished upon deuteration. The remaining AB-pattern may be assigned to the in-plane acetate methylene protons.[12] Therefore, in the present complex, Cl$^-$ ion should be *trans* to a nitrogen atom. This structure is the same as that of the result of the X-ray structure analysis of the corresponding $[Rh(Hedta)(H_2O)]$.[13]

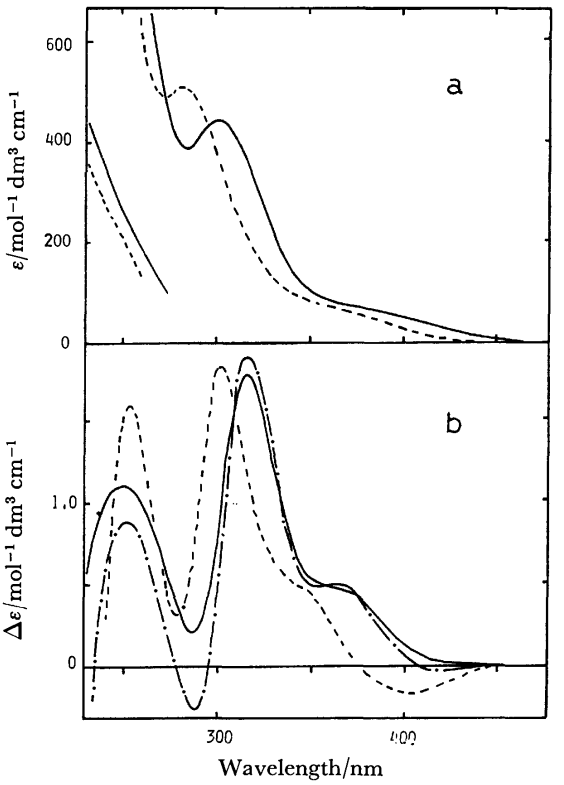

Fig. 4. Electronic and CD spectra of iridium(III) complexes with EDTA and PDTA.
(a): Absorption spectra. ——: $Na[IrCl(Hedta)]\cdot 2H_2O$ or $Na[IrCl(Hpdta)]\cdot 3H_2O$, ------: $[Ir(Hedta)(H_2O)]\cdot 1.5H_2O$.
(b): CD spectra. ——: $(-)_{589}$-$Na[IrCl(Hedta)]\cdot 2H_2O$, —·—: $(-)_{589}$-$Na[IrCl(Hpdta)]\cdot 3H_2O$, ------: $(-)_{589}$-$[Ir(Hedta)(H_2O)]\cdot 1.5H_2O$.

Figure 4 shows the electronic spectra and CD curves. The aqueous solution of $Na[IrCl(Hedta)]\cdot 2H_2O$ and $Na[IrCl(Hpdta)]\cdot 3H_2O$ exhibited a very similar spectral pattern; ε=440 at 303 nm and a shoulder (ε=70) at *ca.* 385 nm. These peaks are tentatively assigned to the d-d transitions, though a possible overlapping of charge-transfer bands in the shorter-wavelength region must be taken into consideration. The spectrum of

[Ir(Hedta)(H_2O)] shifts to shorter wavelengths as compared with that of the parent complex, [IrCl(Hedta)]$^-$, *i.e.*, from 303 nm (ε=440) for the monochloro complex to 290 nm (ε=510) for the monoaqua complex. This is consistent with the spectrochemical series.

Since the sexidentate (*R*)-PDTA complexes of cobalt(III) and rhodium(III) have the *Δ* configuration,[14,15] the corresponding complex of iridium(III) can be expected to have the same configuration. As may be seen from Fig. 4, the CD spectra of the $(-)_{589}$-isomer of EDTA- and PDTA complexes are quite similar. Therefore, it is presumed that $(-)_{589}$-[IrCl(Hedta)]$^-$ has the same structure as that of the sexidentate EDTA complex of the *Δ* configuration, in which one carboxyl group coplanar with the N–C–C–N chelate is free. This is consistent with the presumption presented by Ezerskaya *et al.* on the basis of the Cotton effects of the iridium(III)–EDTA complexes.[16]

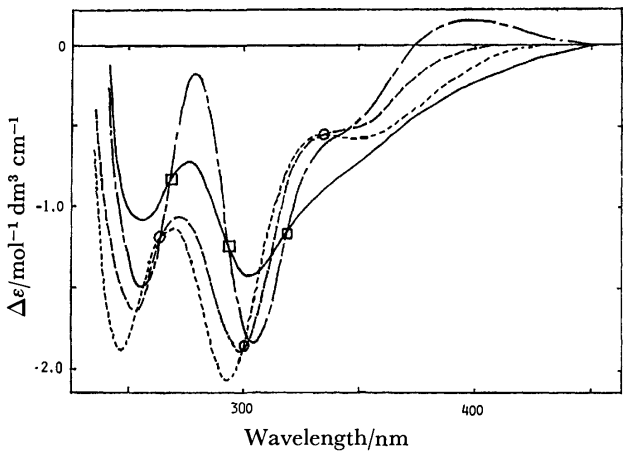

Fig. 5. pH dependence of CD spectra of $(+)_{589}$-[Ir(Hedta)(H_2O)]·1.5H_2O.
·····: pH=1.6, ----: pH=2.6, —·—: pH=7.6, ——: pH=10.0.

It was found that the CD spectra of monoaqua complexes of iridium(III) and rhodium(III) shows a remarkable pH dependence, while those of monochloro complexes change little with the pH of the solution (Fig. 5 and Fig. 7). In the case of the iridium(III) complex, in the acidic region three isosbestic points appear at 335, 309, and 264 nm, while in the basic region they shift to 319, 294, and 268 nm. A plot of $\Delta\varepsilon$ values at 280 nm against the pH gives the curve in Fig. 6, while the curve in Fig. 8 was obtained by a similar plot at 315 nm for $(-)_{589}$-[Rh(Hedta)(H_2O)]. This behavior implies that there exist stepwise acid-base equilibria between species, I, II, and III, of the Ir(III)- and Rh(III) complexes:

$$\mathrm{I} \underset{pK_1}{\rightleftharpoons} \mathrm{II} \underset{pK_2}{\rightleftharpoons} \mathrm{III}$$

From the curves in Fig. 6 and Fig. 8, the pK values are evaluated as:

pK_1=2.5 and pK_2=9.1 for the Rh(III) complex, and pK_1=2.9 and pK_2=8.4 for the Ir(III) complex.

The pK values for the Rh(III)–EDTA complex may be

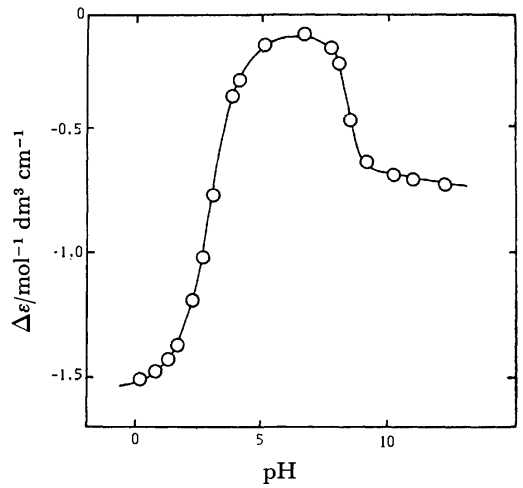

Fig. 6. The plot of $\Delta\varepsilon$ values for $(+)_{589}$-[Ir(Hedta)(H_2O)]·1.5H_2O against pH at 280 nm.

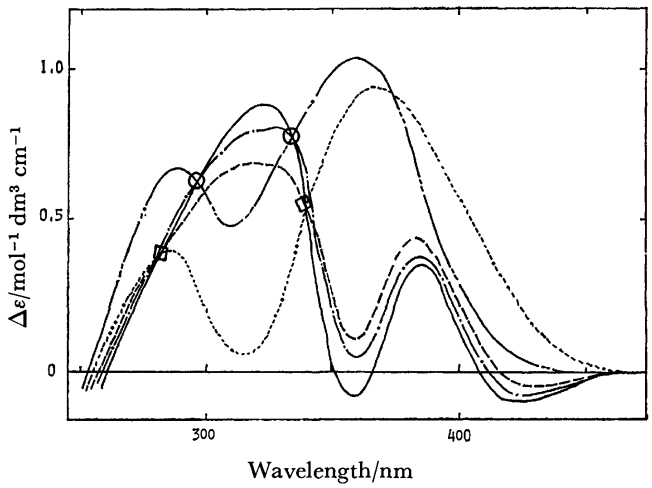

Fig. 7. pH dependence of CD spectra of $(-)_{589}$-[Rh(Hedta)(H_2O)].
—··—: pH=0.8, —·—: pH=2.6, ——: pH=3.5, ----: pH=8.9, ·····: pH=12.1.

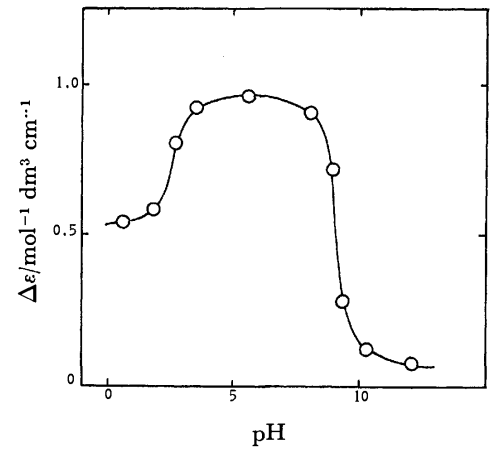

Fig. 8. The plot of $\Delta\varepsilon$ values for $(-)_{589}$-[Rh(Hedta)(H_2O)] against pH at 315 nm.

compared with the values of $pK_1=2.32$ and $pK_2=9.12$ reported by Dwyer and Garvan.[17] Furthermore, the remarkable pH dependence of the CD spectra of the Rh(III) complex may be responsible for the formation of a sexidentate complex, $[Rh(edta)]^-$, in the intermediate pH region (pH=4—8), as has been suggested by Smith and Sawyer on the basis of their PMR study.[18] A similar interpretation should be applicable to the pH dependence of the CD spectra of the iridium(III) complexes, but further study is necessary to elucidate the nature of this observation.

The authors wish to thank Professor Iwao Taminaga of the Tokyo University of Commerce and Navigation for helping with the hydrothermal preparation of the iridium(III) complexes. We also would like to thank Professor Tatsujiro Ishimori of St. Paul's University for his helpful suggestions regarding the chemistry of ruthenium and rhodium.

The Stereochemistry and Reactivity of Metal-Schiff Base Complexes. III. The Kinetic and Thermodynamic Stereoselectivities in the Formation of *N,N'*-Ethylenebis(α-methylsalicylideneaminato)cobalt(III) Complexes with L-Proline, Hydroxy-L-proline, and *allo*-Hydroxy-L-proline

Yuki Fujii,* Katsuji Shiono, Kuniko Ezuka, and Takashi Isago
Department of Chemistry, Faculty of Science, Ibaraki University, Bunkyo-cho, Mito, Ibaraki 310
(Received March 25, 1980)

Under air-oxidation conditions, the reaction of [Co(α-Me-sal$_2$en)] with L-aaH, where α-Me-sal$_2$en represents the dianion of *N,N'*-ethylenebis(α-methylsalicylideneamine) and where L-aaH denotes L-proline, hydroxy-L-proline, or *allo*-hydroxy-L-proline, proceeded rapidly to yield *Λ-cis*-β_2-[Co(α-Me-sal$_2$en)(L-aa)] stereoselectively, followed by the slow isomerization of the *Λ-cis*-β_2-isomer thus formed to give the corresponding *Δ-cis*-β_2-isomer in a yield of almost 100% under equilibrium conditions. The complexes thus formed were isolated and characterized by the use of their absorption, circular dichroism, and ^{1}H-NMR spectra. The preferential formation of the *Λ-cis*-β_2-isomer in the initial reaction was found to be kinetic in origin. The kinetic stereoselectivity was determined to be 87% for L-proline, 56% for hydroxy-L-proline, and 23% for *allo*-hydroxy-L-proline by the measurement of the rotation at 435 nm of the reaction solutions. On the other hand, no kinetic differentiation was observed for the formation of the similar *cis*-β_2-complexes with L-alanine, L-valine, L-methionine, L-phenylalanine, L-tryptophan, *N*-benzyl-L-alanine, and *N*-methyl-L-alanine. On the basis of these data, the mechanism of the initial complexation was discussed. The high thermodynamic stereoselectivity for *Δ-cis*-β_2-isomer was explained in terms of the intramolecular steric interaction between the pyrrolidine ring of the coordinated L-aa and the distorted α-Me-sal$_2$en ligand in the complex.

The asymmetric reaction of metal complexes with chiral amino acid is an attractive problem, and many studies have been directed toward the stereoselectivity or stereospecificity of cobalt(III)–amino acid complexes. However, almost all of the asymmetric reactions reported have been those for the first-order[1-6] or second-order[7] transformations of the diastereoisomers thus formed. For the asymmetric reaction under kinetically controlled conditions, there are few studies, and no kinetic differentiation has been conclusively demonstrated for the formation of the diastereoisomers of cobalt(III) complexes containing chiral amino acid. A kinetic stereoselective formation of *Λ*-[Co(L-glu)(en)$_2$]$^+$ from racemic-[Co(CO_3)(en)$_2$]$^+$ and L-glutamic acid had been proposed by Gillard and his co-workers,[8-11] but subsequently disproven.[12,13] Kinetic differentiation has been claimed in the complexation of racemic-[Co(CO_3)(en)$_2$]$^+$ with the *N*-terminus of chiral peptides,[14] but no evidence has been presented to preclude a thermodynamic equilibrium upon the hydrolysis of the peptide linkage to produce *Λ*- and *Δ*-[Co(L-amino acidato)(en)$_2$]$^{2+}$. Little stereospecificity was found in the synthesis of β_2-[Co(L-pro)(trien)]$^{2+}$ from β-[Co(OH)(H_2O)(trien)]$^{2+}$ and L-proline under kinetically controlled conditions.[15,16] The selective formation of *Λ*-β_2-[Co(L-ala)(tetramine)]$^{2+}$ by the decarboxylation of the α-methyl-α-amino-malonato ligand (AMM) bound to the *Λ*-β_2-Co(tetramine)-complex should be kinetic in origin,[17,18] but it is a kind of ligand reaction of the coordinated AMM and not the direct complexation of chiral amino acid.

On the other hand, we have recently found that the reaction of [Co(α-Me-sal$_2$en)] with L-proline produces, stereoselectively, *Λ-cis*-β_2-[Co(α-Me-sal$_2$en)(L-pro)] under air-oxidation conditions, followed by the slow isomerization of the *Λ-cis*-β_2-isomer to give the corresponding *Δ-cis*-β_2-isomer in a high stereoselectivity (almost 100% at the equilibrium conditions).[19,20] This reaction is very interesting because 1) the preferential formation of the *Λ*-β_2-isomer in the initial reaction seems to be kinetic in origin, and 2) the stereoselectivity for the final product, the *Δ*-β_2-isomer, is quite high as compared with that for cobalt(III)-tetramine complexes with L-proline.[15,21-24] In this paper, the initial complexations between [Co(α-Me-sal$_2$en)] and various L-amino acids[25] are studied in detail, and the kinetic stereoselectivity in the formation of *Λ*- and *Δ-cis*-β_2-isomers of their complexes will be discussed, together with the formation mechanism. The high stereoselectivity for the *Δ*-β_2-isomer of the L-pro-complex will also be discussed from the stereochemical point of view.

Experimental

The Isolation of the Reaction Products. The starting material, [Co(α-Me-sal$_2$en)], was prepared by the method of Bigotto *et al.*[26]

(1) [Co(α-Me-sal$_2$en)(L-pro)]: In a previous communication,[19] methanol was used as the solvent for the reaction between [Co(α-Me-sal$_2$en)] and L-proline; however, in the present study a mixture of chloroform, methanol, and water was used as the solvent. This is mainly done to increase the solubilty of the reactants. L-Proline (1.4 g, 0.012 mol), in a mixed solvent of methanol (20 cm^3) and water (2 cm^3), was added to a chloroform solution (200 cm^3) of [Co(α-Me-sal$_2$en)] (3.7 g, 0.01 mol). The solution was stirred in the open air for about 15 min, until the color of the solution became green. The solution was then filtered to eliminate a trace amount of a brownish by-product.

(a) $(-)_{435}$-Product(2 : 1 Mixture of Λ- *and* Δ-cis-β_2-*Isomers)*: The green filtrate was concentrated as soon as possible to near dryness at room temperature. The green powder thus obtained was washed with a mixture of ether and methanol (9 : 1) and then air-dried. Yield, about 4.9 g (96%). Found:

C, 54.46; H, 6.29; N, 8.20%. Calcd for $CoC_{23}H_{26}N_3O_4 \cdot 2H_2O$: C, 54.87; H, 6.01; N, 8.34%. $[M]_{435} = -10700$ °m mol^{-1} dm^3 in chloroform. When the green product was dissolved in chloroform and the solution was concentrated to near dryness, a green powder with a $[M]_{435}$ value of $-10700°$ was obtained. Found: C, 54.35; H, 6.39; N, 8.25%. However, when this product was slowly recrystallized from methanol, green crystals with a plus rotation were obtained. Found: C, 54.72; H, 5.83; N, 8.31%. $[M]_{435} = +30500°$ in chloroform.

(b) $(\pm)_{435}$-Product (1 : 1 Mixture of Λ- and Δ-cis-β_2-Isomers): The green filtrate obtained above was stirred for a further 3—4 h and then slowly concentrated to a small volume at room temperature. The green powder so obtained was washed with a mixture of ether and methanol (9 : 1) and then air-dried. Yield, about 4.5 g. Found: C, 54.98; H, 5.89; N, 8.33%. Calcd for $CoC_{23}H_{26}N_3O_4 \cdot 2H_2O$: C, 54.87; H, 6.01; N, 8.34%. $[M]_{435} = -600°$ in chloroform. The $(\pm)_{435}$-product was sometimes obtained in the form of no-crystalline water, and the latter was scarcely soluble in various solvents. Found: C, 58.89; H, 5.74; N, 8.85%. Calcd for $CoC_{23}H_{26}N_3O_4$: C, 59.10; H, 5.61; N, 8.99%. When the soluble $(\pm)_{435}$-product was reprecipitated from chloroform by reducing the solution to near dryness, a green powder with $[M]_{435}$ value of $-600°$ (in chloroform) was obtained. However, when it was recrystallized from methanol, green crystals with a plus rotation ($[M]_{435} = +30500°$) were isolated.

(c) $(+)_{435}$-Product (Δ-cis-β_2-Isomer): The green filtrate obtained above was warmed for 1 d at about 40 °C, and then it was concentrated to a small volume. Green crystals with a plus rotation were thus obtained in about a 90% yield. Found: C, 54.98; H, 6.15; N, 8.51%. Calcd for $CoC_{23}H_{26}N_3O_4 \cdot 2H_2O$: C, 54.87; H, 6.01; N, 8.34%. $[M]_{435} = +30500°$ in chloroform.

(2) [Co(α-Me-sal$_2$en)(HO-L-pro)]: Hydroxy-L-proline (0.8 g, 6.1×10^{-3} mol), in a mixed solvent of water (3 cm^3) and methanol (25 cm^3), was added to a chloroform solution (150 cm^3) of [Co(α-Me-sal$_2$en)] (1.85 g, 5.0×10^{-3} mol). The solution was stirred in the open air for about 13 min. After a trace amount of hydroxy-L-proline had then been filtered off, the filtrate was concentrated to dryness as soon as possible at room temperature. A green powder (about 2.5 g) was thus obtained and was treated as follows.

(a) $(-)_{435}$-Product (3 : 2 Mixture of Λ- and Δ-cis-β_2-Isomers): The green powder (2.5 g) was partially dissolved in chloroform (70 cm^3), and the chloroform-soluble component was evaporated to dryness at room temperature. The green powder thus obtained was washed with ether and air-dried. Yield, about 0.3 g. Found: C, 52.92, H, 5.69; N, 7.92%. Calcd for $CoC_{23}H_{26}N_3O_5 \cdot 2H_2O$: C, 53.18; H, 5.82; N, 8.09%. $[M]_{435} = -7500°$ in chloroform.

(b) $(\pm)_{435}$-Product (1 : 1 Mixture of Λ- and Δ-cis-β_2-Isomers): The green powder (2.5 g) was dissolved in methanol (about 100 cm^3), and an equal volume of water was added. The solution was concentrated as soon as possible to a small volume at room temperature. Green crystals with a small rotation ($[M]_{435} = -700°$ in chloroform) were thus obtained in about a 70% yield. Found: C, 54.30; H, 5.91; N, 8.10%. Calcd for $CoC_{23}H_{26}N_3O_5 \cdot 1.5H_2O$: C, 54.12; H, 5.73; N, 8.23%.

(c) $(+)_{435}$-Product (Δ-cis-β_2-Isomer): The green powder (2.5 g) was dissolved in 200 cm^3 of methanol, and then water (20 cm^3) was added. The solution was heated at about 60 °C for 1 h, and then it was allowed to stand at room temperature for 1 d. Green crystals with a plus rotation ($[M]_{435} = +34000°$ in chloroform) were thus obtained in about an 80% yield. Found: C, 54.36; H, 5.90; N, 7.99%. Calcd for $CoC_{23}H_{26}N_3O_5 \cdot 1.5H_2O$: C, 54.12; H, 5.73; N, 8.23%.

(3) [Co(α-Me-sal$_2$en)(allo-HO-L-pro)]: *(a) $(\pm)_{435}$-Product (1 : 1 Mixture of Λ- and Δ-cis-β_2-Isomers)*: [Co(α-Me-sal$_2$en)] (0.7 g, 1.9×10^{-3} mol) was partially dissolved in chloroform (50 cm^3), and then *allo*-hydroxy-L-proline (0.25 g, 1.9×10^{-3} mol) in a mixed solvent of water (2 cm^3) and methanol (5 cm^3) was added. The mixture was stirred vigorously in the open air for about 15 min. After a trace amount of unreacted materials had been filtered off, the green solution was reduced as soon as possible nearly to dryness at room temperature. The green powder thus obtained was washed with ether and air-dried. Yield, about 0.9 g. Found: C, 50.80; H, 5.91; N, 7.65%. Calcd for $CoC_{23}H_{26}N_3O_5 \cdot 3.5H_2O$: C, 50.55; H, 6.09; N, 7.79%. $[M]_{435} = +600°$ in chloroform.

(b) $(+)_{435}$-Product (Δ-cis-β_2-Isomer): The $(\pm)_{435}$-product (0.5 g) obtained above was dissolved in methanol (100 cm^3) and then the solution was slowly concentrated to a small volume. Green crystals with a plus rotation ($[M]_{435} = +48000°$ in chloroform) were thus obtained in about a 70% yield. Found: C, 55.05; H, 5.58; N, 8.19%. Calcd for $CoC_{23}H_{26}N_3O_5 \cdot H_2O$: C, 55.09; H, 5.63; N, 8.38%.

Measurements. The electronic absorption spectra were recorded with a Hitachi EPS-3 Spectrophotometer at 23 °C. The CD spectra were measured with a JASCO J-20 Automatic Recording Spectropolarimeter at room temperature. The optical rotation at 435 nm was measured with a JASCO DIP-180 Automatic Polarimeter at 23 °C. The PMR spectra were recorded with a Hitachi R-20 Spectrometer (60 MHz) at 35 °C, using TMS as the internal reference. The solution for the measurement of the kinetic stereoselectivity was prepared as follows: an amino acid (5.5×10^{-5} mol) was dissolved in a mixed solvent (6 cm^3) of methanol and water (11 : 1 in volume), and this solution was added to a freshly prepared chloroform solution of [Co(α-Me-sal$_2$en)] (2.5×10^{-3} mol dm^{-3}, 20 cm^3). The solution was made up to 50 cm^3 with chloroform as soon as possible and stirred in the open air for 1 or 2 min. After this, the rotation at 435 nm and the absorption at 595 nm of the solution were measured.

Results and Discussion

The Isolation and Properties of the Reaction Products. When [Co(α-Me-sal$_2$en)] (orange in color) was allowed to react with L-proline under air-oxidation conditions, the reaction solution immediately became green in color and exhibited a minus rotation at 435 nm. After this, the absorption spectrum of the green solution scarcely varied any more; however, the rotation at 435 nm slowly increased to show a plus rotation under the equilibrium conditions. The time dependence of the absorption at 595 nm and the mutarotation at 435 nm for the reaction solution are shown in Fig. 1. In order to get informations about the above phenomena, the isolation of the reaction products was attempted. As has been mentioned in the Experimental section, depending upon the reaction time, three green complexes with different rotations could be isolated from the solution: the initial product with a minus rotation at 435 nm (represented by $(-)_{435}$-product), the second with almost no rotation ($(\pm)_{435}$-product), and the final product with a plus rotation ($(+)_{435}$-product). They all had the same composition, corresponding to [Co(α-Me-sal$_2$en)(pro)]$\cdot 2H_2O$.

Also from the reaction solutions of [Co(α-Me-sal$_2$en)] with hydroxy-L-proline and *allo*-hydroxy-L-proline, similar products were obtained. Since the properties

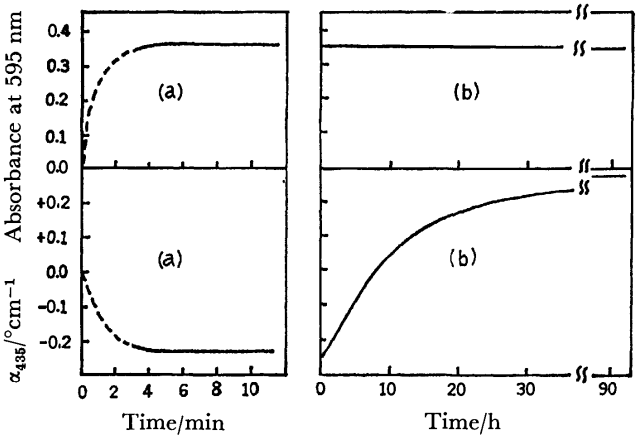

Fig. 1. The time dependences of the absorption (595 nm) and the rotation (435 nm) of the reaction solution between [Co(α-Me-sal$_2$en)] (1.0×10^{-3} M) and L-proline (1.1×10^{-3} M) in the mixed solvent of $CHCl_3$, CH_3OH, and H_2O (88: 11: 1 in volume).
Cell length: 1.0 cm, (a): those for the initial reaction solution, (b): those for full time.

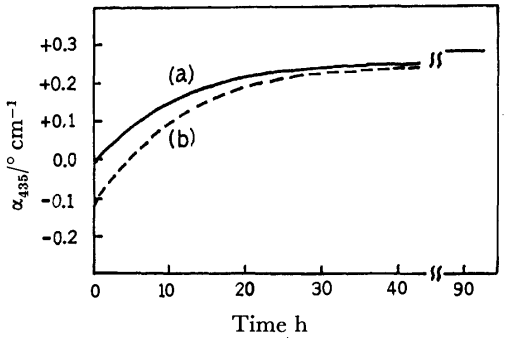

Fig. 2. The mutarotation of [Co(α-Me-sal$_2$en)(L-pro)] complex (1.0×10^{-3} M) in the mixed solvent of $CHCl_3$, CH_3OH, and H_2O (88: 11: 1 in volume).
Cell length: 1.0 cm, (a) (——): $(\pm)_{435}$-product, (b) (------): $(-)_{435}$-product.

of the L-pro-, HO-L-pro-, and *allo*-HO-L-pro-complexes resemble each other quite closely, the L-pro-complex will be used here for an example.

Both the $(-)_{435}$- and $(\pm)_{435}$-products of the L-pro-complex exhibited mutarotation in methanol or in a mixed solvent containing methanol, to show plus rotations under the equilibrium conditions, although the $(+)_{435}$-product showed no observable mutarotation. The mutarotation curves for both the $(-)_{435}$- and $(\pm)_{435}$-products are shown in Fig. 2. From both the equilibrated solutions, the $(+)_{435}$-product was isolated. As may be seen in Fig. 2, the mutarotation curves for both products are quite similar: the plots of $\ln(\alpha_\infty-\alpha_t)$ *vs.* the time for both mutarotation curves give straight lines with the same slope. Accordingly, it is clear that the $(-)_{435}$-product isomerizes to the $(+)_{435}$-product by way of the $(\pm)_{435}$-product. Since the mutarotation curve for the reaction solution of [Co(α-Me-sal$_2$en)] with L-proline in Fig. 1 closely resembles that for the $(-)_{435}$-product in Fig. 2, it can be concluded that the reaction between [Co(α-Me-sal$_2$en)] and L-proline produces $(-)_{435}$-[Co(α-Me-sal$_2$en)(L-pro)] preferentially, followed by its isomerization to give the corresponding $(+)_{435}$-isomer.

The rates of mutarotation for the $(-)_{435}$- and $(\pm)_{435}$-products depend strongly on the nature of the solvent: the rate is comparatively fast in methanol, but it is quite slow in chloroform. Therefore, the molar rotations of the $(-)_{435}$- and $(\pm)_{435}$-products scarcely varied between before and after their recrystallizations from chloroform.

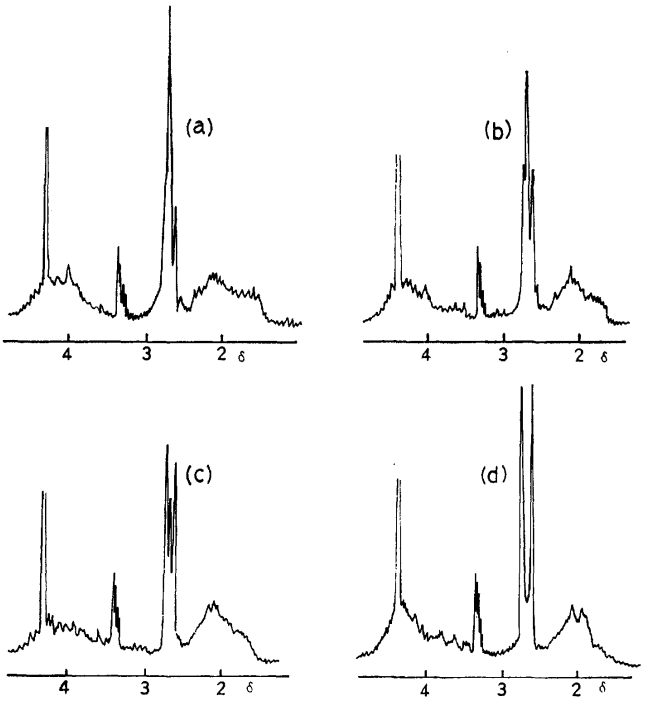

Fig. 3. The ^{1}H-NMR spectra of [Co(α-Me-sal$_2$en)-(L-pro)] complex in the mixed solvent of $CDCl_3$ and CD_3OD (4 : 1) at 35 °C.
(a): $(-)_{435}$-product, (b): $(\pm)_{435}$-product, (d): $(+)_{435}$-product. The ^{1}H-NMR spectra of $(-)_{435}$- and $(\pm)_{435}$-products exhibit time dependence. Those for $(-)_{435}$-product about 40 min and 240 min after dissolution correspond to (b) and (c), respectively, and that at the equilibrium conditions to (d). The ^{1}H-NMR spectra for $(\pm)_{435}$-product about 180 min after dissolution and at the equilibrium conditions correspond to (c) and (d), respectively.

Figure 3 shows the ^{1}H-NMR spectra of the isolated L-procomplexes soon after dissolution. The numerical data are listed in Table 1. The ^{1}H-NMR spectra of the $(-)_{435}$- and $(\pm)_{435}$-products each exhibited a clear time dependence in the methyl signal of the coordinated α-Me-sal$_2$en ligand, and each ^{1}H-NMR spectrum at the equilibrium conditions coincided with that of the $(+)_{435}$-product. However, the $(+)_{435}$-product showed no observable time dependence in its ^{1}H-NMR spectrum. From the time dependence of the methyl signal, the central peak at 2.76 ppm can safely be ascribed to $(-)_{435}$-[Co(α-Me-sal$_2$en)(L-pro)], and the two peaks with an equal intensity at 2.72 and 2.82 ppm, to $(+)_{435}$-[Co(α-Me-sal$_2$en)(L-pro)]. No other shoulders or peaks were observed in the methyl signal. These facts clearly

Table 2. Isomer ratios for the isolated products

Complex	Products	Λ-β_2-Isomer : Δ-β_2-Isomer
[Co(α-Me-sal$_2$en)-(L-pro)]	$(-)_{435}$-	6.6 : 3.3
	$(\pm)_{435}$-	5 : 5
	$(+)_{435}$-	0 : 10
[Co(α-Me-sal$_2$en)-(HO-L-pro)]	$(-)_{435}$-	6 : 4
	$(\pm)_{435}$-	5 : 5
	$(+)_{435}$-	0 : 10
[Co(α-Me-sal$_2$en)-(*allo*-HO-L-pro)]	$(\pm)_{435}$-	5 : 5
	$(+)_{435}$-	0 : 10

indicate that only two species are involved in the isomerization of the $(-)_{435}$- and $(\pm)_{435}$-products.

From the relative peak area of the methyl signal in the ^{1}H-NMR spectra of the isolated products soon after dissolution, the existing ratio between $(-)_{435}$- and $(+)_{435}$-isomers in each product can be estimated; the values are listed in Table 2. In the case of the L-pro-complex, it becomes clear that the $(-)_{435}$- and $(\pm)_{435}$-products are 2 : 1 and 1 : 1 mixtures of $(-)_{435}$- and $(+)_{435}$-[Co(α-Me-sal$_2$en)(L-pro)] respectively, but the $(+)_{435}$-product is the pure $(+)_{435}$-isomer of [Co(α-Me-sal$_2$en)(L-pro)]. Since the $(+)_{435}$-product shows no time dependence in its ^{1}H-NMR spectrum, its thermodynamic stereoselectivity can be concluded to be almost 100%.

Similar results have also been obtained for the HO-L-pro- and *allo*-HO-L-pro-complexes.

The Structure and the Thermodynamic Stereoselectivity of the Complexes. The electronic absorption (AB) and the circular dichroism (CD) spectra of the L-pro-complexes are shown in Fig. 4. The numerical data are listed in Table 3. The CD spectra of the $(-)_{435}$- and $(\pm)_{435}$-products for the L-proline varied gradually in methanol or in a mixed solvent containing methanol, and their CD spectra under the equilibrium conditions coincided with the CD spectrum of the $(+)_{435}$-product, although the variation in their AB spectra was negligibly small. Further, as may be seen in Fig. 4, an isosbestic point is observed at 21.4 k cm^{-1} in their CD spectra. These facts strongly support that only two species, $(-)_{435}$- and $(+)_{435}$-isomers of [Co(α-Me-sal$_2$en)(L-pro)], are involved in the mutarotation of the L-pro-complex. The CD spectrum of the $(+)_{435}$-product showed no observable time dependence.

The AB spectrum of the $(-)_{435}$-product closely resembles that of the $(+)_{435}$-product, and the CD spectrum of the $(-)_{435}$-product is quite similar to that of the $(+)_{435}$-product, except for the reversed CD sign. Therefore, it seems that the $(-)_{435}$- and $(+)_{435}$-isomers take the same geometrical structure with respect to the coordinated atoms. The AB and CD spectra of the $(+)_{435}$-product closely resemble those of $(-)_{435}$-*Λ-cis-*β_2-[Co(α-Me-sal$_2$en)(L-ileu)]·1.5H$_2$O,[3,20] except for the reversed CD sign. Accordingly, the *Δ-cis-*β_2-structure can be assigned to the $(+)_{435}$-isomer of [Co(α-Me-sal$_2$en)(L-pro)], and the *Λ-cis-*β_2-structure, to the $(-)_{435}$-isomer.

Similar results have also been obtained for the HO-L-pro- and *allo*-HO-L-pro-complexes.

Generally, the stereoselectivity under the equilibrium conditions is thermodynamic in origin. The Co(α-Me-sal$_2$en)-complexes with L-pro, HO-L-pro, and *allo*-HO-

a) Soon after dissolution in a mixed solvent of $CHCl_3$+MeOH+H_2O (88 : 11 : 1 in volume).

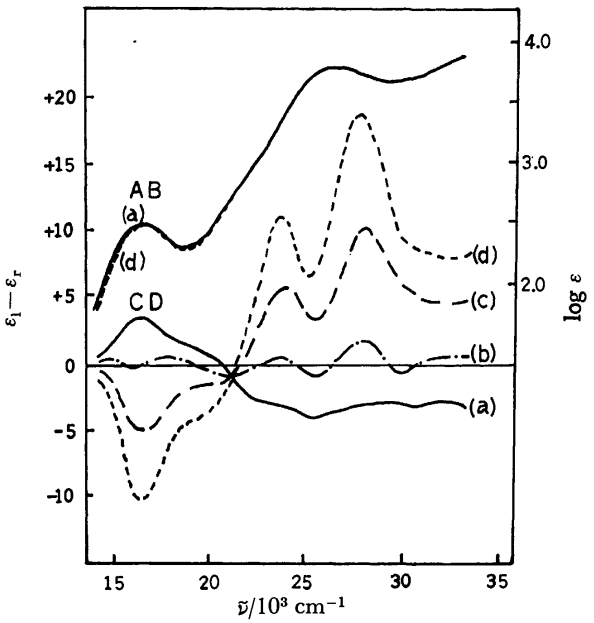

Fig. 4. The AB and CD spectra of [Co(α-Me-sal$_2$en)-(L-pro)] complex in the mixed solvent of $CHCl_3$, CH_3OH, and H_2O (88: 11: 1 in volume) at room temperature.
(a) (——): $(-)_{435}$-product, (b) (-·-·-): $(\pm)_{435}$-product, (d) (----): $(+)_{435}$-product. The CD spectra of $(-)_{435}$- and $(\pm)_{435}$-products exhibit time dependence. Those for $(-)_{435}$-product about 4 and 16 h after dissolution correspond to (b) and (c), respectively, and that at the equilibrium conditions to (d). The CD spectra for $(\pm)_{435}$-product about 12 h after dissolution and at the equilibrium conditions correspond to (c) and (d), respectively.

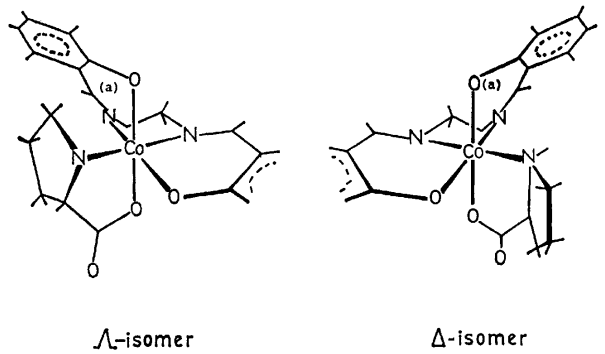

Fig. 5. The steric structure of *Λ-cis-*β_2- and *Δ-cis-*β_2-isomers of [Co(α-Me-sal$_2$en)(L-pro)] complex.

L-pro take the *Λ-cis-*β_2-structure almost always under the equilibrium conditions, as has been mentioned above. This implies that the *Δ-cis-*β_2-isomer is more stable than the corresponding *Λ-cis-*β_2-isomer at about 11.3 kJ mol^{-1} ($-\Delta G$ value of 1 : 100 equilibrium mixture) or more in each complex. On the other hand, in the cases of $[Co(en)_2(L\text{-pro})]^{2+}$ and β_2-$[Co(trien)(L\text{-pro})]^{2+}$, although they favor the *Δ*-configuration, the ratio between the *Δ*- and *Λ*-isomers under the equilibrium conditions is about 3 : 1 ($\Delta G = -2.7$ kJ mol^{-1}) in both complexes. From these facts, it can be said that the stereoselectivity of the Co(α-Me-sal$_2$en)-complexes is much higher than that of the Co(tetramine)-complexes. This high thermodynamic stereoselectivity of the Co(α-Me-sal$_2$en)-complexes comes from the characteristic steric structure of the coordinated α-Me-sal$_2$en ligand. As is shown in Fig. 5, when it takes the *cis-β*-configuration, a chelate ring (a) inclines toward the

side of the coordinated amino acid about 30° from the N–Co–O plane of (a).[3,20] In the case of the L-pro-complex, the molecular model suggests that this inclination of the chelate ring (a) brings about an extreme steric closeness (1.4—1.6 Å) between the distorted chelate ring (a) and the pyrrolidine ring of the L-proline when it has the *Λ-cis-*β_2-structure. However, when it has the *Δ-cis-*β_2-structure, there is no abnormal closeness between them. In the case of the *Δ-cis-*β_2-structure, the pyrrolidine ring somewhat approaches the two phenolic oxygen atoms of α-Me-sal$_2$en (about 2.5 Å), but the steric repulsion in the *Δ-cis-*β_2-structure seems to be much weaker than that between the pyrrolidine ring and the chelate ring (a) in the *Λ-cis-*β_2-structure. Thus, the *Δ-cis-*β_2-structure may be favored under equilibrium conditions.

In the cases of the HO-L-pro- and *allo*-HO-L-pro-complexes, their molecular models indicate that the hydroxy group on each pyrrolidine ring brings about no intramolecular steric interaction with the coordinated α-Me-sal$_2$en ligand, whether it has the *Λ-* or *Δ-cis-*β_2-structure. Therefore, they may also favor the *Δ-cis-*β_2-structure almost always, as is observed in the L-pro-complex.

Kinetic Stereoselectivity. In spite of the thermodynamic advantage of the *Δ-cis-*β_2-structure, the initial reaction between [Co(α-Me-sal$_2$en)] and L-proline produced the thermally unstable *Λ-cis-*β_2-isomer of [Co(α-Me-sal$_2$en)(L-pro)] preferentially. This fact can be explained only when the kinetic advantage in the formation of *Λ-cis-*β_2-isomer is considered. In fact, it has been observed in another of our experiments that the formation rate of *Λ-cis-*β_2-[Co(sal$_2$-(*S,S*)-chxn)(L-pro)] from [Co(sal$_2$-(*S,S*)-chxn)] and L-proline is much faster than that of *Δ-cis-*β_2-[Co(sal$_2$-(*R,R*)-chxn)(L-pro)] from [Co(sal$_2$-(*R,R*)-chxn)] and L-proline, where sal$_2$chxn represents the dianion of *N,N'*-1,2-cyclohexylenebis(salicylideneamine).[4,27] Hence, the initial formation of the *Λ-cis-*β_2-isomer for the Co(α-Me-sal$_2$en)-complex can be regarded as a kinetically controlled reaction. Here, the initial complexations between [Co(α-Me-sal$_2$en)] and various L-amino acids were studied in detail in order to estimate the values of the kinetic stereoselectivity for their reactions. In order to follow the initial reactions, a mixture of chloroform, methanol, and water (88 : 11 : 1 in volume) was used as the solvent. This solvent is used mainly because it will increase the solubiltiy of the reactants, but also partly because it will slow the isomerization rate of the formed complexes. Since the manner of the reactions is quite similar for all the amino acids investigated here, the reactions with L-proline and L-phenylalanine will be given as examples.

Figure 6 shows the absorption spectra of the complexes before and after the reaction. Figure 7 shows the time dependence of the absorbance at 595 nm and the mutarotation at 435 nm of the reaction solution with L-phenylalanine; those for L-proline are shown in Fig. 1. In each case, the absorbance became constant within a few minutes after the initiation of the reaction, and the absorption spectra a few minutes after the initiation of the reaction closely resembled those under equilibrium

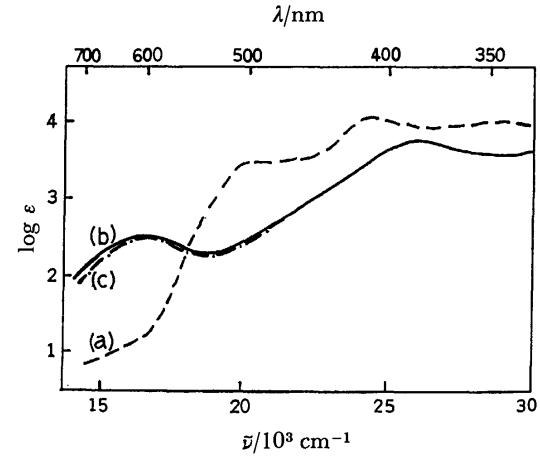

Fig. 6. The absorption spectra of [Co(α-Me-sal$_2$en)] in chloroform (1.0×10^{-3} M) and of the reaction solution between [Co(α-Me-sal$_2$en)] (1.0×10^{-3} M) and L-proline (1.1×10^{-3} M) in the mixed solvent of $CHCl_3$, CH_3OH, and H_2O (88: 11: 1 in volume).

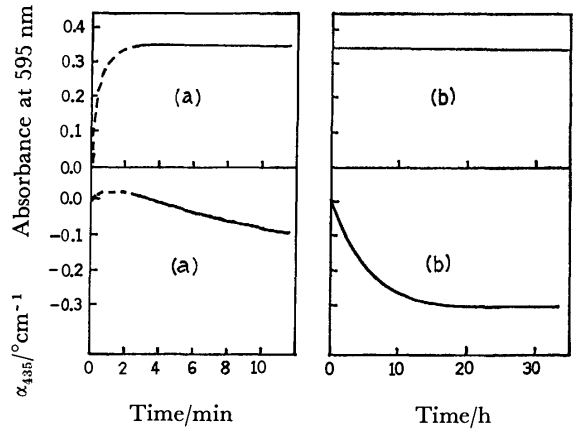

Fig. 7. The time dependences of the absorption (595 nm) and the rotation (435 nm) of the reaction solution between [Co(α-Me-sal$_2$en)] (1.0×10^{-3} M) and L-phenylalanine (1.1×10^{-3} M) in the same solvent with that in Fig. 1.
(a) : Those for the initial reaction solution, (b) : those for full time.

conditions. Further, the absorption spectrum under equilibrium conditions coincided with that of the corresponding complex, *cis-*β_2-[Co(α-Me-sal$_2$en)(L-pro)] or *cis-*β_2-[Co(α-Me-sal$_2$en)(L-phe)].[3,20] From these facts, it is concluded that the complexation of [Co(α-Me-sal$_2$en)] with L-amino acid proceeds quite rapidly under air-oxidation conditions to form *cis-*β_2-[Co(α-Me-sal$_2$en)-(L-aa)] quantitatively.

The plots of $\ln|\alpha_\infty-\alpha_t|$ *vs.* the time for each mutarotation gave a straight line, and the slope coincided with the observed isomerization rate constant between the *Λ-* and *Δ-cis-*β_2-isomers of the corresponding complex (see Table 4). Accordingly, the mutarotation of each reaction solution can safely be ascribed to the isomerization of the *cis-*β_2-complex formed between the *Λ-* and *Δ-*isomers. As is shown in Fig. 7 and Table 4, the

initial rotation of the reaction solution for L-phenylalanine is very small, and it is nearly identical with that of the 1 : 1 mixture of *Λ*- and *Δ*-*cis*-β_2-[Co(α-Me-sal$_2$en)(L-phe)]. Therefore, it is concluded, for L-phenylalanine, that the formation ratio between the *Λ*- and *Δ*-*cis*-β_2-isomers in the initial complexation is about 1 : 1; the kinetic stereoselectivity is estimated to be nearly zero. Similar results have also been obtained for L-ala, L-val, L-met, L-ileu, and L-trp. In the cases of *N*-benzyl-L-ala and *N*-methyl-L-ala, since the rotations of their initial reaction solutions are also very small, their kinetic stereoselectivities are both estimated to be almost zero, although four *cis*-β_2-isomers are possible in the *N*-alkyl-amino acidato complex.

On the other hand, in the cases of L-pro, HO-L-pro, and *allo*-HO-L-pro, each reaction solution initially exhibited a large minus rotation. Since the rotations of the free amino acids were negligibly small under the experimental conditions employed (1×10^{-3} mol dm^{-3}), it is clear that the large minus rotation of each reaction solution comes from the $(-)_{435}$-isomer of the formed complex. Generally, the vicinal effect of the coordinated chiral amino acid is additive in nature. In the cases of the L-pro-, HO-L-pro-, and *allo*-HO-L-pro-complexes, it can be regarded that the rotation of each $(\pm)_{435}$-product corresponds to the vicinal effect of each L-amino acid, because the $(\pm)_{435}$-product is a 1 : 1 mixture of the *Λ*- and *Λ*-*cis*-β_2-isomers of the corresponding L-amino acidato complex. Therefore, the kinetic stereoselectivity for these complexes can be estimated by the use of the following equation:

$$\{([\Lambda]-[\Delta])/([\Lambda]+[\Delta])\}\times100(\%) = |([M]^{A}_{435}-[M]^{B}_{435})/([M]^{C}_{435}-[M]^{B}_{435})|\times100$$

where $[\Lambda]$ and $[\Delta]$ represent the concentrations of the *Λ*- and *Λ*-*cis*-β_2-isomers of the formed complex respectively; $[M]^{A}_{435}$ and $[M]^{C}_{435}$ represent the molar rotations at 435 nm of the complexes in the initial reaction solution (A) and in the equilibrium reaction solution (C) respectively, $[M]^{C}_{435}$ corresponds to the molar rotation of the $(+)_{435}$-isomer, and $[M]^{B}_{435}$ indicates the molar rotation of the $(\pm)_{435}$-product. The estimated values are listed in Table 5. Figure 8 shows the CD spectra for the reaction solutions of L-pro and *allo*-HO-L-pro. From these CD spectra, it is confirmed that: 1) the CD spectrum for the initial reaction solution of L-pro and that for the $(+)_{435}$-*Λ*-*cis*-β_2-isomer of the L-pro-complex are almost mirror images of each other; 2) the *Λ*-*cis*-β_2-isomer is formed with a high kinetic stereoselectivity; 3) the CD-intensity of the initial reaction solution for *allo*-HO-L-pro is much smaller than that for L-pro, while the kinetic stereoselectivity for the *allo*-HO-L-pro-complex is much lower than that for L-pro-complex, and 4) the CD spectrum of the reaction solution under equilibrium conditions coincides with that of the $(+)_{435}$-isomer of the corresponding isolated complex.

TABLE 5. KINETIC STEREOSELECTIVITY IN THE FORMATION OF *Λ*- AND *Δ*-*cis*-β_2-[Co(α-Me-sal$_2$en)(L-aa)]

Amino acid[25]	$([\Lambda]-[\Delta])/([\Lambda]+[\Delta])\times100(\%)$
L-ala, L-val, L-met L-ileu, L-phe, L-trp	≈0
N-benzyl-L-ala, *N*-methyl-L-ala	≈0
L-pro	87
HO-L-pro	56
allo-HO-L-pro	23

From these results and discussion, it can be concluded that 1) the kinetic differentiation in the formation of the *Λ*- and *Λ*-*cis*-β_2-diastereoisomers is characteristic of

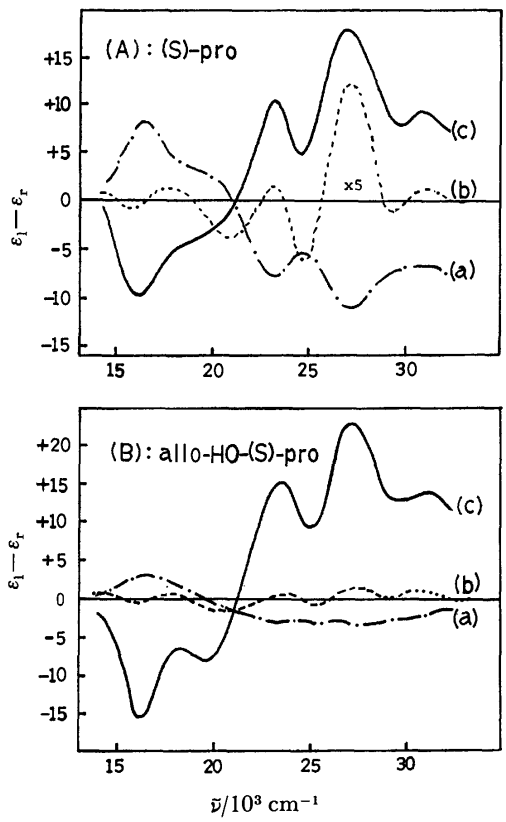

Fig. 8. The CD spectra of the reaction solutions of [Co(α-Me-sal$_2$en)] with L-proline (A) and *allo*-OH-L-proline (B) in the same solvent with that in Fig. 1. The reaction molar ratio=1 : 1.1.

the amino acids with a pyrrolidine ring, but 2) the kinetic stereoselectivity decreases in the order of: L-pro>HO-L-pro>*allo*-HO-L-pro.

The Reaction Mechanism. As has been mentioned above, the reaction between [Co(α-Me-sal$_2$en)] and L-amino acid under air-oxidation conditions proceeded quite rapidly to form *cis*-β_2-[Co(α-Me-sal$_2$en)(L-aa)] quantitatively. However, no reaction occurred under nitrogen. When the L-amino acid neutralized with LiOH was used, the formation of [Co(α-Me-sal$_2$en)-(L-aa)] was rather slow. Further, the rate of the air oxidation of [Co(α-Me-sal$_2$en)] was quite slow in the absence of L-amino acid. On the other hand, it is well known that the planar Co(II)–Schiff base complexes adsorp O_2 to give [Co(Schiff base)(O_2)] or [Co(Schiff base)]$_2O_2$.[28,29] Further, in the presence of a base, *trans*-[Co(Schiff base)(O_2)(Base)][30,31] and *trans*-[Co(Schiff base)(Base)$_2$][+][26,32] are formed. Thus, the formation reaction of [Co(α-Me-sal$_2$en)(L-aa)] from [Co(α-Me-sal$_2$en)] and L-aaH by air-oxidation can be thought to proceed as follows:

$$[\text{Co}(\alpha\text{-Me-sal}_2\text{en})] + O_2 + {}^-\text{OOC-CHR-NH}_3^+ \longrightarrow \textit{trans}\text{-}[\text{Co}(\alpha\text{-Me-sal}_2\text{en})(O_2)(\text{OOC-CHR-NH}_3^+)] \quad (1)$$

$$\textit{trans}\text{-}[\text{Co}(\alpha\text{-Me-sal}_2\text{en})(O_2)(\text{OOC-CHR-NH}_3^+)] \longrightarrow \textit{cis}\text{-}\beta_2\text{-}[\text{Co}(\alpha\text{-Me-sal}_2\text{en})(\text{OOC}\diagdown\diagup\text{NH}_2\text{CHR})] + HO_2. \quad (2)$$

The first reaction (1) is the formation of the O_2-adduct in the presence of amino acid. Since the amino acid exists as a zwitter-ion in solution, here it may coordinate to cobalt, with its carboxylato group as a unidentate ligand. The second reaction (2) is the chelation of the unidentate amino acid, which includes the deprotonation from the ammonium group of amino acid and the subsequent coordination of the amino group to the central cobalt ion, with the departure of O_2 from the O_2-adduct as O_2^- or HO_2.

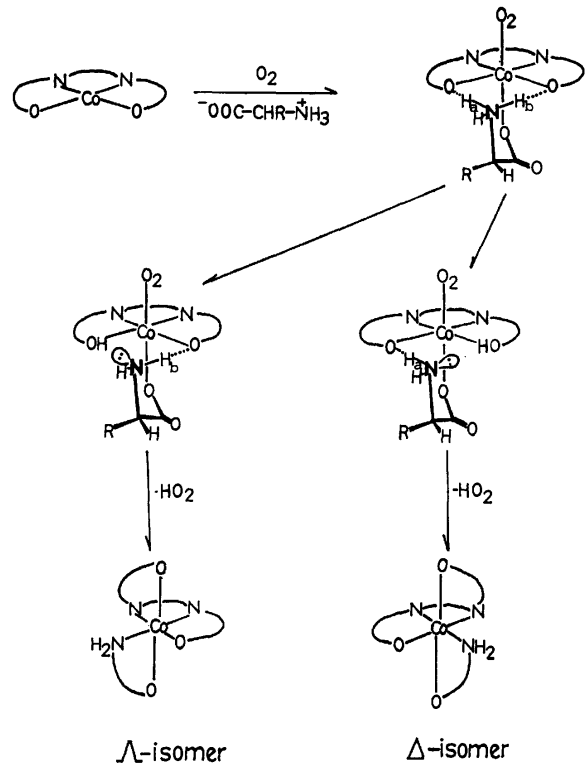

Fig. 9. The proposed reaction mechanism for the formation of *cis*-β_2-[Co(α-Me-sal$_2$en)(L-aa)] complex from [Co(α-Me-sal$_2$en)] and L-aaH under air-oxidation conditions.

In the intermediate, [Co(α-Me-sal$_2$en)(O_2)(OOC-CHR-NH_3^+)], the ammonium group of the amino acid has a positive charge and the phenolic oxygen atoms of the coordinated α-Me-sal$_2$en ligand have a negative charge. Thus, a hydrogen bonding can be expected to exist between them. Further, it has been reported recently that the phenolic oxygen atoms act as proton acceptors.[33] Accordingly, the deprotonation in Reaction (2) may take place by the transfer of one of the protons on the ammonium group to one of the phenolic oxygen atoms through the hydrogen bonding. A plausible reaction mechanism is shown in Fig. 9. In order to explain the kinetic stereoselectivities for various amino acids in Table 5, it is assumed in this mechanism that, when H_a in Fig. 9 is deprotonated, the *Λ-cis*-β_2-isomer is

produced, but when H_b is deprotonated, the *Δ-cis-*β_2-isomer is formed.

In the cases of such amino acids as L-ala, L-phe, and L-ileu, the molecular models indicate that the two protons, H_a and H_b, are sterically equivalent in the intermediate, [Co(α-Me-sal$_2$en)(O_2)(OOC–CHR–NH_3^+)]. This corresponds to the finding that the probability of the deprotonation of H_a and H_b is 50 : 50; the formation ratio between *Λ-* and *Δ-cis-*β_2-isomers is 1 : 1. In fact, as may be seen in Table 5, the kinetic stereoselectivity for such amino acids complexes as L-ala, L-phe, and L-ileu is nearly zero.

In the case of L-pro, the two protons are not equivalent, because L-proline can coordinate as a chelating ligand only when the configuration of the nitrogen atom is in the (*S*)-form. That is, only the deprotonation of H_a is effective in the chelation of L-proline. Therefore, the *Λ-cis-*β_2-isomer may be formed preferentially in the case of the L-pro-complex. On the other hand, in the case of HO-L-pro, because of the equatorial orientation of the hydroxyl group, the conformation of the pyrrolidine ring is not the same as that of L-pro. Hence, the intermediate of the HO–L-pro-complex is not able to take the same hydrogen-bonding structure as that of the L-pro-complex. The most plausible hydrogen bonding in the HO-L-pro-complex is shown in Fig. 10, together with that of the L-pro-complex. In the case of the HO-L-pro-complex, the proton, H_a in Fig. 10, can transfer either of the two phenolic oxygen atoms. Thus, the kinetic stereoselectivity becomes lower than that for the L-pro-complex. In the case of *allo*-HO-L-pro, as is shown in Fig. 11, since an intramolecular hydrogen bonding between the hydroxyl group and the carboxylato group is possible, its pyrrolidine ring takes the same conformation as that for the HO-L-pro-complex. Therefore, the kinetic stereoselectivity for the *allo*-HO-L-pro-complex may become much lower than that for the L-pro-complex.

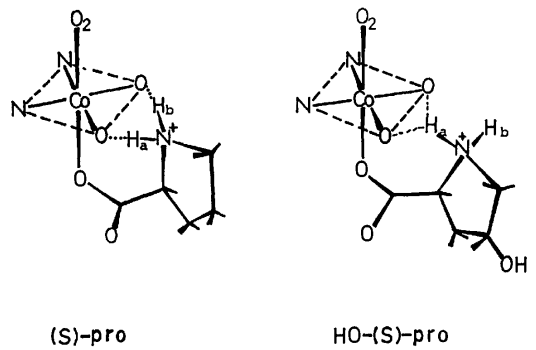

Fig. 10. The hydrogen bonding structure of the reaction intermediates for L-proline and HO-L-proline.

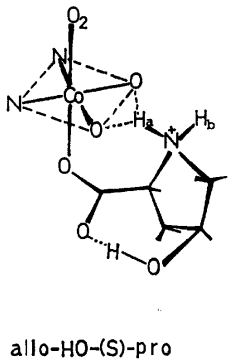

Fig. 11. The proposed structure of the reaction intermediate for *allo*-HO-L-proline.

Regarding the isomerization mechanism between *Λ-* and *Δ-cis-*β_2-isomers, a study is now underway; we have already obtained the reliable experimental result that the isomerization proceeds through a five-coordinated intermediate, [Co(α-Me-sal$_2$en)(OOC–CHR–NH_2)]. This study will be reported in the near future.

The authors wish to express their deep thanks to Professor J. Hidaka of Tsukuba University and to Professor K. Sone and Dr. Y. Fukuda of Ochanomizu University for their kind assistance in the CD spectral measurements. Configurations of Solvated Complex Ions of First Transition Metals in Hexamethylphosphoric Triamide as Inferred from Their Absorption Spectra and Stokes Radii

Yuriko ABE* and Goro WADA
Department of Chemistry, Nara Women's University, Nara 630
(Received April 10, 1980)

The absorption spectra and Stokes radii of solvated complex ions of first transition metals (Mn(II), Fe(II), Co(II), Ni(II), Cu(II), and Zn(II)) were observed in hexamethylphosphoric triamide (HMPA) in order to determine their configurations. It seems that the Stokes radii of complex ions are sensitive to the configurational change, since the diameter of an HMPA molecule is very large as compared with the crystallographic diameters of central metal ions. As to the result, metal ions are tetrahedrally solvated in the cases of Mn(II), Fe(II), Co(II), and Cu(II), while in the case of Ni(II), equilibria are established among octahedral, square planar and tetrahedral solvated species. Zn(II) forms probably a complex ion solvated octahedrally by HMPA.

Syntheses of the transition metal complexes with hexamethylphosphoric triamide (HMPA), and their solid state stereochemistries have been investigated by many workers.[1] In these solid complexes HMPA tends to form tetrahedral configuration around metal ions, when anions such as ClO_4^-, $B(C_6H_5)_4^-$, SCN^-, NO_3^-, SO_4^{2-}, and halide ions, are outside of the coordination sphere, or when some of them are in the coordination sphere as unidentate ligands.[1-4] But when metal ions are coordinated with anions such as NO_3^-, SO_4^{2-}, and CH_3COO^- ions as multidentate ligands, octahedral or square planar configurations are mostly preferred according to the nature of metal ions.[1,4] On the other hand, in nitromethane solution,[2,3,5] the complexes $[M^{II}(hmpa)_4](ClO_4)_2$ formed are mostly tetrahedral when M^{II} is Mn^{II}, Fe^{II}, Co^{II}, Cu^{II}, or Zn^{II}, but not so when it is Ni^{II}.

In HMPA solutions, the stereochemistry of the solvated complex ions of the first transition metals has not been reported yet except for the case of Co(II).[6] In the present study, the absorption spectra and Stokes radii of solvated complex ions of the first transition metals in HMPA were observed in order to determine their configurations. It seems that the Stokes radii are sensitive to the configurational change of solvated complex ions, since the diameter of an HMPA molecule is very large as compared with the crystallographic radii of the central metal ions.

Experimental

Materials. Commercial HMPA of guaranteed reagent grade was distilled under a reduced nitrogen atmosphere of 3 mmHg at 70—80 °C after it had been dried over barium oxide and a small amount of peroxide accidentally contained in HMPA had been decomposed by iron(II) chloride. The distilled HMPA was deoxygenated by passing nitrogen, and then stored in a dark and cool room. Nitromethane was dried over calcium chloride and distilled under atmospheric pressure. Complexes of various metal ions $[M^{II}(hmpa)_4](ClO_4)_2$ ($M^{II}=Mn^{II}$, Fe^{II}, Co^{II}, Ni^{II}, Cu^{II}, or Zn^{II}) were synthesized according to the methods reported by Donoghue and Drago.[2,3] Stock solutions of these metal complexes were prepared, and portions of them were used for the spectrophotometric or conductivity determinations. Anhydrous sodium perchlorate was prepared by heating monohydrous salt which had been recrystallized twice from water.

Procedure. For the determination of absorption spectra, a Hitachi Recording Spectrophotometer Model EPS-3T was used with a thermostated cell. The metal ion concentrations in stock solutions were determined spectrophotometrically by the following methods; Mn(II): formaldoxime method[7] (molar absorptivity $\varepsilon=1.040\times10^4$ M^{-1} cm^{-1} at 450 nm); Fe(II): 2,2'-bipyridine method[8] ($\varepsilon=9.205\times10^3$ M^{-1} cm^{-1} at 522 nm); Co(II): nitroso-R salt method[8] ($\varepsilon=9.350\times10^3$ M^{-1} cm^{-1} at 550 nm); Ni(II): dimethylglyoxime method[8] ($\varepsilon=1.457\times10^4$ M^{-1} cm^{-1} at 450 nm); Cu(II): sodium diethyldithiocarbamate method[8] ($\varepsilon=9.223\times10^3$ M^{-1} cm^{-1} at 430 nm); Zn(II): zincone method[7] ($\varepsilon=2.341\times10^4$ M^{-1} cm^{-1} at 620 nm). (1 M = 1 mol dm^{-3}.)

The measurements of electric conductivities of HMPA solutions containing complex ions were performed with a Yanagimoto Conductivity Apparatus Model MY-8. The cell used was calibrated with a 0.01 M aqueous KCl solution.

complex perchlorates in HMPA (Λ) against the square roots of the equivalent concentrations ($\sqrt{c}$) give straight lines with negative slopes as shown in Fig. 4. Consequently, Eq. 1 holds for these salts;

$$\Lambda = \Lambda_0 - k\sqrt{c}, \tag{1}$$

where Λ_0 is a limiting equivalent conductivity and k is an empirical constant. The limiting equivalent ionic conductivity of a solvated cation (λ_0^+) is obtained by subtracting that of perchlorate ion ($\lambda_0^-=15.5$ cm² Ω^{-1} eq.$^{-1}$)[9] from Λ_0. Then, the Stokes radius of the solvated cation (r^+) can be calculated by Eq. 2:

$$r^+ = \frac{0.82|z|}{\lambda_0^+\eta} \tag{2}$$

where η is the viscosity of HMPA ($\eta=0.0323$ poise at 25 °C)[10,11] and z is the number of electric charges on the solvated cation ($z=2$). The values of Λ_0, λ_0^+, and r^+ thus obtained are listed in Table 1.

Table 1. Limiting equivalent conductivities and Stokes radii of solvated metal ions in HMPA at 25 °C

Ion	Λ_0[a] / cm² Ω^{-1} eq.$^{-1}$	λ_0^+ / cm² Ω^{-1} eq.$^{-1}$	Stokes radius r^+ / Å

Discussion

Configuration of Solvated Co^{2+} Ion in HMPA. In Fig. 1 are shown the absorption spectra of solvated Co^{2+} ion in pure HMPA (Curve A) and of $[Co(hmpa)_4]^{2+}$ in nitromethane at $[[Co(hmpa)_4]^{2+}]=8.0\times10^{-4}$ M and $[HMPA]_0=0.5$ M (Curve B). The

latter absorption spectrum is in good agreement with that obtained in nitromethane by Donoghue and Drago,[2] which is also shown (Curve C) in Fig. 1. These three spectral patterns are similar to that of the solid reflectance spectrum of $[Co(hmpa)_4](ClO_4)_2$ (Curve D), which was reported to be tetrahedral.[2] Therefore, it can be reasonably deduced that the solvated Co^{2+} ion in HMPA is regularly tetrahedral.

In general,[12] the absorption bands due to $\nu_2(^4T_1(F)\leftarrow{}^4A_2)$ and $\nu_3(^4T_1(P)\leftarrow{}^4A_2)$ transitions of tetrahedral cobalt(II) complexes appear in the near-infrared and visible regions, respectively. The molar absorptivities of these bands are of the magnitude of 10—100 M^{-1} cm^{-1} for ν_2 and 100—2000 M^{-1} cm^{-1} for ν_3, respectively. But bands of octahedral cobalt(II) complexes such as $[Co(H_2O)_6]^{2+}$, $[Co(dmso)_6]^{2+}$, $[Co(pyo)_6]^{2+}$ (pyo= pyridine oxide), and $[Co(NH_3)_6]^{2+}$ are observed in the visible region near 500 nm (ε=5—40 M^{-1} cm^{-1}). These bands allow a fairly clear-cut distinction between tetrahedral and octahedral cobalt(II) complexes. Thus, the characteristics of the absorption spectrum of solvated Co^{2+} ion in HMPA coincide with those of the tetrahedral Co(II) complexes. Moreover, the absorption spectrum in HMPA is not affected by temperature. Therefore, it is deduced that no tetrahedral↔octahedral configurational transition of the complex ion exists. Accordingly, it is concluded that the only solvated Co^{2+} ion in HMPA is the tetrahedral $[Co(hmpa)_4]^{2+}$ ion.

The conductivity measurements of HMPA solutions containing $[Co(hmpa)_4]^{2+}$ in the concentration range 10^{-5}—10^{-3} M give the linear relationships as shown in Fig. 4. This shows clearly that $[Co(hmpa)_4]^{2+}$ in HMPA forms no ion-pair, because no deviation from the linearity is seen to occur. The perchlorates $[M^{II}(hmpa)_4](ClO_4)_2$ of other first transition metals also dissociate completely in HMPA.

The value of the Stokes radius (r^+) of tetrahedral $[Co(hmpa)_4]^{2+}$ ion was found to be 5.03 Å. Since an HMPA molecule coordinated to a divalent metal ion is very bulky as compared with the central metal ion, small differences of the crystallographic radii among the divalent metal ions would have little influence on the Stokes radii of the complexes $[M^{II}(hmpa)_4]^{2+}$. Accordingly, when HMPA molecules are tetrahedrally coordinated to the metal ions, it will be reasonable to assume that the values of their Stokes radii are all about 5 Å, irrespective of the kind of the central metal ions.

Configuration of Solvated Ni^{2+} Ion in HMPA. Figure 2 shows the temperature dependence of the absorption spectra of solvated Ni^{2+} ion in HMPA. The spectral change is no longer observed above 60 °C and the final spectrum agrees very closely with that of the solid reflectance spectrum of the tetrahedral $[Ni(hmpa)_4](ClO_4)_2$.[2] Since an isosbestic point appears at 490 nm above 20 °C, the solvated Ni^{2+} ion is supposed to be in equilibrium between two different configurations in HMPA. At 60—70 °C, the solvated Ni^{2+} ions are completely tetrahedral. Below 20 °C, the spectra do not pass through the isosbestic point which appears above 20 °C but approach to that of the octahedral $[Ni(dmso)_6]^{2+}$.[12] Accordingly, the following equilibria seem to exist.

$$\underset{\text{octahedral}}{[Ni(hmpa)_6]^{2+}} \overset{K_2}{\rightleftharpoons} \underset{\text{square planar}}{[Ni(hmpa)_4]^{2+}} \overset{K_1}{\rightleftharpoons} \underset{\text{tetrahedral}}{[Ni(hmpa)_4]^{2+}} \quad (3)$$

The value of ΔH_1 of the reaction from the square planar to tetrahedral configuration is obtained by Eq. 4;

$$\frac{d \ln K_1}{d\ T^{-1}} = d \ln \frac{c\Delta\varepsilon - \Delta A}{\Delta A} \Big/ d\ T^{-1} = -\frac{\Delta H_1}{R} \quad (4)$$

$$\Delta\varepsilon = \varepsilon_t^{633} - \varepsilon_p^{633}$$

$$\Delta A = A_t - A$$

in which ε_t^{633}(=106 M^{-1} cm^{-1}) and ε_p^{633} stand for the molar absorptivities of the tetrahedral and square planar complexes at 633 nm, respectively, A_t and A are absorbances at 60—70 °C and at a certain temperature between 20 °C and 60 °C at 633 nm, respectively, and c is total concentration of Ni(II).

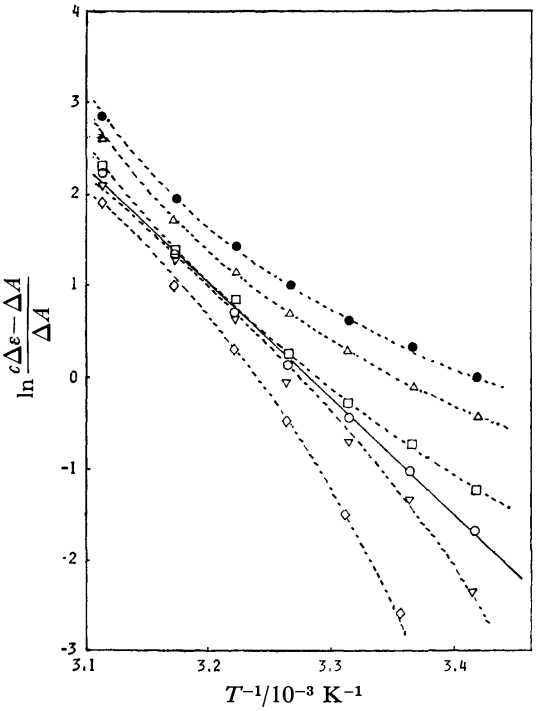

Fig. 5. The plots of $\ln\frac{c\Delta\varepsilon-\Delta A}{\Delta A}$ *vs.* T^{-1} with various values for ε_p^{633}.
ε_p^{633}: ●; 0 M^{-1} cm^{-1}, △; 20 M^{-1} cm^{-1}, □; 40 M^{-1} cm^{-1}, ○; 45 M^{-1} cm^{-1}, ▽; 50 M^{-1} cm^{-1}, ◇; 60 M^{-1} cm^{-1}.

Figure 5 shows the linear relationship between $\ln[(c\Delta\varepsilon-\Delta A)/\Delta A]$ *vs.* T^{-1} according to Eq. 4. When ε_p^{633}=45 M^{-1} cm^{-1} is used, a straight line which satisfies Eq. 4 best can be drawn. Thus, the following results are obtained: ΔH_1=25.1 kcal mol^{-1}, ΔS_1=83 cal K^{-1} mol^{-1}, and ΔG_1=0.6 kcal mol^{-1} at 25 °C (1 cal=4.2 J).

The value of ΔH_2 for the reaction from the octahedral to the square planar configuration is obtained by Eq. 5;

$$\frac{d \ln K_2}{d\ T^{-1}} = d \ln \frac{-(c\varepsilon_o^{633} - A)}{K_1(c\varepsilon_t^{633} - A) + (c\varepsilon_p^{633} - A)} \Big/ d\ T^{-1}$$

$$= -\frac{\Delta H_2}{R} \quad (5)$$

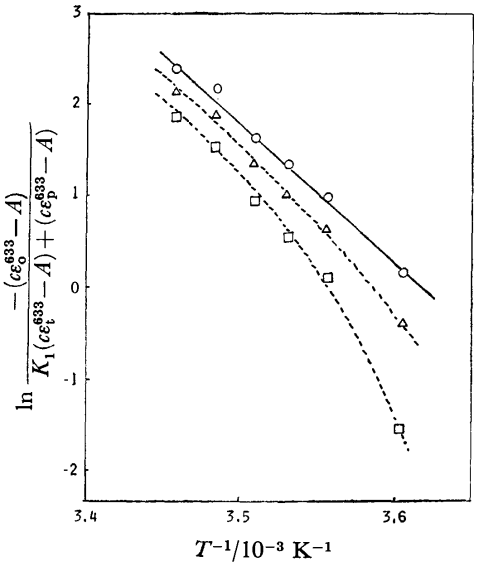

Fig. 6. The plots of $\ln \frac{-(c\varepsilon_o^{633}-A)}{K_1(c\varepsilon_t^{633}-A)+(c\varepsilon_p^{633}-A)}$ *vs.* $1/T$ with various values for ε_o^{633}.
ε_o^{633}: ○; 0 M^{-1} cm^{-1}, △; 10 M^{-1} cm^{-1}, □; 20 M^{-1} cm^{-1}.

where ε_o^{633} is the molar absorptivity of the octahedral configuration at 633 nm. A value $\varepsilon_o^{633}=0$ M^{-1} cm^{-1} satisfies Eq. 5 best as shown in Fig. 6. Therefore, the thermodynamic functions are obtained as follows: $\Delta H_2=27.8$ kcal mol^{-1}, $\Delta S_2=101$ cal K^{-1} mol^{-1}, and $\Delta G_2=0.8$ kcal mol^{-1} at 25 °C.

In general,[12] tetrahedral Ni(II) complexes exhibit a visible band near 600—700 nm (ε: 100—200 M^{-1}cm^{-1}) assignable to $^3T_1(P)\leftarrow{}^3T_1(\nu_3)$ transition and a near-infrared band near 1250 nm (ε: 20 M^{-1} cm^{-1}) assignable to $^3A_2\leftarrow{}^3T_1$ (ν_2) transition. On the other hand, octahedral Ni(II) complexes exhibit visible absorption bands of lower molar absorptivities, (ε: about 1—10 M^{-1} cm^{-1}), while square planar Ni(II) complexes show stronger bands in the visible region (ε: 50—500 M^{-1} cm^{-1}). Consequently, the spectral patterns of the tetrahedral, square planar and octahedral complexes observed are quite reasonable ones, and support the explanation of the solution equilibria proposed above.

The Stokes radius of the solvated Ni^{2+} ion in HMPA is 6.43 Å at 25 °C, at which temperature, the equilibrium of the solvated Ni^{2+} ion between the square planar and tetrahedral configurations is established. Since ΔS_1 value of this reaction is a large positive one, the tetrahedral complex seems to be less strongly solvated than the square planar complex is, although the coordination numbers of both complexes are the same. This may be the reason why the average value of the Stokes radius of solvated Ni^{2+} ion in HMPA at 25 °C is larger than 5 Å expected from the tetrahedral configuration.

ΔS_2 value for the reaction from the octahedral to square planar configuration is a larger positive one than that observed in a similar reaction from the octahedral to square planar configuration,[13] since the HMPA molecules are so closely packed in the coordination sphere of the octahedral complex that the rotational degree of freedom of HMPA is much reduced.

Configuration of Solvated Cu^{2+} Ion in HMPA. A broad absorption maximum near 720 nm in the spectrum at $[[Cu(hmpa)_4]^{2+}]=2.0\times10^{-3}$ M in nitromethane (Curve A) agrees with that obtained by Donoghue and Drago[2] in Fig. 3. In nitromethane at $[HMPA]_0=1.0\times10^{-2}$ M (Curve B), the absorption maximum appears near 850 nm and its peak is lower than that in pure nitromethane. In the $[HMPA]_0$ range 0.1—0.5 M, the absorption maxima shift to longer wavelength, and their peaks become higher (Curves C and D). In nitromethane of the $[HMPA]_0$ range 1.0—2.0 M and in pure HMPA (5.8 M), the absorption spectra shift further to longer wavelength with only slight absorbance changes (Curves E, F, and G).

In nitromethane, $[Cu(hmpa)_4]^{2+}$ is square planar because its absorption spectrum resembles that[14] of square planar $[Cu(Ph_3PO)_4]^{2+}$. When a small amount of HMPA is added to nitromethane, the Cu(II) complex in the solution seems to become tetragonal with HMPA molecules coordinated along the z axis of the square planar complex. The changes in the absorption spectra in the $[HMPA]_0$ range 0.1—0.5 M suggest that a tetragonal↔distorted tetrahedral transition is in equilibrium, and that the changes in the solvent properties due to excess HMPA merely shift this equilibrium. According to Wayland and Drago,[5] the NMR contact shifts are independent of HMPA concentrations in the $[HMPA]_0$ range 0.5—1.5 M. Consequently, $[Cu(hmpa)_4]^{2+}$ becomes only distorted tetrahedral at $[HMPA]_0=1.0$ M. In nitromethane of the HMPA concentrations higher than 1.0 M and in pure HMPA, it seems that the change in the absorption spectrum is not due to the change in the coordination number or in the configuration, but due to that in the degree of distortion of the complex. Liehr theoretically predicted[15] that regularly tetrahedral Cu(II) complexes would show an electronic transition in the near-infrared region but not in the visible one. Accordingly, the distorted tetrahedral $[Cu(hmpa)_4]^{2+}$ at $[HMPA]_0=1.0$ M is gradually liberated from distortion at the HMPA concentrations higher than 1.0 M in nitromethane and finally becoming nearly regular tetrahedral in pure HMPA (5.8 M). The Stokes radius of $[Cu(hmpa)_4]^{2+}$ ion in HMPA, 5.17 Å, supports this deduction. If the solvated Cu^{2+} ion is either square planar or tetragonal in HMPA, the Stokes radius would be larger than 5 Å expected from the tetrahedral configuration. This problem has been discussed at the previous section on the solvated Ni^{2+} ion.

Configurations of Solvated Fe^{2+}, Mn^{2+}, and Zn^{2+} Ions in HMPA. The values of log ε of solvated Fe^{2+} and Mn^{2+} ions in HMPA are 2.6 at 400 nm and −0.002 at 412 nm, respectively, while those of $[Fe(hmpa)_4]^{2+}$ and $[Mn(hmpa)_4]^{2+}$ in nitromethane are 2.6 and −0.002 at the same wavelengths, respectively. These values agree with those of the tetrahedral $[Fe(hmpa)_4]^{2+}$ and the tetrahedral $[Mn(hmpa)_4]^{2+}$ ions in nitromethane reported by Donoghue and Drago.[3] Therefore, it is concluded that solvated Fe^{2+} and Mn^{2+} ions in HMPA are $[Fe(hmpa)_4]^{2+}$ and $[Mn(hmpa)_4]^{2+}$ ions. Stokes radii of solvated Fe^{2+} and Mn^{2+} ions in HMPA are 5.00 Å and 5.47 Å, respectively (Table 1), suggesting

that they are both tetrahedral.

The configuration of solvated Zn^{2+} ion in HMPA can not be decided from the absorption spectrum. The Stokes radius of solvated Zn^{2+} ion in HMPA is 7.5 Å which is 2.5 Å larger than 5 Å expected for the tetrahedral configuration. Consequently, solvated Zn^{2+} ion in HMPA is probably octahedral. This is supported by the complex formation constants of Zn^{2+} ion with HMPA and with bpy; the details on this point will be published later.

General Discussion. Complexes of the first transition metal ions $[M^{II}(hmpa)_4](ClO_4)_2$ (M^{II}=Mn^{II}, Fe^{II}, Co^{II}, Ni^{II}, Cu^{II}, or Zn^{II}) are tetrahedral in nitromethane except for Ni(II) and Cu(II) complexes, although they are all known to be tetrahedral in the solid states.[2,3,5] In HMPA, the Mn(II), Fe(II), Co(II), and Cu(II) ions are tetrahedrally solvated by HMPA, while Ni(II) establishes equilibria among solvated complexes of the octahedral, square planar and tetrahedral configurations. Zn(II) forms probably an octahedrally solvated complex.

In dimethyl sulfoxide (DMSO) and *N,N*-dimethylformamide (DMF), solvated complex ions of the first transition metals are mostly octahedral. Since an HMPA molecule is very bulky as compared with DMSO and DMF, it seems that solvated complex ions in HMPA prefer the tetrahedral configurations to the octahedral ones.

Although Libuś and Uruska describe that the first transition metal complexes tend to be tetrahedral in solutions according to the differences between the crystal field stabilization energies (c.f.s.e.) of the octahedral and the tetrahedral configurations in the following order: Mn(II)~Zn(II)>Fe(II)>Co(II)>Cu(II)>Ni(II),[16] Zn(II) prefers the octahedral configuration in HMPA. Since Zn(II) has no c.f.s.e. in its complexes, it may be better to put it at the last in the sequence in the present case.

Studies of Inorganic Ion Exchangers. V.[1] The Preparation of the Granulated Product from Titanium(IV) Bis(hydrogenphosphate) and Carbonaceous Materials, and Its Ion-exchange Properties

Etsuro KOBAYASHI* and Tadao KANAYAMA

National Chemical Laboratory for Industry, Yatabemachi, Tsukuba-gun, Ibaraki 305

(Received April 12, 1980)

In order to develop an inorganic ion exchanger for industrial use, a mixture of titanium(IV) bis(hydrogenphosphate), a carbonaceous material (sugar, flour, or sodium ligninsulfonate), and an additive (H_2SO_4 or H_3PO_4) was sintered, and the resultant sintered product was crushed to obtain a granulated product, the ion-exchange property of which was then investigated. The mixing ratio of the titanium phosphate to the carbonaceous material has an influence on the ion-exchange capacity and the durability of the granulated product. In consideration of this influence, the weight ratio of the titanium phosphate to carbon included in the carbonaceous material was expediently chosen as 1 : 0.5. The acid additives promoted the carbonization of the carbonaceous material, whereby the sintered product of porosity was obtained. The weight ratio of the carbonaceous part to the titanium phosphate in the product decreased with an increase in the temperature within the range from 185 to 350 °C. In a batch method, a granulated product including $Ti(HPO_4)_2 \cdot H_2O$ adsorbed Na^+, but not K^+. A granulated product including $Ti(HPO_4)_2 \cdot 1/2H_2O$, however, adsorbed these ions, the equilibrium ion-exchange capacities toward Na^+ and K^+ being 1.28—1.78 and 1.56—2.34 meq/g respectively, and the selectivity quotient and the distribution coefficient toward K^+ showed larger values than those toward Na^+. In a column method, when a NaCl (26.66 g/l)-KCl (0.67 g/l) aqueous solution flowed into a column which had been packed with the granulated product (5 g) including the hemihydrate, the ion-exchange capacities of this granulated product toward Na^+ and K^+ were 1.1—1.2 and 0.38—0.58 meq/g, respectively, showing the separation factor (α_{Na}^{K}) of 18—25. When artificial brackish water also flowed into the column, very small quantities of the Mg^{2+} and Ca^{2+} were adsorbed; consequently, a selective ion-exchange property of the granulated product toward K^+ was recognized. Also, the carbonaceous part in the granulated product adsorbed such coloring matter as Methylene Blue.

Some phosphates of multivalent metals are known as inorganic ion-exchangers; among them, zirconium phosphate is used as a typical inorganic ion-exchanger in the field of analytical chemistry. With a view to developing inorganic ion-exchangers for industrial use, our attention was paid to titanium phosphate, which is almost equivalent in stability to zirconium phosphate and which is rather cheap as a raw material. Our studies revealed that titanium(IV) bis(hydrogenphosphate) 0—1/2 hydrate [$Ti(HPO_4)_2 \cdot 0—1/2H_2O$],[2] with an X-ray diffraction pattern quite different from that of the known titanium(IV) bis(hydrogenphosphate) monohydrate [$Ti(HPO_4)_2 \cdot H_2O$],[3] could be prepared by refluxing various titanium compounds with concentrated phosphoric acid and that titanium(IV) bis(hydrogenphosphate) 0—1/2 hydrate had a unique ion-exchange property.[4] In order to establish an industrial method of producing $Ti(HPO_4)_2 \cdot 0—1/2H_2O$, this compound was synthesized by refluxing a sulfuric acid solution of $TiOSO_4$, as an intermediate in the production of titanium(IV) oxide, with concentrated phosphoric acid.[5] In the previous report,[1] the ion-exchange equilibria between titanium(IV) bis(hydrogenphosphate) and an aqueous solution of NaCl–KCl under various conditions were investigated. As a result of the investigation, it was found that K^+ was separated more effectively than Na^+ when the anhydride was added to a solution containing equivalents of NaCl and KCl, but trouble occurred in the separation of the solid phase from the liquid phase because the crystals of the titanium(IV) bis(hydrogenphosphate) were too small. In the batch method, on the other hand, it was not easy to effect the elution of K^+ adsorbed on the microcrystals. These difficulties constituted a great obstacle for the practical use of the compound. Generally, inorganic ion-exchangers of a hydrated oxide or hydroxide formed as a gel have been used for analytical use after a dry solid of the gel has been crushed into particles of an adequate size, but an ideal strength can not be expected for them. In case a column is packed with an inorganic ion-exchanger obtained by further pulverizing the dry solid or supplied in microcrystalline form, water can not pass through the column smoothly. Reported in this paper is a result of our investigations with an eye to granulating the inorganic ion-exchanger. A mixture of microcrystalline titanium(IV) bis(hydrogenphosphate), a viscous carbonaceous material, such as sugar or wheat flour, and some of an additive such as an inorganic acid was sintered at a given temperature, the sintered product was then so crushed as to have a granule size proper for an ion-exchanger. The ion-exchange capacities of the resultant granulated product toward K^+ and Na^+ were examined according to the batch method and compared with those when titanium(IV) bis(hydrogenphosphate) was used as the raw material. A result of the test made to separate K^+ from Na^+ by the column method is also reported in this paper.

Experimental

Preparation and Analysis of Ion-exchangers. Titanium(IV) bis(hydrogenphosphate) as an ion-exchanger was synthesized in accordance with the refluxing method described in previous report.[2,5] The synthetic conditions and the composition of the products are shown in Table 1.

Preparation of Granulated Products. In a 50-ml porcelain crucible was placed given amounts of titanium (IV) bis(hydro-

a) Amorphous titanium phosphate containing TiO_2 42.4%, P_2O_5 33.8%, H_2O 23.3%. b) Solution containing TiO_2 250 and H_2SO_4 1044 g/l.

genphosphate) or a hydrate thereof (a product not as yet rinsed in the production of titanium(IV) bis(hydrogenphosphate), and a carbonaceous material (a reagent-grade saccharoseas sugar, commercially available wheat flour, or a reagent-grade sodium ligninsulfonate). When anhydrous titanium(IV) bis(hydrogenphosphate) was used, 9 M H_2SO_4, 7 M H_3PO_4, and an adequate amount of water were added; the mixture was stirred homogeneously and then dried at 105 °C for about 3 h until it became a dark brown solid. Next, a lid cap was put on the crucible, which was then placed in an electric furnace kept at a given temperature in order to sinter the content of the crucible. After allowing the content to stand and cool, the sintered brown-black product was weighed, crushed so as to have an adequate granule size, sived, throughly washed with water until the acids in the granulated product could no longer be detected, and then dried at 50—60 °C for 24 h. The size distribution of the typical granulated product was found to be as follows; 16—32 mesh 16 w%, 32—42 mesh 52 w%, 42—65 mesh 29 w%, 65—100 meash 3 w%. The strength of the granulated product was determined to be 87—94% with the testing method (JIS-K 1474) used for granular activated carbon.

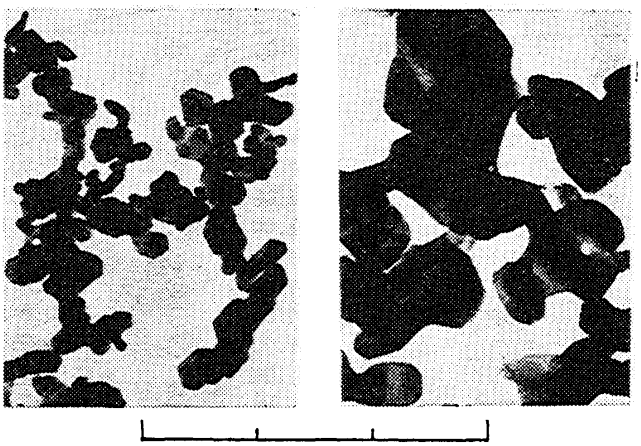
Measurement of Ion-exchange Capacities by the Batch Method. The equilibrium ion-exchange capacity (Q^A, meq/g) between the granulated product and an aqueous solution of the chloride (NaCl, KCl), and the saturated ion-exchange capacity (Q°, meq/g) at pH 4.5 were both measured in accordance with the method previously reported,[4] such ion-exchange characteristics as a selectivity quotient (K_H^M) and a distribution coefficient (K_D) were derived from the above ion-exchange capacities.

Adsorption of Na^+ and K^+ by the Column Method. A column of Pyrex glass (9 mm in inner diameter and 200 mm in height) was packed with 5.0 g of the dried granulated product (60—100 mesh) previously moistened with water. A given volume (500 ml, 1000 ml, or 1500 ml) of a sample solution (the aqueous solution of NaCl–KCl or artificial brackish water; the compositions and concentrations of these solutions are shown in Table 4) was permitted to flow through the column at a flow rate of 0.4—0.5 ml/min. Every 10-ml portion of the effluent from the column was collected in a fraction-collector. The pH value of each fraction was measured, and the Na^+ and K^+ contained therein were determined by flame photometry, while the Mg^{2+} and Ca^{2+} were determined by atomic absorptiometry, thereby estimating the quantity of each ion adsorbed on the granulated product. The cations adsorbed on the granulated product were subjected to complete elution with 30 ml of 6 M hydrochloric acid and an adequate amount of water; each ion in the eluate was determined, whereby the ion-exchange capacity of the granulated product, the distribution coefficient (K_D^M), and the separation factor (α_{Na}^K) were also then calculated.

Adsorption Test of Coloring Matter. To 100 ml of a solution of methylene blue with a concentration of 1 ppm were added 1 g of the granulated product (0.33 g in carbon content) or 0.33 g of active carbon (Pittsburg Co.). The mixture was stirred occasionally, and the coloring matter in the supernatant liquid was determined at a given time interval, using a spectrophotometer at the wave length of 660 nm in order to examine the change in the concentration of methylene blue in the solution with the lapse of time.

Results and Discussion

Titanium(IV) Bis(hydrogenphosphate) as Microcrystals. The titanium(IV) bis(hydrogenphosphate) monohydrate and 0—1/2 hydrate, formed by refluxing various titanium compounds with phosphoric acid, were all microcrystalline. Electron microscope photographs of both hydrates are shown in Fig. 1.



$Ti(HPO_4)_2 \cdot H_2O$ $Ti(HPO_4)_2 \cdot 0—1/2H_2O$

Fig. 1. Electron microscope photographs of titanium (IV) bis(hydrogenphosphate).

As has already been reported,[5] the crystals of these hydrates were quite different in their X-ray diffraction patterns. Besides, they were different in their appearances in the electron-microscope photographs; the monohydrate, showing a good crystallinity, had a crystal structure of hexagonal plates, with a particle size of 0.3—0.6 μ, while the 0—1/2 hydrate has a particle size of 1—2 μ. Since it was very difficult to flow water through a column packed with such microcrystalline hydrates, therefore, the granulation of these microcrystalline hydrates was contemplated.

Granulation of Titanium(IV) Bis(hydrogenphosphate) with The Aid of a Carbonaceous Material. The use of a binder, such as silicic acid gel, poly(vinyl alcohol), or gelatin, came into question for the production of a granulated product of titanium(IV) bis(hydrogenphosphate). Although a composite material of titanium(IV) bis(hydrogenphosphate) and silicic acid gel was expected to have a good stability to heat, it was impossible to produce the composite material possessing satisfactory strength in water according to our present techniques. The granulated product obtained by using poly(vinyl alcohol) or gelation as a binder had good strength, but was devoid of the stability required for inorganic ion-exchangers capable of withstanding use at a high temperature. Hence, an attempt has been made the granulation of titanium(IV) bis(hydrogenphosphate) with the aid of a carbonaceous material as a binder. The conditions for preparing the product and composition thereof are summarized in Table 2.

The carbonaceous material was selected from among saccharose, wheat flour, and sodium ligninsulfonate. A mixture containing saccharose was melted by heating, and the viscous melt was carbonized while bubbling. A mixture containing wheat flour gave a relatively hard sintered product containing nitrogen of proteins. These materials are carbohydrates with a definite carbon content. Sodium ligninsulfonate was chosen from the view point of utilizing pulp-waste liquor. In addition to these materials, a pitch is also regarded as a promising carbonaceous material.

Regarding the proportion of titanium(IV) bis(hydrogenphosphate) to the carbonaceous material in the preparation of the ion-exchanger, the use of a larger amount of the latter increases the strength of the granulated product, but naturally results in decrease in the ion-exchange capacity.

Taking the balance of these effects into consideration, the raw materials were so mixed that the ratio by weight of titanium(IV) bis(hydrogenphosphate) to C was 1 : 0.5. Sulfuric acid or phosphoric acid as an additive served to accelerate the carbonization of the carbonaceous materials by virtue of its dehydration effect and gave a relatively porous sintered product. In Table 2, Nos. 1—5 show the results obtained by using Titanium(IV) bis(hydrogenphosphate) monohydrate and sugar as carbonaceous material, and by sintering the mixture at 185—300 °C. As the carbonization proceeded rapidly at 300 °C, the heating time in this case was shortened. Nevertheless, a decrease in the weight of the granulated product was observed. The ratio by weight of Carb. (carbonaceous part formed by heating) to titanium(IV) bis(hydrogenphosphate) decreased as the temperature was elevated. Accordingly, the product sintered at a relatively lower temperature was not carbonized completely. The same tendency was observed in the cases of Nos. 6—10, wherein titanium(IV) bis(hydrogenphosphate) 0—1/2 hydrate was used.

a) C: Carbon contained in the used carbonaceous material. b) Carb.: Carbonaceous part formed by heating.
c) The values in parentheses indicate the TiP content in the wet sample.

In these cases, a solid centrifuged from the mother liquor in the course of synthesis was directly used as titanium(IV) bis(hydrogenphosphate), so that it contained some phosphoric acid and sulfuric acid, which also functioned as additives. Nos. 11 and 12 show the influence of the additives on the sintered product. As is evident from the above discussion, the carbonization was remarkably promoted by the addition of phosphoric acid and sulfuric acid; the Carb./titanium(IV) bis(hydrogenphosphate) ratio (by weight) was decreased from 0.76 (No. 11 in the case of adding no additive) to 0.62 (No. 12 in the case of adding the additive). In Nos. 12, 13, and 14, the sintering experiments were performed using different kinds of the carbonaceous material. The use of wheat flour or sodium ligninsulfonate as carbonaceous material required a relatively greater amount of water than the case of using saccharose for the kneading of the raw material. No remarkable difference was found in the weights of the sintered products, but the Carb./titanium(IV) bis(hydrogenphosphate) ratio (by weight) was 0.54 in the case of wheat flour, 0.62 in the case of saccharose, and 0.73 in the case of sodium ligninsulfonate. (In the case of the sintered product using sodium ligninsulfonate, the sodium contained therein was extracted with hydrochloric acid, and the product was then dried to obtain the yield. Thus, "Carb." was free from sodium.). For reference's sake, Nos. 15 and 16 show the conditions for the preparation of the granulated products used in the column method and their compositions.

Ion-exchange Capacities of The Granulated Products. The ion-exchange titration curves of the granulated products containing the monohydrate and the 0—1/2 hydrate toward Na^+ and K^+, obtained according to

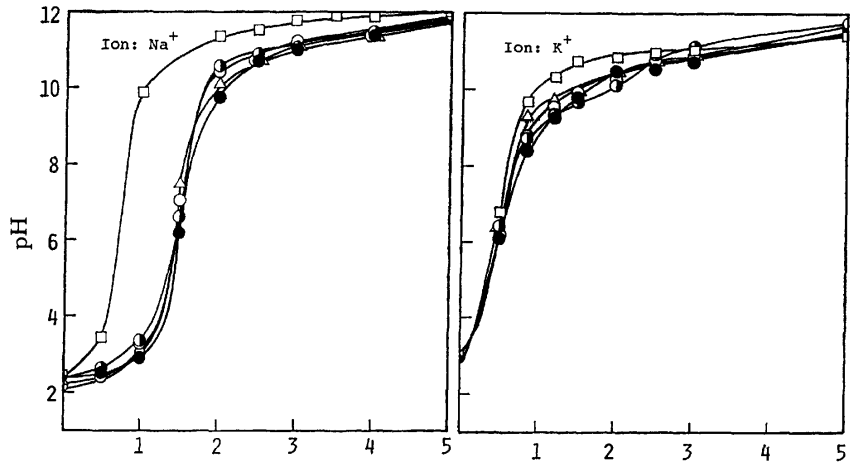

Fig. 2. Ion-exchange titration curves of the product granulated from $Ti(HPO_4)_2 \cdot H_2O$ with carbonaceous material.
Carbonaceous material: Sugar.
Heating temperature: △; 185, ○; 200, ◑; 220, ●; 250, □; 300.

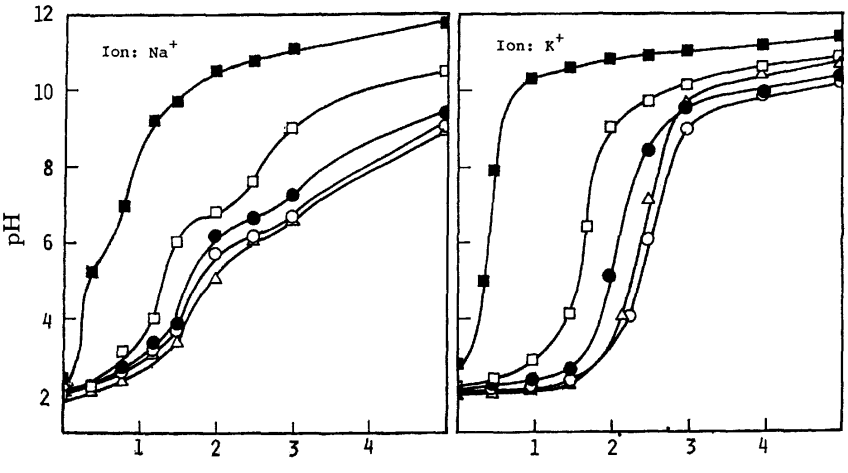

Fig. 3. Ion-exchange titration curves of the product granulated from $Ti(HPO_4)_2 \cdot 0—1/2\ H_2O$ with carbonaceous material.
Carbonaceous material: Sugar.
Heating temperature: △; 185, ○; 200, ●; 250, □; 300, ■; 350.

the method of the previous report,[4] are shown in Figs. 2 and 3 respectively.

In Fig. 2, the ion-exchange capacities toward Na^+ of the granulated products containing the monohydrate were 1.22—1.35 and 1.45—1.55 meq/g at the pH values of 4.5 and 7.0 respectively, except for the case wherein the product was sintered at 300 °C. These values were quite small as compared with those of the ion-exchange capacities of the monohydrate itself given in the previous reports[3,4] (3.6 and 7.5 meq/g at pH values of 4.5 and 7.0 respectively). The noticeable decrease in the ion-exchange capacity of the sintered product at pH 7.0 is considered to be a response to the change in the crystal structure of the monohydrate contained in the granulated product in the course of heating. It may also be considered that the surface of the crystals of titanium(IV) bis(hydrogenphosphate) was coated with the formed Carb. to slow down the speed of ion-exchange; thereafter Na^+ was hydrated in a neutral to alkaline solution to form a hydrated ion which was not adsorbed into the cavities of the ion-exchanger. This resulted, as is shown in Fig. 2, in a rapid rise in the titration curves at the point where the quantities of ion-exchange were small.

The ion-exchange capacities toward K^+ of the granulated product containing the monohydrate were 0.18—0.26 and 0.6 meq/g at pH values of 4.5 and 7.0 respectively. These values were half the values of the ion-exchange capacity of the monohydrate itself.

In Fig. 3, the ion-exchange capacities toward Na^+ of the granulated products containing the 0—1/2 hydrate, were 0.30—1.78 and 0.75—3.25 meq/g at pH of 4.5 and 7.0 respectively. The ion-exchange capacities of the granulated product varied remarkably according to the sintering temperature; these values decreased in the range of 185—350 °C with the elevation of the sintering temperature. This is probably ascribable to the same reason as in the case discussed above wherein the granulated product containing the monohydrate was used.

The ion-exchange capacities toward K^+ of the granulated products containing the 0—1/2 hydrate were 0.40—2.34 and 1.7—2.6 meq/g at pH 4.5 and 7.0 respectively. These values were extremely small as

compared with those of the 1/2 hydrate itself, determined to be 4.1 and 6.7 meq/g at pH 4.5 and 7.0 respectively. However, the ion-exchange capacities within such ranges are almost equal to those of commercially available cation-exchange resins; thus they can be utilized satisfactorily as ion-exchangers.

Ion-exchange Characters of The Granulated Products. The titration curves drawn for the estimation of the quilibrium ion-exchange capacity are shown in Fig. 4. The ion-exchange characters of the granulated product toward Na^+ and K^+ are summarized in Table 3.

The equilibrium ion-exchange capacities (Q^A) toward K^+ and Na^+ of the granulated products containing the monohydrate (Nos. 1—5) were 0.43—0.95 and 0.14—0.24 meq/g respectively.

Although the saturation ion-exchange capacities (Q°) toward Na^+ show significantly large values at pH 4.5, as has been described above, the satisfactory results expected for the separation between Na^+ and K^+ were not obtained in connection with the selectivity quotient (K_H^M) and the distribution coefficient (K_D). On the other hand, the values of Q^A toward Na^+ and K^+ of the granulated product containing the 0—1/2 hydrate were 0.86—1.10 and 1.46—1.98 meq/g respectively, except for those obtained for the product sintered at 350 °C. The values of Q° toward Na^+ and K^+ of the same product were 1.28—1.78 and 1.56—2.34 meq/g respectively, except for those obtained for the product sintered at 350 °C. The values of Q^A and Q° were at their maximum for the granulated product sintered at 200 °C, and these values decreased with the elevation in the sintering temperature. Especially, the values of the ion-exchange capacity for the product sintered at 350 °C decreased to 1/6 of the values for the product sintered at 200 °C. It is considered that, at high temperatures, some changes occurred in the structure of the 1/2 hydrate contained in the sintered product. The values of K_H^M and K_D toward K^+ were extremely large as compared with those toward Na^+, thus proving that the granulated products containing the 1/2 hydrate had an excellent adsorption selectivity toward the K^+ ion. As is evident from the previous paper,[4] the value of K_D toward K^+ was 15.7 for the 1/2 hydrate itself, a value almost equal to that of the granulated product. The value of K_D toward K^+ for the 1/2 hydrate itself was 607.0 ml/g, while the values of K_D for the granulated products decreased to about 1/3—1/5 of the above value, probably becouse the products contained the Carb. These results indicate that the sintering temperature for the granulated products influencing the ion-exchange capacity is most suitably within the range of 200—250 °C. Accordingly, the granulated products sintered at 220 °C were used in the subsequent samples of Nos. 11—14. In Nos. 11 and 12, the influence on the ion-exchange character of the additive at the time of sintering was observed. In the case of the sample of No. 12, wherein the additive was added, a slight increase was observed in the ion-exchange capacity. This phenomenon was probably caused by the fact that the carbonization of the carbonaceous material was promoted by the addition of the inorganic acids; then, the value of the titanium(IV) bis(hydrogenphosphate)/Carb. increased, as is shown in Table 2.

The influence of the carbonaceous material on the ion-exchange properties was examined in Nos. 12, 13, and 14. In these results, the Q^A and Q° values decreased in the order of sugar, wheat flour, and sodium lignin-sulfonate. A similar tendency also appeared in other ion-exchange properties, such as K_H^M and K_D. Among the carbonaceous materials used, sugar showed the best result.

Selective Adsorption toward K^+ as Determined by The Column Method. As has already been reported,[1,4] the values of K_H^M toward Na^+ and K^+ of $Ti(HPO_4)_2 \cdot 0—1/2H_2O$ showed a sufficient value for the separation of the two ions. As the value of K_H^M toward K^+ was large, the elution of adsorbed K^+ on the batch method using hydrochloric acid was not easy. Since titanium-(IV) bis(hydrogenphosphate) was microcrystalline, as has been described above, this compound was quite inappropriate for the column method. Accordingly, the selective adsorption toward K^+ in an aqueous solution of NaCl–KCl and in artificial brackish water was investigated according to the column method, using the granulated product prepared in this study. The results obtained are shown in Table 4.

In the table, the distribution coefficients, K_D^{Na} and K_D^K, are obtained as the values of $\bar{m}Na/mNa$ and $\bar{m}K/mK$ respectively, wherein $\bar{m}Na$ and $\bar{m}K$ stand for the amounts (meq) of Na^+ and K^+ respectively adsorbed on 1 g of the ion exchanger, and mNa and mK, for the amount (meq) of Na^+ and K^+ respectively existing in 1 ml of the solution under the equilibrium adsorption conditions. The separation factor, α_M^K, between K^+ and $M^{1+ \text{ or } 2+}$ (M=Na, Mg, or Ca) is indicated by the following formula:[6]

$$\alpha_M^K = (\bar{m}K \cdot mM)/(\bar{m}M \cdot mK) = k_D^K/k_D^M.$$

In Nos. 1 and 2, the concentration of KCl–NaCl in water was about twice as much as that of natural sea water, and the atomic ratio of Na/K was 50.8. As the

granulated product containing the monohydrate (No. 1) which was packed into a column adsorbed only a little K^+, the product was not suitable as an ion-exchanger for K^+. On the other hand, the granulated product containing the 0—1/2 hydrate (No. 2) showed an ion-exchange capacity of 0.557 meq/g toward K^+, an atomic ratio of the adsorbed Na^+ to the adsorbed K^+ of 1.83, and a separation factor, α_{Na}^{K}, of 27.9. In Nos. 3, 4, and 5, an aqueous solution of NaCl–KCl was used in which the concentrations of NaCl and KCl were almost equal to those in sea water. When this solution was permitted to flow through the column, the amounts of Na^+ and K^+, and the α_{Na}^{K} value were increased according to the increase in the flow. In No. 6, the sum of the concentrations of NaCl and KCl was equal to that in No. 2 (54.66 g), but the concentration of KCl in No. 6 was increased ten times as much as that of No. 2, decreasing the concentration of NaCl accordingly. As a result, the ion-exchange capacity toward Na^+ was decreased from 1.05 to 0.856 meq/g, while the ion-exchange capacity toward K^+ was increased from 0.577 meq/g to 1.05 meq/g. As the concentration of K^+ in the sample solution was comparatively high in this case, the α_{Na}^{K} value was about 5. Artificial brackish water was used as the sample solution in No. 7. As a result, the ion-exchange capacities toward Na^+ and K^+ were both somewhat decreased as compared with the case of No. 4, wherein an aqueous solution of NaCl–KCl with the same concentrations of NaCl and KCl was used. However, the atomic ratio of Na to K in No. 7 was equal to 2.13 in the case of No. 4. Although considerable amounts of Mg^{2+} and Ca^{2+} were contained in the artificial brackish water, those ions were adsorbed very little on the granulated product containing the 0—1/2 hydrate, and both the α_{Mg}^{K} and α_{Ca}^{K} values showed a large number. The pH values of the effluents and the

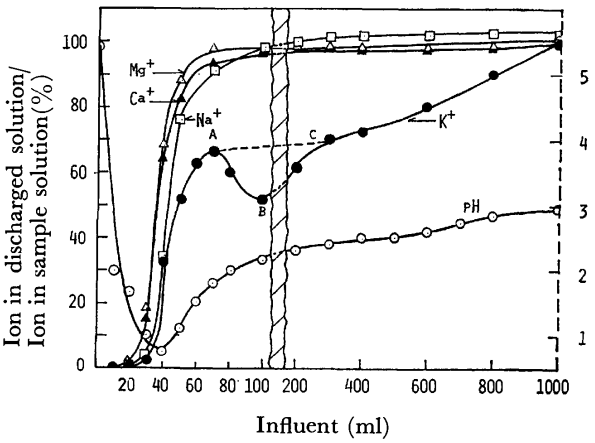

Fig. 5. The concentration of each ion containing in the discharged solution from the column.
Ion-exchanger: glanulated product of $Ti(HPO_4)_2 \cdot 1/2\ H_2O + C$ (5 g), sample solution: artificial brackish water (see Table 4).

changes in the concentration of the individual ions were examined in order to check the behavior of the individual ions adsorbed on the granulated product in the column. The result obtained are shown in Fig. 5.

As soon as the aqueous solution of NaCl–KCl or the artificial brackish water, each having a pH value of 5—6, was passed through the column as a sample solution, an ion-exchange reaction took place whereby the pH value of the effluent decreased so rapidly that the pH value dropped to the minimum value of 0.75 when the volume of the effluent reached 30—40 ml. Thereafter, the pH value gradually increased as the volume of the effluent became larger, shown about 2, 2.5, and 3 at the stages where the volumes of the effluent reached 100, 500, and 1000 ml respectively. As a large amount of

Na^+ was contained in the sample solution, the concentration of Na^+ in the effluent rapidly increased to the same level as that of the sample solution when 30 ml of the effluent discharged from the column. The concentration of Na^+ in the effluent eventually reached 102—103% of that in the sample solution supplied. This phenomenon was considered to show that the Na^+ initially adsorbed on granulated product was gradually replaced by K^+ in the following sample solution. Although K^+ was also contained together with Na^+ in the effluent, the concentration of K^+ showed a peak at Point, A, in Fig. 4 where the volume of the effluent reached about 70 ml. With the increase in the volume of the effluent, the concentration of K^+ was decreased to a valley, B, and then again increased to Point C. This phenomenon was also observed in Nos. 3—5, wherein the concentration of K^+ in the sample solution was low, but it not observed in Nos. 1, 2, and 6, wherein the concentration of K^+ was comparatively high. In the latter case, the concentration of K^+ increased, as is shown by the dotted line connecting Points A and C in Fig. 4. Before Na^+ began to appear in the effluent, Mg^{2+} and Ca^{2+} were contained therein, and their concentrations were increased rapidly. In view of the facts that the α^{K}_{Na} value reached 22.1 by passing the artificial brackish all at once through a column in which the granulated products containing the 0—1/2 hydrate had been placed, and that K^+ could be separated effectively from Mg^{2+} and Ca^{2+}, the effective separation of K^+ from sea water can be expected by further improvement in the technical problems.

Adsorption of Coloring Matter by The Granulated Products. In the preparation of the granulated products, the carbonaceous material used as a binder was converted by heating it into substances composed predominantly of carbon. If this carbonaceous part had an adsorbing effect like active carbon, the granulated products would have the functions of both ion-exchange and adsorption. Using methylene blue as the material to be adsorbed, the granulated product was added to an aqueous solution of methylene blue and the change in the color density with the lapse of time was examined, the resulting being shown in Fig. 6.

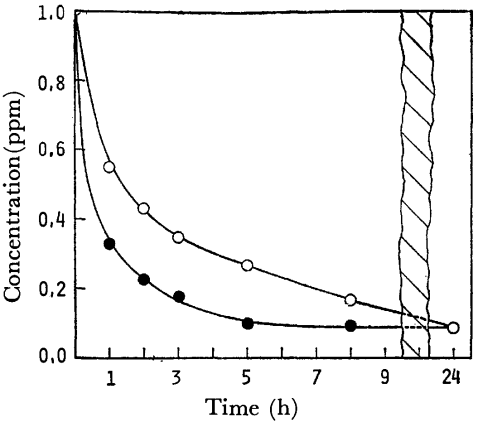

Fig. 6. Adsorption of methylene blue by granulated product and active carbon. 1 g (C; 0.33 g) of granulated product or 0.33 g of active carbon were added to 100 ml of methylene blue aqueous solution (1 ppm), respectively.
○: Granulated product, ●: active carbon.

Since the sintering temperature for preparing the granulated products was as low as 200—250 °C, we were unable to obtain a product with an adsorbing capacity equivalent to active carbon, but the product could adsorb coloring matter to some extent.

(Received April 14, 1980)

Ammonium chloride tetrachlorozincate, $(NH_4)_3Cl[ZnCl_4]$, decomposes to $ZnCl_2$ in two stages through an intermediate phase $(NH_4)_2[ZnCl_4]$. In the first stage, 1 mol of NH_4Cl is lost by one-dimensional diffusion mechanisms with the activation energy of 138 kJ mol^{-1}, and in the second stage the release of two moles of NH_4Cl is controlled by a random nucleation reaction with the activation energy of 126 kJ mol^{-1}, corresponding to the bond-breaking. Anhydrous alkali metal tetrachlorozincate complexes, $M_2[ZnCl_4]$(M=Na, K, Rb, Cs), are obtained by solid reactions with alkali chlorides when $(NH_4)_3Cl[ZnCl_4]$ decomposes. A dry chemical method using $(NH_4)_3Cl[ZnCl_4]$ as a starting material is proposed for the preparation of the anhydrous chlorozincate complexes, which have thus far been difficult to synthesize.

Ammonium chloride tetrachlorozincate, $(NH_4)_3Cl[ZnCl_4]$, is known to decompose to zinc chloride upon heating.[1] However, the mechanisms and kinetics of the thermal decomposition are not well understood. In this study, the mechanisms and kinetics of the decomposition were examined by thermogravimetry (TG), differential scanning calorimetry (DSC), and X-ray diffraction.

The solid reaction which took place in the mixtures of $(NH_4)_3Cl[ZnCl_4]$ and MCl (M=Na, K, Rb, Cs) simultaneously when $(NH_4)_3Cl[ZnCl_4]$ decomposed was also studied by TG, DSC, and X-ray diffraction. The products are interesting because the preparation of the anhydrous chlorozincate complexes is difficult on account of the deliquescence of $ZnCl_2$ and hydrolysis in water, and the anhydrous complexes have yet to be examined. That is, the stereochemistry of the chlorozincate complexes is not obvious other than that of the tetrahedral anion $[ZnCl_4]^{2-}$, though a number of other halogenozincate complexes, such as fluorozincate complexes, $M^{I}ZnX_3$, $M^{I}_2ZnX_4$, $M^{I}_3ZnX_5$, and $M^{I}_4ZnX_6$, have been reported.[2]

Experimental

Materials. Ammonium chloride tetrachlorozincate was prepared by a published method.[3] Commercial alkali chlorides were used without further purification. The samples for the solid reaction were prepared by mixing alkali chloride and $(NH_4)_3Cl[ZnCl_4]$ in a 2 : 1 molar ratio in an agate mortar in a nitrogen atomosphere. For the X-ray diffraction measurements, the samples were prepared by heating pure $(NH_4)_3Cl[ZnCl_4]$ or the mixture powder in a furnace with a nitrogen gas flow for two hours at the temperature where the reaction occurs in the DSC curve.

Measurements. The TG and DSC curves were recorded simultaneously using a Rigaku Thermoflex TG-DSC M8085 by heating the sample in flowing nitrogen gas at a rate of 2 K min^{-1}. About a 10-mg of the sample was placed in a platinum crucible, and α-alumina was used as the reference material. The TG curves were analysed by the method of Šatava and Škvára[4] to obtain the parameters of the reaction mechanisms and kinetics.

Results and Discussion

Thermal Decomposition of $(NH_4)_3Cl[ZnCl_4]$. The TG-DSC curves of $(NH_4)_3Cl[ZnCl_4]$ are shown in Fig. 1. $(NH_4)_3Cl[ZnCl_4]$ decomposed to $ZnCl_2$ in two stages. From the weight loss, the stages are confirmed as:

$$(NH_4)_3Cl[ZnCl_4](s) \longrightarrow (NH_4)_2[ZnCl_4](s) + NH_4Cl(g) \quad (1)$$

$$(NH_4)_2[ZnCl_4](s) \longrightarrow ZnCl_2(s) + 2NH_4Cl(g). \quad (2)$$

The existence of $(NH_4)_2[ZnCl_4]$ as an intermediate phase was also confirmed by X-ray diffraction. The endothermic peak at 313 °C corresponded to the

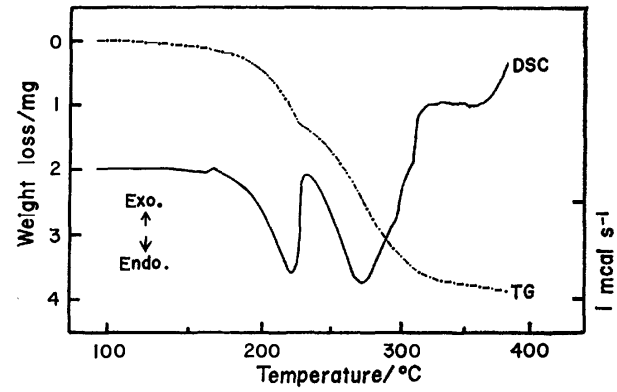

Fig. 1. TG–DSC curves of $(NH_4)_3Cl[ZnCl_4]$. Sample weight: 6.38 mg.

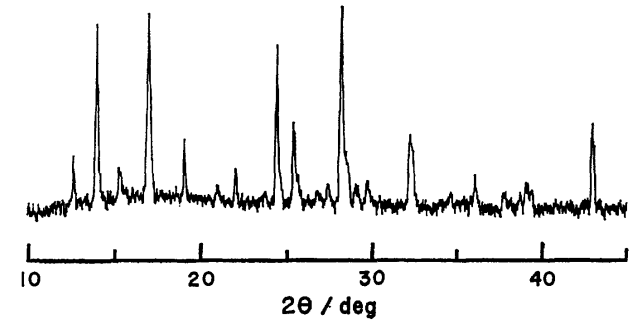

Fig. 2. X-Ray diffraction pattern of $ZnCl_2$ produced by thermal decomposition of $(NH_4)_3Cl[ZnCl_4]$.

melting point of $ZnCl_2$. The $ZnCl_2$ produced was mainly in the β-form, but containing a small amount of α-form, as determined by X-ray diffraction (Fig. 2). The compositions of the two forms changed according to the cooling conditions: the α-form is obtained by the rapid cooling of the melt, and the β-form, by the slow cooling.

The decomposition reaction mechanisms and kinetic parameters are deduced from the TG curve by the method of Šatava and Škvára. This method was used because it allows a fairely quick estimation of the parameters.

The thermogravimetric curve of a decomposition reaction can be expressed by this equation: $\log g(\alpha) - \log p(x) = B$. In this equation, the $g(\alpha)$ function requires a knowledge of the reaction mechanism and can be calculated from the experimental data of α, the fraction of the initial compound reacted. Šatava and Škvára gave data for $\log g(\alpha)$ which cover nine common reaction models.[4] Graphs of $\log p(x)$ can be computed for various activation energies, E, over a given range of temperature. The B values depend only upon the nature of the compound studied and upon the heating rate, not upon the temperature. A graphical comparison of the curves of both $\log g(\alpha)$ and $\log p(x)$ over the known experimental temperature range allows the reaction mechanisms and reaction parameters to be determined. The evaluation of the TG curve of the decomposition of $(NH_4)_3Cl[ZnCl_4]$ by the method of Šatava and Škvára is shown in Fig. 3 as an example. The enthalpy change for the reaction was obtained from the DSC curve.

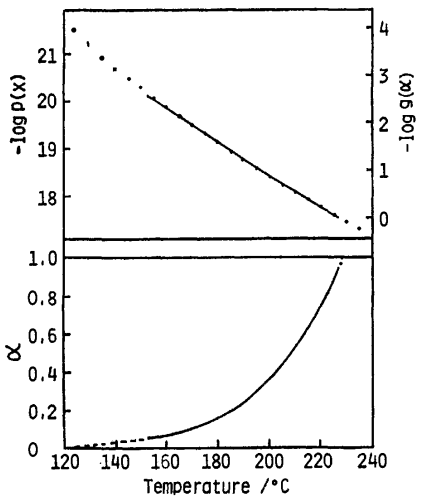

Fig. 3. The evaluation of the TG curve of the first decomposition stage of $(NH_4)_3Cl[ZnCl_4]$. The upper solid line is a plot of $-\log g(\alpha)$ *vs.* T calculated from TG curve (lower curve) for the reaction kinetic equation of one-dimensional diffusion. The dotted line is a plot of $\log p(x)$ *vs.* T for $E=138$ kJ mol^{-1}.

The best fits between experimental and calculated thermogravimetric curves and ΔH for each stage are as follows:

The First Stage: The loss of one mole of NH_4Cl occurs through a one-dimensional diffusion process following the parabolic law ($\alpha^2=kt$). The activation energy of the diffusion process, E, is 138 kJ mol^{-1}, the frequency factor, Z, 4.8×10^{13} s^{-1} mol$^{1/2}$, and ΔH, 85 kJ mol^{-1}.

The Second Stage: The loss of two moles of NH_4Cl is controlled by a random nucleation of one nucleus on each particle, with the activation energy of 126 kJ mol^{-1} corresponding to a bond breaking. The value of Z is 1.2×10^{11} s^{-1} mol$^{1/2}$, and that of ΔH, 134 kJ mol^{-1}.

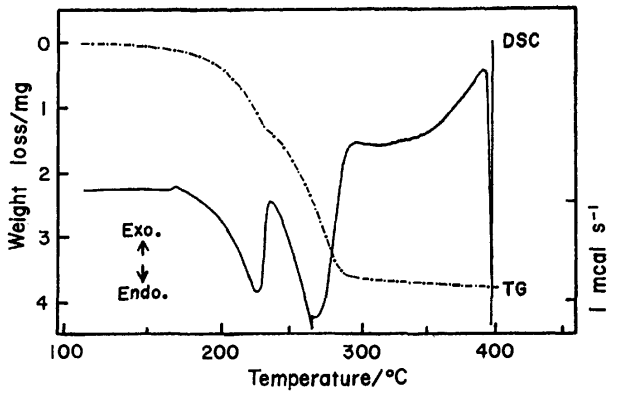

Fig. 4. TG–DSC curves of the mixture powder of $(NH_4)_3Cl[ZnCl_4]$ and NaCl with a 1 : 2 molar ratio. Sample weight: 9.31 mg.

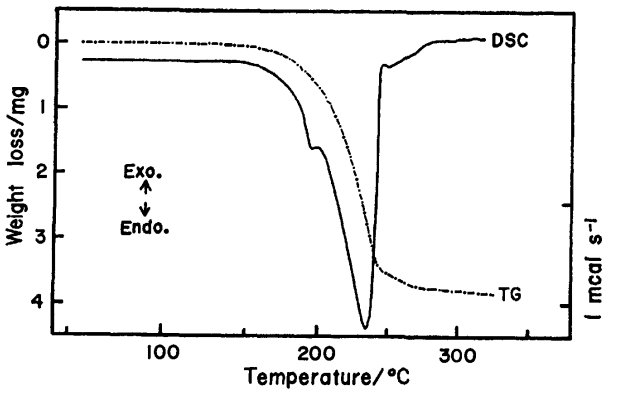

Fig. 5. TG–DSC curves of the mixture powder of $(NH_4)_3Cl[ZnCl_4]$ and CsCl with a 1 : 2 molar ratio. Sample weight: 14.36 mg.

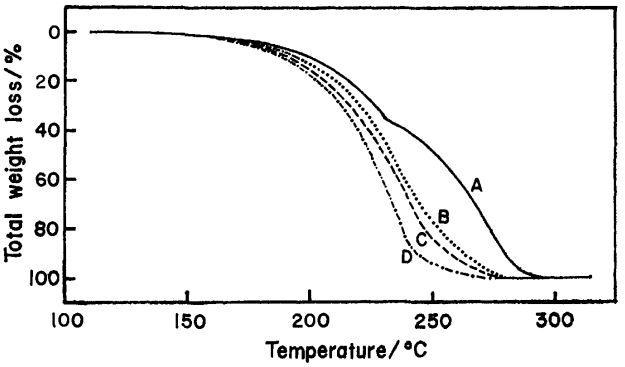

Fig. 6. Weight loss curves of the mixtures of $(NH_4)_3Cl[ZnCl_4]$ and MCl (M=Na, K, Rb, Cs) with a 1 : 2 molar ratio.
A: NaCl, B: KCl, C: RbCl, D: CsCl.

Those results are not inconsistent with the structure of $(NH_4)_3Cl[ZnCl_4]$, in which tetrahedral $[ZnCl_4]^{2-}$ ions are contained.

Solid Reaction between $(NH_4)_3Cl[ZnCl_4]$ and Alkali Chloride. A solid reaction took place between $(NH_4)_3Cl[ZnCl_4]$ and alkali chloride simultaneously when $(NH_4)_3Cl[ZnCl_4]$ decomposed upon the heating of the mixture in a 1 : 2 molar ratio. The mechanisms and kinetics of this reactions were followed in the usual way. The TG-DSC curves of the mixtures of 2NaCl–$(NH_4)_3Cl[ZnCl_4]$ and 2CsCl–$(NH_4)_3Cl[ZnCl_4]$ are shown in Figs. 4 and 5 respectively. The weight-loss curves of the mixtures of MCl (M=Na, K, Rb, Cs) and $(NH_4)_3Cl[ZnCl_4]$ with a 2 : 1 molar ratio are arranged in Fig. 6. The tail parts of the curves were sensitive to the sample properties, such as the paritcle-size distribution, and the contact condition of the reactants.

2NaCl–$(NH_4)_3Cl[ZnCl_4]$: Figure 4 shows that the reaction proceeds in two stages, in the same way as the decomposition reaction of pure $(NH_4)_3Cl[ZnCl_4]$. When the TG-DSC curves in Fig. 4 are compared with the curves in Fig. 1, the first stages of the reactions coincided with each other well, but in the second stage the loss of two moles of NH_4Cl occurs well below the temperature of the pure compound. In Fig. 1 the melting point of $ZnCl_2$ is observed at 313 °C, in accordance with the literature value, whereas in Fig. 4 a large peak is observed at 390 °C, which corresponds to the melting point of the product compound of $Na_2[ZnCl_4]$. Thus, the reaction pattern of the 2NaCl–$(NH_4)_3Cl$-$[ZnCl_4]$ mixture is as follows:

$$(NH_4)_3Cl[ZnCl_4](s) + 2NaCl(s) \longrightarrow (NH_4)_2[ZnCl_4](s) + 2NaCl(s) + NH_4Cl(g) \longrightarrow Na_2[ZnCl_4](s) + 2NH_4Cl(g) \xrightarrow{390°C} Na_2[ZnCl_4](l). \quad (3)$$

$(NH_4)_3Cl[ZnCl_4]$–2MCl (M=K, Rb, Cs): In these mixtures three moles of NH_4Cl were lost at one stage of the reaction, as is shown in Fig. 5. The reaction temperatures at which the loss of NH_4Cl occurs in these mixtures are well below the temperature of the pure compound of $(NH_4)_3Cl[ZnCl_4]$, as is shown in Fig. 6. The product of $Cs_2[ZnCl_4]$ was identified by means of X-ray diffraction. The other products were also confirmed to be $K_2[ZnCl_4]$ and $Rb_2[ZnCl_4]$, though the X-ray data were not available. The melting point of $K_2[ZnCl_4]$ was observed at 450 °C in the DSC curve.

Table 1. Mechanisms and kinetic parameters for the solid reactions between $(NH_4)_3Cl[ZnCl_4]$ and alkali chlorides

MCl	Mechanisms	E / kJ mol^{-1}	Z / s^{-1} mol$^{1/2}$	ΔH / kJ mol^{-1}	Products
KCl	One-dimensional diffusion	159	1.0×10^{15}	226	$K_2[ZnCl_4]$
RbCl	One-dimensional diffusion	159	1.7×10^{15}	231	$Rb_2[ZnCl_4]$
CsCl	One-dimensional diffusion	159	1.8×10^{15}	263	$Cs_2[ZnCl_4]$

The reaction mechanisms and kinetic parameters derived from the TG curves are shown in Table 1, along with the values of ΔH. These results show that the reaction pattern in these mixtures is as follows:

$$(NH_4)_3Cl[ZnCl_4](s) + 2MCl(s) \longrightarrow M_2[ZnCl_4](s) + 3NH_4Cl(g). \quad (4)$$

The mechanisms exhibit one-dimensional diffusion, so that the alkali chloride diffuses over the surface of the $(NH_4)_3Cl[ZnCl_4]$ particles prior to the formation of alkali metal tetrachlorozincate. No difference in the values of the activation energy was distinguished in those mixtures, but the reaction temperatures fall in accordance with the lattice energy of the alkali chlorides, as is shown in Fig. 6. The values of ΔH, as estimated from the DSC curves, changed considerably with the ending part of the curves. However, the values of ΔH were much larger than the values of the activation energy. This disagreement between ΔH and E seems to be ascribable to the contributions to ΔH from the fast reaction stages other than the rate-controlling diffusion process.

A solid reaction which occurs simultaneously when $(NH_4)_3Cl[ZnCl_4]$ decomposes is proposed for the synthesis of the other chlorozincate complexes.

(Received April 22, 1980)

The reaction of erbium sesquioxide (Er_2O_3) or ytterbium sesquioxide (Yb_2O_3) with vanadium dioxide (VO_2) at 1400 °C and 50 kbar and 30 kbar pressures was studied. Quadrivalent vanadium ions were reduced to the trivalent state, erbium vanadite ($ErVO_3$) or ytterbium vanadite ($YbVO_3$) being obtained. The crystal structure of $ErVO_3$ obtained at 50 kbar pressure was vaterite-type isostructural with $ErBO_3$ belonging to a hexagonal system, and that obtained at 30 kbar calcite-type belonging to a rhombohedral (pseudo-hexagonal) system. In the reaction of Yb_2O_3 with VO_2 at high pressure, a perovskite-type crystal was obtained. The electrical and magnetic properties of the vaterite- and the calcite-type $ErVO_3$ were studied.

Success in the synthesis of a diamond has encouraged studies on high-pressure syntheses for the development of new functional materials. In general, increase in pressure tends to stabilize dense phase and lower valence state.[1] It is considered that the most dense ABO_3 phase has cubic-perovskite structure. Rare-earth vanadites ($LnVO_3$) obtained by the reaction of rare-earth sesquioxides (Ln_2O_3) and divanadium trioxide (V_2O_3) at atmospheric pressure are perovskite-type compounds isostructural with orthorhombic $GdFeO_3$.[2] When the reactions were carried out at high pressures, the products were perovskites isomorphous with those obtained by synthesis at atmospheric pressure, their density not depending on pressure.[3]

Pyrochlore-type ytterbium vanadite ($Yb_2V_2O_7$) was obtained by the reaction of ytterbium sesquioxide (Yb_2O_3) and vanadium dioxide (VO_2) at 1400 °C in a vacuum. However, a mixture of perovskite-type $ErVO_3$ and zircon-type $ErVO_4$ was obtained under the same conditions by the reaction between erbium sesquioxide (Er_2O_3) and vanadium dioxide.[4] When the reaction of Er_2O_3 or Yb_2O_3 with VO_2 is carried out at high pressure, the quadrivalent vanadium ions are expected to be reduced to form a type of erbium or ytterbium vanadite ($ErVO_3$ or $YbVO_3$) differing from that of perovskite compounds.

Experimental

Materials. Erbium and ytterbium sesquioxides (Er_2O_3 and Yb_2O_3) (minimum purity 99.9%, Shin-etsu Kagaku Co. Ltd.) were ignited at 1200 °C in order to remove volatile constituents. Divanadium trioxide (V_2O_3) and divanadium pentaoxide (V_2O_5) of special reagent grade were used without further purification. Vanadium dioxide (VO_2) was prepared by heating V_2O_3–V_2O_5 1 : 1 mixture at 1000 °C in a vacuum furnace for 4 h.[5]

Procedure. Er_2O_3 or Yb_2O_3 and VO_2 in 1 : 2 mixtures were weighed and ground with an aluminum mortar and then placed in a cell (Fig. 1). The reactions were carried out at 1400 °C and 50 and 30 kbar pressures with a 15 mm diam. cubic anvil-type apparatus.[6] The samples were subjected to pressure before the temperature was raised. After being kept at 1400 °C for a certain time, the samples were cooled under pressure. The pressure was then released and the products were subjected to X-ray powder-diffraction analysis.

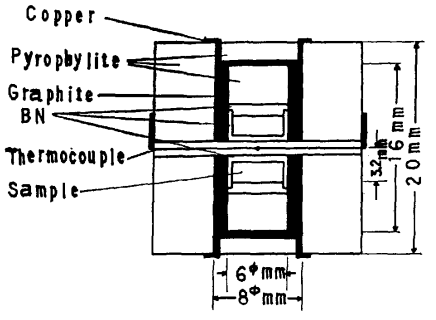

Fig. 1. Cell assemblage for a cubic anvil type high pressure apparatus.

Analysis. The analysis was carried out with a Rigaku Denki Geiger-Flex D-6C diffractometer, using Ni-filtered Cu-K_α radiation ($\lambda = 1.5418$ Å) at a scanning rate of 0.25° (2θ)/min. The diffractometer was calibrated with high-purity silicon.

The atomic ratio of rare-earth to vanadium in the products was determined by fluorescent X-ray analysis with a Rigaku Denki Fluorescent X-ray Analysis Unit.

The valence states of vanadium in the products were inferred from oxygen analysis, which was carried out by igniting the samples in an oxygen stream in order to oxidize all the vanadium ions in the products completely to V^{5+} and calculating their oxygen contents from the weight gain.

Measurements of the Physical Properties. The electrical conductivity measurements were carried out at room temperature (18±1 °C) using polycrystalline pellets, diam. *ca.* 4 mm and thickness 1 mm, by a d.c. two-probe method.

The magnetic suceptibility was measured with a Shimadzu magnetic balance MB-11 equipped with a low temperature apparatus built by members of the Shiokawa Laboratory in the temperature range 4—300 K.

Results and Discussion

The Reaction Products of Er_2O_3 or Yb_2O_3 with VO_2 at High Pressures. Er_2O_3 or Yb_2O_3–VO_2 1 : 2 mixtures were heated at 1400 °C and 50 or 30 kbar pressure. The atomic ratio of erbium or ytterbium to vanadium in the products was determined to be 1.0 by fluorescent X-ray analysis. The valence states of vanadium in the products were inferred from oxygen analysis. The results of oxygen analysis, valence states of vanadium ions and formulas of products obtained by high-pressure

TABLE 1. RESULTS OF OXYGEN ANALYSIS

Starting materials	Reaction conditions	Weight gain %	Valence state of V	Formula
$Er_2O_3+2VO_2$	1400 °C 50 kbar 30 min	5.93	3.0	$ErVO_{3.0}$
$Er_2O_3+2VO_2$	1400 °C 30 kbar 30 min	5.88	3.0	$ErVO_{3.0}$
$Yb_2O_3+2VO_2$	1400 °C 50 kbar 30 min	4.71	3.4	$YbVO_{3.2}$
$Yb_2O_3+2VO_2$	1400 °C 30 kbar 30 min	4.34	3.5	$YbVO_{3.3}$
$Yb_2O_3+2VO_2$	1400 °C 50 kbar 60 min	5.86	3.0	$YbVO_{3.0}$
$Yb_2O_3+2VO_2$	1400 °C 30 kbar 60 min	5.45	3.1	$YbVO_{3.1}$

synthesis are given in Table 1. We see that quadrivalent vanadium ions are reduced gradually to the trivalent states, formulas of the products being eventually $ErVO_3$ or$YbVO_3$.

X-Ray Diffraction Results. X-Ray diffraction data for vaterite (μ-$CaCO_3$)-type $ErBO_3$[7] and the reaction product of 1 : 2 mixtures of Er_2O_3 and VO_2 at 50 kbar are given in Table 2. The fact that the X-ray diffraction pattern for $ErVO_3$ is similar to that of the vaterite-type compound suggests that the compound crystallizes in the hexagonal space group $P6_3/mmc$, $a_0=3.762$ Å and $c_0=8.790$ Å.

X-Ray diffraction data for calcite-type $LuBO_3$[7] and $ErVO_3$ at 30 kbar are given in Table 3. Since the X-ray diffraction pattern for $ErVO_3$ is similar to that of calcite-type $LuBO_3$, the compound seems to crystallize in the rhombohedral (pseudo-hexagonal) space group $R\bar{3}c$-D_{3d}^6, $a_0=4.929$ Å and $c_0=16.429$ Å.

The density of $ErVO_3$ calculated from X-ray diffraction data was 7.99 g/cm³ for the perovskite-type,[8] 7.68 g/cm³ for the calcite-type and 8.25 g/cm³ for the vaterite-type structure. It is the first time that $ErVO_3$ with

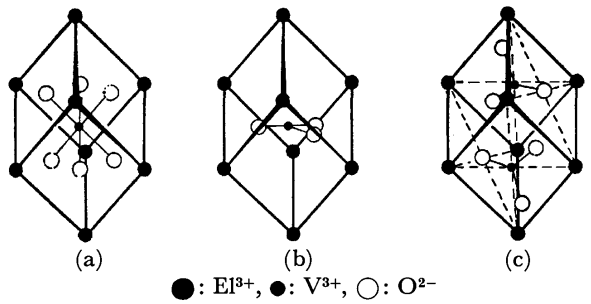

Fig. 2. Comparison of the three structure types of $ErVO_3$.
(a): Perovskite, (b): calcite, (c) vaterite.

density greater than that of perovskite has been obtained. The coordination of atoms in these three structure types is given in Fig. 2. In the vaterite-type structure (Fig. 2(c)), two vanadium ions and two of six oxygen ions are at the center of the faces, two of the oxygen ions in the unit cell, the remainder being out of the cell of the hexahedron consisting of eight erbium ions. $ErVO_3$ having calcite-type or vaterite-type structure, is a salt of Er^{3+} with VO_3^{3-}, rather than a mixed oxide of Er_2O_3 with V_2O_3 as in the perovskite-type $ErVO_3$.

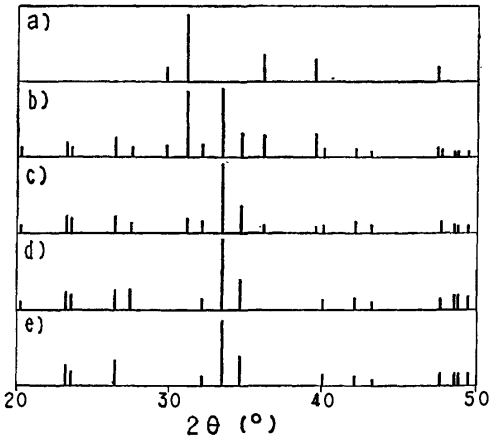

Fig. 3. X-Ray diffraction patterns.
a): Pyrochlore-type $Yb_2V_2O_7$, b): product obtained at 50 kbar for 30 min, c): product obtained at 50 kbar for 60 min, d): product obtained by reheating of c) at 1400 °C in a vacuum for 3 h, e): perovskite-type $YbVO_3$.

The X-ray diffraction patterns of the products obtained by the reaction of Yb_2O_3–VO_2 1 : 2 mixtures along with that of the pyrochlore-type $Yb_2V_2O_7$ and the perovskite-type $YbVO_3$ are shown in Fig. 3. When the reaction was carried out at 1400 °C and 50 kbar pressure for 30 min, a mixture of pyrochlore-type $Yb_2V_2O_7$ and perovskite-type $YbVO_3$ was obtained (Fig. 3(b)). It can be seen that the longer reaction time results in a decrease in $Yb_2V_2O_7$ and an increase in $YbVO_3$. In the reaction of Yb_2O_3 with VO_2, pyrochlore-type $Yb_2V_2O_7$ would be formed first and then transformed into a perovskite-type crystal gradually evolving its oxygen.

Crystal-structures Consideration. Rare-earth vanadites obtained from the reaction of rare-earth sesquioxides and divanadium trioxide at atmospheric or high pressure are perovskite-type compounds isomorphous with orthorhombic $GdFeO_3$. In the case of the reaction of Yb_2O_3 with VO_2 at high pressure, a pyrochlore-type compound $Yb_2V_2O_6O'$ (Fig. 4) is formed first. In this structure, V^{4+} ions occupy corner-shared octahedra and Yb^{3+} ions occupy an eightfold, hexagonal-bipyramid interstice. Two types of tetrahedrally coordinated anions can be distinguished: O^{2-} anions having two Yb^{3+} and two V^{4+} ions as near-neighbors; and O'^{2-} anions having four Yb^{3+} as near-neighbours. The O'^{2-} anions are located at the top and bottom of the apex-shared hexagonal bipyramids. The unique O'^{2-} anion might disappear at high pressure.

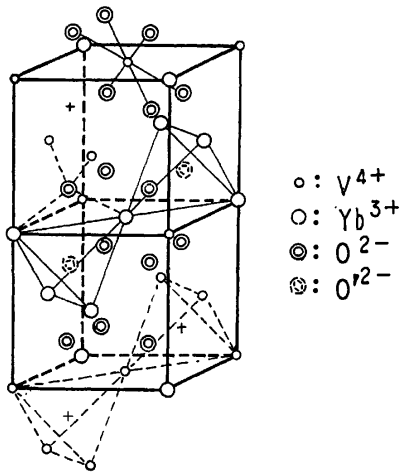

Fig. 4. Idealized crystal structure of a pyrochlore-type $Yb_2V_2O_6O'$ derived from a fluorite-type structure.

The defect pyrochlore $Yb_2V_2O_6$, in which a large electrostatic repulsion between Yb^{3+} cations facing each other across the anion vacancy is introduced, would be transformed easily into a perovskite-type $YbVO_3$ as the tolerance factor of the former was within the limit of perovskite-forming. The reaction product between Yb_2O_3 with VO_2 was a pyrochlore at atmospheric pressure and a perovskite at high pressure. However, in the case of the erbium sesquioxide, the radius ratio, r_{Er}/r_V is so great that no pyrochlore-type structure is formed.[4] It seems that the intermediate phase in the reaction of Er_2O_3 with VO_2 contains no octahedral-site vanadium as in the pyrochlore structure but V_2O_7 clusters of corner-shared tetrahedra or chains of paired trigonal bipyramidal sites sharing corners along a chain and between pairs. Elimination of shared O^{2-} ions would produce VO_3^{3-} clusters, leading to a calcite or vaterite structure.

Physical Properties of $ErVO_3$. The electrical conductivity at 18 °C was 1×10^{-3}, 2×10^{-7} and 1×10^{-7} $\Omega^{-1}\,cm^{-1}$ for perovskite-, calcite- and vaterite-type $ErVO_3$, respectively. The conductivity for calcite- or vaterite-type $ErVO_3$ was much lower than that for perovskite-type $ErVO_3$. This can be interpreted as follows: for perovskite-type $ErVO_3$ electrons are conducted by small polarons produced by anion defects,[8] while calcite- and vaterite-type $ErVO_3$ are salts of Er^{3+} with VO_3^{3-}.

Magnetic susceptibility measurements were carried out in the temperature range 4—300 K. Data for perovskite-type $ErVO_3$ and products obtained by high-pressure synthesis are summarized in Table 4. The

Table 4. Summary of magnetic properties

	Magnetic moment (μ_B)		T_N (K)
Perovskite-type $ErVO_3$	10.0	$T>110$ K	109
	9.3	$T<50$ K	
Calcite-type $ErVO_3$	8.9	$T>70$ K	65
	9.3	$T<50$ K	
Vaterite-type $ErVO_3$	8.8	$T>65$ K	65
	9.3	$T<50$ K	

fact that all the observed values of the magnetic moment for $ErVO_3$ at low temperatures are close to that for Er^{3+} ($\mu_{Er}{}^{3+}=9.4\ \mu_B$) shows that V^{3+} ions order antiferromagnetically at low temperature, and therefore, the observed transitions are attributable to antiferromagnetic ordering of the V^{3+} ions. The perovskite-type $ErVO_3$ is an antiferromagnet with a weak ferromagnetism because of antisymmetric exchange interaction below the transition temperature.[9] All the compounds were paramagnetic, the magnetic susceptibility following the Curie-Weiss law above the transition temperature.

The observed value of the magnetic moment for the perovskite-type $ErVO_3$ above the transition temperature is in good agreement with the calculated value ($\mu_{cal}=9.8\ \mu_B$), if we assume that there was no magnetic interaction between Er^{3+} ions and V^{3+} ions. However, the values for the calcite-type and the vaterite-type

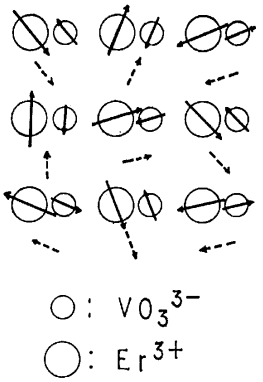

Fig. 5. Proposed orientation of the magnetic moment for the vaterite- or the calcite-type $ErVO_3$ above the transition temperature.

$ErVO_3$ are smaller than the calculated ones. The value of μ_{cal} was calculated by

$$\mu_{cal}=\sqrt{\mu^2_{Er}{}^{3+}+\mu^2_V{}^{3+}}$$

where $\mu_{Er}{}^{3+}=9.4\ \mu_B$ and $\mu_V{}^{3+}=2.8\ \mu_B$. The peculiar magnetic property of these compounds would be interpreted by means of the following. There is a magnetic interaction between an Er^{3+} ion and a V^{3+} ion to make their spins align antiparallel in a unit of $ErVO_3$ (Fig. 5). The net magnetic moment takes the value shown by dotted lines in the figure. The value calculated by $\mu_{cal}=\sqrt{\mu^2_{Er}{}^{3+}-\mu^2_V{}^{3+}}$ is $8.9\ \mu_B$, being in good agreement with the observed one for the calcite- and vaterite-type $ErVO_3$.

Anodic Stripping Semidifferential Electroanalysis of Mercury(II) at Gold Disk Electrode and Its Application to Environmental Analysis

Masashi GOTO,* Kazuhiko IKENOYA, and Daido ISHII

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received April 26, 1980)

Anodic stripping semidifferential electroanalysis using a gold disk working electrode was proposed for the trace determination of mercury(II) ion, theoretical predictions being verified. A gold electrode was steeped in aqua regia, activated electrochemically before use, and rotated during the course of pre-electrolysis. A hydroxylamine hydrochloride medium was selected as supporting electrolyte. The detection limit was found to be *ca.* 0.5 nM under the pre-electrolysis conditions of 10 min at 0 V *vs.* Ag/AgCl. The relative standard deviation was *ca.* ±4% for the measurement at 2 nM level. Removal of the oxygen dissolved in sample solutions was not necessary. Experiments were carried out to examine the feasibility of the technique to environmental analysis. The method consists of only the following procedure: sample acidification, standard mercury(II) ion addition, UV irradiation pretreatment, and medium exchange for stripping. It was successfully applied to river water and sea water to separately evaluate ionic mercury, mercury occluded in organic matter, and total mercury (excluding mercury occluded in inorganic matter).

Environmental scientists realize the increasing nead for reliable methods which can differentiate and determine the chemical forms of trace toxic metals such as mercury in natural waters.[1] Sensitive analytical techniques such as neutron activation analysis and atomic absorption spectrophotometry are not applicable to speciation studies since they deal only with total metal concentration. Anodic stripping voltammetry determines only the labile ionic metal and might be utilized in speciation studies.

Voltammetric methods reported so far for the determination of mercury(II) ion make use of carbon electrodes such as wax-impregnated graphite,[2,3] glassy carbon,[4,5] and carbon paste.[6] However, the methods provide no satisfactory sensitivity for the environmental analysis of mercury(II) ion because of a relatively small affinity of the carbon electrodes with metallic mercury. Recently gold electrodes have drawn renewed attention for trace mercury analysis because of the large solubility of mercury in gold.[7] Sipos *et al.*[8,9] successfully applied the voltammetric method using one or two gold electrodes for the simultaneous determination of total copper and mercury in environmental samples. All the voltammetric methods reported so far for mercury analysis make use of the conventional linear sweep voltammetry at a slow potential scan rate, potentiometry, or differential pulse voltammetry for stripping process. No report seems to have appeared on the systematic speciation analysis of mercury in natural waters.

Goto and Ishii[10] and Dalrymple-Alford *et al.*[11,12] developed a new voltammetric technique "*semidifferential electroanalysis.*" It was applied to anodic stripping analysis of heavy metal ions except mercury(II) ion at a hanging mercury drop[13] and a thin mercury film electrode.[14] Semidifferential electroanalysis has been applied to detection in anodic stripping process at a gold electrode, facilitating the analysis of trace mercury-(II) ion. The method is recommended for simple speciation analysis of mercury in natural waters.

Theoretical

Consider a solution of reduced species in a thin layer of electrode. On oxidation the oxidized species diffuses into a solution of infinite thickness. The trace mercury deposited on a gold disk electrode from a mercury(II) ion solution may be regarded as a solution of mercury in a thin layer of gold. The electrode reaction is considered to be reversible without pre- or post-kinetics. In this case, the same approximate equation between the semiderivative of current, e, with respect to time, t, and the electrode potential, E, as that derived in anodic stripping process at thin mercury film electrode[14] holds under the conditions defined by the dimmentionless parameter, H, less than 1.6×10^{-3}. H is equal to $l^2\sigma/D'$ and $\sigma=nFv/RT$, l is the thickness of gold into which mercury diffuses, D' the diffusion coefficient of mercury in gold and v the potential scan rate, other symbols having their usual meanings. The theoretical e *vs.* E curve for anodic stripping process of mercury from a gold electrode has a maximum and a minimum (Fig. 1).[14] The height from the negative peak to the positive one is given by

$$e_{pp}=\frac{0.429n^{2.5}F^{2.5}Av^{1.5}t_pD^{2/3}N^{1/2}C}{\nu^{1/6}R^{1.5}T^{1.5}}, \quad (1)$$

the negative peak potential by

$$E_{np}=E_{1/2}-\frac{0.656RT}{nF}+\frac{1.15RT}{nF}\log H, \quad (2)$$

and the width between the negative peak and the positive one in the e *vs.* E curve for re-dissolution process of mercury accumulated on a rotating gold disk electrode by pre-electrolyzing trace mercury(II) ion in sample solution by

$$W_{pp}=\frac{2.52RT}{nF}, \quad (3)$$

where A is the electrode area, t_p the pre-electrolysis time, D the diffusion coefficient of mercury(II) ion in solution, N the revolution rate of electrode, C the concentration of mercury(II) ion, ν the kinematic viscosity, and $E_{1/2}$ the d.c. polarographic half-wave

potential. We see that the height is proportional to the mercury(II) ion concentration in sample, the one half powers of the potential scan rate, the square root of the revolution rate of electrode during pre-electrolysis, and the pre-electrolysis time.

Experimental

Apparatus and Reagents. The same apparatus as that reported[14] was used. The working electrode, a gold disk of thickness 0.5 cm and diam. 0.3 cm, was sealed into glass tubing, length 15 cm and i. d. 0.3 cm. The exposed surface of the disk was metallographically polished with emery paper, then with Al_2O_3 powder (0.05 μm) on an acrylic resin plate. The surface had been dipped in aqua regia for 1 min, rinsed with distilled and deionized water, and then kept in 0.5% $HCl \cdot NH_2OH$ solution until use. A rotating electrode assembly (Yanagimoto Co., model P8-RE) was used to rotate the gold disk electrode. The Ag/AgCl (satd KCl) and platinum spiral were used as reference and counter electrodes, respectively, and separated from the sample solution by an agar salt bridge.

The stock solution of 100 mM** $Hg(NO_3)_2$ was prepared by dissolving mercury (99.9999%) in nitric acid. The solution or the mercury standard solution of 1000 ppm for atomic absorption spectrophotometry was used as the standard mercury(II) solution. The stock solutions of 5 M H_2SO_4 and 5% $HCl \cdot NH_2OH$ were prepared for one of supporting electrolytes. All the reagents were of special grade, the solutions being diluted with distilled and deionized water. The cell and all vessels used for sample preparation were filled with 1 M HNO_3 or 0.5 M H_2SO_4 for 1 d, rinsed out, and then filled with distilled and deionized water before use.

Procedure. *Standard Sample*: 25 ml of a standard mercury(II) solution with excess supporting electrolyte was poured into the cell, three electrodes being set. First, the working electrode was rotated, a potential of 0.8 V (*vs.* Ag/AgCl) applied for 30 s to clean the surface of the working electrode, and the required deposition potential of mercury(II) ion was applied for certain time. After this, the rotation was stopped, the potential set to 0 V, and the potential anodically swept at a definite scan rate following a rest period of 30 s. For the re-dissolution process of deposited mercury, the *e vs. E* curve was measured at room temperature (≈20 °C). Next, the working electrode was rotated, a potential of 0.8 V being applied for 30 s, after which the rotation was stopped, the potential of electrode set to 0 V, and the potential anodically swept again at the same scan rate following a rest period of 30 s, to measure the blank *e vs. E* curve. The net *e vs. E* curve was corrected by means of the blank curve.

Environmental Sample: Inland water and sea water were collected in polyethylene bottles and immediately acidified to pH 1 with concd. H_2SO_4. An aliquot of 25 ml of the sample was placed in an open weighing vessel, spiked 25 μl of 30% H_2O_2, and irradiated for a certain time with UV light from a 18 W lamp. The sample was then cooled and the volume adjusted to 25 ml by supplying water to compensate the loss caused by irradiation. The gold disk electrode was activated electrochemically in 0.25 M H_2SO_4 containing 0.5% $HCl \cdot NH_2OH$ by cyclic polarization in the range 0.8—1.6 V at a scan rate of 100 mV/s and again at 0.8 V for 1 min. The electrode was set in the sample solution and electrolysis of mercury(II) ion was carried out at 0 V for 10 min under rotation (rpm 1800) without deaeration of solution. The electrode was then transferred promptly to a medium of 0.25 M H_2SO_4 containing 0.5% $HCl \cdot NH_2OH$. The potential was anodically swept from 0 V to 0.8 V at a scan rate of 100 mV/s following quiet polarization for 30 s at 0 V . The blank *e vs. E* curve was constructed in the same way as in the case of standard sample, electrochemical activation of the electrode being carried out in the same medium. 10 μl of mercury(II) standard solution was then added to the sample solution, the above procedure being repeated to determine mercury.

** 1 M = 1 mol dm^{-3}.

Results and Discussion

e vs. E *Curve in Anodic Stripping Process.* Figure 1 shows a typical *e vs. E* curve of the re-dissolution process of mercury deposited on the gold disk electrode, the corresponding *i vs. E* curve being given for comparison. The dotted *e vs. E* and *i vs. E* curves indicate the blank curves measured after cleaning the gold electrode at 0.8 V for 30 s under rotation. As predicted theoretically, a maximum and a minimum were observed in the *e vs. E* curve for stripping process. We see that the *e vs. E* curve has the following advantages over the ordinary *i vs. E* curve. It is easy to estimate the height from the negative peak to the positive one rather than the peak height from the base line. From a comparison of both blank curves, the semidifferentiation of the *i vs. E* curve seems to reduce the interference of charging current.

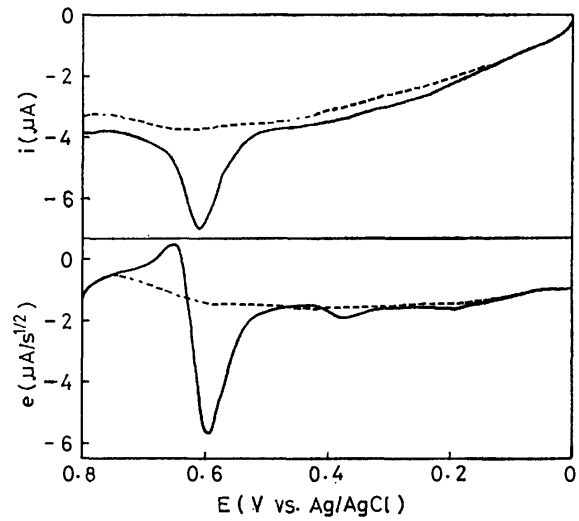

Fig. 1. Typical *e vs. E* curve for the re-dissolution of mercury deposited on the gold disk electrode. Sample: 98.4 nM Hg (II) in 0.25 M H_2SO_4 plus 0.5% $HCl \cdot NH_2OH$, potential scan rate: 100 mV/s, electrode area: 7.07 mm^2, pre-electrolysis potential: 0 V *vs.* Ag/AgCl, pre-electrolysis time: 5 min at rotating electrode and then 30 s at standing one, revolution rate of electrode: 1800 rpm. Dotted lines show the blank curves.

Effect of Supporting Electrolyte. Various supporting electrolytes including sulfuric acid, hydrochloric acid, potassium chloride, potassium thiocyanate, and hydroxylamine hydrochloride were investigated. In a sulfuric acid medium, the anodic stripping waves of mercury appeared at *ca.* 0.9 V, its reproducibility not being

satisfactory. The oxidation of thiocyanate started from *ca.* 0.6 V in thiocyanate medium. A nice stripping wave of mercury was observed in all chloride media (Fig. 1). Since the hydroxylamine hydrochloride medium gave the most reproducible wave in the three chloride media, hydroxylamine hydrochloride was chosen as the supporting electrolyte in addition to 0.25 M H_2SO_4.

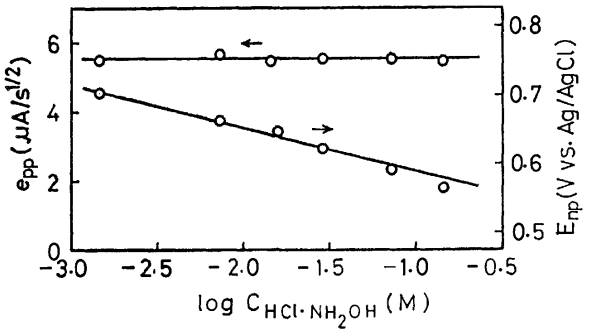

Fig. 2. Dependence of height from the negative peak to the positive one and negative peak potential of *e vs. E* curve for the re-dissolution process on concentration of $HCl \cdot NH_2OH$. Conditions except concentration of $HCl \cdot NH_2OH$ are the same as in Fig. 1.

Figure 2 shows the effect of $HCl \cdot NH_2OH$ concentration in the supporting electrolyte on e_{pp} and E_{np} in the *e vs. E* curve for anodic stripping process. e_{pp} was found to be independent of $HCl \cdot NH_2OH$ concentration. E_{np} shifted to negative potential side with increase in concentration, being linear with its logarithm. This indicates that mercurous ion forms complex with chloride ion:

$$Hg_2^{2+} + pCl^- \rightleftarrows Hg_2Cl_p^{(2-p)-} \quad (4)$$

the electrode reaction being

$$2Hg + pCl^- \rightleftarrows Hg_2Cl_p^{(2-p)-} + 2e \quad (5)$$

where p is the number of ligands involved in the complex. The d.c. polarographic half-wave potential for the electrode reaction of Eq. 5 is given by

$$E_{1/2} = E_s - \frac{RT}{2F} \ln \beta - \frac{pRT}{2F} \ln [Cl^-] \quad (6)$$

where E_s is the standard redox potential of $Hg_2^{2+}/2Hg$ couple and β the stability constant of the chemical reaction of Eq. 4. Thus E_{np} in the *e vs. E* curve should vary linearly with the logarithm of chloride concentration, since E_{np} is the simple function of $E_{1/2}$ (Eq. 2). The slope of the line for E_{np} *vs.* log $C_{HCl \cdot NH_2OH}$ was -62 mV, being comparable with the value -58 mV calculated from $-2.303\ RT/F$. The number of ligand involved in the complex is thus two.

For mercury analysis, the concentration of 0.5% $HCl \cdot NH_2OH$ seems to be most suitable, since the gold electrode itself starts to dissolve from about 0.8 V. A small unknown peak appears at *ca.* 0.4 V, the re-dissolution wave of mercury at this concentration appearing at *ca.* 0.6 V, not overlapping with the undesirable waves.

Pre-electrolysis Potential. The dependence of pre-electrolysis potential on e_{pp} in anodic stripping process was examined. e_{pp} was constant, independent of the pre-electrolysis potentials from 0.4 to -0.9 V. The pre-electrolysis potential of 0 V was chosen for mercury analysis. No influence of dissolved oxygen was observed, removal of oxygen in the solution thus being unnecessary.

Dependence of e_{pp} *on* t_p, v, N, *and* C. The relationship between e_{pp} and t_p at different concentrations was measured by keeping all other parameters constant (Fig. 3). e_{pp} was linear with pre-electrolysis time at rotating electrode up to 5 min at concentration of *ca.* 100 nM and 10 min at that of 10 nM. The positive intersepts with ordinate correspond to the pre-electrolysis for 30 s under standing electrode. Figure 4 shows the relationship between e_{pp} and v, and N. The line of e_{pp} *vs.* $v^{1.5}$ passed through the origin, e_{pp} being

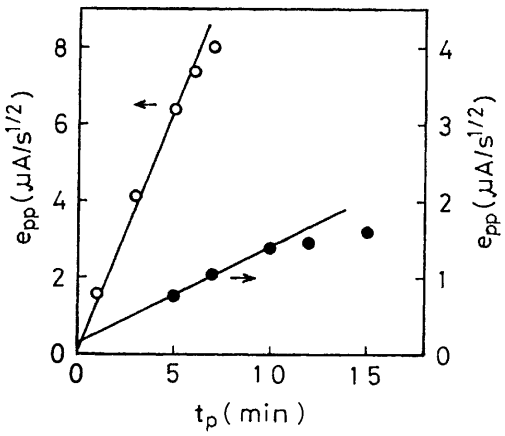

Fig. 3. Relationship between height from the negative peak to the positive one of *e vs. E* curve for the re-dissolution process and pre-electrolysis time at the rotating electrode. Concentration of Hg (II): ○ 98.4 nM, ● 9.8 nM, other conditions are the same as in Fig. 1.

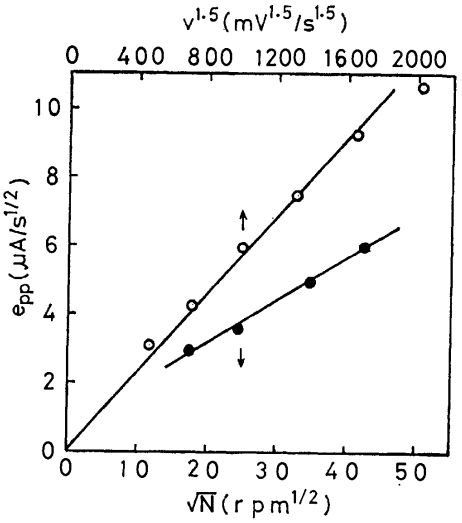

Fig. 4. Relationship between height from the negative peak to the positive one of *e vs. E* curve for the re-dissolution process and potential scan rate (○), and revolution rate of electrode (●). Conditions except potential scan rate (○), and revolution rate of electrode (●) are the same as in Fig. 1.

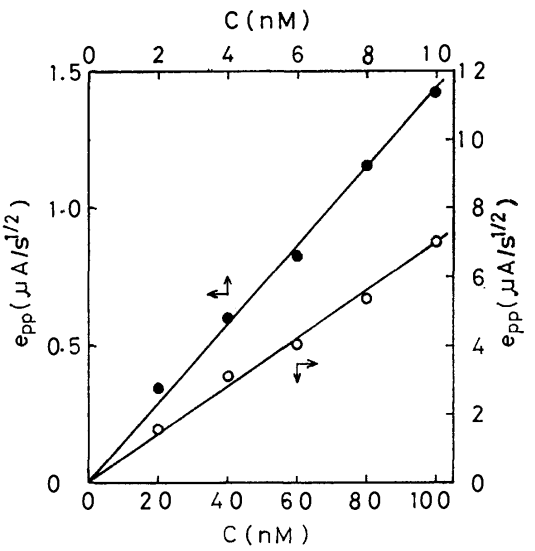

Fig. 5. Relationship between height from the negative peak to the positive one of *e vs. E* curve for the redissolution process and concentrations of Hg (II) present in original solution. Pre-electrolysis time: 5 min for (○), 10 min for (●) at rotating electrode and then 30 s at standing one, other conditions are the same as in Fig. 1.

linear with $N^{1/2}$. Figure 5 shows the relationship between e_{pp} and C at different concentration levels. The pre-electrolysis time employed was 5 min at 10 nM level and 10 min at 1 nM level, respectively. In both cases, e_{pp} was linear with C, the lines passing through the origin.

The results indicate that Eq. 1 applies in the anodic stripping process of mercury from the gold disk electrode.

Dependence of E_{np} *and* W_{pp} *on* C *and* v. The results are given in Table 1. E_{np} is independent of mercury(II) ion concentration to average 0.594 V at the scan rate of 100 mV/s, shifting towards the positive side with increasing scan rate as seen from Eq. 2. W_{pp} averaged *ca.* 52 mV, as compared with the theoretical value of 29 mV for two-electron transfer calculated by means of Eq. 3. This indicates that the electrode reaction (Eq. 5) is not completely reversible.

Analytical Aspects. Table 2 gives the reproducibility for successive measurements of e_{pp} on the same aliquot at different concentrations. The relative standard deviations were ±3% for 10 nM and ±4% for 2 nM. The detection limit of mercury(II) ion was 0.5 nM at the potential scan rate of 100 mV/s and pre-electrolysis time of 10 min.

Application to Environmental Analysis. In order to examine the applicability of the gold electrode for the determination of mercury(II) ion in natural waters, experiments were carried out to see whether the stripping process can be directly performed in natural water

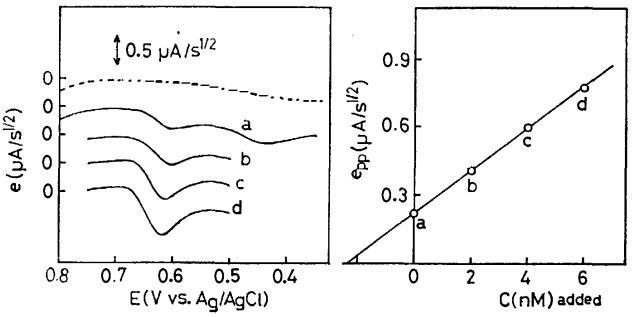

Fig. 6. Performance of anodic stripping semidifferential electroanalysis after medium exchange for 0.25 M H_2SO_4 plus 0.5% $HCl \cdot NH_2OH$ before stripping and regression line for mercury determination by the standard addition method in river water without UV irradiation pretreatment. a: unspiked, b: 2 nM spiked, c: 4 nM spiked, d: 6 nM spiked, pre-electrolysis time: 10 min at rotating electrode and 30 s at standing one after medium exchange, other conditions are the same as in Fig. 1.

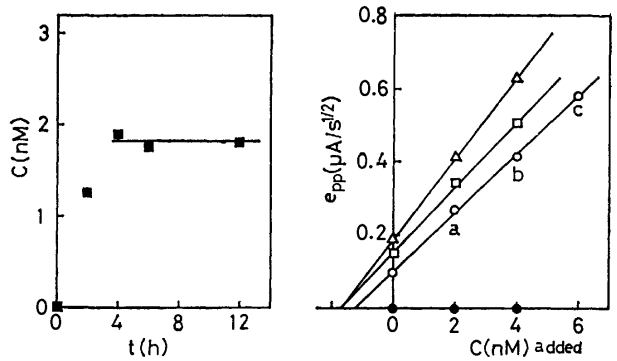

Fig. 7. Effect of pretreatment by UV irradiation on mercury determination in river water by anodic stripping semidifferential electroanalysis after medium exchange. UV irradiation time, t, (h): ● 0, ○ 2, □ 6, △ 12, other conditions are the same as in Fig. 6.

spiked with 0.25 M H_2SO_4 and 0.5% $HCl \cdot NH_2OH$. We were unable to establish the conditions including various electrode pretreatment to get a definite stripping peak of mercury. However, satisfactory results were obtained when the medium was exchanged for the supporting electrolyte solution of 0.25 M H_2SO_4 containing 0.5% $HCl \cdot NH_2OH$ after pre-electrolysis and the gold electrode was electrochemically activated before each run (see Experimental).[9] Figure 6 shows the e *vs.* E curves for the re-dissolution process of mercury after medium exchange following pre-electrolysis in the river water spiked with only 0.05 M H_2SO_4 at different standard mercury(II) ion additions, and the regression line for the determination of mercury in the river water with no pretreatment. The relationship between mercury(II) ion concentration added and e_{pp} remained linear. Samples from river waters frequently contain a large amount of dissolved, colloidal, and particulate organic matter. They must be subjected to UV irradiation to release trace mercury bound to, adsorbed on, and occuluded in components of organic matter by photolytic decomposition by addition of a small amount of H_2O_2. Figure 7 shows the effect of UV irradiation on e_{pp} for mercury analysis at different irradiation times. When the sample was not subjected to UV irradiation, no anodic stripping wave was observed even after standard mercury(II) ion addition. UV irradiation for 2 h with a 18 W lamp gave a regression line similar to that in Fig. 6, the slope increasing with increase in irradiation time. This indicates that the photolytic decomposition of organic matter progresses with irradiation time. The regression concentrations coincide with each other at irradiation times longer than 6 h (Fig. 7), the regression concentration indicating concentration at the intercept of regression line with abscissa.

Mercury Speciation in Natural Waters. The chemical forms of trace heavy metals in natural waters can be classified into the following groups with a slight modification of those given by Florence and Batley:[1] (1) simple hydrated metal ions, (2) labile metal-inorganic complexes, (3) labile metal-organic complexes, (4) stable metal-inorganic complexes, (5) stable metal-organic complexes, (6) metal adsorbed on inorganic colloids and particulate matter, (7) metal adsorbed on organic colloids and particulate matter, (8) metal occluded in inorganic colloids and particulate matter, (9) metal occluded in organic colloids and perticulate matter.

Anodic stripping voltammetry measures only the labile metal ions in (1)—(3) detecting no metal in other chemical form. UV irradiation with H_2O_2 oxidizes organic matter in solution to liberate metal in (5), (7), and (9). The metal-complexing and adsorbing capacity of natural water[15-18] can be determined by the standard addition method in anodic stripping voltammetry. When all metal-complexing and adsorbing material has been consumed, there will be a sudden increase in the slope of regression line. The break point represents the complexing and adsorbing capacity of the water. The slope before the break point would depend on the complexing and adsorbing ability of natural water, while the slope after it should agree with that in pure water.

In the chemical speciation analysis of mercury in river water and sea water by the standard addition method with and without UV irradiation pretreatment (Fig. 8), filtration of natural waters was not carried out in order to eliminate the contamination or loss of mercury. The total labile mercury(II) ions in (1)—(3) can be estimated from e_{pp} obtained with no standard addition and without UV irradiation and the slope of calibration curve in Fig. 5. The regression concentration without UV irradiation may represent the total mercury in (1)—(7), while that with UV irradiation the total mercury in (1)—(7) and (9). The coinciding

Table 3. Examples of mercury concentrations in some forms existing in natural waters

Species of mercury	Sample	
	River water	Sea water
Total ionic mercury	0.2 nM	1.0 nM
Mercury occluded in organic matter	0.9 nM	3.9 nM
Total mercury (excluding mercury occluded in inorganic matter)	1.2 nM	6.0 nM

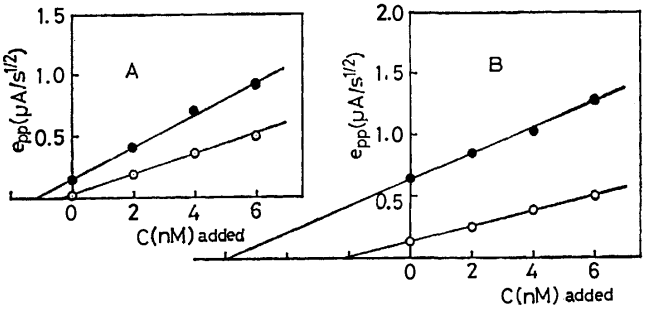

Fig. 8. Typical chemical speciation analysis of mercury in natural waters by the standard addition method with and without UV irradiation pretreatment. Sample: (A) river water, (B) sea water, UV pretreatment: ○ non, ● 12 h at 18 W lamp, other conditions are the same as in Fig. 6.

regression concentrations (Fig. 7) indicate that total mercury excluding (8) can be estimated so far as all mercury in (9) has been liberated, even though the decomposition of organic matter in solution is not complete. The difference between the regression concentrations with and without UV irradiation corresponds to the mercury in (9). When the decomposition of organic matter is complete, e_{pp} obtained with no standard addition and UV irradiation reflects roughly the total mercury in (1)—(3), (5), (7), and (9). Table 3 gives the analytical results of river water and sea water (Fig. 8). The proposed technique for chemical speciation of mercury is applicable to not only inland waters but also sea water.

Thermal Decomposition Reactions of Analogous Penta-amminenitrosylcobalt(III) Complexes

Kikuo Miyokawa,* Hakaru Masuda, and Isao Masuda

Department of Chemistry, Faculty of Science, Fukuoka University, Nanakuma, Nishi-ku, Fukuoka 814

(Received April 30, 1980)

The thermal behavior of five complexes, $[Co(NH_3)_6]Cl_3$ (**1**), $[Co(NH_3)_5NO_2]Cl_2$ (**2**), $[Co(NH_3)_5NO]Cl_2$ (**3**), $[(NH_3)_5Co\text{–}N(O)\text{–}NO\text{–}Co(NH_3)_5]Cl_4\cdot 2H_2O$ (**4**), and $[(NH_3)_5Co\text{–}NO\text{–}ON\text{–}Co(NH_3)_5]Cl_4\cdot 4H_2O$ (**5**), has been investigated. The pyrolysis-gaschromatographic technique has been successfully applied to the N_2- and N_2O-analyses of the gases evolved on the pyrolysis of the complexes. The thermal decomposition of these complexes is characterized predominantly by the reduction process of Co(III) to Co(II). In the simple nitrosyl **3**, the NO^- group reduces the Co(III) ion and dissociates as NO. As for the remaining complexes, a thermally induced transient-state tends to dissociate H^+ from the coordinated ammonia as follows: $Co^{III}\text{–}NH_3 \rightarrow [Co^{III}\text{–}NH_2^{\delta-}\cdots H^{\delta+}] \rightarrow Co^{II} + NH_2 + H^+$. The NH_2 species is subsequently decomposed as $NH_2 \rightarrow 2/3NH_3 + 1/6N_2$. Moreover, H^+ is captured by an anionic species and/or the NH_3 present in the system, that is, by Cl^- and NH_3 forming NH_4Cl in the case of **1**, by NO_2^- and NH_3 forming NH_4NO_2, which then decomposes to N_2 and H_2O, in **2**, and by $N_2O_2^{2-}$ forming $H_2N_2O_2$, which then decomposes to N_2O and H_2O, in **4**. The **5** complex undergoes an exothermic decomposition, affording a larger amount of N_2 and N_2O than those to be expected from the above stoichiometry, suggesting an oxidative behavior of the bridged, dimeric $(\text{–NO–ON–})^{2-}$ group towards ammonia.

Three isomeric compounds with the unitary composition of $[Co(NH_3)_5NO]X_2$, where X=Cl or NO_3, have so far been isolated by the reaction of gaseous NO with an ammoniacal solution of cobalt(II) salt.[1,2] X-Ray diffraction studies have confirmed that the black isomer (Black salt), obtained when the reaction is carried out at −10 °C, is a monomeric nitrosyl complex in which a NO^- group is bound to the cobalt atom in a bent manner,[3] while the red isomer (Red-I salt), obtainable by a similar reaction carried out at room temperature, is a binuclear complex in which two of the $Co(NH_3)_5$ groups are bridged through a *cis*-hyponitrite group, $(\text{–N(O)–NO–})^{2-}$.[4] Recently Miki and Ishimori[2] have isolated another red isomer (Red-II salt) by reacting NO at *ca.* 0 °C with an ammoniacal cobalt(II) solution which had previously been exposed to air for 20 h at *ca.* 20 °C. On the basis of IR and ^{15}N-NMR spectral investigations, they have identified this isomer as a binuclear complex including a $(\text{–NO–ON–})^{2-}$ group bridging two cobalt atoms of $Co(NH_3)_5$ groups.

As these isomers are thought to include intermediary forms of the NO group in a variety of compounds, it seems that it would be interesting to clarify the chemical properties of these isomers. In this work, their pyrolytic behavior in the solid state has been investigated.

Experimental

Materials. $[Co(NH_3)_6]Cl_3$,[5] $[Co(NH_3)_5NO_2]Cl_2$,[6] $[Co(NH_3)_5NO]Cl_2$ (Black salt),[1] $[(NH_3)_5Co\text{–}N(O)\text{–}NO\text{–}Co(NH_3)_5]Cl_4\cdot 2H_2O$ (Red-I salt),[2] and $[(NH_3)_5Co\text{–}NO\text{–}ON\text{–}Co(NH_3)_5]Cl_4\cdot 4H_2O$ (Red-II salt)[2] were prepared according to the published procedure; they were identified by means of cobalt analyses and a study of their infrared spectra.

Measurements. Thermogravimetric (TG) and differential scanning calorimetric (DSC) curves were recorded on a Rigaku Denki thermal analyzer, Model 8002. The measurements were carried out in a nitrogen atomosphere and at a heating rate of 5 °C/min. A 20-mg aliquot of the sample was used. The analyses of the gases evolved were carried out by means of TCD-gaschromatography using a YANAKO G 80 instrument equipped with a YANAKO G 1018 pyrolysis pippeter.[7] A 2.0-mg aliquot of the sample was injected into the pyrolysis pippeter, whose furnace had been kept at the desired temperature; the sample was pyrolyzed rapidly in a helium gas, and the gaseous products were then swept by the helium-gas carrier into the separation column. A stainless steel column (size, 1.5 m×3 mm i.d.; packing, Molecular Sieve 5A, 60/80 mesh or Porapak S, 50/80 mesh) was used. The column and TCD temperature were maintained at 50 °C and 60 °C respectively. The flow rate of carrier gas was 25 cm³/min. The calibration curves for the N_2 and N_2O determinations were made by means of the direct injection of pure gas (0 to 0.25 cm³) into the separation column using a microsyringe; the peak area was measured by means of an integrator. The amount of ammonia evolved was determined by trapping it through bubbling into a standard 0.05 M-sulfuric acid solution and by then titrating the excess acid with a standard 0.1 M-sodium hydroxide solution. The magnetic susceptibility measurements were carried out by the Faraday method. The instrument was calibrated using $[Ni(en)_3]S_2O_3$ as the standard.[8] The IR spectra were recorded on a KBr disk using a Hitachi 345 infrared spectophotometer.

Results

The TG and DSC curves of three isomers are reproduced in Fig. 1, while the analytical results of the gaseous products on pyrolysis are shown in Table 1 and Fig. 2.

As Fig. 1-a shows, Black salt exhibits three endothermic DSC peaks, with maximum temperatures at 135, 230, and 295 °C. Step-by-step weight-losses of 32.2, 6.2, and 7.1% are observed in the TG curve; these seem to correspond to the above DSC peaks. These losses are comparable to those of 31.1, 6.9, and 6.9% calculated by assuming the elimination of 3 mol of ammonia and 1 mol of nitrogen monoxide, of 1 mol of ammonia, and of one further mole of ammonia, respectively. Black salt is well characterized by the IR absorption due to the coordinated NO^- group at 1620 cm^{-1},[9] while the pyrolysis of Black salt at 180 °C resulted in leaving a compound which showed no characteristic absorption in the same range. The results of gas analyses are considered to indicate that,

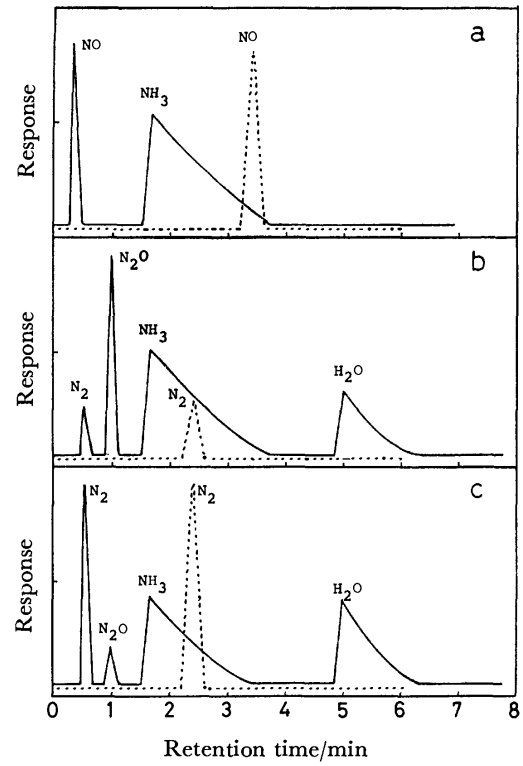

Fig. 2. Pyrolysis gaschromatograms.
a: $[Co(NH_3)_5NO]Cl_2$ (Black salt), pyrolyzed at 200 °C, b: $[Co_2(NH_3)_{10}N_2O_2]Cl_4 \cdot 2H_2O$ (Red-I salt), pyrolyzed at 290 °C, c: $[Co_2(NH_3)_{10}N_2O_2]Cl_4 \cdot 4H_2O$ (Red-II salt), pyrolyzed at 310 °C. Adsorbent: Porapak S: ——, molecular Sieve 5A: -·-·-.

upon pyrolysis at 290 °C, 1 mol of Black salt produces almost quantitatively 1 mol of nitrogen monoxide and 5 mol of ammonia.

The DSC curve of Red-I salt is rather more complicated than that of Black salt, being composed of five endothermic peaks at 150, 170, 185, 230, and 290 °C. The apparent total weight-loss up to 350 °C in the TG curve is 52.3%, which is close to the value of 50.7%, calculated by assuming the final product to be cobalt(II) chloride. The gas-analytical data in Table 1 show that, on the pyrolysis of Red-I salt at 170 °C, only *ca.* 2 mol of ammonia are dissociated, accompanied by water of crystallization. However, pyrolysis at 220 °C causes the evolution of nitrogen and dinitrogen oxide besides ammonia and water. The compound obtained by pyrolyzing Red-I salt at 220 °C contained 27.2% of cobalt and 31.1% of chloride, and showed a magnetic susceptibility of 37.7 cgs. The apparent magnetic moment for the compound is, then, calculated as 4.4 B.M. on the basis of the cobalt content; it falls in the range of the magnetic moments of the high-spin-type Co(II) complexes.[10] By taking these observations into account, the DSC curve of Red-I salt may be interpreted as follows: the first endothermic peak, at 150 °C, corresponds mainly to the dehydration process; the second one, at 170 °C, to the elimination process of a part of the coordinated ammonia, and the third one, at 185 °C, to the decomposition of the coordinated hyponitrite group to dinitrogen oxide and the oxidation process of a coordinated ammonia to nitrogen, as will be discussed later.

The DSC curve of Red-II salt shown in Fig. 1-c is composed of an endothermic peak with a maximum temperature at 230 °C and a large exothermic peak at

Table 1. Analytical data of gaseous products evolved on pyrolysis

Complex	Temp °C	N_2	N_2O	NO[a]	NH_3	H_2O[a]
		(Mol of evolved gas/mol of complex)				
Black salt	200	0.00	0.00	1[b]		
	290	0.07	0.00	1[b]	4.91	
Red-I salt	150	0.00	0.00	—	0.30	○
	170	0.00	0.00	—	1.81	○
	220	0.32	0.96	—		○
	290	0.39	0.96	—		○
Red-II salt	230	0.00	0.00	—		○
	310	2.70	0.21	—		○
$[Co(NH_3)_6]Cl_3$	310	0.17	0.00	—	4.66	
$[Co(NH_3)_5NO_2]Cl_2$	280	1.16	0.00	—	3.62	○

a) Since the calibration curves for these gases could not be obtained under the present experimental conditions, only qualitative data are given for NO and H_2O. Observation of the GC-peak due to H_2O is noted with ○; no observation of the GC-peak due to NO is noted with —. b) The apparent GC-peak of NO is ascribed to a quantitative elimination of NO, for the complex gives no, or only a minor quantity of N_2 and/or N_2O.

265°C, followed by a small endothermic peak at 280 °C. The weight-loss up to 350 °C in the TG curve is 71.0%. Miki and Ishimori[2] have reported, on the basis of the DTA data, that Red-II salt undergoes endothermic dehydration at 220 °C and then vigorous exothermic decomposition at 260 °C. The gas-analytical results shown in Table 1 reveal that only water is evolved on pyrolysis at 230 °C. The IR characteristic bands at 1480, 1280, and 1020 cm^{-1} assigned to the coordinated $(-NO-ON-)^{2-}$ group were observed for the product obtained after pyrolyzing Red-II salt at 230 °C, but not for the product at 265 °C. Nitrogen, dinitrogen oxide, ammonia, and water were detected in the gaseous product evolved on the pyrolysis of this salt at 280 °C; ammonium chloride was also found to be produced. The pyrolysis at 350 °C resulted in leaving a mixture of cobalt(II) chloride and cobalt(III) oxide, which were identified by means of the IR spectrum.

Discussion

The experimental results are indicative of the following pyrolysis process of Black salt:

$$[Co^{III}(NH_3)_5NO]Cl_2 \longrightarrow Co^{II}(NH_3)_2Cl_2 + (3NH_3 + NO)\uparrow$$
$$Co(NH_3)_2Cl_2 \longrightarrow Co(NH_3)Cl_2 + NH_3\uparrow$$
$$Co(NH_3)Cl_2 \longrightarrow CoCl_2 + NH_3\uparrow.$$

Black salt has been depicted formally as having the bonding unit Co(III)–NO^-. Thus, the thermal decomposition in the first stage may be initiated by the electron transfer from the NO^- group to the central Co(III) ion, accompanied by the concomitant elimination of nitrogen monoxide and ammonia. Moreover, the sequence of dissociating ammonia is analogous with that of hexaamminecobalt(II) chloride, which subsequently gives diamminecobalt(II) chloride, monoamminecobalt(II) chloride, and finally cobalt(II) chloride, dissociating ammonia.[11]

Red-I salt includes a *cis*-hyponitrite group bridging two $Co(NH_3)_5$ groups. As is shown in Table 1, the pyrolysis of Red-I salt at $\geqslant$220 °C evolves nitrogen and dinitrogen oxide, besides ammonia and water; the total amount of the former two is more than one mole per mole of the complex. These facts indicate that the nitrogen in these two gases does not originate only from the hyponitrite group. Miki and Ishimori[2] have confirmed that the ammonia groups do not participate in the formation reaction of dinitrogen oxide, for the characteristic $^{14}N^{15}NO$ absorption is not observed in the IR spectrum of the gaseous product obtained by the pyrolysis of Red-I salt, which contains the ^{15}N-substituted hyponitrite group. The formation of nitrogen has not been taken into consideration.

In the investigations of pyrolytic behavior, it has been known that hexaamminecobalt(II) chloride decomposes liberating ammonia and gives cobalt(II) chloride,[11] whereas hexaamminecobalt(III) chloride decomposes in a different manner, depending on the conditions employed.[12-14] On the basis of the results obtained by means of the GEA method, where pyrolysis was carried out in a helium atmosphere and at a heating rate of 1 °C/min, Onodera[12] has recently demonstrated that the latter cobalt(III) complex produces nitrogen and ammonia, following a stoichiometric relation indicated by Eq. 1, which had been proposed by Clark *et al.*:[13]

$$[Co(NH_3)_6]Cl_3 \longrightarrow CoCl_2 + NH_4Cl + 1/6N_2 + 28/6NH_2. \quad (1)$$

However, the reaction mechanism forming nitrogen and/or ammonium chloride still remains obscure. Tanaka and Nagase[14] have pointed out the electron-transfer process involved in the reaction, and they determined, by means of a polarographic technique, the reduction rate of Co(III) to Co(II) on the pyrolysis reaction proceeding *in vacuo*, under isothermal conditions. For a series of the complexes, $[Co(NH_3)_{6-n}X_n]X_{3-n}$ (X=Cl or Br; n=0 or 1), the rates have been found to depend on the nature of X and on the number of n. The results have been interpreted in terms of the reductive behavior of the halide anion. As to the hexaammine complex, then, the following overall reaction has been presented:

$$[Co^{III}(NH_3)_6]X_3 \longrightarrow CoX_2 + 6NH_3 + 1/2X_2. \quad (2)$$

In order to verify nitrogen formation under the present experimental conditions, hexaamminecobalt(III) chloride has been analyzed by pyrolysis-gaschromatography. The results, shown in Table 1, indicate that the amounts of nitrogen and ammonia in the evolved gases are fairly consistent with the stoichiometric relation given in Eq. 1. It should be noticed that the amount of nitrogen is equivalent to that in the one-electron oxidation reaction of ammonia to nitrogen, with a change in the oxidation number from −3 to 0.

By taking the above evidence into consideration, the formation of nitrogen and dinitrogen oxide by Red-I salt can be explained as follows. After dehydrating and dissociating two moles of the coordinated ammonia, the complex is thermally induced to a transient state such as is shown in Eq. 3. Also, the dissociation of this transient species to H^+ and NH_2 species can be accelerated by a concomitant electron-transfer from the NH_2^- moiety to the cobalt(III) and by a subsequent nitrogen-forming reaction (Eq. 4) and dinitrogen oxide-forming reaction (Eq. 5).

$$[Co^{III} - NH_2] \longrightarrow \underbrace{[Co^{III} - NH_2^{\delta-} \cdots H^{\delta+}]}_{\text{transient state}} \longrightarrow$$
$$Co^{II} + NH_2 + H^+ \quad (3)$$
$$NH_2 \longrightarrow 1/6N_2 + 2/3NH_3 \quad (4)$$
$$[H^+ \cdots O-N=N-O \cdots\cdots H^+] \longrightarrow N_2O + H_2O \quad (5)$$

The fact that an ammonia group in the hexaamminecobalt(III) cation readily exchanges the hydrogen atom with deuterium in a D_2O solution is not contrary to the above assumption.[15] The reduced cobalt(II) would release the bonding towards the hyponitrite group. Also, free hyponitrous acid is known to be thermally unstable, and it decomposes at −6 °C.[16]

On the pyrolysis of hexaamminecobalt(III) chloride, the proton expelled by Reaction 3 may be captured by ammonia and the chloride anion, thus forming thermally stable ammonium chloride.

The above assumption can well explain the facts that dinitrogen oxide, one mole per mole of Red-I salt, is produced exclusively from the coordinated hyponitrite

group, and that nitrogen, 1/6 mol per mole of cobalt(III), is produced from a coordinated ammonia.

On the pyrolysis of Red-II salt, the nitrogen evolution is 8—9 times as much as that of Red-I salt. Moreover, the DSC curve in Fig. 1-c shows a large exothermic peak ascribable to the process forming nitrogen and dinitrogen oxide. The proposed structure of Red-II salt includes NO groups in a dimeric $(-NO-ON-)^{2-}$ form, which implies an oxidative behavior of the peroxo moiety. This probably causes an unpredictable oxidation-reaction of ammonia other than that described above.

As for pentaamminenitrocobalt(III) chloride, the gas-analytical data shown in Table 1 are in good agreement with the stoichiometric relation in the following, overall reaction:

$$[Co(NH_3)_5NO_2]Cl_2 \longrightarrow CoCl_2 + 7/6N_2 + 22/6NH_3 + 2H_2O.$$

In this reaction, 1/6 mol of nitrogen can be attributed to the oxidation of the coordinated ammonia by the cobalt(III) ion, and one more mole to the following decomposition of ammonium nitrite, formed by the reaction of the H^+ in Eq. 3 and ammonia and the nitrite anion:

$$NH_4NO_2 \longrightarrow N_2 + 2H_2O.$$

This nitrogen-forming reaction may be understood in terms of an oxidation of ammonia by the nitrite anion. This implies that the nitrogen evolution from Red-II salt would be attributable not only to Reaction 4, but also to an oxidation reaction of ammonia by the dimeric, $(-NO-ON-)^{2-}$ group.

Solubility Isotherms of Systems Containing Optically Active Tris(ethylenediamine)cobalt(III) Ion. I. Reciprocal Salt-pairs, (*Λ*-$[Co(en)_3]^{3+}$, *Δ*-$[Co(en)_3]^{3+}$)-(Br^-, (*R,R*)-$C_4H_4O_6^{2-}$), at 25 °C

Akira Fuyuhiro,* Kazuaki Yamanari, and Yoichi Shimura
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received May 17, 1980)

A four-component solubility isotherm consisting of (*Λ*-$[Co(en)_3]^{3+}$, *Δ*-$[Co(en)_3]^{3+}$)-(Br^-, (*R,R*)-$C_4H_4O_6^{2-}$)-H_2O was determined at 25 °C. It was found that three double salts, *rac*-$[Co(en)_3]Br_3\cdot 3H_2O$, *Λ*-$[Co(en)_3]Br(d\text{-}C_4H_4O_6)\cdot 5H_2O$, and *Λ*-$[Co(en)_3]_{0.48}\cdot$*Δ*-$[Co(en)_3]_{0.52}(d\text{-}C_4H_4O_6)_{1.5}\cdot 5H_2O$ and a gelatinous precipitate exist, six invariant points appearing. Application of this phase diagram to practical optical resolutions is discussed. The solubility of each salt in the system was measured in the range 5—65 °C in water, that of *Λ*- and *Δ*-$[Co(en)_3](d\text{-}C_4H_4O_6)_{1.5}\cdot nH_2O$ being found to be reversed at 42 °C.

A multi-component solubility isotherm containing chiral compounds is important for optical resolution, and those for some systems of metal complexes have been determined.[1,2] In the four-component systems of (*Λ*-$[Co(ox)(en)_2]^+$, *Δ*-$[Co(ox)(en)_2]^+$)-(Cl^-, R^-)-H_2O, where R^- denotes *d*-H_3tart^-, *Δ*-$[Co(edta)]^-$, or *d*-bcs^-((*R,R*)-$C_4H_6O_6\equiv d\text{-}H_4tart$ and (1*R*,3*S*,4*S*,7*R*)-$C_{10}H_{14}OBrSO_3^-\equiv d\text{-}bcs^-$), optically inactive chloride ion does not participate in the formation of diastereomers or pseudoracemates, its introduction thus not playing any part in making optical resolution possible. On the other hand, in the system of $[Co(en)_3]^{3+}$ ion, optical resolution becomes possible by precipitating the diastereomer of double salt, *Λ*-$[Co(en)_3]Br(d\text{-}H_2tart)\cdot 5H_2O$.[3] It would be of interest to find the particular role of the fourth component, Br^-, in this optical resolution.

This paper deals with the determination of the solubility isotherm of reciprocal salt-pairs, (*Λ*-$[Co(en)_3]^{3+}$, *Δ*-$[Co(en)_3]^{3+}$)-(Br^-, *d*-H_2tart^{2-})-H_2O, at 25 °C, and of the solubility of *rac*-$[Co(en)_3]Br_3$, *Λ*-$[Co(en)_3]Br_3$, *Λ*- and *Δ*-$[Co(en)_3](d\text{-}H_2tart)_{1.5}$, and *Λ*-$[Co(en)_3]Br(d\text{-}H_2tart)$ at 5—65 °C.

Experimental

Materials. *Λ*-$[Co(en)_3]X$, $X=Br_3\cdot H_2O$, $Br(d\text{-}H_2tart)\cdot nH_2O$, *and* $(d\text{-}H_2tart)_{1.5}\cdot nH_2O$: The *Λ*-$[Co(en)_3]Br(d\text{-}H_2tart)\cdot 5H_2O$ diasteromer was prepared by the method of Werner,[3] partial asymmetric synthesis,[4] HCl being replaced by HBr, and by addition of equimolar amounts of HBr and *d*-H_4tart to a *rac*-$[Co(en)_3](OH)_3$ solution obtained by treating *rac*-$[Co(en)_3]Br_3$ with an anion exchange resin of OH^- form. Found: C, 21.44; H, 6.85; N, 15.08%. Calcd for *Λ*-$[Co(en)_3]Br(d\text{-}H_2tart)\cdot 5H_2O$: C, 21.55; H, 6.87; N, 15.08%. When a solution of the diastereomer was concentrated at *ca.* 60 °C, a monohydrated sample was obtained. Found: C, 24.67; H, 6.24; N, 17.32%. Calcd for *Λ*-$[Co(en)_3]Br(d\text{-}H_2tart)\cdot H_2O$: C, 24.75; H, 6.23; N, 17.32%. The *Λ*-$[Co(en)_3]Br_3\cdot H_2O$ complex was obtained by the method of Werner.[3] Found: C, 14.47; H, 5.30; N, 17.01%. Calcd for *Λ*-$[Co(en)_3]Br_3\cdot H_2O$: C, 14.50; H, 5.27; N, 16.91%. The diastereomer *Λ*-$[Co(en)_3](d\text{-}H_2tart)_{1.5}\cdot nH_2O$ was prepared from *Λ*-$[Co(en)_3]Br(d\text{-}H_2tart)\cdot 5H_2O$ and $Ag_2(d\text{-}H_2tart)$.[5] At first a paste-like solid precipitated from the solution, gradually turning into needles at room temperature. With a dilute solution the needles deposited directly. The needles are highly efflorescent. Crystallization from a solution at *ca.* 60 °C gave a hygroscopic 1.5-hydrated diastereomer. Found: C, 29.63; H, 6.83; N, 17.30%. Calcd for *Λ*-$[Co(en)_3](d\text{-}H_2tart)_{1.5}\cdot 1.5H_2O$: C. 29.51; H, 6.81; N, 17.21%.

Δ-$[Co(en)_3]X$, $X=Br_3\cdot H_2O$ *and* $(d\text{-}H_2tart)_{1.5}\cdot nH_2O$: The *Δ*-bromide monohydrate was prepared by adding 8 mol dm^{-3} HBr to the filtrate of the less soluble diastereomer *Λ*-$[Co(en)_3]Br(d\text{-}H_2tart)\cdot 5H_2O$. The bromide was optically purified by extraction into water at *ca.* 5 °C and repeated crystallization. Found: C, 14.51; H, 5.33; N, 16.96%. Calcd for *Λ*-$[Co(en)_3]Br_3\cdot H_2O$: C, 14.50; H, 5.27; N, 16.91%. The diastereomer *Δ*-$[Co(en)_3](d\text{-}H_2tart)_{1.5}\cdot nH_2O$ was prepared from *Δ*-$[Co(en)_3]Br_3\cdot H_2O$ and $Ag_2(d\text{-}H_2tart)$.[5] The prismatic crystals, highly efflorescent, have *ca.* 1.5—8 crystal waters. Found: C, 26.84; H, 7.11; N, 15.68%. Calcd for *Δ*-$[Co(en)_3](d\text{-}H_2tart)_{1.5}\cdot 4H_2O$: C, 27.02; H, 7.18; N, 15.76%.

rac-$[Co(en)_3]Br_3\cdot nH_2O$: Racemic bromide trihydrate was prepared by the method of Werner.[3] Found: C, 13.43; H, 5.69; N, 15.66%. Calcd for *rac*-$[Co(en)_3]Br_3\cdot 3H_2O$: C, 13.52; H, 5.67; N, 15.77%. Crystallization of the complex at *ca.* 60 °C gave a very hygroscopic monohydrate. Found: C, 14.40; H, 5.38; N, 16.97%. Calcd for *rac*-$[Co(en)_3]Br_3\cdot H_2O$: C, 14.50; H, 5.27; N, 16.91%.

Λ-$[Co(en)_3]_{0.48}\cdot$*Δ*-$[Co(en)_3]_{0.52}(d\text{-}H_2tart)_{1.5}\cdot 5H_2O$: An apparent nonstoichiometric compound (not a mixture, see Results and Discussion) was prepared from *rac*-$[Co(en)_3]Br_3\cdot 3H_2O$ and $Ag_2(d\text{-}H_2tart)$ in a 2 : 3 mole ratio. Found: C, 26.16; H, 7.25; N, 15.26%. Calcd for $[Co(en)_3](d\text{-}H_2tart)_{1.5}\cdot 5H_2O$: C, 26.14; H, 7.31; N, 15.24%. The exact composition of the cations was determined by circular dichroism(CD)

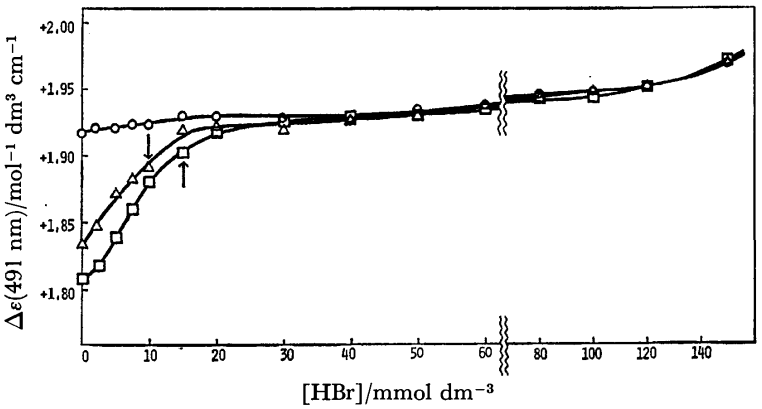

Fig. 2. CD in HBr aqueous solution. The concentration of Λ-$[Co(en)_3]^{3+}$ is 5 mmol dm^{-3}.
○: Λ-$[Co(en)_3]Br_3$, △: Λ-$[Co(en)_3]Br(d\text{-}H_2tart)$, □: Λ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}$.

measurement in solution. The composition ($\Lambda : \Delta = 48\pm1 : 52\mp1$) was reproducible even by repeated recrystallization. Rapid cooling of the solution of $[Co(en)_3](d\text{-}H_2tart)_{1.5}$ sometimes provided a Λ-rich precipitate.

Measurements. *Calibrations of CD:* The molar absorption coefficient of $[Co(en)_3]^{3+}$ at the first d-d band(466 nm) was almost constant in spite of the presence of H^+, Br^-, and/or $d\text{-}H_2tart^{2-}$ in the concentration range 5×10^{-5}—10^{-2} mol dm^{-3} of the complex ion. Since the CD spectrum is considerably affected by the presence of $d\text{-}H_2tart^{2-}$ ion,[6] the influence of this ion on CD intensity was examined in water and in HBr solutions. The Λ-diastereomers, Λ-$[Co(en)_3]Br(d\text{-}H_2tart)$ and Λ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}$, showed a gradual decrease in CD intensity with increase of complex concentration, and the $\Delta\varepsilon$ values at 10^{-2} mol dm^{-3} became 3 and 5% lower than the authentic value ($|\Delta\varepsilon(491\text{ nm})|=1.89$), respectively, the Λ-$[Co(en)_3]Br_3$ complex showing the reversed change (Fig. 1). The corresponding Δ-diastereomers, Δ-$[Co(en)_3]Br(d\text{-}H_2tart)$ and Δ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}$, showed about half decreases in absolute values of $\Delta\varepsilon$ as compared with Λ-diastereomers in the concentration range 5×10^{-5}—10^{-2} mol dm^{-3}. The CD intensities depend a great deal upon the complex concentration in water. Figure 2 shows the variations of CD intensity at 491 nm in HBr solutions. In both systems of Λ-$[Co(en)_3]Br(d\text{-}H_2tart)$ and Λ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}$, the CD intensities were almost constant in HBr solutions (2×10^{-2}—10^{-1} mol dm^{-3}) in Fig. 2, where the arrows indicate the points at which $d\text{-}H_2tart^{2-}$ should exist in acid form $d\text{-}H_4tart$ if we neglect the acid dissociations. The corresponding Δ-diastereomers showed about 2/3 increase in absolute values of $\Delta\varepsilon$ between [HBr]=0 and the plateau as compared with the Λ-diastereomers. Figures 3 and 4 show the concentration dependence of induced CD of *rac*-$[Co(en)_3](d\text{-}H_2tart)_{1.5}$ in water and in HBr solutions, respectively. Since the complex could not be obtained as a solid, the reaction mixture was used in solution, its concentration being determined by optical density. The induced CD peak appears at 461 nm,[6] but the measurements were carried out at 491 nm. Measurements in HBr solutions were found to be more favorable than in water because the CD intensities are almost zero in an appropriate HBr solution irrespective of the complex concentration. Beer's law holds in the concentration range 0—10^{-2} mol dm^{-3} in a 5×10^{-2} mol dm^{-3} HBr aqueous solution.

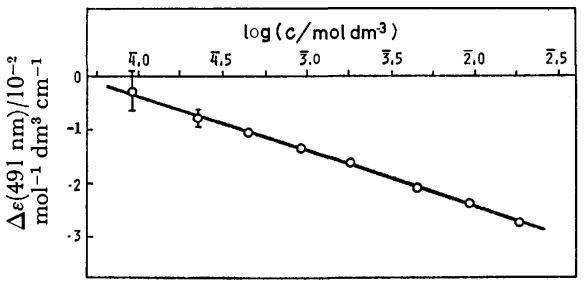

Fig. 3. Concentration dependence of induced CD of *rac*-$[Co(en)_3](d\text{-}H_2tart)_{1.5}$ in water at 491 nm.

Analyses of Saturated Solutions: Solubility in water was determined in molality.[1] Saturated solution weighed was diluted with a 5×10^{-2} mol dm^{-3} HBr aqueous solution to a certain volume. Optical densities and CD were measured under the conditions described above. The concentrations of $\{\Lambda\text{-}[Co(en)_3]^{3+}+\Delta\text{-}[Co(en)_3]^{3+}\}$ were determined from the

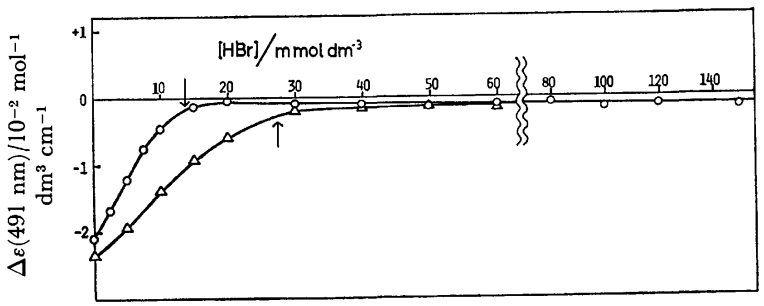

Fig. 4. Induced CD of *rac*-$[Co(en)_3](d\text{-}H_2tart)_{1.5}$ (○; 4.62 mmol dm^{-3} and △; 9.17 mmol dm^{-3}) in HBr aqueous solution.

observed optical densities, referring to the calibrated molar absorption coefficient of $[Co(en)_3]^{2+}$, $\varepsilon(466\,nm)=91.0$, the concentrations of $\{\Lambda\text{-}[Co(en)_3]^{3+}-\Delta\text{-}[Co(en)_3]^{3+}\}$ being obtained from CD intensities calibrated above; $\Delta\varepsilon(491\,nm)=+1.93$ and -1.93 for Λ- and Δ-$[Co(en)_3]^{3+}$, respectively. The concentrations of Λ- and Δ-$[Co(en)_3]^{3+}$ were separately calculated from the concentrations of $\{\Lambda\text{-}[Co(en)_3]^{3+}+\Delta\text{-}[Co(en)_3]^{3+}\}$ and $\{\Lambda\text{-}[Co(en)_3]^{3+}-\Delta\text{-}[Co(en)_3]^{3+}\}$. In the presence of both Br^- and d-H_2tart^{2-} ions, a titration method was combined with the spectral one in order to determine the amount of Br^-. A saturated solution was taken, weighed and diluted with an appropriate amount of water. The solution was titrated with a 0.03 mol dm^{-3} $AgNO_3$ solution till the end point of precipitation of AgBr, which was followed by the electromotive force(e.m.f.) of the following chemical cell: Ag|sample||KNO_3 soln.||3.33 mol dm^{-3} KCl soln.|AgCl(s)|Ag. The e.m.f. jumped distinctly between the precipitation of AgBr and $Ag_2(d\text{-}H_2tart)$, and the end point was calibrated by the known amounts of NaBr, Λ- and *rac*-$[Co(en)_3]Br_3\cdot nH_2O$, Λ-$[Co(en)_3]Br(d\text{-}H_2tart)\cdot 5H_2O$, and Λ- and Δ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}\cdot nH_2O$. In the binary systems the concentration could be derived from only the optical densities. In this way, the amounts of all cations and anions and then the amount of water in the saturated solution were obtained and given in molality.

Analyses of Solid Phases: The solid phases were identified from elemental analyses, absorption and CD spectra, gravimetric analyses, and differential thermal analyses(DTA). The DTA were performed under dry or suspended (in water) conditions at atmospheric pressure. Optical densities were measured with a JASCO UVIDEC-1 spectrophotometer and CD with a JASCO MOE-1 spectropolarimeter.

Results and Discussion

The solubility data are given in Tables 1 and 2, and Figs. 5—11. A saturated solution is expressed as a point defined by summing up the position vectors of the solubilities of the component salt(s) contained.[1)]

Binary Systems between 5 and 65 °C. Figure 5 shows the binary solubility curves of the complexes, a few points of solubility of which have been reported.[5,7)] The more the tartrate ion share in the counter ions, the steeper the slopes of solubility curves. The solubility of Λ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}$ at 60 °C in particular is about 90 times greater than that at 5 °C. The solubility of a pair of diastereomers, Λ- and Δ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}$ is reversed at 42 °C; the Λ-diastereomer is less soluble at temperatures below 42 °C and the Δ above 42 °C. Inflection points were observed in *rac*-[Co-

TABLE 2. EQUILIBRIUM OF (Λ-$[Co(en)_3]^{3+}$, Δ-$[Co(en)_3]^{3+}$)-(Br^-, d-H_2tart^{2-})-H_2O SYSTEM AT 25 °C

In liquid phases, solubility is presented in molality m of the component ions. Abbreviations are as follows: Λ-$[Co(en)_3]^{3+}=\Lambda^{3+}$, Δ-$[Co(en)_3]^{3+}=\Delta^{3+}$, Λ-$[Co(en)_3]Br_3\cdot H_2O=\Lambda Br_3$, Δ-$[Co(en)_3]Br_3\cdot H_2O=\Delta Br_3$, *rac*-$[Co(en)_3]Br_3\cdot 3H_2O=\Lambda\Delta Br_6$, Λ-$[Co(en)_3]Br(d\text{-}H_2tart)\cdot 5H_2O=\Lambda Br(tart)$, Λ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}\cdot nH_2O$ ($n\gtrsim 7$)$=\Lambda(tart)_{1.5}$, Δ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}\cdot nH_2O$ ($n\simeq 8$)$=\Delta(tart)_{1.5}$, and Λ-$[Co(en)_3]_{0.48}\cdot\Delta$-$[Co(en)_3]_{0.52}$-$(d\text{-}H_2tart)_{1.5}\cdot 5H_2O=(\Lambda,\Delta)(tart)_{1.5}$. The gelatinous precipitate(Gela) is treated as solid.

a) Values in parentheses are estimated errors and calculated from twice the standard deviations of measurements repeated 3—14 times.

$(en)_3]Br_3$, Λ-$[Co(en)_3]Br(d\text{-}H_2tart)$, and Λ-$[Co(en)_3]$-$(d\text{-}H_2tart)_{1.5}$ at about 32, 47, and 47 °C, respectively. The points were also clearly observed by DTA. Under dry conditions these three complexes provided no DTA peak at the inflection points, the peaks being observed under suspended conditions in water. The *rac*-$[Co(en)_3]Br_3\cdot nH_2O$ salt showed the peak in both heating and cooling processes, Λ-$[Co(en)_3]Br(d\text{-}H_2tart)\cdot nH_2O$ and Λ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}\cdot nH_2O$ only in heating process. The Λ-$[Co(en)_3]Br(d\text{-}H_2tart)$ salt in high temperature form were gradually transformed into low temperature form in 1—3 h at room temperature, the latter giving the DTA peak again on heating. It took a few days for Λ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}$ to be transformed into low temperature form, the change corresponding to the transfer of the paste-like precipitate to the needles (see Experimental).

The Ternary System, Λ-$[Co(en)_3]Br_3$–Δ-$[Co(en)_3]Br_3$–H_2O. The solubility isotherm of this type determines whether the racemate is spontaneously resolved or not.[8,9] Figure 6 shows the solubility isotherm of the ternary system, Λ-$[Co(en)_3]Br_3$–Δ-$[Co(en)_3]Br_3$–H_2O, at 25 °C. Points A, B, and E_3 indicate the binary solubility of Λ-, Δ-, and *rac*-$[Co(en)_3]Br_3\cdot nH_2O$, respectively, no spontaneous resolution taking place. In this system, two invariant points, E_1 and E_2, appear and the widely spread curve, $E_1E_3E_2$, represents the solubility isotherm of the racemic compound, *rac*-$[Co(en)_3]Br_3\cdot 3H_2O$. Point $E_1(E_2)$ lies extremely close to the left(right) axis, optical purity of the liquid phase at E_1 and E_2 being almost perfect. A similar ternary system, Λ-$[Co(ox)(en)_2]I$–Δ-$[Co(ox)(en)_2]I$–H_2O,[9] is not so extreme as the present system.

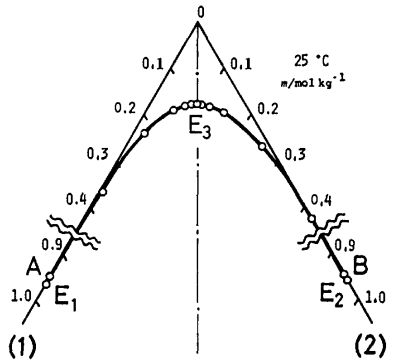

Fig. 6. Solubility isotherm of the ternary system, Λ-$[Co(en)_3]Br_3$–Δ-$[Co(en)_3]Br_3$–H_2O, at 25 °C.
Solubility is presented in molality m of anhydrous salt. (1): Λ-$[Co(en)_3]Br_3$, (2): Δ-$[Co(en)_3]Br_3$.

The Ternary System, Λ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}$–$\Delta$-$[Co(en)_3](d\text{-}H_2tart)_{1.5}$–$H_2O$. The solubility isotherm of this type which consists of a pair of diastereomers and solvent is the simplest one for discussion of optical resolution. Figure 7 shows the system, Λ-$[Co(en)_3]$-$(d\text{-}H_2tart)_{1.5}$–Δ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}$–$H_2O$, at 25 °C. This resembles those of the following systems, Λ-$[Co(ox)(en)_2]R$–Δ-$[Co(ox)(en)_2]R$–H_2O (25 °C); $R^- = 1/2\text{-}[Sb_2(d\text{-}tart)_2]^{2-}$ and *d*-bcs^-, in which the pseudoracemic compounds, Λ-$[Co(ox)(en)_2]\cdot\Delta$-$[Co(ox)(en)_2]\cdot[Sb_2(d\text{-}tart)_2]\cdot 5H_2O$ and Λ-$[Co(ox)(en)_2]\cdot\Delta$-$[Co(ox)(en)_2](d\text{-}bcs)_2\cdot 2H_2O$, respectively, are formed between

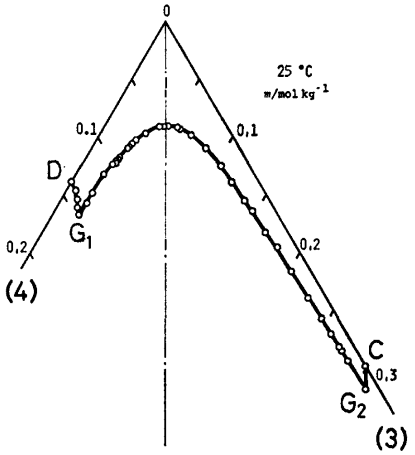

Fig. 7. Solubility isotherm of the ternary system, Λ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}$–$\Delta$-$[Co(en)_3](d\text{-}H_2tart)_{1.5}$–$H_2O$, at 25 °C.
Solubility is presented in molality m of anhydrous salt. (4): Λ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}$, (3): Δ-$[Co(en)_3]$-$(d\text{-}H_2tart)_{1.5}$.

the two diastereomers.[9,10] However, the ratio of *Λ*: *Δ* in the central solid phase of the present system is not 50 : 50% but (48±1) : (52∓1)% on the curve G_1G_2 (Fig. 7). Since the effect of induced CD exerts less than 0.1% for deviation of this ratio (see Experimental), it is reasonable to conclude that the compound is a nonstoichiometric substance with the composition *Λ*-$[Co(en)_3]_{0.48}$·*Δ*-$[Co(en)_3]_{0.52}$(*d*-H_2tart)$_{1.5}$·$5H_2O$. The compound (not mixture) might correspond to the precipitate prepared from a mixed solution of *rac*-$[Co(en)_3]X_3$ (X=Cl and Br) and KNa(*d*-H_2tart) by addition of ethanol.[11] If we attempt optical resolution with this ternary system, *viz.*, a solution of $[Co(en)_3]$-(*d*-H_2tart)$_{1.5}$ is concentrated at 25 °C, only a partially resolved *compound* will be obtained. Thus we must treat a four-component system to resolve the $[Co(en)_3]^{3+}$ complex perfectly.

The Ternary System, Λ-*[Co(en)$_3$](d-H$_2$tart)$_{1.5}$*–Λ-*[Co(en)$_3$]Br$_3$–H$_2$O.* Figure 8 shows the isotherm at

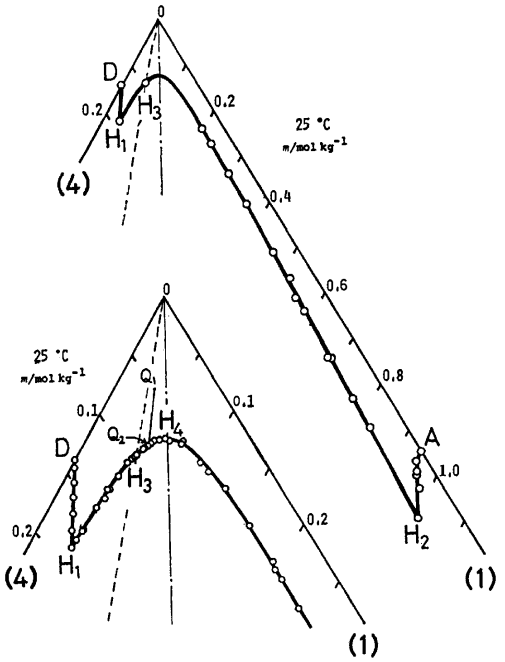

Fig. 8. Solubility isotherm (upper) and its magnification of the ternary system, *Λ*-$[Co(en)_3]$(*d*-H_2tart)$_{1.5}$–*Λ*-$[Co(en)_3]Br_3$–H_2O, at 25 °C.
Solubility is presented in molality *m* of anhydrous salt. (4): *Λ*-$[Co(en)_3]$(*d*-H_2tart)$_{1.5}$, (1): *Λ*-$[Co(en)_3]Br_3$.

25 °C which is irrelevant to a successful optical resolution. Points D, H_3, and A denote the solubility of binary systems, *Λ*-$[Co(en)_3]$(*d*-H_2tart)$_{1.5}$, *Λ*-$[Co(en)_3]$Br-(*d*-H_2tart), and *Λ*-$[Co(en)_3]Br_3$, respectively. Since the central solid has the composition *Λ*-$[Co(en)_3]$Br(*d*-tart)·$5H_2O$, the point of this solid exists on the elongation of line OH_3. The liquid phase composition of minimum solubility of *Λ*-$[Co(en)_3]^{3+}$ corresponds to point H_4 where the ratio of *Λ*-$[Co(en)_3]$(*d*-H_2tart)$_{1.5}$: *Λ*-$[Co(en)_3]Br_3$ is equal to 1 : 1, or (*d*-H_2tart)$^{2-}$: Br^- to 1 : 2, but not to 1 : 1 which agrees with point H_3. When an unsaturated solution of Q_1 is concentrated at 25 °C, the salt *Λ*-$[Co(en)_3]$Br(*d*-H_2tart)·$5H_2O$ will deposit at Q_2 and the composition of the saturated solution will concomitantly move toward the minimum solubility of *Λ*-$[Co(en)_3]^{3+}$(H_4), and in turn, to the point H_2 where two solids, *Λ*-$[Co(en)_3]$Br(*d*-H_2tart)·$5H_2O$ and *Λ*-$[Co(en)_3]Br_3$·H_2O, coexist.

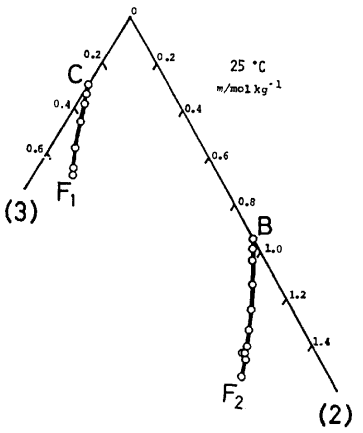

Fig. 9. Solubility isotherm of the ternary system, *Δ*-$[Co(en)_3]$(*d*-H_2tart)$_{1.5}$–*Δ*-$[Co(en)_3]Br_3$–H_2O, at 25 °C.
Solubility is presented in molality *m* of anhydrous salt. (3): *Δ*-$[Co(en)_3]$(*d*-H_2tart)$_{1.5}$, (2): *Δ*-$[Co(en)_3]Br_3$.

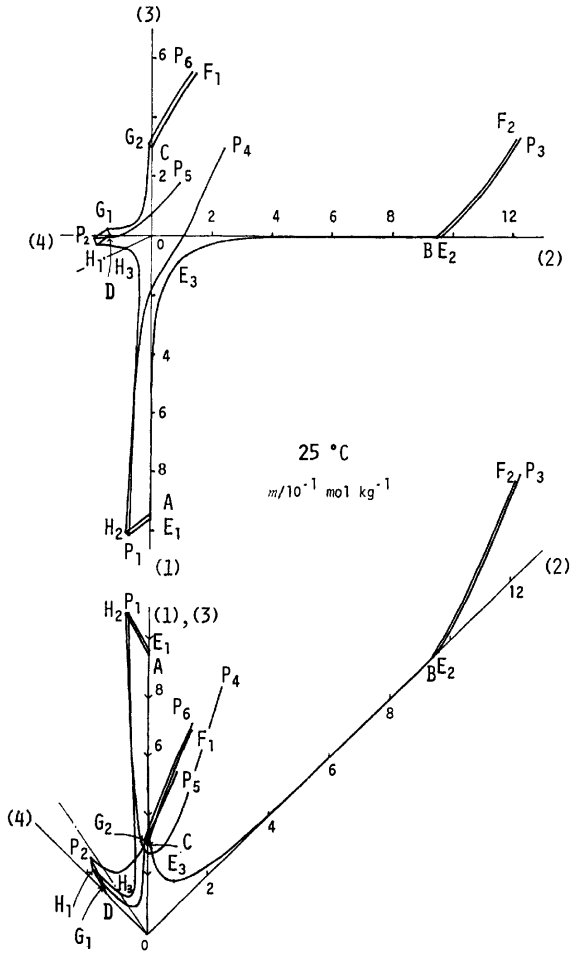

Fig. 10. The plane projection(upper) and the side elevation of solubility isotherm of the system, (*Λ*-$[Co(en)_3]^{3+}$, *Δ*-$[Co(en)_3]^{3+}$)-(Br^-, *d*-H_2tart^{2-})-H_2O, at 25 °C.
Solubility is presented in molality *m* of anhydrous salt. (1): *Λ*-$[Co(en)_3]Br_3$, (2): *Δ*-$[Co(en)_3]Br_3$, (3): *Δ*-$[Co(en)_3]$(*d*-H_2tart)$_{1.5}$, (4): *Λ*-$[Co(en)_3]$(*d*-H_2tart)$_{1.5}$.

The Ternary System, Δ-[Co(en)$_3$](d-H$_2$tart)$_{1.5}$–Δ-[Co(en)$_3$]Br$_3$–H$_2$O. As shown in Fig. 9, the central part of the isotherm is blank owing to the appearance of gelatinous substances; when measurements of the saturated solutions from points C and B were carried out to points F_1 and F_2, respectively, the liquid phase turned into a gelatinous substance. This was obtained from the filtrate of the optical resolution and reported as Δ-[Co(en)$_3$]Br(*d*-H$_2$tart)·5H$_2$O,[3] but the composition and structure have not been determined clearly.

The lines DG_1, CG_2, DH_1, AH_2, CF_1, and BF_2 in Figs. 7—9 go down almost vertically. The situation differs significantly from the one expected from the common ion effect, suggesting that the activity coefficient of each salt becomes very small because of the association between $[Co(en)_3]^{3+}$ and *d*-H_2tart^{2-}.

The Solubility Isotherm of Reciprocal Salt-pairs, (Λ-[Co(en)$_3$]$^{3+}$, Δ-[Co(en)$_3$]$^{3+}$)–(Br$^-$, d-H$_2$tart^{2-})–H$_2$O. The solubility isotherm of reciprocal salt-pairs consisting

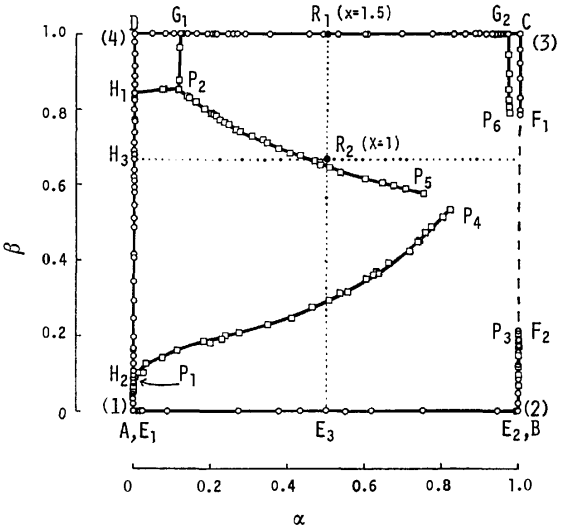

Fig. 11. The clinographic projection of solubility isotherm of the system, (Λ-[Co(en)$_3$]$^{3+}$, Δ-[Co(en)$_3$]$^{3+}$)–(Br$^-$, *d*-H$_2$tart^{2-})–H$_2$O, at 25 °C.
α: mole fraction of Δ-[Co(en)$_3$]$^{3+}$ to all the cations, β: mole fraction of (*d*-H$_2$tart)$_{1.5}^{3-}$ to {(Br$_3$)$^{3-}$+(*d*-H$_2$tart)$_{1.5}^{3-}$}, (1): Λ-[Co(en)$_3$]Br$_3$, (2): Δ-[Co(en)$_3$]Br$_3$, (3): Δ-[Co(en)$_3$](*d*-H$_2$tart)$_{1.5}$, (4): Λ-[Co(en)$_3$](*d*-H$_2$tart)$_{1.5}$, □: solubilities of four-components, ○: solubilities of two- or three-components.

of two cations, two anions, and solvent can be drawn in space and projected on three planes according to the definition[1] in which solubility is expressed in molality of component ions and then the molality of three salts. In the present system, the charges of the component anions differ, molalities of Br^- and *d*-H_2tart^{2-} being calculated as those of $(Br_3)^{3-}$ and (*d*-H$_2$tart)$_{1.5}^{3-}$, respectively. The four-component system includes the ternary systems in the above sections. The plane projection and side elevation are shown in Fig. 10 and the clinographic projection of the isotherm at 25 °C in Fig. 11. The left, right, lower, and upper sides in Fig. 11 correspond to Figs. 8, 9, 6, and 7, respectively. There are three double salts, Λ-[Co(en)$_3$]·Δ-[Co(en)$_3$]Br$_6$·6H$_2$O(=*rac*-[Co(en)$_3$]Br$_3$·3H$_2$O), Λ-[Co(en)$_3$]Br(*d*-H$_2$tart)·5H$_2$O, and Λ-[Co(en)$_3$]$_{0.48}$·Δ-[Co(en)$_3$]$_{0.52}$(*d*-H$_2$tart)$_{1.5}$·5H$_2$O and one gelatinous precipitate in the areas $E_1E_3E_2P_3P_4P_1E_1$, $H_1H_3H_2P_1P_4P_5P_2H_1$, $G_1P_2P_5P_6G_2G_1$, and $F_2F_1P_6P_5P_4P_3F_2$, respectively. In this system six invariant points, P_1—P_6, having four components exist at 25 °C. Since the Λ-[Co(en)$_3$]Br(*d*-H$_2$tart)·5H$_2$O diastereomer covers the area across the "racemic line" R_1E_3 (Fig. 11), the perfect optical resolution of $[Co(en)_3]^{3+}$ ion is possible by using Br^- and *d*-H_2tart^{2-} as resolving agents at 25 °C. However, it should be noted that the saturated solution of *rac*-[Co(en)$_3$]Br(*d*-H$_2$tart) prepared from 1 mol of *rac*-[Co(en)$_3$]Br$_3$ and x mol (x=1) of Ag$_2$(*d*-H$_2$tart) lies on R_2 (Fig. 11), in equilibrium with the partially resolved compound Λ-[Co(en)$_3$]$_{0.48}$·Δ-[Co(en)$_3$]$_{0.52}$(*d*-H$_2$tart)$_{1.5}$·5H$_2$O, but not with the solid Λ-[Co(en)$_3$]Br(*d*-H$_2$tart)·5H$_2$O. In the case of $0.43<x<0.97$, the isothermal concentration in equilibrium at 25 °C would enable us to attain perfect optical resolution.

The authors are grateful to Dr. Takasuke Matsuo and Mr. Yoshichika Yoshioka, Osaka University, for their advice and use of the DTA apparatus.

Polarographic Study on the Transportation of Oxygen by Perfluorocarbon Emulsion as Artificial Blood

Katsumi HAYASHI and Masanosuke TAKAGI*

Department of Agricultural Chemistry, College of Agriculture, University of Osaka Prefecture, Sakai, Osaka 591

(Received May 19, 1980)

Restrictive factors of oxygen release from dispersed particles of perfluorocarbon (PFC) in a form of emulsion have been studied by polarographic reduction currents of oxygen in the emulsion. The oxygen reduction currents in PFC emulsion in open system increased linearly with the volume fraction of PFC component, and were diffusion-controlled. The increase of current was ascribed to the increase of oxygen supply to the electrode from PFC particles in the emulsion. Analyzing the oxygen reduction current due to PFC particles, the ratio of diffusion coefficients of oxygen inside and outside PFC particle (D_i/D_o) and the oxygen partition coefficient between the both sides (C_i/C_o) were obtained. The release of oxygen from PFC particle was rate-determined by oxygen diffusion in the particle and the diffusion itself was determined by inner viscosity of PFC particle. The surfactant layer of PFC particle did not play any appreciable role such as permeability barrier for oxygen transportation.

Clark and Gollan[1] suggested that perfluorocarbons (PFC) with high oxygen solubility were useful materials for artificial blood. Later, the emulsification of PFC developed this kind of investigations,[2-5] since bio-availability of PFC emulsion so far been demonstrated.[6-9] However, few physicochemical studies on uptake or release of oxygen by the dispersed particles in PFC emulsion have been known,[8-10] though relatively many kinetic studies on oxygen transport by erythrocyte were reported by different investigators.[11-14] In order to evaluate the effectiveness of PFC emulsion as artificial blood, the limiting step of uptake or release of oxygen by PFC particle should be clarified and compared with that of erythrocyte. In addition, for better understanding of oxygen transporting capacity of erythrocyte, it may be useful that the PFC particle can be regarded as a simplified model of erythrocyte under some experimental conditions. However, spectroscopic methods, which are advantageous for erythrocytes, are inapplicable to PFC emulsion which exhibits no specific color change in uptaking or releasing oxygen. Consequently, for the estimation of oxygen binding character of such systems, electrochemical methods may be recommended.[15] Especially polarographic techniques seem to have several advantages for PFC emulsion, further for real blood or general oxygen carriers, since the electrode *e.g.*, dropping mercury electrode (DME), to which an appropriate potential is applied, works as a model of biological surface on which oxygen is consumed immediately when it arrives at. The total limiting current due to oxygen discharge then is the value corresponding to the rate of the transport of oxygen from the bulk.

In this study, we applied d.c.-polarographic method to PFC emulsion. Then, the restrictive factors of the release of oxygen from the dispersed particles in PFC emulsion were discussed based on the behavior of the reduction currents of oxygen in PFC emulsion.

Experimental

Materials. Perfluorocarbon emulsion was a product of Green Cross Corporation (Osaka) named Fluosol-43 which is an emulsion of FC-43 (perfluorotributylamine) with a surfactant Pluronic F-68 [poly(oxypropylene)-poly(oxyethylene) copolymer, M.W.=8350]. The average diameter of dispersed particle is 860 Å.[16] Pluronic F-68 and FC-43 were products of Asahi Denka, Inc. (Tokyo) and Dainippon Ink and Chemicals, Inc. (Tokyo), respectively. All other reagents used were of analytical grade unless otherwise stated.

Apparatus and Procedures. Polarograph used was a Yanagimoto Polarograph Model PA 101. The dropping mercury electrode had the following characteristics: $m=1.91$ mg s^{-1}, $t=5.87$ s at open circuit in distilled water with 60 cm height of mercury reservoir. As for oxygen electrode, a Teflon covered gold electrode (TCGE) whose electrode surface area was *ca.* 3 mm^2, was employed for the determination of dissolved oxygen with an applied potential -0.7 *V* (*vs.* SCE). Saturated calomel electrode (SCE) was used as a reference electrode. The viscometer used was a cone and plate viscometer, made by Tokyo Keiki, Ltd. (Tokyo).

Most experiments were carried out in test solutions thermostated and under the oxygen partial pressure equilibrated with open atmosphere. For some experiments with a constant total oxygen amount in solution, a simple vessel designed as presented in Fig. 1 was used. In this vessel no gas phase is

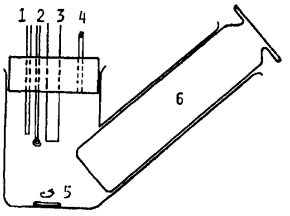

Fig. 1. Electrolytic vessel for oxygen measurement in closed system.
(1): Reference electrode, (2): working electrode, (3): indicater electrode, (4): inlet of sample solution, (5): magnetic stirrer, (6) syringe.

left over the liquid surface and when a given amount of test solution previously deoxygenated by nitrogen streaming, is added, the syringe moves by the increase of volume of the solution.

Results and Discussion

Effects of Pluronic F-68 on Oxygen Reduction Waves. Surfactants usually affect the electrode reaction due to the adsorption to the electrode surface.[17] As is well known, oxygen gives two reduction waves at DME in supporting electrolyte solutions, corresponding to Eqs. 1 and 2.[18]

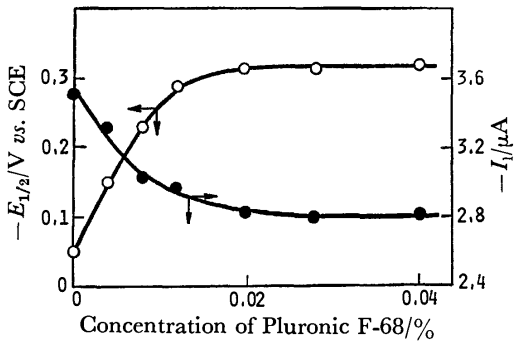

Fig. 2. Effect of Pluronic F-68 on half wave potential ($E_{1/2}$) and limiting current (I_l) of the first wave of oxygen reduction waves.
Medium: 0.1 mol dm^{-3} KNO_3 equilibrated with atmospheric oxygen, ○: $E_{1/2}$, ●: I_l.

$$O_2 + 2e + 2H^+ \longrightarrow H_2O_2 \quad (1)$$

$$H_2O_2 + 2e + 2H^+ \longrightarrow 2H_2O \quad (2)$$

Figure 2 shows the effects of Pluronic F-68 on limiting currents (I_l) and half-wave potential ($E_{1/2}$) of the first wave of oxygen reduction waves. The increase of the concentration of Pluronic F-68 results in a lowering of I_l value and a shift of $E_{1/2}$ to a more negative potential. Electrocapillary curves in Fig. 3 revealed the adsorption

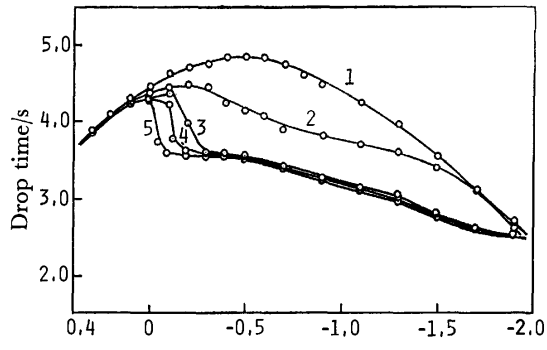

Fig. 3. Effect of Pluronic F-68 on electrocapillary curve.
Medium: the same as for Fig. 2.
Concentration of Pluronic F-68 (w/v %): (1) 0, (2) 0.004, (3) 0.008, (4) 0.016, (5) 0.04.

of the surfactant on the electrode surface corresponding to the decrease of I_l and the shift of $E_{1/2}$ in Fig. 2. Consequently, to study the effect of the volume fraction of PFC component (ϕ) on oxygen reduction waves, experiments must be carried out without changing the concentration of Pluronic F-68. In this study, 3.2% Pluronic F-68, which was the same concentration as that in Fluosol-43, was employed. pH was maintained to be 7.4 with Tris–HCl buffer (ionic strength 0.1 mol dm^{-3}).

Oxygen Reduction Current in PFC Emulsion. The reduction current increased linearly with PFC emulsion in the electrolytic solution, when the system was open to the atmosphere (Fig. 4). Since the ratio of the 1st wave height and the 2nd did not change by adding

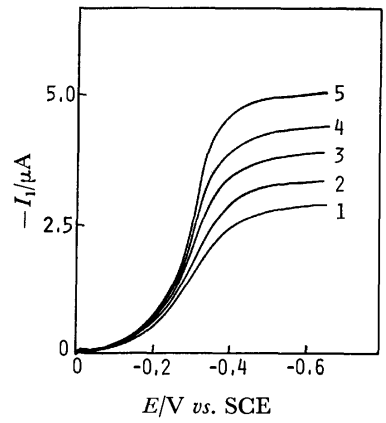

Fig. 4. Change of the oxygen reduction wave (1st wave) with volume fraction of PFC component in the electrolyte solution at 25 °C in open system.
Medium: pH 7.4, Tris–HCl buffer (ionic strength 0.1) with Pluronic F-68 3.2%. Volume fraction of PFC component (ϕ): (1) 0, (2) 0.024, (3) 0.059, (4) 0.083, (5) 0.119.

emulsion, I_l of the 1st wave was examined in most cases. The increase in this I_l with ϕ (as seen in Fig. 4) may be attributed to the reduction of oxygen included in PFC particle, since the concentration of free oxygen in dispersion medium except PFC particles should be constant, equilibrated with atmospheric oxygen, in spite of the change of ϕ. The character of fully diffusion-controlled current was confirmed from the dependence of I_l on mercury head. Similar diffusion-controlled limiting currents of oxygen were also observed in the electrolyte solution containing 3.2% Pluronic F-68 *i.e.* the dispersion medium without PFC particles. As a consequence, the increase of current due to added PFC emulsion must also be diffusion-controlled. Then, the significance of this diffusion-controlled oxygen wave due to PFC component was considered for two possibilities: 1) Diffusion of PFC particle to the electrode and discharge of oxygen involved in PFC at the contact of the particle to the electrode: for example, Hayano and Shinozuka[19-20] reported the reduction current of a dye solubilized in surfactant micelles and concluded that the limiting step of the observed reduction current was the diffusion of surfactant micelle.

If the diffusion of the PFC particle is not adequate for the rate-determining step, other diffusion factors should be considered. 2) Direct contribution of oxygen diffusion in PFC in the particles: since our experimental conditions were sufficiently simple, the diffusion of oxygen in space other than disparsion medium would only be possible in PFC inside the dispersed particles. To simplify the treatment of problem on this assumption, we may assume that PFC particles occupy a relative space on the electrode surface, corresponding to ϕ and the remaining space ($1-\phi$) is covered by the dispersion medium.

The first assumption of the above two was examined as follows: estimating the concentration of PFC particle, its diffusion coefficient calculated from the particle size[16] and Stokes' equation, and the number of oxygen molecules in the particle, Ilkovic equation was applied

to obtain the expected diffusion current due to PFC particles (I_{dem}). The calculation† revealed that the observed diffusion current (I_d) was too large to accept the first assumption. This suggests that I_{dem} is not determined by the diffusion of PFC particle, but by the diffusion of oxygen inside PFC particle. Present case is therefore different from that of the reduction of dye solubilized in micelle.[19-21] For PFC emulsion, it seems reasonable to consider the latter assumption of the above two.

Analysis of Oxygen Diffusion Current in Open System. If we assume that the diffusion of oxygen can be observed only in the direction perpendicular to the electrode surface, but in horizontal direction the diffusion between the particles and the medium can be neglected, the observed diffusion current (I_d) may be written as

$$I_d = I_{do,} + I_{dem}, \tag{3}$$

where $I_{do,}$ and I_{dem} are diffusion current of free oxygen and that due to PFC particles, respectively.
Then,

$$I_{do,} = \kappa\sqrt{D_o}C_o\,(1-\phi), \tag{4}$$

$$I_{dem} = \kappa\sqrt{D_i}C_i\cdot\phi, \tag{5}$$

where D and C are diffusion coefficient and concentration of oxygen, respectively and $\kappa=607\,n\,m^{2/3}\,t^{1/6}$ (at 25 °C) with $n=2$, and ϕ is volume fraction of PFC in the system. Suffix o and i represent outside and inside of the particle, respectively. Equation 3 now can be written as

$$I_d = \kappa\sqrt{D_o}C_o\,(1-\phi) + \kappa\sqrt{D_i}C_i\cdot\phi. \tag{6}$$

Dividing this equation by I_{do}

$$I_d/I_{do} = 1 + (K\sqrt{D_i/D_o} - 1)\phi \tag{7}$$

can be obtained, where I_{do} is I_d at $\phi=0$ ($I_{do}=\kappa\sqrt{D_o}C_o$)†† and $K=C_i/C_o$. Then, the value K should be the partition coefficient of oxygen between FC-43 and water. As seen in Fig. 5, a linear relation between I_d/I_{do} and ϕ was obtained. From the slope, $K\sqrt{D_i/D_o}$ was found to be 8.9 ± 0.2. The evaluation of this value is interesting to prove the validity of the assumption presented as the possibility (2) in the above section. Namely, we must evaluate our K value involved in Eq. 7 on the basis of experimental results, and compare it with that obtained by other methods. Because no further information could be independently obtained with the open system, experiments with closed system were then carried out, in order to estimate K and D_i/D_o.

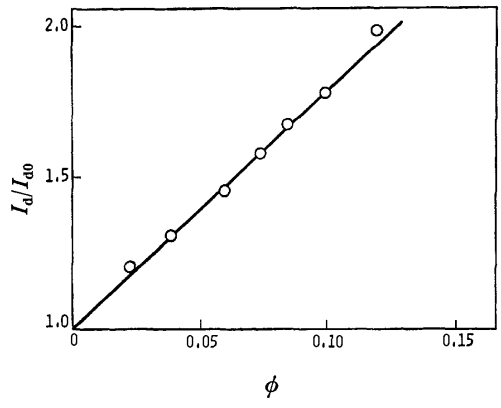

Fig. 5. Plot of I_d/I_{do} against volume fraction of PFC component (ϕ) in electrolyte solution. Explanation in text.

† See Appendix.

†† The diffusion coefficient D_o may change with concentration of emulsion particles. However, for the sake of simplifying the treatment of problem, it was neglected for this study, since the experiments were carried out only in relatively dilute emulsion system, that is $\phi<0.12$. Namely, D_o in emulsion was regarded to be always equal to that in dispersion medium ($\phi=0$).

Evaluation of K *and* D_i/D_o *with Closed System.* Using the vessel shown in Fig. 1, experiments were carried out both with TCGE and DME, but the latter enabled us more intimate analysis than TCGE. So, we introduce here the method with DME more in detail and for TCGE only some discussion will be added.

The above Eq. 6 for open system is also valid for the present closed system. However, since the absolute oxygen content in closed system is constant, the following equation can be added.

$$C_o(1-\phi)V + C_i\phi V = C^0V_0, \tag{8}$$

where V is the volume of the test solution closed against atmosphere and V_0 is V at $\phi=0$. C^0 is the oxygen concentration at $\phi=0$. The experiment starts with a requisite volume of electrolyte solution equilibrated with atmospheric oxygen but now closed against the atmosphere. Then, a small constant volume of deoxygenated PFC emulsion of known concentration may be added. Each I_d can be measured from its polarogram and, ϕ and V are easily calculated.
From Eqs. 6 and 8 the following relation can be derived.

$$I_dV/(I_{do}V_0) = [1 + (K\sqrt{D_i/D_o} - 1)\phi]/[1 + (K-1)\phi] \tag{9}$$

Further, modifying the Eq. 9,

$$\frac{1}{1-(I_dV)/(I_{do}V_0)} = \frac{1}{K(1-\sqrt{D_i/D_o})}\cdot\frac{1}{\phi} + \frac{K-1}{K(1-\sqrt{D_i/D_o})} \tag{10}$$

is available.

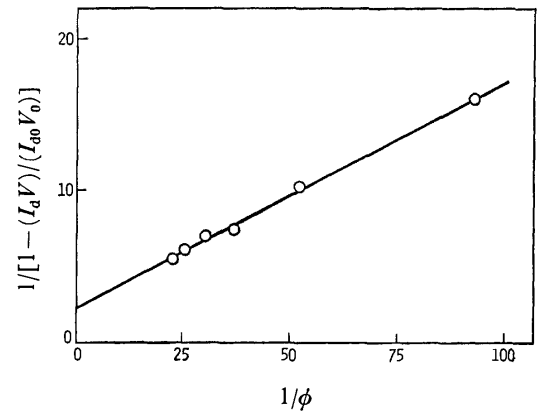

Fig. 6. Graphical treatment for estimation of partition coefficient of oxygen between inside and outside PFC particle $K=C_i/C_o$ and D_i/D_o using the experimental results in closed system. Medium: the same as for Fig. 4. Explanation in text.

As seen in Fig. 6, plot of $1/[1-(I_dV)/(I_{d0}V_0)]$ against $1/\phi$ gave a straight line. From the slope and intercept on ordinate, $K=16.4\pm0.7$ and $\sqrt{D_i/D_o}=0.61\pm0.03$ could be obtained. The D_i value was 7.4×10^{-6} $cm^2\,s^{-1}$, assuming that D_o was 2.0×10^{-5} $cm^2\,s^{-1}$.†††[22,23] Consequently, $K\sqrt{D_i/D_o}=10.0$ which is not identical with the value 8.9 obtained from the experiment in open system. However, The value $\sqrt{D_i/D_o}$ is interesting, since according to Stokes' equation, D should be reciprocally proportional to the viscosity. The validity of 0.61 can be confirmed by measuring the viscosities (η) of both the dispersion medium and that of dispersed substance separately. Our measurement of η for pure FC-43 and that for the electrolyte solution containing the surfactant employed, gave a satisfactory result, *i.e.* $\sqrt{\eta_o/\eta_i}=0.57$. The reciprocal relationship between D_i/D_o and η_i/η_o suggests that the release of oxygen from PFC particles was rate-determined by the viscosity of dispersed phase, and surfactant layer of PFC particle does not play any appreciable role such as the permeability barrier for oxygen release. This favorable permeability of the surfactant layer for oxygen is not due to the dimensions of thickness of surfactant layer of PFC particle, but it may arise from the oxygen-philic property of Pluronic F-68. Because the thickness of surfactant layer of PFC particle, which can be estimated to be *ca.* 70 Å**, is close to that of common biomembranes such as erythrocyte.[24] The K value obtained was nearly equal to the calculated one from the solubility of oxygen in FC-43[25] and in water.[26] The validity of this K value estimation was again proved by applying TCGE to the closed system as described in the following part.

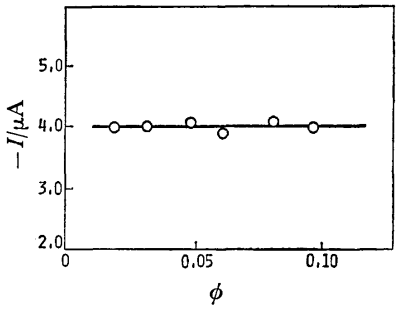

Fig. 7. Effect of PFC emulsion on reduction current of oxygen at Teflon covered gold electrode (TCGE) in open system. Medium: the same as for Fig. 4. Current was measured at −0.7 V (*vs.* SCE).

††† As diffusion coefficient of oxygen in buffer solution pH 7.4, 2.0×10^{-5} $cm^2\,s^{-1}$ was used for the present study, since several investigators have reported similar values with minor deviations for various electrolyte solution at 20—25 °C.

** For the calculation of this value, first we obtained volume fraction of PFC particle (ϕ_p) in the emulsion by centrifugation. This ϕ_p is comprised of both inside PFC component (ϕ) and surfactant layer component. Since the average particle diameter ($2r$) was known experimentally,[16] and ϕ of the stock emulsion was given by the manufacturer, the thickness of the surfactant layer (δ) can be readily obtained by the following equation,

$$\delta = r[1-(\phi/\phi_p)^{1/3}]$$

Estimation of K *by Oxygen Electrode.* Figure 7 shows that in open system the cathodic current obtained by TCGE as oxygen electrode at a fixed applied potential in a relatively low concentration range seems to be constant and proportional to the oxygen concentration in the dispersion medium, irrespective of the change of ϕ in system, while in the same PFC concentration range I_d at DME exhibits an apparent increase. The current obtained by TCGE (I) may be expressed as

$$I = \alpha C_o(1-\phi) \qquad \alpha: \text{const.} \tag{11}$$

For closed system, Eq. 8 is also valid. Then, the following equation can be derived from Eq. 8 and 11.

$$I_0V_0/(IV) = 1 + K\phi/(1-\phi), \tag{12}$$

where I_0 is I at $\phi=0$ and equal to αC_o.

With the experiments similar to those with DME in closed system, $I_0V_0/(IV)$ can be plotted against $\phi/(1-\phi)$ and K can be estimated as a slope of the obtained straight line, which intercepts the ordinate at 1.0, as shown in Fig. 8. Our result gave $K=15.3$ which should

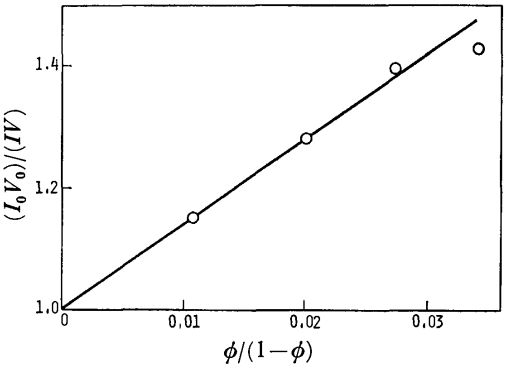

Fig. 8. Graphical treatment for the estimation of partition coefficient of oxygen between inside and outside PFC particle by TCGE in closed system. Medium: the same as for Fig. 4. Explanation in text.

be theoretically equal to that obtained from DME. The disagreement of the values may be partly due to the difficulty of experiment in closed system. Especially the work with oxygen electrode, may require a larger caution for stability of electrode surface under the present conditions. For this reason, we recommend DME method rather than solid electrode method.

Concluding Remarks. The above results may support the validity of the second possibility of the two assumptions presented. Consequently, the restrictive factor of the release of oxygen from PFC particle is the diffusion rate of oxygen inside PFC particle. The oxygen equilibrium between inside and outside of PFC particle seems to attain sufficiently fast. Further, the particle size is not the factor to change I_{dem}, as Ohyanagi and Mitsuno[8] reported that the rate of uptake and release of oxygen by PFC particle was independent of the particle size. The DME method may be expected to give some quantitive informations on the behavior of oxygen inside a larger particle such as erythrocyte. The application will be reported elsewhere.

Appendix

According to the first assumption, the diffusion current of

oxygen due to PFC particles (I_{dem}) is limited by the diffusion of PFC particle itself. Applying Ilkovic equation to I_{dem}, it can be written as

$$I_{dem} = \kappa^* \sqrt{D_p} C_p,$$
$$\kappa^* = 607 n^* m^{2/3} t^{1/6},$$

where D_p and n^* are the diffusion coefficient of PFC particle and the number of electrons transferred at the electrode reaction per PFC particle, respectively. Assuming all of oxygen molecules inside PFC particle might simultaneously discharge at the contact of the particle to the electrode, n^* would be given by multiplying the number of electrons transferred at the reduction of oxygen (n) by the number of oxygen molecules inside PFC particle, that is,

$$n^* = n \cdot C_1 \cdot v \cdot N,$$

where C_1, v, and N are concentration of oxygen dissolved in PFC, the average volume of a PFC particle and Avogadro's number, respectively. C_p is molar concentration of PFC particle, and can be written as

$$C_p = \phi/(v \cdot N).$$

From the above relations, I_{dem} can be rewritten as

$$I_{dem} = \kappa \sqrt{D_p} C_1 \phi,$$
$$\kappa = 607 n m^{2/3} t^{1/6}.$$

On the other hand, the diffusion current due to free oxygen (I_{do_1}) can be written as

$$I_{do_1} = \kappa \sqrt{D_o} C_o$$

The observed diffusion current (I_d) is given by Eq. 3. Therefore, the ratio I_d/I_{do_1} can be written as

$$I_d/I_{do_1} = 1 + K \sqrt{D_p/D_o} \cdot \phi,$$
$$K = C_1/C_o.$$

Now, we can estimate D_p in water to be 4.5×10^{-8} cm^2 s^{-1} at 25 °C, using Stokes' equation, $D = RT/(N \cdot 6\pi\eta r)$, with the average diameter ($2r$) reported: 860 Å,[16] and the viscosity of water as dispersion medium (η): 0.890 cp (1cp$=1 \times 10^{-3}$ N s m^{-2}) at 25 °C. Since 2.0×10^{-5} cm^2 s^{-1} is taken as D_o value, $\sqrt{D_p/D_o} = 4.7 \times 10^{-2}$ can be obtained. At $\phi = 0.12$, I_d/I_{do_2} value can be calculated to be 1.1 with the above obtained values, that is, the diffusion current would increase only by one tenth at this ϕ. In fact, the diffusion current observed was twice that at $\phi = 0$. This result allows us to eliminate the first assumption to explain the increase of diffusion current with ϕ.

The authors thank Green Cross Corporation in Osaka for the kind supply of perfluorocarbon emulsion Fluosol-43 and a surfactant Pluronic F-68.

Kinetic Studies of Fast Equilibrium by High-performance Liquid Chromatography I. Ternary Complex Formation of *N,N*-Disubstituted Dithiocarbamate Chelates of Ni(II) and Cu(II)

Masataka MORIYASU* and Yohei HASHIMOTO

Kobe Women's College of Pharmacy, Motoyamakita-machi, Higashinada-ku, Kobe 658

(Received May 23, 1980)

The equilibrium of labile ternary complex formation of metal dialkyldithiocarbamate chelates ($MA_2 + MB_2 \underset{k-}{\overset{k}{\rightleftharpoons}} 2MAB$, $K=[MAB]^2/[MA_2][MB_2]$) has been investigated by high-performance liquid chromatography, the separation process of which is so fast that kinetically unstable ternary complexes can be eluted with no disproportionation during the course of chromatography. High-performance liquid chromatography makes it possible to halt the progress of considerably fast reactions at the moment when the solution of reaction system is injected into the column. Thus, chromatograms obtained indicate the concentration of each species before chromatography, facilitating the determination of equilibrium constant K of Ni(II) and Cu(II) chelates. The equilibrium constants obtained are always 4.0, suggesting that ternary complex formation is controlled by a statistical factor. Disproportionation takes place by collision of two ternary metal chelates, the rate constants being of the order 10^1—10^2 M^{-1} s^{-1} (Ni(II) chelates) and 10^3 M^{-1} s^{-1} (Cu(II) chelates). The activation parameters of ternary complex formation have been obtained.

Study of fast reactions in solution has drawn the attention of investigators, the flow and relaxation methods being utilized. The conventional method, in which two reactants are mixed and then the change of concentration of reactants or products is measured, was found to be ineffective because of the lack of appropriate means of rapid analysis. High-performance liquid chromatography (HPLC) developed in recent years has been successfully applied to microdetermination of various substances. The merit of rapid separation in HPLC might be hopeful for determining kinetic characteristics of considerably fast reactions in solution.

Since the first report on metal acetylacetonates by Huber and Kraak,[1] only a few reports have appeared on HPLC separation of metal chelates, many of them being on HPLC of metal diethyldithiocarbamates.[2-9] We carried out quantitative determination of various metal diethyldithiocarbamates.[7] This article deals with the applicability of HPLC to kinetical investigation of relatively fast equilibrium of labile ternary complex formation.

Experimental

Reagents. Commercial sodium salts of diethyldithiocarbamic acid and dibenzyldithiocarbamic acid were used. Sodium salts of other *N,N*-disubstituted dithiocarbamic acid were prepared by the usual procedure from dialkylamine, carbon disulfide and sodium hydroxide. They were recrystallized from either chloroform–methanol or chloroform–hexane. Standard solutions of Ni(II) and Cu(II) were prepared by dissolving $NiCl_2 \cdot 6H_2O$ and $CuSO_4 \cdot 5H_2O$ in water. The concentrations of these metal ions were determined by colorimetry as diethyldithiocarbamate chelates.

Apparatus. An HPLC apparatus we constructed was used.[7] The two plunger reciprocal pump (Model KHD-W-294, Kyowa Seimitsu Co. Ltd.), damper, sample injector (5 μl or variable) and column were combined . A single-beamed spectrometer (Model Spectra 20, Toshiba Beckmann Co. Ltd., 210—700 nm) equipped with a flow cell was used as a detector. Since the detector is not designed for HPLC use, its sensitivity is not so high. The upper limit of rate constants determined by the present method is restricted by the sensitivity of the detector. Silica gel packings (LiChrosorb SI 100, 5 μ, E. Merck Darmstadt and Wako gel LC-5H, 5 μ, Wako Pure Chemicals Co. Ltd.) were packed into stainless steel columns (diameter 2 mm, length 25 cm) by a balanced slurry packing technique.[10] A pre-packed silica gel column (Shodex silipak, 5 μ, diameter 4 mm, length 15 cm, Showa Denko Co. Ltd.) was used. Absorption spectra of metal chelates were observed with a double-beamed spectrometer (Model 124, Hitachi Co. Ltd.).

Procedure. In adsorption chromatography, adjustment of column is important as regards the mode of elution and reproducibility, and the water content on silica gel was controlled as follows. *Ca.* 100 cm^3 of water containing acetone (3%) was pumped through the column. At least 200 cm^3 of water saturated hexane flowed out, the activity of silica gel column being reduced. Reproducible results were obtained when water saturated eluent was used. Before use each organic solvent was saturated with water by shaking the mixture of the solvent and water vigorously, followed by standing for 1 d. Since it is desirable in some cases to perform chromatography at low temperature, column temperature was kept low by plunging solvent reservoir and column into an ice bath when necessary.

Metal chelates were prepared by mixing the corresponding metal ion and sodium dialkyldithiocarbamate. The metal chelates produced were extracted with chloroform under conditions of complete extraction (at pH 4.0 in acetate buffer). In order to avoid any effects of residual free ligands in chloroform, the extract was washed with water four times. The standard solutions of each metal chelate (0.1 to 2 mM) thus prepared were used for HPLC after being diluted to proper concentration. Measurements of rate constants were carried out as follows. Two dilute solutions of binary complexes were mixed under thermostated conditions. After the lapse of a certain time, a portion of the mixture was supplied to HPLC. All the measurements were carried out three times.

Theoretical

Possible chromatogram patterns of a mixture of two

different binary complexes, MA_2 and MB_2, will be considered first. It is assumed that no decomposition of each chelate takes place during the course of chromatography. If no interaction exists between the two binary complexes, two peaks corresponding to each complex should appear. However, the chromatogram patterns would be complicated if a mixed ligand complex is formed in the mixture as follows.

$$MA_2 + MB_2 \underset{k_-}{\overset{k}{\rightleftharpoons}} 2MAB \quad (1)$$

$$K = [MAB]^2/[MA_2][MB_2] \quad (2)$$

Equilibrium is hardly attained when M is a metal ion which forms very inert complexes. In such a case, a ternary complex will be formed when the mixture is left to stand for a long time or brought to elevated temperature. The ternary complex formed can be separated by the conventional method without disproportionation. If M is a metal ion which forms very labile complexes, the ternary complex undergoes disproportion into two binary complexes, as soon as it is separated from binary complexes. Studies have been carried out on the equilibrium by mixing two solutions of MA_2 and MB_2 and observing the resulting remarkable change of physico-chemical properties such as UV absorption. The separation process of HPLC is so fast that it might compete with the progress of disproportionation in the column. Possible chromatogram

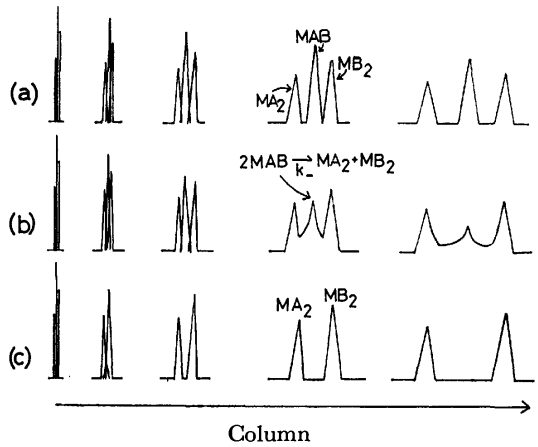

Fig. 1. Possible chromatogram patterns of the system of labile ternary complex formation.

patterns are shown in Fig. 1. When the separation process is so fast that disproportionation of the ternary complex during chromatography can be neglected, three peaks corresponding to MA_2, MB_2, and MAB would appear on the chromatograms (Fig. 1(a)), the chromatograms obtained directly indicating the concentration of each species before chromatography was carried out. When disproportionation is much faster than the separation process, peaks of only two binary complexes would appear on the chromatograms (Fig. 1(c)). In case of the intermediate of these two extremes, the peak of a ternary complex would appear accompanied by disproportionation in the column (Fig. 1(b)). In this case disproportionation is retarded with increase in flow rate, bringing about a change of chromatogram patterns. Thus, if the peak height of the ternary complex remains unchanged with flow rate, disproportionation is negligible.

In HPLC there are some favorable factors to retard disproportionation in the column. (1) Each species is diluted rapidly during the course of chromatography, suppressing disproportionation which is anticipated to occur by the bimolecular collisional process of two ternary complexes. Actual concentration in the liquid phase will be low since a considerable part of each species is retained on the column, collision of two ternary complexes adsorbed on silica gel surface being unlikely to occur. (2) The rate of disproportionation can be controlled by a suitable choice of initial concentrations of MA_2 and MB_2, disproportionation being slow when initial concentrations are low. (3) Control of column temperature is useful, disproportionation being retarded when column temperature is kept low. Thus a combination of high speed separation, rapid dilution, suitable choice of initial concentrations and low temperature, similar to the case of the rapid quenching method,[11] might halt the progress of the reaction in the column. If these conditions are fulfilled, the equilibrium constant K will be determined by direct measurements of peak heights appearing on chromatograms.

Rate constants k and k_- are determined as follows. Two dilute solutions of MA_2 and MB_2 are mixed. A ternary complex is produced gradually and the equilibrium Eq. 1 will be attained. After the lapse of a certain time a portion of the mixed solution is supplied to HPLC. The progress of the reaction ceases when the solution is injected into the column. Thus, concentrations of each species at a definite time after mixing can be determined by HPLC. The rates of formation of ternary complex and decrease of binary complexes are expressed as follows.

$$\frac{d[MA_2]}{dt} = \frac{d[MB_2]}{dt} = k_-[MAB]^2 - k[MA_2][MB_2] \quad (3a)$$

$$\frac{d[MAB]}{dt} = k[MA_2][MB_2] - k_-[MAB]^2 \quad (3b)$$

Assuming that the initial concentrations of MA_2 and MB_2 are the same ($=a_0$), we have

$$\frac{dx}{dt} = 4k_-(a_0 - x)^2 - kx^2$$
$$= (4/K - 1)kx^2 - 8a_0kx/K + 4a_0^2k/K \quad (4a)$$

$$\frac{dy}{dt} = k(a_0 - y/2)^2 - k_-y^2$$
$$= -(ky^2/4)(4/K - 1) - a_0ky + a_0^2k, \quad (4b)$$

where x and y are concentrations of MA_2 (or MB_2) and MAB, respectively. Rate constants k and k_- are determined by means of Eq. 4a or 4b. When $K=4.0$, we have the following equations by integrating Eqs. 4a and 4b.

$$-\ln(1 - 2x/a_0) = ka_0t \quad (5a)$$

$$-\ln(1 - y/a_0) = ka_0t \quad (5b)$$

When $K \neq 4.0$, k and k_- are determined by means of the following equation.[12]

$$k = (2/mt)\left\{\ln\left(\frac{\left(\frac{2a_0-m}{1-4/K}\right)-y}{\left(\frac{2a_0+m}{1-4/K}\right)-y}\right)+\left(\ln\frac{(2a_0-m)}{(2a_0+m)}\right)\right\} \quad (6)$$

$$m = 4a_0\sqrt{1/K}$$

Results and Discussion

Determination of Equilibrium Constant. By use of a well deactivated silica gel-column, various metal chelates of *N,N*-disubstituted dithiocarbamic acid gave chromatograms with no decomposition of chelates. Metal chelates of Cu(II), Hg(II), Ni(II), Pd(II), and Co(III) *etc.* gave linear calibration graphs (detection limit, few μg-few ng). A mixed solution of two different *N,N*-disubstituted dithiocarbamate chelates of Ni(II) always gave three peaks[13,14] (Fig. 2(c)). Peak heights of these three peaks remained unchanged in the flow rate range of the pump 3.0—0.4 cm³/min (Figs. 2(c)—2(f)). This indicates that the conditions shown in Fig. 1(a) are satisfied. When the initial concentrations of two binary complexes were chosen to be the same ($=a_0$), the equilibrium concentrations of the chelates were both $a_0/2$. Thus the equilibrium concentration of ternary complex was equal to a_0. Exactly half of the initial binary complexes was transformed into a ternary complex, the equilibrium constant K being 4.0. Formation of the ternary complex is controlled by a statistical factor. In all the systems of a mixture of two binary complexes K was always equal to 4.0, suggesting that the lack of the factor either stabilizes of destabilizes the ternary complex.[15]

Cu(II) chelates showed different chromatogram

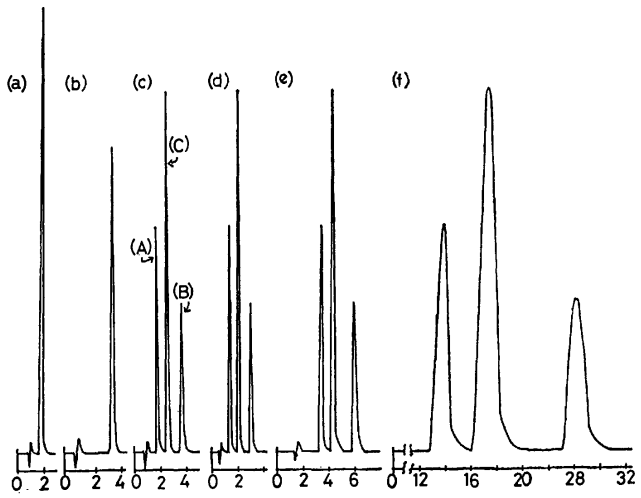

Fig. 2. Chromatogram patterns of two different dithiocarbamate chelates of nickel.
Column: Shodex silipak (4 mm × 15 cm), eluent: hexane : ethyl acetate = 100 : 7 (water saturated), flow rate: (a)—(c) 2.5 cm³/min; (d) 3.0 cm³/min; (e) 1.5 cm³/min; (f) 0.4 cm³/min, detector: 325 nm, sample: (a) 0.4 mM $Ni[(CH_3CH_2CH_2)_2NCSS]_2$ in $CHCl_3$; (b) 0.4 mM $Ni[(CH_3CH_2CH_2)_2NCSS]_2$ in $CHCl_3$; (c) 0.4 mM $Ni[(CH_3CH_2CH_2)_2NCSS]_2$ + 0.4 mM $Ni[(CH_3CH_2)_2NCSS]_2$ in $CHCl_3$, sample size: 5 μl.
(A): $Ni[(CH_3CH_2CH_2)_2NCSS]_2$, (B): $Ni[(CH_3CH_2)_2NCSS]_2$, (C): $Ni[(CH_3CH_2CH_2)_2NCSS][(CH_3CH_2)_2NCSS]$.

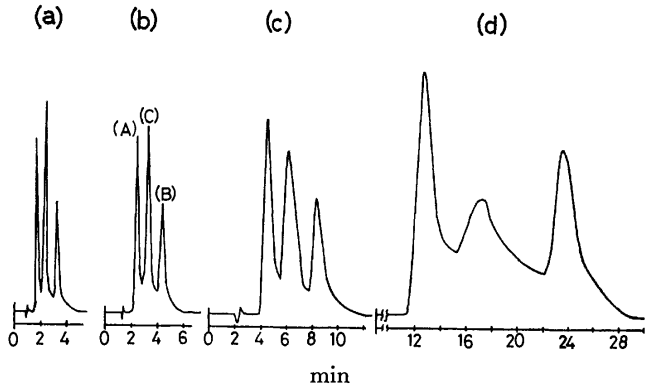

Fig. 3. Chromatogram patterns of two different dithiocarbamate chelates of copper at relatively higher concentrations.
Column: LiChrosorb SI 100 (2 mm × 25 cm), eluent: hexane : cyclohexane : isopropyl acetate = 50 : 50 : 4 (water saturated), flow rate: (a) 1.3 cm³/min; (b) 0.9 cm³/min; (c) 0.5 cm³/min; (d) 0.2 cm³/min, detector: 440 nm, sample: 1 mM $Cu[(CH_3CH_2CH_2)_2NCSS]_2$ + 1 mM $Cu[(CH_3CH_2)_2NCSS]_2$ in $CHCl_3$, sample size: 5 μl.
(A): $Cu[(CH_3CH_2CH_2)_2NCSS]_2$, (B): $Cu[(CH_3CH_2)_2NCSS]_2$, (C): $Cu[(CH_3CH_2CH_2)_2NCSS][(CH_3CH_2)_2NCSS]$. The broadening of this peak (C) is due to disproportionation of this ternary chelate in the column.

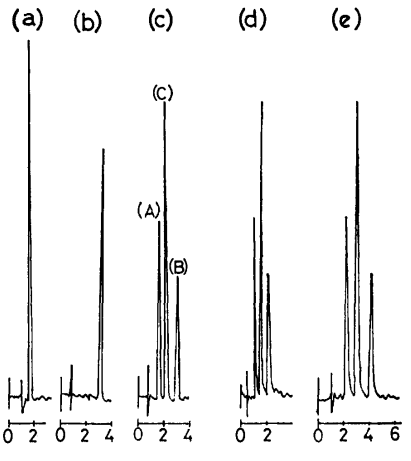

Fig. 4. Chromatogram patterns of two different dithiocarbamate chelates of copper at low concentrations.
Column: Shodex silipak (4 mm × 15 cm), eluent: hexane : ethyl acetate = 100 : 15 (water saturated), flow rate: (a)—(c) 2.5 cm³/min; (d) 3.0 cm³/min; (e) 1.5 cm³/min, detector: 280 nm, sample: (a) 4.0×10^{-6} M $Cu[(CH_3CH_2)_2NCSS]_2$; (b) 4.0×10^{-6} M $Cu[(CH_3)_2NCSS]_2$; (c) 4.0×10^{-6} M $Cu[(CH_3CH_2)_2NCSS]_2 + 4.0 \times 10^{-6}$ $Cu[(CH_3)_2NCSS]_2$; these samples are solutions in hexane : chloroform : ethyl acetate = 8 : 1 : 1, sample size: 50 μl.
(A): $Cu[(CH_3CH_2)_2NCSS]_2$, (B): $Cu[(CH_3)_2NCSS]_2$, (C): $Cu[(CH_3CH_2)_2NCSS][(CH_3)_2NCSS]$.
No disproportionation was observed in this case.

patterns. When a relatively high a_0 was chosen ($a_0 = 1.0\times10^{-3}$ M), chromatogram patterns were seriously affected by the flow rate, suggesting the disproportionation of the ternary complex in the column. On the other hand, when a very low a_0 was chosen ($a_0 = 4.0\times10^{-6}$ M), they were unaffected by the flow rate (from 1.5 to 3.0 cm³/min) (Fig. 4). In order to compensate the decrease of concentration of the sample, it was necessary to inject a large volume of sample. The composition of the solvent of the injected sample should be similar to that of the eluent, otherwise serious broadening of each peak takes place. About 200 μl of sample volume could be injected into the column without remarkable broadening of each peak. For Cu(II) chelates the chromatogram patterns were also sensitive to column temperature. At ambient temperature, when a_0 was chosen 4.0×10^{-5} M, chromatogram petterns were affected slightly by flow rate. However, when column temperature was low, no disproportionation in the column was observed. The values K were also always equal to 4.0 for all the systems of Cu(II) chelates.

Determination of Rate Constants. As shown in Fig. 5, a trace peak of the ternary complex appeared on chromatograms immediately after mixing of two solutions. With the lapse of time the peak of the ternary complex rose while the peaks of binary complexes fell. The rate constants k and k_- were determined by means of Eq. 5b. The results are summarized in Tables 1 and 2 (for Ni(II) and Cu(II) chelates, respectively). The values of k and k_- were sensitive to temperature and composition of solvent of the mixture. Since k and k_- were affected by the water content of the mixed solution, experimental conditions were so chosen that each solution of MA_2 and MB_2 was saturated with water before mixing. Disproportionation was slow when solvent was not saturated with water. Column temperature and composition of eluent play insignificant role. By use of HPLC we can promptly separate various species including kinetically unstable ones and elute them. Varying chromatographic conditions such as composition of eluent, column temperature and flow rate does not change the values of k and k_- if disproportionation can be neglected during the course of chromatography.

The rate constants k of Ni(II) chelates are of the order 10^1—10^2 M^{-1} s^{-1}. Since Cu(II) chelates are more labile than Ni(II) chelates, values of k of Cu(II) chelates are larger and of the order 10^3 M^{-1} s^{-1}. Values of k seems to be small when molecular weights of two

a) In chloroform : ethyl acetate : hexane = 1 : 1 : 3 (water saturated). b) In chloroform : ethyl acetate : hexane = 1 : 1 : 8 (water saturated).

dithiocarbamates are close to each other. Validity of the bimolecular collisional process of disproportionation was confirmed by changing a_0 (Fig. 6). When a_0 exceeds this range, the rate of disproportionation does not increase in proportion to a_0.

The activation parameters of disproportionation was determined by measuring k values at various temperatures. This was carried out by mixing two solutions of MA_2 and MB_2 under thermostated conditions at various temperatures. Results of the system consisting of diethyldithiocarbamic acid, dipropyldithiocarbamic acid and metal ion are given in Table 3. The activation enthalpy of Cu(II) chelates is smaller than that of Ni(II) chelates.

Conclusion

Fast bimolecular reactions can be traced by HPLC. Chromatographic conditions should be so chosen that no decomposition of species occurs during the course of chromatography. This can be done to a certain extent by choice of column packings and solvent systems. The upper limit of the rate constants is restricted by the sensitivity of the detector. Absorption of 0.05 units could be extended to a full scale without serious noise with the spectrometer we used. It seems that rate constants of the order $10^4\ M^{-1}s^{-1}$ can be determined. Since the sensitivity of a commercial UV detector for HPLC is about ten times larger than that of the present one, fast reactions with rate constants of the order $10^5\ M^{-1}s^{-1}$ might be traced by HPLC if absorption coefficient of the detected species is large ($\log\varepsilon>4$). The present method will also be useful for investigation of physicochemical properties of kinetically unstable species in solution.

The Reduction of Hexakis(urea)chromium(III) Ions at the Dropping Mercury Electrodes

Akifumi YAMADA,* Yasuo NAKABAYASHI, Tadatsugu YOSHIKUNI, and Nobuyuki TANAKA

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

(Received June 5, 1980)

The polarographic reduction of hexakis(urea)chromium(III) ions at the dropping mercury electrode has been studied in various supporting electrolyte solutions. This complex exhibits two irreversible reduction waves; the first corresponds to Cr(III)→Cr(II), and the second, to Cr(II)→Cr(0). The kinetic parameters of the electrode reactions were determined in various supporting electrolyte solutions and at varied ionic strengths by means of Tast polarography. The differential-pulse polarographic characteristics of this complex are also given.

The cyclic voltammetry of hexakis(urea)chromium-(III) ions (abbreviated hereafter as $[Cr(urea)_6]^{3+}$) has been briefly reported in dimethyl sulfoxide solutions.[1] This complex exhibits two irreversible reduction waves; the first corresponds to Cr(III)→Cr(II), and the second, to Cr(II)→Cr(0). The present investigation was undertaken to ascertain the electrochemical behavior in aqueous solutions in the hope of gaining further insight into the mechanism of the electroreduction of $[Cr(urea)_6]^{3+}$ ions. The kinetic parameters of the electrode reaction of $[Cr(urea)_6]^{3+}$ ions were also examined by means of Tast polarography.

Experimental

The Tast polarograms were recorded by a Yanagimoto voltammetric analyzer, P-1000. A National digital tester, Model VP-2521A, was used; the current and the the potential were thus measured precisely. A three-electrode cell equipped with a saturated calomel electrode (Yanagimoto MR-P_2-05-1) and a platinum-wire electrode was employed. The DME with a flow rate of 1.10 mg s^{-1} and a drop time of 2.99 s in 0.4 M (1 M=1 mol dm^{-3}) of NaCl containing a 0.1 M acetate buffer solution and 20 μM LEO was used. Poly-(oxyethylene) dodecyl ether (LEO: mean molecular weight, 862) was used as the maximum suppressor.

The complex, $[Cr(urea)_6]Cl_3$, was prepared according to the literature[2] and converted to perchlorate salt. This complex is stable in aqueous solutions.[3] All the other chemicals used were of a guaranteed reagent-grade.

The dissolved oxygen was removed by bubbling purified nitrogen gas through the solution. All the measurements were made at 25 °C unless otherwise stated.

Results

Effects of Surface-active Substances. In the polarographic measurements, the $[Cr(urea)_6]^{3+}$ ions were found not to give a well-defined polarographic wave, but to give two well-defined waves in the presence of a small amount of surface-active substances. The effects of the surface-active substances on the Tast polarogram were examined; the results are shown in Fig. 1.

The addition of 20 μM of LEO to a solution containing 1 mM of complex ions gave satisfactory results; the maximum was suppressed without causing a decrease in the diffusion current. The addition of other surface-active substances, such as 0.0015% Triton X-100, 0.015% PAA (polyacrylamide) and 0.005% gelatin, caused a distortion of the Tast polarogram. The

(a) without maximum suppressor, with (b) 20 μM LEO, (c) 0.005% gelatin, (d) 0.015% polyacrylamide and (e) 0.0015% Triton X-100.

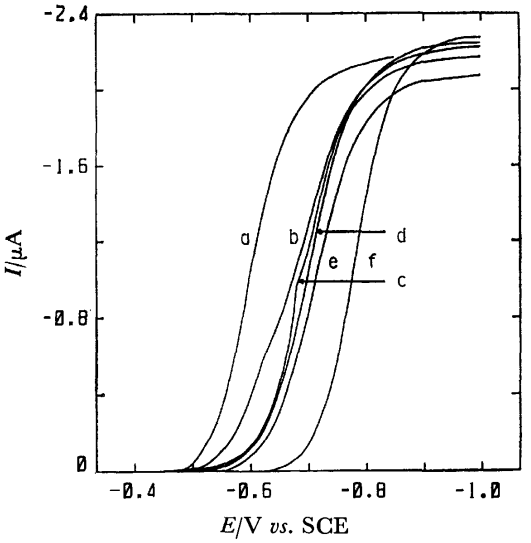

Fig. 2. Tast polarograms for the first wave of 1 mM $[Cr(urea)_6](ClO_4)_3$ obtained in various supporting electrolyte solutions containing 0.1 M acetate buffer and 20 μM LEO (μ=0.5) at 25 °C.
(a) NaI, (b) NaBr, (c) $NaNO_3$, (d) NaCl, (e) Na_2SO_4, (f) NaSCN.

current-potential curves were shifted to more negative potentials by the presence of Triton X-100. Also, the Tast polarogram in the presence of PAA and gelatin did not exhibit a second wave.

Effects of the Supporting Electrolytes. Measurements were made in various supporting electrolyte solutions. Figure 2 shows a Tast polarogram of the first waves of the 1 mM $[Cr(urea)_6]^{3+}$ ions obtained in various supporting electrolyte solutions (ionic strength $\mu=0.5$) containing 0.1 M of an acetate buffer and 20 μM of LEO at 25 °C. The Tast polarogram obtained in the solution containing NaSCN or $NaNO_3$ did not exhibit a second wave.

Conventional polarographic log-plots[4] were tested for the current-potential curves of the $[Cr(urea)_6]^{3+}$ ions. The value of the log-plot slope was found to be far different from the one predicted for a reversible electrode process indicating that the electrode reaction proceeds irreversibly.

The modified log-plots for an irreversible electrode process proposed by Oldham and Parry[5] were examined.

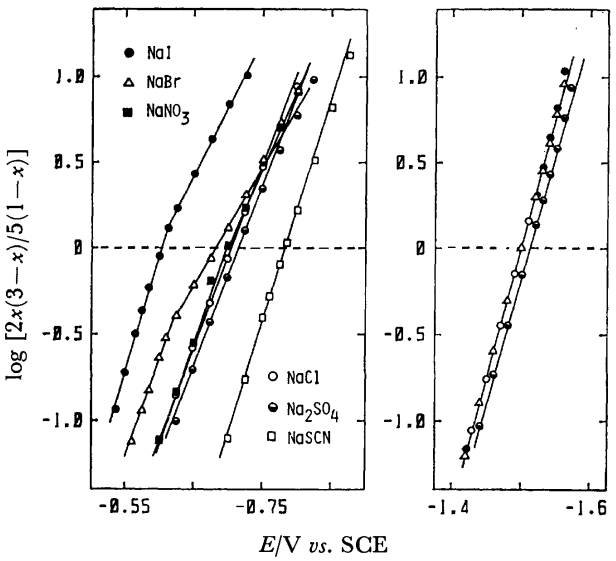

Fig. 3. Log-plots for the first (left) and the second (right) waves of 1 mM $[Cr(urea)_6](ClO_4)_3$ obtained in various supporting electrolyte solutions containing 0.1 M acetate buffer and 20 μM LEO at 25 °C.
(●) NaI, (△) NaBr, (■) $NaNO_3$, (○) NaCl, (◒) Na_2SO_4, (□) NaSCN.

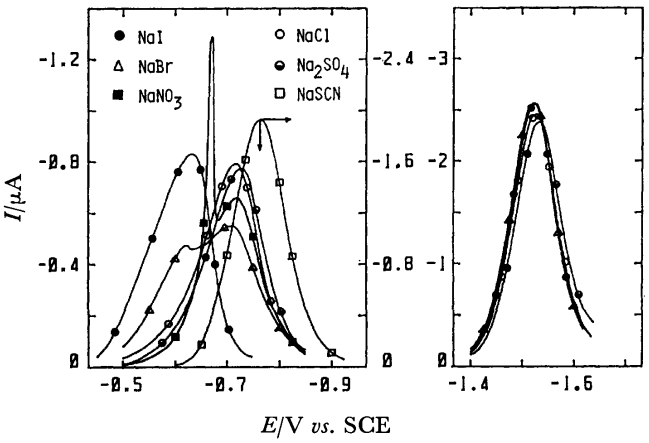

Fig. 4. Differential pulse polarograms of 1 mM $[Cr(urea)_6](ClO_4)_3$ in various supporting electrolyte solutions containing 0.1 M acetate buffer and 20 μM LEO (pH 4.6, $\mu=0.5$) at 25 °C.
(●) NaI, (△) NaBr, (■) $NaNO_3$, (○) NaCl, (◒) Na_2SO_4, (□) NaSCN.

The results for the first and the second waves are given in Fig. 3 (see also Discussion). The log-plots for the first wave in NaBr, NaI, and $NaNO_3$ did not give a straight line.

Differential Pulse Polarogram. Figure 4 shows the differential pulse polarograms of the 1 mM $[Cr(urea)_6]^{3+}$ ions obtained in several media at 25 °C. Much as in the results of the Tast polarography, the first waves appeared over a wide range of potentials, while the second waves appeared in a rather narrow potential range. The peak current for NaSCN was about twice as large as in the other cases.

The peak potential(E_p), the half-width(ΔW), and the peak current(I_p) of the differential pulse polarogram, which were obtained in several media, are given in Table 1. These results suggest that the electroreduction of $[Cr(urea)_6]^{3+}$ to the Cr(II) species proceeds irreversibly.

Measurements were also made at varied ionic strengths. Various parameters which characterize a differential pulse polarogram were obtained; they are shown in Table 2. The peak currents for the first and the second waves decreased with an increase in the ionic strength. The half-width of the first wave increased

with an increase in the ionic strength, while that of the second wave scarcely changed. The shifts in $E_{1/2}$ and E_p were rather complicated.

Discussion

The hexakis(urea)chromium(III) ions gave two well-defined current-potential curves, as may be seen in Fig. 1. The limiting currents of both the first and second waves were diffusion-controlled and were proportional to the concentration of the complex. The limiting current of the second wave was twice that of the first one. The first wave corresponds to the reduction of $[Cr(urea)_6]^{3+}$ to $[Cr(urea)_6]^{2+}$ species.[1] The tervalent chromium species is stable,[3] but the divalent one, produced on the surface of the electrode, is unstable and may undergo hydrolysis. The overall electrode reaction was considered by a comparison of its electrode reaction with that of other chromium(III) complexes.[6-11] Thus,

$$[Cr(urea)_6]^{3+} + e \longrightarrow [Cr(urea)_6]^{2+}, \quad (1)$$

$$[Cr(urea)_6]^{2+} + pH_2O \longrightarrow [Cr(urea)_{6-p}(H_2O)_p]^{2+} + p\text{urea}, \quad (2)$$

for the first wave, and

$$[Cr(urea)_{6-p}(H_2O)_p]^{2+} + 2e \longrightarrow Cr(0) + (6-p)\text{urea} + pH_2O, \quad (3)$$

for the second wave.

The diffusion coefficient of the $[Cr(urea)_6]^{3+}$ ions was measured by means of a method previously reported[12] by using $[Co(NH_3)_6]^{3+}$ as the reference substance; the results are summarized in Table 3.

The reduction of $[Cr(urea)_6]^{3+}$ to chromium(II) species in an acid solution was considered to be irreversible from the facts described above (Fig. 3 and Table 1). For a totally irreversible electrode reaction, the following relations of the Tast polarography are derived:[5]

$$(RT/\alpha nF) \ln [2x(3-x)/5(1-x)] = E_{1/2} - E, \quad (4)$$

with:

$$x = I/I_d, \quad (5)$$

and:

$$E_{1/2} = (RT/\alpha nF) \ln [1.35k_c^\circ (t_d/D)^{1/2}], \quad (6)$$

where I is the current at the potential, E; I_d, the diffusion-controlled current; D, the diffusion coefficient; t_d, the drop time; α, the transfer coefficient; k_c°, the cathodic rate constant at $E=0$; n, the number of electrons; R, the gas constant; F, the Faraday constant, and T the absolute temperature. According to Eq. 4, a plot of $\ln[2x(3-x)/5(1-x)]$ *vs.* E should be a straight line. The transfer coefficient, α, can be obtained from the slope, and the half-wave potential, $E_{1/2}$, from the intersection. The rate constant, k_c°, can be obtained from $E_{1/2}$ by applying Eq. 6. An example of the plots for Eq. 4 has been shown above (Fig. 3).

The kinetic parameters of the electrode reactions thus obtained are given in Table 3. These kinetic parameters obtained were checked by calculating the current according to this relation:

$$2x(3-x)/5(1-x) = 1.35k_c^\circ (t_d/D)^{1/2} \exp(-\alpha nFE/RT). \quad (7)$$

The calculated currents were in agreement with the observed ones except for the cases of NaBr, NaI, and $NaNO_3$.

It has been reported that the interaction reaction between the reduced chromium(II) complex and the nitrate ions occurs to a considerable extent.[13,14] The abnormality of the current-potential curve in a nitrate medium may, therefore, be understood in termes of this effect.

TABLE 3. KINETIC PARAMETERS OF ELECTRODE REACTIONS OF $[Cr(urea)_6](ClO_4)_3$ OBTAINED IN VARIOUS SUPPORTING ELECTROLYTE SOLUTIONS CONTAINING 0.1 M OF AN ACETATE BUFFER AND 20 μM OF LEO AT 25 °C

0.13 M Na_2SO_4	4.40	−0.716	0.63	1.94×10^{-11}	−1.510	0.43	9.32×10^{-26}

a) The values in parentheses were obtained from the more negative potential range.

Table 4. Kinetic parameters of electrode reactions of $[Cr(urea)_6](ClO_4)_3$ obtained at varied ionic strengths in solutions containing 0.1 M of an acetate buffer and 20 μM of LEO at 25 °C

Ionic strength	D	First wave			Second wave		
		$E_{1/2}$	α	k_c°	$E_{1/2}$	α	k_c°
	10^{-6} cm^2 s^{-1}	V *vs.* SCE		cm s^{-1}	V *vs.* SCE		cm s^{-1}
0.1	5.33	−0.681	0.77	1.34×10^{-12}	−1.463	0.50	1.73×10^{-28}
0.3	5.27	−0.696	0.69	7.62×10^{-12}	−1.488	0.46	1.18×10^{-26}
0.5	5.16	−0.705	0.62	3.78×10^{-11}	−1.500	0.44	7.11×10^{-26}
1.0	5.03	−0.718	0.56	1.54×10^{-10}	−1.516	0.43	1.37×10^{-25}
1.5	4.83	−0.693	0.52	8.59×10^{-10}	−1.519	0.42	3.77×10^{-25}
2.0	4.70	−0.682	0.49	2.41×10^{-9}	−1.525	0.41	4.82×10^{-25}
3.0	3.72	−0.663	0.40	2.74×10^{-8}	−1.526	0.39	6.14×10^{-24}

On the other hand, the distortion of the Tast polarogram obtained in solutions containing NaBr or NaI may be explained by the double-layer effect. It is a well-known fact that Br^- and I^- are specifically adsorbed on mercury and change the double-layer potentials.[15] The potential of PZC (point of zero charge) in the presence of Br^- and I^- lies[16] near the potential where the half-wave potential of the Tast polarogram appears. Therefore, the effect of the double layer on the current-potential curves may be more pronounced,[17] since the charge of $[Cu(urea)_6]^{3+}$ ions is high and its electroreduction process is irreversible. This causes a distortion of the current-potential curves. Such a double-layer effect has also been reported for the reduction of $[Cr(NH_3)_6]^{3+}$ ions in the presence of Br^- and I^-.[18]

Kinetic parameters are also obtained at varied ionic strengths in solutions containing 0.1 M of an acetate buffer and 20 μM of LEO at 25 °C. The results are shown in Table 4. The rate constants, k_c°, for the first and the second waves increased with an increase in the ionic strength. The transfer coefficient varied drastically, indicating the presence of a specific adsorption of the complex ions.

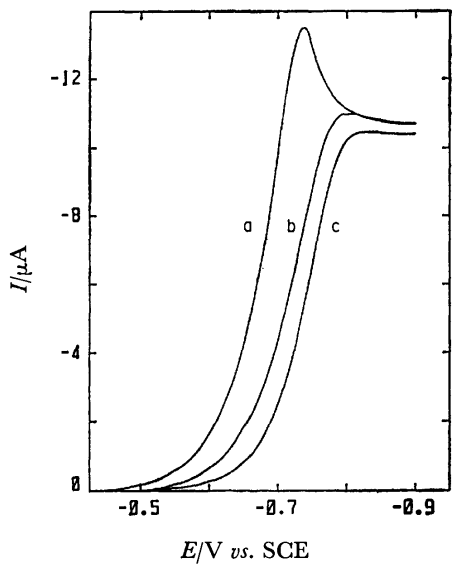

Fig. 5. Normal pulse polarograms of 1 mM $[Cr(urea)_6](ClO_4)_3$ in various halogenide solutions containing 0.1 M acetate buffer and 20 μM LEO (pH 4.6, $\mu=0.5$) at 25 °C.
(a) NaI, (b) NaBr, (c) NaCl.

Anion-induced adsorption[19-21] has been reported for the reduction of some cations, such as Pb(II), Cd(II), and Zn(II), in the presence of I^-, Br^-, Cl^-, *etc.* A similar situation will hold good for the reduction of $[Cr(urea)_6]^{3+}$ ions: the charge of the complex ions is tripositive, and, therefore, the extensive adsorption of $[Cr(urea)_6]^{3+}$ ions on mercury electrodes might be induced from iodide and bromide media. This prediction might be supported by the results of the normal-pulse polarography. Usually, the maximum diminishes at a longer sampling time of the current, but in the present case the maximum still appears at a shorter sampling time ($t_d=50$ ms), as is shown in Fig. 5. For the case of the anion-induced adsorption, the possibility that current-potential curves obtained at shorter sampling times shows a maximum at intermediate potentials has been suggested by Oka and Matsuda.[22]

The diffusion current in Na_2SO_4 was found lower by about 15% than those in other clectrolytes. This is considered to be a result of the formation of ion pairs between $[Cr(urea)_6]^{3+}$ and SO_4^{2-}, by analogy with the electrode reactions of other tervalent complexes.[23,24]

The authors are indebted to Dr. Yoshikiyo Kato for technical assistance. They also wish to thank the Ministry of Education, Science and Culture for the financial support granted for this research.

Potentiometric Study on the Complex Formation of Cobalt(II) Ion with Ethylenediamine-*N*-acetic Acid, Diethylenetriamine, and Iminodiacetic Acid

Takeo OHSAKA, Noboru OYAMA, and Hiroaki MATSUDA*

Department of Electronic Chemistry, Graduate School at Nagatsuta, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received June 6, 1980)

The formation constants of Co(II)–ethylenediamine-*N*-acetate (edma), –diethylenetriamine (dien) and –iminodiacetate (ida) complexes were determined by potentiometric titration in 1.0 M $NaClO_4$ solution at 25 °C. The following results were obtained. Edma: $\log \beta_{101}=7.51$, $\log \beta_{102}=14.05$; dien: $\log \beta_{101}=9.34$, $\log \beta_{102}=16.89$; ida: $\log \beta_{101}=6.54$, $\log \beta_{102}=11.95$, β_{pqr} being the overall formation constant defined in the text. The relative effects of amino and carboxyl groups on the affinity of ligands to Co(II) ion are discussed.

Ethylenediamine-*N*-acetic acid (edma) is a simple, artificial and basic amino acid in products formed during the carboxymethylation of ethylenediamine;[1] Nevertheless, only a few papers have appeared on the complex formation equilibria between metal ions and $edma^-$ anion, in contrast to those of ethylenediaminetetraacetic acid (EDTA). Fujii *et al.*[2-6] have prepared this ligand by a new, simple method and studied the complex formation with Cd(II), Pb(II), Cu(II), and Tl(I) ions by d.c. polarography and with Ni(II) by spectrophotometry. Oyama *et al.*[7] reexamined the Cd(II)–edma system in detail by means of potentiometric titration as well as the d.c. polarographic method. However, no data of complex formation equilibria between Co(II) ion and $edma^-$ anion seem to have been reported.

We have examined the electrode kinetics of the redox couples of Co(II)/Co(III) complexes with tridentate ligands which contain nitrogen and/or oxygen as coordinating atoms, *e.g.*, edma, diethylenetriamine (dien), iminodiacetate (ida). For analysis of electrode kinetics, it is necessary to obtain the equilibrium data of Co(II)–edma, –dien, and –ida complexes under the same conditions as for the examination of electrode kinetics. We have determined the stepwise formation constants of (a) Co(II)–edma, (b) –dien, and (c) –ida complexes in 1.0 M (1 M=1 mol dm^{-3}) $NaClO_4$ solution by potentiometric titration. The formation constants of (b) and (c) for different solution compositions have been reported.[8-10] On the basis of the formation constants, relative effects of amino and acetate groups on the affinity of ligands to Co(II) ion are discussed.

Symbols

- h Concentration of hydrogen ion at equilibrium
- c_{Co} Total concentration of Co(II) ion
- L Ligand ($edma^-$, dien or ida^{2-})
- c_L Total concentration of L
- l Concentration of free ligand
- X Degree of neutralization of ligand, defined by $(-H+h-K_w/h)/c_L$, where H denotes the analytical excess of hydrogen ion in a test solution and K_w the autoprotolysis constant of water in 1.0 M $NaClO_4$ solution ($10^{-13.95}$ mol^2 dm^{-6})[11]
- $\bar{n}$ Average number of protons bound to one L
- $\bar{Z}$ Average number of ligand anions bound to one Co(II) ion
- β_{pqr} Equilibrium constant for the reaction: $pCo^{2+}+qH^+ + rL^{a-} = Co_pH_qL_r^{(2p+q-ra)+}$

Experimental

Reagents. *Cobalt(II) perchlorate* was purified by recrystallizing $Co(ClO_4)_2$ three times, which was prepared from $HClO_4$ and $CoCO_3$, the latter being precipitated from $Co(NO_3)_2$ solution with Na_2CO_3 and then thoroughly decanted. The stock solution contained a small amount of $HClO_4$ to prevent the hydrolysis of Co(II) ion, where the amount of excess $HClO_4$ was determined from the location of end point of neutralization by means of a Gran-plot. The concentration of Co(II) ion in the stock solution was determined by EDTA titration using a murexide indicator. *Diethylenetriamine* was vacuumdistilled twice at ca. 59 °C. *Iminodiacetic acid* was purified by recrystallization twice from water. All other chemicals used were prepared and purified by the method described previously.[7,12]

Potentiometric Measurements. The measurements were performed in a paraffin oil thermostat at 25.00±0.02 °C with use of a glass electrode. Sodium perchlorate was used as an indifferent salt to keep the perchlorate concentration at 1.0 mol dm^{-3} in all runs. The titration vessel and burets were filled with Ar gas before the test, solutions being then introduced. The solutions were deaerated with Ar gas, a vigorous stream of Ar gas being passed through the solution during the course of titration. The Ar gas was freed from O_2 by being passed through hot activated copper and then led through three washing bottles filled with 10% NaOH, 10% $HClO_4$ and 1.0 M $NaClO_4$ solutions, respectively. The apparatus and experimental procedure for potentiometric titration were reported.[12]

Results and Discussion

Evaluation of Protonation Constants of Ligands. The potentiometric titration curves of the Hedma, dien and H_2ida solutions are given in Figs. 1, 2, and 3, respec-

TABLE 1. PROTONATION CONSTANTS OF edma, dien, AND ida BASES IN 1.0 M $NaClO_4$ SOLUTION AT 25 °C

Base	$\log \beta_{011}$	$\log \beta_{021}$	$\log \beta_{031}$
edma	9.97±0.02	16.71±0.02	18.76±0.02
dien	10.76±0.02	20.56±0.02	25.40±0.02
ida	9.05±0.02	11.60±0.02	13.58±0.02

tively. Overall protonation constants of these ligand bases, β_{0q1}, were determined from the formation function, $\bar{n}$, by means of the generalized least squares method.[12] The results are given in Table 1. The values for the edma base are the same as obtained previously.[7] For the dien base Evtimova *et al.*[13] obtained the values log $\beta_{011}=10.03$, log $\beta_{021}=19.39$, and log $\beta_{031}=24.26$ in 1 M NH_4NO_3 solution at 25 °C. Grenthe and Gardhammar[14] obtained log $\beta_{011}=9.32$, log $\beta_{021}=11.89$ and log $\beta_{031}=13.77$ for the ida base under the same experimental conditions as in the present work.

(□): $c_{Co}=0.004504$ mol dm^{-3}, $c_L=0.01979$ mol dm^{-3},
(△): $c_{Co}=0.003079$ mol dm^{-3}, $c_L=0.01355$ mol dm^{-3},
(●): $c_{Co}=0.001503$ mol dm^{-3}, $c_L=0.008135$ mol dm^{-3},
(◑): $c_{Co}=0.001852$ mol dm^{-3}, $c_L=0.01360$ mol dm^{-3}.
Solid lines are the values of X calulated by the use of the for mation constants given in Table 2.

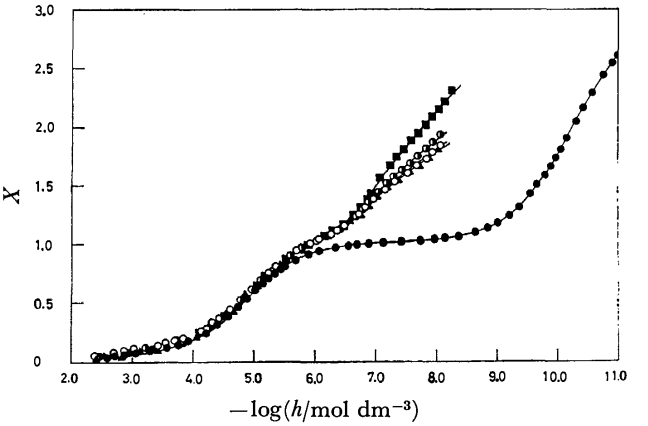

Fig. 2. Degree of neutralization, X, of dien solutions for the Co(II)–dien system.
(●): $c_{Co}=0.0$ mol dm^{-3}, $c_L=0.02000$ mol dm^{-3},
(■): $c_{Co}=0.003639$ mol dm^{-3}, $c_L=0.01086$ mol dm^{-3},
(◑): $c_{Co}=0.002898$ mol dm^{-3}, $c_L=0.01165$ mol dm^{-3},
(○): $c_{Co}=0.003139$ mol dm^{-3}, $c_L=0.01581$ mol dm^{-3},
(▲): $c_{Co}=0.002388$ mol dm^{-3}, $c_L=0.01259$ mol dm^{-3}.
Solid lines are the values of X calculated by the use of the formation constants given in Table 2.

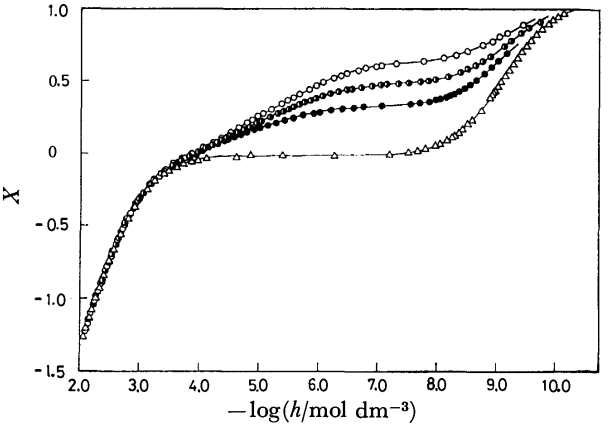

Fig. 3. Degree of neutralization, X, of ida solutions for the Co(II)–ida system.
(△): $c_{Co}=0.0$ mol dm^{-3}, $c_L=0.01004$ mol dm^{-3},
(○): $c_{Co}=0.002945$ mol dm^{-3}, $c_L=0.008965$ mol dm^{-3},
(◑): $c_{Co}=0.002990$ mol dm^{-3}, $c_L=0.01193$ mol dm^{-3},
(●): $c_{Co}=0.003051$ mol dm^{-3}, $c_L=0.01791$ mol dm^{-3}.
Solid lines are the values of X calculated by the use of the formation constants given in Table 2.

We see that the third protonation constant of edma, log $(\beta_{031}/\beta_{021})=2.05$, is almost equal to the average value of the second and third ones of ida, log $(\beta_{021}/\beta_{011})=2.57$ and log $(\beta_{031}/\beta_{021})=1.88$, indicating that these constants correspond to protonation of the carboxyl group. The carboxyl group bound to the imino group of edma and ida is acidic to a greater extent than the acetate (log $\beta_{011}=4.6$).

Determination of the Composition and Formation Constants of the Complexes. Titration curves for the Co(II)–edma, –dien, and –ida solutions are shown in Figs. 1, 2, and 3, respectively. The experiments were performed with the c_L/c_{Co} ratio in the range 2—7, c_{Co} and c_L being varied from 1.5 to 4.5 mmol dm^{-3} and from 8 to 27 mmol dm^{-3}, respectively. In high pH regions above pH 7.5 for the edma system and above pH 8.5 for the dien system, the potential of glass electrode becomes unstable. Thus measured points corresponding to such pH regions are not given in the figures. The instability of glass electrode might result from the interaction of Co(II)L_2 with a very small amount of oxygen remaining in the solutions. Miller *et al.*[15] reported that for Co(II)–dien complexes this interaction may occur even at oxygen concentration below 10^{-8} mol dm^{-3}.

In the pH range 2—5 the values of X for edma system are independent of c_{Co} and c_L, no proton being released from the ligand by complex formation (Fig. 1). On the other hand, above pH 5 the titration curves of solution containing Co(II) ion deviate from that of solution containing only the ligand, indicating that some protons are released from the ligand by the complex formation. As a first approximation for analyzing data we assumed that neither protonated nor polynuclear species are formed, since this was found to be the case for the Cd(II)–edma system.[7] The concentration of the free ligand l and the complex formation function $\bar{Z}$ can be expressed by Eqs. 8 and 9 of Ref. 7, respectively. The plot of $\bar{Z}$ *vs.* log l is shown by curve II in

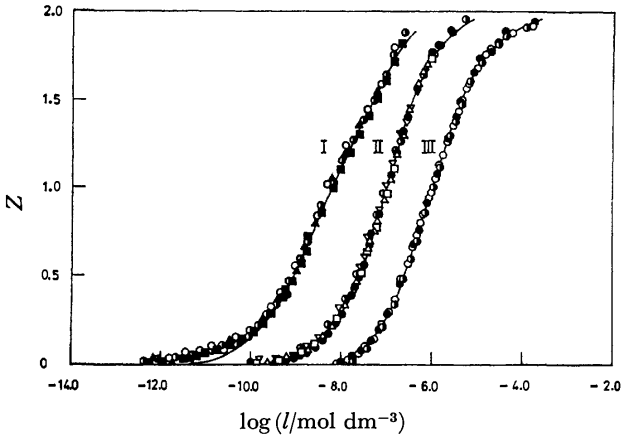

Fig. 4. Relationships between the complex formation function $\bar{Z}$ and log l for the Co(II)–dien, –edma, and –ida systems.
(I): Co(II)–dien, (II): Co(II)–edma, (III): Co(II)–ida. Solid lines are the best fit curves calculated by Eq. 11 of Ref. 7.

Fig. 4. We see that a single curve is obtained regardless of variation of c_L/c_{Co}, c_{Co}, and c_L, satisfying the above assumption, and also that the values of $\bar{Z}$ approach to 2 when the values of log l increase, showing that the complex species of Co(edma)$^+$ and Co(edma)$_2^0$ are formed in the pH range 5—7.

Similarly, for the dien and ida systems, the following conclusion may be deduced from the behavior of curves I and III (Fig. 4): the complex species of 1 to 1 and 1 to 2 compositions are formed in the pH ranges 6—8 (for dien) and 4—10 (for ida). No evidence of the formation of protonated complex species was detected for both systems, although for the dien system a slight deviation from the best fit curve (solid curve) was observed in the region $\log l = -12 - -10.5$. This suggests the formation of protonated complex species. For dien complexes, Miller *et al.*[15] postulated the formation of monoprotonated species such as Co(II)-(dien)(Hdien)$^{3+}$ for interpreting the pH dependence of the rate constant for oxygen uptake by the bis species.

The formation constants of the Co(II)–edma, –dien, and –ida complexes were evaluated by curve fitting using the generalized least squares method.[7] The results are summarized in Table 2. The solid curves in Figs. 1—4 represent the theoretical curves calculated by using these formation constants, which are seen to reproduce the experimental results.

Table 2 indicates that the first step formation constants, K_1 ($=\beta_{101}$), are somewhat larger than the second ones, K_2 ($=\beta_{201}/\beta_{101}$), and also that the coordinating ability of the ligands to Co(II) ion is reduced with

Table 2. Formation constants of Co(II)–edma, –dien, and –ida complexes in 1.0 M $NaClO_4$ solution at 25 °C

Complex	log β_{101}	log β_{102}
Co(II)–edma	7.51±0.02	14.05±0.05
Co(II)–dien	9.34±0.02	16.89±0.05
Co(II)–ida	6.54±0.02	11.95±0.05

increase in the number of replacement of amino group in dien by carboxyl group. Further we see that the following relation holds approximately among the successive formation constants, K_n ($n=1, 2$):

$$\log K_n(\text{edma}) = \frac{1}{2}[\log K_n(\text{dien}) + \log K_n(\text{ida})]. \quad (1)$$

This can be understood from the following consideration: The ligands we used are typical tridentate ones of (N,N,N)-, (N,N,O)-, and (O,N,O)-types, forming the five-membered chelate rings. Their chelate entropy effect[16] as well as steric effect on complex formation may be almost the same. If we assume that the contributions of amino, imino and carboxyl groups to the free energy change, ΔG_n°, of succesive complex formation are constitutive and additive, and denote them by ΔG_n(amino), ΔG_n(imino), and ΔG_n(carboxyl), respectively, ΔG_n° can be given by

$$\Delta G_n^\circ(\text{dien}) = \Delta G_n(\text{imino}) + 2\Delta G_n(\text{amino}) \quad (2)$$

$$\Delta G_n^\circ(\text{edma}) = \Delta G_n(\text{imino}) + \Delta G_n(\text{amino}) + \Delta G_n(\text{carboxyl}) \quad (3)$$

$$\Delta G_n^\circ(\text{ida}) = \Delta G_n(\text{imino}) + 2\Delta G_n(\text{carboxyl}). \quad (4)$$

Combining Eqs. 2—4, we obtain

$$\Delta G_n^\circ(\text{edma}) = \frac{1}{2}[\Delta G_n^\circ(\text{dien}) + \Delta G_n^\circ(\text{ida})]. \quad (5)$$

Equation 5 is identical with Eq. 1. By using the values of successive formation constants available,[8,9] we can show that Eq. 1 holds for Ni(II) and Cu(II) (only for $n=1$) complexes with dien, edma and ida, with somewhat larger deviations, partly because the conditions relevant to each measurement are not the same. A similar relation can be deduced for complexes of some divalent metal ions, such as Co(II), Ni(II), and Cu(II) ions, with the bidentate ligands containing amino and/or carboxyl groups, *e.g.*, ethylenediamine, glycinate and oxalate.[8,9]

The present work was partially supported by a Grand-in-Aid for Scientific Research No. 247065 from the Ministry of Education.

Preparation and Characterization of Dinuclear Cobalt(III) Complexes Bridged by Quadridentate Ligand with Thioether Donor Atoms

Kazuaki YAMANARI* and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received June 21, 1980)

From the reaction of (2-aminoethanethiolato)bis(ethylenediamine)cobalt(III)(2+) complex with α,ω-dibromoalkanes $Br(CH_2)_nBr$, a series of novel monobridged dinuclear cobalt(III) complexes $[(en)_2Co\{NH_2(CH_2)_2S(CH_2)_nS(CH_2)_2NH_2\}Co(en)_2]^{6+}$ ($n=1$, 2, 3, 4, 5, 6, 8, and 10) were prepared and characterized on the basis of their absorption, circular dichroism, and infrared spectra and elemental analyses. In the case of $n=2$, two geometrical isomers, *meso* and *rac*, were isolated and identified.

Thiolato group retains its strong nucleophilic property even after coordinating to a metal ion. This characteristic has been utilized to prepare a variety of new metal complexes containing coordinated thioether,[1] sulfenato,[2] and sulfinato ligands.[3] In particular, alkylation reactions of dithiolato complexes with difunctional alkylating agents have been known to lead to the concomitant formation of two thioether donor atoms and a chelate ring joining them, that is, the formation of macrocyclic ligands.[4] Similar reactions are applicable to the synthesis of bridged complexes.

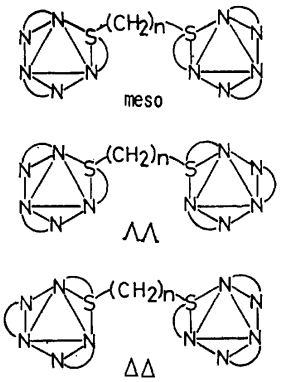

Fig. 1. Three isomers of monobridged dinuclear cobalt(III) complex.

The present report describes the synthesis of monobridged dinuclear cobalt(III) complexes by the reaction of (2-aminoethanethiolato)bis(ethylenediamine)cobalt(III) complex $[Co(aet)(en)_2]^{2+}$ with α,ω-dibromcalkane $Br(CH_2)_nBr$ as bridging agents. As one of advantages of this method, the direct synthesis of optically active bridged complexes becomes possible by starting from the optically active $[Co(aet)(en)_2]^{2+}$ complex.[5] Since the dinuclear complex consists of two optically active octahedral units, a meso (*ΔΛ*) and two optically active (*ΔΔ* and *ΛΛ*) forms are possible (Fig. 1), the latter two of which form a racemate in practice. The isolation of two geometrical isomers of this kind, *meso* and *rac*, has so far been limited to only two cases of $[(en)_2Cr(OH)_2Cr(en)_2]Cl_4\cdot 2H_2O$[6] and $[(en)_2Co(OH)(O_2)Co(en)_2]^{3+}$[7] with double bridged structure, no report being published for the monobridged dinuclear complexes.

Experimental

Preparation and Separation of Complexes. rac- *and/or* meso-$[(en)_2Co\{NH_2(CH_2)_2S(CH_2)_nS(CH_2)_2NH_2\}Co(en)_2]Cl_6$ *($n=1$, 2, 3, 4, 5, 6, 8, and 10)*: A general procedure was developed by using α,ω-dibromoalkanes $Br(CH_2)_nBr$ and *N,N*-dimethylformamide (DMF) as bridging agents and reaction solvent, respectively. To a black solution of four millimoles of *rac*-$[Co(aet)(en)_2](ClO_4)_2$[5] dissolved in 5 cm^3 of DMF was added an excess (2.2 mmol) of α,ω-dibromoalkane. The mixture was allowed to stand for about 20 d at room temperature, leading to a deep-red solution. The DMF and unreacted dibromoalkane were extracted into diethyl ether for several times. The resulting dark red oil was dissolved in water, adsorbed on an SP-Sephadex C-25 cation exchange column (Na^+ form), and eluted with a 0.8 M NaCl solution (1 M= 1 mol dm^{-3}). Five colored bands were eluted in the order, a yellow one of $[Co(en)_3]^{3+}$, a dark brown one of $[Co(aet)(en)_2]^{2+}$, and three orange ones A, B, and C. Each of the orange bands was concentrated to a small volume in a rotary evaporator and after repeated removal of NaCl deposited out the solution was treated with a small amount of ethanol to give orange crystals of the desired chloride salt. Analytical data (Table 1) for the complexes A, B, and C corresponded to $[Co(en)_2\{NH_2(CH_2)_2S(CH_2)_nOH\}]Cl_3$, $[Co(en)_2\{NH_2(CH_2)_2S(CH_2)_nBr\}]Cl_3$, and $[Co_2(en)_4\{NH_2(CH_2)_2S(CH_2)_nS(CH_2)_2NH_2\}]Cl_6$, respectively. This characterization is agreed with the column chromatographic behavior; when developed with a 0.3 M NaCl solution, only the last band C remains on the top of Sephadex resin and therefore seems to be the proposed bridge structure with a hexapositive charge.

For the dinuclear complexes prepared from a racemic starting material *rac*-$[Co(aet)(en)_2]^{2+}$, two geometrical isomers, *meso* and *rac*, are possible. In the case of $n=2$, fractional crystallization of the eluate C produced two different orange crystals: the eluate C was evaporated to a small volume using a rotary evaporator, and the deposit, NaCl, was filtered off. The filtrate was cooled to give first crop of orange crystals (C-1). After filtration the filtrate was further evaporated, a small amount of methanol being added to the concentrated solution, and the deposit, NaCl, was again filtered off. The final filtrate was cooled in an ice bath to give another kind of orange crystals (C-2). Both complexes showed the dinuclear composition, $[Co_2(en)_4\{NH_2(CH_2)_2S(CH_2)_2S(CH_2)_2NH_2\}]Cl_6$, the less soluble C-1 being 3-hydrate and the more soluble C-2 5.5-hydrate.

In order to elucidate the structures, optical resolution was attempted. An aqueous solution containing 0.03 g of the complex C-1 or C-2 was poured into a column of SP-Sephadex C-25 (Na^+ form, 3×80 cm). The adsorbed band was eluted with a mixed solution of 0.5 M NaCl and 0.15 M $Na_2[Sb_2(d-$

tart)$_2$]$\cdot2H_2O$, which produced a broad band. The eluate was separated into fractions of 5 cm^3 each. The fractions of complex C-1 showed no optical activity, while the first fractions of complex C-2 exhibited a positive dominant CD band in the first absorption band region which is completely enantiomeric to that of the last fractions. Thus, the two orange complexes are geometrical isomers, C-1 and C-2 corresponding to *meso* and racemic forms, respectively. In all cases other than $n=2$, the band C could not be splitted into two or more kinds of orange complexes.

Active-$[(en)_2Co\{NH_2(CH_2)_2S(CH_2)_nS(CH_2)_2NH_2\}Co(en)_2]Cl_6$ *($n=2$, 3, 4, 5, 6, 8, and 10)*: Optically active complexes were prepared and separated in the same manner as described above with use of active-$[Co(aet)(en)_2](ClO_4)_2$[5] instead of the racemic starting material. When eluted with a 0.8 M NaCl solution, the column gave the following five band regardless of the kind of $Br(CH_2)_nBr$ used; a yellow bands of $[Co(en)_3]^{3+}$, a dark brown one of $[Co(aet)(en)_2]^{2+}$, and three orange ones A′, B′, and C′. Each orange band was concentrated to a small volume and the chloride salt was crystallized out. Elemental analyses (Table 1) and absorption spectra of the complexes A′, B′, and C′ confirmed their compositions $[Co(en)_2\{NH_2(CH_2)_2S(CH_2)_nOH\}]Cl_3$, $[Co(en)_2\{NH_2(CH_2)_2S(CH_2)_nBr\}]Cl_3$, and $[Co_2(en)_4\{NH_2(CH_2)_2S(CH_2)_nS(CH_2)_2NH_2\}]Cl_6$, respectively.

The distribution of products A′, B′, and C′ under above conditions changed considerably depending upon the number of methylene groups. The yields of the bridged complexes decreased in the following order; $n=3$ and 4 (*ca.* 75%)$>n=5$ (*ca.* 70%)$>n=6$ (*ca.* 65%)$>n=8$ (*ca.* 50%)$>n=10$ (*ca.* 40%)$>n=2$ (*ca.* 20%)$\gg n=1$ (below 5%). The yields of complexes B′ were inversely proportional to those of the corresponding bridged complexes C′ but the total yields of complexes B′ and C′ were almost constant. The yields of complexes A′ were about 5% irrespective of the number of methylene groups, though the products in the case of $n=1$ were so complicated that the yields of the complexes except the bridged one could not be determined.

Measurements. The electronic absorption spectra were measured on a Shimadzu UV-200 spectrophotometer and CD spectra with a JASCO MOE-1 spectropolarimeter in aqueous solution. The infrared spectra were obtained on a JASCO DS-402G spectrophotometer with NaCl prism nsing Nujol mull or KBr disk. All measurements were made at room temperature.

Results and Discussion

Preparation and Characterization of the Complexes. Several preparative methods have been developed for the alkylation of coordinated thiols. It has been noted that DMF is a superior medium for the alkylation

reactions because most alkyl halides and metal perchlorate salts are soluble in this medium.[8] The use of DMF as a reaction solvent in the present study permitted the formation of the alkylated products in a high yield which were not accessible by the use of other solvents such as methanol–water. The formation of $[Co_2(en)_4\{NH_2(CH_2)_2S(CH_2)_nS(CH_2)_2NH_2\}]^{6+}$ is more favorable in a high concentration of reactants than in a dilute one. The concentration dependence can be elucidated from the following mechanism;[9] the reaction of $[Co(aet)(en)_2]^{2+}$ with $Br(CH_2)_nBr$ gives at first an intermediate $[Co(en)_2\{NH_2(CH_2)_2S(CH_2)_nBr\}]^{3+}$ species and then an intermolecular reaction leads to the formation of the bridged complex. In fact, when the reaction mixture was diluted twenty times no orange complexes were detectable under the same condition as described above. The yield of the bridged complexes depends upon the number of methylene groups, being especially low in the cases of $n=1$ or 2 (see Experimental). The low yield seems to be ascribed to the steric and electrostatic repulsion between two tripositive

a) Wave numbers are given in 10^3 cm^{-1} unit and log ε or $\Delta\varepsilon$ values (in parentheses) in mol^{-1} dm^3 cm^{-1}.
b) Shoulder. c) CD intensity was calculated by applying molar absorption coefficient of the corresponding racemate.

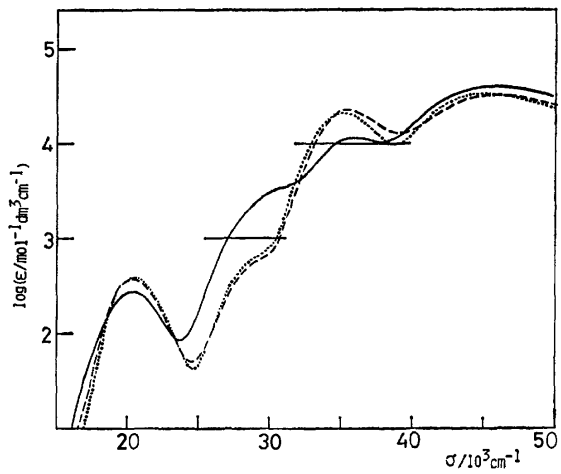

Fig. 2. Absorption spectra of the bridged complexes. $[(en)_2Co\{NH_2(CH_2)_2S(CH_2)_nS(CH_2)_2NH_2\}Co(en)_2]^{6+}$: $n=1$, ——; $n=2$, – – –; $n=8$, ·····.

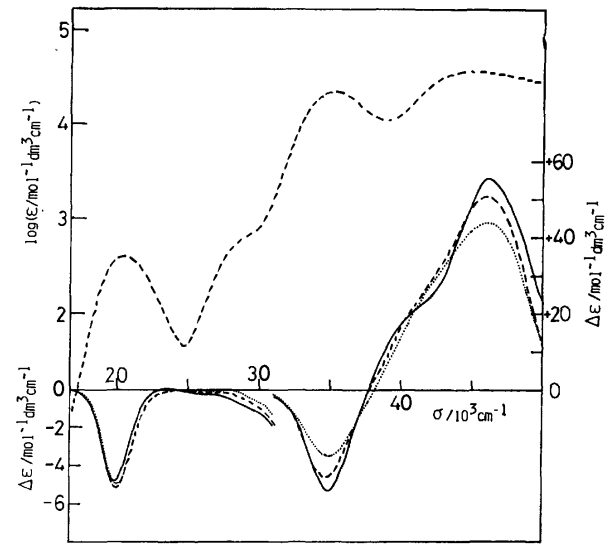

Fig. 3. CD spectra of the bridged complexes $[(en)_2Co\{[NH_2(CH_2)_2S(CH_2)_nS(CH_2)_2NH_2\}Co(en)_2]^{6+}$: $n=2$, ——; $n=4$, – – –; $n=8$, ·····.

groups which must be tied with the shortest methylenic chain.

Absorption Spectra. Figure 2 and Table 2 show the absorption spectra of the present complexes. The bridged complexes exhibit their first d-d absorption bands at about 20400 cm^{-1} which quite agree with those of the $[Co(N)_5(S)]$ type complexes containing a thioether donor atom.[5] The first d-d absorption band shifts slightly to higher energy side with increasing the number of methylene groups, while two charge transfer absorption bands in the near-ultraviolet region reversely.

As for the bridged complex of $n=1$, another intense band appears at *ca.* 30000 cm^{-1} with diminishing the intensity of the charge transfer band characteristic of the coordinated sulfur atoms at 35000 cm^{-1}. This new band seems to be also of charge transfer character judging from its intensity ($\log\varepsilon=3.5$). The other bridged complexes of $n=2$—10 did not show such an intense band but the second d-d absorption band in the same region. Thus, the new band may be due to the *geminal*-sulfur interaction like that observed in organic compounds such as bis(methylthio)methane and 2,2-bis(butylthio)propane,[10] because the interaction reduces the promotion energy of lone-pair electrons. A similar absorption band has been reported in a cobalt(III) complex containing a disulfide ligand, $[Co(en)_2\{S(SCH_2CH_2NH_3)CH_2CH_2NH_2\}]^{4+}$.[11]

Both monomeric complexes, $[Co(en)_2\{NH_2(CH_2)_2S(CH_2)_nBr\}]^{3+}$ and $[Co(en)_2\{NH_2(CH_2)_2S(CH_2)_nOH\}]^{3+}$, show almost the same absorption spectra as those of the corresponding bridged complexes except that their molar extinction coefficients are reduced to one-half the values of dinuclear complexes (Table 2).

CD Spectra. In the preparations of optically active bridged complex, the Δ-$[Co(aet)(en)_2]^{2+}$ complex was used as the starting material whose absolute configuration had been assigned on the basis of the CD sign in the first d-d absorption band region.[5] As shown in Fig. 3, all the bridged complexes exhibit nearly the same CD spectra irrespective of n values, a negative CD band being dominant in the first absorption band region. The spectral pattern is very analogous to that of Δ-$[Co(en)_2(NH_2CH_2CH_2SR)]^{3+}$ ($R=CH_3$ or C_2H_5).[5] Therefore, it is concluded that the alkylation reaction proceeds with retention of the initial absolute configuration and the bridged complexes obtained have the $\Delta\Delta$ absolute configuration.

Both monomeric complexes, $[Co(en)_2\{NH_2(CH_2)_2S(CH_2)_nBr\}]^{3+}$ and $[Co(en)_2\{NH_2(CH_2)_2S(CH_2)_nOH\}]^{3+}$, show a similar CD pattern to that of the bridged complexes, being also assigned to the Δ absolute configuration.

The CD intensities of the bridged complexes are approximately 2 times larger than those of the monomeric $[Co(en)_2\{NH_2(CH_2)_2S(CH_2)_nBr\}]^{3+}$ complexes in almost all regions. However, the CD intensities of $[Co_2(en)_4\{NH_2(CH_2)_2S(CH_2)_2S(CH_2)_2NH_2\}]^{6+}$ and $[Co_2(en)_4\{NH_2(CH_2)_2S(CH_2)_3S(CH_2)_2NH_2\}]^{6+}$ in the thioether charge transfer band region are 3.1 and 3.4 times larger than those of the corresponding monomeric complexes, respectively. This increase of CD intensity seems to represent an additional chirality which arises on the thioether donor atoms of bridged complexes of only $n=2$ or 3 because of a rather short bridge chain and the resulting unbalance of the *R* and *S* chiralities of the asymmetric sulfur atoms. In fact, the CD intensity per one cobalt(III) ion of the dinuclear complex of $n=10$ becomes almost the same as that of the monomeric complex, the increase in the number of methylene groups reducing such interaction between the two coordination centers.

Characterization of Geometrical Isomers. In the case of $n=2$, fractional crystallization of the bridged complex prepared from the racemic starting complex led to the isolation of the two orange crystals, C-1 and C-2. The chromatographic separation with a mixed solution of 0.5 M NaCl and 0.15 M $Na_2[Sb_2(d\text{-tart})_2]\cdot 2H_2O$ as an eluent indicated that only the complex C-2 is resolvable into the optical antipodes. Therefore, it is concluded that the complexes C-1 and C-2 are *meso* and *rac* forms, respectively. As shown in Table

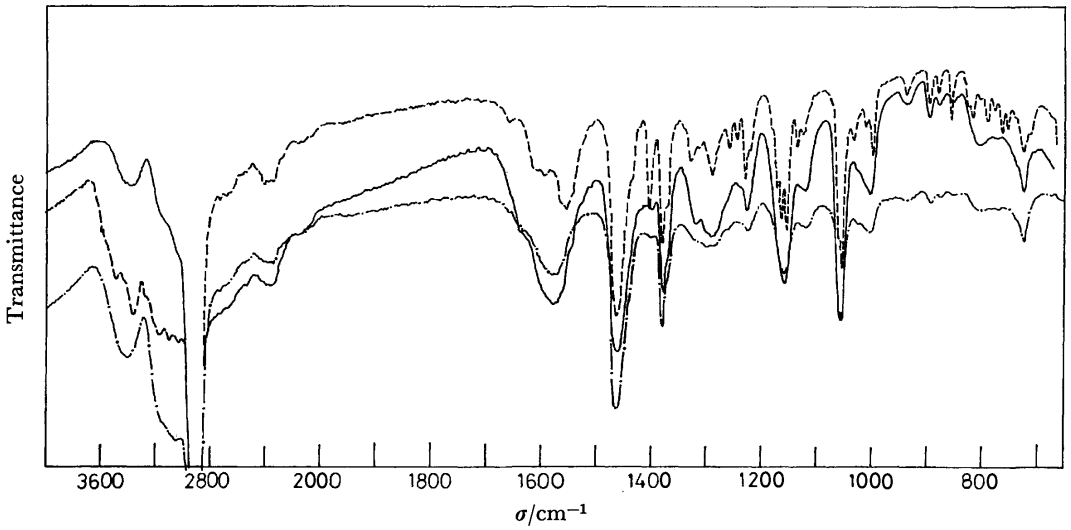

Fig. 4. Infrared spectra of $[(en)_2Co\{NH_2(CH_2)_2S(CH_2)_2S(CH_2)_2NH_2\}Co(en)_2]Cl_6$: C-1, ——; C-2, ——; ΔΔ, ·–·–·.

2, the optically active *ΔΔ* isomer of the bridged complex of $n=2$ exhibits the analogous absorption spectra to that of the racemate C-2 rather than the *meso* form C-1 with respect to both the spectral position and intensity. A similar trend was also observed in the infrared spectra of these complexes (Fig. 4). The chlorides of complexes C-1 and C-2 gave significantly different spectra in the region 4000—400 cm^{-1}. However, the spectrum of active *ΔΔ* isomer is nearly identical to that of the racemate C-2.

In the case of $n=3$, the complex C obtained from *rac*-$[Co(aet)(en)_2]^{2+}$ showed a similar IR spectrum to that of the optically active *ΔΔ* isomer in the region 4000—700 cm^{-1}. Since there appear no other absorption peaks besides those of the active isomer, this complex consists of a single species and could be assigned to the racemic form.

On the Enhancement of the Selectivity of Organic Sulfonate Ion Electrode by Alkylphenols†

Hirokazu HARA, Satoshi OKAZAKI, and Taitiro FUJINAGA*

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received June 23, 1980)

An enhancing effect of alkylphenols on the selectivity of the liquid membrane electrode responsive to organic sulfonate ion has been investigated. The interference of perchlorate ion expressed in terms of the selectivity coefficient decreased to one eighthundredth in the presence of *p*-*t*-octylphenol. This effect was attributed to the formation of the hydrogen bonding between the phenol and sulfonate. The dependence of the potentiometric behavior, paticularly with respect to the selectivity on the membrane components was examined. The optimum composition of the ion-exchanger for sulfonate was found to be 0.05 mol dm^{-3} trioctylmethylammonium *p*-toluenesulfonate with 0.5 mol dm^{-3} *p*-*t*-octylphenol in *o*-dichlorobenzene. The decrease of the selectivity coefficient for perchlorate due to the phenol was also discussed in relation to ion-exchange equilibrium constants, ionic parameters, and dissociation constants of the ion-pair. The effect of the membrane solvents was also discussed in terms of their solubility parameters.

To date, in a liquid membrane electrode, more interest has been shown in the membrane solvent rather than in the ion-exchange site as an effectual dominant of selectivity. Though several useful solvents having wide selectivity ranges, such as nitrobenzene and 1,2-dichloroethane have been recommended,[1,2] the selectivity of the liquid membrane electrode is generally insufficient. Particularly, in the case of an anion sensitive electrode, an ion-exchanger such as a neutral carrier for cation selective electrode has not been developed.

In the previous papers,[3,4] the authors have reported on an organic sulfonate ion selective electrode of a coated wire type and a solid solvent membrane type. In the course of the study on the selectivity characteristics of *p*-toluenesulfonate (pTS) ion selective electrode, the authors found an enhancing effect of an alkylphenol on the selectivity, *i.e.*, the interferences of the inorganic anions such as perchlorate, tetrafluoroborate ions decreased remarkably by the addition of some alkylphenols into the liquid membrane; for example, the logarithmic selectivity coefficient of perchlorate decreased from +2.3 to −0.6 in the presence of 0.5 M† *p*-*t*-octylphenol(*p*-(1,1,3,3-tetramethylbutyl)phenol; ptOP). This effect of the phenol was attributed to the formation of hydrogen bonding between the phenol and pTS anion.

In this paper, the influences of the concentration of ion-pair and phenols upon the membrane response and selectivity were examined. This phenomenon was interpreted on the basis of Sandblom-Eisenman-Walker theory.[5] The effect of some alkylphenols on the selectivity was studied in relation to their hydrogen bonding ability. The effect of the membrane solvents was also discussed with reference to their hydrogen bonding parameters.

Experimental

Reagents. All chemicals were of analytical reagent grade and used without further purification unless otherwise noted. Ion-pair of trioctylmethylammonium(abbreviated as TOMA) with *p*-toluenesulfonate was synthesized as follows: trioctylmethylammonium chloride (commercially available as Capriquat from Dojin Chemicals, Kumamoto) dissolved in chloroform was shaken with an aqueous solution of 0.1 M sodium pTS for 10 min. The extraction was repeated several times until chloride was not detected any more in the aqueous phase. After chloroform was evaporated by a rotary evaporator, the deposit was recrystallized from ethyl acetate. *o*-Dichlorobenzene used for the conductivity measurements was purified by distillation after the dehydration with calcium hydride. Its water content was estimated as 0.02% (v/v) by gas chromatography. A series of the following phenols were examined: *p*-*t*-octylphenol (*p*-(1,1,3,3-tetramethylbutyl)phenol; ptOP), *p*-*t*-pentylphenol (ptPP), *p*-*t*-butylphenol (ptBP) 2,3,5-trimethylphenol, 2,4,6-trimethylphenol, and 2,6-di-*t*-butyl-4-methylphenol.

Preparation of Membranes. A liquid membrane was prepared by dissolving the ion-pair of TOMA pTS into *o*-dichlorobenzene, which was held in a Corning probe with a hydrophobic ceramic junction. A solid solvent membrane[4] was prepared by dissolving the ion-pair in phenol at elevated temperature and then powdered. *Ca.* 30 mg of the ion-exchanger was pressed at a pressure of 3×10^8 Pa on a silver disk of 1 cm in diameter. The electrical contact was taken directly from the silver disk.

Apparatus. Membrane potentials were measured against SCE at 25 °C with an Orion Digital Ionalyzer Model 601 equipped with a Matsushita Pen Recorder Model VP654-A. IR spectra were measured by a JASCO Infrared Spectrophotometer Model DS-402G using a NaCl cell having a light pass length of 0.1 mm. The conductivity was measured at 25 °C by a Yokogawa Universal Bridge Type BV-Z-13B with a cell having a cell constant of 0.1060 s cm^{-1}.

Estimation of Various Parameters. Logarithmic selectivity coefficient, log K^{pot} was measured by the separate solution method; the potential difference between a solution of 10^{-2} M pTS^- and that of interfering anion was divided by the slope of the calibration curve for pTS^-. For the measurement of ion-exchange equilibrium constant, K^{ex}, 50 cm^3 of 10^{-2} M organic solution of TOMA pTS was shaken with the equivolume of 10^{-2} M aqueous solution of sodium perchlorate for 1 h at 25 °C. After the ion-exchange equilibrium in Eq. 1 was reached,

$$(\text{TOMA pTS})_{org} + (ClO_4^-)_{aq} \overset{K^{ex}}{\rightleftharpoons} (\text{TOMA } ClO_4)_{org} + (pTS^-)_{aq}, \quad (1)$$

† A preliminary report has been published: T. Fujinaga, S. Okazaki, and H. Hara, *Chem. Lett.*, **1978**, 1201.

†† Throughout this paper 1 M = 1 mol dm^{-3}.

$$K^{ex} = \frac{[\text{TOMA ClO}_4]_{org}[\text{pTS}^-]_{aq}}{[\text{TOMA pTS}]_{org}[\text{ClO}_4^-]_{aq}}, \quad (2)$$

the concentrations of pTS^- and ClO_4^- in the aqueous phase were measured with the liquid membrane electrodes, the ion-exchanger of which were TOMA pTS plus ptOP and TOMA ClO_4 in *o*-dichlorobenzene for *p*-toluenesulfonate and perchlorate electrodes, respectively. For the associated ion-pair, the mole fractions of ions extracted in the organic phase were assumed to be equal to those of ions eluted inversely into the aqueous phase. Thus, after the equilibrium was reached, following relationships hold; $[\text{TOMA pTS}]_{org}=[\text{ClO}_4^-]_{aq}$, $[\text{TOMA ClO}_4]_{org}=[\text{pTS}^-]_{aq}$. Then, Eq. 2 is simplified as follows,

$$K^{ex} = [\text{pTS}^-]_{aq}^2/[\text{ClO}_4^-]_{aq}^2. \quad (2)'$$

The molar conductivities of ClO_4^- and $TOMA^+$ at infinite dilution were obtained using tetrabutylammonium tetraphenylborate as a reference electrolyte.[6] The dissociation constant, K^D of TOMA ClO_4 in the absence of ptOP was estimated by the Shedlovsky method.[7] Being considered small the interactions between the phenol and $TOMA^+$ or ClO_4^-, the molar conductivity of $TOMA^+$, $\lambda^\circ(\text{TOMA}^+)_p$ in the presence of ptOP, was assumed to have the same magnitude as that in the absence of the phenol. Also $\lambda^\circ(\text{ClO}_4^-)_p$ was estimated so that the K^D values in the presence and absence of the phenol were of the same magnitude. Here, K^D in the presence of the phenol was calculated by Eq. 3,

$$K^D = C(\Lambda/\Lambda_0)^2/(1 - \Lambda/\Lambda_0), \quad (3)$$

where Λ is the conductivity at the concentration $C(10^{-5}\ M < C < 10^{-4}\ M)$ and Λ_0 is the molar conductivity given by the sum of $\lambda^\circ(\text{TOMA}^+)_p$ and $\lambda^\circ(\text{ClO}_4^-)_p$. The $\lambda^\circ(\text{pTS}^-)$ and $\lambda^\circ(\text{pTS}^-)_p$ were obtained assuming that Walden's rule holds in these systems,[8] *i.e.*,

$$\lambda^\circ(\text{pTS}^-) = 0.7 \times \lambda^\circ(\text{ClO}_4^-),$$
$$\lambda^\circ(\text{pTS}^-)_p = 0.7 \times \lambda^\circ(\text{ClO}_4^-)_p. \quad (4)$$

The dissociation constants for TOMA pTS were calculated from Eq. 3 using these relations.

The formation constants, K_1^F between pTS^- and alkylphenols were estimated according to the method reported by Aitken and Gilkerson.[9] The dissociation constant, K^D for TOMA pTS in the absence of a phenol is assumed to be given in Eq. 3. If the dissociation constant varies from K^D to K_p^D by the addition of phenol, then,

$$K_p^D/K^D = (C_p/C)(\Lambda_p/\Lambda_{0p})^2(\Lambda/\Lambda_0)^{-2}(1 - \Lambda/\Lambda_0) \times (1 - \Lambda_0/\Lambda_{0p})^{-1}. \quad (5)$$

This equation can be reduced to Eq. 6, provided that the concentration of ion-pair is constant, *i.e.*, $C_p=C$, and the molar conductivities Λ and Λ_p at concentration C and C_p are much smaller than those at infinite dilution.

$$K_p^D/K^D = (\Lambda_p/\Lambda)^2 \equiv R \quad (6)$$

Those simplifying assumptions are reasonable in a solvent of low dielectric constant such as *o*-dichlorobenzene. The following interactions were assumed to exist between pTS^- or ion-pair and the phenol (denoted by P),

$$\text{pTS}^- + \text{P} \rightleftarrows \text{pTS}\cdot\text{P}^-,\ K_1^F = [\text{pTS}\cdot\text{P}^-]/[\text{pTS}^-][\text{P}] \quad (7)$$

$$\text{TOMA pTS} + \text{P} \rightleftarrows \text{TOMA pTS}\cdot\text{P},$$
$$K_2^F = [\text{TOMA pTS}\cdot\text{P}]/[\text{TOMA pTS}][\text{P}]. \quad (8)$$

Then the ratio, K_p^D/K^D was given by Eq. 9,[9,10]

$$K_p^D/K^D = (1 + K_1^F[\text{P}])/(1 + K_2^F[\text{P}]). \quad (9)$$

The lefthand side of Eq. 9 is approximated by R and the righthand side by $(1+K_1^F[\text{P}])$ at low concentration of the phenol. Consequently, K_1^F can be obtained from the slope of the plot of R *vs.* [P].[9]

Results and Discussion

Effect of ptOP on the Sensitivity and Selectivity. The effects of the concentrations of the ion-pair, TOMA pTS and the phenol on the sensitivity and selectivity of the sulfonate electrode were examined. The potential difference between the pTS^- solutions of 10^{-1} M and 10^{-5} M was defined as a sensitivity factor, $\Delta E_{1\text{-}5}$. In the absence of the phenol, both the sensitivity and selectivity were independent of the ion-pair concentration over the experimental range from 1.5 mM to 50 mM; *i.e.*, $\Delta E_{1\text{-}5} \approx 200$ mV and $\log K^{pot} \approx 2.3$, 0.6, -0.5, -1.0, and -2.0 for perchlorate, iodide, nitrate, bromide, and chloride ions, respectively. When the concentration of the ion-pair was below 0.5 mM, the sensitivity decreased to 170 mV, owing to the decrease of the ion-exchange current density due to the dilution of the ion-exchanger. In the case of the diluted ion-exchanger membrane, as shown in Fig. 1-a, the values of $\log K^{pot}$ were decreased in proportion to the logarithm of the ptOP concentration and also the value $\Delta E_{1\text{-}5}$ was decreased more significantly. When the concentration of the ion-pair was sufficiently high, the membrane maintains still high sensitivity even at high concentration of ptOP, as shown in Fig. 1-b. In conclusion, the optimum concentration of ptOP was chosen at 0.5 M. Figure 2 shows the relationships between the concentration of the ion-pair and the sensitivity factor or logarithmic selectivity coefficients in the presence of 0.5 M

ptOP. The concentration of the ion-pair should be higher than 0.03 M to keep the sensitivity sufficiently high.

As shown in Figs. 1 and 2, the interference of perchlorate decreased remarkably by the addition of ptOP, though perchlorate is one of the most serious interferent against the conventional liquid membrane electrodes. It seems to be noteworthy that the selectivity coefficient for perchlorate is reduced to one eight-hundredth and becomes smaller than one, in other words, perchlorate becomes a "weaker" anion than pTS anion. This remarkable change in selectivity against perchlorate by ptOP can be explained on the basis of Sandblom-Eisenman-Walker theory[5,11] for the liquid membrane potential. In the case of a strongly associated ion-pair, the membrane potential E is given by Eq. 10[11]

$$\frac{F}{RT}E = (1-\tau)\ln\frac{a_i'+\bar{P}a_j'}{a_i''+\bar{P}a_j''} + \tau\ln\frac{a_i'+\bar{K}a_j'}{a_i''+\bar{K}a_j''}, \quad (10)$$

where a_i', a_j', a_i'', and a_j'' are activities of ions i and j in the phases denoted with suffixes (′) and (″). Three selectivity factors $\bar{P}$, $\bar{K}$, and τ are defined by Eqs. 11—13;

$$\bar{P} = \frac{(u_j+u_s)k_j}{(u_i+u_s)k_i} = \frac{u_j+u_s}{u_i+u_s}K^{ex}\frac{K_{js}^p}{K_{is}^p}, \quad (11)$$

$$\bar{K} = \frac{u_{js}}{u_{is}}K^{ex}, \quad (12)$$

$$\tau = \frac{u_s[(u_{js}/K_{js}^p)-(u_{is}/K_{is}^p)]}{(u_i+u_s)(u_{js}/K_{js}^p)-(u_j+u_s)(u_{is}/K_{is}^p)} \quad (0<\tau<1), \quad (13)$$

where u_i, u_j, u_{is}, u_{js} are the mobilities of ions i, j, and ion-pairs in liquid membrane, k_i and k_j are the partition coefficients and K_{is}^p K_{js}^p, are the ion-pair dissociation constants and K^{ex} is the ion-exchange equilibrium constant. Therefore, $\bar{P}$ is governed by the mobilities of ions in the membrane and their partition equilibria, whereas $\bar{K}$ is governed by the mobilities of the ion-pair and the ion-exchange equilibrium constant of Eq. 1. A parameter τ indicates the relative weight between $\bar{P}$ and $\bar{K}$, and depends on the ion dissociation phenomena in the membrane. These parameters estimated with respect to ions pTS^-(i) and ClO_4^-(j) in the presence and absence of ptOP are summarized in Table 1 together with the potentiometric selectivity constant, K^{pot}.

The observed selectivity coefficients in the presence and absence of ptOP agree fairly well with the mean values between $\bar{P}$ and $\bar{K}$. This indicates that the variation of the selectivity coefficient can be interpreted well by this theory. The factors of the mobility ratio and the dissociation constant ratio in Eqs. 11 and 12 vary at most three times by the addition of ptOP. Therefore, it seems that these factors are not responsible for the lowering of the selectivity of perchlorate. Judging from the variation of τ caused by the addition of ptOP, the contribution of the associated species to the selectivity is large in the absence of ptOP, whereas the contribution of the diffusion of free ions becomes important in the presence of ptOP, namely, this variation results from

the promotion of the dissociation of ion-pair by the formation of hydrogen bonding between the ptOP and sulfonate.

Relationship between the Hydrogen Bonding Abilities of Alkylphenols and Selectivity of Sulfonate Electrode. As a measure of the hydrogen bonding abilities of alkylphenols used, the formation constants, K_1^F between pTS^- and the phenols were evaluated from the slopes of the extrapolation of the plot of R *vs.* [P] back to the zero concentration of the phenols, as shown in Fig. 3. In the figure, when the concentration of the phenols becomes high, the plots are curving convexly. This indicates the formation of the associated species between the phenols and the ion-pair. It can be seen in the Figure, that the more sterically hindered the hydroxyl group of the phenols is, the smaller the K_1^F value becomes (A—D). The phenols having small *p*-alkyl substituent were likely to show the large values of K_1^F (D—F). This result does not necessarily indicate that the hydrogen bonding ability increases in the order, D<E< F in *p*-alkyl-substituted phenols, because the molar conductivities of the associated species between pTS^- and these phenols vary with their sizes. Namely, the larger the phenol is, the more slowly the associated species move. In the case of TOMA ClO_4 (curve G), the decrease of R was observed. The result is explained that only the free perchlorate anion is associated with ptOP and the molar conductivity of the associated species decreases in comparison with that of the free perchlorate.

These results obtained by conductometry were confirmed by the IR spectra of these phenols in *o*-dichlorobenzene in the presence of pTS^- or ClO_4^-. The stretching band ν(OH) of phenols near 3600 cm^{-1} shifted to the longer wavelength by the addition of pTS^-, the shift of which was in proportion to the hydrogen bonding abilities of the phenols with sulfonate.[12,13] As shown in Table 2, a good correlation was obtained between the frequency shift of the ν(OH) band and the formation constants measured by conductmetry (A—D). The difference was not entirely observed among the hydrogen bonding abilities of the *p*-alkyl-substituted phenols (D—F), in spite of the remarkable difference in their formation constants. The shift of the ν(OH) band was also observed when ptOP was added to the solution of TOMA ClO_4, and this shift shows the formation of associated species between ptOP and perchlorate. Figure 4 shows the relationships between log K^{pot} and log K_1^F with respect to the liquid membrane(upper) and to the solid solvent membrane (lower), respectively. It can be said that the more sterically hindered the phenols are, the less selective the electrode is in both the liquid and solid solvent

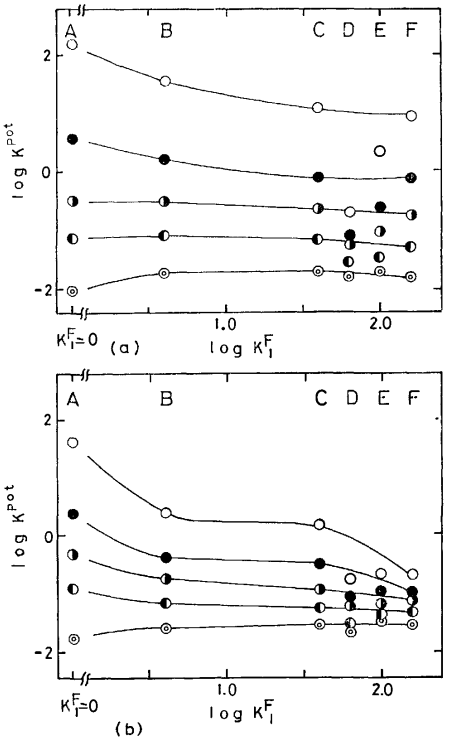

Fig. 4. Relationship between formation constant and selectivity coefficients.

membranes (A—C,F). The effect of the size of *p*-alkyl substituent was significant in the liquid membrane in contrast with the solid solvent membrane (D—F). This result can be explained by the fact that in the liquid membrane the surface concentration of the phenols decreased with decreasing the size of *p*-alkyl substituent by the dissolution of phenol into the aqueous phase. Consequently, the highest selectivity was observed with ptOP having the largest *p*-alkyl substituent among the phenols D,E,F. The lowering tendency of the selectivity in the liquid membrane in comparison with that in the solid solvent membrane can be interpreted in the same way.

Effect of the Membrane Solvents on the Selectivity. The solvent effect on the selectivities of the sulfonate electrode was examined in the presence and absence of ptOP. Jyo *et al.*[2] examined the solvent effects in the liquid membrane electrode and reported that chloroform enhanced the selectivity for halide ion and 1-decanol decreased the selectivity of perchlorate and

tetrafluoroborate, in contrast to the increasing effect of this solvent to the selectivity of organic anions. The hydrogen bonding ability of the solvents seems also to play an important role in the selectivity characteristics of the sulfonate electrode. Table 3 summarizes the solvent effect on the selectivities of the sulfonate electrode in the presence and absence of ptOP. In the table, the hydrogen bonding component δ_h of solubility parameters[14] is also listed. The interference of the inorganic anions such as perchlorate, tetrafluoroborate and others decreased with increasing δ_h. In the presence of ptOP, however, no remarkable effect of the solvents is observed. This shows that the selectivity is primarily determined by ptOP. The effect of ptOP in nitrobenzene was not so significant as that in the other solvents. This result is due to the relatively high dielectric constant of nitrobenzene. No effect of solvents on the selectivity of 1-naphthalenesulfonate and benzenesulfonate was observed. Namely, these organic sulfonates seem to interact with solvent or ptOP in the same way as the objective ion like *p*-toluenesulfonate. The interference of ions such as perchlorate and tetrafluoroborate which interact weakly with proton was decreased remarkably by the addition of ptOP. On the other hand, the interference of ions such as nitrite and chloride which strongly interact with proton did not always decrease but even increased in some cases.

Conclusion

From the above discussion, it is concluded that the phenol primarily governs the selectivity of the sulfonate electrode and the membrane solvent influences in a minor extent. For the optimum selection of phenol in order to obtain the high selectivity, the hydroxyl group of the phenol should be little hindered sterically, and the solubility of the phenol should be large in a membrane solvent and small in a aqueous sample solution.

In conclusion, it was found that the recommended ion-exchanger for *p*-toluenesulfonate was 0.05 M TOMA pTS with 0.5 M ptOP in *o*-dichlorobenzene. The potentiometric response characteristics of this ion-exchanger were as follows: (1) the linear response range is 10^{-1} M—$10^{-3.8}$ M, (2) the usable response range is 10^{-1} M—10^{-5} M, (3) the slope is 61 mV/decade, and (4) the response time at 10^{-2} M is within 3 min.

The authors are grateful to Dr. Ikko Sakamoto in their laboratory for his offer of the samples used in the conductivity measurements and also for his helpful discussions on the results.

Neighboring Group Participation in the Oxidation of Hydroxy Sulfides. Control of the Reaction Courses and Products

Yoshio Ueno,* Tadaaki Miyano, and Makoto Okawara

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received December 20, 1979)

Oxidation of the hydroxy sulfides [$PhS(CH_2)_nCH(OH)R$] with hexabutyldistannoxane (HBD)–bromine system was studied in order to clarify neighboring group participation during the course of reaction. The oxidation products were found to be highly dependent on the positions of the two functional groups [sulfide and hydroxyl group]. Thus hydroxy sulfoxides [$PhSO(CH_2)_nCH(OH)R$] were obtained as the main product when $n=1$ or 2, bromo sulfones [$PhSO_2(CH_2)_nCHBrR$] being predominant when $n=3$ or 4. Keto sulfoxide [$PhSO(CH_2)_nCOR$] was exclusively formed when $n=6$. The results are discussed in terms of the different intramolecular interactions depending on the positions of the two functional groups.

Neighboring group participation is an important factor controlling reactions. For example, neighboring group participation in biological systems operates to fix and activate the substrates in an unequivocal manner particularly in enzymatic reactions.[1]

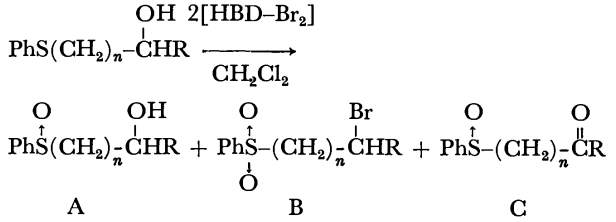
Studies have been carried out to explore the neighboring group participation or intramolecular interactions in static state by means of spectroscopic methods such as IR, UV, Fluorescence, NMR, or ESR spectroscopy.[2] However, no study seems to have been carried out on these subjects during the course of reaction.

In order to investigate neighboring group participation as a function controlling the reaction courses and products, it is important to choose suitable model compounds having two functional groups. We chose hydroxy sulfides, in which both hydroxyl and sulfide groups are isolated systematically by different methylene-chain lengths ($n=1$—6). It was shown that a hexabutyldistannoxane (HBD)–bromine system is an effective oxidant for alcohols[3] or sulfides.[4] Especially this oxidant has one advantage over the existing ones, since sulfides are oxidized selectively to the corresponding sulfoxides without overoxidation to sulfones even in the presence of excess HBD–Br_2. These observations enable us to investigate the oxidation of these two functional groups existing in the same molecule with HBD–Br_2.

Results and Discussion

The hydroxy sulfides were prepared by the usual methods (see Experimental). Oxidation was carried out in dichloromethane at room temperature. Bromine solution (2.4 equiv.) was added to a solution of HBD (2.4 equiv.) and hydroxy sulfides (1 equiv.). The results of oxidation are given in Table 1.

The products were hydroxy sulfoxides (Type A), bromo sulfones (Type B), and Keto sulfoxides (Type C). In some cases, one of the three was formed exclusively.



Distribution of the products depends on the methylene-chain length, Type A being predominant when the two functional groups are located in relatively closer positions ($n=1$ or 2), and Type B when $n=3$ or 4. Keto sulfoxide was formed exclusively when $n=6$. The differences in product distribution should arise from the different neighboring group participations during the course of reaction depending on the distance between the two functional groups. This is discussed in terms of the most fovorable cyclic intermediate in each substrate.

Hydrogen Bonding between Hydroxyl and Sulfoxide Group. Hydroxy sulfoxides (Type A) exibited in their IR spectra an ultimate shift to lower wave numbers of both νO–H (3320—3380 cm^{-1}) and νS–O (990—1020 cm^{-1}) streching frequencies, indicating a strong hydrogen bonding between OH and SO groups. The figures in parentheses indicate isolated yields of hydroxy sulfoxides. The hydrogen bondings seem to prevent the hydroxyl group from further oxidation to the corresponding carbonyl group.

The hydrogen bondings are composed of six-, seven- or eight-membered (less effective) ring systems. Larger ring systems should be extremely unfavorable, since no hydroxy sulfoxides were obtained from **4** and **5**, which should undergo cyclization to nine- and eleven-membered ring, respectively, for the sake of intramolecular hydrogen bonding.

A bulky substituent such as the phenyl group in compound **9** might contribute to the more rigid hydrogen bonding formation by the restriction of the free rotation of the molecule, resulting in a higher yield of hydroxy sulfoxides.

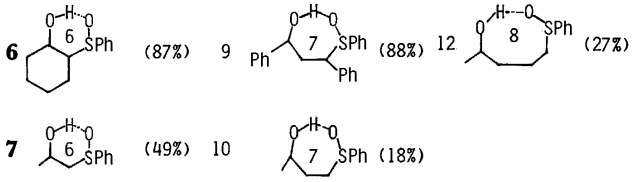
Intramolecular Oxygen Transfer via *Cyclic Alkoxysulfoxonium Ions.* Bromo sulfones (Type B) were obtained unexpectedly, since HBD–Br_2 gave no sulfones. Since both oxidation and work-up were carried out under anhydrous conditions, it is unlikely that the one oxygen atom of the sulfones is derived from the external sources such as water. The formation of bromo sulfones may be best explained by the intramolecular oxygen atom transfer mechanism (Scheme 1).

The detailed mechanism for the formation of the alkoxysulfoxonium bromide (**17**) is not clear. However, a possible scheme is the intramolecular cyclization by the attack of hydroxyl group towards stannyloxysulfonium ion (**16**).[5] This cyclic alkoxysulfoxonium bromide

Table 1. Oxidation of hydroxy sulfides

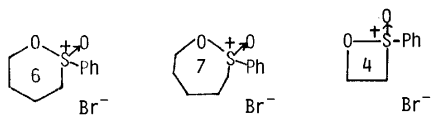
Hydroxy sulfide	Products (%)		
	Hydroxy sulfoxide	Bromo sulfone	Keto sulfoxide
1a 	**6**  (87)		
1b 	**7**  (49)	**8**  (38)	
2a 	**9**  (88)		
2b 	**10** (18)	t[a]	**11**  (24)
3 	**12**  (27)	**14**  (37) (62)	t[a]
4 			
5 			**15**  (97)

a) Formation of a trace amount of the corresponding products was observed.



(**17**)[6] may be a key intermediate, which undergoes cleavage to a bromo sulfone by the attack of bromide ion. This is supported by the fact that the yield of bromo sulfone (**13**) increases (37%→66%), when lithium bromide is added as an additive.

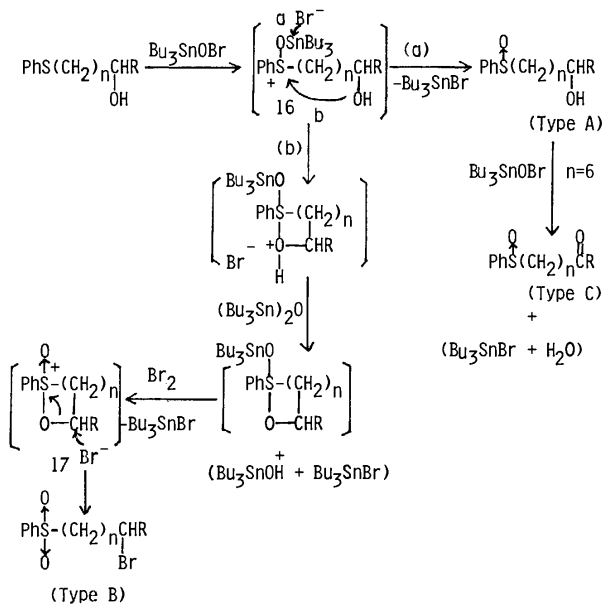
The alkoxysulfoxonium ions again fall into mainly six- and seven-membered rings except one four-membered intermediate.



Keto Sulfoxide Formation. When the hydroxyl and sulfide groups were isolated by six methylene-chains (compound **5**), oxidation proceeded to give keto sulfoxide almost quantitatively. This indicates no appreciable interaction, either hydrogen bonding (eleven-membered ring) or cyclic alkoxysulfoxonium ion formation (nine-membered ring) during the course of reaction, *viz.*, no possible cyclic intermediates more than eight-membered rings opperate, two functional groups behaving independently.

A plausible reaction scheme for the formation of the Type A, B and C products is shown in Scheme 1. Oxidation is assumed to proceed by consumption of twice the molar amount of HBD and bromine except for the formation of Type A product.

In conclusion, mainly more favorable six- and seven-membered cyclic intermediates determine the reaction courses and the products.



Scheme 1.

Experimental

General. Infrared spectra were taken in a film for liquids and KBr pellets for solids using a Hitachi EPI-S2 IR

spectrometer. All NMR spectra were measured with a TMS internal standard using a Varian EM-360 or JEOL JNM-C 100.

Materials. Hydroxy sulfides were prepared by the usual process by means of sodium borohydride reduction of the corresponding keto sulfides in methanol. *trans*-2-Phenylthiocyclohexanol (**1a**) was prepared by the reaction of sodium benzenethiolate with cyclohexene oxide.[7]

1-Phenylthio-2-propanol (1b). This was obtained in 71% yield from 1-phenylthio-2-propanone; bp 100—120 °C/2 mmHg (1 mmHg=133.322 Pa); NMR (CCl_4) δ=1.20 (d,3, J=6 Hz, CH_3), 2.87 (d, 2, J=6 Hz, SCH_2), 3.43 (s, 1, OH), 3.53—4.07 (m, 1, OCH), and 7.00—7.50 (m, 5, C_6H_5).

3-Phenylthio-1,3-diphenyl-1-propanol (2a). This was similarly obtained in 96% yield as an oil from 3-phenylthio-1,3-diphenyl-1-propanone: NMR (CCl_4) δ=2.10 (m, 2, CH_2), 2.93 (s, 1, OH), 4.26 (m, 1, OCH), 4.67 (t, 1, J=6 Hz, SCH), and 6.83—7.37 (m, 15, C_6H_5). Found: C, 78.88; H, 6.23%. Calcd for $C_{22}H_{20}OS$: C, 78.70; H, 6.30%.

4-Phenylthio-2-butanol (2b). This was similarly obtained in 62% yield: bp 105—106 °C/2 mmHg; NMR (CCl_4) δ=1.17 (d, 3, J=6 Hz, CH_3), 1.70 (q, 2, J=6 Hz, CH_2), 2.93—2.97 (m, 3, SCH_2 and OH), 3.87 (m, 1, OCH), and 7.07—7.40 (m, 5, C_6H_5). Found: C, 66.22; H, 8.18; S, 17.45%. Calcd for $C_{10}H_{14}OS$: C, 65.91; H, 7.74; S, 17.56%.

5-Phenylthio-2-pentanol (3). To a solution of pyridinium chlorochromate (14.7 g, 68 mmol) in dichloromethane (90 ml) was added a solution of 4-phenylthiobutanol (6.2 g, 34 mmol) in the same solvent (15 ml) at room temperature. After being stirred for 2 h, dry ether was added to the mixture, the organic layer being decanted three times. The combined etheral solution was washed with saturated aqueous sodium hydrogencarbonate and aqueous sodium chloride. 4-(Phenylthio)butanal was obtained as a colorless oil after the usual work-up in 43% yield: bp 113—115 °C/1 mmHg; IR 1720 cm^{-1} (νC=O). NMR (CCl_4) δ=1.80 (q, 2, J=6 Hz, CH_2), 2.56 (t, 2, J=6 Hz, CH_2CO), 2.93 (t, 2, J=6 Hz, CH_2S), 7.13—7.17 (m, 5, C_6H_5), and 9.53 (t, 1, J=1.2 Hz, CHO), 2,4-dinitrophenylhydrazone; mp 103—105 °C. Found: C, 53.39; H, 4.40; N, 15.73; S, 8.92%. Calcd for $C_{16}H_{16}N_4O_4S$: C, 53.32; H, 4.48; N, 15.55; S, 8.90%.

To a solution of methylmagnesium iodide prepared from methyl iodide (27 mmol) and magnesium (27 mg atom) in dry ether was added a solution of 4-(phenylthio)butanal (1.14 g, 8 mmol) in dry ether (15 ml). After being stirred at room temperature for 3 h, the mixture was treated with water (30 ml) and 0.5 mol/l sulfuric acid for 1 h. After the usual work-up, 5-phenylthio-2-pentanol (**3**) was obtained by distillation in 93% yield as a colorless oil: bp 120—125 °C/2 mmHg; NMR (CCl_4) δ=1.06 (d, 3, J=6 Hz, CH_3), 1.56 (m, 4, CH_2CH_2), 2.83 (t, 2, J=6 Hz, SCH_2), 3.26 (broad s, 1, OH), 3.63 (m, 1, OCH), and 6.96—7.33 (m, 5, C_6H_5). Found: C, 67.30; H, 8.37%. Calcd for $C_{11}H_{16}OS$: C, 67.31; H, 8.23%.

6-Phenylthio-2-hexanol (4). 5-Acetoxyhexyl phenyl sulfide was prepared by the reaction of sodium benzenethiolate and 5-acetoxy-1-bromohexane[8] in 76% yield as an oil. This was treated with 30% aqueous potassium hydroxide (40 ml) and dioxane (40 ml) under reflux for 5 h. The usual work-up gave 6-phenylthio-2-hexanol (**4**) in 95% yield as a colorless oil: bp 135—138 °C/2 mmHg; NMR (CCl_4) δ=1.25 (d, 3, J=7 Hz, CH_3), 1.37—1.86 (m, 6, $(CH_2)_3$), 2.70—3.26 (m, 3, SCH_2 and OH), 3.33—3.37 (m, 1, OCH), and 7.03—7.53 (m, 5, C_6H_5). Found: C, 68.61; H. 8.52%. Calcd for $C_{12}H_{18}OS$: C, 68.51; H, 8.64%.

7-Phenylthio-1-phenyl-1-heptanol (5). 1-Bromo-6-(Phenylthio)hexane (2.28 g, 8 mmol) was treated with magnesium (0.20 g, 8 mg atom) in the presence of a catalytic amount of iodine in dry ether for 70 min under argon atmosphere. Benzaldehyde (0.85 g, 8 mmol) was added dropwise to the mixture. The resulting mixture was refluxed for 1 h. The usual work-up gave 7-phenylthio-1-phenyl-1-heptanol (**5**) in 13% yield: mp 50.5—51.5 °C (pentane); NMR (CCl_4) δ=1.1—2.0 (m, 10), 1.7 (m, 1), 2.9 (t, 2, J=6 Hz), 4.6 (t, 1, J=6 Hz), and 7.2 (m, 10). Found: C, 76.16; H, 7.97%. Calcd for $C_{19}H_{24}OS$: C, 75.97; H, 8.05%.

Oxidation of Hydroxy Sulfides. General Procedure: To a mixture of hydroxy sulfide (6 mmol) and hexabutyldistannoxane (HBD, 13 mmol) in dichloromethane (15 ml) was added dropwise a solution of bromine (13 mmol) in dichloromethane (10 ml). The red color of bromine was immediately discharged and the reaction mixture was stirred at room temperature for 2—3 h. The solvent was removed under reduced pressure and the residue was separated by chromatography on silica gel. Tributyltin bromide was isolated by elution with hexane. Type B and C products were then obtained by elution with chloroform, the type A product being finally eluted with chloroform–ethanol (2 : 1).

2-(Phenylsulfinyl)cyclohexanol (6). After evaporation of dichloromethane the residue was treated with a small amount of pentane with cooling (Dry Ice–acetone bath) to give white solid **6** in 87% yield: mp 154—155 °C (benzene); IR 1008, 990 cm^{-1} (νS–O), 3320 cm^{-1} (νOH), Found: C, 63.80; H, 7.42, S, 14.01%. Calcd for $C_{12}H_{16}O_2S$: C, 64.25, H, 7.19: S, 14.29%. 2-(Phenylsulfinyl)cyclohexanol **6** obtained seems to be trans isomer, since its melting point is close to that reported (mp 156.0—156.6 °C[7]). When the same reaction was carried out in methanol or tetrahydrofuran in place of dichloromethane, hydroxy sulfoxide **6** was obtained in 57 or 60% yield, respectively.

2-Bromopropyl Phenyl Sulfone (8). This was obtained in 38% yield as an oil: IR 1300, 1150 cm^{-1} (νSO_2). NMR ($CDCl_3$), δ=1.88 (d, 3, J=6.9 Hz, CH_3), 3.53—3.70 (m, 2, SO_2CH_2), 4.13—4.67 (m, 1, BrCH), and 7.40—8.10 (m, 5, C_6H_5). This compound is too unstable to be satisfactorily purified for elemental analysis. Found: C, 42.07: H, 4.65; S, 12.45%. Calcd for $C_9H_{11}BrO_2S$: C, 41.07; 4.22; S, 12.18%.

3-Phenylsulfinyl-2-propanol (7).[9] This was obtained as an oil in 49% yield. IR: 3330 cm^{-1} (νOH), 1014, 990 cm^{-1} (νS–O). NMR ($CDCl_3$) δ=1.29, 1.35 (each d, 3, J=6 Hz, CH_3), 2.58—3.25 (m, 2, CH_2), 4.00—4.63 (m, 1, CH), 4.73—5.08 (broad s, 1, OH), and 7.30—7.85 (m, 5, C_6H_5). Found: C, 58.28; H, 6.25%. Calcd for $C_9H_{12}O_2S$: C, 58.69; H, 6.57%.

3-Phenylsulfinyl-1,3-diphenyl-1-propanol (9). This was isolated as a white solid in 88% yield in a similar way as that for compound **6**: mp 148—150 °C (CH_2Cl_2–hexane); IR 3380 (νOH), 1010, 990 cm^{-1} (νS–O). NMR (DMSO-d_6) δ=2.28 (m, 2, CH_2), 3.84 (t, 1, J=3.4 Hz, SOCH), 4.68 (broad s, 1, OH), 5.60 (m, 1, OCH), and 6.76—7.47 (m, 15, C_6H_5). Found: C, 74.62, H, 6.01; S, 10.01%. Calcd for $C_{21}H_{20}O_2S$: C, 74.96; H, 6.00; S, 9.53%.

4-Phenylsulfinyl-2-butanol (10). This was obtained as an oil in 18% yield. IR 3360 cm^{-1} (νOH), 1020 cm^{-1} (νS–O). NMR ($CDCl_3$) δ=1.17 (d, 3, J=6 Hz, CH_3), 1.50—1.98 (m, 2, CH_2), 2.97 (t, 2, J=8 Hz, $SOCH_2$), 3.37—4.10 (m, 2, OH and O–CH), and 7.33—7.73 (m, 5, C_6H_5). Found: C, 60.34; H, 7.23%. Calcd for $C_{10}H_{14}O_2S$: C, 60.59; H, 7.12%.

4-Phenylsulfinyl-2-butanone (11). This was isolated as oil in 24% yield. IR 1720 cm^{-1} (νC=O), 1010 cm^{-1} (νS–O). NMR (CCl_4) δ=2.00 (s, 3, CH_3), 2.40—2.73 (m, 2, CH_2), 2.83—3.17 (m, 2, $SOCH_2$), and 7.00—7.04 (m, 5, C_6H_5), Found: C, 60.86; H, 6.23%. Calcd for $C_{10}H_{12}O_2S$: C, 61.19;

H, 6.17%.

5-Phenylsulfinyl-2-pentanol (12). An oil, 27%. IR 3380 cm^{-1} (νOH), 1010 cm^{-1} (νS–O). NMR ($CDCl_3$) δ=1.15 (d, 3, J=6 Hz, CH_3), 1.32—2.15 (m, 4, CH_2CH_2), 2.62—3.12 (m, 2, $SOCH_2$), 3.45—4.15 (m, 2, OH and OCH), and 7.32—7.82 (m, 5, C_6H_5). The procuct **12** was identified by comparison with the authentic sample prepared by sodium periodate oxidation of hydroxy sulfide **3**.

5-Bromopentyl Phenyl Sulfone (13). This was obtained as an oil in 37% yield. IR 1310, 1150 cm^{-1} (νSO_2). NMR ($CDCl_3$)=δ 1.72 (d, 3, J=4 Hz), 1.96 (m, 4, CH_2CH_2), 3.20 (m, 2, SO_2CH_2), 4.10 (m, 1, BrCH), and 7.60—7.78 (m, 5, C_6H_5). Found: C, 45.51; H, 5.31; S, 11.65%. Calcd for $C_{11}H_{15}BrO_2S$: C, 45.36; H, 5.15; S, 11.00%.

5-Bromohexyl Phenyl Sulfone (14). This was obtained as an oil in 62% yield. IR 1300, 1140 cm^{-1} (νSO_2). NMR ($CDCl_3$)=δ 0.87—2.37 (m, 9, $(CH_2)_3$ and CH_3), 2.92—3.37 (m, 1, BrCH), 3.53 (t, 2, J=7 Hz, SO_2CH_2), and 7.47—8.30 (m, 5, C_6H_5). Found: C, 47.48; H, 5.54%. Calcd for $C_{12}H_{17}BrO_2S$: C, 47.21; H, 5.62%.

1-Phenyl-7-phenylsulfinyl-1-heptanone (15). The oxidation of **5** was carried out at −75 °C. After evaporation of methylene chloride, the residue was treated with ether (50 ml) and aqueous ammonium fluoride (4 g/50 ml) with stirring. The resulting solid was filtered and the filtrate was washed with water and dried over magnesium sulfate. Evaporation of ether followed by cooling with a small amount of hexane gave white solids **15** (97%): mp 62—63 °C (hexane). IR 1675 cm^{-1} (νC=O), 1030 cm^{-1} (νS–O). NMR (CCl_4) δ= 1.1—2.0 (m, 8), 2.6—3.0 (m, 4), 7.2—7.7 (m, 8), and 7.8—8.0 (m, 2). Found: 72.36: H, 7.14; S; 10.40%. Calcd for $C_{19}H_{22}O_2S$: C, 72.57; H, 7.05; S, 10.18%. When the same reaction was carried out at room temperature, keto sulfoxide (**15**) was obtained in 99% yield.

Oxidation in the Presence of Lithium Bromide. To a mixture of hydroxy sulfide **3** (0.35 g, 1.8 mmol), HBD (2.3 ml, 4.5 mmol), and lithium bromide (0.16 g, 1.8 mmol) in chloroform (10 ml) was added dropwise a solution of bromine (3.96 mmol) in chloroform (10 ml) at −70 °C. Stirring was continued at −70 °C for 30 min and then at room temperature for 1 h. The usual work-up gave bromo sulfone **13** in 66% yield.

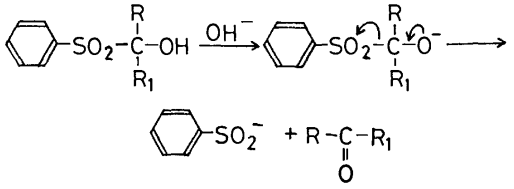
Lithiation of Alkoxyalkyl Phenyl Sulfones. New Approach to Acyl Anion Synthesis

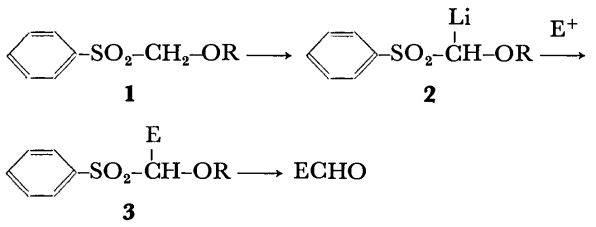
Kazuhiko TANAKA,* Syuichi MATSUI, and Aritsune KAJI
Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606
(Received January 9, 1980)

(1-Ethoxyethoxy)methyl and 1-(1-ethoxyethoxy)ethyl phenyl sulfones undergo metalation with LDA in THF in the presence of HMPA. The resulting lithium salts were easily alkylated with various alkyl halides and hydrolyzed under mild conditions to give the corresponding carbonyl compounds. The new synthetic method for the preparation of aldehydes and ketones employing these carbanions has been developed.

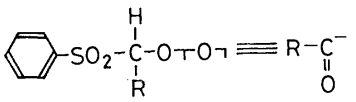
The potential usefulness of sulfur-stabilized carbanions as acyl anion equivalents has been widely recognized.[1] The commonly used "umpolung" reagents include 1,3-dithianes,[2] alkyl alkylthiomethyl sulfoxides,[3,4] vinyl sulfides,[5] dithioesters,[6] and ketene dithioacetals.[7] Few methods exist, however, for the analogous acyl anion equivalents involving an α-sulfonyl carbanion.[8] Recently, Kondo *et al.* and Julia *et al.* reported a route to α,β-unsaturated carbonyl compounds employing the lithium salts of sulfonyl ketone acetals as β-acylvinyl anion equivalents.[9] Most recently, Gokel *et al.* found that the lithio derivative of 4,4-dimethyl-1,3-oxathiolane 3,3-dioxide reacted with alkyl halides to give aldehydes by pyrolysis.[10] An α-hydroxy sulfone, as well as α,β-epoxy sulfones and cyanohydrins, gives readily a carbonyl compounds under basic conditions.[11]



Therefore, the alkylation of the carbanion of α-alkoxy sulfone (**1**) might provide a new method for the syntheses of aldehydes and ketones from alkyl halides.

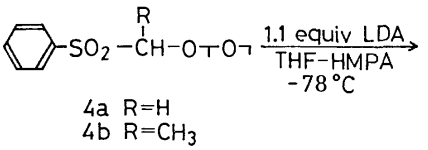


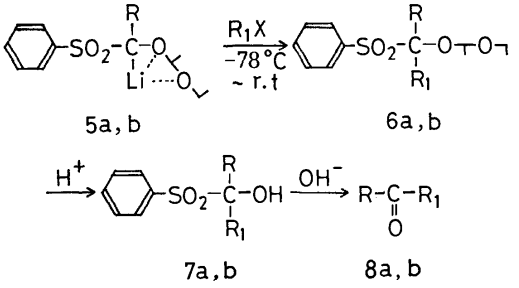
Unfortunately, Magnus and Schank have failed in the alkylation of the carbanion **2** except deuteration and methylation,[8,12] while we have found that the hitherto unknown lithium salts of (1-ethoxyethoxy)methyl phenyl sulfone (**4a**) and 1-(1-ethoxyethoxy)ethyl phenyl sulfone (**4b**) can be successfully generated and are reactive towards alkyl halides. Presumably, the carbanions of **4a** and **4b**, the ethoxyethoxyl group of which was introduced to protect the hydroxyl group, would be advantageously stabilized by the internal lithium chelation.[13] In this report we shall describe the results of our recent work on the use of lithium derivatives (**5a** and **5b**) as acyl anion equivalents.



Results and Discussion

Alkylation of Carbanion **5**. Treatment of α-alkoxyalkyl phenyl sulfone (**4**) with lithium diisopropylamide (LDA) in THF at −78 °C in the presence of HMPA produced the yellow solution of carbanion (**5**).





The anion of sulfone (**4**) was efficiently trapped with alkyl halides to provide the monoalkylated product (**6**), which was hydrolyzed to afford aldehydes or ketones in moderate to good isolated yields (Table 1).

Since the elimination of benzenesulfinic acid from the product (**7**) occurs under mild basic conditions and does

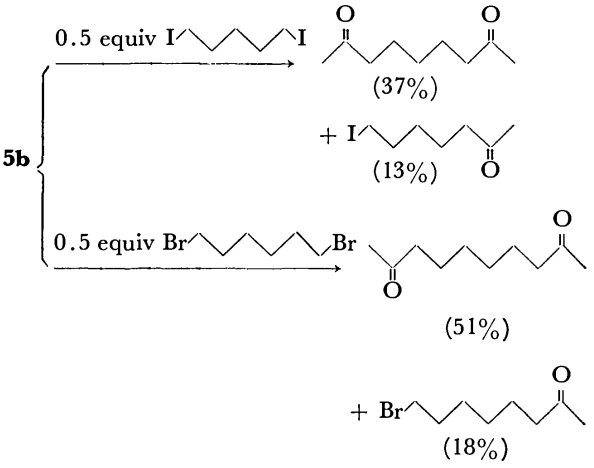


TABLE 1. PREPARATION OF ALDEHYDES AND KETONES FROM CARBANIONS (**5**) AND ALKYL HALIDES (R_1X)

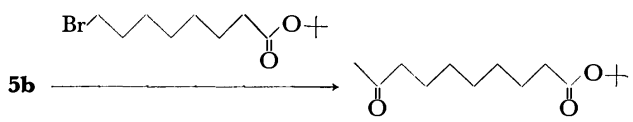
5b	1-Bromononane	$CH_3C(=O)(CH_2)_8CH_3$	66[b,d]	88.0—89.0/10	1720 (neat)	0.70—0.95 (m, 3H), 0.95—1.60 (m, 14H), 2.04 (s, 3H), 2.35 (t, J=8.0 Hz, 2H)	77.69 (77.65)	13.43 (12.94)
5b	1-Bromodecane	$CH_3C(=O)(CH_2)_9CH_3$	51[b]		1720 (neat)	0.70—1.04 (m, 3H), 1.04—2.00 (m, 16H), 2.04 (s, 3H), 2.24 (t, J=7.5 Hz, 2H)	77.58 (78.26)	13.15 (13.04)

a) 133.322 Pa. b) Isolated yields. c) $CH_3(CH_2)_7C(=O)(CH_2)_7CH_3$ was isolated in 26% yield. d) GLPC yields. e) $CH_3(CH_2)_9C(=O)(CH_2)_9CH_3$ was isolated in 14% yield. f) Without HMPA.

not require the use of heavy metal, this sequence constitutes a useful preparation of aldehydes and ketones from alkyl halides. However, the overall yields of these syntheses are insufficient for a synthetic method, and secondary and cyclic halides could not be used successfully in these synthesis. It seems to be attributed to the steric hindrance of sulfonyl group.

The ketone synthesis employing **5b** is also applicable to certain α,ω-diketones. For example, 1,5-diiodopentane and 1,6-dibromohexane were converted to 2,8-nonanedione and 2,9-decanedione, respectively.

t-Butyl 1-bromooctanoate prepared from *t*-butyl acetate and 1,6-dibromohexane was converted to *t*-butyl 9-oxodecanoate, *i.e.*, a key intermediate of 9-oxodec-(*E*)-2-enoate.[14]



(27%)

Furthermore, the monoanion **9a** generated by potassium diisopropylamide–lithium *t*-butoxide (KDA)[15] reacted with ketone to afford hydroxy aldehyde,

Table 2. Preparation of symmetrical ketones from dianions (**10**) and alkyl halides (R_1X)

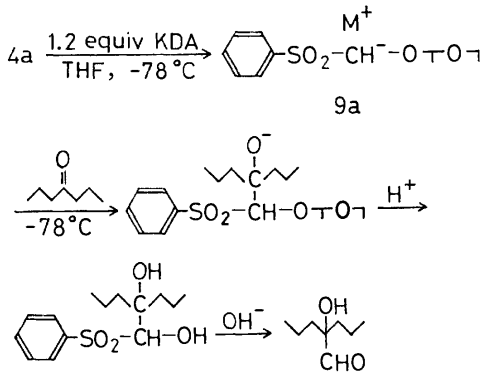
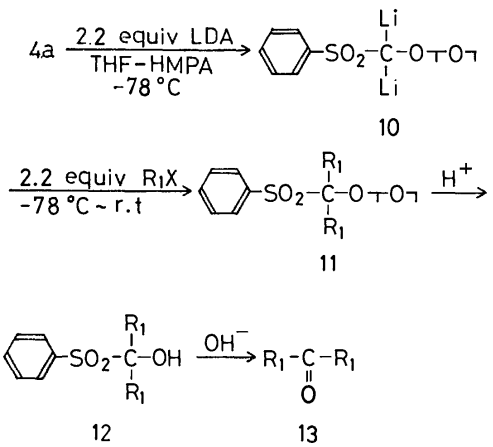
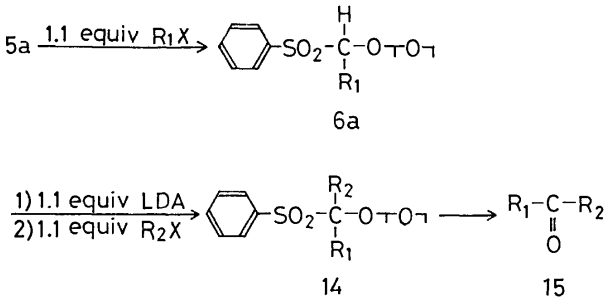
whereas the monoanion **5a** generated by LDA could not be used successfully in the reaction. For example, treatment of **9a** with 4-heptanone in THF produced 2-hydroxy-2-propylpentanal in 63% yield.



Formation and Alkylation of Dianion ***10***. The dianion of (1-ethoxyethoxy)methyl phenyl sulfone (**4a**) was successfully generated on treatment with 2.2 equiv. of LDA in THF in the presence of HMPA. The dianion thus formed reacted with alkyl halides to give symmetrical ketones **13** in good yields (Table 2).



Since it was expected that **4a** is alkylated stepwise with the different kinds of alkyl halides, the unsymmetrical ketone synthesis from **4a** was carried out according to the following route.



The use of 1-bromohexane as R_1X and bromoethane as R_2X afforded a mixture of ethyl hexyl ketone (14%), diethyl ketone (14%) and dihexyl ketone (37%). The low yield of the desired ketone **15** may be attributable to a predominant deprotonation of **6a** with **5a** followed by alkylation with R_1X.

Experimental

Melting points were determined with a Yanagimoto melting point apparatus and are uncorrected. Boiling points were determined during distillation and are uncorrected, Infrared data were obtained using a Hitachi Model 215 spectrophotometer. The proton magnetic resonance spectra were determined on a JEOL PS-100 spectrometer. Chemical shifts are given in δ units, part per million relative to tetramethylsilane as an internal standard.

*(1-Ethoxyethoxy)methyl Phenyl Sulfone (**4a**).* Hydroxymethyl phenyl sulfone was prepared from formaldehyde and benzenesulfinic acid by the reported procedure.[16] To a solution of hydroxymethyl phenyl sulfone (68.0 g, 0.40 mol) in the presence of *p*-toluenesulfonic acid (0.40 g) in 200 ml of dichloromethane at 0 °C was added dropwise a solution of ethyl vinyl ether (0.53 mol) in 100 ml of dichloromethane. The reaction mixture was stirred at 0 °C for 3 h and extracted

with dichloromethane. The combined organic layers were washed successively with water, saturated aqueous solution of sodium hydrogencarbonate, and water, and dried (Na_2SO_4). Removal of the solvent under reduced pressure gave a yellow oil (90.0 g, 92%). Purification by alumina (Woelm B-Super 1) column chromatography (benzene) gave **4a** (50.8 g, 52%) as a colorless oil; IR (neat): 1070, 1140, and 1300 cm^{-1}. ^1H-NMR (CCl_4): δ 1.08 (t, J=6.8 Hz, 3H), 1.20 (*d*, J=6.8 Hz, 3H), 3.20—3.70 (m, 2H), 4.50 (s, 2H), 4.90 (q, J=6.8 Hz, 1H), 7.40—8.00 (aromatic, 5H). Found: C, 54.32; H, 6.69%. Calcd for $C_{11}H_{16}O_4S$: C, 54.08; H, 6.60%.

1-(1-Ethoxyethoxy)ethyl Phenyl Sulfone (4b). 1-Hydroxyethyl phenyl sulfone was prepared by stirring an ethereal solution of benzenesulfinic acid with excess acetaldehyde at 0 °C for 9 h. A solution of ethyl vinyl ether (18.5 g, 0.26 mol) in dichrolomethane (20 ml) was added to a solution 1-hydroxyethyl phenyl sulfone (37.2 g, 0.20 mol) in the same solvent (100 ml) in the presence of catalytic amount of *p*-toluenesulfonic acid (0.20 g). The reaction mixture was stirred at 0 °C for 3 h and extracted with dichloromethane. The subsequent work-up was carried out by the same procedure as described in the preparation of **4a** to give a yellow oil. Purification by alumina (Woelm B-Super 1) column chromatography (benzene) gave **4b** (30.0 g, 60%) as a pale yellow oil; IR (neat): 1300, 1140, and 1080 cm^{-1}. ^1H-NMR (CCl_4): δ 1.12 (t, J=6.8 Hz, 3H), 1.32 (d, J=6.7 Hz, 6H), 3.30—4.00 (m, 2H), 4.38 (q, J=6.7 Hz, 1H), 4.90 (q, J=6.7 Hz, 1H), 7.30—7.90 (aromatic, 5H). Found: C, 55.53; H, 6.44%. Calcd for $C_{12}H_{18}O_4S$: C, 55.82; H, 6.98%

General Procedure. Reaction of the Carbanion 5a with 1-Iodohexane: To a solution of LDA (22 mmol) in a mixture of 80 ml of THF and 4 ml of HMPA at −78 °C was added dropwise under nitrogen a solution of **4a** (20 mmol) in 10 ml of dry THF. After stirring for 1 h, a solution of 1-iodohexane (30 mmol) in 10 ml of dry THF was added dropwise. The reaction mixture was stirred at −78 °C for 2 h and at room temperature for 16 h. After quenching with methanol, the reaction mixture was treated with 2 mol dm^{-3} hydrochloric acid (150 ml) for 1 h and extracted with ether. The combined ethereal layers were treated with an aqueous sodium hydrogencarbonate solution (40 mmol) for 4 h and dried (Na_2SO_4). Removal of the solvent and distillation under reduced pressure gave 1.62 g (71%) of heptanal.

2,9-Decanedione: Mp 57.0—57.5 °C. IR (KBr): 1710 cm^{-1}. ^1H-NMR (CCl_4): δ 1.10—1.70 (m, 8H), 2.06 (s, 6H), 2.36 (t, J=7.8 Hz, 4H). Found: C, 70.31; H, 10.77%. Calcd for $C_{10}H_{18}O_2$: C, 70.59; H, 10.59%.

2,8-Nonanedione: Mp 47.5—48.0 °C. IR (KBr): 1720 cm^{-1}. ^1H-NMR (CCl_4): δ 1.00—1.70 (m, 6H), 2.08 (s, 6H), 2.38 (t, J=7.0 Hz, 4H).

t-*Butyl 9-Oxodecanoate*: Bp 97.0—98.0 °C/146.7 Pa. IR (neat): 1720 cm^{-1}. ^1H-NMR (CCl_4): δ 1.10—1.70 (m, 19H), 2.00 (s, 3H), 2.16 (t, J=7.0 Hz, 2H), 3.34 (t, J=7.0 Hz, 2H). Found: C, 69.17; H, 11.08%. Calcd for $C_{14}H_{26}O_3$: C, 69.42; H, 10.74%.

2-Hydroxy-2-propylpentanal: To a solution of potassium *t*-butoxide (2.52 g, 22 mmol) and diisopropylamine (3.1 ml, 22 mmol) in dry THF (60 ml) at −78 °C under nitrogen was added butyllithium (18 mmol). The mixture was stirred for 10 min at −78 °C, and a solution of **4a** (3.66 g, 15 mmol) in dry THF (10 ml) was added. After stirring at −78 °C for 10 min, a solution of 4-heptanone (2.57 g, 22 mmol) in dry THF (5 ml) was added, and the mixture was maintained at −78 °C for 1 h. The reaction was quenched with methanol (50 ml). The subsequent aqueous work-up was carried out by the same procedure as described previously to give a yellow oil. Chromatography on silica-gel column (hexane–benzene, 1 : 1, v/v) gave 1.36 g (63%) of 2-hydroxy-2-propylpentanal as a colorless oil; IR (neat): 3450 and 1720 cm^{-1}. ^1H-NMR (CCl_4): δ 0.60—1.90 (m, 14H), 3.45 (s, 1H), 9.40 (s, 1H). Found: C, 67.02; H, 10.90%. Calcd for $C_8H_{16}O_2$: C, 66.67; H, 11.11%.

Dihexyl Ketone: To a solution of LDA (44 mmol) in 80 ml of dry THF in the presence of HMPA (8 ml) at −78 °C was added dropwise under nitrogen a solution of **4a** (20 mmol) in 10 ml of dry THF. After stirring for 1 h, a solution of 1-bromohexane (44 mmol) in 10 ml of dry THF was added dropwise and the reaction mixture was stirred at −78 °C for 2 h and at room temperature for 16 h. The subsequent work-up was carried out by the same procedure to give yellow crystals. Recrystallization from ethanol gave 2.18 g (55%) of pure dihexyl ketone as white needles.

S. Matsui wishes to thank the Ministry of Education of Japan for a grant supporting his stay at Kyoto University.

The Conformations of Several Aliphatic Alcohols. The General Occurrence of the Attractive Alkyl/Phenyl Interaction

Jun UZAWA,† Shoji ZUSHI, Yoshio KODAMA, Yoshimasa FUKUDA, Ken NISHIHATA, Koshiro UMEMURA, Motohiro NISHIO,* and Minoru HIROTA††

(Received February 16, 1980)

The conformation has been studied, by means of NMR spectroscopy, for diastereoisomeric pairs of a series of alcohols having the following general structure:

$$CH_3CH(C_6H_5)CH(OH)\text{-}R$$

where R is a methyl, ethyl, isopropyl, or a *t*-butyl group. It has been demonstrated that the alkyl group (R) is oriented close to the phenyl group in the most preferred conformations; this conclusion is essentially in accord with the results obtained for the structurally related sulfoxides. The general occurrence of an attractive interaction (the CH/π interaction) has, therefore, been suggested between an alkyl and a phenyl group.

In recent years it has become clear that an alkyl group often prefers to be close to a phenyl group in certain molecular environments.[1-3] Thus, in compounds having the general structure of $C_6H_5CH(CH_3)$-X-Bu^t, the *t*-butyl group has been found to orient itself *gauche* to the phenyl group, and *anti* to the methyl group, present in the molecule (Fig. 1). The examples include a sulfide[4] (**1**, X=S), a diastereoisomeric pair of sulfoxides[5,6] (X=SO) and alcohols[2] (X=CHOH), a sulfone[4,7] ($X=SO_2$), a ketone[8,9] (X=CO), and a hydrocarbon[9] ($X=CH_2$). Evidence for the hydrocarbon rests on an empirical force-field calculation. The conclusions regarding the other compounds have, in every case, experimental bases (X-ray,[5,7] NMR,[2,5a,8,10] ORD/CD,[5a] dipole moment,[6] IR,[2,9] or product analysis in the stereoselective reactions[1,3,4,11]). We further studied the conformation of a series of diastereoisomeric sulfoxides (**2**), where the *t*-butyl group in the above structure (**1**, X=SO) is replaced by a methyl, ethyl, or isopropyl group.[12] In these cases also, the alkyl group has been shown to be *gauche* to the phenyl group and *anti* to the methyl group in their most preferred conformation (Fig. 2, rotamer **a**). In addition to this, a considerable fraction of the second stable rotamer (rotamer **b**) has been suggested to contribute, whereby the alkyl group is flanked by the phenyl and methyl group; the rotamer **c** seems to be least important.

To account for these findings, an attractive force has been suggested to operate between an alkyl and a phenyl group (CH/π interaction).[1-3] The nature of the weak secondary force remains open, however, we believe this to originate from a hydrogen-bond like interaction of a CH group with the π-system; this might also be regarded as a through-space hyperconjugation. In order to explore the generality of the phenomenon and to obtain insight into the nature of the interactions, the conformation has been studied for diastereoisomeric

a) The chemical shifts induced by the addition of $Yb(fod)_3$ to $CDCl_3$ solutions. The data are normalized to the value for C(8) carbon ($LIS_{rel} = 1.00$). See Tables 1 and 2 for the numbering of the nuclei.

3-phenyl-2-butanols (**3**), 2-phenyl-3-pentanols (**4**), and 2-methyl-4-phenyl-3-pentanols (**5**). Table 3 lists the lanthanoid-induced shifts (LIS) determined for the proton and carbon resonances. The data for the diastereoisomers of 2,2-dimethyl-4-phenyl-3-pentanol (**6**)[2] are also included for the purpose of comparison. In Figs. 4—6 are reproduced parts of the proton NMR spectra of these alcohols (**3**—**5**).

An inspection of the NMR spectra reveals several interesting features. First, the peaks attributed to the proton α to the hydroxyl group (labeled H_x) are broader in the *threo*[13] alcohols (Figs. 5b and 6b) than in the *erythro* series, and in these cases we did not find any signal appropriate to the hydroxyl proton. Quite a similar result has also been reported for the *t*-butyl homologues (**6**; see Fig. 8 in Ref. 2). The spectrum for a methyl homologue (**3**-*th*; Fig. 4b) is the only exception; here we found a quintet for H_x and a sharp singlet for the hydroxyl proton (sharper than that in **3**-*er*). Second, the peaks assignable to the benzylic proton (H_a) appear, in all cases, as a quintet with an intensity ratio of 1 : 4 : 6 : 4 : 1. This implies that the spin-spin coupling constants between H_x and H_a ($^3J_{H_aH_x}$) are similar to each other among the alcohols examined and that they are not far from the value of 6.5 Hz.[14] This is quite in contrast to the observation for the *t*-butyl homologues (**6**-*er* and **6**-*th*), where $^3J_{HH}$ has been found to be *ca.* 4 Hz in both

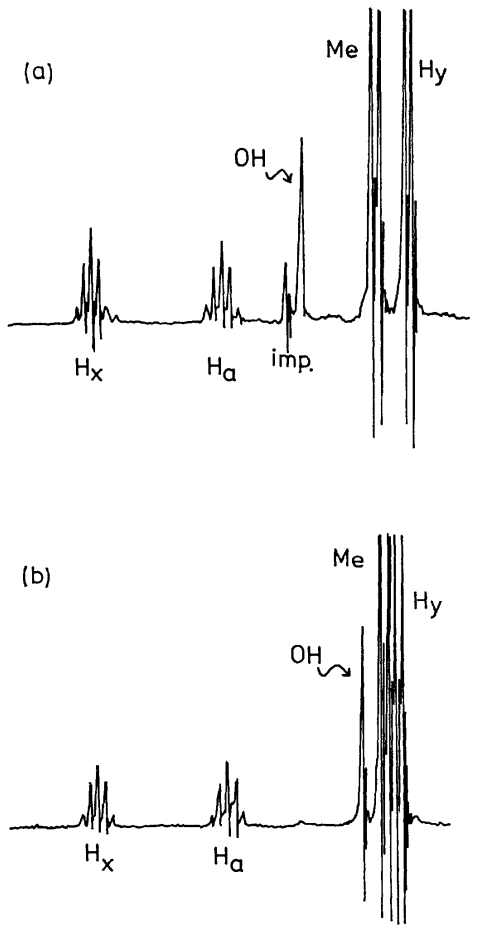

Fig. 4. Proton NMR spectra of (a) **3**-*er* and (b) **3**-*th* obtained for CCl_4 solutions.

cases.[2]

We then carried out the computer-simulation of the LIS[15] for these alcohols; the procedure has been outlined in earlier papers.[2,10,12] The structural parameters were assumed to have the usual values. After several trials and a literature survey, the lanthanoid (Ln)–O–C angle was fixed at 130°.[16,17] The index, A, represents the degree of the distribution of the metal in a mixture of the lanthanoid–substrate complexes (at a given geometry of the substrate) in this equation: $w(\theta)=A/\sqrt{\pi}\ \exp[-A^2\ (\theta-\theta_0)^2]$. On steric grounds, θ_0 was set so that the LSR was always farthest from the phenyl group. A higher value of A, therefore, corresponds to a more localized lanthanoid distribution (centered at θ_0), while the free rotation of Ln in a complex is represented by $A=0$. The Ln–O distance (R) and the torsional angle around the C(7)–C(8) bond were then allowed to vary incrementally at a constant A, in order to search for a reasonable fit of the calculated LIS set [assuming the $(3\cos^2\chi_i-1)/r_i^3$ proportionality] with the observed ones. Figure 7 is a brief illustration of the above procedure; see Ref. 12 for the details.

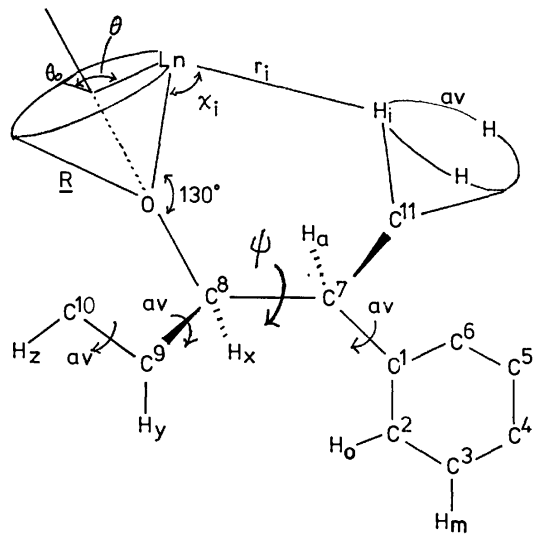

Fig. 7. The procedure for calculating the LIS; av. means the averaging about its rotation (30° increment).

The number of probes which can be used in this program (PSCONT) is limited to 9 nuclei. Therefore, we selected the LIS data which are most appropriate for the present purpose. The data for C(8), which is adjacent to the coordination site, were omitted in view of possible contamination from the contact shift.[18] The data for the β carbons (C7 and C9) should also be used with caution for a similar reason. In order to obtain a reliable result, it is better to use the LIS for the nuclei, the geometrical dispositions of which to the complexation site (OH group) vary with the rotation around the C(7)–C(8) bond. These include the aromatic protons and carbons, H_a, Me, and C(11). Thus, the data which we used for the computation are those for 5—6 protons (H_o and/or H_m; H_a, Me, H_x; H_y and/or H_z) and 3—4 carbons (Cl and/or C2, C3, C4; C9 or C10; and C11). The results have been shown to be rather insensitive to the choice of the probes if an appropriate precaution was taken. The deletion of the carbon LIS, for example, did not significantly affect the qualitative nature of the computed result. The inclusion of the data for C(7), C(8), and/or C(9) did not affect the results appreciably, either, suggesting that the contact shift is unimportant with an ytterbium complex.[18] The Hamilton reliability factor, $AF=[\sum_i(\mathrm{LIS}_i^{\mathrm{obsd}}-\mathrm{LIS}_i^{\mathrm{calcd}})^2/\sum_i(\mathrm{LIS}_i^{\mathrm{obsd}})^2]^{1/2}$, has been used to assess the agreement between the calculated and the observed LIS sets.[19] Figures 8 and 9 plot the AF against the R–C(8)–C(7)–C_6H_5 dihedral angle (ϕ) for these alcohols.[20] The data in Table 4 were extracted from an AF map (R *vs.* ϕ) for a representative case of Compound **5**-*er*.

It should be noted first that, for alcohols having the *erythro* configuration, the essential features of the curve are not significantly affected by a change in the value of A. The minimum AF has invariably been found at ϕ around 60°, accompanied with shallow minima at ϕ *ca.* 160° and 320°. The AF/ϕ profile for the *t*-butyl homologue (**6**-*er*) shows a distinct difference from those of the lower alkyl homologues. Thus, the R/Ph torsional angle at the best agreement is slightly shifted to a larger value ($\phi\approx80°$), while another, rather profound minimum appears at ϕ *ca.* 135°.

For the *threo* alcohols, **4**-*th*, **5**-*th*, and **6**-*th*, on the other hand, the shape of the profile has been shown to be rather sensitive to the value of A. There is a general tendency for a more reasonable agreement to be found with a higher value of the distribution index; this trend is reasonable on steric grounds.[2,10] In view of this,

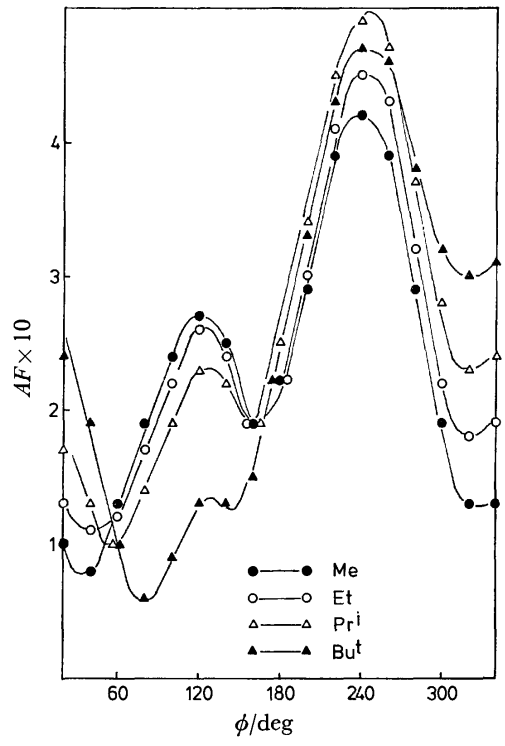

Fig. 8. Plots of AF *vs.* the R/Ph dihedral angle (ϕ) for the *erythro* alcohols, **3**-*er*, **4**-*er*, **5**-*er*, and **6**-*er*. The lanthanoid distribution index (A) and the Ln–O distance (R) are kept constant at 0.8 and 0.30 nm, respectively.

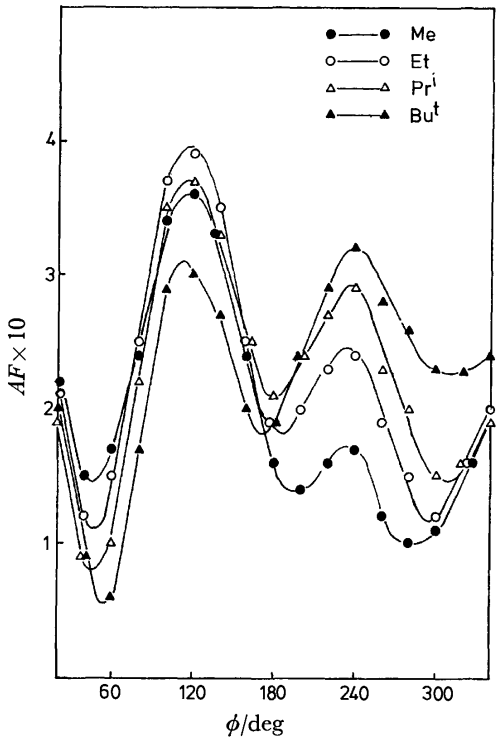

Fig. 9. Plots of *AF vs.* the R/Ph dihedral angle (ϕ) for the *threo* alcohols, **3**-*th*, **4**-*th*, **5**-*th*, and **6**-*th*. The LSR distribution index (A) and the Ln–O distance (R) are kept constant at 0.8 and 0.30 nm, respectively.

Table 4. A part of the *AF* (in %) maps for **5**-*er* (A=0.8; the monitor nuclei were H_a, Me, H_o, H_m, H_z, H_x, C4, C10, and C11)

	ϕ/deg				
R(nm)	20	40	60	80	100
0.26	45	43	28	21	25
0.28	28	25	18	16	21
0.30	17	13	10	14	19
0.32	11	6	7	12	18
0.34	11	7	8	12	18
0.36	14	12	11	13	19
0.38	17	16	13	14	19

we took the results obtained with a higher value of A as relevant; this is consonant with the experience with the sulfoxide analogues.[12] It is interesting that, in these cases also, the curves are always accompanied by three minima of unequal importance. The best fit has been recorded at ϕ *ca.* 50° for **5**-*th* and **6**-*th*, while the profile of **4**-*th* is accompanied with two minima of *ca.* an equal *AF* at $\phi \approx 45°$ and 300°. The profile for the methyl homologue (**3**-*th*) represents an exception. The curve is, in essence, insensitive to the change in A, and the best fit has been found at *ca.* 290°.

Discussion

Consideration of the LIS Results. It should be noted at first that the simulated conformations of the molecules represent the weighted-average geometries of the lanthanoid–substrate complex. A possibility remains that the complexation perturbs the rotameric equilibrium of the free substrate. However, for the presently studied alcohols, the vicinal coupling constant, $^3J_{H_aH_x}$, remained practically unchanged on the addition of the lanthanoid species. This clearly demonstrates that these molecules are conformationally unperturbed by the coordination.

The computation was carried out on the basis of the assumption that there is an unique contribution from a single conformer. Of course, this is not a correct description of the fact in general, but it represents an approximation. It should be noted that the *AF* in a profile corresponds to the reliability for the average geometry at a given ϕ and by no means represents the potential energy (or population) of the respective rotamer. A good fit may result, even with this simplest model, if a single, highly preferred rotamer is present in solution. A significant change for the *AF* would be accompanied, in such a case, with a slight modification in the substrate geometry. However, a geometry corresponding to the minimum *AF* does not necessarily reflect the most stable one if there are several conformers separated by a low free-energy barrier(s). In such a case, an *AF* minimum may represent the weighted-average geometry of the possible rotamers. In view of this, it is noteworthy that the *AF*/ϕ profiles (Figs. 8 and 9) have, in every case, three distinct minima, at ϕ around 60°, 180°, and 300° (*i.e.*, at the staggered geometries of the groups). It is likely that the location of ϕ and the goodness of fit at the respective minimum reflect, though in an indirect manner, the probable geometries of the substrates and the relative importance of the rotamers.

It is suggested that, for all of the alcohols with the *erythro* configuration, the rotamer with $\phi \approx 60°$ (rotamer **a** in Fig. 10) is most populated. In this rotamer, the alkyl group positions itself *gauche* to the phenyl and *anti* to the methyl group. A somewhat twisted conformation ($\phi \approx 80°$) is more plausible for the *t*-butyl homologue. The second stable one is suggested to be the rotamer **c** for **5**-*er* and **6**-*er*, while this is the rotamer **b** in the cases of the lower alkyl homologues (**3**-*er* and **4**-*er*). Note that, in the rotamer **b** the alkyl group is flanked by the methyl and phenyl groups.

In the case of the *threo* alcohols, **5**-*th* and **6**-*th*, the most stable conformation has been suggested to have an R/Ph dihedral angle of *ca.* 60°; the second most stable one seems to be the rotamer **b** for **5**-*th*, but the rotamer **c** for **6**-*th*. The rotamers **a** and **b** can be said to be equally stable for **4**-*th*. The conclusion, in essence, is the same as for the *erythro* alcohols. Thus, the alkyl group, in the preferred conformations, tends to be oriented close to the phenyl group in every case.

The methyl homologue with the *threo* configuration (**3**-*th*) represents an exceptional case. The *AF*/ϕ profile of this compound suggests that the rotamer **b** is most stable. The rotamers **a** and **c** seem to be relatively unimportant and to have an about equal stability. This trend is different from that of the other alcohols having the same (*threo*) configuration.[21] Consonant with this fact is the observation that the hydroxyl proton in **3**-*th* gives rise to a sharp singlet in the NMR

spectrum (*vide supra*). For the *threo* alcohols other than **3**-*th*, the OH peak is absent and the peaks assignable to H_x are broader than those for the *erythro* isomers. The disappearance of the OH proton signal as well as the broadening of the H_x peaks can be ascribed to the presence of the OH/π interaction for the *threo* alcohols.[2,22] Thus, for the *threo* isomers (**4**-*th*, **5**-*th*, and **6**-*th*) where the rotamer **a** (OH/Ph *gauche*) is the most important contributor, the exchange rate of the hydroxyl proton is expected to be slowed down. This likely causes the line broadening (and then disappearance) of the OH signal and the observance of the OH/H_x coupling. For the *erythro* alcohols, on the other hand, the OH group is mostly free from the OH/π complexation (OH/Ph *anti* in the rotamer **a**), thus giving rise to an observable peak. The above exceptional observation for the proton NMR of **3**-*th*, therefore, is in line with the conclusion that the most stable conformer has its OH group *anti* to the phenyl group (rotamer **b**). A question remains, however, as to the reconciliation of the present results with the IR finding[2,22] that the (seemingly) π-bonded OH peak at *ca.* 3595 cm^{-1} is very intense for **3**-*th* relative to those for the other alcohols. It is interesting, at all events, that the findings suggest that the alkyl (methyl) group lies close to the phenyl group in this case also.[23] Figure 10 summarizes the order of stability for the rotamers thus speculated. Note that the relative importance of the rotamers **a** : **b** : **c** varies systematically with a change in the alkyl substituent, R.

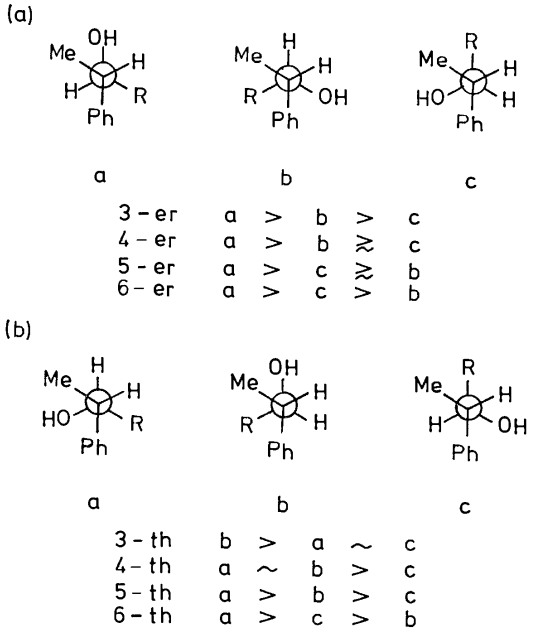

Fig. 10. Possible conformations and the proposed order of the rotamer stability for (a) *erythro* alcohols and (b) *threo* alcohols.

Consideration of the C-13 γ-Effect.[24] The methyl carbon (labeled C11) in **6**-*er* has been shown to be considerably more shielded relative to that in **6**-*th* [$\Delta = \delta(erythro) - \delta(threo) = 16.5 - 22.4 = -5.9$ ppm]. The above phenomenon has been interpreted in terms of the γ-*gauche* effect.[2] In the *erythro* alcohol, the OH group has been shown to be closer to the methyl group (OH/Me dihedral angle *ca.* 40° in the rotamer **a**) than in the *threo* isomer (*ca.* 60°) in their most preferred conformation (see Figs. 8 and 9); thus, the γ-*gauche* effect should be greater for the *erythro* alcohol (**6**-*er*). The result can also be understood in terms of the involvement of a second stable rotamer.[12] For **6**-*th*, the γ-effect (and therefore the shielding) would well be expected to decrease if an appreciable fraction of the rotamer **c** (OH/Me *anti*) is contributing, but this is not so for **6**-*er* (OH/Me *gauche* in the rotamer **c**).

An inverse trend would be expected to be observed for the lower alkyl homologues, for which the relative importance of the rotamer **b** has been suggested. In the rotamer **b**, the OH group is *anti* to Me for the *erythro* alcohols, but is *gauche* to Me for the *threo* isomers. Thus, an involvement of the rotamer **b** would result in the deshielding of the methyl carbon for the *erythro* alcohols, whereas the effect would be not significant for the *threo* alcohols. Therefore, a reversal in the sign of Δ may be observed; this is what we have found for the lower alkyl sulfoxides.[12] This, however, is not the case for the present cases of the ethyl and isopropyl-substituted alcohols. The chemical-shift difference between the isomers (Δ) has, in fact, been found to decrease for the ethyl and isopropyl homologues; however, a reversal in the sign of the shift difference has been recorded only in the case of the methyl homologues (see Table 2). This probably reflects an involvement of the rotamer **c**, but we must reserve further comment until more exact knowledge about the rotameric equilibria becomes available.

Consideration of the Vicinal Spin-Spin Coupling Constants. It has been shown that the spin coupling constant, $^3J_{H_aH_x}$, is about 6.5 Hz in all of the alcohols except the *t*-butyl homologues. The foregoing conclusion regarding the rotameric equilibria should be compatible with these data. A simple consideration of the Karplus relationship would require the vicinal coupling constant to be, *e.g.*, *ca.* 11 and 2 Hz respectively[25] for the **a** rotamers of the *erythro* alcohols (H/H *anti*) and of the *threo* ones (H/H *gauche*). A high preference of these conformers, therefore, cannot be an exact description of the fact. The rotamer **a** is, undoubtedly, the most populated one, but the contributions from the other rotamers should also be taken into account. In view of the limitation of the present methodology, only the perfectly staggered rotamers are considered in Fig. 10. As may be perceived by an inspection of the profiles, however, somewhat twisted versions of these conformations must be the real contributors. The above considerations are in line with the results obtained from the LIS-simulation and the C-13 γ-effect.

Possibility of the Attractive Alkyl/π-system Interaction. The importance of the attractive alkyl/phenyl interaction (CH/π interaction) and the consequences thereof have been argued in previous papers.[1-3,26] The suggestion has been made on the basis of some experimental findings and of a MO calculation. We believe that the findings reported here provide strong support for the above suggestion. Thus, in the conformations

which are found to be preferred, the alkyl group always orients itself close to the phenyl group, irrespective of the nature of the alkyl group and irrespective of the configuration. We feel further that the OH/π interaction is comparatively unimportant in controlling the conformation of these molecules. The van der Waals (repulsive as well as attractive[27]) and the CH/π interaction seem to be more important in the consideration of these problems.[28] The suggestion that the CH/π interaction may be more important than the OH/π interaction is in line with the HSAB (hard and soft acids and bases) principle[29] that a soft acid prefers to interact with a soft base. Thus, a phenyl group (more generally, a π-system) is a soft base, and the CH hydrogen is softer than OH as an acid. The stabilization energy has been estimated to be very small (*ca.* 3.5 kJ mol^{-1} or less)[1-3] for a single CH/π interaction. In spite of this, we suggest the possibility that the CH/π interaction plays an important role in determining molecular shapes and in controlling the subtle behavior of dynamically interacting systems. Generally, a CH group is present in a structure with some kinds of symmetry (methyl, isopropyl, long-chain alkyl groups, *etc.*). The total stabilization energy would thus become important by an accumulation of multiple CH/π bonds. Further, for obvious reasons, an interaction of this type (CH_3/π as well as CH_3/*n*; *n*=lone pair electrons) is entropically advantageous as compared to, *e.g.*, the OH/π interaction. In order to find support for the above suggestion and to ascertain the possible implication, efforts are currently being made in these laboratories.

Experimental

Materials. The alcohols studied in the present work were prepared as has been described in the literature.[14,22] The configurations of these alcohols have been elucidated by Cram,[30] Felkin,[22,31] Kingsbury,[14] and their groups.

NMR Measurements. The proton NMR spectra were recorded on a JEOL MH-100 spectrometer for *ca.* 0.2 M solutions in carbon tetrachloride. The LIS data (^1H and ^{13}C) were determined on a JEOL FX-100 instrument for *ca.* 0.2 M solutions in deuteriochloroform, using $Yb(fod)_3$[18] as the LSR. These values were found to be directly proportional to the LSR/substrate ratio up to a value of *ca.* 0.2 eq mol^{-1}.

19) M. R. Willcott, III, R. E. Lenkinski, and R. E. Davis, *J. Am. Chem. Soc.*, **94**, 1742 (1972). The calculated shifts were normalized to the average experimental LIS in the computational process. In earlier papers,[2,10,12] we used a simpler function, $AF=\sum_i|LIS_i^{obsd}-LIS_i^{calcd}|/\sum_i LIS_i^{obsd}$, for the assessment of the agreement (the calculated LIS's were scaled to the largest experimental LIS). The results have been shown, in essence, to be independent of the error function used.

20) In these figures, the Ln–O distance was fixed at 0.30 nm, since the reasonable fit has invariably been found at *ca.* this value (if there are any solutions). We do not mean this to be the most correct one, but the above value is compatible with the available evidence.[15,16]

21) Note, however, that the relative importance of the rotamers varies systematically with a change in the substituent R; see Fig. 9.

(Received April 19, 1980)

The conformations have been studied by means of NMR spectroscopy, largely by the computer simulation of the lanthanoid-induced shifts, for a series of aliphatic carbonyl compounds with the following structures: $CH_3CH(C_6H_5)CO$–R; R=H, CH_3, C_2H_5, i-C_3H_7, and t-C_4H_9. It has been suggested that two rotamers are important in the conformational equilibria of these ketones, in which the R–C–C–C_6H_5 dihedral angle is *ca.* 30° and *ca.* 90°. The relative stability of the above two rotamers has been found to depend on the nature of the alkyl group, R. The results have been discussed in light of the possible weak attractive forces, the CH/π and CH/n interactions.

In connection with the interest described in the preceding paper,[1] we have now studied the conformation of a series of acyclic carbonyl compounds with the following structures:

$$CH_3CH(C_6H_5)CO\text{–}R$$

R = H(**1**), CH_3(**2**), C_2H_5(**3**), i-C_3H_7(**4**), t-C_4H_9(**5**).

Results

Tables 1 and 2 list the proton and carbon NMR data, respectively, for 2-phenylpropionaldehyde (**1**), 2-phenyl-3-butanone (**2**), 2-phenyl-3-pentanone (**3**), 2-methyl-4-phenyl-3-pentanone (**4**), and 2,2-dimethyl-4-phenyl-3-pentanone (**5**).

The Computer Simulation of the Lanthanoid-induced Shifts. The conformations of these compounds have been studied according to the method described in the preceding paper. For the present purpose of simulating the conformation of a ketone, a modification is necessary for the lanthanoid-distribution parameter. In the case of a carbonyl compound, the LSR can be assumed to be distributed, practically, only in the plane of the C=O double bond and to orient itself toward the lone-pair electrons on the carbonyl oxygen atom; the rationale for this approach has been presented by Montaudo and his co-workers.[2] Here, we used an index, p, the molar fraction of the Type **a** complex in Fig. 1, for describing the proportions of the diastereoisomeric LSR-ketone complexes. The input data were the atomic coordinates (standard values) and the experimental LIS's (Table 3) for the appropriate nuclei. The lanthanoid (Ln)–O–C angle (ω) was fixed at 140.[2b] The Ln–O distance (R) and the R–C(8)–C(7)–Ph dihedral angle (ϕ) were then varied, step by step, at a given LSR-distribution parameter (p) in order to search for the most reasonable fit of the computed LIS's with the observed ones. The number of the monitor nuclei were 9.[1]

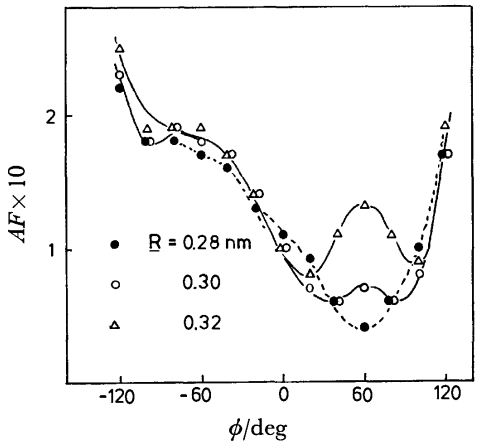

Fig. 2.

the R/Ph dihedral angle (ϕ) for the representative case of Compound **2** (R=Me). Here, the value of p is fixed at 0.4, while the Ln–O distance (R) is varied from 0.28 to 0.32 nm. For R=0.28 nm, the profile shows a single minimum at ϕ=60°, accompanied by a shoulder at *ca.* ϕ=−80°. For a longer Ln–O distance, this minimum splits into two shallow minima at ϕ=40° and 80° (R=0.30 nm), and then into more distinct minima at ϕ=20° and 100° (R=0.32 nm). The agreements have been found to become poorer for R=0.26 and 0.34 nm. A similar trend has also been found to exist for the other ketones and aldehyde. Thus, at a certain Ln–O distance (0.30—0.32 nm) the agreements become reasonably good, and the presence of a second minimum or an inflection becomes most clear. To illustrate this, parts of the *AF* maps for Compounds **4** and **5** (R=Pr^i and Bu^t) are shown in Table 4. The shape of the AF/ϕ profile has been found to be rather insensitive to the population index in the range of *ca.* p=0.2—0.6 in the case of the **2** ketone. The most satisfactory results have been obtained at around p=0.4, 0.4, 0.3, and 0.2 respectively for **2**, **3**, **4**, and **5**.[3]

The Ln–O distance (R) is kept constant at 0.32 nm. ▽: R=H (**1**), ○: R=Me (**2**), ●: R=Et (**3**), △: R=Pr^i(**4**), ▲: R=Bu^t(**5**).

Figure 3 gives the AF/ϕ plots for all of the compounds presently studied (R is fixed at 0.32 nm). We may note at first that there are three minima (or two minima and an inflection) in these figures. The above finding is consonant with the general understanding that there is a three-fold barrier to rotation about the carbon-carbon bond for aliphatic aldehydes and ketones. The agreements are better in the $\phi=0°$—$120°$ range and worst at around $\pm 180°$. The most impressive is perhaps the fact that two AF minima are found at *ca.* $\phi=30°$ and 90° for all of the compounds examined here. The relative importance of these minima appears to be dependent on the nature of the alkyl group, R.[4]

The Relevance of the Present Results to the Conformational Problem of Carbonyl Compounds. A change in the conformational equilibrium may be brought about by the addition of a LSR. This has been found to be negligible in the case of **1**. The vicinal coupling constant between the aldehydic proton and the benzylic proton was found to be *ca.* 1.4 Hz; this was shown to be insensitive to the addition of the lanthanoid species. It is assumed, by analogy, that the rotameric equilibria are not appreciably perturbed by the complex formation for the other compounds in this series, either. This is supported by the fact that the perturbation to the conformational equilibria has been found to be unimportant in the cases of the structurally related sulfoxides[5] and alcohols.[1,6] Except for some particular cases,[2b,7] the conformation of a molecule has been shown not to be influenced by the complexation with a LSR. The internal consistency of the simulated result (*vide infra*) is an additional support for the above assumption.

It has become clear, from earlier studies, that the Ln–O distance (R) at which the best agreement is obtained varies with the nature of the functional group in the substrate molecules. Thus, in the case of the sulfoxides we have noted that the goodness of fit reached its maximum at $R=0.34$—0.38 nm.[5b,8] The best fit has been recorded at $R=0.30$—0.32 nm in the case of alcohols.[1,9] This is illustrated in Table 5 for some representative cases. This does not imply that the above values are necessarily the most correct ones for the Ln–O distance. It is likely, however, that these values reflect the complexing abilities of the SO, OH, and C=O groups. Among these groups, the carbonyl oxygen is intermediate as a base, and it is reasonable to expect that the value of R falls between the above two cases. In view of this, the results computed at around $R=0.32$ nm have been taken to be pertinent to the present problem of the conformational preferences of the ketones. The agreements are, indeed, reasonably good in this range of the Ln–O distance. It is noteworthy that the AF/ϕ plots (for $R=0.30$—0.32 nm) have two distinct minima, at $\phi=20°$—$40°$ and $80°$—$100°$, in all of the cases studied.[10] We believe that this phenomenon is relevant to the present problem of the conformational behavior of these compounds. It is likely that there are two rotamers which correspond approximately

Table 5. The R-dependence of AF[a] for $CH_3(Ph)CH$–X–R compounds

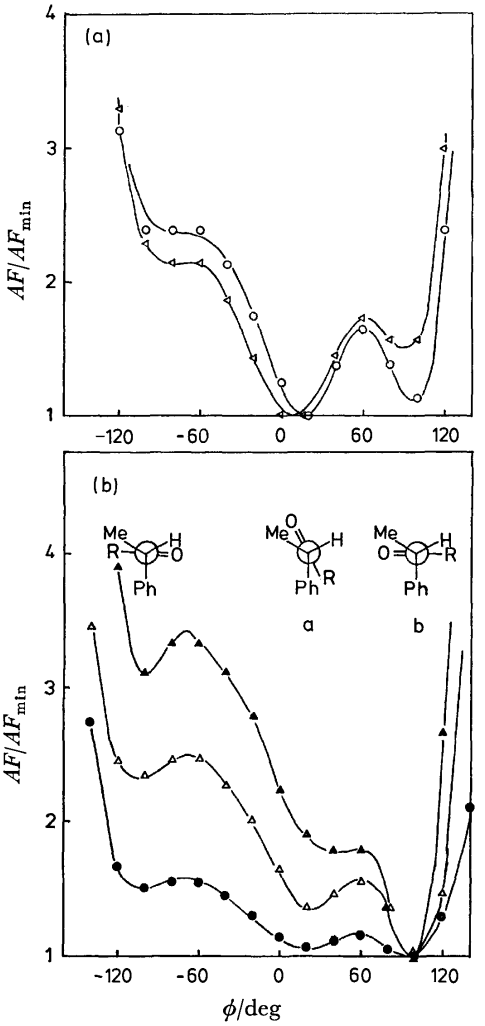

Fig. 4. Plots of the relative AF (AF/AF_{min}) *vs.* the R/Ph dihedral angle (ϕ) for (a) **1** and **2**, and (b) **3**—**5**. The parameters p and R are kept constant at 0.4 and 0.32 nm, respectively. ◁—◁: R=H (**1**), ○—○: R=Me (**2**), ●—●: R=Et (**3**), △—△: R=Pr^i (**4**), ▲—▲: R=Bu^t (**5**).

to these ϕ-values.[11]

The Preferred Rotamers in the Conformational Equilibria of 1—5. In order to see the effect of the alkyl substitution on the conformational preference, the relative *AF* (AF/AF_{min}) was plotted against the R/Ph torsional angle (ϕ).[12] It is clear from Fig. 4 that the relative *AF* values at $\phi \approx 30°$ and $\phi \approx 90°$ (these correspond to the rotamers **a** and **b** in Fig. 5, respectively) vary regularly with the change in the R group. Judging from the shapes of the curves, the contribution of the rotamer **a** appears to be largest for 2-phenylpropionaldehyde (R=H, **1**). The proportion of the rotamer **a** to the rotamer **b** seems to decrease as the aldehydic hydrogen in **1** is replaced by the methyl, ethyl, isopropyl, and then *t*-butyl groups. The two types of rotamers appear to be equally probable in the cases of **2** and **3**; the rotamer **b** is suggested to prevail in the rotameric mixture of **5**.[13]

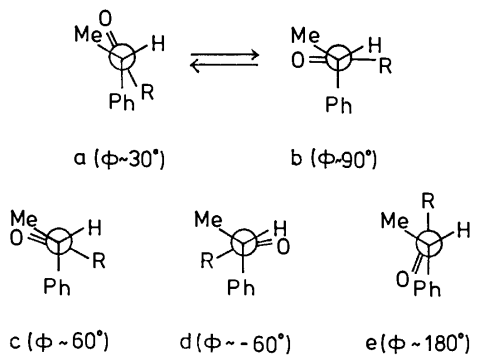

Fig. 5.

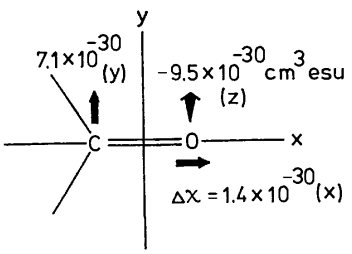

Fig. 6.

Support for the above suggestion regarding the conformational preferences of these compounds is provided by the proton NMR data. The peaks attributed to the benzylic hydrogen (H_a) appear at 3.58 ppm for **1**. They gradually move to a lower magnetic field upon the alkyl sustitution, and finally to a value of 4.26 ppm for the *t*-butyl homologue (**5**). This trend can be well understood in terms of the magnetic anisotropy of the C=O double bond (Fig. 6). Table 6 summarizes the computed data ($\Delta\sigma$ for H_a) for various conformations of a ketone.[15] Thus, in the most preferred conformations, the H_a in **1** positions itself in the shielding region of the carbonyl group, whereas H_a in **5** does not (Fig. 7a). The intermediate data found for the other ketones, **2**, **3**, and **4**, correspond to the suggested change in the conformational equilibria.[17] For the conformation of **1**, another support is provided by the fact that the aromatic protons in this compound are significantly shifted to lower magnetic fields relative to those in other compounds. According to the suggested conformation (Fig. 7b), H_o and H_m in **1** are well positioned in the deshielding region of the carbonyl group. The coupling constant found for the aldehyde is compatible with this conformation.

Table 6.

ψ	ϕ	$\Delta\sigma \times 10^{-30}$/cm^3 esu
150°	90°	−0.40
120°	60°	−0.42
90°	30°	−0.46
60°	0°	−0.81

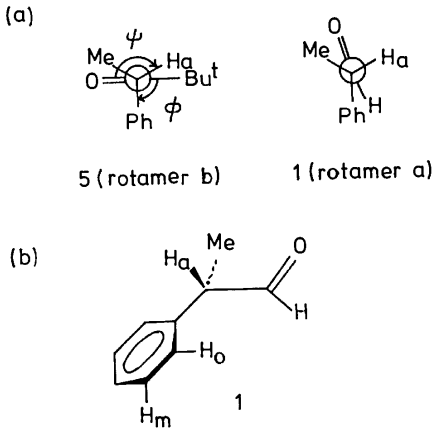

Fig. 7.

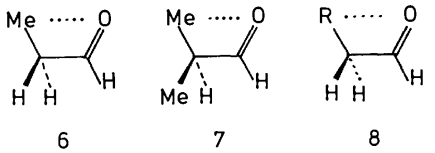
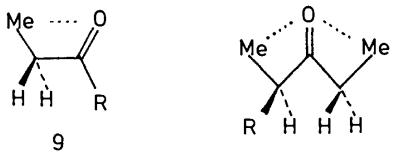
The suggestion that these conformations are important for the **1**—**5** ketones is in line with our thesis that an alkyl group prefers to lie close to a phenyl group; this again indicates the necessity to invoke an attractive force between these groups. The above conformation is compatible with the molecular geometries of some carbonyl compounds previously proposed for describing the transition state of the diastereoface-differentiating reactions.[18] We believe that the present results have an obvious implication in this problem.

Discussion

A Possible Role of the Weak CH···O Hydrogen Bond in Determining the Conformational Preferences of Carbonyl Compounds. The above conclusion is consonant with the general understanding that a methyl group interacts favorably with a carbonyl group. Thus, for a number of aldehydes and ketones, it has been established that a methyl group is nearly eclipsed by the carbonyl oxygen in the preferred conformations. The examples include microwave and NMR studies of propionaldehyde (**6**),[19] an electron-diffraction study of isobutyraldehyde (**7**),[20] and NMR studies of substituted acetaldehydes (**8**),[21] ethyl alkyl ketones (**9**),[22] and 2-substituted 3-pentanones (**10**).[23] For the sake of simplicity, and in



6 7 8



9 10

view of the limitation of the methods as well, the conformations for **6**—**10** are drawn as completely eclipsed. A somewhat twisted conformation, however, is more likely to exist in reality.[21,24] We suggest that such conformations as the above two types (rotamers **a** and **b** in Fig. 5; CH_3/O torsional angle *ca.* $\pm 30°$) are both important in the consideration of the conformational problems of these molecules (**1**—**5**). An inspection of the Dreiding models suggests that it would be easier for a hydrogen-bond like interaction involving the CH_3 and O (*vide infra*) to take place with a slightly distorted conformation. By twisting from the completely eclipsed conformation, a molecule comes to be capable of avoiding the energetically unfavorable vicinal H/H interaction (Fig. 8)[25] and simultaneously participating in a CH/O hydrogen bonding.

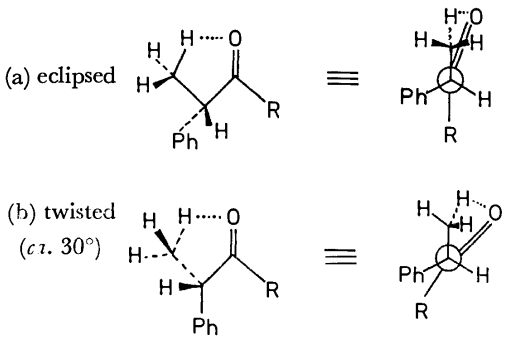


Fig. 8.

There is ample evidence in the literature that a methyl group prefers to be *gauche* or nearly (but not completely) eclipsed to a group with unshared electrons. Figure 9 illustrates some representative cases.[26,27] Several workers have interpreted these phenomena (the favored *gauche* or eclipsed interaction) in terms of the nonbonded van der Waals attraction or the London dispersion force.[28] However, we think it more probable that the favored CH_3/O (more generally CH_3/X, X=O, N, or halogens) interaction traces its origin in a kind of weak hydrogen bond.[6,29] In virtually all cases reported so far, it seems easy for the formation of a 5- or 6-membered intramolecular hydrogen bonding to take place (see **6**—**10**, Figs. 9 and 10). We would refer this hypothetical secondary force to the CH/*n* interaction[29,30] (*n*: unshared electrons).

Supports for the above suggestion have been provided by a number of experimental and theoretical studies.

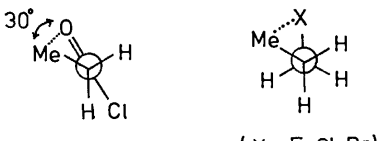

Fig. 9.

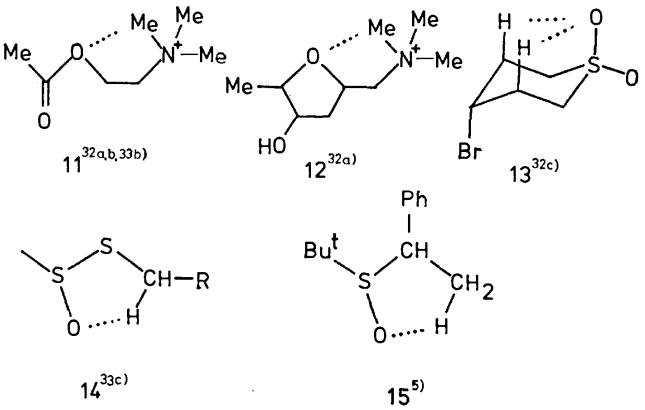
In particular, Sutor presented good evidence, from an extensive X-ray study, that there is strong possibility that a CH (CH_2, CH_3) group participates in a weak hydrogen bond with an oxygen atom.[31] Her proposal has since found a number of supports in X-ray[6,32] and NMR[5b,33] studies of a variety of molecules. Some representative examples are illustrated in Fig. 10. The presence of such a weak, hydrogen-bond like interaction has also been suggested by the MO (semi-empirical[34] as well as *ab initio*[35]) calculations of several model systems.



11[32a,b,33b] 12[32a] 13[32c]

14[33c] 15[5]

Fig. 10.

Karabatsos and his co-workers studied, by NMR, the conformation of a number of substituted acetaldehydes (**8**).[21] They reported that the relative stability of the rotamer **a** to the rotamer **b** (Fig. 11) decreases as the "size" of the alkyl group (R) increases, and explained this in the framework of the bulk-repulsive concept. We prefer to interpret this differently; this may be a proof for the presence of a CH/O hydrogen bond. It seems likely that it is the "number" of the CH group (which can effectively interact with the carbonyl group) which is more important in determining the relative stabilities of the respective rotamers. The factors responsible for the rotamer stability might thus be the number, the nature (5- or 6-membered, the orientation of the CH bond, the kind of X-group, *etc.*), and the probability of participating in the interaction. In fact, it has been reported that, if one of the substituents in **16** is a methyl group (Fig. 11), the most stable rotamer has always its methyl group which is eclipsed by the carbonyl oxygen.[21] The relative stability of the rotamer **a** in relation to the **b** has been reported to decrease when the methyl group is replaced by another alkyl group. This is reasonable, in our view, since the "number" of the CH groups, which can form a 5-membered H-bond with the carbonyl group,[36] decreases

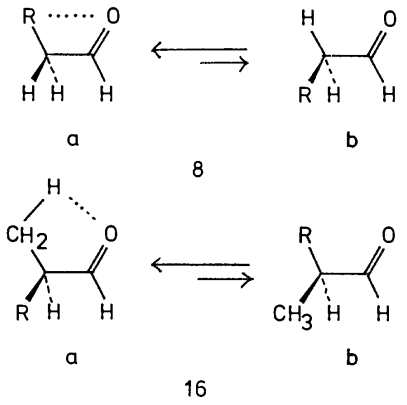


Fig. 11.

on the replacement of the methyl group by another alkyl group.

The Factors Controlling the Relative Stability of the Rotamers ***a*** *and* ***b***; *5- and 6-Membered Intramolecular H-Bond.* With regard to the stability of the rotamer **a** relative to that of the rotamer **b** in Fig. 5, we would invoke the importance of the CH/π interaction. This is a weak attractive force likely to be operative between an alkyl and a π-system,[33a,37,38] the nature of which is ascribed to a kind of weak hydrogen bond. On the basis of experimental and theoretical evidence, the interaction has been suggested to be most effective at a C–H···C(sp^2) interatomic distance of approximately 0.20—0.25 nm.[37,39] An inspection of the Dreiding models (Fig. 12) suggests that such an interaction is likely to occur in the rotamer **a** with the use of a hydrogen (H_y) attached to C9 (Type **a** interaction). If the CH/π interaction is operative with the use of the C-1 carbon, the Type **a** interaction is a kind of 5-membered intramolecular H-bond. Another type of interaction is possible with the use of H_z (Fig. 12; Type **b** interaction). This type of interaction forms a 6-membered H-bond and is most likely to occur with the rotamer **b** (Dreiding model). The 5-membered, Type **a** interaction decreases as the alkyl group changes from being a methyl to an ethyl and then to an isopropyl group; in the case of a *t*-butyl group, it is absent. On the other hand, a 6-membered, Type **b** interaction increases in this order.[40]

To explain the present results, one may argue in the framework of the bulk-repulsive concept. It is conceivable that the London dispersion force[41] is responsible, at least in part. We believe, however, that the present finding is better accommodated by considering the effects of the above two types of CH/π interaction involved there. The basic geometries of the respective rotamers are determined by the more dominant CH_3/n interaction, which we feel to be somewhat stronger than the CH/π bond. It would be pertinent, in this respect, to cite a recent finding of Inamoto and his group in an X-ray study of a very crowded molecule, bis(2,4,6-tributylphenyl)phosphinic chloride (Fig. 13).[32d] Some of the intramolecular distances found in this compound ($CH_3/C_{aromatic} \approx 0.32$, $CH_3/Cl \approx 0.33$, and $CH_3/O \approx$ 0.30 nm) are shorter by 0.04—0.05 nm than the respective van der Waals distances.

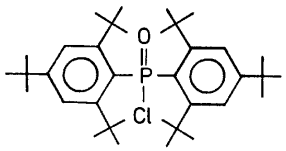

Fig. 13.

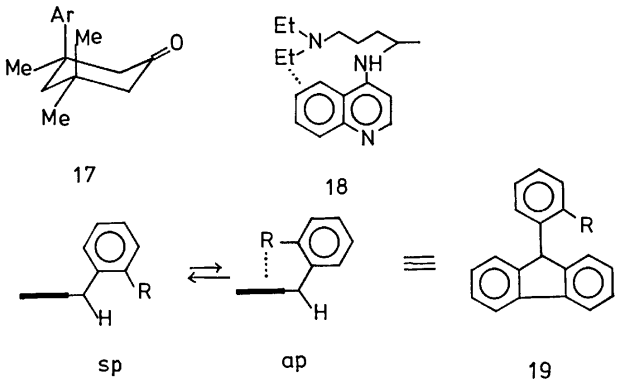
Possible Importance of the CH/π *Interaction in the Conformational and Selectivity Problems of Various Systems; CH/*π *Interaction Hypothesis.* The stabilization energy for a unit CH/π bonding is very small (*ca.* 3.5 kJ mol^{-1} or less).[6,37] However, we suggest that this type of interaction may contribute to bringing about an appreciable difference between the free-energy levels of a competitive interaction (intramolecular or intermolecular) system. The CH groups (as well as π-system) are generally arranged in a chemical structure with a certain symmetry. The difference in the interaction energies might thus become remarkable, since the "number" and the "chance" for the interaction may be expected to increase in such a case.



Intramolecular Interactions: To cite a few possible cases, Shapiro and his group have reported a remarkable preference for the axial aromatic (as opposed to the methyl) group in **17**.[7a,42] The conformation of an antimalarial substance, chloroquine (**18**), was studied by the LIS method; the side-chain alkyl group in this compound has been shown to be curled over the plane of the quinoline ring.[43] Nakamura, Nakamura, and Ōki recently studied the conformational problem of 9-(2-alkylphenyl)fluorenes (**19**).[44] The free-energy

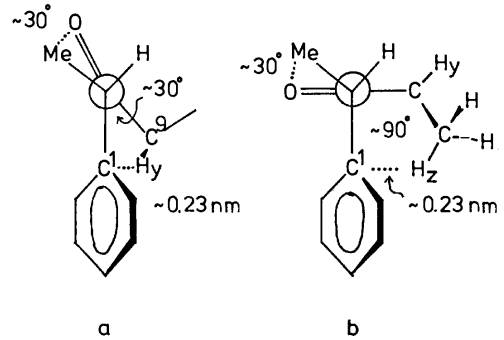


Fig. 12.

differences between the rotamers have been reported to be 0.3, 0.6, and 0.4 kcal mol^{-1} at 0° (in favor of the sp-rotamer) for the methyl, ethyl, and isopropyl derivatives respectively. The above unusual behavior of the isopropyl homologue might be an indication of the involvement of the CH/π interaction.

Evidence about the conformations of flexible molecules is well reflected in the selectivities in certain reactions (see **20**—**26**). The extent of asymmetric synthesis in a Prelog reaction system (**20**) has been shown to be greater for the benzoyl formate ester (R=Ph) than for the pyruvate ester (R=Me).[45] A similar result has been observed for **21** in the case of a 1-methylheptyl ester (R=*n*-C_6H_{13}) *vs.* a 1-phenylethyl (R=C_6H_5) or 1-(1-naphthyl)ethyl (R=$C_{10}H_7$) ester, the former giving rise to the highest optical yield.[46] Corey and his coworkers have reported that the stereoselective reduction of **22** (a prostaglandin precursor) was better accomplished when they used an ester with an aromatic substituent.[47] The examples from **24** to **26** are extracted from the template-directed functionalizations of Breslow and his group;[48] they have presented good evidence that these molecules are extensively folded in solution. Note that, in all of the reactions cited thus far where remarkable selectivities were observed, the reacting species have an aromatic group on one side, and a long-chain (or branched) alkyl group on the other end of the molecule; an alkyl/alkyl or aromatic/aromatic interaction does not seem to yield a good result in a selective reaction. Therefore, we think it very probable that an attractive interaction of the CH/π type plays an important part in determining the molecular shapes of flexible molecules.

Fig. 15.

Intermolecular Interactions: We feel further that the attractive CH/π interaction plays a more important role in controlling the subtle aspects of the dynamically interacting systems,[49] *e.g.*, the efficacy of molecular recognition[50] and the selectivity problems in certain multimolecular reactions. Thus, Closs and Moss reported a remarkable effect of the alkyl substitution on the stereochemical outcome in a carbene addition to a series of olefins (Fig. 14).[51] A similar result has recently been presented in another case.[52] The *endo*-orienting tendency of the methyl group has been demonstrated for a Diels-Alder reaction (Fig. 15).[53] A steroidal enzyme model has been studied by Guthrie and his group;[54] the enolization of **27** has been shown to be most effectively catalyzed when a large aromatic group is incorporated in the substrate molecule. The rate enhancement has been reported to increase regularly when a phenyl group in **27** is replaced by a naphthyl and then by a phenanthryl group. In an enantioface-differentiat-

ing reduction of phenyl alkyl ketones with a chiral Grignard reagent (**28**), Guétté and Capillon[55] have found that the introduction of a methoxyl group to the aromatic moiety of **28** results in an increase (slight but distinct) in the optical yield. The extent of the asymmetric synthesis decreases, in contrast, on substitution with an electron-withdrawing group such as CF_3.

In all of the cases cited above, the free-energy level at the transition state (which leads to the favored product) seems to be stabilized by the interaction of an alkyl group with an aromatic system. Certain of the above results were explained in terms of the van der Waals (repulsive as well as attractive) and the so-called hydrophobic interaction.[56] We feel that the substituent dependence of the product ratio (*cis/trans*) in the cyclopropane formation (Fig. 14) can better be understood by considering the involvement of the CH/π interaction. The effective "number" of the CH group, which can participate in the stabilization of the activated complex, might thus decrease upon a successive α-methylation ($CH_3 \rightarrow CH_2Me \rightarrow CHMe_2 \rightarrow CMe_3$). In fact, a significant increase in the *cis/trans* ratio has been observed upon the replacement of the olefinic hydrogen with a second *cis*-methyl group.[52] The London dispersion force and the hydrophobic interaction[56] perhaps play important parts in the selective enolization of **27**.[54] However, we think it likely that the CH/π interaction plays a role, since the probability of the interaction can be expected to increase with an increase in the surface area of the aromatic ring (phenyl→naphthyl→phenanthryl). At any event, we see no good reason why a compound becomes a good substrate only with an aromatic substituent, if the so-called nonpolar interaction is solely responsible for the observed selectivity.[57] A similar argument may apply to the selectivity problem reported for the reduction of **22** to **23**.[47] Alkyl substituents such as CH_3 and $CH_3(CH_2)_7$ have been reported to be by far less effective than aromatic ones; this is to be anticipated since we have an aliphatic moiety (C_5H_{11}) on the other terminal of the molecule. The results reported for the last example[55] seem to demonstrate that the interaction involved here, in stabilizing the favored transition state, is CH/π in type. The π-donating property of the phenyl group should increase upon the introduction of an electron-donating group, such as CH_3 or CH_3O; the inverse is true for CF_3.

Possibilities of Biological Importance: It is tempting to speculate about the possibilities that the interactions of the above kind play an important role also in the biological system.[29,58] These possibilities include the problems of biopolymer folding [59] and the substrate specificities of some globular proteins, such as enzymes and immunoglobulins. As was emphasized by Watson some 15 years ago,[60] the interactions which determine the subtle behavior of the dynamically interacting, complex biomolecules *should be weak* and orientation-dependent. Our knowledge about the important, weak chemical interactions, however, is still far from complete. We suggest that the CH/π (as well as CH/n) interaction is a good candidate for the above important secondary forces in view of its *weakness* and flexibility. Our study is thus being oriented toward an understanding of the nature and the characteristics of these forces, the biological implications of which will form the subject of a future paper.

Experimental

Materials. The 2-phenylpropionaldehyde (**1**) was obtained from a commercial source. The ketones (**2**—**5**) were prepared by treating **1** with appropriate Grignard reagents, followed by the oxidation of the resulting alcohols. The samples were purified chromatographically and gave correct analytical and spectral data.

NMR Measurements. The NMR spectra and the LIS data were determined as has been described in the preceding paper.[1]

We wish to thank Professors Tadashi Endo (Aoyama Gakuin University) and Naoya Nakagawa (University of Electro-communications) for their discussions, Professor Naoki Inamoto (University of Tokyo) for providing information prior to publication, and Dr. Teiichiro Ito (Meiji Seika Kaisha) for his encouragement.

3) This trend of the Ln-distribution is reasonable in view of the steric consideration.

4) The agreements are very poor for Compound **2** (R=Et). This may be attributed to the absence of $C3$ symmetry for the alkyl group in this molecule. In the above procedure, the contributions from all of the rotamers (regarding the rotation

around the C8–C9 bond) were computed and then averaged. This is a good approximation for compounds with a symmetric group (R=H, Me, or Bu^t), but not for Compounds **3** and **4**. The deletion of the LIS data for H_y, H_z, and/or C10 has, in fact, improved the agreements.

10) The presence of a single rotamer (ϕ *ca.* 60°; rotamer **c** in Fig. 5) may be suggested for **2** if one considers the results obtained with R=0.28 nm to be more appropriate in this case. We, however, feel this to be an artefact which is brought about by the use of an improper Ln–O distance. The above single minimum probably corresponds to the time-averaged geometries of the two rotamers, **a** and **b**, in Fig. 5. It is difficult to believe that the above computational procedure will produce the wrong, artificial conclusion that there is a mixture of two rotamers if, in reality, there is only an unique rotamer prevailing in the solution.

11) The usefulness (as well as the limitations) of the LIS method in studying the conformational problems of carbonyl compounds has been demonstrated by Montaudo *et al.* in the cases of unsaturated ketones and amides.[2)]

12) The position and the goodness of fit at the respective *AF*-minimum reflect, although in an indirect manner, the plausible geometry and the relative importance of a substrate–LSR complex.

13) Impressive also is the fact that the rotamer corresponding to ϕ *ca.* −60° (rotamer **d** in Fig. 5) seems to be rather unimportant for all of the compounds studies here. Another notable feature of the above results is the (suggested) nonexistence of the rotamer corresponding to $\phi \approx 180°$ (rotamer **e** in Fig. 5); this latter conclusion differs significantly from that of a preliminary force-field calculation of these molecules.[14)]

17) The geometrical disposition of the methyl group with respect to the carbonyl group does not differ significantly from the rotamer **a** to the rotamer **b**; the time-averaged geometry of CH_3 *vs.* C=O is not substantially affected by a shift in the rotameric equilibrium. This is, in fact, reflected in the insensitivity of the respective proton resonance to the structural variation (Table 1).

40) We feel that the Type **b** interaction is of minor enthalpy for a unit bond as compared to the Type **a** interaction. In fact, H_y is α to C=O (more acidic) and is, therefore, more prone to participate in the interaction with the phenyl group. H_z is also capable of participating in a 5-membered CH/*n* interaction with the carbonyl oxygen; this is, in fact, reflected in the chemical shifts for C10 (*γ-gauche* effect).

Synthetic Photochemistry. XIX.[1] The Synthesis of Protoilludanes by Photocycloadditions. Protoillud-7-ene and Several Oxygenated Derivatives

Hitoshi TAKESHITA,* Isao KOUNO, Mitsuaki IINO, Hisakatsu IWABUCHI,** and Danji NOMURA**

Research Institute of Industrial Science, 86, Kyushu University, Hakozaki, Fukuoka 812

***Faculty of Agriculture, 46, Kyushu University, Hakozaki, Fukuoka 812*

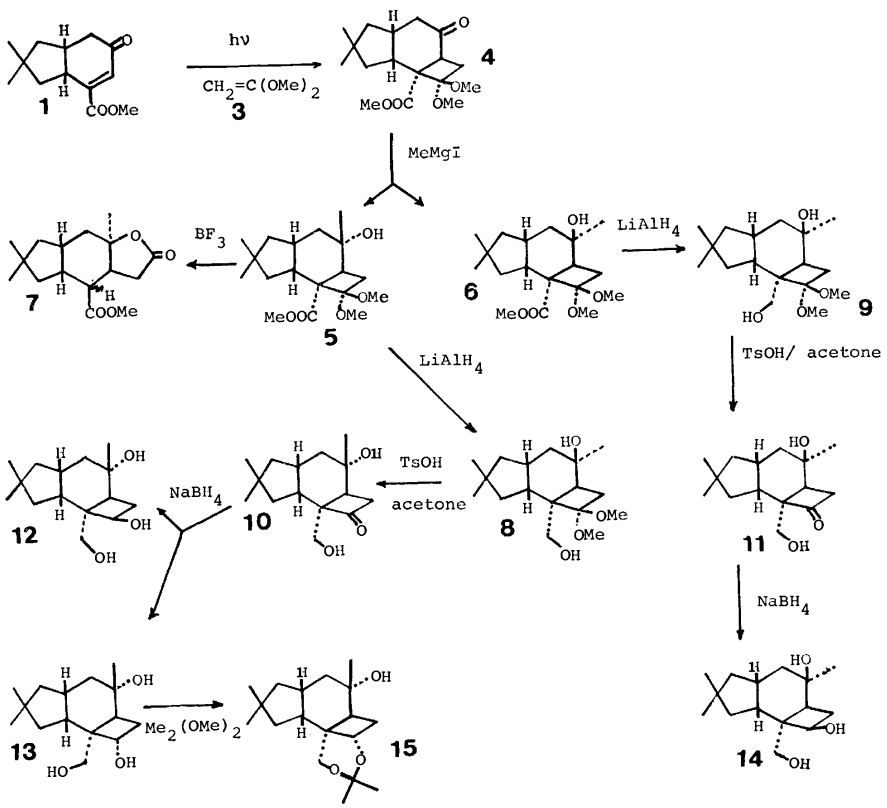
(Received February 27, 1980)

Unlike ethylene, 1,1-dimethoxyethene, an electron-rich olefin, has been photocycloadded to a *cis*-hexahydroindenone to form a norprotoilludane derivative with a correct stereostructure. Methylation and subsequent chemical transformations yielded several oxygenated derivatives, from which the parent hydrocarbon, protoillud-7-ene, was obtained by deoxygenation. Independent evidence for the stereostructures of the synthetic derivatives has been provided by the X-ray crystallographic analysis of a dihydroxy acetal.

In previous papers,[2] we have described a new approach to obtaining several oxygenated protoilludanes, biogenetic precursors of *gem*-dimethylcyclopentane sesquiterpenoids[3] from various organisms,[4] by the application of two-fold photocycloadditions, followed by methylation. However, this approach has a practical limitation; that is, with ethylene (**A**), only the *trans*-isomer (**B**) of the hexahydroindenones, *trans*-2-methoxycarbonyl-8,8-dimethylbicyclo[4.3.0]non-2-en-4-ones, is photochemically reactive, while the stereochemistry of natural protoilludanes possesses the *cis*-relationship. In this paper, we will describe a facile synthesis of the protoilludane derivatives from the *cis*-hexahydroindenones, *cis*-2-methoxycarbonyl-8,8-dimethylbicyclo-[4.3.0]non-2-en-4-one (**1**) and 2,8,8-trimethylbicyclo-[4.3.0]non-2-en-4-one (**2**), with an electron-rich olefin, 1,1-dimethoxyethene (**3**). According to a preliminary study, 1,1-dichloroethene was also photochemically unreactive to **1**, but vinyl acetate gave a complex product mixture.

Results and Discussion

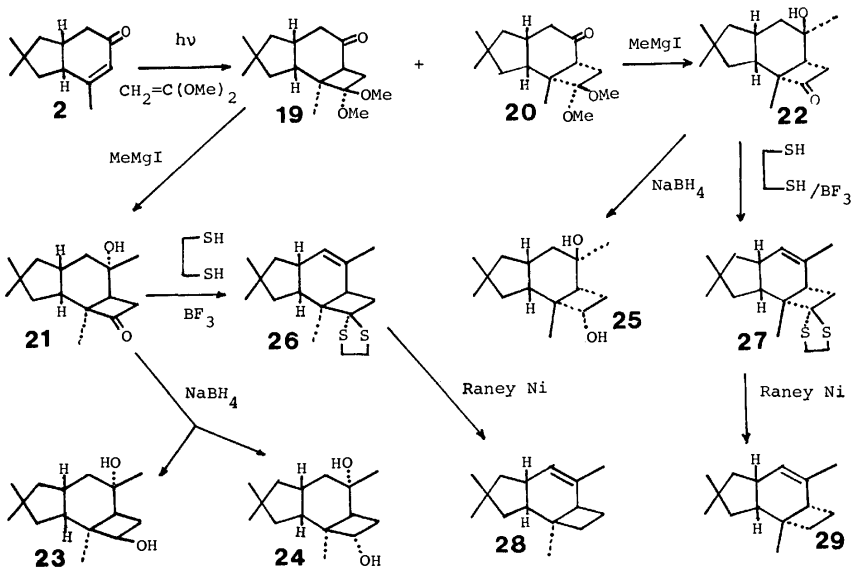
The reaction of **1** with **3** was neat and gave only one adduct, 3,3-dimethoxy-2-methoxycarbonyl-10,10-dimethyltricyclo[6.3.0.$0^{2,5}$]undecan-6-one (**4**). This stereoselective formation itself may be an indication of the desired *cis-transoid-cis*-structure. With regard to this concept, we have decided to carry out further transformations. Thus, by Grignard methylation, **4** was converted to a pair of epimers, 3,3-dimethoxy-2-methoxycarbonyl-6,10,10-trimethyltricyclo[6.3.0.$0^{2,5}$]-



Scheme 1.

undecan-6-ols, **5**, the major product, and **6**. Against the attack of the reagent, the methoxycarbonyl group at the quarternary carbon was intact, as in the case of **B**.[3] Although **5** and **6** could be separated by silica-gel column chromatography, their cyclobutane rings were acid-sensitive; for example, the treatment of **5** with *p*-toluenesulfonic acid (TsOH) caused a ring-cleavage to yield a *seco*-γ-lactone, 4-hydroxy-2-methoxycarbonyl-4,8,8-trimethylbicyclo[4.3.0]non-3-ylacetic acid lactone (**7**), which has the same carbon skeleton as the pterosins.[5] To avoid this, the acetal group was hydrolyzed after an LAH reduction of the methoxycarbonyl group, *via* dihydroxy acetals, 2-hydroxymethyl-3,3-dimethoxy-6,10,10-trimethyltricyclo[6.3.0.$0^{2,5}$]-undecan-6-ols (**8** and **9**), to dihydroxy ketones, 6-hydroxy-2-hydroxymethyl-6,10,10-trimethyltricyclo-[6.3.0.$0^{2,5}$]undecan-3-ones (**10** and **11**). Subsequently, **10** was reduced with sodium borohydride to give isomeric 6-hydroxymethyl-6,10,10-trimethyltricyclo-[6.3.0.$0^{2,5}$]undecan-3,6-diols (**12** and **13**), while **11** yielded only **14**, the isomer of **12** and **13**, on the same treatment. The configuration of the methyl group can be deduced by NMR analysis; *i.e.*, the signals at δ: 1.22 in **6** ascribable to the newly introduced methyl groups have been changed by the reduction of the ester group to 1.12 in **9**, but the 1.12 in **5** has remained unaffected, as appears at 1.12 in **8**. Therefore, from the difference in the chemical shifts, $\Delta\delta_{(5-8)}=0.00$ and $\Delta\delta_{(6-9)}=0.10$, the methyl groups of **5** and **8** may be considered to be *trans* to the substituents carrying oxygen at the quarternary carbon (C-2), while those of **6** and **9** are *cis*. The NMR spectra of **12**, **13**, and **14** also disclosed a stereochemical point: only **13** revealed the methine proton signal (a triplet), which is ascribable to the secondary alcohol on the cyclobutane ring, coupled with the adjacent methylene group, at δ; 4.07 (J=7 Hz); on the other hand, **12**, at 4.10 (br. m), and **14**, at 4.03 (br. m), disclosed a further splitting due to a long-range coupling with the C-6 methine proton. Since such long range couplings arise from the *W*-letter-like geometry, the hydroxyl group of the cyclobutanol of **13** must be *cis* to the methine proton at the ring juncture (C-5), but those of **12** and **14** are *trans*. Independently, an attempted formation of the acetals of **12**, **13**, and **14** with 2,2-dimethoxypropane established the correctness of the assumption; only **13** yielded a cyclic acetal 5,5,10,14,14-pentamethyl-4,6-dioxatetracyclo[10.3.0.-$0^{2,7}$.$0^{2,9}$]pentadecane (**15**), at room temperature, while **12** or **14** resulted in the recovery of the respective starting material, plus unidentified products. The stereochemistry shows that the reduction has occurred preferentially from the same side of the oxygen functions in the molecules, which can form the metal-coordinated intermediate.

This strategy on the synthesis can be extended to the parent protoilludene from **2**. To prepare **2**, a primary choice must be a well known procedure,[6] *i.e.*, the photoaddition of acetylacetone with 4,4-dimethylcyclopentene, followed by the cyclization. However, the photoaddition in this case has been shown to be impractical because of its slow rate. Consequently, **2** was prepared by derivation from **1** as follows: The reaction of **1** with 1,2-ethanediol afforded a 1,3-dioxolane, **16**, which was then reduced by LAH and hydrolyzed by TsOH to give a hydroxy derivative (**17**). An acetate of **17**, *cis*-2-acetoxymethyl-8,8-dimethylbicyclo[4.3.0]-non-2-en-4-one (**18**), was reduced with zinc in acetic acid to form **2**. The photochemical cycloaddition of **2** with **3** produced two photocycloadducts, 3,3-dimethoxy-2,10,10-trimethyltricyclo[6.3.0.$0^{2,5}$]undecan-6-ones (**19** and **20**). Thus, the replacement of the ester group on the quaternary carbon with a methyl group resulted in an inferior stereoselectivity. The Grignard methylation, followed by a mild hydrolysis of **19** and **20**, produced cyclobutanone derivatives, 2,6,10,10-tetramethyl-3-oxotricyclo[6.3.0.$0^{2,5}$]undecan-6-ols (**21** and **22** respectively). By reduction with sodium borohydride, **21** produced an epimeric pair of glycols, 2,6,10,10-tetramethyltricyclo[6.3.0.$0^{2,5}$]undecan-6-ols (**23** and **24**), while **22** produced **25**, the isomer of **23** and **24**, as the



Scheme 2.

sole product. The configurations of their hydroxyl groups were again obtained by means of the NMR spectra: **24** showed a triplet at δ: 4.15 (t, J=8 Hz), but **23** (at 3.68) and **25** (at 3.89) showed multiplets. Therefore, only **24** has a *trans*-relationship to two methine protons on the cyclobutane ring. Both **21** and **22** were converted into 1,3-dithiolanes, **26** and **27**, accompanied by the dehydration of the tertiary alcohol function.[7] The Raney nickel desulfurization of these thio-acetals afforded the parent protoillud-7-ene (**28**), *cis-transoid-cis*-2,6,10,10-tetramethyltricyclo[6.3.0.$0^{2,5}$]undec-6-ene, and epi-protoillud 7-ene (**29**). The identity of **28** with the previous sample was proved by NMR comparison with the reported data.[8,9] Consequently, this constitutes an alternative total synthesis of **28** and its related derivatives.

Although the above synthesis of the derivatives with the correct stereochemistry left no doubt as to the working hypothesis, we have also carried out an X-ray crystallographic analysis in order to provide independent evidence. Since every trial of the halogenated derivatives has failed, a halogen-free derivative, **9**, was submitted to the analysis. The single crystal of **9**, monoclinic, belongs to the space group C2/c, and its crystal data showed the following features: a=15.138, b=11.486, c=20.744$\times 10^{-8}$ cm, β=112.2°, d_x=1.186 g/cm^3, and Z=8. The 1278 non-zero reflections with (F_o) $-2.3\,\sigma$ (F_o) were collected on a Syntex P$\bar{1}$ four-circle diffractometer with graphite-monochromated Mo K_α radiations in the θ-2θ scanning mode. The structure was solved by the direct method.[10] After several cycles of block diagonal least-squares refinement with anisotropic thermal parameters for non-hydrogen atoms and with isotropic ones for hydrogen atoms, except for one of the hydroxyl hydrogens, the final R value was 0.05. Figure 1 shows the structure views along the β-axis.

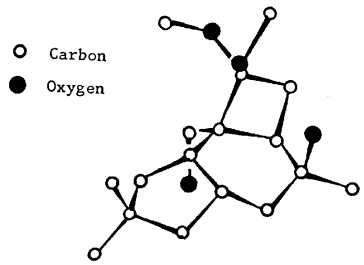


Fig. 1.

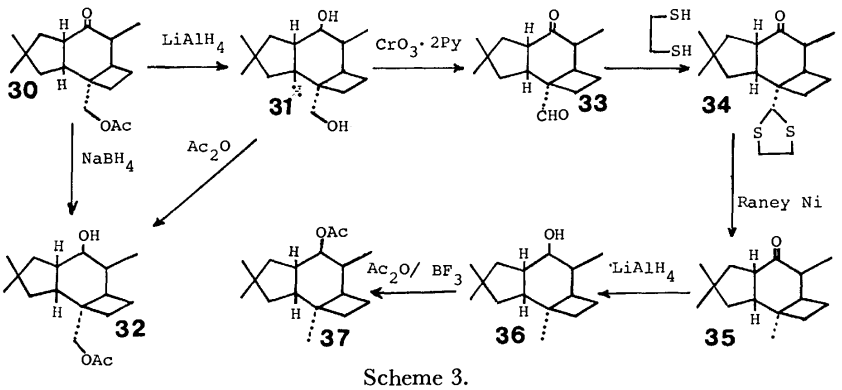
Meanwhile, we have carried out some deoxygenation reactions of the previously obtained protoilludanone, 2-acetoxymethyl-6,10,10-trimethyltricyclo[6.3.0.$0^{2,5}$]-undecan-7-one (**30**).[3] The LAH reduction of **30** afforded 2-hydroxymethyl-6,10,10-trimethyltricyclo-[6.3.0.$0^{2,5}$]undecan-7-ol (**31**), an oil. The acetylation of **31** occurred at only the primary alcohol group to give a monoacetate (**32**), but a chromium(VI) oxide oxidation in pyridine gave a keto aldehyde, 2-formyl-6,10,10-trimethyltricyclo[6.3.0.$0^{2,5}$]undecan-7-one (**33**), in a good yield. Upon treatment with 1,2-ethanedithiol and boron trifluoride etherate, **33** formed a mono(ethylenedithioacetal) (**34**). The Raney nickel desulfurization of **34** gave 2,6,10,10-tetramethyltricyclo[6.3.0.$0^{2,5}$]-undecan-7-one (**35**), which corresponds to 8-oxoprotoilludane; it was then converted to a hydroxy derivative, **36**. An acetate (**37**) of **36** could be prepared only under forced conditions, in acetic anhydride with boron trifluoride, showing the sterically hindered environment of the hydroxyl group.

Finally, we would like to make a comment on the biogenesis of the pterosines (*seco*-protoilludanes).[11] Sakan *et al.*[12] have pointed out that, based on the actual *in vitro* transformation, hypacrone (**C**), a congener *seco*-illudane derivative from brackens, must be a precursor. However, as is shown in the present experiments, oxygenated protoilludanes, like **5** or **6**, caused a retro-aldol cleavage into a pterosane skeleton. Therefore, the oxygenated protoilludanes and their relatives are likely to give these widely distributed aromatic metabolites *in vivo*.

Experimental

The mp's, determined with a Yanagimoto Model apparatus, are uncorrected. The ^{1}H- and ^{13}C-NMR spectra were measured, unless otherwise stated, in $CDCl_3$ by means of an FX 100 Model spectrometer, Nippon Denshi Co. (JEOL), while the chemical shifts expressed are the δ values from the internal standard, Me_4Si. The IR spectra were taken by an A-102 Model spectrometer, Nippon Bunko Kogyo Co. (JASCO), in CCl_4 solutions or KBr disks. The mass spectra were taken by means of an OS G1 Model spectrometer, JEOL, and the high-resolution figures were obtained by visual readings on the photographic plates. The high-pressure liquid chromatography was performed by means of an ALC 440/110 Model Apparatus, Nippon Waters Co. The elemental analyses were performed at The Elemental Analyses Center, The Faculty of Science, Kyushu University.



Scheme 3.

*An Attempted Photoreaction of **1** with 1,1-Dichloroethene.* A mixture of **1** (50 mg) and 1,1-dichloroethene (0.3 cm³) was externally irradiated by means of a high-pressure mercury lamp for 6 h. The NMR analysis revealed only signals ascribable to the recovered materials.

*Photocycloaddition of **1** with Vinyl Acetate.* A mixture of **1** (30 mg) and vinyl acetate (0.5 cm³) was externally irradiated for 6 h. The NMR spectral analysis indicated the occurrence of at least three photoadducts. A silica-gel column fractionation showed an extensive decomposition to aldehydic compounds. No further work was carried out.

*Photocycloaddition Reaction of **1** with **3**.* The freshly prepared **3**, from 2-chloro-1,1-dimethoxyethane (8 g) and potassium *t*-butoxide, was mixed with **1** (1.2 g) and then externally irradiated through a Pyrex glass filter by means of a 400 W high-pressure mercury lamp at 15—20 °C for 20 h under a nitrogen atmosphere. After the evaporation of the volatile material, the residue was purified on a silica-gel column; subsequent elution from ethyl acetate–hexane (1 : 9) yielded a colorless oil, **4**, 1.2 g (67%) [Found: C, 65.81%; H, 8.47%. Calcd for $C_{17}H_{26}O_5$: C, 65.78; H, 8.44%. δ: 1.05 (3H, s), 1.10 (3H, s), 1.2—2.9 (11H, m), 3.20 (3H, s), 3.27 (3H, s), and 3.76 (3H, s). δ (C): 31.9, 32.2 (2C), 35.6, 39.1 (2C), 40.1, 42.6, 43.0, 47.8, 49.3, 50.1, 51.8, 65.7, 103.2, 172.4, and 211.3], which was homogeneous in respect to NMR and gas-liquid chromatography.

*The Grignard Methylation of **4**.* To methylmagnesium iodide prepared from methyl iodide (2.3 g) in ether (20 cm³), an ethereal solution (20 cm³) of **4** (610 mg) was added, drop by drop, over a 3-h period at 0—5 °C; the mixture was then refluxed for 3 h. The mixture was then hydrolyzed and extracted by ether. The extracts were dried ($MgSO_4$) and chromatographed on a silica-gel column to give a colorless oil (420 mg), which was further fractionated by a pre-packed silica-gel column to give colorless crystals, **5** (mp 95—96 °C (from ethyl acetate–hexane); 300 mg (47%) [Found: C, 65.99; H, 9.21%. Calcd for $C_{18}H_{30}O_5$: C, 66.23; H, 9.26%. δ: 0.99 (3H, s), 1.03 (3H, s), 1.12 (3H, s), 1.4—1.9 (7H, m), 1.90 (1H, br. s), 2.1—2.7 (4H, m), 3.19 (3H, s), 3.35 (3H, s), and 3.71 (3H, s). δ (C): 27.6, 30.4, 30.9, 31.3, 34.6, 36.0, 36.6, 40.3 (2C), 44.1, 48.8, 49.6, 50.6, 51.6, 59.8, 70.1, 102.1, and 174.7]), and a colorless oil, **6** (80 mg (12%)[Found: C, 65.95; H, 9.33%. δ: 0.99 (3H, s), 1.01 (3H, s), 1.22 (3H, s), 1.2—2.7 (12H, m), 2.82 (1H, br. s), 3.30 (3H, s), and 3.69 (3H, s). δ (C): 29.7, 30.9, 31.0, 31.4, 34.2, 36.1, 36.8, 37.2, 41.3, 43.7, 47.5, 49.9, 50.3, 51.4, 61.6, 68.5, 103.7, and 173.7]).

*An Acid-catalyzed Formation of a γ-Lactone (**7**) from **5**.* An anhydrous benzene solution (10 cm³) of **5** (10 mg) and BF_3 etherate (60 mg) was kept at room temperature for 5 h. After hydrolysis, the mixture was extracted (ether) and chromatographed on silica gel to give **7** (colorless needles, mp 90—91 °C (from hexane), 7 mg [Found: C, 68.08; H, 8.49%. Calcd for $C_{16}H_{24}O_4$: C, 68.54; H, 8.63%. δ: 0.99 (3H, s), 1.09 (3H, s), 1.42 (3H, s), 3.64 (3H, s), and 1.1—3.1 (12H, m). δ (C): 28.5, 30.2, 31.4, 34.4, 35.9, 36.7, 37.3, 37.5, 38.0, 40.7, 45.7, 46.5, 51.8, 85.2, 174.1, and 175.9]).

*Conversion of **5** to a Keto Glycol, **10**.* An anhydrous ether solution (20 cm³) of **5** (100 mg) was refluxed with LAH (12 mg) for 3 h. Then, a few drops of water were added to the mixture, and the resultant supernatant was collected by decantation. The rest of the solution was acidified and extracted with ether. The combined extract was purified on a silica-gel column to give a colorless oil (68 mg, 75%), **8** [δ: 0.96 (3H, s), 1.04 (3H, s), 1.12 (3H, s), 1.2—2.6 (12H, m), 3.22 (3H, s), 3.23 (3H, m), 3.51 (1H, d, J=11 Hz), and 3.76 (1H, d, J=11 Hz). δ (C): 27.7, 27.9, 29.8, 31.7, 34.8 (2C), 37.7, 38.3, 39.1, 42.8, 49.4, 49.6, 50.0, 54.4, 66.6, 71.7, and 104.2]. Subsequently, an acetone solution (30 cm³) of **8** (50 mg) and TsOH (2 mg) was stirred at room temperature for 2 h. Subsequent silica-gel chromatography of the mixture, using ethyl acetate–hexane (2 : 3), afforded colorless needles, **10** (mp 152—153.5 °C (from ethyl acetate–hexane), 39 mg (94%) [Found: C, 71.32; H, 9.55%. Calcd for $C_{15}H_{24}O_3$: C, 71.39; H, 9.59%. δ: 0.89 (3H, s), 1.02 (3H, s), 1.24 (3H, s), 1.1—1.9 (9H, m), 2.2—2.6 (2H, m), 3.64 (1H, d, J=10 Hz), and 3.79 (1H, d, J=10 Hz). δ (C): 27.0, 29.3, 29.8, 31.9, 35.5, 35.8, 38.1, 38.6, 42.6, 47.8, 49.8, 65.5, 69.4, 72.2, and 216.2]).

*Conversion of **6** to **11**.* Much as in the above conversion of **5** to **10**, **6** (36 mg) was reduced with LAH to yield **9** (colorless plates, mp 128.5—129.5 °C (from ethyl acetate–hexane), 30 mg (86%) [δ: 0.99 (3H, s), 1.07 (3H, s), 1.12 (3H, s), 1.2—1.8 (8H, m), 2.2—2.8 (4H, m), 3.27 (3H, s), 3.34 (3H, s), and 3.60 (2H, m). δ (C): 29.7, 30.3, 30.5, 31.5, 33.7, 35.4, 35.8, 36.3, 41.9 (2C), 47.3, 49.9, 50.4, 53.9, 67.9, 68.3, and 106.1]). Subsequently, an acetone solution (30 cm³) of **9** (28 mg) and TsOH (2 mg) was kept at room temperature for 3 h. The mixture was then chromatographed (silica gel) to give colorless needles, **11** (mp 137—138 °C (from ethyl acetate–hexane), 22 mg (91%) [Found: C, 71.27; H, 9.68%. Calcd for $C_{15}H_{24}O_3$: C, 71.39; H, 9.59%. δ: 0.96 (3H, s), 1.04 (3H, s), 1.31 (3H, s), 1.15—2.0 (6H, m), 2.3—2.75 (2H, m), 2.18 (1H, t, J=7 Hz), 3.10 (2H, d, J=7 Hz), 3.61 (1H, d, J=12 Hz), and 3.84 (1H, d, J=12 Hz). δ (C): 29.1, 30.5, 31.5, 33.3, 34.7, 36.6, 37.2, 41.1, 41.7, 45.1, 47.5, 65.9, 69.1, 69.4, and 213.1]).

*The Sodium Borohydride Reduction of **10**: The Formation of Triols (**12** and **13**).* A methanol solution (20 cm³) of **10** (28 mg) was treated with $NaBH_4$ (5 mg) at 0—5 °C for 3 h. The mixture was then diluted with water, acidified with dil HCl, and extracted with ether. Subsequent silica-gel chromatography of the extracts yielded colorless needles, **13** (mp 95—96 °C (from ethyl acetate), 27 mg (95%) [Found: C, 70.70; H, 10.30%. Calcd for $C_{15}H_{26}O_3$: C, 70.83; H, 10.30%. δ: 1.00 (3H, s), 1.07 (3H, s), 1.15 (3H, s), 1.2—1.95 (8H, m), 2.2—2.7 (3H, m), 3.58 (2H, s), and 4.07 (1H, t, J=7 Hz). δ (C): 27.8, 29.0, 29.7, 30.4, 31.6, 33.3, 35.2, 37.6, 40.2, 40.6, 42.4, 49.4, 68.1, 68.5, and 72.0]), together with a colorless solid, **12** (1.4 mg (5%) [*m/e*, 254 (M^+). δ: 0.90 (3H, s), 1.00 (3H, s), 1.12 (3H, s), 1.2—2.9 (14H, m), 3.78 (2H, m), and 4.10 (1H, m). δ (C): 27.2, 29.3, 29.4, 32.2, 32.3, 37.1, 38.2, 39.2, 40.1, 43.0, 48.3, 50.1, 67.1, 72.4, and 92.6]), which was homogeneous with respect to high-pressure liquid chromatography.

*The Reduction of **11** to **14**.* A methanol solution (20 cm³) of **11** (22 mg) was treated with $NaBH_4$ (5 mg) for 3.5 h. The product mixture was then extracted with ethyl acetate and purifed by silica-gel chromatography to yield colorless needles, **14** (mp 171—172 °C (from ethyl acetate), 21 mg (95%) [Found: 70.64; H, 10.27%. Calcd for $C_{15}H_{26}O_3$: C, 70.83; H, 10.30%. δ: 1.00 (3H, s), 1.05 (3H, s), 1.10 (3H, s), 1.37—2.05 (8H, m), 2.25—2.65 (3H, m), 3.52 (1H, d, J=11 Hz), 3.65 (1H, d, J=11 Hz), and 4.03 (1H, m). δ (C): 29.8, 29.9, 31.1, 31.7, 34.9, 35.0, 37.0, 41.4, 42.3, 42.7, 48.5, 50.8, 67.3, 68.2, and 70.4]).

*Formation of an Acetal (**15**) from **13**.* A mixture of **13** (12 mg) and 2,2-dimethoxypropane (30 cm³) was kept at room temperature for 20 d. The mixture was then heated in *vacuo* to remove the volatile material. The NMR spectrum [δ: 0.98 (3H, s), 1.06 (3H, s), 1.12 (3H, s), 1.2—2.8 (11H, m), 3.11 (3H, s), 3.22 (3H, s), 3.30 (2H, m), and 3.98 (1H, t, J=8 Hz)] confirmed the formation of **15**. Every attempt to purify the material caused hydrolysis into **13**.

*An Attempted Acetal Formation of **12** or **14**.* Similarly, solutions of 2,2-dimethoxypropane (30 cm³) of both **12** and **14** (10 mg) were kept at room temperature for 20 d. The residues subsequently obtained by the evaporation of the volatile material were shown by NMR spectrometry to consist of only the recovered **12** and **14**.

*Conversion of **1** to **17**.* A sample of **1** (1.2 g) and TsOH (50 mg) were dissolved in a mixture of anhydrous benzene (150 cm³) and 1,2-ethanediol (3.1 g), and then the solution was heated for 5 h with an azeotropic removal of water. Subsequently, the mixture was washed with water and extracted by benzene. Silica-gel chromatography of the mixture yielded a colorless oil, **16** (1.5 g (quantitative) [Found: C, 67.47; H, 8.32%. Calcd for $C_{15}H_{22}O_4$: C, 67.64; H, 8.33%. δ: 1.02 (3H, s), 1.06 (3H, s), 1.2—1.4 (2H, m), 1.6—2.0 (4H, m), 2.50 (1H, m), 2.95 (1H, m), 3.71 (3H, s), 4.01 (4H, m), and 6.59 (1H, br. s). δ (C): 30.6, 31.2, 36.0, 36.8, 38.1, 38.8, 45.8, 46.4, 51.6, 64.5, 64.7, 105.5, 135.3, 136.3, and 167.1]). Subsequently, an anhydrous ether solution (50 cm³) of **16** (1.4 g) was refluxed with LAH (490 mg) for 2 h. After hydrolysis, the mixture was extracted with ether, dried (Na_2SO_4), and evaporated to remove the solvent. The residue was then dissolved in acetone (50 cm³) and treated with TsOH (10 mg). A colorless oil thus obtained, **17**, was purified (silica gel) to yield 790 mg (75%) [Found: C, 74.42; H, 9.29%. Calcd for $C_{12}H_{18}O_2$: C, 74.19; H, 9.34%. δ: 1.05 (3H, s), 1.10 (3H, s), 1.2—1.9 (3H, m), 2.3—2.4 (2H, m), 2.6—2.8 (3H, m), 4.22 (2H, br. s), and 6.08 (1H, s). δ (C): 30.6, 31.0, 38.0, 39.0, 39.8, 41.1, 45.8, 46.6, 64.0, 121.5, 166.4, and 200.3].

*Conversion of **17** to **2**.* An acetic anhydride solution (6 cm³) of **17** (755 mg) was kept at room temperature for 12 h. The residue obtained by removal of the volatile material *in vacuo* was chromatographed on silica gel to give a colorless oil, **18** (790 mg (86%) [Found: 71.26; H, 8.50%. Calcd for $C_{14}H_{20}O_3$: C, 71.16; H, 8.53%. δ: 1.05 (3H, s), 1.12 (3H, s), 1.2—1.8 (3H, m), 2.12 (3H, m), 2.3—2.5 (2H, m), 2.6—2.8 (3H, m), 4.65 (2H, br. s), and 5.95 (1H, s). δ (C): 20.5, 30.5, 30.9, 37.8, 38.8, 39.9, 40.8, 45.6, 46.4, 64.3, 122.9, 159.0, 170.0, and 198.2]). Subsequently, this **18** was dissolved in acetic acid (80 cm³) and reduced with activated zinc dust (8 g) for 6 h under reflux. The mixture was then filtered, washed with dil NaOH and $NaHCO_3$, and extracted with hexane. By silica-gel chromatography, the extract yielded a colorless oil, **2** (292 mg (50%) [Found: C, 80.69; H, 10.17%. Calcd for $C_{12}H_{18}O$: C, 80.85; H, 10.18%. δ: 1.04 (3H, s), 1.09 (3H, s), 1.2—2.0 (4H, m), 1.91 (3H, d, J=1 Hz), 2.3—2.4 (2H, m), 2.5—2.8 (2H, m), and 5.79 (1H, q, J=1 Hz). δ (C): 23.2, 30.5, 30.9, 37.5, 38.5, 40.5, 43.9, 45.6, 46.6, 125.4, 163.1, and 199.3]).

*The Photochemical Cycloaddition of **2** with **3**: The Formation of Epimeric 1 : 1-Adducts (**19** and **20**).* A benzene solution (100 cm³) of **2** (680 mg) and **3**, prepared from 2-chloro-1,1-dimethoxyethane (5 g), was irradiated externally by means of a 400-W high-pressure mercury lamp through a Pyrex glass filter for 60 h at 0—5 °C. After the evaporation of the volatile materials, the residue was chromatographed on silica gel to afford an isomeric mixture of photoadducts (**19** and **20**), which was then separated by means of a pre-packed silica-gel column to give two colorless oils, **19** (152 mg (15%) [Found: C, 71.90; H, 9.73%. Calcd for $C_{16}H_{26}O_3$: C, 72.14; H, 9.84%. δ: 1.01 (3H, s), 1.11 (3H, s), 1.28 (3H, s), 1.5—2.0 (4H, m), 2.1—2.9 (7H, m), 3.08 (3H, s), and 3.19 (3H, s). δ (C): 21.8, 31.3, 31.5, 32.3, 35.4, 41.6, 41.7, 42.9, 43.7, 43.9, 47.9, 48.6, 50.1, 54.8, 104.5, and 213.3]) and **20** (48 mg (5%) [Found: C, 71.91; H, 9.80%. δ: 0.94 (3H, s), 1.0—1.9 (5H, m), 1.08 (3H, s), 1.33 (3H, s), 2.0—2.9 (6H, m), 3.18 (3H, s), and 3.20 (3H, s). δ (C): 25.3, 28.0, 29.9, 32.0, 38.5, 40.1, 42.8, 43.0, 43.6, 44.7, 48.6, 48.7, 49.8, 55.1, 104.0, and 216.6]).

*The Grignard Methylation Reaction of **19**: The Formation of **21**.* To an ether solution (15 cm³) of methylmagnesium iodide (prepared from 500 mg of methyl iodide), an ethereal solution of **19** (82 mg) was added, drop by drop. The mixture was refluxed for 2 h and then extracted with ether. The extract was dissolved in acetone (30 cm³) containing TsOH (5 mg) and kept at room temperature for 1 h. After the removal of the solvent, the residue was chromatographed on a silica-gel column to yield **21** (81 mg (85%), colorless crystals, mp 62—63.5 °C [Found: C, 75.94; H, 10.27%. Calcd for $C_{15}H_{24}O_2$: C, 76.22; H, 10.24%. δ: 0.96 (3H, s), 1.05 (3H, s), 1.19 (3H, s), 1.1—2.0 (2H, m), 1.28 (3H, s), 2.2—2.7 (8H, m), and 3.0—3.2 (2H, m). δ (C): 22.5, 29.4, 30.6, 31.6, 33.4, 36.4, 37.0, 41.2, 41.7, 42.5, 43.9, 47.8, 63.3, 69.3, and 213.3]).

*The Grignard Methylation of **20** to **22**.* Similarly, **20** (39 mg) was methylated by methylmagnesium iodide and hydrolyzed in acetone with TsOH to give colorless plates, **22** (33 mg (80%), mp 135—136 °C [Found: C, 75.99; H, 10.18%. δ: 0.89 (3H, s), 1.05 (3H, s), 1.11 (3H, s), 1.37 (3H, s), 1.4—1.75 (5H, m), 1.8—2.5 (5H, m), and 3.0—3.1 (2H, m). δ (C): 24.8, 27.2, 28.9, 29.7, 36.4, 38.3, 38.8, 41.6, 42.6, 43.4, 43.5, 48.7, 65.7, 71.9, and 216.7]).

*The Sodium Borohydride Reduction of **21**: The Formation of **23** and **24**.* A methanol solution (20 cm³) of **21** (18 mg) was treated with $NaBH_4$ (10 mg) for 3 h at 0—5 °C. After the hydrolysis (dil HCl) of the mixture, the product was extracted with ethyl acetate and chromatographed on a silica-gel column to give colorless needles, **23** (mp 116.5—117 °C, 17 mg (93%) [Found: C, 75.37; H, 10.94%. Calcd for $C_{15}H_{26}O_2$: C, 75.58; H, 11.00%. δ: 0.99 (3H, s), 1.04 (3H, s), 1.09 (3H, s), 1.19 (3H, s), 1.2—2.0 (10H, m), 2.05—2.6 (3H, m), and 3.68 (1H, m). δ: (C): 26.4, 28.7, 30.1, 31.1, 31.2, 34.3, 36.5 (2C), 41.6, 42.9, 44.7, 46.5, 48.0, 69.3, and 76.6]), together with an epimer, **24** (colorless needles, mp 106—107 °C, ≈1 mg [Found: *m/e*, 238 (M^+). δ: 0.96 (3H, s), 1.04 (3H, s), 1.05 (3H s), 1.13 (3H, s), 1.1—2.6 (13H, m), and 4.15 (1H, t, J=8 Hz). δ (C): 19.5, 30.1, 31.1, 31.9, 32.1, 33.1, 36.2, 41.5, 42.0, 42.7, 43.2, 45.8, 47.3, 69.3, and 71.8]).

*The Sodium Borohydride Reduction of **22** to **25**.* A methanol solution (20 cm³) of **22** (15 mg) was treated with $NaBH_4$ (9 mg) for 3 h at 0—5 °C. The mixture was then acidified (dil HCl), extracted (ethyl acetate), and chromatographed (silica gel) to yield colorless needles, **25** (mp 170—171 °C (from hexane–ethyl acetate), 14.4 mg (95%) [Found: C, 75.31; H, 11.13%. δ: 0.95 (3H, s), 1.06 (3H, s), 1.14 (3H, s), 1.22 (3H, s), 1.2—2.4 (13H, m), and 3.89 (1H, m). δ (C): 28.7, 29.6, 30.8, 30.9, 37.3, 38.0, 39.1, 42.7 (3C), 46.4, 46.8, 47.2, 71.6, and 74.0]).

*The Formation of a Dithiolane (**26**) from **21**.*[7] To a glacial acetic acid solution (2 cm³) of **21** (44 mg) and 1,2-ethanedithiol (75 mg), BF_3 etherate (50 mg) was added, after which the mixture was kept at room temperature for 12 h. The mixture was then diluted with water and extracted with hexane. The extract was chromatographed (silica gel) to give a colorless oil, **26** (30 mg (55%) [δ: 0.99 (3H, s), 1.00 (3H, s), 1.39 (3H, s), 1.60 (3H, s), 1.0—2.0 (5H, m), 2.0—2.4 (3H, m), 2.70 (1H, m), 3.0—3.3 (4H, m), and 5.29 (1H, br. s)]).

*The Thio-acetal Formation of **22** to **27**.*[7] Similarly, a glacial acetic acid solution (2 cm³) of **22** (15 mg) and 1,2-ethanedithiol (50 mg) was kept at room temperature for 12 h. The mixture was then hydrolyzed (dil HCl), extracted (ethyl acetate), and chromatographed (silica gel) to give colorless oils, **27** (14 mg (93%) [δ: 1.01 (3H, s), 1.03 (3H, s), 1.29 (3H,

s), 1.58 (3H, br. s), 1.1—3.1 (8H, m), 3.05—3.3 (4H, m), 3.44 (1H, m), and 5.13 (1H, s)]).

The Raney-nickel Desulfurization of ***26****: The Formation of Protoillud-7-ene (****28****).* An ethanol solution (30 cm³) of **26** (30 mg) was refluxed with Raney nickel (W-1) (2 g) for 5 h. Then, the catalyst was removed by filtration and washed several times with ethanol. The solvent was evaporated *in vacuo* to leave a colorless oil, which was subsequently chromatographed (silica gel) to give **28** (6.3 mg (30%) [δ (C): 21.3, 24.4, 26.3, 29.7, 30.2, 32.1, 37.5, 38.5, 39.3, 40.8, 41.7, 45.5, 48.2, 125.6, and 132.1]). The ^{1}H-NMR [δ: 0.98 (6H, s), 1.17 (3H, s), 1.59 (3H, br. s), 1.9—2.8 (11H, m), and 5.11 (1H, br. s)] was identical with that of the authentic sample.

The Raney-nickel Desulfurization of ***27****.* Similarly, **27** (19 mg) and Raney nickel (W-1) (1 g) were mixed in ethanol (30 cm³) and then refluxed for 5 h to give and *epi*-protoillud-7-ene, **29** (3 mg (20%) [Found: *m/e*, 204 (M^+). δ: 0.98 (3H, s), 1.01 (3H, s), 1.11 (3H, s), 1.2—2.2 (11H, m), 1.61 (3H, br. s), and 5.42 (1H, br. s). δ (C): 20.7 (2C), 28.5, 28.8, 29.2, 29.8, 38.1, 39.2, 40.5, 42.0, 42.3, 43.5, 48.6, 123.9, and 134.0]).

The LAH Reduction of ***30****.* A sample of **30** (120 mg), prepared by a previously described method,[3] was dissolved in anhydrous ether (120 cm³) and reduced by LAH (20 mg) at 35 °C. The reaction mixture was then hydrolyzed, extracted with ether, and chromatographed (silica gel) to give **31** (a colorless oil, 110 mg (95%) [Found: M. W., 238.1959. Calcd for $C_{15}H_{26}O_2$: 238.1933. δ: 0.92 (3H, s), 0.97 (3H, d, J=7 Hz), 1.01 (3H, s), 1.2—2.6 (14H, m), 3.49 (1H, br. s), 3.50 (1H, d, J=10 Hz), and 3.64 (1H, d, J=10 Hz). δ (C): 14.8, 17.7, 26.5, 26.9, 29.4, 30.0, 36.6, 37.3, 40.0, 41.7, 43.1, 44.7, 47.9, 69.6, and 77.5]) as the sole product.

The Reduction of ***30*** *with Sodium Borohydride.* A methanol solution (10 cm³) of **30** (20 mg) was treated with $NaBH_4$ (10 mg) at 0—15 °C for 2 h. The mixture was then acidified by dil HCl and extracted with ether. Subsequent silica-gel chromatography of the extract yielded a colorless oil, **32** (15 mg (74%) [Found: M. W., 280.2040. Calcd for $C_{17}H_{28}O_3$: 280.2038. δ: 0.92 (3H, s), 0.99 (3H, d, J=5 Hz), 1.02 (3H, s), 1.0—2.6 (13H, m), 2.07 (3H, s), 3.51 (1H, br, s), 3.91 (1H, d, J=11.5 Hz), and 4.15 (1H, d, J=11.5 Hz). ν: 3640—3500, 2940, 1735, and 1240 cm^{-1}]).

The Acetylation of ***31****.* A sample of **31** (10 mg) was treated with acetic anhydride (0.5 cm³) and pyridine (0.3 cm³) at room temperature for 12 h. The usual work-up of the mixture on a silica-gel column subsequently yielded a colorless oil (10 mg, 85%), which was identical with the authentic **32** obtained by the $NaBH_4$ reduction of **30**.

The Chromium(VI) Oxide Oxidation of ***31****: The Formation of 8,13-Dioxoprotoilludane (****33****).* A dichloromethane solution (5 cm³) of **31** (10 mg) was treated with the complex prepared from CrO_3 (30 mg) and pyridine (47 mg) at room temperature for 15 min. The supernatant was collected by decantation, and the residue was washed with ether. The combined organic solution was washed with dil NaOH and dil HCl. The extract was then chromatographed (silica gel) to yield a colorless oil, **33** (8.5 mg (86%) [Found: M. W., 234.1698. Calcd for $C_{15}H_{22}O_2$: 234.1620. δ: 0.96 (3H, d, J=7 Hz), 0.98 (3H, s), 1.09 (3H, s), 1.2—2.2 (8H, m), 2.4—3.4 (4H, m), and 9.57 (1H, s). δ (C): 10.4, 16.9, 25.2, 27.8, 29.5, 39.3 (2C), 40.9, 44.5, 44.7, 44.8, 51.2, 51.3, 201.0, and 215.8]).

The Reaction of 1,2-Ethanedithiol with ***33****.* To a benzene solution (10 cm³) of **33** (50 mg), 1,2-ethanedithiol (400 mg) was added, together with the BF_3 etherate (0.2 cm³). The mixture was kept at room temperature for 20 min, and then it was diluted with water and extracted by ether. The extracts was chromatographed (silica gel) to give a colorless oil, **34**, (52 mg (75%) [δ: 0.88 (3H, d, J=7 Hz), 0.98 (3H, s), 1.06 (3H, s), 1.2—3.2 (12H, m), 3.26 (4H, s), and 4.85 (1H, s)]).

The Raney-Nickel Desulfurization of ***34*** *to* ***35****.* An ethanol solution (50 cm³) of **34** (50 mg) was treated with Raney nickel (W-1) (2 g) for 1 h. The mixture was then filtered, the residue was washed, and the extract was purified on a silica-gel column; the colorless oil thus obtained (25 mg, 74%) was **35** [Found: M.W., 220.1799. Calcd for $C_{15}H_{24}O$: 220.1827. δ: 0.88 (3H, d, J=6 Hz), 0.97 (3H, s), 1.08 (3H, s), 1.19 (3H, s), and 1.2—3.2 (12H, m). δ (C): 10.6, 15.9, 27.1, 27.6, 29.7, 30.6, 37.6, 39.4, 40.3, 45.4 (2C), 47.8, 50.3, 50.6, and 218.0].

The LAH Reduction of ***35*** *to* ***36****.* A sample of **35** (10 mg) was dissolved in ether (15 cm³) and reduced with LAH (5 mg) at room temperature for 3 h. The mixture was then acidified with dil HCl and extracted with ether. The chromatography (silica gel) of the extract afforded a colorless oil, **36** (8.5 mg (84%) [Found: M. W., 222.1994. Calcd for $C_{15}H_{26}O$: 222.1984. δ: 0.93 (3H, s), 0.97 (3H, d, J=7 Hz), 1.01 (3H, s), 1.08 (3H, s), 0.9—2.5 (13H, m), and 3.47 (1H, br. s). δ (C): 14.0, 16.9, 27.1, 28.6, 29.6, 30.8, 32.0, 37.7, 37.8, 42.2, 43.1, 43.5, 44.6, 47.9, and 76.7]).

An Acetylation of ***36*** *under Forced Conditions. The Formation of* ***37****:* A sample of **36** (5 mg) was dissolved in acetic anhydride (0.3 cm³) and the BF_3 etherate (0.03 cm³) for 1 h at room temperature. The mixture was then diluted with water and extracted with ether. Subsequent silica-gel chromatography of the extract gave a colorless oil, **37** (3 mg (50%) [Found: *m/e*, 264 (M^+). δ: 0.88 (3H, s), 0.91 (3H, d, J=6.5 Hz), 0.96 (3H, s), 1.08 (3H, s), 0.8—2.4 (12H, m), 2.10 (3H, s), and 4.57 (1H, br. s). ν: 2950, 1740, 1240, and 1120 cm^{-1}]).

An attempted acetylation, under ordinary conditions (acetic anhydride with pyridine at room temperature) gave only the recovered starting materials.

The Stereochemical Course of the Photochemical Berson-Willcott Rearrangement of *exo*-1-Methoxycarbonylmethyl-3-*t*-butyl-1a,7b-dihydro-1*H*-cyclopropa[*a*]naphthalene to 7-Methoxycarbonylmethyl-5-*t*-butyl-7*H*-benzocycloheptene

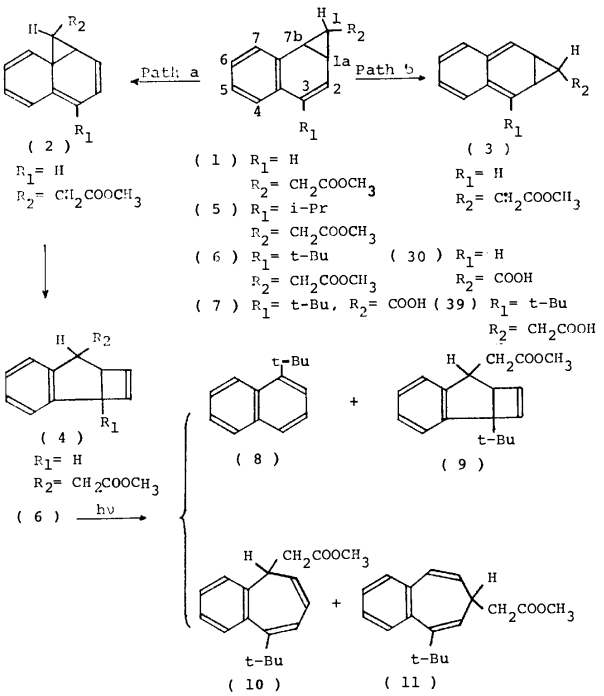
Masahiko KATO,* Keizo TAKATOKU, Satoru ITO, Mitsuru FUNAKURA, and Toshio MIWA
Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558
(Received February 27, 1980)

The photolysis of (1*S*)-*exo*-1-methoxycarbonylmethyl-3-*t*-butyl-1a,7b-dihydro-1*H*-cyclopropa[*a*]naphthalene gave (7*S*)-5-*t*-butyl-7-methoxycarbonylmethyl-7*H*-benzocycloheptene by a 1,5-sigmatropic shift, proving the rearrangement to proceed with the inversion of the configuration of the migrating center.

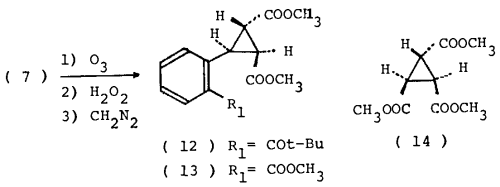
The photochemical Berson-Willcott rearrangement of 1a,7b-dihydro-1*H*-cyclopropa[*a*]naphthalenes has been studied by Pomerantz,[1] Swenton,[2,3] and by us.[4-6] The rearrangement has thus been clarified to proceed *via* two 1,5-shift intermediates[2,3,6] (*e.g.* **2** and **3**).

In the earlier communication,[4] we clarified the rearrangement of methoxycarbonylmethyl derivative (**1**) along the path i proceeded *via* a mechanism with inversion of the configuration of C-1. Because of the molecular symmetry of **3**, it was impossible to establish the stereochemical course of path ii by using this starting material, and accordingly we chose 3-substituted derivative of **1** as a starting material. In a previous paper, we reported the photochemistry of 1a,7b-dihydro-1*H*-cyclopropa[*a*]naphthalenes (**5**) substituted with an isopropyl group at the C-3. In the present study we investigated the photolysis of the *t*-butyl homologue (**6**), with a hope to obtain much larger amount of an unsymmetrical rearrangement product of the path ii,[7] which would allow us to establish the stereochemistry of the reaction.

The starting acid, 3-*t*-butyl-1a,7b-dihydro-1*H*-cyclopropa[*a*]naphthalene-1-*exo*-carboxylic acid (**7**) was prepared from 1-*t*-butylnaphthalene (**8**) through the reaction with ethyl diazoacetate in the presence of copper powder. The acid **7** was transformed by Arndt-Eistert reaction to the next higher homologue (**6**), which was found to be thermally stable below 100 °C.[8] The methyl ester **6** in methanol was photolysed with the aid of a high pressure mercury arc (UM-452) through a Pyrex filter. The products were, in addition to **8** and a small amount of a cyclobut[*a*]indene (**9**) (*exo* : *endo*= 1 : 1), a 5*H*-benzocycloheptene (**10**) and a 7*H*-benzocycloheptene (**11**).[7]



Scheme 1.



Scheme 2.

The acid **7** was carefully resolved into optically active components *via* its brucine salt. The absolute configuration of (+)-**7** was established as (1*R*) by ozonization, oxidative cleavage of the ozonide and subsequent esterification of the product with diazomethane. Of three products, (**12**—**14**), **13** was identical with a sample of known stereochemistry, (1*S*,2*S*)-3-[*o*-(methoxycarbonyl)phenyl]-1,2-bis(methoxycarbonyl)cyclopropane.[4] The optical purity of **7** was estimated, after transformation to its methyl ester, by NMR measurement with use of a chiral shift reagent, tris[3-(2,2,3,3,-4,4,4-heptafluoro-1-hydroxybutylidene)-*d*-camphorato]-europium(III). In the NMR spectra, the racemic ester showed two proton signals for the methoxycarbonyl group in equal intensities, but the (+)-ester showed one strong signal without accompanying signal more intense than 5% of the main one (Fig. 1).

The independent photolysis of each optically active ester **6** under the same conditions as described above gave the optically active esters, **9**, **10**, and **11** as shown in Table 1.

The 7*H*-benzocycloheptene, (+)-**11**, $[\alpha]_D$+127°, was hydrogenated over 10% Pd-C to give (−)-dihydro derivative (**15**), $[\alpha]_D$−61.2°, which was oxidized with purple benzene and was esterified to give a (+)-keto diester (**16**), $[\alpha]_D$+16°. In the same way, (−)-**11**, $[\alpha]_D$−89.9°, was transformed to (−)-**16**, $[\alpha]_D$−15.6°.

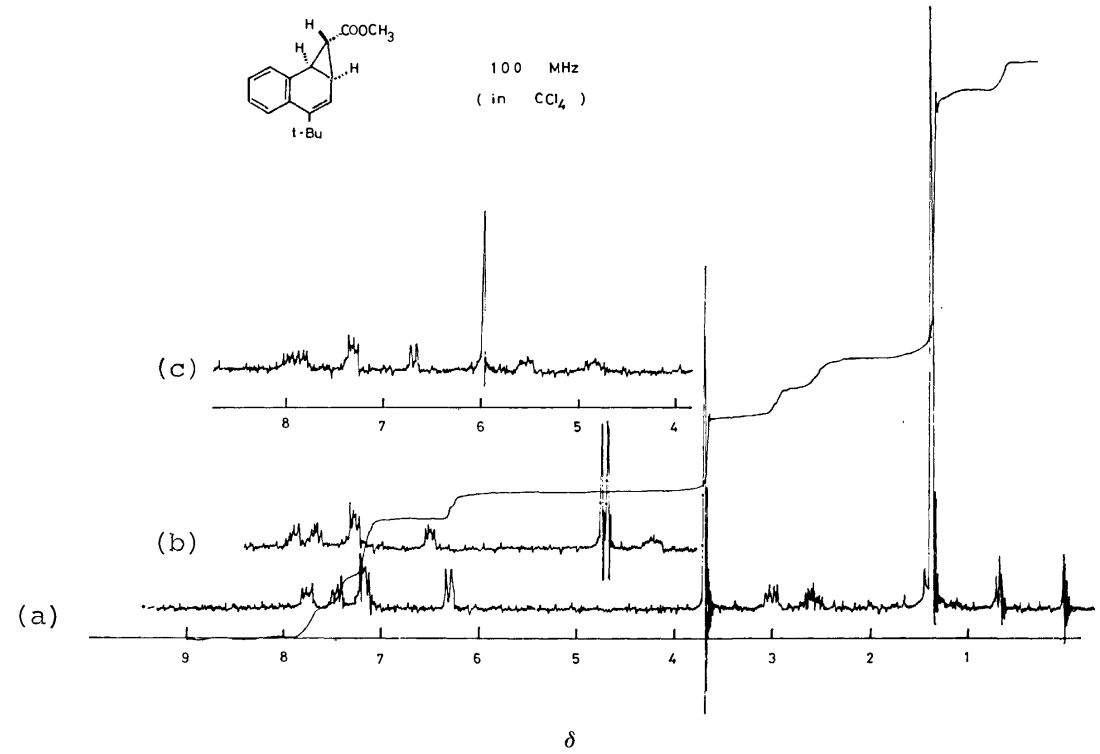


Fig. 1. ^{1}H NMR spectra of the methyl ester of **7**.
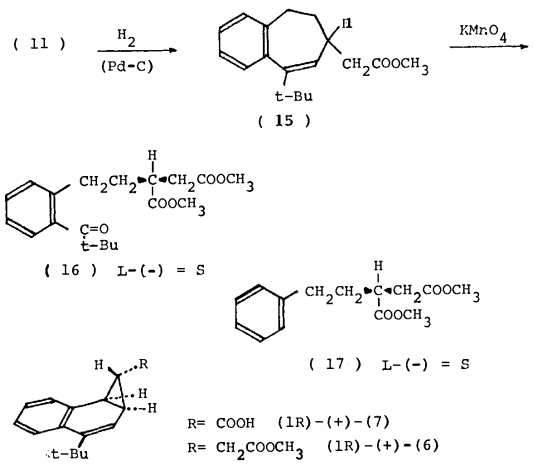
(a) Original spectrum of the racemic ester, (b) after addition of a chiral shift reagent to the above ester, (c) after addition of a chiral shift reagent to the optically active ester, obtained from (+)-acid **7**, $[\alpha]_D = +14.3°$.

Table 1. Specific rotation relationships between optically active ester **6** and the photolysis products

Starting materials		Products			
Acid **7**	Ester **6**		**9**	**10**	**11**
+14.3°	+44.7°	(**9a**)	−55°	−88.3°	+127°
		(**9b**)	+4.2°		
−13.7°	−38.6°	(not measured)			−89.9°

The molecular formula ($C_{19}H_{26}O_5$) of (+)-keto diester **16** was established by elementary analysis and the mass spectrum (M^+ 334). In the proton NMR spectrum, it showed an intense singlet of *t*-butyl at 1.24 ppm, two sharp singlets of methoxycarbonyl group at 3.65 and 3.70 ppm, and 4H broad multiplet of aromatic proton signal centered at 7.2 ppm. All the signals for aliphatic protons, except *t*-butyl one, are very similar both in the shape and the chemical shifts to those of dimethyl 2-phenylethylsuccinate **17**. In the IR spectrum, it showed two carbonyl stretching bands at 1733 and 1689 cm^{-1}, in which the former was assigned to two ester-carbonyl groups and the latter to a keto-carbonyl bound to a phenyl group. A similarity of the NMR spectrum to that of **17** and the exsistence of a disubstituted benzene ring, in addition to a consideration of the structure of the starting material **15**, lead to the structure **16** for the keto diester. The UV spectrum of **16** showed no absorption maximum near 242 nm, the λ_{max} commonly observed in the alkyl phenyl ketones, but only shoulder of ε 2200 at 242 nm. This means that the conjugation between carbonyl and phenyl groups is hindered by a bulky *t*-butyl group (dihedral angle between carbonyl sp^2 and aromatic ring planes is calculated to be 65°).[9] Because the effect of carbonyl function on the ORD curves is believed to be small when the function is located far apart from the optically active center,[10] it would be possible to determine the absolute configuration of dimethyl 2-(*o*-pivaloylphenyl)ethylsuccinate (**16**) by comparing its ORD curve with that of optically active dimethyl 2-phenylethylsuccinate (**17**) of known configuration. In general, it has been shown that L-series of the alkyl or aralkylsuccinic acid show the minus Cotton effect or minus plain curves as follows.[11]



Scheme 3.

Compound	$[M]_{MeOH}$	Observed at	Type
(L)-(−)-Phenylsuccinic acid	−15450°	231 nm	minimum
(L)-(−)-Benzylsuccinic	−5260°	227 nm	minimum
(L)-(−)-2-Phenylethylsuccinic (**17**)	−4180°	222 nm	end absp.
(L)-(−)-3-Phenylpropylsuccinic	−2550°	221 nm	end absp.

The negative rotation of the ORD curve of (−)-**16** supports the (*S*)-configuration. The result shows that (−)-**11** gave (+)-**15**, which was transformed into (*S*)-(−)-**16** by oxidation.

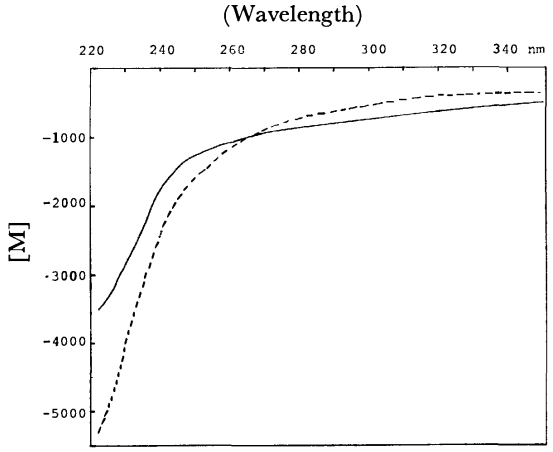


Fig. 2. ORD curves of the oxidation product **16**, $[\alpha]_D$ = −15.4° (solid line) and an authentic **17**, $[\alpha]_D$ −39.7° (dotted line), dissolved in methanol.

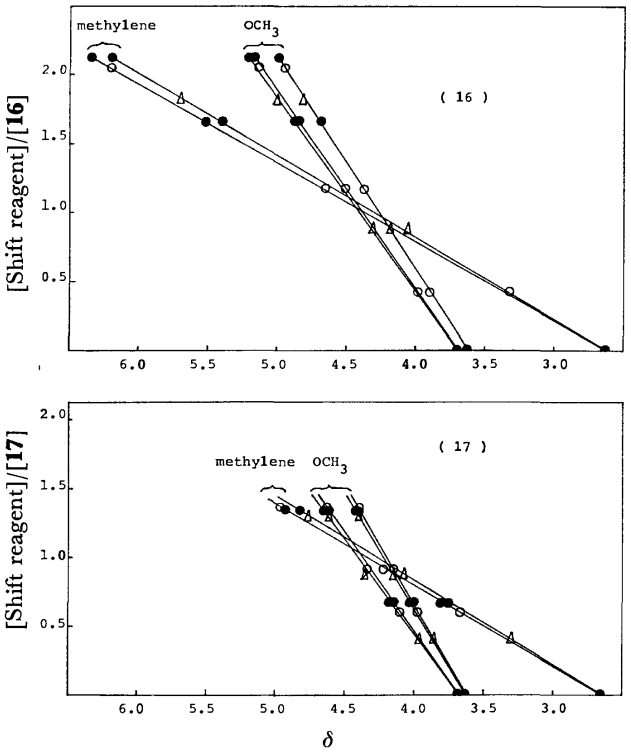

Fig. 3. Chemical shift changes of two methoxyl proton signals and one of methylene proton signal caused by the addition of a chiral shift reagent for compounds **16** and **17**.
△: (*S*)-(−)-Series, ○: (*R*)-(+)-series, ●: (±)-series.

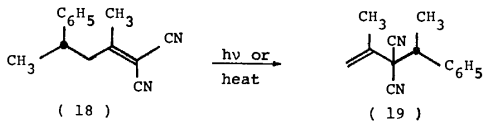
In order to obtain information about the relationship between absolute configurations and the NMR signal shifts caused by a chiral shift reagent,[12] we compared the NMR spectra between the optically active dimethyl 2-phenylethylsuccinates with and without substituent on the phenyl group.

We found that there is a regularity on the shift caused by *tris*-[3-(2,2,3,3,4,4,4-heptafluoro-1-hydroxybutylidene)-*d*-camphorato]europium(III), *i.e.*, the methoxyl-proton signal of lower field of the two methoxyl-proton signals of *S*-(−)-series shifted to the lower field more profoundly than those of *R*-(+)-series, but the signals assigned to one of methylene-protons adjacent to methoxycarbonyl group in the *S*-(−)-series shifted to a lesser extent than those in the *R*-(+)-series (Fig. 3).

From the above results, the two series of correlations among the optically active products of the above transformations were established: *S*-(−)-**16**→*S*-(+)-**15**→*R*-(−)-**11**→(1*S*)-(−)-**6**→(1*S*)-(−)-**7**; *R*-(+)-**16**→*R*-(−)-**15**→*S*-(+)-**11**→(1*R*)-(+)-**6**→(1*R*)-(+)-**7**. Based on these experimental results, we can conclude that the photo-induced rearrangement of **6** to **11** must have proceeded with inversion of the configuration at C-1 in agreement with the prediction of the Woodward-Hoffmann rule.[13,14]

Discussion

The photochemical 1,3-sigmatropic rearrangement of **18** was established to proceed with retention of the configuration at the migrating carbon atom.[15,16] The thermal and photochemical rearrangements including cyclopropane ring are complicated because of the accompanying opening-reclosure process of three membered ring.[17–20] The thermal 1,4-shift in bicyclo-[3.1.0]hexenyl cation (**20**) is a rare example in which such an *exo-endo* isomerization does not accompanied by, and was found to proceed *via* slither motion with inversion of the configuration at C-6.[21]

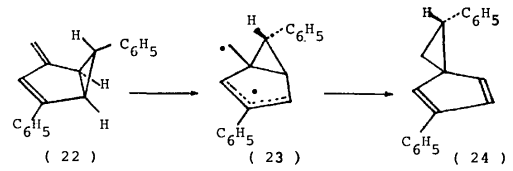


Scheme 4.

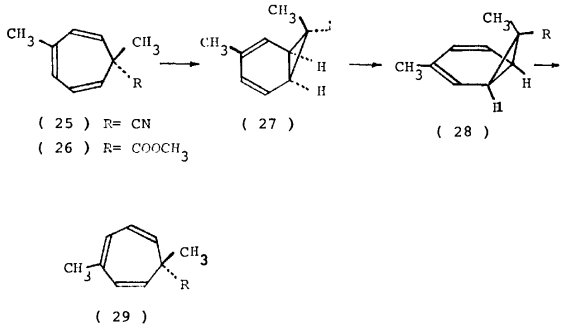
Scheme 5.

Furthermore, Zimmerman established that 4-methylene-2,6-*exo*-diphenylbicyclo[3.1.0]hept-2-ene(**22**) undergoes photoinduced skeletal rearrangement in a manner of slither motion with inversion of the configuration of the shifting carbon center, for which he proposed to rename "bicycle reaction."[22,23]

The Berson-Willcott rearangement of cycloheptatrienes is thought to proceed *via* interconversion among its norcaradiene valence tautomers.[24] The stereochemi-



Scheme 6.



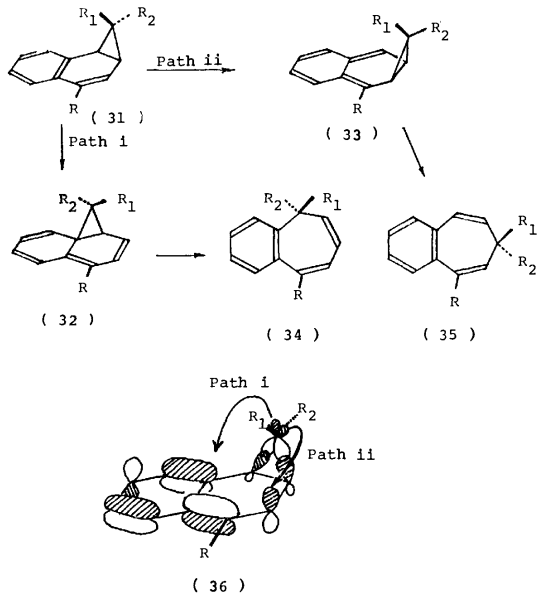
Scheme 7.

cal course of the benzophenone sensitized photochemical rearrangements of **25** and **26** had been studied by Klärner who found that the rearrangement is highly stereoselective (**25** 92% and **26** 76%) and proceeds with inversion at the migrating carbon C-7 similarly to the corresponding thermal rearrangement.[25–28] He proposed a stereoselective diradical process of the triplet states to account for the observed partial racemization.[29] These results are in line with the stereochemical course for path i of our previous results on the direct irradiation of 1a,7b-dihydro-1*H*-cyclopropa[*a*]-naphthalene derivative **1**. The rearrangement *via* path i was highly stereoselective as to configuration at C-1, even when an *exo-endo* mixture, after thermal equilibration of the methyl ester **1** obtained from optically active acid **30**, was used for the photolysis: That is, the product **4** (R_2=CH_2COOCH_3(*exo*)) retained the optical activity in high degree.

Furthermore, we found earlier that, when the *exo* and *endo* isomers of isopropyl derivative **5** were independently photolysed, they gave, without mutual interconversion, the same products each in so different rates as to support a mechanism of "bicycle reaction."[22]

From the above mentioned results, it is unlikely to assume a different stereochemical course for the *endo* isomer from that for the *exo* one. If the *exo*-**1** rearranges into *exo*-**4** *via* a course leading to an inversion at the migrating center and the *endo*-**1** does into *exo*-**4** *via* a course leading to a retention at the migrating center owing to some stereochemical reasons of the reaction, and *vice versa*, the optically active *exo-endo* mixture of **1** would give *exo*-**4** with considerable racemization. But this was not the case.

In the present case, the photochemical isomerization of optically active *exo*-1-ester **6** (optical purity>95%) to *endo*-1-ester was not observed during the reaction and the product **11** *via* path ii after photolysis retained its optical activity in high degree (>95%). For these reasons, we can conclude that the Berson-Willcott rearrangement of 1-methoxycarbonylmethyl-1a,7b-dihydro-1*H*-cyclopropa[*a*]naphthalenes by direct irradiation, in general, takes place by way of 1,5-shift to both directions in a manner of "bicycle reactions," as shown in Scheme 8, in line with the prediction of the Woodward-Hoffmann rule [*Cf.* (**36**)].[6,14]



Scheme 8.

Experimental

The NMR spectra were taken on a JEOL Model PS-100 spectrometer with carbon tetrachloride as the solvent and TMS as the internal standard, unless otherwise specified. The chemical shifts are expressed in ppm from TMS. The IR spectra were recorded on a JASCO spectrometer Model IRE and the UV on a Hitachi Recording Spectrometer Model 323 with 95% ethanol as the solvent. GLC analysis was carried out on a Varian Aerograph Model 90P gas chromatograph under quoted conditions. The light source for photolysis, used throughout the experiments, was a Ushio High Pressure Mercury Lamp, UM-452, with Pyrex filter. The polarimeter used was a Rex Photoelectric one, type NEP-2, and the CD/ORD curves were recorded on a JASCO J-20 Automatic Recording Spectropolarimeter.

*3-t-Butyl-1a,7b-dihydro-1*H*-cyclopropa*[a]*naphthalene-1-carboxylic Acid* (**7**). To a melt of 1-*t*-butylnaphthalene (**8**) (37 g, 0.201 mol) containing 200 mg of copper powder, maintained at 145—150 °C, was added dropwise ethyl diazoacetate (5.14 g, 0.045 mol) over a period of 70 min with vigorous stirring. The mixture was further stirred at 145 °C for 1 h, and then 33.4 g of **8** was recovered by distillation under reduced pressure. The experiment was repeated six times with use of recovered **8**, and the collected residue in CH_2Cl_2 was filtered from copper powder and subsequently distilled to give 23 g of a mixture of three isomeric mono-esters, bp 120—143 °C (0.035 mmHg), contained 50% of ethyl ester of **7**. The oily product (11.8 g, 43.7 mmol) dissolved in 1 M 85% aq ethanolic KOH (130 ml) was refluxed for 20 h. The resulting solution was then diluted with water (130 ml) and reduced to a half volume under reduced pressure. After being washed with ether, the ice-cooled aq solution was acidified carefully with cold 2 M HCl in the presence of ether (100 ml) with stirring. The separated aq solution was extracted three times with ether. Usual work-up[6] of the combined ether solution gave **7** as

colorless crystals (3.31 g: 24% from **8**), mp 199—200 °C. IR ν_{max} (Nujol): 2670, 2580, 1690, 1321, 1214, 965, 897, 879, 771 cm^{-1}. NMR ($CDCl_3$): δ=0.75 (1H, dd, J=3.5, 3.5 Hz, H_1), 1.35 (9H, s), 2.72 (1H, m, H_{1a}), 3.16 (1H, dd, J=3.5 8.5 Hz, H_{7b}), 6.27 (1H, d, J=5.5 Hz), 7.0—7.9 (4H, m, Ar-H). Found: C, 79.37; H, 7.48%. Calcd for $C_{16}H_{18}O_2$: C, 79.37; H, 7.49%.

Optical Resolution of the Carboxylic Acid **7**. A solution of freshly crystallized brucine (8.12 g, 18.8 mmol) and the carboxylic acid **7** (4.06 g, 16.8 mmol) dissolved in 50% aq methanol was allowed to stand for 36 d in a refrigerator, when crystals of the brucine salt have developed. Repeated fractional crystallization of the salt from aq methanol gave colorless prisms (1.06 g), mp 108—111 °C, $[\alpha]_D^{26}$ −44° (c= 1.1, $CHCl_3$). Extraction of this salt dissolved in $CHCl_3$ with 2 M aq NaOH, acidification of the extracts, and extraction with ether followed by recrystallization of the residue, gave colorless amorphous powder (580 mg), $[\alpha]_D^{27}$ −13.7° (c=1.0, $CHCl_3$). Similar treatment of the brucine salt obtained from the filtrate of recrystallization gave the (+)-acid; $[\alpha]_D^{19}$ +14.3° (c=1.1, $CHCl_3$), mp 84.5—86 °C as a colorless amorphous solid. The IR spectra of these optically active acids were identical with those of the racemic acid except for the absorptions at 965 and 879 cm^{-1}, which the active forms lacked. The optical purity of the (+)-acid was estimated to be more than 95% by comparison of the NMR spectrum of its methyl ester with that of the racemic one, using a chiral shift reagent, tris[3-(2,2,3,3,4,4,4-heptafluoro-1-hydroxybutylidene)-*d*-camphorato]Eu(III), as shown in Fig. 1.

The Absolute Configuration of (+)-Acid **7**. Ozone generated from an ozonizer was passed through the carboxylic acid **7** suspended in 75% aq acetic acid (20 ml) for 3 h at room temperature. After addition of 10% aq H_2O_2 (12 ml), the resulting solution was kept at room temperature overnight and subsequently concentrated to dryness. The residue was then dissolved in 5% aq sodium hydrogen carbonate and washed with ether. The acidic fraction obtained from acidified aq solution was then treated with ethereal diazomethane. The GLC separation of the products gave three main peaks; (1) **14**, (4 mg; retention time (r.t.), 2 min); (2) **13** (10 mg; r.t. 10 min); (3) **12** (6 mg; r.t. 14 min). The compound **13** showed an identical NMR spectrum with that of a sample obtained from permanganate-oxidation and subsequent esterification of **30**. **12** NMR δ: 1.25 (9H, s), 2.2—3.1 (3H, m), 3.48 (3H, s), 3.67 (3H, s), 7.17 (4H, bs). IR ν_{max} (liq. film): 1688, 1725 cm^{-1}. Dimethyl *c*-3-[*o*-(methoxycarbonyl)phenyl]-*r*-1,*t*-2-cyclopropanedicarboxylate **13** NMR δ: 2.60 (2H, AB part of ABX), 3.37 (1H, X part of ABX), 3.44 (3H, s), 3.76 (3H, s), 3.89 (3H, s), 7.2—8.0 (4H, m). IR ν_{max} (liq. film): 1723, 1600, 1440, 1308, 1260, 1200, 1175, 1090, 1028, 908, 756 cm^{-1}. Found: C, 62.06; H, 5.67%. Calcd for $C_{15}H_{16}O_6$: C, 61.64; H, 5.52%.

Similar experiment with the (+)-acid **7**, $[\alpha]_D$ +11.7° (c= 1.2, $CHCl_3$), gave the triester **13**, $[\alpha]_D$ −55.8°, which had been previously related to the (+)-acid **30**, $[\alpha]_D$ +150°, of known stereochemistry (1*R*-(+)).[4]

rac- *and (+)-3-t-Butyl-1a,7b-dihydro-1-exo-methoxycarbonylmethyl-1H-cyclopropa[a]naphthalene (6)*. To a stirred and cooled solution of racemic acid **7** (1.45 g, 6.0 mmol), dissolved in anhydrous benzene (120 ml), was added oxalyl dichloride (3.05 g, 24 mmol) at below 15 °C. After stirring the solution for 4.5 h at 6—10 °C, it was evaporated below 20 °C and the residue was evaporated with benzene (three times each 15 ml), under reduced pressure to give the acid chloride (**37**) as a yellow liquid [IR $\nu_{c=o}$: 1760 cm^{-1}]. To a dried ether solution (20 ml) of diazomethane, prepared from *N*-nitroso-*N*-methylurea (6.08 g), was added dropwise **37** dissolved in benzene (10 ml) over a period of 15 min with cooling (ice-water). After further stirring for 14 h at room temperature, the white floatings were filtered off, and the filtrate was concentrated to dryness to give the diazo ketone **38** as a yellow liquid (2.01 g) which solidified soon. The diazo ketone **38**, dissolved in methanol (2.01 g/650 ml) was divided into two portions. Each portion was independently irradiated under nitrogen atmosphere with an HPL for 16 min with external cooling (ice). The solutions were combined and subsequent evaporation of the solvent left an orange liquid (1.82 g), which was chromatographed on silica gel (70 g) with hexane–ether (93 : 3 v/v) as the solvent to give a pale yellow liquid (**6**) (1.02 g; 61% yield). IR ν_{max} (liq. film): 2956, 1736, 1489 1440, 1372, 1251, 1197, 1176, 766, 758 cm^{-1}. NMR δ: 0.22 (1H, m, H_1), 1.36 (9H, s), 1.84 (1H, m, H_{1a}), 2.24 (1H, dd, J=4, 8 Hz, H_{7b}), 3.68 (3H, s), 6.24 (1H, d, J=6 Hz), 7.0—7.8 (4H, m).

For elementary analysis, **6** (173 mg, 0.64 mmol) was hydrolyzed with 1 M 85% aq ethanolic KOH (10 ml) by refluxing for 2 h. The crystalline acid **39** (74 mg, 47%), was obtained by usual work-up and subsequent recrystallization from aq ethanol, mp 154.5—155.5 °C. IR ν_{max} (Nujol): 1700 cm^{-1}. Found: C, 79.61; H, 7.77%. Calcd for $C_{17}H_{20}O_2$: C, 79.65; H, 7.86%.

The same experiment was carried out with the optically active acid **7** (442 mg, 1.83 mmol), $[\alpha]_D$ +14.3°, to give the ester **6** (233 mg; 43%), $[\alpha]_D^{24}$ +44.7° (c=1.03, $CHCl_3$). IR ν_{max} (liq. film): 2956, 1736, 1489, 1440, 1372, 1251, 1197, 1176, 766, 758 cm^{-1}. The spectral data (IR, UV, and NMR) were identical with those of racemic ester **6**.

Photolysis of 3-t-Butyl-1a,7b-dihydro-1-exo-methoxycarbonylmethyl-1H-cyclopropa[a]napthalene (6). The methyl ester **6** (250 mg), dissolved in methanol (300 ml), was irradiated with an HPL through a Pyrex filter for 1 h under nitrogen atmosphere. After evaporation of the solvent, the residue was separated with use of GLC (10% Apiezone L on Chromosorb WAW, column temperature 203 °C): (1) **8** (r.t. 7 min), (2) *exo*- and *endo*-2a,7b-dihydrocyclobut[*a*]indenes **9** (r.t. **9a**, 13.6 min, **9b**, 16 min), (3) methyl 5-*t*-butyl-7*H*-benzocyclohepten-7-acetate (**11**) (r.t. 17 min), (4) methyl 9-*t*-butyl-5*H*-benzocycloheptene-5-acetate (**10**) (r.t. 21 min). The structures of these compounds were assigned based on the spectral data by comparing with those of the corresponding isopropyl derivatives.[6,30] **9a**: NMR δ: 1.08 (9H, s), 2.1—2.74 (2H, m), 2.98 (1H, bd, J= 1.5 Hz), 3.28 (1H, bddd, J=10, 5.5, 1.5 Hz), 3.68 (3H, s), 6.10 (1H, dd, J=2.7, 1.0 Hz), 6.38 (1H, d, J=2.7 Hz), 7.0—7.5 (4H, m). **9b**: NMR δ: 1.03 (9H, s), 2.2—2.8 (2H, m), 3.4—3.7 (2H, m), 3.68 (3H, s), 5.98 (1H, d, J=2.8 Hz), 6.48 (1H, d, J=2.8 Hz), 6.9—7.4 (4H, m) [contaminated with a small amount of aromatic impurities]. **10**: UV λ_{max} (EtOH): 262; λ_{min}: 243 nm. NMR δ: 1.36 (9H, s), 2.8—3.0 (3H, b), 3.62 (3H, s), 5.44 (1H, dd, H_6), 5.96 (1H, dd, H_7), 6.66 (1H, bd, H_8), 7.0—7.1 (3H, m), 7.5—7.66 (1H, m) [double irradiation: $J_{5,6}$=5 Hz, $J_{6,7}$=10 Hz, $J_{7,8}$=5 Hz; contaminated with a small amount of impurities]. **11**: UV λ_{max} (EtOH): 227, 247 (infl.) nm. NMR δ: 1.16 (9H, s), 2.24 (1H, m), 2.54 (2H, bd, J=7.5 Hz), 3.62 (3H, s), 5.75 (1H, d, J=10 Hz), 5.93 (1H, dd, J=10, 5 Hz), 6.48 (1H, dd, J=10, 1.8 Hz), 7.03—7.35 (3H, m), 7.6—7.8 (1H, m). Mass spectrum: *m/e* (%); 270 (40(M^+)), 255 (61), 214 (60), 197 (55), 181 (74), 171 (100), 141 (50), 57 (79). Found: C, 79.96; H, 8.26%. Calcd for $C_{18}H_{22}O_2$: C, 79.96; H, 8.20%. Mp 51.5—52 °C.

The similar photolysis of the (+)-ester **6** (365 mg/430 ml; 16 min) gave **9** (50 mg, 14%), **11** (72 mg, 20%; $[\alpha]_D^{18.5}$ +127° (c=1.0, $CHCl_3$)), **10** (117 mg, 32%) in addition to **8** (41 mg). The optical purity of (+)-**11** was estimated to be more than 95% by applying the chiral shift reagent to its

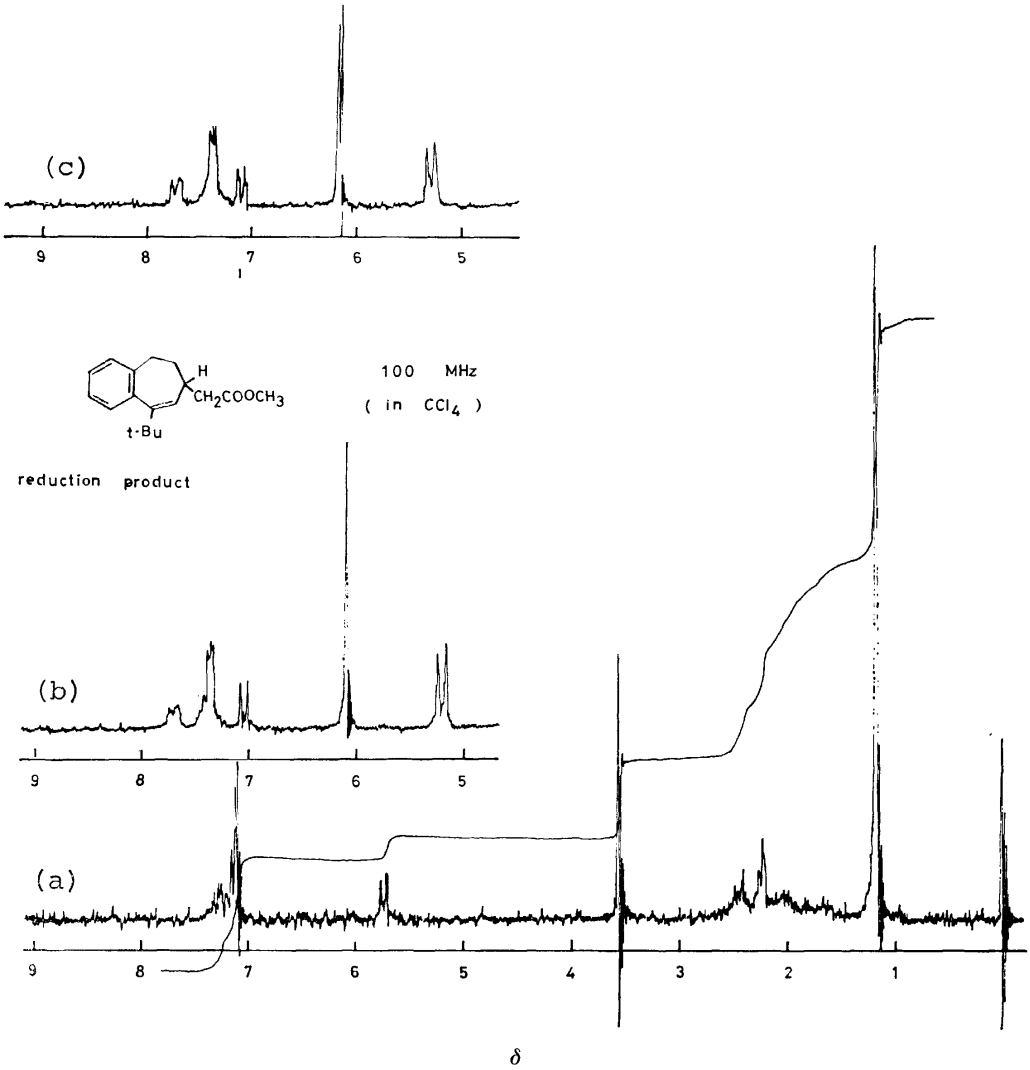


Fig. 4. ^1H NMR spectra of the hydrogenation product **15**.
(a) Original spectrum of optically active **15**, $[\alpha]_D = -61.2°$,
(b) after addition of a chiral shift reagent to the above, (c) after addition of a chiral shift reagent to the racemic ester **15**.

dihydro derivative **15** similarly as mentioned above.

Hydrogenation of the 7H-Benzocycloheptene ***11***. The *7H*-benzocycloheptene **11** (70 mg, 0.26 mmol), dissolved in ethyl acetate (10 ml), was hydrogenated over 10% Pd-C (20 mg) for 3.3 h until one molar equivalent of hydrogen was absorbed. Filtration from the catalyst and subsequent evaporation of the solvent left a yellow liquid (72 mg), which was revealed by NMR to contain **11**, 8,9-dihydro derivative of **11** (**15**), and tetrahydro derivative of **11** in a ratio of 13 : 80 : 7. The dihydro derivative **15** was separated by GLC (10% Apiezone L on Chromosorb WAW, column temperature 205 °C; r.t. 10 min). **15**: $[\alpha]_D$ −61.2° (c=1.0, $CHCl_3$). IR ν_{max} (liq. film): 2960, 1740, 1367, 1175, 1156, 849, 791, 760 cm^{-1}. UV λ_{max} (EtOH): 237 (log ε 3.90) nm, λ_{min} 225 (3.81). NMR δ: 7.25 (1H, m), 7.08 (3H, m), 5.73 (1H, d, J=6 Hz), 3.56 (3H, s), 2.76—1.60 (7H, m), 1.20 (9H, s). Mass spectrum: *m/e* (%); 272 (1.5 (M^+)), 215 (3), 183 (3), 155 (19), 141 (26.6), 128 (13.6), 115 (15.1), 57 (100), 41 (67.2). Found: C, 79.35; H, 8.94%. Calcd for $C_{18}H_{24}O_2$: C, 79.37; H, 8.88%.

Permanganate Oxidation of Methyl 5-t-Butyl-8,9-dihydro-7H-benzocycloheptene-7-acetate ***15***. To a stirred solution of perhydrodibenzo-18-crown-6 (156 mg, 0.42 mmol) in benzene (8 ml) was added potassium permanganate (66 mg, 0.42 mmol). After stirring for 1 h, **15** was added to the purple benzene solution and stirring was continued further for 2 d, until the purple color had beed discharged. Filration from the precipitates, and concentration of the filtrate gave a residue which was taken in benzene and chromatographed on silica gel to give 69% recovery of the starting material. Collected precipitates from repeated oxidation of the recovered ester **15** were combined with the initial precipitates and then extracted with hot water. The aqueous extracts were washed once with ether, acidified with 6 M hydrochloric acid, and extracted with ether to give colorless crystals (47 mg), which were esterified with ethereal diazomethane. Purification by TLC method (silica gel; ether–hexane=1 : 1) gave dimethyl (+)-2-[*o*-(2,2-dimethylpropanoyl)phenyl]ethylsuccinate **16**, $[\alpha]_D^{13.5}$ +16.0° (c=1.28, $CHCl_3$). **16** NMR δ: 7.2 (4H, m), 3.70 (3H, s), 3.65 (3H, s), 2.2—2.9 (5H, m), 1.6—2.0 (2H, m), 1.24 (9H, s). IR ν_{max} (liq. film): 2960, 1733, 1689, 1443, 1170, 969, 763 cm^{-1}. UV λ_{max} (EtOH): 233 (log ε 3.42), 251 (3.08), 271 nm (2.75). Mass spectrum: *m/e* (%); 334 (1.7 (M^+)), 303 (4.2), 277 (56.7), 245 (62.5), 217 (14.7), 185 (100), 57 (38). Found: C, 68.13; H, 7.85%. Calcd for $C_{19}H_{26}O_5$: C, 68.24; H, 7.84%.

The authors wish to thank Professor Hisao Kuroya and Dr. Keiji Matsumoto of our University for measure-

ment of the ORD curves, and Mr. Jun-ichi Goda for the elementary analysis. The authors also indebted to Mr. Masakazu Tsuji for the preliminary experiments on the photo-induced reaction of **6**.

30) The fact that **10** is converted cleanly into a mixture of **9a** and **9b** (7 : 5) under the irradiation conditions supports the assignments. The photochemistry of **10** will be reported in due time together with photo-induced reaction of other 5*H*-benzocycloheptene derivatives.

Modification of Aminocyclitol Antibiotics. 8. Preparation of 5,6″-Dideoxykanamycin B[1]

Tetsuo SUAMI* and Katsumi NAKAMURA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223

(Received March 18, 1980)

In order to obtain an effective antibiotic against a resistant strain of bacteria, two hydroxyl groups on C-5 and 6″ of kanamycin B were removed. 5,6″-Dideoxykanamycin B thus prepared was subjected to antimicrobial tests, its structure being established by mass and ^{13}C NMR spectroscopy.

In connection with the preceding paper,[2] a report is given on the preparation and antimicrobial activity of 5,6″-dideoxykanamycin B.

5-Deoxygentamicin complex[3] and 5-deoxysisomicin[4] exhibit improved activity against resistant strains of bacteria, as compared to gentamicin complex and sisomicin, respectively. Considering the structural similarity between these antibiotics and kanamycin B, 5-deoxykanamycin B[5] can be considered to have improved activity against kanamycin resistant strains of bacteria, but this is not the case. This might be attributed to a complicated structural feature of kanamycin B. The characteristic feature of kanamycin B is the existence of a hydroxymethyl group on C-5″, in contrast with gentamicin complex and sisomicin. If the hydroxyl group is removed from 5-deoxykanamycin B, the resulting 5,6″-dideoxykanamycin B (**5**) might show improved activity.

Results and Discussion

When 1,3,2′,6′,3″-pentakis-*N*-(ethoxycarbonyl)kanamycin B[6] (**1**) reacted with trityl chloride in pyridine and subsequently acylated with benzoyl chloride, tetra-*O*-benzoyl-*O*-trityl derivative (**2**) was obtained in 77% yield. Since trityl chloride attacks a primary hydroxyl group preferentially,[7] and a hydroxyl group on C-5 in kanamycin B is highly hindered against the acylation,[5] the structure of **2** is assigned to a 3′,4′,2″,4″-tetra-*O*-benzoyl-6″-*O*-trityl derivative. The assignment would be verified by the establishment of the structure of **5** by mass and ^{13}C NMR spectrometries.

Detritylation of **2** with hydrogen bromide, followed by halogenation with sulfuryl chloride in pyridine afforded a 5,6″-dichloro-5,6″-dideoxy derivative (**3**) in 50% yield.

Dehalogenation of **3** with tributylstannane gave a

Scheme 1.

5,6″-dideoxy derivative (**4**) in 81% yield.

Hydrolysis of **4** in a sodium hydroxide solution gave **5** in 73% yield. *N*-Acetylation of **5** by the conventional method afforded penta-*N*-acetyl-5,6″-dideoxykanamycin B (**6**).

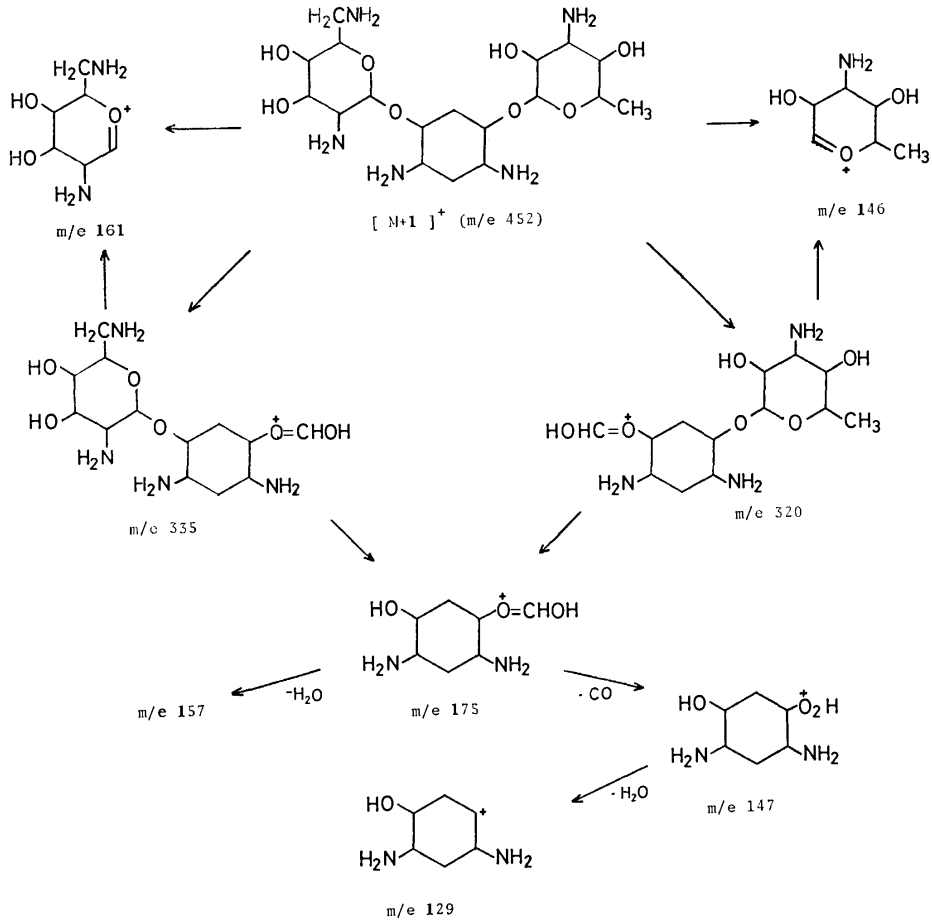
The structure of **5** was established by mass spectroscopy. The mass spectrum of **5** shows $[M+1]^+$ peak at *m/e* 452, corresponding to $[M+1]^+$ of kanamycin B-32. The other peaks are also consistent with the proposed structure of **5** (Scheme 1).

The ^{13}C NMR spectrum of **5** shows eighteen carbon signals (Table 1). In comparison with the spectra of 5-deoxykanamycin B and kanamycin B,[5] large shifts of the signals of C-5 and C-6″, we see in the spectrum of **5**, confirming the structure of **5**.

Compound **5** was subjected to the determination of antimicrobial activity against microorganisms by a dilution method. The MIC (minimum inhibition concentration) values are given in Table 2. As compared to kanamycin B, **5** exhibited improved activity against *Staphylococcus epidermidis* ATCC 12228 and *Klebsiella pneumoniae* 602. Compound **5** was slightly more active than kanamycin B against resistant strains of bacteria: *Staphylococcus aureus* Apo-1, *Klebsiella pneumoniae*, and *Escherichia coli*. Compound **5** showed a marked decrease in activity against *Pseudomonas aeruginosa*.

Experimental

General Method. Melting points were determined in open capillaries in a liquid bath and are uncorrected. Solutions were concentrated under reduced pressure below 40 °C. Optical rotations were measured on a Japan Spectroscopic DIP-SL polarimeter. ^{13}C NMR spectra were determined on a Varian FT-80 spectrometer at 20 MHz, D_2O being used as a solvent with an internal standard of dioxane. The resonance signals are expressed in ppm down-field from the signal of tetramethylsilane ($\delta_c^{TMS}=\delta_c^{dioxane}+67.4$). Mass



Scheme 2.

spectra were recorded with a Hitachi RMU-6M single focusing mass spectrometer. TLC was performed on Wakogel B-10 plates, silica gel (Wakogel C-300) being used in column chromatography.

3',4',2'',4''-Tetra-O-*benzoyl-1,3,2',6',3''-pentakis*-N-*(ethoxycarbonyl)-6''*-O-*tritylkamycin B (2).* Trityl chloride (1.7 g) was added to a stirred solution of 1,3,2',6',3''-pentakis-*N*-(ethoxycarbonyl)kanamycin B[8] (**1**, 1.0 g) in pyridine (50 ml). After 69 h, benzoyl chloride (3 ml) was added to the solution under ice cooling with agitation. After 24 h, the solution was poured into cold water containing $NaHCO_3$. The aqueous mixture was repeatedly extracted with $CHCl_3$, the $CHCl_3$ layers being washed with water, dried over Na_2SO_4 and concentrated. The residue was chromatographed on a SiO_2 column with 1 : 5 (v/v) 2-butanone–$CHCl_3$. From the fractions homogeneous on TLC (R_f 0.72) in 7 : 1 (v/v) benzene–methanol, 1.37 g (77%) of **2** was obtained as amorphous powder, mp 125—131 °C, $[\alpha]_D^{21}$ +85° (*c* 0.56, chloroform).

Found: C, 63.65; H, 5.85; N, 4.66%. Calcd for $C_{80}H_{87}N_5O_{24}$: C, 63.95; H, 5.84; N, 4.66%.

3',4',2'',4''-Tetra-O-*benzoyl-5,6''-dichloro-5,6''-dideoxy-1,3,2',6',3''-pentakis*-N-*(ethoxycarbonyl)-5-epikanamycin B (3).* Glacial acetic acid (3 ml) containing 30% HBr was added to a solution of **2** (1.33 g) in $CHCl_3$ (3 ml) and glacial acetic acid (6 ml) under ice cooling with agitation. After 2 min, the resulting mixture was quenched on ice and repeatedly extracted with $CHCl_3$. The combined organic layers were washed with a $NaHCO_3$ solution, water, dried over Na_2SO_4, and concentrated. Sulfuryl chloride (1.5 ml) was added to a solution of the residue in pyridine (15 ml) under ice cooling with agitation. After 19 h, the solution was poured into ice cold water, precipitates being collected by filtration. The product was chromatographed on SiO_2 with 1 : 5 (v/v) 2-butanone–$CHCl_3$. The fractions homogenous on TLC (R_f 0.47) in 7 : 1 (v/v) benzene–methanol were combined and concentrated to give 0.57 g (50%) of **3**, mp 143—149 °C, $[\alpha]_D^{25}$ +69.4° (*c* 0.54, $CDCl_3$).

Found: C, 56.47; H, 5.52; N, 5.27; Cl, 5.61%. Calcd for $C_{61}H_{71}N_5Cl_2O_{22}$: C, 56.48; H, 5.52; N, 5.40; Cl, 5.47%.

3',4',2'',4''-Tetra-O-*benzoyl-5,6''-dideoxy-1,3,2',6',3''-pentakis* N-*(ethoxycarbonyl)kanamycin B (4).* A solution of **3** (460 mg) and tributylstannane (2.0 ml) in toluene (20 ml) was heated at 80 °C in the presence of α,α'-azobisisobutyronitril (20 mg). After 24 h, the resulting solution was concentrated and the residue was chromatographed on SiO_2 with 15 : 1 (v/v) benzene–methanol. The fractions homogeneous on TLC (R_f 0.38) in the same solvent were combined and concentrated to give 350 mg (80%) of **4**, mp 144—150 °C, $[\alpha]_D^{25}$ +87.8° (*c* 0.47, $CHCl_3$).

Found: C, 59.59; H, 5.95; N, 5.43%. Calcd for $C_{61}H_{73}N_5O_{22}$: C, 59.65; H, 5.99; N, 5.70%.

5,6''-Dideoxykanamycin B (5). A solution of **4** (304 mg) in methanol (6 ml) was added to a 2 M NaOH solution (20 ml) the solution being heated under reflux. After 12 h, the solution was neutralized with HCl and concentrated. The residue was purified on a CG-50 (NH_4^+) resin column. The fractions eluted with 0.3 M NH_4OH gave 81 mg (73%) of **5**, mp 172—175 °C (dec), $[\alpha]_D^{23}$ +136° (*c* 0.44, H_2O). The product showed a single spot (R_f 0.2) on TLC in 5 : 8 : 10 : 7 (v/v) 28% NH_4OH–1-butanol–ethanol–water.

1,3,2',6',3''-Penta-N-*acetyl-5,6''-dideoxykanamycin B (6).* Acetic anhydride (0.1 ml) was added to a solution of **5** (11 mg) in methanol (2 ml), precipitates being collected by filtration to give 13 mg (79%) of **6**, mp 250 °C, $[\alpha]_D^{25}$ +113° (*c* 0.35, H_2O).

Found: C, 48.00; H, 6.67; N, 10.01%. Calcd for $C_{28}H_{47}N_5O_{13}\cdot 2H_2O$: C, 48.20; H, 7.36; N, 10.04%.

Nucleophilic Substitution on Dialkoxy Disulfides. III.[1] Reaction with Thioureas

Hiroaki KAGAMI, Takashi HANZAWA, Nobuo SUZUKI, Shoso YAMAGUCHI, Masami SAITO, and Shinichi MOTOKI*

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received March 26, 1980)

1,3- and 1,1-Disubstituted thioureas reacted with diethoxy disulfide to give carbodiimides and 1,2,4-thiadiazoles respectively. 1,1,3-Trisubstituted thioureas and diethoxy disulfide afforded trialkyl(trialkylamidino)-thioureas.

The alkoxyl group of dialkoxy disulfide (**1**) is readily displaced by various nucleophiles. The reactions of **1** and amines, thiols,[2] thiocarboxylic acids,[3] or *N*-arylhydrazines[1] proceeded readily to give a variety of products. In the case of the reaction of thiobenzamide and diethoxy disulfide (**1a**), hydrogen sulfide was eliminated and benzonitrile was obtained in 80% yield.[2] This interesting dehydrosulfurization by **1** suggested that carbodiimides might be produced by the reaction of **1** and thiourea derivatives.

1a

Results and Discussion

When 1,3-disubstituted thioureas (**2**) were treated with **1a** at room temperature or in refluxing CH_2Cl_2 in the presence of molecular sieves (type 4A), carbodiimides (**3**) were obtained in 19—66% yield. The results are shown in Table 1. Molecular sieves (type 4A) were good absorbents of ethanol and promoted the elimination reaction.

$$\mathrm{R^1NH\text{-}\overset{S}{\overset{\|}{C}}\text{-}NHR^2} + \mathrm{EtOSSOEt} \xrightarrow[-\mathrm{EtOH},\ -\mathrm{S}]{} \mathrm{R^1N{=}C{=}NR^2}$$

2 **1a** **3**

The reaction of 1,1,3-trisubstituted thiourea (trimethylthiourea) (**4a**) and **1a** in refluxing toluene gave a light yellow liquid. The IR spectrum of the product showed an absorption at 1645 cm^{-1} assignable to the C=N stretching band, but no N–H absorption. The NMR spectrum exhibited four methyl singlets; the two signals at 3.27 and 2.88 ppm were assigned to $N(CH_3)_2$ protons. The mass spectrum allowed detection of the typical fragment (M^+—SH) of thiourea. On the basis of these data the product was formulated to be trimethyl(trimethylamidino)thiourea (**5a**). Similarly, *N,N*-diethyl-*N'*-methylthiourea (**4b**) and **1a** gave *N,N*-diethyl-*N'*-methyl-*N'*-(*N*^{1},*N*^{1}-diethyl-*N*^{2}-methylamidino)thiourea (**5b**).

$$2\ \mathrm{R^1_2N\text{-}\overset{S}{\overset{\|}{C}}\text{-}NHR^2} + \mathbf{1a} \longrightarrow \mathrm{R^1_2N\text{-}\overset{R^2N}{\overset{\|}{C}}\text{-}N(R^2)\text{-}\overset{S}{\overset{\|}{C}}\text{-}NR^1_2}$$

4 **5**

On the other hand, 1,1-disubstituted thioureas (**6**) reacted with **1a** in refluxing carbon tetrachloride to give 3,5-bis(disubstituted amino)-1,2,4-thiadiazoles (**7**) with a small amount of disubstituted cyanamides (**8**). The results are shown in Table 2.

$$\mathrm{R_2N\text{-}\overset{S}{\overset{\|}{C}}\text{-}NH_2} + \mathbf{1a} \longrightarrow \mathbf{7} + \mathrm{R_2N\text{-}C{\equiv}N}$$

6 **7** **8**

The thiadiazole systems comprise 1,2,3-, 1,2,4-, 1,2,5-, and 1,3,4-thiadiazoles. However, the structure of the product was identified as 1,2,4-thiadiazole by the ^{13}C-NMR and mass spectra. For example, the off-resonance ^{13}C decoupled spectrum of **7a** was as follows: (1) 12.7 ppm (q), (2) 13.6 (q), (3) 43.2 (t), (4) 45.7 (t), (5) 167.5 (s), (6) 186.6 (s). The four upfield signals correspond to the ethyl carbons, and the two downfield signals correspond to ring carbons. The mass spectrum of the product showed the thiazirene fragment formed by the loss of Et_2NCN from the molecular ion,[4] but no thiirene fragment.[5] All of the evidence supports the

$$\mathbf{7a}^{\ddagger} \longrightarrow \mathrm{N{=}C^{\ddagger}\text{-}S\text{-}NR_2}$$

proposed structure.

The formation of these products can be rationalized by assuming the reaction path shown in Scheme 1. First, the ethoxyl group of **1a** was replaced by **2** to give ethoxy amidino trisulfide (**9**). The trisulfide then

underwent intramolecular substitution by the remaining –NHR group, followed by the elimination of sulfur to give **3**.[2]

The reaction of **4** and **1a** proceeded by successive substitution of **1a** by 2 mol of **4** to give the tetrasulfide (**12**), which then rearranged to yield **5** with elimination of sulfur. In the case of the reaction of **1a** and **2**, intramolecular substitution of **9** would predominate over intermolecular substitution by **2**.

Similarly, **1a** reacted with 2 mol of **6** to give amidinothiourea (**14**). Unlike **5**, however, **14** could cyclize to form **7** with a loss of hydrogen. Presumably **1a** would participate in this step, as in the case of the reaction of **1a** and hydrazine.[1]

The formation of the cyanamide (**8**) as a by-product is considered to be due to the intramolecular substitution of **11**, followed by the loss of sulfur. However, this reaction would not proceed effectively owing to the low nucleophilicity of the imino nitrogen atom in **11**.

Experimental

All melting points and boiling points are uncorrected. Column chromatography was performed on Wako gel C-200 column by eluting with benzene. ^{1}H-NMR spectra were recorded at 100 MHz on a JEOL JNM-FX 100 spectrometer using Me_4Si as the internal standard. The ^{13}C-NMR spectrum was recorded at 25 MHz on a JEOL JNM-FX 100 spectrometer using Me_4Si as the internal standard. Infrared spectra were obtained on a Hitachi model 260-10 infrared spectrometer. Mass spectral data were obtained with a Hitachi Double Focusing Mass spectrometer, RMU-7M.

Diethoxy disulfide (**1a**) was prepared by the method of the literature.[10] Unsymmetrical 1,3-disubstituted thioureas and trialkylthioureas were prepared from isothiocyanates and amines. Molecular sieves (type 4A 1/16 in. pellets) was purchased from Nakarai Chemicals (UCC subdivision). 1,1-Dialkylthioureas were prepared by the methods of the literature.[11] All other reagents were obtained commercially.

Reactions of ***1a*** *with 1,3-Disubstituted Thiourea.* To a solution of 1,3-disubstituted thiourea (**2**, 0.05 mol) and **1a** (0.05 mol) in 100 ml of CH_2Cl_2, 30 g of molecular sieves was added and the mixture was refluxed for 4—23 h. At the end of the reaction the mixture was cooled and the resulting sulfur and molecular sieves were filtered off. The filtrate was evaporated and the residue was distilled to obtain carbodiimide. The carbodiimides (**3**) were identified by their IR spectra and boiling points.[12–16]

Reactions of ***1a*** *with Trialkylthiourea.* A solution of 5.9 g (0.05 mol) of trimethylthiourea and 7.7 g (0.05 mol) of **1a** in 150 ml of toluene was refluxed for 20 h. The toluene was evaporated, the precipitated sulfur was filtered off, and the filtrate was distilled to give 2.8 g (55%) of trimethyl (trimethylamidino)thiourea (**5a**): bp 103 °C (0.6 mmHg); Found: C, 40.45; H, 10.20; N, 31.32; S, 18.01%. Calcd for $C_6H_{18}N_4S$: C, 40.43; H, 10.18; N, 31.44; S, 17.95%. IR (neat): $\nu_{C=N}$ 1645 cm^{-1}; NMR ($CDCl_3$) δ, 3.27 (s, 3H), 3.11 (s, 6H), 2.88 (s, 3H), 2.82 (s, 6H); MS *m/e* 202 (M^+, 4), 187 ($M^+ - CH_3$, 15), 169 ($M^+ - SH$, 4), 158 ($M^+ - NMe_2$, 9), 108 (29), 85 (100). *N,N*-Diethyl-*N*-′

methyl-N'-(N^1,N^1-diethyl-N^2-methylamidino)thiourea (**5b**) was obtained similarly: yield 40%; bp 123 °C (0.5 mmHg); Found: C, 51.20; H, 11.21; N, 24.01; S, 13.65%. Calcd for $C_{10}H_{26}N_4S$: C, 51.24; H, 11.18; N, 23.90; S, 13.68%. IR (neat): $\nu_{C=N}$ 1650 cm^{-1}; NMR ($CDCl_3$) δ, 3.48 (q, 4H), 3.15 (s, 3H), 2.86 (s, 3H), 1.16 (t, 6H), 1.07 (t, 6H); MS *m/e* 258 (M^+, 5), 243 ($M^+ - CH_3$, 4), 225 ($M^+ - SH$, 3), 186 ($M^+ - NEt_2$, 15), 146 (4), 113 (100).

Reactions of ***1a*** *with 1,1-Disubstituted Thiourea.* A suspension of 1,1-disubstituted thiourea (**6**, 0.05 mol) and **1a** (0.05 mol) in carbon tetrachloride was refluxed for 6—11 h. At the end of the reaction the mixture was cooled and the resulting sulfur was filtered off. The filtrate was evaporated and the residue was distilled to obtain 3,5-bis(disubstituted amino)thiadiazole (**7**) and disubstituted cyanamide (**8**). In the cases of *N*-thiocarbamoylmorpholine (**6d**) and 1,1-diphenylthiourea (**6e**), the reaction mixture was evaporated and the residue was chromatographed on Wako gel C-200, using benzene as the eluent. The solvent was evaporated and the residue was recrystallized from ethanol, giving **7d** and **7e**. 3,5-Bis(diethylamino)-1,2,4-thiadiazole (**7a**); Found: C, 52.58; H, 8.80; N, 24.32; S, 13.87%. Calcd for $C_{10}H_{20}N_4S$: C, 52.60; H, 8.83; N, 24.53; S, 14.04%. IR (neat): 1570, 1540, 1420 cm^{-1}. ^{1}H-NMR ($CDCl_3$): δ, 1.19 (m, 12H), 3.43 (m, 8H). ^{13}C-NMR ($CDCl_3$): δ, 12.7, 13.6, 43.2, 45.7, 165.5, 181.6. Studies of Unusual Amino Acids and Their Peptides. XIII. The Chemistry of *N*-(Carboxymethyl)amino Acids. II. The Synthesis of Peptides Containing *N*-(Carboxymethyl)amino Acids

Toshifumi MIYAZAWA

Department of Chemistry, Faculty of Science, Kōnan University, Okamoto, Higashinada-ku, Kobe 658

(Received April 4, 1980)

The basic problems in the synthesis of peptides with *N*-carboxymethyl(Cm-)amino acids were investigated. Several kinds of *N*-protected derivatives of a free Cm-amino acid and the *N*-benzyloxycarbonyl (Z) derivative of its monoester were obtained by the conventional methods used for the parent amino acid. The peptide-bond formation at either carboxyl group of a Cm-amino acid proved to be achievable by the usual methods, such as the carbodiimide, dicyclohexylcarbodiimide–1-hydroxybenzotriazole, or mixed anhydride method, as illustrated by the examples using the Z–Cm-amino acid derivatives as the carboxyl components. On the other hand, a peptide using a Cm-amino acid diester as the amino component could not be prepared by the usual methods mentioned above. The desired compound was eventually obtained by the acid chloride method. A peptide containing a Cm-amino acid with the free imino group was also prepared by the condensation of a bromoacetylated amino acid ester with an amino acid or peptide ester.

In the previous paper,[1] the author has reported on the preparation and properties of a number of *N*-carboxymethyl(Cm-)amino acids and their mono- and diesters. Such polyfunctional amino acids are incorporated in most of the known biologically active peptides. The additional functional groups always pose special problems for the synthesis of peptides and necessitate detailed studies of the amino acids in question. However, nothing is known about the chemistry of peptides containing Cm-amino acids, though bottromycin, an antibiotic, has recently proved to be an example of such a peptide occurring in nature.[2] The present paper will deal with the basic problems in the preparation of peptides containing Cm-amino acids.

Protection of the Carboxyl Groups. The use of a Cm-amino acid[3] for peptide synthesis may involve many types of its *C*-protected derivatives, according to the synthetic routes. Among them, the diester carrying two selectively removable *C*-protecting groups may be the most useful intermediate. The direct preparation of this type of diester from the parent amino acid ester is preferable to the ordinary approach, *i.e.*, the esterification of the free Cm-amino acid prepared beforehand. Thus, as described previously,[1] any derivative of a Cm-amino acid carrying two different ester groups ($R^1 \neq R^2$) can be prepared by condensing an amino acid ester with a haloacetic acid ester (Scheme 1). On the other hand, the esterification of a Cm-amino acid, for example with an alcohol–thionyl chloride, tends to afford its dialkyl ester ($R^1=R^2$). The diester of this type may be utilized for the preparation of a peptide having a Cm-amino acid at the *C*-terminal position.

$$\text{H–AA–OR}^1 + \text{XCH}_2\text{CO}_2\text{R}^2 \longrightarrow \text{H–}\underset{\displaystyle \text{OR}^2}{\underset{|}{\text{C}}}\text{mAA–OR}^1$$

(X = Br or Cl; R^1, R^2 = Me (Et), Bzl, or Bu^t)

Scheme 1.

Protection of the Imino Group. As described in the previous paper,[1] Cm-amino acids are eluted from the strongly acidic cation-exchange resin with water as an eluent. Since this indicates the low basicity of the imino group of a Cm-amino acid, the acylation of this group is presumed to be difficult. Actually, Abderhalden and Haase[4] took advantage of this poor reactivity for the purification of Cm-valine contaminated with valine: Cm-valine was isolated unchanged even after treating the reaction mixture with benzoyl chloride. No other reports concerning the acylation of a free Cm-amino acid have been found. But the *N*-ethylthiocarbonothioyl (ETCT) derivatives of Cm-amino acids were accessible, as described previously.[1] Consequently, the applicability of the conventional methods[5] of *N*-protection to the Cm-amino acid was examined. Cm-alanine, Cm-phenylalanine, and Cm-valine were chosen as model compounds for this purpose.

Contrary to the results reported by Abderhalden and Haase, the benzyloxycarbonyl (Z) group could be introduced by the Schotten-Baumann reaction using the corresponding chloride, though the yields were somewhat poorer than those with the parent amino acids. The *p*-toluenesulfonyl (Tos) derivatives were obtained by the usual method using *p*-toluenesulfonyl chloride as an acylating agent, though in rather low yields. The *o*-nitrobenzenesulfenyl (Nps) derivatives could also be obtained by the use of the corresponding chloride under the Schotten-Baumann conditions. As another type of acylating agent, ethyl trifluoroacetate–1,1,3,3-tetramethylguanidine[6] was tried in the introduction of the trifluoroacetyl (CF_3CO) group. In this case, however, the acylation proceeded quite slowly compared with the case of the parent amino acid and with that of the acylation using a reagent of the acyl chloride type. Interestingly, the formylation using formic acid–acetic anhydride was an exceptional case: the reaction was accomplished in quite a short time. The yields and physical constants of the *N*-protected Cm-amino acids thus obtained are summarized in Table 1. The above examples show that the *N*-protection of a Cm-amino acid can be achieved without any greater difficulty than expected.

Most of the *N*-protected Cm-amino acids were obtained at first as oily substances, and crystallized as the bis(dicyclohexylamine) or bis(cyclohexylamine) salts. Repeated recrystallization and/or prolonged heating of the DCHA salts caused the unsatisfactory

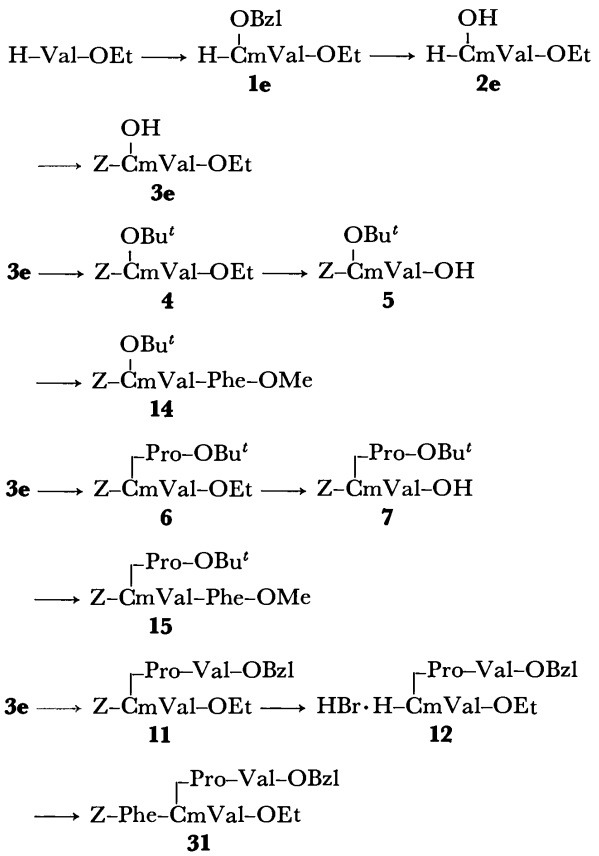
results in elemental analyses, probably due to the partial release of the amine. The melting point of an *N*-protected Cm-amino acid is higher than that of the corresponding derivative of the parent amino acid, while the reverse is the case with their DCHA salts.[7]

The *N*-protection of the monoester of a Cm-amino acid was examined next. A typical example is the benzyloxycarbonylation of the monoester (**2e**) of Cm-valine, prepared from ethyl valinate according to Scheme 2. To avoid the hydrolysis of the ester group, the method using Z–Cl and sodium hydrogencarbonate was chosen. Since the addition of the total amount of the chloride at the beginning had not as usual afforded a good result, its portion by portion addition was tried. By the excessive use of the chloride by 20%, the desired compound (**3e**) was obtained in a yield comparable to the cases of the monoesters of the usual monoamino dicarboxylic acids.

To shorten the synthetic route to the desired compound (**3e**), the direct benzyloxycarbonylation of the reaction mixture obtained by the condensation of ethyl valinate with bromoacetic acid was attempted. (As described previously,[1] the isolation of the monoester (**2e**) from the above mixture was unsuccessful.) The overall yield by this route, however, was no more than 28%; consequently, the route shown in Scheme 2 is more desirable.

The Z derivatives of other Cm-amino acid monoesters could likewise be obtained. These also showed no tendency to crystallize and were characterized as the DCHA or CHA salts (Table 2). As can be seen from Table 2, the DCHA salts of Z derivatives with the free carboxyl group at the glycine moiety (**3a**·DCHA and **3e**·DCHA) have lower melting points than those of their isomers (**3b**·DCHA and **3f**·DCHA).[8]

Formation of the Peptide Bond at the Carboxyl Groups. The peptide-bond formation at the two sorts of carboxyl groups of a Cm-amino acid was investigated, using Cm-valine as a model compound. First, in order to try the coupling at the carboxyl group in the glycine moiety, Z–CmVal–OEt (**3e**) obtained above was used as the carboxyl component, and H–Pro–OBu^t, H–Phe–OBzl,



Scheme 2.

H–Gly–Gly–OEt, H–Phe–Phe–OMe, H–Pro–Val–OBzl, or H–Pro–Val–Val–OBzl as the amino component. The desired di- or tripeptides, or tetrapeptide could be obtained without too much difficulty by the carbodiimide, DCC–HOBt, or mixed anhydride method.[5] All the products were isolated as viscous oils by preparative TLC on silica gel.

The coupling at the carboxyl group in the valine moiety was tried next. Two sorts of carboxyl components (**5** and **7**) were prepared for this purpose, as shown in Scheme 2. Z–CmVal–OEt (**3e**) was converted into the *t*-butyl ester (**4**) with isobutylene in the presence of sulfuric acid. Then the ethyl ester group was cleaved by saponification, to afford **5**. Similarly, the selective removal of the ethyl ester group from the dipeptide **6** afforded **7**. By the DCC–HOBt or mixed anhydride method the desired di- and tripeptide (**14** and **15**)[9] could be obtained, using H–Phe–OMe as the amino component.

When a Z–Cm-amino acid listed in Table 1 was used as the carboxyl component, as illustrated in the case of Z–Cm-phenylalanine, the amino acid ester reacted at both the carboxyl groups and afforded a tripeptide, though in a rather low yield. Cm-proline itself also gave a similar tripeptide (**18**). The yield was better than those with Z–Cm-phenylalanine, though the reaction was heterogeneous, due probably to some remaining zwitter-ionic character of the amino acid.

As illustrated by the above examples, the peptide-bond formation at either carboxyl group of a Cm-amino acid proved to be achievable by the conventional methods. The peptides obtained here are listed in Table 3.

Formation of the Peptide Bond at the Imino Group. As already stated, the acylation of a free Cm-amino acid or its monoester was achieved without too much difficulty. The applicability of the usual coupling methods[5] to the peptide-bond formation at the imino group of a Cm-amino acid was investigated. However, the attempted couplings of Z–Phe–OH with the diester (**1e**) of Cm-valine by such common methods as the mixed anhydride, carbodiimide, DCC–HOBt, or *p*-nitrophenyl ester method all ended in failure. Both the diphenyl phosphorazidate (DPPA) method (a modified azide method) and the carbonyldiimidazole (CDI) method were unsuccessful. This was also the case with the phosphoryl chloride method, or with the phosphazo method, which involves the activation of the

amino component.

The acid chloride is considered to be the most reactive acylating agent, and has often been employed in the coupling with *N*-methylamino acids, in the synthesis of peptolides, and in the cases where other methods give only poor yields. Fortunately, by the use of Z–Phe–Cl[10] in the presence of *N*-ethyldiisopropylamine (or TEA), the desired dipeptide (**27**) was obtained also in the present case, though in a moderate yield (41%) after several successive purification procedures. In the preparation of dehydropeptides, which has recently been reported,[11] the isolation of an acid chloride was omitted and the reaction mixture was directly used for the coupling with the pyridine solution of the amino component. In the present case, however, the yield by this convenient procedure was no more than 17%. This was also the case with the related method using *N*,*N*-dimethylchloroformimidium chloride, the yield being only 13%. Recently the peptide synthesis using 2-fluoro-1,3,5-trinitrobenzene has been reported:[12] the acid fluoride was supposed to be the reactive acylating agent, and the method was applied to the condensation of amino acids containing rather bulky substituents. The coupling in question, however, resulted in a much poorer yield (12%).

A number of other dipeptides could be obtained by the acid chloride method using the diester of Cm-alanine, Cm-phenylalanine, or Cm-valine as the amino component and the phthalyl (Pht) or Z derivative of glycine, alanine, phenylalanine, or valine as the carboxyl component. The results are summarized in Table 4. A considerable amount of the unchanged amino component remaining even after acid washings was removed by treatment with the cation-exchange resin

(Amberlyst 15). The final stage of purification required successive chromatographic separations on silica gel, to afford the desired compound as a viscous oil, except **20**. In the cases where the acid chlorides used were relatively stable, the desired compounds were obtained in moderate yields. On the other hand, the yields of the couplings using Z–Val–Cl[13] were extremely unsatisfactory. This is presumably attributable to both the

instability and the bulkiness of the chloride. In general, the difficulty in the separation of the desired product from the starting Cm-amino acid diester was another factor which affected the yield.

The elongation of the peptide chain from a peptide having a Cm-amino acid at the *N*-terminal position was examined next. As an example, the tetrapeptide **31** could be obtained in a yield comparable to those of the above dipeptides by the reaction of Z–Phe–Cl with **12**, prepared by the debenzyloxycarbonylation of the tripeptide **11** with hydrogen bromide in acetic acid, as shown in Scheme 2.

As an example of the coupling using a Cm-amino acid with the free carboxyl group as the amino component, the reaction of Z–Phe–Cl with the DCHA salt of the monoester (**2e**) of Cm-valine in dichloromethane was attempted.[14] The desired dipeptide was found to be produced in a *ca.* 20% yield. However, the isolation of the purified product was extremely troublesome, and this approach had to be abandoned.

Preparation of Peptides Containing Cm-amino Acids with the Free Imino Group. As an extension of the method for preparing Cm-amino acid diesters shown in Scheme 1, the condensation of a bromoacetylated amino acid ester or peptide ester with the other amino acid ester or peptide ester might be employed for preparing a peptide containing a Cm-amino acid in the middle of the molecule. In practice, the imino-free di- and tripeptides listed in Table 5 were prepared by this approach, though the yields were lower than those of the preparation of the Cm-amino acid diesters. Benzyl *N*-(bromoacetyl)phenylalaninate and benzyl *N*-(bromoacetyl)valinate were prepared by treatment of the corresponding amino acid benzyl esters with bromoacetyl bromide in the presence of TEA. The condensation with an amino acid or peptide ester was conducted in the presence of TEA at room temperature. The products did not form crystalline salts with *p*-toluenesulfonic or picrolonic acid, unlike the diesters of Cm-amino acids, but they changed to a similar blue coloration when sprayed with cobalt(II) thiocyanate.[15]

In conclusion, the results obtained here indicate that, in the synthesis of peptides containing Cm-amino acids, such routes starting from the parent amino acids as shown in Scheme 2 are highly recommendable. In the case where a new peptide bond is to be built at the imino group of a Cm-amino acid, the acid chloride method or an alternative, equally potent method should be employed.

Experimental

All melting points are uncorrected. Optical rotations were measured with a JASCO DIP-4 polarimeter, and ORD curves recorded on a JASCO ORD/UV-5 spectropolarimeter. TLC and preparative TLC were performed on Merck Kieselgel 60 F_{254} and Kieselgel GF_{254} (Type 60), respectively. The amino acids and their derivatives used here are all of the L-configuration.

Preparation of N-*Protected Cm-amino Acids.* The introduction of each *N*-protecting group is illustrated by a typical example below. When the desired compound was obtained as a syrup, it was crystallized as the DCHA or CHA salt. The results are summarized in Table 1.

Z–CmPhe: To a solution of Cm-phenylalanine (1.00 g) in 2 M NaOH (4.5 ml) were added Z–Cl (0.85 g) in ether (3 ml) and 2 M NaOH (2.5 ml) simultaneously with vigorous stirring at 0—5 °C, and the mixture was stirred at room temperature overnight. The turbid reaction mixture was washed with ether and acidified to pH 2 with 2 M HCl. The precipitated oil was extracted with EtOAc, and the extract was washed with water and dried over Na_2SO_4. Evaporation of the solvent afforded a syrup; yield, 1.22 g (76%). Upon the addition of double molar amounts of CHA the corresponding salt separated out; mp 189.5—190 °C (EtOH).

Nps–CmVal: To a solution of Cm-valine (250 mg) in 2 M NaOH (1.4 ml) and dioxane (2 ml) were added *o*-nitrobenzenesulfenyl chloride (300 mg) and 2 M NaOH (0.85 ml) simultaneously with vigorous stirring, and the mixture was stirred at room temperature overnight. After addition of water and filtration, the reaction mixture was acidified to pH 2 with 0.5 M H_2SO_4. The precipitated oil was treated in a manner similar to that described for the preparation of Z–CmPhe, to afford crystals; yield, 244 mg (52%); mp 140—143 °C (EtOAc–petroleum ether).

Tos–CmPhe: To a solution of Cm-phenylalanine (1.00 g) in 1 M NaOH (13.5 ml) was added a solution of *p*-toluenesulfonyl chloride (1.29 g) in ether (6 ml) in five portions at intervals of 1 h, and the mixture was stirred at room temperature overnight. The reaction mixture was washed with ether and acidified to Congo Red with 2 M HCl. (The unchanged amino acid occasionally separated out at a lower pH.) The precipitated oil was extracted with EtOAc, and the extract was washed with 2 M HCl and water, and dried over Na_2SO_4. Evaporation of the solvent afforded crystals; yield, 895 mg (53%) (33%, in a run where an equimolar amount of the chloride was used); mp 173.5—174.5 °C (EtOAc).

CF_3CO–CmAla: A suspension of Cm-alanine (200 mg), ethyl trifluoroacetate (970 mg), and 1,1,3,3-tetramethylguanidine (390 mg) was stirred for 3 d (until an almost clear solution was obtained). After evaporation of excess ethyl trifluoroacetate, the residue was dissolved in water and acidified to pH 2 with 4 M HCl. The precipitated oil was treated in a manner similar to that described for the preparation of Z–CmPhe. Upon the addition of double molar amounts of DCHA to the residual syrup the corresponding salt separated out; yield, 569 mg (69%); mp 168—168.5 °C (EtOAc).

HCO–CmPhe: To a chilled solution of Cm-phenylalanine (500 mg) in 99% formic acid (4.7 ml) was added acetic anhydride (1.6 ml) at 0—3 °C, and the mixture was stirred at this temperature for 30 min and then at room temperature for *ca.* 4 h. After the addition and successive evaporation of water to the reaction mixture had been repeated, the residual crystals were filtered, and washed with water; yield, 360 mg (64%); mp 177.5—178 °C (H_2O).

Preparation of the Z Derivatives of Cm-amino Acid Monoesters. A typical example illustrating the preparation of these compounds is shown below.

OH
|
Z–CmVal–OEt (3e): a) To a stirred solution of H–CmVal–OEt (**2e**) (2.03 g) and $NaHCO_3$ (2.10 g) in water (17.5 ml) was added a solution of Z–Cl (2.70 g) in ether (3 ml) portion by portion, after each consumption, over a period of 4—6 h. Then the mixture was stirred below 5 °C overnight. The reaction mixture was filtered, and the filtrate acidified to pH 2 with 4 M HCl. The deposited oil was extracted with EtOAc, and the extract was washed with water and dried over Na_2SO_4. After evaporation of the solvent, the residual syrup was treated with DCHA (1.81 g), to afford the corresponding

salt; yield, 4.08 g (79%); mp 109.5—110 °C (hexane).

b) A mixture of H–Val–OEt·TosOH (3.17 g), bromoacetic acid (1.53 g), and TEA (2.12 g) was refluxed in THF (30 ml) for 50 h with occasional filtration of the precipitates. After the solvent had been removed under reduced pressure, the residue was mixed with the above precipitates, and benzyloxycarbonylated using Z–Cl and $NaHCO_3$ as described above, to afford 0.95 g of the desired compound (**3e**) (28% yield based on H–Val–OEt·TosOH).

Other Z derivatives were obtained in the same manner as used in Method a), and crystallized as the DCHA or CHA salts. The results are summarized in Table 2.

OBu^t
|
Z–CmVal–OEt (*4*). A mixture of Z–CmVal–OEt (**3e**) (recovered from the DCHA salt by treatment in EtOAc with 1.5 M HCl as usual) (667 mg), liquid isobutylene (*ca.* 2 ml), concd H_2SO_4 (0.02 ml), and dichloromethane (4 ml) was allowed to stand in a pressure vessel at room temperature overnight. The syrup (662 mg), obtained by the usual work-up,[16] was chromatographed on preparative layers of silica gel with benzene–EtOAc (98 : 2); yield, 566 mg (73%); syrup, $[\alpha]_D^{25}$ −48.2° (*c* 1.0, MeOH). TLC: R_f 0.52 (benzene–EtOAc (9 : 1)). Found: C, 64.15; H, 8.16; N, 3.32%. Calcd for $C_{21}H_{31}NO_6$: C, 64.10; H, 7.94; N, 3.56%.

Preparation of Peptides Using Cm-amino Acid Derivatives as the Carboxyl Components. The desired protected peptides were obtained as syrups. The final purification of all of these compounds, except **6**, was performed by preparative TLC on silica gel. The results are summarized in Table 3. Typical examples illustrating the procedures for the preparation of these compounds are shown below.

┌*–Pro–OBu^t*
|
Z–CmVal–OEt (*6*), *by the DCC–HOBt Method*: Z–CmVal–OEt (**3e**) (650 mg), H–Pro–OBu^t (prepared through the debenzyloxycarbonylation of Z–Pro–OBu^t [16,17] (650 mg) by hydrogenation), and HOBt (270 mg) were dissolved in THF (7 ml). To the chilled solution was added DCC (400 mg), and the resulting mixture was stirred at 0 °C for 2.5 h and then at room temperature overnight. After *N,N′*-dicyclohexylurea had been removed by filtration, the filtrate was evaporated under reduced pressure. The residue was dissolved in EtOAc, washed successively with 5% citric acid, water, 5% $NaHCO_3$, and water, and dried over Na_2SO_4. Removal of the solvent afforded a pure product as a syrup; yield, 776 mg (82%); $[\alpha]_D^{25}$ −86.7° (*c* 1.0, MeOH).

┌*–Phe–OBzl*
|
Z–CmVal–OEt (*8*), *by the EDC Method*: To a chilled mixture of Z–CmVal–OEt·DCHA (**3e**·DCHA) (311 mg), H–Phe–OBzl·TosOH (256 mg), TosOH·H_2O (114 mg), and dioxane (6 ml) was added EDC (93 mg). The resulting mixture was stirred at 0 °C for *ca.* 2 h and then at room temperature overnight. After the mixture had been evaporated under reduced pressure, the residue was distributed between EtOAc and water, and the organic layer was further washed with 2% (or 5%) HCl, water, 5% $NaHCO_3$, and water again, and dried over Na_2SO_4. Removal of the solvent afforded a syrup (305 mg), which was chromatographed on preparative layers of silica gel with benzene–EtOAc (9 : 1); yield, 183 mg (53%); syrup, $[\alpha]_D^{25}$ −24.8° (*c* 1.5, $CHCl_3$).

The tripeptides (**16** and **17**) were prepared using double molar amounts of the amino component and EDC in a manner similar to that described above.

┌*–Pro–Val–OBzl*
|
Z–CmVal–OEt (*11*), *by the DCC Method*: To a chilled mixture of Z–CmVal–OEt·DCHA (**3e**·DCHA) (1036 mg), H–Pro–Val–OBzl·HBr (prepared by the debenzyloxycarbonylation of Z–Pro–Val–OBzl[20] (876 mg) with 25% HBr in AcOH (2.64 g) as usual), and CH_3CN (24 ml) was added DCC (415 mg) at 0 °C. The reaction mixture was stirred at this temperature for 2 h and then at room temperature overnight. After filtration of *N,N′*-dicyclohexylurea and a work-up similar to that described for the preparation of **8**, the residual syrup was chromatographed on preparative layers of silica gel with benzene–EtOAc (1 : 1); yield, 640 mg (51%); syrup, $[\alpha]_D^{25}$ −94.7° (*c* 1.1, $CHCl_3$).

OBu^t
|
Z–CmVal–Phe–OMe (*14*), *by the Mixed Anhydride Method*: To a chilled solution of **5** (obtained by the saponification of **4** with 0.5 M NaOH in aq EtOH) (417 mg) and TEA (115 mg) in THF (3 ml) was added isobutyl chloroformate (156 mg) with vigorous stirring below −10 °C. After 5 min a mixture of H–Phe–OMe·HCl (246 mg) and TEA (115 mg) in $CHCl_3$ (3 ml) was added at *ca.* −10 °C. The resulting mixture was stirred below 0 °C for *ca.* 3 h and then at room temperature overnight. After a work-up similar to that described for the preparation of **6**, the residual syrup was chromatographed on preparative layers of silica gel with benzene–EtOAc (9 : 1); yield, 311 mg (52%); syrup, $[\alpha]_D^{25}$ +4.9° (*c* 1.9, $CHCl_3$).

┌*–Phe–OBzl*
|
CmPro–Phe–OBzl (*18*), *by the DCC–HOBt Method*: To a chilled suspension of Cm-proline (157 mg), H–Phe–OBzl·TosOH (778 mg), TEA (184 mg), and HOBt (245 mg) in $CHCl_3$–THF–DMF (6 ml each) was added DCC (374 mg), and the resulting mixture was stirred at 0 °C for *ca.* 2 h and then at room temperature for 2 d. After *N,N′*-dicyclohexylurea had been removed by filtration, the filtrate was treated in a manner similar to that described for the preparation of **8**, to afford a syrup (502 mg). It was chromatographed on preparative layers of silica gel with $CHCl_3$–EtOAc (1 : 1) and then with benzene–EtOAc (3 : 1); yield, 333 mg (57%); syrup, $[\alpha]_D^{25}$ −49.0° (*c* 1.7, MeOH).

Preparation of Dipeptides Using Cm-amino Acid Diesters as the Amino Components. All the desired protected peptides were prepared by the acid chloride method. They were obtained as syrups, except **20**. The final purification of all of these compounds, except **20**, was performed by preparative TLC on silica gel. The results are summarized in Table 4. The carboxyl components, Pht–Gly–Cl,[22] Pht–Val–Cl,[23] Z–Ala–Cl,[24] and Z–Phe–Cl,[10] were prepared according to the literature. Z–Val–Cl[13] was prepared in a manner similar to the case of Z–Ala–Cl as follows: to a stirred solution of Z–Val–OH (350 mg) in dry Et_2O (3 ml) was added PCl_5 (310 mg) portion by portion at 0 °C. After 25 min the resulting solution was filtered, and the filtrate concentrated under reduced pressure below 10 °C. The residual syrup was washed well with dry petroleum ether, and dissolved in dry THF (1.5 ml). The solution was directly used for the coupling reaction. Typical examples are shown below.

OBzl
|
Z–Phe–CmVal–OEt (*27*): To a stirred solution of **1e** (980 mg) and *N*-ethyldiisopropylamine (430 mg) (or TEA (337 mg)) in dry THF (5 ml) was added Z–Phe–Cl (freshly prepared by the reaction of Z–Phe–OH (1.00 g) with PCl_5 (800 mg) in dry ether) in dry THF (2 ml) at 0 °C. The mixture was stirred at this temperature for *ca.* 3 h and then at room temperature for 2 d. The precipitates were filtered off, and the filtrate evaporated under reduced pressure. The residue was distributed between EtOAc (or Et_2O) and water, and the organic layer washed successively with 10% (w/w) HCl, water, 5% $NaHCO_3$, and water. After the dried (over

Na_2SO_4) solution had been evaporated under reduced pressure, the residue was treated batchwise with Amberlyst 15 (*ca.* 2 g) in MeOH, and then chromatographed on preparative layers of silica gel with benzene–EtOAc (9 : 1), to afford a syrup; yield, 787 mg (41%); $[\alpha]_D^{25}$ −43.9° (*c* 1.1, $CHCl_3$).

*Pht–Gly–CmVal(OBzl)–OEt (**20**)*: A mixture of **1e** (2.03 g), *N*-ethyldiisopropylamine (0.89 g), Pht–Gly–Cl (1.70 g), and dry THF (16 ml) was stirred at 0 °C for a few hours and then at room temperature for 2 d. After washing with 10% (w/w) HCl and 0.5 M $NaHCO_3$ the crude product (2.31 g) was obtained as crystals; mp 107—113 °C. It was recrystallized from benzene; yield, 1.44 g (44%); prisms, mp 112.5—114 °C, $[\alpha]_D^{25}$ −16.5° (*c* 1.0, $CHCl_3$).

*Z–Ala–CmPhe(OBzl)–OMe (**23**)*: A solution of **1c**·TosOH (350 mg) and TEA (142 mg) in dry THF (5 ml) was allowed to react with a solution of Z–Ala–Cl (freshly prepared by the reaction of Z–Ala–OH (310 mg) with PCl_5 (310 mg) in dry ether as a syrup and then dissolved in dry THF (1.5 ml)) in a manner similar to that described for the preparation of **27**. The final purification by preparative TLC with benzene–EtOAc (9 : 1) afforded the desired compound (**23**) as a syrup; yield, 104 mg (28%); $[\alpha]_D^{25}$ −67.9° (*c* 0.68, $CHCl_3$).

*Z–Phe–CmVal(Pro–Val–OBzl)–OEt (**31**)*. The tripeptide **11** (310 mg) was treated with 25% HBr in AcOH (0.7 g) for 1 h, and worked up as usual, to afford **12** in a 72% yield. This product (204 mg) was mixed with *N*-ethyldiisopropylamine (107 mg) in dry THF (3 ml), and allowed to react with Z–Phe–Cl (freshly prepared from Z–Phe–OH (238 mg) as described above), at 0 °C for 5 h and then at room temperature for 2 d. After washing in a manner similar to that described for the preparation of **27**, the residual syrup (174 mg) was chromatographed on preparative layers of silica gel with benzene–EtOAc (1 : 1); yield, 84 mg (30%); syrup, $[\alpha]_D^{25}$ −126.1° (*c* 0.62, $CHCl_3$). TLC: R_f 0.09 (benzene–EtOAc (3 : 1)), 0.46 (benzene–EtOAc (1 : 1)). Found: C, 66.34; H, 7.12; N, 7.24%. Calcd for $C_{43}H_{54}N_4O_9$: C, 66.99; H, 7.06; N, 7.27%.

Preparation of Peptides Containing Cm-amino Acids with the Free Imino Group. The final purification of the desired peptides was performed by preparative TLC on silica gel. The results are summarized in Table 5. The general procedure for the preparation of these compounds is illustrated by the following example.

*H–CmVal(Val–OBzl)–OMe (**33**)*: To an ice-chilled solution of H–Val–OBzl·TosOH (3.75 g) and TEA (2.00 g) in THF (30 ml) was added bromoacetyl bromide (2.00 g) in THF (10 ml) drop by drop. Then the mixture was stirred below 5 °C overnight. The usual work-up afforded benzyl *N*-(bromoacetyl)valinate as a syrup; yield, 2.85 g (88%). (Benzyl *N*-(bromoacetyl)phenylalaninate was prepared in a similar manner in an 89% yield.) This product was used for the next reaction without further purification.

To a stirred solution of H–Val–OMe·TosOH (750 mg) and TEA (500 mg) in THF (6 ml) was added the bromoacetylated compound (870 mg) obtained above in THF (4 ml) drop by drop. Then the reaction mixture was stirred at room temperature for a week, with occasional filtration of the precipitates. After the solvent had been removed under reduced pressure, the residue was distributed between EtOAc and water, and the organic layer was washed with water and dried over Na_2SO_4. Removal of the solvent afforded a syrup, which was chromatographed on preparative layers of silica gel successively with $CHCl_3$–EtOAc (9 : 1) and benzene–EtOAc (3 : 1); yield, 442 mg (47%); syrup, $[\alpha]_D^{25}$ −50.3° (*c* 1.5, MeOH).

The author would like to express his deep gratitude to Professors (the late) Hiroshi Watanabe, Shigeru Kuwata (Kōnan University), and Kazuhiro Maruyama (Kyoto University) for their invaluable suggestions and continuous encouragement.

Studies on Nucleosides and Nucleotides. VIII.[1] Preparation and Reactions of Triphenylphosphoranediylnucleosides

Junji KIMURA, Kentaro YAGI, Hideyuki SUZUKI, and Oyo MITSUNOBU*

Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo 157

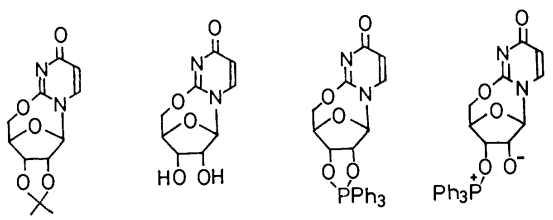
(Received May 12, 1980)

The reaction of uridine, N^4-benzoylcytidine, guanosine, and N^6-*p*-toluoyladenosine with diethyl azodicarboxylate and triphenylphosphine resulted in the formation of the corresponding 2′,3′-*O*-(triphenylphosphoranediyl)-cyclonucleosides. On the other hand, adenosine afforded, under similar conditions, 3′,5′-*O*-(triphenylphosphoranediyl)adenosine (**19**). The difference can be explained in terms of the acidity of base moieties of the nucleosides. The reaction of 2′,3′-*O*-(triphenylphosphoranediyl)-O^2,5′-cyclouridine, N^4-benzoyl-2′,3′-*O*-(triphenylphosphoranediyl)-O^2,5′-cyclocytidine, 2′,3′-*O*-(triphenylphosphoranediyl)-N^3,5′-cycloguanosine, or N^6-*p*-toluoyl-2′,3′-*O*-(triphenylphosphoranediyl)-N^3,5′-cycloadenosine with nucleophiles and with electrophiles addorded the corresponding nucleoside derivatives with free 2′- and 3′-hydroxyl groups. Thus the 2′,3′-*O*-triphenylphosphoranediyl group serves as a protecting group which is readily removed during work-up of the reaction products. **19** reacted with phenyl isocyanate to give 5′-*O*-phenylcarbamoyladenosine and N^6,5′-*O*-bis(phenylcarbamoyl)adenosine. The reaction of **19** with diphenylketene also afforded acyladenosines with free 2′- and 3′-hydroxyl groups. These results suggested that 3′,5′-*O*-triphenylphosphoranediyl group activates the 5′-carbon atom of adenosine.

Since the discovery of 2′,3′-*O*-isopropylidene-N^3,5′-cycloadenosine by Todd and his coworkers, many cyclonucleosides have been synthesized and utilized in synthetic organic chemistry and pharmaceutical as well as in genetic studies.[2] Cyclonucleosides are generally prepared by two stage reactions which involve transformation of a hydroxyl group of the sugar moiety into a leaving group and subsequent intramolecular displacement. Recent study in this laboratory has shown that 2′,3′-*O*-isopropylideneuridine reacts with diethyl azodicarboxylate (**1**) and triphenylphosphine (**2**) giving 2′,3′-*O*-isopropylidene-O^2,5′-cyclouridine (**3**).[3]

In the present paper, we describe the synthesis of triphenylphosphoranediylnucleosides and the use of these compounds in the preparation of nucleoside derivatives.[4]

2′,3′-O-(Triphenylphosphoranediyl)-O²,5′-cyclouridine. In order to obtain unprotected O^2,5′-cyclouridine (**4**), the reaction of uridine with 3 molar equivalents each of **1** and **2** was carried out at room temperature, 2′,3′-*O*-(triphenylphosphoranediyl)-O^2,5′-cyclouridine (**5**) and not the expected **4** being isolated in 65% yield. An alternative structure, **6**, or its position isomer was ruled out by NMR study. A signal is observed in the ^{31}P-NMR spectrum at $\delta = +27.60$, lying in the region characteristic for a phosphorane and not for a phosphonium salt (Table 1).[5] Further support for the structure **5** was provided by the following reactions.

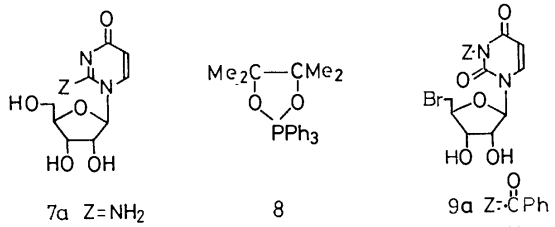


3 4 5 6

Acid or alkaline hydrolysis of **5** afforded uridine and triphenylphosphine oxide in a *ca.* 1 : 1 ratio, **4** being obtained in 70% yield[6] on treatment with H_2O–tetrahydrofuran (THF) at room temperature for 3 d. **4** reacted with **1** and **2** to regenerate **5** in 73% yield. When **5** was treated with ammonia in methanol, isocytidine (**7a**) was isolated which was subsequently converted into 2′,3′-*O*-isopropylideneisocytidine. The results indicate that the removal of triphenylphosphine oxide proceeds smoothly with retention of the configuration of 2′- and 3′-hydroxyl groups.

Bartlett *et al.* reported that 2,2,2-triphenyl-4,4,5,5-tetramethyl-1,3,2-dioxaphospholane (**8**) decomposes into tetramethyloxirane even at room temperature.[7] Unlike **8**, **5** is thermally stable and can be recrystallized from *N*,*N*-dimethylformamide (DMF) at 80 °C. As compared with the isopropylidene group, the –O–P–O– bond of the phosphoranediyl group is somewhat more labile but still stable enough to be treated without difficulty under ordinary atmosphere. **5** could therefore be utilized as a protected O^2,5′-cyclouridine.

The reaction of **5** with methanol under reflux for 10 h afforded O^2-methyluridine (**7b**) in 80% yield. As in the case of **3**,[8] **5** reacted smoothly with benzoyl bromide and with acetyl bromide to give 5′-bromo-5′-deoxy-N^3-benzoyluridine (**9a**; 72%) and 5′-bromo-5′-deoxyuridine (**9b**; 60%), respectively. The fact that no 2′- and/or 3′-acylated products could be detected in these reactions indicates that the phosphoranediyl group is stable under the reaction conditions used.



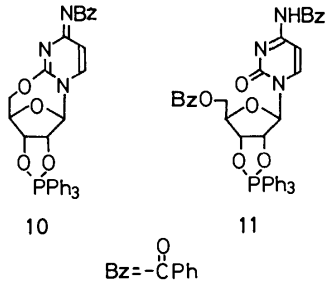
7a Z=NH₂ b Z=OMe 8 9a Z=C(=O)Ph b Z=H

In the reactions of triphenylphosphoranediyl nucleosides with nucleophiles and electrophiles, the isolated

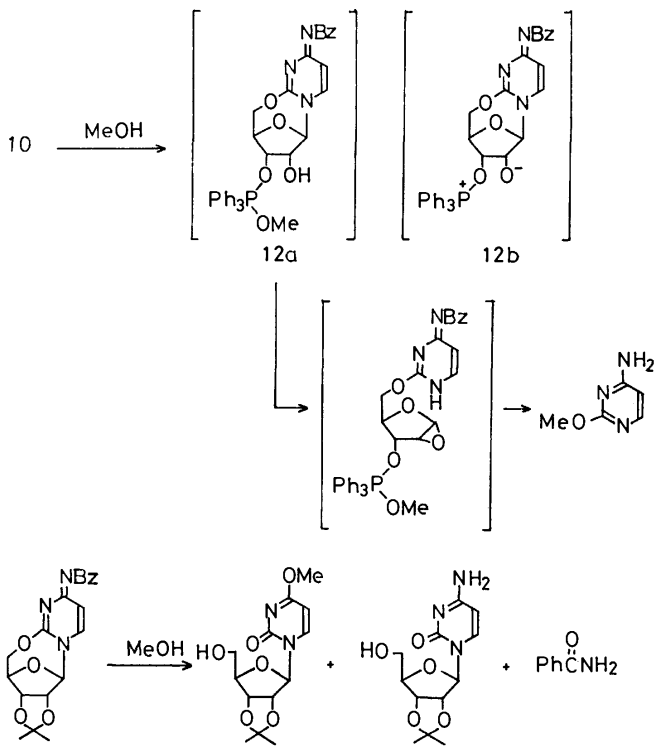
products has no phosphorane ring, presumably because triphenylphosphine oxide was eliminated during the work-up.

N^4-Benzoyl-2′,3′-O-(triphenylphosphoranediyl)-O′,5′-cyclocytidine. When cytidine was allowed to react with **1** and **2** in a similar manner to that described above, unidentified products were formed. The reaction of N^4-benzoylcytidine with **1** and **2**, however, gave N^4-benzoyl-2′,3′-*O*-(triphenylphosphoranediyl)-O^2,5′-cyclocytidine (**10**) in 71% yield.

The O^2,5′-anhydro bond of 2′,3′-*O*-isopropylidene-O^2,5′-cyclocytidine methanesulfonate is known to be more reactive than that of **3**.[9] This is also the case with phosphoranediylcyclonucleosides **5** and **10**. Thus when **10** was treated with acetonitrile–H_2O at room temperature for 2 d, N^4-benzoylcytidine and triphenylphosphine oxide were formed in a *ca.* 1 : 1 ratio. **10** reacted smoothly at room temperature with benzoic acid giving N^4,5′-*O*-dibenzoylcytidine quantitatively.[10] By the reaction with **1** and **2**, N^4,5′-*O*-dibenzoylcytidine afforded N^4,5′-*O*-dibenzoyl-2′,3′-*O*-(triphenylphosphoranediyl)cytidine (**11**) in 49% yield. The configuration of 2′- and 3′-hydroxyl group was thus retained during the migration of the phosphoranediyl group.



Both the anhydro and glycosidic bonds were cleaved by treatment of **10** in methanol at room temperature overnight, O^2-methylcytosine being obtained in 65% yield. Attempts to isolate and identify the products from the sugar moiety were unsuccessful. On the other hand, no glycosidic bond cleavage took place when N^4-benzoyl-2′,3′-*O*-isopropylidene-O^2,5′-cyclocytidine was treated in methanol under the same conditions.

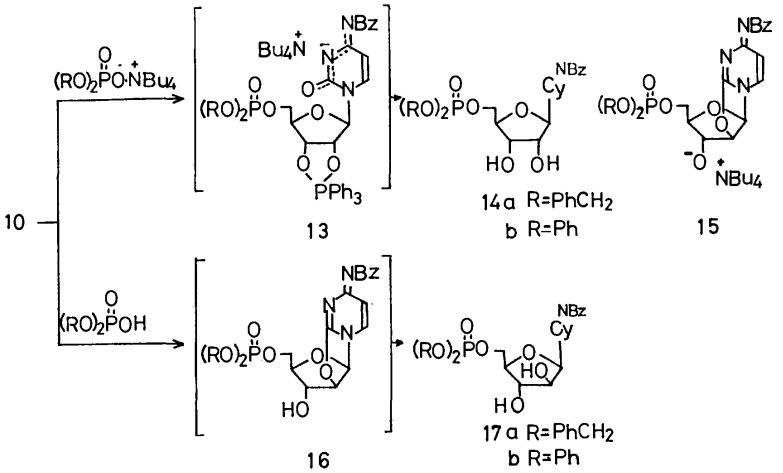


Scheme 1.

In this case O^4-methyl-2′,3′-*O*-isopropylideneuridine, 2′,3′-*O*-isopropylidenecytidine, and benzamide were isolated in 33, 23, and 36% yields, respectively (Scheme 1).

The formation of O^2-methylcytosine might be explained by the initial formation of phosphorane (**12a**) or betaine (**12b**). The glycosidic and O^2,5′-anhydro bonds were successively cleaved by intramolecular nucleophilic displacement and methanolysis as shown in Scheme 1.

The reaction of **10** with phosphoric diesters was studied. As expected, **10** reacted with tetrabutylammonium dibenzyl phosphate at room temperature to afford N^4-benzoylcytidin-5′-yl dibenzyl phosphate (**14a**; 35% isolated yield) which was converted into the corresponding isopropylidene derivatives. Similarly the reaction



Scheme 2.

of **10** with tetrabutylammonium diphenyl phosphate gave **14b** in 15% isolated yield (Scheme 2). On the other hand, when **10** was allowed to react with dibenzyl hydrogenphosphate or diphenyl hydrogenphosphate under the same conditions, neither **14a** nor **14b** could be isolated, but 1-(β-D-arabinofuranosyl)-N^4-benzoylcytosin-5′-yl dibenzyl phosphate (**17a**) and 1-(β-D-arabinofuranosyl)-N^4-benzoylcytosin-5′-yl diphenyl phosphate (**17b**) were isolated in 38 and 52% yields, respectively (Scheme 2).[11] The structure of **17b** was determined by comparison of physical properties with those of an authentic sample prepared by the reaction of 1-(β-D-arabinofuranosyl)-N^4-benzoylcytidine with diphenyl phosphorochloridate.

The difference between the reaction of **10** with a phosphoric diester and with its tetrabutylammonium salt might be explained by the mechanism illustrated in Scheme 2. When a phosphoric diester attacks the 5′-carbon atom of **10**, rearrangement of O^2,5′-anhydro bond takes place with liberation of triphenylphosphine oxide, forming O^2,2′-cyclocytidine 5′-phosphate (**16**) which is hydrolyzed to **17** during the course of manipulation.[12] Since no evidence of the formation of O^2,2′-anhydro bond was obtained in the reaction of **10** with benzoic acid, the anhydro bond rearrangement would be an acid catalyzed process. Since no proton source exists in the reaction of **10** with a tetrabutylammonium salt of phosphoric diester, the anhydro bond rearrangement is unfavorable because of instability of the resulting alkoxide (**15**). The reaction stops at the stage of the formation of **13**.

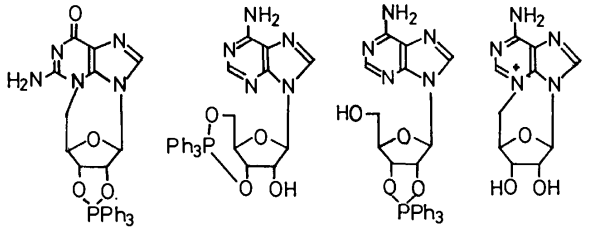
2′,3′-O-(Triphenylphosphoranediyl)-N^3,5′*-cycloguanosine.* Guanosine also reacted with **1** and **2** at 70 °C to give 2′,3′-*O*-(triphenylphosphoranediyl)-N^3,5′-cycloguanosine (**18**) which was readily hydrolyzed to N^3,5′-cycloguanosine and triphenylphosphine oxide in a 1 : 1 ratio. ^{31}P-NMR spectrum also supports the phosphorane structure (Table 1).

TABLE 1. YIELD AND PHYSICAL CONSTANTS OF TRIPHENYLPHOSPHRANEDIYLNUCLEOSIDES

Compound	**5**	**10**	**18**	**19**	**29**
Yield/%	62	71	67	75	24
Mp/°C	>250	200—201	>250	171—172	200—204
UV_{max} (MeCN)/nm	232	235^{sh}, 318	259	260	
$\varepsilon \times 10^{-4}$	2.65	1.46	1.25	0.74	
^{31}P-NMR(δ)[a]	+27.60	+27.54	+26.58	+29.33	

a) Recorded on a Hitachi R-22 spectrometer at 36.414 MHz±1 Hz (^{1}H decoupled; solvent, DMF). Triphenylphosphine sulfide (δ −42.07; Ref. 85% H_3PO_4) was used as an internal standard, the reported chemical shift being relative to 85% H_3PO_4.

3′,5′-O-(Triphenylphosphoranediyl)adenosine. When adenosine was allowed to react with **1** and **2** in dioxane at 70 °C, a phosphorus-containing compound was obtained, showing UV_{max} 260 nm, and a ^{31}P-NMR singlet at +29.33 ppm (Table 1). This compound was hydrolyzed to adenosine and triphenylphosphine oxide in a 1 : 1 ratio. As the structure of the product, both 3′,5′-*O*-(triphenylphosphoranediyl)- and 2′,3′-*O*-(triphenylphosphoranediyl)adenosine (**19** and **20**) are conceivable.



18 19 20 21

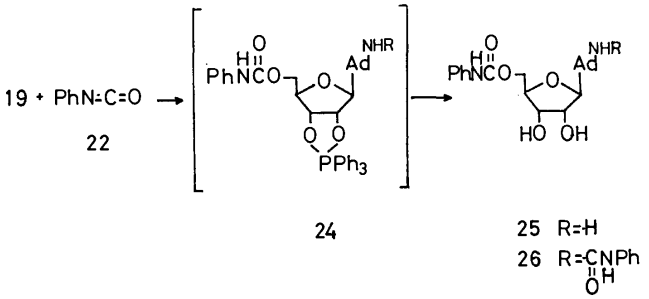
In order to confirm the structure, the product was allowed to react with benzoic acid to form 5′-*O*-benzoyladenosine and N^3,5′-cycloadenosine (**21**) in 59 and 16% yields, respectively. A similar treatment with thiobenzoic acid gave 5′-benzoylthio-5′-deoxyadenosine in 63% yield. It can be concluded that the product obtained by the reaction of adenosine with **1** and **2** is **19** rather than **20**.

The fact that **19** is readily hydrolyzed to adenosine under mild conditions suggests that the compound can be utilized as a starting material for the protection of 2′-hydroxyl group of adenosine. Contrary to expectation, reactions of **19** with acyl halide, acid anhydride or dihydropyran were complicated, giving rise to significant side reactions and affording unidentified products.

The reaction of **19** with phenyl isocyanate (**22**) and diphenylketene (**23**), however, led to definite products. **19** reacted with **22** in pyridine to give 5′-*O*-phenylcarbamoyladenosine (**25**) and N^6,5′-*O*-bis(phenylcarbamoyl)adenosine (**26**) in 34 and 45% yields, respectively. The products were identified by comparison with samples prepared by the reaction of **22** with 2′,3′-*O*-isopropylideneadenosine, followed by removal of the protecting group.

Similarly, **19** reacted with **23** to give 5′-*O*-(diphenylacetyl)adenosine and N^6,5′-*O*-bis(diphenylacetyl)-adenosine in 21 and 41% yields, respectively.

In the reaction of **19** with **22** and with **23**, no 2′- and/or 3′-*O*-carbamoyl- or acyladenosine could be obtained. The results lead to the hypothesis that the 3′,5′-*O*-triphenylphosphoranediyl group "activates" the 5′-carbon atom of **19**. The electrophilic attack at the 5′-carbon atom accompanies 5′-O–P bond rearrangement giving 2′,3′-*O*-(triphenylphosphoranediyl)-



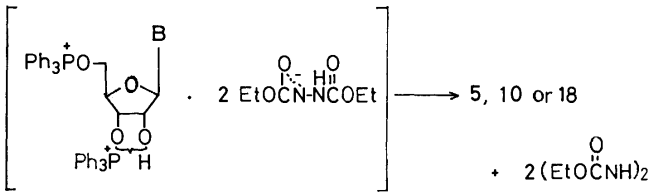
22 24 25 R=H 26 R=CNPh

Scheme 3.

adenosine derivative (**24**) in which the phosphoranediyl group protects 2'- and 3'-hydroxyl groups from further attack of the electrophiles (Scheme 3).[13]

On the basis of NMR studies, Mengel and Bartke have demonstrated that the product obtained by the reaction of adenosine with **1** and **2** is not **19** but **20**.[14] However, it is difficult to explain the formation of 5'-*O*-benzoyladenosine and N^3,5'-cycloadenosine by the structure **20**. A plausible interpretation might be given if we assume equilibrium between **19** and **20** in which the former is reactive species.

Reaction Mechanism. 2'(or 3'),5'-*O*-Bis(triphenylphosphonio)nucleoside (**27**) can be assumed to be a key intermediate for the formation of 2',3'-*O*-(triphenylphosphoranediyl)cyclonucleoside.[1,4] *N,N'*-Bis(ethoxycarbonyl)hydrazinide anion subsequently abstracts hydrogen atoms from the base and the hydroxyl group to form **5**, **10**, and **18** (Scheme 4).



27

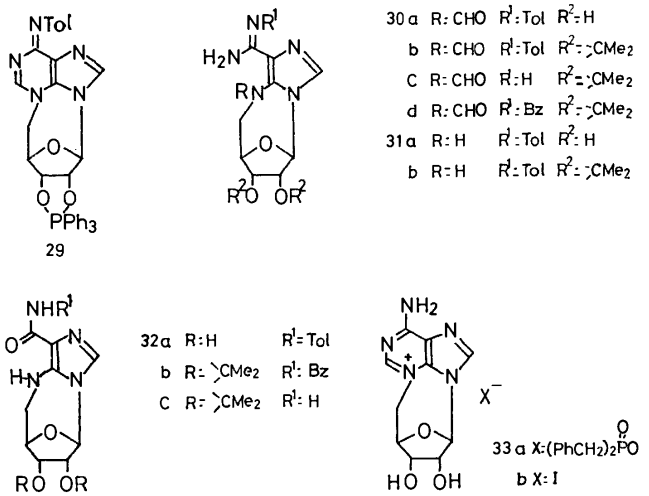
Scheme 4.

5 was obtained as the sole product derived from the nucleoside when the reaction of uridine with equimolar amounts of **1** and **2** was carried out with the intention of preparing **4**. This suggests that phosphorane ring formation is essential for the formation of the anhydro bond.[15]

The reaction of adenosine with **1** and **2** would also proceed through the initial formation of 5'-*O*-(triphenylphosphinio)adenosine (**28**). Since the hydrogen atom of the adenine ring is not so acidic as to be abstracted by hydrazinide anion, the 3'-hydroxyl group of **28** attacks the phosphorus atom giving **19**. Whether anhydro bond is formed or not would depend on the relative acidity of the base moiety of nucleoside and *N,N'*-bis(ethoxycarbonyl)hydrazine. In order to confirm the assumption, we carried out the reaction of N^6-*p*-toluoyladenosine in which N^6-hydrogen atom was expected to become more acidic than *N,N'*-bis(ethoxycarbonyl)hydrazine by the electron withdrawing effect of the *p*-toluoyl group.

The reaction of N^6-*p*-toluoyladenosine with **1** and **2** resulted in the formation of N^6-*p*-toluoyl-2',3'-*O*-(triphenylphosphoranediyl)-N^3,5'-cycloadenosine (**29**) in 24% isolated yield. Since purification of the product was difficult, the crude products obtained under separate experiment were treated with water under reflux to afford N^5,5'-anhydro-5-formamido-4-(*N*-*p*-toluoylamidino)-1-(β-D-ribofuranosyl)imidazole (**30a**) in 74% yield. By treatment with ammonia in methanol, **30a** was converted into **31a** which was hydrolyzed to **32a** under mild acidic conditions.

N^3,5'-Anhydro bond formation also took place when N^6-*p*-toluoyl-2',3'-*O*-isopropylideneadenosine was used. Thus the reaction of the fully protected nucleoside with **1** and **2** afforded imidazole nucleoside (**30b**) in a nearly quantitative yield rather than N^6-*p*-toluoyl-2',3'-*O*-isopropylidene-N^3,5'-cycloadenosine. Thus the precursor of **30b** should be N^6-*p*-toluoyl-2',3'-*O*-isopropylidene-N^3,5'-cycloadenosine which was hydrolyzed to **30b** during the work-up involving preparative layer chromatography. By subsequent treatment with ammonia in methanol, **30b** was converted into deformylated imidazole nucleoside (**31b**).



Reports have been given on the cleavage of N(1)–C(2) bond of N^3,5'-cycloadenosine derivatives. Anzai and Matsui[16] reported that treatment of 2',3'-*O*-isopropylidene-N^3,5'-cycloadenosine methanesulfonate and 5'-*O*-methylsulfonyl-N^6,N^6-dibenzoyl-2',3'-*O*-isopropylideneadenosine with alkali leads to imidazole cyclonucleoside **30c** and **30d**, respectively; they also reported the transformation of **30d** into **32b** and **32c**.

When the reaction of adenosine with **1** and **2** is carried out in the presence of dibenzyl hydrogenphosphate, N^3,5'-cycloadenosine dibenzyl phosphate (**33a**) is formed in good yield.[1] The reaction of adenosine with methyltriphenylphosphonium iodide gave N^3,5'-cycloadenosine iodide (**33b**).[17] It can thus be concluded that the N^3,5'-anhydro bond of adenosine is formed only when the reaction system involves a conjugate base of strong acid which stabilizes the N^3,5'-cycloadenosine cation.

The methods described make phosphoranediylnucleosides readily available. That the phosphoranediyl function serves as a protecting group as well as an activating group suggests a number of possibilities for the transformation of nucleosides.

Experimental

Methods. Preparative layer chromatography (TLC) was carried out on 20 cm × 20 cm or 20 cm × 30 cm glass plates coated with Merck silica gel PF_{254}. ^{1}H-Nuclear magnetic resonance (NMR) spectra were measured on a Hitachi R-20 spectrometer (60 MHz) using tetramethylsilane as an internal standard. We are grateful to Dr. G. Miyajima of Hitachi Co. Ltd. for the measurement of ^{31}P-NMR spectra. Ultraviolet absorption spectra were obtained with a Hitachi EPS-3T

recording spectrometer. Elemental analyses were carried out at the Institute of Physical and Chemical Research, Wako-shi, Saitama.

2′,3′-O-(Triphenylphosphoranediyl)-O²,5′-cyclouridine (5). A solution of **1** (2.61 g, 15 mmol) in THF (2 ml) was added to a mixture of uridine (1.22 g, 5 mmol) and **2** (3.93 g, 15 mmol) in THF (10 ml) at room temperature. The nucleoside dissolved on addition of **1**, precipitation taking place shortly afterwards. After the mixture had been kept stirred at room temperature overnight, the precipitate was collected by centrifugation, washed successively with THF and ether. Recrystallization from DMF (80 °C) gave **5** not melting below 250 °C; UV_{max} (MeCN) 232 nm; NMR (DMSO-d_6) δ=4.32, 4.50, 4.70 (m, 5, $C_{2'}H$, $C_{3'}H$, $C_{4'}H$, $C_{5'}H$), 5.86 (br. s, 1, $C_{1'}H$), 7.28 (15, aromatic H). Found: C, 66.65; H, 4.82; N, 5.81%. Calcd for $C_{27}H_{23}N_2O_5P$: C, 66.67; H, 4.76; N, 5.76%.

When **5** was treated with AcOH–H_2O or dil aqueous ammonia, uridine and triphenylphosphine oxide were formed in a 1 : 1 ratio.

O²,5′-Cyclouridine (4). A solution of **5** (486 mg, 1 mmol) in THF–H_2O (1 : 1 v/v, 10 ml) was stirred over a period of 3 d at room temperature and then evaporated. The residue was washed with acetone in order to remove triphenylphosphine oxide giving **4** (70%), which melted with decomposition at *ca.* 265 °C (lit,[6] dec 212—214 °C). UV_{max} (MeOH) 238 nm. Found: C, 47.75; H, 4.54; N, 12.34%. Calcd for $C_9H_{10}N_2O_5$: C, 47.79; H, 4.46; N, 12.39%.

When **4** was allowed to react with 1.5 molar equivalent each of **1** and **2** in THF at room temperature overnight, **5** was obtained in 73% yield.

O²-Methyl- and O²-Ethyluridine. **5** (1.458 g, 3 mmol) was treated with methanol (100 ml) under reflux for 10 h and then evaporated. The residue was washed with acetone, recrystallization from methanol giving *O²*-methyluridine with mp 171—172 °C (lit,[18] mp 173 °C). UV_{max} (H_2O) 229, 253 nm, UV_{min} 213, 238 nm.

Similarly, *O²*-ethyluridine was isolated in 41% yield, mp 176—177 °C. UV_{max}(H_2O) 228, 253 nm; UV_{min} 213, 237 nm.

Isocytidine. A solution of **5** (120 mg, 0.125 mmol) in saturated methanolic ammonia (10 ml) was left to stand at room temperature for 5 d and then separated by TLC using $CHCl_3$–MeOH (10 : 1) to give isocytidine as a glass almost quantitatively. UV_{max}(MeOH) 230^{sh}, 255 nm, UV_{min} 250 nm. Found: C, 44.23; H, 5.39; N, 17.28%. Calcd for $C_9H_{13}N_3O_5$: C, 44.44; H, 5.72; N, 17.10%.

Isocytidine (100 mg, 0.41 mmol) dissolved in 2,2-dimethoxypropane (2 ml) in the presence of a catalytic amount of *p*-toluenesulfonic acid was stirred for 2 h at room temperature and then neutralized with sodium methoxide. The resulting mixture was separated by TLC using $CHCl_3$–MeOH (10 : 1), giving 50% of 2′,3′-*O*-isopropylideneisocytidine which was purified by re-precipitation from ethanol–ether, mp 191—192 °C (lit,[18] mp 206—207 °C).

Reaction of 5 with Acyl Bromide. A mixture of **5** (484 mg, 1 mmol) and acetyl bromide (492 mg, 4 mmol) in THF (5 ml) was kept stirred at room temperature for 3 h and then evaporated. The residue was separated by TLC using $CHCl_3$–MeOH (95 : 5) giving 173 mg (73%) of **9b** with mp 183—185 °C (lit,[19] mp 180—183 °C).

In a similar way, **5** was treated with benzoyl bromide to give **9a** (300 mg, 73%). The substance softens at 78 °C, showing no definite mp. UV_{max}(MeOH) 255 nm, UV_{min} 226 nm. Found: C, 46.62; H, 3.53; N, 6.60%. Calcd for $C_{15}H_{15}N_2O_5Br$: C, 46.73; H, 3.77; N, 6.81%.

N⁴-Benzoyl-2′,3′-O-(triphenylphosphoranediyl)-O²,5′-cyclocytidine (10). A solution of **1** (4 mmol) in THF (2 ml) was added to a mixture of *N⁴*-benzoylcytidine (694 mg, 2 mmol) and **2** (4 mmol) in THF (4 ml) at room temperature. The nucleoside dissolved as **1** was added and shortly afterwards pale yellow solid began to precipitate. After the mixture had been stored at room temperature for 2 d, the precipitate was collect and recrystallized from dry acetonitrile, giving 830 mg (71%) of **10** which decomposed at 200—201 °C. UV_{max} (MeCN) 235^{sh}, 318 nm (ε 14600), UV_{min} 290 nm; NMR ($CDCl_3$) δ=4.16—4.66 (m, 5, $C_{2'}H$, $C_{3'}H$, $C_{4'}H$, $C_{5'}H$), 5.17 (d, 1, $C_{1'}H$), 6.60 (d, 1, C_5H), 8.20—8.30 (m, 21, aromatic-H, C_6H). Found: C, 69.27; H, 4.79; N, 6.93%. Calcd for $C_{34}H_{28}N_3O_5P$: C, 69.26; H, 4.79; N, 7.13%.

A solution of **10** in MeCN–H_2O (1 : 1) was kept stirred at room temperature for 2 d and then evaporated. The residue was washed with acetone to remove triphenylphosphine oxide, giving *N⁴*-benzoylcytidine in nearly quantitative yield with mp 222—225 °C (lit,[20] mp 219—220 °C). The substance was identical with an authentic sample as confirmed by IR analysis.

N⁴-Benzoyl-2′,3′-O-isopropylidene-O²,5′-cyclocytidine. A solution of **1** (4.5 mmol) in THF (2 ml) was added dropwise at room temperature to a solution of *N⁴*-benzoyl-2′,3′-*O*-isopropylidenecytidine (1.161 g, 3 mmol) and **2** (4.5 mmol) in THF (5 ml). After the mixture had been kept stirred overnight, the precipitate was filtered and recrystallized from $CHCl_3$ giving 484 mg (44%) of the compound with mp 290 °C. UV_{max} (MeCN) 252, 316 nm, UV_{min} 220, 290 nm; NMR (DMF-d_7 and acetone-d_6) δ=1.32 and 1.55 (two s, 6, isopropylidene methyl), 4.02—4.70 (m, 3, $C_{4'}H$, $C_{5'}H$), 5.06 (m, 2, $C_{2'}H$, $C_{3'}H$), 5.55 (d, 1, $C_{1'}H$), 6.51 (d, 1, C_5H), 7.36—8.11 ppm (m, 6, aromatic-H, C_6H).

N⁴,5′-O-Dibenzoylcytidine. *a) With Use of Benzoic Acid*: **10** (589 mg, 1 mmol) was allowed to react with benzoic acid (366 mg, 3 mmol) in THF (8 ml) at room temperature overnight or under reflux for 2.5 h. The TLC of the crude reaction mixture showed that **10** was completely converted into *N⁴*,5′-*O*-dibenzoylcytidine. The solvent was evaporated and the residue was purified by TLC ($CHCl_3$–MeOH= 10 : 1) giving the compound (70%) with mp 187—189 °C (lit,[21] mp 186—190 °C). UV_{max}(EtOH) 229, 261, 305 nm, UV_{min} 245, 289 nm.

b) With Use of Tetrabutylammonium Benzoate: Benzoic acid (1.5 mmol) was added to a 10% solution of tetrabutylammonium hydroxide in methanol (3 ml) and evaporated to dryness. The salt was rendered anhydrous by repeated evaporation of added portion of dry benzene. To the salt was added **10** (1 mmol) and THF (5 ml), and the mixture was kept stirred overnight. The mixture was then worked up as above giving the compound in nearly quantitative yield.

N⁴,5′-O-Dibenzoyl-2′,3′-O-(triphenylphosphoranediyl)cytidine (11). A solution of **1** (3 mmol) in THF (2 ml) was added dropwise at room temperature to a mixture of *N⁴*,5′-*O*-dibenzoylcytidine (910 mg, 2 mmol) prepared as described above and **2** (3 mmol) in THF (8 ml). The nucleoside dissolved as **1** was added, precipitation taking place shortly afterwards. The mixture was kept stirred overnight and filtered to give crude product (1.12 g, 80%) which was dissolved in acetone–$CHCl_3$ and concentrated to small volume *in vacuo*. The concentrated solution was kept standing to precipitate 700 mg (49%) of pure phosphorane which was collected by filtration, mp 183—184 °C (dec). UV_{max}(MeCN) 231, 259, 311 nm, UV_{min} 222, 246, 288 nm. NMR (DMSO-d_6) δ=4.1—4.8 (m, 5, $C_{2'}H$, $C_{3'}H$, $C_{4'}H$, $C_{5'}H$), 5.85 (d, 1, $C_{1'}H$), 7.1—8.2 (m, 27, aromatic-H, C_5H, C_6H), 11.25 ppm (br. s, 1, NH). Found: C, 68.74; H, 4.85; N, 5.44%. Calcd for $C_{40}H_{34}N_3O_7P$: C, 69.19; H, 4.87; N, 5.90%.

The phosphorane was hydrolyzed by treatment with THF–H_2O for 24 h to give N^4,5′-*O*-dibenzoylcytidine and triphenylphosphine oxide in a *ca.* 1 : 1 ratio.

Methanolysis of N⁴-*Benzoyl-2′,3′-O-(triphenylphosphoranediyl)-*O²,*5′-cyclocytidine (10).* One mmol of **10** was treated with methanol (50 ml) under reflux for 5 h or kept stirred at room temperature overnight and then evaporated. O^2-Methylcytosine was isolated in 65% yield (81 mg) by TLC using ethyl acetate. UV_{max} (H_2O) 228, 264 nm, UV_{min} 243 nm. NMR (DMSO-d_6) δ=3.82 (s, 3, CH_3O), 6.16 (d, 1, C_5H), 7.00 (br. s, 2, NH_2), 7.96 ppm (d, 1, C_6H).

Methanolysis of N⁴-*Benzoyl-2′,3′-O-isopropylidene-*O²,*5′-cyclocytidine.* When the title compound was treated with methanol as in the methanolysis of **10**, O^4-methyl-2′,3′-*O*-isopropylideneuridine with mp 235—236 °C was isolated in 33% yield (80 mg) by TLC using $CHCl_3$–MeOH (10 : 1). UV_{max} (MeOH) 276 nm, UV_{min} 240 nm. Found: C, 51.80; H, 6.05; N, 9.37%. Calcd for $C_{13}H_{18}N_2O_6$: C, 52.34; H, 6.08; N, 9.37%. Benzamide (53 mg, 36%, mp 125—128 °C) and 2′,3′-*O*-isopropylidenecytidine (36 mg, 23%, glass) were also obtained.

N⁴-Benzoylcytidin-5′-yl Dibenzyl Phosphate (14a) and Diphenyl-Phosphate (14b). Tetrabutylammonium dibenzyl phosphate was prepared from dibenzyl hydrogenphosphate (417 mg, 1.5 mmol) and tetrabutylammonium hydroxide (3 ml of 10% solution in methanol) by a procedure similar to that for N^4,5′-*O*-dibenzoylcytidine. The salt was allowed to react with **10** (489 mg, 1 mmol) at room temperature overnight, and then evaporated. The residue was purified by TLC using $CHCl_3$–MeOH (10 : 1) giving 210 mg (35%) of **14a** which was recrystallized from MeCN, melting at 136—137 °C. UV_{max} (MeOH) 262 (ε 24100), 306 nm, UV_{min} 235.5, 288 nm. NMR ($CDCl_3$+D_2O) δ=4.0—4.5 (m, 5, $C_2'H$, $C_3'H$, $C_4'H$, $C_5'H$), 5.07 (d, 4, $PhC\underline{H}_2$), 5.92 (d, 1, $C_1'H$), 7.3—8.3 ppm (m, 17, aromatic-H, C_5H, C_6H). Found: C, 59.31; H, 4.98; N, 6.92%. Calcd for $C_{30}H_{30}N_3O_9P$: C, 59.22; H, 5.03; N, 7.06%.

14a (58 mg) was converted into 2′,3′-*O*-isopropylidene derivative by treatment with acetone (1 ml) and 2,2-dimethoxypropane (2 ml) in the presence of *p*-toluenesulfonic acid (20 mg). The NMR spectrum of the product was identical with that of N^4-benzoyl-2′,3′-*O*-isopropylidenecytidin-5′-yl dibenzyl phosphate prepared by the procedure described below.

A similar treatment of **10** with tetrabutylammonium diphenyl phosphate afforded **14b** (15%) with mp 191—192 °C (from MeCN). NMR (DMSO-d_6) δ=5.35, 5.60 (2, 2′-OH, 3′-OH), 5.81 (d, 1, $C_1'H$), 11.10 ppm (br. s, 1, NH).

N⁴-Benzoyl-2′,3′-O-isopropylidenecytidin-5′-yl Dibenzyl Phosphate. Dibenzyl hydrogenphosphate (417 mg, 1.5 mmol) was converted into tetrabutylammonium salt and allowed to react with N^4-benzoyl-2′,3′-*O*-isopropylidene-O^2,5′-cyclocytidine (484 mg, 1 mmol) in THF (5 ml) at room temperature overnight. After being evaporated, the products were separated by TLC ($CHCl_3$–MeOH=19 : 1), giving 422 mg (65%) of the compound which was recrystallized from petroleum ether, melting at 123—124 °C. Found: C, 61.20; H, 5.29; N, 6.49%. Calcd for $C_{33}H_{34}N_3O_9P$: C, 61.14; H, 5.32; N, 6.51%.

*1-(β-D-Arabinofuranosyl)-*N⁴*-benzoylcytosin-5′-yl Dibenzyl Phosphate (17a).* Dibenzyl hydrogenphosphate (1.5 mmol) was allowed to react with **10** (1 mmol) in THF (5 ml) at room temperature overnight and then evaporated. **17a** (233 mg, 38%) was isolated by TLC using $CHCl_3$–MeOH (10 : 1). After recrystallization from MeCN, mp 166—169 °C. UV_{max} (EtOH) 261 (ε 24500), 308 nm, UV_{min} 235, 288 nm. NMR (DMSO-d_6) δ=3.86—4.38 (m, 5, $C_2'H$, $C_3'H$, $C_4'H$, $C_5'H$), 5.03 (d, 4, $PhC\underline{H}_2$), 5.70 (2, 2′-OH, 3′-OH), 6.20 (d, 1, $C_1'H$), 7.0—8.2 ppm (m, 17, aromatic-H, C_5H, C_6H).

*1-(β-D-Arabinofuranosyl)-*N⁴*-benzoylcytosin-5′-yl Diphenyl Phosphate (17b).* *a) Reaction of **10** with Diphenyl Hydrogenphosphate*: The compound was prepared in 52% yield by a procedure similar to that for **17a**. This compound was recrystallized from MeCN, melting at 196—197 °C. NMR (DMSO-d_6) δ=5.78 (2, 2′-OH, 3′-OH), 6.25 (d, 1, $C_1'H$), 11.15 ppm (br. s, 1, NH). Found: C, 58.08; H, 4.61; N, 7.39%. Calcd for $C_{28}H_{26}N_3O_9P$: C, 58.03; H, 4.52; N, 7.25%.

*b) Reaction of 1-(β-D-Arabinofuranosyl)-*N⁴*-benzoylcytosine with Diphenyl Phosphorochloridate*: 1-(β-D-Arabinofuranosyl)-N^4-benzoylcytosine[22] (80 mg, 0.23 mmol) was treated with diphenyl phosphorochloridate (100 mg, 0.37 mmol) in pyridine (1 ml) at room temperature overnight. After the work-up as described in a), **17b** was obtained in 51% yield. The products prepared by procedures a) and b) were identical.

*2′,3′-O-(Triphenylphosphoranediyl)-*N³,*5′-cycloguanosine (18).* A solution of **1** (6 mmol) in dioxane (2 ml) was added dropwise to a suspension of guanosine (566 mg, 2 mmol) and **2** (6 mmol) in dioxane (5 ml) at 70 °C. Guanosine dissolved as **1** was added. The homogeneous solution was kept stirred at 70 °C for 3 h and then allowed to cool to room temperature. The resulting precipitate was filtered. The solid was dissolved in DMF (15 ml) and reprecipitated by the addition of THF (60 ml) giving 700 mg (67%) of **18**, not melting below 250 °C. UV_{max} (MeCN) 235 (ε 26500), 258 (ε 13300) nm, UV_{min} 223, 253 nm. NMR (DMSO-d_6) δ=3.95 (m, 2, $C_5'H$), 4.58—5.00 (m, 3, $C_2'H$, $C_3'H$, $C_4'H$), 6.37 (s, 1, $C_1'H$), 7.00—7.95 ppm (m, 18, aromatic-H, NH_2, C_6H). Found: C, 63.41; H, 4.68; N, 12.80%. Calcd for $C_{28}H_{24}N_5O_4P$: C, 64.00; H, 4.60; N, 13.33%.

18 (400 mg, 0.76 mmol) was treated with 0.1 mol dm^{-3} HCl for 1 h at room temperature, triphenylphosphine oxide (187 mg, 94%) precipitated being filtered off. The filtrate was neutralized with aqueous ammonia and then evaporated. The residue was washed with acetone and recrystallized from H_2O giving N^3,5′-cycloguanosine (177 mg, 88%); mp 265 °C. UV_{max} (H_2O, pH 1) 249 nm, UV_{min} 222 nm. UV_{max} (H_2O, pH 11) 268 nm, UV_{min} 250 nm.

3′,5′-O-(Triphenylphosphoranediyl)adenosine (19). A solution of **1** (15 mmol) in dioxane (10 ml) was added to a mixture of adenosine (2.67 g, 10 mmol) and **2** (15 mmol) suspended in dioxane (20 ml) at 70 °C. Adenosine dissolved as **1** was added. The solution was stirred at 70 °C for 3 h, and then allowed to cool to room temperature. The precipitate thus formed was filtered and recrystallized from dioxane giving 3.95 g (75%) of **19** with mp 171—172 °C. UV_{max} (MeCN) 260 (ε 7400) nm, UV_{min} 245 nm. NMR (DMSO-d_6) δ=4.10—4.84 (m, 5, $C_2'H$, $C_3'H$, $C_4'H$, $C_5'H$), 6.01 (d, 1, $C_1'H$), 7.59 ppm (m, 15, aromatic-H). Found: C, 63.66; H, 5.08; N, 13.20%. Calcd for $C_{28}H_{26}N_5O_4P$: C, 63.75; H, 4.98; N, 13.28%.

On treatment with AcOH–H_2O or dil aqueous ammonia, **19** was hydrolized to adenosine and triphenylphosphine oxide in a 1 : 1 ratio.

*Reaction of **19** with Benzoic Acid.* A mixture of **19** (1 mmol) and benzoic acid (3 mmol) in dioxane (5 ml) was heated at 70 °C for 5 h. The solution was made up to 50 ml. A certain volume of the resulting solution was chromatographed on Toyo Roshi 51A paper using solvent system of 1-BuOH–AcOH–H_2O=5 : 2 : 3 (v/v), the spots and blank areas of the paper being eluted by soaking in water of standard volume and their concentrations determined spectrophotometrically. The yields of 5′-*O*-benzoyladenosine (UV_{max} (H_2O) 238, 260 nm, UV_{min} 224, 252 nm) and N^3,5′-cycloadenosine (**21**; UV_{max} (H_2O) 273 nm, UV_{min} 229 nm) were

determined to be 59 and 16%, respectively. The following molar extinction values of the compounds were used: 5′-*O*-benzoyladenosine, 11000 (260 nm) and N^3,5′-cycloadenosine, 13500 (273 nm).

5′-Thiobenzoyl-5′-deoxyadenosine. Thiobenzoic acid (414 mg, 3 mmol) and **19** (529 mg, 1 mmol) in pyridine (5 ml) was kept stirred under N_2 at room temperature overnight, and then evaporated. The compound was obtained by TLC using $CHCl_3$–MeOH (10 : 1), followed by recrystallization from MeCN–MeOH; 244 mg (63%), mp 159—160 °C. UV_{max} (H_2O) 248, 262 (ε 13800) nm, UV_{min} 225 nm. Found: C, 52.33; H, 4.54; N, 18.10%. Calcd for $C_{10}H_{13}N_5O_3S$: C, 52.71; H, 4.42; N, 18.08%.

*Reaction of **19** with Phenyl Isocyanate.* A mixture of **19** (1 mmol) and phenyl isocyanate (357 mg, 3 mmol) in pyridine (5 ml) was kept stirred at room temperature overnight and then evaporated. 5′-*O*-Phenylcarbamoyladenosine (**25**; 134 mg, 34%) and N^6,5′-*O*-bis(phenylcarbamoyl)adenosine (**26**; 225 mg, 45%), isolated by TLC using ethyl acetate, had the following physical properties.

25 was recrystallized from MeOH, mp 181—183 °C. UV_{max} (H_2O) 237, 259 (ε 12100) nm, UV_{min} 223, 252 nm. Found: C, 50.49; H, 4.99; N, 20.78%. Calcd for $C_{17}H_{18}N_6O_5 \cdot H_2O$: C, 50.75; H. 4.86; N, 20.79%.

26 was recrystallized from MeOH, softing at 145 °C, but showing no definite melting point. UV_{max} (MeOH) 235, 280 (ε 29900)[23] nm, UV_{min} 225, 253 nm.

Reaction of 2′,3′-O-Isopropylideneadenosine with Phenyl Isocyanate. A mixture of 2′,3′-*O*-isopropylideneadenosine (307 mg, 1 mmol) and phenyl isocyanate (3 mmol) in pyridine (5 ml) was kept stirred for 1 d and then evaporated. Ethanol was added to the residue which was evaporated. The residue was treated with 10% aqueous AcOH (40 ml) under reflux for 1.5 h in order to remove isopropylidene group. The products were separated by TLC using MeOH–$CHCl_3$ (10 : 1) giving N^6,5′-*O*-bis(phenylcarbamoyl)adenosine (374 mg, 69%) which was identical with **26** obtained by the procedure described above.

*Reaction of **19** with Diphenylketene.* A mixture of **19** (1 mmol) and diphenylketene (582 mg, 3 mmol) in pyridine (5 ml) was kept stirred at room temperature overnight and then evaporated. The following products were isolated by TLC using $CHCl_3$–MeOH (10 : 1).

5′-*O*-(Diphenylacetyl)adenosine was obtained in 20% (94 mg) yield and recrystallized from MeCN. It began to soften at 180 °C but showed no definite melting point. UV_{max} (MeOH) 260 (ε 12600) nm, UV_{min} 235 nm. Found: C, 62.46; H, 4.69; N, 14.94%. Calcd for $C_{24}H_{23}N_2O_5$: C, 62.46; H, 5.02; N, 15.18%.

N^6,5′-*O*-Bis(diphenylacetyl)adenosine was obtained in 46% (298 mg) yield and recrystallized from benzene–ether. It began to soften at 95 °C. UV_{min} (MeOH) 278 (ε 17500) nm, UV_{min} 240 nm. Found: C, 68.55; H, 5.09; N, 10.32%. Calcd for $C_{38}H_{33}N_5O_6$: C, 69.60; H, 5.07; N, 10.68%.

Reaction of N⁶-p-*Toluoyladenosine with **1** and **2**. a)* N⁶-p-*Toluoyl-2′,3′-O-(triphenylphosphoranediyl)-*N³,5′-*cycloadenosine (**29**).* A solution of **1** (4.1 mmol) in dioxane (1.5 ml) was added dropwise over a period of 1 h to a mixture of N^6-*p*-toluoyladenosine (577 mg, 1.5 mmol) and **2** (4 mmol) in dioxane (1.5 ml) at 70 °C. After the nucleoside had dissolved, the mixture was allowed to cool to room temperature and then kept stirred overnight. The precipitate formed was filtered and washed with ether and dioxane to give **29** (201 mg, 24%). An analytical sample was prepared by recrystallization twice from dioxane–ether. It turned brown above 190 °C, melting at 200—204 °C. UV_{max} (dioxane) 243^{sh}, 307 nm, UV_{min} 289 nm. NMR ($CDCl_3$) δ=2.2 (s, 3, CH_3), 3.7—5.0 (m, 5, $C_{2'}H$, $C_{3'}H$, $C_{4'}H$, $C_{5'}H$), 5.92 (s, 1, $C_{1'}H$), 6.6—8.0 ppm (m, 21, aromatic-H, C_2H, C_8H). Found: C, 67.55; H, 4.82; N, 11.57%. Calcd for $C_{36}H_{30}N_5O_4P \cdot 1/2H_2O$: C, 67.91; H, 4.91; N, 11.00%.

b) N⁵,*5′-Anhydro-5-formamido-4-(*N-p-*toluoylamidino)-1-(β-*D-*ribofuranosyl)imidazole (**30a**)*: N^6-*p*-Toluoyladenosine (770 mg, 2 mmol) was allowed to react with 6 mmol each of **1** and **2** in dioxane (15 ml) in a similar manner to that described in a). The resulting mixture was treated with H_2O (2 ml) under reflux for 1 h, and then evaporated. The residue was separated by TLC ($CHCl_3$–MeOH=10 : 1) giving **30a** in 74% (532 mg) yield. This was recrystallized from acetone, mp 181—183 °C (dec). UV_{max} (MeOH) 270, 309 nm, UV_{min} 245, 290 nm.

N⁵,*5′-Anhydro-5-amino-4-(*N-p-*toluoylamidino)-1-(β-*D-*ribofuranosyl)imidazole (**31a**).* **30a** (162 mg, 0.42 mmol) was treated with saturated methanolic ammonia (15 ml) at room temperature for 1 d and evaporated. **31a** was isolated in 64% yield and recrystallized from acetone–ethanol; dec at 214—216 °C. UV_{max} (MeOH) 255^{sh}, 273, 337 nm, UV_{min} 234, 296 nm.

N⁵,*5′-Anhydro-5-amino-4-(*N-p-*toluoylcarbamoyl)-1-(β-*D-*ribofuranosyl)imidazole (**32a**).* **31a** (90 mg, 0.27 mmol) was treated with *p*-toluenesulfonic acid hydrate (190 mg, 1 mmol) in THF (3 ml) at room temperature for 8 h. The solution was neutralized with triethylamine. The precipitate was collected by filtration and washed with water and methanol giving **32a** in 64% yield. The product was recrystallized from acetone, mp 215—217 °C (dec). UV_{max} (MeOH) 252, 314 nm, UV_{min} 237, 275 nm. Found: C, 56.21; H, 5.13; N, 15.37%. Calcd for $C_{17}H_{18}N_4O_5$: C, 56.98; H, 5.06; N, 15.64%.

N⁵,*5′-Anhydro-5-formamido-4-(*N-p-*toluoylamidino)-1-(2,3-*O-*isopropylidene-β-*D-*ribofuranosyl)imidazole (**30b**).* A solution of **1** (1.5 mmol) in THF (1 ml) was added dropwise at room temperature over a period of 1 h to a mixture of N^6-*p*-toluoyl-2′,3′-*O*-isopropylideneadenosine (425 mg, 1 mmol) and **2** (1.5 mmol) in THF (2 ml). The homogeneous solution was kept standing overnight and then evaporated. **30b** was obtained nearly quantitatively by TLC using ethyl acetate–benzene (1 : 1). It was recrystallized from MeOH, mp 240—242 °C. UV_{max} (MeOH) 270, 310 nm, UV_{min} 253, 290 nm. Found: C, 59.11; H, 5.41; N, 16.71%. Calcd for $C_{21}H_{23}N_5O_5$: C, 59.28; H, 5.45; N, 16.46%.

N⁵,*5′-Anhydro-5-amino-4-(*N-p-*toluoylamidino)-1-(2,3-*O-*isopropylidene-β-*D-*ribofuranosyl)imidazole (**31b**).* **30b** (558 mg, 1.31 mmol) was treated with saturated methanolic ammonia (120 ml) at room temperature for 8 h and then evaporated. The residue was separated by TLC ($CHCl_3$–MeOH=10 : 1) giving **31b** (52%) with mp 250—251 °C (lit,[16a] mp 245—247 °C). UV_{max} (MeOH) 250^{sh}, 272 (ε 18500), 336 (ε 16800) nm, UV_{min} 244, 296 nm (lit,[16a] UV_{max} (MeOH) 270 (ε 18500), 333 (ε 16800) nm. NMR ($CDCl_3$) δ=1.32, 1.43 (two s, 6, isopropylidene-CH_3), 2.37 (s, 3, CH_3), 3.38 (m, 2, $C_{5'}H$), 4.53, 4.94 (a pair of d, 2, $C_{2'}H$, $C_{3'}H$), 4.6 (m, 1, $C_{4'}H$), 5.71 (s, 1, $C_{1'}H$), 7.11, 7.85 ($A'_2B'_2$, 4, aromatic-H), 7.07 ppm (s, 1, C_2H). Found: C, 60.34; H, 5.86; N, 17.74%. Calcd for $C_{20}H_{23}N_5O_4$: C, 60.44; H, 5.83; N, 17.62%.

A Catalytic Effect of Amines on the Reaction of Arenesulfinic Acids with *N,N'*-Thiodiphthalimide[1]

Yasuo ABE,* Toyokazu HORII, Kunio OKA, Shunichi KAWAMURA, and Takeshige NAKABAYASHI

Radiation Center of Osaka Prefecture, Shinke-cho, Sakai 593

(Received May 19, 1980)

In the presence of catalytic amounts of several amines, *N,N'*-thiodiphthalimide has been allowed to react with one or two equiv. of arenesulfinic acids in dichloromethane, thus giving *N*-(arylsulfonylthio)phthalimides or bis(arenesulfonyl) sulfides respectively in good yields. The arenesulfinate anion seems to be a better nucleophile against *N,N'*-thiodiphthalimide than arenesulfinic acid. The mechanism of the catalytic reaction will be discussed.

N,N'-Thiodiphthalimide (**1**) has been known to be a useful sulfur-transfer reagent, giving symmetrical trisulfides[2] and *N,N'*-thiodiamines[3] by reactions with two equiv. of thiols and secondary amines respectively. Unsymmetrical trisulfides and *N*-(alkyldithio- or aryldithio)amines are prepared by the reactions of the intermediates derived from **1** with one equiv. of thiols and amines respectively.[3] It has previously been reported that **1** reacts with one equiv. of arenesulfinic acids (**2**) to give *N*-(arylsulfonylthio)phthalimides (**3**) and with two equiv. of **2** to give bis(arenesulfonyl) sulfides (**4**).[4] In a preceding paper,[5] it was shown that catalytic amounts of amines accelerate the reaction of α-toluenethiol with **1** in benzene or dichloromethane.

We wish now to report our examination to confirm that amines and their ammonium salts catalyze the reaction of **1** with **2** in dichloromethane, and to elucidate the mechanism of the catalyzed reaction. In addition, we will show the IR characteristic absorptions of the S–N bond in the compounds **3a—g** produced in the present reaction.

Results and Discussion

The reaction of **1** with **2** in the presence of catalytic amounts of amines was performed in dichloromethane at the boiling point for 1 h. Representative authentic arenesulfinic acids are stable at the same temperature for several hours in the same solvent. The product **3** was isolated from the reaction mixture by fractional dissolution in benzene and ethanol, and **4**, by column chromatography using silica gel. Preliminary work indicated that Compound **4** was recovered quantitatively from the column; Compound **3** was recovered in a 60—70% yield, but Compound **4** was not detected in the remaining eluate. These experiments suggest that **3** do not give **4** through the column.

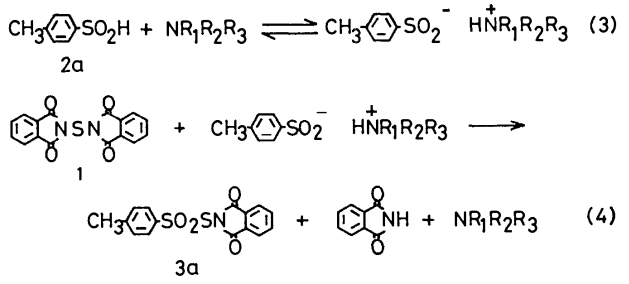
a) All the reactions were performed by the use of **1** (5 mmol), **2** (5 mmol), and an amine (0.5 mmol) in dichloromethane (100 ml) at the boiling point for 1 h.

The Reaction of 1 with One Equiv. of 2. Regardless of the functional group (*i.e.*, primary, secondary, or tertiary), all the amines used here accelerated the reaction of **1** with *p*-toluenesulfinic acid (**2a**). The results of the reactions are summarized in Table 1. The yield of *N*-(*p*-tolylsulfonylthio)phthalimide (**3a**) did not vary significantly with the amine. Previously, the catalytic ability of amine in the reaction of **1** with α-toluenethiol was explained by the S–H–N-type hydrogen bonding.[5] It is more reasonable, however, to expect that the catalytib ability of amine in the present reaction is due to the formation of the corresponding ammonium sulfinate from amine and arenesulfinic acid, since the arenesulfinate anion is generally more nucleophilic to the sulfur atom than the arenesulfinic acid is. The fact that the yield of **3a** increases upon the addition of amine, independent of the pK_a value, compared with that in the reaction without amine, suggests that amine forms a salt with **2a** in dichloromethane. Therefore, a reaction mechanism in which amine revives as a catalyst is



described by Eqs. 3 and 4. When DBU was used, the yield of **3a** was not so good as those with other amines, indicating that DBU would form a very tight salt with **2a**, thus, the migration of the sulfinate anion would be restrained.

To confirm the mechanism proposed above, ammonium salts were first examined as catalysts. When each 0.1 equiv. of pyridinium, imidazolium, or piperidinium *p*-toluenesulfinate was added to the reaction system, **3a** was obtained in yields of 69, 81, and 70% respectively. Comparing the yields with those of the corresponding amines in Table 1, it is clear that the two results are not significantly different.

Second, we examined the catalytic effect of amine hydrochloride and tetraalkylammonium halides, the anions of which are exchangeable. When 0.1 equivalents of each of these salts were used, **3a** was formed in yields of 85%(triethylammonium hydrochloride), 60%(tetraethylammonium chloride), 63%(tetraethylammonium bromide), and 78%(tetraethylammonium iodide). The halide anion is expected to form a hydrogen bonding with the acidic hydrogen atom of arenesulfinic acid and, consequently, to activate the acid in a manner similar to the condensation reactions of a number of organic compounds with alkyl halides in the presence of potassium fluoride.[6] As may be seen in the results with the three tetraethylammonium halides, however, the chloride anion which is more electron-rich and nucleophilic[7] has less catalytic activity than the iodide anion. In other words, the salt with a weaker ionic bonding force has a larger catalytic ability. This fact also suggests that the catalytic ability is due to the formation of a sulfinate anion *via* anion exchange rather than to the activation by hydrogen bonding between a halide anion and sulfinic acid.

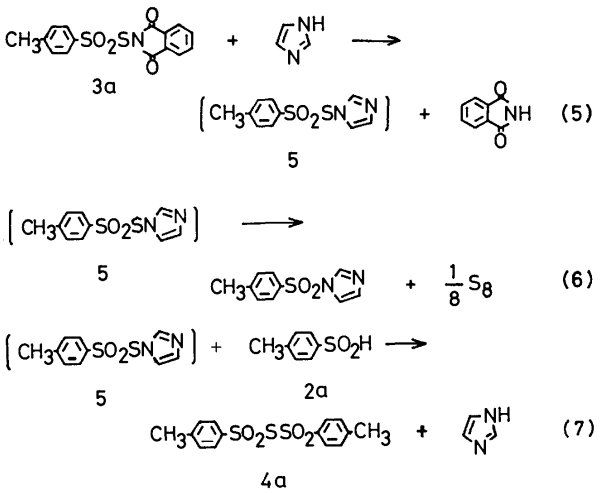
The reaction of aqueous sodium *p*-toluenesulfinate with **1** in dichloromethane was performed with the aid of a phase-transfer reagent. Unfortunately, the yield of **3a** was very poor. The decrease in the yield may be a result of the decomposition of the product, **3a**. Therefore, the stability of **3a** was examined; **3a** was recovered quantitatively after having been boiled for 1 h in a mixture of water and dichloromethane, but it was found to be unstable in an alkaline solution. Since slightly basic sodium phthalimide should be formed by the reaction of sodium *p*-toluenesulfinate with **1**, the product, **3a**, had to decompose. Accordingly, it seems hard to prepare **3** from an aqueous solution of the sulfinate.

The relationship between the amount of imidazole or triethylamine and the yield of **3a** was examined for the reaction of **1** with one equiv. of **2a**; the results are summarized in Table 2. In the case of triethylamine, **3a** was isolated in a considerable yield even if the ratio of triethylamine to **1** was 1. The yield of **3a**, however, decreased with the addition of a 0.2 equiv. of imidazole. With the addition of one equiv. of imidazole, **3a** was not isolated from the reaction mixture, but 1-(*p*-tolylsulfonyl)imidazole and elemental sulfur were isolated. It has been reported that *N*-(alkyldithio)phthalimides react with secondary amine[3] and that the S–N bond of 1,1'-thiodiimidazole is very reactive.[8] The reactivity of the S–N bonds seems to indicate that **3a** reacted with imidazole to give the undesirable products by the course shown by Eqs. 5—7. Equation 5 shows that

Table 2. Effects of the amount of imidazole or triethylamine[a]

Entry	Amine	Ratio[b]	Yield of **3a**(%)
1	None	0	24
2	Imidazole	0.05	78
3	Imidazole	0.1	84
4	Imidazole	0.2	28
5	Imidazole	1	0[c]
6	Triethylamine	0.05	85
7	Triethylamine	0.1	88
8	Triethylamine	0.2	73
9	Triethylamine	1	62

a) All the reactions were performed by the use of **1** (5 mmol), and **2a** (5 mmol) in dichloromethane (100 ml) at the boiling point for 1 h. b) Molar ratio of amine to **1**. c) 1-(*p*-Tolylsulfonyl)imidazole and elemental sulfur were isolated.



imidazole reacted with **3a** to give 1-(*p*-tolylsulfonylthio)-imidazole (**5**), which is an unstable intermediate. The acid, **2a**, still remaining in the reaction mixture would react with it to give **4a** and regenerate imidazole (Eq. 7). However, in the absence of **2a** in the reaction mixture, **5** must be desulfurated to give stable 1-(*p*-tolylsulfonyl)imidazole (Eq. 6). When authentic **3a** was treated with one equiv. of imidazole, 1-(*p*-tolylsulfonyl)imidazole was isolated in a 51% yield.

Taking into account the results obtained above, a series of **3** were prepared by the reactions of **1** with

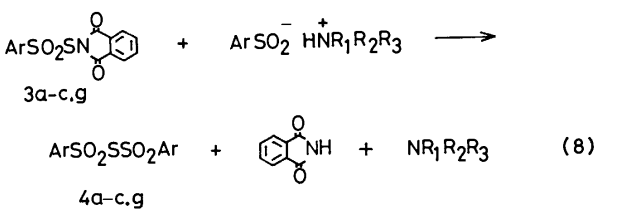
4g	2-Naphthyl	1	63	158—159(153)[10]

a) All the reactions were performed by the use of **1** (2.5 mmol), **2** (5 mmol), and imidazole (0.5 mmol) in dichloromethane (50 ml) at the boiling point. b) Bis(*p*-chlorobenzenesulfonyl)disulfide was isolated in a 39% yield; mp 153—154 °C. c) Bis(*p*-bromobenzenesulfonyl) disulfide was isolated in a 47% yield; mp 175 °C. d) **3f** was isolated in a 95% yield.

several arenesulfinic acids in the presence of catalytic amounts of imidazole, which was chosen as a catalyst because of its convenience. The results are summarized in Table 3. The yields of **3** were improved significantly compared with those in reactions without any catalysts.[4]

The Reaction of 1 with Two Equiv. of 2. The reaction of **1** with two equiv. of **2a** in the presence of 0.2 equiv. of amines was performed in dichloromethane at the boiling point for 1 h. Only **4a** was produced, no **3a**. All the amines also accelerated the reaction. The results are summarized in Table 4. The yield of **4a** increased by the use of amine compared with that in the reaction without amine. This trend is similar to that of the yield of **3a** in Table 1; it implies that, at an early stage of the reaction, **3a** had appeared as an intermediate in the mechanism mentioned above, but reacted quickly with the ammonium salt of the excess **2a** to give **4a** (Eq. 8). A series of **4** were prepared by the



(8)

reaction of **1** with two equiv. of some arenesulfinic acids in the presence of imidazole. The results are summarized in Table 5. The yields of **4** were improved significantly,[4] but **2d—f** did not give **4**. In the case of **2f**, **3f** was isolated in a 95% yield, but no **4f** was. On the other hand, the desired **4g** was obtained in a moderate yield. The difference in the results could be due to the difference in the steric factor of the naphthyl groups. When **2d** or **2e** was used in the reaction, no **4** was formed, but the corresponding bis(arenesulfonyl) disulfide was obtained in a yield of less than 50%. Two possible explanations for the formation of the compound are as follows: (1) the arenethiosulfonate anion, which could be formed by the reaction of the arenesulfinate anion with elemental sulfur in the reaction mixture, reacted with the corresponding **3** to give bis(arenesulfonyl) disulfide, or (2) the arylsulfonylthio group dimerized after the scission of the S–N bond in **3d** or **3e**. In order to confirm these processes, a solution of **3d** or **3e** in dichloromethane was refluxed for 3 h in the presence of imidazole. The compounds, **3d** and **3e**, were stable under these conditions and were recovered quantitatively from the solution. When a solution of **3d** and one equiv. of **2d** in dichloromethane was refluxed for 3 h in the presence of imidazole, **4d** was not formed, but the starting **3d** was recovered from the mixture. The real mechanism for the formation of the bis-

Table 6. Reactions of **3** with **2** in the presence of imidazole[a)]

Entry	Aryl group in **3** and **4**	Reaction time/h	Yield of **4** %
1	Phenyl	2	71
2	*p*-Tolyl	2	94
3	*o*-Tolyl	3	80
4	*p*-Chlorophenyl	3	0[b)]

a) All the reactions were performed by the use of **2** (5 mmol), **3** (5 mmol), and imidazole (0.1 mmol) in dichloromethane (50 ml) at the boiling point. b) The starting material, **3d**, was recovered quantitatively.

(arenesulfonyl) disulfide remains mysterious.

Four authentic **3** were allowed to react with each equiv. of the corresponding **2** to give **4**; the results are summarized in Table 6.

IR Spectra. The IR spectra of **3a**—**g** showed the characteristic bands at 1750 ± 7 cm^{-1} (C=O stretching) and 1139 ± 15 and 1332 ± 12 cm^{-1} (SO_2 stretching), as may be seen in Table 3. Although a few observations have been made on the IR spectra of several organic sulfonamides and sulfenamides near 900 cm^{-1} [11a)] and at 900—985 cm^{-1},[11b)] which are assigned to the S–N stretching, no one has yet reported on the S–N stretching assignment in the IR spectra of *N*-(alkylthio and arylthio)imides. The IR spectra of **1** and **3** showed no conspicuous band in the region of 900—1000 cm^{-1}. Although, the nitrogen atom of organic sulfenamides is able to give its unpaired electron to the vacant *d* orbital of the adjacent sulfur atom, thus forming a stable $\bar{S}=\overset{+}{N}$ canonical structure, the unpaired electrons of the nitrogen atoms of **1** and **3**, which are withdrawn by the two adjacent carbonyl groups, seem not to interact with the *d* orbital of the sulfur atom. Therefore, the S–N absorptions in **3a**—**g** and **1** shift to lower frequencies compared with those of the sulfenamide and sulfonamide; a sharp band at 868 ± 2 cm^{-1} in the IR spectra of those compounds can be assigned to the S–N group.

Experimental

The *N,N'*-thiodiphthalimide (**1**) was prepared according to a previously reported method.[12)] The arenesulfinic acids, **2**, were prepared from the corresponding arenesulfonyl chloride by either of two methods reported in the literature.[13)] The benzene was purified by distillation before use. The other chemical reagents were obtained from commercial sources and were used directly. The IR spectra were recorded on a JASCO-701G grating spectrometer with KBr disks. The elemental analyses were performed by microanalytical laboratories of this Institute and the Osaka Chemical Analytical Center, Sakai, Osaka.

(1) Reaction of 1 with One Equiv. of 2. General Procedure: A solution of **1** (1.62 g, 5 mmol), **2** (5 mmol), and amine or ammonium salt (0.5 mmol) in dichloromethane (100 ml) was refluxed for 1 h. The solution was then evaporated under reduced pressure, and the residue was washed with water and dried. To the residue, 100 ml of benzene was added. After the mixture had stood for 30 min, the remaining solids were removed by filtration . The benzene filtrate was evaporated on a rotary evaporator, and the residue was washed with 50 ml of ethanol to give **3** as white crystals, which were later recrystallized from ethanol or benzene.

The analytical data of the compounds newly obtained here, except for **3a, b, d, e**,[4)] will be presented below:

N-*(o-Tolylsulfonylthio)phthalimide (3c)*: Found: C, 54.22; H, 3.19; N, 4.17; S, 18.92%. Calcd for $C_{15}H_{11}NO_4S_2$: C, 54.04; H, 3.33; N, 4.20; S, 19.24%.

N-*(1-Naphthylsulfonylthio)phthalimide (3f)*: Found: C, 58.55; H, 2.84; N, 3.60; S, 17.05%. Calcd for $C_{18}H_{11}NO_4S_2$: C, 58.53; H, 3.00; N, 3.79; S, 17.36%.

N-*(2-Naphthylsulfonylthio)phthalimide (3g)*: Found: C, 58.93; H, 2.79; N, 3.55; S, 16.80%. Calcd for $C_{18}H_{11}NO_4S_2$: C, 58.53; H, 3.00; N, 3.79; S, 17.36%. The ethanol washings were evaporated, and the residue was chromatographed on silica gel (Wakogel C-200, eluent: benzene). The first fraction gave **4**.

Procedure for a Heterogeneous Reaction: A mixture of **1** (0.811 g, 2.5 mmol), sodium *p*-toluenesulfinate (0.536 g, 2.5 mmol), benzyltriethylammonium chloride (0.144 g, 0.5 mmol), water (50 ml), and dichloromethane (50 ml) was refluxed for 1 h. The mixture was evapotated to remove the dichloromethane under reduced pressure. The aqueous mixture was then filtered, and the residue was washed with water and treated as has been described above, giving **3a** in an 18% yield.

Stability of 3a: A mixture of **3a** (0.834 g, 2.5 mmol), benzyltriethylammonium chloride (0.144 g, 0.5 mmol), water (50 ml), and dichloromethane (50 ml) was refluxed for 1 h. The mixture was treated as has been described above, giving **3a** in a 94% yield.

A mixture of **3a** (0.834 g, 2.5 mmol), potassium phthalimide (0.338 g, 2.5 mmol), benzyltriethylammonium chloride (0.114 g, 0.5 mmol), water (50 ml), and dichloromethane (50 ml) was refluxed for 1 h. The mixture was treated as has been described above, giving **3a** in a 76% yield.

Reaction of 1 with One Equiv. of 2a and Imidazole: A solution of **1** (6.5 g, 20 mmol), **2a** (3.1 g, 20 mmol), and imidazole (1.3 g, 20 mmol) in dichloromethane (100 ml) was refluxed for 2 h. The mixture was then filtered to give 5.3 g (90%) of phthalimide. The filtrate was evaporated under reduced pressure, and the residue was washed with acetone to give 0.4 g (65%) of elemental sulfur. The acetone solution was evaporated, and the residue was washed with water and dried. The residue was extracted with ethanol. The extract was then evaporated to give 1.8 g crude 1-(*p*-tolylsulfonyl)-imidazole (mp 75—95 °C). Recrystallization from hexane gave 1.7 g (39%) of a pure sample (mp 76—78 °C).

Reaction of 3a with Imidazole. A solution of **3a** (1.67 g, 5 mmol) and imidazole (0.34 g, 5 mmol) in dichloromethane (50 ml) was refluxed for 1 h. The solution was then evaporated, and the residue was extracted with benzene to give 0.66 g (90%) of phthalimide. The benzene extract was chromatographed on silica gel (eluent: benzene). The first fraction gave elemental sulfur (0.083 g, 52%). The polar substances remaining in the column were eluted with methanol. The eluate was evaoprated, and the residue was recrystallized from petroleum ether, giving 0.56 g (51%) of 1-(*p*-tolylsulfonyl)-imidazole.

(2) Reaction of 1 with Two Equiv. of 2. A solution of **1** (0.81 g, 2.5 mmol), **2** (5 mmol), and amine (0.5 mmol) in dichloromethane (50 ml) was refluxed for 1—3 h. The solution was treated as the same way described in the reaction of **1** with one equiv. of **2**. The products thus obtained, **4a**—**c**, **g**, were identified by means of their mixed melting points.[9,10)] The analytical data of bis(arenesulfonyl) disulfides obtained unexpectedly are shown below.

Bis(p-chlorobenzenesulfonyl) Didulfide. Found: C, 34.30;

H, 1.76; S, 30.8; Cl, 16.8%. Calcd for $C_{12}H_8Cl_2O_4S_4$: C, 34.70; H, 2.08; S, 30.88; Cl, 17.07%.

Bis(p-Bromobenzenesulfonyl) Disulfide. Found: C, 28.67; H, 1.61; S, 24.4; Br, 31.1%. Calcd for $C_{12}H_8Br_2O_4S_4$: C, 28.59; H, 1.60; S, 25.43; Br, 31.69%.

Reaction of 3 with 2. A solution of **3** (5 mmol), the corresponding **2** (5 mmol), and imidazole (0.068 g, 1 mmol) in dichloromethane (50 ml) was refluxed for 2—3 h. The solution was then treated as has been described in the reaction of **1** with one equiv. of **2**.

New Monoterpene Lactones of the Iridane Type from *Actinidia polygama* Miq.

Tsutomu SAKAI,* Kimiko NAKAJIMA, and Takeo SAKAN

**Suntory Institute for Bioorganic Research, Shimamoto-cho, Mishima-gun, Osaka 618

(Received May 29, 1980)

Fourteen iridoid monoterpene lactones including eight new compounds were isolated from the volatile oil of fresh fruits of the cat- and lacewing-attracting plant *Actinidia polygama* Miq., and their structures were established on the basis of spectral evidence and chemical transformation.

In continuous investigation of the constituents of the cat- and lacewing-attracting plant *Actinidia polygama* Miq.,[1,2] we isolated from the volatile oil of its fresh fruits eight new iridoid monoterpene lactones, which we named dihydroepinepetalactone (**1a**), isodihydroepinepetalactone (**1b**), isoepiiridomyrmecin (**2b**), isoneonepetalactone (**3b**), dehydroiridomyrmecin (**4a**), isodehydroiridomyrmecin (**4b**), actinidialactone (**5a**), and isoactinidialactone (**5b**), together with five previously isolated lactones.[3] The known compounds were identified as neonepetalactone (**3a**),[2] dihydronepetalactone (**6a**), isodihydronepetalactone (**6b**), iridomyrmecin (**7a**), and isoiridomyrmecin (**7b**). In addition, nepetalactone (**8**)[4] was also isolated from this oil.

The present paper deals with the structural elucidation of these new compounds.

*Structures of Three New Saturated Lactones **1a**, **1b**, and **2b**.* These new saturated lactones **1a**, **1b**, and **2b** were isolated by repeated preparative gas chromatography. They have the molecular formula $C_{10}H_{16}O_2$ according to high resolution mass spectra, and a characteristic IR band at 1740—1735 cm^{-1} indicated the presence of a saturated δ-lactone group. The mass spectra of **1a**, **1b**, and **2b** were almost identical to those of **6a**, **6b**, and **7b**, respectively. In their NMR spectra, the C-1 methyl protons signals were observed at δ 1.01, 1.01, and 0.83, while the analogous protons of natural **6a**, **6b**, and **7b** had signals at δ 1.19, 1.19, and 1.05. By comparison of the chemical shifts of the new lactones with those of lactones **6a**, **6b**, and **7b**, we deduced that they were the C-2 epimers of **6a**, **6b**, and **7b**.

The structures and stereochemistry of these new saturated lactones were confirmed by the following chemical evidence. When the lactones **1a** and **1b** were refluxed with sodium methoxide in methanol or potassium carbonate in xylene and followed by acidification with dil HCl, they were converted into **6a** and **6b**. As these conversions were analogous to that of epinepetalactone (**9**) into nepetalactone (**8**),[5] the lactones **1a** and **1b** were assigned as the dihydro derivatives of epinepetalactone, for which we proposed the names dihydroepinepetalactone (**1a**) and isodihydroepinepetalactone (**1b**). LAH reduction of **1a** and **1b** gave the corresponding saturated diols **10a** and **10b**. Their optical rotation data were in accord with those of β-iridodiol (**10a**) and γ-iridodiol (**10b**).[6] The lactone **2b** was also reduced with LAH to give γ-iridodiol (**10b**). From the above spectral and chemical evidence, **2b** was confirmed as the C-2 epimer of isoiridomyrmecin (**7b**) and named isoepiiridomyrmecin.

No epiiridomyrmecin (**2a**) was detected by GC-MS analysis of the oil.

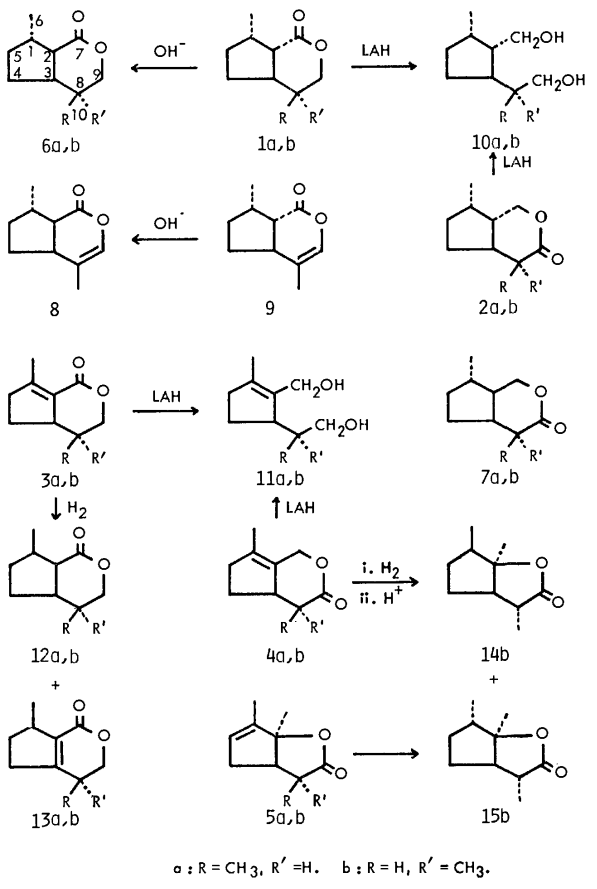
*Structures of Five New Unsaturated Lactones **3b**, **4a**, **4b**, **5a**, and **5b**.* These new unsaturated lactones were also isolated by preparative gas chromatography. They were an α-unsaturated δ-lactone **3b** (MS: M^+ 166, $C_{10}H_{14}O_2$; IR: 1710, 1638 cm^{-1}), a pair of diastereomers of the unsaturated δ-lactones **4a** and **4b** (MS: M^+ 166; IR: 1730 cm^{-1}), and a pair of diastereomers of the unsaturated γ-lactones **5a** and **5b** (MS: M^+ 166; IR: 1770—1760 cm^{-1}). The mass spectrum of **3b** agreed with that of **3a**. The mass spectra of **4a** and **4b** and of **5a** and **5b** were almost identical to each other.

The α-unsaturated δ-lactone **3b** was reduced with LAH to give the corresponding unsaturated diol **11b**, which was identified as isodehydroiridodiol of known absolute configuration.[2] Catalytic hydrogenation of **3b** with Adams catalyst or Raney nickel catalyst gave a mixture of 1-epi-isodihydronepetalactone (**12b**) and the double bond migrated product **13b**, which were characterized on the basis of spectral data. The IR spectrum of **12b** was similar to that of **6b** and the NMR spectrum of **12b** closely resembled that of **6b**, except for the signals of the C-1 methyl protons: the (1*R*)-methyl signals of **12b** appeared at about 0.20 ppm higher field than the (1*S*)-methyl signals of **6b**. The IR, NMR, and mass spectra of **13b** closely resembled those of the lactone **13a** obtained from **3a**.[2] Spectral and chemical evidence showed that the lactone **3b** was the C-8 epimer of neonepetalactone (**3a**) and it was named isoneonepetalactone.

The unsaturated δ-lactones **4a** and **4b** were reduced with LAH to give dehydroiridodiol (**11a**) and isodehydroiridodiol (**11b**), respectively. Catalytic hydrogenation of **4b** gave an unsaturated carboxylic acid.[7] Lactonization of this acid with *p*-toluenesulfonic acid in benzene afforded a mixture of two new saturated γ-lactones **14b** and **15b** in a ratio of 3 : 4, which were determined by spectral analysis. Thus, the lactones **4a** and **4b** were assigned as the $\Delta^{1,2}$-dehydro derivatives of **7a** and **7b**, and designated as dehydroiridomyrmecin (**4a**) and isodehydroiridomyrmecin (**4b**).

The NMR spectra of the new unsaturated γ-lactones **5a** and **5b** showed the presence of a secondary methyl group, a methyl group on a tertiary carbon-bearing oxygen, and a trisubstituted olefinic proton. Spectral characteristics and biogenetic consideration show these compounds to be a pair of diastereomers having an

** The previous name: The Institute of Food Chemistry.



iridane skeleton with a γ-lactone group and a double bond, *i.e.*, structures **5a** and **5b**, for which we propose the names actinidialactone (**5a**) and isoactinidialactone (**5b**). The stereochemistry of **5a** and **5b** was established by the following evidence. (a) Reduction of **5b** with Adams catalyst in ether yielded a mixture of two saturated γ-lactones in a ratio of 12 : 1, which were identical in all respects (IR, NMR, MS, and CD) to the lactones **14b** and **15b** derived from **4b** with the (3*R*,8*R*)-configuration. (b) The CD spectrum of the new lactone **5a** exhibited a positive Cotton curve while **5b** showed a negative one. According to Snatzke's rule,[8] the molecules corresponding to **5a** and **5b** are supposed to show positive and negative Cotton effects, respectively. (c) Close correspondence of the ^{1}H- and ^{13}C-NMR spectra of **5a** and β-episantonin derivatives and of **5b** and α-episantonin derivatives[9,10] definitely confirmed the stereochemistry of the α-methyl-γ-lactone moiety in **5a** and **5b**.[11]

These newly isolated lactones have not yet evaluated for their bioactive effects against Felidae animals.

Experimental

NMR spectra were recorded in $CDCl_3$ with TMS as the internal standard on a JEOL JNM-FX100 instrument. IR spectra were taken as thin films between NaCl plates on a Hitachi EPI-G2 spectrometer equipped with a beam condenser. Optical rotations were measured in $CHCl_3$ on a Perkin-Elmer Model 141 polarimeter. Mass spectra were obtained on a Hitachi RMU-6 mass spectrometer (for GC-MS) or a JEOL JMS-01SG (for high resolution mass spectra) instrument. Gas liquid chromatography (GLC) was performed on a Hitachi 163 (for analytical work) or a Varian aerograph 920 (for preparative work) instrument, using a 40 m × 0.25 mm glass capillary column coated with Thermon 600T (analytical and GC-MS) or a 3 m × 10 mm aluminum column packed with 5% Thermon 1000 on Chromosorb W (preparative).

Isolation of Lactones. Fresh fruits (5.5 kg, collected in Toyama Pref. in August 1979) were steam distilled to give the volatile oil (4.5 g). Figure 1 shows its gas chromatogram.

Its components were separated by repeated preparative GLC (column temp, 180 °C; injector temp., 220 °C; helium flow rate, 40 ml/min). Eight new oily substances and six known lactones were isolated in their pure states. The known lactones were identified by direct comparison with authentic samples.

*Dihydroepinepetalactone (**1a**).* Content: 0.31%;[12] Relative retention time: 1.49;[13] $[\alpha]_D^{25}$ +31.3° (*c* 0.55); IR: 1740 cm^{-1}; NMR: δ 1.00, 1.03 (each 3H, d, J=7 Hz, C-8 Me and C-1 Me), 4.02, 4.35 (each 1H, AB q of ABX, J_{AX}=3 Hz, J_{BX}=4 Hz, J_{AB}=11 Hz, C-9 H_2); MS: 168 (22%, M$^+$), 153 (41), 139 (7), 126 (31), 113 (70), 95 (45), 81 (100), 67 (60), 55 (22), and 41 (36). [Found, M$^+$ 168.1142. $C_{10}H_{16}O_2$ requires, M$^+$ 168.1148].

*Isodihydroepinepetalactone (**1b**).* Content: 0.30%; RRT: 1.16; $[\alpha]_D^{25}$ +90.3° (*c* 0.74); IR: 1740 cm^{-1}; NMR: δ 1.01 (6H, d, J=7 Hz, C-8 Me and C-1 Me), 3.81, 4.35 (each 1H, AB q of ABX, J_{AX}=9 Hz, J_{BX}=5 Hz, J_{AB}=11 Hz, C-9 H_2); MS: 168 (17%, M$^+$), 153 (53), 139 (5), 126 (18), 123 (15), 113 (100), 109 (25), 95 (56), 81 (81), 69 (30), 67 (54), 55 (20), and 41 (30). [Found, M$^+$ 168.1145].

*Isoepiiridomyrmecin (**2b**).* Content: 0.73%; RRT: 1.47; $[\alpha]_D^{25}$ +6.17° (*c* 0.47); IR: 1730 cm^{-1}; NMR: δ 0.86, 1.31 (each 3H, d, J=7 Hz, C-1 Me and C-8 Me), 4.21, 4.48 (each 1H, AB q of ABX, J_{AX}=8 Hz, J_{BX}=5 Hz, J_{AB}=11 Hz, C-7 H_2); MS: 168 (8%, M$^+$), 109 (33), 95 (48), 81 (100), 68 (55), 67 (64), 55 (19), and 41 (25). [Found, M$^+$ 168.1146].

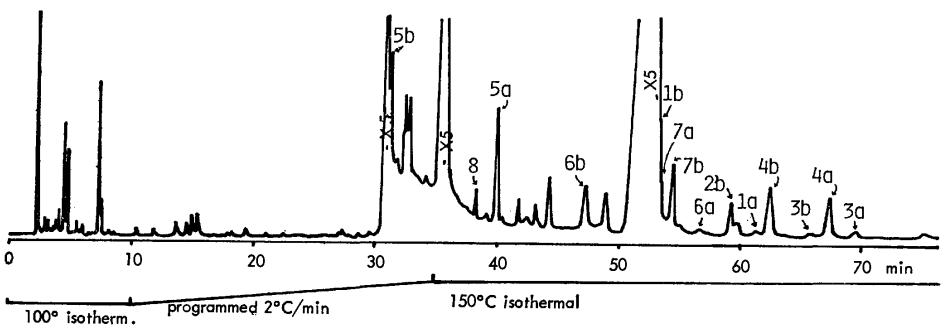


Fig. 1. The gas chromatogram of the volatile oil of fresh fruits.

*Isoneonepetalactone (**3b**).* Content: 0.003%; RRT: 1.77; $[\alpha]_D^{23}$ −66.2° (*c* 0.34); IR: 1710, 1638 cm^{-1}; NMR: δ 0.94 (3H, d, J=7 Hz, C-8 Me), 2.20 (3H, t, J=1 Hz, C-1 Me), 3.89, 4.24 (each 1H, AB q of ABX, J_{AX}=11 Hz, J_{BX}=5Hz, J_{AB}=11 Hz, C-9 H_2); MS: 166 (93%, M^+), 151 (21), 136 (8), 124 (90), 121 (30), 107 (24), 105 (13), 93 (60), 91 (26), 87 (42), 79 (100), 77 (30), 67 (15), 65 (10), 55 (12), 53 (14), 41 (30), and 39 (26). [Found, M^+ 166.0995. $C_{10}H_{14}O_2$ requires: M^+ 166.0993].

*Dehydroiridomyrmecin (**4a**).* Content: 0.80%; RRT: 1.79; $[\alpha]_D^{25}$ −105.6° (*c* 0.90); IR: 1730, 1650 cm^{-1}; NMR: δ 1.14 (3H, d, J=7 Hz, C-8 Me), 1.73 (3H, t, J=1 Hz, C-1 Me), 4.91 (2H, br s, C-7 H_2); MS: 166 (20%, M^+), 151 (1), 138 (5), 122 (22), 121 (18), 107 (57), 105 (26), 93 (100), 91 (42), 81 (21), 79 (36), 77 (34), 67 (12), 55 (14), and 41 (30). [Found, M^+ 166.0998].

*Isodehydroiridomyrmecin (**4b**).* Content: 1.40%; RRT: 1.59; $[\alpha]_D^{25}$ −79.2° (*c* 1.06); IR: 1730 cm^{-1}; NMR : δ 1.27 (3H, d, J=7 Hz, C-8 Me), 1.68 (3H, t, J=1 Hz, C-1 Me), 4.96 (2H, br s, C-7 H_2); MS: 166 (32%, M^+), 151 (2), 138 (9), 121 (6), 109 (12), 107 (13), 98 (14), 93 (100), 81 (25), 67 (7), 55 (11), and 41 (6). [Found, M^+ 166.0993].

*Actinidialactone (**5a**).* Content: 1.38%; RRT: 0.70; $[\alpha]_D^{25}$ −18.3° (*c* 1.15); IR: 1760 cm^{-1}; NMR: δ 1.23 (3H, d, J=7 Hz, C-8 Me), 1.47 (3H, s, C-2 Me), 1.75 (3H, t, J=1 Hz, C-1 Me), 5.56 (1H, br s, C-5H); MS: 166 (3%, M^+), 151 (2), 122 (50), 107 (100), 105 (16), 95 (10), 93 (22), 91 (44), 79 (28), 67 (6), 55 (6), and 43 (4). [Found, M^+ 166.0993].

*Isoactinidialactone (**5b**).* Content: 0.51%; RRT: 0.40; $[\alpha]_D^{25}$ −13.9° (*c* 0.94); IR: 1770 cm^{-1}; NMR: δ 1.29 (3H, d, J=7 Hz, C-8 Me), 1.46 (3H, s, C-2 Me), 1.73 (3H, t, J=1 Hz, C-1 Me), 5.41 (1H, br s, C-5 H); MS: 166 (5%, M^+), 151 (4), 122 (51), 107 (100), 95 (16), 93 (11), 91 (30), 79 (20), 67 (8), 55 (7), and 43 (11). [Found, M^+ 166.1009].

*Conversion of Dihydroepinepetalatone (**1a**) into Dihydronepetalactone (**6a**).* A mixture of 8 mg of **1a**, 10 mg of Na_2CO_3, and 0.5 ml of xylene was heated at 230 °C in a sealed tube for 2 h. The mixture was separated by preparative GLC to give an oily substance (6 mg), $[\alpha]_D^{25}$ +40.8° (*c* 0.60); IR: 1725 cm^{-1}; NMR: δ 0.90, 1.19 (each 3H, d, J=7 Hz, C-8 Me and C-1 Me); MS: 168 (17%, M^+), 153 (36), 139 (6), 126 (23), 113 (42), 95 (46), 81 (100), 67 (75), 55 (32), and 41 (68). The spectral data and the retention time in GLC were identical to those of natural lactone **6a**.

*Conversion of Isodihydroepinepetalactone (**1b**) into Isodihydronepetalactone (**6b**).* A solution of 28 mg of **1b** in 4 ml of methanol containing sodium methoxide (240 mg) was refluxed with stirring for 17 h. Next, 2 ml of water was added to the cooled solution and it was refluxed for another 4 h then acidified with dil HCl. After the usual work-up, the resulting oily material (18 mg) was separated by preparative GLC into two components. The major product (13 mg) showed $[\alpha]_D^{25}$ +1.6° (*c* 0.94); IR: 1725 cm^{-1}; NMR: δ 0.97, 1.18 (each 3H, d, J=7 Hz, C-8 Me and C-1 Me); MS: 168 (17%, M^+), 153 (58), 139 (12), 126 (21), 123 (18), 113 (100), 95 (36), 81 (79), 67 (53), 55 (20), and 41 (37). The spectral data and the GLC retention time were identical to those of natural lactone **6b**.

*LAH Reduction of Dihydroepinepetalactone (**1a**), Isodihydroepinepetalactone (**1b**), and Isoepiiridomyrmecin (**2b**).* Each lactone was refluxed in ether with LAH for 2 h. After the usual work-up, the residual oil was chromatographed over silicic acid. Elution with ether afforded a pure saturated diol. The diol **10a** derived from **1a** showed $[\alpha]_D^{22}$ −49.4° (*c* 0.66); IR: 3320 cm^{-1}; NMR: δ 0.85, 0.95 (each 3H, d, J=7 Hz, C-8 Me and C-1 Me), 3.38, 3.72 (each 1H, AB q of ABX, J_{AX}=5 Hz, J_{BX}=5 Hz, J_{AB}=10 Hz, C-7 H_2), 3.51 (2H, d, J=7 Hz, C-9 H_2), 4.12 (2H, br s, 2×OH); MS: 154 (0.1%, M^+ −18), 123 (38), 109 (10), 95 (60), 81 (100), 67 (45), 55 (77), and 41 (75). This diol had the same $[\alpha]_D$ as authentic β-iridodiol ($[\alpha]_D^{23}$ −62°).[6] The diol **10b** derived from **2b** was identical in all respects to the diol prepared from **1b**. The diol **10b** showed $[\alpha]_D^{24}$ −19.5° (*c* 0.64); IR: 3320 cm^{-1}; NMR: δ 0.91, 0.93 (each 3H, d, J=7 Hz, C-8 Me and C-1 Me), 3.41, 3.70 (each 2H, m, C-7 and C-9 H_2); MS: 154 (0.5%, M^+ −18), 139 (2), 136 (2). 123 (81), 109 (16), 95 (72), 81 (100), 67 (34), 55 (39), and 41 (23). The diol was identical to authentic γ-iridodiol ($[\alpha]_D^{23}$ −19°).[6]

*LAH Reduction of Isoneonepetalactone (**3b**), Dehydroiridomyrmecin (**4a**), and Isodehydroiridomyrmecin (**4b**).* Each lactone was refluxed in ether with LAH for 2 h. The lactone **4a** was reduced with LAH to yield the diol **11a**, $[\alpha]_D^{24}$ −20.7° (*c* 2.28), which was identical in all respects to the authentic sample of dehydroiridodiol.[2] The lactones **3b** and **4b** were reduced with LAH to yield the same diol **11b**, $[\alpha]_D^{24}$ −15.6° (*c* 1.08), which was identical in all respects to the authentic sample of isodehydroiridodiol.[2]

*Catalytic Hydrogenation of Isoneonepetalactone (**3b**).* A mixture of 100 mg of **3b** in 3 ml of ether and 25 mg of PtO_2 catalyst was stirred under a hydrogen pressure of 1 atm at room temp for 5 min. Filtration of the catalyst and evaporation of the solvent afforded a mixture of the reduction products. GLC indicated the presence of 84% of **12b** and 16% of **13b**. A pure sample of **12b** showed $[\alpha]_D^{28}$ −66.1° (*c* 0.46); IR: 1725 cm^{-1}; NMR: δ 0.98 (6H, d, J=7 Hz, C-8 Me and C-1 Me), 3.85, 4.19 (each 1H, AB q of ABX, J_{AX}=10 Hz, J_{BX}=4 Hz, J_{AB}=11 Hz, C-9 H_2); MS: 168 (6%, M^+), 153 (5), 126 (7), 123 (7), 113 (100), 95 (27), 81 (35), 67 (35), 55 (20), and 41 (34). A pure sample of **13b** showed $[\alpha]_D^{24}$ −89.1° (*c* 1.94); IR: 1720, 1640 cm^{-1}; UV: λ_{max}^{EtOH} 235 nm (log ε 4.10); NMR: δ 1.14 (3H, d, J=7 Hz, C-8 Me), 1.18 (3H, d, J=7 Hz, C-1 Me), 4.06, 4.37 (each 1H, AB q of ABX, J_{AX}=6 Hz, J_{BX}=5 Hz, J_{AB}=11 Hz, C-9 H_2); MS: 166 (100%, M^+), 151 (50), 136 (49), 123 (25), 121 (61), 107 (58), 95 (36), 93 (40), 91 (38), 81 (18), 79 (40), 77 (30), 67 (18), 65 (13), 53 (13), 41 (25), and 39 (26).

*Transformation of Isodehydroiridomyrmecin (**4b**) into the New Saturated γ-Lactones **14b** and **15b**.* The lactone **4b** (40 mg) was hydrogenated in ether over PtO_2 catalyst for 40 min. After the usual work-up, the residue was purified by preparative GLC to give a single product. It showed the following spectral data; IR: 3500—2500, 1700 cm^{-1} (COOH); NMR: δ 0.95 (3H, d, J=7 Hz, C-8 Me), 1.61, 1.64 (each 3H, s, C-1 Me and C-2 Me); MS: 168 (10%, M^+), 113 (13), 95 (100), 81 (10), 67 (17), 55 (13), and 41 (9). A solution of 38 mg of the acid in 4 ml of benzene containing 30 mg of *p*-toluenesulfonic acid was refluxed with stirring for 40 min. The solution was washed with 10% $NaHCO_3$ aq and water, then dried over Na_2SO_4. After the solvent was removed, the mixture was separated by preparative GLC into two saturated γ-lactones **14b** and **15b** in a ratio of 3 : 4. A pure sample of **14b** showed $[\alpha]_D^{19}$ +43.3° (*c* 0.09); IR: 1760 cm^{-1}; NMR: δ 1.05 (3H, d, J=6 Hz, C-1 Me), 1.37 (3H, d, J=7 Hz, C-8 Me), 1.48 (3H, s, C-2 Me); MS: 168 (23%, M^+), 153 (1), 140 (6), 125 (100), 109 (22), 95 (23), 81 (6), 72 (23), 69 (15), 55 (31), and 43 (22). A pure sample of **15b** showed $[\alpha]_D^{19}$ +13.8° (*c* 0.08); IR: 1760 cm^{-1}; NMR: δ 0.99 (3H, d, J=6 Hz, C-1 Me), 1.34 (3H, d, J=7 Hz, C-8 Me), 1.35 (3H, s, C-2 Me); MS: 168 (21%, M^+), 153 (1), 140 (5), 125 (100), 109 (22), 95 (28), 81 (7), 72 (32), 69 (18), 55 (45), and 43 (30).

*Catalytic Hydrogenation of Isoactinidialactone (**5b**).* The lactone **5b** (20 mg) was hydrogenated in ether over PtO_2 catalyst for 1.5 h. The reaction mixture was worked up in the usual manner to give a mixture of the lactones **14b** and **15b**

in a ration of 12 : 1. These lactones were identical in all respects to the lactones prepared from **4b** as described above.

Synthesis and Stereochemistry of 2,3,4,6-Tetra-*O*-benzyl-D-glucopyranosylidene Acetals of α-Diols and Monosaccharides

Masatoshi TAMARU,† Shigeomi HORITO, and Juji YOSHIMURA*

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received June 26, 1980)

The title compounds were synthesized by addition of 2,3,4,6-tetra-*O*-benzyl-D-glucono-1,5-lactone to epoxides and by direct dehydration between the lactone and diols in the presence of concentrated sulfuric acid as a catalyst. Stereochemistry of these spiro cyclic acetals was discussed.

The unique type of acetal interlinkage between a glycosylidene(1-dehydroglycosyl) group and a glycose has been found in such oligosaccharide antibiotics as everninomicins,[1] flambamycin,[2] hygromycin B,[3] destomycins,[4] A-396-I,[5] and SS-56C.[6] Recently, these antibiotics were designated as "orthosomycins,"[2] because the spiro cyclic ortho ester at the anomeric carbon is quite different from well-known fused-ring type ortho esters in the carbohydrate chemistry.[7] In general, two configurations are possible in this interlinkage depending on whether the anomeric carbon is (*R*) or (*S*). However, it is left ambiguous except for one of the two linkages in everninomicin D.[8] Moreover, no synthetic anologs have thus far been reported except a communication[9] from our laboratory.

This paper describes in detail the synthesis of the spiro cyclic ortho esters from 2,3,4,6-tetra-*O*-benzyl-D-glucono-1,5-lactone (**1**)[10] and the stereochemistry of their ring-systems.

Results and Discussion

As the applicable methods for the preparation of spiro cyclic ortho esters from **1**, addition of **1** to epoxides[11] and the dehydration condensation of **1** with diols[12] were examined.

Reaction of **1** in dichloromethane with equivalent amount of 1-chloro-2,3-epoxypropane or 1,2-epoxypropane at 28—30 °C for 1 h in the presence of boron trifluoride etherate gave the corresponding spiro cyclic ortho esters (**2** and **3**) as syrups in 45 and 65% yields, respectively. The presence of both of the isomers possible was indicated by the ^{1}H NMR spectra of **2** and **3**, respectively. A similar reaction of **1** with 5,6-anhydro-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-glucofuranose[13] for 1 h gave only one of two possible isomers, 1,2-*O*-isopropylidene-3-*O*-methyl-5,6-*O*-(2,3,4,6-tetra-*O*-benzyl-D-glucopyranosylidene)-α-D-glucofuranose (**4**) in 26% yield. The presence of the ortho ester linkage in **4** was proved by the characteristic signal of ortho ester carbon at δ 110.8 ppm (from Me_4Si) in the ^{13}C NMR spectrum. However, this method was unsuccessful in the case of such epoxides including two secondary carbons as 1,2-epoxycyclohexane and methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-mannopyranoside.[14]

On the other hand, azeotropic dehydration of a solution of equimolar amounts of **1** and ethylene glycol in benzene containing a catalytic amount of concd sulfuric acid during 10 h gave the corresponding spiro cyclic othro ester (**5**) in 43% yield. On continuation of the dehydration for 24 h, **1** disappeared and the yield of **5** rose to 77%. Compound **3** was also obtained quantitatively from **1** and 1,2-propanediol by the same method. Catalytic hydrogenation of **5** in methanol in the presence of palladium-on-charcoal and a few drops of acetic acid gave the de-*O*-benzylated product as a syrup, this was acetylated with acetic anhydride in pyridine to give the corresponding tetraacetate (**6**) in 73% overall yield.

Similar dehydration of a mixture of **1** and *cis*-1,2-cyclohexanediol for 3 h gave a mixture of two isomers of the corresponding ortho esters (**7**) which was separated on a silica gel column to give **7a** and **7b** in 45 and 28% yields, respectively. Similar reaction of *trans*-1,2-cyclohexanediol for 37 h also gave two products (**8a** and **8b**) in 21 and 22% yields, respectively. Reaction of **1** and methyl 2,3-di-*O*-methyl-α-D-glucopyranoside[15] or -α-D-mannopyranoside[16] gave only one of the two possible isomers (**9** and **10**) in 20 and 8% yields, respectively. Reaction of **1** and erythritol gave 1,2 : 3,4-di-*O*-(2,3,4,6-tetra-*O*-benzyl-D-glucopyranosylidene)-erythritol (**11**) in 80% yield. Dehydration of a mixture of **1** and methyl 4,6-di-*O*-benzyl-α-D-mannopyranoside gave unsuccessful result. However, a similar reaction with methyl 4,6-di-*O*-methyl-α-D-mannopyranoside gave a trace amount of 1 : 1 mixture of two possible isomers of methyl 4,6-di-*O*-methyl-2,3-*O*-(2,3,4,6-tetra-*O*-benzyl-D-glucopyranosylidene)-α-D-mannopyranoside (**12**) as a syrup. The separation of these two isomers was unsuccessful, but the presence was indicated by the two characteristic signals assigned to the ortho ester carbon in the ^{13}C NMR spectrum.

Examination of acidic catalysts indicated that *p*-toluenesulfonic acid, phosphorus pentaoxide, and ortho- and polyphosphoric acids were uneffective, while the super acid ($SbF_5 \cdot FSO_3H$) showed the effectiveness of the same level as concd sulfuric acid.

The chemical shifts of ortho ester carbons of glucosylidene acetals synthesized here were summarized in Table 1. The chemical shifts of the ortho ester carbons with 1,3-dioxolane rings (**2,4—8,12**), were 118—122 ppm, whereas that with 1,3-dioxane rings (**9** and **10**) 110.7—110.9 ppm. This difference in the chemical shifts of ortho ester carbons is diagnostic for the ring-size. Consequently, the chemical shift of the carbon in **11** clearly shows that the structure is 1,2 : 3,4-di-*O*-glucosylidene derivative having two 1,3-dioxolane

rings, but not 1,3 : 2,4-di-*O*-substituted derivative with two 1,3-dioxane rings, indicating the former ring is thermodynamically more stable than the latter.

The above results provide interesting problems in stereochemistry. In the case of five-membered spiro cyclic compounds [(A) in Fig. 1], the non-bonded interaction between groups attached to C-2 of the pyranosylidene ring and to the acetal ring can be avoided by a twist conformation of the latter, as was shown in the X-ray analysis of the olgose.[8] For example, in the case of **8** the conformation of the cyclohexane ring with a→b′ bonds will be a less-hindered one than that including b→a′ bonds. In possible formulations of **4**, the bulky D-glucofuranose ring should be attached to either b or a′ position, and therefore, the latter, the (1*R*)-pyranosylidene isomer shown by the structural formula in Scheme 1, will be much the more stable. This trend will be also true in the configuration of **11** from erythritol. In cases of **7** and **12** in which the five-membered acetal ring includes a→a′ bonds or b→b′ bonds, there was no significant difference in the yields of isomers, indicating the dispense of the strain of the two isomers by the direction of twisting of the five-membered ring. The Newman projection of the stable, (1*R*)-isomer of **9** or **10** having a six-membered acetal ring is presented in (B). It is obvious that the ring oxygen side of the glucopyranosylidene moiety is less hindered, though the absolute configuration is not yet determined.

Experimental

General Methods. Melting points were determined on a Yanagimoto micro melting-point apparatus and are uncorrected. ^{1}H and ^{13}C NMR spectra were recorded with a JNM-PS-100 and a JNM FX-100 spectrometers, respectively, in chloroform-*d* containing tetramethylsilane as the internal reference. The chemical shifts and coupling constants were recorded in δ(ppm) and Hz units. Optical rotations were measured in 0.5-dm tubes with a Carl Zeiss LEP-A1 polarimeter. Solvents were evaporated under diminished pressure.

1,2-O-(2,3,4,6-Tetra-O-benzyl-D-glucopyranosylidene)-3-chloro-1,2-propanediol (2). To a solution of tetra-*O*-benzyl-D-glucono-1,5-lactone (**1**) (1.8 g, 3.34 mmol) and boron trifluoride etherate (0.5 g) in dichloromethane (40 ml) was

added dropwise 3-chloro-1,2-epoxypropane (0.4 g, 4.32 mmol) with stirring, at 28—30 °C, during 1 h. The reaction mixture was stirred for 1 h, washed successively with 2.5 M sodium hydroxide and water, then dried and evaporated to give a syrup which was purified on a silica-gel column (7 : 2 hexane–ethyl acetate, R_f 0.41) to give **2** as a syrup in 45.0% yield. Found: C, 70.21; H, 6.61%. Calcd for $C_{37}H_{39}O_7Cl$: C, 70.41; H, 6.23%.

1,2-O-(2,3,4,6-Tetra-O-benzyl-D-glucopyranosylidene)-1,2-propanediol (3). *i*): A similar reaction of **1** (1.8 g, 3.34 mmol) with 1,2-epoxypropane (0.2 g, 3.44 mmol) as above in the presence of boron trifluoride etherate (0.5 g) gave **3** as a syrup (7 : 2 hexane–ethyl acetate, R_f 0.43) in 65.2% yield.

ii): Azeotropic dehydration of a solution of **1** (3 g, 5.57 mmol) and 1,2-propanediol (0.5 g, 6.57 mmol) in dry benzene (60 ml) containing a catalytic amount of concentrated sulfuric acid for 24 h gave **3** (3.2 g) in 96.2% yield. Found: C, 74.47; H, 7.16%. Calcd for $C_{37}H_{40}O_7$: C, 74.47; H, 6.76%.

5,6-O-(2,3,4,6-Tetra-O-benzyl-D-glucopyranosylidene)-1,2-O-isopropylidene-3-O-methyl-α-D-glucofuranose (4). A similar reaction of **1** (1.5 g, 2.78 mmol) and 5,6-anhydro-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-glucofuranose (0.65 g, 3.01 mmol) as **2** in the presence of boron trifluoride etherate (0.4 g), and purification of the product (9 : 1 benzene–acetone, R_f 0.68) gave **4** as prisms (petroleum ether) in 25.9% yield. Mp 131—132 °C, $[\alpha]_D^{22}$ +17.4° (*c* 0.62, $CHCl_3$); Found: C, 70.00; H, 6.78%. Calcd for $C_{44}H_{50}O_{11}$: C, 70.01; H, 6.68%.

Signals of two C-Me groups (δ 1.21 and 1.30), and one OMe (3.42), could be distinguished in the ^1H NMR spectrum, and in addition, those of four benzyl methylene carbons (73.4, 74.8, 75.4, and 75.7 ppm), 6- and 6′-carbons (66.6 and 69.0) and the ortho ester carbon (119.6) in the ^{13}C NMR spectrum.

1,2-O-(2,3,4,6-Tetra-O-benzyl-D-glucopyranosylidene)ethanediol (5). A solution of **1** (2 g, 3.71 mmol) and ethylene glycol (340 mg, 5.45 mmol) in benzene (40 ml) containing a few drops of concentrated sulfuric acid was refluxed for 10 h, and the water formed was removed azeotropically. The benzene solution was successively washed with sodium hydroxide solution and water, then evaporated to give a syrup, which was purified on a silica-gel column (1 : 1 hexane–ether, R_f 0.42). Yield, 0.93 g (43%), mp 51—52 °C (petroleum ether), $[\alpha]_D^{22}$ +51° (*c* 1.0, $CHCl_3$). Found: C, 73.59; H, 6.52%. Calcd for $C_{36}H_{38}O_7$: C, 74.20; H, 6.57%. On continuation of the dehydration for 24 h, **5** was obtained in 77% yield.

1,2-O-(2,3,4,6-Tetra-O-acetyl-D-glucopyranosylidene)ethanediol (6). Catalytic hydrogenation of **5** (1 g, 1.72 mmol) in methanol (20 ml) in the presence of palladium–charcoal (10%, 1 g) and a few drops of acetic acid consumed theoretical amount of hydrogen (170 ml) during 8 h. The reaction mixture was filtered, and the filtrate was neutralized with lead carbonate and concentrated to give a syrup (350 mg, 93%). The syrup in pyridine was acetylated with acetic anhydride by the usual manner to give **6** as needles (toluene). Yield, 0.49 g (73%), mp 143—145 °C, $[\alpha]_D^{22}$ +51° (*c* 1.0, $CHCl_3$). ^1H NMR: 5.7—5.28 (H_2, H_3, H_4 : m), 4.52 (H_6 : q, $J_{5,6}$=4.2, $J_{6,6'}$=12.5), 4.40 ($H_{6'}$: q, $J_{5,6'}$=2.4), 4.32—6.00 (H_5, CH_2CH_2 : m), 2.31, 2.17, 2.10, 2.08 (4×OAc). Found: C, 49.35; H, 5.63%. Calcd for $C_{16}H_{22}O_{11}$: C, 49.23; H, 5.68%.

*1,2-O-(2,3,4,6-Tetra-O-benzyl-D-gluropyranosylidene)-*cis*-1,2-cyclohexanediol (7a and 7b).* Azeotropic dehydration of **1** (2.0 g, 3.7 mmol) and *cis*-1,2-cyclohexanediol (0.8 g, 6.9 mmol) for 30 h as **5**, and separation of the product on a silica gel colume (1 : 1 hexane–ether) gave two isomers of **7a** (650 mg, R_f 0.53) and **7b** (1070 mg, R_f 0.50) as needles in 28 and 45% yields, respectively.

7a: mp 58—60 °C, $[\alpha]_D^{22}$ +45° (*c* 0.90, $CHCl_3$), ortho ester ^{13}C: 119.6 ppm. Found: C, 75.72; H, 7.03%. Calcd for $C_{40}H_{44}O_7$: C, 75.45; H, 6.97%.

7b: mp 98—100 °C, $[\alpha]_D^{22}$ +55° (*c* 1.1, $CHCl_3$), ortho ester ^{13}C: 118.5 ppm. Found: C, 75.80; H, 7.12%. Calcd for $C_{40}H_{44}O_7$: C, 75.45; H, 6.97%.

*1,2-O-(2,3,4,6-Tetra-O-benzyl-D-glucopyranosylidene)-*trans*-1,2-cyclohexanediol (8a and 8b).* A similar azeotropic dehydration of **1** (2.0 g, 3.7 mmol) and *trans*-cyclohexane-1,2-diol (0.8 g, 6.9 mmol) as above gave two isomers of **8a** (490 mg, R_f 0.43, 1 : 1 hexane–ether) and **8b** (470 mg, R_f 0.50) in 21.9 and 21.0% yields, respectively.

8a: syrup, $[\alpha]_D^{22}$ +7.9° (*c* 0.5, $CHCl_3$), ortho ester ^{13}C: 119.1 ppm. Found: C, 75.00; H, 7.11%. Calcd for $C_{40}H_{44}O_7$: C, 75.45; H, 6.97%.

8b: mp 91—93 °C, (prism, petroleum ether), $[\alpha]_D^{22}$ +65° (*c* 0.8, $CHCl_3$), ortho ester ^{13}C: 119.2 ppm. Found: C, 75.43; H, 7.02%. Calcd for $C_{40}H_{44}O_7$: C, 75.45; H, 6.97%.

From the rotational values of **8a** and **8b**, it is deduced that **8a** is the condensation product of (1*R*,2*R*)-cyclohexanediol and **8b** that of (1*S*,2*S*)-isomer.[17]

Methyl 4,6-O-(2,3,4,6-Tetra-O-benzyl-D-glucopyranosylidene)-2,3-di-O-methyl-α-D-glucopyranoside (9). Azeotropic dehydration of **1** (2.0 g, 3.7 mmol) and methyl 2,3-di-*O*-methyl-α-D-glucopyranoside (1.24 g, 5.58 mmol), for 8 h, and purification of the product on a silica-gel column (6 : 1 benzene–ethyl acetate, R_f 0.47) gave **9** in 19.6% (0.54 g) yield. Mp 63—64 °C (prism, peteroleum ether), $[\alpha]_D^{22}$ +93° (*c* 0.92, $CHCl_3$), ortho ester ^{13}C: 110.7 ppm. Found: C, 69.79; H, 6.88%. Calcd for $C_{43}H_{50}O_{11}$: C, 69.52; H, 6.78%.

Methyl 4,6-O-(2,3,4,6-Tetra-O-benzyl-D-glucopyranosylidene)-2,3-di-O-methyl-α-D-mannopyranoside (10). Azeotropic dehydration of **1** (1.0 g, 1.85 mmol) and methyl 2,3-di-*O*-methyl-α-D-mannopyranoside (0.35 g, 1.57 mmol) for 65 h, and purification of the product on a silica-gel column (6 : 1 benzene–ethyl acetate, R_f 0.48), gave **10** (0.10 g) as a syrup in 8.6% yield. $[\alpha]_D^{22}$ +56.4° (*c* 0.5, CH_2Cl_2), ortho ester ^{13}C: 110.9 ppm. Found: C, 69.11; H, 6.98%. Calcd for $C_{43}H_{50}O_{11}$: C, 69.52; H, 6.78%.

1,2 : 3,4-Di-O-(2,3,4,6-tetra-O-benzyl-D-glucopyranosylidene)-erythritol (11). Azeotropic dehydration of **1** (1.5 g, 2.77 mmol) and erythritol (1.3 g, 10.6 mmol) for 24 h gave only one product (9 : 1 benzene–ethyl acetate, R_f 0.30) in 61.7% (1.05 g) yield. Mp 69—74 °C $[\alpha]_D^{22}$ +53° (*c* 0.3, $CHCl_3$), ortho ester ^{13}C: 121.9 ppm. Found: C, 73.95; H, 6.38%. Calcd for $C_{72}H_{74}O_{14}$: C, 74.34; H, 6.41%.

Methyl 2,3-O-(2,3,4,6-Tetra-O-benzyl-D-glucopyranosylidene)-4,6-di-O-methyl-α-D-mannopyranoside (12). Azeotropic dehydration of **1** (1.5 g, 2.77 mmol) and methyl 4,6-di-*O*-methyl-α-D-mannopyranoside (1.5 g, 6.75 mmol), and purification of the product on a silica-gel column (1 : 1 hexane–ether, R_f 0.42) gave a syrup (40 mg) in 0.15% yield. Syrup, ortho ester ^{13}C: 119.1 and 120.5 ppm. Found: C, 69.15; H, 6.62%. Calcd for $C_{43}H_{50}O_{11}$: C, 69.52; H, 6.78%.

The *in Situ*-generated Nickel(0)-catalyzed Reaction of Aryl Halides with Potassium Iodide and Zinc Powder

Kentaro TAKAGI,* Naomi HAYAMA, and Saburo INOKAWA†
College of Liberal Arts and Science, Okayama University, Tsushima, Okayama 700
(Received April 12, 1980)

The *in situ*-generated nickel(0) species, presumably atomic nickel, from nickel(II) salt and zinc powder has been proved to be an effective catalyst for the Finkelstein-type displacement reaction of aryl bromides with potassium iodide to give aryl iodides under mild conditions. This species was also effective for the Ullmann-type coupling of bromides or aryl iodides by the use of zinc powder to give biaryls. Furthermore, in the presence of excess nickel(II) salt, the coupling reaction proceeded smoothly, even at an ambient temperature, to give various biaryls in very good yields.

The chemistry of activated metal species has attracted much attention recently from the standpoint of their great affinity for various substrates, including aryl halides.[1] We have found that nickel(II) salt was readily reduced to elemental nickel with zinc powder in the presence of potassium iodide in hexamethylphosphoric triamide (HMPA). On the other hand, if the reaction was conducted in the presence of aryl halides, such as aryl bromides or aryl iodides, aryl iodides and/or biaryls were produced instead of elemental nickel. This implied that not only a Finkelstein-type displacement reaction (Eq. 1),[2] but also an Ullmann-type coupling reaction using zinc powder (Eq. 2)[3] took place, with the aid of the nickel catalyst, with otherwise inert substrates:

$$ArBr + KI \xrightarrow{Ni^0} ArI + KBr \quad (1)$$

$$2ArI + Zn \xrightarrow{Ni^0} Ar_2 + ZnI_2 \quad (2)$$

Here in this paper, we will report the detailed results of the facile synthesis of aryl iodides or biaryls from aryl halides by means of *in situ*-generated nickel(0) species.[4]

Results and Discussion

Synthesis of Aryl Iodides from Aryl Bromides. At the beginning of this study, some attempts were made to seek a favorable system for the catalytic displacement reaction of bromobenzene with potassium iodide under mild conditions. The results are shown in Table 1. *In situ*-generated nickel(0) species from nickel(II) salt and zinc powder[5] exhibited a great reactivity among the catalysts examined.[6] Some preformed nickel(0) complexes were also reactive catalysts, but preformed elemental nickel exhibited little reactivity. HMPA was the most suitable solvent. Nickel(II) complexes revealed reactivities only at such an elevated temperature as 140 °C.

The results from various aryl bromides with *in situ*-generated nickel(0) species are listed in Table 2. Aryl bromides containing a meta or para substituent afforded the corresponding aryl iodides in fair yields, accompanied by rather large quantities of biaryls. Aryl bromides containing an ortho electron-withdrawing substituent and aryl chlorides were less reactive, and in such runs elemental nickel soon appeared.

Further investigations were undertaken to improve the selectivity (aryl iodide/(aryl iodide+biaryl) ratio); the results are listed in Table 3 and Fig. 1. Table 3 shows that the selectivity depends on the amount of zinc powder: a decreased amount of zinc powder is favorable, but it simultaneously reduces the conversion. Figure 1 shows that biaryl is produced consecutively from aryl bromide *via* aryl iodide and that the transformation of aryl iodide into biaryl proceeds in preference to the desired transformation of aryl bromide into aryl iodide near the end of the reaction. Therefore, in order to enhance the selectivity, the reaction must be interrupted prior to reaching completion.

From the viewpoint of synthetic utility, a nickel(II)-catalyzed displacement reaction at elevated temperatures might bepreferable to a nickel(0)-catalyzed one, since, in the former case, the resulting product is not contaminated with any biaryl (Runs 39 and 40 and Table 1).

Synthesis of Biaryls from Aryl Iodides. The above-mentioned displacement reaction with the aid of *in situ*-generated nickel(0) species was accompanied by a coupling reaction which probably consumed the zinc powder, judging from the results in Table 3. Then, in the presence of an adequate amount of zinc powder,

43	3	12	98	14	100
44	7	5	99	6	86
45	75	3	100	0.15	60

a) Conditions were same as those of Run 18, except for the amount of Zn powder. b) GLC analysis using internal standards. c) Yields based on Zn powder.

the Ullmann-type coupling of aryl iodides by the use of zinc powder (Eq. 2) was considered feasible. Actually, the coupling reaction proceeded smoothly under mild conditions with the aid of *in situ*-generated nickel(0) species.

The results from various aryl iodides are listed in Table 4. The reaction mixture was green during the reaction, but it turned black near the end of the reaction. A stoichiometric amount of zinc powder sufficed for the reaction, but the use of excess zinc powder was desirable. The presence of potassium iodide promoted the reaction efficiently.[7] Preformed elemental nickel exhibited little reactivity for this reaction, either. Aryl iodides containing a meta or para substituent afforded

Table 4. Catalytic synthesis of biaryls[a]

Run	X	Y	Time h	Yield[b] %
46	I	H	3.5	94
47[c]	I	H	3.5	(98)
48[d]	I	H	3.5	(0)
49	I	4-$COCH_3$	3	98
50	I	4-CH_3	10	92
51	I	4-OCH_3	30	87

56	I	2-CO_2CH_3	10	(22)[f]
57[g]	Br	H	7	(98)
58	Cl	H	7	(0)

a) Molar ratio of the components was as follows: ArX/Zn/$NiBr_2$/KI=1.0/1.25—1.85/0.025/1.25. The reaction was carried out on a 0.4—10 mmol scale in HMPA at 50 °C under nitrogen. b) Isolated Yields. Yields in parentheses were determined by GLC. c) PhI/Zn/$NiBr_2$/KI=1.0/0.6/0.05/1.25. d) KI was not added. e) Chlorobenzene 39%. f) Methyl benzoate 67%. g) Two times as much KI was used.

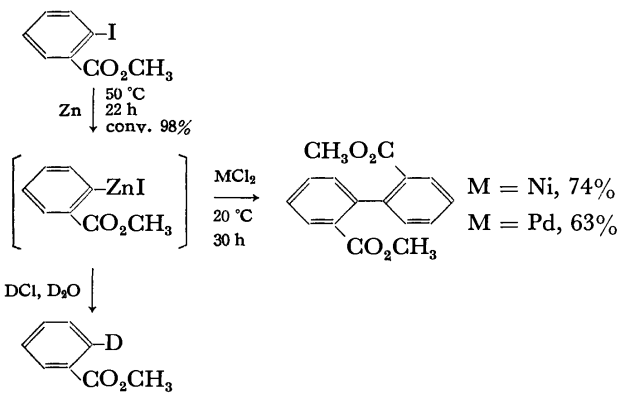
Table 5. Biaryl synthesis at ambient temperature[a]

Run	Y	Z	Time h	Yield[b] %
59	H	H	8	100
60	2-CO_2CH_3	H	6	95
61[c]	2-CO_2CH_3	H	7	28
62	2-CO_2CH_3	4-CH_3	28	(98)
63	2-$COCH_3$	H	6	96(68)[d]
64[e]	2-Cl	H	3.5	84(59)[f]
65[e]	2-CF_3	H	6	75(29)[g]

a) Molar ratio of the components was as follows: ArI/$NiCl_2$/Zn/KI=1.0/1.1/1.0/1.25. The reactions were carried out on a 0.4—8 mmol scale in HMPA at 20 °C under nitrogen. b) GLC analysis using internal standards. Yields in parentheses were isolated ones. c) $PdCl_2$ was used in the place of $NiCl_2$. d) Reaction for 16 h. e) Reaction at 35 °C. f) Reaction at 20 °C for 18 h. g) Reaction at 20 °C for 100 h.

the corresponding biaryls in good yoelds. Biaryls were also produced from aryl bromides under conditions almost identical with those in aryl iodides: this is clearly due to the rapid formation of aryl iodide from aryl bromide under this catalyst system.

Aryl iodides containing an ortho electron-withdrawing substituent afforded large quantities of dehaloprotonated products, which probably arose from organozinc compounds,[8] by-products of the combination of aryl iodides and zinc powder, upon an aqueous workup. The addition of palladium(II) or nickel(II) salt to a prepared mixture including organozinc compounds afforded the biaryls containing electron-withdrawing substituents at the 2,2′-positions, presumably *via* the well-known transfer of organo groups from zinc(II) to palladium(II) or nickel(II).[9,10] A convenient



batch method could be used for the system. That is, in the presence of excess nickel(II) salt, the coupling reaction proceeded smoothly even at an ambient temperature to give various biaryls in very good yields. The results are shown in Table 5. The intermediate use of organozinc compounds in these reactions was, however, omitted on the basis of the fact that the reaction between aryl iodides and zinc powder was by far slower than the present coupling reaction.[11]

Reaction Path. The results and discussion presented above lead to the following equations as the most plausible sequences of the reaction. The atomic nickel which comes from nickel(II) salt and zinc powder (Eq. 3) readily reacts with aryl halide (bromide

$$NiX_2 + Zn \longrightarrow Ni + ZnX_2 \quad (3)$$

$$Ni + ArBr \rightleftarrows \underset{\mathbf{1}}{Ar\text{–}Ni\text{–}Br} \quad (4)$$

$$Ar\text{–}Ni\text{–}Br + KI \rightleftarrows \underset{\mathbf{2}}{Ar\text{–}Ni\text{–}I} + KBr \quad (5)$$

$$Ar\text{–}Ni\text{–}I \rightleftarrows ArI + Ni \quad (6)$$

$$2Ar\text{–}Ni\text{–}I \rightleftarrows \underset{\mathbf{3}}{Ar\text{–}Ni\text{–}Ar} + NiI_2 \quad (7)$$

$$Ar\text{–}Ni\text{–}Ar \longrightarrow Ar_2 + Ni \quad (8)$$

or iodide) to give an oxidative-addition adduct, **1** or **2** (Eqs. 4 and 6).

In a catalytic displacement reaction, the metathetical replacement of **1** with potassium iodide produces another organonickel(II) species **2** (Eq. 5), which subsequently yields aryl iodide and regenerates the atomic nickel to ensure the catalytic reaction (Eq. 6). This is the well-known sequence of oxidative addition, metathesis, and reductive elimination in transition metal chemistry.[12] It is noteworthy that the equilibrium in Eq. 5 is presumed to lie so far to the right, because the concentration of potassium iodide is much higher than that of potassium bromide in our solvent (see Experimental).[13]

In a coupling reaction, the disproportionation of **2** takes place to give nickel(II) salt and a diorganonickel(II) species, **3** (Eq. 7), which subsequently yields biaryl (Eq. 8). This type of decomposition is well-established and is not catalytic by nature.[14] To ensure the catalytic

cycle, the original atomic nickel must be regenerated from the nickel(II) salt thus formed, and then zinc powder in at least a stoichiometric quantity is required.

Some aryl halides, such as aryl chlorides, or aryl bromides and aryl iodides containing an ortho electron-withdrawing substituent, do not undergo either reaction. Presumably, these aryl halides can not trap a generated atomic nickel efficiently; consequently, they condense to form a slurry that no longer exhibits reactivity, even for reactive aryl halides, as has been described above.

Experimental

All reagents were used directly as obtained commercially, unless otherwise noted. The solvents were distilled under nitrogen and were dried over a molecular sieve (3A). The $RhCl(PPh_3)_3$[15] and $Ni[P(OPh)_3]_4$[16] were prepared by previously reported methods. Some aryl iodides were prepared according to a procedure in the literature.[17] The ^1H NMR spectra were obtained on JOEL PMX 60 apparatus. A Hitachi 160 gas chromatograph was used for the GLC analyses.

Reduction of Nickel(II) Chloride by Zinc Powder. A mixture of zinc powder (65 mg, 1.0 mmol), nickel(II) chloride (38 mg, 0.3 mmol), potassium iodide (83 mg, 0.5 mmol), and HMPA (0.5 ml) was evacuated, flushed with nitrogen, and kept at 20 °C with stirring. The initial blue-green solution gradually turned black. After 10 h, the resulting black solid was filtered off and washed with aqueous ammonia and water until the wash was free of the nickel(II) ion. The amount of elemental nickel was determined by the dimethylglyoxime method, which showed that 93% of the nickel(II) chloride had been reduced to elemental nickel.

Preparation of Aryl Iodides. *Preparation of* p-*Iodoanisole*: A mixture of *p*-bromoanisole (0.32 ml, 2.5 mmol), potassium iodide (2.07 g, 12 mmol), a 0.17 mol dm^{-3}-DMF solution of nickel(II) bromide (0.59 ml, 0.10 mmol), tributylphosphine (0.059 ml, 0.20 mmol), and DMF (1.90 ml) was heated to reflux for 2 h with stirring under nitrogen. To the resulting mixture, aqueous sodium chloride (20 ml) was added, and the organic materials, extracted with three 10-ml portions of pentane, were washed successively with three 5- ml portions of concd hydrochloric acid, aqueous sodium chloride (15 ml), aqueous sodium carbonate (15 ml), and aqueous sodium thiosulfate (15 ml), and then dried over anhydrous sodium sulfate. The evaporation of the solvent gave 0.52 g of crude *p*-iodoanisole (87%). Recrystalization from hexane gave the pure iodide. Mp 47—48 °C (lit,[18] 51—52 °C). Found: C, 35.68; H, 3.04%. Calcd for C_7H_7IO: C; 35.92; H, 3.01%. p-*Iodoacetophenone*: Mp 83.5—84 °C (lit,[19] 85 °C). Found: C, 39.21; H, 2.88%. Calcd for C_8H_7IO: C, 39.05; H 2.87%.

Preparation of Biaryls. *Preparation of Dimethyl 3,3'-Biphenyldicarboxylate*: A mixture of methyl *m*-iodobenzoate (524 mg, 2 mmol), a 0.17 mol dm^{-3}-DMF solution of nickel(II) bromide (0.30 ml, 0.05 mmol), zinc powder (164 mg, 2.5 mmol), potassium iodide (415 mg, 2.5 mmol), and HMPA (2.2 ml) was frozen at −78 °C, evacuated, flushed with nitrogen, and then kept at 50 °C for 3 h with stirring. To the resulting mixture, dilute hydrochloric acid (0.4 mol dm^{-3}, 16 ml) was added, and the organic materials, extracted with 15-ml portions of ether–dichloromethane (7 : 1), were washed with aqueous sodium sulfite (15 ml) and three 15-ml portions of aqueous sodium chloride, and dried over anhydrous sodium sulfate. The subsequent evaporation of the solvent gave 260 mg of crude dimethyl 3,3'-biphenyldicarboxylate (96%). Recrystalization from ether gave the pure biaryl. Mp 103—103.5 °C (lit,[20] 104 °C). Found: C, 70.93; H, 5.13%. Calcd for $C_{16}H_{14}O_4$: C, 71.10; H, 5.22%.

Biphenyl: Mp 68—69 °C (lit,[21] 71 °C). Found: C, 92.90; H, 6.48%. Calcd for $C_{12}H_{10}$: C, 93.46; H, 6.54%.

4,4'-Dimethylbiphenyl: Mp 117.5—119 °C (lit,[22] 121 °C). Found: C, 91.96; H, 7.85%. Calcd for $C_{14}H_{14}$: C, 92.26; H, 7.74%.

4,4'-Dimethoxybiphenyl: Mp 169—171 °C (lit,[23] 173 °C). Found: C, 78.36; H, 6.60%. Calcd for $C_{14}H_{14}O_2$: C, 78.48; H, 6.59%.

4,4'-Diacetylbiphenyl: Mp 191—192 °C (lit,[24] 192 °C). Found: C, 80.62; H, 5.91%. Calcd for $C_{16}H_{14}O_2$: C, 80.65, H, 5.92%.

2,2'-Dimethylbiphenyl: Bp 69 °C/67 Pa (lit,[25] 258 °C/98400 Pa). Found: C, 92.31; H, 7.79%. Calcd for $C_{14}H_{14}$: C, 92.26; H, 7.74%.

Preparation of Dimethyl 4,4'-Dimethyl-2,2'-biphenyldicarboxylate: A mixture of methyl 2-iodo-5-methylbenzoate (1.32 ml, 8 mmol), nickel(II) chloride (1.16 g, 9 mmol), zinc powder (1.04 g, 16 mmol), potassium iodide (1.66 g, 10 mmol), and HMPA (10 ml) was evacuated, flushed with nitrogen, and kept at 20 °C for 28 h with stirring. To the resulting mixture, aqueous sodium chloride (80 ml) was added, and the organic materials, extracted with two 60-ml portions of ether, were washed with four 120-ml portions of aqueous sodium chloride and then dried over anhydrous sodium sulfate. The subsequent evaporation of the solvent gave a crude dimethyl 4,4'-dimethyl-2,2'-biphenyldicarboxylate, which was triturated with a small amount of hexane to leave 1.10 g of the pure biaryl (98%). Mp 90—91 °C. Found: C, 72.29; H, 6.00%. Calcd for $C_{18}H_{18}O_4$: C, 72.46; H, 6.08%.

2,2'-Dichlorobiphenyl: Mp 54—55 °C (lit,[26] 59 °C). Found: C, 64.52; H, 3.45%. Calcd for $C_{12}H_8Cl_2$: C, 64.60; H, 3.61%.

2,2'-Diacetylbiphenyl: Mp 90.5—91.°C (lit,[27] 93—94 °C). Found: C, 80.57; H, 5.79%. Calcd for $C_{16}H_{14}O_2$: C, 80.65; H, 5.92%.

2,2'-Bis(trifluoromethyl)biphenyl: Bp 119—121 °C/2130 Pa (lit,[28] 236—237 °C). NMR: 7.1—7.9 (*m*).

Reaction of Methyl o-*Iodobenzoate with Zinc Powder.* A mixture of methyl *o*-iodobenzoate (0.059 ml, 0.4 mmol), zinc powder (52 mg, 0.8 mmol), potassium iodide (83 mg, 0.5 mmol), and HMPA (0.5 ml) was stirred at 50 °C for 22 h under nitrogen. To the resulting mixture, dilute hydrochloric acid was added, and the organic materials were extracted with ether. Subsequent analysis by GLC revealed the presence of 53 mg (0.39 mmol) of methyl benzoate. Atmospheric oxygen inhibited the reaction completely. A similar work-up by means of deuterium oxide–hydrochloric acid-d_1 gave methyl benzoate-d_1. NMR: 7.85—8.07 (*m*, 1H), 7.15—7.62 (*m*, 3H), 3.87 (s, 3H). Found: C, 69.97; H, 5.91%. Calcd for $C_8H_7DO_2$: C, 70.06; H, 5.84%.

An alternative treatment of the resulting mixture with palladium(II) chloride (177 mg, 1.0 mmol) at 20 °C for 30 h under nitrogen, followed by GLC analysis, gave 35 mg (0.13 mmol) of dimethyl 2,2'-biphenyldicarboxylate (63%) and 16 mg (0.12 mmol) of methyl benzoate (30%).

Solubility of Potassium Iodide or Potassium Bromide in HMPA–DMF. After a suspension of potassium iodide (9.0 g, 54 mmol) or potassium bromide (6.4 g, 54 mmol) in HMPA–DMF (22 : 3, 10 ml) has been stirred at 50 °C for 1.5 h, the concentration of the iodide ion or the bromide ion in the solution was determined by the Mohr method. One liter of mixed solvents dissolved about 0.11 mol of potassium iodide or 0.001 mol of potassium bromide respectively.

Synthesis of 2-Formylazulene and Its Derivatives by Oxidative Cleavage of 2-Styrylazulenes

Motoyasu SAITO, Tadayoshi MORITA, and Kahei TAKASE*

Department of Chemistry, Faculty of Science, Tohoku University, Aramaki-aza-Aoba, Sendai 980

(Received April 24, 1980)

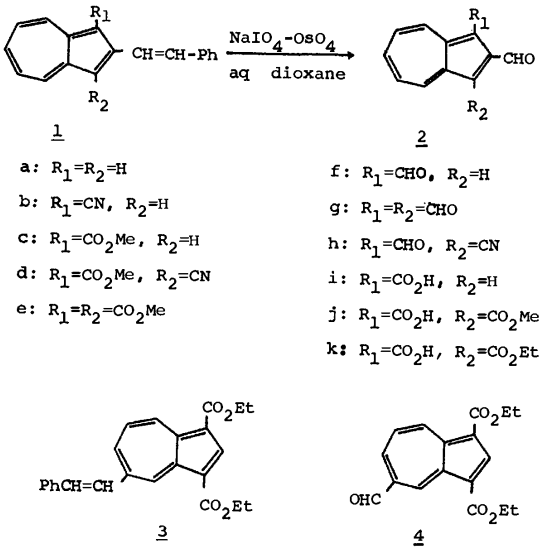
2-Formylazulene and its derivatives were prepared by the oxidative cleavage of styrylazulenes with $NaIO_4$–OsO_4. 1,2-Diformyl-, 1,2,3-triformylazulenes, and 5-formylazulene derivative were also synthesized. The reaction of dimethyl 2-methylazulene-1,3-dicarboxylate with *p*-nitroso-*N*,*N*-dimethylaniline in the presence of NaOR (R=Me or Et) gave the corresponding 3-alkoxycarbonyl-2-[*p*-(dimethylamino)phenyliminomethyl]-azulene-1-carboxylic acids followed by hydrolysis with hydrochloric acid to give 3-alkoxycarbonyl-2-formylazulene-1-carboxylic acids. Acetylation of 2-formylazulene-1-carboxylic acids with acetic anhydride gave five membered lactol acetates.

Formylazulenes are useful for synthesizing various azulene derivatives because of their functional formyl groups. Of five possible positional isomers, 1-formylazulene and its derivatives were easily obtained by formylation of azulenes according to the Vilsmeier-Haack method,[1–3] Gatterman reaction,[4] and with use of triethyl orthoformate–tetrafluoroboric acid[5] or perchloric acid,[6] the properties of which have been investigated.[1,2,7] The oxidation of some 1-methylazulenes with selenium dioxide or potassium permanganate also gave 1-formylazulenes.[8,9] However, preparation of the other isomeric formylazulenes is difficult. Sato[10] reported that 2-formylazulene is derived from 2-cyanoazulene by hydrolysis, esterification, reduction with lithium aluminum hydride, and subsequent oxidation of the resulting alcohol with manganese dioxide.

Arnold and Pahls[11] reported that 6-formyl-4,8-dimethylazulene is obtained from ethyl 4,8-dimethylazulene-6-carboxylate by reduction with lithium aluminum hydride, followed by oxidation by means of the Kröhnke-Karrer method. Hafner and Moritz[12] reported that the formylation of some 1,3-dialkylazulenes by the Vilsmeier-Haack method gives 2-formyl- and 5-formyl derivatives, together with 1-formylazulenes. The oxime of 6-formylazulene derivative was obtained by treatment of diethyl 2-amino-6-methylazulene-1,3-dicarboxylate with isopentyl nitrite.[13] This paper describes a useful method of synthesizing 2-formylazulene and its derivatives by oxidative cleavage of 2-styrylazulenes obtained by the condensation of 2-methylazulene derivative with benzaldehyde in good yields.[14]

Results and Discussion

The Lemieux-Johnson oxidation[15] is effective for oxidative cleavage of the ethylenic linkage of 2-styrylazulenes. Thus, on treatment with sodium periodate in aq dioxane in the presence of a catalytic amount of osmium tetroxide, 2-styrylazulenes (**1a—j**) gave the corresponding 2-formylazulenes (**2a—j**), respectively. A lower yield (13%) of the parent 2-formylazulene (**2a**) may be due to its instability: it changes into a brown, hardly soluble substance on being heated or allowed to stand for a long time. The other 2-formylazulene derivatives, having substituents at the 1-(and 3-)positions, are stable and were obtained in good yields.



Scheme 1.

1,2-Diformyl[16] and 1,2,3-triformylazulenes (**2f,g,h**), not obtained by formylation of 2-formylazulenes (**2a,b,f**) by means of the Vilsmeier-Haack method, were obtained, in a similar manner, from 1-formyl- and 1,3-diformyl-2-styrylazulenes (**1f,g,h**) which were prepared by formylation of 2-styrylazulenes. The Lemieux-Johnson oxidation could be applied to the synthesis of not only 2-formylazulenes but also 5-formylazulenes. Thus, treatment of diethyl 5-styrylazulene-1,3-dicarboxylate (**3**) obtained by condensation of diethyl 5-methylazulene-1,3-dicarboxylate[17] and benzaldehyde with sodium periodate–osmium tetroxide afforded diethyl 5-formylazulene-1,3-dicarboxylate (**4**). The IR spectra (KBr) of 2-formylazulenes show absorptions corresponding to $\nu_{C=O}$ of the 2-formyl groups within the range 1672—1701 cm^{-1} in somewhat lower frequency region than that (1708—1699 cm^{-1})[18] of benzaldehydes; that of 1-formylazulenes appear in a lower frequency region 1610—1650 cm^{-1}.[7b,8] The electronic spectra of 2-formylazulenes conform to the extended Plattner rule.[19] The NMR spectra of 2-formylazulenes, as expected, show a singlet due to the formyl proton at δ 10—11 ppm, as well as signals due to the other protons. 2-Formylazulenes easily gave carbonyl derivatives, such as oximes and hydrazones, and were converted into the corresponding alcohols or carboxylic acids by reduction

with sodium borohydride or oxidation with silver oxide, respectively. 2-Formylazulene-1-carboxylic acids (**2i,j**) possess a structure analogous to that of *o*-formylbenzoic acid which undergoes cyclization easily into the lactol, and existing as a mixture of ring-chain tautomers, the acid and lactol (13 : 87) in dioxane.[20] In the case of **2i** and **2j**, however, the ring tautomers (**5a,b**) could not be detected by either IR (KBr, $CHCl_3$) or NMR ($CDCl_3$), **2i** and **2j** exist predominantly in the acid chain structure. This can be explained by resonance stabilization of the formyl group at position 2 and also by the larger bond angle between two substituents in **2i** and **2j** than in *o*-formylbenzoic acid. On the other hand, the acetylation of **2j** gave a lactol acetate (**6a**), whose structure was established on the basis of spectral data. The IR (KBr) shows an absorption at 1767 cm^{-1} due to the five-membered lactone, and the NMR spectrum ($CDCl_3$) shows singlets at δ 2.20 ($COCH_3$), 3.90 (OCH_3), and 7.78 ppm (methine), as well as signals due to the ring protons at δ 7.6—8.3 (3H,m), 9.10 (1H, bd), and 9.90 ppm (1H, bd).

8b: R=Et, Ar=p-$(Me)_2NC_6H_5$-

Scheme 2.

Reactive methyl or methylene groups are convertible into carbonyl groups by condensation with *p*-nitroso-*N,N*-dimethylaniline (**NDA**)[21] and subsequent hydrolysis of the resulting Shiff base. Such a reaction was carried out for synthesizing 2-formylazulenes from 2-methylazulene derivatives directly. The reaction of dimethyl 2-methylazulene-1,3-dicarboxylate (**7**) with **NDA** proceeded easily in the presence of sodium methoxide or ethoxide to give condensation products **8a** and **8b**. Hydrolysis of non-purified **8a** with acid gave an acidic compound identical with **2j**. **8a** could not be isolated in a pure form since it was easily hydrolyzed to **2j**; **8b** was isolated in pure form. Hydrolysis of **8b** gave 3-ethoxycarbonyl-2-formylazulene-1-carboxylic acid (**2k**). Acetylation of **2k** gave a lactol acetate (**6b**). The structures of **8b**, **2k**, and **6b** were established on the basis of spectral data (IR and NMR).

The fact that **8b** is acidic enough to be soluble in aq $NaHCO_3$ solution also supports the half ester structure of **8b**. The mechanism of the formation of the half ester **8b** is assumed to be similar to that of the formation of the half ester of 2-styrylazulene-1,3-dicarboxylic acid by condensation of **7** and benzaldehyde.[14]

Experimental

All melting points were determined in a capillary and are uncorrected. Electronic spectra were measured on a Hitachi EPS-3 spectrometer, and IR spectra on a Shimadzu IR-27 infracord, and NMR spectra on a Varian A-60 spectrometer in $CDCl_3$ containing TMS.

General Procedure for the Oxidation of 2-Styrylazulenes to 2-Formylazulenes. Finely ground $NaIO_4$ (2—4 molar equivalents) was added in portions to a stirred solution of 2-styrylazulenes and OsO_4 (1—2% by weight) dissolved in aq dioxane (dioxane : H_2O=7 : 3) at room temp over a period of 30—60 min. Stirring was continued for 4—8 h. The reaction mixture was diluted with water and extracted with $CHCl_3$, the extract being washed with H_2O and dried over Na_2SO_4. After evaporation of the solvent the residue was chromatographed over a silica-gel column and eluted with benzene. The first colorless effluent gave benzaldehyde, the second and third colored portions giving 2-styrylazulenes and 2-formylazulenes, respectively.

2-Formylazulene (2a). 2-Styrylazulene (**1a**) (460 mg, 2 mmol) was treated according to the general procedure to give **1a** (30 mg) and **2a** (40 mg, 13% yield) as blue scales (from cyclohexane), mp 62—63 °C (reported[10] mp 63 °C); IR (KBr): 1675 cm^{-1}; $\lambda_{max}^{cyclohexane}$ 244 nm (log ε 4.23), 275 sh (4.50), 288 (4.69), 296 (4.70), 335 (3.68), 346 (3.72), 360 (3.80), 613 (2.61), 664 (2.19); NMR ($CDCl_3$): δ 7.13 (br t, J=10 Hz, H-5,7), 7.67 (br t, J=10 Hz, H-6), 7.70 (s, H-1,3), 8.42 (br d, J=10 Hz, H-4,8), 10.37 (s, CHO). Found: C, 84.63; H, 5.23%. Calcd for $C_{11}H_8O$: C, 84.59; H, 5.16%.

Phenylhydrazone: Green needles (from benzene), mp 197 °C. Found: C, 82.63; H, 5.80; N, 11.08%. Calcd for $C_{17}H_{14}N_2$: C, 82.90; H, 5.73; N, 11.37%.

1-Cyano-2-formylazulene (2b). 1-Cyano-2-styrylazulene (**1b**) (2.25 g, 10 mmol) was treated according to the general procedure to give **1b** (340 mg) and **2b** (1.17 g, 75% yield) as green needles (from benzene), mp 184—185 °C; IR (KBr): 1686, 2217 cm^{-1}; λ_{max}^{MeOH} 233 nm (log ε 4.25), 287 (4.57), 298 (4.79), 345 (3.69), 362 (3.64); NMR ($CDCl_3$): δ 7.2—7.8 (m, H-5,7), 7.96 (br t, J=9 Hz, H-6), 8.58 (br t, J=11 Hz, H-4), 8.78 (br d, J=11 Hz, H-8), 10.48 (s, CHO). Found: C, 79.59; H, 3.80; N, 7.60%. Calcd for $C_{12}H_7ON$: C, 79.55; H, 3.89; N, 7.73%.

Oxime: Brown blue crystals (from $CHCl_3$), mp 264—266 °C. Found: 73.78; H, 3.66; N, 13.92%. Calcd for $C_{12}H_8O_2N_2$: C, 73.46; H, 4.11; N, 14.28%.

Hydrazone: Green crystals (from benzene), mp over 300 °C. Found: C, 73.78; H, 4.46; N, 21.00%. Calcd for $C_{12}H_9N_3$: C, 73.83; H, 4.65; N, 21.53%.

p-*(Dimethylamino)phenylimino Derivative*: Reddish brown crystals (from benzene–cyclohexane), mp 194—196 °C. Found: C, 79.89; H, 5.58; N, 13.88%. Calcd for $C_{20}H_{17}N_3$: C, 80.24; H, 5.72; N, 14.04%.

Methyl 2-Formylazulene-1-carboxylate (2c). Methyl 2-styrylazulene-1-carboxylate (**1c**) (1.30 g, 4.5 mmol) was treated in the usual way to give **1c** (130 mg) and **2c** (560 mg, 64% yield) as green needles (from ethanol), mp 119—120 °C; IR (KBr): 1701, 1678 cm^{-1}; λ_{max}^{MeOH} 238 nm (log ε 4.32), 291

(4.61), 301 (4.68), 335 sh (3.79), 350 (3.84), 369 (3.75), 573 (2.98), 606 (3.02), 650 sh (2.70); NMR ($CDCl_3$): δ 3.98 (s, OCH_3), 7.2—7.6 (m, H-5, 7), 7.63 (s, H-3), 7.83 (tm, J=9 Hz, H-6), 8.47 (br d, J=10 Hz, H-4), 9.62 (br d, J=10 Hz, H-8), 10.92 (s, CHO). Found: C, 72.90; H, 4.82%. Calcd for $C_{13}H_{10}O_3$: C, 72.89; H, 4.71%.

Methyl 3-Cyano-2-formylazulene-1-carboxylate (2d). Methyl 3-cyano-2-styrylazulene-1-carboxylate (**1d**) (3.13 g, 10 mmol) was treated in the usual way to give **1d** (1.02 g) and **2d** (1.29 g, 80% yield) as reddish violet needles (from MeOH), mp 221—223 °C; IR (KBr): 2865, 2219, 1698, 1678, 1115, 1064 cm^{-1}; λ_{max}^{MeOH} 235 nm (log ε 4.55), 267 (4.34), 293 (4.63), 303 (4.73), 340 (3.90), 367 (3.89). Found: C, 70.22; H, 3.82; N, 5.79%. Calcd for $C_{14}H_9O_3N$: C, 70.29; H, 3.79; N, 5.86%.

Dimethyl 2-Formylazulene-1,3-dicarboxylate (2e). Dimethyl 2-styrylazulene-1,3-dicarboxylate (**1e**) (1.38 g, 4 mmol) was treated in the usual way to give **1e** (120 mg) and **2e** (810 mg, 82% yield) as red needles (from MeOH), mp 167—168 °C; IR (KBr): 2865, 1698, 1215, 1192, 1088, 1064 cm^{-1}; λ_{max}^{MeOH} 234 nm (log ε 4.53), 275 sh (4.43), 292 (4.62), 302 (4.70), 340 (3.89), 368 (4.00); $\lambda_{max}^{CHCl_3}$ 525 nm (log ε 2.97); NMR ($CDCl_3$): δ 3.92 (s, 2 OCH_3), 7.5—8.1 (m, H-5—7), 9.73 (dm, J=10 Hz, H-4,8), 10.75 (s, CHO). Found: C, 66.34; H, 4.50%. Calcd for $C_{15}H_{12}O_5$: C, 66.17; H, 4.44%.

1,2-Diformylazulene (2f). 1-Formyl-2-styrylazulene (**1f**) (1.03 g, 4 mmol) was treated in a similar manner to that above to give **2f** (660 mg, 90% yield) as bluish green needles (from cyclohexane), mp 155—156 °C; IR (KBr): 1672, 1643 cm^{-1}; $\lambda_{max}^{chloroform}$ 290 nm (log ε 4.48), 315 (4.60), 325 (4.57), 350 (4.08), 370 (4.08), 390 (4.04), 540 (2.63), 600 (2.94), 640 sh (2.75); NMR ($CDCl_3$): δ 7.3—8.3 (m, H-5—7), 7.83 (s, H-3), 8.75 (br d, J=10 Hz, H-4), 9.87 (br d, J=10 Hz, H-8), 10.87 (s, CHO), 11.00 (s, CHO). Found: C, 78.22; H, 4.39%. Calcd for $C_{12}H_8O_2$: C, 78.25; H, 4.38%.

1,2,3-Triformylazulene (2g). 1,3-Diformyl-2-styrylazulene (**1g**) (600 mg, 2.1 mmol) was treated in the usual way to give **2g** (380 mg, 86% yield) as reddish violet needles (from $CHCl_3$), mp 242—243 °C; IR (KBr): 1689, 1658 cm^{-1}; $\lambda_{max}^{chloroform}$ 304 nm (log ε 4.64), 315 (4.66), 351 (3.98), 377 (3.84), 560 (3.14); NMR ($CDCl_3$): 8.05 (t, J=9 Hz, H-5—7), 8.33 (t, J=9 Hz, H-6), 9.90 (d, J=9 Hz, H-4,8), 10.75 (s, 2 CHO), 11.13 (s, CHO on C-2). Found: C, 73.58; H, 3.69%. Calcd for $C_{13}H_8O_3$: C, 73.58; H, 3.80%.

1-Cyano-2,3-diformylazulene (2h). 1-Cyano-3-formyl-2-styrylazulene (**1h**) (1.42 g, 5 mmol) was treated in the usual way to give **2g** (920 mg, 88% yield) as reddish violet needles (from $CHCl_3$), mp 242—245 °C; IR (KBr): 2212, 1692, 1661 cm^{-1}; $\lambda_{max}^{chloroform}$ 303 nm (log ε 4.64), 312 (4.64), 350 (3.98), 377 (3.84), 570 (3.18); NMR ($CDCl_3$): δ 7.8—8.3 (m, H-5—7), 9.05 (dm, J=10 Hz, H-4), 10.07 (dm, J=10 Hz, H-8), 10.85 (s, CHO), 10.92 (s, CHO). Found: C, 74.48; H, 3.46; N, 6.69%. Calcd for $C_{13}H_7O_2N$: C, 74.64; H, 3.37; N, 6.70%.

2-Formylazulene-1-carboxylic Acid (2i). 2-Styrylazulene-1-carboxylic acid (**1i**) (280 mg, 1 mmol) was treated according to the general procedure to give **2i** (90 mg, 44% yield) as blue needles (from ethanol), mp above 300 °C; IR (KBr): 3200—2857, 1672, 1640 cm^{-1}; $\lambda_{max}^{dichloromethane}$ 308 nm (log ε 4.54), 355 (3.98), 610 (2.99); NMR ($CDCl_3$+DMSO-d_6 (2 : 1)): δ 7.3—8.2 (m, H-5—7), 7.73 (s, H-3), 8.63 (br d, J=10 Hz, H-4), 9.83 (br d, J=10 Hz, H-8), 11.00 (s, CHO). Found: C, 71.82; H, 4.11%. Calcd for $C_{12}H_8O_3$: C, 71.99; H, 4.03%.

2-Formyl-3-(methoxycarbonyl)azulene-1-carboxylic Acid (2j). 3-Methoxycarbonyl-2-styrylazulene-1-carboxylic acid (**1j**) (405 mg, 1.2 mmol) was treated according to the general procedure. Crystals obtained on dilution with water were collected to give **2j** (205 mg, 65% yield) as red prisms (from MeOH), mp 242—245 °C; IR (KBr): 3030—2857, 1701, 1658, 1221, 1092 cm^{-1}. Found: C, 64.82; H, 3.78%. Calcd for $C_{14}H_{10}O_5$: C, 65.12; H, 3.90%.

Diethyl 5-Formylazulene-1,3-dicarboxylate (4). Diethyl 5-styrylazulene-1,3-dicarboxylate (**3**) (100 mg, 0.27 mmol) was treated according to the general procedure to give **4** (52 mg, 64.9% yield) as red needles (from ethanol), mp 137—138 °C; IR (KBr): 1700 sh, 1690, 1205, 1025 cm^{-1}: $\lambda_{max}^{chloroform}$ 275 nm (log ε 4.39), 308 (4.53), 333 (4.11), 406 (4.23), 520 (3.13); NMR ($CDCl_3$): δ 1.47 and 1.49 (t, J=7.0 Hz, 2 OCH_2CH_3), 4.45 and 4.48 (q, J=7.0 Hz, 2 OCH_2CH_3), 7.82 (t, J=10 Hz, H-7), 8.48 (dt, J=1.5 and 10 Hz, H-6), 8.83 (s, H-2), 9.83 (dd, J=1.5 and 10 Hz, H-8), 10.15 (d, J=1.5 Hz, H-4), 10.20 (s, CHO). Found: C, 66.40; H, 4.40%. Calcd for $C_{15}H_{12}O_5$: C, 66.17; H, 4.44%.

1-Formyl-2-stryrylazulene (1f). $POCl_3$ (320 mg) was added to a stirred solution of 2-styrylazulene (**1a**) (480 mg, 2 mmol) in DMF (5 ml) under ice-cooling. After being stirred for 30 min, the mixture was poured into ice-water (200 ml) containing 1 M KOH solution (10 ml). The product was extracted with $CHCl_3$, washed with water and dried over Na_2SO_4. The solvent was evaporated and the residue was chromatogtaphed over an alumina column and eluted with benzene. Recrystallization from cyclohexane gave **1f** (500 mg, 93% yield) as reddish violet needles, mp 125—127 °C; IR (KBr): 2762, 1626, 1610sh, 979 cm^{-1}; $\lambda_{max}^{dichloromethane}$ 345 nm (log ε 4.67), 365sh (4.58), 405 (4.02); NMR ($CDCl_3$): δ 7.0—7.8 (10 H, m, H-5—7, CH=CH–, and C_6H_5), 7.97 (s, H-3). 8.30 (complex d. J=9,Hz, H-4), 9.33 (complex d. J=10 Hz, H-8), 10.73 (s, CHO). Found: C, 88.10; H, 5.38%. Calcd for $C_{19}H_{14}O$: C, 88.34; H, 5.46%.

1,3-Diformyl-2-styrylazulene (1g). A solution of **1f** (510 mg, 2 mmol) in DMF (15 ml) was treated with $POCl_3$ (530 mg) in a manner similar to that described above. Recrystallization from benzene gave **1g** (540 mg, 95% yield) as red needles, mp 174—175 °C; IR (KBr): 1660—1620 (br), 979 cm^{-1}; $\lambda_{max}^{dichloromethane}$ 317 nm (log ε 4.59), 340 (4.59), 500 (2.80): NMR ($CDCl_3$): δ 6.93 (d, J=8.0 Hz, =CH–), 7.2—8.0 (m, H-5—7 and C_6H_5), 7.97 (d, J=8.0 Hz, =CH–), 9.7—9.9 (m, H-4, 8), 10.48 (s, 2 CHO). Found: C, 83.71; H, 4.81%. Calcd for $C_{20}H_{14}O_2$: C, 83.90; H, 4.93%.

1-Cyano-3-formyl-2-styrylazulene (1h). A solution of 1-cyano-2-styrylazulene (**1b**) (1.90 g, 6.7 mmol) in DMF (50 ml) was treated with $POCl_3$ (2 ml) in a similar manner to that described above. Recrystallization of the crude product from benzene gave **1h** (1.96 g, 93% yield) as red needles, mp 222—224 °C; IR (KBr): 2203, 1645, 1613, 952 cm^{-1}; NMR ($CDCl_3$): δ 7.27—8.03 (10 H, m, H-5—7, and protons of styryl group), 8.60—8.83 (m, H-4), 9.57—9.80 (m, H-8), 10.67 (s, CHO). Found: C, 84.86; H, 4.77; N, 4.85%. Calcd for $C_{20}H_{13}NO$: C, 84.78; H, 4.63; N, 4.94%.

Reduction of 2f with $NaBH_4$. To a stirred solution of **2f** (50 mg) in dioxane (2 ml) was added a solution of $NaBH_4$ (6 mg) in MeOH (1 ml) at room temp. After being stirred for 5 min, acetic acid was added in order to decompose excess $NaBH_4$. The reaction mixture was diluted with water and extracted with chloroform. The extract was washed with water and dried (Na_2SO_4). The solvent was evaporated and the residue was chromatographed (silica gel) and eluted with chloroform to give 40 mg of 1-formyl-2-(hydroxymethyl)-azulene as red needles, mp 117—118 °C (from ethanol); IR (KBr); 3400, 1621 cm^{-1}; $\lambda_{max}^{dichloromethane}$ 265 nm (log ε 4.24), 269 (4.29), 315 (4.85), 365 (4.10), 3.80 (4.22), 514 (2.69); NMR ($CDCl_3$): δ 5.13 (s, CH_2OH), 6.2 (br s, OH), 7.32 (s, H-3), 7.38—7.90 (m, H-5—7), 8.45 (br d, J=10 Hz,

H-4), 9.05 (br d, J=10 Hz, H-8), 10.60 (s, CHO). MS: *m/e* (rel intensity), 186 (M^+, 100), 168 (M^+-CO, 28), 157 (48), 139 (42).

1-Cyano-2-(hydroxymethyl)azulene was obtained by the reduction of **2b** with $NaBH_4$ in 93% yield in a similar manner to that described above, violet needles, mp 124—125 °C (from cyclohexane–dichloromethane); IR (KBr): 3460, 2200 cm^{-1}; NMR ($CDCl_3$): δ 2.37 (br s, OH), 5.17 (s, CH_2OH), 7.32 (s, H-3), 7.2—7.9 (m, H-5—7), 7.33 (d, J=9 Hz, H-4), 8.50 (d, J=9 Hz, H-8). MS (25 eV, at 120 °C): *m/e* (rel intensity), 183 (M^+, 83), 167 (83), 166 (100%).

Oxidation of 2b with Ag_2O. To a stirred solution of **2b** (205 mg) in ethanol (5 ml) was added freshly prepared Ag_2O (650 mg). After being stirred for 5 h, the mixture was diluted with water. The resulting crystals were collected and dissolved in a 1 M $NaHCO_3$ solution. The solusion was shaken with benzene and acidified with 6 M HCl to give crystals. Recrystallization from ethanol gave 1-cyanoazulene-2-carboxylic acid (86 mg, 38% yield) as dark green crystals, mp over 300 °C; IR (KBr): 2860 (br), 2217, 1686, 926 cm^{-1}. Found: C, 72.79; H, 3.68; N, 6.96%. Calcd for $C_{12}H_7O_2N$: 73.09; H, 3.58; N, 7.10%.

Diethyl 5-Styrylazulene-1,3-dicarboxylate (3). A mixture of 1.0 g (3.5 mmol) of diethyl 5-methylazulene-1,3-dicarboxylate[17] and 1.86 g (17.5 mmol) of benzaldehyde in a sodium ethoxide solution prepared from 403 mg (17.5 matom) of sodium and 50 ml of anhydrous ethanol was stirred at room temp for 4 d. The reaction mixture was diluted with water and acidified with dilute HCl and then extracted with chloroform. After evaporation of the solvent from the organic extract the residue was chromatographed (alumina, benzene) to give 114 mg of the unreacted diethyl 5-methylazulene-1,3-dicarboxylate from the first effluent and 116 mg (8.9%) of **3** from the second effluent as red needles (from ethanol); mp 127—128 °C (lit,[22] 122.5—123 °C); IR (KBr): 1690—1670 (br), 1200, 950 cm^{-1}; NMR ($CDCl_3$): δ 1.46 and 1.48 (t, J=7.0 Hz, 2 OCH_2CH_3), 4.48 and 4.50 (q, J=7.0 Hz, 2 OCH_2CH_3), 7.3—7.7 (m, C_6H_5), 7.76 (t, J=10 Hz, H-7), 8.23 (dd, J=10, 2 Hz, H-6), 8.93 (s, H-2), 9.76 (d, J=10 Hz, H-8), 10.30 (d, J=2 Hz, H-4). Found: C, 76.59; H, 6.18%. Calcd for $C_{24}H_{22}O_4$: C, 76.98; H, 5.92%. From the third effluent with chloroform, 380 mg (27.7%) of diethyl 5-(2-hydroxy-2-phenylethyl)azulene-1,3-dicarboxylate was obtained as reddish violet needles (from ethanol), mp 159.5—161 °C; IR (KBr): 3450, 1690, 1660, 770, 750 cm^{-1}; NMR ($CDCl_3$): δ 1.41 (t, J=7.0 Hz, 2 OCH_2CH_3), 2.65 (br s, OH), 3.30 (d, J=6.5 Hz, $CH(OH)CH_2$), 4.35 and 4.40 (q, J=7.0 Hz, 2 OCH_2CH_3), 5.50 (t, J=6.5 Hz, $CH(OH)CH_2$), 7.28 (br s, C_6H_5), 7.50 (t, J=9.0 Hz, H-7), 7.73 (br d, J=9.0 Hz, H-6), 8.75 (s, H-2), 9.41 (dd, J=9.0, 2 Hz, H-8), 9.75 (d, J=2 Hz, H-4). Found: C, 73.52; H, 6.35%. Calcd for $C_{24}H_{24}O_5$: C, 73.47; H, 6.16%.

Dehydration of Diethyl 5-(2-Hydroxy-2-phenylethyl)azulene-1,3-dicarboxylate. A mixture of 100 mg of diethyl 5-(2-hydroxy-2-phenylethyl)azulene-1,3-dicarboxylate, $POCl_3$ (3 ml), and pyridine (5 ml) was allowed to stand at room temp for 18 h. The reaction mixture was diluted with water and extracted with ether. The extracts were washed with dilute HCl and dried (Na_2SO_4) and worked up to give 93 mg (98% yield) of **3**.

The Lactol Acetate (6a). A drop of concd H_2SO_4 was added to a suspension of **2j** (100 mg) in Ac_2O (2 ml). After being stirred at room temp for 20 min, the mixture was diluted with water and extracted with $CHCl_3$, the extract being washed with water and dired (Na_2SO_4). The solvent was evaporated and the residue dissolved in benzene and passed through a short alumina column. Recrystallization from benzene gave **6a** (85 mg) as red needles, mp 220—222 °C; IR (KBr): 1767, 1706 cm^{-1}; λ_{max}^{MeOH} 234 nm (log ε 4.73), 271 (4.66), 300 (4.87), 327 (3.93), 355 (4.09), 367 (4.17), 492 (2.96); NMR ($CDCl_3$): δ 2.20 ($COCH_3$), 3.90 (OCH_3), 7.78 (methine), 7.6—8.3 (3H, m), 9.10 (1H, br d), 9.90 (1H, br d). Found: C, 64.37; H, 4.32%. Calcd for $C_{16}H_{12}O_6$: C, 64.00; H, 4.03%.

The Lactol Acetate (6b). The acid **2k** (50 mg) was treated with Ac_2O–concd H_2SO_4 in a silimar manner to that described above. Recrystallization from benzene gave **6b** (40 mg) as red needles, mp 198—200 °C; IR (KBr): 1770, 1701 cm^{-1}; λ_{max}^{MeOH} 235 nm (log ε 4.72), 271 (4.66), 292 (4.76), 301 (4.84), 326 (3.90), 355 (4.09), 368 (4.18). Found: C, 69.61, H, 4.28%. Calcd for $C_{17}H_{14}O_6$: C, 64.96; H, 4.49%.

Reaction of Dimethyl 2-Methylazulene-1,3-dicarboxylate (7) with p-Nitiroso-N,N-dimethylaniline (NDA). *a) In MeOH*: To a stirred solution of NaOMe were added 102 mg (0.39 mmol) of **7** and 100 mg (0.67 mmol) of NDA at room temp. After being stirred for 12 h, the reaction mixture was diluted with water and left to stand for 5 h. The precipitate formed was collected by filtration and chromatographed (silica gel, C_6H_6) to give 12 mg of **7**. The filtrate was acidified with 6 M HCl to give precipitate which was collected by filtration to give 60 mg of **2j** as red crystals.

b) In EtOH: 500 mg (3.3 mmol) of NDA was added to a stirred solution of NaOEt prepared from 150 mg of Na and anhydrous EtOH (3 ml). After being stirred for 12 h, the reaction mixture was diluted with water and extracted with chloroform. The organic layer was washed with water, dried (Na_2SO_4), and concentrated to a small volume. The residue was chromatographed (silica gel) to give 40 mg of **7** from the fraction eluted with C_6H_6. From the fraction eluted with chloroform 400 mg (53% yield) of **8b** was obtained as reddish brown needles; mp 228—229 °C (from benzene). IR (KBr): 1669, 1616, 1587, 813 cm^{-1}; λ_{max}^{MeOH} 239 nm (log ε 4.51), 308 (4.49), 540 (4.25); NMR ($CDCl_3$): δ 1.52 (t, J=7.0 Hz, OCH_2CH_3), 2.97 (s, $N(CH_3)_2$), 4.55 (q, J=7.0 Hz, OCH_2CH_3), 6.67 (2H, d, J=9.5 Hz, $=NC_6H_4N(Me)_2$), 7.45 (2H, d, J=9.5 Hz, $=NC_6H_4N(Me)_2$), 7.5—8.0 (m, H-5—7), 9.48 (br d, J=10 Hz, H-8), 9.70 (s, COOH), 10.50 (dm, J=10 Hz, H-4). Found: C, 70.94; H, 5.75; N, 7.23%. Calcd for $C_{23}H_{22}O_4N_2$: C, 70.75; H, 5.68; N, 7.18%.

3-Ethoxycarbonyl-2-formylazulene-1-carboxylic Acid (2k). A solution of 100 mg of **8b** and 6 M HCl (2 drops) in EtOH (10 ml) was heated at 80 °C for 15 min. The mixture was diluted with water and extracted with chloroform. The organic layer was worked up to give 35 mg of **2k** as red needles, mp 222—223 °C (from benzene). IR (KBr): 3030—2778, 1706, 1654, 1212, 1088, 901 cm^{-1}. Found: C, 65.80; H, 4.43%. Calcd for $C_{15}H_{12}O_5$: C, 66.17; H, 4.44%.

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

Analysis of the Heat of Breaking Glass Ampoules

Tetsuo MORIMOTO* and Masafumi KIRIKI

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700

(Received March 21, 1980)

Synopsis. The heat of breaking was measured on three series of ampoules, containing N_2 at various pressures, N_2 at various pressures as well as saturated H_2O vapor, or different amounts of liquid H_2O as well as the saturated vapor in the unfilled space, respectively. This report gives the method to analyze the heat of breaking of ampoules into three factors: the release of mechanical strain stored in the ampoule under a pressure, heat of evaporation of immersion liquid, and rush-in effect of the liquid.

The heat of breaking of glass ampoules is one of the most troublesome problems in microcalorimetry such as for heat of immersion measurements, and it is quite serious when the solid has low surface energy or small surface area. Three causes have been considered for the heat of ampoule breaking:[1-3] (1) release of mechanical strain stored in the ampoule under a pressure, (2) heat of evaporation of immersion liquid due to the volume change on breaking, and (3) rush-in effect of the liquid, called the PV effect, when the ampoule is filled with the liquid after breaking. It has been reported that a major part of the heat of ampoule breaking is caused by the last effect;[4] it can be much reduced by filling up the ampoule with an inert gas like He.[1,5]

Here, we report the results of an experimental analysis of these three heat effects, from which we can establish the correction of the heat of breaking in microcalorimetry.

Experimental

The ampoules used here were commercial ones, which are cylindrical, having fairly uniform capacity of about 3 cm^3. Three series of sealed ampoules were prepared. The first series contained N_2 at various pressures, and the second series N_2 at various pressures which was saturated with H_2O. The third series contained different amounts of liquid H_2O and its vapor. Special precautions were taken for sealing off the ampoules so as to keep their volumes contant as close as possible. The average volume was 3.2 ± 0.1 cm^3. Measurements were made in H_2O at 28 ± 0.1 °C, in an adiabatic calorimeter equipped with a quartz thermometer as a temperature sensing element.[6] In order to avoid random breaking of ampoules, they were edged uniformly by a file around their circumference, and then were broken between steel knife edges, by using a screw.

Results and Discussion

Figure 1 shows the relationship between the heat of breaking and the N_2 pressure in the ampoule. For a series of ampoules containing N_2 and saturated H_2O vapor, the heat is plotted against the partial pressure of N_2. It is seen from Fig. 1 that heats of breaking of the ampoules containing both N_2 and saturated H_2O vapor are higher than those containing N_2 only, and both series of heat decreased linearly with increasing

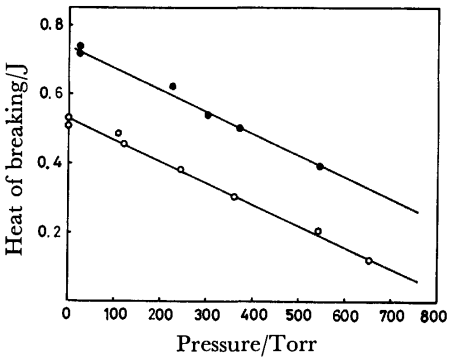

Fig. 1. Heat of breaking glass ampoules as a function of pressure of N_2, in the presence of N_2 only ○, and N_2 and saturated H_2O ●.

pressure of N_2 and in parallel with each other. This fact suggests that a constant amount of H_2O evaporates on breaking the ampoules containing N_2 only, which leads to a decrease in heat generation. This endothermic effect is 0.21 J, which is obtained from the difference between the two straight lines in Fig. 1. The heat of vaporization of H_2O into the space of 3.2 cm^3 at 28 °C can be calculated to be 0.212 J, which is in good agreement with the experimental value. Thus, it is understood that breaking of an ampoule in a liquid is accompanied by evaporation of the liquid, the volume of vapor formed being equal to that of the ampoule, except in the case where the ampoules contain saturated vapor of the immersion liquid, which results in partial cancellation of the heat evolved.

Figure 2 represents the heat of breaking when ampoules having different amounts of liquid H_2O were broken in H_2O. It is seen from Fig. 2 that the heat evolution decreases linearly with increasing amount of H_2O or decreasing space volume. Since the space in these ampoules always contains saturated H_2O, evapora-

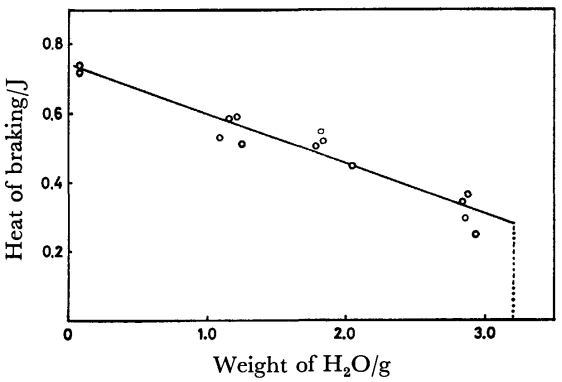

Fig. 2. Heat of breaking glass ampoules as a function of weight of H_2O contained.

tion of H_2O should not occur. Admittedly, both evaporation of H_2O and the rush-in effect of the liquid will disappear when the space volume is zero. In other words, we may consider the heat evolved in this limiting case to be equal to the heat due to the release of mechanical strain stored in the ampoule. This heat value can be obtained by extrapolating the straight line in Fig. 2 to the zero space volume and is found to be 0.28 J. It is easy to understand that the heat value changes with the variety of ampoules and also with the breaking modes.

As determined from Fig. 1, the heat of breaking of an ampoule, when it is empty, is 0.53 J. This value contains of course all the three effects of heat generation. By subtracting the heats due to evaporation of H_2O and the release of mechanical strain from the total heat effect 0.53 J, we obtain the heat due to the rush-in effect, 0.46 J. If we estimate the product of pressure difference between outside and inside the ampoule and its volume, we obtain 0.324 J, which is much less than the rush-in heat. This result suggests that the rush-in effect, formerly called the PV effect, is not only a static effect, but it also includes dynamic processes such as collision of the liquid stream with the glass wall, and of liquid masses with each other and friction of liquid when it rushes into the ampoule.

Further consideration leads to the conclusion that when ampoules containing both N_2 of 1 atm and saturated H_2O vapor are broken, only the effect of release of mechanical strain appear, because the rush-in effect disappears. In fact, the value 0.26 J from Fig. 1 is close to the value, 0.28 J, described above as the heat due to the release of mechanical strain. Thus, it can be understood that the difference of heat evolved under the conditions at both ends of every series of measurements, *i.e.*, at both ends of three straight lines (Figs. 1 and 2), represents the heat due to the rush-in effect; experimental values thus obtained from the three series of experiments are 0.48, 0.47, and 0.47 J, being quite close to each other. Therefore, the enclosure of He at 1 atm into an ampoule can avoid the rush-in effect of liquid in microcalorimetry, but does not eliminate the evaporation effect of the liquid.

Here, it is interesting to remember an ingenious method of Young and Bursh,[7] who broke several glass bulbs containing different weights of sample and extrapolated the results to zero sample content; the intercept was considered to be the heat of breaking the glass bulb, and the slope of the straight line to be the heat of immersion of sample. Strictly speaking, however, on the basis of the present analysis, the slope of the straight line should be the sum of three effects: the heat of immersion of the sample, the decreasing rush-in effect, and the decreasing evaporation effect, the last of which is endothermic.

The Effect of Fatty Alcohols on the Dodecane-Water and the Dodecane-SDS Solution Interfaces

Fumitake MIENO and Keizo OGINO*

Faculty of Science and Technology, Science University of Tokyo, Yamazaki, Noda, Chiba 278

(Received October 1, 1979)

Synopsis. The effects of fatty alcohols ($C_mH_{2m+1}OH$, $m=1$—12) at the dodecane–water and the dodecane–sodium dodecyl sulfate (SDS)-solution interfaces has been investigated by measuring the interfacial tension and by observing the stability of the emulsion. The following results have been obtained: the addition of lower alcohols ($m=1$—3) increases the interfacial tension at the dodecane–SDS-solution interface, and they are considered as emulsion breakers. With regard to middle and higher alcohols, though, the interfacial tension decreases with the increase in the carbon number. They can thus be used as emulsion stabilizers.

The effects of additives on spontaneous emulsification and on the stability of emulsion have been investigated by many investigators.[1-5] We[6] ourselves have previously reported that 1-dodecanol in dodecane and sodium dodecyl sulfate (SDS) in water form emulsions spontaneously in the presence of surfactants or alcohols above certain concentrations. Vold and Mittal[7] have reported that, in a Nujol–water–0.2% SDS emulsion, the stability of the emulsion increases with the addition of 1-dodecanol up to 56%, on the basis of SDS.

In this study, the effect of the carbon-chain length of fatty alcohols has been investigated at the dodecane–water and the dodecane–SDS-solution interfaces.

Experimental

Materials. *Surfactant*: The sodium dodecyl sulfate (SDS) was supplied by Wako Pure Chemical Ind. Ltd., and was extracted with ether and recrystallized from ethanol.

Fatty Alcohols: The methanol, 1-dodecanol (Wako Pure Chemical Ind. Ltd.,), ethanol, 1-propanol, 1-butanol, 1-pentanol, 1-hexanol, 1-heptanol, 1-octanol, 1-nonanol, 1-decanol, and 1-undecanol (Tokyo Kasei Ind. Ltd.,) were of a reagent grade and were used without further purification.

Water and Oil: The distilled water and dodecane (Nikko Petrochemical Co.,) were of a commercial grade and were used without purification.

Apparatus. The interfacial tension and its variation with the time were measured at 30 °C with a Wilhelmy tensiometer, Shimadzu ST-1.

Procedure. Dodecane (8.0 ml) was used as an oil phase. Distilled water (8.0 ml) and 8×10^{-3} M† SDS solution (8.0 ml) were used as a water phase. After the equilibrium of the oil–water interface has been established, fatty alcohol was added to the oil phase with a syringe, and the change in the interfacial tension with the course of time was measured.

The dodecane, fatty alcohols, and 2×10^{-2} M SDS solution were emulsified by stirring. These emulsions were observed and photographed.

Results and Discussion

The Behavior of Fatty Alcohols at the Dodecane–Water Interface. In Fig. 1, the solid line shows the effect of fatty alcohols on the interfacial tension at the dodecane–water interface. The interfacial tension is lowered by the addition of alcohols, the extent of which is the largest in the case of 1-butanol.

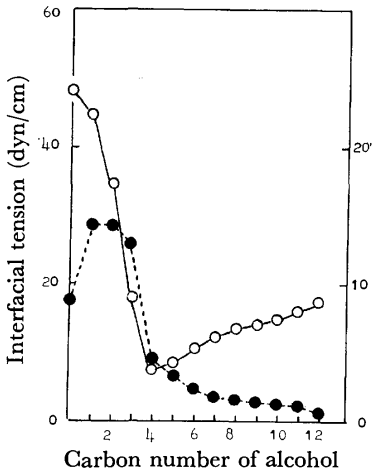

Fig. 1. The effect of carbon number of fatty alcohol on the interfacial tension at the dodecane–water interface. Oil phase : dodecane 8.0 ml, water phase : solid line-distilled water 8.0 ml; ○, dotted line-SDS soln. 8.0 ml; ●, additives : fatty alcohols ($m=1$—12) 0.8 ml.

We tried to calculate the HLB number of alcohols by the Davies method, and the concentration ratio of alcohol in the water phase and the oil phase (C_w/C_o), by means of the following equations:

$$\Delta G_{o\to w} = 800n - \Delta G_{o\to w}(\text{hydrophilic groups}) \quad (1)$$

$$C_w/C_o = \exp(-\Delta G_{o\to w}/RT) \quad (2)$$

where $\Delta G_{o\to w}$ is the free energy when alcohol is transferred from the oil phase to the water phase, n is the number of $-CH_2-$ groups in an alcohol, the increment of

Table 1. Hydrophilic and lipophilic properties of fatty alcohols

m[a)]	H.L.B.	$\Delta G_{o\to w}$ / cal mol^{-1}	C_w/C_o
1	8.4	−2400	53.9
2	8.0	−1600	14.3
3	7.5	− 800	3.7
4	7.0	0	1.0
5	6.5	800	0.26
6	6.1	1600	7.0×10^{-2}
7	5.6	2400	1.8×10^{-2}
8	5.1	3200	4.9×10^{-3}
9	4.6	4000	1.3×10^{-3}
10	4.2	4800	3.4×10^{-4}
11	3.7	5600	9.1×10^{-5}
12	3.2	6400	2.4×10^{-5}

a) m is the carbon number of fatty alcohol.

† Throughout this paper, 1 M = 1 mol dm^{-3}.

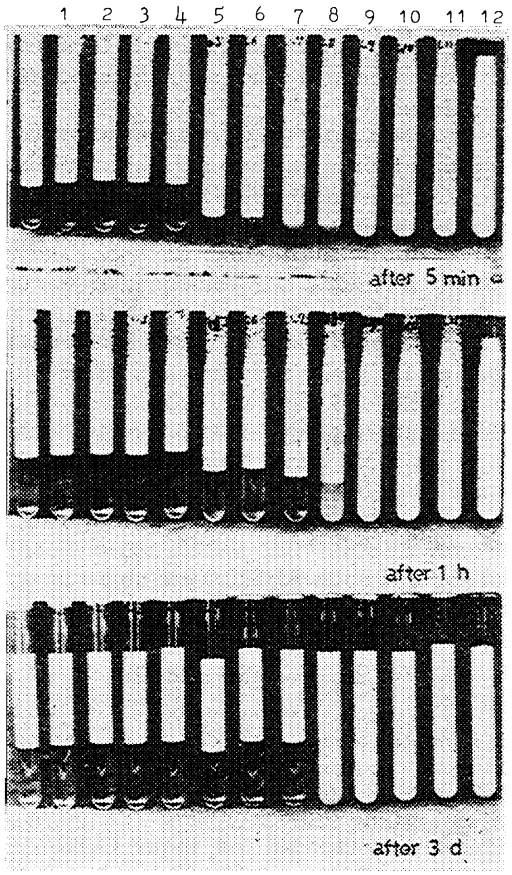

Fig. 2. The observation ofdo decane–water–SDS–fatty alcohol emulsions.
Oil phase : dodecane 3.0 ml, water phase : 2×10^{-2} M SDS soln. 3.0 ml, additives : fatty alcohols ($m=1$—12) 0.1 M in emulsion.

$\Delta G_{o \to w}$ per $-CH_2-$ groups is 800 cal/mol, and $\Delta G_{o \to w}$ (–OH group) is −3200 cal/mol.[1] C denotes the concentration of alcohol, and the subscripts o and w refer to oil and water. The results are shown in Table 1.

The results of calculation and Fig. 1 suggest that 1-butanol is well balanced in hydrophilic and lipophilic properties, and that lower alcohols ($m=1$—3) become more hydrophilic, while alcohols which have more than 4 carbon atoms become more lipophilic.

The Effect of Fatty Alcohols at the Dodecane–SDS-solution Interface. In Fig. 1, the dotted line shows the effect of alcohol on the interfacial tension at the dodecane–SDS-solution interface (right ordinate). From this results, it is considered that lower alcohols ($m=1$—3) have an emulsion-breaking effect, as is shown in Fig. 2. In the cases of the other higher alcohols, the reason for the decrease in the interfacial tension is considered to be as follows. It is well known that a complex is formed by the van der Waals force and a polar force between higher alcohol and the SDS molecule.[8] Thus, the adsorption of alcohol and the SDS molecule at the dodecane–water interface is further increased, and the interfacial tension decreases. Therefore, it may be considered that the stabilizing power of SDS is increased in the presence of alcohols which have a long chain. Figure 2 shows photographs of emulsions which are composed of dodecane, alcohols, SDS, and water. The emulsion without alcohol is at the far left of the photographs. From the left to the right of the photographs, the carbon numbers of the alcohols added increase. We ascertained by the dilution method that these emulsions were of the oil-in-water type. As can be seen from Fig. 2, it is clear that lower alcohols act as emulsion-breakers, while higher alcohols act as emulsion-stabilizers.

The Dehydration of D-Fructose to 5-Hydroxymethyl-2-furaldehyde

Yoshio NAKAMURA* and Shunichi MORIKAWA
The Noguchi Institute, 8-1, Kaga 1-Chome, Itabashi-ku, Tokyo 173
(Received April 4, 1980)

Synopsis. The continuous dehydration of D-fructose is carried out under mild conditions, using the strongly acidic ion-exchange resin with a low divinylbenzene content as the catalyst and dimethyl sulfoxide as the solvent, to give 5-hydroxymethyl-2-furaldehyde in a high yield.

Because of its potential versatility as a starting material for industrial chemicals and polymers,[1] 5-hydroxymethyl-2-furaldehyde (HMF) has been expected to be a staple chemical derived from such renewable raw materials as farm and wood products. The present authors have now investigated the procedure for obtaining HMF from D-fructose, since marked progress in the production of D-fructose from D-glucose is being made.[2]

Bonner *et al.* obtained HMF in a 71 mol% yield (based on the fructose portion) by the iodine-catalyzed dehydration of sucrose in *N,N*-dimethylformamide.[3] On the other hand, HMF has been reported to be obtained in an 80 mol% yield by the acid-catalyzed dehydration of D-fructose in tetrahydrofurfuryl alcohol, but about 40% of the HMF thus formed was found as the ether of the solvent.[4] Recently, the continuous dehydration of D-fructose catalyzed by such homogeneous acids as hydrochloric acid and phosphoric acid has been reported.[5,6] However, a continuous dehydration using a solid catalyst has never been reported.

The dehydration of D-fructose catalyzed by a strongly acidic ion-exchange resin in dimethyl sulfoxide (DMSO) was found to give HMF in a high yield under mild conditions.

TABLE 1. DEHYDRATION OF D-FRUCTOSE CATALYZED BY DIAION PK-216
Fructose, 0.5 M; catalyst, 10 meq.; solvent, DMSO; reaction mixture, 50 ml; 80 °C.

Reaction time / min	Yield of HMF (mol%)
40	30
100	57
200	81
300	89
500	90

The results of the batch-by-batch dehydration of D-fructose with Diaion PK-216 in DMSO are shown in Table 1. As shown in Table 1, HMF is obtained in a 90 mol% yield, based on the D-fructose, after 500 min.

Analyses of the reaction mixture by TLC[7] and GPC (Chromosorb 101, 1 m, 220 °C) showed that only a trace amount of by-products, such as bis(5-formylfurfuryl) ether and levulinic acid, were formed. The total amount of the acids formed during dehydration was found to be 0.34 mmol (1.4 mol% based on the D-fructose) by the titration of the reaction mixture. The dehydration product was identified as HMF by means of its IR and NMR spectra, and the dehydration of D-fructose catalyzed by the resin catalyst in DMSO is quite selective to HMF.

The effect of the divinylbenzene (DVB) content in various ion-exchange resins on the rate of the dehydration of D-fructose to HMF in DMSO was investigated. The rate of HMF formation can be given by;

$$\frac{d[HMF]}{dt} = k([F^\circ]-[HMF])$$

where [HMF], [F°], and k are the concentration of HMF, the initial concentration of D-fructose, and the rate constant, respectively.[8] A plot of the value of $\log [[F^\circ]/([F^\circ]-[HMF])]$ against t gave a straight line at an earlier stage of the reaction. The values of k for the batch-by-batch dehydration were obtained for various resins; they are shown in Table 2, which shows that the dehydration rate depends markedly on the DVB content in the resin used and that the porous resin is more effective than the gel-type ones when the DVB content in the resins is the same.

The apparent volume(V) of the resin containing 10 meq. of the sulfo group was measured after dipping overnight in DMSO. Then the values of k/V (activity per unit volume of the resin catalyst) were calculated; they are also shown in Table 2, with the values of V. Table 2 shows that even the value of k/V increases as the DVB content in the resin decreases.

The stability of the catalytic activity of the resin for the continuous dehydration of D-fructose to HMF in DMSO was examined using Amberlite IR-118 with

TABLE 2. EFFECT OF DVB CONTENT ON THE RATE CONSTANT, k, AND THE VALUE OF k/V
Solvent, DMSO; resin catalyst, 10 meq.[a]

	Resin	DVB content (%)	k (s^{-1})	V (ml)	k/V (s^{-1} ml^{-1})
Porous type	Diaion PK-208	4	3.01×10^{-4}	8.3	3.6×10^{-5}
	Diaion PK-216	8	1.46×10^{-4}	6.3	2.3×10^{-5}
	Diaion PK-228	14	0.17×10^{-4}	3.7	0.46×10^{-5}
Gel type	Amberlite IR-118	4	2.74×10^{-4}	8.9	3.1×10^{-5}

	Lewatit SC-108	8	0.36×10^{-4}	5.2	0.68×10^{-5}

a) Other conditions as given in Table 1.

Table 3. Continuous dehydration of D-fructose using amberlite IR-118 as the catalyst
D-Fructose in feed, 0.5 M.

Elapsed time (h)	Concentration of HMF (M)
50	0.4
100	0.45
200	0.47
400	0.45
900	0.45

a low DVB content. After the feed solution had begun to be supplied into the column reactor containing the resin and DMSO, the concentration of HMF in the eluted solution was measured at varying times. As shown in Table 3, after about 100 h the concentration of HMF reached 0.45 M and stayed there even after 900 h.

The catalytic activity and acidity of the resin used for the continuous dehydration for 900 h were re-examined; no decrease was found in these catalytic properties.

Experimental

Preparation of Catalyst. The resins were washed with distilled water and conditioned by converting them to the sodium form and by then reconverting them to the hydrogen form. Samples were dried under a vacuum (1—2 mmHg) at 60 °C for about 6 h and used after dipping overnight in DMSO. The acidity of the resin was measured by titration.

Batch-by-batch Dehydration. A DMSO solution (50 ml) containing D-fructose (25 mmol) and the resin catalyst (10 meq. as the sulfo group) were added to a 200-ml glass flask, which was then immersed in a bath thermostated at 80±0.1 °C and the solution was stirred by a magnetic stirrer. The quantity of HMF formed was determined by means of UV absorption (λ=284 nm; Hitachi Spectrophotometer-124) after dilution (1×10^2—2×10^2 times) by distilled water. Samples (about 0.1 ml) were withdrawn at varying times.

Continuous Dehydration. Continuous dehydration was carried out using a glass column (inner diameter, 20 mm) packed with the catalyst (74 ml, 86.6 meq. as the sulfo group). The temperature of the column was kept at 60±0.1 °C by the use of a ribbon heater equipped with a thermoregulator. A DMSO solution containing D-fructose (0.5 M) and water (5 vol%)[9] was charged (mean rate=3.7 ml/h) continuously to the top of the column by means of a perista-pump (Atto Corp. SJ-1215), and the content of HMF in the eluted solution was measured as has been described above.

The authors are grateful to Professor Hidefumi Hirai of Tokyo University for his helpful discussion, and to Mr. Katsuyuki Sekino and Mr. Shigenobu Hiraiwa for their experimental assistance.

9) Water was added to prevent the DMSO solution in the line from freezing. It has been found, by the batch-by-batch dehydration of D-fructose, that the addition of 5 vol% of water to the DMSO solution decreases the reaction rate ($k=2.4\times10^{-4}$ s^{-1}, for Diaion PK-208 under the reaction conditions given in Table 2), but scarcely interferes at all with the selectivity to HMF.

The Dynamical Behavior of the Sodium Cation in Some Crown Ether-Na^+-$TCNE^-$ Ternary Complexes as Studied by ESR

Hiroyuki KOHAMA, Mayumi YOSHINAGA, and Kazuhiko ISHIZU*

Department of Chemistry, Faculty of Science, Ehime University, Matsuyama 790

(Received April 25, 1980)

Synopsis. ESR observations were performed for the ternary complexes formed with Na^+–$TCNE^-$ and 5*O*-crown ethers. The temperature dependence of the observed Na hyperfine line width was analyzed by applying Bloch's two-jump model, and the thermodynamical parameters of the complex formation were determined. The stability of the ternary complexes were found to be much affected by the substitution of either the fused benzene ring or the 2,2′-biphenyldiyl group, which acts as a steric restriction during the optimum metal binding to the flexible crown ring.

Usually, the alkali metal salts of tetracyanoethylene (M–TCNE) are insoluble in nonpolar solvents. In the presence of crown ether (CR), however, these salts can be solubilized by the complex formation between the alkali metal cation and the crown ether. Based on the ESR observation of the TCNE–crown ether complexes, Eastman *et al.*[1] previously suggested that the ternary complex, CR–M^+–$TCNE^-$, can be formed in these solutions, but the details of the dynamical behavior of alkali metal cations are not well known in these complexes. In this paper, the ESR measurements were applied to the ternary complexes composed of TCNE and 5*O*-crown ether solubilized in a nonpolar solvent. From the analysis of the temperature dependent line width alterations detected in the Na hyperfine splitting, the thermodynamical parameters of the complex formation were determined. The thermodynamical behavior of the metal cation, which will undergo a thermal vibration in the double minimum electric potential involving TCNE and crown ethers, was discussed with the aid of Bloch's equations for the two-jump processes.

Experimental

The 5*O*-crown ethers shown in Table 1 and NaTCNE were prepared according to the methods described in previous works.[2,3] Pure benzo-15-crown-5 was obtained by recrystallization in hexane; mp 80—82 °C (uncorrected). Elementary analysis: Calcd for $C_{14}H_{20}O_5$: C, 62.69; H, 7.46. Found: C, 62.48; H, 7.46%. 5,8,11,14-Pentaoxa-1,2,3,4-dibenzo-1,3-cycloheptadecadiene was purified by recrystallization using a benzene–hexane mixture (1 : 1); mp 107—109 °C (uncorrected). Elementary analysis: Calcd for $C_{20}H_{24}O_5$: C, 69.77; H, 6.98. Found: C, 69.62; H, 7.07%. 15-Crown-5 purchased from Aldrich Chemicals were used without further purification. The sample was made according to the following procedure: 2 mg of NaTCNE and an excess of CR were placed in the quartz sample tube and the desired amount of the purified solvent was brought into the cell in vacuum.

ESR spectra were measured with a JES-ME-3X spectrometer. The ESR splitting were determined by using $(KSO_3)NO$ ($a^N = 1.305 \pm 0.003$ mT) as a standard.

Table 1 Thermodynamical Parameters of CR–Na^+–$TCNE^-$ Complexes

		Toluene	o-Xylene	m-Xylene
L1		ΔH −14.6	−13.0	−17.6
		ΔS 62.8	50.6	71.6
L2		ΔH −26.4	−26.0	−27.2
		ΔS 98.4	99.6	100.0
L3		ΔH −9.2	−22.2	−15.9
		ΔS 40.6	93.8	70.3

ΔH: K J/mol ΔS: J/mol deg

Results and Discussion

The ESR spectra were measured in the temperature range from −50 to 50 °C. The alkali metal hyperfine

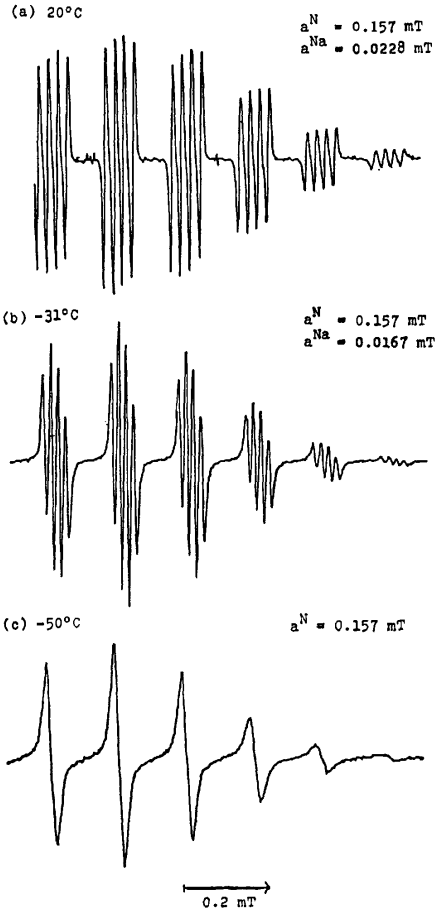

Fig. 1. The higher field halves of ESR spectra of benzo-15-crown-5–Na^+–$TCNE^-$ complex recorded in toluene solution.

line revealed a typical line width variation due to the rapid exchange between the two different paramagnetic species. The observed hyperfine structure measured at room temperature exhibits well resolved hyperfine lines composed of nine lines due to the equivalent four nitrogens ($a^{N}=0.157$ mT), which further split into the Na hyperfine lines ($a^{Na}=0.023$ mT) with equal line intensity [Fig. 1(a)].

Upon lowering the temperature, the magnitude of the alkali metal hyperfine splitting begins to decrease slightly. In addition, the line width corresponding to the alkali metal magnetic quantum number for $M_z=\pm 3/2$ increases in comparison with that for $M_z=\pm 1/2$ [Fig. 1(b)].

At -50 °C, the alkali metal splitting which had decreased by lowering the temperature merges into a single line [Fig. 1(c)].

We assume that the alkali metal cation undergoes a thermal vibration in two different electric potential minima, V_A and V_B which can be defined to CR and $TCNE^-$ respectively. At a lower temperature, a stronger ionic interaction can be expected between the Na^+ and CR, than occurs between Na^+ and $TCNE^-$; that is, $V_A<V_B$, where the alkali metal cation can be so closely accessible to the minimum potential of the CR as to reduce the magnitude of a^{Na}. At room temperature or above, the thermal activation moves the metal cation away from the CR potential; thus the contribution of the V_B could be enhanced, and the larger a^{Na} value was observed.

The equilibrium constant, K, at any temperature T is given by

$$K=\frac{a(T)-a_A}{a_B-a(T)},\quad \underset{A}{CR\text{–}Na^+\cdots TCNE^-} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \underset{B}{CR\cdots Na^+\text{–}TCNE^-}$$

where a_A and a_B are the a^{Na} values of two different ion pairs at the energy minimum for V_A and V_B; $a_A=0$ mT, $a_B=0.0257$ mT, $a(T)$ is the Na splitting measured at the temperature T.

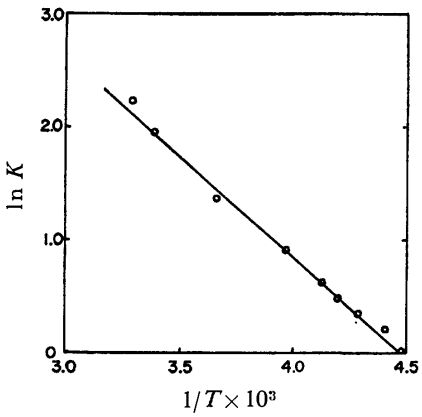

Fig. 2. Plot of ln K *vs.* $1/T$ for benzo-15-carown-5–Na^+–$TCNE^-$ complex in toluene.

The plots for ln K *vs.* $1/T$ gave an excellent straight line over the observed temperature range, as shown in Fig. 2. The value of ΔH and ΔS were calculated from the least-squares fits of the plots; $\Delta H=-14.6$ K J/mol, $\Delta S=62.8$ J/mol deg, respectively.

The rate constants k_1 and k_{-1} were also estimated by using the following equation:[4]

$$k_1=(2.03\times 10^7)\frac{K^2(a_B-a_A)^2(M_z^2-M_{z'}^2)}{(1+K)^3[(I_{M_{z'}}/I_{M_z})^{1/2}-1)\Delta H_{M_{z'}}}\ (s^{-1})$$

$$k_{-1}=\frac{k_1}{K}\ (s^{-1})$$

where I_{Mz} and $I_{Mz'}$ denote the line intensity corresponding to the alkali metal magnetic quantum number ($M_z=\pm 3/2$, $M_{z'}=\pm 1/2$), and $\Delta H_{Mz'}$ is the line width for Mz' peak. The linear plots are obtained between the logarithm of the rate constants ($\ln k_1$, $\ln k_{-1}$) and $1/T$.

The activation energy E_1 and E_{-1} thus estimated are 25.1 and 11.3 K J/mol for the TCNE–15-crown-5 complex. In order to obtain the more detailed view of these ternary complexes, the thermodynamical parameters (ΔH and ΔS) were obtained for several crown ethers, which have different steric factors upon incorporation of the alkali metal cation.

From the inspection of the thermodynamical parameters ΔH and ΔS measured in the different solvents (Table 1), some important features are found concerning the alkali metal complex formation of crown ethers containing five chelating oxygens, L_1, L_2, and L_3. No important difference in the thermodynamical parameters can be recognized by changing the solvent in each complex. This means that ternary complexes are essentially tight ion pairs. The largest values of both ΔH and ΔS are obtained for the L_2 complexes everywhere, while the ΔH values as well as the ΔS values are considerably reduced for the L_2 and L_3 complexes. This will be probably due to the fact that the planar fused benzene ring or sterically hindered 2,2′-biphenyldiyl groups act as restrictions toward any conformational change in the crown ring during the optimum binding of the alkali metal cation.

Dynamic Behavior and Nature of Active Sites Directly Observed by Means of Photoluminescence Spectroscopy

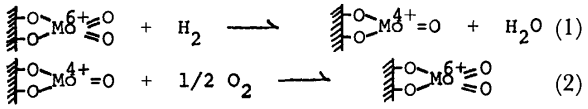
Yasuhiro IWASAWA* and Sadao OGASAWARA

Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Hodogaya-ku, Yokohama 240

(Received May 13, 1980)

Synopsis. The dynamic behavior and properties of the active sites (Types I, II, and III) of SiO_2-supported Mo catalysts during a redox reaction with H_2 or O_2 (in connection with a general two-stage redox mechanism) were observed directly by means of a photoluminescence technique.

It has been demonstrated that photoluminescence is a sensitive technique for obtaining useful information on the surface structures and environments of solid catalysts.[1,2] The tetrahedral dioxo-Mo^{6+} structure of the fixed Mo catalysts (a supported molecular catalyst) has been found to have a spectroscopically uniform nature, but it was found by means of photoluminescence[2] that there were at least three different molybdenum species (Types I, II, and III) in a conventional impregnation catalyst ($Mo/SiO_2=1.7$ wt%). However, it does not naturally follow that the behavior of an individual molybdenum site during a catalytic reaction reflects the static, spectroscopic nature. The reactivities of all the active sites, with different environments, distributed on the SiO_2 surface could not be followed by conventional methods, such as adsorption, kinetics, UV diffuse reflectance spectroscopy, or IR spectrometry. In the present paper the direct observation of the dynamic behavior and the energy aspect of active sites will be reported in connection with the catalysis of Mo catalysts involving a two-stage redox mechanism; the following reaction sequence was chosen as a model process of the catalytic oxidation:



where H_2O was removed from the system by means of a liq.N_2 trap.

Experimental

The photoluminescence spectra of the fixed and impregnation catalysts were taken in a thin quartz cell connected to a vacuum system (base pressure: 1×10^{-5} Torr) at room temperature on a JASCO FP-4 spectrometer. The fixed Mo catalysts with the tetrahedral dioxostructure, $\gtrless$Si–O, O, Mo, $\gtrless$Si–O, O (XPS B.E.(eV): Mo $3d_{3/2}$=235.7, $3d_{5/2}$=232.7), were synthesized by taking advantage of the facile reaction between $Mo(\pi\text{-}C_3H_5)_4$ and OH groups of silica surface, as has previously been described;[2] $Mo/SiO_2=1.7$ wt%. The molybdenum ions fixed on silica were found to be molecularly distributed, with no interaction with one another (the average distance of Mo–Mo: *ca.* 20 Å). The impregnation catalyst was obtained by a conventional impregnation method using an aqueous ammonium paramolybdate solution.

Results and Discussion

The photoexcitation ($3t_2\leftarrow t_1$) of the charge transfer band of a $Mo^{6+}=O^{2-}$ bond in the fixed catalyst (Curve 1 of Fig. 1) and an impregnation catalyst (Curve 1 of Fig. 2) was followed by a strong luminescence from the lowest triplet T_1 state, as has previously been reported.[2] The fixed Mo^{6+} catalyst showing Spectrum 1 of Fig. 1

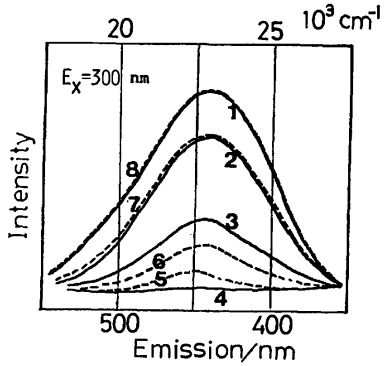


Fig. 1. Behavior of luminescence of the fixed Mo catalyst in the following consecutive redox processes; 1: oxidized catalyst, 2: after reduction of 1 with H_2 (50 Torr) at 723 K for 5 min, 3: H_2 (723 K, 17 min), 4: H_2 (733 K, 1 h), 5: after oxidation of 4 with O_2 (40 Torr) at 473 K for 5 min, 6: O_2 (513 K, 5 min), 7: O_2 (673 K, 5 min), 8: O_2 (823 K, 15 min).

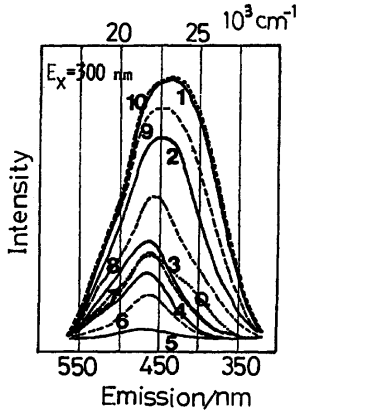

Fig. 2. Behavior of emission of the impregnation catalyst in the following consecutive steps; 1: oxidized catalyst, 2: after reduction of 1 with H_2 (50 Torr) at 673 K for 10 min, 3: H_2 (723 K, 1 h), 4: H_2 (723 K, 45 min), 5: H_2 (863 K, 2.5 h), 6: after oxidation of 5 with O_2 (40 Torr) at 463 K for 15 min, 7: O_2 (513 K, 10 min), 8: O_2 (563 K, 10 min), 9: O_2 (563 K, 20 min), 10: O_2 (823 K, 15 min), Q(quenching by CO_2): after exposure of catalyst (curve 1) to CO_2 (293 K, 280 Torr).

contained no Mo^{5+} ion, according to ESR at 77 and 295 K. The quadrivalent molybdenum with the oxostructure and the bivalent molybdenum showed no emission. Thus, the luminescence observed at 22.9 10^3 cm^{-1} directly illustrates the behavior of the tetrahedral $>Mo^{6+}\langle^{O}_{O}$ species (Type I). Figure 1 shows the variation in the emission of the fixed catalyst in the course of Reactions 1 and 2. The peak position and the shape were invariable during the redox process. On the other hand, the heterogeneous reactivity of the molybdenum species in the impregnation catalyst was observed in Fig. 2. The same emitting species (Type I) as that of the fixed catalyst reacted with hydrogen more rapidly than the molybdenum species (Type II), with an emission of 21.8 10^3 cm^{-1}. Type III, whose luminescence (21.8 10^3 cm^{-1}, Curve Q in Fig. 2) is not quenched by CO, CO_2, O_2, H_2, *etc.*, was also reduced with H_2 at 720 K. The order of ease of the reduction for molybdenum was Type I>Type II$\gg$Type III. The reduced species of the Type I-molybdenum was less reactive in the oxidation (2) (in contrast to the reduction (1)) than the other two types, although the difference among three types was not so large as the difference observed in the reduction, judging from the shapes of the emission spectra. The tetrahedral dioxomolybdenum structure obtained by the straightforward fixation of molybdenum using a reactive Mo $(\pi\text{-}C_3H_5)_4$ complex may be highly distorted and/or located on a coordination-unsaturation site of the SiO_2 surface; these structural factors would raise the T_1 state and also increase the covalency of the Mo=O double bond as active sites. The more the covalency of the Mo=O site, the more the hydrogen pulling step may be promoted.[2-4] The fixed catalyst was kinetically found to be much more active than the impregnation catalyst in the hydrogen-abstraction step in the oxidations of hydrogen,[5] ethyl alcohol,[2] and propylene.[3] Photoluminescence clearly monitored the behavior of active sites during reaction, where the fixed catalyst was found to have an active molybdenum of Type I with a uniform nature, which gave an emission of a relatively high energy.

Energy Transfer in γ-Irradiated Cyclohexane-Benzene Mixture Studied by Spin Trapping-ESR Technique

Takahisa DOBA, Susumu NISHIMURA, Tsuneki ICHIKAWA, Shoji NODA,* and Hiroshi YOSHIDA

Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060

(Received May 29, 1980)

Synopsis. Cyclohexyl and phenyl radicals were detected in γ-irradiated cyclohexane–benzene mixtures by a spin trapping-ESR technique. The dependence of the radical yields upon mixture composition showed that energy transfer occurs efficiently from cyclohexane to benzene with the transfer efficiency of *ca.* 0.5 dm^3 mol^{-1}.

The rate of energy transfer in cyclohexane solutions is equal to or larger than that expected for a diffusion process,[1,2] so that the energy transfer will play an important role in the radiation chemistry of the cyclohexane–benzene mixture. The cyclohexane–benzene mixture is one of the typical systems in which the role of the energy transfer in radiation-chemical reactions has been the most extensively studied.[3] However, there still remains an ambiguity about the efficiency of the energy transfer from an excited cyclohexane to benzene.[2-4]

In this study, the spin trapping technique was utilized to detect cyclohexyl and phenyl radicals produced from cyclohexane and benzene, respectively, and to elucidate further the energy transfer in γ-irradiated cyclohexane-benzene mixture. The spin trapping has been demonstrated to be a pertinent technique to study free radicals in γ-irradiated systems not only qualitatively but also quantitatively.[5,6] The present spin trapping study will supplement the conventional product analysis methods,[3] and the fluorescence spectroscopic method[7] which have been used in the previous studies on the energy transfer. Pentamethylnitrosobenzene (PMNB) is an efficient spin-trap for carbon-centered radicals[8] and is used in this study.

Experimental

Cyclohexane and benzene of spectrograde were used as received. PMNB was synthesized and purified as described previously.[8] Each solution was degassed by the freeze-pump-thaw technique at a vacuum of 10^{-3} Pa and sealed in a quartz ESR tube. The sample was γ-irradiated and the ESR spectrum was recorded by a conventional x-band ESR spectrometer, both at ambient temperature.

Results and Discussion

The spin adduct of cyclohexyl radical was detected from the γ-irradiated cyclohexane solution containing PMNB; its *G*-value (yield for 100 eV energy absorbed) was 2.9, as reported previously.[5] The spin adduct of phenyl radical was detected from the γ-irradiated benzene solution containing PMNB; its *G*-value was found to be 0.06. The spin adducts of both the radicals were observed from cyclohexane–benzene mixtures. A typical ESR signal is shown in Fig. 1; the signal is the superposition of a broad six-line spectrum due to the cyclohexyl radical-spin adduct and a sharp multiplet one due to the phenyl radical-spin adduct.[8,9]

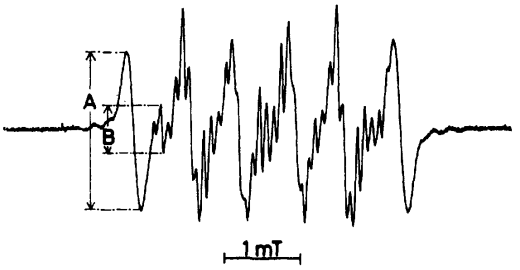

Fig. 1. ESR spectrum recorded from γ-irradiated cyclohexane–benzene mixture (benzene mole fraction, f_B= 0.55) containing 10^{-2} mol dm^{-3} PMNB at room temperature. *G*-values of cyclohexyl and phenyl radicals were calculated from the line intensities, A and B, in referring to the spectra due to the spin adducts of these radicals recorded from cyclohexane or benzene solution.

Although the yield of the spin adducts depended on the PMNB concentration, 10^{-2} mol dm^{-3} of PMNB was found to be sufficient to trap all the scavengeable radicals in the γ-irradiated cyclohexane–benzene mixtures. The yields of spin adducts increased linearly with dose up to ≈200 Gy. Therefore, the *G*-values were determined by irradiating 10^{-2} mol dm^{-3} PMNB solutions to a dose of 100 Gy. The decay of the spin adducts was so slow that it need not to be taken into account for the present determination of the yields of the free radicals by the spin trapping technique.

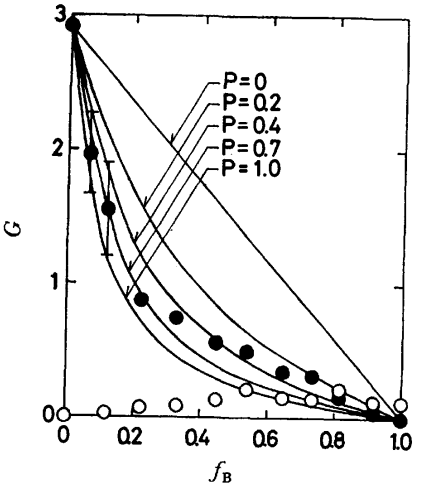

Fig. 2. Dependence of *G*-values of (●) cyclohexyl radical and (○) phenyl radical in γ-irradiated cyclohexane–benzene mixture on the mole fraction of benzene, f_B, at room temperature. The dependence was calculated from Eq. 2 for cyclohexyl radical, and shown by curves for the energy transfer efficiency, *P*, of 0, 0.2, 0.4, 0.7, and 1.0.

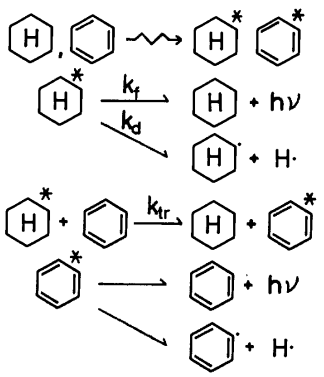
Figure 2 shows the G-values of cyclohexyl and phenyl radicals as a function of the mole fraction of benzene, f_B, in cyclohexane–benzene mixtures. The experimental points without error bars in Fig. 2 have an uncertainty of 20%, which comes from the rapid decay of the spin adducts due to a very minute amount of impurities. The larger error in the low benzene fraction region comes from the steep variation of a yield curve in this region. The addition of a small amount of benzene remarkably reduced the cyclohexyl radical yield, and the further addition of benzene reduced it only slowly. A similar dependence of f_B has been reported for the yields of products[3] and of the emission from excited cyclohexane.[7] The yield of phenyl radical increased with the increasing of f_B, passed a maximum at f_B of about 0.7, and decreased to the value in the pure benzene. These results indicate that the excitation energy transfer occurs efficiently from cyclohexane to benzene.

The relevant reaction scheme will be as follows:



The cyclohexyl and phenyl radicals were spin-trapped and detected. H atoms will form simultaneously and react either with PMNB or with benzene to result in the formation of spin adducts of H or cyclohexadienyl radicals. However, they could not be detected, because the former are unstable[10] and the latter are not reactive with PMNB.[11]

Based on the reaction scheme, the yield of cyclohexyl radical, $G(C_6H_{11}\cdot)$, is given by the following relationship:

$$G(C_6H_{11}\cdot) = G_0(C_6H_{12}^*)\frac{k_d(1-f_B)}{k_f+k_d+k_{tr}[C_6H_6]}, \quad (1)$$

where $G_0(C_6H_{12}^*)$ represents the yield of singlet-excited cyclohexane in pure cyclohexane. Equation 1 leads to:

$$G(C_6H_{11}\cdot)/G_0(C_6H_{11}\cdot) = (1-f_B)/(1+P[C_6H_6]), \quad (2)$$

were $G_0(C_6H_{11}\cdot)$ is the yield of cyclohexyl radical in pure cyclohexane ($f_B=0$) and P is the energy transfer efficiency, $k_{tr}/(k_f+k_d)$. The curves expected from Eq. 2 are also shown in Fig. 2 for selected values of P. Although experimental points do not fall on a single curve, they show that $P=0.5\pm0.3$ mol^{-1} dm^3. The apparent deviation from the additive law (from the straight line for $P=0$) shows that some energy transfer occurs from cyclohexane to benzene.

The energy transfer efficiency has been determined to be 4[2] and 0.65—0.84 mol^{-1} dm^3 [3] by means of the conventional product analysis and 2.8 mol^{-1} dm^3 by using a radical scavenger such as DPPH and the fluorescence spectroscopic method.[7] The P values obtained in the present and previous steady-state studies are in satisfactory agreement. In contrast, a P value of as large as 60 mol^{-1} dm^3 has been reported based on the pulse radiolysis-transient optical emission study.[4] The reason for such a big difference between steady-state and transient methods is not known at the moment.

The yield of the phenyl radical, $G(C_6H_5\cdot)$, shows a peak at about 0.7 of f_B. The peak should appear if $G_0(C_6H_{12}^*)$ is larger than the yield of the singlet excited benzene in pure benzene ($f_B=1$), $G_1(C_6H_6^*)$, and P is larger than $G_1(C_6H_6^*)/\{G_0(C_6H_{12}^*)-G_1(C_6H_6^*)\}[C_6H_6]_1$ ($[C_6H_6]_1$ is the benzene concentration at $f_B=1$). $G_1(C_6H_6^*)$ has been reported to be 1.6.[12] On the other hand, the value of $G_0(C_6H_{12}^*)$ has not been unequivocally determined; it has been reported to be 1.4—1.7[13] and 0.3.[14] The latter value seems to be far too small to fulfill the condition for the $G(C_6H_5\cdot)$ peak to appear.

In conclusion, the spin trapping technique has provided a new approach to the energy transfer in the γ-irradiated cyclohexane–benzene mixture based on the G-values of free radicals involved. This study will show the validity of the quantitative, kinetic utilization of the spin trapping technique.

The Ultraviolet Spectrophotometric Determination of Iron with 2-Thenoyltrifluoroacetone in an Aqueous Solution Containing α-Hydro-ω-dodecyloxynona(oxyethylene)

Tomitsugu TAKETATSU* and Atsuko SATO

College of General Education, Kyushu University, Ropponmatsu, Chuo-ku, Fukuoka 810

(Received April 21, 1980)

Synopsis. 2-Thenoyltrifluoroacetone is used as a spectrophotometric reagent for the iron(III) ion (0—1.5 μg ml^{-1}) in a 0.5% α-hydro-ω-dodecyloxynona(oxyethylene) aqueous solution at pH 3.2—3.8. The molar absorptivities of the iron(III) complex at 338, 388, and 500 nm are 4.75×10^4, 2.30×10^4, and 4.85×10^3 l mol^{-1} cm^{-1} respectively. Many diverse ions do not interfere.

The solvent extraction-spectrophotometric determination of the iron(III) ion with 2-thenoyltrifluoroacetone (TTA) is not practical because the extraction rate of the complex is slow.[1] Many investigators have, therefore, examined the effects of trioctylphosphine oxide (TOPO),[2] tributyl phosphate,[3] the thiocyanate ion,[4] pyridine,[5] and methyltrioctylammonium chloride[6] on the extraction of the iron (III)–TTA complex for the purpose of accelerating the extraction rate.

Recently, we have reported that Eu- and Sm–TTA–TOPO ternary complexes are readily soluble in an aqueous solution containing Triton X-100 and that the strong fluorescence originating from the ternary complexes can be applied to the determination of rare earths.[7] In the present paper, it is shown that iron(III) ions can be determined spectrophotometrically with TTA in an aqueous solution containing α-hydro-ω-dodecyloxynona(oxyethylene), $CH_3(CH_2)_{11}-O\{CH_2-CH_2-O\}_9H$, (BL-9EX). A constant absorption intensity is obtainable within a practical length of time, and the analytical sensitivity is considerably stronger than that of the corresponding extraction method, since the absorption maxima in the ultraviolet region are applicable to the measurement in the present method.

Experimental

Reagent and Apparatus. A standard solution of iron(III) ions was prepared by dissolving the analytical reagent-grade iron(III) chloride in 0.1 mol dm^{-3} hydrochloric acid. The concentration of the metal ions was determined by EDTA titration. A 1×10^{-2} M (1 M=1 mol dm^{-3}) TTA reagent solution was prepared by dissolving a known amount of the reagent (Dojin Co., Ltd.) in 100 ml of a 5% BL-9EX (Nikko Chemical Co., Ltd.) aqueous solution. An acetate buffer solution (pH 3.6) was prepared by adding 10 ml of a 0.1 M sodium acetate solution to 160 ml of 0.1 M acetic acid. All the other chemicals used were of an analytical reagent grade.

A Hitachi 200-20 automatic recording spectrophotometer and a Hitachi 100-10 manual spectrophotometer were used.

Procedure. A dilute hydrochloric acid solution containing 2—30 μg of iron(III) ions was transferred into a beaker. A 2-ml portion of the buffer solution and 2 ml of the TTA reagent solution were added to the beaker. After the pH of the solution had been adjusted to 3.2—3.8 with a dilute hydrochloric acid solution or a sodium hydroxide solution, the solution was transferred into a 20-ml volumetric flask and made up to volume with water. The absorbance was measured at 338 or 388 nm using 10-ml quartz cells. All experiments were done at 20—25 °C.

Results and Discussion

Absorption Spectra. Figure 1 shows the absorption spectrum of the iron(III)–TTA complex in the 0.5% BL-9EX aqueous solution (pH 3.3). The prominent wavelengths of the maxima of the spectrum are at 338 and 388 nm.

Effects of Reaction Variables. The variation in the absorbances at 338, 388, and 500 nm was investigated as a function of the pH. All the intensities at these wavelengths gave constants over the pH range of 3.0—4.0. The variation in the absorbance at 338 nm was examined as a function of the mole ratio of TTA to the iron(III) ion and as a function of the concentration of BL-9EX. The intensity was almost constant

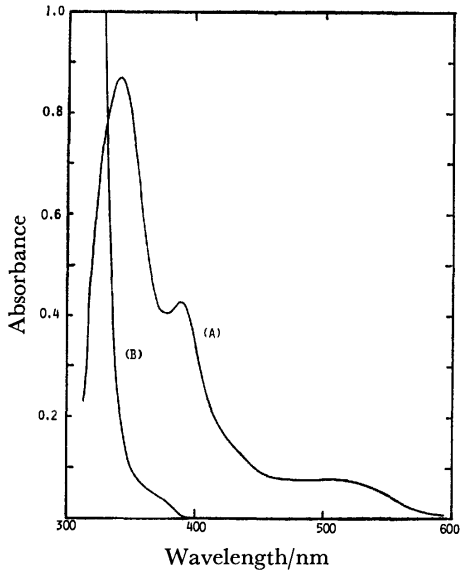

Fig. 1. Absorption spectrum of Fe(III)–TTA complex. (A) Fe(III)–TTA complex: Fe^{3+} 2×10^{-5} M, TTA 1×10^{-3} M, BL-9EX 0.5%, pH 3.3. (B) Reagent blank.

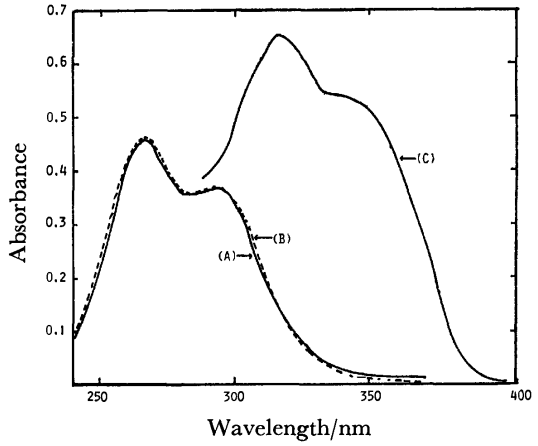

Fig. 2. Absorption spectra of TTA in aqueous solution containing BL-9EX, water, and organic solvents. (A) 0.5% BL-9EX, (B) water (pH 3.4), (C) *n*-heptane or carbon tetrachloride: TTA 5×10^{-5} M.

over the mole-ratio range of 20—100 for TTA to the iron(III) ion and also in the range of 0.2—1% of BL-9EX. With less than about 0.01%, the aqueous solution became turbid because of the precipitating of the complex. The intensity of the absorbance remained constant for 24 h after the preparation of the complex at 25 °C.

Calibration Curve. The absorbances at 338, 388, and 500 nm were linear functions of the concentration in the range of 0—1.5 μg ml^{-1} for the iron(III) ion. The molar absorptivities at the maximum wavelengths of 338, 388, and 500 nm are 4.75×10^4, 2.30×10^4, and 4.85×10^3 l mol^{-1} cm^{-1} respectively.

Effects of Diverse Ions. The effects of diverse ions on the absorbance (Fe^{3+}, 1.12 μg ml^{-1}) were investigated under the optimum conditions. Table 1 shows that 100-fold amounts of magnesium, calcium, nitrate, and sulfate ions, 10-fold amounts of manganese, cobalt, zinc, cadmium, lead, and cerium(III) ions, and equiamounts of nickel and chromium ions do not interfere with measuring the absorbance at 338 nm. However, equiamounts of copper, uranyl, and aluminum ions interfere seriously. The interference of the copper and aluminum ions can, though, be eliminated by measuring the absorbance at 388 nm.

Usually, 0.1—0.2 M TTA solutions in organic solvents are used for the extraction of the iron(III) complex, and so the ultraviolet absorption maxima (at 338 or 388 nm) adopted in the present method are inapplicable to the solvent-extraction method because the concentration of TTA in the reference solution is too high for the ultraviolet spectrum to be drawn. Therefore, the analytical sensitivity obtained by the present method is about ten times larger than that by the corresponding solvent-extraction method. Also, it is a convenience of the present method that the intensity of the absorption spectrum in the range of 320 to 390 nm of the TTA aqueous solution containing BL-9EX is considerably weak in comparison with that in the organic solvents, as is shown in Fig. 2. Also, the figure shows that the pattern of the absorption spectrum of TTA in an aqueous solution (pH 3.4) is scarcely affected by the exsistence of BL-9EX; on the other hand, the pattern of the spectra of these aqueous solutions is quite different from that in heptane or carbon tetrachloride. These facts indicate that most of the TTA exists outside the micelles, *i.e.*, in the bulk phase. After the complexation of the iron(III) ion with TTA, the metal complex can be easily taken in the micellar phase through the large micellar surface.

Optical Resolution of (2-Aminoethyl)butylphenylphosphine and the Absolute Configuration Assigned on the Basis of Circular Dichroism Spectra of Its Palladium(II) Complexes

Isamu KINOSHITA,† Kazuo KASHIWABARA, and Junnosuke FUJITA*

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received May 27, 1980)

Synopsis. (2-Aminoethyl)butylphenylphosphine was resolved with $(+)_D$-di-μ-chlorobis[(*S*)-*N*,*N*-dimethyl-α-methylbenzylamine-2*C*,*N*]dipalladium(II), and the absolute configuration of the chiral phosphorus atom was assigned on the basis of the circular dichroism spectra of dichloro palladium(II) complexes with the resolved aminophosphine.

In recent years, chiral metal phosphine complexes have been widely utilized in various asymmetric syntheses for organic compounds.[1] While a tertiary aminoalkylphosphine also would be an effective ligand for such purposes, one with a chiral phosphorus atom has little been reported. We have succeeded in resolving (2-aminoethyl)butylphenylphosphine with a chiral palladium(II) complex which was developed for the optical resolution of monodentate[2] and bidentate[3] tertiary phosphines.

There has been no convenient way to assign the absolute configuration of a chiral phosphorus atom. In a previous paper,[4] we found a correlation between the absolute configuration of a pair of diastereomers of (*S*(C))-2-(butylphenylphosphinomethyl)pyrrolidine and the circular dichroism (CD) spectra of their palladium(II) complexes. In this note, we have assigned the absolute configuration of (2-aminoethyl)butylphenylphosphine by applying the correlation to the CD spectra of dichloro palladium(II) complexes with the resolved aminophosphine.

Experimental

Free aminophosphines were handled under nitrogen atmosphere until they formed palladium(II) complexes which were stable to air. Solvents were dried in the usual way and degassed by distillation in a stream of pure nitrogen. Absorption, CD, and ^{1}H and ^{13}C NMR spectra were recorded on a Hitachi 323 spectrophotometer, a JASCO J-40 spectropolarimeter, and JEOL PMX-60 and FX-60 spectrometers, respectively.

(2-Aminoethyl)butylphenylphosphine. Preparation: To liquid ammonia (250 cm^3) was added small pieces of sodium (2.3 g, 0.1 mol) and then (2-aminoethyl)diphenylphosphine (11.5 g, 0.05 mol)[5] with vigorous stirring. After 2 h, butyl bromide (14 cm^3, 0.11 mol) was added to the resulting deep red solution, the color of the solution turning gradually orange yellow. Liquid ammonia was evaporated off and the aminophosphine formed was extracted with diethyl ether. The extract was evaporated and distilled under reduced pressure to give colorless liquid, bp *ca.* 115°C/*ca.* 80 Pa. Yield: *ca.* 4.5 g (40%). Issleib and Oehme[6] prepared this aminophosphine from phenylphosphine.

Optical Resolution: To a benzene solution (15 cm^3) of $(+)_D$-di-μ-chlorobis[(*S*)-*N*,*N*-dimethyl-α-methylbenzylamine-2*C*,*N*]-dipalladium(II) (2.06 g)[2] was added a benzene solution (3 cm^3) of *rac*-(2-aminoethyl)butylphenylphosphine (1.49 g) with stirring. After a while, acetone was added to the solution to yield white precipitate which was filtered and washed with acetone. The precipitate was found from the ^{1}H NMR spectrum to be a pure diastereomer of [(*S*)-*N*,*N*-dimethyl-α-methylbenzylamine-2*C*,*N*][(2-aminoethyl)butylphenylphosphine]plladium(II) chloride, (**1a**). Yield: 1.26 g. Found: C, 52.97; H, 6.82; N, 5.58%. Calcd for $PdC_{22}H_{34}N_2PCl$: C, 52.91; H, 6.87; N, 5.61%. The filtrate was evaporated to dryness. The residue was mixed with boiling water (300 cm^3) and filtered. To the filtrate was added an aqueous solution (200 cm^3) of sodium hexafluorophosphate (1.8 g). This was stirred at 40 °C for 4 h and then at room temperature for 18 h. The resulting white precipitate was found from the ^{1}H NMR spectrum to be another optically pure diastereomer of the palladium(II) hexafluorophosphate, (**1b**). Yield: 2.0 g. Found: C, 43.42; H, 5.92; N, 4.54%. Calcd for $PdC_{22}H_{34}P_2F_6$: C, 43.39; H, 5.64; N, 4.60%.

The optically active free aminophosphines were obtained from **1a** and **1b** by adding excess sodium cyanide to the aqueous solutions and by extracting with diethyl ether.

Dichloro[(2-aminoethyl)butylphenylphosphine]palladium(II). Sodium cyanide (100 mg) was added to an aqueous solution (3 cm^3) of the less soluble diastereomer, **1a** (87 mg). The liberated aminophosphine was extracted with diethyl ether (3 cm^3) three times. The extract was mixed with an acetonitrile solution (30 cm^3) of $PdCl_2$ (30 mg) and filtered. The filtrate was evaporated to dryness and the residue was dissolved in a small amount of acetonitrile. The solution was chromatographed with an acidic alumina column and a mixture of acetonitrile and ethanol (4 : 1) for an eluent. The main yellow eluate was evaporated to dryness to give yellow residue which was recrystallized from a mixture of acetonitrile, diethyl ether, and petroleum ether. Yield: 29 mg. Found: C, 36.18; H, 5.20; N, 3.90%. Calcd for $PdC_{12}H_{20}NPCl_2 \cdot 1/2H_2O$: C, 36.43; H, 5.35; N, 3.54%.

[(S)-N,N-dimethyl-α-methylbenzylamine-2C,N][(2-aminoethyl)-diphenylphosphine]palladium(II) Chloride. This complex was prepared by the same method as that for the corresponding (2-aminoethyl)butylphenylphosphine complex. Found: C, 55.11; H, 5.79; N, 5.33%. Calcd for $PdC_{20}H_{38}N_2PCl$: C, 55.50; H, 5.83; N, 5.39%.

Results and Discussion

(2-Aminoethyl)butylphenylphosphine was resolved by forming a pair of diastereomers, **1a** and **1b**. The $(+)_D$-di-μ-chlorobis[(*S*)-*N*,*N*-dimethyl-α-methylbenzylamine-2*C*,*N*]dipalladium(II) complex is known to be a useful resolving reagent for various tertiary phosphines.[2,3] The separation of **1a** and **1b** was complete as evidenced by ^{1}H NMR spectra and both diastereomers were obtained in good chemical yields. For the planar [(*S*)-*N*,*N*-dimethyl-α-methylbenzylamine-2*C*,*N*][(2-aminoethyl)butylphenylphosphine]palladium(II) ion, there are two possible geometrical isomers; one has two

† Present address: Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi, Osaka 558.

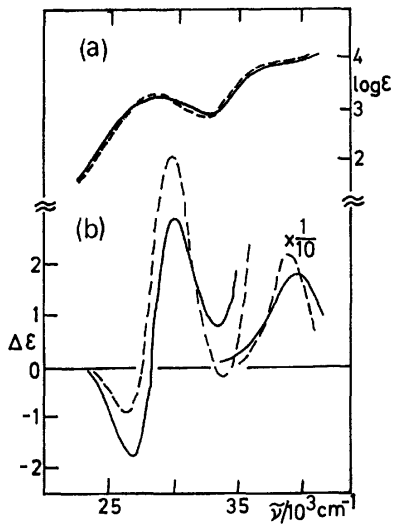

Fig. 1. (a) Absorption spectra of [$PdCl_2$-{(2-aminoethyl)-butylphenylphosphine}] (——) and [$PdCl_2$-{(*S*)-2-(butylphenylphosphinomethyl)pyrolidine}] (---). (b) CD spectrum of [$PdCl_2$-{(2-aminoethyl)butylphenylphosphine}] derived from diastereomer **1a** (——) and calculated vicinal CD curve due to the (*S*)-phosphorus atom in [$PdCl_2$-{(*S*)-2-(butylphenylphosphinomethyl)-pyrrolidine}] (----).[4]

nitrogen donor atoms in the trans positions, and the other those atoms in the cis positions. The **1a** and **1b** isomers show a similar pattern in the ^1H or ^{13}C NMR spectra, in which the long-range couplings between the phosphorus atom and the *N*-methyl protons or the *N*-methyl carbons are observed, respectively. Thus both isomers would have the phosphorus atom trans to the *N*-methyl nitrogen donor atom, the cis(*N*,*N*) configuration. The optically active free aminophosphine can be obtained from **1a** and **1b** by treating with sodium cyanide in water. The aminophosphines obtained from **1a** and **1b** form a pair of enantiomers of the dichloro palladium(II) complex.

In order to assign the absolute configuration of the chiral phosphorus atom, the CD spectrum of the dichloro palladium(II) complex of the aminophosphine obtained from the less soluble chloride, **1a** was compared with the vicinal CD curve for the (*S*)-phosphorus atom calculated from a pair of diastereomers of [$PdCl_2$-{(*S*(C)-2-(butylphenylphosphinomethyl)pyrrolidine}][4] (Fig. 1). The absolute configuration of the *R*(P)-isomer of the latter complex has been determined by the X-ray analysis.[4] Both curves in Fig. 1 are very similar and the absolute configuration of the phosphorus atom in the (2-aminoethyl)butylphenylphosphine complex given can

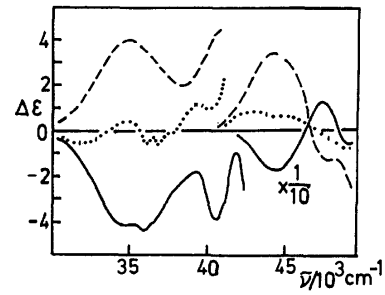

Fig. 2. CD spectra of diastereomers **1a** (——) and **1b** (------) of [Pd-{(*S*)-*N*,*N*-dimethyl-α-methylbenzylamine-2*C*,*N*}-{(2-aminoethyl)butylphenylphosphine}] and [Pd{(*S*)-*N*,*N*-dimethyl-α-methylbenzylamine-2*C*,*N*}-{(2-aminoethyl)diphenylphosphine}] (·····).

be assigned to the (*S*)-configuration. This assignment coincides with the previous one based on the ^1H NMR and CD spectra of the bis(acetylacetonato)cobalt(III) complex of (2-aminoethyl)butylphenylphosphine obtained from the same **1a** isomer.[7]

The CD spectra of diastereomers, **1a** and **1b** are nearly enantiomeric to each other over the whole region (Fig. 2). This indicates that the CD depends largely on the donating chiral phosphorus atom and little on the chiral cyclometallated amine ligand. In fact, the corresponding (2-aminoethyl)diphenylphosphine complex whose phosphorus atom is achiral shows very weak CD. Thus the absolute configuration of chiral phosphorus atoms of aminoalkylphosphines could be assigned from CD spectra of their dichloro- or more conveniently [(*S*)-*N*,*N*-dimethyl-α-methylbenzylamine-2*C*,*N*]palladium(II) complexes.

Binuclear Metal Complexes. XXXV.[1] Synthesis and Magnetism of Binuclear Copper(II) Complexes with 3-[2-(Dialkylamino)ethylthio]-1-propanols

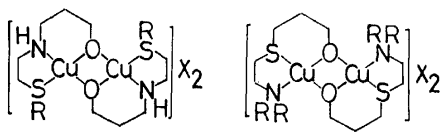
Masahiro MIKURIYA, Hisashi OKAWA,* and Sigeo KIDA

Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812

(Received June 2, 1980)

Synopsis. Binuclear copper(II) complexes with 3-[2-(dialkylamino)ethylthio]-1-propanols, $Cu[R_2N(CH_2)_2S(CH_2)_3O]X$ ($R=CH_3$, C_2H_5; $X=NO_3^-$, ClO_4^-), were prepared and their magnetic properties were investigated in the temperature range 80—300K. The magnetisms were interpreted in terms of the Bleaney-Bowers equation with exchange integral $-J=450$—$495\ cm^{-1}$, which is much larger than the values ($-J=\approx 250\ cm^{-1}$) for $Cu[R_2N(CH_2)_2NH(CH_2)_3O]X$.

As a part of the continuing study on binuclear copper(II) complexes mimic to type III copper,[2] we recently reported the synthesis and spectral and magnetic properties of the binuclear copper(II) complexes with *N*-[2-(alkylthio)ethyl]-3-amino-1-propanols, $Cu[RS(CH_2)_2NH(CH_2)_3O]X$ (abbreviated as Cu(R-sno)X, where R=alkyl, X=anion) (Fig. 1a).[3,4] It was shown that these complexes reveal a stronger antiferromagnetic spin-exchange interaction than the complexes with *N*-[2-(dialkylamino)ethyl]-3-amino-1-propanols (abbreviated as Cu(R-nno)X).[5,6] This suggests that the spin-spin coupling between the copper(II) ions is facilitated by substituting a sulfur donor atom for a nitrogen donor atom.[3,4] In order to examine further the sulfur donation effect on the spin-exchange interaction, we synthesized binuclear copper(II) complexes with 3-[2-(dialkylamino)ethylthio]-1-propanols, $Cu[R_2N(CH_2)_2S(CH_2)_3O]X$ (abbreviated as Cu(R-nso)X, where $R=CH_3$, C_2H_5; $X=ClO_4^-$, NO_3^-) (Fig. 1b) and investigated their magnetic properties in comparison with those of the Cu(R-sno)X and Cu(R-nno)X complexes.



a b

Fig. 1. Structures of complexes.
(a) Cu(R-sno)X and (b) Cu(R-nso)X.

Experimental

Preparation of the Complexes. The ligands, $R_2N(CH_2)_2S(CH_2)_3OH$ ($R=CH_3$, C_2H_5) were prepared after the method described by Clinton *et al.*[7] Preparation of the complexes is exemplified by $Cu(CH_3\text{-nso})ClO_4$. Copper(II) perchlorate hexahydrate (186 mg) and 2,2-dimethoxypropane (2 cm^3) were mixed in absolute ethanol (4 cm^3) and allowed to stand at room temperature for one night in order to decompose water in the solution. This solution was added to a solution of CH_3-nsoH (163 mg) in absolute ethanol (5 cm^3). The mixture was allowed to stand for several days at room temperature to give black needles, which were collected and dried *in vacuo* over P_2O_5. Yield: 75 mg. The $Cu(R\text{-nso})NO_3$ complexes were prepared by a method similar to that for $Cu(R\text{-nso})ClO_4$. Analytical data of the complexes are given in Table 1.

Measurements. Infrared spectra were measured with a Hitachi Grating Infrared Spectrophotometer Model 215 on a KBr disk. Diffuse reflectance spectra were measured with a Shimadzu Multipurpose Spectrophotometer Model MSP-5000. Magnetic susceptibilities were measured by the Faraday method in the temperature range 80—300 K. All the susceptibilities were corrected for the diamagnetism of the constituting atoms by the use of Pascal's constants.[8] Effective magnetic moments were calculated from the equation, $\mu_{eff}=2.828\sqrt{(\chi_A-N\alpha)T}$, where χ_A is the atomic magnetic susceptibility and $N\alpha$ is the temperature-independent paramagnetism.

Results and Discussion

The complexes obtained were sparingly soluble in any conventional solvents. Hence, the electronic spectra of the complexes were measured by reflection on powder samples. The spectra display a fairly broad band centered around $15\times10^3\ cm^{-1}$ which is attributable to d-d transition bands. In addition, the spectra show a band at 22—$24\times10^3\ cm^{-1}$ characteristic of alkoxo-bridged structure.

The infrared spectra of $Cu(R\text{-nso})ClO_4$ showed a strong broad band at 1080—1140 cm^{-1}. Because of little splitting of this band, no coordination of the perchlorate ion to the copper is supposed.[9] The infrared spectra of $Cu(R\text{-nso})NO_3$ show a strong broad band at 1380 cm^{-1} and a sharp band at 820 cm^{-1}. Hence it is assumed that the nitrate ion does not coordinate to the metal.[10] Thus, it is likely that the present complexes possess a binuclear structure with a nearly planar $\overset{S}{N}\!>\!Cu\!<\!\overset{O}{O}\!>\!Cu\!<\!\overset{N}{S}$ skeleton.

Table 1. Analytical data

Complex	C(%) Found (Calcd)	H(%) Found (Calcd)	N(%) Found (Calcd)
$Cu(CH_3\text{-nso})ClO_4$	25.66 (25.85)	4.96 (4.96)	4.29 (4.31)
$Cu(C_2H_5\text{-nso})ClO_4$	30.34 (30.60)	5.80 (5.71)	3.92 (3.96)
$Cu(CH_3\text{-nso})NO_3$	28.90 (29.21)	5.57 (5.60)	9.57 (9.73)
$Cu(C_2H_5\text{-nso})NO_3\cdot 1/2H_2O$	32.99 (33.27)	6.31 (6.51)	8.53 (8.62)

Table 2. Magnetic data of Cu(R-nso)X[a)]

Complex	μ_{eff}/BM (293K)	$2J/cm^{-1}$	$N\alpha$/cgs emu	P
$Cu(CH_3\text{-nso})ClO_4$	0.48	−930	57×10^{-6}	2.2×10^{-2}
$Cu(C_2H_5\text{-nso})ClO_4$	0.58	−900	63×10^{-6}	4.5×10^{-2}
$Cu(CH_3\text{-nso})NO_3$	0.53	−910	59×10^{-6}	3.0×10^{-2}
$Cu(C_2H_5\text{-nso})NO_3\cdot1/2H_2O$	0.72	−990	66×10^{-6}	11.7×10^{-2}

a) For all the complexes $g=2.10$ is assumed.

Magnetic moments per copper atom are very low at room temperature, indicating that a fairly strong antiferromagnetic interaction is operating between copper(II) ions (Table 2). The magnetic susceptibility decreases with lowering of temperature but increases again below 150 K. This feature is most likely due to the binuclear structure and a small amount of mononuclear paramagnetic impurity. Accordingly, the impurity term was added to the Bleaney-Bowers equation[11] giving,

$$\chi_A = \frac{Ng^2\beta^2}{3kT}\left[1+\frac{1}{3}\exp(-2J/kT)\right]^{-1}(1-P) + \frac{0.45P}{T} + N\alpha \quad (1)$$

where χ_A is susceptibility per copper atom, P is the ratio of mononuclear copper(II) ions to total copper(II) ions, and other symbols have the usual meanings.[12] The magnetic data evaluated from the best fit of the experimental data to Eq. 1 are listed in Table 2. The results suggest that these complexes contain an appreciable amount of paramagnetic impurity. Since $Cu(C_2H_5\text{-nso})X$ ($X=ClO_4^-$, NO_3^-) are hygroscopic in the open atmosphere, partial decomposition might take place in these complexes. It is clear that the $-2J$ values for Cu(R-nso)X are more than 900 cm^{-1}. This magnetic behavior is essentially the same as that of Cu(R-sno)X ($-2J=ca.$ 800 cm^{-1}).[3,4] On the other hand, the binuclear copper(II) complexes with *N*-[2-(dialkylamino)ethyl]-3-amino-1-propanols, Cu(R-nno)X, show a weaker spin-exchange interaction; $-2J$ values being evaluated at 500 cm^{-1}.[5,6] Thus, it may be concluded that the binuclear copper(II) complexes with *SNO*- and *NSO*-donor sets exhibit a stronger antiferromagnetic spin-exchange interaction compared with the complexes with *NNO*-donor set.

Catalysis by Heteropolyacid. V. Catalytic Alkylation of Toluene by Mixed-coordination type, $H_4[SiMo_{12-n}W_nO_{40}]$, Heteropolyacid

Kenji NOMIYA, Hidehiko SAIJOH, and Makoto MIWA*

Department of Industrial Chemistry, Faculty of Engineering, Seikei University, Musashino-shi, Tokyo 180

(Received June 5, 1980)

Synopsis. To compare the specific difference between molybdenum and tungsten ions on the catalytic reaction, we investigated the alkylation of toluene with benzyl chloride by mixed-metal heteropolyacids, $H_4[SiMo_{12-n}W_nO_{40}]$ (n=0, 1, 10, and 11). Molybdenum-rich compound is more active than tungsten-rich one.

Recently it has been reported that protonated form of Keggin-structure heteropolyanion, showing strong Brønsted acidity, catalyzes the polycondensation of benzyl alcohols[1] and the Friedel-Crafts-type reaction.[2] Among those heteropolyacids, the mixed-coordination type, which is constituted from two kinds of metal with original Keggin-framework retained and with the total number of metal unchanged, has been marked in comparison with original type. Not so many mixed-coordination compounds, which behave as Brønsted acid, have been known. Mo–W system is one of such examples. In order to examine the role of the metal constituting the Keggin-unit, we have prepared $H_4[SiMo_{12-n}W_nO_{40}]$-type compounds. The compounds corresponding to n=1, 10, and 11 showed the catalytic activity for the alkylation of toluene with benzyl chloride resulting in *o*- and *p*-tolylphenylmethane. In this paper, the data will be compared with those by saturated compounds of n=0 and 12. Molybdenum and tungsten ions have been known to form similar type of complexes and their chemistry has always been treated as an identical family. The heteropolyanions discussed here show the different catalytic activity, although the cause has not been clarified.

TABLE 1. ANALYTICAL RESULTS

$(n\text{-}Bu_4N)_4[SiMo_{12-n}W_nO_{40}]$	Found (Calcd) (%) C	H	N
n=1	26.03 (26.71	5.09 5.01	1.90 1.95)
n=10	20.59 (20.94	3.93 3.92	1.56 1.53)
n=11	20.42 (20.45	3.95 3.83	1.51 1.49)

TABLE 2. IR DATA OF $H_4[SiMo_{12-n}W_nO_{40}]$ (KBr disk, cm^{-1})

n=0	n=1	n=10	n=11	n=12	Assignment[5]
958	955	971	972	982	$\nu(M\text{–}O_d)$
910	908	915	915	930	$\nu(Si\text{–}O)$
860	855	870	870	885	$\nu(M\text{–}O\text{–}M)$
780	775	790	785	792	$\nu(M\text{–}O\text{–}M)$

The n=0, 1, and 12 compounds were prepared according to the literature,[3,4] and the n=10 and 11 compounds were obtained by its modification from the stoichiometric reaction of Na_2SiO_3, Na_2MoO_4 and Na_2WO_4 in aqueous acidic solution. The heteropolyanions were isolated as tetrabutylammonium salts and analyzed. The results are presented in Table 1. The characteristic IR bands of the anions in 1000—750 cm^{-1} region are listed in Table 2, indicating that the original Keggin-unit is retained. These are distinct from those of the mixtures of the n=0 and 12 compounds with corresponding molar ratios. For example, IR bands of the n=1 compound were shown in Fig. 1. These are clearly different from those of the mixture of the n=0 and 12 compounds with molar ratio of 11 : 1. The four-protonated forms of heteropolyanions identified by IR spectra were used for the alkylation reaction of toluene with benzyl chloride.

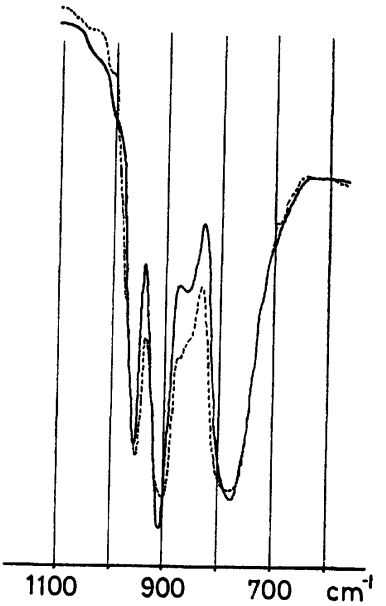

Fig. 1. IR spectra of the n=1 compound and the mixture of n=0 and 12 compounds with molar ratio of 11 : 1; full line : the n=1 compound, broken line : the mixture.

The reaction was performed at *ca.* 110 °C by refluxing the solution of toluene 92 g (1 mol) and benzyl chloride 6.3 g (0.05 mol) in the presence of the heteropolyacid of *ca.* 9.7×10^{-5} mol, where the molar ratio of reactant is designated to avoid the polymerization of benzyl chloride. Although heteropolyacids are undissolved in the solution, they promote the reaction homogeneously. The reaction time was unified to the sufficient time for the lowest active catalyst. After *ca.* 17 h, the reaction was stopped by cooling and the solution once filtered. By shaking the filtrate with chloroform, product and heteropolyacid were separated. Unreacted substrate and chloroform were removed by distillation. The products, *o*- and *p*-tolylphenylmethane, were obtained

Table 3. Experimental conditions and yields

Catalyst $H_4[SiMo_{12-n}W_nO_{40}]$	($\times 10^{-5}$ mol)	Reaction time h	Yields %
$n=0$	9.90	17.5	78
$n=1$	9.68	17.5	71
	9.44	17.0	60
$n=10$	9.92	17.0	56
	9.84	17.0	58
$n=11$	9.61	17.0	58
$n=12$	9.90	17.0	43

by reduced pressure-distillation of the residual solution (8 mmHg, 130 °C). Conditions and yields were presented in Table 3, the yields being estimated from the total amounts of products.

Generally, to compare a reactivity, it is necessary to obtain a rate constant in the initial reaction stage. However, observing the procedure of this experiment, it is not so far from the truth to discuss the activity by the yield at an appropriate time. In Table 3, the $n=0$ compound shows the maximum activity, whereas the $n=12$ compound does the minimum one, and the mixed-coordination compounds do the intermediate and almost equal activity. Moreover, it was shown that (1) all reactions proceed catalytically, (2) Mo-rich compound is more active than that of the W-rich one for the alkylation, however, (3) the activity is not always proportional to the number of exchanged or unexchanged metal.

The pH values of the aqueous solutions of the catalysts studied here have shown no significant difference.

Synthetic Photochemistry. XXI.[1] The Sensitized Photooxygenation of Calarene. A Facile Hock Cleavage of an Allylhydroperoxide and Structure Revision for Aristolenols

Hitoshi TAKESHITA,* Isao SHIMOODA, and Toshihide HATSUI

Research Institute of Industrial Science, 86, Kyushu University, Hakozaki, Fukuoka 812

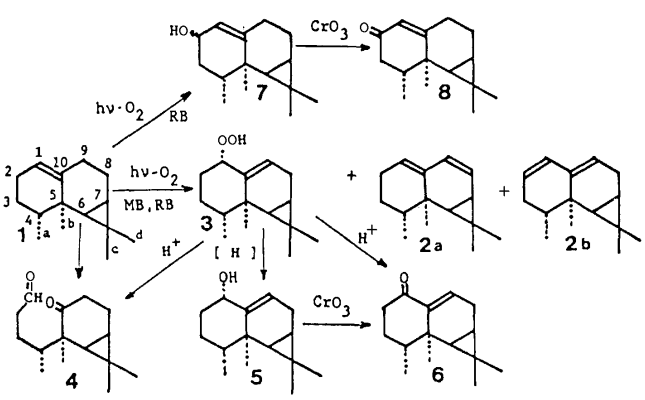
(Received March 28, 1980)

Synopsis. An allylic hydroperoxide formed by the sensitized photooxidation of calarene causes a Hock cleavage. A revised stereochemistry of an aristolenol is given on the basis of the direction of oxygenation.

Calarene (**1**),[2] an unconjugated vinyl cyclopropane, should be incapable of forming a dioxetane in a sensitized photooxygenation,[3] but its structural complexity may reveal some other features in the reactions. In fact, a keto aldehyde formed in the Methylene Blue (MB)-sensitized photooxidation of **1** was a Hock cleavage product.

When **1** and MB were irradiated in a mixture of chloroform and methanol (30 : 1) under an oxygen atmosphere by means of a tungsten lamp, a neat reaction occurred. The silica gel column separation of products yielded, together with an inseparable mixture of aristoladienes (**2a** and **2b**),[4,5] an allylic hydroperoxide (**3**), the major product, and a keto aldehyde (**4**). The separation of **2** from the hydrocarbon mixture was achieved by silver nitrate-impregnated silica-gel chromatography, and it was shown that the selenium dioxide oxidation of **1** also gave **2**. The structure of **3**, a colorless oil, was obtained by NMR [δ:[6] 0.59—0.85 (2H, m), 1.00 (3H, d, J=7 Hz), 1.03 (6H, s), 1.15 (3H, s), 1.1—2.7 (7H, m), 4.28 (1H, m), 5.56 (1H, m), and 7.62 (1H, s, OOH)] spectroscopy and chemical correlations; the sodium borohydride reduction of **3** yielded an oily allylic alcohol (**5**), which was further converted to an α,β-unsaturated ketone (**6**).[4] On the other hand, **4** was identical with the osmium(VIII) oxide-oxidation product of **1**. However, the photochemical formation of **4** is not related to a dioxetane; it was formed from **3** by either a contact with an acidic silica gel for 8 h or gentle heating in a chloroform solution, indicating it to be a Hock-cleavage product.[7,8]

Next, the Rose Bengal (RB)-sensitized oxygenation of **1** in a mixture of methanol and chloroform (1 : 30) mainly produced an ene-reaction product; a work-up after the sodium borohydride reduction yielded **5** (67%) and another allylic alcohol (**7**) (8.5%), which was subsequently oxidized to a known 1(10)-aristolen-2-one (**8**).[9-11] The stereochemistry of the hydroxy group of **7** is likely to be α-equatorial, judging from the large spin splittings revealed in its NMR spectrum, but it would be difficult to conclude the point from the limited evidence available at present. The absence of *cis*-glycol in this case also ruled out the intermediacy of dioxetane.[12] An attempted oxygenation in the dark resulted in the complete recovery of the starting material.



Scheme 1.

For the structure of crystalline allylic alcohol, **A** (designated as **1** in the original paper[4]), isolated from *Nardostachys chinensis* Betalin, Rücker and Kretzchmar have given the structure that we have assigned to **5**. However, the NMR spectrum of **5** taken in dimethyl-d_6 sulfoxide was different from that of **A**,[13] and so **5** might be an isomer of **A**. Mainly, the formulation **A** was deduced from the conformational analysis of the equatorial hydroxyl group. However, for the preferable conformation, an alternative may be possible. On the other hand, the β-configuration of the *gem*-dimethyl cyclopropane ring should prohibit the sterically hindered β-side attack of the oxygen, much as in the case of 2-carene.[14,15] This was supported by the chemical-shift difference for the methyl groups[16,17] on the ring-juncture of **3**, **5**, and **6**; two of the three sets of chemical-shift differences for the singlet methyls between **3** and **5**, $\Delta\delta_n$(3–5), were very small, but $\Delta\delta_b$(3–5), the difference of between the lowest methyl signals which are ascribable to the angular methyls, was significantly large, 1.15—1.23=−0.08. The $\Delta\delta_b$(5–6) value, the difference between **5** and **6**, is +0.16 or +0.24, in accord with only the α-orientation for the oxygen function. Otherwise, the $\Delta\delta_b$(5–6) is estimated to be less than +0.02.

Experimental

MB-sensitized Photooxidation of 1. a): Calarene[18] (**1**, 546 mg) was dissolved in MeOH (1 cm^3) and $CHCl_3$ (30 cm^3) containing MB (77 mg) and irradiated by means of a 500-W tungsten lamp under an oxygen atmosphere for 7 h. Then the mixture was chromatgraphed on a silica gel (Wako Gel C 200) column. From the fractions eluted by hexane we obtained hydrocarbons (**1** and **2**) (147 mg, 27%) and subsequently two colorless oils, **3** (108 mg, 30.5%) [Found: M.W., 236.1772. Calcd for $C_{15}H_{24}O_2$: 236.1776. ν: 3360 cm^{-1}] and **4** (48 mg, 13.5%)[M. W., 236.1802. Calcd for $C_{15}H_{24}O_2$: 236.1776. δ: 0.85 (3H, s), 0.89 (3H, d, J=7 Hz), 1.01 (3H, s), 1.25 (3H, s), 1.1—2.7 (11H, m), and 9.76 (1H, t, J=2 Hz). ν: 2720, 1730, 1710 cm^{-1}]. The hydrocarbon fractions were separated by the use of an $AgNO_3$-impregnated silica-gel column to give **1** (150 mg, 27%) and **2** (a colorless oil, 10 mg, 2.7%) [m/e, 202 (M^+). δ: 0.92 (3H, s), 0.96 (3H, s), 1.00

(3H, d, J=7 Hz), 1.10 (3H, s), 5.25 (1H, m), 5.6—5.9 (2H, m). ν: 1640, 1610, 980 cm^{-1}. λ_{max}^{hex}: 238 nm (ε=27000), 245 (28000)].

b): A mixture of MeOH (1 cm^3), $CHCl_3$ (30 cm^3), **1** (817 mg) and MB (77 mg) was irradiated by means of a tungsten lamp for 13 h under an oxygen atomsphere. The mixture was then diluted with water, extracted with ether, and treated with $NaBH_4$ (20 mg). Subsequent silica-gel chromatography of the product gave, besides the hydrocarbon mixture, two colorless oils **5** (260 mg, 50%) [Found: 220.1827. Calcd for $C_{15}H_{24}O$: 220.1827. δ: 0.5—0.9 (2H, m), 1.00 (3H, d, J= 7 Hz), 1.02 (6H, s), 1.23 (3H, s), 1.0—2.6 (8H, m), 4.17 (1H, m), and 5.42 (1H, m). δ $(CD_3)_2SO$: 0.5—0.8 (2H, m), 0.92 (3H, d, J=6.5 Hz), 0.98 (6H, s), 1.17 (3H, s), 1.07—2.45 (7H, m), 3.98 (1H, m), 4.29 (1H, d, J=2.3 Hz), and 5.28 (1H, m). ν: 3370 cm^{-1}] and **6** (25 mg, 5%) [Found: 218.1672. Calcd for $C_{15}H_{22}O$: 218.1671. δ: 0.6—0.85 (2H, m), 0.99—1.07 (12H, overlapped four methyls), 1.6—2.4 (7H, m), and 6.39 (1H, m). ν: 1690, 1623 cm^{-1}]. Further $AgNO_3$–silica-gel chromatography of the hydrocarbon fractions yielded **1** (333 mg, 41%) and **2** (32 mg, 6.7%).

SeO_2 Oxidation of 1 to 2. To a dioxane solution (15 cm^3) of **1** (175 mg), freshly sublimed SeO_2 (120 mg) was added, after which the mixture was refluxed for 1 h. Then, powdered $Na_2S_2O_3$ was added to the mixture. After the removal of the Se (50 mg) by filtration, the mixture was chromatographed on silica gel to get a hydrocarbon mixture (150 mg). $AgNO_3$-impregnated silica-gel chromatography gave recovered **1** (4 mg) and **2**, a colorless oil (127 mg, 74%). The sample of **2** was identical with those obtained by the photooxygenations (NMR, $AgNO_3$–silica gel, and gas-liquid chromatogram[19]).

RB-sensitized Photooxidation of 1. A mixture of MeOH (1 cm^3), $CHCl_3$ (30 cm^3), **1** (253 mg), and RB (30 mg) was irradiated by means of a tungsten lamp for 8.5 h. After treatment with $NaBH_4$ (50 mg), the mixture was chromatographed on a silica-gel column to give **5** (100 mg, 67%), **7** (colorless crystals, mp 84—86 °C (23 mg, 15%) [M. W., 220.1838. Calcd for $C_{15}H_{24}O$: 220.1827. δ: 0.47—0.8 (2H, m), 0.92 (6H, s), 0.95 (3H, d, J=7 Hz), 1.05 (3H, s), 3.93 (1H, br. m, $W_{h/2}$=14 Hz), 4.51 (1H, d, J=5.5 Hz), and 5.15 (1H, m). ν: 3620—3000 cm^{-1}]) and the recovered **1** (114 mg, 45%).

Conversion of 3 to 4. *a)*: To a hexane solution (5 cm^3) of **3** (25.4 mg), silica gel (Wako Gel C 200, 5 g) was added after which the mixture was kept at room temperature for 7 h. Subsequent extraction with ether gave **4** (12.3 mg).

b): A $CHCl_3$ solution (4 cm^3) of **3** (22.3 mg) was refluxed for 20 min. Subsequent evaporation of the solvent *in vacuo* gave **4** (22 mg).

Osmium(VIII) Oxide Oxidation of 1 to 4. To a solution of **1** (93 mg) in MeOH (5 cm^3), OsO_4 (100 mg) was added, after which the mixture was kept for 24 h. After treatment with $NaIO_4$ (215 mg) and H_2S, the mixture was chromatographed on a silica-gel column to give **4** (43 mg, 40%) which was identical with the sample of photochemical origin.

Jones Oxidation of 5 to Give 6. To a solution of CrO_3 (61 mg) and H_2SO_4 (1 cm^3) in acetone (10 cm^3), **5** (40 mg) was added. After 5 min, the mixture was treated with 2-propanol and extracted with ether. The colorless oil obtained by silica-gel column chromatography was **6**[4] (9 mg, 22%).

Jones Oxidation of 7 to Give Aristolenone (8). Similarly, **7** (12.1 mg) was dissolved in acetone (10 cm^3) containing CrO_3 and H_2SO_4, after which the mixture was oxidized for 5 min. Then, the mixture was treated with 2-propanol and extracted with ether. Silica-gel chromatography of the extract gave colorless crystals (mp 46—47 °C (lit, 39—42 °C,[9] 46.5—47.5 °C[10])), identified as **8** (5.6 mg, 46%), whose NMR NMR [δ: 0.68 (1H, d, J=9 Hz), 0.96 (3H, s), 1.02 (3H, s), 1.06 (3H, d, J=7 Hz), 1.0—2.6 (8H, m), 1.23 (3H, s), and 5.72 (1H, m)] were in accord with the previously reported figures.[9,10]

19) Gas-liquid chromatography on a glass capillary column (tricresyl phosphate at 115 °C) showed two peaks. However, **2** was rather unstable under the preparative chromatographic conditions. An attempted separation by means of a high-pressure liquid chromatograph (Micropolasil–hexane) was unsuccessful.

Application of the MTPA Method to Determination of Abusolute Stereochemistry. The Hydroxymethyl-substituted Chiral Carbon of Carbocycles

Yayoi SUGIMOTO, Takahiko TSUYUKI, Yoshihiko MORIYAMA,† and Takeyoshi TAKAHASHI*

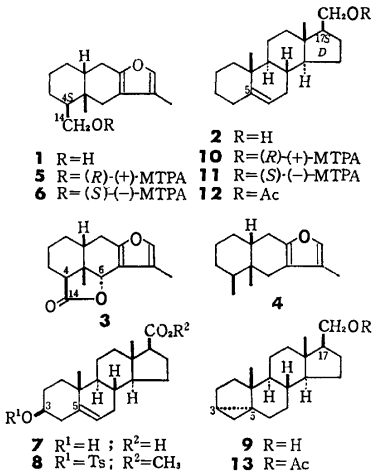
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

†*Institute of Chemistry, Kyoto Prefectural University of Medicine, Taishogun, Kita-ku, Kyoto 603*

(Received May 23, 1980)

Synopsis. Application of the MTPA method is extended to determination of the absolute configuration of primary alcohols such as furanoeremophilan-14-ol and 17β-(hydroxymethyl)androst-5-ene with a hydroxymethyl group on the chiral ring carbon atom of carbocycles.

Recently Yamaguchi and Yasuhara have developed a new convenient method for determination of the absolute configurations of secondary alcohols[1] and primary alcohols with the chiral center at the 2-position.[2] An optically active alcohol was converted to the corresponding (*R*)-(+)-α-methoxy-α-(trifluoromethyl)phenylacetic acid [(*R*)-(+)-MTPA; Mosher's reagent] ester (**A**) and (*S*)-(−)-MTPA ester (**B**) according to Mosher's method.[3] The magnitude of lanthanoid induced shift (LIS) by Eu(fod)$_3$-d_{27} for the methoxyl group of the (*R*)-(+)-MTPA ester (**A**) is larger than that of the (*S*)-(−)-MTPA ester (**B**) when the chiral center is in *R*-configuration. This generality is applicable to many optically active alcohols. However, successful application of this method to primary alcohols is limited to only acyclic carbinols having the chiral carbon atom at 2-position. In connection with a structural study of nigakialcohol,[4] we examined an applicability of this method for optically active primary alcohols in which a hydroxymethyl group is situated on the chiral ring carbon atom of a carbocycle. In this report, we wish to describe a successful application of this method to furanoeremophilan-14-ol (**1**) and 17β-(hydroxymethyl)androst-5-ene (**2**) with known absolute configurations.



Furanoeremophilan-14,6α-olide (**3**), isolated from *Ligularia Hodgsoni* HOOK, f., has been converted to furanoeremophilan-14-ol (**1**),[5] whose absolute stereochemistry at C-4 has been established to be *S* by conversion of **1** into a known furanoeremophilane (**4**).[5] The primary alcohol (**1**) was transformed into the corresponding (*R*)-(+)-MTPA ester (**5**) and (*S*)-(−)-MTPA ester (**6**) by Mosher's method.[3] The LIS values of the methoxyl groups of **5** and **6** were given in Table 1. The ΔLIS_{OMe} value was negative (−0.97) for the diastereomeric MTPA esters of the alcohol (**1**), indicating that the chiral center at C-4 of **1** is in an *S*-configuration, in accordance with the reported stereochemistry.[5]

A cyclopentane D-ring of 17β-(hydroxymethyl)-androst-5-ene (**2**) has an asymmetric carbon atom at C-17 position which bears a hydroxymethyl group, the absolute configuration of this carbon atom being established to be *S*. This alcohol (**2**) was prepared from 3β-hydroxyandrost-5-ene-17β-carboxylic acid (**7**).[6] Esterification and tosylation gave methyl 3β-(tosyloxy)-androst-5-ene-17β-carboxylate (**8**), which on treatment with lithium aluminium hydride afforded a mixture of 17β-(hydroxymethyl)androst-5-ene (**2**)[7] and 17β-hydroxymethyl-3α,5α-cycloandrostane (**9**) in a ratio of *ca.* 1 : 1. Reduction with lithium triethylborohydride in tetrahydrofuran (Super-Hydride) gave the same mixture (**2** and **9**) in a ratio of *ca.* 2 : 1. The ΔLIS_{OMe} value of (*R*)-(+)- and (*S*)-(−)-MTPA esters (**10** and **11**) of 17β-(hydroxymethyl)androst-5-ene (**2**) was negative (−0.36) as shown in Table 1. This indicates that the asymmetric center at C-17 is in an *S*-configuration. From these observations, it is concluded that application of the MTPA method can be extended to primary alcohols such as **1** and **2** with a hydroxymethyl group on the chiral ring carbon of carbocycles.

TABLE 1. LANTHANOID INDUCED SHIFT (LIS) VALUES OF THE METHOXYL GROUP IN THE ACID MOIETY FOR (*R*)-(+)- AND (*S*)-(−)-MTPA ESTERS OF **1** AND **2**

Experimental

Melting points were measured on a Mel-temp capillary melting point apparatus (Laboratory Devices) and were uncorrected. IR spectra were measured using a Hitachi 260-30 spectrometer. Mass spectra (MS) were taken on a Hitachi RMU-6-Tokugata mass spectrometer at 70 eV with a direct inlet system and high resolution mass spectra on a JMS-D300 (JEOL) mass spectrometer. Relative intensities are expressed in % in parentheses. ^{1}H NMR spectra were measured on a Hitachi R-20B (60 MHz) or a Varian EM-390 (90 MHz) spectrometer with TMS as an internal standard. Thin layer chromatography (TLC) was carried out on Kieselgel GF_{254} (E. Merck). Wakogel C-200 (Wako) was used for silica gel column chromatography.

(R)-(+)- and (S)-(−)-MTPA Esters (5 and 6) of Furanoeremophilan-14-ol (1). Furanoeremophilan-14-ol[5] (**1**; 21.6 mg and 18.7 mg) was converted into (*R*)-(+)-MTPA ester (**5**; 17.3 mg, 42% yield) and (*S*)-(−)-MTPA ester (**6**; 27.1 mg, 75% yield) by the usual method.[3] (*R*)-(+)-MTPA ester (**5**): an oil, IR (liq) 1742, 1640, and 1562 cm^{-1}; ^{1}H NMR (60 MHz) δ (CCl_4) 1.00 (3H, s), 1.87 (3H, d, J=2 Hz), 3.53 (3H, $-OCH_3$), *ca.* 4.2—4.6 (2H, m), 6.95 (1H, m), and *ca.* 7.3—7.7 (5H, m); MS *m/e* 450 (M^+) and 189 (100). (*S*)-(−)-MTPA ester (**6**): an oil, IR (liq) 1742, 1642, and 1562 cm^{-1}; ^{1}H NMR (60 MHz) δ (CCl_4) 1.01 (3H, s), 1.88 (3H, d, J= 2 Hz), 3.53 (3H, $-OCH_3$), *ca.* 4.0—4.8 (2H, m), 6.95 (1H, m), and *ca.* 7.3—7.7 (5H, m); MS *m/e* 450 (M^+) and 189 (100).

Methyl 3β-(Tosyloxy)androst-5-ene-17β-carboxylate (8). Methyl 3β-hydroxyandrost-5-ene-17β-carboxylate (30.4 mg), prepared from pregnenolone *via* 3β-hydroxyandrost-5-ene-17β-carboxylic acid (**7**),[6] was treated with tosyl chloride (45.4 mg) in pyridine (8 ml) at room temperature overnight. To the reaction mixtrure, dichloromethane was added and the solution was washed with dilute hydrochloric acid. The organic layer was worked up as usual and the residue was subjected to separation by preparative TLC (developed with diethyl ether–hexane, 1 : 1) to give a tosylate (**8**; 40.5 mg), mp 143.5—144.5 °C (from diethyl ether); IR (Nujol) 1707, 1198, and 1172 cm^{-1}; ^{1}H NMR (90 MHz) δ ($CDCl_3$) 0.67, 0.98, 2.44, 3.67 (each 3H, s), 4.30 (1H, m), 5.28 (1H, m), and 7.30 (2H, d, J=8.5 Hz); MS *m/e* 314 (M−TsOH)$^+$ and 299. No molecular ion peak was observed.

17β-(Hydroxymethyl)androst-5-ene (2). Super-Hydride (0.5 ml; 1 M lithium triethylborohydride solution in tetrahydrofuran, Aldrich) was added to a solution of the tosylate (**8**; 30.0 mg) in tetrahydrofuran (2 ml) and the solution was refluxed for 3 h under nitrogen. Usual work-up afforded a mixture (17.0 mg) of 17β-(hydroxymethyl)androst-5-ene (**2**) and 17β-hydroxymethyl-3α,5α-cycloandrostane (**9**) in a ratio of *ca.* 2 : 1. To the mixture acetic anhydride (3 ml) and pyridine (10 drops) were added and the reaction mixture was stirred overnight at room temperature. After the usual work-up, the reaction product was purified by preparative TLC (developed with hexane–diethyl ether, 4 : 1) to give a mixture (20.3 mg) of acetates (**12** and **13**). This procedure was repeated and two crops of the acetate mixture (**12** and **13**) were combined. The combined mixture (39.7 mg) was subjected to separation by column chromatography on silica gel (15 g) impregnated with 20% silver nitrate. Elution with a mixture of hexane–diethyl ether (19 : 1) gave 5-ene acetate (**12**; 21.3 mg), 3α,5α-cyclo acetate (**13**; 10.2 mg), and a mixture (10.0 mg) of **12** and **13**. **12**: mp 78—79.5 °C (from hexane); IR (Nujol) 1742 cm^{-1}; ^{1}H NMR (90 MHz) δ ($CDCl_3$) 0.67, 1.00, 2.01 (each 3H, s), 4.03 (2H, d-like, J=7 Hz), and 5.23 (1H, m); MS *m/e* 330 (M^+; 92), 270 (26), and 255 (100); Found: *m/e* 330.2568. Calcd for $C_{22}H_{34}O_2$: M, 330.2558. **13**: mp 60—64 °C (from hexane); IR (Nujol) 1742 cm^{-1}; ^{1}H NMR (90 MHz) δ ($CDCl_3$) 0.20—0.55 (3H, m), 0.67, 0.91, 2.02 (each 3H, s), and 4.12 (2H, dd, J=15 and 6 Hz); MS *m/e* 330 (M^+; 77), 270 (32), and 255 (100); Found: *m/e* 330.2555. Calcd for $C_{22}H_{34}O_2$: M, 330.2558.

17β-(Acetoxymethyl)androst-5-ene (**12**; 90 mg) was heated with an excess of lithium aluminium hydride in tetrahydrofuran (5 ml) under reflux for 30 min. The reaction mixture was worked up as usual to give 17β-(hydroxymethyl)androst-5-ene (**2**; 78.4 mg) quantitatively, mp 136—137.5 °C (from diethyl ether–hexane); IR (Nujol) 3380 cm^{-1}; ^{1}H NMR (90 MHz) δ ($CDCl_3$) 0.67, 1.01 (each 3H, s), 3.60 (2H, m), and 5.25 (1H, m); MS *m/e* 288 (M^+; 100), 273 (96), and 255 (38); Found: C, 83.47; H, 11.19%. Calcd for $C_{20}H_{32}O$: C, 83.27; H, 11.18%.

(R)-(+)- and (S)-(−)-MTPA Esters (10 and 11) of 2. (*R*)-(+)-MTPA ester (**10**; 36.9 mg, 96% yield) and (*S*)-(−)-MTPA ester (**11**; 30.4 mg, 87% yield) were prepared from 17β-(hydroxymethyl)androst-5-ene (**2**; 22 mg and 20 mg, respectively).[3] **10**: IR (liq) 1751 cm^{-1}; ^{1}H NMR (60 MHz) δ (CCl_4) 0.68, 0.97 (each 3H, s), 3.49 (3H, $-OCH_3$), 4.20 (2H, m), 5.15 (1H, m), and *ca.* 7.2—7.6 (5H, m); MS *m/e* 504 (M^+; 100) and 255 (63). **11**: IR (liq) 1751 cm^{-1}; ^{1}H NMR (60 MHz) δ (CCl_4) 0.62, 0.97 (each 3H, s), 3.51 (3H, $-OCH_3$), 4.18 (2H, m), 5.16 (1H, m), and *ca.* 7.1—7.6 (5H, m); MS *m/e* 504 (M^+; 87) and 255 (100).

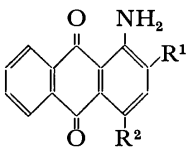
(Received May 28, 1980)

Synopsis. The reaction of 1-aminoanthraquinone with primary aliphatic amines in the presence of cobalt(II) chloride under atmospheric oxygen preferentially gave the corresponding 1-amino-4-(alkylamino)anthraquinones. The reaction did not proceed with aqueous ammonia, bidentate amines, secondary aliphatic amines, and primary arylamines. While, with alicyclic amines the reaction mainly afforded 1-amino-2,4-bis(alkylamino)anthraquinones.

In our previous paper,[1] we have reported a novel direct 4-butylamination of 1-aminoanthraquinone (**1**) promoted by metal ions and proposed the possible mechanism of the reaction: the formation of a metal complex, in which the 1-amino and 9-carbonyl groups of **1** coordinate to the metal ion, increases the electrophilicity of the substituted anthraquinone nucleus and facilitates the nucleophilic attack of butylamine to the 4-position. This direct amination appeared to be a convenient method to introduce amino groups to the anthraquinone nucleus of **1**.

In this paper, similar reactions of **1** with various amines in the presence of cobalt(II) chloride under atmospheric oxygen are examined. The results are summarized in Table 1.



Compd No.	Substituent R¹	Substituent R²
1	H	H
2	H	NH_2
3	H	NHMe
4	H	*n*-BuNH
5	H	*s*-BuNH
6	H	$CH_3(CH_2)_7NH$
7	$CH_3(CH_2)_7NH$	H
8	H	$C_6H_{11}NH$
9	H	$PhCH_2NH$
10	piperidino	piperidino
11	morpholino	morpholino

The reaction of **1** with aqueous ammonia was unsuccessful, while almost primary aliphatic amines reacted with **1** to give the corresponding 1-amino-4-(alkylamino)anthraquinones, which are valuable as dyes and dye intermediates. The reaction of **1** with 40% aqueous methylamine gave 1-amino-4-(methylamino)anthraquinone (**3**) in 39% yield along with a 47% recovery of **1** after 26 h at 30 °C. 1,4-Diaminoanthraquinone (**2**) formed by the demethylation of **3** was also obtained in 8.2% yield. The dealkylation of alkylamino group in 1-amino-4-(alkylamino)anthraquinone was generally observed in the other cases. Especially, with benzylamine the reaction gave **2** (29% yield), the dealkylation product of **9**, much more than the expected 1-amino-4-(benzylamino)anthraquinone (**9**) (5.5%). The reaction of **1** with 1-octylamine was also successful. From the column chromatography of the products, unchanged **1** (45%), 1-amino-4-(octylamino)anthraquinone (**6**) (34%), 1-amino-2-(octylamino)anthraquinone (**7**) (2.4%), and a trace amount of **2** were isolated. The formation of **7**, though only a small amount, suggests that not only the 4-position but also the 2-position of **1** is activated by the formation of a chelate complex between **1** and the cobalt(II) ion. However, with the other primary aliphatic amines the reaction gave only the 4-aminated products but not the 2-aminated products.

The preferential 4-amination may be assisted by the formation of hydrogen-bonding between the *N*-hydrogen atom of alkylamino group and the oxygen atom of the 10-carbonyl group, as suggested in our previous paper.[1]

The amination proceeded smoothly with primary aliphatic amines, while, with bidentate amines such as

Table 1. Alkylamination of 1-aminoanthraquinone (**1**) in the presence of $CoCl_2$[a]

Run	Amine	Temp °C	Time h	Recovery/% (**1**)	Aminated products/% Yield: 4-Isomer	2-Isomer	2,4-Isomer	(**2**)

6	$PhCH_2NH_2$	40	12	53	(**9**) 5.5	0	0	29
7	Piperidine[c]	30	70	13	—	—	(**10**) 58	0
8	Morpholine[c]	40	48	83	—	—	(**11**) 9.1	0
9	Morpholine[c]	40	170	49	—	—	(**11**) 23	0

a) Reactant **1** (9 mmol) was stirred in pyridine (20 ml) with amine (30 ml) and $CoCl_2$ (9 mmol). b) 40% Aqueous methylamine solution (60 ml) was used as reactant and pyridine (60 ml) was added as solvent. c) Piperidine (50 ml) or morpholine (50 ml) was used as reactant without solvent. An addition of pyridine as solvent rather depressed the yields of products.

ethylenediamine and 2-aminoethanol the amination did not proceed. It is reasonable to consider that the cobalt ion is preferentially combined with bidentate amines than with **1**, because the bidentate amines can act as an effective chelating agent. Therefore, the formation of the cobalt complex of **1** was disturbed and the amination was inhibited.

Aromatic amines also did not react with **1**. This lack of reactivity is probably due to the lower nucleophilicity of arylamines compared to the alkylamines. These facts support the nucleophilic attack of alkylamines to the substituted anthraquinone nucleus activated by the formation of a cobalt complex. With diethylamine the amination was also unsuccessful and no amination products were obtained. The lack of reactivity of diethylamine may be attributed to a steric hindrance.

The attack of alkylamine at the 4-position of **1** would cause a considerable steric crowding. Therefore, the increase in the size of the alkyl residue may decrease the reactivity of the amine. For example, *s*-butylamine was much less reactive than *n*-butylamine in spite of their similar basicities. Thus, both the basicity and the size significantly affected the reactivity of amines.

Reaction of **1** with alicyclic amines was very specific and afforded the corresponding 1-amino-2,4-bis(alkylamino)anthraquinones. Trace amounts of some by-products were also noted on chromatography but could not be identified.[2] The cause of the differences in the amination products between primary aliphatic amines and alicyclic amines are not yet clear.

The structure of compounds (**10** and **11**) were confirmed by the elementary analysis, ^{1}H-NMR spectra, and the alternative synthesis of the compounds from 1-amino-2,4-dibromoanthraquinone with the corresponding amines.

Experimental

All the melting points are uncorrected. The visible spectra in methanol solution were measured using a Hitachi EPS-3T spectrometer.

The ^{1}H-NMR spectra were taken on a JEOL Model MH-100 spectrometer with TMS as an internal standard. Elemental analyses were recorded on a Yanaco CHN recorder MT-2. Column chromatography was carried out on activated alumina (Sumitomo KCG-30) using xylene as an eluent.

Reaction Procedure. The general procedure is as follows. A mixture of **1** (9 mmol), $CoCl_2$ (9 mmol), amine (30 ml), and pyridine (20 ml) was stirred in an open flask. After the reaction, the solvent and the excess amine were distilled off under reduced pressure. The mixture was poured into an aqueous NaOH solution (pH=10), and then H_2S gas was introduced into the solution to decompose a chelate complex of the products. The separated precipitate was filtered, washed with water and dried. The crude products were extracted with xylene, separated by column chromatography and recrystallized from benzene.

Characterization and Identification of Products. Compound **2** was identified by comparison with the authentic sample obtained from commercial source. Some properties of the compounds (**3**,[3] **4**,[1] and **8**[4]) were already known, and these were identified by the data described in the literature together with additional following data.

3: ^{1}H-NMR ($CDCl_3$) δ=3.07 (3H, d, $-CH_3$), 6.8—7.2 (4H, m, $H^{2,3}$, and NH_2), 7.68 (2H, m, $H^{6,7}$), 8.30 (2H, m, $H^{5,8}$), 10.45 (1H, b, N<u>H</u>-Me).

8: ^{1}H-NMR ($CDCl_3$) δ=1.0—2.3 (10H, m, $-(CH_2)_5-$), 3.64 (1H, m, -NH-C<u>H</u>-), 6.9—7.4 (4H, m, $H^{2,3}$ and NH_2), 7.85 (2H, m, $H^{6,7}$), 8.50 (2H, m, $H^{5,8}$), 11.12 (1H, b, -N<u>H</u>-).

1-Amino-4-(s-butylamino)anthraquinone (5): Mp 135—136 °C. UV_{max} (CH_3OH), nm, 573 (ε 15400), 616 (ε 18100). Found: C, 73.61; H, 6.33; N, 9.27%. Calcd for $C_{18}H_{18}N_2O_2$: C, 73.45; H, 6.16; N, 9.52%. ^{1}H-NMR ($CDCl_3$) δ=1.03 (3H, t, $-CH_3$), 1.34 (3H, d, $-CH_3$), 1.71 (2H, m, $-CH_2-$), 3.76 (1H, m, -CH-), 7.0—7.4 (4H, m, $H^{2,3}$ and NH_2), 7.80 (2H, m, $H^{6,7}$), 8.46 (2H, m, $H^{5,8}$), 11.06 (1H, b, N<u>H</u>- *s*-Bu).

1-Amino-4-(octylamino)anthraquinone (6): Mp 112.5—113.5 °C. UV_{max} 573 (ε 14400), 617 (ε 17000). Found: C, 75.49; H, 7.54; N, 7.63%. Calcd for $C_{22}H_{26}N_2O_2$: C, 75.40; H, 7.48; N, 7.99%. ^{1}H-NMR ($CDCl_3$) δ=0.84 (3H, t, $-CH_3$), 1.1—1.9 (12H, m, $-(CH_2)_6-$), 3.32 (2H, q, -NH-C<u>H</u>$_2$-), 6.8—7.2 (4H, m, $H^{2,3}$ and NH_2), 7.64 (2H, m, $H^{6,7}$), 8.30 (2H, m, $H^{5,8}$), 10.73 (1H, b, N<u>H</u>-Octyl).

1-Amino-2-(octylamino)anthraquinone (7): Mp 197—198 °C. UV_{max} 539 (ε 10700). Found: C, 74.88; H, 7.67; N, 7.78%. Calcd for $C_{22}H_{26}N_2O_2$: C, 75.40; H, 7.48; N, 7.99%. ^{1}H-NMR (DMSO-d_6) δ=0.89 (3H, t, $-CH_3$), 1.0—1.9 (12H, m, $-(CH_2)_6-$), 3.20 (2H, q, NH-C<u>H</u>$_2$-), 6.13 (1H, b, N<u>H</u>-Oc), 6.56 (1H, d, H^3), 7.59 (1H, d, H^4), 7.70 (2H, m, $H^{6,7}$), 8.0—8.4 (4H, m, $H^{5,8}$ and NH_2).

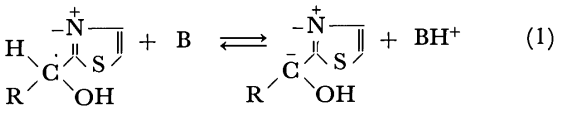
(Received June 16, 1980)

Synopsis. The rates of amine base-catalyzed H-D exchange of 2-methyl hydrogens of 2,3,4-trimethylthiazolium iodide were measured in deuterated methanol by using following amines: α-picoline, imidazole, 2- and 4-aminopyridine. The results indicated that the reaction was subject to a general base catalysis. The solvent effect is also described.

The acyloin condensation catalyzed by thiazolium salts are known to involve multistep reaction pathways.[1] One crucial step of them is the ionization of initially formed 2-(α-hydroxyalkyl)thiazolium salt (**1**) to form so called "active aldehyde (**2**)" (Eq. 1).



1 **2** (1)

Until recently, the mechanism of this step has been left uncertain whether it is subject to specific base or general base catalysis. Recently, the deprotonation from 2,3,4-trimethylthiazolium and 2-(α-hydroxyethyl)-thiazolium ions has been reported to occur by general base catalysis in aqueous buffer solution.[2,3] In contrast, we were unable to detect general base catalysis by an internal dimethylamino group of thiazolium salt in the benzoin condensation in methanol.[4] Therefore it was desired to examine base catalysis of externally added amines, also in methanol. In this paper, we describe the H-D exchange reaction of 2,3,4-trimethylthiazolium iodide (**3**) in deuterated methanol, catalyzed by several amines.

Results and Discussion

The amines employed were α-picoline, imidazole, 2- and 4-aminopyridine. The rate constants of H-D exchange were determined by following the relative peak area of 2-methyl protons and that of non-exchangeable 3- or 4-methyl protons by NMR. No decomposition products were detected under the present reaction conditions. The results are shown in Table 1. The base concentration was changed for imidazole. The rate constants are linearly dependent on the concentration of imidazole. From the slope, the apparent second-order rate constant for imidazole is calculated to be 6.10×10^{-3} M^{-1} s^{-1}. Since pK_a values of the bases in CD_3OD are not available, the estimated pK_a values in CH_3OH were employed. The estimation is based on the fact that the plots of pK_a values of ammonia and substituted anilines in H_2O against those in CH_3OH give a single straight line. Thus, the pK_a of desired amine in CH_3OH can be estimated from the pK_a in H_2O, as indicated in Table 1 for 2- and 4-aminopyridine. Plots of log k_{app} against the pK_a's of the bases gave a straight line [slope$=0.81(\gamma=0.995)$].[5] This may indicate that a general base catalysis is also important for the present H-D exchange reaction in addition to the lyate ion catalysis.

Table 1. The rate constants of H-D exchange reaction of 2,3,4-trimethylthiazolium iodide[a] in methanol-d_4 at 38 °C

Base	pK_a (in MeOH)	10^2[Base]/M	$10^4 k_{obsd}$/s^{-1}	$10^3 k_{app}$/M^{-1} s^{-1}[b]
α-Picoline	6.11[c]	40	0.967	0.242
2-Amino-pyridine	7.9[d]	10	4.03	4.03
Imidazole	8.10[e]	3.3	2.77	
		6.8	4.44	
		13.6	8.41	
		27.2	16.5	6.10
4-Amino-pyridine	9.9[d]	5.0	146	292

a) [Thiazolium salt]$=0.1$ M. b) Apparent second-order rate constants, $k_{app}=\frac{k_{obsd}}{[Base]}$. c) C.H. Rochster, *J. Chem. Soc., B*, **1967**, 33. d) Estimated values. e) M. Tanaka, "Acid and Base," Shoka-bo, Tokyo (1975), p. 46.

Table 2. The rate constants[a] in CD_3OD–D_2O at 38 °C

CD_3OD (%)	D[b]	$10^4 k_{obsd}$/s^{-1}	Rel rate
100	32.6	146	128
50	58.5	21.1	18
10	75.0	1.60	1.4
0	78.5	1.14[c]	1

a) 4-Aminopyridine (0.05 M) was used as a base. b) Dielectric constants in CH_3OH–H_2O system.[7] c) This is the extrapolated value.

In model reactions of thiamine catalysis, it has been shown that all kinetically significant steps proceed faster in ethanol than in water.[6] This suggests that in many thiamine pyrophosphate dependent enzymatic reactions, the catalysis is in large part to occur through the binding of the thiazolium portion of the coenzyme in a hydrophobic region of the protein. Therefore, more detailed solvent effects were also examined for the present exchange reaction, by changing the composition of D_2O in CD_3OD as shown in Table 2.

Regarding this solvent effect, it may be of interest to see a relationship between the dielectric constants and the composition of CH_3OH–H_2O mixture. Albright *et al.* reported that the dielectric constant increases linearly with the increase of water content.[7] As shown in Table 2, log k_{obsd} decreases linearly with the increase

of the apparent dielectric constants. Thus, less polar solvent is more favorable for the present H-D exchange reaction. This may be accounted for by an accepted view that the ionic structure of the reactant state is stabilized more in a polar solvent and the neutral zwitter ionic carbanion is stabilized more in a less polar solvent. This suggests that the enzyme-mediated reaction of thiamine occurs in a relatively nonpolar environment. The results of the above model reaction also support the occurrence of a general base catalysis for the carbanion formation at the α-carbon of 2-(α-hydroxyethyl)thiazolium ion, especially under hydrophobic conditions. Thus, it is tempting to speculate that aminopyrimidine moiety of thiamine would act as an internal base in step of the carbanion formation from 2-(α-hydroxyethyl)thiazolium ion. However, it should also be kept in mind that previous failure to observe internal base catalysis in benzoin condensation has been still left unanswered.

Experimental

NMR spectra were recorded on a Varian A-60 spectrometer.

Materials. Deuterium oxide (99.75%, Merck) and methanol-d_4 (99%, Merck) were used. 2- and 4-Aminopyridines were purified by recrystallization from diethyl ether–hexane, mp 58 °C (lit,[8] mp 58 °C) and mp 156—158 °C (lit,[9] mp 157 °C). Imidazole (Wako Pure Chemical Co.) was used without further purification. Imidazole hydrochloride was prepared from imidazole and HCl in EtOH. Purification was performed by recrystallization (MeOH–diethyl ether). α-Picoline was purified by distillation.

2,3,4-Trimethylthiazolium Iodide was prepared from 2,4-dimethylthiazole and methyl iodide. Mp 250 °C (EtOH), NMR (CD_3OD), δ 2.58 (3H, s), 2.98 (3H, s), 3.96 (3H, s), and 7.60 (1H, s). Found: C, 28.30; H, 3.97; N, 5.46%. Calcd for $C_6H_{10}INS$: C, 28.25; H, 3.95%; N, 5.48%.

Exchange Kinetics. The salt (5×10^{-2} mmol) was weighed accurately in NMR tube and 0.45 ml of CD_3OD was added. This was placed in the probe of the NMR spectrometer for 10 min. The reaction was initiated by adding 0.05 ml of the base solution by a microsyringe. 2-Methyl protons (2.98 ppm) were followed by integration as a function of time, relative to the 3- or 4-methyl protons, which was found not to be exchangeable under the present reaction conditions. The rate constants were calculated as described in the previous paper.[10]
