The Oxidation Reaction of Tl(I) to Tl(III) by the Peroxodisulfate Ion. I. Kinetics and Mechanism in an Aqueous Solution

Masaru KIMURA,* Tsuneko AKAZOME, Kayo TAKENAKA, and Akiko KOBAYASHI

Department of Chemistry, Faculty of Science, Nara Women's University, Nara 630

(Received July 25, 1979)

The oxidation reaction of the thallium(I) ion to the thallium(III) ion by the peroxodisulfate ion has been studied in an aqueous acidic solution. The reaction constituted a chain reaction initiated by the thermal decomposition of the peroxodisulfate ion, the reaction involving no direct reactions between the thallium(I) and peroxodisulfate ions. At thallium(I) ion concentrations larger than 0.004 mol dm^{-3}, the reaction mechanism was assumed to be: $S_2O_8^{2-} \xrightarrow{k_1} 2SO_4^{\cdot-}$; $S_2O_8^{2-}+H^+ \xrightarrow{k_2} HSO_4^-+\frac{1}{2}O_2+SO_3$; $Tl(I)+SO_4^{\cdot-} \xrightarrow{k_3} Tl(II)+SO_4^{2-}$; $S_2O_8^{2-}+Tl(II) \xrightarrow{k_4} Tl(III)+SO_4^{\cdot-}+SO_4^{2-}$; $2Tl(II) \underset{k_{-5}}{\overset{k_5}{\rightleftharpoons}} Tl(I)+Tl(III)$. The rate of the reaction was described as $-d[S_2O_8^{2-}]/dt=(k_1+k_2[H^+])[S_2O_8^{2-}]+k_4(k_1/k_5)^{1/2}[S_2O_8^{2-}]^{3/2}$. The rate constants at an ionic strength of 0.16 mol dm^{-3} were determined to be $k_1=1.99\times10^{19}\exp[-157\text{ kJ mol}^{-1}/RT]\text{s}^{-1}$, $k_2=2.75\times10^{12}\exp[-103\text{ kJ mol}^{-1}/RT]\text{ dm}^3\text{ mol}^{-1}\text{ s}^{-1}$, and $k_4(k_1/k_5)^{1/2}=2.81\times10^{13}\exp[-108\text{ kJ mol}^{-1}/RT]\text{ dm}^{3/2}\text{ mol}^{-1/2}\text{ s}^{-1}$ in 0.01 mol dm^{-3} perchloric acid, the k_4 value being increased with a decrease in the hydrogen-ion concentration. The ionic strength (μ) dependence was described as $\log k_4(k_1/k_5)^{1/2}=-4.17-1.05\,\mu^{1/2}$ in 0.01 mol dm^{-3} perchloric acid at 40 °C. The reaction rate was completely retarded by the addition of 1% acrlyronitrile, 5×10^{-6} mol dm^{-3} cerium(III) sulfate, 1×10^{-3} mol dm^{-3} cerium(IV) sulfate, or 0.1 mol dm^{-3} sodium acetate, and it was also remarkably retarded by the addition of 1×10^{-3} mol dm^{-3} tetranitromethane. The copper(II) ion and molecular oxygen did not appreciably affect the reaction rate, but the iron(III) ion accelerated it greatly.

The peroxodisulfate ion is known as a powerful two-electron oxidizing agent, and the oxidation reactions of the organic and inorganic substrates by the peroxodisulfate ion have been extensively studied by a number of researchers and have been reviewed by House,[1] Wilmarth and Haim,[2] Wilson,[3] and Buist.[4] However, the investigation of the oxidation reaction of the thallium(I) ion by the peroxodisulfate ion has not been done previously. Bednar[5] studied the induced oxidation of the thallium(I) ion by the iron(II) ion-hydrogen peroxide reaction and concluded that the thallium(II) ion is formed as an intermediate by the reaction with the hydroxyl radical. The reaction of thallium(I) with the hydroxyl radical giving the thallium(II) ion also occurs during the photolysis[6] and radiolysis[7] of cerium(IV)-thallium(I) mixtures. It is now believed that the thallium(II) ion exists as an intermediate in the redox reaction of the thallium(I)-thallium(III) couple. In the oxidation reaction of the thallium(I) ion to the thallium(III) ion by the peroxodisulfate ion, three schemes for the reaction can be tentatively assumed: (1) a single step of the two-electron transfer by the direct reaction between the thallium(I) and peroxodisulfate ions; (2) two successive reactions of the one-electron transfer, involving the thallium(II) ion as the intermediate species, and (3) a reaction initiated only by the thermal decomposition of the peroxodisulfate ion, without any direct reactions between the reactants. The present paper intends to characterize each scheme and to ascertain the true mechanism of the reaction.

Experimental

Chemicals. Reagent-grade potassium peroxodisulfate of the Wako Pure Chemicals Co., Inc., was recrystallized twice from redistilled water and dried at 25 °C in a vacuum desiccator. Thallium(I) perchlorate was prepared by dissolving thallium(I) sulfate in a perchloric acid solution, recrystallizing it from an aqueous perchloric acid solution, washing it with ethanol, and drying it at 80 °C in a vacuum-drying oven. The thallium(I) perchlorate was confirmed to be free of sulfate ions. The sodium perchlorate used for adjusting the ionic strength was recrystallized twice from the redistilled water. The thallium(III) perchlorate was prepared by dissolving Tl_2O_3 in about 5 mol dm^{-3} perchloric acid at 60—70 °C for several hours. All the other chemicals used were guaranteed reagents. The redistilled water was prepared from the anion- and cation-exchange resin water by successive distillations from solutions with and without permanganate in a glass still.

Procedure. Most of the experiments were carried out in a solution of 0.1 mol dm^{-3} sodium perchlorate and 0.01 mol dm^{-3} perchloric acid at 40 °C; no buffer solutions were used in any experiments. The reaction vessel was covered with black adhesive-plastic tape to ensure darkness, and was placed in a thermostat bath. The aliquot samples were withdrawn at appropriate times and mixed with a cold solution of 1% acrylonitrile, so that the reaction was almost completely stopped and the temperature of the solution was reduced to about 25 °C. Then the concentrations of the peroxodisulfate and thallium(I) ions remaining were measured by means of polarography. The thallium(I)-ion concentration was determined by means of a.c. polarography at −0.45 V *vs.* SCE in a solution of 0.01 mol dm^{-3} perchloric acid, 0.1 mol dm^{-3} sodium perchlorate, and 0.01% gelatine at 25 °C. After the separation of the thallium(III) ion formed from the peroxodisulfate ion by filtering it through the cation-exchange resin, the peroxodisulfate-ion concentration was determined by means of d.c. polarography at 0.2 V *vs.* SCE in a solution with the same constituents as in the measurement of the thallium(I)-ion concentration. The method of the polarographic determination for the peroxodisulfate-ion concentration is essentially the same as that used in the previous studies.[8,9] The concentration of the thallium(III) ion formed was determined as follows. All the thallium(I) ion remaining in the reacting solution was once precipitated by the addition of a slight excess of CrO_4^{2-} in an acetate buffer solution with a 4.8 of pH. After the separation of the thallium(I) ion as Tl_2CrO_4, the thallium

(III) ion in the filtered solution was precipitated as $Tl(OH)_3$ in 0.1 mol dm^{-3} sodium hydroxide. The sediment of the hydroxo thallium(III) after filtration was dissolved in a perchloric acid solution. Then, the thallium(III)-ion concentrations were determined by means of d.c. polarography at 0.2 V *vs.* SCE under the conditions used for the measurements of the concentrations of the peroxodisulfate and thallium(I) ions. Blank experiments with mixtures of peroxodisulfate, thallium(I), and thallium(III) ions of the same constitutions as those in the reaction mixtures showed that this method of determination yields reliable results. It was also confirmed that no appreciable reaction of the peroxodisulfate ion with the thallium(I) ion occurred during the procedures for the determination of the concentrations.

Results

Stoichiometry. With concentrations of 8.0×10^{-3} mol dm^{-3} in potassium peroxodisulfate and 8.0×10^{-3} mol dm^{-3} in thallium(I) perchlorate, the concentrations of both peroxodisulfate and thallium(I) ions disappearing due to the reaction were determined and the results are shown in Table 1. The results in Table 1 indicate that, at the initial stages of reaction, the concentrations of the peroxodisulfate ion disappearing are almost equivalent to those of the thallium(I) disappearing, and that, at the later stages of reaction, those of the peroxodisulfate ion disappearing become larger than those of the thallium(I) ion disappearing. With 1.6×10^{-2} mol dm^{-3} in potassium peroxodisulfate and 4.0×10^{-3} mol dm^{-3} in thallium(I) perchlorate, the concentration of the peroxodisulfate ion disappearing and that of the thallium(III) ion being formed were determined and the results are shown in Table 2. At the initial stages of reaction, the concentrations of the peroxodisulfate ion disappearing are almost equivalent to those of the thallium(III) ion being formed, and, according to the progress of the reaction, those of the peroxodisulfate ion disappearing become larger than those of the thallium(III) ion being formed.

Reaction Order and Rate Law. The initial rate of the reaction (V_i) was determined at varied concentrations of the thallium(I) and peroxodisulfate ions under given conditions. The results are shown in Figs. 1 and 2. The plot of V_i *vs.* $[Tl(I)]_i$ in Fig. 1 indicates that the rate of the reaction increases linearly

Conditions as in Table 3; except varied concentrations of thallium(I) perchlorate.

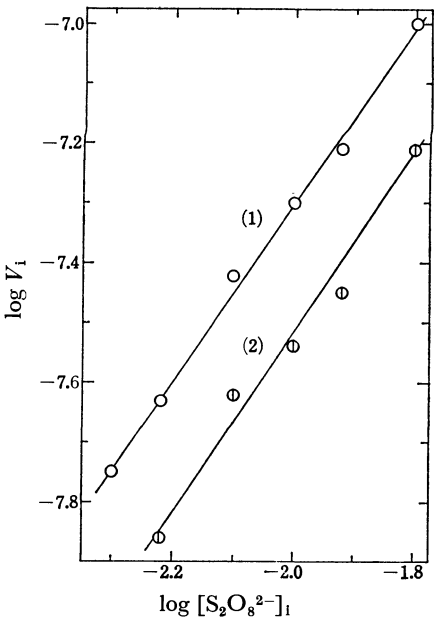

Fig. 2. Plot of log V_i *vs.* log $[S_2O_8^{2-}]_i$.
Conditions as in Table 3; except varied concentrations of potassium peroxodisulfate, and ionic strengths 0.06 and 0.16 mol dm^{-3} for lines 1 and 2, respectively.

with an increase in the thallium(I)-ion concentrations for the low concentrations, and that it then becomes independent of the thallium(I) ion over the range from 0.004 to 0.08 mol dm^{-3}. The plot of log V_i *vs.* log $[S_2O_8^{2-}]_i$ in Fig. 2 shows a straight line with a slope of 1.5±0.1. Those two results indicate that the rate of reaction between thallium(I) and peroxodisulfate ions at concentrations larger than 0.004 mol dm^{-3} thallium(I) is of zero and 1.5 order with respect to the concentrations of thallium(I) and peroxodisulfate ions respectively. Thus, the rate of reaction obeys Eqs. 7 and 9 (*vide infra*).

Effect of Radical Scavengers. The influence of the radical scavengers on the rate of reaction was examined, the results are shown in Table 3. The addition of 1% acrylonitrile completely inhibited the reaction rate, with the production of some amounts of a white sediment of polyacrylonitrile, indicating the existence of $SO_4^{\cdot-}$ and/or OH· radicals in the reacting solutions. Both the cerium(III) and cerium(IV) ions were very strong retarders of the reaction, even 5×10^{-6} mol dm^{-3} cerium(III) or 1×10^{-3} mol dm^{-3} cerium(IV) being able to reduce the reaction rate to the rate of the thermal decomposition of the peroxodisulfate ion. This clearly indicates the existence of both the oxidizing and reducing radicals in the reacting solution. Tetranitromethane was also a strong retarder of the reaction, indicating the existence of a thallium(II) species which can be act as a reducing agent for tetranitromethane. The acetate ion was also a retarder of the reaction, the reaction being completely inhibited by the addition of 0.1 mol dm^{-3} acetate. On the contrary, the iron(III) ion was an accelerator, and the copper(II) ion hardly affected the rate of reaction.

Acidity Dependence. The rate of the thermal decomposition of peroxodisulfate increased with an increase in the acidity of the reaction solution, while the rate of reaction between peroxodisulfate and thallium(I) ions decreased with an increase in the acidity. The results are tabulated in Table 4. The pH in the reacting solution become smaller according to the progress of reaction; this was because of the hydrolysis of the thallium(III) ion formed, *i.e.*, $H_2O+Tl^{3+}\rightarrow TlOH^{2+}+H^+$. However, the pH buffer solution was not used because most buffers may affect the reaction rate much as the acetate ion affects the rate of reaction (see Table 3).

Temperature Dependence. First, the rate of the thermal decomposition of the peroxodisulfate ion was

55	38.0	4.4	16.6

a) Conditions as in Table 4, except for 0.01 mol dm^{-3} perchloric acid and varid temperatures.

measured in 0.01 mol dm^{-3} sodium hydroxide and 0.01 mol dm^{-3} perchloric acid at an ionic strength of 0.16 mol dm^{-3} and at temperatures from 40 to 55 °C. Using the relationship of $-d[S_2O_8^{2-}]/dt=(k_1+k_2[H^+])[S_2O_8^{2-}]$ which has been reported by Kolthoff and Miller,[10] the values of k_1 and k_2 were evaluated to be as shown in Table 5. The activation energies for the k_1- and k_2-reactions were, respectively, 157 kJ mol^{-1} and 103 kJ mol^{-1}, the values being in good agreement with the 140 kJ mol^{-1} and 109 kJ mol^{-1} of the corresponding reactions reported by Kolthoff and Miller.[10] Next, the rate of the decomposition of the peroxodisulfate ion in the presence of the thallium(I) ion was measured in 0.01 mol dm^{-3} perchloric acid at an ionic strength of 0.16 mol dm^{-3} and at temperatures over the range from 30 to 55 °C (Table 6). The plot of ln k_b *vs.* T^{-1} gave a straight line, the k_b being described as $k_b=2.81\times10^{13}\exp[-108\text{ kJ mol}^{-1}/RT]$ dm$^{3/2}$ mol$^{-1/2}$ s^{-1}.

Ionic-strength Dependence. With concentrations of 1.6×10^{-2} mol dm^{-3} in potassium peroxodisulfate, 4.0×10^{-3} mol dm^{-3} in thallium(I) perchlorate, and 0.01 mol dm^{-3} perchloric acid, and with varied concentrations of sodium perchlorate at 40 °C, the initial rates of the disappearance of peroxodisulfate were 9.7×10^{-8}, 8.0×10^{-8}, 6.2×10^{-8}, 5.7×10^{-8}, and 5.2×10^{-8} dm^{-3} mol s^{-1} at ionic strengths of 0.06, 0.11, 0.16, 0.21, and 0.26 mol dm^{-3} respectively. The rate decreased with an increase in the ionic strength (μ), the plot of log k_b *vs.* $\mu^{1/2}$ being rectilinear with a slope of −1.05.

Discussion

The results of Fig. 1 and Table 3 absolutely deviated the schemes, 1 and 2, which were mentioned in the introduction section, but they could be well accounted for by Scheme 3, in which there are no direct reactions between peroxodisulfate and thallium(I) ions. Moreover, all the results obtained could be accounted for by the following reaction mechanism:

$$S_2O_8^{2-} \xrightarrow{k_1} 2SO_4^{\cdot-} \text{ [Initiation]} \quad (1)\,[10]$$

$$S_2O_8^{2-} + H^+ \xrightarrow{k_2} HSO_4^- + \frac{1}{2}O_2 + SO_3 \quad (2)\,[10]$$

$$Tl(I) + SO_4^{\cdot-} \xrightarrow{k_3} Tl(II) + SO_4^{2-} \quad (3)$$

$$S_2O_8^{2-} + Tl(II) \xrightarrow{k_4} Tl(III) + SO_4^{\cdot-} + SO_4^{2-} \quad (4)$$

$$2Tl(II) \underset{k_{-5}}{\overset{k_5}{\rightleftharpoons}} Tl(I) + Tl(III) \text{ [Termination]} \quad (5)\,[11\text{-}14]$$

Reactions 3 and 4 constitute a chain reaction in which Reaction 1 is the initiation reaction. The most probable termination reaction is a disproportionation of the thallium(II) ion. Schwarz *et al.*[11] reported the values for k_5 and k_{-5} to be 1.9×10^8 and 7.5×10^{-25} dm^3 mol^{-1} s^{-1} respectively in 1 mol dm^{-3} perchloric acid. Therefore, the backward reaction of Reaction 5 could actually be negligible. Thus, neglecting the backward reaction, and assuming steady-state concentrations for $SO_4^{\cdot-}$ and Tl(II), the following equations are derived:

$$[Tl(II)] = \sqrt{\frac{k_1[S_2O_8^{2-}]}{k_5}};$$

$$[SO_4^{\cdot-}] = \frac{2k_1[S_2O_8^{2-}]+k_b[S_2O_8^{2-}]^{3/2}}{k_3[Tl(I)]} \quad (6)$$

$$-d[S_2O_8^{2-}]/dt = k_a[S_2O_8^{2-}] + k_b[S_2O_8^{2-}]^{3/2} \quad (7)$$

$$-d[Tl(I)]/dt = k_1[S_2O_8^{2-}] + k_b[S_2O_8^{2-}]^{3/2} \quad (8)$$

where $k_a=k_1+k_2[H^+]$ and $k_b=k_4(k_1/k_5)^{1/2}$.
The first term on the right-hand side of Eq. 7 corresponds to the termal decomposition of the peroxodisulfate ion itself, and it is, except in a stlongly acidic

solution, much smaller than the second term (*e. g.*, see Fig. 1). When the first term on the right-hand side of Eq. 7 is negligible. Eqs. 9 and 10 are derived:

$$-\mathrm{d}[S_2O_8^{2-}]/\mathrm{d}t = k_b[S_2O_8^{2-}]^{3/2} \quad (9)$$

By integrating Eq. 9, we obtain:

$$\frac{1}{\sqrt{[S_2O_8^{2-}]}} = \frac{k_b}{2}t + \frac{1}{\sqrt{[S_2O_8^{2-}]_i}} \quad (10)$$

It may be seen from Fig. 3 that the relationship of Eq. 10 is experimentally satisfied, the slope in the plot of $[S_2O_8^{2-}]^{1/2}$ *vs.* t being unaffected by the initial concentrations of both the thallium(I) ion and the peroxodisulfate ion. The slight deviation from the straight line might be attributable to the first term of $k_a[S_2O_8^{2-}]$ in Eq. 7.

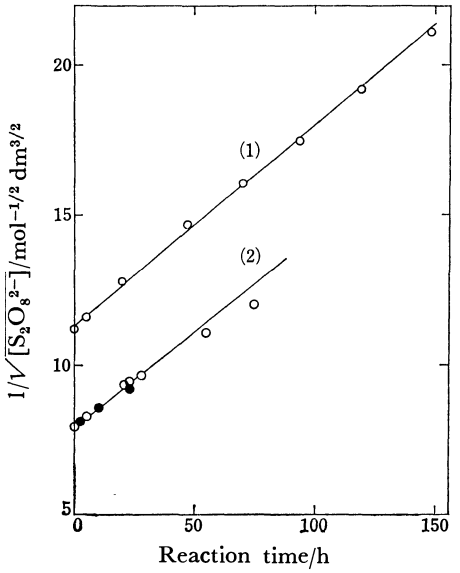

Fig. 3. Plot of $[S_2O_8^{2-}]^{-1/2}$ *vs.* t.
Conditions for line 1 are the same as in *a*) of Table 1 and those of line 2 are 1.6×10^{-2} mol dm^{-3} in potassium peroxodisulfate, 8.0×10^{-3} mol dm^{-3} in thallium(I) perchlorate for the plot ○, and 4.0×10^{-3} mol dm^{-3} in thallium(I) perchlorate for the plot ●. The other conditions are the same as in line 1.

The fact that the concentrations of the peroxodisulfate ion disappearing were larger than those of thallium(I) disappearing in Table 1 is due to the non-radical decomposition of the peroxodisulfate ion of Eq. 2. Thus, Eq. 7 is larger by the $k_2[H^+]\,[S_2O_8^{2-}]$ than Eq. 8. Reaction 3 is a reaction between the thallium(I) ion and the $SO_4^{\cdot-}$ radical. Therefore, when the thallium(I) ion concentration is extremely low, the rate of the whole reaction is controlled by Reaction 3, the rate being dependent on the thallium(I)-ion concentrations. This could, in practice, be observed at concentartions smaller than 2.0×10^{-3} mol dm^{-3} of thallium(I) (Fig. 1). Since the rate of Reaction 3 becomes slow at such low concentrations of the thallium(I) ion, Reactions 11 to 14 may occur together with Reactions 1 to 5, the reactions competing with each other:

$$H_2O + SO_4^{\cdot-} \rightleftharpoons HSO_4^- + OH\cdot \quad (11)^{10,16}$$

$$Tl(I) + OH\cdot \longrightarrow Tl(II) + OH^- \quad (12)^{15}$$

$$Tl(II) + OH\cdot \longrightarrow Tl(III) + OH^- \quad (13)$$

$$Tl(II) + SO_4^{\cdot-} \longrightarrow Tl(III) + SO_4^{2-} \quad (14)$$

The reaction mechanism at low concentrations of the thallium(I) ion is thought to be basically equivalent to that at the higher concentrations of the thallium(I) ion. When the thallium(I) ion concentrations were so high that Reaction 3 could be fast enough, Reactions 11 and 14, and accordingly all the reactions from 11 to 14, would be eliminated from the reaction scheme because the concentrations of $SO_4^{\cdot-}$ at the steady states are extremely low under such conditions. The strong inhibiting effect of acrylonitrile on the reaction rate, with a production of polyacrylonitrile, indicates that the chain-reaction mechanism is initiated by a radical. The inhibiting effect of the cerium(III) ion is due to the competitive reactions, 15 and 16, with Reactions 3, 4, and 5:

$$Ce(III) + SO_4^{\cdot-} \xrightarrow{k_{15}} Ce(IV) + SO_4^{2-} \quad (15)^{17}$$

$$Ce(III) + Tl(II) \underset{k_{-16}}{\overset{k_{16}}{\rightleftharpoons}} Ce(IV) + Tl(I) \quad (16)^{18}$$

Since the chain reaction in 4.0×10^{-3} mol dm^{-3} thallium(I) was completely inhibited by the addition of 5×10^{-6} mol dm^{-3} cerium(III), the rates of Reactions 15 and 16 are thought to be much faster than those of Reactions 3 and 4. The standard reduction potentials for the $Tl^{2+}+e^-\rightleftharpoons Tl^+$ and $Ce^{4+}+e^-\rightleftharpoons Ce^{3+}$ are 2.22 V[14] and 1.61 V[19] respectively at 25 °C. Therefore, Reaction 16 occurs very much towards the right, with an equilibrium constant of $\log K_{16}=10.9$. Thus, the rate constant k_{16} is estimated to be 9×10^5 dm^3 mol^{-1} s^{-1} by using the equilibrium constant with $k_{-16}=4.7\times10^{-5}$ dm^3 mol^{-1} s^{-1} at 50 °C.[18] The k_{16} value estimated is some hundreds times larger than the k_4 value. The cerium(IV) ion was also a strong retarder of the reaction between peroxodisulfate and thallium(I) ions. The inhibiting effect of the cerium(IV) ion is attributable to the occurrence of Reaction 17, which can be followed by Reactions 15 and 16:

$$Ce(IV) + Tl(II) \rightleftharpoons Ce(III) + Tl(III) \quad (17)$$

Since the standard reduction potential for the reaction of $Tl^{3+}+e^-\rightleftharpoons Tl^{2+}$ is 0.33 ± 0.05 V[14] at 25 °C, Reaction 17 occurs towards the extreme right-hand side, with an equilibrium constant of $\log K_{17}=21.7$. Tetranitromethane is an excellent electron-acceptor. Therefore, the inhibiting effect of tetranitromethane is attributable to the occurrence of Reaction 18, which competes with Reactions 4 and 5:

$$Tl(II) + C(NO_2)_4 \xrightarrow{k_{18}} Tl(III) + C(NO_2)_3^- + NO_2 \quad (18)$$

$k_{18} = 4\times10^8$ dm^3 mol^{-1} s^{-1} at pH 8—9[13]

The acceleration effect of the iron(III) ion could be due to the occurrence of Reactions 19, 20, and 21:

$$Tl(II) + Fe(III) \underset{k_{-19}}{\overset{k_{19}}{\rightleftharpoons}} Tl(III) + Fe(II) \quad (19)$$

$$Tl(II) + Fe(II) \xrightarrow{k_{20}} Tl(I) + Fe(III) \quad (20)$$

$$S_2O_8^{2-} + Fe(II) \xrightarrow{k_{21}} Fe(III) + SO_4^{\cdot-} + SO_4^{2-} \quad (21)$$

Schwarz *et al.*[11] reported the k_{19}, k_{-19}, and k_{20} to be 3.4×10^5, 0.0139, and 6.7×10^6 dm^3 mol^{-1} s^{-1} respectively in 1 mol dm^{-3} perchloric acid at 23 °C . The forward reactions of Eqs. 19 and 20 are competitive with Reactions 4 and 5. The rate constant k_{21} at 25 °C is 141 dm^3 mol^{-1} s^{-1} [20] and 25 dm^3 mol^{-1} s^{-1} [21] at an ionic strength of zero and 0.1 mol dm^{-3} respectively. Thus, the k_{21} value is somewhat smaller than the k_4 in Table 4. Nevertheless, the iron(III) ion greatly accelerated the reaction between peroxodisulfate and thallium(I) ions. By the addition of the iron(III) ion, the chain reaction may be carried out by Reactions 3, 4, 19, and 21, the chain termination being Reaction 20 in place of Reaction 5. The occurrence of Reactions 19 and 21, accompanied by the diminution in the termination Reaction 5, is thought to be a probable cause of the acceleration effect of the iron(III) ion. In the presence of the copper(II) ion, the equilibrium Reaction 22 will hold.

$$Tl(II) + Cu(II) \rightleftharpoons Tl(III) + Cu(I) \quad (22)$$

The equilibrium of Eq. 22 occurs towards the extremely left-hand side, with an equilibrium constant of log $K_{22}=-3$, the value being calculated by means of the redox potentials of 0.33 V[14] and 0.153 V[19] for the Tl^{3+}/Tl^{2+} and Cu^{2+}/Cu^{+} couples respectively. The rate constant for the reaction of $S_2O_8^{2-}+Cu(I)\rightarrow Cu(II)+SO_4^{\cdot-}+SO_4^{2-}$ has been reported to be 1.4×10^3 dm^3 mol^{-1} s^{-1} in 1 mol dm^{-3} KCl at 25 °C:[22] the value is almost the same magnitude as the k_4 values. The two conclusions above lead to the conclusion that the copper(II) ion could not be an effective accelerator for the reaction between peroxodisulfate and thallium(I) ions. The rate of the reaction between peroxodisulfate and thallium(I) ions decreased with an increase in the acidity in the reacting solution, whereas the rate of the thermal decomposition of the peroxodisulfate ion increased with an increase in the acidity (Table 4). Considering the relationship of Eq. 7, equation 23 may be assumed:

$$V_i = V_i' + k_b[S_2O_8^{2-}]_i^{3/2} \quad (23)$$

where V_i and V_i' indicate the initial rate of the disappearance of the peroxodisulfate ion in the presence and in the absence of the thallium(I) ion respectively. Equation 23 is satisfied, at least for the initial stages of reactions. The values of k_b and k_4 in Tables 4 and 6 where estimated by using Eq. 23 with the relatioship of $k_b=k_4(k_1/k_5)^{1/2}$. The pH dependence of k_4 may be attributable to the simultaneous reactions of $Tl^{2+}(aq)$ and $Tl(OH)^+$ with the peroxodisulfate ion.

$$S_2O_8^{2-} + Tl^{2+}(aq) \xrightarrow{k_{4a}} Tl(III) + SO_4^{\cdot-} + SO_4^{2-} \quad (4a)$$

$$S_2O_8^{2-} + TlOH^+ \xrightarrow{k_{4b}} Tl(III) + SO_4^{\cdot-} + SO_4^{2-} \quad (4b)$$

where Tl(III) indicates all the thallium(III) ions of the aquated and hydroxo species. The k_4 is described as:

$$k_4 = \frac{k_{4a}[H^+] + k_{4b}K_{TlOH}}{[H^+]+K_{TlOH}} \quad (24)$$

where $K_{TlOH}=[TlOH^+][H^+]/[Tl^{2+}(aq)]$.

Since K_{TlOH} is 3×10^{-5} mol dm^{-3} at 25 °C, Eq. 25 will be satisfied at concentrations larger than 3×10^{-3} mol dm^{-3} of $[H^+]$.

$$k_4 = k_{4a} + k_{4b}K_{TlOH}[H^+]^{-1} \quad (25)$$

The plot of k_4 *vs.* $[H^+]^{-1}$ showed a straight line, as in Fig. 4. The k_{4a} and k_{4b} were obtained as 250 and 9×10^5 dm^3 mol^{-1} s^{-1} from the intercept and the slope respectively. Thus, at a hydrogen-ion concentration of 0.01 mol dm^{-3}, 92% of k_4 corresponds to the second term of Eq. 25. The plot of k_4 *vs.* $[H^+]^{-1}$ greatly deviated from the linear line in the more alkaline region; thus, the $Tl(OH)_2$ species participated in the reaction.

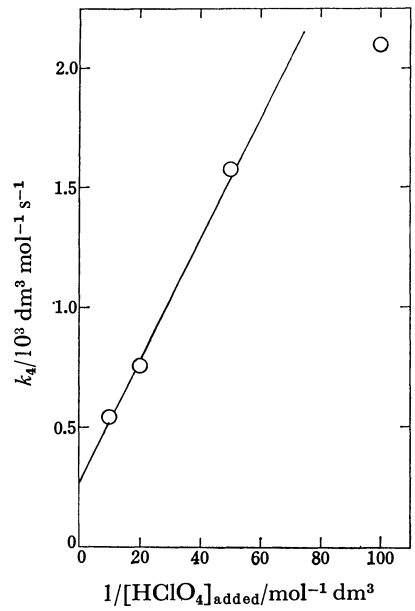

Fig. 4. Plot of k_4 *vs.* $1/[HClO_4]_{added}$ (Eq. 25). Conditions as in Table 4.

It should be noted here that the pH dependence of k_5 is so small as to be constant at hydrogen-ion concentrations over the range from 0.001 to 0.1 mol dm^{-3}. By the same treatments as used for the k_4 values, the following equations are obtained:

$$Tl^{2+}(aq) + Tl^{2+}(aq) \xrightarrow{k_{5a}} Tl(I) + Tl(III) \quad (5a)$$

$$Tl^{2+}(aq) + TlOH^+ \xrightarrow{k_{5b}} Tl(I) + Tl(III) \quad (5b)$$

$$k_5 = k_{5a} + k_{5b}K_{TlOH}[H^+]^{-1} \quad (26)$$

The k_5 at 25 °C is 3.0×10^9 dm^3 mol^{-1} s^{-1} at pH 5.6[13] and 5.2×10^8 dm^3 mol^{-1} s^{-1} at 0.1 mol dm^{-3} of $[H^+]$.[14] Thus, Eq. 26 is written as Eq. 27:

$$k_5 = 5.2\times10^8 + 6.2\times10^3[H^+]^{-1} \quad (27)$$

Equation 27 indicates that the k_5 is actually constant at hydrogen-ion concentrations larger than 6×10^{-4} mol dm^{-3}. Falcinella *et al.*[14] have reported that the k_5 value was independent of the acid concentrations over the range from 0.1 to 1.0 mol dm^{-3} and was slightly dependent on the temperature with an activation free energy, ΔG_5^*, of 7.9 ± 1.5 kJ mol^{-1}. From the temperature dependences for k_1 and k_b shown in Tables 5 and 6, the activation energies,

E_1 and E_b, derived from an Arrhenius plot were 157 and 108 kJ mol^{-1} respectively. Thus, the value of E_4 is obtained as 33 kJ mol^{-1} by the relationship of $E_b=E_4+(E_1-E_5)/2$.

Although Reaction 1 is not sensitive to the ionic strength, the k_4 and k_5 values are probably dependent on the ionic strength, because Reactions 4 and 5 are reactions between two ions of unlike and like signs. Thus, the k_b value which is composed of $k_4(k_1/k_5)^{1/2}$ may be thought to be largely dependent on the ionic strength. However, the ionic-strength dependence on k_b was not very large: the slope value for the plot of log k_b *vs.* $\mu^{1/2}$ was -1.05, an almost equivalent to the case of the reaction between two univalent-ions of unlike signs expected for the equation of log $k=\log k_0+1.02\ Z_-Z_+\ \mu^{1/2}$. As has been mentioned already, the k_{4b} term in Eq. 25 was calculated to be 92% of k_4 under the condition of a hydrogen-ion concentration of 0.01 mol dm^{-3}, this condition being the same as in the experiments for the ionic-strength dependence. Thus, the effective charges of the thallium(II) ion may be close to unity, smaller effective charges may cause the smaller dependence of the k_b on the ionic strength.

In a subscquent paper the reaction between thallium(I) and peroxodisulfate in alkaline solution will be discussed.

Kinetic Studies of the Electron Transfer Reactions in Iron(II) and Iron(III) Systems. IX. Electron Transfer Reactions between Iron(II) and Iron(III) in Water Mixed with Ethanol, 1-Propanol, Ethylene Glycol, Glycerol, and Pentaerythritol

Goro WADA,* Youko OHTA, Sachiko HAYASHIDA, Harumi SUGINO, Toyomi MIZUI, and Yumiko AIHARA

Department of Chemistry, Faculty of Science, Nara Women's University, Nara 630

(Received August 9, 1979)

The rate constants of the electron transfer reactions between Fe(II) and Fe(III) were determined in mixed solvents of water and alcohols, such as ethanol, 1-propanol, ethylene glycol, glycerol, and pentaerythritol. From the acid concentration dependence of the rate, the predominant path of the reaction was estimated to be Fe^{2+}-$Fe(OH)^{2+}$ path with a rate constant k_H. The rate constant k_H increases with increase in the mole fraction x of ethanol and 1-propanol, and decreases with increase in x of methanol, ethylene glycol, glycerol, and pentaerythritol. A straight line is obtained when $\ln k_H$ is plotted against the reciprocal dielectric constant D^{-1} of the mixed solvents for the latter group of alcohols. From the slope of the straight line the distance between Fe^{2+} and $Fe(OH)^{2+}$ is estimated to be 7.8 Å at the intermediate stage of the reaction. Therefore, the reaction is mostly controlled by the electrostatic repulsive force, being influenced by D of the mixed solvents.

The electron transfer reactions between iron(II) and iron(III) in aqueous media proceed by a mechanism of hydrogen-atom transfer in the absence of catalyzing ligands which would make the reactions occur by either inner-sphere or outer-sphere mechanism.[1] In the hydrogen-atom transfer mechanism, an electron is transferred by a hydrogen atom, which can be regarded to behave as a proton carrying an electron, along a chain of hydrogen bondings between OH radicals of water or alcohol, with the oxidant and the reductant species at both ends.

If a foreign substance is added to the reaction system and the chain of hydrogen bondings is broken to some extent, the reactions by this mechanism would be retarded, causing a slowering of the reaction rate. This is what happens when substances such as nitromethane,[2] and some alcohols[3,4] are added. The effect of addition of methanol to the reaction system of the electron transfer between iron(II) and iron(III) was investigated in aqueous solutions.[5] In the present investigation, alcohols other than methanol, such as ethanol, 1-propanol, ethylene glycol, glycerol, and pentaerythritol were used for the purpose of clarifying the influence of the number of OH groups, the hydrophobicity of alkyl groups and the dielectric constants of the alcohols on the reaction rates, and confirming the reaction mechanism. The experimental results are discussed including data of the case of methanol.

Experimental

Materials. Alcohols of specially pure grade were purified as follows: ethanol and 1-propanol were redistilled under ordinary pressure, ethylene glycol and glycerol were redistilled under reduced pressures, and pentaerythritol was twice recrystallized from its aqueous solution. The method of preparation and purification of other materials used were the same as those already reported.[5,6]

Procedures. The hydrolysis constants of Fe^{3+} ion, $K_H=[Fe(OH)^{2+}][H^+]/[Fe^{3+}]$ and the rate constants of the electron transfer reaction, k, in mixed solvents of water and alcohols were determined in the same manner as reported.[5-7] The ionic association between Fe^{3+} ion and ClO_4^- ion was also checked in mixed solvents.[5] For the determination of optical densities, a Hitachi-Perkin-Elmer UV-VIS spectrophotometer Model 139 was used. The ionic strengths of the solutions were adjusted at 0.5 M by use of $NaClO_4$.

Results and Discussion

Hydrolysis Constants of Fe^{3+} Ion, K_H, in Mixed Solvents. In an aqueous solution containing iron(III) perchlorate and perchloric acid, Fe^{3+}_{aq} is partly hydrolyzed to $Fe(OH)^{2+}$ with a hydrolysis constant $K_H=[Fe(OH)^{2+}][H^+]/[Fe^{3+}]$, the following relation being established:[5]

$$\frac{[Fe(III)]}{A_H}=\frac{1}{\varepsilon_H}+\frac{[H^+]}{\varepsilon_H K_H} \quad (1)$$

where ε_H and A_H denote the molar absorption coefficient of $Fe(OH)^{2+}$ and the optical density due to $Fe(OH)^{2+}$ being equal to $\varepsilon_H[Fe(OH)^{2+}]$, respectively. [Fe(III)] and $[H^+]$ are the total concentration of iron(III) which is equal to the sum of $[Fe^{3+}]$ and $[Fe(OH)^{2+}]$ and the concentration of hydrogen ion which is also equal to the sum of the total concentration of perchloric acid added $[HClO_4]$ and the concentration of hydrolyzed species of iron(III), $[Fe(OH)^{2+}]$, respectively. The plot of $[Fe(III)]/A_H$ against $[H^+]$ would give a straight line with an intercept $1/\varepsilon_H$ and a slope $1/\varepsilon_H K_H$. First, the total optical density of the solution A was used instead of A_H, not known empirically, in order to obtain an approximate K_H, and the precise value of K_H could be obtained by means of successive approximations.

In order to determine A_H necessary for Eq. 1, the value of the molar absorption coefficient of Fe^{3+}, ε_0, should be known, since A_H has to be calculated by an equation $A_H=A-\varepsilon_0[Fe^{3+}]$. When acid concentration is varied from 0.01 M to 4 M, the apparent molar absorption coefficient $\varepsilon(=A/[Fe(III)])$ decreases abruptly, passes a broad minimum, and then increases approximately linearly. An example is shown in Fig. 1, for the case of 1-propanol, the curves being quite similar to the case of methanol.[5] The abrupt di-

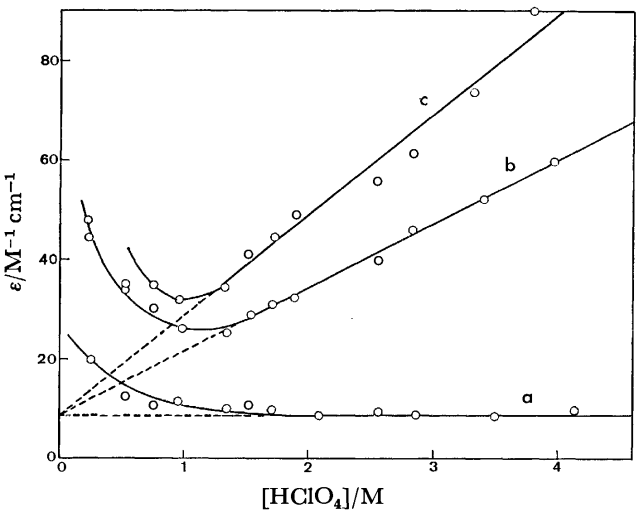

Fig. 1. Variation in apparent absorption coefficient ε of 1-propanol and water mixtures with perchloric acid concentration at $[Fe(III)]=1.5\times10^{-3}$ M, 330 nm, and 25 °C.
a: $x=0$, b: $x=0.10$, c: $x=0.18$.

minution of ε in the lower acid concentration range is due to the decrease in the concentration of hydrolyzed species of $Fe^{3+}{}_{aq}$, since ε_H is much larger than ε_0. On the other hand, the growth of ε in the higher acid concentration range is due to ionic association between Fe^{3+} and ClO_4^- ions, which does not occur in the absence of alcohol, this being observed more markedly at higher mole fraction of alcohol. Thus, ε is expressed by

$$\varepsilon=\frac{\varepsilon_0+\varepsilon_H K_H[H^+]^{-1}+\varepsilon_a K_a[H^+]}{1+K_H[H^+]^{-1}+K_a[H^+]}, \qquad (2)$$

where ε_a and K_a are the molar absorption coefficient and the formation constant of ion-pair, respectively.[5]

If the linear part of a curve is extended to $[HClO_4]=0$ the intercept of the extended straight line would give the value of ε_0 in the alcoholic solution. According to the extrapolation (broken lines in Fig. 1), ε_0 seems to have a constant value independent of the mole fraction of alcohol. In the cases of polyhydric alcohols, however, convergence to a common intercept does not generally take place; ε_0 seems to increase gradually with the increase in x. This might be due to the partial solvation of alcohol molecules into the hydration sphere of iron(III). At any rate, the ε_0 values estimated by this back extrapolation of the curves of ε against acid concentration were used for the calculation of A_H. In the present investigation, the acid concentration was so small that the occurrence of ion-pair formation was ignored.

The linearity of A_H^{-1} *vs.* $[H^+]$ is shown at constant $[Fe(III)]=1.0\times10^{-4}$ M at various mole fractions x of ethanol in Fig. 2. The values of K_H thus obtained are given in Table 1 for various mole fractions of alcohols. The value of K_H increases with the increase in x for all the alcohols studied.[5]

The Rate of Electron Transfer Reaction. The reaction proceeds with an apparent second-order rate constant k_{app} according to McKay's equation[8]

	0.00542	—	5.1	1.2

$$k_{app}=\frac{0.693}{([Fe(II)]+[Fe(III)])t_{1/2}} \qquad (3)$$

where $t_{1/2}$ represents the half period of the reaction,

which can be determined from the slope of a straight line obtained by plotting logarithms of the radioactivities caused by one of the reacting species against the reaction time. The variations of k_{app} in mixed solvents at various mole fractions of various alcohols are shown in Figs. 3—7. In the cases of ethanol (Fig. 3) and 1-propanol (Fig. 4), k_{app} increases with increase in x, contrary to the case of methanol,[5] in which k_{app} remains constant in the biginning, decreasing gradually with increase in x. In the cases of ethylene glycol (Fig. 5) and glycerol (Fig. 6), k_{app} first increases in a similar way to the cases of ethanol and 1-propanol, but then decreases. In the case of pentaerythritol (Fig. 7), k_{app} remains almost unchanged as far as its solubility in water permits the experiments. In all the measurements of k_{app} (Figs. 3—7), the values of k_{app} are always larger at lower acid concentrations.

Reaction Paths. Iron(III) might take part in the electron transfer reactions in two forms such as Fe^{3+}_{aq} and $Fe(OH)^{2+}$, the latter being produced in

a greater amount in lower acid concentrations. The main reaction paths are considered to be as follows:

$$Fe^{2+} + {}^*Fe^{3+} \longrightarrow Fe^{3+} + {}^*Fe^{2+} \quad (k_0) \quad (4)$$

$$Fe^{2+} + {}^*Fe(OH)^{2+} \longrightarrow Fe(OH)^{2+} + {}^*Fe^{2+} \quad (k_H) \quad (5)$$

When the respective rate constants of Paths 4 and 5 are denoted by k_0 and k_H, the apparent second-order rate constant of the electron transfer reaction would be given by[5]

$$k_{app} = \frac{k_0 + k_H K_H [H^+]^{-1}}{1 + K_H [H^+]^{-1}}. \quad (6)$$

In order to confirm the mechanism, the values of $k_{app}(1+K_H[H^+]^{-1})$ were plotted against $[H^+]^{-1}$, linearity being obtained in each case. An example is shown in Fig. 8, where ethanol is adopted as a cosolvent in the $[H^+]$ range 0.03—0.3 M. The values of k_0 and $k_H K_H$ were obtained from the intercepts and the slopes. By using the values of K_H listed in Table 1, the values of k_H were obtained. The values of k_0 are usually very small and, consequently, inaccurate as compared with those of k_H. Therefore, the reaction rate via Path 5 is overwhelmingly greater than that via Path 4, except for the case in which very high acid concentration was used. The following discussion is thus restricted to Path 5.

The variation of k_H with x of various alcohols is shown in Fig. 9, along with that of methanol.[5] The k_H value decreases with increase in x of individual alcohol, the order of the depression effect being methanol<ethylene glycol<glycerol<pentaerythritol, in line with the order mono-<di-<tri-<tetra-hydric alcohols; k_H increases with increase in x in the cases of ethanol and 1-propanol.

Discussion. Both K_H and k_H vary with x (Table 1 and Fig. 9). However, when their logarithms are plotted against the reciprocals of dielectric constants of the mixed solvents,[9] the points lie on a straight line independent of the kind of alcohol with a positive and a negative slope corresponding to the plots of ln K_H and ln k_H respectively (Figs. 10 and 11). There are two exceptions: ethanol and 1-propanol. They give another straight line in Fig. 10 and deviate a great deal from linearity in Fig. 11.

Except for the cases of ethanol and 1-propanol,

the fact that the plots of ln K_H and ln k_H *vs.* D^{-1} lie on a straight line indicates that both the hydrolysis reaction $Fe^{3+} \rightleftharpoons Fe(OH)^{2+} + H^+$ and Path 5 in the electron transfer reaction $Fe^{2+} + Fe(OH)^{2+} \rightarrow Fe(OH)^{2+} + Fe^{2+}$ are mostly influenced by electrostatic repulsion between the ions of the same sign, $Fe(OH)^{2+}$ and H^+, and Fe^{2+} and $Fe(OH)^{2+}$ respectively, in mixed solvents of different dielectric constants. According to Scatchard, these linear correlations are expressed by[10]

$$\ln K_H = \ln K_H^\circ + \frac{Z_A Z_B e^2}{kTd_H D}, \quad (7)$$

$$\ln k_H = \ln k_H^\circ - \frac{Z_C Z_D e^2}{kTd_{Fe} D}, \quad (8)$$

where Z_A, Z_B, Z_C, and Z_D are the numbers of electric charges on the reacting ions, e the elementary electric charge, k the Boltzmann constant, D the dielectric constant of the mixed solvents, and d_H and d_{Fe} the distances of the closest approach between the two reacting ions in the intermediate states during the course of hydrolysis and the electron transfer, respectively. K_H° and k_H° are hypothetical constants in solvents of infinite dielectric constant.

In the case of the hydrolysis, the reaction is the separation of an ion into two ions, $Fe(OH)^{2+}$ and H^+, bearing electric charges $Z_A=+2$ and $Z_B=+1$, while the electron transfer reaction of Path 5 is a collisional encounter of two ions, Fe^{2+} and $Fe(OH)^{2+}$, of $Z_C=Z_D=+2$. From the slopes of the straight lines in Figs. 10 and 11, we obtain the values $d_H=2.1$ Å and $d_{Fe}=7.8$ Å. By taking the approximate values of ionic radii $r(Fe^{2+})=0.8$ Å and $r(Fe^{3+})=0.7$ Å, and of molecular diameter $d(H_2O)=3.0$ Å into account, the values of d_H and d_{Fe} obtained are reasonable, since the intermediate approach in the former reaction might be the direct contact of two ions to each other with d_H nearly equal to the sum of $r(Fe^{3+})$ and $d(H_2O)$, while that in the latter reaction might be the outer-sphere contact of the two with d_{Fe} nearly equal to $r(Fe^{2+})+r(Fe^{3+})+2d(H_2O)$, which would support the plausibility of hydrogen-atom-transfer mechanism between aqua- and hydrolyzed-iron ions.†

The abnormal behavior of k_H observed in the cases of ethanol and 1-propanol has not been clarified. It might be related to the hydrophobicity of alkyl groups in alcohol molecules. The hydrophobic groups would promote the ice-like structure of water surrounding them,[11,12] and increase the hydrogen bondings between water molecules, which would increase the rate of the hydrogen-atom-transfer mechanism, k_H.

† An approximate straight line is drawn on the points for ethanol and 1-propanol (broken line, Fig. 10). From the slope $d_H=8.8$ Å is obtained by use of Eq. 7. This seems to correspond to a distance of $r(Fe^{3+})+nd(H_2O)$, n being approximately equal to 2.7. The physical meanings of this apparent distance are not clear. The exceptional characteristics of K_H for these two alcohols would partly reflect on k_H for the same alcohols as the exceptional behavior.

Crystal and Molecular Structure of (Ethyl methacrylate)-bis(triphenylphosphine)nickel(0)

(Received August 30, 1979)

The crystal and molecular structure of (ethyl methacrylate)bis(triphenylphosphine)nickel, (CH_2=C(CH_3)-$COOC_2H_5$) $(PPh_3)_2Ni$, has been determined by single-crystal X-ray analysis. The crystals are monoclinic, space group $P2_1/c$, with unit-cell dimensions a=13.690(2), b=16.855(2), c=15.699(1)Å, β=105.09(1)°, and Z=4. The structure was solved by the heavy-atom method and refined by block-diagonal least-squares technique, using 4701 independent reflections, the final R value being 0.084 for $|F_o| \geq 3\sigma(F)$. The two phosphine ligands and the two olefinic carbon atoms comprise a distorted square-planar configuration about the Ni atom. The Ni–β-CH_2 bond (1.976(8)Å) is significantly shorter than the Ni–α-C bond (2.029(7)Å). The difference is explained by the contribution of polarized resonance structure in metal-olefin bonding.

Interaction of olefins with transition metals is of particular importance in organometallic and catalytic chemistry. Although extensive structural studies by X-ray analysis have been done on the group VIII transition metal complexes coordinated with olefins,[1-4] reports concerning nickel olefin complexes are rather limited, because of their thermal instability and high reactivity toward oxygen.[2-4] On the other hand, no report on the crystal structure of transition metal–α,β-unsaturated ester π complexes has been made to our knowledge[5] except for a Ru(0) complex with ethyl methacrylate, in which C–H oxidative addition of the ligand to Ru(0) has been found to give an unusual hydrido vinyl complex.[6]

We have studied the reactivities of zero valent nickel complexes with various vinyl compounds and found that the reaction of bis(1,5-cyclooctadiene)nickel with α,β-unsaturated ester (ethyl methacrylate, methyl methacrylate *etc.*) in the presence of tertiary phosphine ligands gives a convenient preparative method of various zerovalent nickel olefin complexes,[7] and the coordination through C=C bond has been postulated from the NMR and IR analyses and their chemical reactions.[8]

In order to get information concerning the bonding mode between nickel and α,β-unsaturated ester, an X-ray analysis of the (ethyl methacrylate)bis(triphenylphosphine)-nickel(0) crystal has been performed.

Experimental

(Ethyl methacrylate)bis(triphenylphosphine)nickel(0) was synthesized by the method previously reported.[7] A crystal suitable for X-ray diffraction, obtained by slow recrystallization from toluene at room temperature under nitrogen, was sealed in a capillary. Density of the crystal was determined by floatation in a mixture of CCl_4 and decalin. Data collection was carried out with a Rigaku computer-controlled four-circle diffractometer, using graphite-monochromated Cu $K\alpha$ radiation (λ=1.54178 Å) The unit-cell parameters were calculated with 37 high angle reflections. The crystallographic data are summarized in Table 1. Intensities were measured in ω-2θ scan mode with scan width of 1.5° (in ω) plus α_1-α_2 divergence at scan speed 4° (in 2θ) min^{-1}. Four reference reflections indicated no significant intensity variations throughout the experiment. Out of 4701 independent reflections in the range $5<2\theta<115°$, 362 weak reflections which gave the counts under background were considered as zero-reflections. The data were corrected for Lorentz and polarization factors but not for absorption effects. The standard deviation for each reflection was estimated by the equation, $\sigma^2(F)=\sigma_p^2+q|F_o|^2$, where σ_p is due to counting statistics and q is 4.39×10^{-6}, derived from the variation of the monitored reflections.

Structure Determination

The structure was solved by the heavy-atom method and the atomic parameters were refined by block-diagonal least-squares technique. The quantity minimized was $\sum w(|F_o|-|F_c|)^2$, with $w=1/\sigma^2(F)$. All the hydrogen atoms assigned on a difference map were included. The zero reflections were included in the least-squares calculation by assuming $|F_o|=F_{1lm}$ where F_{1lm} is 2.67, an observational threshold value, but those for which $|F_c|<F_{1lm}$ were omitted. The final R was 0.098 (R=0.084 for $|F_o|>3\sigma(F)$). The final atomic parameters are listed in Table 2.[9] Atomic scattering factors used were taken from International Tables for X-ray Crystallography.[10]

Table 2. Fractional coordinates ($\times 10^5$; for H, $\times 10^3$) and thermal parameters ($\times 10^4$(/Å^2); for H, $\times 10^3$(/Å^2))

The anisotropic temperature factor has the form: $\exp\{-2\pi^2(h^2a^{*2}U_{11}+k^2b^{*2}U_{22}+l^2c^{*2}U_{33}+2hka^*b^*U_{12}+2hla^*c^*U_{13}+2klb^*c^*U_{23})\}$. The isotropic temperature factor has the form: $\exp\{-(8\pi^2U)\sin^2\theta/\lambda^2\}$.

Results and Discussion

As shown in Fig. 1, the crystal structure consists of discrete molecules. All intermolecular contacts are normal, the shortest being 2.35 Å between H031 atoms related by the inversion center at (1,½, ½). Figure 2 shows a stereo view of the molecule. Tables 3 and 4 list the bond lengths and bond angles, respectively. All the C–C bond lengths and the C–C–C angles of the phenyl rings are normal, although some of these are contracted seemingly by the large thermal motion. The P–C bond distances and the Ni–P–C and C–P–C angles are comparable with those of the related compounds.[2-4]

As shown in Fig. 3, the nickel atom has a distorted square planar coordination of the two C and two P atoms, similar to the related Ni–ethylene complexes, $Ni(C_2H_4)L_2$.[2-4] Although the ethyl methacrylate molecule could coordinate in a variety of modes (*i.e.* through C=C, C=O, or both), only the carbon–carbon double bond has a linkage with the nickel atom, and the

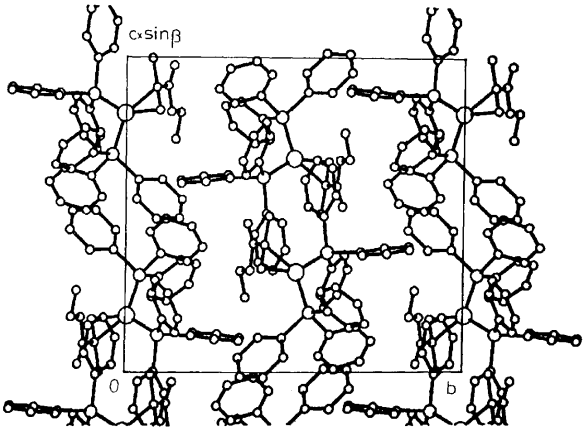

Fig. 1. Molecular packing projected along the a axis.

carbonyl group of the ester turns away from nickel. It seems to be reasonable that the C=C bond lies in the square coordination plane of zero valent metal olefin complex, M(olefin)L_2.[1b]

The coordination mode of ethyl methacrylate ligand mentioned above explains the NMR and IR results reasonably.[7] The large upfield shifts of olefinic protons and carbons in ^{1}H- and ^{13}C-NMR spectra are due to the strong interaction of nickel with the olefinic double bond. The absence of direct interaction between Ni and C=O group supports the slight shifts of ν(C=O) upon coordination.[7,8] The two methylene protons of the ethoxy group, H(51) and H(52), lie in the different circumstances, as indicated by ^{1}H-NMR spectra.[8]

The mean plane of the coordination is expressed by the equation, $0.8841X+0.4174Y+0.2101Z=13.322$ where X, Y, and Z are in Å taken along the directions a^*, b, and c, respectively. The deviations of atoms from the plane are −0.02 (Ni), −0.02 (P(1)), 0.03 (P(2)), 0.07 (C(1)), and −0.06 Å (C(2)). These slight but significant deviations are also described by the dihedral angle of 6.4(4)° between the planes through Ni, P(1), and P(2), and through Ni, C(1), and C(2). In the related Ni(0) and Pt(0) olefin complexes, the dihedral angles range from 1.3 to 18.5°.[2b] Such a twist may be mainly due to a steric effect between the bulky ligand molecules in addition to an electronic effect. The two Ni–P bond distances (2.173 Å and 2.187 Å), the P(1)–Ni–P(2) angle (111.29), the average of the Ni–C bond distances

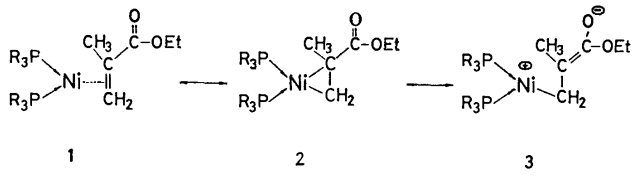

Fig. 4. Some possible resonance structures for (ethyl methacrylate)bis(triphenylphosphine)nickel.

(2.003 Å), and the C(1)–Ni–C(2) angle (41.3°) are comparable with those of the Ni–ethylene complex.[2a-b]

A closer examination, however, shows that the two Ni–C bonds are significantly different, the Ni–C(1) bond distance (1.976 Å) being shorter than Ni–C(2) bond distance (2.029 Å) (Figure 3). The C(1)=C(2) bond is lengthened, whereas the C(2)–C(4) bond is shortened from the normal distances (1.36 Å for C=C and 1.44 Å for C–C in C=C–C=O system)[12]. Although the C(4)–O(1) distance is contracted apparently due to the large thermal motion, a value corrected by the riding model[13] is 1.231 Å. These distances are interpreted by the contribution from three-membered metallacycle **2** and polarized structure **3**, in addition to **1** (see Figure 4)†. This scheme is consistent with the observation in ^{13}C-NMR spectra, that the chemical shift of C(1) varies to a higher field more significantly than that of C(2) with increasing the σ-donor property of tertiary phosphine ligands.[8] In addition the steric effect of the two substituents (methyl and ethoxycarbonyl) attached to C(2) and the two bulky triphenylphosphine ligands may facilitate the unequal coordination mentioned above. These two substituents are bent back away from nickel: the deviation of C(2) from the plane of C(1), C(3), and C(4) is 0.195 Å.

† Similar ionic contribution has been reported by Ibers *et al.* for a platinum(0) 1,1-dichloro-2,2-dicyanoethylene complex.[11] On the contrary, olefin shift to maximize the metal–olefin bond is postulated for Ni-acrylonitrile bond.[3] In the present complex a similar sliding of the olefin along the C=C bond is observed

This geometry suggests an increase of sp^3 character of C(1) and C(2).††

The Ni–P(2) distance is slightly longer than that of Ni–P(1) probably owing to the trans influence of closer C(1) to Ni than C(2).

Figure 1 was drawn by TSD:XTAL which is an interactive modeling program system for computer graphics.[14]

Circular Dichroism Spectra and Their Relation to Asymmetric Distortion of Some Dimeric Molybdenum(V) Complexes Containing Optically Active Amino Carboxylate

Kimiko Z. Suzuki, Yoichi Sasaki,* Shun'ichiro Ooi,† and Kazuo Saito

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

† *Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558*

(Received September 1, 1979)

Circular dichroism (CD) spectra of fifteen kinds of μ-X-μ-Y-bis(oxomolybdenum(V)) complexes, where X=Y=O, X=O and Y=S, and X=Y=S, containing optically active ligands such as (*S*)-cysteinate, its alkyl esters, (*R*)-penicillaminate (*R*-pen), (*S*)-histidinate, and (*R*)-propylenediaminetetraacetate, give two distinctive peaks with opposite signs at *ca.* 26000 and 33000 cm^{-1} in various media including KBr disks. Close examination of the known X-ray structural data of eight complexes indicated that the pseudo-octahedral coordination sphere of two molybdenum(V) ions are asymmetrically twisted around the Mo–Mo axis. The direction of such a twist for the complexes containing the ester ligands and *R*-pen, is opposite to that for the complexes with other ligands. The former and latter complexes give positive and negative, and negative and positive CD peaks at *ca.* 26000 and 33000 cm^{-1}, respectively. Thus the CD signs of the two peaks are related to the asymmetric distortion around the Mo–Mo axis.

Deviation of coordinated atoms from regular octahedron can cause a considerable effect on the circular dichroism(CD) spectra. Such an influence was demonstrated by the crystallographic data of some cobalt (III) complexes, *e.g.* tris(1,2-cyclopentanediamine)cobalt(III),[1] and also by theoretical considerations.[2,3] However, only a few examples are found,[1–4] which are limited to cobalt(III) complexes, and complexes of Schiff's bases with asymmetric diimine moiety.

Molybdenum(V) complexes give doubly bridged binuclear complexes with a μ-X-μ-Y-bis(oxomolybdenum (V)) core, $Mo_2O_2XY^{2+}$ (where X=Y=O, X=O and Y=S, and X=Y=S), and coordination number 5 or 6 depending on the ligands.[5] Their crystal structure exhibits considerable distortion from regular square pyramid or octahedron.[5–13] Such distortions can be asymmetrical when the ligand is optically active. The X-ray structure of $[Mo_2O_4(S\text{-cys})_2]^{2-}$,[8] $[Mo_2O_4(S\text{-hist})_2]$,[9] $[Mo_2O_4(S\text{-mecys})_2]$,[10] $[Mo_2O_2S_2(S\text{-cys})_2]^{2-}$,[11] $[Mo_2O_2S_2(S\text{-hist})_2]$[12], and $[Mo_2O_2S_2(S\text{-etcys})_2]$,[13] where *S*-cys^{2-}, *S*-hist$^-$, *S*-mecys$^-$, and *S*-etcys$^-$ are (*S*)-cysteinate, (*S*)-histidinate, *O*-methyl- and *O*-ethyl-(*S*)-cysteinate, respectively, are schematically shown in Fig. 1a to 1c. They have chelate rings containing asymmetric carbon atoms at the basal edges. The complexes of *O*-alkyl-(*S*)-cysteinate give coordination number 5, whereas those of the others 6. We have examined carefully the crystallographic data of these complexes and found asymmetric distortions around the $Mo_2O_2XY^{2+}$ core.

We have also prepared three (*R*)-propylenediaminetetraacetate (*R*-pdta) complexes with di-μ-oxo,[14] μ-oxo-μ-thio, and di-μ-thio bridges and determined the X-ray structure (Fig. 1d).[15] These complexes have structurally different feature from the hitherto known carboxylate complexes, with asymmetric chelate ring bridging the molybdenum(V) ions across the two apical sites of the dimer. These *R*-pdta complexes also show considerable asymmetric distortions.

The CD and optical rotatory dispersion spectra (ORD) of molybdenum(V) complexes have been reported with only a limited variety of species[14,16–18] and their relation with the structure has not been discussed. We have measured CD spectra of various amino carboxylate and their ester complexes including those mentioned above in various media. We report here a remarkable correlation between the asymmetric distortion around the $Mo_2O_2XY^{2+}$ core and the CD pattern in the ultraviolet region. The CD studies also provide useful informations on the assignment of the electronic absorption bands of the doubly bridged molybdenum(V) complexes.

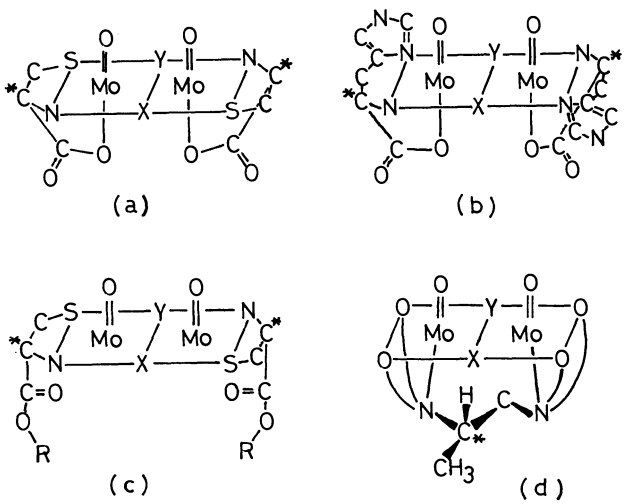

Fig. 1. Schematic drawings of the structure of $Mo_2O_2XY^{(2+)}$-type complexes (X=Y=O, X=O and Y=S, and X=Y=S). Asterisks indicate asymmetric carbons.
(a) $[Mo_2O_2XY(S\text{-cys})_2]^{2-}$, (b) $[Mo_2O_2XY(S\text{-hist})_2]$, (c) $[Mo_2O_2XY(S\text{-Rcys})_2]$ (R=CH_3 or C_2H_5), and (d) $[Mo_2O_2XY(R\text{-pdta})]^{2-}$.

Experimental

Preparation of the Complexes. The following seven complexes were prepared by the known methods; $Na_2[Mo_2O_4(S\text{-cys})_2]\cdot 5H_2O$,[19] $[Mo_2O_4(S\text{-hist})_2]\cdot 2H_2O$,[20] $[Mo_2O_4(S\text{-mecys})_2]$,[21] $[Mo_2O_4(S\text{-etcys})_2]$,[21] $Na_2[Mo_2O_4(R\text{-pdta})]\cdot 3H_2O$,[14,22] $Na_2[Mo_2O_3S(S\text{-cys})_2]\cdot 4H_2O$,[23] and $[Mo_2O_3S(S\text{-etcys})_2]$.[23]

The following three di-μ-thio-bis{oxomolybdenum(V)} complexes were prepared by modifying the methods in the literature.

Sodium di-μ-thio-bis[{(S)-cysteinato}oxomolybdate(V)] Tetrahydrate, $Na_2[Mo_2O_2S_2(S\text{-}cys)_2]\cdot 4H_2O$: A black solid was obtained by Mitchell's method,[19] which contained both soluble and insoluble components in *N,N*-dimethylformamide (DMF) (or dimethyl sulfoxide (DMSO)). The former seemed to be the expected complex. Insoluble component was not formed when the pH of the solution was adjusted carefully as follows. Hydrogen sulfide was slowly bubbled through 200 cm^3 of the solution of $Na_2[Mo_2O_4(S\text{-cys})_2]\cdot 5H_2O$ (2 g; 3 mmol) in water for 1 h, the pH of the solution being kept at *ca.* 7 by the addition of aqueous NaOH solution. The resulting reddish brown solution was evaporated to 25 cm^3 at 40 °C under a reduced pressure. Orange needles were collected after 3 days. Yield, 0.2 g. Found: C, 11.22; H, 2.71; N, 4.46%. Calcd for $C_6H_{18}N_2O_8S_4Na_2Mo_2$: C, 11.18; H, 2.82; N, 4.35%.

Di-μ-thio-bis[{(S)-histidinato}oxomolybdenum(V)] Dihydrate, $[Mo_2O_2S_2(S\text{-}hist)_2]\cdot 2H_2O$: The procedure reported by Spivack and Dori,[24] which involves the passage of H_2S through the aqueous solution of $[Mo_2O_4(S\text{-hist})_2]$, gave a black material, from which the pure complex was not obtained. The pure complex was prepared as follows. Sodium molybdate (2.4 g; 10 mmol) and (*S*)-histidine (1.6 g; 10 mmol) were dissolved in 100 cm^3 of water. Hydrogen sulfide was bubbled slowly through the solution for *ca.* 1 h, while 400 cm^3 of water was added in small portions. The reddish brown solution was purged with nitrogen gas to remove excessive H_2S, and evaporated in a rotary evaporator until yellow solid deposited, which was washed with water until the washing became colorless. The yield of yellow powder was 0.45 g. Found: C, 22.46; H, 2.93; N, 13.05%. Calcd for $C_{12}H_{20}N_6O_6S_2Mo_2$: C, 22.79; H, 3.19; N, 13.29%.

Di-μ-thio-bis[{O-methyl-(S)-cysteinato}oxomolybdenum(V)], $[Mo_2O_2S_2(S\text{-}mecys)_2]$: This was prepared by one of the three methods given by Mitchell,[19] from sodium molybdate (1.2 g, 5 mmol), (*S*)-cysteine methyl ester hydrochloride (3.4 g; 20 mmol) and H_2S. The crude product (0.6 g) was dissolved in acetonitrile, a small amount of insoluble materials was removed, and the solution was kept in air for two days. The brown precipitate was filtered off. Addition of methanol or water to the filtrate gave orange crystals. Found: C, 17.13; H, 2.82; N, 4.97%. Calcd for $C_8H_{16}N_2O_6S_4Mo_2$: C, 17.27; H, 2.90; N, 5.04%.

Five new complexes were prepared by the following methods. The data of elemental analysis and important infrared absorption bands of the new complexes are summarized in Table 1. Each complex shows characteristic infrared bands for its skeletal structure, $Mo_2O_2XY^{2+}$.[23,25]

Sodium di-μ-oxo-bis[{(R)-penicillaminato}oxomolybdate(V)] Dihydrate, $Na_2[Mo_2O_4(R\text{-}pen)_2]\cdot 2H_2O$: The complex ion, $[Mo_2O_4(R\text{-pen})_2]^{2-}$, was described previously,[26] but the preparation method has not yet been reported. Molybdenum pentachloride (3.1 g; 11 mmol) was dissolved in 25 cm^3 of 3 M (M=mol dm^{-3}) HCl. (*R*)-Penicillamine (5 g; 33 mmol) in 20 cm^3 of 3 M HCl was added to the solution. The pH was adjusted to 6—7 with 6 M NaOH, while the solution was cooled in an ice bath. Barium perchlorate (1.7 g; 5 mmol) in 20 cm^3 of water was added to the solution to give orange precipitate of $Ba[Mo_2O_4(R\text{-pen})_2]\cdot 3H_2O$. This barium salt (2.6 g) and a cation exchange regin Dowex 50W-X8 (Na^+-form, 120 cm^3) were stirred in 150 cm^3 of water for *ca.* 5 h. The regin was filtered off, and the filtrate was treated with ethanol (50 cm^3) to give orange precipitate (1.4 g). This was dissolved in a minimum amount of water and treated with acetonitrile to give first oily precipitate. The supernatant was removed by decantation and the oil was further treated with acetonitrile. Orange powder was collected and washed with acetonitrile and dried in air.

μ-Oxo-μ-thio-bis[{(S)-histidinato}oxomolybdenum(V)] Trihydrate, $[Mo_2O_3S(S\text{-}hist)_2]\cdot 3H_2O$: Hydrogen sulfide was bubbled slowly through the solution of molybdenum pentachloride (6.15 g; 23 mmol) in 100 cm^3 of 3 M HCl for *ca.* 2 h. The solution was purged with nitrogen gas to remove excessive H_2S, and a small quantity of brown solid was filtered off. (*S*)-Histidine (1.7 g; 11 mmol) was added to the filtrate. The pH was adjusted to *ca.* 6 with 8 M NaOH solution. Greenish brown precipitate was filtered off, and the filtrate was kept in an ice bath to give yellow crystals. They were dissolved in 50 cm^3 of 3 M HCl, and the pH was adjusted to *ca.* 6 with 8 M NaOH solution. The solution was filtered and kept in a refrigerator for 2 days to give yellow crystals.

μ-Oxo-μ-thio-bis[{O-methyl-(S)-cysteinato}oxomolybdenum(V)], $[Mo_2O_3S(S\text{-}mecys)_2]$: This was prepared by a similar method to that for the corresponding *S*-etcys complex.[23]

Sodium μ-oxo-μ-{(R)-propylenediaminetetraacetato}-μ-thio-bis{oxomolybdate(V)} Tetrahydrate, $Na_2[Mo_2O_3S(R\text{-}pdta)]\cdot 4H_2O$: The procedure for the preparation of $[Mo_2O_3S(S\text{-hist})_2]\cdot 3H_2O$ was followed until the addition of ligand. A solution of (*R*)-propylenediaminetetraacetic acid monohydrate[27] (2.8 g; 9 mmol) in 25 cm^3 of water was added to the molybdate solution, and the pH was adjusted to *ca.* 6 with 8 M NaOH solution. The solution was filtered to remove brown solid, and allowed to stand in a refrigerator for three days. A small quantity of black solid was removed, and the filtrate was evaporated to give first white solid, which was cooled in an ice-bath and filtered off, and then orange needles, which were recrystallized from water by adding ethanol.

Table 1. Elemental analysis and some infrared spectral data of the new compounds

Compound	Elemental analysis (%)			Infrared bands (cm^{-1})[a]		
	C Found(Calcd)	H Found(Calcd)	N Found(Calcd)	(Mo=O$_t$)	(Mo-O$_b$)	(Mo-S$_b$)[b]

a) For the definition of θ_1, θ_2, θ_3, θ_4, and ξ, see Fig. 4a. b) See Fig. 4c. c) Estimated standard deviations in parentheses. d) Values with asterisks are too small to be valid for the discussion in the text.

Yield, 0.2 g.

Sodium μ-{(R)-Propylenediaminetetraacetato}-di-μ-thio-bis{oxomolybdate(V)} Trihydrate, $Na_2[Mo_2O_2S_2(R\text{-pdta})]\cdot 3H_2O$: An aqueous solution (400 cm³) of sodium molybdate (2.7 g; 10 mmol) and (*R*)-propylenediaminetetraacetic acid monohydrate[27] (1.6 g; 5 mmol) was treated with H_2S slowly until the color turned red, and then with nitrogen to remove excessive H_2S. The solution was evaporated under a reduced pressure to 50 cm³ and kept in a refrigerator for a week to give orange crystals. Yield, 0.1 g.

The Aqua Complex Ions, $[Mo_2O_2XY(H_2O)_6]^{2+}$:[28] These ions were obtained in solution by dissolving the corresponding *S*-cys complexes in 2 M $HClO_4$. Complete disappearance of CD indicated complete loss of (*S*)-cysteinate ligand. The absorption spectra of the di-μ-oxo and di-μ-thio complexes were in reasonable agreement with those reported previously.[29,30] The spectrum of $[Mo_2O_3S(H_2O)_6]^{2+}$ is reported for the first time.

Measurements. All the measurements were carried out at room temperature. Electronic absorption and CD spectra of the complexes were measured in water, DMF and DMSO, whenever soluble, and also in KBr disks. The neutral complexes were insoluble in water. The spectra of *O*-alkyl-(*S*)-cysteinato complexes were measured in acetonitrile, too. The spectra in water were measured under nitrogen atmosphere; otherwise the spectra changed slowly.

The electronic absorption spectra were recorded on a Hitachi 323 Recording Spectrophotometer and a Hitachi 124 Spectrophotometer with a Hitachi Recorder QPD-34. The CD spectra were recorded on a JASCO J-40 Automatic Recording Spectropolarimeter, and a JASCO ORD-UV-5 Spectrophotometer with a CD attachment, for compounds either in solutions or in KBr disks. Nitrogen gas was passed through the cell compartment during the measurement in the KBr disk. The infrared absorption spectra were recorded on a JASCO IR-A1 and a JASCO IR-A2 Spectrophotometer in KBr disks. The PMR spectra were measured with a Varian T-60 Spectrometer in D_2O with sodium 3-(trimethylsilyl)propanesulfonate as an internal standard.

The torsion angles listed in Table 2 were calculated using the atomic coordinates given in the literature.[8,10-13,15] The details of positional parameters have not been found for $[Mo_2O_4(S\text{-hist})_2]$.[9]

Results and Discussion

In the following, the X-ray structures are closely examined, first. Then the nature of absorption bands and the corresponding CD bands are discussed. Finally, the correlation between the structure and the CD spectra is discussed.

Geometrical Isomerism of the Complexes. Several geometrical isomers are possible for the *S*-cys complex. We have fractionally crystallized the sodium salt of $[Mo_2O_4(S\text{-cys})_2]^{2-}$ from aqueous solution by adding ethanol slowly. Aqueous solutions of all the precipitates gave almost identical CD spectra. Thus either all the fractions contained the same geometrical isomer, or a rapid isomerization took place in aqueous solution to give an isomeric mixture with the same composition. The CD spectra of the crystalline complex in KBr disk and in aqueous solution show similar pattern (Fig. 2) in visible region to eliminate the latter possibility. The isomer illustrated in Fig. 1a should have been formed stereoselectively. All the other com-

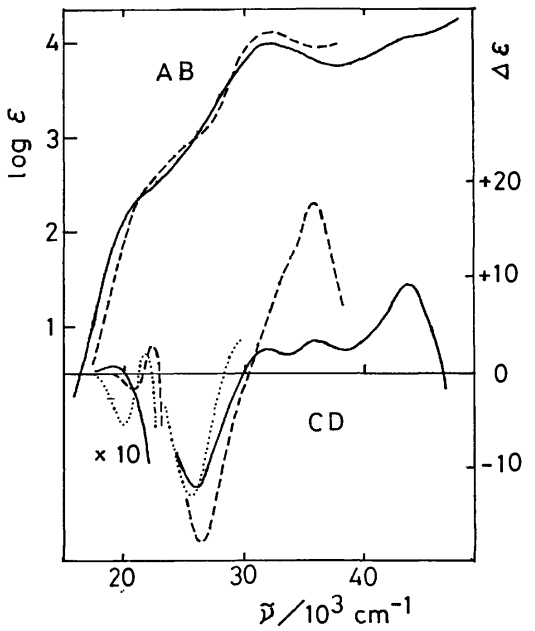

Fig. 2. Comparison in various media of absorption (AB) and CD spectra of $[Mo_2O_4(S\text{-cys})_2]^{2-}$; in water (——), in DMF (----), and in KBr disk (·····).

plexes of *S*-cys, its alkyl esters, *S*-hist and *R*-pen are believed to give the geometrical isomers in Fig. 1 exclusively.

The diamine part of the three *R*-pdta complexes is known to form a distorted λ gauche structure with the methyl group at equatorial direction.[15] The gauche structure of $[Mo_2O_4(pdta)]^{2-}$ was claimed to be fixed at 0—90 °C by the measurements of ^1H[31] and ^{13}C NMR spectra[32] in aqueous solution. Molecular model studies also indicated that the inversion of the gauche structure is difficult owing to the steric hindrance of methyl group with the oxide bridges.[31,32] We thus believe that the diamine part of all the three *R*-pdta complexes is fixed in aqueous solutions as found by X-ray crystallography.[15]

Two geometrical isomers are possible for $[Mo_2O_3S(R\text{-pdta})]^{2-}$ due to relative positions of the bridging oxo and sulfido ligands. The proton NMR spectrum of the complex in D_2O gave only one methyl signal (doublet), indicating only one isomer in the solution. Fractional crystallization failed to give any evidence for the existence of two isomers. The structure of stereoselectively formed isomer determined by X-ray diffraction method,[15] is shown in Fig. 1d.

Close Examination of the X-Ray Structures. Asymmetry caused by the arrangement of coordinated atoms around the $Mo_2O_2XY^{2+}$ core is considered first. A view of $[Mo_2O_4(R\text{-pdta})]^{2-}$ along the Mo–Mo axis (Fig. 3a, the axis perpendicular to the paper plane) clearly shows that the pseudo-octahedron of the molybdenum ion over the paper plane is rotated clockwise around the Mo–Mo axis from that underneath the paper plane. The extent of such a rotation may be expressed by the four torsion angles, θ_1, θ_2, θ_3, and θ_4, defined by the four pairs of metal ligand bonds, Mo–O_t, Mo–O_c, Mo–O_c', and Mo–N, respectively (Fig. 4a). The direction of rotation of each pair can be represented by the sign (P and M, suggested by IUPAC,[33] Fig. 4c) of the torsion angles.

Figure 3b shows the view of the same complex along the axis connecting two bridging oxygens. The coordinated four carboxylate oxygens show alternating

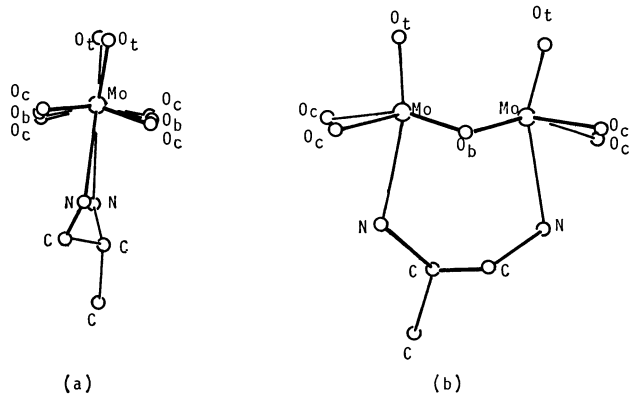

Fig. 3. (a) The projection from the Mo–Mo axis for $[Mo_2O_4(R\text{-pdta})]^{2-}$, and (b) the projection from the axis connecting two oxide bridges for the same ion. Acetate arms are omitted for clarity. (O_t=terminal oxide oxygen, O_b=bridging oxide oxygen, O_c=ligand carboxylate oxygen).

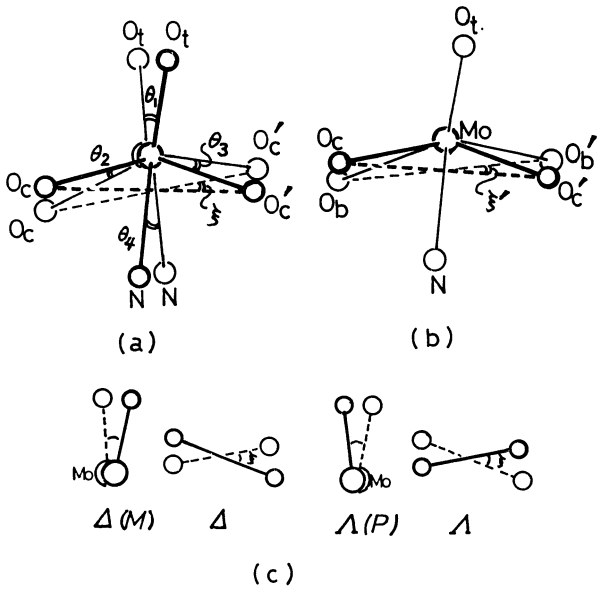

Fig. 4. (a) (b) The definition of torsion angles for $[Mo_2O_4(R\text{-pdta})]^{2-}$. ($O_t$, O_b, and O_c (O_c'), see legend of Fig. 3). (c) The definition of chirality used in this paper.

deviations from the mean plane of these four oxygen atoms. Such a distortion can be understood as a distortion of two basal edges, connecting two carboxylate oxygens, O_c and O_c', on a given molybdenum ion, and represented by the angle, ξ (Fig. 4a). These two basal edges give a skew arrangement, and the chirality of such a distortion can be expressed by the symbol, Δ or Λ.[34] The direction of the distortion of each Mo–ligand bond pair (Mo–O_t, Mo–O_c, Mo–O_c', and Mo–N) can be also expressed by use of Δ or Λ (Fig. 4c). Since the present asymmetry deals with 'conformation' of the two octahedrons of molybdenum(V) ions, δ and λ might be prefered to Δ and Λ. However, δ and λ are used for the conformation of ligand itself. Thus, the symbols, Δ and Λ, are tentatively used hereafter in this paper rather than P and M, since the latters are not always related to asymmetry. Table 2 lists the values of $|\theta_1|$, $|\theta_2|$, $|\theta_3|$, $|\theta_4|$, and $|\xi|$, and the 'chirality of the twist' for various doubly-bridged molybdenum(V) complexes containing optically active ligands. The angle ξ is closely related to θ_2 and θ_3, and is used hereafter as representing these angles.

The chirality of the twist of two Mo–O_t bonds (θ_1), and of the two basal edges (ξ), are the same for a given complex, except for $[Mo_2O_2S_2(S\text{-cys})_2]^{2-}$ and $[Mo_2O_2S_2(R\text{-pdta})]^{2-}$ whose ξ and θ_1, respectively, are negligibly small. It should be noted that the chirality of these twists of the bidentate *S*-cys ester complexes are different from those of the terdentate *S*-cys and *S*-hist complexes, despite of the same absolute configuration of these ligands themselves. The values of $|\xi|$ vary depending on the complex, and those for the *S*-cys ester complexes are considerably big as compared with those of the others. Variation in $|\theta_1|$ values is smaller. The chirality of the twist of two apical bonds (trans to terminal oxo bonds) is Δ for

the *R*-pdta complexes, and Λ for the *S*-cys and *S*-hist complexes, despite that the chirality of the twist of Mo–O_t bonds is Λ for all these complexes.

The asymmetries around each metal ion of the dimer are complicated by the highly distorted structure from the regular octahedron. The asymmetry of the basal plane involving two basal atoms and two bridging ligands may be most important, since the bond trans to Mo–O_t is longer than the others or fails to exist. Such asymmetry may be defined by the angle, ξ', in Fig. 4b. Under the definition the asymmetry around each metal ion of the dimer is considered similarly as that around the dimeric core defined by ξ. The five membered chelate rings at the basal edge form gauche like structure, whose absolute conformations are given in Table 2. The diamine part of *R*-pdta bridging the two apical sites of the $Mo_2O_2XY^{2+}$ core also form gauche like structure, whose absolute conformation is also given in Table 2.

There is no significant asymmetric spiral arrangement of more than two chelate rings in a given complex. No appreciable asymmetric distortion is seen within the $\begin{matrix}\diagup X \diagdown \\ Mo \quad Mo \\ \diagdown Y \diagup\end{matrix}$ core for all the complexes.

Medium Effects on the CD Spectra. The data of absorption and CD spectra of the di-μ-oxo complexes in various media are summarized in Table 3. The CD spectra in the region $<30000\ cm^{-1}$ for all the complexes are characterized by the strong peaks at *ca.* $26000\ cm^{-1}$. The CD pattern of a given complex in this region is very similar to one another regardless of the medium, although the peak in KBr disk shifts always to slightly lower wave number (Fig. 2). Such a similarity suggests that the basic skeletal structure of the complexes in crystals should be retained in the solutions; *i.e.* isomerization and ligand dissociation are not feasible upon dissolution, and the extent of donor atom distortion does not seem to change significantly. Similar conclusion was derived also for the μ-oxo-μ-thio and di-μ-thio complexes.

The CD spectrum of $[Mo_2O_4(S\text{-cys})_2]^{2-}$ in DMSO changed considerably as its concentration changed in less than 0.001 M solution. However, addition of free (*S*)-cysteine to the solution restored a pattern similar to that in solutions of higher complex concentration and that in DMF. Reversible ligand dissociation must take place in dilute DMSO solutions. A similar trend was observed also for $[Mo_2O_3S(S\text{-cys})_2]^{2-}$ in DMSO, but not for the other complexes in any of the solvents examined.

The CD spectrum of $[Mo_2O_4(S\text{-cys})_2]^{2-}$ in water is different from that in DMF in the region $>30000\ cm^{-1}$ (Fig. 2). Also the CD spectrum of $[Mo_2O_4(R\text{-pen})_2]^{2-}$ in water in the same region is significantly different from those in DMF and DMSO, the spectra in the latter two solvents being very similar to each other. Such a difference seems to be due to the difference in strength in the CD band at *ca.* $36000\ cm^{-1}$, the CD strength in DMF being *ca.* 5 times bigger than that in water. The origin of such a solvent effect is not certain. However, it is unlikely that the difference indicates the significant change in skeletal structure of the complex, since no significant change in the CD band in $26000\ cm^{-1}$ region, which is sensitive to the skeletal structure (*vide infra*), is observed. The CD spectra of two other *S*-cys complexes, $[Mo_2O_3S(S\text{-cys})_2]^{2-}$ and $[Mo_2O_2S_2(S\text{-cys})_2]^{2-}$, have similar patterns in water to those in the organic solvents. No significant change in CD spectra was observed for the *R*-pdta complexes in aqueous media and in DMF and DMSO.

The CD patterns of $[Mo_2O_4(S\text{-cys})_2]^{2-}$ and $[Mo_2O_4(R\text{-pen})_2]^{2-}$ are almost completely enantiomeric in a given solvent, suggesting that the replacement of two hydrogens with methyl groups at the adjacent carbon to $-S^-$ does not give significant influence on the CD spectrum.

The *S*-cys ester complexes have vacant apical sites (trans to terminal oxo), which might interact with solvent molecules. However, the solvent effects on the CD spectra of $[Mo_2O_4(S\text{-Rcys})_2]$ ($R=CH_3$, C_2H_5) is very small. No significant change was observed even in pyridine which has a strong donor ability. Probably the oxygen atoms of the ester ligands situate near the apical positions as in crystals,[10,13] to prevent the interaction of the solvent molecules.

The Nature of the Absorption Bands of the Di-μ-oxo Complexes. The $Mo_2O_4^{2+}$ complexes give different spectral patterns from those of the monomeric and single-bridged μ-oxo dimeric molybdenum(V) complexes.[5] The $Mo_2O_4^{2+}$ dimers are diamagnetic, indicating the interaction of the d-orbitals of the two metal ions.[5] The absorption spectrum of $[Mo_2O_4(R\text{-pdta})]^{2-}$ has two bands at 25800 and $33600\ cm^{-1}$, and a shoulder at *ca.* $20800\ cm^{-1}$ in water. Similar absorption patterns are observed for the complexes with the same core, $[Mo_2O_4(H_2O)_6]^{2+}$ (see Fig. 9),[29] $[Mo_2O_4(C_2O_4)_2(H_2O)_2]^{2-}$,[35] $[Mo_2O_4(edta)]^{2-}$,[36] and $[Mo_2O_4(hedta)(H_2O)]^-$,[37] where edta^{4-} and hedta^{3-} stand for ethylenediaminetetraacetate ion and *N*-(2-hydroxyethyl)ethylenediamine-*N*,*N*',*N*'-triacetate ion, respectively.

All the other complexes in this study also have absorption peaks at *ca.* $33000\ cm^{-1}$, but none in lower wave number region. However, they give CD bands in the region $<30000\ cm^{-1}$, suggesting the presence of electronic transitions of corresponding energies. The electronic transition energies of all the complexes can be estimated from either the absorption or the CD peaks, and are summarized in Table 3. Four common transitions are observed in the region from 12000 to $40000\ cm^{-1}$. The energies of these bands change only slightly from one complex to another. It is concluded that these transitions are mainly due to the $Mo_2O_4^{2+}$ core and to a much less extent to the variety of other ligands. Brown *et al.* calculated the electronic transition energies of $[Mo_2O_4(S\text{-cys})_2]^{2-}$ by the SCF-MO method and gave five transition energies, 13250, 20320, 27390, 30870, and $35700\ cm^{-1}$.[17] These transitions were claimed to involve the orbitals mainly located on the two molybdenum atoms, and hence common to other $Mo_2O_4^{2+}$ complexes.[17] The absorption and CD peaks at *ca.* $13250\ cm^{-1}$ should be very weak, if existed, since our results failed to indicate the transition at this wave number in <0.1 M aqueous solutions. The four transitions with the higher wave number

Table 3. The absorption (AB) and CD spectral data for of the di-μ-oxo-bis{oxomolybdenum(V)} complexes

a) s indicates "shoulder". b) Dashed lines indicate the region where data cannot be obtained due to solvent absorption. c) DMF=*N*,*N*-dimethylformamide, DMSO=dimethyl sulfoxide, AN=acetonitrile, KBr=KBr disk.

must correspond to our four common transitions. These are denoted hereafter as band I, II, III, and IV from the low wave number (Table 3).

The band II of the two complexes containing the esters of *S*-cys are somewhat different from those of the other complexes: *i.e.* the position of the band is at a large wave number by nearly 3000 cm^{-1}, and the absorption strength is almost ten times of those of the other complexes. Such differences may be accounted for by the greater distortion of the *S*-cys ester complexes and the absence of apically ligating atoms. The nature of the band is not very different from those of the other complexes.[17]

Characteristics of the CD Spectra of the Di-μ-oxo Complexes. The CD data of the six $Mo_2O_4^{2+}$ complexes are listed in Table 3. The CD spectra in the band I region are weak in intensity and sensitive to the medium. There seems to be more than two components of electronic transitions, as judged from the CD spectra.

The CD sign of band II at *ca.* 26000 cm^{-1} are positive for $[Mo_2O_4(S\text{-mecys})_2]$, $[Mo_2O_4(S\text{-etcys})_2]$, and $[Mo_2O_4(R\text{-pen})_2]^{2-}$, and negative for the others. The CD pattern of this band is least affected by the medium. The $\Delta\varepsilon/\varepsilon$ value of this band is the biggest among those of the four transitions; *i.e.* the values are larger than those of the other bands by five to ten times except for the *S*-cys ester complexes. Therefore the band II should be the most important in considering the optical activity of the complexes. The CD signs at band III are always opposite to those at band II. Hence, the asymmetric source for these two transitions can be common.

No absorption peak is observed at band IV region, but one CD band is always observed. The CD sign of the band IV does not related to those of band II and III. In higher wave number region than 40000 cm^{-1}, a few absorption and CD peaks are observed, but the CD patterns are complicated. No further discussion is made in this study.

Relation between the CD Sign and the Structure of Di-μ-oxo Complexes. Comparison of the CD data in Table 3 with the structural data in Table 2 of three $Mo_2O_4^{2+}$ complexes, leads to the following findings.

The CD signs of the band II and III are related to the chirality of the twist of two Mo–O_t bonds (angle θ_1) and of the twist of the two basal edges (angle ξ). The negative and positive CD peaks at the band II and III regions, respectively, for the *S*-cys and *R*-pdta complexes reflect the Δ chirality of these twists, while the reverse CD signs for the *S*-etcys complex are related to the Λ chirality. It should be noted that the relationship is found for the three complexes which have different ligand environments. Such a relationship for the important band II transition suggests that the distortion around the Mo–Mo axis difined by the torsion angles, θ_1, θ_2, θ_3, and ξ, must be the most important asymmetric source of $Mo_2O_4^{2+}$ complexes.

The CD sign at band IV seems to be related to the absolute configuration of the ligand itself; *i.e.* positive CD peaks for the *S*-cys, *S*-hist, *S*-mecys, and *S*-etcys complexes, and negative CD peaks for the *R*-pdta and *R*-pen complexes. The CD sign at band IV seems to be also related to the conformation of the five membered chelate ring; *i.e.* positive and negative CD peaks corresponding to δ and λ conformations (Table 2), respectively. However, these relations concerning the band IV should be taken as tentative, since the location of relevant asymmetric centers in the molecules are different between the *R*-pdta complex and the others.

The twist of the two bonds trans to Mo–O_t (apical bond) would not be important in determining the CD patterns. These bonds are considerably longer, if existed, than the other bonds and would not give significant influence on the electronic transitions of the $Mo_2O_4^{2+}$ moiety. The asymmetry around each metal ion of the dimer represented by the torsion angle ξ', is parallel to the distortion of the dimer represented by ξ, and thus can also explain the CD signs of band II and III. However, such an explanation is less attractive since the nature of the absorption bands are now assigned to involve the transitions within the dimeric core rather than those within the orbitals of one metal ion.

Absorption and CD Spectra of the μ-Oxo-μ-thio and the Di-μ-thio Complexes. The absorption and CD spectra of $Mo_2O_4^{2+}$, $Mo_2O_3S^{2+}$, and $Mo_2O_2S_2^{2+}$ complexes containing *S*-cys, *S*-mecys, *S*-hist, and *R*-pdta are compared with one another in Figs. 5—8. Absorption spectra of $[Mo_2O_2XY(H_2O)_6]^{2+}$ are shown in Fig. 9. The numerical data of the μ-oxo-μ-thio and di-μ-thio complexes are summarized in Table 4 and 5, respectively.

General Features: The most characteristic feature of the absorption spectra is the remarkable increase in absorption intensity with increase in the number of bridging sulfide in the band II region (*ca.* 26000 cm^{-1}) except for the *S*-mecys complexes. The change in

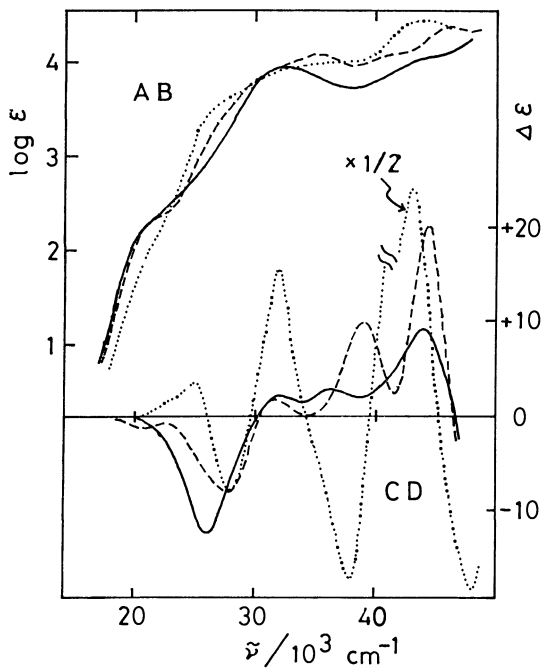

Fig. 5. Absorption (AB) and CD spectra of $[Mo_2O_2XY(S\text{-cys})_2]^{2-}$ in water; X=Y=O (——), X=O and Y=S (----), and X=Y=S (·····).

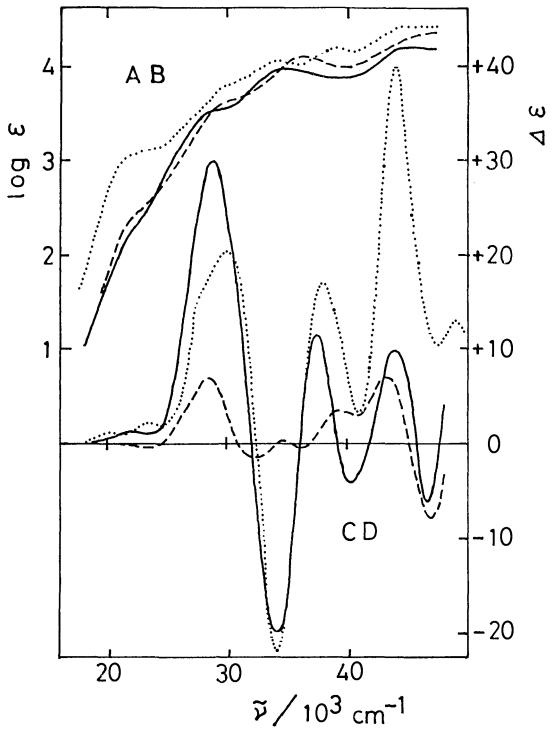

Fig. 6. Absorption (AB) and CD spectra of $[Mo_2O_2XY(S\text{-mecys})_2]$ in acetonitrile; X=Y=O (——), X=O and Y=S (----), and X=Y=S (·····).

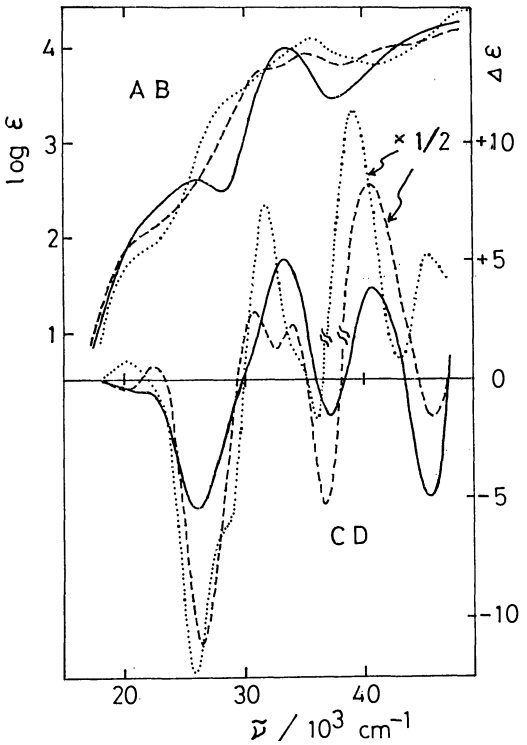

Fig. 8. Absorption (AB) and CD spectra of $[Mo_2O_2XY(R\text{-pdta})]^{2-}$ in water; X=Y=O (——), X=O and Y=S (----) and, X=Y=S (·····).

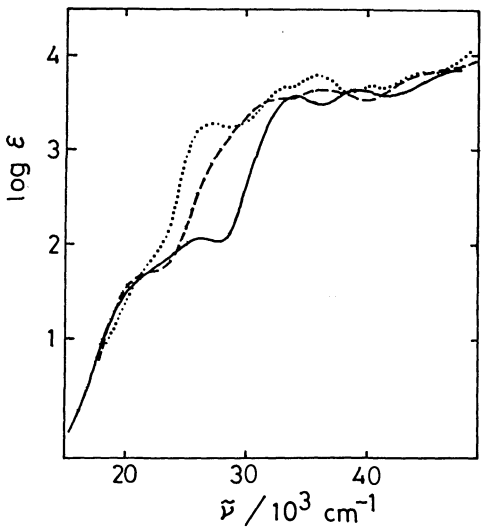

Fig. 9. Absorption spectra of $[Mo_2O_2XY(H_2O)_6]^{2+}$ in 2 M aqueous perchloric acid solution; X=Y=O (——), X=O and Y=S (----), and X=Y=S (·····).

CD spectra with change in the bridging group is rather modest in the band II and III region (25000—35000 cm^{-1}). The general pattern for the di-μ-oxo complexes (two distinctive CD bands with opposite signs) is also appreciated for the μ-oxo-μ-thio and di-μ-thio complexes. Such facts suggest that the nature of CD sensitive transitions at the band II and III region is common to all the complexes, regardless of the bridging groups. The difference in absorption spectra at the band II region is interpreted by the appearance of a strong new band which is less sensitive to CD, in the μ-thio complexes.

The following interpretations for the increase in absorption intensity at band II region, are not feasible, since the corresponding CD change is not accompanied; *i.e.* a) the intensity of 'band II' itself increased, and b) the 'band III' shifted its position to the band II region as the number of sulfide bridge increased.

	38.8 s (3.88)	31.7 (+7.4)*	
	48.4 (4.37)	34.4 s (+0.85)	

a) Data in only one solvent are given. Those in other solvents show similar values. b) Asterisk indicates the band which is assigned to have common nature to band II or III of the corresponding di-μ-oxo complex.

The absorption and CD spectra in the other regions (band I, IV, and V regions) do not show any systematic trend, the number and the energies of absorption or CD bands depending on the bridging structure and the ligand. The *S*-mecys complex gives only slight increase in absorption intensity with increase in the number of bridging sulfide in the band II region. However, the absorption intensity of the di-μ-thio *S*-mecys complex in the band I region is more than five times bigger than those of di-μ-oxo and μ-oxo-μ-thio *S*-mecys complexes.

Ott *et al.* claimed on the basis of absorption spectra that the absorption bands I—IV shift to higher wave number with increase in the number of sulfide bridge. However, the CD spectra do not conform with such a trend.

Band II Region: The CD bands for all the di-μ-thio complexes split into two components. They have opposite signs for the *S*-cys complex, and the same sign for the other complexes. The splitting is accounted for by the appearance of a new band. A comparison of the absorption spectra with the CD

spectra suggests that the CD component corresponding to the new band is the higher and lower wave number component for the *S*-cys and *S*-hist complexes, and for the *S*-mecys and *R*-pdta complexes, respectively. It is seen that the 'band II' not only remains at almost the same position as that for the di-μ-oxo complexes, but also keeps its sign unchanged, regardless of the change in bridging ligand. The new band has much smaller $\Delta\varepsilon/\varepsilon$ than the 'band II' does.

Band III Region: The CD peaks of μ-oxo-μ-thio and di-μ-thio complexes have same sign as those of the di-μ-oxo complexes, except for $[Mo_2O_3S(S\text{-etcys})_2]$ and $[Mo_2O_3S(S\text{-mecys})_2]$ which have no strong CD band in this region. Asymmetric distortion related to the CD strength at this region would be small for the μ-oxo-μ-thio *S*-cys ester complexes.

Relation between the CD Sign and the Structure of the μ-Thio Complexes. The CD bands with common nature to those of the di-μ-oxo complexes in band II and III region, are indicated with asterisks in Table 4 and 5. The same relation to that found for the di-μ-oxo complexes is also found for the μ-thio complexes. The negative and positive CD peaks for the 'band II' and 'band III', respectively, reflect the Δ chirality of the twist of two Mo–O_t bonds and of two basal edges, and the reverse CD patterns are related to Λ chirality of these twists. The relation is thus established for all the complexes regardless of the bridging structure, di-μ-oxo, μ-oxo-μ-thio and di-μ-thio.

Table 2 shows that $|\xi|$ values are much bigger than the $|\theta_1|$ values for most of the complexes. However, the ξ values for the di-μ-oxo and di-μ-thio cys complexes are nearly zero, and thus the twist of the two Mo–O_t bonds must be important in determining CD sign. On the other hand, the θ_1 values of μ-oxo-μ-thio and di-μ-thio complexes of *R*-pdta are practically zero. The donor atom distortion of the basal plane should be important for them. Intensity of the CD peaks of these complexes are not very different. These facts tell that neither the twist of Mo–O_t bonds nor the tetrahedral distortion of the basal plane alone can be the controlling factor of the CD sign at band II and III region. The CD sign must reflect the overall asymmetry caused by the twist of the two molybdenum coordination spheres around the Mo–Mo axis.

Preparation of Copper(I)–Phosphine Complexes Having Cu–N Bonds and Their Reactions with Organic Halides

Takakazu YAMAMOTO,* Yoshio EHARA, Minoru KUBOTA, and Akio YAMAMOTO*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 227

(Received September 7, 1979)

Reactions of a methylcopper complex $CH_3Cu(PPh_3)_2$(diethyl ether)$_{0.5}$ (PPh_3=triphenylphosphine) with active N–H compounds HNR^1R^2 give the corresponding copper derivatives formulated as $R^1R^2NCu(PPh_3)_n$ (n=2 for R^1R^2N=phthalimido, succinimido, *N*-phenylacetamido (**4**), acrylamido, phenylamido, and 2-oxo-1-pyrrolidinyl; n=1 for R^1R^2N=acetamido). The IR and NMR spectroscopic data of the complexes support the bonding of the R^1R^2N group to Cu through nitrogen. The reactions of the Cu(I)–N complexes with alkyl and aryl halides (RX) afford the corresponding *N*-substituted compounds RNR^1R^2 in high yields.

Copper and its compounds have been utilized as reagents or catalysts for various organic synthetic reactions such as the Ullmann reaction, Gattermann-Koch reaction, and Sandmeyer reaction.[1] Although some of the copper-promoted reactions are considered to proceed through the formation of intermediates having Cu–C, Cu–O, or Cu–N bonds, details of the mechanism of the reactions are still vague since chemistry of compounds having Cu–C, Cu–O, or Cu–N bonds has not developed sufficiently. In order to get detailed information concerning the copper-promoted synthetic reactions as well as to develop new copper-promoted synthetic reactions we have prepared Cu(I) complexes having Cu–C,[2] Cu–O,[3] or Cu–S[4] bonds and investigated chemical properties of these complexes. We wish to report on the preparation and properties of Cu(I) complexes having Cu–N bonds. In contrast to bivalent copper complexes for which imido complexes[5a–5b] are known since 1905 and the presence of Cu–N covalent bonds in the complexes has been established in some cases by X-ray crystallography,[5b] only a few reports[6] have appeared on the preparation of univalent Cu–N complexes, including *in situ* preparation[6b,6c] of complexes from CuX and R^1R^2NLi. Concerning other transition metal such as Ti, V, and Mo a number of NH_2– or dialkyl- (or diaryl)amido complexes have been prepared and the presence of metal–N covalent bonds has been demonstrated by X-ray crystallography.[7]

Results and Discussion

Preparation of Complexes. A methylcopper(I) complex $CuCH_3(PPh_3)_2$(diethyl ether)$_{0.5}$ **1**, convenient starting material reacting with active hydrogen compounds,[3,8] reacts smoothly at −20 to 0 °C with compounds having active N–H bond including phthalimide, succinimide, acetanilide, acrylamide, acetamide, aniline, and γ-butyrolactam to give complexes having Cu–N bonds with evolution of one equivalent of methane:

$$CH_3Cu(PPh_3)_2(Et_2O)_{0.5} + HNR^1R^2 \rightarrow \underset{\mathbf{1}}{}$$

$$Cu(NR^1R^2)(PPh_3)_n + CH_4 + 0.5\,Et_2O \qquad (1)$$

2—**8** n=1, 2

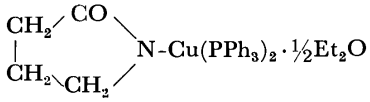
7



8

Generally the reaction with a compound having a more acidic N–H proceeds at a greater rate; the reaction with phthalimide takes only 10 min for completion, that with aniline taking *ca.* 10 h. Compounds with less acidic N–H such as $HN(C_2H_5)_2$ do not react with the methylcopper complex.

Physical properties and analytical data of the complexes are summarized in Table 1. Although most complexes are white, **7** is yellow, showing luminescence sometimes observed in Cu(I) compounds.[9] The complexes have high thermal stability but undergo gradual decomposition on exposure to the air, the decomposition proceeding much faster in solutions. The low electric conductivity of **2** in acetone excludes the possibility of an ionic structure such as $[Cu(PPh_3)_2]^+[N(CO)_2C_6H_4]^-$, suggesting that the imido group is covalently bonded to copper. The phthalimido–copper(I) complex **2** was found to be most stable. It could be prepared also by exchange reactions starting from $ROCu(PPh_3)_n$[3] or from other complexes **3**—**8** by treatment with 1 equiv of phthalimide to liberate ROH or R^1R^2NH. The number of the triphenylphosphine coordinated to copper can be controlled by the relative acidity of the amido or imido moiety as well as by steric factors. In the more acidic phthalimido (pK_a

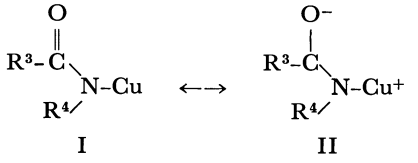
of phthalimido=9.6) and succinimido (pK_a of succinimido=10.5) copper complexes two triphenylphosphine ligands are bonded, while the acetamido (pK_a of acetamido=16) complex contains one triphenylphosphine ligand. The complex containing 2-oxo-1-pyrrolidinyl moiety seems to be situated in the intermediate region; the complex initially formed (complex **8**) has a composition containing two triphenylphosphine ligands. Recrystallization of **8** from toluene gave a complex having one triphenylphosphine ligand based on elemental analysis and NMR data. The value for the carbon content of **8** somewhat lower than the calculated one might be due to the partial dissociation of PPh_3. The triphenylphosphine ligands contained in other bis(triphenylphosphine) complexes are held more firmly.

IR and NMR data of the complexes are summarized in Table 2. The ν(C=C) bands of amides and imides, except for acetanilide, are shifted to lower frequency by 50—110 cm^{-1} on complex formation. The lowering of ν(C=O) frequencies is accounted for by assuming the mixing of the following cannonical structure I and II in the ground state:



I II

In the cases of phthalimide and succinimide the magnitudes of the shifts are comparable to those observed with Pd and Pt imido complexes which have metal–N

σ-bonds.[10] In contrast to these amido and imido–copper complexes the IR spectrum of the *N*-phenylacetamido complex **4** was somewhat different, the ν(C=O) band being slightly shifted to higher frequency than that of the free acetanilide on complex formation. The reason for this is not clear. However, the IR spectrum may be accounted for by assuming the π-azaallylic type bonding between the *N*-phenyl entity and copper as in benzyl–transition metal complexes.[11]

The NMR spectrum of the succinimido complex **3** shows only one sharp singlet for the CH_2 groups, indicating that the two CH_2 groups are magnetically equivalent in line with the bonding of the succinimido ligand to Cu through nitrogen. The aliphatic C–H signals neighboring the amido group (CH_2 of succinimide, CH_3 of acetamide, and $-NC\underline{H}_2-$ and $-COC\underline{H}_2-$ of γ-butyrolactam) are shifted to higher field by 0.3—0.4 ppm on complex formation. This can be accounted for by the electron migration from Cu to the amido or imido ligands from the discussion on the IR spectra. The electron migration would decrease the an anisotropic paramagnetic effect of the C=O group and increase the diamagnetic shielding of atoms around the –NHCO– bond. A similar upfield shift by 0.4 ppm is observed for α-olefinic hydrogens of acrylamide. In contrast to these amido or imido ligands, no shift of the CH_3 signal in *N*-phenylacetamido is observed on complex formation beyond experimental error. This may be related to the unusual small shift of ν(C=O) to higher frequencies on complex formation.

Reactions with Organic Halides. Reactions of the Cu(I)–N complexes with alkyl or aryl halides lead to the substitution of Cu by the alkyl or aryl group, rendering further evidence for the bonding of the NR^1R^2 moiety to copper through nitrogen:

$$(PPh_3)_nCu\text{-}N\begin{matrix}R^1\\R^2\end{matrix} + RX \rightarrow R\text{-}N\begin{matrix}R^1\\R^2\end{matrix} \quad (2)$$

Results of the reactions are summarized in Table 3. The absence of *O*-substituted products excludes the possibility of a structure in which copper is bonded to an oxygen in an enolate form. In the reactions of **2** with aryl halides the yields depend drastically on temperature. For example, the reaction with C_6H_5Br(bp=155 °C) at 140 °C gives only a low yield, whereas that with C_6H_5I(bp=188 °C) or in diglyme (bp=186 °C) at 170 °C gives higher yields. Copper or its compounds are good catalysts for arylation of potassium phthalimide by aryl halides at 155—165 °C, the catalytic reaction being utilized to synthesize aromatic amines.[12] Occurrence of the arylation of **2** with aryl halides gives support to the proposed mechanism[12] involving the formation of a copper phthalimide intermediate during the course of the catalytic reaction.

Reactions of the Cu(I)–N complexes with alkyl halides proceed at much lower temperatures. Complex **2** affords *N*-alkylated phthalimides in almost quantitative yields under mild conditions. Acetyl chloride reacts with **7** to give acetanilide. The same product was obtained also by the reaction of **7** with $(CH_3CO)_2O$ in a 89% yield:

$$\mathbf{7} + CH_3COCl \text{ (or } (CH_3CO)_2O) \rightarrow \underset{89\text{—}92\%}{C_6H_5NHCOCH_3} \quad (3)$$

Experimental

General. Preparation and recrystallization of copper complexes were carried out under deoxygenated nitrogen or argon or in a vacuum. IR spectra were recorded on a Hitachi Model 295 using KBr discs under nitrogen, NMR spectra on a Japan Electron Optics Lab. JNM-PS-100 spectrometer (TMS as an internal standard). The gas evolved was analyzed with a Hitachi RMU 5B mass-spectrometer and a Shimadzu GC-5B gas chromatograph, its volume being measured with a Toepler pump. Microanalysis of carbon, hydrogen and nitrogen was performed by Mr. T. Saito in our laboratory with a Yanagimoto CHN Autocorder Type MT-2.

Material. $CH_3Cu(PPh_3)_2$(diethyl ether)$_{0.5}$ **1** was prepared as reported previously.[2] Solvents were dried by the usual procedure, distilled, and stored under argon or nitrogen. The N–H compounds were confirmed to be pure by gas chromatography.

Preparation of the Cu(I)–N Complexes. *N-Phthalimido-bis(triphenylphosphine)copper(I)* **2**: Diethyl ether (15 cm^3) was

a) The reactions were carried out by using 0.15—1.0 mmol of the complex and 1—2 cm^3 of the organic halide in 2 cm^3 of the solvent.

added to a Schlenk tube containing 670 mg (1.0 mmol) of **1** and 154 mg (1.1 mmol) of phthalimide at −20 °C. Stirring of the mixture for 10 min at −20 °C gave a light green precipitate with evolution of CH_4. Filtration of the solution afforded 680 mg (89%) of the crude product. Recrystallization from acetone yielded light green prisms of **2** (460 mg, 35%). Equivalent conductivity of **2** in acetone at 0 °C was smaller than 1.0 S cm^2.

Succinimidobis(triphenylphosphine)copper(I) ***3***: The complex was prepared by the reaction of **1** (750 mg, 1.2 mmol) with succinimide (120 mg, 1.2 mmol) in a similar way to that for the preparation of **2**. The white precipitate obtained was washed with diethyl ether repeatedly and dried in a vacuum to give **3** (600 mg, 74%).

N-*Phenylacetamidobis(triphenylphosphine)copper(I)* ***4***: Acetanilide (0.200 g, 1.48 mmol) was added to a Schlenk type flask containing **1** (910 mg, 1.4 mmol) suspended in 5 cm^3 of diethyl ether. The yellow suspension was stirred at 0 °C for 0.5 h in the absence of air to give a white precipitate with evolution of methane (0.97 mol per Cu). The precipitate was crystallized from a mixture of diethyl ether and toluene and dried in a vacuum to give white crystals of **4** (800 mg, 76%).

Acrylamidobis(triphenylphosphine)copper(I) ***5***: The complex was prepared by the reaction of **1** (940 mg, 1.5 mmol) with acrylamide (110 mg, 1.5 mmol) in a similar way to that for the preparation of complex **4**. The white precipitate was crystallized from a mixture of diethyl ether and toluene to give white crystals of **5** (810 mg, 83%).

Acetamido(triphenylphosphine)copper(I) ***6***: Diethyl ether (15 cm^3) was added to a Schlenk tube containing 1050 mg (1.6 mmol) of **1** and 98 mg (1.7 mmol) of acetamide at −20 °C. Stirring of the mixture for 10 h at 0 °C gave a white precipitate, which was washed with diethyl ether repeatedly and dried in a vacuum to give **6** (610 mg, 97%).

Phenylamidobis(triphenylphosphine)copper(I) ***7***: Aniline (150 mg, 1.1 mmol) was added to **1** (670 mg, 1.1 mmol) suspended in 5 cm^3 of diethyl ether. Stirring of the yellow suspension at −10—0 °C for 1 day gave a pale-yellow precipitate, which was washed with diethyl ether repeatedly and dried in vacuum to give **7** (520 mg, 73%).

(2-Oxo-1-pyrrolidinyl)bis(triphenylphosphine)copper(I) ***8***: The complex was prepared by the reaction of **1** (1.6 g, 2.5 mmol) with γ-butyrolactam (0.19 cm^3, 2.5 mmol) in a similar way to that for the preparation of complex **7**. Yield=1.2 g (74%).

Reactions of the Cu(I)–N Complexes with Organic Halides: Bromobenzene (2 cm^3, 19 mmol) and diglyme (2 cm^3) were added to a reaction vessel containing 140 mg (0.19 mmol) of **2**. The mixture was stirred for 6 h under reflux. GLC analysis of the reaction mixture showed formation of 12 mmol (64%) of *N*-phenylphtalimide. The other reactions were carried out in a similar way under conditions given in Table 3.

Performances of Lead and Copper(II) Ion-selective Electrodes in Metal Buffer Solutions and the Determination of the Stability Constants of Lead and Copper(II) Complexes

Genkichi NAKAGAWA,* Hiroko WADA, and Takeshi SAKO

Laboratory of Analytical Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466

(Received September 8, 1979)

The behaviour of lead and copper(II) ion-selective electrodes (Denki Kagaku Keiki Co., Japan) at very low activity levels was examined in metal buffer solutions. In the absence of complexing agents, the Nernstian responses were obtained down to 10^{-6} mol dm^{-3} (μ=0.1) Pb^{2+} in the pH range from 4 to 7, and down to 10^{-7} mol dm^{-3} (μ=0.1) Cu^{2+} in the pH range from 4 to 6. The complexing agents which form stable complexes with Pb or Cu(II) were very effective in lowering the detection limits. The stability constants of the Pb and Cu(II) complexes with several ligands[CH_3COO^-, 1,10-phenanthroline(Phen), glycine(Hgly), iminodiacetic acid(H_2ida), nitrilotriacetic acid(H_3nta), *etc.*] were determined by measuring the activities of the free Pb or Cu(II) ion in metal buffer solutions. However, in spite of the high stability of the Pb- or Cu(II)-edta complex, the lower limit of the electrode response was abnormally high and the stability constant of Pb- or Cu(II)-edta complex could not be obtained. Some reasons for the abnormalities with EDTA were discussed.

The response of ion-selective electrodes at very low activity levels has been studied in metal buffer solutions.[1—4] Some authors have used ion-selective electrodes for the determination of the stability constants of metal complexes.[5,7] In these cases, measurements of the activitites of free metal ions at a very low level, *i.e.*, $<10^{-5}$ mol dm^{-3}, are usually required. On the other hand, in the potentiometric titrations of copper (II) or lead(II) with EDTA by the use of copper(II) or lead ion-selective electrodes, the electrode potentials after the equivalence point were found to be higher than the theoretical values.[6] This deviation implies that the determination of the stability constants of copper(II)- or lead-edta complex with copper(II) or lead ion-selective electrodes is impossible.

In our previous work,[7] the potential response of the Orion copper(II) ion-selective electrode Model 94-29 was examined in various copper(II) buffer solutions containing copper complexes and an excess of the ligand; the stability constants of copper(II) complexes were thus determined successfully. In the cases of the $edta^{4-}$ and nta^{3-} complexes, however, good results could not be obtained, while in the case of 1,10-phenanthroline the electrode responded to 10^{-16} mol dm^{-3} of the copper ion. Therefore, we suggested that, for the determination of the stability constants, the lower limits of the electrode response should be checked in a solution containing the same ligand in the same pH range. The use of the ion-selective electrode provides a simple and reliable method for determining the stability constants of metal complexes.

In the present work, the performance of the lead ion-selective electrode from the Denki Kagaku Keiki Co. (DKK), Japan, has been examined, and the stability constants of several lead complexes have been determined. The potential response of the copper(II) ion-selective electrode from the Denki Kagaku Keiki Co. has also been examined, and compared with that of the Orion copper(II) ion-selective electrode Model 94-29.

Experimental

Reagents. A lead(II) standard solution was prepared from analytical-grade lead nitrate and standardized against an EDTA solution by the use of Xylenol Orange as an indicator. A copper(II) standard solution was prepared from metallic copper (99.99% purity).

Ligands: Analytical-grade $Na_2H_2edta \cdot 2H_2O$ and H_3nta were recrystallized. The other ligands were of an analytical-grade and were used without further purification.

The potassium nitrate was recrystallized from distilled water.

Apparatus. Two Hitachi-Horiba F-5 Type pH Meters were used. One was equipped with a lead or copper(II) ion-selective electrode and a Horiba calomel electrode. Before the lead or copper(II) ion-selective electrode was used, the surface of the active membrane was polished with electrode polishing paper from the DKK Co.; then it was soaked in a *ca.* 0.2% CH_3COONa–CH_3COOH buffer (pH 6) containing 0.1% KNO_3 until the electrode potentials dropped down to -150——-170 mV for the lead ion-selective electrode and to 80—50 mV for the copper(II) ion-selective electrode. The electrodes were kept in distilled water. The calomel electrodes were connected to the test solution *via* a salt bridge of 0.1 mol dm^{-3} KNO_3 in agar-agar.

The following cell arrangement was used for measuring the lead or copper(II) ion activities:

Pb or Cu(II) ion-selective electrode	test solution	0.1 mol dm^{-3} KNO_3	calomel electrode (3.33 mol dm^{-3})

The ionic strength of the test solutions was maintained at 0.1 with KNO_3 except in the case of acetate, and measurements were made at 25 °C. During the potential measurements, magnetic stirring was done with a Teflon bar.

The equilibrium potential of this cell is expressed as Eq. 1 from the Nernst equation:

$$E = E' + \frac{RT}{2F}\ln[M^{2+}] \quad (1)$$

where E' is a constant consisting of the standard potential of the electrode, the junction potential and $(RT/2F)\ln\gamma_{M^{2+}}$, and where $[M^{2+}]$ is the concentration of the lead or copper(II) ion.

Response Time of Ion-selective Electrode. The constant potential reading were usually obtained within one minute for 10^{-2}—10^{-3} mol dm^{-3} metal ion solutions, within 5 minutes in 10^{-6} mol dm^{-3} solutions, and within 10 minutes in metal buffer solutions containing less than 10^{-10} mol dm^{-3} free metal ions.

Results

Potential Response of Pb and Cu(II) Ion-selective Electrodes. The potential response of a DKK lead ion-selective electrode was examined over the pH range between 3 and 9. The test solutions were prepared by stepwise dilution of a 10^{-2} mol dm^{-3} lead standard solution, and the pH was adjusted by adding a dilute HNO_3 or NaOH solution. As is shown in Fig. 1, the Nernstian response with a 29.0 mV slope was observed down to 10^{-6} mol dm^{-3} lead ion in the pH region of 4—7. The lowest line (D.L.) in Fig. 1 shows the detection limit of the electrode, which was obtained with the solution containing no lead ion. Below these potentials, the electrode no longer responded to the lead ion activity.

In the case of the copper(II) ion-selective electrode, the Nernstian response with a 29.2 mV solpe was obtained down to 10^{-7} mol dm^{-3} copper(II) ion in the pH range between 4 and 6 (Fig. 2). The detection limit of the DKK copper(II) ion-selective electrode used in this study was lower by one order than that of the Orion copper(II) ion-selective electrode employed in the previous work.

Effects of Complexing Agents on the Detection Limit. The electrode response was examined in a metal buffer solution containing an excess of complexing agents. The broken lines in Figs. 3 and 4 show the detection limits of the lead and copper(II) ion-selective electrodes in the solutions containing a complexing agent and no metal ion. Complexing agents which form stable complexes with the lead or copper(II) ion were very effective in lowering the detection limit, as was observed in the previous work with the Orion copper(II) ion-selective electrode.[7] With the DKK lead ion-selective electrode, the detection limit was

1: NH_3, C_{Cu}: 1.08×10^{-3} mol dm^{-3}, C_L: 1.03×10^{-1} mol dm^{-3}. 2: phen, C_{Cu}: 1.08×10^{-4} mol dm^{-3}, C_L: 4.74×10^{-3} mol dm^{-3}. 3: H_4edta C_{Cu}: 1.08×10^{-3} mol dm^{-3}, C_L: 2.06×10^{-3} mol dm^{-3}.

around 10^{-6} mol dm^{-3} at pH 5 in the absence of complexing agents, while in the presence of 0.01 mol dm^{-3} H_2ida the detection limit was around 10^{-10} mol dm^{-3} at pH 7. Although H_4edta forms stable complexes with lead and copper(II) ions, the detection limits of both the DKK lead and copper(II) ion-selective electrode in H_4edta solutions were abnormally high, as with the Orion copper(II) ion-selective electrode.

The solid lines in Figs. 3 and 4 show the electrode potentials observed in lead and copper(II) buffer solutions respectively. The activities of the lead ion in the lead buffer solutions were much higher than the lower response limits of the lead ion-selective electrode except in the case of H_4edta. In H_4edta solutions the two curves almost coincided with each other; this means that the electrode potential does not give the correct activities of the lead ion in the solution. Again, the DKK copper(II) ion-selective electrode did not respond normally to the activities of the copper(II) ion in the H_4edta solution, as may be seen in Fig. 4.

Determination of Stability Constants of Lead Complexes. If the electrode potentials represent the true pPb values ($-\log[Pb^{2+}]$) in the lead-ion buffer solutions, the stability constants of the lead complexes in the buffer solutions can be determined from the electrode potential measured in the presence of the complexes and a large excess of the ligand, L, at different pH values (Fig. 3). The overall stability constants are defined as (charges are omitted for the sake of generality):

$$\beta_n = \frac{[PbL_n]}{[Pb][L]^n}. \quad (2)$$

Thus, the concentration of the free lead ion in a lead-ion buffer solution is given by:

$$pPb = \log \beta_n + n \log [L] - \log [PbL_n]. \quad (3)$$

$[PbL_n]$ and [L] are calculated by means of Eqs. 4 and 5 respectively;

$$[PbL_n] = C_{Pb} - [Pb], \quad (4)$$

$$[L] = [C_L - n(C_{Pb} - [Pb])]/\alpha_{L(H)}, \quad (5)$$

where C_L and C_{Pb} are the total concentrations of the ligand and the lead ion respectively, and where

$$\alpha_{L(H)} = 1 + \sum_{m=1}^{m} ([H]^m K_1 K_2 \cdots K_m), \quad (6)$$

the successive protonation constants of the ligand being represented as K_1, k_2,$\cdots K_m$. From the cell potential measured, pPb was obtained by means of Eq. 1; then β_n could be calculated. In Fig. 5 the pPb values are plotted against pL($-\log[L]$); straight lines with the slopes of 1 and 2 with CH_3COO^- and Hgly, of 1, 2, and 3 with phen, and of 1 with 8-hydroxy-5-quinolinesulfonic acid(H_2oxs), H_2ida, and H_3nta were obtained, while with H_4edta the slope was 0.4 instead of 1. Except for H_4edta, the values of the stability constants of the lead complexes obtained all agreed with the values reported in the literature.

Determination of the Stability Constants of Copper(II) Complexes. The relations between pCu and pL are plotted in Fig. 6. These plots yielded straight lines with slopes of 4 with NH_3, of 1 and 2 with H_2ida,

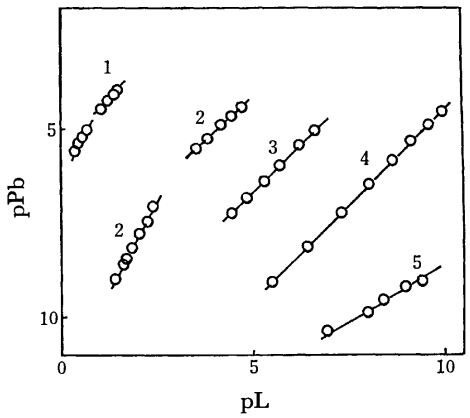

Fig. 5. Plots of pPb *vs.* pL.
1: CH_3COO^-, 2: Hgly, 3: H_2ida, 4: H_3nta, 5: H_4edta.

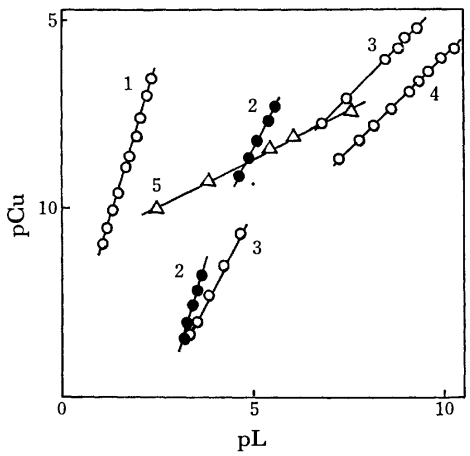

Fig. 6. Plots of pCu *vs.* pL.
1: NH_3, 2: phen, 3: H_2ida, 4: H_3nta, 5: H_4edta.

of 2 and 3 with phen, and of 1 with H_3nta, while it was 0.5 with H_4edta. Although the Orion copper(II) ion-selective electrode employed in the previous work did not give reliable results for the copper(II)–edta or nta complex, with the DKK copper(II) ion-selective electrode a good result was obtained for the H_3nta complex.

The stability constants of the lead and copper(II) complexes determined in this study are summarized in Table 1, along with the values in the literature.[8,9]

Application to EDTA Titrations. The potentiometric titration of lead with EDTA was carried out by means of the lead ion-selective electrode. The results are shown in Fig. 7. The electrode potentials after the equivalence point leveled out at the detection limit of the electrode and deviated from the theoretical titration curves in a way similar to that is the case with the Orion copper(II) ion-selective electrode.

Discussion

The active membranes of the DKK copper or lead ion-selective electrodes consist of mixed sulfides of copper(II) or lead and silver(I), as is the case of the Orion electrodes. Recently several papers have been published concerning the electrode potential of the mixed-sulfide membrane electrodes; however, the mechanism

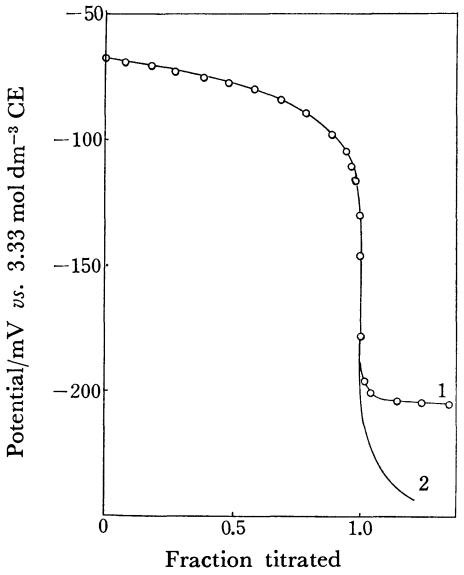

Fig. 7. Titration curve of Pb with EDTA.
1: Experimental, 2: theoretical, C_{Pb}: 1.01×10^{-3} mol dm^{-3}, C_{EDTA}: 1.04×10^{-2} mol dm^{-3}, pH 4.3 (CH_3-COOH-CH_3COONa buffer).

of potential response of these electrodes are not yet fully clarified. As an approximation, the potential response of these electrodes can be understood by considering these materials as the third class of electrodes for the silver(I) ion;

$$Ag_2S + M^{2+} \rightleftharpoons MS + 2Ag^+. \quad (7)$$

Thus, the electrode potentials are given by

$$E = {}^{\circ}E_{Ag^+/Ag} + \frac{RT}{2F}\ln\frac{K_{s(Ag_2S)}}{K_{s(MS)}} + \frac{RT}{2F}\ln a_{M^{2+}}. \quad (8)$$

The difference in the detection limits between the DKK copper(II) electrode and the Orion copper(II) electrode may be attributed to the differences in the methods of preparing the mixed sulfides and the membranes. Although the detection limits of ion-selective electrodes were determined by the solubility of the active materials of the electrode, the observed detection limits of the lead and copper(II) electrodes were much higher than the values calculated from solubility of PbS or CuS; for example, at pH 4 the solubilities of PbS and CuS are calculated to be around 10^{-9} mol dm^{-3} and 10^{-14} mol dm^{-3} respectively. This may be caused by the high activities of lead or copper (II) at the membrane surface resulting from the adsorption of these ions. The strong complexing agent reduces the activities of the copper(II) or lead ion at the membrane surface and shifts the detection limits to lower levels

In H_4edta solutions the detection limits of the lead and copper(II) ions were abnormally high compared with those in the solutions containing the other complexing agents. This fact is explained as follows. Since the stability of the silver complex with edta^{4-} is very small in comparison with the stability of the lead- or copper(II)-edta complex, the decrease in the activity of the silver ion at the membrane surface is not so marked as the decrease in the lead or copper(II) ion activity. Therefore, the equilibrium represented by Eq. 7 is shifted to the left, and finally the surface of the active membrane is converted to Ag_2S. Thus, the electrode would lose its selectivity toward the lead or copper(II) ion, and the detection limits may be determined by the activity of the silver ion at the membrane surface. On the other hand, complexing agents which form fairly stable complexes with both silver and lead or copper(II) ions, such as phen, may shift the detection limits of these electrodes to a very low level. If the electrode potential measured in the metal buffer solution is sufficiently higher than

the detection limits measured in the solution containing the same ligand, reliable stability constants of the metal complexes can be determined.

Recently, it was found that a mixed sulfide of copper(I) and silver(I) such as $Ag_{1.55}Cu_{0.45}S$ was formed in the active material of the copper(II) ion-selective electrode.[10,11] Since H_4edta forms weaker complex with the Cu(I) ion than with the Cu(II) ion, the high activities of the copper(I) ion at the membrane surface may also interfere with the measurement of the activities of copper(II) at very low levels.

Although some authors[1,12] have recommended the use of a metal buffer system which consists of copper (II)–edta or lead–edta for the calibration of the copper(II) or lead ion-selective electrode at low activitity levels, other metal buffer systems rather than H_4edta are to be preferred.

Part of this study was presented at the 26th International Congress of Pure and Applied Chemistry, Tokyo (1977).

Pyrolytic Sulfurization Gas Chromatography. VII. The Simultaneous Determination of the Atomic Ratio between C, H, O, and N in a Halo-organic Compound

Tadashi HARA,* Kaoru FUJINAGA, and Fujio OKUI

Department of Chemical Engineering, Fuculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602

(Received October 24, 1979)

The halide produced from a halo-organic compound interferes with the simultaneous determination of the atomic ratio between C, H, O, and N in the compound by the pyrolytic sulfurization gas chromatography, but the interference can be eliminated by allowing the pyrolytic sulfurization of the compound to proceed in the presence of the sodium sulfide formed by the reaction between sodium azide and sulfur.

According to pyrolytic sulfurization gas chromatography (PSGC), which was originated by the present authors, the atomic ratio between C, H, O, and N in a usual organic compound,[1,2] a metallo-organic compound,[3] and a polymer[4] has been successfully and simultaneously determined.

The present study has been carried out to confirm whether or not PSGC can be applied to the analysis of a halo-organic compound. The chromatogram of a halo-organic compound obtained by PSGC was found to be different from that of the compound consisting of C, H, O, and N alone; that is, there were extra peaks which more or less overlapped with the peaks based on C, H, O, and N. This makes the application of PSGC to a halo-organic compound impossible. In order to eliminate the interference of halides, there seem to be two procedures; one is based on the fixation of halides in an ampule, and the other, on the fixation of halides after the crushing of the ampule. The former is better than the latter, since the flowing path in a gas chromatograph is made of stainless steel, which is apt to react with halides. Various substances were added to a sample for the fixation of halides in an ampule; the sodium sulfide (Na_2S) produced by the reaction between sodium azide (NaN_3) and sulfur(S) in a quartz tube which was closed at one end was found to be best for the present purpose. By this procedure, no peaks of halides were observed on the chromatogram, and a simultaneous determination of the atomic ratio between C, H, O, and N in a halo-organic compound could be successfully carried out.

Experimental

Apparatus and Reagents. The reagents and apparatus used were the same as those previously reported[3-6] except that NaN_3 of a guaranteed grade was newly used.

Samples. 5,7-Dibromo-8-quinolinol of a guaranteed grade was recrystallized from benzene for use. Bis(5,7-dibromo-8-quinolinolato)copper(II) and tris(5,7-dibromo-8-quinolinolato)iron(III) were prepared in accordance with the gravimetric procedure[7] by the use of purified 5,7-dibromo-8-quinolinol. The other samples were of a reagent grade for elemental analysis.

Procedure. After 6 mg of S and approximately 0.4 mg of NaN_3 had been placed in a quartz tube, one end of which was closed, the inside of the quartz tube was completely filled with helium by passing helium through it at the rate of 100 cm³/min; after 10 min the fused end of the tube was carefully heated in an electric furnace. This was followed by the formation of Na_2S by means of the reaction between NaN_3 and S in the tube. To the tube, 0.3—0.5 mg of a sample was then added, and the other end of the tube was fused after 10 minutes' passage of helium at the same flow rate as before, followed by the same operation as in the previous paper.

Results and Discussion

Interferences of Halides. Three typical halides were analyzed by the PSGC method; their chromatograms are shown in Fig. 1, in which (a), (b), and (c) correspond to the chromatograms of ammonium chloride (NH_4Cl), ammonium bromide, and ammonium

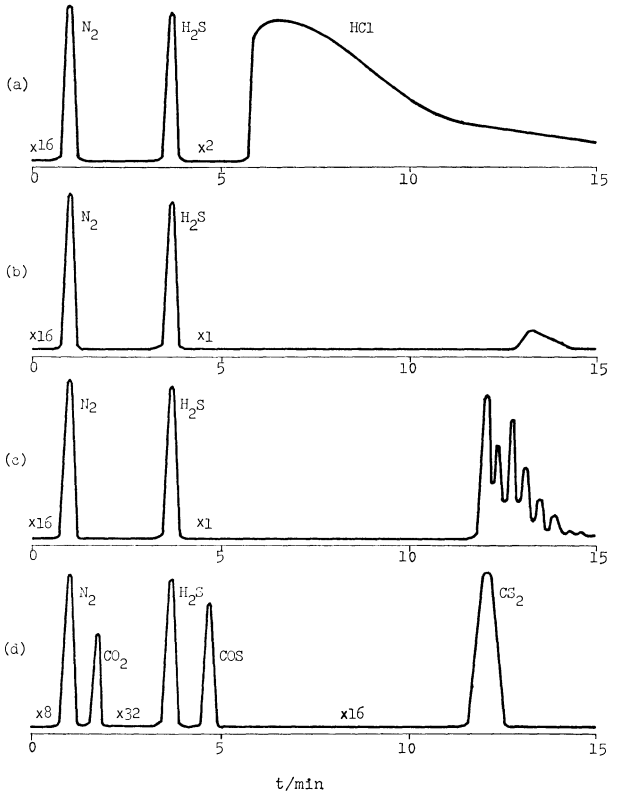

Fig. 1. Typical chromatograms of reaction products between S and ammonium halides by the conventional PSGC method.
(a) NH_4Cl, (b) NH_4Br, (c) NH_4I, (d) glycine as a halogen-free compound.

iodide respectively. As may be seen from Fig. 1, chloride and iodide interfere with the determination of carbon disulfide. Many peaks which appeared after a retention time of approximately 12 min were experimentally confirmed to be due to the compounds formed by the reaction between column packings of the gas chromatograph and iodine or iodide. These results made the application of PSGC to halo-organic compounds impossible. In order to eliminate the interference of halides, a procedure in which halides were fixed in an ampule was adopted, since the flowing path in a gas chromatograph is made of stainless steel, which is apt to react with the halides.

Fixation of Halides. Various substances were added to a sample for the fixation of halides in an ampule, and then the sample was analyzed (Table 1). Since halogen atoms had been completely captured on a silver wire or net in the conventional CH analysis, 1,2,3,4,5,6-hexachlorocyclohexane(γ-BHC) and NH_4Cl were analyzed by the PSGC method in the presence of powdered silver or silver sulfide (Ag_2S), but the peak of hydrogen chloride (HCl) was still observed. Furthermore, when silver chloride was analyzed by the PSGC method in the presence of glycine as a hydrogen source, the peak of HCl was observed. From these results, silver seemed to show a larger affinity for S than chlorine(Cl) and to produce Ag_2S under the present conditions. In these cases, a black solid which might be Ag_2S was observed in an ampule after the pyrolytic sulfurization, differing from the usual yellow contents. Sodium chloride (NaCl) was analyzed similarly as above in the presence of glycine, but no peak of HCl was observed. This suggested that soium (Na) showed a larger affinity for Cl than S under the present experimental conditions. Then γ-BHC and NH_4Cl were analyzed in the presence of the sodium acetate or NaN_3; no peak of HCl was observed, as the authors had expected. γ-BHC was further analyzed in the presence of the acetate of such alkaline earth metals as magnesium(Mg), calcium(Ca), strontium(Sr), and barium(Ba); most of HCl was fixed in all the reaction residues except magnesium acetate ($(CH_3COO)_2Mg$). According to the PSGC method, the acetates of Ca, Sr, and Ba were converted into their sulfides and volatile constituents, while $(CH_3COO)_2Mg$ was converted into its sulfide-oxide mixture and volatile constituents. There might be a correlation between the fixation of HCl and the reaction products obtained from the acetates of alkaline earth metals by the PSGC method. NH_4Cl was sealed into an ampule together with S and NaN_3 to give various atomic ratios of Na to Cl; the evolution of HCl was then investigated (Table 2). As may be seen from Table 2, the sulfide produced by the reaction between S and NaN_3 was found to react with chloride stoichiometrically to produce NaCl. To sum up these results, a basic sulfide was expected to be effective for the fixation of HCl, and so Na_2S was selected and used for the present study. Since Na_2S was very hygroscopic, however, and since its preparation in pure state was also difficult, an attempt was made to produce Na_2S by means of a reaction between S and NaN_3 in a quartz tube on the basis of the facts that NaN_3 decomposed into Na and nitrogen at about 300 °C[8] and Na_2S could be prepared from Na and S.[9,10] The reaction tube containing the Na_2S thus prepared was stable for at least 30 min in contact with air; therefore, the absorption of atmospheric moisture with Na_2S, which might take place during the insertion of the sample, was neglected for the simultaneous determination of the atomic ratio between C, H, O, and N. The present procedure thus established was applied to the three compounds shown in Fig. 1, but no peak based on halides was observed. The present procedure was the same as in the previous papers except for the coexistence of Na_2S, and it could be successfully applied to various halo-organic compounds.

1.0	0.85	−
1.0	1.0	−
1.0	1.2	+

a) NaN_3. b) NH_4Cl.

Analysis of Various Compounds. Various halo-organic compounds, such as chloride, bromide, and iodide, were analyzed by the present procedure (Table 3); metallo-organic compounds containing a halo-organic compound as a ligand were also analyzed (Table 4). It was newly found (*cf.* Table 4) that the atomic ratio between C, H, O, and N in a metallo-organic compound containing both metal and halogen atom could be simultaneously determined.

Analysis of Fluoro-organic compounds. Fluoro-organic compounds were also analyzed by the present procedure (Table 5). As may be seen from Table 5, the result of oxygen was markedly positive. This might be attributed to the formation of water (H_2O) by Eq. 1 in which water hydrogen fluoride (HF) was made to react with the internal surface of a quartz tube, and to the subsequent conversion of H_2O into oxygen-containing compounds:

$$4HF + SiO_2 \longrightarrow SiF_4 + 2H_2O. \quad (1)$$

a) The fluorine atom was neglected in the calculation of the compositions of fluoro-organic compounds, since it could not be determined.

Two experiments were further carried out; in one each ampule contained sodium fluoride (NaF) and S, while in the other each ampule contained NaF, S, and hydrogen. Gaseous oxygen did not evolve in the former, while it did in the latter. It is clear from these results that oxygen is not evolved until HF is produced in an ampule.

According to the present procedure, all the halogen atoms liberated from a halide sample were quantitatively captured in the reaction residues. This suggests a possibility of the simultaneous determination of the atomic ratio between C, H, O, N, and halogen atoms by the subsequent analysis of halogen atoms in the reaction residues.

Mössbauer Studies of the Gamma-ray-irradiation Effects of 1,10-Phenanthroline Compounds

Yonezo MAEDA, Hiroki OHSHIO,* and Yoshimasa TAKASHIMA

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received July 23, 1979)

Mössbauer and infrared spectroscopies have been applied to the study of the gamma-ray-irradiation effects on eleven iron 1,10-phenanthroline compounds: $[Fe(phen)_2X_2]$ (X=Cl^-, $HCOO^-$, NCO^-, $\frac{1}{2}Ox^{2-}$, $\frac{1}{2}Mal^{2-}$, CN^-, and NO_2^-), $[Fe(phen)_3]X_2\cdot nH_2O$ (X=Cl^-, ClO_4^-, $HCOO^-$, and NO_2^-), $[Fe(phns)_2](ClO_4)_2\cdot 2H_2O$ and $[Fe(phnc)_2](ClO_4)_2\cdot H_2O$ (phen=1,10-phenanthroline, phns=1,10-phenantroline-2-carbothioamide, and phnc =1,10-phenantroline-2-carboxamide). For all the low-spin complexes except $[Fe(phen)_3](HCOO)_2\cdot 6H_2O$, no chemical changes were observed on the Mössbauer spectra after irradiation. All the iron(II) complexes in the high-spin state except $[Fe(phen)_2Cl_2]$ and $[Fe(phnc)_2](ClO_4)_2\cdot H_2O$ were, however, changed to iron(III) species under the influence of irradiation. Three iron(II) complexes in the intermediate-spin state were sensitive to gamma-rays.

A large number of investigations have been carried out by means of Mössbauer spectroscopy into the gamma-ray-irradiation effects on various compounds.

Friedt and Danon have reported that the principal effect of the radiolysis in iron(III) chelates could be interpreted in terms of the H radicals originating from the decomposition of the ligands, which had a high mobility and a high reducing property.[1] In iron(III) potassium oxalate, the reduction from iron (III) to iron(II) species by gamma-ray irradiation has been observed.[2] The primary process of this change is a charge transfer from the ligand to the iron, and the new oxidation state is stabilized by the destruction of the complex with an evolution of gases. In the emission Mössbauer spectroscopic study, the relation between the radiosensitivity and the degree of conjugation of the ligand has been elucidated.[3] The higher degree of conjugation a molecule possesses, the lower the probability of the radiolysis of its molecule.

In this work, in order to clarify the relationship of the radiation effect between the ligand field's strength (or the bond character) and the oxidation number (or the ground state of the iron complex), we synthesized several iron complexes with 1,10-phenanthroline and other related compounds as the ligands. The chemical changes which occurred in these complexes upon gamma-ray irradiation were investigated through Mössbauer spectroscopy. The following iron complexes were used; they were prepared according to the methods described in the literature: $[Fe(phen)_3]X_2\cdot nH_2O$ (X=ClO_4^-, $HCOO^-$, and NO_2^-)[4] $[Fe(phen)_2(CN)_2]$,[5] $[Fe(phen)_2(NO_2)_2]\cdot 1/2H_2O$,[6] $[Fe(phen)_2X_2]$ (X=Cl^-, $HCOO^-$, and NCO^-),[7] $[Fe(phen)_2X_2]\cdot nH_2O$ (X=1/2 oxalate, 1/2 malonate, and F^-),[8] $[Fe(phnc)_2](ClO_4)_2\cdot H_2O$,[9] and $[Fe(phns)_2](ClO_4)_2\cdot 2H_2O$.[10]

Experimental

The analytical data of the complexes prepared are listed in Table 1. The microanalyses were carried out at the Elemental Analysis Center of Kyushu University.

All the samples were sealed in glass tubes under a vacuum and were irradiated at a dose rate of 8.7×10^5 Rh^{-1} in a cylindrical tube of a 3500 Ci cobalt-60 unit of Kyushu University. All the irradiations were done at room temperature. The samples were kept at the temperature of

liquid nitrogen from the end of the exposure to the start of the measurement of the Mössbauer and the infrared spectra in order to protect the radiation effect of the samples from thermal annealing. The total radiation dose was 1.0×10^9 R or 5.8×10^8 R.

A gas-chromatographic study was carried out under the conditions to be described below, by using a G-8 type apparatus of the Yanagimoto Co., Ltd. The sensing element consisted of thermal conductivity cells and the potentiometer was operated at 90 mV. The temperature of the conductivity cell block and the column 10 feet long were kept at the same temperature, either 40 or 170 °C. Gaseous products of the irradiated $[Fe(phen)_2(HCOO)_2]$ were injected directly by using a syringe connected to the carrier-gas-inlet line. Helium was used as the carrier gas at a flow rate of about 15 ml min^{-1}, while active carbon was used as the stationary phase.

The Mössbauer spectra of the unirradiated and irradiated samples were obtained at the temperature of liquid nitrogen using a constant-acceleration spectrometer made by Austin Science Associates. The data were stored in a 1024-channel analyser, type 5200 (Ino-tec, Inc). A 5-mCi cobalt-57 diffused into a Pd foil was used as the source. The isomer shift was calibrated relative to the center of the spectrum of an iron foil at 293 K. All the spectra were fitted to the Lorentzian line shape using the least-squares method.

The infrared spectra were obtained by using a Hitachi Grating Infrared Spectrophotometer, type 215, in the region from 650 to 4000 cm^{-1}. The KBr disk was used for the sample preparation.

Results and Discussion

Figures 1—7 show the Mössbauer absorption spectra of the unirradiated and irradiated samples: $[Fe(phen)_3](ClO_4)_3\cdot2H_2O$, $[Fe(phen)_3](HCOO)_2\cdot6H_2O$, $[Fe(phen)_2(HCOO)_2]$, $[Fe(phen)_2(NCO)_2]$, $[Fe(phen)_2Ox]\cdot3H_2O$, $[Fe(phen)_2Mal]\cdot3H_2O$, and $[Fe(phen)_2F_2]\cdot4H_2O$. The Mössbauer parameters before and after irradiation for all the samples are listed in Tables 2—5.

No chemical changes were observed in the Mössbauer spectra of $[Fe(phen)_3](ClO_4)_2$, $[Fe(phen)_3]Cl_2\cdot5H_2O$, $[Fe(phen)_2Cl_2]$, $[Fe(phnc)_2](ClO_4)_2\cdot H_2O$, $[Fe(phns)_2](ClO_4)_2\cdot2H_2O$, and $[Fe(phen)_2Cl_2](ClO_4)$. From these observations, it can be supposed that the radicals produced by the decomposition of 1,10-phenanthroline upon irradiation contribute to indetectable changes in the iron(II) ground state. On the other hand, the low-spin $[Fe(phen)_3](ClO_4)_3\cdot2H_2O$ was reduced to the low-spin iron(II) (55%) species. It is clearly observed that the high-spin complex $[Fe(phen)_2Cl_2](ClO_4)$ is not sensitive to radiation. This may indicate that the irradiation effect in this case depends upon the difference in the ground state of the iron atom, and the reduction from iron(III) to iron(II) species results from the electron transfer from the ligand to the central metal. $[Fe(phns)_2](ClO_4)_2\cdot2H_2O$ and $[Fe(phnc)_2](ClO_4)_2\cdot H_2O$, for which we could not detect any irradiation effect, are in high-spin and low-spin respectively. The difference between the ligands of

the two samples is only that of carbonyl and thionyl groups, which were presumed to be sensitive to gamma-ray irradiation. It may be supposed that, even if the ligands are excited by gamma-rays, the decomposition of the ligands is suppressed because of the highly conjugated π-bond of the ligands.

Gütlich *et al.* have reported that high- and low-spin iron(II) species were observed in the emission spectra of $[^{57}Co(phen)_3](ClO_4)_2$.[11] The appearance of the high-spin iron(II) ion does not agree with the results of our external-irradiation experiment.

New peaks attributable to high-spin iron(II) species in the $[Fe(phen)_3](HCOO)_2\cdot 6H_2O$ and to high-spin iron(III) species in the $[Fe(phen)_2(HCOO)_2]$ and $[Fe(phen)_2(NCO)_2]$ appeared after the exposure to gamma-rays. There may be a possibility that the new peaks attributable to low-spin iron(II) species are hidden

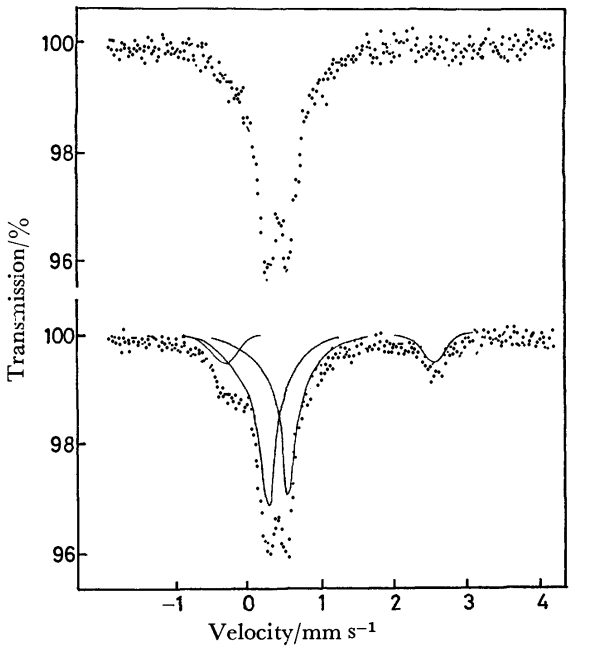

Fig. 6. Mössbauer spectra at 80 K of (a) non-irradiated and (b) irradiated $[Fe(phen)_2Mal]\cdot 3H_2O$.

in the absorption band of the high-spin iron(III) species, because their line widths are too broad to be resolved. However, we can not confirm the existence of the overlapping because of the technical difficulty in the curve fitting. The yield of high-spin iron(II) species produced in the irradiated $[Fe(phen)_3](HCOO)_2\cdot 6H_2O$ was 15%, while those of the high-spin iron(III) species in $[Fe(phen)_2(HCOO)_2]$ and $[Fe(phen)_2(NCO)_2]$ were 43% and 18% respectively. The small values of the isomer shift of iron(III) species in the above two samples suggest that there are four or five coordinated species with 1,10-phenanthroline as a result of the elimination of formate and isocyanate ions by gamma-ray irradiation. A gas-chromatograph-

ic study revealed that a large amount of carbon dioxide and a small amount of carbon monoxide existed in the irradiated $[Fe(phen)_2(HCOO)_2]$. It is considered that iron(III) species with a four- or five-coordinated structure are formed because of the decomposition of the formate ion. The radicals originating from the decomposition of 1,10-phenanthroline and hydrated waters of the second coordination sphere do not bring about the oxidation of the iron atom, because no irradiation effect was observed in $[Fe(phen)_3](ClO_4)_2$ and $[Fe(phen)_3]Cl_2 \cdot 5H_2O$. The new peaks attributable to the high-spin iron(II) species which appeared in $[Fe(phen)_3](HCOO)_2 \cdot 6H_2O$ after irradiation suggest that 1,10-phenanthroline has been decomposed by the reaction of 1,10-phenanthroline with some radicals or electrons arising from gamma-ray decomposition of the formate ion. This is true because the low-spin iron(II) state can be attained only in such a coordination situation as when the iron atom is coordinated with three 1,10-phenanthroline molecules. By comparing $[Fe(phen)_3](HCOO)_2 \cdot 6H_2O$ with $[Fe(phen)_2(HCOO)_2]$, it may be concluded that the oxidation reaction has occurred only in the latter complex. It is obscure, however, whether this difference is attributable to that in the ground states of the central metals, because we can not ignore the reaction of the iron ion with the decomposition products of the coordinated and uncoordinated $HCOO^-$, or the reaction of H_2O with the radicals produced. At present, the real reason why the high-spin iron(III) species appears in $[Fe(phen)_2(HCOO)_2]$ is ambiguous. The yields of high-spin iron(II) and iron(III) species appearing in $[Fe(phen)_3[(HCOO)_2 \cdot 6H_2O$ and $[Fe(phen)_2(HCOO)_2]$ after irradiation were 15% and 43% respectively. This indicates that the radiation effect on the central iron of $HCOO^-$ in the first coordination sphere is about three times as large as that in the second coordination sphere; this result is in good agreement with the result for other complexes done by Sano *et al.*[12]

As can be seen in Figs. 5, 6, and 7, the high-spin iron(II) and iron(III) species in $[Fe(phen)_2Ox] \cdot 3H_2O$, only the high-spin iron(II) species in $[Fe(phen)_2Mal] \cdot 3H_2O$, and two high-spin iron(II) species in $[Fe(phen)_2F_2] \cdot 4H_2O$ are observed after irradiation. The absence of high-spin iron(III) species in $[Fe(phen)_2Mal] \cdot 3H_2O$ after irradiation may be explained by the action of the carbon monoxide originating from the decomposition of the malonate ion, as has been reported in the cases of $M[Mn(mal)_2]$ ($M=NH_4^+$, Na^+, and K^+) and $K[Mn(mal)_2(H_2O)_2]$.[13] A comparison of the infrared spectrum of the unirradiated $[Fe(phen)_2Mal] \cdot 3H_2O$ with that of the irradiated one shows that the intensities of the C–O stretching appearing at 1610 and 1405 cm^{-1} were considerably decreased by the gamma-ray irradiation. This decrease suggests that carbonyl groups have been appreciably decomposed. The high-spin iron(II) species whose isomer shift is about 1.14 mm s^{-1} can be estimated to have a six-coordinated structure. The existence of the S=2 species in the irradiated $[Fe(phen)_2Ox] \cdot 3H_2O$ and $[Fe(phen)_2Mal] \cdot 3H_2O$ indicates that the ligand-field strength of the complex becomes weak. The configurational structure of a whole domain might retain the situation of total spin S=1, but in the spur formed in the path-way of ionizing radiation it might be changed to a state that is unable to maintain the situation of S=1 because of the local rearrangement of the configurational structure. The data obtained may support this assumption. Taking into account the value of the isomer shift (0.97 mm s^{-1}) of the newly produced species in $[Fe(phen)_2F_2] \cdot 4H_2O$ upon irradiation, it is reasonable to regard the species as a tetrahedral compound formed by the elimination of F^- from the coordination sphere. Such a tetrahedral species was not observed in the irradiated $[Fe(phen)_2Cl_2]$. This is because the atomic volume of Cl^- is too large in comparison with that of F^- to be removed from its coordination sphere.

No chemical changes were observed in all the samples listed in Table 5 except that the absorption intensities of $[Fe(phen)_3](NO_2)_2 \cdot 5H_2O$ and $[Fe(phen)_2(NO_2)_2] \cdot 1/2H_2O$ decreased after irradiation.

It may be concluded that in the series of the iron complexes containing 1,10-phenanthroline as a ligand, low- and high-spin iron(II) compounds and high-spin iron(III) compounds, which have ligands with highly conjugated structures, are stable to gamma-ray irradiation. On the other hand, low-spin iron(III) compounds are sensitive to radiation.

Mössbauer Spectroscopic Studies of the Chemical Effects Associated with ^{57}Co(Electron Capture)^{57}Fe Decay in Tris-β-diketonatocobalt(III) Compounds

Yoichi Sakai,† Kazutoyo Endo, and Hirotoshi Sano*

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukasawa,, Setagaya-ku, Tokyo 158

(Received September 10, 1979)

Magnetic hyperfine structures (hfs) were found in the absorption Mössbauer spectra at 78 K of a paramagnetic iron(III) complex diluted in a diamagnetic cobalt(III) or aluminium(III) complex, such as ^{57}Fe(acac)$_3$ in Co(acac)$_3$, ^{57}Fe(oxin)$_3$ in Al(oxin)$_3$, and ^{57}Fe(dbm)$_3$ in Co(dbm)$_3$ (acac=acetylacetonato, oxin=8-quinolinolato, and dbm=dibenzoylmethanato), showing that the magnetic hfs is caused by the spin-spin relaxation through the surrounding diamagnetic species. In the emission Mössbauer experiments, magnetic hfs was observed at 78 K in ^{57}Co-labelled Co(dbm)$_3$, Co(oxin)$_3$, and polystyrene-diluted Co(acac)$_3$, while it was not observed in ^{57}Co-labelled Co(acac)$_3$ and Co(dpm)$_3$ (dpm=dipivaloylmethanato). The former possess π-conjugated systems to a greater extent than the latter, either in the ligands or in the vicinity of the ^{57}Co-labelled Co(III) species. These results were explained in terms of the radiolytic stabilities of the matrices as well as those of ^{57}Co-labelled compounds by showing that the paramagnetic radicals produced in a diamagnetic matrix quench the magnetic hfs because of the increased spin-spin interaction, as a consequence of the local radiolysis by EC-decay.

Emission Mössbauer spectroscopic studies have provided us with important information on the chemical fate of the decayed atom in a solid. We have ourselves reported on the chemical effects in the ^{57}Co(EC)^{57}Fe decay process in cobalt(III) coordination compounds by applying the technique. It was observed that the decayed ^{57}Fe species exist in one or more anomalous charge states within the lifetime of the nuclear excited level of ^{57}Fe.[1-3] It was also found that the yield of anomalous species, the high-spin ^{57}Fe(II) species, produced after the EC-decay and the subsequent Auger process is quite high in the ^{57}Co(III) coordination compounds containing the oxalato ligands or the oxalate anions, such as in $K_3[Co(C_2O_4)_3]\cdot 3H_2O$[1] and $[Co(NH_3)_6]_2(C_2O_4)_3$.[3] In order to explain the results, the local radiolytic process was proposed on the basis of absorption Mössbauer experiments in the γ-ray-irradiated $K_3[Fe(C_2O_4)_3]\cdot 3H_2O$.[4] In the local radiolytic process, the radical formation was assumed in the first stage (*e.g.*, CO_2^- from an oxalato ligand or an oxalate anion). Then, the radical may be stabilized by releasing an electron (*e.g.*, CO_2^- into CO_2+e^-), which results in the reduction of the ^{57}Fe(III) species, enhancing the yield of the ^{57}Fe(II) species. On the other hand, it has been reported that the magnetic hyperfine structure (hfs) caused by spin-spin relaxation was found in the absorption Mössbauer spectra of high-spin iron(III) (S=5/2) coordination compounds diluted in diamagnetic compounds—for example, in the spectra of tris(acetylacetonato)iron(III), Fe(acac)$_3$, diluted in Co(acac)$_3$[2] or Al(acac)$_3$[5]. However, in the emission Mössbauer spectra of ^{57}Co-labelled diamagnetic cobalt(III) coordination compounds, little or no magnetic hfs has been observed at the temperature of the absorption experiments, although the decayed ^{57}Fe(III) species remain in magnetically diluted environments of diamagnetic Co(III) compounds. The discrepancy between the results of the absorption and emission Mössbauer spectroscopic studies can be explained by assuming that the enhanced spin-spin interaction between ^{57}Fe atoms and the radicals produced in the local radiolysis through the EC and Auger processes should quench the magnetic hfs in the emission Mössbauer spectra of ^{57}Co-labelled cobalt(III) coordination compounds.

In the present paper, the emission Mössbauer spectroscopic studies of various tris(β-diketonato)cobalt(III) compounds are described in order to clarify the relation of the magnetic hfs, *i.e.*, the radical formation associated with the ^{57}Co(EC)^{57}Fe decay process, with the radiolytic property of the ligands or matrices in the vicinity of ^{57}Co-labelled compounds.

Experimental

Preparation of Materials Used. The mixed crystals of tris(8-quinolinolato)^{57}Fe(III), ^{57}Fe(oxin)$_3$, and Al(oxin)$_3$ were prepared by the co-precipitation method. The molar fraction of ^{57}Fe(oxin)$_3$ was 0.03; the homogeneity of Fe(oxin)$_3$ diluted in Al(oxin)$_3$ was confirmed by X-ray diffraction analysis to be as shown in Fig. 1, where the X-ray powder patterns of Fe(oxin)$_3$ and Al(oxin)$_3$ are different from each other and where the pattern of the mixed crystals shows that of Al(oxin)$_3$, but not Fe(oxin)$_3$, though the mixture of Fe(oxin)$_3$ and Al(oxin)$_3$ with the same molar fraction shows a small but clear contribution of Fe(oxin)$_3$ in the

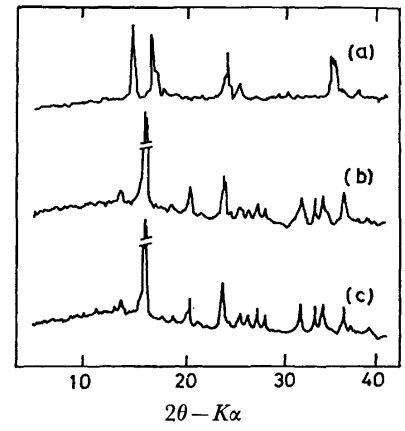

Fig. 1. X-Ray diffraction patterns of a) Fe(oxin)$_3$, b) Al(oxin)$_3$, and c) 3% mol (^{57}Fe-Al)(oxin)$_3$.

† Present address: Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113.

diffraction pattern. The mixed crystals of tris(dibenzoylmethanato)^{57}Fe(III), ^{57}Fe(dbm)$_3$, and Co(dbm)$_3$ were prepared by the freeze-dry method, in which the molar fraction of ^{57}Fe(dbm)$_3$ was 0.03.

The ^{57}Co-labelled Co(acac)$_3$ was prepared according to the literature.[6] The mixture of $CoCO_3$ containing *ca.* 1.0 mCi of ^{57}Co and acetylacetone was refluxed at 90 to 100 °C by adding 10% H_2O_2. When the resultant green solution was cooled in an ice-bath, green crystals were deposited. The crystals were filtered and washed with water and methanol. The crude crystals were recrystallized from a benzene-hexane solution.

The ^{57}Co-labelled tris(dipivaloylmethanato)Co(III) complex, Co(dpm)$_3$, was prepared as follows: A mixture of $CoCO_3$ containing *ca.* 1.0 mCi of ^{57}Co and dipivaloylmethane was refluxed in ethanol by adding 10% H_2O_2. The crude green crystals thus separated were washed with ethanol. The resultant ^{57}Co(dpm)$_3$ was purified by the recrystallization of the benzene–hexane solution.

The ^{57}Co(dbm)$_3$ was prepared by an ordinary method. A mixture of $CoCO_3$ containing 1.0 mCi of ^{57}Co and dibenzoylmethane was strongly refluxed in ethanol by adding 10% H_2O_2. The crude product in the solution was filtered and washed with ethanol. The purification of ^{57}Co(dbm)$_3$ was carried out by alumina-column chromatography in a benzene solution.

The ^{57}Co-labelled Co(oxin)$_3$ was prepared according to Ablob's method;[7] that is, $CoCl_2 \cdot 6H_2O$ containing 1.0 mCi of ^{57}Co and 8-quinolinol were dissolved in ethanol, and the product was precipitated and collected. The purification was carried out by recrystallization.

The ^{57}Co(acac)$_3$ diluted in polystyrene was prepared as follows. The ^{57}Co(acac)$_3$ prepared with 5 mg of $CoCO_3$ containing 1.0 mCi of ^{57}Co was dissolved in benzene, to which a few hundred miligrams of polystyrene were added and dissolved homogeneously. The highly viscous solution was dried in air. The homogeneity of the Co(acac)$_3$ diluted in polystyrene was confirmed by X-ray diffraction analysis in cold experiments. The diffraction pattern of Co(acac)$_3$ diluted in polystyrene showed an amorphous state, while that of the mixture of Co(acac)$_3$ and polystyrene with the same contents as the diluted samples showed the peaks of both the crystalline Co(acac)$_3$ and the amorphous pattern of polystyrene.

The chemical structures of the metal(III) coordination compounds concerned in the present work are illustrated in Fig. 2.

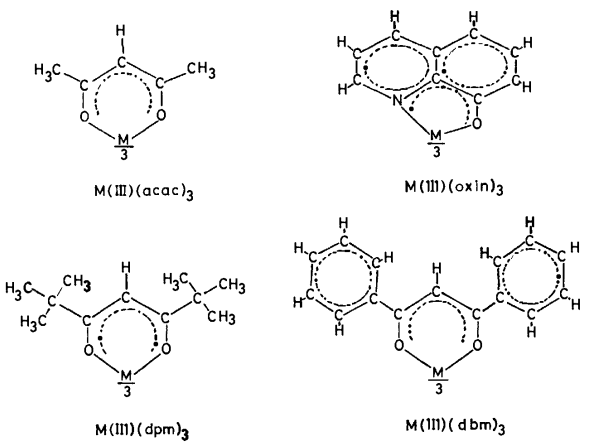

Fig. 2. Chemical structures of tris-β-diketonates of M(III) (M=Al, Fe, and Co).

Measurement of Mössbauer Spectra. The absorption Mössbauer spectra of the samples were measured at 78 K against a ^{57}Co(Pt) source moving in a mode of a constant-acceleration. Since all the emission Mössbauer spectra of the source materials kept at various temperatures (4.2 to 198 K) were measured against a moving ^{57}Fe-enriched stainless-steel as an absorber, both the emission and absorption spectra shown in Figs. 3—7 can be directly compared with each other. Velocity calibration was carried out by normalizing to iron metal in both the absorption and emission experiments.

Results

The absorption Mössbauer spectra at 78 K of ^{57}Fe(oxin)$_3$ diluted in diamagnetic Al(oxin)$_3$, ^{57}Fe(acac)$_3$ diluted in Co(acac)$_3$, and ^{57}Fe(dbm)$_3$ diluted in Co(dbm)$_3$ are shown in Figs. 3 (a), (b), and (c) respectively. The magnetic hfs is found in all the spectra of the mixed crystals at 78 K.

The emission Mössbauer spectra of crystalline ^{57}Co(dpm)$_3$, ^{57}Co(acac)$_3$, ^{57}Co(oxin)$_3$, and ^{57}Co(dbm)$_3$ at 78 K are shown in Figs. 4 (a), (b), (c), and (d) respectively. The magnetic hfs is observed in the spectra of ^{57}Co(oxin)$_3$ and ^{57}Co(dbm)$_3$, while almost no magnetic hfs is found in those of ^{57}Co(acac)$_3$ and ^{57}Co(dpm)$_3$ at 78 K. The emission Mössbauer spectra of ^{57}Co(dpm)$_3$, ^{57}Co(oxin)$_3$, and ^{57}Co(dbm)$_3$ at 4.2 K are shown in Figs. 5 (a), (b), and (c) respectively. The spectra of ^{57}Co(acac)$_3$ at 78 K and 4.2 K were reported by Nath *et al.*;[8] they are very similar to those of ^{57}Co(dpm)$_3$ shown in Figs. 4 and 5. The temperature-dependence of the emission Mössbauer spectrum is demonstrated for ^{57}Co(dbm)$_3$ in Fig. 6. The intensity of the magnetic hfs is found to increase with the decrease in the temperature. The emission

spectrum at 78 K of $^{57}Co(acac)_3$ diluted in polystyrene is shown in Fig. 7, while the crystalline $^{57}Co(acac)_3$ is shown in Fig. 4 (b). The magnetic hfs is clearly found in the diluted sample.

Discussion

The magnetic hfs in the Mössbauer spectrum is known to arise from the interaction between the internal magnetic field caused by the electron-spin and the magnetic moment of the Mössbauer nucleus. In

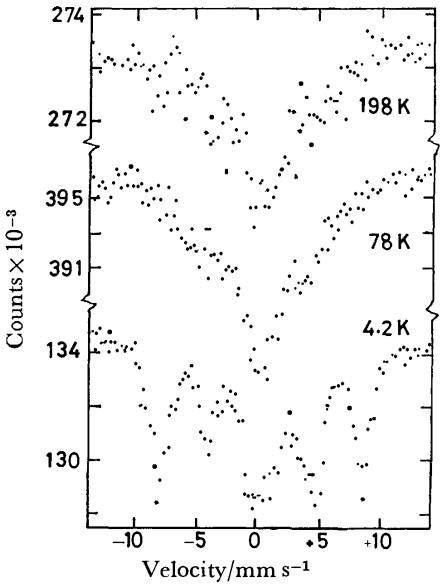

Fig. 6. Temperature-dependence of emission Mössbauer spectra for $^{57}Co(dbm)_3$.

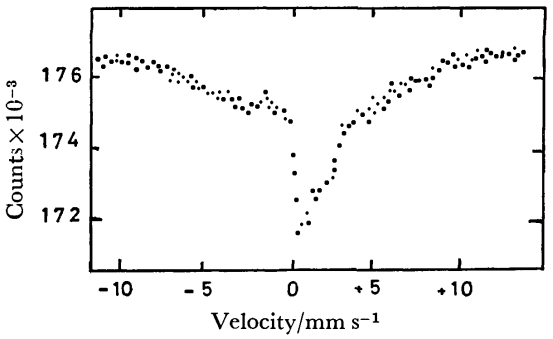

Fig. 7. Emission Mössbauer spectrum at 78 K of $^{57}Co(acac)_3$ diluted in polystyrene.

many paramagnetic iron compounds, however, the magnetic hfs is not observed in the absorption spectrum except at very low temperatures, because the internal magnetic field fluctuates in direction through the spin-spin and spin-lattice interactions with the surrounding atoms and/or molecules. Paramagnetic iron compounds diluted in diamagnetic compounds show the magnetic hfs at higher temperatures because of the decreased spin-spin interaction in the diluent diamagnetic compound. It is also known that a magnetic hfs of a small magnitude can be observed in the absorption spectra of the paramagnetic iron compounds with a large molecular size, as has been demonstrated by Wignall for $Fe(dbm)_3$ at 1.8 K.[9] We have previously reported that paramagnetic $Fe(acac)_3$ diluted in $Co(acac)_3$ shows the magnetic hfs in the absorption spectra at 78 to 230 K, but not $Fe(acac)_3$ diluted in paramagnetic $Mn(acac)_3$ or $Cr(acac)_3$ at the same temperature.[2]

In the present study, the absorption spectra at 78 K of paramagnetic $^{57}Fe(oxin)_3$ diluted in diamagnetic $Al(oxin)_3$ and $^{57}Fe(dbm)_3$ diluted in diamagnetic $Co(dbm)_3$ gave the magnetic hfs as well. As is known, the magnetic hfs is not clearly observed in the emission Mössbauer spectrum at 78 K in most ^{57}Co-labelled

cobalt(III) coordination compounds, such as hexammine cobalt(III), hexacyanocobaltate(III), tris(oxalato)-cobaltate(III), and tris(acetylacetonato)cobalt(III). When paramagnetic ^{57}Fe species produced through the EC-decay remain in environments diluted magnetically by diamagnetic cobalt(III) host compounds, the magnetic hfs might be expected to be observed to the same extent as in the paramagnetic Fe(III) species diluted in diamagnetic Co(III) compounds. In order to explain the experimental results (*i.e.*, that little or no magnetic hfs has been observed in most emission spectra at 78 K of the ^{57}Co-labelled cobalt(III) compounds), we have proposed that some species with an electron-spin should be formed in the vicinity of the decayed ^{57}Fe atoms and that the paramagnetic species with an electron spin should suppress the magnetic hfs through the spin-spin interaction with the paramagnetic ^{57}Fe species. The paramagnetic species were assumed to be radicals produced through the local radiolysis in the EC-decay and the subsequent Auger process.

As may be seen in Fig. 4, the magnetic hfs is observed in the emission spectra at 78 K in the source compounds, ^{57}Co(oxin)$_3$ and ^{57}Co(dbm)$_3$. The emission spectra at 4.2 K of these source compounds show the magnetic hfs to a much greater degree than at 78 K. The spectrum of ^{57}Co(dpm)$_3$ also shows the magnetic hfs at 4.2 K, but the intensity is apparently lower than those found in ^{57}Co(dbm)$_3$ and ^{57}Co(oxin)$_3$. The spectrum of ^{57}Co(acac)$_3$ at the temperature of liquid helium reported by Nath *et al.*[8] is very similar to that of ^{57}Co(dpm)$_3$. The intensities of the magnetic hfs at 4.2 K and 78 K decrease in the following order: ^{57}Co(dbm)$_3$ > ^{57}Co(oxin)$_3$ > ^{57}Co(dpm)$_3$ $\fallingdotseq$ ^{57}Co(acac)$_3$. The former two compounds have aromatic π-conjugated systems in the ligands, while the latter two compounds have no such aromatic system, as may be seen in Fig. 2. The appearance of the magnetic hfs might be related to the chemical structure of the source compound, especially to whether or not the source compound possesses π-conjugated systems in the ligands. Furthermore, the appearance of the magnetic hfs in the emission spectrum at 78 K of ^{57}Co(acac)$_3$ diluted in polystyrene shown in Fig. 7 can be explained in a similar way. The fact that fewer of the paramagnetic radicals are produced in the diluted sample of ^{57}Co(acac)$_3$ in polystyrene than in the neat crystalline ^{57}Co(acac)$_3$ may be ascribed to the effects of the many phenyl groups involved in polystyrene. It is well known in radiation chemistry that the radiolytic stability of compounds with π-conjugated systems is much larger than that of compounds with only σ-bond systems. The G-values of the free ion of various organic compounds in 2 MeV X-ray radiolysis were reported by Schmidt and Allen,[10] who showed that those values in aromatics and olefines are much smaller than in alkanes. From the radiation-chemical point of view, it may be concluded that the appearance of the magnetic hfs in the emission Mössbauer spectrum of a ^{57}Co-labelled cobalt(III) coordination compound proves the radical-formation hypothesis in the local radiolysis through the EC-Auger process.

The Crystal Structure of Bis(2,2′-bipyridine)nitratocopper(II) Nitrate Monohydrate $[Cu(NO_3)(bpy)_2]NO_3 \cdot H_2O$

Hisayoshi NAKAI

Department of Chemistry, Hyogo College of Medicine, Mukogawa-cho, Nishinomiya, Hyogo 663

(Received September 19, 1979)

The crystal structure of the title compound has been redetermined from diffractometer data and refined by the least-squares method to $R=0.053$ for 2448 non-zero reflections. The crystal is triclinic, with $a=7.464(3)$, $b=10.002(5)$, $c=15.503(6)$ Å, $\alpha=111.50(5)$, $\beta=91.43(5)$, $\gamma=90.47(4)°$, space group $P\bar{1}$, and $Z=2$. The copper atom has a square-pyramidal coordination very distorted by the 4 N atoms of the bipyridine ligands and one of the O atoms of the nitrato ligand at the apical position. The disposition of the 4 N atoms at the basal plane is flattened tetrahedral. The Cu atom is displaced by 0.31 Å from the mean plane of the 4 N atoms towards the apical O atom. The Cu–O and the average Cu–N distances are 2.30 and 2.01 Å respectively. In both bipyridine molecules, the two pyridine planes are twisted slightly from each other; the interplanar angle is 2.6° in one bipyridine ligand and 6.0° in the other. The mean planes of the two bipyridine molecules make an angle of 44.6°.

The $Cu(bpy)_2^{2+}$ moiety in bis(bipyridine)copper(II) complexes has been shown to be unable to take a strictly coplanar disposition because of the interligand repulsion. Indeed, in these complexes, the planes of the two bipyridine ligands are usually twisted by 30—60° away from each other; consequently, the four nitrogen atoms are disposed tetrahedrally.[1-3] Such a situation, however, complicates the stereochemistry of penta-coordinate bis(bipyridine)copper(II) complexes; it is difficult to distinguish strictly between a trigonal-bipyramidal and a square-pyramidal structure. In the case of $[Cu(NO_3)(bpy)_2]NO_3 \cdot H_2O$, the coordination geometry of which has been reported briefly as a distorted trigonal bipyramid,[4] the reflectance spectrum is somewhat different from those of the other trigonal-bipyramidal complexes.[5]

In order to make a further investigation into the stereochemistry of bis(bipyridine)copper(II) complexes, a refinement of the crystal structure of the $[Cu(NO_3)(bpy)_2]NO_3 \cdot H_2O$ was performed using the diffractometer intensity data.

Experimental

The blue crystals of $[Cu(NO_3)(bpy)_2]NO_3 \cdot H_2O$ were prepared by Jeager's method[6] and were recrystallized from a water-methanol mixture. Found: C, 46.47; H, 3.67; N, 16.22%. Calcd for $Cu(bpy)_2(NO_3)_2 \cdot H_2O$: C, 46.38; H, 3.50; N, 16.23%.

Preliminary X-ray photographs taken with Cu $K\alpha$ radiation showed $\bar{1}$ Laue symmetry, indicating a triclinic space group. No systematic absences were observed. The space group is either $P\bar{1}$ or P1; the former was confirmed by a successful refinement of the structure.

A crystal with dimensions of $0.20 \times 0.20 \times 0.23$ mm was mounted on a glass fiber for data collection. The lattice constants were determined by a least-squares fit using 32 independent θ-values measured accurately on a diffractometer. Crystal data: $[Cu(NO_3)(bpy)_2]NO_3 \cdot H_2O$, $M.W.=517.9$, triclinic, $a=7.464(3)$, $b=10.002(5)$, $c=15.503(6)$ Å, $\alpha=111.50(5)$, $\beta=91.43(5)$, $\gamma=90.47(4)°$, $U=1076.4$ Å^3, $Z=2$, $D_c=1.60$, $D_m=1.60$ g·cm^{-3} (by flotation in a benzene–bromoform mixture), Mo $K\alpha$ radiation ($\lambda=0.71069$ Å), μ(Mo $K\alpha$)$=10.7$ cm^{-1}, space group $P\bar{1}$.

Intensity data with $2\theta \leqq 56°$ were collected at room temperature by means of the w-2θ scan technique on a Philips PW1100 four-circle diffractometer using graphite-monochromated Mo $K\alpha$ radiation. The scan speed and scan width were 0.03° s^{-1} and $(0.90+0.20\tan\theta)°$ respectively. The background was counted for 10 s at each end of the scan range. Three standard reflections (100, 040, and 002), monitored every 3 h throughout the data collection, showed no significant variation in intensity. A total of 2448 intensities with $I_{top}-2\sqrt{I_{top}}>I_{back}$ were classified as observed; I_{top} is the intensity (counts/s) measured at the top of the peak, while I_{back} is the mean background intensity (counts/s) obtained from the preliminary background measurement for 5 s on each side of the peak. The intensity data were processed with the computer program of Hornstra and Stubbe.[7] No absorption correction was made.

The reflectance spectrum of this compound was also measured, using a Hitachi 139 spectrophotometer fitted with a standard reflectance attachment.

Refinement of the Structure

The refinement of the structure was carried out by means of a block-diagonal least-squares method. The function minimized was $\Sigma w(|F_o|-|F_c|)^2$. A weighting scheme of the type suggested by Hughes[8] was applied, using $w=1.0$ for $F_o \leqq 20.0$ and $w=(20.0/F_o)^2$ for $F_o>20.0$. The atomic scattering factors were taken from Ref. 9.

The initial parameters were those reported earlier.[4] The refinement of the atomic positions and isotropic thermal parameters gave the R value of 0.127 after three least-squares cycles. Subsequent refinement in which each atom was allowed to vibrate anisotropically reduced the value of R to 0.064. The positions of all the hydrogen atoms were obtained from the difference Fourier map calculated at this point. These hydrogen atoms were included in the final refinement, with an isotropic thermal parameter of 4.0 Å^2. The final R value was 0.053 for 2448 observed reflections. All the parameter shifts were less than 0.2σ in the final cycle of the refinement. The atomic coordinates and thermal parameters are listed in Tables 1 and 2. The observed and calculated structure factors are preserved at the Chemical Society of Japan (Document Number 8013). The computer programs used in the calculations were as follows: HBLS-V[10] (least-squares calculation), RHOMAP[10] (Fourier synthesis), and DAPH[10] (interatomic distances and angles, least-squares plane, and coordinates of the H atoms). The calculations were made on the NEAC 2200-700 and

ACOS-800 of Osaka University.

Results and Discussion

The crystal consists of discrete $[Cu(NO_3)(bpy)_2]^+$, NO_3^-, and H_2O. Figure 1 shows the a-axis projection of the crystal structure. The bond lengths and angles, with their estimated standard deviations, are given in Table 3.

Although the two chelate rings composed of Cu and the bpy have substantially the same structure, two Cu–N bonds in each ring are significantly different in length; the average value of the longer bond lengths is 2.034(5) Å, while that of the shorter ones is 1.983(5)

Å. The nitrato group is coordinated virtually as a unidentate ligand through the O(1) atom(Cu–O(1)= 2.299(5) Å), but one more oxygen atom, O(2), is located at a distance of 2.818(7) Å from the copper atom. The copper atom is thus five-coordinate, but the coordination polyhedron around the copper atom seems to be intermediate between a trigonal bipyramid and a square pyramid.

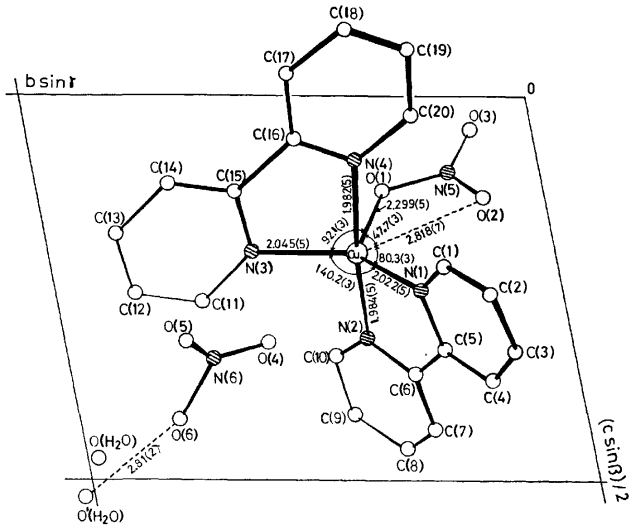

Fig. 1. The crystal structure viewed down the a axis.

If this complex is regarded as assuming a trigonal-bipyramidal structure, I, the N(2) and N(4) atoms can be said to occupy the axial positions, while the Cu, O(1), N(1), and N(3) atoms form an equatorial plane. However, in $[CuX(bpy)_2]^{n+}$-type complexes (X=I, NH_3, Cl, $CS(NH_2)_2$, and Cu^ICl_2) which have been classified as trigonal-bipyramidal structures on the bases of the spectral and X-ray studies,[5,11–15] it has been found that the axial Cu–N distances are significantly (0.06—0.12 Å) shorter than the equatorial ones except for the case of $[CuI(bpy)_2]^+$,[11] and also that the N–Cu–N angle in the equatorial plane is in the 109—123° range, which is close to the angle (120°) in the regular trigonal bipyramid. In the present complex, the difference between the axial and equatorial Cu–N bond distances is 0.038 Å, a little smaller than those in the trigonal-bipyramidal complexes mentioned above. Besides, the angle of N(1)–Cu–N(3) in the equatorial plane is 140.2(3)°; this value is considerably outside the range of 109—123°.

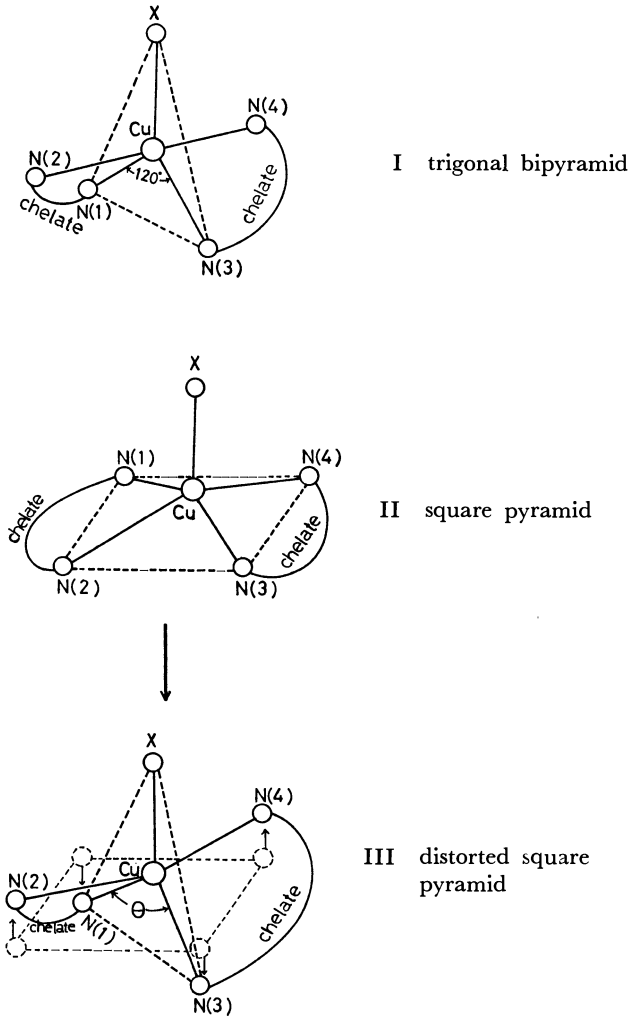
a) $1-x$, $2-y$, $1-z$.



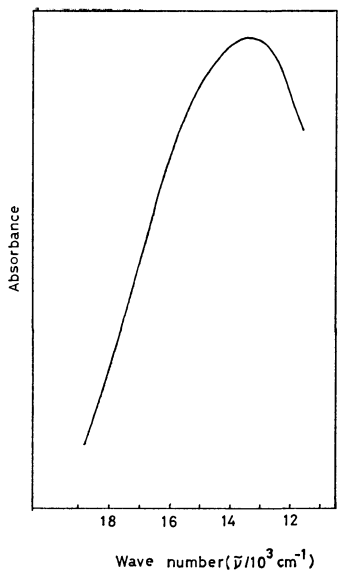


Fig. 2. Electronic reflectance spectrum of $[Cu(NO_3)(bpy)_2]NO_3 \cdot H_2O$.

The electronic reflectance spectrum of this complex in the range of $11.5—20.0 \times 10^3$ cm^{-1} shows a single peak at 13.2×10^3 cm^{-1}. The peak position is considerably different from those for the trigonal-bipyramidal Cu–bpy complexes,[5] in which the spectra have been known to show a single characteristic band with a maximum at $12.0—12.5 \times 10^3$ cm^{-1}. These structural and spectral features are not compatible with those of the trigonal-bipyramidal copper(II) chelates of the bpy.

On the other hand, if the coordination polyhedron of this complex is regarded as a square pyramid, II, the four nitrogen atoms should be taken as forming the basal plane, and the O(1) atom, as occupying the apical position. In this case, however, the nitrogen atoms can not take a planar disposition because of the interligand repulsion, and so presumably have a flattened tetrahedral arrangement, as is shown in III. The scaled model indicates that the N(1)–Cu–N(3)(=θ) and X–Cu–N(1)(=X–Cu–N(3)) angles in III (X= a donor atom in the fifth position) are 140—160° and 100—110° respectively. In the present complex, however, the O(1)–Cu–N(1) angle (127.8°), which corresponds to the X–Cu–N(1) angle in III, is larger than the expected value of about 110°, since the N(1)–Cu–N(3) angle corresponding to θ is 140.2°. On examining the significance of this observation in detail, it should be noted that the O(2) atom of the nitrato group almost lies on the plane, "A", defined by the Cu, O(1), N(1), and N(3) atoms (Fig. 1) and has short contacts with the atoms of the chelate rings: 3.178(8) Å to N(1), 3.205(8) Å to N(2), and 2.66(5) Å to H(C20). The steric interactions with the bipyridine ligands appear to prevent bidentate coordination of the nitrato group. Moreover, the O(2) atom results in the enlargement of the O(1)–Cu–N(1) angle by 35.7° as compared with the O(1)–Cu–N(3). On the basis of the structural features described above, the coordination geometry about the copper atom should

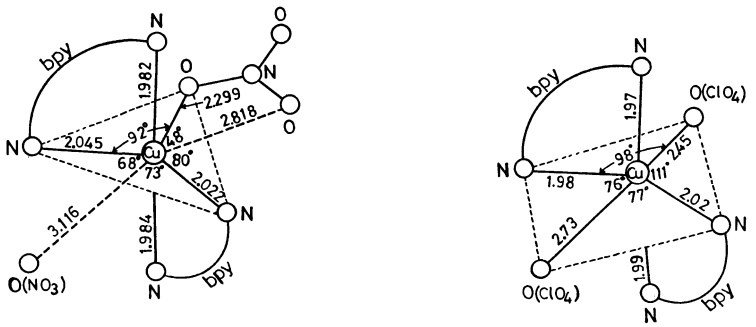

Fig. 3. The resemblance between the stereochemistries of $[Cu(NO_3)(bpy)_2]NO_3 \cdot H_2O$ and $[Cu(ClO_4)(bpy)_2]ClO_4$.

be regarded as a distorted square pyramid.

The copper atom is displaced by 0.31 Å towards the apical O(1) atom from the mean plane of the 4 N atoms. The Cu–N bond distances are 2.008 Å, on the average. The dihedral angle between the Cu$\begin{matrix}/N(1)\\ \backslash N(2)\end{matrix}$ and Cu$\begin{matrix}/N(3)\\ \backslash N(4)\end{matrix}$ planes is 42.8°. The structure of the present complex is thought to be related to that of the distorted *trans*-octahedral $[Cu(ClO_4)(bpy)_2]$-ClO_4.[1] This is illustrated in Fig. 3, which shows a schematic drawing of these two complexes. Although the O(4) atom of the uncoordinated NO_3^- ion is situated nearly at the sixth position in an octahedral coordination, it is 3.12 Å apart from the copper atom.

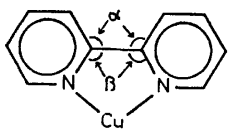
a) Planes are defined as $AX+BY+CZ+D=0$, where X, Y, and Z are Cartesian coordinates which are related to the triclinic cell coordinates(x, y, z) by these transformations: $X=xa+yb\cos\gamma+zc\cos\beta$, $Y=yb\sin\gamma-zc\cos\alpha^*\sin\beta$, and $Z=zc\sin\alpha^*\sin\beta$. b) Atoms not used to define the least-squares plane.

The bipyridine ligands are not planar, but the individual pyridine moiety is planar within ±0.014 Å. The pyridine moieties of the bipyridine molecule are slightly twisted from each other about the 2,2′-carbon bond; the twist angle is 2.6° for the molecule comprising N(1) and N(2) and 6.0° for the other. Furthermore, the bond angle of α is larger than that of β by about 9°. A similar difference in these angles



(5—10°) has also been observed in the crystal structure of the 2,2′-bipyridine molecule[16] and its copper(II) complexes.[1] The bond lengths in the bipyridine ligands range from 1.37(1) to 1.41(1) Å in the aromatic C–C bond, and from 1.34(1) to 1.36(1) Å in C–N, while the 2,2′-carbon bonds are about 1.47 Å long (Table 3). The bond angles of C–C–C, C–N–C, and C–C–N in pyridine rings are 119.1, 119.2, and 121.8° respectively, on the average. The H(C1)---H(C20) and H(C10)---H(C11) distances between the bipyridine chelates are 2.37(7) and 2.27(7) Å. These values are not very different from the sum of the van der Waals radii of the hydrogen atoms.

The nitrato group is planar and acts as a unidentate ligand through the O(1) atom; another O(2) atom is located at the distance of 2.818(7) Å from the copper atom. The angle of Cu–O(1)–N(5) is 109.3(5)°. This mode of coordination of the nitrato group has also been found in the complexes[17] containing unidentate nitrato groups (ex. $[Cu(NO_3)_2(phen)]$[18] and $[Cu(NO_3)(dach)_2]NO_3 \cdot [Cu(H_2O)(dach)_2](NO_3)_2$[19] (dach=1,4-diazacycloheptane)). The N(5)–O(1) bond distance is a little longer (0.02—0.03 Å) than the remaining N(5)–O(2) and N(5)–O(3) ones, and the O(2)–N(5)–O(3) angle is greater (4—5°) than those of O(1)–N(5)–O(2) and O(1)–N(5)–O(3). The dihedral angle between the nitrato plane and the "A" plane is about 10°.

The uncoordinated nitrate ion is linked to the water-oxygen atom, $O'(H_2O)[1-x, 2-y, 1-z]$, through O–H---O hydrogen bonding ($O'(H_2O)$---O(6)=2.81Å).

The author is very grateful to Professor Yukinao Noda for his kind advice and encouragement throughout the present work. The author is also grateful to Professor Emeritus Hisao Kuroya and Dr. Shun'ichiro Ooi of Osaka City University for their valuable discussions and advice, and to Dr. Keiji Matsumoto, Osaka City University, for the use of a Philips PW1100 dif-

fractometer.

An X-Ray Photoelectron Spectroscopic Study of Several Ligands in Coordination Compounds

Tooru YOSHIDA

Osaka Prefectural Industrial Research Institute, 2-1-53, Enokojima, Nishi-ku, Osaka 550

(Received October 13, 1979)

The N(1s) electron binding energies were measured by means of X-ray photoelectron spectroscopy for the complexes of 2-pyridinecarboxylic acid, 8-quinolinol, and anthranilic acid with a variety of bivalent metal ions. The correlations of their binding energies with the electronegativity and the ionic potential (Z/r) of the metal ion and the charge on the nitrogen atom, and the covalent character of the nitrogen-metal bond calculated on the basis of Pauling's concept were examined. The chemical shift in the N(1 s) binding energy was about 1 eV at most. However, it was suggested that it is possible to use the chemical shift to determine the nature and strength of the nitrogen-metal bond in a series of complexes of the same ligand.

X-Ray photoelectron spectroscopy (XPS) is now extensively used to study the electronic and geometric structures of coordination compounds. There have been many studies of the determinations of the oxidation state of elements, the donor-acceptor capacity of ligands, the mode of ligand coordination, the structure of valence levels, *etc.* However, there have been few studies in which the effect of a variety of metal ions of both transition and typical elements on the binding energy of inner-shell electrons of a ligand in a series of complexes of the ligand has been systematically examined.[1)]

The purpose of the present study is to determine the N(1s) electron binding energies of the complexes of the three bidentate ligands involving nitrogen and oxygen donor atoms—2-pyridinecarboxylic acid, 8-quinolinol, anthranilic acid, with various bivalent metal ions, and to examine the correlations of their binding energies with the electronegativity and the ionic potential of the metal ion and the charge on the nitrogen atom and the covalent character of the nitrogen–metal bond calculated based upon Pauling's concept.[2)]

Experimental

The X-ray photoelectron spectra were measured on an AEI ES200 spectrometer. Al k_α (1486.6 eV) and Mg k_α (1253.6 eV) X-ray radiations were used as the excitation sources. Samples were ground to powder and then dusted onto a double-backed adhesive tape. The measurements were run at room temperature under a vacuum of about 10^{-7} Torr. However, a freezing technique was used for a few volatile samples. All the free ligands (abbreviated as LH) were commercially available and of an analytical grade, and they were used after recrystallization from ethanol. The metal salts used were acetates except for the following salts: K_2PtCl_4, $PdCl_2$, $Fe(NH_4)_2(SO_4)_2$, $SnCl_2$, $BeSO_4$, and $Sr(NO_3)_2$. The complexes were prepared based upon the literature methods.[3)] In outline, the methods consisted of the addition of an ethanol or acetic acid solution of ligands to an aqueous solution of metal salts, in some cases followed by neutralization by an aqueous NaOH or ammonia. The ligand-metal ratios were 2:1 for all the complexes except for the beryllium complex of 2-pyridinecarboxylic acid. The composition of the beryllium complex of 2-pyridinecarboxylic acid was $Be_2OL_2\cdot 2H_2O$, as was the case with its 8-quinolinol complex.[4)] Instead of the beryllium complex of 8-quinolinol, that of 2-methyl-8-quinolinol was used; its composition was BeL_2.[5)] The sodium and perchlorate salts of each LH were obtained by treating LH with NaOH and $HClO_4$ in ethanol respectively. All the compounds were checked by elemental analysis. It is reasonable to assume that the C(1s) binding energy is nearly constant within the complexes of the same ligand. Furthermore, as only the relative energies were considered in the present study, the binding energy of the C(1s) electron peak was used as the energy standard throughout the present experiments; it was taken to be 285.0 eV. The reproducibilities of the values thus obtained were within ± 0.1 eV.

Binding-energy Correlations

It has been shown that, in the point-charge model, the core-electron binding energy (abbreviated as BE) can be expressed as follows in terms of the charge density, q_A, on the A atom of interest:[6)]

$$BE = k_A q_A + V + E_R + l_A, \quad (1)$$

where V denotes the electrostatic potential at the nucleus caused by the surrounding atoms, where E_R gives the relaxation energy attributable to photoionization, and where k_A and l_A are constants to be decided from experiments. Here, V is given by the equation: $V=\sum_{A\neq B} q_B/R_{A-B}$, where q_B is the charge on the surrounding atom, B, and where R_{A-B} is the interatomic distance from the B atom to the A atom. For the covalent compound, the summation may be restricted to atomic charges within one molecule. E_R can be expected to be almost constant as long as molecules in similar environments are being compared.[7)]

In this study, the structures of the compounds to be compared are so similar that the N(1s) binding energy may be approximately written as follows:

$$BE = k_N q_N + q_M/R_{M-N} + K \quad (2)$$

where q_N and q_M are the charges on the nitrogen and the metal respectively, where R_{M-N} is the interatomic distance of the metal and the nitrogen atoms, and where K is a constant. Here, all the other terms except for q_M/R_{M-N} in V were regarded as constants.

To a very rough approximation, the N(1s) binding energy is linearly related to the charge of the nitrogen atom.[6)] That is,

$$BE = k'_N q_N + l'_N \quad (3)$$

where k'_N and l'_N are constants.

Results and Discussion

All the compounds used and their N(1s) binding energies are given in Table 1. The electronegativities[8)]

a) Crystal waters in the structural formula were omitted because of the negligible effect of crystal water on the N(1s) binding energy. b) The formula corresponds to the complex of 2-pyridinecarboxylic acid.

and ionic[9] and atomic[10] radii adopted in this study are given in Table 2, along with the calculated charges and covalent characters.

All the N(1s) binding energies of the complexes of the three ligands were equal to, or higher than, those of the corresponding sodium salts, while they were lower than those of the corresponding perchlorates. The changes in the binding energy, the chemical shifts, were about 1 eV at most. These chemical shifts were considered to be attributable to the decreases in the electron density on the nitrogen atoms caused by the coordination of the lone-pair electrons of the nitrogen atoms to the metal.

In this study, the O(1s) binding energies were not discussed because of their small chemical shifts compared with those of the N(1s) binding energies.

Correlations between N(1s) Binding Energies and Electronegativities. Qualitatively, the electronegativity of an element is considered to be a measure of its ability to attract electrons. Therefore, it can be expected that, within the complexes of the same ligand, the binding energy of the donor atom of the ligand increases with the electronegativities of the metal ions involved.

The correlation between the N(1s) binding energy and the electronegativity in the complexes of 2-pyridinecarboxylic acid is shown in Fig. 1. An increase in the binding energy with the increase in the electronegativity could be observed, although the trend was weak. The correlations in the complexes of 8-

quinolinol and anthranilic acid were similar.

Correlations between N(1s) Binding Energies and Charges. The charges, q_N and q_M, in Eq. 2 were calculated by a method[11] utilizing Pauling's partial ionic character. That is, in general, the q_A on the A atom can be expressed as follows: $q_A=Q_A+\sum_{A\neq B} I_{AB}$, where Q_A is the formal charge on the A atom, and where I_{AB} is the partial ionic character of the A–B bond. Here, I_{AB} is given by the equation: $I_{AB}=1-\exp\{-0.25(\chi_A-\chi_B)^2\}$, where χ_A and χ_B are the electronegativities of the A and B atoms. In spite of a great deal of arbitrariness involved in obtaining the charge in this way, many good correlations have been reported between such a charge and the core-binding energy.[12] Because the bond length data for most of the compounds in Table 1 were not known, R_{M-N} in Eq. 2 was replaced for convenience by the sum of the atomic radius of the metal atom and the covalent radius of the nitrogen atom.

The values of q_N, q_M, and q_M/R_{M-N} thus obtained are given in Table 2. Here, the values of q_N in the table are for the complexes of 2-pyridinecarboxylic acid and 8-quinolinol; those for anthranilic acid are omitted.

For the complexes of 2-pyridinecarboxylic acid, the correlations of q_N with the binding energy and the corrected binding energy ($BE-q_M/R_{M-N}$) are shown in Figs. 2 and 3. In both figures, an increase in the binding energy with an increase in the charge was

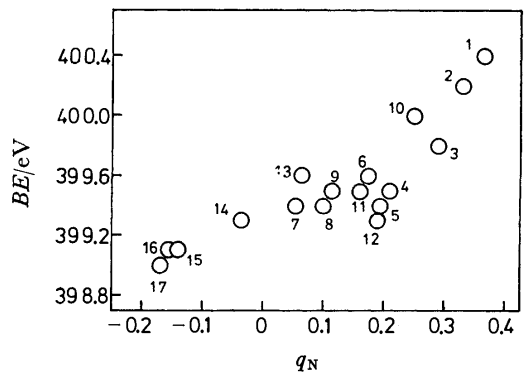

Fig. 2. Correlation between the N(ls) binding energies and the charges on nitrogen atoms. Numbers refer to Table 1.

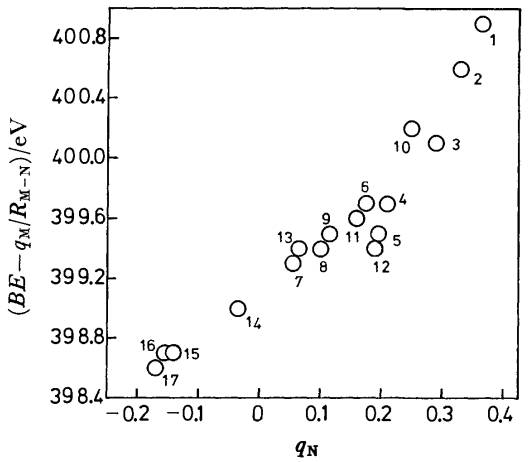

Fig. 3. Correlation between the corrected N(ls) binding energies and the charges on nitrogen atoms. Numbers refer to Table 1.

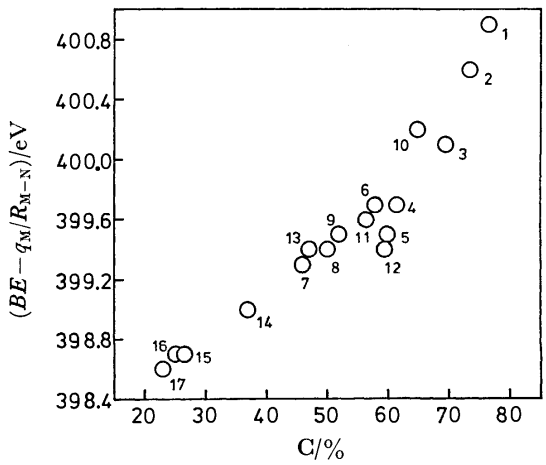

Fig. 4. Correlation between the corrected N(ls) binding energies and the covalent characters of the nitrogen–metal bonds. Numbers refer to Table 1.

observed, although its trend was not linear. As can be seen in Fig. 3, the inclusion of the correction term, q_M/R_{M-N}, slightly improves the correlation. For the complexes of 8-quinolinol and anthranilic acid also, similar correlations were observed.

Correlations between N(1s) Binding Energies and Covalent Characters. The covalent characters (abbreviated as C (%)) of the nitrogen–metal bonds, estimated on the basis of Pauling's partial ionic character,[2] are given in Table 2. That is, the covalent character corresponds to $100(1-I_{MN})$, where I_{MN} is the partial ionic character of the bond. For the complexes of 2-pyridinecarboxylic acid, the correlation between the corrected binding energy ($BE-q_M/R_{M-N}$) and the covalent character is shown in Fig. 4. An increase in the binding energy with the increase in the covalent character was observed. For the complexes of 8-quinolinol and anthranilic acid also, similar correlations were observed.

Considering the $\Delta H-T\Delta S=-RT\ln K$ relationship, it is seen that the stability constants of complexes, K, are functions of both the enthalpy change, ΔH, and the entropy change, ΔS. However, if the ligand is

the same, and there is also no significant difference in the size or structure of the complexes (*i.e.*, if ΔS is practically constant), the variation in their stabilities is primarily attributable to the difference in the strength of the metal-to-donor bond represented by ΔH. Therefore, in a bond in which pi bonding is not involved or in which sigma bonding is dominant, the stronger this bond is, that is, the more the covalent character of the bond, the more is the electron deficiency around the nitrogen atom, resulting in a corresponding increase in the N(ls) binding energy.

The higher binding energies of the complexes of the Pd and Pt of transition metal ions (Nos. 1—7 in the figure), of the Hg of zinc family ions (Nos. 8—10), and of the Be of alkaline earth ions (Nos. 13—17) compared with the other metal ions of each group seem to be consistent with the general trend that the above four metal ions form the more stable complexes in each group.

Correlations between N(1s) Binding Energies and Ionic Potentials. For the complexes of 2-pyridinecarboxylic acid, the correlation between the corrected binding energy and Z/r is shown in Fig. 5. The correlations for the complexes of 8-quinolinol and anthranilic acid were similar to Fig. 5. From the figure, the following facts were observed. In the group of alkaline earth ions, the binding energy increases linearly with Z/r. In the group of transition metal ions and zinc family ions, however, such no trend is observed at all. Furthermore, the binding energies of the latter group were considerably higher than those of the former metal ions with similar ionic potentials.

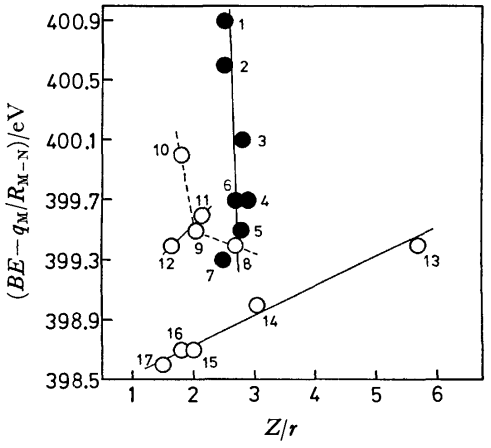

Fig. 5. Correlation between the corrected N(ls) binding energies and ionic potentials. Numbers refer to Table 1.
●: Complexes of transition elements, ○: complexes of typical elements.

These facts clearly suggest the difference in bonding type between the two groups. That is, the bonding type is ionic for the former metal ions and covalent for the latter.

The results of this study seem to support the conclusion that it is possible to use the chemical shift in the N(1s) binding energy by means of XPS, even if it is small, to determine the nature and strength of the nitrogen–metal bond in a group of carefully selected compounds.

The author wishes to thank Drs. Kiyoshi Yamasaki and Shigemasa Sawada for their helpful discussions and suggestions during this work, and Mr. Taichiro Hirohara for the elemental analysis.

The Collection of Uranium from Sea Water with Hydrous Metal Oxide. III. The Effects of Diverse Ions in Sea Water on Uranium Adsorption by Hydrous Titanium(IV) Oxide

Hisao YAMASHITA,* Yoshihiro OZAWA,** Fumito NAKAJIMA, and Toshifumi MURATA**

Hitachi Research Laboratory, Hitachi, Ltd., Kujimachi, Hitachi-shi 319-12

***Energy Research Laboratory, Hitachi, Ltd., Moriyama-cho, Hitachi-shi 316*

(Received April 2, 1979)

The effect of diverse ions present in sea water on the uranium adsorption is elucidated in the present paper. The uranium-adsorption experiments were conducted using sea water and a solution containing 0.72 mol dm^{-3} NaCl and 2.3×10^{-3} mol dm^{-3} $NaHCO_3$. The uranium uptake was about ten times larger from the NaCl–$NaHCO_3$ solution than from sea water. The ions which depressed the uranium uptake were the calcium, magnesium, and fluoride present in sea water. Among these ions, calcium had the largest effect on the uranium uptake. The analysis of calcium and carbonate in the adsorbent after the adsorption experiment has revealed that the molar ratio between calcium and carbonate was about one. It was considered that calcium carbonate was deposited on the adsorbent during the uranium adsorption. The specific surface area and the pore volume decreased after the deposition of calcium carbonate. It was supposed that the decrease in the uranium uptake was caused by the coverage of the surface of hydrous titanium(IV) oxide with calcium carbonate. Magnesium ions depressed the uranium uptake in the same manner as calcium ions. The effect of the magnesium ions, however, was relatively small compared with that of the calcium ions.

For the purpose of collecting uranium from sea water, several methods have been proposed; adsorption,[1-2] coprecipitation,[3] ion exchange,[4] ion floatation,[5] and solvent extraction.[4] The adsorption method has been thought to be most feasible. In the adsorption method, an adsorbent with a high adsorption capacity and selectivity is prerequisite, because the uranium concentration is very low (3 ppb), and a large amount of diverse ions are present in sea water. A large number of adsorbents have been examined. It has been reported that hydrous titanium(IV) oxide is the most suitable as a uranium adsorbent.[1-2]

More than sixty ions are present in sea water. Since hydrous titanium(IV) oxide serves as a cation exchanger in sea water, cations present in sea water may affect the uranium adsorption. Ogata *et al.*[6] reported that the uranium uptake decreased slightly in the presence of phosphate, fluoride, and copper. Kanno *et al.*[7] described that carbonate ions present in sea water had a negative effect on the uranium adsorption. However, these results can not satisfactorily account for the effect of diverse ions on uranium adsorption.

In the present work, the effect of diverse ions present in sea water on the uranium adsorption by hydrous titanium(IV) oxide is described.

Experimental

Preparation of Hydrous Titanium(IV) Oxide. Hydrous titanium(IV) oxide was prepared by adding 7% aqueous ammonia to a solution of 0.6 mol dm^{-3} titanium(IV) chloride at 90 °C. The precipitate was filtered off, washed with water, and dried at room temperature for about 10 d. The dried samples were crushed and sieved, a portion of 300—400 mesh being used in the experiments. The water content was determined by measuring the ignition loss at 800 °C; it was found to be 18%, which corresponded to $TiO_2\cdot H_2O$. X-Ray powder diffraction analysis showed the crystal form of anatase, with an apparent crystal size of 38 Å.

Adsorption Experiments. Sea water and a NaCl–$NaHCO_3$ solution were used in the adsorption experiments.

Table 1. Molar concentrations of uranium and major ions in sea water sampled at the Hitachi seashore

	Concentration/mol dm^{-3}
U	1.3×10^{-8}
Cl	5.4×10^{-1}
Na^+	4.6×10^{-1}
Mg^{2+}	5.2×10^{-2}
SO_4^{2-}	2.7×10^{-2}
Ca^{2+}	9.9×10^{-3}
K^+	9.7×10^{-3}
$HCO_3^-+CO_3^{2-}$	2.3×10^{-3}
pH	8.0—8.1

The molar concentrations of uranium and the major constituents of sea water used in the present work are shown in Table 1. In the case of a NaCl–$NaHCO_3$ solution, the concentration of NaCl was taken to be 0.72 mol dm^{-3} in order for it to be the same ionic strength as that of sea water while that of $NaHCO_3$ was ordinarily chosen to be 2.3×10^{-3} mol dm^{-3}, equal to that of sea water. The concentration of uranium in the solution was taken to be 3—60 ppb by adding a uranyl(VI) chloride solution. In the uranium-adsorption experiments, 40 mg of the adsorbent were introduced into 1000 ml of the solution. The solution was stirred by means of a vertical stirrer at 25 °C. Within 5 h, the adsorption equilibrium was achieved under the present experimental conditions. The adsorbent was separated from the solution, and the change of the uranium concentration in the solution was measured.

The carbonate, calcium, and magnesium uptake was measured by the following procedure; one-fifth gram of the adsorbent was introduced into 5000 ml of the solution, after which the solution was stirred for 5 h at 25 °C. The contents of calcium, magnesium, and carbonate in the adsorbent were then determined.

Analytical Method. The uranium in the solution was determined spectrophotometrically, with Arsenazo III as the indicator.[8] The determination of the carbonate in the

adsorbent was carried out by the following procedure. The adsorbent after the adsorption experiment was washed with distilled water and dried at room temperature. The dried samples were placed in a flask, where N_2 as carrier gas was passed through continuously, about 10 ml of 0.1 mol dm^{-3} HCl solution were then added to the flask at 50 °C. The carbon dioxide thus produced was introduced into the carbon analyzer, Kokusai Denki VK-1-type "Coulomatic C," and was determined by the coulometric titration. The limit of detection was 4.2×10^{-5} mmol as carbon, and the coefficient of variation was found to be 3.5% when 5 mg of calcium carbonate was analyzed by this procedure.

The determination of the calcium and magnesium adsorbed in the adsorbent was carried out by the following procedure; after the adsorption experiment, the dried samples were fused with sodium carbonate and boric acid and dissolved in an HCl solution. The concentration of calcium or magnesium in the HCl solution was then determined by atomic absorption spectrophotometry using a Hitachi 207 Atomic-absorption spectrophotometer.

The specific surface area and pore volume of the adsorbent were determined by means of the N_2 adsorption at −195 °C using a Carlo Erba Sorptomatic Series 1800.

Results and Discussion

Adsorption Isotherm of Uranium. The adsorption isotherm of uranium in sea water or a NaCl–$NaHCO_3$ solution is shown in Fig. 1. Kanno *et al.*[7] reported that the uranium adsorption from sea water gave a Freundlich-type isotherm. As is shown in Fig. 1, the same results were obtained in both sea water and the NaCl–$NaHCO_3$ solution.

The value of n in the Freundlich equation ($v=kC^{1/n}$) was found to be 1.4 and 1.3 for sea water and for the NaCl–$NaHCO_3$ solution respectively.

It is known that uranium in sea water exists in the form of tris(carbonato)dioxouranate(VI) ion $[UO_2(CO_3)_3]^{4-}$. The distributions of uranyl(VI) species in the NaCl–$NaHCO_3$ solution used in the present work were calculated from the stability constants;[9] they

$UO_2(CO_3)_3^{4-}$	84.9

are summarized in Table 2. The tris(carbonato)dioxouranate(VI) ion, which is the major uranyl(VI) species in sea water, is a predominant species in the NaCl–$NaHCO_3$ solution. Although the uranyl(VI) species and the type of adsorption are the same in sea water and in the NaCl–$NaHCO_3$ solution, the uranium uptake is found to be quite different. The difference in the uranium uptake is thought to be attributable to the diverse ions in sea water.

Effect of Diverse Ions in Sea Water. In order to investigate the effect of diverse ions in sea water on uranium adsorption, the uranium uptake was measured with NaCl–$NaHCO_3$ solutions containing 20 ppb uranium and a diverse ion at the concentration equal to that of sea water. The ion species examined are magnesium, calcium, strontium, potassium, borate, sulfate, fluoride, and bromide ions. The results are summarized in Table 3. The uranium uptake from an NaCl–$NaHCO_3$ containing K^+, Sr^{2+}, SO_4^{2-}, Br^-, or BO_3^{3-} was nearly equal to that from the NaCl–$NaHCO_3$ solution. The obtained results show that these ions have no effect on the uranium uptake. On the other hand, the uranium uptake was reduced by the presence of calcium, magnesium, and fluoride ions. Particularly, the presence of calcium ions hindered the uranium adsorption.

The uranium uptake from the solution containing all the ions together (No. 10 in Table 3) agreed well with that from sea water. The effects of calcium, magnesium, and fluoride ions on the uranium uptake

are discussed below.

It was reported in our previous paper[10] that the adsorption site of hydrous titanium(IV) oxide for $[UO_2(CO_3)_3]^{4-}$ may be supposed to be the surface hydroxo group [Ti–OH]. The fluoride ion reacts with Ti–OH to form Ti–F. The reaction is useful for the determination of the surface hydroxo group.[11] It may, therefore, be considered that fluoride ions reduce the uranium adsorption site by forming Ti–F. Since the concentration of fluoride ions in sea water is low, the effect of fluoride ions on the uranium uptake is small.

Figure 2 shows the variation in the uranium uptake with the concentration of calcium ions in NaCl–$NaHCO_3$ solutions containing 20 ppb of uranium. The uranium uptake decreases with an increase in the concentration of calcium ions. Since the deposition of the calcium compound was expected to take place on the adsorbent, the calcium uptake and carbonate uptake were measured in various solutions. The results are shown in Table 4. The calcium uptake was 0.56 mmol g^{-1} from the NaCl–$NaHCO_3$–$CaCl_2$ solution (No. 2 in Table 4) and 0.34 mmol g^{-1} from the NaCl–$CaCl_2$ solution (No. 3 in Table 4). Since hydrous titanium(IV) oxide behaves as a cation exchanger in an alkaline solution,[12] the calcium ion is thought to be adsorbed from the NaCl–$CaCl_2$ solution by means of an ion-exchange reaction. It is deduced that 0.34 mmol g^{-1} of the 0.56 mmol g^{-1} calcium uptake from the NaCl–$NaHCO_3$–$CaCl_2$ solution is attributable to the ion-exchange reaction, and 0.22 mmol g^{-1} (=0.56 mmol g^{-1}—0.34 mmol g^{-1}) to an other adsorption process. The carbonate uptake from the NaCl–$NaHCO_3$–$CaCl_2$ solution is found to be about 0.20 mmol g^{-1} (No. 2 in Table 4), while it is very small without calcium ions (No. 1 in Table 4).

The calcium uptake attributed to the adsorption process other than ion-exchange (0.22 mmol g^{-1}) is nearly equal to the carbonate uptake (0.20 mmol g^{-1}), indicating that calcium carbonate is deposited on the surface of the adsorbent. In the case of sea water, the calcium uptake and the carbonate uptake are in good agreement with those from the NaCl–$NaHCO_3$–$CaCl_2$ solution (No. 2 and No. 6 in Table 4).

The variation in the uranium, calcium, and carbonate uptake with the concentration of $NaHCO_3$ in the NaCl–$CaCl_2$ solution is shown in Fig. 3. The increase in the concentration of $NaHCO_3$ raises the calcium and carbonate uptakes while the uranium uptake markedly decreases. Regardless of the $NaHCO_3$ concentration, the difference between calcium and carbonate

pH of the solution: 8.0, NaCl: 0.72 mol dm^{-3}, uranium: 20 ppb, ●: uranium uptake, ○: carbonate uptake.

uptakes remained constant (about 0.35 mmol g^{-1}); this value corresponds to the calcium uptake by the ion-exchange reaction. The variation in the uranium and carbonate uptakes with the $NaHCO_3$ concentration in the NaCl solution is shown in Fig. 4. In the absence of calcium ions, the carbonate uptake is very small, and the uranium uptake is slightly decreased with the concentration of $NaHCO_3$. It may be supposed that the decrease in the uranium uptake is due to the deposition of calcium carbonate on the adsorbent.

The magnesium uptake by the adsorbent is also shown in Table 4. The magnesium uptake in the presence and in the absence of $NaHCO_3$ were 0.25 mmol g^{-1} (No. 4 in Table 4) and 0.20 mmol g^{-1} (No. 5 in Table 4) respectively. Thus, the effect of carbonate ions on the magnesium uptake is rather small compared with that on the calcium uptake. It is considered that the deposition of magnesium carbonate is more difficult on the adsorbent than that of calcium carbonate. The specific surface area and pore volume of the adsorbent before and after the adsorption experiment are presented in Table 5. With the $NaCl$–$NaHCO_3$ solution, the changes in the surface area and the pore volume are very small.

On the other hand, with the $NaCl$–$NaHCO_3$–$CaCl_2$ solution and sea water, the decreases in the specific surface area and the pore volume are large. These results indicate that the decreases in the specific surface area and pore volume are due to the deposition of calcium carbonate on the adsorbent.

The present experimental results make it possible to conclude that the uranium uptake from sea water by hydrous titanium(IV) oxide is reduced mainly because of the calcium carbonate deposition.

The authors wish to thank Professor Shosuke Imoto of Osaka University for his many helpful discussions and suggestions.

The Thermal Gas-phase Decomposition of Methyl Iodide

Ko Saito,* Hiroyuki Tahara, Osamu Kondo, Teiji Yokubo, Tetsuo Higashihara, and Ichiro Murakami

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi Senda-machi, Naka-Ku, Hiroshima 730

(Received June 8, 1979)

The thermal gas-phase decomposition of methyl iodide diluted in Ar has been studied behind shock waves over the temperature range between 1050 and 1500 K and the total density range of 3.5×10^{-6}—3.9×10^{-5} mol cm^{-3}. The decomposition was monitored by means of the UV absorption of CH_3I at 259 or 275 nm. The initiation reaction was found to be the C-I bond fission, and the process proceeded in the low-pressure region under the present experimental conditions. The low-pressure limit rate constant was obtained as:

$$k_{2nd} = 10^{15.40\pm0.26}\exp\{-(42.56\pm1.50 \text{ kcal mol}^{-1})/RT\}\text{cm}^3 \text{ mol}^{-1} \text{ s}^{-1}.$$

Applying the RRKM strong collision theory, the collision efficiency factor was estimated to be 0.018 at 1300 K.

The thermal decomposition of methyl halides is of interest in connection with the decomposition mechanism and is an important test case for the theory of unimolecular reactions.[1] There have been reported many shock-tube studies of the pyrolysis of fluoro- and chloro-methanes.[2-5] In most cases, the decomposition of these molecules is initiated *via* the molecular elimination of HF and HCl.[6] Moreover, the unimolecular process was found in the fall-off region under the conditions available in shock waves.[7] On the other hand, there are few data on the decomposition of bromo- and iodo-methanes, although they are considered to offer proper kinetic data regarding simple bond-fission reactions of the C–Br and C–I bonds. It is important to determine the pressure dependence of the unimolecular process, because it depends on the energy-transfer efficiency in collisions between the reactant and diluent molecules. In the thermal unimolecular processes of relatively small molecules, at low pressures and at high temperatures the collisional activation is rate-determining. This allows us to derive information on the average energy transferred in collisions, which is difficult to describe theoretically. It is, therefore, necessary to accumulate many experimental data on the thermal unimolecular reactions of common molecules.

In the present work, we have studied the pyrolysis of CH_3I in Ar behind shock waves in order to obtain the unimolecular rate constant of the initiation reaction and to discuss the energy-transfer efficiency.

Experimental

The experiments were performed in shock tubes 5 cm and 9.4 cm in inner diameter. Detailed explanations of the equipment and the procedures have been given elsewhere.[8,9] The shocked gas properties were calculated by using the incident shock speed, assuming non-reaction conditions.

Liquid CH_3I (98% stated minimum purity) was purified by trap-to-trap distillation, while Ar (99.998%) was used as the diluent without further purification. Mixtures (0.2, 0.4, 1.25, 2.5, and 3.0 mol % CH_3I in Ar) were prepared in a 30-l glass flask. They were allowed to stand for more than 12 h before use.

Results

Measurements were performed behind incident and reflected shock waves which covered the following ranges: temperature=1050—1500 K; total density=3.5×10^{-6}—3.9×10^{-5} mol cm^{-3}; $[CH_3I]=4.5\times10^{-8}$—3.5×10^{-7} mol cm^{-3}. The disappearance of the shock-heated methyl iodide was followed by observing the absorption at 259 or 275 nm with FWHM=1.65 nm. The absorption due to the X→A transition of CH_3I has a maximum at 259.1 nm.[10] The absorption profiles obtained in a shock-heated mixture at 259 and 275 nm were essentially the same except for a slight difference which was observed at long reaction times. That is, it appeared that the absorption at 259 nm was largely influenced by some products in the later part of the reaction. Figure 1 shows a typical absorption profile at 275 nm and at the mean temperature of all the experimental runs. The absorption coefficient at this wavelength was about 4×10^5 cm^2 mol^{-1}, with a slight temperature dependence in the range of 1000—1500 K. Lambert-Beer's law was ascertained to hold in the concentration range studied. Values of the first-order rate constant were determined by two different procedures; *i.e.*, for the data obtained at 259 nm, the initial slope method was applied as: $k_{1st}=-\text{d}[CH_3I]/\text{d}t/[CH_3I]_0$, while for the data at 275 nm, the integration method was applied as: $k_{1st}=\ln([CH_3I]_0/[CH_3I])/\text{d}t$. As will be shown later, no

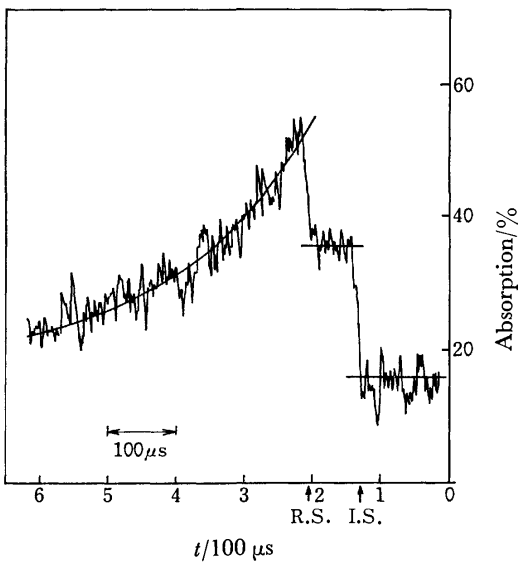

Fig. 1. Typical absorption profile obtained at 275 nm. 1.0 mol% in Ar, $P_1=100$ Torr, $P_5=3.01$ atm, $T_5=1300$ K, total density=2.82×10^{-5} mol cm^{-3}.

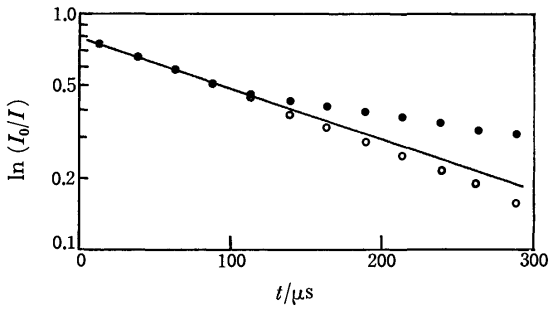

Fig. 2. Logarithmic plot of $\ln(I_0/I)$ *vs.* time for the data in Fig. 1.
● denotes the direct plot of the absorption profile and ○ denotes the corrected profile by substructing the absorption of C_2H_5I (see Ref. 15). The straight line gives $k_{1st}=4.78\times10^3$ s^{-1} and $k_{2nd}=1.71\times10^8$ cm^3 mol^{-1} s^{-1}.

difference is found between the k_{1st} values obtained by the two methods. Figure 2 shows the procedure of the integration method used for the data shown in Fig. 1. In the figure, the closed circles show the data directly obtained from the absorption profile, while the open circles correspond to the data corrected for the absorption of C_2H_5I, which will be discussed later. It appears that the plot (closed circles) shows a straight line at least 100 μs after the shock front passage; *i.e.*, the initial decomposition rate is first-order with respect to $[CH_3I]$ until 35% of the substance decomposes.[11] At higher temperatures, this value decreases slightly, but it is never less than 20%. It was ascertained that k_{1st} was independent of the concentration of CH_3I over the ten-fold range. An Arrhenius expression is given for the data at a total density of 1.6×10^{-5} mol cm^{-3} as:

$$k_{1st} = 10^{10.36\pm0.29}\exp\{-(41.57\pm1.67 \text{ kcal mol}^{-1})/RT\} \text{ s}^{-1},$$

where the error limits are the standard deviations. The value of the preexponential factor obtained is too low for us to consider that the initial process is in the high-pressure region. In fact, from the experiments in which the total density is changed over about ten-fold, k_{1st} was found to be fairly proportional to the total density over the whole range. Figure 3 shows an example of the Arrhenius plots of k_{1st} for three different total densities. They form three pallarel straight lines with the same slope as the above Arrhenius expression. The initial process is, thus, in the low-pressure region under the present experimental conditions. Therefore, the initial decomposition rate is expressed as:

$$-\text{d}[CH_3I]/\text{d}t = k_{2nd}[CH_3I][M],$$

where [M] denotes the total density. From the data of 40 runs, an Arrhenius expression for k_{2nd} is given as:

$$k_{2nd} = 10^{15.40\pm0.26}\exp\{-(42.56\pm1.50 \text{ kcal mol}^{-1})/RT\} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}.$$

An Arrhenius plot of k_{2nd} is given in Fig. 4, where the data evaluated by the two procedures are in good agreement with each other.

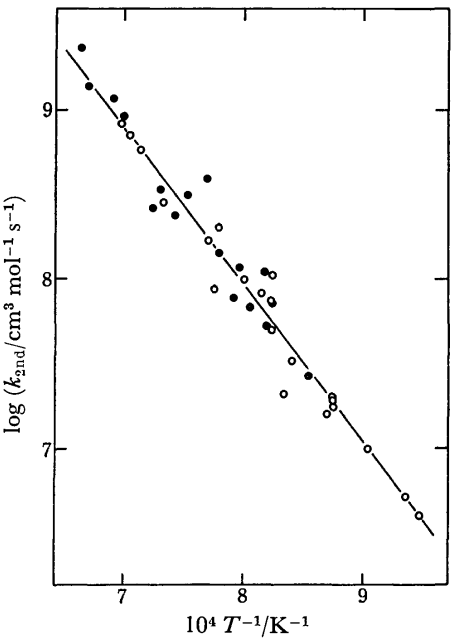

Fig. 4. Arrhenius plot of k_{2nd} evaluated by initial slope (●) and integration method (○).

Discussion

The initiation reaction is the C–I bond fission, not the molecular elimination of HI, because the heat of the reaction of the HI elimination is higher than the energy of the C–I bond fission by 38 kcal mol^{-1}.[12] Thus, the sequence of the reaction in the CH_3I decomposition is assumed to be as follows:

(1) $CH_3I + M \rightleftharpoons CH_3 + I + M$

(2) $CH_3I + I \rightleftharpoons CH_3 + I_2$

Table 1. Elementary reactions

(5) $I_2 + M \rightleftharpoons 2I + M$

(6) $2CH_2I(+M) \longrightarrow C_2H_4I_2(+M)$

(7) $CH_2I + I(+M) \rightleftharpoons CH_2I_2(+M)$

(8) $CH_2I + I_2 \rightleftharpoons CH_2I_2 + I$

(9) $CH_3 + CH_2I(+M) \longrightarrow C_2H_5I(+M)$.

This is based on the mechanism proposed for the photochemical reaction of CH_3I.[13] Table 1 lists the values of ΔH°_{298}, ΔG°_T, and the rate constants for the above reactions. Since there are no data for Reactions 3, 6, 7, and 9, the rate constants were estimated as follows. The value of k_3 was calculated by means of the BEBO method combined with the transition-state theory.[14] The values of k_6 and k_9 were assumed from the data of the recombination of CH_3 radicals. k_{-7} was estimated from the data of the present experiment. Computer simulations (Gear Program) were performed with the values in Table 1 by using the observed k_{2nd} value as the value of Reaction 1. As an example, Fig. 5 shows CH_3I profiles computed under the same conditions as those of the run shown in Fig. 1. It is found that there is no discrepancy between the profiles computed with Reaction 1 (solid line) and with the full reactions (dotted line) until 100 μs after the shock front (corresponding to about a 30% consumption of CH_3I). Therefore, the apparent second-order rate constant, k_{2nd}, which was measured at the early stage of the reaction, can be regarded as the low-pressure unimolecular rate constant of Reaction 1. The corresponding experimental profile is also shown in Fig. 5 by open circles. This is the one shown in Fig. 2 (open circles) connected by considering the effect of the products.[15]

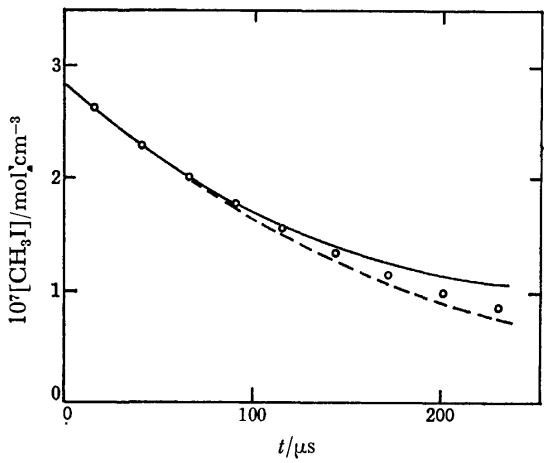

Fig. 5. Concentration profiles of CH_3I.
Conditions are the same as those in Fig. 1. ○: Experimental profile, ——: calculated by Reaction 1 alone, ----: calculated by using full reactions considered.

A rough estimation of the fall-off pressure, $P_{1/2}$, for Reaction 1 leads to $P_{1/2}\simeq 50$ atm at 1300 K (1 atm=101325 Pa).[16] Therefore, the pressure region in this work (0.4—3.2 atm) is considerably below the fall-off pressure. This is consistent with the experimental result that the rate constant of Reaction 1 was given as second-order. The activation energy of k_{2nd} (*i.e.*, k_1 at the low-pressure limit) is lower than the heat of reaction by about 13 kcal mol^{-1}. This may be explained by the low-pressure-limit unimolecular reaction theory. That is, a large part of the discrepancy could be compensated for by the participation of the internal energy in the decomposition. On the other hand, a small part of the discrepancy may be ascribed to the temperature dependence of the collision efficiency. The energy-transfer efficiency in collisions between the reactant and diluent molecules becomes small as the temperature rises. Moreover, at high temperatures available in shock waves, the collisional energy transfer becomes much less than the average thermal energy. From the experimental data of the low-pressure-limit rate constant, it is possible to estimate the collision efficiency and, in turn, the average energy $\langle\Delta E\rangle$ transferred per collision, on the basis of the strong collision rate constant. The value of $\langle\Delta E\rangle$ for a particular collision partner in one reaction is considered to be nearly constant, regardless of the temperature.[17] It is, therefore interesting to ascertain the $\langle\Delta E\rangle$ values for various collision pairs in one reaction.

It is possible to calculate an approximate value of the strong collision rate constant if it is not available from the experiments. An appropriate RRKM strong collision formulation is given as:[17]

$$k_o^{sc} = Z_{LJ}Q_{vib}^{-1}kT\rho_{vib}(E_o)F_E F_{rot}F_{anh}\exp(-E_o/RT),$$

where Z_{LJ} is the Lennard-Jones collision frequency; $\rho_{vib}(E_o)$, the vibrational energy level density at E_o; Q_{vib}, the vibrational partition function; E_o, the threshold energy; F_E, the energy dependence of the density of the states; F_{rot}, the centrifugal correction factor, and F_{anh}, the anharmonicity factor. Table 2 lists the calculated values of k_o^{sc} for several temperatures. The collision efficiency factor is defined as: $\beta_c \equiv k_o^{obs}/k_o^{sc}$, where k_o^{obs} is the low-pressure-limit rate constant obtained experimentally in a given heat bath. As is shown in Table 2, β_c is about 0.02 in the CH_3I–Ar system at the temperatures studied; this is comparable with the data for the simple bond fission of similar molecules (*e.g.*, β_c=0.016—0.020 for CH_4–Ar at 2000 K,[18,19] and β_c=0.020 for CH_3Cl–Ar at 2000 K[6]). The values of $-\langle\Delta E\rangle/kT$ are also listed in Table 2; they were evaluated by using this approximate relation:[17]

$$\beta_c/(1-\sqrt{\beta_c}) \simeq -\langle\Delta E\rangle/F_E kT.$$

The temperature dependence of β_c can be expressed as: $\beta_c \propto T^{-2.0}$. This agrees with the prediction of Tardy and Rabonovitch[20] rather than with the relation, $\beta_c \propto T^{-1}$, predicted by Luther and Troe.[21] The value of $-\langle\Delta E\rangle \simeq 70$ cal mol^{-1} obtained here for the CH_3I–Ar system is not unreasonable compared with the recent data for triatomic molecules diluted in Ar.[22]

It is found from the present results that, as a heat bath, Ar is inefficient in supplying the energy by means of both T-T and T-V energy-transfer processes.[23] Although uncertainties in the details of β_c and $\langle\Delta E\rangle$ remain, the data obtained in the present work make it quite clear that weak collision efficiencies are of importance for high-temperature reactions. Further investigations are needed for the CH_3I pyrolysis in various diluents including polyatomic molecules.

15) Computer simulations showed that, during the pyrolysis of CH_3I, such products as CH_2I_2, C_2H_5I, and $C_2H_4I_2$ increase as the reaction proceeds. Among these products, which are considered to have an absorption at the UV region, the concentration of C_2H_5I increases up to the order of 10^{-10} mol cm^{-3}. On the other hand, the other two products are less than that of C_2H_5I by two orders; thus, they are negligible. In additional experiments, the absorption coefficient of C_2H_5I at 275 nm was measured to be about 4×10^6 cm^2 mol^{-1} in the temperature range of 1000—1300 K. Therefore, the absorption profile obtained for the CH_3I–Ar system was corrected by subtracting the absorption of C_2H_5I.

16) The value of the fall-off pressure was calculated by this relation:

$$P_{1/2} \simeq \nu(\lambda Z)^{-1}\{1+D_o/(n+1)RT\}^{-n}RT,$$

where ν is the mean frequency of the vibrations; D_o, the bond-dissociation energy; λ, the steric factor, and n, the effective number of the internal degrees of freedom for the

reaction. The values of λ and n were determined to be 0.016 and 5.75 respectively by using a classical collision theory.

Electron Transfer Reaction between $\Delta^{2,2'}$-Bi-1,3-dithiole (TTF) and 7,7,8,8-Tetracyanoquinodimethane (TCNQ). Electron Donating Property of TTF

Akihiko Yamagishi and Yôichi Iida*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received July 2, 1979)

The reaction between $\Delta^{2,2'}$-bi-1,3-dithiole (TTF) and 7,7,8,8-tetracyanoquinodimethane (TCNQ) in acetonitrile solution, $TTF+TCNQ \rightleftharpoons TTF^{+\cdot}+TCNQ^{-\cdot}$, was analyzed spectrophotometrically. The thermodynamical data of chemical equilibrium were determined to be $K=(2.8\pm0.1)\times10^{-3}$ at 11 °C, $\Delta H=-6.7\pm1.3$ kJ mol^{-1} and $\Delta S=-72.8\pm17$ J K^{-1} mol^{-1}. The reaction-rate study of the equilibrium in several solvents was also made by temperature-jump technique. The difference in the electron-donating properties between TTF and *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD) is discussed by comparing the results with those of the reaction between TMPD and TCNQ.

Formation of charge-transfer complexes from electron donor and acceptor molecules is well-known. A combination of strong donor and acceptor molecules often gives rise to separated ions (a cation radical of the donor and an anion radical of the acceptor) in solution.[1]

Attention has been paid to a charge-transfer complex of $\Delta^{2,2'}$-bi-1,3-dithiole (TTF)[2] with 7,7,8,8-tetracyanoquinodimethane (TCNQ) because of its unusually high electric conductivity in solid state.[3] TTF is a strong electron donor, and TCNQ a strong acceptor. In the solid complex, however, the charge transfer from TTF to TCNQ takes place incompletely, this being one cause for the TTF–TCNQ complex to show such high electric conduction. We have investigated the charge-transfer reaction from TTF to TCNQ in solution, only a few attempts having been made to study the behavior of the complex in solution. In order to clarify the charge-transfer interaction between TTF and TCNQ in solid state and in solution, we determined the thermodynamic equilibrium constants of reaction and also the kinetics of electron transfer in various solvents.

Experimental

Commercially available TTF (Aldrich Chem. Co.) and TCNQ (Kanto Chem. Co.) were purified by sublimation *in vacuo*. The temperature and concentration dependences of electronic absorption spectra of acetonitrile solutions containing TTF and TCNQ were measured with a Hitachi 808-Type spectrophotometer. The kinetic study of the electron transfer reaction in acetonitrile and dimethyl sulfoxide (DMSO) solution was made by the temperature-jump method, using a Union Giken temperature-jump apparatus. $NaClO_4$ was used as a supporting electrolyte. The detail of temperature-jump method is similar to that described previously.[4]

Results

Chemical Equilibrium of Electron Transfer Reaction. When TTF and TCNQ are mixed in acetonitrile, the observed electronic absorption spectrum almost comprises a superposition of the spectra of neutral TTF and TCNQ molecules. In addition, the spectra which are assigned to ionized TTF cation radical ($TTF^{+\cdot}$) and TCNQ anion radical ($TCNQ^{-\cdot}$) are observed faintly in the spectrum, no charge-transfer absorption due to TTF–TCNQ complex being detected. The observed absorptions around 700—900 nm are attributable to the absorptions of $TCNQ^{-\cdot}$, the absorptions around 600 nm to those of $TTF^{+\cdot}$.[5,6] Thus, the reaction between TTF and TCNQ in acetonitrile solution can be expressed by

$$TTF + TCNQ \rightleftharpoons TTF^{+\cdot} + TCNQ^{-\cdot}. \quad (1)$$

First we obtained the chemical equilibrium data of this electron transfer (*i.e.*, oxidation-reduction) reaction spectrophotometrically. Since the absorption at 842 nm is entirely assigned to that of $TCNQ^{-\cdot}$, the concentration of $TCNQ^{-\cdot}$ in its equilibrium state, $[TCNQ^{-\cdot}]$, was estimated by means of the optical density of the observed spectrum, together with the value of the molar extinction coefficient known for $TCNQ^{-\cdot}$ ($\varepsilon_{TCNQ^{-\cdot}}(842\text{ nm})=4.35\times10^4$). The equilibrium concentrations of the other molecular species in Eq. 1 were estimated by the relation, $[TTF^{+\cdot}]=[TCNQ^{-\cdot}]$, $[TTF]=[TTF]_0-[TCNQ^{-\cdot}]$ and $[TCNQ]=[TCNQ]_0-[TCNQ^{-\cdot}]$, where $[TTF]_0$ and $[TCNQ]_0$ indicate initial concentrations of TTF and TCNQ added, respectively. Assuming that the activity coefficients of these solutes are unity, the equilibrium constant of Eq. 1 is given by

$$K=\frac{[TTF^{+\cdot}]\,[TCNQ^{-\cdot}]}{[TTF]\,[TCNQ]}. \quad (2)$$

The K value thus estimated was found to be constant when $[TTF]_0$ was in the range $(3-0.3)\times10^{-5}$ M and $[TCNQ]_0$ in the range $(4-1)\times10^{-4}$ M, where 1 M= 1 mol dm^{-3}.

Next, we examined the temperature dependence of the observed K value and found almost linear relationship between $\ln K$ and $1/T$ values in the temperature range 11—25 °C. The following thermodynamic data were obtained for the chemical equilibrium of Eq. 1 in acetonitrile solution:

$$K=(2.8\pm0.1)\times10^{-3} \text{ at } 11\text{ °C},$$
$$\Delta H=-6.7\pm1.3\text{ kJ mol}^{-1},$$
$$\Delta S=-72.8\pm17\text{ J K}^{-1}\text{ mol}^{-1}.$$

The K value agrees with $K=2.5\times10^{-3}$ obtained by Tomkiewicz *et al.*[7] The large negative ΔS value indicates that the ordering of solvent molecules around $TTF^{+\cdot}$ and $TCNQ^{-\cdot}$ takes place upon ionization of TTF and TCNQ.

Kinetic Study of Electron Transfer Reaction. We measured the following forward, k_1, and backward, k_{-1}, rate constants by using temperature-jump technique,

$$\mathrm{TTF} + \mathrm{TCNQ} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{TTF}^{+\cdot} + \mathrm{TCNQ}^{-\cdot}. \quad (3)$$

In pure acetonitrile solution, however, the equilibrium constant K is very small. Thus the signal due to $TCNQ^{-\cdot}$ was so small that we could hardly detect any optical density change of $TCNQ^{-\cdot}$ upon temperature jumping.

In order to increase the concentrations of $TTF^{+\cdot}$ and $TCNQ^{-\cdot}$, we examined the chemical equilibrium of Eq. 1 in several mixed solvents of acetonitrile and DMSO, in view of the report that TTF and TCNQ are mostly ionized in *N,N*-dimethylformamide, DMSO and pyridine solutions.[7] In 27 vol% DMSO–acetonitrile mixed solvent, the equilibrium constant K increased to $(12\pm2)\times10^{-3}$ at 11 °C. In 37 vol % DMSO–acetonitrile mixed solvent, we obtained $K=(22\pm4)\times10^{-3}$ at 11 °C, $\Delta H=-10.0\pm1.7$ kJ mol^{-1} and $\Delta S=-67.4\pm20.9$ J K^{-1} mol^{-1}. The values of both K and $-\Delta H$ increased with increase in the ratio of DMSO in mixed solvent. The increase facilitated our observation of the rate constants of Eq. 3 by temperature-jump method. Figure 1 shows the result of the temperature-jump experiment in 37 vol % DMSO–acetonitrile solution; initial and final temperatures were 9 and 12 °C, respectively. The reciprocal of observed relaxation time, τ^{-1}, of the signal due to $TCNQ^{-\cdot}$ is plotted against the concentration of $[TCNQ^{-\cdot}]+[TTF^{+\cdot}]+K\{[TCNQ]+[TTF]\}$. In the reaction of Eq. 3, apparent relaxation time τ upon temperature jumping is given by

$$\begin{aligned}\tau^{-1} &= k_1([TTF]+[TCNQ])+k_{-1}([TTF^{+\cdot}]+[TCNQ^{-\cdot}]) \\ &= k_{-1}\{[TTF^{+\cdot}]+[TCNQ^{-\cdot}]+K([TTF]+[TCNQ])\},\end{aligned} \quad (4)$$

where we used the relation $K=k_1/k_{-1}$. Thus, we can obtain a linear relation between the τ^{-1} and $[TTF^{+\cdot}]+[TCNQ^{-\cdot}]+K([TTF]+[TCNQ])$ values, the slope giving k_{-1}. Our results almost agree with the linear relation. The backward rate constant, k_{-1}, was determined to be $k_{-1}=(5.3\pm1)\times10^8$ M^{-1} s^{-1} from the slope. The forward rate constant, k_1, was obtained as $k_1=k_{-1}K=(1.2\pm0.5)\times10^7$ M^{-1} s^{-1}.

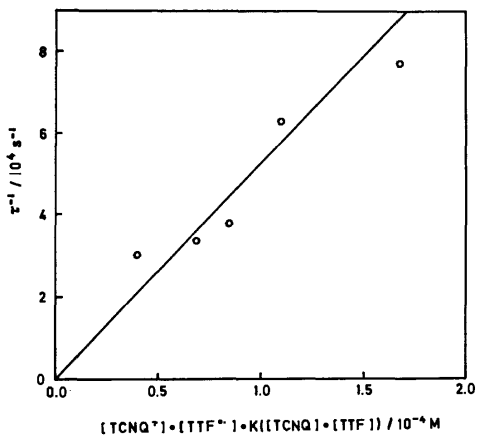

Fig. 1. Temperature-jump experimental result on the reaction of Eq. 3 in 37 vol % DMSO–acetonitrile solution around 11 °C.
Reciprocal of observed relaxation time of the signal due to $TCNQ^{-\cdot}$, τ^{-1}, was plotted against concentration of $[TCNQ^{-\cdot}]+[TTF^{+\cdot}]+K([TCNQ]+[TTF])$. See text.

Discussion

First, let us discuss the experimental result on the chemical equilibrium data. It is of interest to compare the electron transfer reaction of Eq. 1 in acetonitrile with the reaction between *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD) and TCNQ in the same solvent. Since TMPD is a strong electron donor, comparison of the electron donating strength between TTF and TMPD is significant. Yamagishi *et al.* examined the following electron transfer reaction between TMPD and TCNQ in acetonitrile:[8]

$$\mathrm{TMPD} + \mathrm{TCNQ} \rightleftharpoons \mathrm{TMPD}^{+\cdot} + \mathrm{TCNQ}^{-\cdot}, \quad (5)$$

$$K' = \frac{[TMPD^{+\cdot}]\,[TCNQ^{-\cdot}]}{[TMPD]\,[TCNQ]}. \quad (6)$$

In this system, no absorption due to the charge-transfer complex of TMPD–TCNQ was detected. The thermodynamic data on the chemical equilibrium of Eq. 5 were obtained spectrophotometrically as follows:

$$K' = (7\pm2)\times10^{-2} \text{ at } 25\ ^\circ\mathrm{C},$$
$$\Delta H' = -17\pm4 \text{ kJ mol}^{-1},$$
$$\Delta S' = -71\pm21 \text{ J K}^{-1}\text{ mol}^{-1}.$$

Let us combine these data with those of the reaction between TTF and TCNQ of Eq. 1, and consider the following oxidation-reduction reaction between TTF and TMPD in acetonitrile solution:

$$\mathrm{TTF}^{+\cdot} + \mathrm{TMPD} \rightleftharpoons \mathrm{TTF} + \mathrm{TMPD}^{+\cdot}. \quad (7)$$

The equilibrium constant of this reaction, K'', can be derived from

$$K'' = \frac{[TTF]\,[TMPD^{+\cdot}]}{[TTF^{+\cdot}]\,[TMPD]} = \frac{K'}{K}, \quad (8)$$

where the relations of Eqs. 2 and 6 are used. We can also estimate the enthalpy change, $\Delta H''$, and the entropy change, $\Delta S''$, of Eq. 7. The results are:

$$K'' = (3.6\pm1.2)\times10 \text{ at } 11\ ^\circ\mathrm{C},$$
$$\Delta H'' = \Delta H' - \Delta H = -10.0\pm5.4 \text{ kJ mol}^{-1},$$
$$\Delta S'' = \Delta S' - \Delta S = +1.7\pm38 \text{ J K}^{-1}\text{ mol}^{-1}.$$

Let us consider the following equation in the chemical equilibrium of Eq. 7.

$$\begin{aligned}&E_0(\mathrm{TTF},\ \mathrm{TTF}^{+\cdot}) - \frac{RT}{F}\ln\frac{[TTF^{+\cdot}]}{[TTF]} \\ &\quad = E_0(\mathrm{TMPD},\ \mathrm{TMPD}^{+\cdot}) - \frac{RT}{F}\ln\frac{[TMPD^{+\cdot}]}{[TMPD]},\end{aligned} \quad (9)$$

where R and F are gas constant and Faraday constant, respectively, and $E_0(\mathrm{TTF},\ \mathrm{TTF}^{+\cdot})$ and $E_0(\mathrm{TMPD},\ \mathrm{TMPD}^{+\cdot})$ represent the oxidation potentials in the formation of the cation radicals of $TTF \rightleftharpoons TTF^{+\cdot}+$

e and TMPD⇌TMPD$^{+\cdot}$+e, respectively. The reactions are assumed to be reversible electrode reactions in acetonitrile solution. By use of Eq. 8 together with the K'' value, we obtain

$$E_0(\text{TTF, TTF}^{+\cdot}) = E_0(\text{TMPD, TMPD}^{+\cdot}) - 0.086\pm0.008\ \text{V}. \quad (10)$$

As regards the oxidation potentials, the following results were reported for acetonitrile solution.[9]

$$E_0(\text{TMB, TMB}^{+\cdot}) = E_0(\text{TMPD, TMPD}^{+\cdot}) - 0.28\ \text{V}, \quad (11)$$

$$E_0(\text{DMPD, DMPD}^{+\cdot}) = E_0(\text{TMPD, TMPD}^{+\cdot}) - 0.078\ \text{V}, \quad (12)$$

where TMB and DMPD denote *N,N,N',N'*-tetramethylbenzidine and *N,N*-dimethyl-*p*-phenylenediamine, respectively, and E_0(TMB, TMB$^{+\cdot}$) and E_0(DMPD, DMPD$^{+\cdot}$) refer to the reversible oxidation potentials in the formation of the cation radicals, TMB⇌TMB$^{+\cdot}$+e and DMPD⇌DMPD$^{+\cdot}$+e, in acetonitrile solution, respectively. Comparison of Eqs. 10—12 reveals that one-electron donating power of TTF is a little weaker than that of TMPD and is nearly equal to that of DMPD; the order of electron donating strengths is expressed by TMPD>DMPD≳TTF>TMB in acetonitrile solution.

Let us discuss the ionization potential of TTF. In the oxidation-reduction equilibrium of Eq. 7, the observed enthalpy change, $\Delta H''$, is given by

$$\Delta H'' = I_p(\text{TMPD}) - I_p(\text{TTF}) + \Delta\Delta H_{solv}(\text{TMPD}^{+\cdot}, \text{TMPD}) - \Delta\Delta H_{solv}(\text{TTF}^{+\cdot}, \text{TTF}), \quad (13)$$

where I_p(M) is the ionization energy of the neutral molecule, (M=TMPD or TTF), in gas phase, and $\Delta\Delta H_{solv}$(M$^{+\cdot}$, M) is the difference of solvation energy between M$^{+\cdot}$ and M in acetonitrile solution. Note that I_p(M) corresponds to an adiabatic ionization potential, since the reaction of Eq. 7 involves thermodynamic equilibrium. Thus, if we assume that the solvation energy, $\Delta\Delta H_{solv}$(TMPD$^{+\cdot}$, TMPD), is similar to $\Delta\Delta H_{solv}$(TTF$^{+\cdot}$, TTF), the difference of the ionization potentials between TMPD and TTF can be determined by means of Eq. 13. I_p(TMPD)=6.20 eV was chosen as a standard value for the adiabatic ionization potential of TMPD.[9] By use of the value, $\Delta H''=-10.0\pm5.4$ kJ mol^{-1}, the adiabatic ionization potential of TTF was estimated to be I_p(TTF)=6.30±0.06 eV, which is a little larger than that of TMPD, but almost the same as that of I_p(DMPD)=6.28 eV.[9] On the other hand, the vertical ionization potential of TTF has been determined to be 6.86 eV by photoionization method in gas phase.[10] The vertical energy of TTF exceeds the adiabatic energy by 0.56 eV. The vertical ionization potential of TMPD was found to be 6.75 eV by Nakato *et al.*[11] This is less than the 6.86 eV value of TTF by 0.11 eV, being in line with our finding that the adiabatic ionization potential of TMPD is also less than that of TTF by 0.1 eV.

The entropy change, $\Delta S''$, of the equilibrium of Eq. 7 is small. The reason for this is as follows. Although there is a significant entropy effect upon solvation of ion radicals in acetonitrile solution, the entropies due to the solvation of TMPD$^{+\cdot}$ and TTF$^{+\cdot}$ ions are almost the same and cancel each other, resulting in a small entropy change for the equilibrium of Eq. 7. There is some uncertainty in the value of $\Delta S''=+1.7\pm38$ J K^{-1} mol^{-1} obtained from $\Delta S'-\Delta S$ because of the accumulation of errors of $\Delta S'$ and ΔS. Thus, direct measurement of the equilibrium constant of Eq. 7 is desirable in order to obtain a more reliable value of $\Delta S''$ for the sake of confirmation.

The observed k_{-1} value of Eq. 3 in 37 vol% DMSO–acetonitrile solution is smaller than the $k_{-1}=(6\pm2)\times10^9$ M^{-1} s^{-1} value for the reaction of TMPD$^{+\cdot}$+TCNQ$^{-\cdot}$→TMPD+TCNQ in acetonitrile solution.[8] This might be explained in terms of the difference in the solvents used. Ionic species such as TTF$^{+\cdot}$ are solvated more strongly in DMSO than in acetonitrile. Since k_{-1} is for the electron transfer from ionic species to neutral molecules, the process involves release of solvation of the ionic species. Thus, the reaction in DMSO/acetonitrile requires more activation energy for k_{-1} than the reaction in pure acetonitrile, and the k_{-1} rate constant in the former solvent may be smaller than that in the latter. Except for this solvation effect, the reaction rates in the TTF/TCNQ system are almost of the same magnitude as those in the TMPD/TCNQ system. The difference in the molecular structures of TTF and TMPD may make a minor contribution to the kinetic difference.

Concluding Remarks

Let us consider the electronic states of solid TTF–TCNQ and TMPD–TCNQ complexes on the basis of the above discussions. In the TTF–TCNQ complex, there have been evidences for incomplete charge transfer, where 0.59 electron is transferred from TTF to TCNQ. Segregated columns composed of partially ionized TTF and TCNQ exist, giving rise to metallic properties in the TTF–TCNQ complex.[3] On the other hand, the TMPD–TCNQ complex shows almost ionic character of TMPD cation radical and TCNQ anion radical in the solid state. The X-ray analysis by Hanson,[12] ESR study by Kinoshita and Akamatu,[13] and measurement of the crystal spectra by Kuroda *et al.*[14] provide evidences for almost one electron transfer from TMPD to TCNQ. If the complete charge transfer occurs in the solid TMPD–TCNQ complex, the complex would show semiconductive properties of a Mott-Hubbard-type insulator. Actually, its electric conductivity has been reported to be as low as 10^{-6}—10^{-8} Ω^{-1} cm^{-1}.[5]

Since the acceptor TCNQ is common, the difference between incomplete charge transfer in the TTF–TCNQ complex and almost complete charge transfer in the TMPD–TCNQ complex might depend mostly on the difference in adiabatic ionization potentials between TTF and TMPD. In view of the magnitude of the estimated adiabatic ionization potentials of I_p(TMPD)=6.20 eV and I_p(TTF)=6.30±0.06 eV, the TMPD–TCNQ complex might undergo ionization more easily in the solid state than the TTF–TCNQ complex.

McConnell *et al.* showed that, under certain conditions, a slight change in the ionization potential of donor or the electron affinity of acceptor might sharply discriminate ionic state from non-ionic state in solid charge-transfer complex.[15] Recently, Soos reexamined their argument to improve crystal binding energy and found that the $TTF^{+\gamma}$ $TCNQ^{-\gamma}$ complex might be charged with $\gamma \approx 0.35$, the $TMPD^{+\gamma}TCNQ^{-\gamma}$ complex, with $\gamma \approx 0.6$—0.7.[16] Although the estimated $\gamma \approx 0.35$ value in the TTF–TCNQ complex is lower than the experimental $\gamma \approx 0.59$ value, the slight difference in the ionization potentials between TMPD and TTF causes considerable difference in the degree of charge transfer between TMPD–TCNQ and TTF–TCNQ complexes.

Absolute Rate Constants for the Reactions of O(^{3}P) with Several Molecules

Ko-ichi SUGAWARA, Yo-ichi ISHIKAWA, and Shin SATO*

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received October 2, 1979)

Absolute rate constants were measured for several reactions of ground-state oxygen atoms at 296±2 K. The pulse-radiolysis of O_2, CO, or CO_2 in the He diluent was used to produce oxygen atoms, and the atomic concentration was monitored by the resonance absorption. The measurements were made in the pressure range from 50 to 950 Torr (1 Torr ≃133.3 Pa). The rate constants thus obtained were $(2.5\pm0.3)\times10^{-34}$ for O+O_2+He and $(1.0\pm0.2)\times10^{-35}$ for O+CO+He in units of cm^6 molecule^{-2} s^{-1} (1 cm^6 molecule^{-2} s^{-1}≃3.626×10^{35} m^6 mol^{-2} s^{-1}). For simple olefins, the following bimolecular rate constants (k/10^{-12} cm^3 molecule^{-1} s^{-1}) were obtained: Ethylene (1.0±0.2), propene (4.7±0.3), 1-butene (4.7±0.5), *trans*-2-butene (23±3), *cis*-2-butene (20±3), 2-methylpropene (17±2), 2-methyl-2-butene (55±5), 1,3-butadiene (20±2), (1 cm^3 molecule^{-1} s^{-1}≃6.022×10^{17} m^3 mol^{-1} s^{-1}). These rate constants were in fair agreement with the literature values.

The reactions of oxygen atoms with unsaturated hydrocarbons have been investigated by a variety of techniques. Cvetanović used a system of product analysis for the determination of the relative rate constants in his early studies.[1] For the production of oxygen atoms, the mercury-photosensitized decomposition of dinitrogen oxide and the photolysis of nitrogen dioxide were employed. The absolute rate constants were measured in discharge-flow systems combined with a mass spectrometer[2–5] or ESR.[6,7] This technique can, however, be used in only a limited low-pressure range, and it often needs stoichiometry corrections, because of the small difference in concentration between atoms and reactants in the reaction system.

Instead of the discharge-flow method, two other techniques have been employed so as to investigate the reactions under relatively high pressures, at which the concentration of the oxygen atoms is generally much lower than that of the reactants, and where no stoichiometry corrections are necessary. One is the flash-photolysis technique, which is often employed together with the method of resonance fluorescence[4,8–12] or the chemiluminescence of NO_2*[13–15] for the time-resolved measurement of the oxygen-atom concentration. The other is the modulation-phase shift technique, in which oxygen atoms are produced by the modulated mercury-photosensitization of dinitrogen oxide, and the rate constants are obtained as the phase shift between the incident radiation and the NO_2* chemiluminescence.[16–21]

Although a number of rate constants for the reactions of oxygen atoms with unsaturated hydrocarbons have been obtained by using these methods, there remain large discrepancies between the determined values. For example, the rate constant for the reaction of oxygen atoms with ethylene, which is one of the most investigated hydrocarbons, ranges from 5.0×10^{-13} to 1.2×10^{-12} cm^3 molecule^{-1} s^{-1}. Therefore, it is of interest to measure the rate constant using other techniques.

Recently we reported the absolute rate constants at room temperature for the reactions of H and D atoms with seven olefins, using a pulse radiolysis-resonance absorption technique.[22,23] The H and D atoms were generated in hydrogen and deuterium of some hundreds of Torr by the irradiation of an electron pulse, and were monitored by means of the light absorption at the Lyman-α line. This technique was initiated by Bishop and Dorfman[24] and developed by Mihelcic *et al.*[25] The results showed good agreement with those of previous works, and confirmed the validity of our apparatus and technique. This technique was extended to the rate constant measurements on the reactions of nitrogen atoms in the ground state with nitrogen monoxide, seven olefins, acetylene, and 1,3-butadiene.[26] The quenching rate coefficients of N(^{2}D) and N(^{2}P) by N_2 were also obtained.[27]

In the present work, this technique is extended to the measurement of the absolute rate constants for the reactions of oxygen atoms.

Experimental

The details of the apparatus and technique were given in the previous paper;[22] hence, only additional improvements and the major features will be described here.

Figure 1 shows the apparatus schematically. As the source of oxygen atoms, O_2(1.2—6.0 Torr), CO(≈11 Torr), or CO_2 (≈2.6 Torr) diluted with He (50—950 Torr) was used, and the gas mixture was irradiated with an electron pulse (pulse width, 3 ns; upper-limit energy, 600 keV) generated by Febetron 706 (Hewlett Packard Co.). The energy absorbed by 900 Torr He was estimated to be 4×10^{16} eV per pulse at a 25 kV DC charging voltage of

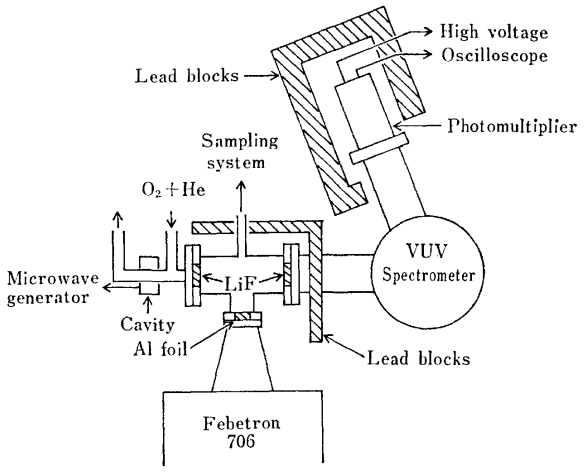

Fig. 1. Schematic diagram of the apparatus.

Febetron 706, on the basis of the measurement of the yields of nitrogen and oxygen in the pulse-irradiated dinitrogen oxide at 900 Torr. The values of 12.4 and 2.1 were taken as the G-values of nitrogen and oxygen,[28] and the energy absorption was assumed to be proportional to the electron density.

The concentration of oxygen atoms was followed by observing the light absorption of the resonance triplet lines of oxygen atoms around 130 nm. The resonance lamp used previously was a water-cooled capillary discharge lamp powered by a DC-current regulator. Since the output of the lamp fluctuated in the time range of μs ($S/N=5$ in the worst case), it was replaced by an electrodeless discharge lamp made of a Pyrex glass tube, 8 mm in inside diameter. A 2450 MHz microwave generator (Ito Chotanpa Co.) was operated at 70 W. A mixture of O_2 (10%) and He was made to flow at the total pressure of 5 Torr. Under these conditions, the highest intensity was obtained at the resonance line of the oxygen atoms. The resonance triplet lines ($^3S_1 \rightarrow {}^3P_{2,1,0}$: 130.217, 130.487, and 130.604 nm) emitted from the lamp passed through the reaction cell, on both sides of which LiF windows (Harshow Chem. Co.) were mounted, and were isolated with a vacuum ultraviolet spectrometer (Shimadzu, Model SGV-50). Since the slit width was open wide (1 mm), the triplet was not resolved. Consequently, the rate constants obtained in the present work are those of the overall reactions of oxygen atoms in the $^3P_2$, $^3P_1$, and $^3P_0$ states. The vacuum ultraviolet light was directly detected with a head-on-type photomultiplier (Hamamatsu TV Co., R976) amplified and monitored with an oscilloscope (Tektronix 465). Lead blocks were placed as is shown in Fig. 1 in order to protect the photomultiplier from the X-rays generated by the electron pulse.

The high-purity, dried He (Nihon Helium Co.) was passed through a trap filled with molecular sieve 4A at 77 K before use. The O_2 (Nihon Sanso Co.) and CO (Takachiho shoji Co.) were used without further purification. Research-grade olefins and CO_2 (Takachiho Shoji Co.) were used after thorough degassing.

Results

For the time-resolved measurements of the concentration of oxygen atoms, we used the resonance absorption method based on Lambert-Beer's law:

$$I_{tr} = I_0 \exp(-D), \quad \text{(I)}$$

$$D = \varepsilon[O]l. \quad \text{(II)}$$

The relative intensities of the incident and transmitted light, I_0 and I_{tr}, were evaluated from photographs such as Fig. 3a, and the optical density, D, was calculated by means of Eq. I. Since the molar absorption coefficient, ε, and the light-pass length, l, are constant, the oxygen-atom concentration, [O], should be proportional to D. However, Beer's law (II) does not always hold, because the line shape of the emission from a lamp is generally broader than that of the absorption in the reaction cell. Figure 2 shows the initial optical density as a function of the He pressure in the range from 50 to 950 Torr. The oxygen pressure was fixed at 3.0 Torr. In the present experiment, the absorption of energy by the gas mixture occurs through He, since O_2 is a minor component, and oxygen atoms are generated in proportion to the He pressure. Consequently, the plots shown in Fig. 2 correspond to the relationship between [O] and D. Evidently a linearity holds below the unity of D. In only this range of D, the photographs obtained were analyzed. As will be described below, the unity of D corresponds to the oxygen-atom concentration of 3×10^{13} cm^{-3}.

The System of O_2 in He. Figure 3a exhibits the transmittance, I_{tr}/I_0, as a function of the time obtained with the O_2 system in He. With this system, all the decay curves obtained fit a first-order decay plot, such as Fig. 3b. The slope of this linear rela-

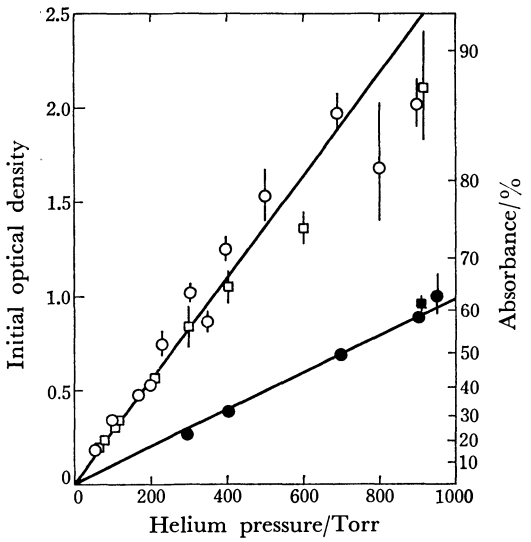

Fig. 2. Initial optical density and absorbance as a function of He pressure.
Charging voltage of Febetron is set at 25 kV (●, ■) and 28 kV (○, □). Circles were obtained with the mixture of 3 Torr oxygen and He. Squares were obtained with the same mixtures in the presence of 0.05 Torr ethylene.

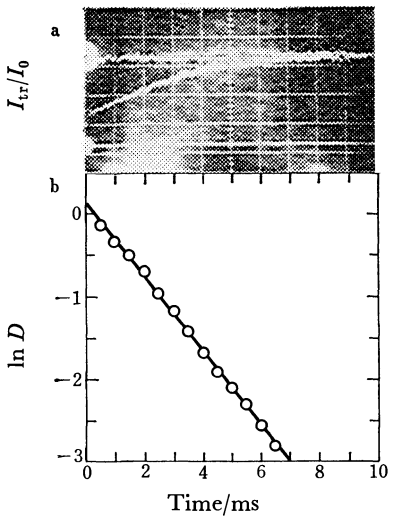

Fig. 3. Time dependence of the transmitted light at 130 nm (a) and the logarithm of the optical density (b).
This photograph was obtained within 10 ms with the mixture of 3.06 Torr oxygen and 604 Torr helium. Charging voltage of Febetron was 27 kV.

tionship gives the decay rate of the oxygen atoms. The reactions occuring in this system may be described by the next two termolecular reactions:

$$O + O_2 + He \longrightarrow O_3 + He, \quad (1)$$

$$O + O_2 + O_2 \longrightarrow O_3 + O_2. \quad (2)$$

The decay rate, k_{dr}, should, then, be given by this equation:

$$k_{dr} = k_1[O_2][He] + k_2[O_2]^2. \quad (III)$$

Here, k_1 and k_2 are the rate constants of Reactions 1 and 2 respectively. The He pressure dependence of the decay rate is shown in Fig. 4, where the oxygen pressures are fixed at 1.2 and 3.0 Torr. The slope and intercept of this linear relationship should correspond to $k_1[O_2]$ and $k_2[O_2]^2$ respectively. Figure 5 shows the O_2 pressure dependence of the decay rate, where the $k_{dr}[O_2]^{-2}$'s are plotted as a function of $[O_2]^{-1}$, with two fixed pressures of He. The slope and intercept should correspond to $k_1[He]$ and k_2 respectively. From these figures, k_1 and k_2 were obtained to be $(2.5\pm0.3)\times10^{-34}$ and $(1\pm3)\times10^{-33}$ cm^6 molecule^{-2} s^{-1} respectively. Since the pressure range of oxygen could not be changed widely, the error limit for k_2 was very large.

The System of CO in He. Figure 6a was obtained by the pulse radiolysis of the mixture of 10.5 Torr of CO and 905 Torr of He at 294 K. The first-order decay plot, Fig. 6b, exhibits that the decay of oxygen atoms seems to occur in two stages. In order to explain this decay curve, we considered the participation of carbon atoms in this reaction system:

$$C + CO + M \longrightarrow C_2O + M \ (M=He, CO) \quad (3)$$

$$O + CO + He \longrightarrow CO_2 + He \quad (4)$$

$$O + CO + CO \longrightarrow CO_2 + CO \quad (5)$$

$$O + C_2O \longrightarrow 2CO. \quad (6)$$

The decay rate of the concentration of oxygen atoms is, then, given by this equation:

$$k_{dr} = k_4[CO][He] + k_5[CO]^2 + k_6[C_2O]. \quad (IV)$$

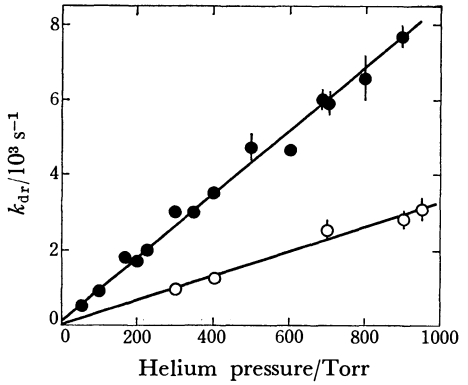

Fig. 4. Decay rate, k_{dr}, as a function of helium pressure.
The oxygen pressure is fixed at 1.2 Torr (○) and 3.0 Torr (●).

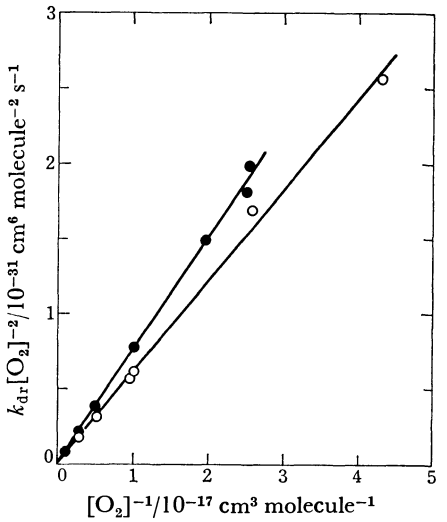

Fig. 5. $k_{dr}[O_2]^{-2}$'s as a function of $[O_2]^{-1}$.
The helium pressure is 700 Torr (○) and 900 Torr (●).

The initial fast decay of oxygen atoms shown in Fig. 6b may be due to the last term of Eq. IV.

Using the rate constant of Reaction 3 (6.3×10^{-32} cm^6 $molecule^{-2}$ s^{-1})[29] and the concentration of oxygen atoms, as will be stated below, we could estimate the rate constant of Reaction 6 to be larger than 5×10^{-11} cm^3 $molecule^{-1}$ s^{-1}.

If this reaction mechanism is correct, the rate constants of Reactions 4 and 5 can be estimated from the slow first-order decay shown in Fig. 6b, as has been done in the case of the O_2 in the He system. Figures 7 and 8 show the pressure dependence of k_{dr} on CO and He respectively. From these figures, the rate constants of Reactions 4 and 5 can be estimated as follows: $k_4=(1.0\pm0.2)\times10^{-35}$ and $k_5=(3\pm2)\times10^{-35}$ in units of cm^6 $molecule^{-2}$ s^{-1}.

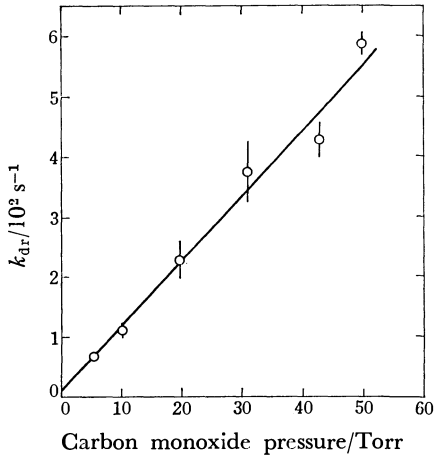

Fig. 7. The decay rate, k_{dr}, of oxygen atoms in the reaction O+CO+He as a function of carbon monoxide pressure. Helium pressure is 900 Torr.

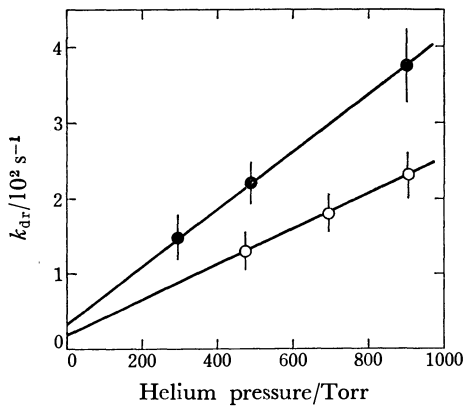

Fig. 8. The decay rate, k_{dr}, of oxygen atoms in the reaction O+CO+He as functions of helium pressure. The carbon monoxide pressures are fixed at 20 (○) and 30 (●) Torr.

The System of CO_2 in He. Similar measurements of the decay rate of oxygen atoms produced in the mixture of 2.6 Torr of carbon dioxide and He, the pressure ranging from 50 to 900 Torr, were carried out. Very slow first-order decays were found. If the oxygen atoms in this system react as follows:

$$O + CO_2 + He \longrightarrow CO_3 + He, \qquad (7)$$

then the upper limit of the rate constant of this reaction is estimated to be $(4\pm2)\times10^{-36}$ cm^6 $molecule^{-2}$ s^{-1}.

The Reactions with Olefins. When a small amount of an olefin is present in any of the three systems of O_2 in He, CO in He, and CO_2 in He, a fast decay of the oxygen atoms can be observed. Figures 9a and b show the decay curves obtained in the absence and presence of propene respectively, with the same sweep time of 0.2 ms per division. Figure 9c represents the first-order decay plots.

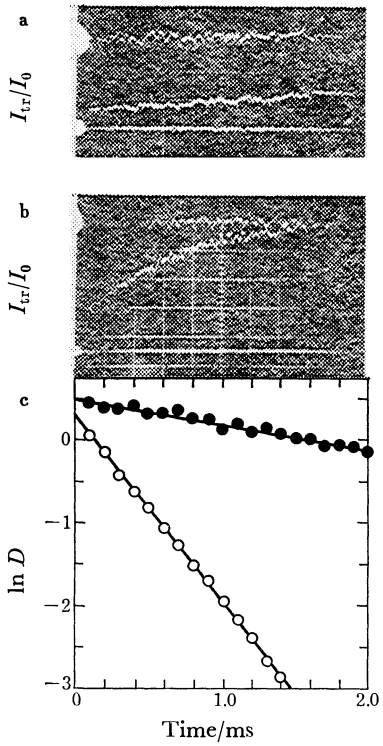

Fig. 9. Time dependence of the transmitted light at 130 nm. (a) was obtained with the mixture of 1.97 Torr O_2 and 904 Torr He, and (b) with the mixture of 0.010 Torr C_3H_6, 3.04 Torr O_2, and 903 Torr He. (c) is the first order plots of the decay curves of (a) (●) and (b) (○).

Figure 10 shows the decay rates of the oxygen atoms obtained by using four different sources of oxygen atoms as a function of the ethylene pressure. The slopes of these linear relationships correspond to the rate constant of the reaction of oxygen atoms with ethylene, and the intercepts, to the decay rates of oxygen atoms in each source of oxygen atoms in the absence of ethylene, *i.e.*, O_2 (3 and 6 Torr), CO (11 Torr), and CO_2 (2.6 Torr) in He (900 Torr). Evidently, the same rate constant for the reaction of the oxygen atoms with ethylene was obtained irrespective of the source of the oxygen atoms. Figure 11 shows that the rate constant is also independent of the helium pressure in the range from 50 to 1000 Torr. From these data, the rate constant of the addition reaction of the oxygen atoms to ethylene was estimated to be $(1.0\pm0.2)\times10^{-12}$ cm^3 molecule^{-1} s^{-1}. Table 3 compares previous studies of this reaction.

When the ratio of $[C_2H_4]/[He]$ was smaller than 10^{-4}, the apparent rate constant of the reaction of

the oxygen atoms was found to be a little larger than that obtained above. This is probably due to the fact that, since the amount of ethylene is small, the radicals produced in the reaction of the oxygen atoms with ethylene can compete with ethylene for the oxygen atoms. Therefore, we took the value obtained with the ratio, $[C_2H_4]/[He]$, larger than 10^{-4}. Such an anomaly could not be observed with any olefins other than ethylene.

Figure 12 summarizes the decay rates of oxygen atoms obtained with all olefins examined, as functions of olefin pressure. The rate constants thus obtained are summarized in Tables 4 and 5 together with those previously reported.

Discussion

Initial Concentration of Oxygen Atoms. When helium containing a small amount of oxygen is irradiated with high-energy electrons, the ionization and excitation of helium occurs first, and then, the oxygen atoms in the ground (^{3}P) and metastable (^{1}D and ^{1}S) states are generated by the decomposition of oxygen through energy transfer from excited helium or through charge transfer from ionized helium, followed by neutralization with electrons.

Boyd *et al.* measured the *G*-value of ozone from a mixture of oxygen and helium, using Febetron 705 as the source of high-energy electrons; they found that $G(O_3)=16$ at total pressures higher than 300 Torr and with oxygen mole fractions ranging from 0.1 to 0.3.[30] In the present experiment, the mole fraction of oxygen is less than 0.06, so that the *G*-value of ozone may be smaller than 16.

In order to estimate the initial concentration of the oxygen atoms produced in a mixture of 3 Torr oxygen and 900 Torr helium, we used the following values: $G(O)=12.8$,[31] 4×10^{16} eV per pulse for absorbed dose, and 150 cm^3 for the effective volume of the reaction cell. The initial concentration of the oxygen atoms thus calculated was 3×10^{13} cm^{-3}, a value which corresponds to the unity of *D* in Fig. 2.

Influence of Other Active Species. When pulse radiolysis is used for the production of atoms, many different active species are generated together with the atoms required. As was discussed in a previous paper,[22] the participation of ionic species is completed within 10 μs after pulse irradiation; therefore, the only active species we have to consider here are two metastable oxygen atoms, ^{1}D and ^{1}S.

Resently Schofield summarized the rate constants

for the reactions of metastable oxygen atoms, ^1D and ^1S, with a number of molecules including oxygen, carbon monoxide, carbon dioxide, and olefins.[32] All rate constants reported are much larger than those obtained with the ground-state ^3P oxygen atoms. Simple calculations using these data can show that the reactions of the ^1D and ^1S oxygen atoms, even if they are produced in the present experimental systems, are all completed before the measurement of the decay of the ^3P oxygen atoms. For example, the O(^1D) atoms are quenched to O(^3P) atoms within 0.3 μs in the system containing 3 Torr of oxygen. Similarly, O(^1S) atoms, if produced in the system containing 0.1 Torr ethylene, are removed within one μs.

Influence of Secondary Reactions. Ozone, which is a product of the reaction of $O+O_2+M$, cannot affect the decay of oxygen atoms in the system of O_2 in helium, because the concentration of ozone produced is small ($<10^{13}$ cm^{-3}) and the rate constant for the reaction of $O+O_3$ is known to be not very large ($(2.5\pm0.5)\times 10^{-14}$ cm^3 molecule^{-1} s^{-1}).[33]

As has been stated in the Results section, when carbon monoxide was used as the source of oxygen atoms, the decay curve for the oxygen atoms was not a simple first-order one. We tentatively explained this as the result of the participation of C_2O in the reaction. This is obviously a subject for further investigation. This complication however, can be ignored in the measurement of the rate constants of the reactions of O+olefins, since the amount of olefins used was much larger than that of the C_2O produced and since the reactions of O+olefins are fast.

In the study of the reaction of oxygen atoms with ethylene, we found the anomaly presented in the Results section. Consequently, we made extensive measurements of this reaction. Some of the results are shown in Fig. 13, where it can be seen that the apparent rate constant for the reaction of oxygen atoms with ethylene increased with the decrease in the ratio of $[C_2H_4]/[O]_0$ below 100. Here, $[O]_0$ stands for the initial concentration of the oxygen atoms.

It is well known that the reaction of $O+C_2H_4$ does not give a stable addition product, but such radicals

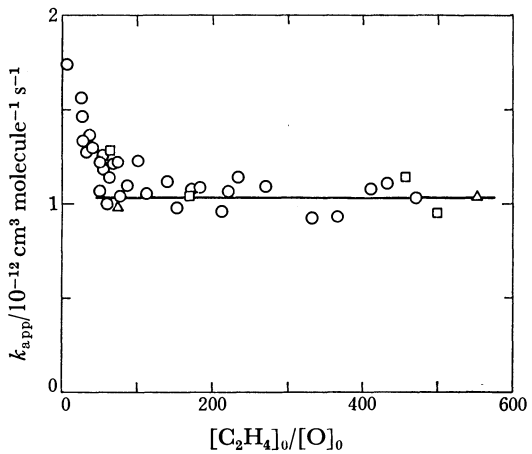

Fig. 13. The apparent rate constant, k_{app}, for the reaction of $O+C_2H_4$ as a function of the ratio, $[C_2H_4]/[O]_0$.
The O_2 (○), CO (△), and CO_2 (□) are used as the source of oxygen atoms.

as CH_3 and CHO, even at atmospheric pressure, while olefins larger than ethylene produce the corresponding addition products.[1] Consequently, the participation of radicals cannot be ignored in the case of ethylene. Let us consider the following simplified reaction mechanism:

$$O + C_2H_4 \longrightarrow R + \text{residue} \qquad k$$
$$R + O_2 + M \longrightarrow RO_2 + M$$
$$O + R \longrightarrow \text{products} \qquad k_R$$
$$O + RO_2 \longrightarrow \text{products} \qquad k_{RO_2}$$

Here, R stands for a radical, and k, k_R, and k_{RO_2}, for the rate constants for each reaction. The amounts of radicals are, of course, time-dependent, but they may be regarded as being in proportion to the initial concentration of the oxygen atoms. Then, the apparent decay rate, k_{app}, of the oxygen atoms may be written by the following equation:

$$k_{app} = k + k_R\frac{[R]}{[C_2H_4]} + k_{RO_2}\frac{[RO_2]}{[C_2H_4]}$$
$$\simeq k\left(1+\alpha(t)\frac{[O]_0}{[C_2H_4]}\right)$$

Therefore, we concluded that the k_{app} value obtained at higher ratios of $[C_2H_4]/[O]_0$ corresponds to the rate constant we are concerned with.

Comparison with Literature Values for the Reactions with Olefins. The rate constants previously obtained for the reaction of $O+C_2H_4$ are summarized in Table 3. They are classified by the method of measurement. The present result is slightly larger than those obtained by the flash-photolysis and modulation-phase-shift techniques, but within the limits of experimental error. Table 4 lists the rate constants for other olefins. The present results agree well with those obtained by Atkinson and Pitts.[15] In addition, the relative rate constants are tabulated in Table 5. All the data are in good agreement with each other, irrespective of the method of measurement.

Studies on 2-Aziridinecarboxylic Acid. IV. Total Synthesis of Actinomycin D (C_1) *via* Ring-opening Reaction of Aziridine

Takumi TANAKA, Kiichiro NAKAJIMA, and Kenji OKAWA*

Department of Chemistry, Faculty of Science, Kwansei Gakuin University, Nishinomiya 662

(Received June 18, 1979)

Actinomycin D (C_1) has been synthesized by a route involving the ester formation between two peptide fragments, (2*S*,3*S*)-1-(2-nitro-3-benzyloxy-4-methylbenzoyl)-3-methyl-2-aziridinecarbonyl-D-valylproline *t*-butyl ester and *N*-benzyloxycarbonylsarcosyl-*N*-methylvaline, *via* a ring-opening reaction of aziridine. Cyclization, followed by reduction and oxidation, gave actinomycin D (C_1). The synthetic actinomycin D (C_1) was indistinguishable from natural substance as regards physical properties and biological activity.

A number of cyclic peptide lactone antibiotics such as actinomycin group, etamycin, and echinomycin have been reported during the last few years. However, since they possess cyclic lactone structure and unusual amino acids, the synthetic approaches were limited.

It was found that the reaction of the peptide containing (2*S*, 3*S*)-3-methyl-2-aziridinecarboxylic acid with *N*-protected amino acids or dipeptides affords *O*-acylthreonine peptides.[1] This paper reports an application of the ester formation method to the synthesis of naturally occurring cyclic peptide lactone, actinomycin D (C_1) (Fig. 1).

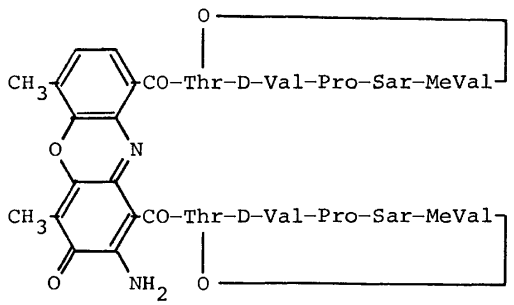

Fig. 1.

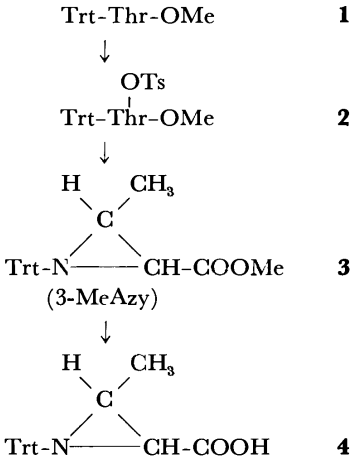
So far, the general synthetic method for peptide lactones involved formation of the ester bond (didepsipeptide) at the start, followed by peptide elongation and cyclization by the formation of the amide bond. A new route is designed in which linear pentapeptide ester **11** is directly formed by the ring-opening reaction of aziridinecarboxylic acid-containing peptide **8** with dipeptide **10** (Scheme 2). The method needs no activating reagent for the preparation of *O*-acylthreonine peptide, no racemization taking place during the course of direct introduction of *N*-protected dipeptide.

(2*S*,3*S*)-1-Trityl-3-methyl-2-aziridinecarboxylic acid (**4**) was prepared from threonine by the following route (Scheme 1). Tritylthreonine methyl ester (**1**) was treated with *p*-toluenesulfonyl chloride in a pyridine solution at −10 °C to give *O*-tosyl derivative **2**, which was refluxed in tetrahydrofuran with triethylamine to convert aziridinecarboxylic acid derivative **3**. Saponification of **3** with lithium hydroxide gave the desired amino acid **4**.

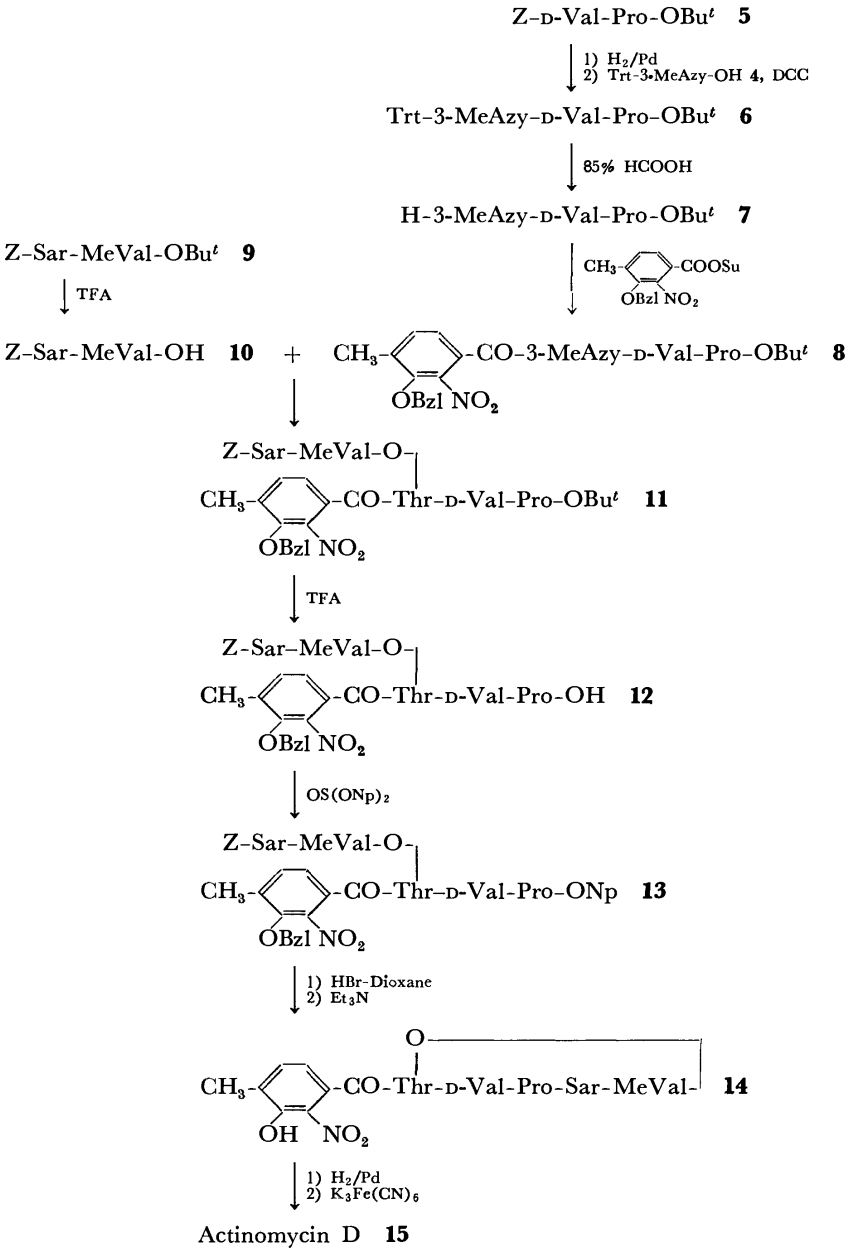
The aziridine segment **8**, (2*S*,3*S*)-1-(2-nitro-3-benzyloxy-4-methylbenzoyl)-3-methyl-2-aziridinecarbonyl-D-valylproline *t*-butyl ester, was synthesized as follows. Coupling of benzyloxycarbonyl-D-valine and proline



Scheme 1.

t-butyl ester using dicyclohexylcarbodiimide (DCC)[2] gave the dipeptide **5**. Hydrogenolysis of **5**, followed by coupling with **4** using DCC gave the tripeptide **6** in 91.5% yield. Selective removal of the trityl group of **6** with 85% formic acid containing a small amount of methanol gave **7** in 94.6% yield, which was then coupled, in the dark, with 2-nitro-3-benzyloxy-4-methylbenzoic acid *N*-hydroxysuccinimide ester. Compound **8** was obtained as colorless amorphous powder in 94.7% yield after purification by silica gel column chromatography using benzene–ethyl acetate (1 : 1 v/v). Benzyloxycarbonylsarcosine was coupled with *N*-methylvaline *t*-butyl ester using DCC to give the dipeptide **9**. *t*-Butyl group of **9** was removed by the action of trifluoroacetic acid to give the dipeptide acid **10** as an acid component.

The formation of the ester bond between *N*-methylvaline and threonine was carried out by heating **8** together with **10** at 110 °C for 5 h, in the dark. The coupling reaction afforded a mixture of **11** and the hydrolyzed product of **8** (threonine derivative), from which **11** was isolated in 45—55% yields by silica gel column chromatography. The *t*-butyl group of **11** was removed by the action of trifluoroacetic acid, the product **12** being treated with bis(*p*-nitrophenyl) sulfite in a pyridine solution to give the *p*-nitrophenyl ester **13**. Deprotection of benzyloxycarbonyl group of **13** with hydrogen bromide in dioxane, followed by neutralization, cyclization [0.98 mmol in 2 l pyridine, 60 °C, 8 h], and purification on Sephadex LH-20 column in methanol, gave cyclic pentapeptide lactone **14** in 21.4% yield. Catalytic hydrogenolysis of **14**,



Scheme 2.

Table 1. Physical properties and biological activities of actinomycin D

Characteristics	Synthetic actinomycin D (**15**)	Natural actinomycin D (Lit.) a)	b)
Melting point/°C	242—243	241—243	246—247

followed by oxidation with potassium hexacyanoferrate(III) in the 1:1 mixture of methanol and 0.067 M phosphate buffer, pH 7.1,[3] gave actinomycin D (C_1) (**15**), which was quantitatively crystallized from ethyl acetate–hexane.

The synthetic actinomycin D (C_1) was indistinguishable from the natural substance as regards physical properties and biological activity against *B. Subtilis*. The physical and biological data are summarized in Table 1.

The method using the ring-opening reaction of aziridine is an efficient means for synthesizing peptide lactone compounds.

Experimental

Melting points are uncorrected. Infrared spectra were obtained on a Hitachi EPI-G3 spectrometer, ultraviolet spectra on a Shimadzu UV-200 spectrophotometer. Optical rotations were determined at the D line on a Perkin-Elmer 141 polarimeter. Thin layer chromatography was carried out on silica gel G in the following solvent systems: R_f^1; chloroform–ethyl acetate (1:1), R_f^2; benzene–ethyl acetate (1:1), R_f^3; chloroform–methanol–acetic acid (8:1:1), R_f^4; chloroform–methanol–ethyl acetate (8:1:1), R_f^5; 1-butanol–acetic acid–water (4:1:1).

*Tritylthreonine Methyl Ester (**1**).* To a solution of threonine methyl ester hydrochloride (85.3 g, 0.5 mol) and triethylamine (140 ml, 1 mol) in $CHCl_3$ (280 ml) was added a solution of trityl chloride (139 g, 0.5 mol) in $CHCl_3$ (250 ml) at 0 °C. After being stirred for 24 h at 0 °C the solution was concentrated *in vacuo* and the residue was dissolved in ethyl acetate. The solution was washed with water, 10% citric acid and water. Drying over Na_2SO_4 and concentration gave an oil (186 g) of **1** in a theoretical yield, R_f^1 0.86, $[\alpha]_D^{23}$ +5.4 (*c* 0.94, $CHCl_3$).

*O-Tosyl-N-tritylthreonine Methyl Ester (**2**).* To a solution of **1** (5.72 g, 15.2 mmol) in dry pyridine (45 ml) was added at −10 °C a solution of *p*-toluenesulfonyl chloride (8.71 g, 45.7 mmol) in dry pyridine (50 ml). After being stirred for 3 d at −10 °C the reaction mixture was poured onto ice water (400 ml). The oily product was extracted with ethyl acetate. The extract was further washed with water, dried over Na_2SO_4, and concentrated *in vacuo*. The residue was crystallized from ethyl acetate–ether–hexane, 6.59 g (81.9%), mp 120—122 °C, $[\alpha]_D^{23}$ +87.7 (*c* 0.9, $CHCl_3$). Found: C, 70.21; H, 6.01; N, 2.50; S, 6.25%. Calcd for $C_{31}H_{31}O_5NS$: C, 70.30; H, 5.90; N, 2.64; S, 6.05%.

*(2S, 3S)-1-Trityl-3-methyl-2-aziridinecarboxylic Acid Methyl Ester (**3**).* A solution of **2** (16.5 g, 31.1 mmol) and triethylamine (36.4 ml, 93.3 mmol) in tetrahydrofuran (100 ml) was refluxed at 80 °C for 2 d. After removal of solvent the oily product was dissolved in ethyl acetate. The solution was washed with water, dried over Na_2SO_4, and concentrated *in vacuo*. The residue was crystallized from methanol, 10.1 g (90.4%), mp 109—110 °C, $[\alpha]_D^{23}$ −102.8 (*c* 1.0, $CHCl_3$). Found: C, 80.29; H, 6.39; N, 3.56%. Calcd for $C_{24}H_{23}O_2N$: C, 80.64; H, 6.48; N, 3.92%.

*(2S, 3S)-1-Trityl-3-methyl-2-aziridinecarboxylic Acid (**4**).* To a solution of **3** (6.0 g, 16.8 mmol) in acetonitrile (80 ml) and methanol (20 ml) was added drop by drop at 20 °C a solution of 2 M lithium hydroxide (24 ml, 84 mmol). After being stirred for 24 h at 20 °C the solvent was removed and the residue was dissolved in ethyl acetate. The solution was washed with 10% citric acid and water, dried over Na_2SO_4, and concentrated *in vacuo*. The residue was crystallized from hexane, 5.47 g (94.8%), mp 173—175 °C, $[\alpha]_D^{23}$ −77.3 (*c* 0.9, $CHCl_3$). Found: C, 79.54; H, 6.23; N, 3.80%. Cacld for $C_{22}H_{21}O_2N$: C, 79.73; H, 6.39; N, 4.23%.

*Benzyloxycarbonyl-D-valylproline t-Butyl Ester (**5**).* To a solution of benzyloxycarbonyl-D-valine (16.5 g, 70.5 mmol) and proline *t*-butyl ester (12.0 g, 70.5 mmol) in CH_2Cl_2 (150 ml) was added at −10 °C a solution of dicyclohexylcarbodiimide (DCC, 14.5 g, 70.5 mmol) in CH_2Cl_2 (50 ml). The reaction mixture was stirred at −10 °C for 3 h, and then overnight in a refrigerator. After removal of *N,N'*-dicyclohexylurea by filtration the filtrate was concentrated *in vacuo*. The residue was dissolved in ethyl acetate and the solution was washed with 10% citric acid, 1 M sodium hydrogencarbonate and water, dried over Na_2SO_4, and concentrated *in vacuo*. The residue was crystallized from ethyl acetate–ether–hexane. 24.5 g (89.9%), mp 90—91 °C, $[\alpha]_D^{23}$ −21.4 (*c* 1.0, MeOH). Found: C, 65.74; H, 8.58; N, 7.13%. Calcd for $C_{22}H_{32}O_5N_2$: C, 65.32; H, 7.97; N, 6.93%.

*(2S, 3S)-1-Trityl-3-methyl-2-aziridinecarbonyl-D-valylproline t-Butyl Ester (**6**).* Compound **5** (12.35 g, 30.5 mmol) was hydrogenated over palladium in methanol for 2 h to give N^{α}-free dipeptide. This was coupled with **4** (9.20 g, 28 mmol) in CH_2Cl_2 (150 ml) containing DCC (6.30 g, 30.5 mmol) using the same method as in the preparation of **5** to give **6**, which was crystallized from methanol, 15.3 g (91.5%), mp 93—94.5 °C, $[\alpha]_D^{23}$ −81.5 (*c* 0.82, MeOH). Found: C, 74.29; H, 7.85; N, 6.99%. Calcd for $C_{37}H_{45}O_4N_3$: C, 74.59; H, 7.61; N, 7.05%.

*(2S, 3S)-3-Methyl-2-aziridinecarbonyl-D-valylproline t-Butyl Ester (**7**).* **6** (12.0 g, 20 mmol) was added to an ice-cold solution of 85% formic acid (80 ml) containing metanol (20 ml), and the resulting solution was stirred for 3 h. After removal of solvent the residue was partitioned between ether and water. Sodium hydrogencarbonate was added to the aqueous layer producing alkaline solution, and the isolated oil was extracted with ethyl acetate. After being dried over Na_2SO_4 the solvent was concentrated *in vacuo* to give **7**, which was crystallized from methanol, 6.69 g (94.6%), mp 81—84 °C, $[\alpha]_D^{23}$ −39.0 (*c* 2.0, MeOH). Found: C, 61.42; H, 9.09; N, 11.79%. Calcd for $C_{18}H_{31}O_4N_3$: C, 61.17; H, 8.84; N, 11.89%.

*(2S, 3S)-1-(2-Nitro-3-benzyloxy-4-methylbenzoyl)-3-methyl-2-aziridinecarbonyl-D-valylproline t-Butyl Ester (**8**).* A mixture of **7** (4.8 g, 13.6 mmol) and 2-nitro-3-benzyloxy-4-methylbenzoic acid *N*-hydroxysuccinimide ester[4] (5.23 g, 13.6 mmol) was stirred in $CHCl_3$ (40 ml) in the dark at room temperature for 24 h. After removal of solvent the residue was dissolved in ethyl acetate, and the solution was washed with 10% citric acid and water, dried over Na_2SO_4, and concentrated *in vacuo*. The crude product was purified by silica gel column chromatography using benzene–ethyl acetate (1:1 v/v) to give **8** as an amorphous powder, 8.53 g (94.7%), R_f^2 0.65, $[\alpha]_D^{23}$ −81.1 (*c* 1.1, MeOH). Found: C, 63.85; H, 7.13; N, 8.71%. Calcd for $C_{33}H_{42}O_8N_4$: C, 63.65; H, 6.80; N, 9.00%.

*Benzyloxycarbonylsarcosyl-N-methylvaline t-Butyl Ester (**9**).* Benzyloxycarbonylsarcosine (17.6 g, 79 mmol), *N*-methylvaline *t*-butyl ester (14.8 g, 79 mmol), and DCC (19.6 g, 95 mmol) were allowed to react in CH_2Cl_2 (250 ml) using the same method as in the preparation of **5**. After purification of the residue by silica gel column chromatography using chloroform–ethyl acetate (1:1 v/v), **9** was obtained as an oil, 29.8 g (96.0%), R_f^1 0.80, $[\alpha]_D^{23}$ −75.8 (*c* 1.4, MeOH).

*Benzyloxycarbonylsarcosyl-N-methylvaline (**10**).* Trifluoroacetic acid (20 ml) was added to **9** (4.79 g, 12.2 mmol) at

−5 °C, and the reaction mixture was stirred for 3 h at the same temperature. After removal of trifluoroacetic acid *in vacuo* the residual oily product was partitioned between ethyl acetate and sodium hydrogencarbonate solution. Citric acid was added to the aqueous layer producing acidic solution, and the isolated oil was extracted with ethyl acetate. The ethyl acetate layer was washed with water successively, dried over Na_2SO_4, and concentrated *in vacuo* to give **10** as an oil, 3.7 g (90.0%), R_f[4] 0.58, $[\alpha]_D^{23}$ −77.7 (*c* 1.07, MeOH).

O-*(Benzyloxycarbonylsarcosyl*-N-*methylvalyl)*-N-*(2-nitro-3-benzyloxy-4-methylbenzoyl)threonyl*-D-*valylproline* t-*Butyl Ester (**11**)*. A mixture of **8** (1.87 g, 3 mmol) and **10** (4.0 g, 12 mmol), protected from light, was heated at 110 °C for 5 h in an oil bath. After cooling the reaction mixture was dissolved in ethyl acetate and the solution was washed with 1 M sodium hydrogencarbonate and water, dried over Na_2SO_4, and concentrated *in vacuo*. The residue was purified by silica gel column chromatography using chloroform–ethyl acetate (1:1 v/v) to give **11** as an amorphous powder, 1.54 g (53.6%), R_f[1] 0.59, $[\alpha]_D^{23}$ −6.47 (*c* 1.12, MeOH). Found: C, 62.65; H, 7.07; N, 8.23%. Calcd for $C_{50}H_{66}O_{13}N_6$: C, 62.61; H, 6.94; N, 8.76%. Another product possessing a lower R_f value (R_f[1] 0.23) was identified as *N*-(2-nitro-3-benzyloxy-4-methylbenzoyl)threonyl-D-valylproline *t*-butyl ester, 769 mg, amorphous powder, $[\alpha]_D^{23}$ −17.4 (*c* 0.9, MeOH). Found: C, 61.20; H, 6.88; N, 8.42%. Calcd for $C_{33}H_{44}O_9N_4$: C, 61.19; H, 6.92; N, 8.74%.

O-*(Benzyloxycarbonylsarcosyl*-N-*methylvalyl)*-N-*(2-nitro-3-benzyloxy-4-methylbenzoyl)threonyl*-D-*valylproline (**12**)*. Trifluoroacetic acid (15 ml) was added to **11** (1.30 g, 1.35 mmol) containing anisole (0.5 ml), and the reaction mixture was stirred for 1 h in the dark. After removal of trifluoroacetic acid, absolute ether was added. The solid precipitate was collected by filtration and washed throughly with absolute ether, 1.00 g (82.0%), R_f[3] 0.85, mp 118—121 °C, $[\alpha]_D^{23}$ −4.5 (*c* 1.0, MeOH). Found: C, 60.80; H, 6.44; N, 9.39%. Calcd for $C_{46}H_{58}O_{13}N_6$: C, 61.18; H, 6.47; N, 9.31%.

O-*(Benzyloxycarbonylsarcosyl*-N-*methylvalyl)*-N-*(2-nitro-3-benzyloxy-4-methylbenzoyl)threonyl*-D-*valylproline* p-*Nitrophenyl Ester (**13**)*. Bis(*p*-nitrophenyl)sulfite (4.4 g, 13.5 mmol) was added to a solution of **12** (1.20 g, 1.32 mmol) in pyridine (20 ml), and the reaction mixture was stirred at room temperature for 20 h in the dark. After removal of solvent the residue was dissolved in ethyl acetate, and the solution was washed with 1 M sodium hydrogencarbonate and water, dried over Na_2SO_4, and concentrated *in vacuo*. The crude product was purified by column chromatography on Sephadex LH-20 in ethyl acetate to give **13** as an amorphous powder, 1.09 g (80.8%), R_f[1] 0.42, $[\alpha]_D^{23}$ −1.7 (*c* 0.29, DMF). Found: C, 60.28; H, 6.00; N, 9.11%. Calcd for $C_{52}H_{61}O_{15}N_7$: C, 60.98; H, 6.00; N, 9.58%.

(2-Nitro-3-hydroxy-4-methylbenzoyl)threonyl-D-*valylprolylsarcosyl*-N-*methylvaline(threonine hydroxyl) Lactone (**14**)*. Hydrogen bromide gas was bubbled at 0 °C, in the dark, into a solution of **13** (1.0 g, 0.98 mmol) in dioxane (10 ml) for 15 min. The reaction mixture was allowed to stand at room temperature for 1 h. After removal of solvent the residue was dissolved in *N*,*N*-dimethylformamide (20 ml) and acetic acid (1 ml). The solution was added drop by drop over a period of 2.5 h to stirred pyridine (2000 ml) containing triethylamine (1 ml) at 60 °C. After being stirred for 5.5 h at the same temperature the pyridine was concentrated *in vacuo* and the residual oil was dissolved in ethyl acetate. The solution was washed with water, 10% citric acid, 1 M sodium hydrogencarbonate and water, dried over Na_2SO_4, and concentrated *in vacuo*. The crude product (568 mg) was purified by column chromatography on Sephadex LH-20 in methanol to give the desired product (159.8 mg, 24.8%), which was crystallized from ethyl acetate–hexane, 137.8 mg (21.4%), R_f[4] 0.38, mp 179—181 °C, $[\alpha]_D^{23}$ −21.0 (*c* 0.5, MeOH). IR (KBr) 1730 (ester C=O), 1655 (amide), 1190 cm^{-1} (ester COC). Found: C, 56.45; H, 6.71; N, 12.62%. Calcd for $C_{31}H_{44}O_{10}N_6$: C, 56.35; H, 6.71; N, 12.72%.

*Actinomycin D (C_1) (**15**)*. A solution of **14** (49 mg, 0.074 mmol) in methanol (10 ml) was hydrogenated over palladium black, in the dark. After 2 h, the mixture was filtered and the filtrate was added to an equal volume of stirred 0.067 M phosphate buffer pH 7.1 containing potassium hexacyanoferrate(III) (70.8 mg, 0.215 mmol). The mixture was stirred at room temperature for 20 min. It was then partitioned between ethyl acetate and water, the aqueous layer being separated and extracted three times with ethyl acetate. The combined ethyl acetate layer was washed successively with 1 M sodium hydrogencarbonate, 1 M HCl, and saturated NaCl, dried over Na_2SO_4, and concentrated *in vacuo* to afford a red crystalline residue, which was recrystallized from ethyl acetate–hexane to give actinomycin D, 44 mg (95.7%), R_f[5] 0.76. Physical and spectral data are given in Table 1. Found: C, 58.59; H, 6.96; N, 13.29%. Calcd for $C_{62}H_{86}O_{16}N_{12}\cdot H_2O$: C, 58.48; H, 6.97; N, 13.20%.

Microbiological Assay. The results of the assay and microorganism employed are given in Table 1. The minimum amount of the compound necessary for the complete inhibition of growth was determined by the Streak method using HI-agar.

The authors wish to express their thanks to the staff of Fujisawa Pharmaceutical Co., Ltd., for the elemental analysis and biological assay.

The Enantioface-differentiating Hydrogenation of the C=O Double Bond with Asymmetrically Modified Raney Nickel. XXXIII. The Preparation of (*R*)- and (*S*)-1,3-Butanediol from 4-Hydroxy-2-butanone

Shigeki MURAKAMI, Tadao HARADA, and Akira TAI*

Institute for Protein Research, Osaka University, Yamada-Kami, Suita, Osaka 565

(Received July 13, 1979)

The enantioface-differentiating hydrogenation of 4-hydroxy-2-butanone (I) to 1,3-butanediol(II) was conducted with asymmetrically modified metal catalysts. Among the modified catalysts examined, Raney nickel modified with a solution containing tartaric acid and NaBr (TA–NaBr–MRNi) gave the best results with respect to the optical and chemical yields. (*R*)-II, an optical purity of 69% was obtained in a quantitative chemical yield by the use of (*R,R*)-TA–NaBr–MRNi. (*S*)-II was also obtained by the use of (*S,S*)-TA–NaBr–MRNi. A simple method for the preparation of optically pure (*S*)-and (*R*)-II from the hydrogenation product was also developed.

1,3-Butanediol (II) is a biologically interesting compound as a synthetic source of dietary calories[1] and a hypoglycemic agent for diabetes.[2]

A recent study has indicated that (*R*)- and (*S*)-II show different physiological activities.[3] In order to make clear the relations between the absolute configuration and the biological activity of II, the development of a simple method of preparing optically active I was required.

This report will deal with our recent efforts to prepare (*S*)- and (*R*)-II by the enantioface-differentiating hydrogenation of 4-hydroxy-2-butanone (I) with an asymmetrically modified metal catalyst.

Results

The substrate of the present work was prepared from acetone and formaldehyde by a modification of Hays's method:[4]

$$CH_3\text{-}\underset{\underset{O}{\|}}{C}\text{-}CH_3 + CH_2O \xrightarrow{\text{Base}} CH_3\text{-}\underset{\underset{O}{\|}}{C}\text{-}CH_2CH_2OH \quad (1)$$

(I)

Since this reaction proceeds in a flow reactor with a short contact time, the large-scale production of the substrate is feasible.

The hydrogenation of I with various metal catalysts modified with (*R,R*)-tartaric acid easily proceeded at hydrogen pressures of 50—100 kg/cm² and at reaction temperatures of 80—140 °C to give II in good chemical yields.

$$CH_3\text{-}\underset{\underset{O}{\|}}{C}\text{-}CH_2CH_2OH \xrightarrow{H_2/cat} CH_3\text{-}\underset{\underset{OH}{|}}{CH}\text{-}CH_2CH_2OH \quad (2)$$

(I) (II)

However, the optical yields of the reaction were generally low except for the cases of nickel catalysts (Table 1). Thus, further studies were carried out with nickel catalysts.

Among the nickel catalysts examined, Raney nickel prepared by leaching the alloy with an alkaline solution at a high temperature (100 °C) was found to give the best-modified catalyst in terms of its enantiodifferentiating ability and the hydrogenating activity (Table 2). The selection of the favorable modifying reagent was carried out with the above-mentioned Raney nickel. As is shown in Table 3, tartaric acid

Table 1. Optical yield in the hydrogenation of I with a modified metal catalyst

Catalyst	Reaction temp °C	$[\alpha]_D^{20}$ of the product	Optical yield %	Chemical yield[c] %
RNi[a]	80	−8.27	27.3	80
RCo[a]	100	−0.23	0.8	82
RCu[a]	100	−0.38	1.3	80
RPd[a]	80	−0.10	0.3	85
Reduced NiO[b]	140	−4.7	15.9	45

a) A 1.5-g portion of Raney alloys (aluminium content: 50%) was leached with 20 ml of a 20% aqueous NaOH solution at 100 °C, and the resulting catalyst was modified with 100 ml of a 1% aq solution of (*R,R*)-tartaric acid at pH 4.0, at 85 °C. I (10 g) in 20 ml of THF and 0.2 ml of acetic acid was subjected to hydrogenation with each catalyst under a hydrogen pressure of 90 kg/cm². b) A 1-g portion of a nickel catalyst prepared from NiO[6] was modified in the same manner as above. c) Determined by GLC.

Table 2. Effect of leaching conditions of Raney alloy on the optical yield

	Amount of leaching solution[a] ml	Leaching temp of alloy °C	$[\alpha]_D^{20}$ of the product	Optical yield %
1	4	28	−2.88	9.8
2	4	50	−3.08	10.4
3	4	100	−4.58	15.5
4	20	100	−4.34	14.7
5	20	100	−8.69	27.3[b]

a) A 0.3-g portion of Raney alloy was leached with a 20% aqueous NaOH solution under the conditions listed in the table. Each catalyst was modified with 20 ml of 1% tartaric acid at pH 4 at 100 °C. I (2 g) in 3 ml of THF was subjected to hydrogenation at 100 °C under a hydrogen pressure of 90 kg/cm² for 14 h. b) The hydrogenation of I was carried out under the same conditions as above except for the addition of 0.04 ml of acetic acid to the reaction mixture.

Table 3. Optical yield of the hydrogenation of I with various sorts of modified Raney nickels[a]

a) A 0.3-g portion of Raney alloy was leached with 20 ml of a 20% aq NaOH solution at 100 °C. b) The pH was adjusted by the addition of NaOH to the solution of each modifying reagent. In the case of neutral amino acid, the aqueous solution was used without any pH adjustment. c) The catalyst was modified with 20 ml of an aqueous solution containing 0.2 g of each modifying reagent at 100 °C. I (2 g) in 3 ml of THF was subjected to hydrogenation with MRNi at 100 °C under H_2 pressure of 90 kg/cm² for 14 h. d) The catalyst was modified with 20 ml of a solution containing 1.6 g of NaBr and 0.2 g of each modifying reagent.

was one of the best modifying reagents in giving a highly enantio-differentiating catalyst.

The addition of sodium bromide to the modifying solution[5] resulted in a great increase in the enantio-differentiating ability of the catalyst when tartaric acid was used as the modifying reagent (Table 3).

Enhancements of the enantio-differentiating ability of the catalyst were observed by the addition of various sorts of inorganic salt to the modifying solution. Among the inorganic salts examined, sodium bromide was the most effective additive for the modifying solution in giving a catalyst with a high enantio-differentiating ability (Table 4).

Table 4. Optical yield of the hydrogenation of I with TA-inorganic salt-MRNi[a]

	Inorganic salt	Amount of salt in modifying solution[b]	Times of modification process	$[\alpha]_D^{20}$ of the product	Optical yield %
1	—	—	1	−9.00	27.3
2	NaF	1.6 g	1	−8.84	29.9
3	NaCl	1.6	1	−10.92	36.9
4	NaBr	1.6	1	−17.77	59.8
5	NaBr	1.6	2	−20.80	70.2
6	NaBr	1.6	3	−20.79	70.2
7	NaI	1.6	1	—	—[c]
8	NaI	4×10^{-4}	1	−5.3	17.7
9	$Na_2B_4O_7$	0.2	1	−5.91	20.0
10	CH_3COONa	0.2	1	−5.86	19.8
11	Na_2SO_4	1.6	1	−8.88	30.3

a) All the experimental conditions were the same as those described in Table 2. b) Into a 20-ml portion of a 1% solution of (*R*,*R*)-tartaric acid, the listed amount of each salt was dissolved. c) Hydrogenation did not proceed.

The relation between the enantio-differentiating ability of the catalyst and the concentration of sodium bromide in the modifying solution is shown in Fig. 1. The maximum enantio-differentiating ability was observed when the catalyst was modified with a solution containing 8% NaBr and 1% tartaric acid. A high concentration of sodium bromide resulted in a decrease in the enantio-differentiating ability. On the other hand, the repetition of the modification procedure under the best conditions of NaBr concentration resulted in an increase in the enantio-differentiating ability of the catalyst (Table 4, Entries 5 and 6).

Thus, the Raney nickel treated twice with a solution containing 8% NaBr and 1% tartaric acid was found to be the best enantio-differentiating hydrogenation catalyst (TA–NaBr–MRNi) for I.

The optical yield of the hydrogenation was also affected by the reaction conditions, such as the sort of solvent employed, the relative amounts of substrate,

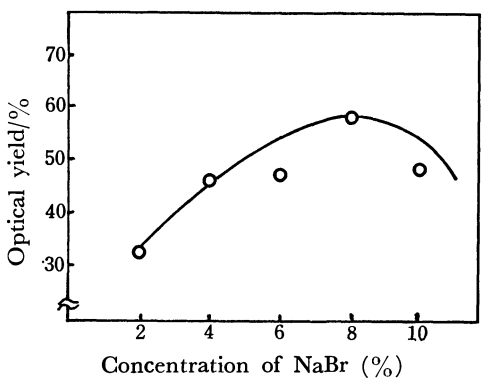

Fig. 1. The relation between optical yield and the concentration of NaBr in modifying solution.

catalyst, and solvent, and the reaction temperature.

As may be seen in Table 5, aprotic moderately polar solvents, such as THF, methyl propionate, and ethyl acetate, gave good optical yields. However, the use of methanol resulted in a poor optical yield.

As is shown in Fig. 2, the optical yields were constantly high over a wide range of the relative amounts of the catalyst, solvent, and substrate. However, the use of small amounts of a catalyst and/or a solvent resulted in poor optical yields.

The optimum optical yield was obtained at the reaction temperature of 85—100 °C (Fig. 3). This temperature was also favorable for giving a good chemical yield.

Under the conditions optimized from all the results mentioned before, (*R*)-II and (*S*)-II with an optical purity of 68—70% were obtained from I with (*R,R*)- and (*S,S*)-tartaric acid–MRNi's in almost quantitative chemical yields and with good reproducibility.

The reaction of the hydrogenation product with phenyl isocyanate gave 1,3-butanedioldicarbanilate (III) as crystals. When a saturated methanolic solution of III with an optical purity of 70% was kept in the presence of small pieces of crystals of optically pure III, optically pure III was crystallized out of the solution in a yield of 64%, based on the total weight of III. The reductive cleavage of the urethane group of optically pure III with $LiAlH_4$ gave optically pure II in a yield of 62% based on III. The overall yield of optically pure II was 40% based on I.

Table 5. Solvent effect on the optical yield of the reaction[a)]

Solvent	$[\alpha]_D^{20}$ of the product	Optical yield %
MeOH	−10.11	34.1
AcOEt	−16.74	56.6
$EtCO_2Me$	−17.76	60.0
THF	−20.50	69.4
THF/Benzene = 3/20	−17.65	59.6

a) The reaction conditions were the same as those described in Footnote a) of Table 1 except for the reaction time (14 h).

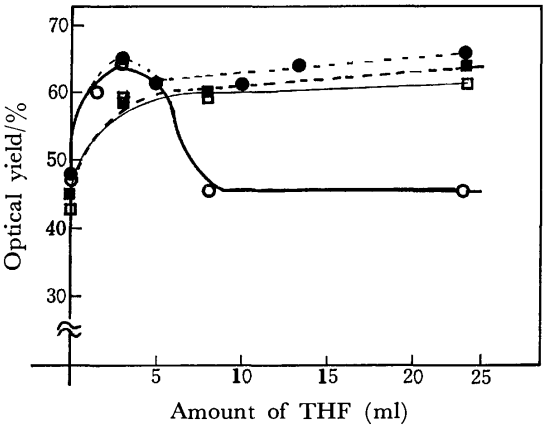

Fig. 2. The effect of the relative amounts of catalyst and solvent on the optical yield.
The substrate (2 g) was subjected to hydrogenation with the catalysts prepared from 0.3 g (–○–), 0.6 g (--●--), 0.9 g (–□–), and 1.5 g (--■--) of Raney alloy, respectively.

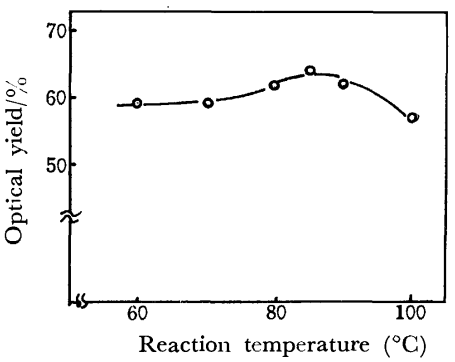

Fig. 3. The effect of reaction temperature on the optical yield.

Discussion

From the results of the present study, the optical yield of the reaction is considered to be determined by two major factors. The first factor is the differentiating ability of the modifying reagent, which depends mostly on the intermolecular interaction between the modifying reagent and the substrate adsorbed on the catalyst. The second factor is the ratio of the enantio-differentiating area to the non-enantio-differentiating area on the surface of the catalyst.

In the course of earlier studies of the enantio-differentiating hydrogenation of the β-ketoester, tartaric acid–MNi was found to be the best enantio-differentiating catalyst, as in the present work.[7)] The excellent result was attributed to the formation of two-site intermolecular interaction through hydrogen bondings between tartaric acid and the β-ketoester (Fig. 4a) in the enantioface-differentiating process.[8)] In a similar manner, tartaric acid can make hydrogen bondings with I, the hydroxyl group of I taking the place of the ester carbonyl group of the β-ketoester (Fig. 4b). The fact that both I and the β-ketoester gave the (*R*)-enantiomer in the hydrogenation over (*R,R*)-tartaric acid–MNi also strongly suggests that the mode of the enantioface-differentiating process of I is identical with that of the β-ketoester. From these considerations, it can be concluded that a high optical yield is obtained when a well-fitting intermolecular interaction is formed

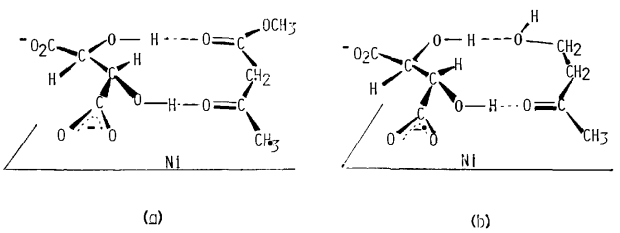

Fig. 4. Schematic representation of the complex of β-ketoester and (*R,R*)-tartaric acid (a) and that of I and tartaric acid (b).

between a modifying reagent and substrate adsorbed on the catalyst.

Such protic solvents as water and alcohol in the reaction system, which can take part in hydrogen bondings with I and/or tartaric acid, interfere with the formation of the rigid interaction between I and tartaric acid. Thus, the use of a protic solvent resulted in a significant decrease in the optical yield.

The dependence of the optical yield on the leaching temperature of the Raney alloy (Table 2) is closely related to the amount of aluminium remaining in the catalyst. It is well documented that Raney nickel prepared at a low temperature contains a large amount of aluminium and shows a high hydrogenation activity. The aluminium in the catalyst is considered to be in a polymeric form of aluminium hydroxide.[9] The hydroxyl groups of tartaric acid on the catalyst and the hydroxyl group of aluminium derivatives may compete in the formation of hydrogen bondings with the substrate. Under these conditions, the formation of a rigid tartaric acid-substrate interaction is disturbed to a large extent. For these reasons, the hydrogenation at the aluminium-enriched part of the catalyst gives the racemic product predominantly. Thus, the use of a Raney nickel leached at a low temperature resulted in a significant decrease in the optical yield.

A Raney nickel leached at a high temperature still contains some of an active nickel in the aluminium-enriched part of the catalyst. Partial poisoning with suitable substances is one way to remove such an active part of the catalyst.

In general, sodium bromide is considered to be a weakly poisoning reagent of a metal catalyst. This compound is apt to be adsorbed on the highly active nickel surface in the aluminium-enriched part of the catalyst. The remarkable increase in the optical yield on the treatment of the catalyst with sodium bromide is caused by the effective blocking of the non-enantiodifferentiating reaction site with sodium bromide.

Experimental

The GLC was carried out with a Shimadzu GC-4APF gas chromatograph using a 3-m, 5-mm-o.d. glass column packed with 5% Tween 80 on Shimalite W at the specified temperature.

The optical rotations were measured with a Perkin Elmer 241 polarimeter. The IR and ^{1}H-NMR spectra were taken with a Shimadzu IR-27G spectrometer and a Hitachi R-24 spectrometer respectively.

Substrate. 4-Hydroxy-2-butanone (I): This compound was obtained, by the aldol condensation of formaldehyde and acetone,[4] in a yield of 28%, based on formaldehyde; bp 56—58 °C/5 mmHg.** The GLC (130 °C) analysis of the distillate showed a 98% purity, with 2% of diacetone alcohol. The NMR and IR spectra of the product were compatible with those expected from the structure of I.

Modifying Reagent. (*R*,*R*)-Tartaric acid, (*S*,*S*)-tartaric acid, (*S*)-aspartic acid, (*S*)-glutamic acid, (*S*)-serine, (*S*)-threonine, (*S*)-valine, and (*S*)-malic acid were commercially purchased.

(2*S*,3*S*)-2-Amino-3-hydroxysuccinic acid ($[\alpha]_D^{20}$ 8.0° (*c* 1, 5 M HCl), lit,[7] 6.4° (*c* 1, H_2O). Anal. Found: C, 31.89; H, 4.73; N, 9.55%. Calcd for $C_4H_7O_5N$: C, 32.22; H, 4.73; N, 9.40%) and (2*S*,3*R*)-2-amino-3-hydroxysuccinic acid ($[\alpha]_D^{20}$ 46.5° (*c* 1, H_2O), lit,[10] 47.0° (*c* 1, H_2O). Anal. Found: C, 31.97; H, 4.71; N, 9.50%) were prepared by the previously reported method.[11]

Catalyst. Raney alloy was leached by adding it portion by portion, to a solution of NaOH under the conditions stated in the tables in the text.

The nickel catalyst was subjected to modification by soaking in the modifying solution for 1 h under the conditions stated in the table in the text.

After the removal of the modifying solution, the modified catalyst was rinsed successively with a 17-ml/(g-catalyst) portion of water, two 80-ml portions of methanol, and a 40-ml portion of the solvent used for the reaction.

Hydrogenation. Hydrogenation was carried out either in a 100-ml autoclave (the data in Tables 1 and 5 were thus obtained) or a 30-ml glass tube in the autoclave (the data in Tables 2,3 and 4 were thus obtained).

After the removal of the catalyst, the reaction prodcut was dried over anhydrous K_2CO_3 (overnight) and then distilled under reduced pressure to give II (bp 117 °C/40 mmHg). Subsequent GLC (130 °C) of the product showed a single peak at a retention time of 14 min. The IR and ^{1}H-NMR spectra of the product were identical with those of the racemic authentic sample (Wako Pure Chemical Co., Ltd.). A 1-g portion of the distillate was diluted in 10 ml of ethanol and, then the optical rotation was determined. The optical purity of the product was calculated based on the optical rotation of optically pure (*R*)-II, $[\alpha]_D^{20}$ −29.6° (*c* 10, EtOH).

Preparation of Optically Pure II. A mixture of II (8.8 g, $[\alpha]_D^{20}$ −20.7° (*c* 10, EtOH) and phenyl isocyanate (22.5 g) was heated at 100 °C for 1 h on an oil bath and then cooled to room temperature to give 30 g of crude III.

A 5-g portion of crude III was dissolved in 14 ml of boiling ethanol. The solution was cooled to room temperature and then mixed with 25 ml of hexane. The mixture was kept overnight at 5 °C. The separation of the crystals from the mixture gave 3.5 g of III ($[\alpha]_D^{20}$ −46.7° (*c* 5, EtOH). Three successive recrystallizations from ethanol–hexane under the same conditions as above gave 2.5 g of III ($[\alpha]_D^{20}$ −56.3° (*c* 5, EtOH)). Three further successive recystallizations resulted in no increase in the optical rotation.

The major portion of the crude III (25 g) was dissolved in 150 ml of methanol under reflux, after which the solution was kept at 5 °C overnight in the presence of small pieces of the crystals of III with $[\alpha]_D^{20}$ −56.3° (*c* 5, EtOH). The crystals were then collected and washed with a 10-ml portion of cold methanol. The crystals thus obtained amounted to 16 g. $[\alpha]_D^{20}$ −56.3° (*c* 5, EtOH), mp 130—131 °C. Found: C, 65.93; H, 6.15; N, 8.55%. Calcd for $C_{18}H_{20}N_2O_4$: C, 65.84; H, 6.14; N, 8.53%.

To the suspension of $LiAlH_4$ (30 g) in 300 ml of dry dioxane, which has been heated at 80 °C on an oil bath, a solution of 15 g of III ($[\alpha]_D^{20}$ −56.3°) in 300 ml of dioxane was added, drop by drop. The reaction mixture was heated for 3 h under reflux, cooled to 5 °C on an ice bath, and then hydrolyzed with 60 ml of water. The insoluble matter was separated by filtration and washed with 30 ml of methanol. The filtrate and washings were then combined and freed of the solvent under reduced pressure at 50 °C. The residue was mixed with 50 ml of water and then washed with three 15-ml portions of benzene. After the evaporation of water from the aqueous layer under reduced pressure, the residue was dried over zeolite 3 A (overnight) and then distilled

** 1 mmHg=133.322 Pa.

under reduced pressure to give 2.5 g II; bp 95—98 °C/10 mmHg, $[\alpha]_D^{20}$ −29.6° (*c* 10, EtOH), $[\alpha]_D^{20}$ −31.6° (*c* 1, EtOH) lit,[11] ($[\alpha]_D^{20}$ −29° (*c* 1, EtOH). The IR and NMR spectra, and the retention time in GLC were identical with those of the authentic sample.

The authors wish to express their thanks to Professor Yoshiharu Izumi and Dr. Hiroshi Ozaki, Institute for Protein Research, Osaka University, for their helpful suggestions. The present work was supported in part by a Grant in Aid for Scientific Research from the Ministry of Education (No. 303530).

Kinetic Studies on the *N,N*-Type Smiles Rearrangement

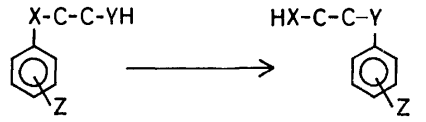
Junzo SUNAMOTO,* Hiroki KONDO, Fumihiro YANASE, and Hiroshi OKAMOTO

Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852

(Received July 28, 1979)

The Smiles rearrangement reaction of DL-2-aminododecanoic acid *N*-methyl-*p*-nitroanilide to DL-2-(*p*-nitrophenyl)aminododecanoic acid *N*-methylamide has been investigated in aqueous alkaline media containing 0—50% (v/v) acetonitrile or ethanol at 25 °C. It was found from the pH-rate profile that the reactive species is the free base form of the substrate. Acetonitrile content in the medium appreciably affected the rate with a maximum at *ca.* 20% in the acetonitrile content. The cationic CTAB micelles accelerated the rate 4.4-fold at pH 10, while the anionic SDS micelles suppressed the reaction almost completely. These effects of solvent and micelles were qualitatively correlated with the transition state of the reaction. A plausible mechanism for this reaction is the Smiles type rearrangement in which a spiro σ-complex is involved. The activation parameters obtained and suppression of the reaction rate by Cu(II) ion are in line with the proposed reaction mechanism.

Intramolecular nucleophilic aromatic substitution reaction (Eq. 1) is known as the Smiles rearrangement.[1]

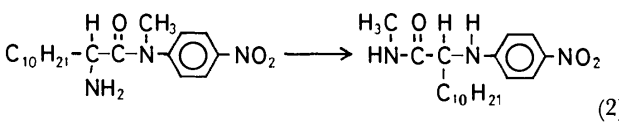


(1)

The original combination of SO_2 and OH for X and YH, respectively, was extended to a variety of combinations, *e.g.*, SO, S, and O for X and SH, NHR, and CONHR for YH.[1,2] Factors that influence the ease of the rearrangement are also well recognized.[2] Recent progress in this field has been achieved by the characterization of the common intermediate:[3,4]

However, detailed information on the reaction mechanism is restricted to a limited number of cases.

During the course of studies on the hydrolysis of carboxylate and carbonate esters or amides, we recently observed that in aqueous media DL-2-aminododecanoic acid *N*-methyl-*p*-nitroanilide (**1**) undergoes a rearrangement reaction, instead of normal hydrolysis, to give DL-2-(*p*-nitrophenyl)aminododecanoic acid *N*-methylamide (**2**). Gilman *et al.* suggested a similar



(2)

1 2

rearrangement in the reaction of 2-bromoacetanilides in methanolic ammonia.[5,6] Although they pointed out factors which affect the feasibility for the substrate to undergo the rearrangement, much remains to be clarified as regards the reaction mechanisms of the *N,N*-type rearrangement. The rearrangement reaction of **1** provides a good means for studying the micellar effects on organic reactions, since, a better understanding of the microscopic field effect that the aqueous micelles are expected to show will be obtained in unimolecular reactions such as the intramolecular rearrangement rather than bimolecular ones.[7,8] Since we obtained **1** as a stable hydrobromide, kinetic studies on the spontaneous and the micelle-catalyzed rearrangement of compound **1** have been performed. We have found that the reaction of **1** belongs to a normal Smiles-type rearrangement according to the S_Ni mechanism *via* an ionic transition state.

Experimental

Details of the synthesis of DL-2-aminododecanoic acid *N*-methyl-*p*-nitroanilide (**1**) were given in a previous paper.[9] DL-2-Aminododecanoic acid was prepared by α-bromination of dodecanoic acid followed by ammonolysis. After protection of the amino group with benzyloxycarbonyl group it was condensed with *N*-methyl-*p*-nitroaniline in the presence of phosphoryl chloride and pyridine. Removal of the protecting group with 12.6% HBr in acetic acid afforded the desired product (**1**) as the hydrobromide; mp 180—187 °C (dec); IR (KBr) 1640, 1580, 1465, 1330, 1100 cm^{-1}; NMR (DMSO-d_6) δ 0.88 (t, J=6 Hz, 3H, CH_3–), 1.24 (m, 16H, –$(CH_2)_8$–), 1.64 (m, 2H, –CH_2–CH–), 3.40 (s, 3H, *N*-CH_3), 4.06 (m, 1H, –CH–), 7.78 (d, J=8 Hz, 2H, phenyl), 8.30 (m, 3H, –NH_3^+), 8.32 (d, J=8 Hz, 2H, phenyl); UV (20% (v/v) aq acetonitrile) λ_{max} 285 nm (ε_{max} 9750). Found: C, 53.04; H, 7.53; N, 9.65%. Calcd for $C_{19}H_{32}N_3O_3Br$: C, 53.02; H, 7.49; N, 9.76%.

Product Analysis. A solution of **1** (402 mg) in 1.0 l of 3% (v/v) aqueous ethanol containing 0.01 M (1 M=1 mol dm^{-3}) sodium hydroxide and 1 M potassium chloride was kept at room temperature for 2 d. The precipitated crystalline mass was collected and recrystallized from carbon tetrachloride: yield, 299 mg (92%); mp 116—117 °C; IR (KBr) 3380, 3275, 1650 cm^{-1}; NMR (DMSO-d_6) δ 0.93 (t, J=6 Hz, 3H, CH_3–), 1.34 (m, 16H, –$(CH_2)_8$–), 1.81 (m, 2H, –CH_2–CH–), 2.75 (d, J=5 Hz, *N*-CH_3), 4.10 (m, 1H, –CH–), 6.98 (d, J=9 Hz, 2H, phenyl), 7.62 (m, 2H, NH), 8.32 (d, J=9 Hz, 2H, phenyl); UV (20% (v/v) aq acetonitrile) λ_{max} 387 nm (ε_{max} 21000); mass spectrum *m/e* 349 (M^+). Found: C, 65.12; H, 9.03; N, 11.70%. Calcd for $C_{19}H_{31}N_3O_3$ (349.48): C, 65.30; H, 8.94; N, 12.02%.

Kinetic Measurements. A three ml aqueous solution containing appropriate amounts of acetonitrile or ethanol, potassium chloride, and buffer salts (below pH 11) or sodium hydroxide (above pH 11) was placed in a cuvette and thermally equilibrated. Thirty μl of a substrate solution in acetonitrile was then injected and the whole mixture was stirred quickly and thoroughly with a slim Teflon rod. The

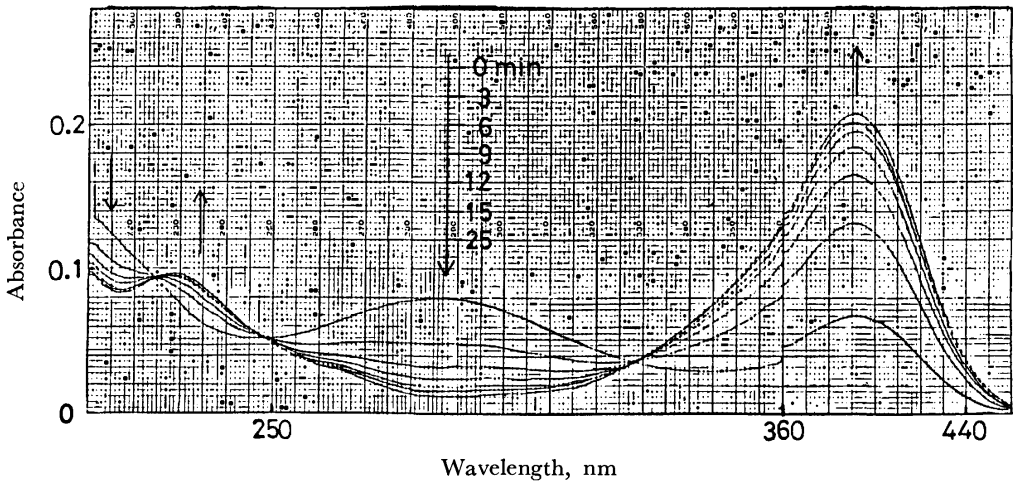


Fig. 1. Time-dependent spectral change in the rearrangement of **1** (9.90×10^{-6} M) in 29.7% (v/v) ethanol–1.0% (v/v) acetonitrile at 25 °C, μ=0.10 (KCl), and "pH" 10.

final concentration of each component in the reaction mixture is given under appropriate Figs. and/or Tables. The rate of rearrangement of **1** was followed spectrophotometrically by monitoring the appearance of the product **2** at 387 nm on a Hitachi 124 recording spectrophotometer. The reaction followed a good first-order kinetics and the apparent first-order rate constant was evaluated by the least-squares calculation. The correlation coefficients were better than 0.99. In some cases in which the concentration of organic solvent was low and precipitation of the product made it impossible to follow the appearance of product (387 nm), the disappearance of substrate was followed at 285 nm. The rapidly scanned spectra were measured on a Union Giken stopped-flow spectrophotometer Model RA-1300.

pH *Measurements.* The pH value of a reaction solution was determined with a TOA HM-5A pH meter connected to a TOA GS-135C combined electrode. For solutions containing a large amount of an organic solvent, the pH was calibrated by means of the conventional buffer salts dissolved in a medium of the same composition as that of the actual reaction solution. For this reason, the pH values given in this article are referred to as the apparent pH.

Results

Stoichiometry of Reaction. The product analysis indicates that **1** undergoes rearrangement in an aqueous alkaline medium to afford almost quantitatively the product **2** (see Experimental). The ^{1}H NMR spectrum of the product supports the structure of **2**: the original singlet of *N*-CH_3 proton signal changed to a doublet due to the coupling with the hydrogen attached to the amide nitrogen. In addition, signals of the hydrogens attached to 2- and 6-positions of the phenyl ring shifted upfield (0.8 ppm) upon the rearrangement. The absorption spectral change of the reaction as a function of time is shown in Fig. 1. The absorption at 285 nm decreased with the progress of reaction, a new band appearing at 387 nm. Isosbestic points were observed at 224.5, 248, and 328 nm throughout the reaction, indicating the absence or no accumulation of stable intermediate during the course of transformation of **1** into **2**. The potential hydrolysis product, *N*-methyl-*p*-nitroaniline was not detected by TLC analysis [silica gel, benzene–methanol (10:1 by volume)]. R_f-Values of **1**, **2**, and *N*-methyl-*p*-nitroaniline were 0.02, 0.16, and 0.55, respectively.

Effect of Solvent Content. The effect of acetonitrile content in the reaction medium on the rearrangement rate was studied at 25 °C and apparent pH 10. As seen in Fig. 2, the rate increases with acetonitrile content until the maximum rate is attained at a concentration of *ca.* 20% (v/v). Thereafter, the rate decreases almost linearly with the acetonitrile content.

pH-*Rate Profile.* The pH-rate profile of the rearrangement reaction was constructed as shown in Fig. 3. The profile is of typical sigmoid shape, indicating the presence of an acid dissociation process (pK_a= 10.34). The pK_a-value is quite reasonable for the acid dissociation constant of the primary amino group of **1**. The profile also demonstrates that the free base of **1** is by far the more reactive with the specific rate constant of 1.84×10^{-3} s^{-1} at 25.0 °C in 20% (v/v) aq acetonitrile. The reactivity of the ammonium species is too poor to estimate the specific rate constant

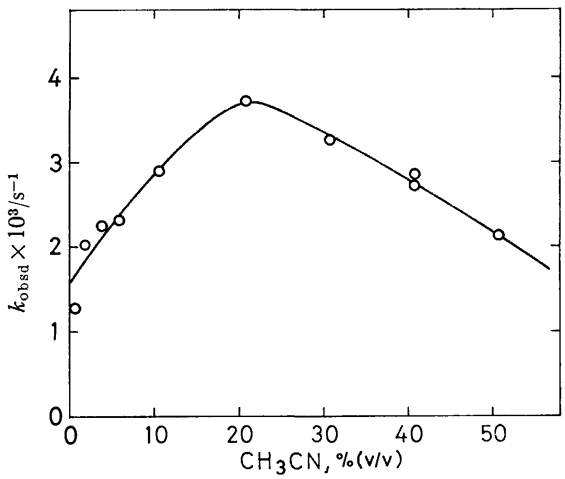

Fig. 2. Effect of acetonitrile content in the medium on the rearrangement rate of **1** (9.90×10^{-6} M) at 25 °C and "pH" 10.

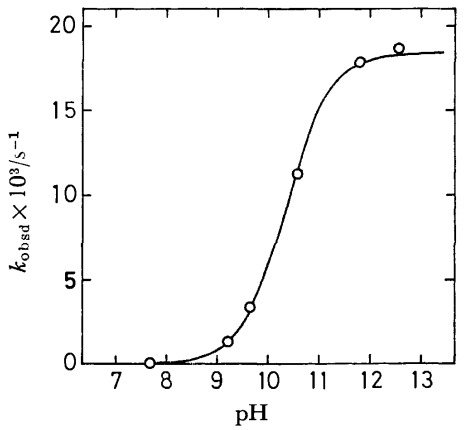

Fig. 3. pH-Rate profile for the rearrangement of **1** (9.90×10^{-6} M) in 20.8% (v/v) acetonitrile at 25 °C and μ=0.10 (KCl).

accurately under the present conditions.

Activation Parameters. In order to gain an insight into the energetics of the rearrangement, kinetic experiments were carried out in 29.7% ethanol–1.0% acetonitrile at pH 10 and at temperatures 20, 25, 30, and 35 °C (Table 1). The activation energy E_a obtained from the conventional Arrhenius plot was 17.7 kcal/mol, from which the following activation parameters were evaluated: 17.1 kcal/mol for the enthalpy of activation, 7.1 e.u. for the entropy of activation, and 14.9 kcal/mol for the free energy of activation at 303 K.

Effect of Additives. Since the substrate has several potential coordination sites, the effect of copper(II) ion on the reaction rate was investigated at 25 °C and pH 8 in 20.6% (v/v) acetonitrile. Addition of an equimolar amount of Cu(II) ion to the substrate showed little effect on the reaction rate, but 13-fold excess of Cu(II) ion brought about an appreciable suppression of the rate. That the reaction pathway was not changed even in the presence of Cu(II) ion was confirmed by product analysis.

Effects of three different micelles on the rate were also studied. The cationic CTAB micelles brought about 4.4-fold rate enhancement at pH 10.0, while the anionic SDS micelles almost completely suppressed the reaction. Nonionic Brij 35 micelles showed little effect. This difference among the three detergents should reflect the electrostatic nature of the intermediate or transition state of the reaction.

Table 1. Rate constants for the rearrangement of **1** at several different temperatures[a]

Temperature °C	$k_{obsd} \times 10^3$ s^{-1}
20	3.07, 3.33
25	5.38, 5.45
30	8.47, 9.12
35	13.2, 13.7

a) Experimental conditions: Medium, 29.7% (v/v) ethanol-1.0% (v/v) acetonitrile; μ=0.10 (KCl); pH 10.

Table 2. Effect of additives on the rate of rearrangement of **1** at 25 °C[a]

Additive	Concentration M	pH	$k_{obsd} \times 10^4$ s^{-1}
None[b]		8.01	1.42
Cu(II)[b]	1.09×10^{-5}	7.94	1.29
Cu(II)[b]	1.29×10^{-4}	8.09	0.763
None[c]		10.0	12.7±0.3

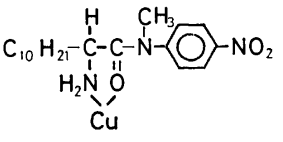
a) Experimental conditions: Initial substrate concentration, 9.90×10^{-6} M; μ=0.10 (KCl) except for SDS. b) Medium, 20.6% (v/v) acetonitrile. c) Medium, 1.0% (v/v) acetonitrile.

Discussion

Gilman *et al.* reported the first example of *N,N*-type Smiles rearrangement.[5,6] However, they carried out the reaction in methanolic ammonia using 2-bromoacetanilides as a starting material for the most part, and postulated the intermediacy of 2-aminoacetanilides. In the present investigation, it was confirmed that amino acid *N*-methyl-*p*-nitroanilides undergo the rearrangement reaction and that the reactive species in the reaction is the free base of the substrate. It is well recognized that a strong base is required to generate a powerful nucleophile, Y^- species (Eq. 1), which brings about a rearrangement.[2] When YH is the amino group, it was suggested that a nitride ion might be necessary for the rearrangement to take place.[10] This, however, does not seem to be the case at least in our present system. The neutral amino group is a sufficiently strong nucleophile to displace the acylamido moiety.

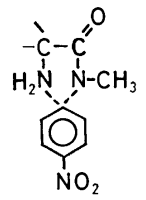
As expected, the addition of Cu(II) ion to the system significantly prohibited the rearrangement, which is attributed to the masking of the reaction site by the coordination of the metal ion. The metal chelation seems to take place at the α-amino and amide carbonyl moieties (**3**), which might lead to facilitation of the amide bond cleavage.[11] Contrary to what might be



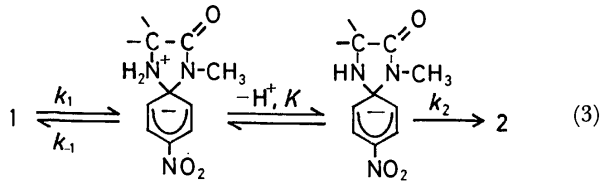
3

expected, no formation of hydrolyzates was observed during the course of reaction in the presence of Cu(II) ion. Hence, the chelation of copper(II) is not so effective as to alter the reaction pathway of the substrate **1**.

The Smiles rearrangement may be classified into two categories:[2] (a) the rearrangement proceeds in a concerted fashion through transition state **4**,[12] (b) the reaction proceeds through a stabilized intermediate **5** or **6** (Eq. 3). Depending on the stability of the intermediate σ-complex, either formation or decomposi-



4



5 6

(3)

tion of the complex becomes the rate-determining step. When the complex is stable, it can be detected by conventional spectroscopy to verify that it takes part in the transformation of the substrate.[3,4] If the complex is not sufficiently stable, however, it is very difficult to confirm its existence.[6]

According to Okada and Sekiguchi,[4] the latter pathway appears to be plausible for the present rearrangement reaction. If we assume that the rate-determining step involves the formation of σ-complex ($k_1 \ll k_{-1}$, k_2), the pK_a obtained experimentally merely reflects the acid dissociation of the substrate, *i.e.*, ammonium$\rightleftarrows$free amine. Since no formation of intermediates was observed between **1** and **2** even by a rapid scanning spectroscopic technique, the subsequent steps should take place very rapidly.

When the decomposition of the complex is the rate-determining step ($k_2 \ll k_1$, k_{-1}), the observed rate constant (k_{obsd}) would be correlated with the specific rate constants of respective stages and equilibrium constant by

$$k_{obsd} = \frac{k_1 k_2 K}{(k_1+k_{-1})[H^+]+k_1 K} \tag{4}$$

which conforms to the observed pH-rate profile (see Results). Rearrangement of Eq. 4 leads to

$$\frac{1}{k_{obsd}} = \frac{k_1+k_{-1}}{k_1 k_2 K}[H^+] + \frac{1}{k_2}. \tag{5}$$

The intercept of the straight line based on the relationship between $1/k_{obsd}$ and $[H^+]$ gives the specific rate constant for the decomposition step (k_2), while a composite of rate and equilibrium constants (k_1, k_{-1}, and K) is obtained from the slope (120×10^{10} $s^{-1} M^{-1}$). Since we can not observe the individual steps independently, each constant can not be defined. However, on the basis of certain assumptions we can estimate roughly each constant as follows. The pK_a value of 10.34 obtained experimentally is too high to be assigned to intermediate **5**. If we arbitrarily assume as an upper limit that the pK of **5** is 7, the ratio k_1/k_{-1} becomes 4.5×10^{-4}. This indicates that the steady state concentration of the intermediates is very low to escape the conventional spectroscopic detection. If the pK value were close to the apparent pK_a and hence the ratio k_1/k_{-1} were somewhere around unity, we could have detected the intermediates **5** and/or **6**. Thus, these two mechanisms are kinetically indistinguishable.

Whichever mechanism is correct, the transition state has anionic or at least more polar character as compared with both the initial and final states. This is generally true for the Smiles rearrangement, polar solvents being favorable for the reaction.[2] The solvent effect observed over the acetonitrile concentration range higher than 20% (v/v) is in line with this consideration. Since substrate **1** carries a long alkyl chain it may entangle itself to form less reactive aggregates in the media of lower acetonitrile concentration,[13] resulting in the stabilization of the ground state. The increase in acetonitrile content defrosts the aggregation, leading to promotion of the rearrangement. Above *ca.* 20% of acetonitrile in the medium, the polarity effect of solvent to destabilize the polar transition state predominates and the reaction rate decreases with increasing acetonitrile concentration.

The observed positive effect of the cationic micelles is explicable in terms of the character of the transition state or intermediates. If the breakdown of the σ-complex intermediates is rate-determining, the CTAB micelles increase the steady state concentration of the anionic complex,[14,15] which is quite low in the absence of such micelles. This leads directly to enhancement of the observed rate constant.

According to the above discussion on the character of the transition state or intermediates, a negative value would be expected for the entropy of activation. The experimental value of +7.1 e.u. is apparently not compatible with this prediction. The discrepancy may have arisen from the fact that the experimental value contains several factors such as solvation to ground and transition states, not taken into consideration in the above argument. In any event, the value does not differ much from zero, indicating that the reaction is essentially unimolecular.

Thanks are due to Prof. Toyoki Kunitake, Department of Organic Synthesis, Kyushu University, for the use of his rapid scanning spectrophotometer.

Aldol Condensations with Metal(II) Complex Catalysts

Kazuo IRIE and Ken-ichi WATANABE*

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158

(Received July 31, 1979)

Aldol condensations of aldehydes with ketones catalyzed by the first-row transition metal(II) complexes have been widely studied. Complexes of Co(II), Ni(II), Cu(II), and Zn(II) acetates with 2,2′-bipyridine were effective catalysts to afford cross-aldol condensation products, α,β-unsaturated ketones, in high yields without any self-condensation products. The reaction of 2-butanone, unsymmetrical aliphatic ketone, with benzaldehyde took place regioselectively to give base-catalyzed-type products.

Aldol condensation reactions catalyzed by transition metal(II) ions have been reported by several workers.[1] For example, Akabori reported that the aldol condensation of bis(glycinato)copper(II) with aldehydes gave copper(II) complexes of serine and so on under basic conditions.[1] In these reactions, however, no reaction products could be liberated without removing the Cu(II) ion from the complexes.

Recently, we have found that the copper(II)–2,2′-bipyridine(bpy) complex catalyzes the aldol condensation of aldehydes with ketones under neutral conditions to afford liberated α,β-unsaturated ketones without any by-product.[2] The product yield in this reaction increases remarkably in comparison with that catalyzed by the copper(II) ion itself. On the other hand, bpy itself has no catalytic activity at all.

It is of great importance that the reaction is largely affected by the kinds of ligands and counter ions of the complexes. We have examined the effects of the first-row transition metal(II) ions, various kinds of ligands, and some counter ions on the reactions. Furthermore, in order to ascertain the scope and limitation of the aldol condensations promoted by the metal(II) complexes, the reactions of various kinds of aldehydes and ketones were carried out. The results will be described in this paper.

Results and Discussion

Effects of Ligands on the Catalysis. In this study, the condensations of benzaldehyde and acetophenone in the presence of Cu(II) complexes were carried out. In order to examine the effects of ligands on the catalyst in the reaction, twelve kinds of ligands(L) were employed.

$$PhCH + CH_3CPh \xrightarrow[80\,^\circ C,\ 18\,h]{Cu(II)L,\ DMF} PhCH{=}CHCPh$$

A solution of benzaldehyde, acetophenone, copper(II) acetate, and a ligand in DMF was heated at 80 °C for 18 h. The complex formation in the solution was observed by means of the color change from the green of copper(II) acetate to other colors when the ligands were added. The amount of the complex catalyst was 16 mol% of the benzaldehyde used. The reaction product was chalcone, and the yield was determined by GLC analysis. The results are shown in Table 1.

The reaction catalyzed only by copper(II) acetate gave chalcone in a 53% yield. Then, upon the addition of Group I ligands, the yields decreased remarkably (Table 1). These carboxylic acids seem to be unfavorable ligands for the reaction. When Group II ligands (aliphatic amines) were employed, the yields of chalcone (53—54%) were similar to the case with copper(II) acetate itself. These results indicate that these aliphatic-amine ligands have no "ligand effect" on this reaction. When Group III ligands (tertiary aromatic amines) were employed, chalcone was formed in increased or decreased yields (22—82%). Such ligands as 2,2′-bipyridine(bpy), 1,10-phenanthroline (phen), and pyridine(py) were found to be fairly effective, since the yields increased predominantly (70—82%). On the other hand, such ligands as 6,6′-dimethyl-2,2′-bipyridine(dm-bpy) and 2,2′:6′,2″-terpyridine(terpy) seemed to inhibit the reactions (22—30%); this could be ascribed as steric hindrance by the bulky ligand molecules. These amines themselves did not catalyze the reaction.

Table 1. The yields of chalcone in the aldol condensation of benzaldehyde and acetophenone with Cu(II) complexes

Group No.	Ligand	Color of complex	Yield of chalcone/%[a]
	None	green	53

Cl^-	0	—	47	0	0	25

a) The yields of the reaction products were determined by NMR. In the cases with NO_3^- and Cl^-, 4-hydroxy-4-phenyl-2-butanone was formed predominantly, along with benzylideneacetone.

studied the catalytic effect of the first-row transition metal (II) acetates with the bpy ligand on the formation of chalcone, since it was found that bpy or phen was the most effective ligand for the reaction. The effects of the molar ratio of bpy on these metal(II) ions were also examined. The results are summarized in Table 2.

When a ligand was not added to the reaction mixture ($n=0$), the copper(II) acetate gave the highest yield. When the molar ratio of bpy to metal(II) acetate was 1:1 ($n=1$), the yields increased very much with all the metal(II) ions. Especially, the reactions with Co(II), Ni(II), and Zn(II) complexes gave quantitative yields. When the molar ratio of bpy to the metal was 2:1 ($n=2$), the yields decreased with Fe(II), Co(II), and Zn(II) and increased with Mn(II) and Cu(II). In the case of $n=3$, the yields decreased in comparison with that of $n=1$. In the case of $n=1$, the order of the product yields is in good agreement with the Irving-Williams series, which is known as the stabilization series of general complexes.[3] It is concluded that the more favorable combinations in the complex catalysts are bpy and Co(II), Ni(II), Cu(II), or the Zn(II) ion and that the molar ratio of M(II) to bpy of 1:1 ($n=1$) is the best.

Effects of Counter Ions on the Catalysis. In our previous report,[2] the yields of the condensation product were reported to be affected by the kinds of counter ions in the Cu(II)X_2-bpy catalysts. In order to clarify the effects of the counter ions of metal(II) complexes, nitrate, chloride, and acetate ions were chosen in M(II)-bpy complexes (1:1). In this study, the aldol condensation of benzaldehyde with acetone was examined in the presence of the complex catalysts at a reflux temperature for 18 h in DMF. The product yields were determined by NMR; the results are summarized in Table 3.

When the counter ion of the metal(II) complex was the acetate ion, benzylideneacetone was formed in a good yield. On the other hand, reactions catalyzed by the bpy-complex of metal(II) nitrate and chloride gave condensation products in a low yield. Therefore, the acetate ion was the best among these three counter ions, and the counter ion played a very important role in the aldol condensation with these metal(II) complex catalysts.

Solvent Effects. In this reaction system, the selection of solvent is important for dissolving the complex catalysts. The condensation of benzaldehyde with acetophenone in the presence of the Zn(II)-bpy complex was carried out in five kinds of polar solvents at 80 °C for 18 h, after which the reaction products were determined by GLC. The results showed that chalcone was formed in good yields in aprotic solvents, such as DMF (100%), DMSO (88%), and CH_3CN (78%). On the other hand, the yields of chalcone were low in protic solvents, such as MeOH (45%) and H_2O (18%). Thus, DMF was the best solvent for the complex-catalyzed reactions.

Condensations of Various Aldehydes with Acetophenone. Next, in order to develop this reaction system, we investigated further the aldol condensations of various kinds of aldehydes and ketones in the presence of the Co(II) acetate-bpy complex catalyst, one of the more favorable M(II) acetate-bpy complex catalysts (M(II): Ni, Co, Cu, Zn). First, the reactions of eighteen kinds of aldehydes with acetophenone were carried out.

To a solution of cobalt(II) acetate in DMF, an equimolar amount of bpy was added. The color of the solution was thus changed to reddish purple, indicating the complex formation. A mixture of aldehyde and acetophenone was then added to the complex solution, and the mixture was stirred at 80 °C for 18 h. The amount of the complex catalyst was 16 mol% of the aldehyde used. Each reaction product was isolated by preparative TLC and was identified as a α,β-unsaturated ketone by the NMR, IR, and the mp. The results are summarized in Table 4.

In the reactions of the *p*-substituted benzaldehydes, **1**—**8**, the substituted chalcones, **28**—**35**, were obtained in good yields, regardless of the kind of substituent group. Further, to examine the effects of substituted groups of aldehydes on the reactivity, the reactions of mono- and di-substituted benzaldehydes, such as *o*-anisaldehyde, **9**, salicylaldehyde, **10**, 2-hydroxy-3-methoxybenzaldehyde, **11**, and 4-hydroxy-3-methoxybenzaldehyde, **12**, were carried out. The reactions of **9** and **10** gave 2-methoxychalcone, **36**, and 2-hydroxychalcone, **37**, both in 72% yields. The reaction of **12** did not occur, the starting materials being recovered, while **11** gave 2-hydroxy-3-methoxychalcone, **38**, in a 47% yield. The difference in the reactivities of **11** and **12** seemed to account for the coordination

TABLE 4. REACTIONS OF VARIOUS ALDEHYDES WITH ACETOPHENONE IN THE PRESENCE OF THE Co(II)-bpy COMPLEX CATALYST

Aldehyde	Product	Yield/%	Mp/°C (lit,[4])

The condensation reactions of aldehydes (1.875 mmol) with acetophenone (5 ml) were carried out in the presence of $Co(OAc)_2$+bpy(1:1)(0.300 mmol) at 80 °C for 18 h in DMF (5 ml).
a) Identified by elemental analysis. b) The reaction was carried out at the reflux temperature, and the product was identified by MS, NMR, and IR.

to Co(II). A chelation of the hydroxyl and formyl groups to Co(II) is possible in the reaction of **11**, since the hydroxyl group is in an ortho position to the formyl group. In **12**, the chelation of the *p*-hydroxyl and *m*-methoxyl groups to Co(II) seemed to be more predominant than that of the formyl group. The reaction of 2-pyridine-, **13**, or 4-pyridinecarbaldehyde, **14**, proceeded smoothly at room temperature for 3 d to give 1-phenyl-3-(2-pyridyl)-2-propen-1-one, **39** or 1-phenyl-3-(4-pyridyl)-2-propen-1-one, **40**, in a 31 or 66% yield respectively. The aldehyde, **14**, gave the reaction product to an extent similar to that in the reactions of *p*-substituted benzaldehyde, **1**—**8**, and no by-product was obtained. On the other hand, **13** gave three kinds of by-products besides the major product, **39**, by TLC. The reactions of the aliphatic-saturated aldehyde showed features different from those of aromatic aldehydes. The reactions of isobutanal, **15**, afforded 1-phenyl-4-methyl-2-penten-1-one, **41**, in a low yield (23%), and 3-phenylpropanal **17**, and chloral, **16**, did not react at all under similar reaction conditions. On the other hand, the reaction of α,β-unsaturated aldehyde, *trans*-cinnamaldehyde, **18**, gave 1,5-diphenyl-2,4-pentadien-1-one, **42**, in a good yield (80%). It may be concluded that the aldol condensations catalyzed by the Co(II)–bpy complex are smoothly promoted in the case of unsaturated aldehydes (aromatic, aliphatic).

Condensations of Various Ketones with Benzaldehyde. Since aromatic aldehydes are favorable substrates in a complex-catalyzed reaction system, the aldol condensations of ten kinds of ketones with benzaldehyde

Table 5. Reactions of various ketones with benzaldehyde in the presence of the Co(II)-bpy complex catalyst

Ketone and ester	Temp °C	DMF ml	Product	Yield/%	Mp/°C (lit,[4])

The condensation reactions of ketones (5 ml) with benzaldehyde (1.875 mmol) were carried out in the presence of $Co(OAc)_2$+bpy(1:1)(0.300 mmol) for 18 h in DMF.
a) Melting point of the phenylhydrazone derivative. b) Identified by NMR and IR.

were carried out. The reaction methods and conditions were almost the same as in Table 4. The results are shown in Table 5.

The reactions of benzaldehyde with methyl ketones, such as acetophenone, **4**, and acetone, **19**, gave chalcone, **31**, and benzylideneacetone, **43**, in 81 and 63% yields respectively. Thus, aliphatic and aromatic ketones showed similar reactivities toward benzaldehyde. The self-condensation reaction of acetone or acetophenone was also examined, but no condensation product was obtained and the starting material was recovered. The reaction of 2-butanone, **20**, an unsymmetrical aliphatic ketone, with benzaldehyde took place regioselectively.

$$PhCH{=}O + CH_3\overset{C_1}{C}(=O)\overset{C_3}{C}H_2CH_3 \xrightarrow[18\,h]{\text{cat., DMF}} PhCH{=}CHCOCH_2CH_3\ (C_1)\ \mathbf{44} + PhCH{=}C(CH_3)COCH_3\ (C_3)\ \mathbf{45}$$

cat: $Co(OAc)_2$+bpy(1:1)

A mixture of 1-phenyl-1-penten-3-one(C_1), **44**, and 3-methyl-4-phenyl-3-buten-2-one(C_3), **45**, was isolated in a 95% yield, and the ratio of C_1:C_3 was determined to be 96:4 by NMR. It was known that the base-catalyzed reaction of 2-butanone gave, preferentially, the condensation product at C_1 of ketone, while the acid-catalyzed reaction occurred preferentially at C_3.[4] The reaction of 2-pentanone, **21**, was also regiospecific, affording a C_1-condensation product, 1-phenyl-1-hexen-3-one, **46**, in a 91% yield. The reaction of the diethyl ketone, **22**, gave no condensation product, probably because it has no α-methyl group. This finding may explain why acyclic unsymmetrical methyl ketones gave regioselective products in these complex-catalyzed reactions. The reaction of cyclopentanone, **23**, as a cyclic α-unsubstituted methylene ketone gave the 2-benzylidenecyclopentanone, **47**, in a 38% yield. It seemed that the difference in the reactivities between cyclic and acyclic α-methylene ketones was ascribable to those pK_a values in the ketones. The reaction of acetylacetone, **24**, as a diketone gave 3-benzylidene-2,4-pentanedione, **48**, in a 19% yield. The reaction of ethyl cyanoacetate, **25**, was carried out at room temperature for 18 h. When a solution of **25** and benzaldehyde in DMF was added to a solution of the Co(II)-bpy complex in DMF, the reddish purple color of the complex was immediately changed to black. Similarly, the color of the reaction mixture of ethyl bromoacetate, **26**, changed to green. The reaction of **25** gave ethyl α-cyanocinnamate, **49**, in a 79% yield, while **26** gave no reaction product, and the starting materials were recovered. Similarly, the reaction of ethyl acetate, **27**, did not give any condensation product at all.

It is generally concluded that M(II)-bpy complexes catalyze cross-aldol condensations of aldehydes with ketones under neutral conditions in DMF to give α,β-unsaturated ketones in good yields. Further, the reactions give base-catalyzed-type products regioselectively. This catalyst system has also been applied to the polymer complex catalyst with good results.[5]

Conclusion. Several reactions catalyzed by the M(II)-bpy complex have been reported.[6] The methylation of ethylenediamine catalyzed by Pt(II)-amine complexes was examined; the *N*-methyl-substituted ethylenediamine was obtained only when the Pt(II)-bpy complex was used.[6a] In this reaction, the driving force of the catalytic activity by the bpy ligand was explained by attributing it to the back π-bonding in the Pt(II)-bpy complex. That is, a higher positive

charge is induced on the metal(II) ion by the coordination of the bpy ligand. Our results shown in Tables 1 and 2 also seem to be elucidated by this "ligand effect" of bpy. The oxygen atoms in the carbonyl groups of aldehyde and ketone may be more activated by coordination to the M(II)–bpy complex than by that to the M(II) ion itself.

It has been known that aldol condensations in a biological system are catalyzed by aldolase enzymes, Class I and Class II.[7] Class II aldolase is known as a metalloenzyme containing the Zn(II) ion at the catalytic site. However, in the reaction of Class II aldolase, the catalysis of Zn(II) ion has not been elucidated enough, since it has never been established that Zn(II) complexes catalyze the aldol condensations. Therefore, our reaction system with the Zn(II)–bpy gives a new clue for understanding the catalysis of Class II aldolase from the point of view of organic catalytic reactions. An investigation of the reaction mechanism is now in progress in connection with Class II aldolase.

Experimental

Materials. All the aldehyde, **1**—**18**, ketones, and esters were commercially available. The **13**—**18** aldehydes were purified by distillation before use. The ligand compounds, such as oxalic acid, mercaptoacetic acid, glycine, ethylenediamine, diethylenetriamine, triethylenetetramine, pyridine, 2,2′-bipyridine, 2,2′: 6′,2″-terpyridine, 1,10-phenanthroline, *N*,*N*,*N*′,*N*″-tetramethylethylenediamine, and 6,6′-dimethyl-2,2′-bipyridine, were provided by the Tokyo Kasei Co. Anhydrous metal(II) acetate(Kojundo Chemical Reseach) was used. In the reactions shown in Table 3, hydrous metal(II) salts (Wako Pure Chemicals) were used.

Instruments. The NMR and IR spectra were taken with a Hitachi Perkin-Elmer R-20A spectrophotometer (60 MHz) and a Hitachi 215 Grating Infrared spectrophotometer respectively. The mass spectra were determined on a Shimadzu-LKB 9000 gas chromatograph-mass spectrometer at 70 eV. The GLC was carried out with a Hitachi K-53 gas chromatograph with a flame ionization detector, using a 1.0 m stainless tube column packed with 10% Carbowax 20M on Diachrom A. The product yields were determined by the two methods of GLC and NMR analyses. Benzophenone and 1,1,2,2-tetrachroloethane were used as the internal standards in the GLC and NMR analyses respectively.

General Procedure of Metal-complex-catalyzed Aldol Condensation Reactions. Reaction of Benzaldehyde with Acetophenone: The Zn(II)–bpy complex was prepared by the addition of 2,2′-bipyridine (0.20 mmol) to a solution of anhydrous zinc(II) acetate (0.2 mmol) in DMF (1 ml), and then benzaldehyde (1.25 mmol) and acetophenone (5 ml) were added to a yellow solution of the complex. The reaction mixture was stirred for 18 h at 80 °C; then the solvent and the excess of acetophenone were removed under reduced pressure to give an oil which was subsequently purified by preparative TLC, using a 1:4 ether–hexane mixture as the eluent. The yellow crystals thus obtained were identified as chalcone by the mp of 55—56 °C (lit,[8a] 55—57 °C), the NMR, and the IR in comparison with an authentic sample. The isolated yield of chalcone was 86%, and the GLC-analyzed yield was 100%.

Reaction of Benzaldehyde with Acetone: The Zn(II)-bpy complex was prepared by the addition of 2,2′-bipyridine (4.0 mmol) to a solution of zinc(II) chloride ($ZnCl_2 \cdot H_2O$, 4.0 mmol) in DMF (10 ml), and then benzaldehyde (2.5 mmol) and acetone (10 ml) were added to a yellow solution of the complex. The reaction mixture was stirred for 18 h at the reflux temperature. Then, the solvent and the excess of acetone were removed under reduced pressure at room temperature to give an oil which was subsequently extracted with an ethyl acetate-and-water system. The organic layer was dried over anhydrous sodium sulfate and then evaporated under reduced pressure at room temperature to give an oil whose NMR showed a mixture of two kinds of products. The curde oil was recrystallized from petroleum ether to give colorless crystals which were identified as benzylideneacetone by the mp of 38—39 °C (lit,[8b] 40—42 °C), the NMR, and the IR in comparison with an authentic sample. The other product was identified as 4-hydroxy-4-phenyl-2-butanone on the basis of sepctroscopic evidence; Mass: *m/e* (%), 164 (M^+, 3), 146 (3), 131(26), 105(100); NMR (CCl_4); δ 2.10 (s, 3H, CH_3), 3.50 (s, OH, H-D-exchange), 5.00 (t, 1H, CH). The total yield of these two products (25%) was determined by its crude NMR, adding 1,1,2,2-tetrachloroethane as the internal standard; the product ratio of benzylideneacetone to 4-hydroxy-4-phenyl-2-butanone was 29:71.

Condensation Products. 4-(Dimethylamino)chalcone, **28**; Mp 117.5—119 °C (lit,[4] 114 °C); IR:1645 cm^{-1}; NMR ($CDCl_3$): δ 2.95 (6H, s, $N(CH_3)_2$).

4-Methoxychalcone, **29**; Mp 72—74 °C (lit,[4] 72—74 °C); IR 1660 cm^{-1} NMR (CCl_4): δ 3.75 (3H, s, CH_3).

4-Methylcahlcone, **30**; Mp 99—100 °C (lit,[4] 96 °C); IR 1650 cm^{-1}; NMR (CCl_4): δ 2.32 (3H, s, CH_3).

Chalcone, **31**; Mp 57—58 °C (lit,[4] 57—58 °C); IR 1650 cm^{-1}; NMR (CCl_4): δ 7.00—8.00 (aromatic proton).

4-Chlorochalcone, **32**; Mp 114—117 °C (lit,[4] 114 °C); IR 1660 cm^{-1}; NMR (CCl_4): δ 7.00—8.00 (aromatic proton).

4-Cyanochalcone, **33**; Mp 162.5—163 °C; IR 2200, 1660 cm^{-1}; NMR ($CDCl_3$): δ 7.50—8.13 (aromatic proton). Mass: *m/e*, 233 (M^+), 156 ($M^+ - C_6H_5$), 128 ($M^+ - C_6H_5CO$).

4-Nitrochalcone, **34**; Mp 158—160 °C (lit,[4] 158—160 °C); IR 1660 cm^{-1}; NMR ($CDCl_3$) δ 7.50—8.50 (aromatic proton).

3-Nitrochalcone, **35**; Mp 143—145 °C (lit,[4] 145—146 °C); IR 1660 cm^{-1}; NMR ($CDCl_3$), δ 7.20—8.20 (aromatic proton).

2-Methoxychalcone, **36**; Mp 61—61.5 °C (lit,[4] 59—60 °C); IR 1660 cm^{-1}; NMR (CCl_4) δ 3.78 (3H, s, OCH_3).

2-Hydroxychalcone, **37**; Mp 152—153 °C (lit,[4] 152—153 °C); IR 1640 cm^{-1}; NMR (DMSO-d_6) δ 7.00—8.00 (aromatic proton), 9.80 (br., OH, H-D exchange).

2-Hydroxy-3-methoxychalcone, **38**; Mp 112—113.5 °C; IR 1650 cm^{-1}; NMR (acetone-d_6) δ 3.87 (3H, s, OCH_3); Found: C, 75.21; H, 5.63%. Calcd for $C_{16}H_{14}O_3$: C, 75.57; H, 5.55%.

1-Phenyl-3-(2-pyridyl)-2-propen-1-one, **39**; Mp 62—63 °C (lit,[4] 60—61 °C); IR 1660 cm^{-1}; NMR (CCl_4) δ 7.00—8.50 (aromatic proton).

1-Phenyl-3-(4-pyridyl)-2-propen-1-one, **40**; Mp 79—80 °C (lit,[4] 70—71 °C); IR 1660 cm^{-1}; NMR (CCl_4) δ 7.30—9.00 (aromatic proton).

1-Phenyl-4-methyl-2-penten-1-one,, **41**; IR 1670, 1650 cm^{-1}; NMR ($CDCl_3$) δ 1.15 (6H, d, CH_3), 1.70 (1H, m, CH), 6.90—8.00 (aromatic proton); Mass: *m/e*, 174 (M^+), 159 ($M^+ - CH_3$), 144 ($M^+ - 2CH_3$), 131 ($M^+ - CH(CH_3)_2$).

Cinnamylideneacetophenone, **42**; Mp 104—105 °C (lit,[4] 102—103 °C); IR 1655 cm^{-1}; NMR (CCl_4) δ 7.00—8.10 (aromatic proton).

Benzylideneacetone, **43**; Mp 41 °C (lit,[4] 41.5 °C); NMR

($CDCl_3$) δ 2.30 (3H, s, CH_3), 6.62 (1H, d, =CH).

1-Benzylidene-2-butanone, **44**; Mp 39—40 °C (lit,[4] 38.5—39.5 °C); NMR ($CDCl_3$) δ 1.17 (3H, t, CH_3), 2.67 (2H, q, CH_2), 6.70 (1H, d, =CH).

1-Phenyl-1-hexen-3-one, **46**; Mp 98—99 °C (lit,[4] 99—100 °C, phenylhydrazone); IR 1690, 1660 cm^{-1}; NMR ($CDCl_3$) δ 0.92 (3H, t, CH_3), 1.60 (2H, m, CH_2), 2.66 (2H, t, CH_2).

2-Benzylidenecyclopentanone, **47**; Mp 66—67 °C (lit,[4] 67—68 °C); IR 1710 cm^{-1}; NMR ($CDCl_3$) δ 2.10 (4H, m, $-CH_2CH_2-$), 2.94 (2H, dt, $COCH_2$), 7.40—7.45 (aromatic proton).

3-Benzylidene-2,4-pentanedione, **48**; IR 1710 cm^{-1}; NMR (CCl_4) δ 2.22 (3H, s, CH_3), 2.38 (3H, s, CH_3).

Ethyl α-cyanocinnamate, **49**; Mp 52—53 °C (lit,[4] 66—67 °C); IR 2230, 1710 cm^{-1}; NMR ($CDCl_3$) δ 1.40 (3H, t, CH_3), 4.35 (2H, q, CH_2); Found: C, 71.55; N, 6.82; H, 5.49%. Calcd for $C_{12}H_{11}NO$: C, 71.63: N, 6.96; H, 5.51%.

The authors wish to express their thanks to Professor Masayoshi Nakahara of Rikkyo University and to Professor Akitsugu Nakahara and Shinnichiro Suzuki of Osaka University for their helpful advice.

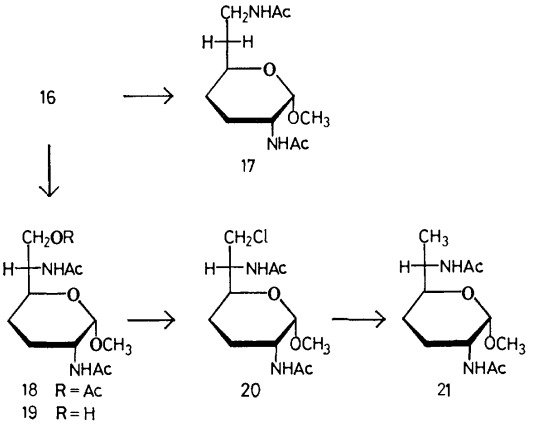
pyridine gave a crystalline 6-*O*-mesyl derivative (**15**) in 86% yield.

Treatment of **15** with sodium isopropoxide in isopropyl alcohol gave an epimino derivative, which was further converted into a crystalline *N*-acetylepimino derivative (**16**) in 84% yield. The presence of an aziridine ring was demonstrated by a characteristic IR absorption of an acylaziridine-carbonyl group at 1700 cm^{-1} [17] and by ^1H NMR spectroscopy. The configuration of **16** was proposed as 6,7-(*N*-acetylepimino)-6,7-dideoxy-L-*lyxo*-heptopyranoside, according to the stereochemistry of an aziridine ring formation which has been well studied by several investigators.[18-22]



Scheme 4.

Catalytic hydrogenation of **16** in ethanol in the presence of Raney nickel gave a crystalline product (**17**) in a quantitative yield, which was found to be analytically pure. ^1H NMR spectrum of **17** revealed the presence of two acetamido and one methoxyl groups, but not a terminal methyl group. Thus **17** was identified as methyl 2,7-di-*N*-acetyl-2,3,4,6,7-pentadeoxy-α-D-*erythro*-heptopyranoside.

Methyl 2,6-di-*N*-acetyl-7-*O*-acetyl-2,3,4,6-tetradeoxy-β-L-*lyxo*-heptopyranoside (**18**) was obtained in 88% yield by heating **16** in glacial acetic acid. In the reaction, nucleophilic attack by an acetate ion on the aziridine ring occurs exclusively at C-7 position. This is in line with the fact that acetolysis of 6,7-(*N*-acetylepimino)-dideoxy-L-*glycero*-α-D-*galacto*-heptopyranoside derivative yielded 6-acetamido-7-*O*-acetyl-L-*glycero*-α-D-*galacto*-heptopyranoside derivative.[17]

De-*O*-acetylation of **18** in methanolic ammonia gave methyl 2,6-di-*N*-acetyl-2,3,4,6-tetradeoxy-β-L-*lyxo*-heptopyranoside (**19**) in 92% yield as crystals. Chlorination of **19** was performed by the triphenylphosphine–carbon tetrachloride procedure[23,24] to give a 7-chloro-7-deoxy derivative (**20**). Dehalogenation of **20** was carried out with tributylstannane[25-27] in the presence of α,α'-azobisisobutyronitrile under nitrogen atmosphere, methyl 2,6-di-*N*-acetyl-6-*epi*-α-D-purpurosamineide B (**21**) being obtained in 56% yield. Compound **21** was identical with an authentic sample prepared by methanolysis of tetra-*N*-acetylfortimicin B.[5]

Experimental

General Methods. Melting points were determined in capillary tubes and are corrected. Solutions were concentrated under reduced pressure below 40 °C. Optical rotations were measured with a Japan Spectroscopic DIS-SL polarimeter. ^1H NMR spectra were recorded with a Varian *EM360A* spectrometer at *60 MHz* or a Varian *XL-100* spectrometer at 100 MHz, peak positions being given in δ values. IR spectra were recorded with a Hitachi 225 spectrophotometer in KBr disks. TLC was performed on Wakogel B-10 (Wako Pure Chemical Co. Ltd.) plates, silica gel (Wakogel C-300) being used for column chromatography.

Methyl 2-Acetamido-2-deoxy-3,4-di-O-mesyl-6-O-trityl-α-D-glucopyranoside (6). Methanesulfonyl chloride (4.9 ml) was added to a stirred solution of methyl 2-acetamido-2-deoxy-6-*O*-trityl-α-D-glucopyranoside[15] (**5**, 10.0 g) in pyridine (50 ml). After being stirred for 2 h at 50 °C, the solution was concentrated, the residue being repeatedly extracted with chloroform and the combined chloroform solution washed with cold water. The chloroform layer was dried over Na_2SO_4 and concentrated. The residue was recrystallized from ethyl acetate to give 12.4 g (95%) of **6**, mp 184—185 °C (dec), $[\alpha]_D^{20}$ +53° (*c* 1.0, chloroform). ^1H NMR: δ 2.01 (s, 3, NAc), 2.52 (s, 3, SCH_3), 3.06 (s, 3, SCH_3), 3.41 (s, 3, OCH_3), 5.89 (d, 1, $J_{2,NH}$=9 Hz, NH).

Found: C, 57.08; H, 5.77; N, 1.95; S, 9.92%. Calcd for $C_{30}H_{35}NO_{10}S$: C, 56.85; H, 5.57; N, 2.21; S, 10.12%.

Methyl 2-Acetamido-2,3,4-trideoxy-6-O-trityl-α-D-erythro-hex-3-enopyranoside (7). Compound **6** (5.0 g) was heated with sodium iodide (50 g) and zinc powder (25 g) in DMF (280 ml) at 150 °C for 18 h with mechanical agitation under reflux. The reaction mixture was filtered and the filtrate was concentrated. The residue was dissolved in chloroform, the chloroform solution being washed repeatedly with 20% sodium thiosulfate solution and water. The solution was dried over Na_2SO_4 and concentrated. The residue was recrystallized from ether to give 2.3 g (64%) of **7**, mp 151—152 °C, $[\alpha]_D^{21}$ −34° (*c* 3.0, chloroform). ^1H NMR: δ 1.97 (s, 3, NAc), 4.80 (s, 1, H-1), 5.87 (d, 1, $J_{2,NH}$=10 Hz, NH).

Found: C, 75.89; H, 6.77; N, 3.12%. Calcd for $C_{28}H_{29}NO_4$: C, 75.82; H, 6.59; N, 3.16%.

By mild acid hydrolysis and subsequent acetylation, **7** was readily converted into methyl 2-acetamido-6-*O*-acetyl-2,3,4-trideoxy-α-D-*erythro*-hex-3-enopyranoside, mp 131—132 °C, $[\alpha]_D^{20}$ −37° (*c* 0.95, chloroform). ^1H NMR: δ 2.01 (s, 3, NAc), 2.10 (s, 3, OAc), 3.48 (s, 3, OCH_3).

Found: C, 54.37; H, 7.05; N, 5.86%. Calcd for $C_{11}H_{17}NO_5$: C, 54.31; H, 7.05; N, 5.76% .

Methyl 2-Acetamido-2,3,4-tridoxy-α-D-erythro-hexopyranoside (8). (*a*): Compound **7** (0.10 g) was hydrogenated in 80% aqueous methanol in the presence of palladium black at 50 °C overnight. After the catalyst had been filtered off, the filtrate was concentrated and the residue was fractionated on a silica gel column using 20:1 (v/v) benzene–ethanol as an eluant. Fractions moving fast on TLC in the same solvent system were combined and concentrated to give 10 mg (23%) of methyl 2-acetamido-2,3,4-trideoxy-6-*O*-trityl-α-D-*erythro*-hexopyranoside (**9**), mp 183—184 °C, $[\alpha]_D^{21}$ +38° (*c* 0.23, chloroform).

Found: C, 75.48; H, 7.03; N, 2.95%. Calcd for $C_{28}H_{31}NO_4$: C, 75.48; H, 7.01; N, 3.14%.

Fractions moving slowly on TLC were combined and concentrated to give 33 mg (72%) of **8** as a syrup, $[\alpha]_D^{21}$ +137° (*c* 1.76, methanol). ^1H NMR (CD_3OD): δ 1.91 (s, 3, NAc),

3.35 (s, 3, OCH_3), 4.54 (d, 1, $J_{1,2}$=3.2 Hz, H-1).

Found: C, 53.36; H, 8.37; N, 6.70%. Calcd for $C_9H_{17}NO_4$: C, 53.18; H, 8.43; N, 6.89%.

(*b*): Compound **7** (3.7 g) was catalytically hydrogenated as described in (a), and the residual mixture was hydrolyzed in 50% aqueous acetic acid (60 ml) at 60 °C for 1 h. The hydrolyzate was diluted with cold water (60 ml) and triphenylmethanol precipitated was removed by filtration. The filtrate was concentrated to give **8** in a quantitative yield as a crude syrup.

Compound **8** (83 mg) was acetylated and the product was recrystallized from ether–petroleum ether to give 70 mg (70%) of methyl 2-acetamido-6-*O*-acetyl-2,3,4-trideoxy-α-D-*erythro*-hexopyranoside, mp 106—107 °C, $[\alpha]_D^{20}$ +100° (*c* 1.0, chloroform). ^{1}H NMR: δ 1.97 (s, 3, NAc), 2.04 (s, 3, OAc), 3.38 (s, 3, OCH_3), 4.61 (d, 1, $J_{1,2}$=3.6 Hz, H-1), 5.67 (d, 1, $J_{2,NH}$=9.0 Hz, NH).

Found: C, 53.97; H, 7.70; N, 5.84%. Calcd for $C_{11}H_{19}NO_5$: C, 53.86; H, 7.81; N, 5.71%.

*Methyl 2-Acetamido-2,3,4-trideoxy-*α*-*erythro*-hexodialdo-1,5-pyranoside (**10**).* A solution of DCC (7.9 g) in DMSO (1 ml) was added under ice cooling to a stirred solution of **8** (2.6 g) in freshly distilled DMSO (4 ml) containing trifluoroacetic acid 0.5 ml) and pyridine (1 ml). Stirring was continued for 6 h at ambient temperature, and a solution of oxalic acid (2.3 g) in methanol (2 ml) was added to the reaction mixture. Dicyclohexylurea precipitated was filtered off and the filtrate containing **10** was used for the subsequent reaction.

A part of the filtrate was treated with 2,4-dinitrophenylhydrazine in phosphoric acid to give a hydrazone of **10**, mp 229—230 °C (dec).

Found: C, 47.27; H, 5.05; N, 18.32%. Calcd for $C_{15}H_{19}N_5O_7$: C, 47.24; H, 5.02; N, 18.37%.

*Methyl 2-Acetamido-2,3,4,7-tetradeoxy-7-nitro-*α*-*D*-ribo-heptopyranoside (**11**).* The filtrate containing **10** described above was diluted with methanol (10 ml). To the solution were added nitromethane (1.2 ml) and methanolic sodium methoxide (0.6 g Na in 5 ml of methanol) under ice cooling. After being settled overnight in a refrigerator, the pH of the solution was adjusted to 4 with Amberlite IR-120 (H^+) resin and concentrated. A solution of the residue in ethyl acetate was washed with cold water, dried over Na_2SO_4 and concentrated. The residue was recrystallized from ethyl acetate to give 1.52 g (45%) of **11**, mp 193—194 °C (dec), $[\alpha]_D^{21}$ +150° (*c* 1.0, methanol). The product showed a single spot at R_f 0.29 on TLC in 7:1 (v/v) benzene–ethanol. ^{1}H NMR (DMSO-d_6): δ 1.78 (s, 3, NAc), 3.24 (s, 3, OCH_3), 4.46 (d, 1, $J_{1,2}$=3.6 Hz, H-1).

Found: C, 45.94; H, 6.84; N, 10.71%. Calcd for $C_{10}H_{18}N_2O_6$: C, 45.79; H, 6.92; N, 10.68%.

From the mother liquor, a second crop of **11** (0.23 g, 7%) was obtained by column chromatography using 10:1 (v/v) benzene–ethanol as an eluant, followed by recrystallization from ethyl acetate.

*Methyl 2-Acetamido-7-amino-2,3,4,7-tetradeoxy-*α*-*D*-ribo-heptopyranoside (**12**).* Compound **11** (186 mg) was hydrogenated in methanol (6 ml) in the presence of Raney nickel overnight. After the catalyst had been filtered off, the filtrate was concentrated to give **12** as an amorphous solid in a quantitative yield, $[\alpha]_D^{21}$ +114° (*c* 2.28, methanol).

*Methyl 2,7-*N*-Acetyl-6-*O*-acetyl-2,3,4,7-tetradeoxy-*α*-*D*-ribo-heptopyranoside (**13**).* Compound **12** (89 mg) was acetylated and the product was recrystallized from ether–methanol to give 85 mg (70%) of **13**, mp 202—203 °C, $[\alpha]_D^{21}$ +101° (*c* 1.0, chloroform). ^{1}H NMR: δ 1.95 (s, 6, 2×NAc), 2.07 (s, 3, OAc), 3.33 (s, 3, OCH_3), 4.57 (d, 1, $J_{1,2}$=4 Hz, H-1), 4.83 (ddd, 1, $J_{6,7}$=6 Hz, $J_{6,7'}$=7 Hz, $J_{5,6}$=4 Hz, H-6), 5.86 (d, 1, $J_{2,NH}$=9.5 Hz, NH-2), 6.16 (t, 1, $J_{7,NH}$=5.5 Hz, NH-7).

Found: C, 52.89; H, 7.62; N, 8.82%. Calcd for $C_{14}H_{24}N_2O_6$: C, 53.15; H, 7.65; N, 8.86%.

^{1}H NMR spectrum of the corresponding 6-*O*-trideuterioacetyl derivative gave signals at δ 1.95 (s, 1, 6, 2×NAc) and 3.33 (s, 3, OCH_3).

*Methyl 2-Acetamido-7-*N*-benzyloxycarbonyl-2,3,4,7-tetradeoxy-*α*-*D*-ribo-heptopyranoside (**14**).* Benzyloxycarbonyl chloride (2.1 ml of 30% toluene solution) was added under ice cooling to a stirred solution of **12** (429 mg) in 94% aqueous ethanol (16 ml) containing sodium hydroxide (180 mg). After being settled in a refrigerator overnight, the reaction mixture was neutralized with 1 M hydrochloric acid and concentrated. The residue was purified on a silica gel column using 10:1 (v/v) benzene–ethanol as an eluant to give 498 mg (74%) of **14** as an amorphous solid, $[\alpha]_D^{21}$ +100° (*c* 1.0, methanol). ^{1}H NMR: δ 1.94 (s, 3, NAc), 3.32 (s, 3, OCH_3), 4.57 (d, 1, $J_{1,2}$=3.6 Hz, H-1), 5.09 (s, 2, benzyl CH_2), 5.48 (broad t, 1, NH-7), 5.81 (d, 1, $J_{2,NH}$=8.8 Hz, NH-2), 7.34 (s, 5, phenyl).

Found: C, 58.89; H, 7.08; N, 7.50%. Calcd for $C_{18}H_{29}N_2O_6$: C, 59.00: H, 7.15; N, 7.65%.

*Methyl 2-Acetamido-7-*N*-benzyloxycarbonyl-2,3,4,7-tetradeoxy-6-O-mesyl-*α*-*D*-ribo-heptopyranoside (**15**).* Methanesulfonyl chloride (0.08 ml) was added to a solution of **14** (336 mg) in pyridine (2 ml). After 3 h, the solution was concentrated and the residue was dissolved in chloroform. The chloroform solution was washed with water, dried over Na_2SO_4 and evaporated. The residue was recrystallized from ethyl acetate–petroleum ether to give 35 mg (86%) of **15**, mp 126—127 °C, $[\alpha]_D^{21}$ +75° (*c* 2.3, chloroform). ^{1}H NMR: δ 1.96 (s, 3, NAc), 2.99 (s, 3, SCH_3), 3.36 (s, 3, OCH_3), 4.61 (d, 1, $J_{1,2}$=3.6 Hz, H-1), 5.11 (s, 2, benzyl CH_2), 5.41 (broad t, 1, $J_{7,NH}$=6.0 Hz, NH-7), 5.71 (d, 1, $J_{2,NH}$=9.6 Hz, NH-2), 7.33 (s, 5, phenyl).

Found: C, 51.47; H, 6.24; N, 6.29; S, 6.99%. Calcd for $C_{19}H_{28}N_2O_8S$: C, 51.34; H, 6.35; N, 6.30; S, 7.21%.

*Methyl 2-Acetamido-6,7-(*N*-acetylepimino)-2,3,4,6,7-pentadeoxy-*β*-*L*-lyxo-heptopyranoside (**16**).* To a solution of **15** (323 mg) in dioxane (5 ml) was added a solution of sodium isopropoxide (40 mg of sodium) in isopropyl alcohol (2 ml). The solution was heated under reflux for 18 h, the progress of the reaction being monitored on TLC in 5:1 (v/v) benzene–ethanol. The starting material **15** (R_f 0.52) finally disappeared, three new spots appearing at R_f 0.10 (major), 0.16 (minor), and 0.64 (minor). The reaction mixture was filtered and the filtrate concentrated. The residue was acetylated with acetic anhydride in methanol, and after 10 min, pH of the solution was adjusted to 8. The solution was concentrated and the residue was extracted with ethyl acetate. The ethyl acetate solution was dried over Na_2SO_4 and concentrated. The residue was triturated in ether to give 156 mg (84%) of **16**, mp 174—175 °C, $[\alpha]_D^{21}$ +12° (*c* 1.0, chloroform). ^{1}H NMR: δ 1.95 (s, 3, NAc), 2.06 (d, 1, $J_{6,7}$=3.2 Hz, H-7), 2.16 (s, 3, AcN=), 2.24—2.59 (m, 2, H-6 and 7′), 3.36 (s, 3, OCH_3), 4.60 (d, 1, $J_{1,2}$=3.6 Hz, H-1), 5.77 (d, 1, $J_{2,NH}$=8.4 Hz, NH).

Found: C, 56.22; H, 7.66; N, 10.78%. Calcd for $C_{12}H_{20}N_2O_4$: C, 56.23; H, 7.87; N, 10.93%.

*Methyl 2,7-Di-*N*-acetyl-2,3,4,6,7-pentadeoxy-*α*-*D*-erythro-heptopyranoside (**17**).* Compound **16** (20 mg) was hydrogenated in ethanol (10 ml) in the presence of Raney nickel under hydrogen atmosphere (3.4 kg/cm^2) overnight. The catalyst was filtered off and the solution was concentrated. The residue was recrystallized from ether–methanol to give

19.5 mg (97%) of **17**, mp 207—208 °C, $[\alpha]_D^{20}$ +122.6° (*c* 0.47, methanol). ^{1}H NMR: δ 2.03 (s, 6, 2×NAc), 3.54 (s, 3, OCH_3), 4.79 (d, 1, $J_{1,2}$=3.2 Hz, H-1).

Found: C, 55.52; H, 8.43; N, 10.94%. Calcd for $C_{12}H_{22}N_2O_4$: C, 55.79; H, 8.59; N, 10.85%.

*Methyl 2,6-Di-*N*-acetyl-7-*O*-acetyl-2,3,4,6-tetradeoxy-β-*L*-lyxo-heptopyranoside (**18**).* A solution of **16** (109 mg) in glacial acetic acid (3 ml) was heated at 50 °C for 1 h and concentrated. The residue was neutralized with a $NaHCO_3$ solution and extracted with ethyl acetate. After being dried over Na_2SO_4, the ethyl acetate layer was concentrated. The residue was triturated in ether to give 119 mg (88%) of an amorphous product. A portion of the product was recrystallized from ether–methanol to give analytically pure **18** as needles, mp 195—196 °C, $[\alpha]_D^{21}$ +73.2° (*c* 1.0, chloroform). ^{1}H NMR: δ 1.97 (s, 3, NAc), 2.03 (s, 6, NAc and OAc), 3.32 (s, 3, OCH_3).

Found: C, 52.93; H, 7.46; N, 8.95%. Calcd for $C_{14}H_{24}N_2O_6$: C, 53.15; H, 7.65; N, 8.86%.

*Methyl 2,6-Di-*N*-acetyl-2,3,4,6-tetradeoxy-β-*L*-lyxo-heptopyranoside (**19**).* A solution of **18** (89 mg) in methanolic ammonia (5 ml) was settled overnight in a refrigerator and concentrated. The residue was purified on a silica-gel column using 4 : 1 (v/v) benzene–ethanol as an eluant. Fractions homogeneous on TLC (R_f 0.13) in the same solvent system were combined and concentrated. The residue was recrystallized from ether–methanol to give 71 mg (92%) of **19**, mp 181—182 °C, $[\alpha]_D^{20}$ +70° (*c* 1.0, chloroform). ^{1}H NMR: δ 1.97 (s, 3, NAc), 2.04 (s, 3, NAc), 3.37 (s, 3, OCH_3), 4.58 (d, 1, $J_{1,2}$=3.2 Hz, H-1), 5.83 (d, 1, $J_{2,NH}$=8.9 Hz, NH), 6.23 (d, 1, $J_{6,NH}$=8.5 Hz, NH).

Found: C, 52.58; H, 7.98; N, 10.15%. Calcd for $C_{12}H_{22}N_2O_5$: C, 52.54; H, 8.09; N, 10.21%.

*Methyl 2,6-Di-*N*-acetyl-7-chloro-2,3,4,6,7-pentadeoxy-β-*L*-lyxo-heptopyranoside (**20**).* To a solution of **19** (198 mg) in acetonitrile (4 ml) was added a solution of triphenylphosphine (247 mg) in carbon tetrachloride (8 ml). The reaction mixture was heated for 2 h and concentrated. The residue was purified on a silica gel column using 5:1 (v/v) benzene–ethanol as an eluant. Fractions homogeneous on TLC (R_f 0.38) in 4 : 1 (v/v) benzene–ethanol were combined and concentrated to give 129 mg (61%) of **20** as a syrup.

*Methyl 2,6-Di-*N*-acetyl-2,3,4,6,7-pentadeoxy-β-*L*-lyxo-heptopyranoside (Methyl 2,6-Di-*N*-acetyl-6-epi-α-*D*-purpurosaminide B) (**21**).* Tributylstannane (0.8 ml) and a small amount of α,α′-azobisisobutyronitrile were added to a solution of **20** (129 mg) in dry dioxane (20 ml). The mixture was heated at 80—90 °C for 2 h under nitrogen atmosphere and then concentrated. The residue was washed with hexane and purified on a silica-gel column using 5:1 (v/v) benzene–ethanol. Fractions homogeneous on TLC (R_f 0.32) in 4:1 (v/v) benzene–ethanol were combined and concentrated to give 64 mg (56%) of **21**, mp 212—213 °C, $[\alpha]_D^{20}$ +63.3° (*c* 1.0, methanol). (Found: C, 55.58; H, 8.46; N, 10.66%). The ^{1}H NMR and IR spectra were superimposable with those of an authentic sample prepared by methanolysis of tetra-*N*-acetylfortimicin B,[5] mp 212—213 °C, $[\alpha]_D^{20}$ +62.9° (*c* 0.98, methanol). The mixed melting point determination of **21** with the authentic sample showed no depression of melting point.

(Received September 1, 1979)

The reaction of olefins with chloromethoxymethane (CMM) and excess formic acid in ether, in the presence of $ZnCl_2$ or $HgCl_2$, afforded mainly four products, 1-chloro- and 1-formyloxy-2-(formyloxymethyl)alkanes, and 3,5-dialkyl-4-chloro- and 3,5-dialkyl-4-(formyloxy)tetrahydropyrans, in various yields. In the case of styrene, the chief products were limited to the former two. Similar products were obtained from 1-chloro-1-ethoxyethane (CEE), but their yields were quite low.

In a previous paper,[1] we reported that the Lewis acid-catalyzed reaction of olefins with chloromethoxymethane(CMM) in acetonitrile gave *N*-[2-(methoxymethyl)alkyl]acetamides (**1**) after hydrolysis. When this reaction was carried out in a mixture of formic acid (a protic and good ionizing solvent) and ether, the expected product, **2** (Y=OCOH), was not formed; instead, two formyloxymethylated products, **3** (or **4**) (Y=Cl and OCOH), were obtained, together with substituted tetrahydropyrans, **5** (Y=Cl and OCOH). This paper will deal with these results.

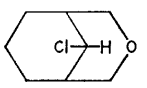
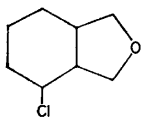
In this connection, it has been reported that the sulfuric acid-catalyzed reaction of olefins with formaldehyde in water or acetic acid (the Prins reaction) affords 1,3-dioxanes and 1,3-diols or their acetates (the homolog of **3** (Y=OCOH)) as the principal products,[2] whereas the reaction of terminal olefins with paraformaldehyde and hydrogen halides in anhydrous media yields mainly 3-alkyl-4-halotetrahydropyrans (correspond to **5** (Y=halogen)).[3]

Results and Discussion

When cyclohexene was allowed to react with CMM and excess formic acid in ether at room temperature for 24 h, in either the presence or absence of a metal chloride, the main distillate from the reaction mixture was found to consist of the following products: *trans*-1-chloro-2-(formyloxymethyl)cyclohexane (**3a**, Y=Cl), *trans*-1-formyloxy-2-(formyloxymethyl)cyclohexane (**3a**, Y=OCOH), and 9-chloro-3-oxabicyclo[3.3.1]nonane (**5a**, Y=Cl), accompanied by a slight amount of probably 9-formyloxy-3-oxabicyclo[3.3.1]nonane (**5a**, Y=OCOH). Besides, small amounts of cyclohexyl chloride and cyclohexyl formate (combined yield, *ca.* 15%) were found in the low-boiling fraction, and some tarry materials remained after distillation. For each of the products purely isolated, the structure was assigned by means of ^1H NMR and elemetal analyses. The presumed 3-oxabicyclo[3.3.1]nonane structure(A) for **5a**(Y=Cl) was confirmed by ^{13}C NMR study. The decoupled spectrum had five signals, as was to be expected from its symmetrical structure (the δ values are given in Table 3). If **5a** (Y=Cl) had the isomeric 3-oxabicyclo[4.3.0]nonane structure(B), it should give rise to eight separate signals.



A



B

In the reaction without any additive, the total yield of **3a**(Y=Cl and OCOH) and **5a**(Y=Cl) was *ca.* 30%; a considerable amount of unreacted cyclohexene was also recovered. However, when $ZnCl_2$, $HgCl_2$, or $SnCl_4$ (1/4—1 eqiv.) was added to the reaction system, the total yield was improved up to around 50%, with the proportion of **3a**(Y=Cl) increasing considerably, and most of the cyclohexene was consumed. For equimolar addition, the above chlorides were nearly equal in their ability to carry Cl^-, but $ZnCl_2$ exhibited a slightly inferior tendency, and $AlCl_3$ and $BF_3 \cdot Et_2O$ were almost ineffective. When the ether solvent was replaced by dichloromethane, the yields of **3a** (Y=Cl and OCOH) decreased significantly. Further, when acetic acid (a less-ionizing solvent) was used in the place of formic acid, the reaction was quite slow and did not afford any of the products expected under the given conditions.

In cases where 1-hexene or styrene was used as an olefin component, the product distributions varied significantly. In the presence of $ZnCl_2$ or $HgCl_2$, the

** Koei Chemical Co., Ltd., Joto-ku, Osaka 536.

products **3c** and **5c** (Y=Cl and OCOH for both) were obtained from 1-hexene in a total yield of 55%. On the other hand, styrene, which does not contain an allylic H atom, gave mainly **4** (Y=Cl and OCOH) in a good total yield, without any accompanying tetrahydropyran derivatives, as had been expected. Here, the ring size for **5c** (Y=Cl and OCOH) was assigned mainly on the basis of the C–O–C stretching frequency (1090 cm^{-1} for both) in the IR spectrum, which corresponds fairly well to that exhibited by tetrahydropyran (1090 cm^{-1}), but not to that of tetrahydrofuran (1070 cm^{-1}).[4] Although both **5c**(Y=Cl and OCOH) were chromatographically (by GLC) homogeneous, the decoupled ^{13}C NMR spectrum of **5c** (Y=Cl) exhibited two similar sets of eight signals which can be assigned to a mixture of 4-chloro-3-propyltetrahydropyran and its isomer, probably 3-(1-chlorobutyl)tetrahydrofuran, in the ratio of *ca.* 4:1, while the ^{13}C analysis of **5c**(Y=OCOH) showed the existence of 4-formyloxy-3-propyltetrahydropyran alone (see Table 3). It should also be noted that the ratio of **3**(Y=Cl)+**3**(Y=OCOH)/**5**(Y=Cl)+**5** (Y=OCOH) varied from *ca.* 85/15 to *ca.* 35/65 as the olefin component was changed from cyclohexene to 1-hexene. The considerable difficulty in cyclization for the former olefin may be explained by the hindering effect in the ring-closure step (see Eq. 3).

Some typical data on the reaction of olefins with CMM and formic acid are shown in Table 1.

CMM is known to be accessible to the β-chloro-α-methoxymethylation of olefins in the presence of Lewis acids in aprotic solvents.[5] However, the present reaction showed quite a different pattern in which the introduction of a formyloxymethyl group, not a methoxymethyl group, occurred at an olefinic C; this might suggest that the formolysis of CMM leading to **6** is involved at an early stage of the reaction (Eq. 1).

$$CH_3OCH_2Cl \xrightarrow{\begin{array}{l}MCl_n\\ \longrightarrow [CH_3OCH_2^+ \cdot MCl_{n+1}^-]\\ HCOOH\ (\text{when } MCl_n \text{ is absent})\end{array}} \underset{\mathbf{6}}{CH_3OCH_2OCOH} + HCl \quad (1)$$

The formation of cyclohexyl chloride as a by-product and the following experimental result appear to support such a pathway *via* **6**: when an equimolar mixture of cyclohexene and **6** (prepared independently) was treated with HCl in formic acid in the presence of $ZnCl_2$, a mixture of **3a**(Y=Cl and OCOH) and **5a** (Y=Cl) was formed, analogous to the cyclohexene–CMM–formic acid reaction.

The succeeding protolysis of **6** may occur at the more basic ethereal O atom to afford the formyloxymethyl cation (**7**), and the addition of this cation and Cl^- (including MCl_{n+1}^-) or formic acid to olefins results in the formation of **3**(Y=Cl or OCOH respectively) (Eq. 2).

$$\left.\begin{array}{l} \mathbf{6} + H^+ \longrightarrow \underset{\mathbf{7}}{{}^+CH_2OCOH} + CH_3OH \\ RCH_2CH{=}CHR' + \mathbf{7} \longrightarrow \left[RCH_2\overset{+}{C}H\text{-}CH(CH_2OCOH)\text{-}R'\right] \\ \qquad\qquad \underset{\mathbf{8}}{} \\ \xrightarrow[\text{or HCOOH}]{Cl^-(\text{or } MCl_{n+1}^-)} \mathbf{3}\ (Y=Cl \text{ or } OCOH) \end{array}\right\} \quad (2)$$

Here, **3**(Y=Cl and OCOH) might be formed by another route, *via* the 1:1 olefin–CMM adduct (**2**, Y=Cl). However, such a possibility can be ruled out for the following reason: if **2**(Y=Cl) undergoes formolysis, the substitution would occur at the secondary C bearing Cl and would give rise to **2**(Y=OCOH),

Table 1. Reaction of olefins with CMM and formic acid in ether

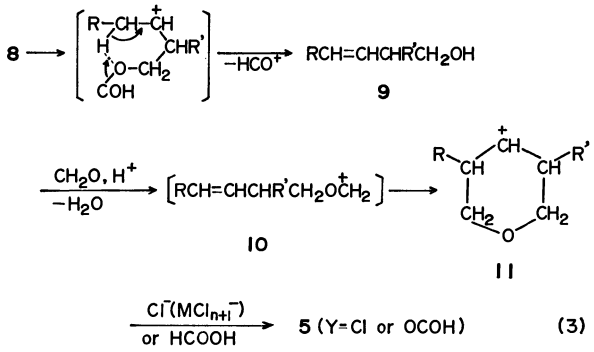
a) Based on olefin (determined by GLC). b) CH_2Cl_2(60 ml) was used as the solvent. c) Experiment on the scale of 1/2. d) A mixture of **5c** (Y=Cl) and its isomer (see Footnote d in Table 3).

not **3**(Y=Cl and OCOH). Moreover, it was proved by a blank experiment that the 1:1 cyclohexene–CMM adduct does not react with formic acid, at least under the given conditions.

A reasonable pathway to tetrahydropyrans **5**(Y=Cl and OCOH) is given below (Eq. 3), in which the route from **9** is essentially the same as that proposed by Stapp:[3]



As to the transformation from **8** to **9**, another path involving the deprotonation of **8**, followed by hydrolysis, is possible. However, a separate experiment revealed that, in the cyclohexene–CMM reaction, the use of *dried* formic acid[6] did not cause any appreciable changes in the yields of all the products; this fact may suggest the participation of a process other than hydrolysis. For the same reason, the formaldehyde, which is required for the conversion of **9** to **10**, may be supposed to be formed by another reaction, such as the acid-catalyzed intramolecular methanolysis of **6** or the splitting of **7** itself, rather than by the acid hydrolysis of CMM or **6**. In view of the moisture-sensitive nature of **6**,[7] however, it seems to be difficult to rule out completely the possibility of its hydrolysis by external moisture.

The ring closure of the **10** cation may proceed in two ways to afford tetrahydropyran derivatives (*via* **11**) and/or tetrahydrofuran ones. In practice, the former type of product was formed either predominantly or exclusively, as has been described above. A quite similar trend has been observed in some related reactions. For example, the modification of the Prins reaction yields the above type of cyclic ethers as the main or side products, in which tetrahydropyran derivatives are either exclusive or predominant.[3,8] Further, in the intramolecular acylation of ω-arylalkanoic acids to give cyclic ketones, the fact that six-membered rings are formed in preference to five-membered ones has been demonstrated by several examples.[9]

Next, the reaction of olefins with 1-chloro-1-ethoxyethane(CEE) was examined under the same conditions as with CMM, but it was rather slow and the yields of products were generally very low (Table 2). Moreover, the ratios of the two formyloxyalkylated products differed from those in the case of CMM. Thus, in the reactions of 1-hexene with CMM and CEE (additive: $ZnCl_2$, 1 equiv.), the **3**(Y=Cl)/**3**(Y=OCOH) and **3'**(Y=Cl)/**3'**(Y=OCOH) ratios were 1.2 and 2.0 respectively, while in those of cyclohexene these ratios were 1.7 and 8.9 respectively. The large difference in the latter system may arise from a severe steric interference between the neighboring 1-(formyloxy)ethyl group of the cation corresponding to **8** and the attacking formic acid molecule (present as a cyclic dimer[11]).

Experimental

Except for the case of CEE, commercial organic materials were used after distillation. The CEE was prepared from paraaldehyde, ethanol, and HCl,[12] and was used after distillation. Commercial inorganic materials were used without further purification. The ^1H NMR spectra (in $CDCl_3$) were recorded with a Varian A-60 apparatus and a JEOL MH-100 apparatus. The ^{13}C NMR spectra were recorded on a JEOL FX-100 spectrometer in the pulse Fourier transform mode at 25.15 M Hz in $CDCl_3$. The IR spectra were determined with a Hitachi EPI-S2 spectrometer. The GLC analyses were carried out on a Shimadzu 5APTF apparatus, using EGSS-X (30%)-Chromosorb-W(lm) (with N_2 as the carrier gas).

Reactions of Olefins with CMM or CEE and Formic Acid. A typical example is given below. To a stirred mixture of cyclohexene (8.2 g, 0.1 mol), formic acid (46 g, 1 mol), and $ZnCl_2$ (13.6 g, 0.1 mol) in ether (45 ml), CMM (8.0 g, 0.1 mol) was added, drop by drop, at 0—5 °C. The mixture was stirred for 24 h at room temperature, and then it was slowly added to a suspension of $CaCO_3$ (50 g) in water. After this mixture had been stirred for 1 h, ether was added and inorganic precipitate was filtered off. The organic layer separated from the aqueous one was washed with aqueous NaCl and dried over $MgSO_4$,

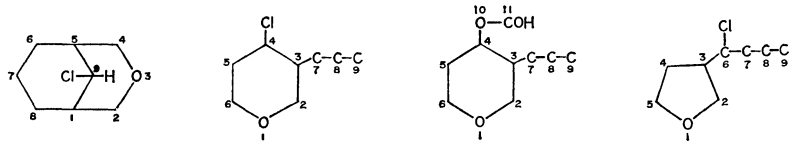
a) *trans*-Isomer. b) Lit, 147 °C/110 Torr. [N. P. Volynskii, G. D. Galpern, and A. B. Urin, *Zh. Org. Khim.*, **2**, 1043 (1966); *Chem. Abstr.*, **65**, 15306 (1966)]. c) The numbering of C atoms is shown below. d) A mixture of **5c** (Y=Cl) and its isomer, probably 3-(1-chlorobutyl)tetrahydrofuran, in an approximate ratio of 4:1. The δ values (in ^{13}C NMR) of the isomer[c]: 67.1(t, C-2), 62.5(t, C-5), 60.8(d, C-6), 40.8(d, C-3), 30.8(t, C-4), 34.7(t, C-7), 19.3(t, C-8), 14.1(q, C-9). e) Lit,[3] 91—95 °C/15 Torr. f) Because of its small quantity, the bp could not be determined.



and most of the solvent was evaporated. Subsequent GLC analysis of the residue, using diphenylmethane as the internal standard, showed the presence of **5a** (Y=Cl) (1.3 g, 8.1 mmol) **3a** (Y=Cl) (4.8 g, 27.2 mmol), probably **5a** (Y=OCOH) (*ca.* 0.3 g), and **3a** (Y=OCOH) (2.9 g, 15.6 mmol). Each compound, except for **5a** (Y=OCOH), was isolated in an analytically pure state by duplicate distillation. The configuration and conformation of **3a** (Y=Cl and OCOH) were deduced from the splittings of the CHCl and CH-(OCOH) protons respectively in the ^{1}H NMR (100 MHz) spectrum, which indicate these protons are in an axial position, coupled strongly to two adjacent axial protons (δ=3.77, d of t, for CHCl; 4.80, d of t, for CHOCOH; and J=4 and 10 Hz for both).

In cases where the complete separation of the products by distillation was difficult, the analytically pure compounds were isolated from the corresponding raw distillates by column chromatography [Wakolgel, hexane–ether (5—10:1), petroleum ether–ether (10—20:1), or hexane–dichloromethane (20:1)].

The NMR spectra and analytical data of pure products satisfied all the given structures. Some representative data are given in Table 3.

*Reaction of Cyclohexene with Methoxymethyl Formate (**6**) and Formic Acid in the Presence of $ZnCl_2$ and HCl.* The formate, **6**, was prepared from CMM and $(HCOO)_2Pb$.[13] Into a

stirred mixture of cyclohexene (4.1 g, 50 mmol), formic acid (23 g, 0.5 mol), **6** (4.5 g, 50 mmol), and $ZnCl_2$ (6.8 g, 50 mmol) in ether (23 ml), dry HCl (*ca.* 2 g, 50 mmol) was introduced at −10——20 °C. The mixture was then kept for 24 h at room temperature under stirring. The work-up procedure was the same as above. Subsequent GLC analysis revealed the formation of **3a** (Y=Cl and OCOH) and **5a** (Y=Cl) (an approximate molar ratio, 11:4:5; total yield, *ca.* 35%).

Attempted Formolysis of 1-Chloro-2-(methoxymethyl)cyclohexane (1:1 Cyclohexene–CMM Adduct). The adduct was prepared by the reported method (in CS_2; cat., $ZnCl_2$).[14] To a stirred suspension of $ZnCl_2$ (6.8 g, 50 mmol) and formic acid (23 g, 0.5 mol) in ether (23 ml), the above adduct (8.1 g, 50 mmol) was added slowly, and then the mixture was stirred for 24 h at room temperature. GLC analysis after the usual work-up procedure showed that only the unreacted adduct was present.

We wish to thank Dr. Sakae Uemura, Institute for Chemical Research, Kyoto University, for his helpful discussions of the NMR data.

(Received October 4, 1979)

The structure of nitronitrosoaconitinic acid, which is an oxidation product of aconitine with nitric acid, was confirmed by spectroscopic methods. This compound is a new type of acid, a 2-nitro-2-cyclohexen-1-one, with a pK_a value comparable to that of carboxylic acids.

A study of the oxidation of aconitine (**1**) with nitric acid was first performed by Brady.[2,3a] The oxidation of aconitine (**1**), mesaconitine (**2**), and their derivatives has been found to yield a nitro *N*-nitroso derivative (**3**).[2,3b,4-7] Compound **3** has been called nitronitrosoaconitinic acid by Suginome.[4] Two alternative molecular formulae, $C_{31}H_{33}O_{13}N_3$[4] and $C_{31}H_{35}O_{13}N_3$,[5,7] have been proposed for **3** on the basis of the elemental analysis. Moreover, Suginome found that, although it retained both benzoyl and acetyl groups of **1**, one of the four methoxyl groups and alkyl group attached to the tertiary nitrogen of **1** are lost in the transformation.[4] Subsequently, extensive studies[5-7] have been carried out, but the structure still remains unknown. Compound **3** has now been subjected to modern structural analyses; in this paper, we wish to propose the **3** structure for this compound.

By field desorption mass spectrometry, **3** was confirmed to have a molecular formula of $C_{31}H_{35}O_{13}N_3$ [*m/e* 658 $(M+1)^+$]. The infrared spectrum exhibited bands attributable to hydroxyl groups at 3400—3700; to an α,β-unsaturated carbonyl and acyl carbonyl groups, at 1700 and 1720; to a nitro group, at 1373 and 1538, and to a benzene ring C–H bond, at 720 cm^{-1}. The UV spectrum in ethanol showed strong absorption bands at 230 (log ε; 4.2) and 343 nm (log ε; 3.4) attributable to an α,β-unsaturated carbonyl group. The ^1H NMR spectrum ($CDCl_3$, δ) showed the presence of an acetoxyl group (1.40, s, 3H), three methoxyl groups (3.18, 3.33, and 3.82, each 3H), and a benzoyloxy group and an olefinic proton (7.26—8.10, m, 6H). The removal of the two acyl groups by the alkaline hydrolysis of **3** afforded a compound (**4**), $C_{22}H_{29}O_{11}N_3$, designated as nitronitrosoaconinic acid,[4] [*m/e* 512 $(M+1)^+$]. The infrared spectrum exhibited bands attributable to hydroxyl groups at 3300—3700; to an α,β-unsaturated carbonyl group, at 1700, and to a nitro group at 1370 and 1535 cm^{-1}. The UV spectrum in ethanol showed strong bands at 230 (log ε; 4.1) and 343 nm (log ε; 3.1) attributable to an α,β-unsaturated carbonyl group. The ^1H NMR spectrum (D_2O, δ) revealed the presence of three methoxyl groups (3.30, 3.34, and 3.57, each 3H) and an olefinic proton (7.63, s, 1H) and indicated the generation of an olefinic proton in the transformation of **1** into **3**. On the acetylation of **4** with acetyl chloride, all of the four free hydroxyl and *N*-nitroso groups reacted and *N,O*-pentaacetyl derivative (**5**), dp 275—279 °C, was obtained as in the case of the acetylation of **3**.[4]

By chemical-ionization mass spectrometry, **5** was confirmed to have the molecular formula of $C_{32}H_{40}O_{15}N_2$ [*m/e* 710 $(M+NH_4)^+$]. The infrared spectrum exhibited bands attributable to an α,β-unsaturated carbonyl and acyl carbonyl groups at 1695 and 1740, and to a nitro group at 1362 and 1533 cm^{-1}. The UV spectrum in ethanol showed strong bands at 228 (logε; 4.3) (shoulder) and 343 nm (logε; 3.8) attributable to an α,β-unsaturated carbonyl group. The ^1H NMR spectrum ($CDCl_3$, δ) established the presence of four acetoxyl and an *N*-acetyl groups (2.00, 2.03, 2.09, 2.11, and 2.20, each 3H), three methoxyl groups (3.32, 3.36, and 3.40, each 3H), and an olefinic proton (7.18, s).

The strucutre of **3** was deduced by the correlation of the ^{13}C NMR signals of **1** with those of **3**. The reported[8] ^{13}C signal assignments of **1**, together with those of **3**, **4**, and **5**, are shown in Table 1. Assignments of the resonances to individual carbon atoms were achieved by using the ^1H single-frequency off-resonance decoupling technique, the chemical shift theory, and a comparison of their chemical shifts with those of aconitine type diterpenoid alkaloids.[8] A comparison of the ^{13}C signal assignments of **1** and **3** reveals the presence of the carbonyl group (singlet at 186.7 ppm) and the lack of C-3 carbon resonance at 70.4 ppm (doublet) in **3**. Thus, the carbonyl group was formed by the oxidation of the secondary hydroxyl group in Ring A. The low-field resonances at 142.8 and 148.8 ppm in **3** are assigned to the olefinic carbons, which correspond to a methine and a quarternaly carbon with a nitro group. The position of this double bond can be assigned to C-1 and C-2 on the basis of the observation of the UV spectrum of **3** and the lack of C-1 and C-2 carbon resonances at 83.4 and 36.0 ppm in **1**. The observation of the unexpected downfield shift (3.3 ppm) of the C-12 carbon in **3** relative to **1** suggests that it is preferable to interchange the chemical shifts of the C-2 and C-12 carbons in **1**.[8] By this interchange, this downfield shift is diminished to 1.3 ppm. On the other hand, on the basis of the observation of the spin-lattice relaxation-time (T_1) maesurements (C-17; 0.2 s and C-16; 0.6 s), the reported assignments of the chemical shifts of C-17 (61.0) and C-16′ (60.7)[8] have been interchanged.[1] The separation of the closely spaced peaks of C-17/C-16′ into positive and negative signals was observed. These data suggest that a large structural change took place only in the A-ring, more specifically, that

Table 1. ^{13}C chemical shifts of aconitine (**1**),[a] nitronitrosoaconitinic acid (**3**), nitronitrosoaconinic acid (**4**), and nitro-*N*-acetylaconinic acid tetraacetate (**5**)

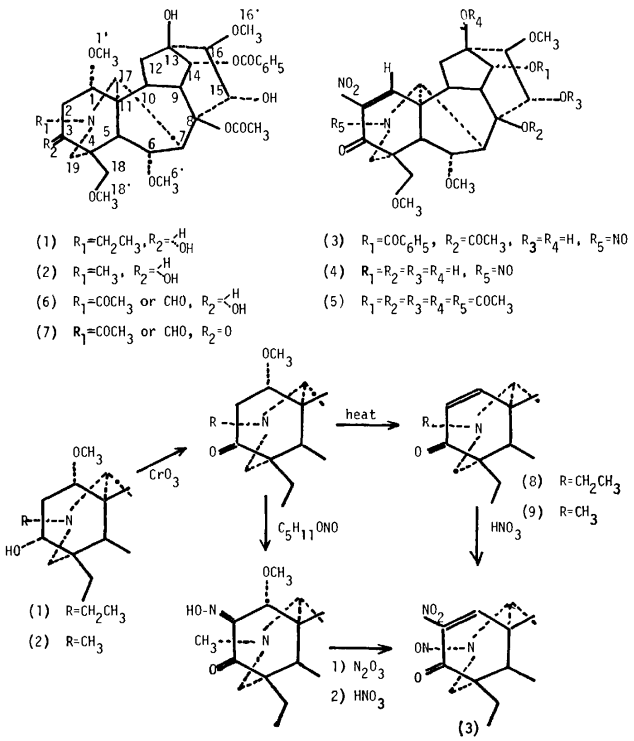
a) Results reported by Pelletier and Djarmati.[8] b) δ, ppm downfield from TMS in $CDCl_3$. c) δ, ppm downfield from TMS in CD_3OD. d) and e) These two values of each compound may be interchanged. f) and g) The reported assignments[8] of the chemical shifts of C-17 (61.0) and C-16′ (60.7) have been interchanged[1]; those of C-2 (36.0) and C-12 (34.0) are also interchanged.

the α,β-unsaturated carbonyl group was introduced into the A ring. The nitro group could be attached to either the α (C-2) or β (C-1) position of the α,β-unsaturated carbonyl group. Compound **3** can be obtained[6] from **2** *via* chromium trioxide oxidation to a ketone, followed by nitrosation at the carbon α to the carbonyl and oxidation with nitric acid. This sequence of reactions allows us to confirm that the nitro group is definitely attached to the C-2. Contrary to the significant differences observed in the chemical shifts of the C-1, C-2, and C-3 between **1** and **3**, only slight differences for C-4, C-5, C-7, C-10, C-18, and C-19 can be seen. These slight differences can be explained as results of the β and γ effects accompanying changes in the C-1, C-2, and C-3 carbons and the amino nitrogen in **1**. On the basis of all the results described above, the structure of nitronitrosoaconitinic acid is formulated as **3**; the series of reactions from **1** and **2** to afford **3**[6] are depicted in Scheme 1. According to this reaction process, the formation of **3** from oxonitine (**6**),[9,10] oxoaconitine (**7**),[5,7] and demethanolaconitinone (aconitoline) (**8**)[5-7] can be understood readily. These experimental data[6] suggest that Compound **9** is not demethanolanhydromesaconitinone $C_{32}H_{37}O_9N$,[6] but demethanolmesaconitinone $C_{32}H_{39}O_{10}N$, as is shown by the partial structure in Scheme 1. The chemical shifts of all of the carbons in **4** and **5** shown in Table 1 are in agreement with the assigned structures, **4** and **5**, considering the effects of using different solvents and the substitution of the hydroxyl for the acetoxyl groups.

The pK_a value of **3** was determined to be 4.9 by spectrophotometric measurements at a wavelength of 343 nm (λ max)[11] in buffer solutions. This value suggests that the acid strength of **3** is nearly equal to that of carboxylic acids. In the ^1H NMR spectrum, a signal due to an olefinic proton at δ 7.63 of **4** in D_2O disappeared slowly in the presence of a small



Scheme 1.

amount of alkali. Therefore, a system formed by the introduction of a nitro group into the α carbon of the double bond of the α,β-unsaturated carbonyl group is considered to be responsible for the acidity. No study concerning the acidity of such a structure has been reported, and further studies are presently in progress in our laboratories.

Experimental

The mps are uncorrected. The IR spectra were determined in KBr discs. The UV spectra were measured by means of a Shimadzu UV-300 spectrophotometer. The MS were measured by JEOL JMS-D300 and Shimadzu GCMS-9000 spectrometers. The Carbon-13 FT NMR spectra were taken at 25.00 MHz using a JEOL FX-100 spectrometer equipped with a JEC 980-24 K computer and 5 mm o. d. tubes. The FT-measurement conditions were: spectra width, 5 kHz; pulse width, 5 μs (45°); pulse repetition time, 1.0 s; number of data points, 8192; numbers of transients, 5000—40000. The values of pH were determined using a Corning model 7 pH meter.

Nitronitrosoaconitinic Acid (3). Mesaconitine (**2**) (2.3 g) was oxidized in 6 ml of HNO_3 (d 1.42) according to the method of a previous report[4] by heating in a water bath at 80 °C for 40 min. The precipitate (2.1 g) formed on the dilution of the reaction mixture was placed in a column of silica gel (100 g) and eluted with chloroform–methanol (100:1). This yielded **3** (575 mg) (needles of pale yellow) after recrystallization from acetone–water; dp 230 °C. UV: λ_{max}^{EtOH} 230 nm (log ε; 4.2) and 343 (log ε; 3.4); IR: ν_{max}^{KBr} 3700—3400, 1720, 1700, 1538, 1373, 720 cm^{-1}; NMR ($CDCl_3$, δ): 1.40 (3H, s, $OCOCH_3$), 3.18 (3H, s, OCH_3), 3.33 (3H, s, OCH_3), 3.82 (3H, s, OCH_3), 7.26—8.10 (6H, m, an olefinic and aromatic protons); MS: m/e 658 $(M+1)^+$. Found: C, 55.71; H, 5.09; N, 6.08%. Calcd for $C_{31}H_{35}O_{13}N_3 \cdot 1/2H_2O$: C, 55.85; H, 5.44; N, 6.30%.

Nitronitrosoaconinic Acid (4). Nitronitrosoaconitinic acid (**3**) was hydrolyzed according to previous report[4] by boiling it with 1 M barium hydroxide solution for 1 h. After cooling, the solution was passed through a column of an ion-exchange resin (Dowex-50W). The eluate was then evaporated. The residue was placed in a column of silica gel and eluted with ethanol. Recrystallization from water gave crystals: **4**; dp 287 °C. UV: λ_{max}^{EtOH} 230 nm (log ε; 4.1) and 343 (log ε; 3.1); IR: ν_{max}^{KBr} 3700—3300, 1700, 1535, 1370 cm^{-1}; ^1H NMR (D_2O, δ): 3.30 (3H, s, OCH_3), 3.34 (3H, s, OCH_3), 3.57 (3H, s, OCH_3) and 7.63 (1H, olefinic proton); MS: m/e 512 $(M+1)^+$. Found: C, 49.43; H, 5.60; N, 7.54%. Calcd for $C_{22}H_{29}O_{11}N_3 \cdot H_2O$: C, 49.90; H, 5.90; N, 7.93%.

Nitro-N-acetylaconinic Acid Tetraacetate (5). A mixture of nitronitrosoaconinic acid (**4**) (100 mg) and acetyl chloride (2 ml) was allowed to stand in a sealed tube for a week. After the subsequent removal of the acetyl chloride, methanol (1 ml) was added to the residue, and the resulting solution was added to ice-cold water. The precipitate (97 mg) thus formed was purified on a silica-gel column by eluting with chloroform–methanol; from the eluate, crystals (34 mg) were obtained; dp 275—279 °C. UV: λ_{max}^{EtOH} 228 nm (log ε; 4.3) (shoulder) and 343 (log ε; 3.8); IR: ν_{max}^{KBr} 1740, 1695, 1533 and 1362 cm^{-1}; ^1H NMR ($CDCl_3$, δ): 2.00, 2.03, 2.09, 2.11 and 2.20 (3H, singlet each, $OCOCH_3 \times 4$ and $NCOCH_3$), 3.32, 3.36 and 3.40 (3H, singlet each, $OCH_3 \times 3$) and 7.18 (1H, s, an olefinic proton); MS: m/e 710 $(M+NH_4)^+$. Found: C, 54.36; H, 5.60; N, 4.40%. Calcd for $C_{32}H_{40}O_{15}N_2 \cdot H_2O$: C, 54.08; H, 5.96; N, 3.94%.

Spectrophotometric Determination of the pK_a of Nitronitrosoacnitinic Acid (3). To a series of 5-ml portions of a saturated solution of **3** in water, 5-ml portions of 0.2 M buffers of different pH values were added, and then the resultant pH values of the mixtures were determined. A series of spectra were recorded at 22 °C. The pK_a value was determined at 343 nm according to the method described by Albert and Serjeant.[12] For the pH range of 4.1—5.6, acetate buffers were employed, and for that of 5.8—6.2, phosphate buffers. The spectra of the molecular and ionized species were determined in 0.005 M HCl and 0.005 M NaOH respectively.

Spectrometric Identification of the Olefinic Proton. To nitronitrosoaconinic acid (**4**) (30 mg) dissolved in 0.2 ml of D_2O, 0.05 ml of a solution of NaOD (60 mg) in D_2O (15.2 ml), divided into three protions, was added over a one-hour period at 22 °C. The NMR spectra were obtained during this period.

The Palladium Catalyzed Nucleophilic Substitution of Aryl Halides by Thiolate Anions

Department of Applied Chemistry, Faculty of Technology, Gunma University, 1-5-1 Tenjincho Kiryu, Gunma 376

(Received December 8, 1979)

In the presence of a catalytic amount of tetrakis(triphenylphosphine)palladium, phenyl and methyl or methoxyphenyl iodides and bromides were found to react with thiolate anions in alcoholic solvents, to give the corresponding aryl sulfides in excellent yield. The reaction is useful to prepare symmetrical or unsymmetrical diaryl sulfides and aryl alkyl sulfides. The reaction mechanism does not involve aryl halide radical anions, but is thought to involve oxidative addition of aryl halide to Pd(0), nucleophilic substitution on the adduct followed by reductive elimination.

Aryl halides which are not activated by electron withdrawing substituents are inert to the usual nucleophilic reagents. Under special conditions, however, such unactivated aryl halides undergo substitution of halogens by nucleophiles. Besides the reactions *via* aryne intermediates under conditions involving high temperature or very strong bases, there have been noticed two kinds of substitution: aromatic $S_{RN}1$ which are stimulated by the presence of good electron donors,[1] and substitution catalyzed by the transition metal complexes.

As examples of the latter kind of reactions, there have been known that Pd(0) or Pd(II) catalyzes the substitution of aryl halides by cyanide,[2] acetylide anions,[3] π-nucleophiles,[4] and other organometallic reagents.[5] Ni(0) catalysts also promote the reaction with acetylide[3] or other carbanions[6] and halogen exchange with halide ions.[7]

As preliminarily reported, it has been found that in the presence of a catalytic amount of tetrakis(triphenylphosphine)palladium, $Pd(PPh_3)_4$, aryl bromides and iodides react easily with thiolate anions in dimethyl sulfoxide (DMSO) to give aryl sulfides in satisfactory yield.[8] Recently, similar reaction of alkenyl halide also has been developed.[9]

$$ArX + RS^- \xrightarrow{Pd(PPh_3)_4} ArSR + X^-$$

X: I, Br and R: Ph, Alkyl

On the other hand, quite similar reaction of aryl halides with arenethiolates giving sulfides has been known to proceed without metal complexes, in liquid ammonia under irradiation of Pyrex-filtered light, and the $S_{RN}1$ mechanism was proposed for the reaction.[10]

The present paper described the results of a further survey on the chemistry of the Pd(0) catalyzed reaction giving sulfides, comparing with that of the $S_{RN}1$ reaction.

Results

Table 1 shows the result of the reaction carried out by heating a solution of aryl halide (2 mmol), arene- or alkanethiol (2 mmol), sodium *t*-butoxide (4 mmol), and a catalytic amount of tetrakis(triphenylphosphine)-palladium in a solvent, the yield of the sulfide being obtained by GLC analysis.

Table 1 apparently shows the catalytic effect of $Pd(PPh_3)_4$. Without the catalyst, PhI, *p*-ClC_6H_4I, *p*-ClC_6H_4Br, and *m*-$MeOC_6H_4I$ reacted with PhS^- in DMSO to give low yield of the corresponding sulfides, and *p*-methyl and *p*-methoxy derivatives scarecely reacted and the aryl halides remained in the mixture under the same conditions. However, the presence of $Pd(PPh_3)_4$ in the reaction mixture converted all aryl halides into the corresponding sulfides in high yield. Palladium acetate also promotes the reaction, but seems inferior to $Pd(PPh_3)_4$ in the catalytic efficiency. Yield of diphenyl sulfide in the reaction of iodo benzene and PhS^- was still lower than that in the $Pd(PPh_3)_4$ catalyzed reaction, even when 10 mol% of $Pd(OAc)_2$ was present.

In preliminary experiments,[8] DMSO was chosen as a solvent, since in such an aprotic solvent nucleophile such as thiolate anion was considered to be more reactive than in a protic solvent. However, the results of the reaction of iodobenzene with benzenethiolate ion carried out in various easily available solvents indicate that alcohols are the most recommendable solvents.

Thus, the reaction in refluxing ethanol gave diphenyl sulfide in almost quantitative yield even in the presence of only 1 mol% of the catalyst, $Pd(PPh_3)_4$.

For preparative scale, it is most convenient to reflux a mixture made by adding aryl halide, thiol and then 1 mol% of $Pd(PPh_3)_4$ to a solution of sodium alcoholate prepared by dissolving sodium metal in the alcoholic solvent (see Experimental part). For the reaction of aryl iodide in ethanol, 4 h refluxing is sufficient to complete the reaction. Starting from iodobenzene (50 mmol), diphenyl sulfide and phenyl *t*-butyl sulfide were isolated in 88 and 65% yield, respectively.

Table 1 shows that the reaction proceeds with not only iodobenzene and its methyl or methoxy derivatives, but also with the corresponding unactivated aryl bromides. Aryl bromides react more slowly than aryl iodides. Thus, the reaction of bromobenzene in refluxing ethanol under which iodobenzene reacted smoothly, gave the sulfide only in low yield, but gave the excellent results under the conditions of refluxing alcohol of higher boiling point, *n*-BuOH.

Aryl chlorides are poor substrates toward the Pd(0) catalyzed substitution. Chlorobenzene was converted into the sulfide in only a trace amount under the same conditions. Chloronaphthalene and EtS^- gave a mod-

erate yield of the sulfide, but the almost same results were obtained even without a catalyst.

As shown in Table 2 a), competitive experiments using large excess of substituted iodobenzenes showed somewhat retarding effects of the electron repelling substituents ($\rho \fallingdotseq +1.0$).

Alkanethiolates such as EtS^-, n-BuS^-, and t-BuS^- are also good substituting reagents. Semiquantitative competitive experiment on the reaction of iodobenzene with excess of a mixture of PhS^- and t-BuS^- showed t-BuS^- reacts about 9 times faster than PhS^- as shown in Table 2 b).

Discussion

The reactions of aryl iodides and bromides with thiolate anions in the presence of $Pd(PPh_3)_4$ were found to be useful for preparation of unsymmetrical diaryl or aryl alkyl sulfides. It should be noteworthy that the reaction can be applied to the aryl halides bearing electron repelling substituents.

The reaction needs no peculiar solvents, but the

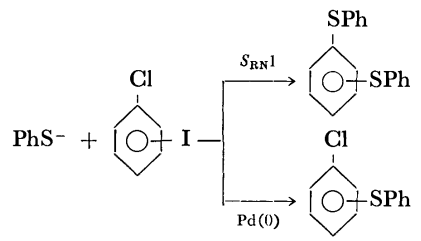
most common solvents, alcohols. Reaction temperature can be regulated by choosing the alcholic solvents depending on the reactivity of substrate. Thus, aryl iodides and bromides react smoothly in refluxing ethanol and 1-butanol, respectively. Work-up for separation of the products is reasonably easy as shown in the experimental part.

It is interesting to compare the features between the present reaction and the sulfenylation of unactivated aryl iodide proceeding through $S_{RN}1$ processes developed by Bunnett and Creary. At first glance on Table 1 in which yields of the sulfide produced through the $S_{RN}1$ is noted in parentheses, both the $S_{RN}1$ and the Pd(0) catalyzed sulfenylation of aryl halides seem to have resembling scope and limitation. Thus, unactivated aryl iodides react smoothly, aryl bromides react more slowly than iodides, and chlorides hardly react. In both reactions 2,6-dimethylphenyl iodide gave the corresponding sulfide, even though the yields are low presumably due to the steric hindrance, showing that both reactions do not proceed *via* elimination-addition involving intermediacy of arynes. However, there can be recognized some different features between these two types of reactions.

The Pd(0) catalyzed reaction is not inhibited by the presence of *p*-dinitrobenzene which has been known to be a good electron acceptor and to inhibit the $S_{RN}1$ processes.[1] The run (No. 3 in Table 1) carried out in the presence of *p*-dinitrobenzene (equimolar to the substrate) gave the excellent yield of diphenyl sulfide.

Secondly, the $S_{RN}1$ reactions of chlorophenyl iodides or bromides with PhS^- give almost exclusively disulfenylated products,[10] but in the Pd(0) catalyzed reaction, monosulfenylated products ClC_6H_4SPh are predominantly formed, even if excess of thiolate is used.



Inhibition by an electron acceptor, and disulfenylation of chlorophenyl halides are the striking features which strongly support the $S_{RN}1$ mechanism involving electron transfer to aryl halides giving anion radicals. Consequently, the present reaction lacking these features should be essentially different from the $S_{RN}1$ reaction, and not involving radical anions.

The most plausible mechanism of the Pd(0) catalyzed sulfenylation involves oxidative addition of aryl halide to Pd(0), followed by nucleophilic attack of thiolate anion on the adduct.

$$Ar\text{-}X + Pd(0) \longrightarrow Ar\text{-}Pd\text{-}X$$
$$RS^- + ArPdX \longrightarrow ArSR + Pd(0) + X^-$$

It has been established that aryl halide adds to $Pd(PPh_3)_4$ to give halo(aryl)bis(triphenylphosphine)-palladium(II), $ArPdX(PPh_3)_2$ in high yield.[11] The observed tendency of the substituent effects in the present reaction ($\rho \fallingdotseq 1.0$) concords with the qualitative observation of the substituent effects in the oxidative addition.[11] Then it is quite natural to consider the oxidative addition as the first step of the Pd(0) catalyzed reaction of aryl halide.

Actually, treatment of iodo(phenyl)bis(triphenylphosphine)palladium(II) prepared by the method of Fitton *et al.*[11] with a solution of PhS^- gave diphenyl sulfide almost quantitatively. Furthermore, competitive reaction of the adduct with excess amounts of PhS^- and *t*-BuS^- showed that *t*-BuS^- reacted about 8 times faster than PhS^-. This is in tolerable agreement with the result of the competitive reaction of iodobenzene with PhS^- and *t*-BuS^- described above. These facts strongly suggest intermediacy of the oxidative adducts between Pd(0) and aryl halide.

By the way, a mechanism involving an electron transfer to give anion radicals $ArX^{\cdot-}$ has been suggested as a initial step in the oxidative addition.[12] This possibility, however, seems unlikely at least in the addition of aryl halide to the Pd(0), because the Pd(0) catalyzed reaction of aryl halide with thiolate anion cannot be considered to involve generation of a radical anion, $ArX^{\cdot-}$. The anion radical once formed, would propagage $S_{RN}1$ reaction, which could show the features different from the present reaction, as discussed above.

The initial step of the reaction between the oxidative adduct and thiolate anion is thought to be a nucleophilic substitution on the palladium atom in the adduct. And reductive elimination on the substituted product may give aryl sulfide, regenerating Pd(0). Besides

$$ArPd\text{-}X + SR^- \longrightarrow Ar\text{-}Pd\text{-}SR + X^-$$

$$Ar\text{-}Pd\text{-}SR \longrightarrow ArSR + Pd(0)$$

thiolate and cyanide anions, triphenylphosphine also was found to react with the unactivated aryl halides in the presence of the Pd(0) catalyst, giving aryltriphenylphosphonium salts in high yield, as shown in Table 3.

a) L. Horner and H. Hoffman, *Chem. Ber.*, **91**, 45 (1958).

These three soft nucleophiles have been found to be particularly reactive toward the platinum atom of *trans*-$[Pt(py)_2Cl_2]$.[13] On the other hand, the Pd(0) catalyzed substitution of aryl halide by hard nucleophiles, for example, alkoxide and various types of carbanions such as $\bar{C}H_2CN$, $\bar{C}H(COOR)_2$, *etc.* was unsuccessful. These tendencies may be compatible with the mechanism involving nucleophilic attack on the palladium atom.

Experimental

All reagents were commercially available and, of reagent-grade quality, unless otherwise noted. Tetrakis(triphenylphosphine)palladium(0) was prepared according to the literature.[14] Reaction products, sulfides and phosphonium salts were identified by comparing their IR spectra with those of the authentic samples. GLC analysis was performed with a Ohkura model 710 gas chromatograph.

Reactions with Thiolate. *Small Scale Experiment*: A solution of aryl halide (2 mmol), thiol (2 mmol), sodium *t*-butoxide (4 mmol), and 1—4% molar amount of $Pd(PPh_3)_4$ in a solvent (20 ml) was heated at 100 °C or boiling points of solvents under a nitrogen stream with stirring. For the reactions of aryl iodides, reactions complete after 3 h, but prolonged heating does not affect yield of the sulfides. It takes more than 10 h to complete the reaction of aryl bromides. Yields of the products were determined by GLC analysis. The results (reaction time: 18 h) are shown in Table 1.

Preparative Scale Experiment: In a three necked flask (500 ml), a solution of sodium ethoxide was prepared by stirring a mixture of ethanol (200 ml) and sodium (3 g) for 30 min under nitrogen. To the solution was added a solution of iodobenzene (50 mmol) and thiophenol (50 mmol) in ethanol (50 ml), and then $Pd(PPh_3)_4$ (0.5 mmol). After refluxing the solution for 4 h with stirring, ethanol was driven off with a rotary evaporator. From the residue the product was extracted into pentane. After washing with water, usual work-up and distillation gave diphenyl sulfide (110—113 °C/5 mmHg) in 88% yield. Similarly the reaction with *t*-butyl mercaptane afforded *t*-butyl phenyl sulfide (85—90 °C/20 mmHg) in 65% yield.

Reaction with Triphenylphosphine. A solution of aryl iodide (2 mmol), triphenylphosphine (2 mmol), and $Pd(PPh_3)_4$ (0.08 mmol) in benzene (3 ml) was placed in a reaction tube. The tube was evacuated and sealed, and then immersed in a bath heated at 100 °C. After 18 h, aryl triphenylphosphonium salt crystallized from the mixture was filtered and washed with benzene. Yield and melting point observed are shown in Table 3.

Competitive Reactions. *Reactions of PhS^- with Large Excess of Aryl Iodides*: An equimolar mixture of iodobenzene (15 mmol) and substituted iodobenzene (15 mmol) was allowed to react with thiophenol (1 mmol) in the presence of alkoxide (2 mmol) and $Pd(PPh_3)_4$ (0.02 mmol) in ethanol (30 ml) at 100 °C for 18 h. From the molar ratio of the produced sulfides relative reactivity of the aryl iodide, k_{ArI}/k_{PhI} was estimated by the following equation.

$$k_{ArI}/k_{PhI} = [ArSPh]_f/[PhSPh]_f$$

Reaction of PhI with PhS^- and t-BuS^-: A solution of iodobenzene (0.5—1.0 mmol), thiophenol (5—10 mmol), 2-methyl-2-propanethiol (2 mmol), alkoxide (20 mmol), and $Pd(PPh_3)_4$ (0.02 mmol) in ethanol (20 ml) was refluxed for 1 h. Amounts of the produced sulfides were determined by GLC method. The relative reactivity $k_{t\text{-}BuS^-}/k_{PhS^-}$ was calculated by the following equation,

$$\frac{k_{t\text{-}BuS^-}}{k_{PhS^-}} = \log\frac{[t\text{-BuSH}]_i - [t\text{-BuSPh}]_f}{[t\text{-BuSH}]_i} \Big/ \log\frac{[PhSH]_i - [Ph_2S]_f}{[PhSH]_i}$$

where the suffixes i and f indicate the initial and final concentrations, respectively.

Reaction of $PhPdI(PPh_3)_2$ with PhS^- and t-BuS^-: Instead of iodobenzene and $Pd(PPh_3)_4$ in the above competitive experiment, $PhPdI(PPh_3)_2$ (0.5 mmol) was used.

The results of these competitive reactions were summarized in Table 2.

The Chloroiodination of Deactivated Olefins with Antimony(V) Chloride–Iodine and Iodine Monochloride

Sakae UEMURA,* Shin-ichi FUKUZAWA, Masaya OKANO, and Seiji SAWADA**

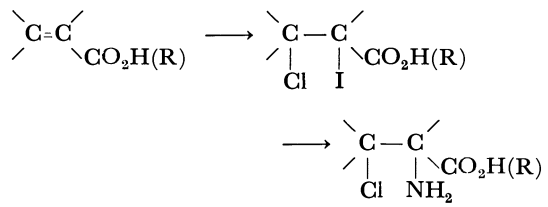
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

** *Department of Chemistry, Kyoto University of Education, Kyoto 612*

(Received October 13, 1979)

By the reactions of olefins with an equimolar mixture of $SbCl_5$ and I_2 in carbon tetrachloride, various chloroiodoalkanes are obtained in fair to good yields. This method is applicable to various deactivated olefins, the reactions of which do not proceed by the reported method using a mixture of $CuCl_2$ and I_2. Iodine monochloride can aslo be used for this reaction, but in this case both the yield and the regiospecificity of the products are sometimes inferior.

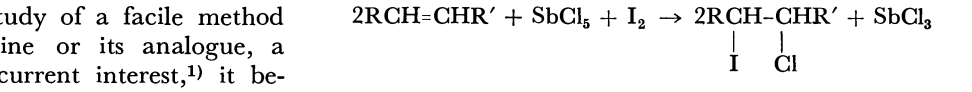
During the course of the study of a facile method for preparing β-chloro-L-alanine or its analogue, a useful "suicide" substrate of current interest,[1] it became necessary for us to prepare α-iodo-β-chloro carboxylic acid or its ester as a precursor, which may be obtained by the chloroiodination of the corresponding α,β-unsaturated carboxylic acid or its ester. Baird *et al.*[2] have reported an efficient chloroiodination of olefins by using $CuCl_2$ and I_2 to produce chloroiodoalkanes, which have not generally been prepared by



the addition of preformed iodine monochloride to olefins. The scope of this reaction is, however, restricted to olefins which have electron-donating substituents, such as alkyl and acetoxyl groups. It has previously been reported that a facile bromochlorination of olefins occurred with a mixture of antimony(V) chloride and bromine; this method is applicable to various deactivated olefins, such as fumaric and maleic esters and 1,2-dichloroethylene.[3] We have now found that a mixture of antimony(V) chloride and iodine can effect the chloroiodination of such deactivated olefins in carbon tetrachloride. It has also been shown that commercial iodine monochloride itself works as a chloroiodinating agent for such olefins, although the yield and the selectivity of the products were sometimes lower than with the $SbCl_5$–I_2 system. As one of a series of our studies of halogenation by the use of antimony(V) chloride,[3,4] we wish here to describe the details of the chloroiodination of olefins by using $SbCl_5$–I_2.

Results and Discussion

The reactions of activated olefins, such as 1-hexene, cyclohexene, and vinyl acetate, with an equimolar mixture of $SbCl_5$ and I_2 in carbon tetrachloride at the reflux temperature gave the corresponding chloroiodoalkanes in good to high yields, as in the cases with $CuCl_2$ and I_2. The stoichiometry of the reaction is given by Eq. 1. Here, the generation of two moles



(1)

(2)

of ICl can be explained by assuming Eq. 2, as in the case of bromochlorination with $SbCl_5$ and Br_2.[3]

The application of this reaction to several deactivated olefins, such as α,β-unsaturated esters and nitriles, resulted in the formation of the expected chloroiodoalkanes in fair to good yields; this is in sharp contrast to the reaction with $CuCl_2$–I_2 system, which did not afford those products from several α,β-unsaturated esters under similar reaction conditions. Some typical results are shown in Table 1. As can be seen from the table, the yields of the products increased when the reaction temperature was raised in the case of α,β-unsaturated esters, while in the case of α,β-unsaturated nitriles the reaction at room temperature gave the most satisfactory results, though the yield was still low. In the latter case, the tarry compounds became almost the sole products at the reflux temperature, while only a trace amount of product was obtained at 0—5 °C.

Iodine monochloride is generally known as an iodinating agent for activated aromatic compounds, and there seem to have been no thorough studies of the chloroiodination of olefins by this reagent.[5] There is even a description in the literature[2] of how chloroiodoalkanes have not generally been prepared by the addition of iodine monochloride to olefins because of the dissociable nature of ICl, which frequently leads to high yields of unstable diiodides, along with small amounts of the desired product. However, when we treated the above olefins with commercial iodine monochloride, the desired chloroiodoalkanes were obtained; the yields of the products were even better for some olefins than those in the $SbCl_5$–I_2 system in the reaction at room temperature. The results are also listed in Table 1. When styrene was used as the substrate, chloroiodination proceeded with iodine monochloride, while (1-chloroethyl)benzene and polymeric tars were obtained by the use of $SbCl_5$–I_2 under the several sets of conditions we employed. It has previously been reported[2] that (1,2-dichloroethyl)benzene was the sole product in the reaction of styrene with $CuCl_2$–I_2. The isomer distributions of the products obtained

from unsymmetrical olefins which were determined by ^{13}C NMR and/or GLC showed that I^+ attacked the electron-rich carbon solely or predominantly, as had been expected. For example, the chloroiodination of ethyl acrylate, methyl crotonate, acrylonitrile, and methacrylonitrile with $SbCl_5$–I_2 gave the corresponding chloroiodoalkanes with a selectivity of more than 80%. As to the isomer distributions of the products, there are not so many differences between the reaction with $SbCl_5$–I_2 and that with ICl, though the selectivity is slightly higher in the case of the $SbCl_5$–I_2 system. The reaction with $SbCl_5$–I_2 seems to involve the *in situ* formation of ICl by Eq. 2, followed by the attack of the ICl thus formed on olefins. Here, iodine monochloride may be activated by the $SbCl_5$ or $SbCl_3$ present in the reaction system to give more polarized species, as has been clarified in the chloroiodination of acetylenes with the same system.[4b]

Experimental

The GLC analyses were conducted on a Shimadzu 4CMPF apparatus, using Silicone DC QF-1 (1 and 3 m) and EGSS-X (1 m) columns (carrier gas, N_2). The ^1H NMR spectra were recorded with a JEOL MH-100 (100 MHz) and a Varian EM-360 (60 MHz) spectrometer in CCl_4, using TMS as the internal standard. The ^{13}C NMR spectra were recorded in the pulsed Fourier transform mode on a JEOL FX-100 spectrometer operating at 25.15 MHz in $CDCl_3$, using TMS as the internal standard.

Materials. All the starting materials—olefins, $SbCl_5$, $SbCl_3$, $CuCl_2$, I_2, iodine monochloride, and CCl_4—were commercially available and were used without further purification. Chloroiodoalkanes from cyclohexene, vinyl acetate, and 1-hexene were confirmed by a comparison of the ^1H NMR spectra and retention times on GLC with those of authentic samples prepared by the reported method.[2] All the other chloroiodoalkanes were isolated by distillation. Commercial 1-phenylethyl chloride was used as an authentic sample for GLC and ^1H NMR.

Syntheses of Chloroiodoalkanes. A typical experimental procedure and the spectral data and boiling points of the products are shown below.

Chloroiodination of Ethyl Acrylate with Antimony(V) Chloride–Iodine. To a dark brown, homogeneous solution of $SbCl_5$ (7.5 g, 25 mmol) and I_2 (6.3 g, 25 mmol) in CCl_4 (100 ml), ethyl acrylate (5.0 g, 50 mmol) was added, drop by drop, at the reflux temperature over a 10-min period, during which the color of the solution turned to purple. After stirring for 1 h, the reaction mixture was treated with water, and the white-to-pale yellow inorganic precipitate thus formed was removed by filtration. The CCl_4 layer was separated from the aqueous one, washed with aq $Na_2S_2O_3$, and dried over Na_2SO_4, and the solvent was evaporated. A liquid fraction boiling at 105 °C/20 mmHg (11.2 g) was collected; it consisted of ethyl 3-chloro-2-iodopropionate(I) and ethyl 2-chloro-3-iodopropionate(II) (I:II=82:18). The structural determination was carried out by means of ^1H and ^{13}C NMR and elemental analysis, while the isomer ratio was determined by ^{13}C NMR by comparing the peak intensities of the ethyl-group carbons of the two compounds. Found: C, 23.10; H, 2.89%. Calcd for $C_5H_8O_2ClI$: C, 22.88; H, 3.07%. ^1H NMR (CCl_4): δ 1.3 (t, 3H), 3.25—4.80 (m, 5H). ^{13}C NMR ($CDCl_3$): δ for I, 13.6 ($\underline{CH_3}$,

q), 16.9 (CHI, d), 44.7 (CH_2Cl, t), 62.1 (OCH_2, t), 168.7 (CO_2, s); δ for II, 2.5 (CH_2I, t), 13.9 (CH_3, q), 54.8 (CHCl, d), 62.4 (OCH_2, t), 168.7 (CO_2, s).

Methyl 3-Chloro-2-iodobutanoate(I) and Methyl 2-Chloro-3-iodobutanoate(II). Bp of I, 63—66 °C/3 mmHg. ^{1}H NMR of I (CCl_4): δ 1.7—1.9 (m, 3H), 3.73 (s, 3H), 4.17—4.45 (m, 2H). ^{13}C NMR ($CDCl_3$): δ for I, 24.6 (CH_3, q), 26.4 (CHI, d), 52.9 (OCH_3, q), 56.1 (CHCl, d), 169.4 (CO_2, s); δ for II, 22.1 (CHI, d), 24.6 (CH_3, q), 52.9 (OCH_3, q), 61.9 (CHCl, d), 169.4 (CO_2, s). Found: C, 23.17; H, 3.05%. Calcd for $C_5H_8O_2ClI$: C, 22.88; H, 3.07%.

3-Chloro-2-iodopropionitrile. Bp 95 °C/10 mmHg. ^{1}H NMR ($CDCl_3$): δ 3.87 (d, 1H, CH_2Cl), 3.90 (d, 1H, CH_2Cl), 4.52 (dd, 1H, CHI). ^{13}C NMR ($CDCl_3$): δ −5.4 (CHI, d), 45.2 (CH_2Cl, t), 116.9 (CN, s).

3-Chloro-2-iodo-2-methylpropionitrile(I) and 2-Chloro-3-iodo-2-methylpropionitrile(II). Bp of a mixture of I and II (I:II=80:20 by GLC), 40—44 °C/5 mmHg. ^{1}H NMR (CCl_4): δ 2.08 (s, CH_3 for II), 2.30 (s, CH_3 for I), 3.62 and 3.81 (d, J=10 Hz, CH_2 for II), 3.86 and 4.14 (d, J=12 Hz, CH_2 for I). ^{13}C NMR ($CDCl_3$): δ for I, 13.2 (s, quarternary C), 30.7 (q, CH_3), 52.9 (t, CH_2Cl), 119.8 (s, CN); δ for II, 11.7 (t, CH_2I), 30.0 (q, CH_3), 68.2 (s, quarternary C), 117.4 (s, CN).

Diethyl threo- *and* erythro-*2-chloro-3-iodosuccinate.* *threo*-Isomer: Bp 84 °C/3 mmHg. ^{1}H NMR (CCl_4): δ 1.3 (t, 6H), 4.18 (q, 4H), 4.4 (d, 1H), 4.8 (d, 1H). *erythro*-Isomer: Bp 100 °C/2 mmHg. ^{1}H NMR (CCl_4): δ 1.27 (t, 3H, CH_3), 1.30 (t, 3H, CH_3), 4.27 (q, 2H, CH_2), 4.30 (q, 2H, CH_2), 4.60—4.70 (m, 2H, CHCl and CHI).

(1-Chloro-2-iodoethyl)benzene. To a brown solution of iodine monochloride (4.05 g, 25 mmol) in CCl_4 (70 ml), we added styrene (2.61 g, 25 mmol) at 20 °C, after which the mixture was stirred for 2 h. After a usual work-up procedure, distillation afforded the product; 5.3 g (79% yield); bp 113 °C/6 mmHg, mp 41 °C (lit,[6] mp 46 °C). ^{1}H NMR ($CDCl_3$): δ 3.67 (d, 1H, CH_2I), 3.69 (d, 1H, CH_2I), 5.00 (dd, 1H, CHCl), 7.3 (m, 5H).

(Received October 16, 1979)

Attempts have been made to elucidate the mechanism for the efficient production of phenyl benzoate, the geminate product, from direct and singlet sensitized irradiations of dibenzoyl peroxide in solution. It is concluded that these irradiations produce a reactive state of the peroxide which can undergo two-bond cleavage of the O–O and C(α)–C(carbonyl) bonds to give a phenyl–benzoyloxy radical pair in a solvent cage, followed by the recombination of the component radicals to give the geminate product or by their diffusion out of the solvent cage to give diffusion products.

Although direct or aromatic hydrocarbon-sensitized photolysis[1-8] of dibenzoyl peroxide (BPO) has been shown to proceed through the singlet excited pathway,[9-15] some aspects of the reaction remain uncertain. Previously we reported[10] that direct photolysis and singlet sensitized decomposition of BPO give a noticeable amount of phenyl benzoate in contrast with triplet sensitization[4,8,16] and thermal decomposition[17,18] which give only a low yield of the ester. It has been shown that phenyl benzoate arises from the geminate recombination of benzoyloxy radicals and phenyl radicals on the basis of its noticeable formation from photolysis of BPO in toluene, *p*-xylene, and chlorobenzene[5] as well as CIDNP results.[11-15]

The efficient formation of the geminate product in the photolysis of BPO cannot be accounted for by the usual cleavage of the peroxide bond to give a pair of benzoyloxy radicals as results from thermolysis,[17,18] because benzoyloxy radicals decarboxylate too slowly[19] to afford a benzoyloxy–phenyl radical pair within the lifetime of the primary solvent-cage. The noticeable formation of the geminate product can be explained by a mechanism in which a significant fraction of excited peroxide molecules decomposes by either concerted or unusually rapid stepwise cleavage of the O–O and C(α)–C(carbonyl) bonds to give benzoyloxy–phenyl radical pairs followed by the cage recombination (Eq. 1).[3,8,20]

$$(PhCO_2)_2 \xrightarrow{h\nu} \overline{PhCO_2\cdot + \cdot OCOPh} \quad \overline{PhCO_2\cdot + Ph\cdot + CO_2} \rightarrow PhCO_2Ph \qquad (1)$$

Lemaire's group[8] investigated direct photolysis of BPO in solution, particularly in view of wavelength dependence of its quantum yield, and postulated that benzoyloxy radicals would be formed in the vibrationally excited state on 313-nm light irradiation, and that irradiation with shorter wavelength light would directly generate phenyl radicals which, in high concentrations of BPO, might attack the peroxide to give phenyl benzoate and benzoyloxy radicals.

On the other hand, McBride *et al.*,[21] by ESR spectroscopic investigation, reported that UV-irradiation of crystalline acetyl benzoyl peroxide at 64 K gave benzoyloxy–methyl radical pairs, and that subsequent irradiation with visible light led to the decarboxylation of the benzoyloxy radicals to give phenyl–methyl radical pairs, with the highest efficiency on irradiation with 750-nm light. The photo-induced decarboxylation of benzoyloxy radicals could explain the noticeable formation of phenyl benzoate in the photolysis of BPO.

In the present paper we report some features of the photolysis of BPO and attempts to elucidate the mechanisms for the formation of the geminate product. The present results will show that the simultaneous two-bond cleavage plays an important role in the noticeable formation of the geminate product, and that concurrent irradiation of visible light does not remarkably contribute to the formation of the geminate product.

Results

Thermal and Photochemical Decomposition of Substituted Dibenzoyl Peroxides. Dibenzoyl, bis(4-methoxybenzoyl), bis(4-methylbenzoyl), and bis(4-chlorobenzoyl) peroxides ($ArCO_2OCOAr$, 0.03 M) were thermally decomposed at 80, 90, and 100 °C and photolyzed at room temperature without any sensitizer in benzene and with chrysene (0.002 M) as a singlet sensitizer in benzene until the peroxides were completely decomposed. The resulting geminate products, $ArCO_2Ar$, were determined by GLPC analysis. The results are summarized in Table 1.[22]

CIDNP in Photolysis of BPO. In order to clearly observe a CIDNP spectrum due to the geminate product, deuterated BPO was employed to eliminate

Table 1. Yield of substituted phenyl benzoates in thermal and photochemical decompositions of bis(4-substituted benzoyl) peroxides

Mode of decomposition	Yield of substituted phenyl benzoate, $ArCO_2Ar$ (mol/mol-peroxide)			
	Ar = $MeOC_6H_4$	MeC_6H_4	C_6H_5	ClC_6H_4
Direct photolysis	0.047	0.072	0.13	0.074

Thermolysis at 90 °C	0.011	0.006	0.023	0.004
Thermolysis at 100 °C	0.010	0.007	0.025	0.006

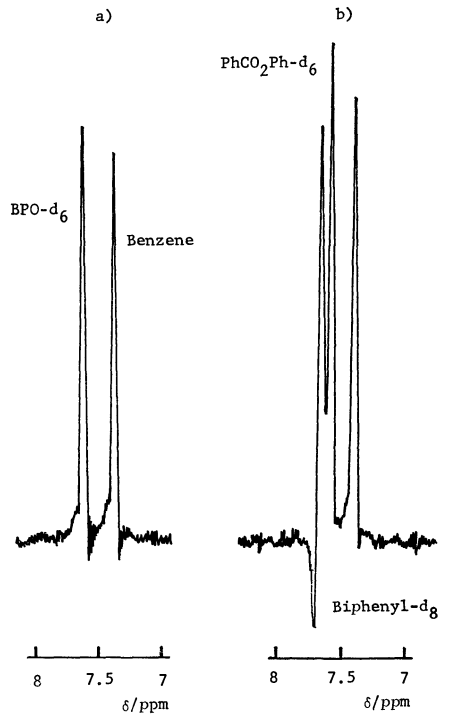

Fig. 1. CIDNP spectrum of BPO-d_6 in benzene-d_6 before irradiation (a) and during irradiation (b).

nuclear spin-spin couplings between aromatic ring protons and lengthen spin-lattice relaxation times of the products. When BPO-2,2′,4,4′,6,6′-d_6 was photolyzed in benzene-d_6 at room temperature with a 1 kW high pressure mercury lamp in the probe of an NMR spectrometer, a very clear polarized spectrum was observed as shown in Fig. 1. The enhanced absorption represents the meta protons on the phenoxyl segment of the geminate product, phenyl-2,4,6-d_3 benzoate-2,4,6-d_3, and the emission is assigned to biphenyl-2,2′,3,4,4′,5,6,6′-d_8. Irradiation of a solution of BPO-d_6 in the presence of naphthalene or chrysene in benzene-d_6 gave the same polarized NMR spectrum as the direct irradiation.

Sensitized Decomposition of BPO in the Presence of a Radical Scavenger. BPO (0.02 M) was irradiated with 366-nm light at room temperature in a mixed solvent consisting of varying fractions of styrene and benzene in the presence of chrysene (0.002 M) as a singlet sensitizer until the peroxide was completely decomposed (3.75 h). The yields of phenyl benzoate were determined by GLPC analysis to be 0.10, 0.10, 0.07, and 0.09 mol per 1 mol of the peroxide at the concentrations of styrene in 0, 1.74, 4.35, and 6.09 M, respectively.

Trapping of Carbon Dioxide in Thermal and Photochemical Decompositions of BPO in the Presence of a Radical Scavenger. In a mixture of varying fractions of benzene and styrene, BPO (0.02 M) was thermally decomposed at 80 °C and photolyzed at room temperature with a 400 W high pressure mercury lamp through a Pyrex wall. The resulting carbon dioxide was absorbed with an Ascarite tube and determined by gravimetry. The results are depicted in Fig. 2. The yields of carbon dioxide were suppressed to approach limiting values

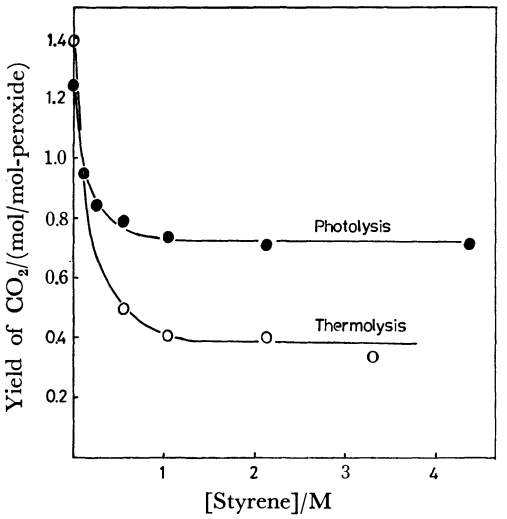

Fig. 2. Change of carbon dioxide yield in thermolysis and photolysis of BPO with concentration of styrene in benzene.

as the fraction of styrene increased in both photolysis and thermolysis. The limiting yields, however, are different between the photolysis (*ca.* 0.7 mol per 1 mol of the peroxide) and the thermolysis (*ca.* 0.3 mol).

Spin Trapping in Decomposition of BPO. When a solution of BPO (0.01 M) in benzene containing *N*-benzylidene-*t*-butylamine oxide (0.1 M) was irradiated in the cavity of an ESR spectrometer at room temperature with a 400 W high pressure mercury lamp for several minutes, signals due to both of the benzoyloxy spin adduct, *N*-*t*-butyl-α-benzoyloxybenzylaminyloxyl ($PhCO_2$–SA, a_N=14.0 G),[23] and the phenyl spin adduct, *N*-*t*-butyldiphenylmethanaminyloxyl (Ph-SA, a_N=15.5 G),[23] were observed in the ESR spectrum. The ratio of these spin adducts, $PhCO_2$–SA/Ph–SA, was determined to be *ca.* 5.6. This value was not varied with irradiation time (5—10 min). On the other hand, heating of a benzene solution of the same composition as above at 40 °C for 8 min gave only the signals due to the benzoyloxy spin adduct.

Effects of Singlet Excitation Energy of Sensitizers on the Geminate Product Yield. BPO (0.03 M) was irradiated in benzene at room temperature in the presence of aromatic hydrocarbons (1.3×10^{-4}—1.8×10^{-2} M) as sensitizers with a 1 kW high pressure mercury lamp through a Pyrex wall. The concentrations of the sensitizers were chosen so that the sensitizers absorbed more than 95% of incident light at 313 nm. Table 2 summarizes the yields of the products determined by GLPC analysis. The yield of phenyl benzoate tends to increase with increasing singlet excitation energy of the sensitizers.

Effects of Longer Wavelength Light on the Product Yields. In order to explore the contribution of the light-induced decarboxylation of benzoyloxy radicals to the formation of the geminate and diffusion products, in the course of the thermal decomposition, UV-irradiation, and nitrogen laser irradiation of BPO (0.03 M) in benzene, the solutions were concurrently irradiated with light of wavelengths longer than 400 nm. In this wavelength region neither BPO nor chrysene has

Table 2. Yields of products in hydrocarbon-sensitized photolysis of dibenzoyl peroxide (0.03 M) in benzene[a)]

Sensitizer	Singlet excitation energy of sensitizer[b)] /kcal mol^{-1}	Concentration of sensitizer /M	Yield (mol/mol-peroxide)

0.68	0.17	0.45	0.37
1	0.14	0.45	0.30

any absorption band. Table 3 summarizes the yields of the products determined by GLPC analysis. The yield of biphenyl seems to be increased by irradiation of the longer wavelength light; however, no remarkable effects on the yield of phenyl benzoate are observed.

Effects of Light Intensity on the Product Yields. BPO (0.03 M) in benzene was irradiated with 313-nm light of varying intensity. The yields of the products determined by GLPC analysis are summarized in Table 4, which shows that the increase of light intensity in nearly five times does not remarkably affect the distribution of the products, although the yields of phenyl benzoate and benzoic acid tend to be slightly reduced with increasing light intensity.

In order to investigate the effect of strong laser pulses on the geminate product formation, an equimolar mixture of BPO (0.015 M) and deuterated BPO, $(C_6D_5CO_2)_2$, (0.015 M) was irradiated in toluene with chrysene with a nitrogen laser at room temperature. Mass spectrometric examination of the resulting ester showed that only the undeuterated ester, $C_6H_5CO_2C_6H_5$, and the ester deuterated on both of the aromatic rings, $C_6D_5CO_2C_6D_5$, were produced but even a trace amount of the ester with one deuterated aromatic ring, $C_6D_5CO_2C_6H_5$ or $C_6H_5CO_2C_6D_5$, was not produced.

Discussion

Production of phenyl benzoate from decomposition of dibenzoyl peroxide (BPO) in solutions under nitrogen remains in a low yield from thermolysis[17,18] but is noticeable from direct and singlet sensitized photolyses.[2,5,7,10] As Table 1 indicates, substituted dibenzoyl peroxides behave like unsubstituted BPO. Thus, the former peroxides also gave geminate products in higher yields in photolyses than in thermolyses. These findings suggest that the direct and singlet sensitized photolyses effectively produce benzoyloxy–phenyl radical pairs to give phenyl benzoate.

Formation of phenyl benzoate as the geminate product is further confirmed by the effect of styrene and CIDNP. As described above, increasing fractions of styrene added in the photolyzing system did not show any significant effect on the yield of phenyl benzoate. In addition, in CIDNP (Fig. 1), the sharp enhanced absorption due to the meta protons on the phenoxyl segment of the resulting phenyl-d_3 benzoate-d_3 indicates that the polarization must be due to phenyl-d_3 radicals which have escaped from the initial polarizing cage and retained some polarization through their recombination with benzoyloxy radicals.[13] This observation accords well with the prediction by Kaptein's[24] and Closs's[25] rules applied to the polarizing pair of benzoyloxy and phenyl radicals.

The effect of styrene and a spin trap revealed the effective decarboxylation taking place during the pho-

tolysis. Figure 2 indicates that as the fraction of styrene increases, the production of carbon dioxide is rapidly suppressed to approach limiting yields in both photolysis and thermolysis. The limiting yield is much higher in the photolysis (*ca.* 0.7 mol per 1 mol of the peroxide) than in the thermolysis (*ca.* 0.3 mol).

On decomposition of BPO in the presence of the spin trap, *N*-benzylidene-*t*-butylamine oxide, both phenyl spin adduct and benzoyloxy spin adduct were obtained in the photolysis in a ratio of 1:5.6, whereas only the benzoyloxy spin adduct was obtained in the thermolysis. The extent of the decarboxylation under spin trapping conditions is estimated to be $1/(1+5.6)=15\%$ and this figure is lower than that estimated from scavenging by styrene to measure carbon dioxide, $0.71/2=35\%$. This difference probably reflects the different ability between styrene and the nitrone to trap benzoyloxy radicals.

From the results mentioned above, it is obvious that the photolysis of BPO produces certain amounts of phenyl radicals and carbon dioxide without the intervention of benzoyloxy radicals of usual lifetimes which would be effectively scavenged by styrene or the spin trap. For the efficient formation of the benzoyloxy–phenyl radical pairs the following three possibilities can be envisaged.

The first possibility is a simultaneous two-bond cleavage of the peroxide in which the singlet excitation energy will be converted to vibrational energy enough to break both the oxygen-oxygen and carbon(α)-carbon(carbonyl) bonds giving simultaneously a benzoyloxy radical, a phenyl radical, and a carbon dioxide molecule (one-photon simultaneous process, Eq. 2). Direct excitation and excited singlet sensitizers seem to provide sufficient energies for the peroxide bond cleavage and the decarboxylation of benzoyloxy radicals in the thermal processes, *ca.* 31[26] and 13[19] kcal mol^{-1}, respectively.

The second possibility is a rapid successive two-bond cleavage in which the photolysis gives vibrationally[8] or electronically excited benzoyloxy radicals followed by their rapid decarboxylation within the lifetime of the solvent cage (one-photon successive process, Eq. 3).

A two-photon process is the third possibility where benzoyloxy radicals once formed are excited by continuing irradiation and decarboxylate within the lifetime of the solvent cage (two-photon successive process, Eq. 4).

$$\mathrm{PhCO_2OCOPh} \xrightarrow{h\nu} \overline{\mathrm{PhCO_2\cdot + CO_2 + Ph\cdot}} \quad (2)$$

$$\mathrm{PhCO_2OCOPh} \xrightarrow{h\nu} \overline{\mathrm{(PhCO_2\cdot)^* + PhCO_2\cdot}} \longrightarrow \overline{\mathrm{Ph\cdot + CO_2 + PhCO_2\cdot}} \quad (3)$$

$$\mathrm{PhCO_2OCOPh} \xrightarrow{h\nu} \overline{\mathrm{PhCO_2\cdot + PhCO_2\cdot}} \xrightarrow{h\nu} \overline{\mathrm{(PhCO_2\cdot)^* + PhCO_2\cdot}} \longrightarrow \overline{\mathrm{Ph\cdot + CO_2 + PhCO_2\cdot}} \quad (4)$$

In the singlet sensitization, the singlet excited hydrocarbon molecule will interact with the peroxide molecule to give a reactive exciplex.[9,10] In this exciplex the singlet excitation energy of the hydrocarbon moiety would be converted to the vibrational energy of the complex to cause the cleavage of the peroxide moiety into free radicals. Table 2 shows that the yield of phenyl benzoate tends to increase with increasing singlet excitation energy of the sensitizers. This result suggests that, on formation of the reactive exciplex, the higher the singlet excitation energy of the sensitizer, the more efficient the cleavage of both of the oxygen-oxygen and carbon-carbon bonds of BPO to give the geminate product.

Table 3 indicates that the concurrent irradiation with a tungsten-bromine lamp, which was used to increase light intensity in the visible region, gives no pronounced effect on the product distribution, although it seemingly enhances the formation of biphenyl in both photolysis and thermolysis. Consequently, under the present experimental conditions, the visible light illumination does not significantly accelerate the decomposition of benzoyloxy radicals in contrast with the reported results for crystalline acetyl benzoyl peroxide.[21]

Concurrent illumination of a tungsten-bromine lamp on the samples irradiated by a nitrogen laser was undertaken for the following intention. Thus, under laser irradiation, the excited peroxide molecules undergo decomposition almost during the nanosecond duration of the pulse, and the resulting benzoyloxy radicals would decarboxylate during the "dark period" of nearly 10 ms before the next pulse irradiation. Accordingly, the concurrent irradiation with a tungsten-bromine lamp could act during the "dark period" on the free radicals. However, as Table 3 indicates, the tungsten-bromine lamp was not effective to induce the decarboxylation of benzoyloxy radicals.

Furthermore, Table 4 shows that on irradiation at 313 nm the increase of light intensity in nearly five times does not remarkably affect the distribution of the products, although the yields of phenyl benzoate and benzoic acid tend to be slightly reduced with increasing light intensity. This finding suggests that 313-nm light also does not significantly induce the decarboxylation of benzoyloxy radicals.

On laser irradiation, it would be expected that the laser pulses, which supply 10^6—10^7 times as many photons as a 1 kW high pressure mercury lamp in a unit time, would transiently generate high concentrations of free radicals, and hence benzoyloxy and phenyl radicals diffused from the different initial solvent cages would combine to give phenyl benzoate as a diffusion product in addition to the geminate product. However, chrysene-sensitized laser irradiation of an equimolar mixture of BPO and BPO-d_{10} in toluene gave no diffusion products, $C_6H_5CO_2C_6D_5$ and C_6D_5-$CO_2C_6H_5$, but gave only a mixture of the geminate products, $C_6H_5CO_2C_6H_5$ and $C_6D_5CO_2C_6D_5$. This result shows that even on irradiation with light of strong intensity benzoyloxy–phenyl radical pairs effectively result in the geminate product, and that the radicals escaped from the solvent cage undergo decomposition or reactions with the solvent before they would randomly combine to give phenyl benzoate.

Therefore it is reasonable to conclude that in the decomposition of BPO from its excited singlet state,

the one-photon simultaneous (Eq. 2) or successive two-bond cleavage (Eq. 3) mainly contributes to the efficient formation of the benzoyloxy–phenyl radical pairs leading to the noticeable formation of the geminate product, and that the contribution of the two-photon process involving the light-induced decarboxylation of benzoyloxy radicals (Eq. 4) would be negligible.

Finally, it should be mentioned that both of the direct irradiation and singlet sensitized irradiation of BPO give nearly the same distribution of the products, suggesting that both photolytic reactions will proceed through the same reactive state of the peroxide. On direct photolysis, the initially produced (Franck-Condon-state), electronically excited peroxide molecule would relax into a reactive state which can dissociate at both of the O–O and C–C bonds. In the singlet sensitization, however, the singlet excited sensitizers do not have sufficient energies to be transferred to give electronically excited peroxide molecules as produced on direct photolysis. Consequently, the excited sensitizer molecules would complex with ground-state peroxide molecules to give reactive exciplexes, in which the electronic excitation energy would be relaxed through vibrational energy probably leading the peroxide moiety to the same reactive state as produced on direct photolysis.

Experimental

Materials. Dibenzoyl peroxide-2,2′,4,4′,6,6′-d_6, dibenzoyl peroxide-2,2′,3,3′,4,4′,5,5′,6,6′-d_{10}, bis(4-chlorobenzoyl), bis(4-methylbenzoyl), and bis(4-methoxybenzoyl) peroxides were prepared from the corresponding acyl chlorides and sodium peroxide, and recrystallized from dichloromethane-methanol. Dibenzoyl peroxide commercially obtained was purified similarly. Benzoyl-2,4,6-d_3 chloride was prepared in the following manner. A mixture of anilinium chloride and deuterated water was refluxed, and the anilinium salt was recovered. This process was repeated three times. Anilinium-2,4,6-d_3 chloride obtained was converted to benzonitrile-2,4,6-d_3 by the Sandmeyer reaction, and its hydrolysis and chlorination gave benzoyl-2,4,6-d_3 chloride. Other substituted benzoyl chlorides were prepared from the corresponding, commercially purchased acids in a usual manner. Aromatic hydrocarbons used as singlet sensitizers were purified by column chromatography and crystallization. Benzene and styrene were purified by distillation. Phenyl-2,4,6-d_3 benzoate-2,4,6-d_3 was prepared by irradiation of BPO-d_6 in carbon tetrachloride in the presence of naphthalene.

Photolysis. A solution of a peroxide (0.03 M) in benzene (3 ml) in a Pyrex tube was degassed by the usual freeze-thaw cycles or deaerated by bubbling of nitrogen, and irradiated by a 400 W or a 1 kW high pressure mercury lamp immersed in a Pyrex cooling well or furthermore surrounded by Toshiba UV-D36B glass filters when chrysene (0.002 M) was used as a sensitizer using a merry-go-round type Riko Rotary Photochemical Reactor, Model RH400-10W. Irradiation was continued for five times the half-life periods of the peroxide determined by iodometric analysis under the same conditions.

Thermolysis. A solution of a peroxide (0.03 M) in benzene (3 ml) in a Pyrex tube was degassed by the usual freeze-thaw cycles and heated in an air bath constantly maintained at 80, 90, and 100 °C for five times the half-life periods. The reaction times were chosen according to the reported decomposition rate constants of peroxides.[27]

Product Analyses. Phenyl benzoate, substituted phenyl benzoates, biphenyl, and benzoic acid were determined by GLPC analysis on a Shimadzu GC 4CM gas chromatograph equipped with a flame ionization detector. The following columns were used for quantitative analyses: Diethylene glycol succinate (5%) with H_3PO_4 (2%), Polyethylene Glycol 20 M (5%), and Silicone GE SE-30 (2%). Carbon dioxide was determined gravimetrically using an Ascarite tube.

Irradiation by a Tungsten-bromine Lamp during Thermolysis and Photolysis. A solution of BPO (0.03 M) in benzene (10 ml) was irradiated under nitrogen atmosphere at room temperature for 3 h by two lamps at the same time, a 1 kW high pressure mercury lamp immersed in a Pyrex cooling well and a 650 W tungsten-bromine lamp (Ushio, Type JCD) through a Toshiba Y-43 glass filter which transmits light longer wavelength than 400 nm.

Thermolysis under illumination of visible light was performed in a water bath kept at 80 °C for 23.75 h, during which the reacting solution was irradiated by the 650 W tungsten-bromine lamp through a water layer and a Toshiba Y-43 glass filter.

Irradiation of 313-nm Light of Varying Intensity. A solution of BPO (0.03 M) in benzene (10 ml) was irradiated under nitrogen atmosphere at room temperature for 11.5—51 h through a filter solution ($NiSO_4 \cdot 7H_2O$, 0.5 g/ml; transmittance, *ca.* 70% at 313 nm) and a Pyrex wall using a 1 kW high pressure mercury lamp. Light intensity was reduced by inserting piled silk cloth between a sample tube and the filter solution. Relative light intensity was calculated from half-life periods determined by iodometry.

CIDNP Measurements and ESR Spectra. CIDNP measurements were performed on a JEOL JNM-PX-100 NMR spectrometer and ESR spectra were recorded on a JEOL JES-ME-1X ESR spectrometer. A 1 kW and a 400 W high pressure mercury lamp were used as light sources in the CIDNP and ESR measurements, respectively.

Laser Photolysis. Nitrogen laser pulses were supplied from a 1 MW (3.5 mJ) Lambda Physik laser pulse generator. A solution of BPO (0.03 M) in benzene (2 ml) containing chrysene (0.006 M) was irradiated by the laser (100 pulses per second). Irradiation was continued for five times the half-life periods determined by iodometry in advance.

Mass Spectrometry. A solution of BPO and BPO-d_{10} (0.015 M, respectively) in toluene (2 ml) containing chrysene (0.006 M) was irradiated by the nitrogen laser. The photolyzed sample was examined by gas chromatography/mass spectrometry (Hitachi RMU-6M GC/MS). The relative intensities of the parent peaks of phenyl benzoate and phenyl-d_5 benzoate-d_5 were found to be different between the ascending part and descending part of the gas chromatographic peak (*e.g.*, 0.7 and 1.6, respectively), but in neither case a peak was detected at *m/e* 203 attributable to phenyl benzoate-d_5 or phenyl-d_5 benzoate.

The authors' thanks are due to Professor K. Maruyama and Dr. T. Otsuki in The University of Kyoto for their kind help in photo-CIDNP measurements. Thanks are also due to the Ministry of Education for their grant to support this research.

Kinetic Studies on the Decomposition of the Most Typical Meisenheimer Complex of Sodium 1,1-Dimethoxy-2,4,6-trinitrocyclohexadienide in Methanol

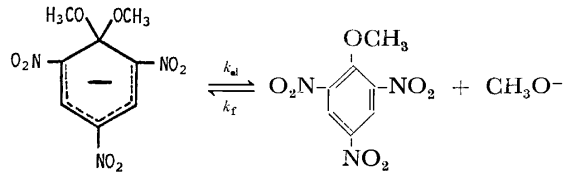
Takehiro Abe

College of General Education, Tohoku University, Kawauchi, Sendai 980

(Received November 1, 1979)

The whole decomposition of the Meisenheimer complex formed from 2,4,6-trinitroanisole (TNA) and sodium methoxide proceeds in three steps and obeys the first-order kinetics in each step. The rate of the whole decrease of concentration of the complex is given by $-d([TNA\cdot CH_3ONa]+[TNA\cdot CH_3O^-])/dt=(k_1[H^+]+k_2[CH_3OH])\times[TNA\cdot CH_3ONa]+(k_3[H^+]+k_4[CH_3OH])\times[TNA\cdot CH_3O^-]-k_5[CH_3O^-]\times[TNA]$, where k denotes a rate constant. This leads to the modification of the conventional unimolecular mechanism shown by $TNA\cdot CH_3O^- \rightarrow TNA+CH_3O^-$.

The decomposition of the most typical Meisenheimer complex (**1**) formed from 2,4,6-trinitroanisole (**2**) and methoxide ion has been widely considered to be unimolecular as follows:[1]



1 **2**

Here k denotes a rate constant. The values of k_d for the decomposition of 1,1-dimethoxy-2,4,6-trinitrocyclohexadienide (**1**) have been directly measured by dissolving appropriate quantities of the sodium or potassium salt of **1** in methanol.[2,3] The value (2.02×10^{-3} s^{-1}) measured by Abe *et al.*[2] for k_d at 25 °C is twice that (1.04×10^{-3} s^{-1}) of Fendler *et al.*[3] An attempt has, therefore, been made to reinvestigate the decomposition of the sodium salt of **1**. This will serve to elucidate the decomposition mechanisms of all the Meisenheimer complexes.

The k_d values have also been indirectly estimated by measuring the apparent pseudo-first-order rate constants (k_{obsd}) for the formation of **1** at various methoxide concentrations much higher than that of **2**, since $k_{obsd}=k_f[CH_3ONa]+k_d$.[3,4] This indirect estimation is, however, unfavorable in obtaining the precise values of k_d, because the estimation leads to noticeable error because of its very small value and **1** associates with cations such as Na^+, K^+, Ba^{2+} and Ca^{2+}.[5-7] At room temperature, the potassium salt of **1** was more easily crystallized from a methanolic solution than the sodium salt of **1**, while the former was less easily dissolved in methanol than the latter. The lithium salt of **1** could not be crystallized from a methanolic solution. The sodium salt of **1** is, therefore, the most appropriate for the present purpose. In comparison with the cases of the potassium salt, the decomposition of the sodium salt of **1** in methanol will be reinvestigated with the help of the results of the decompositions of the sodium salt in buffer solutions and in methanolic solutions containing sodium chloride, crown ether or dimethyl sulfoxide (DMSO).

Experimental

The sodium and potassium salts of **1** were crystallized from methanolic solutions resulting from adding methanolic solutions of sodium and potassium methoxide, respectively, into methanolic solutions of **2**. The IR and NMR spectra of the salts agreed with those of literatures.[1]

The methanolic solutions of the salts showed strong bands at 410—415 nm. The decompositions of the appropriate quantities of the salts in solutions were followed by measuring the absorbances (A) at 420 nm with a Hitachi 100-60 spectrophotometer equipped with a thermostated cell compartment and with a Hitachi 056 recorder (path length, 1.00 cm). In the present work, the rate of decrease of A *vs.* A has been obtained as a decomposition rate in order to discuss the decomposition mechanism easily by the rate of decrease of concentrations of the colored species. The decomposition rate is given by dA/dt which was obtained from a recorded A *vs.* t (time) curve according to $(A_{-\Delta t}-A_{\Delta t})/2\Delta t$. According to the required magnitude of the error in calculating $(A_{-\Delta t}-A_{\Delta t})$, the value of Δt was often taken from 30 s to 5 min in each run. All the linear relationships between the rates and other data were obtained by the least-squares method. All the errors indicated are probable errors with the 50% significance level.

The pH values of buffer solutions (KH_2PO_4–NaOH) of Tokyo Kasei were determined at 20.0 °C with a Hitachi-Horiba pH-meter D-5. Nisso 18-crown-6 (extra pure) was used without further purification.

Results

Decompositions of the Sodium and Potassium Salts of ***1*** *in Methanol.* The rates for four representative runs of decomposition of the sodium salt of **1** are shown in Fig. 1. In each run the rate and absorbance become low with time. The initial concentration of the salt varies with the runs of a, b, c and d. The error in the calculation of dA/dt for $A>1$ is twice that for $A<1$, because the absorbances higher than 1 were recorded on a half-reduced scale. Figure 1 shows that the decomposition of the salt in methanol apparently proceeds in three steps and obeys the first-order kinetics in each step. Of course, the plot of $\ln A$ *vs.* t for each run similarly gave the three first-order rate constants. The rate constants of k_A, k_B, and k_c for the first, second, and third steps, respectively, are listed in Table 1. These constants obtained from the results of six runs were independent of the initial

TABLE 1. APPARENT RATE CONSTANTS OF k_A, k_B, AND k_C FOR THE DECOMPOSITIONS OF SODIUM SALT OF **1** IN METHANOL AND IN THE METHANOL CONTAINING DMSO (25.0 °C)

Mole fraction of DMSO	$k_A/10^{-3}$ s^{-1}	$k_B/10^{-3}$ s^{-1}	$k_C/10^{-3}$ s^{-1}
0	4.2±0.3	1.7±0.1	1.1±0.1
0.0594	2.9±0.2	1.3±0.1	0.83±0.03
0.1243	3.0±0.2	0.83±0.01	0.46±0.03
0.1949	1.3±0.1	0.57±0.03	0.30±0.02

concentrations of the salt whose absorbances were below 2. The values of k_B and k_c correspond to those of Abe *et al.*[2] and of Fendler *et al.*,[3] respectively.

The decomposition of the potassium salt of **1** in methanol gave the similar results to those of the sodium salt. The rate constants (25.0 °C) obtained from four runs for the potassium salt are $k_A=(3.2\pm0.1)\times10^{-3}$ s^{-1}, $k_B=(1.7\pm0.1)\times10^{-3}$ s^{-1} and $k_C=(1.3\pm0.1)\times10^{-3}$ s^{-1}. In this case the initial decreases in absorbance could not be recorded so early as those of the sodium salt, because the potassium salt was not easily dissolved as mentioned above. Therefore, the low value of k_A for the potassium salt compared with that for the sodium salt is not decisive.

Decomposition of the Sodium Salt of ***1*** *in Methanol Containing Sodium Chloride.* The decomposition of the sodium salt of **1** in the methanol containing sodium chloride (1.02×10^{-2} M (1 M=1 mol dm^{-3})) was the same as that of the salt in methanol without sodium chloride. Owing to the poor solubility of sodium chloride in methanol, the concentration of sodium chloride could not be higher than 10^{-2} M. Four runs at 25.0 °C gave $k_A=(4.0\pm0.1)\times10^{-3}$ s^{-1}, $k_B=(1.8\pm0.1)\times10^{-3}$ s^{-1} and $k_C=(1.2\pm0.1)\times10^{-3}$ s^{-1}.

From the ln A—t curves of the slow decompositions of the sodium salt of **1** in methanol at *ca.* 5 °C, the molar absorption coefficient of **1** in methanol was roughly estimated as 2.5×10^{4} cm^{-1} mol^{-1} at 420 nm by the extrapolation of the curve to the intercept. By using the coefficient value, the concentrations of the salts in the present study were estimated to be in the order of 10^{-5} M. Accordingly, the concentration of sodium chloride (1.02×10^{-2} M) was very higher than that of the sodium salt of **1**. In comparison with the results of the decomposition of the salt without sodium chloride, the presence of a small amount of sodium ion (1.02×10^{-2} M) does not apparently affect the decomposition of the salt. Fendler *et al.*[8] have, however, reported that the presence of excess sodium or potassium ion (2 M) slightly decreases the rates for the decomposition of **1** in water (pH=10.8).

Decompositions of the Sodium and Potassium Salts of ***1*** *in Buffer Solutions.* Figure 2 shows that all the decompositions of the sodium salt in the buffer solutions apparently proceed in the first and second steps for which the first-order rate constants of k_I and k_{II} can be given, respectively. In the case of the same buffer solution (pH=7.03), k_I and k_{II} were independent of the initial concentrations of the salt. The decomposition of the sodium salt of **1** in the buffer solution (pH=7.03) afforded a yellowish crude substance after evaporation and extraction with diethyl ether. The IR spectrum of the crude substance exhibited the absorption bands corresponding to **2**. The thin-layer chromatography of the diethyl ether solution of the substance showed the presence of **2** and of a trace of picric acid. The picric acid probably resulted from the further

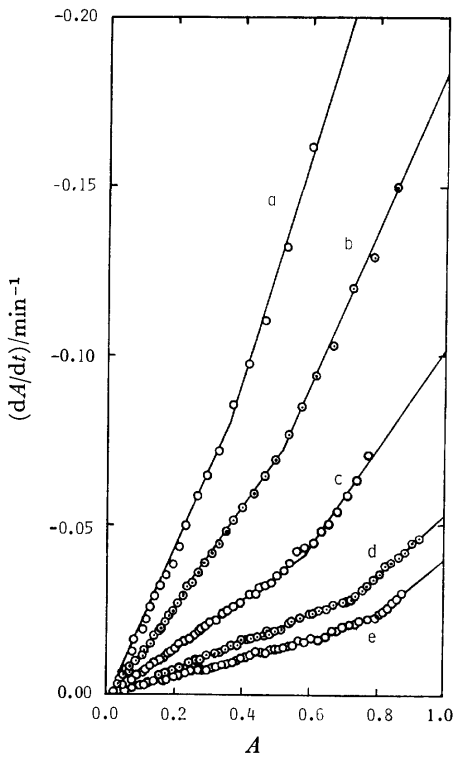

Fig. 2. Plots of dA/dt *vs.* A for the decomposition of the sodium salt of **1** in buffer solutions (20.0 °C).
The values of pH: a; 6.04, b; 6.23, c; 6.61, d; 7.03, e; 7.40.

reaction of **2** with hydroxide ion.[1)]

The decompositions of the potassium salt of **1** in the buffer solutions (pH=6.04, 6.23, and 6.61) gave the values of k_I and k_{II} roughly equal to the corresponding constants for the sodium salt.

Figure 3 shows that there is a linear relationship between k_I and k_{II} as follows:

$$k_I = (8.3\pm0.6) \times 10^{-4}\,s^{-1} + (1.2\pm0.1) \times k_{II}. \quad (1)$$

As shown in Fig. 4, both k_I and k_{II} are linearly proportional to the proton concentration of the buffer solution. The intersections of the straight lines at $[H^+]=0$, *i.e.*, $k_I=(1.2\pm0.1)\times10^{-3}\,s^{-1}$ and $k_{II}=(2.9\pm0.5)\times10^{-4}\,s^{-1}$ mean that the colored species react with not only H^+ but also water molecules (protic solvent molecules). However, even after 30 min the sodium salt of **1** showed the spectra quite identical to the initial ones in the aprotic solvents of DMSO, *N,N*-dimethylformamide, acetonitrile, and acetone. In order to make sure that no decompositions occured prior to records of the initial spectra, conformity to Beer's law was confirmed for the DMSO solution of the sodium salt.

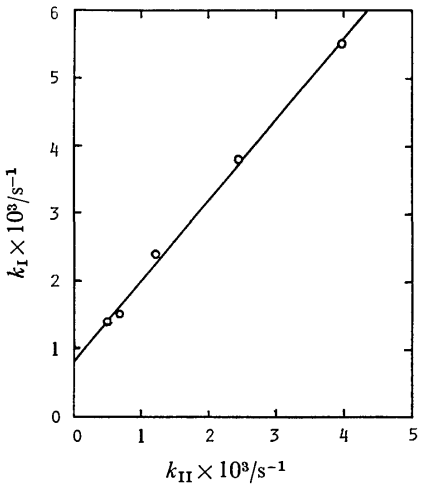

Fig. 3. Correlation of k_I with k_{II} for the sodium salt of **1** (20.0 °C).

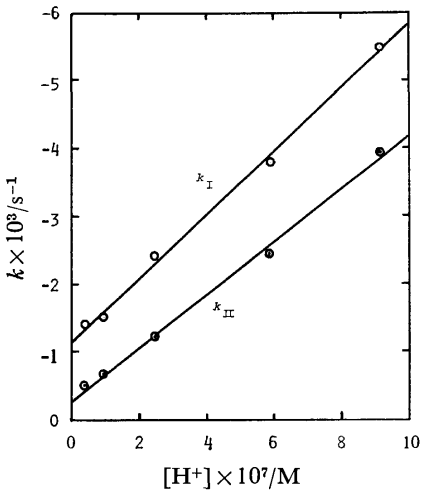

Fig. 4. Correlations of k_I and k_{II} with $[H^+]$ for the sodium salt of **1** (20.0 °C).

In the case of the potassium salt, both k_I and k_{II} were also proportional to $[H^+]$, although there were only three plots for each set of k_I and k_{II}. The plots of k_{II} were roughly similar to those for the sodium salt, while the plots of k_I were considerably scattered because of the hard solubility of the potassium salt.

*Decompositions of Sodium and Potassium Salts of **1** in Methanol Containing Crown Ether.* The sodium salt of **1** was decomposed at 25.0 °C in the methanolic solutions of 18-crown-6 at the concentrations of 4.8×10^{-4}, 2.13×10^{-3}, 6.43×10^{-3}, and 1.37×10^{-2} M. Representative examples for the decomposition rates are shown in Figs. 5 and 6. In the case of 2.13×10^{-3} M the whole decomposition of each run could be divided into three steps in a similar way to that in Fig. 5, while that in the case of 6.43×10^{-3} M was similar to that in Fig. 6. As shown in Fig. 5, the decomposition rates of the second and third steps are high with the decreasing initial concentration of the salt, though the concentration of the crown ether is constant. All the initial decompositions obeyed the first-order kinetics. As shown in Fig. 7, the initial first-order rate constant k_{init} is proportional to the initial concentration of 18-crown-6 ($[18\text{-Crown-6}]_0$).

The decompositions of the potassium salt of **1** in the methanolic solutions of 18-crown-6 at the concentrations of 4.8×10^{-4}, 2.13×10^{-3} and 6.43×10^{-3} M were roughly similar to the corresponding ones for the sodium salt.

*Decompositions of the Sodium Salt of **1** in Methanolic Solutions Containing DMSO.* The sodium salt of **1** was decomposed in the methanolic solutions containing 10, 20, and 30% (v/v) DMSO. Each decom-

The initial concentrations of the salt: a; 2.2×10^{-5} M, b; 3.1×10^{-5} M, c; 6.1×10^{-5} M.

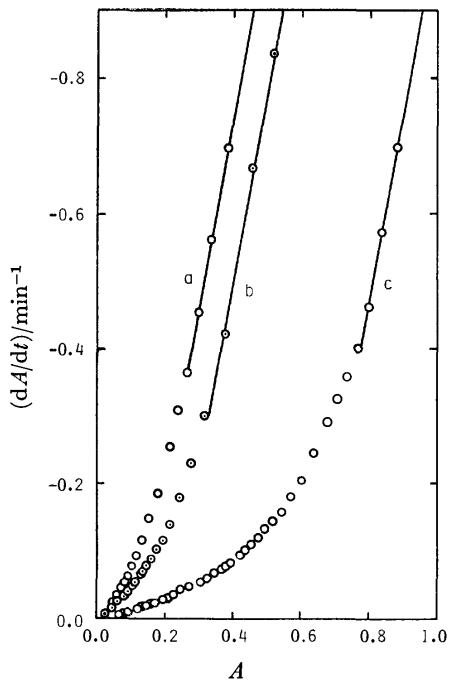

Fig. 6. Plots of dA/dt *vs.* A for the decomposition of the sodium salt of **1** in the methanol containing 18-crown-6 (1.37×10^{-2} M) (25.0 °C).
The initial concentrations of the salt: a; 3.1×10^{-5} M, b; 3.6×10^{-5} M, c; 5.1×10^{-5} M.

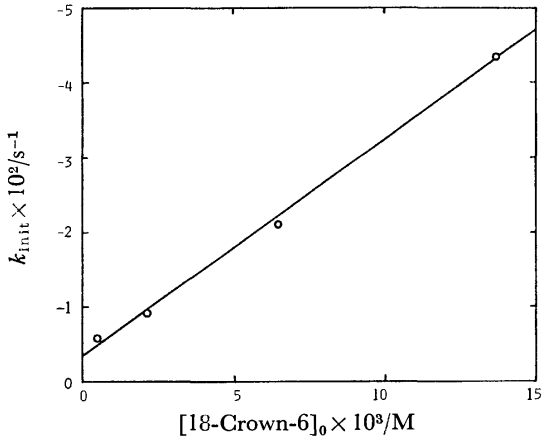

Fig. 7. Correlation of k_{init} with $[18\text{-Crown-6}]_0$ for the sodium salt of **1** (25.0 °C).

position proceeded in three steps like that of the salt in methanol. The apparent rate constants obtained from three or four runs for each DMSO solution are listed in Table 1. The plots of the rate constants against the mole fractions of DMSO (x_{DMSO}) are shown in Fig. 8. There is a linear relationship between the intersections (k_i°) and slopes of the three lines of Fig. 8 as follows:

$$k_i = k_i^\circ + [(1.02\pm0.03)\times10^{-3}\ s^{-1} - (3.02\pm0.01)\times k_i^\circ] \times x_{DMSO} \quad (2)$$

where i=A, B, or C. The term in the bracket on the right hand side of Eq. 2 is the slope of the ith line. Of course, k_i° corresponds to the ith rate constant for the decomposition of the salt in methanol. A

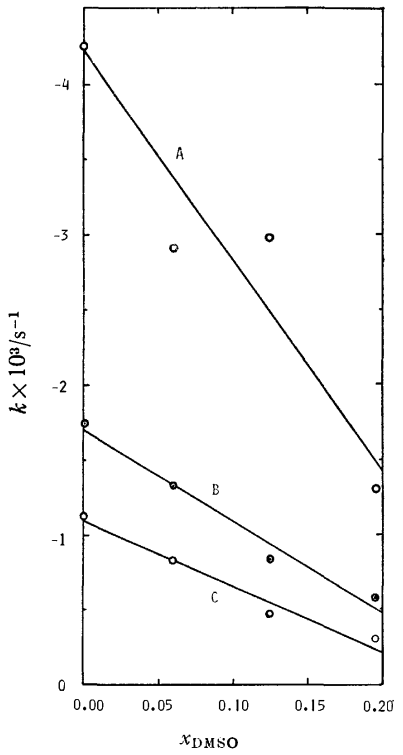

Fig. 8. Correlations of k_A, k_B, and k_C with x_{DMSO} for the sodium salt of **1** (25.0 °C).

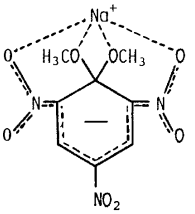
good linear relationship has been found between the logarithmic values of apparent rate constants and x_{DMSO} for the decomposition of **1** in aqueous solutions containing DMSO.[9] In the present case, there was also a good relationship between $\log k_i$ and x_{DMSO}, but the relationship corresponding to Eq. 2 was very poor.

Discussion

According to the crystal structure determination of the potassium salt of **1**,[10] the potassium ion is located close to two oxygen atoms of the C_1–methoxyl groups and to an oxygen atom of the C_2– or C_6–nitro group. Crampton and Khan[5–7,11] have reported the ion-pair (**3**) formed from **1** and its counter ion even in the solution, where the cation is probably held by the four oxygen atoms of the methoxyl groups and *o*-nitro groups.



3

The appearance of the two steps in the decompositions of the salts in the buffer solutions (Fig. 2) needs to be interpreted to be due to the decompositions of both **1** and **3**, because the reformation of Meisenheimer complexes can be neglected in such buffer solutions. From the results of the decomposi-

tions of the salts in the buffer solutions (KH_2PO_4–NaOH), the decomposition mechanism can be written as Scheme 1. Here K denotes an equilibrium constant.

$$\mathbf{3} \overset{K_1^B}{\rightleftharpoons} \mathbf{1} + Na^+ \quad (3)$$

$$\mathbf{3} + H^+ \overset{k_1^B}{\longrightarrow} \mathbf{2} + CH_3OH + Na^+ \quad (4)$$

$$\mathbf{3} + H_2O \overset{k_2^B}{\longrightarrow} \mathbf{2} + CH_3OH + NaOH \quad (5)$$

$$\mathbf{1} + K^+ \overset{K_2^B}{\rightleftharpoons} \mathbf{1}\cdot K^+ \quad (6)$$

$$\mathbf{1}\cdot K^+ + H^+ \overset{k_3^B}{\longrightarrow} \mathbf{2} + CH_3OH + K^+ \quad (7)$$

$$\mathbf{1}\cdot K^+ + H_2O \overset{k_4^B}{\longrightarrow} \mathbf{2} + CH_3OH + KOH \quad (8)$$

$$\mathbf{1} + H^+ \overset{k_5^B}{\longrightarrow} \mathbf{2} + CH_3OH \quad (9)$$

$$\mathbf{1} + H_2O \overset{k_6^B}{\longrightarrow} \mathbf{2} + CH_3OH + OH^- \quad (10)$$

Scheme 1.

The absorbance observed at 420 nm was the sum of those of the colored species in the solution. Scheme 1 gives the rate of the total decrease of concentrations of **1**, **3**, and **1**·K^+ as follows:

$$-\frac{d}{dt}([\mathbf{1}] + [\mathbf{3}] + [\mathbf{1}\cdot K^+]) = (k_1^B[H^+] + k_2^B[H_2O]) \times [\mathbf{3}] + (k_3^B[H^+] + k_4^B[H_2O]) \times [\mathbf{1}\cdot K^+] + (k_5^B[H^+] + k_6^B[H_2O]) \times [\mathbf{1}]. \quad (11)$$

In the buffer solution, $[H^+]$ and $[H_2O]$ are constant. In the present study, the equal molar absorption coefficients are conveniently assumed for all **1**, **3**, and **1**·K^+, as made by Crampton and Khan.[5] Here one assumes the following relations:

$$k_1^B[H^+] + k_2^B[H_2O] = k_5^B[H^+] + k_6^B[H_2O] + \Delta_1$$

$$k_3^B[H^+] + k_4^B[H_2O] = k_5^B[H^+] + k_6^B[H_2O] + \Delta_2$$

where Δ_1 and Δ_2 are constant. Then, Eq. 11 can be written as

$$-\frac{dA}{dt} = \left[(k_5^B[H^+]+k_6^B[H_2O])+\Delta_1 \times \left(1+\frac{K_1^BK_2^B[K^+]}{[Na^+]}+\frac{K_1^B}{[Na^+]}\right)^{-1} + \Delta_2 \times \left(1+\frac{[Na^+]}{K_1^BK_2^B[K^+]}+\frac{1}{K_2^B[K^+]}\right)^{-1}\right] \times A. \quad (12)$$

Since $[Na^+]$ and $[K^+]$ can be assumed to be constant in the same buffer solution, Eq. 12 is reduced to

$$-\frac{dA}{dt} = (k_5^B[H^+]+k_6^B[H_2O]+\Delta_I) \times A, \quad (13)$$

where

$$\Delta_I = \Delta_1 \times \left(1+\frac{K_1^BK_2^B[K^+]}{[Na^+]}+\frac{K_1^B}{[Na^+]}\right)^{-1} + \Delta_2 \times \left(1+\frac{[Na^+]}{K_1^BK_2^B[K^+]}+\frac{1}{K_2^B[K^+]}\right)^{-1}.$$

The value of $[Na^+]$ varies with the pH value of the buffer solution. The contribution of Δ_I is, however, probably small compared with $k_5^B[H^+]$ and $k_6^B[H_2O]$ in Eq. 13, because **1**, **3**, and **1**·K^+ are the same complexes of **1** and both Δ_1 and Δ_2 are probably small. Then, Δ_I may be approximately assumed to be constant for all the buffer solutions. The value of $(k_5^B[H^+]+k_6^B[H_2O]+\Delta_I)$ corresponds to k_I. In the second step (Eqs. 6—10), **3** may vanish in the reaction system. Accordingly, the following final equation can be obtained in the same way as above:

$$-\frac{dA}{dt} = (k_5^B[H^+]+k_6^B[H_2O]+\Delta_{II}) \times A, \quad (14)$$

where Δ_{II} is approximately constant for all the buffer solutions. The value of $(k_5^B[H^+]+k_6^B[H_2O]+\Delta_{II})$ corresponds to k_{II}. Thus, the appearance of the two steps in the decompositions of the sodium salt of **1** in the buffer solutions can be accounted for. The empirical equation 1 may be explained by $k_I=(\Delta_I-\Delta_{II})+k_{II}$. The deviation of the coefficient 1.2 of k_{II} in Eq. 1 from 1 may be due mainly to an experimental error. Equations 13 and 14 show that both k_I and k_{II} should be proportional to the proton concentration in the buffer solution. In Fig. 4 the two straight lines are not completely parallel with each other, but the linear relationship between k_I and k_{II} is found in Fig. 3. The incompletely parallel lines in Fig. 4 seem to be due mainly to the pH dependences of Δ_I and Δ_{II}.

With the help of the results of the decompositions of the salts of **1** in the buffer solutions, the decomposition mechanism of the sodium salt of **1** in methanol can be written as shown in Scheme 2. The formation

$$CH_3OH \overset{K_M}{\rightleftharpoons} CH_3O^- + H^+ \quad (15)$$

$$\mathbf{3} \overset{K_1}{\rightleftharpoons} \mathbf{1} + Na^+ \quad (16)$$

$$\mathbf{3} + H^+ \overset{k_1}{\longrightarrow} \mathbf{2} + CH_3OH + Na^+ \quad (17)$$

$$\mathbf{3} + CH_3OH \overset{k_2}{\longrightarrow} \mathbf{2} + CH_3OH + CH_3ONa \quad (18)$$

$$\mathbf{1} + H^+ \overset{k_3}{\longrightarrow} \mathbf{2} + CH_3OH \quad (19)$$

$$\mathbf{1} + CH_3OH \overset{k_4}{\longrightarrow} \mathbf{2} + CH_3OH + CH_3O^- \quad (20)$$

$$\mathbf{2} + CH_3O^- \overset{k_5}{\longrightarrow} \mathbf{1} \quad (21)$$

Scheme 2.

of **3** from **1** and Na^+ may be essentially neglected, because the effect of the ion pairing has been considered to be small at the cation concentration below 10^{-3} M.[6] In the first and second steps $[CH_3O^-]$ may be neglected, because it is very low in these steps and may be consumed by the carbon dioxide dissolved in the reaction system not degassed. In the reaction system $[H^+]$ may be assumed to be stationary, because the rate of the reaction ($CH_3OH \rightarrow CH_3O^- + H^+$) can be expected to be lower than those of the ionic reactions such as $\mathbf{1}+H^+ \rightarrow \mathbf{2}+CH_3OH$ and $\mathbf{3}+H^+ \rightarrow \mathbf{2}+CH_3OH+Na^+$.

The rate of decrease of concentrations of **1** and **3** for the first step (Eqs. 15—20) is written as

$$-\frac{d}{dt}([\mathbf{1}]+[\mathbf{3}]) = (k_1[H^+]+k_2[CH_3OH])\times[\mathbf{3}] + (k_3[H^+]+k_4[CH_3OH])\times[\mathbf{1}]. \quad (22)$$

Here one writes the following equation:

$$k_3[H^+] + k_4[CH_3OH] = k_1[H^+] + k_2[CH_3OH] + \Delta, \quad (23)$$

where Δ is a constant. Using Eq. 23, one can reduce Eq. 22 to:

$$-\frac{dA}{dt} = (k_1[H^+] + k_2[CH_3OH] + \Delta') \times A, \quad (24)$$

where

$$\Delta' = \Delta \times (1+[Na^+]/K_1)^{-1}. \quad (25)$$

Here Δ' may be approximately constant, because the value of $[Na^+]$ is very small, though it increases with time. Then, k_A corresponds to:

$$k_A = k_1[H^+] + k_2[CH_3OH] + \Delta'. \quad (26)$$

Strictly speaking, Δ' is expected to be high with decreasing initial concentration of the salt, because $[Na^+]$ is low with the decreasing initial concentration. The value of k_A may, therefore, be high to some extent with the decreasing initial concentration. This behavior seems to appear in Fig. 1, since the initial plots for the runs of a and b slope more than the straight lines of k_A, while those of c and d are reverse.

In the second step (Eqs. 15, 19, and 20), **3** may disappear in the reaction system. Accordingly, the rate of decrease of concentration of **1** for this stage may be written as

$$-\frac{d[\mathbf{1}]}{dt} = (k_3[H^+]+k_4[CH_3OH]) \times [\mathbf{1}]. \quad (27)$$

This equation can be reduced to:

$$-\frac{dA}{dt} = (k_3[H^+]+k_4[CH_3OH]) \times A. \quad (28)$$

Then, the rate constant of k_B is written as

$$k_B = k_3[H^+] + k_4[CH_3OH]. \quad (29)$$

In the third step (Eqs. 15 and 19—21), the reverse reaction of formation of **1** may be finally observed, because the final equilibrium absorbances of c and d are more than 0.1 in Fig. 1. From Eq. 29, the value of $k_4[CH_3OH]$ is distinctly smaller than that of k_B (1.7×10^{-3} s^{-1} at 25 °C). On the other hand, the rate constant ($k_5=k_f$) for the formation of **1** is 17.3 s^{-1} M^{-1} at 25 °C.[3] The reaction of Eq. 20 is, therefore, probably much slower than that of Eq. 21 in Scheme 2, since $[CH_3OH]=24.6$ M at 25 °C. Then, $[CH_3O^-]$ may be assumed to be stationary. In the third step, therefore, the decrease of **1** due to the reaction of Eq. 20 may be approximately cancelled out by the reaction of Eq. 21. Accordingly, the rate of decrease of concentration of **1** may be written as

$$-\frac{d[\mathbf{1}]}{dt} = k_3[H^+][\mathbf{1}]. \quad (30)$$

This equation leads to

$$-\frac{dA}{dt} = k_3[H^+]A. \quad (31)$$

From Eq. 31, one obtains

$$k_C = k_3[H^+]. \quad (32)$$

Using the k_d value of Fendler *et al.*,[3] Crampton and Khan[6] have estimated the value of $1/K_1$ as 70 M^{-1} at 25 °C. As Crampton and Khan have described, the value should be regarded as giving the order of magnitude of the association constant rather a precise value. Actually the calculation with the use of 70 M^{-1} leads to the unfavorable result that almost no **3** exists at the initial stage when the sodium salt of **1** is dissolved in methanol at the concentration of 5×10^{-5} M. The precise value of $1/K_1$ will be smaller than 70 M^{-1}. Putting the value of $1/K_1$ smaller than 70 M^{-1} into Eq. 25, one can expect that only the value of k_A among k_A, k_B, and k_C becomes slightly low when the methanolic solution of the sodium salt of **1** contains the sodium chloride at the concentration of 1×10^{-2} M, because Eqs. 29 and 32 contain no $[Na^+]$. Therefore, the experimental results of the effect of sodium chloride on the decomposition of the sodium salt of **1** may be accounted for. Thus, the appearance of the pseudo-first-order rate constants of k_A, k_B, and k_C in the decomposition of the sodium salt of **1** in methanol can be explained by Scheme 2.

The formation of ion-pairs between alkali-polyether cations and anions has been known in an organic phase.[12] In the presence of a small excess of the crown ether, sodium ions have been considered to be taken off from the Meisenheimer complexes of 1,1-dimethoxy-2-methoxycarbonyl-4,6-dinitrocyclohexadienide in methanol.[11] Figure 7 shows that 18-crown-6 decomposes the colored species. Accordingly, the increase in the rate of decrease of concentrations of **1** and **3** in the methanol containing 18-crown-6 seems to be due to the following additional reactions together with those of Scheme 2:

$$Na^+ + \text{18-Crown-6} \rightleftharpoons Na^+\cdot\text{18-Crown-6},$$

$$CH_3O^- + Na^+\cdot\text{18-Crown-6} \rightleftharpoons CH_3O^-\cdot Na^+\cdot\text{18-Crown-6},$$

$$\mathbf{3} + \text{18-Crown-6} \rightleftharpoons \mathbf{1} + Na^+\cdot\text{18-Crown-6},$$

$$\mathbf{3} + \text{18-Crown-6} \longrightarrow \mathbf{2} + CH_3O^-\cdot Na^+\cdot\text{18-Crown-6},$$

$$\mathbf{1} + Na^+\cdot\text{18-Crown-6} \longrightarrow \mathbf{2} + CH_3O^-\cdot Na^+\cdot\text{18-Crown-6}.$$

At the present time, however, the detail of the mechanism for this case can not be discussed.

The pK_a value (27.9[13]) of methanol in DMSO at 25 °C is much larger than the logarithmic value (16.92[14]) of the minus autoprotolysis constant of methanol. Moreover, the activity coefficient of methanol in DMSO–methanol gradually decreases with the increasing mole fraction of DMSO.[15] The empirical equation 2 suggests that DMSO plays the same role in all the steps. Accordingly, the decreases in the apparent rate constants of k_A, k_B, and k_C with the increasing mole fraction of DMSO (Table 1) may be due mainly to the decrease in proton concentration and partly to the decrease in activity coefficient of methanol. The decrease of proton concentration in Eqs. 26, 29, and 32 can explain the decreasing apparent rate constants (Table 1) with the increasing mole fraction of DMSO. Thus, the effects of DMSO on the decomposition of the sodium salt of **1** in DMSO–

methanol can be explained by the mechanism shown in Scheme 2.

In view of the decomposition mechanism of the salt of **1** (Scheme 2), the rate of increase of concentrations of **1** and **3** may be written for the formation of the Meisenheimer complexes from **2** and CH_3ONa in methanol as follows:

$$\frac{d}{dt}([\mathbf{1}]+[\mathbf{3}]) = k_5[CH_3O^-][\mathbf{2}] - \left(k_3[H^+]+k_4[CH_3OH] + \frac{\Delta}{1+K_{-1}[Na^+]}\right) \times ([\mathbf{1}]+[\mathbf{3}]), \quad (33)$$

where K_{-1} is $1/K_1$. As usually made in obtaining the apparent first-order rate constants, one assumes that the initial concentration of sodium methoxide ($[CH_3ONa]_0$) is much higher than that of **2** ($[\mathbf{2}]_0$). Moreover, one assumes that $[CH_3ONa]_0$ is so low that the existence of $[CH_3ONa]$ can be ignored in the methanolic solution. Then, one can write Eq. 33 as

$$\frac{d}{dt}([\mathbf{1}]+[\mathbf{3}]) = \left(k_5[CH_3ONa]_0+k_3[H^+]+k_4[CH_3OH] + \frac{\Delta}{1+K_{-1}[Na^+]}\right) \times \{([\mathbf{1}]_e+[\mathbf{3}]_e)-([\mathbf{1}]+[\mathbf{3}])\}, \quad (34)$$

where the suffix e denotes an equilibrium concentration. Here Δ and $[Na^+]$ may be approximately constant in a methoxide solution, because $[H^+]$ is very low and $[CH_3ONa]_0 \gg [\mathbf{2}]_0$. Moreover, $k_3[H^+]$ may not contribute greatly in the case of the methoxide solution, because the autoprotolysis constant of methanol is very much small.[14] Therefore, the apparent psuedo-first-order rate constant k_{obsd} for the formation of the Meisenheimer complexes in methanol can be related to as follows:

$$k_{obsd} = k_5[CH_3ONa]_0 + k_3[H^+] + k_4[CH_3OH] + \frac{\Delta}{1+K_{-1}[Na^+]}. \quad (35)$$

Among the terms on the right hand side of Eq. 35, the contribution of $k_5[CH_3ONa]_0$ is, of course, the greatest in the case of the methoxide solution. According to Eq. 35, k_{obsd} should be proportional to $[CH_3ONa]_0$. The author obtains the following good linear relationship between k_{obsd} and $[CH_3ONa]_0$ for the data observed by Fendler *et al.*[3] at 410 nm in the range of $[CH_3ONa]_0$ from 1.05×10^{-3} M to 5.45×10^{-3} M:

$$k_{obsd} = (-0.4\pm3.8)\times10^{-3}\ s^{-1} + (18.5\pm1.0)\ s^{-1} \times [CH_3ONa]_0. \quad (36)$$

From Eq. 33, one obtains for the equilibrium state:

$$\frac{1}{[\mathbf{1}]_e+[\mathbf{3}]_e} = \frac{1}{[\mathbf{2}]_0} + \frac{1}{k_5[\mathbf{2}]_0} \times \left(k_3[H^+]_e+k_4[CH_3OH] + \frac{\Delta_e}{1+K_{-1}[Na^+]_e}\right) \times \frac{1}{[CH_3ONa]_0}. \quad (37)$$

Equation 37 shows that the equilibrium absorbance observed at a wavelength should be approximately proportional to $1/[CH_3ONa]_0$. This expectation is verified by using two sets of data[4,16] as shown in Fig. 9. From the intersections of the lines of a and b in Fig. 9, one obtains the values of 2.40×10^4 and $2.86\times10^4\ cm^{-1}\ M^{-1}$, respectively, for the molar extinction coefficient at 410 nm. These values roughly agree with the present coefficient of $2.5\times10^4\ cm^{-1}\ M^{-1}$ at 420 nm.

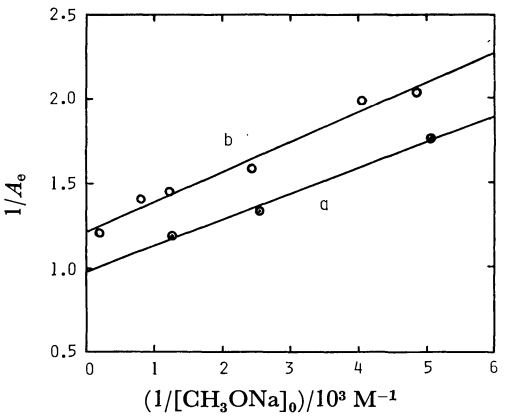


Fig. 9. Correlations of $1/A_e$ with $1/[CH_3ONa]_0$ (25 °C). The data used for the plots of a and b are taken from Refs. 4 and 16, respectively.

In conclusion, the decompositions of the Meisenheimer complexes of **1** and **3** in methanol are not unimolecular, but are due to the proton resulting from the dissociation of methanol and to the protic solvent molecule of methanol as shown in Scheme 2.

Studies on Heterocyclic Analogs of Azulene. VI.[1] Cycloadditions of Styryl-substituted Aza Analogs of Azulene with Dimethyl Acetylenedicarboxylate[2]

Noritaka ABE* and Tarozaemon NISHIWAKI

Department of Chemistry, Faculty of Science, Yamaguchi University, Yamaguchi 753

(Received November 8, 1979)

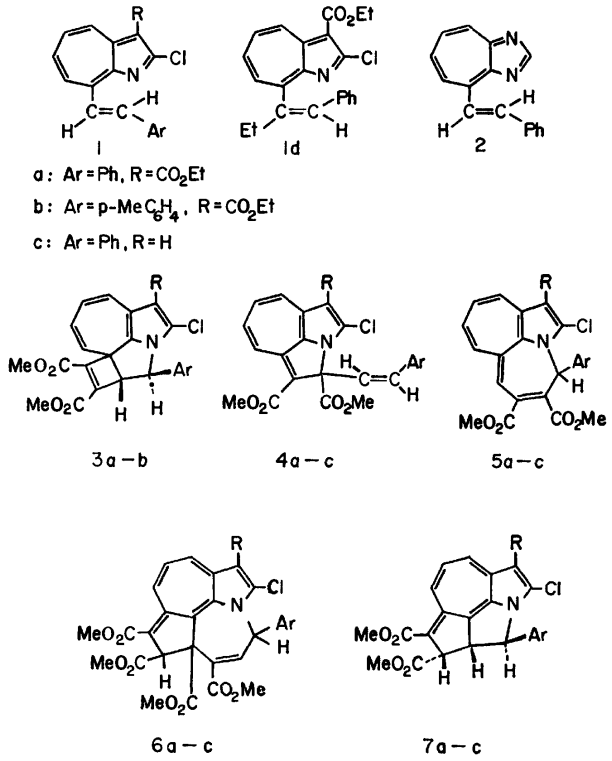
8-[(*E*)-Styryl]-1-azaazulenes stereospecifically react with dimethyl acetylenedicarboxylate to form *trans*-7*H*-6a-azacyclobuta[*j*]cyclopent[*cd*]azulene (**3**), which undergoes thermal rearrangement into 3-[(*E*)-styryl]-3*H*-2a-azacyclopent[*cd*]azulene and 3a,4-dihydro-3*H*-2a-azadicyclopent[*cd, ij*]azulene (**7**), or isomerization into 3*H*-2a-azacyclopenta[*ef*]heptalene by silica gel. Compound **7** is oxidized during the course of reaction to yield 11-oxo-2a*H*-7,10b-methano-2a-azacyclopenta[*ab*]cycloundecene, compound **3** forming 5a,6-dihydro-3*H*-2a-azadicyclopenta[*ef, kl*]heptalene upon reaction with acetylene. The formation of **3** could be accounted for in terms of a symmetry-allowed thermal [$_{\pi}2_{s}+_{\pi}2_{a}+_{\pi}6_{a}$] cycloaddition.

Cycloaddition of nitrogen-heterocycles with alkynes, a versatile synthetic method of heterocycles which are otherwise difficult to obtain,[3] has been utilized recently in the azaazulene[4] and azapentalene ring systems.[5] We report on the cycloaddition of 8-styryl-substituted aza analogs of azulene with dimethyl acetylenedicarboxylate (DMAD).

8-Styryl-1-azaazulenes (**1a**—**d**) and 4-styryl-1,3-diazaazulene (**2**) were prepared by the reaction of the corresponding azaazulene with styrylmagnesium bromide. The (*E*)-configuration about the double bond of compounds **1a**—**c** and **2** follows from the presence of two pairs of 1H doublets at δ 7.5—8.7 (J=17 Hz) in their ^{1}H NMR spectra and an absorption at 970 cm^{-1} in their IR spectra. β-Bromo-β-ethylstyrene required for the preparation of **1d** was synthesized by the decarboxylation of the sodium salt of (*E*)-α,β-dibromo-α-ethylcinnamic acid. The stereochemistry of the styrene thus formed appears to depend on the water content of the solvent.[6] Our conditions (95% ethanol) favor the formation of a (*Z*)-isomer.

Four products were isolated when compound **1a** was heated under reflux with DMAD in benzene. They were characterized as 5-ethyl 8,9-dimethyl 6-chloro-7-phenyl-*trans*-7*H*-6a-azacyclobuta[*j*]cyclopent-[*cd*]azulene-5,8,9-tricarboxylate (**3a**) (24%), 1-ethyl 3,4-dimethyl 2-chloro-3-[(*E*)-styryl]-3*H*-2a-azacyclopent-[*cd*]azulene-1,3,4-tricarboxylate (**4a**) (9%), 1-ethyl 4,5-dimethyl 2-chloro-3-phenyl-3*H*-2a-azacyclopenta[*ef*]-heptalene-1,4,5-tricarboxylate (**5a**) (14%), and 1-ethyl 5,5a,6,7-tetramethyl 2-chloro-3-phenyl-5a,6-dihydro-3*H*-2a-azadicyclopenta[*ef, kl*]heptalene-1,5,5a,6,7-pentacarboxylate (**6a**) (7%), respectively, from consideration of their spectroscopic properties.

The ^{13}C NMR spectrum of **3a** exhibits signals assignable to sp^3 carbon atoms at δ 56.2 (s, C-9a), 61.5 (d, C-7a), and 65.1 ppm (d, C-7). Two 1H doublets (J=2 Hz) assignable to the H-7a and H-7 protons are observed at δ 3.87 and 5.49, respectively, in its ^{1}H NMR spectrum, whereas the protons at the seven-membered ring are observed at δ 5.60 (d, J=11 Hz, H-1), 6.0—6.3 (m, H-2 and H-3), and 7.22 (d, J=11 Hz, H-4). Large downfield shifts of 0.44 (H-7), 0.36 (H-7a), and 0.97 ppm (H-4) induced on addition of tris(dipivaloylmethanato)europium support these assignments. Further evidence supporting the structure **3a** is the fact that its mass spectrum displays intense



peaks at *m/e* 337 and 339 associated with the loss of dimethyl acetylenedicarboxylate or its equivalent from the molecular ion.[7] The $J_{7,7a}$ value indicates the H-7 and H-7a hydrogens to be situated *trans* to each other in the light of J_{cis} (10—13 Hz) and J_{trans} (2—10 Hz) values reported for the vicinal hydrogens of 2-pyrazolines.[8]

Two pairs of doublets at δ 6.0—7.1 (J=16 Hz) in the ^{1}H NMR spectrum of **4a** shows the presence of an (*E*)-styryl moiety, further confirmed by an IR absorption at 980 cm^{-1}, whereas the ^{1}H NMR spectrum of **5a** displays two 1H singlets at δ 5.31 and 6.11; the former is assigned to a benzylic H-3 proton and the latter to an olefinic H-6 proton. The presence of four aromatic protons in the seven-membered rings of **4a** and **5a**, respectively, is evident from their ^{1}H NMR spectra. The UV spectra of **4a** and **5a** are especially instructive for their structural determinations. The spectrum of **4a** is in line with that of 1-ethyl 3,4-dimethyl 2-chloro-3*H*-2a-azacyclopent[*cd*]azulene-1,3,4-

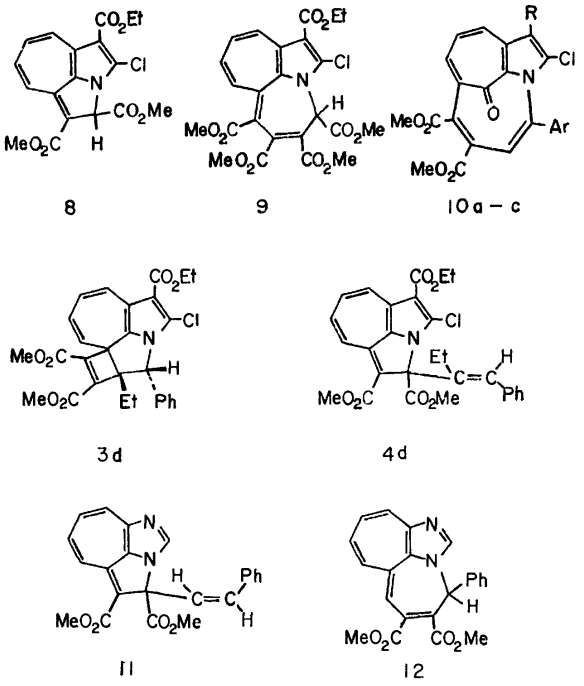
tricarboxylate[4] (**8**) and the spectrum of **5a** is in line with that of 1-ethyl 3,4,5,6-tetramethyl 2-chloro-3*H*-2a-azacyclopenta[*ef*]heptalene-1,3,4,5,6-pentacarboxylate[4] (**9**) except for the presence of additional low-intensity absorptions in the longer wavelength region for **5a**. The ^{13}C NMR spectral features of **4a** and **5a** are also in line with the proposed structures.

The ^1H NMR spectrum of **6a**, 1:2 adduct of **1a** and DMAD, shows the presence of three seven-membered ring protons at δ 6.22 (d, J=6 Hz, H-8), 6.37 (dd, J=10 and 6 Hz, H-9), and 7.39 (d, J=10 Hz, H-10). A singlet at δ 5.71 is assigned to a H-6 proton. There are two pairs of 1H doublets (J=3 Hz) at δ 4.66 and 5.29, the former being assigned to a benzylic H-3 proton and latter to a H-4 one. The ^{13}C NMR spectrum of **6a** exhibits signals assignable to sp^3 carbon atoms at δ 5.60 (s, C-5a), 65.4 (d, C-6), and 68.7 (d, C-3).

Whilst the reaction of **1b** with DMAD in benzene proceeded similarly to produce **3b**, **4b**, **5b**, and **6b**, the reaction of **1c** with DMAD under similar conditions afforded **4c**, **5c**, **6c**, and 4,5-dimethyl 2-chloro-3-phenyl-3a,4-dihydro-3*H*-2a-azadicyclopent[*cd*, *ij*]azulene-4,5-dicarboxylate (**7c**). The seven-membered ring protons of **7c** exhibit signals at δ 6.05 (dd, J=6.5 and 1 Hz, H-6), 6.17 (dd, J=10 and 6.5 Hz, H-7), and 6.84 (d, J=10 Hz, H-8) in its ^1H NMR spectrum. A singlet at δ 6.06 is assignable to a H-1 proton. The H-4 and H-3a protons give rise to the double doublets signals at δ 4.14 (J=8.5 and 1 Hz) and 4.39 (J=8.5 and 2 Hz), respectively. The former shows a long-range coupling with the H-6 proton, and the latter a vicinal coupling with the H-3 proton resonating at δ 5.27 (d, J=2 Hz). The $J_{3,3a}$ value indicates the H-3 and H-3a hydrogens to be situated *trans* to each other in the light of J_{cis} (10—13 Hz) and J_{trans} (2—10 Hz) value reported for the vicinal hydrogens of 2-pyrazolines.[8] The ^{13}C NMR spectrum of **7a** displays sp^3 carbon atoms at δ 42.7 (d, C-3a), 63.0 (d, C-4), and 66.3 (d, C-3).

The reaction of **1a** with DMAD in hot acetonitrile gave a similar result. However, when the reaction was carried out in hot xylene, the yields of the products changed remarkably. Thus, compounds **4a**, **6a**, and **7a** were obtained in 38, 10, and 24% yield, respectively, no compound **3a** being isolated. 1-Ethyl 5,6-dimethyl 2-chloro-3-phenyl-11-oxo-2a*H*-7,10b-methano-2a-azacyclopenta[*ab*]cycloundecene-1,5,6-tricarboxylate (**10a**) was isolated in 6% yield. Compound **10a** was also obtained by the oxidation of **7a** with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone. Its ^1H NMR spectrum displays signals at δ 7.38 (dd, J=11 and 10 Hz, H-9), 8.79 (d, J=11 Hz, H-10), and 9.10 (d, J=10 Hz, H-8) for the seven-membered ring protons. A low-field resonating singlet at δ 7.42 is assignable to H-4 proton. The UV spectrum (λ_{max} 665 nm) suggests the presence of an extended chlomophore, and a ν(C=O) absorption at 1690 cm^{-1} in its IR spectrum the presence of a conjugated ketone. From the results, the structure was assigned.

Application of the forgoing reactions to the azaazulene (**1d**) possessing a (*Z*)-α-ethylstyryl group at C(8) gave a complicated mixture of products among



which the azacyclobuta[*j*]cyclopent[*cd*]azulene (**3d**) and the azacyclopent[*cd*]azulene (**4d**) were identified.

The study was further extended to 4-[(*E*)-styryl]-1,3-diazaazulene (**2**), which gave dimethyl 3-[(*E*)-styryl]-3*H*-1,2a-diazacyclopent[*cd*]azulene-3,4-dicarboxylate (**11**) and dimethyl 3-phenyl-3*H*-1,2a-diazacyclopenta-[*ef*]heptalene-3,4-dicarboxylate (**12**).

The ^1H NMR and ^{13}C NMR spectra of the majority of the compounds are summarized in Tables 1—7.

Mechanistic Discussion. There are two plausible mechanisms leading to the azacyclobuta[*j*]cyclopent-[*cd*]azulene ring system (**3**) from the 8-styryl-1-aza-azulene (**1**): symmetry-allowed thermal [$_\pi 2_s + _\pi 2_a + _\pi 6_a$] cycloaddition,[9] and the thermal [$_\pi 2_s + _\pi 2_a$] cycloaddition of DMAD with **13**, a valence tautomer of **1**, as shown in the scheme. However, the latter is not preferred, since the cyclobutene ring is disposed *trans* toward the five-membered ring and would have a high torsional energy. The experimental results support the first rationale: (i) the ^1H NMR spectrum of **1** lacks a benzylic proton which would be associated with the structure **13**, (ii) the UV spectrum of **1a**

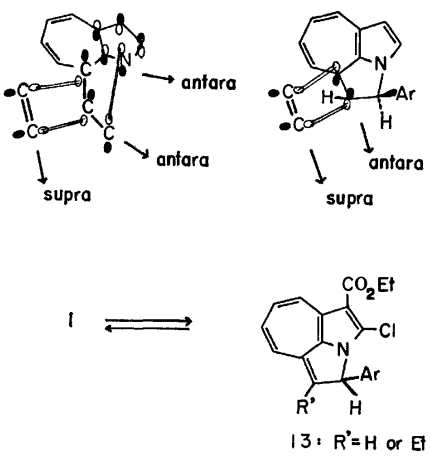


Table 1. ^{1}H NMR bands (δ values) of **1a—d** and **2**

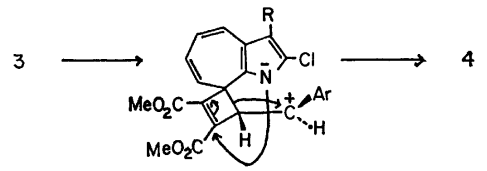
differs a great deal from that of **8**,[4] (iii) the cycloaddition of 8-[(*E*)-styryl]-1-azaazulene (**1a**—**c**) proceeds stereospecifically producing the *trans*-isomer (**3**) only, (iv) no reaction took place even after heating of **4a** with DMAD for 6 d.

Compound **3a**, when heated under reflux in xylene, gave **4a**, **7a**, and **10a**, whereas compound **3d** underwent rearrangement into **4d** upon heating in a neat state. The results indicate that the azacyclopent[*cd*]azulene (**4**) is the thermal product of the azacyclobuta[*j*]-cyclopent[*cd*]azulene (**3**). Thus we can postulate that **4** was formed by the scission of the bond between nitrogen and benzylic carbon atoms of **3** followed by rapid stereospecific recyclization of the intermediate **14**;[10] the absence of a stereoisomer of **4** in the reaction products supports this assumption.

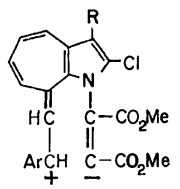


14

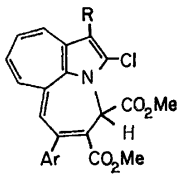
Compound **7** gives **10**, when oxidative cleavage occurs during the reaction, and compound **3** affords **6** upon further reaction with DMAD. However, we have been unable to rationalize the formation of **7** so far.

When a mixture of **3a** and silica gel in benzene was set aside for several days at room temperature, compound **3a** was found to undergo rearrangement into the azacyclopenta[*ef*]heptalene (**5a**) in 56% yield, revealing compound **5** to be a silica gel-induced rearrangement product of **3**.

Dimethyl 5-aryl-3*H*-2a-azacyclopenta[*ef*]heptalene-3,4-dicarboxylate (**16**) to be formed by the intramolecular cyclization of an extended dipolar species[4,11] (**15**) was not detected.



15



16

Experimental

Melting points were uncorrected. ^{1}H NMR spectra were taken with JEOL FX-100 (100 MHz), Hitachi R-40 (90 MHz), or Hitachi R-24B (60 MHz) spectrometers and ^{13}C NMR spectra with JEOL FX-100 or Hitachi R-26 spectrometers (solutions in $CDCl_3$ with Me_4Si as an internal standard). ^{1}H NMR spectral assignments were confirmed by decoupling techniques when necessary. UV spectra were measured for solutions in ethanol unless otherwise stated and IR spectra for Nujol mulls. Kiesel gel 60 was used for chromatography unless otherwise stated. (*E*)-*β*-Bromo-*p*-methylstyrene,[12] (*Z*)-α-ethylcinnamic acid[13] (mp 105—107 °C, lit,[14] mp 107 °C), and (*Z*)-*β*-bromo-*β*-ethylstyrene (bp 120—121 °C/17 Torr, lit,[14] bp 126—128 °C/23 Torr) were prepared by the reported methods.

*Syntheses of **1** and **2**.* A solution of ethyl 2-chloro-1-azaazulene-3-carboxylate (1.00 g) in tetrahydrofuran (30 ml) was slowly added to the Grignard solution prepared from magnesium (0.412 g), (*E*)-*β*-bromostyrene (3.11 g), and tetrahydrofuran (30 ml). The mixture was stirred for 5 min, hydrolyzed with methanol (8 ml) and 2 N-hydrochloric acid (40 ml), and extracted with benzene. The benzene solution was washed with dilute aqueous sodium hydroxide solution, stirred overnight with tetrachloro-*o*-benzoquinone (2.00 g), the solvent was evaporated, and alumina chromatography of the residue with benzene afforded **1a** (0.846 g, 59%). Crystallization from cyclohexane–dichloromethane gave yellow prisms, mp 161—162 °C, UV_{max} 225 nm (log ε 4.51), 295 (4.50), 322^{sh} (4.43), 392 (4.47), and 445^{sh} (3.59); IR 1700 (C=O) and 970 cm^{-1} (*trans* CH=CH). Found: C, 71.21: H, 4.74; Cl, 10.32; N, 3.92%. Calcd for $C_{20}H_{16}ClNO_2$: C, 71.11; H, 4.77; Cl, 10.50; N, 4.15%. By this procedure we made the following: (i) **1b** [81%, mp 147—148 °C (from cyclohexane–dichloromethane), UV_{max} 226 nm (log ε 4.41), 236 (4.41), 287^{sh} (4.40), 297 (4.41), 322^{sh} (4.31), 403 (4.43), and 455^{sh} (3.78); IR 1690 (C=O) and 970 cm^{-1} (*trans* CH=CH). Found: C, 71.81; H, 5.06; Cl, 10.18; N, 3.73%. Calcd for $C_{21}H_{18}ClNO_2$: C, 71.69; H, 5.16; Cl, 10.08; N, 3.98%.]; (ii) **1c** [62%, mp 90—91 °C (from petroleum ether), UV_{max} 247 nm (log ε 4.38), 282 (4.34), 325 (4.31), 385 (4.37), and 467 (3.36); IR 960 cm^{-1} (*trans* CH=CH). Found: C, 77.10; H, 4.54; Cl, 13.35; N, 5.23%. Calcd for $C_{17}H_{12}ClN$: C, 76.84; H, 4.55; Cl, 13.34; N, 5.27%.]; (iii) **1d** [81%, mp 128—129 °C (from cyclohexane–dichloromethane), UV_{max} 236 nm (log ε 4.55) 288 (4.66), 323 (4.10), 366^{sh} (3.46), and 442 (3.17); IR 1690 (C=O) and 835 cm^{-1} (trisubstituted ethylene). Found: C, 72.06; H, 5.75; Cl, 9.85; N, 3.70%. Calcd for $C_{22}H_{20}ClNO_2$: C, 72.23; H, 5.51; Cl, 9.69; N, 3.83%.]; (iv) **2** [87%, mp 148—149 °C (from cyclohexane–dichloromethane), UV_{max} 256 nm (log ε 4.41), 292^{sh} (4.23), 371 (4.31), and 433 (4.04); IR 965 cm^{-1} (*trans* CH=CH). Found: C, 82.77; H, 5.44; N, 11.85%. Calcd for $C_{16}H_{12}N_2$: C, 82.72; H, 5.21; N, 12.06%].

*Reaction of **1a** with DMAD.* (*a*): A solution of compound **1a** (0.25 g) and DMAD (1.052 g) in benzene (30 ml) was heated under reflux for 48 h and the solvent was evaporated. Chromatography of the residue with benzene gave **4a** [0.033 g (9%), red prisms (from cyclohexane), mp 172—173 °C, UV_{max} 252 nm (log ε 4.72), 375 (4.17), 393 (4.13), 440 (3.78), 468 (3.71), 502 (3.51), and 537 (3.06); IR 1750, 1700, and 1675 (C=O) and 980 cm^{-1} (*trans* CH=CH). Found: C, 64.91; H, 4.82; Cl, 7.50; N, 2.82%. Calcd for $C_{26}H_{22}ClNO_6$: C, 65.07; H, 4.62; Cl, 7.39; N, 2.92%]. Further elution afforded a mixture of products, which were fractionally crystallized from cyclohexane–dichloromethane to give **3a** [0.085 g (24%), yellow prisms (from petroleum ether–dichloromethane), mp 168—169 °C, UV_{max} 226^{sh} nm (log ε 4.51) and 290 (3.83); IR 1735, 1722, and 1690 cm^{-1} (C=O); ^{1}H NMR δ=1.35 (3H, t, *J*=7 Hz, Me), 3.70 (3H, s, Me), 3.87 (3H, s, Me), 3.87 (1H, d, *J*=2 Hz, H-7a), 4.28 (2H, q, *J*=7 Hz, CH_2), 5.49 (1H, d, *J*=2 Hz, H-7), 5.60 (1H, d, *J*=11 Hz, H-1), 6.0—6.3 (2H, m, H-2 and 3), 6.85—7.05 (2H, m, phenyl), 7.15—7.3 (3H, m, phenyl), 7.22 (1H, d, *J*=11 Hz, H-4); MS *m/e* 481 and 479 (M^+), 339 and 337 (M^+—DMAD). Found: C, 65.33; H, 4.77; Cl, 7.59; N, 2.88%. Calcd for $C_{26}H_{22}ClNO_6$: C, 65.07; H, 4.62; Cl, 7.39; N, 2.92%] and **5a** [0.05 g (14%), brown needles (from ethanol), mp 148—149 °C (dec), UV_{max}

228 nm (log ε 4.54), 260 (4.28), 434 (4.38), 492sh (3.95), 530 (3.74), and 570 (3.43); IR 1725, 1705, and 1700 cm^{-1} (C=O). Found: C, 65.33; H, 4.68; Cl, 7.25; N, 2.86%. Calcd for $C_{26}H_{22}ClNO_6$: C, 65.07; H, 4.62; Cl, 7.39; N, 2.92%]. Elution with chloroform gave a red oil, which solidified upon trituration with petroleum ether to give **6a** (0.034 g, 7%). Crystallization from ethanol afforded yellow prisms, mp 157—158 °C, UV_{max} 238 nm (log ε 4.28), 288 (3.84), 327 (3.91), and 380 (3.64); IR 1735, 1725, and 1705 cm^{-1}. Found: C, 61.79; H, 4.65; Cl, 5.51; N, 2.14%. Calcd for $C_{32}H_{28}ClNO_{10}$: C, 61.79; H, 4.54, Cl, 5.70; N, 2.25%.

(*b*): A solution of compound **1a** (0.50 g) and DMAD (2.10 g) in xylene (30 ml) was heated under reflux for 24 h and the solvent evaporated. Chromatography of the residue with benzene gave **4a** (0.27 g, 38%) followed by **7a** [0.17 g (24%), yellow needles (from ethanol), mp 177—178 °C, UV_{max} 263 nm (log ε 4.07), 323 (3.95), and 394 (3.58); IR 1735, 1710, and 1690 cm^{-1} (C=O). Found: C, 65.14; H, 4.49; Cl, 7.18; N, 2.87%. Calcd for $C_{26}H_{22}ClNO_6$: C, 65.07; H, 4.62; Cl, 7.39; N, 2.92%]. Further elution gave **10a** (0.046 g, 6%), which crystallized as blue prisms from ethanol, mp 187—188 °C, UV_{max} ($CHCl_3$) 267 nm (log ε 4.54), 301 (4.23), 313 (4.24), 349 (4.63), 391 (3.88), and 665 (3.30); IR 1715, 1690, and 1680 cm^{-1} (C=O). Found: C, 63.24; H, 4.02; Cl, 7.34, N, 2.73%. Calcd for $C_{26}H_{20}ClNO_7$: C, 63.23; H, 4.08; Cl, 7.18; N, 2.84%. Benzene–chloroform (1:1) eluted **6a** (0.088 g, 10%).

Reaction of ***1b*** *with DMAD.* (*a*): A solution of compound **1b** (0.50 g) and DMAD (2.02 g) in benzene (30 ml) was heated and worked-up as for **1a**. Elution with benzene gave **4b** [0.069 g (10%), red prisms (from cyclohexane), mp 198—199 °C, UV_{max} 253 nm (log ε 4.73), 375 (4.14), 394 (4.11), 441 (3.71), 470 (3.66), 503 (3.45), and 542 (3.00); IR 1750, 1695, and 1675 (C=O) and 980 cm^{-1} (*trans* CH=CH). Found: C, 65.83; H, 4.94; Cl, 7.25; N, 2.57%. Calcd for $C_{27}H_{24}ClNO_6$: C, 65.65; H, 4.90; Cl, 7.18; N, 2.84%]. Elution with benzene–chloroform (1:1) afforded a mixture of products, which was fractionally crystallized to yield **3b** [0.385 g (55%), yellow prisms (from cyclohexane), mp 151—152 °C, UV_{max} 240 nm (log ε 4.17) and 293 (3.82); IR 1735, 1720, and 1683 cm^{-1} (C=O); ^{1}H NMR δ=1.34 (3H, t, *J*=7 Hz, Me), 2.30 (3H, s, Me), 3.68 (3H, s, Me), 3.81 (1H, d, *J*=2 Hz, H-7a), 3.85 (3H, s, Me), 4.27 (2H, q, *J*=7 Hz, CH_2), 5.60 (1H, d, *J*=2 Hz, H-7), 5.60 (1H, d, *J*=10 Hz, H-1), 6.0—6.25 (2H, m, H-2 and 3), 6.84 (2H, d, *J*=8 Hz, phenyl), 7.08 (2H, d, *J*=8 Hz, phenyl), 7.18 (1H, d, *J*=10 Hz, H-4). Found: C, 65.72; H, 4.82; Cl, 7.44; N, 2.59%. Found: C, 68.03; H, 4.57; Cl, 8.68; N, 3.35%. Calcd for $C_{23}H_{18}ClNO_4$: C, 67.73; H, 4.45; Cl, 8.69; N, 3.43%]; (iii) **5c** [0.196 g (26%), brown prisms (from cyclohexane), mp 205 °C (dec), UV_{max} 215 nm (log ε 4.58), 250sh (4.34), 285sh (4.15), 440 (4.34), 456 (4.34), 488sh (4.13), 527 (3.97), 565 (3.69), and 618 (3.13); IR 1727 and 1695 cm^{-1} (C=O). Found: C, 67.71; H, 4.60; Cl, 8.63; N, 3.39%. Calcd for $C_{23}H_{18}ClNO_4$: C, 67.73; H, 4.45; Cl, 8.69; N, 3.43%]; (iv) **6c** [0.164 g (16%), yellow prisms (from cyclohexane), mp 182.5—184 °C, UV_{max} 337 nm (log ε 3.75) and 400 (3.52); IR 1735, 1728, and 1707 cm^{-1} (C=O). Found: C, 63.32; H, 4.24; Cl, 6.56; N, 2.51%. Calcd for $C_{29}H_{24}ClNO_8$: C, 63.34; H, 4.40; Cl, 6.45; N, 2.55%].

(*b*): A solution of compound **1c** (0.30 g) and DMAD (1.60 g) in xylene (30 ml) was heated and worked-up as for **1a**. Elution with benzene gave **7c** (0.036 g, 8%), **4c** (0.28 g, 61%), and **10c** [(0.014 g (3%), blue prisms (from ethanol), mp 207—208 °C, UV_{max} ($CHCl_3$) 273 (log ε 4.32), 301 (4.01), 314 (4.04), 353 (4.33), 398 (3.88), 410sh (3.84), and 665 (3.37); IR 1730, 1720, and 1690 cm^{-1} (C=O). Found: C, 65.62; H, 3.91; Cl, 8.36; N, 3.07%. Calcd for $C_{23}H_{16}ClNO_5$: C, 65.49; H, 3.82; Cl, 8.40; N, 3.32%], successively. Elution with benzene-chloroform (1:1) gave **6c** (0.025 g, 4%).

Reaction of ***1d*** *with DMAD.* (*a*): A solution of compound **1d** (0.40 g) and DMAD (1.55 g) in benzene (30 ml) was heated and worked-up as for **1a**. Elution with benzene gave **4d** [0.006 g (1%), red prisms (from petroleum ether), mp 113—114 °C, UV_{max} 246 nm (log ε 4.77), 252sh (4.77), 374 (4.14), 392 (4.10), 439 (3.72), 467 (3.69), 500 (3.51), and 537 (3.10); IR 1730 and 1695 (C=O) and 830 cm^{-1} (trisubstituted ethylene). Found: C, 66.04; H, 5.27; Cl, 7.01, N, 2.71%. Calcd for $C_{28}H_{26}ClNO_6$: C, 66.21; H, 5.16; Cl, 6.98; N, 2.76%]. Further elution afforded **3d** [0.247 g (45%), yellow needles (from petroleum ether), mp 141—142 °C, UV_{max} 238 nm (log ε 4.12) and 291 (3.79); IR 1730 and 1710 cm^{-1} (C=O); ^{1}H NMR δ=0.83 (3H, t, *J*=7 Hz, Me), 1.33 (3H, t, *J*=7 Hz, Me), 1.58 (2H, q, *J*=7 Hz, CH_2), 3.68 (3H, s, Me), 3.85 (3H, s, Me), 4.27 (2H, q, *J*=7 Hz, CH_2), 5.27 (1H, s, H-7), 5.54 (1H, d, *J*=9 Hz, H-1), 6.0—6.5 (2H, m, H-2 and 3), 7.1—7.4 (6H, m, H-4 and phenyl). Found: C, 65,91; H, 5.19; Cl, 7.27; N, 2.74%. Calcd for $C_{28}H_{26}ClNO_6$: C, 66,21; H, 5.16; Cl, 6.98; N, 2.76%]. Elution

with chloroform gave an unidentified red compound (0.127 g).

(*b*): A solution of compound **1d** (0.20 g) and DMAD (0.78 g) in xylene (30 ml) was heated and worked up as for **1a** to yield **4d** (0.009 g, 3%), **3d** (0.042 g, 15%), and a red compound (0.039 g).

Reaction of 2 with DMAD. A solution of compound **2** (0.50 g) and DMAD (3.059 g) in benzene (50 ml) was heated under reflux for 1 h, the solvent was evaporated, and the residue was chromatographed with benzene–chloroform (1:1) to give **11** (0.064 g, 8%), which crystallized from ethanol as yellow needles, mp 184—186 °C (dec), UV_{max} 233 (log ε 4.54), 291 (4.46), 354 (3.95), 370^{sh} (3.94), 415 (3.84), 441 (3.96), 466 (3.92), and 497 (3.67); IR 1725 and 1700 (C=O) and 970 cm^{-1} (*trans* CH=CH). Found: C, 70.49; H, 4.77; N, 7.20%. Calcd for $C_{22}H_{18}N_2O_4$: C, 70.58; H, 4.85; N, 7.48%. Elution with benzene–chloroform (1:2) gave **12** (0.138 g, 17%). which crystallized from cyclohexane as red prisms, mp 167—168 °C (dec), UV_{max} 293 nm (log ε 3.98) and 455 (3.64); IR 1720 cm^{-1} (C=O). Found: C, 70.73; H, 4.88; N, 7.29%. Calcd for $C_{22}H_{18}N_2O_4$: C, 70.58; H, 4.85; N, 7.48%.

Thermal Rearrangement of 3. (*a*): A solution of compound **3a** (0.10 g) in xylene (30 ml) was heated under reflux for 24 h. The work-up gave **4a** (0.04 g, 40%), **7a** (0.02 g, 20%), and **10a** (0.006 g, 6%).

(*b*): Compound **3d** (0.06 g) was heated at 200 °C in a neat state for 10 min and chromatographed. Elution with benzene gave **4d** (0.036 g, 60%).

Oxidation of 7a. A mixture of compound **7a** (0.04 g), 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (0.019 g) in xylene (10 ml) was heated under reflux for 24 h, the solvent was evaporated, and the residue was chromatographed on alumina. Elution with benzene gave **10a** (0.007 g, 17%).

Rearrangement of 3 on Silica Gel. A mixture of compound **3a** (0.05 g) and silica gel (10 g) in benzene was left to stand at room temperature for five days and then chromatographed. Elution with benzene–chloroform (1:1) gave **5a** (0.028 g, 56%). In a similar mannar, a mixture of compound **3b** (0.10 g) and silica gel (20 g) gave **5b** (0.06 g, 60%).

We thank Prof. T. Asao and Dr. M. Yasunami, Tohoku University, and Dr. A. Mori, Kyushu University, for the NMR spectral determinations.

Oxidation of Methyl (Methylthio)methyl Sulfoxide

Katsuyuki OGURA,*,† Michiyo SUZUKI, and Gen-ichi TSUCHIHASHI*

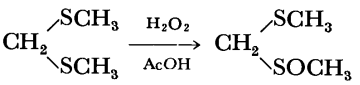
Sagami Chemical Research Center, Nishi-Ohnuma 4-4-1, Sagamihara Kanagawa 229

† *Department of Synthetic Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho 1-33, Chiba 260*

(Received November 9, 1979)

Oxidation of methyl (methylthio)methyl sulfoxide (**2**) with hydrogen peroxide in acetic acid or methanol produced bis(methylsulfinyl)methane in high yield. Similar results were obtained in oxidation of **2** with ozone, sodium metaperiodate, and *m*-chloroperbenzoic acid. In contrast, methyl (methylthio)methyl sulfone (**4**) was exclusively formed when oxidation of **2** with hydrogen peroxide was carried out in methanol in the presence of sodium hydroxide. Furthermore, we established a convenient and efficient method of preparing **4** by oxidation of **2** with potassium permanganate.

Methyl (methylthio)methyl sulfoxide (**2**) can be easily obtained by oxidation of bis(methylthio)methane (**1**) with hydrogen peroxide in acetic acid[1] and this compound has been revealed to be a versatile reagent for synthesizing many kinds of organic compounds.[2]



1 **2**

In order to search further uses for **2**, we examined oxidation of **2** with various oxidants and found an effective method leading to either bis(methylsulfinyl)-methane (**3**) or methyl (methylthio)methyl sulfone (**4**), both of which are expected to be useful synthetic reagents. Details of these oxidation reactions are described in the present paper.

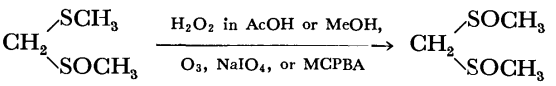
Results and Discussion

Methyl (methylthio)methyl sulfoxide (**2**) was oxidized with one equiv-mol of hydrogen peroxide. In acetic acid, a smooth reaction took place and bis-(methylsulfinyl)methane (**3**) was given in 71% yield (86% yield based on the consumed **2**) as a mixture of its *meso* and *dl* diastereomers in the ratio of 61 : 39.[3] This ratio remained unchanged under moderate heating (150 °C) which is in sharp contrast with reported easy epimerization of bis(benzylsulfinyl)diphenylmethane.[4] In methanol, oxidation of **2** with hydrogen peroxide also afforded **3**, although the reaction proceeded rather slowly, and analogous results were obtained in oxidation of **2** with ozone, sodium metaperiodate, or *m*-chloroperbenzoic acid (MCPBA). The results are summarized in Table 1.

Table 1. Product distribution in oxidation of **2**

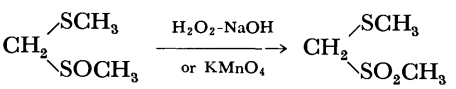
Oxidant	Solvent	Yield/%[a]	
		3	**4**
H_2O_2	AcOH	71 (61 : 39)	—
H_2O_2	MeOH	84 (61 : 39)	—
H_2O_2-NaOH	MeOH	—	78
O_3	CH_2Cl_2	90 (66 : 34)	—
$NaIO_4$	H_2O	85 (69 : 31)	—
MCPBA[b]	CH_2Cl_2	73 (64 : 36)	—
$KMnO_4$	CH_3COCH_3	—	97

a) The value in the parenthesis shows the ratio of the *meso* and *dl* forms. b) *m*-Chloroperbenzoic acid.



2 **3**

When oxidation of **2** with hydrogen peroxide was performed under alkaline conditions, methyl (methylthio)methyl sulfone (**4**) was exclusively produced in stead of **3**. Thus, large excess of hydrogen peroxide (utilized as a 35% aqueous solution) was dropwise added to a solution containing **2** and sodium hydroxide (one equiv to **2**) in methanol under keeping the reaction temperature below 50 °C and **4** was isolated in 78% yield. It is worth noting that **3** was not detected in the reaction mixture by NMR and TLC analyses. The structure of **4** was confirmed by the comparison of its IR and NMR spectra with an authentic specimen prepared by substitution of chloromethyl methyl sulfone with methanethiolate anion.[5]



2 **4**

This exclusive formation of **4** from **2** can be explained in terms of nucleophilic oxidation with a peroxide anion formed by the reaction of hydrogen peroxide with sodium hydroxide, since perbenzoate anion in water–dioxane[6] and 1-phenylethylperoxide anion in a nonpolar solvent[7] were known to attack preferentially the positively-charged sulfur atom of a sulfoxide and convert it into the corresponding sulfone. Similar phenomena were also reported in the reactions with permanganate ion and osmium tetraoxide which could oxidize a sulfoxide without affecting a coexistent sulfide.[8,9] Hence, we tried to oxidize **2** with potassium permangante and established an efficient transformation of **2** into **4**. To a solution of **2** in acetone containing a small amount of water, was added an equiv-mol of potassium permanganate and the mixture was stirred at room temperature for 18 h. Usual work-up followed by column chromatography afforded **4** in 97% yield.

During the course of our investigation, Poje and Balenović reported that **4** was selectively obtained by oxidation of bis(methylthio)methane (**1**) with potassium permanganate.[10] However, the present method seems advantageous to the Poje-Balenović's method

from the synthetic viewpoint,[11] since the latter method requires controlling the reaction temperature at 0 °C for a longer period of time (8—10 d) and gives **4** in only moderate yield (70%).

Experimental

Oxidation of Methyl (Methylthio)methyl Sulfoxide (2) with Hydrogen Peroxide. a) In Acetic Acid: To a solution containing **2** (4.058 g: 32.7 mmol) in acetic acid (40 ml), was dropwise added a 30% aqueous solution (3.70 ml: 32.7 mmol) of hydrogen peroxide under cooling with ice-water and the resulting mixture was stirred for 7 h at room temperature. After addition of dichloromethane (500 ml), the acetic acid was neutralized with potassium carbonate (46.4 g) and the deposited solid was filtered off. The filtrate was dried (Na_2SO_4), evaporated *in vacuo*, and column-chromatographed on silica gel (using ethyl acetate–methanol as an eluent) to give the unconsumed **2** (729 ml: 5.88 mmol) and **3** (3.238 g: 23.1 mmol; 71%) as a colorless oil which crystallized on cooling. An NMR analysis showed that **3** consisted of two diastereomers in the ratio of 61:39:NMR ($CDCl_3$) of the major component: δ 2.94 (6H, s), 3.89 (1H, d, J=13.5 Hz), and 4.15 (1H, d, J=13.5 Hz);[3] NMR ($CDCl_3$) of the minor component: δ 2.85 (6H, s) and 4.09 (2H, s).

An analytical sample (*meso*:*dl*=57:43) was obtained by recrystallization from chloroform-diethyl ether: mp 44—84 °C[12] (lit,[3] mp of the *meso* form and the *dl* form 46—49 °C[13] and 92—94 °C, respectively); IR (neat) 1037 cm^{-1}. Found: C, 25.55; H, 5.80; S, 45.44%. Calcd for $C_3H_8O_2S_2$: C, 25.70; H, 5.75; S, 45.73%.

(b) In Methanol: To a solution of **2** (2.357 g:19.0 mmol) in methanol (10 ml), was added a 35% aqueous solution (2.0 ml: 20.6 mmol) of hydrogen peroxide and the resulting solution was stirred at room temperature for 81.5 h. After addition of dichloromethane (100 ml), the resulting mixture was dried (Na_2SO_4), and evaporated *in vacuo* to give a colorless oil (2.422 g), which was shown by an NMR analysis to consist of **2** (199 mg: 1.60 mmol) and two diastereomers (*meso*: *dl*=61:39) of **3** (2.223 g: 15.9 mmol; 84%).

c) In the Presence of NaOH: To a solution containing **2** (7.020 g: 56.6 mmol) and sodium hydroxide (2.25 g: 56.2 mmol) in methanol (20 ml), was dropwise added a 35% aqueous solution (8.0 ml: 82.3 mmol) of hydrogen peroxide over 40 min under keeping the reaction temperature below 50 °C. Further, a 35% aqueous solution (1.0 ml: 10.3 mmol) of hydrogen peroxide was added in one portion to cause gentle reflux for a time and then the reaction mixture was stirred at room temperature for 30 min. After addition of water (30 ml) and extraction with dichloromethane (70 ml×3), the organic layer was dried (Na_2SO_4), evaporated *in vacuo*, and subjected to column chromatography on silica gel, affording **4** (6.185 g: 44.2 mmol; 78%) as colorless crystals: mp 50—51.2 °C (from diethyl ether) (lit,[5] mp 50—51 °C); IR (KBr) 1293 and 1122 cm^{-1}; NMR ($CDCl_3$) δ 2.40 (3H, s), 3.01 (3H, s), and 3.82 (2H, s). Found: C, 25.78; H, 5.78; S, 45.83%. Calcd for $C_3H_8O_2S_2$: C, 25.70; H, 5.75; S, 45.73%.

These physical data were in complete agreement with those of an authentic sample prepared by substitution reaction of chloromethyl methyl sulfone with sodium methanethiolate as described below.

To a mixture containing dimethyl sulfoxide (19.7 g: 253 mmol) and potassium carbonate (10.0 g) in dichloromethane (150 ml), was portionwise added *N*-chlorosuccinimide (35.0 g: 262 mmol) over 30 min at room temperature under stirring. Then, the insoluble solid was filtered off and the filtrate was evaporated *in vacuo* to give an oil including crystals. After additon of carbon tetrachloride, the insoluble succinimide was removed by filtration and the filtrate was evaporated *in vacuo* to give a colorless oil which consisted mainly of chloromethyl methyl sulfoxide.[14] Without further purification, this oil was dissolved in acetic acid (45 ml) and, after additon of a 35% aqueous solution (45 ml) of hydrogen peroxide, the resulting solution was stirred at room temperature for 2 d. The reaction mixture was neutralized with an aqueous solution of potassium carbonate and extracted with dichloromethane. The extract was dried (Na_2SO_4), evaporated *in vacuo* and crystallized from ethanol to give chloromethyl methyl sulfone (27.43 g: 213 mmol; 79%) as colorless crystals: mp 55—56.5 °C (lit, mp 57.2—58.2 °C[15] and 55—56 °C[16]).

To a solution of chloromethyl methyl sulfone (2.57 g: 20.0 mmol) in *N*,*N*-dimethylformamide (45 ml), was added a 15% aqueous solution (15 ml: purchased from Tokyo Kasei Kogyo Co. Ltd.) of sodium methanethiolate and the resulting mixture was stirred at 50 °C for 3 h. After addition of water followed by extraction with dichloromethane, the organic layer was dried (Na_2SO_4) and evaporated *in vacuo*. The residue was recrystallized from ethanol to afford **4** (1.608 g:11.5 mmol; 57%) as colorless crystals: mp 48.5—50 °C.

Oxidation of 2 with m-Chloroperbenzoic Acid. *m*-Chloroperbenzoic acid (85% active; 1.08 g: 5.32 mmol) was added to a solution of **2** (620 mg; 5.0 mmol) in dichloromethane (10 ml), and then the resulting mixture was stirred for 1.5 h under cooling with ice-water. After addition of water (*ca.* 1 ml) and neutralization with potassium carbonate, the insoluble matter was filtered off and washed with ethyl acetate. The filtrate and the washings were combined and dried (Na_2SO_4). Evaporation *in vacuo* gave a colorless oil which was separated by column-chromatography on silica gel to give **3** (510 mg: 3.64 mmol; 73%). An NMR analysis showed that this product consisted of two diastereomers (*meso*: *dl*=64:36).

Oxidation of 2 with Ozone. Ozone, produced by silent discharge of oxygen, was passed through a solution of **2** (1.040 g: 8.39 mmol) in dichloromethane (10 ml) until the solution became blue. Evaporation *in vacuo* followed by column chromatography on silica gel gave **3** (1.051 g: 7.50 mmol; 90%) as a colorless oil which was shown by an NMR analysis to consist of two diastereomers (*meso*: *dl*=66:34).

Oxidation of 2 with Sodium Metaperiodate. A small amount (*ca.* 1 ml) of water and sodium metaperiodate (863 mg: 4.03 mmol) were added to **2** (498 mg: 4.02 mmol) and the resulting mixture was stirred for 4.5 h under cooling with ice-water. The insoluble solid was filtered off and washed with dichloromethane and ethyl acetate. The filtrate and the washings were combined, dried (Na_2SO_4), and evaporated *in vacuo*. The residue was subjected to column chromatography on silica gel to afford **3** (476 mg: 3.40 mmol; 85%) as a colorless oil which was shown by an NMR analysis to consist of two diastereomers (*meso*: *dl*=69:31).

Oxidation of 2 with Potassium Permanganate. To a solution containing **2** (1.327 g: 10.7 mmol) in acetone (50 ml) and water (2 ml), was added potassium permanganate (1.694 g:10.7 mmol) in several portions and the resulting mixture was stirred at room temperature for 19 h. The insoluble matter was filtered off and the filtrate was evaporated *in vacuo*. The residue was dissolved in dichloromethane and dried (Na_2SO_4). After evaporation *in vacuo*, the residue was subjected to column chromatography on silica gel (dichloromethane) to afford **4** (1.455 g: 1.03 mmol; 97%) as colorless crystals.

The authors would like to express their thanks to Professor Hirotada Iida of Chiba University for his encouragement and helpful discussion. We also wish to thank Mr. Shigeo Tomisawa and Mr. Hiroshi Kitazawa for their technical assistance.

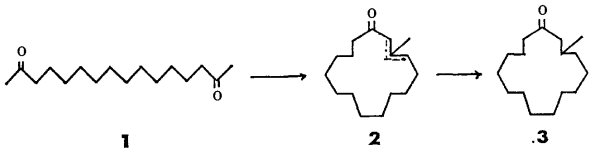
Efficient Regioselective Aldol Condensation of Methyl Ketones Promoted by Organoaluminium Compounds, and Its Application to Muscone Synthesis

Jiro Tsuji,* Toshiro Yamada, Mitsumasa Kaito, and Tadakatsu Mandai
Department of Chemical Engineering, Tokyo Institute of Technology, Meguro, Tokyo 152

(Received November 16, 1979)

Dialkylaluminium aryloxide in combination with a tertiary amine was found to be a good reagent for regioselective aldol condensation of methyl ketones at the methyl side. Regioselective aldol condensation of 2-octanone was carried out using diisobutylaluminium phenoxide–pyridine. The intramolecular aldol condensation of 2,15-hexadecanedione promoted by the same reagent gave a mixture of dehydromuscones in 65% yield. Its hydrogenation produced muscone.

In our continuous effort to synthesize natural products from butadiene telomers, we attempted to synthesize muscone (3-methylcyclopentadecanone) (**3**). Muscone is a naturally occurring fragrant compound with musk odor. Many synthetic attempts for this unique 15-membered cyclic ketone have been made. One method carried out by Stoll is based on the intramolecular aldol condensation of 2,15-hexadecanedione (**1**) to form the 15-membered cyclic ketone (**2**).[1]



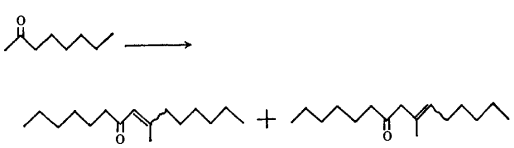
1 **2** **3**

Scheme 1.

Since the methyl group at 3-position of muscone need not be introduced separately, this synthetic scheme would be an elegant method if two inherent problems are solved. The first problem is a good synthetic method for the diketone **1** and the second one is a good method of aldol condensation. Concerning the first problem, the known methods are somewhat tedious.[2,3] We have reported new synthetic methods for this diketone using butadiene telomers.[4,5] Especially the synthesis starting from ethyl 3,8-nonadienoate is the convenient one.[6] The second problem of the intramolecular aldol condensation is an extremely difficult one. Aldol condensation is one of the most important means of carbon–carbon bond formation, but its utility in organic synthesis has been rather limited because of lack of selectivity.[7] The reaction is reversible and other competing reactions take place. Recently several ingenious methods have been reported on the controlled aldol condensation. In these methods, regioselective formation of enolate is essential. Regioselective formation of silyl enolates is a typical example. They are treated with titanium tetrachloride or ammonium fluoride to undergo regioselective cross aldol condensation.[8,9] However, these methods can not be applied to the present purpose of the intramolecular aldol condensation of diketone, because it is impossible to generate silyl enolate from the methyl side of one carbonyl group of the diketone, leaving the other carbonyl group intact. Also common bases such as alkyllithiums, and alkali alkoxides, are not suitable. In order to carry out the intramolecular aldol condensation of a diketone to form a macrocyclic ketone efficiently, the reaction must be rapid, irreversible, and regioselective. For this aldol condensation of the diketone, Stoll used magnesium amide derived from *N*-methylaniline and ethylmagnesium bromide.[1] This base presumably generates a magnesium enolate regioselectively which undergoes the aldol condensation. However, the desired aldol product having the 15-membered ring was obtained only in 17% yield, which is far from satisfaction. Thus it is imperative for us to devise a new method for the aldol condensation of this specific diketone. Our mechanistic consideration of the Stoll's method that the magnesium reagent generates magnesium enolate by coordinating to carbonyl group, while *N*-methylaniline assists the deprotonation leads us to a conclusion that magnesium is not a strong Lewis acid and some other metal compounds which have stronger Lewis acidity should be better. For this purpose, we selected organoaluminium compounds, because stronger Lewis acidity and high affinity to oxygen are expected with aluminium. We found our own organoaluminium compounds, which are very effective for regioselective aldol condensation, and successful aldol condensation of the diketone was achieved. Few studies have been reported on the aldol condensation using aluminium enolate.[10] Recently, successful cross aldol condensation *via* aluminium enolate generated by the treatment of carbonyl compounds with diethylaluminium 2,2,6,6-tetramethylpiperidide at low temperature has been reported.[11] By using our own organoaluminium compounds, successful aldol condensation of the diketone was achieved. A preliminary account of the work has already been given[12] and the details of the studies on the aluminium-promoted aldol condensation are presented in this paper.

Results and Discussion

Aldol Condensation of 2-Octanone. The first requisite in our studies is the regioselective aldol condensation at the methyl side of methyl ketones. For this purpose, we selected 2-octanone as a model compound and studied its aldol condensation using organoaluminium reagents. After considerable screening exper-



Scheme 2.

iments, we found that the aluminium compounds represented by a general formula R_2AlOAr afforded the desired enone as the aldol product selectively, but the yield was not high. The addition of tertiary amines as a proton capture produced the enone in high yields by suppressing undesired proton transfer. Then screening of the reaction conditions using R_2AlOAr–tertiary amine system was carried out by the addition of 2-octanone (1.0 mmol) in THF (3 ml) to a refluxing THF (6 ml) solution of R_2AlOAr–tertiary amine (3.0 mmol–3.0 mmol). The progress of the reaction was monitored by GLC. In this experiment, the aluminium reagent was used in an excess.

Concerning R in the reagent, ethyl and isobutyl were used, but no appreciable difference was observed (Fig. 1). Therefore, the most easily available isobutyl was used throughout this study. Then several phenols were tested as shown in Fig. 2. Phenol and *p*-cresol gave the highest yields, and *p*-*t*-butyl-, 2,6-dimethyl-, and *p*-methoxyphenol were less effective and *p*-nitrophenol was not satisfactory. From these results, phenol was our choice. As for the tertiary amines, no difference was observed among pyridine, 2,6-lutidine, and triethylamine as shown in Fig. 3. From the results of these screening experiments, we decided to adopt *i*-Bu_2AlOPh–pyridine system as the reagent throughout this study.

Then the effect of solvents was studied. The reaction proceeded at room temperature at moderate rate, but very rapidly by heating. The experiments were carried out at boiling temperatures of solvents. As shown in Figs. 4 and 5, nonpolar solvents such as benzene, toluene, and hexane seem to be the best solvents. In ethers, which coordinate to aluminium, the reaction was slower. In dioxane or 1,2-dimethoxyethane at their boiling temperatures, decomposition of the aldol product by secondary reactions took place at the same time. THF gave the better result at its boiling temperature. The reaction was slower in diethyl ether and dichloromethane. Consideration of the solubility of the aluminium reagent leads us to use a mixture of THF and hexane as a suitable solvent. In these experiments, an excess of the aluminium reagent was used, because in the desired intramolecular

aldol condensation of the diketone, the aluminium reagent is present in an excess when the reaction is carried out under high dilution conditions by adding the diketone to the solution of the aluminium reagent, and the reaction conditions for the inter- and intramolecular reactions must be same. The yield of the desired aldol product reached at the maximum within one hour, and then other side reactions began to occur which decrease the yields of the aldol product. Therefore, the reaction must be stopped after short period of time.

Taking the above shown results into consideration, we have carried out the regioselective aldol condensation of 2-octanone in the following way. At first heptane solution of *i*-Bu_2AlH (7.6 mmol) was added at 0 °C to a solution of phenol (8.3 mmol) in THF. Then pyridine (9.0 mmol) was added at room temperature. The solution was brought to reflux and 2-octanone (10 mmol) was added in five minutes. After two hours, the reaction was quenched and the aldol product was isolated in 85% yield. The product was a mixture of 9-methyl-8-pentadecen-7-one and 9-methyl-9-pentadecen-7-one. Catalytic hydrogenation of the mixture afforded 9-methyl-7-pentadecanone as a single product. No product formed by the reaction at the methylene side was detected. 2-Butanone behaved similarly giving the expected aldol product.

Regioselective Aldol Condensation of 2,15-Hexadecanedione. We have confirmed that *i*-Bu_2AlOPh–pyridine is a good reagent for rapid, regioselective aldol condensation of 2-octanone and then we applied this reagent to the intramolecular aldol condensation of 2,15-hexadecanedione (**1**). Results of the experiments carried out under various conditions are summarized in table 1. In order to obtain a high yield of the aldol product, the use of 3—5 equivalents of the aluminium reagent was found to be essential, and the reaction was carried out under high dilution conditions by adding a diketone solution slowly. As the best yield, the desired aldol product was obtained in 65% after column chromatographic separation. In this case, some diketone was recovered, and the yield based on conversion was 78%, which seems to be satisfactory for this type of intramolecular aldol condensation to form the macrocyclic ketone. The reaction was carried out by adding the diketone solution (0.025 M, 40 ml) to *i*-Bu_2AlOPh/pyridine (0.04 M, 100 ml) by using a mechanically driven syringe over a period of 11 h under reflux. The product obtained was a mixture of double bond isomers **2**. Detailed analysis of the NMR spectrum showed that the mixture consists of *trans*-3-methyl-2-cyclopentadecenone (50%), *cis*-3-methyl-2-cyclopentadecenone (30%), and *trans*- and *cis*-3-methyl-3-cyclopentadecenone (20%). The mixture was hydrogenated using palladium on carbon to give muscone as a single product, which was identified by comparing its NMR and IR spectra with those of an authentic sample.

This efficient regioselective aldol condensation can be explained by the following mechanism. Coordination of aluminium to carbonyl oxygen and abstraction of proton from the less hindered methyl side with pyridine proceed concertedly to form the aluminium enolate **4**, which has a considerable life even at refluxing conditions. Then the attack of another carbonyl group forms the aldol product **5** which strongly coordinates to aluminium. Then liberation of diisobutylaluminium

hydroxide forms the enone **2**.

Experimental

IR spectra were recorded as neat films on a JASCO-2 spectrometer. NMR spectra were recorded in CCl_4 on Hitachi R-24 (60 MHz) and Nippon Denshi PS-100 (100 MHz) with Me_4Si as an internal standard. Melting points were measured by Shibata (No. 297) melting point apparatus.

Materials: Diisobutylaluminium hydride was prepared by the thermal decomposition of triisobutylaluminium, followed by distillation, and used as a heptane solution (2.00 M). 2-Octanone, pyridine, and phenol were purified by distillation.

Aldol Condensation of 2-Octanone. A solution of phenol (880 mg, 8.3 mmol) in THF (10 ml) was placed in a 50 ml two-necked flask fitted with a reflux condenser and cooled to 0 °C. The heptane solution of *i*-Bu_2AlH (7.6 mmol, 3.8 ml) was added dropwise to the mixture at 0 °C with stirring. Then pyridine (9.0 mmol, 0.73 ml) was added at room temperature. The solution was gently refluxed and 2-octanone (1.28 g, 10 mmol) in THF (5 ml) was added dropwise in 5 min. After two hours, the mixture was cooled to 0 °C and 3 M-HCl was added. THF was removed *in vacuo*, and the residue was extracted with ether. The extract was washed with 5% NaOH, brine, and dried over $MgSO_4$. After removal of the solvent, the residue was purified by column chromatography (silica gel, hexane–ether 30/1) to give a mixture of 9-methyl-8-pentadecen-7-one and 9-methyl-9-pentadecen-7-one (1.01 g, 8.5 mmol, 85%). IR (neat) 2920, 1715, 1690, and 1620 cm^{-1}. NMR (CCl_4) δ 0.60—1.10 (m, 6H), 1.10—1.80 (m, 15.2H), 1.80—2.70 (m, 7H), 2.85—3.05 (m, 0.8H), and 5.90 (broad s, 1H).

Aldol Condensation of 2,15-Hexadecanedione. A solution of phenol (414 mg, 4.40 mmol) in THF (20.0 ml) was placed in a three-necked flask fitted with a reflux condenser and cooled to 0 °C. The heptane solution of *i*-Bu_2AlH (2.00 ml, 4.00 mmol) was added dropwise to the mixture at 0 °C with stirring. Then pyridine (0.40 ml, 379 mg, 4.80 mmol) and hexane (80.0 ml) were added at room temperature. A solution of 2,15-hexadecanedione (254 mg, 1.00 mmol) in THF–hexane (20 ml+20 ml) was added dropwise using a mechanically driven syringe over a period of 11 h at refluxing temperature with vigorous stirring. The reaction mixture was stirred for an additional hour. The mixture was cooled to 0 °C, and 3 M-HCl was added. The organic layer was separated, and the aqueous layer was extracted with ether (50 ml×3). The combined extracts were washed with 5% NaOH, brine, and dried over $MgSO_4$. Concentration of the extract gave a yellow oil, which was purified by column chromatography (silica gel, hexane–ether 20/1) to give a mixture of dehydromuscones **2** (156 mg, 65%). IR (neat) 2920, 1710, 1680, and 1605 cm^{-1}. NMR (CCl_4) δ 1.00—1.80 (m, 19.6H), 1.80 and 2.10 (s, 3H), 1.85—3.10 (m, 4.4H), 5.10—5.45 (m, 0.2H), and 6.00 and 6.05 (s, 0.8H); mass spectrum *m/e* 236 (M^+).

Preparation of Muscone. Catalytic hydrogenation of the dehydromuscones by Pd on carbon gave (±)-muscone in a quantitative yield. Its NMR and IR data, and GLC analysis were completely identical with those of an authentic sample. IR (neat) 2920 and 1710 cm^{-1}. NMR (CCl_4) δ 0.75—1.05 (m, 3H), 1.05—1.90 (broad s, 23H), and 1.90—2.45 (m, 4H). Semicarbazone mp 131.5—132.5 °C (Lit,[13] 131—132 °C).

Photochemical Type I and II Elimination Reactions of Dialkyl (Trichloromethyl)phosphonates

Nobutaka SUZUKI, Teruyuki KAWAI, Susumu INOUE,
Naoki SANO, and Yasuji IZAWA*

Chemistry Department, Faculty of Engineering, Mie University, Tsu 514

(Received December 7, 1979)

Irradiation of diisobutyl, dipropyl, and diethyl (trichloromethyl)phosphonates in MeCN gave corresponding monoesters and olefins *via* photochemical type II elimination. In addition, products *via* type I elimination were obtained from diisobutyl (trichloromethyl)phosphonate and its dimethyl ester.

In the previous paper, we briefly reported[1] that electron-withdrawing group attached on phosphorus atom of phosphonates compete with a double-bonded oxygen atom to attract electron, resulting in a stiffer P=O double bond and a higher frequence absorption and thus diisobutyl (trichloromethyl)phosphonate (**1a**) having a strongly electron-withdrawing group on phosphorus atom, photochemically decomposed by type II elimination to give the corresponding monoester and isobutylene.

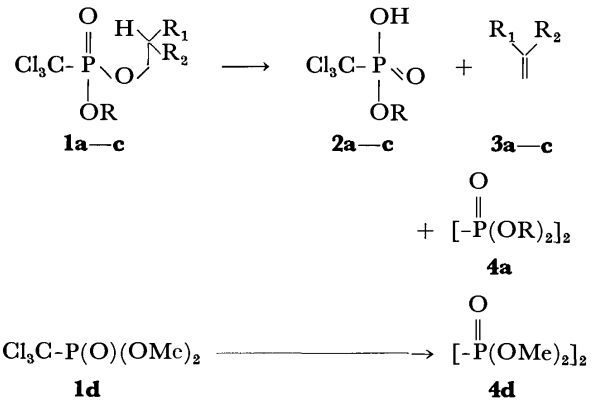
In this paper, we wish to report further investigations on the photochemical elimination of dialkyl (trichloromethyl)phosphonates (**1a**, **1b**, and **1c**) in hope of exploring the exact nature of this reaction.

Results and Discussion

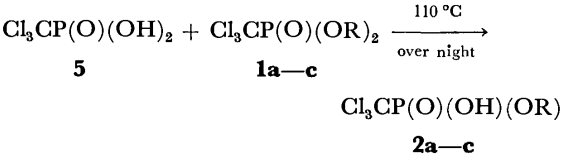
A solution of the phosphonates[2] (**1a**—**d**: 4.2 mmol: 24.7 mmol/l) in acetonitrile (170 ml) was flushed with nitrogen before and during irradiation to prevent photo-oxidation of the starting material and/or the product(s). During irradiation with a low-pressure mercury lamp (30 w; immersion type) the photo-reaction was monitored with GLC as the decrease of **1** (see Table 1).

The generated monoester (**2a**—**c**) and/or tetraalkyl hypophosphate (**4a** and **4d**) were isolated from the each resulting mixture by preparative TLC after evaporation. The R_f values of them were *ca.* 0.1 for **2a**—**c** and *ca.* 0.3—0.4 for **4a** and **4d**, respectively. The results and spectral data for the products, **2**, are shown in Tables 1 and 2, respectively.

Structure of **2a** had been reported in the previous paper[1] as a monoester of **1a** on the basis of its spectral properties. Both **2b** and **2c** showed very similar spectral properties to those of **2a**, respectively. Furthermore, the structures were confirmed by comparing IR spectra with the authentic samples prepared according



to the methods and analogous ones of Kamai and Kharasova[3] from thermal reactions of the parent phosphonic acid **5**[4] and the corresponding diesters (**1a**—**c**). (See Table 3). Thus, we conclude that **2b** and **2c** are the corresponding monoesters of **1b** and **1c**.



Obviously, the olefins and the monoesters are produced *via* the photochemical type II cleavage of **1**. Norrish type II reaction of carbonyl compounds having γ-hydrogen was now well documented,[5,6] however, that of phosphoryl compounds has been reported only in our preceding paper.[1] The present results reveal this type of reaction to be general in the (trichloromethyl)phosphonates.

In contrast, a product (**4d**) from photo-reaction of **1d** which can not give Norrish type II hydrogen abstraction by phosphoryl group, showed its molecular

peak at *m/z* 218 in MS. IR spectrum showed the presence of P=O bond and the absence of P–C and C–Cl bonds, and is identical with that of the authentic sample[7] prepared by the esterification of anhydrous hypophosphoric acid[8] (**6**) with diazomethane in ether. The NMR spectrum showed the presence of methyl protons which exhibited upfield shift by δ 0.32 ppm than that of **1d** and was very similar to that of $HP(O)(OMe)_2$ except P–H signal, and the Beilstein test was negative (Table 3). These data supported the structure, **4d**, which seems to be derived from the type I photo-elimination of **1d** as shown below. Photolysis of **1a** gave also an analogous compound, **4a**. Davies

$$\mathbf{1}^* \xrightarrow{\text{type I}} Cl_3C\cdot + \cdot P(O)(OR)_2$$

$$2\cdot P(O)(OR)_2 \longrightarrow \underset{\mathbf{4}}{[-P(O)(OR)_2]_2}$$

$$2Cl_3C\cdot \longrightarrow \underset{\mathbf{7}}{Cl_3C\text{-}CCl_3}$$

et al. observed the dialkoxyphosphinyl radicals, $\cdot P(O)(OR)_2$, by ESR spectra in photolysis of di-*t*-butyl peroxide in the presence of a dialkyl phosphonate, in the peroxide as solvent (R'=Me, Et, *i*-Pr, or *n*-Bu):[9] However,

$$t\text{-Bu-OO-}t\text{-Bu} \xrightarrow{h\nu} 2t\text{-BuO}\cdot$$

$$t\text{-BuO}\cdot + HP(O)(OR')_2 \longrightarrow t\text{-BuOH} + \cdot P(O)(OR')_2$$

product of hydrogen abstraction by the $\cdot P(O)(OR)_2$ radical, $H\text{-}P(O)(OR)_2$ was not detected in the present reactions. Thus, $\cdot P(O)(OR)_2$ radical would recombine with another one to afford **4**. On the other hand, hexachloroethane (**7**) was detected by GLC, which is supposed to be a coupling product of the partner radical, $\cdot CCl_3$.

The type **4** compounds, somehow, could not be detected in the photolyses of **1b** and **1c**.

The nitrogen streams bubbled through the each reaction mixture during irradiation were introduced into a bromine solution in carbon tetrachloride in order to trap the generated olefins, **3a—c**, and the resulting olefin dibromides (**8a—c**) were determined by GLC. For **1a** and **1e**, the olefin (**3a** and **3e**) in the reaction mixtures were also determined directly by GLC (Table 1).

The each yield of the corresponding **2** and **3** should be equal, if these compounds might be produced only *via* a type II reaction. However, the yields of **2** were lower than those of **3**. The lower yields may be explained by the difficulties on the determination of **2**. Thus, the monoesters (**2**) are very hygroscopic, hard to be eluated, and apt to be hydrolysed. In fact, when chromatographed on the silica-gel TLC, only 52% of the authentic sample of **2a** was recovered on elution. Thus, the yields of **3** were used to evaluate the type II elimination efficiency. For butyl derivative, **1e**, having secondary hydrogen as likely as **1b**, gave also **3** as much as from **1b**. This might suggest that the yield of **3b** reflected the true value of type II elimination.

As shown in Table 1, for **1b** and **1c** type II elimination exclusively occured, while competitive type I and II eliminations occured for **1a**. The competitive α-cleavage and γ-hydrogen abstraction of the phosphonates resemble to those of alkyl phenyl ketones[5c]

or alkanals.[5d] However, the relative rates of γ-hydrogen abstraction calculated from the yields of olefins slightly change as the γ-C–H bond strength, *i.e.*, 0.83, 0.66, and 1.00 for **1a**, **1b**, and **1c**. Comparing with those of phenyl alkyl ketones[6b] the reactivity of phosphoryl compounds is significantly different from that of ketones or alkanals.

Data of Turro and Weiss[5b] clearly demonstrate that the abstraction of the γ-hydrogen by alkyl ketones is most favorable when the hydrogen is directed toward the half-filled n orbital of the n-π^* excited carbonyl, that is, with on the hydrogen lying on the plane of the carbonyl group. The substituents at the γ-carbon atom may not affect sterically on the H-abstraction reaction rates. Therefore, reaction rates for the γ-hydrogen abstraction by an excited carbonyl group generally decrease in the order; tertiary>secondary>primary C–H bonds.

In contrast, for the type II elimination of dialkyl (trichloromethyl)phosphonates (**1**) a steric hindrance may play an important role in the reactivities. Thus, location of the γ-hydrogen near the phosphoryl oxygen atom seems to be sterically hindered by the bulky CCl_3 group. Examination of Dreiding models suggests that the co-planarity of the γ-hydrogen and O=P–C of the n-π^* excited states of phosphoryl group are sterically inhibited in the order; tert>sec≥prim C–H bonds, which probably reflect to the rates of type II elimination. In conclusion the efficiency of the present type II eliminations may be explained by both of the steric and the radical-stabilizing effects.

There were not great differences between the rates of the disappearnace of the starting materials (**1**). For the present reactions, it seems apparently that the type I elimination increases as the type II elimination decreases, which corresponds to that of carbonyl compound having been reported.[5b] Correlationship between the selectivity of the competitive α-cleavage and γ-hydrogen abstraction and their structure may be explained also by the steric hindrance mentioned above.

Experimental

All mp and bp were uncorrected. Following spectrometers were used for spectral measurements: IR: JASCO IR-G; UV: Shimadzu UV-200; NMR: JEOL JNM-MH-100 (100 MHz); MS: JEOL JMS-D-100; high MS were measured by JEOL Co. The spectral data are presented as follows: IR: in cm^{-1}; UV: in nm (ε given in parentheses); NMR: δ in ppm from int. TMS and J in Hz (accuracy ±0.3 Hz); and MS in m/z. GLC were carried out by Yanagimoto Yanaco G-80FP and G-1800F.

Materials. Dialkyl (trichloromethyl)phosphonates (**1a**—**e**) were prepared according to the literatures: **1a**: Colorless liquid, bp 72—74.5 °C/10^{-4} mmHg (lit, bp 109—110 °C/1 mmHg,[1] 144—145 °C/9 mmHg[2]) ν_{max}^{neat} 1280 (P=O), 1020 (P–O–C), 765 (P–C), 545 (C–Cl); λ_{max}^{MeCN} 256.5 (15.4), 300 (2.97); (ε_{254}^{MeCN} 14.9). **1b**: Colorless liquid, bp 59—61 °C/10^{-4} mmHg (lit,[2] bp 144—145 °C/12 mmHg), ν_{max}^{neat} 1275 (P=O), 1018 (P–O–C), 770 (P–C), 550 (C–Cl); (ε_{254}^{MeCN} 1.32). **1c**: Colorless liquid, bp 51—55 °C/5×10^{-3} mmHg (lit,[2] bp 122—123 °C/12 mmHg), ν_{max}^{neat} 1275 (P=C), 1018 (P–O–C), 765 (P–C), 550 (C–Cl); (ε_{254}^{MeCN} 0.39). **1d**: colorless liqiud, bp 52.5—54 °C/1.6×10^{-3} mmHg (lit,[2] bp 120—126 °C/12—13 mmHg; ν_{max}^{neat} 1282 (P=O), 1185, 1020 (P–O–C), 763 (P–C), 550 (C–Cl); (ε_{254}^{MeCN} 0.20). **1e**: Colorless liquid, bp 86—89 °C/4×10^{-3} mmHg (lit,[2] bp 145 °C/7 mmHg); ν_{max}^{neat} 1280 (P=O), 1028 (P–O–C), 768 (P–C), 552 (C–Cl); (ε_{254}^{MeCN} 0.48).

(Trichloromethyl)phosphonic acid (**5**) was prepared according to the literature; mp 158.5—161.5 °C (lit,[4] mp 163.2 °C).

Alkyl (trichloromethyl)phosphonates (**2a**—**c**) were prepared by analogous method of the literature[3] by thermal reactions (110 °C for 12 h in sealed tube) of the phosphonic acid (**5**) (1 equiv.) and the corresponding diester (**1a**—**c**, respectively; 2—3 equiv.). The results and spectral data of the products are summarized in Tables 2 and 3.

Tetramethyl hypophosphate (**4d**) was prepared by the method of the lit,[7] from the esterification of hypophosphoric acid (**7**)[8] with diazomethane in ether: Colorless liquid, bp 80 °C/2×10^{-4} mmHg (lit,[7] bp 85—87 °C/10^{-4} mmHg), m/z 218 (M^+) ν_{max}^{neat} 1460, 1260, 1180, 1020, 850, 825. Tetraisobutyl hypophosphate (**4a**) was prepared by the analogus method as above; colorless liquid, bp 92—94 °C/10^{-4} mmHg; m/z (M^+) 386; (Found: C, 49.42; H, 9.16%. Calcd for $C_{16}H_{36}O_6P_2$: C, 49.734; H, 9.391%).

Isobutylene (**3a**) was prepared with the general procedure dehydrating *t*-BuOH with anhydrous oxalic acid: Colorless liquid, δ (CCl_4) 1.70 (s, 6H), 4.62 (s, 2H). 1-Butene (**3e**) was prepared by the method of lit.,[10] reacting alkyl bromide with Grignard reagent (MeMgI): Colorless liquid, δ (CCl_4) 0.99 (t, 3H, J=7.0), 2.05 (m, 2H), 4.93 (m, 2H), 5.80 (m, 1H). 1,2-Dibromo-2-methylpropane (**8a**) was synthesized according to the lit,[11] Colorless liquid, bp 41—42.5 °C/17 mmHg (lit,[11] bp 165.6—166 °C). Propylene dibromide (**8b**) and ethylene dibromide (**8c**) were purchased from Tokyo Kasei Chem. Co.

Acetonitrile was dried over P_2O_5 and distilled from K_2CO_3 before use.

*Irradiation of Dialkyl (Trichloromethyl)phosphonates (**1a—d**):* Solution of the phosphonate (**1**) (4.2 mmol: 42.7 mM) in MeCN (170 ml) were irradiated directly with a low-pressure mercury lamp (Eikosha PIL-30; 30 w) in an immersion apparatus for 2—5 h at 20 °C. Nitrogen was bubbled through the solution before and during irradiation. Photoreaction was monitored by GLC as the decrease of the starting material (**1**) [10% SE-GE-31 on Diasolid L (60—80 mesh) in a stainless steel column 2.25 m, ϕ 2.5 mm; column temp, 180 °C; inj. temp, 250 °C; carrier gas (N_2); 50 ml/min; internal standard method].

The photoproducts were separated by preparative TLC [Silica gel PF_{254}-gipshaltig (Merck); 20×20 cm, thickness, 2.2 mm; 4-plates, hexane–acetone, 5:1], and the fractions were eluted with acetone. The results and spectral data of the products are summarized in Tables 1, 2, and 3.

The nitrogen streams bubbling through the solution during irradiation were introduced into bromine (0.5 g) solution of CCl_4 (20 ml) to trap the occuring olefins as olefin dibromides (**8**). These solutions were analyzed by GLC with the same column as above, [columm temp, 100 °C; inj. temp., 250 °C; carrier (N_2), 30 ml/min] and the olefin dibromides (**8a**—**c**) were assigned comparing the retention time in GLC with the corresponding authentic samples and the quantities were determined by the internal standard method.

The authors are grateful to JEOL Co. for the measurements of high mass spectra.

The Total Syntheses of Chamaecynone, Isochamaecynone, and Dihydroisochamaecynone[1)]

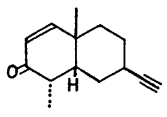
Masayoshi Ando,* Toyonobu Asao,[2)] Norio Hiratsuka,[3)]
Kahei Takase, and Tetsuo Nozoe[4)]

Department of Chemistry, Faculty of Science, Tohoku University, Aramaki-aza-Aoba, Sendai 980

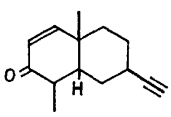
(Received July 16, 1979)

A novel acetylenic nor-sesquiterpene, chamaecynone, and its related natural products, isochamaecynone and dihydroisochamaecynone, have been synthesized starting from α-santonin. In the base-induced equilibration of three pairs of compounds, chamaecynone and isochamaecynone, 4β*H*,5β-13-noreudesm-11-yn-3-one and 4α*H*, 5β-13-noreudesm-11-yn-3-one, and 4β*H*,5β-13-noreudesm-11-en-3-one and 4α*H*,5β-13-noreudesm-11-en-3-one, the ΔH values were determined to be +1.47 kcal/mol, +0.77 kcal/mol, and −2.28 kcal/mol respectively.

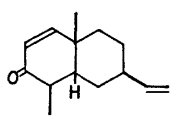
Chamaecynone (**1**), one of the nor-sesquiterpenes originally isolated from the essential oil of the Benihi tree (*Chamaecyparis formosensis* Matsum., Cupressaceae), has been shown to have a novel non-steroid *cis*-decalin conformation and to be one of the first examples of a natural acetylenic compound of terpenoid origin.[5)] Recently this compound has become of particular interest because of its efficient termiticidal activity without any significant toxicity on humans or domestic animals.[6,7)]



(1)



(2)



(3)

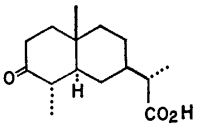
This paper will detail the total syntheses of chamaecynone and the related natural products, isochamaecynone (**2**) and dihydroisochamaecynone (**3**), in optically active forms.

Syntheses

We chose α-santonin (**4**) as the starting material of these syntheses mainly for the following four reasons: 1) Pure α-santonin is commercially available in large quantities, and its total synthesis has already been completed.[8)] 2) α-Santonin is conveniently functionalized as the starting material of the syntheses of chamaecynone and its related compounds, including the absolute configuration. 3) Since the *cis*-decalin intermediates in these syntheses are expected to be conformationally mobile, the optically active starting material is convenient for following the stereochemistry of intermediates by the analyses of CD or ORD curves. 4) Since chamaecynone is a bioactive compound, we want to get enough of chamaecynone and its related compounds in optically active forms for their bioassay.

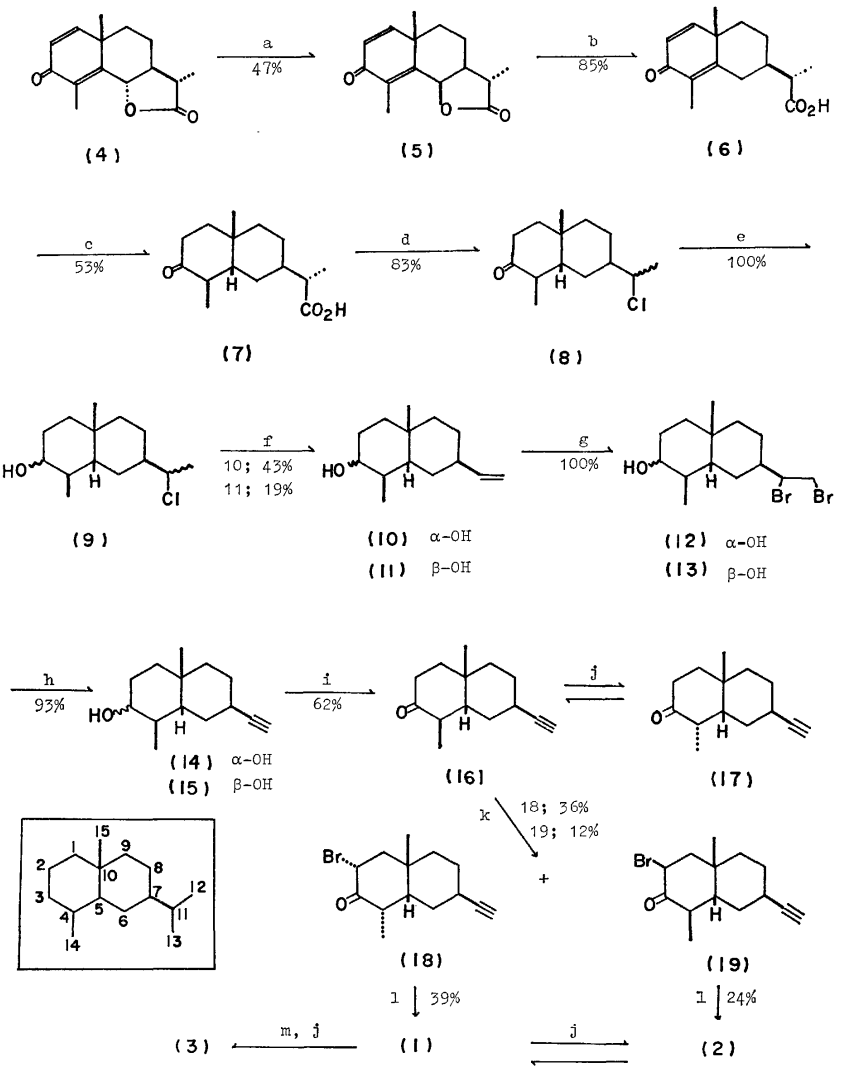
In the syntheses of chamaecynone and its related compounds, there are three problems to overcome: 1) how to introduce the AB *cis*-ring junction, 2) how to introduce the terminal double bond (in dihydroisochamaecynone) or the terminal triple bond (in chamaecynone and isochamaecynone), and 3) how to introduce the α,β-unsaturated carbonyl moiety with an α-oriented methyl group (in chamaecynone) or a β-oriented methyl group (isochamaecynone and dihydroisochamaecynone) at the C_4-position. Keeping these problems in mind, we planned and carried out the syntheses according to the accompanying flow chart.

The first target was the preparation of the *cis*-decalone derivative (**7**). According to the method reported by Ishikawa,[9)] α-santonin was transformed into 6-episantonin (**5**), which was then easily reduced by zinc and acetic acid in methanol to give dienone carboxylic acid (**6**), although α-santonin had been recovered under the same conditions.[10)] Since the stereochemical course of the hydrogenation of α,β-unsaturated ketones is generally influenced by the presence of an acid or base, and by the solvent and catalyst employed,[11)] we examined the conditions of the catalytic hydrogenation of **6**; the best results will be presented below. The catalytic hydrogenation of **6** in ethanol containing potassium hydroxide (1.8 equiv) in the presence of 5% Pd/C gave a *ca.* 3:1 mixture of *cis*-**7** and *trans*-**20**. Fortunately, **7** was easily separated from the mixture by recrystallization. In agreement with the structure, the ORD curve of **7** exhibited a negative Cotton effect; on the contrary, the ORD curve of **20** showed positive Cotton effect.[15)]



(20)

The next problem is the replacement of the carboxyl group of **7** with halogen. For this purpose, the Hunsdiecker reaction is well knwon. The silver salt of **7** was treated with bromine or iodine in carbon tetrachloride, but the results were disappointing. Probably the free halogen employed in this reaction attacked not only the silver salt of carboxyl group, but also the α-position of the carbonyl group to give a complex mixture. The application of Kochi's chlorodecarboxylation reaction[12)] to **7** gave an excellent result. Compound (**7**) was treated with lithium chloride (7 equiv) and lead tetraacetate (8 equiv) in refluxing benzene to give a desired chloro ketone (**8**) as a single stereoisomer, although the stereochemistry at C_{11} was not determined. When the ratio of lithium chloride to lead tetraacetate was increased, the chlorination of the α-position of the carbonyl group occurred, along with chlorodecarboxylation. When lithium bromide or lithium iodide was employed instead of lithium chloride, the reaction gave a complex mixture.

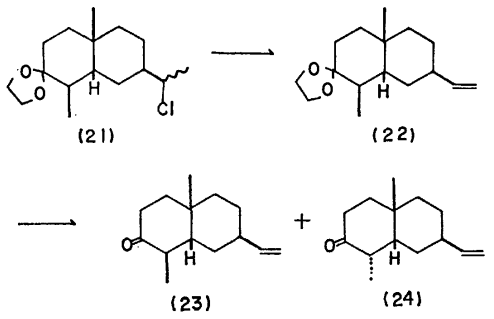


a: HCl gas, DMF; b: Zn, AcOH, MeOH; c: H_2, 5% Pd/C, KOH/EtOH; d: LiCl, $Pb(OAc)_4$, C_6H_6; e: $NaBH_4$, MeOH, ether; f: 1 M *t*-BuOK/*t*-BuOH; g: Br_2, CCl_4; h: 1 M *t*-BuOK/*t*-BuOH, C_6H_6; i: $CrO_3 \cdot 2Py$, Py; j: OH^- or H_3O^+; k: 48% HBr, Br_2, AcOH; l: LiBr, Li_2CO_3, DMF; m: H_2, Lindlar catalyst.

Scheme 1.

In the next step we envisioned the regioselective introduction of a double bond at the terminal position by the dehydrochlorination of **8** or an analogous method. Compound (**8**) was treated with lithium chloride and lithium carbonate in *N*,*N*-dimethylformamide to give a complex mixture of the double-bond isomers. Compound (**8**) was inert toward dehydrochlorination with such amines as *N*,*N*-dimethylaniline and collidines or toward substitution reactions with dimethylamine, bromide ions, and iodide ions. Since attempted dehydrochlorination of **8** with potassium *t*-butoxide gave unidentified acidic products by the air oxidation of the enolate anion of **8**,[13] we decided to try the same reaction after the protection of the carbonyl group.

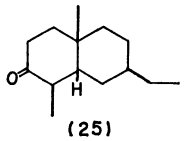
The acetalization of **8** under standard conditions gave chloro acetal (**21**). The treatment of **21** with potassium *t*-butoxide gave the desired olefinic acetal (**22**). The deacetalization of **22** with dil. hydrochloric acid in ethanol gave a 2:1 mixture of **23** and **24**. The



stereochemistry of **23** and **24** will be discussed below.

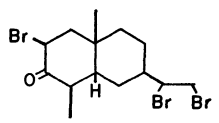
The dehydrochlorination of **8** was achieved by an alternate route. The reduction of **8** with sodium borohydride gave an oily mixture of epimeric alcohols (**9**). The dehydrochlorination of **9** with potassium *t*-butoxide gave a mixture of olefinic alcohols, which then afforded a 3α-alcohol (**10**) and 3β-alcohol (**11**) in 43% and 19% yields respectively after separation,

The oxidation of **10** and **11** gave the same ketone (**23**), while the catalytic hydrogenation of **23** afforded hexahydroisochamaecynone (**25**), which was identical with an authentic sample in its IR and NMR spectra.[5]

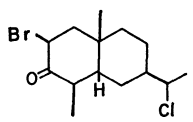


(25)

In the following steps we envisioned an approach to isochamaecynone which consisted of the bromination of **23** and the successive dehydrobromination of the resulting tribromide (**26**). The bromination of **23** with bromine (2 equiv) in carbon tetrachloride gave a tribromide (**26**). The dehydrobromination of **26** with potassium *t*-butoxide gave a complex mixture whose IR spectrum showed a strong absorption of the terminal triple bond at 3280 cm^{-1} but no absorption of an α,β-unsaturated carbonyl group. The treatment of **26** with lithium bromide and lithium carbonate in *N,N*-dimethylformamide or with such amines as *N,N*-dimethylaniline, collidines, and dimethylamine gave a mixture whose IR showed an absorption of an α,β-unsaturated carbonyl group, but no absorption of a triple bond. An attempted synthesis of dihydroisochamaecynone by the dehydrohalogenation of the bromo chloro ketone (**27**), which had been prepared



(26)

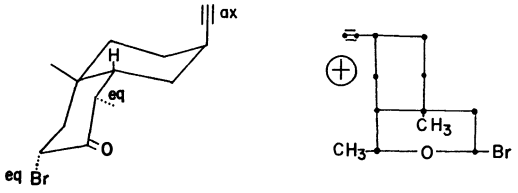


(27)

from **8**, gave analogous negative results. Since these results suggested that the reaction conditions of the formation of an α,β-unsaturated carbonyl moiety and a terminal triple bond were quite different, we decided to introduce these functional groups step by step.

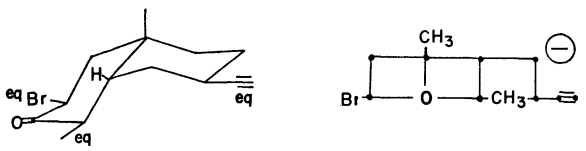
The bromination of **10** gave a dibromide (**12**) as a diastereomeric mixture at C_{11}. The dehydrobromination of **12** with potassium *t*-butoxide gave an acetylenic alcohol (**14**), which was subsequently oxidized with the chromium trioxide–pyridine complex gave the desired acetylenic ketone (**16**). For practical purposes, **16** was prepared from **8** in a 32% overall yield without any separation or purification of the intermediates. The equatorial configuration of the C_4–Me group of **16** was suggested from the solvent effect in the NMR spectrum on passing from CCl_4 to benzene.[14] The ORD curve showed a negative Cotton effect, which was in accordance with the expected sign for **16**, with the steroid conformation bearing a $\beta(eq)$-methyl group at C_4.[15]

The bromination of **16** with bromine in acetic acid in the presence of hydrobromic acid afforded two kinds of unstable monobromides (**18** and **19**) after separation by column chromatography. The NMR spectrum of **18** in CCl_4 exhibited peaks at δ 0.98 (d, J=6.5 Hz, C_4–Me), 1.33 (s, C_{10}–Me), 1.85 (d, J=2.5 Hz, –C≡CH), and 4.57 (q, J=7.5 and 13.0 Hz, C_2–H). In particular, the bromine atom at C_2 was shown to be situated in an equatorial position by the magnitude of the coupling constans of C_2–H. This assignment was also supported by the IR absorption of the carbonyl group, which appeared a frequency higher by 20 cm^{-1} than that of **16**.[16] Judging from the reaction conditions, the C_4–Me group of **18** was deduced to be thermodynamically the more stable equatorial configuration. In addition, the $\alpha(eq)$-configuration of the C_4–Me group was confirmed by the transformation of **18** to chamaecynone, as will be shown later. The ORD curve of this compound showed a positive Cotton effect, which was in accordance with the expected sign for **18**, with the non-steroid conformation bearing an $\alpha(eq)$-bromine atom at C_2 and an $\alpha(eq)$-methyl group at C_4.



(18) Non-Steroid conformation

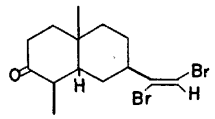
On the other hand, the NMR spectrum of **19** in carbon tetrachloride showed peaks at δ 1.09 (d, J=6.0 Hz, C_4–Me), 1.12 (s, C_{10}–Me), 1.90 (d, J=2.0 Hz, –C≡CH), and 4.75 (q, J=7.0 and 12.5 Hz, C_2–H). The coupling pattern and constant of the signal at δ 4.75 showed that the bromine atom at C_2 was equatorial. This assignment was also supported by the IR spectrum. The C_4–Me group of **19** was deduced to be thermodynamically the more stable equatorial configuration, considering the reaction conditions. In addition, the $\beta(eq)$-configuration of the C_4–Me group was confirmed by the transformation of **19** to isochamaecynone, as will be shown later. The ORD curve of this compound showed a negative Cotton effect, which was explained by the structure **19** in the steroid conformation bearing a $\beta(eq)$-bromine atom at C_2 and a $\beta(eq)$-Me group at C_4.



(19) Steroid conformation

The formation of the bromides **18** and **19** starting from **16** can reasonably be explained as follows. The ketone (**16**) was epimerized at C_4 in the presence of hydrobromic acid to give an equilibrium mixture of **16** and its C_4-epimer, **17**. The bromination of **16** and **17** in the reaction mixture at the C_2-position gave **19** and **18** respectively. The isolation of **17** and a detailed discussion of the stereochemistry will appear in a later section. The preferential formation of α-bromo ketones from **16** under those reaction conditions can also be reasonably explained by the reaction-rate difference between the bromination on an enol double bond and that on a termianl triple bond.[17] On the contrary, when **16** was brominated in acetic

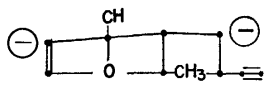
acid in the presence of sodium acetate, **16** absorbed bromine slowly, giving a dibromide (**28**) as the sole product.



(28)

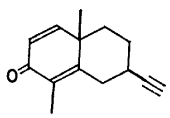
The dehydrobromination of **18** with lithium bromide and lithium carbonate in *N,N*-dimethylformamide produced chamaecynone, which was identical with natural material in its mixed melting point, thin-layer and gas-chromatographic behavior, and IR, NMR, and Mass spectra, and ORD curve.

The dehydrobromination of **19** with lithium bromide and lithium carbonate in *N,N*-dimethylformamide gave isochamaecynone (**2**). Although isochamaecynone was not isolated in a pure state from the natural surce,[5] these NMR absorptions were in accordance with those corresponding to isochamaecynone in the equilibrium mixture of chamaecynone and isochamaecynone, which was easily obtained by the base treatment of chamaecynone. In agreement with the structure **2** the product exhibited the absorption of a terminal triple bond at 3300 and 2123 cm^{-1} and the absorption of an α,β-unsaturated carbonyl group at 1672 cm^{-1} in its IR spectrum (KBr). The ORD curve (n-π^*) showed a negative Cotton effect which agreed with the sign expected from isochamaecynone, with the steroid conformation bearing a $\beta(eq)$-methyl group at C_4.[15,18]



Octant Projection of **2**

Since the isolated yields of the bromides **18** and **19** were poor, probably because of their chromatographic unstability, we tried to prepare chamaecynone and isochamaecynone employing a crude mixture of bromides. In this case, *ca.* a 1:1 mixture of chamaecynone and isochamaecynone was obtained in a 65% yield, based on **16**, accompanied by a 10% yield of dehydrochamaecynone (**29**).



(29)

Since naturally occurring chamaecynone has already been converted to dihydroisochamaecynone, the total synthesis of **3** has also been completed formally.[5]

The Stereochemical Studies

In the course of the structural determination of chamaecynone, it was observed that hexahydrochamaecynone (**30**) was quantitatively isomerized to hexahydroisochamaecynone by base treatment. On the other hand, dihydrochamaecynone (**31**) gave an equilibrium mixture consisting of 10% of dihydrochamaecynone and 90% of dihydroisochamaecynone, whereas chamaecynone afforded an equilibrium mixture of 70% of chamaecynone and 30% of isochamaecynone.[5] These results strongly suggested that the relative stability of normal-series compounds (chamaecynone, dihydrochamaecynone, and hexahydrochamaecynone) to iso-series compounds (isochamaecynone, dihydroisochamaecynone, and hexahydroisochamaecynone) depended upon the bulkiness of the β-substituent at the C_7-position.

In this section we want to deal with the analyses of the energy difference between three pairs of normal- and iso-series compounds, chamaecynone and isochamaecynone, **17** and **16**, and **24** and **23**. The values for ΔH and ΔS of the equilibrium reaction were calculated using the values found for the equilibrium constant, K, and fitting a straight line to Eq. 1:

$$\ln K = -\left(\frac{1}{T}\right)\left(\frac{\Delta H}{R}\right) + \frac{\Delta S}{R} \quad (1)$$

Equilibration of Chamaecynone and Isochamaecynone. Chamaecynone was treated with a 2% potassium hydroxide solution of ethanol for 6 h and then quenched by the use of aqueous acetic acid solution. The ratio of chamaecynone and isochamaecynone was determined by gas-chromatographic analyses. A plot of $\ln K$ *vs.* $1/T$ was made and was found to be linear. From the slope and intercept of the line, the thermodynamic constants of the equilibrium reaction were determined.

ΔH and ΔS were determined to be +1.47 kcal/mol and +2.69 e.u. respectively. Although no equilibration data starting from isochamaecynone were obtained because of its limited aomunt, isochamaecynone gave the same composition mixture as chamaecynone at 25 °C in a 2% potassium hydroxide solution of ethanol.

*Equilibration of **17** and **16**.* The equilibration data for the **17**⇌**16** reaction, starting from **16** were determined to be as shown in Table 2 by the procedures mentioned above.

The C_4-epimer (**17**) was isolated from the equilibrium mixture by column chromatography. The small downfield shift [$\delta_{(CCl_4)}-\delta_{(C_6H_6)}$] of the C_4-methyl

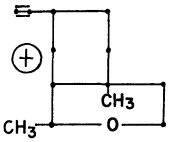
40	0.671	0.25
60	0.714	0.22
80	0.775	0.18

resonance in the NMR spectrum of **17** on passing from carbon tetrachloride to benzene suggested the equatorial configuration of the C_4-methyl group.[14] The ORD curve of **17** showed a positive Cotton effect ($[\phi]_{304}=+897$, $[\phi]_{265}=-1790$, $A=+26.9$), which could reasonably be explained by **17** with a non-steroid conformation bearing a $\beta(ax)$-ethynyl group at C_7 and an $\alpha(eq)$-methyl group at C_4.[14]



Octant Projection of **17**

The equilibration data for the **17**⇌**16** reaction, starting from **17** were also determined to be as shown in Table 3 by the same procedure. The results were in accordance with the results shown in Table 2. A plot of ln K *vs.* $1/T$ was made and found to be linear. From the slope and intercept of the line, ΔH and ΔS were determined to be +0.77 kcal/mol and +1.68 e. u. respectively.

Equilibration of ***24*** *and* ***23***. The equilibration data for the **24**⇌**23** reaction, were determined to be as shown in Table 4 by the procedure used in the cases of the equilibration of chamaecynone and iso-chamaecynone.

The plot of ln K *vs.* $1/T$ became linear, and from the slope and the intercept of the line ΔH and ΔS were calculated to be −2.28 kcal/mol and −3.87 e. u. respectively.

Consideration of the Results. The examination of Dreiding models showed there to be two Me–H and two R–H 1,3-diaxial interactions and two inner H–H interactions, as depicted by the arrows in the normal-series compounds. On the other hand, in the iso-series compounds there are two Me–H 1,3-diaxial interactions and three inner H–H interactions, as depicted by the arrows. Since two Me–H 1,3-diaxial interactions and two inner H–H interactions exist in both series of compounds, the observed ΔH values should reflect the difference between the two R–H 1,3-diaxial interactions in normal-series compounds and one inner H–H interaction in the iso-series compounds. Actually, the observed ΔH values reflect well the bulkiness of R at C_7. When R is the ethynyl group, **17** with non-steroid conformation bearing an axial ethynyl group is the favored isomer and ΔH is +0.77 kcal/mol. In this case, the R group is a linear ethynyl group and the magnitudes of the 1,3-diaxial interactions of this group and of two hydrogen atoms at C_5 and C_9 are the smallest of the three normal-series compounds. On the contrary, when R is a vinyl group, **24**, with a non-steroid conformation, is not the favored isomer and the observed ΔH is −2.28 kcal/mol. In this case, the vinyl group is planar and the magnitudes of the 1,3-diaxial interactions of this group and of the two hydrogen atoms at C_5 and C_9 are larger than that of the linear ethynyl group. When R is a three-dimensional ethyl group, the 1,3-diaxial interactions of R and the two hydrogen atoms at C_5 and C_9 may be expected to be far larger than that of the vinyl group. Actually, hexahydrochamaecynone (**30**) was completely isomerized to hexahydroisochamaecynone (**25**) by base treatment.

The equilibrium reaction of chamaecynone (**1**) and isochamaecynone (**2**) gave a tendency similar with that of the equilibrium reaction of **17** and **16**. The ΔH value is +1.47 kcal/mol, larger than the latter case, because in chamaecynone one Me–H interaction and two inner H–H interactions are eliminated compared with **17** by the introduction of a double bond at C_1, whereas in isochamaecynone one inner H–H interaction is eliminated compared with **16**.

Experimental

All the melting points are uncorrected. The IR spectra were determined on Shimadzu IR-27 and Hitachi EPI-S2 spectrophotometers. The NMR spectra were recorded on Varian A-60 and HA-100 spectrometers, employing tetramethylsilane as the internal reference. Gas-liquid partion chromatography (GLPC) analyses were performed on a Hitachi-Perkin Elmer F-6 apparatus. The ORD spectra were recorded on a Nihonbunko ORD/UV-5 spectrophotometer.

*3-Oxo-6αH,11βH-eudesma-1,4-dieno-13,6-lactone (**5**).* Compound **5** was prepared in a 47% yield as colorless plates by the method reported by Ishikawa;[9] mp 105 °C. IR (KBr): 1786, 1664, 1634, and 831 cm^{-1}. NMR ($CDCl_3$): δ 1.29 (3H, s, C_{10}–Me), 1.38 (3H, d, J=7.5 Hz, C_{11}–Me), 2.06 (3H, s, C_4–Me), 5.57 (1H, d, J=5.5 Hz, C_6–H), 6.25 (1H, d, J=10.0 Hz, C_2–H), and 6.78 (1H, d, J=10.0 Hz, C_1–H) ppm.

*(11S)-3-Oxo-eudesma-1,4-dien-13-oic Acid (**6**).* Compound **6** was prepared in an 85% yield as colorless columns by the method reported by Miki;[10] mp 102 °C. IR (KBr): 3200, 1739, 1650, 1616, 1595, and 836 cm^{-1}. NMR ($CDCl_3$): δ 1.21 (3H, s, C_{10}–Me), 1.23 (3H, d, J=6.5 Hz, C_{11}–Me), 1.83 (3H, s, C_4–Me), 6.17 (1H, d, J=10.0 Hz, C_2–H), and 6.71 (1H, d, J=10.0 Hz, C_1–H) ppm. Found: C, 72.70; H, 8.30; O, 19.31%. Calcd for $C_{15}H_{20}O_3$: C, 72.55; H, 8.12; O, 19.33%.

*(11S)-3-Oxo-4αH,5β-eudesman-13-oic Acid (**7**).* A mixture of **6** (7.41 g, 29 mmol), an ethanol solution (300 ml) of KOH (3 g, 54 mmol), and 5% Pd/C (3 g) was shaken under an atmosphere of hydrogen until the gas absorption had been completed. In 2 h, 1440 ml (1330 ml for one mole equiv) of hydrogen was consumed. After the filtration of the catalyst, the filtrate was poured into water, acidified with 6 M HCl (20 ml), and extracted with ether (200 ml×5). The combined extracts were washed with a satd. NaCl aq solution, dried ($MgSO_4$), and concentrated to give 7.0 g of a semisolid, which was then recrystallized from benzene–cyclohexane (1:2) to give 4.06 g (54%) of **7** as colorless prisms; mp 129 °C. IR (KBr): 1733 and 1675 (this band shifted to 1700 cm^{-1} in $CHCl_3$ or CS_2) cm^{-1}. NMR (CCl_4): δ 0.93 (3H, d, J=6.5 Hz, C_4–Me), 1.03 (3H, s, C_{10}–Me), 1.18 (3H, d, J=7.0 Hz, C_{11}–Me) ppm. ORD (MeOH): $[\phi]_{303}=-760$, $[\phi]_{260}=+2580$, $A=-33.4$.[19] Found: C, 71.12; H, 9.74%. Calcd for $C_{15}H_{24}O_3$: C, 71.39; H, 9.59%. The concentration of the mother liquor gave 3.35 g of a viscous oil, which was then dissolved in ether and methylated with a slight excess of CH_2N_2 in ether. The crude product was chromatographed over neutral alumina (170 g, activity grade 1) and eluted with benzene to give the oily methyl ester of (11*S*)-3-oxo-4*βH*,5α-eudesman-13-oic acid (**20**) (1.14 g, the faster running) and the oily methyl ester of **7** (0.75 g, the slower running). The methyl ester of **20** was hydrolyzed with 2 M KOH aq in EtOH to give 1.03 g of a crude crystalline compound, which was then recrystallized from benzene–cyclohexane (1:2, 5 ml) to give 0.45 g of **20** as colorless prisms; mp 109 °C. IR (KBr): 1727 and 1681 cm^{-1}. NMR (CCl_4): δ 0.91 (3H, d, J=6.5 Hz, C_4–Me), 1.06 (3H, s, C_{10}–Me), and 1.15 (3H, d, J=6.5 Hz, C_{11}–Me) ppm. ORD (MeOH): $[\phi]_{306}=+1010$. Found: C, 71.58; H, 9.78%. Calcd for $C_{15}H_{24}O_3$: C, 71.39; H, 9.59%.

*11-Chloro-4αH,5β-13-noreudesman-3-one (**8**).* A mixture of **7** (1 g, 4 mmol) dissolved in anhydrous benzene (50 ml), $Pb(OAc)_4$ (14.2 g, 32 mmol), and LiCl (1.2 g, 28 mmol) were placed in a round-bottomed flask equipped with a condenser and cooled in a dry ice–acetone bath to freeze the solvent. After the solvent had frozen, the system was evacuated and filled with N_2. The mixture was refluxed under vigorous stirring for 30 min, cooled to room temperature, and filtered. The filtrate was washed with 3 M HCl aq until it became colorless, and then 2 M Na_2CO_3 aq (10 ml×3), which had been acidified with a 6 M HCl aq solution; it was then extracted with ether, dried ($MgSO_4$), and concentrated to give 50 mg (5%) of the recovered **7**. The benzene layer was washed with a satd. NaCl aq solution, dried ($MgSO_4$), and concentrated to give 0.91 g of an oil, which was then chromatographed over silica gel (Merck, <230 mesh) and eluted with $CHCl_3$ to give 800 mg (83%) of **8** as a colorless oil. IR (neat): 1709 cm^{-1}. NMR (CCl_4): δ 0.93 (3H, d, J=7.0 Hz, C_4–Me), 1.04 (3H, s, C_{10}–Me), 1.49 (3H, d, J=6.5 Hz, C_{11}–Me), and 3.87 (1H, m, C_{11}–H) ppm. ORD (MeOH): $[\phi]_{303}=-870$, $[\phi]_{260}=+2470$, $A=-33.4$. Found: C, 68.86; H, 9.45%. Calcd for $C_{14}H_{23}OCl$: C, 69.19; H, 9.54%.

*11-Chloro-4αH,5β-13-noreudesman-3-ol (**9**).* To a solution of **8** (2.05 g, 8.4 mmol) in a mixture of ether (50 ml) and MeOH (34 ml), we added $NaBH_4$ (0.85 g, 22.5 mmol). The mixture was allowed to stand at room temperature for 2 h and then poured into a satd. NaCl aq solution (100 ml). The ether layer was separated after shaking, and the aqueous layer was further extracted with ether (50 ml×2). The combined extracts were washed with a satd. NaCl aq solution, dried ($MgSO_4$), and concentrated to give 2.03 g of **9** as an oil, which was then employed in the next step without any further purification.

A part of the product (152 mg) was chromatographed over silica gel (Merck, <230 mesh) and eluted with $CHCl_3$–CCl_4 (1:1) to give 127 mg of an oil. IR (neat): 3360 cm^{-1}. Found: C, 68.48; H, 9.90%. Calcd for $C_{14}H_{25}OCl$: C, 68.63; H, 10.29%.

*4αH,5β-13-Noreudesm-11-en-3α-ol (**10**) and 4αH,5β-13-Noreudesm-11-en-3β-ol (**11**).* A mixture of **9** (1.45 g, 5.92 mmol) and a 1 M *t*-BuOK/*t*-BuOH soln (60 ml) was refluxed for 44 h under N_2 and then concentrated *in vacuo*. The residue was poured into a satd. NaCl aq solution and extracted with ether (50 ml×3). The combined extracts were washed with a satd. NaCl aq solution, dried ($MgSO_4$), and concentrated to give 1.20 g of an oily crude product, which was then chromatographed over silica gel (Merck, <230 mesh) and eluted with CCl_4–$CHCl_3$ (2:1). The first running gave **11** (234 mg, 19%); mp 49—51 °C. IR (KBr): 3436, 3096, 1639, 993, and 900 cm^{-1}. NMR (CCl_4): 0.93 (3H, d, J=6.5 Hz, C_4–Me), 0.98 (3H, s, C_{10}–Me), 3.70 (1H, m, $W_{h/2}$=5.0 Hz, C_3–H), and 4.65—6.00 (3H, m, ABX pattern olefinic protons) ppm. Found: C, 80.85; H, 11.29%. Calcd for $C_{14}H_{24}O$: C, 80.71; H, 11.61%. The second running gave **10** (527 mg, 43%) as an oily material. IR (neat): 3378, 3115, 1642, 1000, and 909 cm^{-1}. NMR (CCl_4): δ 0.95 (3H, s, C_{10}–Me), 0.97 (3H, d, J=6.0 Hz, C_4–Me), 2.96 (1H, ddd, J=5.0, 9.0, and 9.0 Hz, C_3–H), and 4.65—6.00 (3H, m, ABX pattern olefinic protons) ppm. Found: C, 80.34; H, 11.15%. Calcd for $C_{14}H_{24}O$: C, 80.71; H, 11.61%.

*11,12-Dibromo-4αH,5β-13-noreudesman-3α-ol (**12**).* Into a stirred solution of **10** (0.798 g, 3.83 mmol) in CCl_4 (10 ml), we added a solution of Br_2 (0.70 g, 4.38 mmol) in CCl_4 (5 ml) at 0 °C. The mixture was stirred at 0 °C for 2 h, washed with a 10% Na_2CO_3 aq solution, dried ($MgSO_4$), and concentrated to give **12** (1.44 g, 100%) as a crystalline material, which was then employed in the next step without further purification. A part of this material was recrystallized from CCl_4 to give colorless needles; mp 127—128 °C. IR

(KBr): 3310 cm^{-1}. NMR (CCl_4); δ 0.97 (3H, s, C_{10}–Me), 0.98 (1H, d, J=5.5 Hz, C_4–Me of the minor isomer), 1.01 (2H, d, J=5.5 Hz, C_4–Me of the major isomer), 2.7—3.3 (1H, m, C_3–H), and 3.60—4.35 (3H, m, C_{11}–H, and C_{12}–H) ppm. Found: C, 45.81; H, 6.69%. Calcd for $C_{14}H_{24}OBr_2$: C, 45.65; H, 6.57%.

*4α*H,*5β-13-Noreudesm-11-yn-3α-ol (**14**).* A mixture of **12** (1.44 g, 3.91 mmol), dry benzene (30 ml), and a 1 M *t*-BuOK/*t*-BuOH solution (60 ml) was refluxed for 6.5 h under N_2. After the removal of a half of the volume of the solvent *in vacuo*, the mixture was poured into a satd. NaCl aq solution and extracted with ether (50 ml×3). The combined extracts were washed with a satd. NaCl aq solution, dried ($MgSO_4$) and concentrated to give **14** (754 mg, 93%) as an oily material, which was then employed in the next step without further purification. IR (neat): 3322 and 2123 cm^{-1}.

*4α*H,*5β-13-Noreudesm-11-yn-3-one (**16**).* A solution of **14** (282 mg, 1.37 mmol) in pyridine (2 ml) was added to a CrO_3–Py complex formed from CrO_3 (411 mg, 4.11 mmol) and anhydrous pyridine (6 ml), after which the mixture was allowed to stand at room temperature overnight. Petroleum ether (50 ml) was then added to the mixture, and the precipitate was filtered. The filtrate was washed successively with a satd. NaCl aq solution (50 ml×2), a 2 M HCl aq solution (50 ml×2), and a satd. NaCl aq solution (50 ml), dried ($MgSO_4$), and concentrated to give 251 mg of a crystalline material, which was then chromatographed over silica gel (Merck, <230 mesh, 12 g) and eluted with CCl_4–$CHCl_3$ (1:1) to give spectroscopically pure **16** (172 mg, 62%), mp 71—80 °C. This was recrystallized from pentane to give colorless prisms; mp 89—94 °C.[20] IR (KBr): 3279, 2119, and 1701 cm^{-1}. NMR (CCl_4): δ 0.98 (3H, d, J=6.2 Hz, C_4–Me), 1.08 (3H, s, C_{10}–Me), and 1.90 (1H, d, J=2.0 Hz, C_{12}–H) ppm. NMR (C_6H_6): δ 0.66 (3H, s, C_{10}–Me), 0.91 (3H, d, J=6.2 Hz, C_4–Me), and 1.90 (1H, d, J=2.0 Hz, C_{12}–H) ppm. ORD (MeOH): $[\phi]_{304}=-896$, $[\phi]_{265}=+1790$, $A=-26.9$.[19] MS (70 eV) *m/e*: 204 (M^+). Found: C, 82.20; H, 10.14%. Calcd for $C_{14}H_{20}O$: C, 82.30; H, 9.87%.

*Preparation of **16** from **8** without Purification in Each Step.* To a solution of **8** (637 mg, 2.60 mmol) in a mixture of ether and MeOH (10 ml and 16 ml each), we added $NaBH_4$ (300 mg, 7.93 mmol). The mixture was allowed to stand at room temperature for 2 h, poured into a satd. NaCl aq solution, and extracted with ether. The extract was washed with a satd. NaCl aq solution, dried, and concentrated to give **9** (580 mg, oil).

A mixture of **9** (580 mg) and 1 M *t*-BuOK/*t*-BuOH solution (30 ml) was refluxed for 45 h under N_2, concentrated *in vacuo*, and poured into a satd. NaCl aq solution. The mixture was extracted with ether, and the extract was washed with a satd. NaCl aq solution, dried ($MgSO_4$), and concentrated to give a mixture of **10** and its C_3-epimer (**11**) (370 mg, oil).

To a stirred solution of the resultant mixture of **10** and **11** (370 mg) in CCl_4 (5 ml), we added a solution of Br_2 (320 mg, 2.0 mmol) in CCl_4 (2.5 ml) at 0 °C. The mixture was stirred at room temperature for 2 h, washed with a 10% Na_2CO_3 aq solution, dried ($MgSO_4$), and concentrated to give a crystalline mixture of bromides (**12** and **13**) (658 mg).

A mixture of the resultant bromides (658 mg), anhydrous benzene (10 ml), and 1 M *t*-BuOK/*t*-BuOH solution (10 ml) was refluxed for 6.5 h under N_2. After the removal of a half of the volume of the solvent *in vacuo*, the mixture was diluted with a satd. NaCl aq solution and extracted with ether. The combined extracts were washed with satd. NaCl aq solution, dried ($MgSO_4$), and concentrated to give a mixture of oily alcohols (**14** and **15**) (270 mg).

A solution of the resultant alcohols (270 mg) in anhydrous pyridine (2 ml) was added to the CrO_3–Py complex formed from CrO_3 (411 mg, 4.11 mmol) and anhydrous pyridine (6 ml), after which the mixture was allowed to stand at room temperature overnight. Petroleum ether (50 ml) was then added to the mixture, and the precipitate was filtered. The filtrate was washed successively with a satd. NaCl aq solution, a 2 M HCl aq solution and a satd. NaCl aq solution, dried ($MgSO_4$), and concentrated to give a crude crystalline product (200 mg), which was then chromatographed over silica gel (10 g, Merck, <230 mesh) and eluted with $CHCl_3$–CCl_4 (1:1) to give **16** (171 mg, 32% overall yield from **8**).

*2α-Bromo-4β*H,*5β-13-noreudesm-11-yn-3-one (**18**) and 2β-Bromo-4α*H,*5β-13-noreudesm-11-yn-3-one (**19**).* To a solution of **16** (360 mg, 1.76 mmol) in AcOH (10 ml), we added 48% HBr (0.3 ml) and a solution of Br_2 (281 mg, 1.76 mmol) in AcOH (4 ml) successively. The mixture was stirred for 1 h at room temperature, poured into a satd. NaCl aq solution (100 ml), and extracted with ether (30 ml×3). The combined extracts were washed successively with a 10% Na_2CO_3 aq solution (20 ml×2) and a satd. NaCl aq solution (30 ml), dried ($MgSO_4$), and concentrated to give 467 mg of an oily product, which was then chromatographed over silica gel (30 g, Merck, <230 mesh) and eluted with CCl_4–$CHCl_3$ (4:1). The first running gave an unidentified oily mixture (58 mg). The second running gave 180 mg (36%) of **18** as a crystalline material. IR ($CHCl_3$): 3344, 2123, and 1724 cm^{-1}. NMR (CCl_4): δ 0.98 (3H, d, J=6.5 Hz, C_4–Me), 1.33 (3H, s, C_{10}–Me), 1.85 (1H, d, J=2.5 Hz, C_{12}–H), 4.57 (1H, q, J=7.5 and 13.0 Hz, C_2–H) ppm. ORD (MeOH): $[\phi]_{310}=+396$, $[\phi]_{270}=-1200$, $A=+16$. Found: C, 58.53, H, 6.89%. Calcd for $C_{14}H_{19}OBr$: C, 59.41; H, 6.77%. The third running gave 68 mg (14%) of **19** as a crystalline material.[21] IR ($CHCl_3$): 3344, 2132, and 1727 cm^{-1}. NMR (CCl_4): δ 1.09 (3H, d, J=6.0 Hz, C_4–Me), 1.12 (3H, s, C_{10}–Me), 1.90 (1H, d, J=2.0 Hz, C_{12}–H), and 4.75 (1H, q, J=7.0 and 12.5 Hz, C_2–H) ppm. ORD (MeOH): $[\phi]_{310}=-470$, $[\phi]_{260}=+604$, $A=-10.7$. Found: C, 59.62; H, 6.85%. Calcd for $C_{14}H_{19}OBr$: C, 59.41; H, 6.77%. The fourth running gave **a** complex mixture.

*Chamaecynone (**1**).* A mixture of **18** (105 mg, 0.37 mmol), Li_2CO_3 (90 mg, 1.22 mmol), and LiBr (90 mg, 1.04 mmol) in anhydrous DMF (18 ml) was stirred at 140—165 °C for 2 h under N_2, cooled, poured into a satd. NaCl aq solution (100 ml), and extracted with ether (30 ml×3). The combined extracts were washed successively with a 2 M HCl aq solution (30 ml) and a satd. NaCl aq solution, dried ($MgSO_4$), and concentrated to give 70 mg of an oily material, which was then chromatographed over silica gel (10 g, Merck, <230 mesh) and eluted with CCl_4–$CHCl_3$ (4:1) to give 29 mg (39%) of chamaecynone as a crystalline material, which was subsequently recrystallized from pentane to give colorless prisms; mp 88 °C. This material showed no depression in its melting point when admixed with an authentic specimen and was identical in all respects with the corresponding specimen in IR (KBr), NMR (CCl_4), ORD (MeOH), GLPC (SE 30), and MS (70 eV).

*Isochamaecynone (**2**).* A mixture of **19** (23 mg, 0.08 mmol), Li_2CO_3 (22 mg, 0.3 mmol), and LiBr (22 mg, 0.25 mmol) in anhydrous DMF (6 ml) was stirred at 140—165 °C for 6.5 h under N_2, cooled, poured into a satd. NaCl aq solution (20 ml), and extracted with ether (10 ml×3). The combined extracts were washed successively with **a** 2 M HCl aq solution (10 ml) and a satd. NaCl aq solution, dried ($MgSO_4$), and concentrated to give 18 mg of a crystalline

material, which was then chromatographed over silica gel (3 g, Merck, <230 mesh) and eluted with CCl_4–$CHCl_3$ (4:1) to give 4 mg (24%) of isochamaecynone; mp 79 °C. IR (KBr): 3300, 2123, 1672, and 834 cm^{-1}. NMR (CCl_4): δ 1.12 (3H, d, J=6.5 Hz, C_4–Me), 1.22 (3H, s, C_{10}–Me), 1.90 (1H, d, J=2.0 Hz, C_{12}–H), *ca.* 2.3 (1H, m, $W_{h/2}$= 24.0 Hz, C_7–H), 5.77 (1H, d, J=10.0 Hz, C_2–H), and 6.43 (1H, d, J=10.0 Hz, C_1–H) ppm. NMR (C_6H_6): δ 1.04 (1H, d, J=6.0 Hz, C_4–Me) and 0.71 (3H, s, C_{10}–Me) ppm. MS (70 eV) *m/e*: 202 (M^+). ORD (MeOH): $[\phi]_{340}=-870$.

Conversion of ***16*** *to Chamaecynone (****1****), Isochamaecynone (****2****), and Dehydrochamaecynone (13-Noreudesma-1,4-dien-11-yn-3-one,* ***29****) without the Isolation and Purification of the Corresponding Bromides.* A mixture of **16** (358 mg, 1.75 mmol), AcOH (30 ml), and a 48% HBr aq solution (0.5 ml) was stirred for 2 h at room temperature. To the mixture we then added a solution of Br_2 (290 mg, 1.80 mmol) in AcOH (2 ml). The mixture was stirred for 30 min at room temperature, poured into a satd. NaCl aq solution (100 ml), and extracted with ether (30 ml×3). The combined extracts were washed successively with a 10% Na_2CO_3 aq solution (20 ml×2) and a satd. NaCl aq solution (30 ml), dried ($MgSO_4$), and concentrated to give 494 mg of an oily product, which was then employed for the next reaction.

A mixture of the crude bromide (494 mg), Li_2CO_3 (420 mg, 5.68 mmol), and LiBr (420 mg, 4.83 mmol) in anhydrous DMF (80 ml) was stirred for 5 h at the refluxing temperature under N_2, cooled, poured into a satd. NaCl aq solution (300 ml), and extracted with ether (50 ml×4). The combined extracts were washed successively with a 2 M HCl aq solution (50 ml) and a satd. NaCl aq solution, dried ($MgSO_4$), and concentrated to give 320 mg of an oily material, which was then chromatographed over silica gel (50 g, Merck, <230 mesh) and eluted with CCl_4–$CHCl_3$ (4:1). The first running gave chamaecynone (99 mg). The second running gave a 1:1 mixture of chamaecynone and isochamaecynone (62 mg). The third running gave isochamaecynone (69 mg). The total yield of chamaecynone and isochamaecynone was 230 mg (65%), based on the **16**. The fourth running gave **29** (35 mg, 10%). NMR (CCl_4): δ 1.27 (3H, s, C_{10}–Me), 1.87 (3H, s, C_4–Me), 2.08 (1H, d, J=1.0 Hz, C_{12}–H), 6.09 (1H, d, J=9.8 Hz, C_2–H), and 6.66 (1H, d, J=9.8 Hz, C_1–H) ppm.

*11,12-Dibromo-4*α*H,5*β*-13-noreudesm-11-en-3-one (****28****).* To a mixture of **16** (113 mg, 0.55 mmol) and AcONa (100 mg, 1.22 mmol) in AcOH (100 ml), we added under mechanical stirring, a solution of Br_2 (90 mg, 0.56 mmol) in AcOH (5 ml). After stirring had continued for 4 h at room temperature, the mixture was poured into a satd. NaCl aq solution (100 ml) and extracted with ether (30 ml×3). The combined extracts were washed successively with 10% Na_2CO_3 (20 ml×2) and a satd. NaCl aq (30 ml) solution, dried ($MgSO_4$), and concentrated to give 195 mg of an oily material, which was then chromatographed over silica gel (15 g, Merck, <230 mesh) and eluted with a mixture of $CHCl_3$–CCl_4 (1:1) to give **28** (75 mg, 37%), which was subsequently recrystallized from hexane to give colorless prisms; mp 119 °C. IR (KBr): 3077, 1712, and 833 cm^{-1}. NMR (CCl_4): δ 1.01 (3H, d, J=6.5 Hz, C_4–Me), 1.10 (3H, s, C_{10}–Me), and 6.33 (1H, s, C_{12}–H) ppm. Found: C, 46.66; H, 5.57%. Calcd for $C_{14}H_{20}OBr$: C, 46.15; H, 5.53%.

*11-Chloro-3,3-ethylenedioxy-4*α*H,5*β*-13-noreudesmane (****21****).* A mixture of **8** (1.61 g, 6.63 mmol), ethylene glycol (24 ml), and *p*-toluenesulfonic acid (0.28 g) in dry C_6H_6 (60 ml) was refluxed in a flask equipped with a Dean-Stark column packed with anhydrous $MgSO_4$ for 2 h under N_2. The mixture was then cooled and diluted with a satd. NaCl aq solution (100 ml), and the benzene layer was drawn off. The aqueous layer was further extracted with C_6H_6 (30 ml×3). The combined extracts were washed with a NaCl aq solution, dried ($MgSO_4$), and concentrated to give 1.93 g (100%) of **21**, which was then recrystallized from pentane to give a crystalline material; mp 74 °C. NMR (CCl_4): δ 0.78 (3H, d, J=6.5 Hz, C_4–Me), 0.95 (3H, s, C_{10}–Me), 1.47 (3H, d, J=6.5 Hz, C_{11}–Me), and 3.83 (4H, s,) ppm. Found: C, 67.16; H, 9.39%. Calcd for $C_{16}H_{27}O_2Cl$: C, 66.95; H, 9.48%.

*3,3-Ethylenedioxy-4*α*H,5*β*-13-noreudesm-11-ene (****22****).* A mixture of **21** (1.93 g, 6.72 mmol) and a 1 M *t*-BuOK/*t*-BuOH solution (70 ml) was refluxed for 31 h under N_2, concentrated *in vacuo*, and diluted with a satd. NaCl aq solution. The mixture was then extracted with benzene (50 ml×3). The combined extracts were washed with a NaCl aq solution, dried ($MgSO_4$), and concentrated to give 1.58 g (94%) of **22**, which was then employed in the next step. IR (neat): 3110, 1642, 1000, and 918 cm^{-1}. NMR (CCl_4): δ 0.77 (3H, d, J=6.5 Hz, C_4–Me), 0.96 (3H, s, C_{10}–Me), 3.83 (4H, s,), 4.89 (1H, dd, J=3.5 and 18.0 Hz, C_{12}–H_a), 4.83 (1H, dd, J=3.5 and 10.0 Hz, C_{12}–H_b), and 5.70 (1H, ddd, J=6.0, 10,0, and 18.0 Hz, C_{11}–H) ppm.

Deacetalization of ***22****. The formation of a Mixture of 4*α*H, 5*β*-13-noreudesm-11-en-3-one (****23****) and 4*β*H,5*β*-13-noreudesm-11-en-3-one (****24****).* A mixture of **22** (1.58 g, 6.31 mmol) and a 2 M HCl aq solution (10 ml) in MeOH (50 ml) was refluxed for 4 h, concentrated to a half of the volume, poured into a satd. NaCl aq solution, and extracted with benzene (30 ml×3). The combined extracts were then washed with a satd. NaCl aq solution, dried ($MgSO_4$), and concentrated to give 1.23 g of an oily material, which was subsequently established by NMR and GLPC (SE 30) analyses to be a *ca* 1:2 mixture of **24** and **23**. The NMR (CCl_4) of **24** in the mixture of **24** and **23**: δ 0.88 (3H, d, J=6.5 Hz, C_4–Me), 1.08 (3H, s, C_{10}–Me), and 4.7–6.1 (3H, m, C_{11}– and C_{12}–H) ppm.

*4*α*H,5*β*-13-Noreudesm-11-en-3-one (****23****).* To the CrO_3–Py complex formed from CrO_3 (115 mg, 1.15 mmol) and anhydrous pyridine (2 ml), we added **10** (100 mg, 0.48 mmol) in anhydrous pyridine (4 ml). The mixture was then allowed to stand at room temperature overnight, diluted with petroleum ether (20 ml), and filtered. The filtrate was washed with a 2 M HCl aq solution (20 ml×2) and a satd. NaCl aq solution (30 ml), dried, and concentrated to give 90 mg (91%) of **23** as an oily material, which was then purified by pipe-to-pipe distillation. IR (neat): 3106, 1715, 1637, 995, and 908 cm^{-1}. NMR (CCl_4): δ 0.96 (3H, d, J=6.5 Hz, C_4–Me), 1.04 (3H, s, C_{10}–Me), and 4.7—6.1 (3H, m, C_{11}– and C_{12}–H) ppm. CD (MeOH): $[\theta]_{290}=-1875$. Found: C, 81.22; H, 10.92%. Calcd for $C_{14}H_{22}O$: C, 81.50; H, 10.75%. **11** also gave **23** in 87% in the same procedure.

*Hexahydroisochamaecynone (4*α*H,5*β*-13-Noreudesman-3-one,* ***25****).* A mixture of **23** (20 mg) and 5% Pd/C (20 mg) in MeOH (2 ml) was shaken under H_2 until the hydrogen uptake ceased. The oily crude product (22 mg) was chromatographed over silica gel (1 g, Merck, <230 mesh) and eluted with $CHCl_3$–CCl_4 (1:1) to give **25** (19 mg).

*2*β*,11,12-tribromo-4*α*H,5*β*-13-noreudesman-3-one (****26****).* To a CCl_4 solution (5 ml) of a mixture of **24** and **23** (1:2) (60 mg, 0.29 mmol) which had been formed by the deacetalization of **22**, we added Br_2 (96 mg, 0.60 mmol) in CCl_4 (2 ml). The mixture was stirred for 1 h at 0 °C, poured into a satd. NaCl aq solution (50 ml), and extracted with

benzene (10 ml×3). The combined extracts were washed successively with a 10% Na_2CO_3 aq solution (10 ml) and a satd. NaCl aq solution (20 ml), dried ($MgSO_4$), and concentrated to give 110 mg of an oily material, which was then chromatographed over silica gel (6 g, Merck, <230 mesh) and eluted with $CHCl_3$-CCl_4 (3:7) to give **26** (52 mg, 40%). NMR (CCl_4): δ 1.09 (3H, s, C_{10}–Me), 1.13 (3H, d, J=5.5 Hz, C_4–Me), 3.73 (1H, d, J=11.0 Hz, C_{12}–H_a), 3.80 (1H, d, J=4.5 Hz, C_{12}–H_b), 4.0—4.4 (1H, m, C_{11}–H), and 4.72 (1H, q, J=7.0 and 12.0 Hz, C_2–H) ppm.

2β-Bromo-11-chloro-4αH,5β-13-noreudesman-3-one (27). To a stirred solution of **8** (400 mg, 1.65 mmol) at 0 °C we added Br_2 (320 mg, 2.00 mmol) in CCl_4 (5 ml). The mixture was stirred for 1 h at 0 °C, poured into a satd. NaCl aq solution (100 ml), and extracted with ether (30 ml×3). The combined extracts were washed successively with a 10% Na_2CO_3 aq solution (30 ml) and a satd. NaCl aq solution (50 ml), dried ($MgSO_4$), and concentrated to give 640 mg of a crude, oily material, which was then chromatographed over silica gel (30 g, Merck, <230 mesh) and eluted with $CHCl_3$-CCl_4 (1:1) to give **27** (226 mg, 43%). NMR (CCl_4): δ 1.04 (3H, d, J=6.0, C_4–Me), 1.05 (3H, s, C_{10}–Me), 1.48 (3H, d, J=6.0 Hz, C_{11}–Me), 3.87 (1H, m, C_{11}–H), and 4.68 (1H, q, J=7.0 and 13.0 Hz, C_2-H) ppm.

4βH,5β-13-Noreudesm-11-yn-3-one (17). A solution of **16** (370 mg, 1.81 mmol) in 2% KOH–EtOH (25 ml) was allowed to stand at room temperature for 14 h and was then poured into a satd. NaCl aq solution (100 ml). The mixture was extracted with ether (30 ml×3). The combined extracts were washed with a satd. NaCl aq solution (50 ml), dried ($MgSO_4$), and concentrated to give a mixture of **16** and **17** (1:1.2), as ascertained by GLPC analysis (column: PEG 6000 on Diasolid M; oven temperature: 170 °C; N_2 flow rate: 30 ml/min; **16**: retention time, 16 min; **17**: retention time, 14 min). The mixture (mp 43—65 °C) was chromatographed over silica gel and eluted with CCl_4. The first running gave 111 mg of **17**, which was then recrystallized from pentane to give colorless prisms: mp 103—105 °C. IR (KBr): 3279, 2120, and 1701 cm^{-1}. NMR (CCl_4): δ 0.88 (3H, d, J=6.5 Hz, C_4–Me), 1.30 (3H, s, C_{10}–Me), and 1.91 (1H, d, J=2.5 Hz, C_{12}–H) ppm. NMR (C_6H_6): δ 0.92 (3H, d, J=6.0 Hz, C_4–Me), 0.98 (3H, s, C_{10}–Me) ppm. ORD (MeOH): $[\phi]_{304}$=+897, $[\phi]_{265}$=−1790, A=+26.9. MS (70 eV) *m/e*: 204 (M^+). Found: C, 81.77; H, 9.71%. Calcd for $C_{14}H_{20}O$: C, 82.30; H, 9.87%. The following running gave a mixture of **16** and **17**.

The Temperature Dependence of the Equilibrium in 16 and 17. Four portions of **16** and **17** (20 mg each) were dissolved separately in 2% KOH–EtOH (10 ml) in 100-ml Erlenmeyer flasks. The flasks were stoppered and kept in water baths thermostated at 25 °C, 40 °C, 60 °C, and 80 °C for 6 h. Each solution was then vigorously stirred into a mixture of AcOH (0.2 ml), ether (20 ml), and a satd.NaCl aq solution (60 ml). The ether layer was thus separated, and the aqueous layer was further extracted with ether (20 ml×3). The combined extracts were washed with a satd. NaCl aq solution (50 ml), dried (Na_2SO_4), and concentrated to give a mixture of **16** and **17** as a crystalline meterial. The ratio of **16** and **17** was determined by GLPC (3 mmϕ×1 m column containing 10% carbowax 20 M on diasolid M; oven temperature, 140 °C; N_2 flow rate, 40 ml/min). The retention times of **16** and **17** were 21 min and 18 min respectively.

The Temperature Dependence of the Equilibrium in Chamaecynone and Isochamaecynone. Three portions of chamaecynone (10 mg) were dissolved separately in 2% KOH–EtOH (10 ml) in 100-ml Erlenmeyer flasks. The flasks were stoppered and kept in water baths thermostated at 25 °C, 52 °C, and 80 °C for 6 h. Each solution was treated as has been described above to give a mixture of chamaecynone and isochamaecynone as a crystalline material. The ratio of chamaecynone and isochamaecynone was determined by GLPC (3 mmϕ×1 m containing 10% carbowax 20 M on diasolid M; oven temperature, 140 °C; N_2 flow rate, 40 ml/min). The retention times of chamaecynone and isochamaecynone were 19 min and 25.5 min respectively.

Isomerization of Isochamaecynone. A solution of isochamaecynone (7 mg) in 2% KOH–EtOH (1 ml) was allowed to stand at 25 °C and was then treated in the usual manner to give a mixture of chamaecynone and isochamaecynone (3:1), as determined by GLPC analysis (column: PEG 6000 on diasolid M; oven temperature, 170 °C; N_2 flow rate, 30 ml/min).

The Temperature Dependence of the Equiliblium in 23 and 24. Four portions of **23** (20 mg) were dissolved separately in 2% KOH–EtOH (10 ml) in 100-ml Erlenmeyer flasks. The flasks were then stoppered and kept in water baths thermostated at 25 °C, 40 °C, 60 °C, and 80 °C for 6 h. Each solution was then treated in the manner described above to give a mixture of **23** and **24** as an oily material. The ratio of **23** and **24** was determined by GLPC (3 mmϕ×1 m column containing 10% carbowax 20 M on diasolid M; oven temperature 140 °C; N_2 flow rate, 40 ml/min). The retention times of **23** and **24** were 54.5 min and 60 min respectively.

The authors wish to thank Dr. Takash Toda of the Department of Chemistry for his helpful discussion.

Correlation between Electron Capture Detector Response and Chemical Structure for 1,2,3,4,5,6-Hexachlorocyclohexane

Yukikazu HATTORI,* Yoshio KUGE, and Shingo ASADA

Environmental Pollution Control Center of Osaka Prefecture, 1-3-62, Nakamichi, Higashinari-ku, Osaka-shi, Osaka 537

(Received May 2, 1979)

Synopsis. The relative sensitivities of an electron capture detector for four 1,2,3,4,5,6-hexachlorocyclohexane isomers were measured at different detector temperatures. The temperature dependence of the electron capture coefficients (K) for these compounds was determined. The K values of these compounds increased with a decrease in the detector temperature. These results show that the electron capture reactions of these compounds proceed non-dissociatively.

The electron capture detector (ECD), which exhibits a highly sensitive response to various organic compounds containing halogen, oxygen, and sulfur atoms, is widely used for environmental and other various analyses. Many reports about ECD sensitivities for various compounds have been published,[1-4] but the temperature dependence of the sensitivity was not considered in these studies.

Wentworth *et al.*[5-7] and Kojima *et al.*[8-11] studied the electron capture phenomena by using the pulse-sampling technique, thus elucidating the temperature dependence of the electron capture coefficients (K) for various compounds. They reported a correlation between the ECD response and the chemical structure for many compounds.

The present authors have previously studied[12-14] the ECD response and the temperature dependence for various aromatic halogeno and nitro compounds and for phthalate esters with the d.c. mode.

In this work, we have determined the ECD sensitivities and the temperature dependence for 1,2,3,4,5,6-hexachlorocyclohexane(BHC) isomers and studied the correlation between the ECD response and the chemical structure for these compounds. We intend to use these results for the identification and prediction of unknown compounds.

Experimental

Apparatus and Materials. A Varian aerograph 2100 type gas chromatography with an ECD (^{63}Ni, 8.5 mCi) was used in this experiment. Applied voltage was supplied with the d.c. mode. The glass column (2 mmϕ × 1.5 m) was packed with Gaschrom Q (100—120 mesh) coated with 2% Silicone OV-17. Extra pure nitrogen gas (Teikoku Sanso Co., Ltd.) was used as the carrier gas; it was purified by passage through two tubes packed with Molecular Sieve 5A and through an Oxy-trap tube (Alltech Associates Co., Ltd.), at the flow rate of 30 cm^3/min. The column temperature was set at 170 °C. The injector temperature was kept at 200 °C. The detector temperature was varied from 190 °C to 320 °C. BHC isomers (pesticides, analytical grade) and hexachlorobenzene (HCB)(special grade) were obtained from Wako Pure Chemical Co., Ltd. All the reagents were checked by gas chromatography.

Procedure. The relative sensitivity (RS) was obtained by calculating the relative peak area per mole of the compound, using HCB as a standard. The sample size was so chosen as to keep the peak area within a linear range on the calibration curve. The K values, the electron affinities (EA'), and the RS values were calculated by the method reported in a previous paper.[12]

Results and Discussion

Relative Sensitivities of ECD for BHC Isomers. The RSs of ECD for BHC isomers at three different detector temperatures are tabulated in Table 1. The RSs of the four isomers were in the order of $\alpha > \gamma > \delta \gg \beta$. Especially, the RS for β-BHC was less than those of the other isomers by a factor of about two or three. The RS's of BHC isomers are much larger than that of HCB, which has an equal number of chlorine atoms to BHC. These results may be attributed to the difference in the molecular skeleton and in the coformations of the C–Cl bonds in BHC and HCB.

Table 1. Relative sensitivities for ECD of BHC isomers and hexachlorobenzene

Compound	Relative sens. (230 °C)	Relative sens. (290 °C)	Relative sens. (320 °C)
α-BHC	7.68	4.74	6.21
β-BHC	2.46	1.99	2.74
γ-BHC	6.81	4.67	6.06
δ-BHC	6.27	3.99	4.99
Hexachlorobenzene	1.00	1.00	1.00

The Temperature Dependence of the ECD Response for BHC Isomers. Gas chromatograms of BHC isomers at three different detector temperatures are shown in Fig. 1. As the detector temperature is lowered, the peak heights showing ECD sensitivity become higher. Then the temperature dependences of ECD response were studied. Figure 2 shows the temperature dependence of the K values of four kinds of BHC isomer and HCB. It was found that the temperature dependence of the K values for these compounds showed positive slopes, but that of β-isomer showed an almost zero slope. If the plots of $\ln KT^{3/2}$ against $1/T$ show a positive slope, the electron capture reaction of the compound proceeds non-dissociatively.[6] Therefore, the electron capture reaction for BHC isomers appears to proceed non-dissociatively. These compounds were then supposed to capture an electron and to form stable negative ions. Aue *et al.*[15] studied the products of

three BHC isomers and various polychlorobenzenes in an ECD. They suggested that BHC isomers were largely preserved in contrast to those of other polychlorobenzenes. This fact may support the idea that the electron capture reaction for BHC isomers proceeds non-dissociatively.

In Table 2, the values of the electron affinities (EA') calculated from the magnitude of the positive slopes plotted $\ln KT^{3/2}$ *vs.* $1/T$ and the conformations[16] of the C–Cl bonds in the molecule of BHC are listed. The EA' values of α,γ, and δ isomers were about 13 kJ/mol, while that of HCB was about 8 kJ/mol. The magnitude of the EA' values were in the order of

Table 2. Apparent electron affinities(EA') and conformations of BHC isomers and hexachlorobenzene

Compound	EA' / kJ mol^{-1}	Conformation of chlorine atoms[a] b) c)
α-BHC	12.68	aaeeee
β-BHC	5.06	eeeeee
γ-BHC	12.01	aaaeee
δ-BHC	13.85	aeeeee
Hexachlorobenzene	8.12	—

δ>α>γ>HCB>β. Among the four kinds of BHC isomer, the temperature dependence of the K values, the ECD sensitivity, and the EA' value of β-isomer were very different from those of other isomers. Generally, cyclohexane derivatives adopt the most energetically favarable conformation, in which most substituents are equatorial.[17] All the chlorine substituents of β-isomer are equatorial and so β-isomer has the more stable structure compared with the other BHC isomers. Our experimental results concerning β-isomer may be related to the difference in the conformation. In this way, the electron capture reaction for BHC isomers is affected by the molecular conformations.

A Measurement of the Thermal Decomposition of CS_2 behind Reflected Shock Waves

Ko Saito,* Yoko Toriyama, Teiji Yokubo, Tetsuo Higashihara, and Ichiro Murakami
Department of Chemistry, Faculty of Science, Hiroshima University, Higashi Senda-machi, Hiroshima 730
(Received May 14, 1979)

Synopsis. The thermal decomposition of CS_2 in Ar was investigated in the temperature range of 2000—2900 K by monitoring both the UV absorption and the visible emission of CS_2. A typical induction zone was observed during the decomposition. It was found that the rate constant of the initiation reaction obtained from the induction zone was smaller than that reported by previous workers.

Shock-tube studies of the pyrolysis of CS_2 diluted in Ar have been reported by four research groups in the past.[1-5] In the low-pressure region, the rate of CS_2 disappearance is expressed generally as: $-d[CS_2]/dt=k[CS_2][Ar]+k'[CS_2]^2$, and for highly diluted mixtures, with only a small percentage of CS_2, the second term is neglected. k does not necessarily correspond to the rate constant of the $CS_2+Ar\rightarrow CS+S+Ar$ reaction. However, the values of k reported by the previous workers are consistent with each other within a factor of two, although different experimental conditions, techniques, and data analyses were employed. Among the previous experiments, Arnold *et al.*'s data[5] for k correspond clearly to the complex reaction after an induction period. In our present study by using the UV absorption technique, the induction zone was also found in the CS_2 concentration profile behind reflected shock waves below 3000 K. Moreover, it appeared that the second-order rate constant for the CS_2 decay rate in the induction zone was much smaller than the previous results. At temperatures higher than 3000 K, the induction period was so short that the CS_2 profile showed a simple decay curve, as if the decomposition proceeded *via* a simple mechanism. In this paper, therefore, only the case in which the induction zone apparently exists in the absorption profile is considered.

Experimental

Reaction mixtures containing 0.25 and 0.5 mol% CS_2 in Ar were heated by reflected shock waves in a shock tube 5 cm in inner diameter, previously described elsewhere,[6] and the CS_2 dissociation rate was deduced by monitoring the UV absorption at 220 ± 0.8 nm. In some experimental runs, the emission from the electronically excited CS_2 was monitored at 435 ± 5 nm simultaneously with the absorption record. The experimental conditions were as follows: temperature=1980—2930 K; total concentration=$(3.3—8.0)\times10^{-6}$ mol cm^{-3}; $[CS_2]=(1.5—4.0)\times10^{-8}$ mol cm^{-3}. At 220 nm, the observed absorption coefficient of CS_2 was around 1×10^7 cm^2 mol^{-1} and Lambert-Beer's law was ascertained to hold, at least up to 8×10^{-8} mol cm^{-3} of CS_2.

Results and Discussion

Figure 1 shows a typical trace of the UV absorption. The absorption of CS_2 rises to a maximum just behind the reflected shock front and then begins to decrease slightly; then, after a certain period (we call this the induction period of CS_2 decomposition), it rapidly falls to a steady value. From the two different slopes in the profile, as indicated by I and II in the figure, the corresponding rate constants, k_I and k_{II}, can be determined for each experiment. The visible emission, on the other hand, rose to a peak behind the reflected shock front with a relatively long rise time, while at the end of the induction zone it began to decrease towards a steady value. In the induction zone, the emission profile did not show any such gradient in its intensity as appeared in the simultaneous absorption record. Thus, from the emission profile, the rate of CS_2 disappearance was measured only from the slope behind the induction zone. Figure 2 shows an Arrhenius plot of the second-order rate constants, together with the previous data. The values of k_I and k_{II} were determined from the absorption profile as: $-d(ln[CS_2])/dt/[Ar]$, while the values of k_{III} were obtained by the emission profile as: $-d(lnI)/dt/[Ar]$, where I is the emission intensity. This figure shows that the second-order rate constants, k_{II} and k_{III}, fall in the range of the previous data, although our data show a somewhat larger scatter and, if k_{III} is considered alone, the data seem to have a different temperature dependence because of the lack of data over a wide temperature range. The plot of k_I, the apparent rate constant in the induction zone, lies below that of the previous data, but it shows the same temperature dependence.

An appropriate reaction mechanism was assumed for the CS_2 decomposition involving the 14 elementary reactions listed in Table 1. The simulation by using this mechanism clearly showed a radical chain behavior; thus, the existence of the induction zone, *i.e.*, a rapid decrease in CS_2, began after a time, and was followed by a rapid increase in the sulfur atom. A typical example of the calculation is shown in Fig. 3. Although the mechanism and the rate constants

This reaction probably proceeds *via* a two-step process: $2CS_2\rightarrow CS_3+CS$ and $CS_3+Ar\rightarrow CS_2+S+Ar$. d. T. Higashihara, K. Saito, and I. Murakami, unpublished results. e. N. Basco and A. E. Peason, *Trans. Faraday Soc.*, **63**, 2684 (1967). f. Assumed from the data for $CO_2+O_2=CO+O_3$. g. Adjusted value to fit the experimental data.

used are not necessarily true, the simulation has significance in the sense that the induction period appears also in the calculation.

Since the rate of Reaction 1 is very small compared with that of Reaction 2, the concentration of sulfur atoms should rapidly reach a steady value. In fact, the computer simulation showed that a steady concentration was reached within 10 μs under the present experimental conditions (see Fig. 3). An Arrhenius expression for the initiation reaction rate constant

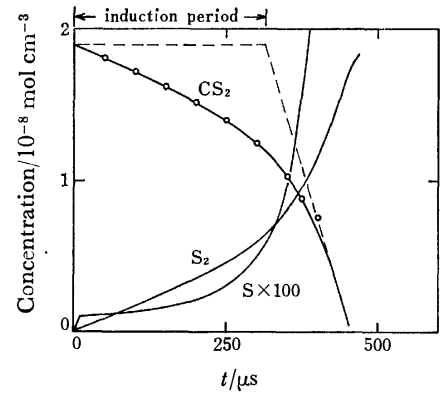

Fig. 3. Example of simulation.
Conditions: $T=2710$ K, $[Ar]=3.76\times10^{-6}$ mol cm^{-3}, $[CS_2]=1.88\times10^{-8}$ mol cm^{-3}. Open circles are the experimental profile of CS_2 under the same conditions.

was thus obtained from the $k_I=2k_1$ relation as:

$$k_1 = 10^{14.4\pm0.5}\exp\{-(74.3\pm6.5\text{ kcal mol}^{-1})/RT\}\ \text{cm}^3\text{ mol}^{-1}\text{ s}^{-1},$$

where the limits of error are the standard deviations. These results are shown in Fig. 2. The value of k_1 obtained in this study gives a collision efficiency factor, β_c,[8] of about 0.01 at 2500 K. This is considered satisfactory compared with the other spin-forbidden reactions of triatomic molecules.

The experimental conditions of Gaydon *et al.* and Arnold *et al.* are the same as those of the present work. Gaydon *et al.* obtained the rate of the CS_2 decomposition by observing the CS and S_2 absorption with relatively long time resolutions. Arnold *et al.* obtained the overall rate from the intensity gradient after the induction period in the emission profile at 450 nm. Therefore, the values of k_{II} and k_{III} measured in this work may be identified with the values of k measured by these workers. Olschewski *et al.* studied the decomposition rate by monitoring the CS_2 absorption at high total concentrations, 10^{-5}—10^{-4} mol cm^{-3}, while the CS_2 concentration was in the same range as in the present study. A calculation using the above assumed mechanism under their experimental conditions showed that the concentration of the sulfur atom reached a steady value within a very short time. Considering this fact, their k_1 values give an overestimate by at least a factor of two.

On the Thermal Decomposition of Shock-heated SO_2

Ko Saito,* Teiji Yokubo, Tetsuo Higashihara, and Ichiro Murakami
Department of Chemistry, Faculty of Science, Hiroshima University, Higashi Senda-machi, Hiroshima 730
(Received May 21, 1979)

Synopsis. The SO_2 pyrolysis was measured behind reflected shock waves under low SO_2 concentrations. A typical induction zone was observed in the decomposition process. It was found that the overall rate constants after the induction zone were in good agreement with the values for the primary reaction obtained by the following investigators: Just and Rimpel, Kiefer, and Grillo *et al.* This implies that, even in highly diluted mixtures at low pressures, the kinetics of the SO_2 decomposition is complicated.

The thermal decomposition of SO_2 behind shock waves has been investigated by many workers.[1-8] However, a problem regarding the second-order rate constant, k_1, for the primary reaction: $SO_2+M\rightarrow SO+O+M$, remains, since the decomposition has been found to proceed in a complex manner when high concentration mixtures are used. Olschewski *et al.*[2] measured the rate constant, k_1, for highly diluted mixtures (less than 0.1 mol % in Ar). Later, their results were revised slightly by Astholtz *et al.*[6] of the same laboratory by using mixtures of SO_2–Ar ranging from 100 to 2000 ppm SO_2 ($5\times10^{-10}<[SO_2]<\sim10^{-8}$ mol cm^{-3}). Just and Rimpel[5] measured k_1 by observing the O-atom production rate by means of atomic resonance absorption spectroscopy. Since they measured the rate for highly diluted mixtures (20—200 ppm SO_2 in Ar) and at low total pressures, corresponding to $\sim10^{-11}<[SO_2]<\sim10^{-10}$ mol cm^{-3}, they assumed that subsequent reactions play only a minor role in the process, and they obtained the k_1 values which were much higher than the values of Astholtz *et al.* (higher more than one order). The values of Just and Rimpel were, though, in rather good agreement with those obtained by Kiefer[4] (3—30% SO_2 in Kr) and by Grillo *et al.*[7] (0.13 and 0.26% SO_2 in Ar). It is considered that, under the experimental conditions in Kiefer's work ($[SO_2]>3\times10^{-8}$ mol cm^{-3}), the obtained data presumably relate to the complex reaction involving the bimolecular reaction of the reactant, not to the primary unimolecular process, although the rate constants were expressed simply as first order in $[SO_2]$, with a very high activation energy (close to the bond dissociation energy of OS–O). In the same sense, the experiments of Grillo *et al.* ($[SO_2]>1\times10^{-8}$ mol cm^{-3}) may also be considered to be connected with the complex reaction.

Thus, the experimental values of k_1 reported hitherto split into two groups, which differ from each other by a factor of about 20. There thus arises the question of whether or not the reaction is really simple in low-concentration mixtures, as in the Just and Rimpel work. There is another problem for the higher k_1 values as to the collision efficiency factor of 0.17 at about 3000 K,[5] which is considerably higher than in the other similar reactions.

Levitt and Sheen[3] observed the visible emission from shock-heated SO_2–Ar mixtures (5—10% SO_2) and obtained the overall rate of the SO_2 decomposition at around 3000 K on the basis of the proportionality between the emission intensity and the concentration of SO_2. This method is considered to give a good time and spatial resolution, without any large noises. In this study, therefore, we tried to measure the decomposition rate of SO_2 by monitoring the light emission from the shock-heated mixtures under the same conditions as those of Just and Rimpel.

Experimental

A shock tube 9.4 cm in inner diameter was used. The test section was evacuated to less than 1×10^{-6} Torr (1 Torr= 133.322 Pa) before each run. The gas conditions behind the reflected shock were calculated by using the incident shock speed in the manner reported in a previous paper.[9] The light emitted from the shock-heated gas was taken out of a quartz window through a slit 0.5 mm wide and was passed again through a second slit 0.5 mm wide placed at 15 cm apart from the window. Then the light was passed through a filter of 392.5±5 nm and was detected by means of a photomultiplier. The output signal was fed to a preamplifier and was recorded by a wave-memory with a sampling speed of 0.2 μs. Since, occasionally, the emission profile varies with a change in the optical arrangement and depends on the conditions of the inner wall of the tube,[10] we carefully checked to see that the field of view in the tube was less than 1 mm and that the reflection diffused by the opposite wall was removed completely.

Commercial SO_2 (99.0% minimum purity) was used after trap-to-trap distillation. Ar (99.998%) was used as the diluent, without any further purification. Mixtures of 0.01 and 0.05 mol% of SO_2 in Ar were prepared by diluting a premixed 5 mol % mixture.

Results and Discussion

The experiments were performed under these conditions: temperature=3000—4700 K; total density= 6.7×10^{-7}—3.3×10^{-6} mol cm^{-3}. Figure 1 shows typical emission records at different temperatures and $[SO_2]\simeq 9\times10^{-11}$ mol cm^{-3}. The peak height was ascertained to be the thermal emission from the electronically excited state of SO_2.[11] That is, a logarithmic plot of the peak intensity per unit of SO_2 concentration *vs.* 1/T agreed with the curve calculated theoretically, considering the temperature dependences of the partition functions of the ground and excited states.

The emission profiles obviously reveal the existence of an induction zone during the pyrolysis, as is shown in Fig. 1. The length of the induction zone decreases with an increase in the temperature, and at high temperatures it disappears from the profile (Fig. 1d).[12] The first-order rate constants, $k_{1st}=-d(\ln I)/dt$, were obtained from the decay curves after the induction

zone, where I is the emission intensity. Then, the values of the second-order rate constant were calculated as: $k_{2nd}=k_{1st}/[Ar]$. In this method, there arises no problem regarding the ambiguousness of the absolute SO_2 concentration in the mixture due to the adsorption of SO_2 on the walls of the reservoir and the shock tube. A plot of the second-order rate constant, k_{2nd}, is shown in Fig. 2, together with the previous data. It is obvious that our data points are near Kiefer's result and also the extended lines of the results of the Just and Rimpel and Grillo *et al.* The values of k_{2nd} correspond clearly to the complex decomposition rate of SO_2, since they were determined not from the initial decay, but from the decay behind the induction zone. The primary reaction rate is considered to reflect the initial decay rate at the earlier position in the induction zone; thus, it should give much smaller values than k_{2nd}. From the emission experiment, however, at least in our present work, no measurable decrease of the intensity was observed in the induction zone. From the present observations, it is likely that the primary reaction rate is as much as one order slower than the overall reaction rate behind the induction zone. In this respect, at the present time, Astholtz *et al.*'s data on the primary reaction rate constant are considered to be the most reliable. As has been described above, the data obtained by Kiefer and Grillo *et al.* obviously correspond to the complex reaction and, therefore, do not conflict with the present results. However, we cannot explain why the observation of the initial production rate of the O atom by Just and Rimpel gave such large values for k_1 under their experimental conditions.

Although, in this work we could not measure the value of k_1, it was confirmed that the decomposition of SO_2 proceeds in a complex manner, even in highly diluted mixtures and at low total pressures. Further investigations with more elaborate techniques will be needed to determine the true value of k_1.

Synopsis. The reflectivity spectrum of two-dimensional cluster compounds, Nb_3I_8, is measured from 5×10^3 to 35×10^3 cm^{-1} and compared to that of Ag_2F. The spectrum has four peaks, at 7.5, 11.8, 20.0, and 28.6×10^3 cm^{-1}.

The physical properties of quasi-low-dimensional compounds have been a subject of considerable interest in recent years. Triniobium octaiodide, Nb_3I_8, is a two-dimensional semiconductor at atmospheric pressure. The resistivity on the ab plane of Nb_3I_8 is 50 Ω-cm, while that along the c axis is about 100 Ω-cm.[1] In a previous paper we have reported the reflectivity of two-dimensional metal Ag_2F and discussed the plasma frequency in the two-dimensional metal.[2] In this report we wish to present the reflectivity spectrum of the single crystal of Nb_3I_8 and compare it to that of Ag_2F.

The crystal structure of Nb_3I_8 is based on a hexagonal closed-packing of the iodine atoms, and three-eighths of the octahedral holes of the iodine octahedra are occupied by niobium atoms. Nb_3I_8 is crystallized in a layer structure similar to the CdI_2 structure. As is to be expected from the compositional ratio, one-fourth of the niobium atoms are left out from the niobium layers. Therefore, the metal atoms are arranged in triangular clusters. The distance between two iodine octahedron centers is 3.8 Å. The positions of the niobium atoms are shifted from the centers of the iodine octahedra. The Nb–Nb distance within a cluster are 3.0 Å, while the shortest Nb–Nb distance between clusters is 4.6 Å.[3] The magnetic property of Nb_3I_8 has also been reported in Ref. 3 to be a weak paramagnetism.

The single crystals of Nb_3I_8 were prepared by the known technique.[4] The crystals grew in the form of plates with a metallic dark gray appearance. The surface of a plate is found by X-ray diffraction analysis to be parallel to the layers of the triangular clusters. A detailed description of reflectivity measurement has already been presented in an earlier paper.[5]

Figure 1 shows the reflectivity spectrum of the Nb_3I_8 single crystal. The reflectivity reaches about 35% at its maximum point. This value is considerably lower than that of the two dimensional metal Ag_2F. The reflectivity spectrum of Ag_2F shows the typical metallic features which are to be expected from Drude's classical free electron theory. On the contrary, the reflectivity spectrum of Nb_3I_8 has four peaks at 7.5, 11.8, 20.0, and 28.6×10^3 cm^{-1}. The Drude-type spectrum is not observed in this two-dimensional semiconductor. Figure 2 shows the real, ε_1, and imaginary, ε_2, parts of the complex dielectric constant. These values are obtained by applying the Kramers-Kronig

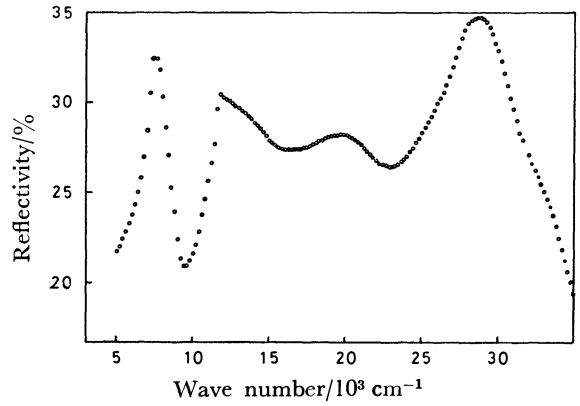

Fig. 1. Reflectivity spectrum of Nb_3I_8 against wave number.

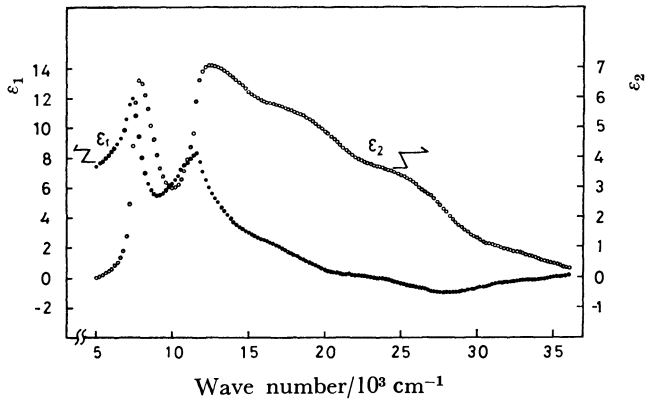

Fig. 2. Plot of the real part (ε_1, ●) and imaginary part (ε_2, ○) of the complex dielectric constant (ε).

analysis to the reflectivity data shown in Fig. 1. The absorption coefficient in Ag_2F increases with a decrease in the wave number in the near-infrared region. On the other hand, in Nb_3I_8, ε_2, which is proportional to the absorption coefficient, decreases with a decrease in the wave number. This suggests that Nb_3I_8 is a typical semiconductor. The resistivity on the ab plane of Nb_3I_8 is 50 Ω-cm, and the thermal-energy gap is about 0.52 eV. The metallic behaviour is not observed even at very high pressures.[1] The 4d electrons in niobium atoms hop among triangle clusters constructed from niobium atoms. The optical-energy gap estimated from the edge of the reflectivity spectrum is comparable to the thermal-energy gap obtained from the temperature dependence of the reflectivity. Therefore, we suggest that the near-infrared band at 7.5×10^3 cm^{-1} may arise from the charge transfer between niobium clusters.

Since NbI_4 is extremely sensitive to water and oxygen, the reflectivity spectrum of NbI_4 has been measured in dry nitrogen stream at room temperature.[7] A broad band was observed at around 21×10^3 cm^{-1}. Judging from the study of the absorption spectra of NbI_4 in pyridine,[8] the broad band in the NbI_4 single crystal may be assigned to the charge-transfer band between niobium and iodine atoms. Therefore, the band near 20×10^3 cm^{-1} in Nb_3I_8 must be attributable to the charge-transfer band between niobium and iodine atoms. Though it is very difficult to identify the two bands at 11.8 and 28.6×10^3 cm^{-1}, these bands may tentatively be assigned. The bond lengths between a central niobium atom and surrounding iodine atoms are listed in Table 1.[3] These bond lengths are divided into two groups. One group of lengths range in distance from 2.75 to 2.76 Å, with a mean distance of 2.75 Å, while the others range in distance from 2.92 to 3.02 Å, with a mean distance of 2.95 Å. On the other hand, the Nb–I lengths of NbI_4 are in the range of 2.65 to 2.90 Å,[6] and the mean length is 2.75 Å. The band 28.6×10^3 cm^{-1} may be assigned to the charge-transfer absorption of the longer-bond-length group. The niobium atoms in a Nb_3I_8 crystal are octahedrally surrounded by iodine atoms, and, according to the chemical analysis of Nb_3I_8, the I/Nb ratio was 2.82. Therefore, the valence state of a niobium atom is considered to be $Nb^{3+}(d^2)$. The bands at 11.8×10^3 cm^{-1} may be assigned to the d-d transition among energy levels split by the octahedral ligand field of iodine atoms.

Nitrogen 14 Nuclear Qnadrupole Resonance of Alloxan·H_2O

Takuya MARUIZUMI, Yukio HIYAMA, and Eiji NIKI*

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo 113

(Received September 26, 1979)

Synopsis. The ^{14}N nuclear quadrupole resonance spectra of alloxan·H_2O have been observed at room temperature. The predominant tautomer in a solid is concluded to be 5,5-dihydroxypyrimidine-2,4,6-trione. The NQR data were interpreted qualitatively by means of the Townes and Dailey theory.

Some nitrogen-containing heterocyclic compounds have been attracting pharmacological and biological interest because of thier pharmaceutical action, mainly attributable to the nitrogen atom's ability to make hydrogen bonds. For this reason, it seems important to obtain information about the electron density on the nitrogen nucleus, and, hence, about the chemical bonding of such heterocyclic compounds. Previously we have reported the ^{14}N NQR of sulfur-substituted uracils and analysed the valence-electron distribution around the nitrogen atom, using the Townes and Dailey theory.[1] In this paper we wish to report the first observation of the ^{14}N NQR of alloxan·H_2O. It is an analogue to barbituric acid and has been extensively studied in order to elucidate its ability to cause diabetes. For ^{14}N NQR, we can expect the three frequencies given in the following formulae,[2]

$$\nu_{\pm} = \frac{3}{4}e^2Qq/h\cdot\left(1\pm\frac{\eta}{3}\right)$$
$$\nu_0 = \nu_+ - \nu_- = \frac{1}{2}\eta\cdot e^2Qq/h \quad (1)$$

where e^2Qq/h is the quadrupole coupling constant and where η is the asymmetry parameter, which is the measure of the deviation from the axially symmetry of the electric field gradient (e.f.g.). The NQR data of alloxan·H_2O were interpreted qualitatively in terms of the Townes and Dailey theory.

Experimental

The nuclear magnetic double resonance in the laboratory frame[3] was employed to detect the NQR transitions. Before performing the double-resonance experiment, the high-field (about 0.6 T) and zero-field spin lattice relaxation times for alloxan·H_2O were measured in order to set the double-resonance time sequence, T-τ (cycle time and zero-field time respectively). NQR searching was carried out from 400 kHz to 4 MHz in 10 kHz steps, so the total experimental error may amount to about 10 kHz. The apparatus was a home-made one and has been described in detail in our previous paper.[4] The sample was a polycrystalline guaranteed-grade chemical obtained from the Tokyo Kasei Kogyo Co., Ltd. The sample volume was about 1 cm^3. All the experiments were performed at room temperature.

Results and Discussion

The proton high-field spin-lattice relaxation time, T_1, of alloxan·H_2O at room temperature was 25 s. In the zero field, the proton magnetization at first decreased quickly with the time constant, T_{1D} (6 s), and later more slowly with the time constant, T_{1N} (44 s). This slow decay of proton magnetization may be caused by the remagnetization of proton system by cross interaction with the ^{14}N system, which has a long spin-lattice relaxation time. From these data, the double-resonance cycle was set as $T=60$ s and $\tau=2$ s. The observed transition frequencies, the quadrupole coupling constants, e^2Qq/h, and the asymmetry parameters, η, of alloxan·H_2O are given in Table 1, together with the data of its analogue, barbituric acid.[5] Figure 1 shows the NQR spectrum of alloxan·H_2O. Before analysing the charge densities, the correct tautomeric structure for alloxan·H_2O must be settled. For alloxan·H_2O, Baeyer supposed the water molecule of alloxan·H_2O to be incorporated into the alloxan molecule as the hydroxyl group.[6] His assigned configurational formula of alloxan·H_2O is Illustration (A), shown below. For this formula, the keto or enol tautomeric forms through the migration of the hydrogen atoms may be possible; see Illustrations (B) and (C).

The nitrogens in (A) are both pyrrole-like, in (B) one is pyrrole-like and the other is pyridine-like, and in (C) both are pyridine-like. A simple criterion for distinguishing pyrrole-like and pyridine-like bond configurations is deduced when the nuclear quadrupole coupling constants of the pyridine-like and pyrrole-like nitrogens are compared, since the coupling constants of pyridine-like nitrogens are usually greater than 4

TABLE 1. NQR TRANSITION FREQUENCIES (kHz), QUADRUPOLE COUPLING CONSTANTS, e^2Qq/h (kHz), AND ASYMMETRY PARAMETERS, η, OF alloxan·H_2O AND ITS ANALOGUE, BARBITURIC ACID

Compound	[ν_+,	ν_-,	ν_0]	e^2Qq/h	η
Alloxan·H_2O	[2670,	2060,	610]	3150	0.39
	[2600,	1980,	620]	3050	0.41
Barbituric acid	[2575,	1895,	—]	2980	0.46
	[2480,	1755,	—]	2823	0.52

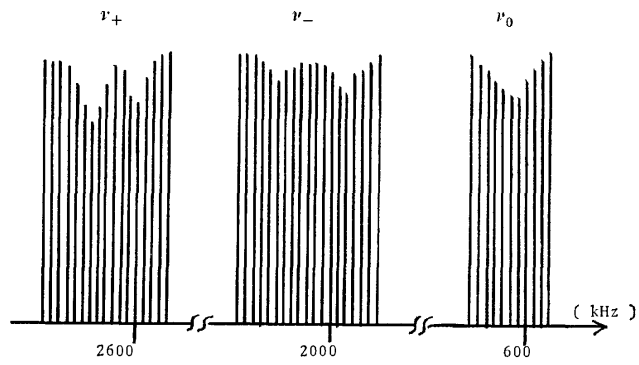

Fig. 1. ^{14}N NQR spectrum of alloxan·H_2O.

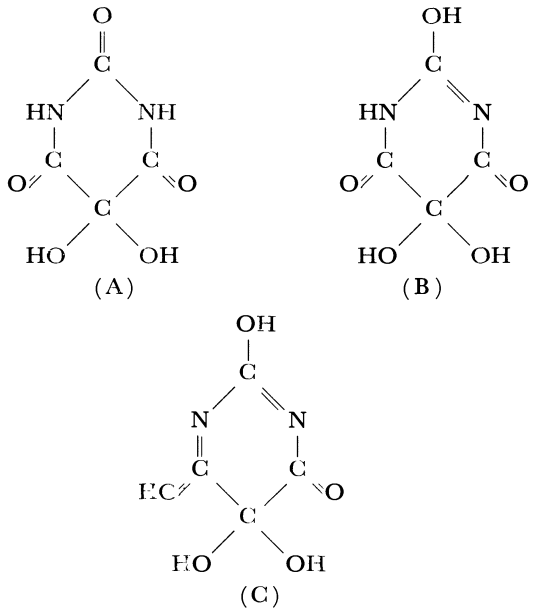

MHz. Additional insight can be obtained from the NQR spectrum shown in Fig. 1. In proton-nitrogen double-resonance experiments, nitrogen not directly bonded to hydrogen atoms gives weak absorption lines, and usually the ν_- lines are smeared out. From these considerations, we can decide that alloxan·H_2O exists predominantly in the triketo configuration (A) in its ground state; this decision agrees with the previous X-ray diffraction study.[7]

As the NC bond lengths and CNC angle for each nitrogen in alloxan·H_2O are quite similar, we can expect that the NQR coupling constants of two nitrogens of alloxan·H_2O are not very different. However the difference of coupling constants is 100 kHz, as may be seen in Table 1. This large difference can be explained by the difference in the intermolecular hydrogen bonds at each nitrogen atom. The two hydrogen bond lengths, N(1)–H(1)–O and N(3)–H(3)–O, differ by 0.164 Å.[7] This large difference would cause a large change in the coupling constants of the nitrogens. It would be possible tentatively to assign one set of observed lines to one particular site by considering the two different intermolecular hydrogen bonds at each nitrogen site and the NQR data experimentally obtained. However, any definitive assignment seems very difficult; therefore, we do not make any such assignment here.

With the Townes and Dailey theory, expressions relating the NQR data to the charge densities are derived as follows;

$$\pi - \sigma_{NC} = \frac{4}{3}\nu_+/(e^2Qq_0/h)$$
$$\sigma_{NH} - \sigma_{NC} = \frac{4}{3}\nu_0/(e^2Qq_0/h)\cdot[1/1-\cot^2\gamma] \quad (2)$$

Table 2. Values of π and σ_{NH} populations for alloxan·H_2O and barbituric acid. π and σ_{NH} are calculated assuming $e^2Qq_0/h=9.1$ MHz, and $\sigma_{NC}=1.200$

Compound	π	σ_{NH}	$[\eta]$[a]
Alloxan·H_2O	1.590	1.320	[0.39]
	1.581	1.322	[0.41]
Barbituric acid	1.577	1.334	[0.46]
	1.563	1.342	[0.52]

a) The asymmetry parameters are used to distinguish the two nitrogen sites in each molecule.

where π is the pi population, σ_{NH} is the NH sigma population, σ_{NC} is the averaged NC sigma population, 2γ is the CNC angle, and q_0 is the electric-field gradient caused by a 2p electron of the nitrogen atom. In order to estimate these charge densities, e^2Qq_0/h, σ_{NC}, and 2γ are set at 9.1 MHz,[8] 1.200, and 126°, the averaged values of the CNC angles for each nitrogen in alloxan·H_2O and barbituric acid.[7] The estimated values of the π and σ_{NH} populations are shown in Table 2. The great π populations and the small sigma populations of alloxan·H_2O compared with those of barbituric acid can easily be understood, since the hydroxyl group is known to be π-electron-donating and σ-electron-withdrawing.

Conclusion

In this paper, the following two conclusions were obtained;

1. Alloxan·H_2O exists predominantly in the 2,4,6-triketo-5,5-dihydroxy structure in a solid; this determination agreed with the results of the X-ray diffraction study.
2. The difference in coupling constants for nitrogens in alloxan·H_2O is attributable to the difference in intermolecular hydrogen bonds for each nitrogen.

The Effects of Added Electrolytes on Mn^{2+}-ion Mobility in Micellar Solutions Studied by the ESR Method

Masako Ueki and Yuhei Uzu*

Department of Chemistry, Faculty of Science, Shinshu University, Asahi, Matsumoto 390

(Received November 1, 1979)

Synopsis. The effects of added electrolytes on manganese-ion mobility in manganese dodecyl sulfate solutions ($Mn(DS)_2$) were measured by means of the ESR method. The addition of aluminum chloride results in line-narrowing and an increase in the signal intensity in the ESR spectra at the concentrations above CMC of the $Mn(DS)_2$ solutions, while the addition of sodium chloride does not affect the ESR spectra.

To obtain information on counterion mobility in the interface between a micelle and the intermicellar solution, some investigations employing the manganese ion as an ESR probe of metal binding to sodium dodecyl sulfate (SDS) micellar solutions have been made by several groups of workers in recent years.[1,2] Above the CMC, it has been found that linewidth-broadening or signal-intensity loss in the ESR spectrum of the Mn^{2+} ion was caused by the Mn^{2+} ion in two environments surrounding the micelle: the manganese ion may be free in the intermicellar solution, or it may be attached to the micelles formed. In the hope of obtaining further corroborating evidence for this postulate, the present study, based on measurements of the linewidth and relative intensity of the Mn^{2+} ion, was performed for $Mn(DS)_2$ solutions, with and without added electrolytes.

The manganese dodecyl sulfate used was prepared by adding an excess of $MnSO_4$ to a SDS solution and by then cooling the solution in a dry ice–water bath. The SDS was synthesized according to the method of Dreger *et al.*[3]

The surface tensions on $Mn(DS)_2$ and SDS aqueous solutions were measured for the determination of the CMC by means of Kyowa Tensiometer. Surface-tension measurements in the redistilled water at 30 °C indicated no minima and CMC values of 8 mmol dm^{-3} for SDS and 1 mmol dm^{-3} for $Mn(DS)_2$, all in good agreement with those in the literature.[4] The inorganic electrolytes added, sodium and aluminum chlorides, were those of extra-pure reagents and had been purified by recrystallization.

For the preparation of the solution investigated, different amounts of the salts were dissolved in the $Mn(DS)_2$ solution at a given concentration above the CMC. For the concentrations below the CMC, the addition of the Al salt made precipitates, and so the measurements were made for solutions containing 5 mmol dm^{-3} and 10 mmol dm^{-3} $Mn(DS)_2$. The solutions thus obtained were directly inserted into a capillary tube 1.5 mm in o.d. and then sealed in the presence of air for the ESR measurements.

The ESR spectra were recorded with a Japan Electron Model JES-ME-3X spectrometer operating at the X band with 100-KHz field modulation.

In each measurement, six typical hyperfine lines were completely resolved. The linewidth (ΔH) was directly measured as the peak-to-peak distance of the fourth line from the low-field side.[5] For a Lorentzian resonance line, the intensity is proportional to the product of the height of the derivative curve and the square of the linewidth. The relative intensity was obtained by comparing the (height) × (linewidth)^2 product with that of the reference sample in the cavity. A sample of 0.01 wt % DPPH dispersed homogeneously in solid KCl was used as the reference standard.[2,6] All the intensity measurements were made with the same sample volume in order to obtain a good reproducibility. In addition, identical microwave power, crystal biasing current, field-scanning rate, and modulation amplitude were used. Figure 1 shows the dependence of the linewidth (ΔH) and the increment

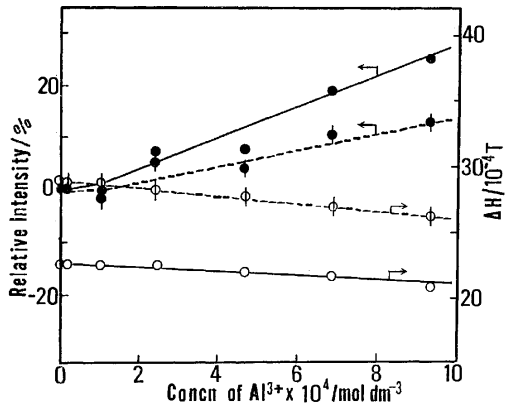

Fig. 1. Relative intensity (full points) and linewidth (open points) of Mn^{2+} as a function of added $AlCl_3$ concentration in $Mn(DS)_2$ solutions. —●—, —○—; 5 mmol dm^{-3} $Mn(DS)_2$, --●--, --○--; 10 mmol dm^{-3} $Mn(DS)_2$.

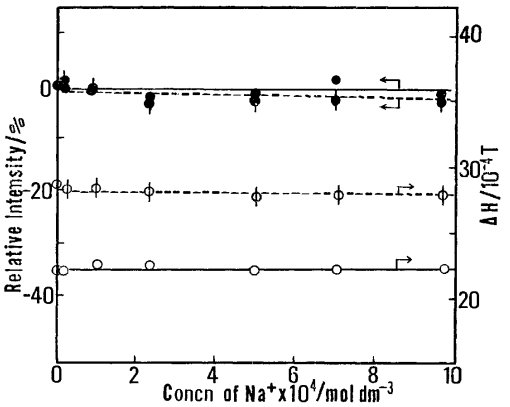

Fig. 2. Relative intensity (full points) and linewidth (open points) of Mn^{2+} as a function of added NaCl concentration in $Mn(DS)_2$ solutions. —●—, —○—; 5 mmol dm^{-3} $Mn(DS)_2$, --●--, --○--; 10 mmol dm^{-3} $Mn(DS)_2$.

in the relative intensity of the Mn^{2+} ion on the concentration of the added $AlCl_3$ at 30 °C, while in Fig. 2 the results for NaCl are presented. Although the figures show some scatter in the relative intensity, the much more pronounced effect of the Al^{3+} ion than that of the Na^+ ion at equimolar concentrations is immediatly obvious. On the further addition of the Al^{3+} ion, the linewidth tends to be appreciably narrower, whereas there is a corresponding increase in the relative intensity. On the contrary, no detectable changes in the ΔH and the intensity were observed upon the addition of NaCl in the range of the concentrations studied. This probably arises in part from the replacement of the Mn^{2+} ion with the more multivalent Al^{3+} ion in the electrical double layer at the micelle surface, followed by the increase in the average number of the free Mn^{2+} ion in the intermicellar solution. This fact was observed upon the addition of Mn^{2+} or VO^{2+} ion to a SDS solution.[1,7] Some support for this result may also be given by the observation of the ESR spectra for $Mn(DS)_2$ solutions with no added salts, as is shown in Fig. 3. In agreement with the earlier finding,[2] the line-broadening is observed at the CMC, and it increases as the concentration is raised. Simultaneously, the signal intensity seems to increase in proportion to the number of the free Mn^{2+} ion, irrespective of the loss in the intensity due to the micellar-bound Mn^{2+} ion above the CMC, as has been stated by Oaks.[2]

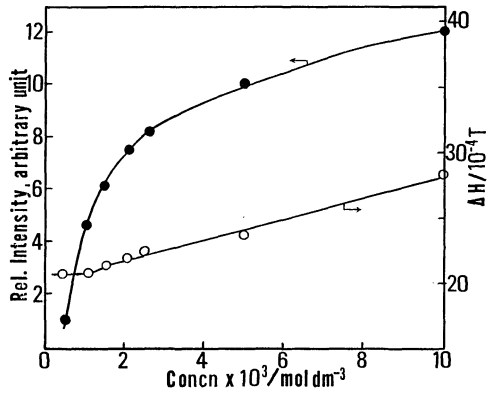

Fig. 3. Relative intensity and linewidth of Mn^{2+} as a function of $Mn(DS)_2$ concentration at 303 K.

On the basis of these deductions concerning the nature of the Mn^{2+} ion motion, the increase in the line-narrowing and intensity with the increase in the concentration of the added Al^{3+} ion can be explained in terms of a decrease in the amount of Mn^{2+} ions bound to the micelle relative to those "free" in the intermicellar solution.

Ground-state Energy Stabilization in Solid Cation Radical Salts Derived from Some Aromatic Hydrocarbons

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received November 26, 1979)

Synopsis. The ground-state energy stabilization due to the charge-transfer interaction between cation radicals was examined with solid cation radical salts of 9,10-dimethylanthracene, 9,10-dichloroanthracene, and perylene with antimony pentachloride and perchlorate anions.

There have been made extensive investigations concerning the optical and magnetic properties of a number of crystalline ion radical salts.[1-7] In such ion radical salts, the planar ion radical moleucles are known to form, in themselves, a segregated stacking into one-dimensional columns so as to make a large overlap between their half-occupied moleuclar orbitals. The electronic and magnetic properties of those solid salts are interesting in comparison with those of ion radical monomer. The electronic spectrum of such solid salt is found to differ distinctly from the monomer spectrum of the corresponding ion radical molecule, but shows a charge-transfer transition between ion radicals in the low-energy region.[1-5] As for the magnetic properties, an antiferromagnetic spin exchange interaction between adjacent ion radicals is known to take place in such solid ion radical salt.[1-6] These optical and magnetic properties can be understood in terms of the charge-transfer interaction between ion radical molecules in segregated one-dimensional columns of solid ion radical salts. In the present paper, we shall examine the ground-state energy stabilization due to the charge-transfer interaction between cation radicals in solid aromatic hydrocarbon cation radical salts of 9,10-dimethylanthracene (DMA) with antimony pentachloride anion, 9,10-dichloroanthracene (DCA) with antimony pentachloride anion, and perylene with perchlorate anion.[2,8]

In a previous paper,[4] we applied Hubbard model to the segregated stack of the aromatic hydrocarbon cation radicals and explained the optical and magnetic behaviors of those solid cation radical salts. As for the DMA and DCA cation radical salts, non-alternant one-dimensional half-occupied Hubbard Hamiltonian was applied to the stack of the DMA or DCA cation radicals. The Hubbard Hamiltonian is given by

$$\mathscr{H} = \sum_{i,j,\sigma} T_{ij} C_{i\sigma}^{+} C_{j\sigma} + I \sum_{i} n_{i\downarrow} n_{i\uparrow}, \qquad (1)$$

where $n_{i\sigma} = C_{i\sigma}^{+} C_{i\sigma}$, and $C_{i\sigma}^{+}$ and $C_{i\sigma}$ are the creation and annihilation operators of an electron with σ-spin at the i-th site, respectively, and where T_{ij} is the electron transfer matrix element between the i-th and j-th sites, and the Coulomb repulsive potential, I, appears only when two electrons with up and down spins are at the same site. In this model, we take the half-occupied molecular orbital of the unpaired electron for one site of cation radical, and assume a model of regular one-dimensional column composed of infinite number of such sites. We further assume that the transfer matrix element of electron exists only between nearest neighbor sites and is denoted by $T(<0)$. In the case of regular one-dimensional half-occupied Hubbard model with $I \gg |T|$, the Hamiltonian of Eq. 1 becomes equivalent to the following effective Hamiltonian,[6]

$$\mathscr{H}_{\text{eff}} = \frac{4T^2}{I} \sum_{i} \left(\boldsymbol{S}_i \cdot \boldsymbol{S}_{i+1} - \frac{1}{4} \right) + 0\left(\frac{T^3}{I^2} \right), \qquad (2)$$

where $\boldsymbol{S}_i$, $(S=1/2)$, is the spin operator of an electron at the i-th site. In the limit of $I/|T| \to \infty$ and $N \to \infty$, where N is the number of sites in one-dimensional system, we can neglect such higher terms as $0(T^3/I^2)$, and the ground-state energy of Eq. 2 is given by

$$E = -\frac{4NT^2}{I} \ln 2. \qquad (3)$$

The ground-state energy of the one-dimensional system of the cation radicals is found to be stabilized by the charge-transfer interaction between cation radicals through the non-zero transfer matrix element, T. Rigorously speaking, the $I/|T|$ value of one-dimensional system of actual ion radical salt is large but not infinite, so that the approximation of E in Eq. 3 has some deviation from exact ground-state energy of Eq. 2. This deviation is caused by neglecting such terms as $0(T^3/I^2)$ in deriving Eq. 3. Therefore, relative error, $\Delta E/E$, in the approximation of Eq. 3 is, at most, of the order of T/I. An advantage of our application of Hubbard model is many-body treatment, so that we can obtain ground-state energy of one-dimensional stack composed of infinite number of ion radicals.

For the DMA cation radical salt, the experimental results of the charge-transfer absorption and the magnetic susceptibilities were well explained in terms of the parameter values of $I = 11600\ \text{cm}^{-1}$ and $T \approx -570\ \text{cm}^{-1}$.[4] In this case, since the magnitude of $I/|T| = 20.4$ is much larger than unity, we can apply, in place of Eq. 1, the effective Hamiltonian of Eq. 2 to the one-dimensional system of the DMA cation radicals. Then, by the use of the approximation of Eq. 3, the value of E was estimated to be $-0.93\ \text{kJ mol}^{-1}$, and the error of its value was within $\pm 0.046\ \text{kJ mol}^{-1}$. In a similar way, for the DCA cation radical salt, the values of $I = 11200\ \text{cm}^{-1}$ and $T \approx -560\ \text{cm}^{-1}$ were estimated with the one-dimensional system of the DCA cation radicals.[4] Then, the ratio of $I/|T| = 20.0$ is found to be much larger than unity, and the approximation with Eq. 3 is again applicable to our case. The ground-state energy was thus estimated as $E = -0.93 \pm 0.047\ \text{kJ mol}^{-1}$.

In the case of perylene cation radical salt, the perylene cation radicals are paired up to form dimers in the solid state.[2,4] Then, we applied a dimer model of Hubbard Hamiltonian, which can by written by

$$\mathscr{H} = \sum T(C_{1\sigma}^{+} C_{2\sigma} + C_{2\sigma}^{+} C_{1\sigma}) + I(n_{1\downarrow} n_{1\uparrow} + n_{2\downarrow} n_{2\uparrow}), \qquad (4)$$

where the notations are common to those in Eq. 1. The suffixes, 1 and 2, denote two sites of perylene cation radicals in a dimer, and $T(<0)$ is the electron transfer matrix element between the cation radicals in the dimer. If we only take the half-occupied molecular orbital of perylene cation radical for each site, there are six bases of the wave functions for the dimer. After solving the eigen value problem, the lowest s tate of the dimer is the singlet state whose energy is given by $E_s=I/2-\sqrt{(I/2)^2+(2T)^2}$.[3] The negative value of E_s means ground-state energy stabilization due to the charge-transfer interaction between cation radicals in the dimer through non-zero transfer matrix element, T. Earlier, we explained the optical and magnetic properties of the perylene cation radical salt with the above approach, and obtained the parameter values of $I=6330\ \mathrm{cm^{-1}}$ and $T=-1630\ \mathrm{cm^{-1}}$.[4] Therefore, the ground-state energy per one mole of perylene cation radicals can be estimated by summing the E_s value with half mole of the dimers, and is calculated to be $-8.19\ \mathrm{kJ\ mol^{-1}}$.

For the above three compounds, the ground-state stabilization energy due to the charge-transfer interaction between cation radicals becomes one of the factors for their cohesive energies. At the present time, there may be no other way to isolate and estimate its magnitude experimentally, but its magnitude is related to the absorption intensity of the charge-transfer transition between cation radicals in their solid-state spectra. In regular one-dimensional infinite stack of cation radicals, the absorption intensity is given, in the small $|T|$ limit, by $N\pi e^2aT^2/I$,[5] where a is the lattice separation. Therefore, the absorption intensity is approximately proportional to the magnitude of the ground-state stabilization energy. In the dimer model of cation radicals, the situation appears to be similar, and the magnitude of the ground-state stabilization energy is also nearly proportional to the charge-transfer absorption intensity of the dimer. In view of the estimated values of the stabilization energies of DMA, DCA, and perylene cation radical salts. the charge-transfer absorption intensity of the perylene cation radical salt will be about nine times stronger than those of the DMA and DCA cation radical salts, and the absorption intensities of the latter two compounds will be of the same magnitude. This prediction appears to be in agreement with the experimental result of the solid-state spectra reported by Sato *et al.*[2]

All of these compounds are ionic crystals and crystal Madelung energy will be the most important factor for their cohesive energies. Although there is no information on the values of Madelung energy for those compounds, the Madelung energies of several other cation radical salts such as Würster's Blue (*N,N,N',N'*-tetramethyl-*p*-phenylenediamine) perchlorate and iodide are of the order of $-4\times10^2\ \mathrm{kJ\ mol^{-1}}$.[6,7] In comparison with great contribution of the Madelung energy, the stabilization energy due to the charge-transfer interaction between cation radicals may make very small contribution to the total cohesive energy in our DMA, DCA, and perylene cation radical salts. However, it is important to note that the mechanism of the charge-transfer interaction does not act in usual ionic crystals such as alkali halides, but only takes place in solid ion radical salts.

8) As for the DMA–$SbCl_5$ and DCA–$SbCl_5$ crystals, in view of their optical and magnetic properties shown in Ref. 2, ion radical species should be only cation radicals of DMA and DCA, and the counter anion of $SbCl_5$ will have some diamagnetic form. Concerning this anion form, Dr. Y. Sato, who is one of the authors of Ref. 2, suggested that the disproportionation to $SbCl_4^-$ and $SbCl_6^-$ might be most probable.

An X-Ray Photoelectron Spectroscopic Study of Several Metal Complexes of 2-Mercaptobenzimidazole and 2-Mercaptobenzoxazole

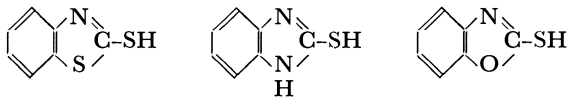
Tooru YOSHIDA

Osaka Prefectural Industrial Research Institute, 2-1-53, Enokojima, Nishi-ku, Osaka 550

(Received August 16, 1979)

Synopsis. The X-ray photoelectron spectra of several metal complexes of 2-mercaptobenzimidazole and 2-mercaptobenzoxazole were measured in order to examine the mode of coordination of the ligands. From their N(1s) and S($2p_{3/2}$) chemical shifts, it was suggested that the ligands are coordinated through both the sulfur and nitrogen atoms in most of the complexes.

Heterocyclic thiols, such as 2-mercaptobenzothiazole, **1**, 2-mercaptobenzimidazole, **2**, and 2-mercaptobenzoxazole, **3**, are widely used as organic reagents for inorganic ions. The complexing properties of these ligands, which exhibit thioketo-thiol tautomerism, have been studied by the use of a variety of techniques: IR, far IR, UV, magnetic measurements, and NMR.[1]



1 **2** **3**

X-Ray photoelectron spectroscopy (XPS) is sensitive to the charge distribution.[2] The XPS study of several metal complexes of **1** has been reported.[3] In that paper, it was proved that the copper was present in a (+1) oxidation state in the complexes obtained from Cu(II) salts and **1**.

The purpose of the present study is to examine the mode of the coordination of the ligands in several metal complexes of **2** and **3** and the oxidation state of copper in their copper complexes by means of XPS.

Experimental

The X-ray photoelectron spectra were measured on an AEI ES200 spectrometer. MgK_α (1253.6 eV) X-ray radiation was used as the excitation source. The samples were ground to powder and then dusted onto double-backed adhesive tape. The measurements were run at room temperature under a vacuum of about 10^{-7} Torr. The binding energy of the C(1s) electron peak was used as the energy standard throughout the present experiments; it was taken to be 285.0 eV. The reproducibilities of the values thus obtained were within ±0.1 eV. All the compounds used and their binding energies are given in Table 1.

Chemicals. Benzimidazole as a reference compound, 2-mercaptobenzimidazole, and 2-mercaptobenzoxazole (abbreviated as L", LH, and L'H respectively) were obtained commercially and were of an analytical grade. They were used after recrystallization from ethanol. The sodium salt (abbreviated as LNa) of LH was obtained by treating LH with NaOH, but the attempt to prepare L'Na was unsuccessful.

Preparations of Metal Complexes. *CuL*: A solution of LH (4 mmol) containing an equivalent amount of NaOH in ethanol (50 ml) was added to a solution of CuX_2 (X= Cl, NO_3, 1/2(SO_4), CH_3COO, ClO_4) (2 mmol) in water (50 ml). A grey-colored compound thus precipitated was digested on a water bath for an hour. The suspension was cooled, and then the precipitate was filtered and washed with ethanol. The yield of the complex was more than 95%, as in other copper complexes.

Cu(LH)Cl, $Cu(LH)_{1.5}(SO_4)_{0.5}$, and $Cu(LH)_{1.5}NO_3 \cdot H_2O$: A solution of LH (4—6 mmol) in ethanol (50 ml) was added to each solution of $CuCl_2$, $CuSO_4$, and $Cu(NO_3)_2$ (2 mmol) in water (50 ml). The ivory-white compounds thus precipitated were treated in a way similar to the procedure for CuL. *CuL'*: A solution of L'H (4 mmol) in ethanol (50 ml) was used instead of the solution of LH containing NaOH in the above procedure for preparing CuL. The color of the compound was ivory-white.

Pb(L–H): An ethanol solution of LH was added to an aqueous solution of $Pb(NO_3)_2$, and the mixed solution was neutralized with aqueous ammonia; a white complex was thus precipitated. *$PbL(CH_3COO)$*: An ethanol solution of LH was added to an aqueous solution of $Pb(CH_3COO)_2$, and then the solution was digested on a water bath; a pale yellow white compound was thus precipitated.

$NiL(OH) \cdot H_2O$ and $NiL'(OH) \cdot H_2O$: An aqueous solution of LH (L'H) containing an equivalent amount of NaOH was added to an aqueous solution of nickel salts, whereby a dark-brown (greenish-brown) compound was precipitated.

Other Metal Complexes: The other metal complexes were prepared based upon the literature.[1]

All the compounds used were dried in an air oven at 95 °C for at least 2 h and then analyzed elementally.

Results and Discussion

The N(1s) spectra of LH and L'H showed a single peak, and the peak could be assigned to the protonated nitrogen atom from its binding energy.[3] This indicates that both LH and L'H exist entirely in the thioketo form. This conclusion is consistent with the results obtained by IR.[4] The N(1s) spectra of LNa and L" showed two peaks with nearly equal intensities; these peaks could easily be assigned to protonated and deprotonated nitrogen atoms, based upon their binding energies.

The N(1s) binding energies of the protonated and deprotonated nitrogen atoms of LNa were 0.3—0.5 eV lower than those of L". The S($2p_{3/2}$) binding energy of LNa is fairly close to that of LH. These findings may suggest that, in LNa, the contribution of $-\overline{N}-\overset{|}{C}=S$ dominates that of $-N=\overset{|}{C}-\overline{S}$, and that an apparent unit negative charge on the nitrogen is delocalized by conjugation within the hetero five-membered ring.[5]

The N(1s) spectra of AgL, HgL_2, $CdL_2 \cdot 0.5H_2O$, $PbL(CH_3COO)$, CuL, $NiL(OH) \cdot H_2O$, $PdL_2 \cdot 2H_2O$, and $PtL_2 \cdot H_2O$ showed the presence of two kinds of nitrogen atoms, that is, protonated and deprotonated nitrogens, similarly to LNa. Those of the other metal complexes showed a single peak, indicating only one kind of nitrogen atom, that is, a deprotonated nitrogen atom for Pb(L–H), in addition to all the com-

plexes of L'H, and a protonated nitrogen for the remaining complexes of LH.

In general, the coordination of a ligand to a metal ion causes a decrease in the electron density on the coordination atom, giving rise to an increase in the core-electron binding energy of the atom.

In the series of the complexes of LH, the chemical shifts of the N(1 s) binding energy of a deprotonated nitrogen atom or of the S($2p_{3/2}$), which are the differences between the N(1 s) or the S($2p_{3/2}$) binding energies of the complexes and LNa, were 0.2—1.1 eV. These chemical shifts were comparable with the values reported for the complexes with other ligands.[6] This seems to suggest that, in all the complexes, the ligand is coordinated through the sulfur atom, and that in the complex containing a deprotonated nitrogen atom the ligand is also coordinated through the nitrogen atom.

It was difficult to confirm the presence of the bond between a metal ion and a protonated nitrogen atom because of the absence of any appreciable difference between the N(1 s) binding energies of the protonated nitrogen atoms of a complex and LH.

In the series of the complexes of L'H, the N(1 s) and S($2p_{3/2}$) chemical shifts were 0.3—1.0 eV and 0.1—0.7 eV respectively. In this case, the N(1 s) binding energy (399.0 eV) of the deprotonated nitrogen atom of L" and the S($2p_{3/2}$) binding energy (162.5 eV) of L'H were used as the standard energies in determining the chemical shifts, because L'Na could not be obtained. The chemical shifts thus obtained seem to suggest that, in all the complexes, the ligand is coordinated through both the sulfur and nitrogen atoms. The O(1 s) electron spectra of all the complexes showed a single peak. There was no appreciable difference between the O(1 s) binding energies of a complex and L'H. This seems to suggest the absence of a metal–oxygen bond. These conclusions were consistent with the results obtained by IR and far IR.[1d]

The N(1 s) electron binding energies of L'H and its complexes were 0.3—0.5 eV higher than those of LH and the deprotonated nitrogen atom of its corresponding metal complexes. This finding suggests that the electron densities on the nitrogen atom of the former compounds are smaller than those of the latter. This seems to be consistent with the fact that the dissociation constant (pK_{N-H}=6.58) of L'H was smaller than that (pK_{N-H}=9.18) of LH.[7]

The Cu ($2p_{3/2}$) electron-region spectra of all the copper complexes in this study did not show at all a satellite characteristic of cupric compounds.[8] Furthermore, the Cu($2p_{3/2}$) binding energies were 2—4 eV lower than those of cupric compounds.[8] These findings indicate that the copper in the complexes is in a (+1) oxidation state, as in the copper complexes of 2-mercaptobenzothiazole.[3] This is apparent also from the stoichiometric analyses of the complexes in the present study.

The author wishes to thank Drs. Kiyoshi Yamasaki and Shigemasa Sawada for their helpful discussions and suggestions during this work, and Mr. Taichiro Hirohara for the elemental analysis.

Chemical Ionization Mass Spectrometry of Epoxides

Shin SUZUKI,* Yoshio HORI, Rebati C. DAS,† and Osamu KOGA

Department of Synthetic Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba 260

(Received June 20, 1979)

Synopsis. The chemical ionization mass spectrometry of epoxides using methane as a reagent gas produces quasi-molecular ions, $(M+1)^+$. This ion has maximum abundance for most epoxides except 1,2-epoxybutane. The method is useful for determination of the molecular weight of epoxides.

Although the behavior of olefines in the photochemical reactions of NO_x–hydrocarbon–O_2 system has attracted interest from the viewpoint of photochemical smog formation,[1–3] all the products from the above reactions were not identified. Epoxides are produced from the reaction of O radical and olefines.[1]

CI mass spectrometry, recently developed,[4] gives abundant quasi-molecular ions ($m/e=(M+1)^+$ or $(M-1)^+$) for many organic compounds, the method being useful for molecular weight determination.[4,5] The present paper gives the results of CI mass spectrometry of the epoxides, as a part of our overall program of identification and analysis of all the products formed in the NO_x–hydrocarbon–O_2 system.

Experimental

A Shimadzu GC-MS apparatus was used. C_2—C_4 epoxides were used as reference materials. Commercial ethylene oxide (Takachiho Chemical Industries), propylene oxide, 1,2-epoxybutane, 2-methyl-1,2-epoxypropane (Wako Pure Industries) and *cis*- and *trans*-2,3-epoxybutane (Tokyo Kasei) were used. All the compounds were separated in the GC column (PEG 400) at room temperature using helium as a carrier gas (flow rate 30 ml/min) before introduction to the ionization chamber.

Results and Discussion

Figures 1—6 give the EI and CI mass spectra of epoxides. The CI patterns were obtained with methane as a reagent gas. Methane gave relatively simple mass spectra for nitrites and nitrates as compared with i-C_4H_{10} as a reagent gas.[6] The spectra were obtained after subtraction of the background.

The operational conditions of the GC-MS apparatus are as follows. EI spectrum: Ion-source temperature 190 °C, Electron energy 70 eV, Pressure†† 7×10^{-7} Torr. CI spectrum: Ion-source temperature 190 °C, Electron energy 350—500 eV, Pressure†† 5×10^{-5} Torr.

The main reactant ions are CH_5^+ and $C_2H_5^+$ when methane is used as a reagent gas.[7] The proton and hydride transfer reactions of these ions are important for analytical purpose, since they generate the quasi-molecular $(M+1)^+$ and $(M-1)^+$ ions, respectively.

$$RH + CH_5^+/C_2H_5^+ \longrightarrow RH_2^+ + CH_4/C_2H_4 \quad (1)$$

$$RH + C_2H_5^+ \longrightarrow R^+ + C_2H_6 \quad (2)$$

All the compounds except 1,2-epoxybutane showed very simple CI mass spectra, giving $(M+1)^+$ ion most abundantly. 1,2-Epoxybutane also gives $(M+1)^+$ ion, but the peak at $m/e=55$ is the highest (Fig. 3). This might be related to the easier γ-cleavage of the 1,2-epoxybutane.[8] EI also gave rise to complex cleavage of epoxides, showing that CI is useful for determination of the molecular weight of epoxides.

A series of mass spectra of C_4H_8O isomers, 1,2-epoxybutane, *trans*- and *cis*-2,3-epoxybutane and 2-methyl-1,2-epoxypropane, are given in Figs. 3—6. Only 1,2-epoxybutane could be identified by the CI method, since it gives a different CI mass pattern. However, CI is useless to distinguish other three isomers. Ethylene oxide gives CI mass spectrum quite similar to that of its isomer, acetaldehyde, which is produced by the photochemical reaction of NO_x–hydrocarbon–air system.†††

Mass fragments other than stated above are as follows. $(2M+1)^+$ fragment ion appeared in ethylene oxide ($m/e=89$, Fig. 1) and *trans*- and *cis*-2,3-epoxybutane ($m/e=145$, Figs. 4 and 5). Such ions very often appear in the CI spectra.[9] Small amounts of $(M)^+$ and $(M-1)^+$ ions were found in C_3—C_4 epoxides. The peaks at $m/e=(M-17)$ are also common to all epoxides except ethylene oxides. This is the highest peak especially for 1,2-epoxybutane. For C_4 epoxides, the peak ($m/e=55$, Figs. 3—6) could be ascribed to $C_3H_3O^+$ or $C_4H_7^+$. C_3 epoxide (propylene oxide) gave the peak, $m/e=41$ (Fig. 2) which might be derived from C_2HO^+ or $C_2H_5^+$. This suggests alcoholic ion formation; certain alcoholic structures were found for ionized epoxides.[10] The peaks at $m/e=(M-13)$ exist in propylene oxide and 1,2-epoxybutane. They are tentatively assigned to $C_3H_7O^+$ for 1,2-epoxybutane and $C_2H_5O^+$ for propylene oxide. The peaks at $m/e=(M-29)$ are small, but appear in all the spectra except for ethylene oxide. They may be $C_2H_3O^+$ or $C_3H_7^+$ for C_4 ($m/e=43$, Figs. 3—6) and CHO^+ or $C_2H_5^+$ for C_3 ($m/e=29$, Fig. 2).

The Liquid-Liquid Extraction of Zinc with Polyethylene Glycol and Poly(oxyethylene)-type Nonionic Surfactants

Toshio SUZUKI,* Naoyuki MURAKAMI, and Takeshi SOTOBAYASHI

Department of Chemistry, Faculty of Science, Niigata University, Ikarashi-Ninocho 8050, Niigata 950-21

(Received September 6, 1979)

Synopsis. The Zn(II) extraction was made from its acidic thiocyanate solution, using polyethylene glycol and its mono(alkylphenyl) ether as extractants. The effects of the number of oxyethylene groups (–O–CH_2–CH_2–) per molecule and of the kind of the counter cation of thiocyanate on the extractability are described, together with some other factors affecting the Zn(II) extraction.

Recently polyethylene glycol (PEG) and its derivatives have been found to useful as extractants in the liquid-liquid extraction of heavy metal and actinoid ions, and their extraction behavior has been briefly reported.[1–3] In the present paper, somewhat detailed results will be reported on the extraction behavior of a trace amount of Zn(II) from hydrochloric-acid solutions of several alkali and alkaline earth metal thiocyanates into some polar organic-solvent solutions of PEG and several poly(oxyethylene)-type nonionic surfactants.

Experimental

Reagents and Apparatus. The PEG, with a nominal molecular weight of 7500 ($HO(EO)_nH$, n: The number of oxyethylene groups (EO's), abbreviated as PEG 7500), and poly(oxyethylene)(–O–CH_2–CH_2–, POE) mono[(6-methylheptyl)phenyl] ether ($C_8H_{17}C_6H_4O(EO)_n$, $n=10$, abbreviated as Triton X-100) were supplied by the Wako Pure Chemicals Co., and the POE mono(nonylphenyl) ethers ($C_9H_{19}C_6H_4O$-$(EO)_nH$, $n=10$—120, abbreviated as NS (10—120), by the Nippon Oils & Fats Co. All these reagents were used for the extraction experiments without further purification. ^{65}Zn was used as a radioactive tracer to determine the distribution ratio of Zn(II) extraction, while the ^{65}Zn radioactivity was measured by means of a well-type NaI(Tl) detector (2.5× 3.0 in.) equipped with a multi-mode scaler (Aloka).

Extraction Procedure. Take 10 ml of an acidic aqueous thiocyanate solution containing a small amount of Zn(II) and 10 ml of a given organic solvent solution of a PEG or POE surfactant into a stoppered centrifuging tube, and then shake the tube for 2 h at 25±0.5 °C. It was proved by the preliminary experiment that the shaking time of 2 h was sufficient to attain the extraction equilibrium. After centrifuging, the radioactivity of a 5 ml aliquot of each phase was measured. The distribution ratio(D) of Zn(II) was determined by means of the radioactivity ratio of the two phases.

Results and Discussion

Effect of Organic Diluent. The extractability of Zn(II) was measured using various organic solvents as the diluent of PEG 7500 or Triton X-100, the results are shown in Table 1, together with the dielectric constants of the organic solvents used. As may be seen from this table, a polar diluent with a high dielectric constant (>10), like nitrobenzene and 1,2-dichloroethane(DCE), gave a high percentage extraction, but o-dichlorobenzene, with a dielectric constant of only 9.93, yielded a very low % E-value of 1.6. Thus, a 1,2-DCE solution of the extractant was used as the organic phase in this work.

Table 1. Effects of organic solvents

Solvent	Dielectric constant	Percentage extraction (%)	
		PEG 7500	Triton X-100
Nitrobenzene	34.8	>99	>99 (>99) [a]
1,2-Dichloroethane	15.1	>99	84.5 (>99)
o-Dichlorobenzene	9.93	1.6	94.8 (—)
Chlorobenzene	5.61	0.2	68.9 (>99)
Benzene	2.28	<0.1	16.8 (95.6)
Toluene	2.37	<0.1	13.6 (45.3)
Xylene	2.57	<0.1	— (15.6)
Carbon tetrachloride	2.23	<0.1	— (6.5)

Aqueous phase: 0.2 M KSCN, 0.01 M HCl, 0.001 M surfactant. a) Aqueous phase: 1.0 M KSCN, 0.01 M HCl, 0.05 M Triton X-100.

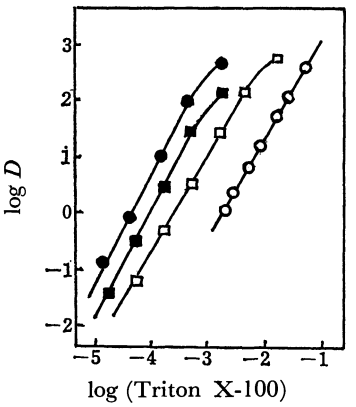

Fig. 1. Effect of surfactant concentration on the Zn(II) extraction.
Aqueous phase: 0.01 mol dm^{-3} HCl, 1.0 mol dm^{-3} thiocyanates. ●: KSCN, ■: NH_4SCN, □: NaSCN, ○: LiSCN. Organic phase: Triton X-100 in 1,2-DCE (w/v %).

Effect of the Extractant Concentration in the Organic Phase and the Kind of the Counter Cation of Thiocyanate in the Aqueous Phase. Figure 1 shows four log-log plots of the distribution ratio(D) of Zn(II) *vs.* the concentration (w/v %) in the organic phase of Triton X-100 for 4 different acidic aqueous phases, each containing an alkali metal and ammonium thiocyanates (1.0 mol dm^{-3}). When compared with each other at a given Triton X-100 concentration in the organic phase, the distribution ratios for these aqueous phases (4 thiocyanates) increased in the following order:

$$LiSCN < NaSCN < NH_4SCN < KSCN.$$

The log-log plots for Li^+, Na^+, NH_4^+, and K^+ give

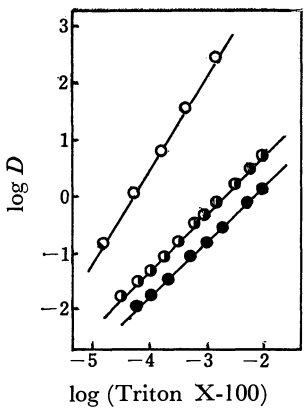

Fig. 2. Effect of surfactant concentration on the Zn(II) extraction.
Aqueous phase: 0.01 mol dm^{-3} HCl, 0.5 mol dm^{-3} thiocyanates. ○: $Ba(SCN)_2$, ◑: $Ca(SCN)_2$, ●: $Mg(SCN)_2$. Organic phase: Triton X-100 in 1,2-DCE.

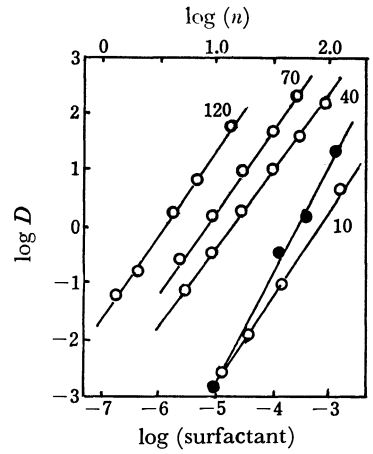

Fig. 3. Effect of the number(n) of EO's per molecule.
Aqueous phase: 0.5 mol dm^{-3} HCl, 1.0 mol dm^{-3} NH_4SCN. Organic phase: NS(10—120) in 1,2-DCE. ○: log *D* *vs.* log (surfactant), ●: log *D* *vs.* log (*n*). (The figures refer to the number of EO's.)

straight lines with slopes of 1.7, 1.7, 1.9, and 2.0 respectively. The plots for Na^+, however, show a tendency to deviate a little from their straight lines at high Triton concentrations of more than 10^{-2} mol dm^{-3}, the plots for NH_4^+ and K^+ show a similar tendency at concentrations of more than 10^{-3} mol dm^{-3}. Such a deviating tendency is not observed in the plot for Li^+, not even at high Triton concentrations of up to 8×10^{-2} mol dm^{-3}. In Fig. 2 the distribution ratio of Zn(II) is plotted against the concentration in the organic phase of Triton X-100, with the respective 0.01 mol dm^{-3} HCl solutions of 3 alkaline earth metal thiocyanates (1.0 mol dm^{-3}) being used as the aqueous phases. It can clearly be seen in Fig. 2 that the log-log plot for the aqueous phase of $Ba(SCN)_2$ has a slope of 1.7, about twice those for the aqueous $Mg(SCN)_2$ and $Ca(SCN)_2$ systems, and rather similar to those for the aqueous alkali metal thiocyanates (2.0—1.7). The *D*-value for the aqueous $Ba(SCN)_2$ system was larger than those for the $Mg(SCN)_2$ and $Ca(SCN)_2$ systems by a factor of at least 10—10^4 in the Triton X-100 concentration in the organic phase studied. The *D*-value for the aqueous phases of the these alkaline earth metal thiocyanates increased in this order:

$$Mg(SCN)_2 < Ca(SCN)_2 \ll Ba(SCN)_2.$$

Effect of the Number of EO's Per Molecule. Zn(II) was extracted from its 0.5 mol dm^{-3} HCl solution of NH_4SCN (1.0 mol dm^{-3}) with NS(10—120) in 1,2-DCE. Figure 3 shows the log-log plots of the distribution ratio(*D*) of Zn(II) *vs.* the formal molar concentration in the organic phase of NS (10—120), or the number of EO's per molecule. As can clearly be seen, at a given concentration in the organic phase of NS (10—120) the *D*-value increased with an increase in the EO number; the *D*-value for NS (120) was more than 10^4 times larger than that for NS(10), whereas the EO number for NS(10) is 12 times larger than that for NS(120). This finding is consistent with the U(VI) extraction dependence on the EO number for a series of PEG's of various molecular weights (200—20000)[3].

†*Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita 565*

(Received September 17, 1979)

Synopsis. Solid state reactions between rare earth orthophosphate (RPO_4) and oxides (SiO_2, Al_2O_3, or CaO) in the air were studied by means of X-ray diffractometry. RPO_4 does not react with SiO_2, decomposing on heating above 1800 °C with Al_2O_3, or above 700 °C with CaO.

Anhydrous RPO_4 is stable in the air at temperatures near 2000 °C.[1,2] However, no study seems to have been carried out on the solid state reactions of RPO_4 with other oxides. The present study deals with such reactions between synthesized RPO_4 (R=La, Ce, Nd, Sm, Y, Dy, Er, or Yb) and oxides (SiO_2, Al_2O_3, or CaO) at temperatures in the range 600—1900 °C in the air.

Experimental

Starting Materials. Powder of monoclinic RPO_4 (R=La, Ce, Nd, or Sm) and that of tetragonal RPO_4 (R=Y, Dy, Er, or Yb), particle size less than 1 μm, and chemical composition very similar to that of theoretical RPO_4, were prepared by the methods reported[1,3-5]. Powder of SiO_2 (α-quartz, Wako Chemical Ind., Ltd.), Al_2O_3 (α-alumina, Nishio Ind., Ltd.) and CaO (Nakarai Chemicals, Ltd.), of high purity and less than 62 μm in length, were prepared from substances of reagent grade.

Solid State Reactions. Mixtures of RPO_4 and oxide in mole ratio 0.1—1 (RPO_4/oxide) were pressed at room temperature into pellets, *ca.* 10 mm diam. under the pressure 500 kgf/cm² (1 kgf/cm²=98.0665 kPa). The pellets were preheated at 600 °C, and then calcined in the temperature range 600—1900 °C for 60 min in an alumina crucible by using a SiC electric furnace (600—1500 °C) or an oxygen-propane gas furnace (1500—1900 °C).

Results and Discussion

Reaction with SiO_2. RPO_4 did not react with SiO_2 at temperature below 1700 °C. X-Ray diffraction patterns of the pellets calcined in the temperature range 600—1700 °C showed only the diffraction lines of the starting materials and none of new reaction products. The pellets softened with an increase in the amount of SiO_2 above 1713 °C (melting point of SiO_2) in the air.

Reaction with Al_2O_3. When the pellets were calcined below 1750 °C, X-ray diffraction patterns were those of the starting materials. However, some pellets (R=Nd, Sm, Y, Dy, Er, or Yb) calcined at 1800 °C and others (R=La, or Ce) calcined at 1850 °C for 60 min showed X-ray diffraction patterns of the reaction products (R_2O_3 or CeO_2).

The X-ray peak intensity of Al_2O_3 in the calcined pellets seems to be little affected by the calcining temperature and the decomposition of RPO_4, while that of R_2O_3 or CeO_2 was much affected, becoming strong with the decomposition of RPO_4. At 1900 °C, the X-ray diffraction lines of RPO_4 disappeared, only Al_2O_3 and R_2O_3 or CeO_2 becoming the main constituents of the calcined pellets. The amount of P of the calcined pellets determined by chemical analysis decreased gradually with the progress of the decomposition of RPO_4 above 1800 °C.

$AlPO_4$ is easily formed by heating mixtures of Al_2O_3 and P_2O_5 in the air. However, no $AlPO_4$ was detected in the pellets calcined at temperatures above 1800 °C for 60 min. Beck[6] reported that $AlPO_4$ is easily decomposed within a few minutes by heating at temperature above 1590 °C in the air, P component evaporating rapidly. Thus, even if $AlPO_4$ is formed in the pellets at temperatures above 1800 °C, it would be decomposed within a few minutes, its detection becoming difficult.

The reaction process might be expressed as follows:

$$2RPO_4 + Al_2O_3 \longrightarrow 2AlPO_4 + R_2O_3 \longrightarrow Al_2O_3 + R_2O_3 + (\text{P component}\uparrow)$$

$$\text{or}\quad 2CePO_4 + Al_2O_3 + 1/2O_2 \longrightarrow 2AlPO_4 + 2CeO_2 \longrightarrow Al_2O_3 + 2CeO_2 + (\text{P component}\uparrow) \quad (1)$$

$$2RPO_4 \xrightarrow{Al_2O_3} R_2O_3 + (\text{P component}\uparrow), \text{ or}$$

$$2CePO_4 \xrightarrow[1/2O_2]{Al_2O_3} 2CeO_2 + (\text{P component}\uparrow) \quad (2)$$

The process is based on the following assumptions: in (1) $AlPO_4$ can be formed in the calcined pellets in the early stages of reaction, and in (2) Al_2O_3 catalyzes the decomposition of RPO_4 in the calcined pellets, and no $AlPO_4$ can be formed because of high temperature.

It is apparent that RPO_4 can be decomposed by Al_2O_3 above 1800 °C in the air. However, which process takes place has not been clarified.

The melting points of Al_2O_3 and R_2O_3 or CeO_2 are higher than 1900 °C. However, the pellets softened at *ca.* 1900 °C, a part of the alumina crucible in contact with the pellets undergoing corrosion. The reason for the pellets softening at *ca.* 1900 °C can be explained by means of the phase diagrams of the systems Al_2O_3–R_2O_3 or CeO_2.[7] There are eutectic points such as 1720 °C (Al_2O_3 77 mol%+Nd_2O_3 23 mol%) or 1850 °C (Al_2O_3 20 mol%+Nd_2O_3 80 mol%) in the Al_2O_3–Nd_2O_3 system.

Reaction with CaO. RPO_4 reacted with CaO at temperatures above 700 °C, $Ca_3(PO_4)_2$ and R_2O_3 or CeO_2 being formed as new reaction products. The ratios of the decomposition of RPO_4 at temperature above 700 °C are expressed by means of the relative X-ray peak intensity ($I_1/(I_1+I_2)$) as shown in Fig. 1.

l_1 is the X-ray integrated peak intensity of RPO_4 ((200) diffraction line), and l_2 that of R_2O_3 or CeO_2 (diffraction line having the strongest intensity in the d range 2.95 (La_2O_3)—3.12 Å (CeO_2)(1 Å=0.1 nm).

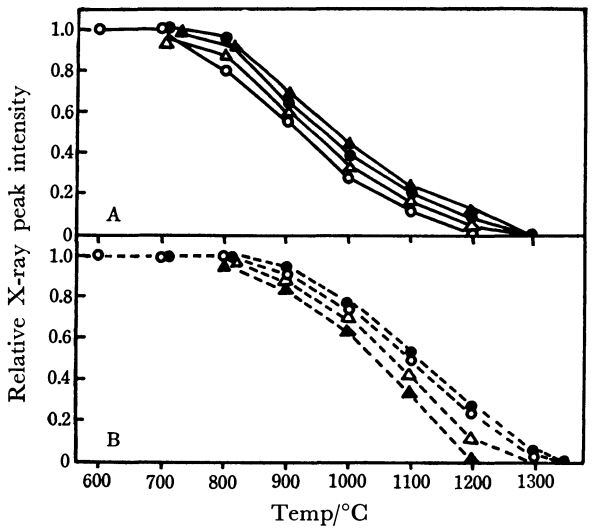

Fig. 1. Relation between the relative X-ray peak intensity and the firing temperature of the pellets[a] fired at various temperatures (600—1350 °C) for 60 min.
a) Mixing mole ratio (RPO_4/CaO) 0.6, A: Monoclinic form RPO_4, B: Tetragonal form RPO_4, ○—○: R=La, ●—●: R=Ce, △—△: R=Nd, ▲—▲: R=Sm, ○---○: R=Y, ●---●: R=Dy, △---△: R=Er, ▲---▲: R=Yb.

The relative X-ray peak intensity began to decrease at 700 °C, becoming O at 1350 °C (mixing mole ratio (RPO_4/CaO) below 0.6). The rate of decomposition of monoclinic RPO_4(A) seems to be slightly higher than that of tetragonal RPO_4(B) (Fig. 1).

The reaction products detected in the calcined pellets were only $Ca_3(PO_4)_2$ and R_2O_3 or CeO_2. The reaction process could be expressed by

$$2RPO_4 + 3CaO \longrightarrow Ca_3(PO_4)_2 + R_2O_3$$

or $$2CePO_4 + 3CaO + 1/2O_2 \longrightarrow Ca_3(PO_4)_2 + 2CeO_2 \quad (3)$$

The pellets softened at temperature below 1800 °C in the air since the melting point of $Ca_3(PO_4)_2$ is lower than that of RPO_4.

The work was partially carried out with Grant-in-Aid for Scientific Research No. 365280 from the Ministry of Education.

Mechanical Strength and Thermal Expansion of Sintered Rare Earth Orthophosphate$(RPO)_4$

Yasuo HIKICHI,* Ken-iti HUKUO, and Jiro SHIOKAWA†

Materials Research Laboratory, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466

†*Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita 565*

(Received September 18, 1979)

Synopsis. RPO_4 powders, obtained by heating a hexagonal form $RPO_4 \cdot 0.5H_2O$ (R=La, Ce, Pr, Nd, or Sm) or a monoclinic form $RPO_4 \cdot 2H_2O$ (R=Y, Er, or Yb) at 800 °C for 3 h, were pressed into plates or spheres at 500 kgf/cm² (1kgf/cm²=98.0665 kPa) and sintered at 1500 °C for 60 min in the air, the sintered bulk density being above 90% of the theoretical. The mechanical strength and thermal expansion of the sintered RPO_4 are : compressive strength 2300—3000 kgf/cm², bending strength 320—500 kgf/cm², and linear thermal expansion coefficients (30—900 °C) $(5.75—10)\times10^{-6}$.

In a previous paper,[1] a report was given on the freezing point of RPO_4 (R=La, Ce, Pr, Nd, Sm, Y, or Yb) measured by the specular reflection method with a heliostat type solar furnace. However, the mechanical strength and thermal expansion were not reported. The present study reports the compressive strength, bending strength and linear thermal expansion coefficients of RPO_4 sintered at 1500 °C in the air.

Experimental and Results

Starting Materials. Starting materials were powders of a monoclinic form RPO_4 (R=La, Ce, Pr, Nd, or Sm) and a tetragonal form RPO_4 (R=Y, Er, or Yb) prepared by heating a hexagonal form $RPO_4 \cdot 0.5H_2O$ (R=La, Ce, Pr, Nd, or Sm) or a monoclinic form $RPO_4 \cdot 2H_2O$ (R=Y, Er, or Yb) at 800 °C for 3 h in the air.[2-4] The particle sizes of the starting materials were less than 1 μm, the chemical composition being almost the same as the theoretical formula, RPO_4.

Sintering. No detailed study seems to have been reported on the sintering of RPO_4. Preliminary experiments were carried out in order to clarify the relation between the bulk density of the calcined RPO_4 pellets and the calcining temperature.

About 1 g of the starting material was pressed at room temperature into pellets of 10 mm diam. under the pressure of 500 kgf/cm². The bulk densities of the pellets were 2.49 ($LaPO_4$), 2.54 ($CePO_4$), 2.59 ($PrPO_4$), 2.61 ($NdPO_4$), 2.67 ($SmPO_4$), 1.82 (YPO_4), 2.69 ($ErPO_4$), and 2.74 g/cm³ ($YbPO_4$). The pellets were heated at 500 °C, and then calcined at various temperatures (900—1500 °C) for 60 min in an alumina crucible by using a SiC electric furnace. It was confirmed that the alumina crucible does not react with the pellets at temperature below 1500 °C in the air.

The bulk densities of the pellets calcined at 900 °C were the same as those of the starting pellets. However, the pellets began to shrink at temperature above 950 °C, their bulk densities increasing with rise in calcining temperature (Fig. 1). The theoretical densities are 5.04 ($LaPO_4$), 5.16 ($CePO_4$), 5.26 ($PrPO_4$),

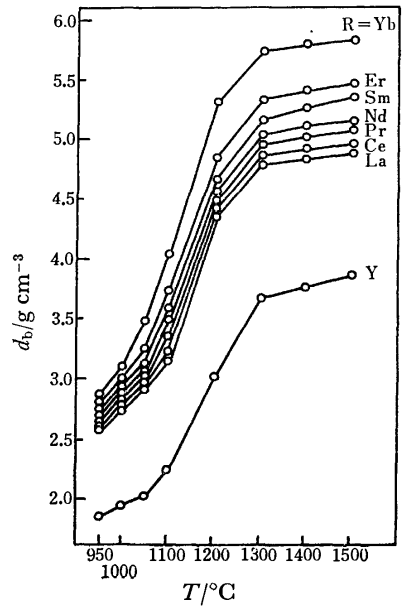

Fig. 1. Relation between the bulk density of the fired RPO_4 pellets and the firing temperature. Firing time: 60 min, d_b: Bulk density.

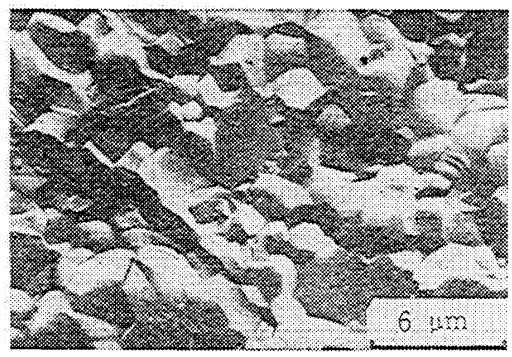

Fig. 2. The fractured surface of the sintered $CePO_4$ at 1400 °C for 60 min, studied by scanning electron microscopy.

5.40 ($NdPO_4$), 5.69 ($SmPO_4$), 4.26 (YPO_4), 6.12 ($ErPO_4$), and 6.36 g/cm³ ($YbPO_4$). The relative densities ((bulk density/theoretical density)×100%) increased rapidly above 1100 °C, becoming greater than 90% at 1500 °C: $LaPO_4$ 97%, $CePO_4$ 97%, $PrPO_4$ 97%, $NdPO_4$ 96%, $SmPO_4$ 94%, YPO_4 91%, $ErPO_4$ 90%, and $YbPO_4$ 92%. Apparent porosity of the pellets calcined at 1500 °C was below 5%. The results show that the sintering of RPO_4 is nearly completed by calcining at 1500 °C for 60 min in the air.

Scanning electron micrographs of the fractured surfaces of the sintered pellets show that the structure becomes dense (Fig. 2).

Mechanical Strength. The compressive strength

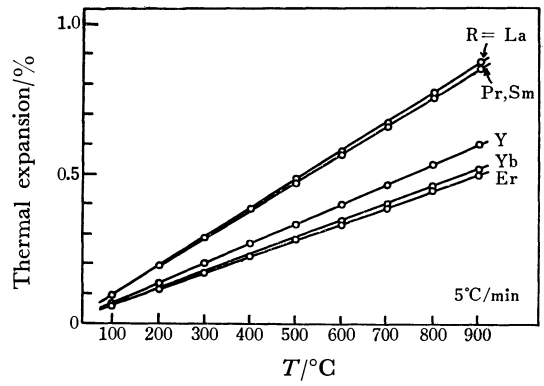

Fig. 3. Thermal expansion curves of the sintered RPO_4.

and 3-point bending strength (gauge length 30 mm) of the specimens sintered at 1500 °C for 60 min were measured. The specimens were cut into the 20 mm × 20 mm × 20 mm size for measurement of the compressive strength, and 50 mm × 20 mm × 10 mm for bending strength. Measurements were carried out for three samples of each sintered RPO_4.

The mean value of the compressive strength for each RPO_4 was in the range 2300—3000 kgf/cm^2, and that of the bending strength 320—500 kgf/cm^2. No definite relation has been found between the mechanical strength and the kind of rare earth element.

As compared with some commercial materials, the compressive strength and bending strength of the sintered RPO_4 seem to be larger than those of silica bricks (470—580 kgf/cm^2 and 27 kgf/cm^2)[5] or fire-clay bricks (340—445 kgf/cm^2 and 57—157 kgf/cm^2),[5] and almost the same as those of feldspathic porcelain (1700—3500 kgf/cm^2 and 100—450 kgf/cm^2)[5] or cordierite porcelain (1400—3100 kgf/cm^2 and 100—200 kgf/cm^2)[5] used for insulators.

Thermal Expansion Coefficient. A horizontal dilatometer with a dial gauge (0.001 mm) was used for measurement, the specimen holder and the extension rod being made of silica glass. The specimens sintered at 1500 °C for 60 min were cut into 4 mmϕ × 13 mm in size, and the measurements carried out in the temperature range 30—900 °C in the air with a heating rate about 5 °C/min.

Thermal expansion curves are shown in Fig. 3. The expansion ratio of the sintered $CePO_4$ and $NdPO_4$ at various temperature is close to that of $LaPO_4$, $PrPO_4$, or $SmPO_4$. The linear thermal expansion coefficients of the specimens calculated from these expansion curves are as follows: 10×10^{-6}($LaPO_4$), 9.90×10^{-6}($CePO_4$), 9.66×10^{-6} ($PrPO_4$), 9.77×10^{-6} ($NdPO_4$), 9.66×10^{-6} ($SmPO_4$), 6.90×10^{-6} (YPO_4), 5.75×10^{-6} ($ErPO_4$), and 5.98×10^{-6} ($YbPO_4$).

The thermal expansion coefficients of the sintered monoclinic form RPO_4 were larger than that of sintered Al_2O_3 (30—900 °C, 8.2×10^{-6}),[6] and smaller than that of fused MgO(30—900 °C, 13.9×10^{-6})[6] or fused CaO (30—900 °C, 12.8×10^{-6}),[6] those of the sintered tetragonal form RPO_4 being smaller than that of the sintered Al_2O_3.

The work was carried out with Grant-in-Aid for Scientific Research No. 365280 from the Ministry of Education.

Preparation and ^{1}H-NMR Spectra of Dialkyl{tetrakis(1-pyrazolyl)borato}-thallium(III) Complexes

Masayoshi Onishi,* Katsuma Hiraki,* and Shigeki Nakagawa

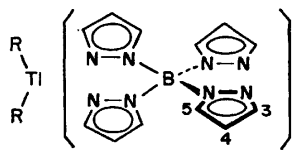
Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Bunkyo-machi, Nagasaki 852

(Received September 17, 1979)

Synopsis. Diethyl- and dibuthyl{tetrakis(1-pyrazolyl)-borato}thallium(III) complexes were prepared and characterized. The ^{1}H-NMR spectra of pyrazolyl protons of the BPz_4 ligand as well as the coupling constants between thallium and alkyl protons are discussed.

Trofimenko[1] reported several pyrazabole compounds, *i.e. boron* compounds of poly(1-pyrazolyl)borate. Storr *et al.* prepared sodium poly(1-pyrazolyl)aluminates and -indates,[2] and a few transition metal complexes of poly(1-pyrazolyl)gallates(III).[2,3] Some pyrazolyl-*N,N'*-bridged complexes of aluminum, gallium,[4] and thallium(III)[5] have also been reported. However, no study seems to have been reported on poly(1-pyrazolyl)borate complexes of IIIB group metals except boron[1] and thallium(I).[6]

This note deals with the preparation and ^{1}H-NMR study of two new dialkyl{tetrakis(1-pyrazolyl)borato} thallium(III) complexes, $[TlR_2(BPz_4)]$ {Pz=1-pyrazolyl, R=Et (**1**), and R=*n*-C_4H_9 (**2**)}.



1, R = Et
2, R = *n*-C_4H_9

Experimental

General Procedure and Materials. Melting points were determined in capillary tubes on a Yanagimoto MP-S3 microstage apparatus and are uncorrected. IR spectra were recorded on a Hitachi model 285 spectrometer, and ^{1}H-NMR spectra on a JEOL model JNM-MH-100 spectrometer (100 MHz) using tetramethylsilane as an internal standard. Molecular weight was determined in dichloromethane using a Mechrolab model 301 vapor pressure osmometer. Molar conductivities were measured with a Toa Denpa CM-6A instrument. Solvents were dried and distilled by the standard methods, all the preparative operations being performed in an atmosphere of dry nitrogen.

Sodium tetrakis(1-pyrazolyl)borate, $\{Na(BPz_4)\}$[7] and dialkylthallium(III) bromides[8] were prepared according to reported procedures.

Reactions of Dialkylthallium(III) Bromides with Na(BPz_4). Sodium tetrakis(1-pyrazolyl)borate (1.66 mmol) was added to a THF solution of diethylthallium(III) bromide (1.46 mmol). After the mixture had been heated under reflux for 4 h, the solvent was evaporated under reduced pressure. The resulting residue was recrystallized from dichloromethane and hexane, affording a white powder of $[TlEt_2(BPz_4)]$ (**1**). A white powder of $[Tl(n\text{-}C_4H_9)_2(BPz_4)]$ (**2**) was prepared using dibuthylthallium(III) bromide in a similar way to that for **1**.

Results and Discussion

Diethyl- and dibutylthallium(III) bromides reacted with $Na(BPz_4)$ in THF under reflux to give **1** and **2**, respectively.[9] Complex **1** is considerably soluble in the usual organic solvents, the yield after recrystallization being fairly low. The molecular weight of **1** determined in dichloromethane was 526, in line with the monomeric structure formulated as $[TlEt_2(BPz_4)]$ (calcd 542). The non-ionic character of these two complexes was confirmed by low conductivity in common organic solvents (Table 1).

Mass spectra of **1** and **2** showed several peak-groups,

the pattern of each being characteristic of the isotopes of thallium (^{203}Tl and ^{205}Tl) and boron (^{11}B and ^{10}B). The highest peak of each peak-group, corresponding to a species containing both ^{205}Tl and ^{11}B was characterized as follows. Complex **1** showed four peaks at *m/e* 475, 513, 542, and 747 ascribable to the ethylthallium species, $[TlEt_2(BPz_3)]^+$, $[TlEt(BPz_4)]^+$, $[TlEt_2(BPz_4)]^+$ (the weak parent peak), and $[Tl_2Et_2(BPz_4)]^+$, respectively, and six peaks at *m/e* 350, 417, 484, 555, 622, and 689 to the dealkylated thallium species, $[Tl(BPz_2)]^+$, $[Tl(BPz_3)]^+$, $[Tl(BPz_4)]^+$, $[Tl_2(BPz_2)]^+$, $[Tl_2(BPz_3)]^+$(weak), and $[Tl_2(BPz_4)]^+$, respectively, the peak at *m/e* 614 not being ascribable to any species. Complex **2** showed four peaks at *m/e* 531, 541, 598, and 803 ascribable to the butylthallium species, $[Tl(C_4H_9)_2(BPz_3)]^+$, $[Tl(C_4H_9)(BPz_4)]^+$, $[Tl(C_4H_9)_2(BPz_4)]^+$ (weak parent peak), and $[Tl_2(C_4H_9)_2(BPz_4)]^+$, respectively, in addition to the six peaks ascribed to the dealkylated species and the unknown one at *m/e* 614 shown for complex **1**. It seems that the {poly(1-pyrazolyl)borato}dithallium fragments are formed in a considerable amount.

The pyrazolyl region in the ^1H-NMR spectrum of both **1** and **2** showed a virtual triplet for four 4-H's and two doublets for four 3-H's and 5-H's (Table 2). This indicates that the four pyrazolyl groups of the BPz_4 ligand are magneto-spectroscopically equivalent and fluxional in solution, similar to the case of $[Zn(BPz_4)_2]$[10] and $[Pd(1\text{-}3\text{-}\eta^3\text{-}C_3H_5)(BPz_4)]$.[10] On cooling to −31 °C,[11] the three signals broadened slightly, no slow-exchange limiting spectrum being obtained even at this temperature. ^1H-NMR data of the pyrazolyl protons of **2** in C_6D_6, CD_2Cl_2, and $(CD_3)_2CO$ are given in Table 3. Two doublets at δ 6.88 and 7.59 in CD_2Cl_2 were attributed to the 3-H's and the 5-H's, respectively, considering the fact that the environment of the outer 3-H's changes more significantly on switching the NMR solvent, than that of the inner 5-H's located near boron atom.

In the ^1H-NMR signals of alkyl groups, couplings to ^{203}Tl and ^{205}Tl were virtually identical (Table 2). Similar large and actually equal coupling constants of these two thallium isotopes were reported on some alkyl- or arylthallium(III) compounds by Maher and Evans, who found that a positive charge delocalized on the thallium atom increases the magnitude of the J(Tl-H) values, through the enhancement of s character upon the thallium atom.[12] The coupling constants of the α- and β-protons in **1** are actually comparable with the respective values [$^2J(H_\alpha Tl)=340$ Hz and $^3J(H_\beta Tl)=628$ Hz] of diethylthallium(III) sulfate,[12] this being the case with the dibutylthallium(III) homologues. This suggests that there is nearly one positive charge on the thallium atom in **1** or **2**, and the bonds between the thallium atom and the pyrazolyl-nitrogens are a kind of contact ion pair. This is in line with the fluxional behavior of the BPz_4 ligand in **1** and **2** at low temperature.

Reactions of 3-Acetyltropolone and Its Methyl Ethers with Methylhydrazine

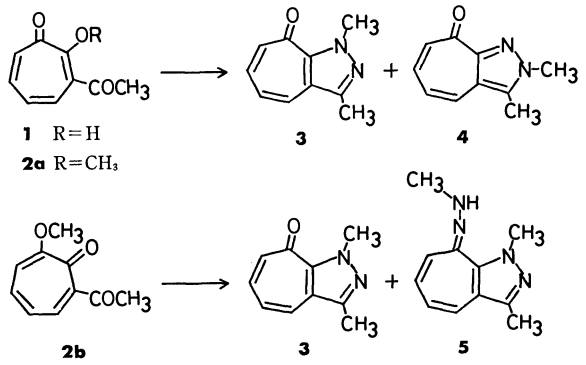
Akio YAMANE,† Kimiaki IMAFUKU,* and Hisashi MATSUMURA

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto 860

(Received August 27, 1979)

Synopsis. The reactions of 3-acetyltropolone and 3-acetyl-2-methoxytropone with methylhydrazine gave 1,3-dimethyl-1,8-dihydrocycloheptapyrazol-8-one (**3**) and 2,3-dimethyl-2,8-dihydrocycloheptapyrazol-8-one. 7-Acetyl-2-methoxytropone reacted with methylhydrazine to afford 1,3-dimethyl-1,8-dihydrocycloheptapyrazol-8-one methylhydrazone, besides a small amount of **3**.

In a previous paper,[1] we reported that 3-acetyltropolone (**1**) and 3-acetyl-2-methoxytropone (**2a**) reacted with hydrazine to afford 3-methyl-1,8-dihydrocycloheptapyrazol-8-one and that 7-acetyl-2-methoxytropone (**2b**) gave the hydrazone and azine of the above cycloheptapyrazolone. In this note, we wish to report the synthesis of 1,8- (**3**) and 2,8-dihydrocycloheptapyrazol-8-one (**4**), which have an additional methyl group at N_1 or N_2 atom, by the reactions of **1**, **2a**, and **2b** with methylhydrazine.



Scheme 1.

Results and Discussion

The refluxing of a mixture of 3-acetyltropolone (**1**) and methylhydrazine, which has two different nucleophilic nitrogen atoms, in methanol for 2 h gave two isomeric products, **3** (mp 96—98 °C) (60%) and **4** (mp 178—179 °C) (8%). The IR spectra of **3** and **4** show absorptions at 1643 and 1650 cm^{-1} respectively for the tropone carbonyl group. The UV spectra of the two isomers (**3** and **4**) are very similar to that of 3-methyl-1,8-dihydrocycloheptapyrazol-8-one,[1] as are shown in Fig. 1. The NMR spectra of **3** and **4** show peaks at δ 4.39 and 4.05 ppm respectively for the N-CH_3 group. The N-CH_3 peak of **3** is seen to shift to a lower field than that of **4** as a result of the anisotropic effect of the tropone carbonyl group. Thus, **3** and **4** were assigned to 1,3-dimethyl-1,8-dihydrocycloheptapyrazol-8-one and 2,3-dimethyl-2,8-dihydrocycloheptapyrazol-8-one respectively.

The refluxing of 3-acetyl-2-methoxytropone (**2a**) with methylhydrazine for 2 h gave the same products, **3** and **4** in 49 and 2% yields respectively.

† Present address: Wakunaga Pharmaceutical Co., Ltd., Koda-machi, Takata-gun, Hiroshima 729-64.

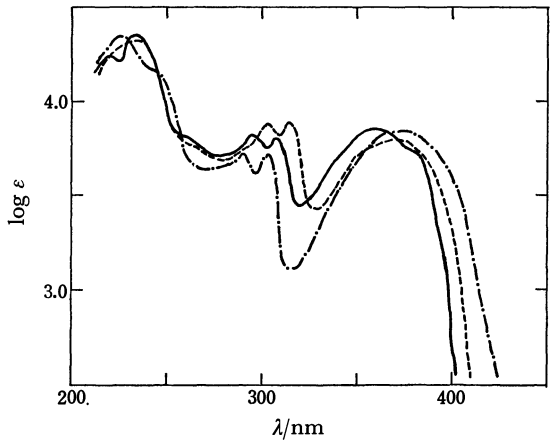


Fig. 1. UV Spectra.
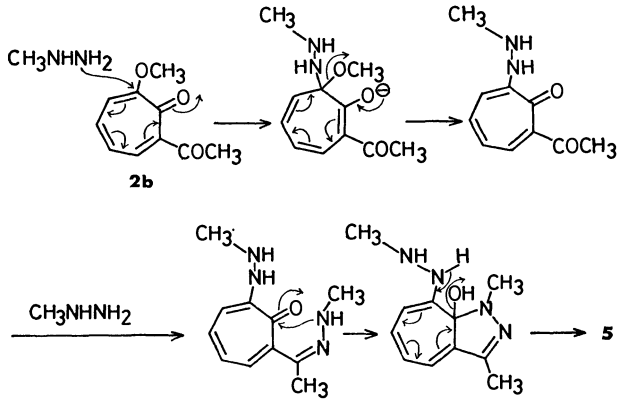
——— 3-Methyl-1,8-dihydrocycloheptapyrazol-8-one,
------ **3**, —·—·— **4**.

A mixture of 7-acetyl-2-methoxytropone (**2b**) and methylhydrazine in methanol was refluxed for 2 h and then chromatographed on silica gel to afford **3** (trace) and **5** (29%). The IR spectrum of **5** shows no band near 1600 cm^{-1} for tropone, but it shows an NH band at 3260 cm^{-1}. Its UV spectrum is very similar to that of 3-methyl-1,8-dihydrocycloheptapyrazol-8-one hydrazone.[1] The NMR spectrum of **5** shows three singlet peaks at δ 2.16 for C-CH_3 and 3.72 for N-CH_3 in the pyrazole ring and 3.12 ppm for N-CH_3 of the methylhydrazono group. Consequently, **5** was assigned to 1,3-dimethyl-1,8-dihydrocycloheptapyrazol-8-one methylhydrazone.

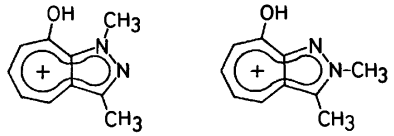
No methylhydrazone (**5**) was obtained from the reaction of **1** and **2a** with methylhydrazine. Furthermore, **3** did not react with methylhydrazine either. It is thoguht that the methylhydrazone (**5**) was directly formed from **2b** by the mechanism shown in Scheme 2. In addition, the formation of the minor product (**3**) from **2b** might be considered to proceed as follows. The nucleophilic attack of methanol (*i.e.*, the solvent) on a C_2-atom of **2b** would give 3-acetyl-



Scheme 2.

tropolone (**1**) which then reacts with methylhydrazine to afford **3**.

The NMR spectra of **3** and **4** in trifluoroacetic acid show a shift of the seven-membered ring protons by *ca.* 1.0—1.2 ppm, and one of the *N*- and *C*-CH_3 protons by *ca.* 0.4 ppm, towards a lower field. This indicates that the positive charge of the cations of **3** and **4** is delocalized over both the seven-membered ring and the pyrazole ring, as is shown in **3′** and **4′**:



3′ **4′**

Experimental

Measurements. The melting points were determined with a Yanagimoto MP-S2 melting-point measuring apparatus and are uncorrected. The IR spectra were taken on a JASCO IRA-1 spectrophotometer, and the UV spectra on a Hitachi EPS-3T spectrophotometer. The NMR spectra were recorded with a Hitachi R-24 spectrometer (60 MHz), with TMS as the internal standard.

*Reaction of 3-Acetyltropolone (**1**) with Methylhydrazine.* A mixture of **1** (345 mg, 2.1 mmol) and methylhydrazine (185 mg, 4.1 mmol) in methanol (20 ml) was refluxed for 2 h. After the removal of the solvent, the residue was chromatographed on a Wakogel B-10 plate (30×30 cm^2) with ethyl acetate to give **3** (218 mg, 60%) and **4** (28 mg, 8%). 1,3-Dimethyl-1,8-dihydrocycloheptapyrazol-8-one (**3**): Pale yellow needles (from hexane); mp 96—98 °C; IR ($CHCl_3$): 1643, 1598 cm^{-1}; UV (MeOH): λ_{max} nm (log ε) 235 (4.33), 303 (3.89), 316 (3.89), 372 (3.80); NMR ($CDCl_3$): δ 2.50 (s, 3H, *C*-CH_3), 4.39 (s, 3H, *N*-CH_3), 6.4—7.5 ppm (m, 4H); NMR (CF_3COOH): δ 2.94 (s, 3H), 4.78 (s, 3H), 7.4—8.5 ppm (m, 4H). Found: C, 68.65; H, 5.76; N, 16.12%. Calcd for $C_{10}H_{10}N_2O$: C, 68.95; H, 5.79; N, 16.08%. 2,3-Dimethyl-2,8-dihydrocycloheptapyrazol-8-one (**4**): Pale yellow needles (from benzene-petroleum ether); mp 178—179 °C; IR ($CHCl_3$): 1650, 1603 cm^{-1}; UV (MeOH): λ_{max} nm (log ε) 226 (4.36), 244 (4.17), 252 (4.04), 290 (3.72), 303 (3.71), 377 (3.84); NMR ($CDCl_3$): δ 2.51 (s, 3H, *C*-CH_3), 4.05 (s, 3H, *N*-CH_3), 6.3—7.4 ppm (m, 4H); NMR (CF_3COOH): δ 2.95 (s, 3H), 4.49 (s, 3H), 7.5—8.5 ppm (m, 4H). Found: C, 68.91; H, 5.87; N, 16.16%. Calcd for $C_{10}H_{10}N_2O$: C, 68.95; H, 5.79; N, 16.08%.

*Reaction of 3-Acetyl-2-methoxytropone (**2a**) with Methylhydrazine.* A mixture of **2a** (423 mg, 2.4 mmol) and methylhydrazine (183 mg, 4.0 mmol) in methanol (20 ml) was refluxed for 2 h. The reaction mixture was then worked up as has been described above to afford **3** (205 mg, 49%) and **4** (8 mg, 2%).

*Reaction of 7-Acetyl-2-methoxytropone (**2b**) with Methylhydrazine.* A mixture of **2b** (357 mg, 2.0 mmol) and methylhydrazine (228 mg, 5.0 mmol) in methanol (20 ml) was refluxed for 2 h. After the removal of the solvent, the residue was chromatographed on two Wakogel B-10 plates (30×30 cm^2) with ether-chloroform (1:2) to give **3** (trace) and **5** (118 mg, 29%). 1,3-Dimethyl-1,8-dihydrocycloheptapyrazol-8-one methylhydrazone (**5**): Orange needles (from benzene-petroleum ether); mp 112—113 °C; IR ($CHCl_3$): 3260, 1530 cm^{-1}; UV (MeOH): λ_{max} nm (log ε) 260^{sh} (3.96), 270^{sh} (3.92), 350 (4.10); NMR ($CDCl_3$): δ 2.16 (s, 3H, *C*-CH_3), 3.12 (s, 3H, *NH*-CH_3), 3.72 (s, 3H, *N*-CH_3), 5.4—6.3 (m, 4H), 8.7—9.3 ppm (br, 1H, NH). Found: C, 65.31; H, 7.02; N, 27.79%. Calcd for $C_{11}H_{14}N_4$: C, 65.32; H, 6.98; N, 27.70%.

We wish to thank Dr. Tetsuo Nozoe, Professor Emeritus of Tohoku University, for his advice and encouragement.

Two-phase Darzens Condensation Reaction with Octopus Compounds as a Catalyst

Sadatoshi AKABORI,* Michiko OHTOMI, and Seiichi YATABE

Department of Chemistry, Faculty of Science, Tōho University, Funabashi, Chiba 274

(Received September 27, 1979)

Synopsis. The octopus compound, readily derived from hexakis(mercaptomethyl)benzene and 1-chloro-3,6,9-trioxadecane, was effectively employed as a catalyst in the two-phase Darzens condensation of carbonyl compounds with chloroacetonitrile to afford the corresponding oxiranes in good yields.

In recent years, phase-transfer catalyses involving crown ether and quarternary ammonium halide have come into widespread use as a tool in organic synthesis.[1] The use of crown ether[2] and quarternary ammonium salts[3,4] to catalyze Darzens condensations with a wide variety of substrates has also been documented; however, to the best of the authors' knowledge, no mention has been made in the literature of condensation reactions catalyzed by an octopus compound. In the course of our studies of the phase-transfer reaction we have found[5] that octopus compounds are useful phase-transfer catalysts for the synthesis of nitriles from the reaction of alkyl halide and sodium cyanide. Therefore, we wish now to describe a convenient and efficient Darzens condensation of ketones with chloroacetonitrile catalyzed by octopus compounds.

The reaction was conducted by stirring a mixture of a carbonyl compound, an excess of chloroacetonitrile, and 50% aq. sodium hydroxide at 15 °C in the presence of an octopus-compound catalyst (**1a** or **1b**). The results are shown in Table 1. The maximum yields of the condensation products under our experimental conditions were obtained by using about 6—9% of the octopus compound by weight to the carbonyl compound. The reaction is exothermic, and the controlled addition of chloroacetonitrile is sometimes necessary. The octopus compounds functions as liquid-liquid phase transfer catalysts: however, the reaction proceeds at a slower rate in the absence of the catalyst. For example, cyclohexanone (**2a**) gives less than 9% of **3a** after 5 h at 15 °C when it is treated with chloroacetonitrile in the absence of **1**, whereas **3a** is formed in a 76% yield within 2 h when **1** is present. Thus, in the Darzens condensation of carbonyl compounds, it is most likely that octopus compounds transport the hydroxide anion into the organic phase, although the possibility of transforming the carbonyl compound into the aqueous phase can not be ruled out. When hexakis(2,5,8,11-tetraoxadodecyl)benzene (**1b**) was employed as the phase-transfer catalyst, the results were usually quite similar,

a) All the products show the same retention time with the authentic sample. b) The values are those obtained by GLC. c) The product (**3e**) was found to be a nearly 1:1 mixture of geometrical isomers (*E*- and *Z*-isomers). d) The total yield of *E*- and *Z*-isomers.

although rather less satisfactory. In the case of acetophenone, the condensation product was shown by the GLC analysis to be a 1:1 mixture of geometrical isomers (*E*- and *Z*-). The yield of **3c** shown in the table is the total yield of *E*- and *Z*-isomers. In further experiments, similar reactions of cyclohexanone (**2a**) or benzophenone (**2c**) with chloroacetonitrile in the presence of 18-crown-6 as a phase-transfer catalyst afforded 1-oxa-spiro-[2,5]-octane-2-carbonitrile (**3a**, 55% yield) or 3,3-diphenyloxirane-2-carbonitrile (**3c**, 47% yield).

Experimental

Analysis. The products were analyzed by gas chromatography. The chromatograms were obtained on a Hitachi 023 gas chromatograph, using 10% Polyester FF on a Chromosorb W AW/DMCS 1 m×3 mm column.

Materials. Hexakis(2-thia-5,8,11-trioxadodecyl)benzene (**1a**) and hexakis(2,5,8,11-tetraoxadodecyl)benzene (**1b**) were prepared according to the procedures described in a previous paper.[5] Authentic samples (1-oxa-spiro[2.5]-octane-2-carbonitrile (**3a**),[6] 3,3-diethyloxirane-2-carbonitrile (**3b**),[7] 3,3-diphenyloxirane-2-carbonitrile (**3c**),[7] 3,3-dimethyloxirane-2-carbonitrile (**3d**),[6] and 3-methyl-3-phenyloxirane-2-carbonitrile (**3e**, *E*-+*Z*-isomers))[6] were prepared according to the procedures described in the literature. Sodium hydroxide and ketones were used without further purification. The solvents used were purified by distillation.

General Procedure. A typical procedure for the reaction of cyclohexanone with chloroacetonitrile is as follows.

*Reaction of Cyclohexanone with Chloroacetonitrile in the Presence of **1a**.* A solution of 50% aq. sodium hydroxide (2 ml), cyclohexanone (1.2×10^{-3} mol), and hexakis(2-thia-5,8,11-trioxadodecyl)benzene (7.0×10^{-5} mol) was stirred for 10 min at 15 °C. Chloroacetonitrile (0.1 ml) was then added all at once, and the heterogeneous mixture (organic-water layers) was stirred for a further 2 h at 15 °C. The reaction mixture was diluted with water (10 ml) and extracted with ether (3×10 ml). The extract was washed with water and dried with anhydrous magnesium sulfate. The solvent was evaporated, and the residue in benzene was subjected to GLC analysis.

Comparison of Lewis Acids as Catalyst for the Alkylation of Benzene with *s*-Butyl Chloride

Masahito SEGI, Tadashi NAKAJIMA, and Sohei SUGA*

Department of Industrial Chemistry, Faculty of Technology, Kanazawa University, Kodatsuno, Kanazawa 920

(Received October 12, 1979)

Synopsis. The Friedel-Crafts alkylation of benzene with *s*-butyl chloride has been carried out in the presence of various Lewis acid catalysts. The relative order of catalyst activity is: $AlBr_3$, $AlCl_3$, $MoCl_5$, $SbCl_5 > TaCl_5 > NbCl_5 > FeCl_3 > ZrCl_4 > TiCl_4 \gg WCl_6$. The effect of addition of nitromethane on alkylation has been investigated.

Recently a report was given on the stereospecific Friedel-Crafts alkylation with optically active secondary alkyl chloride derivatives.[1] The reactions were so sensitive to moisture and the activity of aluminium chloride that it was difficult to control stereospecificity with sufficient reproducibility. The stereospecificity changed a great deal when iron (III) chloride was used as a catalyst instead of aluminium chlroide.[2] The results prompted us to compare Lewis acids as catalyst for the alkylation of benzene with *s*-butyl chloride.

The order of Lewis acid catalyst activity changes with reaction and/or reactant.[3] Comparison of Lewis acids in the Friedel-Crafts reaction has been reported with ethylene and hydrogen chloride,[4] benzyl chloride,[5] and acetyl chloride.[6] However, no report seems to have appeared on the reactions using secondary alkyl chloride as a reactant. The order of catalyst activity did not differ as compared with the case of primary alkyl chloride. Alkylation with $AlCl_3$–CH_3NO_2 catalyst proceeds through a homogeneous system, the catalytic activity of $AlCl_3$ decreasing moderately with the addition of nitromethane.[7] Nucleophiles which possess lone pair electrons, *e.g.* ethers and halides, are available as additives to $AlCl_3$ catalyst, but react with benzene as reactants. We have studied the effects of the addition of nitromethane to some active Lewis acids.

Results and Discussion

s-Butyl chloride and benzene were condensed at various temperatures by means of various Lewis acid catalysts for 10 min. The ratio *s*-butyl chloride : Lewis acid : benzene was kept 1 : 0.15 : 25 in each case. Below 5 °C, dichloromethane (4 ml) was added in order to prevent coagulation of benzene. 2-Phenylbutane produced was determined by GLC.

The Lewis acid catalysts were classified into four groups according to their activities in the alkylation with *s*-butyl chloride: (1) very active catalysts; (2) moderately active catalysts; (3) weak catalysts; (4) inactive catalysts (Table 1). In the case of (1), alkylation gave 2-phenylbutane with 100% conversion at −30 °C for 10 min. Figure 1 shows a comparison of the reaction rates of alkylation in the case of (2) and (3). The relative order of catalyst activity is: $NbCl_5 > FeCl_3 > FeCl_3$–CH_3NO_2 (10 times mol) $\simeq AlCl_3$–CH_3NO_2 (1.3 times mol) $> ZrCl_4 > AlCl_3$–CH_3NO_2 (10 times mol) $> AlCl_3$–$C_6H_5NO_2$ (10 times mol) $> TiCl_4 \gg WCl_6$. It seems that there is no relationship between the order and the configuration of electrons in the metal atom of catalysts. The difference in catalyst activity in the Friedel-Crafts alkylation has been elucidated mainly by means of the electrophilicity of catalyst-reactant complex formed.[8]

Table 1. Classification of Friedel-Crafts catalysts based on their activities in the alkylation with *s*-butyl chloride

(1)	Very active catalysts $AlBr_3$ (IIIa), $AlCl_3$ (IIIa), $MoCl_5$ (VIb), $SbCl_5$ (Va), $TaCl_5$ (Vb)
(2)	Moderately active catalysts $NbCl_5$ (Vb), $FeCl_3$ (VIII), $FeCl_3$-CH_3NO_2 (10 times mol), $AlCl_3$-CH_3NO_2 (1.3 times mol)
(3)	Weak catalysts $ZrCl_4$ (IVb), $AlCl_3$-CH_3NO_2 (10 times mol), $AlCl_3$-$C_6H_5NO_2$ (10 times mol), $TiCl_4$ (IVb), WCl_6 (VIb)
(4)	Inactive catalysts Cu_2Cl_2 (Ib), $ZnCl_2$ (IIb), $CdCl_2$ (IIb), $HgCl_2$ (IIb), $SnCl_4$ (IVa), $BiCl_3$ (Va), VCl_3 (Vb), $NiCl_2$ (VIII), $CoCl_2$ (VIII), $PdCl_2$ (VIII)

( ) is the group of periodic table.

In the presence of the aluminium chloride catalyst the reaction mixture is not homogeneous, due to the limited solubility of the catalyst. It becomes completely homogeneous by the addition of nitromethane, the catalytic activity becoming milder as compared with the case of aluminium chloride only. When $SbCl_5$, $FeCl_3$, $AlCl_3$, $AlBr_3$, $MoCl_5$, $TaCl_5$, or $NbCl_5$ in nitromethane solvent (10 times mol) was used as catalyst at 20 °C for 10 min, the conversion was 100, 100, 17.1, 7.9, 2.5, 2.3, 0%, respectively. It seems that the addition of nitromethane would form a Lewis acid–nitromethane (1:1) complex similar to the case of aluminium chloride,[9] tending to decrease the catalytic activity for alkylation.

Experimental

IR spectra were determined on a JASCO DS-301 spectrometer. GLC analysis was carried out on a 2 m column of 10% Carbowax 20 M on Diasolid L for 2-phenylbutane.

Aluminium chloride of commercial grade was purified by sublimation under nitrogen. Lewis acids of commercial grade were used without further purification. Benzene was washed with concentrated sulfuric acid and water, and distilled after being dried on sodium ribbon. Other solvents were dried[10] and distilled before use.

Reaction Procedures. To a stirred mixture of dry benzene (10 ml) and Lewis acid (0.81 mmol) was added a solution of *s*-butyl chloride (5.4 mmol) in benzene (2 ml) at the

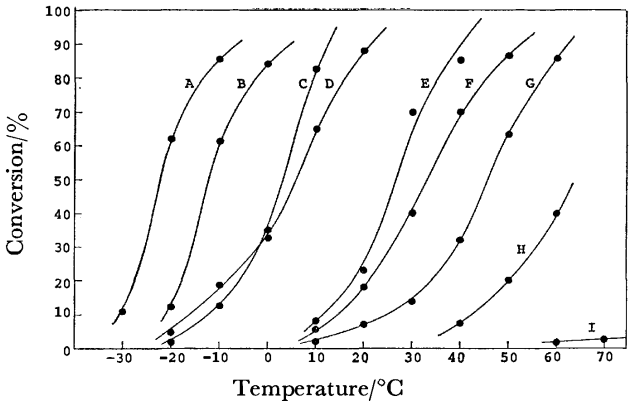

Fig. 1. Conversion percent in the alkylation of benzene with *s*-butyl chloride in the presence of catalysts in Groups 2 and 3 at −30 °C—70 °C for 10 min; A: $NbCl_5$, B: $FeCl_3$, C: $FeCl_3$–CH_3NO_2 (10 times mol), D: $AlCl_3$–CH_3NO_2 (1.3 times mol), E: $ZrCl_4$, F: $AlCl_3$–CH_3NO_2 (10 times mol), G: $AlCl_3$–$C_6H_5NO_2$ (10 times mol), H: $TiCl_4$, I: WCl_6.

rate required to maintain the desired temperature (Fig. 1). The reaction mixture was stirred at this temperature for 10 min, and then poured onto a mixture of crushed ice, concentrated hydrochloric acid (5 ml), and *p*-methylanisole (9.0 mmol) (internal standard). The benzene layer was separated and the aqueous layer extracted twice with 10 ml benzene. The combined organic layers were washed with water (15 ml) and dried over anhydrous sodium sulfate. The product was then determined by GLC by internal standardization technique.

Preparation and Properties of *N*-(Pentafluoropropionyl)amino Acid

Hajimu KAWA and Nobuo ISHIKAWA*

Department of Chemical Technology, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received November 12, 1979)

Synopsis. *N*-(Pentafluoropropionyl)amino acids, which were prepared by treating amino acids with hexafluoro-1,2-epoxypropane in diglyme, were found to be a versatile derivative of amino acids in gas chromatographic analysis.

N-Trifluoroacetylated α-amino acids are known to be useful derivatives for detection and separation of the parent amino acids.[1-7] Various esters of *N*-(trifluoroacetyl)-, *N*-(pentafluoropropionyl)- and *N*-(heptafluorobutyryl)-amino acids, which were prepared by perfluoroacylation with the corresponding perfluorocarboxylic anhydrides, were also reported to be useful in gas chromatographic resolution of the amino acids.[8] *N*-perfluoroacyl-L-α-amino acid chlorides are claimed to be resolving agents for asymmetric amines, as the gas chromatography of the complexes of these compounds provides a rapid, sensitive, and effective method for separating enantiomers.[9]

In the course of our studies on the reactivities of hexafluoro-1,2-epoxypropane, it was revealed that this perfluoro epoxide can be used as a versatile pentafluoropropionylating agent for alcohols, thiols and amines.[10] On extention of this reaction, the perfluoroacylation was applied for the preparation of pentafluoropropionylated amino acids, which are expected to be more volatile and more sensitive to gas chromatography than trifluoroacetyl derivatives.

Our previous method of pentafluoropropionylation of usual amines and alcohols using a hexafluoro-1,2-epoxypropane–triethylamine system in acetonitrile was not applicable to amino acids, as it gave only tarry material. Then we allowed amino acids to react with hexafluoro-1,2-epoxypropane without any amines using diglyme as a solvent. The reaction proceeded smoothly even at room temperature and after 2 or 3 h pentafluoropropionylamino acids were obtained in good yields (Table 1).

Thus by the aid of a fluorine ion hexafluoro-1,2-epoxypropane isomerized to pentafluoropropionyl fluoride, which reacted then with the amine to give pentafluoropropionyl derivative.[10]

$$CF_3CF(O)CF_2 \xrightarrow[\text{diglyme}]{F^-} CF_3CF_2C(=O)F$$

$$CF_3CF_2C(=O)F + H_2N\text{-}CHR\text{-}CO_2H \rightarrow CF_3CF_2C(=O)NH\text{-}CHR\text{-}CO_2H + HF$$

Though pentafluoropropionylamino acids have relatively higher melting points than the corresponding trifluoroacetyl derivatives, they are vaporized more rapidly on gas chromatography as expected (Table 2). It was also found that the pentafluoropropionyl group can be easily removed under mild alkaline conditions without racemization.

Experimental

Pentafluoropropionylation of Amino Acids. A mixture of L-phenylalanine (1.65 g, 10 mmol) and diglyme (10 ml) was placed in a glass pressure vessel and cooled to ≈ −70 °C. Liquefied hexafluoro-1,2-epoxypropane (bp −27 °C, 1.80 g, 10.9 mmol) was then introduced into the vessel and the whole was brought to room temperature with stirring. The mixture gradually became a clear solution, and the stirring was continued additional one hour. The reaction mixture was then poured into dilute aqueous hydrochloric acid, and the product was extracted with diethyl ether. The extract was dried over magnesium sulfate and the solvent was evaporated to give solid material. This crude product was subjected to column chromatography on silica gel using chloroform as an eluent. Pure *N*-(pentafluoropropionyl)-L-phenylalanine (2.18 g) was obtained in a yield of 70%.

Hydrolysis of Pentafluoropropionylamino Acid. A pentafluoropropionyl group was easliy removed under similar conditions to those reported in the case of a trifluoroacetyl group.[11] For example, *N*-(pentafluoropropionyl)-L-phenylalanine (0.62 g, 2 mmol) was added to an ethanol–water solution containing 5% sodium hydroxide, and the mixture was stirred for 1 h at room temperature. After neutraliza-

Catalytic Geometrical Isomerization of *cis*-Chrysanthemaldehyde and Related Ketones[1)]

Tadashi SASAKI,* Shoji EGUCHI, and Masatomi OHNO
Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya 464
(Received November 14, 1979)

Synopsis. *cis*-Chrysanthemaldehyde isomerized cleanly to the *trans*-isomer catalyzed with methoxydimethylsulfonium iodide (**8**) at 25 °C. Zinc halides as well as silica gel were also demonstrated to be effective catalysts. Related aldehydes and ketones isomerized also with **8** at 80 °C but dihydrochrysanthemaldehyde did not isomerize at all.

Stereoisomerization of chrysanthemic acid **1** (2,2-dimethyl-3-(2-methylpropenyl)cyclopropanecarboxylic acid) and its derivatives has drawn much interest for many years because the insecticidal activity of the ester derivative is specific for *d*- and *trans*-isomers.[2)] These isomerizations were demonstrated in the nitrile derivative under anionic conditions,[3)] the ester derivative under thermolytic and photolytic conditions,[4a,b)] and the acid chloride derivative under Lewis acid catalytic conditions.[5)]

We wish to report in this paper facile and convenient geometrical isomerization of *cis*-chrysanthemaldehyde **2** under catalytic conditions, where no competing structural isomerizations[6)] were not observed.

cis-Aldehyde **2** was allowed to react at 25 °C in dimethyl sulfoxide containing a slight excess of methyl iodide to form *in situ* methoxydimethylsulfonium iodide **8**.[7)] After 24 h, ^{1}H NMR inspection indicated the quantitative isomerization to the *trans*-isomer. This clean geometrical isomerization of **2** was also catalyzed with zinc halides.[8)] The iodide, bromide, and chloride salts were all effective as far as used homogeneously in an appropriate solvent such as ether or dioxane. Interestingly, silica gel was found to be useful for this geometrical isomerization;[9)] contact of **2** with silica-gel column (Mallinckrodt 100 mesh) at room temperature for 18 h produced quantitatively the *trans*-isomer.

Several comparative experiments were carried out to test the general applicability of this simple method. Firstly the choice of catalyst for **2** was shown to be critical. The catalyst coordinating much or less with the aldehyde carbonyl did not give satisfactory results; boron trifluoride catalysis led to the formation of an intractable mixture and lithium iodide catalysis resulted in no reaction. *p*-Toluenesulfonic acid catalysis caused undesired ring opening.[11)] Secondly, reactivity of carbonyl compounds with the catalyst **8** was examined by using related aldehydes and ketones **3**—**7**: Chrysanthemyl methyl ketone **3** and phenyl ketone **4** were found to be less reactive than the aldehyde **2**, and thus underwent nearly quantitative isomerization on heating at 80 °C for 2 h and 7 h, respectively. Similarly, 2-phenylcyclopropanecarbaldehyde **5** and methyl ketone **6** isomerized to the corresponding *trans*-isomers in 83% and 46% yields, respectively, on heating as above for 7 h, although they were stable at 25 °C. However, dihydrochrysanthemaldehyde **7**, a saturated analogue of **2**, did not isomerize at all under the same catalytic conditions.

These experimental facts suggest that the geometrical isomerization is significantly affected by a substituent on the cyclopropane ring through conjugation and by the nature of coordination of carbonyl group with catalyst. The reactivity trend of the observed isomerization, *i.e.*, aldehyde>methyl ketone>phenyl ketone and isobutenyl>phenyl>isobutyl substituent[10)] seems to reflect the ability to delocalize the positive charge to the cyclopropane ring. In addition, no deuterium incorporation was observed in the isomerization of **2** with **8** in 1:20 D_2O–DMSO (^{1}H NMR inspection) precluding an enolization pathway. Therefore, this stereoisomerization can be explained most reasonably as follows: The polarization of C=O double bond arising from the appropriate coordination of catalyst can generate a cyclopropylmethyl cation-like intermediate which caused the isomerization to thermally more stable *trans*-isomer. More activated intermediate carbonium ion may be responsible for the other reaction such as structural isomerization.[11)]

Above clean geometrical isomerization of *cis*-alkenylcyclopropanecarbonyl derivative is unprecedented to the best of our knowledge, and may be useful for obtaining pure *trans* isomer from, for instance, *cis* and *trans* mixture of carbonylcarbene adduct with conjugated olefins.

Experimental

Materials. Aldehydes **2**, **5**, and **7** were prepared by oxidation of the corresponding alcohols with pyridine–chromium trioxide.[12a,b,c)] Ketones **3**, **4**, and **6** were prepared from the corresponding carboxylic acids and methyl- or phenyllithium.[12a,d)]

^{1}H NMR Analyses. ^{1}H NMR spectra were obtained with a JEOL JNM-C-60HL spectrometer in carbon tetrachlo-

ride with tetramethylsilane as an internal standard. *Cis* and *trans* ratio was determined by the integral ratio of key signals at δ 5.36 (*cis*) and 4.89 (*trans*) (CH=C) for **2**, 5.28 (*cis*) and 4.82 (*trans*) (CH=C) for **3**, 5.36 (*cis*) and 4.16 (*trans*) (CH=C) for **4**, 8.53 (*cis*) and 9.25 (*trans*) (CHO) for **5**, and 1.87 (*cis*) and 2.19 (*trans*) ($COCH_3$) for **6**, respecuvely.

Geometrical Isomerization. (*A*): The aldehyde or ketone (1 mmol) was dissolved in a solution of methyl iodide (150 mg, 1.06 mmol) in dimethyl sulfoxide (3 ml) and the resulted solution was left in the dark at 25 °C or 80 °C. After the reaction time described in the text, the solution was poured onto water and the isomerized aldehyde or ketone was recovered nearly quantitatively by extraction with hexane, followed by usual work up. The *cis* and *trans* ratio was then determined by ^1H NMR spectra.

(*B*): The aldehyde **2** (152 mg, 1 mmol) was added to a solution of zinc iodide (160 mg, 0.5 mmol) in ether (5 ml), and the solution was left at 25 °C for 24 h. The catalyst was removed by extraction with water and usual work up gave almost quantitatively the *trans*-aldehyde. The reaction with zinc bromide or chloride under the same conditions except for using dioxane as a solvent gave similar results, but a small amount of contaminants was produced in the case of zinc chloride.

(*C*): The aldehyde **2** (152 mg, 1 mmol) was adsorbed on the silica gel (Mallinckrodt 100 mesh) column with chloroform. After 18 h at room temperature, the isomerized aldehyde was recovered quantitatively by eluting out with chloroform.

The Reactions of Copper(I) 1-Alkenyltrimethylborates with Allylic Bromides or 2-Propynyl Bromide

Norio MIYAURA, Takashi YANO, and Akira SUZUKI*
Faculty of Engineering, Hokkaido University, Sapporo 060

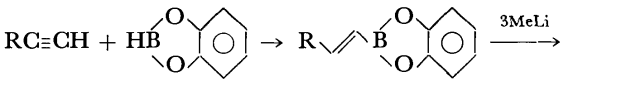
(Received November 16, 1979)

Synopsis. The reactions between copper(I) 1-alkenyltrimethylborates (readily obtainable from 2-(1-alkenyl)-1,3,2-benzodioxaboroles and methyllithium) and allylic bromides or 2-propynyl bromide were found to give corresponding coupling products. These reactions provide new synthetic routes to 1,4-alkadienes or 1,2,7-alkatrien-5-ynes.

In a series of our investigations of the chemistry of copper(I) organoborate complexes,[1-7] we have now discovered a novel cross-coupling reaction of 1-alkenyltrimethylborates with allylic bromides or 2-propynyl bromide. The reactions provide new synthetic procedures for 1,4-alkadienes or 1,2,7-alkatrien-5-ynes from alkynes *via* hydroboration, respectively.

Addition of a solution of lithium (*E*)-1-hexenyltrimethylborate (**1**) prepared from 2-(1-hexenyl)-1,3,2-benzodioxaborole and three equivalents of methyllithium to a suspension of copper(I) iodide in tetrahydrofuran at −30 °C resulted in the disappearance of copper(I) iodide, and a clear solution was obtained as shown in Eqs. 1 and 2. Although we have not undertaken a detailed study of this complex, copper(I) 1-hexenyltrimethylborate (**2**) is considered to be formed *via* metal exchange reaction. No reaction occurred between allyl bromide and lithium 1-hexenyltrimethylborate (**1**) at room temperature, whereas when corresponding copper(I) borate (**2**) was used, the reaction proceeded smoothly (Eq. 3). VPC analysis revealed the formation of 1,4-nonadiene in a 97% yield.

The reaction was then applied to representative alkenylborates and allylic bromides. The results are summarized in Table 1. The 1,4-dienes thus obtained

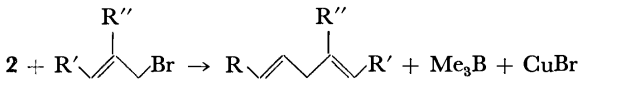


(1)

1

(2)

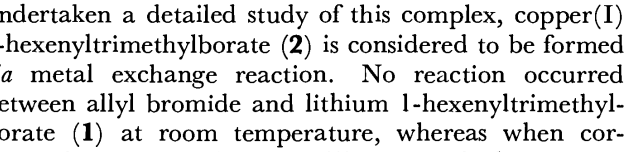
2



(3)

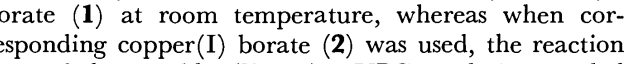
were indicated to be a single isomer in each case by VPC analysis, presumably *E*-isomer, because of IR (955 cm^{-1}) and direct comparison with authentic samples.

In the same way, copper(I) (*E*)-1-alkenyltrimethylborates react with 2-propynyl bromide (Eq. 5). At first, it was expected that the reaction of such copper(I) alkenylborates (**2**) with 2-propynyl bromide should give 4-alken-1-ynes (**3**) or 1,2,4-alkatrienes (**4**) as shown in Eq. 4. The reaction products actually obtained, however, were confirmed as 1,2,7-alkatrien-5-ynes (**5**).



(4)

3 **4**



(5)

5

For example, 2-(1-hexenyl)-1,3,2-benzodioxaborole gave 1,2,7-dodecatrien-5-yne, the elemental analysis and mass spectrum (*m/e*=160, M^+) of which coincided with $C_{12}H_{16}$. The IR spectrum bands at 1955, 855 cm^{-1} due to –CH=C=CH_2, 955 cm^{-1} for *trans*-CH=CH–, and 2180 cm^{-1} for –C≡C– structure were observed. The NMR spectrum indicated the presence of two vinylic hydrogens (–CH_2CH^{α}=CH^{β}–), because H^{α} centered at 4.00 splits into doublet-triplet (J=16 and 6 Hz) and H^{β} at 4.62 splits into a doublet (J=16 Hz), and three allenic protones (–CH_2–CH^{γ}=C=$CH^{\delta}{}_2$),[5] H^{γ} centered at 4.93 splits into triplet-triplet (*J*=6 and 7 Hz) and two H^{δ} at 5.25 split into doublet-triplet (*J*=7 and 3 Hz). All of these data are in good agreement with the 1,2,7-alkatrien-5-yne structure.

Stereoselective formation of alkenylboranes *via* hydroboration of alkynes followed by transfer of stereodefined alkenyl groups to alkyl halides should provide one of the simplest method for the synthesis of stereodefined alkenes. Although it is evident that copper(I) alkenylborates[8] have a considerably high utility for such a purpose, the applicability of the present new reagents to coupling and addition reactions is now under further investigation.

TABLE 1. REACTION OF COPPER(I) ALKENYLTRIMETHYLBORATES WITH ALLYLIC BROMIDES AND 2-PROPYNYL BROMIDE

 R^1=	R^2=	Allylic or 2-propynyl bromides[a]	Product	Yield[b] %

a) Allylic bromide/alkenylborane = 1.2. 2-Propynyl bromide/alkenylborane = 2.4.
b) Based on alkenylboranes employed.

Experimental

Materials. Commercial allylic bromides, alkynes, and 2-propynyl bromide were used. The tetrahydrofuran was

purified by distillation from $LiAlH_4$ before use. 1-Alkenylbenzodioxaboroles are prepared by Brown's method[9] from 1,3,2-benzodioxaborole and alkynes.

The IR and NMR spectra were taken on a Hitachi-Perkin Elmer Model 125 spectrophotometer and a Hitachi R-22 spectrometer at 90 MHz using tetramethylsilane as an internal standard, respectively.

General Procedure. The following procedures for the preparation of 1,4-nonadiene and 1,2,7-dodecatrien-5-yne are representative.

A dry 50 ml flask equipped with a septum inlet and a magnetic stirring bar was flushed with dry nitrogen. The flask was charged with 2-(1-hexenyl)-1,3,2-benzodioxaborole[9] (2.30 g, 10 mmol) and 10 ml of dry tetrahydrofuran. To this mixture was added methyllithium (22 ml of 1.26 M solution, 30 mmol) in ether at 0 °C and stirred for an additional 2 h to form lithium 1-hexenyltrimethylborate. Copper(I) iodide (3.8 g, 20 mmol) and 50 ml of dry THF were placed into a separate 200 ml-flask and cooled to −30 °C. The resultant lithium 1-hexenyltrimethylborate solution was gradually added under vigorous stirring. After 1 h, precipitated copper(I) iodide was completely disolved and a clear solution was obtained. To this solution was added allyl bromide (1.45 g, 12 mmol). The reaction mixture was allowed to warm up to room temperature and stirred for an additional 2 h. After the reaction was complete, the residual organoborane was oxidized with 3 ml of aqueous 3M-NaOH and 3 ml of 30%-H_2O_2 at room temperature for 2 h. The product was extracted by ether. The combined extract was washed with saturated NaCl solution and dried over magnesium sulfate. VPC analysis revealed the formation of 1,4-nonadiene (9.7 mmol, 97%).

The procedure for the preparation of 1,2,7-decatrien-5-yne is as follows: To the solution of copper(I) 1-hexenyltrimethylborate described above was added 2-propynyl bromide (2.86 g, 24 mmol) at −30 °C, and then the mixture was allowed to warm up to room temperature. After 2 h, residual organoborane was oxidized by alkaline hydrogen peroxide. VPC analysis of the ether extract indicated the presence of 5.4 mmol (54%) of 1,2,7-dodecatrien-5-yne.

Identification of the Products. In all cases analytically pure samples were obtained by preparative VPC with Varian autoprep Model-2800 and characterized by NMR, IR, and mass spectra,and refractive indices, and elemental analyses. *1,4-Nonadiene* and *1-phenyl-1,4-pentadiene* were characterized by direct comparison with authentic samples prepared by the methods reported by Negishi[10] and Speziale,[11] respectively.

2-Methyl-1,4-nonadiene: $n_D^{22}=1.4389$. Found: C, 86.74; H, 13.02%. Calcd for $C_{10}H_{18}$: C, 86.88; H, 13.12%. Mass: $m/e=138$ (M^+). IR (CCl_4): 3080, 1650, 975, 895, 965 cm^{-1}. NMR (CCl_4): τ, 9.1 (3H, t, $J=6$ Hz), 8.5—8.8 (4H, m), 8.31 (3H, s), 7.9—8.15 (2H, m), 7.36 (2H, d, $J=5$ Hz), 5.35 (2H, s), 6.59 (2H, m).

2,5-Decadiene: $n_D^{22}=1.4410$. Found: C, 86.65; H, 13.20%. Calcd for $C_{10}H_{18}$: C, 86.88; H, 13.12%. Mass: $m/e=138$ (M^+). IR (CCl_4): 3010, 965, 860 cm^{-1}. NMR (CCl_4): τ, 9.10 (3H, t, $J=6$ Hz), 8.5—8.8 (4H, m), 8.36 (3H, d, $J=4$ Hz), 7.9—8.15 (2H, m), 7.2—7.45 (2H, m), 4.5—4.7 (4H, m).

3-Methyl-1,4-nonadiene: $n_D^{22}=1.4390$. Found: C, 86.69: H, 13.21%. Calcd for $C_{10}H_{18}$: C, 86.88; H, 13.12%. Mass: $m/e=138$ (M^+). IR (CCl_4): 965, 910, 860 cm^{-1}. NMR (CCl_4): τ, 9.10 (3H, t, $J=6$ Hz), 8.93 (3H, d, $J=7$ Hz), 8.5—8.8 (4H, m), 7.85—8.1 (2H, m), 7.05—7.4 (1H, m), 5.09 (1H, d, $J=12$ Hz), 5.06 (1H, d, $J=16$ Hz), 4.55—4.70 (2H, m), 4.05—4.50 (1H, m).

1,4-Undecadiene: $n_D^{22}=1.4370$. Found: C, 86.70; H, 13.02%. Cacld for $C_{11}H_{20}$: C, 86.76; H, 13.24%. Mass: $m/e=152$ (M^+). IR (CCl_4): 3080, 1640, 965, 915, 860 cm^{-1}. NMR (CCl_4): τ, 9.10 (3H, t, $J=6$ Hz), 8.5—8.8 (8H, m), 7.85—8.1 (2H, m), 7.05—7.35 (2H, m), 5.01 (1H, d, $J=10$ Hz), 4.98 (1H, d, $J=16$ Hz), 4.51—4.64 (2H, m), 4.02—4.44 (1H, m).

1-(2-Cyclohexenyl)-1-octene: $n_D^{22}=1.4749$. Found: C, 87.38; H, 12.63%. Cacld for $C_{14}H_{24}$: C, 87.42; H, 12.58%. Mass: $m/e=192$ (M^+). IR (CCl_4): 3010, 970, 865 cm^{-1}. NMR (CCl_4): τ, 9.10 (3H, t, 6 Hz), 8.26—8.90 (12H, m), 7.89—8.17 (4H, m), 7.20—7.47 (1H, m), 4.58—4.73 (2H, m), 4.33—4.54 (2H, m).

1,2,7-Dodecatrien-5-yne: $n_D^{22}=1.5009$. Found: C, 89.93; H, 9.85%. Calcd for $C_{12}H_{16}$: C, 89.94; H, 10.06%. Mass: $m/e=160$ (M^+). IR (CCl_4): 2180, 1955, 955, 855 cm^{-1}. NMR (CCl_4): τ, 9.11 (3H, t, $J=6$ Hz), 8.45—8.9 (4H, m), 7.75—8.10 (2H, m), 6.9—7.17 (2H, m), 5.25 (2H, dt, $J=3$ and 7 Hz), 4.93 (1H, tt, $J=6$ and 7 Hz), 4.62 (1H, d, $J=16$ Hz), 4.00 (1H, dt, $J=6$ and 16 Hz).

1,2,7-Tridecatrien-5-yne: $n_D^{22}=1.4972$. Found: C, 89.39; H, 10.35%. Calcd for $C_{13}H_{18}$: C, 89.59; H, 10.41%. Mass: $m/e=174$ (M^+). IR (CCl_4): 2180, 1960, 950, 845 cm^{-1}. NMR (CCl_4): τ, 9.10 (3H, t, $J=6$ Hz), 8.5—8.85 (6H, m), 7.96 (2H, t, $J=6$ Hz), 6.91—7.13 (2H, m), 5.25 (2H, dt, $J=3$ and7 Hz), 4.93 (1H, tt, $J=6$ and7 Hz), 4.62 (1H, d, $J=16$ Hz), 3.99 (1H, dt, $J=6$ and 16 Hz).

1,2,7-Tetradecatrien-5-yne: $n_D^{22}=1.5012$. Found: H, 89.44; H, 10.78%. Calcd for $C_{14}H_{20}$: C, 89.29; H, 10.71%. Mass: $m/e=188$ (M^+). IR (CCl_4): 2180, 1960, 955, 860 cm^{-1}. NMR (CCl_4): τ, 9.09 (3H, t, $J=6$ Hz), 8.44—8.84 (8H, m), 7.73—8.05 (2H, m), 6.87—7.08 (2H, m), 5.22 (2H, dt, $J=3$ and 7 Hz), 4.90 (1H, tt, $J=6$ and 7 Hz), 4.60 (1H, d, $J=16$ Hz), 3.98 (1H, dt, $J=6$ and 16 Hz).

7-Ethyl-1,2,7-dodecatrien-5-yne: $n_D^{22}=1.5012$. Found: C, 88.76; H, 10.10%. Calcd for $C_{12}H_{16}$: C, 89.94; H, 10.06%. Mass: $m/e=160$ (M^+). IR (CCl_4): 2180, 1960, 860 cm^{-1}. NMR (CCl_4): τ, 9.02 (3H, t, $J=6$ Hz), 8.97 (3H, t, $J=6$ Hz), 7.76—8.07 (2H, m), 6.90—7.11 (2H, m), 5.25 (2H, dt, $J=3$ and 7 Hz), 4.93 (1H, tt, $J=6$ and 7 Hz), 4.37 (1H, t, $J=6$ Hz).

New Applications of Crown Ethers. II. Synthesis of 4'-Formylbenzocrown Ethers[1]

Fumio WADA,* Hiroshi HIRAYAMA, Hiroshi NAMIKI, Kiyoshi KIKUKAWA, and Tsutomu MATSUDA
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812
(Received December 10, 1979)

Synopsis. 4'-Formylbenzo-15-crown-5, -18-crown-6, and bis(4'-formylbenzo)-18-crown-6 were conveniently synthesized in excellent yields by Smith modification of Duff reaction: formylation with hexamethylenetetramine and trifluoroacetic acid or methanesulfonic acid.

4'-Formylbenzocrown ethers are considered to be useful intermediates for the preparation of various substituted benzocrown ethers with the use of the carbonyl function, and have been utilized for the preparation of 4'-(2-carboxyvinyl)-benzo-15-crown-5 (or 3-[3',4'-(1",4",7",10",13"-pentaoxacyclopentadeca-2"-ene)phenyl]acrylic acid),[2] phosphine derivatives,[3] bis(crown ether)s[3,4] and oximes.[5] 4'-Formylbenzo-15-crown-5 (**1**) and -18-crown-6 (**2**) were first prepared from 4-formylcatechol by Smid *et al.*,[6] using the conventional crown ring-forming cyclization. Direct formylation of benzo-15-crown-5 by Vilsmeyer reaction were reported recently by Hyde *et al.*[3] to give **1** in 54% yield. Electrophilic substitution in general seems to be promising for the synthesis of substituted benzocrown ethers. However, the reactions, especially those carried out under the catalysis of metal salts, frequently encounter with deactivation of the catalyst[7] and complexity in the isolation of the product[3] owing to the formation of crown ether complexes.

In our study to get a variety of substituted benzocrown ethers, we needed to disclose a simple method for the preparation of **1** and **2**. Among many reactions being attempted, formylation by Smith modification[8] of Duff reaction was found to be most promising because no inorganic reagent is required in the reaction, and preliminary experiments gave **1** and **2** in 58% and 32% yields, respectively. Other organic acids weaker than trifluoroacetic acid, except for methanesulfonic acid, gave only low yields. In the course of the study to optimize the reaction conditions it was found that the method of isolation of the products was also important factor and marked improvement of the yields could be attained by omission of neutralization of the reaction mixture. The results obtained under optimized conditions are summarized in Table 1. Formylation of dibenzo-18-crown-6 with excess reagents gave bis(4'-formylbenzo)-18-crown-6 (**3**) under similar reaction conditions. Methanesulfonic acid (98%) can be used in place of trifluoroacetic acid, but in certain cases it caused some problems in the isolation of the product due to the formation of emulsion, and led to a depressed yield.

One reason for lowering the yields in the conventional work-up containing neutralization of the excess acid is attributable to the increased solubility of sodium-crown ether complexes in aqueous phase. Another factor may be condensation of formylbenzocrown ethers during the repeated extractions from basic solution. The reasoning is based on the following observation that a mixture consisted of **1** and 4'-acetylbenzo-15-crown-5 in ethanolic sodium hydroxide gave 18% of 1,3-bis-[3',4'-(1",4",7",10",13"-pentaoxacyclopentadeca-2"-ene)phenyl]-propen-1-one after 3 h stirring at room temperature, but after 4 h oily condensation product was the principal product.

Experimental

Materials. Benzo-15-crown-5, -18-crown-6, and dibenzo-18-crown-6 were obtained according to the procedure of Pedersen.[7] Commercial trifluoroacetic acid (99%), methanesulfonic acid (98%) and hexamethylenetetramine were used as received.

*4'-Formylbenzo-15-crown-5 (**1**).* A mixture of benzo-15-crown-5 (2.0 g, 7.5 mmol), trifluoroacetic acid (5.6 ml) and hexamethylenetetramine (1.1 g, 7.5 mmol) was stirred at 85—90 °C under nitrogen for 12 h. The reaction mixture was added to the concentrate and stirred for 1 h. The mixture was extracted with benzene, and the extract was dried ($MgSO_4$). Concentration of the benzene extract under vacuum gave yellow oil, which on cooling solidified to faint yellow crystals, 1.8 g (82%), mp 78.2—81.0 °C. The product could be further purified by either extraction with hot heptane or chromatography on a short alumina column (chloroform–methanol) to give white crystals, mp 80.0—81.5 °C (lit,[6] mp 78—79 °C). When methanesulfonic acid

Table 1. Formylation of benzocrown ethers

Crown (mmol)		Acid (ml)		Hexamine (mmol)	Temp °C	Time h	Yield %

The Removal of Arsenate in Waste Water with an Adsorbent Prepared by Binding Hydrous Iron(III) Oxide with Polyacrylamide

Yasumasa SHIGETOMI,* Yōichi HORI, and Takehiro KOJIMA
Department of Chemistry, Okayama College of Science, Ridai-chō, Okayama 700
(Received June 11, 1979)

Synopsis. Studies have been made to remove arsenate in waste water with an adsorbent prepared by binding hydrous iron(III) oxide with polyacrylamide. Arsenate anions were thus adsorbed over the pH range of 5—8; the adsorption capacity of arsenate was 43 mg per gram of the adsorbent.

The reaction of hydrous iron(III) oxide with several anions has been studied by several workers,[1-3] but the study of the reverse reaction, that is, the desorption or the decomposition, has been seen in only a few papers. It was observed that hydrous iron(III) oxide is a good anion exchanger and that such adsorbed anions as phosphate and fluoride are desorbed by treating them with a dilute solution of sodium hydroxide.[4]

On the other hand, our attempts to avoid the intricate filtration and precipitation of hydrous metal oxides, which detract from its utility for industrial application, have led us to make a proposal for utilizing a composite adsorbent, such a combination of polyacrylamide and hydrous metal oxides.[5] The present paper will report on fundamental work to remove arsenate in waste water by using a composite adsorbent prepared by binding hydrous iron(III) oxide with polyacrylamide.

Experimental

All the chemicals used were of an analytical grade. A stock solution of sodium arsenate was prepared by dissolving 4.1675 g of sodium arsenate in 100 cm^3 of water (1.33×10^{-1} mol dm^{-3} as As).

The most efficient adsorbent was prepared by the following procedure; to 100 cm^3 of water in which are dissolved 5.406 g of iron(III) chloride, we add a concentrated ammonia solution until the pH becomes 7. The precipitate is then separated from mother liquor by centrifuging, and, to the precipitate, 14 g of acrylamide, 4 g of *N,N'*-methylenediacrylamide, and 2 g of ammonium peroxodisulfate as a polymerization initiator, dissolved in 100 cm^3 of water, are added, after which the mixture is stirred vigorously at 70 °C on a water bath. The brown product thus obtained is ground to 50—80 mesh powder in water by using an electric mixer.

All the experiments for the adsorption were carried out by the following procedure, unless otherwise stated: place 50 cm^3 of a solution of sodium arsenate and 0.2 g of the adsorbent in a 100 cm^3 flask. Adjust the pH with an acetate buffer solution. When equilibrium is reached after shaking for 3 h, separate the adsorbent from the solution, determine spectrophotometrically the concentration of arsenate remaining in the solution by means of the molybdenum blue method, and then calculate the percentage of the adsorption from the difference between the initial and the remaining concentrations. In the experiment using a column ($\phi1.7\times2.5$ cm) loaded with 2.5 g of the adsorbent, the 1.33×10^{-3} mol dm^{-3} arsenate solution was passed through the column at a constant and known flow rate, 0.8 cm^3/min. Collect the effluent in a graduated cylinder, testing the outlet continually for the ions to be exchanged.

Results and Discussion

Figure 1 shows the percentage of the adsorption of arsenate as a function of the pH in the solution. Arsenate anions were collected with the adsorbent in amounts greater than 95% over the pH range of 5—6. It seems that the percentage tends to decrease at pH values lower than 4, because arsenic acid is too weak to dissociate.

Figure 2 shows a breakthrough curve when the 1.33×10^{-3} mol dm^{-3} arsenate solution was passed through the column. The breakthrough capacity, as calculated from the curve, is 43 mg per gram of the adsorbent.

The minimal volume of the 0.5 mol dm^{-3} sodium

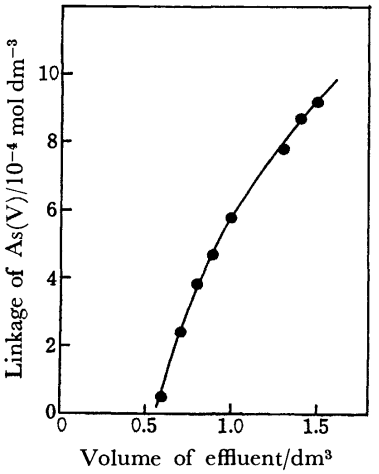

Fig. 2. Breakthrough curve of As(V).
Column: ϕ 1.7×26 cm; adsorbent: 2.5 g; flow rate: 0.83 cm^3/min; As(V): 1.33×10^{-3} mol dm^{-3}.

hydroxide solution required for the elution of arsenate anions can be determined as follows. Collect the effluent in fractions, determine the concentration of arsenate present in a fraction, and then plot the concentration against the volume of the effluent. The volume of the sodium hydroxide solution required for the generation can be determined from the elution curves; fifty cm^3 was sufficient to elute. Further, we examined how the capacity of the adsorption varied when the adsorbent was employed repeatedly. The results are shown in Fig. 3. The capacity was reduced to four-fifth its initial value by ten repetitions. That decrease is attributable to the contamination of the surface. However, if the 0.01 mol dm^{-3} hydrochloric acid is passed through and the adsorbent is washed, the capacity is restored to its original value. Also, we examined how the temperature in the solution affected the adsorption. Arsenate anions were adsorbed from the solution more easily and in greater quantities

Table 1. The adsorption capacity of our efficient adsorbent for various anions

Anions	Adspt. capacity of adsorbent for anions /mg g^{-1}	Initial concn. of anions/mol m^{-3}
AsO_4^{3-}	43 (as As)	2.67×10^{-3}
AsO_3^{3-}	46 (as As)	2.67×10^{-3}
$P_3O_{10}^{5-}$	26 (as P)	6.46×10^{-3}
F^-	24	2.10×10^{-2}
MoO_4^{2-}	12 (as Mo)	4.17×10^{-3}

The experiments were carried out at pH 4.

at a high temperature rather than at room temperature. Last, the adsorption capacities of the adsorbent for several anions were examined by a batch method using 2.67—5.34 mol dm^{-3} solutions of these anions. Table 1 show that the adsorbent can catch fluoride, phosphate, and molybdate, while it does not catch chloride and sulfate. Juging from these results, we can expect that the adsorbent can well be applied to the treatment of waste containing arsenate, such as geothermal waste water after the generation of electricity.

An Application of Microwave Treatment to the Dehydration of Manganese Dioxide for Lithium Nonaqueous Cells

Taketsugu HIRAI,* Isao TARI, and Tsutomu OHZUKU

Department of Synthetic Chemistry, Faculty of Engineering, Okayama University, Tsushima, Okayama 700

(Received October 11, 1979)

Synopsis. A new dehydration technique of manganese dioxide using 2.45 GHz microwave is presented. The so-called γ and γ,β-MnO_2, each containing less than 1 wt% water, which are not attainable by heat treatment, are obtained under specified conditions by this dehydration technique.

In recent years a number of metal oxide cathodes for lithium nonaqueous cells have been investigated.[1] Among them, the manganese dioxide (MnO_2) is one of the most promising cathode materials. The battery-grade electrolytic MnO_2 commercially available, however, originally contains 5 to 10 wt% water. As such water causes serious failures in the lithium-cell system, the development of a dehydration technique has been needed. In order to remove the water, Ikeda *et al.*[2] investigated the heat treatment of electrolytic MnO_2 for lithium-cell use. The continuous heating of electrolytic MnO_2, however, concomitantly caused a structural change in MnO_2.

As has been stated above, the heat treatment of electrolytic MnO_2 is not sufficient for the dehydration of MnO_2. For this reason, we used a microwave shower in the dehydration of electrolytic MnO_2 for a lithium nonaqueous cell. The objective of this study was to determine whether or not the application of 2.45 GHz microwaves to the dehydration of electrolytic MnO_2 is effective.

Experimental

Electrolytic γ-MnO_2, obtained from the Toyo Soda Manufacturing Corporation, had a particle size of 60—100 mesh and a relatively low equi-acidic point of 2.23 on a pH scale, as determined by Tari's pH-shift method.[3]

About 100 g of electrolytic MnO_2 in a 200-ml Pyrex beaker (*ca.* 60 mmϕ × 85 mm) were treated under 2.45 GHz microwave irradiation in a Kenmore microwave oven, model 99701, which had about a 600-W magnetron output and intermittent irradiation controls. In order to determine the effects of a microwave shower on electrolytic MnO_2, the weight loss, the X-ray diffractional pattern, and the water contents of the sample before and after the microwave treatment were measured. X-Ray data were obtained by using a Shimadzu X-ray diffractometer, type VD-11, with iron K_α radiation filtered with manganese. The water contents of the MnO_2 samples were determined by the following, indirect Karl Fischer titration: about 2 g of the MnO_2 sample, which had been crushed to a fine powder, were heated on a boat in a quartz tube at an elevated temperature under a stream of dry nitrogen carrier gas. The exhaust gas was then introduced into a vessel filled with an anhydrated solvent (Mitsubishi anhydrated solvent ME). Titration was automatically achieved by using a Karl Fischer automatic titration apparatus, model MK-AS (Kyoto Electronics Manufacturing Co., Ltd.). The differential thermal analysis and thermal gravimetry were also carried out by means of a Shimadzu Thermal Analyzer, type DT-30. For the sake of magnetron safety, a commercially available microwave absorber (60 mmϕ) was always located in the oven.

Results and Discussion

In the preliminary tests for the dehydration of the electrolytic MnO_2, we selected the intermittent microwave irradiation which consists of 15 s on and 10 s off. Although the continuous irradiation was also an effective method for the dehydration of electrolytic MnO_2, hardly no dehydrated γ or γ,β-MnO_2 was thus obtained. It sometimes caused the decomposition of MnO_2 to Mn_2O_3, which depended on the irradiation time, the microwave power, and the sample weight and/or the apparent volume.

After the preliminary examinations to avoid the decomposition of MnO_2 and to achieve the dehydration, the following conditions were decided on: intermittent microwave irradiation for 5 min, followed by radiation for 25 min; this two-stage treatment was repeated several times.

In order to confirm the effect of microwave irradiation on dehydration, the water content was measured. Figure 1 shows the water distribution of MnO_2 (No. 3 in Fig. 2 and Table 1) well dehydrated by microwave treatment compared with that of the original MnO_2. The water content of the MnO_2 sample shown in Fig. 1 was determined by calculating from the released water at an elevated temperature below 700 °C, assuming that the contained water was zero at 700 °C. The original electrolytic MnO_2 contained 8.3 wt% of water. The rapid decrease in water content below 200 °C was caused by adsorbed water. Because of the decomposition of MnO_2 to Mn_2O_3 up to 500 °C (typically 550 °C), which was confirmed by thermal

Table 1. Effect of microwave treatment on crystal structure and water contents

Sample No.	Microwave treatment	Classification from X-ray data	Water contents[a]/wt%
(Original)	—	γ-MnO_2	2.7±0.3
1	30 min	γ-MnO_2, trace of β-MnO_2?	1.2±0.1
2	60 min	γ-MnO_2, trace of β-MnO_2	0.9±0.1
3	90 min	γ,β-MnO_2	0.85±0.1
4	120 min	γ,β-MnO_2	0.6±0.1

a) Water removed below 200 °C was discarded.

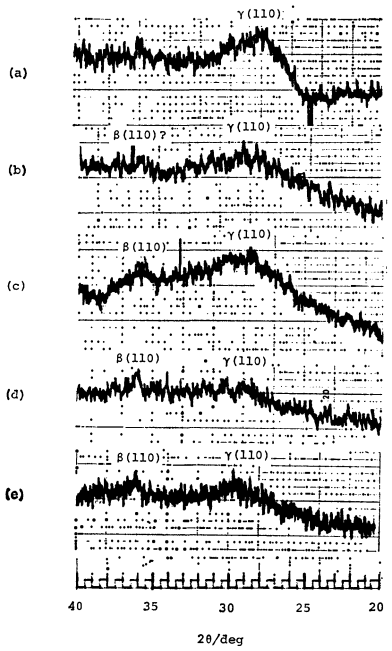

Fig. 2. Change of X-ray diffractional patterns by periodic microwave-treatment which consists of intermittent irradiation (15 s on, 10 s off) for 5 min, and the radiation for 25 min.
(a) Original MnO_2, (b) after 30 min (No. 1), (c) after 60 min (No. 2), (d) after 90 min (No. 3), (e) after 120 min (No. 4).

and X-ray analysis, a water content of less than 1.5 wt% was essentially not attainable by heat treatment.

The structural change caused by microwave treatment were also examined. The original MnO_2 showed the diffractional peaks (2θ) at about 28°, 47°, 54°, and 73°. The peaks at 47°, 54°, and 73° were not changed by microwave treatment. However, the diffused peak at about 28° was gradually decreased in its intensity, and a new peak at about 36° was observed. These delicate changes are shown in Fig. 2.

The above results are summarized in Table 1. The classification of MnO_2 was done according to the work of Fukuda.[4] The microwave treatment was concluded to be effective for the dehydration of MnO_2 from the fact that the so-called γ or γ,β-MnO_2, containing less than 1 wt% water, which could not be attained by heat treatment without the decomposition of MnO_2, was easily obtained by this treatment. Under these irradiation conditions, the water released below 200 °C was large in amount. Such adsorbed water, however, could be completely excluded by heat treatment at 200 °C, at which temperature the structural change in MnO_2 was proved not to occur.[2,3]

Further work related to lithium nonaqueous cells is now in progress in our laboratory.

The γ-Ray Induced Oxidation of Aromatic Hydrocarbons in Liquid Dinitrogen Oxide

Hidetoshi KARASAWA, Rei YUGETA, and Shin SATO*

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received April 4, 1979)

The γ-ray induced oxidation of aromatic hydrocarbons has been studied in liquid dinitrogen oxide, mainly at −18 °C. Various mixing ratios of dinitrogen oxide and four aromatic hydrocarbons have been examined. The main oxygen-containing products observed were the corresponding phenols and benzyl alcohols. The kinetic analysis showed that ionic species, probably N_2O^- ions, are the main precursors at low mole fractions of dinitrogen oxide and that oxygen atoms become important with an increase in the mole fraction. 1-Butene was used as a scavenger of oxygen atoms. The following rate constant ratios were obtained for the reactions of oxygen atoms and N_2O^- ions: $k(O+\text{toluene})/k(O+\text{1-butene})=0.02$, $k(O+\text{toluene})/k(O+\text{benzene})=2.0$, and $k(N_2O^-+\text{1-butene})/k(N_2O^-+\text{toluene})=2.5$. The relative rates for the formation of the corresponding phenols and benzyl alcohols through ionic reactions from aromatic hydrocarbons were obtained as follows: benzene, 1.0; toluene, 2.5; *p*-xylene, 2.2; 1,3,5-trimethylbenzene, 3.1. These values are quite different from the relative rate constants of the reactions of oxygen atoms with these aromatic hydrocarbons.

Recently much interest has been attracted to the γ-ray-induced oxidation of hydrocarbons in liquid carbon dioxide and dinitrogen oxide. The oxidizing species produced in the γ-radiolysis of a carbon dioxide solution are mainly oxygen atoms.[1-3] In a previous paper,[4] we reported on the reactions between oxygen atoms and several olefins in liquid carbon dioxide and discussed the relative rate constants of these reactions and the difference between gas- and liquid-phase reactions.

On the other hand, the oxidizing species produced in the γ-radiolysis of liquid dinitrogen oxide include not only oxygen atoms, but also N_2O^- ions and/or $N_2O_2^-$ ions.[5] When cyclohexene was used as a reactant, these oxidizing species formed different oxygen-containing products; oxygen atoms produced cyclohexene oxide and cyclohexanone, while ionic species led to the formation of cyclohexanol, 2-cyclohexenol, and probably water.

Aromatic hydrocarbons were also used as reactants in γ-ray-induced oxidation in liquid carbon dioxide.[6,7] The main products observed were the corresponding phenol. Sakurai *et al.* discussed the reaction mechanism and concluded that the oxidizing species are oxygen atoms when the mole fraction of carbon dioxide is higher than 0.9.[8-10]

About ten years ago, we studied the liquid-phase γ-radiolysis of benzene in the presence of dinitrogen oxide and measured the *G*-value of phenol.[11] The initial oxidizing species were concluded to be O^- or N_2O^- ions; *i.e.*, phenol seems to be formed from both oxidizing species, oxygen atoms and ionic species.

The present experiment attempted to confirm the formation of phenols in the reactions of ionic species with aromatic hydrocarbons and to obtain the relative rate constants of these reactions.

Experimental

The experimental procedure was the same as that described in a previous paper.[4] The dinitrogen oxide, purchased from the Takachiho Shoji Co., contained no detectable impurities; this was confirmed by means of a gas-chromatograph equipped with a 5-m dimethyl sulfolane column of 20% w/w on celite. The 1-butene, benzene (Merck Co.), toluene, *p*-xylene, and 1,3,5-trimethylbenzene (Tokyo Kasei Co.) were used after thorough degassing.

About 1 cm^3 of a liquid containing various mixing ratios of N_2O and hydrocarbons was irradiated with ^{60}Co γ-rays at −18 °C (sodium chloride–ice slush) except when otherwise stated. The dose was estimated by Fricke dosimetry on the assumption of a proportionality between the electron density and the dose.

The amount of the noncondensable product at 77 K was measured with a Toepler pump and a gas burrette. The other products were analyzed by gas-chromatography after the excess dinitrogen oxide had been removed at −78 °C. The columns used for the analysis were a 2-m Cresol-3M column (Nishio Kogyo Co.) for phenols and benzyl alcohols, and 2-m PEG-1500 and 2-m DNP columns (Gaschro Kogyo Co.) for 1-butene oxide, butanal, and 2-butanone.

Results and Discussion

Toluene–1-Butene–N_2O System. The main products observed in the γ-radiolysis of the mixture of toluene, 1-butene, and dinitrogen oxide are nitrogen, three isomeric cresols, benzyl alcohol, 1-butene oxide, butanal, and 2-butanone. The *G*-values of these products are shown in Figs. 1, 2, and 3 as functions of the electron fraction (ε) of dinitrogen oxide. It is noticeable that the electron-fraction dependence of cresols and benzyl alcohol is quite different from that of 1-butene oxide, butanal, and 2-butanone. This suggests that the two products, the product from toluene and that from 1-butene, are different in the mechanism of their formation.

The Precursor of 1-Butene Oxide. It is now well known that the reaction of oxygen atoms with olefins produces olefin oxides and their isomeric aldehydes and ketones.[12] In the case of 1-butene, 1-butene oxide (0.53), butanal (0.43), and 2-butanone (0.04) are produced. The numbers in parentheses are the fractions of the total addition products observed in the gas phase at room temperature. In a previous paper,[4] we investigated the γ-ray-induced oxidation of several olefins in liquid carbon dioxide at −18 °C and found, in the

case of 1-butene, that the fractions of the total addition products are 0.70 for 1-butene oxide, 0.25 for butanal, and 0.05 for 2-butanone. The difference between these fractions and those obtained in the gas-phase reaction may be attributed to the interaction between the intermediate biradical formed in the reaction of oxygen atoms with 1-butene and carbon dioxide.

When dinitrogen oxide was used in place of carbon dioxide, the formation of 1-butene oxide, butanal, and 2-butanone was again observed, as is shown in Fig. 2,

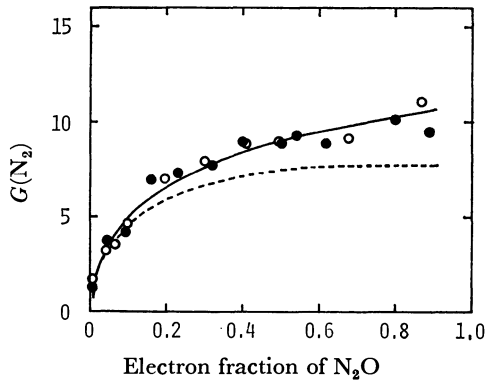

Fig. 1. The G-values of nitrogen from the two reaction systems; toluene (0.9)–1-butene(0.1)–N_2O (●) and benzene (0.6)–1,3,5-trimethylbenzene (0.4)–N_2O (○), as a function of the electron fraction ε of dinitrogen oxide.
The dotted line is the G-value of nitrogen produced by ionic process. Both solid and dotted lines are theoretical.

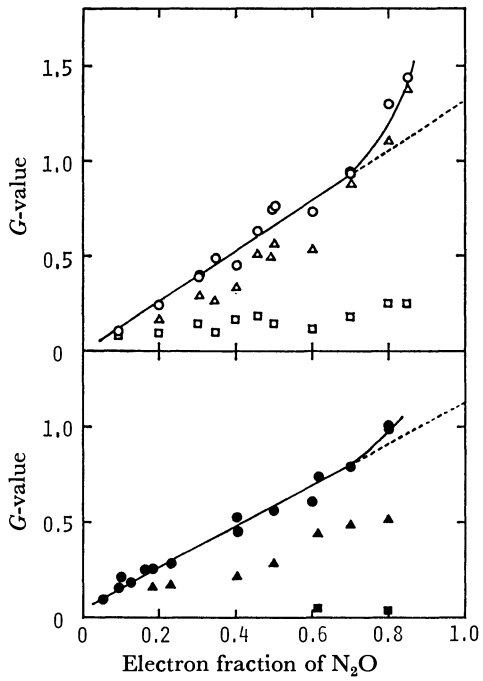

Fig. 2. The G-values of 1-butene oxide (○, ●), butanal (△, ▲), and 2-butanone (□, ■) as functions of the electron fraction ε of dinitrogen oxide.
Open symbols for the 1-butene–N_2O system and filled ones for the toluene (0.9)–1-butene (0.1)–N_2O system.

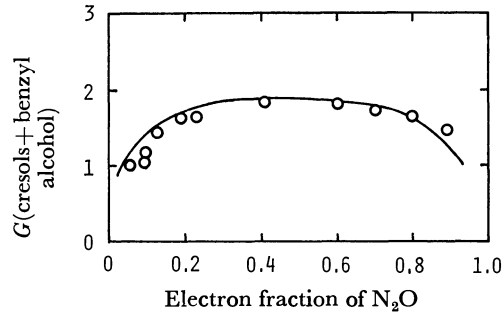

Fig. 3. The G-values of the sum of three kinds of cresols and benzyl alchol as a function of the electron fraction ε of dinitrogen oxide in the toluene (0.9)–1-butene (0.1)–N_2O system.
The solid line was calculated theoretically.

and the G-values were found to be proportional to the electron fraction of dinitrogen oxide up to 0.8, suggesting that these products are formed in the reaction of oxygen atoms generated by the radiolysis of dinitrogen oxide.

$$N_2O \rightsquigarrow N_2 + O \quad (1)$$

$$O + \text{1-Butene} \longrightarrow \text{1-Butene Oxide, Butanal, 2-Butanone} \quad (2)$$

The fractions of these products against the total addition products calculated from the slopes of the linear dependence of the G-values of these products on ε, however, are not the real fractions corresponding to Reaction 2, because a part of butanal and 2-butanone are believed to be formed by the reaction between 1-butene and the ionic species generated in this system. A similar observation has been made with regard to the formation of cyclohexanol in the γ-radiolysis of the mixture of cyclohexene and dinitrogen oxide.[1)]

Above 0.8 of the electron fraction of dinitrogen oxide, another process for the formation of oxygen atoms has to be considered, for which we propose the following reactions:

$$N_2O \rightsquigarrow N_2O^+ + e^- \quad (3)$$

$$e^- + N_2O \longrightarrow N_2O^- \quad (4)$$

$$N_2O^+ + N_2O^- \longrightarrow 2N_2 + 2O \longrightarrow N_2 + O + N_2O. \quad (5)$$

In the presence of a hydrocarbon, a charge transfer will occur, since the ionization potential of any hydrocarbon is smaller than that of dinitrogen oxide:

$$N_2O^+ + A \longrightarrow N_2O + A^+. \quad (6)$$

Here, A stands for a hydrocarbon. This process suppresses the formation of oxygen atoms.

As Fig. 2 shows, the formation of 1-butene oxide was reduced in the presence of toluene. Since toluene is also reactive to oxygen atoms, the decrease in G(1-butene oxide) allows us to estimate the relative rate constant of the oxygen atoms with 1-butene (k_B) and toluene (k_T) as follows:

$$(G_0 - G)/G = k_T[\text{toluene}]/k_B[\text{1-butene}].$$

Here, G and G_0 are the G-values of 1-butene oxide from the reaction system in the presence and in the absence of toluene. The substitution of the data shown in Fig. 2 gives the following ratio:

$$k_T/k_B = (1.30-1.12)/1.12\times 1/9 = 0.02.$$

The rate constants of the gas-phase reactions of oxygen atoms with hydrocarbons have been measured by Atkinson and Cvetanović[13] and by Atkinson and Pitts.[14,15] Using their data, we can estimate the rate constant ratio at −18 °C to be 0.008. Since the experimental error in activation energy is reported to be 30%, the ratio obtained in the present experiment may be regarded as being in agreement with the gas-phase data.

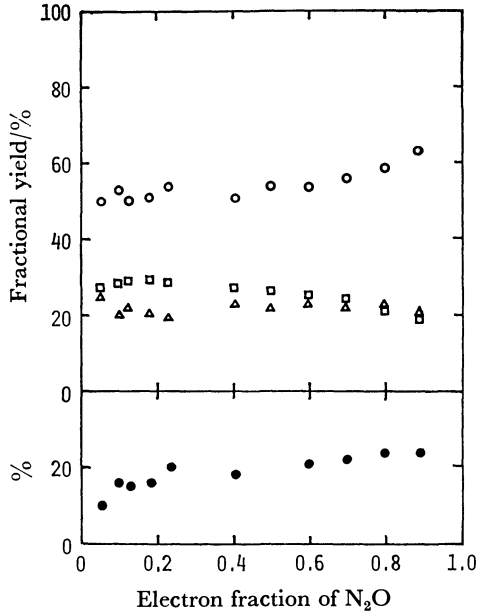

Fig. 4. The fractional yields of three kinds of cresols (○, ortho; □, meta; △, para) and benzyl alcohol (●) as functions of the electron fraction ε of dinitrogen oxide in the toluene (0.9)–1-butene (0.1)–N_2O system.

The Precursors of Cresols. Figure 4 shows the yield ratios of three kinds of cresols and benzyl alcohol from the toluene(0.9)–1-butene(0.1)–N_2O system as functions of the electron fraction of dinitrogen oxide. The numbers in parentheses are the mole fractions of the two hydrocarbons in the mixture. Since the ratio of ortho, meta, and para is dependent upon the electron fraction of dinitrogen oxide, we have to consider at least two precursors for the formation of these products. A comparison of Figs. 2 and 3 suggests that the precursors of cresols and benzyl alcohol are not oxygen atoms at low-electron fractions of dinitrogen oxide. Since dinitrogen oxide is a well-known electron scavenger, it may be natural to consider that the precursor is N_2O^- or O^- ions produced in the electron-scavenging reaction of dinitrogen oxide.

The reactions of N_2O^- ions in hydrocarbons, especially in cyclohexane, have been discussed by a number of researchers,[16–19] but they have not been established yet. In the present experiment, however, the similarity in the N_2O electron-fraction dependence of $G(N_2)$ and G(cresols+benzyl alcohol) at low values of ε strongly suggests that ionic species such as N_2O^- ions are the precursors of these products.

$$A \rightsquigarrow A^+ + e^- \quad (7)$$

$$e^- + N_2O \longrightarrow N_2O^- \quad (8)$$

$$N_2O^- + A \longrightarrow N_2 + AO^- \quad (9)$$

$$AO^- + A^+ \longrightarrow P + A \quad (10)$$

Here, A stands for an aromatic hydrocarbon, and P, for the addition product.

If this mechanism is operative, the ortho-meta-para ratio obtained in a low-electron fraction of dinitrogen oxide in the toluene–1-butene–N_2O system should correspond to the orientation of the addition of O^- to toluene. As Fig. 4 shows, the ratio at the lower limit of the electron fraction of dinitrogen oxide is 53: 27: 20.

In high-electron fractions, this ratio approaches 65: 15: 20 with the increase in ε. This ratio is close to that obtained in the gas-phase reaction of oxygen atoms with toluene (64: 17: 19).[20] In the previous section, we stated that oxygen-atom generation increases with the increase in ε above 0.8. Consequently, we may conclude that oxygen atoms become important precursors for cresols in high-electron fractions of dinitrogen oxide.

Below we will discuss a reaction mechanism which is applicable to all the range of ε; the kinetic treatment will be presented at that time.

Benzene–1,3,5-Trimethylbenzene–N_2O System.
Figure 5 shows the G-values of phenol, 2,4,6-trimethylphenol, and 3,5-dimethylbenzyl alcohol as functions of ε from the mixture of benzene (0.6), 1,3,5-trimethylbenzene (0.4), and N_2O. The numbers in parentheses are the mole fractions of the two hydrocarbons in the mixture. It may be worthwhile to mention here that the electron-fraction dependence of G(phenol) is similar to that of G(3,5-dimethylbenzyl alcohol), but different from that of G(2,4,6-trimethylphenol).

According to Grovenstein and Mosher,[20] the forma-

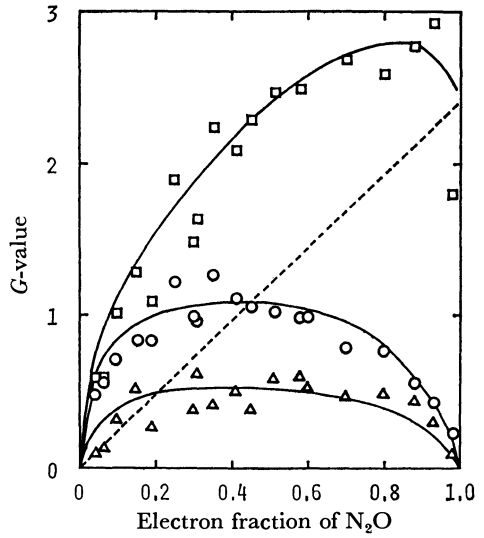

Fig. 5. The G-values of phenol (○), 2,4,6-trimethylphenol (□), and 3,5-dimethylbenzyl alcohol (△) as functions of the electron fraction ε of dinitrogen oxide in the benzene (0.6)–1,3,5-trimethylbenzene (0.4)–N_2O system.
Solid lines are theoretical. The dotted line is the G-value of 2,4,6-trimethylphenol formed in the reaction of oxygen atoms.

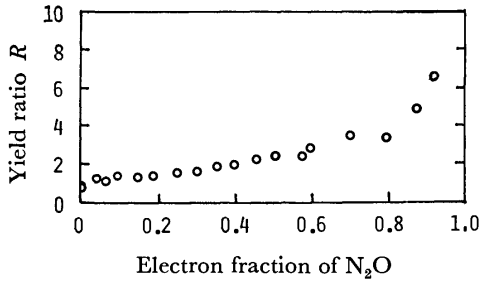

Fig. 6. The yield ratio R of [2,4,6-trimethylphenol]/[phenol] as a function of the electron fraction ε of dinitrogen oxide in the benzene (0.6)–1,3,5-trimethylbenzene (0.4)–N_2O system.

tion of phenols in the gas-phase reactions of oxygen atoms with aromatic hydrocarbons is faster for the more methyl-substituted ones. In the case of the competition between benzene and 1,3,5-trimethylbenzene, the reaction-rate ratio (R) for 2,4,6-trimethylphenol to phenol has been reported to be 77.5. The ratio obtained in the present experiment is plotted in Fig. 6 as a function of ε. As ε approaches unity, the ratio, R, seems to approach the value obtained by Grovenstein and Mosher, while at low values of ε, R is about unity.

In order to estimate the fractions of 2,4,6-trimethylphenol produced through two processes, one from the reaction of oxygen atoms and the other from the reaction of ionic species, we made a few experiments in which the mole fractions of benzene and 1,3,5-trimethylbenzene were changed in the presence of a constant electron fraction of dinitrogen oxide at 0.1. The results are shown in Fig. 7.

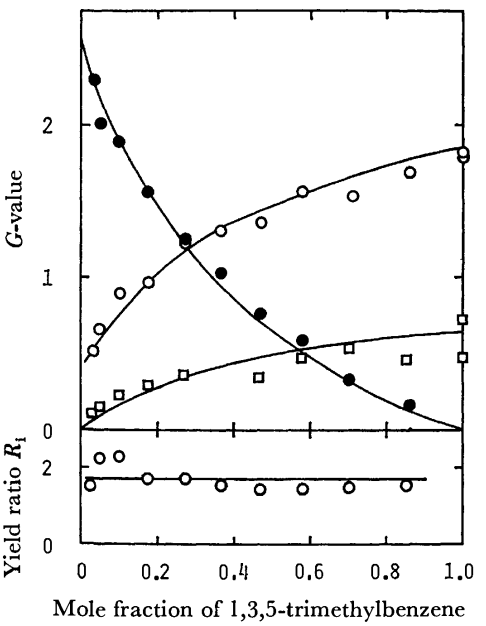

Fig. 7. The G-values of addition products from the benzene–1,3,5-trimethylbenzene system in the presence of dinitrogen oxide ($\varepsilon=0.1$) at 0°C and the yield ratio, R_1, as functions of the mole fraction of 1,3,5-trimethylbenzene.
●, Phenol; ○, 2,4,6-trimethylphenol; □, 3,5-dimethylbenzyl alcohol.

$$R_1=\frac{G_1(\text{2,4,6-trimethylphenol})}{G_1(\text{phenol})}\,\frac{[\text{benzene}]}{[\text{1,3,5-trimethylbenzene}]}$$

It is known in the gas-phase reaction that the phenol formation in the reaction of oxygen atoms with benzene is only 6% of the consumption of oxygen atoms.[21] This percentage may not be very different in the liquid-phase reaction. Moreover, benzene is much less reactive to oxygen atoms than is 1,3,5-trimethylbenzene. The phenol observed in the present experiment, therefore, may be assumed to be produced only from the reaction of ionic species with benzene:

$$\text{benzene} + N_2O^- \longrightarrow \text{phenol} \quad (11)$$

$$\text{1,3,5-trimethylbenzene} + N_2O^- \longrightarrow \text{2,4,6-trimethylphenol} \quad (12)$$

$$\text{1,3,5-trimethylbenzene} + O \longrightarrow \text{2,4,6-trimethylphenol.} \quad (13)$$

Since the formation-rate ratio of the 2,4,6-trimethylphenol produced by Reaction 12 to the phenol produced by Reaction 11 should be constant, this ratio can be calculated by using the data shown in Fig. 7 on the assumption that the extra amount of 2,4,6-trimethylphenol is produced by Reaction 13. The ratio thus estimated is 1.7. The plots for this estimation are also shown in Fig. 7.

Let us go back to the data shown in Fig. 5, where the mole-fraction ratio of benzene to 1,3,5-trimethylbenzene is 0.6: 0.4. Consequently, the G_i(2,4,6-trimethylphenol)/G_i(phenol) ratio in this experiment should be 1.1 ($=1.7\times0.4/0.6$). Here, G_i stands for the G-value of the product formed by the reaction of ionic species. Using this ratio, we can estimate the G-value of the 2,4,6-trimethylphenol produced by the reaction of oxygen atoms, on the assumption that the phenol observed is produced only from the reaction of ionic species. Figure 8 shows the G-values thus calculated as a function of the electron fraction of dinitrogen oxide. The G-values are obviously linearly dependent

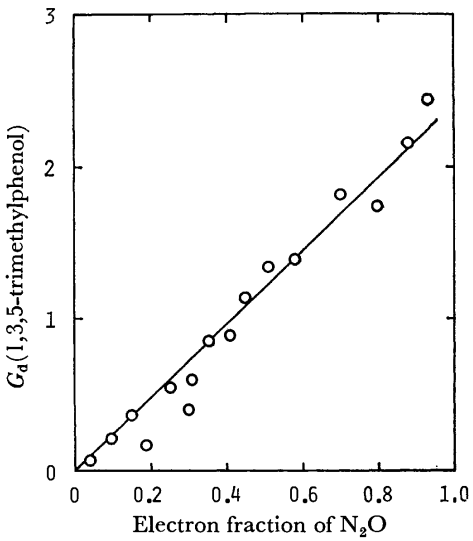

Fig. 8. The G-value of 2,4,6-trimethylphenol formed in the reaction of oxygen atoms produced by the direct radiolysis of dinitrogen oxide.

upon ε; this is consistent with the assumption made above that this part of the 2,4,6-trimethylphenol is produced by the reaction of oxygen atoms. The G-value of the 2,4,6-trimethylphenol produced by this process is calculated to be 2.4ε.

The Precursor of Benzyl-alcohol-type Products. So far two benzyl alcohol-type products have been found; one is benzyl alcohol from the toluene–N_2O system, and the other is 3,5-dimethylbenzyl alcohol from the benzene–1,3,5-trimethylbenzene–N_2O system. The dependence of G(benzyl alcohol) on the electron fraction of dinitrogen oxide was similar to that of G(cresols), although the absolute yield was very small when ε was close to unity. On the other hand, as Fig. 5 shows, the dependence of G(3,5-dimethylbenzyl alcohol) on ε was very similar to that of G(phenol).

According to Jones and Cvetanović,[22] no benzyl alcohol was formed in the gas-phase reaction of oxygen atoms with toluene. Consequently, we may conclude that both benzyl alcohol and 3,5-dimethylbenzyl alcohol are produced from the reaction with ionic species, although the mechanism cannot be specified in detail. In the following treatment, we tentatively assume that the mechanism of the formation of benzyl alcohols is similar to that of the isomeric phenols produced through the ionic process.

Kinetic Treatment. The neutralization reaction of geminate ion-pairs produced in the γ-irradiated system cannot be treated by a simple kinetic treatment in which the reaction rate is assumed to be always proportional to the reactant concentration in the solution. Consequently, several empirical equations have been proposed for the interpretation.[23–25] Among them, the so-called Schuler equation is the most famous.

In a previous paper,[26] we investigated the electron-scavenging process of bromobenzene in the γ-irradiated cyclohexane and 2,2,4-trimethylpentane, and concluded that the following Hummel empirical equation was better than Schuler's in explaining the wide range of concentrations of electron scavengers:

$$G(P) = G_{fi} + G_{gi}[1-\exp(-\sqrt{\alpha S})]. \quad \text{(I)}$$

Here, G(P) is the G-value of the electrons scavenged by a solute, with S as its concentration. G_{fi} and G_{gi} are the G-values of free and geminate electrons respectively, and α is an empirical constant proportional to the rate constant of the electron-scavenging reaction. The $\exp(-\sqrt{\alpha S})$ term on the right-hand side is the fraction which is not scavenged by the scavenger.

On the other hand, if the time distribution of the geminate electrons is denoted by $f_e(t)$, the fraction which is not scavenged by the scavenger may be written as follows:

$$\int_0^\infty f_e(t)\exp(-kSt)\mathrm{d}t = \exp(-\sqrt{\alpha S}). \quad \text{(II)}$$

Here, k is the rate constant of the electron scavenging and is related to α by $\alpha=k/\lambda$. λ is a constant depending on the solvent.[27] Using Eq. II, we can derive the concentration dependence of the electron-scavenging reaction without the knowledge of the time distribution of the geminate electrons.

In order to develop a theoretical treatment, we will now consider the phenol formation through the ionic process in the γ-radiolysis of a mixture of benzene and dinitrogen oxide. We propose the following reaction mechanism:[6]

$$C_6H_6 \rightsquigarrow C_6H_6^+ + e^- \quad (14)$$

$$N_2O \rightsquigarrow N_2O^+ + e^- \quad (15)$$

$$N_2O^+ + C_6H_6 \longrightarrow N_2O + C_6H_6^+ \quad (16)$$

$$e^- + N_2O \xrightarrow{k_e} N_2O^- \quad (17)$$

$$N_2O^- + N_2O \xrightarrow{k_s} N_2 + N_2O_2^- \quad (18)$$

$$N_2O^- + C_6H_6 \xrightarrow{k_a} N_2 + C_6H_6O^- \quad (19)$$

$$C_6H_6O^- + N_2O \xrightarrow{k_b} N_2 + C_6H_6O_2^- \quad (20)$$

$$C_6H_6^+ + e^- \longrightarrow Q \quad (21)$$

$$C_6H_6^+ + N_2O^- \xrightarrow{a} N_2 + P \quad (22)$$

$$C_6H_6^+ + N_2O_2^- \longrightarrow N_2 + Q \quad (23)$$

$$C_6H_6^+ + C_6H_6O^- \xrightarrow{b} P + C_6H_6 \quad (24)$$

$$C_6H_6^+ + C_6H_6O_2^- \xrightarrow{c} P + Q. \quad (25)$$

Here, Q stands for some products other than phenol, and P, for phenol. k_e, k_s, k_a, and k_b are the rate constants for the corresponding reactions. The a, b, and c shown in Reactions 22, 24, and 25 are the fractions of the phenol formation in these reactions. Reaction 20 was included to explain the large G-value of nitrogen. Reaction 22 is regarded as being similar to the reaction of oxygen atoms with benzene; therefore, the parameter, a, is taken to be equal to the conversion ratio of the phenol formation to the consumption of oxygen atoms. The phenol formation was not assumed in Reaction 23, since this reaction may be similar to the reaction of excited O_2 molecules with benzene. The reaction of $N_2O_2^-$ ions with benzene was not included, since the reactivity of $N_2O_2^-$ ions may be similar to that of superoxide ions. Superoxide ions are known not to be reactive to benzene.[28]

First, let us consider the lifetimes of negative species. The lifetime of a geminate electron produced in the system is denoted by t. If this electron is scavenged by N_2O at the time t', the lifetime of the negative charge will be prolonged, since the mobility of negative ions is much smaller than that of electrons. The lifetime of the N_2O^- ions thus produced may be expressed by $(t-t')r_D$, where $r_D=(\mu_e+\mu_+)/(\mu_-+\mu_+)$, and where μ_e, μ_+, and μ_- are the mobilities of electrons, $C_6H_6^+$ ions, and N_2O^- ions respectively. According to Reactions 18 and 19, N_2O^- ions react with N_2O or C_6H_6. If either of these reactions occurs at t'' after the formation of N_2O^- ions, the lifetime of the newly formed $N_2O_2^-$ or $C_6H_6O^-$ ions may be expressed by $[(t-t')r_D-t'']$. Here, we assumed that all of the negative ions have the same mobility, μ_-.

Since the probability that electrons are not scavenged by N_2O by the time t' is expressed by $\exp(-k_e[N_2O]t')$, and, similarly, the probability that N_2O^- does not react with N_2O or C_6H_6 by the time t'' after its generation is expressed by $\exp(-k_s[N_2O]t''-k_a[C_6H_6]t'')$, the fraction of the nitrogen formation by Reaction 18 may be expressed as follows:

$$F_{1s}(N_2) = \int_0^\infty f_e(t)dt \int_0^t k_e[N_2O] \exp(-k_e[N_2O]t')dt' \times \int_0^{(t-t')r_D} k_s[N_2O] \exp(-k_s[N_2O]t'' - k_a[C_6H_6]t'')dt''. \quad (III)$$

After the integrations are carried out, the use of Eq. II gives the following equation:

$$F_{1s}(N_2) = \frac{\beta S}{\beta S+\delta}\left[1-\exp(-\sqrt{\alpha S}) - \frac{\alpha S}{\alpha S-(\beta S+\delta)} \times \{\exp(-\sqrt{\beta S+\delta}) - \exp(-\sqrt{\alpha S})\}\right]. \quad (IV)$$

Here, $\alpha=k_e/\lambda$, $\beta=(k_s/\lambda)r_D$, and $\delta=(k_a[C_6H_6]/\lambda)r_D$. In similar manners, all of the fractions of the nitrogen formation through ionic processes can be derived. As for free electrons, we can use a usual kinetic treatment. Since the concentration of dinitrogen oxide used in the present experiment is not very small, all of the free electrons are assumed to be scavenged by N_2O. The fraction of the nitrogen formation initiated by free electrons may be written as follows:

$$F_{fi}(N_2) = \left(1+\frac{\beta S}{\beta S+\delta}+\frac{\delta}{\beta S+\delta}\frac{R_{20}}{R_{20}+R_{24}}\right). \quad (V)$$

Here, R_{20} and R_{24} are the reaction rates of the corresponding reactions. For simplicity, we assume the following expression for the ratio of R_{20}/R_{24}:[29]

$$R_{20}/R_{24} = [N_2O]/0.1 \quad (VI)$$

Ultimately we can obtain the following expression for the G-value of nitrogen produced through ionic processes:

$$G_i(N_2) = G_{fi}P_1 + G_{gi}[1-\exp(-\sqrt{\alpha S})]P_2 \quad (VII)$$

$$P_1 = F_{fi}(N_2) \quad (VIII)$$

$$P_2 = 2 - \frac{\alpha S}{\alpha S-(\beta S+\delta)}\left\{1-\frac{1-\exp(-\sqrt{\beta S+\delta})}{1-\exp(-\sqrt{\alpha S})}\right\} - \frac{\delta}{\beta S+\delta-\gamma S}\left[\frac{\alpha}{\alpha-\gamma}\left\{1-\frac{1-\exp(-\sqrt{\gamma S})}{1-\exp(-\sqrt{\alpha S})}\right\} - \frac{\alpha S}{\alpha S-(\beta S+\delta)}\left\{1-\frac{1-\exp(-\sqrt{\beta S+\delta})}{1-\exp(-\sqrt{\alpha S})}\right\}\right]. \quad (IX)$$

Here, $\gamma=(k_b/\lambda)r_D$. When this equation is applied to a very low concentration of a scavenger, the term for G_{fi} has to be accurately formulated.[30] In the present calculation, the contribution of G_{fi} is very small, since the G-values of the free electrons in aromatic hydrocarbons are known to be small:[31,32] for example, 0.06 for benzene, 0.05 for toluene, 0.07 for p-xylene, and 0.09 for 1,3,5-trimethylbenzene.

The expression for the phenol formation through an ionic process can similarly be derived as follows:

$$G_i(P) = G_{fi}Q_1 + G_{gi}[1-\exp(-\sqrt{\alpha S})][aQ_2+cQ_3+(b-c)Q_4] \quad (X)$$

$$Q_1 = \left[b+(c-b)\frac{S}{S+0.1}\right]\frac{\delta}{\beta S+\delta} \quad (XI)$$

$$Q_2 = \frac{\alpha S}{\alpha S-(\alpha S+\delta)}\left[1-\frac{1-\exp(-\sqrt{\beta S+\delta})}{1-\exp(-\sqrt{\alpha S})}\right] \quad (XII)$$

$$Q_3 = \frac{\delta}{\beta S+\delta}(1-Q_2) \quad (XIII)$$

$$Q_4 = \frac{\alpha}{\alpha-\gamma}\left[1-\frac{1-\exp(-\sqrt{\gamma S})}{1-\exp(-\sqrt{\alpha S})}\right] - Q_2. \quad (XIV)$$

Here, the phenol formation initiated by free electrons is assumed to result only from Reactions 24 and 25.

In order to determine the parameters appearing in the above expressions, we used two sets of experimental results; one consisted of the G-values of nitrogen and phenol obtained at low concentrations of dinitrogen oxide at room temperature, since benzene containing a small amount of dinitrogen oxide is crystallized at around 0 °C, while the other consisted of G(phenol)'s from a benzene–N_2O system at 0 °C.

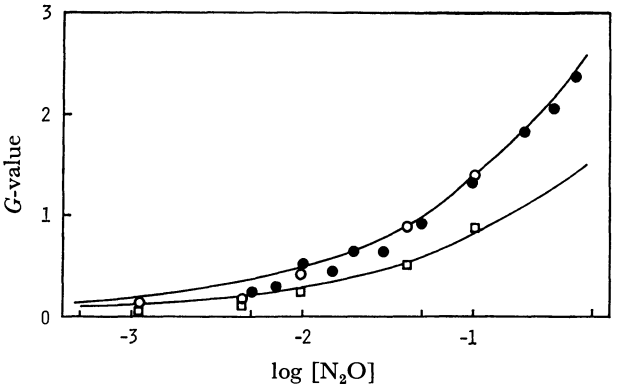

Fig. 9. The G-values of nitrogen (○, ●) and phenol (□) from the benzene–N_2O system at room temperature.
Solid lines are theoretical. Open symbols for the present work, and filled ones for the result of Hentz and Sherman.

Figure 9 shows $G(N_2)$ and G(phenol) at low concentrations of dinitrogen oxide, together with the results obtained by Hentz and Sherman.[33] The solid lines are the results of the calculation using Eqs. VII and X. The parameters used are $G_{fi}=0.06$, $G_{gi}=3.8$, $\alpha=0.5$ dm^3 mol^{-1}, $\beta=\gamma=1.0$ dm^3 mol^{-1}, $\delta=9.0[C_6H_6]$, $a=0.0$, and $b=c=1.0$. Here, we assumed $a=0.0$, since the fraction of the phenol formation against the consumption of oxygen atoms is known to be very small (6%) in the gas-phase reaction of oxygen atoms with benzene.

Figure 10 shows the G(phenol)'s as a function of ε from the benzene–N_2O system obtained at 0 °C. A solid line was calculated by using the same parameter as above. The deviation of the experimental plots at high-electron fractions above 0.9 might be due to the

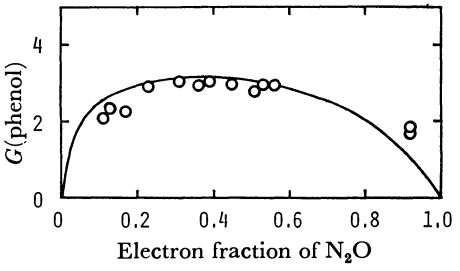

Fig. 10. The G-value of phenol from the benzene–N_2O system at 0°C. A solid line is theoretical.

phenol formation from the reaction of oxygen atoms with benzene. This point will be discussed later.

Now, let us go back to the data of $G(N_2)$ shown in Fig. 1. There are two origins of nitrogen in this reaction system, one is the direct radiolysis of dinitrogen oxide, $G_d(N_2)$, and the other, from the ionic process, $G_i(N_2)$:

$$G(N_2) = G_d(N_2) + G_i(N_2). \quad \text{(XV)}$$

$G_d(N_2)$ should be proportional to ε up to 0.8. The dotted line shown in Fig. 1 is $G_i(N_2)$ calculated by using Eq. VII. A solid line was drawn by adding 3.3ε to $G_i(N_2)$. Because of the scattering of the $G(N_2)$ data, only a wide range of the value, $G_d(N_2)/\varepsilon=3.0$—4.0, can be estimated from Fig. 1. The value of 3.3 was estimated as follows. In the 1-butene–N_2O system, we observed that G(1-butene oxide)$=1.4\varepsilon$. On the other hand, according to Cvetanović,[12] the yield of 1-butene oxide upon the consumption of oxygen atoms is about 0.42 in the gas-phase reaction. If we take this value for the present experiment, the G-value of the oxygen atoms produced by the direct radiolysis of dinitrogen oxide should be 3.3 ($=1.4/0.42$).

If we take this value, 3.3, as the G-value of the oxygen atoms from the direct radiolysis of dinitrogen oxide, the conversion yield, $a=G_d$(2,4,6-trimethylphenol)$/G_d$(oxygen atoms), in the benzene–1,3,5-trimethylbenzene–N_2O system is calculated to be 0.71 ($=2.4/3.3$).

It may be worthwhile here to make some comments on the parameters we have used above. When Hentz and Sherman analyzed $G(N_2)$,[33] they used Schuler's empirical equation, which is exactly the same as Hummel's equation at the lower limit of the scavenger concentration. The α parameter they obtained was about 0.7 dm^3 mol^{-1}. For the β parameter, they could not determine the exact value because of the scattering of data, but they suggested that it is larger than α. We have no knowledge to use for the estimation of the value of γ; however, Reactions 18 and 20 are similar in the mechanism of the oxygen-atom transfer, so that $\beta=\gamma$ may not be an absurd approximation. Reaction 19 is practically the addition reaction of O^- to benzene; therefore, $\delta/[C_6H_6]$ must be much larger than β and γ. We took 9.0 for this ratio.

The Competition of Aromatic Hydrocarbons for the Formation of the Corresponding Phenols by the Ionic Process. In order to investigate the competition of aromatic hydrocarbons for the formation of the corresponding phenols, the following three mixtures were γ-irradiated at various mixing ratios under a constant electron fraction of dinitrogen oxide ($\varepsilon=0.1$); benzene–toluene, benzene–*p*-xylene, and benzene–1,3,5-trimethylbenzene. The results for the last mixture have already been shown in Fig. 7.

When two aromatic hydrocarbons, A and B, are used in place of benzene in the reaction mechanism stated above, competition between A and B occurs in Reactions 19 and 20:

$$N_2O^- + A \xrightarrow{k_A} N_2 + AO^- \quad \text{(19A)}$$

$$N_2O^- + B \xrightarrow{k_B} N_2 + BO^- \quad \text{(19B)}$$

$$AO^- + N_2O \longrightarrow N_2 + AO_2^- \quad \text{(20A)}$$

$$BO^- + N_2O \longrightarrow N_2 + BO_2^-. \quad \text{(20B)}$$

The kinetic treatment including these reactions is somewhat complicated; however, when the electron fraction of dinitrogen oxide is not very large, the following approximate expression can be used:

$$G_i(P_A) = \frac{k_A[A]}{k_A[A]+k_B[B]}[b_A G_{fi} + c_A G_{gi}(1-e^{-\sqrt{aS}})] \quad \text{(XVI)}$$

$$G_i(P_B) = \frac{k_B[B]}{k_A[A]+k_B[B]}[b_B G_{fi} + c_B G_{gi}(1-e^{-\sqrt{aS}})]. \quad \text{(XVII)}$$

Here, the subscripts A and B correspond to the two hydrocarbons, A and B. Since G_{fi} is much smaller than G_{gi}, the contribution of the first term in brackets on the right-hand side is very small compared with the second one. The errors introduced in the estimation of k_A/k_B by using these approximate expressions were calculated numerically and estimated to be within 10%.

Since the gas-chromatographic analysis of products was not very reproducible, as will be shown below, we used the following procedure for the determination of the relative rate constants, k_A/k_B. This procedure has already been used in a previous paper,[4] where the relative rate constants of oxygen atoms with several olefins were determined.

In the case of benzene, the only addition product observed is phenol, but in the case of toluene we observed three kinds of cresols and benzyl alcohol, so that the process for the formation of addition products has to be divided:

$$N_2O^- + A \xrightarrow{m} P_{Am}$$
$$\xrightarrow{1-m} P_{A(1-m)}.$$

Here, m denotes the fraction of the P_{Am} product against the total addition products from the A hydrocarbon. Now, let us introduce a weighted mole fraction, x:

$$x = \frac{f[B]}{[A]+f[B]}, \quad \text{(XVIII)}$$

where f is the factor to be estimated. If the f factor is equal to the k_B/k_A ratio, the plots of $G(P_{Am})$ against x will give a straight line:

$$G(P_{Am}) = mG_A(1-x). \quad \text{(XIX)}$$

Here,

$$G_A = b_A G_{fi} + c_A G_{gi}(1-e^{-\sqrt{aS}}). \quad \text{(XX)}$$

A similar linearity can be obtained for the products of the reaction with the B hydrocarbon:

$$G(P_{Bn}) = nG_B x. \quad \text{(XXI)}$$

Here,

$$G_B = b_B G_{fi} + c_B G_{gi}(1-e^{-\sqrt{aS}}), \quad \text{(XXII)}$$

and n is the fraction of the P_{Bn} product. Such plots are made by varying the f factor until good linearities are obtained for all products.

Figures 11, 12, and 13 show the final plots thus obtained for the reaction systems of benzene–toluene, benzene–*p*-xylene, and benzene–1,3,5-trimethylbenzene respectively. Figure 13 clearly shows the intercept at [1,3,5-trimethylbenzene]$=0$ for the plots of 2,4,6-trimethylphenol. This is due to the reaction of the

oxygen atoms produced in the direct radiolysis of N_2O. The relative rate constants of Reaction 19 thus obtained are summarized in Table 1.

Now, let us go back to Eq. X. Most of the parameters in this equation for the aromatic hydrocarbons are

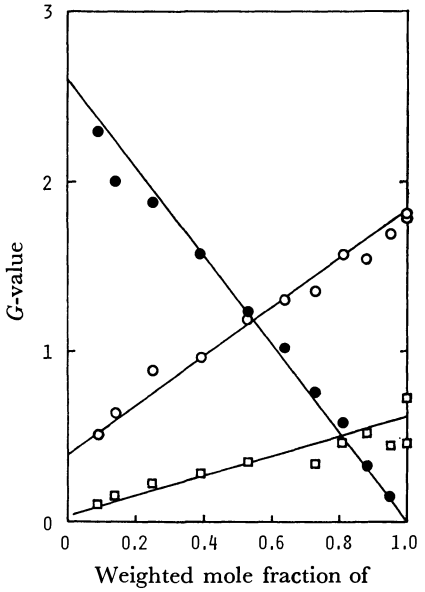

Fig. 13. The *G*-values of addition products from the mixture of benzene and 1,3,5-trimethylbenzene in the presence of dinitrogen oxide ($\varepsilon=0.1$) at 0°C as functions of the weighted mole fraction of 1,3,5-trimethylbenzene.
The value of f is taken as 3.1. ●, Phenol; ○, 2,4,6-trimethylphenol; □, 3,5-dimethylbenzyl alcohol.

TABLE 1. THE RELATIVE RATE CONSTANTS OF REACTIONS OF OXYGEN ATOMS AND N_2O^- IONS WITH SEVERAL HYDROCARBONS IN THE LIQUID PHASE

Reactions	Relative rate constants
O+benzene	1.0
O+toluene	2.0
O+1-butene	100
N_2O^-+benzene	1.0
N_2O^-+toluene	2.5
N_2O^-+*p*-xylene	2.2
N_2O^-+1,3,5-trimethylbenzene	3.1
N_2O^-+1-butene	6.25

known except for a, b, and c. Since ε is 0.1, we can neglect the phenol formation from the reaction of oxygen atoms with benzene, *i.e.*, $a=0.0$ in the case of the benzene system. Similarly, we assume here $a=0.0$ for the toluene system as well, since the ratio of the cresol formation to the consumption of oxygen atoms is known to be small (15%) in a gas-phase reaction.[22] As for 1,3,5-trimethylbenzene, we have already obtained $a=0.71$. For *p*-xylene, we tentatively assume $a=0.4$. As will be shown below, this value is consistent with the experimental results.

The total *G*-value of a specified product, P_α, may now be expressed as follows:

$$G(P_\alpha) = G_d(P_\alpha) + G_i(P_\alpha) \quad \text{(XXIII)}$$

$$G_d(P_\alpha) = laG_d(\text{oxygen atoms}) \quad \text{(XXIV)}$$

$$G_i(P_\alpha) = G_{fi}Q_1la + G_{gi}(1-e^{-\sqrt{aS}}) \times [laQ_2+mcQ_3+m(b-c)Q_4]. \quad \text{(XXV)}$$

TABLE 2. THE PARAMETERS ESTIMATED FOR THE THEORETICAL CALCULATION

$\alpha=0.5$ dm^3 mol^{-1}, $\beta=\gamma=1.0$ dm^3 mol^{-1}, $\delta/[C_6H_6]=9.0$

Reactant	a	$b=c$	Product	l	m
Benzene	0.17	1.0	Phenol	1.0	1.0
Toluene	0.36	0.74	*o*-Cresol	0.64	0.45
			m-Cresol	0.14	0.23
			p-Cresol	0.19	0.16
			Benzyl alcohol	0	0.16
			Phenol	0.03	0
p-Xylene	0.40	0.84	2,5-Dimethylphenol	1.0	0.75
			p-Methylbenzyl alcohol	0	0.25
1,3,5-Trimethylbenzene	0.71	0.81	2,4,6-Trimethylphenol	1.0	0.69
			3,5-Dimethylbenzyl alcohol	0	0.31

a: The fraction of the total addition products to the consumption of oxygen atoms; b: the fraction of the addition products to the consumption of N_2O^- ions; l: fractional yields of the addition products formed in the reaction of oxygen atoms; m: fractional yields of the addition products formed in the reaction of N_2O^- ions, followed by neutralization.

The expressions for Q_1, Q_2, Q_3, and Q_4 have already been shown in Eqs. XI, XII, XIII, and XIV respectively. l is the fraction of a specified product, P_α, against the total addition products formed in the reaction of oxygen atoms.

Table 2 summarizes all of the parameters used. These parameters can reproduce all the data shown in Figs. 11, 12, and 13 by the use of Eq. XXIII. As an example, the mole fraction dependence of the G-values of phenol, 2,5-dimethylphenol, and *p*-methylbenzyl alcohol is shown in Fig. 14. The dotted line shows the G-value of the 2,5-dimethylphenol produced through the ionic process (Eq. X).

The Phenol and Cresol Formations in the Reactions of Oxygen Atoms with Benzene and Toluene. In the above calculation, we assumed $a=0.0$ in the cases of benzene and toluene. In order to estimate the real values, we have investigated the phenol and cresol formations at a high electron fraction of dinitrogen oxide ($\varepsilon=0.92$), where the oxygen atoms produced from the direct radiolysis of dinitrogen oxide are important as the source of phenol formation. The results are shown in Fig. 15. The dotted lines are the G-values of the products formed through the ionic process, which have been calculated by using Eq. X.

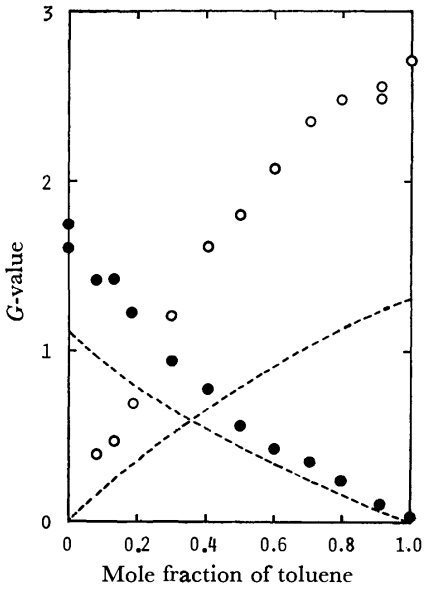

Fig. 15. The G-values of addition products from the benzene–toluene–N_2O system ($\varepsilon=0.92$).
○, The sum of cresols and benzyl alcohol; ●, phenol. Dotted lines are the G-values of each product formed through ionic process.

The difference in G-value between experiment and calculation is plotted in Fig. 16 by using the "weighted-mole-fraction" procedure. From this figure, we can estimate $a=0.17$ ($=0.52/(3.3\times0.92)$) for benzene and 0.36 ($=1.1/(3.3\times0.92)$) for toluene, and also

$$k(\mathrm{O}+\text{toluene})/k(\mathrm{O}+\text{benzene}) = 2.0.$$

Here, k is the rate constant of each reaction. Moreover, we can observe the intercept of G(phenol) at [benzene]=

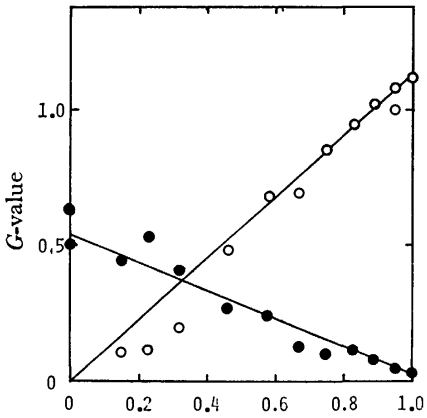

Fig. 16. The *G*-values of addition products formed in the reaction of oxygen atoms in the benzene–toluene–N_2O system (ε=0.92) as functions of the weighted mole fraction of toluene. ○, The sum of cresols; ●, phenol.

0, which suggests that a small amount of phenol is formed in the reaction of oxygen atoms with toluene. The *G*-value is calculated to be 0.03. This type of reaction has already been discussed by Sakurai *et al.*[8]

The Calculations of G(phenol)'s from the Toluene–1-Butene–N_2O System and of the G-values of the Addition Products from the Benzene–1,3,5-Trimethylbenzene–N_2O System. We now have all of the parameters necessary to calculate the *G*-values of the addition products shown in Figs. 3 and 5 by using Eq. XXIII, except for the rate-constant ratio, $k(N_2O^- + \text{1-butene})/k(N_2O^- + \text{toluene})$. For this ratio, we assumed 2.5 so as to explain the experimental data. The calculated results are shown in Figs. 3 and 5 as solid lines: the figures suggest that all the data are now explainable by the reaction mechanism proposed.

Although all the data shown in the present paper can be explained by the proposed reaction mechanism, this does not necessarily mean that such reactions as Reactions 19 and 20 are real reactions occurring in the system for the formation of the corresponding phenols. There might be another interpretation. In order to establish these reactions, we have to observe AO^- and AO_2^- ions directly, or, we have to investigate similar reactions with other aromatic compounds containing different substituents.

30) The accurate expressions for G_{fl} (N_2) and G_{fl} (phenol) can be derived as follows:

$$G_{fl}(N_2) = \frac{1}{\sqrt{k_n D W}}\left\{2k_s[N_2O] + k_a[C_6H_6] + \frac{k_a k_b[N_2O][C_6H_6]}{k_b[N_2O] + \sqrt{k_n D/W}} + \sqrt{k_n D/W}\right\} \left\{1 + \frac{k_s[N_2O]}{\sqrt{k_n D/W}} + \frac{k_a[C_6H_6]}{k_b[N_2O] + \sqrt{k_n D/W}} \times \left(1 + \frac{k_b[N_2O]}{\sqrt{k_n D/W}}\right)\right\}^{-1}$$

$$G_{fl}(P) = \frac{1}{W}\left\{a + \frac{k_a[C_6H_6]}{k_b[N_2O] + \sqrt{k_n D/W}}\left(b + \frac{ck_b[N_2O]}{\sqrt{k_n D/W}}\right)\right\} \left\{1 + \frac{k_s[N_2O]}{\sqrt{k_n D/W}} + \frac{k_a[C_6H_6]}{k_b[N_2O] + \sqrt{k_n D/W}} \times \left(1 + \frac{k_b[N_2O]}{\sqrt{k_n D/W}}\right)\right\}^{-1}.$$

Here, k_n stands for the rate constant of the neutralization reaction between $C_6H_6^+$ ions and negative ions; *i.e.*, we assumed here $k_n = k_{22} = k_{23} = k_{24} = k_{25}$. D is the dose rate, and $W = 100/G_{fl}$; *cf.* K. Okazaki, R. Yugeta, and S. Sato, *Bull. Chem. Soc. Jpn.*, **46**, 2066 (1973).

An ESR Study of the Interaction of Copper(II) Octaethylporphyrin with π Acceptors

Hiroshi Yokoi* and Masamoto Iwaizumi

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira, Sendai 980

(Received May 17, 1979)

The π-π interaction of octaethylporphyrincopper(II) (Cu(OEP)) with π acceptors has been investigated in solution and in magnetically-diluted crystals by ESR, and the perpendicular components of the ESR parameters for Cu(OEP) in various states have also been determined with considerable accuracy. It has been revealed that, upon the formation of charge-transfer complexes between Cu(OEP) and π acceptors, the g values decrease slightly, the copper hyperfine coupling constants remain almost unchanged, and the absolute values of the nitrogen superhyperfine coupling constants increase slightly. Accompanying changes in the electronic structure around the copper ion have been discussed. The ESR parameters of Cu(OEP) doped in Ni(OEP) have been noted to depend significantly upon the polymorphism of the diluent.

The dimerization and/or aggregation of planar metal complexes with π-ligands are phenomena in which the π-π interaction between the metal complexes plays an important role.[1-5] The π-π interaction of metal complexes with π acceptors or donors, which results in the formation of charge-transfer (CT) complexes in some cases, is also a subject of study aimed at elucidating the electron-transfer mechanisms, both in co-ordination chemistry and in biochemistry.[6,7] The CT complexes between metal porphyrins and various π acceptors are the best studied group.[8-10] Little work, however, has been done to investigate how the electronic structure of the metal complexes changes in the CT complexes. In the present work, such an attempt for a copper(II) porphyrin has been made by means of the ESR method.

In ESR studies of copper(II) porphyrins, we must know that it is not easy to determine precisely the perpendicular components of copper ESR parameters from the ESR spectra of frozen solutions and magnetically-diluted polycrystals. The usual computer-simulation method is not always useful for this purpose, since none of the simulated spectra thus far obtained for the systems have been fitted to the observed ones with any considerable accuracy.[11-14] This situation can further be understood from the fact that the $g_\perp$ and $|A_\perp|$ values previously reported for the copper(II) complexes of porphyrins and phthalocyanine are randomly distributed over the wide ranges of 2.031—2.072 and 0—54×10^{-4} cm^{-1} respectively.[11-18] In this work, those parameter values of octaethylporphyrincopper(II) in various states have been estimated on reasonable grounds.

Experimental

Materials. Octaethylporphyrin (abbreviated as $OEPH_2$) was obtained from the Stern Chemical Co., and its Cu(II) and Ni(II) complexes (Cu(OEP) and Ni(OEP) respectively) were prepared and purified according to the literature.[19] 1,3,5-Trinitrobenzene (TNB), 2,4,7-trinitrofluoren-9-one (TNF), piperidine (pip), and toluene were purchased from the Tokyo Kasei Co. and were purified by the standard literature methods. Doped samples were obtained by crystallization from 200: 1 mixtures of the diamagnetic matrix substance and the substituent one in dichloromethane and in *N*,*N*-dimethylformamide (DMF). The 1: 1 CT complexes of M(OEP)·TNF and $OEPH_2$·TNF were deposited as black needles immediately after the addition of an equimolar TNF to the dichloromethane solutions of M(OEP) and $OEPH_2$; the CT complexes were confirmed by elemental analyses. The sample of Cu(OEP) doped in Ni(OEP) will hereinafter be abbreviated as Cu/Ni(OEP); similar abbreviations will also be used for the other doped samples.

Physical Measurements. The ESR spectra at room temperature for both polycrystalline and solution samples and at 77 K for frozen solutions were recorded on a Varian E-4 X-band ESR spectrometer, the field strength being calibrated with an NMR probe and then with bis(2,4-pentanedionato)oxovanadium(IV) in benzene. The visible absorption spectra at room temperature were recorded on a Cary 14 spectrophotometer.

Results

The ESR spectrum of Cu(OEP) in toluene at 77 K is shown in Fig. 1(A). The undulation of the base-line, on which the monomer spectrum is superimposed, indicates the co-existence of triplet-state dimers; this was further evidenced by the half-field spectrum clearly observed around 1550 G.† The dimerization and/or polymerization of metal porphyrins in solution have been extensively studied by ESR[12,13,20-22] and by the other methods.[3-5] Their dimerization ability itself suggests that their molecules have the property

(A) and (B) correspond to those in Fig. 1 respectively.

of interacting readily with other π-systems. The frozen solution ESR spectrum of Cu(OEP) in toluene with excess TNB is shown in Fig. 1(B). This spectrum, in which dimer ESR signals disappear completely, is comparatively sharp in every absorption line. On the other hand, the visible absorption spectra of Cu(OEP) in toluene with and without excess TNB are as shown in Fig. 2. The spectral change on the addition of excess TNB is quite similar to that in the case of Co(OEP),[8] in which the 1:1 CT complex formation of Co(OEP)·TNB has been confirmed.

The ESR parameters determined directly and definitely from such ESR spectra as are shown in Fig. 1 number only three or four, $g_{//}$, $|A_{//}|$, $|A_{\perp}^{N}|$, and, possibly, $|A_{//}^{N}|$.[22] As has already been mentioned, the exact determination of the perpendicular components of g and A is not easy at present. Toluene is generally considered as an inert or non-co-ordinating solvent, and Cu(OEP) is a very stable square-planar complex with strong co-ordination bondings. In such a case, the relations of $g_0=(g_{//}+2g_{\perp})/3$ and $A_0=(A_{//}+2A_{\perp})/3$ hold well, where g_0 and A_0 are the parameters derived from fluid-solution ESR spectra and where the other parameters are those from their frozen-solution ESR spectra.[24] In Fig. 3, the observed ESR spectrum of Cu(OEP) in toluene at room temperature is shown, together with the simulated one, in which isotope effects due to the natural occurrence of ^{63}Cu and ^{65}Cu, a second-order correction of the resonance fields, and Lorentzian line shapes with M_I-dependent linewidths are taken into consideration.[25] The same simulation was done for the toluene solution of Cu(OEP) and excess TNB. The $g_{\perp}$ and $|A_{\perp}|$ values of both spectra shown in Fig. 1 were thus determined with a certain degree of reliability. The $g_{\perp}$ and $|A_{\perp}|$ values of the other frozen-solution type of spectra were obtained by a direct comparison between their spectra and the spectra shown in Fig. 1 in the perpendicular region. Some representative polycry-

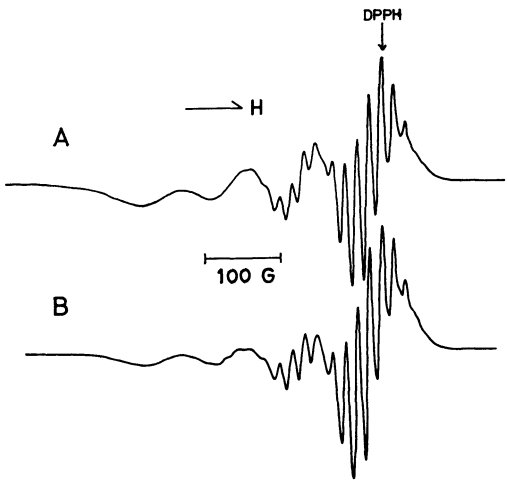

Fig. 3. X-Band ESR spectra of Cu(OPE) in toluene at room temperature.
(A), Observed; (B), simulated with $g_0=2.094$, $|A_0|=86.4$ G, $|A^N{}_0|=16.0$ G, and 3.5, 5.2, 6.9, and 8.7 G for the line widths of $M_I=3/2$, 1/2, $-1/2$, and $-3/2$ lines, respectively.

Table 1. ESR parameters[a] for Cu(OEP) in various states

Complex	Solvent or matrix	$g_{//}$	$g_{\perp}$	g_0	$10^3\|A_{//}\|$	$10^3\|A_{\perp}\|$	$10^3\|A_0\|$	$10^3\|A_{\perp}^{N}\|$ (cm^{-1})	$10^3\|A_{//}^{N}\|$	$10^3\|A_0^{N}\|$
Cu(OEP)	Toluene	2.187	2.047	2.094	20.4	2.4	8.4	1.45	1.83	1.57
Cu(OEP)·TNB	Toluene	2.181	2.045	2.092	20.4	2.5	8.5	1.46	1.85	1.58
Cu(OEP)·pip	Toluene	2.215	2.058		18.9			1.37	1.68	
Cu(OEP)	$OEPH_2$	2.190	2.048		19.8	2.3		1.43	1.70	
Cu(OEP)·TNF	$OEPH_2$·TNF	2.186	2.047		19.9	2.4		1.44	1.71	
Cu(OEP)[b]	Ni(OEP) (I)	2.190	2.049		19.9	2.3		1.46	1.75	
	Ni(OEP) (II)	2.175	2.044		20.2	2.5		1.49	1.75	
Cu(OEP)·TNF	Ni(OEP)·TNF	2.186	2.047		20.0	2.4		1.47	1.76	

a) All the values of copper hyperfine are given for ^{63}Cu. The estimated errors are ±0.001 for g, $\pm0.1\times10^{-3}$ cm^{-1} for A, and $\pm0.01\times10^{-3}$ cm^{-1} for A^N, but the respective relative errors among related complexes cited for comparison are less. All the A^N values were determined from partially enlarged spectra. b) (I), Crystallized from DMF; (II), crystallized from dichloromethane. All the other crystalline complexes were obtained by crystallization from dichloromethane.

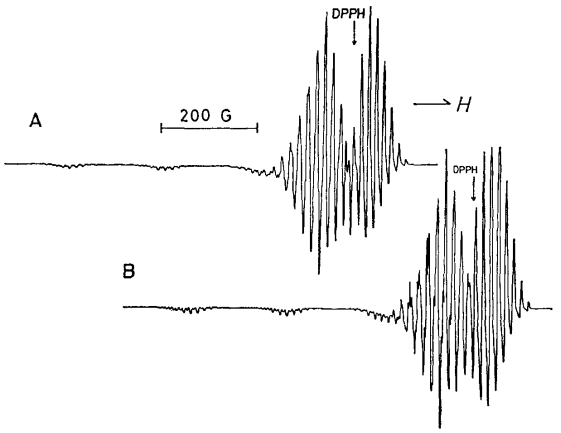

Fig. 4. X-Band polycrystalline powder ESR spectra of (A) Cu(OEP)/$OEPH_2$ and (B) Cu(OEP)·TNF/$OEPH_2$·TNF at room temperature.

stalline ESR spectra are shown in Fig. 4, just for information. All the ESR data thus determined are summarized in Table 1. The $g_\perp$ and $|A_\perp|$ values listed in the table agree well with those recently reported for copper(II) ^{15}N-etioporphyrin I in the free base.[18] This confirms the values in Table 1 to be reliable.

Discussion

Piperidine, which is a basic and saturated molecule with a nitrogen lone-pair, can co-ordinate apically to copper(II) porphyrins to form square-pyramidal five-co-ordinate complexes.[26] The ESR parameters change remarkably on the addition of piperidine to the toluene solution of Cu(OEP), as is shown in Table 1; the g and $|A|$ values remarkably increase and decrease respectively. These types of ESR changes for planar copper(II) complexes are generally caused by a change in the state of apical co-ordination.[27-29]

On the other hand, on the addition of an excess of TNB to the toluene solution of Cu(OEP), the ESR parameters changed, too, but in a different way; the g values decreased slightly, the $A_{//}$ value remained almost unchanged, and the $|A^N|$ values increased slightly. These facts show that piperidine and TNB have quite different types of interaction with Cu(OEP). A closer inspection of the table indicates that there are similar ESR changes in the crystalline states, too. In the case of Cu/Ni(OEP), however, (I) rather than (II) is adopted for comparison; this point will be discussed later. The same kind of ESR results for another complex in crystals can be found in the literature:[30] $g_{//}=2.212$, 2.206, and 2.206, and $10^3|A_{//}|=$ 19.98, 19.91, and 20.15 (cm^{-1}), for $Cu/PdOx_2$, $Cu/PdOx_2$·2TCNE, and $Cu/PdOx_2$·TCNQ respectively, where Ox, TCNE, and TCNQ are the abbreviations of 8-quinolinate, tetracyanoethylene, and 7,7,8,8-tetracyanoquinodimethane respectively. These data, however, have been discussed only from the point of view of a general understanding of host-lattice effects.

As to the host-lattice effects, it is interestingly found in Table 1 that the polycrystals of Cu/Ni(OEP) obtained by crystallization from DMF, (I), are remarkably different in ESR parameters from those crystallized from dichloromethane, (II). The difference is not the kind of difference which can be explained in terms of a change in the state of apical co-ordination. Ni(OEP) is well known to display polymorphism.[31,32] Two crystalline modifications with known X-ray analytical data have quite different molecular geometries and packings, although the complex is naturally very stable. Judging from the essence of polymorphism, however, the difference in energy between the crystalline modifications must not be large. The above-mentioned ESR result of Cu/Ni(OEP) shows that molecular-environmental effects due to polymorphism are sensitively reflected in the ESR parameters. It is noteworhy that the structure and properties of metal porphyrins depend to a marked extent on their molecular environment, and this seems to be of especial significance in view of the functional diversity of the complexes in biological systems. In Table 1, Cu(OEP)/$OEPH_2$ and (I) in Cu/Ni(OEP) have almost the same ESR parameters. This fact suggests that they are crystallographically similar, although the solvents of crystallization are different. In this study, accordingly, (I) in Cu/Ni(OEP), rather than (II), was adopted to compare with Cu/Ni(OEP)·TNF.

On the whole, it may be concluded that, when Cu(OEP) interacts with π acceptors, the g values decrease slightly and the $A_{//}$ value remains almost unchanged. In an axial molecular field, the σ antibonding wavefunction is:[33,34]

$$\psi_\sigma = \alpha d_{x^2-y^2} - (\alpha'/2)(\sigma_1-\sigma_2+\sigma_3-\sigma_4)$$
$$\alpha^2 + \alpha'^2 - 2\alpha\alpha' S = 1$$

where σ_i expresses the ith nitrogen lone-pair orbital and where the other symbols have their usual meanings. The bonding parameter, α, is a measure of the covalency of the in-plane σ bonding. To calculate α^2, an approximate formula based on the copper hyperfine term, $A_{//}$, can be used:[35]

$$\alpha^2 = -(A_{//}/P) + (g_{//}-2) + (3/7)(g_\perp-2) + C$$

where C is a small constant and where $P=2\gamma\beta_0\beta_n$ $\langle r^{-3}\rangle=0.0360$ cm^{-1}. According to this equation, the ESR changes mentioned above obviously lead to a slight decrease in value of α^2. The decrements ($\Delta\alpha^2$) are calculated to be -0.003——-0.008, meaning that the σ bonding becomes a little more covalent when Cu(OEP) interacts with π acceptors. This result is also supported by the experimental fact that both $|A^N_\perp|$ and $|A^N_{//}|$ values simultaneously increase slightly, as is shown in Table 1. The increments of $|A^N|$ are of a reasonable order of magnitude, in view of the relations of $\Delta\alpha'^2 \simeq -\Delta\alpha^2$ and the rough proportionality between $\Delta\alpha'^2$ and $\Delta|A^N|$.[34] This suggests that either of two changes in the electronic structure of Cu(OEP) may take place on the formation of its CT π-complexes. One of the changes is that the π-electron density at the four co-ordinating nitrogen atoms slightly increases in order for the σ co-ordination bonding to become a little more covalent.[24] The other change is that the electronic charge on the central copper atom increases slightly relatively in the CT complexes, so that the copper $d_{x^2-y^2}$ orbital level is lowered and, accordingly, the

orbital becomes easier to be mixed with the ligand σ orbitals.[36,37] These considerations do not seem unreasonable, since a small change in the distribution of π-electrons over the whole Cu(OEP) molecule must actually take place on the formation of its CT π-complexes. Further work will, however, be required to find a solution to this problem.

It is interesting to consider the differences between (I) and (II) in Cu/Ni(OEP) in Table 1, for instance, as to the value of α^2. If we assume $\alpha^2=0.803$ for (I),[25] the α^2 value of (II) can be calculated to be 0.794 from the above-described equation of α^2. This change in α^2, which is a host-lattice effect, is large compared with that in the CT complexes. This fact shows the importance of lattice effects or molecular environmental effects on the properties of metal prophyrins.

14) In most simulation programs so far employed, the effects of the quadrupole interaction and second-order effects of the strong super-hyperfine interaction due to the four nitrogen nuclei have not been taken into consideration explicitly. Besides, there still seems to be much room for a re-consideration of the transition probability, the linewidth, and the convolution function. The simulated spectra in the perpendicular region may change remarkably according to how every problem mentioned above is settled.

Calorimetric Study of the Glassy State. XV.† Thermodynamic Study of Pinacol Hexahydrate and Pinacol-d_2 Hexadeuterate

Masaharu Oguni, Takasuke Matsuo, Hiroshi Suga,* and Syûzô Seki

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received July 16, 1979)

The heat capacities of pinacol hexahydrate and its deuterate analogue were measured in the temperature region between 13 and 260 K. A phase transition was found and the temperature of transition was determined to be 192.14 K for the hydrate and 191.17 K for the deuterate, respectively. The enthalpy and entropy of the transition were estimated to be 924 J mol^{-1} and 5.10 J K^{-1} mol^{-1} for the hydrate and 944 J mol^{-1} and 5.28 J K^{-1} mol^{-1} for the deuterate. The transition was interpreted as the order-disorder change of the orientations of the pinacol molecule. Besides the phase transitions, an additional anomaly was found around 150 K for the hydrate and two around 130 K and around 160 K for the deuterate, respectively. All of them are relaxational in their characteristics and interpreted as glass transitions due to freezing of reorientational motions of the water molecule and the pinacol molecule. The transition temperature and the activation enthalpy for the higher glass transition of the deuterate were estimated to be 167.2 K and (34±4) kJ mol^{-1}, respectively.

The existence of pinacol (2,3-dimethyl-2,3-butane diol) hexahydrate was first shown by Fittig[1] in 1859. The structural feature of the hydrate is that the crystal at room temperature involves two kinds of orientational disorder. X-Ray diffraction study by Kim and Jeffrey[2] revealed that the crystal has a three-dimensional hydrogen-bonded network composed of layers of water molecules and hydroxyl groups of the pinacol molecules. The diol molecules are entrapped in the voids in this framework with two-fold orientational disorder. Thus, the crystal is clathrate-like but not a genuine clathrate because the hydroxyl groups of the alcohol are incorporated in the host lattice.

The dielectric constants of the crystal were measured by Cook and Meakins[3] in the temperature range 240—290 K, and by Garrington and Williams,[4] who observed high values of ε'_0 exceeding 50. On the basis of the systematic measurements on partially dehydrated samples, they showed that the large value of ε'_0 is due to reorientational motions of the water molecules. It is noted in their work that the behaviour of dielectric dispersion and absorption is closely related to that in hexagonal ice crystal. Thus both the pinacol and the water molecules are in orientationally disordered states.

The present paper reports calorimetric studies on pinacol hexahydrate and its deuterate analogue and discusses the observed heat-capacity anomalies in terms of ordering and freezing of the different molecular disorders. This study was undertaken as an extension of the calorimetric investigation on the relaxational heat capacity anomalies observed in stable crystals,[5] including $SnCl_2 \cdot 2H_2O$, $SnCl_2 \cdot 2D_2O$,[6] H_2O,[7] D_2O,[8] H_3BO_3 and D_3BO_3.[9] A study on phase diagram of water-pinacol system is also reported.

Experimental

Pinacol (Aldrich Chem. Co.) was purified by vacuum-distillation at 50—60 °C. The water content of the purified crystal was analysed by use of Karl-Fischer's method to be 0.36 mg cm^{-3}. This crystal was used for the phase diagram study of the pinacol-water system. The hexahydrate crystal was prepared by recrystallization of the purified pinacol from the aqueous solution. The recrystallization was repeated three times for further purification. Excess water in the hexahydrate crystal was removed by equilibrating the crystal in a desiccator with the monohydrate.

Prior to the preparation of the hexadeuterate, the hydroxyl groups of the purified pinacol were deuterated by repeating alternately three times the dissolution of anhydrous pinacol into heavy water (99.75%) and the complete dehydration of the solution by the use of molecular sieve 3A. The anhydrous pinacol thus obtained was vacuum-distilled at 50—60 °C in order to remove the trace of molecular sieve. The hexadeuterate was recrystallized from the heavy water solution of the pinacol-d_2. The deuterated crystal was kept in a desiccator with the monodeuterate as in the case of the hexahydrate. The molecular formula of the deuterate crystal was $(CH_3)_2(OD)CC(OD)(CH_3)_2 \cdot 6D_2O$, and the deuteration level was estimated to be 99.5%.

The heat capacity measurements were carried out by using the calorimetric apparatus described before.[9,10] The crystal was loaded into the calorimeter cell in a polyethylene bag where the water vapor pressure was adjusted in advance so as to prevent dehydration of the crystal. The loaded cell was cooled to liquid nitrogen temperature in a glass vessel, evacuated for twenty minutes, and filled with one-atmospheric pressure of helium gas. The cell was taken out of the vessel and tightly sealed by screwing a cap with a gold gasket. The mass of the sample was 38.970 g for the hydrate and 43.075 g for the deuterate, respectively. The inaccuracy of the heat capacity measurement is estimated to be 1% at liquid hydrogen temperature and less than 0.3% above 40 K.

Results and Discussion

Phase Equilibrium in Water–Pinacol System. The equilibrium phase diagram between water and pinacol was investigated by Pushin and Glagoleva in 1922.[11] They found existence of the stable monohydrate in addition to the hexahydrate. Their interest was concentrated on melting (and eutectic) phenomena, while ours is directed to the transitions in the crystalline state. Figure 1 shows the present results of the phase relation examined by DTA. The melting point of the hexahydrate was found to be 318.5 K, in agreement with Pushin and Glagoleva. Those of the anhydrous pinacol and of the monohydrate were higher by 1.0 K and 0.4 K respectively, than the values determined by them.

As shown in the figure, phase transitions were found

† Part XIV. Bull. Chem. Soc. Jpn., **51**, 1691 (1978). Contribution No. 3 from Chemical Thermodynamics Laboratory.

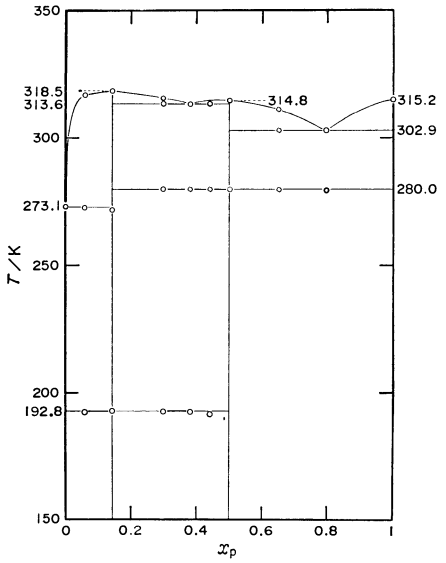

Fig. 1. Phase diagram of the system water–pinacol. x_p is the mole fraction of pinacol.

at 192.8 K and 280.0 K in the crystalline states of the hexahydrate and monohydrate, respectively. From the DTA curves the enthalpy of transition of the monohydrate was found to be larger by more than one order of magnitude than that of the hexahydrate. This is in good agreement with the observation that the room-temperature second moment[12] of the proton magnetic resonance of the monohydrate is considerably smaller than those of the hexahydrate and the anhydrous compound.

Heat Capacity. The heat capacities of the hexahydrate and the hexadeuterate were measured in the temperature region between 13 and 300 K. There appeared anomalies at 273 K and 277 K for the hydrate and the deuterate, respectively. These anomalies were interpreted as the melting of excess water contained in the crystal. Based on the assumption that this anomaly was attributed to melting of pure ice, the amount of excess water was estimated to be 127 mg for the hydrate and 69 mg for the deuterate corresponding to 0.33% and 0.16% of the sample masses,

respectively. The heat capacity contribution from the excess water was corrected for below 260 K by using the heat capacity data of the ice and heavy ice.[7,8] The heat capacity data are collected in Tables 1 and 2. Figure 2 gives the plots of the data together with those for the deuterate in an enlarged scale on the left side (110 K—145 K).

Both the hydrate and deuterate underwent a phase transition around 190 K as expected from the DTA result. Since the transitions are of the first order, all the measurements below the transition temperatures were made on the samples precooled slowly to 100 K in order to avoid incomplete conversion of the crystal into the low temperature phase. The temperature equilibration in the sample proceeded very slowly near the transition points, requiring a few days in the worst case. The temperature drift was followed for 12 h in most of the measurements in this region. The equilibrium temperature for the heat capacity calculation was determined by extrapolation of the temperature *vs.* time curve to the infinity of time assuming the exponential relation between them.

The heat capacity curves have additional small anomalies around 150 K for the hydrate and around 130 K and 160 K for the deuterate, respectively. The data in the anomalous regions are shown in Fig. 3 as the encraty (C_p/T) *vs.* the temperature. The equilibration time became extremely long in these regions, and either an exothermic or endothermic effect was observed depending on the thermal history of the sample. The following series of measurements was performed in order to study the hysteretic behavior in more detail. The hydrate sample was first equilibrated at 180 K and cooled with two different rates, $\simeq$8 mK min^{-1} and $\simeq$1.7 K min.$^{-1}$) The heat capacity measurement of the slowly cooled crystal was started at 125 K and continued up to 170 K by the step-by-step heating method in which the temperature increment was kept

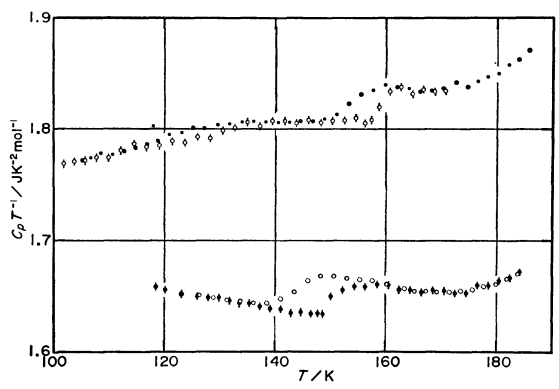

Fig. 3. Encraty (C_p/T) of pinacol hexahydrate (lower curve) and pinacol hexadeuterate (upper curve). The barred circles (⊖ and ●) represent the quenched crystal and the plain circles (○ and ●) the slowly cooled crystal.

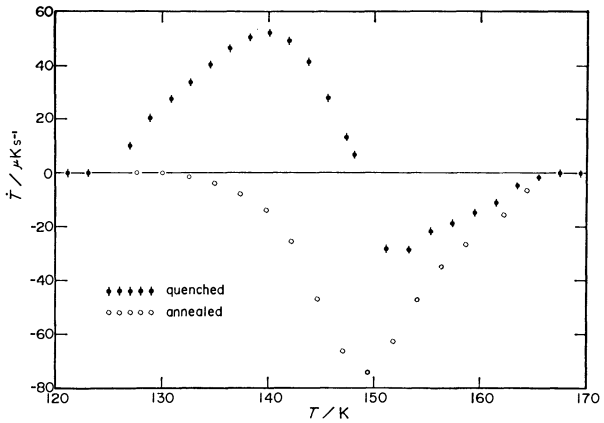

Fig. 4. Temperature drift *versus* temperature curves of pinacol hexahydrate.

approximately equal to 2 K and the drift followed for 35 min. Only endothermic drift was found in this series of measurement.

The measurement on the quenched sample was initiated at 120 K and followed the similar procedure up to 180 K. In this case the exothermic temperature drift occurred first and then an endothermic one as the temperature was raised. The former drift was followed for 40 min, and the latter for 60 min. The exothermic effect started around 125 K, reached the maximum rate at 140 K, decreased rapidly and disappeared around 149 K. The endothermic effect appeared above 149 K and remained appreciable up to 168 K, above which temperature the equilibration time

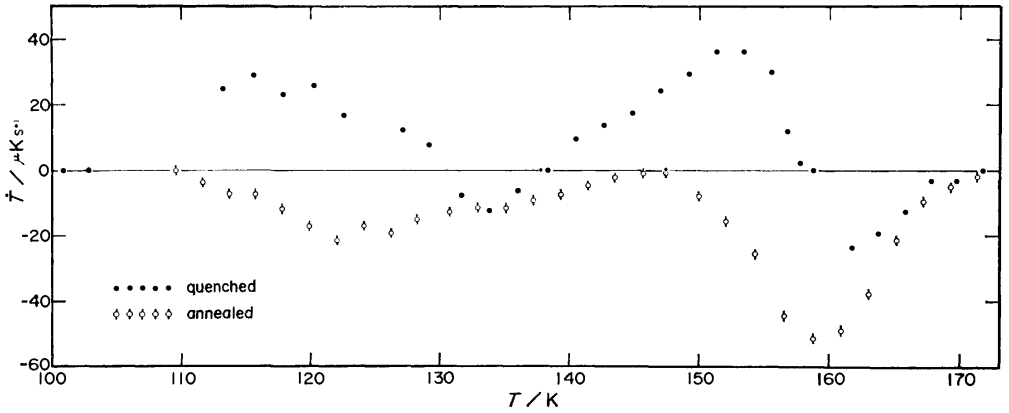

Fig. 5. Temperature drift *versus* temperature curves of pinacol hexadeuterate.

returned to its normal value. Figure 4 shows the rate of the temperature drift of the calorimeter cell determined at 30 min after turning off the heater.

For the deuterate, the temperature of the sample was equilibrated at 175 K where the equilibrium was reached rapidly, and decreased to the liquid nitrogen temperature at two different cooling rates. Measurement of the temperature drift was started at 110 K for the slowly cooled sample and at 100 K for the quenched one. The observed change of the drift rate with the temperature is shown in Fig. 5. In the case of the slowly cooled sample, only an endothermic effect was observed with two minima in the drift rate around 125 K and 160 K. In the quenched sample, positive and negative temperature drifts appeared alternately twice on heating. The drift approached the normal behavior above 170 K.

Appearance of different thermal drifts depending on the cooling rate is characteristic of a glass transition in the extended sense[5] as we have shown with tin chloride dihydrate,[6] hexagonal ice,[7,8] and orthoboric acid.[9] We interpret the relaxational anomalies in the present substances in the similar way. The main consequence of this interpretation is that a relaxational reorientation of the molecules is associated with the glass transition and that its relaxation time at the glass transition temperature is comparable with the time required for a single heat capacity measurement. The two relaxational anomalies in the deuterate crystal suggest that two different molecular processes are involved. The problem is then to assign molecular motions to the anomalies in the hydrate and deuterate and will be discussed later in this section. It should be added that there is an ambiguity in the determination of the heat capacity in the glass transition region due to irreversible changes occurring in the crystal. The values given in Tables 1 and 2 were calculated as elsewhere.[6,9]

Determination of Enthalpy and Entropy of the Transition. The anomalous part of the heat capacity was separated from the total by drawing a base-line which joins smoothly the heat capacity curves above 220 K and

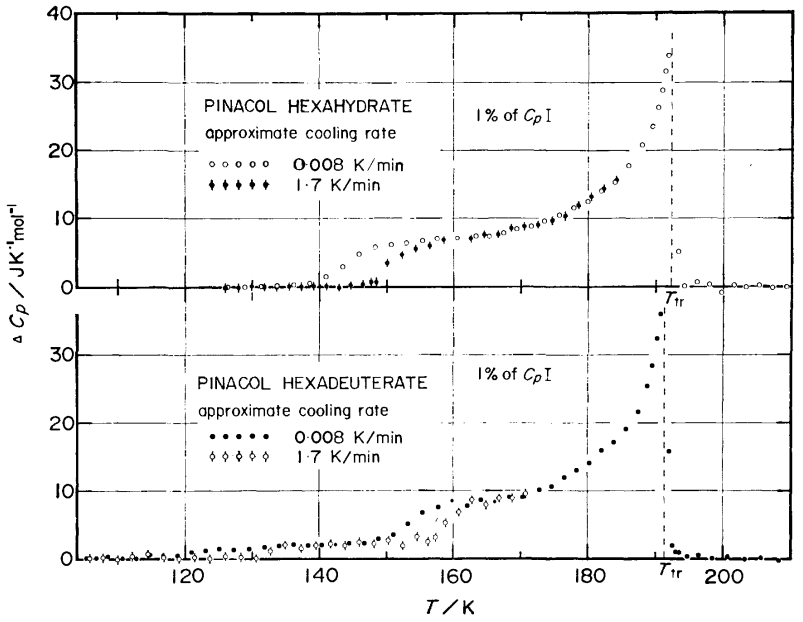

Fig. 6. Anomalous part of the heat capacity of pinacol hexahydrate and pinacol hexadeuterate.

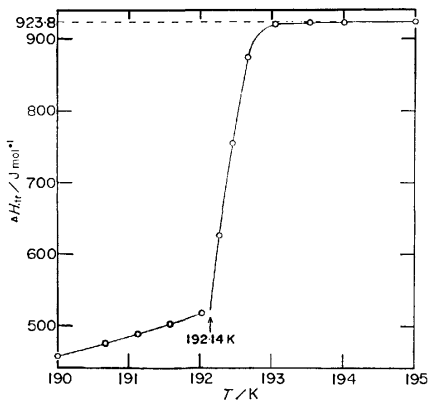

Fig. 7. Excess enthalpy *versus* temperature curve of pinacol hexahydrate.

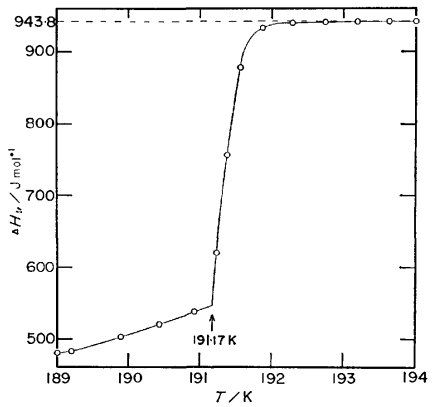

Fig. 8. Excess enthalpy *versus* temperature curve of pinacol hexadeuterate.

below the glass transition, as shown in Fig. 2. The anomalous part thus obtained is plotted in Fig. 6 where the upper half of the figure represents the hydrate and the lower the deuterate. The enthalpy and entropy of the transition were calculated by a numerical integration of the anomalous heat capacity for the slowly cooled sample and found to be 924 J mol^{-1} and 5.10 J K^{-1} mol^{-1} for the hydrate and 944 J mol^{-1} and 5.28 J K^{-1} mol^{-1} for the deuterate, respectively. The transition temperature was determined as the temperature at which the abrupt increase of the enthalpy occurred. Figures 7 and 8 show the excess enthalpy against the temperature around the transition point for the hydrate and the deuterate. The broken lines in the figures represent the total transition enthalpy. The transition temperature is 192.14 K for the hydrate and 191.17 K for the deuterate.

Mechanism of the Phase Transition and the Deuterium Isotope Effect on the Transition Temperature. In an NMR study published separately, we measured the proton spin-lattice relaxation times T_1 and $T_{1\rho}$ of the present substances.[13] The both substances showed almost the same magnitude of discontinuity in $T_{1\rho}$ at the transition temperature. This indicates that the phase transitions are closely related to the motion of the pinacol molecules rather than the water molecules. It has been shown by the X-ray study[2] at the room temperature that the pinacol molecules are in a disordered state. If the phase transitions are due to ordering of the orientational disorder of the molecules the transition entropy is expected to be $R\ln 2$ (=5.76 J K^{-1} mol^{-1}). The entropy change experimentally determined is approximately equal to this value. The phase transition can thus be interpreted in terms of the order-disorder change in the orientation of the pinacol molecules.

The transition temperature may be taken as a certain measure of the strength of the interaction among the pinacol molecules. The deuteration causes a slight decrease ($\simeq$1 K) in the transition temperature, indicating the corresponding decrease in the interaction. If we assume the inverse sixth power dependence of the interaction energy on the pinacol–pinacol distance, the isotope effect in the transition temperature is reproduced by 0.09% increase of the intermolecular separation on deuteration. The lattice constants of the deuterate have not been determined, but in the relatively short ($\simeq$0.26 nm) hydrogen bonds, the O–O distance in the deuterium bond is longer than in the corresponding hydrogen bond by up to 0.0022 nm or 0.8% of the bond length.[14] If a similar elongation of the hydrogen bonding occurs in the pinacol hexadeuterate, the negative isotope effect in the transition temperatures will be understood by the above argument based on the simple geometrical consideration.

The Relaxation Time and Activation Enthalpy. The exothermic and endothermic drift in the high temperature glass transition region of the deuterate were analysed by fitting an exponential function of time in which linear change of the temperature with the time was also taken into account to allow for the residual heat leak between the calorimeter cell and its surrounding. The relaxation times thus calculated are plotted in Fig. 9. The activation enthalpy determined from the plot was (33$\pm$4) kJ mol^{-1}. The relaxation time becomes 1 ks at 167.2 K.

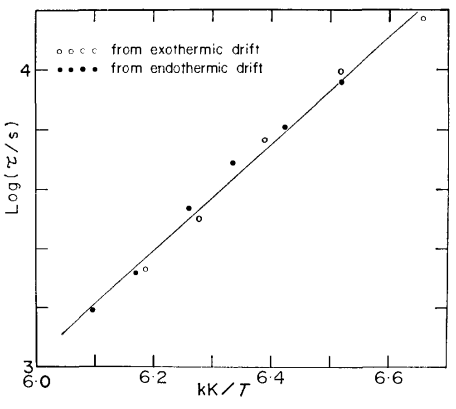

Fig. 9. Arrhenius plot of the enthalpy relaxation time derived from the calorimetric temperature drift at the upper glass transition of pinacol hexadeuterate. The open circles from the exothermic drift of the quenched crystal and the closed circles from the endothermic drift of the slowly cooled crystal.

Origin of the Glass Transitions. A glass transition takes place in principle whenever a molecular process involving passage by the molecule over a potential barrier occurs with the rate constant comparable with the inverse of the time scale of the experiment. There are two possibilities for such molecular motions in the pinacol hexahydrate. Kim and Jeffrey[2] suggested from the crystal symmetry that the hydrogen atoms in the hydrogen bonds are disordered. Cook and Meakins[3] pointed out a close similarity in the dielectric property between the pinacol hexahydrate and the ice I_h crystal. Namely, ε'_0 was found to be 77 along the water layer and 16 perpendicular to the layer, and the maximum absorption frequency at -5 °C is 6 kHz, comparable with 5 kHz in the ice. The large value of ε'_0 can be explained in terms of the reorientation of the water molecules. From the structural and dielectric evidences we can suppose that the hydrogen bonds are in dynamic disorder at the room temperature. At lower temperatures the dynamic disorder will change either to the order through a phase transition or to a static disorder by falling out of thermal equilibrium with other degrees of freedom of the substance. The dielectric study by Cook and Meakins shows that the latter is more likely. If we take 1 ks as the demarcation between the dynamic and static disorder and the Arrhenius parameters given by Cook and Meakins, the glass transition will occur at 170 K.

Another possibility for the molecular origin of the glass transition is the reorientational motion of the pinacol molecule. It was shown already that the orientation of the pinacol molecules orders at the phase transition. Thus, one may at first think that this degree of freedom need not be considered in the discussion of the origin of the glass transition because the orientation of the pinacol molecule is already ordered when the crystal is cooled to the glass transition temperature. However, the ordering can be incomplete at some temperature in the low temperature phase as is often the case in order-disorder transitions. The residual disorder would then cause a glass transition when it freezes into a static disorder. The glassy state so formed has a peculiar property that the frozen-in degree of freedom possesses a long range order. The magnitude of the heat capacity increment at the glass transition is determined by the temperature dependence of the transitional heat capacity and the relaxation time. The glass transitions in tin chloride dihydrate and orthoboric acid are of this kind. The phase transitions in the present substances are of the first order but there are excess heat capacities below the transition temperatures. Therefore the partial disorder in the low temperature phases can be responsible for the glass transitions.

As described in the experimental section, there are two glass transitions in the deuterate around 130 K and 160 K, whereas there is one in the hydrate around 150 K. Our previous experience on the hydrogen bonded systems show that if there is a glass transition in a hydrate crystal then there is a glass transition in the deuterate analogue and *vice versa*. Generalizing this observation to the present case, we assume that two different mechanisms are involved in the glass transition of the hydrate corresponding to the two glass transitions in the deuterate. This assumption is supported by the following evidence. First, the glass transition in the hydrate occurs at an intermediate temperature between the two glass transitions of the deuterate and none occurs above or below. Second, the glass transition region of the hydrate is broader than either of the glass transition regions of the deuterate (Figs. 3 and 4).

If one accepts that both the hydrate and deuterate undergo two glass transitions, the next step is to assign them to the two possible molecular motions discussed above. It was shown by the nuclear magnetic relaxation method that the reorientational motion of the water molecules occurs at higher temperature than the pinacol molecule.[13] The upper glass transition of the deuterate is attributed to the reorientation of the water molecule and the lower to the pinacol molecule. The activation enthalpy derived from the temperature drift data of the deuterate (33 ± 4) kJ mol^{-1} is equal to the activation enthalpy (33 kJ mol^{-1}) of the water reorientation in the hydrate obtained by NMR. In tin chloride dihydrate and ice I_h where reorientation of the water molecules is responsible to the glass transition, the glass transitions shift to higher temperature on deuteration.[6-8] The shifts (5—10 K) of the glass transitions in these compounds are comparable with the difference in temperature of the glass transition of the hydrate and the upper glass transition of the deuterate.

The lower glass transition in the deuterate is assigned to the second of the molecular motion discussed above, the reorientation of the pinacol molecule in the void of the clathrate-like structure. This motion is directly related to the phase transition. In the above, possibility of the lattice expansion on deuteration was discussed in relation to the negative isotope effect in the phase transition temperature. The same lattice expansion will enlarge the void in which the pinacol molecule reorients and thus decrease the height of the potential barrier hindering the molecular motion. This will result in faster reorientation of the pinacol molecule when compared at the same temperature and hence in the lower glass transition temperature in the deuterate than in the hydrate in agreement with above assignment of the molecular motion.

So far as has been known, the glass transition temperature increases invariably on deuteration. The present case is an exception in this respect. This will not be surprising if we consider that only the water and the hydroxyl part of the pinacol molecule were deuterated in the present crystal. The main part of the molecule responsible for the phase transition and the lower glass transition has not been deuterated. In contrast to this, motion of the deuterium itself is responsible for the glass transitions in those substances which undergo positive isotope effect on deuteration in the glass transition temperatures. Properties of the methyl-deuterated pinacol compounds will be interesting in this respect.

Conclusion

We have shown that pinacol hexahydrate and hexadeuterate undergo phase transitions and glass

transitions and discussed their molecular mechanisms from the calorimetric data. The molecular motions emerging from the discussion are generally consistent with the structural, dielectric, and NMR information available. However, a fundamental question of why the water molecules are disordered down to the lowest temperature has not been answered yet. This is closely related to the residual entropy of the ice I_h crystal and is in sharp contrast to the behavior of the layer hydrogen bonded crystals containing metal ions.[15] Low temperature study of other clathrate and clathrate-like hydrates formed by organic molecules will be interesting with regard to their transitional and relaxational properties.

(Received August 20, 1979)

The structure of [(*S*)-1-cyanoethyl][(*S*)(−)-α-methylbenzylamine]bis(dimethylglyoximato)cobalt(III) has been determined by X-ray analysis at 293 K and 173 K. The crystal is monoclinic, the space group being $P2_1$, $Z=2$, with $a=8.768(2)$, $b=13.356(2)$, $c=9.538(3)$ Å, and $\beta=96.73(3)°$ at 293 K, and $a=8.617(4)$, $b=13.222(4)$, $c=9.517(7)$ Å, and $\beta=96.26(7)°$ at 173 K. The structure was deduced by the heavy-atom method and was refined by the block-diagonal least-squares method to the final R values of 0.051 and 0.060 for 1878 and 1848 observed reflections at 293 K and 173 K respectively. The bis(dimethylglyoximato)cobalt moiety is twisted in the opposite way from that of [(*R*)-1-cyanoethyl][(*S*)(−)-α-methylbenzylamine]bis(dimethylglyoximato)cobalt(III). This supports the proposal that the asymmetry of the optically active amine is transferred into the substrate through the twist of the bis(dimethylglyoximato)cobalt moiety in the step of the σ-bond formation.

The serial crystal structures of the cobalt complexes have been determined by X-ray analysis[1-4] in order to clarify the mechanism of inducing asymmetry in the asymmetric hydrogenation of olefins.[5-10] In the crystal structures of [(*R*)-1-(methoxycarbonyl)ethyl][(*R*)(+)-α-methylbenzylamine]bis(dimethylglyoximato)cobalt-(III)[3] and [(*R*)-1-cyanoethyl][(*S*)(−)-α-methylbenzyl-amine]bis(dimethylglyoximato)cobalt(III)[4] (hereafter abbreviated as the R-R ester complex and the R-S cyano complex respectively), it has been shown that the bis(dimethylglyoximato)cobalt moiety (hereafter abbreviated as $Co(dmg)_2$ or cobaloxime) is twisted around its long axis because of the steric repulsion from the substituted alkyl group and α-methylbenzylamine. To examine the twisting of the $Co(dmg)_2$ moiety more closely, we attempted to determine the structure of the title complex, the S-S cyano complex, the only change from the R-S cyano complex in the previous paper being the inversion of the absolute configuration of the cyanoethyl group.

Preliminary experiments revealed that the crystalline-state racemization of the cyanoethyl group also occurs and that the thermal expansion of the crystal is abnormally anisotropic.[11] Therefore, the crystal structures at 293 K and 173 K were determined.

Experimental

Dark red, plate-like crystals of the S-S cyano complex, whose preparation will be reported in detail elsewhere, were obtained from the mother liquor after the fractional precipitation of the R-S cyano complex had been carried out from a solution containing the cyano complex with the racemic cyanoethyl group. A crystal $0.20\times0.25\times0.45$ mm³ in size was placed in a Rigaku four-circle diffractometer, Mo $K\alpha$ radiation monochromated by graphite ($\lambda=0.71069$ Å) being used. The unit-cell dimensions were obtained by the least-squares method with 15 high-angle reflections ($2\theta>20°$). Their values before and after the intensity data collection are shown in Table 1. The average values in the last column were used in this work. The crystal data are summarized in Table 2. The intensity data were collected in the same manner as that used for the R-S cyano complex.[4] A total of 1878 independent reflections, $|F_o|\geqq3\sigma(|F_o|)$, were obtained.

Table 1. The change in the unit-cell dimensions

	Start 1[a]	Start 2[b]	End[c]	Average[d]
a	8.768(2) Å	8.768(2)	8.774(2)	8.771
b	13.356(2) Å	13.380(2)	13.427(2)	13.404
c	9.538(3) Å	9.533(3)	9.520(3)	9.527
β	96.73(3)°	96.85(3)	97.05(4)	96.95
V	1109.2(5) Å³	1110.4(5)	1113.1(5)	1111.8

a) 2 h after the initiation of the X-ray irradiation. The data collection was unsuccessful because the change was so fast. b) After 4 h, at which time the data collection was started. c) After the data collection, about 30 h later. d) The average values between Columns 2 and 3. The structure factors and bond distances and angles are calculated using these values.

Table 2. Crystal data

Formula	$C_3H_4NC_8H_{11}N(C_4H_7N_2O_2)Co$	
F.W.	464.48	
a	8.768(2) Å (293 K)	8.617(4) Å (173 K)
b	13.356(2)	13.222(4)
c	9.538(3)	9.517(7)
β	96.73(3)°	96.26(7)°
V	1109.2(5) Å³	1077.9(10) Å³
Systematic absences	$0k0$; k odd

Z	2	
D_m	1.396 g/cm³	
D_c	1.391 g/cm³	
μ(Mo $K\alpha$)	8.79 cm⁻¹	

The experimental details at 173 K, using a crystal $0.15\times0.15\times0.59$ mm³ in size, were the same as those for the R-S cyano complex. 1848 independent reflections, $|F_o|\geqq3\sigma(|F_o|)$, were obtained. Corrections for Lorentz and polarization factors were made, but no correction for absorption was applied.

Structure Determination

The structure at 293 K was deduced by the heavy-atom method and refined by the block-diagonal least-

squares method. All the hydrogen atoms were found on a difference map. The final refinement was made with the anisotropic and isotropic temperature factors for non-hydrogen and hydrogen atoms respectively. The weighting scheme employed was: $w=0.2$ if $|F_0|>96.91$ and $|F_0|<9.69$ and $w=(0.00211F_0^2-0.22423|F_0|+6.97531)^{-1}$ if $9.69\leqq|F_0|\leqq96.91$. The final R value became 0.051 for 1878 reflections. No peaks higher than 0.30 eÅ^{-3}, except for a peak of 0.45 eÅ^{-3} around the cobalt atom, were found on the final difference map.

The structure at 173 K was refined by the block-diagonal least-squares method using the parameters of the structure at 293 K as the starting parameters. The weighting scheme employed was: $w=0.2$ if $|F_0|>154.32$ and $|F_0|<15.43$ and $w=(0.00117F_0^2-0.19947|F_0|+9.46501)^{-1}$ if $15.43\leqq|F_0|\leqq154.32$. The final R value became 0.060 for 1848 reflections. No peaks higher than 0.45 eÅ^{-3}, except for peaks of 0.55 eÅ^{-3} around the cobalt atom, were found on the final difference map. The atomic scattering factors were taken from the International Tables for X-Ray Crystallography.[12] The final atomic coordinates and their standard deviations at 293 K and 173 K are given in Tables 3 and 4 respectively. Lists of the thermal parameters and the observed and calculated structure factors are kept in the Office of the Chemical Society of Japan (Document No. 8018). The computation was done on M-180 and M-160 computers at this Institute.

Description of the Structure

The equations of the mean planes for four nitrogen atoms and two dmg's are given in Table 5, together with the deviations of the atoms from the planes. The deviations are in good agreement between the two temperatures. The projection of the structure at 293 K on the plane (I) is shown in Fig. 1, in which the short contacts between the non-bonded atoms are also given. In Table 6, the short contacts at 173 K are compared with the corresponding ones at 293 K. The cyano and methyl groups are located over the gaps between the two dmg's. Such a conformation of the cyanoethyl group is also found in the R-S cyano complex,[4] although the locations of the methyl and cyano groups are exchanged because of the opposite configuration at C(17).

The four nitrogen atoms of $Co(dmg)_2$ are nearly coplanar, but the tetragon composed of them is slightly twisted in the opposite way from that of the R-S cyano complex. The twisting of the $Co(dmg)_2$ moiety will be discussed in detail in the following section. The diviation of the cobalt atom from the mean plane of $Co(dmg)_2$ is negligibly small. The oxygen atoms deviate downward to avoid the short contacts with the cyanoethyl group, whereas the carbon atoms deviate upward. These features are also observed in the R-S cyano complex.

The bond distances at 293 K are shown in Fig. 2, while they are compared with the corresponding ones at 173 K in Table 7. The bond angles at both temperatures are listed in Table 8. The Co–C(17) and Co–N(5) bonds at 293 K are longer by 0.011 Å, and shorter by 0.010 Å, respectively, than the corresponding ones at 173 K. This causes an increase in the bond angles of C(19)–C(17)–C(18) and Co–N(5)–C(9) at high temperatures. Considerable differences in the bond of N(5)–C(9) and the angle of N(2)–Co–C(17) are found

between 293 K and 173 K. These differences may be due to the positional changes of the C(17) and N(5) atoms. The other corresponding distances and angles are in good agreement with each other.

The $Co(dmg)_2$ moiety in the methyl[(*R*)(+)-α-methylbenzylamine]cobaloxime, methyl complex, has the C_{2h} symmetry as a result of the steric repulsion from the amine ligand.[2] For the R-R ester complex, the symmetry of C_{2h} holds good with regard to the bond lengths of N–C and C–CH_3 and three angles around the *endo*-cyclic carbon atoms in the $Co(dmg)_2$ moiety. Such a symmetry is no longer conserved for the two cyano complexes, however. This may indicate that the steric and electrostatic interactions between $Co(dmg)_2$ and the substituted alkyl group in the cyano complexes are stronger than those in the methyl and R-R ester complexes.

The crystal structure viewed along the c axis is shown in Fig. 3, in which the short contacts are also given. There is a weak hydrogen bond between N(5) and N(6) in the unit of $(-x, 0.5+y, 1-z)$. The N···N distances are 3.246 and 3.171 Å for 293 and 173 K respectively. The distance of H(N51)···N(6) and the angle of N(5)–H(N51)···N(6) are 2.45 Å and 164° for 293 K, and 2.32 Å and 177° for 173 K. Such a hydrogen bond is also observed in the crystal of the R-S cyano complex. The other contacts are not unusually short.

Discussion

In Part III of this series, concerning the structure of the R-R ester complex, we proposed that the twisting of the $Co(dmg)_2$ moiety, caused by the steric repulsion from the methoxycarbonylethyl group and the amine, is one of the factors inducing asymmetry in the step of σ-bond formation.[3] This proposal must now be examined in connection with the R-S and S-S cyano complexes.

In Table 9, the deviations of the atoms in the $Co(dmg)_2$ moiety from the mean plane composed of four nitrogen atoms and the bond distances of Co–C(17) and Co–N(5) are listed for the complexes determined in this serial study. (The *exo*-cyclic atoms are omitted for the sake of clarity.) For the cyano complexes, the values at both room and low temperatures are given, because they change considerably with the temperature. As the absolute configurations of α-methylbenzylamine are different between the cyano complexes and the other two, the latter complexes are replaced by their enantiomers in the following discussion. Figure 4 shows the structures and the numberings of the atoms for the S-S (enantiomer of R-R) ester and the R-S cyano complexes. The amine is located below the $Co(dmg)_2$ plane, whereas the methyl and the substituted alkyl groups are placed above.

The tetragons, composed of four nitrogen atoms in the S-S ester and R-S cyano (293 K) complexes, are twisted in the same manner. Moreover, the magnitude of the twisting is equal. The tetragon in the S-S cyano (293 K) complex, on the other hand, is twisted in the opposite way, and the magnitude of the twisting is smaller than those of the S-S ester and R-S cyano (293 K) complexes. The methyl of the substituted alkyl group comes close to N(1) in the two structures of S-S ester and R-S cyano complexes. The unusually short contact between the methyl group and N(1) causes N(1) to deviate downward from the plane. The deviation of N(1) from the plane brings about the twist of the tetragon in such a manner that N(3) deviates downward, too, and N(2) and N(4), upward, the cobalt atom being fixed as a center. This twisting is called "clockwise twisting" for the S amine, viewed down along the axis perpendicular to the mean plane of $Co(dmg)_2$. In Fig. 5, the "clockwise twisting" is drawn schematically, the arrows being directed from the lower nitrogen atom to the upper one in each dmg. Although the twisting was defined in the previous paper as the distortion around the long axis of $Co(dmg)_2$, the above notation is more convenient, since the substrate should approach

Table 8. Bond angles (ϕ/°)

the Co atom along the axis perpendicular to the mean plane of $Co(dmg)_2$.

The asymmetric carbon atom, C(9), which comes most closely to $Co(dmg)_2$ among the atoms of the amine except for the coordinating amine group, comes near N(4). The steric repulsion between N(4) and C(9) should give rise to the twisting of the tetragon. The twisting is clockwise. In the two structures of the S-S ester and R-S cyano complexes, the steric repulsions of N(1)···C(18) and N(4)···C(9) result in the same twisting. On the other hand, the C(18) atom of the S-S cyano complex comes close to N(2). This causes a counterclockwise twisting of the tetragon. Because the repulsion of N(4)···C(9) would give a clockwise twisting, the $Co(dmg)_2$ moiety must have a more planar conformation than that of the R-S cyano complex. As the repulsion of N(2)···C(18) is stronger than that of N(4)···C(9), the tetragon shows the counterclockwise twisting.

The bond distance of Co–C(17) in the S-S cyano (293 K) complex is significantly longer than that of the R-S cyano (293 K) complex. Because the tetragon can not be twisted enough to avoid the short contact of N(2)···C(18), the Co–C(17) bond is lengthened. This may indicate that the strength of the Co–C bond is fairly weak.

At low temperatures, the Co–C(17) bonds in the R-S and S-S cyano complexes have the same distances, and the magnitude of the twisting in the R-S cyano complex becomes smaller than that at room temperature. As is shown in Table 10, the Co–C(sp^3) distance is lengthened with an increase in the number of the non-hydrogen substituents bonded to the coordinating carbon atom; that is, the Co–CH_3 and Co–CH_2R values are 2.00 and 2.04 Å respectively. As Table 10 shows, the Co–C(17) bond in the cyanoethyl complexes is estimated to have a distance between 2.04 and 2.067 Å, because the cyanoethyl group has two non-hydrogen substituents and the cyano and methyl groups are located over the gaps between two dmg's whereas the methoxycarbonyl

a) The S-S ester is the enantiomer of the R-R ester complex.

and methyl groups in the S-S ester complex lie on the dmg rings. Therefore, the Co–C(17) distance of 2.057 Å at a low temperature seems to be a reasonable value. When the temperature is raised, the molecular packing in the crystal becomes loose and the strain in the molecule is released. For the R-S cyano complex, the tetragon composed of four nitrogen atoms is twisted to a greater extent and the Co–C bond becomes shorter, whereas the Co–C bond is lengthened for the S-S cyano complex. The abnormally anisotropic thermal expansion of the two cyano complexes may relate to the fact mentioned above. Because the reaction under investigation proceeds in solution, the conformation at room temperature may more closely resemble those in the intermediate state of the reaction.

It is noteworthy that the Co–N(5) bonds are altered

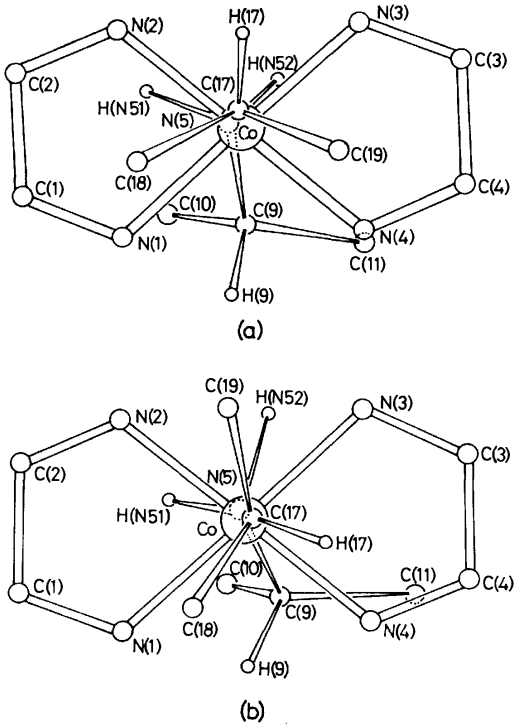

Fig. 4. Projections of the atoms around the Co atom onto the mean plane of four nitrogen atoms (a) for the S-S ester complex, the enantiomer of R-R,[3] and (b) for the R-S cyano complex.

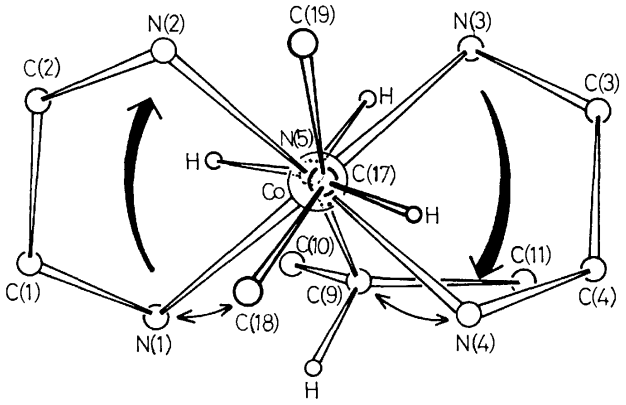

Fig. 5. Clockwise twisting of $Co(dmg)_2$ in the R-S cyano complex. The arrows are drawn from the lower nitrogen atoms to the upper ones in the Co-dmg rings. Such a twisting is brought about by the steric repulsions, N(1)···C(18) and N(4)···C(9).

in their lengths as the Co–C(17) distance in the cyano complexes is varied. All the sums of the Co–N(5) and Co–C(17) distances in both cyano complexes at low and room temperatures are nearly the same, the average value being 4.124 Å. This can be explained by the "trans influence" suggested by Brückner and Randaccio.[16]

In summary, the tetragon of $Co(dmg)_2$ is twisted significantly and the Co–C bond is shortened for the R-S cyano complex, while the tetragon has a slightly twisted conformation and the Co–N bond is shortened

C(18)···(N(1) or N(2))[a]	2.946	2.935	0.011
C(19)···(N(2) or N(1))[a]	2.863	2.847	0.016
C(19)···(O(2) or O(1))[a]	3.148	3.113	0.035
N(6)···(O(2) or O(1))[a]	3.284	3.212	0.071

a) The former atoms are for the R-S cyano complex, and the latter, for the S-S cyano complex.

for the S-S cyano complex. Table 11 shows the short interatomic distances between $Co(dmg)_2$ and the axial ligands for the two cyano complexes. Any distance of the R-S cyano complex is longer than the corresponding one of the S-S cyano complex. The repulsive energy of the former complex must be lower than that of the latter complex. The energy differences caused by the different lengths of the axial bonds, Co–C and Co–N, are considered to be compensated for the two cyano complexes, because the sums of the two bond distances are nearly the same.

In conclusion, the tetragon of the $Co(dmg)_2$ moiety is twisted because of the steric repulsion from the substituted alkyl group and the optically active amine. If the way of the twisting caused by the substituted alkyl group is in accord with that brought about by the amine, the tetragon is twisted and the steric repulsion between $Co(dmg)_2$ and the two axial ligands decreases. If both twistings are in the opposite way, on the other hand, the tetragon has a nearly planar conformation and the steric effect increases. The two σ-complexes have different repulsive energies, indicating that the two diastereomeric pathways in this reaction have different energies of activation in the "kinematically controlled asymmetric process."[17] This must be one of the factors inducing asymmetry in this asymmetric hydrogenation.

Neutron Diffraction Study of Liquid Acetyl Chloride

Norio OHTOMO† and Kiyoshi ARAKAWA*

Research Institute of Applied Electricity, Hokkaido University, Sapporo 060

†*Faculty of Engineering, Hokkaido University, Sapporo 060*

(Received September 17, 1979)

The structure factor $S_m(Q)$ for liquid acetyl chloride at room temperature has been determined in the range Q, 0.9—27 Å^{-1}, by means of the time-of-flight (TOF) neutron diffraction method using the electron linear accelerator (LINAC). The structural parameters of CD_3COCl, bond distances, bond angles, and rms amplitudes, in liquid phase have been determined by a comparison of calculated curves with observed data, and it has been concluded that a molecule within the liquid takes an essentially identical conformation as a rotational isomer with that in gaseous phase, which was determined by microwave spectroscopy.

Studies on neutron diffraction have been extensively carried out during the last three decades. Neutron diffraction as well as X-ray and electron diffraction has turned out to be a powerful means for determining the structure of condensed matter directly.[1] The method has been applied to structural studies of molecular liquids recently. The positions of light atoms as hydrogen (deuterium) contained in the molecules of organic liquids can be determined. A typical molecular liquid as an object of studies by means of neutron diffraction is heavy water. Studies were carried out by Page and Powles,[2] Narten,[3] and the authors.[4,5]

Neutron diffraction studies on molecular liquids including water have provided useful information. Dore *et al.* studied diatomic liquids (N_2, O_2, and Br_2) and other non-hydrogenous and heteronuclear molecular liquids (C_2O_3, $VOCl_3$, and XCl_4: X=C, V, Si, Ti, Ge, and Sn). Structure factors $S_m(Q)$ for a wide range of momentum transfer Q were determined for these materials.[6] Bertagnolli *et al.* carried out measurements for hydrogenous molecular liquids (CD_3CN and $CDCl_3$) and determined $S_m(Q)$ in the range of low Q.[7] In order to determine the structure and conformation of molecules in liquids, it is necessary to obtain the $S_m(Q)$ data in a wide range of Q values. The neutron diffraction experiment by LINAC is extremely useful for obtaining data for higher Q values.

The result of a neutron diffraction study on liquid acetyl chloride is given in the present paper. Studies were carried out on the molecular structure of acetyl chloride in gaseous phase with use of electron diffraction and microwave spectroscopy,[8–10] Sinnott's[9] result by microwave spectroscopy being considered to be accurate. However, the structure and configuration of the molecule in liquid state have never been studied. Conformation of the molecule within the liquid is of interest in comparison with that in gaseous phase as considered from the viewpoint that strong molecular interactions within liquid may cause a change of conformation as a rotational isomer. The authors have been able to obtain the $S_m(Q)$ for a wide range of Q which is sufficient to make a precise determination of the structure of the molecule within the liquid.

Experimental

Procedure for Measurements. The experiment was performed by means of the TOF neutron diffraction method by LINAC.[4,5] Details of the apparatus and procedure were reported.[4,11]

Deuterated acetyl chloride CD_3COCl (purity of deuteration 99%, Stohler Isotope Chemicals (USA)) was used. The coherent scattering amplitude, scattering cross sections, and the absorption cross section for each atom are given in Table 1. The effect of strong absorption by chloride nuclei at lower Q can be corrected easily since the atoms absorb neutrons according to the $1/v$ law in the low energy region (v: neutron velocity).

Table 1. Coherent scattering amplitude (b_{coh}), scattering cross sections (σ_{coh} and σ_{inc}) and absorption cross section (σ_a)[a]

Element	b_{coh} (fermis)	σ_{coh} (barns)	σ_{inc} (barns)	σ_a (barns)
D	6.67	5.59	2.0	0.00046
C	6.65	5.56	0	0.0033
O	5.80	4.23	0	<0.002
Cl	9.6	11.58	3.5	33.6
V	−0.4	0.02	4.9	4.98

$\sigma_{coh}=4\pi b_{coh}^2$ and $\sigma_{inc}=4\pi b_{inc}^2$, where b_{inc} is the incoherent scattering amplitude. a) B. Dorner and R. Comès, "Dynamics of Solids and Liquids by Neutron Scattering," ed by S. W. Lovesey and T. Springer, Springer-Verlag, Berlin (1977), Chap. 3, pp. 136—141.

Measurements were carried out at room temperature (16 °C) at two different scattering angles (2θ=45° and 150°). Time-of-flight of neutrons was analyzed with a multi-channel time analyzer with channel widths of 20 μs and 10 μs at the scattering angles of 45° and 150°, respectively. Thin-walled cyrindrical quartz vessels were used to contain samples.

We obtained the $S_m(Q)$ data for low Q region (Q=0.95—14 Å^{-1}) and those for a higher Q region (Q=3.0—27 Å^{-1}) by measurement at each scattering angle. The count rate time-spectrum is given in Fig. 1 together with smoothed spectra for vanadium and background normalized in burst number of LINAC.

Corrections and Calibrations of Raw Scattering Data.[2,4] In order to determine structure factors, corrections for multiple scattering, absorption, background counting, and inelastic scattering are necessary. Absolute normalization of data was performed with use of scattering data from a standard vanadium rod of the same shape and dimensions as the sample.[4] $S_m(Q)$ data obtained after the correction except for inelastic scattering are given in Fig. 2.

A steady fall in $S_m(Q)$ values, caused by the inelastic scattering of neutrons by light nuclei, is observed at higher Q. For compensating of the effect, several conventional and useful

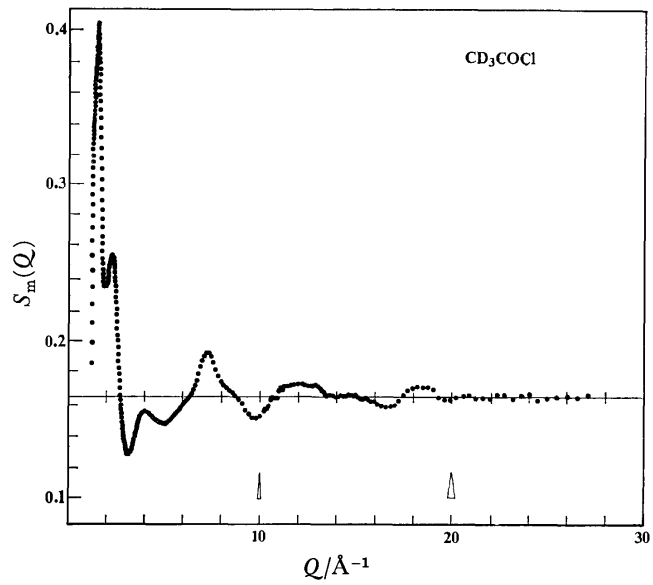

Fig. 3. The final structure factor $S_m(Q)$.
The magnitudes of the instrumental resolution are indicated by triangles at two points.

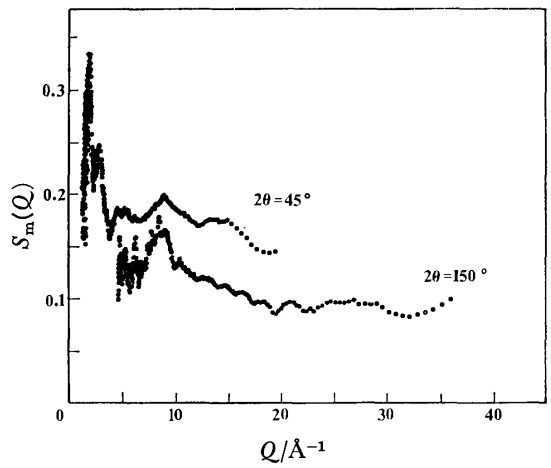

Fig. 2. The observed structure factor obtained after the application of corrections except that for inelastic scattering.

correction methods can be used. In the present study the Placzek method[12] was applied in a lower Q region and a dynamical correction method[13] in a higher Q region.

Calibration of absolute values for high Q data was performed considering the fact that $S_m(Q) \rightarrow \sum b_n^2/(\sum b_n)^2$ as $Q \rightarrow \infty$, where n ranges over all the nuclei in a molecule. Calibration for low Q data was made by overlapping the $S_m(Q)$ curves in the range 8—10 Å^{-1} for the two data sets. Thus, combining the two data sets,[6] we have obtained the final $S_m(Q)$ curve for the range of Q, 0.9—27 Å^{-1} (Fig. 3). The magnitudes of resolution ΔQ are given as triangles along the abscissa.[4] The statistical error was found to be smaller than 2.5% in the whole range of Q.

Results and Discussion

Analysis of Experimental Data. The structure factor $S_m(Q)$ for molecular liquids consists of an intramolecular structure factor $S_m^{(1)}(Q)$ and an intermolecular one $S_m^{(2)}(Q)$:

$$S_m(Q) = S_m^{(1)}(Q) + S_m^{(2)}(Q). \quad (1)$$

The higher the Q values, the smaller the $S_m^{(2)}(Q)$. Accordingly, structure factors for a higher Q region are characteristic of a single molecule, *viz.* the intramolecular structure factor

$$S_m(Q) \rightarrow S_m^{(1)}(Q) \text{ for high } Q. \quad (2)$$

For acetyl chloride the intramolecular structure factor becomes

$$S_m^{(1)}(Q) = (3b_D+2b_C+b_O+b_{Cl})^{-2}[3b_D^2+2b_C^2+b_O^2+b_{Cl}^2 + \sum_{i \neq j} b_i b_j j_0(Qr_{ij}) \exp(-\gamma_{ij}Q^2)], \quad (3)$$

where b_D, b_C, b_O, and b_{Cl} denote the coherent neutron scattering length of deuterium, carbon, oxygen, and chloride nucleous, respectively, $j_0(Qr)$ is a spherical Bessel function of zeroth order, and $(2\gamma_{ij})^{1/2}$ the rms amplitude to a bond length r_{ij}. The summation involved fifteen independent terms corresponding to different bond lengths.

The molecular model of acetyl chloride is shown in Fig. 4. The structure of the molecule except the methyl group is assumed to be a plane configuration,[9,10] and deuterium atoms in the methyl group are considered to

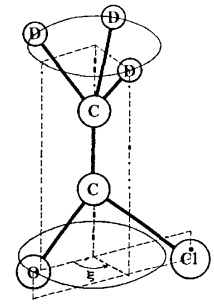

Fig. 4. The molecular model of acetyl chloride.

rotate about the C–C axis. At the rotational angle $\xi=0°$, a methyl deuterium atom eclipses oxygen atom (Fig. 4).

The structure of the molecule is characterized by the magnitudes of structural parameters: four bond lengths ($r_{C=O}$, r_{C-C}, r_{C-Cl}, and r_{C-D}), four rms amplitudes ($(2\gamma_{C=O})^{1/2}$, $(2\gamma_{C-C})^{1/2}$, $(2\gamma_{C-Cl})^{1/2}$, and $(2\gamma_{C-D})^{1/2}$), four bonding angles ($\angle$C–C=O, $\angle$C–C–Cl, $\angle$D–C–C, and $\angle$D–C–D), and a rotational angle ξ (Fig. 4). Values of these parameters determined so far for gas molecules of CH_3COCl by means of electron diffraction and microwave spectroscopy are summarized in Table 2,[8–10,14,15] the rms amplitudes being cited from the results of electron diffraction studies of formic acid (C=O)[14] and of *n*-propyl chloride (C–C, C–Cl, and C–H).[15]

Determination of the Intramolecular Structure within Liquid. In order to determine the molecular parameters and investigate the internal rotation of the methyl group by means of Eq. 2, $S_m^{(1)}(Q)$ was calculated for a number of structure models using Eq. 3, the magnitudes of the parameters being varied in reference to the values given in Table 2. The procedure of analysis is as follows.

Firstly, $S_m^{(1)}(Q)$ values were calculated with a variation of ξ successively at intervals of 10° from 0° to 80° and also for the averaged values corresponding to the free rotation of the methyl group about the C–C axis.[2,4] The parameters involving deuterium atom only (r_{C-D}, $\angle$D–C–D, and $\angle$D–C–C) were varied as follows: r_{C-D}, 1.085—1.105 Å at 0.005 Å step, $\angle$D–C–D, 108.5±1.0° and $\angle$D–C–C, 110.5±1.0°. The remainder of parameters were fixed to the values in Table 2. At the first stage we calculated the $S_m^{(1)}(Q)$ for 495 models. A typical example of the $S_m^{(1)}(Q)$ curves calculated with the variation of ξ is shown in Fig. 5. The best fit curve at the first stage of analysis with the experimental data is obtained at $\xi=0°$, $r_{C-D}=1.095$ Å, $\angle$D–C–D=108.5° and $\angle$D–C–C=110.0°.

Secondly, in order to determine more precisely the eight parameters (r_{C-C}, $r_{C=O}$, r_{C-Cl}, r_{C-D}, $\angle$C–C=O, $\angle$C–C–Cl, $\angle$D–C–D, and $\angle$D–C–C), keeping the value of ξ at 0° and fixing the values of rms amplitudes to the values in Table 2, we calculated $S_m^{(1)}(Q)$ for 435 models, the parameters being varied in the range given

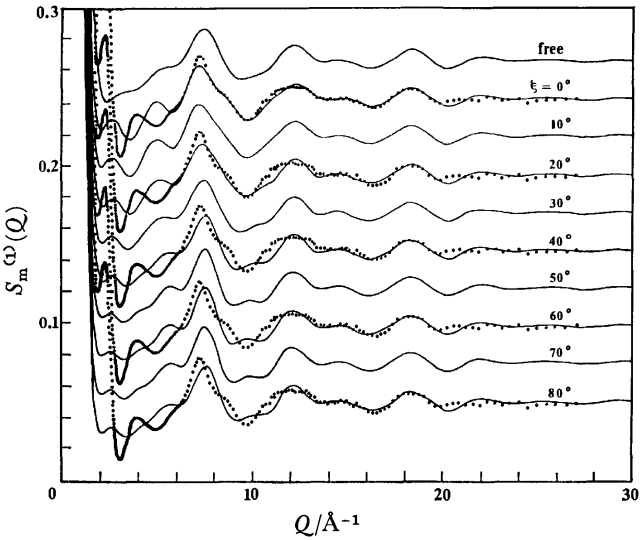

Fig. 5. The calculated $S_m^{(1)}(Q)$ with the variation of rotational angle ξ.
●: $S_m(Q)$ observed, ——: $S_m^{(1)}(Q)$ calculated.

TABLE 3. RANGE OF PARAMETERS

Parameter	Range	Interval of variation
	(Å)	(Å)
$r_{C=O}$	1.400—1.600	0.005
r_{C-C}	1.175—1.205	0.005
r_{C-Cl}	1.775—1.805	0.005
r_{C-D}	1.085—1.105	0.005
	(degree)	(degree)
$\angle$C–C=O	125.0—129.0	1.0
$\angle$C–C–Cl	110.5—113.5	1.0
$\angle$D–C–D	107.5—109.5	0.5
$\angle$D–C–C	109.5—111.5	0.5

TABLE 4. MOLECULAR PARAMETERS DETERMINED BY NEUTRON DIFFRACTION METHOD

	r_{1j} (Å)	$(2\gamma_{1j})^{1/2}$ (Å)		Bond angle (degree)
C=O	1.190±0.010	0.029	$\angle$C–C=O	127.0±1.0
C–C	1.500±0.005	0.036	$\angle$C–C–Cl	112.5±1.0
C–Cl	1.790±0.010	0.052	$\angle$D–C–D	108.5±0.5
C–D	1.095±0.005	0.066	$\angle$D–C–C	110.0±0.5

in Table 3. From a comparison of the calculated curves with experimental result, the parameters (except rms amplitudes) which gave the best fit model were determined (Table 4).

Finally, for the case of the parameter set thus determined calculations for 32 models with the variation of the rms amplitudes were carried out and the curves obtained compared with experimental results. The magnitudes of the rms amplitudes are also given in Table 4. The best fit curve with the experimental data is shown in Fig. 6. Agreement of both curves is excellent in the range of Q values, 5.5—20 Å^{-1}. The apparent deviations beyond $Q\gtrsim20$ Å^{-1} are insignificant and negligible. The deviation of the calculated $S_m^{(1)}(Q)$

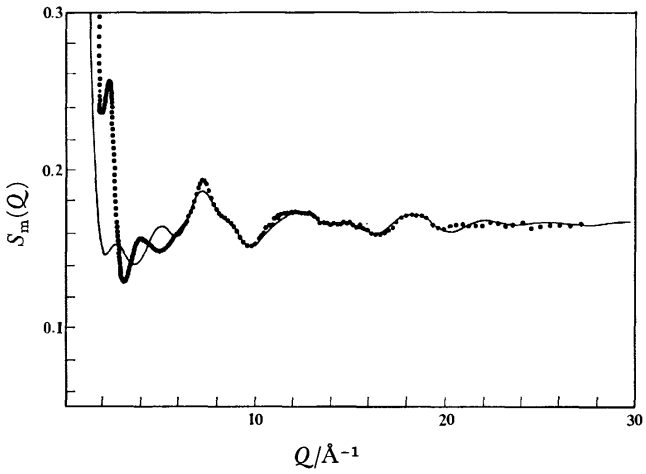

Fig. 6. Comparison of the calculated $S_m^{(1)}(Q)$ with the observed $S_m(Q)$.
●: $S_m(Q)$ observed, ——: $S_m^{(1)}(Q)$ calculated for the best model.

from the experimental curve in low Q region ($Q \lesssim 5.5$ Å^{-1}) is ascribed to the intermolecular contribution in liquid not included in the calculation (Eq. 3).

The results show that one methyl deuterium atom eclipses oxygen atom for the molecule in liquid as well as in gaseous phase. The molecular parameters assigned for liquid acetyl chloride (Table 4) are nearly identical with those determined for the molecule in gaseous phase by Sinnott.[9] The C–D bond length ($=1.095 \pm 0.005$ Å) is slightly larger than those in methyl groups.[9]

Conformation of a Molecule in Liquid Acetyl Chloride in Comparison with That in Gaseous Phase. A molecule within a system often changes its conformation through a phase transition. A typical example is the case of 1,2-dichloroethane ($C_2H_4Cl_2$) which has been studied fairly in detail.[16,17] A $C_2H_4Cl_2$ molecule in solid phase takes trans-conformation only; in liquid phase trans- and gauche-molecules are present at a ratio of *ca.* 1 : 1.92 in number; in gaseous phase the fraction of gauche-molecules decreases.

A molecule in gaseous phase seems to change its conformation as a rotational isomer in liquid and solid phase, as considered from the stronger effects of molecular interactions in condensed phases. According to the present result the situation for CD_3COCl differs from that for $C_2H_4Cl_2$. We have confirmed that all the CD_3COCl molecules in liquid phase take the conformation in which a deuterium atom in CD_3 group of the molecule eclipses the oxygen atom like that in gaseous phase.[18] A CD_3COCl molecule as a rotational isomer about the C–C axis does not change its conformation essentially through a phase change from gaseous to liquid state, the conformation being kept as shown in Fig. 4.

Microwave spectroscopy and electron diffraction have been used widely for determination of the structure of molecules, but application of the methods is mostly confined to gaseous systems. For determination of the molecular conformation within liquid, the neutron diffraction technique is considered important when used in combination with other techniques applicable to gases.

(Received October 17, 1979)

Fortamine, L-3-amino-1-methoxy-6-methylamino-1,3,6-trideoxy-*chiro*-inositol, is a component of fortimicins which are potent aminocyclitol antibiotics. The space group is $P2_1$ with $a=9.454(1)$, $b=6.6957(8)$, $c=7.622(1)$ Å, $\beta=95.93(2)°$, and two $C_8H_{18}N_2O_4$'s per unit cell. The structure was solved by direct methods, least-squares refinement using 932 reflexions giving the final R value of 0.033. The ring conformation of fortamine is closer to the ideal chair form than that of the fortamine moiety in fortimicin B. The strain caused by the intramolecular hydrogen bond and glycosidic bond in fortimicin B is released in fortamine.

Fortimicins[1,2] are potent broad-spectrum aminocyclitol antibiotics produced by a strain of *Micromonospora olivoasterospona*.[3-5] The conformation of the 1,4-diaminocyclitol moiety of fortimicins is probably related to their activity.[1,3,4] We have determined the absolute configuration of fortimicin B (Fig. 1) by X-ray analysis.[6] An intramolecular hydrogen bond is formed between O(5)–H and N(2′), the fortamine ring being distorted from the ideal chair conformation. It is of interest to examine whether the ring distortion is due to the glycosidic bond or the intramolecular hydrogen bond. We have carried out an X-ray analysis of fortamine obtained by the hydrolysis of fortimicin B.

Experimental and Structure Determination

Fortamine was prepared by the hydrolysis of fortimicin B with hydrochloric acid. Crystals of fortamine were grown from a methanol solution. A $0.5\times0.3\times0.3$ mm³ crystal sealed in a glass capillary was used for data collection on a Rigaku four-circle automated diffractometer with graphite-monochromated Mo $K\alpha$ radiation ($\lambda=0.71069$ Å). Preliminary unit cell dimensions and space group were obtained from photographs. The space group was determined from systematic absence ($0k0$ for odd k). Accurate cell dimensions were determined by least-squares calculations with the 2θ values of 15 high-angle reflexions measured on the diffractometer. Crystal data are summarized in Table 1. All reflexions within the range $2\theta\leqq55°$ were collected by use of the ω-2θ scan mode with a scanning rate of $4°(2\theta)$ min^{-1}. Stationary background counts were accumulated for 10 s before and after each scan. Periodic checks of the intensity values of three standard reflexions showed no significant X-ray damage or crystal decay. Corrections for absorption or extinction were not applied. A total of 1191 independent reflexions were obtained, of which 932 ($|F_0|>3.0\sigma(|F_0|)$) were considered as observed.

The phases of 185 reflexions with $|E_0|\geqq1.2$ were assigned with MULTAN.[7] The best set of phases was used to calculate an E map, which gave 14 chemically significant peaks. The structural parameters were refined by block-diagonal least-squares methods with a modified HBLS program. At the stage $R=0.17$, all the hydrogen atoms were found by the difference Fourier synthesis. Refinement using anisotropic and isotropic temperature factors for the non-hydrogen and hydrogen atoms, respectively, gave the final R value 0.033 for 932 reflexions. The weighting system used in the final stage was $w=0.3$ for $|F_0|<1.51$ and $|F_0|>35.57$, and $w=(0.00792(F_0)^2-0.29822|F_0|+3.76458)^{-1}$ for $1.51\leqq|F_0|\leqq35.57$. Six strong reflexions, 1 −1 0, 1 −4 1, −1 −1 4, 1 0 0, −2 3 3, and −3 4 3, were excluded because they seemed to suffer from secondary extinctions. Atomic scattering factors were taken from "International Tables for X-Ray Crystallography".[8] The final positional and thermal parameters are given in Table 2. The tables of observed and calculated structure factors are kept as Document No. 8024 at the Chemical Society of Japan.

Results and Discussion

Hydrogen Bond and Crystal Structure. The numbering system of atoms and the crystal structure viewed along the b axis are shown in Figs. 1 and 2, respectively. Hydrogen bond lengths and angles are given in Table 3. In the fortamine moiety of fortimicin B, only the O(2) hydroxyl group is involved in the intermolecular hydrogen bond. In fortamine, on the other hand, all functional groups except the methoxyl are involved in the intermolecular hydrogen bonds, there being no

C–C bond length, 1.522 Å, is equal to that of fortimicin B. The value is essentially the same as that of cyclohexane (1.532 Å)[9] and *myo*-inositol (1.521 Å).[10] The bond shortening of C(1)–C(6) and C(5)–C(6) in fortimicin B might be due to the glycosidic linkage. The long C(4)–C(5) distance of 1.546 Å in fortimicin B is probably caused by the strong intramolecular hydrogen bond. The results and geometries of cyclohexane rings in other compounds[9–13] suggest that the endocyclic C–C bond lengths can easily vary from 1.50 to 1.55 Å according to the intra- and intermolecular interactions.

The C(2)–O(2) and C(4)–N(4) bond lengths in fortamine are greater than those in fortimicin B by over 3σ. While O(2) in fortimicin B is weakly hydrogen bonded to solvent molecules with an O···O distance of 2.926(7) Å, that in fortamine is fairly strongly hydrogen bonded to the O(1) hydroxyl group with an O···O distance of 2.781(3) Å. Similarly, the N(4) atom in fortimicin B does not participate in a hydrogen bond, but that in fortamine is hydrogen bonded to the O(1) hydroxyl group. Such hydrogen bonds, therefore, seem to lengthen the bonds of C(2)–O(2) and C(4)–N(4) in fortamine.

The endocyclic bond angles C(1)–C(6)–C(5) and C(4)–C(5)–C(6) in fortimicin B are 113.9 and 113.5°, respectively, significantly larger than the average angle 111.5° in cyclohexane.[9] The corresponding values in fortamine having neither a glycosidic linkage nor an intramolecular hydrogen bond are 111.2 and 112.0°. The relatively large C(1)–C(2)–C(3) angle of 112.6° is probably due to the strong O(2)–H···O(1) hydrogen bond. The exocyclic bond angles of C(4)–C(5)–O(5) and O(5)–C(5)–C(6) are asymmetrical in fortimicin B because of the intramolecular hydrogen bond, while in fortamine they are symmetrical. Although O(3)–C(3)–C(4) and O(3)–C(3)–C(2) angles in fortimicin B are asymmetrical, they are symmetrical in fortamine.

Bond lengths and angles in fortamine are closer to the normal values than those in fortimicin B. Thus the glycosidic linkage and the intramolecular hydrogen bond might influence the local bond lengths and angles of fortamine ring.

Table 5. Torsional angles (τ/°)

	Fortamine	Fortimicin B
C(6)–C(1)–C(2)–C(3)	53.9	58.0
C(1)–C(2)–C(3)–C(4)	−56.1	−61.0
C(2)–C(3)–C(4)–C(5)	56.3	55.6
C(3)–C(4)–C(5)–C(6)	−56.4	−50.4
C(4)–C(5)–C(6)–C(1)	54.6	50.9
C(5)–C(6)–C(1)–C(2)	−52.6	−53.6
N(1)–C(1)–C(2)–O(2)	−62.2	−57.7
O(2)–C(2)–C(3)–O(3)	−59.8	−67.1
C(7)–O(3)–C(3)–C(4)	−110.1	−152.7
C(7)–O(3)–C(3)–C(2)	129.2	85.4
O(3)–C(3)–C(4)–N(4)	173.9	170.7
C(8)–N(4)–C(4)–C(5)	166.5	167.0
C(8)–N(4)–C(4)–C(3)	−70.9	−71.5
N(4)–C(4)–C(5)–O(5)	−60.1	−52.3
O(5)–C(5)–C(6)–O(1)	−57.9	−66.4
O(1)–C(6)–C(1)–N(1)	65.2	66.7

Conformation of the Molecule. A stereoscopic drawing of the molecule is shown in Fig. 3. The conformations of the ring and substituents of fortamine are essentially the same as those of fortimicin B. All torsional angles in the molecule are compared in Table 5. The overall flattening of fortamine rings is essentially the same in these two compounds with mean C–C–C–C torsional angles of 54.9° for fortimicin B and 55.0° for fortamine. These values are close to 54.9° in cyclohexane as determined by electron diffraction study.[9] In *epi*- and *myo*-inositol,[10] however, the ring is more puckered with the mean C–C–C–C torsional angles of 56.3 and 56.8°, respectively.

Closer examination shows that the present molecule takes a more symmetrical conformation than fortimicin B. The characteristics of the ring conformation are illustrated in Fig. 4, where the distance, d, is defined as the deviation of the two atoms from the least-squares plane of the other four atoms forming the seat of a chair. They are good indicies to show the puckering or the flattening of cyclohexane ring. The flattening, d= 0.601 Å, of the C(4)–C(5)–C(6) part in fortimicin B by the intramolecular hydrogen bond is accompanied

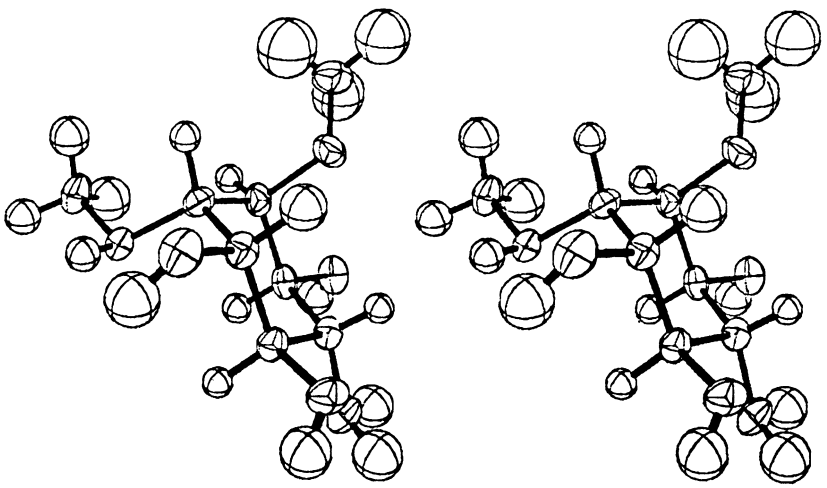

Fig. 3. Stereoscopic view with thermal ellipsoids at 50% probability.

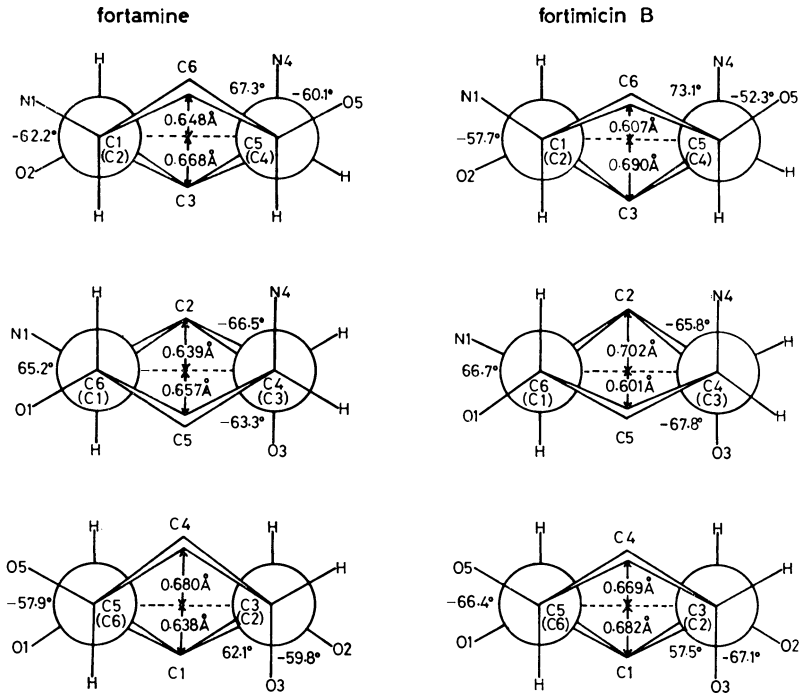

Fig. 4. Schematic drawing of chair forms of fortamine and fortimicin B.

by the puckering of the C(1)–C(2)–C(3) part, d=0.702 Å. The C(1)–C(6)–C(5) part in fortimicin B is flattened, (d=0.607 Å), probably due to the effect of the glycosidic bond, the flattening being followed by the puckering of the C(2)–C(3)–C(4) part, d=0.690 Å. In fortamine a slight puckering, d=0.680 Å, is seen at the *N*-methyl part but the ring as a whole takes essentially a symmetric structure.

These characteristics are related to the torsional angles. The C(3)–C(4)–C(5)–C(6), C(4)–C(5)–C(6)–C(1), C(1)–C(2)–C(3)–C(4) and C(6)–C(1)–C(2)–C(3) angles are significantly different between fortamine and fortimicin B. It seems that the remarkably small values of C(3)–C(4)–C(5)–C(6) and C(4)–C(5)–C(6)–C(1) angles in fortimicin B are mainly due to the intramolecular hydrogen bond. The effect of this local deformation of the chair geometry of the ring is discussed by calculating minimum energy conformation.[14] The calculation shows that the deformation of a torsional angle around an endocyclic bond induces an inverse deformation of the torsional angle around the opposite endocyclic bond in the ring. The extent is about 30% of the original deformation. The increase in C(1)–C(2)–C(3)–C(4) and C(6)–C(1)–C(2)–C(3) angles in fortimicin B are explained by this effect.

The results indicate that the glycosidic bond and the intramolecular hydrogen bond considerably flatten the fortamine ring locally.

Direct Observation of the Type II Biradical and Triplet State of Valerophenone Excited by the Fourth Harmonic of a Nd:YAG Laser

Hisaharu HAYASHI and Saburo NAGAKURA*
Institute of Physical and Chemical Research, Wako, Saitama 351
(Received November 17, 1979)

The Norrish type II reaction of valerophenone was studied by the ns-laser photolysis technique, the fourth harmonic (266 nm) of a Q-switched Nd: YAG laser being used as an exciting light source. Transient absorptions due to the triplet state and 1,4-biradical of valerophenone were observed in both polar and nonpolar solvents. Quenching experiments with *cis*-1,3-pentadiene were also carried out. Transient absorptions due to the biradical were observed in the 350—300 nm region with the lifetimes of 103 ns (in methanol), 99 ns (in 2-propanol), 71 ns (in acetonitrile), and 31 ns (in 1,2-dichloroethane). Transient absorptions due to the triplet state were also observed in the 440—300 nm region.

Biradicals produced by the Norrish type II reaction of carbonyl molecules[1] have been regarded as important reaction intermediates in organic photochemistry. However, their existence had not been proved directly before the studies of Small and Scaiano with the aid of the ns-laser photolysis technique were carried out.[2-4] They used an N_2 laser (337.1 nm) as an exciting light source and observed the lifetimes of some type II biradicals through the rise curves of the absorptions of transient specimens produced by the electron transfer from the biradicals to some electron acceptors.

They also succeeded in observing directly transient absorptions due to the biradicals with a laser photolysis apparatus of very high sensitivity using a Q-switched frequency doubled ruby laser (347.1 nm) as an exciting light source.[5] They observed the transient absorptions of the biradicals in the 500—370 nm region, the spectra of which resembled that of the acetophenone ketyl radical.[6,7] Besides these weak bands, the ketyl radical has a much stronger band in the region below 370 nm.[6,7] From a similarity in the electronic structures of both specimens, the biradical might also be expected to have a strong band in the shorter wavelength region. However, it is very difficult to measure the transient absorption in the wavelength region shorter than that of the exciting light source. We recently constructed a ns-laser photolysis apparatus, the fourth (266 nm), third (355 nm), or second (532 nm) harmonics of a Q-switched Nd: YAG laser being used as an exciting light source. We have undertaken to measure the transient absorption due to the type II biradical of valerophenone extending the measurement region to 300 nm exciting the sample by the fourth harmonic of the laser.

The triplet-triplet (T_n-T_1) absorption of acetophenone overlaps the absorption of its ketyl radical.[7] A similar overlap is expected for the T_n-T_1 absorption of valerophenone and the absorption of the biradical, although Small and Scaiano did not consider the overlap.[5] In the present study, we have tried to measure the biradical absorption separately from the T_n-T_1 absorption by quenching experiments with *cis*-1,3-pentadiene.

Experimental

Valerophenone (Tokyo Kasei) was purified by distillation under reduced pressure. All solvents of spectrograde (Wako or Tokyo Kasei) were used without further purification. *cis*-1,3-Pentadiene (Tokyo Kasei Ultra Pure) purified by vacuum distillation was used for quenching studies. The samples contained in quartz cells with an optical length of 10 mm were degassed by four freeze-pump-thaw cycles. The concentration of valerophenone was 0.0065 mol dm^{-3}.

A block diagram of the laser photolysis apparatus is shown in Fig. 1. A Q-switched Quanta-Ray DCR-1 Nd: YAG laser was used as an exciting light source, a Quanta-Ray HG-1 harmonic generator providing the second, third, or fourth harmonics of the laser. The fourth harmonic was used as exciting light source, pulse width being 5 ns and maximum power 30 mJ. In order to avoid thermal lensing effects, the actual power was reduced as much as possible. Flash lamps for exciting the laser were discharged at 10 Hz, the maximum power being obtained. Its Q-switching was operated every 16 shots of the flash lamps (0.625 Hz) in order to prevent photochemical changes of the samples. The monitoring light with pulse width of 300 μs was obtained from a pulsed xenone arc (Ushio 150 W), irradiating the sample synchronously with the laser (0.625 Hz). Laser and monitoring light beams were crossed at right angles to each other. The monitoring light intensity was detected with

an HTV-R636 photomultiplier through a grating monochromator (Nikon G-250). An electronic shutter (Vincent 225L0A25X5[8] or Copal EMS #0[9]), opening synchronously with the laser pulse was used in order to protect the sample and the photomultiplier from continuous irradiation by the xenon arc. The time profiles of the shutter, monitoring light, and laser are also shown in Fig. 1. The transient signals were recorded by taking the photographs of the images on a Tektronix 7904 oscilloscope.

Results and Discussion

We have measured the transient absorption caused by the excitation of valerophenone in both polar and nonpolar solvents, in the region 440—300 nm. As examples, time-resolved absorption spectra were observed for the methanol and cyclohexane solutions (Fig. 2), the decay curve of the transient absorption being observed for these solutions (Fig. 3). We see that the decay curve for the methanol solution consists of two components:

$$I(t) = I_1 \exp(-t/\tau_1) + I_2 \exp(-t/\tau_2) \quad (1)$$

where τ_1 and τ_2 are the lifetimes of the fast and slow components, respectively, and I_1 and I_2 are the corresponding pre-exponential factors. The observed τ_1 and τ_2 values are given in Table 1.[10]

diene. The primary photochemical process of valerophenone in the ns-region is shown by Scheme 1, where G, T, and B denote the ground and triplet states of valerophenone and its biradical, respectively,[1] [Q] is the concentration of *cis*-1,3-pentadiene and k_T, k_B, and k_q are the respective rate constants. From measurement of the [Q] dependence of τ_1, τ_2, and I_2 (Figs. 4 and 5), we see that τ_2 is independent of [Q] and the inverse of the pre-exponential factor of the slow component, $1/I_2$, increases with increasing [Q]. This indicates that the slow component is safely assigned to the biradical and that curve b (Fig. 2) corresponds to its spectrum.[11] On the other hand, the fast component can be assigned to the triplet state, the only observable precursor of the biradical. Thus curve a (Fig. 2) can be considered to be a combination of curves due to the triplet state and the biradical. However, its 440—350 nm region may be mainly due to the triplet state, since the absorption intensity of the biradical is weak in this region.

When $k_T > k_B$, $1/I_2$ can be represented by (See Appendix)

$$1/I_2 = c[(k_T - k_B)/k_T + k_q[Q]/k_T] \quad (2)$$

where c is a constant. The following result is obtained from the $1/I_2$—[Q] line (Fig. 5):

$$k_q = (61 \pm 24) \times (k_T - k_B) \text{ mol}^{-1} \text{ dm}^3 \quad (3)$$

Since k_B and k_T were determined to be 0.97×10^7 s^{-1}, larger than 0.83×10^8 s^{-1}, respectively, k_q was calculated to be larger than $(4.5 \pm 1.8) \times 10^9$ s^{-1} mol^{-1} dm^3. This value is reasonable compared with the assumed one (5.5×10^9 s^{-1} mol^{-1} dm^3).[5]

We observed similar two component transient absorptions in acetonitrile, 2-propanol, and 1,2-dichloroethane. The observed fast and slow lifetimes are given in Table 1. The time-resolved spectra for these systems observed immediately and 100 ns after excitation are similar to those observed in methanol.

The cyclohexane solution also has a transient absorption in the region 420—300 nm (curve c, Fig. 2). Its decay curve, however, unlike that of the methanol solution, has only one component (Fig. 3). The lifetime, τ, for the cyclohexane solution was found to be 23±3 ns. The [Q] dependence of τ is also shown in Fig. 4. Since the observed τ values are not corrected, they are the upper limits of the real lifetimes, but we can conclude that τ decreases with increasing [Q]. Therefore, the observed transient absorption can be considered to be mainly due to the triplet state. Thus the spectrum obtained with the cyclohexane solution may be due to the triplet state, although possibility of contamination of the biradical absorption still remains.

We observed a similar one component decay curve of the transient absorption for the heptane solution (Table 1). The transient spectrum in heptane is similar to that in cyclohexane.

From the results, we conclude that the transient spectrum observed for valerophenone in the polar solvents in the 350—300 nm region can be assigned to the 1,4-biradical. It resembles that of the acetophenone ketyl radical.[7] Small and Scaiano observed the transient absorption spectra of the biradicals produced from γ-methylvalerophenone and valerophenone in the 500—370 nm region.[5] They are also similar to the spectrum of the acetophenone ketyl radical. The biradical absorption in this region is weak. We extended the wavelength region of the measurement to 300 nm, making it much easier to carry out such precise mechanistic works as quenching experiments.

As is shown in Table 1, the observed lifetimes for the biradical of valerophenone in polar solvents in this work agree with those obtained by Small and Scaiano with the indirect[3] and direct[5] methods. However, they could not observe the fast component in their transient absorption of valerophenone, and estimated the lifetime of the triplet state of valerophenone in methanol to be 16 ns through the indirect method.[3] This value is somewhat longer than the present result (less than 12 ns). The disagreement might be due to their underestimation of the k_q value.

In nonpolar solvents, Small and Scaiano also observed transient absorptions for γ-methylvalerophenone and valerophenone in the 500—370 nm region and assigned them to the biradical.[5] For example, the lifetimes of the biradicals of γ-methylvalerophenone and valerophenone in cyclohexane were reported to be 37 ns and 38 ns, respectively. The assignment for the former can be considered to be correct, since its triplet lifetime was confirmed to be much shorter than 37 ns,[5] but the assignment for the latter should be reexamined.

Appendix

The rate equations for [T] and [B] can be written as follows:

$$d[T]/dt = -k_T[T] - k_q[Q]\cdot[T], \quad \text{(A-1)}$$

$$d[B]/dt = k_T[T] - k_B[B]. \quad \text{(A-2)}$$

From Eq. (A-1), we get

$$[T] = [T]_0 \exp(-kt), \quad \text{(A-3)}$$

where $[T]_0$ is the initial concentration of [T] and k is given by

$$k = k_T + k_q[Q]. \quad \text{(A-4)}$$

When $t=0$, $[B]=0$. Thus [B] can be expressed by

$$[B] = A[\exp(-k_B t) - \exp(-kt)], \quad \text{(A-5)}$$

where A is a constant. When $k > k_B$, I_2 is proportional to A. Introducing Eqs. (A-3) and (A-5) into Eq. (A-2) we get

$$A = k_T[T]_0/(k-k_B). \quad \text{(A-6)}$$

Thus we can derive Eq. 1.

The authors' sincere thanks are due to Mr. Katsuo Nishi, the Institute of Physical and Chemical Research, for his kindness in designing the electric circuits of our laser photolysis apparatus. The present work was partially supported by Research Grant-in-Aids Nos. 412212 and 454135, the Ministry of Education, Science, and Culture.

Studies on the Aqueous Solutions of Guanidinium Salts. XIV. Effect of Guanidinium Bromide on the Surface Tension of Aqueous Solutions of the Cationic Surfactants

Koichiro MIYAJIMA,* Hiromitsu YOSHIDA, Junko MAETANI, and Masayuki NAKAGAKI
Faculty of Pharmaceutical Sciences of Kyoto University, Yoshida Shimoadachi-cho, Sakyo-ku, Kyoto 606
(Received November 29, 1979)

The surface tensions of decyl-, tetradecyl-, and hexadecyl-trimethylammonium bromides were measured in the aqueous solutions of potassium bromide (KBr) and guanidinium bromide (GuBr). The critical micelle concentrations (CMC's) of the above surfactants decreased with increase of the concentration of KBr, while the CMC's showed minimum values in the aqueous GuBr solution, as the concentration of GuBr increased. The Langmuir coefficient, K_C, increased with decrease of the CMC. The influence of the salts on the surface tension and the micellization were well described in terms of the activity of the surfactant calculated by combining the Debye-Hückel law and Setschenow's equation.

A large number of studies have been reported on the effect of various electrolytes on the surface tension, the adsorption on the air-water interface and the micellization of surfactants.[1–9] The association and the adsorption to the air-water interface of ionic surfactant in aqueous solution are governed by two opposing forces. The hydrophobic force which is mainly due to the ordered water molecules around the hydrophobic tail of surfactant repelles the surfactant molecules or ions from the aqueous bulk solution to the interface or the micelle core. The polar head group favour the aqueous bulk phase rather than such ordered phase, because the electrostatic repulsive force between the head groups makes the surfactant molecule difficult to associate. In this connection, inorganic salts decrease the CMC and increase the adsorption to the air-water interface. The effect of the inorganic electrolytes were roughly described in terms of the change of the activity of surfactant in the presence of the salts.[10,11] In this treatment, however, the activity of surfactant was estimated by the Debye-Hückel theory and the effect of the salts on the hydrophobic hydration was ignored.

The organic salts, such as guanidinium and biguanide salts have been known to influence significantly the hydrophobic hydration.[12–14] The reduction of the hydrophobic hydration must decrease the activity of surfactant and increase the CMC.

From these point of view, we measured the surface tension of some alkyltrimethylammonium bromides (C_nBr) in aqueous solutions of guanidinium bromide (GuBr) and KBr, and obtained anomalous results for the C_nBr–GuBr–H_2O system. To interpret these results by the phase separation model, we introduced a new expression for the activity coefficient of ionic surfactant in salt solutions by taking into consideration the effects of salts on the hydrophobic group besides the ionic head group. Based on the activity thus obtained, the variations of CMC and surface tension depending on the concentration and the kind of salts were well interpreted in terms of the change of the activity of the surfactants in salts solutions.

Experimental

Materials. Dodecyl-, tetradecyl-, and hexadecyltrimethylammonium bromides were synthesized from corresponding alkyl bromides and trimethylamine by the method described elsewhere.[15] The crude product was recrystallized from ethanol two or three times. To remove the raw materials, Soxhlet's extracter was employed using ether as the solvent. After extraction, recrystallization from ethanol-ether mixture gave a white crystalline product. In elementary analysis, the experimental values were in good agreement with those of the calculated values as shown in Table 1. Guanidinium bromide used was the same compound reported previously.[12] Reagent grade 1-butanol, 1-hexanol, 1-octanol, and 1-decanol (Nakarai Chemical Co., Ltd.) were used without further purification. The purities of these alcohols were more than 98%. All solutes were dissolved in deionized and redistilled water. Aqueous solutions of GuBr and KBr were purified through activated charcoal powder before use.

Surface Tension Measurements. The surface tension was measured by Du Nouy tensiometer. The platinum ring with diameter 23 mm was heated by oxidizing flame before use. All glass apparatus were preserved in chromate-sulfric acid mixture and linsed well with distilled water before use. Temperature of the thermostat was maintained at 25 ± 0.2 °C. For the calculation of the surface tension of aqueous solutions, the value of 71.96 $mN \cdot m^{-1}$ was used as the surface tension of pure water at 25 °C. The experimental determination of the surface tension was precise to ±0.1 $mN \cdot m^{-1}$.

Table 1. Elementary analysis of cationic surfactants (%)

		H	C	N

Solubility Measurements. The saturated aqueous solutions of alcohols were obtained by mixing the excess amount of alcohol and water in a thermostat bath with magnetic stirrer at 25±0.1 °C. It took 2—3 d to reach equilibrium. After equilibrium, UV spectra of the saturated solutions were measured for the detection of the emulsification of alcohols. The differences of the intensities at 265 nm between water and the saturated aqueous alcohol solutions were not observed except for aqueous 1-butanol solution. The solubilized amount of alcohol was determined from the peak height of the gas chromatogram (GC). GC conditions are as follows; Column: 10% PEG20M on Chromosorb W, 100—200 mesh packed in 3 mm×1 m glass tubing; Column temperature: 120 °C; Carrier gas: He; Flow rate: 40 $cm^3 \cdot min^{-1}$; Injection temperature: 170—190 °C; Detector: FID.

Results

Surface Tensions of C_nBr Solutions. The surface tension, γ, at constant salts concentrations are shown as a function of logarithm of the concentration of $C_{14}Br$ in Figs. 1 and 2. The concentrations of surfactant and the added salts are expressed by C/mol·dm^{-3} and C_s/mol·dm^{-3}, respectively. At constant C_s, the surface tension decreased with increase of C. The break point for each curve is regarded as the critical micelle concentration (CMC) which is given in Table 2 together with those of $C_{12}Br$ and $C_{16}Br$. As shown in Fig. 1, the surface tension at a constant C decreases with increase of the concentration of KBr. Therefore, the curve of surface tension *vs.* log C shifts to the lower concentration region of surfactant with increase of C_s. However, as shown in Fig. 2, the behavior of the surface tension *vs.* log C curves for the $C_{14}Br$–GuBr–H_2O system is different from that of the $C_{14}Br$–KBr–H_2O system. At constant C, the surface tension decreases with increase of C_s up to about 1 mol·dm^{-3} and above this concentration,

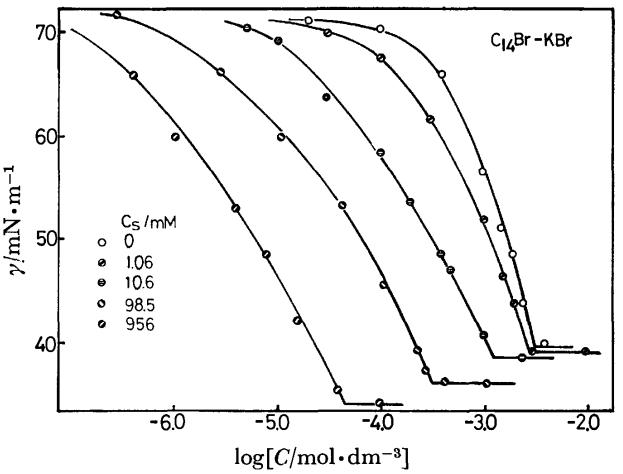

Fig. 1. The plot of the surface tension, γ, against the concentration of $C_{14}Br$, C, in aqueous KBr solution.

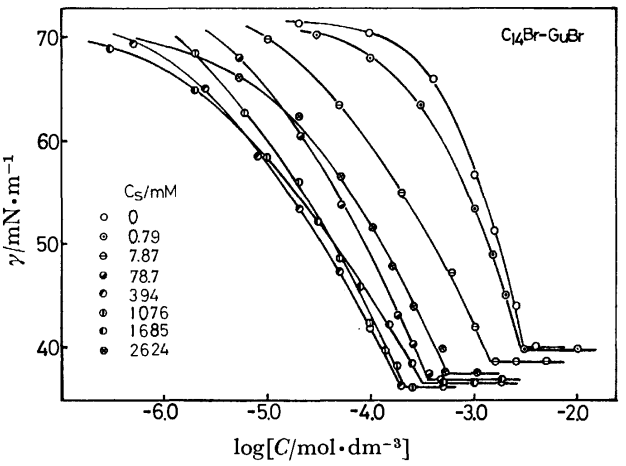

Fig. 2. The plot of the surface tension, γ, against the concentration of $C_{14}Br$, C, in aqueous GuBr solution.

the surface tension increases with the concentration of GuBr. This phenomenon was also observed in the $C_{12}Br$–GuBr–H_2O and $C_{16}Br$–GuBr–H_2O systems.

Effect of the Counter Ion Concentration on CMC. Using the CMC values obtained from Figs. 1 and 2, the values of log CMC were plotted against logarithm

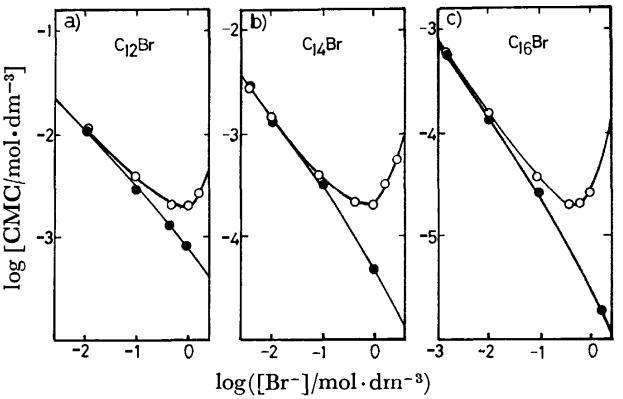

Fig. 3. The plot of log CMC against log [Br^-] in aqueous salt solution.
Salt; ○: GuBr, ●: KBr.

of counter ion concentration, log[Br^-].[1,3] They are shown in Figs. 3-a, 3-b, and 3-c. In the C_nBr–KBr–H_2O system, the values of log CMC decrease with increase of log[Br^-] values. The degree of CMC-lowering increases with the alkyl chain length. However, in the C_nBr–GuBr–H_2O system, the value of log CMC decreases with increase of log[Br^-], reaches a minimum and then increases with log[Br^-]. The concentrations of counter ion at the minimum points decrease with increase of alkyl chain length.

Adsorption at the Air-Water Interface. The adsorption amount of surfactant, Γ, is essentially defined by the Gibbs adsorption equation.[1,16]

$$\Gamma = -\frac{1}{RT}\left(\frac{\partial\gamma}{\partial \ln a}\right)_{T,P}, \quad (1)$$

where a is the activity of surfactant. If the activity coefficient can be regarded as unity, Eq. 1 is rewritten as Eq. 2,

$$\Gamma = -\frac{1}{iRT}\left(\frac{\partial\gamma}{\partial \ln C}\right)_{T,P}, \quad (2)$$

where

$$i = \nu_-\left(\frac{\nu_- C}{\nu_- C+\nu_{s-}C_s}\right) + \nu_+. \quad (3)$$

In Eqs. 1, 2, and 3, R, T, and P are the usual meanings,

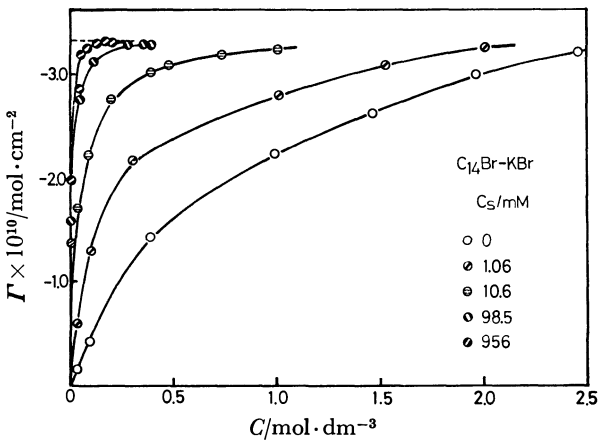

Fig. 4. Adsorption isotherms of $C_{14}Br$ in various concentrations of KBr solutions at 25°C.

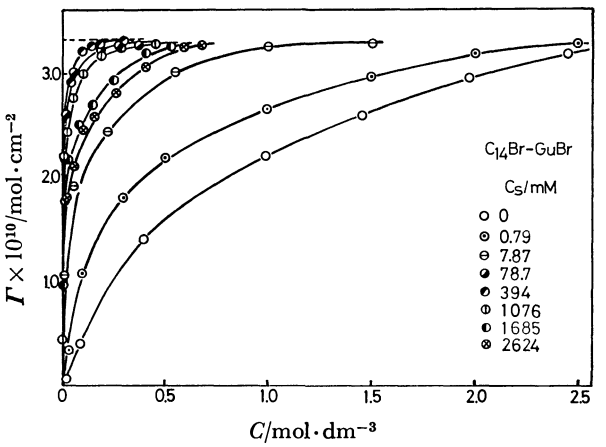

Fig. 5. Adsorption isotherms of $C_{14}Br$ in various concentrations of GuBr solutions at 25°C.

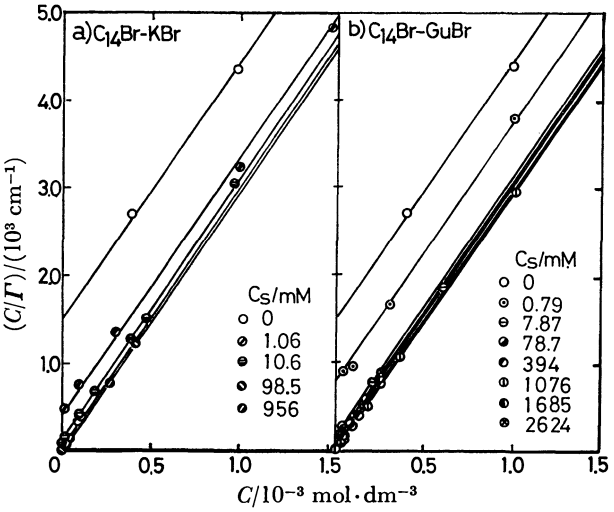

Fig. 6. Plots of C/Γ *vs.* C in various concentrations of salt solutions.

and ν_+ and ν_- are the number of moles of cation and anion formed from 1 mol of ionic surfactant, respectively, and ν_{s-} is the number of moles of anion fully dissociated from 1 mol of the added salt. As shown in Figs. 4 and 5, the Γ values of $C_{14}Br$ calculated from Eq. 2 are plotted against C at various C_s's. The Langmuir equation was applied to these systems.

$$\Gamma = \frac{\Gamma_s K_c C}{1+K_c C}, \quad (4)$$

where Γ_s is the saturated adsorption amount and K_c is the constant concerning the strength of adsorption. Equation 4 is rewritten as,

$$\frac{C}{\Gamma} = \frac{1}{\Gamma_s K_c} + \frac{1}{\Gamma_s}C. \quad (5)$$

The plot of C/Γ against C for the $C_{14}Br$–KBr–H_2O and $C_{14}Br$–GuBr–H_2O systems are shown in Figs. 6-a and 6-b, respectively. In accordance with Eq. 5, linear relationships exist between C/Γ and C. The values of Γ_s and K_c obtained from the slopes and the intercepts are shown in Table 3. In both the systems, Γ_s takes a constant value, 3.32×10^{-10} mol/cm^2, *i.e.* 50.1 Å^2/molecule. In the $C_{14}Br$–KBr–H_2O system, K_c values increase with the concentration of KBr, but in the $C_{14}Br$–GuBr–H_2O system, K_c values once increase and then decrease

with increase of the concentration of GuBr.

Relationship between CMC and K_c. In order to elucidate the relation between micelle equilibrium and adsorption equilibrium in aqueous salt solution, the values of log K_c were plotted against the values of log CMC. (Fig. 7) The arrow sign represents the direction of the increase of salt concentrations. Though the shapes of two curves are different from each other, the relation between K_c and CMC is similar, that is, the value of log K_c increases with decrease of the value of log CMC. This fact indicates that the adsorption at air-water interface is closely related to the micellization.

Discussion

Micellization. In most studies concerning the effect of electrolyte on the micelle formation, the plot of log CMC against the logarithm of counter ion concentration has been considered linear. The slope was regarded as a parameter related to the state of the dissociation of counter ion or the formation of ionic atmosphere by counter ions around the micelle. However, our investigation revealed that these plots are not linear in aqueous ternary system, especially in the C_nBr–GuBr–H_2O system. Therefore, it is not adequate to take into account the effect of electrolyte on micellization on the basis of only electrostatic effect of counter ion. Shinoda and Huchinson,[16] and Herraman[17] analyzed the experimental results thermodynamically, by regarding the micellization phenomenon as a kind of phase separation and met with success. Recently, it was pointed out that the activity, instead of the concentration, of surfactant should be used for the analysis of the experimental data.[10] Therefore, we used the activity of surfactant for the analysis of data. According to the phase separation model, it may be considered that the micelle formation occured when the activity of surfactant has reached a certain value.

The activity of cationic surfactant at CMC, a_m, in the aqueous solution of electrolyte with common anion may be written as,

$$a_m = f_\pm^{\nu}(CMC)^{\nu_+}(\nu_-(CMC)+\nu_{s^-}C_s)^{\nu_-}, \quad (6)$$

where $f_\pm$ is the mean ionic activity coefficient of surfactant and $\nu=\nu_+ + \nu_-$. In this work, $\nu_+=\nu_-=\nu_{s^-}=1$ and $\nu=2$. $f_\pm$ in Eq. 6 has been mostly determined from the Debye-Hückel equation for the activity coefficient.[18] However, only the electrostatic interaction is taken into consideration with the Debye-Hückel theory. In this respect, this law is originally suitable for inorganic electrolytes or their mixtures. Organic electrolytes such as surfactants have a large hydrophobic group besides an ionic head group. The hydrophobic group of surfactant is surrounded by the ice-like structure which decreases the entropy of the system and leads to the micelle formation. Inorganic electrolytes such as KBr and CsBr have a different effect from organic electrolytes such as guanidinium salts on the activity coefficient of hydrophobic compound. Alkali halides usually salt out the hydrophobic compound, while guanidinium halides salt in.[12] Therefore, when we discuss the activity coefficient of ionic surfactant in the presence of another salt, we must take into consideration the interaction between the hydrophobic moiety and ions, besides the interaction between the ionic head group and ions. In this connection, the salt effect on the activity of surfactant is considered to be the sum of these two contributions. The Debye-Hückel equation for $f_\pm$ represents the contribution from the interionic interaction. Güntelberg's approximation of the Debye-Hückel law[18] was used for the estimation of this interaction. In order to estimate the salt effect on the hydrophobic group, we introduced the Setschenow equation which represents the effect of salt on the solubility of nonelectrolyte.[19] This equation is written as,

$$\log(f_s/f_{s0}) = \log(S_0/S) = k_s'C_s, \quad (7)$$

where $f_s(f_{s0})$ and $S(S_0)$ are the activity coefficient and the solubility of nonelectrolyte in the presence (absence) of salt, respectively, and k_s' is the salting-out coefficient of nonelectrolyte. Assuming that the value of f_{s0} is

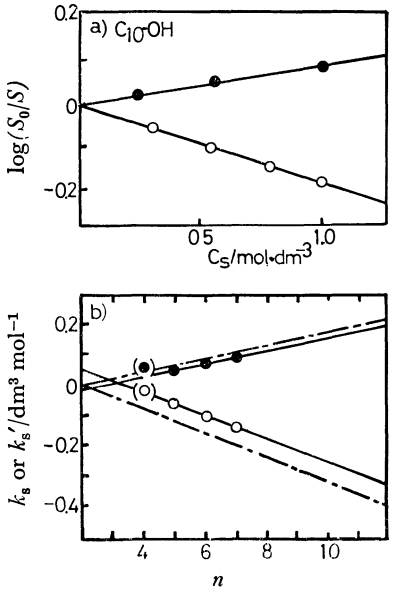

Fig. 8. a) The plot of $\log(S_0/S)$ of l-decanol against C_s.
b) k_s or k_s' value against carbon number of l-alcanols, n.
Salt; ○: GuBr, ●: KBr.

unity because of the low solubility of hydrophobic nonelectrolyte, Eq. 7 reduces to Eq. 8,

$$\log f_s = k_s' C_s. \quad (8)$$

Based on the above discussion, the activity coefficient of the ionic surfactant may be expressed by Eq. 9,

$$\log f_\pm = \frac{-A\sqrt{I}}{1+\sqrt{I}} + k_s C_s, \quad (9)$$

where I is the ionic strength and A is the constant, 0.5115 for 1:1 electrolyte at 25 °C, and k_s is the salting-out coefficient for the hydrophobic alkyl group. In order to obtain the k_s values for the hydrocarbon group of surfactant, the solubilities of n-alcohols with 6, 8, and 10 carbons were measured in the aqueous solutions of KBr and GuBr. As shown in Fig. 8, the value of $\log(S_0/S)$ for 1-decanol increases with the concentration of KBr and decreases with increase of the concentration of GuBr. From the slopes, the k_s' values were determined to be 0.092 and −0.147 for KBr and GuBr solutions, respectively. The values of k_s' of 1-hexanol and 1-octanol were obtained from the similar plots to 1-decanol. These values are shown in Table 4. To

Table 4. The values of salting-out coefficients of n-alkyl alcohols and n-alkyl groups in aqueous KBr and GuBr solutions

		k_s'/dm³·mol⁻¹ KBr	GuBr
Alcohol	1-Butanol	0.049	−0.023
	1-Hexanol	0.056	−0.066
	1-Octanol	0.069	−0.106
	1-Decanol	0.092	−0.147
Alkyl group	Dodecyl	0.12	−0.21
	Tetradecyl	0.14	−0.26
	Hexadecyl	0.16	−0.32

obtain the k_s values of dodecyl, tetradecyl, and hexadecyl groups, k_s' value was plotted against the carbon number of alcohols, n. As shown in Fig. 8-b, linear relationships exist between the k_s' values and n in each salt system. Therefore it is reasonable to determine the k_s' values of higher alcohols by extraporation. These k_s' values are not for the alkyl groups, but for alcohols, because they include the contribution of OH group. The salting-out coefficients of alkyl groups, k_s were obtained by subtracting the value of intercept from the k_s' values, on the assumption that the intercept represents the contribution of OH group. The k_s values of alkyl group thus obtained are also shown in Table 4. From the signs of k_s values, the effects of KBr and GuBr on the solubility of alcohols are consistent with those of these salts on the solubility of tetraalkylammonium salts.[20] Judging from the signs of k_s, the hydrophobic tails of surfactant molecules can associate more easily in the salt solution with a positive sign of k_s and less easily in the salt solution with a negative sign of k_s than in pure water. The difference of the sign of k_s indicates that the influence of KBr on the water structure in the vicinity of surfactant molecule is different from that of GuBr.[12,13]

From Eqs. 6 and 9, we obtain,

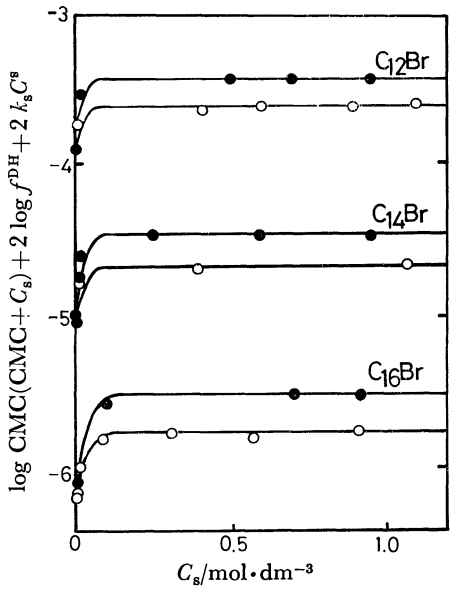

Fig. 9. The plot of log CMC (CMC+C_s)+2 log f^{DH}+2 k_sC_s against C_s in aqueous salts solutions.
Salt; ○: GuBr ●: KBr.

$$\log a_m = \log \mathrm{CMC}(\mathrm{CMC}+C_s) + 2\log f^{DH} + 2k_sC_s, \quad (10)$$

where $\log f^{DH}$ is the first term of the right hand side of Eq. 9. If the micellization occurs at constant activity in the aqueous solution, Eq. 10 must be constant. As shown in Fig. 9, the value of a_m is constant irrespective of C_s, except the low concentration of salt. Since the value of (CMC+C_s) is equal to [Br⁻], Eq. 10 is rewritten as,

$$\log \mathrm{CMC} + 2\log f^{DH} + 2k_sC_s = \log a_m - \log [Br^-]. \quad (11)$$

When Eq. 11 is applied to the $C_{14}Br$–KBr(or GuBr)–H_2O system, the slope of (log CMC+2 log f^{DH}+2 k_sC_s) *vs.* log [Br⁻] curve must be −1. As shown in Figs. 10-a and 10-b, the plots of log CMC or (log CMC+2 log f^{DH}) against log [Br⁻] are not linear, but the plot (log CMC+

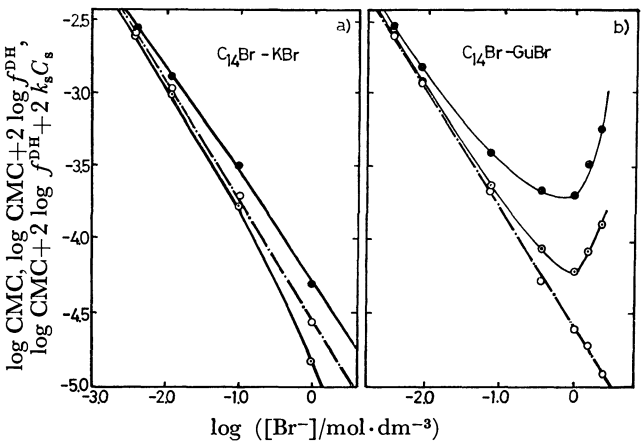

Fig. 10. The plot of log CMC, (log CMC+2 log f^{DH}), or (log CMC+2 log f^{DH}+2 k_sC_s) against log [Br⁻] for the $C_{14}Br$–salt–H_2O system.
Salt; a) KBr, b) GuBr.
●: log CMC *vs.* log [Br⁻],
⊙: log CMC+2 log f^{DH} *vs.* log [Br⁻],
○: log CMC+2 log f^{DH}+2 k_sC_s *vs.* log [Br⁻].

$2\log f^{DH}+2k_sC_s$) against log[Br^-] is linear in each ternary system and the slopes of both systems are -0.9, which is close to -1.

Surface Tension and Adsorption at Air-Water Interface. In the previous section, the micellization phenomena of cationic surfactants in salt solution were interpreted in terms of the constant activity of surfactant. Similarly, the behaviour of surfactant below CMC in salt solution was considered on the basis of the activity, a, defined by Eq. 12,

$$a = f_{\pm}^2 C(C+C_s) \quad (12)$$

where $f_{\pm}$ is the activity coefficient defined by Eq. 9.

The modified Szyszkowski equation obtained from the integration of Eq. 1 with the Langmuir equation by using a instead of C was applied to these ternary systems.[10]

$$\gamma_0 - \gamma = \Gamma_s RT \ln(1+K_a \cdot a), \quad (13)$$

where γ_0 and γ are the surface tension of pure water and surfactant solution, respectively, and K_a is the Langmuir coefficient. As shown in Figs. 11 and 12, the quantity of $\exp[(\gamma_0-\gamma)/\Gamma_s RT]-1$ is proportional to a. The values of K_a obtained from the slopes and Γ_s (3.32×10^{-10} mol/cm^2) are 4.16×10^6 dm^6·mol^{-2} and 3.82×10^6 dm^6·mol^{-2} for the $C_{14}Br$·KBr–H_2O and $C_{14}Br$–GuBr–H_2O systems, respectively. The value of K_a is a constant independent of C_s, while the K_c value varies with C_s.

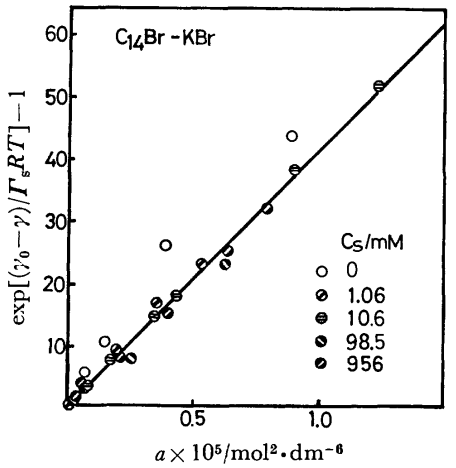

Fig. 11. The plot of $\exp[(\gamma_0-\gamma)/\Gamma_s RT]-1$ against a in aqueous KBr solution.

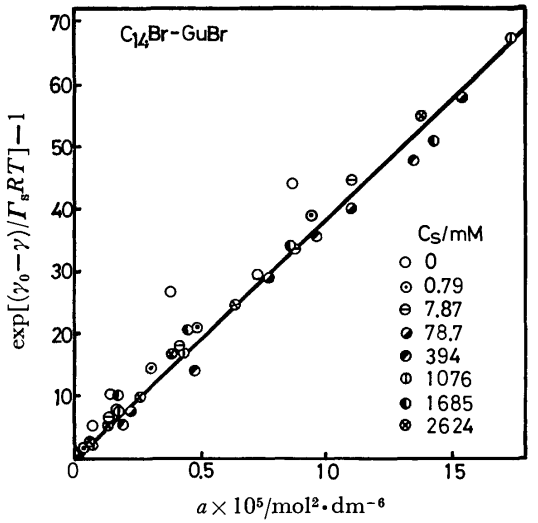

Fig. 12. The plot of $\exp[(\gamma_0-\gamma)/\Gamma_s RT]-1$ against a in aqueous GuBr solution.

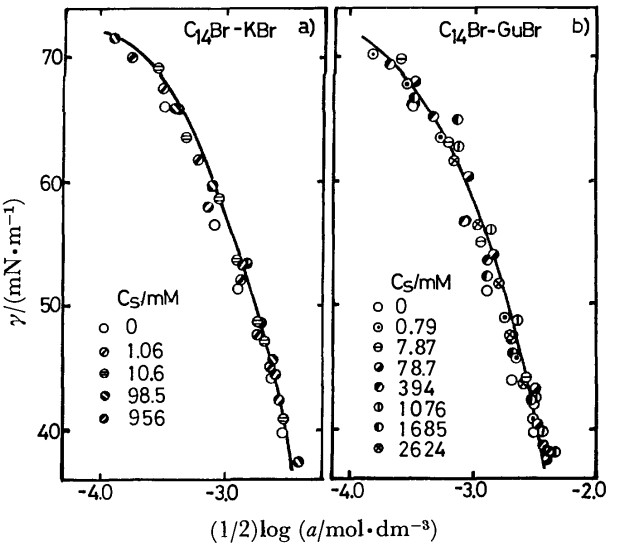

Fig. 13. The relationship between γ and 1/2 log a for the $C_{14}Br$– salt–H_2O system.

When the surface tension of $C_{14}Br$ is replotted against (1/2)log a as shown in Figs. 13-a and 13-b, every experimental value is located on the same curve obtained from Eq. 13 by using the values of K_a and Γ_s. The comparison of these figures with Figs. 1 and 2 indicates that the variation of curves in Figs. 1 and 2 is originally caused by the ignorance of the activity coefficient.

Conclusion

For the analysis of the salt effect on the CMC and the surface tension of cationic surfactant, we introduced a new expression for the activity coefficient in salt solution by taking into consideration the salt effect on the hydrophobic group of surfactant, besides the ionic head group. The electrostatic interaction between the ionic residue of surfactant and ions always decreases the activity of surfactant. However, the interaction between the hydrophobic group of surfactant and salt increases or decreases the activity of surfactant according to the sign of salting-out coefficient of salt. The salt with the negative sign of k_s decreases the activity coefficient of surfactant, resulting in the increase of CMC and the decrease of Γ, and *vice versa* for the salt with the positive sign. The opposite effect of GuBr to KBr on the CMC at relatively high concentration is mainly due to the difference of the sign of k_s.

Guanidinium salts denaturate proteins in aqueous solution. The main effect for the denaturation is believed to be the reduction of hydrophobic bonding in protein. Our experimental results are consistent with the above view of protein denaturation by guanidinium salts.

Vibrational Distribution of HF Produced by Mercury Photosensitized Decomposition of Fluoroethylenes

Hajime WATANABE, Hiroyuki HORIGUCHI, and Soji TSUCHIYA*

Department of Pure and Applied Sciences, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153

(Received December 15, 1979)

Distributions of vibrationally excited HF produced by Hg-photosensitized reactions of fluoroethylenes are determined by means of the IR emission measurement of HF fundamentals. The distributions are almost of Boltzmann type with temperatures of 11400, 13700, 7200, 5700, 5700, and 2200 K for respective parent molecules of CH_2=CHF, CH_3CF=CH_2, CH_2=CF_2, *cis*-, *trans*-CHF=CHF, and CHF=CF_2. The fractions of vibrational energy of HF† among the energies available for distribution in various degrees-of-freedom of product molecules are 19, 23, 11, 7.6, 7.6, and 1.7% for the above molecules, respectively. The statistical calculation results in much less energy disposal in HF vibration in the decompositions of CH_2=CHF, CH_3CF=CH_2, and CH_2=CF_2, while the distributions of HF† in CHF=CHF and CHF=CF_2 are closer to those predicted by the statistical calculation. The deactivation rate of HF† in CH_2=CHF is about three times larger than that in CH_2=CF_2, and the latter values resemble those in HF.

Experimental observations on energy partitioning among internal and external degrees-of-freedom of product molecules in chemical reactions have given deep insight into the mechanism and dynamics of the relevant molecular processes. In this paper, we discuss the energy partitioning in the Hg-photosensitized reaction of HF elimination from fluoroethylene (hereafter F-ethylene). The first experiment which demonstrated production of vibrationally excited HF (hereafter HF†) in photolysis of F-ethylenes was made by Berry and Pimentel,[1] who confirmed lasing actions of HF†. Almost at the same time, Clough, Polanyi, and Taguchi[2] determined the vibrational distribution of HF† produced by the reaction of Hg^*+CH_2=CF_2. The distribution shows relatively larger populations in higher levels than those predicted by the statistical calculation. The non-statistical vibrational energy disposal in the HCl produced by the UV photolyses of Cl-ethylenes was also reported by Berry,[3] who postulated a simple Golden Rule model to simulate the vibrational distribution of HCl. It was also reported that vibrationally excited HF was produced in reactions of H and O atoms with fluoroethylenes, and that the vibrational distribution of HF was predicted well by the model proposed by Berry.[4,5]

As for the mechanism of the present Hg-photosensitized reaction, Trobridge and Jennings[6] observed the quantum yield of CH≡CH from CH_2=CHF to be almost unity indicating the HF elimination as a dominant reaction channel. They also suggested two kinds of excited species as reaction intermediates. Discussion of the same line was given on the basis of the calculation of energy levels by Strausz *et al.*,[7] who postulated the mechanism: F-ethylene $\xrightarrow{Hg^*}$ $(\text{F-ethylene})^*_{\text{triplet}} \longrightarrow (\text{F-ethylidene})^*_{\text{triplet}} \longrightarrow (\text{F-ethylidene})^*_{\text{singlet}} \longrightarrow$ decomposition. Experimental studies to test this postulate were carried out by measuring yields of isomerization in *cis*- or *trans*-CHF=CHF[7] and of CH≡CH from CH_2=CHF.[8]

We report here observations of the vibrational distributions of HF formed by the Hg-photosensitized decompositions of CH_2=CHF, CH_2=CF_2, *cis*- and *trans*-CHF=CHF, CH_3CF=CH_2, and CHF=CF_2. The method is based on the IR emission measurement of HF† by the use of a modulation technique to separate the vibrational relaxation effect from the initial vibrational excitation. The results will be compared with the statistical partitioning of the excess energy among all degrees-of-freedom concerned.

Experimental

The apparatus is similar to that employed in the previous study.[9] A gas mixture of Ar and F-ethylene was made to flow through a quartz reaction cell (24 cm long and 3 cm dia.) *via* a liquid N_2 trap to a rotary vacuum pump (900 dm^3 min^{-1}). A pressure increase due to addition of F-ethylene to the main flow of Ar was monitored differentially by a capacitance manometer (M. K. S. Baratron, 210H). A trace of Hg vapor which was less than 1×10^{-3} Torr** was mixed to the flow. The reaction cell was surrounded by six low pressure Hg lamps (Toshiba, 10 W germicidal lamp) whose power was supplied through ballast resistor from an ac source (Elgar, 251) with variable frequencies in the range of 50 Hz—10 kHz in order to modulate the 253.7 nm intensity at twice the frequency of the ac source. One end of the reaction cell was sealed by a CaF_2 window from which the ac component of the IR emission spectrum of HF† was observed by a monochromator (Spex, 1700 III with a grating of 300 l mm^{-1}, blazed at 3 μm) equipped with a photovoltaic InAs detector (Santa Barbara Research Center). The output of the detector was treated by a preamplifier (P. A. R., 181) and a lock-in amplifier (Ithaco, 393) whose reference signal was taken from the modulated 253.7 nm radiation. Thus, both the intensity and the phase-delay angle of the emission were determined, and this made it possible to obtain information on both the production of HF† and its relaxation. Since an average residence time in the reaction cell was about 50 ms and the 253.7 nm radiation intensity was on the order of 10^{15} photon $cm^{-3}s^{-1}$, a fraction of decomposed F-ethylene did not exceed 10% when its partial pressure was less than 10^{-2} Torr. Vinyl fluoride, 1,1-difluoroethylene (Matheson, 99.9% and 99.0%, respectively), *cis*- and *trans*-1,2-difluoroethylene, 2-fluoropropene, and 1,1,2-trifluoroethylene (P.C.R.) were treated by repeated solidification at liquid N_2 temperature. Gas chromatographic analyses of the latter four compounds were made to confirm less than 1% of impurities included.

Results

Analysis of Data. Figure 1 shows an example of the observed IR emission spectrum of HF†. Based on the molecular constants of HF given by Webb and Rao,[10] each emission line may be assigned to respective vibration-rotation transition as noted in Fig. 1. In order to determine a relative population in each vibration-rotation level from the spectrum, the spectroscopic data summarized by Meredith and Smith[11] and Herbelin and Emanuel[12] were employed. The emission intensity of the $v'J'$—$v''J''$ transition is formulated as

$$I_{v'J',v''J''} = [hc(\omega_{v'J',v''J''})^4/(2J'+1)(\omega_{v',v''})^3] \times S_{J',J''}F_{v'J',v''J''}A_{v',v''}N_{v'J'}, \quad (1)$$

where $\omega_{v'J',v''J''}$ and $\omega_{v',v''}$ are the wavenumbers of the relevant transition and the band center, respectively, and $S_{J',J''}$ represents the contribution of rotation to the dipole matrix element, and $A_{v',v''}$ is the spontaneous emission rate of the vibrational transition, and $N_{v',J'}$ is the population of the $v'J'$ state. In Fig. 2, plots of log $[I_{v'J',v''J''}/(\omega_{v'J',v''J''})^4 S_{J',J''}F_{v'J',v''J''}]$ are shown as a function of $J'(J'+1)$. The rotational equilibrium at room temperature is established in levels of $v'=1$—3 in the reaction system with the Ar pressure of more than 1 Torr. Thus, the rotational distribution in the level v' is described by

$$N_{v'J'} = N_{v'0} \exp[-B_{v'}J'(J'+1)/kT_{rot}]. \quad (2)$$

$N_{v'0}$ is determined by extrapolation of linear lines in Fig. 2, and is denoted hereafter as N_v. The population in the $v=4$ level is estimated from the line intensity of P(3 or 4) line of $v=4\rightarrow3$ transition assuming $T_{rot}=300$ K. As is seen from Fig. 2(b), a rotational non-equilibrium distribution is found in a low pressure reaction system. The observed distribution is almost in accord with that reported by Clough *et al.*,[2] and is partially relaxed due to collisional transitions in the gas phase as well as on the wall of the cell. Since it is difficult to estimate the selection rule for rotational transitions in collisions with the cell wall, the initial distribution may not be determined from the data obtained in the present flow apparatus.

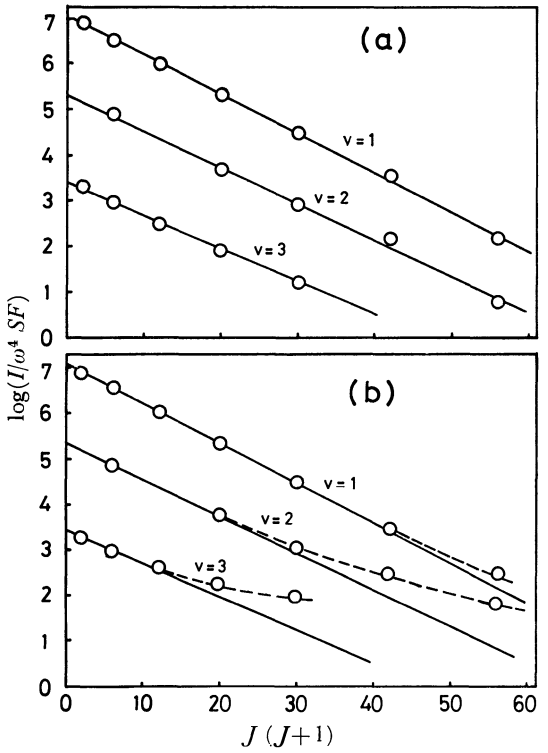

Fig. 2. Plots of $\log(I/\omega^4 SF)$ *vs.* $J(J+1)$.
The emission spectrum is observed at 1.2 kHz modulation in the mixtures of (a) 0.006 Torr CH_2=CF_2+3 Torr Ar and (b) 0.001 Torr CH_2=CF_2+0.2 Torr Ar. The slopes of the solid lines result in the rotational temperature of *ca.* 300 K.

Corresponding to the modulated 253.7 nm radiation intensity, the population in the level v is described as

$$N_v = \bar{N}_v + \tilde{N}_v \exp(i\omega t), \quad (3)$$

where the first term represents the DC component of N_v and the second the AC, and $\tilde{N}_v$ is a complex number to describe the quantity with a phase-delay angle. The kinetic equation for the population in the level v is formulated as follows.

$$dN_v/dt = K_v - R_{v,v-1}N_v + R_{v+1,v}N_{v+1}, \quad (4)$$

where K_v is the production rate of HF† in the level v, and $R_{v,v-1}$ the collisional plus radiative transition rate of $v \rightarrow v-1$. Here, it is assumed that a single quantum transition for the deactivation of HF†. An error caused by this assumption would not be very large, because the initial vibrational populations in higher levels are much smaller than those in lower levels as described later, and thus the contribution of multiple quantum transitions to the population in the relevant level v must be negligible. Equation 4 may be rewritten by the use of Eq. 3 as

$$i\omega\tilde{N}_v = \tilde{K}_v - R_{v,v-1}\tilde{N}_v + R_{v+1,v}\tilde{N}_{v+1}. \quad (5)$$

The imaginary part of this equation results in the equation

$$R_{v,v-1} = \omega(\cot\phi_v) + R_{v+1,v}(\tilde{N}^I_{v+1}/\tilde{N}^I_v), \quad (6)$$

where $\tilde{K}^I_v = 0$ and $\cot\phi_v = \tilde{N}^R_v/(-\tilde{N}^I_v)$ in which subscripts R and I denote the real and imaginary parts, respectively. The real part of Eq. 5 gives the formula

$$\tilde{K}^R_v = \omega(-\tilde{N}^I_v) + (R_{v,v-1}\tilde{N}^R_v - R_{v+1,v}\tilde{N}^R_{v+1}). \quad (7)$$

Thus, if the population in each level is obtained as a function of ω, the relaxation rate $R_{v,v-1}$ and the formation rate $\tilde{K}^R_v$ of HF† in respective vibrational level may be determined.

Vibrational Relaxation of HF†. In Fig. 3, tangent of the phase-delay angle of the R(1) line of the $v=1\rightarrow0$ transition is plotted against the modulation frequency. According to Eq. 6, tan ϕ_{vJ} is almost proportional to ω if the contribution of cascading supply to the population in the vJ level is not large. From Fig. 3, it is found that tan ϕ_{vJ} is not dependent on the Ar pressure if it exceeds 1 Torr, while tan ϕ_{vJ} is reduced at lower pressures of Ar. This means that Ar may not contribute to the deactivation of HF† and that the decrease of tan ϕ_{vJ} at a lower pressure may be attributed to deactivation of HF† by collisions on the wall of the cell. Thus, the later experiments were carried out in the mixture of Ar+F-ethylene at the total pressure of more than 1 Torr which is high enough to avoid the wall-collision effect.

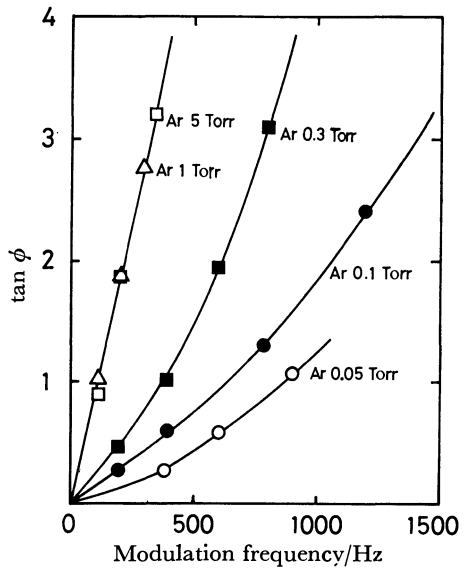

Fig. 3. Tangent of the phase -delay angle of R (1) line of $v=1\rightarrow0$ transition as a function of Ar pressure with the CH_2=CF_2 partial pressure of 0.006 Torr.

3	34±5	11±2	10±2	6.2[b]
4	40	30	—	10[b]

a) Ref. 13. b) Ref. 14.

In the analysis of the data by the use of Eq. 6, multiple quantum transitions are disregarded. However, the magnitude of the second term in the r.h.s. of Eq. 6 does not exceed 10% of the first term and thus, the error due to the above approximation must be much less than 10% and the obtained rate of $R_{v,v-1}$ may be interpreted as $\sum_{\delta\geq1} R_{v,v-\delta}$. The determined rates are plotted as a function of the partial pressure of F-ethylene in Fig. 4. The linear relation indicates that the dominant deactivation process occurs by collisions of HF† with F-ethylene. The slopes of these lines give the deactivation rate constants of HF† as summarized in Table 1. The deactivation of HF† in CH_2=CHF is about three times more efficient than in CH_2=CF_2, and the rate constants of HF($v=1,2$) are of the magnitude similar to those in HF.[13,14] While, larger rate constants of

HF(v=3,4) in F-ethylene than in HF indicate that the resonance effect is improved in higher levels of HF† for the V-V energy transfer from HF† to the CH stretching modes of F-ethylene.

Vibrational Distribution of HF. The observed sets of $|\tilde{N}_v|$ and ϕ_v of HF† produced from six kinds of F-ethylenes are given in Fig. 5. Values of ϕ_v's increase at higher modulation frequencies approaching to 90°, though they are relatively small for higher vibrational levels. The latter fact would be due to larger deactivation rates in higher levels. Contrary to this result, $|\tilde{N}_v|$ of v=1 or 2 is reduced very much as the modulation frequency increases. This means that the vibrational relaxation from upper vibrational levels contributes in large part to populations in lower levels. Thus, in order to determine the initial vibrational distribution, it is necessary to take into proper account the vibrational relaxation effect according to Eq. 7. First, $R_{v,v-1}$ is determined utilizing Eq. 6 and assuming no initial population in levels of $v \geqslant 5$. The data employed to estimate $R_{v,v-1}$ are obtained with a modulation frequency which results in ϕ_v's in the range of 30°—50°. This range is selected to obtain good accuracy of the determined $R_{v,v-1}$'s. Then, the relative magnitude of K_v may be determined by extrapolating the data of Fig. 5 to the case of infinitely fast modulation, where

$\phi_v=90°$. The initial distributions of HF† are plotted also in Fig. 5 and their numerical values are given in Table 2. The values are close to the uncorrected ones of $|\tilde{N}_v|$ obtained at a modulation frequency of *ca.* 5 kHz. This fact rationalizes the procedure to uncover the initial vibrational distribution from the observed relaxed distribution. The initial distribution is almost of the Boltzmann type with 11400, 13700, 7200, 5700, 2200 K for respective parent molecules of CH_2=CHF, CH_3CF=CH_2, CH_2=CF_2, *trans*- and *cis*-CHF=CHF, and CHF=CF_2. The result for CH_2=CF_2 is in good agreement with that reported by Clough *et al.*[2]

Discussion

A schematic diagram explaining the energy levels of initial, intermediate, and final states in the reactions of CH_2=CHF and CH_2=CF_2 is given in Fig. 6. As pointed out already,[7] the triplet state of F-ethylene may be realized in the initial stage of the reaction. The lowest level of the triplet state is estimated by Coggiola *et al.*[15] to be around 420 kJ mol^{-1} from the ground state. Unfortunately, no information is obtained from the present experiment to judge whether the reaction proceeds *via* a second excited intermediate of F-ethylidene or it does through a vibrationally high state of the ground state F-ethylene.[17] Energetically, E_{avail} calculated from ΔH_f's listed in Table 3 must be shared among internal and external degrees-of-freedom of product molecules HF and CH≡CH or CH≡CF. E_{avail} for the reaction of CH_3CF=CH_2 is estimated assuming the products of HF + CH_3C≡CH though no experimental evidence is available. If HF and CH_2=C=CH_2 are produced, E_{avail} is reduced to 389 kJ mol^{-1}. Assuming the Boltzmann distribution of HF† with T_{vib} in Table 2, the amount of the HF† vibrational energy disposed may be calculated, although this procedure might overestimate populations in levels of $v\geqslant 5$. As noted in Table 2, 23—1.7% of E_{avail} is converted to the vibrational energy of HF†. It may be noticed that if a parent molecule involves more hydrogen atoms, a larger fraction of E_{avail} is disposed into the HF† vibration. Shock-tube experiments of thermal decomposition of F-ethylene were carried out to determine the activation energies listed in Table 3. It is only a speculation, however, that the activated state in the thermal decomposition is similar to the critical transition state in the Hg-photosensitized reaction. Two isomers of *cis*- and *trans*-CHF=CHF result in quite the same distribution of HF†. This leads to the conclusion that the critical state just before the decomposition is common to both isomers, and accords with the fact that the quantum yields for the *cis*↔*trans* isomerization are identical for both of the forward and backward directions.[7]

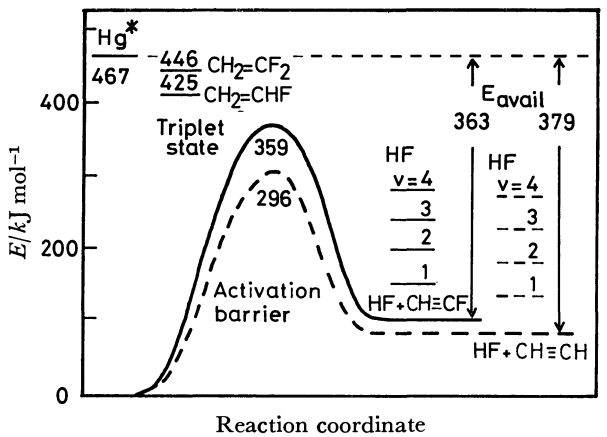

Fig. 6. Schematic potential energy diagram of HF elimination from CH_2=CHF and CH_2=CF_2.
The data source is given in Table 3.

A statistical calculation on the partitioning of E_{avail} in various degrees-of-freedom of product molecules is carried out for the Hg-photosensitized decompositions of F-ethylenes. In the calculation, the following assumptions are postulated. (1) A loose complex of HF and CH≡CH, CH≡CF, or CH_3C≡CH is assumed in the transition state for the decomposition. (2) The complex is formed on the top of the barrier which is realized in the effective potential composed of a long-range attractive potential due to a multipole interaction and the centrifugal force originating from the orbital angular momentum between HF and CH≡CH, CH≡CF, or CH_3C≡CH. (3) The angular momentum of the complex is in thermal equilibrium at the translational temperature of the reaction system. The vibrational state

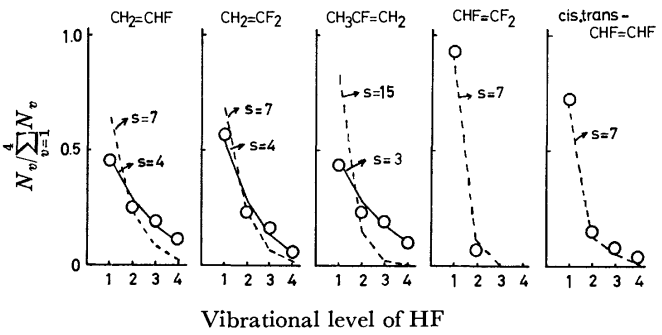

Fig. 7. The observed vibrational distribution (○) of HF† and the statistically calculated one.
Broken lines are the results calculated assuming total number of vibrational modes in a loose complex as active modes and solid lines are those assuming limited number of modes as active modes.

density is calculated by the Whitten-Rabinovitch equation[24] and the ones in another degrees-of-freedom are given in a book of Forst.[25] The calculation is based on the RRKM theory modified by Safron *et al.*[26] The vibrational frequencies of CH≡CH, CH≡CF, and $CH_3C{\equiv}CH$ are taken from Tables of Shimanouchi,[27] and CF≡CF from Ref. 20. The calculated results are shown in Fig. 7 together with the experimental data. The statistical calculation for CH_2=CHF, CH_3CF=CH_2, and CH_2=CF_2 gives much less populations in higher vibrational levels, while the calculation for *cis*- and *trans*-CHF=CHF and CHF=CF_2 results in the values close to the experimental ones.

The fact that the distributions of HF from *cis*-, *trans*-CHF=CHF and CHF=CF_2 are close to the statistical expectation may lead to the conclusion that the reaction scheme is different from that in other species. Strausz *et al.*[7] gave a speculation that CHF=CHF and CHF=CF_2 did not decompose *via* an intermediate of ethylidene type and resulted in primary products: C=CHF and HF in which HF was produced by the αα-elimination directly from excited F-ethylene. If this is the case, E_{avail} must be reduced very much causing less energy disposal to the HF vibration than that observed in the present experiment. According to Strausz *et al.*'s discussion, in the other molecules than CHF=CHF and CHF=CF_2, the decomposition occurs from the corresponding ethylidenes. However, more direct experimental information must be accumulated in order to discuss their speculation. As far as the present experiment is concerned, no positive evidence for their postulate was obtained.

The excess populations of HF† in comparison with the statistical expectation might be attributed to a non-random distribution of E_{avail} among the internal degrees-of-freedom of the CH≡CH·HF and CH≡CF·HF complexes. If the number of oscillating modes s is limited to three or four, the disagreement between the calculation and the experiment disappears as shown in Fig. 7. This may support the conclusion that E_{avail} is locally distributed among particular degrees-of-freedom in the complex. However, the disagreement may be caused by another mechanism. As described in Fig. 6, a potential barrier exists in the course of the decomposition. Hence, a strong force is possible to act upon the separating HF and CH≡CH or CH≡CF while sliding down the barrier. This possibility was suggested by Berry[3] as a cause for the vibrational excitation of HF in his bootstrap model. The similar type of discussion on energy partitioning has been made in F-substitution reactions of Cl- or Br-ethylenes. McDonald and coworkers[28] have made IR emission measurements of various modes of F-ethylenes produced, and found statistical distributions if a potential barrier does not exist on the passage to the reaction exit and non-statistical distributions if a barrier exists.

Table 3. Heats of formation ΔH_f, activation energies for thermal decomposition E_a, triplet energy level E_t of F-ethylenes and related species

Species	ΔH_f, 298 K/ kJ mol^{-1}	E_a/kJ mol^{-1}	E_t[h]/kJ mol^{-1}
CH_2=CHF	−135.2[a]	297[g]	426
CH_2=CF_2	−334.4[b]	359[e]	447
cis-CHF=CHF	−330[c]	288[e]	414
trans-CHF=CHF	−330[c]	276[e]	405
CHF=CF_2	−49[b]	—	426
CH_3CF=CH_2	−159[c]	—	—
CH≡CH	226.51[d]		
CH≡CF	42[e]		
CF≡CF	21[d]		
$CH_3C{\equiv}CH$	185.1[f]		
HF	−272.3[d]		

a) Ref. 17. b) Ref. 18. c) Estimated by a method described in Ref. 19. d) Ref. 20. e) Ref. 21. f) Ref. 22. g) Ref. 23. h) Ref. 15.

In Table 3, it is seen that the heat of the HF elimination reaction of CHF=CF_2 is much larger than those of CH_2=CHF and CH_3CF=CH_2, so that the barrier height for the backward reaction, $E_a-\Delta H$, is reduced to *ca.* 80 kJ mol^{-1} in the reaction of CHF=CF_2. Since no experimental data of ΔH_f is available for *trans*- and *cis*-CHF=CHF, an approximate method,[19] in which a mean contribution of each bond in F-ethylene molecules to ΔH_f is empirically estimated, is adopted to result in a common value of ΔH_f for three compounds of *trans*- and *cis*-CHF=CHF and CH_2=CF_2. However, $-\Delta H_f$ of CHF=CHF is probably between those of CH_2=CF_2 and CHF=CF_2, so that $E_a-\Delta H$ of CHF=CHF may not be of a smaller magnitude than that of CH_2=CF_2. Thus, it would be reasonable that the observed vibrational distributions of HF formed from *trans*- and *cis*-CHF=CHF and CHF=CF_2 are close to those calculated statistically, while the other F-ethylenes produce HF† with non-statistical vibrational distributions due to energy release through high exit barriers.

The above findings are supported by the crossed molecular beam reactions studied by Farrar and Lee.[29] Recently, they report a result slightly different from the IR chemiluminescence measurement of McDonald and coworkers. Non-statistical velocity distributions of products are found for both of CH_2=CHBr+F and +Cl reactions,[30] of which the product vibrational

distribution is statistical in the former reaction and nonstatistical in the latter on the basis of the IR emission measurement. If a molecule activated by a collision with a reactive or excited atom has a significant amount of energy exceeding a barrier height, the resulting short lifetime of the activated molecule may result in a non-statistical velocity distribution of product molecules. While, an intramolecular vibrational relaxation changes a non-statistical distribution to a statistical one before product molecules emit IR photons. This is an explanation for the discrepancy between the two experiments. However, since HF has discrete vibration-rotation levels in the present energy region and an intramolecular relaxation is impossible, the distribution observed in this experiment must be interpreted as the ones at the reaction exit. Thus, the observed vibrational distribution of HF is caused mainly by a dynamical force which acts on HF separating from CH≡CH or CH≡CF while sliding down from the barrier top.

Oxidation of Nitrotoluenes with Electro-generated Superoxide Ion

Hiromitsu SAGAE, Masamichi FUJIHIRA, Henning LUND,† and Tetsuo OSA*
Pharmaceutical Institute, Tohoku University, Aobayama, Sendai 980
(Received December 20, 1979)

The oxidation of *o*-, *m*-, and *p*-nitrotoluenes with electro-generated superoxide ion in dimethylformamide was studied using cyclic voltammetry and controlled potential macro-electrolysis. The electrochemical reduction of oxygen in the presence of *o*- and *p*-nitrotoluenes yielded the corresponding carboxylic acids because the methyl groups in these derivatives are activated by the nitro group. An intermediate in these oxidations should be the corresponding nitrobenzaldehyde. The reaction mechanism is discussed.

Recently superoxide ion, $O^{\cdot}$, has attracted a great deal of attention of organic and biological chemists, because it is novel activating reagent for organic synthesis and is one of the most important activated forms of molecular oxygen in biological systems.[1-3] Superoxide ion is produced by the electrochemical reduction of oxygen dissolved in non-aqueous solvents, such as pyridine, acetonitrile, and dimethylformamide (DMF) at −0.85 V *vs.* silver-silver chloride (Ag/AgCl)[2,3] as shown in Eq. 1:

$$O_2 + e \rightleftarrows O_2^{\cdot} \quad (1)$$

Alkali metal superoxides, such as potassium and sodium superoxides, are well known but their insolubility in the usual organic solvents makes them of little preparative use.[4] The electrochemical method is experimentally more convenient because the continuous generation of superoxide ion is possible on the electrode and the solubility of the superoxide ion in the presence of tetraethylammonium cations of the supporting electrolyte is sufficiently high.[5]

We have previously reported preliminary results on the reaction of nitrotoluenes and nitroethylbenzene with electro-generated superoxide ion.[6] In this paper, we describe in detail the reaction of nitrotoluenes with electro-generated superoxide ion in DMF solution, using macro-electrolysis and cyclic voltammetry.

There are many reports[7-10] on the oxidation of nitrotoluenes to nitrobenzoic acids using various oxidizing reagents and conditions, such as cobaltic salts,[7a] nitric acid,[8a] and basic condition.[7b] However, the oxidation with superoxide ion has not previously been reported. Advantageous characteristics of oxidation by electro-generated superoxide ion are two-fold; the oxidation proceeds under mild conditions and does not require any oxidizing chemicals. Elucidation of the reaction mechanism of the oxidation of nitrotoluenes with electro-generated superoxide ion should also prove to be useful in understanding the metabolism of such compounds in certain insects.[11]

Experimental

Materials. DMF was dried over anhydrous $CuSO_4$ for 24 h and then distilled under reduced pressure. Further purification was achieved by passage through a column of molecular sieves (4A 1/16) and activated alumina (both pre-treated by heating at 400 °C). Tetraethylammonium perchlorate (TEAP) was synthesized and purified in the usual manner.[12] Nitrotoluene, *p*-nitrobenzaldehyde, and nitrobenzoic acids of E. P. grade were purchased commercially (Wako Pure Chemical Industries) and were recrystallized before use.

Cyclic Voltammetry. Cyclic voltammetry was carried out in DMF solution containing 0.1 M (1 M=1 mol dm^{-3}) TEAP as a supporting electrolyte on a hanging mercury drop electrode (HMDE). The cathode potentials were referred to Ag/AgCl, aq 1 M KCl. Cyclic potential sweeps were generated by an NF Circuit Design Block FG-100AD function generator in conjunction with a potentiostat which was self-made according to the literature.[13]

Controlled Potential Macro-electrolysis. For controlled potential macro-electrolysis, a three compartment cell was employed in which cathodic and anodic chambers were separated by two porous glass disks and a reference electrode with a Luggin capillary was put near the cathode. A mercury pool with a surface area of 16 cm^2 was used as the cathode, and platinum gauze as the anode. The electrolyte solution (0.1 M TEAP) of 60 cm^3 containing 0.06 M substrate was placed in the cathodic chamber, 40 cm^3 of the electrolyte solution in the anodic chamber, and 10 cm^3 of the electrolyte solution in the middle chamber. Oxygen was bubbled through the cathode. The cathode potential was controlled with a Yanagimoto VE-8 controlled potential electrolyzer. The quantity of electricity passed was measured with a copper coulometer.

Separation of Nitrobenzoic Acid. The main products of the electrolyses, nitrobenzoic acids, were separated and identified by the following procedure. The catholyte was poured into 200 cm^3 of 10% aqueous $NaHCO_3$ solution. The starting material and products other than nitrobenzoic acids in this solution were removed by extraction with CH_2Cl_2. Since nitrobenzoic acids could not be precipitated by acidification of the aqueous layer due to the presence of DMF in the water, the aqueous layer was evaporated to dryness *in vacuo* to remove the DMF. The resulting solid was dissolved in water and acidified with 5% aqueous HCl to precipitate the nitrobenzoic acids. The products were purified by recrystallization from alcohol and identified as the expected carboxylic acids by comparing their melting points and infrared spectra (IR) with those of authentic samples. As described later, the peak potentials of the cyclic voltammograms of these products were also found to agree with those of the authentic carboxylic acids.

p-Nitrobenzoic Acid from p-*Nitrotoluene.* The macro-electrolysis of oxygen in the presence of 0.5 g of *p*-nitrotoluene was carried out at −0.9 V *vs.* Ag/AgCl. The electrolysis time was *ca.* 24 h and the total amount of charge passed was *ca.* 2000 C. About 0.22 g of *p*-nitrobenzoic acid was obtained using the method mentioned above, and about 0.11 g of *p*-nitrotoluene was recovered. The IR spectrum of the product

† On leave from Department of Organic Chemistry, University of Aarhus, DK-8000, Aarhus C, Denmark.

agreed with that of authentic *p*-nitrobenzoic acid. Mp 241—242 °C (lit, 242 °C)[14]

o-*Nitrobenzoic Acid from* o-*Nitrotoluene.* The macro-electrolysis of oxygen in the presence of 0.5 g of *o*-nitrotoluene was carried out at −0.9 V *vs.* Ag/AgCl. The electrolysis time was *ca.* 24 h and the total amount of charge passed was *ca.* 2050 C. About 0.21 g of *o*-nitrobenzoic acid was obtained using the method mentioned above, and about 0.12 g of *o*-nitrotoluene was recovered. The IR spectrum of the product agreed with that of authentic *o*-nitrobenzoic acid. Mp 146—147 °C (lit, 147—148 °C)[14]

p-*Nitrobenzoic Acid from* p-*Nitrobenzaldehyde.* The macro-electrolysis of oxygen in the presence of 0.5 g of *p*-nitrobenzaldehyde was carried out at −0.9 V *vs.* Ag/AgCl. The electrolysis time was *ca.* 24 h and the total amount of charge passed was *ca.* 1100 C. About 0.35 g of *p*-nitrobenzoic acid was obtained using the method mentioned above, and 0.08 g of *p*-nitrobenzaldehyde was recovered. The IR spectrum of the product agreed with that of authentic *p*-nitrobenzoic acid. Mp 241—242 °C (lit, 242 °C)[14]

m-*Nitrobenzoic Acid.* *m*-Nitrobenzoic acid was not obtained from the electrolysis of oxygen in the presence of *m*-nitrotoluene at −0.9 V *vs.* Ag/AgCl.

Results and Discussion

Controlled Potential Macro-electrolysis. The reduction peak potentials of nitrotoluenes, together with those for oxygen, nitrobenzoic acids, and *p*-nitrobenzaldehyde, in cyclic voltammetry are listed in Table 1.

Table 1. Reduction peak potentials of nitrotoluenes, *p*-nitrobenzaldehyde, and nitrobenzoic acids

Compound	E_p^1	E_p^2	E_p^3
o-Nitrotoluene	−1.23	−1.92	
m-Nitrotoluene	−1.14	−1.75	
p-Nitrotoluene	−1.10	−1.85	
p-Nitrobenzaldehyde	−0.82	−1.35	
o-Nitrobenzoic acid	−0.90	−1.20	−1.73
m-Nitrobenzoic acid	−0.92	−1.23	−1.75
p-Nitrobenzoic acid	−0.80	−1.16	−1.70
Cf. oxygen	−0.85	−1.75	

E/V *vs.* Ag/AgCl, solvent: DMF, supporting electrolyte: TEAP, electrode: HMDE.

The controlled potential macro-electrolyses of oxygen in the presence of nitrotoluenes were carried out at −0.9 V *vs.* Ag/AgCl in DMF solution. At −0.9 V *vs.* Ag/AgCl, only oxygen was reduced, to the superoxide ion, while nitrotoluenes were not reduced. The results of the electrolyses are collected in Table 2. *p*-Nitrotoluene reacted with electro-generated superoxide ion to yield *p*-nitrobenzoic acid (Eq. 2). Controlled potential macro-electrolysis of oxygen in the presence of *p*-nitrobenzaldehyde was carried out because *p*-nitrobenzaldehyde is predicted to be an intermediate in the oxidation of *p*-nitrotoluene to *p*-nitrobenzoic acid. As expected, the reaction of *p*-nitrobenzaldehyde with superoxide ion yielded *p*-nitrobenzoic acid fairly readily (Eq. 5), although *p*-nitrobenzaldehyde was not isolated when *p*-nitrotoluene was oxidized. These results indicated that the produced *p*-nitrobenzaldehyde reacts with electro-generated superoxide ion immediately, or is reduced at the electrode directly, owing to a more positive reduction potential (−0.82 V *vs.* Ag/AgCl) than that used for the controlled potential electrolysis. *o*-Nitrobenzaldehyde is also considered to be a most probable intermediate in the reaction of *o*-nitrotoluene with superoxide ion.

In order to investigate the positional effect of the nitro group attached to the benzene ring, macro-electrolyses of oxygen in the presence of *o*- and *m*-nitrotoluene were carried out. *o*-Nitrobenzoic acid was obtained from *o*-nitrotoluene, while *m*-nitrobenzoic acid was not obtained from *m*-nitrotoluene (Eqs. 3 and 4). This result indicates that the electro-generated superoxide ion reacts only with a methyl group which is activated by the nitro group attached to the benzene ring, to yield the corresponding carboxylic acid.

Cyclic Voltammetry of Nitrotoluenes. Cyclic voltammetry of nitrotoluenes, *p*-nitrobenzaldehyde, and *p*-nitrobenzoic acids in the presence and in the absence of oxygen was carried out in order to investigate the reaction mechanism. Cyclic voltammograms of *p*-nitrotoluene in the presence and in the absence of oxygen, together with that of oxygen, in DMF solution as shown in Fig. 1. In the cyclic voltammogram of oxygen, the first reversible reduction wave at −0.85 V *vs.* Ag/AgCl corresponded to the one-electron reduction of oxygen to the superoxide ion. The second irreversible reduction wave at −1.75 V *vs.* Ag/AgCl corresponded to the further one-electron reduction of superoxide ion to the peroxide ion, O_2^{2-}, followed by protonation. In the cyclic voltammogram of *p*-nitrotoluene under a nitrogen atmosphere, a reversible reduction wave at −1.1 V *vs.* Ag/AgCl and an irreversible reduction wave at −1.8 V *vs.* Ag/AgCl appeared. In the presence of oxygen, the first wave and the second wave are the corresponding first reduction waves of oxygen and *p*-nitrotoluene respectively. The second wave of oxygen

Table 2. Formation of carboxylic acids from nitrotoluenes

Starting material	Amount of nitrobenzoic acid produced/g	Yield/%	Selectivity/%	Current[a] efficiency/%
o-Nitrotoluene	0.21	45 (45—50)[b]	42 (42—96)[b]	52 (40—62)[b]
m-Nitrotoluene	undetected	—	—	—
p-Nitrotoluene	0.22	56 (50—60)	44 (44—95)	55 (45—65)
Cf. p-nitrobenzaldehyde	0.35	68 (55—70)	70 (70—90)	49 (49—65)

a) The current efficiency calculated as the electrons of 4 Faradays are necessary to obtain 1 mol of the corresponding acid from nitrotoluene, and 2 Faradays from nitrobenzaldehyde. b) The electrolysis was carried out several times and the range of the values are shown in parentheses.

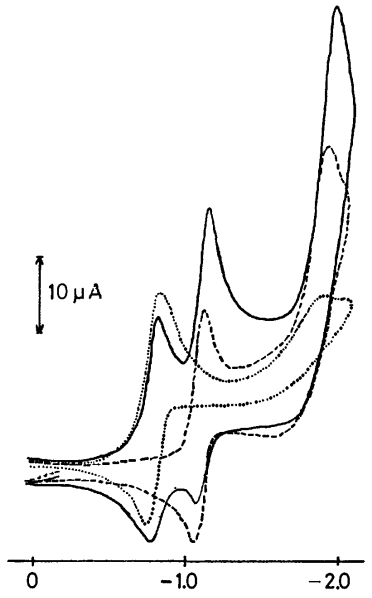

Fig. 1. Cyclic voltammograms of *p*-nitrotoluene. Concentration of *p*-nitrotoluene: *ca.* 10mM, electrolyte: 0.1 M TEAP/DMF, electrode: HMDE, sweep rate: 0.1 V s^{-1}, ------: in the absence of oxygen, ——: in the presence of oxygen. *Cf.* ·····: cyclic voltammogram of oxygen.

overlapped with the second wave of *p*-nitrotoluene at −1.8 V *vs.* Ag/AgCl. In this case no other reduction wave appeared except those for oxygen and *p*-nitrotoluene. Cyclic voltammetry of *o*- and *m*-nitrotoluenes in the presence and in the absence of oxygen gave similar results to those for *p*-nitrotoluene.

Cyclic Voltammetry of Nitrobenzoic Acids. The cyclic voltammogram of *p*-nitrobenzoic acid in DMF solution under a nitrogen atmosphere is shown in Fig. 2. The first and third reduction waves, whose reduction peak potentials are −0.8 V and −1.7 V *vs.* Ag/AgCl

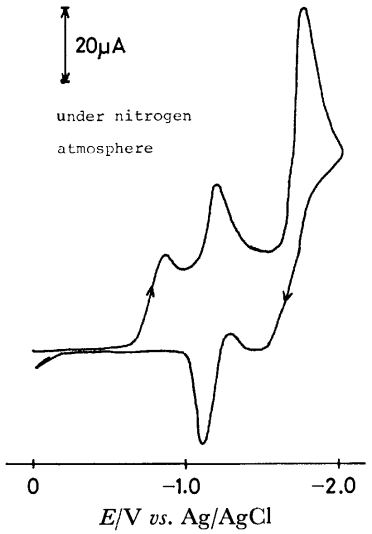

Fig. 2. Cyclic voltammogram of *p*-nitrobenzoic acid. Concentration of *p*-nitrobenzoic acid: *ca.* 10 mM, electrolyte: 0.1 M TEAP/DMF, electrode: HMDE, sweep rate: 0.1 V s^{-1}.

respectively, are irreversible. The second reduction wave is reversible with a reduction peak potential of −1.1 V *vs.* Ag/AgCl. Anomaly in shape of the corresponding reoxidation wave at *ca.* −1.1 V of the second reduction wave can be interpreted by the streaming phenonmenon, observed initially by Santhanam and Bard,[15] which occurs during oxidation of radical anion in cyclic voltammetric experiments. The cyclic voltammograms of *o*- and *m*-nitrobenzoic acids under a nitrogen atmosphere are similar to that of *p*-nitrobenzoic acid, and their reduction peak potentials are collected in Table 1.

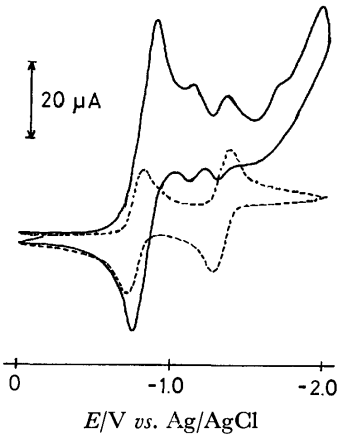

Fig. 3. Cyclic voltammograms of *p*-nitrobenzaldehyde. Concentration of *p*-nitrobenzaldehyde: *ca.* 10 mM, electrolyte: 0.1 M TEAP/DMF, electrode: HMDE, sweep rate: 0.1 V s^{-1}, ------: in the absence of oxygen, ——: in the presence of oxygen.

Cyclic Voltammetry of p-*Nitrobenzaldehyde.* Cyclic voltammetry of *p*-nitrobenzaldehyde, expected to be an intermediate in the oxidation of *p*-nitrotoluene, in the presence and in the absence of oxygen was carried out. The results are shown in Fig. 3. Two reversible reduction waves are observed under a nitrogen atmosphere with reduction peaks at −0.82 V and −1.35 V *vs.* Ag/AgCl. In the presence of oxygen a reversible reduction wave at −1.1 V and an irreversible reduction wave at −1.65 V *vs.* Ag/AgCl appeared as well as those for oxygen and *p*-nitrobenzaldehyde. These new reduction peak potentials corresponded to those of the second and third waves of *p*-nitrobenzoic acid. The first reduction wave of *p*-nitrobenzoic acid overlapped with the first wave of *p*-nitrobenzaldehyde and oxygen. This result indicates that *p*-nitrobenzoic acid was formed during cyclic voltammetry of *p*-nitrobenzaldehyde.

Cyclic Voltammetry of the Catholyte. In the course of macro-electrolysis of oxygen in the presence of *p*-nitrotoluene, cyclic voltammetry of the catholyte was carried out. The result is shown in Fig. 4. Since the *p*-nitrotoluene remained as a major substrate in the solution, two large reduction waves observed at −1.1 V and −1.9 V *vs.* Ag/AgCl should be due to *p*-nitrotoluene. The reduction waves at *ca.* −0.8 V and *ca.* −1.6 V *vs.* Ag/AgCl corresponded to the first and third

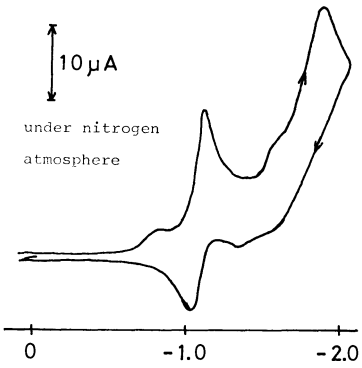

Fig. 4. Cyclic voltammogram of the catholyte in the course of the electrolysis in the presence of *p*-nitrotoluene. Electrolyte: 0.1 M TEAP/DMF, electrode: HMDE, sweep rate: 0.1 V s^{-1}.

reduction waves of *p*-nitrobenzoic acid. The second reduction wave of *p*-nitrobenzoic acid overlapped with the first reduction wave of *p*-nitrotoluene. In the cyclic voltammogram of *p*-nitrotoluene in the presence of oxygen (solid line in Fig. 1), no reduction wave appeared other than those for oxygen and *p*-nitrotoluene. These results indicate that *p*-nitrobenzoic acid was not formed during cyclic voltammetry, and consequently the reaction rate of the superoxide ion with *p*-nitrotoluene is deduced to be slow. Since the reduction wave corresponding to *p*-nitrobenzaldehyde did not appear in the course of macro-electrolysis in the presence of *p*-nitrotoluene as shown in Fig. 4, it is assumed that the produced *p*-nitrobenzaldehyde reacted instantaneously with electro-generated superoxide ion to yield *p*-nitrobenzoic acid. In the cyclic voltammogram of *p*-nitrobenzaldehyde in the presence of oxygen (solid line in Fig. 2), two reduction waves corresponding to those of *p*-nitrobenzoic acid appeared. The reaction rate of superoxide ion with *p*-nitrobenzaldehyde is therefore faster than that of superoxide ion with *p*-nitrotoluene.

Scheme 1.

Reaction Scheme for the Oxidation. A reaction scheme for the oxidation of *p*- and *o*-nitrotoluenes with electro-generated superoxide ion can be suggested as shown in Scheme 1. One of the hydrogen atoms of the methyl group of the *o*- or *p*-nitrotoluene is abstracted by the electro-generated superoxide ion in DMF solution (Eq. 6). The resulting species reacts with oxygen (Eq. 7) and is further reduced to the peroxy anion by superoxide ion or by an electron from the electrode (Eq. 8). In a basic solvent such as DMF, release of hydroxy anion from this peroxy ion, which yields aldehyde (Eq. 9), occurs predominantly, rather than proton abstraction from the environment by the peroxy anion.[16] This hydrogen abstraction reaction by superoxide ion is similar to the reaction of the superoxide ion with 9,10-dihydroanthracene to yield anthraquinone.[17] The produced nitrobenzaldehyde can be reduced with superoxide ion as well as from the electron uptake at the electrode directly owing to its more positive reduction peak potential (−0.82 V *vs.* Ag/AgCl) (Eq. 10), and the formed anion radical reacts oxygen to produce hydrogen percarboxylic acid anion radical (Eq. 11). As the possible another route, superoxide ion reacts directly carbonyl group to yield addition product,[18] that is, hydrogen percarboxylic acid anion radical (Eq. 12). The nitrobenzaldehyde also reacts with superoxide ion instantly to yield an acyl radical (Eq. 13), which reacts with hydrogen peroxide anion (Eq. 14). The percarboxylic acid anion radical formed by Eqs. 11, 12, and 14 releases hydroxide anion, yielding the carboxyl radical (Eq. 15). This carboxyl radical is finally reduced to carboxyl anion by the superoxide ion or by an electron from the electrode (Eq. 16).

In conclusion, *o*- and *p*-nitrotoluene are considered to react with electro-generated superoxide ion in DMF solution to yield the corresponding nitrobenzoic acid *via* the nitrobenzaldehyde (Eq. 17) as described above.

In Situ Measurement of Electrode Surface Change by Photoacoustic Spectroscopy

Hideki MASUDA, Akira FUJISHIMA,* and Kenichi HONDA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received December 25, 1979)

Photoacoustic spectroscopy (PAS) was used for the study of electrode-electrolyte interfaces *in situ*. The design of the PAS cell and the experimental procedure are given. The change in absorption at the interface during electrochemical reaction at Au electrodes, as measured by PAS technique, is described.

In resent years, there has been much interest in photoacoustic spectroscopy (PAS)[1-4] as a new tool for the investigation of the surface condition of various materials. One of the advantages of PAS is that absorption spectra can be obtained even for solid samples that are difficult to measure by conventional spectroscopic techniques on account of light scattering problems. We have noted this characteristics of PAS from the viewpoint of spectro-electrochemistry, and attemped to apply PAS to studies of the electrode surface *in situ*. Generally, spectro-electrochemical behavior is measured by using an electrode that is optically transparent,[5,6] internally reflective,[7,8] or specularly reflective,[9,10] by ellipsometric techniques,[11,12] and so on, for the purpose of characterizing the electrode-solution interfaces, or measuring the kinetic behavior of electrode reaction. It is expected that PAS will be more advantageous than conventional spectroscopic techniques in observing the electrode-solution interfaces, because preparation of a sample electrode is not difficult, that is, the surface does not need to be highly polished. Some work has been reported on the application of PAS to electrochemical studies,[13,14] but PAS was used in these cases to measure the absorption spectra of the electrode surface in the air after removal from the electrolysis cell. Here, we have applied PAS to study the surface behavior of metal electrode *in situ*.

In a conventional PAS cell, a sample is placed inside a closed chamber containing a suitable gas, and is illuminated through a window. For *in situ* investigation of an electrode surface that is in contact with the solution, such a cell can not be used in the usual way. Another technique for measuring electrode surfaces by PAS used a piezo electric pressure transducer,[15,16] but this method seems unsuitable for a solid-liquid system, especially an electrochemical one in which gas evolution may occur by electrolysis because the presence of bubbles in the solution would adversely affect the acoustic signal.

Therefore we constructed another type of cell, in which the sample was mounted outside the gas chamber. Heat on the surface of the sample resulting from radiationless transition due to irradiation with light is transported to the rear of the sample, causing the sealed gas to expand. Until now this technique has been scarcely used, because it has been thought that in the case of relatively thick samples the photoacoustic signal in this type of cell is liable to decrease during the conduction of heat from the active surface to the rear. As exceptional examples, Kanstad *et al.* measured the middle infrared region PAS spectra of specimens kept on a thin Al plate called open membrane spectrophone,[17] and Adams *et al.* applied this type of cell to determine the thermal diffusibility of thin polymer films.[18] Since even in these cells, the photoacoustic signals did not seem to decrease significantly, this technique can be put to practical use. The present work is concerned with the photoacoustic signal change in electrode-solution interfaces in the course of the electrode reaction, oxidation of an Au electrode or electrochemical deposition of other metals on the Au electrode.

Experimental

Figure 1 shows detail of the PAS cell employed in this study. The PAS cell was constructed from acrylic resin and used for spectroscopic measurement in electrolytic solutions. This PAS cell was 3.0 cm in width and 7.0 cm in height, and its internal volume was approximately 0.4 cm^3. An electret condenser microphone (Sony Model ECM-150) was employed in this cell as a pressure transducer. The working electrode was a flat gold plate 0.1 mm thick and 7.0 mm in diameter, which was polished to a bright surface with 3 μm alumina powder and then mounted on one side of the PAS cell by a silicone O-ring to ensure an air-tight seal. In this work, a PAS cell of the ordinary type was also used as a control for the results obtained using the cell shown in Fig. 1.

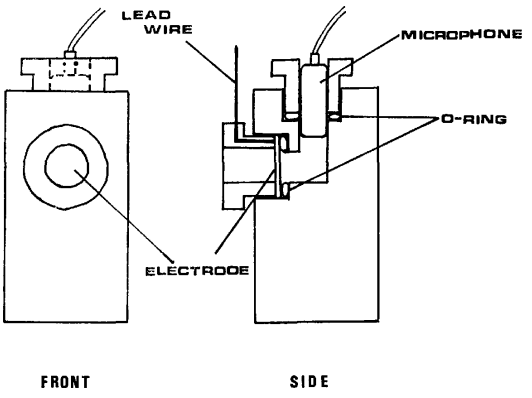

Fig. 1. PAS cell and sample arrangement.

Figure 2 shows the experimental set up. The light source was either a 500 W Xe lamp (Ushio Electric) or 3 W Ar ion laser (Spectra Physics Model 164). In measuring the photoacoustic spectrum using the Xe lamp, the radiation was focused on the electrode surface using a convex lens through a series of 10 nm bandwidth interference filters (Koshin Kogaku) and the light intensities of each wavelength were

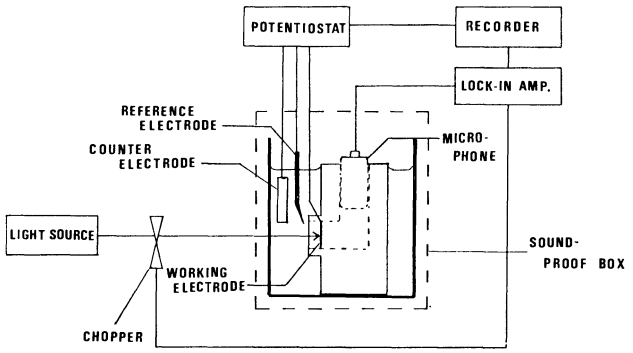

Fig. 2. Experimental set up for PAS–electrode system.

normalized by comparison with spectrum of carbon measured under identical conditions. The diameter of the laser beam was approximately 1.5 mm. The light beam was chopped mechanically by light chopper and the photoacoustic signal detected by the microphone was fed to a lock-in amplifier (Brookdeal Model 9501, or Nihon Bunko Model LA-120). The measurement was carried out using a chopping frequency of 125 Hz by considering both of the light power per pulse and the frequency characteristics of the microphone employed in this work. Electrolysis was carried out in a pyrex cell which had an optically flat window. This cell was held in a lead box to reduce external acoustic noises. A potentiostat (Nikko Keisoku Model NPGS-301) with a potential programmer (Nikko Keisoku Model NPS-2) was used to obtain current-potential curves. A saturated calomel electrode (SCE) was used as a reference electrode and the counter electrode was of platinum. A coulometer (Kowa Electronics Model DCM-150) was used to determine the total charge. The influence upon the photoacoustic signal of temperature changes resulting from electrode reactions, which is known as the electrochemical peltier effect,[19] was considered to be negligible because only the AC component of temperature change was detected by the lock-in amplifier. Current-potential, photoacoustic signal-potential and photoacoustic signal-charge curves were recorded on a X-Y-Y′ recorder (Riken Denshi Model D-72 or Yokokawa Model 3078).

Results and Discussion

Open Membrane Type Photoacoustic Cell. Before a measurement with the PAS cell shown in Fig. 1, we checked whether this cell could work well or not. Then, the photoacoustic signal at the open membrane type cell (Fig. 3A, the same type as that in Fig. 1) was compared with that of the conventional type cell

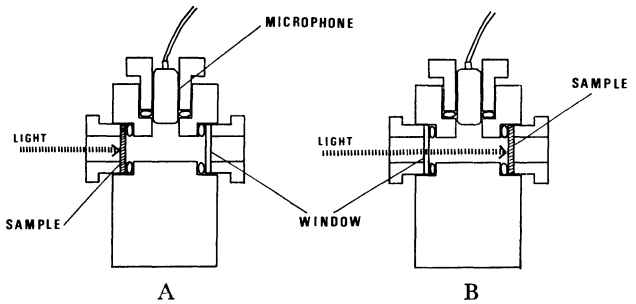

Fig. 3. Schematic diagram for measurement of signal magnitude. A) Open membrane type, B) conventional type.

Table 1. Comparison of the magnitudes of signals of PAS
(Irradiation by Ar ion laser, 0.5 W, 514.5 nm, 125 Hz)

	(A) Open membrane type	(B) Conventional type
Carbon (0.5 mm)	17 (μV)	44 (μV)
Au plate (0.1 mm)	19 (μV)	35 (μV)
Au plate (0.05 mm)	42 (μV)	35 (μV)

(Fig. 3B), where ways of irradiation to the sample were different. Table 1 shows the magnitude of the photoacoustic signal for a glassy carbon pellet and Au plates with the both cells. The signals were affected by the condition of the surfaces, especially in that of the Au plates. However, for the samples tested, the magnitude of the photoacoustic signals of the open membrane type cell was not significantly smaller than those of the conventional type cell. Further, for the thin Au plate (0.05 mm) the signal was observed to be larger than that of the conventional type cell, perhaps because in the latter illuminating intensity decreased on account of reflection at the glass window.

Even when the open membrane cell was immersed in the solution so that the sample surface was in contact with the solution, the photoacoustic signals did not decrease greatly. The signal ratio S(solution)/S(air) was approximately 0.9 in the case of the Au plate. These results show that the open membrane type PAS cell is well suited for practical use. Therefore, results shown below were obtained by use of the PAS cell shown in Fig. 1 (*i.e.* the open membrane type PAS cell).

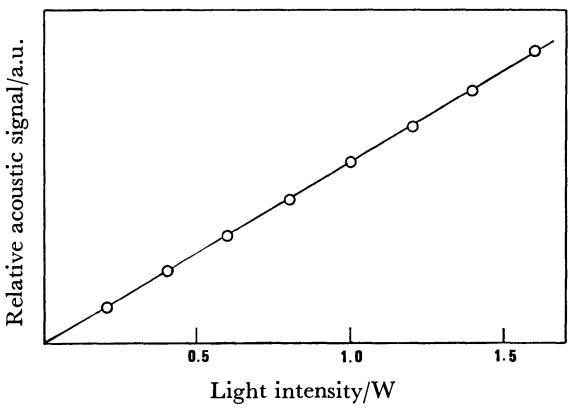

Fig. 4. Relationship between signal magnitude and incident light intensity for Au plate.

Figure 4 shows the relationship between the magnitude of the acoustic signal and the incident light intensity for the Au plate, where irradiation was carried out using the Ar ion laser (514.5 nm). The plot of the PAS signal against light intensity is relatively linear, and we consider that the photoacoustic signal does not appear to reach saturation even in high intensity region observed in this study.

Measurement of the Electrochemical Deposition of Cu on Au Electrode. Figure 5 shows the photoacoustic spectra

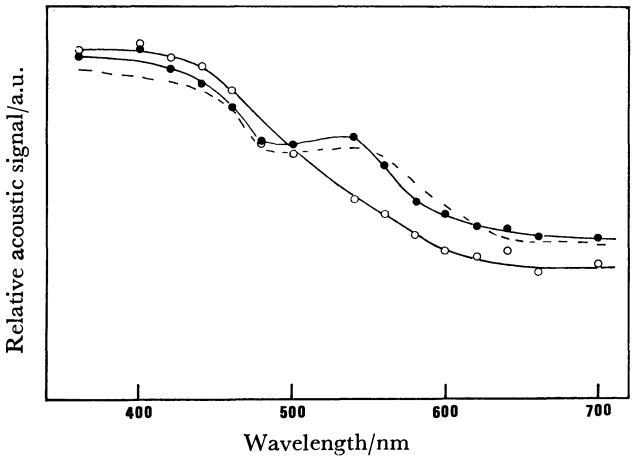

Fig. 5. Photoacoustic spectra of Au electrode; before (-○-), after (-●-) electrotysis in 5×10^{-3} M Cu^{2+} and of Cu plate (------).

of the Au electrode before and after electrolysis at −0.2 V *vs.* SCE in 1 M $HClO_4$ (1 M=1 mol/dm^3) containing 5×10^{-3} M Cu^{2+}, along with that of a 0.05 mm thick Cu plate, which was measured separately. Since the spectrum after electrolysis agreed with that of the Cu plate, it indicates that the Au electrode surface was covered with a Cu layer.

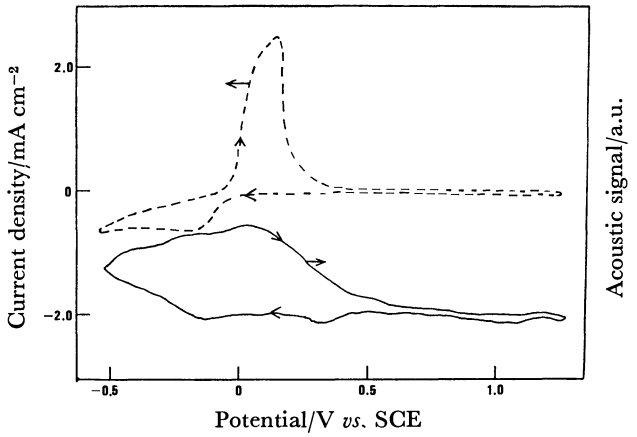

Fig. 6. Photoacoustic signal *vs.* potential (——) and current *vs.* potential (------) curves of Au electrode in the presence of Cu^{2+} ion.
5×10^{-3} M Cu^{2+}, 1 M $HClO_4$, potential sweep rate 40 s/V, λ=514.5 nm.

Figure 6 is a plot of the photoacoustic signal *versus* potential and current *versus* potential curves in the same electrolyte solution as in Fig. 5. The result in Fig. 5 shows that the light absorption of Cu is larger than that of Au when irradiated by a 514.5 nm Ar ion laser. The reduction current around −0.1 V in the cathodic sweep was due to the electrochemical deposition of Cu, and at almost the same potential it was observed that the photoacoustic signal began to increase. On the other hand, the anodic current peak at 0.20 V was attributed to the dissolution of the Cu layer. At that time the photoacoustic signal began to decrease

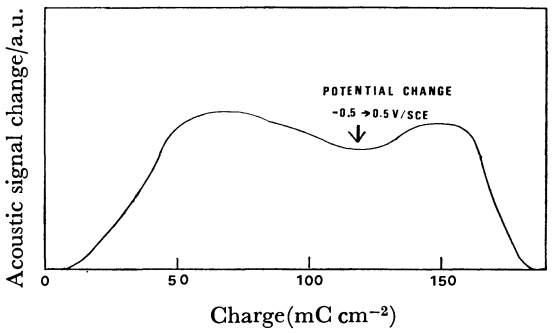

Fig. 7. Relative change in photoacoustic signal *vs.* charge for electrochemical deposition of Cu.
5×10^{-3} M Cu^{2+}, 1 M $HClO_4$, potential −0.5 V and +0.5 V *vs.* SCE. λ=514.5 nm.

and then returned to the value for the bare Au surface.

Figure 7 shows the change in the photoacoustic signal relative to the electric charge associated with the electrochemical deposition of Cu on the Au surface at −0.5 V. The photoacoustic signal increased in proportion to the charge and then became the constant value at about 50 mC/cm^2. At this charge, the thickness of the deposited copper layer was estimated to be 20 nm, assuming that the layer was uniform. The linear relationship between the photoacoustic signal and the charge can be interpreted on the basis of the McIntyre-Aspnes approximation,[20] in which the change in reflectivity is proportional to the thickness of thin film formed. In the flat region the photoacoustic signal would seem to be the result of absorption at the Cu layer alone. As shown in Fig. 7, the photoacoustic signal decreased a little in the region where the deposited layer became thicker. The reason for this is uncertain, but one can assume that one of the reasons is an increase in the surface heat radiation as the rough copper layer is formed. In anodic reaction, the photoacoustic signal decreased on a reverse path until it reached the value for the bare Au surface.

In *in situ* measurements such as those in Figures 6 and 7, the time constant of the phase sensitive detection is one of the significant factors. When the time constant is large compared with the reaction rate, a time lag is liable to be caused in the photoacoustic signal change.

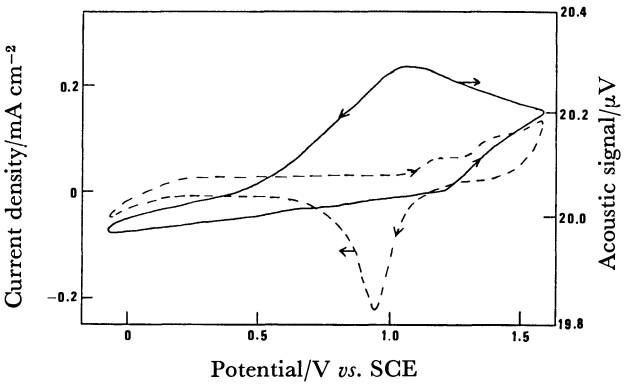

Fig. 8. Photoacoustic signal *vs.* potential (——) and current *vs.* potential (------) curves of Au electrode.
1 M $HClO_4$, potential sweep rate 40 s/V, λ=514.5 nm.

In this work, the photoacoustic signal was measured at a time constant of 1—3 s.

Measurement of Formation of an Oxide Layer at Au. Figure 8 shows the curve for the photoacoustic signal *versus* applied potential together with a current *versus* potential curve in 1 M $HClO_4$ solution on an Au electrode where photoacoustic signal was measured at a wavelength of 514.5 nm from the Ar ion laser with light intensity of 0.8 W. It has been widely reported that oxide layers are formed on the Au electrode with anodic polarization in an acid solution.[21-24] The anodic current at 1.2 V in the anodic sweep was attributed to the formation of the oxide layer on the Au electrode. As shown in Fig. 8 the increase in the photoacoustic signal began at almost the same potential as increase of the anodic current. The increase in the photoacoustic signal was mainly due to the increase in absorption resulting from formation of the oxide layer on the Au electrode, because the absorption coefficient of the oxide is greater than that of Au irradiated at 514.5 nm. On the other hand, in the cathodic sweep, a current peak was observed around 0.9 V due to the reduction of the oxide layer and at that time the photoacoustic signal decreased gradually depending on the amount of cathodic electricity. When the cathodic current decreased to the original value around 0.65 V, the photoacoustic signal also showed the same value as that on the bare Au surface.

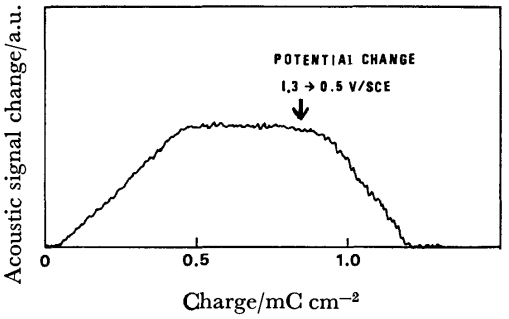

Fig. 9. Relative change in photoacoustic signal *vs.* charge for the formation of gold oxide.
1 M $HClO_4$, potential +1.3 V and 0.5 V *vs.* SCE. λ=514.5 nm.

Figure 9 shows the relationship between the change in the relative photoacoustic signal and the charge flowing. Figure 9 also showed the change in the photoacoustic signal, stepping the applied potential from 1.3 V to 0.5 V, at which potential the oxide is reduced. In Fig. 9 the photoacoustic signal increased linearly with the quantity of electricity for the oxidation process, and then reached a constant at about 0.5 C/cm^2, where the thickness of the oxide layer was estimated to be 0.5 nm, assuming the composition of the oxide layer to be Au_2O_3 with a bulk density of 6 g/cm^3.[24] In the rising region in Fig. 9, the acoustic signal seems to increase in proportion to the degree of surface coverage of the oxide layer. When the oxide layer was reduced by changing the applied potential from 1.3 V to 0.5 V, the photoacoustic signal decreased to the value at the bare Au surface.

Conclusion. The instrumentation used is simple and unsophisticated, but this technique was found to be useful for the study of electrode-solution interfaces *in situ*.[25] This PAS technique may be applicable for kinetic studies concerning electrode reactions, as well as for qualitative analysis by spectroscopic measurement. Sensitivity was fairly high, *e.g.*, in the order of monolayer change when using laser irradiation, and could be further improved by modification of the PAS cell, *e.g.*, smaller internal cell volume. Since PAS is influenced by external acoustic noises, exhaustive counterplan against the acoustic noise would be also required. In addition, by employing a double-beam PAS system, the signal to noise ratio could be expected to improve.

This technique is considered to be applicable to any type of samples (*e.g.* rough or porous surfaces) which are difficult to examine by conventional techniques. Since the metal electrodes employed in this work had flat, highly reflective surface, photoacoustic signals were relatively small. Semiconductors, however, have more definitive characteristics especially concerning their light effect, so this technique would be more useful for their electrode systems.

A Spectrophotometric Study of Tributyl Phosphate Adducts of Three Bis(β-diketonato)copper(II) Complexes in Carbon Tetrachloride

Tatsuya SEKINE* and Teruyuki TOSAKA

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received August 23, 1979)

Adduct formation equilibria between bis(2-thenoyltrifluoroacetonato)-, bis(trifluoroacetylacetonato)-, and bis(hexafluoroacetylacetonato)copper(II) chelates and tributyl phosphate (TBP) in water-saturated carbon tetrachloride were studied spectrophotometrically at 25 °C. The chelates added one TBP molecule and decreased the absorption, but not very much. The formation constants obtained from the changes in the absorption, given as a function of the TBP concentration, agreed very well with those obtained previously by a solvent-extraction method.

The adduct formation of uncharged metal chelates with neutral ligands in the organic phase in solvent-extraction systems enhances the metal-chelate extraction; this enhancement is often called "synergism." The equilibria of the adduct formation can be measured from an analysis of the enhancement of the extraction, which is determined as a function of the ligand concentration in the organic phase; also, the formation constants of the adduct metal chelates have been determined in several systems under various conditions.[1–4]

The formation of adducts may affect the spectral properties of the complex. This has been observed in several metal chelate systems,[5] especially when the adduct-forming ligands were organic bases, such as homologues or derivatives of pyridine and quinoline. The appearance of strong absorptions upon the addition of organic bases to metal chelates in the organic phase in solvent-extraction systems has been used in the colorimetry of the metal ion; the sensitivity has thus been found to be much higher than in the absence of the adduct-forming ligand.[6,7]

The change in the absorption by adduct formation as a function of the ligand concentration may also be used in the determination of the formation constants. In studies of the synergism of metal extraction as chelates on the addition of heterocyclic organic bases, the adduct-formation constants have been spectrophotometrically determined and discussed in relation to the synergism.[8,9] Such quantitative spectrophotometric studies of adduct chelate formation equilibria with heterocyclic organic bases have been reported several times.[10–22]

Another group of ligands which have been studied frequently in connection with their ability to form adduct chelates are neutral phosphorus compounds such as tributyl phosphate (TBP); the changes in the absorptions have also been discussed in relation to the enhancement of the extraction.[23,24] However, not much quantitative analysis of the changes in the absorption has been done, and few spectrophotometric determinations of the adduct formation constants with such neutral organophosphorus compounds have been made.

In the course of a series of studies of metal-chelate extraction with several β-diketones and their synergism with neutral ligands in our laboratory, it was found that the optical absorption also changed upon adduct-formation in the copper(II) extraction systems with β-diketones in conjunction with TBP and that the equilibrium constants obtained from these spectrophotometric data agreed very well with those obtained from the solvent-extraction data.

Experimental

The experimental conditions were the same as in the previous solvent-extraction study,[25,26] except that the changes in the absorption spectra were measured instead of those in the distribution ratio.

The bis(β-diketonato)copper(II) ($Cu(acac)_2$) and the β-diketones were supplied by the Dojindo Co., Kumamoto. The tributyl phosphate was supplied by the Tokyo Kasei Co., Tokyo, and was purified by the same method as before.[25,26] The carbon tetrachloride was an analytical-grade solvent. Two UV-VIS spectrophotometers (Hitachi type-556 and -139) were used.

A weighed amount of $Cu(acac)_2$ was dissolved in water-saturated carbon tetrachloride containing 0.1 mol dm^{-3} of 2-thenoyltrifluoroacetone (Htta), trifluoroacetylacetone (Htaa), or hexafluoroacetylacetone (Hhfa) and converted into $Cu(tta)_2$, $Cu(taa)_2$, or $Cu(hfa)_2$. These solutions were used as the stock solutions. A portion of a stock solution and a portion of a water-saturated carbon tetrachloride solution of TBP were mixed; when necessary, another portion of carbon tetrachloride was added in order to bring the initial concentrations of the bis(β-diketonato)copper(II), the β-diketone and TBP up to the wanted values. The solution was stored for 1 h, and the absorption spectrum was measured using a glass cell with a 1 cm light path. The temperature was kept at 25±0.3 °C.

Statistical

In this paper, the chemical species with the subscript "aq" are those in aqueous solutions, while the lack of any subscript indicates those in carbon tetrachloride solutions.

The ligand-exchange equilibria of acetylacetonate ions in $Cu(acac)_2$ with a β-diketone, Ha, may be written as:

$$Cu(acac)_2 + Ha \rightleftarrows Cu(acac)(a) + Hacac \quad (1)$$

$$Cu(acac)_2 + 2Ha \rightleftarrows Cu(a)_2 + 2Hacac \quad (2)$$

$$K_{x1} = [Cu(acac)(a)][Hacac][Cu(acac)_2]^{-1}[Ha]^{-1} \quad (3)$$

$$K_{x2} = [Cu(a)_2][Hacac]^2[Cu(acac)_2]^{-1}[Ha]^{-2}. \quad (4)$$

The values of K_{x1} and K_{x2} can be obtained from the solvent-extraction constants as follows:

$$Cu^{2+}(aq) + 2Hacac \rightleftarrows Cu(acac)_2 + 2H^+(aq) \quad (5)$$

$$Cu^{2+}(aq) + Hacac + Ha \rightleftarrows Cu(acac)(a) + 2H^+(aq) \quad (6)$$

$$Cu^{2+}(aq) + 2Ha \rightleftarrows Cu(a)_2 + 2H^+(aq) \quad (7)$$

$$K_{ex(acac)} = [Cu(acac)_2][H^+]_{aq}^2[Cu^{2+}]_{aq}^{-1}[Hacac]^{-2} \quad (8)$$

$$K_{ex(mix)} = [Cu(acac)(a)][H^+]_{aq}^2[Cu^{2+}]_{aq}^{-1} \times [Hacac]^{-1}[Ha]^{-1} \quad (9)$$

$$K_{ex(a)} = [Cu(a)_2][H^+]_{aq}^2[Cu^{2+}]_{aq}^{-1}[Ha]^{-2}. \quad (10)$$

Here, the statistical values of $K_{ex(mix)}$ are obtained as:[27]

$$K_{ex(mix)} = 2\sqrt{K_{ex(acac)}K_{ex(a)}}. \quad (11)$$

Although the statistical value of $K_{ex(mix)}$ could, to some extent, be different from the experimental value, it may be used in this study, taking its concentration as an approximate value.

$$K_{x1} = K_{ex(mix)}K_{ex(acac)}^{-1} \quad (12)$$

$$K_{x2} = K_{ex(a)}K_{ex(acac)}^{-1}. \quad (13)$$

The formation equilibrium of the adduct can be written as:

$$Cu(a)_2 + tbp \rightleftarrows Cu(a)_2(tbp) \quad (14)$$

$$\beta_{1(org)} = [Cu(a)_2(tbp)][Cu(a)_2]^{-1}[tbp]^{-1}. \quad (15)$$

When the molar extinction coefficients of the $Cu(a)_2$ and $Cu(a)_2(tbp)$ species at a certain wavelength are ε_0 and ε_1 respectively, then the optical density can be written as:

$$E = \varepsilon_0[Cu(a)_2] + \varepsilon_1[Cu(a)_2(tbp)]. \quad (16)$$

The following equations may be valid in these systems:

$$[Cu(II)]_{total} = [Cu(a)_2] + [Cu(a)_2(tbp)] \quad (17)$$

$$[tbp]_{total} = [tbp] + [Cu(a)_2(tbp)]. \quad (18)$$

By using a least-squares program, the values of $\beta_{1(org)}$ and ε_1 can be computed by successive approximation procedures.

Results and Discussion

The equilibrium constants for the ligand exchange in Eqs. 3, 4, 12, and 13 were calculated from the extraction constants in the literature, as listed in Table 1. Since the maximum amount of Hacac produced by the ligand exchange should be twice that of the $Cu(acac)_2$ chelate added, it should be lower than 1×10^{-3} mol dm^{-3}. Thus, it may be seen from Eqs. 12 and 13 and the values of the constants in Table 1 that more than 99% of the initial bis(acetylacetonato)copper(II) should be converted into the complexes when the β-diketone concentration is 0.1 mol dm^{-3}. It was also confirmed by spectrophotometric measurements that the optical-absorption spectrum of the solution thus obtained by the ligand exchange was identical to that of the solution of each β-diketone complex within the limits of experimental error. This exchange formed free acetylacetone and decreased the concentration of that β-diketone. The change in the absorption caused by the changes in these concentrations was corrected on the basis of the molar extinction coefficients of the β-diketones and the concentration of copper(II).

Table 1. Equilibrium constants for the ligand exchange of copper(II) chelates in CCl_4

Ligand	log K_{ex}[a]	log $K_{ex(mix)}$[b]	log K_{x1}	log K_{x2}
Hacac	−3.47	—	—	—
Htta	−1.08	−1.98	1.49	2.39
Htaa	−1.12	−2.00	1.47	2.35
Hhfa	−0.26	−1.57	1.90	3.21

a) When the aqueous phase was 0.1 mol dm^{-3}, (Na, H)ClO_4. Taken from refs. 25 and 26. b) Calculated statistical values.

The total copper(II) concentration was maintained at 5×10^{-4} mol dm^{-3}. Optical measurements were carried out in the region where the molar extinction coefficient is higher than 2×10^2 and where the absorption due to the reagent is not high. This region was from 400 to 420 nm at twenty-one different points for the $Cu(tta)_2$ chelate, from 350 to 400 nm at fifty-one different points for the $Cu(taa)_2$ chelate, and from 370 to 390 nm at twenty-one different points for the $Cu(hfa)_2$ chelate. The absorption of the $Cu(hfa)_2$ chelate and its TBP adduct could not be measured below 370 nm because, in this region, the absorption of the reagent was very high. Absorptions were also measured up to 800 nm, but no high absorption due to the adduct formation ($\varepsilon_1 > 200$) was found in this region. Thus, the range of the wavelengths of the data used for the calculation was narrow in all the cases, as can be seen from Fig. 1. Several sets of data of the optical absorption, E, in Eq. 16 at this copper(II) concentration and various total TBP concentrations were obtained at each wavelength.

The least-squares calculation of the values of $\beta_{1(org)}$

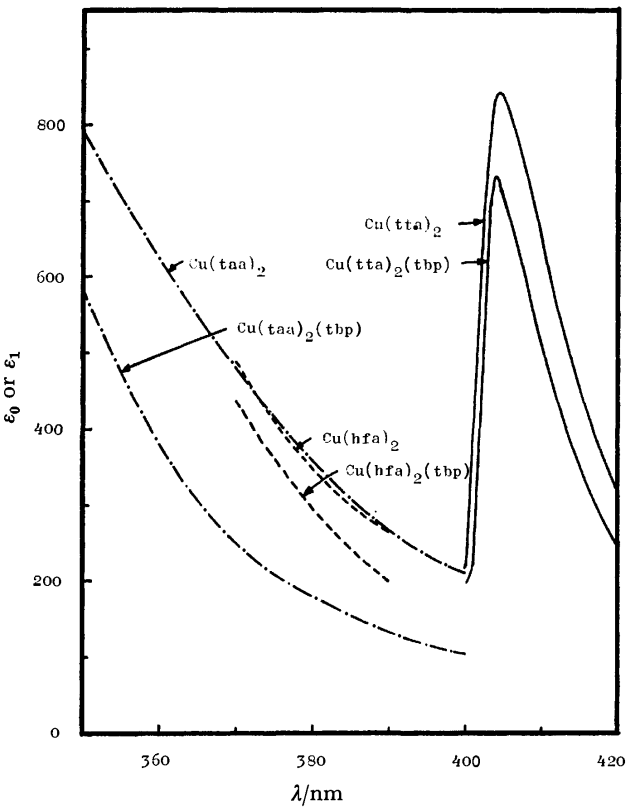

Fig. 1. Absorption spectra of bis(β-diketonato)copper (II) chelates and their tbp adducts given by molar absorptivity as a function of wavelength.

Table 2. Summary of formation constants of TBP adduct chelate complexes

Chelate	$\log \beta_{1(org)}$ [a] (by spectrophotometry)	$\log \beta_{1(org)}$ [b] (by solvent extraction)
$Cu(tta)_2$	2.21±0.1	2.27
$Cu(taa)_2$	2.15±0.1	2.16
$Cu(hfa)_2$	4.63±0.1	4.60

a) Present work; the limit of error is 3σ. b) Refs. 25 and 26.

and ε_1 at each wavelength were carried out from the set of data, together with the ε_0 of that bis(β-diketonato)-copper(II) which was determined at that wavelength in the absence of TBP. The variation in the values of $\beta_{1(org)}$, the formation constants of the TBP adducts, obtained from the data at different wavelength was rather small; the values are listed in Table 2, together with the corresponding values obtained by the solvent-extraction method in the previous study. The constants obtained by these two different methods agreed very well, as may be seen in Table 2. The values of ε_1, the molar extinction coefficient of the TBP adducts, were also obtained from the experimental data by these calculations. The values of ε_1 are shown in Fig. 1, together with the values of ε_0 of the bis(β-diketonato)-copper(II) complexes.

Since the carbon tetrachloride solutions were saturated by water, the effect of water in the carbon tetrachloride on the adduct-formation equilibrium should be identical with that in solvent extraction systems. However, if spectrophotometric experiments were to be made at various water concentrations, the effect of water in the solvent which can not be made by the solvent extraction method could be determined.

As may be seen from Fig. 1, the absorption spectra of each bis(β-diketonato)copper(II) complex and its TBP adduct are rather similar, although the absorption curve of the bis(hexafluoroacetylacetonato)complex and of its TBP adduct become a little closer in the lower-wavelength region. In all the cases, the molar extinction coefficient of the adduct is smaller than that of the chelate ($\varepsilon_1/\varepsilon_0$ is 0.75 to 0.85 with $Cu(tta)_2$, 0.50 to 0.65 with $Cu(taa)_2$, and 0.75 to 0.90 with $Cu(hfa)_2$). However, the $\varepsilon_1/\varepsilon_0$ values are not far from 1, so the adduct formation by TBP seems to have only a slight effect on the electronic state of the complex. This is quite different from the observation that, by the formation of bis(β-diketonato)complexes with organic bases, a strong absorption appears in the higher wavelength region.[6,7]

The difference in the two absorption spectra is not large, but the adduct-formation constants, $\beta_{1(org)}$, could be determined accurately in the present study. This indicates that the spectrophotometric determination may be used for the adduct-formation equilibria in several other systems. However, since the metal concentration can not be lowered very much for accurate optical measurements, the error in the constants must be larger than those obtained by the solvent extraction method, which can be studied even at tracer metal concentrations, if the value of $\beta_{1(org)}$ is very large, for example, as in the case of the $Cu(hfa)_2$ chelate.

The authors are grateful to Dr. Yuko Hasegawa and Dr. Naohiko Ihara for their contributions to this work in the preliminary stage and for their valuable discussions.

(Received September 13, 1979)

Crown ether dyes were synthesized in order to develop photometric reagents which are highly selective to alkali and alkaline earth metals. They contain dissociable protons attached to the chromophores of crown ether molecule. Their extraction behavior for alkali and alkaline earth metal ions as neutral complex was examined. The dyes extract potassium and alkaline earth metals, respectively. Dyes with picrylamino chromophore are effective for extractive photometric determination of potassium. A molecular design of colorimetric reagents is discussed on the basis of crown ethers.

In view of the recent success in extraction photometric determination of alkali metals by crown ether-based chromogenic reagents,[2,3)] a series of crown ethers dyes with dissociable protons attached to the chromophores were synthesized, and their extraction behavior for alkali and alkaline earth metal ions was examined. Since only a very few chromogenic crown ethers are known,[4)] development of this type of compound is highly desirable for its use as a crown ether reagent in analysis.

Results and Discussion

Synthesis. The dyes synthesized are summarized in structural formulae **1**—**6**, and the synthetic routes are illustrated in (1)—(6). Since the reactions involved are the chemical transformations, no details are given except for the method of purification. Most of the dyes were isolated and purified by column chromatography followed by recrystallization. Readily crystallizable compounds, *e.g.*, **1a**, **1b**, **1d**, **5a**, or **5b**, were isolated by recrystallization, the yields being often very low, due to loss by repeated recrystallization (**1b** and **1d**). It is preferable to carry out a rough separation of the reaction product first by column procedure either on silica gel or alumina. The recrystallization of the main product then becomes easier. Preparation of crown ether dyes was difficult due to the difficulty in isolation. For example, the synthesis of benzein dye from 4′-formylbenzo-15-crown-5 and phenol by reactions similar to (4) could not be achieved, since the isolation of triarylmethane precursor of the dye was unsuccessful. The compound is difficult to handle, being both hydrophilic and lipophilic as regards solubility.

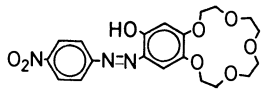
and ε values for the undissociated dyes in chloroform solution, are summarized in Table 1. The dissociation constants reflect the structural characteristics of the dyes.

The dyes sythesized are sparingly soluble in water but appreciably soluble in most organic solvents. Some of the dyes (**3**, **5b**, **5c**, **6a**, and **6b**) are not very soluble in the usual solvents and it is difficult to increase the concentration sufficient for spectrophotometry. The extraction behavior of the dyes **1**—**4** toward potassium, an element which seems to be the most easily extracted[2,3] was studied under various conditions. No spectral change was observed for azo dyes **1** dissolved in organic solvents such as chloroform, isobutyl methyl ketone, nitrobenzene or 1-pentanol, when the solution was brought in contact with 1 M K^+ aqueous solution buffered at pH 9.5—12.5 with carbonate (K_2CO_3) or borate ($Li_2B_4O_7$–LiOH). The spectra of the organic solution remained as those of HA (undissociated form), indicating that no extraction of K^+A^- type species took place. The azo crown ether dye **7** (pK_a, 9.2; 10% dioxane)[5] was found to behave similarly (no extraction).



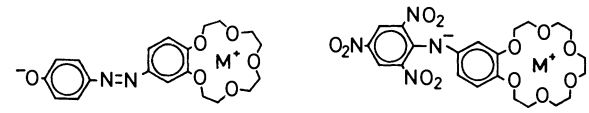
7

In the presence of potassium in aqueous solution the dye partially leaked out from organic into aqueous phase for **1b**. This suggests that with azo dyes **1a** and **1d**, complexation of potassium with the benzo-15-crown-5 function occurs, but the resulting complex of zwitter ion structure M^+A^- is hardly distributed in either organic or aqueous phase. At most, the complex partially goes into aqueous phase with relatively less lipophilic dye such as **1b**.

In contrast to azo dyes **1**, the picrylamino-substituted benzo-18-crown-6 (**2**) extracts potassium successfully. This is in line with the behavior of benzo-15-crown-5 homologues.[2,3] In fact, **2** is an extraction reagent for potassium, more effective than benzo-15-crown-5 homologues, and can be used for the determination of ppm level of potassium.[6] The dibasic ether dye **3** behaves similarly, but a detailed study could not be made because of the low solubility of the compound (in chloroform) and the precipitation of metal complex at high concentration of potassium. No alkaline earth metal ions were extracted by **3**.

The benzein dye **4** was studied in a similar way for the extraction of potassium. The absorbance of the organic phase at 600 nm was 0.02 (optical path, 1 cm) when 3.8×10^{-5} M solution of **4** in isobutyl methyl ketone was shaken with an equal volume of 0.1 M Li_3EDTA–OH (trilithium salt of *N'*-(2-hydroxyethyl)-ethylenediamine-*N,N,N'*-triacetic acid, pH 10.1). On addition of potassium chloride, the absorbance increased to 0.09 (0.01 M KCl) and 0.19 (0.1 M KCl), indicating the extraction of K^+A^-. However, the dye was unstable in alkaline solution, probably because of the irreversible oxidation of ionized species.

The difference in extraction behavior between hydroxyarylazo- and picrylamino-substituted benzo crown ethers should be mentioned. Both types of dyes would extract metals by forming complexes of the zwitter-ion structure, *e.g.*, **8** and **9**, as in the following.



8 **9**

8 and **9** each represent perhaps the most important of the many canonical formulae for the resonance stabilized zwitter-ion complexes from the corresponding azo and picrylamino crown ether dyes, respectively. In **9**, there is a steric congestion around anionic nitrogen, and the hydration would be considerably hindered. On the other hand, the phenolate oxygen in **8** may be easily hydrated and this canonical structure should be greatly stabilized in aqueous solution. In other words, negative charge of the dye would be more delocalized in **9** than in **8**. A negative-positive charge separation in the complex might be smaller with the picrylamino crown ether complexes than with azo crown ether complexes. This might increase the distribution of the picrylamino metal complexes in organic solution. That the benzein dye extracts potassium to some extent suggests the better charge delocalization than in azo dyes.

Compounds **5** and **6** were synthesized with the hope that chelate-type coordination by phenolate anion to the crown ether-encapsulated metal might help increase both stability and extractability of the alkali as well as alkaline earth metals.

The extraction of alkali and alkaline earth metal ions by dyes **5c**, **5d**, **5e**, **6a**, and **6b** was studied, only **5e** being found to extract the metals. Figure 1 shows the spectra of 9.4×10^{-6} M **5e** in chloroform in contact

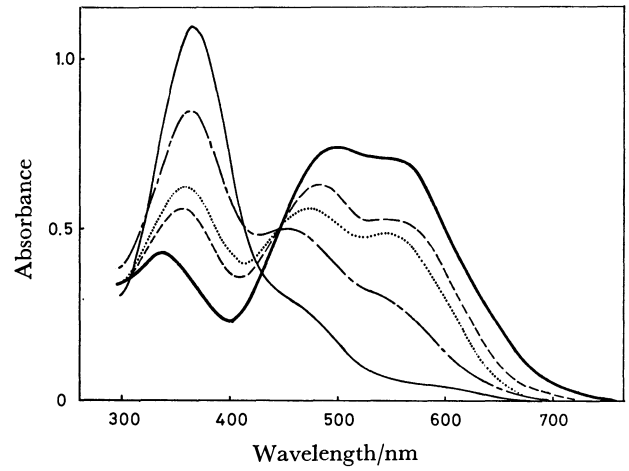


Fig. 1. Absorption spectra of 9.4×10^{-6} M **5e** in chloroform contacted with an equal volume of 1 M metal chloride solution buffered with 1 M triethanolamine at pH 10.9.
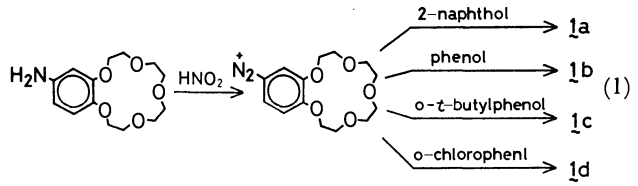
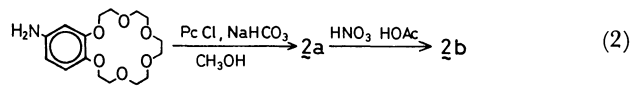
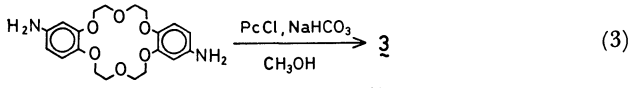
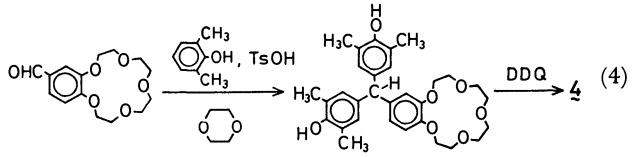
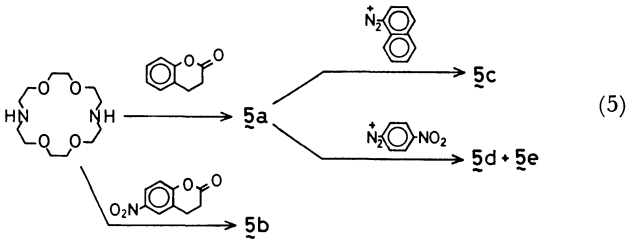
——, Without metal chloride (blank); –·–·–, LiCl; ·····, $CaCl_2$; – – –, $BaCl_2$; ——, 9.4×10^{-6} M **5e** in 0.1 M LiOH (20% dioxane), 25 °C.

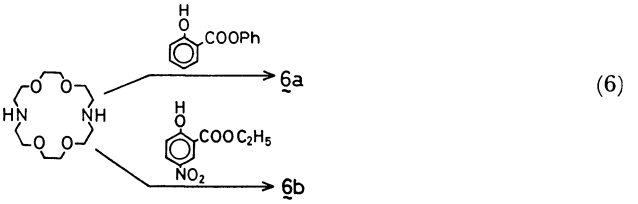




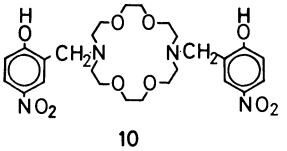








with an equal volume of 1 M LiCl, $CaCl_2$ or $BaCl_2$ solution buffered with 1 M triethanolamine at pH 10.9. Change in spectrum from the blank (1 M metal being absent) to that in the presence of 1 M metal chlorides is irregular (no apparent isosbestic point) due to the distribution of the dye to aqueous phase. However, a regular increase in absorbance at 500—550 nm region is observed from lithium to calcium and barium. From a comparison of the result with a limiting spectra taken in 0.1 M LiOH (20% dioxane), the metals seem to be extracted as $M^{II}A$ or M^{I}_2A (**5e**=H_2A) type complexes. With potassium salt a considerable fraction of the dye is distributed into aqueous phase. Dyes **5c**, **5d**, **6a**, and **6b** are distributed completely into aqueous solution under similar extraction conditions.



10

While **6b** does not extract alkaline earth metals, the analogous crown ether dye **10** does.[7] The difference might be due to the lower donor property of the amide nitrogen combined with an unfavorable orientation of phenolic group in **6b** for coordination. The phenolic hydroxyl would be coplanar with the amide group because of conjugation and hydrogen bonding, prohibiting access of the phenolate group to the center of the diaza-18-crown-6 ring where the metal ions are to be captured. The introduction of the two methylene groups between the amide carbonyl and aromatic nucleus in **5e** releases the steric constraint enforced by the amide bonding, making it possible for phenolate anions to occupy the axial positions of the encapsulated metal. The increased acidity of phenolic hydroxyl groups assisted by two *p*-nitrophenylazo groups for each aromatic neucleus also helps increase the degree of formation of metal complex at a lower pH. That the phenolate anion in **10** can reach the encapsulated metal is readily envisaged by stereomodel inspection. The unusually high stability of alkaline earth metal complexes from *N,N'*-dipropionic acid derivative of the diaza-18-crown-6[8] supports this view.

In conclusion, the two factors seem to be most important in the molecular design of crown ether based extraction photometric reagents for alkali and alkaline earth metals: an extensive delocalization of anionic charge and a minimum distance of positive-negative charge separation in the resulting metal complex. Both factors are essential if the metal complexes are of zwitter-ion structure as with **2**. The charge delocalization factor would not be essential if the metal complexes can assume a chelate-type coordination structure (**5e** and **10**). In this case, however, a structural requirement which allows the coordination of the dye anion to the metal should be considered.

Experimental

Apparatus and Instruments. IR spectra were recorded on a JASCO DS-403G infra-red spectrophotometer, UV and visible absorption spectra on a Hitachi 200 double beam spectrophotometer and a Hitachi 556 dual wave-lengths double beam spectrophotometer. ^{1}H-NMR spectra were measured with either a Varian A-60 or a Bruker WH-90. The pH measurements were made on an Orion 801A ion-analyzer equipped with TOA GST-155C hybrid glass electrode.

Acid Dissociation Constant. Several miligrams of the dye sample was weighed and dissolved in 20 ml dioxane in a 100 ml measuring flask. Lithium chloride (0.42 g) was then added along with a small amount of aqueous acetic acid to make ionic strength and pH of the final solution 0.10 and $\leq$5, respectively, the mixture being diluted with water to 100 ml. One tenth molar lithium hydroxide was added, and the pH and the absorption spectra were measured. The effect of lithium salt and organic solvent (dioxane) on pH measurements was not corrected. The acid dissociation constant was obtained from the slope of the plot, $\Delta A[H^+]/[HA]_t$ *vs.* $\Delta A/[HL]_t$, by means of the equation

$$\frac{\Delta A[H^+]}{[HA]_t} = K_a\left(\Delta\varepsilon - \frac{\Delta A}{[HA]_t}\right).$$

Where $\Delta A(=A-A_0)$ is the increment of absorbance at any pH from the initial absorbance (A_0) where all the dye molecule (HA) exist in undissociated form. $[HA]_t$ is the total concentration of the dye and $\Delta\varepsilon$ is the difference between ε_A-

and ε_{HA}.

Synthesis of Dyes. The synthetic procedures are not optimized for the maximum yield of the product.

1a. 4′-Nitrobenzo-15-crown-5 was hydrogenated in ethanol over Pd/C catalyst.[9] After removal of the catalyst, 3—5 times molar excess of fluoroboric acid was gradually added and the mixture stored in a refrigerator overnight. The fluoroborate salt of 4′-aminobenzo-15-crown-5 was obtained as white needles. Yield, 90%. The salt (0.30 g, 0.82 mmol) and 1.6 ml of 1 M HCl were dissolved in 10 ml water and diazotized in the usual manner. 2-Naphthol (117 mg, 0.82 mmol) dissolved in 2.7 ml of 1M NaOH was chilled below 5° C. To this solution was added the diazotized solution under stirring. After being stirred for an hour, the mixture was acidified by addition of acetic acid, and the red precipitates formed were collected. The crude product was then digested in a small amount of hot methanol, turning into fine red crystals. Yield, 0.28 g, 66%; mp 162—163 °C; IR(KBr) 3440(OH), 1600(aromatic nuclei), and 1130 cm^{-1} (C–O–C); NMR($CDCl_3$) δ=3.76 (8H, s, OCH_2CH_2O), 3.85—4.10 (4H, m, OCH_2CH_2O), 4.10—4.30 (4H, m, OCH_2-CH_2O), 6.80—7.90 (9H, m, aromatic H). Found: C, 63.75; H, 5.93; N, 6.22%. Calcd for $C_{24}H_{26}N_2O_2$: C, 63.62; H, 5.94; N, 6.39%.

1b. Phenol and benzo-15-crown-5-4′-diazonium salt were allowed to react by a procedure similar to that for **1a**. Crystals with blackish-green sheen: yield 11%; mp 72—74 °C; IR(KBr) 3480(OH), 1590, 1502 (aromatic nuclei), 1261, and 1120 cm^{-1} (C–O–C); NMR ($CDCl_3$) δ=3.76 (8H, s, OCH_2CH_2O), 3.86—4.10 (4H, m, OCH_2CH_2O), 4.10—4.30 (4H, m, OCH_2-CH_2O), 6.82—7.87 (9H, m, aromatic H). Found: C, 54.62; H, 6.87; N, 6.38%. Calcd for $C_{20}H_{24}N_2O_6\cdot 3H_2O$: C, 54.29; H, 6.76; N, 6.31%.

1c. *o-t*-Butylphenol and benzo-15-crown-5-4′-diazonium salt were reacted by a procedure similar to that for **1a**. The crude product was passed through an alumina column with chloroform/ether (1/1, v/v), the main band being collected. The product was recrystallized from ethanol. Orange powder; yield 34%; mp 107—108 °C; IR(KBr) 3440(OH), 1590, 1502 (aromatic nuclei), 1265, and 1125 cm^{-1} (C–O–C); NMR ($CDCl_3$) δ=1.36 (9H, s, $C(CH_3)_3$), 3.80 (8H, s, OCH_2-CH_2O), 3.88—4.11 (4H, m, OCH_2CH_2O), 4.11—4.36 (4H, m, OCH_2CH_2O), 6.71—7.98 (6H, m, aromatic). Found: C, 62.15; H, 7.48; N, 5.90%. Calcd for $C_{24}H_{32}N_2O_6\cdot H_2O$: C, 62.33; H, 7.66; N, 6.01%.

1d. The compound was synthesized by reacting benzo-15-crown-5-4′-diazonium salt with *o*-chlorophenol. The product was purified by recrystallization from aqueous acetone. Needles with blackish-green sheen; yield 11%; mp 62—64 °C; IR(KBr) 3480 (OH), 1592, 1502 (aromatic nuclei), 1260, and 1120 cm^{-1} (C–O–C); NMR (acetone-d_6) δ=3.76 (8H, s, OCH_2CH_2O), 3.82—4.07 (4H, m, OCH_2CH_2O), 4.07—4.36 (4H, m, OCH_2CH_2O), 6.98—8.17 (6H, m, aromatic H). Found: C, 54.14; H, 5.31; N, 6.34%. Calcd for $C_{20}H_{23}N_2O_6Cl\cdot H_2O$: C, 54.45; H, 5.23; N, 6.36%.

2a. 4′-Nitrobenzo-18-crown-6[9] (0.50 g, 1.5 mmol) was hydrogenated on Pd/C in ethanol. The reaction mixture after removal of the catalyst was concentrated under reduced pressure, the residue being redissolved in a small amount of methanol. Picryl chloride (0.4 g, 1.7 mmol) and sodium hydrogencarbonate (0.15 g) were added in succession. After being stirred for 30 min, the mixture was acidified by hydrochloric acid and then concentrated to dryness under reduced pressure. The residue was taken into chloroform, washed with water, dried, concentrated, and applied to a silica-gel column. Elution with chloroform/ether (1/1, v/v) gave the main band, from which a dark reddish mass was obtained by concentration. A careful recrystallization (several days) from aqueous acetone or aqueous methanol gave dark-red needles. Yield, 0.52 g, 45%; mp 55—56 °C; IR(KBr) 3300 (NH), 1620 (aromatic nuclei), 1510, 1330 (NO_2), and 1128 cm^{-1} (C–O–C); NMR ($CDCl_3$) δ=3.70 (4H, s, OCH_2-CH_2O), 3.76 (8H, s, OCH_2CH_2O), 3.85—4.35 (8H, m, OCH_2CH_2O), 6.35—6.9 (3H, m, aromatic H) and 9.05 (2H, s, aromatic H). Found: C, 48.81; H, 4.91; N, 10.58%. Calcd for $C_{22}H_{26}N_4O_{12}$: C, 49.07; H, 4.87; N, 10.41%.

2b. To a chloroform solution (25 ml) of **2a** (0.85 g) was added dropwise a mixture of 1.5 ml each of glacial acetic acid, chloroform, and fuming nitric acid (*d*, 1.42) at room temperature. The reaction mixture was then washed four times with 20 ml water, and the chloroform solution was evaporated to dryness. The residue was recrystallized from aqueous acetone. Orange crystals; yield, 0.30 g, 32%; mp 160—161 °C; IR (KBr) 1620 (aromatic nuclei), 1520, 1330 (NO_2) and 1130 cm^{-1} (C–O–C); NMR ($CDCl_3$) δ=3.69 (4H, s, OCH_2CH_2O), 3.73 (8H, s, OCH_2CH_2O), 3.85—4.35 (8H, m, OCH_2CH_2O), 6.38 (1H, s, aromatic H), 7.76 (1H, s, aromatic H), 9.19 (2H, s, aromatic H), 11.76 (1H, s, NH). Found: C, 45.24; H, 4.29; N, 11.80%. Calcd for $C_{22}H_{25}N_5O_{14}$: C, 45.29; H, 4.30; N, 12.00%.

3. *trans*-Dinitrodibenzo-18-crown-6[10,11] (1.0 g, 2.2 mmol) was suspended in acetic acid (10 ml) and hydrogenated over Pd/C catalyst. The catalyst was removed by filtration, and the acetic acid solution was concentrated under reduced pressure to a thick oil, which was redissolved in a small amount of methanol and neutralized with excess sodium hydrogen carbonate (0.85 g). Picryl chloride (1.5 g 6 mmol) was added and stirred at room temperature for a half hour. The reaction mixture was worked up in a similar manner to that for **2**. The compound becomes less soluble in chloroform with increase in purity. Recrystallization from aqueous *N,N*-dimethylformamide gave reddish brown crystalline powder. Yield, 1.2 g, 67%; mp 222—226 °C; IR(KBr) 1620 (aromatic nuclei), and 1130 cm^{-1} (C–O–C); NMR (DMSO-d_6) δ=3.76, 4.25 (16H, broad, OCH_2CH_2O), 6.67, 6.89 (6H, s, aromatic H), 8.79 (4H, s, aromatic H), 10.21 (2H, s, NH). Found: C, 47.03; H, 3.54; N, 13.33%. Calcd for $C_{32}H_{28}$-$N_8O_{18}\cdot 1/4H_2O$: C, 47.03; H, 3.49; N, 13.72%.

4. 4′-Formylbenzo-15-crown-5[9] (0.50 g, 1.7 mmol), 2,6-dimethylphenol (0.60 g, 4.9 mmol), and *p*-toluenesulfonic acid (0.32 g, 1.7 mmol) were refluxed in 25 ml dioxane for 30 h. After removal of dioxane under reduced pressure, the residue was taken into chloroform and subjected to silica gel column chromatography with an eluting solvent starting from chloroform, chloroform/ether (1/1, v/v), ether to ether/ethanol (1/1, v/v). The main band appeared in ether fraction, giving light yellowish needles by recrystallization from aqueous acetone. The compound was found to be 4′-[bis(3,5-dimethyl-4-hydroxyphenyl)methyl]-benzo-15-crown-5, the precursor compound of **4**, from the analytical data. Yield, 0.37 g, 42%; mp 171—172.5 °C; IR(KBr) 3450 (OH), 1580 (aromatic nuclei), and 1150 cm^{-1} (C–O–C); NMR ($CDCl_3$) δ=2.05 (12H, s, CH_3), 3.5—4.1 (16H, m, OCH_2CH_2O), 4.48 (2H, s, OH), 5.05 (1H, –CH–), 6.51 (7H, s, aromatic H). Found: C, 70.61; H, 7.33%. Calcd for $C_{31}H_{38}O_7\cdot 1/4H_2O$: C, 70.65; H, 7.31%. The compound (λ_{max}, 410 nm; ε, 480; $CHCl_3$) is slightly contaminated with **4** due to the air-oxidation during the work-up. One tenth gram (0.19 mmol) of the dye precursor obtained above was dissolved in 10 ml anhydrous methanol, and 43 mg (0.19 mmol) of DDQ (dichlorodicyano-*p*-benzoquinone) was added under stirring. The color of the solution turned red, and red crystalline power precipitated after stirring for 10 min. Yield, 90 mg, 90%; mp 244—245 °C; IR(KBr) 3400 (OH), 1620, 1590 (aromatic nuclei), 1265, and

1140 cm^{-1} (C–O–C); NMR ($CDCl_3$) δ=2.15 (12H, s, CH_3), 3.75 (8H, s, OCH_2CH_2O), 3.85—4.05 (4H, m, OCH_2CH_2O), 4.05—4.30 (4H, m, OCH_2CH_2O), 6.65—7.35 (5H, m, aromatic H). Found: C, 70.83; H, 6.97%. Calcd for $C_{31}H_{36}O_7 \cdot 1/4H_2O$: C, 70.92; H, 6.96%.

5a. 3,4-Dihydrocoumarin (0.90 g, 6.1 mmol) and Kryptofix 22 (E. Merck, 7,16-diaza-1,4,10,13-tetraoxacyclooctadecane) (0.30 g, 1.1 mmol) were mixed and heated at 200 °C for 18 h under nitrogen. The excess dihydrocoumarin was then removed under reduced pressure, and the residue recrystallized from ethyl acetate to give white plates. Yield, 0.52 g, 80%; mp 131—131.5 °C; IR (KBr) 3400 (OH), 1620 (amide), 1590 (aromatic nuclei), 1285, and 1120 cm^{-1} (C–O–C); NMR ($CDCl_3$) δ=2.65—2.85 (8H, m, CH_2CH_2-CO), 3.15—3.65 (24H, m, OCH_2CH_2O), 6.80—7.25 (8H, m, aromatic H). Found: C, 64.22; H, 7.59; N, 4.91%. Calcd for $C_{30}H_{42}N_2O_8$: C, 64.52; H, 7.64; N, 5.02%.

5b. 6-Nitro-3,4-dihydrocoumarin (0.60 g, 3.0 mmol)[12] and Kryptofix 22 (0.20 g, 0.7 mmol) were mixed and heated at 140 °C for 15 h under nitrogen. After removal of excess 6-nitro-3,4-dihydrocoumarin by vacuum sublimation, the residue was recrystallized from a mixed solvent consisting of *N,N*-dimethylformamide, methanol and water. Yellow powder; Yield, 0.24 g, 48%; mp 124—125 °C; IR(KBr) 3400 (OH), 1620 (amide), 1510, 1345 (NO_2), 1285, and 1120 cm^{-1} (C–O–C); NMR (DMSO-d_6) δ=2.65, 2.85 (8H, m, CH_2CH_2CO), 3.15—3.65 (24H, m, OCH_2CH_2O), 6.85, 7.05 (2H, m, aromatic H), 7.90, 8.10 (4H, m, aromatic H).

5c. **5a** was reacted with 1-naphthalene diazonium salt in the usual manner at pH ≈9 for 1 h. The crude product was treated with a silica gel column with an eluting solvent starting from chloroform and ether to ethyl acetate. The main product appeared in ether fractions, from which brown powder was obtained by recrystallization. Yield, 0.20 g, 43%; mp 88—92 °C; IR(KBr) 3400 (OH), 1620 (amide), 1595 (aromatic nuclei), 1250, and 1130 cm^{-1} (C–O–C); NMR ($CDCl_3$) δ=2.65—2.85 (8H, m, CH_2CH_2CO), 3.15—3.65 (24H, m, OCH_2CH_2O), 6.90—8.0 (20H, m, aromatic H). Found: C, 68.99; H, 6.57; N, 9.10%. Calcd for $C_{30}H_{56}N_6O_8 \cdot 1/4H_2O$: C, 68.77; H, 6.48; N, 9.63%.

5d and *5e*. *p*-Nitroaniline (0.20 g, 1.5 mmol) was diazotized in the usual manner and added to an ice-cooled solution of **5a** (0.20 g, 0.36 mmol) in 1M LiOH (10 ml). The mixture was stirred at pH 8—9 for a half hour and acidified by acetic acid to give brownish powder. The precipitates were collected, washed with water and dried. The crude product (0.30 g) was dissolved in chloroform and chromatographed on a column of silica gel with an eluting solvent chloroform/ethyl acetate (1/1, v/v). The first fraction contained **5d** and the second fraction **5e**. **5d**. Yellowish brown crystalline powder; yield, 0.15 g, 49%; mp 196—203 °C (dec); IR (KBr) 1640 (amide), 1590 (aromatic nuclei), 1520, 1340 (NO_2), 1280, and 1095 cm^{-1} (C–O–C); NMR ($CDCl_3$) δ=2.65—2.85 (8H, m, CH_2CH_2CO), 3.15—3.65 (24H, m, OCH_2CH_2O), 6.75—7.15 (6H, aromatic H), 7.65—8.65 (8H, m, aromatic H). Found: C, 57.67; H, 5.50; N, 13.19%. Calcd for $C_{42}H_{48}N_8O_{12} \cdot H_2O$: C, 57.66; H, 5.72; N, 12.81%. *5e*. Blackish brown powder; yield, 70 mg, 14%; mp 144 °C (dec); IR (KBr) 3400 (OH), 1640 (amide), 1520, 1340 (NO_2), 1280 and 1105 cm^{-1} (C–O–C); NMR ($CDCl_3$) δ=2.60—2.90 (4H, m, CH_2Ar), 2.92—3.14 (4H, m, CH_2CO), 3.40—3.76 (24H, m, OCH_2CH_2O), 7.80—8.10 (10H, m, aromatic H), 8.20—8.50 (10H, m, aromatic H). Found: C, 54.56; H, 4.80; N, 15.77%. Calcd for $C_{54}H_{54}N_{14}O_{16} \cdot 2H_2O$: C, 54.45; H, 4.87; N, 16.47%. A contamination from tris(*p*-nitrophenylazo) derivative could not be excluded.

6a. Phenyl salicylate (0.90 g, 6.9 mmol) and Kryptofix 22 (0.30 g, 1.1 mmol) were mixed and heated (melted) under nitrogen at 160 °C for 16 h. The excess phenyl salicylate was hydrolyzed by the addition of water followed by heating (3 h). Salicylic acid and phenol were removed by vacuum sublimation, and the residue was recrystallized from ethyl acetate/ether. White crystalline powder; yield, 0.21 g, 36%; mp 141—142 °C; IR(KBr) 3400 (OH), 1625 (amide), 1595 (aromatic nuclei), 1255, and 1140 cm^{-1} (C–O–C); NMR ($CDCl_3$) δ=3.05—3.75 (24H, m, OCH_2CH_2O), 6.65—7.30 (8H, m, aromatic H), 9.55 (2H, s, OH). Found: C, 61.61; H, 6.98; N, 5.32%. Calcd for $C_{26}H_{34}N_2O_8 \cdot 1/4H_2O$: C, 61.60; H, 6.72; N, 5.53%.

6b. Ethyl 5-nitrosalicylate (0.65 g, 3.0 mmol) was allowed to react with Kryptofix 22 (0.20 g, 0.8 mmol) at 140 °C for 15 h under nitrogen. The excess ethyl 5-nitrosalicylate was removed by vacuum sublimation, and the residue was recrystallized from ethanol to given yellowish powder. It was found by analysis that the preparation is contaminated by the mono *N*-salicyloyl-substituted product. Reactions under prolonged reaction time introduced decomposition products. Yield, 0.17 g, 38%; mp 114.5—117 °C; IR (KBr) 3400 (OH), 1620 (amide), 1590 (aromatic nuclei), 1315 (NO_2), and 1120 cm^{-1} (C–O–C); NMR ($CDCl_3$) δ=3.20—4.10 (24H, m, OCH_2CH_2O), 6.95 (1H, d, aromatic H), 8.25 (1H, q, aromatic H), 8.81 (1H, d, aromatic H). Found: C, 51.69; H, 6.42; N, 8.15%. Calcd for $C_{26}H_{32}N_4O_{12} \cdot 1/2H_2O$: C, 51.19; H, 5.36; N, 9.31%.

(Received September 28, 1979)

Kinetics of reactions of tetra-μ-acetato-dicopper(II) (copper(II) acetate dimer: $Cu_2(OAc)_4$) with lithium chloride and hydrogen chloride (XCl where X denotes Li or H) in acetic acid have been studied spectrophotometrically by using a stopped-flow technique with a computer-assisted averaging device. The rate of decomposition of copper(II) acetate dimer to the monomeric chloro complex is expressed as $-d[Cu_2(OAc)_4]/dt=k^{XCl}[Cu_2(OAc)_4][XCl]$. At 25 °C $k^{LiCl}=(3.5\pm0.6)\times10^5$ mol^{-1} kg s^{-1} ($\Delta H^*=50\pm10$ kJ mol^{-1} and $\Delta S^*=30\pm20$ J mol^{-1} K^{-1}) and $k^{HCl}=(4.8\pm1.0)\times10^5$ mol^{-1} kg s^{-1} ($\Delta H^*=23\pm10$ kJ mol^{-1} and $\Delta S^*=-60\pm20$ J mol^{-1} K^{-1}). Mechanisms are proposed for the decomposition of copper(II) acetate dimer and some discussions are made on the difference in reactivities of LiCl and HCl.

Acetic acid has been used as a convenient solvent for the titration of weak bases.[2] It is a non-dissociating solvent having low dielectric constant ($D=6.18$ at 20 °C[3]), while it is similar in nature to water for its amphiprotic character. Grunwald and co-workers have studied kinetic behavior of proton exchange and ion-pair exchange (metathesis) in acetic acid.[4] Although plenty of information has been so far gathered on equilibria of metal complexes in anhydrous acetic acid media,[5-7] kinetic and mechanistic studies of metal complexes are scarce.[8,9] It appeared of particular interest for us to make a kinetic and mechanistic study of the reactions of the tetra-μ-acetato-dicopper(II) (henceforth we call it copper(II) acetate dimer) with lithium chloride and hydrogen chloride in acetic acid. The present study should provide some information on the reactivity of the dimeric copper entity.

Experimental

All starting chemicals were of reagent grade. Solutions of reagents were prepared in a glove box filled with dried air.

Reagents. *Acetic Acid:* Potassium permanganate (30 g) was added to acetic acid (3 dm^3) and after refluxing for *ca.* 10 h, the solution was distilled. The distillate was then refluxed again with about 200 g of boron triacetate for 12 h and distilled. Calculated amount of acetic anhydride was added to remove residual water in the acetic acid, and it was allowed to stand for *ca.* 4 d at 110 °C.[10] The resultant acetic acid contained at most 1.5×10^{-3} mol dm^{-3} of water and presumably the same amount of acetic anhydride as that of remaining water.

Copper(II) Acetate: Copper(II) acetate was recrystallized from water. Then it was recrystallized first from reagent grade acetic acid and then from anhydrous acetic acid, and dried in a desiccator over sodium hydroxide for a few days under a reduced pressure. The copper(II) acetate solution was prepared by weighing crystals, and standardized by EDTA after evaporating excess acetic acid and then adding NH_3 to make the pH buffered at *ca.* 4.3. The determination of copper in copper(II) acetate crystals by electrolysis confirmed the composition of $Cu_2(CH_3CO_2)_4$.

Lithium Chloride: Lithium chloride was recrystallized twice from distilled water and dried at 120 °C. The solution was prepared by weighing. Its concentration was checked by the Mohr method with K_2CrO_4 as indicator.

Hydrogen Chloride Solution: Hydrogen chloride generated from NaCl with concentrated H_2SO_4 was dried with concentrated H_2SO_4 and was led to anhydrous acetic acid. A hydrogen chloride solution was handled as gently and carefully as possible in order to avoid volatilization of hydrogen chloride. The concentration of each hydrogen chloride solution for kinetic measurements was determined by means of mercury(II) thiocyanate method[11] after dilution of the acetic acid solution with water.

Perchloric Acid Solution: Aqueous solution of perchloric acid (*ca.* 60%, super special grade, Wako Pure Chemical Industries, Ltd.) was diluted with acetic acid, and acetic anhydride equivalent to water was added dropwise to the perchloric acid solution keeping temperature of the solution below 25 °C. The concentration of perchloric acid was standardized against potassium hydrogen phthalate, Crystal Violet being used as indicator.

Lithium Acetate: Lithium acetate was recrystallized twice from acetic acid. Crystals were dried over sodium hydroxide *in vacuo*. The lithium acetate crystals were dissolved in acetic acid and the concentration was determined with a standard perchloric acid in acetic acid using Crystal Violet as indicator.

Measurements. Spectral measurements were performed on a highly sensitive spectrophotometer (SM 401, Union Giken Co. Ltd., Osaka) which enables us to measure spectra at a full scale of 0.01 optical density. The concentration of water was determined by the Karl-Fisher aquametry.

Dynamic reactions were followed by means of a stopped-flow technique using a highly sensitive stopped-flow spectrophotometer with a computer-assisted averaging device,[12] which enable us to follow reactions slower than around 1 ms of half-life. Although the sensitivity of the instrument is very high by itself (0.01 absorbance/full scale per cm path length of light), it gives a poor SN ratio when used as a detector of a stopped-flow apparatus. Then by repeating the flow up to 500 times and averaging signals in a microcomputer, it was possible to improve considerably the SN ratio and to obtain a smooth reaction trace even at highest sensitivity of the instrument. The requirement for signal averagers is that the signal be repetitive. In this apparatus, since reactant solutions was driven by nitrogen gas pressure controlled by solenoid valves, the flow was easily controlled for repeated mixing of reactant solutions. Hence a high

reproducibility of each signal was attained. In the present study, the averaged trace obtained from 10—50 flows was recorded on an X-Y recorder.

Equilibria. There have been some studies on the monomer-dimer equilibrium of copper(II) acetate in acetic acid

$$Cu_2(OAc)_4 \overset{K_{dim}}{\rightleftharpoons} 2Cu(OAc)_2 \quad (1)$$

Cheng and Howald,[13] and Grasdalen and Svare[14] determined the monomer-dimer equilibrium constant as a function of the water concentration in acetic acid. According to them, the dissociation constant K_{dim} is less than 5×10^{-6} mol dm^{-3} at 25 °C in dry acetic acid. We have measured the absorbance of copper acetate solution at 680 nm, where the dimer has an absorption maximum and the dissociation products absorb little. Over the copper(II) acetate concentration range from 10^{-5} to 10^{-2} mol kg^{-1}, the molar absorption coefficient of copper(II) acetate remained almost constant (Fig. 1). The spectra of the solution remained unchanged and showed the characteristic absorption maxima at 370 nm and 680 nm, indicating the dimeric structure of copper(II) acetate. We estimated $K_{dim}\leq10^{-7}$ mol dm^{-3}. Thus the copper(II) acetate exists solely as a dimer under our experimental conditions.

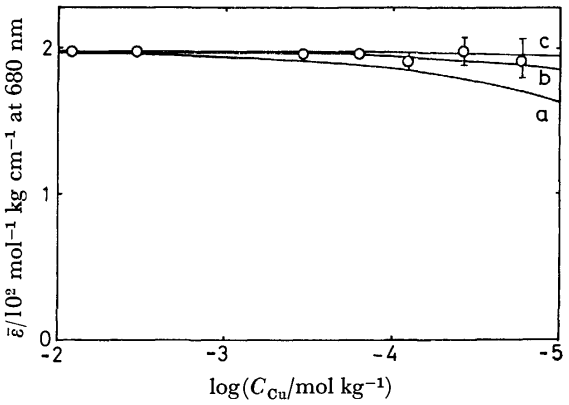

Fig. 1. Dependence of apparent molar absorption coefficient ($\bar{\varepsilon}$) on copper (II) acetate concentration (C_{Cu}). C_{Cu} refers to the concentration per copper atom in mol kg^{-1}. Curves a, b, and c are calculated with $K_{dim}=10^{-6}$, 10^{-7}, and 10^{-8} mol kg^{-1}, respectively.

The presence of a small amount of water (*ca.* 10^{-3} mol kg^{-1}) is inevitable in the present reaction systems. Water in acetic acid can behave as a base, but it is very weak. Perchloric acid and hydrogen chloride, reacting with water, produce their corresponding hydrates $H_3O^+ClO_4^-$ and $H_3O^+Cl^-$. However, these reactions do not occur to an appreciable extent under our experimental conditions. Judging from the equilibrium constant (0.6 ± 0.3 mol^{-1} dm^3) for the replacement of one of the two acetic acid molecules on the axial sites of the copper(II) acetate dimer by water in acetic acid:[6]

$$Cu_2(OAc)_4(HOAc)_2 + H_2O \rightleftharpoons Cu_2(OAc)_4(H_2O)(HOAc) + HOAc \quad (2)$$

the monohydrate may be excluded under our experimental conditions. The equilibria of copper(II) acetate dimer with hydrogen chloride, perchloric acid and lithium acetate in acetic acid have been investigated in detail:[7]

$$Cu_2(OAc)_4 + 2HCl \rightleftharpoons 2CuCl(OAc) + 2HOAc \quad (10^{4.7}\ \text{mol}^{-1}\ \text{kg}) \quad (3)$$

$$Cu_2(OAc)_4 + 4HCl \rightleftharpoons 2CuCl_2 + 4HOAc \quad (10^{15.2}\ \text{mol}^{-3}\ \text{kg}^3) \quad (4)$$

$$Cu_2(OAc)_4 + 2HClO_4 \rightleftharpoons 2Cu(OAc)(ClO_4) + 2HOAc \quad (10^{3.5}\ \text{mol}^{-1}\ \text{kg}) \quad (5)$$

$$Cu_2(OAc)_4 + 4HClO_4 \rightleftharpoons 2Cu(ClO_4)_2 + 4HOAc \quad (10^{10.4}\ \text{mol}^{-3}\ \text{kg}^3) \quad (6)$$

$$Cu_2(OAc)_4 + 2LiOAc \rightleftharpoons Li_2Cu_2(OAc)_6 \quad (10^{0.89}\ \text{mol}^{-2}\ \text{kg}^2) \quad (7)$$

$$Cu_2(OAc)_4 + 4LiOAc \rightleftharpoons 2Li_2Cu(OAc)_4 \quad (10^{-0.4}\ \text{mol}^{-3}\ \text{kg}^3) \quad (8)$$

where the values of equilibrium constants for the relevant over-all reactions are given in parentheses. Coordinating solvent molecules are omitted for simplicity. The constant for the formation of chloro copper(II) complex from $Cu_2(OAc)_4$ and LiCl not being available, it was confirmed spectrally that the equilibrium was much favored to the formation of monomeric chloro complex under our experimental conditions. Comparison of the spectrum of $Cu_2(OAc)_4$ with that of the reaction mixture revealed that it was reasonable to follow the rate of the reaction at 300—320 nm, where the change in absorbance was large. Most of the runs were thus performed at 315 nm for LiCl and at 305 nm for HCl. From knowledge of the equilibria mentioned above we were able to set the appropriate conditions for kinetic measurements.

Results

The kinetics have been followed under conditions where the reverse reaction can be neglected in the kinetic study. The increase in absorbance with reaction time in the presence of a large excess of XCl was satisfactorily fitted to a pseudo-first-order rate law. Conditional first-order rate constants, k_0^{XCl}, were obtained from linear plots according to $\ln (A_\infty-A_0)/(A_\infty-A_t) = k_0^{XCl} t$, where A_0, A_t, and A_∞ denote respectively the absorbances at zero, at time t and at infinite time. Thus rate equation for the appearance of monomeric chloro copper complex (Cu–Cl) or decomposition of copper(II) acetate dimer is given by

$$\frac{1}{2}\frac{d[Cu\text{–}Cl]}{dt} = -\frac{d[Cu_2(OAc)_4]}{dt} = k_0^{XCl}[Cu_2(OAc)_4], \quad (9)$$

where $[Cu_2(OAc)_4]$ refers to a concentration of copper(II) acetate dimer ($Cu_2(OAc)_4\cdot2HOAc$), and two solvent molecules coordinated to the axial sites are omitted for simplicity. Conditional rates were found to be unaffected by the initial Cu(II) concentration (4.31×10^{-6}—7.48×10^{-5} mol kg^{-1}), while the increase in the XCl concentration resulted in the increase in k_0^{XCl}. The plot of k_0^{XCl} against total concentration of XCl, C_{XCl}, is linear with no intercept (Fig. 2). Then the rate law is

$$-\frac{d[Cu_2(OAc)_4]}{dt} = k^{XCl}[Cu_2(OAc)_4][XCl], \quad (10)$$

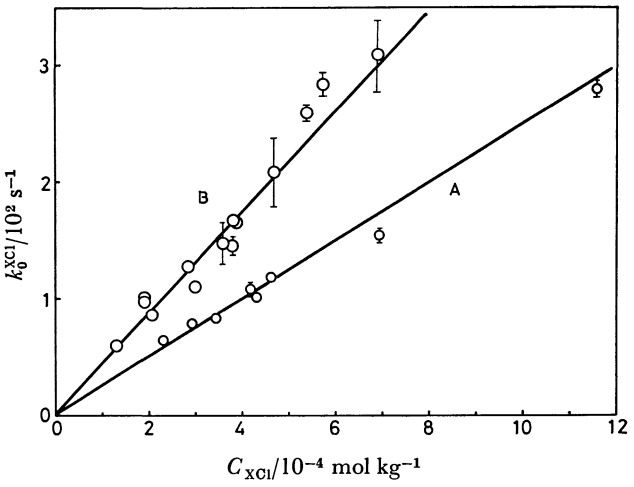

Fig. 2. Plots of conditional first-order rate constant (k_0^{XCl}) against the concentration of XCl (C_{XCl}). A: LiCl, B: HCl, at 20 °C.

Table 1. Effect of added water on the conditional rate constants

LiCl system[a]		HCl system[b]	
$10^2C_{H_2O}$/mol kg^{-1}	k_0^{LiCl}/s^{-1} ($\pm$10)[c]	$10^2C_{H_2O}$/mol kg^{-1}	k_0^{HCl}/s^{-1} ($\pm$15)[c]
<0.2[d]	151$\pm$25[e]	<0.2[d]	120$\pm$25[e]
0.43	151	0.28	108
1.3	170	0.61	105
2.3	177	0.89	105
3.4	191	1.4	106
6.1	233	1.9	119
9.8	244	3.1	140
		3.9	156

a) Conditions: $C_{Cu}=9.64\times10^{-6}$ mol kg^{-1}, $C_{LiCl}=4.31\times10^{-4}$ mol kg^{-1}, 25 °C. b) Conditions: $C_{Cu}=8.52\times10^{-6}$ mol kg^{-1}, $C_{HCl}=2.50\times10^{-4}$ mol kg^{-1}, 25 °C. c) Deviation from an average value of several experimental points. d) No added water. The concentration of water was less than 2×10^{-3} mol kg^{-1}. e) This value was estimated from data at 25 °C in Table 2.

where k^{XCl} is a second-order rate constant. Some kinetic experiments were carried out to have an idea of the effect of added water in the present reaction (Table 1). There was no effect of water at least up to 10^{-2} mol kg^{-1}. As the amount of water in our reaction systems is at most 3×10^{-3} mol kg^{-1}, the contribution of water to reaction rates can be neglected. From the temperature dependence of k^{XCl} (Eyring's plot), the activation parameters are calculated, and tabulated in Table 2.

The reaction of copper(II) acetate dimer ($C_{Cu}=9.39\times10^{-6}$ mol kg^{-1}) with LiCl ($C_{LiCl}=4.95\times10^{-4}$ mol kg^{-1}) was followed in the presence of lithium acetate over the concentration range from 3.59×10^{-5} to 1.20×10^{-4} mol kg^{-1}, which does not appreciably favor equilibria 7 and 8 to the right. We found no kinetic effect of lithium acetate, which is one of the strongest bases in acetic acid. The kinetic run of $Cu_2(OAc)_4$ (8.45×10^{-6} mol kg^{-1}) with HCl (2.72×10^{-4} mol kg^{-1}) was carried out in the presence of up to 1.2×10^{-5} mol kg^{-1} of $HClO_4$. Perchloric acid at such a concentration level does not appreciably favor equilibria of $Cu_2(OAc)_4$ shown in Eqs. 5 and 6. The rate constant remained unchanged in the presence of such amounts of $HClO_4$, which is the strongest acid in acetic acid.

Table 2. Second-order rate constants and activation parameters

Temp/°C	$10^{-5}k^{LiCl}$/mol^{-1} kg s^{-1}	$10^{-5}k^{HCl}$/mol^{-1} kg s^{-1}
17	1.9$\pm$0.3 (8)[a]	4.0$\pm$0.7 (6)
20[b]	2.5$\pm$0.5 (8)	4.2$\pm$0.9 (14)
25	3.5$\pm$0.6 (22)	4.8$\pm$1.0 (19)
30	4.8$\pm$0.8 (2)	6.0$\pm$1.5 (4)
35	6.0$\pm$1.0 (2)	7.3$\pm$1.5 (4)
$\Delta H^{\ddagger}$/kJ mol^{-1}	50$\pm$10	23$\pm$10
$\Delta S^{\ddagger}$/J mol^{-1} K^{-1}	30$\pm$20	$-$60$\pm$20

a) Figure in parenthesis indicates number of runs carried out at different XCl concentrations. b) Data for this are given in Fig. 2.

The reaction of copper(II) acetate dimer with perchloric acid ($Cu_2(OAc)_4+4HClO_4\rightarrow2Cu(ClO_4)_2$) was followed at 680 nm where the difference in absorbance of $Cu_2(OAc)_4$ and $Cu(ClO_4)_2$ is maximum. The reaction was too fast to be followed in the present conditions ($C_{HClO_4}=10^{-3}$ mol kg^{-1}, $C_{Cu}=10^{-4}$ mol kg^{-1}, 25 °C). Judging from the dead time of our apparatus, we presume the half life time is less than 0.5 ms. Then, provided the order is first with respect to $HClO_4$, the second-order rate constant (k^{HClO_4}) seems to be larger than 3×10^6 mol^{-1} kg s^{-1}.

Discussion

The values of activation enthalpy and entropy for k^{LiCl} and k^{HCl} are very different. We shall consider the present results in the light of the exchange of acetic acid at the axial positions of copper(II) acetate dimer. Grasdalen[15] has studied the exchange rate of acetic acid at the axial positions of the dimeric copper(II) acetate by measuring ^{1}H NMR line width and line shift in acetic acid/ethanol solutions ($k_{ex}=3.0\times10^4$ s^{-1} (25 °C), $\Delta H^{\ddagger}_{ex}=44.8$ kJ mol^{-1} and $\Delta S^{\ddagger}_{ex}=9.2$ J mol^{-1} K^{-1}). We have also made measurements of the temperature dependence of the solvent acetic acid proton line broadening and shift for solutions of copper(II) acetate dimer in acetic acid, acetic acid/chloroform and acetic acid/dichloromethane solutions. Activation parameters for acetic acid exchange were determined to be $k_{ex}=(1.2\pm0.2)\times10^4$ s^{-1}, $\Delta H^{\ddagger}_{ex}=50\pm4$ kJ mol^{-1} and $\Delta S^{\ddagger}_{ex}=2\pm5$ J mol^{-1} K^{-1} for both HOAc/$CDCl_3$ solution ([HOAc]=5.24 mol kg^{-1}) and HOAc/CD_2Cl_2 solution ([HOAc]=1.79 mol kg^{-1}).[16] The values of activation enthalpy $\Delta H^{\ddagger}_{ex}$ for the exchange of acetic acid are the same even in different diluent solvent (ethanol, chloroform and dichloromethane) and even for different concentration of acetic acid in the bulk. The fact clearly indicates that the rate-determining step for k_{ex} should be the same in these mixed solvents and also,

most probably in pure acetic acid solution.

In ethanol solution the axial ethanol molecule on the copper acetate dimer is readily replaced by acetic acid.[14] This is contrary to the prediction based on the difference in the basicity between acetic acid and ethanol: the latter is much more basic than the former. The geometry should thus favor the coordination of acetic acid by an extra hydrogen bonding with the bridging acetate.[14] This hydrogen bonding appears to account for the unexpectedly slow exchange rate of acetic acid at the copper acetate dimer without recourse to the exchange between axial and bridging ligands.[15,17]

In view of the fact that the activation enthalpy for the reaction of copper acetate dimer with lithium chloride is the same as that for the acetic acid exchange, it seems reasonable to suppose that the reaction of copper acetate dimer with lithium chloride is a dissociative interchange mechanism: in the transition state the chloride ion in LiCl[18] enters the apical coordination site vacated in the solvent dissociation. Positive activation entropy for k^{LiCl} is in harmony with this dissociative mode of activation. The coordination of chloride to copper initiates the decomposition of the dimeric structure, followed by fast reactions leading to monomeric chloro complexes.

The activation enthalpy for k^{HCl} is smaller than for k_{ex}, while the activation enthalpy for k^{LiCl} is identical with that for k_{ex} within experimental errors. The rate for the reaction of $Cu_2(OAc)_4$ with $HClO_4$ is much faster than that with HCl. At this stage it is of interest to consider the role of ionization and dissociation of reactants in the present reaction systems. Dissociation of AB is written as

$$AB \rightleftharpoons A^+B^- \rightleftharpoons A^+ + B^-$$

with the overall dissociation constant K_D:

$$K_D = \frac{[A^+]+[B^-]}{[AB]+[A^+B^-]} = \frac{K_iK_d}{1+K_i}$$

where K_i is an ionization constant and K_d is a dissociation constant.[19] Available values of K_d are $10^{-7.10}$ for LiCl,[20,21] $10^{-6.78}$ for LiOAc,[20,22] $10^{-8.55}$ for HCl,[20] $10^{-10.1}$ for H_2O,[20] and $10^{-5.87}$ for $HClO_4$.[20] K_d can be calculated by an equation of the type derived by Fuoss for ion-pair formation.[23] Therefore unknown K_d values may be predicted, at least to a correct order of magnitude. On this basis, K_d is estimated to be about 10^{-6} mol dm^{-3} for all of these 1 : 1 electrolytes. Then values of K_i for LiCl, LiOAc, HCl, and H_2O can be estimated to be $10^{-1.1}$, $10^{-0.8}$, $10^{-2.6}$, and $10^{-4.1}$, respectively. Hydrogen chloride and water are largely unionized, while lithium chloride and lithium acetate are to a considerable extent in the form of undissociated ion-pair. It should be noted that the extent of ionization is largest for perchloric acid.

It seems likely that the rate-determining step for HCl and $HClO_4$ is the proton-assisted cleavage of a copper-oxygen bond. Since perchloric acid is ionized to a much larger extent than hydrogen chloride, it may act more effectively on copper–oxygen bond than un-ionized HCl molecule. The addition of a proton from HCl to a bridged oxygen results in a polarized transition state leading to the cleavage of a copper–oxygen bond. Subsequent formation of monomeric chloro copper(II) complexes should be fast. The negative activation entropy for k^{HCl} is consistent with preequilibrium involving HCl addition: polarized transition state should favor the solvation of the activated complex.

We are grateful to the Ministry of Education, Science and Culture for financial support through Grant No. 347029. P. B. thanks Japan Society for the Promotion of Science for the award of a Fellowship, which enabled his visit and study in Japan.

Dissociation of μ-Oxo-bis[oxobis(8-quinolinolato)vanadium(V)] and μ-Oxo-bis[oxobis(4-isopropyltropolonato)-vanadium(V)] in Chlorobenzene

Akio YUCHI, Hiroshi MURANAKA, Shinkichi YAMADA, and Motoharu TANAKA*

Laboratory of Analytical Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received November 15, 1979)

Dissociation of dimeric vanadium(V) complexes with 8-quinolinol(Hox) and 4-isopropyltropolone(Hipt), $V_2O_3(ox)_4$ and $V_2O_3(ipt)_4$, in organic solvents was studied spectrophotometrically. The equilibrium is found to be

$$V_2O_3L_4 + H_2O \rightleftarrows 2VO_2L + 2HL$$

with the following logarithmic equilibrium constants: log $K = -12.9$ for $L = ox^-$ and -12.8 for $L = ipt^-$ in chlorobenzene. VO_2L was synthesized and characterized by IR, UV, and visible spectroscopy for these ligands and also for 2-methyl-8-quinolinol.

Vanadium(V) reacts with 8-quinolinol(Hox) in weakly acidic media to form a black precipitate. This complex was thought to be $VO(OH)(ox)_2$ and has been the subject of a number of studies.[1–8]

In the preceding papers we have studied the complexation of vanadium(V) with 8-quinolinolate ion in aqueous solutions, and established the formation of the following species: $VO_3(ox)^{2-}$, $VO_3H(ox)^-$, $VO_2(ox)$, and $VO_2(ox)_2^-$.[9] Then taking these findings into consideration we have analyzed the extraction behavior of vanadium(V) with 8-quinolinol, and the extracted species from less acidic media is identified to be $V_2O_3(ox)_4$.[10] Furthermore by IR spectroscopy in solid state this complex is shown to have an oxo-bridged dimeric structure, $VO(ox)_2$–O–$VO(ox)_2$.[10]

In this paper dissociation of $V_2O_3(ox)_4$ dissolved in organic solvents are investigated spectrophotometrically. The 1:1 complex synthesized from $V_2O_3(ox)_4$ is characterized with UV, visible, and IR spectroscopy. Furthermore, 4-isopropyltropolone (Hipt) and 2-methyl-8-quinolinol(Hmeox) complexes are also studied and compared with the 8-quinolinolate complex.

Experimental

Reagent. 4-Isopropyltropolone was recrystallized twice from ligroin and dried under reduced pressure.

Chlorobenzene and nitrobenzene were shaken three times with sulfuric acid, sodium hydroxide solution, and finally with distilled water. Then the solvents were dehydrated over calcium chloride, refluxed over phosphorus pentaoxide, and distilled. The middle 80% was collected for use. The concentration of water in these solvents was about 4×10^{-3} mol dm^{-3}. Water saturated solvents were obtained by shaking these solvents with distilled water again, which contained about 2×10^{-2} mol dm^{-3} water. Solvents of different concentrations of water were obtained by mixing these two solvents.

Ammonium metavanadate, 8-quinolinol, and 2-methyl-8-quinolinol were purified as described previously.[10]

Measurement. All the experiments were carried out in a room thermostated at 25±0.5 °C. All the measurements were performed in a thermoelectric circulating bath at 25±0.1 °C.

UV, visible, and IR spectra were recorded on a UNION High Sens spectrophotometer SM-401 with a thermostated cell compartment and a JASCO infrared spectrophotometer IR-S, respectively. The absorbance was measured with a Karl Zeiss spectrophotometer model 1 PMQ II.

Thermogravimetric analysis was performed using a Shimadzu thermogravimeter TGA-30 and a Shimadzu thermal analyzer DT-30B.

The concentration of water was determined by the Karl-Fischer method with the coulometric generation of iodine. Vanadium(V) was determined spectrophotometrically with PAR.[11]

Preparation. *μ-Oxo-bis[oxobis(8-quinolinolato)vanadium(V)]*: $VO(ox)_2$–O–$VO(ox)_2$ was prepared as described previously.[3,4]

Dioxo-8-quinolinolatovanadium(V): $VO_2(ox)$ was prepared by heating the above complex in Abderhalden's dryer with sodium hydroxide as a trap for vaporized 8-quinolinol. Crude complex was recrystallized from chlorobenzene.

μ-Oxo-bis[oxobis(4-isopropyltropolonato)vanadium(V)]: $VO(ipt)_2$–O–$VO(ipt)_2$ was prepared by mixing dioxovanadium(V) perchlorate solution and 4-isopropyltropolone and adjusting pH at 3.5 by the addition of ammonia. After standing overnight the precipitate was filtered off and dried at 80 °C. Prolonged heating over 100 °C resulted in the gradual weight loss.

Dioxo-4-isopropyltropolonatovanadium(V): $VO_2(ipt)$ was prepared as in the corresponding 8-quinolinolate complex.

Hydroxooxobis(2-methyl-8-quinolinolato)vanadium(V) Dihydrate: $VO(OH)(meox)_2\cdot2H_2O$ was prepared as described previously.[5]

Dioxo-2-methyl-8-quinolinolatovanadium(V): $VO_2(meox)$ was prepared as in the case of $VO_2(ox)$.

Results

Vanadium(V)-8-quinolinolate complex, dissolved in chlorobenzene (about 10^{-4} mol dm^{-3}), shows a broad absorption maximum at around 550 nm. The spectrum of this solution changes under different conditions: the concentration of water, the concentration of excess 8-quinolinol, and the total concentration of the vanadium(V) complex.

Reaction with Water. The reaction of the complex with water results in the decrease of the absorbance in all the visible region. After the completion of this reaction (one or two hours) the absorbance was measured. Because of the limited change of water concentration (0.006—0.018 mol dm^{-3}), we were not able to obtain sufficient data for precise analysis. However, the reaction proceeds to a larger extent and more rapidly with increasing water concentration. It

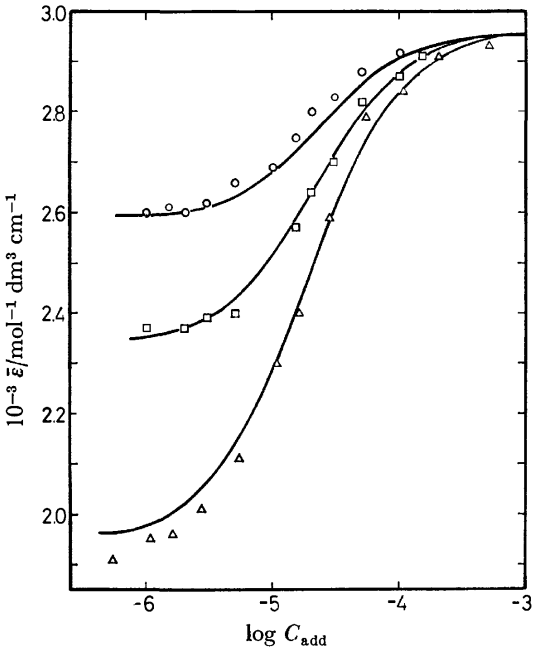

Fig. 1. Molar absorbance change at 480 nm as a function of log C_{add}.
$C_{H_2O}=1.13\times10^{-2}$ mol dm^{-3}; C_V/mol dm^{-3}: ○: 1.19×10^{-4}, □: 5.95×10^{-5}, △: 2.98×10^{-5}. The solid lines are curves calculated with the constants obtained.

should be noted that in the presence of excess amounts of 8-quinolinol we observe no reaction. The chlorobenzene solution of vanadium(V)-8-quinolinolate showed the absorption spectrum very similar to the reflection spectrum of the complex. Thus it may be concluded that we are dealing with the same compound in solution as in solid state.

Reaction with Excess 8-Quinolinol. The reaction of the complex with 8-quinolinol results in the increase of the absorbance in all the visible region. The reaction completes within a minute. The absorbance at 480 nm was then measured. Apparent molar absorbance, $\bar{\varepsilon}$, was plotted against the logarithmic concentration of added 8-quinolinol, log C_{add} (Fig. 1).

In the absence of the added 8-quinolinol, $\bar{\varepsilon}$ is smaller for lower total concentration of the complex and/or for higher water concentration. $\bar{\varepsilon}$ increases with increasing concentration of 8-quinolinol, and it becomes constant beyond 10^{-3} mol dm^{-3} regardless the conditions. These facts point to the presence of only one species, $V_2O_3(ox)_4$, under these conditions.

Dependence of the Absorbance on the Total Concentration of the Complex. Dependence of $\bar{\varepsilon}$ on the total concentration of the vanadium(V) complex, C_V, in the absence of excess 8-quinolinol and at constant amounts of water was studied using quartz cells with light path lengths of 10 and 50 mm (Fig. 2) Upon dilution of the complex solution Beer's law is not obeyed, and the apparent molar absorbance decreases. The limiting values of $\bar{\varepsilon}$ at lower ligand concentration in Fig. 1 are well accommodated in the plot given in Fig. 2.

On the other hand in the presence of sufficient amount of 8-quinolinol, as seen from Fig. 2, $\bar{\varepsilon}$ values are constant for different complex concentrations.

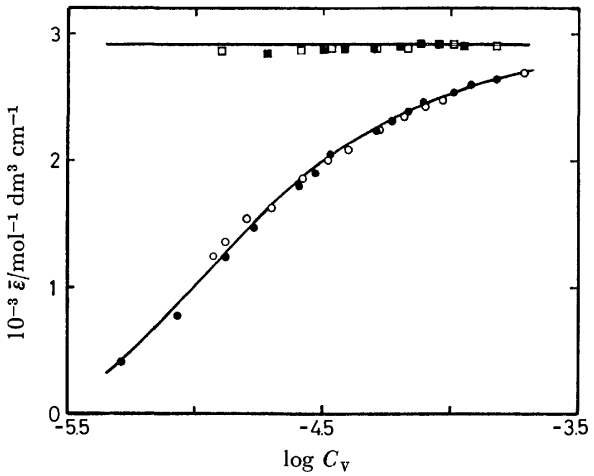

Fig. 2. Molar absorbance change at 480 nm as a function of log C_V.
C_{H_2O}/mol dm^{-3}: ○, □: 1.00×10^{-2}, ●, ■: 1.13×10^{-2}, C_{add}/mol dm^{-3}: ○, ●: 0, □, ■: 2.60×10^{-3}. The solid lines are curves calculated with the constants obtained.

Treatment of Equilibria. The reaction of $V_2O_3(ox)_4$ with water to its lower complex is expressed by Eq. 1 (see below about the composition of the lower complex).

$$V_2O_3(ox)_4 + H_2O \overset{K}{\rightleftharpoons} 2VO_2(ox) + 2Hox \qquad (1)$$

The concentration of water being in large excess compared with the other species and kept constant, the conditional dissociation constant, K', is given by Eq. 2:

$$K' = K[H_2O] = \frac{[VO_2(ox)]^2[Hox]^2}{[V_2O_3(ox)_4]}. \qquad (2)$$

The apparent molar absorbance at 480 nm is expressed by Eq. 3:

$$\bar{\varepsilon} = \frac{\varepsilon_{24}[V_2O_3(ox)_4] + \varepsilon_{11}[VO_2(ox)]}{2[V_2O_3(ox)_4]+[VO_2(ox)]}, \qquad (3)$$

where ε_{11} and ε_{24} are the molar absorbances of $VO_2(ox)$ and $V_2O_3(ox)_4$, respectively. The value of ε_{11} and K' were refined to give minimum error square sum of data, $U=\Sigma(\bar{\varepsilon}_{obsd}-\bar{\varepsilon}_{cald})^2$, with an electronic computer. The value of ε_{11} approached to zero, which is consistent with the spectrum of $VO_2(ox)$.

Then the obtained logarithmic conditional dissociation constants under various conditions were plotted against

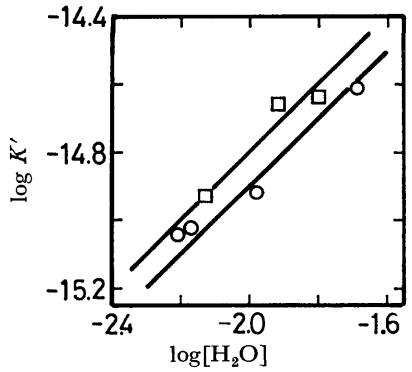

Fig. 3. The plot of log K' against log[H_2O].
○: 8-Quinolinolate complex, □: 4-isopropyltropolonate complex.

the logarithmic concentration of water (Fig. 3). The plot falls along a straight line with a slope of unity. This confirms the validity of Eq. 1. From the intercept the dissociation constant is obtained:

$$V_2O_3(ox)_4 + H_2O \rightleftarrows 2VO_2(ox) + 2Hox$$
$$: \log K = -12.9.$$

The possibility for the formation of the lower complex, $V_2O_4(ox)_2$, given by Eq. 4 was also examined. The assumption of this species lead to a systematic deviation from the experimental data.

$$V_2O_3(ox)_4 + H_2O \rightleftarrows V_2O_4(ox)_2 + 2Hox \quad (4)$$

Dissociation of 4-Isopropyltropolonate Complex ($V_2O_3(ipt)_4$). Similar measurements were performed on 4-isopropyltropolonate complex under various conditions. All the data were analyzed by the same treatment as in the case of 8-quinolinolate complex to give K' and ε_{11}. The value of ε_{11} is close to zero, which is also consistent with the spectrum of VO_2(ipt) (see below). The plot of log K' against log[H_2O] falls along a straight line with a slope of unity (Fig. 3). From the intercept the following dissociation constant is obtained:

$$V_2O_3(ipt)_4 + H_2O \rightleftarrows 2VO_2(ipt) + 2Hipt$$
$$: \log K = -12.8.$$

Properties of Crystals. Thermogravimetry and Visible Spectroscopy: For the 8-quinolinolate complex, a weight loss was observed about 240 °C as reported by Borrel and Pâris.[1] (Fig. 4a) But the form of the thermogram depends upon the rate of heating, and no distinct plateau was observed at 240 °C at 0.5 °C min^{-1}. Thus no definite species can be found at this temperature. On the other hand, over 500 °C it approached to a constant weight corresponding to VO_2(ox). At 240 °C we have a mixture of the species VO_2(ox) with free 8-quinolinol, which gives a characteristic yellow solution just after dissolution in chlorobenzene. This solution, having an absorption maximum at 398 nm and no absorption at longer wavelength than 450 nm, returned to black in a day. The reaction was accelerated by the addition of 8-quinolinol. Thus the complex heated at 240 °C is the molten mixture of VO_2(ox) and Hox, and vaporization of 8-quinolinol occurs at higher temperature.

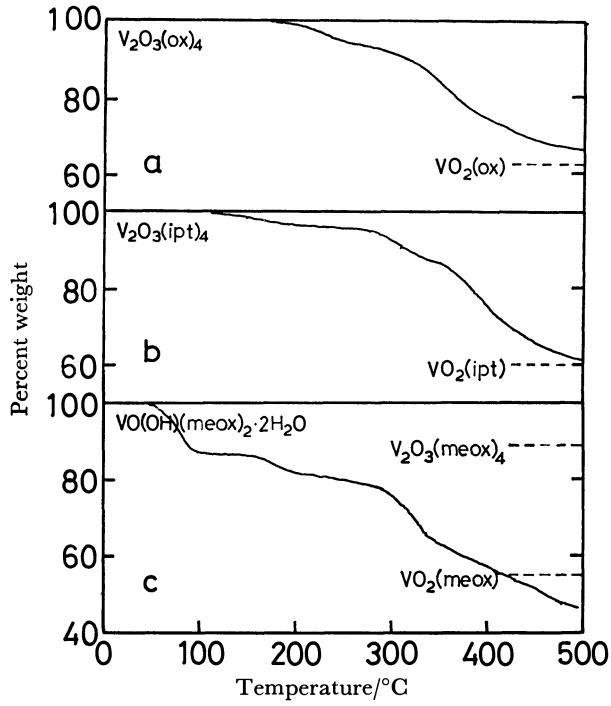

Fig. 4. Thermograms of vanadium (V) complexes.
a: 8-Quinolinolate complex, b: 4-isopropyltropolonate complex, c: 2-methyl-8-quinolinolinolate complex.

For the 4-isopropyltropolonate complex, the thermogram approached to a constant weight corresponding to VO_2(ipt) beyond 500 °C (Fig. 4b). The complex dried at 240 °C, when dissolved in chlorobenzene, showed an absorption maximum at 366 nm and no absorption at longer wavelength than 450 nm, and also returned to black in a day.

For the 2-methyl-8-quinolinolate complex, a weight loss corresponding to 2.5 water molecules from VO(OH)(meox)$_2 \cdot 2H_2O$ to $V_2O_3(meox)_4$ was observed below 100 °C.[10,12] Further heating also dissociates the complex into VO_2(meox) and Hmeox (Fig. 4c), which is overlapped with oxidative decomposition of the ligand.

Table 1. Summary of the properties of vanadium(V) complexes

Complex	λ_{max}[a] / nm	ν(V=O)[b] / cm^{-1}	ν(V–O–V)[c] / cm^{-1}
8-Quinolinolate			
$V_2O_3(ox)_4$	550	950	715
VO_2(ox)	398	990[e]	—
4-Isopropyltropolonate			
$V_2O_3(ipt)_4$	530	950	715
VO_2(ipt)	366	990[e]	—
2-Methyl-8-quinolinolate			
VO(OH)(meox)$_2 \cdot 2H_2O$	340	925	—
$V_2O_3(meox)_4$	—[d]	960	715
VO_2(meox)	388	980[e]	—

a) λ_{max} is the wavelength of the absorption maximum in the UV and visible spectrum. b, c) ν(V=O) and ν(V–O–V) are the wavenumbers of the IR spectrum of V=O and V–O–V, respectively. d) The spectrum was unmeasurable in solution because of rapid change to the monomeric complex. e) The absorption was very broad and unsymmetric.

Infrared Spectra: IR bands of ν(V=O) and ν_{asym} (V–O–V) of the complexes are summarized in Table 1. All the dimeric compounds have ν(V=O) near 950 cm^{-1} in addition to ν_{asym}(V–O–V) at 715 cm^{-1} as in oxo-bridged dimeric Mo(V) complexes.[13]

The lower complexes are expected to have tetrahedral configuration. As the bonds between vanadium and oxo groups are much stronger than those of vanadium and organic ligands, the O–V–O skelton may be approximated as bent triatomic system and expected to have two vibrational mode in metal-oxo double bond region. But the symmetric and antisymmetric modes in bent triatomic system having similar wavenumber in many cases, the broad bands near 990 cm^{-1} seems to consist of these two bands and should not be

compared with those of dimeric compounds. The absence of a band near 715 cm^{-1} excludes the possibility of a dioxo-bridged dimeric structure, $VO(ox)\langle{}^{O}_{O}\rangle VO(ox)$ for the lower complex.

Discussion

The visible spectrum of vanadium(V)–8-quinolinolate complex has been reported by many authors. The molar absorbance at 480 nm calculated from the literature are listed in Table 2. In the presence of excess amounts of 8-quinolinol the value of $\bar{\varepsilon}$ of extracted species or dissolved complex is well consistent with ours. In the absence of excess ligand the molar absorbance varies with experimental conditions, as evident from our findings.

Table 2. The molar absorbance of vanadium(V)-8-quinolinolate complex in the literature

$\bar{\varepsilon}$ / mol^{-1} dm^3 cm^{-1}	C_v / mol dm^{-3}	C_{add} / mol dm^{-3}	Remarks	Ref.
2450—2500	1.96×10^{-4}	0	dissolved	3
2250—2500	—	0	dissolved	5
2950	2.0×10^{-4}	6.76×10^{-3}	dissolved	14
2640	1.1×10^{-4}	0	extracted	15
2910	1.1×10^{-4}	5.01×10^{-3}	extracted	15
3000	0.8×10^{-4}	7.94×10^{-3}	extracted	16

The dissociation constants of the two complexes, $V_2O_3(ox)_4$ and $V_2O_3(ipt)_4$, differ little: the difference is not large enough to discuss the effect of donor atoms: N and O for 8-quinolinolate, and O and O for 4-isopropyltropolonate. With this constant it is well understood that no lower complex was found in the extraction of vanadium(V) with 8-quinolinol.[10]

This type of ligand dissociation is anticipated to be promoted by heating. Actually the nitrobenzene solution of $V_2O_3(ox)_4$ changes to yellow when heated and it returns to black reversibly in cold.[17] The products of this reaction should not be identified as V_2O_5 and Hox but as $VO_2(ox)$ and Hox. Heating of solid complex also promote dissociation and, when the dissociated ligand is removed by NaOH, $VO_2(ox)$ is obtained.

We have shown the presence of $VO_2(ox)$ in aqueous solution, and proposed the structure of $VO(OH)_2(ox)(H_2O)$ from the comparison of pK_a between vanadic acid and complexes.[9] Accordingly the equilibria given by Eq. 5 is shifted completely to the right in aqueous solutions, while it is much favored to the left in organic solvents.

$$VO_2(ox) + 2H_2O \rightleftarrows VO(OH)_2(ox)(H_2O) \quad (5)$$

The 1 : 1 vanadium(V) complexes with β-diketonates have been reported.[18,19] They were identified as $VOL\langle{}^{O}_{O}\rangle VOL$ or VO_2L (L: β-diketonate) depending upon the presence or absence of infrared absorption near 715 cm^{-1} ascribed to the oxo bridging.

The visible spectrum of vanadium(V)-4-isopropyltropolonate complex has been reported from an analytical point of view by a few authors as $VO(OH)(ipt)_2$.[20–22] The spectrum of extracted species in the presence of excess amounts of 4-isopropyltropolone has an absorption maximum at 520 nm,[22] which is consistent with ours, whereas that of extracted species from strongly acidic media (6.6 mol dm^{-3} HCl) has an absorption maximum at 590 nm.[21] This blue shift is ascribed to the protonation of the complex, which has been found in the extraction of the 8-quinolinolate complexes.[10]

In the extraction of vanadium(V) with 4-isopropyltropolone, the extracted species was identified to be $VO(OH)(ipt)_2$.[23] The characteristics of UV, visible, and IR spectra,[10] however, point to the dimeric structure, $V_2O_3(ipt)_4$, as in the case of the 8-quinolinolate complex.

We gratefully acknowledge the Grand-in-Aid from Ministry of Education, Science and Culture (No. 347029).

Selective Ester-exchange Reactions of Dibenzyl-aspartate and -glutamate in the Coordination Sphere of Copper(II) Ion

Yasuo NAKAO,*,† Masaaki DEMICHI, and Akitsugu NAKAHARA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

†*Chemical Laboratory, Faculty of Education, Okayama University, Okayama 700*

(Received September 29, 1979)

Copper(II) complexes of the Schiff bases derived from salicylaldehyde and dibenzyl aspartate or glutamate have been prepared for the first time. Upon refluxing the solution of these complexes in methanol for 30 min, bis(α-methyl β-benzyl *N*-salicylideneaspartato)copper(II) and bis(α-methyl γ-benzyl *N*-salicylideneglutamato)-copper(II) were obtained. The mechanism of these selective ester-exchange reactions in the metal-coordination sphere has been discussed. Several Schiff bases were obtained and characterized.

Many reactions of amino acids, such as transamination, racemization, substitution of α-hydrogen and decarboxylation, proceed *via* formation of metal Schiff base chelates as intermediates, most of them being useful as models for pyridoxal-dependent enzymatic reactions.[1,2]

A number of studies have been carried out on the ligand reactivities of the metal complexes of Schiff bases derived from amino acid esters and carbonyl compounds. The ester-exchange reaction was reported by Pfeiffer *et al.*,[3] extended by other investigators.[4—7] However, most of the studies have been confined to the reactions of those containing simple amino acid esters. Nakao and Nakahara studied the selective ester-exchange reaction in copper(II) chelate of the Schiff base composed of salicylaldehyde and dibenzyl DL-aspartate.[8] In this paper we report on the mechanism of selective ester-exchange reactions occurring in the coordination sphere of copper(II) ion, on the basis of our recent study on the other copper(II) chelates.

Experimental

Benzyl Glycinate Benzenesulfonate was prepared by the method of Cipera and Nicholls.[9]

p-*Toluenesulfonates of Benzyl β-Alaninate and γ-Aminobutyrate* were prepared according to the reported method.[10]

Dibenzyl L- *and* DL-*Aspartate Benzenesulfonate* were obtained by a similar procedure to that for benzyl glycinate benzenesulfonate.[9] Melting points and analytical data of these compounds recrystallized from ethanol are as follows: L-Asp(OBzl)$_2$·$C_6H_5SO_3H$: mp 113—114 °C. Found: C, 60.99; H, 5.41; N, 3.01%. DL-Asp(OBzl)$_2$·$C_6H_5SO_3H$: mp 134—134.5 °C. Found: C, 60.81; H, 5.47; N, 3.05%. Calcd for $C_{24}H_{25}O_7NS$: C, 61.12; H, 5.35; N, 2.97%

Dibenzyl L- *and* DL-*Glutamate Benzenesulfonate* were prepared according to the reported method.[10]

Dibenzyl DL-*Glutamate Hydrochloride* was obtained from the corresponding benzenesulfonate described above.[11]

α-Methyl-β-benzyl L- *and* DL-*Aspartate Hydrochloride.* β-Benzyl L- and DL-Aspartate were prepared by the procedure reported by Izumiya *et al.*[12] The L-compound was identified by a comparison of melting point. Melting point and analytical data of β-benzyl DL-aspartate recrystallized from hot water containing a small volume of triethylamine are as follows: mp 211—214 °C (dec.). Found: C, 59.25; H, 5.89; N, 6.30%. Calcd for $C_{11}H_{13}O_4N$: C, 59.18; H, 5.87; N, 6.28%.

β-Benzyl N-*Benzyloxycarbonyl*-L- *and* -DL-*aspartate*: The L-compound was obtained by the method reported by Ariyoshi *et al.*[13] from β-benzyl L-aspartate. The DL-compound was prepared by the same method, being recrystallized from ethyl acetate-petroleum ether. Mp 99—101 °C. Found: C, 63.60; H, 5.39; N, 3.95%. Calcd for $C_{19}H_{19}O_6N$: C, 63.86; H, 5.36; N, 3.92%.

β-Benzyl-N-*carboxy*-L- *and* -DL-*aspartate Anhydride*: The compounds were prepared from β-benzyl *N*-benzyloxycarbonyl-L- and -DL-aspartate by the method of Berger and Katchalski.[14] The L-compound was identified by comparing the melting point with that reported.[14] Melting point and analytical data of DL-compound washed with petroleum ether are as follows: mp 150—153 °C. Found: C, 57.70; H, 4.54; N, 5.66%. Calcd for $C_{12}H_{11}O_5N$: C, 57.82; H, 4.46; N, 5.62%.

α-Methyl β-benzyl L- and DL-Aspartate Hydrochloride were prepared according to the method of Ariyoshi *et al.*[13] DL-Asp(α-OMe)(β-OBzl)·HCl: mp 120—121 °C. Found: C, 52.72; H, 5.97; N, 5.13%. Calcd for $C_{12}H_{16}O_4NCl$: C, 52.66; H, 5.90; N, 5.12%.

α-Methyl-γ-benzyl L-*Glutamate Hydrochloride.* γ-Benzyl L-Glutamate,[15] γ-Benzyl *N*-Benzyloxycarbonyl-L-glutamate[16] and γ-Benzyl *N*-carboxy-L-glutamate Anhydride[16] were prepared according to the reported method.

α-Methyl γ-benzyl L-Glutamate Hydrochloride was prepared by the same method as that for the corresponding α-methyl β-benzyl L-aspartate hydrochloride,[13] using γ-benzyl-*N*-carboxy-L-glutamate anhydride instead of β-benzyl-*N*-carboxy-L-aspartate anhydride. Mp 129—131 °C. Found: C, 53.81; H, 6.25; N, 5.03%. Calcd for $C_{13}H_{18}O_4NCl$: C, 54.26; H, 6.32; N, 4.87%.

Copper(II) Complex of the Schiff Base Derived from Salicylaldehyde and Benzyl Glycinate, [*Cu(Sal=GlyOBzl)*$_2$], ***1a***. A mixture of 6.4 g (0.02 mol) of benzyl glycinate benzenesulfonate and 3.1 g (0.01 mol) of bis (salicylaldehydato)copper (II) was dissolved in 40 cm^3 of water. The reaction mixture was then stirred at 40 °C for 2 h. After it had been cooled, a brownish green crystal was filtered, and washed several times by water, yield 60%. IR(KBr) 1735 cm^{-1} (ester C=O). Found: C, 63.44; H, 5.06; N, 4.69%. Calcd for [Cu($C_{32}H_{28}O_6N_2$)]: C, 64.04; H, 4.71; N, 4.67%.

Copper (II) Complexes of the Schiff Bases Derived from Salicylaldehyde and Benzyl β-Alaninate and γ-Aminobutyrate, [*Cu(Sal=β-AlaOBzl)*$_2$], ***1b*** *and* [*Cu(Sal=γ-N-BuOBzl)*$_2$], ***1c***. These complexes were prepared in a similar manner using benzyl β-alaninate *p*-toluenesulfonate and benzyl γ-aminobutyrate *p*-toluenesulfonate, respectively. [Cu(Sal=β-AlaOBzl)$_2$]: yield 60%. IR (KBr) 1730 cm^{-1} (ester C=O). Found: C, 64.80; H, 5.47; N, 4.29%. Calcd for [Cu($C_{34}H_{32}O_6N_2$)]: C, 65.00; H, 5.14; N, 4.46%. [Cu(Sal=γ-*N*-BuOBzl)$_2$]: yield 43%. IR (KBr) 1725 cm^{-1} (ester C=O). Found: C, 64.58; H, 5.31; N, 4.00%. Calcd for [Cu($C_{36}H_{36}O_6N_2$)]·1/2H_2O: C, 64.99;

H, 5.62; N, 4.21%.

The Reactions of Copper(II) Complexes ***1a, 1b, and 1c*** *with Methanol.* The reaction mixture of 1 g of the complex **1a**, **1b**, or **1c** and methanol (200 cm³)–chloroform (100 cm³) was heated under reflux for 30 min. After it had been filtered, the filtrate was cooled to give brownish green crystals. They were collected by filtration, the same additional product being obtained by removing the solvent. The products were identified as the copper(II) chelates of the Schiff bases derived from salicylaldehyde and methyl glycinate, β-alaninate, and γ-aminobutyrate, respectively, from the results of elemental analyses. [Cu(Sal=GlyOMe)$_2$]: 92% yield. IR(KBr.) 1750 cm^{-1} (ester C=O). Found: C, 53.20; H, 4.76;N, 6.14%. Calcd for [Cu($C_{20}H_{20}O_6N_2$)]: C, 53.62; H, 4.51; N, 6.25%. [Cu(Sal=β-AlaOMe)$_2$]: 66% yield. IR(KBr) 1720 cm^{-1} (ester C=O). Found: C, 55.16; H, 5.33; N, 5.95%. Calcd for [Cu($C_{22}H_{24}O_6N_2$)]: C, 55.50; H, 5.09; N, 5.88%. [Cu(Sal=γ-*N*-BuOMe)$_2$]: 60% yield. IR(KBr) 1730 cm^{-1} (ester C=O). Found: C, 55.45; H, 5.78; N, 5.57%. Calcd for [Cu($C_{24}H_{28}O_6N_2$)]·H_2O: C, 55.21; H, 5.80; N, 5.37%.

Copper(II) Complexes of Schiff Bases Derived from Salicylaldehyde and Dibenzyl L- *and* DL-*Aspartates,* [*Cu(Sal=*L- *or* DL-*Asp(OBzl)$_2$)$_2$*], ***3a.*** To a mixture of 5.6 g (0.012 mol) of dibenzyl L- or DL-aspartate benzenesulfonate and 60 cm³ of water was added 1.9 g (0.006 mol) of bis(salicylaldehydato)-copper (II). The reaction mixture was stirred at 40 °C for 3 h, and allowed to stand for a few hours at room temperature. The precipitate was collected by filtration, and washed with water and ethanol. [Cu(Sal=L-Asp(OBzl)$_2$)$_2$]: 40% yield. Mp 130.5—132 °C. IR(KBr) 1735 cm^{-1} (ester C=O). Found: C, 67.04; H, 5.11; N, 3.30%. Calcd for [Cu($C_{50}H_{44}$-$O_{10}N_2$)]: C, 66.98; H, 4.96; N, 3.13%. [Cu(Sal=DL-Asp-(OBzl)$_2$)$_2$]: 96% yield. Mp 138—140 °C. IR(KBr) 1735 cm^{-1} (ester C=O). Found: C, 67.30; H, 5.12; N, 3.17%. Calcd for [Cu($C_{50}H_{44}O_{10}N_2$)]: C, 66.98; H, 4.96; N, 3.13%.

Copper(II) Complexes of Schiff Bases Derived from Salicylaldehyde and Dibenzyl L- *and* DL-*Glutamate,* [*Cu(Sal=*L- *or* DL-*Glu(OBzl)$_2$)$_2$*], ***3b.*** The complexes were prepared by a similar procedure to that for **3a** using dibenzyl L-glutamate benzenesulfonate and dibenzyl DL-glutamate hydrochloride. [Cu(Sal=L-Glu(OBzl)$_2$)$_2$]: 82% yield. Mp 105—107 °C. IR (KBr) 1740, 1710 cm^{-1} (ester C=O). Found: C, 66.70; H, 5.29; N, 3.03%. Calcd for [Cu($C_{52}H_{48}O_{10}N_2$)]·1/2H_2O: C, 66.90; H, 5.30; N, 3.00%. [Cu(Sal=DL-Glu(OBzl)$_2$)$_2$]: 86% yield. Mp 98—100 °C. IR(KBr) 1745, 1710 cm^{-1} (ester C=O). Found: C, 67.70; H, 5.34; N, 2.75%. Calcd for [Cu($C_{52}H_{48}O_{10}N_2$)]: C, 67.55; H, 5.24; N, 3.03%.

Reactions of Copper(II) Complexes ***3a*** *and* ***3b*** *with Methanol.* Complex **3a** (1 g) was refluxed in a mixture of methanol (200 cm³)–chloroform (30—50 cm³) for 30 min, and then filtered. The filtrate was cooled to give brownish green needles. After removing the solvent from the mother liquor, the same prcduct was also isolated. A similar treatment was carried out for **3b**. The reaction prouduct from [Cu(Sal=L-Asp-(OBzl)$_2$)$_2$] and CH_3OH: 30% yield. Mp 134—135.5 °C. IR (KBr) 1740 cm^{-1} (ester C=O). Found: C, 60.83; H, 4.88; N, 3.91%. Calcd for [Cu($C_{38}H_{36}O_{10}N_2$)]: C, 61.32; H, 4.89; N, 3.76%. The reaction product from [Cu(Sal=DL-Asp(OBzl)$_2$)$_2$] and CH_3OH: 63% yield. Mp 130—131 °C. IR (KBr) 1740 cm^{-1} (ester C=O). Found: C, 61.00; H, 5.03; N, 3.98%. Calcd for [Cu($C_{38}H_{36}O_{10}N_2$)]: C, 61.32; H, 4.89; N, 3.76%. The reaction product from [Cu(Sal=L-Glu(OBzl)$_2$)$_2$] and CH_3OH: 40% yield. The reaction product from [Cu(Sal=DL-Glu(OBzl)$_2$)$_2$] and CH_3OH: 52% yield. IR (KBr) 1740, 1715 cm^{-1} (ester C=O). Mp 102—104 °C. Found: C, 61.72; H, 5.56; N, 3.70%. Calcd for [Cu($C_{40}H_{40}$-$O_{10}N_2$)]: C, 62.20; H, 5.23; N, 3.63%.

Copper(II) Complexes of the Schiff Bases Derived from Salicylaldehyde and α-Methyl β-benzyl L- *and* DL-*Aspartate,* [*Cu(Sal=*L- *or* DL-*Asp(α-OMe)(β-OBzl))$_2$*], ***4a.*** A mixture of 0.81 g (0.0030 mol) of α-methyl β-benzyl L- or DL-aspartate hydrochloride and 0.45 g (0.0015 mol) of bis(salicyladehydato)copper (II) was dissolved in 10 cm³ of water. The mixture was stirred at 30—40 °C for 3 h, and then cooled. A brownish green crystalline product was filtered and washed several times with water containing a small amount of ethanol. [Cu(Sal=L-Asp(α-OMe) (β-OBzl))$_2$]: 43% yield. Mp 132—132.5 °C. IR(KBr) 1740 cm^{-1} (ester C=O). Found: C, 61.16; H, 4.89; N, 3.82%. Calcd for [Cu($C_{38}H_{36}O_{10}N_2$)]: C, 61.32; H, 4.89; N, 3.76%. [Cu(Sal=DL-Asp(α-OMe) (β-OBzl))$_2$]: 56% yield. Mp 131—133 °C. IR(KBr) 1740 cm^{-1} (ester C=O). Found: C, 61.41; H, 4.94; N, 3.95%. Calcd for [Cu($C_{38}H_{36}O_{10}N_2$)]: C, 61.32; H, 4.89; N, 3.76%.

Copper(II) Complex of the Schiff Base Derived from Salicylaldehyde and α-Methyl γ-benzyl L-*Glutamate,* [*Cu(Sal=*L-*Glu(α-OMe) (γ-OBzl))$_2$*], ***4b*** was prepared in the same way as that for chelate **4a**. 32% yield. IR(KBr) 1740, 1710 cm^{-1} (ester C=O). Found: C, 60.61; H, 5.27; N, 3.76%. Calcd for [Cu($C_{40}H_{40}O_{10}N_2$)]·H_2O: C, 60.78; H, 5.37; N, 3.55%.

Isolation of Schiff Bases ***5a—d*** *from Various Copper (II) Chelates.* To a solution of 0.5 g of each copper(II) chelate in 20 cm³ of chloroform was added 10% aqueous solution of disodium ethylenediaminetetracetate (20 cm³). The mixture was stirred at room temperature for several hours (Scheme 3). After the chloroform fraction had been dried over anhydrous magnesium sulfate, the filtrate was evaporated to dryness. Characterization of the yellow crystals or oily products obtained is given in Table 1. The results of elemental analysis are as follows. SalH=DL-Asp(OBzl)$_2$: Found: C, 72.19; H, 5.26; N, 3.50%. Calcd for $C_{25}H_{23}O_5N_2$: C, 71.92; H, 5.56; N, 3.36%. SalH=L-Asp(OBzl)$_2$: Found: C, 72.06; H, 5.26; N, 3.50%. Calcd for $C_{25}H_{23}O_5N$: C, 71.92; H, 5.56; N, 3.36%. SalH=DL-Asp(α-OMe) (β-OBzl): Found: C, 66.21; H, 5.69; N, 4.09%. Calcd for $C_{19}H_{19}O_5N$: C, 66.65; H, 5.89; N, 4.09%. SalH=L-Glu(OBzl)$_2$: Found: C, 72.37; H, 5.82; N, 3.23%. Calcd for $C_{26}H_{25}O_5N$: C, 72.37; H, 5.84; N, 3.25%.

*Direct Synthesis of SalH=*DL-*Asp(OBzl)$_2$.* The Schiff base was also synthesized from salicylaldehyde and dibenzyl DL-aspartate benzenesulfonate. The dibenzyl DL-aspartate[11] prepared from 4.7 g (0.01 mol) of dibenzyl DL-aspartate benzenesulfonate was dissolved in 50 cm³ of chloroform. To the mixture was added 1.2 g (0.01 mol) of salicylaldehyde and refluxed for 2 h. After it had been filtered, the filtrate was evaporated to dryness. The dry residue obtained as a syrup was rubbed with petroleum ether, and the resulting crystalline suspension filtered. The other Schiff bases were obtained by the same method.

*Reduction of SalH=*L-*Asp(OBzl)$_2$.* Sodium cyanohydroborate was added to a cold solution of SalH=L-Asp(OBzl)$_2$ (1 g) in methanol (200 cm³) until the yellow color of the solution disappeared. The reaction mixture was evaporated to dryness *in vacuo*, and the residue was washed several times with water and then extracted with chloroform. After the chloroform fraction had been dried over anhydrous magnesium sulfate, the solvent was removed from the filtrate under reduced pressure to give the ligand **11**, as a pale yellow oily product. IR(Nujor) 3300 cm^{-1} (N–H) and 1740 cm^{-1} (ester C=O). NMR($CDCl_3$) δ 2.74 (2H, d, –CH-C$\underline{H}_2$), 3.69 (1H, t, -C$\underline{H}$–CH_2), 4.61 (2H, s, -C$\underline{H}_2$–NH–), 5.03 and 5.10 (2H, s, Ar–C$\underline{H}_2$), and 7.26—6.59 ppm (14H, m, Ar-$\underline{H}$).

This substance was used for subsequent reaction without further purification.

Copper(II) Chelate **12**. To a solution of 0.8 g (0.002 mol) of **11** in 20 cm³ of chloroform was added 0.13 g (0.001 mol) of anhydrous copper (II) chloride. The mixture was stirred at room temperature for 3 h. After it had been filtered, the filtrate was evaporated to give a greenish oily product, which was washed with petroleum ether. IR (Nujor) 3300 cm^{-1} (N–H) and 1735 cm^{-1} (ester C=O).

Reaction of Copper(II) Complex **12** *with Methanol*. A mixture of complex **12** (0.5 g) and methanol (150 cm³) was heated under reflux for 30 min. After it had been filtered, a green-brown oily product, **13**, was obtained upon removal of methanol from the filtrate. IR(Nujor) 3300 cm^{-1} (N–H) and 1735 cm^{-1} (ester C=O).

Isolation of **14** *from Copper(II) Complex* **13**. Isolation was carried out in the same way as that for **3a**—**b** or **4a**—**b** (Scheme 3). Compound **14** was obtained as an oily product. IR (Nujor) 3300 cm^{-1} (N–H) and 1740 cm^{-1} (ester C=O). NMR ($CDCl_3$) δ 2.82 (2H, d, –CH–C$\underline{H}_2$), 3.68—3.79 (4H, m, –C$\underline{H}$–C$\underline{H}_2$ and –COOC$\underline{H}_3$), 4.71 (2H, s, –C$\underline{H}_2$–NH–), 5.18 (2H, s, –COOC$\underline{H}_2$–Ar), and 7.42—6.82 ppm (9H, m, Ar–$\underline{H}$).

*Reaction of SalH=*L*-Asp(OBzl)₂,* **5a**, *with Methanol in the Presence of* $CuCl_2$. A typical reaction is as follows: To a solution of **5a** (0.8 g, 0.002 mol) in 200 cm³ of methanol was added 0.0027 g (0.00002 mol) of anhydrous copper (II) chloride. The reaction mixture was heated under reflux for 30 min. After it had been filtered, the filtrate was evaporated to dryness. A greenish oily product obtained was treated by the same procedure as for the isolation of **14** from **13**. Evaluation of the extent of the ester-exchange reaction occurred in the system was carried out on the basis of each peak area for –COOC$\underline{H}_3$, –COOC$\underline{H}_2$–Ar and –CH=N in PMR spectrum.

Measurements. Melting points were determined on a micro melting point apparatus and are uncorrected. IR spectra were recorded with a Hitachi 215 grating infrared spectrophotometer with KBr disk and Nujor mull, UV absorption spectra with a Union Giken SM-401 high sensitivity recording spectrophotometer, and PMR spectra with a JEOL JNM-MH-100 spectrometer with TMS reference. Thin layer chromatography (TLC) was carried out on silica gel (Merck Silica Gel 60 F_{254}). Chloroform was used as a solvent in all cases.

Results and Discussion

Ester-exchange Reactions in the Copper(II) Chelates of the Schiff Bases derived from Salicylaldehyde and Benzyl Glycinate, β-Alaninate or γ-Aminobutyrate. The copper(II) chelates of benzyl *N*-salicylidene-glycinate, -β-alaninate, and -γ-aminobutyrate, **1a**—**c**, were prepared by the condensation of bis(salicylaldehydato)copper(II) with benzyl ester of each amino acid. When chelates **1a**—**c** were refluxed in methanol for 30 min, the copper(II) chelates **2a**—**c** of methyl *N*-salicylidene-glycinate, -β-alaninate, and -γ-aminobutyrate were obtained in good yields. This indicates that the benzyl ester groups at α-, β-, or γ-position in the copper(II) chelates **1a**—**c** can be replaced by a methyl ester group (Scheme 1).

Selective Ester-exchange reactions in the Copper(II) Chelates of the Schiff Bases derived from Salicylaldehyde and Dibenzyl Aspartate or Glutamate. The copper(II) chelates of dibenzyl *N*-salicylidene-aspartate and -glutamate, **3-a** and **-b**, were prepared by warming a mixture of bis(salicylaldehydato)copper(II) and dibenzyl aspartate or glutamate. A methanol–chloroform solution of complex **3a** was refluxed for 30 min to yield a copper(II) chelate, of which half of the original benzyl groups were replaced by methyl groups. Elemental analysis of the reaction product shows that ester-exchange reaction takes place, though it is not clear in what position. We therefore, synthesized separately the copper(II) chelates of the Schiff bases derived from salicylaldehyde and α-methyl β-benzyl-DL- or -L-aspartates **4a**. The IR spectra of the authentic complexes thus obtained and the products of ester-exchange reaction agree with each other. The melting points for both the compounds showed no essential difference. From the results it can be concluded that the ester-exchange reaction in the complexes **3a** occurs selectively at the α-position in dibenzyl L- and DL-aspartate moiety (Scheme 2). No ester-exchange reaction in compound **5a**, the ligand of complex **3a**, was observed in the absence of copper(II). The α-ester group in dibenzyl L- and DL-glutamate moiety of the complexes **3b** is also preferably replaced in the same way by methyl groups.

For the sake of confirmation, the Schiff bases were isolated from the copper(II) complexes **3**- and **4-a** and **-b** (Scheme 3). The physical properties of Schiff bases **5a**—**d** are given in Table 1 and the PMR spectra of the L-isomers in Figs. 1 and 2. By comparing Figs. 1-a and -b we see that ligand **5a** of the original complex **3a** exhibits two peaks around 5 ppm (5.05 and 5.14 ppm), and ligand **5b** of the reaction product **3b** only one peak (5.08 ppm) in the same region. Since these peaks are caused by benzyl groups, the decrease in the number of peaks from 2 to 1 shows that the ester-exchange reaction takes place at only one of the two benzyl

b) $[Cu(Sal=L\text{-}Asp(OBzl)_2)_2] \xrightarrow{EDTA}$ reaction product. c) Salicylaldehyde + L-Asp(α-OMe)(β-OBzl) → reaction product. d) $[Cu(Sal=L\text{-}Asp(OBzl)_2)_2] \xrightarrow[\text{reflux, 30 min}]{CH_3OH}$ reaction product $\xrightarrow{EDTA}$ reaction product. e) Salicylaldehyde + L-$Asp(OMe)_2$ → reaction product.

ester groups. This is also supported by the following facts. The peak (3.69 ppm, s, 3H) due to methoxyl group is seen in the spectrum for ligand **5b** of the reaction product, the number of protons of aromatic rings decreasing from 14 to 9 with the exchange reaction. The results of TLC for the Schiff bases consisting of salicylaldehyde and some diesters of L-aspartic acid are summarized in Table 2. It was confirmed from the R_f values that the ester-exchange reaction takes place selectively at the α-position in the chelates **3a**. The same variation in PMR spectra was also observed in glutamate-Schiff base chelates (Fig. 2). The two peaks at 5.02 and 5.12 ppm arising from the methylene protons of benzyl groups in **5c** decrease to one peak (5.08 ppm) in the ligand **5d** of the reaction product. Appearance of a new peak (3.72 ppm) due to the methoxyl group and decrease of the peak for protons of aromatic rings with the ester-exchange reaction were also observed.

Reaction Mechanism. Two essentially different mechanisms have been proposed[5,7] to elucidate the ester-exchange reactions occurring in the presence of metal ion. Although both mechanisms were proposed

for the esters of the neutral amino acids such as glycine, α- and β-alanine, they were applied to explain the present kind of diesters of acidic amino acids. In the mechanism of Gillard and Wootton[7] (Scheme 4), the addition of methanol molecule would first take place at the azomethine double bond. In the structure of the intermediate **6**, the oxygen atom of the methoxyl group would readily attack nucleophilically the carbon atom of the α-ester group, since the methoxyl group is located very closely to the α-ester group. On the other hand, the attacking of the same methoxyl group seems to be difficult against the β- or γ-ester group because of its distant location. Furthermore, there might be a steric interruption of the α-ester group. The reason why the selective ester-exchange reaction occurs is thus reasonably explained on the basis of the mechanism of Gillard and Wootton.[7] The selective and highly catalytic activity of enzyme reactions are said to be understandable on the basis of the proximity and the orientation effects of the functional groups in enzymes and substrates. In this respect, the present mechanism bears a resemblance to the enzyme reactions. In the mechanism according to Houghton and Pointer[5] (Scheme 5), the reaction begins with a dissociation of one of the two Schiff base ligands in complex **3a**, followed by the formation of tridentate chelation of the remainder ligand. In structure **7** (or **8**) the carbon atom of α-ester group would be readily attacked by oxygen atom of methanol because of the electrophilic character of the former and the nucleophilic character of the latter. Although coordination of the ester group at the β- or γ-position is also possible, it would be much more difficult than that of the α-ester group, in view of the structure-stability relationship in the fused chelate ring system.[10,17] In the Houghton and Pointer mechanism, preferential formation of the terdentate chelate **7** (or **8**) would play an important role for the selective ester-exchange reaction. If the selective ester-exchange reactions of the present kind proceed *via* the Gillard and Wootton mechanism, the reactions would not occur in chelates **12** which lacks azomethine double bonds. As a matter of fact, the selective ester-exchange reaction in **12** was observed under the same conditions. Accordingly, the possibility of the Gillard and Wootton mechanism is slight. Further, the reactions of **5a** with methanol in the presence of catalytic concentrations of copper(II) chloride indicate that a slight amount of copper(II) ion is insufficient to cause the ester-exchange reaction, while increasing amount of copper(II) chloride promotes it (Table 3). The mechanism of Houghton and Pointer has the advantage of interpreting the result described above. Though the efficiency of the ester-exchange reaction is low in the presence of minute quantities of copper(II), it is understandable in view of the observa-

tion that the major complex in solution is probably **3a** rather than **7** which are the active species for ester-exchange reaction. In conclusion, we are more in line with the Houghton and Pointer mechanism, which involves the dissociation and recoordination of Schiff base ligand.

We are grateful to Mr. Yoshio Terawaki of the Faculty of Engineering Science of this university for PMR measurements. Expense for this work were defrayed in part by grants from the Takeda Science Foundation and the Ministry of Education.

(Received October 13, 1979)

The (lel_3), (lel_2ob), and ($lelob_2$) isomers of $[Co(rac\text{-cptn})_3]^{3+}$ were obtained by the reaction of *trans*-$[CoCl_2(pyridine)_4]^+$ with *rac*-cptn, where cptn denotes *trans*-1,2-cyclopentanediamine. No indication for the formation of the (ob_3) isomer was found. The isomers were resolved into optical isomers by SP-Sephadex column chromatography. The circular dichroism spectra of these optical isomers were measured and the results compared with those of the related complexes. The anomalous circular dichroism pattern of the (lel_3) isomer in the region of the first absorption band was found to result from the contribution of the strong vicinal effect of the chiral cptn chelate ligand as compared with that of the configurational effect.

The tris(*rac-trans*-1,2-cyclopentanediamine)cobalt(III) ion, $[Co(rac\text{-cptn})_3]^{3+}$ has four possible diastereomers, each of which exists in a pair of enantiomers (Δ and Λ). Since the ligand forms a gauche-type (δ and λ) chelate ring upon coordination, these diastereomers can be designated as lel_3($\Delta(\lambda\lambda\lambda)$ and $\Lambda(\delta\delta\delta)$), lel_2ob ($\Delta(\lambda\lambda\delta)$ and $\Lambda(\delta\delta\lambda)$), $lelob_2$($\Delta(\lambda\delta\delta)$ and $\Lambda(\delta\lambda\lambda)$), and ob_3($\Delta(\delta\delta\delta)$ and $\Lambda(\lambda\lambda\lambda)$).[1]

Jaeger and Blumendal[2] found in their studies on metal complexes with *rac*-cptn that $[M(rac\text{-cptn})_3]^{3+}$ (M=Co(III), Rh(III)) exists in only one pair of enantiomers, $(+)_{589}$-$[M((-)\text{-cptn})_3]^{3+}$ and $(-)_{589}$-$[M((+)\text{-cptn})_3]^{3+}$. Ito *et al.*[3] prepared $(-)_{589}$-$[Co((+)\text{-cptn})_3]^{3+}$ and determined its absolute configuration by the X-ray method to be $\Lambda(\delta\delta\delta)(lel_3)$-$[Co(S,S\text{-cptn})_3]^{3+}$. They found that this isomer shows a main circular dichroism (CD) band with the negative sign in the region of the first absorption band in contrast with Λ-$[Co(en)_3]^{3+}$ (en=ethylenediamine) and other Λ-tris(1,2-diamine)cobalt(III) complexes whose main CD bands are always positive in this region. Toftlund and Pedersen[4] found that the reaction of *trans*-$[CoCl_2py_4]^+$ (py=pyridine) with (*R,R*)-cptn gives $\Delta(\lambda\lambda\lambda)(lel_3)$- and $\Lambda(\lambda\lambda\lambda)(ob_3)$-$[Co(R,R\text{-cptn})_3]^{3+}$ in the formation ratio 10: 1. The Λ-ob_3 isomer, although it was not isolated as crystals but only separated as a fraction in the column chromatography, also showed an anomalous CD pattern in the region of the first absorption band, its main CD being negative.

In order to elucidate such anomalous CD spectra of $[Co(cptn)_3]^{3+}$, it is desirable to isolate all diastereomers of this complex. This paper deals with the preparation and resolution of diastereomers of $[Co(rac\text{-cptn})_3]^{3+}$ and their CD spectra.

Experimental

Ligands. *Trans*-1,2-cyclopentanediamine (cptn) was prepared and resolved by the method of Toftlund and Pedersen.[4] The (+)-cptn isomer has (*S,S*)-configuration, forming a δ-gauche chelate ring upon coordination.[3]

$[Co(cptn)_3]^{3+}$. *a)*: *Trans*-$[CoCl_2py_4]Cl\cdot 6H_2O$ was mixed with (−)-cptn in 2-methoxyethanol.[4] The product was carefully chromatographed by use of a column of SP-Sephadex C-25 (ϕ 2.7×130 cm). By elution with 0.15 mol/dm³ disodium hydrogenphosphate, 0.2 mol/dm³ sodium sulfate, or 0.15 mol/dm³ sodium $(+)_{589}$-tartratoantimonate (III), the column always gave only one band of the $\Delta(\lambda\lambda\lambda)(lel_3)$ isomer. No indication for the presence of the $\Lambda(\lambda\lambda\lambda)(ob_3)$ isomer was observed.

b): An *N,N*-dimethylformamide solution (50 cm³) containing *trans*-$[CoCl_2(R,R\text{-cptn})_2]ClO_4$[5] (0.55 g, 1.3 mmol) and *R,R*-cptn (0.13 g, 1.3 mmol) was stirred at room temperature for a day. The resulting red solution was diluted with water to 1 dm³, adjusted to pH 4 with hydrochloric acid, and poured on a column of SP-Sephadex C-25 (ϕ 2.7×130 cm). The adsorbed band was eluted by the same method as the above to give only one $\Delta(\lambda\lambda\lambda)(lel_3)$ isomer, no $\Lambda(\lambda\lambda\lambda)(ob_3)$ isomer being detected on the column.

c): To a 2-methoxyethanol solution (3 cm³) of *rac*-cptn (3 g, 30 mmol) was added dropwise a 2-methoxyethanol solution (10 cm³) of *trans*-$[CoCl_2py_4]Cl\cdot 6H_2O$ (5 g, 8.5 mmol). The red $[Co(cptn)_3]Cl_3$ complex was precipitated immediately and filtered at 0 °C after 1 h. It was washed three times with 3 cm³ portion of ethanol and air dried. (yield: 85%). A small portion (*ca.* 0.2 g) of this crude complex was dissolved in water and the solution was poured on a column of SP-Sephadex C-25 (ϕ 2.7×130 cm). By elution with a 0.2 mol/dm³ Na_2SO_4 solution, three red bands, T_1, T_2, and T_3 were obtained in succession. Each eluate was diluted with 10^{-2} mol/dm³ HCl and poured again on a small column of SP-Sephadex C-25. The adsorbed band was eluted with 2 mol/dm³ HCl after the column had been washed thoroughly with 10^{-2} mol/dm³ HCl in order to remove Na^+ ions. The eluate was evaporated to dryness in a vacuum desiccator over NaOH and P_2O_5. The residue was washed with a small amount of ethanol and recrystallized from water to give red crystals. T_1, T_2, and T_3 formed in the ratio 10: 4: 1, are racemates of the lel_3, lel_2ob, and $lelob_2$ diastereomers, respectively.

The diastereomers were resolved by SP-Sephadex column chromatography.[6] The T_1 isomer adsorbed on a column of SP-Sephadex C-25 (ϕ 2.7×130 cm) was eluted with a 0.3 mol/dm³ sodium $(+)_{589}$-hydrogentartrate solution. Two bands were separately eluted. From the fast and the slowly eluted fractions, $(-)_{589}$-$\Lambda(\delta\delta\delta)(lel_3)$-$[Co(S,S\text{-cptn})_3]Cl_3\cdot 4H_2O$ and $(+)_{589}$-$\Delta(\lambda\lambda\lambda)(lel_3)$-$[Co(R,R\text{-cptn})_3]Cl_3\cdot 4H_2O$, respectively, were isolated by a method similar to that for the racemates described above. Elution with sodium $(+)_{589}$-tartratoantimonate (III) resulted in poor separation between the bands of the enantiomers.

The T_2 and T_3 isomers were resolved similarly with an eluent, a 0.15 mol/dm³ sodium $(+)_{589}$-tartratoantimonate (III)

† Present address: Department of Chemistry, Faculty of Science, Shizuoka University, Shizuoka 420.

TABLE 1. ANALYTICAL DATA OF THE cptn COMPLEXES

Complex	C/%		H/%		N/%	
	Found	Calcd	Found	Calcd	Found	Calcd

cptn=$C_5H_{12}N_2$.

solution, and the optical isomers were isolated by the same method as that for the T_1 isomer. The fast eluting enatiomers of T_2 and T_3 are $(-)_{589}$-$\Lambda(\delta\delta\lambda)(lel_2ob)$-$[Co(S,S\text{-cptn})_2(R,R\text{-cptn})]Cl_3\cdot 5H_2O$ and $(+)_{589}$-$\Lambda(\delta\lambda\lambda)(lelob_2)$-$[Co(S,S\text{-cptn})(R,R\text{-cptn})_2]Cl_3\cdot 3H_2O$, respectively. Their antipodes obtained from the slowly eluted bands are thus $(+)_{589}$-$\Delta(\lambda\lambda\delta)(lel_2ob)$-$[Co(R,R\text{-cptn})_2(S,S\text{-cptn})]Cl_3\cdot 5H_2O$ and $(-)_{589}$-$\Delta(\lambda\delta\delta)(lelob_2)$-$[Co(R,R\text{-cptn})(S,S\text{-cptn})_2]Cl_3\cdot 3H_2O$.

[Co(en)$_2$(R,R-cptn)]$^{3+}$. This complex was prepared from *trans*-$[CoCl_2(en)_2]Cl$ and (*R,R*)-cptn in dimethyl sulfoxide by a method similar to that reported.[7] The isomers were separated by an SP-Sephadex column chromatographic method. By elution with a 0.2 mol/dm^3 Na_2SO_4 solution, two orange bands of $\Delta(\lambda)$- and $\Lambda(\lambda)$-$[Co(en)_2(R,R\text{-cptn})]^{3+}$ were eluted in succession. From the eluates, orange crystals of the complex chlorides were obtained by the same method as that for the tris(cptn) complex. Both isomers showed positive rotation at 589 nm.

[Co(NH$_3$)$_4$(R,R-cptn)]$^{3+}$. This complex was prepared from $[Co(NH_3)_5(H_2O)](ClO_4)_3$ and (*R,R*)-cptn by a method similar to that for the corresponding en complex.[8] Since an orange fraction obtained by chromatography with an eluent, 0.2 mol/dm^3 Na_2SO_4, was contaminated with the starting aqua complex, the fraction was rechromatographed with a 0.2 mol/dm^3 disodium tartrate solution. The complex chloride was isolated by the same method as that for the tris(cptn) complex and recrystallized from a mixture of water and methanol. Analytical data of all the complexes are given in Table 1.

Measurements. Absorption and CD spectra were recorded in aqueous solutions on a Hitachi 323 spectrophotometer, and a JASCO J-40 spectropolarimeter, respectively. Optical rotations were measured with a JASCO DIP-4 polarimeter. ^{13}C-NMR spectra were obtained with a Jeol JNM FX-60 spectrometer using TMS as an external reference in aqueous solutions by locking to D_2O. For the measurements, the tris (cptn) complex chlorides were converted into acetates with QAE-Sephadex A-25 anion exchanger in the acetate form in order to increase the solubility.

Results and Discussion

The Isomers of [Co(cptn)$_3$]$^{3+}$. Toftlund and Pedersen[4] obtained $\Delta(\lambda\lambda\lambda)(lel_3)$- and $\Lambda(\lambda\lambda\lambda)(ob_3)$-$[Co(R,R\text{-cptn})_3]^{3+}$ in the ratio 10: 1 by the reaction of *trans*-$[CoCl_2py_4]Cl\cdot 6H_2O$ with *R,R*-cptn in 2-methoxyethanol. However, all attempts to prepare the (ob_3) isomer were unsuccessful (Experimental). On the other hand, three (T_1, T_2, and T_3) of the four possible diastereomers (lel_3, lel_2ob, $lelob_2$, and ob_3) were obtained in the ratio 10: 4: 1, by a method similar to that of Toftlund and Pedersen using *rac*-cptn instead of *R,R*-cptn. No indication for the presence of more than three isomers was observed in the column chromatography. The isomers were completely resolved by SP-Sephadex column chromatography.

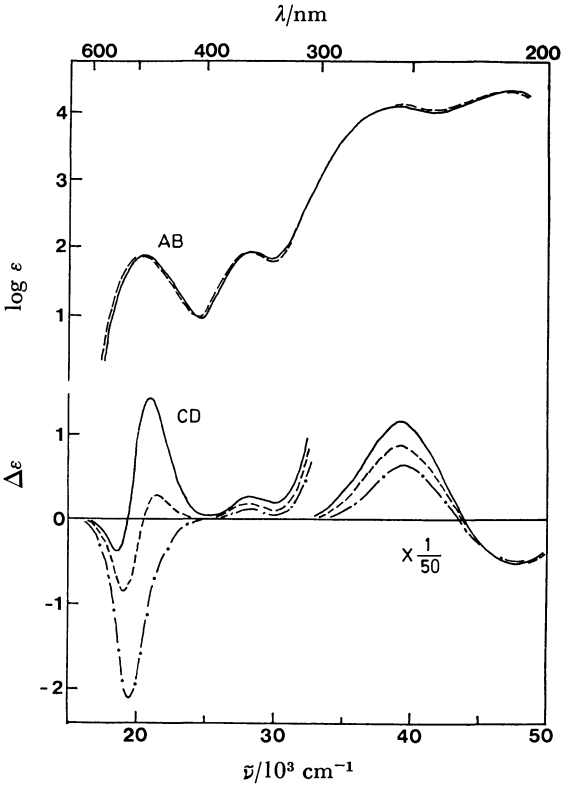

Fig. 1. Absorption and CD spectra of $[Co(cptn)_3]^{3+}$.
——: $(+)_{589}$-$\Delta(\lambda\lambda\lambda)$ (lel_3)-$[Co(R,R\text{-cptn})_3]^{3+}$ (T_1), ------: $(+)_{589}$-$\Delta(\lambda\lambda\delta)$ (lel_2ob)-$[Co(R,R\text{-cptn})_2(S,S\text{-cptn})]^{3+}$ (T_2), -·-·-: $(-)_{589}$-Δ $(\lambda\delta\delta)$ $(lelob_2)$-$[Co$ $(R,R\text{-cptn})$ $(S,S\text{-cptn})_2]^{3+}$ (T_3).

The CD spectra of the enantiomers obtained from the more slowly eluted bands on the columns are given in Fig. 1 and the spectral data in Table 2. The CD spectrum of T_1 is the mirror image of that of $\Delta(\delta\delta\delta)(lel_3)$-$[Co(S,S\text{-cptn})_3]^{3+}$ whose absolute configuration has been determined by the X-ray method.[3] Thus T_1 is assigned to $\Delta(\lambda\lambda\lambda)(lel_3)$-$[Co(R,R\text{-cptn})_3]^{3+}$. The other T_2 and T_3 isomers (Fig. 1) can be assigned to $\Delta(\lambda\lambda\delta)(lel_2ob)$-$[Co(R,R\text{-cptn})_2(S,S\text{-cptn})]^{3+}$ and $\Delta(\lambda\delta\delta)(lelob_2)$-$[Co(R,R\text{-cptn})(S,S\text{-cptn})_2]^{3+}$, respectively, for the following reasons: 1) The CD spectra in the region of the first absorption band change remarkably but regularly in the order T_1, T_2, and T_3, but those in the ultraviolet

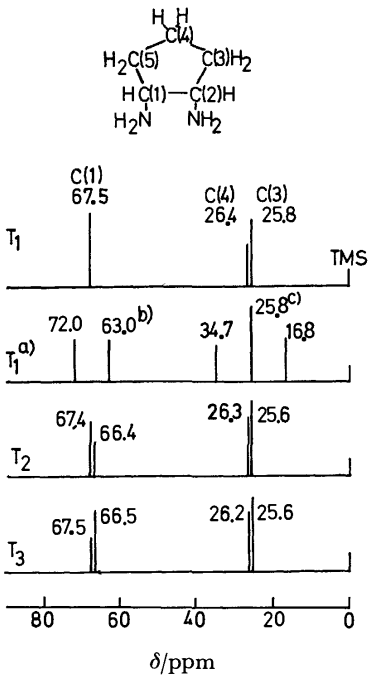

Fig. 2. ^{13}C-NMR spectra of the three isomers of [Co(cptn)$_3$] $(CH_3COO)_3$ in D_2O (15.04 MHz, The signals due to CH_3COO^- are omitted).
a) The off-resonance spectrum, b) J_{C-H}=135.5 Hz. c) J_{C-H}=134.3 Hz.

region are very similar to one another, indicating the same absolute configuration.[9] 2) The reactions with optically active *R,R*-cptn give only one isomer of (*lel*$_3$), no (*ob*$_3$) isomer being obtained. 3) The yields of T_1, T_2, and T_3 decrease in this order. Since the stability of (*lel*$_{3-n}$*ob*$_n$) isomers of [Co(1,2-diamine)$_3$]$^{3+}$ decreases with an increase in the number of the *ob* ligands,[1,10] the order suggests the *lel*$_3$, *lel*$_2$*ob*, *lelob*$_2$ isomers for T_1, T_2, and T_3, respectively. The assignments are supported by ^{13}C-NMR spectroscopy (Fig. 2). The peak assignment can be made on the basis of the off-resonance and a comparison of relative intensities of the peaks. The T_1(*lel*$_3$) isomer which has D_3 symmetry[3] shows three kinds of carbons of the ligands. In the off-resonance spectrum, the lowest field peak at 67.52 ppm splits into two, while the two high field peaks at 26.37 and 25.80 ppm give a triplet due probably to accidental degeneracy of two triplets. The latter two peaks show a remarkable difference in intensity. Thus, the peaks at 67.52, 26.37, and 25.80 ppm can be assigned to the C(1), C(4), and C(3) atoms, respectively (Fig. 2). The T_2(*lel*$_2$*ob*) and T_3(*lelob*$_2$) isomers, both of which should have C_2 symmetry, each exhibits two C(1) peaks of different intensity. The T_2(*lel*$_2$*ob*) isomer shows a strong peak at a similar frequency value to that of the T_1(*lel*$_3$) isomer, and a weak peak in a little higher magnetic field. The T_3(*lelob*$_2$) isomer shows two similar peaks, but whose relative intensities are reversed (Fig. 2). Thus, the ^{13}C-NMR spectra strongly support the previous assignment that T_1, T_2, and T_3 are the *lel*$_3$, *lel*$_2$*ob*, and *lelob*$_2$ isomers, respectively.

The $\Lambda(\lambda\lambda\lambda)(ob_3)$ isomer reported[4] seems to be the $\Lambda(\lambda\lambda\delta)(lel_2ob)$ isomer, the formation of which might have resulted from incomplete resolution of the ligand. The CD spectrum reported for this isomer is very similar to that of our $\Lambda(\lambda\lambda\delta)(lel_2ob)$ isomer. The reason for the *ob*$_3$ isomer not being formed under the experimental conditions given is not known. However, the formation ratio of T_1, T_2, and T_3 (10:4:1) suggests that the stability of isomer decreases a great deal with an increase in the number of the *ob* ligands. The analogous [Co(chxn)$_3$]$^{3+}$ (chxn=*trans*-1,2-cyclohexanediamine) complex gives the *lel*$_3$, *lel*$_2$*ob*, *lelob*$_2$, and *ob*$_3$ isomers in the formation ratio of *ca.* 14:11:4:1 in equilibrium at 100 °C.[11] The differences among these values are small as compared with those of [Co(cptn)$_3$]$^{3+}$. The difference in the stability caused by replacing the *lel* ligand with the *ob* one in [Co(cptn)$_3$]$^{3+}$ would be much larger than that in [Co(chxn)$_3$]$^{3+}$. Attempts to equilibrate the isomers of [Co(cptn)$_3$]$^{3+}$ were unsuccessful because of the decomposition of the complex.

Absorption and CD Spectra. The three isomers of [Co(cptn)$_3$]$^{3+}$ give very similar absorption spectra, but the first absorption bands shift toward the smaller wavenumber side by *ca.* 100 cm^{-1} as the number of the *ob* ligands increases by one (Fig. 1 and Table 2). The magnitude of the shift is fairly large as compared with that of other tris(1,2-diamine) complexes. For [Co(chxn)$_3$]$^{3+}$ [11] and [Co(pn)$_3$]$^{3+}$ (pn=propylenediamine),[12] the differences in the absorption maxima between the *lel*$_3$ and *ob*$_3$ isomers are only 50 and 20 cm^{-1}, respectively. The large shift of the first absorption

band due to replacement of the *lel* ligand with the *ob* one in $[Co(cptn)_3]^{3+}$ also suggests that the complex becomes unstable rapidly with an increase in the number of the *ob* ligands.

The red $[Co(cptn)_3]^{3+}$ complex gives all the absorption bands at wavenumbers smaller than those of the corresponding bands of the orange $[Co(chxn)_3]^{3+}$ [11] and $[Co(pn)_3]^{3+}$.[12] The red shift of the charge-transfer band, in particular, amounts to 5000—8000 cm^{-1}. Such red shifts might be brought about by a strained structure of the cptn chelate ring as pointed out by Ito *et al.*;[3] the N–N distance of 3.14 Å in a strain-free, free ligand decreases in length to 2.76 Å on forming a chelate ring, which give considerable strain in bond angles of the chelate ring. In cobalt(III) complexes with strain caused by various factors such as congestion due to bulky ligands or steric requirement, as in the case of cptn, the d-d absorption bands shift to the small wavenumber side.[13] The shift of the charge-transfer band might also be correlated with such a strained structure of the cptn chelate ring. No appreciable strain is observed for bond angles of the chelate rings in $[Co(chxn)_3]^{3+}$ [14] and $[Co(pn)_3]^{3+}$.[15]

The CD spectra of three isomers of the $[Co(cptn)_3]^{3+}$ complex are compared in Fig. 1. If we assume that all the isomers have the same Δ-configuration, the CD contributions due to the configurational and the vicinal effects can be estimated by the equations

$$\Delta\varepsilon(\Delta) = 1/2[\Delta\varepsilon(T_2: \Delta\lambda\lambda\delta) + \Delta\varepsilon(T_3: \Delta\lambda\delta\delta)]$$

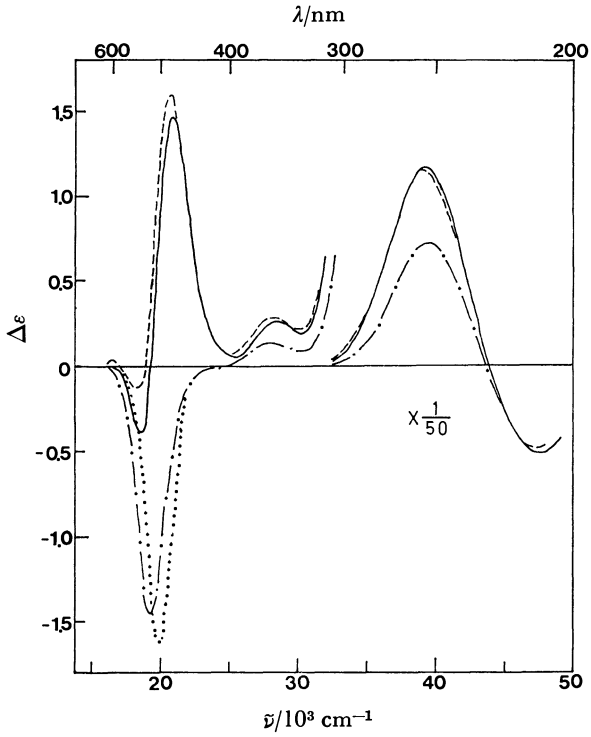

Fig. 3. Configurational effect CD ($\Delta\varepsilon(\Delta)$) of $[Co(cptn)_3]^{3+}$.
——: Observed CD of $\Delta(\lambda\lambda\lambda)$-$[Co(R,R\text{-cptn})_3]^{3+}$ (T_1), –·–·–: Calculated $\Delta\varepsilon(\Delta) = 1/2[\Delta\varepsilon(T_2: \Delta\lambda\lambda\delta) + \Delta\varepsilon(T_3: \Delta\lambda\delta\delta)]$, – – –: Calculated $\Delta\varepsilon[\Delta(\lambda\lambda\lambda)] (= \Delta\varepsilon(\Delta) + 3\Delta\varepsilon(\lambda))$, ……: Calculated $\Delta\varepsilon(\Delta)$ from $\Delta(\lambda)$- and $\Lambda(\lambda)$-$[Co(en)_2(R,R\text{-cptn})]^{3+}$ ($1/2\{\Delta\varepsilon[\Delta(\lambda)] - \Delta\varepsilon[\Lambda(\lambda)]\}$).

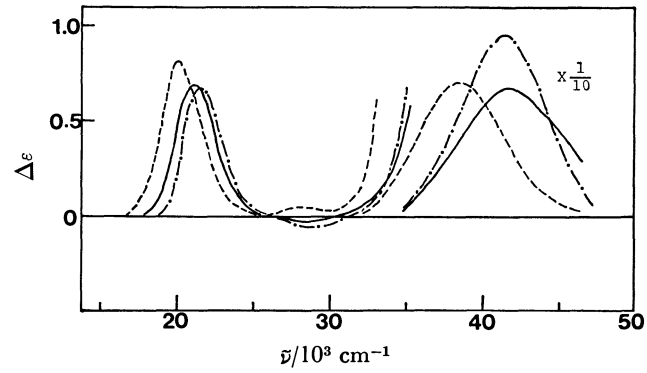

Fig. 4. Vicinal effect CD ($\Delta\varepsilon(\lambda)$) of the $\lambda(R,R$-cptn) ligand.
——: Observed CD of $[Co(NH_3)_4(R,R\text{-cptn})]^{3+}$, – – – –: Calculated $\Delta\varepsilon(\lambda) = 1/2[\Delta\varepsilon(T_2: \Delta\lambda\lambda\delta) - \Delta\varepsilon(T_3: \Delta\lambda\delta\delta)]$, –·–·–: Calculated $\Delta\varepsilon(\lambda)$ from $\Delta(\lambda)$- and $\Lambda(\lambda)$-$[Co(en)_2(R,R\text{-cptn})]^{3+}$ ($1/2\{\Delta\varepsilon[\Delta(\lambda)] + \Delta\varepsilon[\Lambda(\lambda)]\}$).

$$\Delta\varepsilon(\lambda) = 1/2[\Delta\varepsilon(T_2: \Delta\lambda\lambda\delta) - \Delta\varepsilon(T_3: \Delta\lambda\delta\delta)]$$

where $\Delta\varepsilon(T_2: \Delta\lambda\lambda\delta)$ and $\Delta\varepsilon(T_3: \Delta\lambda\delta\delta)$ are the observed CD for $(+)_{589}$-T_2 and $(-)_{589}$-T_3 isomers, respectively, and $\Delta\varepsilon(\Delta)$ and $\Delta\varepsilon(\lambda)$ the CD of the Δ-configurational and the $\lambda(R,R$-cptn)-vicinal effects, respectively. The calculated CD curves of these two effects are shown in Figs. 3 and 4 in which CD curves of the related complexes are given for comparison. The CD curve calculated for $\Delta\varepsilon[\Delta(\lambda\lambda\lambda)] (= \Delta\varepsilon(\Delta) + 3\Delta\varepsilon(\lambda))$ agrees with the observed CD spectrum of $(+)_{589}$-$T_1\Delta(\lambda\lambda\lambda)(lel_3)$-$[Co(R,R\text{-cptn})_3]^{3+}$ over the whole region (Fig. 3). This indicates that the additivity[9,16] in CD between the configurational and the vicinal effects holds in the CD of $[Co(cptn)_3]^{3+}$. The $\Delta\varepsilon(\Delta)$ curve also resembles the Δ-configurational CD curve obtained similarly from the CD spectra of a diastereomeric pair, $\Delta(\lambda)$- and $\Lambda(\lambda)$-$[Co(en)_2(R,R\text{-cptn})]^{3+}$ ($1/2\{\Delta\varepsilon[\Delta(\lambda)] - \Delta\varepsilon[\Lambda(\lambda)]\}$). On the other hand, the $\lambda(R,R$-cptn)-vicinal CD curve, $\Delta\varepsilon(\lambda)$, is very similar in pattern and strength to the observed CD spectrum of $[Co(NH_3)_4(R,R\text{-cptn})]^{3+}$, and also to the vicinal CD curve obtained from $\Delta(\lambda)$- and $\Lambda(\lambda)$-$[Co(en)_2(R,R\text{-cptn})]^{3+}$ ($1/2\{\Delta\varepsilon[\Delta(\lambda)] + \Delta\varepsilon[\Lambda(\lambda)]\}$). All the results support the validity of the additivity. Hence the configurational and the vicinal CD of the $[Co(cptn)_3]^{3+}$ complex can be compared with those of other diamine complexes.

The configurational ($\Delta\varepsilon(\Delta)$) and the vicinal ($3\Delta\varepsilon(\lambda)$) CD curves of $[Co(R,R\text{-cptn})_3]^{3+}$ in the region of the first absorption band are compared with those of $[Co(R,R\text{-chxn})_3]^{3+}$ [11,17] and $[Co(R\text{-pn})_3]^{3+}$ [9,17] (Fig. 5). The signs of the configurational and the vicinal CD of the R,R-cptn complex are the same as those of the corresponding CD of the other complexes. However, there is a big difference in the relative CD strength of these two effects. In the $[Co(R,R\text{-cptn})_3]^{3+}$ complex, the vicinal CD is much stronger than the configurational CD, the relation being reversed in the other complexes. However, if the CD strength is neglected, there is no anomaly in the CD of the R,R-cptn complex; the Δ-configurational and the λ-gauche vicinal effects give CD with negative and positive signs, respectively, in the region of the first absorption band, in line with the

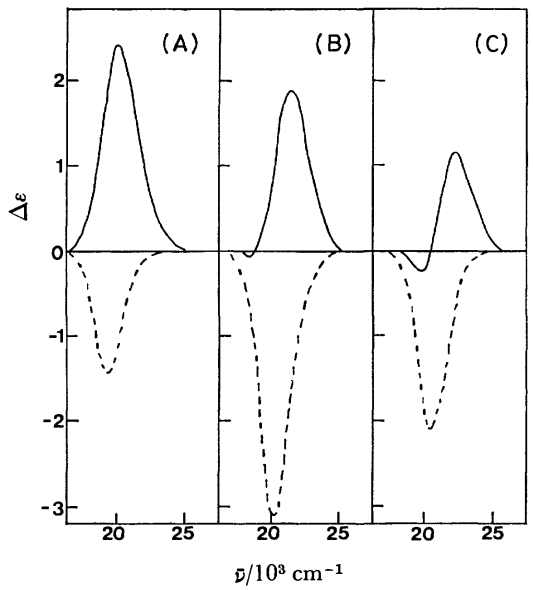

Fig. 5. Comparison of configurational ($\Delta\varepsilon(\Delta)$) (——) and vicinal ($3\Delta\varepsilon(\lambda)$) (——) effect CD of the $\Delta(lel_3)$-[Co(diamine)$_3$]$^{3+}$ complexes.
Diamine: (A) *R,R*-cptn, (B) *R,R*-chxn, (C) *R*-pn.

Diamine: *R,R*-cpth (——), *R,R*-chxn (——), *R*-pn (-•-•-).

general rule concerning the CD sign in this region and the absolute configuration of a cobalt(III) complex. It is therefore concluded that the anomalous CD pattern, the positive sign of the main CD band of $\Delta(\lambda\lambda\lambda)$-[Co(*R,R*-cptn)$_3$]$^{3+}$ results from the contribution of the stronger positive vicinal effect than the negative configurational effect. The Δ-[Co(*R,R*-chxn)$_3$]$^{3+}$ and Δ-[Co(*R*-pn)$_3$]$^{3+}$ complexes which give the negative main CD band in line with the general rule have a strong negative configurational CD as compared with the positive vicinal CD.

The reason why the cptn complex shows such anomalous CD differing from those of the chxn and pn complexes is not clear. Ito *et al.*[3] suggested from a comparison of the data of X-ray crystal analyses on several tris(diamine) complexes that the important factor governing the rotatory strength of d-d transitions in metal complexes is the cumulative effect of various distortions of the ligand atoms. The cptn chelate ring involves strain. The bond angles, NC(1)C(5)(119°) and C(2)C(1)C(5)(110°) deviate from the normal tetrahedral angle.[3] The [Co(tn)$_3$]$^{3+}$ complex (tn=trimethylenediamine) exhibiting an extremely weak CD in the region of the first absorption band[18] is also strained in the bond angle (CoNC=117.4°),[19] although the complex consists of six-membered chelate rings in the chair form. These strained complexes show CD spectra in the region of the first absorption band differing from those of other strain-free complexes. On the other hand, the vicinal effect CD of a 1,2-diamine chelate ligand depends on the chiral gauche conformation rather than on the asymmetric carbon atom.[20,21] The conformation of the chelate ring should be achiral, when it is in a *cis*, planar conformation. Thus the CD strength due to the vicinal effect of a chiral 1,2-diamine chelate ligand would depend on the dihedral angle of the N–C–C–N moiety of the puckered chelate ring. The strength of the vicinal CD increases in the order of the *R*-pn, *R,R*-chxn, and *R,R*-cptn complexes (Figs. 5 and 6). The order agrees with an increasing order of the observed dihedral angles of the chelate rings in (lel_3)-[Co(diamine)$_3$]$^{3+}$; *R*-pn(51°),[15] *R,R*-chxn(59°),[14] and *R,R*-cptn(61.5°).[3] Thus, the anomalous CD pattern in the region of the first absorption band of $\Delta(\lambda\lambda\lambda)(lel_3)$-[Co(*R,R*-cptn)$_3$]$^{3+}$ is understandable in terms of the strong vicinal effect of the cptn chelate ligand.

The authors wish to thank Dr. Shunji Utsuno, Shizuoka University, for the ^{13}C-NMR spectra. The work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education (No. 243013).

Kinetics and Mechanism of the Reactions of Bis(acetylacetonato)-palladium(II) with Alkylamines

Shinichi MATSUMOTO and Shinichi KAWAGUCHI*

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received October 15, 1979)

The reactions of bis(acetylacetonato)palladium(II), $Pd(acac)_2$, with alkylamines (L) such as butyl-, cyclohexyl-, diethyl-, and dipropylamines in methanol to afford $[Pd(acac)L_2](acac)$ obey the usual two-term rate law, rate$=(k_0+k_1[L])[Pd(acac)_2]$. On the other hand, the rate of reaction of $Pd(acac)_2$ with diethylamine in THF and benzene is expressed by rate$=(k_1+k_2[L])[L][Pd(acac)_2]$. A mechanism is proposed which presumes the hydrogen-bonding interaction of $Pd(acac)_2$ with methanol and amine. Intermediacy of Pd(acac)(acac-C^3)L in these reactions was denied on the basis of the kinetic studies, and the carbon-bonded complex was concluded to be produced *via* $[Pd(acac)L_2](acac)$. The equilibrium constants for the reactions, $Pd(acac)_2+2Et_2NH\rightleftarrows[Pd(acac)(Et_2NH)_2](acac)$ and $Pd(acac)(acac\text{-}C^3)(Et_2NH)+Et_2NH\rightleftarrows[Pd(acac)(Et_2NH)_2](acac)$ were determined in dichloromethane and methanol.

The central-carbon-bonded complexes of acetylacetone and other β-dicarbonyl compounds have long been known for platinum, mercury, and other rather soft metal ions.[1] Strange to say, the palladium(II) complex of this sort had not been reported before 1971, when Baba *et al.* found that bis(acetylacetonato)palladium(II), $Pd(acac)_2$,** reacts with bases such as triphenylphosphine, pyridine, and diethylamine to convert one of the chelating ligands into the central-carbon-bonded state.[2] The molecular structure of Pd(acac)(acac-C^3)PPh_3 was confirmed by X-ray analysis.[3] Similar reactions have been successfully carried out with $Pt(acac)_2$,[4] $AuMe_2(acac)$,[5] and $Pd(etac)_2$ (etac=O,O'-chelated monoanion of ethyl acetoacetate)[6] to obtain the central-carbon-bonded complexes of β-dicarbonyl compounds.

When bis(β-diketonato)palladium(II) was reacted with excess nitrogen bases (L), *e.g.* in neat liquid, the β-diketonate anion, (β-dik), such as acetylacetonate, trifluoroacetylacetonate, and hexafluoroacetylacetonate was expelled from the coordination sphere to produce $[Pd(\beta\text{-dik})L_2](\beta\text{-dik})$ or $[PdL_4](\beta\text{-dik})_2$ depending on the nature of L.[7] In order to clarify whether or not the chelated β-diketonate ligand dissociates *via* the central-carbon-bonded state, kinetic and equilibrium studies on the reactions of $Pd(acac)_2$ with several alkylamines have been performed by the spectrophotometric method.

Experimental

Materials. Bis(acetylacetonato)palladium(II) was prepared according to the literature[8] and recrystallized twice from benzene. Found: C, 39.52; H, 4.64%. Calcd for $C_{10}H_{14}O_4Pd$: C, 39.46; H, 4.59%. All of the amines used in the following preparation of complexes were dried with sodium sulfate and distilled before use. Methanol and benzene were dried with Linde Molecular Sieves 3A and 4A, respectively, and distilled. Tetrahydrofuran (THF) was kept standing with lithium aluminium hydride for several days prior to distillation. The distillate was dried with Linde Molecular Sieve 3A and redistilled. Dichloromethane was treated with potassium carbonate, dried with Linde Molecular Sieve 4A and distilled. Water contents of organic solvents were checked with an MCI digital water microanalyzer CA-OI to be $1—2\times10^{-3}$ mol dm^{-3} in benzene and $3—4\times10^{-3}$ mol dm^{-3} in other solvents employed.

Acetylacetonatobis(diethylamine)palladium(II) acetylacetonate, $[Pd(acac)(Et_2NH)_2](acac)$, was prepared by the method reported by Okeya *et al.*[7]; $Pd(acac)_2$ (0.400 g) was dissolved in hot diethylamine (5 ml) and the solution was cooled to -20 °C to deposit the product in a 22% yield. Found: C, 47.86; H, 8.08; N, 6.02%. Calcd for $C_{18}H_{36}O_4N_2Pd$: C, 47.97; H, 8.05; N, 6.21%.

Acetylacetonato(acetylacetonato-C^3)(diethylamine)palladium(II), Pd(acac)(acac-C^3)(Et_2NH), was prepared according to Baba *et al.*[2] and recrystallized from dichloromethane–petroleum ether (bp *ca.* 50 °C). Found: C, 47.11, H, 5.07; N, 3.71%. Calcd for $C_{14}H_{25}O_4NPd$: C, 47.11; H, 5.00; N, 3.65%.

Acetylacetonatobis(cyclohexylamine) palladium(II) acetylacetonate, $[Pd(acac)(cyhxNH_2)_2](acac)$, was obtained as pale yellow fuzzy needles in a 68% yield on addition of diethyl ether to a reaction mixture of $Pd(acac)_2$ (0.200 g) with cyclohexylamine (2 ml) in dichloromethane (10 ml) after 30 min stirring at room temperature, and recrystallized from dichloromethane–diethyl ether. Found: C, 52.74; H, 8.15; N, 5.80%. Calcd for $C_{22}H_{40}O_4N_2Pd$: C, 52.57; H, 8.02; N, 5.57%.

Preparation and recrystallization of these mixed-ligand complexes must be carried out quickly to obtain pure substances. Prolonged handling in solution induces side reactions. Acetylacetonatobis(butylamine)palladium(II) and acetylacetonatobis(dipropylamine) palladium(II) acetylacetonates were also prepared but did not give satisfactory analyses, probably owing to contamination with by-products containing the carbon-bonded acetylacetonate ligand.

Kinetic and Equilibrium Measurements. Absorption spectra were measured with a Hitachi EPS-3T recording spectrophotometer. The reactions of $Pd(acac)_2$ with alkylamines were followed spectrophotometrically at 330 nm, the absorption maximum of the startimg complex. A large excess (50—10000 times) of amine was employd against $Pd(acac)_2$ ($6—50\times10^{-5}$ mol dm^{-3}) to attain the pseudo first order condition. The reaction of Pd(acac)(acac-C^3)(Et_2NH) with diethylamine was also followed spectrophotometrically at 295 nm and the pseudo first order condition was fulfilled by using 5000—15000 times amine against the complex ($8—11\times10^{-5}$ mol dm^{-3}).

** In this paper, acac represents an acetylacetonate anion chelated to a metal ion through two oxygen atoms, and acac-C^3 and acac-O stand for acetylacetonate anions bonded as a unidentate to a metal ion through the central carbon and an oxygen, respectively.

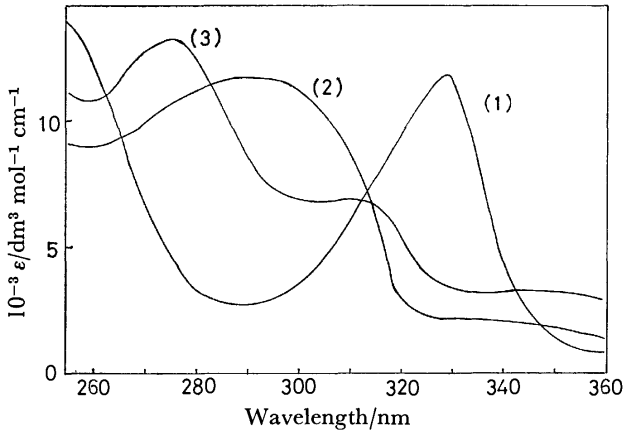

Fig. 1. Absorption spectra of $Pd(acac)_2$ (1), [Pd(acac)-$(Et_2NH)_2$] (acac) (2), and Pd (acac) (acac-C^3) (Et_2NH) (3) in dichloromethane.

In the experiments to determine the equilibria in dichloromethane, solutions containing [Pd(acac)$(Et_2NH)_2$] (acac) (1—4×10^{-2} mol dm^{-3}) and diethylamine (0—4×10^{-2} mol dm^{-3}) were kept at 25 °C for 24 h. Absorption spectra were measured immediately after dilution of the equilibrated solution to *ca.* 10^{-4} mol dm^{-3}, and absorbances at 290, 300, 320, and 330 nm were used to determine concentrations of three complexes, $Pd(acac)_2$, Pd(acac)(acac-C^3)(Et_2NH), and [Pd-(acac)$(Et_2NH)_2$](acac) on the basis of their spectra displayed in Fig. 1. Equilibria in methanol were attained by mixing solutions of $Pd(acac)_2$ (2—8×10^{-5} mol dm^{-3}) and diethylamine (2—15×10^{-4} mol dm^{-3}) and keeping the mixture at 25 °C for 24 h. Absorbances at 330 nm were utilized to obtain the equilibrium concentrations of Pd $(acac)_2$ and [Pd(acac)$(Et_2NH)_2$] (acac).

Results

Kinetics of the Reactions of Pd(acac)$_2$ with Alkylamines. Figure 2 shows, as an example, the change of absorption

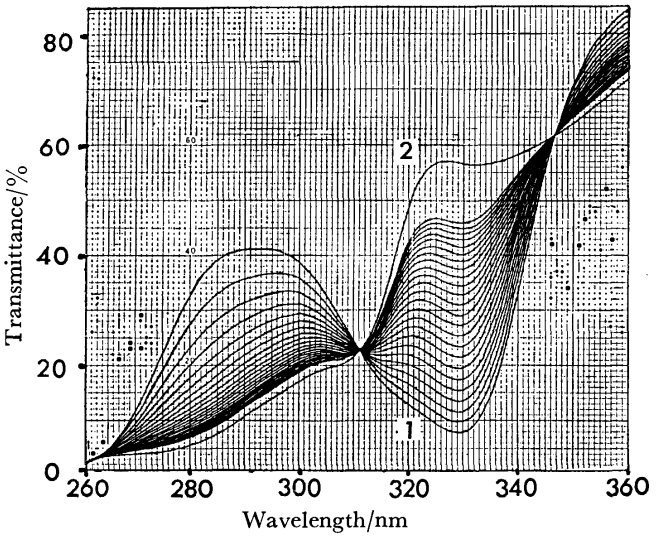

Fig. 2. The change of absorption spectrum with time during the reaction of $Pd(acac)_2$ (6.860×10^{-5} mol dm^{-3}) with diethylamine (2.039×10^{-1} mol dm^{-3}) in THF at 25.0 °C, curves 1 and 2 being spectra 2 min and *ca.* 4 h after commencement of the reaction, respectively.

spectrum with time during the reaction of $Pd(acac)_2$ with excess diethylamine in THF at 25 °C. Two distinct isosbestic points are observed at 311 and 347 nm, and curve 2 recorded *ca.* 4 h after the commencement of reaction coincides with the spectrum of authentic $[Pd(acac)(Et_2NH)_2](acac)$. These facts indicate that the overall reaction followed spectrophotometrically is expressed by Eq. 1 and there is no absorbing species involved in an appreciable amount except the starting and final complexes.

$$Pd(acac)_2 + 2Et_2NH \longrightarrow [Pd(acac)(Et_2NH)_2](acac) \quad (1)$$

Plots of $\log(A_t - A_\infty)$ *vs.* time gave straight lines over four half lives. Here A_t and A_∞ denote absorbances of the reaction mixture at time t and after completion of reaction, respectively. The same reaction in methanol and benzene also obeyed the pseudo first order kinetics.

Reactions of $Pd(acac)_2$ with other bases were carried out mainly in methanol. Reactions with cyclohexylamine and dipropylamine gave the final spectra, of which the former coincided with the spectrum of authentic $[Pd(acac)(cyhxNH_2)_2](acac)$. For the reaction with butylamine, a satisfactory spectrum at the infinite time could not be obtained owing to the succeeding reactions to yield $[Pd(BuNH_2)_4](acac)_2$, and the Guggenheim method[9] was employed to analyze the kinetic data.

Table 1 shows that the pseudo first order rate constants increase with the concentration of amine. However the exact dependence varies with the nature of solvent. As is seen in Fig. 3, the rate constants obtained from the reactions of several alkylamines in methanol increase with the amine concentration in accordance with the two term rate equation(2) which is characteristic of the ligand substitution reactions of square planar complexes which proceed according to the associative (**A**) mechanism.[10]

$$k_{obsd} = k_0 + k_1[amine] \quad (2)$$

These straight lines gave a practically common non-zero intercept, indicating the contribution of the solvent path. As is listed in Table 2, the second order rate constants exhibit a remarkable difference between the primary and secondary amines, the former reacting several times faster than the latter. The basicities of these amines are not so different; the pK_a values of the

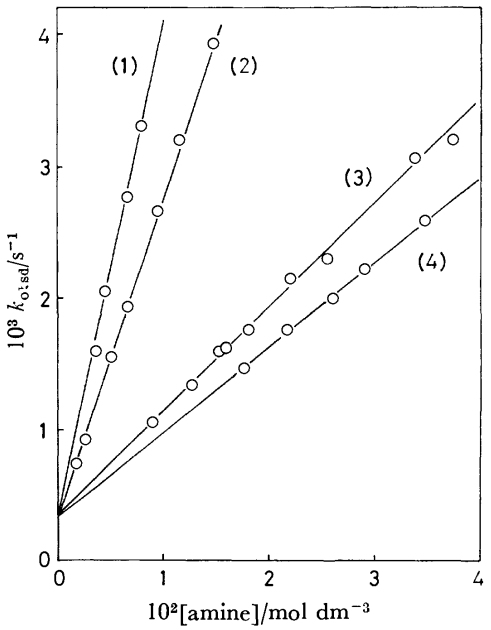

Fig. 3. Variation with the amine concentration of the pseudo first order rate constants for the reactions of $Pd(acac)_2$ with butylamine (1), cyclohexylamine (2), diethylamine (3), and dipropylamine (4) in methanol at 25 °C.

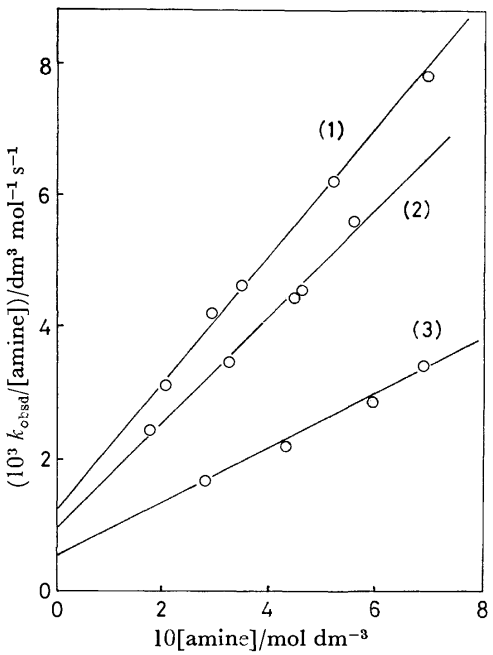

Fig. 4. Dependence on the amine concentration of the pseudo first order rate constants for the reactions of $Pd(acac)_2$ with diethylamine in THF (1) and benzene (2), and with dipropylamine in benzene (3) at 25 °C.

Table 2. Rate data for the reactions of $Pd(acac)_2$ with various amines at 25 °C

Solvent	Amine	10^4k_0 / s^{-1}	10^2k_1 / $dm^3\ mol^{-1}\ s^{-1}$	10^3k_2 / $dm^6\ mol^{-2}\ s^{-1}$
CH_3OH	butylamine	3.30±0.08	37.7 ±0.2	
	cyclohexylamine	3.32±0.07	24.3 ±0.2	
	diethylamine	3.40±0.09	8.27 ±0.09	
	dipropylamine	3.48±0.09	6.40 ±0.08	
THF	diethylamine		0.114±0.009	9.75±0.11
C_6H_6	diethylamine		0.094±0.007	8.10±0.08
	dipropylamine		0.035±0.007	4.80±0.07

conjugate acids are recorded as 10.64, 10.64, 10.93, and 11.00 at 25 °C for butylamine, cyclohexylamine, diethylamine, and dipropylamine, respectively.[11] The weaker nucleophilicity of the secondary amines than the primary amines seems to stem from their bulkiness. Steric influences of the entering as well as the leaving ligands have been established for amine substitution reactions of some platinum(II) complexes.[12]

On the other hand, the kinetic data obtained for the secondary amines in benzene and THF did not give linear plots similar to those in Fig. 3, but instead gave straight lines when k_{obsd}/[amine] was plotted against the amine concentration (Fig. 4), thus conforming to Eq. 3.

$$k_{obsd} = (k_1 + k_2[\text{amine}])[\text{amine}] \quad (3)$$

In these non-coordinating solvents the solvent path is not observed. The first term in Eq. 3 may correspond to the second term in Eq. 2, representing the reagent path. It should be noted, however, that the values of k_1 for the reactions of diethylamine in benzene and THF are about 1/80 of k_1 in methanol and k_1 for the dipropylamine reaction in benzene is less than 1/180 of that in methanol (Table 2). The k_2 path showing the second order dependence of the rate on the amine concentration has not been observed for usual substitution reactions of the square planar complexes. Some kind of specific interaction between $Pd(acac)_2$ and amine might assist the displacement of the acetylacetonate ligand. Table 3 lists the rate constants for the reaction of diethylamine at various temperatures and the kinetic parameters obtained from the Eyring plots.

Table 3. Rate constants at various temperatures and kinetic parameters for the reaction of $Pd(acac)_2$ with diethylamine

	10^2k_1 in CH_3OH / $dm^3\ mol^{-1}\ s^{-1}$	10^3k_1 in C_6H_6 / $dm^3\ mol^{-1}\ s^{-1}$	10^3k_2 in C_6H_6 / $dm^6\ mol^{-2}\ s^{-1}$

With the aim of gaining an insight into the solvent effect, the reaction of $Pd(acac)_2$ with diethylamine was followed in mixtures of methanol and THF at various compositions. Figure 5 indicates that the rate equation (1) holds for the reactions in mixed solvents containing more than 4 mol dm^{-3} methanol, giving the k_0 and k_1 values as listed in Table 4. When the methanol content is as low as 0.485 mol dm^{-3}, on the other hand, the rate data deviate remarkably from linearity, but conform to the rate law (3) with $k_1 = 4.39 \times 10^{-3}$ $dm^3\ mol^{-1}\ s^{-1}$ and $k_2 = 1.05 \times 10^{-2}$ $dm^6\ mol^{-2}\ s^{-1}$. The rate data in solutions containing 2.25 and 1.18 mol dm^{-3} methanol well lie on straight lines, but gave negative k_0 values. The quadratic term with respect to the amine

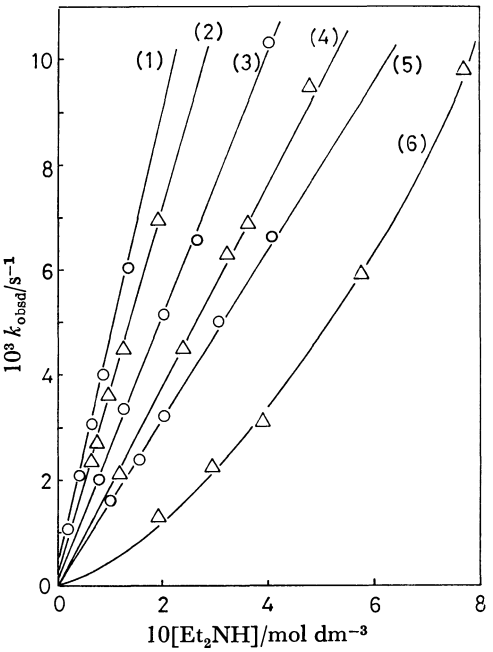

Fig. 5. Variation with the amine concentration of the pseudo first order rate constants for the reactions of $Pd(acac)_2$ with diethylamine in methanol-THF mixed solvents containing 12.4 mol dm^{-3} (1), 8.24 mol dm^{-3} (2), 4.12 mol dm^{-3} (3), 2.25 mol dm^{-3} (4), 1.18 mol dm^{-3} (5), and 0.485 mol dm^{-3} (6) methanol at 25 °C.

Table 4. Rate data for the reactions of $Pd(acac)_2$ with diethylamine in mixtures of methanol and THF at 25 °C

Mole fraction of CH_3OH	$[CH_3OH]$ / mol dm^{-3}	10^4k_0 / s^{-1}	10^2k_1 / $dm^3\ mol^{-1}\ s^{-1}$	10^2k_2 / $dm^6\ mol^{-2}\ s^{-1}$
1	24.7	3.40±0.09	8.27±0.09	
0.668	12.4	1.92±0.10	4.66±0.05

0	0		0.114±0.009	0.975±0.011

concentration might contribute to the observed rates progressively with increase in the amine concentration, thus making slopes of the straight lines steeper than expected from Eq. 2. In the region where the methanol concentration is smaller than 1 mol dm^{-3}, k_1 decreases suddenly and the k_2 term contributes appreciably to the overall rate.

Kinetics of the Reaction of Acetylacetonato(acetylacetonato-C³)(diethylamine)palladium(II) with Diethylamine. Although the spectral change exemplified by Fig. 2 appears to correspond to a simple reaction, the reaction of $Pd(acac)_2$ with two molecules of amine such as Eq. 1 can not occur as an elementary reaction, but must consist of at least two steps, involving an intermediate which contains a unidentate acetylacetonate ligand.

$$Pd(acac)_2 + Et_2NH \longrightarrow Pd(acac)_2(Et_2NH) \quad (4)$$

$$Pd(acac)_2(Et_2NH) + Et_2NH \longrightarrow [Pd(acac)(Et_2NH)_2](acac) \quad (5)$$

As stated already, the reaction of $Pd(acac)_2$ with diethylamine in the preparative scale gave Pd(acac)-(acac-C^3)(Et_2NH) in a high yield.[2] In order to clarify whether the carbon-bonded acetylacetonato complex is involved as an intermediate in reaction (1), the rate of reaction (6) was measured in methanol at 25 °C.

$$Pd(acac)(acac\text{-}C^3)(Et_2NH) + Et_2NH \longrightarrow [Pd(acac)(Et_2NH)_2](acac) \quad (6)$$

The pseudo first order rate constants listed in Table 5 conform to the two term rate law (2) with $k_0=(9\pm3)\times10^{-6}$ s^{-1} and $k_1=(9.70\pm0.08)\times10^{-4}$ dm^3 mol^{-1} s^{-1}. Contribution of the solvent path (k_0) is negligibly small and the value of k_1 is two orders of magnitude smaller than that for the overall reaction (1). Thus the mixed-ligand complex containing a carbon-bonded acetylacetonate anion can not be an intermediate in reaction (1).

Table 5. Pseudo first order rate constants for the reaction of Pd(acac)(acac-C^3)Et_2NH with diethylamine in methanol at 25 °C

10^5[complex] / mol dm^{-3}	[amine] / mol dm^{-3}	$10^4 k_{obsd}$ / s^{-1}
11.08	0.656	6.19

	1.129	10.7
8.524	0.921	8.64
	1.301	12.20

Equilibrium Studies. When a solution of [Pd(acac)(Et_2NH)$_2$](acac) in dichloromethane was kept standing for 24 h at 25 °C, an equilibrium was attained. Concentrations of three complexes involved were determined spectrophotometrically and used to calculate the equilibrium constants. The least-squares treatment of six sets of data gave the values $K_1=32.9\pm1.1$ dm^6 mol^{-2} for

$$Pd(acac)_2 + 2Et_2NH \overset{K_1}{\rightleftharpoons} [Pd(acac)(Et_2NH)_2](acac) \quad (7)$$

and $K_2=0.224\pm0.007$ dm^3 mol^{-1} for

$$Pd(acac)(acac\text{-}C^3)(Et_2NH) + Et_2NH \overset{K_2}{\rightleftharpoons} [Pd(acac)(Et_2NH)_2](acac). \quad (8)$$

Similar experiments were also performed in methanol, but the carbon-bonded complex was not involved in the equilibrium mixtures, the spectra being analyzed almost satisfactorily as mixtures of $Pd(acac)_2$ and [Pd(acac)(Et_2NH)$_2$](acac). A more precise value of K_1 in methanol at 25 °C was obtained as $(3.93\pm0.04)\times10^6$ dm^6 mol^{-2} from seven determinations started with a mixture of $Pd(acac)_2$ and diethylamine. The value is five orders of magnitude larger than that in dichloromethane, indicating an overwhelming stability of the salt-like complex in polar solvents such as methanol. In dichloromethane, on the other hand, the salt-like complex is unfavorable and converted into the carbon-bonded complex.

In order to see whether the carbon-bonded acetylacetonate can be transformed to the usual *O,O'*-chelate, *ca.* 10^{-5} mol dm^{-3} solutions of Pd(acac)(acac-C^3)-(Et_2NH) in dichloromethane and methanol were left standing. Spectroscopic assays at intervals over a period of several hours revealed no sign of production of $Pd(acac)_2$ but a slow decomposition was noticed. Thus the direct mutual conversion between the *O,O'*-chelated and the central-carbon-bonded states of acetylacetonate in palladium(II) complexes does not occur at all, but is reallized only *via* the outer-sphere complex.

Discussion

Kinetic studies on the bonding mode transformation of the β-diketonate ligand in metal complexes have scarcely been performed. Fish prepared a two-coordinate mercury(II) complex of 1,1,1,2,2,3,3-heptafluoro-7,7-dimethyl-4,6-octanedione and determined the rates at several temperatures of transformation of one of the two central-carbon-bonded ligands to the unidentate oxygen-bonding by means of the ^{1}H NMR spectroscopy.[13] He suggested a *C,C,O*-trihapto transition state for the intramolecular keto-enol tautomerization. Ito, *et al.* determined rates and kinetic parameters of three steps in the following reactions by ^{1}H NMR.[14]

$$Pt(acac)_2 \overset{+py}{\longrightarrow} Pt(acac)(acac\text{-}C^3)py \overset{+py}{\underset{-py}{\rightleftharpoons}} Pt(acac\text{-}C^3)_2(py)_2 \quad (9)$$

They also presumed a η^3-oxoallylic intermediate for the conversion of the *O,O'*-chelate to central-carbon-bonding.

In the present palladium(II) case, however, the kinetic studies unequivocally denies the intramolecular mechanism and supports the intermolecular one, one of the chelated acetylacetonate ligands leaving the coordination sphere first (Eq. 7), and then making a counterattack upon the metal atom as a carbanion (the reverse reaction of Eq. 8). Nucleophilic attack by the acetylacetonate carbanion upon the coordinated organic ligand has been occasionally demonstrated.[15,16] Although similar reactions of acetylacetonate with metal centers have not been documented explicitly thus far, the nucleophilic attack of the carbanion must be involved in preparation of the carbon-bonded acetylacetonato complexes with various metal ions.[1]

Reaction (8) is reversible and the carbon-bonded acetylacetonate can be displaced by an amine molecule. Thus formation and dissociation of the carbon-bonded acetylacetonate complex proceed *via* the outer-sphere complex, and the former can not be an intermediate in the formation reaction of the latter from $Pd(acac)_2$. The exact nature of the unidentate bonding of acetylacetonate in the intermediate complex (Eq. 4) is not clear, since the intermediate is not involved in an appreciable amount to allow the spectroscopic detection. However, the acetylacetonate in question may

be bonded to palladium *via* an oxygen atom. Such an ether-like bonding was first reported for the trialkyl(acetylacetonato-*O*)silicon complexes,[17] and was more recently found in Pt(acac-*O*)$_2$(PEt$_3$)$_2$[18] and Pt(acac-*O*)$_2$-(piperidine)$_2$.[19]

Pearson and Johnson[20] studied hydrolysis and other substitution reactions of Pd(acac)$_2$ in 91% water—9% methanol. A rapid equilibrium is assumed between the starting bis-chelate and an intermediate containing an oxygen-unidentate acetylacetonate ligand, which is displaced by a water molecule in the succeeding rate determining step. If this is the case for the present system, that is, if reaction (4) proceeds much faster and (5) is rate-determining, then reaction (4) should attain an equilibrium. When the equilibrium concentration of the intermediate is not negligibly small, it should be detected spectrophotometrically. On the other hand, when the equilibrium is not favorable to the intermediate, its concentration will increase with amine and the overall rate should be second order with respect to amine. In reality, the intermediate is not observed (Fig. 2) and the second order rate concerning amine is not observed for reactions in methanol. Thus reaction (4) is considered to be rate-determining, (5) proceeding faster.

The rate equation obtained in methanol (Eq. 2) and that in THF and benzene (Eq. 3) differ from each other. Although Eq. 2 involves the solvent term, Eq. 3 does not in spite of the fact that the donor number of THF (20.0) is similar to that of methanol (19.0).[21] Furthermore, k_1 which expresses the rate of the so-called reagent path increases quite remarkably when methanol is added to THF (Table 4). These results suggest some kind of interaction between Pd(acac)$_2$ and methanol to assist the attack of an amine molecule upon the palladium atom and/or the splitting of the Pd–O(acac) bond. Davis and Fackler showed from IR measurements that methanol forms hydrogen bonds with β-diketone chelates of various metal ions.[22] Recently Murthy and Shah found a slight blue shift and absorbance increase in the spectrum of tetrakis(acetylacetonato)thorium(IV) in dichloromethane on addition of methanol and other alcohols, and determined equilibrium constants for the adduct formation reactions, K for methanol being 2.0 dm^3 mol^{-1} at 30.0 °C.[23] Unfortunately the present Pd(acac)$_2$—methanol system showed no appreciable IR or electronic spectral change, but the hydrogen bond formation between them is conceivable and the scheme depicted in the upper part of Fig. 6 is proposed to the reaction in methanol. Analogously the second order term in Eq. 3 is presumed to originate from the hydrogen-bond interaction between Pd(acac)$_2$ and amine, and the lower part of Fig. 6 is proposed to the reaction in aprotic solvents.

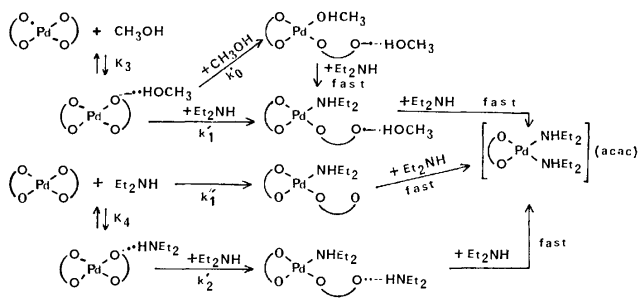

Fig. 6. Proposed mechanism for the reactions of Pd(acac)$_2$ with diethylamine in methanol and other aprotic solvents such as THF and benzene.

According to the proposed scheme the pseudo first order rate constant is calculated to be

$$k_{obsd} = \frac{k_0'K_3[CH_3OH]^2+(k_1'K_3[CH_3OH]+k_1''+k_2'K_4[amine])[amine]}{1+K_3[CH_3OH]+K_4[amine]}. \quad (10)$$

For the reaction in THF or benzene, this reduces to

$$k_{obsd} = \frac{(k_1''+k_2'K_4[amine])[amine]}{1+K_4[amine]}, \quad (11)$$

which coincides with Eq. 3 when $1 \gg K_4[amine]$, resulting in

$$k_1 = k_1'' \text{ and } k_2 = k_2'K_4. \quad (12)$$

In methanol $K_3[CH_3OH] \gg 1+K_4[amine]$, that is all of the Pd(acac)$_2$ molecules are presumed to interact with methanol, and Eq. 10 reduces to Eq. 2, k_0 and k_1 being $k_0'[CH_3OH]$ and k_1', respectively.

For reactions in mixed solvents which obey the rate equation (2) rather than (3), the pseudo first order rate constant will be expressed by

$$k_{obsd} = \frac{k_0'K_3[CH_3OH]^2+(k_1'K_3[CH_3OH]+k_1'')[amine]}{1+K_3[CH_3OH]}, \quad (13)$$

giving, on comparison with Eq. 2,

$$k_0 = \frac{k_0'K_3[CH_3OH]^2}{1+K_3[CH_3OH]} \quad (14)$$

$$\frac{[CH_3OH]}{k_0} = \frac{1}{k_0'} + \frac{1}{k_0'K_3[CH_3OH]},$$

and

$$k_1 = \frac{k_1'K_3[CH_3OH]+k_1''}{1+K_3[CH_3OH]} \quad (15)$$

$$\frac{1}{k_1-k_1''} = \frac{1}{k_1'-k_1''} + \frac{1}{(k_1'-k_1'')K_3[CH_3OH]}.$$

Although the plot of $[CH_3OH]/k_0$ *vs.* $1/[CH_3OH]$ shows a straight line except one point (Fig. 7), the k_0 data are insufficient and include larger uncertainties with

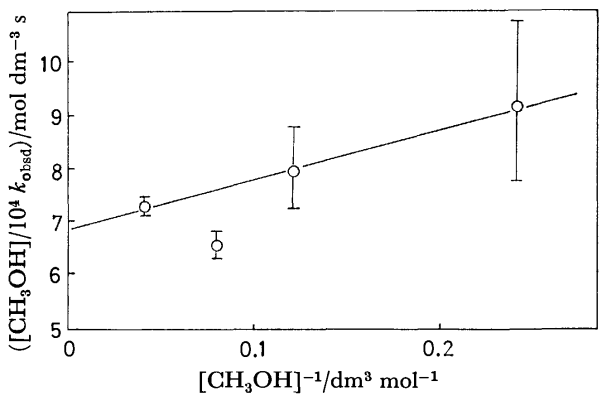

Fig. 7. Plot of k_0 with respect to the methanol concentration in methanol–THF solutions.

decreasing methanol concentration, precluding assignment of reliable values to k_0' and K_3. The trial to find an appropriate value for k_1'' to obtain a good linear plot according with Eq. 15 has also failed. Contrary to expectation based on Eq. 15, k_1 increases almost linearly with the concentration of methanol (Table 4). The rate constants k_1' and k_1'' might change intrinsically with the nature of medium. It is regrettable that various kinds of solvents can not be used for the present reaction owing to the solubility trouble.

We wish to thank the Ministry of Education for the Grant-in-Aid for Scientific Research (No. 243014).

Equilibrium, X-Ray, and ^{1}H-NMR Studies of the $ZrCr_2$–H System

Hideo Imoto,† Motoshige Sasaki,†† Taro Saito, and Yukiyoshi Sasaki*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received October 16, 1979)

The pressure isotherms of the $ZrCr_2$–H system (20—200 °C, 10—700 Torr) and powder X-ray diffraction have shown the occurrence of two phases, cubic $ZrCr_2H_x$ ($x<1.0$) and hexagonal $ZrCr_2H_x$ ($2.5<x<3.5$). From the gradual change in the diffraction pattern with x, it has been concluded that samples with a low hydrogen concentration ($x<0.8$) contain another hexagonal phase. All these phases have Laves-type structures (C14 and C15). At 106 K, $ZrCr_2H_{2.66}$ has a much smaller second moment (7.2 G) of ^{1}H-NMR than the value calculated from the random-distribution model (77.9 G), which shows that the nearest sites can not be filled by hydrogen atoms at the same time. The system of $TiCr_2$–H has also been studied for comparison.

In 1961, Beck reported that the intermetallic compound $ZrCr_2$ absorbs hydrogen up to $ZrCr_2H_{3.42}$.[1] More recently, Pebler and Gulbransen have studied the equilibria of the system and have established the formation of a solid solution of hydrogen in the hexagonal-metal phase.[2] They observed at lower temperature, a tendency for phase separation which may occur below 0 °C, but no new phase was detected by X-ray diffraction studies. The present paper will show evidence for the formation of three different phases on the hydrogenation of $ZrCr_2$ by the use of X-ray and dissociation-pressure measurements. The results of the study of the $TiCr_2$–H system will be mentioned only briefly, because more extended data have been published after the completion of this work.[3] It is, though, worthy of note that our samples of $TiCr_2$ were of the C14 type and not the C15 type used by Reilly in Ref. 3.

$ZrCr_2$ and $TiCr_2$ are the only intermetallic phases in Zr– and Ti–Cr systems, and both form Laves phases. The low-temperature form of $TiCr_2$ has the cubic $MgCu_2$ (C15) structure, and it is transformed into the hexagonal $MgZn_2$ (C14) structure at 1220 °C. About the polymorphic nature of the $ZrCr_2$ compound, the literature presents conflicting reports. For instance, Rostoker reported that the transformation from the low-temperature form with the $MgCu_2$ structure to the form with the $MgZn_2$ structure occurs at 990—994 °C.[4] However, according to Alisova *et al.*, the $MgZn_2$-type structure is the low-temperature form and the transition temperature is 1480±10 °C.[5] As will be discussed later, the $ZrCr_2$ used in this work contained both the cubic and hexagonal forms.

Experimental

Materials. The starting materials were electrolytic chromium (99.2%), sponge titanium (99.8%), and sponge zirconium (99.8%). Intermetallic compounds were prepared by non-consumable arc-melting in an atomsphere of argon, the buttons being inverted and remelted several times to ensure homogeneity. X-Ray diffraction analyses showed both samples to contain only the intermetallic phases. It was found by X-ray fluorescence analysis that the non-iron impurity did not exceed 0.05% in the $ZrCr_2$ sample; the results of the chemical analyses were: Zr, 46.83% (calcd. 46.73%); Fe, 0.091%. The hydrogen for the experiments was obtained by the thermal decomposition of titanium hydride, which had been prepared from sponge titanium and high-purithy hydrogen (99.9999%). The titanium hydride was stored in a vacuum and had never been taken out into the atmosphere before experiments.

Equilibrium Studies and Preparation of Hydrided Samples. The apparatus for the measurements of the dissociation pressure and for the preparation of hydrided samples was a vacuum line made of glass equipped with four gas reservoirs, a silica tube in which samples were laid, and another silica tube for the generation of hydrogen from titanium hydride. The vacuum of the system before the experiments was under 10^{-6} Torr. The pressure of hydrogen was measured with a mercury manometer. The hydrogen composition (x) was calculated from the changes in the quantity of hydrogen gas, as determined by the pressure measurements. Corrections for the volume change of the manometer and for the temperature of the heated part of the sample tube had been previously determined. The temperature of the sample was controlled within ±1 °C by the use of a thermostat and an oil bath. For the measurements of the dissociation pressures, several grams of the intermetallic compounds crushed into grains (10—20 mesh) with an Ellis mortar were used. The samples for X-ray and ^{1}H-NMR studies were prepared as follows: after preliminary hydrogenation, the intermetallic compound was powdered, dehydrided and hydrided again to give samples containing certain quantities of hydrogen. The samples were not crushed or powdered after the final preparation.

X-Ray and ^{1}H-NMR Studies. The X-ray studies were performed with a powder diffractometer using Ni-filtered Cu K_α radiation at an ambient temperature. Silicon was used as the internal standard. For the intensity measurements, samples were sprinkled on sample holders coated with adhesive agent. The least squares of the lattice parameters and the calculation of the reflection intensities were performed on a HITAC 8700/8800 computer at the Computer Centre of the University of Tokyo. The ^{1}H-NMR was measured with a Varian VF-16 wide-line spectrometer with a Varian variable-temperature accessory.

Results

The observed isotherms of the $ZrCr_2$–H and $TiCr_2$–H systems are shown in Fig. 1 and Fig. 2. The enthalpy and entropy changes of the reaction:

$$1/1.5\ ZrCr_2H_{1.0} + 1/2\ H_2 \longrightarrow 1/1.5\ ZrCr_2H_{2.5}$$

were calculated as $\Delta H = -11$ kcal/mol and $\Delta S = -26$ cal/K/mol (1 cal=4.184 J) from the temperature

dependence of the plateau pressure. The isotherms for the $ZrCr_2$–H system with plateaus showed that two phases coexist in the samples in the $1<x<2.5$ region, and the X-ray data confirmed it. A hydrogen-rich phase (α' phase) with a hexagonal $MgZn_2$-type structure (C14) and a hydrogen-poor phase with a cubic $MgCu_2$-type structure were observed with the X-ray techniques in the samples in the two-phase region. While the powder pattern of the hydrogen-rich phase did not change with the x value except for the lattice expansion, a gradual variation in the powder pattern was observed in the samples with low hydrogen concentrations, as is shown in Fig. 3. The powder pattern of the sample with $x=1.0$ is identical with the calculated pattern of the cubic structure (C15), while the pattern of the sample with a very low hydrogen concentration is similar to the hexagonal structure (C14) (Fig. 4). The sample with x value between these two extremes have powder patterns generated by the superposition of these two patterns. Though the calculated patterns of the hexagonal and cubic structures are very similar, some reflections, such as (103) and (213), of the hexagonal structure do not correspond to any reflection of the cubic phase. From the measurements of the intensities

of these reflections, the following was concluded: the starting material, $ZrCr_2$, which has been prepared by the dehydrogenation of $ZrCr_2H_x$, as has been described in the Experimental section, consists *ca.* 40% of the cubic (α_c) and *ca.* 60% of the hexagonal (α_h) phase. The samples with $x<0.8$ also consist of cubic (α_c) and hexagonal (α_h) phases, but the percentage of the cubic phase increase with the x value until it reaches 100% at $x=0.8$.

Table 1. Lattice constants of $ZrCr_2H_x$ and $TiCr_2H_x$
Standard deviations in parentheses.

	a/Å	c/Å
$ZrCr_2$ (α_h)	5.107(3)	8.290(8)
$ZrCr_2H_{0.250}$ (α_h)	5.119(2)	8.356(6)
$ZrCr_2H_{0.516}$ (α_h)	5.141(3)	8.383(8)
$ZrCr_2H_{1.582}$ (α')	5.342(2)	8.747(6)
$ZrCr_2H_{2.047}$ (α')	5.354(1)	8.746(10)
$ZrCr_2H_{2.824}$ (α')	5.376(1)	8.774(3)
$ZrCr_2H_{2.953}$ (α')	5.386(1)	8.801(3)
$ZrCr_2H_{3.340}$ (α')	5.420(1)	8.856(6)
$TiCr_2$	4.923(2)	7.990(4)
$TiCr_2H_{0.171}$	4.938(3)	8.026(10)
$TiCr_2H_{0.318}$	4.946(3)	8.074(12)
$TiCr_2H_{0.526}$	4.967(5)	8.131(14)
$ZrCr_2$ (α_c)	7.211(3)	
$ZrCr_2H_{0.250}$ (α_c)	7.237(2)	
$ZrCr_2H_{0.516}$ (α_c)	7.264(1)	
$ZrCr_2H_{0.795}$ (α_c)	7.298(4)	
$ZrCr_2H_{1.012}$ (α_c)	7.306(2)	
$ZrCr_2H_{1.232}$ (α_c)	7.322(3)	
$ZrCr_2H_{1.582}$ (α_c)	7.328(3)	

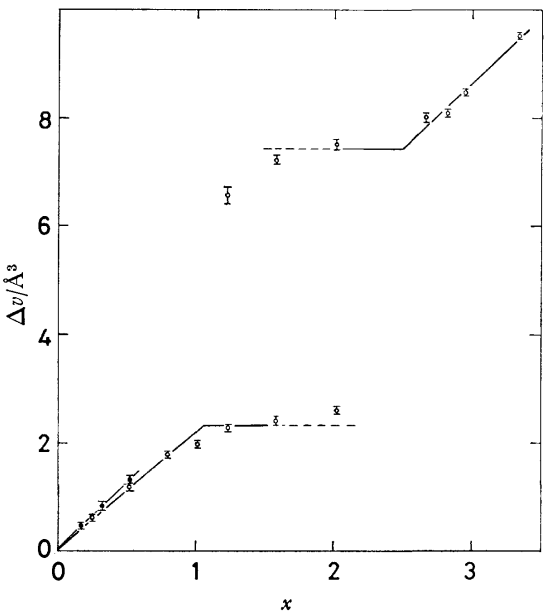

Fig. 5. Hydrogen-concentration dependence of the volume of MCr_2H_x with standard derviations.
M is Ti (filled circles) or Zr (unfilled circles). Δv means $\Delta V/Z$, where ΔV is the increase of the unit-cell volume of MCr_2H_x and Z is the number of MCr_2H_x units in a unit cell. $ZrCr_2H_x$) $0<x<1$) has two stuructures, but their Δv's are practically equal.

In contrast with $ZrCr_2H_x$, $TiCr_2H_x$ ($x<0.6$) had only a hexagonal $MgZn_2$-type structure (C14). The lattice constants of $ZrCr_2H_x$ and $TiCr_2H_x$ are shown in Table 1, while the increase of the volumes with the x value is shown in Fig. 5. The volume increase per hydrogen atom was 2.5 Å^3 for $TiCr_2H_x$ and 2.2 Å^3 for $ZrCr_2H_x$. These values are a little smaller than the values for palladium alloy–hydrogen systems reported by Baranowski *et al.* (11.5/4 Å^3=2.9 Å^3).[6]

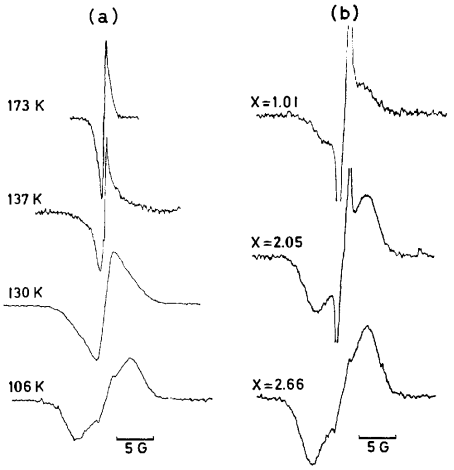

Fig. 6. ^{1}H-NMR spectrum of $ZrCr_2H_x$ at 3700 G.
(a) Temperature-dependence of the ^{1}H-NMR spectrum of $ZrCr_2H_{2.66}$; (b) Hydrogen-concentration dependence of the ^{1}H-NMR spectrum of $ZrCr_2H_x$ at 106 K.

The temperature dependence of the ^{1}H-NMR spectrum of $ZrCr_2H_x$ is shown in Fig. 6. A widening of the signal of hydrogen in the α' phase was observed at 173—106 K, but the signal of hydrogen in the α_c and α_h phases showed motional-narrowing even at 106 K. The second moment of the $ZrCr_2H_{2.66}$ sample at 106 K was 7.2 G^2 (1 G=10^{-4} T).

Discussion

The dissociation pressures of the $ZrCr_2$–H system obtained by the present authors are higher than those reported by Pebler and Gulbransen, as is shown in Fig. 1. To explain this discrepancy, the present authors assume some width of the nonstoichiometry of the $ZrCr_2$ phase, as in the case of $TiCr_2$, though it has not yet been reported how wide the phase is. Therefore, the difference in the dissociation pressure of $ZrCr_2H_x$ probably depends on the composition of the $ZrCr_2$ phase. A very small difference may be enough to explain the discrepancy in these two sets of data. The small variation in the dissociation pressure in the two-phase region ($1.0<x<2.5$) may also be caused by the nonstoichiometry of $ZrCr_2$, since a small inhomogeneity may inevitably be brought about in the sample prepared by arc-melting, which causes a fluctuation in the dissociation pressure of the sample.

In a Laves-phase compound, AB_2, if it has the ideal structure of the Laves phase, there are 24 tetrahedral holes around one larger atom, A, whether its structure is the $MgZn_2$ type or the $MgCu_2$ type. All these holes

have the same size, and hydrogen atoms are assumed to enter into these holes, because they are the largest ones. If all these holes were filled with hydrogen atoms, the composition of the compound would be AB_2H_{12}. Because the c/a ratios of the lattice constants of hexagonal $ZrCr_2$ and $TiCr_2$ are very close to the value of the ideal structure, $2\sqrt{6}/3$, and since they change very slightly with the x value, we can assume in the following discussions that they have the ideal structure of the Laves phase.

The tetrahedral holes in $ZrCr_2$ and $TiCr_2$ are all of almost the same size. Strictly speaking, the radii of the largest spheres that these holes can hold are calculated to be 0.349 Å for $ZrCr_2$ and 0.360 Å for $TiCr_2$ if we assume the atomic radii to be 1.2866 Å for chromium, 1.4615 Å for titanium, and 1.6027 Å for zirconium,[7] and if we assume the unit-cell volumes to be equal to the observed values of $ZrCr_2$ and $TiCr_2$. Therefore, the difference in the hydrogen-absorption ability between $ZrCr_2$ and $TiCr_2$ can not be attributable to the difference in the size of the holes of each intermetallic compound.

Since, around 106 K, the ^{1}H-NMR spectrum of $ZrCr_2H_{2.66}$ did not broaden as the temperature decreased, the hydrogen atoms are thought to form a rigid lattice. Therefore, the second moment of the spectrum can be compared with the theoretical value calculated using the following equation:[8]

$$M = \frac{9}{10}\gamma^2 N^{-1} \sum_{j \neq k} r_{jk}^{-6}$$

where M, γ, N, and r_{jk} are the second moment, the magnetic moment of a proton, the number of protons, and the distance between the protons j and k respectively. If we assume a random distribution of hydrogen atoms in all of the tetrahedral holes mentioned above, we get 77.9 G^2 as M, which is much larger than the observed value (7.2 G). This discrepancy suggests that a hydrogen atom occupying a hole prevents other hydrogen atoms from entering the neighboring holes. This seems probable, because the distance between the nearest holes are only about 1.2 Å. For the purpose of getting an approximate value of the second moment for the restricted random distribution in which a hydrogen atom has no neighbor within 1.5 Å, the above equation, excluding the terms in which r_{jk} is less than 1.5 Å has been calculated. The result of this calculation was 14.2 G^2; this value agrees better with the observation.

The transformation from the hexagonal α_h phase to the cubic α_c phase shown by the intensity variation in the X-ray diffraction in $ZrCr_2H_x$ is not analogous to any other found in metal–hydrogen systems, but the facts described below may support the occurrence of this transformation. The only difference between the two structures is their stacking order, the cubic phase having the ABCABC....order and the hexagonal phase having the ABAB....order.[9] Therefore, the transformation between the two structures may take place easily by means of a shear mechanism; indeed, in the $TiFe_2$ system a martensitic transformation between these structures has been proposed on the basis of the temperature dependence of the electric conductivity at low temperatures.[10] The reason why the coexistence of these two phases has not been shown by the isotherms may be that the plateau pressure is lower than the measured pressure range.

The authors gratefully acknowledge Dr. Keiichi Nakamura for his help in preparing samples and in NMR measurements at the Research Institute for Metals.

Circular Dichroism and Stereochemistry of Tetranuclear Cobalt(III) Complexes of Hexol Type. III.[1] The *meso*-2,3-Butanediamine, (*R*)-1,2-Propanediamine, and (*R,R*)-1,2-Cyclohexanediamine Complexes

Tomikatsu KUDO* and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received October 24, 1979)

Eight, six, and four optical isomers of diamine hexols $[Co\{(OH)_2Co(diamine)_2\}_3]^{6+}$ containing *meso*-2,3-butanediamine, (*R*)-1,2-propanediamine, and (*R,R*)-1,2-cyclohexanediamine, respectively, were separated by column chromatography. The absorption and CD (circular dichroism) spectra were measured in the visible and ultraviolet regions in 0.01 mol dm^{-3} HCl, the absolute configurations being determined mainly on the basis of the CD spectra. Assuming that the configurational chiralities are identical to those of the corresponding ethylenediamine hexol isomers, it has been established that the *lel* and *ob* orientations of the (*R*)-diamine ligand show different vicinal CD curves due to the asymmetric carbon atom in the ligand.

Eight optical isomers $\Lambda(\Lambda\Lambda\Lambda)$, $\Lambda(\Delta\Lambda\Lambda)$, $\Lambda(\Delta\Delta\Lambda)$, $\Lambda(\Lambda\Lambda\Delta)$, $\Lambda(\Delta\Delta\Delta)$, $\Lambda(\Delta\Lambda\Delta)$, $\Lambda(\Delta\Delta\Lambda)$, and $\Lambda(\Lambda\Delta\Lambda)$ are theoretically possible for a hexakis(diamine)-hexa-μ-hydroxo-tetracobalt(III) ion $[Co\{(OH)_2Co(diamine)_2\}_3]^{6+}$. All the eight isomers of $[Co\{OH)_2Co(en)_2\}_3]^{6+}$ (en hexol) were separated by column chromatography,[1] CD (circular dichroism) spectra being studied in comparison with that of the corresponding ammine hexol $[Co\{(OH)_2Co(NH_3)_4\}_3]^{6+}$.[2] Only a few investigations have been reported for hexol complexes containing optically active diamines; for example, Masuda and Douglas[3] reported only two and one of the possible eight optical isomers of $[Co\{(OH)_2Co((S)$- and (*R*)-1,2-propanediamine$)_2\}_3]^{6+}$, respectively. The present paper deals with the preparation and separation of $[Co\{(OH)_2Co(diamine)_2\}_3]^{6+}$ isomers, assignment of their absolute configurations, and discussion on the so-called vicinal CD curves due to the optically active diamines. (*R*)-(−)-1,2-propanediamine (*R*-pn), (*R,R*)-(−)-1,2-cyclohexanediamine (*R,R*-chxn), and *meso*-2,3-butanediamine (*meso*-2,3-bn) were used as diamine ligands.

Experimental

Preparation and Separation of Isomers. *1)* $[Co\{(OH)_2Co(meso\text{-}2,3\text{-}bn)_2\}_3]^{6+}$: The complex nitrate was prepared by a modification of the method for the corresponding ethylenediamine complex.[4] To 17.4 g of $Co(NO_3)_2\cdot 6H_2O$ in 20 cm^3 of water was slowly added 40 cm^3 of a 10% ice-cold aqueous solution of *meso*-2,3-butanediamine with stirring in an ice-bath. The mixture was vigorously stirred and oxidized by blowing compressed air on the surface for *ca.* 2h after cooling, the remaining solid being filtered off and washed with a small amount of water. The filtrate and washings were poured into a column (5 × 135 cm) of strong-acid ion-exchanger (SP Sephadex C-25, Na^+ form). After a broad pink-red band had been swept out with 0.1 M (1 M = 1 mol dm^{-3}) sodium d-tartrate solution, the adsorbed band was eluted with a sodium d-tartrate solution (0.17 M in the early stage of elution, and then 0.25 and 0.34 M successively in the later stages). During the course of elution the column was cooled by flushing cold (5 °C) water. The eluted eight brown bands were numbered B-1, B-2, ···, and B-8 in the order of elution. Each eluate was diluted about ten times with cold water which had been acidified to pH 4 with $HClO_4$, and the solution was passed through a small amount of strong-acid ion-exchanger (SP Sephadex C-25, Na^+ form). The complex on the exchanger was washed with a cold 0.01 M $NaClO_4$ solution and eluted with a cold 5 M $NaClO_4$ solution which had been acidified to pH 4 with $HClO_4$. Powdered sodium perchlorate was added to this eluate, and the solution was kept in a refrigerator. The desired complex was collected by filtration and washed with a cold ethanol–water (1: 1) solution, ethanol, and then ether. The brown crystals were dried in a vacuum desiccator over calcium chloride. Found for isomer B-1: C, 19.20; H, 5.48; N, 11.14%. Calcd for $[Co\{(OH)_2Co(meso\text{-}2,3\text{-}bn)_2\}_3](ClO_4)_6\cdot 2H_2O = C_{24}H_{78}N_{12}O_{30}Cl_6Co_4\cdot 2H_2O$: C, 19.22; H, 5.51; N, 11.21%. Found for isomer B-2: C, 19.22; H, 5.56; N, 11.08%. Calcd for $C_{24}H_{78}N_{12}O_{30}Cl_6Co_4\cdot 2.5H_2O$: C, 19.11; H, 5.55; N, 11.14%. The other isomers underwent mutarotation in the coures of crystallization, the products obtained showing the same CD pattern as that of the isomer B-1 or B-2 in the region 740—200 nm.

2) $[Co\{(OH)_2Co(R\text{-}pn)_2\}_3]^{6+}$: The isomers were prepared and separated by a similar procedure to that described in *1)* using (*R*)-1,2-propanediamine instead of *meso*-2,3-butanediamine. Eleven brown bands were confirmed on the chromatograph. Measurements of absorption and CD spectra confirmed that the first four and the next three bands give identical CD curves, respectively. Because of their low yields, the first four and the next three bands were combined respectively. They are denoted by P-1 and P-2, the remaining four bands being denoted by P-3, P-4, P-5, and P-6 in the order of elution. Crystallization was carried out as described in *1)*. Found for isomer P-1: C, 14.55; H, 4.89; N, 11.23%. Calcd for $[Co\{(OH)_2Co(R\text{-}pn)_2\}_3](ClO_4)_6\cdot 3H_2O\cdot 0.5NaClO_4 = C_{18}H_{66}N_{12}O_{30}Cl_6Co_4\cdot 3H_2O\cdot 0.5NaClO_4$: C, 14.47; H, 4.89; N, 11.23%. Found for isomer P-2: C, 15.01; H, 4.97; N 11.52%. Calcd for $C_{18}H_{66}N_{12}O_{30}Cl_6Co_4\cdot 2.5H_2O\cdot 0.25NaClO_4$: C, 14.86; H, 4.92; N, 11.55%. Found for isomer P-3: C, 13.66; H, 5.25; N, 10.61%. Calcd for $C_{18}H_{66}N_{12}O_{30}Cl_6Co_4\cdot 8H_2O\cdot 0.5NaClO_4$: C, 13.64; H, 5.22; N, 10.61%. Found for isomer P-4: C, 14.22; H, 5,34; N, 11.30%. Calcd for $C_{18}H_{66}N_{12}O_{30}Cl_6Co_4\cdot 7H_2O$: C, 14.36; H, 5.36; N, 11.17%. Found for isomer P-5: C, 13.93; H, 4.62; N, 10.90%. Calcd for $C_{18}H_{66}N_{12}O_{30}Cl_6Co_4\cdot 2.5H_2O\cdot NaClO_4$: C, 13.98; H, 4.63; N, 10.87%. Found for isomer P-6: C, 14.67; H, 5.14; N, 11.17%. Calcd for $C_{18}H_{66}N_{12}O_{30}Cl_6Co_4\cdot 5H_2O\cdot 0.25NaClO_4$: C, 14.41; H, 5.11; N, 11.21%.

3) $[Co\{(OH)_2Co(R,R\text{-}chxn)_2\}_3]^{6+}$: The isomers were prepared and separated by a similar procedure to that described in *1)* using (*R,R*)-1,2-cyclohexanediamine instead of *meso*-2,3-

butanediamine. The four brown bands on the chromatographic column are denoted by C-1, C-2, C-3, and C-4 in the order of elution. Each eluate was diluted *ca.* ten times with cold water which had been acidified to pH 4 with HCl, and was then adsorbed again on a small amount of strong-acid ion-exchanger (SP Sephadex C-25, Na^+ form). This was washed with a cold 0.01 M NaCl solution and eluted with a cold 3 M NaCl solution which had been acidified to pH 4 with HCl. Powdered sodium chloride was added to the eluate, and the solution was kept in a refrigerator. The desired complex was collected by filtration and washed with a cold ethanol–water (1: 2) solution ,ethanol, and then ether. The brown needle crystals were dried in a vacuum desiccator over calcium chloride. Isomer C-3 was obtained in a low yield because of its high solubility. Found for isomer C-1: C, 31.25; H, 7.60; N, 12.06; Cl, 16.79%. Calcd for $[Co\{(OH)_2Co(R,R\text{-chxn})_2\}_3]Cl_6 \cdot 7.5H_2O \cdot 0.5NaCl = C_{36}H_{90}N_{12}O_6Cl_6Co_4 \cdot 7.5H_2O \cdot 0.5NaCl$: C, 30.89; H, 7.56; N, 12.01; Cl, 16.46%. Found for isomer C-2: C, 32.05; H, 7.80; N, 12.13; Cl, 15.96%. Calcd for $C_{36}H_{90}N_{12}O_6Cl_6Co_4 \cdot 7.5H_2O$: C, 31.54; H, 7.72; N, 12.26; Cl, 15.52%. Found for isomer C-3: C, 31.01; H, 7.61, N, 12.07; Cl, 16.64%. Calcd for $C_{36}H_{90}N_{12}O_6Cl_6Co_4 \cdot 7.5H_2O \cdot 0.5NaCl$: C, 30.89; H, 7.56; N, 12.01; Cl, 16.46%. Found for isomer C-4: C, 31.90; H, 7.53; N, 12.30; Cl, 17.17%. Calcd for $C_{36}H_{90}O_6N_{12}Cl_6Co_4$ $6H_2O \cdot 0.5NaCl$: C, 31.49; H, 7.49; N, 12.24; Cl, 16.78%.

Measurements. The visible and ultraviolet absorption spectra were measured with a Shimadzu UV-200 spectrophotometer, and CD spectra with a JASCO MOE-1 spectropolarimeter. Measurements were carried out at room temperature in 0.01 M HCl and 0.15 M Na_2SeO_3.

Results and Discussion

Characterization of Isomers. The absorption and CD data of $[Co\{(OH)_2Co(meso\text{-}2,3\text{-}bn)_2\}_3]^{6+}$ isomers are summarized in Table 1. Since isomers B-3 to B-8 were not obtained as solid salt, their CD values were estimated on the basis of concentration which was calculated from the absorbance at 618 nm assuming the molar absorption coefficient $\varepsilon_{618} = 115$ mol^{-1} dm^3 cm^{-1}, which is the value for B-1 and B-2. The absorption intensities of eight en hexol isomers were almost equal at this wave-length.[1] It is evident from the CD data that B-1 is enantiomeric to B-2, as is B-3 to B-4, B-5 to B-6, and B-7 to B-8. The CD curves of isomers B-1, B-3, B-5, and B-7, all of which have a positive CD band at about 16200 cm^{-1}, are shown in Fig. 1. The data for the isomers of *R*-pn and *R,R*-chxn hexols are summarized in Tables 2 and 3, and the absorption and CD curves are shown in Figs. 2 and 3.

The absorption and CD spectra of the present hexols remained unchanged in the eluting solution at room temperature for *ca.* 24 h, being the same as those in 0.01 M HCl and in H_2O. All isomers, except for P-5, are fairly stable against mutarotation in 0.01 M HCl, in 0.15 M Na_2SeO_3, and in H_2O. P-5 undergoes mutarotation rather rapidly in 0.15 M Na_2SeO_3 and slowly in H_2O, but is fairly stable in 0.01 M HCl. In the column chromatography, P-1 and P-2 consist of four and three subbands, respectively. The subbands of each isomer show the same CD spectra in 0.01 M HCl. This indicates the occurrence of geometrical isomers due to the difference in arrangements of the asymmetric carbons. MacDermott[5] and Kojima

Table 1. Absorption and CD data of $[Co\{(OH)_2Co(meso\text{-}2,3\text{-}bn)_2\}_3]^{6+}$ in 0.01 M HCl

Wave numbers are given in 10^3 cm^{-1} unit, log ε or $\Delta\varepsilon$ values (in parentheses) in mol^{-1} dm^3 cm^{-1}.

Isomer	Absorption σ_{max} (log ε)	CD σ_{ext} ($\Delta\varepsilon$)

a) sh=shoulder.

et al.[6-8] separated such geometrical isomers of mononuclear complexes *Δ*- and *Λ*-$[Co(R\text{-pn})_3]^{3+}$, *Λ*-$[Co(i\text{-bn})_3]^{3+}$, and *Λ*-$[Co(meso\text{-2,3-bn})_3]^{3+}$ by column chromatography (*i*-bn=2-methyl-1,2-propanediamine), but found their separation to be difficult, the absorption and CD spectra of the separated isomers being nearly identical. A similar kind of geometrical isomerism was expected for the *meso*-2,3-bn hexol, but no band separation was observed in the chromatography.

Absorption and CD Spectra. The absorption and CD spectra of the present hexols are similar to those of $[Co\{(OH)_2Co(en)_2\}_3]^{6+}$.[1] The absorption bands at *ca.* 16200 and 20200 cm^{-1} are assigned to the first d-d transition bands of CoO_6 and CoN_4O_2 chromophores, respectively. The second d-d transition bands of both chromophores seem to be masked by an intense band at *ca.* 32000 cm^{-1}, which is due to the charge transfer transition from the oxygen atom of the OH bridge groups to the central metal, $p_\pi(O)\rightarrow e_g(Co)$. The CD spectra show two extrema (the A_2 and E_a components of approximate D_3 symmetry) in the first d-d transition region of CoO_6 chromophore and one extremum (combined $B_1+A_2+B_2$ components) in the region of CoN_4O_2 chromophore. The CD intensity of CoN_4O_2 chromophore band at *ca.* 20000 cm^{-1} varies widely from isomer to isomer. The CD patterns in the d-d transition region are very similar, while those in the charge transfer transition region somewhat differ (Figs. 1—3).

When the CD spectrum of each isomer of *meso*-2,3-bn hexol is compared with that of the isomer of en hexol with the same fraction-number, *e.g.*, B-1 with E-1, the CD intensity and band shape in the d-d transition region are almost identical but the CD extremum

positions shift to lower energy side in the isomer of *meso*-2,3-bn hexol. The shift approximately corresponds to the difference between the absorption peaks of *meso*-2,3-bn hexol and en hexol in the CoN_4O_2 chromophore region. The CD bands of not only CoN_4O_2 chromophore but also of CoO_6 chromophore shift to lower energy side. The d-d absorption peak of CoN_4O_2 chromophore varies in the following order of energy: NH_3[2]$<$*R,R*-chxn$\lesssim$*meso*-2,3-bn$<$*R*-pn$\lesssim$en.[1] The order coincides

approximately with that for mononuclear complexes of CoN_6 type.

Absolute Configuration. From the close resemblance between the CD spectra of $[Co\{(OH)_2Co(meso\text{-}2,3\text{-}bn)_2\}_3]^{6+}$ and $[Co\{(OH)_2Co(en)_2\}_3]^{6+}$ isomers, isomers B-1, B-3, B-5, and B-7 are assigned to $\Lambda(\Lambda\Lambda\Lambda)$, $\Lambda(\Delta\Lambda\Lambda)$, $\Lambda(\Delta\Delta\Lambda)$, and $\Lambda(\Delta\Delta\Delta)$, respectively, and B-2, B-4, B-6, and B-8 to $\Delta(\Delta\Delta\Delta)$, $\Delta(\Delta\Delta\Lambda)$, $\Delta(\Delta\Lambda\Lambda)$, and $\Delta(\Lambda\Lambda\Lambda)$, respectively. In a similar way, the absolute configurations of isomers P-1 and P-3 of $[Co\{(OH)_2Co(R\text{-}pn)_2\}_3]^{6+}$ are assigned to $\Lambda(\Lambda\Lambda\Lambda)$ and $\Lambda(\Delta\Delta\Lambda)$, respectively, and P-2, P-4, P-5, and P-6 to $\Delta(\Delta\Delta\Lambda)$, $\Delta(\Lambda\Lambda\Lambda)$, $\Delta(\Delta\Lambda\Lambda)$, and $\Delta(\Lambda\Delta\Lambda)$, respectively. Isomer P-5 underwent mutarotation in aqueous solution in a manner similar to that of the corresponding $\Delta(\Delta\Lambda\Lambda)$ isomer of en hexol. Isomers C-1, C-2, C-3, and C-4 of $[Co\{(OH)_2Co(R,R\text{-}chxn)_2\}_3]^{6+}$ are assigned to the absolute configurations $\Lambda(\Lambda\Lambda\Lambda)$, $\Delta(\Delta\Delta\Lambda)$, $\Lambda(\Delta\Delta\Lambda)$, and $\Delta(\Lambda\Lambda\Lambda)$, respectively. C-4 might be assigned alternatively to $\Delta(\Delta\Lambda\Lambda)$ from the CD pattern, particularly in the region of charge transfer transitions. The $\Delta(\Delta\Lambda\Lambda)$ isomers of en, *meso*-2,3-bn, and *R*-pn hexols underwent mutarotation, but not the isomer C-4. In view of vicinal effect, it is not adequate to assign this isomer to the $\Delta(\Delta\Lambda\Lambda)$ configuration. The absolute

Table 4. Absolute configurations of $[Co\{(OH)_2Co(diamine)_2\}_3]^{6+}$ isomers

Absolute configuration	en	*meso*-2,3-bn	*R*-pn	*R,R*-chxn

$\Delta(\Delta\Delta\Delta)$	E-2	B-2	P-2	C-2
$\Lambda(\Delta\Delta\Delta)$	E-3	B-3	P-3	C-3
$\Delta(\Lambda\Lambda\Lambda)$	E-4	B-4	P-4	
$\Lambda(\Delta\Lambda\Lambda)$	E-5	B-5		
$\Delta(\Delta\Lambda\Lambda)$	E-6	B-6	P-6	C-4
$\Lambda(\Delta\Lambda\Lambda)$	E-7	B-7		
$\Delta(\Delta\Delta\Lambda)$	E-8	B-8	P-5	

configurations of all the hexol isomers containing diamines are given in Table 4.

The numbers of isomers of individual hexols obtained decrease in the order of diamines en>*R*-pn>*R,R*-chxn, the reverse order of bulkiness of the *C*-substituent groups. The repulsion between the non-bonded atoms seems to exist in the remaining less stable isomers, this being partly confirmed by the construction of molecular models of the missing isomers.

Additivity of CD Contributions. Assuming that the chromophore and configurational chirality of an *R*-pn (or *R,R*-chxn) hexol isomer are identical to those of the corresponding en hexol isomer, we get the following equation for the CD of these complexes:

$$\left.\begin{aligned} \Lambda(\Delta\Delta\Delta)^{R} &= \Lambda(\Delta\Delta\Delta)^{\mathrm{en}} + 6(R) \\ \Lambda(\Delta\Delta\Lambda)^{R} &= \Lambda(\Delta\Delta\Lambda)^{\mathrm{en}} + 6(R) \\ &\cdots\cdots\cdots\cdots \\ \Lambda(\Lambda\Lambda\Lambda)^{R} &= \Lambda(\Lambda\Lambda\Lambda)^{\mathrm{en}} + 6(R) \end{aligned}\right\} \quad (1)$$

where $\Lambda(\Delta\Delta\Delta)^{R}$ and $\Lambda(\Delta\Delta\Delta)^{\mathrm{en}}$ denote the CD of isomers $\Lambda(\Delta\Delta\Delta)$ of *R*-pn (or *R,R*-chxn) and en hexol, respectively, and (R) is the vicinal contribution of an *R*-pn (or *R,R*-chxn) ligand. By applying the observed CD curves of *R*-pn (*R,R*-chxn) and en hexol isomers to Eq. 1, the vicinal contribution curves (R) can be calculated (Figs. 4 and 5). The calculation was performed by using the observed CD curves of en hexol isomers, which were shifted by α (in cm^{-1}) to lower energy side (Table 5). The shift α was estimated from the difference between the CoN_4O_2 absorption peaks of the diamine and en hexol isomers. In the case of

meso-2,3-bn hexol, the ligand has two asymmetric carbons of opposite chiralities, (R) and (S), no contribution of vicinal chiralities being expected in total. The calculated vicinal contribution is zero in the region 13800—30000 cm^{-1}.

As is seen in Figs. 4 and 5, the calculated vicinal contributions are equal when the isomers have the same absolute configuration in the three CoN_4O_2 chromophores, regardless of the absolute configuration of CoO_6 chromophore. However, the calculated vicinal CD curves are not equal when the absolute configuration of the three CoN_4O_2 chromophores is reversed, *viz.*, $(R)_{\Delta\Delta\Delta} \neq (R)_{\Lambda\Lambda\Lambda}$. The calculated vicinal CD curves of the *R*-pn and *R,R*-chxn hexol isomers with the same absolute configuration of CoN_4O_2 chromophores have very similar patterns, the CD intensity of vicinal contribution of *R,R*-chxn being about twice that of *R*-pn; thus the intensity is proportional to the number of asymmetric carbons.

The *R*-pn and *R,R*-chxn chelate rings have a λ

conformation. In the light of the *lel* and *ob* orientations[9] of C–C bonds of diamine chelate rings relative to the pseudo C_3 axis of individual CoN_4O_2 tris(chelate) chromophores, it is evident that the isomer $\{\Delta(\lambda\lambda)\Delta(\lambda\lambda)\Delta(\lambda\lambda)\}$ has the $lel_2lel_2lel_2$ form, $\{\Delta(\lambda\lambda)\Delta(\lambda\lambda)\Delta(\lambda\lambda)\}$ $lel_2lel_2ob_2$, $\{\Delta(\lambda\lambda)\Lambda(\lambda\lambda)\Delta(\lambda\lambda)\}$ $lel_2ob_2ob_2$, and $\{\Delta(\lambda\lambda)\Lambda(\lambda\lambda)\Lambda(\lambda\lambda)\}$ $ob_2ob_2ob_2$. Thus, Eq. 1 should be rewritten as follows:

$$\left.\begin{aligned}
\Delta(\Delta\Delta\Delta)^R &= \Delta(\Delta\Delta\Delta)^{en} + 6(R)_{lel} \\
\Delta(\Delta\Delta\Lambda)^R &= \Delta(\Delta\Delta\Lambda)^{en} + 4(R)_{lel} + 2(R)_{ob} \\
\Delta(\Delta\Lambda\Lambda)^R &= \Delta(\Delta\Lambda\Lambda)^{en} + 2(R)_{lel} + 4(R)_{ob} \\
\Delta(\Lambda\Lambda\Lambda)^R &= \Delta(\Lambda\Lambda\Lambda)^{en} + 6(R)_{ob} \\
&\cdots\cdots\cdots\cdots \\
\Lambda(\Lambda\Lambda\Lambda)^R &= \Lambda(\Lambda\Lambda\Lambda)^{en} + 6(R)_{ob},
\end{aligned}\right\} \quad (2)$$

where $(R)_{lel}$ and $(R)_{ob}$ denote the vicinal contribution due to the *lel* and *ob* forms of *R*-pn (or *R*,*R*-chxn) ligand, respectively. Thus, the vicinal CD curves calculated from isomers P-1, P-4, and C-1 are $(R)_{ob}$, and the curves calculated from isomers P-2, P-3, C-2, and C-3 are $(R)_{lel}$. The $(R)_{lel}$ curve differs definitely from the $(R)_{ob}$ one.

The vicinal contributions, $(R)_{lel}$ and $(R)_{ob}$, can be also calculated from the observed CD curves of isomers $\Delta(\Delta\Delta\Delta)$ and $\Delta(\Delta\Delta\Lambda)$ by applying Eq. 2:

$$(R)_{lel} = [2\{\Delta(\Delta\Delta\Lambda)^R - \Delta(\Delta\Delta\Lambda)^{en}\} - \{\Delta(\Delta\Lambda\Lambda)^R - \Delta(\Delta\Lambda\Lambda)^{en}\}]/6, \text{ and}$$

$$(R)_{ob} = [2\{\Delta(\Delta\Lambda\Lambda)^R - \Delta(\Delta\Lambda\Lambda)^{en}\} - \{\Delta(\Delta\Delta\Lambda)^R - \Delta(\Delta\Delta\Lambda)^{en}\}]/6.$$

As is seen in Fig. 6, the vicinal CD curves calculated from isomers $\Delta(\Delta\Delta\Lambda)$ and $\Delta(\Delta\Lambda\Lambda)$ agree with those calculated from $\Delta(\Delta\Delta\Delta)$, $\Delta(\Delta\Lambda\Lambda)$, $\Lambda(\Delta\Delta\Delta)$ or $\Lambda(\Lambda\Lambda\Lambda)$. This shows that the two vicinal contributions, $(R)_{lel}$ and $(R)_{ob}$, are additive.

Both vicinal contribution curves, $(R)_{lel}$ and $(R)_{ob}$, show rather strong CD even in the absorption region of CoO_6 chromophore which is separated far from the asymmetric carbons.

It was difficult to assign exactly the absolute configuration of the isomer C-4 of $[Co\{(OH)_2Co(R,R\text{-chxn})_2\}_3]^{6+}$ only from the CD pattern; it might be assigned to either $\Delta(\Delta\Delta\Lambda)$ or $\Delta(\Delta\Lambda\Lambda)$. If we apply the additivity between $(R)_{lel}^{R,R\text{-chxn}}$ and $(R)_{ob}^{R,R\text{-chxn}}$ obtained from C-1, C-2, or C-3 isomers, it is possible to see which of the following two relations is adequate:

a) $\{\Delta\varepsilon(\text{C-4}) - \Delta(\Delta\Delta\Lambda)^{en}\}/6 = \{2(R)_{lel}^{R,R\text{-chxn}} + (R)_{ob}^{R,R\text{-chxn}}\}/3$

b) $\{\Delta\varepsilon(\text{C-4}) - \Delta(\Delta\Lambda\Lambda)^{en}\}/6 = \{(R)_{lel}^{R,R\text{-chxn}} + 2(R)_{ob}^{R,R\text{-chxn}}\}/3.$

We see from Fig. 7 that the calculated curve $\{\Delta\varepsilon(\text{C-4}) - \Delta(\Delta\Lambda\Lambda)_{en}\}/6$ is very similar to the curve $\{(R)_{lel}^{R,R\text{-chxn}} + 2(R)_{ob}^{R,R\text{-chxn}}\}/3$. The calculated curve in this case is very similar to the curve calculated (intensity was doubled) from P-6 ($\Delta(\Delta\Lambda\Lambda)$). The absolute configuration of the isomer C-4 is therefore exactly assigned to $\Delta(\Delta\Lambda\Lambda)$.

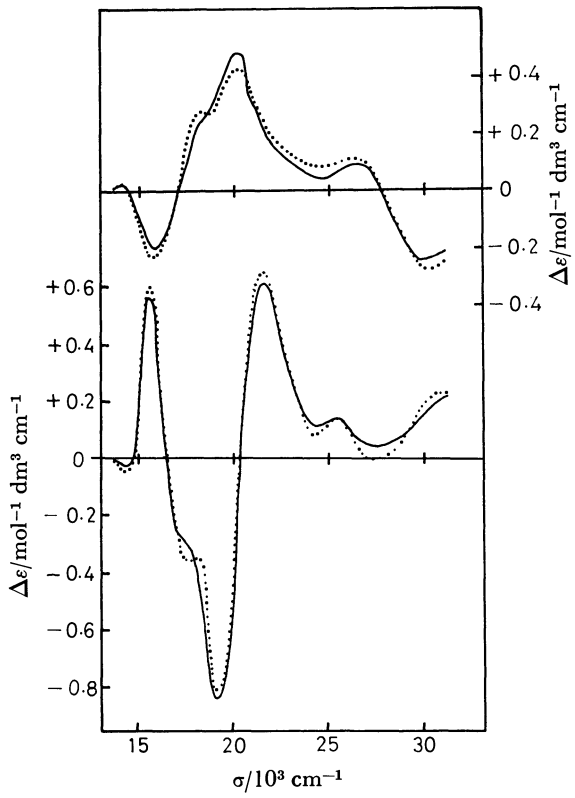

Fig. 6. Calculated vicinal CD curves.
$(R)_{lel}^{R\text{-pn}} = [2\{\Delta\varepsilon(\text{P-6}) - \Delta\varepsilon(\text{E-6})\} - \{\Delta\varepsilon(\text{P-5}) - \Delta\varepsilon(\text{E-8})\}]/6$ (——), and $\{\Delta\varepsilon(\text{P-3}) - \Delta\varepsilon(\text{E-3})\}/6$ (------) (upper curves); and $(R)_{ob}^{R\text{-pn}} = [2\{\Delta\varepsilon(\text{P-5}) - \Delta\varepsilon(\text{E-8})\} - \{\Delta\varepsilon(\text{P-6}) - \Delta\varepsilon(\text{E-6})\}]/6$(——), and $\{\Delta\varepsilon(\text{P-1}) - \Delta\varepsilon(\text{E-1})\}/6$ (------) (lower curves).

a) sh=shoulder.

The vicinal contribution of an (*R*)-diamine ligand consists of the conformational one (λ) and the vicinal one in a limited sence (*R*) due to the asymmetric carbons. Thus the vicinal contribution of an *R*-pn or *R,R*-chxn is presented by $(\lambda)+(R)$, the (*R*) being proportional to the number of asymmetric carbon atoms, *viz.*, $(R)^{R,R\text{-chxn}}=2(R)^{R\text{-pn}}$. On the other hand, the intensity of vicinal curves calculated by Eq. 2 for *R,R*-chxn hexol is about twice that of the *R*-pn hexol. The vicinal contribution due to the asymmetric carbons should be a dominant factor in this case, the conformational contribution hardly contributing at all to the overall vicinal CD. This indicates that the diamine conformation in en hexol is identical to that in *R*-pn or *R,R*-chxn hexol. An alternative but more plausible explanation is that the conformational contributions of diamine chelate rings are negligibly small in all the hexol type complexes. In many mononuclear complexes, the conformational effect contributes mainly to the overall vicinal CD.[10,11] In a limited number of mononuclear complexes, however, the vicinal contribution due to asymmetric carbons becomes a dominant factor.[12] The diamine hexols present an interesting example of the latter case.

Numerical data (mean values) of the individual vicinal CD contributions are given in Table 6.

Stereoselective Association between Acetylacetonatobis(ethylenediamine)cobalt(III) and Malonate Ions as Studied by Nuclear Magnetic Resonance[1]

Hiroshi NAKAZAWA, Ushio SAKAGUCHI, and Hayami YONEDA*
Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730
(Received October 27, 1979)

The effect of added malonate upon the chemical shift and the exchange rate of amine hydrogens of acetylacetonatobis(ethylenediamine)cobalt(III) ion, $[Co(acac)(en)_2]^{2+}$, have been investigated by ^1H and ^{13}C NMR spectroscopy. In the absence of malonate, the amine groups give rise to two signals in the ^1H spectra and two rate constants of amine exchange due to *trans* and *cis* (to coordinated oxygen) amine groups. Upon addition of malonate, the *trans* NH_2 undergoes a down-field shift, the *cis* NH_2 resonance splitting into two peaks. In the presence of malonate, all of the four kinds of amine hydrogens of $[Co(acac)(en)_2]^{2+}$ exhibit different exchange rates. The following conclusion was obtained from the results coupled with ^{13}C NMR data. (i) The malonate ion works in two ways in amine exchange, as a general base catalyst and to form an exchange-inert ion-pair. (ii) The two *trans* hydrogens that are directed approximately parallel to the two-fold axis of the complex ion hydrogen-bond simultaneously to the two carboxyl groups of malonate, leading to a retardation of amine exchange rates. (iii) The rates of the other *trans* hydrogens and *cis* hydrogens are determined by a compromise between acceleration due to general base catalysis and deceleration due to forming ion-associated species. (iv) The conformation of coordinated ethylenediamine is fixed as either ($\delta\delta$) or ($\lambda\lambda$) in the hydrogen-bonded species.

The amine groups of *cis*-$[CoX_2(en)_2]^+$ ions give rise to two broad singlets in their proton NMR spectra. However, the assignment of these singlets to *cis* and *trans* amines, which are *cis* and *trans* to coordinated X ligands, respectively, is not straightforward owing to their equal intensities. A method of assigning these signals on the assumption that the chemical shifts of amine hydrogens are determined primarily by the magnetic anisotropy of the central cobalt(III) ion was proposed.[2] Although the theory based on the magnetic anisotropy could explain the chemical shift variations for a series of pentaamminecobalt(III) ions, the agreement was not good for *cis*-$[CoX_2(en)_2]^+$ type of complexes.

While ion-associated species in solution are believed to have well-defined structures, little evidence seems to have been obtained, particularly in the case of diamagnetic metal complexes.[3] A limited number of structures of ion-pairs in solution are proposed[4] mainly from studies of circular dichroism spectra. The circular dichroism technique is limited to optically active compounds. The kinetic behavior of amine hydrogen exchange of *cis*-$[CoX_2(en)_2]^+$ ions might be affected by added anions. Thus stereochemical information obtained from the effects of added anions on the hydrogen exchange kinetics, could be applied to many complexes irrespective of optically active and inactive complexes.

The aim of this work is twofold: (a) to obtain evidence in support of the postulated NMR assignments and (b) to obtain stereochemical information on the ion-paired species. We chose the system $[Co(acac)(en)_2]^{2+}$ and malonate, mal^{2-} for the following reason. Since the cation carries a higher positive charge than most *cis*-$[CoX_2(en)_2]^+$ compounds which are usually univalent, it will interact more strongly with added anions and the effects of ion association would be significant.

Experimental

$[Co(acac)(en)_2]I_2 \cdot H_2O$ was prepapared and recrystallized analytically pure.[5] Extra pure sodium malonate (Katayama Kagaku Kogyo Co. Ltd.) was used without further recrystallization. Sample solutions were made by dissolving the materials in D_2O (Merck, 99.75 atom % D minimum). The concentration of $[Co(acac)(en)_2]I_2$ of all solutions was 0.1 mol dm^{-3} and that of Na_2mal was varied from 0 to 1.0 mol dm^{-3} at suitable intervals.

^1H NMR spectra were measured on a Varian T-60 spectrometer operating at 60 MHz. The rate of amine hydrogen exchange was determined by measuring the NMR signal intensities of *cis* NH_2 and *trans* NH_2 at suitable time intervals. Proton chemical shifts are referred to internal sodium 2,2-dimethyl-2-silapentane-5-sulfonate, DSS. All measurements were made at 36.4 °C. Proton noise decoupled and undecoupled ^{13}C NMR spectra were recorded for H_2O solutions at 22.6 MHz on a Hitachi R-42 spectrometer by the FT technique. The pH of the sample solution was measured with a Hitachi-Horiba Model F-7 pH meter using a microelectrode immediately after kinetic measurements.

Results

Chemical Shifts. The ^1H NMR spectra of $[Co(acac)(en)_2]I_2$ in D_2O contain two broad signals at 5.02 ppm and 4.42 ppm from internal DSS, due to *cis* NH_2 and *trans* NH_2, respectively, which denote amine hydrogens *cis* and *trans* to oxygen atoms of coordinated acetylacetone.

Figure 1 shows the amine hydrogen portion of the ^1H NMR spectra of $[Co(acac)(en)_2]I_2$ with 0, 0.4, 0.8, and 1.0 mol dm^{-3} of Na_2mal taken immediately after dissolution in D_2O. Chemical shift values of each peak are given in Table 1. With an increase in the concentration of Na_2mal, the signal of *trans* NH_2 shifted to low fields. While *cis* NH_2 appeared as a single peak in the absence of Na_2mal, the *cis* peak became broader, its height being almost half of that of *trans* NH_2 when 0.4

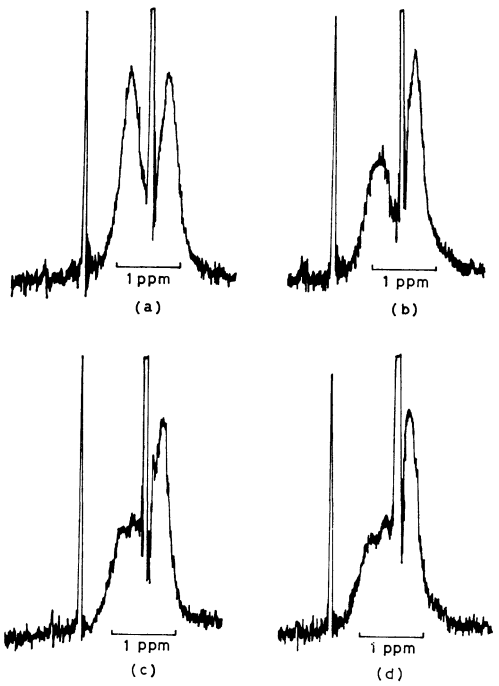

Fig. 1. The amine hydrogen portion of the ^1H NMR spectra of $[Co(acac)(en)_2]I_2$ with 0 (a), 0.4 (b), 0.8 (c), and 1.0 mol dm^{-3} (d) of Na_2mal, taken immediately after dissolution in D_2O. The strong central singlet is due to solvent HDO and to the left of the spectrum is the methine hydrogen of acac.

Table 1. ^1H chemical shifts in δ(ppm) from internal DSS for *cis* and *trans* NH_2

Two peaks appear for *cis* NH_2 when Na_2mal exceeds 0.4 mol dm^{-3}.

Na_2mal (mol dm^{-3})	0	0.4	0.8	1.0
cis NH_2	5.02	5.07	5.11	5.13
		4.97	4.90	4.89
trans NH_2	4.42	4.47	4.52	4.53

mol dm^{-3} of Na_2mal was added. With 0.8 and 1.0 mol dm^{-3} of Na_2mal, the *cis* resonance eventually split into two peaks. The chemical shift difference of these two peaks increased with increasing concentration of Na_2mal. However, the average of their chemical shift values remained unaffected, being equal to the position of *cis* NH_2 without Na_2mal. The ^{13}C chemical shifts of $[Co(acac)(en)_2]I_2$ in the absence and presence of Na_2mal, referred to the methyl carbon resonance of internal methanol, are given in Table 2. The assignment was based on the splitting pattern of each resonance in the undecoupled spectrum.

Rates of Amine Hydrogen Exchange. In the absence of Na_2mal, the plots of ln(intensity) *vs.* time were linear for both *cis* and *trans* NH_2. The result for the solution with 0.1 mol dm^{-3} Na_2mal is shown in Fig. 2, where plots for *trans* NH_2 turn out to be a curve in contrast with a straight line for *cis* NH_2. Analysis of the rate data for *trans* NH_2 gave two pseudo-first-order rate

Table 2. ^{13}C chemical shifts in ppm of $[Co(acac)(en)_2]I_2$ in H_2O referred to the methyl carbon of internal methanol

The concentration of $[Co(acac)(en)_2]I_2$ and Na_2mal is 0.1 and 1.0 mol dm^{-3}, respectively. s, d, t, and q stand for singlet, doublet, triplet, and quartet signals in proton coupled spectra.

	CO(acac)	$COO^-(mal^{2-})$	CH(acac)	CH_3OH	$CH_2(mal^{2-})$	CH_2(en)	CH_2(en)	CH_3(acac)
Without Na_2mal	142.67(s)	——	49.45(q)	0	——	−3.77(t)	−5.66(t)	−22.83(q)
With Na_2mal	142.50(s)	128.02(s)	no signal	0	−2.06(t)	−3.86(t)	−5.75(t)	−22.83(q)

Table 3. First-order rate constants (s^{-1})

$k_{t(f)}$ and $k_{t(s)}$ denote faster and slower rate constants of *trans* NH_2, respectively. Without Na_2mal only one rate is obtained. $k_{c(L)}$ and $k_{c(H)}$ denote *cis* NH_2 when appeared separately at lower and higher fields, respectively. The signal of *cis* NH_2 does not split into two peaks when Na_2mal is 0 and 0.1 mol dm^{-3}.

Na_2mal (mol dm^{-3})	0	0.1	0.1	0.4	0.4
Apparent pH	6.72	6.18	6.44	5.91	5.80
$k_{t(f)}$	1.31×10^{-3}	2.89×10^{-3}	2.55×10^{-3}	9.78×10^{-4}	5.69×10^{-4}
$k_{t(s)}$		4.88×10^{-4}	5.29×10^{-4}	8.00×10^{-5}	7.80×10^{-5}
$k_{c(L)}$	4.57×10^{-4}	3.48×10^{-4}	3.23×10^{-4}	1.70×10^{-4}	7.54×10^{-5}
$k_{c(H)}$					2.15×10^{-5}

Na_2mal (mol dm^{-3})	0.6	0.6	0.8	0.8	1.0
Apparent pH	5.99	5.93	5.84	5.84	5.88
$k_{t(f)}$	7.70×10^{-4}	9.06×10^{-4}	5.29×10^{-4}		
$k_{t(s)}$	7.28×10^{-5}	8.53×10^{-5}	8.10×10^{-5}		
$k_{c(L)}$	8.67×10^{-5}	1.33×10^{-4}	7.73×10^{-5}	8.60×10^{-5}	7.35×10^{-5}
$k_{c(H)}$	6.47×10^{-5}	1.08×10^{-4}	2.44×10^{-5}	4.77×10^{-5}	4.02×10^{-5}

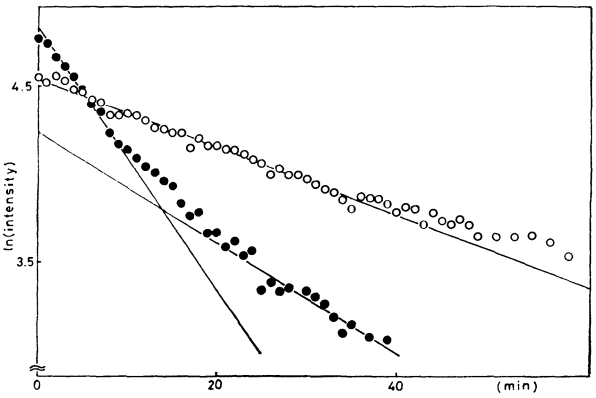

Fig. 2. The plots of ln (intensity) *vs.* time for *cis* (○) and *trans* (●) NH_2 of $[Co(acac)(en)_2]^{2+}$ with 0.1 mol dm^{-3} of Na_2mal.

constants $k_{t(f)}$ and $k_{t(s)}$, which denote faster and slower exchange rates of *trans* NH_2, respectively. The rate constants with varying concentration of Na_2mal are given in Table 3, along with apparent pH. The *trans* NH_2 peak underwent a down-field shift with Na_2mal and at 0.8 mol dm^{-3} of Na_2mal was too close to the strong HDO peak, making the measurement difficult. Since the *cis* resonance splits into two peaks when the Na_2mal concentration exceeds *ca.* 0.5 mol dm^{-3}, two rate constants, $k_{c(H)}$ and $k_{c(L)}$, refer to the peaks at higher and lower magnetic fields, respectively.

Discussion

The Assignment of Amine Signals. In a previous paper a method was proposed for assigning two NH_2 signals of *cis*-$[CoX_2(en)_2]^+$ ions.[2] It was based on the assumption that the chemical shifts of amine hydrogens are primarily determined by the magnetic anisotropy of the central cobalt(III) ion. It has been proposed that for *cis*-$[CoX_2(en)_2]^+$ ions the *cis* NH_2 resonates at a field lower than the *trans* NH_2 if the ligand X is ranked lower, like acac, than en in the spectrochemical series. Thus the *trans* NH_2 of $[Co(acac)(en)_2]^{2+}$ is expected to appear at higher magnetic field than the *cis* NH_2. On the other hand, in a kinetic study of amine hydrogen exchange for several *cis*-$[CoX_2(en)_2]^+$ type of complexes,[6] it was found that the *trans* amine hydrogens are exchanged much faster than the *cis* hydrogens if X is a weaker ligand than en (acac is an example). In the absence of malonate the high field NH_2 signal decreased in intensity more rapidly than the low field one, indicating assignment of the high field signal to the *trans* NH_2.

The results suggest that the high field resonance at δ 4.42 is due to the *trans* NH_2 of $[Co(acac)(en)_2]^{2+}$. The effect of added malonate on amine exchange kinetics can be consistent only when we adopt this assignment.

HD Exchange Kinetics. The *trans* NH_2 exhibits two exchange rates in the presence of Na_2mal, in contrast with only one rate in the absence of malonate. This indicates that two kinds of hydrogens of *trans* NH_2 are discriminated by mal^{2-} in solution. A molecular

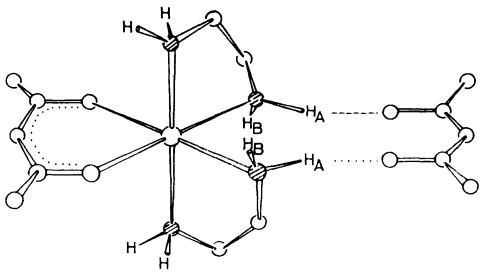

Fig. 3. The proposed structure of ion-associated species, $[Co(acac)(en)_2]^{2+}\cdots\cdots mal^{2-}$.
H_A is approximately parallel to the C_2-axis. Malonate ion approaches from the side opposite to acac along the C_2-axis and hydrogen bonds only to H_A.

model shows that *trans* NH_2 has two kinds of hydrogens, H_A (pointing approximately parallel to the molecular two-fold axis of $[Co(acac)(en)_2]^{2+}$) and H_B, and that two carboxyl groups of mal^{2-} can hydrogen-bond simultaneously to two H_A's (Fig. 3). It is reasonable that mal^{2-} approaches the complex electrostatically from the side opposite acac along the two-fold axis because minus charge is localized on acac. The shift of *trans* NH_2 to low fields caused by addition of Na_2mal supports this view since hydrogen bonding causes downfield shifts.[7] We thus assign the slower exchange rate, $k_{t(s)}$, to H_A and the faster one, $k_{t(f)}$, to H_B. Since double hydrogen bonding would greatly stabilize the chelate structure, we might expect that *trans* H_A is not exchanged while retaining the hydrogen bond.[8]

HD exchange rate constants of coordinated amine groups are proportional to the concentration of OD^- ion.[9]

$$k \propto [OD^-]$$

The equation still holds for such situations where a stable ion-associated species is formed between the metal complex and added anions. In such cases the second-order rate constant $k'=k/[OD^-]$ decreases gradually with an increasing anion concentration. This has been ascribed to an increase in the number of ion-associated species for which amine hydrogen exchange is considered extremely slow. Yamatera and Fujita[10] utilized this behavior to obtain the association constant between *Λ*- and *Λ*-$[Co(en)_3]^{3+}$ and *d*-tartrate ions. Their result can be rationalized by invoking the face-to-face multifunctional hydrogen bonding in solution, as found in the crystal structure of *Λ*-$[Co(en)_3]Br$(*d*-tartrate)$\cdot 5H_2O$.[11] We will discuss our results in terms of the second-order rate constants $k_i'=k_i/[OD^-]$ (i=c, t(s), t(f)), which were derived by using $K_w(D_2O)$,[12,13] corrected according to the ionic strength of the solution extending from 0.3 to 2.5. k' values were plotted against $[Na_2mal]/[complex]$ in order to see the dependence of k' on the concentration of malonate (Fig. 4).

The $k'_{t(f)}$ values for *trans* H_B increase sharply upon addition of Na_2mal, followed by a gradual decrease in the concentration of Na_2mal. Since the rate enhancement can not be due to pH-effect, mal^{2-} and $Hmal^-$ work as general base catalysts, enhancing the rate of *trans* H_B. This may be performed through an ion-pair such as

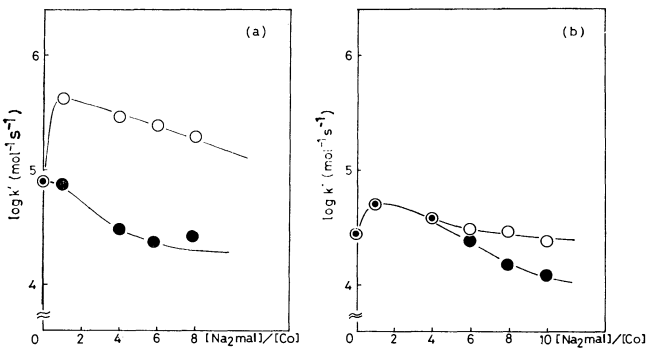

Fig. 4. The plots of logarithms of second-order rate constants (mol^{-1} s^{-1}) *vs.* the molar concentration ratio of Na_2mal to [Co(acac) $(en)_2$]I_2.
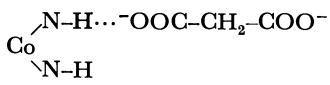
(a) For *trans* NH_2; Two rates, $k'_{t(f)}$ (○) and $k'_{t(s)}$ (●), are detected in the presence of Na_2mal. (b) For *cis* NH_2; Addition of Na_2mal brought about a splitting of the *cis* peak into two peaks, hence $k'_{c(L)}$ (○) and $k'_{c(H)}$ (●).



where one of the carboxyl groups hydrogen-bonds to an amino group, the other dangling and not interacting with amino hydrogens. A similar rate enhancement due to general base catalysis by acetate and malonate has been confirmed for *cis*-$[CoX_2(en)_2]^+$ ions with X_2= mal^{2-}, $(CN)_2$, $(NO_2)_2$.[14] The gradual reduction of $k_{t(f)}$ may be interpreted as follows. The number of predominant ion-associated species increases with an increase in the concentration of malonate (Fig. 3). Since associated species have zero electric charge, it is improbable that mal^{2-} or $Hmal^-$ ion approaches this associated species, acting as general base catalysis on the associated complexes.

The $k_{t(s)}$ value, which refers to *trans* H_A, decreases with an increase in the concentration of Na_2mal, indicating that the number of the species in which mal^{2-} associates with two *trans* H_A through hydrogen bond, increases with increasing concentration of Na_2mal. However, the steady decrease of $k_{t(s)}$ seems to indicate not the inaccessibility of general base to H_A but retardation due to ion-pairing offsetting the effect of general base catalysis.

For *cis* NH_2, an average of $k'_{c(H)}$ and $k'_{c(L)}$ increases up to 0.1 mol dm^{-3} of Na_2mal, though the increase is about one-fourth of that of $k'_{t(f)}$ at the same Na_2 mal concentration; the increments are 1.6 and 6.6 times for k'_c and $k'_{t(f)}$, respectively, as compared with the corresponding values in the absence of malonate. Although the increase of k'_c indicates that the malonate ion works as general base catalysis on *cis* NH_2, the effect on k'_c is smaller than that on $k'_{t(f)}$. This suggests that the malonate ion approaches *cis* NH_2 less frequently, which is quite likely from electrostatic consideration. The subsequent gradual decrease of k'_c may be explained in a manner similar to that for $k'_{t(f)}$.

The results can be summarized as follows. Malonate ion can work as general base catalyst for exchanging amine hydrogens. The values of $k'_{t(f)}$ for *trans* H_B and k'_c for *cis* NH_2 would be taken as a compromise of two opposing factors: rate acceleration due to general base catalysis by malonate ion and rate retardation due to ion-pairing (Fig. 3). The initial increase of $k'_{t(f)}$ and k'_c is due to general base catalysis and the subsequent gradual retardation to additional hydrogen bond effect. The steady decrease of $k'_{f(s)}$ for *trans* H_A caused by malonate ions is explained by the selective hydrogen bond between mal^{2-} and *trans* H_A.

Conformation of Ethylenediamine Chelates. With an increase in the concentration of Na_2mal, the ^1H signal of *cis* NH_2 split into two peaks, the separation increasing. In ^{13}C NMR spectra, both peaks assigned to en carbons underwent high field shifts by about 0.1 ppm upon addition of Na_2mal. This suggests that the conformational equilibrium of the two en chelates is driven toward either ($\delta\delta$) or ($\lambda\lambda$) by the presence of mal^{2-}.

The conformation of ethylenediamine coordinated to metal ions is rapidly interconverting between the δ and λ forms in aqueous solution.[15] If the conformations of two ethylenediamine rings are fixed as ($\delta\lambda$) or ($\lambda\delta$), the number of expected resonance peaks may be up to four for *cis* NH_2 on ^1H NMR spectra and also four for CH_2 resonance of en on ^{13}C NMR. However, the energy difference between ($\delta\lambda$) and ($\delta\delta$) or between ($\delta\lambda$) and ($\lambda\lambda$) is generally accepted as very small and the relative populations of these two conformations would be virtually 1 : 1. Thus the observed ^{13}C chemical shift, being an average with 1 : 1 weights, should be the midpoint between the shifts expected for the δ and λ conformers. On the other hand, if the conformation of two ethylenediamine is fixed as ($\delta\delta$) or ($\lambda\lambda$), the corresponding ^1H and ^{13}C spectra should consist of only two peaks. Since our system would be in rapid dynamical equilibrium between free and the associated species, and the conformation of en ring would be considered to be constrained by hydrogen bonding with mal^{2-} in the associated species, the observed spectra should be an average weighted by the abundance of respective species.

The signals split upon addition of malonate are not those with which malonate is proposed to be interacting, *i.e.*, *trans* NH_2. However, if we accept the view that conformational equilibrium is shifted to either ($\delta\delta$) or ($\lambda\lambda$) upon addition of malonate, the two kinds of hydrogens of *cis* NH_2 will have stereochemically different disposition, especially with respect to the cobalt-acac chelate; one of the *cis* NH_2 is poised over the chelate ring and the other is not. This will bring about a large chemical shift difference for the two *cis* hydrogens but not for the two *trans* ones. The effect of the magnetically anisotropic ring current of the chelate ring has not been clarified. However, the former hydrogen might be to a greater extent shielded than the latter.[16] On electrostatic grounds the *cis* NH poised over the chelate ring might undergo exchange more slowly. Experimentally, of the two *cis* signals the high field one is exchanged more slowly than the other, which is in line with our assumption.

The authors would like to thank Dr. Y. Uchio and Prof. S. Hayashi for ^{13}C NMR measurements. One

Effects of Sodium Tetraborate as an Additive on the Reaction of α-Alumina with Sodium Carbonate

Byong-Tae CHANG,* Jae-Gun OH, and Suk-Ja OM
Department of Chemistry, Korea University, Kodaira, Tokyo 187
(Received November 2, 1979)

Effects of sodium tetraborate as an additive in the reaction of α-alumina with molten sodium carbonate have been studied mainly in a N_2 atmosphere. Addition of sodium tetraborate accelerates the reaction, the α-alumina reacted increasing from 31.7% to 99.3% by addition of sodium tetraborate corresponding to the initial B_2O_3/Na_2O molar ratio of only 1/15 under the other same conditions. By means of the Jander equation the activation energy was found to be 53 kcal/mol for the α-Al_2O_3–Na_2CO_3–$Na_2B_4O_7$ system, which was lower by 10 kcal/mol than that for the α-Al_2O_3–Na_2CO_3 system. X-Ray diffraction and thermal data were analyzed in relation to the phase equilibrium of the melt.

Production of alumina from resources other than bauxite is becoming important. A number of reports have appeared on the production of alumina from various low-grade sources such as clay, aluminous shale, anorthosite, nephelite, *etc.*[1–8]

A lime-soda sinter process is one of the most important methods for extracting alumina from low-grade sources to which the Bayer process can not be applied because of high silica content. Raw materials reacted with molten sodium carbonate form sodium aluminate which is soluble in both acidic and basic aqueous solutions. The reaction of various types of alumina with sodium carbonate is fundamental in the complex lime-soda sinter process.

In a previous paper the lime-soda sinter process was discussed with use of Korean diaspore, cyanite and kaolinite as starting materials.[9] Christie *et al.* studied the reaction rate of α-alumina with sodium carbonate in relation to gasification of coal in melts containing sodium carbonate, showing that the reaction process is considerably hindered by diffusion.[10]

Sodium tetraborate is often used as a flux for the decomposition of minerals by molten Na_2CO_3. The purpose of the present work is to clarify the promoting action of sodium tetraborate on the reactivity of α-alumina with sodium carbonate.

Experimental

Reagent grade α-alumina was ground and sized into −150 —+200 mesh (No. 1) and −200 mesh (No. 2). The specific surface area of No. 2 was found to be 0.90 m^2/g by the BET method. Reagent grade anhydrous sodium carbonate and sodium tetraborate decahydrate (borax) were dried at 500 °C for 1 h. Nitrogen and oxygen were purified by the usual methods. Other materials were of reagent grade and used without further purification.

The percentage of α-alumina reacted with sodium carbonate, η, was determined as follows: Samples in a platinum boat were laid in an electric furnace at 900—1250 °C. The sinter was cooled down to room temperature as fast as possible in N_2 gas, and leached with hot 1 mol/dm^3 HCl solution for 30 min. The leachate was filtered. $Al(OH)_3$ was precipitated by adding aqueous ammonia to the filtrate and weighed in the form of Al_2O_3 after heating. The value of η was calculated from the weight of alumina leached.

Results and Discussion

Effect of Gas Atmosphere. α-Alumina reacts with sodium carbonate to form sodium aluminate:

$$Al_2O_3(s) + Na_2CO_3(l) = 2NaAlO_2(s) + CO_2(g). \quad (1)$$

From the large negative value of Gibbs free energy for this reaction[11] α-alumina is expected to react completely with molten Na_2CO_3 at temperatures above 900 °C. However, the experimental results (Fig. 1)

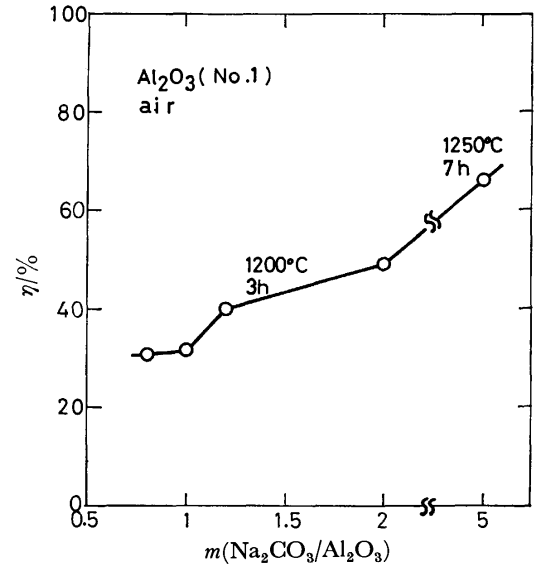

Fig. 1. Variation of the percents of α-alumina reacted with initial Na_2CO_3/Al_2O_3 molar ratio.

indicate that the reaction is not complete in the air. For example, the value of η was found to be low at 66% even for the initial molar ratio(m) 5 of Na_2CO_3/Al_2O_3 and reaction time 5 h at 1250 °C. The sinters obtained in the air were colored brown, the Pt boat containing the sinter being considerably corroded. In spite of the disappearance of α-alumina in X-ray diffraction patterns of the sample sintered for a long time, the value of η was much lower than 100% (Fig. 3a).

Maegawa found that the atmosphere influences the sintering process, and that H_2O gas atmosphere enhances the rate of reaction of α-alumina with sodium carbonate in comparison with O_2, H_2+CO, or CO_2 gas atmos-

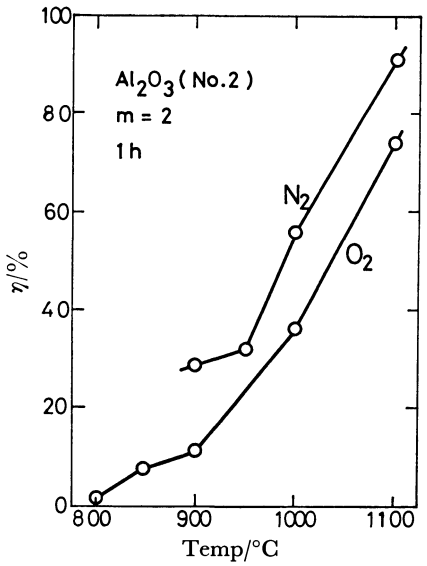

Fig. 2. Difference between the effect of N_2 and O_2 gas atmospheres on the reaction of Al_2O_3 with Na_2CO_3.

phere.[12] Figure. 2 shows changes in the η values with reaction temperature in purified N_2 and O_2 with constant flow rates of 80 ml/min. The values of η obtained in O_2 were found to be lower than those obtained in N_2, the corrosion of the Pt boat being much enhanced in O_2. The sinter obtained in N_2 remained white with no corrosion of the Pt boat; those obtained in O_2 were colored red-brown as in the air. The same results were obtained when a Ni boat was used. By comparing Fig. 3a with 3b, we see that there are compounds other than α-Al_2O_3(a), Na_2CO_3(n), and $NaAlO_2$(na). Carbon dioxide,[10] as well as O_2 seems to hinder the sinter process.

Effect of Additives. Sodium tetraborate and aluminium fluoride were used as additives to facilitate Reaction 1. Addition of sodium tetraborate was found to be very effective (Fig. 4). The greater the initial

Curve 1; α-Al_2O_3+Na_2CO_3+AlF_3 (20 wt%), 2; α-Al_2O_3+Na_2CO_3+NaF(20 wt%), 3; α-Al_2O_3+Na_2CO_3.

B_2O_3/Na_2O molar ratio(n), the greater the effect. The sinters to which sodium tetraborate had been added remained white, causing no corrosion of the Pt boat. The sinter having $\eta=100\%$ obtained for the Al_2O_3–Na_2CO_3–$Na_2B_4O_7$ system gave only the diffraction patterns of $NaAlO_2$ and probably sodium borate(b) (Fig. 3c).

The effects of AlF_3 and NaF as additives were also studied. The effect of AlF_3 on Reaction 1 depends a great deal on the value of m (Fig. 5). When 20 wt% AlF_3 was added to a mixture with m of 2.0, the value of η increased from 36% to 100%. Aluminium fluoride reacts with molten Na_2CO_3 partly to form $NaAlO_2$:

$$AlF_3 + 2Na_2CO_3 = 3NaF + NaAlO_2 + 2CO_2, \quad (2)$$

$$AlF_3 + 3NaF = Na_3AlF_6. \quad (3)$$

If all the AlF_3 added were converted into NaF, the effect of NaF would be observed similar to that of AlF_3. However, this was not the case (Fig. 5). X-Ray diffraction analysis of the sinter obtained in the case of $m=2$ and $\eta=100\%$ showed the presence of $NaAlO_2$ and a fluoride compound(f), probably Na_3AlF_6. In the case of $m=1$ and $\eta=27\%$, η was found to be low, in spite of the absence of the diffraction pattern for α-Al_2O_3. This suggests that α-Al_2O_3 might merely dissolve in Na_3AlF_6 formed by the reaction of AlF_3 with Na_2CO_3.

Reaction Rate as a Function of Temperature. Figures 6 and 7 show changes in η with reaction time, t, at three temperatures for α-Al_2O_3–Na_2CO_3($m=2$) and α-Al_2O_3–Na_2CO_3–$Na_2B_4O_7$($m=2$ and $n=1/15$).

Since a protective layer of sodium aluminate having very low solubility in molten Na_2CO_3,[10] is formed on alumina, the diffusion of CO_3^{2-} ion through the sodium aluminate layer would be the rate-determining step.[10,12] The results were analyzed by means of the Jander equation

$$[1-(1-\eta)^{1/3}]^2 = kt, \quad (4)$$

$$k = \frac{2DC_0}{\rho r_0^2}, \quad (5)$$

where k is a rate constant, D diffusion coefficient, C_0 the concentration of CO_3^{2-} ion in the bulk, ρ is the density of

the slopes giving the k values. At 1000 °C the k value for α-Al_2O_3–Na_2CO_3–$Na_2B_4O_7$ system is larger by *ca.* 11 times than that for α-Al_2O_3–Na_2CO_3 system. Figure 10 shows Arrhenius-type plots of k *vs.* $10^4/T$. The activation energy calculated from the slopes is 53 kcal/mol for the former, lower by 10 kcal/mol than that for the latter (kcal means $kcal_{th}$; 1 $kcal_{th}$=4184 J). For the Arrhenius activation energy for the reaction of α-Al_2O_3 with Na_2CO_3, Christie *et al.*[10] and Maegawa *et al.*[12] reported the values of 62±3 and 58.8 kcal/mol, respectively, which agree with our results.

Discussion on the Effect of Sodium Tetraborate as an Additive. Molten Na_2CO_3 is completely ionized and consists of species such as Na^+, CO_3^{2-}, and ion pair $(Na^+CO_3^{=})^-$, the dissociation of CO_3^{2-} into CO_2 and O^{2-} ion being finite at temperatures above melting point.[13] Thus the reaction of α-alumina with Na_2CO_3 can be expressed by a series of elementary steps as follows:

$$Na_2CO_3(l) = Na^+(l) + (Na^+CO_3^{=})^-(l), \quad (6)$$

$$(Na^+CO_3^{=})^-(l) = Na^+(l) + CO_3^{2-}(l), \quad (7)$$

$$CO_3^{2-}(l) = O^{2-}(l) + CO_2(g), \quad (8)$$

$$Al_2O_3(s) + O^{2-}(l) = 2AlO_2^-(l), \quad (9)$$

$$Na^+(l) + AlO_2^-(l) = NaAlO_2(s). \quad (10)$$

According to the Lux-Flood concept of basicity of oxides,[14,15] a base is defined as an oxide donor and an acid as an oxide acceptor:

$$(acid) + O^{2-} = (base) \quad (11)$$

The reaction of α-alumina with sodium carbonate might be the neutralization between acidic Al_2O_3 and basic Na_2O. Thus pO^{2-}[*i.e.* $-\log a(O^{2-})$] was chosen as a scale of basicity. According to the calculation of the relative basicity of oxides by Yagisawa *et al.*, B_2O_3 is more acidic than Na_2O and Al_2O_3.[16] Duffy and Ingram,[17] who presented a concept of optical basicity for the melt, reported that an increase in B_2O_3 content lowers the basicity of Na_2O–B_2O_3 melt; B_2O_3 has a

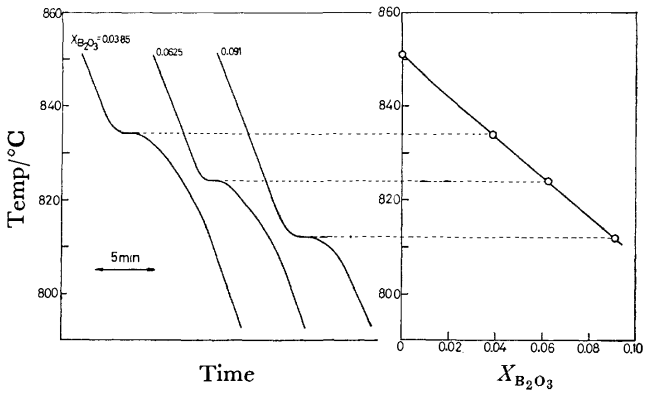

Fig. 11. Cooling curves for mixed melts of Na_2CO_3 and $Na_2B_4O_7$, and the melting points *vs.* $X_{B_2O_3}$.

tendency to consume O^{2-} ion:

$$B_2O_3 + 5O^{2-} = 2BO_4^{5-} \quad (12)$$

It is thus concluded that the effect of the addition of sodium tetraborate is not caused by the increase in the basicity of the melt.

The phase diagram of Na_2O–B_2O_3 system has been reported only for the region $B_2O_3 \geq 50\%$.[18] Basic sodium borates such as $5Na_2O \cdot B_2O_3$, $2Na_2O \cdot B_2O_3$, and $3Na_2O \cdot B_2O_3$ are known in the region $B_2O_3 \leq 50\%$. Figure 11 shows cooling curves for Na_2CO_3–$Na_2B_4O_7$ melts. Addition of sodium tetraborate to sodium carbonate give rise to the lowering of solidification point of the melt in proportion to the molar fraction of B_2O_3. With the progress of Reaction 1, the concentration of B_2O_3 in the melt increases as a result of consumption of Na_2CO_3, lowering the melting point; the nearer the reaction approaches 100% completion, the greater the lowering in melting point. The activation energy for diffusion is approximately proportional to melting point.[19] The activation energy for the α-Al_2O_3–Na_2CO_3–$Na_2B_4O_7$ system, having lower melting points, was found to be lower by 10 kcal/mol than for the α-Al_2O_3–Na_2CO_3 system. The lowering of the melting point results in the lowering of the viscosity of the melt, promoting the contact of α-alumina with the melt and the diffusion of CO_3^{2-} and/or $(Na^+CO_3^{=})^-$ ion(s) through a porous layer of $NaAlO_2$ formed on the surface of α-alumina.

The Chromatographic Concentration of Mercury in Sea Water with 2-Mercaptobenzothiazole Supported on Silica Gel

Kikuo TERADA,* Kumiko MORIMOTO, and Toshiyasu KIBA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received August 29, 1979)

A solid chelating material, 2-mercaptobenzothiazole supported on silica gel (MBT-SG), was prepared and used for the preconcentration of inorganic and organic mercury compounds from a sea-water sample. The chelating capacity of the material was 12 μeq. Hg/g. The mercury(II) ion, the methylmercury ion, and the ethylmercury ion were quantitatively retained on the MBT-SG at pH values of 1.0, 5.0, and 4.0 respectively from an aqueous solution, and at pH values of 4.0, 4.5, and 5.0 respectively from a sea-water. A column packed with the material provided a quantitative recovery of these ions from a sea-water sample at a high flow rate (1—3 l h^{-1}). Mercury was eluted by the use of a acetone–hydrochloric acid mixture (25: 1) or a 1% thiourea solution in 0.1 mol dm^{-3} hydrochloric acid. The latter effluent was submitted atomic-absorption spectrometry after reductive vaporization for the determination of mercury.

The analytical data on mercury in sea water which have been obtained up to the present time vary widely, from 2 to 2800 ng l^{-1}.[1-6] Such a wide variation in the values may be attributed to the following factors; i) contamination from an acid added to the sample for preservation;[7,8] ii) a change in chemical species, accompanied by an acidification of the sample,[9-11] iii) contamination from the container material,[12] iv) loss by vaporization and adsorption from the water sample[13,14] and contamination from air-borne particulate in the laboratory.[15-19] Therefore, it is preferable that mercury be concentrated as early as possible after sample collection in order to minimize the loss and contamination during storage.[20,21]

Previously, a simple method for the preconcentration and determination of several metals in natural waters was reported by Terada *et al.*[22] By their method, copper, zinc, lead, and cadmium in sea water could be rapidly concentrated on a column of a newly prepared chelating material, 2-mercaptobenzothiazole supported on silica gel (MBT-SG). This material was also found to be useful for the rapid concentration of inorganic and organic mercury compounds from sea water. A simple method for the rapid concentration, followed by the atomic-absorption spectrometric determination, of mercury in sea water using the MBT-SG column will be described in the present paper.

Experimental

Reagents. 2-Mercaptobenzothiazole-silica gel (MBT-SG) was prepared in the same way as was described in a previous paper.[22] Before use, the silica gel was washed with hydrochloric acid (1+1), nitric acid (1+2), and deionized water, succesively.

Standard Solution of Mercury (II) Nitrate. A 0.5 g of distilled mercury was dissolved in 30 ml of nitric acid and then diluted to 250 ml with deionized water.

Chloromethylmercury and Chloroethylmercury Labelled with ^{203}Hg.[23] About 0.3 g of dimethylmercury or diethylmercury was dissolved in about 2 ml of cold ethanol (Solution A). About 0.3 g of mercury (II) chloride was dissolved in about 2 ml of cold ethanol and spiked with ^{203}Hg (Solution B). To Solution A, Solution B was added, then, after a few seconds, the product separated as a white crystalline precipitate was filtered through a filter paper, Toyo No. 5C, washed with cold ethanol, and then dried by means of an air current at the pump. Finally, the labelled chloromethylmercury or chloroethylmercury was crystallized from a hot ethanol solution. The specific activities of these compounds were 1.3×10^8 cpm g^{-1} and 2.7×10^8 cpm g^{-1} respectively. The radioactive tracer ^{203}Hg was purchased from the Radiochemical Centre, Amersham (England). The radioactive purity of this tracer was checked by means of a Ge (Li) detector coupled with a 1024 multichannel analyzer.

Standard Solution of Chloromethylmercury. 40.2 mg of labelled chloromethylmercury was dissolved in water, and then 8 ml of hydrochloric acid was added. The solution was diluted to 100 ml with deionized water. This solution was diluted to the desired concentration with deionized water before every use.

Standard Solution of Chloroethylmercury. 50.3 mg of labelled chloroethylmercury was dissolved in a small volume of ethanol (1 ml), and the then mixture was diluted with deionized water. Eight milliliters of hydrochloric acid were then added to this solution, and the solution was diluted to 100 ml with deionized water. This solution was diluted to the desired concentration before every use.

1% Thiourea Solution in 0.1 mol dm^{-3} Hydrochloric Acid.

10% Tin (II) Chloride Solution in 1 mol dm^{-3} Hydrochloric Acid. The solution was bubbled by the air pump for 10 min at a flow rate of 0.5 l min^{-1}.

10 mol dm^{-3} Sodium Hydroxide Solution.

Apparatus. The apparatus used included two Hitachi-Horiba pH meters, M-5 and M-7; a Kobe Kogyo Co., Model STL-200 (44.5×50.8 mm NaI (Tl) crystal), well-type scintillation counter; a Hitachi 170-50 atomic-absorption spectrometer with a 18-cm-long quartz-absorption cell (this apparatus was connected to a Hitachi recorder).

The chromatographic column was a glass tube 12 mm in diameter and 140 mm in length, with a coarse sintered-glass disc and a stop-cock at the bottom.

A Toyo E-E SF200A fraction collector was also used.

Procedure for Batch Experiments. Two milliliters of the mercury test solution, (50 ppm, containing ^{203}Hg for mercury (II), 37.4 ppm and 46.5 ppm as mercury for chloromethylmercury and chloroethylmercury respectively), 10 ml of a buffer solution, and 0.5 g of MBT-SG were put into a 50-ml centrifuge tube and mixed. The mixture was then agitated mechanically at 340 strokes min^{-1} for 5 min at room temperature. The supernatant was filtered through a dry sheet of Toyo No. 5C filter paper. Each 3 ml of the filtrate was submitted to gamma-ray counting, afetr which the retention recovery was calculated.

Procedure for Column Method. The chromatographic tube (12 mm in diameter) was filled with 5 g of dried MBT-SG, and then a piece of filter paper was placed on the top of the column. In this case, the bed length became about 7 cm. A given volume of sea water containing individual mercury species was adjusted to a suitable pH, and then percolated through the column at a flow rate of 1—3 l h^{-1}. After washing the column with about 10 ml of deionized water, the mercury was eluted by the use of a 1% thiourea solution in 0.1 mol dm^{-3} hydrochloric acid or a solvent mixture of acetone and hydrochloric acid (25: 1) at the flow rate of about 1 ml min^{-1}. Then the effluent was made up to 25 ml, and a 3-ml aliquot of the solution was pipetted into a test tube for the measurement of its radioactivity by means of a gamma-ray scintillation counter.

Recommended Analytical Procedure. The following procedure is recommended: after the sample is collected, a 1- to 2-l portion is immediately adjusted to *ca.* pH 5.5 with hydrochloric acid and then pessed through the MBT-SG column (2 g of the material), which had been washed with 25 ml of the thiourea eluting solution and 25 ml of mercury-free sea water successively, at the flow rate of 1 to 2 l h^{-1} under gentle suction. Mercury-free sea water is prepared by passing sea water through the MBT-SG column. Subsequently, about 25 ml of the 1% thiourea eluting solution is passed through the column at the flow rate of about 1 ml min^{-1}. Then, the column is washed with about 10 ml of deionized water. The effluent and the washing are collected in a 100-ml Erlenmyer flask, and an additional 10 ml of deionized water is added to the flask. In a 50-ml beaker, about 6 ml of 10 mol dm^{-3} sodium hydroxide solution is placed, and then 5 ml of a 10% tin (II) chloride solution in hydrochloric acid is added under vigorous stirring, after which the solution is poured into the above Erlenmyer flask containing the column effluent. The flask is immediatly closed with a silicon rubber stopper provided with inlet- and outlet-tubes, the former being connected to a small air pump, and the latter, to a glass tube containing magnesium perchlorate. Then, the content is submitted to the determination of mercury by means of atomic-absorption spectrometry. The front of the magnesium perchlorate tube has been connected to a quartz atomic absorption cell 18 cm in length. After the flask has been shaken for 1.5 min, the air is bubbled through the solution at the flow rate of 0.5 l min^{-1} using an air pump. The absorbance is measured at 254 nm.

The reagent blank test has to be carried out throughout the whole procedure except for passing the sample water down the column.

Results and Discussion

Characteristics of the Chelating Material. The chelating capacity of MBT-SG for mercury, as measured by the column method, was found to be about 12 μmol per g of MBT-SG. This is comparable with that obtained for copper(II) (10 μmol per g of MBT-SG) and appears to be enough to collect mercury from a large amount of sea water, because 1 l of sea water is estimated to contain as little as about 0.3 μmol of heavy metal ions in all. This is compatible with 0.03 g of MBT-SG.

This solid chelating material also showed no loss of the mercury once retained on it even after a storage period of about one year. Therefore, this material can be submitted to atomic-absorption spectrometry or radioactivation analysis for mercury after carrying back it to laboratory without any loss and contamination of the element. An ordinary disposable syringe tube (5 ml) may be conveniently used as a column tube on board ship.

Recovery of Mercury(II), Methylmercury, and Ethylmercury ions at Various pH *Values.* The recovery of each individual mercury species was examined for a simple aqueous solution and for sea water of various pH values by the batch-experiment technique, as has been described previously. The pH of the solution was adjusted by sodium acetate plus hydrochloric acid for pH 1—5, and potassium dihydrogen phosphate plus sodium hydroxide for pH 6—8.

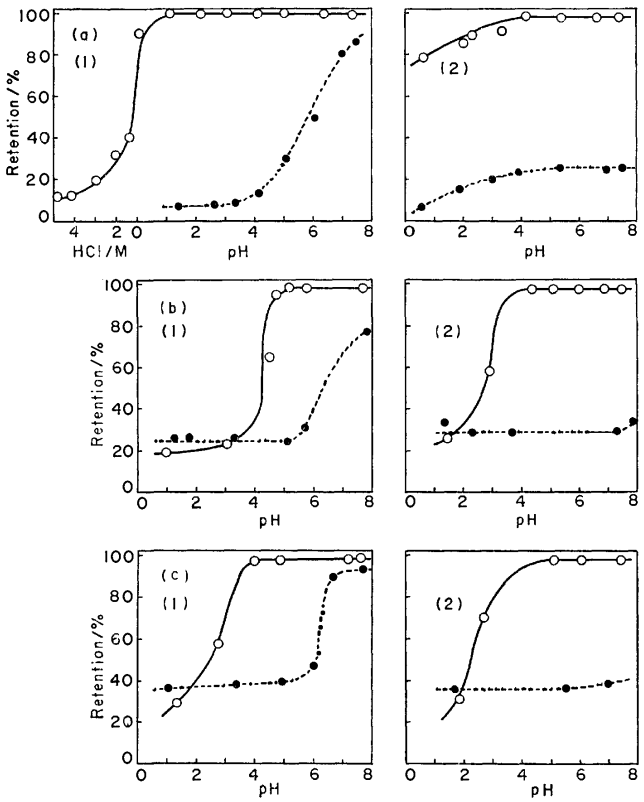

Fig. 1. Effect of pH on retention of (a) mercury(II), (b) methylmercury(I), and (c) ethylmercury(I).
(1): Aqueous solution, (2): sea water;
—○— MBT-SG; ---●--- untreated silica gel.

The results are shown in Fig. 1, along with those obtained by using untreated silica gel. The pH value mentioned is that measured after the equilibration. The mercury(II) ion was found to be retained completely on the chelating material at pH 1 for the aqueous solution and at pH 4 for sea water, but when untreated silica gel was put into an aqueous solution, the mercury-(II) ion began to be adsorbed at pH 4. In the case of sea water, however, a recovery of 30% was only obtained at pH values of 6 or above.

The complete retention of the methylmercury ion from an aqueous solution and sea water were achieved at pH 4.5 and 4 respectively with MBT-SG, and a remarkable difference in adsorbability between the

two adsorbents was observed. In the aqueous solution, the ethylmercury ion behaved quite similarly to the methylmercury ion, but in sea water a quantitative retention of ethylmercury on MBT-SG was obtained at pH 5.

Consequently, the pH value of 5 to 5.5 was chosen as the operating pH for the column experiments.

Retention of Individual Ions on the Column. One-liter portion of sea water containing a metal ion in various concentration were passed through the column at different flow rates. Each mercury species retained on the column was eluted with 20 ml of a mixture of acetone and hydrochloric acid (25: 1). The effluent was made up to 25 ml, and then a 3 ml portion of the aliquot was pipetted into a test tube for gamma-ray counting. Table 1 shows that the quantitative recovery of the mercury(II) ion in the concentration range of 0.032—20 ppb was attained from 1 l of sea water.

Table 1. Recovery of mercury(II), methylmercury(I), and ethylmercury(I) by the column method[a)]

Ion	Concentration / ppb	Flow rate / $l\ h^{-1}$	Recovery / %
Hg(II)	20	1—2	100
	1	2—3	100
	0.032	1—3	100
$CH_3Hg(I)$	200	1—2	100
$C_2H_5Hg(I)$	200	1—2	100

a) MBT-SG: 5 g; column: $\phi 12 \times 70$ mm.

In the cases of methylmercury and ethylmercury ions, their quantitative retention was also observed from 1 l of sea water of a very low concentration (below 0.2 ppm), and they were easily released from the column with the same mixed solution of acetone and hydrochloric acid. Thus, the preconcentration of the inorganic and organic mercury from 1 l of a sample solution is easily attainable within only 20 to 30 min.

Effect of Various Ions and Organic Substances on the Adsorption of Mercury. Since various metal ions are well-known to react with MBT, copper(II), lead(II), zinc(II), cadmium(II), nickel(II), cobalt(II), and iron(III) were examined for their effects on this preconcentration procedure of mercury. One liter of sea water, containing the mercury(II) ion in a concentration of 1 ppb, both methylmercury and ethylmercury ions in a concentration of 0.2 ppm, and one of the above-mentioned ions in a concentration of 1 ppm, was passed through a column containing 5 g of MBT-SG (70 mm long) at the flow rate of 2 l h^{-1}. As shown in Table 2, none of these metal ions at the 1 ppm level had any effect on the adsorption of any mercury species. Sea water generally contains only 50 ppb of heavy metal ions in all; therefore, the effects of these metal ions on the adsorption of mercury from sea water may, for practical purposes, be disregarded.

Table 2. Effect of diverse ions on the recovery of mercury compounds by the column method

Ion	Concn. / ppm	Recovery/% Hg(II)	$CH_3Hg(I)$	$C_2H_5Hg(I)$
Cu(II)	1	100	100	100
Pb(II)	1	100	100	100
Zn(II)	1	100	100	100
Cd(II)	1	100	100	100
Ni(II)	1	100	100	100
Co(II)	1	100	100	100
Fe(III)	0.1	100	100	100

Table 3. Effect of various substances on the recovery of mercury(II) by the column method[a)]

Substance	Concentration / mol dm^{-3}	Recovery / %
Cysteine	10^{-4}	83
Cystine	10^{-4}	80
EDTA	10^{-4}	100
Citric acid	10^{-4}	98
Tartaric acid	10^{-4}	99
SCN^-	10^{-4}	96

a) MBT-SG: 3 g; column: $\phi 12 \times 50$ mm.

Some organic compounds were also examined for their effects. In this case, a solution containing mercury in a concentration of 20 ppb and the organic compounds in a concentration of about 100 times that of mercury was passed through the column. The results are shown in Table 3. Several organic ligands such as EDTA, citric acid, and tartaric acid, did not interfere, and thiocyanate slightly reduced the adsorbability of mercury on MBT-SG. On the other hand, cysteine and cystine appreciably reduced the recovery of mercury. Apparently, this is due to the higher affinity of these ligands to mercury. For methylmercury and ethylmercury ions, similar experiments were not done because each specific activity of their labelled compounds became too low to perform the test of a reasonably low concentration of mercury. However, comparable recoveries of them with the mercury(II) ion can be expected from the results shown in Fig. 1 and Table 2.

Since, in sea water, these organic substances are never found beyond the concentration shown in the Table, the interference of these substances may also be negligible. In fact, in the present recovery experiment, the quantitative retention of each of the three kinds of mercury ions was achieved from a sea-water sample which had been collected at Tsukumo Bay, Noto Peninsula, and assumed to be more polluted by domestic activity than open sea water.

Elution of Mercury. Mercury was retained intimately on the column, therefore, elution with a single mineral acid, such as hydrochloric acid or nitric acid, gave a poor recovery of mercury. Various kinds of solvents and their mixtures were tested for adoption as the eluent by the batch method; the results are shown in Table 4. Among the various kinds of solutions tested, a solvent mixture of acetone and hydrochloric acid (in a mixing ratio of 9: 1 or 25: 1)[22] and a 1% thiourea solution in 0.1 mol dm^{-3} hydrochloric acid[21] were found to be most adequate for the elution of

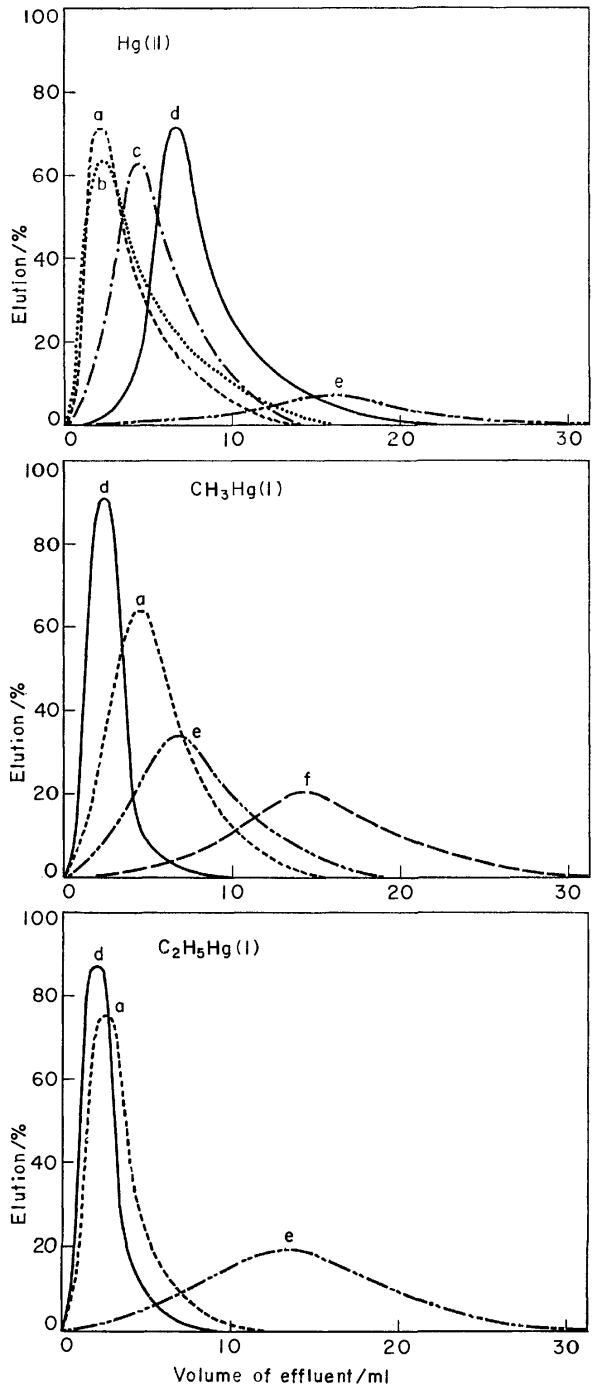

Fig. 2. Elution of mercury(II), methylmercury(I), and ethylmercury(I) retained on MBT-SG.
(a) Ethanol, (b) 1% thiourea in HCl (0.1 mol dm^{-3}), (c) acetone–HCl (9: 1), (d) acetone–HCl (25: 1), (e) HCl (1 mol dm^{-3}), (f) HCl (0.1 mol dm^{-3}).

mercury from the column.

The elution curves with various eluting solutions are shown in Fig. 2, from which about 20 ml of the solvent mixture of acetone and hydrochloric acid, and 20 ml of the 1% thiourea solution in hydrochloric acid seem to be suitable for obtaining quantitative recovery of mercury from the column. The former solvent mixture, however, released not only mercury, but also the chelating reagent from the column to some extent, and became difficult to submit the eluate to the subsequent atomic-absorption spectrometry of mercury because of the interference of the coexisting reagent, which was likely to give a higher value of mercury. On the other hand, the latter solvent could not dissolve the chelating reagent, and no interference occured in the atomic-absorption spectrometry of mercury in the effluent.

Table 4. Release of mercury(II) retained on MBT-SG (Batch Experiment)

Substance	Released/%
HCl (1 mol dm^{-3})	5.4
HCl (6 mol dm^{-3})	12.4
HCl (10 mol dm^{-3})	7.9
HCl (1 mol dm^{-3})+NaCl	23.2
HNO_3 (1 mol dm^{-3})	8.8
HNO_3 (6 mol dm^{-3})	49.6
H_2SO_4 (3 mol dm^{-3})	15.0
Ascorbic acid	6.8
Ethanol	50.7
Acetone–HCl (9: 1)	76.4
Acetone–HCl (25: 1)	75.0
1% thiourea in HCl (0.1 mol dm^{-3})	76.0

Shaking time: 5 min.

Blanks were usually obtained when MBT and thiourea were employed. However, if the column was washed with the thiourea eluting solution by passing it through the column prior to the passage of the sample, a rather higher blank attributable to the MBT reagent was completely eliminated, and the overall blank value reached that caused by thiourea (about 2 ng of mercury).

Reductive Vaporization of Mercury. According to Umezaki *et al.*,[24] both inorganic and organic mercury compounds can be reduced to metal by the use of the tin(II) ion in a 1 mol dm^{-3} sodium hydroxide solution containing a trace amount of the copper(II) ion; also, the mercury can be driven off by the aeration of this solution. In the present study, this treatment was directly applied to the effluent containing a radioactive tracer of mercury, and the mercury thus evolved was introduced into 10 ml of the 1% potassium permanganate solution. After diluting this solution to 25 ml, a 3 ml portion was taken out and its gamma activity was counted. About 93% of the mercury in the effluent vaporized and was absorbed in the permanganate solution. Therefore, the result obtained by this procedure has to be corrected by this factor. On the other hand, when the initial effluent was made up to 1 mol dm^{-3} in a hydrochloric acid solution containing tin(II) chloride, mercury was not vaporized at all.

Table 5. Analysis of sea water

Method	Preconcentration factor	Mercury content ng/l
Direct analysis after MnO_4^- oxidation[a]	—	280±40
The present method[b]	8	280±20

a) Sample: 50 ml. b) Sample: 200 ml.

Analysis of Sea Water for Mercury. The present method was applied to a sea-water sample collected from a very shallow beach near Kanazawa Harbour. The sea water was filtered through cleaned absorbent cotton and analyzed after preconcentration by a factor of eight. The results are given in Table 5, along with those obtained by direct analysis without preconcentration after the permanganate oxidation of the sample. The mercury content is rather high for coastal water, but the two sets of results show a good agreement.

Conclusion

2-Mercaptobenzothiazole-silica gel(MBT-SG) provides an easy means for the preconcentration of mercury(II), methylmercury(I), and ethylmercury(I) prior to the ordinary cold-vapor atomic-absorption spectrometry. The great advantages of this chelating material, in spite of its relatively low chelating capacity, are the ease of preparation and the fast adsorptions of mercury compounds from the water sample. Moreover, mercury retained on MBT-SG can be preserved without any loss or any contamination for one year. The loss of the reagent from the column during the passage of a large volume of sample solution is inappreciably small, so 2—5 l of sea water can be treated with a relatively small column. The mercury ion preconcentrated in this way can be eluted from the column with a small volume of an eluent with a high concentration factor. Furthermore, as mercury compounds in sample water rapidly react with MBT on the column, the time necessary for the preconcentration is considerably shorter than in the other method. By the present method, mercury in concentration range of 2—50 ng can be determined.

The authors wish to thank the Ministry of Education for a Grant-in-Aid (Special Project Research, "Fundamental Research for the Preservation of the Marine Environment," Project No. 111313).

Binuclear Metal Complexes. XXXI.[1] Synthesis and Magnetic Property of Binuclear Manganese(III) Complexes with 3-Salicylideneamino-1-propanol and Its Homologues[2]

Naoyuki TORIHARA, Masahiro MIKURIYA, Hisashi OKAWA,* and Sigeo KIDA
Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashiku, Fukuoka 812
(Received November 19, 1979)

Binuclear manganese(III) complexes with 3-salicylideneamino-1-propanol and its homologues, MnL(ac) and $MnLXH_2O$ (L=Schiff base dianion; ac=acetate ion; $X^-=Cl^-$, Br^-, N_3^-), were synthesized. It was shown that manganese(III) ions were bridged by the deprotonated alcoholic oxygen of the Schiff base in the equatorial plane and coordinated by bidentate acetate ion or X^- and H_2O groups in apical positions to form six-coordination. Cryomagnetic measurements indicated that an antiferromagnetic spin-exchange interaction operates between a pair of manganese(III) ions; exchange integral being evaluated at -13.5——-20.4 cm^{-1}.

Binuclear manganese(III) complexes are of interest in studying spin-exchange interaction of d^4–d^4 system. Recently di-μ-oxo bridged binuclear manganese(III) complexes were found to be a model of photosystem-II in green plant photosynthesis, where manganese functions as a redox catalyst for the oxidation of water to molecular oxygen.[3] In spite of the growing interests in magnetism and in bioinorganic aspect, characterized binuclear manganese(III) complexes with di-μ-oxo bridging system are very few.[4-6]

Zelentsov *et al.*[5] prepared manganese(III) complexes with 2-(salicylideneamino)ethanol and its homologues. The magnetic moments of these complexes are higher at room temperature but lower near liquid nitrogen temperature than the spin-only value. They assumed that the complexes have a di-μ-oxo bridged binuclear structure, in which a ferromagnetic spin-exchange interaction is operating between the metal ions. In general binuclear metal complexes with 2-(salicylideneamino)ethanol markedly differ in magnetic property from those of 3-salicylideneamino-1-propanol. For example, copper(II) complex with 3-salicylideneamino-1-propanol forms a discrete binuclear structure which displays a very strong antiferromagnetic spin-exchange interaction.[7,8] On the other hand, the complex with 2-(salicylideneamino)ethanol shows a normal magnetic moment at room temperature and obeys the Curie-Weiss law with a positive Weiss constant.[7] The latter complex was considered to have a "cubane-type" tetranuclear structure, which has been confirmed for the copper(II) complex with the Schiff base derived from acetylacetone and 2-aminoethanol.[9] Thus, it was aimed in this study to prepare binuclear manganese(III) complexes with 3-salicylideneamino-1-propanol and its homologues and to investigate their magnetic property in comparison with the complexes obtained by Zelentsov *et al.*

The ligands used in this study are Schiff bases obtained by condensing salicylaldehyde, *o*-vaniline, 5-bromosalicylaldehyde, or 2-hydroxy-1-naphthaldehyde with 3-amino-1-propanol. They are abbreviated as H_2spa, H_2vpa, H_2brspa, and H_2npa respectively. Two types of binuclear complexes, MnL(ac) and $MnLXH_2O$ (H_2L=Schiff base; $X^-=Cl^-$, Br^-, N_3^-), were synthesized in this study. Mononuclear complexes, $Mn(Hspa)_2ClO_4$ and $Mn(Hspa)_2NCS$, were also prepared.

Experimental

Syntheses. *$Mn(Hspa)_2ClO_4$*: A solution of salicylaldehyde (2.4 g), 3-amino-1-propanol (1.5 g) and manganese(II) perchlorate hexahydrate (14.4 g) in methanol (300 ml) were refluxed for 2 h. A deep black-green solution thus obtained was slowly concentrated at a temperature below 20 °C to give black prisms. They were collected by suction and dried under reduced pressure.

Found: C, 46.87; H, 4.67; N, 5.49%. Calcd for $C_{20}H_{24}N_2O_8ClMn$: C, 47.02; H, 4.74; N, 5.48%.

$Mn(Hspa)_2NCS$: $Mn(Hspa)_2ClO_4$ (1.0 g) was dissolved in methanol (50 ml) and to this solution was added NaNCS (0.8 g). The mixture was refluxed for 30 min, filtered while hot and allowed to stand over night. Black prisms which separated were collected and dried under reduced pressure.

Found: C, 53.53; H, 5.11; N, 9.01%. Calcd for $C_{21}H_{24}N_3O_4SMn$: C, 53.73; H, 5.15; N, 8.95%.

Mn(spa)(ac). To a solution of salicylaldehyde (2.4 g) and 3-amino-1-propanol (1.5 g) in methanol (300 ml) was added manganese(II) acetate tetrahydrate (9.8 g) to give a deep green solution. After refluxing for 5 h, the volume of the solution was concentrated to *ca.* 30 ml at a temperature lower than 20 °C to give black-green prisms. They were collected and recrystallized from methanol.

Found: C, 49.06; H, 4.79; N, 4.72%. Calcd for $C_{12}H_{14}NO_4Mn$: C, 49.50; H, 4.85; N, 4.81%.

Mn(vpa)(ac). This complex was obtained as black-green prisms in the same way as that of Mn(spa)(ac) except for using *o*-vaniline instead of salicylaldehyde.

Found: C, 48.67; H, 5.03; N, 4.20%. Calcd for $C_{13}H_{16}NO_5Mn$: C, 48.61; H, 5.02; N, 4.36%.

Mn(brspa)(ac)·MeOH. This complex was obtained as green prisms in the same way as that of Mn (spa) (ac) except for using 5-bromosalicylaldehyde instead of salicylaldehyde.

Found: C, 38.79; H, 4.25; N, 3.50%. Calcd for $C_{13}H_{17}NO_5BrMn$: C, 38.83; H, 4.26; N, 3.48%.

Mn(npa)(ac)·MeOH. This complex was obtained as black prisms by reacting 2-hydroxy-1-naphthaldehyde, 3-amino-1-propanol and manganese(II) acetate tetrahydrate in methanol.

Found: C, 54.72; H, 5.15; N, 3.77%. Calcd for $C_{17}H_{20}NO_5Mn$: C, 54.70; H, 5.13; N, 3.75%.

$Mn(spa)ClH_2O$. A solution of salicylaldehyde (2.4 g), 3-amino-1-propanol (1.5 g) and manganese(II) perchlorate hexahydrate (14.4 g) in methanol (300 ml) was refluxed for 2 h. To a black-green solution thus obtained was added sodium hydroxide (1.6 g) and the mixture was stirred for 5 d

to give reddish black solution. When the solvent was evaporated, there remained an oily substance. It was dissolved in methanol (50 ml) to which lithium chloride (4.2 g) was added. The mixture was stirred under reflux for 30 min and filtered. The filtrate was allowed to stand over night to give deep green crystals, which were collected by suction and dried under reduced pressure.

Found: C, 41.96; H, 4.60; N, 4.90%. Calcd for $C_{10}H_{13}NO_3ClMn$: C, 42.05; H, 4.59; N, 4.90%.

Mn(spa)BrH$_2$O. This complex was obtained as deep green prisms in the same way as that of Mn(spa)ClH$_2$O except for using sodium bromide instead of lithium chloride.

Found: C, 36.10; H, 3.94; N, 4.31%. Calcd for $C_{10}H_{13}N_4O_3Mn$: C, 36.39; H, 3.97; N, 4.24%.

Mn(spa)N$_3$H$_2$O. This complex was obtained as deep green crystals in the same way as that of Mn(spa)ClH$_2$O except for using sodium azide instead of lithium chloride.

Found: C, 41.30; H, 4.49; N, 19.03%. Calcd for $C_{10}H_{13}N_4O_3Mn$: C, 41.11; H, 4.48; N, 19.18%.

Measurements. Infrared spectra of the complexes were measured with a Hitachi infrared spectrophotometer Model 215 on a KBr disk and a nujol mull. Electronic spectra were measured with a Shimadzu multipurpose spectrophotometer Model MSP-5000 by a reflection on a powder sample. Magnetic susceptibilities were measured by Faraday method in a temperature range from liquid nitrogen temperature to room temperature. Magnetic moments were calcualted by the expression, $\mu_{eff}=2.828\sqrt{\chi_A \times T}$, where χ_A is the magnetic susceptibility per one manganese ion corrected for diamagnetism using Pascal's constants.

Results and Discussion

In general manganese(II) complexes with Schiff bases are air-sensitive and easily oxidized to manganese(III) complexes by molecular oxygen. All complexes obtained in this study must be manganese(III) complexes judging from their elemental analyses and deep color.

Infrared spectrum of mononuclear Mn(Hspa)$_2$ClO$_4$ shows a strong band around 3400 cm^{-1}, which is attributed to the non-coordinated alcoholic OH group. This fact implies that Hspa$^-$ acts as a bidentate ligand. The Cl–O stretching frequency of perchlorate ion splits into three (1130, 1080, and 1040 cm^{-1}). This suggests that the perchlorate ion coordinates to manganese(III) ion as a bidentate ligand, because the splitting is quite similar to that (1130, 1093, and 1058 cm^{-1}) of blue form of Ni(en)$_2$(ClO$_4$)$_2$ in which perchlorate ion functions as a bidentate ligand.[10] On the other hand, two OH-stretching bands were found for Mn(Hspa)$_2$NCS at 3500 and 3250 cm^{-1}. It is likely that one Hspa$^-$ acts as a bidentate ligand and the other as a tridentate ligand. The C–N and C–S stretching bands of NCS$^-$ ion were observed at 2070 and 810 cm^{-1}, respectively, indicating the donation of NCS$^-$ ion to the metal at the nitrogen atom.[11] Thus, the infrared spectra and the compositions of the mononuclear complexes indicate that they possess structures of six-coordination.

Electronic spectrum of Mn(Hspa)$_2$ClO$_4$ shows bands at 15600 and 20600 cm^{-1}. The spectrum of Mn(Hspa)$_2$NCS shows bands at 12500, 15600, 20800, and 22200 cm^{-1}. The bands in the region 12000—16000 cm^{-1} are assigned to the d-d transitions. Although the correct intensities of the bands in the region 20000—23000 cm^{-1} are not known from reflectance spectrum, they are much weaker than the intra-ligand band near 28000 cm^{-1}. In addition to this, many manganese(III) complexes show d-d bands whose frequencies are higher than 20000 cm^{-1}. Thus, we tentatively assigned the bands in the region 20000—23000 cm^{-1} to d-d transitions. Since manganese(III) ion under O_h symmetry should show only one spin-allowed d-d band, it is likely that the geometry around the metal is much distorted from regular octahedron. Magnetic moments of Mn(Hspa)$_2$ClO$_4$ and Mn(Hspa)$_2$NCS at room temperature are 4.88 and 4.82 BM respectively, which are quite common for high-spin manganese(III) complexes.

Infrared spectra of the binuclear complexes do not show OH-stretching band of the alcoholic group. For the binuclear complexes with 3-salicylideneamino-1-propanol, alcoholic oxygen-bridged and phenolic oxygen-bridged binuclear structures are known.[12] The phenolic oxygen-bridged structure can be characterized by a skeletal band near 1550 cm^{-1},[12] which is higher in frequency than that of its related mononuclear complex. Although the skeletal band of MnL(ac) is concealed from a strong C–O band of carboxyl group, the band of MnLXH$_2$O is well resolved and observed at 1550 cm^{-1}. This frequency is almost the same as that of mononuclear Mn(Hspa)$_2$ClO$_4$ and Mn(Hspa)$_2$NCS. Thus, we may conclude that the complexes possess the  skeleton bridged by the alcoholic oxygen. This is compatible with the result of Miners and Sinn that the alcoholic oxygen-bridged binuclear structure is prefered to the phenolic oxygen-bridged structure when the complex is formed in alkaline media.[12]

The antisymmetric and the symmetric C–O stretching bands of acetate group in MnL(ac) were found at 1550 and 1400 cm^{-1} respectively. In general the antisymmetric and the symmetric C–O stretching bands of carboxylate ion coordinated to a metal as a unidentate ligand shifts to higher and to lower frequencies respectively, as the metal–O bond becomes strong.[13] On the other hand, both of the carbonyl bands shift in the same direction with a change of the metal–O bonding, when the carboxylate ion bridges metal ions.[13] The carboxyl bands of the present complexes seem to belong to the class of the latter type of bonding. Therefore, it is assumed that the acetate group in MnL(ac) functions as a bridge. Coordination of water molecule and azide ion to the metal for Mn(spa)N$_3$H$_2$O was confirmed by IR bands at 3250 and 2050 cm^{-1}. Coordination of chloride and bromide ions is supposed for Mn(spa)ClH$_2$O and Mn(spa)BrH$_2$O by the analogy of the above case. Based on these facts we assumed that two types of the binuclear complexes possess the structures given in Fig. 1.

Reflectance spectra of binuclear complexes of MnL(ac) and MnLXH$_2$O are similar to each other in that they have four absorption bands in the visible region. These bands are tentatively assigned to d-d

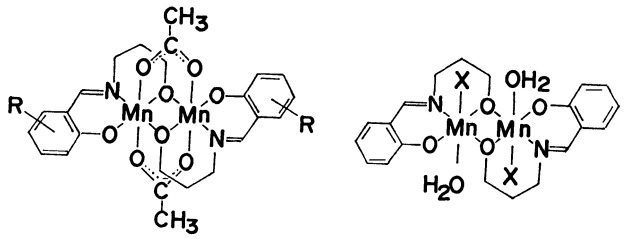

Fig. 1. Possible structures of binuclear complexes.

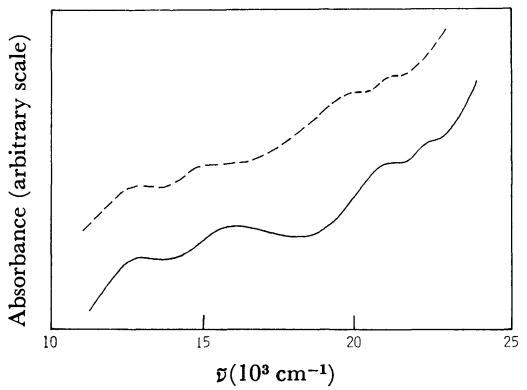

Fig. 2. Reflectance spectra of (——) Mn(spa)(ac) and (-----) Mn(spa)ClH_2O.

Table 1. Magnetic parameters of complexes

	J/cm^{-1}	g
Mn(spa)(ac)	−19.1	1.99
Mn(vpa)(ac)	−20.4	2.00
Mn(brspa)(ac)·MeOH	−13.5	1.99
Mn(npa)(ac)·MeOH	−18.9	1.99
Mn(spa)ClH_2O	−16.0	2.00
Mn(spa)BrH_2O	−16.8	2.00
Mn(spa)N_3H_2O	−14.4	2.00

transitions. Typical examples of electronic spectra are shown in Fig. 2. It is likely that the coordination geometry of the complexes is distorted from regular octahedron so that the ^5E_g and the $^5T_{2g}$ states of an octahedral manganese(III) ion split into five orbitally singlet states.

Effective magnetic moments of MnL(ac) and $MnLXH_2O$ at room temperature fall in the range 3.84—4.22 BM, which are lower than the moments (4.8—5.0 BM) found for most high-spin manganese(III) complexes. The operation of antiferromagnetic spin-exchange interaction between a pair of manganese(III) ions appears to be the main reason for the subnormal magnetic moments. Cryomagnetic measurements have shown that the magnetic susceptibility of the complexes has a maximum around 100 K. These magnetic behaviors can be well interpreted in terms of the magnetic susceptibility expression for the high-spin d^4–d^4 system based on the isotropic spin-exchange model ($\mathcal{H}=-2J\sum\hat{s}_i\hat{s}_j-g\beta s_z'H$, total spin s_z' being calculated by Kambe's approach),

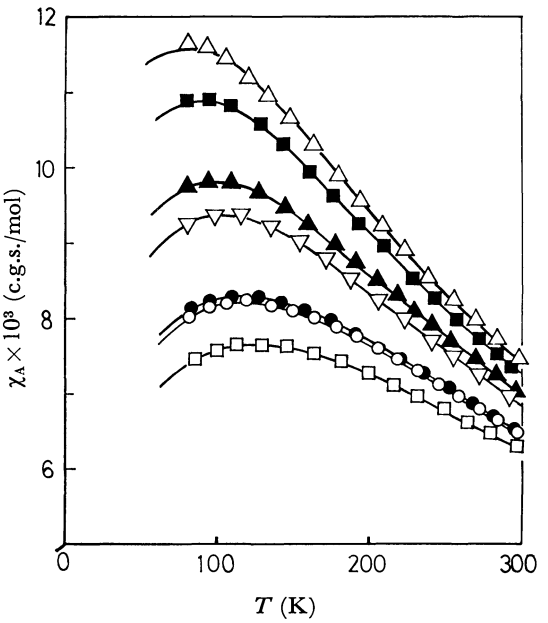

Fig. 3. Temperature variations of magnetic susceptibilities. (○) Mn(spa)(ac), (□) Mn(vpa)(ac), (△) Mn(brspa)(ac)·MeOH, (●) Mn(npa)(ac)·MeOH, (▲) Mn(spa)ClH_2O, (▽) Mn(spa)BrH_2O, and (■) Mn(spa)N_3H_2O.

where J is the exchange integral and other symbols have their usual meanings. Good agreements between the experimental and the theoretical susceptibilities are shown in Fig. 3. Magnetic parameters, g and J, determined from the best-fit technique, assuming $N\alpha$ at zero, are given in Table 1. Thus, it may be concluded that the manganese(III) complexes with 3-salicylideneamino-1-propanol and its homologues possess a discrete binuclear structure in which an appreciably strong antiferromagnetic spin-exchange interaction is operating between the metal ions.

In contrast to the above, the magnetisms of manganese(III) complexes with 2-(salicylideneamino)-ethanol and its homologues are quite strange. According to Zelentsov *et al.*,[5] the complexes consist of binuclear units and their magnetisms can be interpreted in terms of intramolecular ferromagnetic spin-exchange interaction (J=20—30 cm^{-1}) and a large zero-field splitting (*ca.* 8 cm^{-1}). However, the presence of such a large zero-field splitting is unlikely, since magnetisms of most mononuclear manganese(III) complexes obey the Curie-Weiss law with a small Weiss constant (θ= 0——25K).[14] When we plotted the inverse magnetic susceptibilities measured by Zelentsov *et al.* against the temperature, nearly straight lines were drawn in the temperature range 80—300K and the Weiss constants were estimated at −40——−120K. Very large negative Weiss constants can most naturally be explained in terms of a predominantly operating antiferromagnetic spin-exchange interaction in the molecule.

$$\chi_A=\frac{Ng^2\beta^2}{kT}\times\frac{30+14\exp(-8J/kT)+5\exp(-14J/kT)+\exp(-18J/kT)}{9+7\exp(-8J/kT)+5\exp(-14J/kT)+3\exp(-18J/kT)+\exp(-20J/kT)}+N\alpha,$$

Thermal Square Planar-to-Octahedral Transformation of Nickel(II) Complexes Containing 2-Aminobenzimidazole in the Solid Phase[1)]

Yoshinori IHARA* and Ryokichi TSUCHIYA†

Laboratory of Chemistry, Faculty of Education, Kanazawa University, Kanazawa 920
†*Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920*

(Received November 30, 1979)

Thermal reactions of the complexes, $[Ni(abi)_4]X_2 \cdot nH_2O$ (abi, 2-aminobenzimidazole; X, Cl, Br, I, NO_3, ClO_4, or $1/2SO_4$; *n*, 3 for chloride and bromide, 1 for nitrate, and 0 for others) were investigated. Distinct color changes from orange to green were observed in the three complexes of chloride, bromide, and nitrate upon heating. It was found from the changes in absorption and far-IR spectra and magnetic susceptibilities under the thermal reactions that the complexes undergo transformation from square planar to tetragonally distorted octahedral structures, involving an increase in the coordination number from four to six. No such transformation could be found in the corresponding iodide, perchlorate, and sulfate. The effect of the introduced amino group on the structural conversion reactions of the abi complexes is discussed as compared with the corresponding benzimidazole complexes, $[Ni(bimd)_4]X_2$, which underwent transformation from square planar to octahedral structure upon heating when X is I or NO_3.[2)]

Nickel(II) ion forms complexes of various structures, *e.g.*, octahedral, tetrahedral, and square planar structures, depending on the ligand, mutual transformation often occurring among them.[3)] Few studies in the solid phase, however, are known.

Tsuchiya *et al.* reported the structural transformation of $[Ni(H_2O)_2(NN\text{-deen})_2]X_2$, where *NN*-deen is *N,N*-diethylethylenediamine and X halide ion.[4)] The chloride, upon heating, evolved two moles of coordinated water accompanied by anation of chloride ions with retention of the original octahedral structure, whereas the bromide underwent transformation from octahedral to square planar structure without anation of bromide ions after the liberation of water molecules. In addition to nickel(II) complexes containing *N*-substituted diamine, the thermal behavior of the complexes with the *C*-substituted diamines, 2-methyl-1,2-propanediamine and 1,2-diphenylethylenediamine, has been studied in the solid phase by Farago *et al.*[5)] and Lifschitz *et al.*,[6)] respectively. Transformation from octahedral to square planar structure was also observed in these complexes. The studies deal with the structural transformation of nickel(II) complexes containing diamine derivatives, accompanied by the change of the coordination number from six to four, upon heating in the solid phase.

Interesting thermal, mutual transformations have been reported as regards spectral measurements. The structure of bis(*N,N*-diethylethylenediamine)copper(II) tetrafluoroborate, perchlorate, and nitrate turns to square planar with fall in temperature, and to octahedral with rise in temperature.[7)] Tsuchiya *et al.* found a new transformation from square planar to octahedral structure in the benzimidazole complexes, $[Ni(bimd)_4](NO_3)_2 \cdot 2.5C_2H_5OH$ and $[Ni(bimd)_4]I_2$, in the solid phase.[2)] The study is characterized by the reactions involving the increase in the coordination number from four to six upon heating, and by the use of imine derivatives as the ligand which acts as a unidentate one.

The present study was undertaken to prepare the square planar nickel(II) complexes containing 2-aminobenzimidazole, and to investigate their thermal transformation into octahedral structure in the solid phase, and the effect of the amino group introduced to benzimidazole on the thermal reactions.

Experimental

Preparation. The ligand, 2-aminobenzimidazole, and the nickel (II) complexes were prepared by the methods reported,[8,9)] their chemical formulas being identified by elemental analyses and spectral measurements.

Thermal Analysis. TG and DSC measurements were carried out with a Rigaku Denki standard TG-DSC apparatus. All the measurements were carried out under constant flow of nitrogen at a heating rate 1.25 °C min^{-1}.

Isothermal Measurements. The green products were obtained by isothermal heating using the electrical furnace in static air.

Spectral Measurements. The electronic spectra in the solid state were measured by a diffuse reflectance method with a Hitachi EPU-2A spectrophotometer equipped with a standard Hitachi reflection attachment (Type R-3). The far-IR spectra were measured by the Nujol method with a JASCO IR-F far-infrared spectrophotometer.

Measurements of Magnetic Susceptibilities. The effective magnetic moments were evaluated from the magnetic susceptibilities measured by the Gouy method at room temperature. $Hg[Co(NCS)_4]$ was employed as a reference material. The susceptibilities of the complexes were corrected by using Pascal's constants for each element or atomic group contained.

Results and Discussion

Thermal Analyses. Since a distinct color change from orange to green was found for the three complexes, chloride, bromide, and nitrate, by the qualitative thermal technique, thermal analyses were carried out by TG-DSC measurements. The results are shown in Figs. 1—3. On the other hand, the iodide, perchlorate, and sulfate complexes decomposed without obvious color change upon heating.

Chloride turns from orange to green at the endothermic peak near 215 °C, at which melting seems to occur (Fig. 1). The exothermic peak near 150 °C seems to be attributable to a slight change in the packing of the crystal, since the changes in color and thermo-

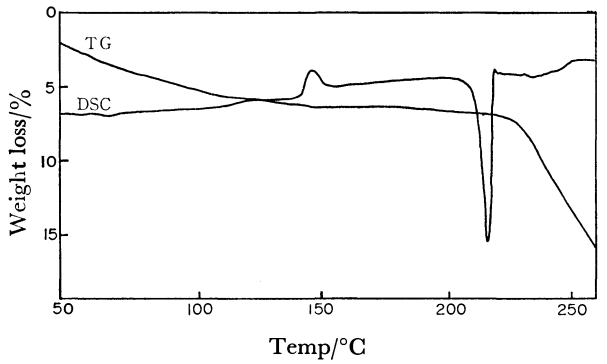

Fig. 1. Thermal analysis of $[Ni(abi)_4]Cl_2 \cdot 3H_2O$.

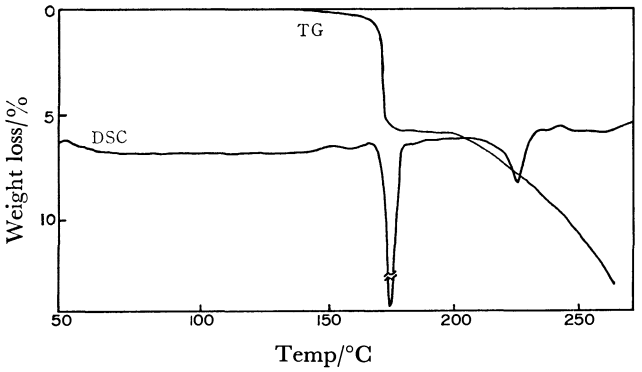

Fig. 2. Thermal analysis of $[Ni(abi)_4]Br_2 \cdot 3H_2O$.

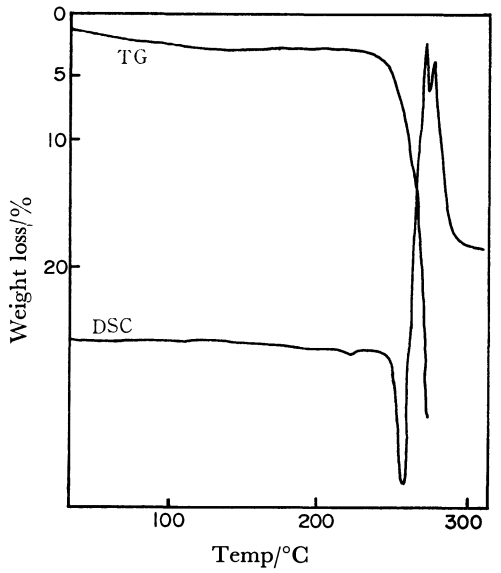

Fig. 3. Thermal analysis of $[Ni(abi)_4](NO_3)_2 \cdot H_2O$.

gravimetric curve are scarcely found in the complex at temperatures lower and higher than that of the peak. Bromide was converted into green completely at 175 °C, accompanied by the liberation of three moles of lattice water, decomposing gradually (TG curve, Fig. 2). For nitrate, no plateau predicting the formation of the stable product was observed (TG curve, Fig. 3), moss-green product being obtained by means of isothermal technique. The endothermic peak involving melting just before the exothermic peak appears with abrupt weight loss near 250 °C seems to indicate simultaneous occurrence of the structural transformation.

The most suitable conditions of isothermal heating for obtaining the products for identification of their structures are as follows: at 200 °C for 2—3 min, at 170 °C for 4—5 min, and at 230 °C for 2—3 min for chloride, bromide, and nitrate, respectively.

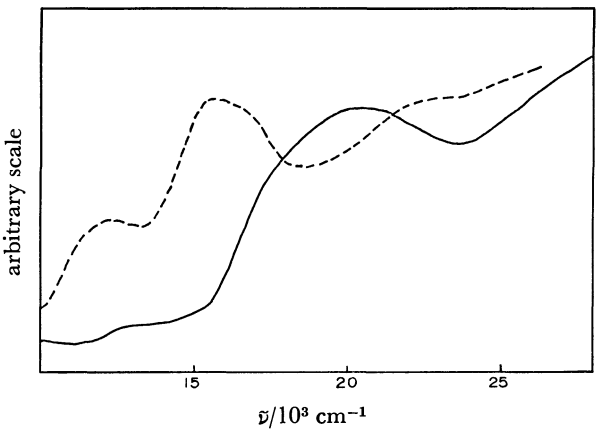

Fig. 4. Electronic spectra of $[Ni(abi)_4]Cl_2 \cdot 3H_2O$ before heating (——) and after heating (– – –).

Electronic Spectra. The electronic spectral change of chloride in the solid phase upon heating is shown in Fig. 4, the spectral data of all the green products being summarized in Table 1, together with the magnetic moments and the analytical data.

The chloride, before heating, has a broad absorption band near 20×10^3 cm^{-1} due to the square planar structure of nickel(II) complexes, and a charge transfer band characteristic to the complexes containing imidazole derivatives (Fig. 4). After heating, the chloride shows three absorption bands in visible region, but they slightly deviate from the general feature of the spectral pattern of octahedral nickel(II) complexes. This is similar to the case of $[Ni(NCS)_2(abi)_4]$ considered to have a tetragonally distorted octahedral structure[9]

Table 1. Electronic spectra data, magnetic moments, and analytical data of the heated products

Products	C(%)		H(%)		N(%)		Absorption Maxima ($\tilde{\nu}/10^3$ cm^{-1})			μ_{eff}(B.M.)
	Found	Calcd	Found	Calcd	Found	Calcd				
$[NiCl_2(abi)_4] \cdot H_2O$	49.48	49.44	4.33	4.45	24.64	24.71	12.5w	16.3	23.1sh	1.98
$[NiBr_2(abi)_4]$	46.55	44.77	3.56	3.76	23.44	22.38	12.5w	16.4	22.5sh	1.56
$[Ni(NO_3)_2(abi)_4] \cdot H_2O$	46.21	45.85	3.79	4.13	26.90	26.74	12.4w	16.5	23.4sh	2.12
$[Ni(NCS)_2(abi)_4]$							13.3w	16.3	22.2sh 26.5	

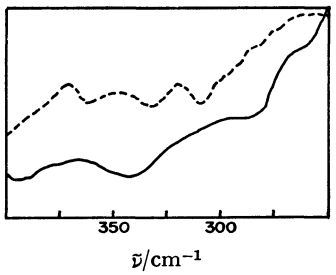

Fig. 5. Far-IR spectra of $[Ni(abi)_4](NO_3)_2 \cdot H_2O$ before heating (——) and after heating (-----).

(Table 1). Some of the octahedral benzimidazole complexes, $[NiX_2(bimd)_4]$, prefer tetragonal distortion.[10] All the products are expected to have the same structure.

Far-IR Spectra. Figure 5 shows the far-IR spectra of nitrate before and after heating. A distinct difference in their spectra lies in the appearance of the peak at 310 cm^{-1} after heating. Ferraro and Walker[11] pointed out that anhydrous metal nitrates, $Cu(NO_3)_2$ and $Co(NO_3)_2$, exhibit a peak in the range 250—350 cm^{-1} assigned to metal-oxygen vibration owing to the coordination of nitrate ion to central metal. The new peak, appearing in the nitrate heated can be ascribed to Ni–O(NO_3) stretching vibration. If so, the nitrate ions situated in the outer sphere before heating approach the central metal making the coordinated bond in the product.

Magnetic Moments. The magnetic moments of the products are given in Table 1. The complexes, showing diamagnetism before heating, are converted into paramagnetic ones upon heating. The values 1.56—2.12 BM are considerably lower than those of the nomal paramagnetic octahedral nickel(II) complexes. However, the values for the tetragonally distorted octahedral structures fall below 2.0 BM.[12] The data of magnetic moments together with the results of the electronic spectra suggest the formation of the tetragonally distorted octahedral complexes by thermal treatment.

Thermochromism of the three complexes, chloride, bromide, and nitrate, from orange to green is considered to result from the structural transformation from square planar to octahedral structures, involving considerably tetragonal distortion. The transformation can be represented by the following scheme.

$$[Ni(abi)_4]X_2 \cdot nH_2O \xrightarrow[\Delta]{-nH_2O} [NiX_2(abi)_4]$$

(X=Cl, Br, NO_3)

The analytical data of the products (Table 1) give no confirmation on the decomposition of 2-aminobenzimidazole in coordination sphere upon heating.

One mol of the lattice water appearing in the products of chloride and nitrate is that adsorbed when the products are placed at room temperature. They give the weight loss corresponding to 1 mol of water when heated again at 50 °C.

Enthalpy Changes. The enthalpy changes and the reaction temperatures of the structural transfer reactions determined by the DSC analyses are given in Table 2. Though all the reactions proceed endothermically, no reversibility of the transfer reactions was observed.

Table 2. Enthalpy changes and reaction temperatures

Starting complexes	ΔH(kJ/mol)	Reaction temp/°C
$[Ni(abi)_4]Cl_2 \cdot 3H_2O$	8.8	215
$[Ni(abi)_4]Br_2 \cdot 3H_2O$	8.8	175
$[Ni(abi)_4](NO_3)_2 \cdot H_2O$	7.1	250

The enthalpy changes seem too small for bromide to be caused by the dehydration of three moles of the lattice water alone. It can be explained in terms of the simultaneous occurrence of the structural transformation presumed to proceed exothermically besides the dehydration reaction. In the case of chloride and nitrate the enthalpy changes can be interpreted to be due to the structural transfer reactions being accompanied by endothermic melting.

Table 3. Possibility of square planar-to-octahedral transformation

X	bimd	abi
Cl	(not prepared)	possible
Br	(not prepared)	possible
I	possible	decomposed
NO_3	possible	possible
ClO_4	decomposed	decomposed
SO_4	(not prepared)	decomposed

Comparison with bimd Complexes. The possibilities of the transformation from square planar structure to octahedral one of bimd and abi complexes by the thermal treatment are summarized in Table 3. One striking difference between bimd and abi complexes is the possibility of formation of the square planar structure in the latter complexes containing chloride or bromide ion. The green octahedral dihalogenotetrakis (benzimidazole) complexes were prepared without appearance of the square planar structure for the chloride or bromide, whereas the complexes containing the iodide or nitrate ion were converted from square planar structure into the octahedral diacido complexes by thermal treatment. The results suggest that the ionic radii of anions in bimd complexes are important in stereochemical requirement for the preparation of the starting complexes and structural transformation, *viz.*, the smaller ion fits to a greater extent the packing of the *trans* sites of the coordination plane surrounded by the four bimd molecules.

The square planar species are formed in abi complexes. This seems to depend on steric hinderance by the amino group introduced and on the higher basicity in the abi ligand surrounding a nickel(II) ion. Another feature of the abi complexes is that thermal structural transformation prefers tetragonal distortion in the products heated than in the bimd complexes.

We wish to thank Mr. Hiroyasu Imai, Department of Pharmaceutical Science, Hokuriku University, for the TG-DSC measurements.

The Extraction of Several Anions by Methyltrioctylammonium into Various Solvents

Yasushi INOUE* and Osamu TOCHIYAMA

Department of Nuclear Engineering, Faculty of Engineering, Tohoku University, Aramaki-aza-aoba, Sendai 980

(Received September 7, 1979)

The back extraction of methyltrioctylammonium chloride (MTOACl) from ten kinds of organic solvents was investigated as a function of the MTOACl concentration. The chemical species of the ammonium salt in the organic phase were found to be in the form of dissociated ions, of ion pairs, or of dimeric ion pairs, according to the dielectric constant of the solvent. MTOACl was better extracted into more polar and acidic solvents, such as nitrobenzene, 3-methyl-1-butanol, and chloroform. The selectivity coefficients ($K_{X/Cl}$) of MTOA for the exchange of Br^-, I^-, ClO_4^-, *vs.* Cl^- were obtained from the study of the distribution of several organic color reagents; they were found to increase with the anion size, irrespective of the organic solvent used. For all but acidic solvents, the values of $K_{X/Cl}$ were similar to each other. Such acidic solvents as 3-methyl-1-butanol and chloroform, however, reduced the selectivity of the extraction for anions.

Quaternary ammonium salts have been extensively used for metal extractions[1] and more recently have received attention as phase transfer catalysts[2] and exchangers for ion-selective electrodes.[3] However, our knowledge of the properties of substituted ammonium salts in solution is too limited to give a general guide for such applications. Knowledge of their property of extracting simple anions is, above all, most important in understanding many related reactions.

In this paper, the extraction of simple anions, such as chloride, bromide, iodide, and perchlorate, by methyltrioctylammonium (MTOA) into various organic solvents was investigated. MTOA was chosen as a representative long-chain alkylammonium because MTOA and closely related tertiary amine, trioctylamine (TOA) have been commonly used in extraction studies. The organic solvents were selected so as to furnish a wide variation in character. The extraction of chloride was first investigated by the analysis of the distribution of MTOACl between two phases to obtain the general idea of the extraction reaction. The extraction of other anions by MTOA was then indirectly studied through the ion-exchange reaction between the ion to be studied and the anions of several organic reagents, such as thenoyltrifluoroacetone (TTA), tetrabromophenol sulfonephthalein (Bromophenol Blue, BPB), and *p*-nitrophenol (*p*-NP), which coexisted in the system (hereafter, these reagents are referred to as "indicators"). These results were integrated in terms of the selectivity coefficients against chloride and discussed on the basis of various properties of the solvents and anions, as will be described below.

Experimental

Reagents. Methyltrioctylammonium chloride (Capriquat, Dotite reagent) was used as received. The effective concentration of the quaternary ammonium base was determined by acid-base titration in acetic acid.[4] All the other reagents were of a reagent grade and were used without further purification.

Apparatus. A shaker (Takabayashi Rika RL-6) and a centrifuge (Kubota KH-180) were used for the extraction experiment. A pH meter (Tōa Dempa HM-6A) was used for the pH measurements. The absorption spectra were measured with a Hitachi EPS-3 recording spectrophotometer using a quartz cell (1 cm light path).

Procedures. *General Procedure*: Equal volumes (4 cm^3) of an aqueous and an organic solution with the desired compositions were brought into contact in a glass tube and shaken mechanically for 15 min (140 times/min) at room temperature (23±2 °C). If necessary, the phase separation was accelerated by centrifugation. After phase separation, the concentration of the solute of interest was measured by a suitable analytical method. The aqueous phase was used for the pH measurements.

Distribution Ratio of MTOACl: An organic solution containing a definite concentration of MTOACl and an aqueous solution were equilibrated, and the concentration of MTOA in the aqueous phase was determined. The MTOA in the aqueous solution was extracted with BPB into xylene at pH about 11 ($[Na_2CO_3]=0.05$ mol dm^{-3}),[5] then the absorbance of the xylene solution was measured at 607 nm. The concentration of MTOA was calculated from the calibration curve, which obeyed Beer's law over the range from 2.5×10^{-6} to 2.5×10^{-5} mol dm^{-3}. The concentration of MTOA in the organic phase was calculated from the difference between the initial added concentration and the concentration in the aqueous phase after equilibration.

Extraction Exchange Constants: An organic solution containing MTOACl was equilibrated with an aqueous solution containing the desired concentrations of a certain anion (as a sodium salt) and buffer reagents (0.05 mol dm^{-3} of acetic acid, plus a variable concentration of ammonium hydroxide or 0.05 mol dm^{-3} sodium carbonate, depending on the pH of the solution to be studied) in the presence of an indicator which had been added to the organic (TTA) or the aqueous phase (BPB, *p*-NP). When TTA was used as an indicator, the absorption spectrum of TTA in the organic phase was measured to give the ratio of the salt to the acid form of TTA.[6] When BPB or *p*-NP was used as an indicator, the distribution ration was obtained from the measurement of the absorbance of the organic phase (at 600—608 nm for BPB) or the aqueous phase (at 402 nm for *p*-NP).

Results and Discussion

Extraction of MTOACl. Since the extracted ammonium salt may be in the form of dissociated ions, of ion pairs, or of still higher ion associations, the concentration of MTOA in the organic phase can be expressed as:

$$C_{Q,o} = [Q^+]_o + [QCl]_o + 2[Q_2Cl_2]_o + \cdots, \quad (1)$$

assuming that Cl^- is the only anion present. Here, Q^+ denotes the cation of MTOA; square brackets show the concentration of the enclosed species; the subscript o stands for the organic phase; the absence of any subscript indicates the aqueous phase. C is the total (analytical) concentration; in this case, the subscript a stands for the aqueous phase, and the absence of any subscript represents the total of C_0 plus C_a. As the electrical neutrality relation in the organic phase,

$$[Q^+]_o = [Cl^-]_o, \quad (2)$$

holds, Eq. 1 can be transformed into:

$$C_{Q,o} = K_{1/2}([Q^+][Cl^-])^{1/2} + K_1[Q^+][Cl^-] + 2K_2([Q^+][Cl^-])^2 + \cdots, \quad (3)$$

where $K_{1/2}$, K_1, and K_2 are these concentration quotients:

$$K_{1/2} = ([Q^+]_o[Cl^-]_o/[Q^+][Cl^-])^{1/2}, \quad (4)$$

$$K_1 = [QCl]_o/[Q^+][Cl^-], \quad (5)$$

$$K_2 = [Q_2Cl_2]_o/([Q^+][Cl^-])^2. \quad (6)$$

When no excess anions exist in the system, the relation in the aqueous phase:

$$[Q^+] = [Cl^-], \quad (7)$$

also holds and Eq. 3 can be expressed as:

$$C_{Q,o} = K_{1/2}[Q^+] + K_1[Q^+]^2 + 2K_2[Q^+]^4 + \cdots. \quad (8)$$

As it is obvious that

$$C_{Q,a} = [Q^+], \quad (9)$$

the plot of log $C_{Q,o}$ *vs.* log $C_{Q,a}$ will show the slopes according to the predominant species in the organic phase: 1 (dissociated ions), 2 (ion pairs), or 4 (dimers). When a large excess of chloride over Q^+ is present in the system, $[Cl^-]$ in Eq. 3 is considered to be constant and the slopes are 1/2 (dissociated ions), 1 (ion pairs), and 2 (dimers). Figures 1—3 show the results obtained in the back extraction of MTOACl from various organic solvents into water or 0.1 mol dm^{-3} of NaCl. The distribution behavior of MTOACl can be grouped into three classes according to the organic solvents used.

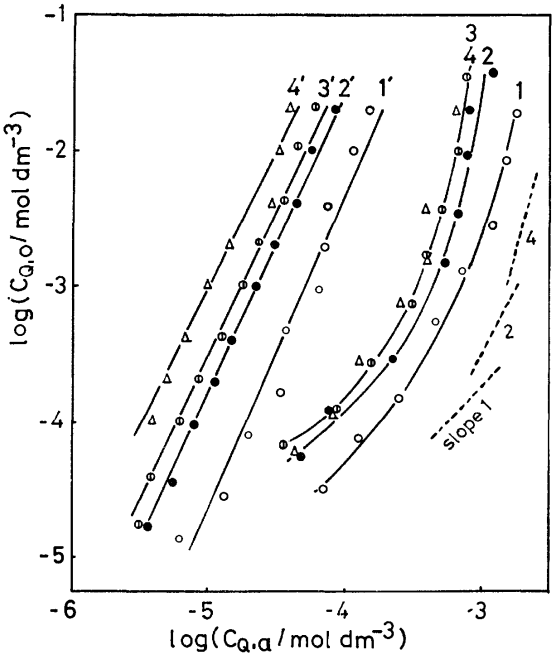

Fig. 1. Extraction of MTOACl (1).
1,1′: Hexane, 2,2′: xylene, 3,3′: carbon tetrachloride, 4,4′: benzene, 1—4: *vs.* water, 1′—4′: *vs.* 0.1 mol dm^{-3} NaCl.

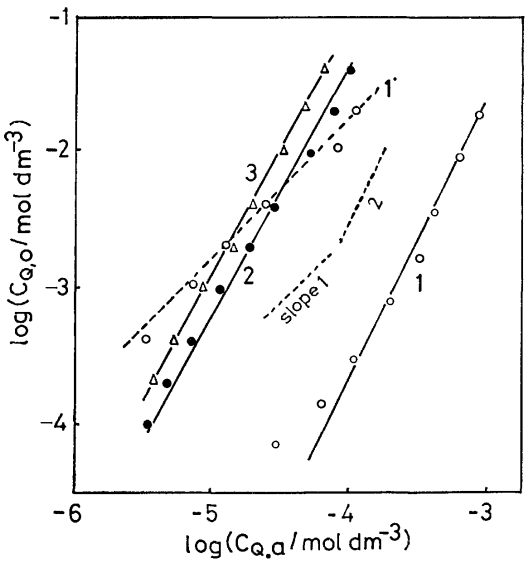

Fig. 2. Extraction of MTOACl (2).
1,1′: Butyl acetate, 2: dichloromethane, 3: chloroform, 1—3: *vs.* water, 1′: *vs.* 0.1 mol dm^{-3} NaCl.

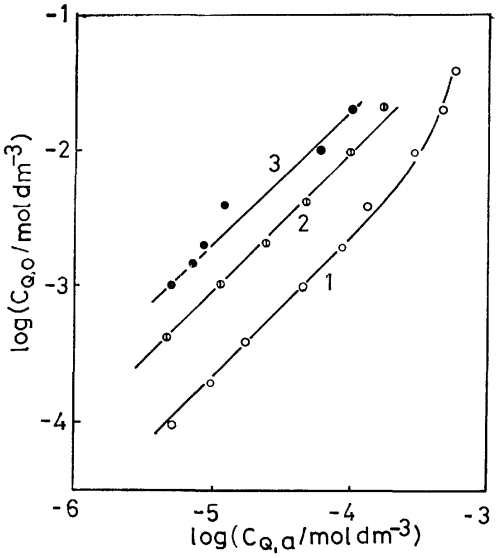

Fig. 3. Extraction of MTOACl (3).
1: 4-Methyl-2-pentanone, 2: nitrobenzene, 3: 3-methyl-1-butanol, 1—3: *vs.* water.

Figure 1 shows the distribution behavior of MTOACl between water or 0.1 mol dm^{-3} NaCl and four so-called "inert solvents." The slope of 2 obtained for 0.1 mol dm^{-3} NaCl and the maximum slope of 4 for water suggest that MTOACl is in the form of dimers in the organic phase. For water, however, the slope of the curves varies from 1 to 4, depending on the C_Q. As the pH of the aqueous phase was found to decrease slightly after the equilibration, species containing hydroxide

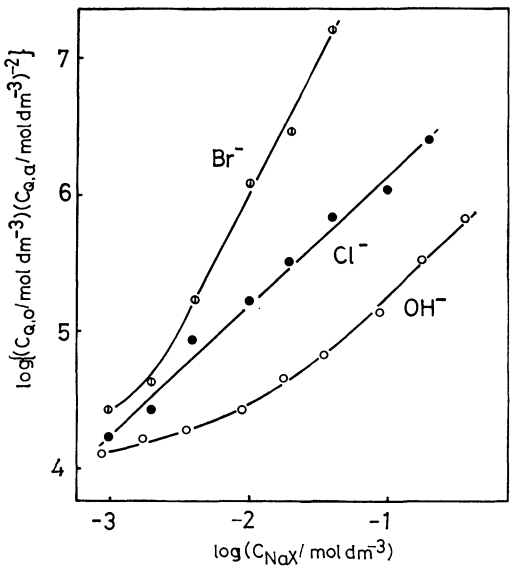

Fig. 4. Effect of anions on the extraction of MTOA into xylene.
$C_Q = 8 \times 10^{-3}$ mol dm^{-3}.

ions may also participate in the extraction of MTOA. If we consider that only dimers are present in the organic phase, it can easily be deduced that the slope of the log $(C_{Q,o}/C_{Q,a}^2)$ *vs.* log [X^-] (X^- denotes anions participating in the extraction) plot will give the mean number of anions in the extracted species. Figure 4 clearly indicates that a mixed dimer such as Q_2ClOH was also extracted along with Q_2Cl_2, while Q_2Br_2 was extracted when a considerable amount of bromide was present. Therefore, the smaller slopes in the lower concentration range of MTOA, shown by Curves 1—4 in Fig. 1, do not mean the extraction of a monomer nor dissociated ions, but the extraction of the mixed dimer. The approximate values of the extraction constants, K_2, were estimated from the data over the concentration range where the slope of Curves 1—4 equals 4, as is shown in Table 1.

Figure 2 shows the results for three solvents which are considered to have intermediate polarity. The slopes of 2 and 1 for the curves obtained for water and for 0.1 mol dm^{-3} NaCl (for butyl acetate) respectively indicate the existence of ion pairs over the concentration range studied. For butyl acetate, however, the contribution of hydroxide ions may not be neglected in the lower concentration range of MTOA.

Figure 3 shows the results for highly polar solvents, such as 4-methyl-2-pentanone, nitrobenzene, and 3-methyl-1-butanol. The slope of 1 observed for these solvents suggests the dissociation of ion pairs, except for 4-methyl-2-pentanone in the higher concentration range of MTOA, where some degree of ion-pair formation is considered to occur since the plots deviate upward from the straight line.

Table 1 summarizes the results of the extraction of MTOACl. To compare the extractability of organic solvents for MTOACl, the logarithms of the distribution ratios of MTOA, log D_Q=log $(C_{Q,o}/C_{Q,a})$, at $C_Q = 2 \times 10^{-3}$ mol dm^{-3} are also given. The general features of the extraction of MTOACl are quite similar to those of hydrohalic acids by tridodecylamine (TDA), as investigated by Müller and Diamond.[8] The dielectric constant of the organic solvents directly affects the degree of association or dissociation of ion pairs. In the extraction of TDAHX (X^-=Cl^-, Br^-, I^-, SCN^-), the presence of ion pairs (in chloroform), ion pairs and higher ion aggregates (in benzene, carbon tetrachloride, and cyclohexane), and ion pairs and free ions (in nitrobenzene) have been reported. In the extraction of MTOACl, however, the existence of only one chemical form for one solvent was verified under the experimental conditions adopted; dimers alone in benzene, carbon tetrachloride and hexane, ion pairs in chloroform, and free ions alone in nitrobenzene. The difference in the results for nitrobenzene between TDAHX and MTOACl may be attributable to the presence of the hydrogen bond in the ion pairs. The dielectric constant of the solvents plays an important role also in determining the extractability; polar solvents are favorable for the

Table 1. Extraction constants of MTOA chloride

Species in organic phase and solvent	ε[a]	AN[b]	Extraction constant	log D_Q[d]
Q_2Cl_2 (or Q_2ClOH)			log (K_2 mol^3 dm^{-9})	
Hexane	1.89	0	8.9	0.2
Xylene	2.37	—	10.1	0.5
Carbon tetrachloride	2.24	8.6	10.5	0.6
Benzene	2.28	8.2	10.6	0.6
QCl			log (K_1 mol dm^{-3})	
Butyl acetate	5.01	—	4.35	0.79
Dichloromethane	9.08	20.4	6.76	2.03
Chloroform	4.81	23.1	7.07	2.18
$Q^+ + Cl^-$			log $K_{1/2}$	
4-Methyl-2-pentanone	13.11	—	1.32	1.32
Nitrobenzene	34.82*	14.8	1.97	1.97
3-Methyl-1-butanol	14.7*	(33.5)[c]	2.30	2.30

a) Relative dielectric constant at 20 °C or 25 °C (marked by *) from Ref. 7. b) Acceptor number from Ref. 9; for water, AN=54.8. c) Value for 2-propanol. d) At $C_Q = 2 \times 10^{-3}$ mol dm^{-3}.

extraction of MTOACl and TDAHX. Furthermore, it is certain that the acidic properties of the solvents influence the extraction, as evidenced by the correlation between the extraction constants and the acceptor numbers which have been introduced by Gutmann[9] as a measure of the acidity of electrophilic solvents. As a whole, MTOACl is better extracted by the more polar and acidic (as a Lewis acid) solvents.

Ion-exchange Selectivity of MTOA. As has been discussed above, the extraction of MTOACl shows complex features depending upon the solvents and upon the concentrations of MTOA and anions. In order to compare the extraction of various anions by MTOA, therefore, it is preferable to apply a method which can simplify both the experimental and theoretical treatments. For this purpose, we have studied the exchange property of MTOA for several anions. If we assume that the concentration of exchangeable counter anions in the organic phase governs the equilibrium,[10] the exchange reaction may be described as follows:

$$(\cdots Y^{m-})_o + mX^- = m(\cdots X^-)_o + Y^{m-}, \quad (10)$$

where Y denotes the anion with the charge m and where $(\cdots Y^{m-})_o$ and $(\cdots X^-)_o$ indicate the exchangeable anions in the organic phase; *i.e.*,

$$[\cdots X^-]_o = C_{X,o}, \quad (11)$$

$$[\cdots Y^{m-}]_o = C_{Y,o}, \quad (12)$$

when the charge of these anions balances with that of MTOA cations in the organic phase. The constant for the exchange reaction (10) is defined as:

$$(K_{X/Y})^m = (C_{X,o})^m[Y^{m-}]/C_{Y,o}[X^-]^m. \quad (13)$$

When $m=1$, Eq. 13 can be written as follows according to the predominant species of MTOA salt in the organic phase:

(*i*) For free ions,

$$K_{X/Y} = [X^-]_o[Y^-]/[Y^-]_o[X^-], \quad (14)$$

(*ii*) for monomers,

$$K_{X/Y} = [QX]_o[Y^-]/[QY]_o[X^-], \quad (15)$$

(*iii*) and for dimers,

$$K_{X/Y} = \frac{(2[Q_2X_2]_o+[Q_2XY]_o)[Y^-]}{(2[Q_2Y_2]_o+[Q_2XY]_o)[X^-]}, \quad (16)$$

In the case of (*i*) or (*ii*), it can be easily seen that $K_{X/Y}$ gives a constant value. On the other hand, in the case of dimers, it is doubtful if the right-hand side of Eq. 16 gives a constant value. It is clear that the combination of the extraction constant for pure dimers,

$$K_{2,X} = [Q_2X_2]_o/([Q^+][X^-])^2, \quad (6')$$

$$K_{2,Y} = [Q_2Y_2]_o/([Q^+][Y^-])^2, \quad (6'')$$

leads to the following relationship:

$$K_{2,X}/K_{2,Y} = [Q_2X_2]_o[Y^-]^2/[Q_2Y_2]_o[X^-]^2. \quad (17)$$

The assumption made for Eq. 10 means that the two exchange sites in dimers do not interact with each other; in other words, the dimerization from QX and QY to Q_2X_2, Q_2Y_2, or Q_2XY occurs statistically. Therefore, the concentration of each species in the organic phase can be described as:

$$[Q_2X_2]_o = (C_{X,o})^2/2(C_{X,o}+C_{Y,o}) = (C_{X,o})^2/2C_{Q,o}, \quad (18)$$

$$[Q_2XY]_o = C_{X,o}C_{Y,o}/(C_{X,o}+C_{Y,o}) = C_{X,o}C_{Y,o}/C_{Q,o}, \quad (19)$$

$$[Q_2Y_2]_o = (C_{Y,o})^2/2(C_{X,o}+C_{Y,o}) = (C_{Y,o})^2/2C_{Q,o}. \quad (20)$$

The substitution of these equations into Eq. 17 gives the relationship as:

$$K_{2,X}/K_{2,Y} = (C_{X,o})^2[Y^-]^2/(C_{Y,o})^2[X^-]^2 = (K_{X/Y})^2. \quad (21)$$

Therefore, we can now understand that Eq. 16 gives a constant value, which may in turn be written as:

$$K_{X/Y} = [Q_2XY]_o[Y^-]/[Q_2Y_2]_o[X^-] = [Q_2X_2]_o[Y^-]/[Q_2XY]_o[X^-]. \quad (22)$$

Hence, we can conclude that Eq. 13 holds regardless of the form of the predominant species in the organic phase if the dimer formation occurs statistically. Furthermore, Eq. 13 can be applied when monomers coexist with dimers. When free ions and monomers coexist, however, Eq. 13 no longer holds as long as QX and QY differ in the dissociation constant in the organic phase. The assumption made here was warranted by the fact that Eq. 13 could be successfully applied to the experimental results, as will be described later. Therefore, we can simply compare the extraction of various anions by MTOA under the notion of the exchange reaction, Eq. 10, except when free ions coexist with monomers.

From Eq. 13, the distribution ratio of Y can be represented as follows:

$$D_Y = C_{Y,o}/[Y^{m-}] = (1/K_{X/Y})^m(C_{X,o}/[X^-])^m. \quad (23)$$

When D_Y is obtained for an indicator Y, $C_{X,o}$, and $[X^-]$ can be calculated from the respective initial concentrations as follows:

$$C_Y = C_{Y,o} + [Y^{m-}], \quad (24)$$

$$C_Q = mC_{Y,o} + C_{X,o} = mC_Y(1+1/D_Y)^{-1} + C_{X,o}, \quad (25)$$

$$C_X = C_{X,o} + [X^-]. \quad (26)$$

Then the exchange constant of X against Y can be obtained from the plot of log D_Y *vs.* log $C_{X,o}/[X^-]$. When TTA is used as an indicator, the constant, $K'_{X/T}$ was obtained from the next relationships:

$$K'_{X/T} = ([HT]_o/[\cdots T^-]_o)(C_{X,o}/[H^+][X^-]), \quad (13')$$

$$D'_T = [\cdots T^-]_o/[HT]_o = (1/K'_{X/T})(C_{X,o}/[H^+][X^-]), \quad (23')$$

$$C_T = [\cdots T^-]_o + [HT]_o + [T^-], \quad (24')$$

$$C_Q = [\cdots T^-]_o + C_{X,o}, \quad (25')$$

$$C_X = C_{X,o} + [X^-]. \quad (26)$$

The distribution ratios of BPB or *p*-NP, or the ratios of the salt to the acid form of TTA in the organic phase, were measured at various concentrations of NaX or at various pH values. From the experimental plots thus obtained, some of which are shown in Figs. 5—7, the exchange constants were estimated to be as is shown in Tables 2—4. HT, H_2B, and HR denote the acid forms of TTA, BPB, and *p*-NP respectively. The straight lines obtained by the method of least squares have the slopes to be expected from the number of acidic hydrogen in the indicators, that is, close to 1 for the TTA and *p*-NP systems and 2 for the BPB system. In some exceptional cases, however, the slopes deviate somewhat from

C_Q=10^{-4} mol dm^{-3}, C_R=5×10^{-5} mol dm^{-3}.

these values; the reason for this is not clear, but the difference in the degree of dissociation of ion pairs, or the extraction of some other species, such as QHB, QNaB, and QHR_2, may be considered to be responsible. As long as the slopes are similar for a certain pair of anions, however, it is possible for us to obtain the selectivity coefficient for the pair because the method adopted is based on the comparison of the concentrations of anions which give D_Y (or D'_T)=1 for the distribution of the indicator. The standard deviations for the values of the exchange constants in Tables 2—4 were around 0.06. They amounted to about 0.1 for exceptional cases where the experimental conditions were such that it was difficult to obtain the data with a satisfactory accuracy. From Tables 2—4, the logarithm of the selectivity coefficient for X_1 *vs.* X_2 can be estimated by means of the following equation:

TABLE 2. EXCHANGE CONSTANTS OF MTOA SALT (TTA)[a]

Solvent	log $K'_{X/T}$ (Eq. 13′)					
	Cl	Br	I	ClO_4	NO_3	SCN
Hexane	1.18 (0.9)[b]	2.09 (1.0)	3.90 (1.0)	5.41 (1.1)		
Xylene	1.26 (1.0)	2.49 (1.0)	4.51 (1.0)	6.57 (0.8)	3.25 (1.0)	5.44 (1.0)
	1.30*(1.0)	2.61*(1.0)	4.49*(0.9)		3.25*(0.9)	
Benzene	1.45 (0.8)	2.84 (1.0)	5.03 (1.0)	7.06 (0.9)		
Chloroform	4.22 (1.0)	5.60 (1.0)			5.48 (1.0)	6.84 (1.2)

a) Obtained from data at various C_X values at a constant pH (4—6), except for values marked with *, which were obtained from data at various pH values at a constant C_X (0.01—0.1 mol dm^{-3}), both at C_Q=(5—10)×10^{-5} mol dm^{-3} and C_T=5×10^{-5} mol dm^{-3}. b) Numbers in parentheses indicate the slope, *m*, obtained by the method of least squares.

Table 3. Exchange constants of MTOA salt (BPB)[a]

Solvent	log $K_{X/B}$ (Eq. 13)			
	Cl	Br	I	ClO_4

Table 5. Comparison of selectivity coefficients obtained by different reagents

Solvent	X_1	X_2	log K_{X_1/X_2} (Eq. 27)		
			HT	BPB	*p*-NP
Xylene	ClO_4	I	2.07	1.68	
Benzene	ClO_4	I	2.03	1.64	
Butyl acetate	I	Br		1.77	1.71
Chloroform	Br	Cl	1.38	1.37	
4-Methyl-2-pentanone	Br	Cl		1.48	1.34
	I	Br		1.88	1.91
Nitrobenzene	I	Br		2.20	2.26

$$\log K_{X_1/X_2} = \log K_{X_1/Y} - \log K_{X_2/Y}. \quad (27)$$

As is shown in Table 5, the values obtained through the use of different indicators agreed with each other within the limits of experimental error, except for the cases of log $K_{ClO_4/I}$ in xylene and benzene. These last two disagreements are beyond the limits of experimental errors, and further experiments must be carried out to understand the reason for these disagreements.

The selectivity coefficients of MTOA for the exchange of anions *vs.* Cl^- are summarized in Table 6, as are those of Dowex-1X8—10[11] for purposes of comparison. The table indicates that the values of log $K_{X/Cl}$ increase in the order $Br^-<I^-<ClO_4^-$ and are similar to each other for most of the solvents used in spite of the marked difference in their extraction power and in the chemical species of MTOACl in these solvents.

However, it is interesting to note that the solvent with a higher acceptor number has a lower selectivity for anions; such acidic solvents as 3-methyl-1-butanol and chloroform are inferior in selectivity to other solvents. Because of the specific interaction of alcohols in alkylammonium systems,[12] 3-methyl-1-butanol is a good solvent for the extraction of MTOA salts, but its selectivity for anions is inferior to that of other solvents (about the same degree as solid-ion exchangers). Carbon tetrachloride and chloroform have abnormally small log $K_{ClO_4/I}$ values. One possible explanation is the specific reaction of alkylammonium salt with halo-

Table 6. Summary of selectivity coefficients of MTOA salt[a] and TDAH salt[b]

Solvent	log $K_{X/Cl}$				
	MTOA			TDAH	
	Br	I	ClO_4	Br	I
Hexane	0.91	2.72	4.23		
Cyclohexane				0.96	2.40

a) When values obtained by different reagents disagreed, mathematical means were adopted. b) Calculated from K_{app} in Ref. 8. $K_{app}=C_{TDAH,o}/C_{TDA,o}a_{HX}$ at a total TDAHX concentration of 0.1 mol dm^{-3}. c) Ref. 11.

genated hydrocarbons,[13] for example, the deprotonation of chloroform producing CCl_3^- anions and finally dichlorocarbene in a strongly alkaline solution, which is the important reaction in phase-transfer catalysis.[2]

MTOA salts and trialkylammonium salts, $(alkyl)_3NH^+X^-$, resemble each other in the general features of these selectivity. In Table 6, the selectivity coefficients of tridodecylammonium for the exchange of anions *vs.* Cl^- are also shown; they were estimated from the apparent extraction constant of TDAHX obtained by Müller and Diamond.[8] On the whole, the selectivity of MTOA for anions is higher than that of TDAH; the difference increases with both the polarity of the solvents and the size of the anions. These findings are compatible with the common understanding[1] that the higher substituted alkylammonium have higher selectivities.

In conclusion, a better extraction of MTOA salts can be obtained by the use of polar and acidic solvents; in the case of acidic solvents, however, there should be a low selectivity for anions. Therefore, in the extraction of anionic complexes of metal ions in the presence of a large excess of such acids as HCl and HNO_3, aromatic solvents will meet the requirement of selectivity at the cost of extractability. On the other hand, acidic solvents such as chloroform and alcohols may be used for the extraction of chelate complexes of metal ions from aqueous solutions at the sacrifice of selectivity. Polar, aprotic solvents, such as nitrobenzene and 4-methyl-2-pentanone, are considered to be the best, although they have other disadvantages in practical use.

(Received July 30, 1979)

The Arbuzov reaction of trimethyl and triethyl phosphites with acyl chlorides gave 1-oxoalkylphosphonates in 57—80% yields. The Wittig reaction of the phosphonates with methylenetriphenylphosphorane gave vinylphosphonates in 25—59% yields. Hydroboration of vinylphosphonates in oxolane gave 2-hydroxyethylphosphonates in 50—65% yields. The procedure seems to be a good synthetic method to afford 1-alkyl-substituted 2-hydroxyethylphosphonates which have one more carbon atom than the starting 1-oxoalkylphosphonates.

5,6-Dideoxy-5-*C*-(phenylphosphinyl)-D-glucose derivatives have been synthesized by the development of information on the chemical modification of sugars.[1,2] Methods for preparing a phosphorus–carbon bond on a secondary carbon of the sugar skeleton played a key role. Methods for preparing primary carbon–phosphorus bonds are comparatively simple, the yields being usually high, *e.g.*, Arbuzov and Becker reactions.[3] The present paper deals with the synthesis of 1-oxoalkylphosphonates, Wittig reaction of the 1-oxoalkylphosphonates to make a secondary carbon–phosphorus bonds, and hydroboration of vinylphosphonates to synthesize 2-hydroxyethylphosphonates, which have a partial structure of phosphorus-sugars.

Results and Discussion

1-Oxoalkylphosphonates were synthesized by the reaction of trialkyl phosphites with 1.2 mol equivalent of acyl halides at room temperature for 12 h or at 40—60 °C for 2—3 h.[4]

$$RC(=O)Cl + P(OR')_3 \longrightarrow RC(=O)P(=O)(OR')_2 + R'Cl$$

1a: R=Me, R'=Me

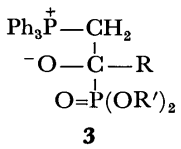
1e: R=Ph, R'=Me
1f: R=Me, R'=Et
1g: R=Et, R'=Et

The Wittig reaction of 1-oxoalkylphosphonates with methylenetriphenylphosphorane to prepare secondary alkylphosphonate derivatives was studied. Treatment of methylenetriphenylphosphonium bromide suspended in anhydrous benzene with sodium amide at room temperature for 15 h followed by filtration gave a solution of methylenetriphenylphosphorane. To this was added compound **1** under ice cooling. After the coloration of ylide had vanished, the temperature was raised to room temperature, stirring being continued for additional 4—5 h. Removal of benzene *in vacuo* gave compound **2**. The yields and boiling points are summarized in Table 1.

$$\underset{\mathbf{1}}{RC(=O)P(=O)(OR')_2} \xrightarrow{Ph_3P=CH_2} \underset{\mathbf{2}}{RC(=CH_2)P(=O)(OR')_2} + Ph_3PO$$



3

The betaine intermediate of the formula **3** should be stabilized when R is an electron-withdrawing substituent (*e.g.*, Ph), and protonated by a 1-oxo-3-phenylpropyl group bearing active methylenes. The successive cleavage process to give olefin and phosphine oxide could be so depressed that the yields of compounds **2d** and **2e** are lowered.[5]

Wittig reactions of ethylidenetriphenylphosphorane with 1-oxoethylphosphonates **1a** and **1f** were carried out under various conditions. The reactions seem to be less effective to produce 1-methyl-1-propenylphosphonates. The Horner type reaction of compound **1a** with diethyl ethylphosphonate in the presence of butyllithium in oxolane gave no expected olefinic product, probably because of abstraction of proton from 1-oxoethylphosphonate by the phosphonate carbanion. Reactions of compounds **1a** and **1f** with ethylidene- and methoxymethylenetriphenylphosphoranes were also

Table 1. Preparation of 1-alkylvinylphosphonates (**2**) *via* Wittig reaction

Compound	R	R'	Yield/%	Bp(°C/mmHg)

unsuccessful. The Wittig reaction of methylenetriphenylphosphorane with 1-oxoalkylphosphonates seems to be a convenient method for preparing 1-alkylvinylphosphonates under mild conditions.

Hydroboration of compound **2f** was carried out according to the method of Brown and his co-workers.[6] To the oxolane solution containing compound **2f** and 20% mole excess of sodium tetrahydroborate was added 20% mole excess of trifluoroborane etherate at 0—5 °C. Coolant was removed after the addition of the etherate. Allowing the reaction mixture to stand for 2 h followed by oxidation with hydrogen peroxide, work-up, and distillation gave 22% yield of diethyl 2-hydroxy-1-methylethylphosphonate (**4f**) and 50% of unreacted **2f**.

When 2.4 fold excess amount of sodium tetrahydroborate and trifluoroborane etherate were used, consumption of almost all the starting phosphonate was revealed by TLC and NMR analyses after 15 h reaction period. The reaction rate of sterically hindered olefin with borane decreases a great deal at the third addition stage of borane, *i.e.*, formation of trialkylborane.[7] This seems to be the reason for the excess amount of hydroboration reagents being required for complete consumption of the starting phosphonates. The results of hydroboration are summarized in Table 2.

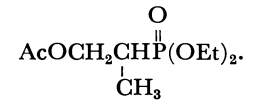
4g: R=Et, R′=Et

Hydroboration of compound **2h** (R=Ph, R′=Et) gave a complicated result. TLC analysis of the reaction mixture showed at least three components, which should consist of diethyl 2-hydroxy-[8] and 1-hydroxy-1-phenylethylphosphonates. In the hydroboration of styrene, α- and β-hydroxy compounds were produced, where electron-withdrawing substituents such as *p*-Cl depressed the β-hydroxy product, increasing the portion of the α-hydroxy compound.[9] The effect should be an important factor for making the hydroboration reaction of compound **2h** complicated.

Diethyl 2-hydroxy-1-methylethylphosphonate (**4f**) was treated with acetic anhydride–pyridine at room temperature for 3 d. The NMR spectrum of the product purified by TLC on silica gel (43% isolated yield) showed the presence of one acetoxyl group (δ, 2.20 ppm). IR (ν_{max}, 1740 cm^{-1}, C=O) and mass spectra [*m/e*, 238 (M^+)] also supported the view that the compound is diethyl 2-acetoxy-1-methylethylphosphonate as given by



5f

The reaction sequence seems to be satisfactory for preparing β-hydroxyalkylphosphonates having one carbon atom more than that of the starting phosphonates.

Experimental

Measurements. Melting and boiling points were uncorrected. ^{1}H-NMR spectra were measured on Hitachi-Perkin-Elmer R-20 (60 MHz) and Hitachi R-24 (60 MHz) spectrometers with tetramethylsilane as an internal standard, and IR spectra on a Japan Spectroscopic Co. Ltd. A-3 infrared spectrophotometer. Optical rotations were measured with a DIP-4 polarimeter.

Materials. The following materials were synthesized according to reported methods: dimethyl 1-oxoethylphosphonate (**1a**, 60% yield, bp 58—61 °C/1 mmHg),[10] dimethyl-1-oxo-1-phenylmethylphosphonate (**1e**, 68% yield, bp 144—146 °C/3.5 mmHg),[10] diethyl 1-oxoethylphosphonate (**1f**, 61% yield, bp 54—55 °C/0.5 mmHg),[11] diethyl 1-oxopropyl phosphonate (**1g**, 57% yield, bp 69—73 °C/0.3 mmHg),[12] ethyltriphenylphosphonium iodide (mp 166—168.5 °C)[13] and bromide (mp 202—204 °C),[14] diethyl ethylphosphonate (bp 45 °C/1.5 mmHg),[15] and diethyl 1-phenylvinylphosphonate (**2h**, bp 93—95 °C/0.05 mmHg).[16]

*Synthesis of Dimethyl 1-Oxopropylphosphonate (**1b**).* Propionyl chloride (5.4 g) was added to trimethyl phosphite (6.0 g) at 0 °C. The mixture was allowed to stand overnight at room temperature. Distillation under reduced pressure gave compound **1b** (4.7 g) in 59% yield, bp 58—61.5 °C/0.5 mmHg. ^{1}H-NMR ($CDCl_3$) δ 1.10 (t, J=7.1 Hz, 3H, $CH_2\underline{Me}$), 2.94 (q, J=7.1 Hz, 2H, CH_2), 3.96 (d, J=10.8 Hz, 6H, OMe); IR ν_{max}^{neat} 1704 cm^{-1} (C=O).

Found: C, 36.08; H, 6.93%. Calcd for $C_5H_{11}O_4P$: C, 36.14; H, 6.63%.

*Synthesis of Dimethyl Cyclohexylcarbonylphosphonate (**1c**).* Reaction of trimethyl phosphite (3.4 g) with cyclohexanecarbonyl chloride (3.7 g) under the same conditions as mentioned above gave compound **1c** (5.5 g) in 64% yield, bp 90—93 °C/0.5 mmHg.[4] ^{1}H-NMR ($CDCl_3$) δ 1.0—2.2 [m, 10H, $(CH_2)_5$], 2.4—3.3 (m, 1H, CH), 3.85 (d, J_{POCH}=11.7 Hz, 6H, POMe), IR ν_{max}^{neat} 1693 cm^{-1} (C=O).

*Synthesis of Dimethyl 1-Oxo-3-phenylpropylphosphonate (**1d**).* Treatment of trimethyl phosphite (3.9 g) with 3-phenylpropionyl chloride (4.4 g) at 0 °C to room temperature as mentioned for the synthesis of compound **1b** gave compound **1d** (3.0 g) in 48% yield, bp 127—129 °C/0.5 mmHg. ^{1}H-NMR ($CDCl_3$) δ 2.96 (t, J=5.3 Hz, 2H, CH_2), 2.99 (t, J=5.3 Hz, 2H, CH_2), 3.77 (d, J_{POCH}=11.4 Hz, 6H, POMe), 7.0—7.4 (m, 5H, Ph); IR ν_{max}^{neat} 1698 cm^{-1} (C=O).

Found: C, 54.38; H, 6.41%. Calcd for $C_{11}H_{15}O_4P$: C, 54.55; H, 6.20%.

*Synthesis of Dimethyl Isopropenylphosphonate (**2a**) by Wittig Reaction.* Methyltriphenylphosphonium bromide (6.0 g) in benzene (60 ml) was treated with sodium amide (1.8 g) at room temperature for 15 h. The sodium bromide formed and sodium amide unreacted were filtered off under nitrogen flow, the ammonia formed being removed *in vacuo*. To the solution of methylenetriphenylphosphorane was added compound **1a** (2.0 g) dropwise under ice cooling and the mixture

was allowed to react at room temperature for 5 h. Removal of benzene followed by distillation *in vacuo* afforded 1.0 g of compound **2a** (50% yield), bp 38—41 °C/1 mmHg (lit,[17] bp 66.5—67 °C/8 mmHg).

*Synthesis of Dimethyl 1-Ethylvinylphosphonate (**2b**) via Wittig Reaction.* To a benzene solution of methylenetriphenylphosphorane prepared from methyltriphenylphosphonium bromide (6.0 g) and sodium amide (1.8 g) was added compound **1b** (2.2 g) dropwise. Processing of the reaction mixture as described above followed by vacuum distillation gave 1.2 g of compound **2b** (55% yield), bp 46—49 °C/0.9—1.0 mmHg. ^{1}H-NMR ($CDCl_3$) δ 1.11 (t, J=7.5 Hz, 3H, Me), 1.90—2.6 (m, 2H, CH_2), 3.73 (d, J_{POCH}=10.4 Hz, 6H, POMe), 5.80 [ddt, $J_{PC=CH(trans)}$=48.0 Hz, $J_{HC=CCH}$=1.8 Hz, $J_{HH(gem)}$=1.5 Hz, 1H, PC=CH(*trans*)], 6.04 [ddt, $J_{PC=CH(cis)}$=22.5 Hz, $J_{HC=CCH}$=1.1 Hz, $J_{HH(gem)}$=1.5 Hz, 1H, PC=CH(*cis*)].[18]

Found: C, 43.82; H, 8.10%. Calcd for $C_6H_{13}O_3P$: C, 43.90; H, 7.93%.

*Synthesis of Dimethyl 1-Cyclohexylvinylphosphonate (**2c**).* Wittig reaction of compound **1c** (2.4 g) with methylenetriphenylphosphorane at room temperature for 5 h followed by a similar procedure to that above and distillation *in vacuo* afforded compound **2c** (1.0 g, 42% yield), bp 80—81° C/1 mmHg. ^{1}H-NMR ($CDCl_3$) δ 0.5—2.5 (m, 11H, C_6H_{11}), 3.74 (d, J_{POCH}=11.1 Hz, 6H, POMe), 5.88 [d, $J_{PC=CH(trans)}$=50.3 Hz, 1H, PC=CH(*trans*)], 6.09 [d, $J_{PC=CH(cis)}$=24.0 Hz, 1H, PC=CH(*cis*)].[18]

Found: C, 54.88; H, 9.10%. Calcd for $C_{10}H_{19}O_3P$: C, 55.05; H, 8.72%.

*Synthesis of Diethyl 1-Methylenepropylphosphonate (**2g**).* To methylenetriphenylphosphorane, prepared from methyltriphenylphosphonium bromide (6.5 g) and sodium amide (2.1 g) in benzene (70 ml) was added compound **1g** (2.9 g) under ice cooling. The reaction at room temperature for 4 h followed by the work-up mentioned above and distillation gave 1.7 g of compound **2g** (59% yield), bp 50—52 °C/0.1 mmHg. ^{1}H-NMR ($CDCl_3$) δ 1.12 (t, J=7.5 Hz, 3H, $CCH_2C\underline{H}_3$), 1.32 (t, J=7.1 Hz, 6H, $OCH_2C\underline{H}_3$), 2.27 (dqdd, J_{PCCH}=12.0 Hz, J_{HCCH}=7.5 Hz, $J_{HC=CCH}$=1.0 and 1.8 Hz, 2H, CH_2), 4.06 (dq, J_{POCH}=7.1 Hz, J_{HH}=7.1 Hz, 4H, $POCH_2$), 5.72 [ddt, $J_{PC=CH(trans)}$=46.6 Hz, $J_{HC=CCH}$=1.8 Hz, $J_{HH(gem)}$=1.3 Hz, 1H, PC=CH(*trans*)], 6.98 (ddt, $J_{PC=CH(cis)}$=21.3 Hz, $J_{HC=CCH}$=1.0 Hz, $J_{HH(gem)}$=1.3 Hz, 1H, PC=CH(*cis*)].[18]

Found: C, 49.84; H, 8.62%. Calcd for $C_8H_{17}O_3P$: C, 49.98; H, 8.93%.

Compound **1f** was converted into compound **2f** (45% yield) by the same procedure, bp 44—47 °C/1 mmHg (lit,[19] bp 46.5—47.0 °C/1 mmHg).

*Reaction of Compounds **1a** and **1f** with Phosphoranes.* Reaction of compounds **1a** and **1f** with ethyltriphenylphosphonium iodide in the presence of base (sodium amide or sodium hydride in benzene, oxolane, or dimethyl sulfoxide) gave only a trace amount of 1-methyl-1-propenylphosphonate, the reaction with methoxymethylenetriphenylphosphorane giving no corresponding vinylphosphonates.

Hydroboration of Diethyl Isopropenylphosphonate. To an oxolane solution (15 ml) of sodium tetrahydroborate (0.60 g) and compound **2f** (4.5 g) was added trifluoroborane etherate (2.9 g) in oxolane (3.0 ml) dropwise at 0—5 °C over a period of 1 h. The reaction mixture was kept at room temperature until the complete consumption of compound **2f** was confirmed by TLC and NMR analyses (15 h), 3 mol dm^{-3} sodium hydroxide (45 ml) and 30% hydrogen peroxide (45 ml) then being added at 0—5 °C for oxidation. Evaporation of oxolane followed by extraction with chloroform and distillation *in vacuo* afforded 1.5 g of diethyl 2-hydroxy-1-methylethylphosphonate (**4f**, 30% yield), bp 87—90 °C/0.2 mmHg. ^{1}H-NMR ($CDCl_3$) δ 1.30 (t, J_{HH}=7.5 Hz, 6H, $OCH_2C\underline{H}_3$), 1.40 (dd, J_{PCCH}=13.5 Hz, J_{HH}=7.5 Hz, 3H, $CHC\underline{H}_3$), 1.70—2.15 (m, 1H, $C\underline{H}CH_3$), 3.55—3.95 (m, 2H, $C\underline{H}_2OH$), 4.15 (s, 1H, OH), 4.20 (dq, J_{HH}=7.5 Hz, J_{POCH}=7.5 Hz, 4H, $POCH_2$); IR ν_{max}^{neat} 3320 cm^{-1} (OH); mass spectrum, *m/e*, 196 (M$^+$).

Found: C, 43.58; H, 8.85%. Calcd for $C_7H_{17}O_4P$: C, 42.86; H, 8.73%.

Hydroboration of Diethyl 1-Ethylvinylphosphonate. Treatment of compound **2g** (3.0 g) with sodium tetrahydroborate (0.4 g) and trifluoroborane etherate (1.8 g) in oxolane (8 ml) followed by oxidation with 30% hydrogen peroxide (1.7 ml) and 3 mol dm^{-3} sodium hydroxide (1.7 ml), similar work-up and distillation to that described above afforded diethyl 2-hydroxy-1-ethylethylphosphonate (1.1 g, 33% yield), bp 87—89 °C/0.15 mmHg. ^{1}H-NMR ($CDCl_3$) δ 0.98 (t, J=7.5 Hz, 3H, $CHCH_2C\underline{H}_3$), 1.33 (t, J=6.8 Hz, 6H, $POCH_2C\underline{H}_3$), 1.50—2.0 (m, 3H, $C\underline{H}C\underline{H}_2CH_3$), 3.5—4.2 (m, 2H, $C\underline{H}_2OH$), 4.05 (s, 1H, OH), 4.16 (bq, J_{POCH}=6.9 Hz, J_{HH}=6.9 Hz, 4H, $POC\underline{H}_2CH_3$); IR ν_{max}^{neat} 3300 cm^{-1} (OH).

Found: C, 45.51; H, 9.31%. Calcd for $C_8H_{18}O_4P$: C, 45.70; H, 9.13%.

Hydroboration of Dimethyl 1-Cyclohexylvinylphosphonate. Hydroboration of compound **2c** (1.9 g) with sodium tetrahydroborate (0.3 g) and trifluoroborane etherate (1.3 g) in 7 ml of oxolane followed by oxidation with 30% hydrogen peroxide (1.2 ml) and 3 mol dm^{-3} sodium hydroxide (1.2 ml) at 0—5 °C as mentioned for the preparation of compound **4f** and separation of the products by preparative TLC (silica gel; eluent, acetone: petroleum ether=3: 1) gave dimethyl 1-cyclohexyl-2-hydroxyethylphosphonate (0.41 g, 20% yield). ^{1}H-NMR ($CDCl_3$) δ 0.60—2.15 (m, 12H, $C_6\underline{H}_{11}$–$C\underline{H}$), 3.72 and 3.75 (pair of d, J_{POCH}=10.5 Hz, 6H, POMe), 3.85 (s, 1H, OH), 3.60—3.90 (m, 2H, $C\underline{H}_2OH$); IR ν_{max}^{neat} 3260 cm^{-1} (OH); mass spectrum, *m/e*, 236 (M$^+$).

*Hydroboration of Diethyl 1-Phenylvinylphosphonate (**2h**).* Hydroboration of compound **2h** gave three products, R_f values on TLC being 0.50, 0.30, and 0.15 (silica gel; eluent, ethyl acetate: chloroform=3: 2). Separation of the products by TLC followed by NMR measurement showed an OH group at 2.83 ppm. The integrated signal for phenyl ring protons seemed to be *ca.* 10% less than that for the expected product. The result indicates the presence of impurities in the sample.

*Acetylation of Compound **4f**.* Treatment of compound **4f** (0.60 g) in anhydrous pyridine (0.90 g) with 1.3 g of acetic anhydride at room temperature for 3 d followed by removal of volatile materials *in vacuo* and washing the chloroform solution with water afforded a crude product, which was subjected to chromatography on silica gel giving dimethyl 2-acetoxy-1-methylethylphosphonate (0.30 g) in 43% yield. ^{1}H-NMR ($CDCl_3$) δ 1.22 (dd, J_{PCCH}=17.2 Hz, J_{HH}=7.2 Hz, 3H, $CHC\underline{H}_3$), 1.34 (t, J=6.6 Hz, 6H, $POCH_2C\underline{H}_3$), 2.08 (s, 3H, COMe), 2.1—2.8 (m, 1H, PCH), 4.14 (dq, J_{POCH}=7.2 Hz, J_{HH}=7.2 Hz, 4H, $POCH_2$), 4.40—4.65 (m, 2H, $C\underline{H}_2OAc$); IR ν_{max}^{neat} 1742 cm^{-1} (C=O), 1217 (P=O); mass spectrum, *m/e*, 238 (M$^+$).

Found: C, 45.05; H, 8.23%. Calcd for $C_9H_{19}O_5P$: C, 45.38, H, 8.04%.

The Synthesis of Tedanin and Its Isomer, 3-Hydroxy-2,3-didehydro-β,φ-caroten-4-one[1]

Mitsuki YASUHARA,[2] Kazuko INANAGA, Takashi KUMAE, Hemat Rysona BRAHMANA, Nobuhisa OKUKADO, and Masaru YAMAGUCHI*

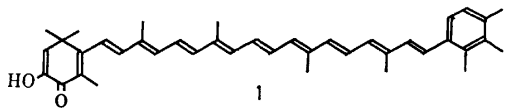
Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received August 13, 1979)

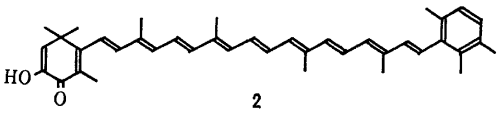
The structure, 3-hydroxy-2,3-didehydro-β,χ-caroten-4-one, assigned to tedanin, the main carotenoid pigment of the marine sponge "*Tedania digitata* (O. Schmidt)," has been confirmed by total synthesis starting with β,χ-carotene. An isomer, 3-hydroxy-2,3-didehydro-β,φ-caroten-4-one, was also synthesized from β,φ-carotene.

Tedanin was first isolated as the main carotenoid from the sea sponge "*Tedania digitata* (O. Schmidt)," and its chemical structure has been established to be 3-hydroxy-2,3-didehydro-β,χ-caroten-4-one (**1**)[3] by Okukado on the basis of chemical and spectroscopic evidence.[4] This pigment was also found in a sea sponge, "*Clathria frondifera* (Bowerbank)," by Tanaka and Katayama.[5]

In this paper, we wish to report a total synthesis of tedanin which has unambiguously confirmed the proposed structure. We also wish to report the synthesis and characterization of the isomer, 3-hydroxy-2,3-didehydro-β,φ-caroten-4-one (**2**), in which a χ-ring end group of tedanin was replaced by a φ-end group. Although its natural existence has not yet been established, the isomer can be expected to exist in nature with a high probability since a φ-end group has often been encountered in natural carotenoids.[6]



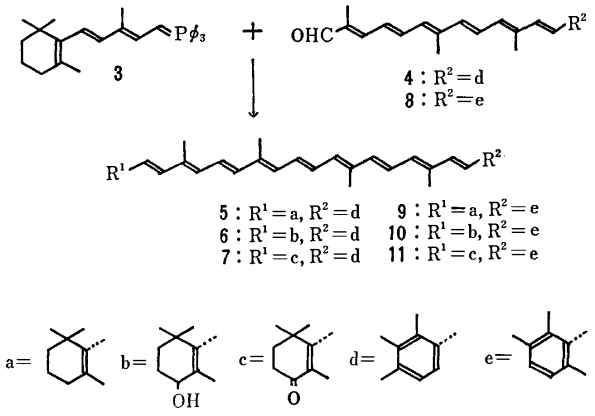
1



2

Results and Discussion

The synthesis of tedanin started with β,χ-carotene (β-isorenieratene) (**5**). The latter compound had previously been synthesized by Weedon *et al.*[7] and later reported to occur in some species of photosynthetic brown bacteria (*Phaebium*).[8] The synthesis by Weedon *et al.* was carried out according to the $C_{10}+C_{20}\rightarrow C_{30}$, $C_{30}+C_{10}\rightarrow C_{40}$ building scheme; however, a different construction principle, $C_{15}+C_{25}\rightarrow C_{40}$, was used in the present study. Thus, the Wittig reaction of 5-(2,6,6-trimethyl-1-cyclohexenyl)-3-methyl-2,4-pentadienylidenetriphenylphosphorane (**3**)[9] with 12'-apo-χ-caroten-12'-al (**4**), which we had previously used for the synthesis of 7,8-didehydrorenieratene,[10] gave β,χ-carotene (**5**) in a 51% yield after purification by column chromatography on alumina. The physical and spectroscopic properties were identical with those reported by Weedon *et al.* The treatment of **5** with *N*-bromosuccinimide and glacial acetic acid in chloroform, followed by saponification with methanolic potassium hydroxide,[11] afforded an alcohol (**6**) in a 74% yield. The alcohol has the molecular formula of $C_{40}H_{52}O$, which was determined by elemental analysis and mass spectrum; it shows ^1H NMR signals at δ 1.02(3H), 1.04(3H), 1.85(3H), and 4.02(1H), which can be assigned to protons of the 4-hydroxy-2,6,6-trimethyl-1-cyclohexenyl moiety.[12] The treatment of **6** with active manganese dioxide prepared by Attenburrow's method[13] gave a ketone (**7**) as purplish black crystals in a 61% yield. When γ-manganese dioxide[14] was used for this oxidation, no desired ketone (**7**) was obtained; the reaction products consisted of several components with shorter wavelength absorptions than those of the alcohol (**6**). The oxidation from **6** to **7** resulted in a bathochromic shift (8 nm), accompanied by a complete loss of fine structures in the UV spectrum.[15] Finally, the oxidation of **7** by oxygen in the presence of potassium *t*-butoxide[16] yielded tedanin (**1**) in a 71% yield after purification by chromatography on silica gel. The identity of the synthetic material with the natural specimen was established by a mixed melting-point determination and mixed chromatography as well as by a comparison of the IR, UV, NMR, and mass spectra.



The synthesis of 3-hydroxy-2,3-didehydro-β,φ-caroten-4-one (**2**) was carried out starting from β,φ-carotene (**9**) by the route adopted for the synthesis of tedanin. The chromatographic behavior of **2** was very similar to that of tedanin. The physical and spectroscopic properties will be described in the Experimental section. As expected, the isomer (**2**) showed its absorption maximum in benzene at 483 nm, shorter by 7 nm than that of tedanin (**1**), which has a χ-end group. This can be explained on the basis of the fact that the chromophore system of **2** was more distorted than that of **1** because of the steric interference between the polyene chain

and two methyl substituents at the 1- and 5-positions in the ϕ-end group compared with one substituent at the 1-position in the χ-end group.[7]

Experimental

All the melting points are uncorrected. All the reactions and operations were carried out under an atmosphere of nitrogen as far as possible. The instruments and solvents used for the measurements of the spectra were as follows: UV spectra: Hitachi, Model EPS-3T (benzene). IR spectra: Hitachi, Model R-215 (KBr). NMR spectra: Hitachi, Model R-20B ($CDCl_3$, with TMS as the internal standard). Mass spectra: Hitachi, Model RMU-6MG.

β,χ-Carotene (5). An ethereal solution of phenyllithium (1.1 mol dm^{-3}, 9 ml) was added, at room temperature, to a stirred suspension of 5-(2,6,6-trimethylcyclohexenyl)-3-methyl-2,4-pentadienyltriphenylphosphonium bromide[9] (3.015 g) in dry ether (40 ml). After 5 min, dry dichloromethane (5 ml) was added to destroy the excess phenyllithium. To this deep red solution of the ylid we then added a solution of 12′-apo-χ-caroten-12′-al[10] (**4**) (900 mg) in dichloromethane (30 ml). The mixture was stirred for 2 h at room temperature, poured into water, and extracted with benzene. The extract was dried with sodium sulfate and evaporated. The reddish residue was chromatographed on neutral alumina [Merck, deactivated by the addition of water (2%)], with a benzene–petroleum benzine mixture (3 : 7) as the developer. The main red zone was eluted with a benzene–methanol mixture (9: 1), and the eluate was concentrated under reduced pressure to give a crude product, which was then recrystallized from a dichloromethane–ethanol mixture. Red crystals (51%); mp 165 °C (lit,[7] mp 164 °C). Found: C, 89.92; H, 9.81%. Calcd for $C_{40}H_{52}$: C, 90.15; H, 9.85%. λ_{max} 506, 474 nm ($\varepsilon = 1.31 \times 10^5$); IR 3040, 2980, 2950, 1655, 970, 835 cm^{-1}; NMR δ 1.04 (6H, s, 1, 1-dimethyl), 1.75 (3H, s, 5-methyl), 2.00, and 2.09 (9H, s, and 3H, s, respectively; chain methyls), 2.23, and 2.32 (3H, s, and 6H, s, respectively; aryl methyls); MS 532 (M), 453, 440, 426, 399, 395, 374, 133, 106, 105, 92, 91.

β,χ-Caroten-4-ol (6). A cooled solution of NBS (109 mg) in a mixture of glacial acetic acid (0.49 ml) and chloroform (13 ml) was stirred into a solution of **5** (300 mg) in dry chloroform (33 ml) which had been cooled at −60 °C with Dry Ice–chloroform bath. After stirring at −60 °C for 2 h, *N*-ethylmorpholine (1.45 ml) was added; the mixture was stirred for 2 h at 0 °C and then heated under reflux for 2 h. The mixture was washed three times with aqueous hydrochloric acid (0.1 mol dm^{-3}), aqueous sodium hydrogencarbonate, and then water. After the removal of the solvent, the residue was dissolved in benzene (30 ml) and treated overnight with a 15% methanolic potassium hydroxide solution (33 ml) at room temperature. The mixture was then diluted with water, and the organic layer was washed with water, dried, and evaporated. The residue was chromatographed on alumina [deactivated by the addition of water (5%)] with benzene. The main red zone was eluted with a benzene–methanol mixture (9 : 1); the subsequent removal of the solvent gave a crude product, which was purified by recrystallization with a benzene–ethanol mixture. Purplish red needles (74%); mp 153—154 °C. Found: C, 87.22; H, 9.54%. Calcd for $C_{40}H_{52}O$: C, 87.53; H, 9.55%. λ_{max} 506, 474 ($\varepsilon = 1.28 \times 10^5$), 449 nm; IR 3460, 3040, 2950—2850, 1560, 1445, 960, 816, 804 cm^{-1}; NMR δ 1.02 and 1.04 (each 3H, s, 1,1-dimethyl), 1.85 (3H, s, 5-methyl), 1.99 and 2.07 (9H, s and 3H, s, respectively; chain methyls), 2.21 and 2.31 (3H, s and 6H, s, respectively; aryl methyls), 4.02 (1H, m, 4-methin), 6.18—7.10 (16H, m, olefinic and aromatic protons); MS 548 (M), 530, 515, 438, 424, 372, 133, 106, 105, 92, 91.

β,χ-Caroten-4-one (7). A solution of **6** (143 mg) in acetone (12 ml) and dichloromethane (24 ml) was stirred into a suspension of active manganese dioxide[13] (1.43 g) in acetone (12 ml), after which the mixture was stirred for 2.5 h at room temperature. After the filtration of the manganese dioxide and the removal of the solvent, the resulting red solid was recrystallized from a dichloromethane–ethanol mixture. Purplish black prisms (77%); mp 197—198 °C. Found: C, 87.66; H, 9.38%. Calcd for $C_{40}H_{50}O$: C, 87.86; H, 9.22%. λ_{max} 482 nm ($\varepsilon = 1.05 \times 10^5$); IR 3040, 2980—2850, 1655, 970, 835 cm^{-1}; NMR δ 1.20 (6H, s, 1,1-dimethyl), 1.89 (3H, s, 5-methyl), 2.01 and 2.08 (9H, s and 3H, s, respectively; chain methyls), 2.22 and 2.32 (3H, s and 6H, s, respectively; aryl methyls), 2.54 (2H, m, 3-methylene), 6.20—7.42 (16H, m, olefinic and aryl protons); MS 546 (M), 531, 459, 440, 388, 343, 158, 133, 106, 105, 92, 91,

Tedanin (1). A solution of potassium *t*-butoxide in *t*-butyl alcohol (*ca.* 1 mol dm^{-3}, 2.5 ml) was added to a solution of **7** (20.5 mg) in a mixture of dry benzene (12 ml) and *t*-butyl alcohol (18 ml); after stirring at room temperature for 20 min, dry oxygen gas was bubbled into the mixture for 6 h at 45 °C. The reaction mixture was then diluted with benzene, and the solution was washed successively with water, aqueous hydrochloric acid (0.1 mol dm^{-3}), aqueous sodium hydrogencarbonate, and water. After the removal of the solvent, the resulting residue was chromatographed on silica gel with a chloroform–benzene mixture (3 : 7). The elution of the main red zone and the removal of the solvent gave a crude product, which was subsequently recrystallized from a dichlomethane–ethanol mixture. Purplish black prisms (71%); mp 189—190 °C (lit,[4] mp 188—189 °C), undepressed by admixture with a natural specimen. Mixed chromatography of the synthetic and the natural pigment showed no separation on silica gel and sucrose columns. Found: C, 85.39; H, 8.67%. Calcd for $C_{40}H_{48}O_2$: C, 85.66; H, 8.63%. The spectral properties, such as the UV, IR, and NMR, were also identical with those of natural tedanin previously reported.

β,φ-Carotene (9). This was prepared by a method similar to that described above for the synthesis of β,χ-carotene (**5**), starting with **3** and 12′-apo-φ-caroten-12′-al[10] (**8**) (244.2 mg). Red plates (46%); mp 137—138 °C (lit,[7] 128 °C). Found: C, 90.02; H, 9.78%. Calcd for $C_{40}H_{52}$: C, 90.16; H, 9.84%. λ_{max} 494, 465 ($\varepsilon = 1.14 \times 10^5$), 437 nm; IR 3030, 3000—2850, 970, 955, 830, 810 cm^{-1}; NMR δ 1.04 (6H, s, 1,1-dimethyl), 1.72 (3H, s, 5-methyl), 2.00 and 2.10 (9H, s, and 3H, s, respectively; chain methyls), 2.25 and 2.28 (3H, s and 6H, s, respectively; aryl methyls), 6.15—6.90 (14H, m, olefinic protons), 6.97 (2H, s, aryl protons); MS 532 (M) 440, 426, 374, 317, 133, 105, 91.

β,φ-Caroten-4-ol (10). This was obtained from **9** (212.3 g) by a method similar to that used for β,χ-caroten-4-ol (**6**). Purplish red needles (57%); mp 136—136.5 °C. Found: C, 87.24; H, 9.29%. Calcd for $C_{40}H_{52}O$: C, 87.53; H, 9.55%. λ_{max} 492, 463 ($\varepsilon = 1.28 \times 10^5$), 436 nm; IR 3450, 3033, 2922—2858, 1560, 1445, 964, 808 cm^{-1}; NMR δ 1.03 and 1.06 (each 3H, s, 1,1-dimethyl), 1.87 (3H, s, 5-methyl), 2.00 and 2.11 (9H, s and 3H, s, respectively; chain methyls), 2.25 and 2.28 (3H, s and 6H, s, respectively; aryl methyls), 4.03 (1H, m, 4-methin), 6.05—6.85 (14H, m, olefinic protons), 6.98 (2H, s, aromatic protons); MS 548 (M), 530, 424, 372, 133, 105, 92, 91.

β,φ-Caroten-4-one (11). This was prepared from **10** (108 mg) by the same method as **7**. Purplish black needles

(62%); mp 178—179 °C. Found: C, 87.99; H, 9.22%. Calcd for $C_{40}H_{50}O$: C, 87.86; H, 9.22%. λ_{max} 469 nm ($\varepsilon=1.70\times10^5$); IR 3030, 2970—2790, 1645, 975, 830, 810 cm^{-1}; NMR δ 1.20 (6H, s, 1,1-dimethyl), 1.89 (3H, s, 5-methyl), 2.00 and 2.10 (9H, s and 3H, s, respectively; chain methyls), 2.25 and 2.28 (3H, s and 6H, s, respectively; aryl methyls), 2.49 (2H, m, 3-methylene), 6.10—6.85 (14H, m, olefinic protons), 6.98 (2H, s, aromatic protons); MS 546 (M), 454, 133, 119, 91, 84.

3-Hydroxy-2,3-didehydro-β,φ-caroten-4-one (**2**). This was obtained from **11** (38 mg) by a method similar to that used for tedanin (**1**). Purplish black needles (49%); mp 170—171 °C. Found: C, 85.63; H, 8.61%. Calcd for $C_{40}H_{48}O_2$: C, 85.67; H, 8.63%. λ_{max} 483 nm ($\varepsilon=1.87\times10^5$); IR 3425, 3030, 2990—2830, 1695, 1620, 972, 830, 808 cm^{-1}; NMR δ 1.30 (6H, s, 1,1-dimethyl), 2.02 and 2.04 (each 6H, s; chain methyls), 2.24 and 2.28 (3H, s and 6H, s, respectively; aryl methyls), 6.06—6.85 (15H, m, olefinic protons), 6.98 (2H, s, aromatic protons); MS 560(M), 544, 468, 454, 408, 204, 157, 119, 105, 91.

Studies of Polymeric Flocculants. XI.[1] The Preparation and Properties of Polyampholytes

Takamasa NONAKA* and Hiroaki EGAWA

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860

(Received August 23, 1979)

The polyampholytes were prepared by treating potassium polymethacrylate with (3-chloro-2-hydroxypropyl)-trimethylammonium chloride. The solution viscosity behavior and the potentiometric titration of the polyampholytes were studied. The flocculating ability of the polyampholytes was also investigated by the use of kaolin suspensions. The amine/acid ratio could be varied as desired to some extent by means of changing the reaction temperature. However, the polyampholytes containing more amino groups than about 46% could not be obtained. The resulting polyampholytes showed characteristic viscosity behavior. The results of the flocculation of kaolin suspensions with the polyampholytes showed that the polyampholytes can be expected to become a new type of polymeric flocculants, in which the chain expansion and the charge sign can be varied by changing the pH values of the solutions.

Some polyampholytes have been prepared and studied by a number of investigators,[2-8] but the flocculation of suspensions with polyampholytes had not been investigated. In the present paper, the preparation and properties of potassium methacrylate–[2-hydroxy-3-(methacryloyloxy)propyl]trimethylammonium chloride copolymer as a new polyampholyte were investigated. Furthermore, the flocculating ability of the polyampholytes was studied by the use of kaolin suspensions.

Experimental

Preparatoin of Potassium Polymethacrylate. The pH values of a methacrylic acid aqueous solution were adjusted to 7.0—7.2 by adding a 2-mol dm^{-3} KOH aqueous solution. Potassium methacrylate in an aqueous solution was polymerized at 40 °C for 48 h, and then the aqueous solution was poured into an excess of ethanol in order to precipitate potassium polymethacrylate. The intrinsic viscosity was measured in a 2-mol dm^{-3} $NaNO_3$ aqueous solution at 25 °C. The number-average molecular weight of the potassium polymethacrylate was calculated by means of the following equation: $[\eta]=KM^a$.[9]

Preparation of (3-Chloro-2-hydroxypropyl)trimethylammonium Chloride. (3-Chloro-2-hydroxypropyl)trimethylammonium chloride (**1**) was prepared by a method described previously.[10] At first, 9.6 g of trimethylammonium hydrochloride was dissolved in 10 cm^3 of water. Into this solution 9.3—14.0 g of epichlorohydrin were then stirred, drop by drop, at 40—50 °C, after which the reaction mixture was heated at the same temperature for an additional hour. The product was purified by crystallization from methanol. The total chlorine content of **1** was determined by means of a flask-combustion method.[11] The chloride-ion content was determined by means of the Mohr method.[12]

Preparation of Polyampholytes. The potassium methacrylate–[2-hydroxy-3-(methacryloyloxy) propyl] trimethylammonium chloride copolymers were prepared by treating potassium polymethacrylate with **1** at 40—120 °C for 2—10 h. The reaction mixture was poured into an excess of ethanol in order to precipitate the polyampholytes. The polyampholytes were then purified by Soxhlet extraction with ethanol for 30 h. The amine content of the polyampholytes was calculated on the basis of the nitrogen content of the polyampholytes thus obtained. The polyampholytes for an elemental analysis were obtained as follows: about 0.5 g of the polyampholytes was dissolved in 50 cm^3 of a 1-mol dm^{-3} HCl solution, after which the solution was poured into an excess of ethanol in order to precipitate the polyampholyte. The polyampholyte was purified by Soxhlet extraction with ethanol for 30 h and dried *in vacuo* at 50 °C for 5 h.

Measurement of Solution Viscosity of Polyampholytes. The viscosities were measured in an aqueous solution of various concentrations of the polyampholytes at different pH values. In order to determine the isoelectric point of the polyampholytes, the viscosities were also measured by varying the pH values of the aqueous solution of the polyampholytes. All the viscosities were measured by means of an Ostwald viscosimeter at 30 °C.

Potentiometric Titration. The polyampholytes, dissolved in 50 cm^3 of a 0.1 mol dm^{-3} KCl solution, were titrated with a 0.1 mol dm^{-3} KOH (or 0.1 mol dm^{-3} HCl)–0.1 mol dm^{-3} KCl solution. The pH values of the solution were then measured by means of a Hitachi-Horiba pH meter.

Flocculation Tests. The flocculating ability was studied by observing the sedimentation rate and the sedimented volume by a test tube. The kaolin was supplied by the Wako Junyaku Kogyo Co. Ltd.,; its composition and particle size distribution are shown in Table 1 and Fig. 1 respectively. The pH value of a 5% suspension of this kaolin in water was 4.15. The sedimentation data were obtained at room temperature using a 25-cm^3 graduated test tube (1.7 cm

Table 1. Components of kaolin

Component	Weight percentage
SiO_2	78.1
Al_2O_3	13.9
Fe_2O_3	0.1
Ignition loss	3.0

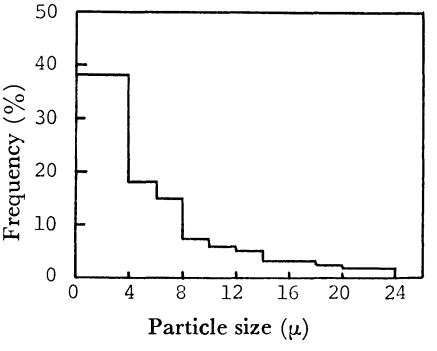

Fig. 1. Particle size distribution of kaolin.

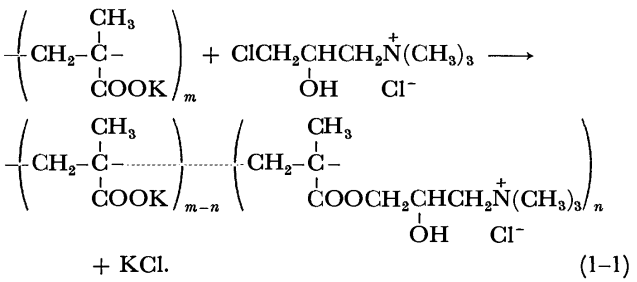
inner diameter and 18.0 cm long). 20 cm^3 of a 6.25% (w/v) kaolin suspension was poured into the test tube. An aqueous solution of a polymer was added, and then water was added to the test tube until the total volume amounted to 25 cm^3. The contents were mixed by inverting the test tube 25 times at a speed of one time per 4 seconds. Then it was allowed to settle. The sedimentation rate was determined by plotting the height of the solid-liquid boundary as a function of the time. The sedimented volume was determined by measuring the volume of the kaolin after 24 h.

Results and Discussion

Potassium Polymethacrylate and **1**. Potassium polymethacrylate with a different degree of polymerization was obtained by an aqueous-solution polymerization of potassium methacrylate using a different amount of the initiator (ammonium persulfate). **1** was prepared by the method described previously.[10] When **1** was prepared by treating 1.2 mol of epichlorohydrin with 1 mol of trimethylamine hydrochloride, the values of the elemental analysis of the products were in good agreement with the values calculated for $C_6H_{15}NOCl_2$. Found: C, 38.43; H, 7.97; N, 7.42; Cl, 37.70%. Calcd for $C_6H_{15}NOCl_2$: C, 38.29; H, 7.98; N, 7.45; Cl, 37.70%. The chloride-ion content was 50.19 per cent of the total chlorine of the product.

Preparation of Polyampholytes. In order to prepare polyampholytes containing both amino groups and carboxyl groups in the desired ratio, the reaction of potassium polymethacrylate with **1** was carried out under a variety of conditions. The reaction equation was as follows:



+ KCl. (1-1)

The results are shown in Table 2. It was found that the conversion (amine content) was greatly affected by the reaction temperature. The conversion decreased to 37.9% when the reaction was carried out at 120 °C. The reason why the conversion decreased can not be explained at present. The conversion was, on the other hand, little affected by the other conditions. Consequently, the polyampholytes containing more amino groups than about 46% could not be obtained. This is probably due to the steric hindrance of the bulky amine compound to be introduced into potassium polymethacrylate.

The reaction of potassium polyacylate with **1** was carried out under the same conditions as those used for potassium polymethacrylate. Some results are shown in Table 2. In this case, it was found that the conversion was also affected by the reaction temperature. The polyampholytes obtained at temperatures above 80 °C were insoluble in water. Therefore, a more detailed investigation was not carried out with this polyampholyte.

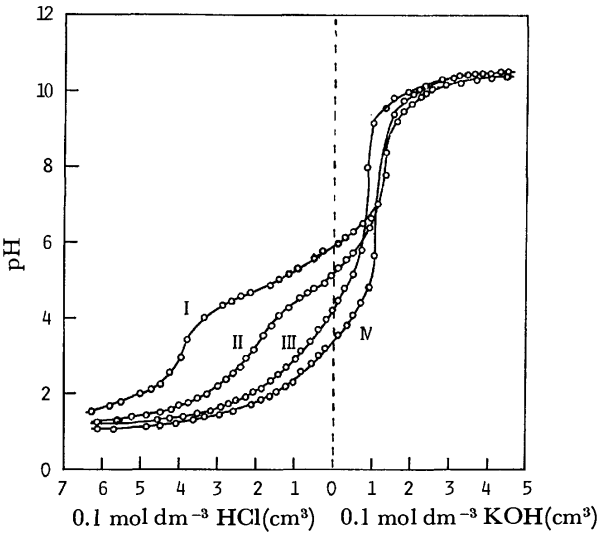


Fig. 2. The pH titration curves of the polyampholytes. Polymer concentration: *ca.* 0.16 g/100 cm^3.

	I	II	III	IV
Polyampholyte	**A**	**B**	**C**	**D**
Amine/Acid mole ratio	8.1/91.8	29.2/70.8	37.6/62.4	45.5/54.5

pH *Titration Curves of the Polyampholytes*. The pH titration curves of the polyampholytes obtained are shown in Fig. 2. The pH titration curves show that each potassium methacrylate–[2-hydroxy-3-(methacryloyloxy)propyl]trimethylammonium chloride copolymer contained about 0.56 meq/g of the acid form of carboxyl groups. An obvious inflection point in the titration curves can be observed with the polyampholyte **A** (amine/acid mole ratio=8.1/91.9) obtained at 40 °C and the polyampholyte **B** (amine/acid mole ratio= 29.2/70.8) obtained at 60 °C in the low pH region. These points probably correspond to the completed change from potassium salt to the acid form of carboxyl groups in the polyampholytes. However, such an obvious inflection point in the titration curves can not

be observed with the polyampholyte **C** (amine/acid mole ratio=37.6/62.4) obtained at 80 °C and the polyampholyte **D** (amine/acid mole ratio=45.5/54.5) obtained at 100 °C.

The Solution Viscosity and the Isoelectric Point of the Polyampholytes. The relation between the reduced viscosities and the concentrations of the polyampholytes **A** and **D** are shown at different pH values in Figs. 3 and 4 respectively. It was found that the polyampholytes showed viscosity vehavior typical of common polyelectrolytes. A difference in the order of the reduced viscosities at different pH values was observed with the polyampholytes with different amine/acid mole ratios. In the cases of the polyampholytes **A** and **B**, the reduced viscosities at different pH values increased in the order of pH 10>pH 7>pH 4. In the cases of the polyampholytes **C** and **D**, the reduced viscosities increased in the order of pH 4>pH 7>pH 10. These phenomena are characteristic of polyampholytes. The relation between the reduced viscosities of these polyampholytes and the pH values are shown in Fig. 5. Figure 5 shows that the reduced viscosities of the polyampholytes **A** and **B** increased with an increase in the pH values in the pH region from 5.3 to 8.2. This viscosity increase is ascribed to the chain expansion caused by the repulsion of the negatively charged carboxyl groups. On the other hand, the reduced viscosities increased a little with a decrease in the pH values in the pH region from

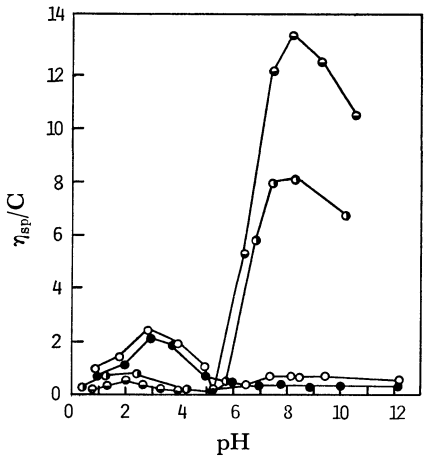

Fig. 5. Relation between the reduced viscosities of the polyampholytes with the different amine/acid ratio and pH values.
Polyampholyte; ◒: **A**, ◑: **B**, ○: **C**, ●: **D**.

5.3 to 2.0. This viscosity increase is ascribed to the chain expansion caused by the repulsion of a small amount of the positively charged amino groups in the polyampholytes. The reduced viscosities decreased at pH values above 8.2 and below 2.0. This viscosity decrease is ascribed to the chain contraction of the polyampholytes caused by the increase in the ionic strength by the addition of KOH or HCl to adjust the pH values of the solution. The reduced viscosities of the polyampholytes **C** and **D** scarcely increased at pH values above 5.3. As the amino groups in the polyampholytes obtained are quaternary amino groups, they dissociate even in an aqueous solution with the pH values above 7. Therefore, the viscosity decrease is ascribed to the chain contraction of the polyampholytes caused by the formation of the polyioncomplexes by means of interaction between the amino groups and carboxyl groups in the polyampholytes in the high pH region.

The isoelectric point, characterized by a minimum in the solution viscosity, of the polyampholytes **A** and **B** was obvious, but the isoelectric point of the polyampholytes **C** and **D** could not be obviously observed.

The Flocculation of Kaolin Suspension with the Polyampholytes. We have previously reported the preparation of cationic polymers and their flocculating ability.[13-15] The flocculation of suspensions with polyampholytes has not, however, been reported. The polyampholytes are expected to become a new type of flocculants, as the chain expansion and the charge sign of the polyampholytes can be varied by changing the pH values of the solution. Therefore, the flocculating ability of the polyampholytes was investigated by the use of kaolin suspensions at different pH values (3, 5.5, and 8). These pH values correspond, respectively, to the pH values at which the maximum, minimum, and maximum in the reduced viscosities of the polyampholytes were observed (Fig. 5). The polymers used are the polyampholytes **A**, **B**, **C**, and **D**. The results are shown in Figs. 6, 7, and 8. Figure 6 shows that the sedimentation rate of kaolin at pH 3 with the polyampholytes increased in the order of the polyampholytes **A**>**B**>**C**>**D** when more than 0.02% of the polyampholytes were added to kaolin. This order of the sedimentation rate was not in agreement with the order of the reduced viscoisities of the polyampholytes in pH 3. The sedimentation rate and the sedimented volume of kaolin with potassium polymethacrylate with the same degree of polymerization (600) as the polyampholytes are also shown in Fig. 6. The sedimentation rate of kaolin with potassium polymethacrylate increased slightly with an increase in the amount of the polymers added, but the sedimented volume of kaolin was almost the same as that in the case of no addition of a polymer. It is said that the flocculation of kaolin with sodium polyacrylate in a low pH region was brought about by a hydrogen bonding between the polymers and kaolin particles.[16] In the flocculation of kaolin with the polyampholytes at pH 3, it is considered that the flocculation was brought about with both amino groups and carboxyl groups in the polyampholytes.

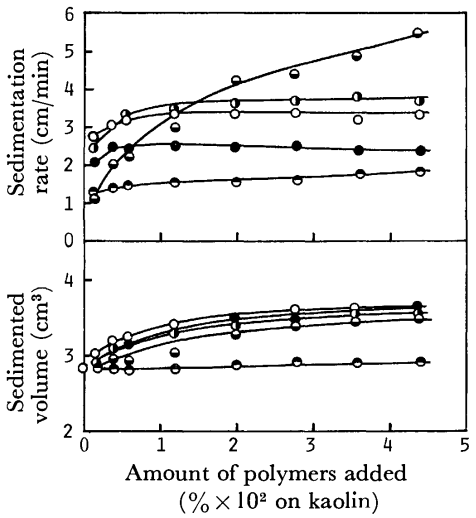

Fig. 6. Relation between sedimentation rate (or sedimented volume) and the amount of the polymer added at pH 3.

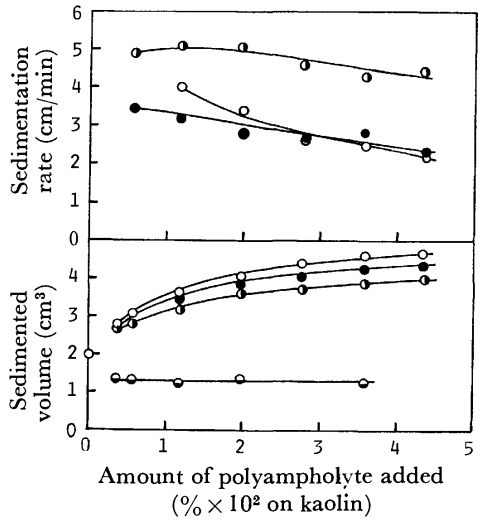

Fig. 7. Relation between sedimentation rate (or sedimented volume) and the amount of the polymer added at pH 5.5.
Polyampholyte; ◒; **A**, ◑: **B**, ○: **C**, ●: **D**.

Figure 7 shows that the highest sedimentation rate, at pH 5.5, was observed with the polyampholyte **B**. At pH 5.5, the kaolin suspension was not flocculated with the polyampholyte **A** and potassium polymethacrylate. The sedimented volume of kaolin with the polyampholyte **A** was smaller than that in the case of the addition of no polymer. These data show that the polyampholyte **A** acted as a dispersing agent of the negatively charged kaolin particles.

Figure 8 shows that, at pH 8, the kaolin suspension was not flocculated with the polyampholytes **A** and **B**, but was flocculated with the polyampholytes **C** and **D**, when a large amount of the polyampholytes was added. It is considered that, at pH 8, the polyampholytes (**A** and **B**) containing many carboxyl groups acted as dispersing agents of the negatively charged kaolin particles. This consideration was also confirmed by the

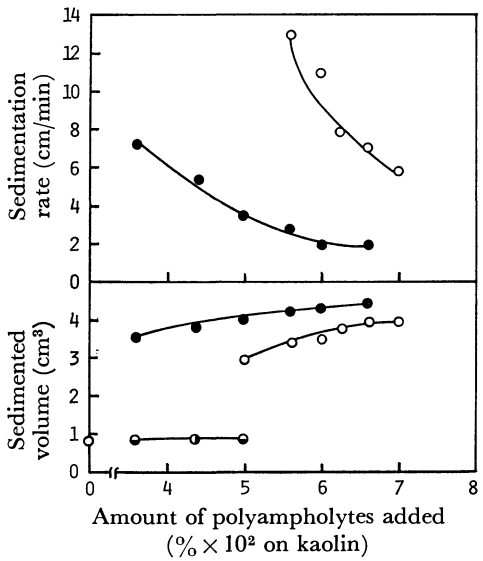

Fig. 8. Relation between sedimentation rate (or sedimented volume) and the amount of the polymer added at pH 8.
Polyampholyte; ◒: **A**, ◑: **B**, ○: **C**, ●: **D**.

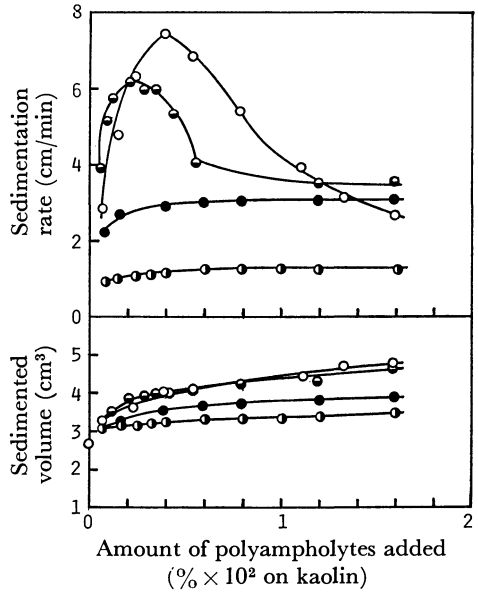

Fig. 9. Effect of the degree of polymerization of the polyampholytes on the flocculation of kaolin.

small sedimented volume of kaolin with the polyampholytes **A** and **B**. Consequently, the polyampholytes **A** and **B** may be said to be excellent polymeric flocculants for positively charged particles in a high pH region, although the flocculation of positively charged particles with the polyampholytes was not investigated in this paper.

The sedimentation rate of kaolin with the polyampholyte **C** was higher than that with the polyampholyte **D**. On the other hand, the sedimented volume of kaolin with the polyampholyte **C** was smaller than that with the polyampholyte **D**. In the flocculation of kaolin with the polyampholytes, no definite relation between the sedimentation rate and the sedimented volume was observed.

Effect of the Degree of Polymerization of the Polyampholytes on the Flocculation. Many investigators have reported that the flocculating ability increased with an increase in the degree of polymerization of polymeric flocculants.[13,14,17,18] The flocculation of the kaolin suspension was investigated with polyampholytes with different degrees of polymerization at pH 3. The results are shown in Fig. 9. Figure 9 shows that the flocculating ability of the polyampholytes increased with an increase in the degree of polymerization of the polymers, in the same manner as with cationic[13,14] or nonionic[17,18] polymeric flocculants. For comparison, the sedimentation rate and the sedimented volume of kaolin with Primafloc C-7,[19,20] which is a commercial cationic polymeric flocculant, *i.e.*, a polyvinylimidazoline with the molecular weight of more than a million, prepared by Rohm and Haas Co., America, are also shown in Fig. 9.

As has been mentioned above, the polyampholytes could be prepared by treating potassium polymethacrylate with **1** and the amine/acid ratio could be varied as desired to some extent by means of changing the reaction temperature. The polyampholytes can be expected to become a new type of polymeric flocculant, in which the chain expansion and the charge sign can be varied by changing the pH values of the solution.

N-Acylimidazoles-Trifluoroacetic Acid System as the Acylating Agent for Aromatic Hydrocarbons

Takashi KEUMI,* Hiroshi SAGA, and Hidehiko KITAJIMA

Department of Fiber and Dyestuff Chemistry, Faculty of Engineering, Fukui University, Bunkyo, Fukui 910

(Received September 20, 1979)

N-Benzoylimidazole in trifluoroacetic acid could benzoylate electron-rich aromatic compounds, such as durene, *p*-dimethoxybenzene, mesitylene, anisole, thiophene, and fluorene, to give the corresponding benzophenone derivatives in good yields. It was further elucidated, in the reaction of fluorene, that *N*-acylimidazoles composed of a variety of acyl groups also could be used for the ketone synthesis. Therein, the imidazolides of aliphatic carboxylic acids or substituted benzoic acids with an electron-donating group gave ketones in high yields. The above-mentioned aromatic compounds were also acylated with *N*-trifluoroacetylimidazole and free carboxylic acids in trifluoroacetic acid. The mechanism for these reactions was assumed to proceed *via* a mixed anhydride between trifluoroacetic acid and carboxylic acid.

Acylation is one of the most important reactions in organic chemistry. Many kinds of procedures for the acylation of hetero atoms of amines or alcohols, and for that of aliphatic carbons are available[1] but only a few routes for aromatic carbons are known. Of them, the Friedel-Crafts reaction using aluminum chloride as the catalyst is the most famous and the most useful.[2] However, the Friedel-Crafts acylation generally requires molar amounts of a catalyst which is a hygroscopic solid and which forms complexes with the product. A work-up, consequently, is needed to decompose these complexes, and the catalyst is usually non-recoverable. In addition, a large amount of hydrochloric acid evolves during the reaction and at the hydrolysis of the complexes. Therefore, the use of aluminum chloride as the catalyst for ketone synthesis is sometimes inconvenient, particularly when carrying out a large-scale reaction.

Recently, some methods capable of acylating aromatic hydrocarbons with a small amount of a catalyst or none at all have been developed.[3–5] Above all, it is very interesting, in the reports by Bourne[4] and Effenberger,[5] that a mixed anhydride of carboxylic acid with trifluoroacetic acid or trifluoromethanesulfonic acid can be used for the acylation of aromatic hydrocarbons without the use of aluminum chloride. We ourselves have previously reported that trifluoromethylsulfonyloxypyridine can be used for the condensation of carboxylic acid and aromatic hydrocarbon to give the ketone.[6] In the present paper, we will report that *N*-acylimidazoles are useful as acylating agents for some aromatic compounds in trifluoroacetic acid.

Results and Discussion

The chemistry of imidazolides has been well established and reviewed precisely by Staab.[8] *N*-Acylimidazoles generally are very powerful acylating agents for hetero atoms of alcohols or amines, but they can not be used with aromatic carbons. Ried and Shubert[9] attempted the application of *N*-acylimidazoles as the acylating agents in the Friedel-Crafts ketone synthesis, and they observed that the imidazolides were not more suitable than acyl chlorides or acid anhydrides for the reactions. We also attempted the benzoylation of fluorene with *N*-benzoylimidazole, using aluminum chloride as the catalyst in dichloromethane at room temperature, but little benzoylfluorene was obtained.

The enhanced reactivities of *N*-acylimidazoles to the hetero atoms can be explained as being due to the delocalization of the lone-pair electron of the amide-nitrogen to make up the aromatic sextet and the electron-withdrawing effects of the other one, behaving like pyridine-nitrogen.[8] If the imidazolide is used together with a strong Brönsted acid, the pyridine-like nitrogen is protonated to form an imidazolium ion, so the electrophilicity of the acyl group might be increased. Thus, we found that *N*-acylimidazoles could acylate aromatic hydrocarbons in conjunction with trifluoroacetic acid to give ketones in good yields. For example, 2-benzoylfluorene was isolated in a yield of 80% by heating under reflux for 5 h a mixture of fluorene, *N*-benzoylimidazole, and trifluoroacetic acid in a molar ratio of 1: 1.2: 10 respectively. Under the same conditions, other aromatic compounds, such as durene, *p*-dimethoxybenzene, anisole, mesitylene, and thiophene, were benzoylated to give the corresponding ketones in good yields. However, benzophenone could not be obtained by this procedure. The results are summarized in Table 1 (Method A).

The validity of *N*-acylimidazoles as the acylating agent for aromatic substrates was further investigated by an examination of the reaction of fluorene with a wide variety of *N*-acylimidazoles. The results are summarized in Table 2 (Method A). The reactions were carried out under the same conditions, that is, by heating, under reflux for 10 h, a mixture of fluorene, *N*-acylimidazole, and trifluoroacetic acid in a molar ratio of 1: 1.2: 10 respectively.

All the imidazolides, except for *N*-(*p*-nitrobenzoyl)-imidazole, gave the corresponding 2-acylfluorenes in satisfactory yields. The imidazolides of aliphatic carboxylic acids or aromatic carboxylic acids containing an electron-donating group gave 2-acylfluorenes in especially high yields. Although we can not discuss the results in detail, for this work is not a quantitative one, the Hammett plots for the logarithm of ketone yields indicated a correlation with the reaction constant of -1.62 ($r=0.872$, $n=8$). If the *N*-acylimidazole generates an acyl cation which attacks the aromatic nucleus, as in usual Friedel-Crafts reactions, or if the acyl group of the imidazolide attacks directly through a cooperative activation by trifluoroacetic acid (Eq. 1

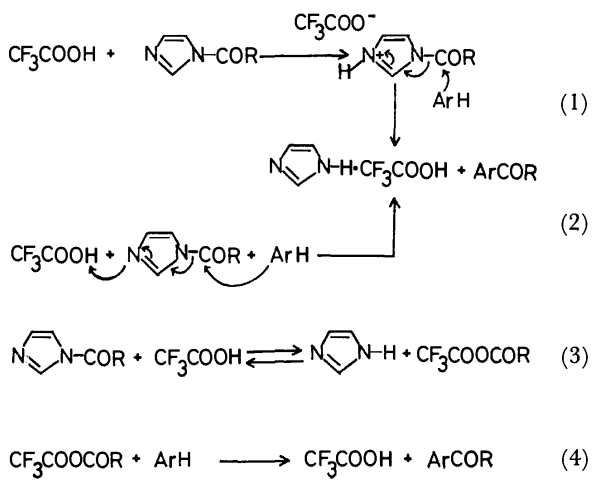
a) The remainder was the unreacted fluorene.



or 2), the reaction constant should be a positive value, because the reaction constants for the aluminum chloride-catalyzed Friedel-Crafts benzoylation[10] and the hydrolysis of the *N*-benzoylimidazoles[11] have been reported to be +1.858 and +1.85 respectively. Hence, this reaction mechanism does not to be a direct electrophilic attack on the aromatic nucleus by either the acyl cation or the *N*-acylimidazole.

It is well known that imidazolides generally react with carboxylic acids to give acid anhydrides.[12] Furthermore, according to Bourne,[4] a mixed anhydride between trifluoroacetic acid and carboxylic acid can work as the acylating agent for some aromatic hydrocarbons in the presence of trifluoroacetic acid. Therefore, it can be considered that this kind of mixed anhydride, *i.e.*, carboxylic trifluoroacetic anhydride, could be yielded

at the first of the reaction and that it then attacks the aromatic carbon to give ketone (Eqs. 3 and 4). A cleavage of the carbon–oxygen bond between the trifluoroacetate and the acyl group would be involved in the transition state, so that the yield of the ketone would be lower in the reaction with mixed anhydrides containing a strong electron-withdrawing group, because the bond in such anhydrides is difficult to break down. If this assumption is correct, results similar to those observed above should be obtained in the reaction of an aromatic substrate with carboxylic acid and *N*-trifluoroacetylimidazole which affords the carboxylic trifluoroacetic anhydride according to Eq. 5:

(5)

Thus, the acylation reactions of aromatic compounds with *N*-trifluoroacetylimidazole and carboxylic acids were examined. The reactions were carried out by heating, under reflux for 10 h, a mixture of an aromatic substrate, carboxylic acid, and *N*-trifluoroacetylimidazole, in a molar ratio of 1: 1.2: 1.2 respectively, in trifluoroacetic acid. The results are summarized in Tables 1 and 2 (Method B).

As expected, the aromatic compounds shown in Table 1, except for toluene and *p*-xylene, were benzoylated in good yields with free benzoic acid and *N*-trifluoroacetylimidazole in trifluoroacetic acid. This method was also established to be useful in reactions with a variety of carboxylic acids. The substituent effects of substituted benzoic acids on the ketone yield were similar to those which were obtained in the reaction with the *N*-acylimidazole–trifluoroacetic acid system. Consequently, the acylation with the *N*-acylimidazole–trifluoroacetic acid system is considered to proceed *via* the carboxylic trifluoroacetic anhydride. It has already been shown by Bourne[4] that the mixed anhydride can be used as the acylating agent for some aromatic compounds. However, the use of the mixed anhydride as the starting material is, in general, troublesome because these compounds are sensitive to moisture and tend to be disproportionate.[13] In addition, excess trifluoroacetic anhydride must be used to prepare them. We have now established that we can acylate aromatic hydrocarbons with *N*-acylimidazoles in trifluoroacetic acid without the use of this kind of mixed anhydride nor trifluoroacetic anhydride. Trifluoroacetic acid, which is now very popular, has a moderate boiling point, making it easy to recover from the reaction mixture by distillation. *N*-Acylimidazoles can also be easily prepared and are relatively stable.

In conclusion, the *N*-acylimidazole–trifluoroacetic acid system seems to offer one method capable of acylating aromatic hydrocarbons without the use of the classical Friedel-Crafts catalyst. Above all, the *N*-trifluoroacetylimidazole–trifluoroacetic acid system is superior as a reagent for a condensation between aromatic compounds and free carboxylic acids to give aromatic ketones.

Experimental

Materials and Measurements. All the *N*-acylimidazoles used for the acylation were synthesized according to the procedure described in the literature.[7] All the other materials were commercially available and were purified, when necessary, by distillation or recrystallization. All the acylated products were identified by comparing their physical data with those of authentic samples synthesized by Classical Friedel-Crafts reactions. All the melting points are uncorrected. The infrared spectra were obtained on a Hitachi EPI-S2 model infrared spectrophotometer.

Method A; *Benzoylation of Anisole by* N-*Benzoylimidazole in Trifluoroacetic Acid.* To a mixture of 8.9 mmol of *N*-benzoylimidazole and 7.5 mmol of anisole, 5 ml of trifluoroacetic acid were added, after which the new mixture was heated under reflux for 5 h. After cooling, water was added. The resulting precipitates were collected by filtration, washed with water and aqueous sodium carbonate, and dried to obtain 1.54 g of crude benzoylanisole (mp 52—57 °C; 96% yield). Crystallization from ethanol gave pure *p*-methoxybenzophenone (1.38 g; mp 61—63 °C; 86% yield).

Butyrylation of Fluorene by N-*Butyrylimidazole in Trifluoroacetic Acid.* To a mixture of 6 mmol of fluorene and 7.2 mmol of *N*-butyrylimidazole, 5 ml of trifluoroacetic acid were added, after which the new mixture was heated under reflux for 5 h. After cooling, water was added to the mixture, the unreacted fluorene was distilled off with steam, and the residue was separated by filtration to obtain butyrylfluorene (1.37 g; mp 112—115 °C; 96% yield). Crystallization from ethanol gave 2-butyrylfluorene (mp 118—119 °C). Unreacted fluorene was recovered (3%) from the distillate.

Method B; *Benzoylation of Durene by* N-*Trifluoroacetylimidazole and Benzoic Acid in Trifluoroacetic Acid.* To a mixture of 7.5 mmol of durene, 9 mmol of benzoic acid, and 5.5 ml of trifluoroacetic acid, 9 mmol of *N*-trifluoroacetylimidazole were added, after which the new mixture was heated under reflux for 10 h. Then water was added, and the resulting precipitates were collected by filtration, washed with water, and dried to obtain benzoyldurene (1.76 g; mp 118—120 °C; 99% yield). Crystallization from ethanol gave 3-benzoyldurene (mp 119—120 °C).

Butyrylation of Fluorene by N-*Trifluoroacetylimidazole and Butyric Acid in Trifluoroacetic Acid.* To a mixture of 6 mmol of fluorene, 7.2 mmol of butyric acid, and 5 ml of trifluoroacetic acid, *N*-trifluoroacetylimidazole (7.2 mmol) was added, after which the new mixture was heated under reflux for 5 h. After cooling, water was added to the mixture, then, after the unreacted fluorene had beed distilled off with steam, the residue was collected by filtration, washed with water, and dried to obtain butyrylfluorene (1.30 g; mp 112—114 °C; 92% yield). Crystallization from ethanol gave 2-butyrylfluorene (mp 118—119 °C). Unreacted fluorene was recovered in a 7% yield from the distillate.

Stereochemistry of Nucleophilic Addition Reactions. VIII.[1] Preparation of 1,5-Anhydro-4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-D-*erythro*-hex-2-enitol and Its Reactions with Some Nucleophiles

Tohru SAKAKIBARA,* Yutaka NOMURA, and Rokuro SUDOH

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received October 15, 1979)

The title compound was synthesized from 1,5-anhydro-D-glucitol *via* nitromethane cyclization. The reduction of the compound with sodium borodeuteride afforded a mixture of saturated nitro compounds having an axial and equatorial deuterium atom at C-2 in an approximate ratio of 2: 1. On the other hand, the reaction with hydrogen cyanide gave predominantly the adduct with the *manno* configuration, together with small amounts of a cyano olefin. The reaction with hydrazoic acid yielded addition products with the *gluco* and *manno* configurations; the ratio was strongly affected by the solvent used.

Our own studies of nucleophilic addition reactions to methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-β-D-*erythro*-hex-2-enopyranoside (**1**)[2] and its α-anomer **2**,[3] 1-*O*-acetyl-4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-β-D-*erythro*-hex-2-enopyranose (**3**), and its α-anomer **4**,[4] and methyl 6-*O*-benzoyl-2,3-dideoxy-α-D-*glycero*-hex-2-enopyranosid-4-ulose,[5] as well as other reports,[6] strongly suggest that these reactions are controlled by steric hindrance, stereoelectronic control, and electrostatic interaction. In the reactions of **1** with nucleophiles, we have proposed an important role of electrostatic interaction between the incoming nucleophile and both C_1–O_1 and C_1–O_5 bonds.[2a] If a nucleophile is an anion or has nonbonded electron pairs, electrostatic repulsion becomes the decisive factor, but if a nucleophile is electronically neutral, it becomes less important and the reaction is probably controlled by other factors. Furthermore, if a nucleophile has a cationic part, attractive forces such as hydrogen bonding may be operative. On the basis of this surmise, we can explain the results of many reactions.

In order to confirm this surmise and to elucidate whether or not both C_1–O_1 and C_1–O_5 bonds are required to control the approach of a nucleophile at C-2, we have synthesized the title compound **8** and performed some nucleophilic addition reactions.

Results and Discussion

Oxidation of 1,5-anhydro-D-glucitol (**5**)[7] with sodium metaperiodate, followed by nitromethane cyclization in the presence of catalytic amounts of sodium methoxide, afforded a syrup, the subsequent benzylidenation of which gave 1,5-anhydro-4,6-*O*-benzylidene-3-deoxy-3-nitro-D-glucitol (**6**) in 40% yield from **5**. Acetylation of **6** with pyridine–acetic anhydride or sodium acetate–acetic anhydride afforded the acetate **7** in good yield. In contrast to the corresponding methyl α-[8] and β-pyranoside,[9] treatment of **7** with sodium hydrogencarbonate in refluxing benzene caused a partial double-bond migration from C-2 to C-1, giving the glucal **9** besides the desired nitro olefin **8**, before the completion of the elimination of acetic acid. The double-bond migration was observed even when **8** was warmed in a methanol–DMSO solution at 50 °C. The reaction, therefore, was stopped at the stage where the intensities of the absorption bands of the unsaturated and saturated nitro groups were nearly equal in the IR spectrum. After the separation of most **7** by crystallization from carbon tetrachloride, these compounds were separated by column chromatography. The nitro olefin structure for **8** was deduced from elemental analysis, IR (1525 cm^{-1} conjugated nitro olefin), and the NMR spectrum (olefinic proton at δ 7.00 in chloroform-*d*). The glucal structure for **9** was determined from the IR (1640 and 1560 cm^{-1} nonconjugated carbon–carbon double bond and saturated nitro group respectively) and the NMR spectrum (olefinic proton at δ 6.48 and 4.37 in chloroform-*d*), together with elemental analysis.

17

Selective reduction of the double-bond moiety of **1** and **2** was achieved by Baer and Rank; however, its stereochemistry was not investigated.[10] Reduction of **1** and **2** with sodium borodeuteride in methanol-d_4 exclusively afforded the saturated nitro compounds, **10** and **11**, respectively. The signals for the H-1 of **10** and **11** appeared as doublets with splitting of 9.8 and <1.0 Hz respectively. A similar reduction of the 2-deuterated derivative of **2** with sodium borohydride afforded the compound **12** ($J_{1,2}$=3.5 Hz).[11] These results showed that the deuteride ion exclusively entered from the opposite side of the glycosidic group. An

a) Me_4Si as the internal standard; (se) and (o) indicate sextet and octet respectively. b) This compound was recorded in benzene-d_6. c) $\delta=1.78$ (o, 1, H-2a) and 1.34 (m, 1, H-2e); $J_{1a,2e}=2.5$, $J_{1e,2a}=5.2$, $J_{1e,2e}=1.5$, and $J_{2a,2e}=12.7$ Hz. d) The assignments of H-1a and H-1e were tentative.

important role of the anomeric methoxyl group in such a highly stereoselective reduction was proved by a similar reduction of **8**, in which a mixture of saturated nitro compounds with axial and equatorial deuterio groups was formed in an approximate ratio of 2: 1, as judged from the NMR spectrum. It is noteworthy that the C-3 position of the crude product, produced by sodium borodeuteride reduction of **1** in methanol-d_4, was also deuterated; however, this deuterium atom was exchanged for a hydrogen atom after purification by column chromatography on silica gel.

On the other hand, a selective axial approach, as in the cases of **2**[3a] and **4**,[4] was observed in the reaction of **8** with hydrogen cyanide. When the nitro olefin **8** was treated with hydrogen cyanide in acetonitrile in the presence of small amounts of aqueous potassium cyanide, three products were formed which were detectable by TLC and NMR spectroscopy. Separation by column chromatography afforded the *manno* isomer **16** as the major product, together with trace amounts of an unidentified product and a cyano olefin **17**. The *manno* configuration for **16** was deduced from the NMR data, analyzed by the help of the decoupling technique; $J_{1a,2}=2.2$, $J_{1e,2}=1.9$, $J_{2,3}=5.2$, and $J_{3,4}=10$ Hz. The structure of the cyano olefin **17**, which was obtained in good yield by treatment of **16** with triethylamine, was determined from the IR (2210 cm^{-1}; CN) and NMR data (olefinic proton at δ 3.76). This reaction was proved to be insensitive to the solvents used (THF, dioxane, acetonitrile, and DMF), giving the *manno* isomer **16** as the major product. When trace amounts of triethylamine were used as a catalyst, double-bond migration predominantly occurred to give the glucal **9**, together with small amounts of the addition products, as judged from the NMR spectrum.

More complicated results were obtained in the reaction of **8** with hydrazoic acid. Treatment of **8** with hydrazoic acid in THF afforded a mixture of the *manno* **18** and the *gluco* isomer **19** in an approximate ratio of 1.2: 1, as judged by NMR spectroscopy. Under the

TABLE 2. SOLVENT EFFECTS ON THE REACTION OF **8** WITH HYDRAZOIC ACID[a]

Entry	Solvent (ml)		Product ratios 0.5 h	1.5 h	5 h	20.5 h[b]
1	Benzene	(0.15)	r	r	r	r

3	$CDCl_3$	(0)[c]	r	r	r (t of **19**)	8 : 1 (t of **8**)
4	THF	(0.15)	r	1 : 1.2 (70% r)	1 : 1.2 (55% r)	1 : 1.2
5	Acetone-d_6	(0.15)	1 : 1.2 (70% r)	1 : 1.2 (35% r)	1 : 1.2	1 : 1.2
6	DMSO-d_6	(0.15)	1 : 5	1 : 5	1 : 5	1 : 5

a) The nitro olefin **8** (13 mg, 0.05 mmol) was treated with hydrazoic acid (*ca.* 0.08 mmol) in $CDCl_3$ (0.05 ml) in a NMR sample-tube at room temperature, and the ratio was determined by NMR spectroscopy. b) Reaction time. c) Without dilution, 0.2 ml of a $CDCl_3$ solution containing hydrazoic acid was used. d) r and t indicate recovery and trace amounts respectively.

same conditions, the reaction of **1**[12] and **3**[4] with hydrazoic acid exclusively affordcd the *gluco* isomer (90 and 84% yields respectively), whereas the same reaction of **2**[3a] and **4**[4] predominantly afforded the *manno* isomer (76 and 82% respectively). The present finding, therefore, indicated the important role of the substituent at the anomeric carbon for the approach of the azide ion to C-2.

Compounds **18** and **19** were separated by column chromatography on silica gel. The IR spectra of both compounds showed the presence of an azide (2110 cm^{-1}) and a nitro group (1560 cm^{-1}). The *manno* and *gluco* structures for **18** and **19** were assigned from the coupling constants; $J_{1a,2}=1.5$, $J_{1e,2}=2.0$, $J_{2,3}=3.7$, and $J_{3,4}=9.7$ Hz for **18** and $J_{1a,2}=12.5$, $J_{1e,2}=5.0$, $J_{2,3}=10$, and $J_{3,4}=10$ Hz for **19**.

As shown in Table 2, the product ratios and the rates were strongly affected by the solvents. In such a relatively nonpolar solvent as chloroform, the reaction did not occur even after 20.5 h (Entries 1 and 3); however, in the presence of excess hydrazoic acid (*ca.* 6 equiv.), it slowly proceeded to give the *gluco* isomer **19**, as the major product (Entry 3). On the other hand, in DMSO the reaction occurred readily to afford the *manno* isomer **18**, as the major product (Entry 6). Furthermore, in THF and acetone it was somewhat retarded, affording nearly equal amounts of **18** and **19** (Entries 4 and 5). Similar solvent effects had previously been observed in the case of **2**[3a] and **4**;[4] the exceptional, predominant formation of the *gluco* isomer in a chloroform solution was attributed to hydrogen bonding between hydrazoic acid and the oxygen atom (O-1) at the anomeric carbon atom. However, this explanation is not applicable to the present reaction, because compound **8** has no such oxygen atom. Presently we can not give any reasonable explanation of these solvent effects.

Because the reactions of the 1,5-anhydro sugar **8** as well as the α-anomers (**2** and **4**) with hydrazoic acid were affected by the solvents, the similar reaction of the β-anomer **1** was performed in several solvents (DMSO, THF, and chloroform). It was found to be insensitive to these solvents, affording exclusively the *gluco* isomer.

As had previously been described, nucleophiles predominantly entered from the axial side of **8**, except in one case, to give the *manno* isomer. Therefore, the stereoselective approach of nucleophile from the equatorial side of the β-anomers (**1** and **3**) requires, at least, an equatorially orientated anomeric methoxyl or acetoxyl group.

Experimental

The melting points were determined in capillaries and are uncorrected. The IR spectra were recorded on KBr discs with a Hitachi 215 IR spectrometer. The NMR spectra were determined for solutions in chloroform-*d* (tetramethylsilane as internal standard), unless otherwise noted, with a JNM-PS-100 (JEOL) spectrometer. The solutions were evaporated under reduced pressure. Column chromatography was carried out on silica gel (C-300, Wakogel, Japan). Silica gel CF-254 was used for the TLC.

*1,5-Anhydro-4,6-O-benzylidene-3-deoxy-3-nitro-*D*-glucitol (6).* A solution of sodium metaperiodate (47 g, 0.22 mol) in 300 ml of water was cooled in an ice–water bath, and then a mixture of 1,5-anhydro-D-glucitol (**5**) (16.4 g, 0.1 mol)[7] and sodium hydrogencarbonate (8.4 g, 0.1 mol) was added in portions over 20 min with stirring. The mixture was allowed to warm to 21 °C and was stirred for additional 3 h, and then the precipitated sodium iodate was removed by filtration. The filtrate was concentrated to a partly crystalline mass, to which 100 ml of ethanol was added. After the removal of the insoluble material, the solution was evaporated to a syrup, which was subsequently dissolved in ethanol; the solution was then filtered from the remnant salt and evaporated. This procedure was repeated if the dissolution of the resulting syrup in ethanol caused an appreciable quantity of salt to separate. The syrupy dialdehyde was dissolved in 200 ml of methanol, and 6 ml (0.11 mol) of nitromethane was added. This solution was cooled in an ice–water bath, and 1 mol dm^{-3} sodium methoxide was added until the solution showed pH 9. The solution was brought to 21 °C, kept at that temperature for overnight, and then deionized by Amberlite IR-120 (H^+) cation-exchange resin. After the removal of the resin, the solution was evaporated completely to a syrup, the IR spectrum of which showed the presence of a nitro group (1560 cm^{-1}). Without further purification, the syrup was benzylidenated. Powdered anhydrous zinc chloride (26 g) was added to a flask containing the syrup and benzaldehyde (60 ml). The mixture was stirred at 21 °C for 20 h and then poured into a solution of water (100 ml) and hexane (250 ml) with stirring, whereby the crude acetal was precipitated. The precipitate was washed well with water and hexane. Recrystallization from ethanol afforded 11.8 g of **6** (40.4% from **5**); mp 154—155.5 °C; $[\alpha]_D^{21}$ −36.2 (*c* 1, $CHCl_3$); IR 3545, 3450, 3210 (OH), and 1555 cm^{-1} (NO_2).

Found: C, 55.57; H, 5.43; N, 5.13%. Calcd for $C_{13}H_{15}NO_6$: C, 55.51; H, 5.38; N, 4.98%.

*2-i-O-Acetyl-1,5-anhydro-4,6-O-benzylidene-3-deoxy-nitro-*D*-glucitol (7).* *a*): A solution of **6** (9 g, 0.032 mol) in 90 ml of anhydrous pyridine was cooled in an ice–water bath, and to this solution was added slowly 26 ml of acetic anhydride. The mixture was brought to 21 °C, kept at that temperature for 3 h, and then poured into 300 ml of ice–water. The precipitate was filtered and washed with water. Recrystallization from ethanol gave 7.6 g (73.8%) of **7**; mp 199—199.5 °C; $[\alpha]_D^{21}$ −31.7° (*c* 1, $CHCl_3$); IR 1760 (CO) and 1560 cm^{-1} (NO_2).

Found: C, 56.04; H, 5.36; N, 4.37%. Calcd for $C_{15}H_{17}NO_7$: C, 55.72; H, 5.30; N, 4.33%.

b): The nitro alcohol **6** (100 mg, 0.36 mmol) and sodium acetate (200 mg) in acetic anhydride (2 ml) were heated at *ca.* 100 °C for 5 min, until the solution turned orange. The mixture was then poured into ice–water, and the precipitate that separated was collected and washed with water. Recrystallization from ethanol gave 64 mg (55.6%) of **7**.

Elimination of Acetic Acid from the Acetate **7**. The acetate **7** (646 mg, 2 mmol, desiccator-dried) and sodium hydrogencarbonate (1.5 g, desiccator-dried) were added to distilled benzene (10 ml). The mixture was heated under reflux with stirring. From time to time, a small test sample was withdrawn from the supernant solution and allowed to evaporate on a sodium chloride plate for inspection by means of IR spectroscopy. A gradual decrease in the relative intensity of the carbonyl band at 1760 cm^{-1} and a gradual increase in the nitro olefin band at 1530 cm^{-1} and in the carbon–carbon double bond at 1635 cm^{-1} indicated that the isomerization of **8** to **9** occurred before the completion of the elimination of acetic acid. When the intensities of the bands of the unsaturated and saturated nitro group were almost the same

(*ca.* 7 d), the reaction was stopped. After cooling, the inorganic material was filtered off and washed with acetone. The filtrate was evaporated to give a solid residue (610 mg). Most of the starting material, **7** (270 mg), was removed by the addition of carbon tetrachloride (10 ml), followed by filtration. The filtrate was evaporated and chromatographed on silica gel, eluting with benzene. Each fraction was inspected by IR spectroscopy. The first fraction consisted of 90 mg of crystalline **9**, which was recrystallized from diisopropyl ether; 79 mg (15%); mp 90.0—91.0 °C; $[\alpha]_D^{21}$ −158° (*c* 1, $CHCl_3$); IR 1635 (C=C) and 1550 cm^{-1} (NO_2); R_f 0.61 (benzene)

Found: C, 59.09; H, 4.98; N, 5.21%. Calcd for $C_{13}H_{13}NO_5$: C, 59.31; H, 4.98; N, 5.32%.

The second fraction was a mixture of **8** and **9** (52 mg) (1.5: 1 from NMR spectroscopy).

The third fraction consisted of 145 mg of **8**, which was recrystallized from diisopropyl ether; 128 mg (24.3%); mp 87.5—88.0 °C; $[\alpha]_D^{21}$ −238° (*c* 1, $CHCl_3$); IR 1530 cm^{-1} (NO_2); R_f 0.36 (benzene).

Found: C, 59.57; H, 5.03; N, 5.26%. Calcd for $C_{13}H_{13}NO_5$: C, 59.31; H, 4.98; N, 5.32%.

The fourth fraction consisted of 35 mg of **7** (total 305 mg, 47.2%); R_f 0.28 (benzene).

*Reduction of the Nitro Olefiins **1**, **2**, and **8** with Sodium Borodeuteride.* To a solution of **1** (20 mg, 0.07 mmol) in methanol-d_4 (0.4 ml) was added sodium borodeuteride (5 mg, 0.12 mmol) at 21 °C. The mixture was allowed to stand for 20 min and then concentrated. The NMR spectrum of the crude product showed that it was deuterated both at C-2 (equatorial position) and C-3; NMR δ=4.55 (d, 1, $J_{1,2}$=9.8 Hz, H-1), 2.18 (d, 1, H-2a) and 4.17 (d, 1, $J_{4,5}$=9.7 Hz, H-4). The crude product was chromatographed on silica gel, eluting with benzene-ethyl acetate (10: 1, v/v), to give 17 mg (84%) of **10**; NMR δ=4.55 (d, 1, $J_{1,2}$=9.8 Hz, H-1), 2.18 (q, 1, $J_{2,3}$= 11.9 Hz, H-2a), 4.78 (q, 1, $J_{3,4}$=9.7 Hz, H-3), 4.17 (t, 1, $J_{4,5}$=9.7 Hz, H-4), 3.46 (m, 1, H-5), 3.86 (t, 1, $J_{5,6a}=J_{6a,6e}$= 10.4 Hz, H-6a), and 4.38 (q, 1, $J_{5,6e}$=4.5 Hz, H-6e).

A similar reduction of **2** (20 mg) afforded **11** in 91% yield (after purification with column chromatography); NMR δ= 4.87 (broad s, 1, $J_{1,2}$ <1.0 Hz, H-1), 2.46 (broad d, 1, $J_{2,3}$= 5.2 Hz, H-2e), and 5.06 (q, 1, $J_{3,4}$=10 Hz, H-3).

A similar reduction of methyl 4,6-*O*-benzylidene-2,3-dideoxy-2-deuterio-3-nitro-α-D-*erythro*-hex-2-enopyranoside (20 mg)[13] with sodium borohydride (5 mg) yielded **12** (89%, after column chromatography); NMR (60 MHz) δ=4.85 (d, 1, $J_{1,2}$=3.5 Hz, H-1), 2.34 (q, 1, $J_{2,3}$=11.2 Hz, H-2a), and 5.04 (q, 1, $J_{3,4}$=9.7 Hz, H-3).

A similar reduction of **8** (56.3 mg. 0.21 mmol) with sodium borohydride (15.6 mg, 0.41 mmol) in methanol (1.2 ml) afforded 45 mg (79%) of a syrup (after column chromato, graphy). Crystallization from diisopropyl ether–hexane afforded 30 mg (52.6%) of **15**; mp 71—71.5 °C; $[\alpha]_D^{24}$ −26° (*c* 0.5, $CHCl_3$); IR 1545 cm^{-1} (NO_2); R_f 0.41 (benzene).

Found: C, 58.84; H, 5.70; N, 5.14%. Calcd for $C_{13}H_{15}NO_5$: C, 58.86; H, 5.70; N, 5.28%.

A similar reaction of **8** (18 mg, 0.07 mmol) with sodium borodeuteride (5 mg) afforded a mixture (14 mg) of **13** and **14** as a syrup. Although the H-2a and H-2e signals overlap in chloroform-*d*, they separate in benzene-d_6; the ratio of **13**: **14**=2: 1 was determined. The assignment of the signals of these compounds was performed by comparison with the deuterated and the corresponding undeuterated products.

*1,5-Anhydro-4,6-O-benzylidene-2-cyano-2,3-dideoxy-3-nitro-D-mannitol (**16**).* To an acetonitrile solution (3.3 ml) containing hydrogen cyanide (*ca.* 6 equiv.) was added **8** (78.9 mg, 0.3 mmol) and an aqueous solution of potassium cyanide (0.06 ml, 1.9 mg) at 28 °C. The mixture was stirred at the ambient temperature for 2.5 h and then evaporated to give a residue. The residue was dissolved in chloroform and washed with water. The organic layer was evaporated to give a residue, which was subsequently crystallized from ethanol to give 74 mg of **16**. Recrystallization from isopropyl alcohol afforded 65 mg (74.7%) of **16**; mp 124—125 °C; $[\alpha]_D^{20}$ −154° (*c* 1, $CHCl_3$); IR 2230 (CN) and 1565 cm^{-1} (NO_2); R_f 0.41 (benzene–ethyl acetate, 10: 1, v/v).

Found: C, 57.75; H, 4.93; N, 9.63%. Calcd for $C_{14}H_{14}N_2O_5$: C, 57.93; H, 4.86; N, 9.65%.

The mother liquor was concentrated and chromatographed on silica gel, eluting with benzene–ethyl acetate (30: 1, v/v); the first fraction consisted of 6 mg of **17**, which was found to be identical with an authentic sample by a comparison with the IR and NMR spectral data. The second fraction consisted of 5 mg of an undetermined product, although it seems to be the *gluco* isomer, as judged from IR and NMR spectroscopy. The third fraction was composed of 5 mg of **16** (total yield of **16**: 80.4%).

*1,5-Anhydro-4,6-O-benzylidene-2-cyano-2,3-dideoxy-D-erythro-hex-2-enitol (**17**).* To a solution of **16** (22 mg, 0.067 mmol) in acetone (1.5 ml) was added triethylamine (0.2 ml). The mixture was stirred at 30 °C for 6 h and then evaporated to give a solid residue (18.4 mg). Recrystallization from isopropyl alcohol gave 13 mg (70.6%) of **17**; mp 170.5—171.5 °C; $[\alpha]_D^{20}$ +36.9° (*c* 1, $CHCl_3$); IR 2210 cm^{-1} (CN); R_f 0.69 (benzene–ethyl acetate, 10: 1, v/v).

Found: C, 69.15; H, 5.37; N, 5.96%. Calcd for $C_{14}H_{13}NO_3$: C, 69.12; H, 5.39; N, 5.76%.

*Attempt at the Direct Preparation of **17** from **8**.* To an ice–water-cooled chloroform solution (2.1 ml) of **8** (13 mg, 0.05 mmol) containing hydrogen cyanide (5 equiv.) was added 0.02 ml of triethylamine. The mixture was kept for 23 h in a refrigerator and then washed with *ca.* 1 mol dm^{-3} HCl solution and water. The NMR spectrum of the crude product showed that it consisted of **9** (>60%) and small amounts of **16** and **17**.

*1,5-Anhydro-2-azido-4,6-O-benzylidene-2,3-dideoxy-3-nitro-D-mannitol (**18**) and glucitol (**19**).* *a) From the Nitro Olefin **8**:* To a solution of **8** (26.3 mg, 0.1 mmol) in acetone (0.5 ml) was added a chloroform solution containing hydrazoic acid (0.3 mmol) at 21 °C. The mixture was allowed to stand at that temperature for 21 h and then evaporated to give a syrup (30 mg), the NMR spectrum of which showed the presence of only **18** and **19** in a ratio of 1.2 : 1. The syrup (30 mg+28 mg) was chromatographed on silica gel, eluting with benzene; the first fraction consisted of 20 mg of NMR spectroscopically pure **19**. Recrystallization from ethanol gave 16 mg (26%) of **19**; mp 126.5—127.5 °C; $[\alpha]_D^{20}$ —66.9° (*c* 0.5, $CHCl_3$); IR 2110 (N_3) and 1560 cm^{-1} (NO_2); R_f 0.59 (benzene).

Found: C, 51.14; H, 4.48; N, 18.18%. Calcd for $C_{13}H_{14}N_4O_5$: C, 50.98; H, 4.61; N, 18.29%.

The second fraction was a mixture of **18** and **19** (8 mg).

The third fraction was composed of 28 mg of pure **18**, which crystallized from diisopropyl ether to afford 20 mg (32.7%) of **18**; mp 127.5—128.5 °C; $[\alpha]_D^{20}$ −170° (*c* 0.5, $CHCl_3$); IR 2100 (N_3) and 1560 cm^{-1} (NO_2); R_f 0.47 (benzene).

Found: C, 51.15; H, 4.50; N, 18.03%. Calcd for $C_{13}H_{14}N_4O_5$: C, 50.98; H, 4.61; N, 18.29%.

*b) From the Acetate **7**:* To a solution of **7** (83 mg, 0.26 mmol) in acetonitrile (4 ml)–water (0.5 ml) was added sodium azide (19 mg, 0.29 mmol). The mixture was stirred at 28 °C for 24 h and then evaporated to give a residue. The residue was dissolved in dichloromethane and washed with water.

The organic layer was dried over $MgSO_4$ and evaporated to give a solid residue, which was similarly chromatographed on silica gel to give a mixture (52 mg) of **18** and **19** (3.1: 1, as judged from NMR spectroscopy), besides the starting material (14 mg).

The Reaction of 2-Chloroazulene Derivatives with Lithium Acetylide in Liquid Ammonia

Tadayoshi MORITA, Taira FUJITA, and Kahei TAKASE*

Department of Chemistry, Faculty of Science, Tohoku University, Aramaki-aza-Aoba, Sendai 980

(Received October 18, 1979)

The reaction of diethyl 2-chloroazulene-1,3-dicarboxylate (**1a**) with lithium acetylide in liq ammonia gave diethyl 4- and 6-ethynylazulene-1,3-dicarboxylates by an abnormal substitution reaction. In a similar manner, some 2-chloroazulenes, possessing alkoxycarbonyl and/or cyano substituents at the 1- and 3-positions of azulene nucleus, gave the corresponding 4 (or 8)- and 6-ethynylazulenes. The same type reaction proceeded when lithium phenylacetylide, sodium indenide, and sodium fluorenide were used as the reagents, **1a** giving diethyl 4- and 6-(phenylethynyl)-, 6-(3-indenyl)-, and 6-(9-fluorenyl)azulene-1,3-dicarboxylates, respectively.

The halogeno substituents of haloazulenes are directly replaced by some nucleophilic reagents, such as alkoxides, amines, thiolates, or carbanions derived from active methylene compounds, to give the corresponding "normal substitution products."[1-3] On the other hand, no replacement of the chloro substituent occurred in the reaction of 2-chloroazulene derivatives with Grignard reagents.[4] Addition of the reagents took place at the 4- or 6-position with formation of the dihydrozulene-type addition products, whose dehydrogenation with tetrachloro-*o*-benzoquinone afforded 4- and 6-substituted azulene derivatives in which the chloro substituent at the 2-position remained.

We have recently found a third type of reaction of haloazulene derivatives with nucleophilic reagents; the reaction of 2-chloroazulene derivatives with alkali metal acetylide in liq ammonia yielded 4- and 6-ethynylazulene derivatives by an abnormal substitution reaction.[5] This paper describes the details of the reaction of 2-chloroazulene derivatives with lithium acetylide and its related carbanions in liq ammonia.

Results and Discussion

Diethyl 2-chloroazulene-1,3-dicarboxylate (**1a**),[2] when allowed to react with lithium acetylide in liq ammonia at −40 °C for 1 h, gave a mixture of diethyl 4- (**2a**) and 6-ethynylazulene-1,3-dicarboxylates (**3a**) in good yields. A similar result was obtained with use of sodium acetylide instead of lithium acetylide. 2-Chloroazulenes (**1b**, **1c**, **1d**, and **1e**) also readily reacted with lithium acetylide to give mixtures of isomeric 4-, 6-, and 8-ethynylazulenes (**2b**, **3b**, and **4b**), (**2c** and **3c**), (**2d** and **4d**), and (**2e** and **4e**), respectively. Each product was isolated from a mixture by silica-gel chromatography (Table 1).

The structures of the ethynylazulene derivatives were determined on the basis of spectral data (Tables 2, 3, and 4), as well as the results of elemental analyses. The electronic spectra indicate that the compounds are azulene derivatives.[6] The presence of the ethynyl group is shown by the sharp absorption bands in IR spectra corresponding to the $\nu_{C\equiv C}$ and $\nu_{\equiv CH}$ (ethynylic). The NMR spectra also reveal the singlets assignable to ethynylic protons. The positions of the substituents in the compound are deduced from the NMR signal patterns corresponding to the ring protons: an AA'BB'-type signal is found in the NMR spectra of symmetrical 6-ethynyl derivatives (**3a**, **c**) and two AB-type signals with long-range coupling in the unsymmetrical 6-ethynyl derivative (**3b**), together with a singlet due to H-2.

Table 1. Reaction of 2-chloroazulene derivatives with lithium acetylides

2-Chloro-azulene derivatives	Products (yield/%)		
	4-Ethynyl-	6-Ethynyl-	8-Ethynyl-
1a	**2a** (25.2)	**3a** (35.7)	
1b	**2b** (30.7)	**3b** (25.6)	**4b** (1)
1c	**2c** (44.5)	**3c** (4.9)

1e	**2e** (43.2)		**4e** (14.9)
1f		**3f** (58.3)	
1g		**3g** (39.9)	
1a	**5** (44.8)[a]	**6** (38.3)	

a) (Phenylethynyl)azulene.

On the other hand, a complex multiplet due to the adjacent four-proton system is found in the spectra of 4- (**2a**, **b**, **c**, **d**, **e**) and 8-ethynyl derivatives (**4b**, **d**, **e**), together with a singlet due to H-2 (**2a**, **b**, **c**) or an AB-type signal due to H-2 and H-3 (**2d**, **e** and **4d**, **e**). The structural correlations between pairs of the isomeric 4-ethynyl (**2b**, **d**, **e**) and 8-ethynyl derivatives (**4b**, **d**, **e**) were confirmed by the fact that the NMR peaks corre-

a) In chloroform.

sponding to H-8 of 4-ethynyl derivatives are found at lower field, because of the diamagnetic anisotropy due to the CO_2R or CN group in the peri-position, than those corresponding to H-4 of 8-ethynyl derivatives. In a similar manner to that of **1a**, 5-alkyl-2-chloroazulenes (**1f**[7] and **1g**[8]) also reacted with lithium acetylide to give the 6-ethynylazulenes (**3f**) and (**3g**), respectively. In these cases only 6-ethynyl derivatives, whose structures were confirmed by spectral data (Tables 2, 3, and 4), were obtained in spite of the presence of the alkyl group at the 5-position of the azulene nucleus.

From the results, it was found that the reaction of 2-chloroazulenes (**1a—g**) with lithium acetylide in liq ammonia gave no 2-ethynylazulene derivatives, normal substitution product, but 4(or 8)- and 6-ethynylazulenes, abnormal substitution products, which were formed in such a way that the reagent entering into a position not that at which the leaving chloro substituent was attached. A mechanism for this abnormal substitution reaction seems to involve the additional-elimination process (Scheme 1). The acetylide attacks 2-chloroazulenes (**1**) at the 4(or 8) or 6-position of the azulene nucleus to give an anionic intermediate (**A** or **A'**) of a cyclopentadienide structure. Such attack of the reagent would be facilitated by the aid of electron-withdrawing alkoxycarbonyl or cyano groups at the 1- and/or 3-positions, because of stabilization of the anion (**A** or **A'**). This is supported by the fact that 2-chloroazulene did not react with acetylide under the same conditions.

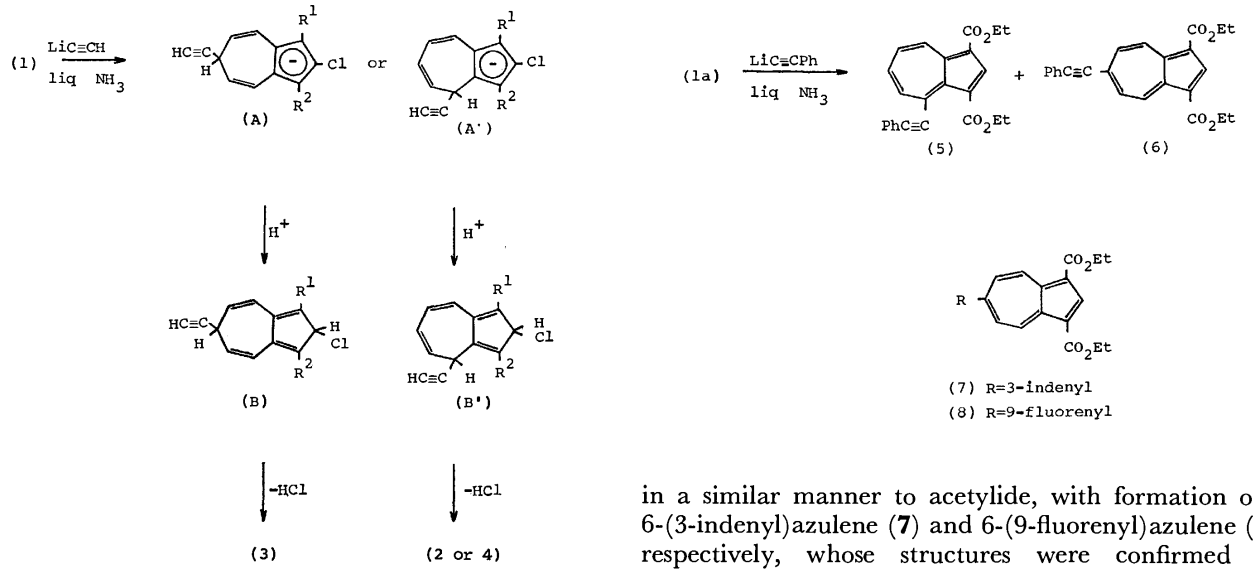

Scheme 1. A mechanism for the reaction of 2-Chloroazulene derivatives with lithium acetylide.

Dehydrochlorination from the protonated intermediate (**B** or **B'**), produced from the anion (**A** or **A'**) afforded 4(or 8)-ethyl- (**2** or **4**) or 6-ethynylazulenes (**3**). The same type of reaction proceeded when lithium phenylacetylide was used as a reagent instead of lithium acetylide; **1a** easily reacted with this reagent to give 4-(phenylethynyl)- (**5**) and 6-(phenylethynyl)azulene (**6**) in 44.8 and 38.3% yields, respectively. The structures of these products were determined on the basis of spectral data (Tables 2, 3, and 4).

Sodium indenide and fluorenide also reacted with **1a** in a similar manner to acetylide, with formation of a 6-(3-indenyl)azulene (**7**) and 6-(9-fluorenyl)azulene (**8**), respectively, whose structures were confirmed by spectral data (Experimental).

It is evident that such bulky groups could attack only the less hindered 6-position rather than the more hindered 4(or 8)-position with two ethoxycarbonyl groups in the peri-position.

Experimental

Melting points are uncorrected. The electronic spectra were measured on a Hitachi EPS-3 Spectrometer and IR spectra on a Shimadzu IR-27 infracord. The NMR spectra were measured with a Varian A-60D Spectrometer; in some cases on a JNM-100 instrument in the Fourier transform mode. TMS was used as an internal standard. The mass spectra were recorded on Hitachi RMU-6 mass spectrometer

at 25 eV. The THF employed was distilled from calcium hydride before use.

*Methyl 2-Chloro-3-cyanoazulene-1-carboxylate (**1b**).* Dry HCl gas was bubbled into a benzene solution (600 ml) of methyl 2-amino-3-cyanoazulene-1-carboxylate[9] (4.5 g, 19.9 mmol) at 5 °C for 15 min. To the solution was added isopentyl nitrite (4.5 g) with stirring. After stirring for 2 d at room temp, water (600 ml) was added to the mixture. The reaction mixture was extracted with benzene. The organic layer was washed with water, satd. $NaHCO_3$ aq, dried (Na_2SO_4), and evaporated to give a reddish brown residue. Chromatography (alumina, with benzene) of the residue gave **1b** (4.3 g, 87.95 mmol), red prisms (from ethanol), mp 207—209 °C; λ_{max} (chloroform), nm (log ε): 297 (4.89), 307 (4.98), 353 (4.15), 370 (3.99), 496 (3.09), 510 (3.08); IR (KBr) 2210 (C≡N), 1690 cm^{-1} (C=O); NMR ($CDCl_3$): δ 4.03 (s, CO_2Me), 7.67—8.27 (m, H-5,6, and 7), 8.72 (dm, J=10 Hz, H-4), 9.75 (dm, J=10 Hz, H-8). Found: C, 63.48; H, 3.14; N, 5.56%. Calcd for $C_{13}H_8ClNO_2$: C, 63.55; H, 3.28; N, 5.70%.

*2-Chloro-1,3-dicyanoazulene (**1c**).* A mixture of 1,3-dicyano-2-hydroxyazulene[10] (100 mg, 0.54 mmol), $POCl_3$ (5 ml), and a trace of pyridine was heated in a sealed tube at 150 °C for 8 h. After distillation of excess $POCl_3$, the residue was treated with ice and water, and extracted with a large amount of chloroform. The organic extract was washed with water, dried (Na_2SO_4), and concentrated. The residue was chromatographed on alumina with chloroform to give **1c** (84 mg, 73.4%), red prisms (from ethanol), mp over 300 °C. $\lambda_{max}^{chloroform}$ nm (log ε): 297 (4.70), 310 (4.83), 347 (3.89), 353 (3.89), 372 (3.71), 498 (2.86), 520 (2.85). IR (KBr): 2200 cm^{-1} (C≡N). Found: C, 67.67; H, 3.32; N, 13.36%. Calcd for $C_{12}H_5ClN_2$: C, 67.78; H, 3.37; N, 13.18%.

*2-Chloro-1-cyanoazulene (**1e**).* A mixture of **1b** (2.0 g) and 75% H_2SO_4 (40 ml) was heated at 70 °C until the evolution of CO_2 ceased, and the mixture was poured into ice and water, and then extracted with chloroform. The organic layer was washed with satd. NaCl aq, dried (Na_2SO_4), and concentrated to give a red residue. Chromatography of the residue on alumina with chloroform gave **1e** (1.3 g, 85%), red needles (from ethanol), mp 160—162 °C. $\lambda_{max}^{chloroform}$ nm (log ε): 290 (4.78), 303 (4.88), 340 (3.74), 353 (3.86), 365 (3.47), 520 (2.72), 550 (2.69). IR (KBr): 2200 cm^{-1} (C≡N). NMR ($CDCl_3$): δ 7.30 (s, H-3), 7.67—8.07 (m, H-5—7), 8.50 (dm, J=10 Hz, H-4), 8.70 (dm, J=10 Hz, H-8). Found: C, 70.74; H, 3.81; N, 7.49%. Calcd for $C_{11}H_6NCl$: C, 70.63; H, 3.21; N, 7.45%.

Reaction of 2-Chloroazulene Derivatives with Lithium Acetylides: General Procedure. The reaction of 2-chloroazulene derivatives with alkali metal acetylides was carried out as follows: A stream of acetylene gas was introduced into a blue colored fresh lithium metal in liq ammonia at −40 °C until the blue color of the solution disappeared. After stirring for 5 min, a solution of the 2-chloroazulene derivatives in dry THF was added to the solution of lithium acetylide. The mixture was kept at −40 °C for 1 h with stirring. Methanol was then added and excess ammonia was removed by evaporation at room temperature. The residue was mixed with ice–water, acidified slightly with 6 mol dm^{-3} HCl and extracted with benzene. The organic extract was washed with satd. $NaHCO_3$ aq, water, and dried (Na_2SO_4). The benzene solution, after concentration to a small volume, was chromatographed (silica gel, with benzene as an eluent). The yields of the ethynylazulene derivatives are given in Table 1, their electronic spectral data in Table 2, IR spectral data in Table 3, and NMR spectral data in Table 4.

*Reaction of **1a**[2] with Lithium Acetylide.* A solution of **1a** (550 mg, 1.8 mmol) in dry THF (30 ml) was treated with a lithium acetylide solution, prepared from lithium metal (69 mg, 10 mmol), liq NH_3 (20 ml) and gaseous acetylene. The reaction mixture was worked up. The first elution from chromatography afforded **3a** as reddish violet crystals (190 mg, 35.7%), which were recrystallized from ethanol to give reddish violet needles, mp 164—165 °C (Found: C, 73.14; H, 5.62%. Calcd for $C_{18}H_{16}O_4$: C, 72.96; H, 5.44%). The second elution gave **2a**, blue crystals (134 mg, 25.2%), which were recrystallized from ethanol to give blue prisms, mp 81—82 °C (Found: C, 72.65; H, 5.54%. Calcd for $C_{18}H_{16}O_4$: C,72.96; H, 5.44%). Treatment of **1a** (1.50 g, 4.89 mmol) with a sodium acetylide solution (prepared from 500 mg of sodium metal, 30 ml of liq NH_3, and acetylene) gave **3a** (580 mg, 40.0%) and **2a** (610 mg, 42.1%).

Reaction of **1b** (1.000 g, 4 mmol) in dry THF (50 ml) with lithium acetylide (prepared from 110 mg of Li, 30 ml of liq NH_3, and acetylene) yielded 245 mg (25.6%) of methyl 3-cyano-6-ethynylazulene (**3b**), violet needles, mp over 300 °C, from ethanol (Found: C, 76.97; H, 3.79; N, 6.03%. Calcd for $C_{15}H_9NO_2$: C, 76.58; H, 3.86; N, 5.96%), 295 mg (30.7%) of methyl 3-cyano-4-ethynylazulene-1-carboxylate (**2b**), violet needles, mp over 300 °C, from ethanol (Found: C, 76.45; H, 3.54; N, 6.02%. Calcd for $C_{15}H_9NO_2$: C, 76.58; H, 3.86; N, 5.96%), and 10 mg (1%) of methyl 3-cyano-8-ethynylazulene-1-carboxylate (**4b**), violet needles, mp over 300 °C, from ethanol[mass: *m/e* 235 (M^+, 100%)].

Reaction of 2-chloro-1,3-dicyanoazulene (**1c**) (426 mg, 2 mmol) with lithium acetylide (prepared from 42 mg of Li, 30 ml of liq NH_3, and acetylene) yielded 20 mg (4.9%) of 1,3-dicyano-6-ethynylazulene (**3c**), red prisms, mp over 300 °C, from ethanol (Found: C, 83.54; H, 3.02; N, 13.72%. Calcd for $C_{14}H_6N_2$: C, 83.15; H, 2.99; N, 13.85%) and 180 mg (44.5%) of 1,3-dicyano-4-ethynylazulene (**2c**), reddish violet prisms, mp over 300 °C, from ethanol (Found: C, 82.83; H, 3.06; N, 14.03%. Calcd for $C_{14}H_6N_2$: C, 83.15; H, 2.99; N, 13.85%).

Reaction of **1d** (702 mg, 3 mmol) in dry THF (30 ml) with lithium acetylide (prepared from 63 mg of Li, 20 ml of liq NH_3, and acetylene) gave 492 mg (73.2%) of ethyl 4-ethynylazulene-1-carboxylate (**2d**), violet needles, mp 60—61 °C, from light petroleum ether [mass: *m/e* 244 (M^+, 82.6%), 179 (M^+ −45, 100%), 152 (42.1%)] and 30 mg (4.5%) of ethyl 8-ethynylazulene-1-carboxylate (**4d**), blue oil [mass: *m/e* 244 (M^+, 100%)].

Reaction of **1e** (760 mg, 4 mmol) in dry THF (30 ml) with lithium acetylide (prepared from 100 mg of Li, 30 ml of liq NH_3, and acetylene) afforded 307 mg (43.2%) of 1-cyano-4-ethynylazulene (**2e**), blue needles, mp 150—153 °C, from ethanol [mass: *m/e* 177 (M^+, 100%)] and 107 mg (14.9%) of 1-cyano-8-ethynylazulene (**4e**), blue needles, mp 85—86 °C, from ethanol [mass: *m/e* 177 (M^+, 100%)].

Reaction of diethyl 2-chloro-5-methylazulene-1,3-dicarboxylate (**1f**)[7] (115 mg, 0.36 mmol) in 20 ml of THF with lithium acetylide (prepared from 10 mg of Li) yielded 965 mg (58.3%) of diethyl 6-ethyl-5-methylazulene-1,3-dicarboxylate (**3f**), reddish violet needles, mp 169—170 °C, from ethanol (Found: C, 73.31; H, 5.84%. Calcd for $C_{19}H_{18}O_4$: C, 73.53; H, 5.85%).

Reaction of diethyl 2-chloro-5-isopropylazulene-1,3-dicarboxylate (**1g**)[8] (1.050 g, 3 mmol) in 30 ml of THF with lithium acetylide (prepared from 63 mg of Li) yielded 407 mg (39.9%) of diethyl 6-ethynyl-5-isopropylazulene-1,3-dicarboxylate (**3g**), reddish violet needles, mp 122—123 °C, from ethanol (Found: C, 74.29; H, 6.43%. Calcd for $C_{21}H_{22}O_4$: C, 74.53; H, 6.55%).

Reaction of **1a** (3.00 g, 9.79 mmol) in 50 ml of THF with

phenylacetylide (prepared from 207 mg (29.5 mmol) of Li, 4.0 g of phenylacetylene, 30 ml of liq NH_3) gave 1.394 g (38.3%) of diethyl 6-(phenylethynyl)azulene-1,3-dicarboxylate (**6**), reddish violet needles, mp 160—161 °C, from ethanol (Found: C, 77.24; H, 5.73%. Calcd for $C_{24}H_{20}O_4$: C, 77.40; H, 5.41%) and 1.631 g (44.8%) of diethyl 4-(phenylethynyl)-azulene-1,3-dicarboxylate (**5**), bluish violet needles, mp 104—105 °C, from ethanol (Found: C, 77.24; H, 5.37%. Calcd for $C_{24}H_{20}O_4$: C, 77.40; H, 5.41%).

Diethyl 6-(3-Indenyl)azulene-1,3-dicarboxylate (7). A solution of **1a** (352 mg, 1.1 mmol) in 30 ml of THF was added with stirring to a solution of sodium indenide prepared from 138 mg of Na, 20 ml of liq NH_3, and 700 mg of indene in 50 ml of THF at −40 °C. After being stirred for 90 min, the reaction mixture was quenched with 30 ml of MeOH and worked up. The first elution from chromatography gave unreacted indene. The second elution gave 222 mg (52.3%) of **7**, red prisms, mp 130—131 °C, from ethanol, $\lambda_{max}^{chloroform}$ nm (log ε): 247 (4.48), 268 (4.44), 309 (4.63), 348 (4.39), 372 (4.29), 516 (2.91), 552 (2.80 sh), 605 (2.42 sh); IR (KBr): 1680 (C=O), 1195 (C–C(=O)–O), 1039 (O–C–C) cm^{-1}; NMR ($CDCl_3$): δ 1.45 (t, J=7.0 Hz, 2 $OCH_2C\underline{H}_3$), 4.45 (q, J=7.0 Hz, 2 $OC\underline{H}_2CH_3$), 3.58 (2H, d, J=2.0 Hz, H-1′), 6.80 (d, J=2.0 Hz, H-2′), 7.67—7.25 (4H, m, phenyl protons), 7.97 (br d, J=11.0 Hz, H-5,7), 8.83 (s, H-2), 9.80 (br d, J=11.0 Hz, H-4,8). Found: C, 77.34; H, 5.76%. Calcd for $C_{25}H_{22}O_4$: C, 77.70; H, 5.74%.

Diethyl 6-(9-Fluorenyl)azulene-1,3-dicarboxylate (8). A solution of **1a** (306 mg, 1 mmol) in 20 ml of THF was added with stirring to a solution of sodium fluorenide prepared from 75 mg of Na, 20 ml of liq NH_3, and 500 mg of fluorene in 20 ml of THF at −40 °C. After being stirred for 1h, the reaction mixture was worked up. The first elution from the chromatography gave 108 mg (18.5%) of **8**, red prisms, mp 192—193 °C, from cyclohexane. λ_{max}^{MeCN} nm (log ε): 233 (4.71), 270 (4.66), 310 (4.79), 375 (3.42), 500 (2.88). IR (KBr): 1684 (C=O), 1208 (C–C(=O)–O), 1028 (O–C–C) cm^{-1}. NMR ($CDCl_3$): δ 1.40 (t, J=7.0 Hz, 2 $OCH_2C\underline{H}_3$), 4.36 (q, J=7.0 Hz, 2 $OC\underline{H}_2CH_3$), 5.18 (s, H-9′), 7.00—7.37 (6H, m, H-2′—7′), 7.83 (m, H-1′, 8′), 7.35 (br d, J=11.0 Hz, H-5,7), 8.76 (s, H-2), 9.51 (br d, J=11.0 Hz, H-4,8). Found: C, 79.60; H, 5.49%. Calcd for $C_{26}H_{24}O_4$: C, 79.79; H, 5.54%.

The Reactions of (1-Halo-1-alkenyl)dialkylboranes with Lead(IV) Acetate or (Diacetoxyiodo)benzene. A Stereoselective Synthesis of 1-Halo-1,2-dialkylethylenes

Yuzuru Masuda, Akira Arase,* and Akira Suzuki**

(Received October 30, 1979)

The reaction of (1-halo-1-alkenyl)dialkylboranes with lead(IV) acetate or (diacetoxyiodo)benzene was studied. (1-Bromo-1-alkenyl)dialkylboranes gave 1-bromo-1,2-dialkylethylenes. When alkyl groups on the boron atom of vinylboranes were bulky or the reaction temperatures were low, *Z*-isomers were afforded, whereas when alkyl groups on the boron atom were small or the reaction temperatures were relatively high, *E*-isomers were afforded as the main products. (1-Chloro-1-alkenyl)dialkylboranes gave (*Z*)-1-chloro-1,2-dialkylethylenes regardless of the reaction conditions. (1-Iodo-1-alkenyl)dialkylboranes failed to give satisfactory yields of 1-iodo-1,2-dialkylethylenes.

The authors previously reported a stereospecifically defined synthesis of 1-bromo-1,2-dialkylethylenes by the reaction of (1-bromo-1-alkenyl)dialkylboranes with lead(IV) acetate (LTA) or (diacetoxyiodo)benzene (DIB).[1]

$$R_2BCBr{=}CHR' \xrightarrow{Pb(OAc)_4 \text{ or } PhI(OAc)_2} RCBr{=}CHR' \ (Z \text{ or } E)$$

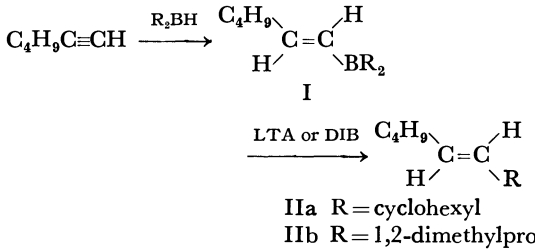
Alkenyl halides are potentially important compounds in organic synthesis because of their wide use as reaction intermediates for introduction of some substituents to alkenyl group *via* alkenylmagnesiums,[2] lithiums,[3] and coppers.[4] Several synthetic methods for alkenyl halide have hitherto been reported. Brown and his co-workers described a route to terminal and internal alkenyl halides from alkynes by the reaction of alkenyldialkylborane[4] and alkenylboronic ester[5] with molecular halogen. In these reactions, "anti-Markownikoff" addition of hydrogen halide to alkyne was realized. On the other hand the reaction reported by us,

$$RC{\equiv}CR' \xrightarrow{HBR_2''} RCH{=}CR'BR_2'' \xrightarrow{X_2} RCH{=}CR'X$$

involves a migration of an alkyl group from the boron atom to the alkenyl carbon atom. Thus the latter reaction has a great advantage in that the several types of internal alkenyl bromide can be synthesized almost arbitrarily by selecting the combination of starting alkyne and alkene. Thus in this report, more detailed studies including some related reactions are presented.

Results and Discussion

The reactions of organoborane with oxidizing agents at times give peculiar reaction products. Among those, the reaction with LTA or DIB is one of interesting classes, because in the reaction with such reagent, trialkylborane affords corresponding alkyl acetate,[6] whereas in the reaction of 1-alkenyldialkylborane (I) an intramolecular migration of one alkyl group from boron atom to the alkenyl carbon atom adjacent to the boron atom occurs to give a corresponding *E*-alkene (II) (Table 1).



IIa R = cyclohexyl
IIb R = 1,2-dimethylpropyl

Although stereoselective syntheses of internal alkene from alkenyldialkylboranes have been achieved by Zweifel *et al.*,[7] Negishi *et al.*,[8] and Yatagai *et al.*,[9] these reactions are carried out under strong basic conditions. Consequently, they can not be used when organoboranes have alkyl groups sensitive to base. In contrast, there are no problems even for such organoboranes in the present reaction, because the reaction proceeds under almost neutral conditions. Further, our findings suggest the possibility that a combination of alkyl group with haloalkenyl group occurs by the reaction of (1-halo-1-alkenyl)dialkylboranes with above reagents.

Thus, 1-bromo-1-hexyne, readily prepared from 1-hexyne in a high yield,[10] was hydroborated by dicyclohexylborane or bis(1,2-dimethylpropyl)borane to (1-bromo-1-hexenyl)dialkylborane (III),[7a,8] and LTA or DIB was added to the reaction mixture. As was expected, (*Z*)-1-bromo-1-cyclohexyl-1-hexene (IVa) or 4-bromo-2,3-dimethyl-4-nonene (IVb) was obtained in a moderate yield with a high stereoselectivity (Table 2).

Table 1. Reaction[a] of 1-hexenyldialkylboranes with LTA or DIB

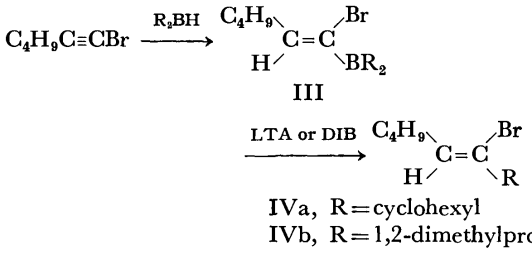
R	Reagent	Solvent	Product (*E* : *Z*)	Yield/%[b]
Cyclohexyl	DIB	$CHCl_3$	IIa (92 : 8)	60 (54)[c]
	LTA	C_6H_6	IIa (85 : 15)	45
1,2-Dimethylpropyl	LTA	CH_2Cl_2	IIb (93 : 7)	53 (50)[c]

a) Carried out at 0—25 °C for 4 h. Mole ratio; organoborane/reagent=1. b) Determined by GLPC based on BH_3 employed. c) Isolated by elution with hexane on silica-gel column.

Table 2. Reaction[a] of (1-bromo-1-hexenyl)dialkylboranes, derived from sterically hindered olefin, with LTA or DIB

R	Reagent	Solvent	Temp/°C	Time/h	Product (Z : E)	Yield/%[b]
Cyclohexyl	DIB	CH_2Cl_2	0	4	IVa (95 : 5)	55 (51)[c]
	DIB	CH_2Cl_2	−25	4	IVa (98 : 2)	58 (54)[c]
	LTA	CH_2Cl_2	−50	8	IVa (98 : 2)	43
1,2-Dimethylpropyl	DIB	CH_2Cl_2	−25	4	IVb (96 : 4)	42
	LTA	CH_2Cl_2	−50	8	IVb (98 : 2)	56 (50)[c]
	LTA	C_6H_6 / n-C_6H_{14}	0	4	IVb (97 : 3)	40

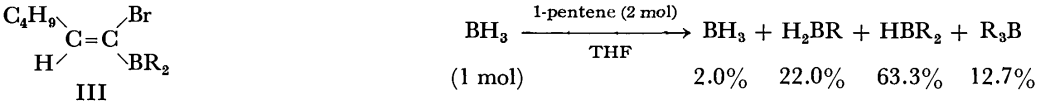
a) Mole ratio; organoborane/reagent=1. b) Determined by GLPC based on BH_3 employed.
c) Isolated by elution with hexane on silica-gel column.



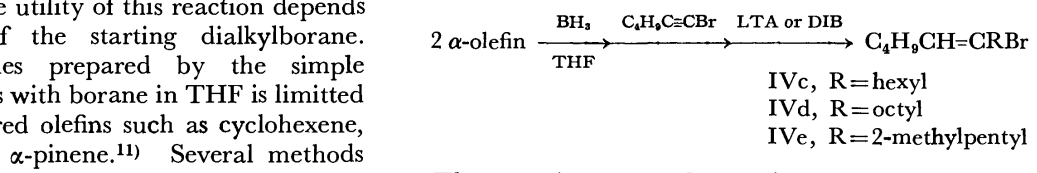
IVa, R=cyclohexyl
IVb, R=1,2-dimethylpropyl

It is apparent that the utility of this reaction depends on the availability of the starting dialkylborane. However, dialkylboranes prepared by the simple hydroboration of alkenes with borane in THF is limitted to only sterically hindered olefins such as cyclohexene, 2-methyl-2-butene, and α-pinene.[11] Several methods for the general synthesis of dialkylboranes have been proposed.[12] However, they did not give satisfactory results in the present reaction, probably because of the complexity of the procedure or contaminations of some compounds which were liable to inhibit the reactions.

Accordingly, we employed another easier procedure for the synthesis of dialkylborane. Brown *et al.*[13] have reported that the reaction of 2 mol of 1-pentene and 1 mol of borane in THF at room temperature results in the formation of a mixture containing 63.3% of dipentylborane. Consequently, the introduction of a solution of such a hydroboration stage to our reaction



seemed togive corresponding alkenyl bromides. Actually, acceptably pure 1-bromo-1,2-dialkylethylenes (IVc, IVd, and IVe) were obtained in about 50—60% yields uncontaminated with by-products which obstructed the isolation of the alkenyl bromides in column chromatography. The results are summarized in Table 3.



IVc, R=hexyl
IVd, R=octyl
IVe, R=2-methylpentyl

The most important feature in the results is the fact that stereospecifically defined bromoalkenes were obtained by merely controlling the reaction conditions, such as temperature and solvent, when LTA was employed. That is, (*Z*)-(1-bromo-1-hexenyl)dialkylborane, obtained *via* the hydroboration of 1-bromo-1-hexyne with dialkylborane, gave (*Z*)-6-bromododecene at −50 °C in dichloromethane, while the same organoborane gave *E*-isomer at 0 °C in a mixture of benzene and hexane (1: 1). Similar results were obtained when 1-octene and 2-methyl-1-pentene were employed as the starting alkene, suggesting the wide applicability of the

Table 3. Reaction of (1-bromo-1-hexenyl)dialkylboranes, derived from 1-alkyne, with LTA or DIB

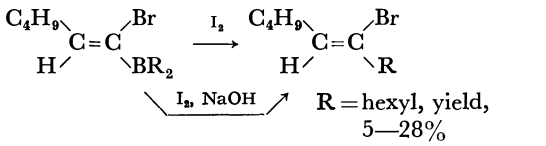
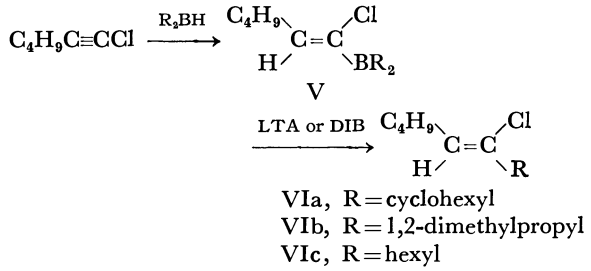
present reaction for the syntheses of several types of 1-bromo-1,2-dialkylethylene.

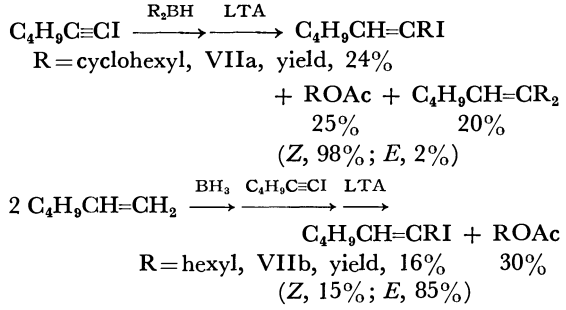
On the other hand, in the Zweifel reaction,[7] the migration of alkyl group from the boron atom of 1-alkenyldialkylborane to the alkenyl carbon atom adjacent to the boron atom with iodine under alkaline solutions, was applied on the same (1-bromo-1-hexenyl)-dialkylborane, but only a small amount of the corresponding Z-isomer was found to be obtained.



Then we undertook the reaction of (1-chloro-1-alkenyl)dialkylborane(V), obtained from 1-chloro-1-hexyne[14] and dialkylboranes, with LTA or DIB. The results are shown in Table 4. In all cases examined, corresponding (Z)-1-chloro-1,2-dialkylethylenes were afforded in moderate yields with high stereoselectivities. Unfortunately, E-isomers could not be obtained as predominant products, even by controlling the reaction conditions, such as temperature and solvent.



(1-Iodo-1-hexenyl)dialkylborane failed to give satisfactory yields of 1-iodo-1,2-dialkylethylenes in the similar treatment with LTA. In these cases appreciable amounts of by-products, such as alkyl acetate and trisubstituted alkene, presumably formed by a migration of two alkyl groups, were contaminated.



The present reaction provides a new method for the stereoselective synthesis of (Z)- or (E)-1-bromo-1,2-dialkylethylene, and also of (Z)-1-chloro-1,2-dialkylethylene. It is interesting that sterically defined (Z)- or (E)-1-bromo-1,2-dialkylethylene is obtained by controlling the reaction conditions when LTA is used. The manner of the elimination of the dialkylboryl group from the carbon atom seems to influence the stereochemistry of the product. A further work involving such a mechanistic study is now under investigation.

Experimental

Instruments. IR spectra (film) were recorded by using a Hitachi-285 spectrometer. PMR (CCl_4, TMS) were run on a Hitachi R-20A spectrometer. Mass spectra were recorded by using a Hitachi M-52 mass spectrometer.

Reagents. Cyclohexene, 1-hexene, and 1-octene were distilled under argon stream after drying over lithium aluminium hydride. Commercial 2-methyl-2-butene, 2-methyl-1-pentene, and 1-hexyne were used without any purification. Solvents were purified by appropriate methods respectively and they were distilled before use. 1-Chloro-1-hexyne,[14] 1-bromo-1-hexyne,[10] and 1-iodo-1-hexyne[15] were prepared by the methods described in the literatures. Borane in THF, [11c] lead (IV) acetate,[16] above 98% purity,[17] and (diacetoxyiodo)benzene[18] were prepared by the methods described in the literatures.

Identification of the Products. E- and Z- isomers were isolated respectively from the reaction mixture by repeated applications on the column chromatography, and subjected to the analysis. They were identified by reference to literatures.[2,19]

1-Bromo-1-cyclohexyl-1-hexene (IVa). A 100-ml round bottomed flask, equipped with a gas inlet for argon, a sample inlet with a serum cap, a dropping funnel and a magnetic stirring bar, was flushed with argon, and then in the flask dicyclohexylborane was prepared by the addition of cyclohexene (1.64 g, 20 mmol) to BH_3 (10 mmol) in THF. To the solution, 1-bromo-1-hexyne (1.61 g, 10 mmol) was slowly added at −10 °C and then the solution was stirred for 3 h at 0 °C. Then DIB (3.2 g, 10 mmol) in dichloromethane (30 ml) was dropped at −25 °C and the reaction mixture was stirred at the same temperature. After completion of the reaction, hexane (20 ml) was added, and the solution was washed with NaCl-saturated water once and then dried over anhydrous sodium sulfate. After the removal of the solvent under reduced pressure, the reaction mixture was put on a column packed with silica gel (Wako gel Q-50) giving 1.32 g (5.4 mmol, 54%) of IVa (Z, 98%; E, 2%) by elution with benzene. Z-Isomer was isolated by repeated applica-

tions on column chromatography of the above mixture: n_D^{20} 1.4940; PMR δ 5.52 (t, 1H); [2,19] IR $\nu_{c=c}$ 1655 cm^{-1};[2] mass spectrum *m/e* 244, 246 (M^+). Found: C, 59.11; H, 8.69%. Calcd for $C_{12}H_{21}Br$: C, 58.78; H, 8.63%.

4-Bromo-2,3-dimethyl-4-nonene (IVb). To the solution of (1-bromo-1-hexenyl)bis(1,2-dimethylpropyl)borane, obtained in the similar manner as described above, LTA (4.5 g, 10 mmol) in dichloromethane (50 ml) was dropped at −50 °C and the stirring was continued for 8 h at the same temperature. Then, water (5 ml) and hexane (20 ml) were added to the solution at 0 °C. By the same procedure as described in the synthesis of IVa, 1.17 g (5.0 mmol, 50%) of IVb (*Z*, 98%; *E*, 2%) was obtained. *Z*-isomer was isolated by column chromatography of the above mixture: n_D^{20} 1.4638; PMR δ 5.53 (t, 1H);[2,19] IR $\nu_{c=c}$ 1655 cm^{-1};[2] mass spectrum *m/e* 232, 234 (M^+). Found: C, 56.50; H, 9.02%. Calcd for $C_{11}H_{21}Br$: C, 56.66; H, 9.08%.

(Z)-6-Bromo-5-dodecene (IVc-Z). In the same reaction apparatus as described above, flushed with argon, 1-bromo-1-hexyne (1.61 g, 10 mmol) was placed, and then the solution, prepared by the hydroboration (25 °C, 24 h) of 1-hexene (1.68 g, 20 mmol) with BH_3 (10 mmol, in THF), was dropped into the flask by using a syringe at −25 °C followed by the stirring for 2 h at −10 °C. Then LTA (4.5 g, 10 mmol) in dichloromethane (50 ml) was slowly added at −65 °C and the solution was stirred at −50 °C for 4 h. After the reaction, a mixture of water (3 ml) and THF (5 ml) was added to the solution at −50 °C, and then the solution was allowed to return to room temperature. By the same procedure as described in the synthesis of IVa, 1.38 g (5.6 mmol, 56%) of IVc (*Z*, 96%; *E*, 4%) was obtained. *Z*-isomer was isolated by column chromatography: n_D^{20} 1.4682; PMR δ 5.51 (t, 1H);[2,19] IR $\nu_{c=c}$ 1655 cm^{-1};[2] mass spectrum *m/e* 246, 248 (M^+). Found: C, 58.46; H, 9.29%. Calcd for $C_{12}H_{23}Br$: C, 58.30; H, 9.38%.

(Z)-6-Bromo-5-tetradecene (IVd-Z). This compound was obtained in the similar manner as described in the synthesis of IVc-*Z*; PMR δ 5.51 (t, 1H);[2,19] IR $\nu_{c=c}$ 1660 cm^{-1};[2] mass spectrum *m/e* 274, 276 (M^+). Found: C, 61.18; H, 9.80%. Calcd for $C_{14}H_{27}Br$: C, 61.09; H, 9.89%.

(Z)-6-Bromo-8-methyl-5-undecene (IVe-Z). This compound was obtained in the similar manner as described in the synthesis of IVc-*Z*; PMR δ 5.52 (t, 1H);[2,19] IR $\nu_{c=c}$ 1660 cm^{-1};[2] mass spectrum *m/e* 246, 248 (M^+). Found: C, 58.39; H, 9.36%. Calcd for $C_{12}H_{23}Br$: C, 58.30; H, 9.38%.

(E)-6-Bromo-5-dodecene (IVc-E). To the solution of (1-bromo-1-hexenyl)dialkylborane, prepared by the procedure as described in the synthesis of IVa, a mixture of benzene (20 ml) and hexane (20 ml) was added, and then powdered LTA (4.5 g, 10 mmol) was introduced slowly to the solution at −10 °C, followed by stirring for 4 h at 0 °C. Then, water (5 ml) was added. By the similar procedure as described in the synthesis of IVa, 1.28 g (5.2 mmol, 52%) of a mixture (*Z*, 5%; *E*, 95%) was obtained. *E*-Isomer was isolated by column chromatography: n_D^{20} 1.4718; PMR δ 5.71 (t, 1H);[2,19] IR $\nu_{c=c}$ 1645 cm^{-1};[2] mass spectrum *m/e* 246, 248 (M^+). Found: C, 58.48; H, 9.31%. Calcd for $C_{12}H_{23}Br$: C, 58.30; H, 9.38%.

(E)-6-Bromo-5-tetradecene (IVd-E). This compound was obtained in the similar manner as described in the synthesis of IVc-*E*; PMR δ 5.72 (t, 1H);[2,19] IR $\nu_{c=c}$ 1645 cm^{-1};[2] mass spectrum *m/e* 246, 248 (M^+). Found: C, 58.35; H, 9.38%. Calcd for $C_{12}H_{23}Br$: C, 58.30; H, 9.38%.

(Z)-1-Chloro-1-cyclohexyl-1-hexene (VIa), (Z)-4-Chloro-2,3-dimethyl-4-nonene (VIb), (Z)-6-Chloro-5-dodecene (VIc), (Z)-1-Iodo-1-cyclohexyl-1-hexene (VIIa) and (E)-6-Iodo-5-dodecene (VIIb). These compounds were synthesized in the similar manners as described in the syntheses of the corresponding bromo compounds. Analytical data are as follows.

VIa: PMR δ 5.31 (t, 1H);[2,19] IR $\nu_{c=c}$ 1660 cm^{-1};[2] mass spectrum *m/e* 200, 202 (M^+). Found: C, 71.87; H, 10.53%. Calcd for $C_{12}H_{21}Cl$: C, 71.80; H, 10.54%.

VIb: PMR δ 5.31 (t, 1H);[2,19] IR $\nu_{c=c}$ 1660 cm^{-1};[2] mass spectrum *m/e* 188, 190 (M^+). Found: C, 70.03; H, 11.16%. Calcd for $C_{11}H_{21}Cl$: C, 70.00; H, 11.21%.

VIc: PMR δ 5.03 (t, 1H);[2,19] IR $\nu_{c=c}$ 1655 cm^{-1};[2] mass spectrum *m/e* 202, 204 (M^+). Found: C, 71,12; H, 11.41%. Calcd for $C_{12}H_{23}Cl$: C, 71.08; H, 11.43%.

VIIa: PMR δ 5.30 (t, 1H);[2,19] IR $\nu_{c=c}$ 1640 cm^{-1};[2] mass spectrum *m/e* 292 (M^+). Found: C, 49.38; H, 7.20%. Calcd for $C_{12}H_{21}I$: C, 49.33; H, 7.24%.

VIIb: PMR δ 6.03 (t, 1H);[2,19] IR $\nu_{c=c}$ 1630 cm^{-1};[2] mass spectrum *m/e* 294(M^+). Found: C, 49.03; H, 7.84%. Calcd for $C_{12}H_{23}I$: C, 48.99; H, 7.88%.

Enolate Anions. II. Substituent Effects of Sodium Ethyl Phenylacetates in DMSO[1]

Syun-ichi KIYOOKA,* Yoshinobu UEDA, and Kojiro SUZUKI
Department of Chemistry, Faculty of Science, Kochi University, Akebono-cho, Kochi 780
(Received October 31, 1979)

The UV-visible, IR, and ^{1}H-NMR spectra of the sodium enolates of ethyl phenylacetates (substituents; *p*-CH_3O, *p*-CH_3, *m*-CH_3, H, *p*-Cl, *p*-CH_3CO, *m*-CH_3CO, *p*-$COOC_2H_5$, *p*-CN, and *p*-NO_2) in DMSO were measured at room temperature. The derivatives with electron-attracting groups at the *para* position exhibit their absorption maxima with $\varepsilon > 10^4$ in visible regions above 400 nm. The visible spectra suggest the presence of a resonance between their electron-attracting groups at the para position and the enolate anion parts through the benzene ring. The carbonyl-stretching vibrations of the enolates in the IR spectra and the chemical shifts of the residual methine proton of the enolates in the ^{1}H-NMR spectra can be well explained by using the substituent constants, σ and σ^-. The ρ values of the *meta* and *para* lines are extremely different. In the case of the *p*-NO_2 derivative, the ^{1}H-NMR spectra of the benzene-ring protons indicate that the free rotation of the partially double bond between the benzene ring and the enolate-anion part is fixed at room temperature.

The methylene protons adjacent to the electron-attracting groups, such as the nitro, cyano, and ester groups, are acidic enough to give anions when treated with sodium hydride.[2] Such an anion is not a localized carbanion, but a delocalized enolate anion, as well as one derived from ketone.[3] Studies of the structure of the metal enolate anions are rapidly increasing in number, though they are almost entirely restricted to mono- and diketones.[4] Zaugg *et al.* have pointed out that the reactivity of enolate anions depends on the states of the ions and ion-pairs. However, spectroscopic studies of enolate anions have not given more definitive results about the states of ions and ion-pairs than about those of carbanions.[5,6]

The states of the ions and ion-pairs of enolate anions were mainly presumed on the basis of kinetic evidence. In the alkylation of enolate anions, the reaction rate was greatly accelerated by the addition of dipolar aprotic solvents, such as DMSO and DMF. The enhanced rate was explained on the basis of the presence of more dissociated species (free ions and solvent-separated ion-pairs) in the reaction.[5]

In DMSO, the ^{13}C-NMR spectra of the enolate anions of some diethyl alkylmalonates apparently gave a simple pattern which could be assigned to only one species at room temperature.[1] So long as sodium metal is used as a counter cation, the metal cation can be sufficiently solvated with the dipolar aprotic solvent. Therefore, the apparent species in the ^{13}C-NMR spectra seem to depend on the equilibrium among some predominant configurations of the enolate anion on an NMR time scale. The structure of the sodium enolate anions, derived from ethyl phenylacetates, may be determined by means of the steric and electronic stabilities of the configuration and/or the conformation of the enolate-anion part in DMSO.

In spite of the importance of the electronic perturbation in estimating the reactivity of enolate anions, the substituent effects have scarcely been investigated at all. This paper will deal with the substituent effects in the UV-visible, IR, and ^{1}H-NMR spectra of enolate anions and the correlation between the effects and their configurations.

Results and Discussion

Molecular spectroscopy (UV-visible and IR) can generally reflect the configurations and conformations of substrates in solution, while magnetic resonance spectroscopy gives some informations about structure, including the proportions of the configurations and dynamic information about the transformation process among the configurations. A systematic examination of substituent effects in the UV-visible, IR, and ^{1}H-NMR spectra of enolate anions can clarify the alteration in their structure by substituents.

UV-Visible Spectra. In writing the resonance structures for the benzylic anion, the coplanarity of the ring with the α-methylene group is implied, because there can be an effective overlap between the p-orbital of the α-carbon with the unshared pair of electrons and the p_π-orbitals of the benzene ring.[7] The UV-visible spectrum of benzyllithium was observed at 330 nm (λ_{max}) with an absorption intensity of log $\varepsilon = 3.98$ (yellow color).[8] The enolate anion of ethyl phenylacetate gave the absorption maximum at 345 nm. It can, therefore, be presumed that this enolate anion has a resonance structure, analogous to the benzyl anion.

Table 1 shows the data of the UV-visible spectra of the enolate anions. The absorption maxima of the

a) These original esters have no absorption bands in the UV-visible region (300—700 nm). b) Accurate ε_{max} values could not be obtained at low concentrations (10^{-5} mol/dm^3).

enolate anion with electron-releasing substituents and hydrogen at the *para* position are present at the range of 340—350 nm. The overlaps between the p-orbital of α-carbon and the p_π-orbitals of the benzene ring are of nearly the same degree as in these enolate anions because of similar λ_{max}. The absorption maxima of these enolate anions are mostly extinguished by dilution with DMSO to a concentration of 10^{-5} mol/dm^3, so that the accurate ε_{max} can not be obtained. This may be attributed to the presence of an equilibrium between the enolate anions and DMSO.

On the other hand, the enolate anions which have electron-attracting substituents at the *para* position are stable at low concentrations (10^{-5} mol/dm^3) because of the high acidity enhanced by these substituents. The more bathochromic shifts of λ_{max} were observed in the region above 400 nm for the more electron-attracting groups, which are conjugated with the enolate-anion part through the benzene ring. The marked tendency of the enolate anions to show a bathochromic effect is similar to that of phenolate anions.[9] Hence, the pattern of the additional resonance of the enolate anions seems not to be far from that of the phenolate anions. Two adsorption maxima with nearly equal intensities were observed in the case of the enolate anions of ethyl *p*-nitrophenylacetate; these are characteristic of *para* nitro substituents.[10]

IR Spectra. Table 2 shows the wave numbers of the carbonyl (CO) stretching vibrations in the ethyl phenylacetates and their enolate anions. These wave numbers are very important in examining the electron density at the CO double bond. The original esters have definite wave numbers (1724—1730 cm^{-1}) in spite of the variation in the substituents. The CO stretching vibration bands of enolate anions are illustrated by some typical representative spectra (*p*-Cl and *p*-CN) in Fig. 1.

The enolate anions with substituents other than *para* electron-attracting substituents give only one absorption band with a strong intensity in the region of 1587—1593 cm^{-1}, like the *p*-Cl derivative in Fig. 1. In the enolate anion of ethyl phenylacetate, the CO absorption band was observed at a lower frequency, 135 cm^{-1}, than in the original ester. This low-frequency shift indicates an increase in the electron density of the polarized CO bond in the enolate anion.

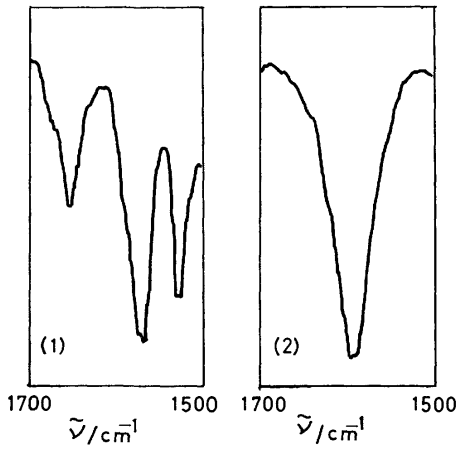

Fig. 1. The carbonyl streching vibration bands (1500—1700 cm^{-1}) of enolate anions; (1) *p*-CN derivative, (2) *p*-Cl derivative.

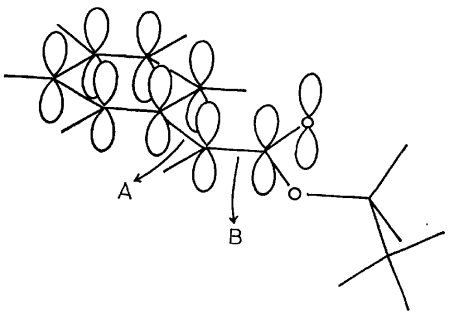
In contrast, the enolate anions with *para* electron-attracting substituents gave one CO absorption band with a medium intensity, together with two other absorption bands (1575—1550 and 1520—1510 cm^{-1}) which seem to be attributable to the resonance. The stronger electron-attracting ability of the substituent shifts the CO stretching absorption band of the enolate anion to a higher frequency region; in the *para* nitro derivative, the absorption band was obtained 51 cm^{-1} higher than in the *para* hydrogen derivative. This high-frequency shift suggests that the delocalized electrons flow into the benzene ring rather than being present in the polarized CO bond.

^{1}H-NMR Spectra. The ^{1}H-NMR measurements of enolate anions are useful for the investigation of the structures in solution.[11] On the basis of a consideration of molecular models of the enolate anion derived from ethyl phenylacetate, one of the stable configurations is illustrated below:



In the above figure, the A bond forms the maximum overlap between the p-orbital of the enolate-anion part and the p_π-orbitals of the benzene ring, while the benzene ring is located at a position *trans* to the ethoxyl group with respect to B bond. For detailed descriptions

a) Chemical shifts of original esters. b) Chemical shifts of enolate anions. c) Differences (a—b). A plus sign represents a high-field shift.

of the configurations, these two partially double bonds (A and B) are very important.

As the rotational barrier of the B bond in the enolates derived from ethyl phenylacetates is assumed to be of a similar degree to that of the partially double bond in lithio isobutyrophenone (>27 kcal mol^{-1}),[12] the rotation about the B bond may be restricted and fixed to a preferential *trans* configuration at room temperature. On the other hand, the A bond would be allowed to rotate at room temperature, because the analogous partially double bond in stryl anions has rotational barriers (11—14 kcal mol^{-1})[13] which are clearly connected with the delocalization of the negative charge into the benzene rings. Table 3 shows the ^{1}H-NMR chemical shifts of the alkyl parts in enolate anions derived from ethyl phenylacetates. From the simple pattern of the observed spectra of the alkyl parts, the species in the solution can be attributed to only one structure, which presumably corresponds to the *trans* configuration.[14] The chemical shifts of $-CH_2-$ and $-CH_3$ in the enolate anions are observed at higher fields (+0.2—+0.6 and <+0.1 ppm, respectively) than those of the original esters. The chemical shifts of the residual active methine proton are obtained at fields +0.2—+0.6 ppm higher than those of original esters; these shifts evidently show substituent effects.

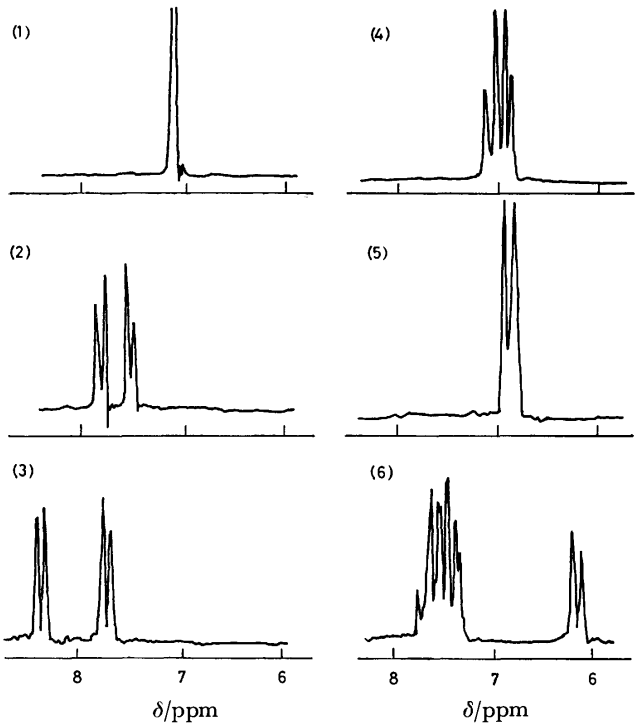

Fig. 2. The ^{1}H-NMR spectra of original esters [(1), (2), (3)] and enolate anions [(4), (5), (6)] at δ 6—8 ppm; (1), (4): *p*-Me derivative, (2), (5): *p*-CN derivative, (3), (6): *p*-NO_2 derivative.

The ^{1}H-NMR spectra of benzene-ring protons are shown in Fig. 2 (*p*-CH_3, *p*-CN, and *p*-NO_2 compounds). In the *p*-CH_3 derivative, the apparent singlet pattern of benzene-ring protons in the original ester is changed to the AB pattern in the enolate anion. In the *p*-CN derivative, the apparent AB pattern of benzene-ring protons in the original ester is changed to a doublet pattern with a large high-field shift in the enolate anion. The ^{1}H-NMR patterns of the benzene-ring protons in these enolate anions are symmetrical, as has been mentioned above. Such observations suggest that the partially double bond A has a free rotation because of the equivalence in the magnetic environments of two *ortho* protons and two *meta* protons. In the *p*-NO_2 derivative, however, the symmetric AB pattern of the benzene-ring protons in the starting ester changed to a dissymmetric pattern with an extreme high-field shift (at 6.32 ppm) of one proton, distinguished from three benzene-ring protons, in the enolate anion. The partially double bond A in the *p*-NO_2 enolate anion is assumed to be almost fixed on the basis of this observation.[14] Such a greatly enhanced double-bond character of the A bond is also supported by the chemical shift (4.75 ppm) of the residual methine proton in the *p*-NO_2 enolate anion, measured in the olefinic regions.

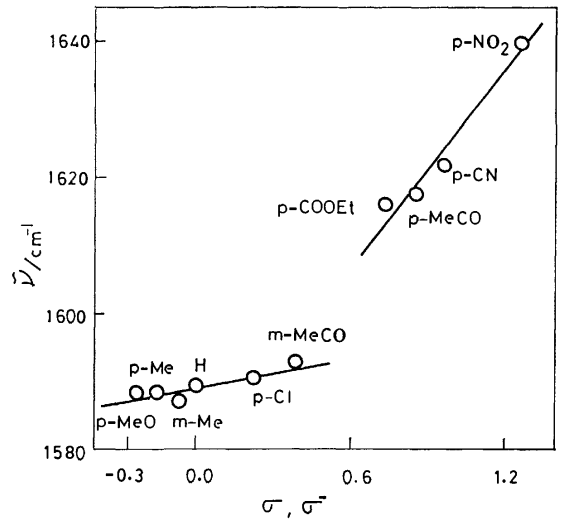

Fig. 3. Hammett plot of the frequencies of carbonyl stretchings in enolate anions of ethyl substituted phenylacetates.

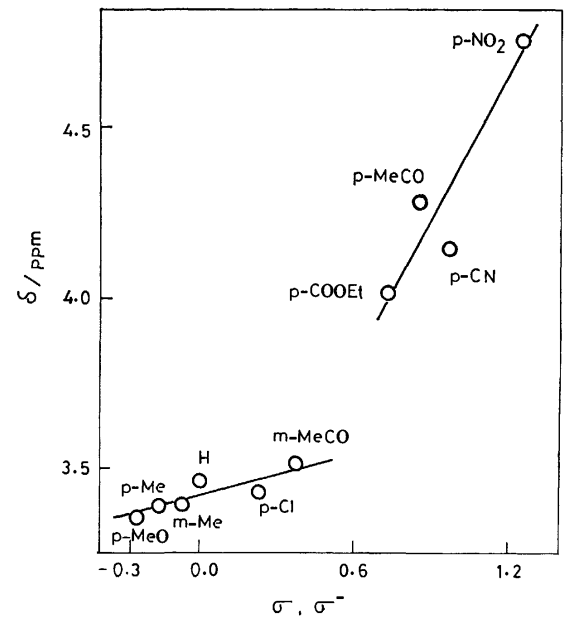

Fig. 4. Hammett plot of the chemical shifts of residual methine proton in enolate anions of ethyl substituted phenylacetates.

Substituent Effects. It has been reported[15] that there is a good linear correlation between the CN stretching-vibration bands of the anions derived from substituted benzyl cyanides and the substituent constants, σ^-. The substituent effects related to anion system are generally correlated by σ^- constants.[16] The CO stretching-vibration bands of the enolate anions derived from ethyl phenylacetates are plotted against σ and σ^- in Fig. 3, which shows two characteristic lines. The plot of the chemical shifts of the residual methine protons *vs.* σ and σ^- is similar to that of the CO wave numbers, as is shown in Fig. 4.

These two lines, which constitute a meta-line of both meta substituents and para electron-releasing substituents for σ and a *para*-line of *para* electron-attracting substituents for σ^-, have extremely different ρ values, suggesting that two different mechanism are required to account for the substituent effects in a sodium-phenylacetate system. The behavior promoted by *para* electron-attracting substituents is consistent with all the observations of the UV-visible, IR, and ^{1}H-NMR spectra of the enolate anions presented above.

Experimental

Materials. Substituted phenylacetic acids and the ethyl esters were prepared according to the following routes:

1. The phenylacetic acids (*p*-CH_3O, *p*-CH_3, and *m*-CH_3) were synthesized by the Willgerodt reaction of the acetophenones[17,18] derived from the corresponding substituted benzoic acids.

2. The ethyl phenylacetates (*p*-CH_3CO and *m*-CH_3CO) were synthesized by the acetylation[19] of ethyl phenylacetate.

3. The phenylacetic acids (*p*-Cl, *p*-NO_2, *p*-CN, and *p*-$COOC_2H_5$) were synthesized by the nitration[20] of phenylacetonitrile, hydrolysis,[21] reduction,[22] and a Sandmyer reaction.[23] Thease synthesized compounds were identified by means of the IR and ^{1}H-NMR spectra and by CHN elementary analysis. The bp's or mp's of the esters are shown in Table 4, together with the literature values.

Preparation of Enolate Anions. Sodium hydride (NaH), the mineral oil having been washed out with dry DMSO, was added to DMSO (2—3 cm^3) in a 50 cm^3 three-necked flask equipped with a gas-inlet tube, a condenser, and a magnetic stirrer. Under an argon atmosphere, ethyl phenylacetates, equivalent to the NaH, in dry DMSO (1 cm^3) were added to the solution, and the resulting mixture was stirred for 30 min at room temperature. According to the above

Table 4. Physical constants of ethyl phenylacetates

procedures, the solution of the enolate anions was about 0.5 mol/dm^3. Spectral-grade DMSO (Dojinyaku Kagaku) was used for the measurements of the visible and IR spectra, and DMSO-d_6 (Merck), for the measurements of the ^{1}H-NMR spectra.

Measurement of Visible Spectra. The prepared enolate solution was diluted to 10^{-4} mol/dm^3, transferred into a crystal cell (d=1 cm), covered with argon, and measured over the range of 300—700 nm, using a Hitachi 557 Double-wavelength Double-beem Spectrophotometer.

Measurement of IR Spectra. The prepared enolate solution was diluted to 0.2 mol/dm^3, transferred into a liquid cell (d=0.2 mm), and measured using a JASCO A-302 Diffraction Grating Infrared Spectrophotometer.

Measurement of ^{1}H-NMR Spectra. The prepared enolate solution (0.5 mol/dm^3) was transferred into a NMR tube (ϕ=5 mm) filled with argon, sealed, and measured using a JEOL MH-100 NMR Spectrometer (100 MHz). The proton signals present in the solvent, 99% DMSO-d_6, were employed as an internal standard for the chemical shifts.

Heterofulvalenes. II. Synthesis and Reaction of 2,3 : 7,8-Dibenzo-1,4-dithia-6-azafulvalene

Juzo NAKAYAMA,* Mimiko IMURA, and Masamatsu HOSHINO
Department of Chemistry, Faculty of Science, Saitama University, Urawa, Saitama 338
(Received November 7, 1979)

Reaction of 2-isopentyloxy-1,3-benzodithiole with indole in acetic acid gave a 93% yield of 3-(1,3-benzodithiol-2-yl)indole (**4a**) which was converted to 2-(3-indolyl)-1,3-benzodithiolylium tetrafluoroborate (**5a**) in a 77% yield by treatment with trityl tetrafluoroborate. **5a** was also prepared by reaction of indole with 2 molar amounts of 1,3-benzodithiolylium tetrafluoroborate. Treatment of **5a** with triethylamine afforded the title compound **6a** in 93% yield. **6a** was protonated, methylated, and benzoylated at its 6-position by tetrafluoroboric acid, methyl iodide, and benzoyl chloride, respectively. Reaction of **6a** with dimethyl acetylenedicarboxylate gave a 1,6-dipolar intermediate which was trapped as an adduct with ethanol. **6a** was smoothly reduced by sodium borohydride to give its 5,6-dihydro derivative.

In recent years synthetic studies of tetrathia- and tetraselenafulvalenes and their derivatives have been extensively done in order to find excellent organic semiconductors.[1] In this connection, 1,4-dithia-azafulvalenes seem to be compounds of current interest, although only slight attention has been paid to their chemistry.[2] In Part I of this series, we reported the synthesis of 1,4-dithia-5-aza- and 6-azafulvalenes (**1** and **2**), and their spectroscopic properties are suggestive of the considerable contribution of the polarlized structures (**1′** and **2′**) to the ground state of these compounds.[3] We now report the synthetic studies of dibenzo analogs of **1** and **2** and the reaction of the title compound.

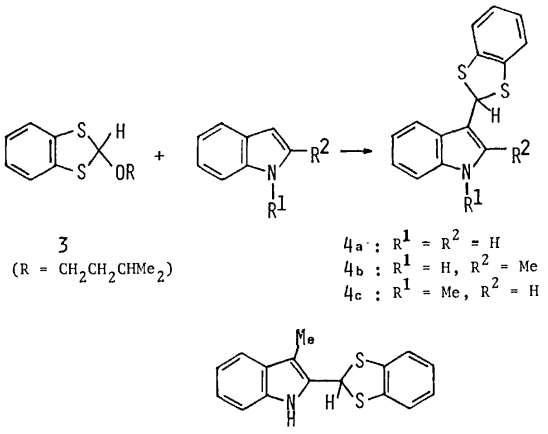
Results and Discussion

Synthesis. 2-Isopentyloxy-1,3-benzodithiole (**3**) which has recently become readily obtainable[4] can react with a wide variety of nucleophiles.[5] Thus, **3** reacted with indole at room temperature to give 3-(1,3-benzodithiol-2-yl)indole (**4a**) in a 93% yield. Similarly, **3** reacted with 2-methyl- and 1-methylindoles giving **4b** (98%) and **4c** (95%), respectively. 3-Methylindole, carrying a methyl at its most reactive position towards electrophiles, reacted at its 2-position to give **4d** in a 96% yield.[6]

In the light of the reaction of 1,3-benzodithiole with trityl tetrafluoroborate (**7**) producing 1,3-benzodithiolylium tetrafluoroborate (**8**) in a good yield,[8] treatment of **4a** with **7** seems to be a promising route to 2-(3-indolyl)-1,3-benzodithiolylium tetrafluoroborate (**5a**). Thus, **4a** smoothly reacted with an equivalent of **7** to give the desired product **5a** in a 77% yield. Similarly,

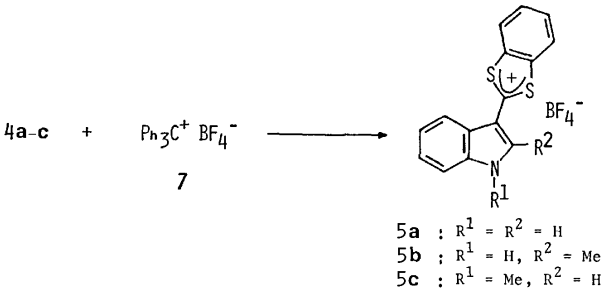


3 (R = $CH_2CH_2CHMe_2$)

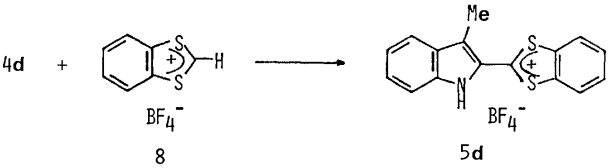
4a : $R^1 = R^2 = H$
4b : $R^1 = H$, $R^2 = Me$
4c : $R^1 = Me$, $R^2 = H$

4d

treatment of **4b** and **4c** with **7** gave **5b** (75%) and **5c** (71%), respectively. However, the reaction of **4d** with **7** failed to furnish **5d** (a 68% yield of **4d** was recovered

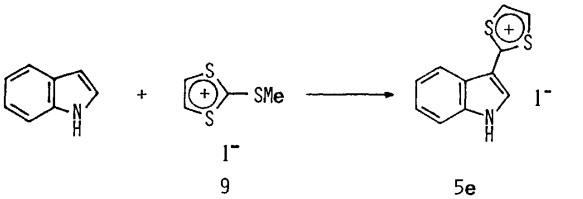


5a : $R^1 = R^2 = H$
5b : $R^1 = H$, $R^2 = Me$
5c : $R^1 = Me$, $R^2 = H$



8

5d



9

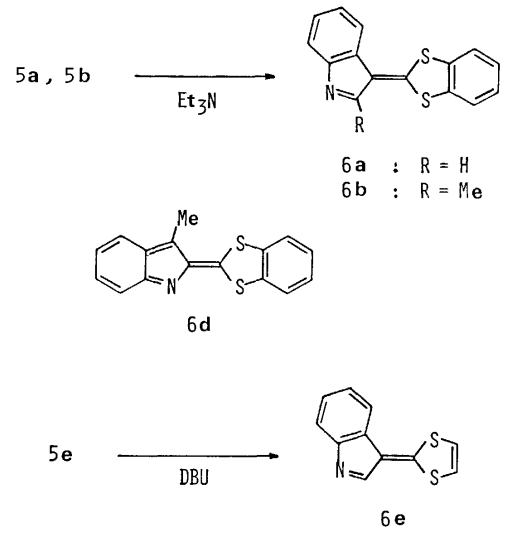
5e

and the yield of triphenylmethane resulting from hydride abstraction by trityl cation was only 15%).

Recent studies have shown that **8** can abstract a hydride from 2-substituted 1,3-benzodithioles yielding 2-substituted 1,3-benzodithiolylium tetrafluoroborates.[3,9] In fact, treating **4d** with an equivalent of **8** afforded **5d** in a 63% yield. This result, together with the fact that the formation of **4** from **3** and indoles involves 1,3-benzodithiolylium ion as intermediate,[7] is indicative that treatment of indoles with 2 molar amounts of **8** would produce **5** in a single step; one mole of **8** reacts with indoles to give **4** and another mole of **8** abstracts a hydride from **4** to yield **5**. Expectedly, the reaction of 3-methylindole with 2 molar amounts of **8** furnished **5d** in a 54% yield. In a similar way, **5a** (60%) and **5b** (51%) were also obtained.

We also prepared 2-(3-indolyl)-1,3-dithiolylium iodide (**5e**); heating indole with the salt **9** at 50 °C in acetonitrile gave **5e** in a 58% yield. However, **9** failed to react with 3-methylindole.

The final step is the deprotonation of **5**. In the case of **5a** and **5b**, this was easily achieved by treating them with triethylamine in acetonitrile at 0 °C; the title compound **6a** and its methyl derivative **6b** were obtained in 93 and 92% yields, respectively. However, treatment of an acetonitrile solution of **5d** with triethylamine resulted in the black reaction mixture, from which an unstable compound, which was converted to the starting material **5d** on treatment with tetrafluoroboric acid, was isolated in a good yield. We could not detect the presence of the desired product **6d**. Attempted trapping of **6d** by dimethyl acetylenedicarboxylate was also unsuccessful. Treatment of **5e** with 1,8-diazabicyclo-[5.4.0]undec-7-ene (DBU) as base yielded **6e** quantitatively.



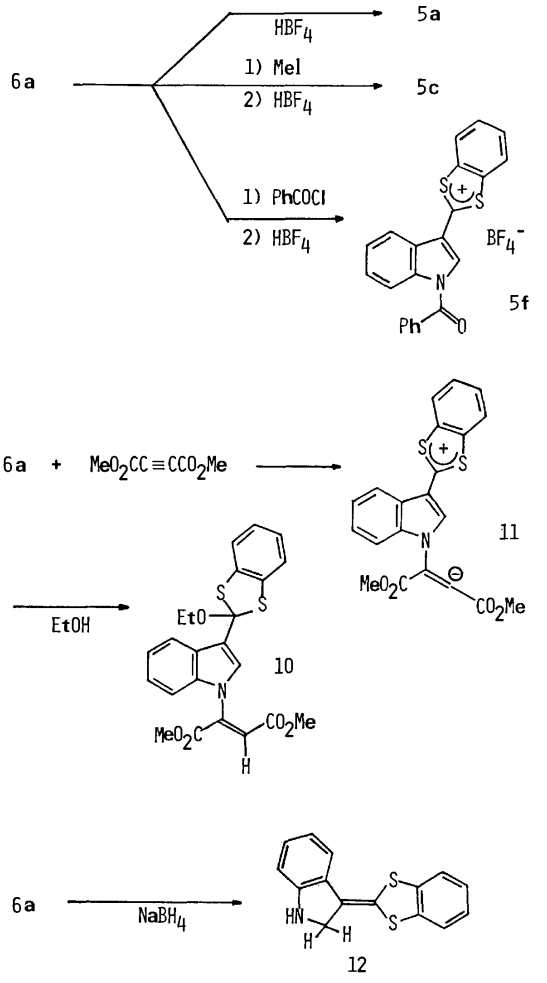
Reaction. Broadly speaking, the spectroscopic features of compounds **5** and **6** are similar to those observed with **1**, **2**, and their protonated species[3] (see Experimental section).

Treatment of **6a** with tetrafluoroboric acid gave **5a** quantitatively. Heating **6a** with methyl iodide and then treating the resulting product with tetrafluoroboric acid gave **5c** in a 91% overall yield. When **6a** was allowed to react with benzoyl chloride in acetonitrile and then the mixture was treated with tetrafluoroboric acid, a 70% yield of 2-(1-benzoyl-3-indolyl)-1,3-benzodithiolylium tetrafluoroborate (**5f**) was obtained.

Heating **6a** with dimethyl acetylenedicarboxylate in boiling chloroform containing ethanol produced compound **10** in a 60% yield. The IR spectrum of **10** has absorptions at 1735 and 1705 cm^{-1} due to the ester carbonyl groups. The NMR spectrum determined in $CDCl_3$ showed two singlets of methyls at 3.80 and 3.96 ppm, a triplet of methyl at 1.26 ppm, and a quartet of methylene at 3.67 ppm. The *trans* geometry of the methoxycarbonyl groups was elucidated from the chemical shift value of the olefinic proton which appeared at 6.27 ppm. It is documented that the olefinic proton of the *trans* form of this type of compounds appears at 5.99—6.27 ppm, whereas that of the *cis* form resonates at 6.63—6.94 ppm.[10] The formation of **10** can best be rationalized by capture of the 1,6-dipolar intermediate **11** by ethanol.

In all the examples described above, **6a** easily reacted at its 6-position with electrophiles. This can be understood as a result of the contribution of polarlized structure corresponding to **2'** to the ground state of **6a**.

Reaction of **6a** with nucleophiles was next examined. **6a** resisted reaction with phenylmagnesium bromide, but it smoothly reacted with sodium borohydride at



room temperature in a mixture of tetrahydrofuran and water. Workup of the mixture gave **12**, the dihydro derivative of **6a**, in an 89% yield as unstable compound in solution. Structure of **12** was determined by spectroscopic and elemental analyses. The result indicates that hydride ion as nucleophile attacks on the 5-position of **6a** rather than the dithiole ring carbon. This is not in harmony with the expected reactivity of **6a** from the contribution of the canonical structure like **2'** and further investigation, emphasis placed on this point, will be needed.

Experimental

2-Isopentoxy-1,3-benzodithiole (**3**),[4] trityl[11] and 1,3-benzodithiolylium[8] tetrafluoroborates (**7** and **8**), and 2-methylthio-1,3-dithiolylium iodide (**9**)[12] were prepared by reported methods. Acetonitrile was refluxed over and distilled from calcium hydride.

Preparation of 4. 3-(1,3-Benzodithiol-2-yl)indole (**4a**). A solution of 1.17 g (10 mmol) of indole and 2.64 g (11 mmol) of **3** in 30 ml of acetic acid was allowed to stand at room temperature for 4 h. The solution was diluted with 100 ml of water, and the resulting precipitate was triturated, collected, washed with water, and dried to give 2.50 g (93%) of **4a**, which melted at 96—98 °C after recrystallization from cyclohexane. NMR ($CDCl_3$) δ 6.60 (1H, s, methine), 6.9—7.4 (8H, m), and 7.7—7.9 (2H, m). Found: C, 66.95; H, 4.19; N, 5.18; S, 23.78%. Calcd for $C_{15}H_{11}NS_2$: C, 66.91; H, 4.12; N, 5.20; S, 23.77%.

In a similar way as described with **4a**, compounds **4b—d** were prepared in 98, 95, and 96% yields, respectively.

3-(1,3-Benzodithiol-2-yl)-2-methylindole (**4b**), mp 120—121 °C (from ethanol). NMR ($CDCl_3$) δ 2.30 (3H, s, Me), 6.90 (1H, s, methine), 6.95—7.30 (7H, m), 7.65 (1H, broad s, NH), and 7.95 (1H, m). Found: C, 67.30; H, 4.65; N, 4.95; S, 22.70%. Calcd for $C_{16}H_{13}NS_2$: C, 67.84; H, 4.63; N, 4.95; S, 22.59%.

3-(1,3-Benzodithiol-2-yl)-1-methylindole (**4c**), mp 139—140 °C. NMR ($CDCl_3$) δ 3.60 (3H, s, Me), 6.58 (1H, s, methine), 6.8—7.3 (8H, m), and 7.7 (1H, m). Found: C, 67.70; H, 4.66; N, 5.01; S, 22.57%. Calcd for $C_{16}H_{13}NS_2$: C, 67.84; H, 4.63; N, 4.95; S, 22.59%.

2-(1,3-Benzodithiol-2-yl)-3-methylindole (**4d**), mp 127—128 °C (from cyclohexane). NMR ($CDCl_3$) δ 2.26 (3H, s, Me), 6.64 (1H, s, methine), 7.0—7.3 (7H, m), 7.45—7.55 (1H, m), and 8.3 (1H, broad s, NH). Found: C, 67.96; H, 4.68; N, 4.89; S, 22.45%. Calcd for $C_{16}H_{13}NS_2$: C, 67.84; H, 4.63; N, 4.95; S, 22.59%.

2-(3-Indolyl)-1,3-benzodithiolylium Tetrafluoroborate (5a).
a) From 4a and 7: A solution of 2.59 g (7.85 mmol) of **7** in 15 ml of anhydrous acetonitrile was added dropwise over a period of 15 min to a stirred and ice-cooled solution of 2.11 g (7.85 mmol) of **4a** in 15 ml of anhydrous acetonitrile. The mixture was warmed to room temperature and stirred for 1 h. The resulting crystalline precipitate was collected and washed with a small amount of acetonitrile to give 2.17 g (77%) of **5a**, which melted at 246—247 °C (dec) (orange needles) after recrystallization from acetonitrile. IR (Nujol) 3300 (NH) and 1000—1120 cm^{-1} (BF_4^-); NMR (CF_3CO_2D, 65 °C), δ 7.5—7.7 (3H, m), 7.7—8.2 (4H, AA'XX'm), 8.02 (1H, m), and 8.70 (1H, s, -NH-CH=); UV (CH_3CN) (log ε) 453 nm (4.69). Found: C, 50.57; H, 2.85; N, 3.85%. Calcd for $C_{15}H_{10}NS_2BF_4$: C, 50.72; H, 2.84; N, 3.94%.

b) From Indole and 2 Molar Amounts of 8: A soliuton of 2.40 g (10 mmol) of **8** in 15 ml of anhydrous acetonitrile was added dropwise during 10 min to a stirred and ice-cooled solution of 0.59 g (5 mmol) of indole in 5 ml of anhydrous acetonitrile. After stirring for 4 h at room temperature, the resulting crystalline precipitate was collected and washed with a small amount of acetonitrile to give 0.85 g of **5a** as orange crystals. The filtrate was diluted with 10 ml of ether and the resulting precipitate was collected to give another crop of **5a** (0.23 g); total yield (60%). **5a**, thus obtained, agreed in all respects with a specimen obtained from **4a** and **7**.

2-(2-Methyl-3-indolyl)-1,3-benzodithiolylium Tetrafluoroborate (5b). Under the same conditions as described with **5a**, 1.42 g (5 mmol) of **4b** and 1.65 g (5 mmol) of **7** gave 1.38 g (75%) of **5b**, mp 284—286 °C (dec), yellow needles (from acetonitrile). IR (Nujol) 3270 (NH) and 1000—1120 cm^{-1} (BF_4^-); NMR (CF_3CO_2D) δ 2.93 (3H, s, Me), 7.4—7.6 (3H, m), 7.7—8.2 (4H, AA'XX'm), and *ca.* 8.0 (1H, m); UV (CH_3CN) (log ε) 441 nm (4.57). Found: C, 52.04; H, 3.33; N, 3.63%. Calcd for $C_{16}H_{12}NS_2BF_4$: C, 52.05; H, 3.28; N, 3.79%.

5b was also obtained from 2-methylindole and 2 molar amounts of **8** in a 51% yield.

2-(1-Methyl-3-indolyl)-1,3-benzodithiolylium Tetrafluoroborate (5c). Under the same conditions as described with **5a**, 1.42 g (5 mmol) of **4c** and 1.65 g (5 mmol) of **7** gave 1.32 g (71%) of **5c**, mp 276—278 °C, orange needles (from acetonitrile). NMR (CF_3CO_2D) δ 4.02 (3H, s, Me), 7.5—8.2 (8H, m), and 8.62 (1H, s, -NMe-CH=). Found: C, 52.17; H, 3.25; N, 3.63%. Calcd for $C_{16}H_{12}NS_2BF_4$: C, 52.05; H, 3.28; N, 3.79%.

2-(3-Methyl-2-indolyl)-1,3-benzodithiolylium Tetrafluoroborate (5d). *a) From 4d and an Equivalent of 8*: A solution of 576 mg (2.4 mmol) of **8** in 4 ml of anhydrous acetonitrile was added dropwise over a period of 10 min to a stirred and ice-cooled solution of 680 mg (2.4 mmol) of **4d** in 10 ml of acetonitrile. The mixture was stirred for 3 h while warmed to room temperature. The resulting precipitate was collected to give 557 mg (63%) of **5d**, mp 236—237 °C (dec), violet needles (from acetonitrile). NMR (CF_3CO_2D) δ 2.74 (3H, s, Me), 7.13 (1H, m), 7.45 (2H, m), 7.69 (1H, d), and 7.76—8.30 (4H, m, AA'XX'm); UV (CH_3CN) (log ε) 467 nm (4.70). Found: C, 52.21; H, 3.40; N, 3.52; S, 17.33%. Calcd for $C_{16}H_{12}NS_2BF_4$: C, 52.05; H, 3.28; N, 3.79; S, 17.37%.

b) From 3-Methylindole and 2 Molar Amounts of 8: Under the same conditions as described with **5a**, 1.31 g (10 mmol) of 3-methylindole and 5.28 g (22 mmol) of **8** gave 1.98 g (54%) of **5d**, mp 231—233 °C (dec).

c) Attempted Synthesis from 4d and 7: A solution of 0.83 g (2.5 mmol) of **7** in 10 ml of anhydrous acetonitrile was added dropwise over a period of 10 min to a stirred and ice-cooled solution of 0.71 g (2.5 mmol) of **4d** in 20 ml of anhydrous acetonitrile. After stirring for 2 h, the mixture turned dark red without precipitation of product. Dilution of the mixture with 30 ml of anhydrous ether also caused no precipitation. Therefore, the mixture was poured into 100 ml of ice water and extracted with three 100 ml portions of ether. The extract was washed with water, dried, and evaporated. The residure was chromatographed on a column of silica gel, which afforded 0.10 g (15%) of triphenylmethane, mp 93—94 °C, 0.47 g (68%) of **4d**, and 0.36 g (53%) of triphenylmethanol, mp 161—162 °C.

2-(3-Indolyl)-1,3-dithiolylium Iodide (5e). A mixture of 117 mg (1 mmol) of indole and 276 mg (1 mmol) of **9** in 15 ml of anhydrous acetonitrile was heated at 50 °C for 8 h. The resulting crystalline precipitate was collected to give 200 mg

(58%) of **5e**, mp 280 °C, reddish brown needles (from DMF–nitromethane). UV (CH_3CN) (log ε) 438 nm (3.53); NMR (DMSO-d_6) δ 7.3—8.2 (4H, m), 8.50 (2H, s, dithiole ring), and 9.07 (1H, s, –NH–CH=). Found: C, 38.30; H, 2.29; N, 4.01; S, 18.75%. Calcd for $C_{11}H_8INS_2$: C, 38.27; H, 2.34; N, 4.06; S, 18.57%.

2,3 : 7,8-Dibenzo-1,4-dithia-6-azafulvalene (6a). To a stirred and ice-cooled solution of 0.71 g (2 mmol) of **5a** in 20 ml of anhydrous acetonitrile was added dropwise 0.5 ml of triethylamine. The reaction occurred immediately with precipitation of yellow crystals. After stirring for 1 h at room temperature, the precipitate was collected and washed with acetonitrile to give 0.50 g (93%) of **6a**, which melted at 212—213 °C (yellow needles) after recrystallization from benzene. IR (Nujol) 1600, 1578, 1566, 1538, 1460, 1438, 1290, 1220, 1195, 875, 765, and 740 cm^{-1}; UV (C_6H_6) (log ε) 417 nm (4.55); MS *m/e* 267 (M^+); NMR ($CDCl_3$) δ 7.2—7.4 (4H, m), 7.4—7.7 (4H, m), and 8.20 (1H, s, –N–CH=). Found: C, 67.76; H, 3.61; N, 5.24; S, 23.83%. Calcd for $C_{15}H_9NS_2$: C, 67.41; H, 3.39; N, 5.24; S, 23.95%.

5-Methyl-2,3: 7,8-dibenzo-1,4-dithia-6-azafulvalene (6b). Treatment of 0.74 g (2 mmol) of **5b** with 0.5 ml of triethylamine at 0 °C gave 0.52 g (92%) of **6b**, mp 183—184 °C (dec), yellow needles (from benzene). UV (C_6H_6) (log ε) 400 nm (4.40); MS *m/e* 281 (M^+); MNR ($CDCl_3$) δ 2.58 (3H, s, Me), 7.15—7.36 (4H, m), and 7.40—7.70 (4H, m). Found: C, 68.72; H, 4.02; N, 4.83; S, 22.67%. Calcd for $C_{16}H_{11}NS_2$: C, 68.32; H, 3.94; N, 4.98; S, 22.75%.

7,8-Benzo-1,4-dithia-6-azafulvalene (6e). To a stirred solution of 200 mg (0.58 mmol) of **5e** in 20 ml of anhydrous acetonitrile was added 0.1 ml of DBU. The mixture was stirred for 0.5 h and diluted with 100 ml of ice water. The resulting precipitate was collected, washed with water, and dried to give 108 mg (100%) of **6e** as golden yellow crystals, mp 134—135 °C. MS *m/e* (%) 217 (M^+, 100), 159 (8), 149 (32), 78 (22), and 76 (33); NMR ($CDCl_3$) 6.85 (2H, s, dithiole ring), 7.15—7.80 (4H, m, benzene ring), and 8.17 (1H, d, –N–C=H–). Found: C, 60.95; H, 3.31; N, 6.22%. Calcd for $C_{11}H_7NS_2$: C, 60.79; H, 3.25; N, 6.45%.

Attempted Synthesis of 6d. To a stirred and ice-cooled suspension of 369 mg (1 mmol) of **5d** in 13 ml of anhydrous acetonitrile was added 0.3 ml of triethylamine. The yellow suspension turned dark red immediately. The mixture was stirred for 1.5 h at room temperature and a small amount of tarry insoluble material was filtered off. The dark filtrate was diluted with water and the resulting precipitate was collected and washed with methanol to give 200 mg of a pink solid, mp 154—156 °C; IR (Nujol) 3380 (NH) and 1115 cm^{-1} (aliphatic ether). Attempted purification of this compound by recrystallization or reprecipitation suffered extensive decomposition. The addition of 1 ml of 42% tetrafluoroboric acid to a solution of 209 mg of this compound in 10 ml of acetic anhydride resulted in the formation of 154 mg of **5d**.

To a stirred and ice-cooled solution of 156 mg (1.1 mmol) of dimethyl acetylenedicarboxylate and 0.2 ml of triethylamine in 20 ml of anhydrous acetonitrile was added 369 mg (1 mmol) of **5d** in small portions. The mixture was warmed to room temperature and heated at 50 °C for 5 h. Workup of the mixture gave only intractable tars.

Treatment of 6a with Tetrafluoroboric Acid. A mixture of 67 mg (0.25 mmol) of **6a** in 2 ml of 42% tetrafluoroboric acid was stirred for 0.5 h and the resulting precipitate was collected and washed with anhydrous ether to give 87 mg (98%) of **5a**.

Treatment of 6a with Methyl Iodide. To a stirred suspension of 195 mg (0.73 mmol) of **6a** in 10 ml of acetonitrile was added 0.5 ml of methyl iodide and the mixture was heated under reflux for 1 h. The resulting precipitate was collected to give 278 mg (93%) of 2-(1-methyl-3-indolyl)-1,3-benzodithiolylium iodide as red crystals, whose IR spectrum is essentially the same as that of **6a**. This compound (123 mg) was stirred in a mixture of 1 ml of 42% tetrafluoroboric acid and 5 ml of acetic anhydride for 20 min to give 109 mg of **5c**, mp 275—277 °C, whose IR spectrum agreed in all respects with that of a specimen obtained from **4c** and **7**.

Tretment of 6a with Benzoyl Chloride. A mixture of 134 mg (0.5 mmol) of **6a** and 141 mg (1 mmol) of benzoyl chloride in 10 ml of acetonitrile was stirred at room temperature for 0.5 h. The mixture was cooled to 0 °C and a mixture of 1 ml of 42% tetrafluoroboric acid and 10 ml of acetic anhydride was added. After stirring for 1 h at room temperature, the resulting precipitate was collected and washed with ether to give 161 mg (70%) of 2-(1-benzoyl-3-indolyl)-1,3-benzodithiolylium tetrafluoroborate (**5f**), mp 240 °C, yellowish orange needles (from acetonitrile). IR (Nujol) 1700 (C=O) and 1000—1120 cm^{-1} (BF_4^-). Found: C, 57.32; H, 3.00; N, 2.83; S, 14.07%. Calcd for $C_{22}H_{14}NOS_2BF_4$: C, 57.53; H, 3.07; N, 3.05; S, 13.96%.

Reaction of 6a with Dimethyl Acetylenedicarboxylate. To a stirred solution of 267 mg (1 mmol) of **6a** in 15 ml of chloroform containing 0.5—0.9% of ethanol as a stabilizer was added a solution of 312 mg (2.2 mmol) of dimethyl acetylenedicarboxylate in 5 ml of chloroform. The mixture was stirred for 0.5 h at room temperature and then refluxed for 2 h. Analysis by TLC showed the formation of a single product. Evaporation of the solvent left a yellow solid, which was washed with ether to give 216 mg (60%) of **10**, mp 171.5—172 °C (from CCl_4), colorless needles. IR (Nujol) 1735 and 1705 cm^{-1} (C=O); NMR ($CDCl_3$) δ 1.26 (3H, t, J=7 Hz, Me), 3.67 (2H, q, J=7 Hz, CH_2), 3.80 (3H, s, Me), 3.96 (3H, s, Me), 6.27 (1H, s, olefinic), 7.1—7.6 (8H, m), and 7.9 (1H, m). Found: C, 60.42; H, 4.51; N, 3.13; S, 13.86%. Calcd for $C_{23}H_{21}NO_5S_2$: C, 60.66; H, 4.65; N, 3.08; S, 14.05%.

Reduction of 6a with Sodium Borohydride. To a stirred mixture of 80 mg (2.1 mmol) of sodium borohydride in 20: 1 tetrahydrofuran/water (21 ml) was added 267 mg (1 mmol) of **6a** in small portions. The mixture was stirred for 0.5 h and a trace amount of insoluble material was filtered off. The filtrate was diluted with 20 ml of water and the resulting precipitate was collected and dried to give 240 mg (89%) of **12** as faint yellow crystals, mp 128—129 °C. This compound is unstable in solution; when it was dissolved in chloroform, yellow polymeric material, scarcely soluble in organic solvents, deposited a few minutes later. This made it impossible to obtain a good NMR spectrum; δ ($CDCl_3$) 4.10 (2H, s, CH_2) and 6.5—7.4 (8 or 9H, m). IR (KBr) 3380 (NH), 3050, 2870, and 2840 (CH_2), 1605, 1585, 1475, 1445, 1320, 1280, 1250, and 740 cm^{-1}. Found: C, 66.64; H, 4.17; N, 5.44; S, 23.71%. Calcd for $C_{15}H_{11}NS_2$: C, 66.91; H, 4.12; N, 5.20; S, 23.77%.

Studies on 1-(Thiosulfinylaminothio)piperidines

Syoji MORIMURA, Hideo HORIUCHI, Chihiro TAMURA, and Takao YOSHIOKA
Central Research Laboratories Sankyo Co., Ltd., Hiromachi Shinagawa-ku, Tokyo 140

(Received November 7, 1979)

Hindered piperidine derivatives with a new functional group(–S–N=S=S), 2,2,6,6-tetramethyl-1-(thiosulfinylaminothio)piperidines (**4**) were obtained from the corresponding piperidines **1**, sulfur monochloride and ammonia. These compounds were also prepared from bis(2,2,6,6-tetramethylpiperidino) disulfides or bis(2,2,6,6-tetramethylpiperidino) trisulfides under similar reaction conditions. In much lower yields, unhindered 1-(thiosulfinylaminothio)piperidines (**8**) were also obtained. The photochemical and thermal stabilities of **4** and **8** were nearly the same. Reaction pathways were disucssed.

Recently the reaction of hindered amines such as 2,2,6,6-tetramethylpiperidine (**1b**) with sulfur chlorides has been studied by Bennett *et al.*[1] who found that sulfur dichloride (SCl_2) curiously gave bis(2,2,6,6-tetramethylpiperidino) disulfide (**2b**) in the presence of triethylamine and *N*,*N*-dimethylformamide (DMF) (Eq. 1), and that sulfur monochloride (S_2Cl_2) gave bis(2,2,6,6-tetramethylpiperidino) trisulfide (**3b**) in

hexane or ether (Eq. 2). The disulfides **2** have been shown by us to be effective stabilizing reagents for polyurethane.[2] While trying to find an improved means of synthesizing **2**, it was found that in the presence of

1 + S_2Cl_2 ⟶ **2** (Eq. 3)

DMF and an excess amount of **1**, S_2Cl_2 normally gives the disulfides **2** in excellent yields (Eq. 3).[2] During this research, we further found that piperidine derivatives with a new functional group (–S–N=S=S), 2,2,6,6-tetramethyl-1-(thiosulfinylaminothio)piperidines (**4**) are obtained when equimolar amounts of **1** and S_2Cl_2 are allowed to react and the resulting mixture is quenched with aqueous ammonia. In this paper, we wish to report the preparation and properties of **4** as well as possible reaction pathways for formation of **4**.

Results and Discussion

Compounds **4** was prepared not only from **1** but also from the disulfide **2** or the trisulfide **3**, under similar reaction conditions.

*Preparation of 2,2,6,6-Tetramethyl-1-(thiosulfinylaminothio)piperidines (**4a—d**) from 2,2,6,6-Tetramethylpiperidines (**1a—d**).* The reaction mixture of **1** with S_2Cl_2 was pale yellow. When the mixture was treated with 10% aqueous ammonia, the color turned to deep red immediately. The red mixture contained the trisulfide **3** (major product) accompanied by a small amount of the disulfide **2** (Eq. 4). However pure **2** and **3** are colorless.

1 $\xrightarrow[\text{ii) aq } NH_3]{\text{i) } S_2Cl_2}$ red subst. **4** + **3**(maj.) + **2**(min.) (Eq. 4)

A comparative experiment showed that similar treatment of the reaction mixture (from **1b**) with a 10% aqueous solution of potassium hydrogencarbonate instead of aqueous ammonia gave a colorless mixture containing **3b** (major product) and **2b** (minor product) (Eq. 5). Thus it became apparent that ammonia is

Table 1. Properties of compounds **4a—d**

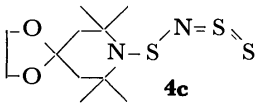
the cause of the coloration. In order to clarify the cause of the coloration, the red substances were isolated and their structures were determined. Chromatographic separation of the mixture gave small amounts (Y=6—14 %) of red oils or prisms (**4a**—**d**) whose physical properties are given in Table 1. Typical structure determination was carried out as follows. **4c** has the formula, $C_{11}H_{20}N_2O_2S_3$, based on the satisfactory elemental analysis and molecular weight determination (308), as shown both by VPO method and mass spectrum. Since the NMR spectrum showed three singlets at δ 1.45 (12H), 1.92 (4H), and 3.97 (4H), the "$C_{11}H_{20}NO_2$" part of **4c** ("$C_{11}H_{20}NO_2$"+"NS_3") was characterized as both the piperidine part with four methyl groups and the ethylene acetal part ($CDCl_3$). However, the "NS_3" part of **4c** ($C_{11}H_{20}NO_2$+"NS_3") could not be characterized by spectroscopic analysis. Thus the whole structure determination was carried out by X-ray crystallographic analysis.[3a] Phases were assignable by the symbolic addition procedure, and structure factors were refined by the block-diagonal least-squares technique to a final R-factor of 6.7%. Consequently, **4c** was determined as 7,7,9,9-tetramethyl-1-(thiosulfinylaminothio)-1,4-dioxa-8-azaspiro[4.5]-decane (**4c**), containing the new thiosulfinylaminothio group, –S–N=S=S (Fig. 1). Structures **4a**, **4b**, and **4d** were analogously assigned on the basis of visible, mass, NMR spectra and/or elemental analyses. The new compounds **4a**—**d** indicated fungicidal activity,[3b] besides offering UV protecting in polyolefins, like polypropylene.



4c

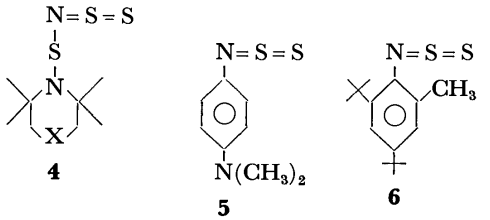
Fig. 1.

Preparation of 4 from Bis(2,2,6,6-tetramethylpiperidino) disulfide (2) or Bis(2,2,6,6-tetramethylpiperidino) trisulfide (3). First, we wanted to see whether 1-(thiosulfinylaminothio)piperidine (**4**) was the secondary product given by an interaction of ammonia with the disulfide **2** and/or trisulfide **3**. This is because, as shown in Eqs. 4 and 5, treatment of the reaction mixture with 10% aqueous ammonia gave **4**, **3**, and **2**; whereas treatment of the same mixture with 10% aqueous $KHCO_3$ gave **3** and **2** without **4**.

The desired examination was carried out as follows. Treatment of pure, freshly prepared **2a** or **3a** with 10% aqueous ammonia caused no reaction under reaction conditions similar to those used in Eq. 4. However, in the presence of equimolar amounts of S_2Cl_2 relative to **2a** or **3a**, similar treatment with ammonia gave the expected **4a** (Eq. 6) in a yield of 35.2 or 32.7%, respectively, higher than that of 8.6% from **1a**. The yields were based on the assumption that 1 mol of the starting **1**, **2**, or **3** gives 1 mol of **4**. Thus **2** and/or **3** may be the precursor of **4**. The relatively low yield of **4** from **1** is reasonably explained by assuming that **1** consumes sulfur monochloride to give **2** and/or **3**.

$$\mathbf{2a} \xrightarrow[\text{ii) aq } NH_3]{\text{i) } S_2Cl_2} \mathbf{4a} \qquad \mathbf{3a} \xrightarrow[\text{ii) aq } NH_3]{\text{i) } S_2Cl_2} \mathbf{4a} \qquad \text{(Eq. 6)}$$

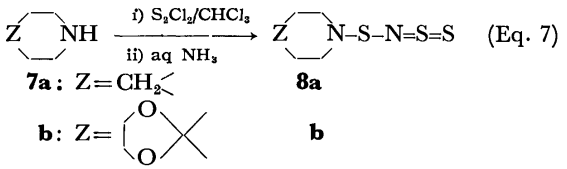
Although the reaction of secondary amines with sulfur monochloride has been shown in many papers to give bis(disubstituted amino) polysulfides,[4] no compounds having the –S–N=S=S group have yet been reported. For primary amines, on the contrary, the analogous function, the thiosulfinylamino group (–N=S=S) was recently reported by Barton *et al.*[5] and Inagaki *et al.*[6] Aromatic primany amines having an electron-donating group at the *p*-position, or bulky groups at the 2 and 6-positions, *e.g.* *p*-dimethylaminoaniline or 2,4-di-*t*-butyl-6-methylaniline, react with sulfur monochloride to give the corresponding *N*-thiosulfinylaniline **5** or **6**, as shown in Fig. 2, which was relatively stable. Interestingly, substituted aniline with less bulky groups at the 2 and 6 positions, such as 2,4,6-trimethylaniline, gives the corresponding *N*-thiosulfinylaniline in a low yield. They explained the stability of *N*-thiosulfinylaniline in term of the steric effect.[6]



4 **5** **6**

Fig. 2.

Formation of Non-Hindered 1-(Thiosulfinylaminothio)-piperidines (8). In order to investigate whether the contribution of the steric effect by the tetramethyl group is necessary for the formation of 1-(thiosulfinylaminothio)piperidines (**8**), piperidines unsubstituted at the 2 and 6-positions (**7a** and **7b**) were examined. **7a** and **7b** similarly gave the corresponding 1-thiosulfinylaminothio derivatives **8a** and **8b** (Eq. 7), respectively, in much

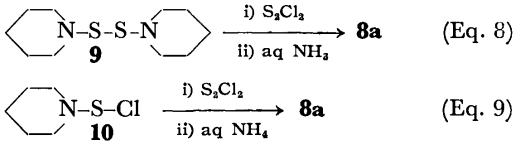


7a: Z=CH_2 **8a**

b: Z= **b**

(Eq. 7)

lower yield (*ca.* 0.4%),[7] under the same reaction conditions as described in Eq. 4. The isolated **8a** was characterized by its high resolution mass spectrum exhibiting an M^+ peak at *m/e* 193.9986, which consisted with the calculated value for $C_5H_{10}N_2S_3$ (194.0006), and by its visible spectrum (410 nm in ethanol). Additionally, the compound **8a** was also prepared in 2.8% yield[7] from the corresponding disulfide **9** (Eq. 8)



9 **10**

(Eq. 8) (Eq. 9)

in a manner similar to that shown in Eq. 6.

As will be discussed later, 1-sulfenylpiperidine chloride (**10**)[8] may be one of the precursors of **8a** (Eq. 9). In order to examine this assumption, freshly prepared **10** was treated by a method similar to that described in Eq. 6. Expectedly **10** also gave **8a** (Eq. 9) in 1.2% yield.[7]

Thus it was found that **8a** was obtained from **7a**, **9**, or **10**. However the yield of **8a** is much lower than that of **4a**. The difference may depend upon that of the stability of **4a** and **8a**. In order to check this explanation, we tried following experiments.

The Photo- and Thermal Behavior of Hindered (4) and Nonhindered (8) 1-(Thiosulfinylaminothio)piperidines. The photochemical behavior of sterically hindered 1-(thiosulfinylaminothio)piperidines (**4**) and unhindered 1-(thiosulfinylaminothio)piperidines (**8**) under natural diffused light at room temperature was studied. Relative fading rates of both **4** and **8** were compared at a concentration of $5—10\times10^{-5}$ M in hexane or ethanol for a period of 1 h, measuring the decrease in visible absorption at 410 nm (Table 2). Blank experiments on **4** and **8** in the dark at room temperature showed no detectable change in hexane and ethanol. Table 2 shows that the photochemical behavior of **4** and **8** are nearly the same, and therefore, their photochemical behavior does not depend on the bulk of the substituents at the 2 and 6 positions.

Table 2. Photochemical behavior of 1-(thiosulfinylaminothio)-piperidines, **4** and **8**

Compound	% Loss during 1 h[a,b]	Solvent[c]
4a	5	H and E
4b	5	H and E
4c	7	H and E
4d	7	H and E
8a	5	H and E

a) On allowing to stand under natural diffused light. b) By measuring the decrease at 410 nm. c) H: hexane; E: ethanol.

Thermal behavior of **4** and **8** was similarly studied. Refluxing a $5—10\times10^{-5}$ M solution of **4** or **8** in chloroform for 3 h showed no detectable change in visible absorption.

Accordingly the much lower yield of **8** than **4** could not be explained in terms of the product stability. Thus the difference in the yield of **4** or **8** seems to depend on other causes, *e.g.*, properties of an uncertain intermediate to be discussed later.

Possible Reaction Pathways. Equation 2, along with as described in Eqs. 4, 5, and footnote 9 shows that piperidines, **1** or **7**, react with sulfur monochloride to give the corresponding disulfides, **2** or **9**, and the trisulfide **3**. The resulting **2**, **3**, or **9** may further react with sulfur monochloride at the first stage (Fig. 3) to give the corresponding 1-sulfenyl chloride **10** or **12**, since sulfur monochloride has been known to polarize to $Cl^{\delta-}.....^{\delta+}S_2Cl$.[4] Additionally, a presumed compound, **11** simultaneously prepared from **2**, **3**, or **9** may also give **10** or **12**. Equations 6 and 8 show that the di- and trisulfides **2**, **9**, and **3** actually give the corresponding 1-(thiosulfinylaminothio)piperidines **4** and **8**. Further Eq. 9 also shows that the sulfenyl chloride **10** actually gives **8**.

Thus it can be explained that the new 1-(thiosulfinylaminothio)piperidines **4** or **8** are prepared *via* the corresponding disulfides **2** or **9** and/or the trisulfides **3** and, subsequently, such sulfenyl chloride as **10**. Tentatively it is assumable that **4** and **8** may be prepared *via* the postulated intermediates **13** and **14** derived from the sulfenyl chloride **12** or **10** (Fig. 3) although the intermediary presence of **13** and **14** are unconfirmed. From this assumption, the much lower yield of **8** (R=H), described above, may be explained by the decrease of stability of the intermediate **13** or **14** (R=H).

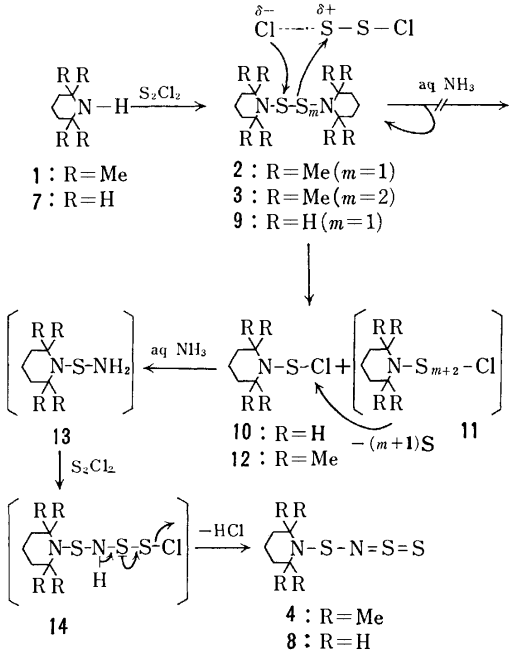


Fig. 3.

Experimental

Mps were not corrected.

NMR spectra were obtained using a Varian A-60 NMR spectrometer, using TMS as an internal standard.

Mass spectra were obtained using a JEOL-JMS-OISG mass spectrometer with an ionizing energy of 75 eV.

Thin-layer chromatography (TLC) was performed on TLC-plates Silica Gel F_{254} (0.25 mm) (Merk).

Bis(2,2,6,6-tetramethylpiperidino) Disulfide (2a) (X: $CH_2<$). Into a solution of 48 g (0.34 mol) of 2,2,6,6-tetramethylpiperidine (**1a**) (X: $CH_2<$) in 120 ml of DMF and 350 ml of hexane was added dropwise a solution of 4.58 g (0.034 mol) of sulfur monochloride in 40 ml of hexane with stirring at −20——25 °C for 30 min. After the addition was completed, the internal temperature was gradually raised to room temperature over a period of 30 min. The reaction mixture was then poured into ice and extracted with benzene. The benzene layer was washed with a 3% aqueous solution of hydrochloric acid and three times with water and dried over sodium sulfate. Evaporation of the benzene under diminished pressure gave 11.2 g of the crude product **2a** which was recrystallized from methanol to give 9.4 g of an

analytically pure colorless compound (needles), mp 83—84 °C, [lit,[1] mp 84—85 °C]. The combined yield of crystalline product (80.2%) and of the residue in solution (as determined by NMR using anisol as an internal standard) was 88.8% based on the starting sulfur monochloride. Found: C, 62.49; H, 10.71; N, 7.97; S, 18.60%. Calcd for $C_{18}H_{36}N_2S_2$: C, 62.73; H, 10.52; N, 8.12; S, 18.60%.

Bis(4-oxo-2,2,6,6-tetramethylpiperidino) Disulfide (2b) (X: O=C<) was prepared by our improved method described in Refs. 2a and 2c.

Bis trisulfides 3a and 3b were prepared by the method of Bennett *et al.*[1]

Isolation of 1-(Thiosulfinylaminothio)piperidines (4) and Detection of Bis(2,2,6,6-tetramethylpiperidino) Disulfides (2) and Bis(2,2,6,6-tetramethylpiperidino) Trisulfides (3). (Eq. 4)

4-Oxo-2,2,6,6-tetramethyl-1-(thiosulfinylaminothio) piperidine (4b): Into a solution of 31 g (0.2 mol) of **1b** in 500 ml of toluene was added dropwise a solution of 27 g (0.2 mol) of sulfur monochloride in 80 ml of hexane with stirring at 10—15 °C over a period of about 2 h. After the addition was completed, the reaction mixture was poured into 300 g of ice and 200 g of 35% aqueous ammonia. The organic phase was then separated, washed with water and dried over magnesium sulfate. Evaporation of the solvent under diminished pressure gave a red solid, which was chromatographed on 1.5 kg of Silica Gel 60 (Merck, 70—230 mesh) with benzene to give red crude crystals in 14% yield. Recrystallization of the crude crystals from hexane gave analytically pure red prisms, mp 116.5—118 °C. NMR (CCl_4) δ 1.47 (S, 12H), 2.60 (S, 4H). MS *m/e* 264 (M^+). Found: C, 40.52; H, 6.00; N, 10.61; S, 36.04%. Calcd for $C_9H_{16}N_2OS_3$: C, 40.87; H, 6.09; N, 10.59; S, 36.73%.

The trisulfide 3b and a trace amount of the disulfide 2b were detected in the reaction mixture by TLC and NMR-analysis.

4-Benzoyloxy-2,2,6,6-tetramethyl-1-(thiosulfinylaminothio)-piperidine, (4d). Into a solution of 4.8 g (0.0184 mol) of 4-benzoyl-2,2,6,6-tetramethylpiperidine **1d** in 20 ml of chloroform was added dropwise a solution of 2.5 g (0.0185 mol) of sulfur monochloride in 10 ml of chloroform with stirring at 10—15 °C over a period of 20 min. After the addition was completed, the reaction mixture was poured into 30 g of ice and 20 g of 35% aqueous ammonia. Then the chloroform was separated, washed with water, and dried over magnesium sulfate. Evaporation of the chloroform under diminished pressure gave a red solid, which was chromatographed on 150 g of Silica Gel 60 (Merck, 70—230 mesh) with a mixture of benzene and hexane (1: 1) to give red crude crystals in 6% yield. Recrystallization of the crude crystals from hexane gave analytically pure red prisms, mp 99—100 °C. NMR ($CDCl_3$) δ 1.46 (S, 6H), 1.54 (S, 6H), 1.75 (br. d, 2H), 2.27 (dd, 2H, J=12 and 4.5 Hz), 5.58 (tt, J=12 and 4.5 Hz), 7.3—8.3 (m, 5H). MS *m/e* 370 (M^+). Found: C, 51.53; H, 5.91; N, 7.68; S, 26.21%. Calcd for $C_{16}H_{22}N_2O_2S_3$: C, 51.86; H, 5.98; N, 7.55; S, 25.95%.

1-(Thiosulfinylaminothio) piperidines, 4a, 4c, 8a, and 8b, were prepared from the corresponding amines by a method similar to that described for **4b** and **4d**. **4a** (Y=8.6%) was identified visible, NMR, and mass spectra. NMR ($CDCl_3$) δ 1.40 (S, 12H), 1.5—1.8 (m, 6H). MS *m/e* 250 (M^+). Data of **4c** (Y=7%) were given in the text. Found: C, 42.83; H, 6.31; N, 9.00; S, 31.46%. Calcd for $C_{11}H_{20}N_2O_2S_3$: C, 42.82; H, 6.53; N, 9.08; S, 31.18%. Unhindered **8a** and **8b**, separated by column chromatography, were identified by visible, mass, and/or high resolution mass spectra. Data of **8a** was given in the text. R_f-value (SiO_2-TLC/hexane) was 0.25. **8b:** The mass spectrum (*m/e* 252, M^+) was consistent with the theoretical value. λ_{max} (in EtOH): 410 nm.

Experiment A (Eq. 5). The reaction mixture, which was obtained during the preparation of **4b**, was poured into ice and 10% aqueous potassium hydrogencarbonate instead of ammonia. In the resulting organic phase, **3b** and a trace amount of **2b** were observed by TLC and NMR analysis.

Experiment B (Eqs. 6, 8, and 9). Under the same reaction conditions as used in Eq. 4, an equimolar mixture of **2a**, **2b**, **3a**, **9**, or **10** and sulfur monochloride were treated with aqueous ammonia. The results were shown in the text.

7b was prepared from the corresponding 1-methylpiperidine by the modified method of Fischer *et al.*[12]

9 was prepared by the method of Dogadkin *et al.*[10]

10 was prepared by the method of Weiss *et al.*[8]

The authors thank Director of Central Research Laboratories, Dr. Keisuke Murayama, and Director of Fine Chemical Research in these Laboratories, Dr. Nobuo Soma for their encouragement and valuable comments throughout this study. The authors are also indebted to the members of the analytical section of these laboratories for the elemental analyses and spectral data.

The Reaction of Alkenylboranes with Palladium Acetate. Stereoselective Synthesis of Olefinic Derivatives†,[1]

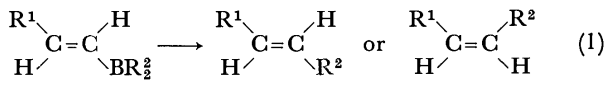
Hidetaka YATAGAI

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606

(Received November 14, 1979)

The reactions of alkenylboranes with palladium acetate were investigated. Alkenyldialkylboranes, derived from terminal alkynes, underwent intramolecular migration reaction in the presence of an equimolar amount of palladium acetate and triethylamine to give (*E*)-olefins. On the other hand, under the same conditions as above or even in the presence of catalytic amounts of palladium acetate, alkenyldialkylboranes derived from internal alkynes underwent protonolysis reaction to produce (*Z*)-olefins. An alkenylpalladium intermediate which was presumably involved in the latter reaction was trapped by allylic chloride to give 1,4-dienes.

Organic syntheses *via* boranes have been broadening the synthetic applicability of olefinic or acetylenic derivatives, since organoboranes are easily obtainable *via* hydroboration. Especially, application of alkenylboranes toward organic syntheses may enchant synthetic chemists in view of introduction of alkenyl groups with *trans* configuration into organic molecules. Indeed, various synthetic methods using alkenylboranes have been developed.[2] As for the C–C bond formation which is accomplished by the intramolecular migration reaction as shown in Eq. 1,[3] there lies a limitation

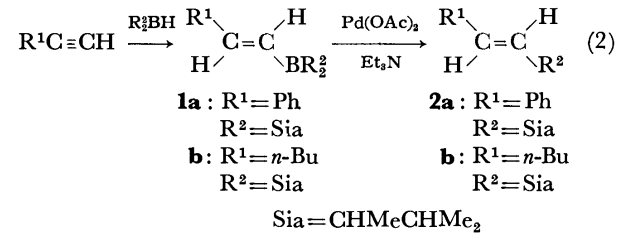


(1)

concerning to the R^2 group; R^2 is limited to the secondary. The methodology of transmetallation from less reactive B–C bond to a reactive other metal-carbon bond seems to exclude this limination and provide a possibility of versatile intermolecular C–C bond formations.[4] It was reported in previous papers that such a transmetallation was realized in the case of copper by the reaction between methylcopper and alkenylboranes.[4a] This result prompted to investigate other transition metal such as palladium,[5,7] which was of potentially wide applicability to organic synthesis.[6] In this paper the reactions of alkenylboranes with various palladium complexes are examined and three types of reactions, 1) intramolecular migration reaction,[1a] 2) protonolysis reaction,[1b] and 3) cross-coupling reaction are reported.

Results and Discussion

Intramolecular Migration Reaction Promoted by Palladium Acetate. First, alkenyldialkylboranes (**1**) derived from terminal alkynes were tried to react with an equimolar amount of various palladium complexes such as $PdCl_2$, $Pd(AcAc)_2$, $Pd_2(DBA)_3$, $Pd(PPh_3)_4$[7] and $Pd(OAc)_2$. Quite interestingly, only palladium acetate reacted smoothly at room temperature with **1** to produce (*E*)-olefins (**2**) as the coupling product between alkenyl and alkyl groups. (Eq. 2).



(2)

1a: R^1=Ph, R^2=Sia; **1b**: R^1=*n*-Bu, R^2=Sia

2a: R^1=Ph, R^2=Sia; **2b**: R^1=*n*-Bu, R^2=Sia

Sia=$CHMeCHMe_2$

This reaction essentially needed triethylamine and the yield of **2** depended upon the amount of triethylamine. When catalytic amounts of triethylamine (7 mol %) were used in the reaction of (*E*)-styryldisiamylborane (**1a**), **2a** was obtained in the highest yield. In contrast to this, when R^1 was alkyl such as (*E*)-1-hexenyldisiamylborane (**1b**), an equimolar amount of triethylamine gave the best result. (see, Table 1).

Table 1. Reaction of **1** with $Pd(OAc)_2$ in the presence of various amounts of amine[a]

1 (**1a** or **1b**)	Product (**2a** or **2b**)	Et_3N mmol	Yield of **2**[b] %
1a	**2a**	2	64
		1	68
		0.35	79
		0.07	98
		0	60
1b	**2b**	2	55
		1	74
		0.05	33
		0	10

a) **1** (1 mmol), $Pd(OAc)_2$ (1 mmol).
b) By GLPC yield.

Taking account of these results, various types of (*E*)-olefins (**2**) were synthesized from alkynes (Table 2). The stereochemistry of the products in each case was over 96% *trans* as determined by the strong absorption at 965 cm^{-1} region in IR spectra and GLPC examination in comparison with the corresponding *Z*-isomer.

Previously, Zweifel and his co-workers reported the stereoselective synthesis of (*E*)-olefins from alkenylboranes using BrCN.[3a] Attempts to apply this procedure to styrylboranes (Table 2 entries 1, 3, and 4) resulted in failure; reaction of **1a** with BrCN gave

† Thesis submitted by the author (H. Y.) to Kyoto University in partial fulfillment of the requirements for the degree of Rigaku-Hakushi (Ph. D.).

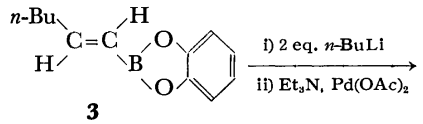
Table 2. Reaction of **1** with $Pd(OAc)_2$–Et_3N[a]

Entry	Acetylene	Borane[c]	Product[d]	Yield[e] (Isoln)[b]
1[f]	PhC≡CH	 **1a**	 **2a**	94 (86)
2[g]	*n*-BuC≡CH	 **1b**	 **2b**	74 (58)
3[f]	PhC≡CH	 **1c**	 **2c**	58 (35)
4[f]	PhC≡CH	 **1d**	 **2d**	(86)
5[g]	$Cl(CH_2)_3C{\equiv}CH$	 **1e**	 **2e**	(62)

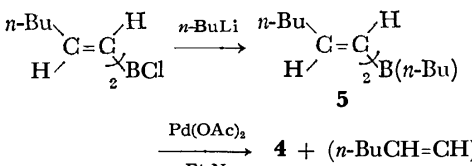
a) All reactions were performed on a 1 mmol scale. b) Isolation was carried out on a 5 mmol scale. c) Sia=CHMeCHMe$_2$. d) Identified by IR and NMR spectroscopies, elemental analyses, and/or comparison with authentic materials. e) By GLPC based on the acetylenes. f) Catalytic amounts of Et_3N (7 mol %) were used. g) Stoichiometric amounts of Et_3N were used.

styrene instead of **2a**. Consequently, the present reaction offers a noteworthy improvement in the existing methodology of intramolecular migration reaction.

By the hydroboration method for the preparation of alkenyldialkylboranes, the alkyl groups are limited to secondary groups. Thus, the introduction of the primary alkyl group was achieved by the two methods as shown in Eqs. 3 and 4. Although the desired (*E*)-5-decene (**4**) was obtained by both methods, yields were low and the reaction in Eq. 4 gave 1,3-diene (**6**) as a by-product.



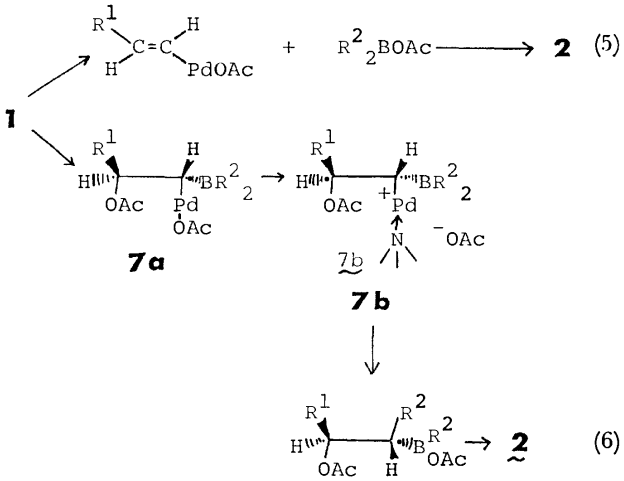
3 → *n*-BuCH=CH(*n*-Bu) **4** (3)



5 → **4** + (*n*-BuCH=CH)$_2$ **6** (4)

31% 57%

Two mechanisms appear reasonable to consider for this transformation; a) intermolecular coupling process *via* the alkenylpalladium acetate on the analogy of transmetallation to Hg[4c] and Pd[5] (Eq. 5), and b) intramolecular process *via* acetoxypalladation-migration-elimination (Eq. 6). Although a mixture of **1a** and dicyclohexylacyloxyborane was treated with $Pd(OAc)_2$–Et_3N, cross-coupling product (β-cyclohexylstyrene) could



(5)

(6)

not be obtained thus excluding the intermolecular mechanism. Therefore, intramolecular migration is reasonable. There remain the following two possibilities; 1) *cis* acetoxypalladation-migration[3] from boron to the α-carbon with inversion at the migration terminus syn elimination[3a,8,9] or 2) *trans* acetoxypalladation-inversion anti elimination.[3b,8a] The hitherto known migrations proceed with inversion of configuration and the anti β-elimination is restricted to the reaction in the presence of strong base. Consequently, intramolecular process 1) demanding the *cis*-acetoxypalladation is favorable.[10]

The orientation of the acetoxypalladation may be explained as follows. The vacant p orbital of boron atom interacts with π-electrons of the double bond[11] to make the β-carbon of alkenylborane electropositive.

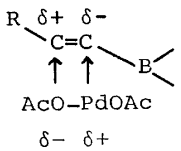


Fig. 1.

Therefore the nucleophilic acetoxyl group can attack this β-carbon to give **7** (Fig. 1).[12]

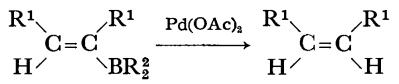
The investigation of effect of various amines showed that the yield of **2b** had a relation with coordination ability of amines with trimethylborane (Table 3). That is, the present reaction can proceed smoothly under the conditions in which amine coordinates with palladium rather than boron. Et_3N could satisfy these conditions and coordinate with palladium to give cationic palladium complex (**7b**) which may induce alkyl migration more easily.[13]

Table 3. Reaction of **1b** with $Pd(OAc)_2$ in the presence of amine[a]

Amine	Yield of **2b** (%)	Amine: BMe_3 dissociation const.[b]
	32	0.301
Me_3CNH_2	49	9.46
Et_3N	74	—[c]

a) **1b** (1 mmol), $Pd(OAc)_2$ (1 mmol), amine (1 mmol). b) H. C. Brown, "Boranes in Organic Chemistry," Cornel Univ. Press **1972**, p. 59. c) Too highly dissociated to be measured.

Application of this type of reaction to alkenyldialkylboranes (**8**), derived from internal alkynes, resulted in failure giving (*Z*)-olefins (**9**) instead which were formed *via* retentive protonalysis of the alkenylgroup of **8** (Eq. 7).

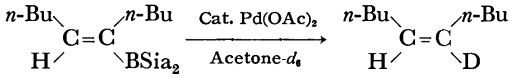


(7)

8a: R^1=*n*-Bu, R^2=Sia **9a**: R^1=*n*-Bu

Protonolysis of Alkenyldialkylboranes (8) Catalyzed by Palladium Acetate. As mentioned above, treatment of (*E*)-5-decenyldisiamylborane (**8a**) with an equimolar amount of palladium acetate and triethylamine produced **9a** in a yield of 71%. Quite interestingly, this protonolysis reaction proceeded successfully even in the presence of catalytic amounts of palladium acetate (5—10 mol%). The results are summarized in Table 4. Judging from Table 4, applicability of this method appears to be general for internal alkynes. However, similar treatment of alkenylborane derived from terminal alkyne gave unsatisfactory result.

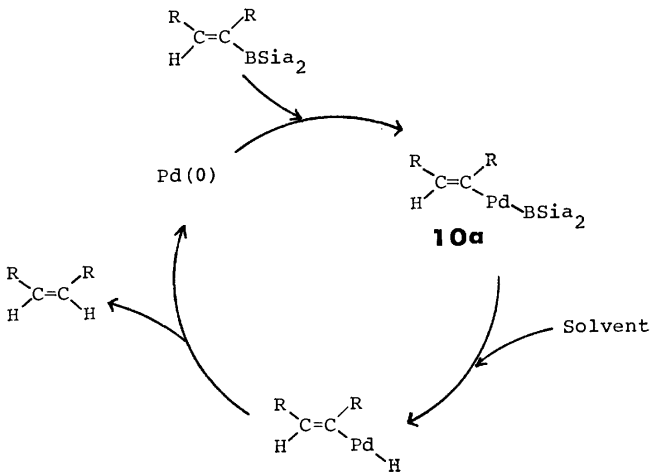
Previous methods for the protonation of alkenylboranes under acidic[14] or basic[15] conditions have several disadvantages; *e.g* incompatibility with various acid or base sensitive functional groups. The present procedure under a neutral and mild conditions can give a solution to this problem.



(8)

8a *d*-Content 88%

The experiment using acetone-d_6 as a solvent gave deuterium incorporated olefin[16] (Eq. 8). Accordingly, the proton source was confirmed to be the solvent. A mechanistic rationale which readily accounts for the observed catalytic process and deuterium labelling in



Scheme 1.

Table 4. Protonolysis of **8** with catalytic amounts of $Pd(OAc)_2$[a]

a) All reactions were performed on a 1 mmol scale. b) Isolation was carried out on a 5 mmol scale. c) Identified by IR, NMR, and/or comparison with the authentic materials. d) By GLPC, based on alkenylboranes. e) Mixture of 2*E* and 2*Z*-isomers.

acetone-d_6 is shown in Scheme 1; a) oxidative insertion of Pd(0) into the C–B bond followed by b) H-abstraction from the solvent and c) reductive elimination. Supposedly, in contrast to the alkenylboranes derived from terminal alkynes, migration of the alkyl group of **8** to the α-carbon must proceed quite sluggishly due to bulky alkenyl group of **8** compared to that of **1**.

Cross-coupling of Alkenylboranes Catalyzed by Palladium Acetate. The mechanistic consideration of the protonolysis reaction as suggested above indicates that this reaction might proceed *via* an alkenylpalladium intermediate such as **10**. It appears possible that such an intermediate may be trapped by an appropriate olefin. Actually, allyl chloride reacted with the intermediate to give (*E*)-1,4-dienes (**11**) stereoselectively. The protonolysis reaction, however, competed with the cross-coupling reaction (Eq. 9). This problem was solved by using alkenyl-9-borabicyclo[3.3.1]nonane (alkenyl-9-BBN) as a starting material. (see, Table 5).

$$\underset{\textbf{8a}:\ R^1=n\text{-Bu},\ R^2=\text{Sia}\quad \textbf{8b}:\ R^1=n\text{-Bu},\ BR^2_2=\text{9-BBN}}{R^1CH{=}CHBR^2_2} \xrightarrow[\text{Cat. From	**8a**:	23%	65%
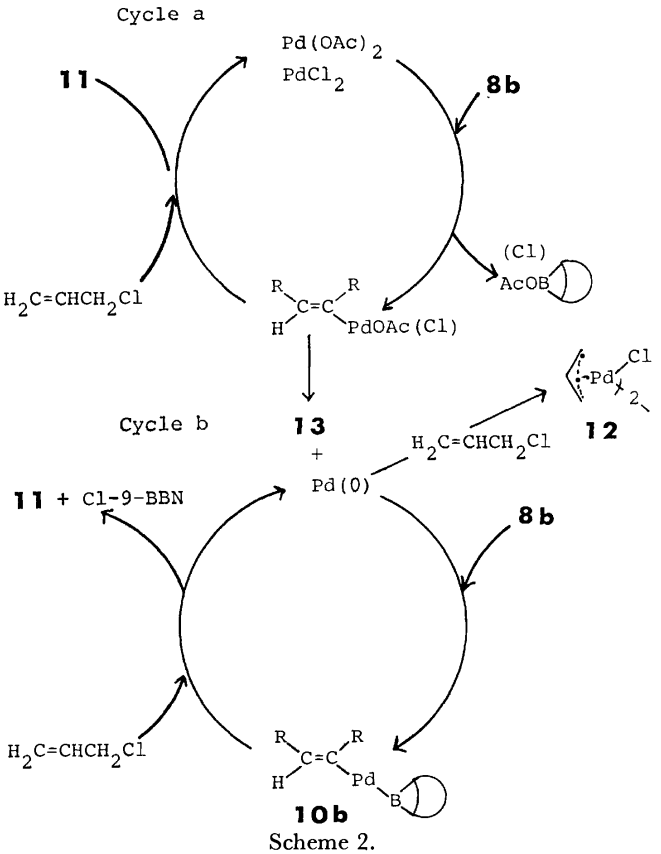
	8b:	70%	13%

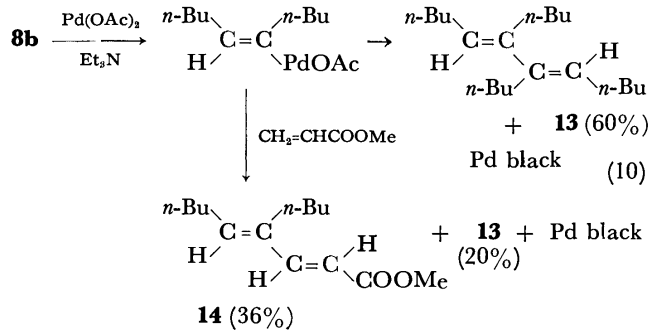
Allyl chloride and 3-chloro-1-butene underwent the effective cross-coupling (entries 2, 3, and 5), while crotyl chloride gave a poor result (entry 4). The cross-coupling reaction proceeded completely as S_N2' process and with retention of configuration of the double bond of alkenylboranes. Unfortunately the reaction of 1-alkenyl-9-BBN derived from terminal alkynes with allyl chloride gave only trace amounts of desired diene.

This reaction nearly completed within 30 min at room temperature, and at this time di-π-allyl-μ,μ'-dichlorodipalladium (**12**) was formed. Since it was confirmed that **12** did not react with **8a** or **8b**, **12** was not a real catalyst. Two catalytic cycles are possible for the reaction (Scheme 2); a) direct transmetallation of the B–C bond followed by insertion and elimination which is a process similar to Heck's[17] and Larock's[18] reaction, might be involved; b) oxidative addition of alkenyl boranes to Pd(0) produces **10**, which is considered to be an intermediate in the protonolysis reaction, and the subsequent insertion of allylic chloride and elimination give the product. The reaction of stoichiometric



Scheme 2.

amounts of palladium acetate with **8b** gave the dimeric product (**13**), presumably *via* alkenylpalladium acetate. In the presence of methyl acrylate[5] the cross-coupling product (**14**) was also obtained (Eq. 10). Therefore, there might be a possibility for the cycle a. However, cycle b can not be discarded on the basis of the following results; the addition of allyl chloride, after stirring the mixture of **8b** and catalytic amounts of palladium acetate for 1 h, also produced **11a** in a yield of 45%. In this system catalytic species is considered to be Pd(0) since palladium acetate must be reduced by the initial reaction[20] *via* the transmetallation and dimerization as shown in Eq. 10[21] Accordingly it is favorable to



consider that b is a main cycle for this reaction and formation of **12** extinguishes Pd(0) species. In the reaction with crotyl chloride, the formation of **12** might prevail over the insertion of crotyl chloride into **10b** owing to its steric effect.[22]

Experimental

NMR spectra were recorded on a JEOL-PS-100 spectrometer; chemical shifts in CCl_4 are expressed in parts per Million relative to Me_4Si. IR spectra were recorded on a JASCO-IR A-1 and GLPC analyses were performed on a JEOL-JGC-20K instrument, using a 2m column packed with SE-30 or Silicone DC-550 on Celite 545 AW. GC-MS were measured on a HITACHI-MR-1 using a 1 m column (SE-30). Elemental analyses were performed by the Microanalytical Laboratory of Kyoto University, Kyoto, Japan. Air sensitive materials were handled *via* the standard techniques described in Chapter 9 of Ref. 14. The reaction flasks were fitted with a side arm capped with a rubber septum. All reactions were carried out under a static pressure of nitrogen.

Reagent-grade solvents were purified by standard techniques and kept over a drying reagent. BH_3: THF and 9-borabicyclo[3.3.1]nonane (9-BBN) were prepared according to Ref. 14. Alkenylboranes[14] were prepared *in situ* without distillation. (*E*)-5-Decenyl-9-BBN,[23] di[(*E*)-1-hexenyl]chloroborane,[24] and 2-[(*E*)-1-hexenyl][1,3,2]benzodioxaborole[13] were distilled and their physical data are listed in Ref. 25. Commercially available *n*-BuLi was titrated by Eastham's method.[26] $Pd(OAc)_2$,[27] $Pd_2(DBA)_3$,[28] $Pd(PPh_3)_4$,[29] and $Pd(AcAc)_2$[30] were prepared according to the known procedures. Spectral data of products are listed in Table 6.

General Procedure for Synthesis of **2**. Syntheses of **2a**, **2c**, and **2d** were as follows. To a solution of $Pd(OAc)_2$ (5 mmol) and triethylamine (0.35 mmol) in THF (20 ml), **1** (5 mmol) was added. Palladium black soon precipitated from the resulting mixture. After stirring overnight at room

Table 6. Spectral data of products

Product	NMR	(IR cm^{-1})	Anal. (%) or MS
(*E*)-3,4-Dimethyl-1-phenylpentene (**2a**)	7.38—7.05 (5H, m), 6.35 (1H, d, J=15 Hz), 6.09 (1H, d-d, J=15, 7.5 Hz), 2.31—1.95 (1H, m), 1.80—1.35 (1H, m), 1.05 (3H, d, J=7 Hz), 0.93 (6H, d, 7 Hz)	965	Found: C, 89.88; H, 10.47 Calcd: C, 89.59; H, 10.41

a) Comparison with an authentic material prepared by Zweifel method.[3a]

temperature the mixture was concentrated under reduced pressure. Essentially pure products were obtained simply by passing this residue through an alumina column. **2b** and **2e** were isolated by the same method using 5 mmol of triethylamine. The investigation of the effect of amine was performed on 1 mmol scale and the reaction mixture was analyzed by GLPC. IR and NMR spectra of **2b** and **2e** were identified with those of authentic materials, prepared by the Zweifel method.[3a] Other products exhibited the expected spectroscopic characteristics.

Isomeric Purity of 2. In every case, the corresponding *Z*-isomers were synthesized by the Zweifel method; iodine-promoted intramolecular migration reaction.[3b] The GLPC examination (DC-550) revealed that each of **2a**, **2c**, and **2d** had longer retention time than that of corresponding *Z*-isomer. On the other hand, each of **2b** and **2e** had almost the same retention time as that of the corresponding *Z*-isomer, making the analysis difficult. It was found, however, that the corresponding epoxides of these compounds were easily separated by GLPC (DC-550).[31] Each Epoxide of *E*-isomers had shorter retention time than that of *Z*-isomers.

Synthesis of 4. *a*): *n*-BuLi in hexane (2 mmol) was added to **3** (1 mmol) in THF (2 ml) at 0 °C. The resulting mixture was stirred for 30 min at 0 °C and then triethylamine (1 mmol) and $Pd(OAc)_2$ (1 mmol) were added. The mixture was stirred overnight. The formation of **4** was confirmed by GC-MS in comparison with an authentic material and GLPC examination by internal standard method revealed this solution contained **4** in 27% yield.

b): **6** (1 mmol) was prepared in situ by the slow addition of *n*-BuLi (1 mmol) to di[(*E*)-1-hexenyl]chloroborane (1 mmol) in THF at −78 °C. To this solution, $Pd(OAc)_2$ (1 mmol) and triethylamine (1 mmol) were added at room temperature. GLPC examination by the same method as above revealed that this solution contained **4** in 31% yield accompanied by **6** in 57% yield.

General Procedure for the Synthesis of 9. Alkynes (5 mmol) were hydroborated by disiamylborane (5 mmol) to form alkenyldisiamylboranes (**8**). To this solution, $Pd(OAc)_2$ (0.5—0.1 mmol) was added under a static pressure of nitrogen at room temperature and the resulting mixture was stirred overnight. THF was removed under reduced pressure. The products were isolated through an alumina column. All products were identified by comparison with authentic materials which were obtained commercially or by the reduction of the corresponding alkynes.[32] IR spectra of all products showed no absorption at 965 cm^{-1}.

Deuterium Labelling Study. 5-Decyne was hydroborated by disiamylborane (1 mmol). THF was removed under reduced pressure. To remove THF completely, BCl_3 (2 mmol) in hexane was added to this residue and precipitated THF: BCl_3 was filtrated. The solvent and excess BCl_3 were removed under reduced pressure and the residue was utilized for the protonolysis reaction in acetone-d_6 (2 ml) catalyzed by $Pd(OAc)_2$ (0.1 mmol). The deuterium content was determined by GC-MS and NMR to be 88%.

General Procedure for (E)-1,4-Dienes (11). To a solution of alkenyl-9-BBN (5 mmol) and allyl chloride (5 mmol), $Pd(OAc)_2$ (0.5—0.1 mmol) was added and the resulting mixture was stirred overnight at room temperature. The products were isolated through an alumina column. Stereochemistry of **11a** was determined as follows. An authentic sample of **11a** was prepared according to Eisch method;[33a] NMR (δ, CCl_4) 5.65 (d-d, J=18, 10 Hz, 1H), 5.00 (t, J=6 Hz, 1H), 4.98—4.76 (m, 2H), 2.66 (d, J=6 Hz, 2H), 2.10—1.80 (m, 4H), 1.52—1.08 (m, 8H), 0.90 (t, J=6 Hz, 6H). IR (cm^{-1}), 990, 910. (*Z*)-4-Butyl-1,4-nonadiene, stereoisomer of **11a**, was prepared by the Zweifel method;[33b] 5-decyne (5 mmol) was hydroaluminated by $(i\text{-Bu})_2$-AlHMeLi, prepared from $(i\text{-Bu})_2AlH$ and MeLi. Then allyl bromide (10 mmol) in THF was added and resulting mixture was refluxed for 2 h. After addition of aq H_2SO_4 (0.5 M), the resulting mixture was extracted several times with hexane. The hexane solution was washed with aq $NaHCO_3$ and sat. solution of NaCl. Hexane was evaporated and the residue was chromatographed over alumina by using petroleum ether. Kuhgel rohr distillation gave (*Z*)-4-butyl-1,4-nonadiene; bp 140—160 °C/20 mmHg (40% yield), NMR (δ, CCl_4), 5.65 (d-d, J=10 Hz, 1H), 5.10 (t, J=6 Hz, 1H), 5.06—4.80 (m, 2H), 2.73 (d, J=6 Hz, 2H), 2.16—1.80 (m, 4H), 1.52—1.14 (m, 8H), 0.88 (bt, J=6 Hz, 6H), IR (cm^{-1}) 1630, 990, 905. Consequently, these isomers could be clearly discriminated by the chemical shift at the region between 2.66 and 2.73 ppm and NMR spectrum of the reaction product completely accorded with that of 4*E*-isomer. Furthermore, these isomers could be separated by GLPC (3m, 30% of Apiezon on Celite 545 AW). The retention time of 4*Z*-isomer was shorter than that of 4*E*-isomer, and the GLPC analysis of the reaction product showed a single sharp peak, whose retention time accorded with that of 4*E*-isomer. Accordingly, the reaction product can be assigned to pure 4*E*-isomer. This result indicates that the cross-coupling products retain the stereochemistry of the starting alkenyl-9-BBN. The stereochemical result could apply to other cross-coupling reaction. **11b** was assigned to a mixture of 2*E* and 2*Z*-isomers, since the IR spectrum showed a weak absorption at 965 cm^{-1} region.

Synthesis of 13. To a THF solution (4 ml) of Et_3N (1 mmol) and $Pd(OAc)_2$ (1 mmol), **8b** (1 mmol) was added. After stirring for 1 h at room temperature, palladium black was precipitated. GLPC examination revealed that **13** was formed in 60% yield, the structure of which was confirmed by GC-MS in comparison with an authentic material.[34]

Synthesis of 14. To a THF solution (4 ml) in which $Pd(OAc)_2$ (1 mmol), Et_3N (1 mmol), and methyl acrylate (2 mmol) were dissolved, **8b** (1 mmol) was added at room temperature. After stirring for 1 h, GLPC examination revealed that **14** and **13** were formed in 36 and 20% respectively. **14** was isolated through an alumina column by using hexane; NMR (δ, CCl_4), 7.10 (d, J=16 Hz, 1H), 5.80 (t, J=6 Hz, 1H), 5.68 (d, J=16 Hz, 1H), 3.64 (s, 3H), 2.30—2.00 (m, 4H), 1.60—1.20 (m, 8H), 1.00—0.80 (m, 6H). MS; 223 (M^+).

Mechanistic Study. THF solution (2 ml) of $Pd(OAc)_2$ (10 mg) showed an absorption at 400 nm (ε=30). By the addition of **8a** or **8b** (1 mmol) this absorption disappeared, and then the solution was stirred for 1 h. After addition of allyl chloride (1 mmol), a new absorption at 350 nm appeared in UV spectrum. This absorption corresponded with that of di-π-allyl-μ,μ'-dichlorodipalladium (**12**) in THF. In the stoichiometric reaction (1 mmol scale), **12** was isolated in 10% yield by column chromatography (alumina-hexane). GLPC examination revealed that the cross-coupling took place within 30 min and yield was 45%.

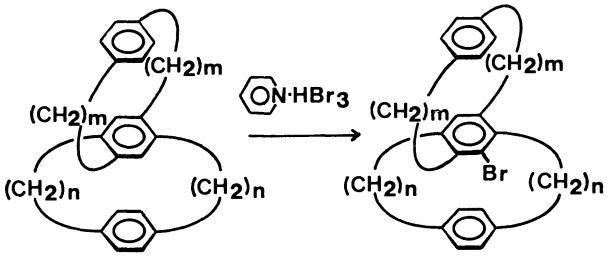
Layered Compounds. LXIII.[1] Bromination of Double- and Triple-layered Paracyclophanes

Tetsuo Otsubo,† Hisanori Horita, Yosuke Koizumi, and Soichi Misumi*
The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka 565
(Received November 19, 1979)

[*m.m*][*n.n*]Triple-layered paracyclophanes underwent bromination to give exclusively monobromo derivatives substituted to the inner benzene. The reactions were markedly accelerated by the transannular electronic interaction as compared to [*n*]- and double-layered paracyclophanes, and their enhanced reactivities were demonstrated by some competitive reactions. The relative rates of [2.2] and [3.3]systems are in reverse order for the triple-layered and double-layered series. Their reaction mechanisms were discussed.

It is well-known that layered compounds exhibit unique properties originated from the transannular π-electronic interaction of the faced benzene rings.[2] The enhancement in chemical reactivities based on the interaction was observed in some studies on the electrophilic aromatic substitution of double-layered compounds such as [*n.n*]paracyclophanes[3] and janucene.[4] Since multilayered cyclophanes show a stronger π-electronic interaction than double-layered series,[2] it is very interesting to study their chemical properties. Multilayered [2.2]paracyclophanes are expected to be highly reactive for electrophilic aromatic substitutions. However, their severe strain prevents normal Friedel-Crafts reaction and leads to unusual reactions such as skeletal rearrangement.[5]

[3.3]Paracyclophane and its derivatives are expected to show a reactivity reflecting the transannular π-electronic interaction alone because they have far less strain than those of the corresponding [2.2]phane systems. In addition, they may give some of the information on the reactions, in which the formation of π-complex is an important step of aromatic substitution, since [3.3]paracyclophane show a strong π-basicity.[6] In these regards we have investigated the bromination of double and triple-layered paracyclophanes with [2.2] and [3.3]types of bridging chains and related cyclophanes.



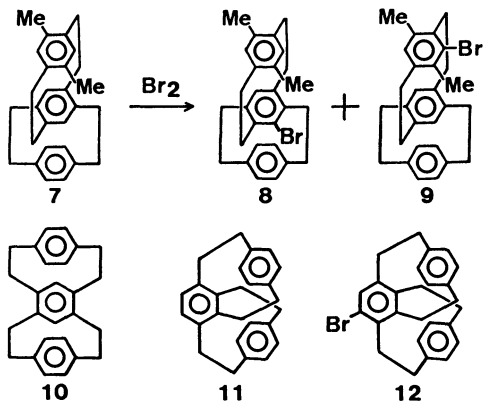
1, m = n = 2
2, m = 2, n = 3
3, m = n = 3
4, m = n = 2
5, m = 2, n = 3
6, m = n = 3

Scheme 1.

Results and Discussion

Bromination. Triple-layered paracyclophanes **1**—**3**[1,7,8] gave easily the corresponding monobromo derivatives **4**—**6** as a sole product by non-catalytic bromination. In the reactions, pyridinium hydrobromide perbromide afforded the bromides in better yields than with bromine alone. These brominations were complete in a shorter time than for [*n*]paracyclophane or double-layered paracyclophane, indicating an acceleration of the reaction based on strong transannular electronic stabilization in the transition state. No dibromo derivative was formed even if an excess of the reagent was used or the reaction time was prolonged. The first-introduced bromine substituent may prevent the following substitution because the steric requirement and the inductive effect of the very bromo group probably makes difficult the formation of the second σ-complex at the inner benzene.

On the other hand, bromination of 4,7-dimethyl-[2.2][2.2]paracyclophane **7**[7] afforded an equimolar mixture of inner-bromo derivative **8** and outer-bromo derivative **9**. Both reaction sites, the inner and the dimethylated outer benzenes, are in a similar electronic state with regard to alkyl substituent effect, but the outer benzene is of greater advantage than the inner with regards to steric surroundings. This sterical disadvantage for bromo-substitution at the inner benzene must be compensated by a stabilization of the intermediate due to a larger transannular electronic interaction to yield an equal amount of **8** and **9**.



Scheme 2.

Treatment of **1** with bromine in the presence of iron powder gave skeletal rearrangement products **10**—**12**[5] together with **4**. Our previous papers reported that **1**

† Present address: Department of Applied Chemistry, Faculty of Engineering, Hiroshima University, Sendamachi, Hiroshima 730.

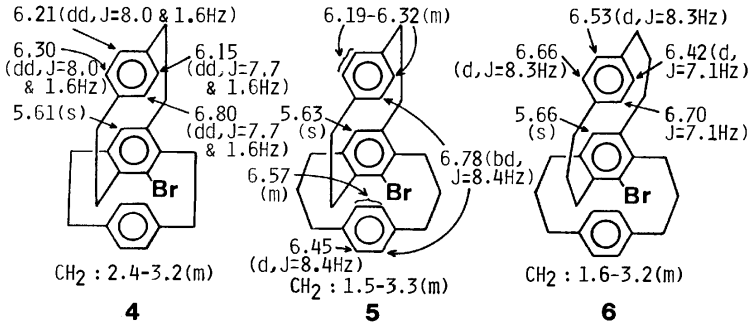


Fig. 1. NMR data of monobromo triple-layered paracyclophanes **4**—**6** in deuteriochloroform (δ, 100 MHz).

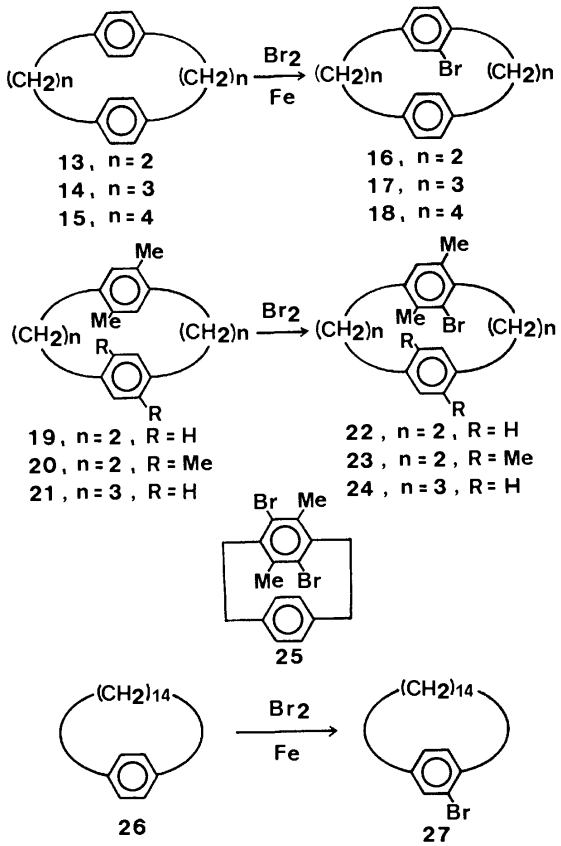
underwent the same skeletal rearrangement by catalysis of a variety of Brønsted acids such as tin(IV) chloride–hydrogen chloride.[5] So, it can be presumed that a similar acid, *e.g.*, iron(III) bromide–hydrogen bromide, was formed in the bromination reaction and acted as a catalyst for the rearrangement.



Scheme 3.

Monobromination of [*n.n*]paracyclophanes, **13**,[9] **14**,[10] and **15**, and [14]paracyclophane **26** was accomplished by bromine and iron catalyst. Methyl substituted [*n.n*]paracyclophanes **19**—**21**, on the other hand, were readily brominated by bromine alone. In this case, use of excess reagent provided dibromo derivative as represented by **25**, and pyridinium hydrobromide perbromide was less reactive.

Physical Properties of Bromo Derivatives. The structures of all the bromo derivatives were confirmed by NMR and mass spectra and elemental analyses. The NMR spectra of bromo triple-layered paracyclophanes show a characteristic pattern (Fig. 1). The aromatic signals of the parent triple-layered compounds appear at higher field due to the anisotropic effect of the faced aromatic rings,[11] but the introduction of bromine atom gives rise to a considerable downfield shift of the proton pseudo-gem to the bromine (0.65 ppm for the [2.2][2.2]system and 0.30 ppm for the [3.3][3.3]-system).[10,12] This may be explained in terms of steric compression effect of the bromine atom.

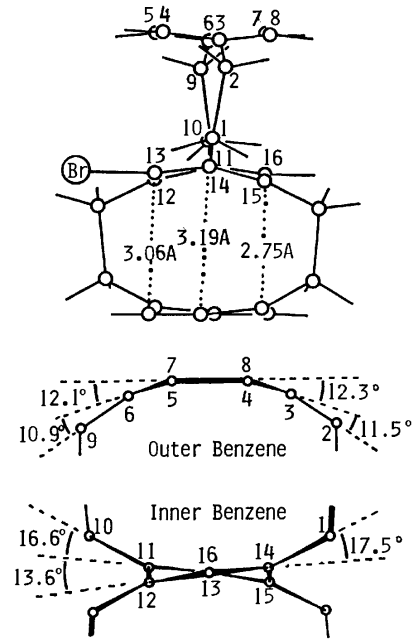


Fig. 2. Molecular structure of monobromo triple-layered [2.2]paracyclophane **4**.

An exact molecular structure of **4** was determined by X-ray crystallographic analysis (Fig. 2).[13] Its structural features are described below. The bending of the outer benzenes are almost the same as those of [2.2]paracyclophane **13**[14] and tetramethyl quadruple-layered [2.2]-paracyclophane,[15] and the inner benzene is twisted by a nearly equal twisting angle, *ca.* 13°, as that of the quadruple-layered paracyclophane. The non-bonding distance between the bromine and the pseudo-gem proton is an unexpectedly large value, 3.218 Å which is equal to or rather longer than ordinary van der Waals

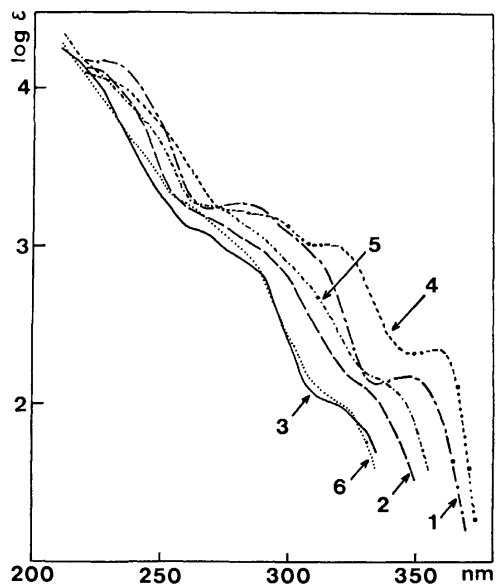

Fig. 3. The electronic spectra of triple-layered [*m.m*]-[*n.n*]paracyclophanes **1**—**3** and their monobromo derivatives **4**—**6** in tetrahydrofuran.

contact. Accordingly, it is concluded that the introduction of a bromine atom exerts less influence on the original structure of the parent hydrocarbon than expected from NMR analysis.

As shown in Fig. 3, the strong transannular electronic interactions of triple-layered paracyclophanes are indicated by marked bathochromic shifts of bands in their electronic spectra.[7,16] Although the spectrum of benzene itself is little affected by bromo substituent,[17] the substitution to triple-layered paracyclophanes gives rise to further bathochromic shifts of the longer wavelength bands except the [3.3][3.3]system. Thus, the substituent effect is dependent on the interplanar distance in the parent compounds, *viz.*, [2.2][2.2]PC **1**>[2.2][3.3]PC **2**>[3.3][3.3]PC **3** (PC=paracyclophane). Figure 4 shows the electronic spectra of monobromo dimethyl derivatives **8** and **9**. The inner bromo derivative **8** exhibits a significant red shift, whereas the outer bromo derivative **9** a hypsochromic shift of the longest wavelength band, supporting a much larger transannular electronic interaction due to the bromo substitution at the inner benzene as described above.

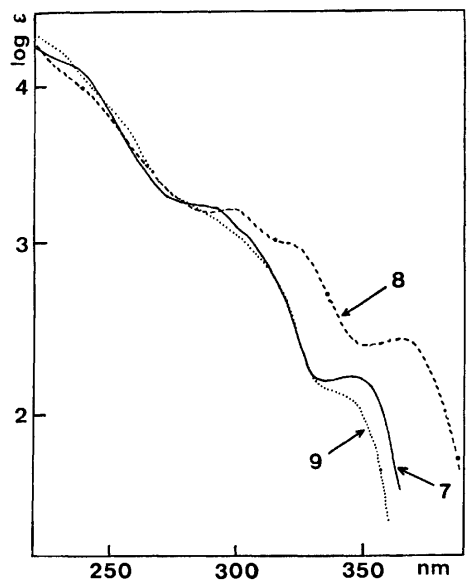

Fig. 4. The electronic spectra of dimethyl triple-layered [2.2]paracyclophane **7** and its monobromo derivatives **8** and **9** in tetrahydrofuran.

Table 1. Competitive reactions of paracyclophanes

Run	Compounds	Reagent[a]	Product ratio
1	**1** and **2**	A or B	**4** : **5**=20 : 1
2	**2** and **3**	A	**5** : **6**= 3 : 1
3	**7**	B	**8** : **9**= 1 : 1

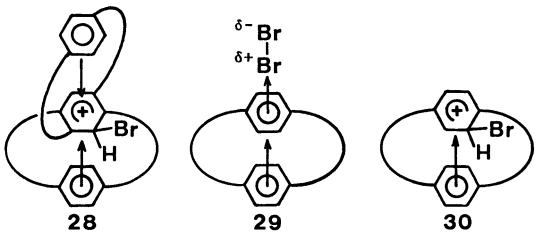
a) A: Pyridinium hydrobromide perbromide. B: Bromine. C: Bromine and iron powder.

Competitive Reactions. The bromination of layered paracyclophanes is surely accelerated by the transannular electronic interaction in the transition state. The magnitude of the acceleration was estimated by competitive reactions summarized in Table 1. The reactions are obviously speeded up with an increase of the layer number regardless of kinds of reagent. Especially the reactions of triple-layered series are overwhelmingly faster than those of double-layered series (Runs 10—14). The relative rate of triple-layered series is [2.2][2.2]PC **1**: [2.2][3.3]PC **2**: [3.3][3.3]PC **3**=60: 3: 1 (Runs 1 and 2). This order is in accord with the relative strength of transannular electronic interaction above-stated in the electronic spectra.

On the other hand, the relative rate of double-layered series using [14]paracyclophane **26** as a standard is as follows; [3.3]PC **14**: [2.2]PC **13**: [4.4]PC **15**: [14]PC **26**=29: 13: 1.4: 1 (Runs 5—7). The rather higher reactivity of [3.3]system **14** than [2.2]system **13** is particularly surprising and in conflict with the results of triple-layered series. The difference between iron-catalytic and non-catalytic conditions can be ruled out for interpretation of the above problem because a non-catalyzed competitive reaction of the dimethyl series, **19** and **21**, gave also the same order, although the advantage of [3.3]system becomes relatively smaller in the presence of methyl groups having a large substituent effect.

The difference in relative rates of the two series may be explained by a mechanism described below. In the substitution reaction of triple-layered cyclophanes **1**—**3**, the formation of π-complex on the inner benzenes is



Scheme 4.

sterically impossible although their π-basicities are increased by four alkyl substituents. Therefore, the electrophile must directly attack the inner benzenes to form σ-complex **28** which is stabilized by transannular charge delocalization to both outer benzenes. Since the transition state resembles the σ-complex, the relative rate of triple-layered series reflects the transannular electronic interaction of σ-complex. On the other hand, the reactions of double-layered paracyclophanes are expected to proceed *via* the formation of π-complex **29** followed by σ-complex **30** like an ordinary electrophilic aromatic substitution. The transannular electronic interaction must be more effective in the σ-complex having ionic structure than in the π-complex having charge-transfer character. When the σ-complex is highly stabilized by such an interaction, its potential energy may be at lower level than that of the π-complex. This consideration is consistent with Olah's proposal that in highly exothermic electrophilic aromatic substituion the reaction state with the highest energy leads to the formation of a π-complex.[18] On taking account of a noticeable property that [3.3]paracyclophane **14** interacts as a much stronger π-base than [2.2]paracyclophane **13**,[6] the reaction pathways are understood by the diagram shown in Fig. 5. The figure reveals that the formation of π-complex is rate-determining and the [3.3]system takes a lower energy path than the [2.2]system. Thus, the rate-determining step resembles σ-complex for triple-layered series and π-complex for double-layered series, respectively.

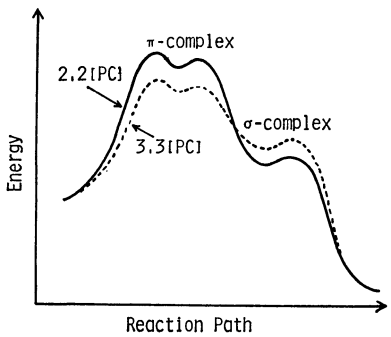


Fig. 5. A reaction diagram for bromination of [2.2]- and [3.3]paracyclophanes.

The above explanation is also supported from a viewpoint of steric effect. The introduction of methyl groups at the outer benzene of triple-layered [2.2][2.2]-paracyclophane **1** results in a 66% reduction of the rate for the inner substitution (Run 4). The methyl group must block the formation of σ-complex or the elimination of proton from σ-complex. On the other hand, such a steric blocking of pseudo-methyl group is not recognized in the reactions of double-layered cyclophanes. In a competitive reaction of **19** and **20**, (Run 8), **20** having pseudo-gem methyl group is rather more reactive than **19**. This also confirms that the formation of π-complex is rate-determining because the pseudo-gem methyl group does not sterically prevent the formation of π-complex but accelerates it due to larger stabilization resulted from an increased transannular electron release of the attached, non-complexed benzene.

Experimental

Melting points are uncorrected. All the solvents are of reagent grade unless otherwise stated. NMR spectra were taken with Hitachi Perkin-Elmer R-20 (60 MHz) and JEOL FX-100 (100 MHz) spectrometers using TMS as an internal standard, MS with Hitachi RMU-7 spectrometer at 70 eV using a direct insertion technique, and UV with Hitachi EPS-3T spectrophotometer.

The syntheses of all the starting material except **21** were reported in the previous papers.[7,8,19,20] 5,8-Dimethyl[3.3]-paracyclophane **21** was prepared in the same way as that used for [3.3]paracyclophane **14**;[19] colorless scales from hexane, mp 119—120.5 °C, MS *m/e* 264 (M^+). NMR ($CDCl_3$, 100 MHz): δ 1.8—2.3 (m, 4H, CH_2), 2.17 (s, 6H, CH_3), 2.4—2.9 (m, 8H, benzylic CH_2), 6.38 (s, 2H, ArH), 6.65 (dd, J=7.8 and 1.8 Hz, 2H, ArH), 6.89 (dd, J=7.8 and 1.8 Hz, ArH).

12-Bromo[2.2][2.2]paracyclophane **4**. *a) With Pyridinium Hydrobromide Perbromide*: A mixture of [2.2][2.2]paracyclophane **1**[7] (1 g, 2.95 mmol) and pyridinium hydrobromide perbromide (2.36 g, 7.39 mmol) in 80 ml of dry dichloromethane was stirred for 2.5 h at 0 °C. The reaction mixture was filtered through a column of neutral alumina and recrystallized from benzene to give colorless prisms, 0.909 g (74%), mp 236 °C (dec. in sealed tube), MS *m/e* 416, 418 (M^+). Found: C, 74.82; H, 5.86; Br, 18.73%. Calcd for $C_{26}H_{25}Br$: C, 74.82; H, 6.04; Br, 19.14%.

b) With Bromine–Iron: Into a solution of **1** (100 mg, 0.30 mmol) in 15 ml of dry dichloromethane was dropwise added bromine (101 mg, 0.63 mmol) in 2.8 ml of carbon tetrachloride. The mixture was stirred for 20 min at room temperature and filtered through a short column of neutral alumina. Recrystallization of the eluted product from benzene gave colorless prisms, 44 mg (36%).

c) With Bromine–Iron: Iron powder (11 mg) was stirred with 4 ml of dichloromethane and 0.5 ml of a solution of bromine (133 mg, 0.83 mmol) in 4 ml of carbon tetrachloride for 2.5 h at 25 °C. Dichloromethane (18 ml) was added and the resulting mixture was brought to reflux. [2.2][2.2]-Paracyclophane **1** (245 mg, 0.72 mmol) was added in one portion and the remaining bromine solution was added dropwise within 10 min to the refluxing, stirred solution. The mixture was stirred under reflux for 30 min and quenched with 10% $NaHSO_3$ solution. The organic layer was separated and washed with water, sat. $NaHCO_3$ solution, and water, successively. After dryness over anhyd magnesium sulfate, the solvent was condensed and the remainder was chromatographed on alumina with 1:9 dichloromethane–hexane. The main fraction consisted of a mixture of four products **4**, **10**, **11**, and **12**. Careful rechromatography on silica gel with 1: 50 benzene-hexane gave first **4** (14.4 mg,

4.8%), secondly **11**[5] (23.0 mg, 9.4%), and finally a mixture of **10** and **12**. Separation of the mixture was accomplished by gel permeation liquid chromatography, **10**[5] (8.4 mg, 3.4%) and **12**[5] (9.2 mg, 3.1%).

12-Bromo[2.2][3.3]paracyclophane ***5***. A mixture of [2.2]-[3.3]paracyclophane **2**[19] (25.2 mg, 0.07 mmol) and pyridinium hydrobromide perbromide (43.5 mg, 0.14 mmol) in 2.5 ml of dry dichloromethane was stirred for one hour at room temperature. The solution was washed with dil sodium sulfite solution and then sat sodium chloride solution. After drying over anhyd magnesium sulfate, the solvent was evaporated. The residue was chromatographed on silica gel with benzene and the eluted product was recrystallized from hexane–benzene to give colorless plates, 22.6 mg (74%), mp 186—188 °C, MS *m/e* 444, 446 (M^+). Found: C, 75.31; H, 6.41; Br, 17.92%. Calcd for $C_{28}H_{29}Br$: C, 75.50; H, 6.56; Br, 17.94%.

14-Bromo[3.3][3.3]paracyclophane ***6***. [3.3][3.3]Paracyclophane **3**[8] (9.6 mg, 0.024 mmol) was treated with pyridinium hydrobromide perbromide (15 mg, 0.047 mmol) in 2 ml of dry dichloromethane for 7 h at room temperature. The mixture was worked up as described for **5**. Recrystallization from hexane gave colorless prisms, 5.0 mg (44%), mp 207—208 °C, MS *m/e* 472, 474 (M^+). Found: C, 75.93; H, 7.08; Br, 16.64%. Calcd for $C_{30}H_{33}Br$: C, 76.10; H, 7.02; Br, 16.88%.

12-Bromo- and 5-Bromo-4,7-dimethyl[2.2][2.2]paracyclophanes ***8*** *and* ***9***. Into a stirred solution of bromine (116 mg, 0.73 mmol) in 3 ml of carbon tetrachloride and 20 ml of dichloromethane was added 4,7-dimethyl[2.2][2.2]paracyclophane **7**[7] (100 mg, 0.27 mmol) in one portion. The mixture was stirred for 30 min at 19 °C. After evaporation of the solvents, the residue was chromatographed on silica gel with hexane, 1: 50 benzene–hexane, and 1: 20 benzene–hexane, successively. From the first eluate was obtained one isomer **9**, 9.9 mg (8%), colorless prisms from benzene–hexane, mp 193—194 °C, MS *m/e* 444, 446 (M^+). NMR ($CDCl_3$, 60 MHz): δ 1.92 (s, 3H, CH_3), 1.97 (s, 3H, CH_3), 2.1—3.5 (m, 16H, CH_2), 5.68 (s, 1H, inner ArH), 5.72 (s, 1H, inner ArH), 5.91 (s, 1H, outer ArH), 6.24 (s, 4H, outer ArH). Found: C, 75.24; H, 6.43; Br, 18.14%. Calcd for $C_{28}H_{29}Br$: C, 75.50; H, 6.56; Br, 17.94%.

From the second eluate was obtained another isomer **8**, 9.9 mg (8%), colorless prisms from hexane, mp 172—173 °C, MS *m/e* 444, 446 (M^+). NMR ($CDCl_3$, 60 MHz): δ 1.97 (s, 3H, CH_3), 2.15 (s, 3H, CH_3), 2.3—3.4 (m, 16H, CH_2), 5.79 (s, 1H, inner ArH), 5.92 (s, 1H, outer ArH), 5.94 (s, 1H, outer ArH), 6.14 (dd, J=8 and 2 Hz, 1H, outer ArH), 6.25 (dd, J=9 and 2 Hz, 1H, outer ArH), 6.36 (dd, J=9 and 2 Hz, 1H, outer ArH), 6.87 (dd, J=8 and 2 Hz, 1H, outer ArH). Found: C, 75.57; H, 6.46; Br, 17.90%. Calcd for $C_{28}H_{29}Br$: C, 75.50; H, 6.56; Br, 17.94%.

Bromination of [n.n]paracyclophanes. The preparation of 4-bromo[2.2]paracyclophane **16**[9] is described below as a typical experiment.

Iron powder (8 mg) was added in a solution of bromine (156 mg, 1 mmol) in 3.8 ml of carbon tetrachloride and stirred for one hour at room temperature. [2.2]Paracyclophane **13** (166 mg, 0.8 mmol) in 20 ml of dry dichloromethane was added, and the stirring was continued for 4 h. The reaction was quenched with dil sodium hydrogensulfite soln, washed with sat. aq sodium chloride soln, and dried over magnesium sulfate. After evaporation of the solvents, the residue was chromatographed on silica gel with benzene and recrystallized from hexane to give almost pure 4-bromo[2.2]-paracyclophane **16**, 167 mg (73%). An analytical sample was purified by gel permeation liquid chromatography and again recrystallization from hexane, colorless plates, mp 133—134 °C, MS *m/e* 286, 288 (M^+). NMR ($CDCl_3$, 100 MHz): δ 2.6—3.7 (m, 8H, CH_2), 6.48 (dd, J=7.9 and 2.0 Hz, 1H, pseudo-ortho ArH), 6.50 (m, 4H, ArH), 7.14 (dt, J=7.9, 2.0, and 2.0 Hz, 1H, pseudo-gem ArH). Found: C, 66.69; H, 5.04; Br, 27.81%. Calcd for $C_{16}H_{15}Br$: C, 66.91; H, 5.26; Br, 27.82%.

5-Bromo[3.3]paracyclophane ***17***: Yield 73%, colorless crystals from hexane, mp 149—150 °C (lit,[10] mp 153—154 °C), MS *m/e* 314, 316 (M^+). NMR ($CDCl_3$, 100 MHz): δ 1.7—3.2 (m, 12H, CH_2), 6.61 (s, 2H, meta and para ArH), 6.66 (d, J=8.4 Hz, 1H, pseudo-ortho ArH), 6.75 (s, 2H, pseudo-meta and -para ArH), 6.90 (s, 1H, ortho ArH), 7.03 (d, J=8.4 Hz, 1H, pseudo-gem ArH).

6-Bromo[4.4]paracyclophane ***18***: Yield 81%, colorless plates from pentane, mp 89—89.5 °C, MS *m/e* 342, 344 (M^+). NMR ($CDCl_3$, 100 MHz): δ 1.1—3.0 (m, 16H, CH_2), 6.58 (dd, J=7.6 and 1.5 Hz, 1H, para ArH), 6.6—6.9 (m, 5H, ArH), 6.96 (d, J=1.5 Hz, ortho ArH). Found: C, 69.85; H, 6.67; Br, 23.00%. Calcd for $C_{20}H_{23}Br$: C, 69.97; H, 6.75; Br, 23.27%.

5-Bromo-4,7-dimethyl[2.2]paracyclophane ***22*** *and 5,8-Dibromo-4,7-dimethyl[2.2]paracyclophane* ***25***. Into a solution of 4,7-dimethyl[2.2]paracyclophane **19**[7] (300 mg, 1.27 mmol) was added bromine (234 mg, 1.46 mmol) in 6 ml of carbon tetrachloride. The mixture was stirred for 2.5 h at 35 °C, and worked up as described in the bromination of [*n.n*]paracyclophanes. Chromatography of the crude product on silica gel with hexane gave dibromo product **25** from the first eluate and monobromo derivative **22** from the following few fractions.

22: yield 310 mg (78%), colorless plates from hexane, mp 97.5—98.5 °C, MS *m/e* 314, 316 (M^+). NMR ($CDCl_3$, 60 MHz): δ 2.11 (s, 3H, CH_3), 2.15 (s, 3H, CH_3), 2.4—3.5 (m, 8H, CH_2), 6.14 (s, 1H, ArH), 6.44 (dd, J=8 and 2 Hz, 1H, ArH), 6.68 (dd, J=8 and 2 Hz, 1H, ArH), 6.80 (dd, J=8 and 2 Hz, 1H, ArH), 6.95 (dd, J=8 and 2 Hz, 1H, ArH). Found: C, 68.50; H, 5.97; Br, 25.05%. Calcd for $C_{18}H_{19}Br$: C, 68.56; H, 6.08; Br, 25.36%.

25: yield 30 mg (6%), colorless scales from benzene–hexane, mp 168.5—169.5 °C, MS *m/e* 392, 394 (M^+). NMR ($CDCl_3$, 60 MHz): δ 2.21 (s, 3H, CH_3), 2.8—3.6 (m, 8H, CH_2), 6.64 (dd, J=8 and 2 Hz, 2H, ArH), 6.91 (dd, J=8 and 2 Hz, 2H, ArH). Found: C, 54.67; H, 4.43; Br, 40.06%. Calcd for $C_{18}H_{18}Br_2$: C, 54.83; H, 4.61; Br, 40.56%.

5-Bromo-4,7,12,15-tetramethyl[2.2]paracyclophane ***23***. 4,7,12,15-Tetramethyl[2.2]paracyclophane **20**[7] (246 mg, 0.93 mmol) in 20 ml of dry dichloromethane was treated with bromine (151 mg) in 5 ml of carbon tetrachloride at 28 °C. After 60 min from the start, the mixture was worked up as usual. The main product **23** was purified by column chromatography on silica gel with hexane and recrystallization from hexane, 237 mg (74%), colorless plates, mp 159.5—160 °C, MS *m/e* 342, 344 (M^+). NMR ($CDCl_3$, 60 MHz): δ 2.03 (s, 3H, CH_3), 2.12 (s, 3H, CH_3), 2.18 (s, 3H, CH_3), 2.28 (s, 3H, CH_3), 2.4—3.8 (m, 8H, CH_2), 6.40 (bs, 3H, ArH). Found: C, 69.93; H, 6.78; Br, 22.97%. Calcd for $C_{20}H_{23}Br$: C, 69.97; H, 6.75; Br, 23.28%.

6-Bromo-5,8-dimethyl[3.3]paracyclophane ***24***. 5,8-Dimethyl[3.3]paracyclophane **21** (26.4 mg, 0.10 mmol) in 3 ml of dry dichloromethane was treated with bromine (20 mg, 0.13 mmol) in 0.5 ml of carbon tetrachloride at room temperature. After 4 h, the mixture was worked up as usual. The main product **24** was purified by gel permeation liquid chromatography and then column chromatography on silica gel with hexane, 16 mg (46%), colorless scales from ethanol, mp 108—109 °C, MS *m/e* 342, 344 (M^+). NMR ($CDCl_3$, 100 MHz): δ 1.7—3.2 (m, 12H, CH_2), 2.18 (s, 3H, CH_3),

2.29 (s, 3H, CH_3), 6.27 (s, 1H, ArH), 6.71 (ABd, J=9 Hz, 1H, ArH), 6.75 (ABd, J=9 Hz, 1H, ArH), 6.91 (ABbd, J=9 Hz, 2H, ArH). Found: C, 69.73; H, 6.61; Br, 23.09%. Calcd for $C_{20}H_{23}Br$: C, 69.97; H, 6.75; Br, 23.27%.

16-Bromo[14]paracyclophane **27**. Bromine (20 mg, 0.13 mmol) in 0.5 ml of carbon tetrachloride was stirred with iron powder (5 mg) for 30 min at room temperature. [14]Paracyclophane **26**[20] (29 mg, 0.105 mmol) in 5 ml of dry dichloromethane was added at once. The mixture was stirred for 1.5 days and worked up in the usual way. The main product **27** was purified by column chromatography on silica gel with hexane and gel permeation liquid chromatography, 15 mg (40%), colorless oil, MS *m/e* 350, 352 (M^+). NMR ($CDCl_3$, 100 MHz): δ 0.6—1.8 (m, 24H, CH_2), 2.4—3.0 (m, 4H, benzylic CH_2), 7.01 (dd, J=7.7 and 0.5 Hz, 1H, ArH), 7.08 (d, J=7.7 Hz,1H,ArH),7.33 (d, J=0.5 Hz,1H,ArH). Found: C, 68.14; H, 9.11; Br, 23.04%. Calcd for $C_{20}H_{31}Br$: C, 68.37; H, 8.89; Br, 22.74%.

Competitive Reactions. An equimolar mixture of two cyclophanes (2 mol) was treated with a reagent (1 mol) indicated in Table 1. The reaction conditions were essentially the same as in the experimental part above-stated for the bromination of each cyclophane. The reaction time was controlled in such a way that about one-half amount of the more reactive component was consumed. Analysis of the reaction mixture was carried out by proton NMR measurement. The product ratio was determined on the basis of the integration of the isolated, appropriate peaks. On the other hand, carbon NMR analysis was performed for Run 6 alone, because nothing was clearly isolated peaks in the PMR spectrum of the products.[21]

CMR datum of **16** ($CDCl_3$, TMS standard, JEOL FX-100):[22] δ 33.477 (C-1), 34.793 (C-2), 35.475 and 35.816 (C-9,10), 126.941 (C-4), 128.648 (C-13), 131.424 (C-7), 132.203, 132.835, and 133.225 (C-12,15,16), 134.980 (C-8), 137.170 (C-5), 139.026 (double) and 139.268 (C-6,11,14), 141.513 (C-3).

CMR datum of **18**:[22] δ 26.460 (C-3), 28.458, 28.653, and 28.848 (C-2,12,13), 34.842 (C-1), 35.134 (double) and 35.280 (C-4,11,14), 123.386 (C-6), 127.186 (C-17), 128.063 (C-9), 128.352 (double) and 128.843 (C-16,19,20), 130.839 (C-10), 132.936 (C-7), 137.809 (C-8), 139.026 and 139.268 (C-15,18), 141.607 (C-5).

Photochemical Reactions of Dicyanobenzenes with Aliphatic Amines

Mamoru OHASHI,* Kentaro MIYAKE, and Kazuo TSUJIMOTO
Department of Materials Science, The University of Electro-Communications, Chofu, Tokyo 182
(Received November 22, 1979)

Upon irradiation, *p*-dicyanobenzene reacted with primary, secondary, and tertiary aliphatic amines to give substitution products in which one of the cyano groups was replaced by the amine at α-CH position or by an alkyl group of the amine. *o*-Dicyanobenzene reacted similarly, but the *meta*-isomer did not react under similar conditions. The rates of the fluorescence quenching of *p*-dicyanobenzene with the amines are close to the diffusion-controlled rate, but are somewhat dependent on the ionization potentials of the amines. When the substitution product was irradiated, the corresponding alkylation product was obtained. The mechanisms of these reactions have been investigated by the use of such proton donors as MeOH(MeOD); on the basis of those investigations, new photochemical reactions involving charge-transfer, followed by proton-transfer and then addition-elimination, are proposed, as well as a new type of photo-induced Birch reduction.

Since Bryce-Smith and his co-workers first reported the photoaddition of aliphatic amines to benzene in 1967,[1] a number of photochemical reactions of arenes with amines have been extensively studied. For instance, naphthalene,[2] stilbene[3] and anthracene[4] undergo photoaddition of various amines. It has been well-documented that these photochemical reactions proceed through exciplexes or solvated radical anion-radical cation pairs.

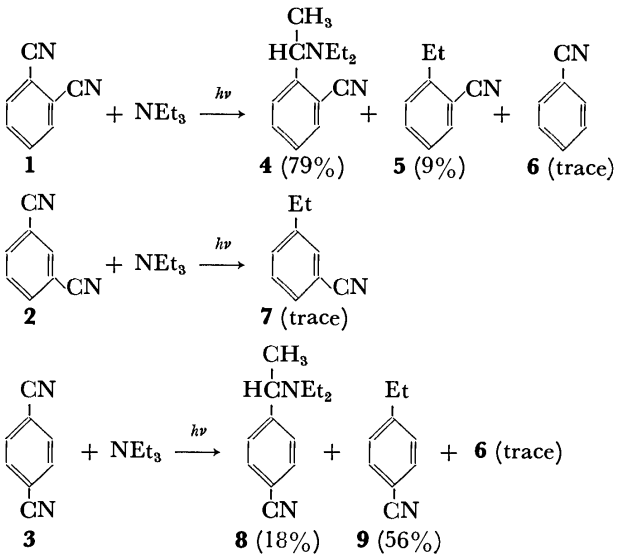
For several years we also have examined the photochemical reactions of charge-transfer complexes and have established several new reactions which proceed through radical anion-radical cation pairs. For instance, on charge-transfer excitation, such typical electron acceptors as tetracyanobenzene (TCNB),[5] tetracyanoquinodimethane (TCNQ),[6] and tetracyanoethylene (TCNE),[7] react with π-donor toluene derivatives, or n-donor ethers, to give substitution or addition products. Here, irradiation within the charge-transfer absorption bands of the system produces a donor radical cation as well as an acceptor radical anion. Subsequent proton-transfer from the donor to the acceptor yields a radical pair, which then couples to lead to an addition product. The energy required for the electron transfer is related to the ionization potential of the donor and the electron affinity of the acceptor according to the Weller equation.[8] It has been shown that the smaller the donor's ionization potentials, and the larger the acceptor's electron affinity, the easier the charge-transfer reaction. In accordance with this, strong donor-acceptor pairs, such as TCNQ or TCNE–amine systems, undergo addition reactions upon only heating,[9] while the reaction of TCNE, TCNQ, or TCNB with aromatic hydrocarbons or ethers takes place only in the excited state, not in the ground state.

Now we have examined photochemical reactions of dicyanobenzenes, relatively weak electron acceptors, with amines, strong electron donors.[10] Since the ultraviolet spectra of dicyanobenzene–amine systems do not exhibit any charge-transfer absorption band, charge-transfer complex formation in the ground state is either absent or very weak. In this case, the electron-transfer reactions do take place upon irradiation.

Results and Discussion

Photochemical Reactions of Dicyanobenzenes with Triethylamine. The irradiation of a mixture of *o*-dicyanobenzene (0.05 M, **1**) and triethylamine (0.5 M) in acetonitrile with a low-pressure mercury arc gave a substitution product (**4**) in 79% yield, together with small amounts of *o*-ethylbenzonitrile (**5**, 9%) and benzonitrile (trace). The quantum yield of the disappearance of the starting material was measured at 0.15 by means of trioxalatoferrate (III) actinometry. Similarly, *p*-dicyanobenzene (**3**) reacted with triethylamine under similar conditions to give the corresponding substitution product (**8**) and *p*-ethylbenzonitrile (**9**) in 18 and 56% yields respectively. A trace amount of benzonitrile was also detected. Again, the quantum yield of disappearance of *p*-dicyanobenzene was 0.15. On the contray, *m*-dicyanobenzene (**2**) was inert under similar conditions: after long irradiation (20 h), only a trace amount of *m*-ethylbenzonitrile (**7**) was detected by gas chromatography-mass spectrometry and a large amount of the starting materials was recovered.

Although the photochemical reactivities of **1** and **3** were similar, their product distributions were different; *i.e.*, in the photochemical reaction of **1**, the substitution product, **4**, was the major one, while the alkylated product, **9**, was the major one in the case of **3**. It is also remarkable that the *meta*-isomer (**2**) has a very low reactivity in comparison with that of the *ortho*- or



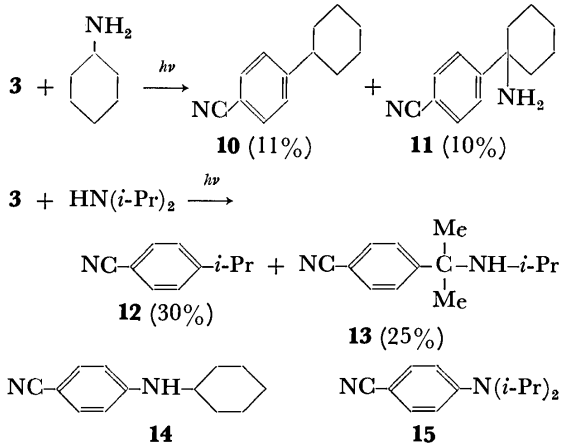
Scheme 1.

para-isomer. The difference in the reactivities of the isomers may suggest that a complication is involved in the reactions.

Reactions analogous to those in Scheme 1, but using tetramethylurea in place of triethylamine, have been reported.[11]

Photochemical Reactions of p-*Dicyanobenzene with Primary and Secondary Amines.* It has been reported that the photoaddition of primary and secondary amines to benzene or the photosubstitution in a difluorobenzene–diethylamine system occurs at the NH group in the amine.[1,12] Similar results have been reported in anthracene-amine systems.[4] We ourselves have found that, in contrast with the benzene or anthracene-primary or secondary amine systems, cyclohexylamine, a primary amine, and diisopropylamine, a secondary amine, reacted with **3** upon irradiation not at the NH group, but at the α-CH instead.[10b] Recently, it has also been reported that the photoamination of pyridine or chlorobenzene resulted in the formation of substitution derivatives at the α-CH position of the amine.[13]

The irradiation of a solution of **3** (0.046 M) and cyclohexylamine (2.6 M) in acetonitrile with a medium-pressure mercury arc for 13 h gave *p*-cyclohexylbenzonitrile (**10**), along with a substitution product (**11**), in 11 and 10% yields respectively. Similarly, the irradiation of **3** in acetonitrile in the presence of diisopropylamine (0.87 M) under similar conditions gave *p*-isopropylbenzonitrile (**12**) and a substitution product (**13**) in 30 and 25% yields respectively. A small amount of benzonitrile was also detected in both reaction mixtures by gas chromatography-mass spectrometry. The reactivities of the amines, however, were very low in comparison with that of triethylamine. The reaction scarcely occured under the same irradiation conditions as those of the aforementioned **3**-triethylamine system. The structures of the alkylated products, **10** and **12** were confirmed by direct comparison with the authentic specimens. Structures of **11** and **13** were assigned to the substitution products on the basis of elementary analyses and spectral investigations; the IR spectrum of **11** shows peaks at 3380 and 3310 cm^{-1}, characteristic of a NH_2 groups, while **13** shows a peak at 3330 cm^{-1} (NH) in the IR spectrum and a singlet 6H peak ($>CMe_2$) at δ 1.40 in the NMR spectrum, indicating that the compounds have structures substituted at the α-CH groups of the amines. Structures **14** and **15** were ruled out by the spectroscopic evidence (see Experimental section). No products corresponding to the adducts of **3** at the NH groups of the amines have been detected.

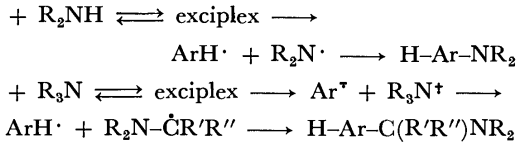


Scheme 2.

Mechanism for the Substitution Reactions. When the reaction of **1** with triethylamine was carried out in CH_2Cl_2, the reaction did not proceed; this suggested that the reaction takes place *via* a dipolar intermediates. Methanol also quenched the reaction. This behavior is similar to the case of the photo-induced substitution of TCNB–toluene systems, implying the participation of a proton-transfer process.[5a,b] When the reaction of **3** with triethylamine was carried out with oxygen bubbling through the mixture, **8** and **9** were not detected as products in the reaction mixture, but a trace amount (<1%) of *p*-cyanobenzamide was obtained instead, along with a large amount of the recovered starting materials. The quenching action of oxygen suggests that the reaction proceeds through a triplet state or an ion-radical intermediate. 1,3-Pentadiene (0.01 M), however, failed to quench the reaction. In order to clarify the multiplicity of the reactive state, fluorescence quenching experiments were performed.

The results of the Stern-Volmer treatments of the fluorescence quenching of **3** with the amines are summarized in Table 1. The kq values obtained are close to the diffusion-rate constant. The trend for amines with lower ionization potentials to be more efficient quenchers resembles that to be found in anthracene–amine systems and other general electron donor–acceptor systems.[4] Neither charge-transfer absorption nor exciplex emission was observed in these systems. The fluorescence of *o*-dicyanobenzene (**1**) was similarly quenched by triethylamine with a $k_q\tau$ value of 133 M^{-1}. It may be concluded from these experiments that the reactive species is a singlet state of the dicyanobenzene and that the primary photochemical step must be electron-transfer from the amine to the aromatics, as is usual in arene–amine systems.

The mechanisms of the fluorescence quenching of arenes by amines are probably the same in these systems, but those of the subsequent substitution differ. For instance, while the quenching of anthracene fluorescence by secondary amines and by tertiary amines proceeds *via* the same mechanism, the photochemical reactions of anthracene with secondary amines proceed *via* a different mechanism from that with a tertiary amine.[4] Concerning the molecularities of these reactions, it has been suggested that the excited charge-transfer species of a benzene–secondary amine system decay through proton-transfer in which two molecule of the amine participate,[1] while the photo-induced reaction of anthracene with *N*,*N*-dimethylaniline takes place *via* a triple exciplex.[4] It has also been demonstrated that



Scheme 3.

Table 1. Fluorescence quenching of **3** with amines

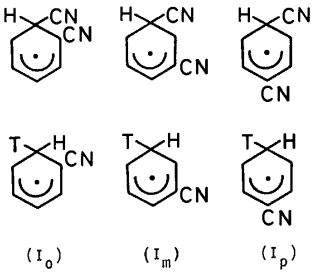
Amine	Solvent	k_q (M^{-1})[a]	k_q ($\times 10^9$ M^{-1} s^{-1})[a]	Concn of **3** ($\times 10^{-4}$ M)	*Ip* (eV)
a) Triethylamine	MeCN	158	8.8	2.18	7.50
b) Triethylamine	CH_2Cl_2	116	6.4	9.97	75.0
c) Diisopropylamine	MeCN	145	8.1	1.09	7.73
d) Cyclohexylamine	MeCN	126	7.0	2.18	8.86

a) The k_q values were calculated, based on τ being 18 ns.[15] See Fig. 1 for the amine-concentration range. Exciting light at 283 nm. Fluorescence at 394 nm.

the reactions of arene with secondary amines seem to proceed through exciplexes in which hydrogen transfer, followed by radical coupling, takes place; consequently, the 1,2- or 1,4-addition of the NH group in the amine results (Scheme 3).[3,4] Unlike the case of secondary amines, electron-transfer from the amine to the arene occurs in an arene–tertiary amine systems to form a pair of solvated radical ions, which then collapse to radicals *via* proton-transfer and subsequently couple to give the addition product at the α-CH bond of the amine to the arene. These mechanisms are shown in Scheme 3. A full electron-transfer is necessary to render the α-CH bond sufficiently acidic for proton-transfer to occur.[3]

In view of those investigations, two possible mechanisms are conceivable. One is that, since the electron affinity of **3** is larger than that of benzene, electron-transfer from the amine to the aromatics must be easier than in the hydrocarbon–amine systems and the pair of radical ions can be produced even by using the secondary or primary amine as an electron donor. Subsequent proton-transfer occurs predominantly from the α-CH position rather than from the NH group, though the acidities of the α-CH and the NH group of diisopropylamine or cyclohexylamine radical cation have not yet been determined. A similar hydrogen-transfer from the α-CH position has been observed in the photochemical reactions of ketones with primary amines.[14] The other is that, as is the case with a secondary amine–arene system, hydrogen-transfer from the NH group occurs in the exciplex or the radical ion pair, with the resulting radicals coupling to give an unstable *N*-addition product (**16**) as an intermediate. If the elimination of HCN occurs, an *N*-substitution product, **14** or **15**, will be produced. On the other hand, if the elimination of the amine takes place, the starting materials will be recovered, with the photochemical reactions working as radiationless decay processes of the excited species. This is probably the actual case. This mechanism accounts for the low reactivities of the primary and the secondary amines in comparison with those of triethylamine. The quenching of the reaction of **3** with triethylamine by methanol is also accounted for by a similar mechanism; methanol protonates the anion radical in the exciplex or the ion pair to give the neutral radical, from which the back transfer of an electron to the cation radical, followed by deprotonation, then gives the starting materials again.

Although the reduction potential of *m*-dicyanobenzene (−2.17 V) is similar to those of the *o*- or *p*-isomers (−2.12 and −1.97 V respectively),[15] the fact that the meta-isomer has much less reactivity than the *ortho*- and *para*-isomers is remarkable. In order to account for this fact, we assume that a proton from the radical cation transfers to the *ipso*-position of the dicyano compounds, and that the resulting radical is stabilized by conjugation with the cyano group in the *ortho*- and *para*-isomers, but not in the *meta*-isomer. Since the proton-transfer step is supposed to determine the rate for these reactions,[6] the stabilization of the radical intermediate may control the reactivity of the acceptor employed. A similar trend has been reported in the light-induced hydrogen isotope exchange in benzonitrile, where the exchange occurred mainly at the para(89.8%) and ortho(10%) positions, but scarcely at all at the meta(0.2%) position, in the benzonitrile–triethylamine–tritiated water system.[16] It was concluded from those results that the stability of the inter mediate radical is in the order of $I_p > I_o > I_m$, which is in accord with our assumption (Scheme 4).

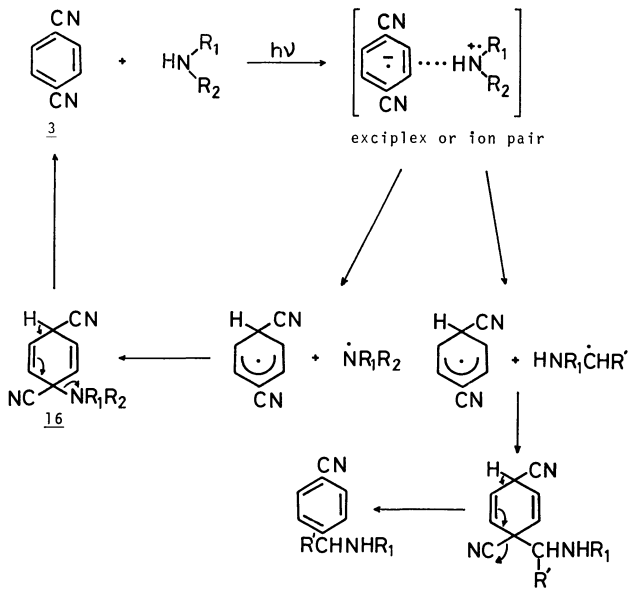


Scheme 4.

On the basis of these results, we propose the following mechanism, in which the two processes involved in the hydrogen-transfer step compete with each other. Hydrogen- or proton-transfer from the NH group probably results in the recovery of the starting materials, while proton-transfer from the α-CH position gives the substitution products, as is shown in Scheme 5.

Mechanism of the Formation of Alkylated Products. To identify the route to the alkylated products, the substitution product, **4**, was irradiated in acetonitrile under nitrogen with a low-pressure mercury arc; the alkylated product, **5**, was thus obtained in a good yield. Triethylamine added to the system slightly increased (1.4 times) the yield of the product, while methanol slightly decreased it (0.7 times). From these results, it is clear that the alkylated products have been derived from the corresponding substitution products through a new photo-induced reductive cleavage of the benzylic C–N bond.

Although many studies have been reported on the photolytic solvolysis of benzyl acetate,[17] alcohols,[18] ammonium salts,[19] halides[20] and sulfonium salts,[21] the photo-induced reductive cleavage of benzylic C–O or C–N bonds by electron donor has scarcely been examined at all.[22] Recently it was reported that



Scheme 5.

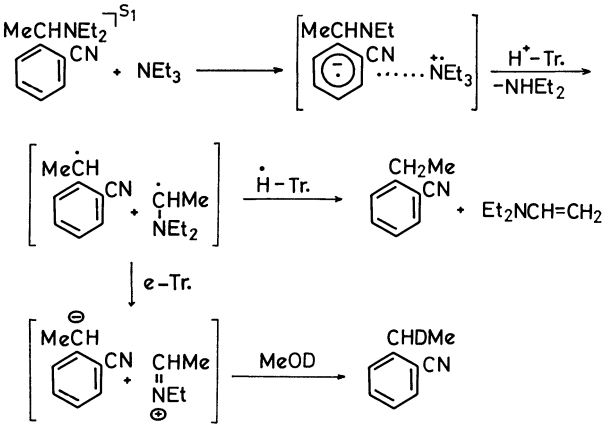
photo-induced intramolecular charge-transfer gives rise to the cleavage of benzylic C–O bonds through a carbonium-ion mechanism.[17]

In our case, the intramolecular charge-transfer excitation from the amino group to the aromatic moiety is negligible, because the absorption spectrum of **4** is identical to that of *o*-tolunitrile. The emission spectrum of **4**, however, exhibits a broad weak band at 350—400 nm, along with a strong band at 316 nm. The former may be assigned to the fluorescence from the excited singlet state of the intramolecular charge-transfer configuration. The Stern-Volmer treatments of the quenching of both emission bands by triethylamine gave linear plots with a $k_q\tau$ value of 163 M^{-1}. Here again, a charge-transfer interaction between the singlet state of **4** and triethylamine is conceivable.

When the reaction was carried out in MeOD in place of acetonitrile, 0.51 atoms of deuterium were incorporated in the product, **5**, indicating that a proton-transfer step participated in the reaction process. A similar deuterium incorporation (0.55 atoms) was obtained in the case of the acetonitrile–MeOD–triethylamine system. The NMR spectrum of the deuterated **5** indicated that the incorporated deuterium was located mainly in the benzylic methylene group. The irradiation of **5** under similar conditions showed that no significant incorporation of deuterium by H–D exchange occurred.

Barltrop has shown that the photo-induced Birch reduction of naphthalene by triethylamine in the presence of D_2O resulted in the formation of a dihydro product in which 1.6 atoms were deuterated. He concluded that the naphthalene radical anion produced by photoinduced electron-transfer picks up the deuterium and that the resulting deuterated radical is reduced in two parallel paths, *i.e.*, one proceeding by means of electron-transfer, followed by deuterium-transfer giving a dideuterated product, and the other involving hydrogen-atom transfer.[2b]

Referring to those observations, we propose a reduction-elimination mechanism for the present unique reduction. The reaction probably proceeds through an excimer of **4** or an exciplex between **4** and triethylamine when the amine is present in the system. Electron-transfer, followed by proton-transfer in the excited donor-acceptor system, gives a radical intermediate with the ejection of diethylamine, from which two parallel paths, as in the case of the naphthalene–triethylamine system, proceed; hydrogen-transfer, and electron-transfer followed by proton-transfer. Scheme 6 represents the possible mechanism for the photochemical reaction of **4** with triethylamine in the presence of MeOD. The intramolecular charge-transfer excitation may only result in an increase of the radiation-less decay; it may be that no chemical reactions proceed from this configuration.[23]



Scheme 6.

Experimental

Melting points were determined with a Kofler hot-stage apparatus and are uncorrected. IR spectra were taken with a JASCO model IRA-1 instrument, while UV spectra were obtained with a Hitachi 124 spectrophotometer. ^1H NMR spectra were recorded with Hitachi R-24 and R-20B instruments, with tetramethylsilane as the internal standard. Mass spectra were recorded with a Hitachi RMU-6MG single-focusing instrument equipped with a direct/in-beam ion source; ionizing energy, 70 or 20 eV, source temperature, *ca.* 200 °C. Fluorescence spectra were measured with a Hitachi 204 fluorescence spectrophotometer. Irradiations for photochemical reactions were carried out with a low-pressure mercury lamp(Ushio ULO-6DQ, 6 W) or with a medium-pressure mercury lamp(Ushio UM-102, 100W). A merry-goround spparatus (Taika-Kogyo MGR) was used for the actinometry.

The dicyanobenzenes, purchased from the Tokyo Kasei Co., were recrystallized from benzene. The amines, purchased from the Wako-Junyaku Co., were reagent-grade and were distilled befor use.

Photochemical Reactions of o-Dicyanobenzene with Triethylamine. A solution of *o*-dicyanobenzene (955 mg, 7.5 mmol) in acetonitrile (70 ml) in the presence of triethylamine (7 g, 70 mmol) was irradiated with a low-pressure mercury lamp (6 W) for 16 h under nitrogen. The solvent was then evaporated *in vacuo*, and the residue was chromatographed on silica gel (Wako C-200) to give **4** (657 mg, 79%), **5** (50 mg, 9%), **6** (trace, detected by gas chromatography-mass spectrometry, identified by a mass spectral comparison with an authentic

sample), and the starting material (534 mg).

o-[*1-(Diethylamino)ethyl*]*benzonitrile* (**4**). Bp 70 °C (17 mg Hg); IR (liq) 2230 cm^{-1}; NMR (CCl_4) δ 0.96 (t, 6, J= 7.0 Hz), 1.32 (d, 3, J=7.0 Hz), 2.58 (q, 4, J=7.0 Hz), 4.14 (q, 1, J=7.0 Hz), 7.06—7.77 (m, 4); mass spectrum, 70 eV, m/z (rel. intensity) 204 (14), 187 (100), 159 (3), 130 (36), 103 (3), 72 (4), 58 (48), mass spectrum calcd for $C_{13}H_{18}N_2$: m/z 202.1470, found: 202.1455.

o-*Ethylbenzonitrile* (**5**).[24] Identified by direct comparison with the authentic specimen synthesized according to the Bissell[25] and Newman[26] methods.

Photochemical Reaction of m-*Dicyanobenzene with Triethylamine.* A solution of *m*-dicyanobenzene (1.02 g, 5.63 mmol) and triethylamine (11 g, 1.09 mmol) in acetonitrile (170 ml) was irradiated for 20 h under similar conditions. A usual work-up gave a trace amount of *m*-ethylbenzonitrile[24] [3 mg, mass spectrum, 20 eV, m/z (rel. intensity) 132 (12), 131 (47), 130 (9), 117 (17), 116 (100), 104 (15), 103 (20), 89 (12)]. The retention time of this compound in the gas chromatography-mass spectrometry was different from those of **5** and **9**.

Photochemical Reaction of p-*Dicyanobenzene with Triethylamine.* A solution of *p*-dicyanobenzene (744 mg, 5.81 mmol) and triethylamine (9.0 g, 89.1 mmol) in acetonitrile (170 ml) was irradiated with a low-pressure mercury arc (6 W) for 6 h under nitrogen. The solvent was removed *in vacuo*, and the residue was chromatographed on silica gel to give **8** (138 mg, 18%), **9** (282 mg, 56%), **6** (trace), and the starting material (257 mg).

p-[*1-(Diethylamino)ethyl*]*benzonitrile* (**8**). IR (liq) 2220 cm^{-1}; NMR (CCl_4) δ 0.95 (t, 6, J=7.0 Hz), 1.27 (d, 3, J= 7 Hz), 2.49 (q, 4, J=7.0 Hz), 3.83 (q, 1, J=7.0 Hz), 7.04—7.91 (m, 4); mass spectrum, 70 eV, m/z (rel. intensity) 202 (20), 187 (100), 173 (9), 130 (21), 116 (5), 103 (21); mass spectrum calcd for $C_{13}H_{18}N_2$: m/z 202.1470, Found: 202.1476.

p-*Ethylbenzonitrile* (**9**).[24] Identified by direct comparison with the authentic specimen synthesized according to the Bissell[25] and Newman[26] methods.

Photochemical Reaction of p-*Dicyanobenzene with Cyclohexylamine.* A mixture of *p*-dicyanobenzene (501 mg, 3.91 mmol) and cyclohexylamine (21.7 g, 219 mmol) in acetonitrile (60 ml) was irradiated with a medium-pressure mercure arc (100 W) for 13.5 h under nitrogen. A usual work-up gave pale yellow crystals **11** (31 mg, 10%), an oil **10** (32 mg, 11%), **6** (trace), and the starting material (305 mg).

p-(*1-Aminocyclohexyl*)*benzonitrile* (**11**). Mp 61—63 °C (from benzene–cyclohexane); IR (KBr) 3380, 3310, 2230, 1605 cm^{-1}; NMR (CCl_4) δ 0.90—2.20 (m, 10), 7.59 (d, 2, J=9.5 Hz), 7.69 (d, 2, J=9.5 Hz); mass spectrum, 20 eV, m/z (rel. intensity) 200 (20), 184 (2), 171 (8), 157 (100), 144 (6), 129 (6), 116 (3), 103 (1). Found: C, 77.48; H, 8.28; N, 13.87%. Calcd for $C_{13}H_{16}N_2$: C, 77.96; H, 8.05; N, 13.99%.

p-*Cyclohexylbenzonitrile* (**10**). IR (liq) 2215 cm^{-1}; NMR (CCl_4) δ 0.80—3.20 (m, 11), 7.20 (d, 2, J=9.0 Hz), 7.46 (d, 2, J=9.0 Hz); mass spectrum, 20 eV, m/z (rel. intensity) 185 (59), 159 (9), 143 (13), 129 (100), 117 (15), 116 (12), 103 (3), 102 (3). The structure was identified by a direct comparison of the spectra with those of the authentic specimen synthesized as follows: cyclohexylbenzene (25 g, 156 mmol) was treated with bromine (26 g, 163 mmol) in the presence of iodine (1.7 g, 6.5 mmol) according to Bissell's method[25] to give *p*-bromocyclohexylbenzene[10 g, 27%, bp 85 °C (1 mmHg)], which was then treated with copper (I) cyanide (4.0 g, 44.6 mmol) in pyridine (10 ml) according to Newman's method[25] to give **10** (1.9 g).

Photochemical Reaction of p-*Dicyanobenzene with Diisopropylamine.* A solution of *p*-dicyanobenzene (1.00 g, 7.81 mmol) and diisopropylamine (15 g, 149 mmol) in acetonitrile (150 ml) was irradiated with a medium-pressure mercury arc (100 W) for 9 h under nitrogen. A work-up in the usual manner gave an oil **12** (258 mg, 30%), an other oil **13** (294 mg, 25%), **6** (trace), and the recovered starting material (241 mg).

p-(*1-Isopropylamino-1-methylethyl*)*benzonitrile* (**13**). IR (liq) 3330, 2230 cm^{-1}; NMR (CCl_4) δ 0.86 (d, 6, J=6.5 Hz), 1.40 (s, 6), 2.69 (sep, 1, J=6.5 Hz), 7.05—7.85 (m, 4); mass spectrum, 20 eV, m/z (rel. intensity) 202 (4), 187 (100), 173 (2), 159 (3), 145 (48), 144 (22), 130 (4), 116 (9), 104 (3), 100 (8), 44 (31). Picrate, mp 196—199 °C (dec from ethanol). Found: C, 52.54; H, 4.86; N, 15.90%. Calcd for $C_{19}H_{25}N_5O_7$: C, 52.90; H, 4.91; N, 16.23%.

p-*Isopropylbenzonitrile* (**12**).[24] The structure was confirmed by a direct comparison of the spectra with those of the authentic material, synthesized by alternative method; the bromination of cumene (20 g, 167 mmol) with bromine (27 g, 169 mmol) and iodine (3.4 g, 13.4 mmol) according to the method in the literature[25] gave the bromide (18 g, 54%), which was then treated with copper(I) cyanide (10 g, 112 mmol) in pyridine (15 ml) for 22 h under nitrogen according to Newman's method[26] to give **12** (2.0 g, 16%).

Photochemical Reaction of p-*Dicyanobenzene with Triethylamine under Oxygen.* A solution of *p*-dicyanobenzene (720 mg, 5.63 mmol) and triethylamine (12 g, 119 mmol) in acetonitrile (120 ml) was irradiated with a low-pressure mercury arc (6 W) for 17 h. Oxygen was bubbled through the solution during the course of irradiation. A work-up in the usual manner gave *p*-cyanobenzamide (3 mg, 1%); colorless crystals; mp 224—226 °C (lit,[27] 224 °C).

Solvent Dependency of the Photochemical Reaction of **1** *with Triethylamine.* Each solution of **1** (90 mg, 0.703 mmol) and triethylamine (1 ml), dissolved in 10 ml of acetonitrile, methanol, or dichloromethane, was irradiated by means of a merry-go-round apparatus with a low-pressure mercury arc (10 W) for 22 h. The relative yields of the product, **4**, were estimated by means of gas chromatography (Degs 1.5% on Diasolid ZF 80-100), using 2-methoxynaphthalene as the internal standard. The complete quenchig of the reaction in methanol and in dichloromethane was determined.

Quantum Yields of the Disappearance of **3** *in the Photochemical Reaction of* **3** *with Triethylamine.* A solution of **3** (80 mg, 0.625 mmol) and triethylamine (1.0 g, 9.91 mmol) in acetonitrile (10 ml) was irradiated by means of a merry-go-round apparatus with a low-pressure mercury arc (10 W) for 6 h. The amount of unreacted **3** was then determined by means of gas chromatography, the conversion of **3** was found to be less than 10%. Trioxalatoferrate(III) actinometry was used (1.15×10^{16} quanta/s) to determine the quantum yields of the consumption of **1** and **3**, they were both 0.15.

Photochemical Reaction of **4**. Various solutions (Table 2) of **4**, isolated and purified by vacuum distillation, were irradiated by means of a merry-go-round apparatus with a low-pressure mercury arc (10 W) for 3.5 h. The yields of **5** was then determined by means of gas chromatography.

Table 2. Relative yields of **5** in the photolysis of **4** under different conditions

	4 (mg)	CH_3CN (ml)	NEt_3 (ml)	MeOH (ml)	Yield
a	24.5	5.0	—	—	1.0
b	24.5	4.7	0.3	—	1.4
c	24.7	4.0	0.3	0.7	0.65

The results are summarized in Table 2.

Photochemical Reaction of 4 in the Presence of MeOD. **4** (80 mg) was irradiated under various conditions (Table 3) by means of a merry-go-round apparatus with a low-pressure mercury arc (10 W) for 20 h. The solvent was then removed, and the residue was chromatographed on silica gel to give **5**. The isotopic purity of each specimen was determined by mass spectrometry. The results are summarized in Table **3**. The methanol-d_1 was purchased from the Wakenyaku Co., its isotopic purity was better than 99%.

Table 3. Deuterium incorporation of **5**

	CH_3CN (ml)	MeOD (ml)	NEt_3 (ml)	D-incorporation(%)
a	—	12	—	51
b	—	11	1	53
c	11	1	—	40
d[a)]	10	1	1	55

a) In the case of d), the NMR spectrum exhibited the following peaks of the relative intensities: δ 7.30 (m, 4.0H), 2.84(q, 1.4H), and 1.25(t, and d, 3.2H).

The Synthesis of Unsubstituted Crown Ethers by the Reaction of Oligoethylene Glycols with Arenesulfonyl or Alkanesulfonyl Chlorides

Ping-Lin Kuo, Norio Kawamura, Masaki Miki, aud Mitsuo Okahara*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received November 29, 1979)

A new facile method of synthesizing crown ethers from oligoethylene glycols by treating them with arenesulfonyl or alkanesulfonyl chlorides in the presence of alkali metal hydroxide or alkoxide was described. 15-Crown-5 and 21-crown-7 were synthesized from pentaethylene glycol and heptaethylene glycol respectively in good yields, while 18-crown-6 was obtained from both hexaethylene glycol and triethylene glycol. Although the main product was 24-crown-8 in the reaction of tetraethylene glycol/TsCl/Na(K)OH in dioxane, 12-crown-4 was obtained in a moderate yield from the reaction of tetraethylene glycol/benzenesulfonyl chloride/*t*-BuOLi in *t*-BuOH. Furthermore, the analogous treatment of PEG 200 afforded a mixture of 15-, 18-, 21-, and 24-crown ethers. The reaction conditions were investigated, and the scope of the reaction was discussed.

One feature of the remarkable recent developments in the field of macrocyclic compounds has been the publication of numerous reports during the past ten years.[1,2]

The various methods proposed for the synthesis of crown compounds may be classified into two categories: 1) A modified Williamson ether synthesis by means of a reaction between oligoethylene glycols or aromatic dihydroxy compounds, and oligoethylene glycol dichlorides or ditosylates, in the presence of alkali, which has the appropriate template atom,[3-7] and 2) a Lewis acid-catalyzed cyclo-oligomerization of ethylene oxide using special metal salts.[8,9]

Although the former method has been widely adopted for the synthesis of crown compounds, the intramolecular cyclization of a polyoxyethylene compound with a hydroxyl group at one end and a leaving group at the other end, which corresponds to the intermediate in the former method, may be a more convenient way to get crown compounds.[10]

In view of this, an attempt was undertaken in our laboratory to get such compounds,[11] and we have recently reported a new method of obtaining a variety of crown compounds through the *in situ* formation of such precursors.[12,13]

The detailed results of the synthesis of unsubstituted crown ethers from oligoethylene glycols by treatment with arenesulfonyl or alkanesulfonyl chlorides in the presence of alkali metal hydroxide will be described in this paper.

Experimental

The IR and ^{1}H NMR spectra were recorded on a JASCO IR-E spectrophotometer and a JEOL JMN-PS-100 spectrometer respectively. The GLC analyses were performed on a Shimadzu gas chromatograph GC-3BF, equipped with a flame-ionization detector.

Oligoethylene Glycols. The penta-, hexa-, and heptaethylene glycols were each purely separated from a polyethylene glycol mixture with an average molecular weight of 250 by distillation at a reduced pressure. The di-, tri-, and tetraethylene glycols were commercial products and were used without purification.

Synthesis of 15-Crown-5 (IIc) from Pentaethylene Glycol. Pentaethylene glycol (4.8 g, 0.02 mol) and *p*-toluenesulfonyl chloride (4.0 g, 0.02 mol) were dissolved in 30 ml of monoglyme, after which the solution was slowly added, drop by drop, into a suspension of powdered sodium hydroxide (6.0 g, 0.15 mol) in 30 ml of monoglyme over a period of 2 h at room temperature. After the addition was complete, the reaction was continued for one more hour, and the reaction product was filtered. The precipitate was washed with dichloromethane, and then the solvent was removed from the combined solution of filtrate and washings to leave the 15-crown-5 complex as an almost colorless liquid. It was found by GLC to consist 61% of 15-crown-5 (10% Carbowax 20 M or Silicone DC 550 on Celite 545, 220 °C, carrier gas N_2). When a part of the complexes (3.6 g) was thermolyzed using Kugelrohr distillation apparatus, free 15-crown-5 (IIc, 1.7 g, 50%) was obtained as a viscous liquid. NMR (CCl_4, δ): 3.53 s, MS (*m/e*): 220 (M^+).

Small-scale experiments for the investigation of the reaction conditions were carried out using 1.0 g (4.2 mmol) glycol in 60 ml of a solvent in manner similar to that described above.

Synthesis of 18-Crown-6 (IId) from Hexaethylene Glycol. Hexaethylene glycol (3.0 g, 0.011 mol) and *p*-toluenesulfonyl chloride (2.0 g, 0.011 mol) were dissolved in 40 ml of dioxane, after which the solution was added, drop by drop, into a suspension of powdered potassium hydroxide (2.4 g, in 40 ml dioxane) at 40 °C. The white solid (4.8 g) thus obtained was found to contain 2.68 g (92%) of 18-crown-6 (IId) and no unreacted glycol by GLC. When a part of the crude product (3.5 g) was thermolyzed by means of a Kugelrohr apparatus at reduced pressure, IId (1.6 g, 75%) was isolated in a pure state. MS (*m/e*): 264 (M^+), NMR (CCl_4, δ): 3.50 s.

Synthesis of 21-Crown-7 (IIe) from Heptaethylene Glycol. Heptaethylene glycol (3.0 g, 9.2 mmol) was treated with *p*-toluenesulfonyl chloride (1.75 g, 9.2 mmol) in 80 ml of dioxane in a manner simmlar to that described above at 50 °C. The crude complex (3.3 g) was extracted by the use of hexane in a continuous extractor to give 1.67 g (59%) of pure 21-crown-7 (IIe) as a colorless liquid. IR (neat): 2880 s, 1465 m, 1360 m, 1300 m, 1255 m, 1115 s, 945 m, and 850 w cm^{-1}. MS (*m/e*, rel. intensity): 308 (M^+, amplified), 133 (20), 89 (49), 87 (29), 73 (21), 72 (13), 59 (18), 58 (17), 45 (100), 44 (23), and 43 (29). NMR (CCl_4, δ): 3.54 s. Analysis for $C_{14}H_{28}O_7$: C, 53.98 (Calcd. 54.53); H, 8.99 (9.15).

Reaction of Tetraethylene Glycol with Sulfonyl Chloride. a): A solution of tetraethylene glycol (3.9 g, 0.02 mol) and *p*-toluenesulfonyl chloride (4.0 g, 0.02 mol) in monoglyme (30 ml) was added into a suspension of sodium hydroxide

(6.0 g) in 30 ml of monoglyme at 20 °C. The crude product (3.3 g), which was found by GLC to contain 3% of 12-crown-4, was treated on a silica-gel column to give a low-melting solid (0.42 g) from an acetone–hexane eluent. IR (neat): 2880 s, 1460 w, 1350 m, 1300 w, 1250 w, 1150—1110 s, 950 w, and 850 w cm^{-1}. MS (*m/e*, rel. intensity): 352 (M^+, 5), 177 (5), 133 (24), 117 (24), 101 (14), 89 (60), 87 (37), 73 (30), 59 (25), 58 (25), 45 (100), 44 (32), and 43 (40). NMR (CCl_4, δ): 3.52 s. From the above spectral data, it was identified as 24-crown-8 (IIf). Yield: 12%, b): Tetraethylene glycol (7.77 g, 0.04 mol) and benzenesulfonyl chloride (7.36 g, 0.04 mol) were dissolved in 90 ml of *t*-butyl alcohol, after which the solution was added, drop by drop, into a suspension of lithium *t*-butoxide (12.8 g, 0.16 mol) in 90 ml of *t*-butyl alcohol over a period of 2 h. After the reaction was complete, the *t*-butyl alcohol was removed *in vacuo* and dichloromethane (100 ml) was added to the residue and filtrate. After the solvent had then been removed, the crude complex was thermolyzed to give a colorless liquid (3.5 g). It was further purified by distillation at reduced pressure. IIb, 1.93 g (27%). IR (neat): 2925 s, 1465 w, 1375 m, 1300 m, 1255 m, 1140 s, 1100 s, 1095 m, 1020 m, 920 m, and 850 m cm^{-1}. MS (*m/e*, rel. intensity): 176 (M^+, amplified), 133 (8), 89 (30), 87 (18), 73 (15), 59 (15), 58 (19), 57 (11), 45 (100), 44 (33), 43 (40), and 28 (29). NMR (CCl_4, δ): 3.56 s.

Also, the crude complex of IIb (3.95 g; IIb content, 38%), obtained in another reaction, was dissolved in methanol (10 ml), after which the solution was extracted continuously by hexane for 9 h. The colorless liquid thus obtained (1.96 g) was distilled under reduced pressure to afford IIb (0.65 g, 31%) in a pure state.

Reaction of Mixture of Glycols with Sulfonyl Chloride. a): Tetraethylene glycol (3.9 g, 0.02 mol), triethylene glycol (3.0 g, 0.02 mol), *p*-toluenesulfonyl chloride (8.0 g, 0.04 mol), and potassium hydroxide (10 g) was allowed to react at 60 °C in dioxane to afford a crude product (9.8 g). It was found by GLC determination to contain three kinds of crown ethers: 18-crown-6 (1.02 g, 19%), 21-crown-7 (2.06 g, 33%), and 24-crown-8 (0.98 g, 14%), *b)*: Tetraethylene glycol (1.94 g, 0.01 mol), diethylene glycol (1.06 g, 0.01 mol), *p*-toluenesulfonyl chloride (4.0 g, 0.02 mol), and potassium hydroxide (2.7 g) were allowed to react in dioxane at 60 °C. The crude complex (2.2 g) was analyzed by GLC and found to contain 18-crown-6 (0.60 g, 23%) as the major product, together with small amounts of 24-crown-8 (3%) and 12-crown-4 (<1%).

Conversion of Polyethylene Glycol 200 to Crown Ethers. 3.0 g of commercial polyethylene glycol 200, which was a mixture of di- (1 wt%), tri- (26%), tetra- (36%), penta- (29%), and hexaethylene glycol (8%), was treated with *p*-toluenesulfonyl chloride (2.9 g) in the presence of sodium hydroxide (1.3 g)

Table 1. Synthesis of 15-crown-5 from pentaethylene glycol

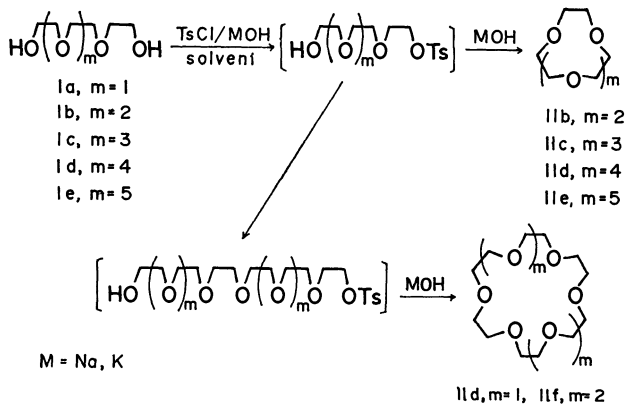
a) Determined by GLC. b) Values in parentheses are the yields of crown ethers isolated by thermolysis (Nos. 7, 9, 10, and 27), hexane extraction (No. 19), or column chromatography (No. 24). c) Reflux temperature.

and potassium hydroxide (3.0 g) in 60 ml of dioxane at 60 °C. The crude complex (3.5 g) thus obtained was found by GLC analysis to contain 15-crown-5 (0.67 g), 18-crown-6 (0.38 g), 21-crown-7 (0.49 g), and 24-crown-8 (0.40 g).

Results and Discussion

The overall reaction scheme for the synthesis of crown ethers is shown in Scheme 1.



Scheme 1. Synthesis of crown ethers from oligoethylene glycols.

Pentaethylene glycol, hexaethylene glycol, and heptaethylene glycol were converted easily to the corresponding crown ethers, *i.e.*, 15-crown-5, 18-crown-6, and 21-crown-7 respectively. The results are shown in Tables 1 and 2.

On the other hand, tetraethylene glycol gave only a very small amount of 12-crown-4 (3%) under reaction conditions similar to those of the higher homologues, in spite of complete consumption of the starting glycol. Instead, 24-crown-8 was isolated in a 12% yield from the reaction product, suggesting that the template effect was not effective for the cyclization of tetraethylene glycol to 12-crown-4.[14]

However, the yield of 12-crown-4 could be increased up to 49% by altering the alkali/solvent system from Na(K)OH/dioxane to *t*-BuOLi/*t*-BuOH.

The solvent may play an important role in this reaction.[15] In the reactions in dioxane, THF, monoglyme, and diglyme, the yields of crown ethers were almost all the same and well satisfactory, while the reactions in ether, acetonitrile, and benzene gave somewhat poorer yields, and in hexane, the yield was very low, probably because of the limited solubility of

glycol. On the other hand, although a slight amount of 15-crown-5 was obtained in the reaction in DMF, no crown ether was obtained in the DMSO solvent and the glycols were recovered unchanged. Sulfonyl chlorides seemed to react with these solvents in preference to glycols when alkali metal hydroxide was present.

The kind of sulfonyl chloride also has some effect on the reaction. Among the sulfonyl chlorides investigated, benzenesulfonyl chloride was most effective with the *o*- and *p*-toluenesulfonyl chlorides following. The alkanesulfonyl chlorides seemed less effective than arenesulfonyl chlorides.

With respect to the effect of the alkali metal cation as the template ion, results almost the same as in the previous investigations were obtained.[5,6] The order of the effectiveness of sodium cation for the oligoethylene glycol was: *penta*>*hexa*>*hepta*>*octa*≫*tetra*, while that of the potassium cation was: *hexa*>*hepta*>*penta*>*octa*≫*tetra*. Other cations, such as Li^+, Ba^{++}, and Ca^{++} were found to be ineffective.

The temperature effect has already been reported briefly.[16] A temperature of around 60 °C was found to be optimum for the synthesis of most of the crown ethers investigated.

The concentration of the glycols and the addition rate may also affect the reaction, because the intramolecular cyclization to a crown ether may be preferable to the intramolecular oligomerization in a dilute solution. However, the addition time was settled as 2 h for the convenience of comparison, while the concentration was changed over the range from 0.07 to 0.7 mol/l in the synthesis of 15-crown-5.

Although the yield was observed to decrease slightly in concentrations (0.7 mol/l) higher than that in the dilute solution (0.07 mol/l), the difference in the yields between the concentrations was not so remarkable that, by controlling the addition rate, a satisfactory result can be expected even in production on a large scale.

Furthermore, as to such glycols as tri- and tetraethylene glycol, which are difficult to cyclize to the corresponding crown ethers, cyclization was observed to occur after the dimerization or trimerization of glycol, as 24-crown-8 instead of 12-crown-4 was obtained in the reaction of tetraethylene glycol. Thus, when triethylene glycol was treated with an equimolar amount of *p*-toluenesulfonyl chloride, 18-crown-6 was obtained in the maximum yield of 72%, as is shown in Fig. 1 (Curve II).

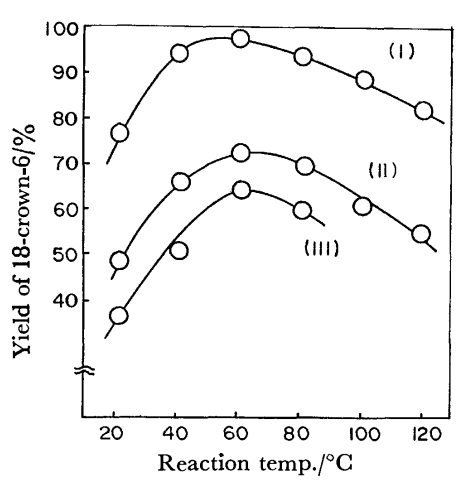


Fig. 1. Yield of 18-crown-6 in various reactions.
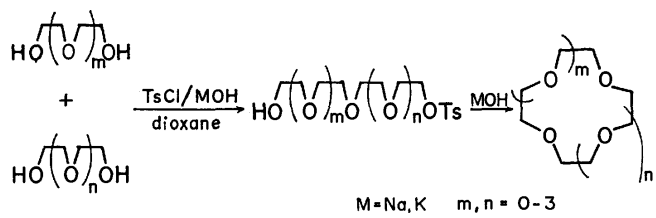
Curve I : Cyclization of hexaethylene glycol by TsCl.
Curve II : Condensation of two moles of triethylene glycol by TsCl.
Curve III: Condensation of triethylene glycol and triethylene glycol ditosylate.

The yield was somewhat lower than that of the cyclization of hexaethylene glycol (Curve I), but better than that of the condensation between triethylene glycol and triethylene glycol ditosylate (Curve III).[4,16]

Similarly, the three expected crown ethers, *i.e.*, 18-crown-6, 21-crown-7, and 24-crown-8, were obtained in the molar ratio of 4: 7: 3 from the reaction of an equimolar mixture of triethylene glycol and tetraethylene glycol (Scheme 2 and Table 3).



Scheme 2. Synthesis of crown ethers from mixtures of oligoethylene glycols.

Table 3. Synthesis of crown ethers by the coupling reaction of glycols

Exp. No.	*m*	*n*	MOH	Product	Yield/%[a]
1	3	0	NaOH	15-crown-5	trace[b]
2	3	1	KOH	18-crown-6	23[b]
3	3	2	NaOH	18-crown-6	19
			KOH	21-crown-7	33
				24-crown-8	14
4	3	3	KOH	12-crown-4	2
				24-crown-8	24

a) Determined by GLC. b) The presence of a small amount of 24-crown-8 was detected.

However, our attempts to prepare crown ethers using ethylene glycol or diethylene glycol were not successful because of their prompt conversion to ethylene oxide or dioxane.

Furthermore, the treatment of the commercial polyethylene glycol 200, which is composed mainly of tri-, tetra-, penta-, and hexaethylene glycols, with *p*-toluenesulfonyl chloride at 60 °C in the presence of

Table 4. Synthesis of crown ethers from polyethylene glycol 200

Product	PEG Source	Yield/wt%[a]
15-Crown-5	penta	26
18-Crown-6	hexa, tri×2	15
21-Crown-7	tri+tetra	20
24-Crown-8	tetra×2, tri+penta	16

a) Determined by GLC.

NaOH/KOH afforded a mixture of 15-, 18-, 21-, and 24-crown ethers, with the complete consumption of the glycols (Table 4).

Free crown ethers were isolated from their complexes with sodium (potassium) chloride or *p*-toluenesulfonate by thermal decomposition under reduced pressure using a Kugelrohr distillation apparatus, column chromatography or continuous extraction by hydrocarbon solvents. The last means was preferable to the others, especially for the separation of 15- and 21-crown ethers from their complexes.

Nucleophilic Reactions of Hexafluoro-1,2-epoxypropane with 1,2-Bifunctional Ethanes

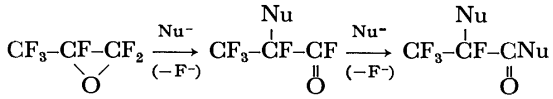
Hajimu KAWA, Hamdy A. HAMOUDA, and Nobuo ISHIKAWA*

Department of Chemical Technology, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

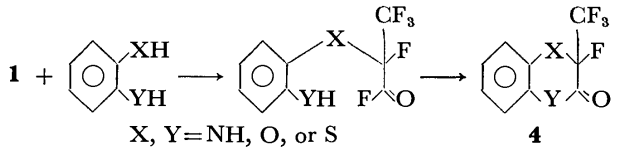
(Received December 12, 1979)

Reactions between hexafluoro-1,2-epoxypropane and 1,2-bifunctional ethanes were studied. Ethylenediamine, 2-aminoethanol and 2-aminoethanethiol gave corresponding *N*- and *O*-pentafluoropropionylated products, while ethylene glycol, 2-mercaptoethanol, and 1,2-ethanedithiol afforded ring closed products, such as 1,4-dioxanone, 1,4-oxathianone, and 1,4-dithianone compounds.

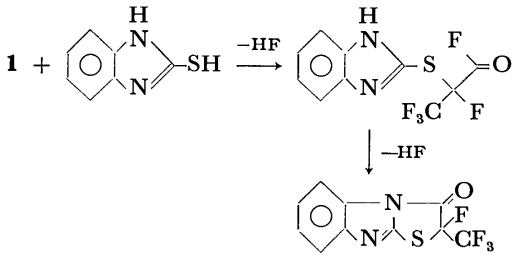
Hexafluoro-1,2-epoxypropane (**1**) is easily attacked by nucleophiles usually at the 2-position, and the resulting carboxylic acid fluorides (**2**) further react with another molecule of the nucleophile to give 2-substituted tetrafluoropropanoic acid derivatives (**3**).[1-3] Utilizing



these reactivities of **1** for nucleophiles, we have prepared several fluorinated 2,3-benzo-fused 1,4-diheteracyclic compounds (**4**) by the reaction between **1** and 1,2-bifunctional benzenes.[4] Another example of the



preparation of fluorinated heterocycles from **1** is the condensation with mercaptobenzimidazoles giving thiazolobenzimidazolones which are interesting from the pharmaceutical point of view.[5] Since the formation of

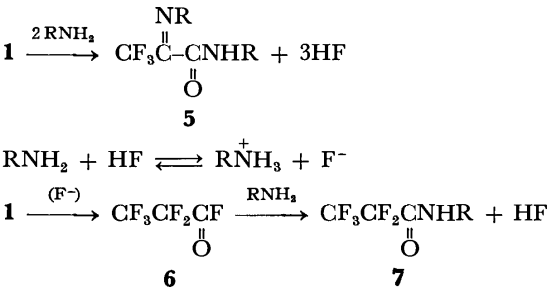


other kind of 1,4-diheteracyclic compounds had been expected, these works have now been extended and reactions between **1** and 1,2-bifunctional ethanes were examined. The reactions were, however, not so simple like those with 1,2-bifunctional benzenes and some interesting behaviors of 1,2-bifunctional ethanes were observed.

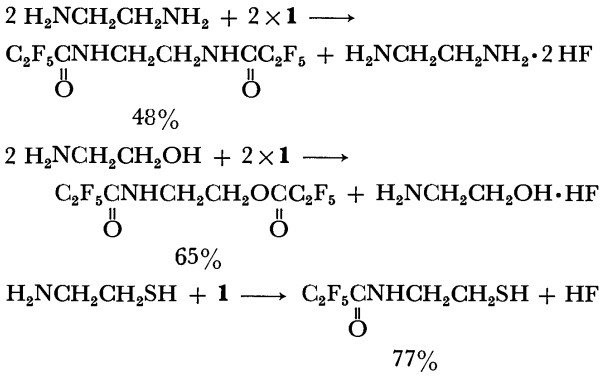
Results and Discussion

Reactions of Hexafluoro-1,2-epoxypropane with Ethylenediamine, 2-Aminoethanol and 2-Aminoethanethiol. Hexafluoro-1,2-epoxypropane is known to isomerize easily into pentafluoropropanoic acid fluoride (**6**) by the aid of a fluoride ion or a strong base.[6,7]

The reaction with an alkylamine is reported to give some amount of *N*-alkylpentafluoropropionamide (**7**)



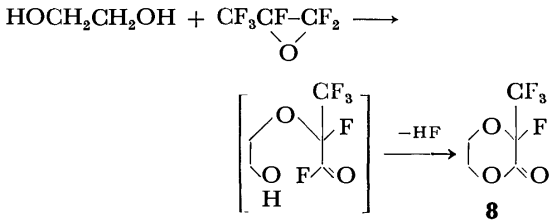
together with the main 2-substituted amide (**5**). When we allowed **1** to react with an equimolar amount of ethylenediamine, 2-aminoethanol or 2-aminoethanethiol in diglyme at room temperature, only *N*- and *O*-pentafluoropropionylated products were obtained and no 2-substituted tetrafluoropropanoic acid derivatives.



Thus, by the nucleophilic reactions of **1** with 2-functional ethylamines, none of heterocyclic compounds were obtained. This is in contrast to those with *ortho*-functional anilines which gave 2,3-benzo-fused 1,4-diheteracyclic compounds in good yields.[4] The difference should be ascribed to the stronger basicities of aliphatic amines than those of the aromatic amines. The strong basicity of ethylenediamine or 2-aminoethanol must have promoted the isomerization of **1** to **6** rather than the nucleophilic reaction at the 2-position of **1**.

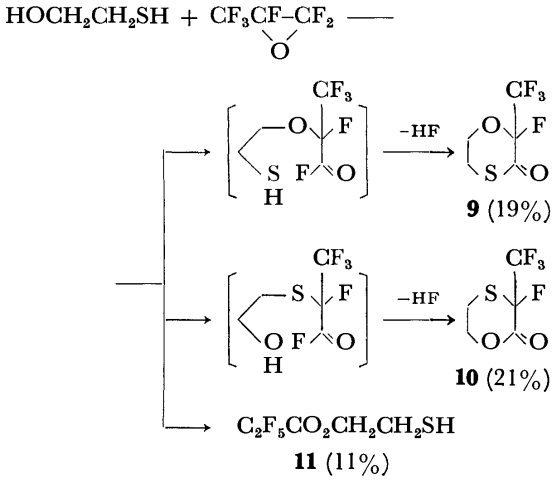
Reactions of Hexafluoro-1,2-epoxypropane with Ethylene Glycol, 2-Mercaptoethanol, and 1,2-Ethanedithiol. As described above, the amino group of 2-functional ethylamines was found to accelerate the formation of acid fluoride **6**. Then we examined the reaction of **1** with non-basic 1,2-bifunctional ethanes, *i.e.*, ethylene glycol, 2-mercaptoethanol and 1,2-ethanedithiol.

Ethylene glycol reacted smoothly with **1** in diglyme and 3-fluoro-3-trifluoromethyl-1,4-dioxan-2-one (**8**) was

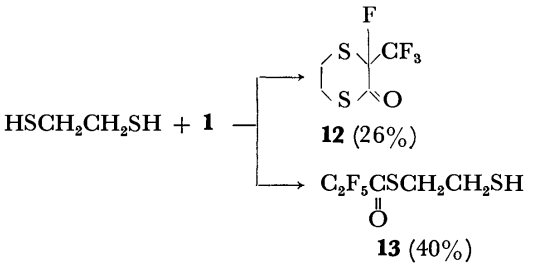


expectedly obtained. In the case of mercaptoethanol, two isomers of 1,4-oxathianone (**9**, **10**) were obtained in almost similar yields.

It is evident that **9** was formed by the nucleophilic attack by the OH group of mercaptoethanol first, while **10** was formed by that of the SH group first. In addition to these two heterocyclic compounds, a considerable amount (11%) of *O*-pentafluoropropionyl compound (**11**) was isolated from the reaction mixture.



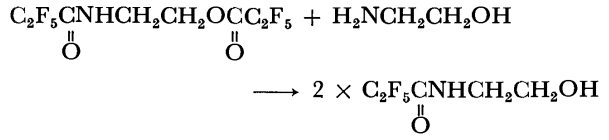
With 1,2-ethanedithiol, 2-fluoro-2-trifluoromethyl-1,4-dithian-3-one (**12**) was expectedly formed, though the yield was rather poor (26%), and a larger amount of *S*-pentafluoropropionyl compound (**13**) was obtained.



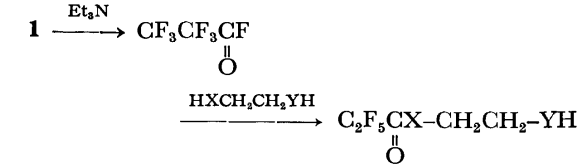
The formation of pentafluoropropionylated products in the case of reactions with the thiol and the dithiol should have resulted from the partial isomerization of **1** to **6** by the aid of the mercapto group, which behaved as a weak base.

Equilibrium among N-, O- *and* S-*Pentafluoropropionyl Groups.* From the results obtained heretofore, we noticed that there are differences among *N*-, *O*-, and *S*-pentafluoropropionyl groups in their thermodynamic stabilities.

For example, when *N*,*O*-bis(pentafluoropropionyl)-2-aminoethanol was treated with an equimolar amount of 2-aminoethanol, proportionation reaction occurred, and the *N*-(pentafluoropropionyl) compound was obtained quantitatively.

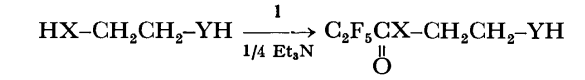


Further, we examined pentafluoropropionylation of 1,2-bifunctional ethanes by having them react with **1** in acetonitrile in the presence of triethylamine, the reaction which was used for the pentafluoropropionylation of



alcohols and amines.[8] The results are shown in Table 1. It is notable that when two different kinds of groups present in a molecule, only one group of them was exclusively pentafluoropropionylated. An amino group was always predominantly pentafluoropropionylated rather than a hydroxyl or a mercapto group, and between the latter two groups, a hydroxyl group was more readily perfluoroacylated. From these results, it was evident that the order of thermodynamic stabilities of pentafluoropropionyl groups is C_2F_5CONH> $C_2F_5CO_2$>C_2F_5COS. This order is in accordance with the general stabilities of acyl compounds,[9] but the trend seems to be more remarkable in a series of perfluoroacyl compounds.[10]

Table 1. Pentafluoropropionylation of 1,2-bifunctional ethanes



Product		Yield[a]/%
C_2F_5COX	YH

The ^{19}*F-NMR Spectra.* Most of the qualitative and quantitative analyses of reaction products in this work were easily done by means of the ^{19}F-NMR spectra.

In a series of $-X-CF-CF_3$ moieties, the NMR signals for C<u>F</u> and C<u>F</u>$_3$ of X=O compounds were characteristically distinguishable from those of X=S compounds. Thus, in comparison with those of X=O compounds, the signals due to <u>F</u> and C<u>F</u>$_3$ of X=S compounds shift considerably up and down field

TABLE 2. THE ^{19}F-NMR FOR Et–X–CF(CF$_3$)–CO$_2$Et

X	Chem. Shift (ppm)[a]		J_{CF-CF_3} (Hz)
	CF	CF_3

S	+72.0	−3.5	10.8

a) Upfields from ext. CF_3CO_2H in Et_2O.

respectively, and the coupling constants J_{F-CF_3} were much larger. The results are shown in Table 2.

The fluorine atom of the S–CF group is supposed to be more shielded than that of the O–CF group due to the more positive character of the sulfur atom than the oxygen atom. In the case of the –N=C–CF_3 group, the signal due to CF_3 appeared, of course, as a singlet at about −20 ppm.

As to the ^{19}F chemical shifts for $CF_3CF_2C(=O)XR$, characteristic patterns were observed depending on the X atom, as shown in Table 3. In general, the signals due to CF_2 in X=NH, O, and S compounds appeared at 45—46, 43—44, and 42—43 ppm upfield from CF_3CO_2H standard respectively. These values could be used for the identification of the pentafluoropropionyl groups.

Experimental

All the ^{19}F-NMR chemical shifts throughout this article are given in δ ppm upfield from external CF_3CO_2H.

N,N'-Bis(pentafluoropropionyl)ethylenediamine. A mixture of ethylenediamine (1.20 g, 20 mmol) and diglyme (20 ml) was placed in a glass pressure vessel and cooled to≈ −70 °C. Liquefied hexafluoro-1,2-epoxypropane (bp −27 °C, 3.50 g, 21 mmol) was then introduced into the vessel and the whole was brought to room temperature. After stirring of 1 h, the reaction mixture was poured into water and an oily material was extracted with diethyl ether. The extract was dried over magnesium sulfate and the solvent was removed, yielding a solid material. The crude product was recrystallized from aqueous methanol to give pure *N,N'*-(bispentafluoropropionyl)-ethylenediamine (1.69 g, 48%), mp 169 °C. IR: 3315 (NH), 1690 (C=O) cm^{-1}. ^{19}F-NMR (in acetone): δ 5.5 (CF_3), 44.5 (CF_2) ppm. Found: C, 27.43; H, 1.81; N, 7.76%. Calcd for $C_8H_6N_2O_2F_{10}$: C, 27.29; H, 1.72; N, 7.96%.

N,O-Bis(pentafluoropropionyl)-2-aminoethanol. 2-Aminoethanol (1.22 g, 20 mmol) instead of ethylenediamine was used in the above procedure. Reaction was continued for 2 h at room temperature and worked up similarly. Distillation gave 1.70 g (66%) of *N,O*-bis(pentafluoropropionyl)-2-aminoethanol, bp 81—82 °C/3 mmHg. IR (film): 3310 (NH), 1710 (C=O), 1700 (C=O) cm^{-1}. ^{19}F NMR (neat): δ 7.0 (2× CF_3), 45.0, 47.0 (CF_2) ppm. Found: C, 27.64; H, 1.65; N, 4.33%. Calcd for $C_8H_5NO_3F_{10}$: C, 27.21; H, 1.43; N, 3.97%.

N-Pentafluoropropionyl-2-aminoethanol. 2-Aminoethanol (0.30 g, 5 mmol) was added to a mixture of *N,O*-bis(pentafluoropropionyl)-2-aminoethanol (1.29 g, 5 mmol) and diglyme (10 ml) at room temperature. After 30 min of stirring the solvent was removed, and almost pure *N*-pentafluoropropionyl-2-aminoethanol (1.56 g, 98%), bp 99—100 °C/5 mmHg was obtained. IR: 3500—3300 (NH, OH), 1700 (C=O) cm^{-1}. ^{19}F-NMR (neat): δ 6.0 (CF_3), 45.5 (CF_2) ppm. Found: C, 29.11; H, 2.87; N, 6.76%. Calcd for $C_5H_6NO_2F_5$: C, 28.99; H, 2.92; N, 6.76%.

N-Pentafluoropropionyl-2-aminoethanethiol. Pentafluoro-1,2-epoxypropane (3.50 g, 21 mmol) and 2-aminoethanethiol (1.54 g, 20 mmol) were allowed to react at room temperature for 2 h in diglyme (20 ml). *N*-Pentafluoropropionyl-2-aminoethanethiol (3.60 g, 77%), bp 108—109 °C/11 mmHg was obtained after usual treatment. IR: 3310 (NH), 2550 (SH), 1700 (C=O) cm^{-1}. ^{19}F-NMR (neat): δ 6.0 (CF_3), 45.5 (CF_2), ppm. Found: C, 26.13; H, 2.57; N, 5.82%. Calcd for $C_6H_5NOSF_5$: C, 26.91; H, 2.71; N, 6.28%.

When a mixture of this compound (1.11 g, 5 mmol), 2,4-dinitrochlorobenzene (1.01 g, 5 mmol), potassium hydroxide (0.3 g, 5 mmol) and ethanol (30 ml) was refluxed for 3 h, *S*-(2,4-dinitrophenyl)derivative (1.4 g, 72%) was obtained. Recrystallization from chloroform gave a pure material, mp 138 °C. IR: 3310 (NH), 1700 (C=O) cm^{-1}. ^{19}F-NMR (acetone): δ 6.0 (CF_3), 45.5 (CF_2) ppm. Found: C, 33.68; H, 2.08; N, 10.73%. Calcd for $C_{11}H_8N_3O_5SF_5$: C, 33.94; H, 2.07; N, 10.79%.

3-Fluoro-3-trifluoromethyl-1,4-dioxan-2-one (8). A mixture of pentafluoro-1,2-epoxypropane (5.81 g, 35 mmol), ethylene glycol (1.86 g, 30 mmol) and diglyme (20 ml) in a sealed glass tube was allowed to react for 50 h at room temperature. The reaction mixture was poured into water and the resulting organic layer was separated and dried over magnesium sulfate. Vacuum distillation gave pure dioxanone (2.25 g, 40%), bp 100—101 °C/25 mmHg. IR: 1780 (C=O) cm^{-1}. ^{19}F-NMR (neat): δ 3.6 (CF_3), 35.4 (CF) ppm. Found: C, 31.74; H, 2.10%. Calcd for $C_5H_4O_3F_4$: C, 31.91; H, 2.13%.

2-Fluoro-2-trifluoromethyl-1,4-oxathian-3-one (9) and 3-Fluoro-3-trifluoromethyl-1,4-oxathian-2-one (10). 2-Mercaptoethanol (2.34 g, 30 mmol) was allowed to react with pentafluoro-1,2-epoxypropane (5.81 g, 35 mmol) in diglyme (20 ml) for 20 h at room temperature. The reaction mixture was poured into water and the separated oil was dried ($MgSO_4$) and distilled carefully to give the following products:

O-Pentafluoropropionyl-2-mercaptoethanol (0.74 g, 11%), pb 68 °C/77 mmHg. IR: 1785 (C=O) cm^{-1}. ^{19}F-NMR (neat): δ 4.8 (CF_3), 43.1 (CF_2) ppm. Found: C, 26.48; H, 2.42%. Calcd for $C_5H_5O_2SF_5$: C, 26.79; H, 2.42%.

The mixture of two isomers 1,4-oxathianone (2.45 g, 40%), bp 60—85 °C/2 mmHg. The ratio of these two isomers, **9**: **10**= 1: 1, was determined by ^{19}F-NMR and they were practically separated by column chromatography (Silica Gel) using hexane as an eluent.

9: bp 93.5—94.5 °C/16 mmHg. IR: 1680 (C=O) cm^{-1}.

^{19}F-NMR (neat): δ 2.9 ($C\underline{F}_3$), 36.0 ($C\underline{F}$) ppm.

Found: C, 29.16; H, 1.90%. Calcd for $C_5H_4O_2SF_4$: C, 29.41; H, 1.96%. **10**: bp 84—85 °C/2 mmHg. IR: 1770 (C=O) cm^{-1}. ^{19}F-NMR (neat): δ −1.2 ($C\underline{F}_3$), 55.0 (CF) ppm. Found: C, 29.21; H, 1.88%.

*2-Fluoro-2-trifluoromethyl-1,4-dithian-3-one (**12**).* The reaction of 1,2-ethanedithiol (2.82 g, 30 mmol) and pentafluoro-1,2-epoxypropane (5.81 g, 35 mmol) in diglyme (20 ml) was carried out for 12 h at room temperature. The reaction mixture was then poured into water and worked up as usual. Fractional distillation gave the following two porducts:

S-Pentafluoropropionyl-1,2-ethanedithiol (2.88 g, 40%): bp 69—70 °C/30 mmHg. IR: 1680 (C=O) cm^{-1}. ^{19}F-NMR (neat): δ 4.7 ($C\underline{F}_3$), 42.0 ($C\underline{F}_2$) ppm. Found: C, 24.66, H, 2.00%. Calcd for $C_5H_5OS_2F_5$: C, 25.00; H, 2.08%. **12** (1.72 g, 26%): bp 83—84 °C/6 mmHg. IR: 1680 (C=O) cm^{-1}. ^{19}F-NMR (neat): δ −3.0 ($C\underline{F}_3$), 52.5 ($C\underline{F}$) ppm. Found: C, 27.03; H, 1.80%. Calcd for $C_5H_4OS_2F_4$: C, 27.27; H, 1.82%.

Reaction of 1,2-Biflunctional Ethanes with Hexafluoro-1,2-epoxypropane in the Presence of Triethylamine. General Procedure. A solution of 1,2-bifunctional ethane (10 mmol) and triethylamine (0.25 g, 2.5 mmol) in acetonitrile (10 ml) was cooled to −70 °C, then liquefied pentafluoro-1,2-epoxypropane (1.66 g, 10 mmol) was introduced into the vessel and the whole was brought to room temperature. After 30 min of stirring, benzylidyne trifluoride (1.46 g, 10 mmol) was added as an internal standard and the yield was determined by ^{19}F-NMR spectral analysis (Table 1).

For the isolation of the product, the reaction mixture was poured into water and the separated oily material was subjected to vacuum distillation. *O*-Pentafluoropropionylethylene glycol, for example, was obtained in 63% yield. bp 44 °C/5 mmHg. IR: 3350 (OH), 1710 (C=O) cm^{-1}. ^{19}F-NMR (neat): δ 5.5 ($C\underline{F}_3$), 44.5 (CF_2) ppm. Found: C, 27.08; H, 2.42%. Calcd for $C_5H_5O_3F_5$: C, 26.80; H, 2.25%.

Wittig-type Reaction of Dimetallated Carbodianion Species as Produced by Zinc Reduction of *gem*-Polyhalogen Compounds in the Presence of Lewis Acids

Kazuhiko TAKAI, Yuji HOTTA, Koichiro OSHIMA,* and Hitosi NOZAKI

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606

(Received December 27, 1979)

Treatment of R^1COR^2 with a suspension prepared from diiodomethane, trimethylaluminum and excess zinc in tetrahydrofuran at room temperature affords olefins $R^1R^2C{=}CH_2$ in fair (R^1,R^2=alkyl) to good (R^1=alkyl, R^2=H) yields. The ketone methylenation is better carried with another system consisting of CH_2Br_2–Zn–$TiCl_4$. Ketones and aldehydes are transformed into α-chloro α,β-unsaturated esters or α,β-unsaturated esters in good yields on treatment with methyl trichloroacetate or *t*-butyl dichloroacetate (ethyl dibromoacetate) in the presence of diethylaluminum chloride and zinc.

Metallic zinc is widely used in organic synthesis[1] and often activated by plating the surface with such metals as copper, mercury or silver.[2] The organoaluminum compounds have been found to facilitate the reduction of α-halo carbonyl compounds with zinc greatly and the dramatic effect of co-existing diethylaluminum chloride on the Reformatsky type aldol reaction has been observed.[3] We report here further exploitation for (1) terminal olefin synthesis[4] and (2) α,β-unsaturated ester synthesis by means of species as produced upon zinc reduction of *gem*-polyhalogen compounds in the presence of certain Lewis acid reagents.

Terminal Olefin Synthesis. The Wittig type carbonyl methylenation by means of CH_2I_2–Zn has been described already especially in the presence of a large excess of zinc,[5,6] although the recorded yields are far from satisfactory from the preparative point of view. We wish to report that a mixture of CH_2I_2, Zn, and trimethylaluminum (1 : 3 : 0.2 mol ratio) reacts with carbonyl compounds to produce olefins much more effectively as summarized in Table 1.

Table 1. Reaction of R^1COR^2 with CH_2I_2–Zn–Me_3Al affording $R^1R^2C{=}CH_2$[a]

Entry	R^1COR^2		Temp	Time	$R^1R^2C{=}CH_2$
	R^1	R^2	°C	h	Y/%[b]
1	Ph	H	25	1	86[c]
2	Ph	Me	25	2	67[c]
3	PhCH=CH–	H	0	1	75
4	$CH_3(CH_2)_{10}$–	H	0	4	81
5	$CH_3(CH_2)_7$–	$CH_3(CH_2)_2$–	25	2	62
6	–$(CH_2)_{11}$–		25	6	65
7	(citral)		25	4	80

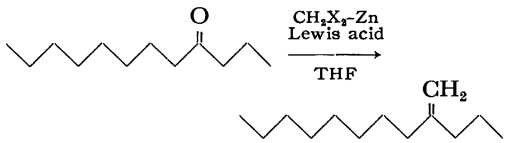
a) Three mol of CH_2I_2, nine mol of Zn and 0.6 mol of Me_3Al were employed per mol of carbonyl compounds. b) Isolated yield unless otherwise specified. c) GLPC yield by internal standard method.

Rather surprisingly, careful examination of the products failed to prove any traces of cyclopropane derivatives, which should be ascribed to the Simmons-Smith reaction of the olefinic linkage of the carbonyl components (entry 3, 7) or of the resulting $R^1R^2C{=}CH_2$. Although the reaction of the Simmons-Smith reagent with Me_3SnCl gives ICH_2SnMe_3,[7] the present reagent has been found to afford $CH_2(SnMe_3)_2$[8] exclusively under the same conditions and no ICH_2SnMe_3.

We therefore are tempted to attribute the formation of Wittig type olefins to the carbodianion species, although the identity of counter ions attached are still not clear. This *gem*-dimetallic nature of the present reactive intermediate has been further confirmed by the fact that preformed iodohydrin $PhCH(OH)CH_2I$[9] was recovered practically unchanged after treatment with excess of the reagent prepared as above. Olefination of aldehyde and ketone carbonyls by *gem*-dimetallic reagent of the type Mtl–CH_2–Mtl′ has been described to afford variable yields.[10] Exclusive carbonyl methylenation of enals (entry 3, 7) is unprecedented.

The yields of the methylenated products from ketones could not be improved over 70% in spite of various attempts made by means of the CH_2I_2, Zn, and R_3Al system. Other Lewis acids have been examined in the

Table 2. Effects of various lewis acid on the transformation of 4-dodecanone to 2-propyl-1-decene[a]



Lewis acid	Yield/% of 2-Propyl-1-decene	
	CH_2I_2	CH_2Br_2
Me_3Al	62	14
Et_3Al	55	27
Et_2AlCl	56	23
$AlCl_3$	42	<5
$TiCl_4$	83	89
VCl_4	73	20
$ZrCl_4$	34	<5
WCl_6	<5	<5

a) Three mol of CH_2I_2 or CH_2Br_2, 9 mol of Zn and 1 mol of Lewis acid were employed per mol of 4-dodecanone. Reaction mixture was stirred for 12 h at 25 °C and 2-propyl-1-decene was isolated by column chromatography.

transformation of 4-dodecanone to 2-propyl-1-decene with CH_2X_2 and zinc (Table 2). Among them, $TiCl_4$ has proved to be the best enabling to use CH_2Br_2 instead of CH_2I_2.

The results of methylenation with CH_2Br_2, Zn, $TiCl_4$ system are shown in Table 3. Neither cyclopropane compounds nor isomerized olefins were isolated. Entry 3[11] and 4[12] showed the superiority of the method over the Wittig reaction. The reductive coupling of the carbonyl component[13] was observed only with an aldehyde (entry 6), although the desired olefin was still predominant.

Both systems of CH_2I_2–Zn–Me_3Al and CH_2Br_2–Zn–$TiCl_4$ are complementary. The mild conditions and high yields characterize the two systems as a useful alternative for the Wittig carbonyl methylenation.[14]

Table 3. Reaction of R^1COR^2 with CH_2Br_2–Zn–$TiCl_4$ affording $R^1R^2C{=}CH_2$[a]

Entry	R^1COR^2		Temp	Time	$R^1R^2C{=}CH_2$
	R^1	R^2	°C	h	Y/%[b]
1	$CH_3(CH_2)_7$–	$CH_3(CH_2)_2$–	25	12	89
2	–$(CH_2)_{11}$–		25	12	80
3	–$(CH_2)_6$–		25	6	83[c]
4	(camphor)		25	40	92[c]
5	(geranylacetone)		25	12	83
6	$CH_3(CH_2)_{10}$–	H	0	4	55[d]

a) One and a half mol of CH_2Br_2, 4.5 mol of Zn and 1.1 mol of $TiCl_4$ were employed per mol of carbonyl compounds. b) Isolated yield. c) GLPC yield by internal standard method. d) $CH_3(CH_2)_{10}CH(OH)$-$CH(OH)(CH_2)_{10}CH_3$ was also obtained (24%).

α-Chloro α,β-Unsaturated Ester and α,β-Unsaturated Ester Syntheses. The reaction between ethyl trichloroacetate and carbonyl compounds in the presence of zinc[15] or Mg–$HgCl_2$[16] has been reported to result in the formation of α,α-dichloro β-hydroxy esters or the further reduced β-hydroxy esters. Meantime, we have disclosed that co-existence of diethylaluminum chloride in these classical Reformatsky reaction changes the reaction path dramatically to afford α-chloro α,β-unsaturated esters[17] instead. The results are summarized in Table 4.

$$CCl_3COOR^1 + R^2COR^3$$

Mg–$HgCl_2$ | Zn | Zn–Et_2AlCl

$$\begin{array}{ccc} \overset{OH}{\underset{R^3}{\overset{R^2}{\diagdown}}}\!\!\diagup\!\!\underset{H}{\overset{H}{\diagdown}}\!\!-\!\!COOR^1 & \overset{OH}{\underset{R^3}{\overset{R^2}{\diagdown}}}\!\!\diagup\!\!\underset{Cl}{\overset{Cl}{\diagdown}}\!\!-\!\!COOR^1 & \overset{R^2}{\underset{R^3}{\diagdown}}\!\!C{=}C\!\!\overset{Cl}{\diagup}\!\!\diagdown\!\!COOR^1 \end{array}$$

Remarkably, a Reformatsky product $Me_2C{=}CHCH_2$-$CH_2C(CH_3)(OH)CCl_2COOMe$ prepared by the conventional way has been recovered unchanged on treatment with the Zn–Et_2AlCl system. Furthermore, α,β-unsaturated esters were produced in the similar reaction of dichloro- or dibromoacetate with carbonyl in fair yields, which are shown in Table 5. The present method provides an alternative for the Emmons-Wadsworth-Horner reaction[18] and would very probably involve a Mtl–C(X)=C(OMtl')OR (X=Cl or H) type species. It should be noted that the presence of diethylaluminum chloride is crucial to the formation of α,β-unsaturated esters, since its absence results in ordinary Reformatsky products, halohydrins.[24]

Experimental

The IR spectra were determined on a Shimadzu IR-27-G spectrometer; the mass spectra, on a Hitachi RMU-6L machine; and the NMR spectra, on a JEOL C-60-H or a Varian EM-390H spectrometer. The chemical shifts are given in δ, with TMS as the internal standard. The analyses were carried out by the staff at the Elemental Analyses Center of Kyoto University. Commercial zinc dust was washed several times with 5% hydrochloric acid, washed in turn with water, methanol, and ether, and dried.[19] Tetrahydrofuran (THF) was dried on benzophenone ketyl and distilled. All the experiments were carried out under an argon atmosphere. Purification of products were performed by preparative thin layer chromatography (TLC) or column chromatography on silica gel (Merck Kieselgel 60). Analytical GLPC was performed with a Yanagimoto GCG-550-F. Product percentages were calculated from peak area ratios without correction for detector response. Preparative GLPC was performed with a JEOL-JGC-20K apparatus.

Preparation of Terminal Olefins by Means of CH_2I_2–Zn–Me_3Al System. To a suspension of zinc dust (1.18 g, 18 mmol) and diiodomethane (1.61 g, 6.0 mmol) in dry THF (10 ml) was added a hexane solution of trimethylaluminum (1.0 M, 1.2 ml, 1.2 mmol) at 25 °C. The resulting mixture was stirred until the exothermic reaction had subsided (10 min). A solution of carbonyl compound (2.0 mmol) in THF was added dropwise at 25 °C (0 °C). After stirring at this temperature for an appropriate time described in Table 1, the reaction mixture was diluted with ether (10 ml), poured into 1 M hydrochloric acid (20 ml), and extracted with ether. The separated organic layer was washed with brine (2×20 ml), dried over anhydrous sodium sulfate, and concentrated under reduced pressure. The crude product was purified by column chromatography on silica gel (20 g) using hexane as an eluent.

Preparation of Terminal Olefins by Means of CH_2Br_2–Zn–$TiCl_4$ System. To a suspension of zinc dust (0.59 g, 9.0 mmol) and dibromomethane (0.52 g, 3.0 mmol) in THF (10 ml) was added a dichloromethane solution of titanium tetrachloride (1.0 M, 2.2 ml, 2.2 mmol) at 25 °C. Instantaneous reaction occurred under evolution of heat and rapid color change to dark brown. After 15 min, a THF solution of carbonyl compound (2.0 mmol) was added dropwise and the resulting mixture was stirred at 25 °C (0 °C) for an appropriate time described in Table 3. The reaction mixture was diluted with ether (10 ml), poured into 1 M hydrochloric acid (20 ml), and extracted with ether. The separated organic layer was washed with brine (2×20 ml), dried over anhydrous sodium sulfate, and concentrated under reduced pressure. The crude product was purified by column chromatography on silica gel (20 g) using hexane as an eluent.

2-Propyl-1-decene: Bp 82 °C (bath temp, 2 Torr); IR (neat): 3080, 1643, 1470, 890 cm^{-1}; NMR (CCl_4): δ 0.90 (t, J=6 Hz, 6H), 1.15—1.55 (bm, 14H), 1.94 (t, J=6 Hz, 4H), 4.60 (s, 2H); MS *m/e* (%): 182 (M^+, 4), 139 (5), 97 (12), 56 (100); Found: C, 85.73; H, 14.62%. Calcd for $C_{13}H_{26}$: C, 85.63; H, 14.37%.

Methylenecyclododecane: Bp 85 °C (bath temp, 2 Torr); IR (neat): 3080, 1645, 1485, 1445, 890 cm^{-1}; NMR (CCl_4): δ 1.15—1.60 (bm, 18H), 1.93—2.20 (bt, 4H), 4.80 (s, 2H); MS *m/e* (%): 180 (M^+, 18), 109 (32), 97 (66), 82 (82), 55 (100). The compound was identical with the authentic sample.[20]

4,8-Dimethyl-1,3,7-nonatriene: Bp 53 °C (bath temp, 2 Torr); IR (neat): 3080, 1648, 1600, 1450, 990, 892 cm^{-1}; NMR (CCl_4): δ 1.60 (s, 3H), 1.67 (s, 3H), 1.74 (s, 3H), 1.95—2.17 (bm, 4H), 4.80—5.15 (bm, 3H), 5.76 (d, J=10 Hz, 1H), 6.46 (ddd, J=10, 10, 17 Hz, 1H); MS *m/e* (%): 150 (M^+, 7), 135 (6), 107 (11), 81 (18), 69 (100); Found: C, 87.87; H, 12.21%. Calcd for $C_{11}H_{18}$: C, 87.93; H, 12.07%.

Methylenecycloheptane: Bp 135 °C (1 atm); IR (neat): 3100, 1640, 1450, 880 cm^{-1}; NMR (CCl_4): δ 1.53 (bm, 8H), 2.23 (bt, 4H), 4.60 (s, 2H); MS *m/e* (%): 110 (M^+, 19), 95 (55), 82 (74), 67 (100). The compound was identical with the authentic sample.[21]

2-Methylenebornane: Mp 67—70 °C (sublimes appreciably at room temperature); IR (neat): 3070, 1655, 1450, 870 cm^{-1}; NMR (CCl_4): δ 0.77 (s, 3H), 0.88 (s, 6H), 1.08—2.60 (m, 7H), 4.40—4.65 (bdd, 2H); MS *m/e* (%): 150 (M^+, 25), 135 (45), 121 (24), 107 (100), 79 (79). The compound was identical with the authentic sample.[12]

2,6,10-Trimethyl-1,5,9-undecatriene: Bp 78 °C (bath temp, 2 Torr); IR (neat): 3080, 1650, 1450, 885, 825 cm^{-1}; NMR (CCl_4): δ 1.57, 1.65, 1.67, 1.70 (s, 12H), 1.85—2.20 (bm, 8H), 4.62 (s, 2H), 4.90—5,14 (bm, 2H); MS *m/e* (%): 192 (M^+, 3), 177 (3), 136 (9), 121 (9), 81 (52), 69 (100); Found: C, 87.20; H, 12.82%. Calcd for $C_{14}H_{24}$: C, 87.42; H, 12.58%.

1-Phenyl-1,3-butadiene and 1-Tridecene: These compounds were identical with the authentic samples.[22,23]

Reaction of Dodecanal with the Reagent Prepared from CH_2Br_2–Zn–$TiCl_4$ System. Dodecanal (0.37 g, 2.0 mmol) was treated with the reagent prepared from dibromomethane (0.52 g, 3.0 mmol), zinc (0.59 g, 9.0 mmol), and titanium tetrachloride (2.2 ml of a 1.0 M dichloromethane solution, 2.2 ml) in THF (10 ml) at 25 °C. The crude product was submitted to preparative TLC (hexane–ether, 1: 1) on silica gel. The faster-moving band (R_f=0.79) provided the desired olefin, 1-tridecene (0.20 g, 55%). The slower-moving band (R_f=0.25) consisted of 12,13-tetracosanediol (89 mg) as a solid; mp 88 °C; IR (KBr): 3300, 2900, 1470, 1068, 708 cm^{-1}; NMR ($CDCl_3$): δ 0.89 (t, J=6 Hz, 6H), 1.10—1.52 (m, 40H), 3.30—3.60 (m, 2H); Found: C, 77.77; H, 13.82%. Calcd for $C_{24}H_{50}O_2$: C, 77.77; H, 13.60%. The compound was identical with the authentic sample.[13]

Reaction of Trimethyltin Chloride with the Reagent Derived from CH_2I_2–Zn–Me_3Al in THF. The reagent was prepared from diiodomethane (0.54 g, 2.0 mmol), zinc (0.39 g, 6.0 mmol), and trimethylaluminum (0.5 ml of a 1.0 M hexane solution, 0.5 mmol) in THF (10ml) as mentioned before. After stirring at 25 °C for 30 min, the mixture was allowed to stand for 20 min and the supernatant was transformed to an another flask. To this was added a THF solution of trimethyltin chloride (0.80 g, 4.0 mmol) at *ca.* 40 °C and the resulting mixture was stirred at the same temperature for 4 h. After a usual workup, the crude product was purified by column chromatography on silica gel (10 g) using hexane as an eluent (R_f=0.55 (hexane)). Successive distillation gave methylenebis (trimethylstannane) (0.18 g, 27%) as a colorless oily liquid; bp 63 °C (bath temp, 5 Torr); IR (neat): 1465, 1262, 1190, 1100, 1025, 955, 760, 600 cm^{-1}; NMR (CCl_4) δ 0.05 (Sn–CH_3, 18H, J_{Sn-H}=51 Hz), −0.29 (Sn–CH_2–Sn, 2H, J_{Sn-H}=55 Hz); MS *m/e* (%): 329 (56), 327 (67), 325 (M^+–CH_3, 64), 165 (100). Values of *m/e* are given for the isotope ^{118}Sn. The relative intensities of the peaks of the isotopic varieties of the ions correspond to the calculated values; Found: C, 24.63; H, 6.17%. Calcd for $C_7H_{20}Sn_2$: C, 24.61; H, 5.90; Sn, 69.49%. The compound was identical with the authentic sample.[8]

Preparation of α-Chloro α,β-Unsaturated Esters by Means of CCl_3COOMe–Zn–Et_2AlCl System. To a stirred suspension of zinc dust (0.39 g, 6.0 mmol) and diethylaluminum chloride (0.67 ml of a 1.5 M hexane solution, 1.0 mmol) in THF (10

ml) was added a THF solution of methyl trichloroacetate (0.43 g, 2.4 mmol) and carbonyl compound (2.0 mmol) at 0 °C over a period of 3 h. After stirring for an additional 1 h, the resulting mixture was diluted with ether (20 ml), poured into 1 M hydrochloric acid (20 ml), and extracted with ether. The separated organic layer was washed with brine (2×20 ml), dried over anhydrous sodium sulfate, and concentrated under reduced pressure. The crude product was purified by column chromatography (hexane–ether, 20: 1) on silica gel (20 g).

Methyl (Z)-2-Chloro-3-phenylpropenoate: Bp 87 °C (bath temp, 2 Torr); IR (neat): 2955, 1730, 1620, 1495, 1450, 1438, 1265, 1040, 765, 690 cm^{-1}; NMR (CCl_4): δ 3.83 (s, 3H), 7.20—7.90 (m, 6H); MS *m/e* (%): 198 (M^++2, 21), 196 (M^+, 62), 165 (22), 161 (73), 160 (24), 137 (35), 129 (52), 102 (100); Found C, 61.38; H, 4.69%. Calcd for $C_{10}H_9O_2Cl$: C, 61.08; H, 4.61%. (*E*)-Isomer was not detected by GLPC.

Methyl Chlorocyclohexylideneacetate: Bp 80 °C (bath temp, 3 Torr); IR (neat): 2950, 1725 ,1610, 1438, 1270, 1245, 1210, 1030, 760 cm^{-1}; NMR (CCl_4): δ 1.50—1.80 (m, 6H), 2.38—2.55 (bt, J=6 Hz, 2H), 2.55—2.75 (bt, J=6 Hz, 2H), 3.75 (s, 3H); MS *m/e* (%): 190 (M^++2, 32), 188 (M^+, 91), 157 (54), 156 (50), 134 (65), 121 (96), 93 (100), 91 (64); Found: C, 57.29; H, 7.32%. Calcd for $C_9H_{13}O_2Cl$: C, 57.30; H, 6.95%.

Methyl (E)- and (Z)-2-Chloro-3,7-dimethyl-2,6-octadienoate: GLPC (20% PEG 6000, 2 m, 150 °C) indicated two peaks, T_r=14.1 min ((*E*)-isomer, 28%), T_r=12.4 min ((*Z*)-isomer 72%). The analytically pure samples of both isomers were prepared by preparative GLPC (20% PEG 6000). (*E*)-Isomer: bp 70 °C (bath temp, 2 Torr); IR (neat): 2940, 1772, 1645, 1438, 1260, 1020, 760 cm^{-1}; NMR (CCl_4): δ 1.62 (s, 3H), 1.68 (s, 3H), 1.95—2.67 (m, 4H), 2.15 (s, 3H), 3.76 (s, 3H), 5.07 (bt, 1H); MS *m/e* (%): 218 (M^++2, 1), 216 (M^+, 3), 181 (9), 148 (14), 139 (9), 116 (10), 69 (100), 53 (10); Found: C, 61.24; H, 8.15%. Calcd for $C_{11}H_{17}O_2Cl$: C, 60.97; H, 7.91%. (*Z*)-Isomer: bp 72 °C (bath temp, 2 Torr); IR (neat): 2940, 1722, 1615, 1438, 1250, 1025, 775 cm^{-1}; NMR (CCl_4): δ 1.63 (s, 3H), 1.69 (s, 3H), 2.02 (s, 3H), 2.05—2.70 (m, 4H), 3.27 (s, 3H), 5.08 (bt, 1H); MS *m/e* (%): 216 (M^+, 1), 181 (12), 148 (13), 139 (7), 116 (10), 69 (100), 41 (51); Found: C, 60.93; H, 8.09%. Calcd for $C_{11}H_{17}O_2Cl$: C, 60.97; H, 7.91%.

Methyl (E)- and (Z)-2-Chloro-3-phenyl-2-butenoate: GLPC (10% PEG 20 M, 2 m, 140 °C) indicated two peaks, T_r=27.0 min ((*E*)-isomer, 9%), T_r=19.6 min ((*Z*)-isomer, 91%). The analytically pure samples of both isomers were prepared by preparative GLPC (30% PEG 20 M). (*E*)-Isomer: bp 85 °C (bath temp, 2 Torr); IR (neat): 2960, 1730, 1492, 1440, 1250, 1048, 760, 695 cm^{-1}; NMR (CCl_4): δ 2.39 (s, 3H), 3.80 (s, 3H), 7.00—7.40 (m, 5H); MS *m/e* (%): 212 (M^++2, 15), 210 (M^+, 44), 180 (24), 179 (30), 178 (56), 116 (19), 115 (100); Found: C, 63.01; H, 5.41%. Calcd for $C_{11}H_{11}O_2Cl$: C, 62.72; H, 5.26%. (*Z*)-Isomer: bp 87 °C (bath temp, 2 Torr); IR (neat): 2960, 1735, 1620, 1495, 1440, 1240, 1090, 695 cm^{-1}; NMR (CCl_4): δ 2.26 (s, 3H), 3.46 (s, 3H), 7.00—7.38 (m, 5H); MS *m/e* (%): 212 (M^++2, 13), 210 (M^+, 40), 180 (23), 179 (24), 178 (66), 116 (21), 115 (100); Found: C, 62.87; H, 5.36%. Calcd for $C_{11}H_{11}O_2Cl$: C, 62.72; H, 5.26%.

Preparation of α,β-Unsaturated Esters from Ketones by Means of Cl_2CHCOO^tBu–Zn–Et_2AlCl System. To a stirred suspension of zinc dust (0.59 g, 9.0 mmol) and diethylaluminum chloride (2.0 ml of a 1.5 M hexane solution, 3.0 mmol) in THF (10 ml) was added a THF solution of *t*-butyl dichloroacetate (0.56 g, 3.0 mmol) and ketone (2.0 mmol) at 25 °C over a period of 3 h. After stirring for additional 3 h, the resulting mixture was diluted with ether (10 ml), poured into 1 M hydrochloric acid (20 ml), and extracted with ether. The separated organic layer was washed with brine (2×20 ml), dried over anhydrous sodium sulfate and evaporated to remove solvent. The crude product was purified by column chromatography (hexane–ether, 20: 1) on silica gel (20 g) and distilled *in vacuo*.

t-Butyl (E)- and (Z)-3-Phenyl-2-butenoate: TLC (hexane–ether, 10: 1) showed two UV active bands, R_f=0.28 ((*E*)-isomer, 62%), R_f=0.42 ((*Z*)-isomer, 38%). (*E*)-Isomer: bp 61 °C (bath temp, 2 Torr); IR (neat): 2980, 1725, 1720, 1640, 1368, 1300, 1145, 960, 860 cm^{-1}; NMR (CCl_4): δ 1.20 (s, 9H), 2.12 (s, 3H), 5.72 (s, 1H), 7.05—7.40 (bm, 5H); MS *m/e* (%): 218 (M^+, 3), 162 (100), 161 (72), 145 (50), 144 (72), 117 (22), 116 (26), 115 (34), 57 (30): Found: C, 77.06; H, 8.44%. Calcd for $C_{14}H_{18}O_2$: C, 77.03; H, 8.31%. (*Z*)-Isomer: bp 60 °C (bath temp, 2 Torr); IR (neat): 2970, 1710, 1632, 1368, 1274, 1145, 870, 768 cm^{-1}; NMR (CCl_4): δ 1.48 (s, 9H), 2.50 (s, 3H), 5.96 (s, 1H), 7.20—7.50 (bm, 5H); MS *m/e* (%): 218 (M^+, 4), 162 (100), 161 (70), 145 (63), 144 (71), 117 (25), 116 (29), 115 (41), 57 (42); Found: C, 77.07; H, 8.54%. Calcd for $C_{14}H_{18}O_2$: C, 77.07, H, 8.31%.

t-Butyl Cyclododecylideneacetate: Bp 120 °C (bath temp, 1.5 Torr); IR (neat): 2980, 1712, 1640, 1470, 1364, 1240, 1130, 874, 708 cm^{-1}; NMR (CCl_4): δ 1.20—1.40 (bm, 18H), 1.43 (s, 9H), 2.13 (t, J=6 Hz, 2H), 2.62 (t, J=6 Hz, 2H), 5.53 (s, 1H); MS *m/e* (%): 224 ($M^+-(H_2C{=}CMe_2)$, 64), 207 (38), 164 (56), 100 (48), 57 (88), 55 (60), 41 (100); Found: C, 77.36; H, 11.77%. Calcd for $C_{18}H_{32}O_2$: C, 77.09; H, 11.50%.

t-Butyl (E)- and (Z)-3,7-Dimethyl-2,6-octadienoate: GLPC (10% PEG 20 M, 2 m, 120 °C) indicated two peaks, T_r=7.4 min ((*E*)-isomer, 59%), T_r=9.7 min ((*Z*)-isomer, 41%). The analytically pure samples of both isomers were prepared by preparative GLPC (30% PEG 20 M). (*E*)-Isomer: bp 65 °C (bath temp, 2 Torr); IR (neat): 2980, 1710, 1648, 1450, 1364, 1240, 1144, 852 cm^{-1}; NMR (CCl_4): δ 1.44 (s, 9H), 1.60 (s, 3H), 1.65 (s, 3H), 2.00—2.10 (bm, 7H), 5.10 (bt, 1H), 5.48 (s, 1H); MS *m/e* (%): 224 (M^+, trace), 168 ($M^+-(H_2C{=}CMe_2)$, 17), 151 (16), 123 (22), 100 (33), 69 (100), 57 (30); Found: C, 74.84; H, 10.97%. Calcd for $C_{14}H_{24}O_2$: C, 74.95; H, 10.78%. (*Z*)-Isomer: bp 67 °C (bath temp, 2 Torr); IR (neat): 2990, 1715, 1670, 1368, 1230, 1135, 865 cm^{-1}; NMR (CCl_4): δ 1.44 (s, 9H), 1.57 (s, 3H), 1.66 (s, 3H), 2.00—2.20 (bm, 7H), 5.02 (bt, 1H), 5.48 (s, 1H); MS *m/e* (%): 168 ($M^+-(H_2C{=}CMe_2)$, 20), 151 (16), 125 (9), 123 (24), 100 (44), 69 (100), 57 (40); Found: C, 74.96; H, 10.95%. Calcd for $C_{14}H_{24}O_2$: C, 74.95; H, 10.78%.

Preparation of α,β-Unsaturated Esters from Aldehydes by Means of $Br_2CHCOOEt$–Zn–Et_2AlCl System. To a stirred suspension of zinc dust (0.91 g, 14.0 mmol) and diethylaluminum chloride (2.0 ml of a 1.5 M hexane solution, 3.0 mmol) in THF (10 ml) was added a THF solution of ethyl dibromoacetate (0.98 g, 4.0 mmol) and aldehyde (2.0 mmol) at 25 °C over a period of 2 h. After stirring for an additional 1 h, the resulting mixture was diluted with ether (20 ml), poured into 1 M hydrochloric acid (20 ml), and extracted with ether. The separated organic layer was washed with brine (2×20 ml), dried over anhydrous sodium sulfate, and evaporated to remove solvent. The crude product was purified by column chromatography (hexane–ether, 20: 1) on silica gel (20 g).

Ethyl (E)-2-Tetradecenoate: Bp 115 °C (bath temp, 2 Torr); IR (neat): 2925, 1725, 1660, 1604, 1470, 1264, 1234, 1040, 975 cm^{-1}; NMR (CCl_4): δ 0.87 (t, J=6 Hz, 3H), 1.27 (bm, 23H), 2.03—2.33 (bt, 2H), 4.08 (q, J=6 Hz, 2H), 5.66 (d, J=16 Hz, 1H), 6.82 (dt, J=6, 16 Hz, 1H); MS *m/e* (%): 254 (M^+, 7), 209 (33), 166 (25), 127 (29), 101 (63), 55 (93), 43 (100);

Found: C, 75.67; H, 11.92%. Calcd for $C_{16}H_{30}O_2$: C, 75.54; H, 11.89%. The product was contaminated by <5% of the (*Z*)-isomer (by NMR).

The Electronic Spectra of Intramolecular Charge-transfer Compounds and Their Marked Solvatochromism in a Strong Hydrogen-bonding Solvent: 2-(Arylmethylene)-1,3-indandiones and 2-(1-Naphthyl)-*p*-benzoquinone

Kazuhiko CHIBA, Jun-ichi AIHARA,* Kotaro ARAYA, and Yoshio MATSUNAGA

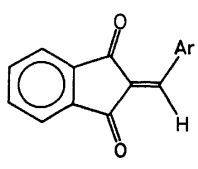
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received September 6, 1979)

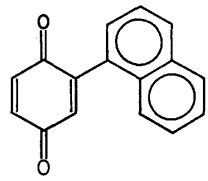
The first electronic absorption bands of the title compounds can all be assigned to the intramolecular charge-transfer transitions. The solvent effects on these bands are quite analogous to those on the absorption bands characteristic of binary charge-transfer complexes. Especially, when the title compounds are dissolved in trifluoroacetic acid, marked bathochromic shifts of the first bands are observed, in harmony with their charge-transfer character. Such solvatochromism is obviously due to the hydrogen-bond formation between the solute and the solvent molecules. When strong hydrogen bonding occurs, the electron affinity of the 2-methylene-1,3-indandione moiety increases by about 0.41 eV.

Very many papers have so far been published concerning binary charge-transfer (CT) complexes in the solution phase.[1] The physical and chemical properties of these complexes have thus been clarified widely. However, our understanding of intramolecular CT compounds in solution is still far from satisfactory.[2–4] Here, an intramolecular CT compound is an organic compound in which an electron-attracting group with a large electron affinity is attached to an electron-donor molecule, forming a single conjugated system as one whole.[3] This kind of compound has the following two characteristics. First, as in the case of binary CT complexes, the first electronic absorption bands are mostly related to the charge-transfer, each within a single conjugated system. Second, such compounds are structurally much less flexible in solution than binary CT complexes. This might make the analysis of the electronic spectra much less ambiguous than that of binary CT complexes. It is noteworthy that some aspects of the solution spectra of binary CT complexes remain elusive.[5] This is primarily due to the fact that the general response of a CT transition to a solvent is inconsistent with the dielectric theory of solute-solvent interactions.[6] In this context, we can fully expect that some intramolecular CT compounds might be useful in exploring further the intrinsic features of CT-type transitions.

In this paper, we would like to present the first systematic survey of the electronic transitions typical of the intramolecular CT compounds. The first absorption bands of 2-(arylmethylene)-1,3-indandiones (**A**) and 2-(1-naphthyl)-*p*-benzoquinone (**B**) will be examined below in conjunction with the solvent effects on binary CT complexes.



A



B

Experimental

The 2-(arylmethylene)-1,3-indandiones listed in Table 1 and 2-(1-naphthyl)-*p*-benzoquinone were prepared and purified according to the procedures found in the literature.[7,8] In each of them, a ring system with two carbonyl groups bonds a benzenoid compound. The absorption spectra of these compounds were measured using a Beckman DK-2A spectrophotometer. All the solvents were of a guaranteed grade and were used without further purification.

Intramolecular CT Character of the First Absorption Bands

An intramolecular CT transition is defined as an electronic transition from an occupied molecular orbital localized in a part of a conjugated system to an unoccupied molecular orbital localized in the other part of the same conjugated system.[2–4] All the 2-(arylmethylene)-1,3-indandiones (**A1—7**) and 2-(1-naphthyl)-*p*-benzoquinone (**B**) exhibit intramolecular CT bands isolated on the low-energy side of the electronic absorption spectra. The intramolecular CT character of the first absorption bands was verified as follows.

First, the molecular orbital (MO) calculations provide theoretical evidence for it. The Pariser-Parr-Pople MO calculations carried out by Meyer[9] and by us[10] indicate that, for all compounds investigated, the highest occupied molecular orbital (HOMO) is localized mainly at the benzenoid ring, whereas the lowest unoccupied molecular orbital (LUMO) is localized mainly at the 2-methylene-1,3-indandione (or *p*-benzoquinone) ring. Accordingly, the benzenoid ring can be considered as a good electron donor, as usual, and the methyleneindandione (or *p*-benzoquinone) ring as a good electron acceptor. Meyer has already assigned the first absorption band of 2-benzylidene-1,3-indandione to the lowest intramolecular CT transition.[9] The situation is exactly the same for the other compounds.

The MO calculations show that a geometrical HOMO-LUMO separation depends straightforwardly upon the dihedral angle between a benzenoid donor ring and an acceptor ring.[10] For most of the compounds

Table 1. Intramolecular CT absorption bands of 2-(arylmethylene)-1,3-indandiones in chloroform

Aryl group (Ar)	$h\nu_{ICT}$ / 10^3 cm^{-1}	ε[a]	I_p[b]/eV
Phenyl (**A1**)	29.09	33400	9.24[c]
Styryl (**A2**)	25.95	45100	8.60[d]
1-Naphthyl (**A3**)	24.81	17600	8.12[c]
2-Naphthyl (**A4**)	27.35	29100	8.12[c]
p-Dimethylaminophenyl (**A5**)	20.78	86400	7.51[e]
1-Pyrenyl (**A6**)	20.51	43700	7.41[f]
9-Anthryl (**A7**)	20.25	10700	7.40[c]

a) Extinction coefficient. b) Vertical ionization potential. c) Ref. 12. d) R. A. W. Johnstone and F. A. Mellon, *J. Chem. Soc., Faraday Trans. 2*, **69**, 1155 (1973). e) Ref. 13. f) Ref. 14.

in Table 1, it is not possible to take a planar configuration because of serious steric hindrance. This structural feature is quite favorable to the HOMO-LUMO separation, thus improving the intramolecular CT character of the first absorption band. Especially, a large dihedral angle between the two parts of 2-(9-anthrylmethylene)-1,3-indandione (**A7**) can be inferred from the small extinction coefficient of the first absorption band.

In a simplified MO treatment,[11] the overlap integral between two bonded $2p_z$ orbitals which belong to different chromophores is found to be proportional to $\cos\Theta$, where Θ is the dihedral angle between them, and the absorption intensity may be expected to be proportional to $\cos^2\Theta$. The extinction coefficient of the first band of **A7** is about one-eighth that of 2-(*p*-dimethylaminobenzylidene)-1,3-indandione (**A5**) and about one-fourth that of 2-(1-pyrenylmethylene)-1,3-indandione (**A6**). We may assume that the donor ability is almost the same for these three compounds, since the ionization potentials of the isolated donors (*i.e.*, anthracene, *N,N*-dimethylaniline, and pyrene) are nearly equal to each other.[12-14] Therefore, if we assume **A5** and/or **A6** to be planar in shape, the dihedral angle in **A7** must be at least 60°. This angle can be justified by inspecting a molecular model of this compound.

Next, the good acceptor ability of a methyleneindandione ring is supported by the crystal structure of **A5**.[15] The methyleneindandione ring of each molecule is therein in close contact with the *p*-dimethylaminophenyl ring of its adjacent molecule, the two forming a CT-type self-complex. Since the donor part has a good electron-donating character, such a self-complex formation in the solid phase witnesses the good acceptor ability of the methyleneindandione ring.[2,4,16] The electron affinity of *p*-benzoquinone is 1.89 eV;[17] it is also a good electron acceptor, even if it becomes a part of a larger conjugated system, as in the case of 2-(1-naphthyl)-*p*-benzoquinone. The intramolecular CT character of the first absorption bands of several 2-aryl-*p*-benzoquinones has previously been confirmed experimentally.[4,16]

Finally, the most conclusive proof of the intramolecular CT character is obtained by plotting the electronic absorption maximum against the ionization potential of the donor part for **A1—7**. In general, a CT transition energy is linearly related to an ionization potential of the donor molecule if the acceptor molecule is common to all the CT complexes concerned.[18,19] In the case of intramolecular CT compounds with common acceptor parts, an intramolecular CT transition energy, $h\nu_{ICT}$, may analogously be expressed as:

$$h\nu_{ICT} = a_1 I_p - b_1, \quad (1)$$

where a_1 and b_1 are constants characteristic of the acceptor part and where I_P is, of course, an ionization potential of the donor part, *e.g.*, an ionization potential of anthracene in the case of **A7**.

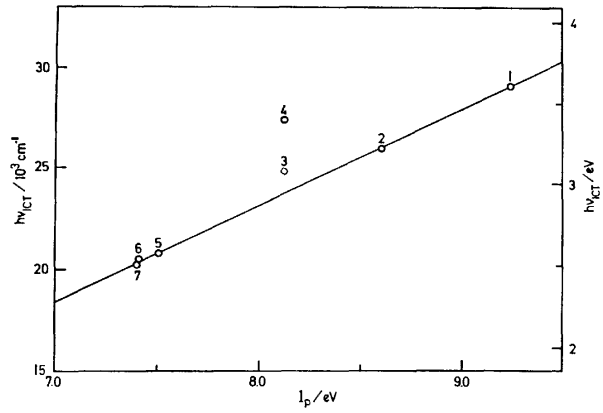


Fig. 1. Correlation of the intramolecular CT absorption maxima with the donor ionization potentials: 1, **A1**; 2, **A2**; 3, **A3**; 4, **A4**; 5, **A5**; 6, **A6**; **7**, **A7**.

As is shown in Fig. 1, this relationship was found to hold well for most 2-(arylmethylene)-1,3-indandiones dissolved in chloroform. The two exceptions are the 1- and 2-naphthylmethylene derivatives (**A3** and **A4**). For the other compounds, a_1=0.592 and b_1=1.840 when $h\nu_{ICT}$ and I_P are given in units of eV. Although the absorption maxima of the two exceptional compounds deviate upward from Eq. 1, there are clear absorption shoulders near the energy predicted by this relationship. They are located at 23500 cm^{-1} for **A3** and at 25000 cm^{-1} for **A4**. There may be some structural factor in these intramolecular CT compounds which causes a marked change in the Franck-Condon envelope. The appearance of such a vibrational structure is not unusual when an intramolecular CT compound is dissolved in a relatively inert solvent.[4] Accordingly, we can safely say that Eq. 1 is valid for all 2-(arylmethylene)-1,3-indandiones. It is, then, quite natural to attribute the first absorption band of every compound in Table 1 to an intramolecular CT transition between HOMO and LUMO. For binary CT complexes in solution, the a_1 value lie in the 0.83—0.97 range,[1] a little larger than that for the intramolecular CT bands considered above. According to Flurry's MO description of CT transitions,[19] the a_1=0.592 value indicates that 1.592 of the two frontier electrons reside in the donor ring in the ground state. Consequently, these intramolecular CT compounds can really be regarded as undissociable CT complexes.

Solvatochromism Caused by a Strong Hydrogen-Bonding Solvent

If a given electronic absorption band is of the CT type, its solvent dependence might be similar to that of binary CT complexes.[5] In order to examine this possibility, the first absorption maxima of **A7** in various solvents were plotted against the dielectric constants of the solvents[20] (*cf.* Fig. 2). In general, *n*-donor solvents,

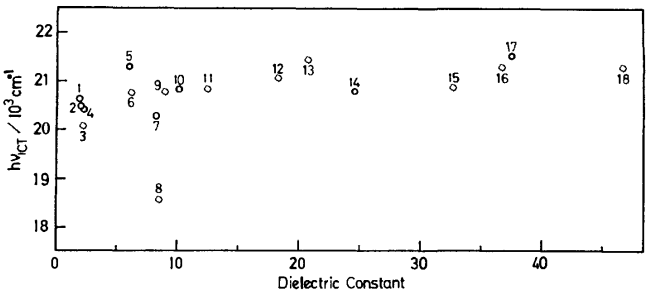

Fig. 2. The first absorption maximum of **A7** as a function of solvent dieletric constant: 1, hexane; 2, cyclohexane; 3, carbon tetrachloride; 4, benzene; 5, ethyl acetate; 6, acetic acid; 7, 1,2,2,2-tetrachloroethane; 8, trifluoroacetic acid; 9, dichloromethane; 10, 1,2-dichloroethane; 11, pyridine; 12, cyclohexanone;13, acetone; 14, ethanol; 15, methanol; 16, *N*,*N*-dimethylformamide; 17, acetonitrile; 18 dimethyl sulfoxide.

such as ketones, alcohols, and nitriles, shifted the intramolecular CT band to the higher-energy side. This spectral aspect is quite consistent with that of binary CT complexes,[1] but is evidently contrary to the prediction of the dielectric theory of solute-solvent interactions.[6] Such a response to solvents further supports the CT character of the electronic transition concerned.

When the intramolecular CT compounds were dissolved in trifluoroacetic acid (TFAA), an unusually large bathochromic shift of the first absorption band occurred. In 1975, Sep *et al.* observed very large bathochromic shifts of the CT bands when anthracene complexes with typical acceptors were dissolved in TFAA.[21] The same effect can be seen in Fig. 2, where TFAA (8) marks a singular point, as in the case of binary CT complexes.[21] In order to analyze such bathochromism induced by TFAA, we used dichloromethane (DCM) as the reference solvent. The dielectric properties of these two solvents are quite similar to each other.[20] The dielectric constants are 8.55 for TFAA and 8.93 for DCM. The refractive indexes are 1.285 for TFAA and 1.421 for DCM. This pair of solvents, therefore, lend themselves to the study of specific solvation effects.

It is noteworthy that, for the compounds investigated, the energy difference between the first absorption bands of the DCM and the TFAA solution amounts to 1270—2400 cm^{-1}. By the way, the second absorption band of **A7** is a local-excitation band, in the sense that the molecule is excited locally at the anthracene ring.[10] The 0–0 vibrational component of this band is located at 26400 cm^{-1}, while that of the first band of anthracene is located at 26400 cm^{-1}, too, both in DCM. The vibrational spacing of the former band is about 1380 cm^{-1}, which is comparable to that of the latter band (1415 cm^{-1}). In contrast to the first band of **A7**, the TFAA-to-DCM shift of the second band (*i.e.*, the local-excitation band) is about 200 cm^{-1}, about one-tenth that of the first intramolecular CT band. The TFAA-to-DCM solvent shift of the intramolecular CT band is thus an order of magnitude larger than that of an allowed excitation band localized in a nonpolar conjugated hydrocarbon ring.

Such an anomalous bathochromic shift of the intramolecular CT band begins to occur when only a drop of TFAA is added to a few ml of the DCM solution. When the amount of TFAA reaches a certain mol %, the TFAA effect on the absorption spectrum becomes substantially saturated. After that, the absorption peak remains almost unmoved. In other words, the curve of a peak position versus the solvent composition is linear, with essentially no slope, as long as the concen-

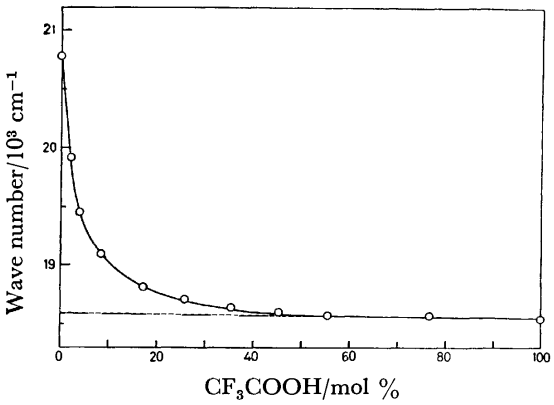

Fig. 4. The intramolecular CT absorption maximum as a function of solvent composition of the CH_2Cl_2–CF_3COOH–**A7** system.

tration of TFAA is sufficiently high. Figures 3 and 4 illustrate this situation. Let the linear portion in the curve be extrapolated to the 100% pure DCM solution, and we can, in principle, estimate the peak position of the TFAA solution which would be exhibited if TFAA had exactly the same dielectric properties as DCM. The slope of this linear portion, if any, might be interpreted as due to a slight difference in dielectric properties between TFAA and DCM.

Accordingly, an extrapolated point in the energy scale, $h\nu_0$, can be taken as the reference energy in evaluating the degree of specific solvatochromism caused by TFAA. A net bathochromic shift not due to the dielectric properties of TFAA can, then, be expressed as:

$$\Delta h\nu_{ICT} = h\nu_{ICT} - h\nu_0. \quad (2)$$

Here, $h\nu_{ICT}$ indicates the energy of the first absorption maximum of the TFAA solution. The numerical values concerning Eq. 2 are all listed in Table 2. As for this expression, one exceptional compound may be 2-(1-naphthyl)-*p*-benzoquinone, for which there is little linear portion in the band-peak *versus* solvent-composition curve. In this case, the tangent at the 100% pure TFAA solution was extrapolated to the other end of the solvent composition. Fortunately, the tangent had no inclination.

Table 2. Bathochromic shifts of intramolecular CT bands of 2-(arylmethylene)-1,3-indandiones and 2-(1-naphthyl)-*p*-benzoquinone in trifluoroacetic acid

Compd[a]	$h\nu_{ICT}/10^3$ cm^{-1}		$\Delta h\nu_{ICT}$	ΔE_a
	CH_2Cl_2	CF_3COOH[b]	10^3 cm^{-1}	eV
A1	29.15	27.88(27.88)	1.27	0.27
A2	26.02	24.13(24.13)	1.89	0.40
A3	25.00	22.60(22.60)	2.40	0.50
A4	27.83	25.88(25.88)	1.95	0.41
A6	20.92	19.01(19.01)	1.91	0.40
A7	20.78	18.54(18.59)	2.19	0.46
B	23.22	19.80(19.80)	3.42	—

a) See Table 1 for abbreviations. b) Values for $h\nu_0$ are given in parentheses.

As may be seen from Table 2, $\Delta h\nu_{ICT}$ is almost the same as the energy difference between the first absorption bands of the DCM and the TFAA solution. The value of $\Delta h\nu_{ICT}$ stays in the 1270—2400 cm^{-1} range for 2-(arylmethylene)-1,3-indandiones and is somewhat larger for 2-(1-naphthyl)-*p*-benzoquinone.
