Research Institute of Applied Electricity, Hokkaido University, Sapporo 060

(Received July 2, 1979)

An ultrasonic method for determining the difference in hard-sphere volume of conformational isomers from sound velocity has been worked out, its accuracy being improved by taking the temperature dependence of the effective hard-sphere diameter into account. The difference for 1,2-dibromoethane, 1,1,2-trichloroethane, methylcyclohexane, and 1,2-dichloroethane was determined. The fractions of volume differences $\Delta V/V$ in these liquids were found to be 4.5, 5, 11, and 19% for 1,2-dibromo-, 1,1,2-trichloroethane, methylcyclohexane, and 1,2-dichloroethane, respectively.

Determination of the effective hard-sphere volume of molecules in liquids is of interest from theoretical and practical points of view.[1] In most studies on conformational isomerism, *e.g.*, halogenated ethanes and cyclohexane derivatives,[2-6] the effect of difference in hard-sphere volume of conformers has been assumed to be negligibly small. Recently, questions with respect to this assumption have been raised.[1,7] The lack of a good experimental method is the main reason for the volume difference not being considered in these studies. Wyn-Jones *et al.*[7] adopted the ultrasonic absorption method, but its merit was restricted.

In the preceding paper,[1] we proposed for 1,2-dichloroethane (DCE) a method for determining the volume difference from sound velocity based on the recent development of the theory of solutions.[8] However, DCE is a special example: For the determination of ΔV it is necessary to know the magnitude of the hard-sphere volume for one of the two conformers from other sources. This is ascribed to the following property of the sample: The energy difference between the two isomers is zero in its liquid state,[2,4] the population ratio of the two conformers remaining unchanged with varying temperature. Further, the effect of relaxational processes was not taken into consideration.

We have improved the method and applied it to cases in which the energy difference between conformers is not zero, enhancing the accuracy by taking the temperature dependence of the effective hard-sphere diameter[9] into account. 1,2-dibromoethane (DBE), 1,1,2-trichloroethane (TCE), cyclohexane (CH), and methylcyclohexane (MeCH) were investigated. It was found that the method is useful for determining the difference in hard-sphere volume of conformers.

Method of Analysis

Formula for Isothermal Compressibility Derived from the Lebowitz Equation of Binary Mixtures.[1] An equilibrium mixture of conformational isomers is considered to be a hard-sphere mixture with two components. We obtained a formula for isothermal compressibility of the equilibrium mixture by means of the Lebowitz equation. The outline of the theoretical procedure is given here, the details being reported.[1] An analytical solution of the Percus-Yevick equation for binary hard-sphere mixtures[8] is

$$\frac{p}{kT}=\frac{1}{(1-\xi)^3}\left[(\rho_1+\rho_2)(1+\xi+\xi^2)-\frac{18}{\pi}\eta_1\eta_2(R_1-R_2)^2\times\{R_1+R_2+R_1R_2(\eta_1R_1^2+\eta_2R_2^2)\}\right],$$

$$\xi=\frac{\pi}{6}(\rho_1R_1^3+\rho_2R_2^3), \tag{1}$$

where p is pressure, k Boltzmann constant, T temperature, ξ packing fraction, $\rho_i=N_i/V$ number density, $\eta_i=\pi\rho_i/6$, and R_i hard-sphere diameter of the i-th component. Let us express R_i by

$$R_1=R_0,\quad R_2=R_0(1+\delta), \tag{2}$$

considering that δ is smaller than 0.1.[1]

The isothermal compressibility $\kappa_T=-(1/V)(\partial V/\partial p)_T$ is derived from Eq. 1 as

$$\kappa_{T,0}=\frac{V(1-\xi)^4}{RT(1+2\xi)^2}\left[1-\frac{\pi x_1x_2R_0^3\rho\delta^2}{2(1+2\xi)^2}\left\{4+2\xi+\frac{\pi}{2}R_0^3\rho+\delta(2+\xi+\frac{\pi}{2}R_0^3\rho(1+2x_2))+\delta^2\frac{3\pi}{2}R_0^3\rho x_2+\delta^3\frac{\pi}{2}R_0^3\rho x_2\right\}\right]^{-1}, \tag{3}$$

where suffix 0 indicates κ_T for fluids consisting of hard-sphere molecules, R gas constant, V molar volume, and x_i mole fraction of the i-th component. The second term in square brackets is smaller than 0.01.[1] Equation 3 can thus be approximated by

$$\kappa_{T,0}=\frac{V(1-\xi)^4}{RT(1+2\xi)^2}, \tag{4}$$

where ξ is the fraction of hard-sphere volumes of all molecules to molar volume of the liquid and is expressed by

$$\xi=\frac{\pi\rho(N_1R_1^3+N_2R_2^3)}{6N_A}=\frac{\rho(N_1v_1+N_2v_2)}{N_A}=\frac{\pi}{6}a^3\rho=\rho v_a,$$

$$\frac{N_1R_1^3+N_2R_2^3}{N_A}=a^3. \tag{5}$$

Here N_i is number of the i-th component, N_A Avogadro number, $\rho=N_A/V$, $v_i=\pi R_i^3/6$ hard-sphere volume of the i-th component, $v_a=\pi a^3/6$ average hard-sphere volume, and a the "average hard-sphere diameter."

For the usual fluids, it is necessary to take the effect of attractive forces into consideration. κ_T is expressed in this case by[1]

$$\kappa_T=\left[\frac{RT(1+2\xi)^2}{V(1-\xi)^4}-\frac{2}{V}(\Delta H_v-RT)\right]^{-1}, \tag{6}$$

where ΔH_v is enthalpy of vaporization.

Determination of Average Hard-Sphere Volume and Volume, Difference between Conformers. From adiabatic compressibility κ_S determined from sound velocity and density data, we obtain

$$\kappa_T = \kappa_S + \frac{TV\alpha^2}{C_p}, \quad \kappa_S = \frac{1}{dv^2}, \tag{7}$$

where α is thermal expansion coefficient of the liquid, C_p molar heat capacity at constant pressure, d density, and v sound velocity. When the values of T, V, κ_T, and ΔH_v are substituted into Eq. 6, the value of ξ and subsequently the average hard-sphere volume can be evaluated.

The values of V and N_i in Eq. 5 vary with temperature. The population ratio of two conformational isomers, N_2/N_1, is given by

$$\frac{N_2}{N_1} = \exp(-\Delta G/RT) = A\exp(-\Delta H/RT), \tag{8}$$

where ΔG is free energy difference between conformers, ΔH enthalpy difference, and A constant. Thus, if we know ξ from sound velocity data at various temperatures, we can estimate the hard-sphere volumes of each conformer, combining the temperature dependence of N_2/N_1 with that of ξ.

The total compressibility for an equilibrium system is given by

$$\kappa_T = \kappa_{T,\infty} + \kappa_{T,r}, \tag{9}$$

where $\kappa_{T,\infty}$ is an instantaneous part and $\kappa_{T,r}$ a relaxational one.[6,10] According to the magnitude of ultrasonic relaxation frequency f_r, the procedure for determination of average hard-sphere volumes can be classified into: (a) for CH and MeCH[6,11,12] in which f_r is much smaller than the frequency f used for the measurement of sound velocity, and (b) for DCE, DBE, and TCE.[6,7,13,14]

When $f \gg f_r$, the contribution of $\kappa_{T,r}$ to κ_T can be ignored and Eq. 9 is reduced to

$$\kappa_T = \kappa_{T,\infty}. \tag{10}$$

Substituting the value of κ_T into Eq. 6, we can determine the magnitude of ξ. In Eq. 5, the value of the average hard-sphere volume is related to hard-sphere volumes of components v_1 and v_2, and also to the population ratio of isomers. The temperature dependence of the average hard-sphere volume is chiefly ascribed to the temperature dependence of the population ratio, and the molar volume difference ΔV can be evaluated from Eqs. 5 and 8, where

$$\frac{\Delta V}{V} = \frac{N_A}{\xi V}(v_2 - v_1) = \frac{v_2 - v_1}{v_a}. \tag{11}$$

When $f \ll f_r$, the contribution of $\kappa_{T,r}$ to κ_T should be considered. According to Hall,[15] $\kappa_{T,r}$ is given by

$$\kappa_{T,r} = \frac{V(\Delta V/V)^2}{2RT\{1+\cosh(\Delta G/RT)\}}, \tag{12}$$

where ΔV is identical with that defined by Eq. 11.[16] Substituting the right hand sides of Eqs. 6 and 12 into Eq. 9, the following expression of κ_T is obtained.

$$\kappa_T = \left[\frac{RT(1+2\xi)^2}{V(1-\xi)^4} - \frac{2}{V}(\Delta H_v - RT)\right]^{-1} + \frac{V(\Delta V/V)^2}{2RT\{1+\cosh(\Delta G/RT)\}}. \tag{13}$$

The procedure for determining hard-sphere volumes of isomers starting from Eq. 13 is the same as in the preceding case.

Temperature Dependence of the Effective Hard-Sphere Volume. For the determination of hard-sphere volumes for conformers described above, the temperature dependence of the average hard-sphere volume is attributed to that of the population ratio only. However, we should consider also the contribution from the temperature dependence of the effective diameter of hard-sphere.[9,17-19]

According to the perturbation theory of fluid by Barker and Henderson, the "softness" of the hard core of a molecule is taken into consideration[9] and the effective hard-sphere diameter becomes

$$a_t = \int_0^\sigma [1-\exp\{-u(r)/kT\}]dr, \tag{14}$$

where $u(r)$ is an intermolecular pair potential and $u(\sigma)=0$. The temperature coefficient of a_t, l, becomes

$$l = \frac{1}{a_t}\frac{da_t}{dT} = -\frac{\int_0^\sigma \frac{u(r)}{kT^2}\exp\{-u(r)/kT\}dr}{\int_0^\sigma [1-\exp\{-u(r)/kT\}]dr}. \tag{15}$$

The Lennard-Jones (6—12) potential is chosen as $u(r)$, and $l(l<0)$ is computed numerically. Thus the effective hard-sphere volume at temperature T is expressed by

$$v_T = v_0(1+\alpha_t\Delta T) \text{ and } \alpha_t = 3l, \tag{16}$$

where v_0 is the value at T_0 as reference temperature and ΔT the deviation from T_0.

Experimental

Sound velocity was measured with an interferometer working at 3 MHz[20] and density with a pycnometer. Measurements were carried out at temperatures in the range 15—45 °C, the temperature being controlled within ±0.05 °C. Samples were carefully purified before measurements. The accuracy of v is ±0.3 m/s. Values of d and v compared with other data[21] at 20 °C are given in Table 1.

Results

Values of d, v, κ_S, and κ_T determined in the present experiment for DBE, TCE, CH, and MeCH are summarized in Table 2. Values of thermodynamic quantities required for the determination of κ_T and v_a, C_p, α, and ΔH_v are summarized in Table 3, together with energy difference ΔH between conformers for these liquids.

In the case of CH, only the chair form exists at room temperature since the energy difference is as large as 22 kJ/mol.[3] It can be regarded as one component system in the temperature range of the present study.

The temperature coefficient of the effective hard-sphere diameter was calculated by Eq. 15 and is plotted against ε/k at 25 °C in Fig. 1 (ε: an energy parameter in $u(r)=4\varepsilon[(\sigma/r)^{12}-(\sigma/r)^6]$). The curve is useful for

practical purposes. The variation of T from 0 to 100 °C shows a very slight difference in l, and l can be regarded as practically independent of the variation of T in the range 15—45 °C. The values of ε/k used for the estimation of l are 330, 430, 400, 330, and 330 K for DCE, DBE, TCE, CH, and MeCH,[22-24] respectively. When ε/k is larger than 300 K, the variation of l is small. The temperature dependence of the effective hard-sphere volume was estimated by using Eq. 16 (T_0: 25 °C) with the value of l given in Fig. 1.

The magnitudes of v_a, v_i, and $\Delta V/V$ for MeCH ($f \gg f_r \simeq 100$ kHz[6,11,12]) were determined by means of Eqs. 5, 6, 8, and 11. For DBE ($f \ll f_r$) and TCE ($f < f_r \simeq 16$ MHz at 25 °C[6,7]), those of v_a, v_i, and $\Delta V/V$ were determined by means of Eqs. 5, 8, 11, and 13. In the case of DCE[25] ($f \ll f_r$), the values of v_a and $\Delta V/V$ were calculated by means of Eqs. 5, 11, and 13 and the reported data.[1] For CH which is regarded as one component system, the average hard-sphere volume v_a was determined by the use of Eqs. 5 and 6. The results

for v_a and $\Delta V/V$ thus obtained are summarized in Table 4.

Discussion

Examination of the Former Results Obtained by the Ultrasonic Absorption Method. In studies on conformational isomerism by means of the ultrasonic absorption method, it has been assumed so far that $(\Delta V/V)(C_p/\Delta H\alpha) \ll 1$,[6] and the effect of ΔV is negligible. However, we realized that there is no satisfactory evidence for the assumption, leading to an examination of the assumption. Wyn-Jones *et al.*[7] suggested that the assumption is not suitable when the value of $\Delta V/V$ is of the order of 0.1% or larger. For DBE, TCE, and MeCH, the magnitudes of $(\Delta V/V)(C_p/\Delta H\alpha)$ are estimated to be 2.0, 6.5, and 2.5, respectively, by using the data in Tables 3 and 4, indicating that the assumption is inadequate. For DCE, the value of ΔH in liquid state is zero;[2,4] the assumption does not hold.

According to Wyn-Jones *et al.*, the values of $\Delta V/V$ in conformational isomerism are *ca.* 1—3% for TCE in various solvents, and surmised to be 6% for pure liquid of TCE, the error of the estimation of ΔV being *ca.* 50%.[7] In the present study, the error might be small (<20%) as compared with that of the ultrasonic absorption method.

Consideration on the Magnitudes of v_1 *and* ΔV. All the values of $\Delta V/V$ are negative (Table 4). The value of v_1 for a stable isomer is larger than that of v_2 for another isomer. v_1 corresponds to the *anti*-form for DCE, DBE, and TCE, and to the equatorial form for MeCH.

The value of $\Delta V/V$ for DCE is found to be larger than that for DBE. This is reasonable, according to the suggestion by Findenegg *et al.*[26] based on the cell theory. For TCE, it is 5% in the present study, 6% by means of the ultrasonic absorption method of Wyn-Jones *et al.*,[7] and 4% from the pressure effect of infrared spectroscopy reported by Christian *et al.*[27]

For MeCH, the value of $\Delta V/V$ becomes 11% and the hard-sphere volume for the equatorial form is larger than that for the axial one. No data for MeCH directly correlated with our present result has been reported so far. It was suggested from density data[7,11] of similar substances that the volume of the equatorial form is larger than that of the axial one. For instance, *cis*-1,3-dimethylcyclohexane has two equatorial methyl groups in its chair form and *trans*-stereoisomer has an equatorial group together with an axial methyl group. The difference in density between the *trans*- and *cis*-stereoisomers is supposed to correspond to the volume difference between the axial and the equatorial form of conformational isomers for MeCH. The volume difference between stereoisomers for 1,3-dimethylcyclohexane is estimated to be 2.2%.[7] Though the volume difference between separable stereoisomers is not the same as that between conformational isomers, it is certain that the volume of the equatorial form is larger than that of the axial one. Our present result for MeCH confirms this.[27]

Polymerization of Silicic Acid Adsorbed on Iron(III) Hydroxide

Takushi YOKOYAMA, Tatsuo NAKAZATO,** and Toshikazu TARUTANI*

Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812

(Received July 9, 1979)

Adsorption of silicic acid on iron(III) hydroxide from aqueous solution and polymerization of adsorbed silicic acid were affected by pH, concentration of silicic acid before and after adsorption, or the relative amount of silicic acid and iron(III) hydroxide. The amount of adsorbed silicic acid and the rate of its polymerization were maximum at pH 9. The polymerization reaction of silicic acid on the surface of iron(III) hydroxide was found to consist of two steps: (1) polymerization of adsorbed monosilicic acid and (2) polymerization between monosilicic acid in the solution and silicic acid species already present on the surface of iron(III) hydroxide, giving a three-dimensional gel structure.

Iron(III) hydroxide removes silicic acid from a solution in a high amount by adsorption or coprecipitation reaction. Kato[1] reported that dissolved silica is controlled by the oxidation-reduction cycle of iron and manganese in lake water. Ferruginous sinters deposited from hot spring waters contain a large amount of silica. However, few reports have been published with respect to the behavior of silicic acid adsorbed on or coprecipitated with iron(III) hydroxide.

Harder and Flehmig[2] found the formation of quartz in iron(III) hydroxide-silica-precipitates. Kojima and Tarutani[3] reported that monosilicic acid adsorbed on iron(III) hydroxide polymerizes in a short period of time. Herbillon and Vinh An[4] studied precipitates formed by the addition of iron(III) and iron(II) chloride solutions to sodium silicate solutions. Their results indicate that Si is incorporated into the precipitate by two distinct processes. When SiO_2/Fe_2O_3 mole ratio (MR) was less than 0.1, Si was chemisorbed. In the range MR$>$0.1, silica polymerized as a separate phase.

In this work, factors controlling the amount of silicic acid adsorbed on iron(III) hydroxide and the polymerization of adsorbed silicic acid were studied. The term "monosilicic acid" refers to the total sum of monosilicic acid, H_4SiO_4, and its conjugate base, $H_3SiO_4^-$, the term "polysilicic acid" refers to dimer and larger polymer species.

Experimental

Samples and Reagents. All the reagents were of analytical reagent grade. A stock solution of monosilicic acid was prepared by dissolving silica gel (Mallinckrodt Chemical Works) in sodium hydroxide solution. Monosilicic acid solution of desired concentration was prepared by diluting stock solution.

Iron(III) hydroxide was precipitated by adding sodium hydroxide solution to iron(III) chloride solution and then washed with distilled water. Iron(III) hydroxide was prepared immediately before each experiment.

Procedure. Monosilicic acid solution (500 ml) of an appropriate concentration was adjusted to the desired pH with hydrochloric acid or sodium hydroxide solution. A known amount of iron(III) hydroxide was then introduced into the solution and the pH of the solution was readjusted. The suspension was stirred vigorously with a magnetic stirrer. The variation of pH of the suspension was maintained in the range of $\pm$0.1 pH by adding hydrochloric acid or sodium hydroxide solution. Adsorption experiments were carried out in a thermostated bath at 25 °C. After 5 h, an aliquot of suspension was pipetted and filtered through a membrane filter having pores of 0.1 μm. The concentration of monosilicic acid in the filtrate was determined by colorimetry. The iron(III) hydroxide on the membrane filter was dissolved with 1 mol dm^{-3} hydrochloric acid, the resulting solution being filtered and diluted to 50 ml with distilled water (solution A). After iron(III) ion in an aliquot of the solution A had been removed by treating with cation exchange resin, the amount of monosilicic acid was determined by colorimetry and the total silicic acid was determined after decomposition of polysilicic acid with alkali. Silica larger than 0.1 μm remaining on the filter was determined by colorimetry after the filter had been ashed and the silica was fused with sodium carbonate. Iron(III) ion concentration in solution A was determined by colorimetry.

The size distribution of polysilicic acids formed on the surface of iron(III) hydroxide was determined by gel chromatography. After iron(III) ion in solution A had been eliminated by treating with cation exchange resin, the pH of the solution was adjusted to 2 and silicic acid was chromatographed on an 1$\times$60 cm column of Sephadex G-25 according to the procedure of Shimada and Tarutani.[5] After the effluent had been collected with a fraction collector, the amounts of silicic acid in the fractions were measured by colorimetry after decomposition of polysilicic acid with alkali.

The following symbols are used. Si/Fe(MR): the mole ratio of monosilicic acid and iron(III) hydroxide in the initial solution, Si(M): the amount of monosilicic acid in solution A, Si($<$0.1): the total amount of silicic acid (smaller than 0.1 μm) in solution A, Si($>$0.1): the amount of silica larger than 0.1 μm remaining on the filter, Si(T): the sum of Si($<$0.1) and Si($>$0.1), Fe(A): the amount of iron(III) ion in solution A, Si(T)/Fe(A): the mole ratio of silicic acid adsorbed and iron(III) hydroxide, Si(M)/Si(T): the mole ratio of monosilicic acid and total silicic acid adsorbed on iron(III) hydroxide. This ratio indicates the degree of polymerization of adsorbed silicic acid.

Results

The Kinetics of Adsorption. The kinetic data for adsorption of silicic acid on iron(III) hydroxide at three Si/Fe(MR) ratios and at pH 9 are shown in Fig. 1. The initial concentration of monosilicic acid was 300 ppm (SiO_2). A rapid decrease in monosilicic acid concentration occurred in one hour, the rate of adsorption of silicic acid then becoming relatively slow with

** Present address: Hirata-machi, Naze-shi, Kagoshima 894.

Initial monosilicic acid concentration: 300 ppm.
Si/Fe(MR): —●— 1.31, —○— 0.65, —+— 0.44.

time. Since monosilicic acid did not polymerize in the solution of 300 ppm within 5 h, only monosilicic acid was adsorbed by iron(III) hydroxide.

Effect of pH. Adsorption of silicic acid by iron(III) hydroxide and polymerization of adsorbed silicic acid were examined in the pH range 4—12. The results are shown in Figs. 2 and 3. Si(T)/Fe(A) ratio increased in the pH range 4—9, declining above pH 9. The maximum adsorption with respect to pH occurred at pH 9 (Fig. 2). Si(M)/Si(T) ratio decreased with increasing pH up to 9, increasing with further increase in pH. This indicates that the polymerization of silicic acid adsorbed on iron(III) hydroxide is most rapid at pH 9. In 300 ppm monosilicic acid solution, monosilicic acid adsorbed polymerized in the pH range 4—12. In 100 ppm monosilicic acid solution, the concentration being lower than the solubility of amorphous silica, monosilicic acid adsorbed polymerized in weakly alkaline solutions.

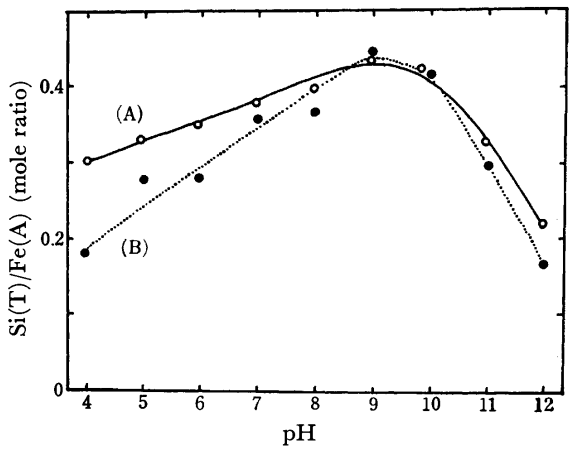

Fig. 2. The effect of pH on the amount of silicic acid adsorbed on iron(III) hydroxide after 5 h.
Initial monosilicic acid concentration: (A) 300 ppm, (B) 100 ppm.
Si/Fe(MR): (A) 0.63, (B) 1.31.

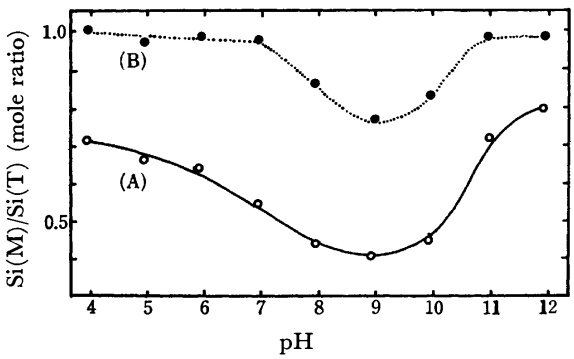

Fig. 3. The effect of pH on the degree of polymerization of silicic acid adsorbed on iron(III) hydroxide after 5 h.
The experimental conditions are the same as those of Fig. 2.

Distribution of Particle Size of Polysilicic Acids. As shown in Fig. 3, the amount of polysilicic acid formed on the surface of iron(III) hydroxide differs with pH. No information is available on the change in particle size of the polymers.

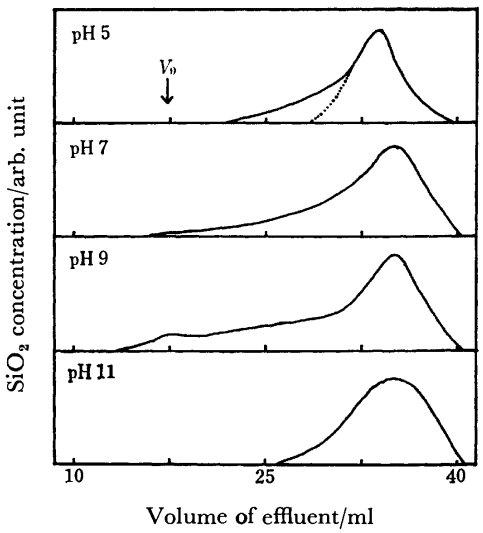

Fig. 4. Gel chromatograms for silicic acid adsorbed on iron(III) hydroxide at various pH after 5 h.
Initial monosilicic acid concentration: 300 ppm.
Si/Fe(MR): 0.63.

Silicic acid adsorbed on iron(III) hydroxide at various pH was chromatographed on Sephadex G-25 column. Elution curves for silicic acid are shown in Fig. 4. The dotted line is the elution curve for monosilicic acid, the position V_0 being the elution volume of Blue Dextran 2000, which does not seem diffusible in the gel phase. Polysilicic acid is eluted between the position V_0 and the elution position of monosilicic acid, the elution volume of polymer decreasing with increasing particle size. Polymers larger in size than those in the possible separation range for the gel are eluted together at V_0. From the elution curves we see that the growth of polymers is most rapid at pH 9.

Effect of Initial Concentration of Monosilicic Acid. Figure 5 shows the variation of Si(T)/Fe(A) and Si(M)/Si(T) ratios with initial concentration of monosilicic acid, the former increasing with an increase in the initial concentration of monosilicic acid and the latter decreasing. The amount of adsorbed silicic acid

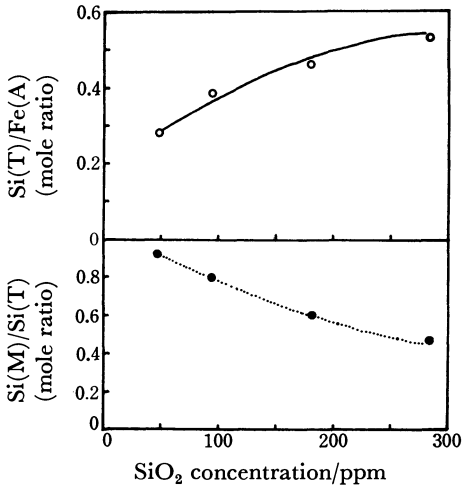

Fig. 5. The variation of Si(T)/Fe(A) and Si(M)/Si(T) ratios as a function of initial silicic acid concentration.
pH: 9. Reaction time: 5 h. Si/Fe(MR): 0.87.

and the degree of polymerization are greatly influenced by initial monosilicic acid concentration.

Effect of the Relative Amount of Silicic Acid and Iron(III) Hydroxide. Figure 6 shows the variation of Si(T)/Fe(A) and Si(M)/Si(T) ratios as a function of the Si/Fe(MR) ratio. Increase in the Si(T)/Fe(A) ratio and decrease in the Si(M)/Si(T) ratio were rapid with an increase in Si/Fe(MR) ratio in 300 ppm monosilicic acid solution. On the other hand, in 100 ppm monosilicic acid solution, at above Si/Fe(MR) ratio of unity, the Si(T)/Fe(A) ratio reached a limiting plateau region, indicating a *ca.* 0.38 Si(T)/Fe(A) ratio. The decrease in the Si(M)/Si(T) ratio became very slow at above a 2 Si/Fe(MR) ratio.

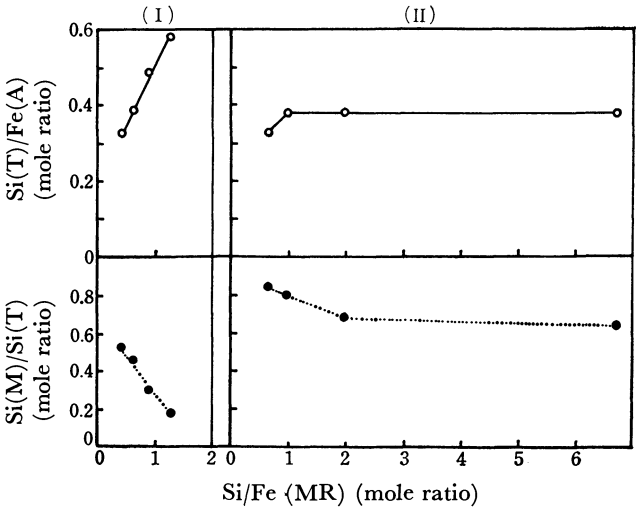

Fig. 6. The variation of Si(T)/Fe(A) and Si(M)/Si(T) ratios as a function of Si/Fe(MR) ratio.
Initial monosilicic acid concentration: (I) 300 ppm, (II) 100 ppm.
pH: 9. Reaction time: 5 h.

Effect of Standing Time. The variation of Si(T)/Fe(A) and Si(M)/Si(T) ratios with time in 300 ppm monosilicic acid solution is shown in Fig. 7. At a 0.65 Si/Fe(MR) ratio, both Si(T)/Fe(A) and Si(M)/Si(T) ratios reached limiting values after 10 h, indicating that adsorption and polymerization of silicic acid apparently do not proceed after 10 h.

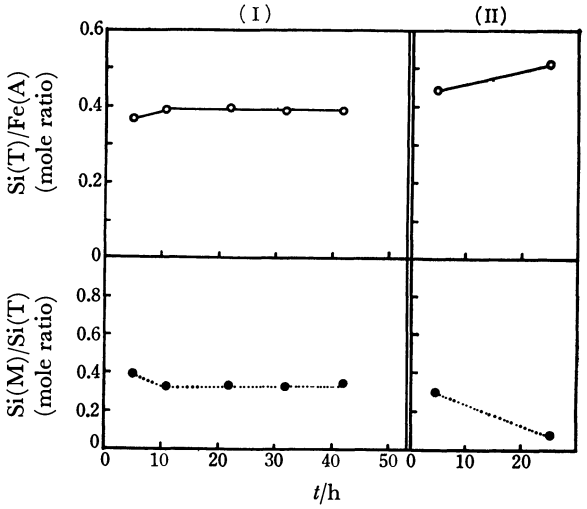

Fig. 7. The variation of Si(T)/Fe(A) and Si/(M)Si(T) ratios with time.
Initial monosilicic acid concentration: 300 ppm.
Si/Fe(MR): (I) 0.65, (II) 2.1. pH: 9.

At a 2.1 Si/Fe(MR) ratio, the Si(T)/Fe(A) ratio increased with time, the Si(M)/Si(T) ratio decreasing. Silica of size larger than 0.1 μm was obtained after 5 h, its amount increasing with time.

Discussion

Since the amount of silicic acid adsorbed on iron(III) hydroxide and the degree of polymerization of adsorbed

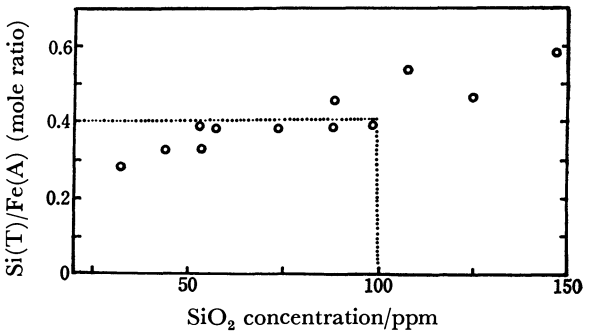

Fig. 8. Relationship between Si(T)/Fe(A) ratio and the concentration of monosilicic acid after 5 h at pH 9.

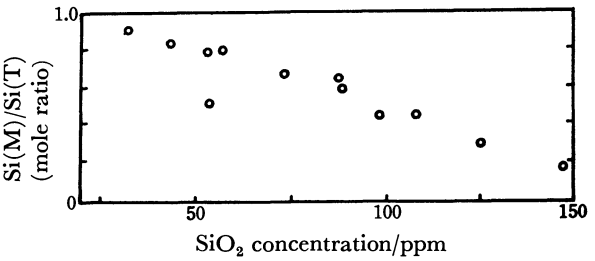

Fig. 9. Relationship between Si(M)/Si(T) ratio and the concentration of monosilicic acid after 5 h at pH 9.

silicic acid were largest at pH 9 (Figs. 2 and 3), the behavior of silicic acid was studied at pH 9.

The Si(T)/Fe(A) ratio increased with increasing initial concentration of silicic acid, the Si(M)/Si(T) ratio decreasing (Fig. 5). However, these ratios are expected to be affected also by silicic acid concentration after adsorption. On the basis of the experimental data (Figs. 5 and 6), Si(T)/Fe(A) and Si(M)/Si(T) ratios measured after 5 h were plotted against the concentration of silicic acid in the solutions. The results are shown in Figs. 8 and 9. The Si(T)/Fe(A) ratio is *ca.* 0.39 in the silicic acid solutions in the concentration range 50—100 ppm. Tarutani and Kato[6] reported that when 50 ppm monosilicic acid solution of pH 8 is continuously flowed through a flask containing iron(III) hydroxide, the Si(T)/Fe(A) ratio reaches the limiting value 0.39 after 10 d. It may be concluded that this value is the adsorption capacity of iron(III) hydroxide for silicic acid. When silicic acid concentration is higher than 100 ppm, the Si(T)/Fe(A) ratio increases with increasing silicic acid concentration. The Si(M)/Si(T) ratio decreased with increasing concentration of silicic acid (Fig. 9), suggesting that polymerization is affected by the concentration of silicic acid after adsorption as well as the initial silicic acid concentration.

The following conclusion was made. The polymerization reaction of silicic acid on the surface of iron(III) hydroxide consists of two steps: (1) the polymerization of adsorbed monosilicic acid and (2) the polymerization between monosilicic acid in the solution and silicic acid species already present on the surface of iron(III) hydroxide, giving rise to a three-dimensional gel structure.

In the solution of initial silicic acid concentration of 100 ppm, the amount of adsorbed silicic acid is nearly constant at above Si/Fe(MR) of unity, but the amount of polysilicic acid gradually increases with increasing Si/Fe(MR) ratio (Fig. 6). This suggests that polysilicic acid is mainly formed by Reaction 1. In silicic acid solutions in the concentration range 50—100 ppm, the Si(T)/Fe(A) ratio is almost constant (Fig. 8). When silicic acid concentration is higher than 100 ppm, the Si(T)/Fe(A) ratio increases with increasing silicic acid concentration. This seems to be caused by Reaction 2.

Amorphous silica of size larger than 0.1 μm is formed after 5 h on the surface of iron(III) hydroxide in the solution of initial silicic acid concentration of 300 ppm at a 2.1 Si/Fe(MR) ratio (Fig. 7). This suggests that polysilicic acid rapidly grows on the surface of iron(III) hydroxide in silicic acid solution which has a concentration higher than the solubility of amorphous silica.

Kinetics of the Gas-phase Photochlorination of Dichloromethane in a Tubular Photoreactor†

Takuo SUGAWARA,* Makoto SUZUKI, and Hiroyasu OHASHI
Department of Fuel Chemistry, Mining College, Akita University, Akita 010
(Received July 23, 1979)

The gas-phase photochlorination of dichloromethane was conducted at a low extent of conversion from 9 °C to 100 °C in a tubular flow reactor irradiated by means of a circular array of low-pressure mercury lamps. The kinetics were studied with due consideration taken of the radial variation in light intensity across the reactor and with the proper selection of kinetic equations, including the recombination of dichloromethyl radicals as the dominant termination step. The dependence of the absorbed radiant energy on the chlorine concentration was well simulated by the use of the radial-light and line-source model. The predominance of the observed production rate of hydrogen chloride over that of chloroform was also reproduced well by the appropriately selected kinetic expressions, without any use of the long-chain approximation. The recombination rate constant of dichloromethyl radicals was determined to be $10^{13.5}$ cm^3 mol^{-1} s^{-1}; this is larger than the previously reported value by the factor of 12.6, and is in fair agreement with the theoretical value, $10^{13.3-13.4}$, calculated from the statistical factor, and with the collision rate constant based on the hard-sphere model.

Information has been accumulating for the past two decades on design procedures for photoreactors. The reaction characteristics were examined for a simple kinetic system, combined with the effects of the diffusion rates, the velocity distribution in a flow reactor, and the internal light filtered by a product or by an intermediate.[1,2] However, little work has been reported on photoreactor performance for a reaction system with a complex mechanism. Sugawara *et al.*[3] recently studied the photochlorination of chloroform in an annular reactor. They indicated the necessity for precise information on the kinetics as well as the incident light intensity, especially in the case of a high radiation intensity. Now that research on the angle characteristics of radiation from various types of light sources[4,5] has made possible kinetic studies by the use of a high-intensity lamp in an arbitrary position, it could be possible to examine the effect of a termination step on the overall rates of a reaction with a chain mechanism more precisely than with previous conventional approaches.[6,7]

The motivation of this study was mainly to investigate photoreactor performance in a flow system for series-parallel reactions. First of all, the authors studied the kinetics of the gas-phase photochlorination of dichloromethane in a tubular reactor within a circle of low-pressure mercury lamps. They then discussed the applicability of the long-chain approximation and determined the rate of the recombination of dichloromethyl radicals, one of the termination steps, using the radial-light and line-source model[4] to estimate the radial intensity distribution. The determined rate constant may also be used to estimate the behavior of such air pollutants as dichloromethane and chloroform in the atmosphere.

Stoichiometry and Reaction Mechanism

The stoichiometric equations for the gas-phase photochlorination of dichloromethane are given by Eqs. 1—4, while the proposed reaction mechanisms are given from Eq. 5 through Eq. 17:

$$Cl_2 + CH_2Cl_2 = CHCl_3 + HCl \quad (1)$$

$$Cl_2 + 2CH_2Cl_2 = C_2H_2Cl_4 + 2HCl \quad (2)$$

$$Cl_2 + CHCl_3 = CCl_4 + HCl \quad (3)$$

$$Cl_2 + 2CHCl_3 = C_2Cl_6 + 2HCl \quad (4)$$

Initiation: $Cl_2 \xrightarrow{\phi I_a} 2Cl\cdot$ (5)

Propagation: $Cl\cdot + CH_2Cl_2 \underset{k_3}{\overset{k_2}{\rightleftharpoons}} CHCl_2\cdot + HCl$ (6)

$$CHCl_2\cdot + Cl_2 \underset{k_5}{\overset{k_4}{\rightleftharpoons}} Cl\cdot + CHCl_3 \quad (7)$$

$$Cl\cdot + CHCl_3 \underset{k_7}{\overset{k_6}{\rightleftharpoons}} CCl_3\cdot + HCl \quad (8)$$

$$CCl_3\cdot + Cl_2 \underset{k_9}{\overset{k_8}{\rightleftharpoons}} Cl\cdot + CCl_4 \quad (9)$$

Termination: $CHCl_2\cdot + Cl\cdot \xrightarrow{k_{10}} CHCl_3$ (10)

$$CHCl_2\cdot + CHCl_2\cdot \xrightarrow{k_{11}} C_2H_2Cl_4 \quad (11)$$

$$CCl_3\cdot + Cl\cdot \xrightarrow{k_{12}} CCl_4 \quad (12)$$

$$CCl_3\cdot + CCl_3\cdot \xrightarrow{k_{13}} C_2Cl_6 \quad (13)$$

$$CHCl_2\cdot + CCl_3\cdot \xrightarrow{k_{14}} C_2HCl_5 \quad (14)$$

$$Cl\cdot + Cl_2 \underset{k_{16}}{\overset{k_{15}}{\rightleftharpoons}} Cl_3\cdot \quad (15)$$

$$Cl_3\cdot + Cl\cdot \xrightarrow{k_{17}} 2Cl_2 \quad (16)$$

$$Cl\cdot + \text{wall} \xrightarrow{k_{18}} \frac{1}{2}Cl_2 \quad (17)$$

The rate constants recommended in the literature are shown in Table 1.[7-11] The published value of k_{11}, $10^{12.4}$, may be open to question, since it is much lower than k_{13}; a simple kinetic model study[12] suggests that the recombination rate of dichloromethyl radicals should not deviate so much from that of trichloromethyl radicals.

Experimental

Reagents. *Dichloromethane*: The reagent on the market contains ca. 0.5% ethanol as a stabilizer. It produces acetyl chloride and hydrogen chloride by means of this stoichiometric equation (Eq. 18):

$$C_2H_5OH + 2Cl_2 = CH_3COCl + 3HCl \qquad (18)$$

Since the rate of the above reaction was observed in a preliminary study to be much faster than that of the photochlorination of dichloromethane, the ethanol was removed by shaking the mixture with a concentrated sulfuric acid solution and then with a dilute sodium hydroxide solution, followed by distilled water, and finally by drying it with calcium chloride. The remaining dichloromethane was further purified by distillation.

Chlorine and Nitrogen: The effect of the oxygen impurities in chlorine and nitrogen on the photochlorination of dichloromethane was considered negligible because of their extremely small amounts, *i.e.*, several ppm in each cylinder.

Experimental Apparatus and Procedure. A schematic diagram of the apparatus is shown in Fig. 1. Dichloromethane, fed in constantly with a microfeeder (2), was instantaneously vaporized in a vaporizer (4), diluted with nitrogen, and mixed with chlorine in the mixing chamber (6). The reactant gas mixture was then led to a quartz tube (7) through a connecting tube with an inside diameter of 8 mm and a length of 4.5 m. The reactants were irradiated in a test section located *ca.* 15—30 cm downstream from the inlet by means of 3, 6, or 12 low-pressure mercury lamps (Toshiba GL-30, 200 V-30 W; illuminating length, *ca.* 890 mm) arranged in a circle as is shown in the figure. current was applied, was minimized by setting one-third of the total number of lamps separately from the three-phase alternating current. The reactor dimensions are summarized in Table 2.

The spectral distribution of the molar absorption coefficient of chlorine,[13] α_λ, is shown in Fig. 2, along with the radiant emission spectra effective for the photochlorination.[14]

Quantitative Analysis. Gas sampled at the reactor inlet or outlet was led into a potassium iodide solution (9) which had been made slightly acidic with hydrochloric acid. The unreacted chlorine and the formed hydrogen chloride were determined with 0.1 mol dm^{-3} sodium thiosulfate and 0.01 mol dm^{-3} sodium hydroxide solutions respectively. Gas sampled through a packed column (14) to be described below was analyzed for dichloromethane, chloroform, and carbon tetrachloride by means of gas chromatography. The column (14) for the adsorption of chlorine was made of a glass tube with an inner diameter of 6 mm and a length of 300 mm, packed with small pellets containing calcium hydroxide, potassium iodide, and calcium chloride. It was ascertained beforehand that the adsorption of the other reactant and products was negligible within the limits of precision of the analysis. A gas chromatograph equipped with a copper column with an inner diameter of 3 mm and a length of 2.2 m, and packed with T.C.P. 30%/celite 545 (80—100 mesh), was operated at 88 °C and at a flow rate of 28.5 cm^3 (20 °C, with 1 atm) min^{-1} of hydrogen as the carrier gas.

Experimental Conditions. All the experiments were conducted under conditions in which a differential reactor could be assumed, where the extent of the conversion of chlorine and dichloromethane was low and where the production of carbon tetrachloride was negligible. The experimental conditions are shown in Table 2. The dark reactions were negligible under the conditions studied.

Results

Incident Light Intensity. It was previously reported that the incident light intensity got lower as time elapsed because of deposits on the reactor wall in the gas-phase photochlorination of hydrocarbons.[8,11,15] A study with a potassium trioxalatoferrate(III) actinometer[16] revealed a gradual drop in intensity, especially during the initial period of usage, but the rate of drop was so slow after about ten hours that the intensity in a run could be considered constant for several hours.

Production Rates of Hydrogen Chloride and Chloroform. Figures 3 and 4 show examples of the effect of the chlorine concentration, and Fig. 5 that of the dichloromethane concentration on the production rates of hydrogen chloride, ○, and chloroform, △. These figures indicate that the effect of chlorine is much greater than that of dichloromethane. The effect of the tempera-

ture is shown in Fig. 6. Figures 3—6 show that the production rates of hydrogen chloride are higher than that of chloroform, especially at low temperatures.

Discussion

Kinetics under the Conditions of a Low Extent of Conversion. Practical kinetic expressions should be derived to simulate the experimental results, since the proposed reaction mechanism is too complex. First, Eqs. 8, 9 and 12—14 may be neglected, because the chloroform produced was in a low concentration and no appreciable carbon tetrachloride was observed under the experimental conditions studied. Second, back reactions for Eqs. 6 and 7 are insignificant since k_3 and k_5 are much smaller than k_2 and k_4 respectively, as may be seen in Table 1. Third, the concentrations of the chlorine atom and the dichloromethyl radical, calculated by means of Eqs. 6, 7, and 10, and the observed formation rates of hydrogen chloride and chloroform revealed that the effect of Eqs. 15—17 on the total formation rate of chlorine atom is less important than that of Eqs. 6, 7, and 10, in which the trichloro-radical concentration could safely be estimated from the stationary-state hypothesis according to the method of Hutton and Wright.[10]

According to the above discussion, the following kinetic expressions may be considered to be reasonable under the experimental conditions studied:

$$\text{Initiation:}\quad Cl_2 \xrightarrow{\phi I_a} 2Cl\cdot \tag{5}$$

$$\text{Propagation:}\quad Cl\cdot + CH_2Cl_2 \xrightarrow{k_2} CHCl_2\cdot + HCl \tag{19}$$

$$CHCl_2\cdot + Cl_2 \xrightarrow{k_4} Cl\cdot + CHCl_3 \tag{20}$$

$$\text{Termination:}\quad CHCl_2\cdot + Cl\cdot \xrightarrow{k_{10}} CHCl_3 \tag{10}$$

$$CHCl_2\cdot + CHCl_2\cdot \xrightarrow{k_{11}} C_2H_2Cl_4 \tag{11}$$

The production rates of chloroform and hydrogen chloride are represented by Eqs. 21 and 22.

$$\frac{d[CHCl_3]}{dt} = k_4'[CHCl_2\cdot] + k_{10}[Cl\cdot][CHCl_2\cdot] \tag{21}$$

$$\frac{d[HCl]}{dt} = -\frac{d[CH_2Cl_2]}{dt} = k_2'[Cl\cdot] \tag{22}$$

where

$$k_2' = k_2[CH_2Cl_2] \simeq k_2[CH_2Cl_2]_o,$$
$$\text{and}\quad k_4' = k_4[Cl_2] \simeq k_4[Cl_2]_o, \tag{23}$$

and where the subscript o indicates the value at the reactor inlet.

$[Cl\cdot]$ and $[CHCl_2\cdot]$ are obtained by solving Eqs. 24 and 25:

$$\frac{d[Cl\cdot]}{dt} = 2\phi I_a - k_2'[Cl\cdot] + k_4'[CHCl_2\cdot] - k_{10}[Cl\cdot][CHCl_2\cdot] \tag{24}$$

$$\frac{d[CHCl_2\cdot]}{dt} = k_2'[Cl\cdot] - k_4'[CHCl_2\cdot] - k_{10}[Cl\cdot][CHCl_2\cdot] - 2k_{11}[CHCl_2\cdot]^2 \tag{25}$$

If the long-chain approximation is applicable, Eq. 26 is obtained for the prediction of the production rates of both chloroform and hydrogen chloride:

$$\frac{d[CHCl_3]}{dt} = \frac{d[HCl]}{dt} = \frac{(\phi I_a)^{1/2}k_4[Cl_2]}{\{(k_4k_{10}[Cl_2]/k_2[CH_2Cl_2]) + k_{11}\}^{1/2}} \tag{26}$$

Since some difference was observed in the production rates of chloroform and hydrogen chloride, simulation was conducted without the use of the long-chain approximation.

Radial Distribution of Light Intensity in the Reactor. It is necessary to know the relation of the radiant energy absorbed to the chlorine concentration if we are to determine the dependence of the rate of the initiation step on the chlorine concentration.

Now, it is assumed that the radial variation in the chlorine concentration and the effects of reflection and refraction are negligible, and that Beer's law is valid for the absorption of light at each wavelength. Then the light intensity at an arbitrary point P, $I_\lambda(r,\beta)$, and the total energy absorbed, I_a, are given by Eqs. 27 and 28 respectively when the radial-light and line-source model[4] is applied:

$$I_\lambda(r,\beta) \propto \sum_{j=1}^{n}\left\{\frac{1}{\overline{PO_j}}\exp\left(-\alpha_\lambda[Cl_2]\overline{PQ_j}\right)\right\} \tag{27}$$

$$I_a = \sum_\lambda I_{a,\lambda} \tag{28}$$

where

$$I_{a,\lambda} = \frac{\alpha_\lambda[Cl_2]}{\pi {r_o}^2}\int_0^{r_o}\int_0^{2\pi} rI_\lambda(r,\beta)d\beta dr \tag{29}$$

$$\overline{PO_j} = ({l_o}^2 + r^2 - 2l_o r\cos\beta_j)^{1/2} \tag{30}$$

$$\overline{PQ_j} = r\cos\alpha_j + (r_o^2 - r^2\sin^2\alpha_j)^{1/2} \quad (31)$$

$$\alpha_j = \sin^{-1}[\sin^2\beta_j/\{1+(r/l_o)^2-2(r/l_o)\cos\beta_j\}]^{1/2} \quad (32)$$

$$\beta_j = \beta - 2\pi(j-1)/n \quad (33)$$

Symbols refer to Fig. 7.

Figures 8 and 9 show examples of the computed results. The relative radiant energy absorbed, $I_a/I_{a,s}$,[††] as is shown in Fig. 9, was used for the estimation of I_a.

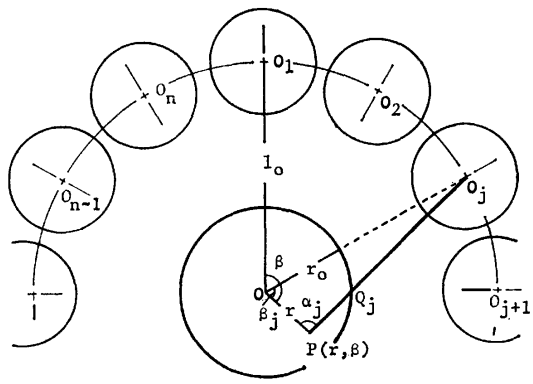

Fig. 7. Arrangement of a reactor and lamps.

Conditions; $n=6$, λ/nm=313.2, l_o/cm=5.98, r_o/cm=0.345, and α_λ/cm^2 mol^{-1}=1.246×10^5. $[Cl_2]\times10^5$/mol cm^{-3}=1.0(A), 1.5(B), and 2.0(C).

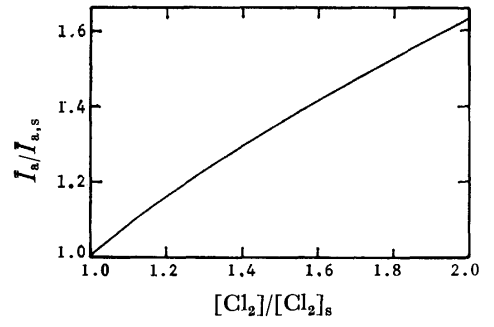

Fig. 9. Relative radiant energy absorbed *vs.* Cl_2 concentration by radial-light and line-source model.
Conditions; $n=6$, l_o/cm=5.98, r_o/cm=0.345, and $[Cl_2]_s$/mol cm^{-3}=1.0×10^{-5}.

†† The subscript s means the value at the reference concentration, $[Cl_2]$/mol cm^{-3}=1.0×10^{-5}.

The procedure will be described in the following section. Funayama *et al.*[5] showed that the radial-light and line-source model was applicable when the distance between a reactor and a low-pressure mercury lamp was less than one-fourth and more than one-eleventh of the lamp length. Thus, we may assume the radial light and line source for the geometric relation in this study.

Determination of the Rate Constant, k_{11}. Assuming no appreciable radial concentration gradient for any reactant, Eqs. 21 and 22 were used to simulate the experimental results. The steady-state chlorine-atom and dichloromethyl-radical concentrations were computed by means of Eqs. 24 and 25, and then applied to Eqs. 21 and 22. The RKG algorithm was used for the computation with the FACOM 270/20, throughout which the quantum efficiency, ϕ, was assumed to be constant. The preliminary study of the parametric sensitivity revealed that $\phi I_{a,s}$ and k_{11} affected the absolute and relative values of the production rates of chloroform and hydrogen chloride respectively when k_2 and k_4 were fixed so as to be correct. It should be noted that k_{10} was less effective than k_{11} for Eqs. 24 and 25, since the chlorine-atom concentration was calculated to be much lower than the dichloromethyl-radical concentration under the conditions studied. I_a for any chlorine concentration was estimated with the relative radiant energy absorbed, $I_a/I_{a,s}$, calculated in the above section, and with an appropriately selected value of $I_{a,s}$ so as to fit the experimental value of the production rate of *chloroform* at a chlorine concentration of 1.0×10^{-5} mol cm^{-3}. Then, the rate constant of the recombination of dichloromethyl radicals, k_{11}, was the parameter to be determined for the estimation of the experimental values of the production rate of *hydrogen chloride*. An example of the simulation is shown in Fig. 3. The solid and the broken lines represent the computed production rates of chloroform and hydrogen chloride respectively, with three sets of $\phi I_{a,s}$ and k_{11}. Although the dependence of ϕI_a on the chlorine concentration was fairly well simulated, the experimental results were not reproduced well for the cases of (A) and (B) in the figure where the previously reported value[8] of k_{11}, $10^{12.4}$, was adopted. Therefore, we sought to optimize k_{11} with an appropriately selected value of $\phi I_{a,s}$.

The experimental data were well simulated when $\phi I_{a,s}$ was assigned a value of 3.50×10^{-8} mol cm^{-3} s^{-1} and when the value of the rate constant, k_{11}, was chosen as $10^{13.5}$ cm^3 mol^{-1} s^{-1}, as is seen in the case of (C) in Fig. 3. The curves thus determined are shown in Figs. 4, 5, and 6, along with the specified values of $\phi I_{a,s}$ and k_{11} and the relative radiant energy absorbed, estimated by means of the radial-light and line-source model. The agreement between the computed and observed values is good, irrespective of changes in the chlorine and dichloromethane concentrations and in the reaction temperature from 9 °C to 100 °C. The good simulation while changing the reaction temperature indicates the reliability of the temperature dependence of the rate constants of the propagation steps and no appreciable activation energy for k_{11}. The determined value of k_{11},

$10^{13.5}$, is in fair agreement with the theoretical ones, $10^{13.3}$ at 9 °C and $10^{13.4}$ at 100 °C, calculated from the statistical factor and the collision-rate constant based on the hard-sphere model.[12] The radius of the dichloromethyl radical was assumed to be equal to that of dichloromethane[17] in the calculation of the collision-rate constant.

Conclusion

For basic information on flow-reactor performance for photoreactions with complex mechanisms, the gas-phase photochlorination of dichloromethane was kinetically studied at a low extent of conversion (from 9 °C to 100 °C) in a tubular quartz reactor irradiated by a circular array of low-pressure mercury lamps. The intense irradiation made it possible to examine the effect of the termination step, the recombination of dichloromethyl radicals, on the overall reaction rate more precisely than with conventional techniques.

The dependence of the absorbed radiant energy on the chlorine concentration was well simulated by the radial-light and line-source model, which takes the radial-intensity variation into consideration. The predominance of the observed production rate of hydrogen chloride over that of chloroform was also reproduced well by the appropriately selected kinetic equations without any use of the long-chain approximation.

The recombination-rate constant of the dichloromethyl radicals was determined to be $10^{13.5}$ cm^3 mol^{-1} s^{-1}. No appreciable activation energy was observed in the temperature range from 9 °C to 100 °C. The determined value is larger than the previously reported one by a factor of 12.6, and it is in fair agreement with the theoretical one, $10^{13.3-13.4}$, calculated from the statistical factor and the collision-rate constant based on the hard-sphere model.

This paper was prepared when one of the authors (T.S.) was at the University of Minnesota. Professor R. W. Carr's comments are appreciated. The authors also appreciate the experimental assistance of Mr. Hajime Muto. This work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Japan, in 1973 (No. 875485).

Quenching of Excited Zinc(^3P_J) and Zinc($^1P_1$) Atoms by Several Gases

Shunzo YAMAMOTO,* Takashi TAKEI, Norio NISHIMURA, and Shigeo HASEGAWA
Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700
(Received July 23, 1979)

The intensities of the 307.6 nm and 213.9 nm resonance lines of zinc were measured at different pressures of several gases, and the quenching rate constants were determined on the basis of the Stern-Volmer plots. The quenching cross-sections obtained here were compared with those for mercury and cadmium. The simple charge-transfer curve-crossing theory proposed by Breckenridge and Renlund for the quenching of excited cadmium and mercury atoms by N_2, CO, CO_2, and so on was found to be useful for the quenching of excited zinc atoms, as well. Isotope effects on the quenching of Zn(^3P_J) and Zn($^1P_1$) by H_2 and D_2 were also discussed.

Recently, Breckenridge *et al.* have measured the quenching cross-sections of excited cadmium (^3P_J) and cadmium ($^1P_1$) atoms by several gases.[1] They have compared their values with those for the quenching of mercury ($^3P_1$ and $^3P_0$) atoms and other excited atoms, and have discussed several possible exit channels for the quenching of excited metal atoms.

In spite of several comprehensive studies of the quenching and chemical reactivity of excited mercury[2-4] and cadmium[5] atoms, there have been almost no studies of the excited states of zinc (valence isoelectronic atom with cadmium and mercury). Since the excitation energy of Zn($^3P_1$) lies between those of Cd($^3P_1$) and Hg($^3P_1$), we expected that a comparison of the reactions photosensitized by these three atoms would give further information about the detailed mechanism of the reactions.

In a previous short communication,[6] we reported the quenching cross sections of Zn(^3P_J) by H_2, D_2, and CH_4. The present paper will report the details of the quenching of Zn(^3P_J) and Zn($^1P_1$).

Experimental

The apparatus was the same as that previously described.[6] The reaction cell and the zinc lamp made of quartz were kept in a furnace at 305±2 °C. Two resonance lines (213.9 and 307.6 nm) are emitted from the lamp. These lines give rise to Zn($^1P_1$) and Zn($^3P_1$) atoms respectively. In the measurement of the quenching rate of the Zn(^3P_J) atoms, the 213.9 nm resonance line was filtered out by inserting a Pyrex plate between the cell and the lamp. The light intensities from the cell were measured by means of a Hitachi spectrophotometer, Model 139. The pressure of the gases was measured by means of a W & T model 62-075 pressure gauge (Nagano Keiki Co). The low pressures of the quenching gases were measured using calibrated expansion volumes.

The zinc metal used was high-purity zinc (99.9999%) manufactured by the Osaka Asahi Metal Co. Research-grade H_2(99.999%), D_2(99.5%), CH_4(99.95%), N_2(99.999%), CO(99.8%), and CO_2(99.99%) purchased from the Takachiho Shoji Co., were used without further purification. Pure-grade NH_3 (Takachiho Shoji Co. 99.5%) was freeze-pumped several times. Pure-grade Ar (Daido Sanso Co. 99.999%) was used without further purification.

Results

Pressure Dependence of the Emission Intensities at 213.9 and 307.6 nm. When a cell containing zinc vapor was illuminated by means of the exciting lamp, two resonance lines were observed, at 213.9 and 307.6 nm. The 213.9 nm resonance line disappeared when a Pyrex plate was inserted between the cell and the lamp. Upon the addition of argon, the intensities of the lines increased with the increase of the pressure, as is shown in Fig. 1.

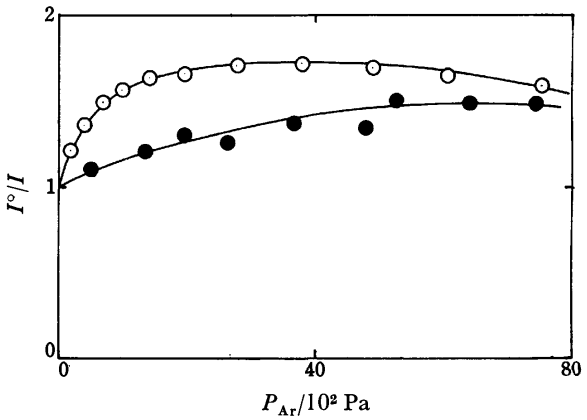

Fig. 1. Intensities of resonance lines at 213.9 (○) and 307.6 nm (●) as functions of argon pressures.

A similar increase of the intensity of the 326.1 nm resonance line of cadmium was previously observed; it was attributed to the increase in the light intensity absorbed by cadmium atoms because of the pressure broadening of the absorption line.[7] In order to minimize the pressure dependence of the absorption of the resonance line, quenchers were diluted with a large

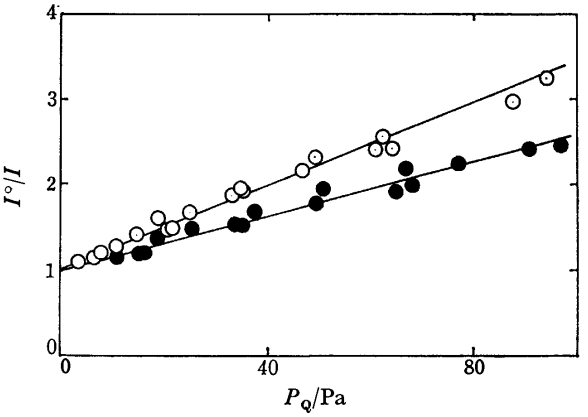

Fig. 2. Stern-Volmer plots for quenching of resonance line at 213.9 nm by H_2 (●) and D_2 (○). The total pressure is 4000 Pa.

amount of argon and the total pressure in the reaction cell was kept constant (4000 and 1300 Pa in the cases of the measurements at 213.9 and 307.6 nm respectively).

When quencher-argon mixtures were added, the intensities of the resonance lines decreased with the increase in the partial pressure of the quenchers. Representative Stern-Volmer plots for the quenching of the 213.9 and 307.6 nm resonance lines by several quenchers are shown in Figs. 2 and 3, where I° and I

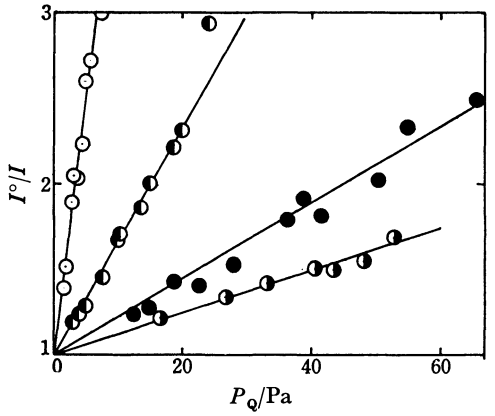

Fig. 3. Stern-Volmer plots for quenching of resonance line at 307.6 nm by CO_2 (○), CO (◐), N_2 (●), and CH_4 (◑). The total pressure is 1300 Pa.

are the intensities of the resonance lines in the absence and in the presence of quenchers respectively. All of the plots form straight lines, the intercepts of which are unity. Similar plots were obtained for other quenchers.

Quenching of the 307.6 nm Resonance Line. By analogy with the mechanism presented for the quenching of $Cd(^3P_J)$,[1a] the quenching of $Zn(^3P_J)$ can be discussed in terms of the following reactions:

$$Zn(^1S_0) + h\nu(307.6) \longrightarrow Zn(^3P_1) \quad I_a$$
$$Zn(^3P_1) \longrightarrow Zn(^1S_0) + h\nu(307.6) \quad k_0$$
$$Zn(^3P_1) + M \rightleftarrows Zn(^3P_0) + M \quad k_1, k_{-1}$$
$$Zn(^3P_1) + M \rightleftarrows Zn(^3P_2) + M \quad k_2, k_{-2}$$
$$Zn(^3P_0) + Q \longrightarrow \text{quenching} \quad k_3$$
$$Zn(^3P_1) + Q \longrightarrow \text{quenching} \quad k_4$$
$$Zn(^3P_2) + Q \longrightarrow \text{quenching} \quad k_5$$

Here, M denotes Ar and/or quenchers. As the energy differences between $Zn(^3P_0)$ and $Zn(^3P_1)$, and between $Zn(^3P_1)$ and $Zn(^3P_2)$ are very small (2.30 and 4.73 kJ/mol), equilibria must be attained fairly rapidly among these three states. By assuming the steady-state for $Zn(^3P_0)$, $Zn(^3P_1)$, and $Zn(^3P_2)$, the following equation can be derived:

$$\frac{[Zn(^3P_1)]_{Q=0}}{[Zn(^3P_1)]} = 1 + \frac{1}{k_0}\left(\frac{k_1}{k_{-1}}k_3 + k_4 + \frac{k_2}{k_{-2}}k_5\right)[Q] \quad (1)$$

As $I^\circ_{307.6} = k_0[Zn(^3P_1)]_{Q=0}$ and $I_{307.6} = k_0[Zn(^3P_1)]$, the above equation becomes:

$$\frac{I^\circ_{307.6}}{I_{307.6}} = 1 + \frac{1}{k_0}\left(\frac{k_1}{k_{-1}}k_3 + k_4 + \frac{k_2}{k_{-2}}k_5\right)[Q] \quad (2)$$

The linear Stern-Volmer plots in Fig. 3 are accounted for by Eq. 2. As the *f*-value of the zinc 307.6 nm line is about one-tenth of that of the cadmium 326.1 nm line,[8] the absorption of the 307.6 nm line by the zinc vapor at 0.36 Pa (305 °C) seems to be too small to cause any significant radiation trapping. If the lengthening of the effective radiation lifetime of $Zn(^3P_1)$ caused by radiation imprisonment is not negligible for the vapor pressure of zinc at 305 °C, the effective lifetime must be dependent on the total pressure. In Fig. 4, the values of $I^\circ_{307.6}/I_{307.6}$ obtained for H_2 and N_2

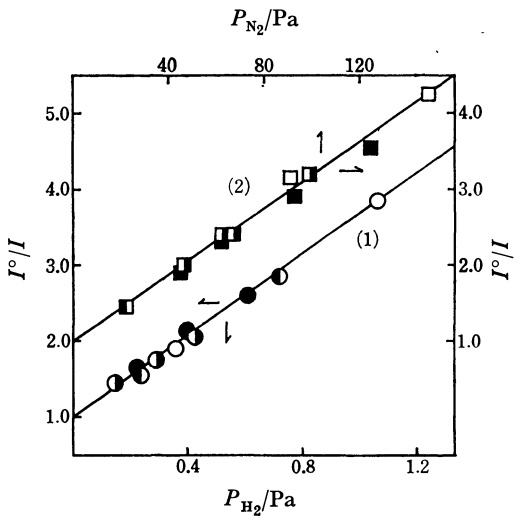

Fig. 4. Stern-Volmer plots for quenching of resonance line at 307.6 nm by H_2 and N_2.
1) H_2; total pressure are 7200 (○), 4900 (◐), 1300 (●), and 1000 (◑) in Pa. 2) N_2; 7200 (□), 4900 (◧), 1300 (□), and 1000 (◨).

at various total pressures are plotted as functions of the partial pressures of the quenchers. The points for each quencher lie on a straight line, and no dependence on the total pressure can be seen. This strongly suggests that the radiative lifetime of the $Zn(^3P_1)$ atoms in this system is independent of the pressure of the foreign gas. Therefore, k_0 can be taken as the reciprocal of the natural lifetime of $Zn(^3P_1)$ ($\tau = 2.0 \times 10^{-5}$ s[9]).

From the slopes of the straight lines in Fig. 3, the composite rate constants of the quenching, $(k_1/k_{-1})k_3 + k_4 + (k_2/k_{-2})k_5$, are estimated. Since the three triplet states are in equilibrium, $k_1/k_{-1} = (1/3)\exp(2300/RT)$ and $k_2/k_{-2} = (5/3)\exp(-4730/RT)$, and at 305 °C k_1/k_{-1} and k_2/k_{-2} are 0.54 and 0.62 respectively. The quenching rate constants, $k_q(=0.54k_3 + k_4 + 0.62k_5)$, are listed in Table 1. The corresponding quenching cross-sections

Table 1. Quenching of $Zn(^3P_J)$ by various gases

Gas	$10^{11}k_q$ / cm^3 molecule^{-1} s^{-1}	$10^{16}\sigma_q^2$ / cm^2
H_2	106.6±7.2	13.6±0.9
D_2	64.1±4.5	11.3±0.8
N_2	0.92±0.01	0.37±0.01
CO	2.58±0.18	1.04±0.07
CO_2	9.44±0.75	4.41±0.35
NH_3	9.54±0.93	3.20±0.31
CH_4	0.50±0.01	0.16±0.01

for equilibrated $Zn(^3P_{0,1,2})$ are calculated using the simple collision theory expression:

$$\sigma_q^2 = k_q\left(8\pi RT\frac{M_{Zn}+M_Q}{M_{Zn}M_Q}\right)^{-1/2} \quad (3)$$

where M_{Zn} and M_Q are the atomic and molecular weights of zinc and the quenchers respectively. The cross-sections are also listed in Table 1.

Quenching of the 213.9 nm Resonance Line. The quenching of $Zn(^1P_1)$ can be discussed in terms of the following reactions:

$$Zn(^1S_0) + h\nu(213.9) \longrightarrow Zn(^1P_1)$$
$$Zn(^1P_1) \longrightarrow Zn(^1S_0) + h\nu(213.9) \qquad k_r$$
$$Zn(^1P_1) + Q \longrightarrow \text{quenching} \qquad k_Q$$

The steady-state treatment gives the following relation:

$$\frac{I^\circ_{213.9}}{I_{213.9}} = 1 + \frac{k_Q}{k_r}[Q] \quad (4)$$

Here, $I^\circ_{213.9}$ and $I_{213.9}$ are the emission intensities at 213.9 nm in the absence and in the presence of quenchers respectively. From the slopes of the straight lines in Fig. 2, the values of k_Q/k_r can be obtained; they are listed in Table 2. k_r is the effective rate constant for the escape of 213.9 nm fluorescent photons from the reaction vessel. Contrary to the case of the 307.6 nm resonance line, k_r must be significantly different from the limiting rate of natural radiative decay at a very low vapor concentration, because radiation imprisonment can not be neglected because of the large absorption coefficient. Therefore, it is difficult to estimate the absolute k_Q values. Since the quenchers are diluted with a large amount of argon, it can be assumed that k_r is independent of the pressures of the quenchers and of the kind of quencher. The relative values of k_Q and relative quenching cross-sections are listed in Table 2.

TABLE 2. QUENCHING OF $Zn(^1P_1)$ BY VARIOUS GASES

CH_4	1.37±0.01	0.56	1.44

Discussion

Breckenridge *et al.* discussed several factors which govern the quenching efficiencies of $Cd(^1P_1)$ and $Cd(^3P_J)$ by several gases.[1] They found that there is a correlation of the cross-sections for the quenching of excited metal atoms with a parameter, Δ, the energy difference between Me^*+Q and $Me^+ + Q^-$ at an infinite Me—Q distance, which is itself given by:

$$\Delta = I_p(Me^*) - E_a(Q)$$

They described[1b] that, in general, the cross-section increases with a decrease in Δ for the quenching of $Cd(^1P_1)$, $Cd(^3P_J)$, $Hg(^3P_0)$, and $Hg(^3P_1)$ by N_2, CO, CO_2, and so on, and that the charge-transfer curve-crossing theory is useful in explaining the magnitudes of the quenching cross-sections.

In Table 3, a comparison of the quenching cross-sections of $Zn(^3P_J)$, $Cd(^3P_J)$, $Hg(^3P_0)$, and $Hg(^3P_1)$ is shown. In this table, the values of Δ are also included. For mercury, the cross-section for the quenching processes, $^3P_1 \rightarrow {}^1S_0$ and $^3P_0 \rightarrow {}^1S_0$, have been determined separately.[4] However, for cadmium and zinc, only the composite cross-sections for the quenching of the ^3P_J states can be determined, for the equilibration reactions among these states are very rapid.

The quenching cross-sections of $Zn(^3P_J)$ by CH_4, N_2, CO, and CO_2 increase in this order. This order is almost the same as those for $Cd(^3P_J)$ and $Hg(^3P_1)$; it is also consistent with the order of the decrease in Δ. In the cases of $Cd(^3P_J)$ and $Hg(^3P_1)$, these orders have been successfully explained in terms of the charge-transfer curve-crossing mechanism.[1b] Therefore, it is reasonable to consider that the same mechanism may be valid for $Zn(^3P_J)$.

For a single quencher, the correlation between the cross-sections and Δ is not simple. For CO_2, the cross-sections increase with a decrease in Δ, but for the other quenchers they do not do so. Since the difference in Δ between the quenchers is comparatively large, the order of the quenching cross-sections for an excited atoms must be determined by only the magnitudes of Δ. However, since the difference in Δ between the metal

TABLE 3. COMPARISON OF QUENCHING CROSS-SECTIONS OF VARIOUS EXCITED METAL ATOMS

a) The cross-sections are actually sums of population weighted cross-sections for equilibrated $Zn(^3P_{0,1,2})$ and $Cd(^3P_{0,1})$: $\sigma_q^2(Zn) = 0.54\sigma_0^2 + \sigma_1^2 + 0.62\sigma_2^2$; $\sigma_q^2(Cd) = 1.37\sigma_0^2 + \sigma_1^2$. b) Ref. 1. c) Ref. 4.

atoms is small, the order can not be determined by only the magnitudes of Δ; such other factors as the polarizability of the Me^+-Q^- complex must also be taken into account, as has been mentioned by Breckenridge and Renlund.[1b]

One major channel in the quenching of $Cd(^3P_J)$ and $Hg(^3P_{0,1})$ by NH_3 has been shown to involve the formation of Cd–NH_3* and Hg–NH_3* exciplexes, and the emission from these exciplexes has been observed.[10,11] In the $Zn(^3P_J)$–NH_3 system, however, the exciplex emission could not be observed. One of the following reasons may be responsible for this; (a) the exciplex does not form; or (b) even if the exciplex forms, it is completely quenched before emission, or (c) the exciplex emission is too weak to be observed by our detector. By analogy with the Cd–NH_3 and Hg–NH_3 systems, it does not seem reasonable to consider reason (a) and/or (b) to be responsible for the lack of luminescence in the Zn–NH_3 system.

If the quenching of $Zn(^3P_J)$ by ammonia occurs exclusively through the formation of the exciplex in a manner similar to that of $Cd(^3P_J)$, the emission intensity from the exciplex can be expressed as follows;

$$I_e = I^\circ[k_e/(k_e+k_n[Ar])] \quad (5)$$

where I° is the intensity of the resonance line and where k_e and k_n are the rate constants for the following reactions:

$$Zn\text{–}NH_3^* \longrightarrow Zn + NH_3 + h\nu_e \qquad k_e$$

$$Zn\text{–}NH_3^* + Ar \longrightarrow Zn + NH_3 + Ar \qquad k_n$$

In order to consider the emission intensity of the Zn–NH_3* exciplex by comparing the intensity with that for the Cd–NH_3* exciplex, we measured the cadmium-photosensitized luminescence of ammonia using our apparatus; we could thus observed an emission band consistent with that shown in the literature.[10] It was proved that, by our apparatus, we can not observe an emission whose intensity is smaller by a factor of 500 than that from the Cd–NH_3* exciplex. (The light intensity which can be detected by our spectrophotometer with the maximum sensitivity was estimated by means of potassium ferrioxalate actinometry to be about 5×10^{-14} Einsteins s^{-1} cm^{-2} at 400 nm at the incidence slit.) The intensity ratio of the resonance line of zinc to that of cadmium, corrected for the sensitivity of the spectrophotometer at 307.6 and 326.1 nm, was about 1/100 (the intensity of the zinc lamp was about 1/3 of that of the cadmium lamp; the other factor must be based on the difference in the absorption coefficients). Therefore, if the value of $k_e/(k_e+k_n[Ar])$ in the Zn–NH_3 system is smaller by a factor of 5 than that for the Cd–NH_3 system (0.67 for an argon pressure of 13300 Pa[10]), the emission from the Zn–NH_3* exciplex can not be detected by our apparatus. This seems the most reasonable explanation for our failure to observe the exciplex emission in the zinc-photosensitized reaction of ammonia.

In Table 4, the relative quenching cross-sections of $Zn(^1P_1)$ and the values of Δ are shown. For comparison, these values for $Cd(^1P_1)$ are also included. The quenching cross-sections of $Zn(^1P_1)$ and $Cd(^1P_1)$ by N_2, CO, and CO_2 again increase with a decrease in Δ. Thus,

a) Ref. 1.

by analogy with the case of $Zn(^3P_J)$, it is reasonable to consider that the charge-transfer mechanism may be valid for $Zn(^1P_1)$.

As is shown in Table 3, $Zn(^3P_J)$ is quenched efficiently by the isotopic hydrogens. The difference between the quenching cross-sections of $Hg(^3P_0)$ and $Hg(^3P_1)$ by hydrogen has been explained simply by the difference in the energy content.[4] If the cross-sections are of a comparable magnitude for the quenching of the ^3P_J states of zinc and for those of cadmium by hydrogen, the cross-sections for $Hg(^3P_1)$ should be compared with half those for $Zn(^3P_J)$ and $Cd(^3P_J)$.[6] It can be said that the cross-sections of $Cd(^3P_1)$, $Zn(^3P_1)$, and $Hg(^3P_1)$ increase in this order; this order is consistent with the order of the excitation energy of metal atoms.

In a previous letter,[6] we discussed the isotope effects on the quenching of $Zn(^3P_1)$, $Cd(^3P_1)$, and $Hg(^3P_1)$ by hydrogen in terms of the following processes:

$$Me^* + Q \underset{k_b}{\overset{k_a}{\rightleftharpoons}} (Me-Q)^* \begin{cases} \xrightarrow{k_c} \text{decomposition of Q} \\ \xrightarrow{k_d} \text{vibrational excitation of Q} \end{cases}$$

Here, $(Me-Q)^*$ denotes a short-lived intermediate. The quenching rate constant, k, becomes:

$$k = k_a\frac{k_c+k_d}{k_b+k_c+k_d} \quad (6)$$

For the quenching of $Hg(^3P_1)$ by H_2 and D_2, it was pointed out that k is nearly equal to k_a, since $k_c \gg k_b$ and $k_c \gg k_d$, for the energy content of the complex is large enough to decompose H_2 and D_2; therefore, it does not show a large isotope effect.[4,12] On the other hand, in the cases of $Zn(^3P_1)$ and $Cd(^3P_1)$ the excitation energies are smaller than the bond energies of H–H and D–D, and perhaps k_c is not large enough for us to neglect k_b and k_d; therefore, the overall quenching-rate constants probably depend on the values of k_c+k_d. (1) If $k_c \gg k_d$, the quenching rate depends on the rates of the decomposition of H_2 and D_2, and the isotope effect based on the difference in the zero-point energies of H_2 and D_2 should be observed. (2) If $k_c \approx k_d$ or $k_c < k_d$, no conclusive explanation for the isotope effects can be deduced, since we have no information about the isotope effects on k_d. In this case, the observed isotope effects might indicate that $k_d(D_2) \approx k_d(H_2)$ or $k_d(D_2) < k_d(H_2)$. Actually, the quenching cross-sections of $Cd(^3P_1)$, $Zn(^3P_1)$, and $Hg(^3P_1)$ increase in this order,

while the isotope effects decrease in this order.

Recently, Breckenridge and Renlund measured the quenching cross-sections of $Cd(^3P_J)$ and $Cd(^1P_1)$ by means of isotopic hydrogens and compared these cross-sections with those of other excited metal atoms.[1c] They pointed out that the adiabatic pathways from Me^*+H_2 to MeH+H provide a reasonable explanation of the quenching of excited zinc, cadmium, and mercury atoms by hydrogen. In Table 5 the ratios of the quenching cross-sections of H_2 and D_2 for $Zn(^1P_1)$, $Zn(^3P_J)$, $Cd(^1P_1)$, $Cd(^3P_J)$, and $Hg(^3P_1)$ are shown.

TABLE 5. ISOTOPE EFFECT ON QUENCHING CROSS-SECTIONS

Reaction	$\frac{\Delta H}{\text{kJ mol}^{-1}}$	$\sigma_q^2[H_2]/\sigma_q^2[D_2]$
$Zn(^1P_1)+H_2\rightarrow ZnH+H$	−209	
$+D_2\rightarrow ZnD+D$	−204	1.11
$Zn(^3P_J)+H_2\rightarrow ZnH+H$	−39	
$+D_2\rightarrow ZnD+D$	−33	1.20
$Cd(^1P_1)+H_2\rightarrow CdH+H$	−158	
$+D_2\rightarrow CdD+D$	−151	0.80
$Cd(^3P_J)+H_2\rightarrow CdH+H$	0	
$+D_2\rightarrow CdD+D$	5	1.95
$Hg(^3P_0)+H_2\rightarrow HgH+H$	−53	
$+D_2\rightarrow HgD+D$	−47	0.72
$Hg(^3P_1)+H_2\rightarrow HgH+H$	−74	
$+D_2\rightarrow HgD+D$	−68	1.08

In Table 5 are also shown the ΔH values for the processes:

$$Me^* + H_2(D_2) \longrightarrow MeH(D) + H(D)$$

where Me^* is the $^1P_1$ state for $Zn(^1P_1)$ and $Cd(^1P_1)$ and is the $^3P_1$ state for $Zn(^3P_J)$, $Cd(^3P_J)$, and $Hg(^3P_1)$. For $Cd(^1P_1)$, $Zn(^3P_1)$, and $Hg(^3P_1)$, the $Me^*+H_2(D_2)\rightarrow MeH(D)+H(D)$ processes are both exothermic; therefore, the quenching cross-sections show very little isotope effect. However, in the case of $Cd(^3P_1)$, the $Cd^*+H_2\rightarrow CdH+H$ reaction is thermoneutral, while the $Cd^*+D_2\rightarrow CdD+D$ reaction is slightly endothermic. Therefore, for $Cd(^3P_1)$ a little larger isotope effect is observed. This explanation corresponds to the more detailed one for Case (2) of our explanation.

As is shown in Table 5, for $Zn(^1P_1)$ the reactions are largely exothermic and the isotope effect is very little. These findings are consistent with the above explanation of Breckenridge.

Dielectric Properties of the Hydrogen-bonded Liquids. Steric Effects on Dielectric Properties in Glycerol and Acetylated Glycerols

Eiji IKADA,* Kousaku YAMAMOTO, and Michio ASHIDA

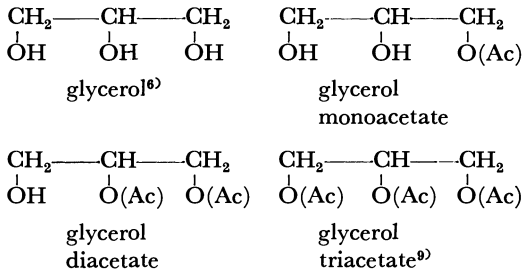
Faculty of Engineering, Kobe University, Nada, Kobe 657

(Received August 7, 1979)

The dielectric constant and the dielectric loss of a monohydroxy molecule (glycerol diacetate) and a dihydroxy molecule (glycerol monoacetate) in the pure liquid state were measured over the frequency range from 23 Hz to 3 MHz in order to elucidate the relation between the steric effects of the acetoxyl group and the dielectric properties of alcohols. For a better understanding, the results of this work were discussed together with those of glycerol and glycerol triacetate. The static dielectric constants decrease in the order of glycerol, glycerol monoacetate, glycerol diacetate, and glycerol triacetate. This order agrees with the order of the decreasing number of hydroxyl groups per molecule. On the other hand, the four curves of a temperature variation of the relaxation times almost form one curve, although the molecular weights and interaction, which are important factors for the determination of relaxation times, differ greatly among the four molecules. Accordingly, it is concluded that the decrease in molecular weight due to the replacement of the acetyl group CH_3CO by a hydrogen atom counteracts the enhanced molecular interaction due to the increased OH···O hydrogen bonds. The experimental Cole-Cole arcs of the complex dielectric constants were well represented by the calculated curve of the Davidson-Cole empirical equation, for glycerol mono- and diacetate as well as for glycerol.

The dielectric properties of a hydrogen-bonded liquid are of interest because such a liquid generally shows abnormal dielectric behavior which is not observed in a non-hydrogen-bonded liquid. With some exceptions, such as acetic acid, the static dielectric constant of a hydrogen-bonded liquid is generally larger than that for a normal polar one, mainly because of the regular alignment of a dipolar molecule in the hydrogen-bonded cluster.[1] The static dielectric constants of alcohols,[2] *N*-methylamides,[3] and cyano compounds[4,5] are particularly large.

Another typical phenomenon with regard to the dielectric properties for a hydrogen-bonded liquid is seen in the distribution of relaxation times. For example, it is well known that a Debye-type semi-circular relaxation is generally observed for a liquid monohydroxy alcohol; on the other hand, a Davidson-Cole-type skewed arc relaxation is observed for liquid polyhydric alcohols, such as diol and triol.[6] As for the relaxation of liquid dielectrics, we have ourselves reported that a Havriliak-Negami-type relaxation, often observed in the α-relaxation of polymers,[7,8] is observed in the relaxation of a non-hydrogen-bonded liquid.[9] This relaxation is not, however, observed in a hydrogen-bonded liquid. A number of dielectric studies have made it clear that the distribution of the relaxation times of organic liquids is associated with both the liquid structure and the molecular structure. In this study we have compared the dielectric properties of glycerol[6] and its acetylated derivatives as follows:



where Ac is the acetoxyl group.

Hitherto, there have been a number of studies of the dielectric properties of aliphatic mono- and polyhydric alcohols,[10] such as ethanol and pentanediol, however, little is known about the dielectric properties of the substituted alcohols.

Experimental

Purification of Glycerol Monoacetate and Diacetate. The glycerol monoacetate (Eastman Kodak Co.) and the glycerol diacetate (Merck Co.) are both commercial products, and both are mixtures composed of glycerol monoacetate, diacetate, and triacetate. Therefore, it is necessary to separate the mixtures into pure fractions. The fractional distillation under reduced pressures was, however, ineffective for this purpose. Next, a chromatographic column method was tested and adopted. Here, the packing gel was Wako Gel C-200 (Wako Chemical Co.), and the mobile phase used as the developer was a mixture of benzene and methanol, in a ratio which was continuously changed. The results of separation were examined by means of GLPC.

Dielectric Measurement. The dielectric constant and dielectric loss were measured with a ratio-arm transformer bridge (Ando Electric Co., TR-1BK type) over the frequency range from 23 Hz to 3 MHz. The dielectric cell for the liquid studied was a platinum concentric glass cell.

Results and Discussion

Static Dielectric Constant. The dielectric properties of glycerol and glycerol triacetate have been studied by Davidson and Cole[6] and by Ikada and Watanabe[9] respectively.** For comparison, the data have been cited from each reference. The temperature dependence of the static dielectric constant of all four molecules in the liquid state is represented by the linear relation shown in Fig. 1. We, however, recognize a marked variation in the values with the number of hydroxyl

Ras and Bordewijk also studied the dielectric properties of glycerol triacetate, tripropionate, and tributyrate (A. M. Ras and P. Bordewijk, *Recl. Trav. Chim. Pays-Bas*, **90, 1055 (1971)).

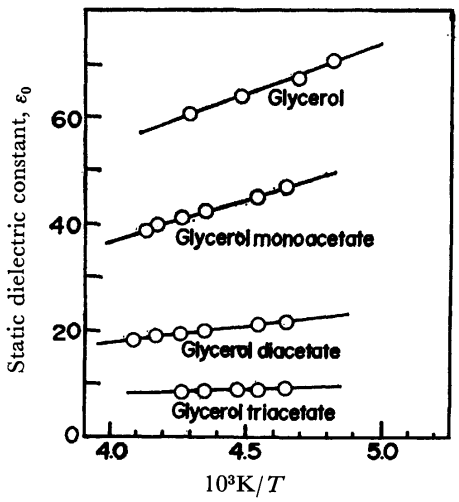


Fig. 1. Temperature dependence of the static dielectric constants of the four liquids. The data of glycerol and glycerol triacetate were cited from Ref. 6 and Ref. 9, respectively.

group per molecule, as the static dielectric constants for glycerol, *ca.* 60, are very large, while, on the other hand, those for glycerol triacetate are less than 10. Doubtless, this step-by-step variation in the static dielectric constant depends mainly on the number of intermolecular hydrogen bonds in each liquid structure, although the detailed conformation of the hydrogen-bonded cluster is not yet known. Strictly speaking, it is necessary to determine the dipole moment *in vacuo* of these molecules for a quantitative estimation of the local ordering due to hydrogen bonds in the liquid structure.[10] However, we can easily see a gradual decrease in the intermolecular hydrogen bonds with an increase in the replacement of a hydroxyl group by a non-hydrogen bonding acetoxyl group. For example, the static dielectric constants of glycerol diacetate are smaller than those for a monohydroxy aliphatic alcohol with the same main chainlength, such as 1-propanol. This decrease in the static dielectric constant of glycerol diacetate proves that the molecular association is destroyed by the hindrance of the large acetoxyl group on forming the hydrogen-bonded cluster.

Dielectric Relaxation. As for the relaxation mechanism of liquid normal alcohols, which has been discussed by many investigators and summarized in many books,[1,10] the explanation is explicit and seems to be well recognized. The proton jump along a hydrogen-bonded chain of monohydric alcohols clarifies the absence of any distribution of the relaxation times. On the other hand, the relaxation mechanism in such polyhydroxy compounds as glycerol appears to remain undetermined, partly because of difficulty in the structural analysis of liquid polyols. The contribution of the hydrogen bond to the dynamic properties of the polyhydric alcohol is apparent in the comparatively high viscosities of the liquids. In other words, the long relaxation times in polyols are due to the accompanying breaking and reforming of the hydrogen bonds on the molecular relaxation. Moreover, the fact that almost all the polyhydric aliphatic compounds show merely the Davidson-Cole-type relaxation in the liquid state makes us imagine a rather similar relaxation mechanism for the molecular motion in these molecules. However, the relaxation mechanism of polyol compounds has not yet been thoroughly clarified in detail. Almost all of the polyols show empirically the Davidson-Cole-type relaxation:[6]

$$\varepsilon^* - \varepsilon_\infty = \frac{\varepsilon_0 - \varepsilon_\infty}{(1+j\omega\tau_0)^\beta}$$

where ε^* is the complex dielectric constant, ε_0 and ε_∞ are the limiting low- and high-frequency dielectric constants respectively, ω is the angular frequency, τ_0 is the mean relaxation time, j is $\sqrt{-1}$, and β is the distribution parameter. As has been described above, Davidson and Cole reported that glycerol shows a Davidson-Cole-type relaxation.[6] On the other hand, glycerol triacetate, a completely acetylated glycerol, does not show this relaxation, but a Havriliak-Negami-type relaxation:[9]

$$\varepsilon^* - \varepsilon_\infty = \frac{\varepsilon_0 - \varepsilon_\infty}{[1+(j\omega\tau_0)^{1-\alpha}]^\beta}$$

where $1-\alpha$ is also the distribution parameter of the relaxation times. The distribution of the relaxation times of glycerol triacetate is wider than that for glycerol, as may be seen in Table 1. The broadening of the relaxation times results from the lack of a hydrogen bond in the liquid structure. The same broadening may be seen in a comparison of the dielectric properties of ethylenediamine and 2-aminoethanol.[12]

Table 1. Distribution parameters $(1-\alpha)$ and β in the Davidson-Cole and the Havriliak-Negami-type relaxations

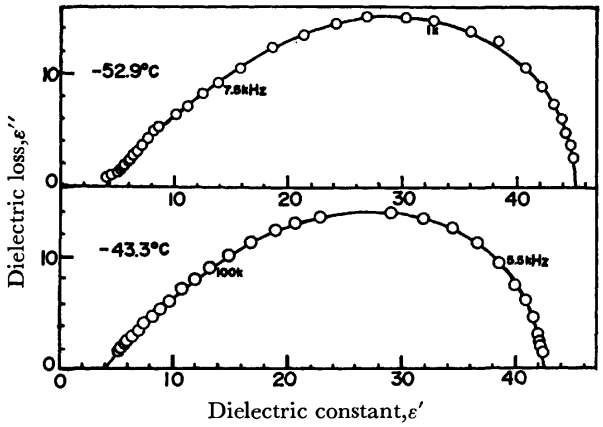

Fig. 2. Cole-Cole plots of glycerol monoacetate.

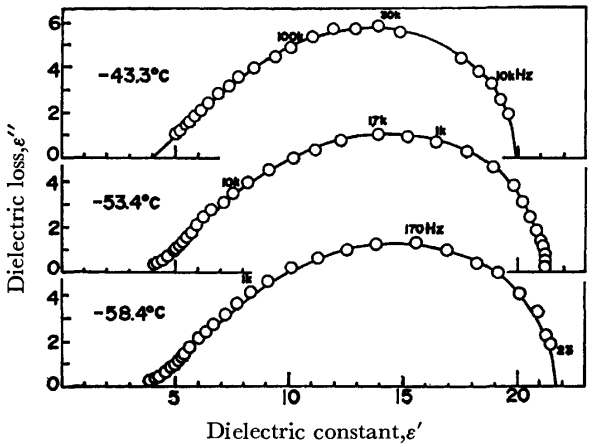

Fig. 3. Cole-Cole plots of glycerol diacetate.

Figure 2 shows the Cole-Cole plots of glycerol monoacetate. The experimental arcs agree well with the curves calculated according to the Davidson-Cole equation. It may, therefore, be concluded that the liquid structure of glycerol monoacetate is not so different from that of glycerol and that the steric hindrance of large CH_3CO–group in this molecule for hydrogen bonding is not so clearly seen. Figure 3 shows the Cole-Cole plots of glycerol diacetate. As may clearly be seen in this figure, these relaxations are expressed by the Davidson-Cole empirical equation. According to our expectations, glycerol diacetate, a monohydric alcohol, should show a Debye-type semicircular relaxation. The result fell short of our expectations, however. Judging from the small static dielectric constants, the hydrogen bonds in glycerol diacetate are much fewer in number than in normal alcohol. On the other hand, glycerol triacetate shows a Havriliak-Negami-type relaxation. The hydrogen bond in glycerol diacetate also contributes to the narrowing of the relaxation times.

Relaxation Times. Empirically, it is considered to be correct that the dielectric relaxation time of an organic molecule in the liquid state depends on the molecular size and weight. Figure 4 shows the relaxation times against the reciprocals of the absolute temperatures. The esterification of the hydroxy group by

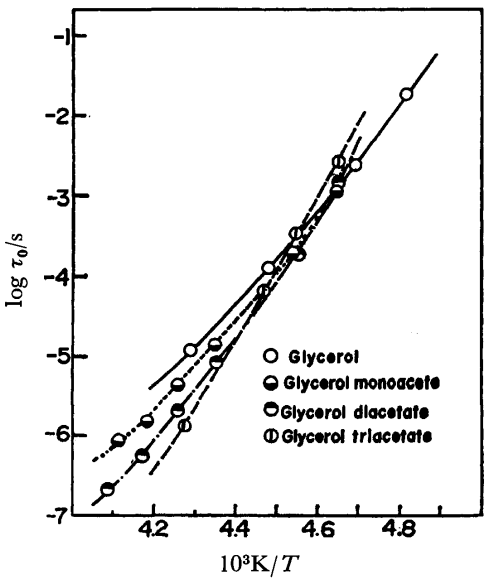

Fig. 4. Arrhenius plots of the relaxation times of the four glycerols. The unit of relaxation times is second.

acetic acid in glycerol leads to a large increase in the molecular size and weight. Nevertheless, the relaxation times do not increase, as is seen in Fig. 4, so much as would be expected from the molecular weight increase.

Another important factor determining a relaxation time is a molecular interaction such as an intermolecular hydrogen bond. The dielectric relaxation of a hydroxy compound in the liquid state generally appears at low frequencies because of this comparatively strong interaction. Thus, the esterification should also lead to a decrease in the intermolecular hydrogen bonds in the liquid structure, and consequently to a decrease in the relaxation times. Figure 4, however, does not show this anticipated tendency; Rather, it shows the four molecules to have almost the same values of relaxation times. The hidden effect due to the change in two important factors, *i.e.*, the molecular weight and the interaction, explains why the relaxation times of the four molecules do not change very much, although the two factors change markedly upon the replacement. The answer is thus given that the two effects counteract each other; therefore, apparently the relaxation times do not differ largely.

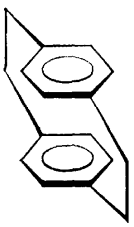
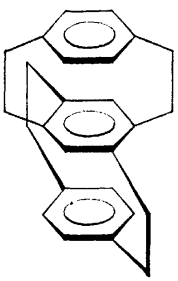
(Received August 13, 1979)

The measurements of enthalpies of combustion by use of precision oxygen-bomb combustion calorimeter together with the measurement of carbon dioxide recovery were made for double- and triple-layered [2.2]paracyclophanes. The enthalpies of sublimation were also determined by the measurement of temperature dependence of the vapor pressures for the two compounds. The following values are reported for the standard enthalpy of combustion ΔH_c°(298.15 K)/kJ mol^{-1} and standard enthalpy of sublimation ΔH_s°(298.15 K)/kJ mol^{-1}, respectively: double-layered [2.2]paracyclophane, 8729.48$\pm$1.80, 99.6$\pm$1.8; triple-layered [2.2]paracyclophane, 14230.87 $\pm$3.59, 125.9$\pm$2.5. From analyses of the derived standard enthalpy of formation in gaseous state the following two values for total strain energy U_S/kJ mol^{-1} of a molecule of triple-layered [2.2]paracyclophane were obtained: 251.9$\pm$5.6 with group method and 245.6$\pm$9.8 with chemical similarity method, respectively. These values are approximately twice the magnitudes of the corresponding quantities for double-layered [2.2]paracyclophane. From the analysis of the total strain energy by use of the result of Boyd's molecular mechanical calculation, the contribution from the twisting of the inner benzene ring to the total strain energy of triple-layered [2.2]paracyclophane was estimated to be almost twice that from one outer bent benzene ring.

Molecular and crystal structures of double-layered [2.2]paracyclophane (**1**) have been studied by X-ray diffraction method first by Brown,[1] and later reinvestigated by Lonsdale *et al.*,[2] by Bekoe *et al.*[3] and by Hope *et al.*[4] The various striking features in the molecular structure of **1** are as follows: (i) bent aromatic rings, (ii) short contact between aromatic rings, (iii) out-of-plane deformation of methylene carbon and aromatic hydrogen atoms from the plane defined by the nearest and next-nearest three aromatic carbon atoms, and (iv) eclipsing of bridge methylene groups. These features are considered to be resulted, directly or indirectly, from trans-annular π-electron repulsion in the molecule. Hope *et al.*[4] have shown that in the ordinary temperature phase of the crystal each molecule is statistically disordered to simulate a dynamic disorder that occurs by a twist of the aromatic rings with the amplitude of 3° in opposite directions about their common normal. Additional support for the twist can be found in spectroscopic[43] and thermal[28] results.



Compd. 1



Compd. 2

Standard enthalpy of formation of **1** in the crystalline state has been reported by Boyd[5] and by Rodgers *et al.*[6] A significant difference of 9.4 kJ mol^{-1} has been found between these two values. Enthalpy of sublimation has been determined for this compound by Boyd[5] from the measurement of vapor pressure as a function of temperature. Strain energy has been estimated by Boyd[5] and by Rodgers *et al.*[6] from standard enthalpy of formation in gaseous state thus evaluated.

Boyd has also made calculation for this molecule based on a molecular mechanical method,[7] which enables simultaneous determination of molecular geometry, strain energy and thermodynamic quantities. Kao and Allinger[8] have applied a combined molecular orbital-molecular mechanics method to this molecule. They derived 199.2 kJ mol^{-1} for the standard enthalpy of formation in gaseous state which is significantly lower than both of the corresponding experimental values reported by Boyd[5] and by Rodgers *et al.*[6] and harboured a suspicion that the experimental results might be inaccurate. Lindner[9] also calculated standard enthalpy of formation for this compound in gaseous state by using a similar method.[10]

Molecular and crystal structures of triple-layered [2.2]paracyclophane (**2**) itself have not been reported. However, those for 1,4-bromo derivative of triple-layered [2.2]paracyclophane (**3**)[11] and for 4,4′,7,7′-tetramethyl-substituted centrosymmetric quadruple-layered [2.2]paracyclophane (**4**)[12] have been studied by X-ray diffraction method. While outer aromatic rings in these molecules are boat-shaped, inner aromatic

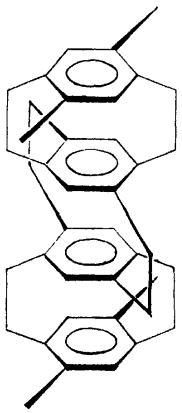
Compd. 3



Compd. 4

rings are twisted by two upper and two lower methylene bridges. Most of the remaining anomalous features present in the molecule of **1** are found also in these molecules. It seems to be highly probable that the molecular geometry of **2** is similar to that of **3**. No thermodynamic study has been reported for this compound.

The present study has been carried out to examine the validity of the suspicion presented by Kao and Allinger[8] on the reported experimental results of **1** and to estimate the strain energy of **2**.[13] For this purpose, standard enthalpies of formation of **1** and **2** in the crystalline and gaseous states have been determined by bomb combustion calorimetry and by the measurement of temperature dependence of vapor pressure.

Experimental

Materials. Compound **1** was prepared by 1,6-Hofmann elimination method according to Winberg *et al.*[14] and purified by successive operations of gel-permeation liquid chromatography, recrystallization from chloroform (twice) and finally sublimation under vacuum (*ca.* 0.1 Pa).

Compound **2** was prepared as previously reported[15] and purified by gel-permeation liquid chromatography and then recrystallization from toluene solution (three times).

Combustion Calorimetry. An isoperibol precision rotating bomb calorimetric system described elsewhere[16] was used in this study without rotating the bomb. The following minor modifications were made on the calorimetric system after the publication of the previous paper: (1) The vacuum tube jacket temperature controller was replaced with a solid state device with proportional, integral and derivative actions. (2) The cooling device of the jacket water using ice was substituted with a refrigerator using semi-conductor Peltier elements which could supply cold water thermostatted within ± 30 mK. (3) The "Teflon" gasket for bomb-sealing was replaced with a rubber "O" ring. (4) The two unified connector-valves on the lid of the bomb using "Swagelok" fittings were replaced with the ones in which rubber "O" rings were used for sealing. (5) For connecting four lead wires to the calorimeter can, pin-connectors were used in place of soldering. (6) The oil-sealing of the calorimeter can were omitted to allow moderate vaporization of calorimeter water.

The calorimeter was calibrated by burning thermochemical standard benzoic acid (N.B.S. SRM-39i) under the standard bomb conditions.[17] The calibration experiments were interspersed between combustion experiments. Energy equivalents for the standard calorimetric system were derived from seven and eight calibration experiments for **1** and **2**, respectively. Mean and standard deviation of the mean were (15162.26 ± 1.08) J K^{-1} and (15164.06 ± 0.48) J K^{-1} for **1** and **2**, respectively.

Compound **1** was pressed into pellets by using a hand-press and an ordinary unevacuable die-set. The pellets exhibited a tendency to explode when partly burnt in the bomb. A deep crucible with a baffle described previously[18] was used for this compound.

Compound **2** was pressed into pellets by using a pellet press and a die-set usually used for making a KBr disk in infrared spectrometry. The pellets were burned in an ordinary platinum crucible. In two of experiments, a pellet of benzoic acid (thermochemical standard) weighing *ca.* 0.2 g was placed upon and under the pellet of the compound, respectively. In any experiments, a pellet of the compound did not explode when burned and significant amount of carbon monoxide was not detected from the bomb gas after combustion. However, the formation of a small amount of soot was observed in the crucible in every experiment.

In order to examine the completeness of combustion and/or the purity of a sample, carbon dioxide recovery was determined by the method developed by Rossini.[19] The absorption tube used in this study is shown in Fig. 1, which is similar in design to Pilcher's.[20] Ascarite (A.H. Thomas & Co., Ltd.) was used as an absorbent of carbon dioxide. In order to capture a small amount of water, which might be removed from the Ascarite layer, a small amount of Anhydrone

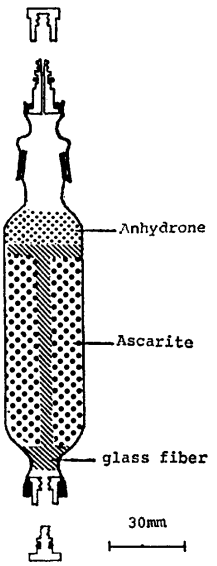


Fig. 1. Absorption tube for carbon dioxide analysis.

(Nakarai, S.P.R.) was placed next to the Ascarite layer. Heart of the absorption tube is the use of a small bundle of glass fiber placed from the inlet through the central portion of the Ascarite layer. The bundle of glass fiber exhibited a significant effect to secure the passage of bomb gas even after more than a half amount of Ascarite had lost its ability to absorb carbon dioxide. The ground glass joint was sealed with picein cement. The use of "O" ring along with metal connectors served to keep the absorption line leak-proof without loss of simplicity of experimental procedures. The flow rate of the gas liberated from the bomb was adjusted to *ca.* 2 $cm^3 s^{-1}$ with a needle valve. The gas was dried thoroughly by passage through the first absorption tube where Anhydrone was packed. The dried gas was then introduced into the second absorption tube, in which Ascarite was packed, and then examined for carbon monoxide by a detector tube (Kitagawa carbon monoxide detector type C, Kōmyo-Rikagaku Co., Ltd.) and finally released to air.

Before the analysis, the absorption train was flushed with oxygen. The carbon dioxide absorption tube was then disconnected, both the inlet and the outlet being closed, and the outer surface was cleaned with a piece of wiping paper wetted with ethyl ether, and then the tube was allowed to stand for 30 minutes. Just before weighing, pressure inside the tube was equalized with outside one by opening the gas inlet instantly. The tube was weighed and connected again to the train to start the absorption of carbon dioxide. After the pressure in the bomb decreased to atmospheric pressure, the bomb was flushed with oxygen (*ca.* 10 dm^3) at the average flow rate of 2 $cm^3 s^{-1}$. This flushing was performed to purge carbon dioxide in the gaseous and liquid phases completely. The absorption tube was then removed from the train and weighed in the same way as before.

From apparent increase in mass of the absorption tube Δm(tube), true mass of carbon dioxide captured, $m(CO_2$, obsd), was calculated by the following expression given by Rossini:[19]

$$m(CO_2, \text{obsd}) = 1.00045 \times \Delta m(\text{tube}).$$

In order to examine the validity of the results obtained by the procedure described above, combustion products of the calibration experiments were also analyzed. Carbon dioxide recovery defined as ratio of recovered to calculated masses of carbon dioxide $m(CO_2$, obsd$)/m(CO_2$, calcd) for successful seven analyses of the calibration experiments is as follows: 1.0000, 0.9997, 1.0002, 0.9999, 0.9999, 1.0001 and 1.0000. Mean and standard deviation of mean were 1.0000 ± 0.0001.

The CO detector is capable of detecting the concentration range of 0 to 3 ppm. Presence of carbon monoxide at the level of 3 ppm gives rise to an error of only 0.0015% in the standard energy of combustion.

Ordinary eight minutes flushing of the bomb prior to charging it with oxygen was sufficient to suppress the amount of nitric acid to a level less than 10^{-5} mol as the substances burned in this study contained no nitrogen. The nitric acid was determined spectrophotometrically using a UV absorption band at 202 nm.[21]

Determination of Sublimation Enthalpy. Enthalpies of sublimation were determined from temperature dependence of vapor pressure. Vapor pressures were measured by using a DuPont model 916 Thermal Evolution Analyzer which was a plug-in module of DuPont 990 Thermal Analysis System. The measurement is based on the gas saturation method in which a flame ionization detector (FID) is used to detect organic vapor present in carrier gas (usually nitrogen).[22]

A small amount (*ca.* 10 mg) of sample was placed in a cylindrical metallic cell with a small hole at the center of the lid together with silver granules used for improving heat conduction. The cell was inserted in a "Vycor" glass tube placed in a temperature-regulated furnace and the carrier gas was allowed to flow at a constant rate only outside the cell. FID current was then recorded. After thermal equilibrium was found to be established in the cell from the recorder trace, a small portion of the carrier gas was allowed to flow through the cell, while the total flow rate was kept constant. Organic vapor ran out through the hole into external carrier gas flow and the FID current increased. After saturation of the internal carrier gas flow with organic vapor was confirmed from the recorder trace, the carrier gas flow pattern was restored. Change in the FID current caused by changing the flow pattern was determined as a function of temperature. The change in the FID current was assumed to be proportional to saturated vapor pressure of the compound at that temperature and logarithm of it was plotted against reciprocal temperature. From the slope of the derived straight line, sublimation enthalpy at a mean temperature was obtained on the basis of the second law method.

The reliability of the method was examined by using naphthalene (Kishida Chemicals, SMA-SP-16) as a test substance in accordance with the recommendation of IUPAC.[23] The naphthalene sample is an organic micro-analytical standard sample certified by the Sub-committee of Organic Microanalysis of the Japan Society for Analytical Chemistry. Enthalpy of sublimation was derived from the vapor pressures in the range 301.8 to 347.2 K (fourteen measurements). The enthalpy of sublimation 70.7 kJ mol^{-1} at 324.5 K was reduced to the value at 298.15 K using heat capacities for gaseous[24] and solid[25] states. Enthalpy of sublimation at 298.15 K obtained in this way was 71.7 kJ mol^{-1}, while the value recommended by IUPAC[23] is 72.5 ± 0.25 kJ mol^{-1}. Accordingly, uncertainty of ± 1.5 kJ mol^{-1} was assigned tentatively to values obtained in this study.

Table 1. Auxiliary quantities

a) Estimated value.

Auxiliary Quantities. Experimental results in this paper are based on 1961 atomic weights. Auxiliary data adopted in the calculation of molar standard enthalpies of combustion ΔE_c°, *i.e.* the composition formula and the values (for 298.15 K) of density, ρ, of specific heat capacity, c_p, and of compression energy, $(\partial E/\partial p)_T$, for the combustible substances, are given in Table 1. The values for **1** were taken from Ref. 6. The density **2** was determined from the dimension of a pellet of known mass. Other auxiliary quantities are also collected in the table. Uncertainties are uncertainty intervals defined by Rossini,[26] unless otherwise stated.

Standard energies and enthalpies of combustion given in this paper refer to the following idealized combustion reaction at 298.15 K:

$$C_aH_b(c) + (a+b/4)O_2(g) = aCO_2(g) + (b/2)H_2O(l),$$

where $a=16$, $b=16$ for **1** and $a=26$, $b=26$ for **2**.

Results

Combustion Calorimetry. Results of typical combustion experiments for **1** and **2** are given in Table 2.

a) CO_2 analysis was unsuccessful. b) $m(CO_2, obsd)$ and $m(CO_2, calcd)$ are observed and calculated masses of carbon dioxide for the total of combustible substances in the bomb, respectively.

Of thirteen combustion experiments on **1**, eight gave at least reasonably reliable calorimetric data. In Table 3, results of the successful experiments are summarized together with results of carbon dioxide and monoxide analyses and also with remarks on the presence of soot on the bomb wall after combustion. In no experiments in Table 3, soot was found in the crucible. Numerical values of ΔE_c° given in Table 3 are calculated on the basis of masses of samples.

In the previous letter,[13] the values of ΔE_c° for five experiments (No. 3, 4, 5, 6, and 11), in which no soot formation was observed and carbon dioxide recovery was not less than 99.85% (in the cases where the analysis was successful) have been used to calculate mean and standard deviation of the mean to obtain the following result: $\Delta E_c^\circ = -(8717.13 \pm 1.33)$ kJ mol^{-1} (Procedure I).

Discrepancy between the values of ΔE_c° reported by Boyd[5] and Rodgers *et al.*[6] amounted to only 9.4 kJ mol^{-1} (0.108% of the total) and carbon dioxide recovery higher than 99.90% was experienced only in two (No. 5 and 6) of the experiments given in Table 3. From these viewpoints, re-examination of the results of combustion calorimetry by different procedures seems to be desirable in order to estimate a correct value of ΔE_c° more confidently.

Use of results of experiments No. 5, 6, and 11, where no soot formation was observed and carbon dioxide analysis was successful, instead of the five results used in Procedure I, leads to the following result: $\Delta E_c^\circ = -(8716.20 \pm 0.29)$ kJ mol^{-1} and $m(CO_2, obsd)/m(CO_2, calcd) = 0.9991 \pm 0.0002$, where uncertainties are standard deviation of mean(Procedure I'). This Presult differs little from that of Procedure I. The carbon dioxide recovery is not satisfactorily high enough to allow for the precise estimation of a correct value for ΔE_c°. It appears to be reasonable to assume that the above-mentioned value gives a lower limit of possible ΔE_c° values.

One of possible procedures is to calculate the individual numerical values of ΔE_c° based on carbon dioxide recovery. Mean and standard deviation of the mean calculated in this way from the results of six experiments where the analysis was successful are as follows: $\Delta E_c^\circ = -(8726.21 \pm 1.33)$ kJ mol^{-1} (Procedure II). This procedure would be favorably applicable if a sample contaminated with incombustible impurities, such as water, was completely burnt or incompletely burnt in the sence that part of the sample remained unchanged after a combustion experiment. The same would hold if a pure sample was burnt incompletely in the same sence as described above. However, the present sample is not likely to be contaminated with incombustible impurities in view of the method of purification and possible impurities, if present, would be organic in nature. In addition to this, soot on the bomb wall is the product of the most significant side reaction. The numerical value of the mean given by Procedure II would therefore give an upper limit of possible ΔE_c° values.

Another possible procedure is to apply a least-squares analysis for the results of experiments to which Procedure II has been applied, to get ΔE_c° as a linear function of carbon dioxide recovery, $[m(CO_2, obsd)/m(CO_2, calcd)]$ (Procedure III). Derived linear function is as follows: ΔE_c°/kJ mol^{-1} $= -3669.00\,[m(CO_2, obsd)/m(CO_2, calcd)] - 5050.56$. Extrapolation of the function to $[m(CO_2, obsd)/m(CO_2, calcd)] = 1$ leads to the following result: $\Delta E_c^\circ = -(8719.56 \pm 0.56)$ kJ mol^{-1}, where uncertainty is standard deviation. In this procedure, results of, rigorously speaking, more or less incomplete combustion experiments for a sample of unknown purity are extrapolated practically to complete combustion of a pure sample. This procedure appears to the authors to be more reasonable than the other ones.

Consequently, the numerical value estimated by Procedure III was adopted as a correct ΔE_c° value for **1**.

Six of seven experiments on **2** were successful. The results are summarized in Table 4. The more complete combustion was achieved in general than for **1** possibly because of improvement in the preparation of the pellets, although a small amount of soot was found in the crucible after every experiment. The numerical values of ΔE_c° given in Table 4 are calculated on the basis of the masses of samples and corrected for soot formation by using ICSU-CODATA key value for

Table 4. Summary of combustion calorimetric results for triple-layered [2.2]paracyclophane

Exp. No.	$-\Delta E_c^\circ$(c)[a] / kJ mol^{-1}	$m(CO_2$, obsd)[b] / $m(CO_2$, calcd)	$10^6 x$ (CO)	m(soot) / mg

2	14208.94	0.9994(0.9997)	0.2	0.14
3	14217.38	———(———)[e]	0	0.14
4	14212.18	0.9990(0.9993)	0.6	0.17
6	14214.52[d]	0.9986(0.9991)	0.9	0.26
7	14210.88[d]	0.9984(0.9987)	0.1	0.16
mean and sdm[c]	14214.76±1.65	0.9992±0.0004 (0.9995±0.0003)		

a) Corrected for soot formation. b) Numerical values in parenthesis are corrected for soot. c) Standard deviation of mean. d) Benzoic acid was used as an auxiliary substance. e) CO_2 analysis was unsuccessful.

$\Delta H_f^\circ(CO_2, g)$.[27] The correction amounted to −8.52 kJ mol^{-1} (0.085% of the total) for an extreme case and to −5.57 kJ mol^{-1} in average. As an error was found in the calculation of the soot correction given in the previous letter,[13] ΔE_c° values are increased by 4.61 kJ mol^{-1} in comparison with the previous values. Corresponding revisions were made also on the numerical values of ΔH_c°(c) and ΔH_f°(c). As no significant difference was observed between the results of experiments with and without the use of benzoic acid as an auxiliary substance, all the values in Table 4 were used equally to calculate the mean value.

Enthalpy of Sublimation. Plots of log h against reciprocal temperature T^{-1} are given in Figs. 2 and 3 for **1** and **2**, respectively, where h is the increase in FID current caused by changing the flow pattern of the carrier gas so that part of the carrier gas flows through the sample cell while keeping the total flow rate constant. Analyses of the experimental data by means of the

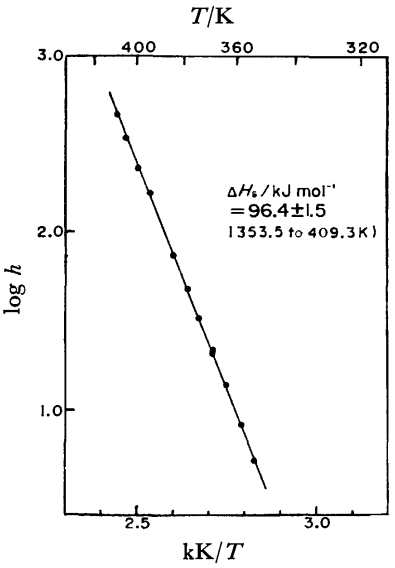

Fig. 2. Temperature dependence of vapor pressure of double-layered [2.2]paracyclophane in the crystalline state. Unit of FID current h, which is proportional to vapor pressure, is arbitrary.

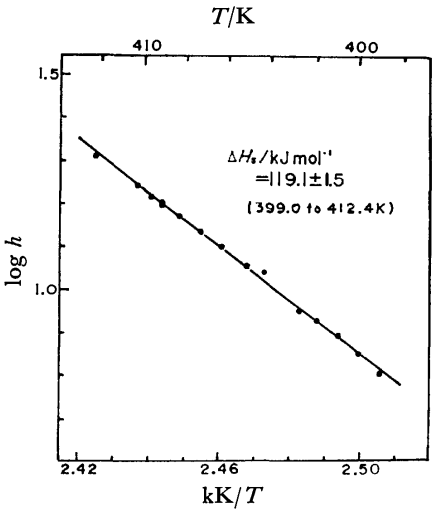

Fig. 3. Temperature dependence of vapor pressure of triple-layered [2.2]paracyclophane in the crystalline state. Unit of FID current h, which is proportional to vapor pressure, is arbitrary.

second law method gave the following enthalpies of sublimation at mean temperatures: 96.4±1.5 kJ mol^{-1} at 381.4 K and 119.1±1.5 kJ mol^{-1} at 405.7 K for **1** and **2**, respectively. Enthalpies of formation at 298.15 K were derived by use of the Kirchhoff's equation. For **1**, molar heat capacities of the gas calculated by Boyd[7] and those of the solid obtained by extrapolation of experimental heat capacities measured by Andrews and Westrum[28] were used in the calculation. For **2**, molar heat capacities of the gas and the solid were estimated from the corresponding values of **1** by assuming that specific heat capacity is of the same magnitude for both compounds. The corrections to 298.15 K amounted to 3.2±1.0 kJ mol^{-1} and 6.8±2.0 kJ mol^{-1} for **1** and **2**, respectively, where uncertainties were estimated arbitrarily.

Thermodynamic Quantities. Standard thermodynamic quantities at 298.15 K were calculated and summarized in Table 5. ICSU-CODATA key values[27] were used in the calculation of standard enthalpies of formation. Uncertainty for ΔE_c° of **2** was calculated as if all the combustion experiments were carried out by use of benzoic acid. So the result will be naturally overestimated.

Discussion

Comparison with Qiterature Values. The selected numerical value of ΔH_c° for **1** given in Table 5 is only by 2.21 kJ mol^{-1} more negative than the previously

Table 5. Thermodynamic quantities

	Double-layered [2.2]paracyclophane	Triple-layered [2.2]paracyclophane
$-\Delta E_c^\circ$(c)/kJ mol^{-1}	8719.56±1.80	14214.76±3.59
$-\Delta H_c^\circ$(c)/kJ mol^{-1}	8729.48±1.80	14230.87±3.59
ΔH_f°(c)/kJ mol^{-1}	146.69±2.77	283.82±4.96
ΔH_s°/kJ mol^{-1}	99.6± 1.8	125.9 ±2.5
ΔH_f°(g)/kJ mol^{-1}	246.3± 3.3	409.7 ±5.6

reported value of the authors[13] and lies between the values reported by Boyd[5] and by Rodgers *et al.*,[6] being closer to the latter. Both of the literature values are barely in the range of possible ΔH_c° values as estimated in the preceding section. It appears to be more reasonable and more consistent to employ the present value for the discussion in later sections, partly because the present value is substantiated by carbon dioxide analysis.

The present value for ΔH_s° at 298.15 K for **1** agrees with the Boyd's value 96.2 ± 4.2 kJ mol^{-1} [5] within the sum of assigned uncertainties. Re-examination of Boyd's experimental values of vapor pressure reveals that in the log p *vs.* T^{-1} plots one (at 373.10 K) deviates significantly from a straight line obtained by a least squares treatment of the remaining four values. Neglect of the deviated point leads to the following result (instead of reported 92.8 kJ mol^{-1}): $\Delta H_s^\circ = 94.2$ kJ mol^{-1} at 363 K. Furthermore, correction from 363 to 298.15 K was recalculated by using the (extrapolated) experimental molar heat capacities of Andrews and Westrum.[28] The correction amounted to $+2.5$ kJ mol^{-1}. Enthalpy of sublimation at 298.15 K thus calculated is (96.7 ± 4.2) kJ mol^{-1}, where uncertainty is unchanged from the original one. This value is close to Boyd's original value. Method and apparatus used in the present determination of ΔH_s° were examined as described in the preceding section, while no description is found in Boyd's papers.[5,29] Hence, the present value has been adopted to calculate the value of ΔH_f°(g).

Standard enthalpy of formation for gaseous **1** derived in this study is 246.3 ± 3.3 kJ mol^{-1}, which is 47.1 kJ mol^{-1} more positive than the value predicted by Kao and Allinger[8] based on the combined molecular orbital-molecular mechanics method. Even if scatter of experimental values of ΔH_c° and ΔH_s° described above and their uncertainties were taken into consideration, the predicted value is definitely away from the range of possible ΔH_f°(g) values. Generally speaking, the method of Kao and Allinger[8] were successful in reproducing precisely experimental enthalpies of formation of a number of gaseous conjugated hydrocarbons, but the above-mentioned fact seems to reveal that the method has been applied, in this case, to a too highly strained molecule beyond the applicability limit. On the other hand, ΔH_f°(g) value deduced from Lindner's[9] calculated enthalpy of atomization† is 257 kJ mol^{-1}, which is rather closer to the present experimental value.

No literature values are available for ΔH_c° and ΔH_s° of **2**.

Estimation of Strain Energy of Triple-Layered [2.2]-Paracyclophane. Strain energy brought about in a molecule of **2** by the formation of two larger ring systems composed of aromatic rings and methylene groups was estimated by the following two different methods.

(i) Group Method. In order to estimate the total strain energy U_s, standard enthalpy of formation in gaseous state for a "strain-free" reference structure ΔH_f°(g, ref.) was calculated by means of the group increments given by Cox and Pilcher,[30] which, together with terms for steric effect from *ortho* alkyl groups, had been proved to account for standard enthalpies of formation in gaseous state of nineteen simple alkyl-substituted benzenes within ± 4 kJ mol^{-1}, and it was compared with experimental standard enthalpy of formation in gaseous state ΔH_f°(g, exp.):

$$U_s = \Delta H_f^\circ(\text{g, exp.}) - \Delta H_f^\circ(\text{g, ref.}) - 2RT \qquad (1)$$

The final term in Eq. 1 is the (PV) correction,[31] which is needed in *a priori* estimation of ring strain energy. In this paper, standard enthalpy of formation in gaseous state for the reference structure was calculated without inclusion of steric effect from *ortho* methylene groups. The resultant value of ΔH_f°(g, ref.) is 152.8 kJ mol^{-1} for **2** and substitution of this value in Eq. 1 gives 251.9 ± 5.6 kJ mol^{-1} for the total strain energy. Total strain energy for **1** calculated similarly amounts to 126.0 ± 3.3 kJ mol^{-1}, which is of a half magnitude in comparison with the corresponding value for **2**.

(ii) Chemical Similarity Method. Another approach for estimating the total strain energy is to compare the reaction enthalpy for gas-phase homolytic hydrogenation-cleavage of four dimethylene bridges of **2** with four times the reaction enthalpy for the corresponding cleavage of the central C–C bond of 1,2-diphenylethane. The procedure, together with estimate of the total strain energy, is summarized in Table 6. Standard enthalpy of formation of gaseous toluene and xylene were taken from Ref. 32. The value of ΔH_f°(g) for 1,2-diphenylethane was calculated from standard enthalpy of formation in the crystalline state[32] and enthalpy of sublimation reported by Morawetz.[33] The value of ΔH_f°(g) for 1,2,4,5-tetramethylbenzene was calculated from standard enthalpy of formation for undercooled liquid at 298.15 K[34,35] and hypothetical enthalpy of vaporization at 298.15 K derived from Antoine equation analysis of liquid vapor pressures.[36] Derived strain energy 245.6 ± 9.8 kJ mol^{-1} is almost twice the value for **1**, 122.6 ± 5.4 kJ mol^{-1}, derived similarly. The strain energies calculated by this method agree with the corresponding values derived in the preceding section within the sum of uncertainties.

Analysis of the Total Strain Energy of Triple-Layered [2.2]paracyclophane. For **1**, Gantzel *et al.*[37] made an *a priori* estimation of total strain energy by using Brown's structure[1] and Whiffen's spectroscopic force constants.[38] Boyd[5] also made a similar analysis by using structure determined by Lonsdale[2] and force constants given by Kakiuti and Shimanouchi.[39] Later, Boyd[7] carried out a calculation based on molecular mechanics to determine molecular structure, strain energy and thermodynamic functions, simultaneously. The distribution of the total strain energy amounting to 147 kJ mol^{-1} among six parts thus determined is as follows: (i) out-of-plane deformation of aromatic rings, 43 kJ mol^{-1}; (ii) deformation of *para*-substituents, 35 kJ mol^{-1}; (iii) aliphatic bridge eclipsing, 29 kJ mol^{-1}; (iv) aliphatic bridge angle deformation, 3 kJ mol^{-1}; (v) aliphatic bridge bond stretching, 3 kJ mol^{-1}; and (vi) ring repulsion(non-bonded aromatic C···C), 34 kJ

† The quantity given if Ref. 9 as "Atomisierungenergie" is supposed to mean the enthalpy of atomization from the context of Refs. 9 and 10. The value 152.06 eV/molecule derived by the improved method II was employed in the calculation of the value in the text.

TABLE 6. SCHEME FOR ESTIMATING THE STRAIN ENERGY OF TRIPLE-LAYERED [2.2]PARACYCLOPHANE (2) BY CHEMICAL SIMILARITY METHOD

(i) Compd. **2** (g) + $4H_2$(g) = $2CH_3$-  -CH_3(g) +  (g)

ΔH_f°(g)/kJ mol^{-1}:	409.7±5.6	0	18.0±0.9	−48.1±2.0[a]

ΔH_r°(i) = −421.8±6.2 kJ mol^{-1}

(ii) 4  -CH_2CH_2-  (g) + $4H_2$(g) = 8 CH_3-  (g)

ΔH_f°(g)/kJ mol^{-1}:	143.0±1.8	0	50.1±0.3

ΔH_r°(ii) = −171.2±7.6 kJ mol^{-1}

Strain energy, $U_s = \Delta H_r^\circ(\text{ii}) - \Delta H_r^\circ(\text{i}) - 2RT$ = 245.6±9.8 kJ mol^{-1}

a) Assigned uncertainty

mol^{-1}. Rodgers *et al.*[6] suggested the necessity of downward revision for the value of item (iii), because two methylene groups eclipse completely in the final conformation determined by Boyd.[7] However, general agreement between the calculated and experimental structures and the calculated and experimental total strain energies is to be noted. Wynberg *et al.*[40] and Iwamura *et al.*[41] studied the stability of a bent benzene ring theoretically by molecular orbital methods.

In this paper, the total strain energy of **2** has been analyzed by dividing it into components in a similar way to that used in Boyd's molecular mechanical calculation.[7] The total strain energy of **2**, U_s, is expressed in a general form as follows:

$$U_s = 2U_1 + U_1^* + 2U_2 + 2U_2^* + 4U_3 + 4U_4 + 4U_5 + 2U_6 + 2U_7, \quad (1)$$

where U_1 is the contribution from the out-of-plane deformation of the outer aromatic ring, U_2, that from the deformation of the *para*-substituent on the outer aromatic ring, U_3, that from a pair of the eclipsing bridge methylenes, U_4, that from the deformation of the aliphatic bridge angle, U_5, that from the stretching of the aliphatic bridge bond, U_6, that from the repulsion between a pair of the aromatic rings, U_7, that from the repulsion between a pair of bridge methylenes bonded *ortho* with each other to the inner aromatic ring, U_1^*, that from the twisting of the inner aromatic ring, and U_2^*, that from the deformation of the substituent on the inner aromatic ring. Similarly, total strain energy of **1**, U_s', is expressed as follows:

$$U_s' = 2U_1' + 2U_2' + 2U_3' + 2U_4' + 2U_5' + 2U_6', \quad (2)$$

where U_i'(i=1∼6) are quantities corresponding to U_i(i=1∼6), respectively.

In Table 7, distances and angles which are relevant to the components of the total strain energies are compared among compounds **1**,[4] **3**[11] and **4**.[12] The symbols for distances and angles in Table 7 are schematically illustrated in Fig. 4. Similarity of the values for the parameters between **3** and **4** indicates that **3** can be a good model compound for **2** with respect to molecular structure. The values of parameters l_1, l_2, l_3, l_4, α, β, δ and ε for **1** are nearly equal to the corresponding values for **3**. This fact leads to an approximation that

$$U_i = U_i' \ (i=1\sim6) \quad (3)$$

In the preceding section, the following relation has been shown experimentally to hold:

$$U_s = 2U_s'. \quad (4)$$

From equations (1) to (4), the following expression is obtained:

$$U_1^* = 2U_1 + 2(U_2 - U_2^*) - 2U_7. \quad (5)$$

TABLE 7. COMPARISON OF MOLECULAR PARAMETERS RELEVANT TO STRAIN ENERGY COMPONENTS

Strain energy component[a]	Distance or angle[b]	Compound		
		Compd. **1**[4]	Compd. **3**[11]	Compd. **4**[12]
U_6, U_6'	l_1/nm	0.278	0.2744, 0.2753	0.2776, 0.2781
	l_2/nm	0.309	0.3061, 0.3047	0.3130, 0.3043
	l_3/nm	—	0.3184, 0.3192	0.3161, 0.3259
U_5, U_5'	l_4/nm	0.1562 (0.1593)[c]	0.1587, 0.1581	0.1581, 0.1597
U_1, U_1'	α/°	12.6	12.1, 12.3	12.5, 12.9
U_2, U_2'	β/°	11.2	10.9, 11.5	11.8, 10.8
U_2^*	β'/°	—	4.4, 6.7	6.5, 6.9
U_1^*	γ/°	—	13.6	13.4
U_4, U_4'	δ/°	113.7	111.6, 113.1	112.7, 112.0
	δ'/°	—	112.3, 111.8	111.5, 112.1
U_3, U_3'	ε/°	(6.4)[c]	6.8	8

a) For symbols, see the text. b) Symbols were defined as illustrated in Fig. 4. c) Distances and angles in compd. **1** have been determined less definitely due to the presence of molecular disorder in the crystal at room temperatures. Parenthesized values and the remaining values were calculated from parameters of Tables 7 and 1, respectively, of Ref. 4.

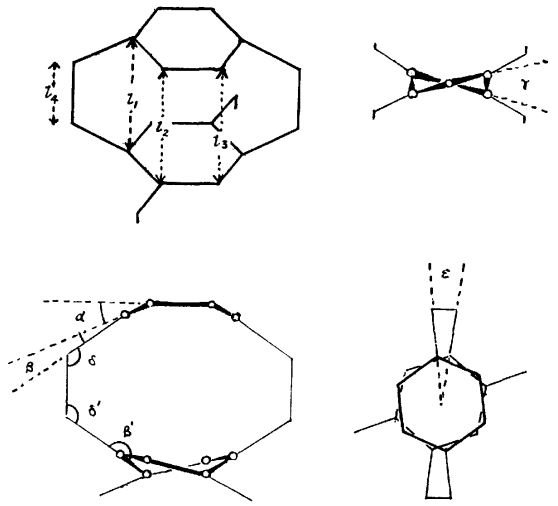

Fig. 4. Schematic illustration of interatomic distances and angles given in Table 7.

U_2* is estimated to be much smaller than U_2 on the basis of Boyd's definition of strain energy,[7] because a methylene carbon atom attached to the inner aromatic ring is significantly more coplanar with the adjacent three carbon atoms on one and the same aromatic ring than the one attached to the outer aromatic ring as shown in Table 7. The magnitude of U_7 is evaluated to be *ca.* 2 kJ mol^{-1} from extra contribution, assigned by Cox and Pilcher,[30] of a pair of *ortho* methyl and/or methylene groups to standard enthalpy of formation in gaseous state. Boyd's calculation[7] gave 21.5 and 17.5 kJ mol^{-1} for U_1' and U_2', respectively. From these considerations, the contribution from the twisted inner aromatic ring is estimated to be of more than two-fold magnitude as compared with that from the bent outer aromatic ring.

In the foregoing discussion, the contribution from transannular π-electron repulsion in **1** and **2** were assumed to be equal in magnitude. While this appears to be a sound approximation from the comparison of the values of l_1, l_2 and l_3 given in Table 7, there are evidences which indicate that the transannular repulsion is more enhanced in **2** than in **1**. Charge transfer bands in tricarbonylchromium,[42] tetracyanoethylene[15a] and 1,3,5-trinitrobenzene[15a] complexes of multilayered[2.2]-paracyclophanes show bathochromic shifts with the increase of the number of layers. Infrared bands for the tricarbonylchromium complexes associated with C=O stretching shift to lower frequencies with the increase of the number of layers. These facts show enhanced Lewis basicity of π-electrons with the increase of the number of layers, which reflects enhancement of the transannular π-electron repulsion. While there is little characteristic in the electronic spectra of multilayered [2.2]metacyclophanes in which transannular π-electron interaction is estimated to be much weaker than in [2.2]paracyclophanes due to small overlap of the aromatic rings, the electronic spectra of multilayered [2.2]paracyclophanes show marked bathochromic and hyperchromic shifts with the increase of the number of layers. This fact also suggests that the transannular π-electron repulsion is enhanced with the increase of the number of layers.

If this effect is taken into account, the contribution from the twisted inner aromatic ring is decreased correspondingly. While the magnitude of U_6' was evaluated to be 36 kJ mol^{-1} by Boyd, that of U_6 is still unknown at present. However, the difference between U_6 and U_6' is supposed to be small from the similarity of relevant nonbonding interatomic distances.

In conclusion, even if various approximations and suppositions made in the foregoing discussions were taken into consideration, it seems to be valid to argue that the twisted inner aromatic ring in triple-layered [2.2]paracyclophane molecule is at least more strained energetically than the bent outer ones, or that the contribution from the former ring to the total strain energy is approximately twice that from the latter ring. In other words, stabilization due to π-electron delocalization in the former ring is deteriorated at least more significantly than in the latter ring or possibly deteriorated by twice the magnitude as compared with that in the latter ring.

The authors are indebted to Dr. G. Pilcher of University of Manchester, England, and Dr. A. J. Head of National Physical Laboratory, England, for teaching the technique of carbon dioxide analysis to one of the authors (M. S.).

Calculations of g Tensors and Hyperfine Splitting Tensors for Molecules in Their Triplet States

Tetsuo MORIKAWA, Yasumasa J. I'HAYA,*,† and Junji NAKANO

School of Pharmaceutical Science, Toho University, Funabashi-shi, Chiba 274

†*Department of Materials Science, The University of Electro-Communications, Chofu-shi, Tokyo 182*

(Received August 14, 1979)

The g tensors and hyperfine splitting (hfs) tensors of simple organic radicals in their triplet states have been calculated by using an all valence electron SCF MO method with a first order perturbation treatment. The molecular orbital spin density is partitioned into the σ- and π-electron spin delocalization (SD) terms and the rest terms of spin polarization (SP) which arise from the CI effect. The g tensors for CH_2 and several other carbenes which have triplet ground states and for formaldehyde in its $n\pi^*$ and $n\sigma^*$ excited triplet states are evaluated. The calculated α-proton hfs constants of CH_2 contributing from the π orbital well compare with the observed hfs constants of the triplet naphthalene and the doublet malonic acid radical. The anisotropic carbon-13 hfs constants of CH_2 are determined almost completely by the SD contribution and their absolute values are in good accord with those observed for CD_2. Contribution of the SP terms to the isotropic hfs constant is found to be fairly large. Prediction of the hfs constants in CF_2 and CHF is made.

Theoretical investigation and prediction of the g tensors and the hyperfine splitting (hfs) tensors of organic radicals give us valuable information on molecular geometry, identification of excited states, spin-orbit interactions, and so on in the radicals. Since measurements of the g tensors of molecules in their triplet states by means of electron paramagnetic resonance (EPR) spectroscopy were first reported,[1] rigorous theoretical prediction of the g tensors has rarely been found in the literature. The pioneering series of work done by McWeeny[2] are of course important and more recent efforts are made by Dalgaard and Linderberg[3] with a theory of electron propagator and by Nakatsuji and Hirao[4] with a symmetry-adapted cluster expansion. However, most of theoretical calculations carried out hitherto have been focused the zero-field splitting constants by using the π-electron approximation.

Quite recently, accurate principal g values have become available with the improvement of the EPR technique. For example, the observed deviation of the g values of triplet deutero methylene CD_2 from a free electron g_e is very large (0.0027—0.0285)[5,6] in comparison with those of organic (doublet) free radicals, for example 0.0003 in the CH_3 radical.[7] The present paper first intends to analyze the g tensors of CH_2 and other carbene radicals in their triplet states. The methylene radical has two unpaired electrons, one in a σ MO and the other in a π MO, so that the radical is supposed to have a dual characteristic of σ and π radicals. By partitioning an MO set, a total spin density operator is expressed as a sum of the MO spin density operators for the σ and π MO's in which an odd electron is placed and higher order terms arising from the CI effect. The former yields σ and π electron spin delocalization effect that extends over the entire system and the latter the spin polarization effect. We also report the results of our calculation on the α-proton and carbon 13 hyperfine splitting (hfs) tensors for CH_2 and the carbon 13 and fluorine 19 hfs tensors for CF_2 and CHF.

Spin Density Analysis

A method of spin density analysis which will be described below is a traditional one but we show that the method can be applied to any kinds of molecules in their triplet states, though a way of construction of MO's is restricted by the symmetry of a molecule to be considered. The spin density of paramagnetic radicals will be analyzed by a partitioning technique for the spin density operators and the spin density matrices. In this connection, we try to obtain some useful concepts and relationships which will be able to elucidate properties of the spin density. The method will explore the mechanisms of spin polarization and spin delocalization in triplet molecules.

According to McConnell,[8] a normalized spin density function $\rho(x, y, z)$ at a spatial point x, y, z whose origin is suitably taken in a molecule is defined as

$$\rho(x, y, z) = S_z^{-1}\sum_k{}'\langle \Psi, \hat{S}_{zk}\Psi\rangle_k. \quad (1)$$

Here, Ψ is the complete wave function of a paramagnetic molecule, which is an eigenfunction of the total z component of the electron spin angular momentum operator $\hat{S}_z=\sum_k\hat{S}_{zk}$ with eigenvalue S_z, $\hat{S}_{zk}$ being the z component of spin angular momentum for electron k. The quantity $\langle\Psi, \hat{S}_{zk}\Psi\rangle_k$ denotes a matrix element to be calculated by integrating over the spin and space coordinates of all the electrons except the space coordinates of electron k. The prime on the summation symbol indicates that after the sum has been carried out the indices k should be dropped. Equation 1 shows that a quantity $\rho(x, y, z)$ gives an expectation value of $\hat{S}_z$ at point x, y, z. The circumflex symbol denotes an operator quality hereafter.

If one expands Ψ, a single determinant and/or a linear combination of them, in terms of orthonormal functions ϕ_i, one can write $\rho(x, y, z)$ in terms of the density matrix referred to these discrete bases, $\rho=[\rho_{ij}]$;

$$\rho(x, y, z) = \sum_{i,j}\rho_{ij}\phi_j^*\phi_i. \quad (2)$$

The spin density function is associated with the one-particle density matrix $\gamma_1(x'; x)$;[2]

$$\rho(x, y, z) = S_z^{-1}\int \hat{S}_{z1}\gamma_1(x_1'; x_1)d\tau, \quad (3)$$

which shows that if the so-called natural spin-orbitals are used to constract Ψ then $\rho(x, y, z)$ is diagonalized, though we will not follow this procedure. We can define a normalized spin density operator $\hat{\rho}$ by the relation

$$\langle\phi_i, \hat{\rho}\phi_j\rangle = \rho_{ij}, \quad (4)$$

or using Dirac's bra-ket notation we write

$$\hat{\rho} = \sum_{i,j}|\phi_i\rangle\rho_{ij}\langle\phi_j| = \sum_{i,j}\hat{\rho}_{ij} = \sum_{i,j}\rho_{ij}\hat{P}_{ij}. \quad (5)$$

The last equation of Eq. 5 indicates that $\hat{\rho}$ can be expanded in terms of the projection (the transition-projection in the strict sense) operators $\hat{P}_{ij}\equiv|\phi_i\rangle\langle\phi_j|$.

When one introdues a row matrix $|\phi\rangle\equiv[|\phi_i\rangle]$, Eq. 5 is written compactly as

$$\hat{\rho} = |\phi\rangle\boldsymbol{\rho}\langle\phi|. \quad (6)$$

If molecular orbital functions are chosen as the basis $\{|\phi_i\rangle\}$, the matrix $\boldsymbol{\rho}$ may be called an MO spin density matrix and $\hat{\rho}_{ij}$ an MO spin density operator for orbitals ϕ_i and ϕ_j. The total MO spin density operator $\hat{\rho}$ is of course self-adjoint and normalized to unity; $\mathrm{tr}(\hat{\rho})=\sum_i\rho_{ij}=1$.

If one employs another set of $|\chi\rangle$ whose elements $|\chi_\mu\rangle$ are linearly independent but not necessarily orthonormal, first one constructs a set of orthonormalized vectors $|e\rangle=|\chi\rangle\boldsymbol{S}^{-1/2}$ with $\boldsymbol{S}\equiv\langle\chi|\chi\rangle$ (Löwdin's symmetric orthonormalization[9]), then one obtains instead of Eqs. 5 and 6

$$\hat{\rho} = \sum_{\mu,\nu}|e_\mu\rangle\bar{\rho}'_{\mu\nu}\langle e_\nu| = \sum_{\mu,\nu}\hat{\bar{\rho}}'_\nu = e\rangle\bar{\boldsymbol{\rho}}'\langle e|. \quad (7)$$

Further if one puts $\boldsymbol{S}^{-1/2}\bar{\boldsymbol{\rho}}'\boldsymbol{S}^{-1/2}\equiv\bar{\boldsymbol{\rho}}$, then one has

$$\hat{\rho} = |\chi\rangle\boldsymbol{S}^{-1/2}\bar{\boldsymbol{\rho}}'\boldsymbol{S}^{-1/2}\langle\chi| = \sum_{\mu,\nu}\bar{\boldsymbol{\rho}}_{\mu\nu} = |\chi\rangle\bar{\boldsymbol{\rho}}\langle\chi|. \quad (8)$$

The relationship $\bar{\rho}'=\boldsymbol{S}^{1/2}\bar{\rho}\boldsymbol{S}^{1/2}$ is important because it is useful in a general case which contains the overlap effect discussed by McConnell.[10] When $|\chi\rangle$ is chosen as a set of AO's, $\bar{\boldsymbol{\rho}}$ may be called the AO spin density matrix and $\hat{\bar{\rho}}_{\mu\nu}$ the AO spin density operator for AO's $|\chi_\mu\rangle$ and $|\chi_\nu\rangle$. Note that $\mathrm{tr}(\hat{\bar{\boldsymbol{\rho}}})=\mathrm{tr}(\bar{\boldsymbol{\rho}}')=\mathrm{tr}(\boldsymbol{S}^{-1/2}\bar{\boldsymbol{\rho}}\boldsymbol{S}^{-1/2})=\mathrm{tr}(\bar{\boldsymbol{\rho}}\boldsymbol{S})=1$. When $|\phi_i\rangle$ is expressed as a linear combination of $|\chi_u\rangle$'s

$$|\phi_i\rangle = |\chi\rangle\boldsymbol{C}_i \text{ or } |\phi\rangle = |\chi\rangle\boldsymbol{C}, \quad (9)$$

the matrices $\bar{\boldsymbol{\rho}}$ and $\boldsymbol{\rho}$ are related to one another in the way as[8]

$$\bar{\boldsymbol{\rho}} = \langle\eta|\hat{\rho}|\eta\rangle = \langle\eta|\phi\rangle\boldsymbol{\rho}\langle\phi|\eta\rangle = \boldsymbol{C}\boldsymbol{\rho}\boldsymbol{C}^\dagger, \quad (10)$$

where $|\eta\rangle=|\chi\rangle\boldsymbol{S}^{-1}$, that is $|\eta\rangle$ is the reciprocal vector with respect to $|\chi\rangle$. Note that Eq. 10 is valid in either case that $|\chi\rangle$ is orthonormal or not.

Now we mention the essence of the present method. First, we partition an MO set $|\phi\rangle$ into appropriate subsets, σ and π MO's *etc.*, and AO's $|\chi\rangle$ into those centered at atom A, B, $\cdots$:

$$|\phi\rangle \equiv (|\phi_\sigma\rangle|\phi_\pi\rangle\cdots),\ |\phi_\sigma\rangle \equiv (|\phi_{\sigma 1}\rangle|\phi_{\sigma 2}\rangle\cdots),$$
$$|\chi\rangle \equiv (|\chi_A\rangle|\chi_B\rangle\cdots),\ |\chi_A\rangle \equiv (|\chi_{A1}\rangle|\chi_{A2}\rangle\cdots). \quad (11)$$

Since the total MO spin density operator $\hat{\rho}$ may be considered to be totally symmetric only if those partitioned $|\phi_\sigma\rangle$ and $|\phi_\pi\rangle$ belong to irreducible representations of the σ and π symmetries (this is the case for Hartree-Fock MO's), the relationships $\langle\phi_\sigma|\hat{\rho}|\phi_\pi\rangle=0$ *etc.* hold and we obtain

$$\hat{\rho} = \hat{\rho}_{\sigma\sigma} + \hat{\rho}_{\pi\pi} + \cdots$$
$$= |\phi_\sigma\rangle\boldsymbol{\rho}_{\sigma\sigma}\langle\phi_\sigma| + |\phi_\pi\rangle\boldsymbol{\rho}_{\pi\pi}\langle\phi_\pi| + \cdots. \quad (12)$$

Here, the whole MO spin density matrix $\boldsymbol{\rho}$ is in general diagonalized in such a way that

$$\boldsymbol{\rho} = \begin{array}{c} \\ \sigma_1 \\ \sigma_2 \\ \vdots \\ \pi_1 \\ \pi_2 \\ \\ \end{array}\!\!\begin{array}{c} \begin{array}{cc} \sigma_1\sigma_1\cdots & \pi_1\pi_2\cdots \end{array} \\ \left[\begin{array}{c|c|c} \boldsymbol{\rho}_{\sigma\sigma} & 0 & \\ \hline 0 & \boldsymbol{\rho}_{\pi\pi} & \\ \hline & & \end{array}\right] \end{array}. \quad (13)$$

In short, the corresponding MO spin density operators $\hat{\rho}_{\sigma\sigma}$ and $\hat{\rho}_{\pi\pi}$ yield leading terms of the spin density for σ-type and π-type radicals, respectively. These terms actually manifest the so-called spin-delocalization (SD) effect.[11] The remaining higher order terms which are not shown in Eq. 12 come from the CI effect and contribute to spin-polarization.[11] Therefore, total $\hat{\rho}$ is a sum of operators which count out the spin density due to spin-delocalization and that which yields spin-polarization:

$$\hat{\rho} = \hat{\rho}^{SD} + \hat{\rho}^{SP}, \quad (14)$$

where one should note that $\mathrm{tr}(\hat{\rho}^{SD})=1$ and $\mathrm{tr}(\hat{\rho}^{SP})=0$.

What follows is an extention of the spin density formulation. Though we do not actually apply it to the present numerical analyses, it will be useful for more detailed exploration of the mechanism of spin polarization and spin delocalization. The degree of localization of the spin density of atom A is measured by

$$\bar{\rho}_A = \sum_{\mu\in A}\langle\eta_\mu|\hat{\bar{\rho}}|\eta_\mu\rangle = \bar{\rho}_A{}^{SD} + \bar{\rho}_A{}^{SP}, \quad (15)$$

where

$$\bar{\rho}_A{}^{SD} = \sum_{\mu\in A}\langle\eta_\mu|\hat{\bar{\rho}}^{SD}|\eta_\mu\rangle \quad (16)$$

and

$$\bar{\rho}_A{}^{SP} = \sum_{\mu\in A}\langle\eta_\mu|\hat{\bar{\rho}}^{SP}|\eta_\mu\rangle. \quad (17)$$

Then, one can say that the complete delocalization takes place on atom A when $\bar{\rho}_A=0$, and the complete localization occurs on atom A when $\bar{\rho}_A=1$. In the case that atom A is considered to be a radical center, the measure of delocalization of the spin density on the radical center is expressed as $1-\bar{\rho}_A$. On the other hand, a measure of localization of the spin density in bond A–B is given by

$$\bar{\rho}^{AB} = \sum_{\mu\in A,\ \nu\in B}\langle\eta_\mu|\hat{\bar{\rho}}|\eta_\nu\rangle, \quad (18)$$

which cannot be assigned to either of atom A and atom B.

Since the Hermitian matrix $\boldsymbol{\rho}_{\sigma\sigma}$ can be diagonalized such that $\boldsymbol{d}_\sigma=\boldsymbol{U}_\sigma^\dagger\boldsymbol{\rho}_{\sigma\sigma}\boldsymbol{U}_\sigma$ ($\boldsymbol{U}_\sigma$ is a unitary matrix), one obtains

$$\hat{\rho}_{\sigma\sigma} = |\phi_\sigma'\rangle\boldsymbol{d}_\sigma\langle\phi_\sigma'|, \quad (19)$$

with

$$|\phi_\sigma'\rangle = |\phi_\sigma\rangle\boldsymbol{U}_\sigma. \quad (20)$$

We may call $\boldsymbol{d}_\sigma$ an MO occupation spin density and $|\phi_\sigma'\rangle$ a spin density naturalized MO. A similar definition can be made for π MO's and higher symmetry MO's.

Using a unitary matrix $\boldsymbol{U}$ which diagonalizes $\boldsymbol{\rho}$, one can obtain a relationship which is similar to Eq. 10:

$$\vec{\boldsymbol{d}} = \boldsymbol{C}'\vec{\boldsymbol{d}}\boldsymbol{C}'^{\dagger}, \text{ with } \boldsymbol{C}' = \boldsymbol{U}^{\dagger}\boldsymbol{C}\boldsymbol{U}. \tag{21}$$

The quantity d^{A} defined by

$$d^{A} = \sum_{\mu\in A} d_{\mu\mu} = \sum_{\mu\in A}\langle\eta_{\mu}'|\hat{\rho}|\eta_{\mu}'\rangle \tag{22}$$

may be called an atomic occupation spin density on atom A, while $d_{\mu\mu}$ may be termed as an AO occupation spin density centered at atom A.

g Tensors of Triplet Molecules

First we describe the method of calculation of the 3×3 matrix elements $g^{ij}(i,j=\mathrm{x},\mathrm{y},\mathrm{z})$ of the g tensor. It is well known that in a π doublet radical certain negative spin density occurs on the proton in the molecular plane through the σ-π interaction.[8] This also will be the case for triplet radicals. Assuming such perturbation is small, we may construct a total wavefunction so as to mix the ground state function with excited functions by making use of a first-order perturbation theory.

Let $\Psi_{G}^{M}(M=-1, 0, 1)$ be the Slater determinant of the triplet ground state of a molecule, in which nondegenerate molecular orbitals ϕ_{m} and ϕ_{n} accomodate one unpaired electron each:

$$\Psi_{G}^{M} = |\phi_1\bar{\phi}_1\cdots\phi_i\bar{\phi}_i\cdots\phi_{m-1}\bar{\phi}_{m-1}\phi_m\phi_n|. \tag{23}$$

The one-electron excited state determinantal wave functions which are eigenfunctions of $\hat{S}_z$ and $\hat{S}^2$ are divided into the following four classes:

$$\left.\begin{aligned}\Psi_{i\to m}^{M} &= |\phi_1\bar{\phi}_1\cdots\phi_i\bar{\phi}_m\cdots\phi_m\phi_n|,\\ \Psi_{m\to k}^{M} &= |\phi_1\bar{\phi}_1\cdots\phi_i\bar{\phi}_i\cdots\phi_k\phi_n|,\end{aligned}\right\} \tag{24}$$

$$\left.\begin{aligned}\Psi_{i\to k}^{M}(A) &= (\Psi_1^{(m)}+\Psi_2^{(m)})/\sqrt{2},\\ \Psi_{i\to k}^{M}(B) &= (\Psi_1^{(m)}-\Psi_2^{(m)}-2\Psi_3^{(m)})/\sqrt{6},\\ \text{and/or } \Psi_{i\to k}^{M}(C) &= (\Psi_1^{(m)}-\Psi_2^{(m)}-2\Psi_3^{(n)})/\sqrt{6}\end{aligned}\right\} \tag{25}$$

with

$$\left.\begin{aligned}\Psi_1^{(m)} &= |\phi_1\bar{\phi}_1\cdots\phi_i\bar{\phi}_k\cdots\phi_m\phi_n|,\\ \Psi_2^{(m)} &= |\phi_1\bar{\phi}_1\cdots\phi_k\bar{\phi}_i\cdots\phi_m\phi_n|,\\ \Psi_3^{(m)} &= |\phi_1\bar{\phi}_1\cdots\phi_i\phi_k\cdots\bar{\phi}_m\phi_n|,\\ \Psi_3^{(n)} &= |\phi_1\bar{\phi}_1\cdots\phi_i\phi_k\cdots\phi_m\bar{\phi}_n|,\end{aligned}\right\} \tag{26}$$

where the suffices i and k refer to doubly occupied MO's and vacant MO's in Ψ_{G}^{M}, respectively. By direct calculation, we found that the former two (Eq. 24) contribute to the g tensor ffnd the latter two (Eq. 25) have an effect to the σ-π interaction in hfs tensor.

After mixing the former two functions, $\Psi_{i\to m}^{M}$ and $\Psi_{m\to k}^{M}$, with Ψ_{G}^{M} through the spin-orbit interaction $\hat{H}_{LS}=\sum_{t,j}\zeta_t\hat{L}_{jt}\cdot\hat{S}_j$ where $\hat{L}_{jt}$ is the orbital angular momentum operator for the jth electron with respect to the tth nucleus and ζ_t is the spin-orbit coupling constant, the total wave function Ψ_{T}^{M} to be used for the calculation of the g tensor is expressed as

$$\Psi_{T}^{M} = \Psi_{G}^{M} - \sum_{I,M'}\lambda_{I}^{M'}\Psi_{I}^{M'}, \quad (M'=-1, 0, 1) \tag{27}$$

where

$$\lambda_{I}^{M'} = \langle\Psi_{I}^{M'}|\hat{H}_{LS}|\Psi_{G}^{M}\rangle/[E(\Psi_{I}^{M'})-E(\Psi_{G}^{M})], \tag{28}$$

and I refers to $i\to m$ and $m\to k$.

As is well known, the anisotropic g tensor in the expression of the effective spin Hamiltonian $\hat{H}_{eff}=\mu_B H\cdot g\cdot\hat{S}'$, where μ_B is the electronic Bohr magneton, H the external magnetic field, and $\hat{S}'$ the ficititious spin, is estimated by the aid of the true Hamiltonian for the magnetic interaction $\hat{H}=\mu_B H\cdot(\hat{L}+g_e\hat{S})$, g_e being the gyromagnetic factor for a free electron ($g_e=2.00232$). That is, after calculating the 3×3 matrices for $\hat{H}_{eff}$ and $\hat{H}$ by using $\Psi_{T}^{M}(M=-1, 0, 1)$ as bases, and comparing the corresponding matrix elements term by term, one obtains the components of the g tensors as in the following:

$$g^{xy} = g_e\delta_{xy} + \Delta g^{xy}, \tag{29}$$

$$\Delta g^{xy} = \Delta g_m^{xy} + \Delta g_n^{xy}, \tag{30}$$

$$\Delta g_m^{xy} = \sum_i\Delta g_{mi}^{xy} - \sum_k\Delta g_{mk}^{xy}, \tag{31}$$

$$\Delta g_{mi}^{xy} = (2S)^{-1}(\Lambda_{mi}^{xy}+\Gamma_{mi}^{xy})/[E(\Psi_{i\to m}^{M'})-E(\Psi_{G}^{M})], \tag{32}$$

$$\Lambda_{mi}^{xy} = \langle\phi_m|\sum_{t,j}\hat{L}_{jt}^{x}|\phi_i\rangle\langle\phi_i|\sum_{t,j}\zeta_t\hat{L}_{jt}^{y}|\phi_m\rangle, \tag{33}$$

$$\Gamma_{mi}^{xy} = \langle\phi_m|\sum_{t,j}\hat{L}_{jt}^{y}|\phi_i\rangle\langle\phi_i|\sum_{t,j}\zeta_t\hat{L}_{jt}^{x}|\phi_m\rangle, \tag{34}$$

and so on. If the molecular axes coincide with principal axes of the g tensor, the two terms in the numerator of Eq. 32 reduce to one term. We can thus calculate the principal values of g by diagonalizing the matrix Δg^{xy} or g^{xy}.

Hyperfine Splitting Tensors

For triplet radicals having the ground state wave function Ψ_{G}^{M} of Eq. 23, the leading term of the total MO spin density operator $\hat{\rho}$, as given in Eq. 12, becomes

$$\hat{\rho}(\Psi_{G}^{M};\Psi_{G}^{M}) = \hat{\rho}_{mm}^{SD} + \hat{\rho}_{nn}^{SD}, \tag{35}$$

that is, corresponding to Eq. 13,

$$\rho(\Psi_{G}^{M};\Psi_{G}^{M}) = \begin{array}{c} \\ m \\ n \\ \\ \end{array}\begin{array}{c} \begin{array}{cccc} & & m & n \end{array} \\ \begin{bmatrix} 0 & \vdots & \vdots & \\ \cdots & 0.5 & \vdots & 0 \\ \cdots & \cdots & 0.5 & \\ & 0 & & 0 \end{bmatrix} \end{array}. \tag{36}$$

In the SCF framework, Ψ_{G}^{M} does not mix with $\Psi_{i\to m}^{M}$ and $\Psi_{m\to k}^{M}$ of Eq. 24 due to the Brillouin theorem. Also, $\hat{\rho}(\Psi_{G}^{M};\Psi_{i\to k}^{M}(A))=1/\sqrt{2}\,(-\hat{P}_{ik}+\hat{P}_{ik})=0$. Therefore, the ground state wave function Ψ_{T}^{M} can be improved by the mixing of only $\Psi_{i\to k}^{M}(B)$ and $\Psi_{i\to k}^{M}(C)$ of Eq. 25:

$$\Psi_{T}^{M} = \Psi_{G}^{M} + \sum_{i,k}\{\lambda_{ik}^{(m)}\Psi_{i\to k}^{M}(B)+\lambda_{ik}^{(n)}\Psi_{i\to k}^{M}(C)\}, \tag{37}$$

where

$$\left.\begin{aligned}\lambda_{ik}^{(m)} &= \frac{1}{\sqrt{6}}[3(mi|km)+(ni|kn)]/\Delta E^{(m)},\\ \lambda_{ik}^{(n)} &= \frac{1}{\sqrt{6}}[3(ni|kn)+(mi|km)]/\Delta E^{(n)},\end{aligned}\right\} \tag{38}$$

$$\left.\begin{aligned}\Delta E^{(m)} &= E(\Psi_{i\to k}^{M}(B)) - E(\Psi_{G}^{M}),\\ \Delta E^{(n)} &= E(\Psi_{i\to k}^{M}(C)) - E(\Psi_{G}^{M}),\end{aligned}\right\} \tag{39}$$

and

$$(pq|rs) = \iint\phi_p^*(1)\phi_q(1)(e^2/r_{12})\phi_r^*(2)\phi_s(2)dv(1)dv(2). \tag{40}$$

We thus finally obtain the total MO spin density

$$\rho(\Psi_{T}^{M};\Psi_{T}^{M}) = \rho_{mm}^{SD} + \rho_{nn}^{SD} + \rho^{SP}, \tag{41}$$

$$\rho^{SP} = \rho_{ik}^{(m)} + \rho_{ik}^{(n)} = -\frac{1}{\sqrt{6}}(\lambda_{ik}^{(m)} + \lambda_{ik}^{(n)}). \quad (42)$$

The AO spin density contribution due to spin polarization is obtained by means of Eq. 10:

$$(\bar{\rho}^{SP})_{\mu\nu} = \sum_i \sum_k (\rho^{SP})_{ik}(C_{\mu i}C_{\nu k}^* + C_{\mu k}C_{\nu i}^*). \quad (43)$$

The MO and AO spin density matrices necessary for the present calculation are listed in Appendix A.

The matrix elements of the anisotropic hfs tensor for nucleus N, A^{Nij}, are calculated by[12]

$$A^{Nij} = tr(\rho\Omega^{Nij}), \quad (i, j = x, y, z) \quad (44)$$

$$\Omega_{rs}^{Nij} = -g\mu_B\hbar\gamma_N t_{ij}(\chi_r\chi_s), \quad (45)$$

$$t_{ij}(\chi_r\chi_s) = \langle\chi_r(1)|r_{1N}^{-5}(r_{1N}^2\delta_{ij} - 3r_{1N}^i r_{1N}^j)|\chi_s(1)\rangle. \quad (46)$$

Here, $t_{ij}(\chi_r\chi_s)$ is the electron-nuclear dipolar interaction integral and γ_N the gyromagnetic ratio of nucleus N. By diagonalizing the matrix A^{Nij}, we obtain the principal values of the anisotropic hfs tensor and the direction cosines between the molecular and principal axes. The dipolar integrals $t_{ij}(\chi_r\chi_s)$ are evaluated by using the following approximations: (1) All the three-center integrals and all the two-center integrals involving the product $\chi_r\chi_s$ in which χ_r and χ_s belong to different atoms are neglected and the remaining one- and two-center integrals are analytically evaluated over the Slater-type orbitals; (2) the one-center dipolar integrals are improved by the use of Löwdin's SCF AO's.[13] Analytical formulas of the dipolar integrals are given in Appendix B.

The isotropic hfs constant for nucleus N is given by[12]

$$a^N = tr(\rho Q)^N, \quad (47)$$

$$(Q^N)_{rs} = (8\pi/3)g\mu_B\hbar\gamma_N\langle\chi_r(1)|\delta(r_{1N})|\chi_s(1)\rangle, \quad (48)$$

δ being the Dirac δ-function. The one-center integrals $\langle\chi_r(1)|\delta(r_{1N})|\chi_s(1)\rangle$ are evaluated over the Löwdin SCF AO's.[13]

Results and Discussion

First, we apply the above-mentioned calculation schemes to the g tensor of the methylene radical in its triplet state $^3B(n, \pi)$. The molecular geometry is as follows;[14] the C–H bond length 1.078 Å, the HCH bond angle 136°. The electron configuration is $(1a_1)^2(1b_1)^2(2a_1)^1(1b_2)^1(3a_1)^0(2b_1)^0$, the six valence electrons being taken into account. The molecular z axis is taken in the molecular plane so as to bisect the HCH angle and the y axis perpendicular to the molecular plane. The MO wave functions are obtained by using Roothaan's open-shell SCF operator[15] with the INDO approximation for integrals over AO's.[16] A pseudo-potential is added to Roothaan's operator in order to obtain fast and perfect convergence.[17] The exchange energy between the first excited singlet and the ground triplet states, $2K_{mn}$, is calculated to be 1.74 eV which is much larger than the electronic Zeeman energy. This gives convincing proofs of our assumption that the g tensor can be calculated by a perturbation treatment.

Methylene has the characteristics of both the double σ radical and the doublet π radical, since one of the two unpaired electrons occupy the σ orbital $2a_1$ and the other the π orbital $1b_2$. This situation is well expressed by Eq. 30 which can be written in this case as

$$\Delta g^{xy} = \Delta g^{xy}(2a_1) + \Delta g^{xy}(1b_2). \quad (49)$$

With Eqs. 30—34 and their analogues, the contribution of the one-electron excited wave functions of the type shown in Eq. 24 to the diagonal elements of Δg is calculated to be as in the following: (0, 12, 0) for $1b_1 \rightarrow 2a_1$, (0, −12, 0) for $2a_1 \rightarrow 2b_1$, (0, 0, 15) for $1b_1 \rightarrow 1b_2$, (−10, 0, 0) for $1b_2 \rightarrow 3a_1$, and (0, 0, −19) for $1b_2 \rightarrow 2b_1$, where the figures in parentheses denote the value of $(\Delta g^{xx}, \Delta g^{yy}, \Delta g^{zz}) \equiv \Delta g$ in units of 10^{-5}. The Δg values which come from other wave functions, $1a_1 \rightarrow 2a_1$, $1a_1 \rightarrow 1b_2$, and $2a_1 \rightarrow 3a_1$, are found to be very close to zero.

The principal values of the g tensor of methylene are then calculated to be (2.00222, 2.00232, 2.00228) which lie close to the free electron value g_e. We have confirmed that the structural dependence is rather small; *e.g.*, $\Delta g = (-12, 2, -4)$ when $\angle HCH = 111°$ and $(-8, -3, -5)$ when $\angle HCH = 150°$, all in units of 10^{-5}. The observed principal values of the g tensor for CD_2 in the xenon matrix at 4K are (1.9995, 1.9984, 1.9984),[5] which are 0.003—0.004 below our predicted values for an isolated CH_2. More recently, there have been reported much smaller g values; (1.9738, 1.9953, 1.9946) for CD_2 and (1.9742, 1.9955, 1.9942) for $^{13}CD_2$ both in xenon matrices.[18] These are not to be compared with our calculated values, since a solid solution matrix usually causes a large deviation from the g_e value due to intermolecular interactions with a host molecule and the effects of deuteration and molecular orientation.[19] The tendency that the deviation from g_e (and also anisotropy among the principal g values) is very small in the present prediction is in accord with experimental findings for organic doublet free radicals containing carbon and hydrogen only; 0.0003 for CH_3,[20] 0.0001 for $CH{=}CH_2$,[20] 0.0003 for $C{\equiv}CH$,[21] in their doublet ground states in solid solution matrices.

Table 1. Calculated principal g tensors of triplet molecules

	g^{xx}	g^{yy}	g^{zz}	g_{av}*)
CH_2	2.00222	2.00232	2.00228	2.00228

*) $g_{av} = (1/3)(g^{xx} + g^{yy} + g^{zz})$

Table 1 lists the calculated principal values of the g tensor for other triplet molecules for which the very same calculation scheme has been used. Contrary to CH_2 in which the carbon atom mainly contributes to Δg because the spin-orbit interaction constant of hydrogen is negligibly small, anisotropy in CF_2 is rather large; our estimate made by the use of the partitioning method, $\Delta g = \Delta g_C + \Delta g_F + \Delta g_{F'}$ (geometry: $r(C\text{–}F) = 1.3$ Å, $\angle FCF' = 125°$), is $\Delta g_C = (-33, -1, -14)$ and $\Delta g_F = \Delta g_{F'} = (10, 58, 55)$ in units of 10^{-5}. The deviation

of the simple average value of g, $g_{av}=(1/3)(g^{xx}+g^{yy}+g^{zz})$, from the g_e value is larger in CF_2 and also in CHCHO.

At the bottom of Table 1, are shown the principal values of the g tensor calculated for the excited triplet states $^3A_2(n, \pi^*)$ and $^3B_1(n, \sigma^*)$ of formaldehyde. The molecular geometry corresponding to the minimum total energy is $r(C=O)=1.30$ Å, $r(C-H)=1.10$ Å, and $\angle HCH=121°$, the z axis being taken along the C=O bond and the y axis perpendicular to the molecular plane. We have assumed a planar structure for these excited triplet states of formaldehyde, though at least the $^3A_2(n\pi^*)$ state is known to have a bent structure (out of plane angle 35°).[23] This is simply because there are no experimental data available for the g tensors of these states and we try to compare the calculated results with the only available datum for the planar triplet benzophenone molecule.[22] The observed g tensor of the triplet benzophenone molecule is (1.9990, 1.9994, 2.0097),[22] the x and y axes here making angles of 60° and 30° respectively with the plane of the carbonyl group. Apart from these inclination of the x and y axes, the g^{xx} and g^{yy} values calculated for formaldehyde are larger than those observed for benzophenone, so is the case of the triplet ground state of methylene. On the contrary, the calculated g^{zz} value of formaldehyde is smaller than the experimental g^{zz} value of benzophenone, this being reversed in the case of methylene. Further investigation is needed as for whether these discrepancies are physically significant. From the experimental point of view, the two triplet excited states of formaldehyde are expected to be identified by an accurate measurement of the g tensor.

The effect of spin polarization in the MO spin density ρ of CH_2 calculated by using Eq. 42 is shown in Table 2. We should note that the non-vanishing off-diagonal elements are all negative and their values are within 6.4% of the diagonal element 0.5. Table 3 lists the AO spin density $\bar{\rho}=\bar{\rho}^{SP}+\bar{\rho}^{sp}$ of CH_2. The diagonal elements for the s orbitals are proportional to the corresponding isotropic hfs constants. The AO spin density of the carbon $2p_z$ orbital is 0.5 and the sum of the remaining diagonals is 0.5. Note that the negative spin density appears on the two protons.

TABLE 2. MOLECULAR ORBITAL SPIN DENSITY $\rho=\rho^{SD}+\rho^{SP}$ OF CH_2

MO	$1a_1$	$1b_1$	$2a_1$	$1b_2$	$3a_1$	$2b_1$
$1a_1$	0	0	0	0	−0.032	0.0
$1b_1$	0	0	0	0	0.0	−0.018
$2a_1$	0	0	0.500	0	0	0
$1b_2$	0	0	0	0.500	0	0
$3a_1$	−0.032	0.0	0	0	0	0
$2b_1$	0.0	−0.018	0	0	0	0

Table 4 shows the results on the analysis of the α-proton isotropic hfs constant, a^H, and the principal values of the α-proton anisotropic hfs tensor, A_{ii}^H(i=x, y, z), of the triplet CH_2 radical. Comparison of the third, fourth, fifth, and sixth columns shows that the anisotropic terms are determined almost completely by the spin delocalization contribution. Figures listed in the seventh column are the values per unit spin which come from the $1b_2$ π MO only, a simple double of a sum of the values in the fourth and the sixth columns since the spin density in the $1b_2$ π MO is 0.5. These values are well compared with the observed α-proton hfs constants per unit spin for triplet naphthalene[24] and the doublet malonic acid radical.[25] Going into details, the calculated isotropic constant is rather small; this is probably because the present perturbation treatment underestimates the contribution of spin polarization. Incidentally, a semi-quantitative estimate on a CH fragment ($S=1/2$) made by McConnell and Strathdee[26] is as follows: $a^H=-63$, $A_{xx}^H=-40$, $A_{yy}^H=42$, $A_{zz}^H=-6$ (all in MHz), the x axis being along the $2p\pi$ carbon

orbitals and the z axis along the C–H bond.

The calculated carbon 13 hfs constants of CH_2 are listed in Table 5 together with the observed values for CD_2. Comparison of the second and the third columns shows that the anisotropic terms are determined almost completely by the spin delocalization contribution as in the case of the α-proton hfs constants, while the isotropic term receives a considerable effect of spin polarization. The fourth column shows the delocalization contribution from the spin densities on the hydrogen atoms to hfs constants; the effect of hydrogen is negligibly small. In the fifth and the sixth columns is divided the total contribution of ρ^{SD} into those from the $2a_1$ σ orbital and from the $1b_2$ π orbital. It is interesting to compare the algebraic signs and magnitudes of these contributions with those of ρ^{SD} (the third column). The spin polarization terms are also divided into those contributing from the σ and π orbitals in the seventh and the eighth columns. Their contribution to the isotropic hfs constant is large while those to the anisotropic hfs constants are small as mentioned before. The last three columns list the available experimental data for CD_2, though their algebraic signs are not determined by an EPR experiment. The magnitudes of our predicted hfs constants well compare with those observed.

We list in Table 6 our prediction of the hfs constants in CF_2 and CHF for which no experimental data are available. It is hoped that our predictions will serve as a guide in future experimental analyses for these radicals.

Appendix A. The MO and AO Spin Density Operators

The MO spin density operators over the states given in Eqs. 23—26 of the text are expressed in terms of the transition-operators $\hat{P}_{ij} \equiv |\phi_i\rangle\langle\phi_j|$ as follows:

$$\hat{\rho}(\Psi_G^M; \Psi_G^M) = \frac{1}{2}(\hat{P}_{mm} + \hat{P}_{nn}),$$

$$\hat{\rho}(\Psi_{i\to m}^M; \Psi_G^M) = -\frac{1}{2}\hat{P}_{im},$$

$$\hat{\rho}(\Psi_{m\to k}^M; \Psi_G^M) = \frac{1}{2}\hat{P}_{mk},$$

$$\hat{\rho}(\Psi_{i\to k}^M(A); \Psi_G^M) = 0,$$

$$\hat{\rho}(\Psi_{i\to k}^M(B); \Psi_G^M) = \hat{\rho}(\Psi_{i\to k}^M(C); \Psi_G^M) = -(1/\sqrt{6})\hat{P}_{ik},$$

$$\hat{\rho}(\Psi_1^{(m)}; \Psi_G^M) = -\hat{\rho}(\Psi_2^{(m)}; \Psi_G^M) = -\frac{1}{2}\hat{P}_{ik},$$

$$\hat{\rho}(\Psi_3^{(m)}; \Psi_G^M) = \hat{\rho}(\Psi_3^{(n)}; \Psi_G^M) = 0.$$

The AO spin density matrix $\bar{\rho}$ for the resultant state Ψ_T^M is easily obtained by making use of Eq. 10 of the text, whose element is

$$\bar{\rho}_{rs} = \frac{1}{2}(C_{rm}C_{sm}^* + C_{rn}C_{sn}^*) + \sum_i^{\text{doubly occupied}} \sum_k^{\text{vacant}} (1/\sqrt{6})(\lambda_{ik}^{(m)} + \lambda_{ik}^{(n)})(C_{ri}C_{sk}^* + C_{rk}C_{si}^*),$$

where λ_{ik}'s are given in Eq. 38 of the text.

Appendix B. Analytical Derivation of Dipolar Integrals

The formulas for the dipolar integrals over AO's which are needed in the evaluation of anisotropic hfs tensors are obtained by the use of the method of McConnell and Strathdee[26] with the corrections of Pitzer, Kern, and Lipscomb.[27]

In the case when the Slater-type AO's are centered at nucleus N, the evaluation of dipolar integrals is straightforward:

$$t_{ij}(2p_k, 2p_l) = (c/120)\{2\delta_{ij}\delta_{kl} - 3(\delta_{ik}\delta_{jl} + \delta_{il}\delta_{jk})\},$$

where $c = (Z/a_0)^3$, a_0 being the first Bohr radius, and all the dipolar integrals over spherically symmetric AO's vanish. Constant c in the above equation for the improved one-center dipolar integrals over the Löwdin SCF AO's is[13]

$$c = \frac{\sum_{k,k'} B_k B_{k'} (b_k + b_{k'})^{-2}}{\sum_{k,k'} B_k B_{k'} (b_k + b_{k'})^{-5} a_0^3},$$

Table A1. Formulas of dipolar integrals involving 1s, 2s, 2p STO's when nucleus N lies on the z axis

$t_{ij}(2p_k2p_l)=(e_{ik}e_{jl}+e_{il}e_{jk}-2e_{kl}u_iu_j)B^x_{xx}/2+\{e_{ij}e_{kl}-e_{kl}u_iu_j-(e_{ik}e_{jl}+e_{il}e_{jk})/2\}B^y_{xx}+(e_{ik}u_ju_l+e_{jl}u_iu_k+e_{il}u_ju_k+e_{jk}u_iu_l)B_{xz}+(e_{ij}-2u_iu_j)u_ku_lB_{zz}$

$u_x=X/R$, $u_y=Y/R$, $u_z=Z/R$, $e_{ij}=\delta_{ij}-u_iu_j$

where B_k and b_k are Löwdin's notation and which yields 268.73, 483.42, and 795.75 Å^{-3} for carbon, nitrogen, and oxygen, respectively.

When nucleus N lies on the z axis, the relevant two-center dipolar integrals over the Slater-type AO's, $t_{ij}(\chi_r\chi_s)$, are listed in Table A1, where R is the distance between nucleus N and the atom to which AO's χ_r and χ_s are centered and $a=ZR/a_0$.

The dipolar tensors for which nucleus N lies at point (X, Y, Z) can be obtained by the usual transformation. Table A2 is derived in this way in terms of the terms listed in Table A1.

Thermal Diffusion Measurements of Symmetric Tetraalkylammonium Bromides in Water

Zen'ei Yogi, Hiroshi Kitano, Izumi Tōma, Kazuhiro Kijima, and Toshio Ikeda*
Department of Chemistry, Faculty of Science, Shizuoka University, 836 Ohya, Shizuoka 422
(Received August 20, 1979)

The Soret coefficients for 0.01 M aqueous solutions of R_4NBr (R=H, Me, Et, *n*-Pr, *n*-Bu, *n*-Pen, *n*-Hex, and *n*-Hep) were measured by the Snowdon-Turner conductimetric method with accuracy within ±0.1%, and were found to be −0.13, −4.18, −7.16, −9.05, −9.61, −9.47, −8.65, and −7.34, respectively in 10^{-3} K^{-1}, at the mean temperature 25 °C. They show a maximum at the carbon number 4 or 5 in R, whereas the diffusion coefficients show a minimum at the same carbon number in an exactly inverse manner. The apparatus and procedure are described.

The peculiar property of tetraalkylammonium salts, *viz.* they are easily soluble in water despite the fact that they consist of ammonium type ions entirely substituted by hydrophobic alkyl chains, has attracted attention. Measurements on molar volumes,[1] activity coefficients,[2] specific conductivities,[3] viscosity *B*-coefficients,[4] NMR chemical shifts,[5] and apparent energies of activation[6] have been reported by many workers, the results being interpreted in terms of "hydrophobic bond,"[7] which emphasizes the water structure around the tetraalkylammonium ions. However, studies on the diffusion (ordinary and thermal) of tetraalkylammonium salts do not seem have been carried out. One of us (T. I.) predicted that tetraalkylammonium salts would show very large Soret coefficients in water,[8] and gave proper estimates which were found to be of the right order of magnitude by experiments using "combined thermocell" technique.[9,10] However, the technique provides essentially the Soret coefficients relative to an appropriately selectred reference, *e.g.*, LiCl, which shows a negligiblly small Soret effect. It is desirable to carry out direct, accurate determination of the Soret coefficients of tetraalkylammonium salts.

Experimental

Cell Assembly. Measurements were carried out according to the Snowdon-Turner conductimetric method[11,12] with minor revision. The cell (Fig. 1) consists of a rectangular cylindrical hole (10 mm ϕ, 10 mm height) drilled at a corner of 100×100 mm^2, 10 mm thick "Acrylite" (poly(methyl methacrylate)) plate, the remaining flat area being used as an apron on which a well calibrated level can be placed for levelling the cell. Platinized platinum disk electrodes, 20 mm ϕ, 0.5 mm thick (P_1 and P_2) are stuck watertight on either side of the top and bottom of the cell cylinder with a small amount of silicone paste ("Black Silicone" sealant, Tōre Chem. Ind. Co. Ltd.) which was drawn circularly along the peripheral region within 1 mm from the ends of the cylinder using a special applicator (Fig. 2) cut out from polyethylene plate, 1 mm thick. The silicone sealing is convenient and very effective for its adaptability and sufficient elasticity as well as for repelling water.

The cell cylinder is equipped with two capillaries, 2 mm ϕ, both at right angle to the cylindrical cell wall at the half level, extending horizontally through the cell and opening directly outside to the neighboring sides of the square cell at S_1 and S_2. The cell is filled through the 2 mm ϕ capillary *via* S_1 which is closed with a 5 mm ϕ teflon screw plug through which a pinhole (0.5 mm ϕ) is bored to allow for thermal expansion of the solution. The opening S_2 is closed by a 5 mm ϕ teflon screw plug through which a platinized platinum needle electrode P_3 (0.5 mm ϕ) is threaded, extending through the 2 mm ϕ hole to the point near the innermost, narrowed part of the capillary (0.2 mm ϕ) which communicates with the cell cylinder. The Acrylite cell cylinder, with the platinum disk electrode P_1 and P_2 stuck on either side, is sandwiched between two platinum plated copper plates (5 mm thick and 50×50 mm^2 area)

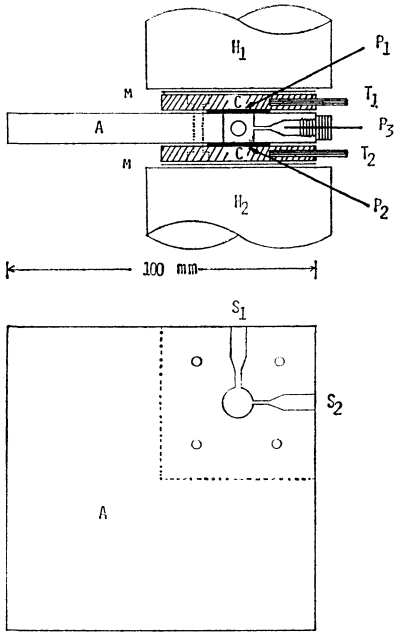

Fig. 1. Cell assemblies. A: Acrylite cylinder and apron. C: Heat conducting Cu-plate. M: Mica sheet. H_1 and H_2: Heat reservoirs. T_1 and T_2: Thermister probes. S_1 and S_2: Side holes. P_1 and P_2: Pt-disc electrodes. P_3: Pt-needle electrode.

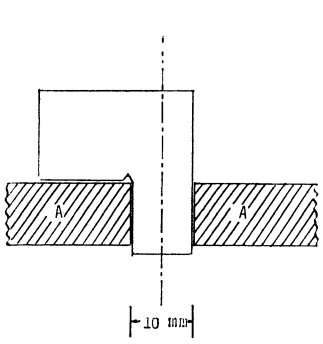

Fig. 2. Polyethylene applicator for pasting sealants.

which serve as a conductor for heat as well as electricity. They are fixed tightly together evenly with polycarbonate bolts and nuts at the four corners (Fig. 1). The cell assembly is further sandwiched between two heat reservoirs, H_1 and H_2, *via* mica sheet for electric insulation. The temperature of the heat reservoirs was maintained constant within ± 0.01 °C by circulation of thermostated water at 20 °C on the lower reservoir H_2 and at 30 °C on the upper H_1 to keep the mean temperature at 25 °C with thermo-circulators (CTE-2 and CTR-120,Komatsu Electronics Co. Ltd.).

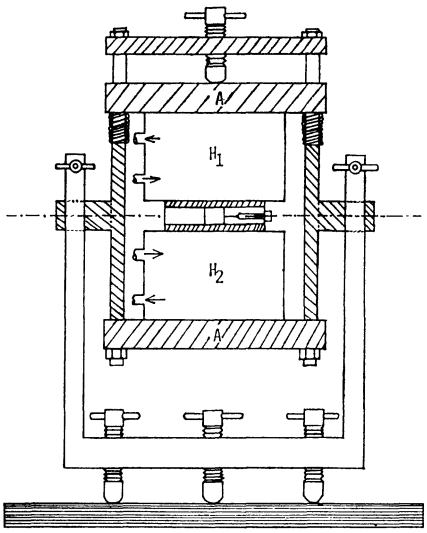

Fig. 3. Rotary cradle. H_1 and H_2: Heat reservoirs.

The entire system, including cell and heat reservoirs, was built in a stout rotary cradle supported on a massive iron rack provided with tripod screw for levelling (Fig. 3). This was placed in a large, foamy polystyrene box (30 mm thick wall) for thermal insulation from the exterior, empty space being stuffed loosely with cotton. Air conditioning of the laboratory around 25 °C (± 1 °C) is desirable.

The temperature of the platinum disk electrode was assumed to be the same as that of the central region of the heat conducting copper plate in contact with it, the latter being measured with a well-calibrated precision thermister thermometer (T-005A, Takara Instrument Co. Ltd.) to an accuracy ± 0.005 °C, where the thermister probe of 3.1 mm ϕ was mounted in a hole 3.2 mm ϕ and 25 mm deep reaching the center of the heat conducting plate.

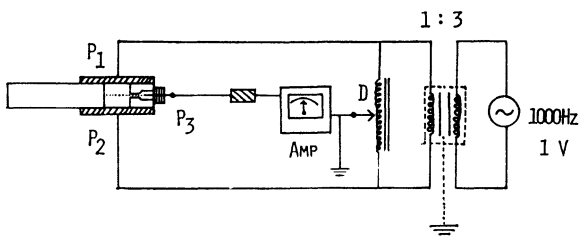

Fig. 4. Electric circuit. P_1, P_2, and P_3: Pt-electrodes. D: Decade ratio transformer. Amp: AC-amplifier as a detector.

Bridge Circuit. A block diagram of the bridge is shown in Fig. 4. Our aim was to find directly the ratio of resistances (impedances) Z_l and Z_u of the lower and upper halves of an electrolyte solution in the cell cylinder with respect to the central electrode P_3 by using a transformer bridge. A decade ratio transformer ("Decatran", DT-1145, Electroscientific Industries Ltd. U. S. A.) was used, with which we can read the resistance ratio, x, where $x=Z_u/(Z_l+Z_u)$, to the 5th figure below the decimal point, visually to the 6th. The sensitivity of this order is sufficient for the limited accuracy of the temperature control within ± 0.01 °C. Audiofrequency of 1 kHz and 1 V was supplied by an oscillator (VP-722, Matsushita Communication Ind. Co. Ltd.) driven by a battery source, but was dropped down to (1/3) V through a matching transformer before being applied across the top and bottom electrodes of the cell. By this arrangement the Joulean heat that evolves in the solution can be nearly swept away by the steady heat flow caused by the temperature gradient of 10 °C per cm between the two heat reservoirs. A highly sensitive AC amplifier 4402-AV-13C of Yokogawa-Hewlet-Packard (120 dB with sensitivity of 1 μV) was used as a zero indicator for the balancing of the bridge by means of an impedance matching preamplifier.

Sample Solutions. In the series of symmetric tetraalkylammonium bromides, R_4NBr (R=H, Me, Et, *n*-Pr, *n*-Bu, *n*-Pen, *n*-Hex, and *n*-Hep), the first six compounds were obtained from Wakō Pure Chem. Ind. Ltd., and the last two from Eastman Kodak Co. These chemicals were recrystallized from ethanol and used to make 0.01 M (1 M=1 mol dm^{-3}) solutions with conductance water, the concentration being determined by volumetric or potentiometric titration as regards bromide ions. Before use, all the solutions were subjected to partial deareation by boiling for about 10 s under reflux, followed by rapid cooling, thus avoiding the formation of minute bubbles on the surface of the platinum electrode on the hot side, which spoil the experiments, when temperature difference is imposed across the cell.

Conditioning of the Cell and Measurement. Thorough washing of the cell inside with running fresh water is essential. *Ca.* 10 L of partially deareated hot water (70—90 °C) was allowed to enter the cell cylinder by means of a siphon *via* the side hole S_1 and to run out of the second side hole S_2 over a period of *ca.* 10 h, while leaving both platinum electrodes at the short circuit. The cell cylinder was then rinsed several times with the sample solution with a syringe and left to stand overnight with the solution in it so that it might soak through all the corners inside the cell cylinder including the two side holes. The solution was renewed and the cell assembly was warmed up for measurement, fixed on the cradle, first in the reverse position, the top at 20 °C and the bottom at 30 °C (mean 25 °C) for 1 h to make the solution uniform throughout by the violent convective flow caused by an inverse temperature gradient. The cradle was then turned to the normal position, this instant being regarded as the time zero. The measurement was started after the levelling of the assembly had been roughly made within the first 10 s and completely within 5 min. Incomplete levelling causes a convective flow in the cell, spoiling the measurements. The bridge balance reading, x, read on the Dekatran were made every 5 min in the early stage and every hour in the latest stage. The duration of a run varied from 6 h for the fastest diffusing solute to 12 h for the slowest. Essential points for measurements are as follows: Thorough rinsing and soaking of the cell, strict control of temperature, correct levelling of the system, correct setting of the cell assembly, and deareation of solutions.

Analytical Method. General Description: Let R_l and R_u denote the resistance of the lower and upper, respectively, halves of the solution in the cell cylinder with respect to the center-tap electrode P_3 at time t after a temperature difference ΔT has been applied across the cell. With use of $Y(t)$, a function of time t, defined by

$$Y(t) = \frac{R_l - R_u}{R_l + R_u} \quad (1)$$

Agar and Turner[11] derived the following equation for the determination of the Soret coefficient σ:

$$Y(t) - Y(0) = \frac{8 b_{01} \sigma \Delta T}{\pi^3} F\left(\frac{t}{\theta}\right) \quad (2)$$

$$F\left(\frac{t}{\theta}\right) = \frac{\pi^3}{32} - \sum_{n=1}^{\infty} \frac{1}{n^3} \sin\left(\frac{n\pi}{2}\right) \exp\left(-\frac{n^2 t}{\theta}\right) \quad (3)$$

where $Y(0)$ is the Y value at time $t=0$. θ denotes the characteristic time constant defined by

$$\theta = \frac{a^2}{\pi^2 D} \quad (4)$$

where a is the cell height, D the diffusion coefficient at the mean temperature. σ is the Soret coefficient at the mean temperature defined by $\sigma = -(\partial \ln m / \partial T)_p$ in the steady state, where m is the molality. b_{01} is defined by

$$b_{01} = -\left(1 + \frac{\partial \ln \Lambda}{\partial \ln c}\right)_{T,P} \quad (5)$$

where Λ is the equivalent conductivity at concentration c at constant temperature T and pressure P.

When an appropriate value of θ is found, we can obtain σ readily from the slope of the $Y(t)$-F plot. However, it is difficult to find the exact value of θ from the values of a and D measured independently, since, owing to the elasticity of the silicone sealants, fluctuation in a values may result depending on the pressure put on the cell assembly when sandwiched between two heat reservoirs H_1 and H_2 and the value of D is scarcely known experimentally for tetraalkylammonium salts except n-Bu_4NBr.[13] Though D might be estimated from conductance data, it would be inaccurate. Consequently, we adopted an alternative method of finding a suitable, effective value of the characteristic time constant, θ_{eff}.

Determination of θ_{eff}: Since in the same run ΔT is kept constant (10 °C), we have

$$Y(t) - Y(0) = \alpha F\left(\frac{t}{\theta}\right) \quad (6)$$

where α is a constant. When Eq. 6 is satisfied, the following function which involves four observational points Y_1, Y_2, Y_3, and Y_4 at respective times t_1, t_2, t_3, and t_4,

$$G(\theta) = \frac{Y_1 - Y_2}{Y_3 - Y_4} - \frac{F\left(\frac{t_1}{\theta}\right) - F\left(\frac{t_2}{\theta}\right)}{F\left(\frac{t_3}{\theta}\right) - F\left(\frac{t_4}{\theta}\right)} = \frac{x_1 - x_2}{x_3 - x_4} - \frac{F\left(\frac{t_1}{\theta}\right) - F\left(\frac{t_2}{\theta}\right)}{F\left(\frac{t_3}{\theta}\right) - F\left(\frac{t_4}{\theta}\right)} \quad (7)$$

should be equal to zero (the Decatran reading x_i may be used instead of Y_i). Solving Eq. 7 we can find the value of θ that fits the experimental results, θ_{eff}. Calculation was performed by using a minicomputor TI-59 Texas Instrument. The results are given in Table 1. By means of this effective value θ_{eff}, we obtained a linear relation between $Y(t)$ and F with a correlation coefficient exceeding 0.9999, which is sufficient if we consider that the temperature control was accurate within ±0.01 °C.

In case of NH_4Br, however, θ_{eff} could not be obtained by this method, since NH_4Br shows a very slight Soret effect,[10] giving a small value of Y, and making $G(\theta)$ practically indefinite. The value of θ for NH_4Br was calculated from the diffusion coefficient D and the cell height a in a similar way as described below.

Results and Discussion

The results for aqueous 0.01 M solutions of R_4NBr are shown in Figs. 5-a and 5-b, where $Y(t)$ is plotted against t and F. The linearity of the Y-F relation is good. The Soret coefficients obtained from the slope in the $Y(t)$-F diagram and given in Table 1 are plotted in Fig. 6 against the carbon number of the alkyl chains of the tetraalkylammonium bromides in terms of the molar heats of transfer Q^* ($Q^* = -2RT^2B\sigma$ for uni-univalent electrolytes, where R is the gas constant and B is defined by $B = [1 + (\partial \ln \gamma_\pm / \partial \ln m)]_{T,P}$, $\gamma_\pm$ being the mean activity coefficient.). All the results for 0.01 M aqueous solutions, except for n-Hep_4NBr whose concentration was 0.000978 M owing to its limited solubility, are given at the mean temperature 25 °C, where a possible shift was within ±0.03 °C during 6—12 h of the measurements (Table 1). Q^* shows a maximum around the carbon number 4—5 of the alkyl chain of R_4NBr. The present Soret coefficients of 0.01 M tetraalkyl-

ammonium bromides are somewhat lower than those observed by Snowdon and Turner[12] by a similar method. One of us (T. I.) estimated theoretically the Soret coefficients of 0.01 M aqueous solutions of a series of R_4NBr, in the range R=H—R=*n*-C_5H_{11}, from the initial thermoelectric powers of thermocells of 0.01 M solutions of R_4NBr families by taking 144 JK^{-1} mol^{-1} for the molar transported entropy of the bromide ions.[8] The calculated values of the Soret coefficients σ (Table 1) are much greater than those observed, not showing any maximum but appearing to approach asymptotically a certain limit with increase in the carbon number of

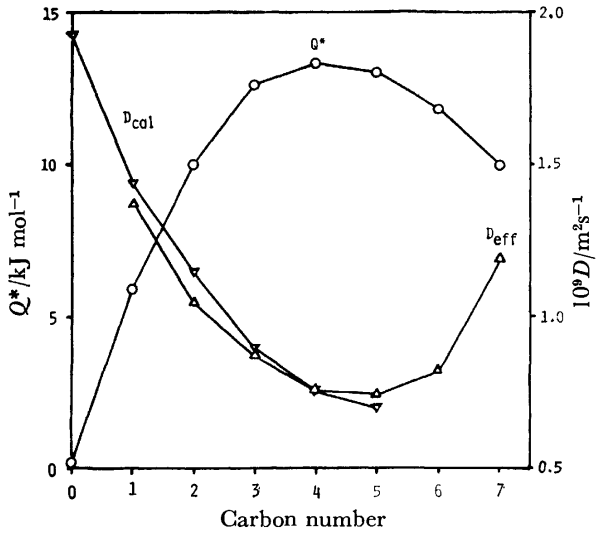

Fig. 6. Dependence of the heat of transfer or of the diffusion coefficient on the carbon number of the alkyl chain of R_4NBr.
○, Q^*; △, D_{eff}; ▽, D_{cal}.

the alkyl chain. This indicates that there is a limitation for calculation of the Soret coefficients from the initial thermoelectric power and the transported entropy, as in the case of the bromide ions where hydrophobic hydration becomes predominant, particularly in R_4NBr families with alkyl chain of higher carbon numbers beyond 4.

The diffusion coefficient, D, of the R_4NBr series has been determined experimentally only for n-Bu_4NBr.[13] For the other bromides, we could get rough estimates of D by (i) using θ_{eff} for the solution in question and the effective value of the cell height, a_{eff}, determined from the θ_{eff} for a reference solution such as Na_2SO_4 or n-Bu_4NBr, whose diffusion coefficient is known (D_{eff} in Table 1), and (ii) calculating the ionic equivalent conductance with use of the Nernst-Hartley equation,[14] (D_{calcd}). If we take into consideration the fact that D_{eff} and D_{calcd} were obtained from entirely different sources, the two diffusion coefficients are in fairly good agreement. We see that the D values pass minimum around the carbon number 4—5 of the alkyl chain, in an inverse tendency of Q^* showing maximum around the same carbon number (Fig. 6). This might be explained as a result of competition between two opposite tendencies: the enhancement of the water structure (hydrophobic bond formation) around the alkyl chain moieties of the tetraalkylammonium ion with increasing chain length, and the decrease in the number of completely dissociated free ions with increasing chain length owing to the reinforced ion-pairing effect[2,15] caused by the enhanced water structure around the ions.

The work was supported by Grant-in-Aid for Scientific Research Project No. (C)-754073 from the Ministry of Education.

Electron Spin Resonance of 2,2′-Bipyridyl, Dimethyl-2,2′-Bipyridyls, and 2,2′-Biquinolyl in their Phosphorescent Triplet States

Jiro HIGUCHI,* Mikio YAGI, Takashi IWAKI, Makoto BUNDEN, Katsumi TANIGAKI, and Takeshi ITO**

Department of Chemistry, Faculty of Engineering, Yokohama National University, Hodogaya-ku, Yokohama 240

(Received September 28, 1979)

Electron spin resonance (ESR) of phosphorescent triplet states of 2,2′-bipyridyl, 3,3′-, 4,4′-, 5,5′-, and 6,6′-dimethyl-2,2′-bipyridyls, and 2,2′-biquinolyl has been studied in ethanol glasses. For 2,2′-bipyridyl, the ESR spectrum of both the *E* and *Z* conformers was observed in poly(vinyl alcohol) films and their assignment was examined by changing the direction of applied magnetic field. Using such a technique, the stretched polymer-film method has been developed for determining the molecular conformations which are difficult to be estimated from zero-field splitting (ZFS) parameters obtained in rigid glasses. As a result, the conformations in the phosphorescent triplet states of molecules studied here are confirmed to be all *E* in ethanol glasses, even for a case with a relatively small *E* value.

2,2′-Bipyridyl (BPY)† is one of typical bidentate ligands which are coordinated with many metal ions in the *Z* conformation. In the solutions or in the crystal, however, the ground state of the molecule is in the *E* conformation,[1,2] although the structure may not perfectly be planar. As a result, the *Z* conformer of free BPY has not conclusively been identified in any kind of experiments. Recently, we have succeeded in observing two sets of electron spin resonance (ESR) signals which are originated from the *Z* and *E* conformers in the phosphorescent triplet state when the molecules were dissolved in poly(vinyl alcohol) (PVA) films.[3,4] For the phosphorescent triplet states of symmetrically substituted dimethyl-2,2′-bipyridyls (DMBPY's)† and 2,2′-biquinolyl (BQL)†, the conformations are also expected to be *E* but any experimental evidence for it has not yet been reported. In the present work, therefore, a further ESR study of these molecules in ethanol glasses was carried out, in connection with their conformations. In this case, we have developed a new technique for determining the *Z* and *E* conformations of paramagnetic species by applying the stretched polymer-film method.

In the triplet state of molecules, the magnetic fine structure may well be explained by the following spin Hamiltonian:

$$\begin{aligned}\mathcal{H} &= g\mu_B \boldsymbol{B}\cdot\boldsymbol{S} + \boldsymbol{S}\cdot\boldsymbol{D}\cdot\boldsymbol{S} \\ &= g\mu_B \boldsymbol{B}\cdot\boldsymbol{S} - XS_x^2 - YS_y^2 - ZS_z^2 \\ &= g\mu_B \boldsymbol{B}\cdot\boldsymbol{S} + D[S_z^2 - (1/3)S(S+1)] + E[S_x^2 - S_y^2] \\ &\qquad (S=1).\end{aligned}$$

Here, $\boldsymbol{D}$ is the fine structure tensor with principal values of $-X$, $-Y$, and $-Z$, and D and E are the zero-field splitting (ZFS) parameters. The other symbols have their usual meaning and the anisotropy of g was disregarded. Assuming a planar structure of molecule in the phosphorescent triplet state, the coordinate axes were taken as follows: the principal magnetic axes, x and y, are in the molecular plane (the x axis is taken rather close to the long direction of molecule), while the z axis is perpendicular to the molecular plane.

In *Z* conformers of BPY's (or BQL), the x axis is taken to be parallel to the central C–C bond which connects the two pyridine (or quinoline) rings (hereafter, we will refer to such a direction as b), while that of *E* conformers should be separated to the b in direction by some angle of $\alpha_x (0 < |\alpha_x| < \pi/4)$. Such a difference on the direction of magnetic axis is certainly important for determining the conformation of molecules studied here.

Application of Stretched Polymer-Film Method for Determining Conformations

Only from the ESR spectrum observed in a rigid glass, the assignment of each peak is directly impossible and information about the conformation of the molecule studied is not easily obtainable. For symmetrically substituted biphenyls, bipyridyls, and related compounds, the molecular structures in the phosphorescent triplet state may in general be nearly planar, because of the increase of bond order in the central C–C bond which connects two of the same aromatic rings. For the *Z* conformers with symmetry C_{2v}, one of the principal axes of the $\boldsymbol{D}$ tensor, say x axis, should be parallel to this bond (x||b), while for the *E* conformers with symmetry C_{2h} the x axis is in a direction separated from b by α_x. When the magnetic induction $\boldsymbol{B}$ is applied parallel to one of the principal magnetic axes, the peak intensity at the corresponding resonance field is maximum in regularly oriented molecular assembly. These relations make possible to determine the conformation of these molecules by applying the stretched polymer-film method following the procedure described below.

When a PVA film containing appropriate amount of molecules to be studied is stretched more than 200% of stretch, we have already confirmed that these molecules are partially oriented with the following tendency: (1) the molecular plane is difficult to be oriented perpendicular to the stretched direction (s); (2) the long molecular axis has a tendency to align to the s direction; (3) the molecular plane is preferably oriented parallel to the film plane. From such a stretched film, we made several kinds of narrow oblong strips, the

† In the present paper, 2,2′-bipyridyl, dimethyl-2,2′-bipyridyl, and 2,2′-biquinolyl are abbreviated as BPY, DMBPY, and BQL, respectively.

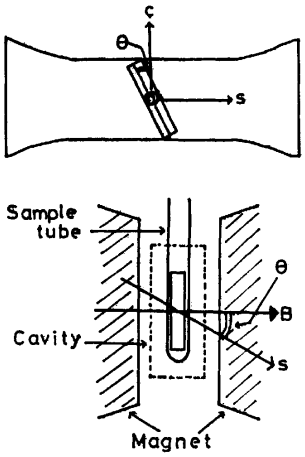

Fig. 1. Coordinate system in stretched PVA films, and the narrow oblong strips used in ESR measurements.

long sides of which were cut at various angles θ's with direction c which is perpendicular to s in the film plane, as shown in Fig. 1. When several sheets of such strips with the same θ are inserted and fixed in the same direction in the sample tube in the cavity, their s direction makes an angle of θ with $\boldsymbol{B}$ which is applied in the film plane. We will designate an angle between the principal magnetic x axis and the s direction as θ_X. Actually, the line shape of the ESR spectrum changes from the case with $\theta=\theta_X$ by using the strips with another angle of θ.

If the guest molecules are oriented in perfect ordering as in a single crystal, the intensities of the X peaks should be maximum when $\theta=\theta_X$ where the x axis is placed parallel to $\boldsymbol{B}$ (hereafter, we will refer to an angle giving the maximum intensity as θ_M). Although the molecules dissolved in stretched PVA films are partially oriented, the peak intensity decreases if the direction of $\boldsymbol{B}$ deviates from that of the principal magnetic axes. This means that the maximum intensity of each peak should be observed at $\theta_M \approx \theta_X$, even if the line shapes are generally broad in PVA films as compared with the case of a single crystal. As a result, we can reasonably distinguish the E conformer with $\theta_X \neq 0$ from the Z conformer with $\theta_X=0$, except the case when the θ_X of the E conformer is nearly zero. For E conformers in stretched polymer films, there are two types of orientations where the principal magnetic axes make angles $\pm\theta_X$ with the s direction even in an ideal alignment. Consequently, the X peak of the E conformer may be rather broad as compared with that of the Z conformer if the former θ_X is fairly small. Therefore, we may pertinently assign the conformation as follows: a peak with $\theta_X \neq 0$ and/or with relatively broad line shape generally arises from the E conformer, whereas that with $\theta_M=0$ and with relatively sharp line shape is attributed to the Z conformer.

Experimental

The ESR measurements were carried out for BPY, 3,3′-, 4,4′-, 5,5′-, and 6,6′-DMBPY's and BQL in ethanol glasses. A purified sample of 3,3′-DMBPY used was donated by Dr. H. M. Suzuki (Government Industrial Research Institute, Tohoku, Nigatake), and purified 4,4′- and 5,5′-DMBPY's were donated by Dr. Y. Kaizu (Tokyo Institute of Technology). All the other compounds were purchased from Tokyo Kasei Co.. BPY and BQL were purified by recrystallization, but DMBPY's were used without further purification.

In determining the conformation of some of these molecules, PVA films containing its appropriate amount were prepared by either the solution-evaporating method[3] or the diffusion-penetrating method.[4] In the case of BPY, the former method was used, that is, after mixing of an aqueous solution of PVA with an ethanol solution of BPY, a film with 2×10^{-2} cm thick was obtained by evaporating solutions on a glass plate. On the other hand, the latter method was used for 5,5′-DMBPY and BQL because of their insolubility in water, that is, a pure PVA film with 2×10^{-2} cm thick was made on a glass plate by evaporating water from the aqueous solution. After heat treatment for about an hour at 80 °C and swelling in water for about three hours at 30 °C, the film was soaked in methanol solution of a sample until its appropriate amount was penetrated into the film by diffusion. Then, the film thus prepared by either of the methods was stretched for about five minutes at about 60 °C. The obtained stretched films are about 7×10^{-3} cm thick, and with about 250% of stretch in the s direction and about 30% of contraction in the c direction.

For the ESR measurement, a sample tube containing ethanol solution with appropriate concentration of a compound was set in a quartz dewar with fingertip which was inserted in the cavity. The ESR spectra were observed at 77 K using JEOL JES-ME-3X spectrometer with 100 kHz modulation at microwave frequencies close to 9.2 GHz and the applied $\boldsymbol{B}$ between 0.1 and 0.5 T. The microwave field was perpendicular to $\boldsymbol{B}$ and the microwave frequency was measured with a cavity frequency meter. The magnetic induction was calibrated with a proton magnetic resonance technique. The exciting light was provided by a 500 W super-pressure mercury arc lamp filtered through 5 cm of distilled water and a Toshiba UV-31 or UV-D25 filter.

In the case of 3,3′-DMBPY, the observed ESR signals were considerably weak and accumulated by using a signal averager (1024 channel Kawasaki Electronica TM-1610S) for improving the signal to noise ratios in the following way: appropriate times of scans were accumulated with the exciting light on and the same times of scans were subtracted with the light off. In this way, we obtained a spectrum without perceptible baseline drifts which were due to signals of free radicals produced by UV irradiation and of magnetic contaminants in the cavity.

Results

In ethanol glasses, all the X, Y, and Z peaks for the $\Delta m=\pm1$ transitions of the phosphorescent molecules studied here were clearly observed as shown in Figs. 2 and 3, except the Y and Z signals of 3,3′-DMBPY and the high-field Y peak of BQL shown in Fig. 4. Accordingly, the Y and Z values of 3,3′-DMBPY were estimated from the resonance fields of X component and the trace-less relation of $\boldsymbol{D}$ tensor. The X, Y, and Z values of the other BPY's were directly obtained from the corresponding set of resonance fields. Since the observed resonance fields of DMBPY's did not significantly deviate from those of (E)-BPY, they were assigned to be in the same ordering of magnitude as those of (E)-BPY. For BQL, however, the assignment of the resonance fields has not yet been performed.[5] Therefore,

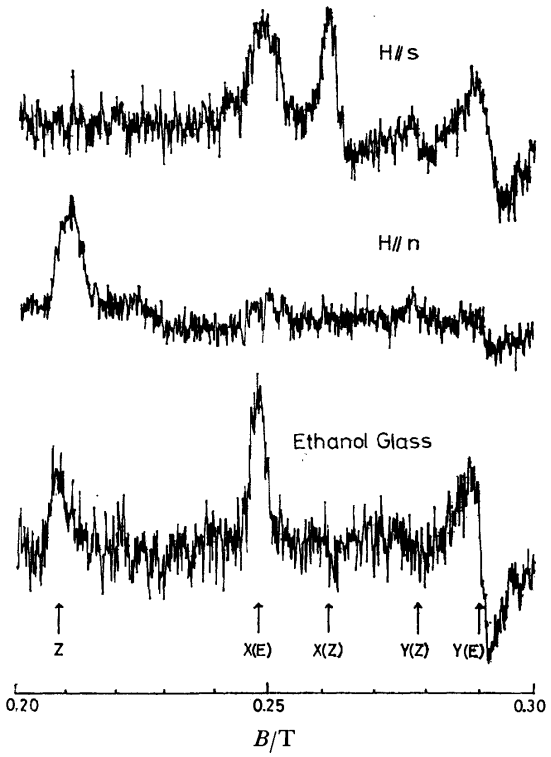

Fig. 2. ESR spectra of the low field $\Delta m=\pm 1$ transitions for the phosphorescent triplet state of (*Z*)- and (*E*)-2,2′-bipyridyl in a stretched PVA film and in ethanol glass at 77 K.

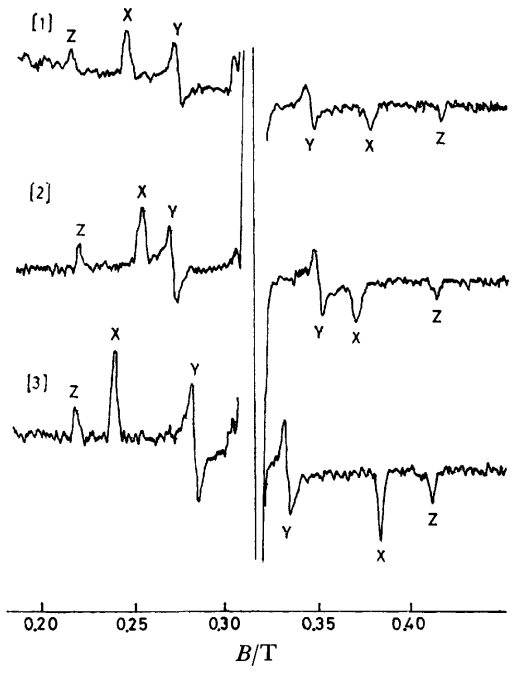

Fig. 3. ESR spectra of the $\Delta m=\pm 1$ transitions for the phosphorescent triplet states of 4,4′-dimethyl-2,2′-bipyridyl (1), 5,5′-dimethyl-2,2′-bipyridyl (2), and 6,6′-dimethyl-2,2′-bipyridyl (3) in ethanol glasses at 77 K.

we have carried out it by using the stretched polymer-film method[3,4] with reference to Fig. 4. The ZFS parameters thus obtained are listed in Table 1.

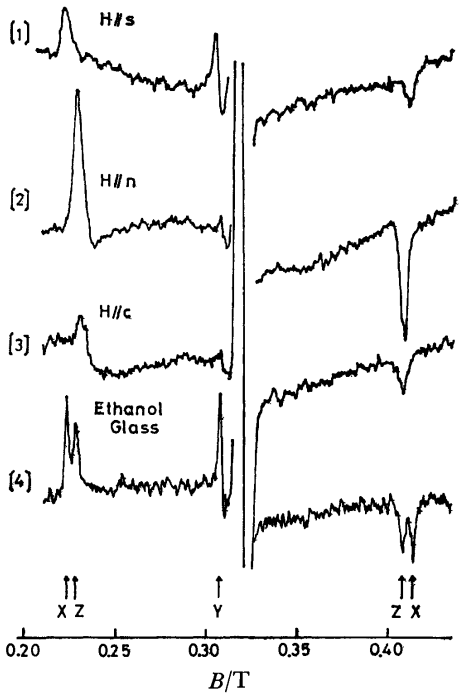

Fig. 4. ESR spectra of the $\Delta m=\pm 1$ transitions for the phosphorescent triplet state of 2,2′-biquinolyl in stretched PVA films (1—3), and in ethanol glass (4) at 77 K.

ESR measurements for the phosphorescent triplet state of BPY have already been carried out in rigid glasses[5,7] or in stretched PVA films.[3,4] Especially in the latter case, we observed two sets of X and Y peaks and one set of Z peaks for the $\Delta m=\pm 1$ transitions as shown in Fig. 2. When $\boldsymbol{B}||$s, the intensities of the X and Y peaks which can be observed in ethanol glasses are not much different from each other, but the other X peaks are relatively enhanced as compared with the other Y peaks. As a result, we have reasonably concluded that the former set of signals is pertinent to the *E* conformer and the latter to the *Z* conformer, since $\theta_X=0$ for the *Z* conformer while $\theta_X \neq 0$ for the *E* conformer.

Under these circumstances, we have tried to determine these conformation by applying the technique described previously. First, we prepared narrow oblong strips of the stretched BPY-containing PVA films with various θ. The ESR measurements were carried out for these samples under irradiation. In this case, the intensities of X peaks for the *Z* and *E* conformers, $I_X(Z)$ and $I_X(E)$, respectively, were actually changed by using a sample with different value of θ, while that of Z peaks, I_z, should not be varied if the strips prepared from the identical stretched film were used under the same condition of electromagnetic field in the cavity. Plotting the relative intensities of $I_X(Z)/I_z$ and $I_X(E)/I_z$, we found $\theta_M=0°$ and $\theta_M \approx 5°$ for the *Z* and the *E* conformer, respectively, although the variation of $I_X(E)/I_z$ is relatively gentle near θ_M as compared with that of $I_X(Z)/I_z$. This may apparently imply the facts that the previous conclusion is exactly correct and that the stretched polymer-film technique is actually available for determing the conformation of molecules even if only one set of peaks were observed. The ZFS para-

meters obtained in the stretched PVA films are also given in Table 1.

For 3,3′-DMBPY, the *Z*-conformer should not be planar because of the steric hindrance between the two methyl groups. In such a case, the *D* value may be fairly large as compared with the planar (*Z*)-BPY by considering the result of phosphorescent 2,2′-dimethylbiphenyl by Scheve and Wagner.[8] Since the *D* value obtained is rather small as compared with that of BPY, one may reasonably infer that 3,3′-DMBPY observed in the present work is actually the *E* conformer.

4,4′- and 6,6′-DMBPY's are *meta*-methyl-substituents to the carbon 2 (and 2′) which is bonded to another pyridine ring. In these cases, the electronic structures may not be much different from that of BPY, and the *D* and *E* values of each conformer are expected to be relatively close to those by BPY with the same conformation. In the present result, the *D* and *E* values obtained for these molecules are rather close to those of (*E*)-BPY than those of (*Z*)-BPY. This may suggest the fact that the ZFS parameters of 4,4′- and 6,6′-DMBPY's listed in Table 1 are apparently those of the *E* conformers.

For 5,5′-DMBPY, the obtained *D* and *E* values appear to be close to those of (*Z*)-BPY rather than those of (*E*)-BPY. However, the molecule is a *para*-methyl-substituent to the carbon 2 (and 2′), and the influence of substitution to the electronic structure may not be very small. Further, all the other BPY's observed here are *E* conformers in ethanol glasses. Considering these facts, we have applied the stretched polymer-film technique for determining the conformation of the molecule. The experimental procedure adopted was quite the same as in the case of BPY. The resonance fields were scarcely changed from the case of ethanol glasses if the microwave frequency was kept nearly the same, and no new peak was detected. This is a quite different situation from the case of BPY where the peaks of both the *Z* and *E* conformers were observed. Then the relative intensity I_X/I_Z was plotted against θ and its maximum value was found at $\theta_M\approx 5°$. This may imply that 5,5′-DMBPY observed was the *E* conformer, inspite of its relatively small *E* value.

In the phosphorescent triplet state of BQL, the conformation has not conclusively been determined, although the possibility of *E* was discussed by Rabold and Piette.[5] For determining the conformation, therefore, experiments similar with those of 5,5′-DMBPY were carried out using the stretched BQL-containing PVA films. The resonance fields were almost unchanged from the case of ethanol glasses if the microwave frequency was kept nearly the same, and no new peak was observed. In this case, we have found a small peak for relative intensity of I_X/I_Z near $\theta_M\approx 15°$, although its variation is very gentle. This may possibly suggest the fact that the conformation of BQL detected here is also *E* as in its ground state.

Discussion

Applying the stretched polymer-film technique, we have succeeded in assigning the conformation of BPY's and BQL in the phosphorescent triplet state. As a further study, we leave some possibility to proceed for determining the direction of principal magnetic axes by improving the present procedure. In the present study, however, such a work was not undertaken, since the molecules studied here are rather reactive with the environments in the excited state and the ESR signals decrease rapidly during UV irradiation. For the purpose of such a determination, therefore, it may be desirable to choose a set of guest compound and host polymer which are stable with each other under irradiation. In this case, the analysis may actually become easier in the use of a stretched polymer film with better alignment of guest molecules, such as a stretched film without contraction in the c direction.[9] However, one should remember that there are two types of orientations with $\pm\theta_X$ for *E* conformers in stretched polymer films, even in an ideal alignment of guest molecules. Especially when the $|\theta_X|$ is small and/or when the *Z* conformers exist together with the *E* conformers with a small $|\theta_X|$, these ESR peaks may become overlapped with each other. As a result, one should analyze the ESR line shape by a satisfactory computer simulation using a distribution function with orthorhombic character.

In the present work, we have confirmed that the stable conformations of BPY, 3,3′-, 4,4′-, 5,5′-, and 6,6′-DMBPY's and BQL in the phosphorescent triplet

state are all E in ethanol glasses. This is a quite natural conclusion in consideration of the intramolecular steric interactions for the Z and E conformations, similar with those in the ground state. In these molecules, the D and E values have not hitherto been determined except for the case of BPY, although the D^* values of 4,4'- and 5,5'-DMBPY's[10] and BQL[5] have already been reported.

Among DMBPY's, the E values listed in Table 1 are fairly different from each other, whereas the change of the D values is relatively small. Such a difference of E values may be rather complicated because of the superposition of the change of spin distribution caused by the nitrogen heteroatom upon that by the substitution of another pyridine ring. As a result, the conformation of these molecules is generally difficult to determine merely from the magnitude of E value when only one of the conformers was detected.

In examining the trend of the ZFS parameter to the spin distribution, the E values of these molecules were simply evaluated from the lowest triplet configuration, in which one electron is excited from the highest occupied orbital ϕ^{ho} of the ground state to the lowest vacant orbital ϕ^{lv}. Using the simple LCAO-MO's with Streitwieser's parameters,[11] the spin densities at each atom, ρ^{ho} and ρ^{lv}, which originate from the singly occupied orbitals of ϕ^{ho} and ϕ^{lv}, respectively, were separately obtained within McLachlan's approximation.[12] Then the E values were roughly estimated from these spin densities by including only interactions between the neighboring atoms. In this calculation, the molecules were assumed to be planar, all the bond lengths and bond angles were taken the values of the ground state of benzene molecule,[13] and the electron spin dipoles were assumed to be located at each nucleus with the above spin distributions. In fact, such a treatment may be allowed to estimate in-plane components of the **D** tensor.

TABLE 2. E/hc VALUES OF 2,2'-BIPYRIDYLS CALCULATED FROM THE SPIN DENSITIES OF SINGLY OCCUPIED ORBITALS (cm^{-1})

	$E(Z)_{calcd}/hc$	$E(E)_{calcd}/hc$	$[E(E)_{obsd}-E(E)_{calcd}]/hc$[a]
2,2'-Bipyridyl	0.0089	0.0106	0.0015
3,3'-Dimethyl-2,2'-bipyridyl	0.0142	0.0161	−0.002
4,4'-Dimethyl-2,2'-bipyridyl	0.0059	0.0097	0.0012
5,5'-Dimethyl-2,2'-bipyridyl	0.0089	0.0089	−0.0023
6,6'-Dimethyl-2,2'-bipyridyl	0.0097	0.0158	0.0013

a) $E(E)_{obsd}$'s are the values observed in ethanol glasses.

As given in Table 2, the result thus obtained is in qualitative agreement with the experimental one except that the E value of 3,3'-DMBPY is slightly larger than that of 6,6'-DMBPY. Such a qualitative agreement may imply that the difference among the E values is mainly due to the change of spin distribution arising from the methyl position in each pyridine ring. As the overestimation of E value for 3,3'-DMBPY is actually small, this discrepancy may possibly be due to the formation of hydrogen-bond between the nitrogen atom and one of the methyl protons. It may be noted here that if the spin density of the triplet state at each atom $\rho_i=(\rho_i^{lv}+\rho_i^{ho})/2$ is used in such an evaluation only a qualitative trend for the E values cannot satisfactorily be obtained, since the ZFS originates from the interaction between two different electron spins. Actually, the present evaluation should be applicable to a comparison among molecules with similar structures because of its simplicity.

If the a axis is taken to be perpendicular to the b direction (parallel to the central C–C bond) in the molecular plane of BPY or symmetrically substituted BPY's, the off-diagonal component of the **D** tensor, $(3/4)g^2\mu_B^2\langle -2ba/r^5\rangle$, is non-zero for the E conformer, while it is zero for the Z conformer. So far as the simple LCAO-MO's are used for the evaluation of spin distribution, the other components of $(3/4)g^2\mu_B^2\langle(r^2-3z^2)/r^5\rangle$ and $(3/4)g^2\mu_B^2\langle(a^2-b^2)/r^5\rangle$ of the E conformer are unchanged from those of the corresponding Z conformer. As a result, one may roughly infer that the E value of the Z conformer is generally small as compared with that of the corresponding E conformer, while the D values in these conformations are nearly the same, as in the case of BPY. It may be noted here that such a relation should not be valid for cases where the higher order effects on the spin distribution are not very small and there are exceptions for some of the related molecules. For example, the E value of (Z)-dimethylbiphenyls is rather larger than that of the corresponding E conformer, although the difference between them is relatively small.[8]

Since the point-dipole approximation is less satisfactory to the out-of-plane component in the **D** tensor, the D values were not evaluated in the present work. A more detailed calculation of the ZFS parameters will be published in the forthcoming paper.

The authors wish to thank Professor M. Kinoshita, The University of Tokyo, and Professor K. Itoh, Osaka City University, for their kind advise. Also, they wish to thank Dr. Y. Kaizu, Tokyo Institute of Technology, for donating 4,4'- and 5,5'-DMBPY's, Dr. H. M. Suzuki, Government Industrial Research Institute, Tohoku, Nigatake, for donating 3,3'-DMBPY, and Professor T. Hoshi, Aoyama Gakuin University, for supplying BPY- and 5,5'-DMBPY-containing PVA films in the preliminary step of the present work. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 347005 from the Ministry of Education, Science and Culture.

^{13}C Spin-lattice Relaxation and Molecular Motion in Liquid and Plastic 2,2-Dimethylpropanoic Acid

Tooru HASEBE*† Nobuo NAKAMURA, and Hideaki CHIHARA
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received October 4, 1979)

Individual ^{13}C spin-lattice relaxation times (T_1) of 2,2-dimethylpropanoic acid (DMPA) in plastic and liquid phases have been measured by a pulse Fourier transform NMR technique at 15.036 MHz. In the plastic phase (278.9 K to 308.5 K), the minimum in the T_1 was observed; 0.35 s at 289.0 K for methyl carbon and 2.67 s at 289.0 K for quaternary carbon. The temperature dependence of the T_1 was analyzed by extending Woessner's treatment to the case of three independent degrees of reorientational freedom; internal methyl reorientation, *t*-butyl reorientation about C–COOH bonding axis, and isotropic molecular reorientation. In the plastic phase the isotropic reorientation of molecular dimeric units formed through hydrogen bonds is responsible for the ^{13}C-relaxation. The activation parameters for this motion were obtained; $E_a=56.4\pm6.3$ kJ mol^{-1} and $\tau_0=(4.6\pm4.0)\times10^{-19}$ s. In the liquid phase from the melting point to 351 K, the T_1 showed a monotonous increase with increasing temperature. In this liquid phase the isotropic molecular reorientation of the dimer units of DMPA is also responsible for the ^{13}C-relaxation. The E_a of 23.4 ± 2.4 kJ mol^{-1} and the τ_0 of $(9.6\pm5.8)\times10^{-14}$ s for this motion were obtained.

2,2-Dimethylpropanoic acid ($C(CH_3)_3COOH$, hereafter abbreviated as DMPA) is a globular molecule and crystallizes in a face-centered cubic structure[1] which exists between 278.9 K and the melting point, 308.5 K. This phase is known as an orientationally disordered phase and its static and dynamic properties have been studied by various techniques.[2–11] A dielectric measurement by Kondo and Oda[2] reported relatively low dielectric constants both in the plastic and liquid phases in spite of the existence of the strongly polar carboxyl group in the molecule. They interpreted this phenomenon in terms of possible dimerization in these phases. They also observed that a small jump in the dielectric constant on passing the melting point is consistent with the change in the density accompanied with fusion, suggesting that the extent of the excitation of the molecular rotational motion in the plastic phase is comparable to that in the liquid. Measurements of the nuclear magnetic relaxation times provide information about the nature of the molecular translational diffusion in addition to the molecular rotational motion. Measurements of ^1H spin-lattice relaxation times T_1 in the laboratory-fixed coordinate system[6,8,10] as well as $T_{1\rho}$ in the rotating frame[6,10] on DMPA showed that the molecules undergo rapid isotropic reorientation in the plastic phase with the correlation time of about 10^{-9} s[10] at the melting point. The activation energy E_a in the plastic phase was reported to be 50.2 ± 8.4 kJ mol^{-1} (from $T_{1\rho}$)[10] and 63 ± 5 kJ mol^{-1} (from $T_{1\rho}$)[6] for the translational diffusion which are smaller than that found by a radio-active tracer experiment[4] by a factor of 0.55.

On the other hand, the correlation time at the infinite temperature, τ_0, determined by NMR[10] is larger than that by the tracer experiment[4] by a factor of 10^7. A similar discrepancy has been recognized in the case of cyclohexane.[12,13]

If it happens that the carboxyl proton can migrate independently of the molecular body, the proton relaxation time should be affected b its motion. It should be noted here that the relaxation measurement of ^{13}C instead of ^1H might provide information about the motion of the molecule as a whole: For it is reasonable to consider that the T_1 of ^{13}C nuclei located in the inner part of the molecule is determined dominantly *via* the dipolar interaction with the intramolecular protons and weakly depends on the motion of the other molecules. In order to examine the characteristics of the motion of the molecular body as a whole in more detail, we measured the spin-lattice relaxation time of ^{13}C in both the plastic and the liquid phases of DMPA. In the course of the present study preliminary experimental results of the T_1 measurements of ^{13}C in DMPA were published by Graham and Darby,[11] but no detailed analysis was made as to the modes of molecular motions nor the activation parameters were presented. This paper will present the results of the measurements of T_1 of ^{13}C and report the activation parameters deduced from these experiments. The microscopic modes of the molecular motions in the plastic and liquid phase will be discussed in relation to the previous works on ^1H-NMR and Rayleigh scattering.[9]

Experimental

DMPA (G.R.) was purchased from Tokyo Kasei Kogyo Co., LTD. The material was subjected to vacuum distillation and degassing *via* freeze-pump-thaw cycles and then sealed under vacuum in a Pyrex 8 mm tube in outside diameter. The ^{13}C spin-lattice relaxation time was measured at the frequency of 15.036 MHz by the $[\pi-t-\pi/2\ (\mathrm{FID})-t_0-]_n$ pulse sequences ($n=20$ and t_0—$10T_1$ in our experiment) using pulse Fourier transform NMR equipment JEOL-PFT-60, where FID stands for the free induction decay of magnetization. These measurements were performed between 278.9 K and 351 K. The proton decoupling technique was used at a power of 4 W of a noise modulated continuous rf wave at 59.80165 MHz; the noise band width was 2.5 kHz. A nuclear Overhauser effect (NOE) for the methyl carbon was determined by dividing the integrated intensity in the proton-decoupled ^{13}C-NMR spectra by the total integrated intensities in the proton-coupled ^{13}C-NMR spectra. The overall spec-

† Present address: Department of Chemistry, Faculty of Education, Fukushima University, Matsukawa-machi, Fukushima 960-12.

tral frequency range was 800 Hz and the number of accumulation was 500. The temperature was measured with a copper-constantan thermocouple and was controlled to within ± 1 K by means of a gas-flow crystat. The static magnetic field was controlled by the technique of NMR locking using an external deuteron standard.

Results and Discussion

Plastic Phase. Three resonance lines were observed in the ^{13}C-NMR of DMPA by the proton decoupling method. The most intense line at the highest frequency was assigned to the methyl carbon by means of the proton-coupling method. The lowest frequency line was due to the carboxyl carbon and the other one was due to the quaternary carbon. The temperature dependence of the line shapes of these signals are shown in Fig. 1. The chemical shift of the quaternary carbon

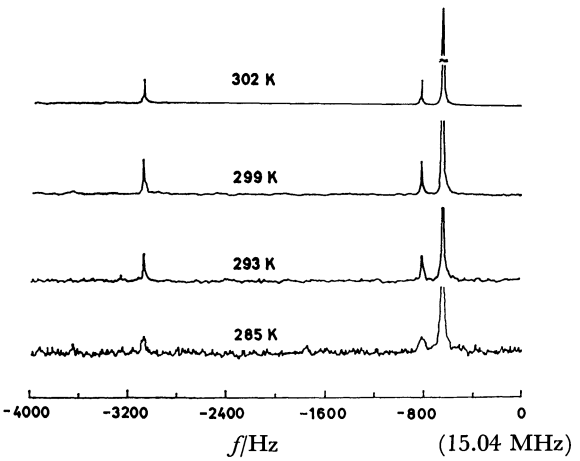

Fig. 1. Temperature dependence of line shape in plastic DMPA.

with respect to the methyl carbon is 11.44 ± 0.07 ppm and that of the carboxyl carbon is 158.62 ± 0.07 ppm. The magnitudes of these chemical shifts were almost temperature-independent. A coupling constant (J_{C-H}) between ^{13}C and ^{1}H nuclei in the methyl group is 127 ± 2 Hz at 302.2 K. Graham and Darby[11] pointed out that the J_{C-H} in the plastic phase differs by $\approx$20 Hz from that in the liquid phase, but such a difference was not observed in the present experiment within the experimental error. The line-width of each signal decreases gradually with increasing temperature in a way similar to the case of ^{1}H-NMR experiments,[3,5] suggesting the onset of the progressive excitation of self-diffusion. The temperature dependence of the T_1 for the methyl and the quaternary carbon is shown in Fig. 2, which shows the existence of a shallow minimum in T_1 of the methyl carbon at 289.0 K (0.35 s) and of the quaternary carbon at 289.0 K (2.67 s).

Jackson and Strange[6] observed a sudden jump of T_1 just below the melting point in their ^{1}H-NMR and attributed this phenomenon to some kinds of liquid-like behavior in the plastic phase. However, we did not find such a jump of T_1 up to the melting point in our ^{13}C-relaxation study. Kimtys[14] reported from his high

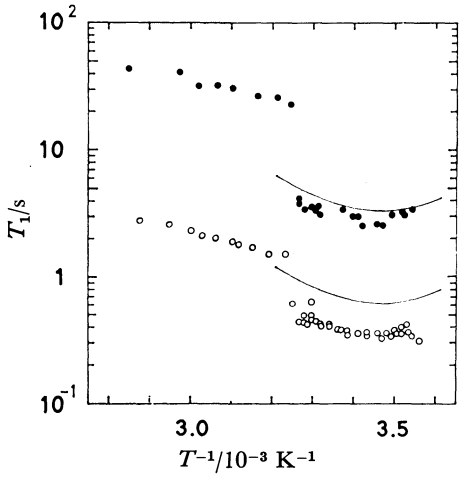

Fig. 2. Temperature dependence of spin-lattice relaxation times; ● for quaternary carbon and ○ for methyl carbon.
Two solid lines are calculated T_1 values.

resolution ^{1}H-NMR experiment that the carboxyl proton signal was accompanied with a satellite line on the low frequency side which he regarded as due to the hydrogen bonding effect; The intensity of that satellite line increased with decreasing temperature, whereas the intensity of the main carboxyl proton line decreased. In the case of the carboxyl ^{13}C signal in our experiment, however, such a phenomenon was not observed as is evident from Fig. 1. This fact suggests that the contribution of the motion of the carboxyl proton to the relaxation time of ^{13}C would be much smaller than that of the carboxyl proton to the ^{1}H-relaxation. Therefore, we can safely disregard the effect of the dynamics of the carboxyl proton in the analysis of the relaxation results of ^{13}C.

The basic expression for the ^{13}C nuclear spin-lattice relaxation rate due to dipole-dipole interaction under the proton-decoupled conditions is given by[15]

$$1/T_1 = \gamma_C^2\gamma_H^2\hbar^2 I(I+1)\sum\{J^{(0)}(\omega_C-\omega_H)/12 + 3J^{(1)}(\omega_C)/2 + 3J^{(2)}(\omega_C+\omega_H)/4\} \quad (1)$$

where γ_C and γ_H are the nuclear gyromagnetic ratios for ^{13}C and ^{1}H nuclei, respectively, $\hbar$ is Dirac's constant, I is the nuclear spin quantum number of the ^{1}H nucleus ($I=1/2$), and ω_C and ω_H are the Larmor frequencies of precession in the static magnetic field; In the present case these values are $\omega_C/2\pi=15.036$ MHz and $\omega_H/2\pi=59.802$ MHz, respectively. The sum in Eq. 1 is taken over all ^{13}C–^{1}H pairs. We assume that the following three types of molecular motions may occur in the plastic phase: (1) the internal reorientation of the methyl groups (C_3-reorientation), (2) the reorientation of the *t*-butyl group about the bonding axis between the quaternary carbon and the carboxyl carbon in the molecule (C_3'-reorientation), and (3) the isotropic molecular reorientation. These motions may be characterized by three different correlation times: τ_m (C_3-reorientation), τ_M (C_3'-reorientation), and τ_r (isotropic molecular reorientation). The self-diffusion is not taken into the consideration because it was found by our experiment[16] of the pressure dependence of the T_1

(^{1}H-NMR) that the self-diffusion was not responsible for the T_1 in the plastic phase of DMPA.

Woessner calculated T_1 for two identical spins ($I=1/2$) in the presence of anisotropic reorientation.[17] By extending his treatment to the case of three independent degrees of reorientational freedom mentioned above, we obtained the theoretical T_1 for the methyl carbon as follows:

$$1/T_1 = (3\gamma_C^2\gamma_H^2\hbar^2/10r^6)\{Wg(\omega_C, \omega_H, \tau_r) + Xg(\omega_C, \omega_H, \tau_1) + Yg(\omega_C, \omega_H, \tau_2) + Zg(\omega_C, \omega_H, \tau_3)\}, \quad (2)$$

where r is the ^{13}C–^{1}H internuclear distance in a methyl group and the function $g(\omega_C,\omega_H,\tau)$ has the form

$$g(\omega_C,\omega_H,\tau) = \tau/\{1+(\omega_C-\omega_H)^2\tau^2\} + 3\tau/\{1+\omega_C^2\tau^2\} + 6\tau/\{1+(\omega_C+\omega_H)^2\tau^2\}. \quad (3)$$

Here τ_i's are defined by

$$\tau_1 = 1/(1/\tau_r+1/\tau_M),$$
$$\tau_2 = 1/(1/\tau_r+1/\tau_m), \quad (4)$$
$$\tau_3 = 1/(1/\tau_r+1/\tau_M+1/\tau_m).$$

Coefficients W, X, Y, and Z were calculated to be

$$W = (3\cos^2\Delta-1)^2(3\cos^2\theta-1)^2/16,$$
$$X = 3(3\cos^2\Delta-1)^2(\sin^2 2\theta + \sin^4\theta)/16,$$
$$Y = 9(\sin^2 2\Delta \sin^2 2\theta+\sin^4\Delta \sin^4\theta)/32,$$
$$Z = 3\{4\sin^2 2\Delta(2-3\sin^2 2\theta/4) + \sin^4\Delta(3\sin^2 2\theta/4+3\cos^2\theta+5)\}/32, \quad (5)$$

where Δ is the angle between the ^{13}C–^{1}H internuclear vector and the C_3-axis, and θ is the angle between the C_3-axis and the molecular C_3'-axis. Here intermethyl interactions and cross-correlation effect have been ignored. In our model $\Delta=\theta=\cos^{-1}(1/3)$ and these coefficients become $W=1/81$, $X=8/81$, $Y=160/729$, $Z=488/729$; Here the bond angles of H–C–H in methyl group and C–C–H has been assumed to be tetrahedral. As the C_3- and the C_3'-reorientations are rapid enough in the plastic phase (*e.g.*, $\tau_m\approx10^{-11}$ s and $\tau_M\approx10^{-12}$ s just below the transition point[10]), all terms except the first in the braces of Eq. 2 are negligibly small compared with the first term. Hence Eq. 2 can be written as

$$1/T_1 = (3W\gamma_C^2\gamma_H^2\hbar^2/10r^6)g(\omega_C, \omega_H, \tau_r). \quad (6)$$

The activation parameters for the isotropic molecular reorientation were obtained by fitting the T_1 data of Fig. 2 to Eq. 6 assuming the Arrhenius type of activation process

$$\tau = \tau_0 \exp(E_a/RT). \quad (7)$$

The results for the methyl carbon are E_a(methyl)$=56.4\pm6.3$ kJ mol^{-1} and τ_0(methyl)$=(4.6\pm4.0)\times10^{-19}$ s, and tabulated in Table 1 together with the results reported previously. The theoretical T_1 calculated by use of Eq. 6 is given in Fig. 2 where $r=0.109$ nm was assumed; $T_{1\,min}$(calcd)$=0.64$ s at 287.2 K. If the same mechanism governs the T_1 of the quaternary carbon, we obtain the T_1 for this carbon as follows,

$$1/T_1 = (9W'\gamma_C^2\gamma_H^2\hbar^2/10l^6)g(\omega_C, \omega_H, \tau_r) \quad (8)$$

where $\Delta=28.2°$ and $\theta=\cos^{-1}(1/3)$ and the coefficient W' is 0.04911. l is the internulear distance between the quaternary carbon and a methyl proton. We obtained from the curve-fitting the activation parameters for the quaternary carbon as E_a(quat.)$=56\pm11$ kJ mol^{-1} and τ_0(quat.)$=(4.3\pm4.0)\times10^{-19}$ s. These activation parameters coincide with those for the methyl carbon. The calculated T_1 curve with $l=0.216$ nm is shown in Fig. 2; $T_{1\,min}$(calcd)$=3.23$ s at 287.2 K. The activation parameters obtained here do not agree with the results of the ^{1}H-NMR experiments; E_a is twice as large as E_a from ^{1}H-NMR (25.1—36.0 kJ mol^{-1})[6,10,16] and τ_0 is very short compared with that of ^{1}H-NMR (10^{-13}—10^{-15} s).[6,10,16] Our results agree well with the results ($E_a=60.0\pm4$ kJ mol^{-1} and $\tau_0=3.7\times10^{-19}$ s) of depolarized Rayleigh scattering experiment by Bird, *et al.*[9] but do not agree with the results ($E_a=30.9\pm3.9$ kJ mol^{-1} and $\tau_0=3.1\times10^{-14}$ s) obtained by Beysens, *et al.*[18] Although our activation parameters may involve some error which comes from the neglect of the contributions to the T_1 other than the molecular overall rotation, the discrepancy between our value and those obtained by the ^{1}H resonance exceeds the combined experimental uncertainty. This fact suggests that the migration of the acidic protons with some smaller activation energy[7] contributes to the relaxation times of the protons.

As shown in Fig. 2 the calculated T_1(methyl) is twice as large as the observed T_1(methyl), and the calculated T_1(quat.) is larger than the observed T_1 (quat.) by about 20 per cent. Such a discrepancy is probably due to the neglect of contributions of the C_3- and C_3'-reorientations to the T_1. It is interesting to see that the correlation time (10^{-8} to 10^{-9} s) for the isotropic molecular reorientation is much longer in DMPA than those in other undimerized plastic crystals. For example, the correlation time of 5.5×10^{-12} s (at 295 K) in plastic $C_6F_9H_3$ was obtained from the neutron scattering study[19] and that of 10^{-12}—10^{-13} s in plastic $C(CH_3)_4$ was obtained by the infrared,[20] the Raman scattering,[20] and the cold neutron scattering studies.[21] The very slow reorientational motion of DMPA may be attributed to the hydrogen bonding between neighbouring molecules which probably hinders the reorientation. This mechanism is supported by the

dielectric study[2] and also by the X-ray diffraction study[1] which reports that the crystal is made up of dimers orienting randomly. Recently we measured T_1 of DMPA as a function of pressure and obtained the activation volume of $\Delta V^* = (0.24—0.26) V_m$,[16] which is about twice as large as those in normal undimelized plastic crystals.[22] This fact also supports the formation of the dimers in the plastic phase of DMPA. Therefore, we conclude that the isotropic molecular reorientation of the dimer units is responsible for the ^{13}C spin-lattice relaxation in the plastic phase.

Liquid Phase The observed T_1 for the methyl and quaternary carbon in the liquid phase increase monotonously as shown in Fig. 2. The T_1 values of the quaternary carbon are larger than those of the methyl carbon by a factor of 16 but the slopes of the T_1 for these two kinds of carbons agree with each other within experimental error. No change has been observed on melting in the magnitude of the relative chemical shifts of the quaternary carbon as well as the carboxyl carbon with respect to the methyl carbon. The J_{C-H} values in a methyl group are 128.0±0.3 Hz at 319 K and 128.0± 0.3 Hz at 333 K, respectively, and depend little on temperature.

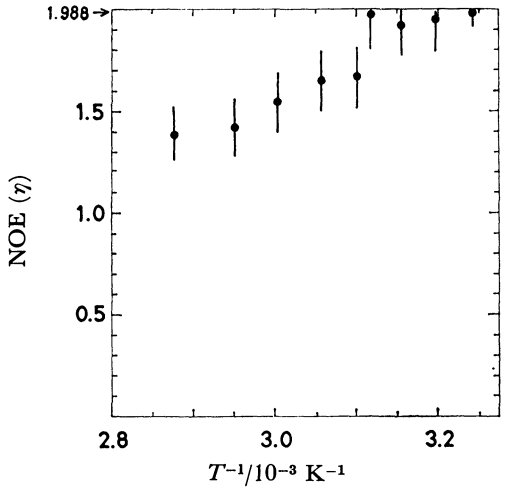

Fig. 3. Temperature dependence of NOE for methyl carbon.

The nuclear Overhauser effect (η) for the methyl carbon decreases from $\eta=1.988$ to 1.38 with increasing temperature as shown in Fig. 3. It shows that dipolar contribution to the relaxation becomes small with increasing temperature. When the ^{13}C–^{1}H dipole-dipole interaction is the dominant mechanism in the ^{13}C-relaxation, the theoretical maximum NOE (η) shoud be $\eta=1.988$.[23] In the present case, the dipole-dipole relaxation competes with other relaxation mechanisms, *e.g.* spin-rotational relaxation, chemical shift anisotropy relaxation, scalar relaxation, *etc.* The contribution of the dipole-dipole interaction to the spin-lattice relaxation time, T_1^{DD}, may be calculated by using the experimental NOE;[23,24]

$$T_1^{DD} = 1.988 T_1^{obsd}/\eta, \quad (9)$$

where T_1^{obsd} stands for the observed value. The temperature dependences of T_1^{obsd} and T_1^{DD} are shown

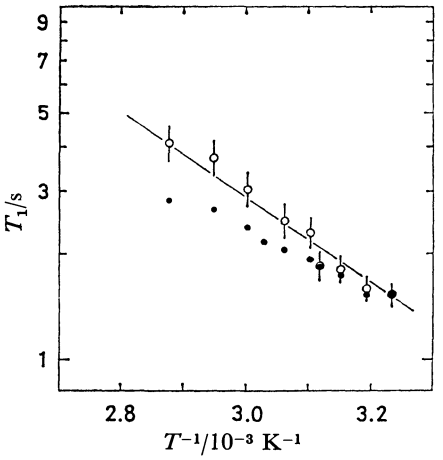

Fig. 4. Temperature dependence of T_1 for methyl carbon in the liquid phase; ● for T_1^{obsd} and ○ for T_1^{DD}.

in Fig. 4 by closed circles and open circles, respectively. Under the condition of the proton decoupling it may be assumed that the intermolecular dipole-dipole relaxation is insignificant, as has been mentioned by Kuhlmann *et al.*[23] We may also neglect the contribution of the C_3- and C_3'-reorientations to the T_1^{DD} in the liquid state. Therefore only one dominant relaxation mechanism is the isotropic reorientation of the molecules and, under the condition of the extreme narrowing limit, Eq. 6 leads to the expression of the T_1^{DD} as

$$1/T_1^{DD} = 3W\gamma_C^2\gamma_H^2\hbar^2\tau/r^6, \quad (10)$$

where τ is the correlation time for the isotropic molecular reorientation. The correlation time, which decreases slightly from 8.8×10^{-10} s at the melting point to 2.9×10^{-10} s at 351 K calculated from Eq. 10 with $r=$ 0.109 nm is longer by a factor of ten than the correlation time (6.5×10^{-11} s at the melting point decreasing to 3.1×10^{-11} s at 351 K) of the liquid DMPA obtained by depolarized Rayleigh scattering experiment by Beysens *et al.*[18] From the slope of the correlation time against the inverse of temperature, we obtained the activation parameters of $E_a=23.4\pm2.4$ kJ mol^{-1} and $\tau_0=(9.6\pm5.8)\times10^{-14}$ s. These parameters are to be compared with those obtained by Beysens *et al.*[18]—$E_a=$ 15.4±1.0 kJ mol^{-1} and $\tau_0=1.6\times10^{-13}$ s. It is interesting to see that the correlation time obtained here is longer than those in the non-associated globular compounds by a factor of 10^2 to 10^3, *e.g.*, liquid $C(CH_3)_4$ (10^{-12}—10^{-13} s),[20] and liquid norbornadiene ($\approx10^{-13}$ s).[25] This fact also suggests that the DMPA molecules behave as the self-associated dimeric units even in the liquid state.

Conformations of Acetanilide and Related Compounds Studied by Ultraviolet Photoelectron Spectroscopy

Ryoichi NAKAGAKI,# Tsunetoshi KOBAYASHI,† and Saburo NAGAKURA*

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

† *The Institute of Physical and Chemical Research, Hirosawa, Wako, Saitama 351*

(Received October 19, 1979)

Conformations of acetanilides were studied by UPS in the vapour phase. The dihedral angle, θ, between the amide group and the phenyl group was evaluated from the difference in the vertical ionization energy, ΔE_{iv}, between the two MO's, the anti-bonding and bonding type combinations of the benzene ring $e_{1g}(S)$ orbital and the highest occupied π orbital of the amide group. The steric inhibition of conjugation due to *N*-methylation is larger than that due to ortho-methylation. For this series of compounds, ΔE_{iv} is directly proportional to $\cos\theta$ and this simple relationship is useful for the rough estimation of θ.

Ultraviolet photoelectron spectroscopy (UPS) is useful for the study of conformations of rather large molecules in the vapour phase. UPS has hitherto been used for the investigation of steric hindrance effects upon the conformations of various aromatic compounds such as nitrobenzenes, anilines, biphenyls, phenylethylenes, and so forth.[1-5] In this paper we report the conformations of some gaseous acetanilides studied by UPS, comparing the conformational data in the vapour phase with those in the crystalline state obtained by the X-ray diffraction method.

Experimental

The compounds studied are as follows: acetanilide (**1**), *o*-methylacetanilide (**2**), *N*-methylacetanilide (**3**), *N*,*o*-dimethylacetanilide (**4**), *N*,2′,6′-trimethylacetanilide (**5**), and oxindole (**6**).

1: $R_1=R_2=R_3=H$
2: $R_1=R_2=H$, $R_3=CH_3$
3: $R_1=CH_3$, $R_2=R_3=H$
4: $R_1=R_2=CH_3$, $R_3=H$
5: $R_1=R_2=R_3=CH_3$

The photoelectron spectra of these compounds were measured with the photoelectron spectrometer described previously,[1] the 21.22 eV He I resonance line being used as the excitation source.

Results and Discussion

The photoelectron spectra of acetanilide and related compounds were measured with the results shown in Fig. 1. The vertical ionization energies, E_{iv}, derived from the spectra are listed in Table 1. In the region of 8—11 eV, the spectra of **1**, **2**, **3**, **4**, and **6** consist of four bands: two bands correspond to the two molecular orbitals, $\pi_-(S)$ and $\pi_+(S)$, which are interpreted approximately to be brought about by the antibonding and bonding type combinations of the benzene ring $e_{1g}(S)$ orbital and the highest occupied π orbital of the acetylamino group; the other two bands correspond to the a_2-like MO, $\pi(A)$, derived from the benzene ring $e_{1g}(A)$ orbital and to the non-bonding orbital of the carbonyl oxygen, n(O).

The assignments of $\pi_-(S)$, $\pi_+(S)$, $\pi(A)$, and n(O)

Present address: The Department of Chemistry, The University of British Columbia, Vancouver, B.C., Canada V6T 1W5.

bands of **1**, **2**, **3**, **4**, and **6** were made on the basis of the previous interpretation of the photoelectron spectra of anilines[1] and aliphatic amides.[6] The result is given in Table 1. The assignments of π(A) and n(O) bands were supported by the methyl substituent effect. Ortho-methylation is expected to decrease the ionization energy of π(A) MO, while *N*-methylation may have little effect on the value. The ionization energies of the n(O) MO's of **1**, **2**, **3**, **4**, and **6** are expected to vary only slightly by the alkylation on the ortho-position of the ring or on the nitrogen atom and to have the values similar to those of aliphatic amides, *i.e.*, 9.5—10 eV.[6] Comparative consideration of the E_{iv} values between **1** and **2** and between **1** and **3** leads us to the assignment given in Table 1. The UPS bands of the other compounds were assigned in a similar manner. In all cases except for **5** (see the later discussion) the first bands correspond to the ionization from the π_-(S) MOs.

The ionization energy difference between the π_+(S) and π_-(S) bands of acetanilides, $\Delta E_{iv}[\pi_+(S), \pi_-(S)]$, is approximately given by the following equation[2] (the two-orbital model):

$$\Delta E_{iv}[\pi_+(S), \pi_-(S)] = E_{iv}[\pi_+(S)] - E_{iv}[\pi_-(S)] = [(A_{Am} - A_{Ph})^2 + 4B_\theta^2]^{1/2}, \quad (1)$$

where $A_{Am} = \langle\psi_{Am}|H|\psi_{Am}\rangle$,

$A_{Ph} = \langle\psi_{Ph}|H|\psi_{Ph}\rangle$,

and $B_\theta = \langle\psi_{Am}|H|\psi_{Ph}\rangle$.

ψ_{Am} and ψ_{Ph} are the wave functions of the acetylamino (Am) and phenyl (Ph) moieties, respectively, and A_{Am} and A_{Ph} are set equal to the negative of the first E_{iv}'s of the corresponding *N*-methylated acetamides[6] and those of the benzenoid molecules,[1b] respectively. The off-diagonal element, B_θ, depends on the dihedral angle, θ, between both moieties and is assumed to be represented by the following relation: $B_\theta = B\cos\theta$ where B is the matrix element for the completely planar molecule, oxindole ($\theta = 0°$). The dihedral angles evaluated by putting the numerical values into Eq. 1 are listed in Table 2 together with the ΔE_{iv} values.

In the case of the trimethylated anilide, **5**, the assignment of the first UPS band around 9 eV was not unambiguous because of the considerable overlap of the π_-(S), π(A), and π_+(S) bands. If the first peak is of π(A) nature, as for *m*-xylene,[7] the dihedral angle should be very close to 90°, and if it is attributed to the π_-(S) MO, the dihedral angle is calculated to be 85°. In either case the dihedral angle is surely larger than that of the dimethylated anilide, **4**.

The enhancement of non-planarity by *N*-methylation was also found by means of the X-ray crystal analysis technique.[8] In the crystalline phase the dihedral angles of **1** and **3** were reported to be 17.6°[8a] and 90°,[8b] respectively. It is interesting to note that the twisting of the amide group in **3** is not so extreme in the vapour phase as in the solid state, while those of **1** in both phases are comparable to each other.

From Table 2, it is concluded that *N*-methylation causes more drastic steric inhibition of conjugation than ortho-substitution. By considering the conformational change induced by *N*-methylation, the conspicuous hypsochromic effect observed for the *N*-methylated anilides, **3** and **4**, can be explained in terms of reduced π conjugation.[9]

Table 2. Difference in ionization energies, ΔE_{iv}, and dihedral angles, θ

Compound	ΔE_{iv}/eV[a]	θ/° (gas)[b]	θ/° (crystal)[c]
Acetanilide (**1**)	2.29	23	17.6
o-Methylacetanilide (**2**)	2.25	27	
N-Methylacetanilide (**3**)	1.21	60	90
2′,6′-Dimethylacetanilide	1.10[d]	69	
N,*o*-Dimethylacetanilide (**4**)	0.57	77	
N,2′,6′-Trimethylacetanilide (**5**)	(0.2)	85—90	
Oxindole (**6**)	2.50	0	

a) Experimental error of ±0.05 eV. b) Uncertainty of ±3° is estimated for θ values from the error of ΔE_{iv}. Numerical values used in the calculation of the dihedral angles were as follows: $A_{Am} = -9.68$ eV for the secondary amides, **1**, **2**, and **6**, $A_{Am} = -9.09$ eV for the tertiary amides, **3**, **4**, and **5**,[6] $A_{Ph} = -9.23$ eV for the benzene derivatives, **1** and **3**, $A_{Ph} = -9.13$ eV for the toluene derivatives, **2**, **4**, and **6**, and $A_{Ph} = -9.03$ eV for the *m*-xylene derivative, **5**.[1b] A virtual MO for toluene which results in the formation of acetanilide derivatives is estimated to have an orbital energy of −9.13 eV, which is the negative of the average ionization energy of the corresponding MO's for benzene and *m*-xylene: the benzene e_{1g} π orbital with E_{iv} of 9.23 eV and the *m*-xylene b_1 π orbital with E_{iv} of 9.03 eV.[1b] This averaging procedure is based on the additive nature of the methyl substituent effect on the lower π ionization energies of benzenes (see, for example, Ref. 1b). c) Determined by means of the X-ray diffraction[8]. d) From Ref. 5.

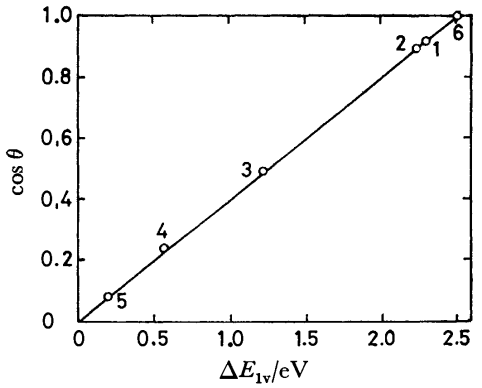

Fig. 2. Plot of cos θ against the difference in ionization energy, $\Delta E_{iv}[\pi_+(S), \pi_-(S)]$.

Finally, the cos θ's estimated for the vapour phase are plotted against $\Delta E_{iv}[\pi_+(S), \pi_-(S)]$'s in Fig. 2. The plotted points fall on a straight line passing through the origin. This is because the $(A_{Am} - A_{Ph})$ term values in Eq. 1 are small for the compounds studied here. The linear relation in Fig. 2 may be useful for the rough estimation of the dihedral angles in acetanilides.

We are indebted to Dr. Michio Kondo, Central Research Laboratories, Sankyo Co. Ltd., for his kindness in giving us *N*,2′,6′-trimethylacetanilide.

Correlation NMR Spectroscopy with a Water Signal Subtracting System

Hideo AKUTSU, Yoshimasa KYOGOKU,* and Isao KAGAWA†
Institute for Protein Research, Osaka University, Suita, Osaka 565
†*JEOL Technical Service Co. Ltd., Nishinakajima 5-14-22, Yodogawa-ku, Osaka 532*
(Received October 23, 1979)

A modified correlation NMR method which includes the baseline correction systems in both hard- and softwares has been developed. By applying this method the proton signals of cytochrome b_5 and adenosine 5′-monophosphate at low concentration in H_2O solutions were obtained.

In the investigation of biological systems by proton magnetic resonance very strong signal of the solvent H_2O or HOD is troublesome. It is especially serious in the measurements of the imino and amino proton signals of proteins and nucleic acids. They are slowly exchangeable with water protons and their signals can only be detected in H_2O solutions. If a normal pulse Fourier transform (FT) NMR is applied for H_2O solutions, the signals of the sample at low concentration are hardly detected because the ratio of the sample signal to the solvent signal is too small that the finite dynamic ranges of the receiver and analog-digital (A/D) converter overlook the sample signal. Some groups have tried to eliminate or reduce the effect of the strong solvent signal by modifying the pulse FT NMR.[1-6] Another important device to solve the problem is correlation NMR, which has been introduced by Dadok and Sprecher,[7] and developed by other groups.[8-10] In this method the spectrum can be scanned only in the necessary frequency region and optimum conditions for observing the spectra are easily adjustable. We tried to develope the method taking its advantage into account. At the present work we will show a system of correlation NMR spectroscopy containing baseline correction systems in a sampling process, which is useful to eliminate the tail of the solvent signal. And also some applications to the biological substances in H_2O solutions will be presented. We are successful in getting the spectra at low concentrations.

Instrumentation

The principle for obtaining a correlation spectrum is based on the report of Gupta *et al.*[8] The method with a reference signal is employed instead of a theoretical function method to eliminate wiggles.

Figure 1 shows the block diagram of our system of the correlation NMR spectroscopy. A JEOL PS-100 NMR spectrometer was used together with a DP-1A pulse programmer and a EC-100 computer. The computer has 20 K words of memory (16 bits/word). We constructed a sweep generator where sawtooth waves are digitalized by the use of a D/A converter (12 bits). The digitalization of the sawtooth wave is essential to determine the chemical shift because we can know the exact sweep range from the frequency counter by holding the

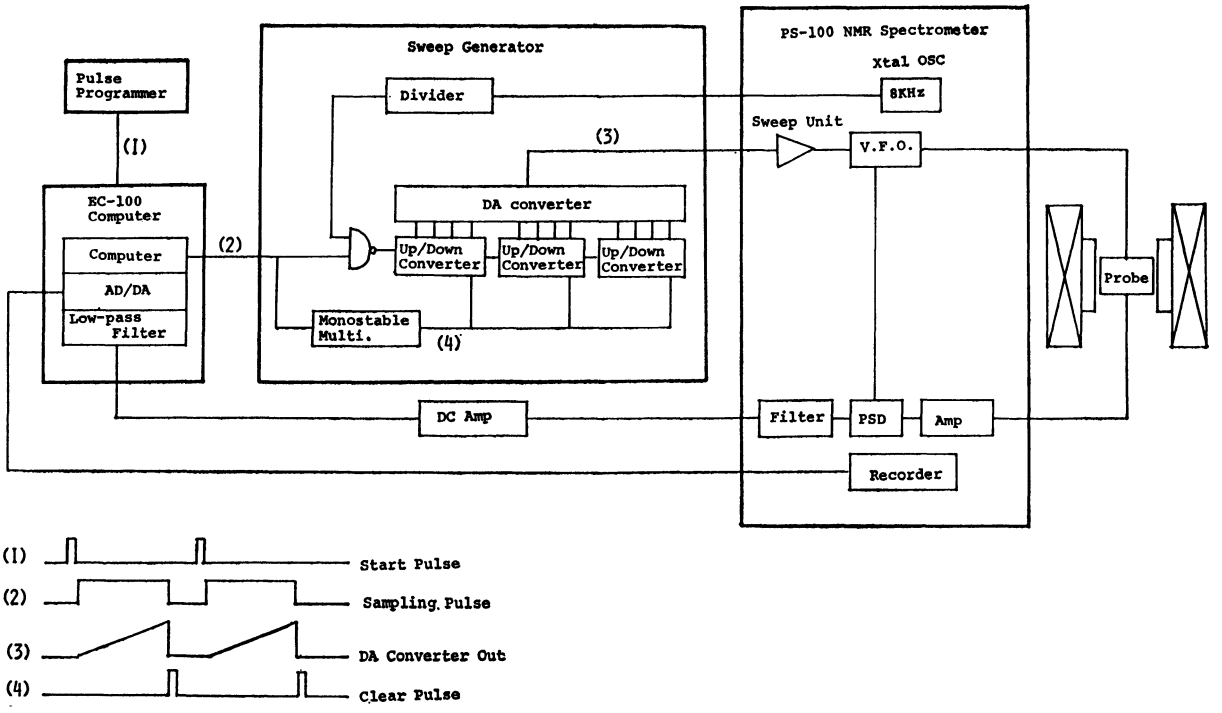

Fig. 1. A block diagram of a correlation spectrometer and a timing diagram for a computer control of a digitalized frequency sweep.

voltage of the sawtooth at the beginning and the end of the scan. The shapes of the control pulses and their relations with each other are also shown in Fig. 1. The transient response to the frequency sweep is passed through a low-pass filter and A/D converter (12 bits), then collected in the computer. The computer program for the system was written down by modifying the JEOL PFT-100 computer program. When we collect a transient response of a sample in a 4K words memory area and that of a reference signal in another 4K words memory area, we can get a final spectrum in a 8K words memory area (a 4K area for a real part and the other 4K area for an imaginary part). We confirmed the linearity of the frequency sweep and the accuracy of the chemical shift by measuring the mixture of chloroform, dichloromethane, dioxane, 1,1,1-trichloroethane, acetone, cyclohexane, and tetramethylsilane. The linearity was good enough so that the error of the chemical shift of every signal was less than 0.1%.

A hardware system for the baseline correction in the process of collecting the data was added to this correlation NMR spectrometer in order to reduce the effect of the tail of the H_2O signal. The flow chart of this system was illustrated in Fig. 2. Two kinds of baseline correction treatments were introduced into the hard and softwares. The process to eliminate the effect of a large tail of the solvent signal is as follows. At the first step, a function (a quadratic or exponential function) is subtracted from the transient response in an electronic circuit just before the phase sensitive detector (hardware subtraction). Beforehand the same treatment was done for the signal of pure solvent under the same conditions and stored in a certain memory area of the computer. This residual baseline of the solvent is further subtracted from the hardware treated sample spectrum in the computer (software subtraction). The transient response can be accumulated for certain times before this subtraction. The resultant spectrum was further accumulated in another memory area. It should be noted that the first baseline correction took away to some extent the saturation of the phase sensitive detector (PSD) by the strong solvent signal and improved the signal condition to pass through the dynamic range restriction of the A/D converter. The second step enchanced the efficiency of accumulation.

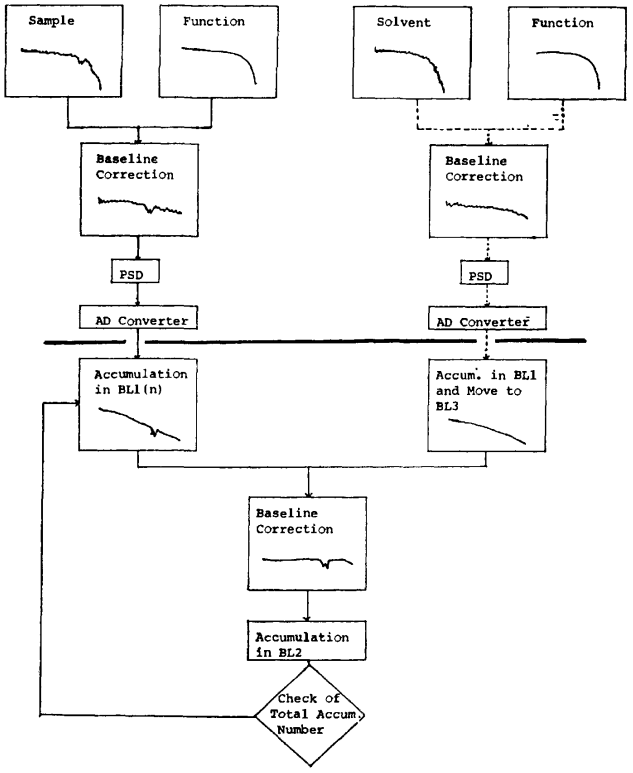

Fig. 2. A flow chart of a baseline correction system. Upper: in a hardware, lower: in a software. The part shown in broken lines indicates the one which should be operated before the treatment of the sample signal. BL1 (2 or 3): Block 1 (2 or 3) in the memory area.

Spectral Measurement

The above described correlation NMR spectroscopic method was applied to the aqueous solutions of some biological substances. Figure 3 is the 100 MHz proton magnetic resonance spectrum of the aromatic region of the oxidized cytochrome b_5 (solubilized with trypsin from rabbit liver microsomes) in D_2O solution (0.1 M phosphate buffer pD 7.0). The protein concentration is 7 mM (*MW=ca.* 12000). The chemical shift is expressed relative to the internal standard of sodium (2,2,3,3-tetradeuterio-3-trimethylsilyl)propionate (TMSP-d_4). The conditions of the measurement are given in the figure legend. All spectra hereafter were measured under the internal lock on H_2O (or HOD) signal. And their correlation was taken with a transient response

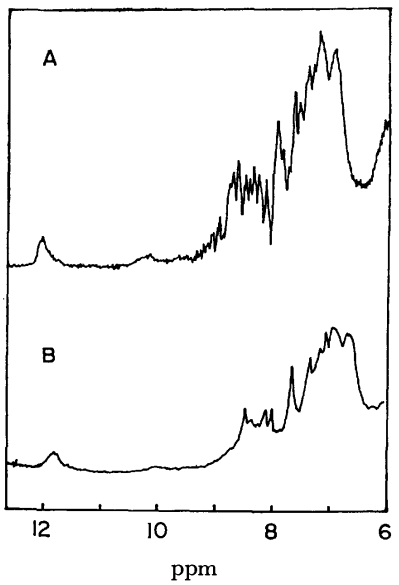

Fig. 3. (A) Transient response and (B) correlation spectrum of oxidized cytochrome b_5 from rabbit liver microsome in D_2O (0.1 M phosphate buffer pD 7.0). The concentration is 7 mM (*MW=ca.* 12000). The reference is TMS signal. Sweep direction: from higher to lower field, sampling point: 4096, sweep rate: 381.5 Hz/s, sampling time: 2.03 s, sweep repetition time: 2.10 s, filter: 250 Hz, number of accumulation: 3000. Chemical shifts are given relative to the signal of TMSP-d_4.

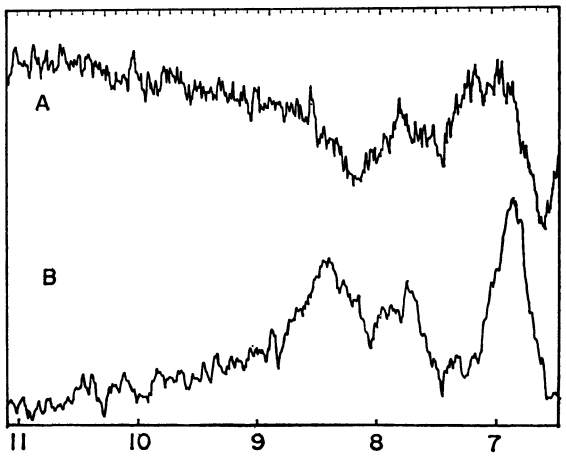

Fig. 4. (A) Transient response and (B) correlation spectrum of oxidized cytochrome b_5 in H_2O(0.1 M phosphate buffer pH 7.0). Concentration: 1 mM, reference: TMS, sweep direction: from lower to higher field, sampling point: 4096, sweep rate: 122.3 Hz/s, sampling time: 4.08 s, sweep repetition time: 5.00 s, filter: 20 Hz (sample), 125 Hz (reference), number of accumulation: 3000. Chemical shifts are given relative to the signal of TMSP-d_4.

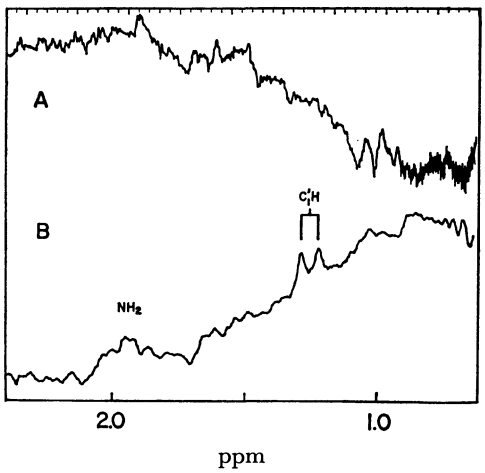

Fig. 5. (A) Transient response and (B) correlation spectrum of adenosine 5′-monophosphate sodium salt in H_2O.
Concentration: 2.5 mM, reference: TMS, sweep direction: from lower to higher field, sampling point: 4096, sweep rate: 51.3 Hz/s, sampling time: 4.09 s, sweep repetition time: 6.00 s, filter: 20 Hz, number of accumulation: for the second baseline correction(in BL 1) 10, and total 1000. A quadratic function was subtracted in the first baseline correction. Chemical shifts are given relative to the signal of H_2O.

of tetramethylsilane (TMS). Figure 3(A) is the transient spectrum and (B) is the obtained final spectrum. The spectrum shows good quality. As can be seen in Fig. 3(B) the effect from the linewidth of the reference signal (TMS) is negligible in the case of such macromolecules as proteins.

At the next step we tried to get the spectrum of the same sample in a dilute H_2O solution in the same frequency region. The spectra in Fig. 4 were obtained from the 1 mM H_2O solution of the oxidized cytochrome b_5 (0.1 M phosphate buffer at pH 7.0). Because of its severe conditions the spectrum in the higher field region than 7 ppm is not reliable. Comparing it with Fig. 3 we can see the contribution from NH_2 or NH group of this protein at 8.5 ppm. It is often required to take the spectra of proteins in H_2O at such a low concentration because of the low solubility and limitted amount of the sample.

Finally we tried to get a weak signal located closely to the solvent H_2O signal with the aid of our baseline correction system. Figure 5 shows the 100 MHz proton spectrum of the H_2O solution of adenosine 5′-monophosphate sodium salt (5′-AMP) at 2.5 mM. The observed doublet signal at about 1.2 ppm lower field from water signal comes from the C-1 proton of the ribose moiety and the broad signal at about 2 ppm is due to the amino protons of the adenine base. The long range noises arise from the subtracted baseline in a software. They obscure the broad signal to some extent. The important point of this system is to use a highly smoothed baseline at the second step of baseline correction. Otherwise, the noises are accumulated and disturb the spectrum. It should be noted, however, that a weak signal at about 1 ppm from water (6 ppm from TMSP-d_4) could be obtained, while it was impossible without the baseline correction system as shown in Fig. 4.

Discussion

Although a modified WETT method,[3] the water signal saturation method,[4] and Redfield pulse method[5] in FT NMR have shown their usefulness for aqueous solution systems, they have some disadvantages respectively. Those methods usually can eliminate only one strong signal. And it is necessary for the first method that the relaxation time of nuclei which give the signal to be eliminated is much longer than those of the other nuclei. The second method can not be applied to the exchangeable protons such as NH_2 and NH protons because of the saturation transfer from the irradiated solvent protons. The Redfield method is hard in setting the pulse condition and troublesome in baseline correction. The correlation method can avoid such disadvantages and Ozawa and Arata introduced an elegant wing processing method in correlation NMR to correct a titled baseline.[11] However correlation NMR had not yet been so far successful in getting weak signals within 1 ppm from water resonance, which was performed by the modified WEFT method.[3] It can be said that our method with a baseline correction system is promising in getting the proton signals of biological substances very close to the water resonance of solution. The system can also be applied to biomembranes or proteins in detergents where not only the solvent signal but the strong signals due to the CH_2 group of phospholipids and detergents also disturb the observation of the aimed resonance signals.

Authors wish to thank Mr. K. Nakagawa, JEOL Co. Ltd., for his kind help in the programming and also Mr. S. Tajima, Institute for Protein Research, Osaka University, for the gift of cytochrome b_5.

The Crystal Structure of *N*-(*t*-Butoxycarbonyl)-L-methionylglycine Benzyl Ester

Takashi YAMANE,* Takashi UMEMURA, Tadao KOJIMA, Yasuyuki YAMADA, and Tamaichi ASHIDA

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa, Nagoya 464

(Received October 25, 1979)

The crystal structure of *N*-(*t*-butoxycarbonyl)-L-methionylglycine benzyl ester has been determined. The crystal data are: $P2_1$, $a=15.884(4)$, $b=5.083(2)$, $c=13.296(3)$ Å, $\beta=94.54(2)°$, $Z=2$. The final R is 0.055 for 1518 reflections. In the methionyl residue the C^{α}–C^{β} bond is longer than the C^{β}–C^{γ} bond. The tendency is consistent with that found in the other methionine compounds. The methionyl side chain has the most stable trans zig-zag conformation ($\chi^1=-73.2$, $\chi^2=175.3$, and $\chi^3=174.9°$). The peptide main chains are packed in a parallel β-sheet structure, the torsion angles (ϕ,ψ) of the methionyl residue being (−110.6, 108.3°).

The structure analyses of proteins have shown that the secondary structures, such as, α-helix,[1] β-structure,[2] and β-turn[3] play an important role in the folding of proteins. On the other hand, in the crystalline state many oligopeptides are also found to have either one of the secondary structures.[4] This fact suggests that the secondary structures are significant in the peptide structures of not only polymers but also oligomers. Thus, the precise parameters of the secondary structures obtained by the crystal analyses of oligopeptides are substantially important in the refinements and the model buildings of the protein structures or the structural analyses of fibrous proteins.

In this paper the structure of *N*-(*t*-butoxycarbonyl)-L-methionylglycine benzyl ester(Boc-L-Met-Gly-OBz)† having a parallel β-pleated sheet structure is reported.

Experimental

Boc-L-Met-Gly-OBz was prepared from dicyclohexylammonium *N*-(*t*-butoxycarbonyl)-L-methionate and glycine benzyl ester tosylate in a $CHCl_3$ solution. Needle crystals were obtained from an ethyl acetate–hexane solution. Crystal data are: $C_{19}H_{28}N_2O_5S$, $M.W.=396.50$, $P2_1$, $a=15.884(4)$,

† The abbreviations used in this paper are: Boc-, *N*-(*t*-butoxycarbonyl); Ac-, *N*-acetyl; -OBz, benzyl ester; -OMe, methyl ester; -OEt, ethyl ester; -NMe, *N*-methylamide.

$b=5.083(2)$, $c=13.296(3)$Å, $\beta=94.54(2)°$, $D_m=1.235$, $D_x=1.242$ g cm^{-3}, $Z=2$, μ(Cu $K\alpha$)$=15.7$ cm^{-1}.

The intensity data were collected on a Hilger & Watts four-circle diffractometer, using Ni-filtered Cu Kα radiation. 1518 independent reflections with $2\theta \leq 110°$ were obtained, of which non-zero reflections were 1490. The ω-2θ step scan was adopted. The crystal used for the data collection had the dimensions of $0.09\times0.20\times0.43$ mm. The intensity data were corrected for Lorentz and polarization effects, but an absorption correction was not made.

Structure Determination

The structure was solved by the use of MULTAN.[5] The refinement was carried out by the block-diagonal least-squares method.[6] In the refinement, the function minimized was $\sum w(|F_o|-k|F_c|)^2$. The assignment of weight is; $w=(\sigma^2(F)+a|F_o|+b|F_o|^2)^{-1}$ for $|F_o|>0$ and $w=c$ for $|F_o|=0$, where $\sigma(F)$ is the standard deviation based on the counting statistics, and $a=-0.0479$, $b=0.0045$, and $c=0.3675$. The final R value is 0.055 for all reflections.

The atomic scattering factors were taken from "International Tables for X-Ray Crystallography," Vol. IV.[7] The calculations were carried out on a FACOM 230-75 computer at Nagoya University. The final atomic parameters are listed in Tables 1 and 2.[8]

Discussion

Bond lengths and angles of non-hydrogen atoms are listed in Table 3. The torsion angles of the peptide chain are shown in Fig. 1, together with the numbering of atoms. The definition of the torsion angles given by IUPAC-IUB Commission on Biochemical Nomenclature[9] is adopted. The stereoscopic view of the molecule drawn by ORTEP II[10] is shown in Fig. 2.

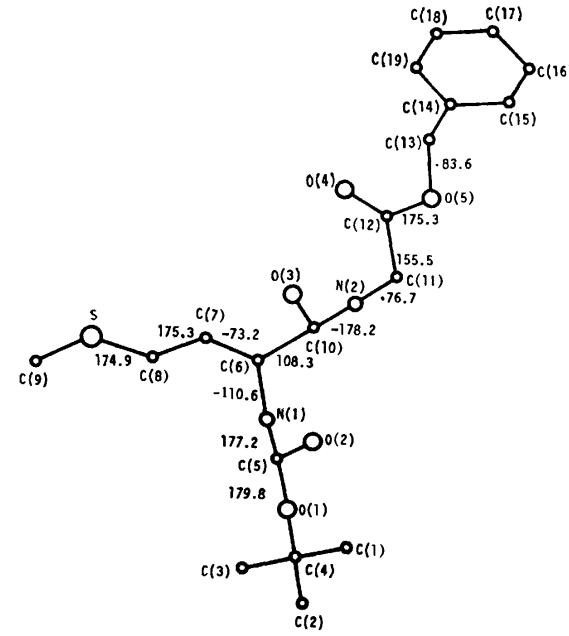

Fig. 1. Torsion angles of the peptide chain. Definitions for these angles are those given by IUPAC-IUB Commission on Biochemical Nomenclature (1970).

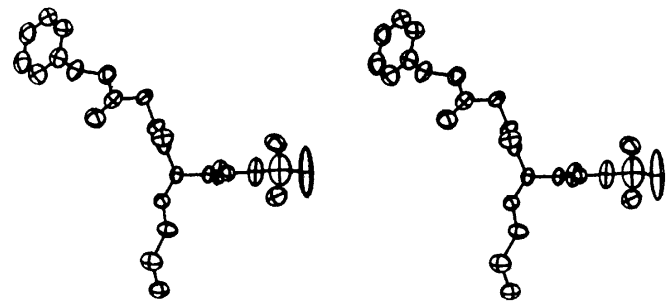

Fig. 2. Stereoscopic view with thermal ellipsoids drawn to enclose 50% probability.

The molecule is constructed with five planar groups, that is, ester I(Boc-L-Met), peptide, ester II(Gly-OBz), phenyl and methionyl side chain groups. The equations of the best planes and the related data are given in Table 4. Each pair of neighboring planes intersect roughly perpendicularly with each other, thus avoiding close contacts between the groups.

In the Boc group, the C(2)-C(4) bond length of 1.470(24) Å is significantly short. This may be attributed to the large thermal vibration of C(2), as shown in Fig. 2. The significant deformation of the bond angles

around C(4), O(1), and C(5) are found, which are common in the Boc group.[11)]

The bond lengths and angles of the methionyl residue in several derivatives are compared in Table 5. The average bond lengths of C^{α}–C^{β} and C^{β}–C^{γ} of the methionyl residues are 1.535(6) and 1.515(5) Å, respectively. The corresponding bond lengths in the present peptide, 1.539(8) and 1.515(9) Å, are consistent to the average values. Thus in the side chain of the methionyl residue, the C^{α}–C^{β} bond is longer than the C^{β}–C^{γ} bond. As shown in Table 5, the C^{α}–C^{β}–C^{γ} angle is usually larger than the C^{β}–C^{γ}–S^{δ} angle, except for L-Met-L-Met (second).[16)] The C^{γ}–S^{δ}–C^{ε} angle of 101.1(4)° in the present peptide is close to the average of 100.4(1.2)°.

The torsion angles of the side chain of the methionyl residue are listed in Table 6, together with those of some methionine derivatives. The methionyl side chain, together with C′(=C(10)), has the most stable trans zig-zag conformation. The torsion angles of the side chain in the present peptide, χ^1=−73.2, χ^2=175.3, and χ^3=174.9°, coincide roughly with those of D,L-Met (β-form)[12)] and Ac-L-Met-OMe.[14)] In Table 6, the χ^1 values distribute uniformely in the values near −60, 180, and 60°. The present peptide takes χ^1 of −60°, which is favored as C^{γ} is between N and H. The χ^2 angle is around 180°, except for L-Met (molecule B),[13)] and it seems that the χ^3 angle tends to be predominantly near 180°.

The parallel β-sheet structure extended along the b axis is seen in the crystal, as shown in Fig. 3. The main chain torsion angles (ϕ,ψ) of the methionyl residue (−110.6, 108.3°) are close to those, (−119, 113°), of the parallel β-pleated sheet structure.[18)] The ten-membered

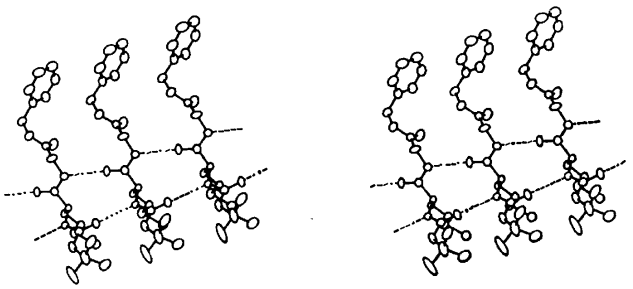

Fig. 3. Packing scheme viewed along the a axis (stereoscopic view). The parallel β-pleated sheet structure is formed. Hydrogen bonds are drawn as dotted lines.

ring hydrogen bonding pattern is formed from one molecule to the next molecule translated along the b axis. The geometries of the hydrogen bonds are: N(1)···O(2) 2.961 Å, H···O(2) 2.44 Å, ∠N(1)–H···O(2) 145°; N(2)···O(3) 2.897 Å, H···O(3) 2.19 Å, ∠N(2)–H···O(3) 159°.

The parallel β-structure is found in several other oligopeptides. Their torsion angles (ϕ,ψ) are; (−126, 132°) in Gly-L-Phe-Gly,[19)] (−102, 106°) in Br-Ac-L-Phe-L-Phe-OEt,[20)] (−100, 110°) in Cl-Ac-L-Phe-L-Phe-OEt,[20)] (−124, 103°) in Boc-(S-benzoyl)-L-Cys-Gly-OMe,[21)] (−106, 108°) in Ac-D,L-Phe-NMe,[22)] and (−107, 104°) in Ac-L-Phe-NMe.[23)]

The authors express their thanks to Professor Jiro Tanaka of Nagoya University, who kindly allowed them to use the diffractometer in his laboratory.

Minimum-energy Conformation of Different Tropocollagen Models Calculated for Poly(Gly-Pro-Pro) by Considering Helical Constraints

Kenji Okuyama,* Haruaki Eto, Ikuo Nakaya, and Motowo Takayanagi
Department of Applied Chemistry, Faculty of Engineering, Kyushu University 36, Fukuoka 812
(Received November 27, 1979)

The minimum conformational energies for three helical models of tropocollagen were calculated by using energy functions and values of parameters obtained by Momany *et al.*. Three types of helical models containing 7/1, 10/1, and 12/1 helices were employed. Among the models with the 7/1 helix, only the conformation having the $N(Gly_1)\cdots O(Pro_2)$ type hydrogen bond was found to be energetically stable. Thus all the three helical models had the same type of hydrogen bond. The minimum-energy conformation of the 7/1 helix model was found to be more stable than those of the other two models by about 7 kcal/mol per tripeptide unit. This difference mainly came from the non-bonded energy terms of both intra- and inter-chains. Since the conformation of the 7/1 helix model was widely spread in the conformational space compared with those of the other models, it was concluded that the unit twist of the 7/1 helix model is well suited for peptide chains to conform a triplehelical structure. The above results strongly supported the 7/1 helix model for tropocollagen.

Collagen proteins form the connective tissues, such as bone, skin, tendon, cornea, and basement membrane, and are responsible for the structural integrity of the animal body. The collagen molecule (tropocollagen) is distinctive in containing the glycine residues in every third position, and has been designated as poly(Gly_1–R_2–R_3) in brief. Another feature of collagen is its high content of proline and hydroxyproline residues at the positions of R_2 and R_3. It is well known that the basic structure of tropocollagen has involved three stranded helices,[1] but its definite conformation has not been determined because of the meagre availability of the X-ray fiber patterns obtained from native collagen. So far, many researchers have proposed many structural models for tropocollagen. These models are basically divided into two types. One group contains 30 amino acid residues per turn in each chain of three strands,[2–5] and the other contains 36 residues per turn.[6] Recently two of us (K. O. and M. T.) and others[7] proposed the third type of collagen model having 21 amino acid residues per turn based on the structural analysis of single crystals of $(Pro\text{–}Pro\text{–}Gly)_{10}$ prepared.

On the other hand, some attempts have been made to determine the most stable conformation of tropocollagen by the method of conformational energy calculation. Tumanyan[8] minimized conformational energies of the triple-stranded helix of $(Gly\text{–}Pro\text{–}Pro)_n$ from many different combinations of the dihedral angles as starting points, using the Lennard-Jones pairwise potential function and the simple Morse-type potential function of hydrogen bonds. According to his calculations, the reasonable ranges for unit height and unit twist of the repeating unit Gly–Pro–Pro were 8.22—8.76 Å and 25—40°, respectively. Miller and Scheraga[9] calculated the conformational energies of $(Gly\text{–}Pro\text{–}Pro)_n$ for three different structures, that is, single-chain polymer, triple-stranded parallel-chain complexes and triple-stranded coiled-coils, and found that the last structure was the most stable. The unit heights and the unit twists of 10/1 and 12/1 helix models are within the corresponding ranges proposed by Tumanyan,[8] and the unit twist of the 7/1 helix model is far from this range. Miller and Scheraga,[9] however, showed that their lowest-energy structure was in good agreement with the 7/1 helix structure proposed for $(Pro\text{–}Pro\text{–}Gly)_{10}$.[10] The above calculations for $(Gly\text{–}Pro\text{–}Pro)_n$ were made without considering any constraints of helical structure. The present research is aimed to examine what type of helical model for tropocollagen is the most stable in terms of energetics by calculating the conformational energies under conditions with the helical constraints.

Method and Calculation

Three Helical Models for Tropocollagen. The polyproline II[11] type helix, the component of the triple-stranded coiled-coil structure of tropocollagen, has three amino acid residues in one turn (Fig. 1a), and it can be described as a 3/1 helix, since a chemical repeating unit contains one amino acid residue. If the helix axis of 3/1 helix further coils around the central axis, a coiled-coil structure is constructed (Fig. 1b). Here, the 3/1 helix is called the minor helix and the larger one with a longer period is called the major helix. If we consider the one turn of the minor helix (*i.e.*, three amino acid residues) as one repeating unit, the tropocollagen structure can be simply described as composed

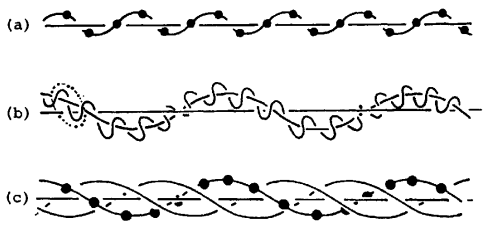

Fig. 1. Schematic representation of a triple-stranded helix of tropocollagen. (a) Simple 3/1 helical structure which contains three repeating units (filled circles) per turn. (b) Coiled-coil structure which is constructed by a further coiling of helix axis of (a). (c) Triple-stranded helix of tropocollagen. The filled circle represents one repeating unit, that is, one turn of the 3/1 helix which is shown by the dotted ellipse in (b).

TABLE 1. THREE HELICAL MODELS FOR TROPOCOLLAGEN

	Amino acid sequence $(Gly_1\text{–}R_2\text{–}R_3)_n$	Types of hydrogen bond	Helical parameters h	θ

"standard"	R_2 imino acid impossible	$N(Gly_1)\cdots O(R_3)$	8.73 Å	30.0°
structure[b),6)]	R_3 any residue	$N(R_2)\cdots O(R_2)$		
"one-bonded"	R_2 Pro	$N(Gly_1)\cdots O(R_2)$	8.73 Å	30.0°
structure[b),6)]	R_3 Hypro			

a) The structure is based on three dimensional X-ray diffraction patterns of single crystal of synthetic polypeptide $(Pro\text{–}Pro\text{–}Gly)_{10}$ whose distribution of molecular weight is monodispersed. b) These structures are based on X-ray fiber diagram of native collagen. c) The structure is based on X-ray fiber diagram of synthetic polypeptide $(Pro\text{–}Gly\text{–}Pro)_n$ whose molecular weight is about 15000. Throughout this paper 1Å= 0.1 nm, 1 cal=4.184 J.

of three identical helices with a common central axis (Fig. 1c). The helical models proposed so far can be divided into three types according to the number of the repeating units in the major helix (Table 1). The first type includes the structure of Collagen I and II proposed by Rich and Crick[3] and of $(Pro\text{–}Gly\text{–}Pro)_n$ proposed by Yonath and Traub,[4] which may be represented by a 10/1 helix model since they have 10 repeating units per one turn. The second type of models are Ramachandran's "standard" (or two-bonded) and one-bonded structures,[6] which may be represented by a 12/1 helix model. The third is our model[7] which may be described as a 7/1 helix model. In the case of last model, two possible types are proposed as has been described previously.[10] One type has the $N(Gly_1)\cdots O(Pro_3)$ type hydrogen bond (Model 1) and the other has the $N(Gly_1)\cdots O(Pro_2)$ type hydrogen bond (Model 2). The tropocollagen models are characterized by two helical parameters, h and θ. Here, h means the unit height, a vertical distance of one repeating unit along the helix axis. θ means the unit twist, a rotational angle of the unit around the helix axis. The h and θ values for the present models are listed in Table 1.

In this study, we assumed that the tropocollagen was constructed of three identical helices of poly(Gly–Pro–Pro) for the computational convenience, as had been adopted in energy calculations by Tumanyan[8] and by Miller and Scheraga.[9] Almost all conformations of poly(Gly–Pro–Pro) have been found to be those of a collagen-like triple-helix, since imino acid residues at the positions of R_2 and/or R_3 promote the construction of the triple-stranded helix. In fact, the single crystals of $(Pro\text{–}Pro\text{–}Gly)_{10}$ molecule were found to exhibit a 7/1 helix.[10] The fiber of $(Pro\text{–}Gly\text{–}Pro)_n$ gave an X-ray fiber pattern very similar to the native collagen and it was once proposed that the polypeptide chain formed a 10/1 helix.[4] These facts show that the above assumption may be reasonable.

Molecular Geometry. The backbone conformation in the three-residue repeating unit is defined not only by the coordinates of corresponding atoms, but also by bond lengths, bond angles, and dihedral angles of the backbone chain. Since bond lengths and bond angles are not so different among the homologous compounds, we can fix these at the known values of low molecular weight homologues. The latter method is advantageous for constructing conformations of fibrous large molecules. In the case of poly(Gly–Pro–Pro), there are 9 dihedral angles in a repeating unit. These are shown in Figure 2. The dihedral angles ϕ_2 and ϕ_3

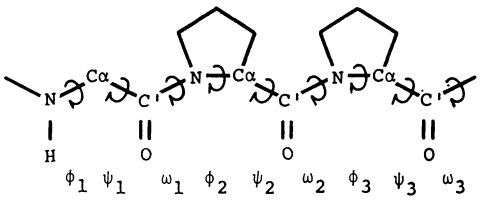

Fig. 2. Structural formula and the notation of dihedral angles in one repeating unit, Gly–Pro–Pro.

are restricted within narrow limits by pyroridine rings and they were fixed at −75° in the calculations. Further, if we confine the conformation to one of the above models, the two dihedral angles (in these calculations, ϕ_1 and ψ_1) will become dependent upon others. Then, the variable parameters were reduced to only five dihedral angles, ω_1, ψ_2, ω_2, ψ_3, and ω_3. The fixed values of bond lengths and bond angles, and the initial coordinates of pendant atoms (C_β, C_γ, and C_δ atoms in proline residues and all oxygen and hydrogen atoms) were according to Momany *et al.*[12] The definition of dihedral angles followed the recommendation of IUPAC IUB Commission.[13] Five dihedral angles were

changed systematically and the coordinates of all atoms in the unit were represented in the right-handed Cartesian coordinate system.[14] In this system, the origin coincided with a given atom of the back bone chain. One of the neighbouring atoms of the origin lay on the x-axis, and the other axes were chosen arbitrarily. Then the coordinate system was converted into the right-handed Cartesian coordinate system having the z-axis coinciding with the helix axis by the method of Sugeta and Miyazawa.[15] When the coordinates of the jth atom in the nth unit of the standard ($m=0$) chain are expressed in terms of $(x_j^{n,0}, y_j^{n,0}, z_j^{n,0})$, those of the corresponding atom in the next ($(n+1)$th) unit of the same chain $(x_j^{n+1,0}, y_j^{n+1,0}, z_j^{n+1,0})$ may be obtained by the following equations.

$$\boldsymbol{X}_j^{n+i,0} = \boldsymbol{R}_1 \boldsymbol{X}_j^{n,0} + i\boldsymbol{T},$$

where

$$\boldsymbol{X}_j^{n,0} = \begin{pmatrix} x_j^{n,0} \\ y_j^{n,0} \\ z_j^{n,0} \end{pmatrix}, \quad R_1 = \begin{pmatrix} \cos(i\theta) & -\sin(i\theta) & 0 \\ \sin(i\theta) & \cos(i\theta) & 0 \\ 0 & 0 & 1 \end{pmatrix},$$

and

$$\boldsymbol{T} = \begin{pmatrix} 0 \\ 0 \\ h \end{pmatrix}.$$

Similarly, the coordinates of the jth atom in the nth unit of the neighbouring chains $(x_j^{n,m}, y_j^{n,m}, z_j^{n,m})$ are obtained by the following equations.

$$\boldsymbol{X}_j^{n,m} = \boldsymbol{R}_2 \boldsymbol{X}_j^{n,0} + \frac{m}{3}\boldsymbol{T},$$

where

$$\boldsymbol{X}_j^{n,m} = \begin{pmatrix} x_j^{n,m} \\ y_j^{n,m} \\ z_j^{n,m} \end{pmatrix}, \quad R_2 = \begin{pmatrix} \cos(m\theta') & \sin(m\theta') & 0 \\ -\sin(m\theta') & \cos(m\theta') & 0 \\ 0 & 0 & 1 \end{pmatrix},$$

and $\theta' = 120° - \theta/3$.[10] m is the chain number (0, 1, or 2). When looking down the helical axis from the carbonyl- to the amino-terminus, the value m of the right-side chain is 2 and that of the left-side chain is 1 with respect to the standard chain (0).

Conformational Energies. Electrostatic energy (E_{es}), non-bonded energy (E_{nb}), and torsional energy (E_{ts}) were considered. The total conformational energy for one repeating unit (E_{tot}) was the sum of these energies. The hydrogen bond energy was included in non-bonded energy term. The energy functions and parameter values used were the same as those of Momany *et al.*[12] The torsional energy was calculated only about three peptide bonds in the unit. The same functions and values were used for both intra- and inter-chain energy calculations. The intramolecular energy for a unit was calculated for the region from this unit to the third one of the carbonylterminal side, since the interaction energy between a given unit and any of its three amino-terminal side neighbours was the same as that between the same unit and the corresponding carbonyl-terminal side neighbour. The intermolecular energy was calculated between a central unit of A-chain ($m=0$) and the nearest four unit both up and down along the B-chain ($m=1$) from the central unit of A. Since three chains are identical in each other, the energy between A- and C-chains ($m=2$) equals to the energy between B- and A-chains. In the case of 7/1 helix model, the units which were taken into account of calculations are shown in the radial projection of Fig. 3. The open circle in this figure represents one repeating unit. The solid lines denote the peptide chain direction and a down side of this line points to the amino terminal side. The letters A, B, and C correspond to the peptide chain number in the triple-stranded helix, 0, 1, and 2, respectively. The conformational energies of isolated triple-stranded helix were calculated by summing up the energy in the central unit (filled circle) and the interaction energies between the central unit and all the independent unit (half-filled circles) within about 30 Å from the central unit.

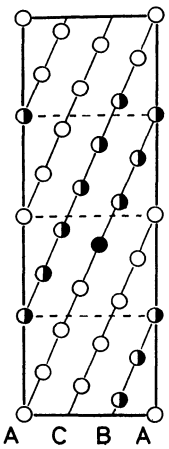

Fig. 3. The range of energy calculations of 7/1 helix model. The open circle denotes one repeating unit and the solid lines A, B, and C denote the peptide chains. The filled circle is the unit which conformational energy is calculated and the half-filled circle is the other unit responsible for the inter-unit conformational energy calculations.

It has been found that several water molecules per tripeptide unit are involved in the triple helices of tropocollagen[16] and model peptides of collagen[17] by way of hydrogen bonding. In addition to the stabilization by triple-helix itself, these hydrogen bonds may also contribute to the stabilization of the collagen-like triple-helix. However, Engel *et al.*[18] have shown that the peptides remain in a triple-helical conformation after dehydration, and concluded that water is not an essential component of forming the triple-helical structure. Therefore, in this study we did not take into account of water in order to simplify the problem, and calculated only the conformational energies of isolated triple-helix in a vaccum.

Computational Procedure. As described above, the

Table 2. Computational regions of dihedral angles

ω_1	175°—180°——175°
ϕ_2	−75° (fixed)
ψ_2	100°—180°——170°
ω_2	175°—180°——175°
ϕ_3	−75° (fixed)
ψ_3	100°—180°——170°
ω_3	175°—180°——175°

molecular conformation of poly(Gly–Pro–Pro) is defined by five dihedral angles (ω_1, ψ_2, ω_2, ψ_3, and ω_3) and helical parameters (h and θ). So the energy-minimum conformation of each model is included in the five

Table 4. Atomic distances used in the preliminary calculations

Atomic pair	Distance (Å)

a) ϕ_1 and ψ_1 were calculated numerically from other dihedral angles and helical parameters of the model.

dimensional space of conformation with the range shown in Table 2. All the dihedral angles of the peptide bond, ω_1, ω_2, and ω_3, were assumed to be *trans* conformation. Although it has been known that the peptide bond preceding proline residue is able to have a *cis* conformation (*e.g.*, the structures of poly-L-proline I[19] and of z-Gly-Pro-Leu[20]), these were taken to be *trans* in all the previous models of collagen. Then we considered only *trans* conformation in our calculations. The dihedral angles of C_α–C′ in the proline residue, ψ_2 and ψ_3, were assumed to lie in the ranges of 100°—180°—−170° based on the structural analyses of oligopeptides[21,22] and the energy calculations of prolyl oligomers.[23]

At first the above conformational space was divided into 9747 grid points which were obtained by varing each dihedral angle at 5° intervals, and remaining dihedral angles (ϕ_1 and ψ_1) at each grid point were calculated numerically by using the helical parameters.[24] The conformations which gave the ϕ_1 and ψ_1 values outside the ranges of −180°——30° and 20°—180°——150°, respectively, were rejected in the following calculations. These criteria for glycyl residue are based on the regions of left-handed polyproline II structure in the energy map of diglycine.[25] In the resulting conformations, the dihedral angle ϕ_1 for three models was in the range of −130°——30°, and the angle ψ_1 for the 7/1, 10/1, and 12/1 helix models was in the range of 145°—180°——165°, 140°—180°——175°, and 140°—175°, respectively. The number of solutions for each model was listed in Table 3. The number of grid points which satisfied the above criteria was assumed to be about one half of solutions, since the most grid points had two solutions.

In order to reduce the time of computation, the number of conformations was further decreased by the preliminary energy calculations and the examinations of inter-chain hydrogen bonds. That is, the conformations were removed, if they exhibit the non-bonded distance between pairs of atoms in different chains which was shorter than the corresponding distance listed in Table 4. The values shown in Table 4 were the distances which gave the non-bonded energies 100 times as large as those at the minimum positions ($<r_g^{kk}>$ or $<r_g^{kl}>$) of Ref. 26, and calculated from the Lennard-Jones 6-12 expression. It has been proposed that in the case of poly(Gly–Pro–Pro), the 10/1 and 12/1 helix models and one of the 7/1 helix models (Model 2) have the $N(Gly_1)\cdots O(Pro_2)$ type hydrogen bond.[3,6,10] Model 1 of the 7/1 helix model has the $N(Gly_1)\cdots O(Pro_3)$.[10] For each of these models the conformations which have the hydrogen bond distance $r(N\cdots O)$ longer than 4.5 Å or the hydrogen bond angle $\angle HNO$ larger than 60° were removed because these conformations would not have hydrogen bonds by only the small change of variable dihedral angles. The number of remaining conformations for each model are given in the last column of Table 3. The conformational energy was calculated for all of these conformations. The dihedral angles, total potential energies, and hydrogen bond parameters $r(N\cdots O)$ and $\angle HNO$, of only 10 low energy conformations of each model are given in Table 5. The conformations of Model 1 of the 7/1 helix model had rather high potential energies than all the other types of models. Of the conformations obtained only four with negative energies are listed. All of the conformations shown in Table 5 which had the $N(Gly_1)\cdots O(Pro_2)$ type hydrogen bond were taken as the starting points for energy minimization procedure according to Fletcher and Powell.[27] The helical parameters for each model were held constant during these procedures. When the energy did not change as much as 0.0001 kcal/mol per tripeptide unit within an iteration of the Fletcher-Powell algorism, or when all of the variable dihedral angles did not change as much as 0.01° within an iteration, it was regarded that the energy-minimum in the conformational space has been reached.

Results and Discussion

Comparison of Models 1 and 2 of the 7/1 Helix Model. According to the type of hydrogen bonding, the 7/1 helix models were divided into Models 1 and 2 (see above). The number of conformations of Model 1 after preliminary calculations was very few as seen in the last column of Table 3, and their total conformational energies were very high compared with those of Model 2 (Table 5). In the four conformations of Model 1 shown in Table 5, the hydrogen bond distances of $N(Gly_1)\cdots O(Pro_3)$ are about 4.4 Å, while those of $N(Gly_1)\cdots O(Pro_2)$ are 2.96, 3.17, 3.61, and 2.86 Å, in an increasing order of the conformational energy. It seems, therefore, that the hydrogen bond of $N(Gly_1)\cdots O(Pro_2)$ is stronger than that of $N(Gly_1)\cdots O(Pro_3)$. Further investigation showed that the 23 conformations out of 34 of Table 3 had the hydrogen bond of $N(Gly_1)\cdots O(Pro_2)$ with distance less than 4.5 Å. Therefore, they were also included in the 216 conformations of Model 2. The resulting conformation after minimization starting from No. 1 of Model 1 (Table 5) was in agreement with that of Model 2 (Table 6) with a deviation of each dihedral angle less than 1.5°. The above findings showed that the global minimum conformation in the conformational space of the 7/1 helix model was included in the region with the hydrogen bond of $N(Gly_1)\cdots O(Pro_2)$, and some conformations within this region had a rather short hydrogen bond of $N(Gly_1)\cdots O(Pro_3)$ and a high conformational energy compared with the global minimum one. Thus it was concluded that the structures of Model 1 were unstable and could not be present. Hereafter, the word "7/1 helix model" may indicate that the conformation has helical parameters of (8.61 Å, 51.4°) and a hydrogen bond of $N(Gly_1)\cdots O(Pro_2)$.

12/1 Helix Model. The 12/1 helix model, which was proposed by Ramachandran[6] as a modification of 10/1 helix model, is somewhat different from the 7/1 and 10/1 helix models. If the amino acid sequence of tropocollagen is represented by poly(Gly_1–R_2–R_3), the true repeating period in the 7/1 and 10/1 helix models is one-third the pitch length of the peptide chain, as we see in the radial projections (a) and (b) of Fig. 4. This period is 20.1 Å for the 7/1 helix model and 28.6 Å for the 10/1 helix model. In this figure the open circle denotes a tripeptide unit, Gly_1–R_2–R_3, and the solid

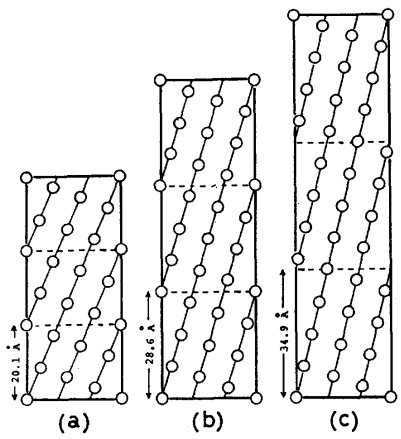

Fig. 4. Radial projections for three different kinds of tropocollagen models. The open circle denotes one repeating unit, Gly_1–R_2–R_3, and the solid line denotes the peptide chain direction. (a) 7/1 helix model, (b) 10/1 helix model, and (c) 12/1 helix model.

line denotes a direction of the peptide chain. Because of the finite molecular length of tropocollagen (about 3000 Å) and irregularities of occurrence of amino acids at the positions of R_2 and R_3 in the real sequence, these periods were usually called "pseudo-period."

On the other hand, the period obtained from X-ray fiber patterns of native collagen was taken to be 20.1 Å in the case of the 7/1 helix model or 28.6 Å in the case of 10/1 helix model. The above difference of the periods occurs from the ambiguity of indexing the layer lines which appear in the fiber patterns of native collagen. That is, if we take the meridional reflection of the spacing 2.86 Å as the 7th layer, the fiber period will be 20.1 (2.86×7) Å. And if we take that reflection as the 10th layer, the fiber period will be 28.6 (2.86×10) Å. In both 7/1 and 10/1 helix models, each pseudo-period of the models is naturally the same as that obtained from X-ray fiber patterns, because each model is constructed by using the periods obtained from the fiber pattern itself. In the case of 12/1 helix model, however, the one-third the pitch length is not a perfect repeating period as we see in Fig. 4(c), even though the amino acid sequence is represented by poly(Gly_1-R_2-R_3). Further, this value, 34.9 Å (2.91×12), does not agree with the period 29.1 Å obtained by Ramachandran.[6] Despite the apparent discrepancy, the conformational energy of the 12/1 helix model could be calculated in a similar manner as other models, since this did not affect the results obtained in the present study.

Comparison of Minimum-energy Conformations of the Three Models. The conformations with the minimum-energy for the three models are listed in Table 6 together with their energy terms and hydrogen bonding parameters. Tumanyan[8] carried out the minimization of conformational energies from many quadraplets of the dihedral angles (ϕ_1, ψ_1, ψ_2, and ψ_3) as starting points without constraints of helical parameters, and concluded that the minimum-energy conformation was obtained with helical parameters within the ranges of 8.22 Å$<h<$8.76 Å and $25°<\theta<40°$. It was also suggested by

Table 6. Minimum-energy conformations of three helical models

	7/1 helix	10/1 helix	12/1 helix
Dihedral angle/°[a]			
ϕ_1[b]	−62.3	−48.3	−53.0
ψ_1[b]	179.4	158.2	164.3
ω_1	−179.6	−172.2	−174.6
ψ_2	167.0	164.1	155.0
ω_2	180.0	−175.3	−179.2

H-bond parameter[c]			
r(N···O)/Å	3.17	3.54	3.50
∠HNO/°	16	18	20
Energy/[kcal/mol of (Gly–Pro–Pro)][d]			
E_{nb}(intra)	−0.30	3.59	3.53
E_{nb}(inter)	−9.18	−6.63	−6.62
E_{es}(intra)	−15.06	−15.28	−15.26
E_{es}(inter)	−1.70	−1.03	−1.11
E_{ts}	0.15	0.52	0.33
E_{tot}	−26.09	−18.83	−19.12

a) $\phi_2=\phi_3=-75.0°$. b) ϕ_1 and ψ_1 were calculated numerically from other dihedral angles and helical parameters of each model. c) These parameters are for N(Gly_1)···O(Pro_2) type of hydrogen bond. d) E_{nb} refers to the non-bonded energy term, E_{es} to the electrostatic energy term, E_{ts} to the torsional energy term: intra in the parenthese to intrachain, inter to interchain. $E_{tot}=E_{nb}$(intra)$+E_{nb}$(inter)$+E_{es}$(intra)$+E_{es}$(inter)$+E_{ts}$

Ramachandran[6] that the conformations whose unit twist is 50° or more cannot be stable because of short contacts between atoms in adjacent chains and worse situations about hydrogen bonds. According to our calculations as shown in Table 6, however, the conformations of the 7/1 helix model, whose unit twist is 51.4°, can exist stably and further, the minimum conformational energy of this model was the lowest among the three helical models. The energy difference of 7 kcal/mol per tripeptide unit between the 7/1 and the other two helix models is attributable to the non-bonded energy terms. With respect to the hydrogen bond, the distance of N(Gly_1)···O(Pro_2) of the 7/1 helix model is 3.17 Å and those of 10/1 and 12/1 helix models are somewhat longer (3.54 and 3.50 Å, respectively). Further, as seen in Table 5, the conformations in considerably wide regions of conformational space of the 7/1 helix model tend to have lower energies and more stable hydrogen bonds in comparison with those of the 10/1 and 12/1 helix models. It seems that these preponderance of the 7/1 helix model results from its large unit twist compared with those of the 10/1 and 12/1 helix models. (Unit heights are almost the same among these models (Table 1).) That is, in the case of 7/1 helix model, the number of conformations (4433), where the backbone conformation with no pendant atoms can be constructed, is much larger than those of the other models (4003 for 10/1 and 2989 for 12/1 helix model). And the last column shows the resulting numbers of conformation after preliminary calculations,

in which the conformations were removed if they have very short contacts between atoms or a hydrogen bonding distance longer than 4.5 Å. The differences between the numbers of conformation for the three models clearly showed that the conformational space of the 7/1 helix model at this stage is increasingly wider than those of the others, although the absolute space is narrower than that of the previous stage.

The difference of non-bonded energies between the 7/1 and the other two (10/1 and 12/1) helix models was the sum of the differences of inter- and intra-chain non-bonded energies, 2.5 and 4.0 kcal/mol per tripeptide unit, respectively (Table 6). As there were no short contact between atoms of different chains in each model structure, the stabilization of interchain non-bonded energy of the 7/1 helix model showed that the chain molecule with this conformation was suited to be packed into a collagen-like triple-stranded structure. On the other hand, the difference between intrachain non-bonded energies resulted from short contacts between atoms in the same chain. For example; for the 7/1 helix model, $H_\alpha(Pro_2)\cdots H_\delta(Pro_3)$, 2.09 Å; for the 10/1 helix model, $H_\alpha(Pro_2)\cdots H_\delta(Pro_3)$, 2.06; $O(Pro_3)\cdots C'(Gly_1)$, 2.74; $H_\alpha(Gly_1)\cdots C_\delta(Pro_2)$, 2.56; $H_\alpha(Gly_1)\cdots H_\delta(Pro_2)$, 2.02 Å; and for the 12/1 helix model, $H_\alpha(Pro_2)\cdots C_\delta(Pro_3)$, 2.45; $H_\alpha(Pro_2)\cdots H_\delta(Pro_3)$, 1.98; $H_\alpha(Gly_1)\cdots H_\delta(Pro_2)$, 2.08 Å. The atomic coordinates of the minimum-energy conformation of the 7/1 helix model are shown in Table 7.

The molecular structures with the minimum-energy conformations for the three models are illustrated in Fig. 5, in which the chains are projected along the direction perpendicular to the helix axis. As already mentioned, the periods along the helix axis for the 7/1 and 10/1 helix models are 20.1 and 28.6 Å, respectively. The period of the 12/1 helix model, however, is neither 29.1 nor 34.9 Å. In this case the true period is the pitch length itself, 2.91×36 Å.

Table 7. Atomic coordinates of the minimum-energy conformation with 7/1 helix

Residue	Atom	x/Å	y/Å	z/Å
Gly	N	1.61	0.00	0.00
	C_α	1.60	1.28	0.69
	C′	2.48	1.24	1.94
	O	3.09	0.22	2.24
Pro	N	2.58	2.36	2.65
	C_α	3.39	2.46	3.85
	C_β	3.58	3.95	4.07
	C_γ	2.49	4.64	3.27
	C_δ	1.90	3.62	2.31
	C′	2.71	1.75	5.03
	O	1.54	1.39	4.95
Pro	N	3.50	1.55	6.11
	C_α	2.99	0.89	7.30
	C_β	4.23	0.45	8.07
	C_γ	5.38	1.29	7.52
	C_δ	4.92	1.93	6.23
	C′	2.09	1.82	8.10
	O	2.37	3.01	8.22

The results obtained from above calculations showed that the minimum-energy of the 7/1 helix model is less than those of the other two models with 10/1 and 12/1 helices by about 7 kcal/mol per tripeptide unit. It is unknown that the present 7/1 helix model may represent the true conformation of the native tropocollagen.

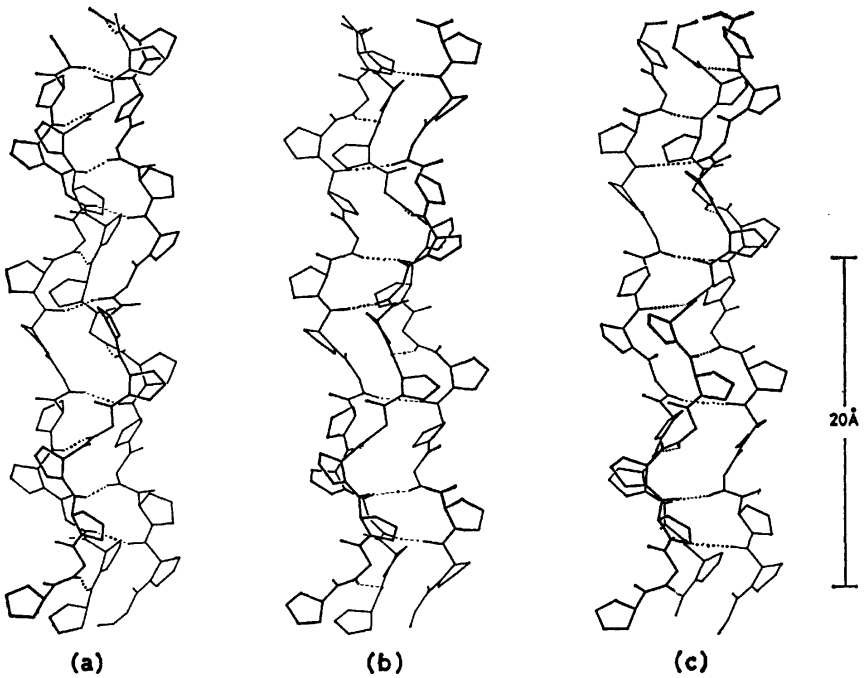

Fig. 5. Conformations with minimum-energy as projected along the direction perpendicular to helix axis. The dashed line denotes a hydrogen bond of $N(Gly_1)\cdots O(Pro_2)$. (a) 7/1 helix model, (b) 10/1 helix model, and (c) 12/1 helix model.

However, several lines of evidence suggest that this is the case. First, the synthesized molecule of $(Pro\text{–}Pro\text{–}Gly)_{10}$ as a collagen model can form a 7/1 helix in its single crystals.[10] Second, the hydrophobic interactions between tropocollagen molecules can form the stable microfibril structure only when the tropocollagen has a 7/1 helix model.[28] Third, the X-ray fiber diagram obtained from native collagen can be interpreted in terms of not only a 10/1 helix model but also a 7/1 helix model.[7] Taken these facts together with the present results, we may conclude that the 7/1 helix model is the best of the models so far presented for tropocollagen.

Preparation and Solid-phase Thermal Reactions of Hexaamminechromium(III) Amino Polycarboxylates under Quasi-isothermal and -isobaric Conditions[1)]

Ryokichi Tsuchiya,* Akira Uehara, and Kazuhiko Kobayashi
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920
(Received July 31, 1979)

The following hexaamminechromium(III) amino polycarboxylates were prepared: $[Cr(NH_3)_6]Naedta \cdot 3H_2O$, $[Cr(NH_3)_6]Napdta \cdot 6H_2O$, $[Cr(NH_3)_6]HK_3Cl(nta)_2 \cdot 2H_2O$ and $[Cr(NH_3)_6]KCl(nta) \cdot 2H_2O$, where edta, pdta and nta denote ethylenediaminetetraacetate, propylenediaminetetraacetate and nitrilotriacetate ions, respectively. Their thermal reactions in the solid-phase were examined by Q-derivatography (quasi-closed system; quasi-isothermal and -isobaric conditions) and D-derivatography (open system; dynamic conditions). The reactions in open system were too complicated to yield uniform intermediates. On the other hand, each reaction step in the quasi-closed system was definite and reproducible, the products obtained in each reaction step being remarkably pure.

Studies on the thermal reactions of metal complexes in the solid-phase have mostly been carried out in the open system.[2)] Two inherent problems have frequently been encountered, (a) difficulty of keeping the desired temperatures uniform over all parts of the sample, (b) change in the results caused by experimental conditions such as type of instrument, amount of sample, heating rate *etc.*

Recently, a new thermoanalytical instrument (Q-derivatograph) was developed, with which thermal reactions of samples can be followed under quasi-isothermal and -isobaric conditions.[3)] We studied the thermal reactions of hexaamminechromium(III) amino polycarboxylates under Q- and D-conditions[4)] and found that the results obtained under Q-conditions are reproducible and the intermediates in each reaction step can be obtained remarkably pure.

The present study was undertaken (1) to prepare the hexaamminechromium(III) amino polycarboxylates, (2) to observe the thermal reactions of the complexes under Q-conditions together with those under D-conditions, and (3) to test the possibility of synthesis of amino polycarboxylato-complexes by using the thermal reactions in the solid-phase.

Edta, pdta, and nta ions, which denote ethylenediaminetetraacetate, propylenediaminetetraacetate and nitrilotriacetate ions, respectively, were chosen mainly because of the expectation that the products obtained upon heating could be identified with certainty by referring to the well-known chromium(III) complexes containing these agents.

Experimental

Preparation of Complexes. Hexaamminechromium(III) Sodium Ethylenediaminetetraacetate Trihydrate, $[Cr(NH_3)_6]Naedta \cdot 3H_2O$. Fifteen grams (50 mmol) of H_4edta was dissolved in a solution of NaOH (8 g, 20 mmol) in 50 cm³ of water. The solution was then added to a solution of $[Cr(NH_3)_6]Cl_3$ (13 g, 50 mmol) in 50 cm³ of water. The resulting mixture was allowed to stand for a few days in a refrigerator, 18 g of yellow well-defined crystals being obtained and recrystallized from water.

Found: C, 22.82; H, 7.25; N, 21.21%. Calcd for $C_{10}H_{36}N_8O_{11}CrNa$: C, 23.12; H, 6.99; N, 21.57%.

Hexaamminechromium(III) Sodium Propylenediaminetetraacetate Hexahydrate, $[Cr(NH_3)_6]Napdta \cdot 6H_2O$. Sixteen grams (50 mmol) of H_4pdta was dissolved in a solution of NaOH (8 g, 20 mmol) in 70 cm³ of water. The solution was then added to a solution of $[Cr(NH_3)_6]Cl_3$ (13 g, 50 mmol) in 50 cm³ of water, to which *ca.* 10 cm³ of ethanol was gradually added. The resulting mixture was allowed to stand for several days in a refrigerator. 20 g of the products was thus obtained, which was recrystallized from water. The color of the samples containing $[Cr(NH_3)_6]$ cation was yellow irrespective of the anions involved.

Found: C, 22.39; H, 7.66; N, 19.11%. Calcd for $C_{11}H_{44}N_8O_{14}CrNa$: C, 22.49; H, 7.55; N, 19.07%.

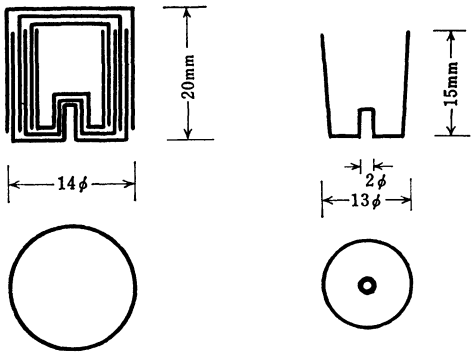
Hexaamminechromium(III) Hydrogen Tripotassium Chloride Bis(nitrilotriacetate) Dihydrate, $[Cr(NH_3)_6]HK_3Cl(nta)_2 \cdot 2H_2O$. H_3nta (19 g, 100 mmol) was added to a solution of $[Cr(NH_3)_6]Cl_3$ (13 g, 50 mmol) in 150 cm³ of water. The slurry was continuously stirred under ice-cooling, aqueous KOH being added drop by drop in amounts enough to dissolve the H_3nta and to obtain a solution of pH 8. To this was added *ca.* 10 cm³ of ethanol, and the resulting solution was left to stand for a week in a refrigerator. 18 g of plate-like crystals was obtained. Recrystallization was carried out as follows. The crystals were dissolved in a small amount of water, a small amount of ethanol then being added and the resulting solution kept standing in a refrigerator for about a week. Purified triangular plate-like crystals were obtained.

Found: C, 20.36; H, 5.55; N, 15.36%. Calcd for $C_{12}H_{35}N_8O_{14}ClCrK_3$: C, 20.01; H, 4.90; N, 15.56%.

At first, the composition of the compound could not be determined, but the following nitrilotriacetate ($[Cr(NH_3)_6]KCl(nta) \cdot 2H_2O$) was obtained. This differs considerably in property from the former compound; for example the former was somewhat acidic in water (pH 4—5), whereas the latter was slightly alkaline (pH 8—9). A comparison of analytical data, IR spectra and thermal behavior between them revealed that the above composition is valid for the former complex.

Hexaamminechromium(III) Potassium Chloride Nitrilotriacetate Dihydrate, $[Cr(NH_3)_6]KCl(nta) \cdot 2H_2O$. Ten grams (50 mmol) of H_3nta was added to a solution of $[Cr(NH_3)_6]Cl_3$ (13 g, 50 mmol) in 150 cm³ of water. To the mixture was added aqueous KOH drop by drop with continuous stirring under ice-cooling, the final pH of the solution being adjusted to 10. *Ca.* 10 cm³ of ethanol was added to the resulting solution, which was kept standing in a refrigerator for a week, 12 g of the products being obtained. Recrystallization was carried out from water containing a small amount of ethanol. Octahedrally shaped crystals were obtained.

Found: C, 16.23; H, 6.12; N, 21.58%. Calcd for C_6H_{28}-



(a) Labyrinth crucible (b) Coverless crucible

Fig. 1. Pt crucibles employed in Q-derivatograph (a) and D-derivatograph (b).

N_7O_8ClCrK: C, 15.91; H, 6.23; N, 21.65%.

The presence of K^+ and Cl^- was quantitatively determined by the use of $[Co(NO_2)_6]^{3-}$ and Ag^+ ions.

Isolation of the Products Obtained in Each Thermal Reaction Step. Temperature and heating time were determined from the data obtained under Q- and/or D-conditions.

(1) $NH_4[Cr(edta)]\cdot 2H_2O$ from $[Cr(NH_3)_6]Naedta\cdot 3H_2O$: $[Cr(NH_3)_6]$Naedta·$3H_2O$ (1 g, 2 mmol) was put in a labyrinth crucible (Fig. 1-(a)), and heated at 150 °C for 5 h in an air-bath. A violet product (Na[Cr(edta)]) obtained was dissolved in a small amount of water. NH_4Cl (1 g, 16 mmol) was added and the solution was allowed to stand in a refrigerator for a few days, 0.5 g of violet crystals being obtained.

Found: C, 30.31; H, 5.25; N, 10.82%. Calcd for $C_{10}H_{20}N_3O_{10}Cr$: C, 30.47; H, 5.08; N, 10.66%.

Since the preparation of sodium salts was difficult, the products were purified as ammonium salts.

(2) $Na[Cr(pdta)]\cdot 3H_2O$ from $[Cr(NH_3)_6]Napdta\cdot 6H_2O$: One gram (2 mmol) of $[Cr(NH_3)_6]$Napdta·$6H_2O$ was charged in a labyrinth crucible and heated at 210 °C for one hour. Violet product (Na[Cr(pdta)]) thus obtained was dissolved in a small amount of water. Ethanol (one tenth of the whole volume) was added and the solution was allowed to stain in a refrigerator for about one week. 0.5 g of violet crystals were obtained.

Found: C, 30.42; H, 4.88; N, 6.45%. Calcd for $C_{11}H_{20}N_2O_{11}CrNa$: C, 30.64; H, 4.67; N, 6.50%.

(3) $Na_3[Cr(nta)_2]\cdot 5H_2O$ from $[Cr(NH_3)_6]HK_3Cl(nta)_2\cdot 2H_2O$: $[Cr(NH_3)_6]HK_3Cl(nta)_2\cdot 2H_2O$ (1.5 g, 2 mmol) was charged in a labyrinth crucible and heated at 135 °C for 3.5 h in an air-bath. A pink product ($K_3[Cr(nta)_2]$) was obtained, which was dissolved in water. The solution was passed through a column of Dowex 1-X8 (Cl-form) resin. The pink band was developed on the column, which was eluted with 0.4 mol cm^{-3} NaCl solution. The effluent was then concentrated to one-third of its volume at about 30 °C on a rotary evaporator, and kept standing in a refrigerator overnight. 0.2 g of pink powdered crystals were obtained.

Found: C, 24.35; H, 2.60; N, 4.68%. Calcd for $C_{12}H_{17}N_2O_{17}CrNa_3$: C, 24.75; H, 2.94; N, 4.81%.

(4) $[Cr(nta)(NH_3)_2]KCl$ from $[Cr(NH_3)_6]KCl(nta)\cdot 2H_2O$: $[Cr(NH_3)_6]$KCl(nta)·$2H_2O$ (1 g, 2 mmol) was put in a labyrinth crucible and heated at 130 °C for 6.5 h in an air-bath. 0.75 g of reddish brown products was obtained, which could not be purified because of the absence of suitable solvents. The products were highly soluble and readily hydrolyzed in water, so purification from water failed. The KCl contained in the products could not be removed. The results of elemental analyses indicate that the composition of the products is substantially uniform. This is a typical example showing that the thermal reaction of the samples proceeds uniformly under Q-conditions. It has not yet been clarified whether the KCl in the products is present in the crystals ($[Cr(nta)(NH_3)_2]KCl$) or as the contaminants ($[Cr(nta)(NH_3)_2]$+KCl).

Instruments. The TG curves of the complexes were measured under Q- and D-conditions by using a Q-derivatograph[3] and a D-derivatograph.[5] Figure 1 shows the Pt crucibles employed in this study. In the case of D-derivatography, all the measurements were caried out at a heating rate of 1 °C min^{-1}, 0.5 g of the samples being used in a coverless Pt crucible (Fig. 1-(b)). In Q-derivatography, 0.5 g of the samples were taken into a labyrinth Pt crucible (Fig. 1-(a)).[3] The crucible consists of three Pt cups and three Pt covers. They are joined alternately. The sample decomposes on heating, evolving gases. The gases first occupy the inside of the crucible. Excess gases go out from the crucible only when the inside pressure exceeds the outside pressure. Thus, the inside of the crucible fulfills the autogenerated quasi-isobaric condition. IR and UV spectra were measured with the same apparatus as employed previously.[6]

Results and Discussion

TG Curves of $CuSO_4\cdot 5H_2O$. $CuSO_4\cdot 5H_2O$ is used as a typical example to explain the difference in the results obtained under Q- and D-conditions. Figure 2 shows the TG curves measured under Q-conditions

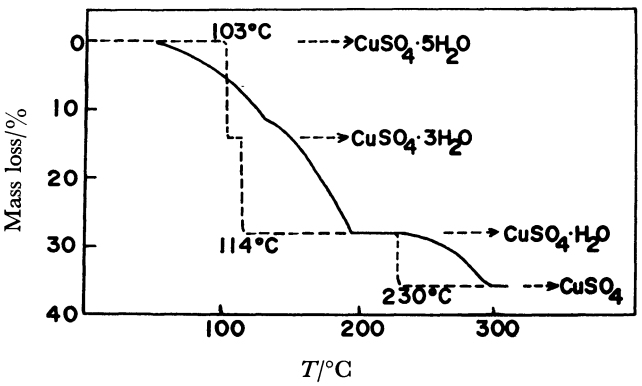


Fig. 2. TG curves of $CuSO_4\cdot 5H_2O$ measured under Q-(----) and D-conditions (——).

(broken line) and D-conditions (solid line). A general TG pattern measured under D-conditions, often influenced by experimental conditions such as instruments employed, sample amount and heating rate, is shown. Stepwise dehydration is distinctly detectable under Q-conditions. The TG pattern was not influenced by experimental conditions. Figure 3 shows the relationship between dissociation pressure (p) and temperature (T) in $CuSO_4\cdot 5H_2O$.[7] The first, second and third dehydration steps under one atmosphere are 102, 108 and 227 °C, respectively, close to the temperature (103, 114 and 230 °C) obtained under Q-conditions (Fig. 2). This indicates that under Q-conditions each dehydration step proceeds in a monovariant system and pure intermediates are obtainable in each plateau.

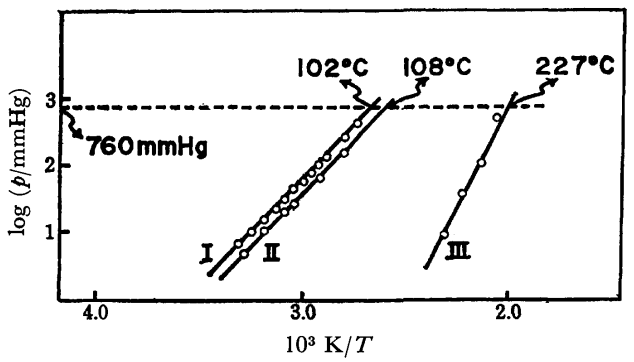

Fig. 3. Relationships between dissociation pressures (p) and temperatures (T) in $CuSO_4 \cdot 5H_2O$.
I. $CuSO_4 \cdot 5H_2O \rightleftharpoons CuSO_4 \cdot 3H_2O + 2H_2O$
II. $CuSO_4 \cdot 3H_2O \rightleftharpoons CuSO_4 \cdot H_2O + 2H_2O$
III. $CuSO_4 \cdot H_2O \rightleftharpoons CuSO_4 + H_2O$

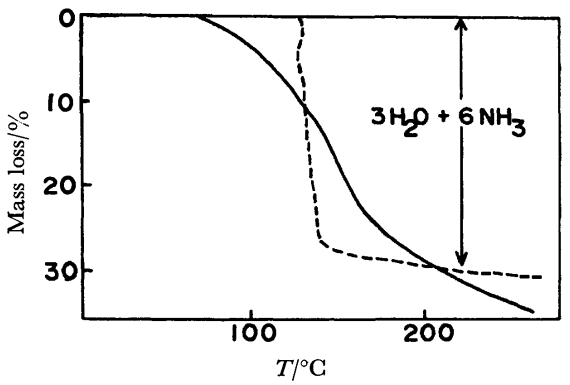

Fig. 4. TG curves of $[Cr(NH_3)_6]Naedta \cdot 3H_2O$ measured under Q-(——) and D-conditions (——).

TG Curves of the Complexes. *$[Cr(NH_3)_6]Naedta \cdot 3H_2O$*: Figure 4 shows the TG curves of $[Cr(NH_3)_6]$-Naedta·$3H_2O$. Under D-conditions (solid line), the complex begins to decompose at *ca.* 70 °C and gradually loses the weight of ($3H_2O+6NH_3$) up to about 200 °C; no plateau is detectable. Under Q-conditions (broken line), the complex suddenly loses weight at 130 °C and decomposes nearly isothermally, *viz.*, the complex evolves the gases ($3H_2O+6NH_3$) in a narrow temperature range (130—140 °C), after which a clear plateau is obtained in the TG curve. At this stage, the original yellow complex turned violet, indicating that the edta anion in outer-sphere is coordinated to Cr(III) ion upon heating. From the results, 150 °C for 5 h was selected as the optimal heating conditions for obtaining Na[Cr(edta)] from $[Cr(NH_3)_6]Naedta \cdot 3H_2O$.

$[Cr(NH_3)_6]Napdta \cdot 6H_2O$: The TG curve of the compound under D-conditions (Fig. 5) is essentially similar to that of the foregoing edta salt: the compound evolves the gases ($6H_2O+6NH_3$) at 50—200 °C and then decomposes gradually. Under Q-conditions, the complex begins to decompose at 80 °C, the weight loss up to 20 wt% taking place nearly isothermally and reaching a plateau at *ca.* 200 °C. The coloration turned from yellow to violet at this plateau, from which the optimal condition for obtaining Na[Cr(pdta)] from $[Cr(NH_3)_6]Napdta \cdot 6H_2O$ was selected as 200 °C for 1 h.

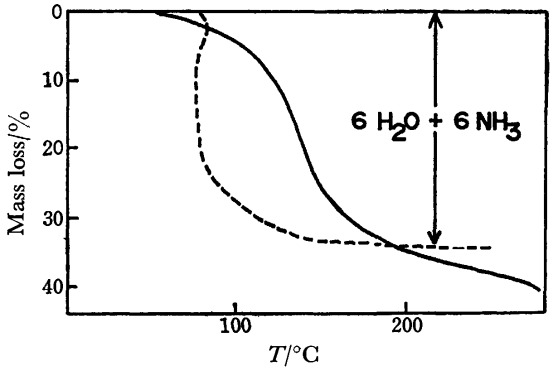

Fig. 5. TG curves of $[Cr(NH_3)_6]Napdta \cdot 6H_2O$ measured under Q- (——) and D-conditions (——).

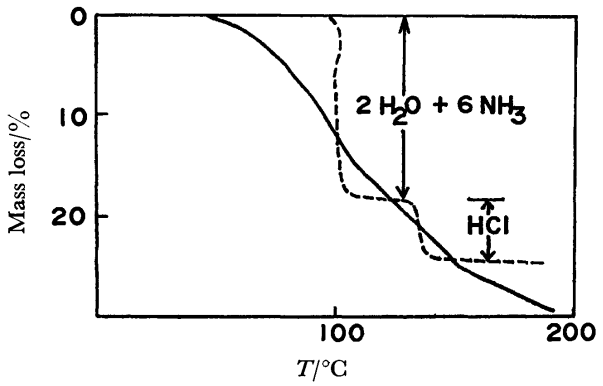

Fig. 6. TG curves of $[Cr(NH_3)_6]HK_3Cl(nta)_2 \cdot 2H_2O$ measured under Q- (——) and D-conditions (——).

It should be noted that the complex melts in its own crystalline water at the begining of the reaction under Q-conditions. A slight temperature drop appearing immediately after the weight loss begins is probably due to melting of the sample.

$[Cr(NH_3)_6]HK_3Cl(nta)_2 \cdot 2H_2O$: The TG curves of $[Cr(NH_3)_6]HK_3Cl(nta)_2 \cdot 2H_2O$ are shown in Fig. 6. The salt continues to decompose monotonously from 45 °C under D-conditions (solid line), no plateau being obtained in the TG curve. In contrast, two distinct plateaus are detectable under Q-conditions, one of which corresponds to the loss of the gases ($2H_2O+6NH_3$) at 100—105 °C and the other to the loss of one mole of hydrogen chloride at 130—135 °C. The inintial yellow complex turned pink at the first plaueau, the coloration remaining unchanged at the second plateau. The change in coloration indicates that the complex is in turn converted into $K_3[Cr(nta)_2]HCl$ and then $K_3[Cr(nta)_2]$. The condition (135 °C for 3.5 h) is suitable for preparing $K_3[Cr(nta)_2]$ from $[Cr(NH_3)_6]$-$HK_3Cl(nta)_2 \cdot 2H_2O$. $K_3[Cr(nta)_2]$ is readily hydrolyzed in water to yield $K[Cr(OH)(nta)(H_2O)]$,[8] but the situation is not so severe in the sodium salts and hence the thermal products were purified as sodium salts.

$[Cr(NH_3)_6]KCl(nta) \cdot 2H_2O$: The TG curve of the compound under D-conditions starts to fall at about 50 °C without reaching plateau (Fig. 7). Under Q-conditions, the complex evolves the gases ($2H_2O+4NH_3$) at 110—120 °C, a plateau being reached. The coloration turned from original yellow to reddish brown,

Table 2. Electronic spectral data due to d-d transition ($\tilde{\nu}/10^3$ cm^{-1})

Complex[a)]	$\tilde{\nu}_I$(log ε)	$\tilde{\nu}_{II}$(log ε)
$[Cr(NH_3)_6]Naedta \cdot 3H_2O$	21.55(1.59)	28.40(1.47)
$NH_4[Cr(edta)] \cdot 2H_2O$	18.40(2.33)	25.45(2.07)
$[Cr(NH_3)_6]Napdta \cdot 6H_2O$	21.55(1.57)	28.40(1.46)
$Na[Cr(pdta)] \cdot 3H_2O$	18.35(2.33)	25.45(2.04)
$[Cr(NH_3)_6]HK_3Cl(nta)_2 \cdot 2H_2O$	21.55(1.61)	28.40(1.49)
$Na_3[Cr(nta)_2] \cdot 5H_2O$	19.87(1.64)	27.84(1.47)
$[Cr(NH_3)_6]KCl(nta) \cdot 2H_2O$	21.55(1.59)	28.40(1.47)
$[Cr(nta)(NH_3)_2]KCl$[b)]	18.5	24.5

a) All the spectra were measured in water except for that of $[Cr(nta)(NH_3)_2]KCl$. b) The spectrum was measured by a diffuse reflectance method because the complex rapidly aquated in water.

indicating that the complex is converted into $[Cr(nta)(NH_3)_2]KCl$. Preliminary experiments showed that 130 °C for 6.5 h is the best condition for obtaining $[Cr(nta)(NH_3)_2]KCl$ from $[Cr(NH_3)_6]KCl(nta) \cdot 2H_2O$. The products were highly soluble and rapidly hydrolyzed in water, purification from water thus being always unsuccessful.

IR Data. The IR data obtained from the C=O stretching vibrations utilized for determining the coordination modes of carboxylato groups are summarized in Table 1. IR spectral studies on the metal complexes containing amino polycarboxylates reveal that the bands due to free carboxylic acid (-COOH), coordinated carboxylate (-COO-Metal) and ionic carboxylate (-COO$^-$) appear at 1700—1740, 1620—1690 and 1550—1600 cm^{-1}, respectively.[9] $[Cr(NH_3)_6]Naedta \cdot 3H_2O$ and $[Cr(NH_3)_6]Napdta \cdot 6H_2O$ give the band at 1580 and 1590 cm^{-1}, respectively, indicating that both the edta and pdta ions are present in ionic form in the salts. The presence of the bands (1650 cm^{-1}) in $NH_4[Cr(edta)] \cdot 2H_2O$ and $Na[Cr(pdta)] \cdot 3H_2O$ suggests that the carboxylato groups in both the complexes are coordinated to Cr(III) ions. The appearance of the bands (1715 and 1590 cm^{-1}) in $[Cr(NH_3)_6]HK_3Cl(nta)_2 \cdot 2H_2O$ indicates that the salt has free carboxylic acid and ionic carboxylato groups. The presence of both coordinated and ionic carboxylato groups in $Na_3[Cr(nta)_2] \cdot 5H_2O$ is supported by the bands at 1640 and 1593 cm^{-1}. The results also show that the nta ion in $[Cr(NH_3)_6]KCl(nta) \cdot 2H_2O$ is present in ionic form (1580 cm^{-1}), but that in $[Cr(nta)(NH_3)_2]KCl$ is in coordinated form (1650 cm^{-1}).

Electronic Spectral Data. Electronic spectral data due to d-d transition obtained in water are given in Table 2. The first and second bands of the hexaammine-chromium(III) complexes appear at 21.55 and 28.40×10^3 cm^{-1}, respectively, irrespective of anions. The bands at 18.40 and 25.45×10^3 cm^{-1} in $NH_4[Cr(edta)] \cdot 2H_2O$ and 18.35 and 25.45×10^3 cm^{-1} in $Na[Cr(pdta)] \cdot 3H_2O$ resemble those of $[Cr(edta)(H_2O)]^-$ ion (18.4 and 25.5×10^3 cm^{-1}).[10] This is due to the fact that both complexes are converted into $[Cr(edta \text{ or } pdta)(H_2O)]^-$ ion in water. $Na_3[Cr(nta)_2] \cdot 5H_2O$ has bands at 19.87 and 27.84×10^3 cm^{-1}, which are in the proximity of those of *trans*(N)-$(NH_4)_3[Cr(nta)_2] \cdot 4H_2O$ (20.0 and 27.8×10^3 cm^{-1}).[8] The spectrum of $[Cr(nta)(NH_3)_2]KCl$ was measured by a powder diffuse reflectance method since the complex is rapidly hydrolyzed in water. The bands at 18.5 and 24.5×10^3 cm^{-1} are substantially close to those of [Cr(nta)(bipy)] (18.6 and 24.6×10^3) where bipy denotes 2,2'-bipyridine.[11] It seems that the chromium(III) ion in the products is surrounded by a N_3O_3 chromophore.

Study on the thermal reactions of $[Cr(NH_3)_6]X_3$ (X is a simple monodentate anion such as Cl^-, Br^- and I^-) showed that the complexes undergo anation upon heating in open system and are successively converted into $[CrX(NH_3)_5]X_2$, $[CrX_2(NH_3)_4]$ and $[CrX_3(NH_3)_3]$.[12] It was found that under Q-conditions, even the complexes containing more complicated anions such as edta, pdta and nta ions undergo participation of these ions in the coordination sphere giving the corresponding

amino polycarboxylato-complexes. The use of thermal reactions in the quasi-closed system would lead to the production of other new metal complexes, which do not seem to have been prepared in solutions.

The authors wish to express their thanks to Hungarian Optical Works and Kubota Trading Co. for the use of Q-derivatograph.

The Coprecipitation of Antimony(III or V) with Iron(III) Hydroxide

Yoshikazu INOUE and Makoto MUNEMORI*

Laboratory of Environmental Chemistry, College of Engineering, University of Osaka Prefecture, Mozu-Umemachi, Sakai 591

(Received August 2, 1979)

The coprecipitation of antimony(III or V) with iron(III) hydroxide as a function of the pH in the range from 4 to 12 was studied in the presence of the chloride ion. Antimony(III) is coprecipitated more easily at any given pH value than antimony(V). The coprecipitation of antimony(III) is quantitative in the pH range from 4 to 10 and is not affected by the chloride ion. On the other hand, the coprecipitation of antimony(V) is affected not only by the pH range, but also by the chloride-ion concentration.

Iron(III) and manganese(IV) oxides(or hydroxide) have been noted as substances which exert a major effect on the concentrations of other heavy metal ions in natural waters,[1-3] because these oxides associate with the heavy metal ions. For example, cadmium(II) and lead(II) are incorporated into the hydrous oxides of iron and manganese.[4,5] Arsenic(III),[6] chromium-(III),[7] and mercury(II)[8] are incorporated into iron-(III) hydroxide. This incorporation can be ascribable to adsorption, ion-exchange, or coprecipitation. Leckie and James[9] have suggested that the hydrolysis of the heavy metal ion plays an important role in these processes. The hydrolysis reaction differs depending on the oxidation state of the metal ion and is also affected by the presence of complexing agents.

In a previous paper,[10] we studied the coprecipitation of mercury(II) with iron(III) hydroxide in the absence and in the presence of halogenide ions and indicated that the coprecipitation behavior can be explained in terms of the hydrolysis of mercury, *i.e.*, the formation of $Hg(OH)_2$. The present investigation was undertaken in order to evaluate the coprecipitation of antimony-(III or V) with iron(III) hydroxide in the presence of the chloride ion. It has been reported that antimony-(III) is coprecipitated with iron(III) hydroxide and manganese(IV) oxide.[11,12] Fujinaga *et al.*[11] studied the coprecipitation of antimony(III) with iron(III) hydroxide in natural and artificial seawater and indicated that antimony(III) is quantitatively coprecipitated with iron(III) hydroxide in the vicinity of pH 7. For antimony(V), however, little has been published regarding coprecipitation with heavy metal hydroxides in natural waters.

This paper will describe a coprecipitation study of the antimony(III or V)-iron(III) system and will discuss the effect of the hydrolysis of antimony on its coprecipitation with iron(III) hydroxide and the antimony species which is responsible for coprecipitation from the viewpoint of chemical equilibrium.

Experimental

Reagents. The antimony(III) stock solution, 8.2×10^{-2} mol cm^{-3}, was prepared by dissolving antimony metal (99.999 %) in sulfuric acid with heating and by then diluting the mixture with dilute hydrochloric acid. The antimony(V) stock solution, 8.2×10^{-2} mol dm^{-3}, was prepared by dissolving potassium antimonate(V) in dilute hydrochloric acid(the antimonate is not appreciably soluble in sulfuric acid). The iron(III) stock solution was prepared by dissolving iron(III) sulfate in dilute sulfuric acid and was standardized by titration with potassium permanganate after reduction with zinc. The working solutions were prepared immediately before use by diluting the stock solutions. Sodium chloride was used as the source of the chloride ion. All the chemicals were of an analytical reagent grade.

Procedure. The hydrolysis study was carried out by employing a 500-ml portion of an 8.2×10^{-4} mol dm^{-3} antimony(III or V) solution. The solution was adjusted to pH 4, 10, or 12 with sodium hydroxide and was allowed to stand while it was being stirred at 25 °C. At fixed intervals of time, a 20-ml portion of the solution was filtered through a filter paper(Toyo filter paper No. 2). In the coprecipitation study, a 200-ml portion of a solution containing 8.2×10^{-4} mol dm^{-3} antimony(III or V) and 7×10^{-3} mol dm^{-3} iron(III) was used to obtain the data reported below unless otherwise indicated. The solution was adjusted to an appropriate pH value with sodium hydroxide and then allowed to stand while it was being stirred at 25 °C. After equilibrium had been reached(it required about 20 min), the solution was filtered through a filter paper(Toyo filter paper No. 2). All the pH values reported are equilibrium values. The antimony remaining in the filtrate was colorimetrically determined by the Rhodamine B method. Antimony(V) was reduced to antimony(III) with sodium sulfite by heating[13] and was then subjected to the Rhodamine B method immediately after the reoxidation of antimony(III) to antimony(V) with cerium.

Results and Disccusion

Hydrolysis of Antimony(III). The hydrolysis of antimony(III) was first studied at pH 4, 10, and 12 in

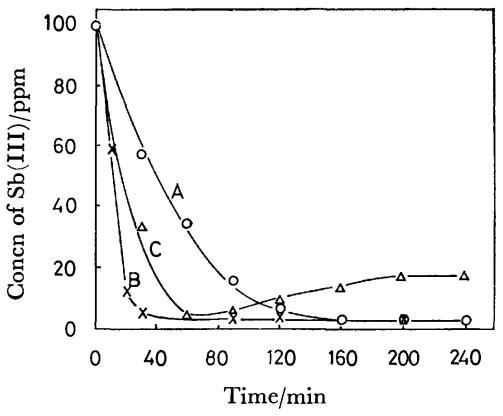

Fig. 1. Effect of pH on the hydrolysis of antimony(III) in the presence of 6×10^{-2} mol dm^{-3} chloride and 1.8×10^{-2} mol dm^{-3} sulfate (A) pH 4, (B) pH 10, and (C) pH 12.

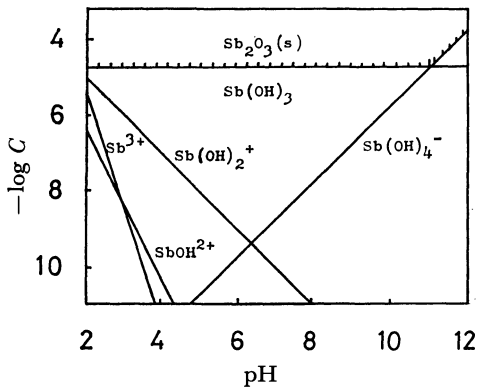

Reactions	Equilibrium constants
$Sb_2O_3(s)+3H_2O=2Sb^{3+}+6OH^-$	$10^{-4.14}$
$Sb_2O_3(s)+2H^++H_2O=2Sb(OH)_2^+$	$10^{-3.11}$
$Sb_2O_3(s)+3H_2O=2Sb(OH)_3$	$10^{-4.7}$
$Sb_2O_3(s)+2OH^-+3H_2O=2Sb(OH)_4^-$	$10^{-2.06}$
$SbOH^{2+}+H_2O=Sb(OH)_2^++H^+$	$10^{-1.4}$
$Sb(OH)_2^++H_2O=Sb(OH)_3+H^+$	$10^{-0.87}$
$Sb(OH)_3+H_2O=Sb(OH)_4^-+H^+$	$10^{-11.0}$

Fig. 2. Log concentration-pH solubility diagram for $Sb_2O_3(s)-H_2O$ system. The diagram was calculated using representative values[14,15] for equilibrium constants for solubility and hydrolysis.

the presence of chloride (6×10^{-2} mol dm^{-3}) and sulfate (1.8×10^{-2} mol dm^{-3}) ions. Figure 1 shows the results as a function of the time. At pH 4 and 10, the concentration of antimony(III) in the solution decreased continuously, depending on the pH, with the lapse of time until equilibrium was established. At pH 12, on the other hand, the concentration of antimony(III) once decreased to minimum and then increased until equilibrium was established. The equilibrium concentration at pH 4 and 10 was about 3 ppm (2.46×10^{-5} mol dm^{-3}), which agrees fairly well with the solubility of $Sb_2O_3(s)$ (2×10^{-5} mol dm^{-3}) as derived from Fig. 2. The equilibrium concentration at pH 12 was about 18 ppm (1.48×10^{-4} mol dm^{-3}), which corresponds with the solubility of $Sb_2O_3(s)$ at pH 12 (1.8×10^{-4} mol dm^{-3}) (Fig. 2). These results indicate that neither chloride nor sulfate ions affect the hydrolysis equilibrium for antimony(III); this is in accordance with the theoretical expectation based on the small formation constants of the antimony(III) chloride and sulfate complexes. Therefore, the hydrolysis of antimony can be expressed by the following chemical equations, even in the presence of chloride and sulfate ions:

$$Sb^{3+} + H_2O = SbOH^{2+} + H^+ \quad (1)$$

$$SbOH^{2+} + H_2O = Sb(OH)_2^+ + H^+ \quad (2)$$

$$Sb(OH)_2^+ + H_2O = Sb(OH)_3 + H^+ \quad (3)$$

$$2Sb(OH)_3 = Sb_2O_3(s) + 3H_2O \quad (4)$$

At pH 4 and 10, Reactions 1 to 4 take place and antimony(III) is precipitated as Sb_2O_3. Reactions 1 to 3 may be expected to be faster at higher pH values, while Reaction 4 is probably independent of the pH; therefore, the precipitation equilibrium is established faster at pH 10 than at pH 4.

At pH 12, however, Reaction 5 or 6 occurs in addition to the above reactions to produce the $Sb(OH)_4^-$ ion, while the formation of $Sb_2O_3(s)$ is retarded.

$$Sb(OH)_3 + OH^- = Sb(OH)_4^- \quad (5)$$

$$Sb_2O_3(s) + 2OH^- + 3H_2O = 2Sb(OH)_4^- \quad (6)$$

The appearance of the minimum solubility during the hydrolysis process clearly indicates that Reaction 6 is predominant.

Coprecipitation of Antimony(III) with Iron(III) Hydroxide. In the antimony(III)–iron(III) system, antimony(III) was precipitated within 20 min over a wide pH range. The concentration of antimony(III) remaining in the aqueous phase at pH 8 was less than 0.05 ppm (4.1×10^{-7} mol dm^{-3}), far less than that expected from the solubility of $Sb_2O_3(s)$ (2×10^{-5} mol dm^{-3}). These results indicate that antimony(III) is coprecipitated with iron(III) hydroxide. The concentration of the chloride ion in the range from 1×10^{-3} to 5.4×10^{-1} mol dm^{-3} did not affect the results, suggesting the absence of any effect of the ionic strength on the coprecipitation.

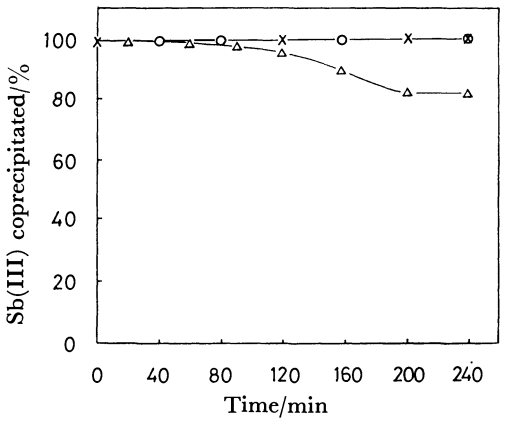

Fig. 3. Effect of hydrolysis of antimony(III) its coprecipitation with iron(III) hydroxide (○) pH 4, (×) pH 10, and (△) pH 12.

Effect of Hydrolysis of Antimony(III) on its Coprecipitation with Iron(III) Hydroxide. Figure 3 shows the effect of the hydrolysis of antimony(III) on its coprecipitation with iron(III) hydroxide. The experiment was performed in the following manner. Prior to the addition of iron(III), the antimony(III) solution was adjusted to pH 4, 10, or 12 with sodium hydroxide and then allowed to stand for a given time while it was being stirred at 25 °C. The time is taken as the abscissa in Fig. 3. The iron(III) solution was adjusted to pH 4, 10, or 12, and antimony and iron solutions with the same pH value were mixed. After the mixture has then been allowed to stand for 5 min while it being stirred at 25 °C, the suspension was filtered through a filter paper (Toyo filter paper No. 2). At pH 4 and 10, as is shown in Fig. 3, antimony(III) was quantitatively coprecipitated with iron(III) hydroxide, irrespective of the time needed for the hydrolysis of antimony. The concentration of antimony(III) remaining in the aqueous phase at both pH values was less than 0.05 ppm. At pH 12, the coprecipitation of antimony(III) was quantitative as long as the antimony(III) solution was allowed to stand for a period of less than 30 min

before mixing. After standing for a longer period, however, the extent of the coprecipitation of antimony(III) gradually decreased to a constant value, and then the concentration of antimony(III) remaining in the aqueous phase was 19 ppm (1.6×10^{-4} mol dm^{-3}), approximately equal to the solubility of Sb_2O_3(s) at pH 12. The coprecipitation behavior of antimony(III) described above can be explained by assuming that the $Sb(OH)_4^-$ ion is not coprecipitated with iron(III) hydroxide.

It can be concluded from the results presented above that the antimony(III) species except Sb_2O_3(s) are coprecipitated with iron(III) hydroxide, but there is no evidence to determine what species among Sb^{3+}, $SbOH^{2+}$, $Sb(OH)_2^+$, and $Sb(OH)_3$ is predominantly responsible for the coprecipitation process. Further investigation will be required for a more detailed elucidation of the coprecipitation mechanism.

Coprecipitation of Antimony(V) with Iron(III) Hydroxide. The effect of the pH on the formation of antimony(V) oxide was examined prior to the coprecipitation study of the antimony(V)–iron(III) system. Antimony(V) must be precipitated as Sb_2O_5 in an acid medium when its concentration is higher than 2×10^{-4} mol dm^{-3}.[16] In reality, however, no precipitate appeared when solutions containing 8.2×10^{-4} mol dm^{-3} antimony(V) and 6×10^{-2} mol dm^{-3} chloride were allowed to stand for about 200 min at 25 °C after the pH had been adjusted to 0, 4, 10, and 12. It seems, then, that antimony(V) is present in the solution as chloro complexes, *e.g.*, $Sb(OH)_xCl_{6-x}$ ions (x=2—6).

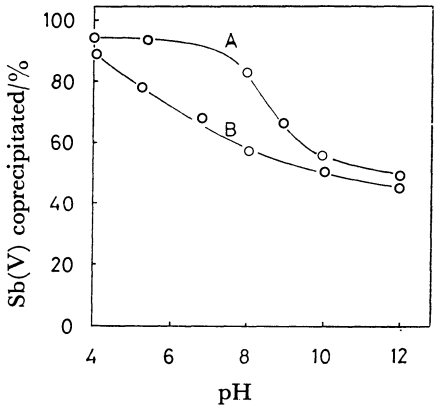

Fig. 4. Coprecipitation of antimony(V) with iron(III) hydroxide in the presence of chloride ion (A) 6×10^{-2} mol dm^{-3} and (B) 5.4×10^{-1} mol dm^{-3}.

In the antimony(V)–iron(III) system, however, antimony(V) was precipitated in the pH range shown in Fig. 4(A). These results indicate that antimony(V) is coprecipitated with iron(III) hydroxide. The coprecipitation of antimony(V) was affected by the concentration of the chloride ion, as is shown in Fig. 4 (A and B). With the increase in the chloride-ion concentration, the coprecipitation is prevented. The effect of the chloride ion may be attributed to the complex formation between antimony(V) and chloride ions, though the speciation of antimony is complicated at the present

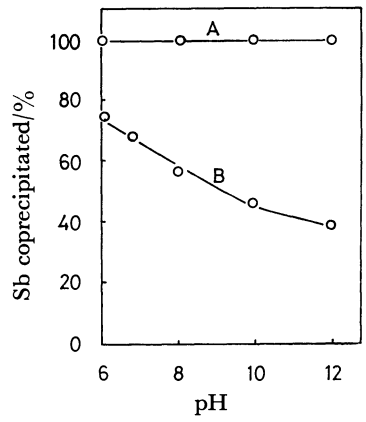

Fig. 5. Coprecipitation of antimony(III or V) with iron(III) hydroxide in artificial seawater (A) antimony(III) (B) antimony(V).

time[16,17] and further investigation will be required before we can infer the coprecipitation mechanism.

The Coprecipitation of Antimony(III or V) in Artificial Seawater. Coprecipitation behavior was studied in a mixture whose composition was similar to that of seawater with respect to inorganic anions, *i.e.*, 5.4×10^{-1} mol dm^{-3} chloride, 8.1×10^{-4} mol dm^{-3} bromide, 5.3×10^{-5} mol dm^{-3} fluoride, 3.2×10^{-7} mol dm^{-3} iodide, 2.8×10^{-2} mol dm^{-3} sulfate, 2.3×10^{-3} mol dm^{-3} carbonate, and 4.2×10^{-5} mol dm^{-3} borate ions. The results are shown as a function of the pH in Fig. 5. In the artificial seawater, antimony(III) was coprecipitated with iron(III) hydroxide more easily than antimony(V). At pH 8, for example, the concentration of antimony present in the solution was about 43 ppm (3.5×10^{-4} mol dm^{-3}) for antimony(V) and less than 0.05 ppm (4.1×10^{-7} mol dm^{-3}) for antimony(III). From these results, it may be said that, if the coprecipitation of antimony with iron(III) hydroxide occurs in seawater, antimony(III) will be coprecipitated more easily than antimony(V). The fact that antimony is mainly present in seawater as the quinquevalent state[18,19] is possibly ascribable to the difference in hydrolysis behavior between antimony(III) and antimony(V) described above.

Conclusion

The results described above indicate that the hydrolysis of antimony is a crucial step in the coprecipitation of antimony with iron(III) hydroxide. Antimony(III) is not coprecipitated with iron(III) hydroxide in the form of $Sb(OH)_4^-$ ion. The coprecipitation of antimony(V) is somewhat complicated when the chloride ion is present; therefore, further investigation will be required to elucidate the coprecipitation mechanism. The hydrolysis of antimony(III) is independent of the concentration of the chloride ion. The coprecipitation of antimony(III) is not affected by the chloride ion and takes place over a wide range of pH values. On the other hand, the coprecipitation of antimony(V) is affected not only by the pH, but also by the chloride-ion concentration. Accordingly, in seawater which contains

a large amount of chloride ion (*ca.* 5.4×10^{-1} mol dm^{-3}), antimony(III) may be coprecipitated with iron(III) hydroxide more easily than antimony(V).

The authors wish to acknowledge the assistance given by Mr. Yoshio Nishioka in the experimental work.

An X-Ray Diffraction Study on the Structures of Bis- and Tris(ethylenediamine)cadmium(II) Complexes in Solution

Tadao FUJITA and Hitoshi OHTAKI*

Department of Electronic Chemistry, Tokyo Institute of Technology at Nagatsuta, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received August 30, 1979)

The structures of cadmium(II) complexes with ethylenediamine(en) have been determined by means of X-ray diffraction. The measurements were performed at 25 °C for aqueous ethylenediamine solutions of cadmium nitrate, the mole ratios (en/Cd) in the solutions being 2.188 and 3.387. In the solution of the lower en/Cd mole ratio, the bis(ethylenediamine)cadmium(II) complex was predominant, whereas in the other solution the tris-(ethylenediamine)cadmium(II) complex was contained as the main species. From the analysis of the X-ray scattering data of the solutions, it was shown that in the bis-complex four nitrogen atoms within the two ethylenediamine molecules were tetrahedrally coordinated to the cadmium(II) ion at a distance of 2.339(4) Å. The nonbonding Cd···C distance within the bis-complex was also determined to be 3.04(1) Å. In the tris-complex the cadmium(II) ion was coordinated with six nitrogen atoms and the Cd–N and Cd···C distances were 2.371(5) and 3.19(1) Å, respectively. The strength of the Cd–N bond with changing coordination number of the complexes was discussed in terms of the frequencies of the Cd–N bond in the Raman spectra of these solutions and the bond lengths found from the X-ray scattering measurements.

In a previous paper,[1] the structures of the bis- and tris(ethylenediamine)zinc(II) complexes in solution have been investigated by the X-ray diffraction method. In the present study, we have attempted to determine the structures of the bis- and tris(ethylenediamine)-cadmium(II) complexes in aqueous nitrate solutions in a series of structural studies of chelate complexes of transition metals in solution. No crystallographic investigation of ethylenediamine complexes of cadmium-(II) has been reported so far.

Raman spectra of the test solutions were also studied for comparing the strength of the Cd–N bonds within the bis- and tris-complexes.

Experimental

Preparation and Analysis of Sample Solutions. Ethylenediamine was purified by the method previously described.[1] Cadmium(II) nitrate of reagent grade was purchased from Wako Pure Chemical Co., Osaka and was recrystallized twice from water. The sample solutions were prepared by dissolving cadmium(II) nitrate into aqueous ethylenediamine solution as in the similar way to that in the previous paper.[1]

Concentrations of cadmium(II) ions in the test solutions were determined by EDTA titration and electrogravimetry. The results of the two independent methods agreed each other within 0.2%. The concentration of the nitrate ion was determined from the stoichiometry of the cadmium nitrate. The density of the solutions was determined pychnometrically. The composition of the test solutions is given in Table 1.

TABLE 1. THE COMPOSITION (g-atom/dm³) AND THE STOICHIOMETRIC VOLUME V PER CADMIUM ATOM IN THE SOLUTIONS

	Solution	
	A	B
Cd	1.916	1.760
N	16.81	11.22
C	12.98	7.702
O	38.03	46.95
H	105.0	103.6
en/Cd	3.387	2.188
V/Å³	866.6	946.6
Density/g cm^{-3}	1.321	1.303

Method of Measurements and Treatment of X-Ray Scattering Data. The X-ray diffractometer used, the method of measurements and treatment of X-ray scattering data were the same as those described elsewhere.[1,2] Mo $K\alpha$ radiation (λ=0.7107 Å) was used for the measurements over the range $1°<\theta<70°$ (2θ is the scattering angle). The data were recorded twice over

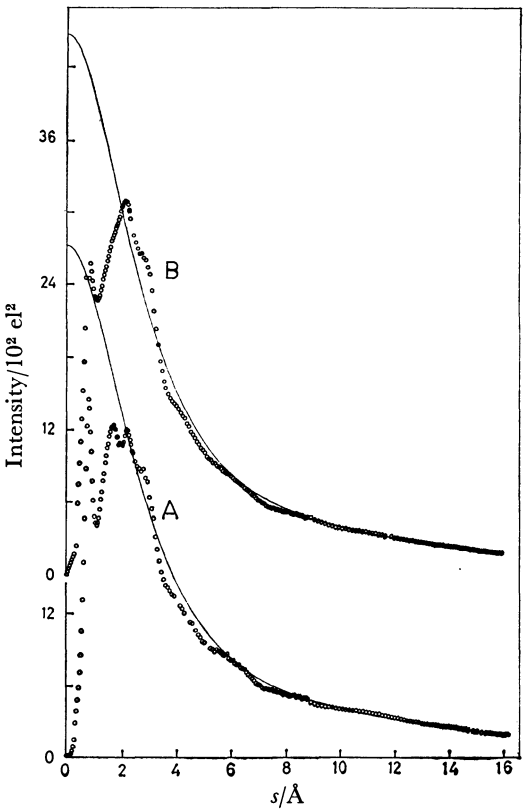

Fig. 1. Coherent scattering intensities of the sample solutions A and B. Experimentally obtained intensities I^{coh} are shown by circles and calculated independent scattering intensities by solid lines.

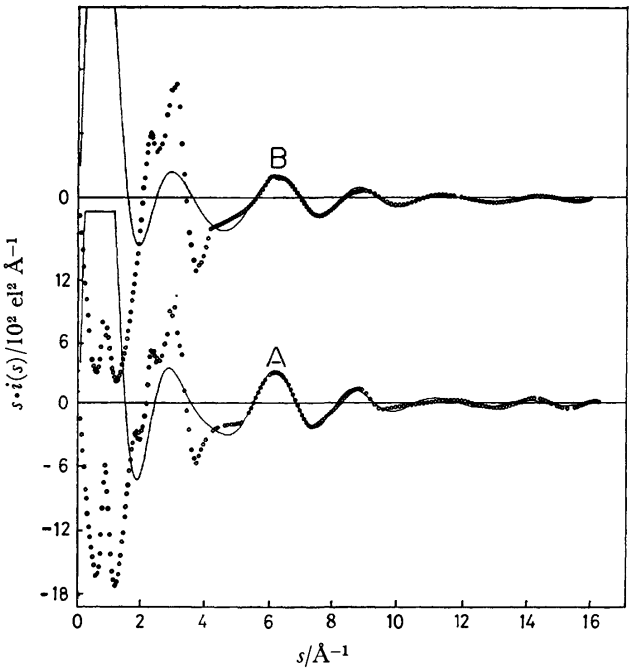

Fig. 2. The reduced intensities multiplied by s for solutions A and B. The observed $s \cdot i(s)$ curve is shown by circles and the calculated one by solid lines.

the whole angle range. The corrections and analysis of the scattering data were performed in the same ways as those in the previous papers.[1,2] Coherent intensities and reduced intensities multiplied by s of the test solutions are given in Figs. 1 and 2, respectively. The radial distribution function $D(r)$ was calculated by the usual method:

$$D(r) = 4\pi r^2\rho_0 + \frac{2r}{\pi}\int_0^{s_{max}} s \cdot i(s) \cdot M(s) \cdot \sin(sr)\mathrm{d}s, \quad (1)$$

where ρ_0 is the average scattering density in the stoichiometric volume V of the solution per cadmium atom, and s_{max} denotes the maximum s-value ($s = 4\pi\sin\theta/\lambda$) attained in the measurement ($s_{max} = 16.7$ Å^{-1}). $M(s)$ is the modification function, the function $[f_{Cd}(0)^2/f_{Cd}(s)^2] \cdot \exp(-0.01\, s^2)$ being chosen. The reduced intensities $i(s)$ are given by

$$i(s) = I^{coh}(s) - \sum_i n_i\{(f_i(s) + \Delta f_i')^2 + (\Delta f_i'')^2\}, \quad (2)$$

where n_i is the number of atom i and $f_i(s)$ denotes the scattering factor of atom i at s. $\Delta f_i'$ and $\Delta f_i''$ represent the real and imaginary parts of the anomalous dispersion, respectively. The radial distribution curve $D(r)$ of the solutions was drawn after the Fourier transform of the reduced intensity multiplied by s.

Results and Discussion

Solution A contains the tris(ethylenediamine)-cadmium(II) complex as the main species according to the formation constants so far reported.[3] In solution A, however, coexistence of the bis-complex may not be neglected. In solution B the bis(ethylenediamine)-cadmium(II) complex may be contained with a small amount of the tris-complex. Therefore, a successive approach of the analysis as described in the preceding paper[1] was employed in order to obtain the best fitted results for both radial distribution and reduced intensity curves of the test solutions.

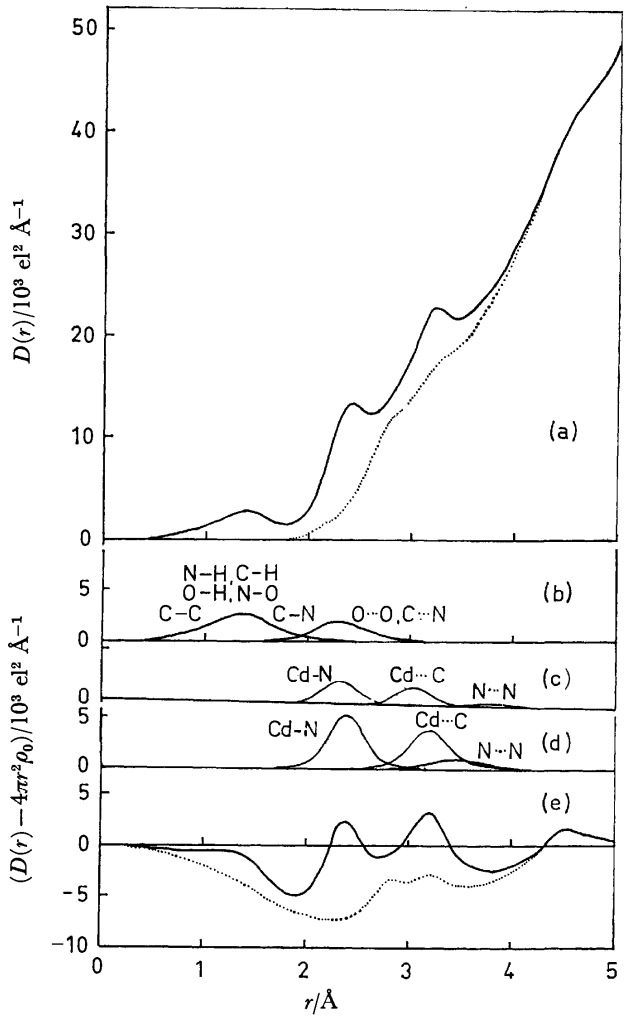

Fig. 3. (a) The radial distribution curve for solution A. (b) The theoretical peak shapes for the O–H bond within water, the N–H, C–H, C–C, C–N, and C···N pairs within an ethylenediamine molecule, and the N–O and O···O contacts within a nitrate ion. (c) The theoretical peak shapes for the Cd–N, Cd···C, and N···N pairs within the $Cd(en)_2^{2+}$ complex. (d) The theoretical peak shapes for the Cd–N, Cd···C and N···N interactions within the $Cd(en)_3^{2+}$ complex. (e) The corresponding $(D(r) - 4\pi r^2\rho_0)$ curve to the $D(r)$ in (a). The dotted lines in (a) and (e) show the residual radial and residual differential radial distribution curves, respectively, after subtraction of these theoretical peaks.

Solution A. The radial distribution curve of solution A showed four major peaks over the range 1—5 Å (Fig. 3a). A small peak at about 1.3 Å is composed of the peaks due to the O–H bond within water, the N–H, C–H, C–C and C–N bonds within an ethylenediamine molecule and the N–O bond within a nitrate ion (see Fig. 3b). The second peak appearing at 2.4 Å may be attributed to the interaction between a cadmium(II) ion and the nitrogen atoms of the ethylenediamine molecules coordinated to the central metal ion. The distances corresponding to the nonbonded C···N pairs within an ethylenediamine molecule and the O···O contacts within an NO_3^- ion may partly contribute to the peak. The third peak at 3.2 Å may be

ascribed to the nonbonded interactions between cadmium(II) ion and the carbon atoms within the ethylenediamine molecules coordinated. The broad peak at around 4—5 Å may include contributions from the relatively long range intermolecular interactions among the complexes, free ligands and solvent molecules, which we will not discuss in this paper. The temperature factors of atom pairs within water and ethylenediamine molecules and a nitrate ion used in this investigation were the same as those used in Ref. 1.

At a first approach, the Cd–N and Cd···C distances within the tris-complex were estimated from the radial distribution curve by assuming that the only tris-complex existed in the solution. The bond distances of 2.38 and 3.18 Å for the Cd–N and Cd···C interactions, respectively, were found, the temperature factor of the former bond being about 0.003 Å^2 and that of the latter 0.008—0.01 Å^2. The parameter values thus obtained for the tris-complex were inserted into the analytical procedure of determining the parameter values of the bis-complex in solution B. The procedure was continued until a smooth background of the radial distribution curve was obtained by assuming suitable concentrations of the bis- and tris-complexes in the solutions and parameter values of the former complex. The parameter values thus estimated for the both bis- and tris-complexes were again turned back to the calculation of the radial distribution curve of solution A in order to refine the values of the tris-complex at a fixed parameter values of the bis-complex and changing concentration ratio of the tris-complex to the bis-complex. The successive analyses were continued until no appreciable peak was left in the background of the radial distribution curves of the both solutions A and B. The values thus obtained were further refined by the least-squares method applied to the reduced intensities of the solutions.

Solution B. A successive approach for analyzing the radial distribution curve of solution B was employed as described in the previous section. The Cd–N and Cd···C distances within the bis-complex were estimated to be 2.35 and 3.05 Å, respectively (Fig. 4). The temperature factor of the former bond was about 0.003 Å^2, while that of the latter one was 0.006—0.008 Å^2.

A peak still remained at around 2.9—3.3 Å in the residual radial distribution curves of the both systems (dotted lines in Figs. 3 and 4) were attributed to the structures of bulk water and hydrated nitrate ions.[4]

Least-Squares Refinements. The parameter values (bond distance r, temperature factor b and frequency factor n) of the interactions in the models adopted were refined by comparing the observed $s \cdot i(s)$ curves with theoretical ones of solutions A and B at high angle regions. The refinements were carried out so as to obtain a minimum error-square sum $U=\sum s^2\{i_{obsd}(s)-i_{calcd}(s)\}^2$ by using the NLPLSQ program.[5] The s-region was varied in the calculations in order to avoid introduction of errors due to relatively long range intermolecular interactions, which mainly contribute to the intensity data at a low angle region, to the refined parameters.

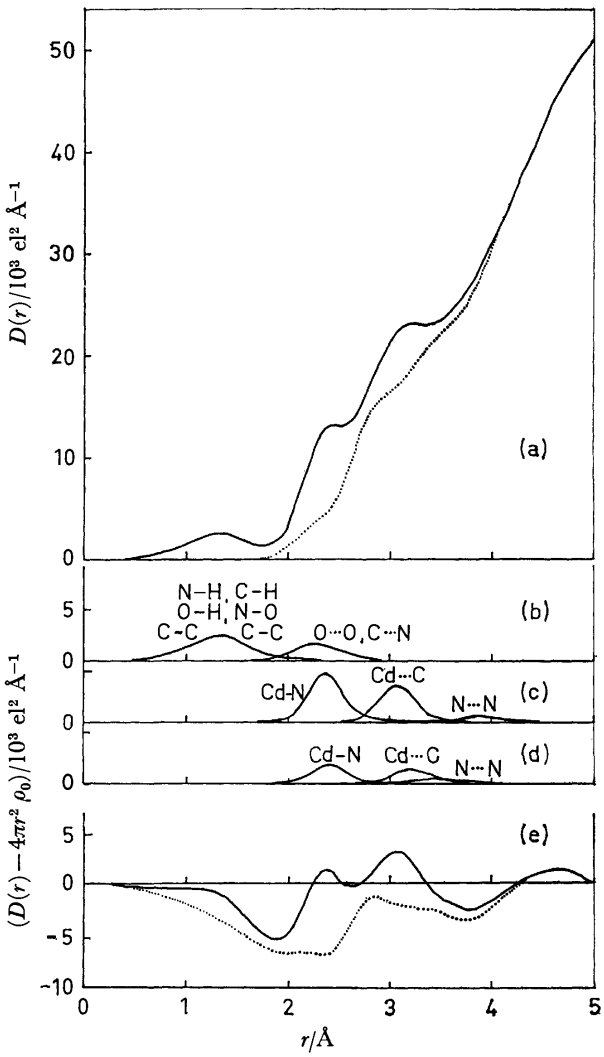

Fig. 4. (a) The radial distribution curve for solution B. (b) The theoretical peak shapes for the O–H bond within water, the N–H, C–H, C–C, C–N, and C···N pairs within an ethylenediamine molecule, and the N–O and O···O contacts within a nitrate ion. (c) The theoretical peak shapes for the Cd–N and Cd···C and N···N pairs within the $Cd(en)_2^{2+}$ complex. (d) The theoretical peak shapes for the Cd–N, Cd···C and N···N pairs within the $Cd(en)_3^{2+}$ complex. (e) The corresponding $(D(r)-4\pi r^2\rho_0)$ curve to the $D(r)$ in (a). The dotted lines in (a) and (e) show the residual radial and residual differential radial distribution curves, respectively, after subtraction of these theoretical peaks.

For the tris-complex the parameter values were refined with four ways (A-1, A-2, A-3, and A-4). In type A-1, fourteen parameter values (indicated by italic letters) listed in Table 2 were allowed to change simultaneously on the assumption of the tetrahedral structure of the bis-complex, which is confirmed as described later. In type A-2, an octahedral structure of the tris-complex was also assumed, that is, the frequency factor of the Cd–N and Cd···C interactions were fixed at 6 and the only bond distances and temperature factors of the models were refined. In both treatments, the frequency factors of the interactions within

the bis-complex were fixed and the temperature factors of the N···N interactions within both bis- and tris-complexes were held constant at 0.01 Å^2, which was obtained in the gas phase. Beside A-2, various attempts were made for the sets of the parameters with descretely changing temperature factors of the N···N interactions of the complexes over the range $b_{N...N}$ from 0.01 to 0.006 Å^2 (twice of the $b_{Cd...N}$ value). However, no appreciable change for all parameter values was found, typical results being shown in A-3 and A-4 of Table 2. In these treatments $r_{N...N}$ and $b_{N...N}$ of the bis- and tris-complexes were fixed and $n_{Cd...C}$ of the tris-complex was varied in A-3, while $n_{Cd...C}$ of the tris-complex was fixed at 6 in A-4. Thus, it was found that the temperature factor of the N···N interactions within the complexes were insensitive to the parameter values given in Table 2. The parameter values were not practically influenced by changing s_{min} from 4.5 to 7.0 Å^{-1} (s_{max} was 16.7 Å^{-1}).

Similar treatments were examined for evaluating parameter values of the bis-complex. Thus, for solution B four types of the refinement (B-1, B-2, B-3, and B-4 in Table 3) were carried out. In types B-1 and B-3, the frequency factors of the Cd–N and nonbonding Cd···C interactions, as well as other parameter values indicated by italic, were refined. In types B-2 and B-4, on the other hand, a tetrahedral structure of the bis-complex was assumed. In B-1 and B-2, the temperature

factor of the N···N interaction within the bis-complex was assumed to be 0.01 Å^2, whereas the value was fixed at 0.006 Å^2 in the treatments of B-3 and B-4. In these four refinements, all of the parameter values of the tris-complex were fixed, because the concentration of the tris-complex was so low compared with that of the bis-complex that a reasonable refinement of the parameter values of the tris-complex could not be achieved by the least-squares method for the reduced intensities of the solution. Therefore, the parameter values of the tris-complex determined in the previous section were used in these calculations. In the refinement of the values of solution A, however, the parameter values of the bis-complex were also optimized, together with those of the tris-complex, since the concentration of the bis-complex was about 30 mol%.

The results obtained by these refinements obviously exclude the existence of the octahedral $Cd(OH_2)_2(en)_2^{2+}$ complex as the bis-species. If the $Cd(OH_2)_2(en)_2^{2+}$ complex would form, instead of $Cd(en)_2^{2+}$, the frequency factor for the Cd–N interaction within the bis-complex would be optimized to 6 in the treatments of B-1 and B-3, because the Cd–O bond would not be clearly distinguished from the Cd–N bond by the present measurements. When we fixed the n_{Cd-N} values of the bis-complex at 6, a fairly large error-square sum was resulted compared with that of B-4 in which n_{Cd-N} was fixed at 4. Moreover, the n_{Cd-N} value of the bis-complex tended to decrease and approached 4 in the course of the least-squares refinement of the $s \cdot i(s)$ values. Therefore, we concluded that the formation of the $Cd(en)_2^{2+}$ complex of a tetrahedral structure was confirmed and the existence of the $Cd(OH_2)_2(en)_2^{2+}$ was excluded. The parameter values listed in Table 3 were practically independent of varying s-regions from 5.0, 6.0, and 7.0 to 16.7 Å^{-1}. Since almost the same parameter values were obtained for the bis-complex regardless of the assumptions set for the calculations in the both solutions, the pre-assumption of $n_{Cd-N}=4$ for the bis-complex made in the treatment of solution A was confirmed as a reasonable one.

The observed intensities were compared with the calculated ones by using parameter values given in Tables 2 (A-2) and 3 (B-2) and Eq. 3:

$$i_{calcd}(s) = \sum\sum n_{ij}\{(f_i(s)+\Delta f_i')(f_j(s)+\Delta f_j') + (\Delta f_i'')(\Delta f_j'')\} \cdot \frac{\sin(r_{ij}s)}{(r_{ij}s)} \exp(-b_{ij}s^2). \quad (3)$$

A reasonable agreement was found for both curves A and B in Fig. 2 except at the low angle part of the intensity curves where long range intermolecular interactions significantly contribute to the curves.

In the bis- and tris(ethylenediamine)zinc(II) complexes,[1] the Zn–N bond of the former complex is shorter than that of the latter, as is expected from the smaller crystal ionic radius of zinc(II) ion within a complex of a tetrahedral structure than that of an octahedral one. In crystal the ionic radius of cadmium(II) ion having the coordination number 4 is also smaller than that of the coordination number 6.[6] However, in cadmium(II) iodide complexes in solution, we have found that the Cd–I bond distance within the distorted octahedral $CdI(H_2O)_5^+$ complex does not appreciably change by replacing the five water molecules to three iodide ions to form the tetrahedral CdI_4^{2-} complex.[2,7] In the case of cadmium ethylenediamine complexes, the change in the Cd–N bond distance with changing coordination number of the cadmium(II) ion was only a few hundredths ångstroms, which is much smaller than the difference of the bond length in the crystalline state.[6] The distance of the Cd–NH_3 bond within the $Cd(NH_3)_6^{2+}$ complex is also 2.37 Å.[8]

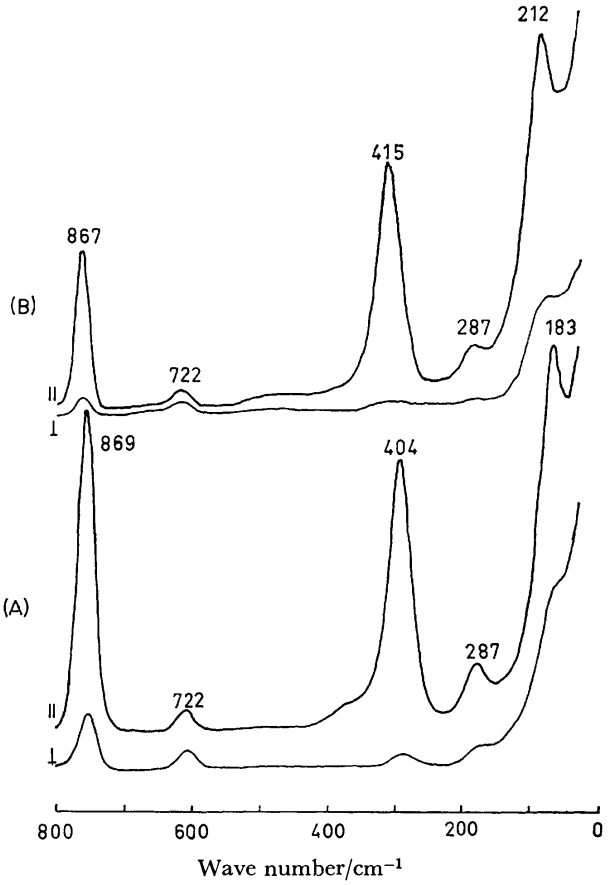

Fig. 5. Raman spectra of solutions A and B. The lines are the components parallel(∥) and perpendicular (⊥) to the direction of polarization of the incident light.

Raman Spectra of Solutions A and B. Krishnan and Plane[9] reported Raman spectra of the tris(ethylenediamine)cadmium(II) complex in an aqueous solution and assigned the line at 400 cm^{-1} to the totally symmetric Cd–N stretching vibration of the tris-complex. In solution A in this study we found a strongly polarized band at 404 cm^{-1} (Fig. 5). Another strong line observed at 869 cm^{-1} was ascribed to the CH_2 rocking vibration within ethylenediamine molecules.[10] A weak band at 722 cm^{-1} was assigned to the ν_4-vibration of nitrate ions. Some lines found in the region 170—300 cm^{-1} were not assignable. Krishnan and Plane[9] observed a line at 435 cm^{-1}, which was assigned to the totally symmetric Cd–N stretching for the bis(ethylenediamine)cadmium(II) complex. However, in solution B we found a strongly polarized band at 415 cm^{-1} which might be ascribed to the totally symmetric Cd–N stretching of the

bis-complex. The band of the bis-complex shifted by only 11 cm^{-1} to the higher frequency compared with that of the tris-complex. The bands appearing at 722 and 867 cm^{-1} were assignable to the nitrate ν_4 and CH_2 rocking vibrations, respectively.

The difference of the frequencies of the Cd–N stretching of the bis- and tris-complexes was small in contrast to the case of the zinc(II) ethylenediamine complexes.[1] The Cd–N bond distances within the bis-complex was almost the same as that of the tris-complex, whereas in the zinc(II) system the Zn–N bond length within the bis(ethylenediamine)zinc(II) complex was much shorter than that within the tris(ethylenediamine)zinc(II) complex, and the shorter Zn–N bond having a higher frequency within the bis-complex was concluded to be stronger than the longer Zn–N bond with lower frequency within the tris-complex, as described in the preceding paper.[1] In the case of cadmium ethylenediamine complexes, however, strength of the Cd–N bonds within the bis- and tris-complexes may not be appreciably different, because the lengths of the Cd–N bonds within the both complexes are practically the same and the shift of the frequency of the stretching vibration of the Cd–N bond within these complexes by changing their structures was small.

The Cd–N stretching vibration of the $Cd(NH_3)_6^{2+}$ complex appears at 341 cm^{-1},[8] which is lower than that of the tris-complex by about 63 cm^{-1}. The Cd–N bond distances within the hexaamminecadmium(II) and the tris-complexes are not significantly different, however. The higher frequency of the Cd–N stretching of the ethylenediamine complex may be due to coordination of a less freely movable amino group, which is attached to a CH_2 group, to the central metal ion, and the strength of the Cd–N bond within the $Cd(en)_3^{2+}$ and $Cd(NH_3)_6^{2+}$ complexes may be almost identical, because the enthalpy changes of the formation of the tris-complex ($\Delta H^\circ \simeq -84$ kJ mol^{-1}) is essentially the same as that of the hexaamminecadmium(II) complex ($\Delta H^\circ \simeq -88$ kJ mol^{-1}).[11]

ECE Mechanism as a Tool for the Investigation of Unstable Metal Complexes. II. Current-Potential Characteristics for the Reversible Deposition of an Insoluble Species: Case of Electrochemical Reduction of *trans*-Dibromobis-(ethylenediamine)cobalt(III) Complexes

Akifumi YAMADA,* Tadatsugu YOSHIKUNI, Yoshikiyo KATO, and Nobuyuki TANAKA
Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980
(Received September 6, 1979)

Theoretical relations were derived for the ECE mechanism involving the reversible deposition of an insoluble species at constant potential (potentiostatic method). Assuming that the activity of deposit becomes equal to unity immediately after the beginning of electrolysis, current-potential relations were obtained for the case in which the first electron transfer step is irreversible and the second one, reversible. The method was used to study the acid hydrolysis of bivalent cobalt complex in the reduction of *trans*-dibromobis(ethylenediamine)cobalt(III) complex. The measurement made at 5 °C in 0.1 M acetate buffer solutions (pH 4.8) gave 0.4 s^{-1} for the acid hydrolysis of *trans*-dibromobis(ethylenediamine)cobalt(II) which was produced by the reduction of cobalt(III) complex.

The ECE electrode reaction mechanism[1] has attracted attention in recent years in both theoretical and experimental fields. Theoretical studies have been carried out for electrochemical methods such as chronopotentiometry, potential step chronoamperometry, cyclic voltammetry, a.c. polarography, and d.c. polarography.[2]

Although experimental studies were carried out for the ECE electrode reaction of organic substances, only a few examples have been reported in inorganic electrochemistry.[3–11] In previous chronopotentiometric[8,9] and polarographic[7,10] studies, the rate constant of the complex-forming reaction for ethylenediaminetetraacetate and chromium(II) (electrochemically produced from chromium(III) complex) was successfully determined. The results have confirmed that the concept of ECE mechanism is useful for the study of an unstable intermediate electrochemically generated.

A test of the electrode reaction of cobalt(III) complexes revealed that the ECE mechanism involving reversible deposition of an insoluble species proceeds with complexes having ligands such as Cl^-, Br^-, and I^-. This was also pointed out by Vlček.[4] For example, the mechanism can be observed by the reduction of *trans*-dibromobis(ethylenediamine)cobalt(III) complex at the mercury electrode. When the cobalt(III) complex is reduced to cobalt(II), the cobalt(II) complex liberates bromide ions because of its lability. The electrochemically generated bromide ions are easily oxidized at the electrode to form insoluble mercury(I) bromide as long as the potential is positive. This series of electrode reaction takes place through the following electrode process:[12]

$$\textit{trans}\text{-}[CoBr_2(en)_2]^+ + e^- \longrightarrow \textit{trans}\text{-}[CoBr_2(en)_2], \quad (1)$$

$$\textit{trans}\text{-}[CoBr_2(en)_2] + 6H_2O \longrightarrow [Co(H_2O)_6]^{2+} + 2Br^- + 2en, \quad (2)$$

$$2Br^- + 2Hg \longrightarrow Hg_2Br_2 + 2e^-. \quad (3)$$

In this process, electrolytic deposition of an insoluble species is encountered. In order to include the reversible deposition of an insoluble species, an extension of the theory of the potentiostatic method for ECE mechanism seems necessary. This paper presents such an extension.

Experimental data were obtained for the potentiostatic reduction of *trans*-dibromobis(ethylenediamine)cobalt-(III) complex. The current-potential curves were compared with simulated ones. Calculation was made on the rate constant of the acid hydrolysis reaction of *trans*-dibromobis(ethylenediamine)cobalt(II) produced by the first electron transfer step.

Theoretical

ECE electrode reaction mechanism for many soluble species have been widely studied in the past,[1–11] but few quantitative analyses can be found for the ECE mechanism involving the reversible deposition of an insoluble species. This is understandable because of the inherent difficulty: the activity of the deposit cannot usually be known before the electrode becomes completely covered with at least a monolayer of deposit. In view of this we have considered a case in which it can be assumed that the activity of the deposit becomes equal to unity immediately after the beginning of electrolysis. For the sake of convenience, we describe the case which the first electron transfer step is irreversible and the second one reversible. This is the case for *trans*-$[CoBr_2(en)_2]^+$, and appears to be fairly general for ECE mechanism of halogenocobalt(III) complexes.[12]

The chronoamperometric technique applied to the analysis of the ECE mechanism has been described in detail by Alberts and Shain.[13] The boundary value problem for the electrode reaction

$$A + n_1e \xrightarrow{k_c} B \quad (4)$$

$$B \xrightarrow{l} C \quad (5)$$

$$C + n_2e \overset{E_0}{\rightleftharpoons} D \text{ (insoluble)} \quad (6)$$

is similar to that used by them, although specific boundary conditions are somewhat different. Here, A, B, C, and D represent the species, k_c is the heterogeneous rate constant, l the homogeneous rate constant, E_0 the standard potential of Reaction 6, and $n_j (j=1, 2)$ the number of electrons involved in the j-th electro-

chemical reaction: $n_j<0$ and $n_j>0$ correspond to reduction and oxidation, respectively. A, B, and C are soluble, and D is insoluble.

Assuming a linear diffusion, Fick's second law gives

$$\frac{\partial c_A}{\partial t} = D_A\left(\frac{\partial^2 c_A}{\partial x^2}\right), \tag{7}$$

$$\frac{\partial c_B}{\partial t} = D_B\left(\frac{\partial^2 c_B}{\partial x^2}\right) - lc_B, \tag{8}$$

$$\frac{\partial c_C}{\partial t} = D_C\left(\frac{\partial^2 c_C}{\partial x^2}\right) + lc_B, \tag{9}$$

where c and D are the concentration and diffusion coefficients, respectively, of a species indicated by subscripts, x is the distance from the electrode, and t the time.

The initial and boundary conditions are:

$$t = 0,\ x \geq 0:\ c_A = c^\circ,\ c_B = c_C = 0 \tag{10}$$

$$t \geq 0,\ x \to \infty:\ c_A = c^\circ,\ c_B, c_C \to 0 \tag{11}$$

$$t > 0,\ x = 0:$$

$$D_A\left(\frac{\partial c_A}{\partial x}\right)_{x=0} + D_B\left(\frac{\partial c_B}{\partial x}\right)_{x=0} = 0, \tag{12}$$

$$D_A\left(\frac{\partial c_A}{\partial x}\right)_{x=0} = k_c(c_A)_{x=0}, \tag{13}$$

$$(c_C)_{x=0} = \exp\left[\frac{n_2 F}{RT}(E - E_0)\right] = \theta, \tag{14}$$

where c° is the bulk concentration of A. Equation 14 represents a reversible deposition of the insoluble species D whose activity is assumed to be unity.

The equation for the total current is given by

$$I = Fq\left[n_1 D_A\left(\frac{\partial c_A}{\partial x}\right)_{x=0} + n_2 D_C\left(\frac{\partial c_C}{\partial x}\right)_{x=0}\right], \tag{15}$$

where F is the Faraday constant and q the electrode area. In this equation, anodic current is positive and cathodic current negative. This boundary value problem can be solved by means of the Laplace transform. The result is

$$\frac{I}{I_d} = \lambda\sqrt{\pi t}\exp(\lambda^2 t)\operatorname{erfc}(\lambda\sqrt{t}) - \frac{n_2}{n_1}\left(\frac{\theta}{c^\circ\sqrt{D_A/D_C}}\right) + \frac{n_2}{n_1}\left(\frac{D_C l}{D_C - D_B}\right)\lambda\sqrt{\pi t}\left[\exp(\lambda^2 t)\operatorname{erfc}(\lambda\sqrt{t}) * \exp\left(-\frac{D_C l t}{D_C - D_B}\right)\right] - \frac{n_2}{n_1}\sqrt{\frac{D_B}{D_C}}\left(\frac{D_C l}{D_C - D_B}\right)\lambda\sqrt{\pi t} \times\left[\frac{\exp(-lt)}{\sqrt{\pi t}} * \left\{\frac{1}{\sqrt{\pi t}} - \lambda\exp(\lambda^2 t)\operatorname{erfc}(\lambda\sqrt{t})\right\} * \exp\left(-\frac{D_C l t}{D_C - D_B}\right)\right], \tag{16}$$

with

$$\lambda = \frac{k_c^\circ}{\sqrt{D_A}}\exp\left[-\frac{\alpha n F}{RT}E\right] = \frac{k_c}{\sqrt{D_A}}, \tag{17}$$

$$I_d = \frac{n_1 F q^\circ\sqrt{D_A c}}{\sqrt{\pi t}}, \tag{18}$$

where k_c° is the heterogeneous rate constant at $E=0$ and α the transfer coefficient. The symbol * represents the convolution.

It is evident from Eq. 16 that the current is stable when $D_C \geqq D_B$ but unstable or divergent when $D_C < D_B$. If $D_C < D_B$, peculiar phenomena might develop with time such as relaxational oscillations and jumps.

If Reaction 5 proceeds very rapidly and the condition $(D_C/D_B)\exp(lt) \gg 1$ is fulfilled, Eq. 16 is reduced to

$$\frac{I}{I_d} = \left(1 + \frac{n_2}{n_1}\right)\lambda\sqrt{\pi t}\exp(\lambda^2 t)\operatorname{erfc}(\lambda\sqrt{t}) - \frac{n_2}{n_1}\left(\frac{\theta}{c^\circ\sqrt{D_A/D_C}}\right) - \frac{n_2}{n_1}\sqrt{\frac{D_B}{D_C}}\lambda\sqrt{\pi t}\int_0^t \frac{\exp[-l(t-u)]}{\sqrt{\pi(t-u)}} \times\left(\frac{1}{\sqrt{\pi u}} - \lambda\exp(\lambda^2 u)\operatorname{erfc}(\lambda\sqrt{u})\right)du. \tag{19}$$

If $lt \gg 1$, Eq. 19 can be further simplified to

$$\frac{I}{I_d} = \left(1 + \frac{n_2}{n_1}\right)\lambda\sqrt{\pi t}\exp(\lambda^2 t)\operatorname{erfc}(\lambda\sqrt{t}) - \frac{n_2}{n_1}\left(\frac{\theta}{c^\circ\sqrt{D_A/D_C}}\right) - \frac{n_2}{n_1}\sqrt{\frac{D_B}{D_C}}\frac{\lambda}{\sqrt{l}} \times\left[\frac{1}{\sqrt{\pi t}} - \lambda\exp(\lambda^2 t)\operatorname{erfc}(\lambda\sqrt{t})\right]. \tag{20}$$

Equation 16 was solved numerically by the integral method of Gauss (Appendix). As expected, the computer results agree with the approximation given by Eq. 20 when the rate constant is large.

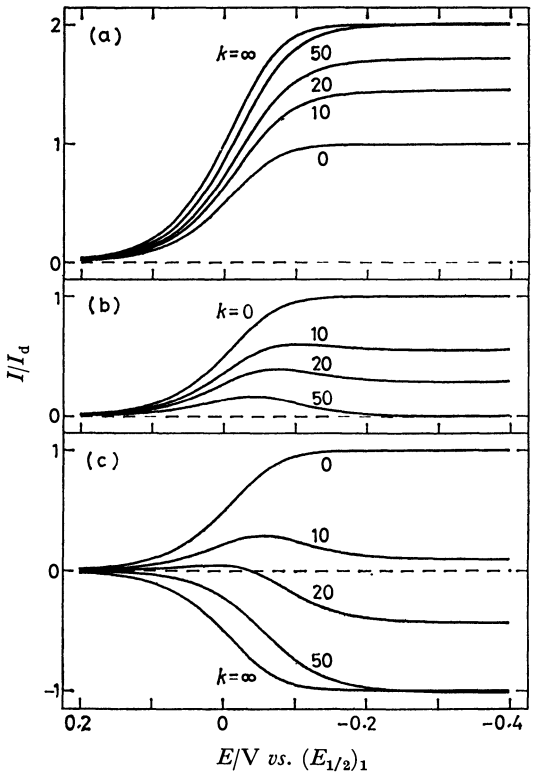

Fig. 1. Examples of predicted effects of homogeneous reaction rate on the current-potential curve for the consecutive ECE pathway (a) and the parallel ECE pathway (b, c).
Half-wave potential ($E_{1/2}$) and number of electrons (n) are: $(E_{1/2})_1 = 0$ V, $(E_{1/2})_2 = +0.5$ V, $n_1 = -1$, $n_2 = -1$ for curve (a); $(E_{1/2})_1 = 0$ V, $(E_{1/2})_2 = -0.5$ V, $n_1 = -1$, $n_2 = +1$ for curve (b); and $(E_{1/2})_1 = 0$ V, $(E_{1/2})_2 = -0.5$ V, $n_1 = -1$, $n_2 = +2$ for curve (c). Other parameter values are: $T = 25$ °C, $t = 0.05$ s, $\alpha = 0.5$, $D_A = B_B = 5 \times 10^{-6}$ cm^2 s^{-1}, $D_C = 10 \times 10^{-6}$ cm^2 s^{-1}. Homogeneous rate constants (in s^{-1}) are shown in figures.

According to Ruzic *et al.*[2] the ECE mechanism can be classified into a consecutive ECE pathway and a parallel one, the former dealing with the case where both heterogeneous steps are of the same type ($n_1n_2>0$), and the latter with heterogeneous electrode processes operating in the opposite direction ($n_1n_2<0$). Examples of the current-potential curve at various chemical reaction rates are shown in Fig. 1 for some interesting cases. Increase in current with increasing chemical reaction rate is seen for the consecutive ECE pathway (Fig. 1(a)), and decrease in current for the parallel ECE pathway (Fig. 1(b, c)). For a sufficiently fast chemical reaction the limiting current is diffusion-controlled for $n_1+n_2\neq 0$, but the net current is zero for $n_1+n_2=0$. This is a special case of parallel ECE pathway. Examples for $n_1+n_2=0$ are known for the electrode reaction of some chromium[6-10] and cobalt[3] complexes, though these are of soluble species.

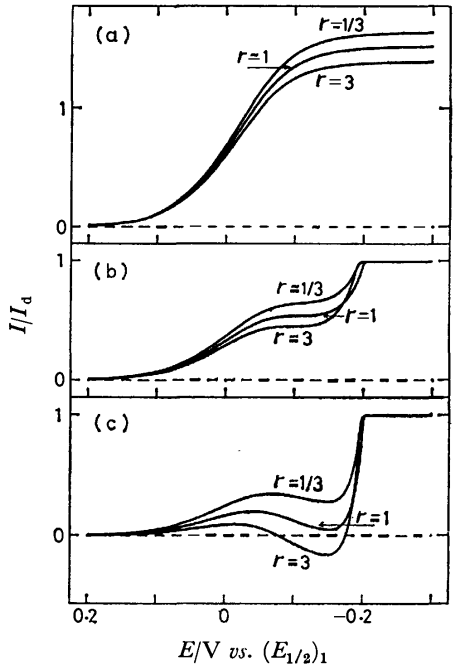

Fig. 2. Examples of predicted effects of the diffusion coefficient on current-potential curve for the consecutive ECE pathway (a) and the parallel ECE pathway (b, c). Ratios of diffusion coefficients of B and C (r) are shown in figures. Notation and parameter values are: $D_A=D_B=5\times10^{-6}$ cm^2 s^{-1}, $(E_{1/2})_1=0$ V, $l=15$ s^{-1}, $T=25$ °C, $t=0.05$ s, $\alpha=0.5$, $(E_{1/2})_2=+0.2$ V (a), -0.2 V (b, c). Number of electrons (n) are same as Fig. 1.

Figure 2 shows examples of the current-potential curve at different diffusion coefficients, calculated for the case of $D_B>D_C$, $D_B=D_C$, and $D_B<D_C$ when $D_A=D_B$. The effect of the diffusion coefficient on the current-potential curve dose not seem to be very small.

The current-potential curve should exhibit either one or two waves according to the difference in the half-wave potential of electrode reactions 1 and 3. This is shown clearly in Fig. 3, which depicts the current-potential curves with fast homogeneous chemical reactions.

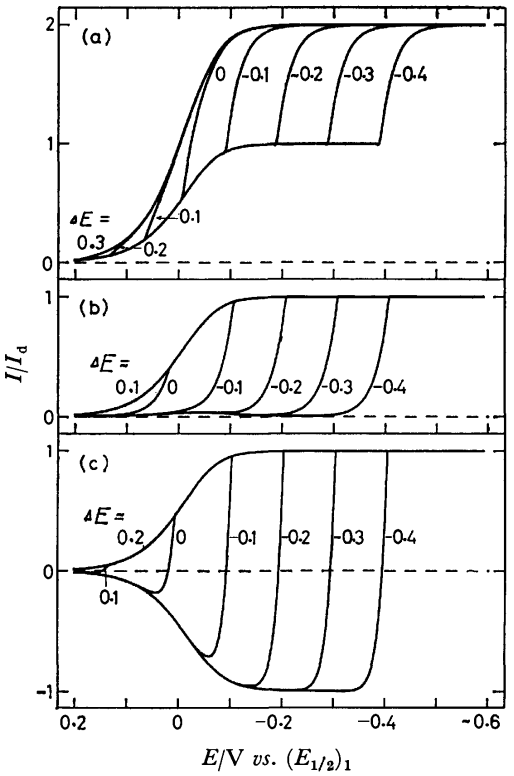

Fig. 3. Examples of predicted effects of the difference of half-wave potential corresponding to first and second electron-transfer steps on resolution of the current-potential curve for the consecutive ECE pathway (a) and the parallel ECE pathway (b, c). Potential differences ($\Delta E=(E_{1/2})_2-(E_{1/2})_1$) are shown in figures. Notation and parameter values are: $D_A=D_B=5\times10^{-6}$ cm^2 s^{-1}, $D_C=10\times10^{-6}$ cm^2 s^{-1}, $(E_{1/2})_1=0$ V, $l=100$ s^{-1}, $T=25$ °C, $t=0.05$ s, $\alpha=0.5$. Number of electrons (n) are same as Fig. 1.

When the two half-wave potentials are sufficiently separated with substance C which is more difficult to be reduced than A, the current-potential curve exhibits two waves (Fig. 3(a)). In this case, the current corresponding to the first wave represents the reduction of A only, depending on the kinetic parameters of the electrode reaction 1. The second wave is affected strongly by variation in the rate constant of chemical reaction 3. The current increases suddenly from the first wave, decreasing gradually after the diffusion current is reached.

When substance C is oxidized at a less positive potential than the reduction potential of substance A the cutoff of the first wave occurs: the decrease in current is pronounced with the increase in the rate of chemical reaction 2 (Fig. 3(b, c)). With $n_1+n_2=0$, the wave starts from the base line, increasing gradually. Theoretically, the slope of the current-potential curve should be infinite at the point where the current becomes diffusion-controlled. In the case $n_1+n_2>0$, the current starts from the anodic portion, increasing gradually. Then it decreases, crossing the zero current line. The final current is cathodic and controlled by Reaction 1. The shape of the current-potential curve is also angular at the beginning of the diffusion plateau.

Experimental

The current-potential curve were recorded with a Fuso Model 312 polarograph using a Watanabe Model WX441 x-y recorder. A three-electrode cell equipped with a saturated calomel reference electrode(SCE) and a platinum wire electrode(counter electrode) were employed. A junction of 0.1 M(1 M= 1 mol dm^{-3}) $NaNO_3$ was used between the SCE and the solution in order to avoid chloride contamination. A dropping mercury electrode (flow rate 1.17 mg s^{-1}, drop time 3.97 s in 0.1 M acetate buffer solutions) was used as a working electrode.

The complex used was prepared according to the procedure of Werner *et al.*[14] and identified by elemental analysis. A small amount of gelatin was added as a maximum suppressor.

Results and Discussion

Current-Potential Behavior. Figure 4 shows the current-potential curves of 0.5 mM *trans*-$[CoBr_2(en)_2]NO_3$ and 0.5 mM KBr obtained in 0.1 M acetate buffer solution at 25 °C. As expected from the electrode reaction of other cobalt(III) complexes,[15] *trans*-$[CoBr_2(en)_2]^+$ gave two polarographic waves, the first corresponding to the reduction of Co(III) to Co(II) and the second to the reduction of Co(II) to Co(0).

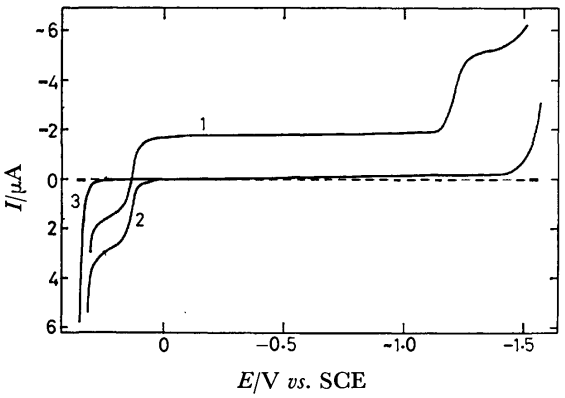

Fig. 4. Current-potential curves of (1) 0.5 mM *trans*-$[CoBr_2(en)_2]NO_3$ and (2) 0.5 mM KBr obtained in (3) 0.1 mM acetate buffer solutions containing 0.005% gelatin at 25 °C.

The first wave appears partly above and partly below the zero current line on the polarogram in Fig. 4. The cathodic limiting current of the first wave was diffusion-controlled and proportional to the concentration of the complex. The anodic limiting current of the first wave was also diffusion-controlled. The diffusion coefficients of the complex and Br^- ions were determined by means of the method reported.[16] The values are: 8.32×10^{-6} $cm^2\,s^{-1}$ for *trans*-$[CoBr_2(en)_2]^+$ and 25.1×10^{-6} $cm^2\,s^{-1}$ for Br^- at 25 °C and ionic strength 0.1.

The magnitude of the anodic current of the first wave was found to be identical with that of the cathodic one which corresponds to the reduction of Co(III) to Co(II). The first wave was very similar in shape to the dissolution wave of the mercury in the presence of Br^- ions (Fig. 4). This suggests that the mass transport toward the electrode is controlled not by the diffusion of Br^- ions but by that of *trans*-$[CoBr_2(en)_2]^+$. The shape of the first wave also indicates that the current-potential curve is characterized mainly by the anodic depolarization wave of Br^- ions. Thus, the overall electrode reaction in acid media might be expected to follows a mechanism given by Eqs. 1—3.

If we classify the ECE mechanism into the two types, consecutive and parallel ECE pathways,[2] the electrode reaction of *trans*-$[CoBr_2(en)_2]^+$ belongs to the parallel case. When the tervalent cobalt complex is reduced to the bivalent one, the substitution-labile bivalent complex liberates 2 mol of Br^- ions and dissolution wave of mercury by Br^- ions appears. This gives rise to the net current anodic. When the electrode potential becomes negative, dissolution ceases and a wave appears with a half-wave potential nearly equal to that of the anodic depolarization wave of Br^- ions.

The foregoing situation corresponds to the curve at $\Delta E=-0.3$ or -0.4 V (Fig. 3(c)) which depicts a global shape of the simulated parallel ECE pathway for $n_1=+2$. Strictly speaking, n_2 should be replaced by $2n_2$ for the electrode reaction of *trans*-$[CoBr_2(en)_2]^+$. Details are given below. In order to confirm the theory, a current-potential curve was simulated and the result compared with the measured one.

Simulation of Current-Potential Curve. Current-potential curves at more positive potential were obscured by the free dissolution wave of mercury.[17] However, both anodic and cathodic waves of *trans*-$[CoBr_2(en)_2]^+$ were resolved, each showing a limiting current plateau (Fig. 4). Thus, the half-wave potential of Reaction 1 would lie at least 0.3 V more positive than that of Reactions 3 as expected from Fig. 3(c). The current under these conditions does not depend on the heterogeneous rate constant of Reaction 1, but on the homogeneous rate constant of Reaction 2 as well as on the characteristics of electrode reaction 3.

The implicit solution of Eq. 16 is given in the Appendix. The current is given by Eq. A-2, where λ is made infinite and n_2 is replaced by $2n_2$ since 2 mol of Br^- ions are liberated from 1 mol of complex (Reaction 2). Thus, we have

$$\left(\frac{I}{I_d}\right)_{\lambda\to\infty} = 1-\frac{2n_2}{n_1}\left(\frac{\theta}{\sqrt[\circ]{D_A/D_C c}}\right)+\frac{2n_2}{n_1}\phi(a\sqrt{t}) - \frac{2n_2}{n_1}\sqrt{\frac{D_C}{D_B}}\exp(-lt)\phi\left(\sqrt{\frac{D_B}{D_C}}a\sqrt{t}\right), \quad (21)$$

with

$$\phi(x) = 2x\exp(-x^2)\int_0^x \exp(u^2)\mathrm{d}u, \quad (22)$$

where $a=\sqrt{D_C l/(D_C-D_B)}$.

For the sake of approximation, plane electrodes were assumed for derivation. This is because the corresponding derivation for an expanding plane electrode would be far more difficult and the activity of deposit during the course of expansion is not be known until the electrode is completely covered with deposit. Our data represent a preliminary study to demonstrate some phenomena predicted theoretically.

In the range of anodic current plateau, θ in Eq. 21 becomes zero. It follows that

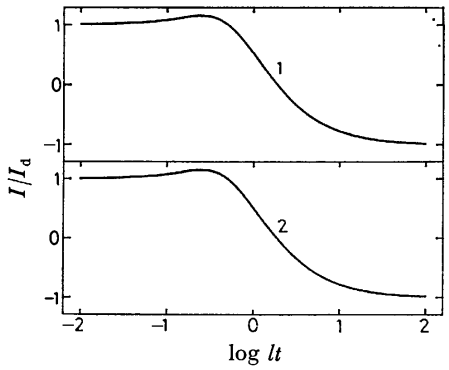

Fig. 5. Working curves for calculation of homogeneous rate constant. Diffusion coefficients are: (1) $D_A=D_B=8.32\times10^{-6}$ cm^2 s^{-1}, $D_C=25.1\times10^{-6}$ cm^2 s^{-1} and (2) $D_A=D_B=4.67\times10^{-6}$ cm^2 s^{-1}, $D_C=13.7\times10^{-6}$ cm^2 s^{-1}.

$$\frac{I}{I_d}=1+\frac{2n_2}{n_1}\left[\phi\left(\sqrt{\frac{D_C lt}{D_C-D_B}}\right)-\sqrt{\frac{D_C}{D_B}}\exp(-lt)\phi\left(\sqrt{\frac{D_B lt}{D_C-D_B}}\right)\right]. \quad (23)$$

In order to evaluate the rate constant, the value of I/I_d was calculated against lt and is plotted in Fig. 5 for two sets of diffusion coefficients. In this calculation, curve 1 corresponds to the case at 25 °C ($D_A=D_B=8.32\times10^{-6}$ cm^2 s^{-1}, $D_C=25.1\times10^{-6}$ cm^2 s^{-1}) and curve 2, to the case of 5 °C ($D_A=D_B=4.67\times10^{-6}$ cm^2 s^{-1}, $D_C=13.7\times10^{-6}$ cm^2 s^{-1}).

The value of I/I_d at +0.25 V *vs.* SCE was found to be 1 at 25 °C. This indicates that the acid hydrolysis reaction 2 proceeds very rapidly. The rate constant was obtained by varying temperature. The measurement made at 5 °C gave $l=0.4$ s^{-1} for the acid hydrolysis rate constant. The value was determined from the working curve 2 in Fig. 5. Reliability of the rate of Reaction 2 was tested by the following simulation of current-potential curves.

The preceding preliminary estimation indicates $(D_C/D_B)\exp(lt)\gg1$. Thus, Eq. 21 can be simplified to

$$\frac{I}{I_d}=1+\frac{2n_2}{n_1}\left(1-\frac{\theta}{c^\circ\sqrt{D_A/D_C}}\right)-\frac{2n_2}{n_1}\sqrt{\frac{D_B}{D_C}}\exp(-lt). \quad (24)$$

If $\theta=0$ and $D_B=D_C$, the relation agrees with the equation of Alberts and Shain.[13] In Eq. 24 the second term represents the depolarization term of Br$^-$ ions at mercury electrode, which can be calculated from the dissolution wave of mercury in the presence of Br$^-$ ions only. The anodic dissolution wave with Br$^-$ ions is given by[18]

$$I=(I_d)_C\left(1-\frac{\theta}{c^*}\right), \quad (25)$$

where $(I_d)_C=n_2Fqc^*\sqrt{D_C}/\sqrt{\pi t}$. Thus, $1-\theta/c^\circ\sqrt{D_A/D_C}$, which is required in the calculation of Eq. 24, can be obtained experimentally from the current-potential curve at $c^*=c^\circ\sqrt{D_A/D_C}$.

The simulated current-potential curves for the reduction of *trans*-$[CoBr_2(en)_2]^+$ at 25 °C and 5 °C are shown in Fig. 6 together with the experimental data. Curve 1 for $l>3$ s^{-1} and curve 2 for $l=0.4$ s^{-1}. In this

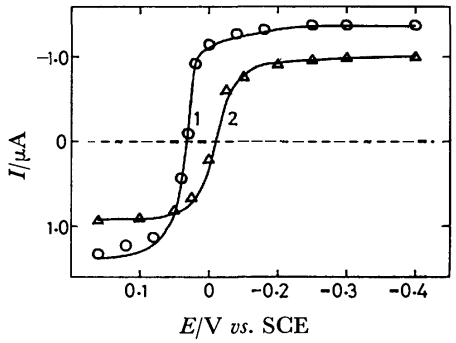

Fig. 6. Comparison of observed and simulated current-potential curves for the reduction of *trans*-$[CoBr_2(en)_2]NO_3$ at (1) 25 °C and (2) 5 °C. Circles and triangles, experimental; solid lines, theoretical.

calculation, when the current-potential curve of Br$^-$ ions was used for $c^*=c^\circ\sqrt{D_A/D_C}$, the zero-cross potential was *ca.* 25 mV more positive than the observed one. Good agreement was obtained by taking a value of $c^*=0.7$ mM for curve 1 and $c^*=0.6$ mM for curve 2. These values were used to construct the current-potential curves shown in Fig. 6. The discrepancy between theory and experiment is most likely due to the change in the activity of insoluble film.

The calculation given in Fig. 6 basically conforms to the concept of parallel ECE pathway. The current-potential behavior of *trans*-$[CoBr_2(en)_2]^+$ is thus in line with the overall mechanism given by Reactions 1—3 in which the parallel ECE pathway occurs.

Appendix

The boundary value problem stated by Eqs. 7—15 was solved by a straight-forward application of the laplace transformation. The following equation was obtained for the current:

$$I(s)=n_1Fc^\circ\sqrt{D_A\lambda}\frac{1}{\sqrt{s}(\sqrt{s}+\lambda)}+n_2F\sqrt{D_A}\left(\frac{D_C l}{D_C-D_B}\right)c^\circ\lambda\times\frac{1}{\sqrt{s}(\sqrt{s}+\lambda)\left(s+\frac{D_C}{D_C-D_B}l\right)}-n_2F\sqrt{D_C}\theta\frac{1}{\sqrt{s}}-n_2F\sqrt{D_A}\sqrt{\frac{D_B}{D_C}}\left(\frac{D_C l}{D_C-D_B}\right)c^\circ\lambda\times\frac{1}{\sqrt{s+1}(\sqrt{s}+\lambda)\left(s+\frac{D_C l}{D_C-D_B}\right)}. \quad (A\text{-}1)$$

The inverse transform of this expression can be found by using the convolution theorem[19] which is

$$L^{-1}[f_1(s)\cdot f_2(s)]=\int_0^t F_1(u)F_2(t-u)\mathrm{d}u=F_1(t)*F_2(t)$$

with $L[F_1(t)]=f_1(s)$ and $L[F_2(t)]=f_2(s)$.

Equation 16 is obtained from the table of Laplace transform pairs.[19]

For the numerical calculation, Eq. 16 can be rewritten as

$$\frac{I}{I_d}=\lambda\sqrt{\pi t}\exp(\lambda^2t)\operatorname{erfc}(\lambda\sqrt{t})-\frac{n_2}{n_1}\left(\frac{\theta}{c^\circ\sqrt{D_A/D_C}}\right)+\frac{n_2}{n_1}(\pm a^2)\lambda\sqrt{\pi t}\exp(\mp a^2t)$$

$$\times \int_0^t \exp\left[(\lambda^2 \pm a^2)u\right] \operatorname{erfc}\left(\lambda\sqrt{u}\right) du$$

$$-\frac{n_2}{n_1}\sqrt{\frac{D_B}{D_C}}\lambda\sqrt{\pi t}\left(\frac{\pm a^2}{\lambda^2 \pm a^2}\right)\int_0^t G(u)H(t-u)du \qquad \text{(A-2)}$$

with

$$G(u) = \exp\left(\mp a^2 u\right)\left[\lambda \pm a\frac{2}{\sqrt{\pi}}\int_0^{a\sqrt{u}} \exp\left(\pm r^2\right) dr\right]$$

$$-\lambda \exp\left(\lambda^2 u\right) \operatorname{erfc}\left(\lambda\sqrt{u}\right) \qquad \text{(A-3)}$$

$$H(u) = \frac{\exp\left(-lu\right)}{\sqrt{\pi u}} \qquad \text{(A-4)}$$

where $a=\sqrt{D_C l/(D_C - D_B)}$. The upper sign holds if $D_C > D_B$, the lower if $D_C < D_B$. Equation A-2 was computed numerically by the intergral method of Gauss.[20] The change of variable, $x=\sqrt{t-u}$, was employed in order to remove the singularity at $u=t$.

The function $\sqrt{\pi}x\exp(x^2)\operatorname{erfc}(x)$ in Eq. A-2 was calculated by a method described previously.[21]

The research was carried out by a Grant-in-Aid from the Ministry of Education. A part of the work was supported by Scientific Research Grant No. 364205.

A Polarographic Rate Study on the Acid Hydrolysis of Several Halogeno Cobalt(III) Complexes

Akifumi YAMADA,* Tadatsugu YOSHIKUNI, Yoshikiyo KATO, and Nobuyuki TANAKA
Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980
(Received September 10, 1979)

A polarographic rate study of the acid hydrolysis of $[CoX(NH_3)_5]^{2+}$- and *trans*-$[CoX_2(N)_4]^+$-type complexes (X=Cl^- and Br^-; $(N)_4=(NH_3)_4$, $(ethylenediamine)_2$, $(propylenediamine)_2$ and $(1,2\text{-cyclohexanediamine})_2$) has been carried out in 0.1 M acetate buffer solutions. These complexes gave two polarographic waves; the first wave corresponds to the reduction of Co(III) to Co(II) and the second one, to the reduction of Co(II) to Co(0). The relation between the current and the time of the first wave in a positive potential was dependent on the dissolution wave caused by halogenide ions produced by acid hydrolysis and also on the parallel ECE mechanism. The acid-hydrolysis rate of tervalent cobalt complexes was determined from the variation in the current of the first wave. The rates are: 1.31×10^{-6} s^{-1} for $[CoCl(NH_3)_5](NO_3)_2$, 6.25×10^{-4} s^{-1} for *trans*-$[CoCl_2(NH_3)_4]ClO_4$, 3.20×10^{-5} s^{-1} for *trans*-$[CoCl_2(en)_2]NO_3$, 4.28×10^{-5} s^{-1} for *trans*-$[CoCl_2(pn)_2]ClO_4$, 1.53×10^{-4} s^{-1} for *trans*-$[CoCl_2(chxn)_2]ClO_4\cdot H_2O$, 5.80×10^{-6} s^{-1} for $[CoBr(NH_3)_5](NO_3)_2$, 4.19×10^{-3} s^{-1} for *trans*-$[CoBr_2(NH_3)_4]ClO_4$, 1.51×10^{-4} s^{-1} for *trans*-$[CoBr_2(en)_2]NO_3$, 3.30×10^{-4} s^{-1} for *trans*-$[CoBr_2(pn)_2]ClO_4\cdot0.5H_2O$ and 5.10×10^{-4} s^{-1} for *trans*-$[CoBr_2(chxn)_2]NO_3$ at 25 °C and an ionic strength of 0.1.

The acid hydrolysis of several halogeno cobalt(III) complexes, such as $[CoX(NH_3)_5]^{2+}$ and $[CoX_2(N)_4]^+$, where X is Cl^- and Br^-, and where $(N)_4$ represents $(NH_3)_4$, $(en)_2$ and $(pn)_2$, has been studied by chemical and spectrophotometric methods.[1-6] There have, however, been only a few papers on the determination of the acid-hydrolysis rate constant under the same conditions. The accuracy is not yet satisfactory.

When the acid hydrolysis of a halogeno cobalt(III) complex proceeds, one mole or two moles of halogenide ions are liberated. It is well known that the halogenide ions, such as chloride and bromide ions, give a well-defined diffusion-controlled polarographic wave.[7] Therefore, by monitoring these liberated halogenide ions polarographically, the rate of the acid hydrolysis of such complexes can be obtained very accurately.

This paper will describe the polarographic determination of the acid-hydrolysis rate of halogeno cobalt(III) complexes, since we have obtained more satisfactory results.

Experimental

The electrolysis cell was of a conventional design, comprising a 50-ml cell, a platinum wire anode, and a saturated calomel electrode. The dropping mercury electrode (flow rate, 1.17 mg s^{-1} and drop time, 3.97 s in 0.1 M acetate buffer solutions (1M=1 mol dm^{-3})) served as a working electrode. The current-time curves during aquation were recorded by the use of a Fuso Model 312 polarograph with a Watanabe Model WX441 x-y recorder.

The complexes used were prepared according to the literature,[8-19] with partial modifications. The analytical data for all the complexes obtained are summarized in Table 1, together with the literature of the syntheses.

In a series of determinations of the acid-hydrolysis rates of various halogeno cobalt(III) complexes, the electrochemical procedure was as follows. After measurements of the residual current of a 40-ml portion of the supporting electrolyte solution, a solid sample of the cobalt complex being tested was added to the solutions. As soon as the complex had been dissolved by bubbling in nitrogen gas, the current attributable to the halogenide ions was measured against the time. All the measurements were carried out at 25 °C. A small amount of gelatin was added as a maximum suppressor.

TABLE 1. ANALYTICAL DATA FOR Co(III) COMPLEXES

Complex	C(%)		H(%)		N(%)	
	Found	Calcd	Found	Calcd	Found	Calcd

Results

The series of $[CoCl(NH_3)_5]^{2+}$, $[CoBr(NH_3)_5]^{2+}$, *trans*-$[CoCl_2(N)_4]^+$ and *trans*-$[CoBr_2(N)_4]^+$ complexes (where $(N)_4$ represents $(NH_3)_4$, $(en)_2$, $(pn)_2$ and $(chxn)_2$) gave two polarographic waves. Figure 1 shows examples of the current-potential curves of these halogeno cobalt(III) complexes obtained in 0.1 M acetate buffer solutions at 25 °C.

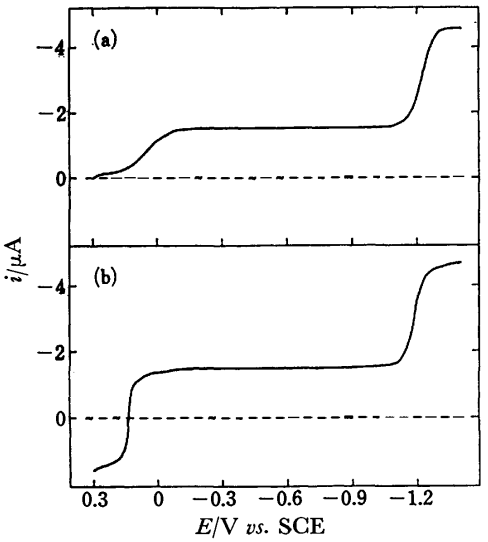

Fig. 1. Current-potential curves of 0.5 mM halogeno cobalt(III) complexes obtained in 0.1 M sodium acetate buffer solutions (pH 5.0) containing 0.005% gelatin at 25 °C. (a) $[CoCl(NH_3)_5](NO_3)_2$, (b) *trans*-$[CoBr_2(en)_2]NO_3$.

The first wave appeared in the field of the cathodic current for the monohalogeno cobalt(III) complex or in the field of the anodic and cathodic currents for the dihalogeno cobalt(III) complex. The first wave was considered to be a one-electron reduction of Co(III) to Co(II). Since the limiting current of the second wave was twice that of the first one, the second wave was considered to be a two-electron reduction, that is, Co(II)→Co(0), in analogy with the electrode reaction of other cobalt complexes.[20]

The cathodic limiting current of the first wave was diffusion-controlled and was proportional to the concentration of the complex. The anodic limiting current of the first wave was also diffusion-controlled, but increased gradually with the time elapsed corresponding to the acid hydrolysis of the tervalent cobalt complex, as is seen in Fig. 2. When the anodic current increased with the time, the cathodic current decreased slightly.

The polarographic characteristics, such as the diffusion current(i_d), the half-wave potential ($E_{1/2}$), and the reciplocal slope of the log-plot, are given in Table 2; they were obtained immediately after dissolving 0.5 mM of the complex in 0.1 M sodium acetate buffer solutions

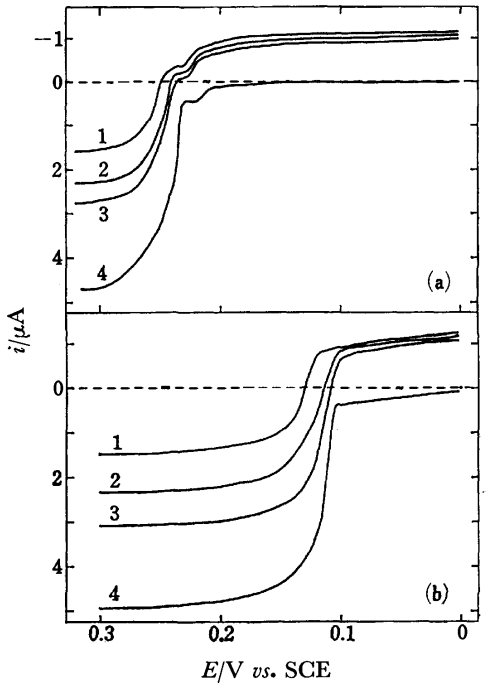

Fig. 2. Current-potential curves of (a) 0.5 mM *trans*-$[CoBr_2(chxn)_2]ClO_4 \cdot H_2O$ and (b) 0.5 mM *trans*-$[CoBr_2(pn)_2]ClO_4 \cdot 0.5H_2O$ obtained in 0.1 M sodium acetate buffer solutions (pH 5.0) containing 0.005% gelatin at 25 °C. Currents are measured (1) immediately after dissolving complex, (2) after 20 min and (3) after 40 min. Curves 4 are the current-potential curves of (a) 1 mM KCl and (b) 1 mM KBr, respectively.

Table 2. Polarographic characteristics of 0.5 mM halogenocobalt(III) complexes obtained in a 0.1 M sodium acetate buffer (pH 5.0) containing 0.005% gelatin at 25 °C

trans-$[CoBr_2(NH_3)_4]ClO_4$	1.50	0.10_5	2.99	−1.219	73

at 25 °C.

It has been reported that halogeno cobalt(III) complexes undergo acid hydrolysis with first-order kinetics and liberate halogenide ions:[1-4,6,21]

$$[Co^{III}X(NH_3)_5]^{2+} + H_2O \longrightarrow [Co^{III}(H_2O)(NH_3)_5]^{3+} + X^-, \quad (1)$$

$$trans\text{-}[Co^{III}X_2(N)_4]^+ + 2H_2O \longrightarrow [Co^{III}(H_2O)_2(N)_4]^{3+} + 2X^- \quad (2)$$

($X^- = Br^-$ and Cl^-;
$(N)_4 = (NH_3)_4$, $(en)_2$, $(pn)_2$ and $(chxn)_2$).

Thus, by monitoring the concentration of halogenide ions, the acid-hydrolysis rate can be measured.

Halogenide ions give a well-defined polarographic wave in the presence of gelatin:[7]

$$2Cl^- + 2Hg \longrightarrow Hg_2Cl_2 + 2e^-, \quad (3)$$

$$2Br^- + 2Hg \longrightarrow Hg_2Br_2 + 2e^-. \quad (4)$$

An example of the polarogram of the halogenide ions is also shown in Fig. 2. The anodic limiting current around *ca.* +0.25—+0.30 V *vs.* SCE is, therefore, given as the sum of the current attributable to the remaining halogeno cobalt(III) complex ($i_{complex}$) and the liberated halogenide ions ($i_{halogen}$). Assuming a first-order kinetics, the concentration of the liberated halogenide ions and that of remaining halogeno complex are represented[22] as $pc^\circ(1-\exp(-kt))$ and $c^\circ\exp(-kt)$, where c° is the initial concentration of the complex and where k is the first-order rate constant of acid hydrolysis given by Eq. 1 or 2. The anodic current can, therefore, be expressed as:

$$\begin{aligned} i_a &= i_{complex} + i_{halogen} \\ &= \alpha_1 c_{complex} + \alpha_2 c_{halogen} \\ &= \alpha_1 c^\circ \exp(-kt) + \alpha_2 pc^\circ(1-\exp(-kt)), \end{aligned} \quad (5)$$

where α_1 and α_2 are the proportional constant with respect to the concentration and where p is the number of halogenide ions liberated. In the present case, $p=1$ for the monohalogeno complex and $p=2$ for the dihalogeno complex.

The first-order rate constant of the acid hydrolysis of tervalent cobalt complex can be determined from the time variation of the current given by Eq. 5. The rearrangement of Eq. 5 yields:

$$\ln \frac{pc^\circ}{pc^\circ - c} = kt + \ln\left(1 - \frac{1}{p}\frac{\alpha_1}{\alpha_2}\right)^{-1}, \quad (6)$$

with:

$$c = \frac{i}{\alpha_2}. \quad (7)$$

Equation 6 shows that, if the values of α_1 and α_2 are constant with the time, the plot of $\ln[pc^\circ/(pc^\circ-c)]$ against the time should be a straight line. From the slope of this plot, the rate constant of acid-hydrolysis can be obtained.

The rate constant for the acid-hydrolysis of tervalent cobalt complexes was determined according to Eq. 5 with the concentrations obtained from the working curve prepared with the standard solutions of potassium chloride or potassium bromide. Examples of these plots are shown in Fig. 3, while the rate constants obtained are given in Table 3. The relation between $\ln[pc^\circ/(pc^\circ-c)]$ and the time gave a straight line with an intercept.

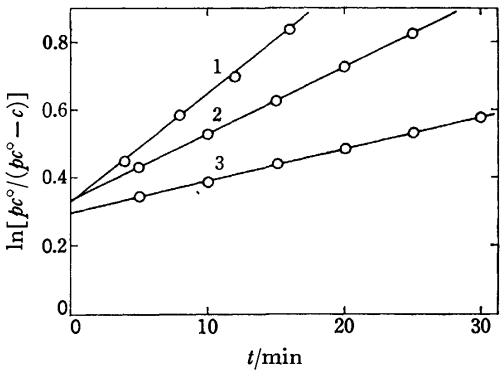

Fig. 3. Relations of $\ln[pc^\circ/(pc^\circ-c)]$ against time for (a) *trans*-$[CoBr_2(chxn)_2]NO_3$, (2) *trans*-$[CoBr_2(pn)_2]ClO_4 \cdot 0.5H_2O$ and (3) *trans*-$[CoCl_2(chxn)_2]ClO_4 \cdot H_2O$ obtained at ionic strength of 0.1 at 25 °C.

Discussion

For the series of $[CoX(NH_3)_5]^{2+}$ and *trans*-$[CoX_2(N)_4]^+$ complexes, all the rate data followed the first-order rate relation given by Eq. 6 with a satisfactory linearity. A good agreement between the data obtained in the present study and those in the literature was obtained except for *trans*-$[CoCl_2(NH_3)_4]^+$ and *trans*-$[CoBr_2(NH_3)_4]^+$ (Table 3). This suggests that the polarographic method based on the measurement of the dissolution wave can be applied for the determination of the acid hydrolysis of complexes by analogy with the chemical[2,3] and the spectrophotometric method.[2,3,6]

As for *trans*-$[CoCl_2(NH_3)_4]^+$, the value of 2.05×10^{-3} s^{-1} has been reported.[5] From our results, however, this value seems to be fast: if it is ture, aquation should proceed to an extent of 22% 2 min after the complex

Table 3. Rate data for the acid hydrolysis of Co(III) complexes obtained at 25 °C and an ionic strength of 0.1

Complex	$X^-=Cl^-$		$X^-=Br^-$	
	This study k/s^{-1}	Other studies k/s^{-1}	This study k/s^{-1}	Other studies k/s^{-1}
$[CoX(NH_3)_5]^{2+}$	1.31×10^{-6}	1.7×10^{-6} [1]	5.80×10^{-6}	6.3×10^{-6} [1]
trans-$[CoX_2(en)_2]^+$	3.20×10^{-5}	3.5×10^{-5} [6]	1.51×10^{-4}	1.4×10^{-4} [2-4]
trans-$[CoX_2(pn)_2]^+$	4.28×10^{-5}	6.2×10^{-5} [6]	3.30×10^{-4}	3.13×10^{-4} [6]
trans-$[CoX_2(chxn)_2]^+$	1.53×10^{-4}	2.16×10^{-4} [21]	5.10×10^{-4}	—
trans-$[CoX_2(NH_3)_4]^+$	6.25×10^{-4}	2.05×10^{-3} [5,6]	4.19×10^{-3}	*ca.* 7×10^{-3} [6]

is dissolved. Our results clearly indicate that this is not so. The literature values[6] for *trans*-$[CoBr_2(NH_3)_4]^+$ were estimated to be 3.5 times the rate constant for the dichloro analog; also the accuracy is not satisfactory. The acid-hydrolysis rate of *trans*-$[CoBr_2(chxn)_2]^+$ has not yet been reported, but the present value seems valid in comparison with the other halogeno analog.

The extinction coefficients of the halogeno complex are *ca.* 30—100 mol^{-1} cm^{-1}. Therefore, if a number of products with the same order of the extinction coefficient are produced, it seems difficult to determine the rate constant with any accuracy. On the other hand, in the polarographic method, only halogenide ions gave an anodic wave; furthermore, the diffusion coefficients of halogenide ions are about 3 times those of complexes. Therefore, the present polarographic method is very useful in the determination of the acid hydrolysis of such halogeno cobalt(III) complexes.

It is a well-known fact that the presence of excess mercuric ions accelerates the rate of the acid hydrolysis of several kinds of complexes.[23-25] In the case of the dropping mercury electrode, however, since mercurous and mercuric ions are in equilibrium, and since the mercuric ions amount to less than 1/120 of the mercury(I) ions,[26-28] the influence of the mercury(II) ions on the acid-hydrolysis of complex may be neglected compared with the large quantity of the bulk concentration of the complexes.

With the advance in acid hydrolysis, the cathodic limiting current decreased slightly. There are many factors to account for this: the effects of an ionic radius,[29] an increase or decrease in the charge,[30] a complex formation,[31] and an ion-pair formation.[32,33] However, those effects can not explain the present decrease in the current with the time. The decrease in the cathodic limiting current can be expected from the discussion given in connection with the change in the diffusion coefficient. The cathodic current of the first wave may be written as the sum of the current due to the remaining halogeno cobalt(III) and the aquated cobalt(III) complexes. Thus,

$$i_c = i_{complex} + i_{aquated} = \alpha_1 c_{complex} + \alpha_3 c_{aquated}, \quad (8)$$

where α_3 is the proportional factor of the aquated complex with respect to the concentration. If the current is diffusion controlled, α_1 and α_3 are related to the diffusion coefficient thus:[34]

$$\alpha_3 = An_1\sqrt{D_{Co(III)}}, \quad (9)$$

$$\alpha_3 = An_1\sqrt{D_{Co(III)aq}}, \quad (10)$$

where $D_{Co(III)aq}$ is the diffusion coefficient of the aquated cobalt(III) complex and where A is the constant including the flow rate of mercury and the drop time. Thus, the cathodic current is;

$$i_c = An_1\sqrt{D_{Co(III)}}c^\circ \exp(-kt) + An_1\sqrt{D_{Co(III)aq}}c^\circ(1-\exp(-kt)). \quad (11)$$

If the diffusion coefficient of the aquated complex is smaller than that of the original complex, the current will decrease with the time.

This speculation was confirmed by ascertaing the diffusion coefficients of the halogeno and aqua complexes. Some of the observed and reported values for the diffusion coefficient are listed in Table 4. The method for the precise determination of the diffusion coefficient has been described previously.[29] In this determination, the diffusion-controlled currents of the cobalt complex, Cl^- ions, and Br^- ions were measured at −0.70, +0.30 and +0.25 V *vs.* SCE respectively.

Table 4. Diffusion coefficient of Co(III) complexes and halogenide ions obtained in a 0.1 M sodium acetate buffer (pH 5.0) containing 0.005% gelatin at 25 °C

Complex	Diffusion coefficient ($D/10^{-6}$ cm^2 s^{-1})
$[CoCl(NH_3)_5]^{2+}$	9.13

trans-$[CoCl_2(NH_3)_4]^+$	9.37
$[CoBr(NH_3)_5]^{2+}$	9.11
trans-$[CoBr_2(en)_2]^+$	8.32
trans-$[CoBr_2(pn)_2]^+$	7.93
trans-$[CoBr_2(chxn)_2]^+$	6.56
trans-$[CoBr_2(NH_3)_4]^+$	9.18
cis-$[Co(H_2O)_2(en)_2]^{3+}$	6.18
cis-$[Co(AcO)_2(en)_2]^+$	6.15
cis-$[Co(AcO)_2(pn)_2]^+$	5.63
cis-$[Co(H_2O)_2(NH_3)_4]^{3+}$	7.11
Cl^-	22.31
Br^-	25.14

Although the aqua and acetato complexes are *cis*-type, the diffusion coefficients of the aqua and acetato complexes are smaller than those of the halogeno complexes. By using these diffusion coefficients, the cathodic limiting current at −0.7 V *vs.* SCE was calculated from Eq. 11 for various times elapsed. The calculated values agreed with the experimental ones within the limits of experimental error.

In the present study, the plot for first-order kinetics, $\ln[pc^\circ/(pc^\circ-c)]$ *vs.* t, has the intercept to be seen in Eq. 6, whereas the conventional plot has no intercept.[22] This arises from the parallel ECE pathway represented by the reaction:[35]

$$[Co^{III}X(NH_3)_5]^{2+} + e^- \longrightarrow [Co^{II}X(NH_3)_5]^+, \quad (12a)$$

$$[Co^{II}X(NH_3)_5]^+ + 6H_2O \longrightarrow [Co^{II}(H_2O)_6]^{2+} + X^- + 5NH_3, \quad (12b)$$

$$X^- + \frac{1}{2}Hg \longrightarrow \frac{1}{2}Hg_2X_2 + e^-, \quad (12c)$$

($X^- = Cl^-$ and Br^-)

or:

$$trans\text{-}[Co^{III}X_2(N)_4]^+ + e^- \longrightarrow trans\text{-}[Co^{II}X_2(N)_4], \quad (13a)$$

$$trans\text{-}[Co^{II}X_2(N)_4] + 6H_2O \longrightarrow [Co^{II}(H_2O)_6]^{2+} + 2X^- + (N)_4, \quad (13b)$$

$$2X^- + 2Hg \longrightarrow Hg_2X_2 + 2e^-. \quad (13c)$$

($X^- = Cl^-$ and Br^-;
$(N)_4 = (NH_3)_4$, $(en)_2$, $(pn)_2$, and $(chxn)_2$)

When the tervalent cobalt complex is reduced to the bivalent one, the bivalent complex, which is substitution-

labile, liberates one mole or two moles of halogenide ions and the dissolution wave of mercury attributable to halogenide ions appears. This results in a net current anodic for dihalogeno complexes and in a net current cathodic for monohalogeno complexes. As the potential becomes negative, dissolution ceases, and a wave with a half-wave potential nearly equal to that of the dissolution wave in the presence of bromide ions appears (Fig. 1).

At 25 °C, Reaction 13b for the acid hydrolysis of dibromo cobalt(II) may proceed very rapidly, and the net current for the parallel ECE pathway becomes diffusion-controlled. From the theory of parallel ECE pathway,[35,36]

$$\alpha_1 = A(n_1+n_2)\sqrt{D_{Co(III)}}, \quad (14)$$

and:

$$\alpha_2 = An_2\sqrt{D_{Br^-}}, \quad (15)$$

where n_1 and n_2 are the number of electrons involved in Reactions 12a and 13c respectively. The intercept (the second term on the right-hand side in Eq. 6) was calculated from the diffusion coefficients given in Table 3, and $n_1=-1$ and $n_2=+1$. The values are: 0.360 for *trans*-$[CoBr_2(NH_3)_4]^+$, 0.339 for *trans*-$[CoBr_2(en)_2]^+$, and 0.330 for *trans*-$[CoBr_2(pn)_2]^+$, while the observed values are 0.36, 0.34, and 0.33 respectively.

As for other complexes, α_1 was dependent on the electrode potential because the current-potential curve did not give a diffusion plateau. No kinetic parameters of the two electrode reactions 12a and 13a have been reported, and so no further calculation was made for these cases.

Electrochemical Oxidation and Reduction of Ferredoxin Adsorbed on Mercury Electrode Surface. Phase-selective A. c. Polarography at DME†

Tadaaki KAKUTANI, Kazunobu TORIYAMA, Tokuji IKEDA, and Mitsugi SENDA*

Department of Agricultural Chemistry, Faculty of Agriculture, Kyoto University, Kyoto 606

(Received November 5, 1979)

The electrochemical behavior of *Clostridium pasteurianum* ferredoxin (Cl.Fd) was studied by a.c. polarography with the dropping mercury electrode. The a.c. polarograms observed in acidic media (pH<7) were assigned to RSH/RSHg redox reaction of the cysteine residues of apoferredoxin, whereas those observed in basic media (pH>8) were assigned to a two-step one-electron transfer (EE mechanism) to the iron-sulfur clusters of Cl.Fd adsorbed on the mercury electrode surface ($(Cl.Fd)_{ad}$). The a.c. polarographic behavior of $(Cl.Fd)_{ad}$ observed in basic media was interpreted by theory of a.c. polarography of a two-step surface redox reaction. The formal standard oxidation-reduction potential of $(Cl.Fd)_{ad}$ was determined to be −0.33 V *vs.* NHE at pH 7.0, and its pH dependence was −30 mV/pH between pH 8 and 10.

In a previous paper[1] we have shown that ferredoxin is adsorbed irreversibly on the surface of mercury electrode and decomposes gradually to apoferredoxin (cluster-free ferredoxin) in the adsorption layer. D.c. and a.c. polarographic studies on ferreoxins have been reported by several workers.[2-7] However, these authors did not fully consider the adsorption nature of ferredoxins on the electrode surface. Accordingly further examination is needed to find the exact relationship between the measured potentials being characteristic of the polarograms of ferredoxins and their oxidation-reduction potentials. In this study we have investigated the a.c. polarographic behavior of *Clostridium pasteurianum* ferredoxin (Cl.Fd) at the dropping mercury electrode (DME) with exact reference to the adsorption of ferredoxin on the electrode surface. The results show that the a.c. polarographic study of Cl.Fd with DME in basic media enables us to determine the electrochemical oxidation-reduction potential of the iron-sulfur clusters of the ferredoxin adsorbed on the electrode surface.

Experimental

Preparations of *Clostridium pasteurianum* ferredoxin and apoferredoxin as well as apparatus and methods of electrochemical measurements have been described previously.[1] The dropping mercury electrode was of a common type having a mercury flow rate of 1.01 mg s^{-1} and a drop time of 9.5 s at open circuit in distilled water at 45 cm height of mercury reservoir. Real and imaginary components of the alternating currents were recorded against d.c. potential applied to the DME. The a.c. current intensities were taken at the moment of the maximum growth of each mercury drop. Potentials were measured against a saturated calomel electrode (SCE). All measurements were carried out at 25 °C.

Results and Discussion

Figure 1 shows the real and imaginary components of the a.c. waves of 1.7 μM Cl.Fd at pH 4.4 (Fig. 1A) and at pH 9.2 (Fig. 1B). The wave heights grew up to a certain limit with increasing concentration of Cl.Fd, as seen in Fig. 2, where the peak heights of the imaginary a.c. wave, $\delta_1 I_p^{imag}$, are plotted against the Cl.Fd concentration, $C_{Cl.Fd}$, at pH 6.9. This indicates that Cl.Fd is accumulated on the DME surface and that the a.c. polarograms are due to the redox reaction of Cl.Fd adsorbed on the electrode surface. Upon assuming that the adsorption is a diffusion-controlled process,[1,8] $\delta_1 I_p^{imag}$ is given by $\delta_1 I_p^{imag} = kA\Gamma = kA(6/7)(7D_{Cl.Fd}\tau/3\pi)^{1/2} C_{Cl.Fd}$ at the initial linear portion of $\delta_1 I_p^{imag}$ *versus* $C_{Cl.Fd}$ plot in Fig. 2, where k is the proportionality constant, Γ the surface concentration in mole per cm^2

† A main part of the experimental results of this work was presented at the 23rd Annual Meeting on Polarography, Nov. 4—5, 1977, Osaka: abstract; T. Ikeda, K. Toriyama, and M. Senda, *Rev. Polarogr. (Kyoto)*, **23**, 26 (1977).

of the adsorbed Cl.Fd, $D_{Cl.Fd}$ the diffusion coefficient of Cl.Fd, and A and τ are the surface area and the drop time of the DME, respectively. At high Cl.Fd concentrations a maximum current, $\delta_1 I_p^{max}$, is attained, which is given by $\delta_1 I_p^{max} = kA\Gamma^{max}$, where Γ^{max} is the maximum surface concentration of adsorbed Cl.Fd. Applying these two equations to the plot in Fig. 2, we estimated the Γ^{max} value as 1.4×10^{-11} mol/cm^2, $D_{Cl.Fd}=1.4\times10^{-6}$ cm^2 s^{-1} being assumed.[1] Adsorption of Cl.Fd also caused a decrease of the imaginary a.c. current in the potential region where the faradaic current does not appear, indicating that the differential double layer capacity of the mercury-solution interface decreases due to the adsorption of Cl.Fd on the electrode surface (see Fig. 2). Upon assuming that the relative decrease of the double layer capacitance, C_{dl}, is proportional to the surface coverage, θ, due to adsorption of Cl.Fd, that is, $\theta=\Gamma/\Gamma^{max}=(C_{dl}^{\circ}-C_{dl})/(C_{dl}^{\circ}-C_{dl}^{max})$, where C_{dl}° and C_{dl}^{max} are the double layer capacitances in the absence of Cl.Fd and at the maximum adsorption of Cl.Fd, respectively, Γ^{max} can be estimated by $\Gamma^{max}=(6/7)(7D_{Cl.Fd}/3\pi)^{1/2}C_{Cl.Fd}/((C_{dl}^{\circ}-C_{dl})/(C_{dl}^{\circ}-C_{dl}^{max}))$, where a diffusion-controlled adsorption of Cl.Fd is assumed. Application of this equation to the relative decrease of the imaginary a.c. current at -0.45 V at pH 6.9 leads to the Γ^{max} value of 1.3×10^{-11} mol/cm^2. These two Γ^{max} values agree well with each other and with the Γ^{max} value of 1.3×10^{-11} mol/cm^2 obtained for apoferredoxin (cluster-free ferredoxin) with the hanging mercury drop electrode (HMDE).[1]

In all a.c. polarograms of Cl.Fd recorded in this study, the peak potentials of the real and imaginary components, E_p^{real} and E_p^{imag}, coincided with each other and were independent of a.c. frequency between 50 and 500 Hz (see Table 1). As shown in Fig. 3 the peak potentials shifted by -60 mV/pH at pH lower than 7 and by -30 mV/pH at pH higher than 8. In the previous paper[1] we have shown that Cl.Fd adsorbed on the HMDE surface decomposes to the corresponding apoferredoxin and that the apoferredoxin gives d.c. and a.c. voltammograms due to the RSH/RSHg redox reaction of the cysteine residues of the apoferredoxin. At pH lower than 7 the peak potentials of the a.c. polarograms obtained with the DME agreed with the peak potentials of the RSH/RSHg redox couple observed with the HMDE.[1] Furthermore we found that at pH lower than 7 apo-Cl.Fd gives practically the same a.c. polarograms as Cl.Fd with the DME. These results indicate that at pH lower than 7 Cl.Fd adsorbed on the DME surface decomposes rapidly to apo-Cl.Fd and that the a.c. polarograms of Cl.Fd obtained here at pH lower than 7 should be assigned to the RSH/RSHg redox reaction of the cysteine residues of apo-Cl.Fd.

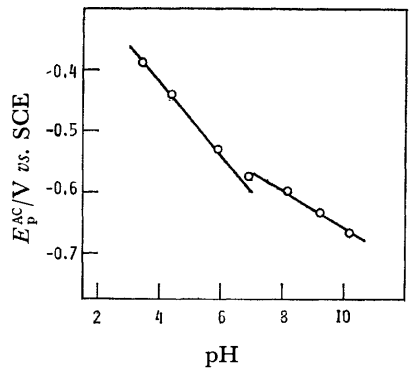

Fig. 3. Dependence of the peak potential, E_p^{AC}, on pH.

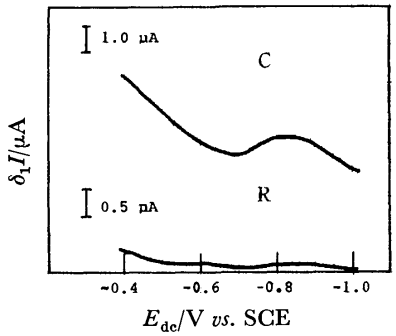

Fig. 4. A.c. polarograms of 1.5 μM apo-Cl.Fd at pH 9.2. R: Real component, C: imaginary component.

On the other hand at pH higher than 8 the a.c. polarograms of Cl.Fd with the DME (Fig. 1B) were obviously different from those of apo-Cl.Fd with the DME (Fig. 4). Furthermore the peak potentials of the a.c. polarograms of Cl.Fd with the DME in basic media (pH>8) were much more positive than the peak potentials of the steady-state cyclic a.c. or d.c. voltammograms at the HMDE which were assigned to the RSH/RSHg redox reaction of cysteine residues of apoferredoxin.[1] These results indicate that in basic media Cl.Fd adsorbed on the DME surface may remain undecomposed at least for a drop life of the DME, usually less than 9 s, and that the a.c. polarograms observed with DME in basic media should be assigned to the redox reaction of the iron-sulfur clusters of Cl.Fd adsorbed on the electrode surface. Figure 5 shows

dependences of the peak heights of the two a.c. components on a.c. frequency at pH 9.2. The peak potentials, E_p^{real} and E_p^{imag}, and the half-peak widths, $\Delta E_{p/2}^{real}$ and $\Delta E_{p/2}^{imag}$ of the two components at pH 9.2 are gievn in Table 1.

The redox reaction of the iron-sulfur clusters of Cl.Fd in bulk solution has been studied by several authors using equilibrium techniques.[9–13] These studies have revealed that the stoichiometry of electron equivalents, n, is 2, whereas the potentiometric data fit the Nernst equation for which $n=1$.[10–13] Eisenstein and Wang[13] interpreted these results by assuming that Cl.Fd, which has two iron-sulfur clusters, is reduced in two reduction steps, each step involving a one-electron transfer to each cluster. More direct evidence was provided by Orme-Johnson and Beinert[14] and Mathews *et al.*,[15] who observed two different ESR signals arising sequentially during a reductive titration of Cl.Fd. Therefore, it is reasonable to suppose that the adsorbed Cl.Fd also is electrochemically reduced in two reduction steps at the mercury electrode surface.

According to theory of a.c. polarography[16] for a two-step surface redox reaction,

$$\begin{aligned} O_{ad} + n_1e &\rightleftharpoons S_{ad} \\ S_{ad} + n_2e &\rightleftharpoons R_{ad} \end{aligned} \qquad \text{(I)}$$

in which the interaction between the adsorbed reactants is taken into account, the real and imaginary components of the a.c. wave, $\delta_1 I_F^{real}$ and $\delta_1 I_F^{imag}$, for d.c. reversible process and $n_1=n_2=1$ may be, under appropriate simplifications,[17] expressed as

$$\delta_1 I_F^{real} = \frac{(r_1r_2-y_1y_2-x_1x_2)(r_1+r_2)+(r_1y_2+r_2y_1)(y_1+y_2+x_1-x_2)}{(r_1r_2-y_1y_2-x_1x_2)^2+(r_1y_2+r_2y_1)^2}\delta_1E \qquad \text{(1a)}$$

$$\delta_1 I_F^{imag} = \frac{(r_1y_1+r_2y_1)(r_1+r_2)-(r_1r_2-y_1y_2-x_1x_2)(y_1+y_2+x_1-x_2)}{(r_1r_2-y_1y_2-x_1x_2)^2+(r_1y_2+r_2y_1)^2}\delta_1E \qquad \text{(1b)}$$

with

$$r_1 = [(F^2/RT)\Gamma_t k_{sap}\bar{f}_1^{1/2}\bar{f}_2^{1/2}]^{-1}$$

$$r_2 = [(F^2/RT)\Gamma_t k_{sap}\bar{f}_2^{1/2}(1-\bar{f}_1-\bar{f}_2)^{1/2}]^{-1}$$

$$y_1 = [(F^2/RT)\Gamma_t\omega]^{-1}[(1/\bar{f}_1)+(1/\bar{f}_2)-G\theta_t]$$

$$y_2 = [(F^2/RT)\Gamma_t\omega]^{-1}[(1/\bar{f}_2)+(1/(1-\bar{f}_1-\bar{f}_2))-G\theta_t]$$

$$x_1 = -x_2 = [(F^2/RT)\Gamma_t\omega]^{-1}[(1/\bar{f}_2)-(1/2)G\theta_t]$$

In these equations δ_1E is the amplitude of applied ac voltage, ω the angular frequency, Γ_t the total surface concentration defined by $\Gamma_t=\Gamma_O+\Gamma_S+\Gamma_R$, Γ_i(i=O, S, or R) being the surface concentration of species i, θ_t the total surface coverage defined by $\theta_t=\Gamma_t/\Gamma^{max}$, Γ^{max} being the maximum value of Γ_t, $\bar{f}_1$ and $\bar{f}_2$ are the mean fractions of the surface coverages defined by $f_1=\overline{\Gamma}_O/\Gamma_t$ and $f_2=\overline{\Gamma}_S/\Gamma_t$, respectively, $\overline{\Gamma}_i$ is the mean or "d.c." value of Γ_i, k_{sap} the apparent rate constant of the charge transfer which depends on the adsorption parameters and on the total surface coverage θ_t, and G the parameter representing the interaction between the adsorbed reactants. The mean fractions $\bar{f}_1$ and $\bar{f}_2$ are related to the d.c. potential, E_{dc}, by

$$E_{dc} = E'_o + (RT/F)[\ln\sqrt{K}+\ln(\bar{f}_1/\bar{f}_2) - (1/2)(1-2\bar{f}_2)G\theta_t] \qquad \text{(2a)}$$

$$E_{dc} = E'_o + (RT/F)[-\ln\sqrt{K}+\ln(\bar{f}_2/(1-\bar{f}_1-\bar{f}_2)) + (1/2)(1-2\bar{f}_2)G\theta_t] \qquad \text{(2b)}$$

with

$$E'_o = (E'_{o1}+E'_{o2})/2 \qquad (3)$$

$$K = \exp[(F/RT)(E'_{o1}-E'_{o2})] \qquad (4)$$

where E'_{o1} and E'_{o2} are the formal standard potentials of the first and second surface redox steps, respectively. E'_o corresponds to the formal standard potential of the adsorbed redox couple O_{ad}/R_{ad}. The parameter K corresponds to the formation constant of the intermediate S_{ad}. These equations predict that both components of the a.c. wave are symmetrical with respect to the E'_o-axis and that within limited values of the parameters K, $G\theta_t$, and (ω/k_{sap}) the peak potentials of both components are independent of a.c. frequency and coincide with each other and with E'_o. These predictions are consistent with the present results. In Table 1 are also given values of the half-peak widths as calculated from these equations by assuming $K=1$, $G\theta_t=3.2$, and $k_{sap}=3.9\times10^3\ s^{-1}$. Solid lines in Fig. 5 are drawn by these equations using the same values of the parameters as above. Apparent agreement between the theory and experimental results seems reasonably good. However, it must be noted that the data can equally well fit the simplified equations (1) and (2) with other sets of k_{sap}, $G\theta_t$, and K for $0\leqq K\lesssim3$: for example, $k_{sap}=4.3\times10^3\ s^{-1}$, $G\theta_t=4$ and $K=3$, or $k_{sap}=5.8\times10^3\ s^{-1}$, $G\theta_t=2.5$ and $K=0.1$, or even $k_{sap}=5.0\times10^2\ s^{-1}$, $G\theta_t=0.95$ and $K=0$. The last set with $K=0$ corresponds to a single two-electron redox reaction, $O_{ad}+2e\rightleftarrows R_{ad}$[18] (II). In conclusion we may state that the a.c. polarographic behavior of Cl.Fd at DME in basic solution is explained by the redox reaction mechanism (I) with $0\leqq K\lesssim3$ (note that $K=0$ corresponds to the mechanism (II)).

As described above, the peak potentials of the a.c. polarograms, E_p^{AC}, in basic media should correspond to the formal standard redox potential of the iron-sulfur clusters of Cl.Fd adsorbed on the electrode surface. Table 2 summarizes our E_p^{AC} values and the values (extra- or interpolated to pH 7.0) of the standard redox potential, E'_o, of Cl.Fd determined by various equilibrium techniques.[9–13] The E'_o value cited from

a) Value extra- or interpolated to pH 7.0.

Ref. 9 was determined by the direct potentiometric titration in the presence of mediators using a Pt electrode as an indicator electrode [direct method]. On the other hand, the E_o' values cited from Refs. 10 to 13 were measured by equilibrating a ferredoxin with another reducing redox couple such as H_2/H^+[10-12] or methyl viologen[13] using spectrophotometry [indirect method]. As seen from Table 2, our E_p^{AC} value extrapolated to pH 7 (= −0.33 V *versus* NHE) is *ca.* 60 to 70 mV more positive than the E_o' values determined by the "indirect" method.[10-13] This difference may be due to the difference in the free energy between the adsorbed redox couple and the redox couple in bulk of solution. On the contray the E_p^{AC} value agreed well with the E_o' value determined by the "direct" method (the value interpolated to pH 7.0 is −0.33 V *versus* NHE).[9] In addition the E_o' determined by the "direct" method shifted by −30 mV/pH, which is also in agreement with the pH dependence of the E_p^{AC} observed here in basic media. In the "direct" method a Pt electrode was used as an indicator electrode. Adsorption of plant ferredoxins on a Pt electrode was also reported.[5] Therefore it is likely that the E_o' determined by the "direct" method corresponds to the formal standard redox potential of the iron-sulfur clusters of Cl.Fd adsorbed on the Pt electrode surface.

This work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Pyrolytic Sulfurization Gas Chromatography. VI. The Continuous and Simultaneous Determination of the Atomic Ratio between C, H, O, and N in Various Compounds

Tadashi HARA,* Kaoru FUJINAGA, and Fujio OKUI

Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602

(Received March 19, 1979)

The simultaneous determination of the atomic ratio between C, H, O, and N in various compounds including a metal organic chelate one has been presented in our previous papers.[1-3] With the objective of reducing the analysis time, an apparatus by which a continuous and simultaneous determination of the atomic ratio between C, H, O, and N can be carried out has been newly designed and constructed. Using this apparatus, many samples can be treated continuously at the rate of about 20 min for one sample, with satisfactory results.

It has been reported in the previous papers[1-3] that the simultaneous determination of the atomic ratio between C, H, O, and N in various compounds, including a metal organic chelate one, can be achieved with satisfactory results by pyrolytic sulfurization gas chromatography (PSGC). Since the analysis by the PSGC is, however, batch-by-batch, time-consuming, and laborious, an apparatus which made it possible to determine the atomic ratio between C, H, O, and N in a sample continuously and simultaneously was newly designed and constructed. An analysis can be carried out more rapidly and simply by this apparatus than by the previous one. In place of a Teflon-made gas sampler,[1] a new gas sampler consisting of three stainless steel crushing devices was constructed. The quartz ampule containing a sample was easily dashed to pieces in the present apparatus by driving the plunger of the crushing device in place of the jack used in the previous paper.[1] In the present gas sampler, the crushing device can be used for many analyses, unlike the more fragile Teflon tube in the previous paper. The analytical procedure using the crushing device consists of the following steps; 1) the introduction of an ampule, 2) the replacement of the air in the crushing device with helium(He) as a carrier gas, 3) analysis by gas chromatography, and 4) the recycling of these steps. Three crushing devices are set up in parallel with a gas chromatograph and operated separately in different steps. By this procedure the time necessary for an analysis was minimized; a sample could be analyzed within about 20 min, while it took about 30 min in the previous procedure. Using the present procedure, operating at the rate of 3 samples per hour, about three times as many samples as in the previous procedure could be treated; precision could also be improved by optimizing the reaction conditions.

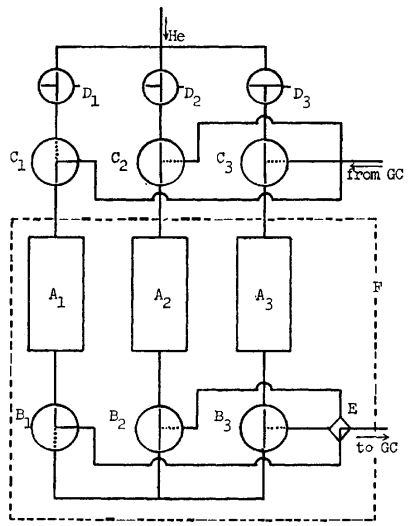

Fig. 1. Schematic flow diagram of the gas sampler. A_1, A_2, A_3: Crushing devices, B_1, B_2, B_3: electric valves-(heat-resistant), C_1, C_2, C_3: electric valves, D_1, D_2, D_3: three-way cocks, E: rotary cock, F: oven at 150 °C.

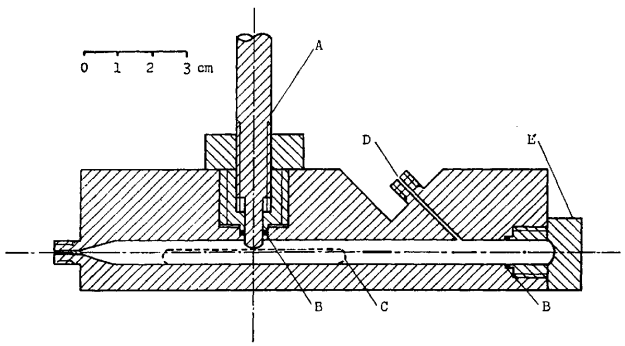

Fig. 2. Crushing device. A: Plunger for crushing an ampule, B: seals, C: an ampule containing a sample, D: carrier gas inlet, E: screwed cap for an ampule insertion.

Experimental

Apparatus. The new gas sampler is shown in Fig. 1. The gas sampler consists of three stainless steel crushing devices A(Fig. 2) and electric valves for the regulation of the gaseous flow. The inside of the crushing device was treated preliminarily by coating it with an aqueous solution of water glass, by drying it at room temperature under the reduced pressure, and by then elevating the temperature. The three crushing devices(A_1, A_2, and A_3) were laid out so as to connect them in parallel with a gas chromatograph by operating electric valves. The temperature of the gaseous flow between A and a gas chromatograph was held at 150 °C. The gas sampler was heated by connecting the crushing devices and electric valves with a hot brass plate into which cartridge heaters had been inserted. A Shimadzu GC-4B gas chromatograph was used for the analysis, while the other parts of the apparatus were the same as in the previous paper.

Reagents. The sulfur used as an oxidizing agent was obtained by purifying[4] commercially available sulfur (chemically pure). The organic compounds used as standard samples were of an analytical grade, while the metal organic chelate compounds were prepared carefully by the method found in the literature for their gravimetric analysis. The polymer samples were the same as in the previous paper.[5]

Procedure. The ampule containing a sample was prepared and the sample was made to react with sulfur as follows: Definite amounts of sulfur and a sample were placed in a quartz tube in which one end had been sealed, and the inside of the quartz tube was replaced with He, after which the other end of the quartz tube was sealed. The ampule thus obtained was held at 600 °C for 10 min and at 950 °C for 30 min. Thereafter, the ampule at 950 °C was slowly cooled in an electric furnace to room temperature by lefting it stand. Three ampules were at first inserted into the crushing devices, A_1, A_2, and A_3, and then the three flows including A_1, A_2, and A_3 were replaced with He, after which one of the three flows was connected with a gas chromatograph. Figure 1 shows that the flow-1 is in a state of an analyzing system, while the flows-2 and -3 are in a state of a replacing system. Here, A_2 is connected in series with A_3. Thus, the system replaced with He is shown by Scheme 1:

$$He \rightarrow D_2 — C_2 — A_2 — B_2 — B_3 — A_3 — C_3 — D_3 \rightarrow Exhaust$$

Scheme 1.

After the sample in the flow-1 has been completely analyzed, the flow-2 is connected with a gas chromatograph by turning the rotary cock, E, to the flow-2, while the flows-1 and -3 are in a state of a replacing system. Thus, the system replaced with He is shown by Scheme 2:

$$He \rightarrow D_3 — C_3 — A_3 — B_3 — B_1 — A_1 — C_1 — D_1 \rightarrow Exhaust$$

Scheme 2.

Here, the residual quartz pieces in A_1 are taken off and the next ampule is newly charged. After the 5 min necessary for the stabilization of the base line in a gas chromatogram, the column of the gas chromatograph is cooled for 5 min; then the ampule is broken with the plunger of A_2, followed by the gas-chromatographic analysis. In the present gas sampler, B and C in the same flow are designed so as to operate simultaneously. The analysis was carried out continuously by repeating the above-mentioned operation. The gas chromatogram was obtained under conditions similar to those used in a previous paper.[2]

Results and Discussion

Reaction Conditions. In the previous procedure the ampule at 950 °C was cooled to 90 °C immediately after the reaction, while it is cooled slowly to room temperature by being left standing in the electric furnace in the present procedure. The results obtained by the present procedure are superior to those obtained by the previous one in the following points; 1) the fluctuation of the individual peak area ratio on the chromatogram, 2) the evolution of carbon monoxide (CO) as an impurity, and 3) the fluctuation of the correction factors. The fluctuation of the ratio of the peak areas in the previous and the present procedures, which was obtained by analyzing 5 samples of glycine and by estimating the coefficient of variation in the ratio of the individual peak area, is shown in Table 1.

The amount of CO evolved in the present procedure was smaller than that in the previous procedure and was neglected much as before. As may be seen from the fact that the peak of CO overlaps with that of nitrogen(N_2) on the chromatogram, the present procedure may be expected to be more precise than the previous one. This is shown in Fig. 3 with regard to the compound consisting of C, H, and O, the relationship between the peak areas of carbonyl sulfide (COS) and of CO is plotted. It can easily be seen from Fig. 3 that the peak area of CO is approximately proportional to that of COS. No linear relationship was, however, obtained experimentally between CO and carbon dioxide or carbon disulfide. On the basis of these results, CO was considered to evolve by means of the equilibrium shown in Eq. 1:

$$CO(g) + \frac{1}{x}S_x(g) \rightleftharpoons COS(g). \quad (1)$$

By taking the complete decomposition of COS at high temperatures into consideration, and by supposing that the above equilibrium could not be established completely when the temperature was suddenly lowered to 90 °C from 950 °C, the evolution of a larger amount of CO in the previous procedure as compared with that in the present one was easily understood. The amount of CO evolved by dropping the ampule into water at 950 °C was found to be several times as great as the amount of CO evolved by the present procedure. This makes the above considerations reasonable.

TABLE 1. FLUCTUATION OF THE RATIO OF PEAK AREAS IN THE PREVIOUS AND THE PRESENT PROCEDURES

Procedure	Coefficient of variation (%)[a]				
	N_2	CO_2	H_2S	COS	CS_2
Present	0.2365	1.026	0.3895	0.1678	1.141
Previous	1.331	2.437	0.8553	1.406	1.940

a) Calculated from five runs for glycine.

○: Present procedure, ●: previous procedure.

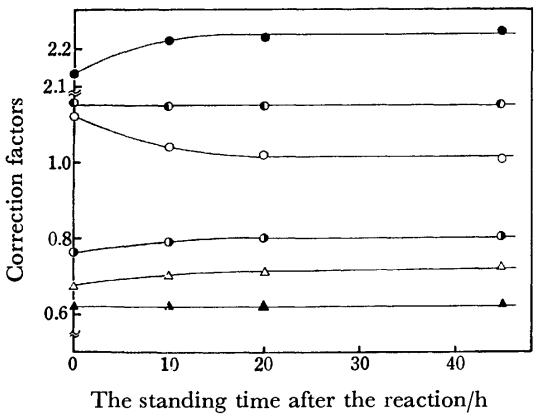

Fig. 4. Effect of the standing time on correction factors. ◐: $K(N_2)$, ○: $K(CO_2)$, △: K(COS), ●: $K(H_2O)$, ◑: $K(SO_2)$, ▲: $K(CS_2)$.

According to the experimental results, the correction factors changed with the standing time within several hours after the completion of the reaction (Fig. 4). It may also be seen from Fig. 4 that a definite period of standing for an ampule is indispensable for obtaining a good result. The correction factor of $N_2(K(N_2))$, which was defined by $K(N_2)=A(H_2S)/A(N_2)$, was obtained by the use of dicyandiamide.[2] Hydrogen sulfide was concluded to be stable, irrespective of the standing time of the ampule throughout the experiment, since N_2 was stable under the conditions of PSGC and since $K(N_2)$ was also constant experimentally. Though hydrogen (H_2) could not be detected under the conditions of PSGC, it was unnecessary, in the light of the above results, to pay much attention to H_2. Based on these results, the previous procedure was improved as in the present one, in which the ampule was analyzed for a definite period of standing after the reaction.

Pretreatment of a Crushing Device. The results obtained by the use of a crushing device without pretreating the internal surface fluctuated from sample to sample, and the peak of water (H_2O) was observed in spite of the fact that the H_2O should not evolve under the present experimental conditions. To avoid these phenomena, the internal surface of the crushing device was treated with an aqueous solution of disodium phosphate or water glass. The pretreatment with an aqueous solution of water glass was found to improve the analytical results markedly and to reduce the amount of evolved water to traces from $H_2O/N_2=0.0381$, which was obtained as the mean value of the peak-area ratio in 5 analyses of glycine. Therefore, the internal surfaces of all the crushing devices were coated with water glass for use.

Gas Sampler. The gas sampler used in the previous papers was made of Teflon and was occasionally broken with a piece of quartz. The previous procedure was also time-consuming, since such operations as 1) the removal of quartz pieces and the insertion of a sample, 2) the replacement of the air in the inside of a gas sampler with He, and 3) the analysis of the reaction products with a gas chromatograph were carried out with only one gas sampler. By setting up three crushing devices in parallel with a gas chromatograph, the gas sampler could be used for a long time and the time necessary for an analysis was minimized to about 20 min from the period of about 30 min needed in the previous procedure. According to the present procedure, the analysis could be carried out continuously at the rate of 3 samples per hour.

Analysis of Various Compounds. Various organic compounds, metal organic chelate compounds, and polymers were analyzed by the present procedure; the results are shown in Tables 2, 3, and 4, respectively. As may be seen from Tables 2—4, both precision and accuracy were superior to those by the previous procedure. After the sample in an ampule treated at 950 °C

Metal Complexes of Amino Acids. XII.[1] The Deuteration of α-Hydrogen Atoms in Cobalt(III) Complexes Containing α-Amino Carboxylates

Tomoharu AMA,* Hiroshi KAWAGUCHI, Makoto KANEKIYO, and Takaji YASUI

Department of Chemistry, Faculty of Science, Kochi University, Akebono-cho, Kochi 780

(Received June 29, 1979)

The second-order rate constants (rate=$k_{D(base)}$[Complex][OD^-]) for the deuterium exchange of α-methylene or α-methine protons in the amino carboxylato complexes, *trans(O)*-, C_1-*cis(O)*-, and C_2-*cis(O)*-$[Co(gly)_2(en)]^+$ and -$[Co(gly)_2(tn)]^+$, $[Co(gly)(NH_3)_4]^{2+}$, $[Co(gly)(en)_2]^{2+}$, $[Co(gly)(tn)_2]^{2+}$, $[Co(sar)(en)_2]^{2+}$, and *Λ*- and *Δ*-$[Co(L\text{-ala})(en)_2]^{2+}$, were determined by the ^{1}H-NMR measurement. The major factors determining the deuteration rate of α-hydrogens in the amino carboxylate chelate are the geometry and charge of the complex, and the nature of the substituent bonded to the chelate ring to be deuterated; the minor factor is the chelate-ring size of the ligands other than amino carboxylate in a complex molecule.

It is well-known that the metal ions increase the reactivity of α-methylene protons in α-amino carboxylate. Since the magnitude and specificity of the effect were first shown by Williams and Busch[2] through a ^{1}H-NMR study of cobalt(III) complexes containing glycinate, alaninate, and ethylenediaminetetraacetate, a large number of studies involving the deuteration of the cobalt(III) complexes have been undertaken.[3-14] Many of these studies have treated polyamino carboxylato complexes. On the other hand, few studies have been made of the α-amino carboxylato complexes. It had been found that the deuteration rate of the glycinate methylene proton in the polyamino carboxylato complex is related to the chelate-ring strain; *i.e.*, the methylene protons of out-of-plane glycinate (less strained) in $[Co(edta)]^-$ are more rapidly deuterated than those of in-plane glycinate (strained).[2] However, factors (the charge and geometry of the complex and substituent in the ligand, and so on) other than the ring strain must also be related to the deuteration rate. In order to determine these factors, a study using α-amino carboxylato complexes is more profitable than one using polyamino carboxylato complexes because then we can exclude the effect of the chelate-ring strain.

In the present paper, we will evaluate the deuteration rates of α-protons in several types of cobalt(III) complexes containing the chelated glycinate, L-alaninate, and sarcosinate; we will also discuss the relation between the deuteration rate and the geometry of the complex, the charge of the complex ion, and the nature of the substituent in a ligand.

Experimental

Preparation of the Complexes. Synthesis and Separation of the Isomers of Bis(glycinato)(trimethylenediamine)cobalt(III) Chloride: A solution containing 10 g of cobalt(II) chloride hexahydrate in 10 ml of water was added to a solution containing 5 g of trimethylenediamine and 6.4 g of glycine in 30 ml of water. Lead dioxide (10 g) was then gradually added to the solution on a water bath, after which the solution was mechanically stirred at 55 °C for about 30 min. The precipitates were filtered off, and the filtrate was kept in a refrigerator overnight. The precipitates were filtered off again, and the filtrate was poured into a column containing a cation-exchange resin (Dowex 50W×8, 200—400 mesh, K^+ form). The column was flushed with water to sweep out any nonelectrolytic or anionic complexes, and then the adsorbed band was developed with a 0.2 M aqueous solution of potassium chloride. Two bands appeared: a violet one (lower) and a red-violet one (upper). It was confirmed from their absorption spectra that the early- and late-eluted solutions contain *trans(O)* and *cis(O)* (mixture of C_1-*cis(O)* and C_2-*cis(O)*) isomers respectively. Each eluted solution was evaporated to a small volume using a rotary evaporator, a small amount of ethanol was added to the concentrated solution, and the potassium chloride was filtered off. A crude product of the *trans(O)* isomer was obtained from the above solution (early eluate) on the addition of more ethanol. The C_1-*cis(O)* isomer was deposited as columnar crystals by the further addition of a small amount of ethanol to the above ethanolic solution (late eluate) and by then keeping the solution in a refrigerator overnight. After the C_1-*cis(O)* isomer had been removed by filtration, a large amount of ethanol was added to the filtrate. A crude product of the C_2-*cis(O)* isomer was obtained as fine needle crystals. Each isomer was recrystallized from water by the addition of ethanol. Found for the *trans(O)* isomer: C, 25.91; H, 6.14; N, 17.15%. Calcd for $[Co(gly)_2(tn)]Cl\cdot 0.5H_2O$: C, 25.81; H, 5.88; N, 17.20%. Found for the C_1-*cis(O)* isomer: C, 25.20; H, 6.13; N, 16.85%. Calcd for $[Co(gly)_2(tn)]Cl\cdot H_2O$: C, 25.12; H, 6.02; N, 16.74%. Found for the C_2-*cis(O)* isomer: C, 24.63; H, 6.29; N, 16.08%. Calcd for $[Co(gly)_2(tn)]Cl\cdot 1.5H_2O$: C, 24.46; H, 6.11; N, 16.30%.

The other cobalt(III) complexes examined here were prepared by the published methods[15-21] and were found to be analytically pure.

Measurements of Deuteration Rate. The deuteration runs were carried out under a flow of nitrogen in order to avoid a decrease in the pD by the absorption of CO_2 in air. Each complex (1 mmol) was dissolved in 9 ml of D_2O. The sample solution was kept at 30.0, 40.0, or 50.0 °C (±0.05 °C) in a thermostat, and then 20 μl of *t*-butyl alcohol and 1 ml of a 1 M Na_2CO_3–D_2O solution (or a 0.5 M Na_2CO_3–0.5 M $NaDCO_3$–D_2O solution) were added to the sample solution. The deuteration of the methylene protons of chelated glycinate began immediately after the Na_2CO_3–D_2O solution was added to the sample solution. At prescribed time intervals, 0.5-ml aliquot sample solutions were taken out from the container, kept in a thermostat. The exchange reaction was immediately stopped by adding the sample solution to 0.05 ml (or 0.038 ml) of 2 M DCl and by then cooling the mixture to 0 °C. The pD of the sample solution in the container was measured by the use of a pH meter (Beckman LABOMATE II) with a combination electrode. The pD=pH+0.4[22] and $[OD^-]=3.0\times 10^{-15}[D^+]^{-1}$ formulae were used to evaluate $[D^+]$ and $[OD^-]$ re-

spectively.

The ^{1}H-NMR spectra of the neutralized solutions were recorded at 100 MHz using a JEOL MH-100 NMR spectrometer at room temperature. The intensities of the ^{1}H-NMR signals of the methylene protons in the chelated glycinate were estimated by comparing them with that of *t*-butyl alcohol as a standard. The ^{1}H-NMR data are given with the chemical shifts *vs.* DSS.

Results and Discussion

trans(O), C_1-cis(O), and C_2-cis(O) Isomers of $[Co(gly)_2(en)]^+$. The ethylene proton signals arising from the chelated ethylenediamine were unchanged throughout the experiment. In addition, on developing the residual solution of each deuteration run in the cation-exchange column (SP-Sephadex), only one band was observed; no complexes resulting from decomposition or isomerization were detected. The neutralized solution used for the ^{1}H-NMR measurement did not show any change in its NMR intensity or spectral pattern for at least one day at room temperature.

The resonance peaks of the methylene protons of chelated glycinate appeared in the range of 3.4—3.7 ppm. The two glycinate methylenes in the C_2-*cis(O)* and *trans(O)* isomers are equivalent, but those in the C_1-*cis(O)* isomer are not. Figure 1 shows the resonance patterns which are to be expected from the symmetries of these isomers. Yoneda *et al.*[23] assigned the methylene signal at 3.60 ppm to the $H_a(H_a')$ of glycinate and that at 3.44 ppm to $H_b(H_b')$ (Fig. 1).

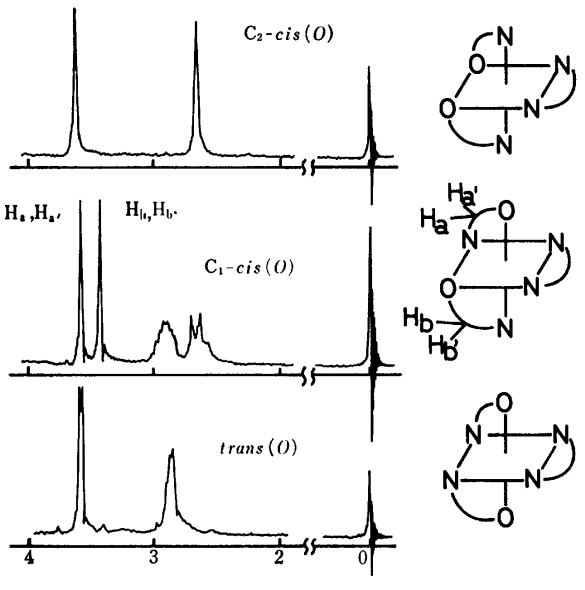

Fig. 1. ^{1}H-NMR spectra of C_2-*cis(O)*-, C_1-*cis(O)*-, and *trans(O)*-$[Co(gly)_2(en)]^+$ complex ions.

Plots of log *I vs.* the deuteration time at a constant pD yield straight lines, where *I* denotes the relative NMR intensities of the glycinate methylenes to the *t*-butyl alcohol methyls, the internal standard (Fig. 2). Accordingly, the deuteration rate at a constant pD

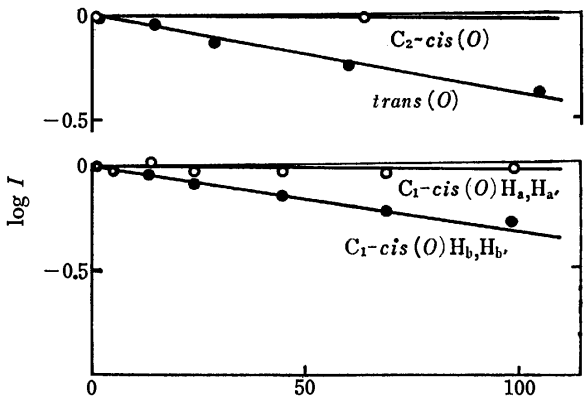

Fig. 2. Plots of log *I* (*I* denotes the relative NMR intensity of α-hydrogens) *vs.* deuteration time of three isomers in $[Co(gly)_2(en)]^+$ complex ion. pD=11.7; Temperature, 30.0 °C.

can be expressed as:

$$-\frac{d[complex]}{dt} = k'_{D(base)}[complex],$$

where $k'_{D(base)}$ is the apparent rate constant for the base-catalyzed deuteration at a constant pD. This result agrees with that obtained from the study of EDDA–Co(III) complexes by Sudmeier and Occupati.[5] The rate constants of the deuterium exchange of methylene protons in the chelated glycinate are given in Table 1. Sudmeier and Occupati showed, in their study of the base-catalyzed deuterium exchange of EDDA–Co(III) complexes, that the reaction was first-order in $[OD^-]$. Our present result coincides with their result; *i.e.*, the $k'_{D(base)}[OD^-]^{-1}$ values of the present complexes are constant at a given temperature.

The deuteration rates of the methylene protons in the chelated glycinate at 50 °C decrease in this order; *trans(O)*$\geq H_b(H_b')$ of C_1-*cis(O)*$>C_2$-*cis(O)*$\geq H_a(H_a')$ of C_1-*cis(O)*. Dabrowiak and Cooke[24] studied the reaction of acetaldehyde with cobalt(III) complexes containing chelated glycinate. They showed that the order of reactivity is: $[Co(gly)(en)_2]^{2+}$>*trans(O)*-$[Co(gly)_2(en)]^+$ >C_1-*cis(O)*-$[Co(gly)_2(en)]^+$>C_2-*cis(O)*-$[Co(gly)_2(en)]^+$. This order agrees with that of the deuteration rate determined in the present study. The fact that the rates are different among the geometrical isomers of the present complexes with the same 1+ charge suggests that the geometry of the complex is one of the most important factors affecting the deuteration rate.

It is obvious from Table 1 and Fig. 2 that the two non-equivalent glycinates in the bis(glycinato) complex differ in their deuteration rates; *i.e.*, the rate of the deuterium exchange of $H_b(H_b')$ in C_1-*cis(O)*-$[Co(gly)_2(en)]^+$ is larger than that of $H_a(H_a')$. It is known that the deuteration of the "out-of-plane" glycinate protons in $[Co(edta)]^-$ is far more rapid than those of any other CH_2 protons in the complex. Williams and Busch[2] suggested that such a difference between the two non-equivalent glycinates in $[Co(edta)]^-$ is a function of the ring strain. In the present complex, C_1-*cis(O)*-$[Co(gly)_2(en)]^+$, no such chelate-ring strain as in

TABLE 1. RATE CONSTANTS FOR THE DEUTERIUM-EXCHANGE REACTION OF GLYCINATE α-HYDROGENS IN *trans(O)*-, C_2-*cis(O)*-, AND C_1-*cis(O)*-$[Co(gly)_2(en)]^+$ COMPLEX IONS

TABLE 2. ACTIVATION PARAMETERS FOR THE BASE-CATALYZED DEUTERATION OF GLYCINATO α-HYDROGENS IN *trans(O)*-, C_2-*cis(O)*-, AND C_1-*cis(O)*-$[Co(gly)_2(en)]^+$ COMPLEX IONS

Species	$\Delta G^{\ddagger}$(50 °C) (kJ mol^{-1})	$\Delta H^{\ddagger}$ (kJ mol^{-1})	$\Delta S^{\ddagger}$ (JK^{-1} mol^{-1})
trans(O)	77±8	131±4	168±14
C_2-*cis(O)*	82±10	120±5	117±16
C_1-*cis(O)* $H_b(H_b')$	78±13	128±6	154±20
C_1-*cis(O)* $H_a(H_a')$	82±11	139±5	176±18

$[Co(edta)]^-$ can be expected between the two non-equivalent glycinates. Nevertheless, the rate constant of $H_b(H_b')$ is about five times as large as that of $H_a(H_a')$. This suggests that, in the bis(glycinato) complexes, there are factors other than the chelate-ring strain.

The activation parameters of these isomers are given in Table 2. Both the enthalpy and the entropy of activation for these isomers increase in this order: C_2-*cis(O)*< $H_b(H_b')$ of C_1-*cis(O)*<*trans(O)*<$H_a(H_a')$ of C_1-*cis(O)*. The order of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ is different from the order of the deuteration rate.

trans*(O)*, C_1-cis*(O)*, *and* C_2-cis*(O) Isomers of* $[Co(gly)_2(tn)]^+$. The ^{1}H-NMR spectra of these complexes are shown in Fig. 3. The methylene resonances of the glycinates in the *trans(O)* and C_2-*cis(O)* isomers were observed at 3.57 and 3.58 ppm respectively. The methylene resonances of the C_1-*cis(O)* isomer appeared as singlet peaks at 3.57 ppm (assigned to H_a and H_a' on the basis of the theory proposed by Yoneda *et al.*)[23] and 3.35 ppm (assigned to H_b and H_b'). These isomers did not decompose or isomerize under the given conditions, and the neutralized solution used for the ^{1}H-NMR measurement did not indicate any change in NMR intensity and spectral shape for at least one day at room temperature.

The deuteration rates of the methylene protons of glycinates decrease in this order: $H_b(H_b')$ of C_1-*cis(O)*≳ *trans(O)*>C_2-*cis(O)*>$H_a(H_a')$ of C_1-*cis(O)* (at 50 °C; Table 3). This order is almost the same as that of the isomers of $[Co(gly)_2(en)]^+$. The difference in the deuteration rate between the two non-equivalent glycinates in the C_1-*cis(O)* isomer is obvious, as has been shown for the C_1-*cis(O)* isomer of the $[Co(gly)_2(en)]^+$ complex. The trimethylenediamine and ethylenediamine complexes indicated a nearly equal deuteration rate for each corresponding isomer.

Stereochemical Nonrigidity of {Poly(1-pyrazolyl)borato}palladium(II) Complexes Containing a Metal-1-Alkenyl or -Alkyl Bond†

Masayoshi ONISHI,* Katsuma HIRAKI,* Masaharu SHIRONITA, Yuzo YAMAGUCHI, and Shigeki NAKAGAWA

Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Bunkyo-machi, Nagasaki 852

(Received July 30, 1979)

New{poly(1-pyrazolyl)borato}palladium(II) complexes, [Pd{CH=CCl-CMe$_2$(NMe$_2$)-1-*C,N*}(BPz$_4$)] (Pz= 1-pyrazolyl) **1**, [Pd{CH$_2$CMe(OMe)-CH$_2$S-*t*-Bu-1-*C,S*}(BPz$_3$Y)] (Y=Pz or H), and [Pd{CH$_2$CMe(OMe)-CH$_2$NMe$_2$-1-*C,N*}(BPz$_3$Y)] were prepared and characterized by means of elemental analysis and IR and ^{1}H-NMR spectroscopy. The stereochemical nonrigidity of these complexes was discussed on the basis of ^{1}H-NMR data. The fluxional behavior of the BPz$_4$ ligand in **1** was analyzed in detail by means of an approximate method based on the Bloch equation, and found to consist of three kinds of motions: inversion of the Pd-(N-N)$_2$-B boat-type six-membered ring, rotation of the BPz$_4$ ligand about the Pd-pyrazolyl nitrogen bond accompanying the inversion, and a tumbling process.

Stereochemical nonrigidity of a poly(1-pyrazolyl)-borate ligand of transition metal complexes has received considerable attention.[1-7] Fluxional motions of the tridentate poly(1-pyrazolyl)borate (BPz$_3$Y, Pz=1-pyrazolyl, Y=Pz or H) ligand in formally seven-coordinated molybdenum complexes, [Mo(1-3-η-CH$_2$CRCH$_2$)(BPz$_3$Y)(CO)$_2$][2] or in penta-coordinated platinum ones, [PtMe(BPz$_3$Y)L] (L=neutral ligand)[3] were analyzed by means of a simplified density matrix method. It is of interest to investigate the stereochemical nonrigidity of bidentate BPz$_3$Y ligands in square planar transition metal complexes, in comparison with that of the tridentate BPz$_3$Y ligands in molybdenum[1,2] or platinum complexes.[3]

Fluxional behavior has been reported for several {poly(1-pyrazolyl)borato}palladium(II) complexes which contain both metal-aryl and -nitrogen bonds.[6,7] ^{1}H-NMR spectra of these complexes involve fairly complicated aromatic protons, overlapping with some 1-pyrazolyl protons and it was difficult to analyze quantitatively the fluxional motion of the BPz$_3$Y ligands of the complexes.

We have prepared some {poly(1-pyrazolyl)borato}-palladium(II) complexes having a metal-1-alkenyl or -alkyl bond assisted by chelation with a nitrogen- or a sulfur donor site; the stereochemical nonrigidity of these complexes is discussed on the basis of ^{1}H-NMR spectra. The line shape analysis was carried out quantitatively as regards the fluxional motion of {2-chloro-3-(dimethylamino)-3-methyl-1-butenyl-1-*C,N*}{tetrakis(1-pyrazolyl)borato}palladium(II) [Pd(cdamb)(BPz$_4$)] {cdamb =CH=CCl-CMe$_2$(NMe$_2$)-1-*C,N*} (**1**).

Experimental

General Procedure. IR spectra were recorded and melting points determined according to the method given in the previous paper.[7] ^{1}H-NMR spectra at various temperatures were observed on a Japan Electron Optics Laboratory model MH-100 spectrometer (100 MHz), using CDCl$_3$, CD$_2$Cl$_2$, or CD$_3$CN as a solvent and tetramethylsilane as an internal standard. The temperature of the NMR samples was determined with methanol or 1,3-propanediol within an error of ±1 °C.

Sodium tetrakis(1-pyrazolyl)borate Na[BPz$_4$],[8] sodium hydrotris(1-pyrazolyl)borate Na[BPz$_3$H],[8] and starting dinuclear 1-alkenyl- or alkylpalladium(II) complexes, [{PdCl(cdamb)}$_2$],[9] di-μ-chloro-bis{3-(*t*-butylthio)-2-methoxy-2-methylpropyl-1-*C,S*}dipalladium(II) [{PdCl(btmmp)}$_2$] {btmmp=CH$_2$CMe(OMe)-CH$_2$S-*t*-Bu-1-*C,S*},[10] di-μ-chloro-bis{3-(dimethylamino)-2-methoxy-2-methylpropyl-1-*C,N*}dipalladium(II) [{PdCl(dammp)}$_2$] {dammp=CH$_2$-CMe(OMe)-CH$_2$NMe$_2$-1-*C,N*}[11] were prepared according to the reported methods.

Preparation of [Pd(cdamb)(BPz$_4$)]. A benzene suspension (25 ml) containing [{PdCl(cdamb)}$_2$] (0.61 mmol) and Na[BPz$_4$] (1.31 mmol) was stirred at room temperature for 16 h. The resulting solids were filtered off. The remaining solution was concentrated at a reduced pressure, followed by addition of hexane. On cooling, the mixture yielded pale yellow crystals, which were recrystallized from benzene–hexane to give [Pd(cdamb)(BPz$_4$)] (**1**).

Preparations of [Pd(btmmp)(BPz$_4$)] and [Pd(btmmp)(BPz$_3$H)]. A benzene suspension (20 ml) containing [{PdCl(btmmp)}$_2$] (0.63 mmol) and Na[BPz$_4$] (1.26 mmol) was stirred at room temperature for 2 h. The resulting supernatant solution was evaporated in a rotary evaporator to yield yellow oil. The oil was dissolved in diethyl ether, followed by addition of hexane at 5—8 °C. White needles precipitated, which were recrystallized from diethyl ether–hexane to afford [Pd(btmmp)(BPz$_4$)] (**2**).

Complex [Pd(btmmp)(BPz$_3$H)] (**3**) was prepared by a similar method, Na[BPz$_3$H] being used in place of Na[BPz$_4$].

Preparation of [Pd(dammp)(BPz$_4$)] and [Pd(dammp)(BPz$_3$H)]. A benzene suspension (20 ml) involving [{PdCl(dammp)}$_2$] (0.63 mmol) and Na[BPz$_4$] (1.26 mmol) was stirred at ambient temperature for 2 h. The resulting solid was filtered off and the remaining solution concentrated. On cooling, white solids precipitated gradually, which were collected and washed with diethyl ether and hexane to give [Pd(dammp](BPz$_4$)] (**4**).

A white complex [Pd(dammp)(BPz$_3$H)] (**5**) was synthesized in a similar manner to the preparation of **2**.

Line Shape Analysis

Method of Approximation. Fluxional motion of the BPz$_4$ ligand corresponds to the exchange of four protons at a given position on the four pyrazolyl groups. Line shape analysis of **1** was performed for a spin system of

† A preliminary report of this work was presented at the VIIIth International Conference on Organometallic Chemistry, Kyoto, September 1977. Abstract p. 161.

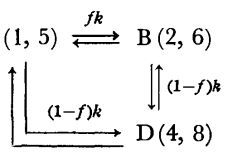
four pyrazolyl 3-H's of the BPz_4 ligand, since the 3-H's displayed well-resolved spectra of four doublets due to coupling to neighboring 4-H at low temperature, as shown in Fig. 2. In terms of spin notation, the process is an exchange of an ABCDXYZW spin system, since resonance frequencies of the 3-H's are far apart from those of the 4-H's. In a strict sense, complete line shape analysis of this spin system should be carried out by the density matrix method,[2,3,12,13] which is applicable to a spin-exchange system having spin-spin couplings. However, it needs too much computer-calculations to obtain theoretical spectra of the present exchanging system by this method. For a good approximation overcoming the difficulty, four doublets of the 3-H's were analyzed by means of the modified Bloch equation,[14] which should be applied to a spin system with no coupling, instead of the density matrix method, since the chemical shifts of the 4-H's are far apart from those of the 3-H's, and the mixing transition between spins of 3-H's and those of 4-H's might be small. A similar approximation has been reported on the NMR analysis of a restricted rotation of a tetrahedral carbon in 9-isopropyltriptycenes.[15]

Absorption intensity $I(\omega)$ at each frequency ω is derived from the modified Bloch equation:[14]

$$I(\omega) = \frac{1}{\pi}\mathrm{Re}[-P\cdot\{i(\Omega-\omega)+D\}^{-1}\cdot l]$$

where the notation of the matrices (P,Ω,ω,D,l) refer to the work of Johnson,[13] Re representing the real part of the matrix.

^{1}H-NMR spectra of three pyrazolyl 3-H's of the BPz_4 ligand showed remarkable temperature-dependency in the region 76——30 °C, while the doublet {at δ 7.49 (3 and 7) at −30 °C, in Fig. 2} corresponding to the fourth 3-H remained unchanged below 43 °C and showed temperature-dependent spectra only above 58 °C. The present analysis deals with the spin system of the four 3-H's appearing in the ^{1}H-NMR spectra in the range 43——30 °C. Concerning the former three pyrazolyl 3-H's, the exchange rate between two 3-H's {at δ 6.82 (1 and 5) and 7.25 (2 and 6) at −30 °C} differs from that between the former two 3-H's and the third one {at δ 7.59 (4 and 8) at −30 °C}. A parameter f was introduced in order to express these two different exchange rates. The terms fk and $(1-f)k$ denote the former and latter exchange rates, respectively.



This treatment is based on the assumption that activation energies for these two exchange processes are virtually equal, since it is very difficult for the present exchange system to detect a fine difference between the two activation energies.

Moreover, as regards the exchange of the three 3-H's in the temperature range 43——30 °C, upper-field signals (1, 2, and 4 in Fig. 2) of the three doublets were assumed to undergo exchange with each other, as well as the lower-field ones (5, 6, and 8). It is unlikely that the lower-field level of one 3-H doublet exchanges with a higher-field level of another doublet. A similar assumption has been reported by Suzuki *et al.*[15]

Accordingly, the matrix D of the probability of the spin transfer is given as follows.

$$D = \begin{vmatrix}
-k-\frac{1}{T_1}, & fk, & 0, & (1-f)k, & 0, & 0, & 0, & 0, \\
fk, & -k-\frac{1}{T_2}, & 0, & (1-f)k, & 0, & 0, & 0, & 0, \\
0, & 0, & -\frac{1}{T_3}, & 0, & 0, & 0, & 0, & 0, \\
(1-f)k, & (1-f)k, & 0, & -2(1-f)k-\frac{1}{T_4}, & 0, & 0, & 0, & 0, \\
0, & 0, & 0, & 0, & -k-\frac{1}{T_5}, & fk, & 0, & (1-f)k, \\
0, & 0, & 0, & 0, & fk, & -k-\frac{1}{T_6}, & 0, & (1-f)k, \\
0, & 0, & 0, & 0, & 0, & 0, & -\frac{1}{T_7} & 0, \\
0, & 0, & 0, & 0, & (1-f)k, & (1-f)k, & 0, & -2(1-f)k-\frac{1}{T_8}
\end{vmatrix}$$

Full width in Hz at half height of the i-th peak is $(\pi T_i)^{-1}$ in the absence of exchanging broadening, and the parameter T_i is a transverse relaxation time modified by some effects, such as long-range coupling to 5-H, mechanical fluctuation of resolving power, and mixing transition. ^{1}H-NMR spectrum at −30 °C was actually a slow-exchange limiting one, and the parameters T_i's were obtained readily from line widths of respective peaks. Above this temperature, T_i's were estimated from the values at −30 °C, using observed line widths of signals of 1,1,2,2-tetrachloroethane as a reference.

Calculations. For the given parameter f and the rate constant k together with chemical shifts and line widths in the absence of the exchanging broadening, calculations of the theoretical spectra were carried out with a FACOM 270-20 computer. The spectra were accomodated in order to get the best visual fitting with

the observed spectra by varying both f and k. The theoretical spectra were checked up as regards 1/2, 3/4, 4/5, and 6/7 of f.

Results and Discussion

General Properties. The chloro-bridging dinuclear cyclopalladated complexes reacted fairly smoothly with $Na[BPz_3Y]$ in the suspension of a non-polar solvent, such as benzene, to afford the corresponding new {poly(1-pyrazolyl)borato}palladium(II) complexes **1**—**5**. Yields, analytical data, and some physical properties of the new palladium(II) complexes are summarized in Table 1. Complexes **1**—**5** are stable in a solid state in the air, and soluble in the usual organic solvents except saturated hydrocarbons. Complexes **2**—**5** are soluble even in diethyl ether, and can not easily be purified by recrystallization. The compositions of **1**—**5** were confirmed by elemental analysis (Table 1), IR data (Table 2), and ^{1}H-NMR evidence (Table 3). ^{1}H-NMR spectra of these five complexes showed considerable temperature-dependency in the region 85—−36 °C.

Two coordination types of the BPz_3Y ligands are possible for **1**—**5**. Possible structures for **1** are shown in Fig. 1, as a typical example. The definite structure in the solid phase should be determined by X-ray analysis. The BPz_3Y ligands of **1**—**5** in solution were assumed to serve as a bidentate chelate (structure **E**) for the following reasons.

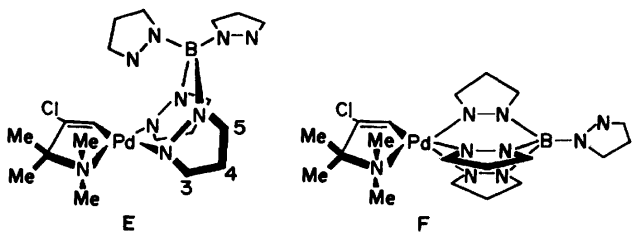


Fig. 1. Possible structures of **1**.

(1) The bidentate coordination of the BPz_3Y ligands was found in (acetophenone oximato-2-*C*,*N*){tetrakis(1-pyrazolyl)borato}platinum(II)[7] similar to **1**, **4**, and **5**, in $[Pd(1\text{-}3\text{-}\eta\text{-}C_3H_5)(BPz_4)]$,[1] and in $[PtMe(BPz_3H)(CO)]$ in the solid phase.[16]

(2) The relatively electron-rich palladium atom in **1**—**5** presumably prevents the third 1-pyrazolyl group of the BPz_3Y ligand from being coordinated to the palladium atom, in contrast with $[PtMe(BPz_4)(CO)]$ in solution[3] or $[PtMe(BPz_3H)(un)]$ {un=$F_3C\text{-}C{\equiv}C\text{-}CF_3$[17] or $F_2C{=}CF_2$[3]}, each of which possesses a considerably strong π-back-bonding ligand, CO or un.

(3) As regards the ^{1}H-NMR spectrum of **1** at −30 °C, both the chemical shift difference between two 3-methyl groups and that between two *N*-methyl ones are considerably large (Table 3). It seems unlikely that the conformation of the uncoordinated 1-pyrazolyl group in structure **F** would cause these large differences in **1**.

*^{1}H-NMR Spectra of $[Pd(cdamb)(BPz_4)]$ **1**.* At −30 °C, **1** exhibited the limiting slow exchange ^{1}H-NMR spectrum (Table 3). At this temperature, the four pyrazolyl groups are spectroscopically unequal, the BPz_4 ligand being coordinated to the central metal in a spectroscopically rigid state. In this state, it is expected that the differences in environments and chemical shifts among the four 3-H's are larger than those among the 5-H's, by considering the proposed

Table 1. Yields and elemental analyses of the new complexes

	Complex	Yield[a] %	Mp[b] °C	Found (Calcd) (%) C	H	N
1	$[Pd(cdamb)(BPz_4)]$	57	164—166	42.58 (42.88)	4.74 (4.73)	23.61 (23.69)

arrangement **E** shown in Fig. 1.

Two higher-field 3-H doublets (A and B at −30 °C, in Fig. 2)[18)] broadened at −6 °C, apparently disappearing at 19 °C. Above −6 °C, the third 3-H doublet at the lowest field (D in Fig. 2) broadened more gradually as compared with the former two. These three 3-H signals coalesced into a very broad hump at 43 °C, its height increasing slowly with rise in temperature. The fourth 3-H doublet (C in Fig. 2) remained actually unchanged below 43 °C, beginning to broaden only near 58 °C.

Two sharp 3-methyl singlets observed at −30 °C broadened near −6 °C, coalesced at 10 °C, turning into a sharp singlet at δ 1.29 at 43 °C. The 4-H's and 5-H's of the BPz_4 ligand and *N*-methyl signals of the cdamb moiety changed, corresponding to the 3-H's and the 3-methyl protons upon warming from −30 °C. Complex **1** in CD_3CN gave no limiting fast-exchange spectrum even at 79 °C.

There is a clear difference between the collapsing rates of the signals corresponding to the three pyrazolyl groups upon warming from −30 °C; the signals of the two pyrazolyl groups collapse more readily than that of the third pyrazolyl one. The former two pyrazolyl groups are reasonably associated with two uncoordinated ones at low temperature. Upon warming, an inversion of a Pd–$(N\text{–}N)_2$–B boat-type six-membered ring is expected to take place readily with no rupture of palladium-pyrazolyl nitrogen bond, accompanied by a simultaneous fluttering of two coordinated pyrazolyl groups. A similar inversion has been reported as for $[Mo(\eta^5\text{-}C_5H_5)(BPz_3Y)(CO)_2]$[4,5)] and $[Mo(\eta^5\text{-}C_5H_5)\text{-}(BPz_2Et_2)(CO)_2]$.[5)]

The third pyrazolyl group was assigned to the one coorrdinated at a *trans* position to a carbon-palladium σ-bond of the cdamb moiety, since comparatively strong *trans* influence of the 1-alkenyl group possibly gave rise to a moderately weak binding of the palladium-pyrazolyl nitrogen bond *trans* to the 1-alkenyl-palladium σ-bond. Above −6 °C, the third pyrazolyl group participated gradually in the fluxional motion, *viz.*, in a rotation of the three pyrazolyl groups around a palladium-nitrogen bond located at a *trans* position to a dimethylamino group, accompanied by a more rapid inversion of the Pd–$(N\text{–}N)_2$–B ring. Above 58 °C, the fourth pyrazolyl group began to participate in the fluxional motion of all pyrazolyl groups, *i.e.* in a "tumbling process."

As regards line shape analysis, agreement between the observed spectra and the theoretical ones was excellent, when the parameter f was 6/7, *viz.*, the inversion rate was six times greater than the exchange rate between the two pyrazolyl groups and the third one. Figure 3 shows the relationship between (log k) and $10^3/T$, obtained from the line shape analysis of **1**. From the results and Arrhenius' and Eyring's equations,

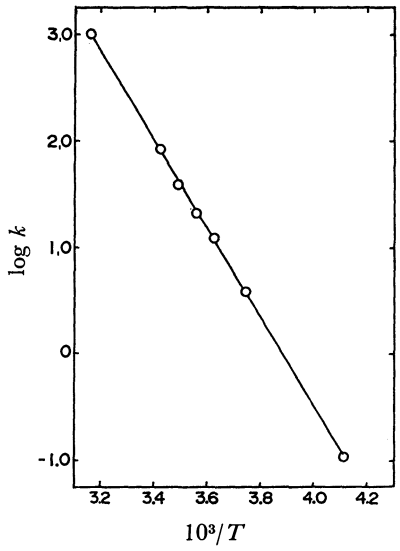

Fig. 3. The relationship between (log k) and $10^3/T$, obtained for **1**.

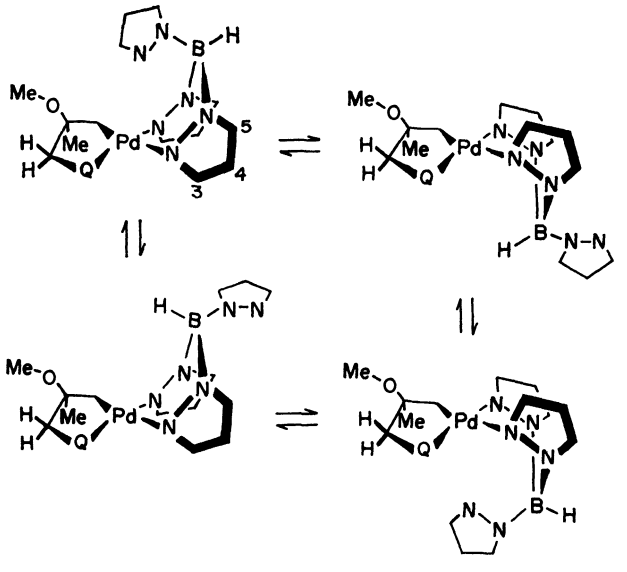
we find that $E_a=17.8\pm1.7$ kcal/mol, $\Delta G^{\ddagger}_{298}=14.5$ kcal/mol, $\Delta H^{\ddagger}_{298}=17.2$ kcal/mol, and $\Delta S^{\ddagger}=9.1$ cal/deg·mol for the fluxional motion of the three pyrazolyl groups. The value $\Delta G^{\ddagger}_{298}$ is considerably greater than $\Delta G^{\ddagger}_{198}$ for an internal rotation of the uncoordinated pyrazolyl ring and that for the exchange among the three coordinated pyrazolyl rings in $[PtMe(BPz_4)(CO)]$,[3] being comparable with $\Delta G^{\ddagger}_{298}$ for the exchange among the three coordinated pyrazolyl rings in $[PtMe(BPz_3H)(CO)]$.[3] The positive value of the $\Delta S^{\ddagger}$ for **1** is in contrast with the negative values of the $\Delta S^{\ddagger}$'s for $[PtMe(BPz_3Y)(CO)]$,[3] suggesting that the palladium-pyrazolyl nitrogen bonds are elongated, becoming loose in the transition states for the fluxional motion of **1**.

It is noteworthy that the fluxional motion of the BPz_4 ligand in **1** actually consists of three kinds of motion, *i.e.* inversion of the Pd–$(N–N)_2$–B ring, rotation of the three pyrazolyl rings accompanying a more rapid inversion, and the tumbling process, shifting from the former to the latter continuously upon warming from −30 °C. A similar behavior was observed also for **2** and **4**.

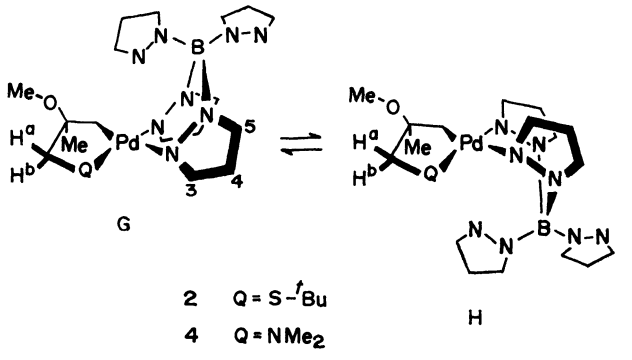
^{1}H-NMR Spectra of [Pd(btmmp)(BPz$_3$Y)] 2 and 3. As regards the BPz_3H ligand of **3** in CD_3CN, each of 3-H's and 5-H's gave a doublet at 28 °C, which turned into a broad signal at −36.5 °C. This indicates that the BPz_3H ligand is stereochemically non-rigid above −36.5 °C, the exchange rate decreasing moderately on cooling. The ^{1}H-NMR spectrum of the btmmp moiety at 28 °C contained three sharp singlets at δ 1.12 (9H, *t*-Bu), 1.40 (3H, 2-Me), and 3.32 (3H, OMe). Each of these singlets broadened near 8 °C and separated into a fairly sharp singlet and a small broad one with an intensity ratio *ca.* 8: 1 at −0.5 °C, Thus, the signals of the btmmp moiety separated into the two sets at this temperature, but not each of the pyrazolyl protons even at −36.5 °C. This indicates that an exchange of the two configurations of the *t*-butyl group takes place above −0.5 °C, independent of the stereochemically nonrigid motion of the BPz_3H ligand. Four conformational isomers were expected to be present owing to asymmetric 2-carbon and boron atoms, when the motion of the BPz_3H ligand was quenched at low temperature (Fig. 4), but could not be detected at −36.5 °C.



3 Q = S-^{t}Bu

5 Q = NMe$_2$

Fig. 4. Conformations of **3** and **5**.



2 Q = S-^{t}Bu

4 Q = NMe$_2$

Fig. 5. Conformations of **2** and **4**.

At 85 °C, the ^{1}H-NMR spectrum of the btmmp moiety of **2** in CD_3CN showed three sharp singlets at δ 1.10 (9H, *t*-Bu), 1.44 (3H, 2-Me), and 3.38 (3H, OMe). Each of these singlets separated into a fairly sharp singlet and a small broad one with an intensity ratio *ca.* 6: 1 at −0.5 °C. In consideration of the very similar ^{1}H-NMR spectra of **2** to those of **3**, the two sets of the btmmp-signals are also associated with two configurations of the *t*-butyl group, which undergo exchange with each other rapidly at high temperature. Although two conformational isomers (**2G** and **2H** in Fig. 5) occur owing to an asymmetric 2-carbon atom when the stereochemically nonrigid motion of the BPz_4 ligand is quenched at low temperature, it seems unlikely that these isomers cause the two sets of the btmmp-signals.

The BPz_4 ligand of **2** exhibited a limiting slow exchange ^{1}H-NMR spectrum at −36 °C. It appears that the two configurational isomers due to the *t*-butyl group and the conformational isomers due to the quenching of the motion of the BPz_4 ligand show virtually identical signals as for the 3-H protons of the BPz_4 ligand. Three high-field 3-H doublets broadened at −21 °C and coalesced near −0.5 °C, whereas the fourth 3-H doublet remained unchanged below this temperature and began to collapse near 20 °C. These four 3-H signals united to a broad one near 47 °C and exhibited a slightly broad signal at 85 °C, while four pyrazolyl 5-H's resonated at δ 7.76 as a well-resolved doublet, indicating a fairly fast tumbling motion of the BPz_4 ligand on the NMR time scale. From the results it seems that the pyrazolyl groups in **2** move also in a similar mode to the case of **1** in the range −36—85 °C.

*^{1}H-NMR Spectra of [Pd(dammp)(BPz_3Y)] **4** and **5**.* At 85 °C, the ^{1}H-NMR spectrum of **4** in CD_3CN contained four sharp methyl singlets in the dammp moiety and three slightly broad pyrazolyl proton resonances at δ 6.4 (4H, 4-H's), 7.2 (4H, 3-H's), and 7.8 (4H, 5-H's). This spectrum did not correspond to a fast exchange limit, whereas the tumbling motion of the BPz_4 ligand was fairly fast on the NMR time scale.

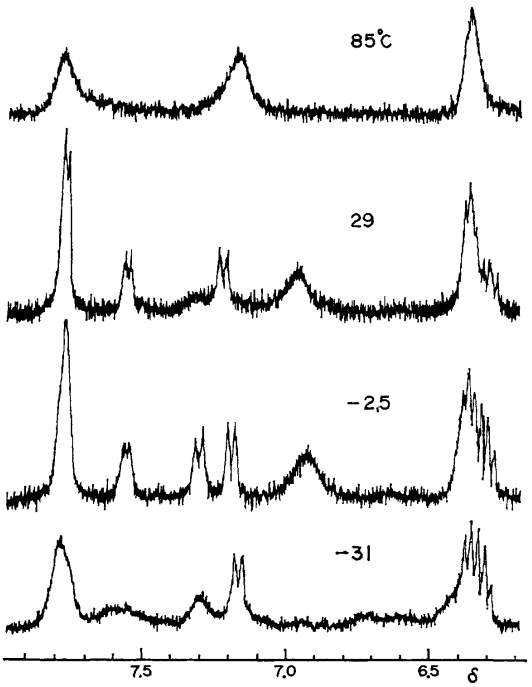


Fig. 6. ^{1}H-NMR spectra of the BPz_4 region of **4** in CD_3CN.

At 29 °C, the pyrazolyl 3-H resonance separated into a doublet at δ 7.18 (1H) and two broad signals at δ 6.9 (2H) and 7.3 (1H). The last broad signal turned into a doublet at −2.5 °C and broadened again at −31 °C. The larger broad signal at δ 6.9 separated into very broad humps near δ 6.6, 6.7, and 7.1 (overlapping with the doublet at δ 7.18) (Fig. 6). These broad humps were observed more obviously in CD_2Cl_2 (Table 3), and are tentatively ascribed to 3-H's of two conformational isomers (**4G** and **4H** in Fig. 5), which were distinguishable owing to the slowdown of the inversion of the Pd-$(N\text{-}N)_2$-B ring at low temperature. The broadening of the doublet at δ 7.3 at −31 °C might be due to the exchange between these two conformers. Each of the four methyl singlets also broadened considerably at this temperature, but did not separate into two signals expected for the two conformers. Complex **4** exhibited the three stages of the stereochemically non-rigid motion of the BPz_4 ligand, similar to **1**, no slow exchange limiting spectrum for **4** being obtained.

Concerning the BPz_3H group of **5** in $CDCl_3$ at 60.5 °C, each of 3-H's and 5-H's gave a doublet at δ 7.56 and 7.67, respectively, corresponding to a fast exchange limiting spectrum. The 3-H signal broadened at 25 °C, and separated into three broad ones of an equal intensity at −2.5 °C. The highest-field 3-H signal changed into a doublet at δ 7.33 at −36 °C, indicating that one of the three pyrazolyl groups is fixed and the others undergo exchange with each other at a slow rate. Above 25 °C, each of four methyl protons of the dammp moiety resonated as a sharp singlet, which broadened considerably with no separation at −36 °C, corresponding to the 3-H signals.

The BPz_3H ligand in **3** and **5** was more stereochemically non-rigid as compared with the BPz_4 ligand in **2** or **4**, analogous to the case of (acetophenone oximato-2-*C,N*){poly(1-pyrazolyl)borato}palladium(II) complexes.[7]

The authors are grateful to Miss Yumi Kojima and Mr. Yushichiro Ohama, Nagasaki University, for the ^{1}H-NMR measurements and technical assistance.

An Application of the Extended Principal Component Analysis to Circular Dichroism and Optical Rotatory Dispersion. A Case of Poly(α-L-glutamic acid) in the Helix-Coil Transition Region

Kiwamu YAMAOKA,* Takumi MATSUDA, and Mineo TAKATSUKI
Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730
(Received June 4, 1979)

The extended principal-component-analysis (PCA) method has been applied to circular dichroism (CD) and optical rotatory dispersion (ORD). The validity of this method has been examined with ideal binary and ternary equilibrium systems, for which the data CD spectra and ORD curves were computer-generated. Satisfactory results were obtained for these multicomponent optically active systems. As an example, the ultraviolet CD spectra of poly(α-L-glutamic acid) in the pH-induced helix-coil transition region were analyzed with the PCA procedure. By the extended PCA method, the pure CD spectra for both helix and random-coil conformations and the helix fractions in the transition region were determined from eight experimentally obtained CD spectra. By introducing an empirical parameter α into the Henderson-Hasselbalch equation, the helix-coil transition curve was reproduced reasonably well.

Many vectorial methods have been developed for the analysis of the optical spectra which result from either the light-absorbing species in chemical equilibria or the components in conformational equilibria.[1-18] The total number of species or conformers (both simply denoted as components) in such equilibria can be determined by means of rank analysis,[1-5] factor analysis,[6] and principal component analysis.[7-13] The principal component analysis (hereafter abbreviated as the PCA method) was extended by Kankare[10] and by the present authors[11-13] in order to resolve the observed optical spectra into the spectra of individual components involved in an equilibrium system.

The concentrations of individual components may be determined by factor analysis,[6] the least-square-curve-fitting method,[14-17] and the reciprocal function method.[18] Some of these methods have been applied to the circular dichroism (CD) spectra and optical rotatory dispersion (ORD) curves of optically active biopolymers in solution in order to interpret the observed optical data in terms of the various conformations.[5,6,14-18] In these methods, however, an appropriate reference spectrum must be assumed for each component. It is highly desirable to obtain the number of unknown polymer conformations (*i.e.*, components), the pure CD spectra or ORD curves of these components, and the fraction of each component, without assuming any reference spectra *a priori*. Therefore, the application of the PCA method to both CD and ORD is attempted in this work.

The extended PCA method has been utilized to analyze the absorption spectra of associative dyes in the monomer-dimer and acid-base equilibria[11] and in the binding with polyelectrolytes.[12,13] Two obvious physical conditions can be attached to the analysis of a given system: the absorbance and the concentration of each component are always non-negative. However, the CD and ORD are both signed quantities. The only remaining physical restriction is the non-negative concentration. Nevertheless, the extended PCA method is applicable to the CD and ORD data in a manner similar to the absorption, yielding the proper equilibrium scheme, the equilibrium constant, the number of optically active components, and the component CD spectra or ORD curves. As an illustration, the pH-induced change of the CD spectra of poly(α-L-glutamic acid) will be dealt with.

The Outline of the Extended PCA Method

Since the extended PCA method has previously been described in detail,[11,12] the procedure pertaining to the CD and ORD data will be given here. Suppose that m data CD spectra or ORD curves are experimentally available for a chemical system in equilibrium, which contains p optically active components, and that each data spectrum is a sum total of the p component spectra. The purpose of the extended PCA method is to determine the unknown number of components, p, and then the concentration and the pure spectrum of each component.

Over a certain wavelength region, m data CD spectra or ORD curves may be measured for m solutions, each of which contains a maximum of p components in equilibrium. If the Lambert-Beer-type additivity holds for the component CD spectra or ORD curves, as in the case of absorption spectra, the data matrix, $\boldsymbol{D}_\theta$ or $\boldsymbol{D}_\phi$, may be expressed as the product of the concentration matrix, $\boldsymbol{C}$, and the CD or ORD spectral matrix, $\boldsymbol{\theta}$ or $\boldsymbol{\phi}$, of the p components measured at n selected wavelengths:

$$\boldsymbol{D}_\theta = \boldsymbol{C}\boldsymbol{\theta} = \begin{bmatrix} C_{11} & \cdots & C_{1p} \\ \vdots & C_{ij} & \vdots \\ C_{m1} & \cdots & C_{mp} \end{bmatrix} \begin{bmatrix} \theta_{11} & \cdots & \theta_{1n} \\ \vdots & \theta_{jk} & \vdots \\ \theta_{p1} & \cdots & \theta_{pn} \end{bmatrix}, \quad (1)$$

or:

$$\boldsymbol{D}_\phi = \boldsymbol{C}\boldsymbol{\phi} = \begin{bmatrix} C_{11} & \cdots & C_{1p} \\ \vdots & C_{ij} & \vdots \\ C_{m1} & \cdots & C_{mp} \end{bmatrix} \begin{bmatrix} \phi_{11} & \cdots & \phi_{1n} \\ \vdots & \phi_{jk} & \vdots \\ \phi_{p1} & \cdots & \phi_{pn} \end{bmatrix}. \quad (2)$$

In these expressions, C_{ij} denotes the concentration of the jth component in the ith data spectrum, while

θ_{jk} and ϕ_{jk} are the θ and ϕ quantities of the jth component at the kth selected wavelength λ_k respectively.

A second-moment matrix, $\boldsymbol{A}$, is constructed from the data matrix as:

$$\boldsymbol{A} = {}^t\boldsymbol{D}_\theta\boldsymbol{D}_\theta \text{ or } \boldsymbol{A} = {}^t\boldsymbol{D}_\phi\boldsymbol{D}_\phi. \quad (3)$$

The eigenvalues $\Lambda_i (i=1, n)$ and the corresponding eigenvectors, $\boldsymbol{e}_i$, can be calculated from the $\boldsymbol{A}$ matrix by diagonalization. The relative magnitude of Λ_i permits us to determine the number of significant components.[11,12] Two new matrices, $\boldsymbol{f}$ and $\boldsymbol{t}$, are introduced as follows:

$$\boldsymbol{D}_\theta = \boldsymbol{f}_\theta\boldsymbol{e}_\theta \text{ or } \boldsymbol{D}_\phi = \boldsymbol{f}_\phi\boldsymbol{e}_\phi, \quad (4)$$

and:

$$\boldsymbol{\theta} = \boldsymbol{t}_\theta\boldsymbol{e}_\theta \text{ or } \boldsymbol{\phi} = \boldsymbol{t}_\phi\boldsymbol{e}_\phi. \quad (5)$$

The $\boldsymbol{e}$ matrix, consisting of p eigenvectors, is transformed to the $\boldsymbol{D}$ matrix by the $\boldsymbol{f}$ matrix, and also to the $\boldsymbol{\theta}$ and $\boldsymbol{\phi}$ matrices by the $\boldsymbol{t}$ matrix. The concentration matrix, $\boldsymbol{C}$, is given as:

$$\boldsymbol{C} = \boldsymbol{f}\boldsymbol{t}^{-1}. \quad (6)$$

Equations 4—6 indicate that the pure spectra of unknown components and their concentrations contributing to each data spectrum may be evaluated, once the elements of the $\boldsymbol{t}$ matrix are available.

In order to determine the $\boldsymbol{t}$ matrix, an appropriate equilibrium scheme must be selected.[11-13] The general expression for the scheme may be written as:

$$K = \prod_{i=1}^{q} [X_i]^{\nu_i}, \quad (7)$$

where K is the equilibrium constant, X_i is the ith component, which may be either optically active or inactive, and the ν is the stoichiometric coefficient. The brackets denote the molar concentration. It should be noted that the number of q is always larger than, or equal to, p. The coefficient of variation, S, is defined as:

$$S = \left[\frac{1}{m}\sum_{j=1}^{m}(K_j - \bar{K})^2\right]^{1/2} \Big/ \bar{K}, \quad (8)$$

where $\bar{K}$ is the mean equilibrium constant averaged over m equilibrium constants $K_j (j=1, m)$, by which an equilibrium (Eq. 7) is specified in m solutions (*i.e.*, m data spectra). Hence, the magnitude of the S value is the criterion for selecting the proper scheme for a given multicomponent equilibrium system.[11,12] It should be noted that, in any equilibrium system in which both L- and D-isomers of an optically active compound are involved, the $\boldsymbol{C}$ matrix (Eq. 6) describes only the difference in concentration between the two isomers. Thus, the number of components will be one instead of two in a racemization reaction (*e.g.*, L-isomer⇆D-isomer).

Results and Discussion

Ideal Binary System. Consider the following chemical equilibrium, in which an optically active chemical species, X_2, dissociates into an optically active species, X_1^-, and a proton:

$$X_2 \rightleftarrows X_1^- + H^+. \quad (9)$$

The quilibrium constant, K_a, is given by:

$$K_a = \frac{[X_1^-][H^+]}{[X_2]}. \quad (10)$$

When $K_a = 1 \times 10^{-6}$ M (=mol/dm^3) and when the pH of the system is varied from 7 to 5 by 0.25 pH units, a set of nine data CD spectra or ORD curves will be computer-generated, according to Eq. 10, by a linear combination of the hypothetical, component spectra of the X_1^- and X_2 species.

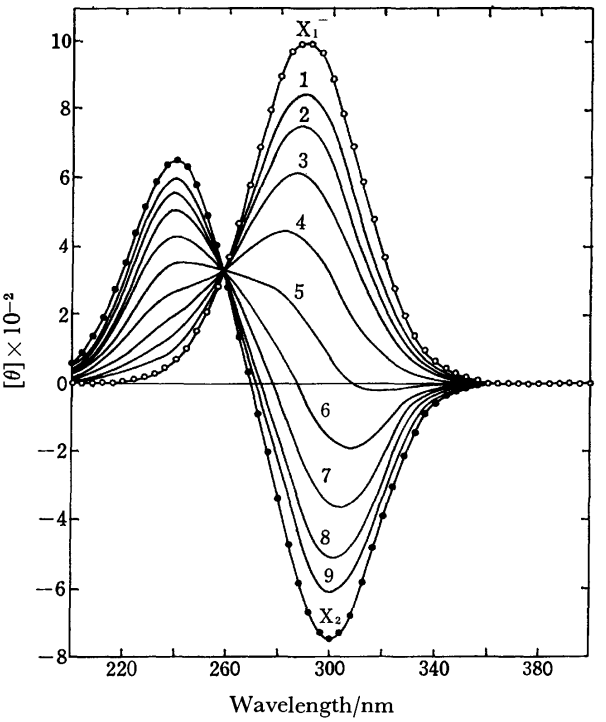

Fig. 1. The hypothetical component CD spectra (X_1^-, X_2) and the generated data CD spectra (1—9) for an ideal binary equilibrium system. The data spectra were computed according to Eq. 10 and expressed with the molar ellipticity [θ]. Symbols (○ and ●) indicate the estimated pure component spectra. The pH values of spectra 1 and 9 were set to be 5 and 7, respectively. For other details, see text.

The Case of CD. Figure 1 shows the component CD spectra of X_1^- and X_2. They were synthesized from a single Gaussian curve and a more complex Gaussian curve respectively. By using these component spectra, nine data CD spectra (Nos. 1—9) were computed at 4 nm intervals between 200 and 400 nm and at nine pH values. It is interesting to note that the data CD spectra (Nos. 1—9) all cross each other at a single wavelength near 260 nm, which may be termed the *isoelliptic* or *isodichroic* point by analogy with the isosbestic point of the absorption spectra. The presence of this point for a set of experimentally observed spectra should be taken as evidence for the two-optically-active-component system.

The supposedly unknown number of components in the equilibrium scheme (Eq. 9) is found from the eigenvalues of the second-moment matrix constructed from the nine data spectra. Figure 2(a) shows that a large gap exists between the second and third components. The gap

Table 1. The dependence of the S values on the parameter, α, in equilibrium expressions (Eqs. 12 and 16) for the ideal binary and ternary systems

α	Binary System (CD and ORD in 200—400 nm)[a)]	Ternary System (CD and ORD in 200—400 nm)[a)]
0.7	0.144	0.0012
0.8	0.082	0.0009
0.9	0.035	0.0005
1.0	0.000	0.0000
1.1	0.026	0.0009
1.2	0.040	0.0018
1.3	0.062	—
1.4	0.074	—

a) Identical results were obtained for both CD and ORD in the two narrower wavelength regions of 280—400 nm and 340—400 nm respectively.

indicates the correctness of the computing procedure for the assumed binary system. Analysis of the data spectra with Eq. 10 produced the values of 1×10^{-5} for S and 1×10^{-6} M for $\bar{K}_a$, the latter agreeing excellently with the preset value. The pure CD spectra of the X_1^- and X_2 components (open and filled circles) were reproduced quite well, as is shown in Fig. 1. The relative error between the computer-generated input data spectra and the iterated output component spectra was always less than 0.01% throughout the present work.

In actual CD measurements, experimental difficulties, such as the high absorbance and low CD signal of a solution, often limit the measurable wavelength region. Therefore, the 200—400 nm region was reduced to two narrower wavelength regions of 280—400 nm and 320—400 nm in this simulation, and the same PCA procedure as above was applied to each region. The values of $\bar{K}_a$ and S were all the same regardless of the wavelength region. This is conceivable because no experimental error was taken into account in the ideal system. Conversely, however, it is not necessary to cover the entire wavelength region where the complete CD features prevail if CD measurements are carried out with a sufficiently high accuracy.[11)]

In order to examine whether or not the given equilibrium scheme (Eq. 9) has been determined uniquely, a check is made with a general equilibrium scheme given as:

$$nX_2 \rightleftarrows nX_1^- + mH^+. \qquad (11)$$

The corresponding equilibrium constant, K_b, is written as:

$$K_b = \left(\frac{[X_1^-]}{[X_2]}\right)^{\alpha}[H^+], \qquad (12)$$

where $\alpha=n/m$. The data spectra in Fig. 1 were analyzed with the aid of the various values of α in Eq. 12 in order to compare the variation in S with the exponent α. The results are given in Table 1, which shows that the value of S increases as the α value deviates from unity. This trend is what should be expected for the present binary system, since the equilibrium scheme was generated with $\alpha=1$.

The Case of ORD. Experimental difficulties often forbid the CD spectra to be measured in the wavelength region where positive or negative bands are anticipated. In this case, the application of the PCA method is impracticable. The ORD is a dispersive quantity and displays the Cotton effect associated with a CD band. The peak or the trough of the Cotton effect, together with the sign and magnitude, can often be observed on the long-wavelength side removed from the CD band. In ORD measurements the optical path length of a sample solution may easily be increased outside the absorption peak. These facts lead to the usefulness of the highly accurate data ORD curves for the rigorous PCA treatment. The ORD data are thus valuable in complementing the shortcomings of the corresponding CD data. Therefore, the PCA procedure

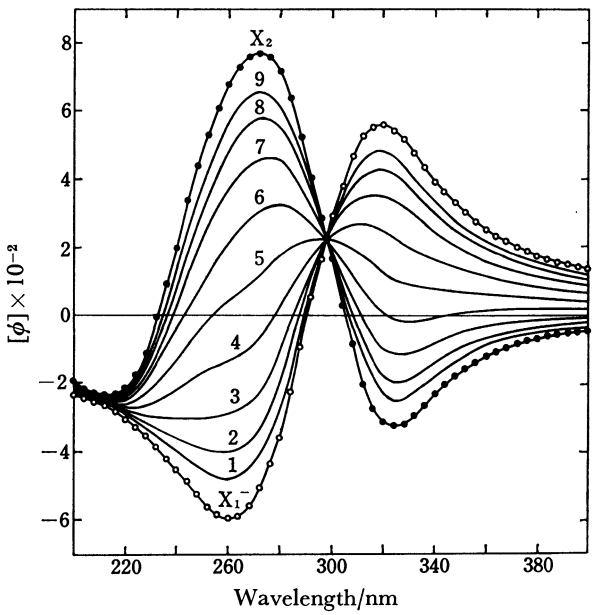

Fig. 3. The hypothetical component ORD curves (X_1^-, X_2) and the generated data ORD curves (1—9) expressed with the molar rotation $[\phi]$ for the same binary system as in Fig. 1. Symbols (○ and ●) indicate the estimated pure component curves.

is applied to the ORD data of the same ideal binary system as above.

Consider the same equilibrium scheme (Eq. 9) and the expression Eq. 10 with $K_a=1\times10^{-6}$ M. The hypothetical ORD curves for the X_1^- and X_2 components were computed from the corresponding CD spectra by the use of the Kronig-Kramers transform:[19,20]

$$[\phi(\lambda)] = \frac{2}{\pi}\int_{\lambda'_1}^{\lambda'_n}[\theta(\lambda')]\frac{\lambda'}{\lambda^2-\lambda'^2}d\lambda', \qquad (13)$$

where $[\theta]$ and $[\phi]$ are the molar ellipticity and the molar rotation respectively. The nine data ORD curves were similarly computed from the corresponding data CD spectra and are shown in Fig. 3. The *unknown* number of optically active components present in the equilibrium was determined from the eigenvalues using these curves. The result is shown in Fig. 2(b), in which a large gap again exists between the second and third components, indicating the system to be in a two-component equilibrium.

The PCA procedure was applied to this binary system using the general equilibrium scheme (Eq. 11). The results are given in Table 1. As in the CD treatment, the best simulation was obtained with $\alpha=1$ in Eq. 12, resulting in $S=1\times10^{-5}$ and $\bar{K}_b=1\times10^{-6}$ M, all of which are very close to the preset values. The pure ORD curves for X_1^- and X_2 (open and filled circles) resulting from the analysis of the nine data curves are in excellent agreement with the component ORD curves (X_1^- and X_2), as is shown in Fig. 3. As in the case of CD, the wavelength range was reduced to two narrower regions of 280—400 nm and 340—400 nm. The narrowing of the selected wavelength region did not affect the results. This indicates that even the *normal* ORD curves removed from the Cotton effect region are useful for extracting information on the equilibrium by the PCA method. Figure 3 suggests that the observed ORD curves should all cross each other at a wavelength which may be termed the *isodispersive point* if the concentration of one of the components is varied relative to the other in a two-component equilibrium system.

Ideal Ternary System. Consider a more complex equilibrium system which is composed of three optically active components, X_1, X_2, and X_3. The following equilibrium scheme is assumed:

$$X_1 + X_2 \rightleftarrows X_3, \qquad (14)$$

and:

$$K_c = \frac{[X_3]}{[X_1][X_2]} \qquad (15)$$

The CD spectrum and the corresponding ORD curve for each component were constructed in the same manner as in the binary system; they are shown in Figs. 4(a) and (b) respectively. Thirteen data CD spectra were generated (Nos. 1—13) from three pure component CD spectra with $K_c=5\times10^5$ M^{-1} in Eq. 15. In this case, the X_1 component was assumed to be titrated with X_2 to yield X_3 in such a way that the ratio of the concentration of the added X_2 to the initial concentration of X_1 was varied from 0.1 to 1.3. Since this series of data CD or ORD was synthesized from three components, the spectral features are very complicated, varying with the concentrations of the reactants, X_1 and X_2; *viz.*, no isoelliptic or isodispersive point exists.

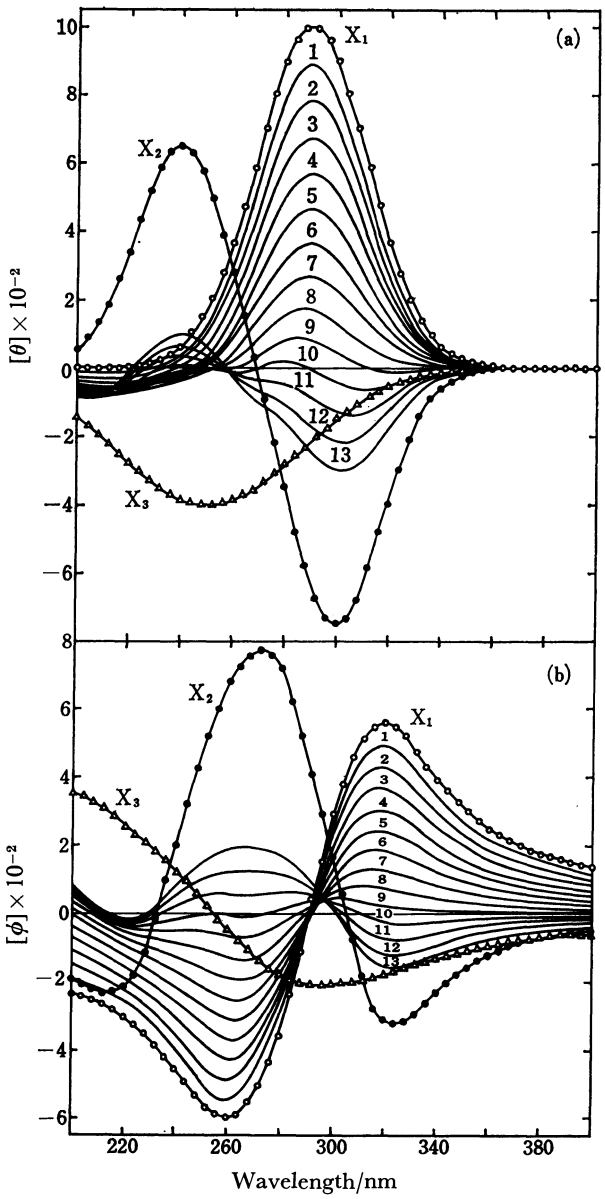

Fig. 4. The hypothetical component CD spectra and ORD curves (X_1, X_2, X_3) and the generated data (1—13) for an ideal ternary equilibrium system: (a) CD data were calculated from Eq. 15. (b) ORD data were computed from the corresponding CD spectra according to Eq. 13. Symbols (○, ●, and △) indicate the estimated pure component CD and ORD.

No visual inspection of these data CD spectra or ORD curves allows us to predict the number of optically active components involved in this equilibrium. The number was determined to be three by the PCA procedure, as is shown in Figs. 5(a) and (b). A large gap of eigenvalues exists between the third and fourth components, confirming the presence of three components. The most suitable expression for the chemical equilibrium has been searched for in the various equilibrium schemes by the use of the following general expression:

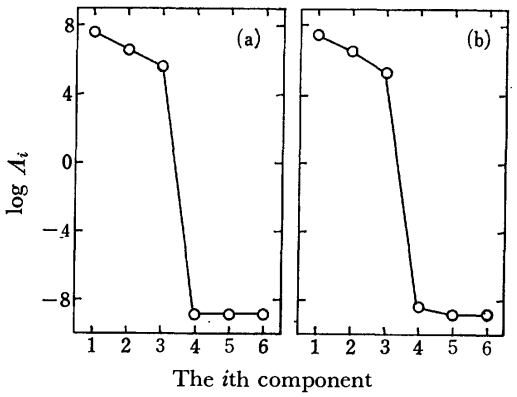

Fig. 5. The relation between eigenvalue Λ_i and the ith component for the ideal ternary system. (a) the CD data and (b) the ORD data in Fig. 4.

$$K_d = \left(\frac{[X_3]}{[X_1]}\right)^{\alpha}[X_2]^{-1}, \qquad (16)$$

in which the parameter, α, was varied from 0.7 to 1.2. The trial-and-error computer analysis produced the minimized S value of 1×10^{-5} at $\alpha=1$ and $\bar{K}_d=5\times10^5$ M^{-1}. These values all satisfy the originally assumed equilibrium conditions. A good agreement is seen between the component CD spectra or ORD curves originally set for the computer-generation and those determined from the thirteen data spectra by the PCA procedure, as is indicated by circles and triangles in Figs. 4(a) and (b). The S value increases as the α is varied from the preset value of unity. Thus, Eq. 15 is discriminated from the remainder as the most appropriate expression. No effect was observed on the final result when the wavelength region covered for the selected wavelengths was restricted, as in the case of the binary system.

A Real System of Poly(α-L-glutamic acid) in the Helix-Coil Transition Region. To the eight data CD spectra shown in Fig. 6, the PCA procedure was applied in order to determine the number of components (or conformations) present in poly(Glu) in the pH range of 5.13—7.49.[21] The eigenvalues are plotted against the components in Fig. 7, in which a considerable gap is observed between the second and third components. Since the difference in $\log\Lambda_i$ between the first and the third components is about 4, the poly(Glu) system can be concluded to consist of two components. This is the result that has been anticipated from the data CD spectra which all cross each other at 203.5 nm (the isoelliptic point).[21] These components may be assigned to the helical and random-coil conformations of poly(Glu).

Although the mechanism of the pH-induced helix-coil transition has not yet been fully resolved, the pH-induced transition may be formally written as:

$$\text{Helix} \rightleftarrows \text{Coil} + H^+ \qquad (17)$$

with an equilibrium constant, K. The equilibrium expression for scheme (17) is difficult to derive theoretically. Hence, the modified Henderson-Hasselbalch equation[22,23] is utilized under the assumption that it represents the experimental data by adjusting the parameter, α:

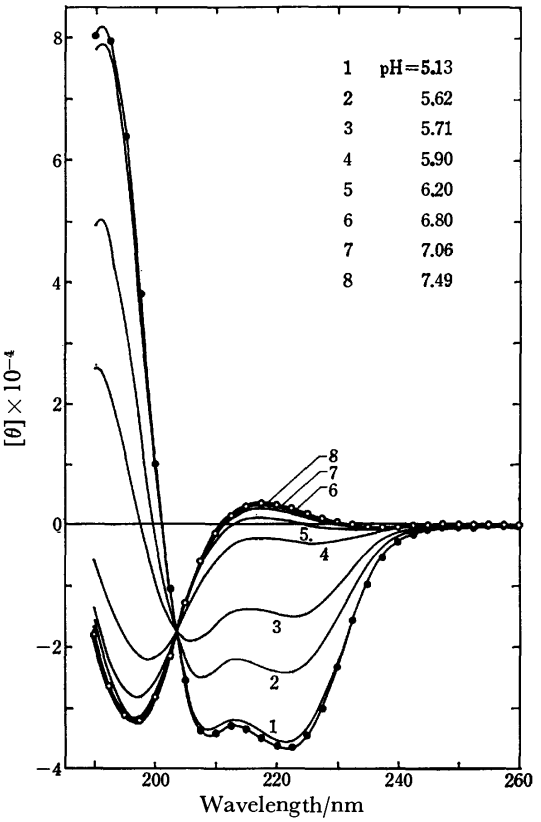

Fig. 6. The observed CD spectra of poly(α-L-glutamic acid) in the helix-coil transition region and the estimated pure helix (—●—) and pure coil (—○—) CD spectra. The data spectra are expressed with the molar ellipticity $[\theta]$ and taken from Ref. 21, to which the experimental details should be referred. The residue concentration was 8.0 mM in *ca.* 7.5 mM NaCl solutions throughout the pH range.

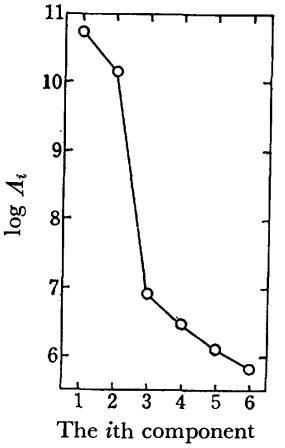

Fig. 7. The relation between the eigenvalue Λ_i and the ith component for the poly(Glu) system shown in Fig. 6.

$$\text{pH} = \text{p}K - \alpha\log\frac{[\text{Helix}]}{[\text{Coil}]}, \qquad (18)$$

where [Helix] and [Coil] denote the concentrations of the helix and coil conformations of poly(Glu). Equation 18 is quite suitable for the computer analysis, because it contains a single adjustable parameter, α, similar to the one that was determined uniquely in the ideal systems.

Table 2. The dependence of the S and $p\bar{K}$ values on the parameter, α, of the modified Henderson-Hasselbalch equation applied to the helix-coil transition of poly(Glu)

α	S	$p\bar{K}$
0.2	0.0262	5.75
0.3	0.0198	5.76
0.4	0.0150	5.74
0.5	0.0125	5.68
0.6	0.0132	5.60
0.7	0.0172	5.52
0.8	0.0229	5.41
0.9	0.0294	5.29
1.0	0.0368	5.18

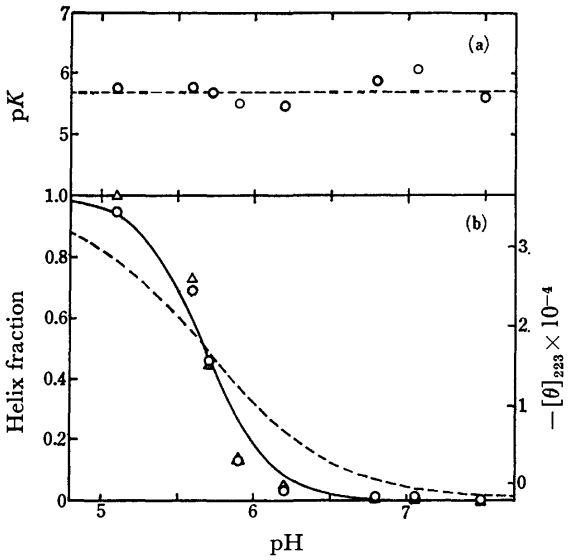

Fig. 8. (a) The pH dependence of pK values estimated from the PCA method and (b) the pH dependence of the helix fraction of poly(Glu). The helix fraction conventionally estimated from $[\theta]_{223}$ is indicated with triangles,[21] whereas the fraction obtained from the PCA procedure is denoted with circles. The solid curve was calculated by the use of the modified Henderson-Hasselbalch equation with $pK=5.68$ and $\alpha=0.5$. The dashed curve was calculated from the same equation with $\alpha=1$. For other details, see text.

The parameter should be considered to be only an empirical one which implicitly contains the effects on the conformational change of the ionic strength, the electrostatic surface potential, the shape factor, and other polyelectrolyte properties. The results of the PCA procedure are given in Table 2. Since the concentration of protons is measured in terms of pH, the S value is evaluated in terms of pK rather than K; it reaches its minimum at $\alpha=0.5$. The pK values for eight data CD spectra are plotted against pH in Fig. 8(a), where the average pK value, $p\bar{K}$, is 5.68 (dashed line). The pK values deviate from $p\bar{K}$ in a random fashion over the entire pH range, 5.1—7.5. This indicates that the PCA procedure is correctly applied to the appropriate equilibrium scheme.

The helix fraction at a given pH, which is defined as [Helix]/([Helix]+[Coil]), can be calculated from Eq. 18 with $p\bar{K}=5.68$ and $\alpha=0.5$. The results are plotted by the solid curve in Fig. 8(b). This curve is in good agreement with the helix fraction calculated from the $\boldsymbol{C}$ matrix by the PCA procedure (circles). Figure 8(b) also indicates that poly(Glu) is in the random-coil form almost completely at pH 7, but that nearly 95% of poly(Glu) is in the helix conformation at pH 5. The helix fraction has usually been calculated from the experimentally obtained molar ellipticity $[\theta]$ at a selected single wavelength, often at 222 or 223 nm, with the empirically chosen values of $[\theta]$ at two reference pH's which are assigned to the complete coil and helix conformations.[16,24] The results obtained from the PCA method make it clear that the conventional method (triangles) also yields a similar helix-coil transition curve.

It is worth emphasis that the modified Henderson-Hasselbalch equation with the single parameter, α, can describe the pH-induced helix-coil transition of poly(Glu) reasonably well over an entire pH range, permitting the evaluation of the helix fraction by the extended PCA method. The unmasked CD spectra for the complete helix and coil conformations are shown by filled and open circles respectively in Fig. 6. While the observed CD spectra at pH>7.1 may be considered as the pure CD spectrum for a coil, the pure CD spectrum for a helix is slightly higher than the highest observed CD spectrum at pH 5.13. Thus, the conventional estimation from $[\theta]_{223}$ would overestimate the helix fraction by approximately 5% in the low-pH region.

Finally, the results of the present work encourage the analysis of more complicated multicomponent systems, such as polylysine in alkaline solutions, in which three conformations (α-helix, β-structure, and random-coil) coexist, or natural proteins which undergo denaturation by environmental changes. For this purpose, our instrumental techniques must be improved so as to give highly accurate data worthy of the elaborate PCA procedure. The extended PCA method has so far been proved applicable to such optical spectra as the absorption, CD, and ORD. It may also be employed to analyze other spectral data like NMR, for which a Lambert-Beer-type linear combination rule holds.

Conclusion

The features of the extended PCA method as applied to both CD and ORD data of multicomponent equilibrium systems are: (1) the number of optically active components may be deduced from a set of data CD spectra or ORD curves (except for enantiomers), and (2) the unknown pure spectra of those components are determined by analyzing the data with appropriately chosen equilibrium expressions. Thus, the extended PCA method requires no presumption of the number of components (or conformations) or their characteristic spectra; these quantities must, by contrast, be assumed in other analytical methods. The application of the extended PCA method to the CD data of poly(Glu) has confirmed that the pH-induced helix-coil transition

can be described by a two-state equilibrium model over the pH range of 5.1—7.5.

Spin Exchange and Translational Diffusion of Nitroxide Radicals in Micelles. ESR Experiments and Spectra Simulation by Modified Bloch Equations

Masayuki AIZAWA,* Tsuyoshi KOMATSU, and Tsurutaro NAKAGAWA
Department of Polymer Science, Faculty of Science, Hokkaido University, Sapporo 060
(Received August 6, 1979)

The dependence of the ESR linewidth of hydrophobic radicals on their concentration in micelles is investigated in two solubilization systems at several temperatures. One system consists of 2,2,6,6-tetramethyl-4-benzoyloxy-1-piperidinyloxyl (BzONO) as a solubilizate and hexadecyltrimethylammonium bromide (CTAB) as a surfactant, and the other, of 2,2,6,6-tetramethyl-4-myristoyloxy-1-piperidinyloxyl (MyONO) and sodium dodecyl sulfate (SDS). The plot of the linewidth against the mole fraction of the radical is not represented by a straight line, as in the previous study. The propriety of the two kinds of models for the solubilization states of radicals which were proposed in the previous paper to explain the unusual shape of these plots is examined by spectra simulation with modified Bloch equations. As these models have proved to be inadequate, a new model taking account of the distribution of the radicals among the micelles is proposed. The simulation based on this model shows a good agreement with the experimental results. The translational diffusion coefficients of radicals in micelles are estimated on the basis of this model. Their values are in the range of $(1.5—2.9)\times10^{-11}$ m²/s.

In the previous study,[1] linewidth measurements of the ESR spectra of 2,2,6,6-tetramethyl-4-benzoyloxy-1-piperidinyloxyl (BzONO, Fig. 1(a)) in sodium dodecyl sulfate (SDS) micelles were carried out at various concentrations of BzONO. The plot of the linewidth, W, against the mole fraction, X, of the radical in micelles did not yield a straight line; rather, a break point seemingly appeared at a certain mole fraction, X_B. Except for one other workers' study,[2] no results like this have yet been reported.

Considering the electron spin-spin relaxation mechanism which causes the line broadening, it was inferred that the dipolar interaction predominates at $X<X_B$, whereas the spin-exchange interaction predominates at $X\geqq X_B$. This inference is based on the temperature dependence of the gradients of the lines in the two mole fraction ranges: at $X<X_B$, the gradient decreases with an increase in the temperature, but at $X\geqq X_B$, it behaves inversely.

In order to explain these unusual results, three kinds of models for a solubilization state of radicals were proposed. From the two of them, the translational diffusion coefficients of BzONO in SDS micelles at 31 °C were estimated to be 1.6×10^{-11} and 2.4×10^{-11} m²/s respectively.

Recently, studies of micellar solutions have been carried out with fluorescent probes.[3] The measurements of the fluorescence decay or quenching, the excimer formation, and so on have brought out several interesting pieces of information on micellar properties.

Some abnormal results, however, have been reported by these studies. For instance, Khuanga and his coworkers[4] have found that the concentration dependence of the intensity ratio ϕ'/ϕ of excimer/monomer fluorescence of pyrene in a 0.1 M aqueous SDS solution is not linear, but curves upwards at higher concentrations, and that when the quencher, oxygen, is added to the solution, the ϕ'/ϕ is increased. In homogeneous solutions, however, the addition of quenchers never increases ϕ'/ϕ. They have explained these results qualitatively on the basis of the distribution of the pyrene molecules among the micelles.

The unusual results obtained in our previous study may also be explained on the same basis.

Thus, the purposes of the present study are: a) to assure that other solubilization systems give a similar, unusual behavior of the W-X plots; b) to reexamine the propriety of the three models in the previous paper; c) to examine whether or not the behavior of the W-X plots can be explained by the distribution of the solubilizates among the micelles, and, finally, d) to estimate more reasonably the translational diffusion coefficients of the radicals in the surfactant micelles.

In order to achieve b) and c), the experimental spectra will be simulated by modified Bloch equations, including the terms for two exchange processes: spin exchange in the micelles and exchange of radicals between the bulk water and the micellar environment.

Experimental

The nitroxide radical, 2,2,6,6-tetramethyl-4-myristoyloxy-1-piperidinyloxyl (MyONO, Fig. 1(b)), was synthesized by the reaction of the corresponding acid chloride with the nitroxide alcohol in a way similar to that in the literature.[5] The crude MyONO was purified by Mr. Fujioka by column chromatography with silica gel (CH_2Cl_2 as the eluent), and then distilled at 122—124 °C under 1 mmHg. The results of the elemental analysis of MyONO was as follows: Found: C, 72.41; H, 11.71; N, 3.43%. Calcd for $C_{23}H_{44}NO_3$: C, 72.20; H, 11.59; N, 3.66%; mol wt 382.6.

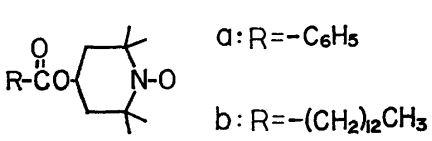

Fig. 1. (a) BzONO and (b) MyONO.

Hexadecyltrimethylammonium bromide (CTAB) of an extra pure grade was recrystallized several times from water solutions. Its CMC was 9.2×10^{-4} mol/dm³ at 25 °C.

In order to estimate the solubilization limits of radicals in surfactant solutions, the ESR spectra of radicals in the saturated solutions were recorded at 20, 30, and 40 °C.

The calculation of the spectra simulation was executed by means of the FACOM 230-60/75 computer in the Hokkaido University Computing Center.

The other experimental procedures and materials have been described in previous papers.[1,6]

Results and Discussion

As an example of the homogeneous solutions, the *W-X* plot of BzONO in ethanol is shown in Fig. 2. The linear relationship between W and X in the figure agrees with the theory of spin-spin interaction in homogeneous solutions.[7]

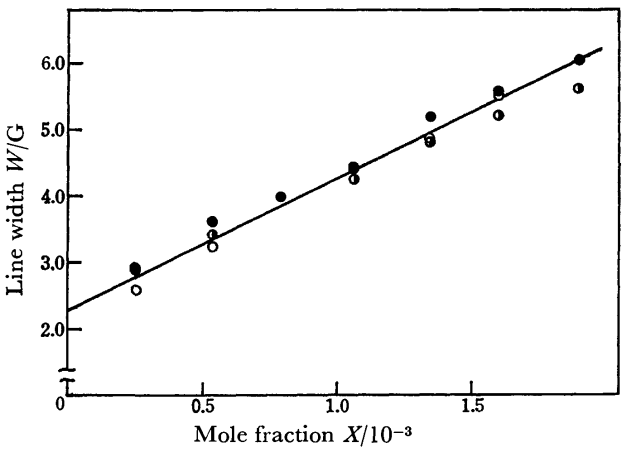

Fig. 2. Plot of W against X of BzONO in ethanol solution at 21 °C. ○: $M_I=+1$, ◑: $M_I=0$, and ●: $M_I=-1$ line width.

In SDS micelles in water, however, the same plot gives a straight line with a break point, as was reported in a previous paper.[1]

In the present study, two solubilization systems, BzONO/CTAB and MyONO/SDS, are investigated at several temperatures in a similar way.

Figures 3 and 4 show the *W-X* plots of MyONO/SDS at 30 °C and of BzONO/CTAB at 40 °C respectively. It may be observed that there is no simple linear relationship between W and X such as is seen in Fig. 2. The plots of the other results showed similar behavior.

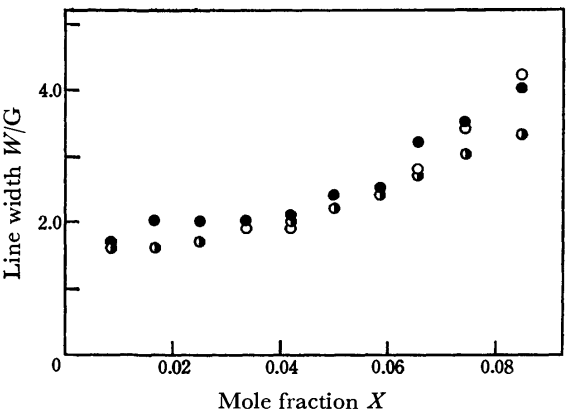

Fig. 3. Plot of W against X of MyONO in SDS micelles at 30 °C. ○: $M_I=+1$, ◑: $M_I=0$, and ●: $M_I=-1$ line width. [SDS]=5.30 wt%.

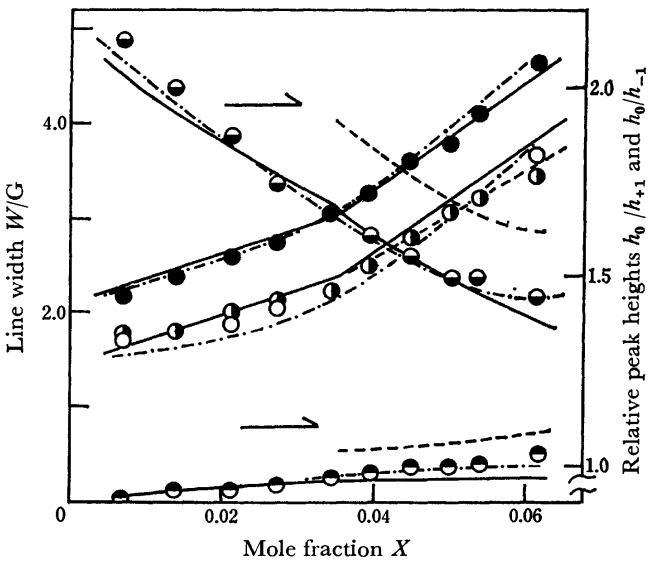

Fig. 4. Plots of W, h_0/h_{+1}, and h_0/h_{-1} against X of BzONO in CTAB micelles at 40 °C.
○: $M_I=+1$, ◑: $M_I=0$, and ●: $M_I=-1$ line width; ◓: h_0/h_{+1} and ◒: h_0/h_{-1}. [CTAB]=5.12%. Full, dotted and dot-dash lines represent the same plots obtained by the simulation with Model 1, Model 2, and the new model in which the distribution of solubilizates among micelles is considered, respectively.

If one considers that the plots can be represented by a straight line which breaks at a certain mole fraction, X_B, the value of X_B is estimated to be 0.035 for BzONO/CTAB and 0.045 for MyONO/SDS. The latter value coincides with that for BzONO/SDS.[1]

Thus, it may be concluded that, in the cases of radicals in ionic micelles in water, the concentration dependence of the linewidth is different from that in homogeneous solutions.

In the previous paper,[1] in seeking to explain this behavior of the *W-X* plots, three kinds of models for the solubilization states of the radicals in the micelles were proposed; they could account for, at least, the appearance of a break point. The propriety of the models, however, must also be examined by spectra simulation with modified Bloch equations.[8]

In the present solubilization systems, most of the nitroxide radicals are solubilized in a micellar environment, while a small amount of them is dissolved in the bulk water. In each of the two environments, the radicals exist in three energy states, which are split by the contact interaction between an electron spin ($S=1/2$) and a ^{14}N nuclear spin ($I=1$). Between the six energy states, there are two exchange processes: one is the exchange of a radical between the micellar environment and the bulk water,[9] and the other is a spin exchange in the micellar environment.[10] The spin exchange in the bulk water can be disregarded, since a molecular collision between radicals scarcely occurs in it at all.

Thus, the exchange scheme in the system is illustrated by Fig. 5. The symbols in the figure, W_{-1}, W_0, and W_{+1}, represent the three states in the bulk water, and M_{-1}, M_0, and M_{+1}, those in the micellar environment.

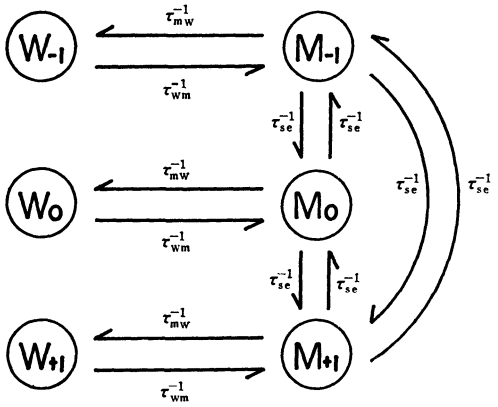

Fig. 5. Proposed scheme of radical exchange.

Their subscripts, -1, 0, and $+1$, correspond to the quantum numbers of a ^{14}N nuclear spin. τ_{mw}^{-1}, τ_{wm}^{-1}, and τ_{se}^{-1} are the exchange probabilities in the corresponding processes.

The modified Bloch equations including these exchange processes are formulated as follows:

$$\begin{cases} dG_{-1}^{w}/dt + \alpha_{-1}^{w}G_{-1}^{w} = Lp_{-1}^{w} - \tau_{wm}^{-1}G_{-1}^{w} + \tau_{mw}^{-1}G_{-1}^{m} \\ dG_{0}^{w}/dt + \alpha_{0}^{w}G_{0}^{w} = Lp_{0}^{w} - \tau_{wm}^{-1}G_{0}^{w} + \tau_{mw}^{-1}G_{0}^{m} \\ dG_{+1}^{w}/dt + \alpha_{+1}^{w}G_{+1}^{w} = Lp_{+1}^{w} - \tau_{wm}^{-1}G_{+1}^{w} + \tau_{mw}^{-1}G_{+1}^{m} \\ dG_{-1}^{m}/dt + \alpha_{-1}^{m}G_{-1}^{m} = Lp_{-1}^{m} + \tau_{wm}^{-1}G_{-1}^{w} - \tau_{mw}^{-1}G_{-1}^{m} \\ \qquad + \tau_{se}^{-1}(G_{+1}^{m}+G_{0}^{m}) - 2\tau_{se}^{-1}G_{-1}^{m} \\ dG_{0}^{m}/dt + \alpha_{0}^{m}G_{0}^{m} = Lp_{0}^{m} + \tau_{wm}^{-1}G_{0}^{w} - \tau_{mw}^{-1}G_{0}^{m} \\ \qquad + \tau_{se}^{-1}(G_{-1}^{m}+G_{+1}^{m}) - 2\tau_{se}^{-1}G_{0}^{m} \\ dG_{+1}^{m}/dt + \alpha_{+1}^{m}G_{+1}^{m} = Lp_{+1}^{m} + \tau_{wm}^{-1}G_{+1}^{w} - \tau_{mw}^{-1}G_{+1}^{m} \\ \qquad + \tau_{se}^{-1}(G_{0}^{m}+G_{-1}^{m}) - 2\tau_{se}^{-1}G_{+1}^{m} \end{cases} \quad (1)$$

where:

$$\alpha_{-1}^{w} = T_{2w}^{-1}(-1) + i(H-H_{-1}^{w}),$$
$$\alpha_{-1}^{m} = T_{2m}^{-1}(-1) + i(H-H_{-1}^{m}),$$
$$\alpha_{0}^{w} = T_{2w}^{-1}(0) + i(H-H_{0}^{w}),$$
$$\alpha_{0}^{m} = T_{2m}^{-1}(0) + i(H-H_{0}^{m}),$$
$$\alpha_{+1}^{w} = T_{2w}^{-1}(+1) + i(H-H_{+1}^{w}),$$
$$\alpha_{+1}^{m} = T_{2m}^{-1}(+1) + i(H-H_{+1}^{m}),$$

and $L=-2\pi i\nu M_0$=constant.

The notations in these equations have the following meanings.

G_{-1}^{w}, G_{0}^{w}, G_{+1}^{w}, and G_{-1}^{m}, G_{0}^{m}, G_{+1}^{m}: the complex magnetic moments at the energy states, with $M_I=-1$, 0, $+1$ in the bulk water, and with $M_I=-1$, 0, $+1$ in the micellar environment respectively.

$T_{2w}^{-1}(-1)$, $T_{2w}^{-1}(0)$, $T_{2w}^{-1}(+1)$, and $T_{2m}^{-1}(-1)$, $T_{2m}^{-1}(0)$, $T_{2m}^{-1}(+1)$: the spin-spin relaxation rates in the energy states, with $M_I=-1$, 0, $+1$ in the bulk water, and with $M_I=-1$, 0, $+1$ in the micellar environment respectively.

p_{-1}^{w}, p_{0}^{w}, p_{+1}^{w}, and p_{-1}^{m}, p_{0}^{m}, p_{+1}^{m}: the mole fractions of the radicals in the energy states, with $M_I=-1$, 0, $+1$ in the bulk water, and with $M_I=-1$, 0, $+1$ in the micellar environment respectively. $p_{-1}^{w}=p_{0}^{w}=p_{+1}^{w}=(1/3)p_w$, $p_{-1}^{m}=p_{0}^{m}=p_{+1}^{m}=(1/3)p_m$.

H_{-1}^{w}, H_{0}^{w}, H_{+1}^{w}, and H_{-1}^{m}, H_{0}^{m}, H_{+1}^{m}: the strength of the resonance magnetic fields in the energy states, with $M_I=-1$, 0, $+1$ in the bulk water, and with $M_I=-1$, 0, $+1$ in the micellar environment respectively. $H_{-1}^{w}-H_{0}^{w}=H_{0}^{w}-H_{+1}^{w}$, $H_{-1}^{m}-H_{0}^{m}=H_{0}^{m}-H_{+1}^{m}$.

ν: the frequency of the applied rotating rf field.

M_0: the z-component of the equilibrium magnetic moment.

i: the imaginary unit.

The sum of the solutions of these equations under the condition that $dG_{-1}^{w}/dt=\cdots=dG_{+1}^{m}/dt=0$ gives the total complex magnetic moment, G, in the stationary state. The real part of G corresponds to the dispersion line, and the imaginary part, to the absorption. Since the first derivative of the absorption line is recorded in the ESR experiment, the first derivative of G is obtained; its imaginary part, $f(H)$, is calculated for the sake of the spectra simulation as a function of the strength of the magnetic field, H—in practice, as a function of $(H-H_0^w)$.

Among the input values needed for the calculation of $f(H)$, τ_{mw}^{-1}, τ_{se}^{-1}, and the mole fraction, p_m, of the radicals in the micelles are fitting parameters, since $p_w=1-p_m$ and $\tau_{wm}^{-1}=\tau_{mw}^{-1}p_m/p_w$ hold. In the present systems, p_m is nearly equal to 1.0 and τ_{mw}^{-1} is negligibly small, as was reported in previous papers.[11,12]

Moreover, the spin-spin relaxation rate, T_{2D}^{-1}, by the dipolar interaction must be introduced as a parameter, since, in all three models, the dipolar interaction is considered to be an electron spin-spin interaction as well as a spin-exchange interaction. T_{2D}^{-1} is added to the spin-spin relaxation rates, T_{2m}^{-1}'s, in the micelles.

The other input values are obtained from the ESR spectra at a low radical concentration in water and from those in micelles. The values of T_{2m}^{-1}'s, however, are corrected to fit the experimental values of the relative peak heights of the three lines. This is because the linewidth, $W(=(2/\sqrt{3})T_2^{-1})$, in the present systems contains a contribution from the protons in the methyl groups adjacent to a nitroxide group in addition to that from a ^{14}N nuclear spin.[13] Equation 1 includes only the effect of a ^{14}N nuclear spin.

The concentration dependences of T_{2D}^{-1} and τ_{se}^{-1} as parameters will now be described on the basis of the respective models.

Model 1. According to this model, a micelle is constituted of several clusters of some surfactant molecules. Therefore, below the break point, X_B, which corresponds to the concentration at which each cluster solubilizes just one radical, only the dipolar interaction occurs.

On the other hand, above X_B, the spin-exchange interaction relaxes the electron spins as well as the dipolar interaction.

Thus, T_{2D}^{-1} and τ_{se}^{-1} can be written, at $X<X_B$, as:

$$\begin{cases} T_{2D}^{-1} = K_D X \\ \tau_{se}^{-1} = 0, \end{cases} \quad (2\text{-a})$$

and at $X\geqq X_B$, as:

$$\begin{cases} T_{2D}^{-1} = K_D X \\ \tau_{se}^{-1} = k_E'(X-X_B), \end{cases} \quad (2\text{-b})$$

where K_D and k_E' are the proportionality constants.

Model 2. In this model, X_B is regarded as the concentration at which a structural change in the micelles is induced by the solubilization. This structural

change quickly makes the dipolar interaction weaker near X_B.

T_{2D}^{-1} and τ_{se}^{-1} are given by the following expressions: At $X<X_B$;

$$\begin{cases} T_{2D}^{-1} = K_D X \\ \tau_{se}^{-1} = 0. \end{cases} \quad (3\text{-a})$$

At $X \geqq X_B$;

$$\begin{cases} T_{2D}^{-1} = 0 \\ \tau_{se}^{-1} = k'_E X. \end{cases} \quad (3\text{-b})$$

Model 3. This model, in which some association of the radicals in equilibrium with the monomeric one in a micelle is assumed, cannot be employed in the simulation, because it is impossible to separate the signal of the radical associates from that of monomeric ones. This fact indicates that this model is not applicable to the solubilization state of radicals.

Thus, on the first two models, the simulation was carried out by the calculation of $f(H)$ using the values of $p_m=1.0$ and $\tau_{mw}^{-1}=0$ and the parameters of τ_{se}^{-1} and T_{2D}^{-1}. The values of parameters which fit the experimental linewidth and the relative peak height were thus found.

The full lines and dotted lines in Fig. 4 represent the results of the simulations with Model 1 and Model 2 respectively. The relative peak heights, h_0/h_{+1} and h_0/h_{-1}, indicate the ratios of the peak height of the central line ($M_I=0$) to that of the low- ($M_I=+1$) and high-field ($M_I=-1$) lines respectively.

The full lines with $K_D=20.1$ G ($=2.01\times10^{-3}$ T) and $k'_E=15.6$ G and the dotted ones with $K_D=20.1$ G and $k'_E=25.7$ G agree with the experimental values so far as the linewidth is concerned. There is, however, a difference in the relative peak heights. The experimental values of h_0/h_{-1} decrease monotonously throughout the mole-fraction range, while the full line has a discontinuity of its gradient at X_B and does not agree with the experimental values at lower and higher mole fractions. The dotted line also has a discontinuity at X_B. (At $X<X_B$, the dotted lines coincide with the full ones).

Therefore, it can be said that each of the three models proposed in the previous study is improper as a basis for the calculation of the translational diffusion coefficients of the radicals in the micelles.

Another way to explain the unusual W-X plot is by taking account of the distribution of the radicals among the micelles. If one regards a micelle as a thermodynamical system which is surrounded by an aqueous phase and which is exchanging its components with the aqueous phase, there may be a certain distribution in the number of the radicals among the micelles.

The distribution function, $P_m(n)$, is described by the following equation, known as the binomial function:[14]

$$P_m(n) = {}_{N_m}C_n \chi^n/(1+\chi)^{N_m}, \quad (4)$$

$$\chi = \langle n\rangle/(N_m-\langle n\rangle), \quad (5)$$

where ${}_{N_m}C_n$ is the binomial coefficient; N_m, the maximum number of solubilizates in a micelle; χ, the quantity defined by Eq. 5 and related with the chemical potential of solubilizates in micelles, and $\langle n\rangle$, the mean number of solubilizates in a micelle.

$P_m(n)$ indicates the fraction of the number of micelles with n solubilizates in relation to the total micelles. This function is obtained on the assumptions that χ is independent of n and that all the micelles have the same N_m value. If $n \ll N_m$, the Poisson distribution function can be derived from Eq. 4.

Transforming $P_m(n)$ into the probability, $P_r(n)$, that a solubilizate belongs to a micelle with n solubilizates, one can write:

$$P_r(n) = nP_m(n)/\sum_{n=1}^{N_m} nP_m(n). \quad (6)$$

If the line-shape function, $f_n(H)$, of a radical in a micelle with n radicals is given, the apparent line-shape function, $F(H)$, is calculated as:

$$F(H) = \sum_{n=1}^{N_m} P_r(n) f_n(H). \quad (7)$$

Thus, the spectra simulation on this model is carried out as follows.

Firstly, $f_n(H)$ is calculated using four parameters, p_m, τ_{se}^{-1}, τ_{mw}^{-1}, and T_{2D}^{-1}, in the same way as in the previous case of $f(H)$. τ_{mw}^{-1}, however, can be neglected for the above-mentioned reason. T_{2D}^{-1} is also omitted, since the radicals in the micelles have enough mobility to make the dipolar interaction fade away, according to Scandella and his co-workers' results.[15]

The spin-exchange rate, τ_{se}^{-1} in a micelle with n radicals is described as:

$$\tau_{se}^{-1} = K_s(n-1)(N_s+1)/(N_s+n-1), \quad (8)$$

where K_s is constant and corresponds to τ_{se}^{-1} when $n=2$, and where N_s is the aggregation number of the surfactant molecules in a micelle. Here, as N_s, the mean aggregation number given in the literature[3] is used in the case of CTAB. However, in the SDS system, one is obliged to use a value lower than that in the literature, since the value in the literature produces the break point at a mole fraction lower than the experimental one. As p_m in Eq. 1, values near 1.0 are used.

TABLE 1. INPUT VALUES USED IN SPECTRA SIMULATION

	a_N^w/G	a_N^m/G	Δg_{mw}/G	N_s	N_m
BzONO/SDS	17.1	16.7	0.2	54	7
MyONO/SDS	17.1	16.6	0.2	54 (44)[a]	11 (9)[a]
BzONO/CTAB	17.1	16.3	0.4	60	6

a) The values at 40 °C.

These values and other input values are listed in Table 1. $a_N^w(=(H_{-1}^w-H_{+1}^w)/2)$ and $a_N^m(=(H_{-1}^m-H_{+1}^m)/2)$, respectively, mean the isotropic hyperfine splitting constants of the radicals in the bulk water and in the micellar environment. Δg_{mw} represents the difference in the resonance magnetic field of the central line between the two environments, $H_0^w-H_0^m$.

Secondly, using arbitrary values of $\langle n\rangle$ lower than N_m, $P_m(n)$ is calculated by means of Eqs. 4 and 5, and then $P_r(n)$ is derived from Eq. 6. Here, N_m is obtained from a mole fraction of a radical saturated in a micelle. The estimation of its mole fraction is performed by plotting the linewidth of the ESR spectra of the radicals

TABLE 2. K_s VALUES AND TRANSLATIONAL DIFFUSION COEFFICIENTS OF NITROXIDE RADICALS IN MICELLES

Temp °C	BzONO/SDS		MyONO/SDS		BzONO/CTAB	
	K_s/G	$D_{tr}/10^{-11}$ m^2 s^{-1}	K_s/G	$D_{tr}/10^{-11}$ m^2 s^{-1}	K_s/G	$D_{tr}/10^{-11}$ m^2 s^{-1}
20	0.40—0.45	1.8—2.0	0.33—0.35	1.5—1.6		
30	0.53—0.58[a)]	2.4—2.6[a)]	0.38—0.43	1.7—1.9	0.35—0.38	1.9—2.0
40	0.60—0.65	2.7—2.9	0.60—0.63	2.2—2.3	0.40—0.45	2.1—2.4
50					0.45—0.50	2.4—2.7

a) The values at 31°C.

saturated in the micellar solution on the W-X curves.

Finally, by substituting these $f_n(H)$ and $P_r(n)$ into Eq. 7, the apparent line-shape function, $F(H)$, at $<n>$ is obtained. If one executes a similar calculation of $F(H)$ with various values of $<n>$, the W-X plot can be represented by this relation: $<n>=Xp_mN_s/(1-X)$.

The dot-dash lines in Fig. 4 show the results of simulation on BzONO/CTAB at 40 °C by the calculation of $F(H)$. These lines were obtained by the simulation with $p_m=0.98$ and $K_s=0.45$ G. It may be observed that the dot-dash lines are in good agreement with the experimental values.

Therefore, it may be said that the appearance of an apparent break point in the W-X plot is caused by the distribution of the radicals among the micelles. The relation that the peak heights are inversely proportional to the square of their linewidths in the spectra of the Lorentzian lineshape contributes greatly to the phenomenon.

All the other systems are also simulated very well by this scheme. The values of K_s which give the best fits are listed in Table 2.

The translational diffusion coefficients, D_{tr}, of the nitroxide radicals in the micelles were calculated with the following equation, using these K_s values:

$$D_{tr} = \gamma_e K_s \lambda^2 (1+N_s)/4\pi \quad (9)$$

where $\gamma_e(=1.7608\times10^7$ s/rad·G) is the magnetogyric ratio of the electron and where λ^2 is the surface area of one polar head group. The values of λ^2 in the SDS micelles and the CTAB micelles are 5.8×10^{-15} and 6.2×10^{-15} cm^2 respectively.[16] Strictly speaking, the effects of the difference in the solubilization site of the solubilizates and of the deformation of the micellar shape induced by the solubilization of the radicals must also be taken into account in Eq. 9.

The values of D_{tr} obtained are listed in Table 2. These values are of the order of 10^{-11} m^2/s, the same as in the previous study.[1] They are taken to be reliable enough, because they are calculated on a reasonable model, as has been revealed in the above simulation.

It may be noticed in Table 2 that, at the same temperature, D_{tr} in BzONO/SDS is greater than in either MyONO/SDS or BzONO/CTAB. This fact may be related to the strength of the adhesion between the hydrophobic groups of the radicals and those of the surfactant molecules.

We would like to thank Professor Yoshio Matsunaga of the Department of Chemistry in Hokkaido University for his kind permission to use the ESR instruments.

The Vibrational Fine Structure of the $^1T_{1g}\leftarrow{}^1A_{1g}$ Absorption Band of $[Co(NH_3)_6]^{3+}$

Yoshinori Komi and Akio Urushiyama*

Department of Chemistry, Faculty of Science, Rikkyo University, Nishiikebukuro, Toshima-ku, Tokyo 171

(Received August 17, 1979)

The crystal absorption spectra of $[Co(NH_3)_6][Ir(CN)_6]$ and $[Co(ND_3)_6][Ir(CN)_6]$ were studied at 4.2 K. The vibrational fine structure observed on the $^1T_{1g}\leftarrow{}^1A_{1g}$ absorption band of the hexaamminecobalt(III) complexes was interpreted in terms of a vibronic intensity scheme in comparison with the vibrational frequencies of the complexes. The deuteration shifts helped to confirm the assignments of the structure. It was found that, as well as the skeletal vibrations of the CoN_6 group, the NH_3 (and ND_3) rocking and the H–N–H symmetric deformation modes are effective in the vibronic intensity mechanism of the bands.

The vibrational fine structure of the $^1T_{1g}\leftarrow{}^1A_{1g}$ absorption band of $[Co(NH_3)_6]^{3+}$ was first studied by Wentworth.[1] He observed, in his low-temperature spectroscopic work, that at least twelve members of a progression with a spacing of about 420 cm^{-1} were superimposed on the band. Since then, several reports[2] have appeared concerning the temperature dependence of the band intensity and the vibronic interaction with the odd skeletal modes of the CoN_6 group. Recently, we examined the transmission spectra of $[Co(NH_3)_6][Co(CN)_6]$ at 4.2 K and resolved each progressional line into several components.[3] As a result of these transmission studies, it is thought that measurements with a higher resolution may give definite information as to the structure of the band.

It is our experience that the clarity of the fine structure observed on the $^1T_{1g}\leftarrow{}^1A_{1g}$ absorption band of the hexaamminecobalt(III) complexes is very dependent on particular crystal lattices. In the present paper, the low-temperature crystal-absorption spectra of $[Co(NH_3)_6][Ir(CN)_6]$ and $[Co(ND_3)_6][Ir(CN)_6]$ will be reported. These crystals showed the most extensive structure in our studies. The observed fine structure was interpreted on the basis of the infrared and Raman data of the complexes.

Experimental

Single-crystals of $[Co(NH_3)_6][Ir(CN)_6]$ were obtained when aqueous solutions of $[Co(NH_3)_6]Cl_3$ and $K_3[Ir(CN)_6]$ were mixed extremely slowly in a glass tube. The infrared and Raman spectra suggested that the skeletons of the complexes are retained through the procedure. Found: Co, 11.7%. Calcd for $[Co(NH_3)_6][Ir(CN)_6]$: Co, 11.6%. The deuterium-substituted compound was similarly obtained from D_2O solutions. The infrared and Raman bands of the hexaamminecobalt(III) complex shifted toward the low-wavenumber side (Table 1). Weissenberg photographs showed that the crystal of $[Co(NH_3)_6][Ir(CN)_6]$ belongs to the trigonal crystal system, $a=7.35(2)$ Å, $\alpha=97.9(1)°$, with the space group of R3 or $R\bar{3}$. The crystals of $[Co(ND_3)_6][Ir(CN)_6]$ are found to be very similar in appearance to those of $[Co(NH_3)_6][Ir(CN)_6]$ under a microscope. The low-temperature polarized absorption spectra of appropriate crystal samples were measured by the method previously reported.[3] All the spectra were taken with a spectral slit width of less than 160 μm, which corresponds to a resolution of 10 cm^{-1}. The fine structure observed on the band of $[Co(ND_3)_6]^{3+}$ was obscured after several days' exposure of the sample crystal in room air. The temperatures of an indium plate in which the samples were set with Apiezon N grease on a pinhole ($\phi=0.1$ mm) were monitored by means of a thermocouple (Au: Fe chromel). The sample dimensions were estimated by the use of a micrometer ocular. The infrared and Raman spectra were taken with a JASCO IR-F spectrometer and Narumi 750Z-1200 Raman spectrometer respectively.

Results and Discussion

Figures 1 and 2 show the crystal absorption spectra of $[Co(NH_3)_6][Ir(CN)_6]$ and $[Co(ND_3)_6][Ir(CN)_6]$ respectively in the $^1T_{1g}\leftarrow{}^1A_{1g}$ absorption region of the hexaamminecobalt(III) complexes. The counter complex anion, $[Ir(CN)_6]^{3-}$, can be expected to show no absorption in the visible region.[4] Some structure was detected also on the $^1T_{2g}\leftarrow{}^1A_{1g}$ absorption bands in the near-ultraviolet region. However, no detailed analysis was possible because of the low resolution. The absorption spectra taken with the polarized lights whose electric vectors are parallel and perpendicular to the crystal [111] axis were observed to be almost identical in the two samples.

It was found that the $^1T_{1g}\leftarrow{}^1A_{1g}$ band of $[Co(NH_3)_6]^{3+}$ consists of the progressional members of,

Table 1. Vibrational frequencies of hexaamminecobalt(III) complexes[a]

	$\delta_s(NH_3)$, (ND_3) / cm^{-1}	$\rho_r(HNH)$, (DND) / cm^{-1}	$\nu_1(a_{1g})$ / cm^{-1}	$\nu_2(e_g)$ / cm^{-1}	$\nu_3(t_{1u})$ / cm^{-1}	$\nu_4(t_{1u})$ / cm^{-1}	$\nu_6(t_{2u})$ / cm^{-1}

a) Vibrations are denoted according to K. Nakamoto, "Infrared and Raman Spectra of Inorganic and Coordination Compounds," 3rd ed, John Wiley and Sons, New York (1978). b) T. V. Long, II, A. W. Herlinger, E. F. Epstein, and I. Bernal, *Inorg. Chem.*, **9**, 459 (1970). c) K. H. Schmidt and A. Muller, *J. Mol. Struct.*, **22**, 343 (1974). d) Present work on $[Co(ND_3)_6][Ir(CN)_6]$. e) W.A. Yeranos, *Inorg. Chem.*, **7**, 1259 (1968).

apparently, five structure components, (*na*), (*nb*), (*nc*), (*nd*), and (*nf*). The average spacing of the progression was estimated to be 401 cm^{-1}. In the case of $[Co(ND_3)_6]^{3+}$, the spacing of the progression was reduced to 370 cm^{-1}, and a new component, (*ne*), appeared distinctly in the lower-wavenumber vicinity of the $(n+1\,d)$ components. However, the energy differences between the components of (*na*), (*nb*), (*nc*), and (*nd*) exerted no significant change on the deuteration of the ligands.

Assuming a vibronic intensity scheme, the positions of the structure components can be expressed as $^1A_{1g}(O) \rightarrow {}^1T_{1g}(O') + \nu_i + n\nu_j$, where ν_i=the frequency of the odd vibration, ν_j=the frequency of the even vibration, and n=the integer. A large displacement of the potential surface of the electronic excited state from that of the ground state along the Q_j internal coordinate gives a long Frank-Condon progression with a spacing corresponding to that of ν_j on the band. An electronic excitation to the anti-bonding e_g orbital may relax the Co–N bonds and result in some frequency reductions in the electronic excited state.

The vibrational frequencies of the complexes studied are summarized in Table 1. The observed average spacings of 401 and 370 cm^{-1} may be correlated to the $\nu_1(a_{1g})$ vibrations of the CoN_6 skeletons of $[Co(NH_3)_6]^{3+}$ and $[Co(ND_3)_6]^{3+}$ respectively. However, as in the case of the $^4T_{2g} \leftarrow {}^4A_{2g}$ absorption band of $[Cr(NH_3)_6]^{3+}$ discussed by Wilson *et al.*,[5] there is, indeed, a possibility that the $\nu_2(e_g)$ mode is involved in the progression of the bands. In general, the $\nu_1(a_{1g})$ and the $\nu_2(e_g)$ M–N stretching modes of the hexacoordinated transition metal complexes are observed to have almost the same frequencies.[6] Therefore, further spectroscopic studies are necessary for more reliable assignments of the progression observed on the bands associated with the $t_{2g} \rightarrow e_g$ electronic transition of the complexes.

It is known[6] that the frequencies of the CoN_6 skeletal vibrations of the hexaamminecobalt(III) complex are lowered by about 10% on the deuteration of the ligands, whereas the NH_3 rocking, the H–N–H deformation, and the N–H stretching frequencies are reduced by as much as 20—28% on the deuteration. If the observed intervals between the components are compared with those of the infrared frequencies shown in the table, the following assignments seem reasonable:

(*na*) $\cdots {}^1A_{1g}(O) \longrightarrow {}^1T_{1g}(O') + \nu_{lattice} + n\nu_1(\nu_2)$
(*nb*) $\cdots + \nu_6 + n\nu_1(\nu_2)$
(*nc*) $\cdots + \nu_4 + n\nu_1(\nu_2)$
(*nd*) $\cdots + \nu_3 + n\nu_1(\nu_2)$
(*ne*) $\cdots + \nu(NH_3, ND_3 \text{ rocking}) + n\nu_1(\nu_2)$
(*nf*) $\cdots + \nu(\text{H–N–H sym. def.}) + n\nu_1(\nu_2)$.

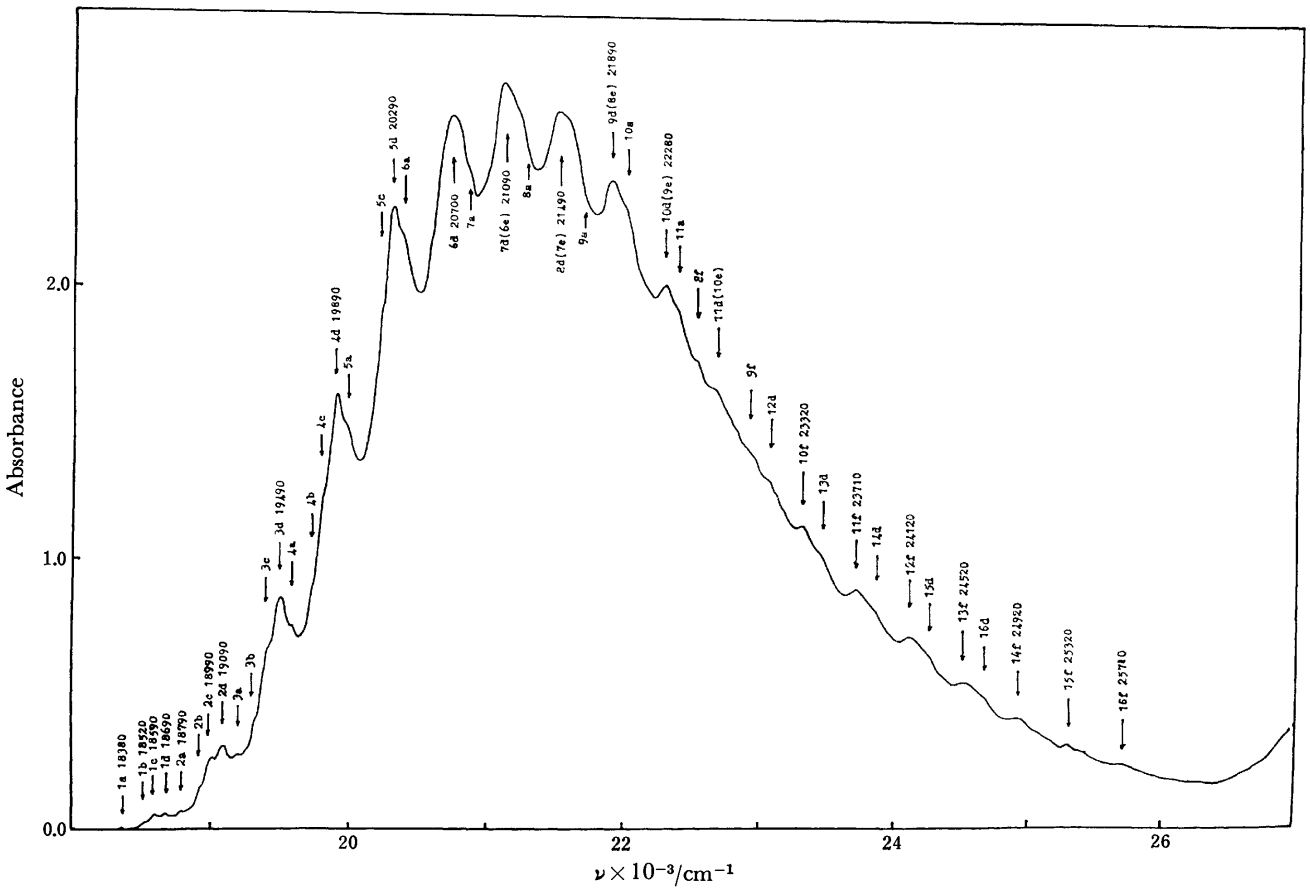

Fig. 1. Crystal absorption spectrum of $[Co(NH_3)_6][Ir(CN)_6]$ at 4.2 K with the polarized light whose electric vector parallel to the crystal [111] axis (crystal thickness is 0.14 mm).

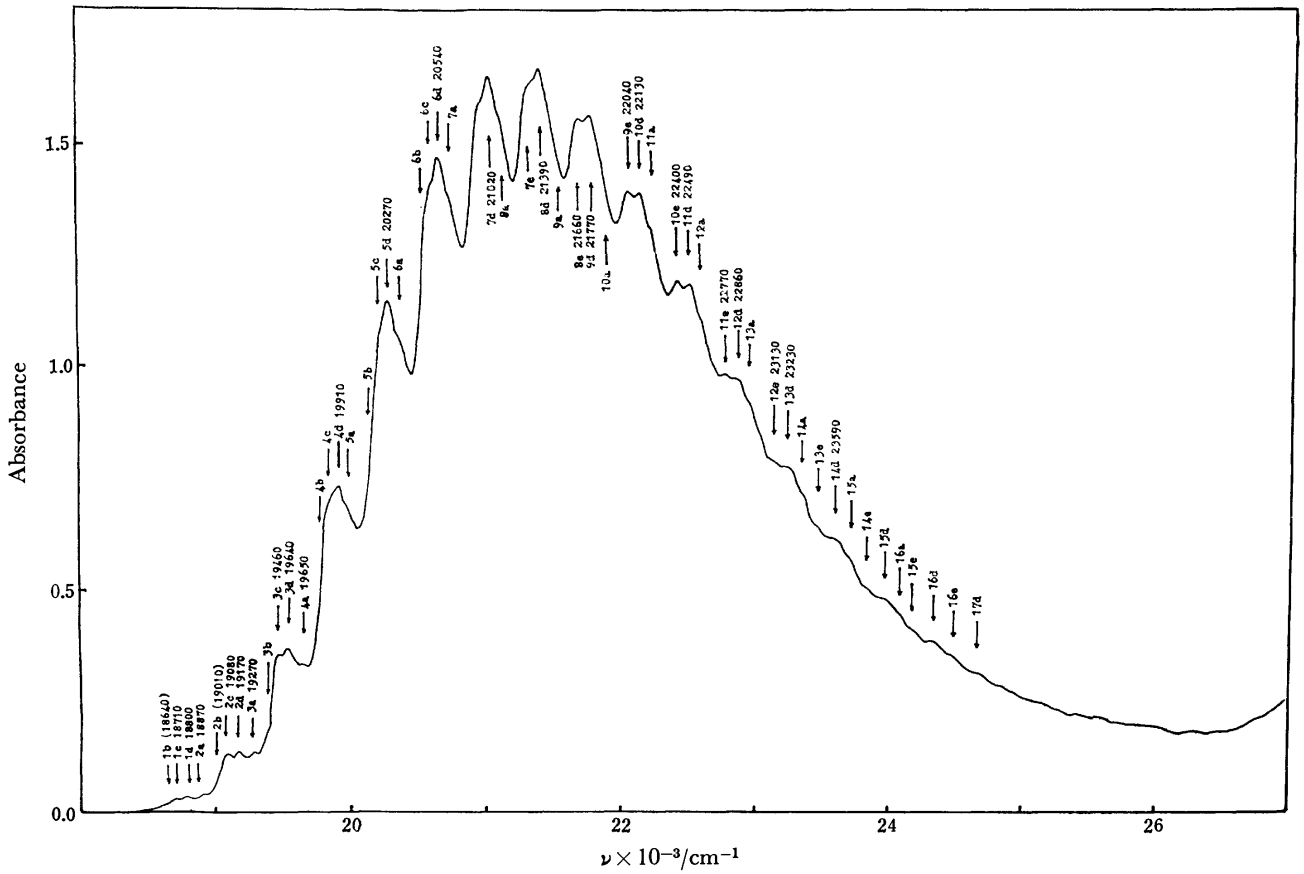

Fig. 2. Crystal absorption spectrum of $[Co(ND_3)_6][Ir(CN)_6]$ at 4.2 K with the polarized light whose electric vector parallel to the crystal [111] axis (crystal thickness is 0.08 mm).

The weak components, (*na*), were assigned to lattice vibrations of the crystals. In the case of $[Co(NH_3)_6]^{3+}$, the (*ne*) components are thought to be obscured due to their locations close to $(n+1\ d)$. The components of (*nf*) were also obscured on the band of $[Co(ND_3)_6]^{3+}$. A preliminary measurement of the $^4T_{2g}\leftarrow{}^4A_{2g}$ absorption band of $[Cr(NH_3)_6]^{3+}$ showed distinct structure components on the higher-wavenumber side of the band very similar to the (*ne*) and (*nf*) components in the present cases. As a matter of course, no structure components corresponding to (*ne*) and (*nf*) were reported in the fine structure of the $^1T_{1g}\leftarrow{}^1A_{1g}$ absorption band of $[PtF_6]^{2-}$ studied by Patterson *et al.*[7] In the present measurements, the O–O′ lines could not be detected even if the thickness of the samples was increased to 0.8 mm.

Flint *et al.*[8] have studied the structure of the $^4A_{2g}\leftarrow{}^2E_g$ emission of $[Cr(NH_3)_6]^{3+}$ and have detected the dominant vibronic components of the NH_3 rocking and the H–N–H sym. def. modes, as well as the skeletal modes of the CrN_6 group. They proposed that the spin-allowed absorption band of $^4T_{2g}\leftarrow{}^4A_{2g}$ should also involve the vibronic components attributable to the NH_3 rocking and the H–N–H sym. def. vibrations, since the mixing of the $^4T_{2g}$ state into the ^2E_g state is responsible for the intensity of the $^4A_{2g}\leftarrow{}^2E_g$ transition. The present experimental results are in line with their suggestion also in the case of the $^1T_{1g}\leftarrow{}^1A_{1g}$ absorption band of $[Co(NH_3)_6]^{3+}$ and $[Co(ND_3)_6]^{3+}$.

The authors wish to express their thanks to Professor Yukio Kondo, Rikkyo University, for his encouragement. We also would like to thank Dr. Hiroshi Saito for obtaining the Raman spectra and Miss Akiko Goto for her help in the analysis of some samples.

The X-Ray Study of Several Reaction Products of Substituted Benzodicyclobutene. I. 2,7-Di-*t*-butyl-11,11,12,12-tetracyano-4,5,9,10-tetraphenyltetracyclo[4.4.2.0^{1,8}.0^{3,6}]dodeca-2,4,7,9-tetraene

Harumichi Tsukada,* Hirotaka Shimanouchi, and Yoshio Sasada

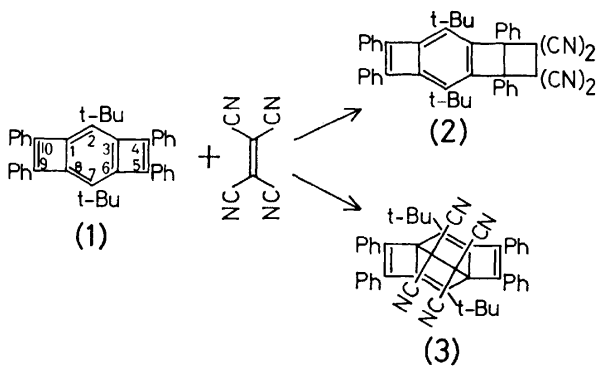
Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received August 22, 1979)

As a part of the studies of the reaction mechanism of a substituted benzodicyclobutene (**1**), the X-ray analysis of the title compound was carried out. The crystals are monoclinic; space group $P2_1/a$, $a=23.159(3)$, $b=20.369(3)$, $c=8.589(1)$ Å, $\beta=104.27(1)°$. The structure was solved by the direct method and was refined by the block-diagonal least-squares method to the final R factor of 0.070 for 5553 observed reflections. In the molecular structure, there is a bridge-bond formed by the "cross" addition of tetracyanoethylene (TCNE) to the C(1) and C(6) sites of **1**. The intermolecular interaction was calculated so as to make clear what kind of addition reaction is preferable for the molecule **1**. The result is consistent with the observation that, in addition to the linear adduct, a cross adduct is also obtained as a by-product.

There are several theoretical approaches to organic reactions based on electronic considerations. One of the most popular and useful theories is the Woodward-Hoffmann rule[1] for a Diels-Alder reaction between some planar conjugated molecules. In the reactions affected by steric hindrance, however, the rule sometimes fails to predict the observed reaction. For example, the Diels-Alder reaction of substituted heptafulvalene and tetracyanoethylene (TCNE) gives an unexpected adduct.[2] The calculation including all the valence electrons responsible for such a repulsion will require a great deal of time and effort. It may be better to deal with the non-bonded interaction using empirical parameters obtained in the investigation of the crystal packing.[3]

A series of the adducts of substituted benzodicyclobutene[4] (**1**) with some dienophiles are most profitable for such an energetic investigation of chemical reactions. This molecule undergoes many kinds of addition reactions, since there are many sites which dienophiles can attack. We can obtain "linear" adducts if dienophile adds to the C(4)–C(5) position of the molecule **1**. Addition to the C(3)–C(4) and C(1)–C(6) positions will produce "angular" and "cross" adducts respectively. TCNE reacts with **1** to give not only the linear adduct (**2**) as the main product, but also the cross adduct (**3**) as a by-product.[5,6] The structure determination of the former had been reported previously.[7] The present X-ray analysis of the latter has revealed the stereochemical difference between the main by-products, which will give some information regarding the steric effect of the bulky substituents on the reaction.



Experimental and Structure Determination

Crystals suitable for structure determination were provided by Professor Fumio Toda of Ehime University. The crystals were colorless needles. From the oscillation and Weissenberg photographs, the space group was uniquely assigned as $P2_1/a$. A Rigaku automated four-circle diffractometer with graphite-monochromated Mo $K\alpha$ radiation ($\lambda=0.71069$ Å) was used for the determination of the accurate unit-cell dimensions and for the measurement of the diffraction intensities. The crystal data are listed in Table 1. A total of 6901 independent reflections ($2\theta\leqq50°$) were obtained, of which 5553 had net intensities greater than the background. The intensities were corrected for the Lorentz and polarization effects, but not for the absorption and extinction.

Table 1. Crystal data of 2,7-di-*t*-butyl-11,11,12,12-tetracyano-4,5,9,10-tetraphenyltetracyclo-[4.4.2.0^{1,8}.0^{3,6}]dodeca-2,4,7,9-tetraene

D_m	1.135 g cm^{-3}
D_x	1.135

The structure was solved by the direct method.[8] The E map, calculated from 450 normalized structure factors ($E\geqq1.7$) with determined signs, clearly revealed 52 non-hydrogen atoms. Fourier synthesis including all these atoms showed no other spurious peaks at all. The atomic parameters were refined by the block-diagonal least-squares method. After the convergence of the positional and isotropic thermal parameters, the contribution from hydrogen atoms located geometrically was included. At the subsequent stage of the refinement, with the introduction of anisotropic thermal parameters for the nonhydrogen atoms, the parameters of the

hydrogen atoms were not shifted, but their positions were recalculated at the last stage. The weighting scheme was; $w=0.8$ for $|F|=0$, $w=1.0$ for $0<|F|\leqq 30$, and $w=1/\{1+0.14(|F|-30)\}$ for $|F|>30$. The final R factor was 0.070 for 5553 observed reflections. In the final cycle of the least-squares, no shifts exceeded one tenth of their e.s.d's. The atomic scattering factors were taken from the "International Tables for X-Ray Crystallography.[9]" The final atomic parameters are listed in Table 2,[10] while the crystallographic numbering scheme is shown in Fig. 1.

Description of the Structure

A stereoview of the crystal structure is shown in Fig. 2. The intermolecular contacts are normal, judging from the relevant van der Waals radii. Two perspective views of a single molecule are given in Fig. 3. This structure is consistent with that presumed by the spectroscopic study.[6] The molecular framework contains a bridge bond formed by the addition of TCNE at the bridge heads C(1) and C(6) for which the name "cross adduct" is suitable. It consists of three planar parts, which all include the C(1)–C(6) interatomic vector. The deviations of the atoms from the least-squares planes and the dihedral angles between these planes are given in Table 3. The chemically equivalent planes, I and II, make a dihedral angle of 125.0°, which is bisected by the plane, III, formed by the addition of TCNE.

Although these three planes have no significant distortion, the four-membered rings annelated to those parts are slightly but significantly folded, the C(4) atom approaching the cyano groups. On the other hand, the *t*-butyl groups are kept away from the cyano groups, the deviation of the tertiary carbon atoms from the planes, I and II, being 0.13 Å. These trends may be attributed to the steric effects of the bulky substituents, which may play an important role in the addition reaction.

The bond lengths and angles are listed in Tables 4 and 5 respectively. As this molecule has an approximate two-fold axis, average values are used in the following discussion. The lengths of two double bonds, C(2)=C(3)

and C(4)=C(5), are, though normal, somewhat different from each other. The atomic chain of C(2)=C(3)–C(4)=C(5) lies nearly on a plane and has almost the same bond lengths as those of *trans*-butadiene.[11] The two single bonds connecting the phenyl and the four-membered rings have significantly different lengths. This may be related to the dihedral angle between the four-membered and phenyl rings; one dihedral angle is 86.4°, and the other, 25.6°. The shorter single bond, C(5)–C(27), is accompanied by the smaller dihedral angle, indicating a conjugation effect between the π electron systems of the skeleton and the phenyl ring.

As for the other single bonds, it should be mentioned that they are stretched to some extent. In particular, C(11)–C(12) is 1.625 Å, about 0.09 Å longer than the normal C_{sp^3}–C_{sp^3} bond length.[12] These elongations may be partly the result of the electron-withdrawing effect of the cyano group; at the same time, the nearly eclipse conformation around this bond, the average torsion angle being 2.1°, may greatly affect the bond length. This is also the case with the compound **2** previously reported,[7] the corresponding values being 1.612 Å and 5.8° respectively.

Discussion

The theoretical approaches are quite difficult for the various chemical reactions of complicated organic molecules. We have treated interactions between the reacting molecules by dividing them into two parts: the electronic interaction between the active sites of both the pertinent molecules, and the non-bonded steric effect of the bulky substituents.

Electronic Interaction in the Intermediate State. Benzodicyclobutene is a molecule with a conjugate planar skeleton. Therefore, the electronic interaction between this molecule, **R**, and a dienophile, **S**, can be calculated by using the equation presented by Fueno;[13]

$$\Delta E = 2(\sum_{i}^{occ}\sum_{j}^{un} - \sum_{i}^{un}\sum_{j}^{occ})(a_{ir}b_{js}\gamma_{rs} + a_{it}b_{ju}\gamma_{tu})^2/(E_i - E_j),$$

where E_i and E_j indicate the energy levels of the two molecules, where a_{ir} and b_{js} are the coefficients of the MO's and where γ is the resonance integral between the overlapping atoms. All these values were obtained by CNDO/2 calculation.[14] The distance between the two molecules is assumed to be 3.4 Å. The calculated energy corresponds to the stabilization of the intermediate state of the reacting molecules. The results are summarized in Table 6.

The sites of the molecule, **R**, (1,6), (3,4), and (4,5), indicate the "cross," "angular," and "linear" positions respectively. The stabilization is greatest in the cross addition. Although the electron-withdrawing effect of the cyano groups lowered the energy of the linear addition mode, it is less preferable than the cross addition mode. The result is not, however, consistent with the reactivity of the molecule **1** or the substituted **R**, with TCNE, since the main product is the linear adduct. Therefore, it is necessary to take account of the non-bonded interaction between the bulky substituents.

TABLE 6. ELECTRONIC INTERACTION ENERGY (eV)

R S

Non-bonded Interaction Energy. In the previous paper, we calculated the non-bonded interaction energy between the molecule **1** and the approaching TCNE. It was found that the energy is at its minimum when they have a slight torsion angle along the axis of the approaching direction and that the torsion angle is in qualitative agreement with that of the cyclobutane ring of **2**. Therefore, this kind of calculation, which has been used mainly for conformational or packing analysis, can be applied to the intermolecular interaction between the approaching reactants. In the present study, we shall extend this method to the discussion of what approaching mode is most to be preferred.

The potential function:

$$V(r) = Ae^{-Br}/r^D - C/r^6$$

and the parameters used were taken from Giglio.[3] Two parameters were used for the orientation of the approaching molecules, the distance, d, between the molecular planes, and the relative rotational angle, θ. (Fig. 4) The former was varied from 4.0 Å to 3.0 Å with 0.1 Å steps, and the latter, from 0° to 180° with 10° steps. In the two-dimensional energy map of d and θ (Fig. 5), there are three potential grooves along the former. The relative rotational angles for these approaches are 0°, 50°, and 130° (or −50°). The first one implies the addition of TCNE to the C(2)–C(7) of the molecule **1**, while the latter two will give the "cross" adduct. Since the two-dimensional energy map is inconvenient for a detailed comparison of the three approaching modes in the calculation or between the "linear" and "cross" addition, the cross section at the distance of 3.4 Å is shown in Fig. 6. The distance of 3.4 Å is chosen because it is the so-called van der Waals contact at which the π electron system of two molecules may, to some extent, interact with each other. Although the conformations of the substituents were varied in

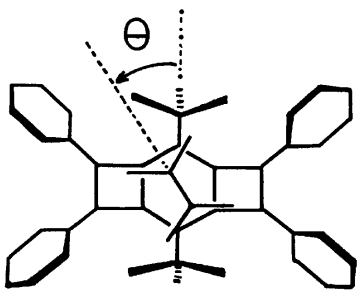

Fig. 4. Relative orientation θ in the cross approaching mode.

(a) Dihedral angle of the phenyl ring from the four-membered ring being 60°, and (b) 50°. (c) The conformation of the *t*-butyl groups being fixed like Fig. 7. (d) All the substituents bent down 10° opposite to the approaching TCNE.

the subsequent calculation, the approaching direction was restricted as in Fig. 4 so as to reduce the number of total parameters. In all the energy maps hereafter, the value of the linear addition will be shown by a solid curve, and that of the cross addition, by a dashed curve.

In the conformer **a**, four phenyl groups are rotated by 60° from the four-membered ring in a propeller-like manner, and the *t*-butyl groups are fixed as in the figure. The conformer **b** has a relatively smaller rotational angle of the phenyl groups (50°), so as to make it possible to estimate the variation in the total

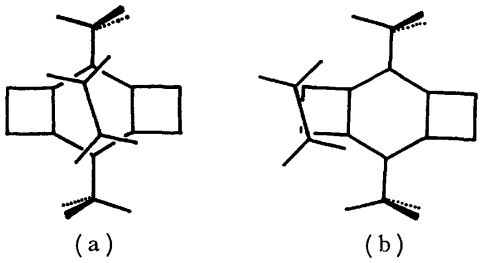

Fig. 7. Conformation model of the *t*-butyl groups.

energy with respect to the conformational change. The conformations of the *t*-butyl groups were varied for the same purpose; their conformations were assumed to be as in Fig. 7(a) and Fig. 7(b) in the linear and cross approaching modes respectively.

In the case of the 60° rotation of the phenyl groups (Fig. 6(a)), the potential groove of the cross approach is somewhat lower than that of the linear approach. Moreover, the width of the groove is narrower in the latter. Both these trends suggest that the cross addition is preferable. However, once the conformation of the terminal phenyl groups is varied in the calculation, the energy change in the linear addition is serious (Fig. 6(b)). This is attributable to the decrease in the repulsive contacts of TCNE with ortho hydrogen atoms of the phenyl groups. On the contrary, the energy of the cross approaching mode is not lowered so much as that of the linear one. In this energy map, the solid curve around 0° (or 180°) is lower by 30 kcal mol^{-1}† than the dashed curve around 60°. The former corresponds to the linear approach, and the latter, to the cross approach.

The results of the calculation in which the *t*-butyl groups are so arranged as to have the smallest repulsive contacts with the approaching TCNE indicate a more characteristic feature (Fig. 6 (c)). The minimum energy is greatly lowered in both of the approaching modes. The shape of the groove of the cross approach is, however, very narrow, whereas the shape of the solid curve shows no such drastic change. Although the difference between the minimum energies of the two modes is very small, the high energy potential barrier in the dashed curve prevents TCNE from approaching and so producing the cross adduct.

This discussion is based on the assumption that the substituent atoms directly attached to the skeleton of the molecule **1** are exactly on this plane. In order to check the effect of breaking this assumption, another calculation was carried out for the mode in which all the bonds connecting the substituents with the skeletal plane are bent by 10° from the plane toward the opposite side of the approaching TCNE. The results are shown in Fig. 6(d). The energy curves for both the cross and the linear addition are greatly lowered compared to those in Fig. 6(b), and the minimum around 0°(180°) suggests the linear addition; there is no substantial change as far as the preference of the reaction modes is concerned.

The results of calculation may be summarized as

† 1 kcal mol^{-1}=4.184 kJ mol^{-1}.

follows:

(1) The calculation of the stabilization energy of the reaction intermediates indicates that the skeletal molecule, without bulky substituents, would produce the "cross" adduct rather than the "linear" one. However, this is not the case in the observed reaction.

(2) Taking the non-bonded interaction energy into account, we can see that the linear approaching mode is preferable in terms of both the minimum value and the shape of the potential groove.

(3) The preference of the linear addition is, however, dependent on the conformation of the substituents of the molecule **1**. This is consistent with the fact that the cross adduct is obtained as a by-product.

Since any estimate of the relative weights of the electronic and steric energies must be quite ambiguous at present, it cannot be concluded which type of addition reaction will really take place. However, the qualitative agreement between our calculation and the observation indicates that the contribution of the non-bonded interaction energy should be included in any theoretical approaches to the chemical reaction.

Studies of related compounds are now in progress.

The authors are indebted to Professor Fumio Toda of Ehime University for supplying the sample and also for his valuable suggestions.

Liquid Crystal Formation in Binary Systems. I. An Interpretation of the Phase Diagrams of the Azoxydianisole–Schiff Base Systems

Kotaro ARAYA and Yoshio MATSUNAGA*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received August 25, 1979)

In order to confirm the presence of a transition at the temperature where the liquid crystal-isotropic liquid transition curve in the nematogen-rich region is met by the other transition curve, five binary systems comprising azoxydianisole (AA) and a Schiff base were examined by means of differential scanning calorimetry. A small but sharp endothermic peak due to a phase change is observable at the expected temperature upon heating, provided that it is well separated from the eutectic temperature. When the above-mentioned curve intersects the solid-liquid transition curve on the Schiff base-rich side, a liquid crystal coexisting with the solid base is transformed into an isotropic liquid coexisting with the same solid at this temperature. The presence of a nematic phase below this temperature could be demonstrated by measuring the separation of the outer hyperfine extrema in the ESR spectrum of bis(acetylacetonato)oxovanadium(IV) dissolved in the mixtures. The sequence of the transformation is entirely different when the intersection occurs on the AA-rich side. However, attempts to confirm the transition of the latter type by ESR were not successful.

Liquid crystal formation in binary systems, in which both, or one, or none of the component compounds give a mesomorphic phase, has been extensively studied by many workers. Nevertheless, the majority of reported phase diagrams are far from complete. For example, the system comprising azoxydianisole (AA), a mesomorphic compound, and *N*-(*p*-methoxybenzylidene)-*p*-anisidine, a non-mesomorphic compound, has been examined by Dave and Dewar employing the optical and thermal methods.[1] Although the nematic liquid crystal-isotropic liquid (N-L) transition curve on the AA-rich side is met well above the eutectic temperature by the solid-liquid (S-L) transition curve on the Schiff base-rich side, it is not clear whether or not the transition from the nematic liquid crystal (N) to the isotropic liquid (L) with the coexisting solid can be observed at the temperature of the intersection.

In the present series of papers, we are planning to report on the mesomorphic phases induced by some sort of molecular complexing in binary systems. In order to interpret our results, we felt that the subject mentioned above is of fundamental importance and should be clarified. For this purpose, we chose five representative systems of AA mixed with Schiff bases. As it is well known that an N phase can serve as an orienting solvent in magnetic resonance studies, measurements of the degree of alignment of the bis(acetylacetonato)oxovanadium(IV) molecules dissolved in the systems were attempted on the basis of the ESR spectrum. This particular chelate has been noted by Glarum and Marshall to be ordered to about the same extent as AA.[2] In this way, we hoped to establish the temperature ranges where an N phase exists with or without a solid-component compound.

Experimental

Materials. The AA was obtained from the Tokyo Chemical Industry Co. and was purified by recrystallization from ethanol. On the calorimetric curves, it melted at 117.5 °C and had an N-L transition point of 135 °C. These values are in good agreement with the literature values.[1] The Schiff bases were prepared by a condensation reaction between a *p*-X derivative of benzaldehyde and *p*-Y derivative of aniline; they were then recrystallized several times from ethanol and finally sublimed in a vacuum if necessary. Mixtures of AA and a Schiff base in known proportions were melted in small test tubes, shaken well to insure homogeneity, and then rapidly cooled.

Measurements. The calorimetric curves were recorded on a Rigaku Denki Thermoflex differential scanning calorimeter during the processes of heating and cooling. The heating rate in this work was 2.5 °C min^{-1}. The temperature was calibrated with the transition points of hexachloroethane (45 and 71 °C) and hexamethylbenzene (111 °C) and the melting points of naphthalene (80 °C), pyrene (150 °C), and indium (157 °C). The ESR spectra were recorded on a JEOL model JES-ME-3X (X band) spectrometer with 100 kHz modulation in the range between a temperature below the eutectic and a temperature above the S-L or N-L transition. The magnetic-field span was calibrated with Mn^{2+}-doped MgO powder.

Results and Discussion

*AA–*N-*(*p-*Methoxybenzylidene)*-p-*anisidine (X=Y=CH_3O) System.* The phase diagram has been reported by Dave and Dewar.[1] According to them, the N-L transition curve is met at 116.5 °C by the S-L transition curve on the Schiff base-rich side. They have drawn a horizontal dashed line at this temperature and marked four points observed in the cooling process above 40 mol% of AA. The eutectic point was located at 105 °C and about 72 mol% of AA. Our results are presented in Fig. 1. The open and shaded circles indicate the transitions found during the processes of heating and cooling respectively. The shaded circles are omitted when they coincide exactly with the open circles. The N-L transition above 60 mol% of AA is reversible, but the N phase is readily supercooled below the eutectic temperature and is suddenly solidified. When the AA content is less than 50 mol%, a sharp endothermic peak assignable to the N-L transition with the coexisting solid is observed at 117 °C on heating. This temperature is that of the intersection between the N-L transition curve and the S-L transition curve. Contrary to the observation reported by Dave and Dewar, the L phase in this composition range is super-

The open and shaded circles are transitions observed in the processes of heating and cooling respectively.

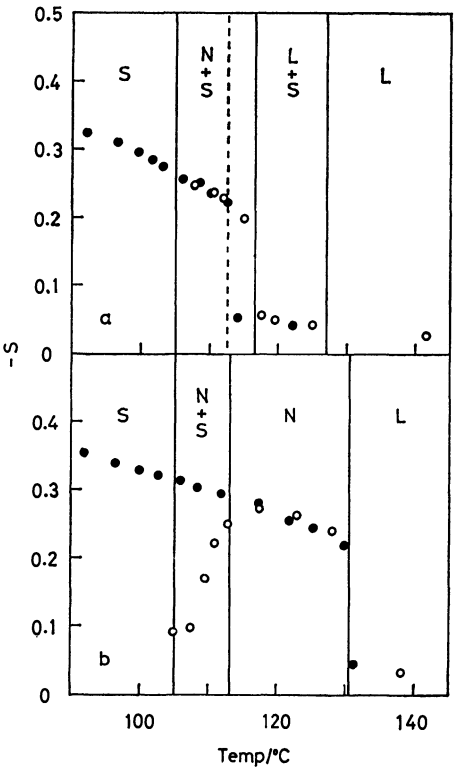

Fig. 2. Temperature dependence of the parameter S in AA–*N*-(*p*-methoxybenzylidene)-*p*-anisidine, (a) 42.5 and (b) 88.5 mol% of AA.
As to the open and shaded circles, see the caption of Fig. 1.

cooled and changes into the N phase. The transformation takes place at temperatures on a continuation of the reversible N-L transition curve, which is almost straight. Such a linear relationship has also been observed for a number of binary N systems when there is no significant difference in the molar volumes or densities of the components.[3-7] The value at 0 mol% of AA found by extrapolation may be considered to be the latent L-N transition temperature of the Schiff base. If the molten base could be cooled without solidification, the N phase would monotropically appear at about 97 °C.

In the N phase, the spin-probe molecules are not distributed uniformly in θ, the angle between the V=O bond direction of the chelate molecule and the magnetic field. The order parameter, S, defined by $<3\cos^2\theta-1>/2$, can be approximated by $(<A>-a)/2(a-A_\perp)$, where $A_\perp$ is the component perpendicular to the V=O bond direction of the nearly axial hyperfine tensor, a is the isotropic hyperfine constant, and $<A>$ is one-seventh of the separation of the outer hyperfine extrema. If the alignment of the probe is perfect, the parameter, S, is $-1/2$, because $<A>=A_\perp$. When the medium becomes isotropic, the probe molecules may rapidly tumble, and one may observe $S=0$. Thus, a marked difference in the S value can be expected below and above the N-L transition temperature. The ESR spectrum was measured at 42.5 and 88.5 mol% of AA (they are indicated by Arrows a and b in Fig. 1) as a function of the temperature. The parameter was calculated with the values of $A_\perp$ and a estimated from the ESR spectra in molten *o*-terphenyl, namely, 68 and 108 G (1 G=10^{-4} T). The results, shown in Figs. 2a and b, clearly support our interpretation of the phase diagram. Here again, the open circles were obtained in the process of heating, and the shaded ones, in the process of cooling. The vertical lines represent the transition temperatures taken from Fig. 1. In Fig. 2a, a sudden change in the order parameter is found at the N-L transition temperature, even in the presence of a solid Schiff base. Furthermore, the supercooling of the L phase is clearly demonstrated by a shaded circle located between the dashed line and the N-L transition line. In the other temperature ranges, the open and shaded circles are nearly on the same curve, indicating the reversibility. As the S value estimated using the above-mentioned $A_\perp$ and a is essentially zero in the L phase of pure AA, there must be some changes in $A_\perp$ and a upon mixing with the Schiff base. At 88.5 mol% of AA, a large hysteresis is seen in the heterogeneous region where the N phase coexists with solid AA (see Fig. 2b). The rapid change in the order parameter upon heating suggests that the coexisting solid AA strongly disturbs the alignment of the N phase. To avoid such a complication, the measurement at a lower content of AA seemed to be desirable. However, the temperature range where the N phase coexists with solid AA is too narrow to carry out the desired measurement, as the eutectic point is located at about 72 mol% of AA. Consequently, two more similar systems with eutectics at lower AA contents were examined.

*AA–*N-(p-*Nitrobenzylidene)*-p-*anisidine* (*X*=NO_2, *Y*=CH_3O) *System.* Dave and Dewar have reported the eutectic at 93 °C and 57 mol% of AA for this system.[5] The diagram reproduced by the S-L and L-N transition temperatures tabulated in their paper is in fair agreement with ours, shown in Fig. 3. Although the temperatures of the intersection of the L-S and N-L transition curves and of the eutectic agree well with

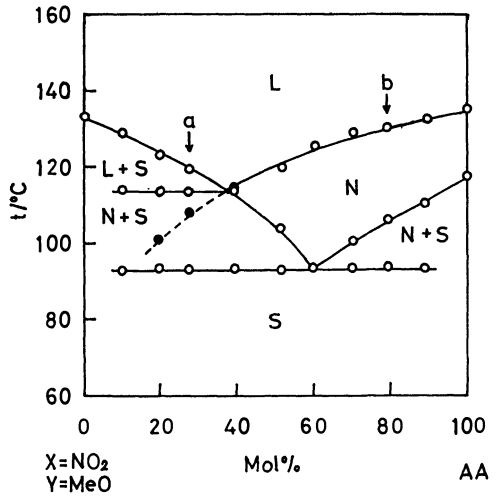

Fig. 3. The system AA–*N*-(*p*-nitrobenzylidene)-*p*-anisidine.

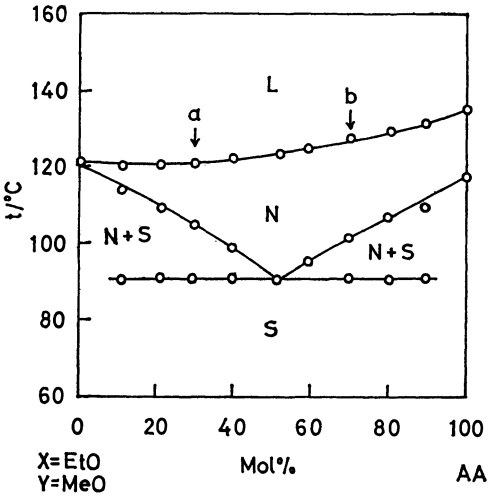

Fig. 4. The system AA–*N*-(*p*-ethoxybenzylidene)-*p*-anisidine.

those of Dave and Dewar, the compositions obtained by us are a little higher. It must be emphasized, however, that Dave and Dewar have reported neither the transitions at the horizontal N-L line of 113.5 °C on the Schiff base-rich side nor the transitions on the extrapolated part of the N-L curve on the AA-rich side. Contrary to the AA-*N*-(*p*-methoxybenzylidene)-*p*-anisidine system, the N-L curve on the AA-rich side is markedly convex upwards. The latent N-L transition temperature of about 80 °C is deduced by extrapolation to 0 mol% of AA.

The order parameter of the spin probe was measured at 27.6 and 79.3 mol% of AA (a and b in Fig. 3 respectively). At the former composition, the results are similar to those presented in Fig. 2a; however, the *S* values in the N+S region obtained during the process of heating are definitely higher than those in the supercooled N phase, possibly because of a larger difference between the two transition temperatures. As we hoped, the difference in the *S* value between the heating and cooling processes at the latter composition is much less than that found in Fig. 2b. The parameters measured on heating are about −0.23 throughout the N+S region and also in a part of the N phase.

AA-N-(p-*Ethoxybenzylidene*)-p-*anisidine* ($X=C_2H_5O$, $Y=CH_3O$) *System.* The Schiff base melts at 121.5 °C. When the melt is cooled, a monotropic transition to the N phase occurs at 121 °C. Therefore, the N-L transition curve looks as if it is met by the S-L transition curve at 0 mol% of AA. As is shown in Fig. 4, the N-L transition curve is slightly concave upwards; in other words, it shows a negative deviation from a linear relationship between the N-L transition temperatures of the two components. The eutectic is at 91 °C and about 51 mol% of AA. The order parameters of the spin probe examined at the compositions a and b are presented in Fig. 5. There is no supercooling of the L phase at either of the compositions. At 29.3 mol% of AA, the temperature variation in *S* is nearly reversible. On the other hand, a small but definite difference in the *S* value can be seen between the processes of heating

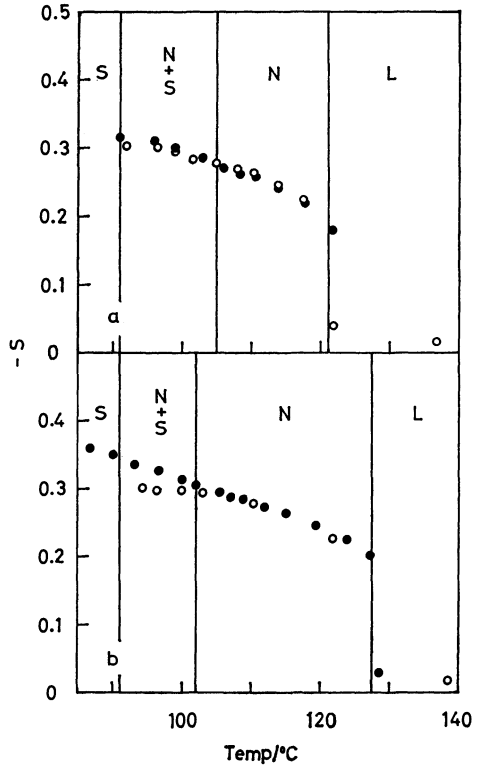

Fig. 5. Temperature dependence of the parameter *S* in AA–*N*-(*p*-ethoxybenzylidene)-*p*-anisidine, (a) 29.3 and (b) 70.5 mol% of AA.

and cooling in the N+S region at 70.5 mol% of AA. As the compositions a and b are selected almost symmetrically to the eutectic, the amount of the coexisting solid Schiff base at the composition a must be about the same as that of solid AA at the composition b. Therefore, the results in Fig. 5 indicate that the orientation of the AA-rich N phase by the magnetic field is more strongly disturbed by the coexisting solid AA than is the orientation of the Schiff base-rich N phase by the coexisting solid base.

The negative deviation of the N-L transition curve

from the ideal linear relationship may be due to the slightly repulsive interaction between the AA and Schiff-base molecules compared to the interaction between like molecules. On the other hand, the deviation found in the AA–*N*-(*p*-nitrobenzylidene)-*p*-anisidine system is in the direction opposite to the above-mentioned and is as much as 14 ° in the range of 40 to 50 mol% of AA, reflecting a strong attractive interaction between the AA and Schiff-base molecules in the N phase. A similar enhancement of the N-phase stability has been found by Park *et al.* in the binary system *N*-(*p*-methoxybenzylidene)-*p*-butylaniline and 4-cyano-4′-pentylbiphenyl and several other, closely related systems.[8] They have attributed the enhancement to molecular complexing by a weak charge-transfer interaction. This sort of intermolecular interaction may be more significant if one of the components carries a strong electron-donating substituent such as a dimethylamino group and the other, a strong electron-accepting substituent such as a nitro group. Work along this line will be reported in forthcoming papers of this series.

AA–N-(p-*Methylbenzylidene*)-p-*anisidine* (*X*=CH_3, *Y*=CH_3O) *System.* According to the work by Dave and Dewar, the eutectic is located at 72 °C and 25 mol% of AA, and the N-L transition curve is met by the transition curve on the AA-rich side at 100 °C and 62 mol% of AA.[5] In this case, the phase diagram is expected to be more complicated than those of the three systems described above. Below the temperature of the intersection, the isotropic L phase should coexist with solid AA, as is indicated by the endings of the isothermal tie-lines. Upon heating, this mixture is transformed into a mixture of the N phase and solid AA at the temperature of the intersection, then into the N phase only, and finally into the L phase. Thus, the sequence of the transformation at the temperature of the intersection is reversed compared with that we have found in the previous diagrams. Dave and Dewar reported neither the expected horizontal transition line nor the L-N transition to be shown by supercooled melts in the composition range below the intersection.

These missing transitions could, however, be detected by the present calorimetric measurements. The results are plotted in Fig. 6. The N-L transition curve observed with supercooled melts is slightly bent below 50 mol% of AA. The boundary between the N phase and the heterogeneous region where the N phase coexists with solid AA is straight. On the other hand, the S-L transition curve is really curved. The last two curves are of a different nature; that is, one of them represents the solubility of AA in the N phase, and the other, the solubility of AA in the L phase. Therefore, the discontinuity of the slope at the intersection is not unexpected, The eutectic was found at 72.5 °C and 27 mol% of AA, and the intersection, at 102 °C and 60 mol% of AA. The ESR measurements attempted at 68.2 and at 80.0 mol% of AA failed to prove the N phase to coexist with solid AA, probably because of the narrow temperature range and/or the disturbance from the relatively large amounts of solid AA. However, the L-N transition at 102 °C could be visually confirmed with the aid of a hot stage equipped with a polarizing microscope.

AA–N-(p-*Methoxybenzylidene*)-p-*chloroaniline* (*X*=CH_3O, *Y*=*Cl*) *System.* The binary system consisting of AA and *N*-(*p*-chlorobenzylidene)-*p*-anisidine gives a phase diagram of the same type. The intersection occurs at 98.5 °C and 60 mol% of AA, in good agreement with the results reported by Dave and Dewar.[5] This temperature is so close to the eutectic temperature, 92 °C, that the expected small endothermic peak is not detectable because of overlapping with a much larger peak due to the eutectic. The present system comprising AA and the isomeric Schiff base is, consequently, included as a further example. The eutectic has been located at 79.5 °C and 35 mol% of AA, and the intersection, at 99 °C and about 62 mol% of AA, by Dave and Dewar.[5] They made no mention of the horizontal transition line expected at the latter temperature and the L-N transition of supercooled melts. As is shown in Fig. 7, our measurements could indicate more complete relations for this system. The temperature of the intersection is firmly established at 100.5 °C by the transitions observed between 69.5 and 88.5 mol%

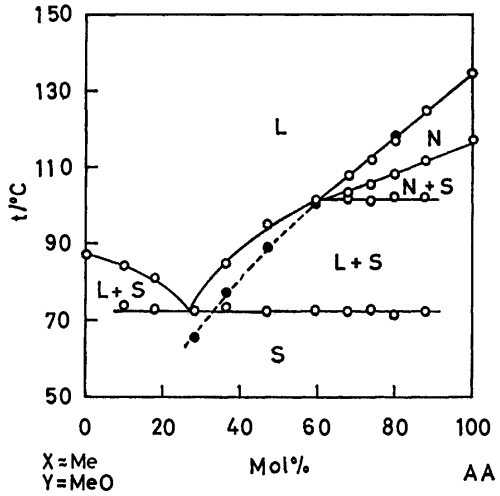

Fig. 6. The system AA–*N*-(*p*-methylbenzylidene)-*p*-anisidine.

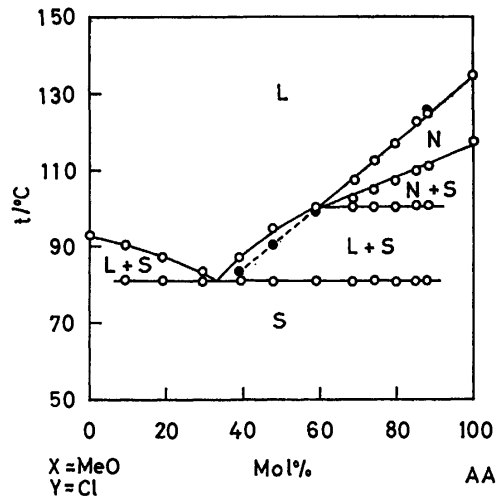

Fig. 7. The system AA–*N*-(*p*-methoxybenzylidene)-*p*-chloroaniline.

of AA. The N-L transition curve, now extended to 40 mol% of AA by the observations of the monotropic transformation of the supercooled melts, is essentially straight. If the curve is not bent below this composition, the latent L-N transition temperature of this Schiff base may be about 50 °C. The S-N transition curve is essentially straight, and its slope is considerably different from that of the S-L transition curve at the intersection. Attempts to confirm the N phase coexisting with solid AA by the ordering of the spin probe at 74.3, 79.8, and 85.6 mol% of AA did not meet with any success.

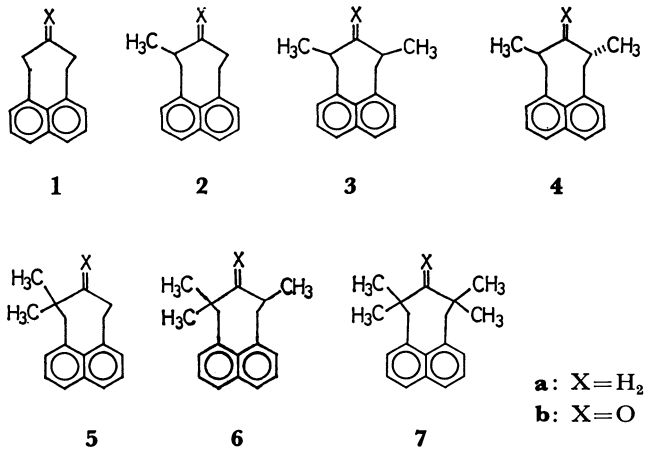
The Conformations and the Ring Inversions of Some 8- and 10-Methyl-substituted 8,9,10,11-Tetrahydro-7*H*-cycloocta[*de*]naphthalenes and Their 9-Oxo Derivatives

Toshihiro KAMADA* and Osamu YAMAMOTO
National Chemical Laboratory for Industry, Tsukuba Research Center, Ibaraki 305
(Received February 23, 1979)

The IR and NMR studies on the conformations of several 8- and 10-methyl-substituted 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalenes (*cis*-8,10-dimethyl (**3a**), *trans*-8,10-dimethyl (**4a**), 8,8-dimethyl (**5a**), 8,8,10-trimethyl (**6a**), and 8,8,10,10-tetramethyl (**7a**)) and their 9-oxo derivatives (**3b**—**7b**) have been described. It was found that compounds **3**—**7** exist exclusively in a boat conformation in the ground state, the peri ring of which is somewhat distorted (puckered) as a result of the steric repulsion between the interior benzyl protons; the molecules of **3a** and **3b** are rather strongly puckered, while those of **7a** and **7b** exist in a less puckered form than the conformations of the other methylated compounds. In the latter case, a novel type of the reflex effect was found arising from the 1,3-synaxial CH_3–CH_3 steric interaction and the interior benzyl H–H interaction. Moreover, it was revealed that free energy barriers ($\Delta G^{\ddagger}$) to boat inversion for compounds **5a**, **5b**, **7a**, and **7b** are markedly increased ($\Delta\Delta G^{\ddagger}$= 4.8—5.9 kcal/mol) as compared with the unmethylated compounds. These results were discussed in terms of the boat-to-boat interconversion process in which the pseudorotations of the peri bonds are involved. Some discussion was also made on the spectral and conformational features of the eight-membered pericyclized naphthalene ring system.

Previously, as parts of our studies on the chemistry of pericyclized naphthalene system, we have studied the conformations of 8,9,10,11-tetrahydro-7*H*-cycloocta-[*de*]naphthalene (**1a**)[1] and its 9-oxo compound **1b**.[2] Studies on the conformational equilibria of 8-monomethyl-substituted derivatives of this system **2a**[3] and **2b**[4] have also been reported. In these studies, it was found that the 8-membered peri rings in these compounds are rather strained due to the peri interaction inherent in the peri-substituted naphthalenes.[5] In the present paper, in order to determine the effects of the methyl substituent on the ring geometry and the ring inversion in these 8-membered pericyclized naphthalenic compounds, we have extended our study to more highly methylated compounds of this system, 8- and 10-methyl-substituted 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalenes (*cis*-8,10-dimethyl (**3a**), *trans*-8,10-dimethyl (**4a**), 8,8-dimethyl (**5a**), 8,8,10-trimethyl (**6a**), and 8,8,10,10-tetramethyl (**7a**)) and their 9-oxo derivatives (**3b**—**7b**).



Here, we report the conformations of this series of methyl compounds based on the IR and NMR (^{1}H and ^{13}C) spectra, and discuss about the spectral and conformational features of these methylated compounds in comparison with the parent compounds **1a** and **1b** as well as the monomethyl derivatives **2a** and **2b**. Further we report the activation energies for ring inversions of some of the methylated compounds **3**—**7** by a study of the variable-temperature ^{1}H NMR spectra. Detailed discussion on these points will also be described.

Results and Discussion

The ^{1}H and ^{13}C NMR data of a series of the methylated compounds (**3a**—**7a**) and (**3b**—**7b**) are summarized in Tables 1 and 2. The assignment was made based on the data of the parent compounds **1a**[1] and **1b**[2] and the substituted derivatives **2a**[3] and **2b**,[4] as well as those of the deuterated compounds **3b**-8,10-d_2, **4b**-8,10-d_2, and **6b**-10-*d*. Also off-resonance technique was employed for the assignments of the ^{13}C spectra.

It is shown in the table that all the ^{1}H spectra of these compounds are relatively simple and the splitting patterns of the benzyl methylene protons in the hydrocarbons (**a**) are very similar to those in the corresponding 9-oxo compounds (**b**). This suggests that each methyl compound studied exists in one conformation in its ground state and both hydrocarbons (**a**) and ketones (**b**) assume the same geometry in each class of the methylated compounds.

It has previously been shown[1-4,6,7] that the interior benzyl protons (H_{in}) on C-7 and C-11 in the 8-membered pericyclized naphthalene system resonate at much lower field than the exterior protons (H_{ex}) due to the steric compression effect. In 8,8-dimethyl-8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene (**5a**) and its 9-oxo derivative **5b**, the interior proton on C-11 (H_{11in}) is coupled strongly with an adjacent C-10 proton (J=13.3 and 13.1 Hz). This indicates that the peri rings in these compounds exist in the boat form (**5B**) rather than in the chair (**5C**), since, as can

a) All the samples except **4a** and **4b** were measured at room temperature. b) The chemical shifts are expressed in δ (ppm) from internal reference tetramethylsilane and are considered accurate to be ±0.1 ppm. c) Measured at −51.6 °C. d) Measured at −44.0 °C.

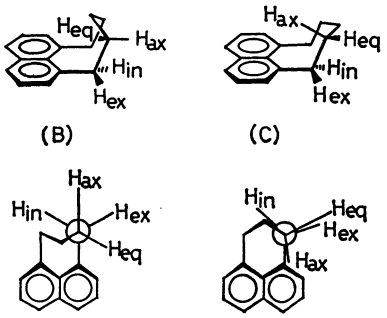

Fig. 1. The boat (**B**) and the chair (**C**) conformations for the 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene ring and their Newman projections about the C_7–C_8 (C_{10}–C_{11}) bonds.

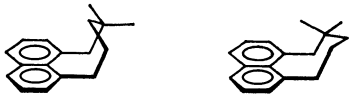
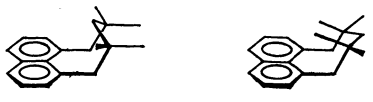


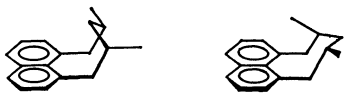
be seen in Fig. 1, the H_{in} proton in the boat conformation is situated in a position *trans* to an adjacent equatorial proton and thus a strong coupling is expected between these two protons. If the chair **5C** would be the predominant conformation for **5a** and **5b**, then the large J_{vic} value could be observed for the H_{ex} proton. Additionally, the splitting patterns of the C-11 interior protons observed in **5a** and **5b** are analogous to those of the parent compounds[1,2] and the monosubstituted derivatives,[3,4] which exist in the boat conformations alone. The **5B** conformation is also suggested from the line widths of the methyl and the benzyl protons. In both **5a** and **5b**, the equatorial methyl group shows somewhat broadened signal (half-width; 1.9 and 2.2 Hz) as compared to that of the axial methyl group (1.6 and 1.8 Hz), while the signal of the C-7 interior proton of **5b** is broader (3.6 Hz) than that of the corresponding exterior proton (3.0 Hz). This arises possibly from the long-range spin coupling of the interior proton with the equatorial methyl group because of their *trans* steric relationship,[7] and is a further evidence in favor of the boat conformation **5B** for **5a** and **5b**.

Similar type of long-range spin coupling is observed in the spectra of 8,8,10,10-tetramethyl compounds **7a** and **7b** (in both compounds, the signals of the interior benzyl proton and the equatorial methyl group are apparently broader than those of the exterior proton and the axial methyl group, respectively; see Table 1). Therefore, these compounds clearly assume a boat form (**7B**). This is strongly supported by the line widths

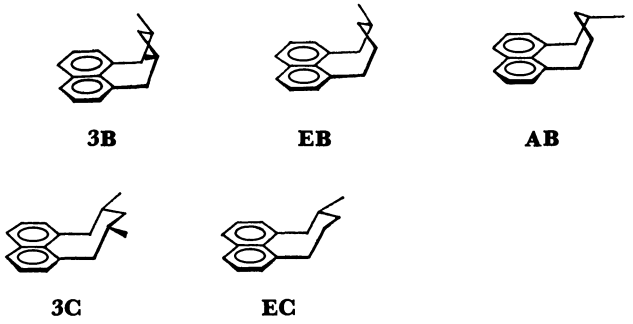


of the exterior benzyl protons; as can be seen in the table, the line widths of the interior benzyl protons are almost equal between the hydrocarbon **7a** (2.8 Hz) and the ketone **7b** (2.9 Hz), while the exterior proton of **7a** clearly shows a broadened signal (2.5 Hz) as compared to that of **7b** (2.0 Hz). This may be reasonably explained in terms of the W-type long-range spin coupling of the exterior proton with the C-9 equatorial proton, which is characteristic of the boat conformation as described before.[7]

In *trans*-8,10-dimethyl compounds **4a** and **4b**, the value of spin coupling constant between the C-7 interior proton and C-8 methine proton is small (J=6.5 and 5.8 Hz), while it is large between the C-11 interior proton and the C-10 methine proton (J=12.8 and 11.5 Hz). Thus it is clear that **4a** and **4b** exist in a boat (**4B**) in which the C-8 methyl is equatorial and that on C-10 is axial.

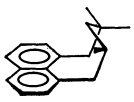


On the other hand, in the *cis*-dimethyl compounds **3a** and **3b**, the small J_{vic} values (6.5 and 6.4 Hz) observed between the interior benzyl proton and the vicinal methine proton suggest that **3a** and **3b** exist either in a boat form (**3B**) or in a chair form (**3C**) bearing equatorial methyl groups. However, in view of the fact that the equatorial isomers of the monomethyl compounds **2a** and **2b** exist exclusively in the boat conformation (**EB**) in their ground states (corresponding chair conformation **EC** is not obtained),[3,4] it seems reasonable to consider that the dimethyl compounds **3a** and **3b** exist in the boat (**3B**) rather than in the chair (**3C**). Actually, the chemical shifts and coupling

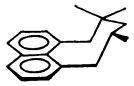


constants of the benzyl and the methyl protons observed in **3a** and **3b** are very similar to those found for the corresponding protons of the **EB** isomer. Moreover, the equilibration experiment revealed[8] that the *cis*-dimethyl ketone **3b** is much more stable than the *trans* isomer **4b** (**4B** conformation). Thus, considering the fact that the equatorial conformation (**EB**) is more stable than the axial conformation (**AB**),[3,4] it is apparent that the conformation of **3a** and **3b** is the boat form **3B**.

For the same reason, the small J_{vic} values (6.4 and 6.7 Hz) observed between the C-11 interior proton and the C-10 methine proton in the trimethyl compounds **6a** and **6b** suggest that these compounds exist in a boat (**6B**), in which the C-10 methyl group is equatorial. The somewhat broadened signal of the equatorial methyl group on C-8 (half-width; 1.8 Hz) in comparison

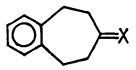


6B

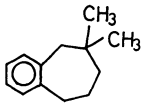


6C

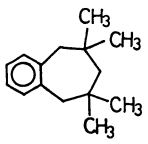
with that of the corresponding axial methyl group (1.4 Hz) observed in **6b** results possibly from the long-range spin coupling of the equatorial methyl group with the C-7 interior proton as observed in **5B** and **7B** conformations.



8a; X=H_2
8b; X=O



9



10

Consequently, it became clear that all the compounds (**3**—**7**) exist solely in the boat conformations (**3B**—**7B**) in their ground states. This result is in striking contrast to the case of structurally analogous benzocyclic compound, 6,7,8,9-tetrahydro-5*H*-benzocycloheptene system (**8**). It has been reported that 6,6-dimethyl- (**9**)[9] and 6,6,8,8-tetramethylbenzocycloheptene derivatives (**10**)[10] as well as the unsubstituted compounds **8a**[10,11] and **8b**[12] assume only the chair conformations in their ground states. The unusually greater stability of the boat conformation (**3B**—**7B**) over the chair (**3C**—**7C**) observed in **3**—**7** results chiefly from much lower torsional energy about the C_7—C_8 and C_{10}—C_{11} bonds of the boat conformation (staggered) than the chair (eclipsed), which is one of the unique features in the 8-membered pericyclized naphthalene system (Fig. 1). All compounds of this system studied so far, including the parent compounds[1,2,6] as well as the substituted derivatives,[3,4,7] exist solely in the energetically stable boat conformations. In addition, the closeness of the axial methyl group to the naphthalene ring in the chair[7] (**4C**—**7C**) makes this much less stable than the boat conformation (**4B**—**7B**).

The ^{13}C data of **3**—**7** shown in Table 2 fully agree with the boat conformations (**3B**—**7B**) described above. Thus a high-field shift of C-7 signal relative to that of C-11 ($\Delta\delta$=1.7 ppm) in the *trans*-dimethyl compound **4a** is caused by a gauche interaction[3,4] between the equatorial methyl group on C-8 and the peri bond. This interaction is also observed in the spectra of the *cis*-dimethyl (**3a**) and the trimethyl compounds (**6a**), the C-11 carbons of which show chemical shifts approximately equal to the value found in the C-7 carbon of **4a**. On the other hand, the C-8 carbon of **4a** is markedly shielded relative to the C-10 carbons of **3a** and **4a** ($\Delta\delta$=6.3 and 7.2 ppm, respectively) because of the so-called γ-effect.[3,4,13] By the same effect, the C-10 carbon of **6a** shifts to a 3.7 ppm higher field than that of **3a**, while the C-10 carbon of the *gem*-dimethyl compound **5a** is more shielded than the corresponding carbons of the parent compound **1a** and the monomethyl compound **2a** (**EB** conformer) by 3.0 (see footnote in Table 3) and 2.7 ppm,[3] respectively. Moreover, the C-9 carbons of **4a** and **5a** resonate at appreciably higher field than the C-9 carbon of **3a** ($\Delta\delta$=3.6 and 3.3 ppm, respectively) as a result of the γ-effect.

Thus, in compounds **3a**—**7a**, since the axial and the equatorial methyl carbons experience shieldings due to the γ-effect and the gauche interaction, respectively, the shift difference between the axial and the equatorial methyl groups in these compounds is considerably decreased ($\Delta\delta$=1.4—2.2 ppm) as compared with the cyclohexane ring (6.0 ppm).[13] This effect is also reflected in the chemical shifts of the methine carbons; the chemical shift difference between the methine carbon having an axial methyl group (C-10 of **4a**) and that having an equatorial methyl group (C-10 of **3a**) is only 0.9 ppm, much smaller than the value (4.5 ppm)[13] observed in the cyclohexane ring.

Similar spectral features are observed in the ketones (**3b**—**7b**) due to the gauche interaction and the γ-effect (see Table 2). In addition to this, in this series, also the methyl-carbonyl interaction[14,15] is observed as in the case of the monomethyl ketone **2b**.[3,4] Table 4 summarizes the effect of this interaction on the ^{13}C chemical shifts (Δ) of the methyl and the peri ring carbons in each class of the methyl compounds (**3**—**7**), which is obtained from the differences of the carbonyl substituent effects (δ^{ab}) (Table 3) between the methylated compounds (**3**—**7**) and the parent compound **1** ($\Delta=\delta^{ab}$ (**3**—**7**)$-\delta^{ab}$ (**1**); see Tables 3 and 4 and

Table 3. Effect of 9-keto function on the ^{13}C chemical shifts of some 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalenes (δ^{ab} in ppm)[a]

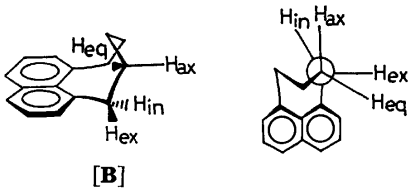
a) Obtained from the difference of the carbonyl substituent effect (δ^{ab}) (Table 3) between the methylated compounds (**2**—**7**) and the unsubstituted compound, $\Delta=\delta^{ab}_{(2-7)}-\delta^{ab}_{1}$; a minus sign indicates a low-field shift.
b) Data taken from Table 3.

footnotes therein). From this it is clear that, in all the methyl compounds, the axial methyl groups of the ketones (**b**) give chemical shifts almost comparable to the values found in the corresponding hydrocarbons (**a**), whereas the equatorial methyl groups of the ketones suffer marked shieldings (5.6—7.4 ppm) due to the eclipsed interaction between the carbonyl function and the equatorial methyl group. The carbonyl carbons of **3b**—**7b** ($\Delta\delta$=10.8—22.6 ppm) together with the C-8 (of **3b**—**7b**) and the C-10 (of **3b**, **6b**, and **7b**) carbons, which have the equatorial methyl groups on them ($\Delta\delta$=2.2—4.8 ppm), are also markedly shielded by the effect of this interaction.

The ^1H and ^{13}C data in the table show other spectral and conformational features characteristic of the boat conformation of the peri-eight membered ring. In both hydrocarbons (**a**) and the ketones (**b**), the proton chemical-shift differences between the axial and the equatorial methyl groups in **3**—**7** are greatly increased ($\Delta\delta$=0.35—0.55 ppm for **3a**—**7a** and 0.51—0.56 ppm for **3b**—**7b**) as compared with the cyclohexane system ($\Delta\delta$=0.07 ppm for methylcyclohexane[16] and 0.14 ppm for 2-methylcyclohexanone[17,18]) by the effect of the ring current of naphthalene.[3,7] The C-8 axial proton (H_{8ax}) of **3a** is greatly deshielded (*ca.* 0.8 ppm) relative to the corresponding proton (H_{1ax}) of *cis*-1,3-dimethylcyclohexane,[16] (see footnote in Table 1) since the H_{8ax} proton, which experiences the magnetic anisotropy effect of the adjacent C–C bondings smaller than that of the H_{1ax} proton (H_{8ax} is *trans* to the C_7–C_{6a} peri bond, see Fig. 1), is further deshielded by the ring-current effect of naphthalene ring (a calculation[7,19] reveals that the ring current of naphthalene deshields the axial and the equatorial protons on C-8 (and C-10) by *ca.* 0.52 and 0.37 ppm, respectively). Similar effect is observed for the H_{10ax} proton of **6a**, which is *ca.* 0.7 ppm deshielded relative to the corresponding proton of the cyclohexane ring.[16] On the other hand, marked deshieldings of the axial proton (H_{10ax}) (**3**, **5**, **6**; $\Delta\delta$= 1.02—1.21 ppm) relative to the equatorial proton (H_{10eq}) (**5**; $\Delta\delta$=0.84 ppm) by the effect of the carbonyl function might be caused chiefly by the σ-π bond overlap[20] as observed in the parent ketone **1b**.[2]

In all the compounds (**3**—**7**), whereas the chemical shifts of the exterior benzyl protons (δ=2.5—3.03 ppm) are almost comparable to the values (δ=2.219—2.875 ppm) found for the benzyl protons of the benzocyclic compounds **8**—**10**,[9-11] the interior protons of **3**—**7**, in contrast, are markedly deshielded (δ=3.71—4.86 ppm) due to the steric compression effect (the interatomic distance between the two interior protons has been calculated to be 0.652 Å for **1a**[1] and 0.632 Å for **1b**[3]). Thus it is expected that, as in the case of the parent compounds[1] and the monomethyl derivatives,[3] all the boat conformations (**3B**—**7B**) of compounds **3**—**7** exist in a somewhat distorted (puckered) form, in which the two interior protons are pushed apart mutually to relieve the steric repulsion between them.



[B]

Fig. 2. The distorted (puckered) boat conformation [**B**] and its Newman projection about the C_7–C_8 (C_{10}–C_{11}) bonds.

Recently, the crystal structures of the non-cyclized 1,8-disubstituted naphthalenes have been studied based on the X-ray analyses. This shows that the peri bonds of 1,8-dimethylnaphthalene undergo in-plane bending to give a planar structure,[5,21] while, in the most of the other compounds including 1,8-di-tert-butylnaphthalene,[5,22] the molecules are seriously distorted from planarity due to the out-of-plane bending of the substituting groups. In the present case, since the molecules of **3** and **7** have a C_s symmetry as have been suggested from the NMR spectra, it is reasonable to consider that, as in the case of the parent compound **1**, the peri bonds of **3**—**7** undergo chiefly in-plane bending rather than out-of-plane bending in solution to result in a symmetric (C_s passing through the C-9 and the angular carbon atoms of naphthalene nucleus) peri ring conformation [**B**] (Fig. 2) or a conformation close near to it (the contribution of the out-of-plane deformation, even if it actually existed in **3**—**7**, seems very small, since it would give unsymmetrical conformations).

Actually, the spectra of **3**—**6** show features characteristic of the distorted conformation—*i.e.*, the axial proton (H_{ax}) always couples more strongly with the interior proton (H_{in}) (J_{vic}=5.8—6.7 Hz) than with

the exterior proton (H_{in}) (J_{vic}=0—2.3 Hz)—as observed in **1** and **2**. This result may be explained much better by the space arrangement of the distorted conformation [**B**] (the dihedral angle (θ) for the H_{in} and H_{ax} protons is smaller than 60°, while it is larger than 60° for the H_{ex} and H_{ax} protons) than by the space arrangement of the undistorted conformation (**B**) (θ is close to 60°) (see Figs. 1 and 2).

Furthermore, the distortion of peri ring is also indicated from the internal dihedral angles (Ψ) calculated from the vicinal coupling constants about the C_{10}—C_{11} bonds of the *gem*-dimethyl compounds **5a** and **5b** (the calculations were performed using *R*-value method[23] as reported previously[1]). The magnitudes of Ψ obtained for these compounds (Ψ=47° for **5a** (*R* value; 1.1) and 48° for **5b** (*R* value; 1.2)) are approximately equal to the value found in the parent compound **1a** (46°)[1] and much smaller than the value of cyclohexane (58°)[23] which has an almost staggered conformation. Consequently, it seems reasonable to consider that all compounds **3**—**7** exist in the puckered conformation [**B**] rather than in the normal boat conformation (**B**) as a result of the steric repulsion of the interior benzyl protons.

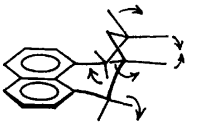


Fig. 3. Reflex effect in the 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene ring.

Examination of molecular models reveals that the puckering of the boat conformation is accompanied by the following geometrical changes of the peri ring. Namely, as can be seen in Fig. 3, (i) the two axial methyl groups on C-8 and C-10 are compressed, (ii) the equatorial groups on these carbons come at a position more distant from the naphthalene nucleus, and (iii) the C–C–C bond angle at C-9 carbon becomes contracted.

Thus it is expected that molecules of the tetramethyl compounds **7a** and **7b** exist in a less distorted (thus more flattened) form than those of the other compounds (**1**—**6**) due to the steric repulsion between the 1,3-synaxial methyl groups (on the other hand, the presence of steric congestions around the C-9 carbon in **7a** and **7b** have been suggested from the difficulties in effecting reactions at this position[8]). This is clearly indicated from the observation that the axial methyl protons of **7a** are 0.13 ppm more deshielded than those of compounds **5a** and **6a** due to the steric compression,[24] while the equatorial methyl protons of **7a**, which come spatially closer to the naphthalene ring than the equatorial methyl protons of **3a**, are 0.10 ppm more shielded than the latter protons by the effect of the ring current of naphthalene (in the cyclohexane system in which the effect of the naphthalene ring is absent, the equatorial methyl protons of the 1,1,3,3-tetramethyl derivative give chemical shift value approximately equal to that (δ=0.88 ppm) found for the equatorial methyl protons of the *cis*-1,3-dimethyl derivative[24]).

Moreover, whereas, in compounds **5** and **6**, the axial methyl protons of the geminal methyl group are more greatly deshielded (0.26 and 0.27 ppm) than the corresponding equatorial methyl protons (0.11 and 0.13 ppm) by the effect of the carbonyl function, in contrast, in the case of the tetramethyl compound **7**, the magnitude of the carbonyl deshielding effect is almost comparable for the axial (0.19 ppm) and the equatorial methyl (0.18 ppm) protons probably due to the flattening of the boat conformation described above (Table 1).

The flattening of the boat in **7** is also suggested from the chemical shifts of the benzyl methylene protons. Table 5 summarizes the chemical shift values of the benzyl methylene protons of compounds **3**—**7** calculated from the chemical shifts of the parent compounds **1a** and **1b** and those of the axial and the equatorial isomers

Table 5. Calculated ^1H chemical shifts of the benzyl protons of compounds (**3**—**7**) (in ppm)[a,b]

Compound	H_{7in}	H_{7ex}	H_{11in}	H_{11ex}

a) The chemical shifts of compounds (**3a**—**7a**) were calculated from the chemical shifts of the parent compound **1a** (Ref. 1) and the values of the methyl substituent effects obtained from the chemical shifts of the axial (**AB**) and the equatorial isomers (**EB**) of the 8-monomethyl derivative **2a** (Ref. 3); **2a-AB**: −0.30 (H_{7in}), −0.04 (H_{7ex}), −0.10 (H_{11in}), −0.04 ppm (H_{11ex}), **2a-EB**: 0.28 (H_{7in}), −0.30 (H_{7ex}), 0.02 (H_{11in}), −0.02 ppm (H_{11ex}) (a minus sign indicates a high-field shift). Similarly, the chemical shifts of (**3b**—**7b**) were calculated from those of **1b** (Ref. 2) and the values of the methyl substituent effects, obtained from the chemical shifts of the **2b-AB** and **2b-EB** isomers (Ref. 4); **2b-AB**: −0.33 (H_{7in}), −0.03 (H_{7ex}), −0.12 (H_{11in}), −0.08 ppm (H_{11ex}), **2b-EB**: 0.25 (H_{7in}), −0.31 (H_{7ex}), −0.12 (H_{11in}), −0.08 ppm (H_{11ex}). b) Figures in parentheses denote the differences of the chemical shifts between the observed (Table 1) and the calculated values; $\Delta\delta=\delta_{obsd}-\delta_{calcd}$.

of the monomethyl derivatives **2a** and **2b** (see footnotes in Table 5). Comparison of these calculated values with those observed in the spectra of **3**—**7** (Table 1) reveals that the chemical shift values observed in the hydrocarbons (**3a**—**6a**) differ from the calculated values by only −0.09—0.08 ppm, while the value observed for the interior benzyl protons of the tetramethyl compound **7a** is greatly increased (0.22 ppm) relative to the value obtained by the calculation. Similar result is obtained for the ketones (**3b**—**7b**), in which the chemical shift value observed for the interior benzyl protons of the tetramethyl ketone **7b** is larger than the calculated value by 0.37 ppm. The pronounced deshielding of the interior benzyl protons in **7a** and **7b** results possibly from the less puckered conformation of **7** mentioned above, since the distance of the interior protons in such conformation is somewhat shortened relative to that of the other compounds due to the synaxial CH_3–CH_3 interaction and thus the interior protons of **7a** and **7b** are expected to be more greatly compressed than the interior protons of the latter compounds.

The above result is also reflected in the ^{13}C NMR spectra. The methyl carbons (both axial and equatorial) of **7a** are considerably deshielded (2—3 ppm) relative to those of **5a** and **6a** (Table 2), while the carbonyl shielding effect in **7** is rather decreased (equatorial methyl, 5.6 ppm) as compared with the latter compounds (6.9—7.0 ppm) (Table 3). The deshielding of methyl carbons due to the steric compression has also been observed in other ring systems.[25]

In Table 6 are shown the chemical shifts of the peri ring carbons of compounds (**3**—**7**) calculated from the chemical shifts of the parent compounds **1a**[26] and **1b**[2] and the monomethyl compounds **2a**[3] and **2b**[4] (see footnotes in the table). This indicates that, in the hydrocarbons (**3a**—**7a**), the calculated values well agree with the observed data in Table 2 (*ca.* ±1 ppm) for all the positions except the C-8 carbon of the tetramethyl compound **7a**, which resonates at appreciably lower field (4.4 ppm) than the calculated value (the rather large deviations of the observed values for the C-8 and C-10 carbons from those calculated in **5a** might be caused chiefly by the geminal effect as observed in the cyclohexane ring;[13] the observed data of **6a** and **7a** in Table 2 are in better agreement with the calculated values by use of the data of **5a** rather than by use of the data of **2a** alone (this effect is also observed in the ketone **5b**)). Similar result is obtained for the ketones (**3b**—**7b**), where the C-8 carbon of **7b** is markedly deshielded (*ca.* 5 ppm) relative to the value obtained by the calculation (although details are not known at present, the relatively large deviations of the observed data from those calculated for the carbonyl carbons might be attributed chiefly to the alterations in geometry around the carbonyl group, since the magnitude of the carbonyl–methyl shielding effect is highly dependent on the steric arrangement between the two interacting groups[3]).

Consequently, it can be considered that the molecules of **7a** and **7b** are more greatly destabilized than those of **1**—**6** in their ground states due to the steric repulsions arising from the interior benzyl protons as well as the 1,3-synaxial methyl groups. This is a novel type of the "reflex effect" inherent in the 8-membered pericyclized naphthalene system, though the analogous effect is reported for the cyclohexane system.[27] Here, it is interesting that, whereas the interior benzyl protons of **7a** and **7b** are more greatly deshielded relative to those of the other compounds (**1**—**6**) by virtue of the reflex effect (Table 5), the chemical shifts of the benzyl

a) The chemical shifts of compounds (**3a**—**7a**) were calculated from the chemical shifts of the parent compound **1a** (see footnote inTabe 3) and the values of the methyl substituent effects, obtained from the chemical shifts of the axial (**AB**) and the equatorial isomers (**EB**) of the 8-monomethyl derivative **2a** (Ref. 3); **2a-AB**: 8.0 (C-7), 4.4 (C-8), 5.6 (C-9), −5.3 (C-10), −0.3 ppm (C-11), **2a-EB**: 6.0 (C-7), 3.5 (C-8), 8.3 (C-9), −0.3 (C-10), −0.7 ppm (C-11) (a minus sign indicates a high-field shift). Similarly, the chemical shifts of **3b**—**7b** were calculated from those of **1b** (Ref. 2) and the values of the methyl substituent effects obtained from the chemical shifts of the **2b-AB** and **2b-EB** isomers (Ref. 4); **2b-AB**: 8.6 (C-7), 6.0 (C-8), 3.8 (C-9), −4.2 (C-10), −0.2 ppm (C-11), **2b-EB**: 6.6 (C-7), −0.8 (C-8), 0.7 (C-9), −0.2 (C-10), 0.4 ppm (C-11). b) Figures in brackets indicate the calculated shift values obtained by use of the observed data of **5a** or **5b** (Table 2). c) Figures in parentheses are the differences of the chemical shifts between the observed (Table 2) and the calculated values; $\Delta\delta=\delta_{obsd}-\delta_{calcd.}$

methylene carbons of **7a** and **7b**, in contrast, are little influenced by the steric compression effect (Table 6). On the other hand, the steric compression of the synaxial methyl groups in **7a** and **7b** is clearly reflected in both proton and carbon chemical shift values of the axial methyl group as described above.

Similar result is obtained from the spectra of the parent compound **1a**. Comparison of the ^{13}C data of **1a** (see footnote in Table 3)[26] with those of the structurally analogous benzocyclic compound **8a** (36.6 (C-5,9), 28.2 (C-6,8), 32.6 ppm (C-7))[28] reveals that, although the interior benzyl protons of **1a** are markedly deshielded ($\Delta\delta$=1.1—1.2 ppm)[1] relative to the benzyl protons of **8a** due to the steric compression, the chemical shift values of the benzyl methylene carbons are quite equal (δ=36.6 ppm) between these two compounds; however, it should be noted here that the C-9 carbon of **1a** which has the gauche steric arrangements with the peri bonds (C_7–C_{6a} and C_{11}–C_{11a} bonds) in the boat conformation (see Newman projection in Fig. 1) is greatly shielded ($\Delta\delta$=11.3 ppm) relative to the C-7 carbon of **8a** which exists in the chair conformation.

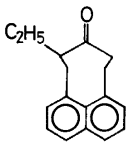
It is seen in Table 1 that in each class of methyl compounds, the interior benzyl protons of the ketones (**b**) are always greatly deshielded ($\Delta\delta$=0.51—0.63 ppm) relative to those of the corresponding hydrocarbons (**a**) (the values of shift difference are only 0.09—0.19 ppm for the corresponding exterior protons). Similar result was obtained for compounds **1** ($\Delta\delta$=*ca.* 0.67 ppm)[1,2] and **2** ($\Delta\delta$=0.5—0.7 ppm).[3,4] This result may be attributed chiefly to the difference in the interatomic distance of the interior benzyl protons. That is, the H_{in} protons of the ketone, the distance of which is shorter than that in the case of the hydrocarbon, are more greatly compressed and more greatly deshielded than the H_{in} protons of the hydrocarbon. However, in view of such large $\Delta\delta$ values found in the ketone, it is probable that the difference of the H_{in} distance between the ketone and the hydrocarbon is, in practice, somewhat larger than the value of 0.02 Å obtained from the calculation[1,3] (see above). Therefore it may be considered that the ketone exists somewhat in a less puckered form than the conformations of the hydrocarbon in each class of compound probably due to the rigid C-9 double (C=O) bond (see Fig. 3).

In the case of compounds **3a** and **3b** which have *cis*-diequatorial methyl groups, the molecules are expected to be more strongly puckered than the other compounds to relieve the steric interaction between the equatorial methyl groups and the naphthalene ring[3,4] (Fig. 3). The small $J_{ex,ax}$ value observed in **3a** (this coupling is small enough not to be resolved) probably reflects this (see Newman projection in Fig. 2).

The distortion of the peri ring is also reflected in the IR spectra. Table 7 shows the carbonyl stretching frequencies ν(C=O) of the methyl ketones (**2b**—**7b**) determined in the chloroform solution. The magnitudes of the ν(C=O) values obtained apparently depend on the orientations of the substituting methyl groups. This may be explained in terms of the inverse relationship between the stretching frequency and the carbonyl angle (>C=O)[27] as follows.

The carbonyl stretching frequency of the ketone **2b** (1706 cm^{-1}) having an equatorial methyl group (in **2b**, the methyl group prefers the equatorial conformation (**EB**) to the axials (**AB**) by 0.07 kcal/mol at room temperature)[4] is 3 cm^{-1} higher than the absorption (1703 cm^{-1})[29] of the unsubstituted ketone **1b**. This arises probably because the molecule of **2b** is more distorted (puckered) than that of **1b** to relieve the methyl-naphthalene interaction, which makes the carbonyl angle of **2b** somewhat smaller than that of **1b** (Fig. 3). This effect is more clearly shown in the spectrum of **3b** which has *cis*-diequatorial methyl groups. The carbonyl frequency of **3b** is increased by 8 cm^{-1} as compared with the parent ketone **1b**.

On the other hand, introduction of an axial methyl group at C-8 or at C-10 position of these compounds (**2b** and **3b**) results in a 5—8 cm^{-1} decrease in the carbonyl frequency (thus, 0—2 cm^{-1} decrease relative to **1b**) as observed in compounds (**4b**—**6b**), because the carbonyl angle in these compounds is, to some extent, expanded (thus the peri ring exists in a less puckered form) relative to that of the ketones **2b** and **3b** due to the 1,3-synaxial CH_3-H steric interactions (the existence of this interaction is also suggested from the observation that the C-8 or C-10 axial protons which have a synaxial steric relationship with a methyl group resonate at *ca.* 0.1—0.3 ppm lower field than the protons without such steric interactions; see footnote in Table 1). This effect is also observed in the axial isomer (**AB**) of 8-ethyl-8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalen-9-one (**11**) (in this compound, the



11

axial conformation is preferred to the equatorial conformation by 0.69 kcal/mol at room temperature),[4] where the carbonyl stretching frequency is lowered by 3 cm^{-1} as compared with the parent ketone **1b**.

The above result is in sharp contrast to the case of the α-methylcyclanones including the cyclohexane system previously reported. In 3-keto steroids,[30] introduction of one methyl group in the 2- or the 4-position causes a 4—7 cm^{-1} decrease in the carbonyl stretching frequencies, irrespective of whether the methyl group is in the axial or in the equatorial conformation; the carbonyl frequencies of the α-*gem*-dimethylated 3-keto steroids, therefore, are more greatly decreased (12—13 cm^{-1}) by the effect of the methyl groups[30] than in the case of the ketones (**4b**—**6b**) (0—2 cm^{-1}) which experience the puckering distortion due to the methyl(eq)–naphthalene steric interaction.

The carbonyl stretching frequency of the fully methylated ketone **7b** is greatly decreased (14 cm^{-1}) as compared with the parent ketone **1b**. Thus it is suggested that the carbonyl angle of **7b** is greatly expanded (thus the peri ring is flattened) relative to that of (**1**—**6**) in excellent agreement with the NMR spectra described above. Analogous effect was

TABLE 7. CARBONYL STRETCHING FREQUENCIES (νC=O) OF THE METHYL KETONES (**2b**—**7b**)[a]

Compound	Frequency ν(cm^{-1})	$\Delta\nu$[b]
Unsubstituted ketone (**1b**)[c]	1703

Cyclohexanone	1708[g]	+5

a) The IR spectra were measured in chloroform (spectro grade) at room temperature, using a 0.1 mm-length KBr cell. The concentration of the samples was *ca.* 0.1 mol/l for all the ketones and the measurements were run twice for each sample. The positions of absorption maxima were obtained from the expanded spectra and calibrated with polystyrene ($\Delta\nu=\pm0.5$ cm^{-1}). b) Frequency shift from the parent ketone **1b**. c) Ref. 29. d) The equatorial isomer (**EB**) is more favored than the axials(**AB**) by 0.07 kcal/mol at 30 °C (Ref. 4). e) The axial conformation is preferred to the equatorial conformation by 0.69 kcal/mol at 30 °C (Ref. 4). f) Shifted to 1705 cm^{-1} in carbon tetrachloride (Lit. 1703 cm^{-1}; Ref. 31). g) Reported to be 1716 cm^{-1} in carbon tetrachloride (Ref. 31).

reported[30] for 2,2,4,4-tetramethylcholestan-3-one, in which the carbonyl frequency is lowered by *ca.* 17 cm^{-1} as compared with the unmethylated compound.

As can be seen in Table 7, the carbonyl frequency of **1b** (1703 cm^{-1})[29] is 9 cm^{-1} higher than that of cyclooctanone and 5 cm^{-1} lower than that of cyclohexanone. Therefore it may be considered that the carbonyl angle of **1b** is probably between that of these two cyclanones, if it could be assumed that the magnitude of the carbonyl frequency depend solely upon the carbonyl angle irrespective of the ring system to which the ketones belong. This is consistent with the NMR result that the internal bond angle at C-9 carbon of the peri-8-membered ring system is, to some extent, contracted as a result of the puckering of the boat conformation (Fig. 3).

Previously, we have studied the ring inversions in compounds **1a**[1] and **1b**.[2] In order to determine the effect of the C-8 and C-10 methyl substituent on the ring inversions in the 8-membered pericyclized naphthalene system, the free energy barriers to boat-to-boat interconversion process were investigated for several methylated compounds (8-methyl (**2a**), *trans*-8,10-dimethyl (**4a**), 8,8-dimethyl (**5a**), and 8,8,10,10-tetramethyl (**7a**)) and their 9-oxo derivatives (**2b**, **4b**, **5b**, and **7b**) by use of the variable-temperature ^{1}H NMR technique. In these conformational changes, three types of ring inversions are observed. In compounds **4** and **7**, a degenerate process occurs in which the conformer exchanges with itself. In compound **5**, the ring inversion process is enantiomeric, while **2** undergoes conformational inversion into its diastereomer. In all of these conformational processes, the methyl group in each compound is interchanged between the axial and the equatorial conformations of equal conformational energies (since the ($-\Delta G^\circ$) values for **2a**[3] and **2b**[4] are very small, the populations of the two isomers in these compounds were assumed to be equal at the temperatures studied).

We therefore examined the ^{1}H NMR spectra of the methyl groups of each compound as a function of the temperature (for **2a**, **2b**, and **4b**, the deuterated derivatives **2a**-8,10,10-d_3,[3] **2b**-8,10,10-d_3,[4] and **4b**-8,10-d_2 were employed, respectively). The methyl signals in all compounds show a change typical of the dynamic exchange processes on varying the temperature—*viz.*, the two separated methyl signals at low temperature broaden, coalesce, and then sharpen as the temperature is increased. From these spectral changes the free energy barrier (ΔG^*) to boat inversion for each methyl compound is calculated by means of the coalescence temperature (T_c) method (see footnotes in Table 8).[32] The results are summarized in Table 8 together with the data of the parent compounds **1a**[1] and **1b**[2] previously reported.

As can be seen in the table, the free energy barriers (ΔG^*) for 8-monomethyl derivative **2a** and *trans*-8,10-dimethyl compound **4a** are almost comparable to the value of the parent compound **1a** ($\Delta\Delta G^*=0.4$ and 0.6 kcal/mol, respectively), whereas barriers for the *gem*-dimethyl compound **5a** and the tetramethyl compound **7a** are markedly increased as compared with **1a** ($\Delta\Delta G^*=5.4$ and 5.9 kcal/mol, respectively). A similar trend is observed in the ΔG^* values of the ketones, where the ΔG^* for **5b** and **7b** is much higher than the value of **1b** ($\Delta\Delta G^*=4.8$ and 5.6 kcal/mol, respectively), whereas that of **2b** and **4b** is approximately equal to the value of **1b** ($\Delta\Delta G^*=-0.1$ and 0.2 kcal/mol, respectively). The observation of the same trend in ΔG^* for the hydrocarbons (**a**) and the ketones (**b**) strongly suggests that the boat conformation of both classes of methyl compounds interconverts through the same pathway. Therefore, it seems reasonable to assume[32] that ΔG^* differences in Table 8 ($\Delta\Delta G^*$) are fair approximations to $\Delta\Delta H^*$ for all the methylated compounds studied.

Recently, it has been shown that the boat-to-boat interconversion in the 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene ring proceeds by pseudorotations of the peri bonds *via* the twist-boat conformation (**TB**) as an intermediate,[1,6] the transition state for this process being possibly a high-energy conformation (**TS**)[1,2] (see Fig. 4). The ΔG^* value of each methyl compound in Table 8 can be adequately explained in terms of the boat inversion mechanism described above.

In **2a** and **2b**, the methyl substituent could produce no serious steric interaction either in the (**TS**) or in the (**TB**) conformation during the ring inversion as is seen in Fig. 5. In these compounds, the transition state of boat inversion may somewhat be elevated as a result of the methyl substitution (which could cause some increase in the torsional barrier for rotation about the C_8–C_9 and C_9–C_{10} bonds in (**TS**)), but the ground state is also elevated due to the transannular synaxial CH_3–H interaction or to the eq-CH_3–naphthalene gauche

Table 8. Free energy barriers ($\Delta G^{\ddagger}$) to boat inversion for several 8- and 10-methyl-substituted 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalenes (**a**) and their 9-oxo compounds (**b**)[a,b]

Compound	Signal obsd	$\Delta\nu$/Hz[e]		T_c/°C		$\Delta G^{\ddagger}$/kcal·mol^{-1} [f]		Difference[g]

7; $R_1=R_2=R_3=R_4=CH_3$

Fig. 5. Steric interaction in the twist-boat conformation (**TB**)(C_2) of compounds (**1**—**7**) viewed from in front of the C-9 carbon (naphthalene moiety is omitted).

interaction, as the result of which the effect of the methyl group on the barrier to ring inversion seems very small. Similar arguments are also valid for **4a** and **4b** (see Fig. 5). Therefore it is understandable to observe that the $\Delta G^{\ddagger}$ values for compounds **2a**, **2b**, **4a**, and **4b** are almost comparable to the values for the parent compounds or slightly higher than the values of the latter compounds.

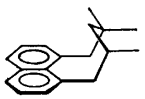
On the other hand, in the case of compounds **5a** and **5b** which have one *gem*-dimethyl group in the C-8 position, the pseudorotations of the peri bonds give rise to a close approach of the methyl substituent to the peri hydrogen (at C-11) in the transition state as well as in the (**TB**) conformation (in compounds **2** and **4** without a *gem*-dimethyl group at C-8, this interaction is avoidable) (Fig. 5). Therefore, it is expected that the (**TS**) of **5a** and **5b** is more greatly elevated relative to **4a** and **4b** by the interaction of these two groups. In view of this together with that the energy of the ground state of **5a** and **5b** is close near to that of **4a** and **4b** (in both cases, the synaxial CH_3–H interaction and the (eq)CH_3–naphthalene interaction are the most important), it is understandable to observe that the $\Delta G^{\ddagger}$ values of **5a** and **5b** are unusually higher than the values of **4a** and **4b** as well as those of **2a** and **2b**.

For the same reason, the $\Delta G^{\ddagger}$ for the tetramethyl compounds **7a** and **7b** is also markedly increased as compared with the parent compounds (see Fig. 5). In this case, the $\Delta G^{\ddagger}$ value for **7a** and **7b** shows only a small increase ($\Delta\Delta G^{\ddagger}<1$ kcal/mol) relative to **5a** and **5b**, respectively, though the (**TS**) and (**TB**) of the former compounds are more greatly destabilized than those of the latter compounds (**7a** and **7b** involve twice a steric interaction as that present in **5a** and **5b**; Fig. 5). This arises probably because the ground state of **7** is greatly destabilized by virtue of the reflex effect arising from the the synaxial CH_3–CH_3 steric interaction coupled with the interior benzyl H–H interaction as described above.

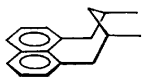
The above result is in striking contrast to the case of other ring systems such as the cyclohexane and 6,7,8,9-tetrahydro-5*H*-benzocycloheptene (**8**). The $\Delta G^{\ddagger}$ value for the chair inversion of 6,6-dimethyl- (**9**) and 6,6,8,8-tetramethylbenzocycloheptene derivatives (**10**) is only slightly increased (**9**; 0.6 kcal/mol) or lowered (**10**; 0.3 kcal/mol) relative to the unmethylated com-

pound **8a**.[9] Similarly, the $\Delta G^{\ddagger}$ value for the 1,1-dimethyl- and 1,1,3,3-tetramethylcyclohexane derivatives is slightly higher (0.1 kcal/mol) or lower (0.9 kcal/mol), respectively, than the value for the parent cyclohexane.[33]

In each methyl compound, $\Delta G^{\ddagger}$ for the ketone (**b**) is always lower than the value for the corresponding hydrocarbon (**a**) by 2.4—2.7 kcal/mol. Similar trend has been observed for the parent compounds ($\Delta\Delta G^{\ddagger}$= 2.1 kcal/mol).[1,2] This result may be adequately explained in terms of the boat inversion mechanism described above. The pseudorotations of the peri bonds in the boat inversion are accompanied by rotations about the C_9–C_{10} and C_8–C_9 bonds in the conversions of (**B**)⇆(**TS**)⇆(**TB**) and (**TB**)⇆(**TS**)*⇆(**B**)*, respectively.[1] Thus, in view of the barriers to methyl rotation in propane (3.3 kcal/mol)[27] and acetone (0.8 kcal/mol),[33] it is expected that energies necessary for reaching the transition states in the ketone (**b**) are smaller than in the case of the hydrocarbon (**a**) by the value close to the difference in the barrier between propane and acetone.[33] Actually, the difference in $\Delta G^{\ddagger}$ observed between the ketone and the hydrocarbon in each methyl compound is almost comparable to the value observed in propane and acetone. Moreover, in each compound of (**2**—**7**), the effect of the methyl group on $\Delta G^{\ddagger}$ is always larger for the hydrocarbon than for the ketone by 0.3—0.6 kcal/mol. This might be taken chiefly as a reflection of the difference in the torsional barriers about the C_8–C_9 and/or C_9–C_{10} bonds between the hydrocarbon and the ketone caused by the steric interaction with the methyl group.



6B′



3B′

On the other hand, the ^{1}H NMR spectra of **3b** and **6b** reveals that conformations of **3B** and **6B** are also enough stable at room temperature (these spectra show no change below 90 °C), because another boat (**3B′** and **6B′**) involves steric repulsion due to the synaxial methyl groups and the (**TS**) and (**TB**) states involve the peri-H-CH_3 steric interaction as illustrated in Fig. 5.

All the results presented above provide a strong evidence that the boat inversion is caused by pseudorotations of the peri bonds in the 8-membered pericyclic naphthalene ring system. Consequently, this study reveals that the molecule of the 8-membered pericyclized naphthalenic compounds exists in a steric circumstance very different from that of the cycloalkanes and the benzocyclic compounds not only in the ground state but also in the transition state due to the peri strains involved.

Experimental

The synthesis of 8- and 10-methyl-substituted 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalenes (**3a**—**7a**) and their 9-oxo derivatives (**3b**—**7b**) have been reported previously.[8] The deuterated compounds, *cis*-8,10-dimethyl-8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalen-9-one-8,10-d_2 (**3b**-d_2), *trans*-8,10-dimethyl-8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]-naphthalen-9-one-8,10-d_2 (**4b**-d_2), and 8,8,10-trimethyl-8,9,10,-11-tetrahydro-7*H*-cycloocta[*de*]naphthalen-9-one-10-*d* (**6b**-*d*) were obtained from the ketones **3b** and **6b** using the deuterium exchange procedure previously described.[1] Deuteration of **3b** in a boiling mixture of potassium carbonate in dioxane and deuterium oxide gave an equilibration mixture from which **3b**-d_2 and **4b**-d_2 were isolated by recrystallization from ethanol. Similar result was obtained on reaction (boiling with a solution of sodium deuteroxide in dioxane and deuterium oxide) with diethyl 8,10-dimethyl-9-oxo-8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene-8,10-dicarboxylate.[8] The structures of the deuterated compounds were confirmed on the basis of the TLC, melting points (**3b**-d_2; 228—229 °C (**3b**; 230—231 °C),[8] **4b**-d_2; 125—126 °C (**4b**; 126—127 °C),[8] **6b**-*d*; 125—126 °C (**6b**; 124.5—125 °C)[8]), and their spectra (IR and NMR).

The ^{1}H NMR spectra were determined on a Varian HA-100D spectrometer at 100 MHz using a *ca.* 10% (w/v) solution of samples in deuteriochloroform (for compound **3b**, a *ca.* 3% solution was employed); the chemical shifts are expressed in ppm (δ) downfield from the internal standard, tetramethylsilane, and the coupling constants (J), in Hz with an accuracy of ±0.1 Hz. The variable-temperature ^{1}H NMR studies were carried out using a deuteriochloroform solution for all compounds except **5a** and **7a**, which were measured in *o*-dichlorobenzene. The sample temperature was controlled by passing precooled nitrogen through the sample cavity and measured by a calibrated copper–constantan thermocouple. The ^{13}C NMR spectra were determined on a Varian NV-14 FT NMR spectrometer operating at 15.087 MHz, using deuteriochloform as a solvent and tetramethylsilane as an internal standard (accuracy, ±0.1 ppm). The IR spectra were measured on a JASCO IR-G grating infrared spectrometer using a *ca.* 0.1 mol/l solution of samples in chloroform (spectro grade) with a 0.1 mm-length KBr cell. The measurements were run twice for each compound, and the positions of absorption maxima were calibrated with polystyrene ($\Delta\nu$= ±0.5 cm^{-1}).

Synthetic Photochemistry. XIII.[1] Chiroptical Retention for the Reported "*antara-antara*"-3,3-Sigmatropy of Bicyclo-[3.2.0]hepta-3,6-dien-2-ones

Hitoshi TAKESHITA,* Masatoshi KUMAMOTO, and Isao KOUNO
Research Institute of Industrial Science, 86, Kyushu University, Hakozaki, Fukuoka 812
(Received March 26, 1979)

Troponoids were shown to form 2: 1-complexes with β-cyclodextrin and 1: 1-complexes with α-cyclodextrin. The photoisomerization of complexed tropolone and 2-methoxytropone gave optically active 1-hydroxy- and 1-methoxybicyclo[3.2.0]hepta-3,6-dien-2-ones in improved yields. The pyrolysis of the (+)-1-methoxybicyclo-[3.2.0]hepta-3,6-dien-2-one gave the (+)-3-methoxybicyclo[3.2.0]hepta-3,6-dien-2-one, ruling out the two-fold *supra-antara*-1,3-sigmatropy.

The utilizations of inclusion complexes for organic syntheses have been of interest,[2,3] but although there are many applications in various aspects including photolyses,[4] the photochemical valence-isomerization of guest molecules seems not to have been studied. We will herein describe the results of the photoisomerization of cyclodextrin (CDX)-complexed tropolone derivatives to give bicyclo[3.2.0]hepta-3,6-dien-2-ones, primary photoproducts, with improvements in the yields and in the rates of the reaction, For the large-scale preparation of bicyclo[3.2.0]heptadienones, the previous method, photoisomerization in solutions,[5,6] was inadequate.

When an aqueous solution of β-CDX was mixed with tropolone (**1**), colorless precipitates were formed immediately. According to the titrations, the precipitates, [**1**: β-CDX], were analyzed and found to contain 2 mol of **1** for a CDX unit. A similar type of 2: 1-complex was formed from 2-methoxytropone (**2**) and tropone (**3**). On the contrary, α-CDX was shown to form 1: 1-complexes with these troponoids.

The regeneration of troponoids from the complexes required a prolonged liquid-liquid extraction; a simple separatory extraction or solid-liquid (Soxlét) extraction was not effective.

By the external irradiation of [**1**: β-CDX] as a water dispersion, a known photoisomer of **1**, 1-hydroxybicyclo[3.2.0]hepta-3,6-dien-2-one (**4**),[6] was obtained in a 64% yield after the liquid-liquid extractions. As a minor product, 4-oxo-2-cyclopentenylacetic acid (**7**)[6] was also obtained. On the other hand, [**2**: β-CDX] and [**2**: α-CDX] were relatively soluble in water, and the photoreaction needed a prolonged time to give **5**, **6**, and **8**,[5] while in hexane the isomerization proceeded more efficiently. There is an apparent correlation between the solubility and the rate of the reaction; the less soluble the media, the greater the rate of the reaction. Figure 1 shows the comparative figures of this medium effect. It can also be noticed that, except for water, the rates of the reaction are not very different

Chart 1.

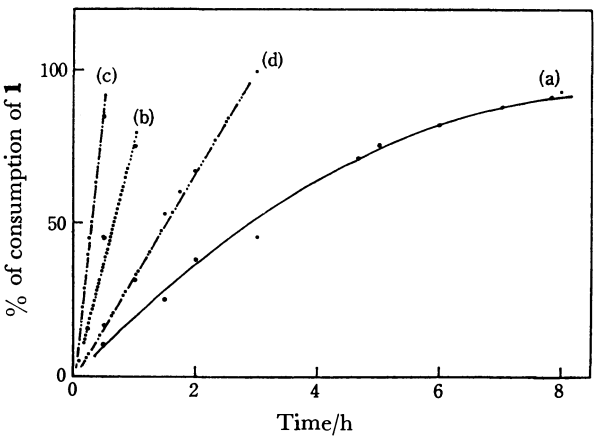

Fig. 1. Relative rates of photoreaction of **1** under various conditions. (a) in water without CDX, (b) in hexane without CDX, (c) as [**1**: α-CDX] in water, and (d) as [**1**: β-CDX] in water.

TABLE 1. THE PRODUCT DISTRIBUTIONS FOR THE PHOTOREACTION OF [**1**: CDX][a] IN VARIOUS SOLVENTS

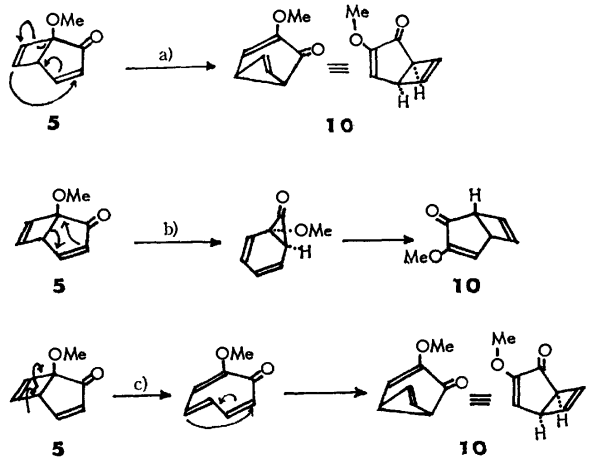
Complexes	Media for dispersion	Isolated yields for **4**	Isolated yields for **7**
[**1**:α-CDX]	Water	68	21
	Methanol	65	15
	Acetone	58	10
	Hexane	66	20
[**1**:β-CDX]	Water	64	22
	Methanol	55	20
	Acetone	60	18
	Hexane	55	15

a) For each run, *ca.* 250 mg of **1** was used to prepare the complexes.

in various organic media, protic or aprotic; this is probably a reflection of a tight inclusion of troponoids in CDX. In the case of **2**, it is well known that the original product (**5**) was easily converted into the secondary photoproduct (**6**).[5]

These photoisomers were optically active; their ORD and CD curves are illustrated in Fig. 2, while some $[\alpha]_D^{20}$ values are shown in Table **2**.[7] The amplitudes of the optical rotation of the photoproducts obtained from [β-CDX] were larger than those obtained from

[α-CDX], and the amplitudes for the products of aprotic solvents were larger than those for protic solvents. Although we do not know the mechanism of this asymmetric reaction in detail, a host-guest interaction, *e.g.*, hydrogen bonding, may result in the geometrical fixation of troponoids in the asymmetric circumstance of the CDX molecules.[8] In this sense, it is interesting that the signs of the Cotton effect of **4** from **1** (proton-donor) and of **5** from **2** (proton-acceptor) are opposite. Furthermore, the opposite Cotton effects for **5** and **6** probably represents an inversion of asymmetric centers during the isomerization of **5** into **6**. This is in accord with the allowed 3*s*,3*s*-sigmatropy *via* the ketene intermediate (**B**), as has already been established.[9] The other path, the 1*s*,3*s*-process, retains the sign of the Cotton effect.



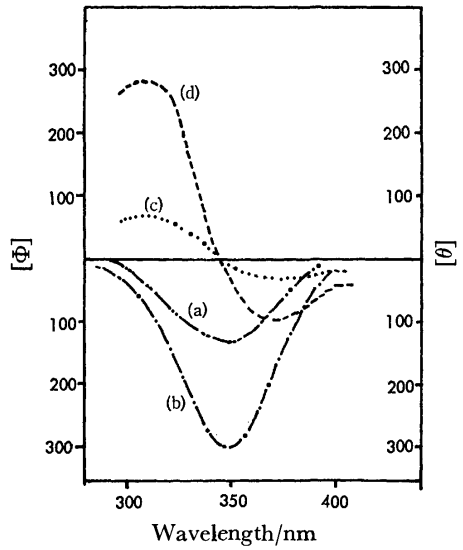


Fig. 2. The CD and ORD spectra of **4** obtained from [**1**: CDX]. (a) CD curve of **4** from [**1**: α-CDX] in water, (b) CD curve of **4** from [**1**: β-CDX] in water, (c) ORD curve of **4** from [**1**: α-CDX] in water, and ORD curve of **4** from [**1**: β-CDX] in water.

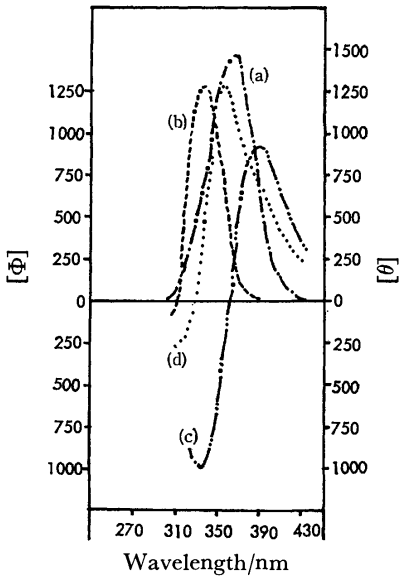

Fig. 3. The CD and ORD spectra of **5** and **10**. (a) CD curve of **5**, (b) CD curve of **10**, (c) ORD curve of **5**, and (d) ORD curve of **10**.

Table 2. The specific rotations of photoproducts

	$[\alpha]_D^{20}$(Concentration)	Irradiation conditions
4	−10.9°(*c*=1.15, MeOH)	(**1**: β-CDX) in H_2O
4	nil	(**1**: α-CDX) in H_2O
4	−9.8°(*c*=0.25, MeOH)	(**1**: α-CDX) in Hexane
5	+104°(*c*=0.24, MeOH)	(**2**: β-CDX) in H_2O
6	−22.7°(*c*=0.38, MeOH)	(**2**: α-CDX) in H_2O
6	−91.8°(*c*=0.24, MeOH)	(**2**: β-CDX) in H_2O

When a xylene solution of **4** was refluxed for 30 min, 3-hydroxybicyclo[3.2.0]hepta-3,6-dien-2-one (**9**) (25%) was obtained, together with **1** (25%). **9** has lost its optical activity. Even a brief heating at 110—115 °C for 5 min caused a complete racemization of the recovered **4** by means of a degenerated acyloin rearrangement.[10]

Then, an *o*-dichlorobenzene solution of **5** was refluxed for 3.5 h to give 3-methoxybicyclo[3.2.0]hepta-3,6-dien-2-one (**10**) (15%) as the sole isolable compound. **10** has retained its optical activity, with the same sign as the starting material, **5** (see Fig. 3).

This type of rearrangement, **5** to **10**, was originally found by Mukai *et al.*[11] during the pylolysis of the 6-isopropyl derivative of **5**; at the sametime, the arrangement of the carbon atoms in the products was proved by using deuterio derivatives. Since then, this has been referred to as a unique example of a 3*a*,3*a*-sigmatropy (Route a)) in the literature,[12-15] but the mechanism of the reaction is still a point in dispute. Routes b), a two-fold 1*s*,3*a*-sigmatropy,[16] and c), an intermediary formation of a *cis-trans-cis*-triene (a *trans*-tropone),[17] which then suffers a thermal conrotatory cyclization,[18] have been alternatively suggested as plausible mechanisms. The differentiation of a), a concerted process, and c), a step-by-step process, may come from the view of the intermediate *trans*-tropone, and the present results alone can not provide information on such a point. However, the retention of the sign of the optical rotation for **10**

TABLE 3. CHARACTERIZATIONS OF CDX-COMPLEXES OF TROPONOIDS

Complexes	Yields/%	Ratio of tropones/host by UV spectrometry
[**1**: α-CDX]	85	0.85
[**1**: β-CDX]	83	1.80
[**2**: α-CDX]	45	0.87
[**2**: β-CDX]	65	1.91
[**3**: α-CDX]	75	0.76
[**3**: β-CDX]	68	1.66

clearly rules out Route b), by which chiroptically inverted **10** should be produced, as is shown in Chart 2. At the same time, any route involving a radical process,[15,16] which has been discarded on kinetical grounds,[12] can be conclusively eliminated.

According to Day *et al.*,[6] the formation of **7** can be diminished also by irradiation in aprotic solvents; however, this does not mean an improvement of the yields. In fact, a satisfactory yield of **4** was obtained only by the reaction in a very diluted solution; otherwise, a tarry, intractible mass was formed.

Experimental

Preparation of Inclusion Complexes (General Method). To an aqueous solution of CDX, two molar equivalents (for β-CDX) or one molar equivalent (for α-CDX) of troponoids, **1**, **2**, and **3**, were added. The precipitates thus formed were collected by filtration. The subsequent evaporation of the filtrate and washings of the residue with hexane yielded an additional amount of complexes.

The UV Titrations of the Troponoids–CDX Complexes. A constant weight of the CDX complexes of troponoids was dissolved in water and then determined by UV spectrometry. The results are summarized in Table 3.

Titrations of [1: CDX]. Aqueous solutions of [**1**: CDX] were diluted with constant volumes of 0.01 M (1M=1 mol dm^{-3}) KOH solutions and titrated by 0.01 M HCl. The results showed **1**/α-CDX=0.97 and **1**/β-CDX=1.82.

Photochemical Reaction of 1 as the Inclusion Complex with CDX. a): (General Method). A powdered complex of **1**, [**1**: β or α-CDX], was dispersed in a solvent (water, ethanol, hexane, or acetone) and irradiated by means of a 400-W high-pressure mercury lamp for several hours. Water was then added to the mixture, and it was continuously extracted with diethyl ether. The extracts were purified by silica gel chromatography; fractions eluted with benzene: diethyl ether (10: 1) afforded **4**, while subsequent fractions eluted with benzene: diethyl ether (5: 1) afforded **7**.

b): [**1**: β-CDX] (820 mg) was spread over an aluminum foil and externally irradiated by means of a 100-W high-pressure mercury lamp for 5 h. Continuous liquid-liquid extraction (diethyl ether: water) and subsequent silica gel chromatography of the extracts afforded **4** (23 mg, 36%), **7** (10 mg, 16%), recovered **1** (45 mg, 42%), and an unidentified oil (3 mg).

Photochemical Reaction of 1 in Hexane (Without CDX). a): A hexane solution (45 cm^3) of **1** (20 mg) was externally irradiated by means of a 100-W high-pressure mercury lamp for 10 h. Subsequent silica gel column chromatography of the mixture afforded **4** (8.3 mg, 42%), **7** (3.9 mg, 17%), and an unidentified oil (3 mg).

b): A hexane solution (45 cm^3) of **1** (120 mg) was similarly irradiated. The separation of the mixture gave **4** (6.7 mg, 5.6%) and **7** (2.5 mg, 1.7%).

Photochemical Reaction of 2 as the Inclusion Complex with β-CDX. a): A water (45 cm^3) suspension of [**2**: β-CDX] (300 mg) was externally irradiated by means of a 100-W high-pressure mercury lamp for 72 h. The reaction mixture was then continuously extracted with diethyl ether and chromatographed on a silica-gel column; from benzene, **6**, 13 mg (45%), and **5**, 7 mg (24%), were obtained, while from benzene: diethyl ether (10: 1), **8**, 3 mg (9%), was obtained together with the recovered **2**, 5 mg.

b): [**2**: β-CDX] (480 mg) was dispersed in hexane (50 cm^3) and then irradiated by means of a high-pressure mercury lamp for 24 h. The subsequent separation of the reaction mixture yielded **5** (19 mg, 30%), **6** (20 mg, 32%), and **8** (9 mg, 13%), together with the unreacted **2** (12 mg).

Pyrolysis of 4. Optically active **4** (48 mg) was dissolved in dimethyl sulfoxide (0.5 cm^3) and heated at 130—135 °C for 2 h. The NMR spectrum of the mixture indicated the presence of **9** and **1** in a ratio of 3: 2, but every attempt to isolate **9** failed; only **1** (15 mg, 31%) was obtained by silica-gel chromatography. The $[\alpha]_D^{20}$ value of the pyrolysate mixture was determined to be $\pm 0°$.

A Brief Heating of 4. **4** (15 mg) was dissolved in dimethyl sulfoxide (0.5 cm^3) and heated at 110—115 °C for 5 min, after which, the mixture was fractionated to isolate the recovered **4** (8 mg, 53%). The $[\alpha]_D^{20}$ value of the recovered **4** was $\pm 0°$. The CD spectrum showed no Cotton effect.

Pyrolysis of 5. **5** (20 mg) was dissolved in *o*-dichlorobenzene (3 cm^3) and refluxed for 3.5 h. The mixture was heated *in vacuo* to remove the solvent; the residue was then chromatographed on a silica-gel column to give oily **10** (3 mg, 15%) as the sole product.

18) J. H. Baldwin and M. S. Kaplan, *J. Chem. Soc., Chem. Commun.*, **1970**, 1560. Their main reason for proposing Process c) is based on the fact that the rearrangement requires a conjugated diene system in the molecules.

Cyclopentenone Synthesis from 1,1-Dichloroallyllithium–Ketone Adducts as Well as from Dichlorocarbene–Allyl Alcohol Adducts

Tamejiro HIYAMA,* Masaki SHINODA, Masao TSUKANAKA, and Hitosi NOZAKI
Department of Industrial Chemistry, Kyoto University, Yoshida, Kyoto 606
(Received July 3, 1979)

Treatment of (3,3-dialkyl-2,2-dichlorocyclopropyl)methanols with hydrobromic acid gives 2-cyclopentenones through postulated intermediates, 3-chlorocyclopentadienyl cations. Another method which should give the same cationic intermediates involves trifluoroacetic acid catalyzed reaction of 3,3-dichloro-1-alken-4-ols. This is found to be particularly useful for cyclopentenone annulation.

The construction of five-membered carbocyclic system is important in the synthesis of physiologically active natural products.[1] We wish to describe two new methods based on the thermal conrotatory ring-closure of 3-chloropentadienyl cation.[2]

During the course of the study of carbenoid chemistry,[3] it was found that dichlorocarbene generated by the phase-transfer technique[4] adds efficiently to allyl alcohols, in contrast to the previous observation by Seyferth and Mai.[5] For example, 4-methyl-3-penten-2-ol was converted into the dichlorocyclopropane **1** in 92% yield without appreciable deoxygenation[6] or chlorination.[7] When the adduct **1** was heated in 47% hydrobromic acid at 100 °C, 3,5-dimethyl-2-cyclopentenone (**2**)[8] was produced in 83% yield. Application of this procedure to various allyl alcohols **3** gave 2,3-disubstituted 2-cyclopentenones **5** (Table 1).

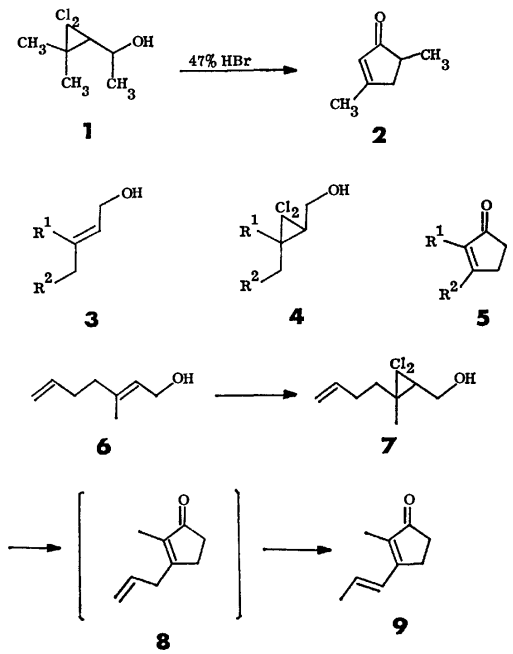
Table 1. Synthesis of 2-cyclopentenones from allyl alcohols

Allyl Alcohol	Dichlorocyclopropane[a] %yield	Cyclopentenone[b] % yield
3a	**4a**, 79	**5a**,[c] 44
3b	**4b**, 79	**5b**,[d] 56
3c	**4c**, 60	**5c**,[d] 59
3d	**4d**, 77[e]	**5d**,[f] 76

a) Dichlorocarbene was generated by the phase-transfer technique. b) The (dichlorocyclopropyl)methanol **4** was heated in hydrobromic acid at 100 °C for several hours unless otherwise specified. c) Ref. 28. d) Ref. 24. e) Alcohol was converted into α-ethoxyethyl ether before the dichlorocarbene addition and afterwards the protecting group was removed. f) Heating **4d** in trifluoroacetic acid under reflux for 90 h.

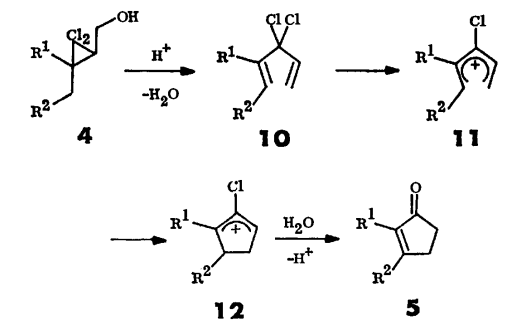
Although the dichlorocarbene addition generally proceeds well,[9] the yield of the particular adduct **4d** was very unsatisfactory, the overall yield of **5d** being only 37%.[2a] However, the yields were much improved by protecting the hydroxyl group with ethyl vinyl ether. Protection, dichlorocarbene addition and regeneration of the hydroxyl group[10] gave **4d** in 77% isolated yield. Subsequent acid treatment of **4d** was best performed with trifluoroacetic acid (TFA) which was found to be a less reactive reagent than hydrobromic acid but far more selective to give the desired enone **5d** in 76% yield.

The cyclopropylmethanol **7** obtained by selective $:CCl_2$ addition to the allyl alcohol **6**[4] was transformed into 2-methyl-3-(*trans*-1-propenyl)-2-cyclopentenone (**9**). Under these acidic conditions the anticipated cyclopentenone **8** isomerized to the conjugated dienone **9**.



a, $R^1=CH_3$, $R^2=H$
b, $R^1=CH_3$, $R^2=n\text{-}C_4H_7$
c, $R^1=CH_3$, $R^2=n\text{-}C_5H_{11}$
d, R^1, $R^2=-(CH_2)_{10}-$

The mechanism of the cyclopentenone formation can be rationalized by Scheme 1. Conjugate dehydration of **4** gives a dichlorodiene **10**, which undergoes solvolysis to yield a chloropentadienyl cation **11**. Thermal conrotatory ring closure of **11** gives a chlorocyclopentenyl



Scheme 1.

cation **12**, deprotonation followed by hydrolysis giving the cyclopentenone **5**. Noteworthy is the regiochemistry of the reaction. Heating **4b** in hydrobromic acid afforded 3-butyl-2-methyl-2-cyclopentenone (**5b**) exclusively, and none of the corresponding isomer, 2-pentyl-2-cyclopentenone was detected. It should be noted that the original methyl group is not incorporated into the five-membered ring and a long alkyl appendage resides at the C(3) position. The initial dehydration of **4** and the final deprotonation in **12** are controlled to give the more substituted olefins.[11]

In order to confirm the above mechanism we chose a dichlorohomoallyl alcohol (Scheme 2) as an alternative precursor of the intermediates **10**—**12**. The dichlorohomoallyl alcohol **14** was prepared according to the reported method.[12] Thus, 1,1-dichloroallyllithium was prepared *in situ* and directly allowed to react with ketone by adding lithium diisopropylamide to a mixture of a ketone and 3,3-dichloropropene. The adduct was successively subjected to acidic conditions. First we studied the conversion of **13d** into **5d** and found that various acids are effective. Acid, conditions, and % yield were: hydrobromic acid–acetic acid, reflux, 3 h, 55; titanium tetrachloride-dichloromethane, room temp, 3 h, 81; TFA, reflux, 1.5 h, 89; TFA, room temp, 1.5 h, 90. Thus, under the last condition **13c**—**g** were transformed into **5**. The results are summarized in Table 2.

Table 2. Cyclopentenone annulation

Ketone	Dichlorohomoallyl alcohol,[a] % yield	Cyclopentenone[b] % yield
13c	**14c**, 73	**5c**, 87
13d	**14d**, (66)[c]	**5d**,[d] 90
13e	**14e**, 68	**5e**,[d] 80
13f	**14f**, 63	**5f**,[e] 87
13g	**14g**,[f] 56	**5g**,[g] 71

a) The adducts were obtained by adding 1.5 equivalents of lithium diisopropyl amide to a mixture of **13** and 3,3-dichloropropene (1.5equiv) in tetrahydrofuran at −78°C. See Ref. 12a. b) Transformation of **14** to **5** was carried out in TFA at room temperature for a couple of hours. c) The yield was taken from Ref. 12a. d) Ref. 25. e) Ref. 26. f) This compound was synthesized by Seyferth *et al.* (Ref. 12b) using dichloroallyllithium generated by transmetallation. g) Ref. 27.

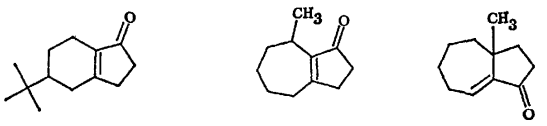
f, R^1, $R^2=-(CH_2)_5-$
g, R^1, $R^2=-(CH_2)_4-$

Scheme 2.

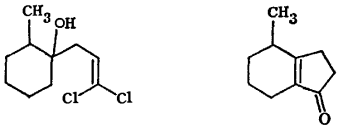
Apparently the two step procedure is applicable to both cyclic and acyclic ketones and particularly efficient for cyclopentenone annulation. Although cationic intermediates are involved in the reaction sequence, transannular by-path[13] is negligible in the cyclization of the medium-ring compound **14e** which gives cyclopentenone **5e** in 54% overall yield. The two step process makes 5-substituted tetrahydroindanone derivatives more readily accessible as illustrated for the synthesis of **15** (55% overall yield) from 4-*t*-butylcyclohexanone.



15 **16** **17**

Regioselectivity of the cyclopentenone formation depends on the structure of the substrate. 2-Octanone was converted into 2-methyl-3-pentyl-2-cyclopentenone (**5c**) exclusively. The selectivity may be explained in terms of the favored formation of the more substituted olefin at the dehydration step. On the other hand, when 2-methylcycloheptanone–dichloroallyllithium adduct was subjected to the annulation reaction, only **16** was produced with no trace of its isomer **17**.[14-16]

The key of the cyclopentenone annulation is the addition of 1,1-dichloroallyllithium at C(1) carbon. Although Seyferth *et al.*[12b] suggested that the regioselectivity of the addition of the lithium reagent to ketones or aldehydes is controlled by electronic rather than steric factor, 2-methylcyclohexanone gave only the adduct **18** in contrast to cyclohexanone or 2-methylcycloheptanone. Thus, steric hindrance as well as ring size[17] appear to determine the regiochemistry of the addition. TFA catalyzed reaction of **18** gave cyclopentenone **19**[18] in 47% yield.



18 **19**

The two cyclopentenone forming reactions are summarized in Scheme 3. Both **3** and **14** give a common intermediate **11** and finally cyclopentenone **5** upon acid treatment. The carbonyl carbon of **5** originates from *gem*-dichloro carbon of **3** and **14**, which plays the role of a protected carbonyl. Particular attention should be paid to **14** whose dichloro carbon is introduced as a

nucleophile with Umpolung[19] of the carbonyl function. The latter methodology is highly effective for cyclopentenone annulation,[14,20] which involves addition of a three carbon chain followed by electrocyclic ring closure.[21-23]

Experimental

Distillation was carried out by use of Kugel-rohr (Buchi) and boiling points were determined by measuring the bath temperature. All the temperatures are uncorrected. PMR spectra (tetramethylsilane as an internal standard) were taken on a JEOL C-60H, Varian EM 360, or EM 390 spectrometer, chemical shifts being recorded in ppm unit. IR spectra were obtained on a Shimadzu IR-27G spectrometer in neat liquid film unless otherwise stated, MS on a Hitachi RMU-6L spectrometer, exact mass on a JEOL-JMS-D300 spectrometer. Tetrahydrofuran (THF) was freshly distilled before use over benzophenone ketyl. Commercially available hydrobromic acid (47%), chloroform, hexadecyltrimethylammonium bromide and butyllithium were used. Preparative TLC was prepared by use of Merck Kiesel-gel PF_{254}. Column chromatography was carried out with Wakogel C-100 (Wako Pure Chemical Co.).

Dichlorocarbene Addition to Allyl Alcohol. A Typical Procedure for ***1***. A mixture of 4-methyl-3-penten-2-ol (1.00 g, 10.0 mmol), chloroform (5.0 ml, 62 mmol) and hexadecyltrimethylammonium bromide (100 mg, 0.27 mmol) was heated at 50—55 °C, aqueous sodium hydroxide (0.60 g, 15 mmol, in 0.6 ml of water) being added drop by drop under vigorous stirring over a period of *ca.* 1 h. After addition was completed, the reaction mixture was maintained at the same temperature for 3 h and then cooled, neutralized with dil hydrochloric acid and extracted three times with dichloromethane. The organic phase was dried (Na_2SO_4), concentrated *in vacuo* and the residue distilled at 100 °C (bath temp)/45 Torr. The distillate (1.68 g, 92% yield) solidified and was recrystallized from hexane to give colorless needles (1.58 g) of **1**, mp 72—73 °C (Found: C, 45.76; H, 6.53%). Spectral data are in line with those recorded.[5] The characteristics of other adducts **4** are summarized in Table 3.

*Synthesis of 2-Methyl-3-pentyl-2-cyclopentenone (***5c***)*

Aqueous sodium hydroxide (1.5 g, in 1.5 ml of water) was added dropwise over a period of 15 min to a solution of 3-methyl-2-nonen-1-ol (**3c**) (880 mg, 5.64 mmol) and hexadecyltrimethylammonium bromide (50 mg) in chloroform (1 ml) under a nitrogen atmosphere at 55 °C. After being stirred for 3 h the mixture was neutralized with dilute hydrochloric acid and then worked up. Distillation at 120—125°C/5 Torr gave the adduct **4c** (806 mg, 60% yield). Spectral characteristics of **4c** are given in Table 3. The alcohol **4c** (476 mg, 2 mmol) was mixed with 47% hydrobromic acid (3 ml) and heated at 100 °C for 9 h. The reaction mixture was diluted with water and extracted with ether. The ethereal extract was washed with brine, aq sodium hydrogencarbonate solution, and finally with brine, dried (Na_2SO_4) and concentrated *in vacuo*. TLC purification of the crude product (silica gel, ether–hexane 3: 1, R_f 0.7) gave **5c** (196 mg, 59% yield, see Table 3).

*Synthesis of 2,3-Decamethylene-2-cyclopentenone (**5d**).* 2-(Cyclododecylidene)ethanol (342 mg, 1.62 mmol) was mixed with ethyl vinyl ether (1 ml) and dichloromethane (2 ml) containing pyridinium tosylate[10] (50 mg) and the mixture was stirred for 1 h. The usual work-up gave an oil which was dissolved in chloroform (2 ml) containing hexadecyltrimethylammonium bromide (30 mg). To the resulting mixture was added sodium hydroxide (0.6 g in 0.6 ml of water) over a period of 15 min with vigorous stirring at 50 °C under an argon atmosphere. Stirring was continued for 4h, and the reaction mixture was diluted with water, neutralized with 5% hydrochloric acid and extracted with dichloromethane. The organic phase was dried (Na_2SO_4) and concentrated. The crude product was dissolved in ethanol (5 ml) in the presence of pyridinium tosylate (50 mg) at room temperature for 1 h. The work-up followed by short column chromatography (silica gel, dichloromethane elution) gave the desired adduct **4d** (366 mg, 77% yield).

The adduct **4d** (170 mg, 0.58 mmol) dissolved in TFA (5 ml) was heated to reflux for 90 h under an argon atmosphere. Concentration and preparative TLC of the residue (silica gel, dichloromethane) gave **5d** (R_f 0.3—0.45) (88 mg, 76%) along with an oil tentatively assigned as a trifluoroacetate of **4d** (R_f 0.95—0.98) (*ca.* 35 mg); IR (neat): 1794, 1225, 1160 cm^{-1}.

*Synthesis of [3-(3-Butenyl)-3-methyl-2,2-dichlorocyclopropyl]-methanol (**7**).* Sodium hydroxide (1.0 g) dissolved in water (1 ml) was added dropwise over 15 min at 40—50 °C to a mixture of the (*E*)-3-methyl-2,6-heptadien-1-ol (**6**) (504 mg, 4.0 mmol), chloroform (2.8 ml, 34 mmol) and benzyl-(2-hydroxyethyl)dimethylammonium hydroxide (20 mg). After being stirred for 3 h at 50 °C, the reaction mixture was diluted with water (20 ml) and dichloromethane (20 ml). The aqueous phase was neutralized with dil hydrochloric acid and the organic phase was separated. The aqueous phase was extracted with dichloromethane (2×10 ml), organic phase being combined, washed with brine and concentrated *in vacuo*. Column chromatography on silica gel (benzene–ether 2: 1) gave the adduct **7** (450 mg, 57% yield, see Table 3).

Addition of 1,1-Dichloroallyllithium to Ketones. This reaction was carried out according to the reported conditions.[12a] Physical properties of simple ketone adducts are given in Table 4.

*Synthesis of Bicyclo[10.3.0]pentadec-1(12)-en-13-one (**5d**).* The dichlorohomoallyl alcohol **14d** (105 mg, 0.36 mmol) was dissolved in TFA (1.3 ml) at room temperature and the solution was vigorously stirred for 1.5 h, the color tunring from light red to dark red. The work-up was effected by adding ether (10 ml), neutralizing with aq sodium hydrogencarbonate solution and by extracting with ether (4×20 ml). The ethereal solution was dried (Na_2SO_4), and concentrated *in vacuo* to give an oil which was purified by preparative TLC (silica gel, dichloromethane–ether 10: 1, R_f 0.3—0.5), affording **5d** (71 mg, 90% yield). PMR: δ 0.9—1.9 (m, 16H), 1.9—2.6 (m, 8H); IR: 1690, 1634 cm^{-1}; MS *m/e* (rel intensity): 220 (M^+, 65), 177 (93), 163 (98), 149 (100), 110 (65).

*Synthesis of 3-t-Butylbicyclo[4.3.0]non-1(6)-en-7-one (**15**).* At −78 °C lithium diisopropylamide (15 mmol) in THF (10 ml) was added drop by drop over a period of 2 h to a THF (20 ml) solution of 4-*t*-butylcyclohexanone (1.54 g, 10.0 mmol) and 3,3-dichloropropene (1.33 g, 12.0 mmol) under an argon atmosphere. After the addition was completed the resulting dark purple solution was stirred for 80 min at −78 °C and then treated with methanol (2 ml) at −78 °C. The mixture was warmed to room temperature, treated with water (*ca.* 50 ml) and extracted with ether (4×20 ml). The organic phase was dried (Na_2SO_4) and concentrated under reduced pressure. The crude product was purified by column chromatography (silica gel, hexane–ether 50: 3) to give the desired adduct (1.42 g, mp 100.8—101.1 °C (hexane), 54% yield, 76% yield based on the consumed ketone) and the starting material (0.45 g). The adduct showed the following spectra. PMR: δ 0.83 (s, 9H, *t*-Bu), 1.0—2.1 (m, 10H), 5.32 (dd, J= 10, 1 Hz, 1H), 5.68 (dd, J=16, 1 Hz, 1H), 6.31 (dd, J=16, 10 Hz, 1H). IR: 3480, 981, 964, 933 cm^{-1}. Found: C, 59.02; H, 8.35%. Calcd for $C_{13}H_{22}Cl_2O$: C, 58.87; H, 8.36%.

The adduct (537 mg, 2.0 mmol) was mixed with THF (3 ml) at room temperature and the solution was stirred for 2.5 h. The work-up followed by preparative TLC (silica gel, hexane–ether 1: 1) gave the desired **15** (279 mg, 72% yield). Bp 102—110 °C (bath temp)/0.05 Torr. PMR: δ 0.93 (s, 9H, *t*-Bu), 1.1—2.6 (m, 11H); IR: 1692, 1658 cm^{-1}; MS *m/e* (rel intensity): 192 (M^+, 27), 164 (8), 136(74), 57 (100). Found: C, 80.91; H, 10.65%. Calcd for $C_{13}H_{20}O$: C, 81.20; H, 10.48%.

*Synthesis of 6-Methylbicyclo[5.3.0]dec-1(7)-en-8-one (**16**).* Under a nitrogen atmosphere at −78 °C, lithium diisopropylamide (15 mmol in THF 10 ml) was added drop by drop over 1.75 h to a THF (15 ml) solution of 2-methylcycloheptanone (1.26 g, 10.0 mmol) and 3,3-dichloropropene (1.33 g, 12.0 mmol), and the reaction mixture was stirred for 1.5 h at −78 °C and worked up. Column chromatography (silica gel, hexane–ether 20: 1) of the crude product gave the desired adduct (1.19 g, 50% yield). The adduct was apparently homogeneous as evidenced by PMR spectrum and TLC assay (silica gel, hexane–ether, 1: 1, R_f 0.63). Bp 118—124 °C (bath temp, partial decomposition)/0.05 Torr. PMR: δ 1.0—2.9 (m+d (δ 1.05, J=6.0 Hz), 15H), 5.25 (dd, J=10, 1 Hz, 1H), 5.68 (dd, J=16, 1Hz, 1H), 6.29 (dd, J=16, 10 Hz, 1H); IR: 3550, 3475, 982, 930 cm^{-1}; MS *m/e* (rel intensity): 236 (M^+, 1), 201 (11), 187 (29), 165 (28), 152 (28), 127 (47), 109 (74), 67 (89), 55 (100). Correct elemental analysis was not achieved due to partial decomposition on distillation.

The adduct (341 mg, 1.4 mmol) was dissolved in TFA (4 ml) at room temperature and the resulting solution was kept at room temperature for 6 h and at reflux temperature for 18 h. The work-up followed by preparative TLC (silica gel, hexane–ether, 2: 1, R_f 0.2—0.3) gave the desired product **16** (138 mg, 58% yield). Bp 122—128 °C (bath temp)/3 Torr. PMR: δ 0.96 (d, J=7.0 Hz, 3H), 1.1—2.1 (m, 6H), 2.1—3.2 (m, 7H); IR: 1689, 1638 cm^{-1}; MS *m/e* (rel intensity): 164 (M^+, 100), 149 (88), 136 (64), 122 (58), 107 (70), 93 (80). Found: C, 80.40; H, 10.08%. Calcd for $C_{11}H_{16}O$: C, 80.44; H, 9.82%.

Addition of 1,1-Dichloroallyllithium to 2-Methylcyclohexanone. Lithium diisopropylamide (23.0 mmol prepared from diisopropylamine (3.2 ml) and butyllithium (1.81 M hexane solution, 13.3 ml) in THF (15 ml) at 0 °C) was added drop

by drop at −78 °C under a nitrogen atmosphere to a THF (20 ml) solution of 2-methylcyclohexanone (1.67 g, 14.9 mmol) and 3,3-dichloropropene (2.00 g, 18.0 mmol) over a period of 2 h, and the resulting solution was stirred for another hour at −78 °C until quenching with methanol (1 ml) at −78 °C. The work-up followed by column chromatography (silica gel, hexane–ether 20: 1) gave the adduct **18** (0.94 g, 28% yield). Bp 126—131 °C (bath temp)/4 Torr. PMR: δ 0.75 (d, J=7.0 Hz, 3H), 0.9—2.7 (m, 10H), 4.12 (d, J=7.0 Hz, 2H), 6.15 (t, J=7.0 Hz, 1H); IR: 3480, 1642, 988, 850, 785 cm^{-1}; MS *m/e* (rel intensity): 226 (M^+ +4, 3), 224 (M^+ +2, 5), 222 (M^+, 19), 187 (54), 173 (86), 152 (75), 117 (69), 95 (72), 68 (100); Exact mass; 222.0561, 224.0533, 226.0514. Calcd for $C_{10}H_{16}Cl_2O$: 222.0577 (M^+), 224.0548 (M^+ +2), 226.0519 (M^+ +4). Elemental analysis gave an error of 0.46% for C probably due to partial decomposition on distillation.

The alcohol **18** (192 mg, 0.86 mmol) was dissolved in TFA (1.5 ml) and the solution was stirred at room temperature for 2.5 h. The work-up gave the hydroindanone **19**[18] (61 mg, 47%). PMR: δ 1.06 (d, J=6.0 Hz, 3H), 1.2—2.0 (m, 4H), 2.0—2.8 (m, 7H); IR: 1690, 1639 cm^{-1}; MS *m/e* (rel intensity): 150 (M^+, 83), 135 (39), 122 (48), 108 (96), 93 (100), 79 (65).

The work was carried out with Grant-in-aid for Scientific Research Nos 185188, 203014, 375462 from the Ministry of Education.

Layered Compounds. LXI.[1] Carbon-13 NMR Study of [*n*]-, [*n.n*]-, and Multilayered [2.2]Paracyclophanes

Takahiro KANEDA, Tetsuo OTSUBO,† Hisanori HORITA, and Soichi MISUMI*

(Received August 9, 1979)

The carbon resonances of several [*n*]paracyclophanes (*n*=8—12) were assigned with the aid of partially deuterated derivatives. The ^{13}C NMR spectra of the title paracyclophanes were examined from viewpoints of the steric compression effect and the ring-current effect. Although the compression effect is a dominant factor for carbon resonances of closely stacked paracyclophanes, the ring-current effect was evidently observed in the spectra of [10]paracyclophane–[10](9,10)anthracenophane pair, [3.3]paracyclophane, and multilayered [2.2]paracyclophanes.

It is well known that ^1H NMR spectra of a variety of cyclophanes are characterized by extraordinary upfield shifts due mainly to the ring-current effect of the benzenoid rings. Multilayered paracyclophanes composed of closely stacked benzenes were reported as suitable models for evaluating systematically such an effect.[2] On the other hand, it is difficult to evaluate the ring-current effect on ^{13}C NMR spectra because the range of carbon chemical shifts is much greater than that of proton chemical shifts and thereby carbon shieldings are often sensitive to other effects.[3] Especially in rigid or crowded systems there was observed the steric compression as a dominant effect which often obscured the ring-current effect. Recently, a small extent of the ring-current effect was reported on the resonances of the middle methylene carbons of [12]paracyclophane **5**.[4] The conclusion is, however, somewhat questionable because their assignment of methylene carbons remained equivocal. In order to investigate the anisotropic effect of a benzene ring on ^{13}C NMR in detail, we measured ^{13}C NMR spectra of [*n*]paracyclophanes **1**—**6**[5] and a dibenzo derivative, *viz.*, [10](9,10)anthracenophane **7**[6] as well as [*n.n*]-paracyclophanes **8**—**16**[7,8] and multilayered [2.2]-paracyclophanes **17**—**20**,[8] some of whose geometries are well confirmed by X-ray crystallography.

Experimental

All the samples were prepared as described in the previous papers.[5-8] The ^{13}C NMR measurements were made on deuteriochloroform solutions (concentration 0.2—0.5 M) using TMS as an internal standard. The spectra of most of the cyclophanes were recorded at 25.05 MHz on a JEOL FX-100 spectrometer equipped with a Fourier transform system, JEC-980B computer, ^2H field frequency lock, and noise-modulated proton-decoupling system. The observed free-induction decay after a 45° pulse width of 6 μs was sampled in 8192 data points with a spectrum width of 5000 Hz and a repetition time of 3 s (digital resolution 1.25 Hz). The spectra of [10](9,10)anthracenophane **7** and alkylbenzenes, **21** and **22**, were run on a Varian XL-100-15FT spectrometer (25.2 MHz), ^1H noise decoupling, 0.2 M $CDCl_3$, TMS as an internal standard, $\delta \pm 0.1$ ppm.

[11]Paracyclophane **4**. Catalytic hydrogenation of [11]-paracyclopha-3,5-diyne[19] (500 mg) by the usual method (5% Pd–C in MeOH) gave [11]paracyclophane **4** as a colorless liquid (427 mg, 82.4%), bp 168—178 °C (bath)/9 mmHg 1 mmHg=133.322Pa. Found: C, 88.40; H, 11.54%; M^+, 230. Calcd for $C_{17}H_{26}$: C, 88.62; H, 11.38%; MW 230.

Deuteration of [n]*Paracyclophadiynes*. Catalytic deuteration of [*n*]paracyclophadiynes[9] was performed by treatment of the substrate with 5% Pd–C and MeOD (Merck D-content >99%) at 40—60 °C for 1.5 h in an atmosphere of deuterium, which was evolved by addition of aluminium to *ca.* 2M D_2SO_4 prepared from concd D_2SO_4 (96—98%, Merck, D-content >99%) and D_2O (Merck, D-content>99.75%). Distillation of the crude product gave deuterated [*n*]paracyclophanes (*n*=10—12), **23**—**26**, in 84—93 wt% yield, bp 135—180 °C (bath)/4—5 mmHg. Deuterium-content and -distribution in these products were determined by mass spectrometry. Relative intensity ratios of the parent peaks due to isotopic species and of the base peaks due to *p*-xylene fragment showed that 79—85% of the products consisted of [*n*]paracyclophane-d_7—d_{11}, and isotopic species substituted by more than two deuterium atoms at the two benzyl methylenes were contained by 4—9% in the products.

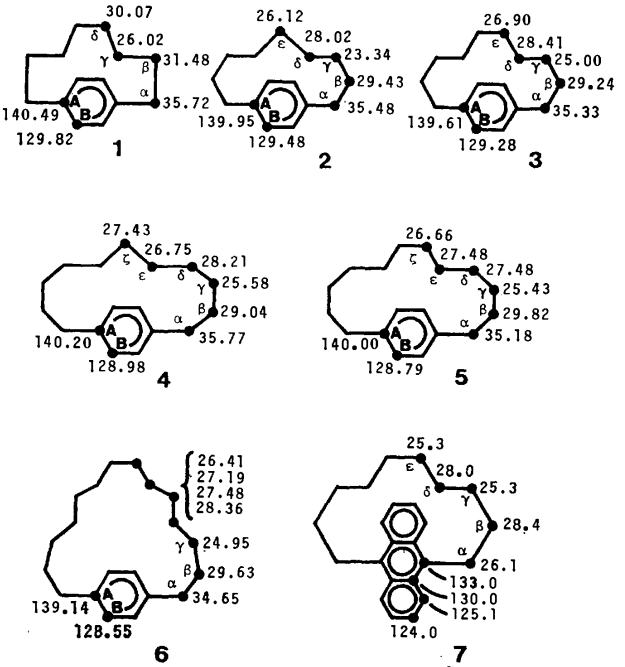

Fig. 1. ^{13}C NMR data of [*n*]paracyclophanes and [10]-(9,10)anthracenophane (δ value).

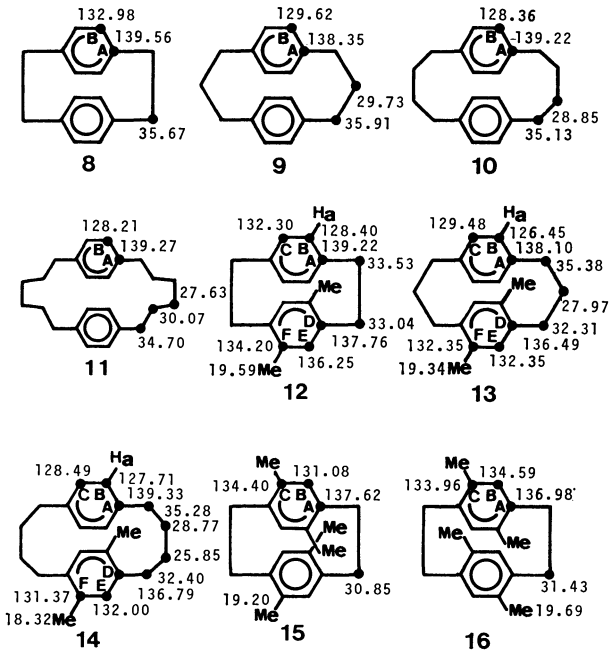
† Present address: Department of Applied Chemistry, Faculty of Engineering, Hiroshima University, Sendamachi, Hiroshima 730.

Results

All the ^{13}C NMR data are summarized in Figs. 1, 2, and 3. The ^{13}C signals were assigned by means of ^{1}H off-resonance and selective decoupling techniques. Comparisons of signal intensities and chemical shifts were also helpful to assign a group of similarly constructed compounds. The resonances of alkyl derivatives of the cyclophanes were assigned by considering the substituent effect on the data observed for non-substituted, parent cyclophanes. Additional shift parameters for dimethyl substitution can be evaluated by comparing the carbon resonances of **21** and **22** (Fig. 3).



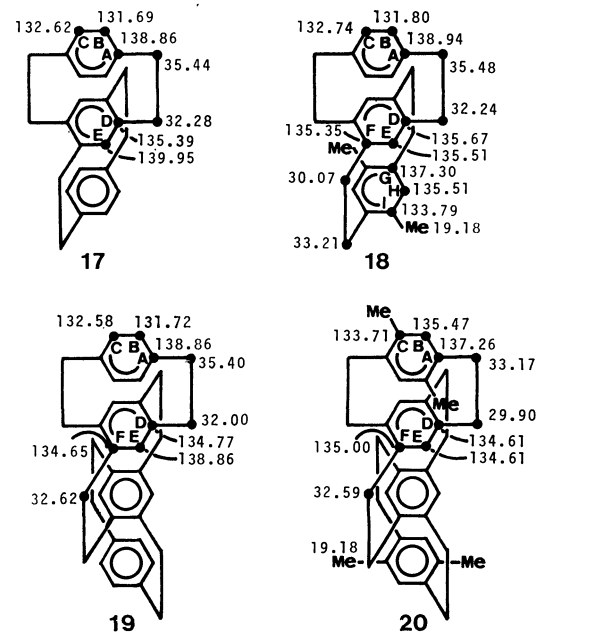


Fig. 2. ^{13}C NMR data of [*n.n*]paracyclophanes and multilayered paracyclophanes (δ value).

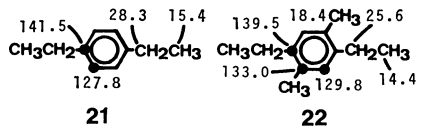

Fig. 3. ^{13}C NMR data of alkylbenzenes (δ value).

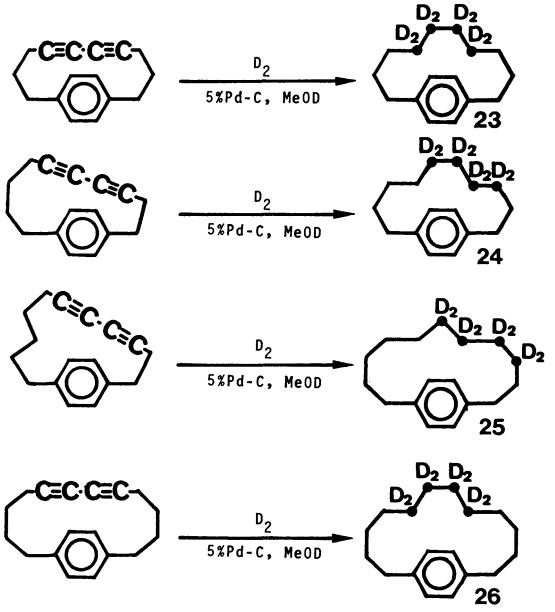

Fig. 4. Catalytic deuteration of [*n*]paracyclophadiynes.

The assignment for medium-sized [*n*]paracyclophanes has been not so easy because of closely positioned signals of the polymethylene carbons. This difficulty was overcome, for example, by deuterium substitution of the four middle methylene groups as seen in catalytic deuteration of a few [*n*]paracyclodiynes (Fig. 4).[9] [10]Paracyclophane **3** shows five signals of the methylene carbons, of which two signals at lower field, δ 35.33 and 29.24, are easily assigned to the α and β methylene carbons, respectively. Of the remaining three signals the two at δ 26.90 and 28.41 disappear in the spectrum of deuterated [10]paracyclophane **23**. For its isomeric deuterated [10]paracyclophane **24**, on the other hand, only one signal (δ 26.90) disappears and other two signals (δ 25.00 and 28.41) decrease to one-half of the initial intensities. Consequently, the three signals at δ 25.00, 28.41, and 26.90 are explicitly assigned to γ, δ, and ε methylene carbons, respectively.

TABLE 1. ^{1}H NMR DATA OF THE METHYLENE PROTONS OF [*n*]PARACYCLOPHANES (100 MHz, δ value)[b]

		α	β	γ	δ	ε	ζ
[8]PC[a]	**1**	2.64	1.43	0.87	0.19		
[9]PC	**2**	2.59	1.42	0.96	0.33	0.59	
[10]PC	**3**	2.60	1.54	1.07	0.48	0.69	
[11]PC	**4**	2.55	1.55	1.18	0.79		0.68
[12]PC	**5**	2.60	1.57	1.06	1.00		0.78

a) PC: paracyclophane. b) The spectra were recorded in $CDCl_3$ at ambient temperature on a JEOL FX-100 spectrometer equipped with a FT system and JEC-980B computer, using TMS as an internal standard.

The deuterium substitution of [*n*]paracyclophanes concomitantly enabled the signal assignment of methylene protons, which has not been clear so far. The data are given in Table 1. The middle methylene protons of the smallest cycle, [8]paracyclophane **1**, are situated just above the benzene ring according to X-ray analysis[10] and thereby resonate at a higher field than the other methylene protons owing to the magnetic anisotropy. On the other hand, the chemical shifts of the middle methylene protons are not the case for [9]- and [10]paracyclophanes **2** and **3**. As shown in Table 1, our assignment for **2** and **3** is the order of proton resonance: α, β, γ, ε, δ with the δ proton at highest field, which is distinct from the orders by Waugh and Fessenden:[11] α, β, δ, γ, ε and by Agarwal *et al.*:[12] α, β, γ, δ, ε. In addition, the present assignment emphasizes that the central methylene protons may not always appear at the highest field.

Discussion

[*n*]Paracyclophanes have a unique structure, in which a polymethylene chain is bridged at para-positions of the benzene ring and placed above the ring, and the benzene ring is bent into a boat shape as the length of the bridging chain shortens.[13] Therefore, the middle methylene groups are essentially shielded by the ring-current of the benzene and appear at higher fields as seen in Table 1. Levin and Roberts reported that in the ^{13}C NMR spectrum of [12]paracyclophane **5** the high-field resonances of the methylene carbons are attributed to the ring-current effect of the benzene ring.[4] However, noteworthy is that γ carbon signals appear in the highest fields for all the present [*n*]paracyclophanes. This upfield shift of γ carbons seems to be independent of the shielding effect of the benzene ring since the γ methylenes are presumably located in positions insusceptible to the effect, according to the ^{1}H NMR data in Table 1.

In the ^{13}C spectrum of [8]paracyclophane **1**, the methylene carbons reveal considerable deshieldings and no explicit dependence of the ring-current effect which is responsible for striking upfield shift of δ methylene protons in the ^{1}H spectrum. This can be explained by a direct carbon-carbon compression in the strained, small cyclic compound since the ring-current effect likely is concealed by the steric effect. For somewhat less strained compound or [9]paracyclophane **2**, however, the middle methylene carbon resonates at a relatively higher field, suggesting the ring-current effect.[18] Clear-cut evidence for the ring-current effect on ^{13}C shielding is given by comparison of two further less strained decamethylene compounds, [10]paracyclophane **3** and [10](9,10)anthracenophane **7**. In the latter compound, the two fused benzo groups do not affect steric environment of the middle methylene carbons. Accordingly, a marked upfield shift of the carbon resonances of **7** relative to **3** is ascribed to the larger ring-current effect of the anthracene ring than that of the benzene ring.[14]

[n.n]*Paracyclophanes and Methyl Derivatives.* The two benzenes of [*n.n*]paracyclophanes are, as $n<6$, stacked in parallel and brought close to each other with decreasing number of *n*. In [2.2]- and [3.3]paracyclophanes, the ring-to-ring distances are within the van der Waals contact, 3.4 Å, according to crystallographic analyses.[15] Therefore, the aryl carbons of both paracyclophanes are undoubtedly compressed by π-π repulsive interaction as described by Sato and coworker.[16] In order to pursue such a compression effect, the aryl carbon resonances of **8** were compared with those of strainless cyclophanes, [6.6]paracyclophane **11** and [14]paracyclophane **6**. A marked downfield shift was observed for the protonated carbon C_B, while no difference for the bridgehead carbon C_A. This downfield shift is comprehended with much easier polarization based on the π-π compression.

As one would expect, the protonated carbon C_B of [3.3]paracyclophane **9** exhibits a similar but smaller downfield shift reflecting its own less compression. On the other hand, the bridgehead C_A signal of **9** appears at a higher field by a little less than 1 ppm compared to those of **11** and **6**. This upfield shift is probably responsible for the ring-current effect of the faced benzene. In the case of [2.2]paracyclophane **8**, the chemical shifts of both aromatic carbons are explained by concealing the ring-current with strong compression effect.

The ^{13}C shifts of [4.4]- and [6.6]paracyclophanes **10** and **11** are almost the same as that of [14]paracyclophane **6**, indicating that the two benzenes in **10** and **11** are too apart from each other to interact sterically and magnetically.

Methyl substitution of [2.2]paracyclophane **12** gives a large perturbation on the shieldings not only for aryl carbons of the methyl-attached ring, but also for aryl carbons of the faced ring. The aryl carbon C_B pseudo-geminal to the methyl substituent is subjected to no deshielding effect compared to the corresponding carbon resonances of **6** and **11**, whereas the pseudo-ortho carbon C_C reveals a marked deshielding. This can be understood by depression of the polarization along the C_B–Ha bond due to strong compression of the methyl group on the proton Ha, since the compression was provided by ^{1}H chemical shifts.[2] Similar phenomena were observed for the pseudo-gem protonated carbons of other methyl derivatives, C_B of **15**, C_E of **18**, and C_E of **20**.

Dimethyl[3.3]paracyclophane **13** also shows the shielding of the protonated carbon C_B pseudo-geminal to the methyl group besides the bridgehead carbons C_A and C_D. Compared with the difference in C_B resonances of **8** and **12**, such a considerable upfield shift of C_B of less strained **13** indicates that the contribution of the ring-current effect on ^{13}C resonance becomes relatively larger in the [3.3]phane system than in the [2.2]phane system, while the compression effect becomes relatively lower. In the case of dimethyl[4.4]paracyclophane **14**, pseudo-gem C_B signal is shifted slightly upfield, although there are no longer steric and magnetic transannular effects in the parent cyclophane **10**. It is probably due to a weak compression effect of the bulky methyl group on the Ha proton.

Such a steric contribution by a methyl group is also

supported by progressive downfield shift of methyl carbon resonances as the methylene number of [*n.n*]-paracyclophanes decreases, that is, the ring-to-ring distance between two benzene rings shortens. A marked downfield shift of methyl carbon resonance due to the methyl-methyl compression is observed for centro-symmetric isomer **16** of tetramethyl[2.2]paracyclophane.

Triple- and Quadruple-layered [2.2]Paracyclophanes. The π-π compression also exerts pronounced effect on ^{13}C spectra of multilayered [2.2]paracyclophanes **17**—**20**. Thus, aryl carbons of all the outer benzene rings reveal the same extent of downfield shifts as those of double-layered series. The non-equivalence of protonated aromatic carbons C_B and C_C of **17**—**19** is caused by depressed C_B–H polarization due to the compression with the bridge methylene group, which is smaller than the compression with a methyl group.

It is noticeable that triple-layered [2.2]paracyclophane **17** provides a novel example of the double compression effect. The signal of aryl carbon C_E of **17** is shifted to a lower field by 7.95 ppm than the corresponding carbon resonance of a reference compound, **14**. This downfield shift is about twice as large as the difference value (4.25 ppm) between **12** and **14**, indicating an additivity of the steric compression contribution on carbon resonances.

Triple- and quadruple-layered [2.2]paracyclophanes may permit a straightforward evaluation of the anisotropic contribution arising from additional third and fourth benzene rings which are stacked on double-layered [2.2]paracyclophane, providing that the steric contribution can be eliminated from the total effect by choice of a suitable reference compound. The outer benzene rings of **17** and **19** have a geometry very similar to the double-layered homolog as revealed by the X-ray analyses.[17] Accordingly, a small upfield shift observed for the bridgehead carbon signal of the outer benzene of triple-layered cyclophanes **17** and **18** is considered to be due to the third benzene (C_A of **17** *vs.* C_A of **12**, −0.36 ppm; C_A of **18** *vs.* C_A of **12**, −0.28 ppm; C_G of **18** *vs.* C_A of **15**, −0.32 ppm), being close to an average shielding value (−0.22 ppm) seen in ^1H NMR data.[2] However, the shielding effect (*ca.* −0.05 ppm) of the fourth benzene was observed to be negligible by comparing the bridgehead carbon resonances of outer benzenes of both quadruple-layered cyclophanes, **19** and **20**, and triple-layered cyclophanes, **17** and **18**.

The authors are greatly indebted to Mr. Y. Takai and Dr. K. Lee for ^{13}C NMR measurements. The present work was partially supported by a Grant-in-Aid for Developmental Scientific Research No. 984015 from the Ministry of Education, Science and Culture.

The Enantioface-differentiating (Asymmetric) Hydrogenation of the C=O Double Bond with Modified Raney Nickel. XXXIV. The Adsorption Mode of 2-Hydroxy Acid on Raney Nickel

Tadao HARADA

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Yamada-Kami, Suita, Osaka 565

(Received August 11, 1979)

The adsorbed species of the modifying reagent and the surface states of the catalyst caused by the modification of a Raney nickel with 2-hydroxy acid at various pH regions were investigated. The adsorption mode of 2-hydroxy acid was proposed in each modifying-pH region; that is, (1) in a pH region intrinsic to the solution of the free 2-hydroxy acid, nickel salt of 2-hydroxy acid was adsorbed on the catalyst surface corroded by the acid; (2) under weakly acidic conditions, nickel salt and sodium salt of 2-hydroxy acid were adsorbed on the catalyst surface partially corroded by the acid; (3) under neutral conditions, the sodium salt was adsorbed on the surface of the fresh Raney nickel, and (4) under strongly basic conditions, the sodium salt and NaOH were adsorbed on the surface of the fresh Raney nickel.

The modification of the metal surface to yield an enantioface-differentiating (asymmetric) hydrogenation catalyst has been intensively studied since 1962.[1] Among those substances examined, 2-hydroxy acids were found to be some of the most effective modifying reagents. In the course of the study, the enantioface-differentiating step was found to occur prior to the hydrogen addition to the adsorbed substrate.[2] That is, the interaction of the substrate with the modifying reagent adsorbed on the catalyst causes the substrate to face the catalyst surface predominantly with one of the enantiofaces. Therefore, the investigation of the adsorption mode of 2-hydroxy acid on Raney nickel (RNi) is essential to an understanding of the mechanism of the enantioface-differentiation.

Recently, the adsorptions of hydroxy acids on nickel were investigated by employing physicochemical techniques. Groenwegen *et al.* studied the adsorption of hydroxy acids from the vapor onto silica-supported nickel and inferred from their IR spectra that hydroxy acids were adsorbed as carboxylates.[3] Suetaka *et al.* studied the orientation of hydroxy acids on nickel plate and assumed, from their reflection IR spectra, that hydroxy acids were adsorbed as undissociated forms.[4]

Physicochemical techniques are not always relevant to studies of the modified Raney nickel catalyst (MRNi), because these techniques are mostly applied under conditions quite different from those of the modification or reaction processes. With this in view, some workers have studied the adsorption modes of hydroxy acids in connection with the enantioface-differentiating ability of MRNi. Tatsumi suggested that tartaric acid was adsorbed on the surface of RNi with two carboxyl groups under acidic conditions and with the 2-hydroxyl group and the 1-carboxyl group under neutral conditions.[5] Tanabe *et al.* studied the effect of the bases used for the pH adjustment of the modifying solution on the enantioface-differentiating ability of the catalyst, and concluded that, in the case of tartaric acid at pH 5, one of the carboxyl groups participated in the adsorption onto the catalyst, while the other was free from the catalyst surface.[6] Yasumori *et al.* investigated the effect of the modifying pH on the optical yield and the amount of tartrate adsorbed on a nickel powder catalyst, and inferred that, when the catalyst was modified with tartaric acid, tartrate dianion was the most effective species for the enantioface-differentiation, without reference to the counter-ion.[7] Harada proposed that the adsorption mode of 2-hydroxy acid was influenced by the pH value of the modifying solution and that the enantioface-differentiating ability of MRNi was directly governed by the adsorption mode of 2-hydroxy acid.[8]

This paper will describe our studies of the adsorbed species of 2-hydroxy acid at various pH regions of the modifying solution and on the change in the surface state of the catalyst caused by the modification.

Results and Discussion

Effect of the Modifying pH *on the Adsorbed Species and the Surface States.* When RNi was soaked in the modifying solution, some amounts of metallic nickel were corroded by the modifying reagent and were dissolved into the modifying solution as the nickel ion.

The amounts of the nickel ion produced during the

TABLE 1. AMOUNTS OF THE NICKEL ION IN THE RECOVERED MODIFYING SOLUTIONS (Ni(II)/mol)

Modifying reagent	Modifying pH			
	2.3	5.1	7.4	10.0
(*RS*)-Mandelic acid	2.9×10^{-4}	—	0.0×10^{-4}	0.0×10^{-4}
(*RS*)-Lactic acid	3.7×10^{-4}	—	0.2×10^{-4}	0.0
Glycolic acid	4.4×10^{-4}	1.1×10^{-4}	0.2×10^{-4}	0.0

Catalyst: 1.5 g as the alloy (Ni: Al=42: 58). Modifying solution: 100 ml of a 1% aqueous solution of the modifying reagent. The pH was adjusted with 1 M NaOH. Modification: at 0 °C for 90 min.

TABLE 2. AMOUNTS OF ADSORBED MODIFYING REAGENTS

No.	Reagent for acid treatment (g in 100 ml H_2O, pH)	Modifying reagent (g in 100 ml H_2O, pH)	Adsorbed glycolate (mol)
1	(*RS*)-Mandelic acid (1, pH 2.3)	Nickel glycolate[a)] (0.1, pH 6.8)	1.1×10^{-4} (Mandelate: 0.1×10^{-4})
2	—	Nickel glycolate[a)] (0.1, pH 6.8)	0.9×10^{-4}
3	Glycolic acid (1, pH 2.3)	Nickel glycolate[a)] (0.1, pH 6.8)	1.3×10^{-4}
4	—	Glycolic acid (1, pH 2.3)	1.3×10^{-4}

Catalyst: 1.5 g as the alloy (Ni: Al=42: 58). Acid-treatment and modification: at 0 °C for 90 min, using 100 ml of an acid-treating or modifying solution. a) The concentration (0.1%) of the nickel glycolate solution is comparable to that of the nickel glycolate found in the modifying solution after the modification with a 1% solution of glycolic acid at pH 2.3 (Table 1).

modification with 2-hydroxy acids at various modifying pH regions are listed in Table 1. Only trace amounts of nickel metal were corroded by the modification under neutral or basic conditions. Thus, no appreciable changes in the modifying reagent (*i.e.*, sodium salt to nickel salt of 2-hydroxy acid) or in the surface state of RNi were assumed during the modification under neutral or basic conditions.

The formation of the nickel ion in large amounts by soaking the catalyst in a 2-hydroxy acid solution suggested that the modifying reagent was no longer the free acid, but the nickel salt of the acid in the neighborhood of the catalyst surface, and also that the surface state of RNi was drastically changed by the corrosion. Thus, the MRNi prepared under acidic conditions was assumed to be quite different from those prepared under neutral or basic conditions with respect to the surface state of the catalyst and the species of the adsorbed modifying reagent.

In order to make clear the above-mentioned differences, modifications with nickel glycolate or glycolic acid were carried out using two types of RNi catalysts. One was prepared by a method reported before (fresh RNi),[9] while the other was prepared by the treatment of fresh RNi with 2-hydroxy acid (acid-treated RNi). The amounts of the glycolate adsorbed on the two types of catalysts are compared in Table 2. As is shown in Entry 1, most of the mandelate used for the preparation of the acid-treated RNi was replaced by glycolate on modification with nickel glycolate. By a comparison of the result shown in Entry 1 with that shown in Entry 2, it is apparent that the loading capacity of the catalyst for nickel glycolate was increased by prior treatment with 2-hydroxy acid.

As is shown in Entries 3 and 4, the modification of fresh RNi with a 1% solution of glycolic acid (pH 2.3) and the modification of an acid-treated RNi with a 0.1% solution of nickel glycolate (pH 6.8) gave the same results with respect to the amount of adsorbed glycolate. This fact strongly suggests that the modification of RNi with glycolic acid under acidic conditions consists of two processes; that is, the conditioning process of the RNi surface with the acid, and the following adsorption process of the nickel salt produced *in situ*.

After the modification of fresh RNi was performed with a solution of nickel glycolate, the molar ratio of the glycolate to the nickel ion adsorbed on the catalyst was found to be 1.8: 1 (Table 3). This value is close to that for $Ni(CH_2(OH)CO_2)_2$. Therefore, in this case

TABLE 3. AMOUNTS OF ADSORBED GLYCOLATE AND ADSORBED NICKEL ION ON MODIFICATION WITH NICKEL GLYCOLATE

	Modifying solution (solute/mol)		Adsorbed solute (mol)
	Initial	Final	
Ni(II)	4.9×10^{-4}	4.4×10^{-4}	0.5×10^{-4}[a)]
Glycolate	10.6×10^{-4}	—	0.9×10^{-4}

Catalyst: 1.5 g as the alloy (Ni: Al=42: 58). Modifying solution: 100 ml of an aqueous solution of nickel glycolate. Modification: at 0 °C for 90 min. a) Caculated value.

TABLE 4. AMOUNTS OF ADSORBED GLYCOLATE AND ADSORBED POTASSIUM ION ON MODFICATION WITH POTASSIUM GLYCOLATE

	Modifying solution (solute/mol)		Adsorbed solute (mol)
	Initial	Final	
K(I)	2.0×10^{-4}	1.8×10^{-4}	0.2×10^{-4}[a)]
Glycolate	2.0×10^{-4}	—	0.2×10^{-4}

Catalyst: 1.5g as the alloy (Ni: Al=42: 58). Modifying solution: 50 ml of an aqueous solution of potassium glycolate. Modification: at 0°C for 90 min. a) Calculated value.

the major adsorbed species is found to be $Ni(CH_2(OH)CO_2)_2$.

The adsorbed species on modification under neutral conditions were examined in the same way as in the modification with nickel glycolate. Table 4 shows the amounts of the adsorbed glycolate and the adsorbed potassium ion when the fresh RNi was modified with a solution of potassium glycolate (pH 6.8). The molar ratio of the glycolate to the potassium ion adsorbed on the catalyst was found to be exactly 1: 1. Therefore, the species adsorbed on modification with potassium glycolate is found to be potassium glycolate. Similarly, when sodium glycolate is used as the modifying reagent, sodium glycolate is assumed to be the adsorbed species.

Under weakly acidic modifying conditions, RNi was partially corroded by the acid to form a mixture of the catalyst with a fresh surface and with an acid-treated surface. The species adsorbed under this modifying conditions are expected to form a mixture of nickel glycolate and sodium glycolate.

Under strongly basic modifying conditions, the adsorbed species are considered to be the alkali salt

Table 5. Effects of acid treatment on the enantioface-differentiating ability of the catalysts

No.	Reagent for acid treatment (g in 100 ml H_2O)	Modifying reagent (g in 100 ml H_2O)	$[\alpha]_D^{20}$ of Methyl 3-hydroxybutyrate/°
1	(*S*)-3-Phenyllactic acid (1)	Nickel (*S*)-3-phenyllactate (0.1)	+0.58
2	(*RS*)-Lactic acid (1)	Nickel (*S*)-3-phenyllactate (0.1)	+0.62
3	—	Nickel (*S*)-3-phenyllactate (0.1)	+0.30
4	—	(*S*)-3-Phenyllactic acid (1)	+0.60
5	Sodium (*S*)-3-phenyllactate (1)	Nickel (*S*)-3-phenyllactate (0.1)	+0.36
6	—	Sodum (*S*)-3-phenyllactate (1)	+0.15
7	—	(*S*)-3-Phenyllactic acid (1)+NaOH (pH 5)	+0.30
8	—	(*S*)-3-Phenyllactic acid (1)+NaOH (pH 12)	−0.35

Catalyst: 1.5 g as the alloy (Ni: Al=42: 58). Acid-treatment and modification: at 0 °C for 90min. Substrate: 17.5 ml of methyl acetoacetate. Hydrogenating conditions: at 60 °C under an initial H_2 pressure of 90 kg/cm^2.

of 2-hydroxy acid and the alkali hydroxide. This consideration is supported by the fact that the amount of the adsorbed salt of 2-hydroxy acid was drastically decreased when the modifying pH was increased.[8]

The Effect of the Modifying pH *on the Enantioface-differentiating Ability of MRNi.* In the preceding section, MRNi was classified into four types on the basis of the adsorbed species and the surface states: that is, MRNi prepared in a pH region intrinsic to the solution of the free 2-hydroxy acid, under weakly acidic conditions, under neutral conditions, and under strongly basic conditions. Each type of MRNi was examined in order to elucidate the relationship between the enantioface-differentiating ability of MRNi and the adsorption mode of 2-hydroxy acid. (*S*)-3-Phenyllactic acid and its salts were used as the optically active modifying reagents. The ability of MRNi was evaluated by means of the optical yield of the hydrogenation of methyl acetoacetate to methyl 3-hydroxybutyrate. The results are summarized in Table 5.

As is shown in Entries 1 and 4, the same ability was obtained by MRNi prepared from an acid-treated RNi and a solution of nickel (*S*)-3-phenyllactate (pH 6.8), and MRNi prepared from fresh RNi and a solution of (*S*)-3-phenyllactic acid (pH 2.3). In addition, the difference in the acid used for the acid-treatment of fresh RNi did not influence the ability of MRNi (Entries 1 and 2). On the other hand, MRNi prepared from fresh RNi and a solution of nickel (*S*)-3-phenyllactate (pH 6.8) showed a lower ability (Entry 3).

The above results are well compatible with the results obtained in the adsorption studies. That is, MRNi prepared from fresh RNi and a solution of free 2-hydroxy acid is equivalent to that prepared from an acid-treated RNi and a solution of nickel salt of the acid. The difference in the ability between the nickel salt–MRNi prepared from the acid-treated RNi and that prepared from the fresh RNi indicates that the ability of MRNi depends not only on the adsorbed species of the modifying reagent, but also on the surface state of RNi.

The treatment of fresh RNi with a solution of sodium (*S*)-3-phenyllactate (pH 8.2) prior to the modification did not influence the ability of nickel (*S*)-3-phenyllactate–MRNi (Entries 3 and 5). This fact is in accordance with the result obtained in the preceding section; that is, the treatment of fresh RNi with sodium salt of 2-hydroxy acid resulted in no detectable change in the surface state of the catalyst.

Sodium (*S*)-3-phenyllactate–MRNi prepared from fresh RNi showed a different ability from that of nickel (*S*)-3-phenyllactate–MRNi prepared from fresh RNi (Entry 6). The difference can be explained in terms of the difference in the adsorbed species.

The ability of the catalyst modified with a solution containing both 2-hydroxy acid and its sodium salt (pH 5.1) was intermediate between that of 2-hydroxy acid–MRNi and that of its sodium salt–MRNi (Entry 7).

The ability of the catalyst modified under strongly basic conditions was quite different from that of the sodium salt–MRNi (Entry 8). In this case, the direction of the enantioface-differentiation was different from that of the sodium salt–MRNi. This fact indicates that the adsorbed sodium hydroxide drastically affects the adsorption mode of methyl acetoacetate on the catalyst.

As a whole, it can be concluded that the pH-dependence of the enantioface-differentiating ability can also be explained by common factors: the adsorbed species of the modifying reagent and the surface states of the catalyst.

Experimental

The preparation of the modified Raney nickel catalyst, the determination of the absorbed (*RS*)-mandelate and glycolate, the hydrogenation of methyl acetoacetate, and the measurement of the enantioface-differentiating ability of the catalyst were all carried out by the use of the procedures described in a previous paper.[9]

The Preparation of an Acid-treated RNi. A Raney-nickel catalyst obtained from 1.5 g of the alloy[9] was soaked in 100 ml of a 1% aqueous solution of the reagent for acid treatment at 0 °C for 90 min. The mixture was shaken every 15 min. After the acid treatment, the solution was removed by decantation and the catalyst was washed once with 10 ml of deionized water and then with three 50 ml portions of methanol. The resulting catalyst was used for the modification.

The Determination of Ni(II). The nickel ions in the modifying solution were determined by the EDTA titration method at pH 10—12, using murexide as the indicator and triethanolamine as the masking reagent for the aluminium ion.[10]

The Determination of K(I). The potassium ions in the modifying solution were determined by the gravimetric technique using sodium tetraphenylborate.[11]

The author wishes to thank Professors Yoshiharu Izumi and Akira Tai, Osaka University, for their many helpful discussions and suggestions in the course of this work.

Thione S-Imides. The Reaction with Carbon-Hetero Atom Double Bond

Takao SAITO, Isao OIKAWA, and Shinichi MOTOKI*

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received August 14, 1979)

9-Fluorenethione *S*-*p*-toluenesulfonimide reacted as a 1,3-dipole with imines, oximes, and thiones to form (3+2)cycloadducts, while with symmetrical azines and aldehydes, unsymmetrical azines, *N*-(*p*-tolylsulfonyl) imines and fluorenone were obtained as a result of the decomposition of the cycloadducts.

Thione *S*-imides,[1] new thiocumulenes, have recently been synthesized by several workers.[2] However, there have been few reports on the cycloaddition reactions of the imides.[3]

Previously,[4] we reported the 1,3-dipolar, Diels-Alder-type cycloaddition, and ene reactions of 9-fluorenethione *S*-*p*-toluenesulfonimides (**1**) with compounds containing C=C bond(s). We have now attempted the reaction of **1** with compounds containing C=X bond(s) (X=NR, O, S) *i.e.*, imines (**2**), oximes (**6**), azines (**8**), aldehydes (**11**), and thiones (**14**).

Results and Discussion

The treatment of **1** with aldimines (**2**) in 1,2-dichloroethane at room temperature gave (3+2)cycloadducts, spiro[fluorene-9,5′-[1,2,4]thiadiazolidine] derivatives (**3**), regiospecifically. The results are shown in Tables 1 and 2. The adducts showed no characteristic νS=N absorption band in the IR spectra, and their mass-spectral fragmentation patterns exhibited *N*-(fluorenylidene)-*p*-toluenesulfonamide (Fl=NTs‡), *N*-(fluorenylidene)arylamine (Fl=NC$_6$H$_4$R^{2‡}), and aldimine (R^{1}C$_6$H$_4$CH=NC$_6$H$_4$R^{2‡}) ion peaks. Among these adducts, **3i** was a particularly unstable compound; it decomposed to form **5** in a solution. These observations are consistent with the proposed structure, **3**, rather than with the regioisomeric structure, **4**.

The reactions of **1** with *N*-alkylalkanimines or *N*-alkylarylmethanimines (*N*-cyclohexyl-2-butanimine, *N*-cyclohexyl-1-(2-methyl)propanimine, *N*-(2-butyl)-2-butanimine, *N*-cyclohexylphenylmethanimine, and *N*-(2-propyl)phenylmethanimine) resulted in complicated decomposition reactions, fluorenone and tar being formed. Reactions with ketimines such as *N*-phenyldiphenylmethanimine did not proceed under the same reaction conditions, whereas prolonged treatment at room temperature or by refluxing the 1,2-dichloroethane solution caused only decomposition reactions.

The reaction of **1** with oximes (**6**) proceeded rapidly to give (3+2)cycloadducts **7** (Tables 3 and 4). The IR spectra of **7** showed a distinct band at 3220—3320 cm^{-1} due to the hydroxyl group, but no νS=N band. The mass-spectral fragmentation pattern resembled that of **3**.

The treatment of **1** with azines (**8**) afforded unsymmetrical azines (**9**) and *N*-(*p*-tolylsulfonyl) imines (**10**) (Tables 5 and 6). In this case, one of the arylmethylene moiety of **8** was replaced by the fluorenylidene group. This *trans*-imidation reaction can be explained by assuming a path involving a 1,3-dipolar cycloaddition reaction,[5] followed by ring fragmentation with an elimination of sulfur, as is shown in the scheme.

Aromatic aldehydes (**11**) reacted slowly with **1a** to afford *N*-(*p*-tolylsulfonyl)arylmethanimines (**12**) and fluorenone (**13**) (Table 7). The formation of these products also suggests the presence of an intermediary cycloadducts, as is shown in the scheme. No reaction was observed between **1a** and ketones, such as 2-propanone, 2-butanone, and benzophenone under the same conditions. On the contrary, diaryl thioketones (**14**) reacted with **1a** to form (3+2)cycloadducts, 1,4,2-dithiazolidines (**15**) (Tables 8 and 9). The mass-spectral fragmentations which involve $R_2C{=}NTs^+$, $Fl{=}S^+$, $Fl{=}NTs^+$, and $R_2C{=}S^+$ ion peaks are compatible

with the proposed structure.

As has been described above, it has been found that **1** underwent 1,3-dipolar cycloaddition reactions with the dipolarophiles containing carbon-hetero atom double bond(s), such as **2**, **6**, **8**, **11**, and **14**, to afford the adducts as isolable products or unstable intermediates regiospecifically. However, the adducts, **3**, **7**, and **15**, are not quite stable and are gradually decomposed on long standing in a solid state or in a solution. When **3** or **7** adducts were dissolved in warm 1,2-dichloroethane, the solution turned orange-red immediately,[6] while the

solution of **15** turned blue gradually. However, these adducts were recovered by cooling the solution or by evaporating the solvent. On the other hand, when the suspension of **3** in hexane was refluxed for several hours, **1** and **2** were recovered in good yields. These results suggest that the adducts can readily dissociate into their components reversibly in an appropriate solvent.

Experimental

All the melting points are uncorrected. The IR spectra were measured on a Hitachi Model 260-10 spectrometer. The NMR spectra were measured on a JEOL JNM-FX 100 or PMX-60 spectrometer. The mass spectra were recorded on a Hitachi double-focusing RMU-7M mass spectrometer. The elemental analyses were performed using a Shimadzu universal UM-3B organic micro analyzer and a Shimadzu NA-1 rapid-nitrogen analyzer.

Materials. The thione *S*-imides (**1**) were prepared by the reaction of triphenylphosphonium 9-fluorenylide with *N*-sulfinyl-*p*-toluenesulfonamide.[2f] The other reagents employed were commercial materials or were prepared by the usual methods.

Typical Procedures. Reaction of Thione S*-Imides (1) with Aldimines (2).* A mixture of **1a** (0.50 g, 1.37 mmol) and benzylideneaniline (**2a**) (0.37 g, 2.01 mmol) was stirred in dry 1,2-dichloroethane (10 cm^3) at room temperature for 2 h. The solvent was then evaporated *in vacuo*, and the residue was triturated by a good rubbing in cold diethyl ether–hexane (*ca.* 1 : 1). The resultant yellowish powder was collected and recrystallized from dichloromethane (3 cm^3)–hexane (6 cm^3) to give **3a** as colorless crystals in a 90% yield; mp 128—130 °C (dec), MS (15 eV) *m/e* 333 (1), 255 (10), 181 (100).

Decomposition of 3i. A solution of **3i** in 1,2-dichloroethane was allowed to stand overnight at room temperature. The solvent was then evaporated *in vacuo*, and the residue was subjected to column chromatography on silica gel, using

benzene as the eluent. *N*-(2-nitrofluorenylidene)aniline (**5**) was obtained as orange crystals in an 81% yield (recrystallized from benzene–hexane); mp 146—147 °C (lit,[7] mp 141 °C), IR (KBr) 1655 (C=N), 1520 and 1340 cm^{-1} (NO_2); NMR ($CDCl_3$) δ 6.6—8.0 (m, 10H), 8.28 (dt, 1H, J=2.0, 8.0 Hz), 8.72 (d, 1H, J=2.0 Hz); MS (70 eV) *m/e* 300 (100, M^+), 254 (43, $M^+ - NO_2$). Found: C, 76.01; H, 4.11; N, 9.51%. Calcd for $C_{19}H_{12}O_2N_2$ C, 75.99; H, 4.03; N, 9.33%.

Reaction of Thione S-*Imides (1) with Oximes (6).* A mixture of **1a** (1.00 g, 2.74 mmol) and acetone oxime (**6a**) (0.25 g, 3.42 mmol) was stirred in dry 1,2-dichloroethane (20 cm^3) at room temperature for 5 min. A work-up similar to that described for the preparation of **3** gave **7a** as colorless crystals in a 92% yield; mp 127—129 °C (dec); MS (70 eV) *m/e* 333 (14), 236 (19), 196 (10), 180 (50), 155 (34), 91 (85), 73 (10), 56 (100).

Reaction of Thione S-*Imide (1a) with Azines (8).* A mixture of **1a** (0.5 g, 1.37 mmol) and benzaldehyde azine (**8a**) (0.30 g, 1.44 mmol) was stirred in dry 1,2-dichloroethane at room temperature for 4 d. The solvent was then evaporated *in vacuo*, and the residue was column-chlomatographed on silica gel, using benzene as the eluent, to give **9a** as orange needles (recrystallized from benzene–hexane) in a 47% yield; mp 87—88 °C. Subsequent elution with the same solvent gave **10a** as colorless crystals in a 76% yield; mp 108—109 °C (lit,[8] mp 107 °C) (recrystallized from benzene–hexane).[9]

Reaction of Thione S-*Imide (1a) with Aromatic Aldehydes (11).* A mixture of **1a** (0.50 g, 1.37 mmol) and excess benzaldehyde (**11a**) was stirred in 1,2-dichloroethane at room temperature for 6 d. After the evaporation of the solvent, the residue was column-chromatographed on silica gel, using benzene as the eluent (followed by chloform), to give **12a** (mp 105—106 °C (lit,[8] mp 107 °C))[9] in a 23% yield and fluorenone (**13**) (mp 83—84 °C (lit,[10] mp 83.0—83.5 °C); IR 1720 cm^{-1} (C=O)) in a 98% yield (accompanied by the excess aldehyde). The yields of **13** and the recovered excess aldehyde were estimated by GLC.

Reaction of Thione S-*Imide (1a) with Thiones (14).* Into a suspension of **1a** (0.73 g, 2.0 mmol) in 1,2-dichloroethane (10 cm^3), a solution of 4,4-dimethoxythiobenzophenone (**14c**) (0.62 g, 2.4 mmol) in 1,2-dichloroethane (10 cm^3) was stirred, drop by drop, at room temperature. A colorless solid precipitated in a few min. After stirring for 30 min, the solid was collected and washed with ether–hexane to give **15c** in an 88% yield; mp 140—142 °C (dec); NMR ($CDCl_3$) δ 6.67—7.67 (m, 20H, arom), 3.85 (s, 6H, OCH_3), 2.38 (s, 3H, CH_3(Ts)), MS *m/e* 395 (11, *p*-$CH_3OC_6H_4C{=}NTst^+$), 333 (20, Fl=$NTst^+$) 269 (12, Fl=N–Tol-*p*·$^+$), 258 (25, *p*-$CH_3OC_6H_4)_2CS{\cdot}^+$), 240 (62, (*p*-$CH_3OC_6H_4)_2CN^+$), 196 (100, Fl=$S^+$). In the other cases, the reaction mixture was concentrated *in vacuo*, since no precipitation occurred. The residue was triturated in ether–hexane to afford the product.[11]

Liquid-phase Peptide Synthesis by Fragment Condensation on a Soluble Polymer Support. III.[1] The Influence of the Content and the Chain Length of a Peptide Anchored to a Soluble Polymer Support on the Reactivity of the Amino-free Terminal of the Peptide

Mitsuaki NARITA,* Shin-ichi ITSUNO, Masanori HIRATA, and Kazuya KUSANO

Department of Industrial Chemistry, Tokyo University of Agriculture and Technology, Nakamachi, Koganei, Tokyo 184

(Received August 18, 1979)

In order to investigate the influence of the content and the chain length of a peptide anchored to a soluble polymer support on the reactivity of the amino-free terminal of the peptide, chloromethylated polystyrene, which is a starting material for peptide synthesis on a matrix, was prepared by the copolymerization of (chloromethyl)-styrene with styrene. By the copolymerization, the chloromethyl content on the resin was easily controlled and obtained as reproducible. The repetitive peptide-chain elongations of a pentapeptide, $-(Ala_2-Leu_3)-$, and a decapeptide, $-(Ala_2-Leu_3-Pro_2-Leu_3)-$, were performed by the usual method, using soluble polymer supports with various contents of Ile–Ile, which was used as the internal reference to evaluate the coupling yields by means of amino-acid analyses of the resulting peptide resins. The solubility of the peptide resin, which depends on the content of the peptide and the solubility of the peptide fragment on the matrix, was found to be one of the important factors for an efficient coupling in liquid-phase fragment condensations on a soluble polymer support.

Solid-phase peptide synthesis by fragment condensation seems to be the most promising method for the synthesis of large, homogeneous proteins.[2,3] This strategy will alleviate the difficulty[3-5] in the purification of a peptide and sequence-dependent problems[6] in the coupling and deprotecting steps. These problems are serious in solid-phase peptide synthesis by step-by-step elongation. An annoying problem in the fragment condensation method is, however, of the lower yield in the coupling step, resulting mainly from the restriction of the permeability of an *N*-protected peptide fragment into a random cross-linked polymer support which carries the amino-free terminal of peptide.[2] The use of soluble polymer supports for peptide synthesis has several advantages in carrying out peptide synthesis under homogeneous conditions. In previous papers,[1,7] we have reported that the fragment condensation on a soluble polymer support can achieve an efficient coupling of an *N*-protected tetrapeptide acid to the amino-free terminal anchored to the soluble polymer support and that the peptide-chain length of the *N*-protected tetrapeptide acid has no influence on the reactivity of the *C*-terminal amino acid in the coupling reaction using DCC[8] plus HOBt and DEPC as the coupling reagents. In this paper, we wish to report on the influence of the content and the chain-length of the peptide anchored to the soluble polymer support on the coupling reaction of Boc-peptide acids with the amino-free terminal of the peptide on the matrix.

Results and Discussion

For the above purpose, it is desirable to obtain a chloromethylated polystyrene with a controlled chlorine content. Merrifield resins which have been used in peptide synthesis generally started from the chloromethylation of a copolymer of styrene with divinylbenzene.[9] The chloromethylation of polystyrene with chloromethyl methyl ether, which is a polymer reaction, is usually accompanied by concomitant cross-linking due to the intermolecular Friedel-Crafts reaction with a tin(IV) chloride catalyst; also, it is difficult to control the chlorine content.[10,11] One could expect the cross-linking to produce sterically unfavored reaction sites, which are chemically reactive but physically inaccessible.[12] A skillful technique is also required to get a reproducible chlorine value by the chloromethylation of polystyrene with chloromethyl methyl ether.[13] The use of tin(IV) chloride as a catalyst has been further claimed to be disadvantegeous in causing a clustering of the reaction sites.[14] The preparation of a soluble chloromethylated polystyrene by the copolymerization of styrene with (chloromethyl)styrene seems, though, to have several advantages. The copolymerizations of (chloromethyl)styrene (a mixture of *m*- and *p*-isomers, 63: 28, Tokyo Kasei Co.) with styrene, using AIBN as the initiator, were, therefore, carried out in benzene at 70 °C in molar ratios of (chloromethyl)-styrene as 1 mol%, 3 mol%, 10 mol%, and 30 mol% respectively. The results are summarized in Table 1. The chlorine contents of the chloromethylated polystyrenes were determined by the Volhard method after a reaction with pyridine; they were in fair agreement with those calculated from the feed-molar ratios. The molecular weights of the polymers were measured by vapor-pressure osmometric equilibrium (VPOE) method. The reactivity ratios of (chloromethyl)styrene with styrene were not determined, since the (chloromethyl)styrene used was a mixture of *m*- and *p*-isomers. The polymer was free from an insoluble material, homo-polystyrene. This was confirmed by the fact that the pyridinium chloride derived from the reaction of 10 mol% chloromethylated polystyrene with pyridine was soluble in methanol. It could, therefore, be estimated that the chloromethyl groups were distributed at random on the resin. In comparison with the chloromethylation of soluble polystyrene,[10] which is liable to cause a heterogeneous environment due to partial

Table 1. Results of the copolymerization of (chloromethyl)styrene with styrene[a)]

Monomers to be fed (mmol)		Mol% of (chloromethyl)-styrene (mmol/g)	Product

146	63	30 (2.53)[b)]	72	2.43	21000

a) The copolymerizations were carried out using AIBN (0.5 mol %) as the initiator in benzene at 70±0.5°C for 40 h. b) One mol % of AIBN was used as the initiator. c) Determined by the Volhard method. d) Determined by the VPOE method.

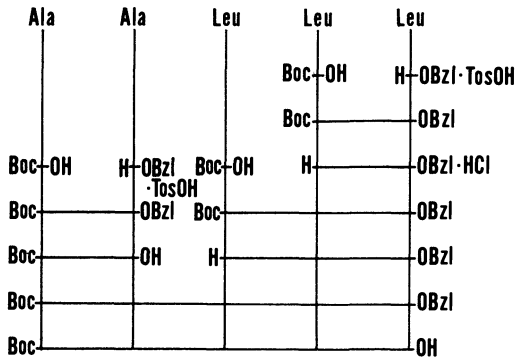
Table 2. Estimated secondary structures of Boc-peptide acids and peptides on polymer supports

Peptide	Estimated secondary structure
Boc–Ala_2–Leu_3–OH	β-Sheet
Boc–Ala_2–Leu_3–Pro_2–Leu_3–OH	Randam coil
H{Ala_2–Leu_3}$_n$$Ile_2$–$OCH_2$–resin	α-Helix ($n \geqq 2$)
H{Ala_2–Leu_3–Pro_2–Leu_3}$_n$$Ile_2$–$OCH_2$–resin	Randam coil ($n \geqq 1$)

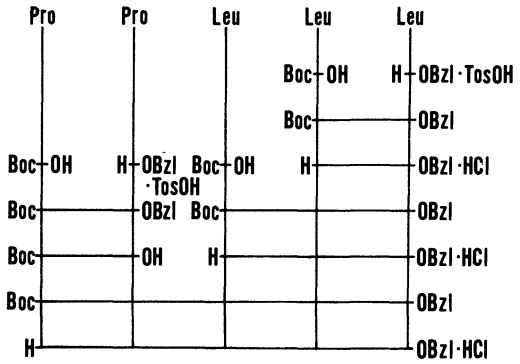
cross-linking, the copolymerization of (chloromethyl)-styrene with styrene has several advantages; 1) easy control of the chloromethyl content on the resin; 2) the absence of any cross-linking reaction, affording polymers with a nearly homogeneous structure; 3) easy preparation of polymers with a reproducible chloromethyl content; 4) the exclusion of the use of carcinogenic chloromethyl methyl ether, and 5) the exclusion of the clustering of chloromethyl groups when tin(IV) chloride is used as the catalyst.

The efficient peptide-bond formation on the polymer support is put under the influence of several factors, such as the permeability of reagents, the steric micro-environment of reactive sites on the polymer support (peptide-peptide or peptide-resin steric interactions),[5] the secondary or tertiary structure of the *N*-protected peptide acid (reagent) and the peptide on the polymer support,[6] and the solvation of the matrix and the peptide chain.[5,6,15] In order to evaluate these difficulties, the repetitive elongation of a decapeptide or a pentapeptide on the polymer support was carried out using polymer supports with various Ile-Ile contents. Boc–Ala_2–Leu_3–OH and Boc–Ala_2–Leu_3–Pro_2–Leu_3–OH were used as the *N*-protected penta- and decapeptide acids respectively. The secondary structures of the sequential poly(penta- and decapeptide)s are estimated to be the α-helix and the random coil respectively by the methods of Chou and Fasman[16] and Katakai,[17] as is shown in Table 2.

All the peptides used here were synthesized using DCC and HOBt as coupling reagents. The deprotection of the Boc group was carried out in 3 M HCl–AcOEt, and the deprotection of Bzl group, by hydrogenolysis using 5% Pd/C as the catalyst. The amino group was liberated from the salt with NMM. The preparations of Boc–Ala_2–Leu_3–OH and H–Pro_2–Leu_3–OBzl·HCl are shown in Schemes 1 and 2. Boc–Ala_2–OBzl, Boc–Pro_2–OBzl, and Boc–Leu_2–OBzl were prepared in 93%, 76%, and 71% yields respectively by the coupling reactions of Boc-amino acids with benzyl esters. Boc–Leu_3–OBzl was prepared in a 67% yield by the step-by-step elongation, starting from H–Leu–OBzl·TosOH. Boc–Ala_2–Leu_3–OBzl and Boc–Pro_2–Leu_3–OBzl were obtained in 91% and 82% yields respectively by the coupling reactions of H–Leu_3–OBzl with Boc–Ala_2–OH and Boc–Pro_2–OH. The reaction between Boc–Ala_2–Leu_3–OH and H–Pro_2–Leu_3–OBzl gave Boc–Ala_2–Leu_3–Pro_2–Leu_3–OBzl in an 87% yield; this then provided the desired *N*-protected peptide acid, Boc–Ala_2–Leu_3–Pro_2–Leu_3–OH, in an 81% yield by hydrogenolysis.



Scheme 1.



Scheme 2.

Ile–Ile was anchored to soluble polymer supports as the internal reference by the reaction of chloromethylated polystyrenes (1 mol%, 3 mol%, and 30 mol% chlorine content) with Boc–Ile_2–OH, using potassium carbonate in DMF, followed by deprotection and neutralization, to give Ile_2–OCH_2–resins (Resins A, B, and C respectively). Residual benzylic chlorine atoms, which cause unavoidable cross-linking, were removed by heating the Boc–Ile_2–OCH_2–resins with sodium acetate in DMF. The Ile contents in acid hydrolysates of Boc–Ile_2–OCH_2–resins (Resins A′, B′, and C′) are summarized in Table 3.

Table 3. Amino-acid analyses of Boc–Ile_2–OCH_2–resins (Resins A′, B′, and C′)

Cl content of the starting resin (mol %)	Product	Ile_2 content (mmol/g)	Conversion[b] (%)
1	Resin A′	0.088(0.093)[a]	95
3	Resin B′	0.25(0.261)[a]	96
30	Resin C′	1.24(1.39)[a]	89

Scheme 3.

Each repetitive peptide-chain elongation of the penta- and the decapeptides was performed using the cycle summarized in Table 4. The reaction of each step is shown in Scheme 3. The fragment condensation on the soluble polymer support was carried out in DMF, using DCC and HOBt as coupling reagents (Step 1); this procedure had been shown to be effective for the fragment condensation.[7,18] The residual amino group was terminated by the treatment with acetic acid in DMF, using DCC and HOBt as coupling reagents (Step 3). The Boc group was removed with 5 M HCl–THF or 20% CF_3COOH–CH_2Cl_2 (v/v) (Step 5),[19] while the amino group was liberated from the salt, formed with the excess of the acid used for deprotection, by treatment with Et_3N in DMF (Step 7). In these processes, the inherent simplicity of peptide synthesis using the polymer support can be preserved for the separation and purification of intermediate resins (Steps 2, 4, 6, and 8). In these steps, the recovery of the resulting peptide resin by precipitation from the solution with a non-solvent was in a near-quantitative yield. After the termination reaction on each cycle, an aliquot of peptide resin was hydrolyzed with acid and analyzed for its amino-acid composition. The amino-acid ratios in the acid hydrolysates of the resulting peptide resins and the coupling yields in each cycle for the fragment condensations of Boc–Ala_2–Leu_3–OH and Boc–Ala_2–Leu_3–Pro_2–Leu_3–OH using the three resins, A, B, and C, are summarized in Tables 5 and 6. The yield of the coupling reaction on cycle n was calculated, by making correction by the use of the coupling yields of the n-2 and/or n-1 cycles, from the recovery of Leu in the acid hydrolysate, taking the recovery of Ile as the standard. The coupling reactions of the penta- and decapeptide acids with each resin kept a more than 90% yield in the first cycle. The yield on the reaction of the pentapeptide acid with the B and C resins in the second and third cycles decreased gradually in accordance with the decrease in the solubility of peptide resins in DMF. In the coupling reactions of the second cycles, in practice, gelation took place in the solutions of resins in which the peptide-bond formation was proceeding. Using Resin A, which bound peptides to the smallest degree, the peptide-bond formation on each cycle could proceed homogeneously and keep a high coupling yield. A tendency for the yield of the peptide-chain elongation to decrease was observed in the coupling reaction of the decapeptide acid with Resin C, which bound peptide to the highest degree. The solubility of Boc–Ala_2–Leu_3–Pro_2–Leu_3–OBzl in organic solvents is greater than that of Boc–Ala_2–Leu_3–Ala_2–Leu_3–OBzl, which is only slightly soluble in DMF, ethanol, and methanol. The solubility of the peptide fragment on the matrix directly affects that of the peptide resin.

In conclusion, the solubility of peptide resin, which is related to the solvation of the matrix and the peptide chain, the permeability of reagents, and the steric microenvironment of the reactive sites on the matrix,

Table 4. A cycle for the addition of one oligopeptide in each repetitive peptide elongation

Step	Function	Reagent, solvent, and/or nonsolvent
1	Coupling	Boc–peptide acid, DCC, and HOBt in DMF
2	Precipitation, wash, and dry	Ethanol, water, and methanol
3	Termination	Acetic anhydride and pyridine in DMF
4	Precipitation, wash, and dry	Ethanol, water, and methanol
5	Deprotection	5 M HCl–THF or 20% CF_3COOH–CH_2Cl_2
6	Precipitation, wash, and dry	Ethanol, water, and methanol
7	Neutralization	Et_3N in DMF
8	Precipitation, wash, and dry	Ethanol, water, and methanol

is one of the most important factors in determining the efficient coupling yield in liquid-phase peptide synthesis on the soluble polymer support by means of fragment condensation. This technique has several advantages; 1) the reaction can easily be done in a homogeneous system and in a near-quantitative yield by controlling the peptide content on the matrix, 2) the intermediates can easily be handled for separation and purification, 3) the solubility of intermediates can easily be observed, and 4) there is a possibility of the optical analysis of the secondary structure of the peptide chain anchored to the matrix. There is, in fact, the prospect of the homogeneous synthesis of a large (50 amino acids or more) peptide or protein (100 amino acids or more).

Experimental

General. The uncorrected capillary melting points will be reported. The infrared spectra were recorded on a JASCO Model DS-403G. The molecular weights were determined by the VPOE method, using a Hitachi Model 117 molecular-weight-measurement instrument. The optical rotations were taken in a 1-dm cell on a JASCO Model ORD/UV-5 optical rotatory dispersion recorder. The elemental analyses were performed on a Perkin Elmer Model 240 elemental analyzer.[20] The amino-acid compositions of the acid hydrolysates were determined with a Hitachi Liquid Chromatograph, Model 034. The acid hydrolyses of the peptide resins were carried out on 20—40 mg samples of resins with propionic acid–12 M HCl (2: 1 v/v) for 35 h at 115 °C in sealed tubes. Ascending TLC was performed on silica gel plates (Wakogel Plate from Wako, Tokyo) using the following solvent system: chloroform–methanol–acetic acid (45: 4: 1 by vol).

Materials. The (chloromethyl)styrene (a mixture of *m*- and *p*-isomers, 63: 28) was purchased from the Tokyo Kasei Co., Tokyo, and was used without purification. The Boc-amino acids were prepared according to Nagasawa *et al.*[21] The amino acid benzyl ester tosylates[22a] and HOBt[22b] were prepared by the methods given in the literature. The DMF was purified as follows. To 1.5 l of DMF we added 75 g of phthalic anhydride, after which the mixture was kept overnight at room temperature and then distilled under reduced pressure. It was then redistilled under reduced pressure. The benzene, styrene, THF, and AcOEt were purified in the usual manners. All the other reagents were obtained from commercial sources and were used without further purification.

Soluble Chloromethylated Polystyrene. The copolymerizations of (chloromethyl)styrene with styrene, using AIBN as the initiator, were carried out in benzene for 40 h at 70 °C in molar ratios of (chloromethyl)styrene of 1 mol%, 3 mol%, 10 mol%, and 30 mol% under the conditions described previously.[7] The results are summarized in Table 1. The chlorine contents of the polymers were determined by the Volhard method after the reaction with pyridine. The 10 mol% polymer (0.5 g) was reacted in 3 ml of pyridine for 2 h at 100 °C, after which the solution was poured into water and a small amount of saturated aqueous sodium chloride was added. The precipitated polymer, pyridinium salt, was collected by filtration and dried *in vacuo*. It was soluble in methanol and free from insoluble material.

Boc–Ala$_2$–OBzl, Boc–Leu$_2$–OBzl, Boc–Pro$_2$–OBzl, and Boc–Ile$_2$–OBzl. Boc–Ala–OH (9.72 g, 51 mmol) and H–Ala–OBzl·TosOH (16.42 g, 47 mmol) were dissolved in 90 ml of THF, followed by the addition of NMM (4.72 g, 47 mmol) dissolved in 10 ml of THF and HOBt (7.20 g, 47 mmol). To the solution cooled at 0 °C we then added DCC (10.60 g, 51 mmol) dissolved in 30 ml of THF; the mixture was stirred for 2 h at 0 °C and then overnight at room temperature. After the solution had then been cooled for 30 min at 0 °C, the precipitates were filtered off and the filtrate was concentrated under reduced pressure. The residue was dissolved in 200 ml of AcOEt, and the solution was successively washed in the

usual way three times with 10% aqueous citric acid, twice with aqueous sodium chloride, three times with 4% aqueous sodium hydrogencarbonate, and twice with aqueous sodium chloride, and dried over sodium sulfate, using charcoal for decolorization. After the removal of the solvent *in vacuo*, the residue was dissolved in a mixture of AcOEt (90 ml) and petroleum ether (180 ml), and the solution was kept for 30 min at 0 °C. The precipitated *N,N'*-dicyclohexylurea was filtered off, and the filtrate was concentrated to give a crude peptide (15.3 g, 93% yield). Subsequent recrystallization from a mixture of AcOEt (20 ml) and hexane (120 ml) gave a substance, mp 69—71 °C (lit,[23] 68—70 °C); $[\alpha]_D^{22} = -60.2°$ ($c = 1.0$, CH_3OH); a single spot by TLC in the solvent system (R_f, 0.65). Boc-Leu_2-OBzl (mp 92—93 °C, lit,[24] 92—92.5 °C), Boc-Pro_2-OBzl (oil), and Boc-Ile_2-OBzl (mp 89.5—91.5 °C) were similarly prepared.

Boc-Leu_3-OBzl. The preparation was performed as has been described above using Boc-Leu-OH·H_2O (18.52 g, 74.3 mmol) and H-Leu_2-OBzl·HCl (27.55 g, 74.3 mmol), prepared by the treatment of Boc-Leu_2-OBzl with 3 M HCl-AcOEt in the usual way; 84% yield. Subsequent recrystallization from a mixture of AcOEt (20 ml) and hexane (200 ml) gave a substance, mp 127—128.5 °C; $[\alpha]_D^{25} = -64.9°$ ($c = 1.0$, CH_3OH); a single spot by TLC in the solvent system (R_f, 0.75). Found: C, 65.28; H, 9.06; N, 7.71%. Calcd for $C_{30}H_{49}N_3O_6$: C, 65.78; H, 9.02; N, 7.67%.

Boc-Ala_2-OH, Boc-Pro_2-OH, and Boc-Ile_2-OH. Boc-Ala_2-OBzl (14.0 g, 40 mmol) was hydrogenated at atmospheric pressure in a mixture of methanol (30 ml) and acetic acid (20 ml) in the presence of 5% Pd/C (1.0 g) as a catalyst. The reaction mixture was then stirred overnight at room temperature. After the removal of the Pd/C, the filtrate was concentrated under reduced pressure, followed by the repetition of the addition of water and its removal under reduced pressure to eliminate acetic acid, and drying *in vacuo*. The product was recrystallized from a mixture of AcOEt (80 ml) and hexane (120 ml) to give, in a near-quantitative yield, a material, mp 120—121 °C (lit, 85.5—87 °C,[25] 128—129 °C,[2d] 132—133 °C[26]); $[\alpha]_D^{22} = -39.1°$ ($c = 1.0$, CH_3OH); a single spot by TLC in the solvent system (R_f, 0.34). Boc-Pro_2-OH was purified as the dicyclohexylamine salt; mp 161—162 °C, $[\alpha]_D^{23} = -72.8°$ ($c = 1.0$, CH_3OH), R_f 0.40. Found: C, 65.86; H, 9.66; N, 8.67%. Calcd for $C_{27}H_{47}N_3O_5$: C, 65.69; H, 9.60; N, 8.51%.

Boc-Ala_2-Leu_3-OBzl and Boc-Pro_2-Leu_3-OBzl. The preparation of Boc-Ala_2-Leu_3-OBzl was carried out in THF in a manner similar to that described for the preparation of Boc-Ala_2-OBzl, using Boc-Ala_2-OH (11.5 g, 44 mmol) and H-Leu_3-OBzl·HCl (17.9 g, 37 mmol), prepared by the treatment of Boc-Leu_3-OBzl with 3 M HCl-AcOEt in the usual way; 91% yield. Subsequent recrystallization from a mixture of AcOEt and hexane (1: 3) gave a material, mp 230—235 °C (dec); $[\alpha]_D^{22} = -70.5°$ ($c = 1.0$, CH_3OH); a single spot by TLC in the solvent system (R_f, 0.53). Found: C, 62.40; H, 8.70; N, 9.93%. Calcd for $C_{36}H_{59}N_5O_8$: C, 62.68; H, 8.62; N, 10.15%.

Boc-Pro_2-Leu_3-OBzl was obtained by a similar method in an 82% yield. Subsequent recrystallization from a mixture of AcOEt and hexane (1: 3) gave a material, mp 91.5—93 °C; $[\alpha]_D^{26} = -119.2°$ ($c = 1.0$, CH_3OH); a single spot by TLC in the solvent system (R_f, 0.58). Found: C, 65.02; H, 8.56; N, 9.28%. Calcd for $C_{40}H_{63}N_5O_8$: C, 64.75; H, 8.56; N, 9.44%.

Boc-Ala_2-Leu_3-OH. The hydrogenolysis of Boc-Ala_2-Leu_3-OBzl in the manner described for the preparation of Boc-Ala_2-OH gave Boc-Ala_2-Leu_3-OH in an 87% yield. Subsequent recrystallization from a mixture of ethanol and AcOEt (1: 6) gave a substance, mp 265—270 °C (dec); $[\alpha]_D^{23} = -69.5°$ ($c = 1.0$, CH_3OH); a single spot by TLC in the solvent system (R_f, 0.46). Amino-acid ratios in acid hydrolysate: Ala 2.00, Leu 2.94. Found: C, 57.68; H, 8.73; N, 11.38%. Calcd for $C_{29}H_{53}N_5O_8$: C, 58.07; H, 8.91; N, 11.68%.

Boc-Ala_2-Leu_3-Pro_2-Leu_3-OBzl. Boc-Ala_2-Leu_3-OH (7.73 g, 12.9 mmol) and H-Pro_2-Leu_3-OBzl-HCl (7.95 g, 11.7 mmol), prepared from Boc-Pro_2-Leu_3-OBzl in the usual way, were dissolved in 100 ml of DMF, and then NMM (1.19 g, 11.7 mmol), dissolved in 20 ml of DMF and HOBt (1.98 g, 12.9 mmol), was added. To the solution cooled at 0 °C we then added DCC (2.66 g, 12.9 mmol), dissolved in 30 ml of DMF; the reaction mixture was stirred for 2 h at 0 °C and then overnight at room temperature. After the mixture had then been cooled for 1 h at 0 °C, the precipitates were filtered off and the filtrate was concentrated under reduced pressure. To the residue we added water to give a solid. On a glass filter, it was successively washed with 10% aqueous citric acid, water, 4% aqueous sodium hydrogencarbonate, and water, and dried *in vacuo*; yield, 87%. Recrystallization from AcOEt gave a material, mp 194—194.5 °C; $[\alpha]_D^{25} = -119.4°$ ($c = 1.0$, CH_3OH); a single spot by TLC in the solvent system (R_f, 0.54). Found: C, 62.45; H, 8.78; N, 11.33%. Calcd for $C_{64}H_{106}N_{10}O_{13}$: C, 62.82; H, 8.73; N, 11.45%.

Boc-Ala_2-Leu_3-Pro_2-Leu_3-OH. Boc-Ala_2-Leu_3-Pro_2-Leu_3-OBzl (9.0 g, 7.4 mmol) was hydrogenated at atmospheric pressure in a mixture of methanol (100 ml) and acetic acid (20 ml) in the presence of 5% Pd/C (1.0 g) as a catalyst; then it was subjected to the work-up procedures described in the preparation of Boc-Ala_2-OH. The product was recrystallized from a mixture of ethanol and AcOEt (1: 6) to give, in an 81% yield, a material, mp 187—188.5 °C; $[\alpha]_D^{25} = -134.2°$ ($c = 1.0$, CH_3OH); a single spot by TLC in the solvent system (R_f, 0.48). Amino-acid ratios in acid hydrolysate: Ala 2.00, Leu 5.95, Pro 2.09. Found: C, 60.31; H, 8.61; N, 11.89%. Calcd for $C_{57}H_{100}N_{10}O_{13}$: C, 60.40; H, 8.89; N, 12.36%.

H-Ile_2-resins (Resins A, B, and C). As a typical example, 1 mol% chloromethylated polystyrene (Cl content, 0.096 mmol/g; 10.0 g) and Boc-Ile_2-OH (0.99 g, 2.88 mmol) were dissolved in 100 ml of DMF. To the solution, maintained at 40 °C, we added potassium carbonate (0.20 g, 1.44 mmol), after which the reaction mixture was stirred for 100 h at 40 °C. The addition of this mixture to ethanol (1 l) caused the precipitation of a solid, which was collected, homogenized with water, filtered off again, washed with water and methanol, and dried *in vacuo*. A solution of the product in THF (200 ml) was poured into ethanol. For the precipitate we repeated the work-up procedures described above. The yield was 10.2 g (99%). Residual benzylic chlorides were removed by a reaction with sodium acetate in DMF at 105 °C for 24 h, as has been described in the literature.[10] The Resin A' obtained was negative to a Beilstein test, indicating it to be free from chlorine. The removal of the Boc-group with the saturated HCl-THF solution and the neutralization of the amine salt with Et_3N were performed by procedures similar to those described in the literature[10] to give Resin A. Resins B and C were obtained from 3 mol% and 30 mol% chloromethylated polystyrene respectively by the same work-up procedures. The Ile content of each resin is shown in Table 3.

A Cycle of Peptide-chain Elongation on the Matrix for the Addition of One Oligopeptide. Each repetitive peptide-chain elongation of the penta- and the decapeptides was performed using the cycle summarized in Table 4. The reaction conditions are shown in Table 7. As a typical example, Resin B (amino content, 0.25 mmol/g; 4.00 g), a two-fold equivalent of Boc-Ala_2-Leu_3-OH (1.20 g, 2.00 mmol), and HOBt (0.336 g, 2.20 mmol) were dissolved in DMF (60 ml). To the solution

Step	Reagents[a]	Solvent	Reaction conditions	
			Time/h	Temp/°C
1	Two-fold equivalent each of Boc-peptide acid and DCC, and a 2.2 times equivalent of HOBt	DMF 12—20 ml/g-resin	48 24[b]	0 r.t.
3	Two-fold equivalent each of acetic acid and DCC, and a 2.2 times equivalent of HOBt	DMF 12—20 ml/g-resin	20	r.t.
5[c]	5 M HCl–THF	THF 10—40 ml/g-resin	15	0
7	4—5 times equivalent of Et_3N	DMF or THF 20—40 ml/g-resin	10 min	r.t.

a) The amounts used were based on the amount of the Ile amino-free terminal of the starting resins, A, B, and C. b) On Cycles 2 and 3, 48 h. c) In the case of Cycle 2 using Resin C, the removal of the Boc group was performed in 20% CF_3COOH-CH_2Cl_2 (v/v), 20—30 ml/g resin, for 2 h at room temperature.

cooled at 0 °C we then added DCC (0.412 g, 2.00 mmol) dissolved in DMF (20 ml) and cooled at 0 °C; the mixture was stirred for 48 h at 0 °C and then for 24 h at room temperature. The reaction mixture was near-negative to a ninhydrin test. It was then poured into ethanol (1 l), and 10% aqueous sodium chloride (30 ml) was added. The precipitated resin was filtered off and washed successively with water and methanol to remove the soluble reactant. The resin was homogenized with ethanol (200 ml) overnight at room temperature under magnetic stirring, filtered off again, washed with water and methanol, and dried *in vacuo* at 50 °C. The yield was 4.45 g (recovery yield, 97%).

The termination reaction of the unreacted N-terminal amino group of the resin was carried out as follows. The resin (4.05 g) obtained above, acetic acid (0.12 g, 2.0 mmol), and HOBt (0.34 g, 2.2 mmol) were dissolved in DMF (120 ml). To the solution we then added DCC (0.41 g, 2.0 mmol) dissolved in DMF (30 ml), after which reaction mixture was stirred for 20 h at room temperature. The reaction mixture was negative to a ninhydrin test. The addition to ethanol (1 l) caused the precipitation of a solid, which was collected by filtration, washed with water and methanol, and dried *in vacuo* at 50 °C.

The removal of Boc-group with 6 M HCl–THF and the neutralization of the amine salt with Et_3N were performed in the usual ways under the conditions described in Table 7.

(Received August 18, 1979)

Methylenecyclohexane and its 2-methyl derivative were hydrogenated competitively in cyclohexane at 30 °C over platinum group metals. The methyl derivative was less reactive than the unsubstituted olefin on all the metal catalysts used. The reactivity of the methyl derivative relative to the unsubstituted olefin was not much different in going from one catalyst to another. However, Pd was unique in its very high activity for double bond migration. MINDO/2 calculations have revealed that the olefinic double bonds of the substituted and unsubstituted olefins are essentially identical in bond order but somewhat different in charge density. The observed methyl substituent effect is compared with that observed previously in hydrogenation of cyclohexanone and its 2-methyl derivative.

In a previous work[1] of this series, we conducted competitive hydrogenation of cyclohexanone and its methyl derivatives (2-, 3-, and 4-methylcyclohexanone) using group VIII metals as catalysts in order to study the substituent effects. All of the methylcyclohexanones were less reactive than cyclohexanone. Interestingly, the reactivity of a methylcyclohexanone relative to cyclohexanone could be correlated with the atomic radius of the catalyst metal: among those catalysts on which the same type of reaction scheme operates, the greater the atomic radius the greater the relative reactivity.

A question may now be raised: is this correlation confined to ketone hydrogenation alone or does it extend to include hydrogenation of other types of organic compounds such as olefinic and acetylenic species? The purpose of the present study is to investigate this question by means of competitive hydrogenation of methylenecyclohexane and its 2-methyl derivative. Since this olefin pair is a structural analog of the earlier studied ketone pair, *i.e.*, cyclohexanone and its 2-methyl derivative, the present study will be compared with the earlier one to see how olefin hydrogenation is different from or similar to ketone hydrogenation.

Table 1 lists the abbreviated notations used subsequently for the starting olefins, isomerized olefins, and hydrogenation products.

Table 1. Nomenclature

Compound	In sentence	As subscript
(Starting olefins)		
Methylenecyclohexane	MeneC	A
2-Methylmethylenecyclohexane	2-MMeneC	B
(Isomerized olefins)		
1-Methylcyclohexene	1-MCene	
1,2-Dimethylcyclohexene	1,2-DMCene	
2,3-Dimethylcyclohexene	2,3-DMCene	
(Hydrogenation products)		
Methylcyclohexane	MC	P
cis-1,2-Dimethylcyclohexane	*c*-1,2-DMC	*c*-Q
trans-1,2-Dimethylcyclohexane	*t*-1,2-DMC	*t*-Q

Experimental

Catalysts. The Ru, Rh, Pd, and Os catalysts were prepared fresh from ruthenium trichloride, rhodium trichloride, palladium dichloride, and osmium tetraoxide, respectively, according to the procedure described in the previous paper.[1]

Two methods were used for preparation of the Ir catalyst. (a) It was prepared using iridium trichloride (Mitsuwa Kagaku Yakuhin, 99.9%) as the starting material according to the procedure described previously.[1] (b) A suspension of iridium tetrahydroxide (Mitsuwa Kagaku Yakuhin) in water was reduced at 100 °C for 20 min using an initial hydrogen pressure of 90 kg/cm^2 (1 kg/cm^2≈1 atm=1.013 $\times 10^5$ Pa). The resulting metal precipitate was washed repeatedly with water until the washings were neutral to Thymol Blue, dried under reduced pressure, and stored over silica gel.

The Pt catalyst was prepared by adding aqueous NaOH (10 wt%) in small portions to a stirred warm (60—70 °C) suspension of $PtCl_2$ (Koso Chemical) in water. The mixture was allowed to stand in that temperature range for half an hour. The resulting precipitate was filtered off, washed with water until the washings were neutral, and suspended in water. The reduction of this hydroxide suspension to a metal black was conducted in a glass reaction vessel at ambient temperature using hydrogen at atmospheric pressure. The resulting Pt black catalyst was washed and stored as described above for Ir catalyst (b).

Olefins. MeneC was either purchased from Aldrich Chemical Co. or prepared in our laboratory. The preparation of MeneC and 2-MMeneC was made using as the starting materials hexahydrobenzoic acid and its 2-methyl derivative, respectively. The procedure of Cope and Ciganek[2] was employed with slight modifications. One modification was the substitution of ether extraction for steam distillation in collecting *N,N*-dimethylcyclohexylmethylamine, one of the synthetic intermediates. Another important modification was made to the last stage of the synthetic procedure, *i. e.*, to the procedure for purifying the final product. In the original method, the crude MeneC was washed successively with diluted HCl, aqueous $NaHCO_3$, and with water. Because our preliminary experiment revealed that the alkali washing is prone to contaminate the final product with a trace of basic material (probably *N,N*-dimethylhydroxylamine), we

omitted this operation, and just repeated washing with water before and after HCl washing. The MeneC so prepared had a bp 101—102 °C with n_D^{25} 1.4472 (lit,[2] 102 °C, n_D^{25} 1.4474) and its yield was 18%. The 2-MMeneC obtained had a bp 126.5—128 °C with n_D^{25} 1.4510 (lit,[3] 124.5—124.8 °C/745 mmHg, n_D^{25} 1.4514) and its yield was 13%.

The 1,2- and 2,3-DMCene used as gas chromatography standards in identification of a few isomerized reaction intermediates were prepared from 2-methylcyclohexanone according to the method of Signaigo and Cramer.[4] In brief, 2-methylcyclohexanone was treated with the Grignard reagent CH_3MgI to form 1,2-dimethylcyclohexanol, and this alcohol was then dehydrated by distillation from anhydrous aluminum sulfate. The resulting olefin mixture of 1,2- and 2,3-DMCene and 2-MMeneC was fractionated between 110 and 140 °C. (lit,[3] bp 136.2 °C/745 mmHg for 1,2-DMCene and 130.3—130.7 °C/745 mmHg for 2,3-DMCene).

Procedures. Competitive hydrogenations were conducted according to a procedure similar to that used for the previous study[1] of competitive ketone hydrogenations. In brief, 10 ml of an equimolar solution of MeneC and 2-MMeneC (0.4 mol/l of each) in cyclohexane was placed, together with a weighed sample of metal catalyst (varying from 0.8 to 135 mg), in the glass reaction vessel — the one used in the previous study. The reaction vessel was further charged with an atmospheric pressure of hydrogen, and shaken at a reaction temperature of 30 °C. The reaction was followed volumetrically by measuring the hydrogen uptake and also gas chromatographically by analyzing aliquots of the reaction mixture at appropriate time intervals. The reaction temperature and hydrogen pressure were chosen to be identical with those in the earlier ketone study to permit direct comparison of both kinetic data.

Gas chromatography was carried out on a Yanako Model G 80 FID chromatograph using two columns in series (2.5 m ×3 mm i.d. 20 wt% trixylyl phosphate on Chromosorb W and 5 m×3 mm i.d. 30 wt% 3,3′-oxydipropionitrile on Chromosorb PAW at 65 °C). Base line resolution was obtained for all the peaks.

Two series of experiments were conducted using these procedures so as to measure R_B/R_A for all the catalyst metals in each series. In series I, both starting olefins MeneC and 2-MMeneC were prepared, stored in a refrigerator, and used without redistillation before use. In series II, commercial MeneC and prepared 2-MMeneC were used as the starting olefins. They were kept in the refrigerator and redistilled under nitrogen immediately before use. Ir catalyst (b) was employed in series I, and Ir catalyst (a) in series II.

Treatment of Kinetic Data

In this report we are dealing with competitive hydrogenation of the two olefins, *i.e.*, MeneC and 2-MMeneC. Let us assume that the reaction rate of each olefin is first order in the amount adsorbed, that the catalyst surface is bare in the presence of saturated hydrocarbons alone, and also that olefin adsorption obeys the Langmuir isotherm. These premises lead to the relative rate expression:

$$\frac{R_B}{R_A}\left(\equiv\frac{k_BK_B}{k_AK_A}\right)=\frac{d(C_{c\text{-}Q}+C_{t\text{-}Q})/C_B}{dC_P/C_A} \quad (1)$$

where R is the reaction rate per unit concentration of A or B, k is the rate constant, K is the adsorption coefficient and C is the concentration. The subscripts are listed in Table 1. Let $C_{A(i)}$ and $C_{B(i)}$ stand for the initial concentrations of C_A and C_B, respectively. Neglecting double bond migration and any other side reactions,

$$C_A = C_{A(i)} - C_P \quad (2)$$

and

$$C_B = C_{B(i)} - C_{c\text{-}Q} - C_{t\text{-}Q}. \quad (3)$$

Inserting Eqs. 2 and 3 into Eq. 1 and integrating between the limits $C_P=0$ and C_P and between $C_{c\text{-}Q}+C_{t\text{-}Q}=0$ and $C_{c\text{-}Q}+C_{t\text{-}Q}$ yields

$$\frac{R_B}{R_A}=\log\left(\frac{C_{B(i)}}{C_{B(i)}-C_{c\text{-}Q}-C_{t\text{-}Q}}\right)\Big/\log\left(\frac{C_{A(i)}}{C_{A(i)}-C_P}\right) \quad (4)$$

Results

Side Reactions. Over the $VIII_3$ metals (Os, Ir, Pt) little or no double bond migration occurred (always less than 1% of the conversion to the saturated products). Over Ru and Rh, double bond migration was appreciable but still less than 6% of the total MeneC conversion and less than 2% of the total 2-MMeneC conversion. In the case of Pd, double bond migration was even faster than hydrogenation at the initial stage. These results were not unexpected because group $VIII_2$ metals (Ru, Rh, Pd) were reported to be more active than group $VIII_3$ metals for double bond migration.[5-7] Especially in hydrogenation of 2-MMeneC with Pd, Mitsui *et al.*[8] observed, in accord with our experiments, isomerization/hydrogenation ratios of greater than unity.

Figure 1 shows a typical reaction profile on Pd. This result indicates that *endo*-olefins are much more slowly hydrogenated than *exo*-olefins.[9,10] The same tendency was observed with Ru and Rh.

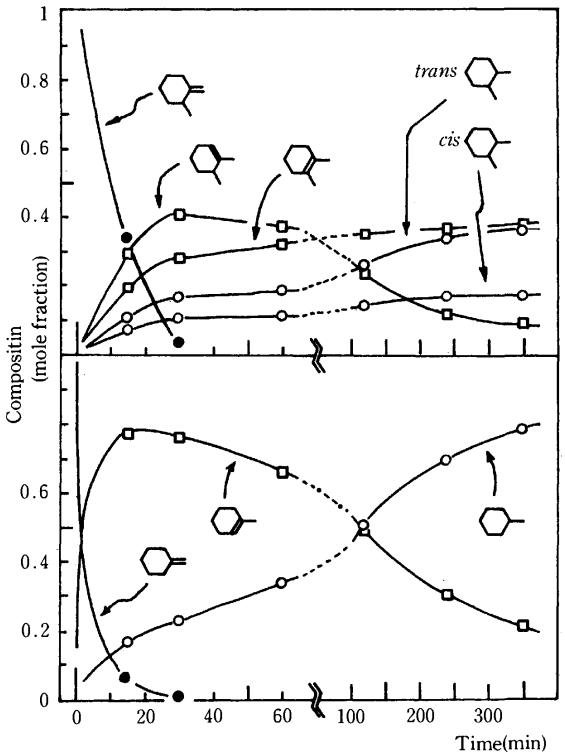

Fig. 1. Typical reaction profile on Pd.

Molar hydrogen uptake and molar olefin consumption were the same within experimental error for all the catalysts. This indicates that little or no hydrogenolysis occurred.

Substituent Effects. As in the earlier work on ketone hydrogenation, let us take the relative reactivity R_B/R_A as a measure of the methyl substituent effect. Except for Pd, the first-order log-log plots according to Eq. 4 were straight, and the R_B/R_A values were obtained from the slope of these plots. In an attempt to estimate the R_B/R_A values also for Pd, the sum $C_{c-Q}+C_{t-Q}$ was plotted against C_P and several slopes on that curve were inserted into Eq. 1 as the differential coefficient. The R_B/R_A values thus worked out, however, did not converge around a constant value.

Table 2. Substituent effect and stereoselectivity

Catalyst	R_B/R_A		*c*-1,2-DMC/*t*-1,2-DMC	
	Series I	II	Series I	II
Ru	0.19	0.14	1.7	3.6
Rh	0.26	0.21	1.1	3.2
Pd	—	—	0.6—0.7	0.5—0.7
Os	0.20	0.14	3.1	4.5
Ir	0.26	0.26	2.4	5.4
Pt	0.29	0.31	2.0	1.9

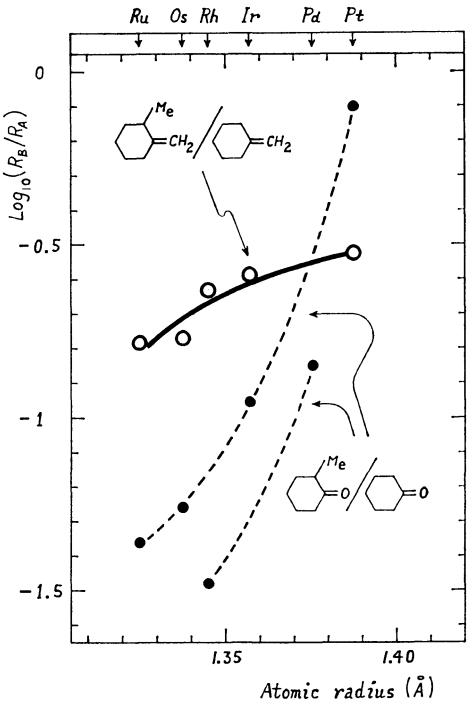

Fig. 2. Relative reactivity as a function of atomic radius of catalyst metal.

In series I, four or five competitive hydrogenation runs were carried out for each catalyst metal using different amounts of catalyst samples. In most cases, values of R_B/R_A for the same catalyst metal agreed within 8%, unless the catalyst amount was extremely small, say 2 mg or below. The experiments with such a small catalyst sample gave rise to either unusually high or low R_B/R_A values. In this case a sizable fraction of the catalyst surface may have been covered by some undetected impurities, and consequently the nature of the catalyst may have been altered so as to give such unusual results. Discarding the unusual R_B/R_A values, the others were averaged for each catalyst and are listed in Table 2. In series II, only one measurement of R_B/R_A was made for each metal catalyst using an appropriate amount of the catalyst. The values obtained are also listed in Table 2. For Ir and Pt, the agreement in R_B/R_A between series I and II is satisfactory. The cause of the small differences observed for the other metals is not clear.

In Fig. 2, the logarithm of R_B/R_A is plotted against the atomic radius of the catalyst metal,[11] where each of the R_B/R_A values is the average of the two values listed for each metal in Table 2. Figure 2 also includes for comparison the corresponding data for the earlier competitive hydrogenation of cyclohexanone and its 2-methyl derivative. It is seen that the $\log(R_B/R_A)$ values for the olefin system depends only slightly upon the atomic radius in contrast with a strong dependence of the ketone system. However, both olefin and ketone systems are alike in that the greater the atomic radius of the catalyst, the less negative is the value of $\log(R_B/R_A)$ or the less pronounced is the methyl substituent effect.

MINDO/2 Calculations. The charge densities and bond orders for MeneC and 2-MMeneC are basic to the understanding of the observed methyl substituent effect; they have been calculated using the MINDO/2 method on a Fujitsu computer Facom 230-75. It is very likely that MeneC is conformationally similar to cyclohexane, and that the chair form is its predominant ground-state conformation.[12] While definitive structural parameters for MeneC and 2-MMeneC are still lacking, a small difference from the cyclohexane skeleton would be expected because of the influence of the olefinic double bond. In particular, the bond angle C_2–$C_1(sp^2)$–C_6 in MeneC would be slightly larger than the cyclohexane C–C–C angle, 111.6°.[12,13] For our MINDO/2 calculations the following geometrical parameters were used for both MeneC and 2-MMeneC: angles 117° (C_2–$C_1(sp^2)$–C_6), 121.5° (C_2–$C_1(sp^2)$–$C_7(sp^2)$ and (C_6–$C_1(sp^2)$–$C_7(sp^2)$), 109.5° (for any other carbon set), 120° ($C_1(sp^2)$–$C_7(sp^2)$–H), 109.5° (H–C(sp^3)–H); distances 1.37 Å (C=C), 1.54 Å (C–C), 1.09 Å (C–H). The methyl substituent in 2-MMeneC was assumed to occupy the equatorial position. In order to define the rotational conformation of the methyl substituent, let us denote the three methyl hydrogens by H_α, H_β, and H_γ, with H_α representing the hydrogen that is taken as parallel to the axial C_3–H bond, and with H_γ representing the hydrogen that points away from the C_1=C_7 double bond. Were the six-membered ring of 2-MMeneC quite identical with that of cyclohexane, then the C_1–C_7–C_2 plane would bisect the H_α–C_8–H_β angle, and hence the distance H_α–C_7 would be equal to the distance H_β–C_7. However, owing to the widening of the C_2–C_1–C_6 angle and to the resulting structural deformation, C_7 should be closer to H_β than to H_α. The distances employed for MINDO/2 calculations

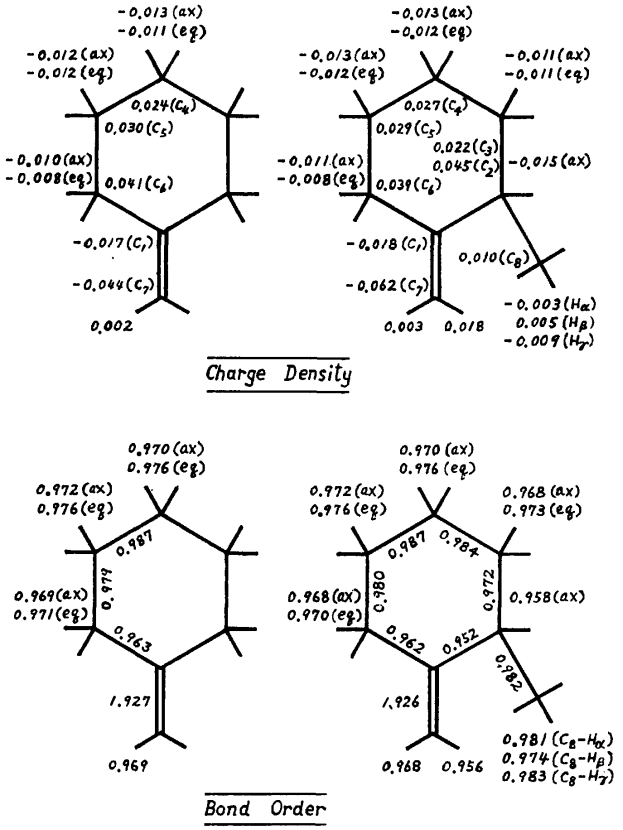

Fig. 3. Charge densities and bond orders for MeneC and 2-MMeneC.

were 2.26 Å for H_α–C_7 and 1.94 Å for H_β–C_7.

The results of the MINDO/2 calculations are shown in Fig. 3. Obviously, MeneC and 2-MMeneC are similar in bond order over the whole molecule, but dissimilar in charge density at and around the functional methylene group. The C=C double bond of 2-MMeneC is more negative and more polarized than that of MeneC. These results are reminiscent of a report of Libit and Hoffmann,[14] who made various molecular orbital calculations on propylene and toluene and showed that there is little net electron transfer from the methyl group to the ethylene or benzene but a significant polarization of the π electron system.

Other Data. Although not directly relevant to the substituent effect, the stereoselectivities measured in this study might be worth noting. Except for Pd, the observed isomeric ratios *c*-1,2-DMC/*t*-1,2-DMC were almost constant at conversions greater than 5%. The constant values are listed in Table 2. It is seen that except for Pd and Pt the absolute values for the isomeric ratio are considerably different between series I and II. However, the order of increasing *cis*/*trans* ratio in series I, Pd<Rh<Ru<Pt<Ir<Os, is not very much different from that in series II, Pd<Pt<Rh<Ru<Os<Ir, and these two sequences also resemble that observed by Nishimura and his associates, Pd≪Rh≈Ru=Pt<Os≈Ir.[15] Palladium is unique in that it produces more *trans* isomer than *cis*. Such *trans* selectivity on Pd was also reported earlier by others.[10,15]

Discussion

It might be worthwhile to make a few comments on Fig. 2 where a comparison is made of 2-methyl substituent effects between two structural analogs—MeneC and cyclohexanone. In the earlier ketone study, we could unambiguously rule out any polar factor because molecular orbital calculations have revealed that the carbonyl group of cyclohexanone and that of its methyl derivative are quite identical in charge densities and bond orders. In contrast, as seen in Figure 3, the olefinic double bond of MeneC is significantly different from that of 2-MMeneC in charge density. Thus, it is difficult to determine the main cause of the methyl substituent effect in the olefin system.

The present olefin system contrasts kinetically with the earlier ketone system in two respects; (i) with the exception of Pt, the olefin system is less negative in $\log(R_B/R_A)$ and (ii) the $\log(R_B/R_A)$ value depends only slightly upon the catalyst in the case of the olefin system, but very strongly in the case of the ketone system. Although more work is needed before these contrasts can be explained, the following matters may have some bearing. First, MeneC and its methyl derivatives are less flexible than their respective cyclohexanone counterparts.[16,17] Therefore, if the boat conformation play any role at all, this role would be more significant in ketone hydrogenation. Secondly, there can exist two distinct half-hydrogenated intermediates, *i.e.*, the C_1-metal- and C_7-metal-monoadsorbed species for olefins and the C_1-metal- and O-metal-monoadsorbed species for ketones. For either system, a larger substituent effect is expected when hydrogenation proceeds through the C_1-metal intermediate because the methyl substituent is closer to the catalyst surface on this intermediate. Thus, the substituent effect is probably influenced by the relative importance of these two intermediates. This relative importance may be quite different between olefin hydrogenation and ketone hydrogenation. Thirdly, the conformational equilibrium, *eq*-Methyl⇋*ax*-Methyl, is shifted further to the right in 2-MMeneC than in its ketone counterpart. Servies, *et al.*[18] experimentally determined the axial-methyl conformer content of 2-methylcyclohexanone to be 10.3% at 31.9 °C. On the other hand, Allinger *et al.*[13] calculated the enthalpy for the conformational equilibrium of 2-MMeneC (*eq*-Methyl⇌*ax*-Methyl) to be 0.50 kcal/mol. Assuming no entropy difference between the two conformers, this enthalpy value gives rise to an axial methyl content of 30.5% for 2-MMeneC at 31.9 °C. Finally, let us compare the C_1,C_7-diadsorbed olefin intermediate with its ketone counterpart, *i.e.*, the C_1,O-diadsorbed intermediate. Since the atomic radius of carbon is a little larger than that of oxygen, the C_7–metal bond in the adsorbed olefin must be a little longer than the O–metal bond in the adsorbed ketone.[19] Therefore, the 2-methyl substituent in the adsorbed olefin is expected to hang down a little further away from the catalyst surface compared with that in the adsorbed ketone. The further away the methyl substituent from the catalyst surface, the smaller

will be its hindrance to adsorption. This might be responsible in part for the less pronounced substituent effect in the olefin system compared with the ketone system on most of the catalyst metals.

Interestingly, Table 2 shows that the relative rate data are fairly reproducible on each catalyst despite large scatter in the *cis/trans* ratio data. This would mean that, compared to the relative rate, the *cis/trans* ratio is more profoundly affected by uncontrolled small variations of catalyst properties and environmental conditions, *e.g.*, change in surface structure due to aging and in minute traces of undetected impurities. The relative rate and the *cis/trans* ratio may be controlled by different steps of the overall hydrogenation pathway.

It is a pleasure to thank Dr. L. Breger (Inst. Phys. Chem. Res.) and Prof. F. S. Howell (Sophia Univ.) for their linguistic comments on the original manuscript.

The Total Synthesis of Hydroxyisochamaecynone and Its Stereochemical Assignment[1)]

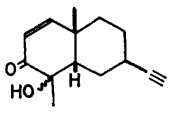
Masayoshi Ando,* Toyonobu Asao,† and Kahei Takase

Department of Chemistry, Faculty of Science, Tohoku University, Aramaki-aza-Aoba, Sendai 980

(Received August 27, 1979)

The structure of an acetylenic nor-sesquiterpene, hydroxyisochamaecynone, was determined to be 4α-hydroxy-5β*H*-13-noreudesm-1-en-11-yn-3-one (Ib) by means of the stereoselective total syntheses of two possible stereoisomers, Ib and 4β-hydroxy-5β*H*-13-noreudesm-1-en-11-yn-3-one.

The acetylenic nor-sesquiterpene alcohol named "hydroxyisochamaecynone" has been isolated from the essential oil of the Benihi tree (*Chamaecyparis formosensis* Matsum., Cupressaceae) as an extremely minor component,[2)] together with the related acetylenic compounds.[2,3)] The structure of this compound has been inferred to be as is shown in I, except for the stereochemistry at C_4 by only the spectral evidence. This paper will give details of the total syntheses of 4β-hydroxy-5β*H*-13-noreudesm-1-en-11-yn-3-one (Ia) and its C_4-epimer, 4α-hydroxy-5β*H*-13-noreudesm-1-en-11-yn-3-one (Ib), in optically active forms in the regio- and stereo-selective manners, with the object of establishing the structure of "hydroxyisochamaecynone."



(I)

Fig. 1.

We chose an acetylenic ketone (**1**) as the starting material mainly for the following three reasons: 1) The ketone **1** can easily be obtained from *l*-α-santonin by means of the previously reported method,[4)] 2) the ketone **1** is conveniently functionalized as the starting material of both of Ia and Ib, and 3) although acetylenic ketone, **1**, and its related compounds are conformationally mobile and their reaction mode is rather complex, their stereochemical behavior has been well documented and their stereochemical reaction course is predictable.[4)]

The starting point of the synthesis is the enol acetylation of **1**. The treatment of **1** with isopropenyl acetate in the presence of *p*-TsOH gave mainly the thermodynamically more stable trisubstituted enol acetate (**2**). The amount of undesired $\Delta^{2,3}$-enol acetate (**16**) formed under these conditions was negligible, judging from the NMR spectrum of the crude product. In Compound **2** there are two possible conformers, the non-steroid conformation (**A**) and the steroid conformation (**B**), as is shown in Fig. 2. Judging from the results of the equilibrium reaction between **1** and its C_4-epimer (**17**),[5)] which was reported in the previous paper of this series,[4)] Compound **2** is presumed to exist as an equilibrium mixture of the **A** and **B** conformers in solution. Actually, the NMR spectrum of **2** showed

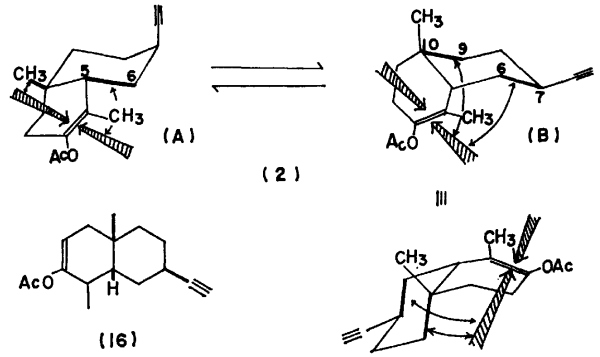


Fig. 2.

two pairs of methyl groups, possibly corresponding to **A** and **B**.

The treatment of **2** with monoperoxyphthalic acid gave an epoxide (**3**) as a single product. The high stereoselectivity of this reaction was explained as follows (Fig. 2). In the non-steroid conformation (**A**) the β-side approach of the incoming reagent is hindered by the angular methyl group, while its α-side approach is hindered by the C_5–C_6 bond. On the contrary, in the steroid conformation (**B**) there is no significant hindrance in the convexed β-side, although the α-side is strongly hindered by the C_6–C_7 and C_9–C_{10} bonds. Thus, in the epoxidation of the equilibrium mixture of the **A** and **B** conformers the reagent attacks the least hindered β-side of **B** to give β-epoxide (**3**) stereoselectively. This stereochemical assignment was confirmed by the epoxidation of the enol acetate (**12**) with a rigid conformation. A detailed discussion of this will appear below.

The hydrolysis of **3** gave a hydroxy ketone (**4**). The hydroxyl group of **4**, which was introduced newly at C_4, was assigned a β-configuration the same as that of the epoxide ring of **3**. Although we expected the preferential formation of α-bromo ketone (**6**) in the bromination of **4** in the presence of HBr,[4,6)] **4** gave a mixture of a tribromide (**5**) and the desired α-bromo ketone (**6**) under those reaction conditions. Probably the C_2 position of the enol form of **4** is sterically hindered, and the addition rate of Br_2 to the terminal triple bond and the enol double bond is comparable. In agreement with the **6** structure, IR ($CHCl_3$) showed carbonyl absorption at 1727 cm^{-1} and NMR (CCl_4) showed C_2–H at δ 5.05 (1H, q, J=7.0 and 13.0 Hz).

The dehydrobromination of **6** with LiBr–Li_2CO_3 in DMF produced 4β-hydroxy-5β*H*-13-noreudesm-1-en-11-yn-3-one (Ia), which exhibited completely different IR

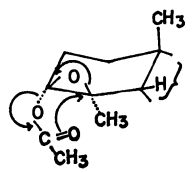

Fig. 4.

($CHCl_3$), NMR ($CDCl_3$), ORD (MeOH), and mass (70 eV) spectra from those of naturally occurring "hydroxyisochamaecynone." In accordance with the Ia structure with its non-steroid conformation, as is shown in Fig. 3, the NMR (CCl_4, 100 MHz) spectrum showed a long-range coupling (J=1.5 Hz) between C_1–H and C_5–H. The half-band width of C_7–H was *ca.* 14 Hz, which agreed with the expected value of α-(*eq*) C_7–H. The IR spectrum of Ia in CCl_4 showed absorption bands at 3580 (w) and 3500 (s) cm^{-1}, which suggested the existence of β(*ax*)-OH,[7,8] in accordance with the Ia structure with its non-steroid conformation.

Our next target was the synthesis of 4α-hydroxy-5β*H*-13-noreudesm-1-en-11-yn-3-one (Ib), the C_4-epimer of Ia. The thermal rearrangement of **3** gave a keto acetate (**7**). From the consideration of the reaction mechanism[9] depicted in Fig. 4, the stereochemistry of the newly introduced acetoxyl group was deduced to be the α-orientation. The hydrolysis of **7** gave a hydroxy ketone (**8**), which was the C_4-epimer of **4**. The bromination of **8** gave a mixture of an addition product (**9**) and the desired α-bromo ketone (**10**). The ratio of **9** to **10** depended upon the reaction conditions. Judging from the carbonyl absorption (1727 cm^{-1}) in IR (KBr) and the coupling pattern of C_2–H [δ 5.53 (q, J=7.0 and

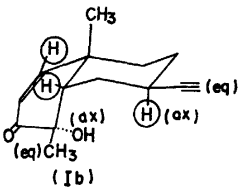

Fig. 5

13.0 Hz)] in NMR (CCl_4), the bromine atom at C_2 of **10** is situated in the $\beta(eq)$-configuration. The dehydrobromination of **10** with LiBr–Li_2CO_3 in DMF produced 4α-hydroxy-5β*H*-13-noreudesm-1-en-11-yn-3-one (Ib), which was identical with naturally occurring "hydroxyisochamaecynone" in its IR (KBr), NMR ($CDCl_3$), ORD (MeOH), and mass (70 eV) spectra and which showed no depression in its melting point when admixed with an authentic specimen. In accordance with the stereo-structure Ib with the steroid conformation, shown in Fig. 5, the NMR (100 MHz) did not show a long-range coupling between C_1–H and C_5–H. The half-band width of C_7–H was *ca.* 24 Hz, which agreed with the expected value of α(*ax*) C_7–H. The IR spectrum (CCl_4) of Ib showed two absorption bands, at 3590 (w) and 3500 (s) cm^{-1}, which agreed with the stereo-structure of a steroid conformation possessing an α(*ax*)–OH bond.[7,8] From the stereoselective syntheses mentioned above and the spectroscopic evidence concerning Ia and Ib, the structure of naturally occurring "hydroxyisochamaecynone" was concluded to be 4α-hydroxy-5β*H*-13-noreudesm-1-en-11-yn-3-one (Ib) with the steroid conformation, as is depicted in Fig. 5.

In the above-mentioned syntheses, we employed the epoxidation of a conformationally mobile enol acetate (**2**) as a key step and concluded by an examination of the Dreiding molecular models that the reagent should approach from the β-side. Since there is no similar example in the literature, we decided to confirm the above conclusion by the following chemical correlation. Hexahydroisochamaecynone (**11**) was employed as the starting material. The enol acetylation of **11** gave an enol acetate (**12**). Since this compound has a bulky ethyl group at C_7, the conformation was considered to be fixed in the steroid conformation, as is shown in Fig. 6. In this case, the epoxidation of **12** occurred, apparently from the convexed β-side,[10] giving a β-epoxide (**13**). The hydrolysis of **13** gave a hydroxy ketone (**14**), which was identical with the tetrahydro derivative obtained by the catalytic hydrogenation of **4**, in accordance with the above-mentioned conclusion.

The ORD Studies of the Synthetic Intermediates of Ia and Ib. In the *cis*-decalone derivatives with a mobile conformation, the studies of the ORD curves are a convenient method for predicting their conformations. For the application of this method to Ia, Ib, and their synthetic intermediates, we need to know the degree of the contribution of the axial hydroxyl group at the α-position of the carbonyl group. The ORD data of **4** and Ia and the corresponding deoxy derivatives (**17** and **18**) are summarized in Table 1. This table shows that the contribution of the β(*ax*)-hydroxyl group to the Cotton effect of **4** and Ia is negative, as predicted by the octant rule.

On the other hand, the ORD data of **15**, **8**, **10**, and Ib and the corresponding deoxy derivatives (**19**, **1**, **20**, and **21**), summarized in Table 2, show that the

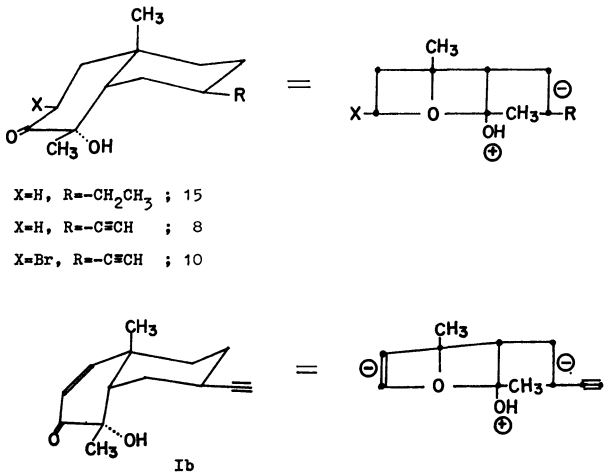

Fig. 8

contribution of the α(*ax*)-hydroxyl group of **15**, **8**, **10**, and Ib to the Cotton effect is positive, as predicted by the octant rule, though the magnitude of the ΔA value is irregular.

In conclusion, although the axial hydroxyl substituent at the α-position of the carbonyl group contributes to the Cotton effect, as predicted by the octant rule, it is difficult to estimate the conformation of the flexible hydroxy ketones on the basis of the ORD data only, because the magnitude of the contribution of the hydroxyl group to the Cotton effect is not constant.

Experimental

All the melting points are uncorected. The IR spectra were recorded on Shimadzu IR-27, Hitachi EPI-S2, and Hitachi EPI-G28 spectrophotometers. The NMR spectra were recorded on Varian A-60, Nichiden-Varian T-60, and Varian HA-100 spectrometers, employing tetramethylsilane as the internal reference. The ORD and CD spectra were recorded on a Nihonbunko ORD/UV-5 spectrophotometer.

3-Acetoxy-5βH-13-noreudesm-3-en-11-yne (2). A solution of 4α*H*,5β*H*-13-noreudesm-11-yn-3-one (**1**) (600 mg, 2.94 mmol) in isopropenyl acetate (6 ml) containing *p*-toluenesulfonic acid (60 mg) was heated under N_2 at the boiling point and then concentrated in 30 min to give a brown, oily residue, which was subsequently dissolved in ether (100 ml). The ether solution was washed with a saturated aq soln of NaCl (50 ml×2), dried ($MgSO_4$), and concentrated to give 600 mg of an oily material, which was a mixture of two conformers of **2**. IR (neat): 3300, 2160, and 1755 cm^{-1}. NMR (CCl_4): δ 1.02 (s, C_{10}–Me of the major component), 1.05 (s, C_{10}–Me of the minor component), 1.50 (m, C_4–Me of the major component), 1.56 (m, C_4–Me of the minor component), 1.90 (1H, d, J=3.0 Hz), and 2.03 (3H, s, –C(=O)–C<u>H</u>$_3$) ppm.

3α-Acetoxy-3β,4β-epoxy-5βH-13-noreudesm-11-yne (3). To a solution of **2** (600 mg, 2.44 mmol) in $CHCl_3$ (15 ml) we added a solution of monoperoxyphthalic acid (500 mg, 2.75 mmol) in ether (15 ml). The mixture was allowed to stand at room temperature for 7 days and then filtered to remove the phthalic acid. The filtrate was poured into an aq soln of KI and stirred for a few min. The organic layer was separated, and the aqueous layer was extracted with $CHCl_3$ (20 ml×2). The combined extracts were washed successively with a 0.2 M aq soln of $Na_2S_2O_3$, a saturated aq soln of $NaHCO_3$, and a saturated aq soln of NaCl, dried ($MgSO_4$), and concentrated to give 668 mg of an oily material, which was employed for the next reaction. This crude oil (445 mg) was chromatographed over silica gel (40 g, Merck, <230 mesh) and eluted with CCl_4–$CHCl_3$ (1:1) to give 103 mg of spectroscopically pure **3** (mp 48—50 °C), which was then recrystallized from pentane to give a crystalline material; mp 68—69 °C. IR ($CHCl_3$): 3289, 2123, and 1748 cm^{-1}. NMR (CCl_4): δ 1.13 (3H, s), 1.25 (3H, s), 2.02 (3H, s, –C(=O)–C<u>H</u>$_3$), 1.92 (1H, d, J=2.5 Hz, C_{12}–H), and 2.80 (1H, m, $W_{h/2}$=*ca.* 10 Hz, C_7–H) ppm. Found: C, 73.38; H, 8.45%. Calcd for $C_{16}H_{22}O_3$: C, 73.25; H, 8.45%.

4β-Hydroxy-5βH-13-noreudesm-11-yn-3-one (4). Into a solution of **3** (610 mg) [prepared from **1** (600 mg, 2.94 mmol) without any purification at any step] in ethanol (30 ml) we added a 10% aq soln of KOH (9 ml). The mixture was allowed to stand at room temperature overnight, poured into a saturated aq soln of NaCl (100 ml), and extracted with ether (30 ml×3). The combined ether layers were washed with a saturated aq soln of NaCl, dried ($MgSO_4$), and evaporated to give an oily material, which was then chromatographed over silica gel (25 g, Merck, <230 mesh) and eluted with CCl_4–$CHCl_3$ (1:1) to give spectroscopically pure **4** (214 mg, 33% overall yield from **1**); mp 89 °C. This was recrystallized from pentane to give the analytical sample;

mp 95 °C. IR (KBr): 3480, 3300, 2130, and 1712 cm^{-1}. NMR (CCl_4): δ 1.27 (3H, s), 1.45 (3H, s), and 1.90 (1H, d, J=2.5 Hz, C_{12}–H) ppm. ORD (MeOH): $[\phi]_{310}$=−1490, $[\phi]_{260}$=+2000; A=−35. Found: C, 76.51; H, 8.96%. Calcd for $C_{14}H_{20}O_2$: C, 76.32; H, 9.15%.

Bromination of ***4****. Formation of 2α,11,12-Tribromo-4β-hydroxy-5βH-13-noreudesm-11-en-3-one (****5****) and 2α-Bromo-4β-hydroxy-5βH-13-noreudesm-11-yn-3-one (****6****).* To a solution of **4** (170 mg, 0.77 mmol) in AcOH (5 ml) we added a 48% aq soln of HBr (0.1 ml) and Br_2 (140 mg, 0.88 mmol). The mixture was stirred for 1 h at room temperature, poured into a saturated aq soln of NaCl, and extracted with ether (20 ml ×3). The combined extracts were washed with a saturated aq soln of NaCl, dried ($MgSO_4$), and concentrated to give an oily product (250 mg), which was then chromatographed over silica gel (18 g, Merck, <230 mesh) and eluted with CCl_4–$CHCl_3$ (1: 1). The first fraction gave **5** (105 mg, 30%) as a crystalline material. IR (KBr): 3521, 3106, and 1730 cm^{-1}. NMR (CCl_4): δ 1.12 (3H, s), 1.47 (3H, s), 5.47 (1H, q, J=6.5 and 13.0 Hz, C_2–H), and 6.37 (1H, s, C_{12}–H) ppm. The second fraction gave **6** (77 mg, 33%) as a crystalline material. IR ($CHCl_3$): 3546, 3333, 2119, and 1727 cm^{-1}. NMR (CCl_4): δ 1.42 (3H, s), 1.59 (3H, s), 1.93 (1H, d, J=2.0 Hz, C_{12}–H), and 5.05 (1H, q, J=7.0 and 13.0 Hz, C_2–H) ppm.

4β-Hydroxy-5βH-13-noreudesm-1-en-11-yn-3-one (4β-Hydroxychamaecynone Ia). A mixture of **6** (22 mg, 0.10 mmol), Li_2CO_3 (22 mg, 0.30 mmol), and LiBr (22 mg, 0.25 mmol) in anhydrous DMF (4 ml) was stirred at 140—150 °C for 6.5 h under N_2, cooled, poured into a saturated aq soln of NaCl (30 ml), and extracted with ether (10 ml×3). The combined extracts were washed successively with 2 M HCl (10 ml) and a saturated aq soln of NaCl, dried ($MgSO_4$), and concentrated to give 17 mg of an oily material, which was then chromatographed over silica gel (2 g, Merck, <230 mesh) and eluted with CCl_4–$CHCl_3$ (1: 1) to give 7 mg (44%) of Ia as a crystalline material; mp 71 °C, IR ($CHCl_3$): 3521, 3322, 2114, and 1672 cm^{-1}. NMR (CCl_4, 100 MHz): δ 1.34 (3H, s), 1.44 (3H, s), 1.93 (1H, d, J=2.5 Hz, C_{12}–H), 2.83 (1H, m, $W_{h/2}$=*ca.* 14 Hz, C_{17}–H), 5.88 (1H, d, J=10.0 Hz, C_2–H), and 6.43 (1H, dd, J=1.5 and 10.0 Hz, C_1–H) ppm. UV (MeOH): λ_{max}=228 nm (ε=7400). ORD (MeOH): $[\phi]_{360}$=−560, $[\phi]_{310}$=+220, A=−7.8. CD (MeOH): $[\theta]_{340}$=−560.

*4α-Hydroxy-5βH-13-noreudesm-11-yn-3-one (****8****).* The crude epoxide (**3**, 860 mg) [prepared from **1** (800 mg, 3.92 mmol)] was heated at 170—178 °C under N_2 to give 4α-acetoxy-5β*H*-13-noreudesm-11-yn-3-one (**7**) as an oily material. IR (neat): 3279, 1730, and 1721 cm^{-1}. This crude material was dissolved in a mixture of EtOH (24 ml) and a 10% aq soln of KOH (8 ml). The mixture was allowed to stand at room temperature for 100 min, poured into a saturated aq soln of NaCl (100 ml), and extracted with petroleum ether (20 ml×4). The combined extracts were washed with a saturated aq soln of NaCl, dried ($MgSO_4$), and concentrated to give 463 mg of an oily material, which was then chromatographed over silica gel (25 g, Merck, <230 mesh) and eluted with a mixture of CCl_4–$CHCl_3$ (1: 1). The first fraction gave **4** (58 mg, 7% overall yield from **1**). The second fraction gave 163 mg (19% overall yield from **1**) of **8**, which was recrystallized from pentane to give colorless prisms; mp 103 °C. IR (KBr): 3436, 3268, 2119, and 1712 cm^{-1}. NMR (CCl_4): δ 1.22 (3H, s), 1.25 (3H, s), and 1.92 (1H, d, J=2.5 Hz, C_{12}–H) ppm. ORD (MeOH): $[\phi]_{325}$=−520, $[\phi]_{300}$=0, A=−5.2. CD (MeOH): $[\theta]_{312}$=−274. Found: C, 76.35; H, 9.09%. Calcd for $C_{14}H_{20}O_2$: C, 76.32; H, 9.15%.

Bromination of ***8****. Formation of 11,12-Dibromo-4α-hydroxy-5βH-13-noreudesm-3-one (****9****) and 2β-Bromo-4α-hydroxy-5βH-13-noreudesm-11-yn-3-one (****10****).* A solution of **8** (122 mg, 0.55 mmol) in AcOH (5 ml) was stirred in the presence of a 48% aq soln of HBr (0.1 ml) for 10 min at room temperature. Into the mixture we then added a solution of Br_2 (108 mg, 0.68 mmol) in AcOH (1 ml). The mixture was stirred for 40 min at room temperature, poured into a saturated aq soln of NaCl (50 ml), and extracted with petroleum ether (20 ml ×4). The combined extracts were washed successively with a 10% aq soln of Na_2CO_3 and a saturated aq soln of NaCl, dried ($MgSO_4$), and concentrated to give 172 mg of an oily material, which was then chromatographed over silica gel (10 g, Merck, <230 mesh) and eluted with $CHCl_3$–CCl_4 (1: 1) to give spectroscopically pure **10** (54 mg, 33%) as a semisolid compound. This was subsequently recrystallized from petroleum ether–ether to give prisms; mp 140.5 °C. IR (KBr): 3497, 3300, 2105, and 1727 cm^{-1}. NMR (CCl_4): δ 1.30 (3H, s), 1.50 (3H, s), 1.93 (1H, d, J=2.0 Hz), and 5.53 (1H, q, J=7.0 and 13.0 Hz, C_2–H) ppm. ORD (MeOH): $[\phi]_{310}$=−990, $[\phi]_{270}$=0, A=−9.9. Found: C, 57.34; H, 5.81%. Calcd for $C_{14}H_{19}O_2Br$: C, 56.23; H, 6.41%. In another experiment, to a solution of **8** (130 mg, 0.59 mmol) in AcOH (5 ml) we added a 48% aq soln of HBr (0.1 ml) and Br_2 (110 mg, 0.69 mmol) successively. The mixture was stirred for 40 min at room temperature, poured into a saturated aq soln of NaCl (50 ml), and extracted with petroleum ether (20 ml×4). The combined extracts were washed successively with a 10% aq soln of Na_2CO_3 and a saturated aq soln of NaCl, dried ($MgSO_4$), and concentrated to give 207 mg of an oily material, which was chromatographed over silica gel (10 g, Merck, <230 mesh) and eluted with CCl_4–$CHCl_3$ (1: 1). The first fraction gave spectroscopically pure **9** (61 mg, 27%) as a crystalline material; this was subsequently recrystallized from pentane to give microcrystals; mp 90 °C. IR (KBr): 3521, 3086, and 1706 cm^{-1}. NMR (CCl_4): δ 1.11 (3H, s), 1.46 (3H, s), and 6.35 (1H, s) ppm. Found: C, 44.25; H, 5.26%. Calcd for $C_{14}H_{20}O_2Br_2$: C, 44.21; H, 5.30%. The second fraction gave **10** (29 mg, 16%).

4α-Hydroxy-5βH-13-noreudesm-1-en-11-yn-3-one (4α-Hydroxyisochamaecynone, Ib). A mixture of **10** (83 mg, 0.28 mmol), LiBr (88 mg, 1.01 mmol), and Li_2CO_3 (88 mg, 1.19 mmol) in anhydrous DMF (10 ml) was stirred at 150—155 °C for 5 h under N_2, cooled, poured into a saturated aq soln of NaCl (50 ml), and extracted with ether (15 ml×3). The combined extracts were washed successively with 2 M HCl (15 ml) and a saturated aq soln of NaCl, dried ($MgSO_4$), and concentrated to give 75 mg of a crystalline material, which was subsequently chromatographed over silica gel (5 g, <230 mesh) and eluted with CCl_4–$CHCl_3$ (1: 1) to give spectroscopically pure Ib (41 mg, 68%) as a crystalline material, which was then recrystallized from pentane to give colorless prisms; mp 160 °C. This material showed no depression in its melting point when admixed with an authentic sample of natural "hydroxyisochamaecynone" and was identical in all respects with this specimen in IR (KBr), NMR ($CDCl_3$), ORD (MeOH), and MS (70 eV).

*Synthesis of 4β-Hydroxy-5βH-13-noreudesm-3-one (****14****) from 4αH,5βH-13-Noreudesman-3-one (Hexahydroisochamaecynone,* ***11****).* A solution of **11** (760 mg, 3.65 mmol) in isopropenylacetate (8 ml) containing *p*-toluenesulfonic acid (80 mg) was heated under N_2 at the boiling point and then concentrated for 30 min to give a brown, oily residue, which was subsequently dissolved in ether (100 ml). The ether solution was washed with a saturated aq soln of NaCl (50 ml×2), dried ($MgSO_4$), and concentrated to give 780 mg of crude 3-acetoxy-5β*H*-noreudesm-3-ene (**12**).

To a solution of this crude material (780 mg) in $CHCl_3$

Table 3.

Compound	Absorptions of -OH (cm^{-1})		Absorptions of C=O (cm^{-1})
	Weak band	Strong band	
1			1716
Ia	3580	3500	1708 (sh), 1684
4	3590	3490	1715
14	3595	3475	1713
Ib	3590	3500	1710 (sh), 1685
8	3600	3490	1718
15	3597	3480	1716

These IR spectra were recorded by a Hitachi-EPI-G28 instrument in a 0.2 M CCl_4 solution.

(16 ml) we added a solution of monoperoxyphthalic acid (728 mg, 4.00 mmol) in ether (16 ml). The mixture was allowed to stand at room temperature for 5 days and then filtered to remove any phthalic acid. The filtrate was poured into an aq soln of KI and stirred for a few min. The organic layer was then separated, and the aqueous layer was extracted with $CHCl_3$ (30 ml×2). The combined extracts were washed successively with a 0.2 M aq soln of $Na_2S_2O_3$, a saturated aq soln of $NaHCO_3$, and a saturated aq soln of NaCl, dried ($MgSO_4$) and concentrated to give 850 mg of crude 3α-acetoxy-3β,4β-epoxy-5β*H*-13-noreudesmane (**13**). which was almost pure, judging from the TLC analysis and the spectroscopic evidence. IR (neat): 1739 cm^{-1}. NMR (CCl_4): δ 0.96 (3H, s), 1.38 (3H, s), and 2.03 (3H, s) ppm.

Into a solution of this crude material (850 mg) in EtOH (30 ml) we added a 10% aq soln of KOH (10 ml). The mixture was allowed to stand at room temperature for 2 h, poured into a saturated aq soln of NaCl (100 ml), and extracted with ether (30 ml×3). The combined ether layers were washed with a saturated aq soln of NaCl, dried ($MgSO_4$), and evaporated to give a crystalline material, which was subsequently chromatographed over silica gel (10 g, Merck, <230 mesh) and eluted with CCl_4–$CHCl_3$ (1: 1) to give spectroscopically pure **14** (143 mg, 17% overall yield from **11**). This was recrystallized from pentane to give needles; mp 91.5 °C. IR (KBr): 3484 and 1715 cm^{-1}. NMR (CCl_4): δ 1.12 (3H, s) and 1.35 (3H, s) ppm. ORD (MeOH): $[\phi]_{315}=-1100$, $[\phi]_{245}=+2610$, $A=-37$. Found: C, 75.08; H, 10.49%. Calcd for $C_{14}H_{24}O_2$: C, 74.95; H, 10.78%.

Catalytic Hydrogenation of **4**. *Formation of* **14**: A mixture of **4** (50 mg), EtOH (3 ml), and 5% Pd/C was shaken under an atmosphere of H_2 for 2 h and then filtered. The filtrate was concentrated to give **14** (50 mg) as a crystalline material.

Catalytic Hydrogenation of **8**. *Formation of 4α-Hydroxy-5β*H*-13-noreudesm-3-one (***15***)*: A mixture of **8** (40 mg), EtOH (3 ml), and 5% Pd/C was shaken under an atmosphere of H_2 for 2 h and then filtered. The filtrate was concentrated to give **15** (30 mg) as an oily material. IR (neat): 3472 and 1715 cm^{-1}. NMR (CCl_4): δ 1.05 (3H, s) and 1.32 (3H, s) ppm. ORD (MeOH): $[\phi]_{325}=+160$, $[\phi]_{260}=+1000$, $A=-8.4$. CD (MeOH): $[\theta]_{295}=-372$.

The authors wish to thank Dr. Takashi Toda of this Department for his helpful discussion.

The Structure and Configuration of (+)-Glutionosone and (+)-Oxyglutinosone[1)]

Akio Murai, Hirofumi Taketsuru, Fujio Yagihashi, Nobukatsu Katsui, and Tadashi Masamune*

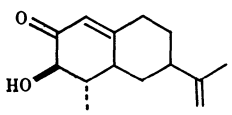
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received August 28, 1979)

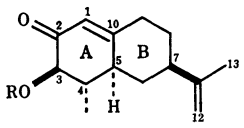
The structure elucidation of (+)-glutinosone and (+)-oxyglutinosone, antifungal norsesquiterpenes qualified as phytoalexins in diseased tobacco leaves and in diseased potato tubers, respectively, is described.

In recent preliminary communications[2,3)] we reported the structure and configuration of (+)-glutinosone (**1**) and (+)-oxyglutinosone (**2**), antifungal norsesquiterpenes qualified as phytoalexins in diseased tobacco leaves and in diseased potato tubers, respectively. In the present paper we describe the details of the structure elucidation.

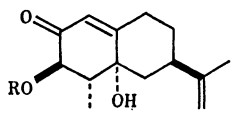
Glutinosone was isolated from leaves of *Nicotiana glutinosa* infected with tobacco mosaic virus and assigned formula **1'** by Burden and coworkers.[4)] However, the disposition of an isopropenyl group and the configuration of all asymmetric centers have not completely been determined yet. The following transformation of rishitin (**3**) into (+)-glutinosone[5)] has established that the relevant norsesquiterpene is represented correctly by formula **1**.



1'



1 R=H
1a R=Ac



2 R=H
2a R=Ac

Treatment of (−)-rishitin[6)] (**3**) with acetic anhydride (2.3 equiv) in a 1: 20 mixture of pyridine and benzene (room temp, 5 h) followed by chromatography afforded the 2- and 3-monoacetates (**3a** and **3b**), mp 60.5—62.5 °C and 107—107.5 °C, in 34 and 23% yields, respectively, with the 2,3-diacetate[6)] (**3c**, 5%) and the starting glycol (**3**, 35%): **3a**, δ 3.31 (1H, t, J=8.5 Hz, 3-H) and 4.72 (3H, br, 2- and 12-H): **3b**, δ 3.62 (1H, do t, J= 6.5, 8.5, and 8.5 Hz, 2-H) and 4.60 (1H, t, J=8.5 Hz, 3-H). The 2- and 3-monoacetates (**3a** and **3b**), when oxidized with the Jones reagent in a heterogeneous mixture of ether and water (room temp, 16 and 21 h), were converted into the corresponding dehydro compounds, 3-oxo 2-acetate and 2-oxo 3-acetate (**4a** and **4b**), each oily, in 41 and 61% yields, respectively. In accordance with the assigned structures, the respective compounds (**4a** and **4b**) exhibited two strong absorption maxima at the carbonyl regions (**4a**, ν_{max} 1757 and 1737 cm^{-1}; **4b**, ν_{max} 1757 and 1744 cm^{-1}) and signals due to the protons at C-2 or C-3 [**4a**, δ 5.21 (1H, do d, J=11 and 8 Hz, 2-H); **4b**, δ 4.84 (1H, d, J=9 Hz, 3-H)] in the IR and NMR spectra.

Transformation of the oxo acetates (**4b** and **4a**) into glutinosone (**1**) was undertaken under various conditions. Treatment of **4b** with base (KOAc in ethanol or alumina in dry benzene, room temp, 24 h) gave a complex mixture containing at least five compounds, while acid treatment (dil HCl in diglyme, room temp, 16 h) led to recovery of the starting material (**4b**). On the other hand, attempted isomerization of **4a** with base [NaOAc or $(CH_3)_4NOAc$ in water–ether, room temp, 45 h] failed, **4a** being recovered unchanged. One-step conversion of **3b** into **1** or **1a** under conditions of a modification[7)] of the Oppenauer oxidation (aluminium isoproxide and *N*-methyl-4-piperidone, reflux, 5 h) also resulted only in hydrolysis of the acetoxyl group, giving **3**. The aimed transformation was achieved under most usual conditions; treatment of oxo acetate **4b** with base (KOH, 1.2 equiv) in methanol (room temp, 25 min) effected migration of the 5(10)-double bond with concomitant hydrolysis to give $\Delta^{1(10)}$-3-hydroxy 2-ketone (**1**), oily, in 46% yield, with the corresponding 3-acetate (**1a**, 41%), oily; **1**, λ_{max} 237 nm (ε 14500); ν_{max} 3470, 1676, 1645, and 1620 cm^{-1}; δ 3.79 (1H, d, J=12 Hz, 3-H) and 5.90 (1H, br s, W_H=4 Hz, 1-H). All these spectra were identical with those of natural glutinosone[4)] (**1**), establishing the

5

absolute configurations at C-3, C-4, and C-7 of (+)-glutinosone.[5]

Reduction of (+)-glutinosone (**1**) with sodium borohydride gave glycol[4] (**5**), mp 136—138 °C, in 44% yield. The NMR spectrum [δ 3.18 (1H, do d, J=10 and 8 Hz, 3-H) and 4.06 (1H, br d, J=8 Hz, 2-H)] indicated that the A ring existed in a half-chair conformation. Addition of 0.6 mol equiv of the shift reagent Eu(dpm)$_3$ effected complete separation of the NMR signals due to individual protons on the A ring, as shown in Fig. 1. Irradiation at δ 3.89 (14-H) collapsed a broad multiplet at 6.80 (4-H) into a slightly broad triplet (J=10 Hz), indicating the coupling constant

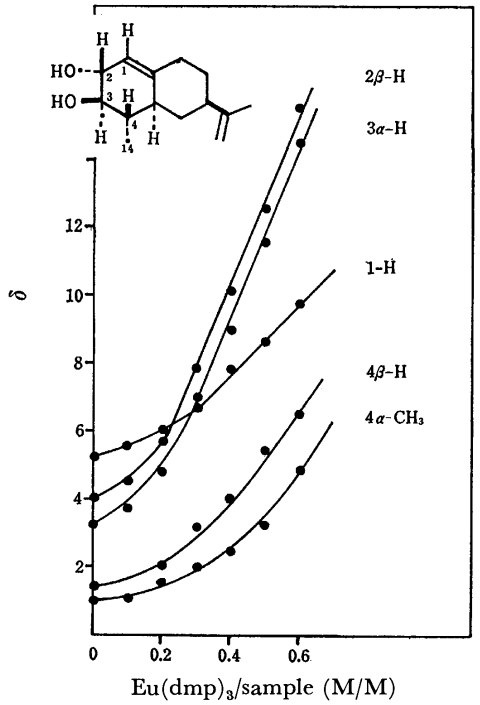

Fig. 1. Induced paramagnetic shifts for compound **5**.

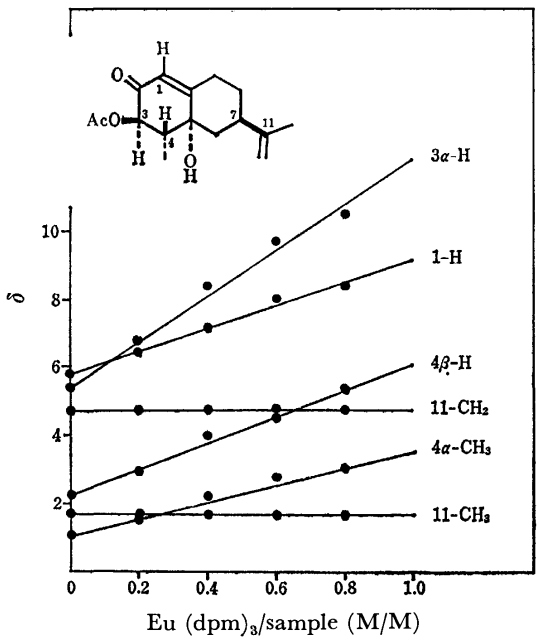

Fig. 2. Induced paramagnetic shifts for compound **2a**.

between two protons at C-4 and C-5 to be 10 Hz. It follows that the proton in question at C-5 must be oriented axial (α-configuration) and hence (+)-glutinosone is represented by formula **1**.

Oxyglutinosone (**2**) was isolated from tuber tissues of potatoes (*Solanum tuberosum*×*S. demissum*) infected by an incompatible race of *Phytophthora infestans* as follows. Neutral chloroform extracts (59 g), obtained from the diseased potato tubers (300 kg), were separated as described previously[6] to give "lubimin fraction" (Fraction E,[6] 4.7 g). This fraction was further purified by repeated chromatography to yield an oxyglutinosone and isolubimin-rich fraction (160 mg), with lubimin and epilubimin-rich fractions (174 and 110 mg), which on acetylation followed by preparative TLC over silica gel afforded oxyglutinosone (**2**) and isolubimin[3,8] (**6**) as the respective acetate (**2a**, 43 mg, and **6a**, 37 mg).

Oxyglutinosone acetate (**2a**), mp 99—101 °C and $[\alpha]_D$ +166°, was analyzed for $C_{16}H_{22}O_4$ [*m/e* 278 (M^+)] and hydrolyzed in a 1:1:2 mixture of trimethylamine, water and methanol (room temp, 3 h) to give oxyglutinosone (**2**), oily and $[\alpha]_D$ +130°, in 56% yield after purification by preparative TLC. The UV, IR, and ^{1}H-NMR spectra of these compounds indicated that oxyglutinosone (**2**) contained the following structural in units: a secondary methyl group [**2a**, δ 1.10 (3H, d, J=7 Hz)]: an isopropenyl [**2a**, ν_{max} 1642 (or 1638) and 897 cm^{-1}; δ 1.75 (3H, s) and 4.75 (2H, br s, W_H=6 Hz)]: an α,β-unsaturated carbonyl [**2a**, λ_{max} 230 nm (ε 12100); ν_{max} 1699 and 1638 (or 1642) cm^{-1}; δ 5.79 (1H, d, J=1.5 Hz, 1-H)]: two (secondary and tertiary) hydroxyl groups [**2**, δ 4.10 (1H, d, J=12 Hz, 3-H); **2a**, ν_{max} 3610, 3480, 1739, and 1240 cm^{-1}; δ 2.19 (3H, s) and 5.39 (1H, d, J=13 Hz, 3-H)]. These spectra, coupled with spin-decoupling studies on the spectra in the presence of the shift reagent [Eu(dpm)$_3$, 0.2—0.8 mol equiv] (Fig. 2), indicating the existence of the following partial formula; (*)-(CH_3)CH–CH-($OCOCH_3$)–C(=O)–CH=(*) in **2a**, in which (*) denotes a quaternary carbon, suggesting that oxyglutinosone (**2**) would be a 5-hydroxy derivative of glutinosone (**1**). This was supported by comparison of the ^{13}C-NMR spectra (Table 1) of both the 3-acetates

Table 1. The ^{13}C-NMR spectra of glutinosone acetate (**1a**) and oxyglutinosone acetate (**2a**)

(**1a** and **2a**) and confirmed as follows.

Rishitin 3-acetate (**3b**) was oxidized with *t*-butyl hydroperoxide in the presence of bis(acetylacetonato)-oxovanadium(IV)[9] [VO(acac)$_2$] to the 5α,10α-epoxide (**7**), mp 142—143 °C, in 83% yield. The α-configurational assignment to the epoxy group was deduced from the IR and ^{1}H-NMR spectra; namely, (i) a broad absorption due to the hydrogen bond between the 2α-hydroxyl and epoxy groups was observed at 3480 cm^{-1} in highly dilute carbon tetrachloride solution (0.0012 M, cell length, 50 mm), and (ii) a ^{1}H-NMR signal due to the hydroxyl proton at δ 3.11 (1H, d, J=10 Hz) remained unchanged on dilution. The Collins oxidation of epoxide **7** followed by treatment with silica gel afforded hydroxy α,β-unsaturated ketone, mp 99—101 °C and $[\alpha]_D$ +153°, in 54% yield, whose spectra (MS, UV, IR, and ^{1}H-NMR) were identical with those of natural oxyglutinosone (**2a**). This transformation has established that oxyglutinosone (**2**) is 5α-hydroxy-glutinosone.

Experimental

All the melting points were uncorrected. The purity of each compound was always checked by TLC over silica gel (Wako-gel B-5 or Merck, Kieselgel GF-254) with various solvent systems, and the spots were developed with cerium(IV) sulfate in dil sulfuric acid, iodine, vaniline–sulfuric acid[6] and/or the Ehrlich reagent. The optical rotations, UV, IR, and NMR (100 MHz) spectra were measured in ethanol, ethanol, chloroform, and chloroform-*d*, unless otherwise stated. The abbreviations "s, d, t, q, m, br, and do" in the NMR spectra denote "singlet, doublet, triplet, quartet, multiplet, broad, and double," respectively. The preparative TLC was carried out over silica gel (Merck, Kieselgel GF-254) and the column chromatography over silica gel (Merck, Kieselgel 70—230 mesh).

Partial Acetylation of Rishitin (3). Compound **3** (3.09 g, $[\alpha]_D$ −35.1°) was treated with acetic anhydride (3.0 ml) in benzene (80 ml) and pyridine (4 ml) at room temperature for 5 h under stirring. After addition of water, the mixture was separated into organic (benzene) and aqueous layers, and the latter was extracted with ether. The benzene and ether solutions were combined, washed with 2 M hydrochloric acid (HCl), 5% aq sodium hydrogencarbonate ($NaHCO_3$) and water, dried over anhydrous sodium sulfate and evaporated to leave resinous material (3.68 g), which was separated by column chromatography over silica gel (400 g), benzene–ether mixtures being used as solvents. Fraction eluted with benzene–ether (5: 1) afforded reshitin diacetate[6] (**3c**, 0.22 g), mp 68—70 °C (from hexane), which was identical with an authentic sample. Early fractions eluted with benzene–ether (4: 1) gave rishitin 2-acetate (**3a**, 1.25 g), mp 60.5—62.5 °C and $[\alpha]_D$ −33.6°; MS, *m/e* 204 (base, M$^+$ −AcOH), 189, 186, 175, 171, and 161; IR, ν_{max} (Nujol) 3320, 3245, 3080, 1735, 1643, 1248, 1069, 1032, and 897 cm^{-1}; NMR, δ (CCl_4) 1.16 (3H, d, J=6.5 Hz, 14-H), 1.72 and 2.05 (each 3H, s, 13-H and $OCOCH_3$), 3.31 (1H, t, J=8.5 Hz, 3-H), and 4.72 (3H, br, 2-H and 12-H). Found: C, 72.82; H, 9.22%. Calcd for $C_{16}H_{24}O_3$: C, 72.69; H, 9.15%. Fractions eluted with benzene–ether (4: 1 and 3: 1) yielded rishitin 3-acetate (**3b**, 0.83 g), mp 107—107.5 °C (from hexane–diisopropyl ether) and $[\alpha]_D$ −38.9°; MS, *m/e* 204 (base, M$^+$ −AcOH), 189, 186, 175, 171, and 161; IR, ν_{max} (Nujol) 3440, 3400, 3080, 1736, 1644, 1239, 1075, 1032, 1021, 1009, and 883 cm^{-1}; NMR, δ (CCl_4) 1.03 (3H, d, J= 7 Hz, 14-H), 1.72 and 2.09 (each 3H, s, 13-H and $OCOCH_3$), 3.62 (1H, do t, J=6.5, 8.5, and 8.5, 2-H), 4.60 (1H, t, J= 8.5 Hz, 3-H), 4.60 and 4.68 (each 1H, br s, 12-H). Found: C, 68.37; H, 8.85%. Calcd for $C_{16}H_{24}O_3 \cdot H_2O$: C, 68.05; H, 9.28%. Fractions eluted with ethyl acetate gave rishitin (**3**, 1.07 g).

Oxidation of 3a and 3b. i) To a heterogeneous mixture of ether (5 ml) containing **3a** (52 mg) and water (2.5 ml) was added the Jones reagent (1 ml, 2.16 mmol) under stirring, and the mixture was further stirred vigorously at room temperature for 16 h. After dilution with ether, the mixture was separated into ether and aqueous layers, and the aqueous solution was extracted with ether. All the ether solutions were combined, washed with 5% aq sodium thiosulfate ($Na_2S_2O_3$), 5% aq $NaHCO_3$ and saturated brine, dried and evaporated to leave oil (44 mg), which was purified by chromatography over silica gel with benzene–ether (5: 1) to give 3-dehydrorishitin 2-acetate (**4a**, 24 mg), oily and $[\alpha]_D$ +9.6°; MS, *m/e* 262 (M$^+$), 202, 187, 172, 159 (base), 134, 105, and 60; IR, ν_{max} (neat) 3070, 1757, 1737, 1643, 1231, 1019, and 889 cm^{-1}; NMR δ (CCl_4), 1.19 (3H, d, J=7.5 Hz, 14-H), 1.75 and 2.10 (each 3H, s, 13-H and $OCOCH_3$), 2.92 (1H, q, J=7.5 Hz, 4-H), 4.67 and 4.73 (each 1H, br s, W_H=4.5 Hz, 12-H), and 5.21 (1H, do d, J=11 and 8 Hz, 2-H).

ii) Compound **3b** (159 mg) was oxidized with the Jones reagent (2.0 ml) in ether (16 ml) and water (7.5 ml) at room temperature for 21 h under stirring. The mixture was worked up as described above to leave an oily substance (159 mg), which was purified by chromatography over silica gel (8 g) with benzene–ether (5: 1) to give 2-dehydrorishitin 3-acetate (**4b**, 96 mg), oily and $[\alpha]_D$ +59.4°; MS, *m/e* 262 (M$^+$), 202, 187, 159, (base), 134, 91, and 60; IR, ν_{max} (neat) 3080, 1757, 1744, 1643, 1226, 1050, and 889 cm^{-1}; NMR, δ (CCl_4) 1.14 (3H, d, J=7 Hz, 14-H), 1.74 and 2.10 (each 3H, s, 13-H and $OCOCH_3$), 2.59 (1H, br, 4-H), 2.71 and 2.95 (each 1H, ABq, J=19 Hz, 1-H), 4.65 and 4.70 (each 1H, br s, W_H=4.5 Hz, 12-H), and 4.84 (1H, d, J=9Hz, 3-H). Fractions eluted with benzene–ether (3: 1) afforded the starting alcohol (**3b**, 29 mg).

Transformation of 4b into 1a and 1. To a methanol solution (2.0 ml) of **4b** (12.3 mg) was added 0.12 M potassium hydroxide in methanol (0.46 ml), and the whole solution was stirred at room temperature for 25 min under stirring. The solution was made acidic by addition of 3 M HCl and water, evaporated, and extracted with ethyl acetate (4×10 ml). The extracts were worked up as usual to leave oily residue (11.9 mg), which was separated into two fractions by preparative TLC over silica gel with benzene–ether (5: 1). A more mobile fraction gave an oily substance (5.0 mg), $[\alpha]_D$ +64.8°, showing a single spot on TLC and the following spectra: MS, *m/e* 262 (M$^+$), 234, 202, 173, 162, 159, 147, 134, 131, 121, 94 (base), and 91; UV, λ_{max} 236 nm (ε 15200); IR, ν_{max} 1748, 1692, 1643, 1627, 1228, and 895 cm^{-1}; NMR, δ 1.12 (3H, d, J=6 Hz, 14-H), 1.76 and 2.21 (each 3H, s, 13-H and $OCOCH_3$), 4.74 (2H, br s, W_H=5 Hz, 12-H), 5.11 (1H, d, J=12 Hz, 3-H), and 5.86 (1H, br s, W_H=5 Hz, 1-H). These spectral data were completely identical with the reported of glutinosone acetate.[4] A less mobile (more

polar) fraction afforded an oily substance (4.7 mg), $[\alpha]_D$ +57.2°, showing a single spot on TLC; MS, *m/e* 220 (M^+), 192, 191, 162, 147, 134, 121, and 94 (base); UV, λ_{max} 237 nm (ε 14500); IR, ν_{max} 3470, 1676, 1645, 1620, and 896 cm^{-1}; NMR, δ 1.23 (3H, d, J=6 Hz, 14-H), 1.73 (3H, s, 13-H), 3.72 (1H, s, OH), 3.79 (1H, d, J=12 Hz, 3-H), 4.72 (2H, br s, W_H=5 Hz, 12-H), and 5.90 (1H, br s, W_H=4 Hz, 1-H). These spectra were identical with the reported of glutinosone[4] (**1**). The latter (**1**, 3.6 mg), when treated with acetic anhydride (0.5 ml) and pyridine (1.0 ml) at room temperature for 14 h and then purified by chromatography over silica gel (1.0 g) with benzene–ether (1: 1), was converted into the acetate (4.0 mg), whose spectral data were identical with those of **1a**.

Hydride Reduction of 1. Compound **1** (20.5 mg) was treated with sodium borohydride (16.0 mg) in ethanol (3.0 ml) at room temperature for 2.5 h under stirring. After addition of acetic acid, the mixture was evaporated and shaken with water and ethyl acetate (4×10 ml). The acetate solution was worked up as usual to leave crystalline residue (13.3 mg), which was purified by preparative TLC with ether and recrystallized from ethyl acetate–hexane to yield dihydroglutinosone (**5**, 9.0 mg), mp 136—138 °C (lit,[4] 129—132 °C) and $[\alpha]_D$ −29.6°; MS, *m/e* 222 (M^+), 204, 189, 176, 161, 133, 123, 121, 107, 105, 96 (base), 93, and 91; IR, ν_{max} 3580, 3400, 3070, 1643, 1069, 1047, 1041, and 894 cm^{-1}; NMR, δ 1.11 (3H, d, J=6 Hz, 14-H), 1.73 (3H, s, 13-H), 3.18 (1H, do d, J=10 and 8 Hz, 3-H), 4.06 (1H, br d, J=8 Hz, 2-H), 4.70 (1H, br s, W_H=4 Hz, 12-H), and 5.28 (1H, br s, W_H=5 Hz, 1-H).

Isolation of Oxyglutinosone (2). The fraction E (4.7 g), described in the section of "Isolation of rishitin,"[6] was separated roughly into two fractions, less polar epilubimin and lubimin-rich (2.50 g) and more polar oxylubimin and isolubimin-rich fractions (2.14 g), by chromatography over silica gel (200 g) with a 5: 1 mixture of hexane and ethyl acetate mixture. The latter was further separated into less polar (158 mg), middle (688 mg) and polar fractions (773 mg) by chromatography over silica gel (100 g), hexane–ether mixtures (10: 1—3: 1) being used as solvents. The middle fraction was again submitted to chromatography over silica gel (50 g) with hexane and hexane–ethyl acetate mixtures to yield epilubimin-rich (110 mg), and oxyglutinosone and isolubimin-rich fractions (160 mg). The last fraction (160 mg) was treated lubimin-rich (174 mg) with acetic anhydride (1 ml) and pyridine (5 ml) at room temperature for 16 h. The reaction mixture was worked up as usual to give an oily substance (140 mg), showing two main spots on TLC, which was separated and purified by preparative TLC (3 plates) over silica gel. A less polar fraction gave isolubimin acetate[3,8] (**6a**, 37 mg) mp 49—51 °C (from diisopropyl ether) and $[\alpha]_D$ +34.4°, which a more polar fraction afforded oxyglutinosone acetate (**2a**, 43 mg), mp 101 °C (from diisopropyl ether) and $[\alpha]_D$ +166°; MS, *m/e* 278 (M^+), 260, 250, 218, 200, and 178 (base); UV, λ_{max} 230 nm (ε 12100); IR, ν_{max} 3610, 3480, 1739, 1699, 1642, 1638, 1240, and 897 cm^{-1}; NMR, δ 1.10 (3H, d, J=7 Hz, 14-H), 1.75 and 2.19 (each 3H, s, 13-H and OCOCH_3), 4.75 (2H, br s, W_H=6 Hz, 12-H), 5.39 (1H, d, J=13Hz, 3-H), and 5.79 (1H, d, J=1.5 Hz, 1-H).

The acetate (**2a**, 4 mg) was dissolved in a 1: 1: 2 mixture (2 ml) of triethylamine, water and methanol, and stirred at room temperature for 3 h. The solution was concentrated below 16 °C, and the residue was extracted with ether (20 ml). The ether solution was washed with saturated brine (10 ml), dried and evaporated to dryness to leave oily residue, showing two spots on TLC, which was separated by preparative TLC (1 plate) over silica gel to give the starting acetate (**2a**, 1.5 mg) and oxyglutinosone (**2**, 2.2 mg), oily and $[\alpha]_D$ +130°; MS, *m/e* 236 (M^+), 218, 200, and 178 (base); UV, λ_{max} 230 nm (ε 12100); IR, ν_{max} 3560, 3440, 1682, 1643, and 890 cm^{-1}; NMR, δ 1.25 (3H, d, J=6 Hz, 14-H), 1.74 (3H, s, 13-H); 4.10 (1H, d, J=12 Hz, 3-H), 4.73 (2H, br s, W_H=7 Hz, 12-H), and 5.89 (1H, d, J=1.5 Hz, 1-H).

Conversion of 3b into 2a. i) Compound **3b** (85 mg) was oxidized with *t*-butyl hydroperoxide (0.1 ml) in the presence of $VO(acac)_2$ (2 mg) in benzene (1.2 ml) under reflux for 10 min. After being cooled, the mixture was stirred with 5% aq sodium hydrogensulfite ($NaHSO_3$, 3 ml) at room temperature for 1 h. The benzene solution, after being separated from the aqueous solution, was washed with 5% aq $NaHSO_3$ (10 ml), 5% aq $NaHCO_3$ (10 ml) and saturated brine (10 ml), dried and evaporated to leave crystalline residue (75 mg), which was recrystallized from diisopropyl ether to give 5α,10α-epoxyrishitin 3-acetate (**7**, 75 mg), mp 140—143 °C and $[\alpha]_D$ −14°; IR, ν_{max} (Nujol) 3480, 1730, 1640, 1240, 1037, and 893 cm^{-1}; NMR, δ 1.27 (3H, d, J=6 Hz, 14-H), 1.71 and 2.07 (each 3H, s, 13-H and OCOCH_3), 3.11 (1H, d, J=10 Hz, OH), 3.69 (1H, do q, J=10, 5, 5, and 5 Hz, 2-H), and 4.70 (3H, br m, 3- and 12-H).

ii) To a suspended mixture of chromium(VI) oxide (70 mg) in dry pyridine (0.14 ml) and dichloromethane (2 ml) was added **7** (28 mg) in dichloromethane (0.4 ml) under stirring, and the whole mixture was stirred vigorously at room temperature for 15 min. The mixture was diluted with ether 30 ml) and filtered. The filtrate was washed with 5% aq $NaHCO_3$ and saturated brine, dried and evaporated to leave oily residue (21 mg), showing two spots on TLC. The residue was dissolved in chloroform (1 ml), put on front lines of silica gel plates (Merck, DC-Alufolien Kieselgel 60 F-254, 20×20 cm^2, 3 plates) for 20 min, and developed with a 1: 1 mixture of ethyl acetate and hexane. A fraction showing an UV spectrum was extracted with ethyl acetate to give **2a** (15 mg), mp 99—101 °C and $[\alpha]_D$ +153°, whose spectra (MS, UV, IR, and ^{1}H-NMR) were identical with the corresponding of natural oxyglutinosone acetate (**2a**).

The Synthesis of (±)-Glutinosone[1)]

Akio Murai, Hirofumi Taketsuru, and Tadashi Masamune*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received August 28, 1979)

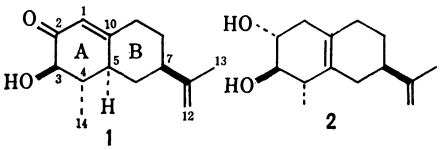
The synthesis of (±)-glutinosone, an antifungal norsesquiterpene from *Nicotiana glutinosa* infected with tobacco mosaic virus, is described. It has been completed by two processes, one being based on the Robinson annelation method and another on a modification of the Dastur procedure.

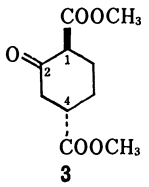
In the preceding paper[1b)] we reported the structure elucidation of (+)-glutinosone (**1**), a norsesquiterpene isolated from leaves of *Nicotiana glutinosa* infected with tobacco mosaic virus and qualified as a phytoalexin.[2)] The structure and configuration of **1** are characterized by a noreudesmane skeleton with a double bond at an angular position as well as three asymmetric centers in the A ring susceptible to facile aromatization. We now report that the synthesis of (±)-glutinosone [(±)-**1**] has been completed by two independent procedures.

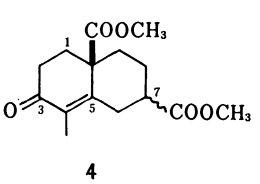
The first synthesis[3)] of (±)-glutinosone was achieved by stereoselective functionalization of the A ring of a *trans*-decalin derivative and subsequent introduction of a double bond at the angular position, as in the case of that[4)] of rishitin (**2**). The Robinson annelation[5)] of dimethyl *trans*-2-oxocyclohexane-1,4-dicarboxylates[6)] (**3**) with 1-diethylamino-3-pentanone methiodide and sodium methoxide produced a 1: 1 mixture of C-7-epimers of dimethyl 4-methyl-3-oxooctahydronaphthalene-7,10-dicarboxylates[7)] (**4**) in a 52% yield. The octalone mixture (**4**), when hydrogenated over 10% alladium–charcoal in acetic acid, treated with acid ($HClO_4$ in acetic acid) and then with base ($NaOCH_3$ in methanol), and esterified with diazomethane,[5,8)] was converted into a *trans*-decalone (**5**), mp 105—106 °C, showing a single peak by GLPC and TLC, in a 66% yield. The spectral data [*m/e* 282 (M^+); ν_{max} 1735, 1720, and 1169 cm^{-1}; δ 1.08 (3H, d, J=7 Hz, $C\underline{H}_3$ at C-4), 3.06 (1H, do q, J=11, 7, 7, and 7 Hz, 4-$\underline{H}$), 3.71 and 3.79 (each 3H, s, $COOC\underline{H}_3$)] were in good accord with the structure (**5**).

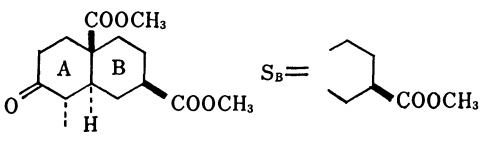
Functionalization of the A ring of the *trans*-decalone was commenced by treatment of **5** with isopropenyl acetate and *p*-toluenesulfonic acid (*p*-TsOH) under reflux to give the corresponding enol acetate (**6**) in a 91% yield, in which the location of the double bond at C-2–C-3 was revealed by the NMR spectrum [δ 5.27 (1H, br d, J=6 Hz, 2-$\underline{H}$) and 1.04 (3H, d, J=7 Hz, $C\underline{H}_3$ at C-4)]. The compound (**6**), when oxidized with perbenzoic acid, was converted almost quantitatively into 2α,3α-epoxy 3-acetate (**7**), mp 138—139 °C. The α-configuration of the epoxy group was deduced tentatively from attack of the reagent from the less-hindered side (α) and confirmed by the following reactions. Treatment of the epoxy acetate (**7**) with acid (*p*-TsOH in acetic acid, room temp)[10)] effected rearrangement to give 3-oxo 2α-acetate (**8**), mp 142—143 °C, in a 90% yield. Further treatment of **8** with tetramethylammonium acetate in acetone[11)] led to formation of a 1: 1 equilibrium mixture of the starting 3-oxo 2α-acetate (**8**) and its isomeric 2-oxo 3β-acetate (**9**), mp 131—132 °C, from which the latter (**9**) could be isolated in a 46% yield. The structure and configuration of the two oxo acetates were determined on the basis of the NMR spectra: **8**, δ 1.68 (1H, t, J=13 Hz, 1α-$\underline{H}$), 2.59 (1H, do d, J=13 and 6 Hz, 1β-$\underline{H}$), and 5.05 (1H, do d, J=13 and 6 Hz, 2β-$\underline{H}$); **9**, δ 2.36 and 2.76 (each 1H, ABq, J=14 Hz, 1-$\underline{H}$) and 4.86 (1H, d, J=10.5 Hz, 3α-$\underline{H}$). The 2-oxo 3β-acetate (**9**) was then derived smoothly to the 3,3-ethylene acetal (**10**), mp 126—128 °C, in an 85% yield by a standard procedure.

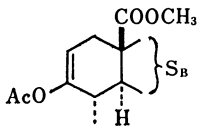
Transformation of the methoxycarbonyl group at

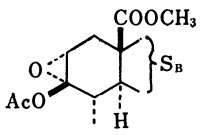


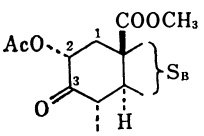


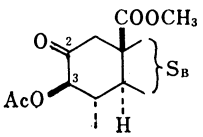


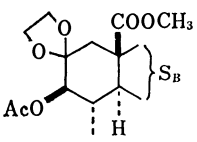












C-7 into an isopropenyl group was carried out by a modification[12] of the Wittig reaction; treatment of **10** with a *large excess* of methylenetriphenylphosphorane in dimethyl sulfoxide (DMSO) at 50 °C for 3 h produced a mixture of δ-lactones, which was separated roughly into two fractions by chromatography. One fraction eluted early afforded isopropenyl δ-lactone (**11**), mp 108—110 °C, in a 22% yield. On the other hand, another fraction eluted later, consisting mainly of acylated phosphorane (**11a**),[12] was hydrolyzed with base (10% KOH in methanol), treated with acetic anhydride and pyridine, and then purified by chromatography to give acetyl δ-lactone (**12**), mp 146—148 °C, in a 50% yield from **10**. The latter (**12**) was again submitted to the Wittig reaction under usual conditions [$(C_6H_5)_3P{=}CH_2$ (3 mol equiv) in DMSO], giving the afore-mentioned δ-lactone (**11**) in an 88% yield. In accordance with the assigned noreudesmane structure, compound **11** displayed following spectra: *m/e* 292 (M^+); ν_{max} 1757 (δ-lactone), 1642 and 895 cm^{-1} (terminal methylene); δ 1.24 (3H, d, J=7 Hz, 14-H), 1.68 (3H, s, 13-H), 1.85 and 2.08 (each 1H, ABq, J=14 Hz, 1-H), 3.97 (4H, br s, W_H=5 Hz, OC_2H_4O), 4.07 (1H, d, J=3 Hz, 3-H), and 4.68 (2H, br s, W_H=4 Hz, 12-H).

14

Hydrolysis of the δ-lactone (**11**) with base (10% KOH in methanol) produced hydroxy acid (**13**), mp 201—203 °C, in a 97% yield, which, on treatment with acetyl chloride and pyridine in ethyl acetate, was converted into the corresponding acetate (**13a**), mp 238—241 °C, in an 80% yield without regeneration into the δ-lactone (**11**). The acid was smoothly esterified with diazomethane into the methyl ester (**13b**), mp 139—140 °C. Treatment of the acid (**13a**) with lead(IV) acetate and pyridine in *N*,*N*-dimethylformamide (DMF) at room temperature[13] resulted in oxidative decarboxylation to give an olefin mixture (**14**) in a 78% yield. The olefins (**14**), when treated with base without further purification and then with triphenylmethyl fluoroborate in dichloromethane at room temperature,[14] were transformed into a mixture containing phenols, from which an α,β-unsaturated ketone, mp 63—65 °C, was obtained as a sole isolable product in a 30% yield. The ketone exhibited the following spectra: *m/e* 220 (M^+), 192, 191, 162, 147, 134, 121, and 94 (base); λ_{max} 234 nm (ε 13400); ν_{max} 3490, 1676, 1621, and 896 cm^{-1}; δ 1.22 (3H, d, J=6 Hz, 14-H), 1.73 (3H, s, 13-H), 3.72 (1H, s, OH), 3.77 (1H, d, J=12 Hz, 3-H), 4.72 (2H, br s, W_H=5 Hz, 12-H), and 5.89 (1H, br s, W_H=4.5 Hz, 1-H). All these spectra were identical with those reported for glutinosone[1b,2] (**1**), establishing a synthesis of (±)-glutinosone [(±)-**1**]. The overall yield amounted to 2.80% from compound **3**.

The second, improved synthesis of (±)-glutinosone was completed mostly according to a modification of the Dastur elegant procedure[15] for synthesis of (±)-nootkatone. The Diels-Alder reaction[16] of 3,6-dihydro-3,5-dimethylanisole, prepared by the Birch reduction of 3,5-dimethylanisole, with methyl acrylate at 150 °C in the *absence* of Lewis acids[16] afforded a 1 : 3 mixture of methyl 1-methoxy-5,8-dimethylbicyclo[2.2.2]oct-5-ene-2-carboxylates (**15a** and **15b**). While the mixture was used for subsequent transformations without further purification, it was separated by chromatography to yield each diastereoisomer (**15a** and **15b**). The spectral data of each isomer [**15a**, δ 0.81 (3H, d, J=6 Hz, CH_3 at C-8) and 2.66 (1H, do do d, J=11, 5, and 2.5 Hz, 2-H); **15b**, δ 0.83 (3H, d, J=6 Hz) and 2.78 (1H, do d, J=9 and 6 Hz)] and the following reaction indicated that (i) these isomers differed only in the configuration at C-2 and (ii) the methyl group at C-8 would probably be oriented *anti* to the secondary bridge and hence *cis* to the hydrogen atom at C-4; namely, each of these esters (**15a** and **15b**) was converted smoothly into the corresponding tertiary alcohols (**16a** and **16b**) in 90 and 90% yields. The respective alcohols, when treated with acid ($HClO_4$ in acetic acid), produced the same dienone (**17**), showing the following spectra: *m/e* 193 and 192 (M^+); ν_{max} 1670 and 1626 cm^{-1}; δ 1.02 (3H, d, J=6 Hz), 1.64, 1.73, and 1.97 (each 3H, s), 5.11 (1H, br t, J=6 Hz), and 5.76 (1H, br s, W_H=5 Hz).

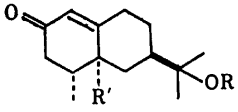
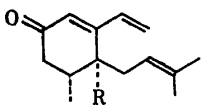
Scheme 1.

aldehydes (**18**) [λ_{max} 233 nm (ε 8700); ν_{max} 2705 and 1680 cm^{-1}; δ 9.40 and 9.46 (total 1H, each s, CHO)] in a 77% yield. The Wittig reaction of aldehydes **18** under usual conditions [$(C_6H_5)_3P=CH_2$ (1.1 mol equiv) in DMSO at room temp] led to formation of dienes (**19**) in a 63% yield with recovery of the starting aldehydes (31%). The dienes (**19**) was then submitted to the Grignard reaction with an excess of methyllithium to yield the corresponding tertiary alcohols (**20**) almost quantitatively. The spectra were consistent with the assigned formulas (Experimental).

Treatment of the alcohols (**20**) with formic acid at room temperature followed by neutralization produced a mixture of bicyclic enones, which were isolated as the tertiary alcohol (**21**) and its formate (**21a**) in 45 and 41% yields, respectively. Naturally the formate (**21a**) was hydrolyzed easily to give the alcohol (**21**) in an 88% yield. This acid transformation of the bicyclooctenes (**20**) into the bicyclic enones (**21** and **21a**) would probably proceed *via* the same process (Scheme 1) as that proposed by Dastur for that of the corresponding 4-methyl derivatives (**22**), in which he emphasized the presence of the relevant methyl group as a factor controlling the configuration of C-7 in the resulting bicyclic enones (**23** and **23a**) (*cf.*, Schemes II and III in Ref. 15). However, the present high yield (86%) formation of the desired bicyclic enones (**21** and **21a**) indicates that, contrary to the Dastur rationalization,[15] the methyl group in question does not an important role in the cyclization of proposed intermediates (**24** and **25**). The structure of the alcohol (**21**) was supported completely by the spectral data: *m/e* 223 (M^++1) and 204; λ_{max} 237 nm (ε 14300); ν_{max} 3440, 1660, and 1624 cm^{-1}; δ 1.09 (3H, d, J=6 Hz, 14-H), 1.20 (6H, s, 12- and 13-H), and 5.81 (1H, br s, W_A=4 Hz, 1-H).



21 R=R'=H
21a R=CHO, R'=H
23 R=H, R'=CH_3
23a R=CHO,R'=CH_3



24 R=H
25 R=CH_3

Transformation of the intermediates (**21** and **21a**) into (±)-glutinosone was carried out in usual manners. Treatment of **21** with thionyl chloride in pyridine resulted in dehydration to yield an olefin mixture, which was separated by chromatography over silica gel containing 10% silver nitrate to give isopropenyl (**26**) and isopropylidene bicyclic enones (**27**) in 41 and 20% yields, respectively: **26**, ν_{max} 891 cm^{-1}; δ 1.75 and 4.73 (3H and 2H, each s, 13- and 12-H); **27**, δ 1.70 (6H, br s, 12- and 13-H). Likewise, the formate (**21a**), when treated with aluminium(III) oxide in collidine under reflux, produced a complex mixture, from which compounds **26** and **27** were isolated in 41 and 11% yields, respectively. Oxidation of the isopropenyl bicyclic enone (**26**) with lithium diisopropylamide (LDA) in tetrahydrofuran (THF) at −70 °C and then with the molybdenum peroxide complex MoO_5·Py·HMPA (MoOPH)[17] effected only hydroxylation at C-3 to afford a mixture of diastereoisomeric hydroxy ketones in a rather good yield (60%), with the starting ketone (**26**) (20%), from which equatorial and axial acetoxy ketones (**28a** and **29a**) were isolated in 33 and 59% yields, respectively, after acetylation and subsequent purification by preparative TLC: **28a**, ν_{max} 1753 cm^{-1}; δ 5.10 (1H, d, J=12 Hz, 3-H): **29a**, ν_{max} 1748 cm^{-1}; δ 5.47 (1H, d, J=5 Hz). These acetoxy ketones (**28a** and **29a**) were hydrolyzed with base (K_2CO_3 in ethanol) to give the corresponding hydroxy ketones (**28** and **29**) in 60 and 55% yields, respectively. The former (**28**), mp 64—66 °C, exhibited the same spectra as synthetic and natural samples of glutinosone, constituting an alternate, more efficient synthesis of (±)-glutinosone [(±)-**1**]. The synthesis involved only nine steps and the overall yield amounted to 3.64% from the bicyclooctanone mixture (**15a** and **15b**).

Experimental

All the melting points were uncorrected. The homogeneity of each compound was checked by TLC on silica gel (Wakogel B-5F) with various solvent systems, and the spots were developed with cerium(IV) sulfate in dil sulfuric acid. The UV, IR, and NMR (^{1}H-NMR) spectra were measured in ethanol, chloroform, and chloroform-*d*, respectively, unless otherwise stated. Abbreviations "s, d, t, q, m, br, and do" in the NMR spectra denote "singlet, doublet, triplet, quartet, multiplet,

broad, and double," respectively. The preparative TLC and column chromatography were carried out over silica gel (Wakogel B-5F, 20×20 cm²) and over silica gel (Merck, Kieselgel 60, 70—230 mesh), respectively.

The Robinson Annelation of Dimethyl trans-*2-Oxocyclohexane-1,4-dicarboxylate (3).* Compound **3** (1.08 g) was prepared by addition of an ether solution saturated with diazomethane into the corresponding diacid[6] (0.94 g) in ether (5 ml). The ester (**3**) had mp 99—100 °C (from methanol) (lit,[6] 75—77 °C) and showed the following spectra: MS, *m/e* 214 (M^+), 183, 182, 155, 154, and 123 (base); IR, ν_{max} (Nujol) 1732, 1704, 1201, 1162, and 1031 cm^{-1}; NMR δ 2.70 (1H, m, 4-H), 3.42 (1H, do d, J=9 and 5 Hz, 1-H), 3.74 and 3.78 (each 3H, s, $COOCH_3$). Found: C, 56.19; H, 6.78%. Calcd for $C_{10}H_{14}O_5$: 56.07; H, 6.59%.

To a methanol solution containing sodium methoxide, prepared from sodium (48 mg) and methanol (1 ml), were added **3** (264 mg) in methanol (9.0 ml) and then 1-diethylamino-3-pentanone methiodide in methanol, prepared from 1-diethylamino-3-pentanone (203 mg) and methyl iodide (267 mg) in methanol (1.0 ml). The whole mixture was stirred at room temperature for 17 h and then refluxed for 4.5 h. After being cooled, the mixture was evaporated and shaken with water and ether (6×20 ml). The ether solution was washed with 10% aq sodium carbonate (Na_2CO_3) and water, dried over anhydrous sodium sulfate, and evaporated to leave an oily substance, which was purified by preparative TLC over silica gel with chloroform to yield a 1:1 (by GLPC) mixture of 4-methyl-3-oxooctahydronaphthalene-7,10-dicarboxylates[7] (**4**, 181 mg): MS, *m/e* 280 (M^+), 248, 221, 220, and 161 (base); UV, λ_{max} 246 nm (ε 12400); IR, ν_{max} (neat) 1725, 1664, 1617, and 1175 cm^{-1}; NMR, δ 1.88 and 1.91 (each 1.5H, s, CH_3 at C-4), 3.67 and 3.71 (each 1.5H, s, $COOCH_3$ at C-7), and 3.75 (3H, s, $COOCH_3$ at C-10).

*Dimethyl (4*RS, *5*RS, *7*SR, *10*SR*)-4-Methyl-3-oxo-decahydronaphthalene-7,10-dicarboxylate (5).* Compounds **4** (494 mg) were hydrogenated over 10% palladium–charcoal in acetic acid at room temperature for 15 h. After removal of the catalyst by filtration and subsequent addition of 60% aq $HClO_4$ (one drop), the mixture was again stirred at room temperature for 15 h, diluted with water, and extracted with ether (3×20 ml). The ether extracts were worked up as usual to leave oily residue (480 mg), which was dissolved in methanol (4.0 ml). The methanol solution was added to methanol containing sodium methoxide, prepared from sodium (167 mg) and methanol (6.0 ml), and the whole mixture was refluxed under nitrogen for 40 min. After being cooled, the mixture was evaporated below 30 °C, diluted with water, made acidic with dil sulfuric acid, and extracted with ether (3×20 ml). The ether solution was washed with water, dried and mixed with an ether solution saturated with diazomethane, and evaporated to leave a crystalline substance (**5**, 327 mg), which was so pure as to be used for the next reactions. This was recrystallized from hexane-acetone for analysis and had mp 105—106 °C: MS, *m/e* 282 (M^+), 250, 223, 222, 163, 162, and 145 (base); IR (Nujol) and NMR, in the text. Found: C, 63.75; H, 7.80%. Calcd for $C_{15}H_{22}O_5$: C, 63.81; H, 7.85%.

*Dimethyl (4*RS, *5*RS, *7*SR, *10*SR*)-3-Acetoxy-4-methyl-1,4,5,-6,7,8,9,10-octahydronaphthalene-7,10-dicarboxylate (6) and Its 2α,-3α-Epoxide (7).* i) A solution of **5** (4.40 g) in isopropenyl acetate (23.0 ml) was evaporated slowly in the presence of *p*-TsOH (416 mg) for 13 h, the acetate (total 13 ml) being added dropwise during the time, when 16 ml of the acetate had been removed. After addition of water, the reaction mixture was mixed with water and extracted with ether (3×50 ml). The ether solution was washed with 5% aq sodium hydrogencarbonate ($NaHCO_3$) and water, dried and evaporated to leave an oily substance, which was purified by chromatography over silica gel. Fractions eluted with benzene–ether (19:1) afforded **6** (4.56 g), showing a single spot on TLC: MS, *m/e* 324 (M^+) and 282 (base); IR, ν_{max} (neat) 1762, 1742, 1734, 1683, 1210, 1180, 1151, and 1123 cm^{-1}; NMR, δ 1.04 (3H, d, J=7 Hz, CH_3 at C-4), 2.10 (3H, s, $OCOCH_3$), 2.64 (1H, do d, J=16 and 6 Hz, 1β-H), 3.69 (6H, s, $COOCH_3$), and 5.27 (1H, br d, J=6 Hz, 2-H). Found: C, 63.10; H, 7.55%. Calcd for $C_{17}H_{24}O_6$: C, 62.95; H, 7.41%.

ii) To a solution of **6** (5.54 g) in chloroform (30 ml) cooled with ice-water was added dropwise perbenzoic acid (purity 94%, 4.77 g) in chloroform (20 ml). The mixture was allowed to stand in a refrigerator for 15 h, and washed with 5% aq sodium hydrogensulfite ($NaHSO_3$), 5% aq $NaHCO_3$ and water, dried and evaporated to leave a crystalline substance (**7**, 5.80 g), mp 138—139 °C; NMR, δ 1.18 (3H, d, J=7 Hz, CH_3 at C-4), 2.05 (3H, s, $OCOCH_3$), 2.84 (1H, do d, J=15 and 6 Hz, 1β-H), 3.43 (1H, d, J=6 Hz, 2-H), 3.69 and 3.77 (each 3H, s, $COOCH_3$). This was used for the next reaction without purification.

*Dimethyl (2*SR,*4*SR,*5*RS,*7*SR,*10*SR*)-2-acetoxy-4-methyl-3-oxodecahydronaphthalene-7,10-dicarboxylate (8), Its 3-Acetoxy-2-oxo Isomer (9), and Its 3,3-Ethylene Acetal (10).* i) Compound **7** (2.5 g) was treated with *p*-TsOH (0.8 g) in acetic acid (100 ml) at room temperature for 14 h under stirring. The mixture, after being worked up as usual, afforded a crystalline substance (**8**, 2.3 g), which was so pure as to be used for the next rearrangement. The sample was recrystallized from hexane–acetone to give an analytical sample, mp 142—143 °C: MS, *m/e* 340 (M^+), 298, 281, 280, 266, 254, 238, and 226 (base); IR, ν_{max} (Nujol) 1762, 1735, 1730, 1237, and 1166 cm^{-1}; NMR, δ 1.09 (3H, d, J=7 Hz, CH_3 at C-4), 1.68 (1H, t, J=13 Hz, 1α-H), 2.14 (3H, s, $OCOCH_3$), 2.30 (1H, do d, J=10 and 2 Hz, 7-H), 2.59 (1H, do d, J=13 and 6 Hz, 1β-H), 3.18 (1H, do q, J=11, 7, 7, and 7 Hz, 4-H), 3.68 and 3.79 (each 3H, s, $COOCH_3$), and 5.05 (1H, do d, J=13 and 6 Hz, 2-H). Found: C, 59.98; H, 7.12%. Calcd for $C_{17}H_{24}O_7$: C, 59.99; H, 7.11%.

ii) An acetone solution (50 ml) containing **8** (1.16 g) was refluxed with tetramethylammonium acetate (0.72 g) for 16 h. The mixture was evaporated, mixed with water and extracted with ethyl acetate (3×50 ml). The acetate solution was washed with saturated brine, dried and evaporated to leave amorphous residue (1.18 g), which was separated by chromatography over silica gel (60 g) with a 4:3:2 mixture of hexane, ether and diisopropyl ether. Fractions eluted early afforded the starting material (**8**, 0.63 g), while those eluted later gave a crystalline substance (**9**, 0.53 g), which on recrystallization from hexane–acetone had mp 131—132 °C: MS, *m/e* 340 (M^+) and 298 (base); IR, ν_{max} (Nujol) 1735, 1242, 1212, and 1172 cm^{-1}; NMR, δ 1.10 (3H, d, J=7 Hz, CH_3 at C-4), 2.36 and 2.76 (each 1H, ABq, J=14 Hz, 1-H), 3.67 and 3.69 (each 3H, s, $COOCH_3$), and 4.86 (1H, d, J=10.5 Hz, 3-H). Found: C, 60.18; H, 7.12%. Calcd for $C_{17}H_{24}O_7$: C, 59.99; H, 7.11%.

iii) A solution of **9** (390 mg) in benzene (20 ml) was refluxed with ethylene glycol (0.4 ml) in the presence of *p*-TsOH (75 mg) for 20 h, water being removed by a Dean-Stark apparatus. The solution was cooled, evaporated, mixed with water and extracted with ethyl acetate (3×50 ml). The acetate solution was worked up as usual to leave amorphous residue (490 mg), which crystallized on trituration with hexane–acetone, and was collected by filtration and amounted to 130 mg. The filtrate was concentrated and then purified by chromatography over silica gel (9 g) with benzene–ether (6:1) to give an additional crystalline substance (250 mg). Both the crystal-

line substances (**10**, 380 mg) were recrystallized from hexane–acetone to give an analytical sample, mp 126—128 °C: MS, *m/e* 384 (M^+), 352, and 325 (base); IR, ν_{max} (Nujol) 1748, 1736, 1237, 1199, 1181, 1157, 1069, and 1032 cm^{-1}; NMR, δ 0.89 (3H, d, J=7 Hz, C$\underline{H}_3$ at C-4), 2.09 (3H, s, OCOC$\underline{H}_3$), 2.20 (1H, d, J=14 Hz, 1β-$\underline{H}$), 3.66 (6H, s, COOC$\underline{H}_3$), 3.90 (4H, br m, $C_2\underline{H}_4O_2$), and 4.72 (1H, d, J=11 Hz, 3-$\underline{H}$).

*(3*RS,*4*RS,*5*RS,*7*SR,*10*SR*)-7-Isopropenyl- (**11**) and (3*RS,-*4*RS,*5*RS,*7*SR,*10*SR*)-7-Acetyl-4-methyl-2-oxodecahydronaphthalene 10,3-Carbolactone 3,3-Ethylene Acetal (**12**).* i) To a solution of methyltriphenylphosphonium iodide (1.31 g) in DMSO (8.0 ml) was added a hexane solution (2.16 ml) containing 15% butylithium, and the whole solution was stirred at room temperature for 2 h. To a part (3.16 ml, 1.10 mmol equiv) of the ylide solution was added dropwise **10** (44 mg) in DMSO (1.5 ml). The mixture was stirred at room temperature for 1 h and then at 50 °C for 3 h, and the reaction was ceased by addition of water. The reaction mixture was ceased by addition of water. The reaction mixture was extracted with ethyl acetate (5×50 ml), and the acetate extracts were washed with saturated brine, dried and evaporated to leave resinous material (242 mg), which was submitted to chromatography over silica gel (7 g). Fractions eluted with benzene–ether (7: 1) afforded a crystalline substance (**11**, 7 mg), which was recrystallized from hexane–acetone to give an analytical sample, mp 108—110 °C; MS, *m/e* 292 (M^+, base), 207, 204, 165, 149, and 138; IR, ν_{max} 3100, 1757, 1642, 1192, 1097, and 895 cm^{-1}; NMR, δ 1.24 (3H, d, J=7 Hz, 14-$\underline{H}$), 1.68 (3H, s, 13-$\underline{H}$), 1.85 and 2.08 (each 1H, ABq, J=14 Hz, 1-$\underline{H}$), 3.97 (4H, br s, W_H=5 Hz, $C_2\underline{H}_4O_2$), 4.07 (1H, d, J=3 Hz, 3-$\underline{H}$), and 4.68 (2H, br s, W_H=4 Hz, 12-$\underline{H}$). Fractions eluted with methanol were combined and evaporated, and the residue (210 mg) was refluxed with 10% potassium hydroxide (KOH) in methanol (20 ml) for 2 d. The reaction mixture was evaporated, mixed with water, made acidic with 3M hydrochloric acid (HCl), and extracted with ethyl acetate (4× 50 ml). The acetate solution was worked up as usual to leave amorphous residue (540 mg), which was purified by chromatography over silica gel (24 g). Fractions eluted with benzene–ether (5: 1) afforded a crystalline substance (**12**, 17 mg), which was recrystallized from hexane–acetone to give an analytical sample, mp 146—148 °C; MS, *m/e* 294 (M^+), 251, 209, 208, 149, and 99 (base); IR, ν_{max} 1760, 1710, 1176, and 1099 cm^{-1}; NMR, δ 1.29 (3H, d, J=7 Hz, 14-$\underline{H}$), 1.89 and 2.15 (each 1H, ABq, J=15 Hz, 1-$\underline{H}$), 2.18 (3H, s, COC$\underline{H}_3$), 4.01 (4H, br s, W_H=4.5 Hz, $C_2\underline{H}_4O_2$), and 4.12 (1H, d, J=3 Hz, 3-$\underline{H}$).

ii) To a solution of methylenetripehnylphosphorane, prepared by addition of 15% butyllithium in hexane (0.22 ml) to methyltriphenylphosphonium iodide (164 mg) in DMSO (1 ml) and stirring at room temperature for 2.5 h, was added **12** (43 mg) in DMSO (1.5 ml). The solution was stirred at room temperature for 1.5 h and then at 50 °C for 5.5 h. The reaction mixture was worked up as described above to leave amorphous residue, which was purified by chromatography over silica gel (10 g) with benzene–ether (7: 1) to give **11** (37 mg), mp 107—110 °C, identical with an authentic sample (IR and NMR).

*(3*RS,*4*RS,*5*RS,*7*SR,*10*SR*)-3-Hydroxy-7-isopropenyl-4-methyl-3-oxodecahydronaphthalene-10-carboxylic Acid 3,3-Ethylene Acetal (**13**), Its 3-Acetate (**13a**), and Its Methyl Ester (**13b**).* Compound **11** (62 mg) was refluxed with 10% KOH in methanol (8 ml) for 3 h. After being cooled, the reaction mixture was evaporated, mixed with water, acidified with 3M HCl, and extracted with ethyl acetate (7×30 ml). The acetate extracts were worked up as usual to leave an amorphous substance (**13**, 72 mg), which on trituration with ether crystallized and had mp 201—203 °C: IR, ν_{max} (Nujol) 3325, 1715, 1642, 1180, 1165, 1074, 1039, and 890 cm^{-1}; NMR, δ 1.11 (3H, d, J=7 Hz, 14-$\underline{H}$), 1.73 (3H, s, 13-$\underline{H}$), 3.21 (1H, d, J=10.5 Hz, 3-$\underline{H}$), 4.04 (4H, br s, W_H=7 Hz, $C_2\underline{H}_4O_2$), and 4.72 (2H, br s, W_H=4 Hz, 12-$\underline{H}$).

The crude sample (72 mg) of **13** was stirred with acetyl chloride (0.1 ml) and pyridine (0.2 ml) in ethyl acetate (3 ml) at room temperature for 14 h. The reaction mixture was worked up as usual to leave amorphous residue (96 mg), which was purified by preparative TLC (2 plates) over silica gel, a 20: 1 mixture of benzene and acetic acid being used as a solvent, to give an amorphous substance (**13a**, 60 mg), which on trituration with ether crystallized and had mp 238—241 °C; IR, ν_{max} 2750—2580, 1739, 1711, 1644, 1237, 1036, and 893 cm^{-1}; NMR, δ 0.88 (3H, d, J=7 Hz, 14-$\underline{H}$), 1.71 and 2.11 (each 3H, s, 13-$\underline{H}$ and OCOC$\underline{H}_3$), 2.50 (1H, d, J=14 Hz, 1β-$\underline{H}$), 3.96 (4H, br m, W_H=18 Hz, $C_2\underline{H}_4O_2$), and 4.71 (2H, s, 12-$\underline{H}$), 4.76 (1H, d, J=11 Hz, 3-$\underline{H}$), and 6.60 (1H, br s, O$\underline{H}$).

The 3-acetate (**13a**) was converted quantitatively into the methyl ester (**13b**), mp 139—140 °C (from hexane–acetone) with diazomethane in ethyl by a standard procedure; MS, *m/e* 366 (M^+), 334, 307, 278, 239, 218, and 183 (base); IR, ν_{max} 1738, 1645, 1240, 1175, 1035, and 897 cm^{-1}; NMR, δ 0.86 (3H, d, J=6 Hz, 14-$\underline{H}$), 1.63, 2.07, and 3.63 (each 3H, 13-$\underline{H}$, OCOC$\underline{H}_3$, and COOC$\underline{H}_3$), 3.79 (4H, br m, W_H=30 Hz, $C_2\underline{H}_4O_2$), 4.65 (2H, s, 12-$\underline{H}$), and 4.70 (1H, d, J=11 Hz, 3-$\underline{H}$).

*Transformation of **13a** into (±)-Glutinosone [(±)-**1**].* A solution of **13a** (23.6 mg) in DMF (3 ml) containing pyridine (0.2 ml) was stirred with lead(IV) acetate (123.6 mg) in DMF (3 ml) at room temperature for 3 h. After addition of water, the mixture was made acidic with 3M aq HCl and extracted with ethyl acetate (5×20 ml). The acetate solution was worked up as usual to leave oily residue, which was separated by chromatography over silica gel (20 g). Fractions eluted with benzene–ether (5: 1) afforded an oily olefin mixture (**14**, 18.3 mg); ν_{max} 1737, 1644, 1374, 1244, 1043, and 895 cm^{-1}; NMR, δ 0.95 and 1.13 (total 3H, each d, J=7 Hz, 14-$\underline{H}$), 4.93, 4.99, and 5.13 (total 1H, each d, J=11, 10, and 13 Hz, 3-$\underline{H}$), 5.54 and 5.90 (total 2/3H, each br s, W_H=9 and 5 Hz, 1- and 9-$\underline{H}$).

The olefin mixture (**14**, 18.3 mg) was stirred with 5% KOH in methanol (1.5 ml) at room temperature for 70 min. The reaction mixture was worked up as described before to leave oily material (14.5 mg), which was stirred with triphenylmethyl fluoroborate (28.8 mg) in dichloromethane (2.1 ml) at room temperature for 1 h. The reaction mixture was then stirred with 5% aq $NaHCO_3$ (2 ml) at room temperature for 10 min. The aqueous layer was extracted with chloroform (2×10 ml). The dichloromethane and chloroform solutions were combined, washed with saturated brine, dried and evaporated to leave oily residue (35.8 mg), which was separated by preparative TLC (2 plates) over silica gel with benzene–ether (5: 1) to give an oily substance (3.3 mg, 23% from **13a**), whose spectra (in the text) were completely identical with the reported of natural glutinosone (**1**). The resulting (±)-glutinosone crystallized on standing and had mp 63—65 °C.

The Diels-Alder Reaction of 3,6-Dihydro-3,5-dimethylanisole and Methyl Acrylate. A mixture of the dihydroanisole[16] (47.6 g) and methyl acrylate (100.8 g) was heated at 150—155 °C (bath temp) for 40 h in an autoclave. After being cooled, the mixture was evaporated under reduced pressure, when most of excess of the acrylate and the dihydroanisole (10.6 g) were recovered at room temperature (8 Torr) and at 90—100 °C (8 Torr), respectively. The residue was then distilled to give a *crude* adduct (34.3 g) at 80—100 °C (0.3 Torr), which was used for the next reaction without further purification. A

part (3.9 g) of the crude adduct was separated by chromatography over silica gel, benzene and benzene–ether mixtures being used as solvents. Early fractions eluted with benzene and benzene–ether (50: 1) afforded an oily substance (1.26 g), which was assigned formula **30** [methyl 2-(3,5-dimethylphenyl)propionate] on the basis of the spectral data and the analogous examples:[18] MS, *m/e* 192 (M^+) and 133 ($M^+ - CO\text{-}OCH_3$); IR, ν_{max} (neat) 1743, 1605, 1198, 1175, and 1164 cm^{-1}; NMR, δ 1.46 (3H, d, J=7 Hz, 3-H), 2.27 (6H, s, CH_3 at C-3′ and C-5′), 3.64 (3H, s, $COOCH_3$), 3.66 (1H, q, J=7 Hz, 2-H), and 6.91 (3H, br s, W_H=4 Hz, 2′-, 4′-, and 6′-H). Middle fractions eluted with benzene–ether (20: 1) gave an exo-adduct, methyl 1-methoxy-5,8-dimethylbicyclo[2.2.2]oct-5-ene-2-carboxylate (**15a**, 0.21 g), showing a single spot on TLC: MS, *m/e* 224 (M^+), 193, 182, 138, 123 (base); IR, ν_{max} (neat) 1736, 1207, 1167, and 1098 cm^{-1}; NMR, δ 0.81 (3H, d, J=6 Hz, CH_3 at C-8), 1.81 (3H, br s, W_H=4 Hz, CH_3 at C-5), 2.66 (1H, do do d, J=11, 5, and 2.5 Hz, 2-H), 3.37 and 3.71 (each 3H, s, OCH_3 and $COOCH_3$), and 5.97 (1H, br s, W_H=7 Hz, 6-H). Next fractions eluted with benzene–ether (20: 1) afforded a 1: 1 (by NMR) mixture (0.72 g) of two adducts (**15a** and **15b**). Final fractions eluted with benzene–ether (20: 1) gave an isomeric endo-adduct (**15b**, 1.21 g), showing a single spot on TLC: MS, *m/e* 224 (M^+), 193, 182, 138, and 123 (base); IR, ν_{max} (neat) 1744, 1203, 1165, and 1103 cm^{-1}; NMR, δ 0.83 (3H, d, J=6 Hz, CH_3 at C-8), 1.86 (3H, br s, W_H=4 Hz, CH_3 at C-5), 2.78 (1H, do d, J=10 and 6 Hz, 2-H), 3.31 and 3.61 (each 3H, s, OCH_3 and $COOCH_3$), and 5.77 (1H, br s, W_H=6 Hz, 6-H).

*2-(1-Methoxy-5,8-dimethylbicyclo[2.2.2]oct-5-en-2-yl)-2-propanols (**16a** exo, and **16b** endo), and t-3-dimethyl-r-4-(3-methyl-2-butenyl)-2-cyclohexen-1-one (**17**).* i) A solution of **15a** (165 mg) in ether (3 ml) was stirred with methyllithium (3%) in ether (1 ml) at room temperature for 1 h. After addition of saturated brine under cooling, the mixture was extracted with ether (3×10 ml). The ether extracts were worked up as usual to give **16a** (160 mg), showing a single spot on TLC; MS, *m/e* 224 (M^+), 209, 207, 206, 149, 138, 124, and 123 (base); IR, ν_{max} (neat) 3490, 1391, 1377, 1165, and 1083 cm^{-1}; NMR, δ 0.82 (3H, d, J=6 Hz, CH_3 at C-8′), 1.10 and 1.33 (each 3H, s, $C(CH_3)_2OH$], 1.75 (3H, br s, W_H=4 Hz, CH_3 at C-3′), 3.34 (3H, s, OCH_3), and 5.98 (1H, br s, W_H=7 Hz, 2′-H).

Compound **16a** (127 mg) was stirred with 60% aq $HClO_4$ (one drop) in acetic acid (1 ml) at room temperature for 30 min. The mixture was diluted with water, basified with 6M aq ammonia, and extracted with ether (3×20 ml). The ether extracts were worked up as usual to give oily residue (118 mg), which was purified by chromatography over silica gel (5 g). Fractions eluted with benzene–ether (20: 1) gave an oily substance (**17**, 68 mg), showing a single spot: MS, *m/e* 193, 192 (M^+), 124 and 109 (base); IR, ν_{max} (neat) 1670, 1626, and 1244 cm^{-1}; NMR, δ 1.02 (3H, d, J=6 Hz, CH_3 at C-8), 1.64 and 1.73 [each 3H, s, $=C(CH_3)_2$], 1.97 (3H, s, CH_3 at C-3), 5.11 (1H, br t, J=6 Hz, 2′-H), and 5.76 (1H, br s, W_H=5 Hz, 2-H).

ii) Compound **15b** (251 mg) in ether (4 ml) was stirred with methyllithium (3%) in ether (3 ml) at room temperature for 1 h. The reaction mixture was worked up as described above to give **16b** (243 mg), showing a single spot: MS, *m/e* 224 (M^+), 209, 207, 206, 138, 124, and 123 (base); IR, ν_{max} (neat) 3490, 1391, 1377, 1167, and 1098 cm^{-1}; NMR, δ 0.84 (3H, d, J=6 Hz, CH_3 at C-8′), 1.04 [6H, s, $C(CH_3)_2OH$], 1.78 (3H, br s, W_H=4 Hz, CH_3 at C-3′), 3.37 (3H, s, OCH_3), and 5.82 (1H, br s, W_H=7 Hz, 2′-H).

Compound **16b** (193 mg) was stirred with 60% aq $HClO_4$ (0.06 ml) in acetic acid (1.5 ml) at room temperature for 30 min. The reaction mixture was worked up and purified as described above to give **17** (116 mg), whose spectral data were identical with the afore-mentioned.

*Methyl 5-Formyl-1-methoxy-8-methylbicyclo[2.2.2]oct-5-ene-2-carboxylates (**18**).* i) A solution of a mixture (247 mg) of the Diels-Alder reaction products (**15a** and **15b**), free from methyl phenylacetate (**30**), in dioxane (10 ml) was refluxed with selenium(IV) oxide (123 mg) for 16 h under nitrogen, when precipitates were removed by fitration. The precipitates were washed with ether. The dioxane (filtrate) and ether solutions were combined, dried and evaporated to leave oily residue, which was separated by chromatography over silica gel (10 g). Fractions eluted with benzene–ether (10: 1) gave a mixture (198 mg) of aldehydes (**18**), bp 105—120 °C (bath temp) (0.1 Torr): MS, 238 (M^+), 209, 152, 147, 123, and 99 (base); UV, λ_{max} 233 nm (ε 8700); IR, ν_{max} (neat) 2705, 1742, 1680, 1633, 1206, 1168, and 1106 cm^{-1}; NMR, δ 0.72 (3H, d, J=7 Hz, CH_3 at C-8), 3.33 (3H, s, $COOCH_3$), 3.57 and 3.68 (3H, each s, OCH_3), 7.00 and 7.06 (each, 1H, s, 6-H), 9.40 and 9.46 (1H, each s, CHO).

ii) The crude adduct mixture (**15a** and **15b**, 30.0 g) containing **30** (*cf.*, the Diels-Alder reaction described above) in dioxane (390 ml) was refluxed with selenium(IV) oxide (15.0 g) for 16 h under nitrogen. The reaction mixture was worked up as mentioned above to leave oily residue (42 g), which was separated by chromatography over silica gel (1 kg). Fractions eluted with benzene–ether afforded **30** (9.0 g) and those eluted with benzene–ether (10: 1) gave an aldehyde mixture (**18**, 17.0 g), whose spectra were practically the same as those described above.

*Methyl 1-Methoxy-8-methyl-5-vinylbicyclo[2.2.2]oct-5-ene-2-carboxylates (**19**).* A solution of methyltriphenylphosphonium iodide (46.7 g) in DMSO (240 ml) was treated with butyllithium (15%) in hexane (72 ml) at room temperature. A part (260 ml) of the resulting ylide solution was added to a solution of **18** (17.7 g) in DMSO (150 ml), and the whole mixture was stirred at room temperature for 30 min and then at 50 °C for 2 h. After addition of water, the reaction mixture was extracted with ethyl acetate (6×200 ml). The acetate solution was washed with saturated brine, dried and evaporated to leave oily residue (52 g), which was separated by chromatography over silica gel (450 g). Fractions eluted with benzene–ether (20: 1) afforded an oily substance (**19**, 12.9 g): MS, *m/e* 236 (M^+), 177, 161, 150, and 135 (base); UV, λ_{max} 235 nm (ε 18500); IR, ν_{max} (neat) 3090, 1742, 1630, 1593, 1203, 1165, 1107, 989, and 895 cm^{-1}; NMR, δ 0.78 and 0.81 (total 3H, each d, J=6 Hz, CH_3 at C-8), 3.38 and 3.44 (total 3H, each s, $COOCH_3$), 3.67 and 3.74 (total 3H, each s, OCH_3), 5.05 and 5.29 (each 1H, br d, J=10 and 18 Hz, $CH{=}CH_2$), and 6.08—6.63 (2H, m, $CH{=}CH_2$ and 6-H).

*2-(5-Methoxy-8-methyl-5-vinylbicyclo[2.2.2]oct-5-en-2-yl)-2-propanols (**20**).* To compounds **19** (10.0 g) in ether (30 ml) was added dropwise an ether solution (110 ml) containing methyllithium, prepared from methyl iodide (12.0 ml) and lithium (2.7 g), under cooling with an ice–water bath, and the whole mixture was stirred at room temperature for 2 h. After addition of 1M aq ammonium chloride, the mixture was extracted with ether (3×200 ml), and the ether extracts were worked up as usual to leave oily substance (**20**, 9.8 g), which was used for the next reaction: MS, *m/e* 236 (M^+), 221, 219, 218, 203, 150, and 135 (base); UV, λ_{max} 235 nm (18000); IR, ν_{max} (neat) 3495, 3045, 1631, 1591, 1390, 1377, 1208, 1166, 1100, 1077, 989, and 897 cm^{-1}; NMR, δ 0.76 (3H, d, J=7 Hz, CH_3 at C-8′), 0.95 and 0.97 [total 6H, each s, $C(CH_3)_2OH$], 3.39 (3H, s, OCH_3), 4.80 (1H, s, OH), 4.99 and 5.23 (each 1H, br s, J=11 and 17 Hz, $CH{=}CH_2$), 6.02—6.58 (2H, m, $CH{=}CH_2$ and 2′-H).

(4RS,5RS,7SR)-7-(1-Hydroxy-1-methylethyl)-4-methyl-2,3,4,-

5,6,7,8,9-octahydro-2-naphthalenone (21) and Its Formate (21a). Compounds **20** (5.6 g) were dissolved in formic acid (500 ml) and stirred at room temperature for 2 h under nitrogen. The solution was neutralized carefully by addition of 11.5 M aq sodium hydroxide (NaOH) under cooling and extracted with ether (4×500 ml). The ether solution was washed with saturated brine, dried and evaporated to leave oily residue (5.9 g), which was separated into two fractions by chromatography over silica gel (180 g). More mobile fractions eluted with benzene–ether (1: 1) afforded **21a** (2.40 g), showing a single spot on TLC: MS, 251 (M^++1), 234, 210, 204, and 162 (base); UV, λ_{max} 236 nm (ε 14500); IR, ν_{max} (neat) 1724, 1666, 1626, and 1197 cm^{-1}; NMR, δ 1.12 (3H, d, J=6 Hz, 14-H), 1.51 (6H, s, 12- and 13-H), 5.85 (1H, br s, W_H=5 Hz, 1-H), and 8.05 (1H, s, OCHO). Found: C, 71.79; H, 8.84%. Calcd for $C_{15}H_{22}O_3$: C, 71.97; H, 8.86%. Less mobile fractions eluted with ether–ethyl acetate (9: 1) gave **21** (2.4 g), showing a single spot on TLC: MS, *m/e* 223 (M^++1), 207, 205, 204, 164, 149, 107, and 59 (base); UV, IR, and NMR, in the text. Found: C, 75.48; H, 9.06%. Calcd for $C_{14}H_{22}O_2$: C, 75.63; H, 9.97%.

A solution of **21a** (102 mg) in *t*-butyl alcohol (3 ml) was stirred with 0.5 M aq NaOH at room temperature for 15 h. The mixture was evaporated to remove the alcohol, mixed with water and extracted with ethyl acetate (3×5 ml). The acetate solution was worked up as usual to leave oily residue (108 mg), which was purified by passing through a silica gel column (5.0 g) to yield **21** (78 mg), whose spectra were identical with those described above.

(4RS,5RS,7SR)-7-Isopropenyl-4-methyl-2,3,4,5,6,7,8,9-octahydro-2-naphthalenone (26) and the Corresponding 7-Isopropylidene Compound (27). i) A solution of **21** (3.56 g) in pyridine (51 ml) was stirred with thionyl chloride (1.5 ml) at 0 °C (bath temp) for 5 min. The reaction mixture was poured into ice–water under stirring, and extracted with ether (4×100 ml). The ether solution was washed with 2 M aq HCl and saturated brine, dried and evaporated to leave oily residue (2.48 g), which was separated by chromatography over a silica gel column (100 g) containing 10% silver nitrate, benzene–ether mixtures being used as solvents. Early fractions eluted with benzene–ether (7: 1) gave **27** (0.42 g), showing a single spot: MS, *m/e* 204 (M^+), 189, and 171 (base); UV, λ_{max} 232 nm (ε 13200); IR, ν_{max} (neat) 1667 and 1622 cm^{-1}; NMR, δ 1.11 (3H, d, J=6 Hz, 14-H), 1.70 (6H, br s, W_H=6 Hz, 12- and 13-H), and 5.84 (1H, br s, W_H=5 Hz, 1-H). Found: C, 82.24; H, 9.96%. Calcd for $C_{14}H_{20}O$: C, 82.30; H, 9.87%. Fractions eluted with benzene–ether (5: 1) afforded **26** (1.32 g), bp 95—105 °C (bath temp) (13 Torr), showing a single spot on TLC: MS, *m/e* 204 (M^+), 189, 176, 162, 147, 134, 121, and 94 (base); UV, λ_{max} 237 nm (ε 15100); IR, ν_{max} (neat) 3080, 1669, 1622, and 891 cm^{-1}; NMR, δ 1.09 (3H, d, J=6 Hz, 14-H), 1.75 and 4.73 (3H and 2H, each s, 13- and 12-H), and 5.82 (1H, br s, W_H=4 Hz, 1-H). Found: C, 82.21; H, 9.96%. Calcd for $C_{14}H_{20}O$: C, 82.30; H, 9.87%.

ii) A solution of **21a** (521 mg) in collidine (35 ml), distilled over calcium hydride, was heated with aluminium(III) oxide [Merck, Aluminiumoxide 90 (Aktivitätsstufe II—III) 70—230 mesh, 275 mg] under reflux for 16 h. The mixture was cooled, mixed with water, neutralized with 2 M aq HCl and extracted with ethyl acetate (4×50 ml). The acetate solution was washed with 2 M aq HCl, and saturated brine, dried and evaporated to leave oily residue (490 mg), which was separated by chromatography over silica gel (15 g). Fractions eluted with benzene–ether (49: 1, 40: 1, 19: 1, and 9: 1) afforded a 4: 1 (by NMR) mixture (281 mg) of **26** and **27**: MS, *m/e* 204 (M^+), 189, 161, 147, 133, 119, 93,, and 91 (base); IR, ν_{max} (neat) 3070, 1722, 1714, 1646, and 889 cm^{-1}; NMR, δ 1.01 and 1.06 (total 3H, each s, 14-H), 1.76 [3.6H, s, =C-(CH_3)$_2$ and -C(CH_3)=CH_2], and 4.74 [1.6H, br s, W_H=5 Hz, -C(CH_3)=CH_2]. Fraction eluted with benzene–ether (3: 1) and only with ether afforded **21a** (37 mg) and **21** (54 mg), respectively.

(±)-Glutinosone [(±)-1=28], Its 3-Epimer (29), and Their Acetates (28a and 29a). i) To a solution of LDA, prepared from diisopropylamine (0.35 ml) and butyllithium (15%) in hexane (1.5 ml) in THF (3 ml) cooled at −70 °C, was added **26** (125 mg) in THF (2 ml) under cooling at the temperature. To the mixture cooled at the temperature for 30 min was added rapidly MoOPH (814 mg), dried over diphosphorus pentaoxide in a desiccator, at −70 °C. The mixture was stirred at the temperature for 80 min, and the reaction was ceased by addition of water at room temperature. The heterogeneous mixture was shaken with ethyl acetate (3×30 ml). The acetate solution was washed with 2 M aq HCl, 5% aq $NaHCO_3$, and saturated brine, dried and evaporated to leave oily residue (189 mg), which was separated by preparative TLC (6 plates) over silica gel with benzene–ether (20: 1). A fraction with large R_f value gave the starting ketone (**26**, 26 mg), while that with small R_f value afforded a mixture (80 mg) of **28** and **29**, which resisted further purification. The mixture (37 mg) was then treated with acetic anhydride (1 ml) and pyridine (2 ml) at room temperature for 38 h under stirring. The reaction products were mixed with water and extracted with ethyl acetate (3×10 ml). The acetate extracts were worked up as usual to leave oily residue (46 mg), which was separated by preparative TLC (3 plates) over silica gel with benzene–ether (20: 1). A more mobile fraction gave a crystalline substance (**29a**, 25 mg), mp 80—85 °C, showing a single spot on TLC: MS, *m/e* 262 (M^+), 234, 220, 202, 201, 121, and 94 (base); IR, ν_{max} 3075, 1748, 1692, 1641, 1631, 1230, and 894 cm^{-1}; NMR, δ 1.04 (3H, d, J=6 Hz, 14-H), 1.73 and 2.17 (each 3H, s, 13-H and OCOCH_3), 4.74 (2H, br, s, 12-H), 5.47 (1H, d, J=5 Hz, 3-H), and 5.81 (1H, br s, W_H=4 Hz, 1-H). A less mobile fraction gave **28a** (16 mg), oily, showing a single spot; MS, *m/e* 262 (M^+), 234, 220, 202, 121, and 94 (base); IR, ν_{max} (neat) 3075, 1753, 1691, 1640, 1627, 1226, and 887 cm^{-1}; NMR, δ 1.08 (3H, d, J=6 Hz, 14-H), 1.72 and 2.19 (each 3H, s, 13-H and OCOCH_3), 4.72 (2H, s, 12-H), 5.10 (1H, d, J=12 Hz, 3-H), and 5.85 (1H, br s, W_H=4 Hz, 1-H).

ii) A solution of **29a** (8.5 ml) in ethanol (1 ml) was stirred with 0.27 M aq K_2CO_3 (0.15 ml) at room temperature for 12 h. After addition of water, the mixture was evaporated to remove ethanol and extracted with ethyl acetate (4×5 ml). The acetate solution was worked up as usual to leave an oily substance (5.8 mg), which was purified by passing through a silica gel column (3 g) with a 10: 1 mixture of benzene and ether to give **29** (3.6 mg), oily; MS, *m/e* 220 (M^+), 192, 177, 162, 147, 121, and 94 (base); UV, λ_{max} 237 nm (ε 12000); IR, ν_{max} 3380, 1677, 1646, 1631, 1090, and 893 cm^{-1}; NMR, δ 0.93 (3H, d, J=6 Hz, 14-H), 1.71 (3H, s, 13-H), 3.53 (1H, s, OH), 4.35 (1H, d, J=5 Hz, 3-H), 4.72 (2H, br s, W_H=7 Hz, 12-H), and 5.83 (1H, br s, W_H=3 Hz, 1-H).

A solution of **28a** (16.0 mg) in ethanol (1.5 ml) was stirred with 0.22 M aq K_2CO_3 (0.3 ml) at room temperature for 12 h under argon. The reaction mixture was worked up as described above to leave oily residue (16 mg), which was separated by preparative TLC (1 plate) over silica gel with benzene–ether (10: 1). While a more mobile fraction afforded the starting acetate (**28a**, 4.6 mg), a less mobile fraction gave **28** [(±)-**1**, 5.7 mg), which crystallized on standing and had mp 64—66 °C: MS, UV, IR, and NMR, in the text.

The Synthesis of Benzofuroquinolines. II. Two Benzofuroquinolinones and Some Benzofuroquinoline Derivatives

Yoshiyuki KAWASE,* Seiji YAMAGUCHI, Mariko MORITA, and Taeko UESUGI
Department of Chemistry, Faculty of Science, Toyama University, Gofuku, Toyama 930
(Received September 3, 1979)

Two benzofuroquinolinones, 6,11-dihydrobenzofuro[2,3-*b*]quinolin-11-one and 5,6-dihydrobenzofuro[3,2-*c*]-quinolin-6-one, were obtained by the demethyl-cyclization of 4-hydroxy-3-(*o*-methoxyphenyl)-1,2-dihydroquinolin-2-one. The chlorination of these benzofuroquinolinones afforded the corresponding chlorobenzofuroquinolines which were then converted to the cyanobenzofuroquinolines. The linear chlorobenzofuroquinoline was converted to 11-methoxy- and 11-ethoxybenzofuro[2,3-*b*]quinolines, and the linear cyanobenzofuroquinoline to benzofuro-[2,3-*b*]quinoline-11-carboxylic acid and -11-carboxamide. The linear benzofuroquinolines thus obtained were oxidized to the corresponding *N*-oxides.

In the course of our studies of polycyclic heteroaromatics, we studied the synthesis of benzofuroquinolines in order to investigate their chemical reactivities and also to test their activities as mutagens, carcinogens, and also as anti-tumor substances. In a previous paper,[1] we reported the synthesis of benzofuro[2,3-*b*]quinoline, benzofuro[3,2-*c*]quinoline, and their methyl, styryl, and carboxy derivatives. Mohanty *et al.*[2] reported the synthesis of benzofuro[2,3-*b*]quinolin-11-ol (**1a**) by the condensation of anthranilic acid and 2(3*H*)-benzofuranone. However, they showed a very low melting point of 93—95 °C compared to those of our reported[1] benzofuroquinolines, and also had ambiguous elemental analysis data; Found: C, 75.95; H, 3.80%. Calcd for $C_{15}H_9NO_2$: C, 76.60; H, 3.83%. We checked this condensation reaction, but could not obtained the same compound. Therefore, in this paper, we will report the synthesis of two benzofuroquinolinones (corresponding to benzofuroquinolinols) and their conversion to chloro- and cyanobenzofuroquinolines.

4-Hydroxy-3-(*o*-methoxyphenyl)-1,2-dihydroquinolin-2-one (**5**) was prepared according to the reported procedure.[1] The amide (**4**), prepared from *o*-methoxyphenylacetyl chloride and methyl anthranilate, was cyclized to a hydroxyquinolinone (**5**) by the action of sodium hydroxide. The demethyl-cyclization of **5** by heating with pyridine hydrochloride furnished a mixture of two benzofuroquinolinones, an alkali-soluble benzofuroquinolinone (**6**) and an alkali-insoluble benzofuroquinolinone (**7**). These benzofuroquinolinones were converted to the corresponding chlorobenzofuroquinolines (**1b** and **2b**) by chlorination with phosphorus

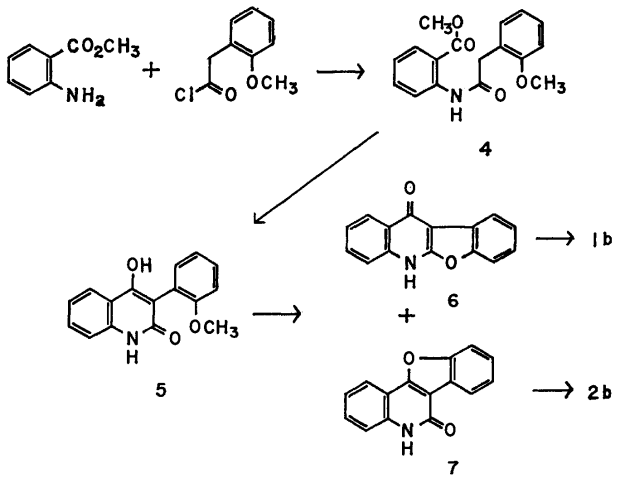

Chart 2.

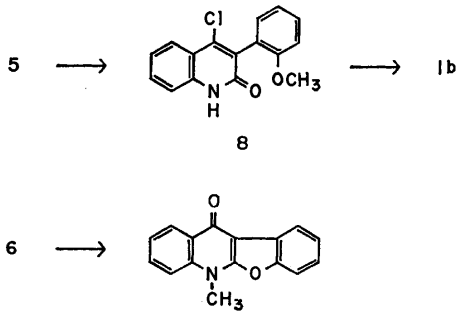

Chart 3.

pentachloride in phosphoryl chloride. In the UV spectra, 4,5-dihydrofuro[3,2-*c*]quinolin-4-one[3] corresponded to the benzofuroquinolinone (**7**) more than to the benzofuroquinolinone (**6**) (Fig. 1); the chlorobenzofuroquinoline (**1b**) derived from **6** was similar to linear benzofuro[2,3-*b*]quinoline,[1] and the chlorobenzofuroquinoline (**2b**) was similar to angular benzofuro[3,2-*c*]quinoline[1] (Fig. 2). These facts show that the benzofuroquinolinone (**6**) was linear 6,11-dihydrobenzofuro[2,3-*b*]quinolin-11-one with a quinolinol tautomerism, while the benzofuroquinolinone (**7**) was angular 5,6-dihydrobenzofuro[3,2-*c*]quinolin-6-one. The linear chlorobenzofuroquinoline (**1b**) was also obtained from **5** *via* 4-chloro-3-(*o*-methoxyphenyl)-1,2-dihydroquinolin-2-one (**8**) by monochlorination,

followed by demethyl-cyclization. The linear benzofuroquinolinone (**6**) gave 6-methyl-6,11-dihydrobenzofuro[2,3-*b*]quinolin-11-one (**9**) by *N*-methylation with methyl iodide. 11-Cyano-, 11-methoxy-, and 11-ethoxybenzofuro[2,3-*b*]quinolines (**1c**, **d**, **e**) were obtained from **1b** by means of nucleophilic substitution reactions with sodium cyanide, methanol–sodium hydroxide, and ethanol–sodium hydroxide, respectively. The acid hydrolysis of **1c** gave benzofuro[2,3-*b*]-quinoline-11-carboxylic acid (**1f**), and the alkaline hydrolysis of **1c** in ethanol gave benzofuro[2,3-*b*]-quinoline-11-carboxamide (**1g**). However, the alkaline hydrolysis of **1b** and **1c** in dimethyl sulfoxide gave a mixture of two benzofuroquinolinones (**6** and **7**). The cyanation of angular **2b** with sodium cyanide afforded linear **1c**, but this cyanation to angular 6-cyanobenzofuro[3,2-*c*]quinoline (**2c**) was effected with copper(I) cyanide. The benzofuroquinolines (**1b**, **c**) thus obtained were converted to the corresponding *N*-oxides (**3b**, **c**) by *N*-oxidation with trifluoroperacetic acid, but the

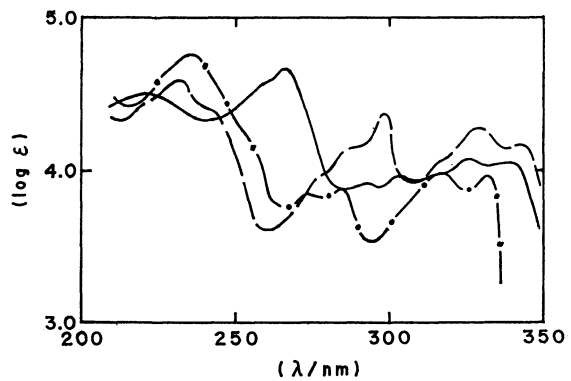

Fig. 1. The UV spectra of two benzofuroquinolones (**6** and **7**) and 4,5-dihydrofuro[3,2-*c*]quinolin-4-one.[3]

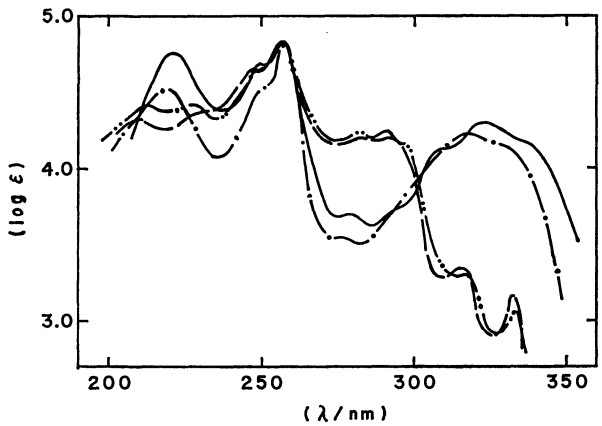

Fig. 2. The UV spectra of two chlorobenzofuroquinolines (**1b** and **2b**), linear benzofuro[2,3-*b*]quinoline,[1] and angular benzofuro[3,2-*c*]quinoline.[1]

N-oxidation of the angular benzofuroquinolines (**2b**, **c**) was unsuccessful under these conditions.

Compounds (**5**), (**7**), and (**8**) seem to possess 2-quinolone structures principally, since they have ν_{CO} bands around 1650 cm^{-1} in their IR spectra. In both the IR and UV spectra, compound (**6**) was similar to 6-methyl-6,11-dihydrobenzofuro[2,3-*b*]quinolin-11-one (**9**), not to 6-methoxybenzofuro[2,3-*b*]quinoline (**1d**). This evidence shows that compound (**6**) has mainly a benzofuroquinolinone, not a benzofuroquinolinol, structure.

Experimental

The melting points have not been corrected; the mass spectra were measured on a JEOL JMS-OISG-2 mass spectrometer, the IR spectra, on a Hitachi EPI-S2 spectrophotometer, and the UV spectra, on a Hitachi 124 spectrophotometer in an ethanol solution. The UV and elemental analyses data are summarized in the figures and the tables.

N-(o-*Methoxycarbonylphenyl*)-o-*methoxyphenylacetamide* (*4*). *o*-Methoxyphenylacetyl chloride (prepared from 25 g of *o*-methoxyphenylacetic acid and thionyl chloride) was added to a solution of methyl anthranilate (23 g) in pyridine (50 ml), after which, the mixture was refluxed for 1 h with stirring. The cooled reaction mixture was treated with water. The resulting precipitates were collected and recrystallized from ethyl acetate to give 34 g (75%) of **4** as colorless crystals; mp 116—117 °C; IR (KBr); 1710 and 1680 cm^{-1}.

*4-Hydroxy-3-(*o-*methoxyphenyl)-1,2-dihydroquinolin-2-one* (*5*). A mixture of **4** (34 g), sodium methylate (prepared from 10 g of sodium metal and absolute methanol), and dry benzene (210 ml) was refluxed for 6 h. The cooled reaction mixture was treated with water. The aqueous layer was acidified with dilute hydrochloric acid. The resulting precipitates were collected and recrystallized from *N,N*-dimethylformamide to give 31 g (80%) of **5** as colorless crystals; mp 311—312 °C; IR (KBr): 1645 cm^{-1}.

Demethyl-cyclization of 5. A mixture of **5** (2.6 g) and anhydrous pyridine hydrochloride (26 g) (bp 218 °C) was refluxed vigorously for 1.5 h. The cooled reaction mixture was treated with water, and the resulting precipitates were collected. Then the precipitates were treated with a 5% sodium hydroxide aqueous solution and filtered. The remaining precipitates were crystallized from ethanol to give 0.52 g (21%) of **7** as colorless crystals; mp 294—296 °C; MS (M^+): 235; IR (KBr): 1670 cm^{-1}. The filtrate was acidified with dilute hydrochloric acid, and the resulting precipitates were collected and recrystallized from ethanol to give 1.54 g (63%) of **6** as colorless needles; mp 342—344 °C (dec); MS (M^+): 235; IR (KBr): 1655 cm^{-1}.

11-Chlorobenzofuro[*2,3-*b]*quinoline* (*1b*). A mixture of **6** (3.9 g), phosphoryl chloride (23 ml), and phosphorus pentachloride (4.3 g) was refluxed for 2 h. The cooled reaction mixture was treated with water, and the resulting white precipitates were recrystallized from ethanol to give 3.6 g (85%) of **1b** as colorless crystals; mp 211—212 °C; MS (M^+): 253.

6-Chlorobenzofuro[*3,2-*c]*quinoline* (*2b*). By a method similar to that described for **1b**, a mixture of **7** (4.2 g), phosphorus pentachloride (4.6 g), and phosphoryl chloride (25 ml) afforded the crude chloride, which was recrystallized from ethanol to give 4.1 g (91%) of **2b** as colorless crystals; mp 157.5—158.5 °C; MS (M^+): 253.

11-Cyanobenzofuro[*2,3-*b]*quinoline* (*1c*). A mixture of **1b** (2.0 g), sodium cyanide (0.5 g), and *N,N*-dimethylformamide (30 ml) was refluxed for 6 h. The cooled reaction mixture was treated with water. The resulting precipitates were collected and recrystallized from ethanol to give 1.6 g (82%) of **1c** as colorless crystals; mp 242—243 °C; MS (M^+): 244; IR (KBr): 2230 cm^{-1}. Under these cyanation condition, 1c was also obtained from the angular chloride (**2b**) in a 72% yield.

6-Cyanobenzofuro[*3,2-*c]*quinoline* (*2c*). A mixture of **2b** (0.5 g), copper(I) cyanide (0.3 g), and *N,N*-dimethylformamide (5 ml) was refluxed for 6 h. The cooled reaction mixture was treated with ethylenediamine (10 ml) and water and extracted with diethyl ether. The ether layer was washed with a 10% sodium cyanide aqueous solution, filtered, washed with water, and dried over anhydrous sodium sulfate. The residue from the evaporation of the ether was crystallized from ethanol to give 0.1 g (21%) of **2c** as colorless crystals; mp 182—184 °C; MS (M^+): 244; IR (KBr): 2230 cm^{-1}.

Monochlorination of 6. A mixture of **6** (2.0 g), phosphorus pentachloride (2.0 g), and phosphoryl chloride (30 ml) was refluxed for 2 h. A treatment similar to that described for **1b** afforded white precipitates, which were recrystallized from methanol to give 0.95 g (44%) of **8** as colorless crystals; mp 101—103 °C; IR (KBr): 1640 cm^{-1}.

Demethyl-cyclization of 8. A mixture of **8** (0.55 g) and anhydrous pyridine hydrochloride (5.5 g) was refluxed for 1.5 h; this afforded 0.28 g (14%) of **1b** (mp 211—212 °C), which was identified with a sample obtained by the chlorination of **6**.

N-*Methylation of 6 to 9.* A mixture of **6** (0.5 g), sodium hydroxide (1.0 g), methyl iodide (1.3 g), and ethanol (30 ml) was refluxed for 3 h. After cooling, the reaction mixture was treated with dilute hydrochloric acid and filtered. The resulting precipitates were collected and recrystallized from ethanol to give 0.34 g (64%) of **9** as dark silky needles; mp 360—362 °C; MS (M^+): 249; IR (KBr): 1660 cm^{-1}.

11-Methoxy- and 11-Ethoxybenzofuro[*2,3-*b]*quinolines* (*1d,e*). A mixture of **1a** (0.53 g), potassium hydroxide (0.3 g), and methanol (15 ml) was refluxed for 2 h. The cooled reaction mixture was treated with water. The resulting precipitates were collected and recrystallized from cyclohexane to give 0.33 g (64%) of **1d** as a colorless powder; mp 165—165.5 °C; MS (M^+): 249. Similarly, **1b** afforded **1e** as a powder in a 23% yield; mp 72—73 °C; MS (M^+): 263.

Acid Hydrolysis of 1c. The linear cyano derivative (**1c**) (0.51 g) was suspended in 20 ml of 70% aqueous sulfuric acid. The mixture was refluxed for 3 h, and then treated with cold water. The resulting precipitates were collected and recrystallized from ethanol to give benzofuro[2,3-*b*]quinoline-11-carboxylic acid (**1f**); mp 326 °C (dec), as reported in the previous paper.[1]

Alkaline Hydrolysis of 1c. A mixture of **1c** (0.80 g), a 50% potassium hydroxide aqueous solution (1 ml), and ethanol (20 ml) was refluxed for 3 h. The resulting precipitates were collected and recrystallized from ethanol to give 0.32 g (38%) of benzofuro[2,3-*b*]quinoline-11-carboxamide (**1g**); mp 265—266 °C; MS (M^+): 262; IR (KBr): 1660 cm^{-1}. However, the similar hydrolysis in dimethyl sulfoxide converted **1c** to a mixture of **6** and **7** in 19 and 20% yields respectively.

Alkaline Hydrolysis of 1b. A mixture of **1b** (1.0 g), a 50% potassium hydroxide aqueous solution (20 ml), and dimethyl sulfoxide (10 ml) was refluxed for 3 h. After a treatment similar to that described for the demethyl-cyclization of **5**, 0.40 g (43%) of **6** and 0.17 g (19%) of **7** were obtained.

N-*Oxidation of 1b and 1c.* To a solution of **1b** (1.0 g) in trifluoroacetic acid (6 ml), a 30% hydrogen peroxide aqueous solution (0.7 ml) was added, after which the mixture was heated at 60—70 °C for 3 h. The heating was continued at

the same temperature for 6 additional hours with the addition of more of the 30% hydrogen peroxide aqueous solution (0.4 ml). The reaction mixture was then concentrated under reduced pressure and neutralized with a sodium carbonate aqueous solution. The resulting precipitates were collected and recrystallized from ethanol to give 0.63 g (59%) of **3b** as dark yellow needles; mp 257—259 °C; MS (M^+): 269. Similarly, **1c** (1.0 g) was oxidized to **3c** (0.52 g, 49%); mp 259.5—261 °C (from ethanol); MS (M^+): 260; IR (KBr): 2230 cm^{-1}.

The Reaction of 2-(Trialkylsiloxy)furans with Lead(IV) Acetate. The Synthesis of *dl*-Pyrenophorin

Morio Asaoka, Noboru Yanagida, Naoyuki Sugimura, and Hisashi Takei*

Department of Life Chemistry, Tokyo Institute of Technology, Nagatsuta-cho, Midori-ku, Yokohama 227

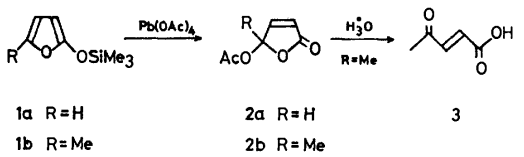
(Received September 25, 1979)

The reaction of 2-(trimethylsiloxy)furans with lead(IV) acetate afforded the corresponding α,β-unsaturated γ-acetoxy-γ-lactones in good yields. The lactones were easily converted into the corresponding 3-acylacrylic acids. Utilizing this reaction, *dl*-pyrenophorin was synthesized.

Several macrolide antibiotics incorporate a γ-oxo α,β-unsaturated lactone moiety.[1] A variety of methods are available for the synthesis of 3-acylacrylic acids, but the methods applicable to the macrolide synthesis are not so simple and efficient.[2] Previously, we reported the synthesis of 2-(trialkylsiloxy)furans from unsaturated lactones and their reactions with dienophiles and some electrophiles.[3,4] In this paper we will describe the conversion of 2-(trialkylsiloxy)furans into 3-acylacrylic acids.

Results and Discussion

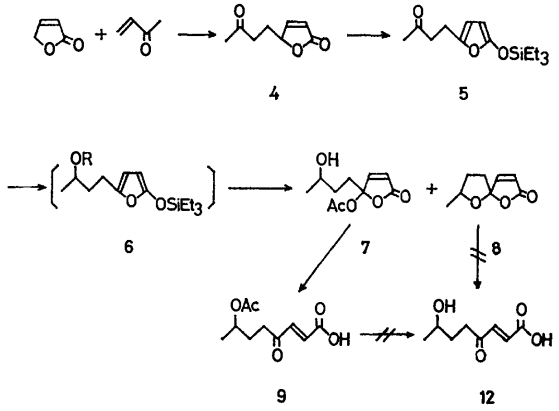
The treatment of 2-(trimethylsiloxy)furan (**1a**) and 5-methyl-2-(trimethylsiloxy)furan (**1b**) with lead(IV) acetate gave 4-acetoxy-2-buten-4-olide (**2a**) and 4-acetoxy-2-penten-4-olide (**2b**) in 87 and 76% yields respectively. The conversion of the latter product to 4-oxo-2-pentenoic acid (**3**) in an 86% yield was easily performed by acid hydrolysis.



1a R=H 1b R=Me 2a R=H 2b R=Me 3

Scheme 1.

This three-step synthesis of 3-acylacrylic acid starting from unsaturated γ-lactones (formation of siloxyfurans, oxidation with Pb(IV) acetate, and acid hydrolysis) seems to be widely applicable, since a variety of methods of synthesizing unsaturated γ-lactones[5] are available and each step can be carried out in a high yield. Thus, the application of this strategy to the synthesis of pyrenophorin, a 16-membered dilactone isolated as a metabolite of plant pathogenic fungi,[1a] was examined. The starting material, 7-oxo-2-octen-4-olide (**4**), was easily obtained by the Michael addition of 2-buten-4-olide to 3-buten-2-one or the reaction of 2-(trimethylsiloxy)furan with 3-buten-2-one in the presence of Lewis acid. The silylation of **4** using triethylchlorosilane and triethylamine afforded the corresponding siloxyfuran derivative, **5**, in an 88% yield. First, the reduction of the carbonyl group, followed by the oxidation of siloxyfuran with lead(IV) acetate, was examined. The reduction of the carbonyl group proceeded smoothly by lithium aluminium hydride, but the oxidation of **6** (R=Li or Al) with lead(IV) acetate afforded the expected compound, **7**, in only a 16% yield, the major product was found to be the spiro compound (**8**, 51%; about a 1 : 1 mixture of the stereoisomers).[6] Though the yield of **7** was improved to 45% when **6** (R=H) was treated with lead(IV) acetate, the formation of **8** (35%) could not be avoided. When the siloxyfuran (**6**, R=Li or Al) was oxidized with copper(II) chloride, the spiro compound was obtained in a 60% yield. The 3-acylacryric acid derivative, **9**, was obtained in an almost quantitative yield by heating **7** in xylene in the presence of a small amount of 2-pyridinethiol. However, all attempts to prepare the hydroxy acid, **12**, from **9** or **7** failed. The hydrolysis of **9** as well as **7** under various reaction conditions afforded mainly the spiro compound, **8**.

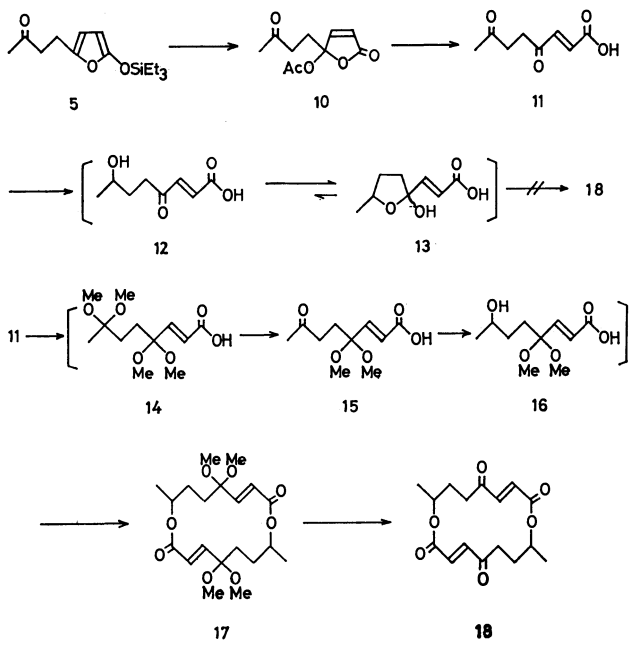


4 5 6 7 8 9 12

Scheme 2.

Then, the oxidation of **5** with lead(IV) acetate, followed by the reduction of carbonyl group, was examined. The oxidation of **5** with lead(IV) acetate gave 7-oxo-4-acetoxy-2-octen-4-olide (**10**) in an 83% yield. The acid hydrolysis of **10** yielded the desired 4,7-dioxo-2-octenoic acid (**11**) in a 75% yield. First, the selective reduction of **11**, followed by the dimerization cyclization, was examined. The selective reduction of **11** was achieved with sodium borohydride at −78 °C. However, the cyclization of the reduction product to pyrenophorin failed, probably because of the predominance of the hemiacetal structure, **13**. Then, the protection of the carbonyl groups of **11** was examined. The acetalization of two carbonyl groups was carried out using trimethyl orthoformate and methanol in the presence of an acid catalyst. The selective hydrolysis of **14** to **15** proceeded smoothly in THF–water. Sodium borohydride reduction of **15** at −30 °C afforded the hydroxy acid, **16**. All three of these compounds (**14**, **15**, and **16**) were relatively unstable oils and could not be

obtained in pure forms by silica-gel chromatography. However, the crude **16** was almost homogenious on TLC; thus, the crude **16** was used for the next lactonization step. The dimerization lactonization was carried out according to the method of Mitsunobu *et al.*,[7] using triphenylphosphine and diethyl azodicarboxylate; a mixture of *dl*- and *meso*-pyrenophorin bis(dimethyl acetal)s (**17**) was thus obtained in a 17% over-all yield from **11**. The acid hydrolysis of the diacetals with acetic acid–water proceeded quantitatively to give *dl*- and *meso*-pyrenophorin[8] (**18**), which could be separated by TLC. The structures of both were comfirmed by their elemental analyses and spectral data.



Scheme 3.

Experimental

4-Acetoxy-2-buten-4-olide (2a). To a suspension of lead(IV) acetate (1.17 g, 2.64 mmol) in dry dichloromethane (10 ml), 2-(trimethylsiloxy)furan (**1a**, 375 mg, 2.4 mmol)[3] was added, drop by drop, at −21 °C. The reaction temperature was gradually raised to room temperature over a period of 1 h. After the addition of ether (30 ml), the precipitate was filtered off. The filtrate was concentrated under reduced pressure, and the residue was purified by column chromatography on silica gel to give **2a** (297 mg, 87%), using hexane–ether as the eluent. IR(NaCl): 1820—1740 cm^{-1} (C=O), 1612 cm^{-1} (C=C), NMR ($CDCl_3$): δ 2.13 (3H, s), 6.26 (1H, d), 6.92 (1H, s), 7.35 (1H, d). Found: C, 50.57; H, 4.23%. Calcd for $C_6H_6O_4$: C, 50.71; H, 4.26%.

4-Acetoxy-2-penten-4-olide (2b). The reaction of 5-methyl-2-(trimethylsiloxy)furan (**1b**, 1.74 g, 10.2 mmol)[3] with lead(IV) acetate (6.6 g, 15 mmol) was carried out in dry benzene (40 ml) at 4 °C—room temperature for 3 h. Purification by short silica-gel column chromatography, followed by bulb-to-bulb distillation, afforded **2b** in a 76% yield (1.21 g); bp 150—155 °C/23—24 mmHg (bath temp.). NMR($CDCl_3$): δ=1.80 (3H, s), 2.05 (3H, s), 6.15 (1H, d), 7.59 (1H, d). IR(NaCl): 1770—1790, 1750 cm^{-1} (C=O), 1611 cm^{-1} (C=C). Found: C, 53.57; H, 5.14%. Calcd for $C_7H_8O_4$: C, 53.84; H, 5.16%.

4-Oxo-2-pentenoic Acid (3). A mixture of 4-acetoxy-2-penten-4-olide (**2b**, 1.21 g, 7.78 mmol) in 1 M hydrochloric acid (20 ml) was stirred for 3 d at room temperature. After the subsequent removal of the hydrochloric acid under reduced pressure, the residue was dissolved in benzene, which contained a catalytic amount (*ca.* 1 mg) of 2-pyridinethiol,[9] and heated to reflux. Upon cooling, **3** was precipitated as colorless crystals. After filtration, the filtrate was concentrated under reduced pressure. The residue was treated with 2-pyridinethiol in hot benzene as has been described above, and then these operations were repeated to give 760 mg (86%) of **3**; mp 126 °C. IR(KBr): 1670—1730 cm^{-1} (C=O), 1623 cm^{-1} (C=C). NMR($CDCl_3$): δ=2.36 (3H, s), 6.61 (1H, d), 7.06 (1H, d), 9.1—9.8 (1H, m). Found: C, 52.92; H, 5.36% Calcd for $C_5H_6O_3$: C, 52.63; H, 5.30%.

7-Oxo-2-octen-4-olide (4). A mixture of 2-buten-4-olide (176 mg, 2.1 mmol) and 3-buten-2-one (147 mg, 2.1 mmol) was cooled to −50 °C, and then 1 drop of 0.1 M potassium hydroxide was added to the mixture, After it had then been warmed to room temperature, the mixture was neutralized with Amberlite IRC-50. The crude product was purified by TLC to give **4** in a 75% yield; bp 144—146 °C/4.5 mmHg. IR(NaCl): 1720, 1760—1780 cm^{-1} (C=O), 1600 cm^{-1} (C=C), NMR ($CDCl_3$): δ=2.00 (2H, dt), 2.16 (3H, s), 2.68 (2H, t), 5.00—5.30 (1H, m), 6.12 (1H, dd), 7.52 (1H, dd). Found: C, 61.85; H, 6.57%. Calcd for $C_8H_{10}O_3$: C, 62.32; H, 6.54%. This compound was also synthesized according to the following procedure. 2-(Trimethylsiloxy)furan (**1a**, 37.5 g, 0.24 mol) and 3-buten-2-one (17.6 g, 0.25 mol) dissolved in dry dichloromethane (50 ml) were cooled to −78 °C. After the addition of tin(IV) chloride (500 mg), the reaction mixture was warmed to room temperature over a period of 12 h. After the addition of water, the product was extracted with dichloromethane. Purification by silica gel column chromatography (hexane–ether) afforded **4** (19 g, 52%).

5-(3-Oxobutyl)-2-(triethylsiloxy)furan (5). A mixture of triethylchlorosilane (4.98 g, 33 mmol) and triethylamine (3.34 g, 33 mmol) was added to 7-oxo-2-octen-4-olide (**4**, 4.62 g, 30 mmol) under an argon atmosphere. After three days, dry benzene was added and the precipitated ammonium salt was filtered off under an argon atmosphere. The subsequent distillation of the filtrate gave **5** in an 88% yield; bp 105—106 °C/0.06 mmHg. IR(NaCl): 1720 cm^{-1} (C=O). NMR($CDCl_3$): δ=0.43—1.22 (15H, m), 2.18 (3H, s), 2.78 (4H, s), 5.04 (1H, d), 5.86 (1H, d).

4-Acetoxy-7-hydroxy-2-octen-4-olide (7) and 7-Methyl-1,6-dioxaspiro[4,4]non-3-enone (8). After the addition of lithium aluminium hydride (280 mg) to a solution of **5** (2.58 g, 10 mmol) in dry tetrahydrofuran (20 ml), the mixture was stirred at room temperature for 0.5 h and then cooled to −10 °C. Lead (IV) acetate (5.0 g) was added in one portion, after which the reaction mixture was allowed to warm to room temperature over a period of 2 h. After the removal of metal salts by short silica gel column chromatography, the concentrated eluate was put on a silica-gel column and eluted with hexane–ether to give **7** (338 mg, 16%) and **8** (791 mg, 51%).

7: IR (NaCl): 3400 cm^{-1} (OH, broad), 1750—1800 cm^{-1} (C=O), 1615 cm^{-1} (C=C). NMR ($CDCl_3$): δ=1.22 (3H, d), 1.36—1.82 (2H, m), 2.10 (3H, s), 2.00—2.48 (2H, m), 3.60—4.10 (1H, m), 6.28 (1H, d), 7.68 (1H, d). Found: C, 56.05; H, 6.59%. Calcd for $C_{10}H_{14}O_5$: C, 56.07; H, 6.59%.

8: IR(NaCl): 1760—1770 cm^{-1} (C=O), 1615 cm^{-1} (C=C). NMR ($CDCl_3$): δ=1.28 (1.5H, d), 1.40 (1.5H, d), 2.04—2.48 (4H, m), 4.20—4.70 (1H, m), 6.10 (1H, d), 7.15 (1H, d). Found: C, 62.16; H, 6.54%. Calcd for $C_8H_{10}O_3$: C, 62.32; H, 6.54%.

A mixture of **5** (546 mg, 2.03 mmol) and lithium aluminium hydride (30 mg, 0.75 mmol) in tetrahydrofuran (10 ml) was stirred for 1 h at room temperature. The reaction mixture was then filtered through cellite and silica gel under an argon atmosphere and evaporated. The residue was dissolved in dry dichloromethane (5 ml) and added to a precooled suspension of lead(IV) acetate (910 mg, 2.04 mmol) in dry dichloromethane at −10 °C. The reaction mixture was then allowed to warm to room temperature for 2 h. The subsequent separation of the products by TLC gave **7** (45%) and **8** (35%).

The spiro compound, **8**, was also obtained by the following procedure. A mixture of **5** (536 mg, 2 mmol) and lithium aluminium hydride (38 mg, 1 mmol) dissolved in tetrahydrofuran (5 ml) was stirred at room temperature for 0.5 h. Anhydrous copper(II) chloride (540 mg, 4 mmol) was then added to the stirred solution at −40 °C, and the reaction mixture was warmed to room temperature. After the removal of the metal salts by short silica gel column chromatography, the purification of the product by TLC (hexane–ether) afforded **8** (186 mg, 60%).

*7-Acetoxy-4-oxo-2-octenoic Acid (**9**).* A solution of **7** (178 mg) and 2-pyridinethiol (1 mg) in xylene (3 ml) was refluxed for 1.5 h. The subsequent removal of the solvent under reduced pressure gave almost pure **9**; mp 66.0—66.5 °C (from cyclohexane–benzene). IR(KBr): 2350—3600 cm^{-1} (COOH, broad), 1675, 1695, 1735 cm^{-1} (C=O). NMR ($CDCl_3$): δ=1.26 (3H, d), 2.04 (3H, s), 2.02 (2H, t), 2.76 (2H, t), 6.64 (1H, d), 7.14 (1H, d), 9.56 (1H, s). Found: C, 56.28; H, 6.40%. Calcd for $C_{10}H_{14}O_5$: C, 56.07; H, 6.59%.

*4-Acetoxy-7-oxo-2-octen-4-olide (**10**).* To a suspension of lead(IV) acetate (980 mg, 2.2 mmol) in dry benzene, **5** (482 mg, 1.8 mmol) dissolved in dry benzene (4 ml), was added, drop by drop, at 4 °C. The mixture was put in a short silica gel column and eluted with ether. The eluate was evaporated under reduced pressure, and the residue was separated by TLC to give **10** in an 83% yield (316 mg). An analytical sample was obtained by bulb-to-bulb distillation; bp 115—120 °C/0.02 mmHg (bath temp). IR (NaCl): 1750—1805 cm^{-1} (C=O), 1720 cm^{-1} (C=C). NMR ($CDCl_3$): δ=2.05 (3H, s), 2.17 (3H, s), 2.2—2.5 (2H, m), 2.5—2.8 (2H, m), 6.17 (1H, d), 7.18 (1H, d). Found: C, 55.91; H, 5.66%. Calcd for $C_{10}H_{12}O_5$: C, 56.60; H, 5.70%.

*4,7-Dioxo-2-octenoic Acid (**11**).* Hydrochloric acid (1M, 40 ml) was added to **10** (2.8 g), and the heterogeneous mixture was stirred for 4 d. The resulting homogenious solution was extracted several times with ethyl acetate. After the removal of the ethyl acetate, the residue was treated with a catalytic amount of 2-pyridinethiol in benzene as described before (see the synthesis of **3**) to give **11** (1.69 g, 75%); mp 112—113.5 °C. IR (KBr): 1705, 1680 cm^{-1} (C=O), 1627 cm^{-1} (C=C). NMR ($CDCl_3$): δ=2.21 (3H, s), 2.86 (4H, s), 6.70 (1H, d), 7.10 (1H, d). Found: C, 56.47; H, 5.83%. Calcd for $C_8H_{10}O_4$: C, 56.46; H, 5.92%.

meso- *and* dl-*Pyrenophorin Bis(dimethyl acetal)s (**17**).* 4,7-Dioxo-2-octenoic acid (**11**, 200 mg, 1.18 mmol), trimethyl orthoformate (1 ml), amberlyst 15 (50 mg), and methanol (4 ml) were stirred for 1.5 h at room temperature. After filtration through the celite, the trimethyl orthoformate and the methanol were removed. Tetrahydrofuran (6 ml) and water (2 ml) were then added to the residue, and the mixture was stirred for 1 h at 45 °C and then cooled to room temperature. Sodium hydrogencarbonate (118 mg, 1.4 mmol) was then added, and most of the tetrahydrofuran was removed under reduced pressure. After the addition of methanol (8 ml), sodium borohydride (60 mg, 1.58 mmol) was added at −38 °C. One hour later, acetone (2 ml) was added, and the mixture was warmed to room temperature. The solution was passed through an acidic resin column, and the solvent was evaporated under reduced pressure. In order to remove the boric acid, the addition and evaporation of methanol was repeated. The residue was almost homogeneous on TLC. The crude 7-hydroxy-4,4-dimethoxy-2-octenoic acid (**16**) [IR (NaCl): 3400 cm^{-1} (OH, broad), 2820 cm^{-1} (OMe), 1700 cm^{-1} (COOH); NMR ($CDCl_3$): δ=1.2 (3H, d), 1.2—2.25 (4H, m), 3.15 (6H, s), 3.5—4.1 (1H, m), 6.2 (1H, d), 6.7 (1H, d)] was used for the next step without further purification. Dry toluene (200 ml) and triphenylphosphine (800 mg, 3.05 mmol) were added to **16**, and the resulting mixture was cooled to −25 °C. After the addition of diethyl azodicarboxylate (540 mg, 3.10 mmol) dissolved in dry toluene, the reaction temperature was gradually raised to room temperature for 3 d. A mixture of *meso* and *dl* pyrenophorin bis(dimethyl acetal)s (40 mg, 17%) was obtained by using TLC; mp 143—144 °C. IR (KBr): 1715 cm^{-1} (C=O), 1650 cm^{-1} (C=C). NMR ($CDCl_3$): δ=1.22 (6H, d), 1.3—2.1 (8H, m), 3.10 (6H, s), 3.19 (6H, s), 4.8—5.3 (2H, m), 6.09 (2H, dd), 6.45 (2H, d). MS: *m/e* 400 (M^+). Found: C, 60.17; H, 7.99%. Calcd for $C_{20}H_{32}O_8$: C, 59.98; H, 8.05%.

dl- *and* meso-*Pyrenophorin (**18**).* Pyrenophorin bis(dimethyl acetal)s (13 mg) was dissolved in tetrahydrofuran/acetic acid/water 1:3:1 (2 ml) and warmed for 2 h at 40 °C. After the removal of the solvent, isolation with TLC gave *dl*-pyrenophorin (4 mg) and *meso*-pyrenophorin (6 mg). *dl*-Pyrenophorin; mp 139—140 °C (lit,[8b] 139—140 °C). IR (KBr): 1717, 1694 cm^{-1} (C=O), 1631 cm^{-1} (C=C), NMR ($CDCl_3$): δ=1.30 (6H, d), 1.9—2.3 (4H, m), 2.4—2.8 (4H, m), 4.8—5.3 (2H, m), 6.60 (2H, d), 6.89 (2H, d). MS: *m/e* 308 (M^+). Found: C, 62.30; H, 6.37%. Calcd for $C_{16}H_{20}O_6$: C, 62.32; H, 6.54%. *meso*-Pyrenophorin: mp 128—128.5 °C; (lit,[8b] 126—127.5 °C). IR (KBr): 1717, 1694 cm^{-1} (C=O), 1631 cm^{-1} (C=C); NMR ($CDCl_3$): δ=1.31 (6H, d), 1.9—2.4 (4H, m), 2.4—2.7 (4H, m), 4.8—5.3 (2H, m), 6.51 (2H, d), 6.85 (2H, d), MS: *m/e* 308 (M^+). Found: C, 62.25; H, 6.37%. Calcd for $C_{16}H_{20}O_6$: C, 62.32; H, 6.54%.

Direct Conversion of Arylamines to the Halides by Deamination with Thionitrite or Related Compounds and Anhydrous Copper(II) Halides

Shigeru OAE,* Kōichi SHINHAMA, and Yong Hae KIM

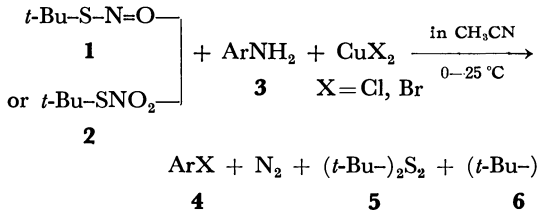
Department of Chemistry, University of Tsukuba, Niiharigun, Ibaraki 305

(Received September 25, 1979)

Reactions of various arylamines with either *t*-butyl thionitrite, *t*-butyl thionitrate, or *p*-toluenesulfonyl nitrite in the presence of anhydrous copper(II) halides under mild conditions gave corresponding aryl halides in good yields. This reaction in the presence of such olefins as acrylonitrile, styrene, and acrylic acid gave the corresponding 2-aryl-1-haloethanes as the main products. *t*-Butyl thionitrite, *t*-butyl thionitrate, and *p*-toluenesulfonyl nitrite were found to be better deaminative reagents than alkyl nitrites or alkyl nitrates due to their weak sulfur–nitrogen bonds.

We reported recently that various thionitrites can be prepared simply by treating thiols with one equivalent of dinitrogen tetraoxide,[1,2] whereas *t*-BuSH can be easily converted the corresponding thionitrate with excess (over 2 eq.) dinitrogen tetraoxide in a good yield.[3]

We now have found that various arylamines (**3**) reacted readily with either *t*-butyl thionitrite (**1**) or *t*-butyl thionitrate (**2**) in the presence of anhydrous copper(II) halides under mild conditions to afford the corresponding halides (**4**) in good yields (Eq. 1).

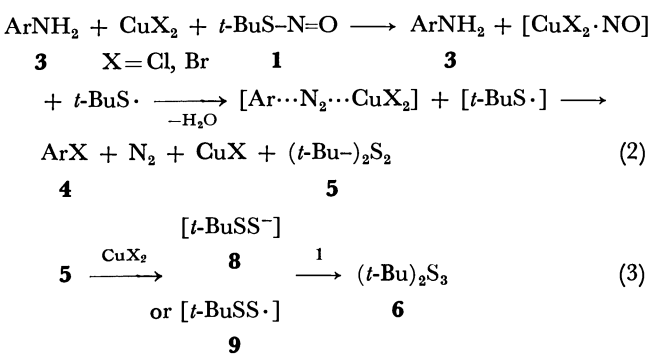


$$\left.\begin{matrix} t\text{-Bu–S–N=O} \\ \mathbf{1} \\ \text{or } t\text{-Bu–SNO}_2 \\ \mathbf{2} \end{matrix}\right\} + \mathrm{ArNH_2} + \mathrm{CuX_2} \xrightarrow[0\text{–}25\,^\circ\mathrm{C}]{\text{in } CH_3CN} \underset{\mathbf{3}}{\mathrm{X=Cl,\ Br}}$$

$$\mathrm{ArX} + \mathrm{N_2} + (t\text{-Bu–})_2\mathrm{S_2} + (t\text{-Bu–})_2\mathrm{S_3} \quad (1)$$
$$\mathbf{4} \qquad\qquad \mathbf{5} \qquad\quad \mathbf{6}$$

Both thionitrites and thionitrates are generally known to be unstable, however, *t*-butyl derivatives, *i.e.*, thionitrite **1** and thionitrate **2**, which can be readily synthesized quantitatively by mixing the thiol and dinitrogen tetraoxide, are stable enough to be used for these reactions. Although other nitrosyl compounds such as nitrosyl halide[4] and alkyl nitrite[5,6] have been successfully used for the same reaction, thionitrites or thionitrates are considered to be better reagents for deaminative halogenation of arylamines **3** due both to the relatively weaker S–N bond of thionitrite **1** or thionitrate **2** than the O–N bond of alkyl nitrites and also to the stronger complexation of thio-derivatives with copper salt than the oxygen and chloro analogs. Indeed, this was found to be the case. Starting with arylamines **3**, corresponding halides **4** were obtained in good yields at room temperature as shown in Table 1. Although alkyl nitrates did not give any deaminative product from arylamines even upon heating with copper(II) halides, thionitrate **2** was found to be an amazingly effective deaminative reagent. The nitroso or nitro group in thionitrite **1** or thionitrate **2** is used for the initial diazotization of arylamines **3**. The rest of the molecules was found to be converted to di-*t*-butyl disulfide (**5**) and di-*t*-butyl trisulfide (**6**), which was identified by elemental analysis, while N_2, quantitatively evolved and collected during the reaction, was identified by mass-spectroscopy. All the products were identified by comparing their IR and NMR spectra and melting or boiling points with those of authentic samples.

Treatment of arylamines **3** with thionitrite **1** and anhydrous copper(II) halides probably involves an initial formation of an intermediate diazonium salt (Eq. 2) like in the case with alkyl nitrites.[6] Trisulfide **6** was formed probably by the attack of *t*-butyldithio anion (**8**) or *t*-butyldithio radical (**9**) formed by heterolysis or homolysis of disulfide **5** on thionitrite **1** (Eq. 3).



$$\underset{\mathbf{3}}{\mathrm{ArNH_2}} + \mathrm{CuX_2} + \underset{\mathbf{1}}{t\text{-BuS–N=O}} \longrightarrow \underset{\mathbf{3}}{\mathrm{ArNH_2}} + [\mathrm{CuX_2 \cdot NO}]$$

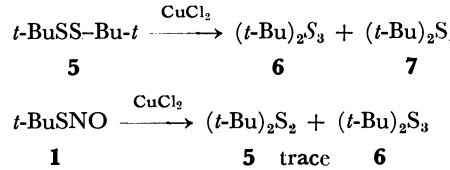
$$\mathrm{X=Cl,\ Br}$$

$$+\ t\text{-BuS}\cdot \xrightarrow[-H_2O]{} [\mathrm{Ar\cdots N_2\cdots CuX_2}] + [t\text{-BuS}\cdot] \longrightarrow$$

$$\underset{\mathbf{4}}{\mathrm{ArX}} + \mathrm{N_2} + \mathrm{CuX} + \underset{\mathbf{5}}{(t\text{-Bu–})_2\mathrm{S_2}} \quad (2)$$

$$\underset{\mathbf{5}}{} \xrightarrow{\mathrm{CuX_2}} \underset{\text{or } [t\text{-BuSS}\cdot]}{\underset{\mathbf{8}}{[t\text{-BuSS}^-]}} \xrightarrow{1} \underset{\mathbf{6}}{(t\text{-Bu})_2\mathrm{S_3}} \quad (3)$$
$$\mathbf{9}$$

The reaction of disulfide **5** with $CuCl_2$ under the same conditions afforded both the trisulfide **6** and the di-*t*-butyl tetrasulfide (**7**). Probably, in the presence of thionitrite **1** or thionitrate **2**, the anionic intermediate *t*-BuSS$^-$ or radical intermediate *t*-BuSS· reacts with the thionitrite **1** or the thionitrate **2** to give the trisulfide **6**. It is noteworthy that trisulfide **6** is formed as the major product along with a minor product *i.e.*, disulfide **5**.



$$\underset{\mathbf{5}}{t\text{-BuSS–Bu-}t} \xrightarrow{CuCl_2} \underset{\mathbf{6}}{(t\text{-Bu})_2\mathrm{S_3}} + \underset{\mathbf{7}}{(t\text{-Bu})_2\mathrm{S_4}}$$

$$\underset{\mathbf{1}}{t\text{-BuSNO}} \xrightarrow{CuCl_2} \underset{\mathbf{5}}{(t\text{-Bu})_2\mathrm{S_2}} + \underset{\text{trace}}{} \underset{\mathbf{6}}{(t\text{-Bu})_2\mathrm{S_3}}$$

When thionitrate **2** was used instead of thionitrite **1**, nearly the same results were obtained (Table 2). If the reaction proceeds *via* a similar path as in the case of the thionitrite **1** either H_2O_2(instead of H_2O) or N_2O(instead of N_2) should be formed according to Eq. 4 or 5. However, the GC mass spectrum of gas trapped during the reaction showed only N_2 but not N_2O. A possibility of decomposition of N_2O to NO and N_2 in the mass process was ruled out by a control mass spectroscopic analysis of the authentic sample of N_2O, which showed a strong molecular peak (M^+, 44) of N_2O. Though H_2O_2 could not be confirmed, thiane and diphenyl sulfide in acetic acid was added for trapping H_2O_2

Table 1. Deamination of amines with thionitrite **1**, thionitrate **2**, or sulfonyl nitrite **14** and anhydrous copper(II) halides

Amine ($R-NH_2$)	Reagent	Reaction temp/°C	Reaction time/min	Yield of the product/% RCl	RBr	Other

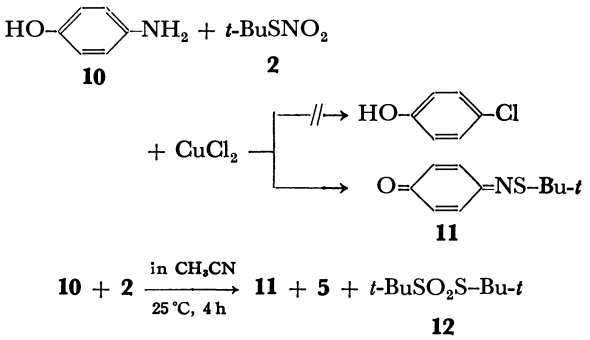
a) Isolated yield. b) GC yield. c) Other side products originated from thionitrite **1** (7.5 mmol) were disulfide **5** (0.32 mmol) and trisulfide **6** (2.2 mmol). d) Other products originated from thionitrate **2** (7.5 mmol) were disulfide **5** (0.31 mmol) and trisulfide **6** (2.1 mmol). e) Benzaldehyde (13%) and benzyl alcohol (26%) were isolated. f) Benzaldehyde (32%) and benzyl alcohol (16%) were isolated. g) Compound **11** was isolated in 40% yield. h) Even in the reaction of p-aminophenol with thionitrate **2** without CuX_2, compound **11** was obtained in 43% of GC yield based on the amount of p-aminophenol.

into the reaction mixture both at the begining and after the completion of the reaction. However, both sulfides were recovered quantitatively and no sulfoxide was detected. H_2O_2 formed in the reaction may be readily consumed for further oxidation of copper complex. The reaction is presumed to proceed *via* a diazonium salt intermediate as shown by Eq. 4.

$$\underset{\mathbf{3}}{ArNH_2} + CuX_2 + \underset{\mathbf{2}}{t\text{-BuSNO}_2} \longrightarrow \underset{\mathbf{3}}{ArNH_2} + [CuX_2NO_2]$$

$$+\ t\text{-BuS}\cdot \begin{cases} \xrightarrow{-H_2O_2} [Ar\cdots N_2\cdots CuX_2] + t\text{-BuS}\cdot \longrightarrow ArX + N_2 + CuX + \mathbf{5} + \mathbf{6} \quad (4) \\ \qquad\qquad\qquad\qquad\qquad\qquad \mathbf{4} \\ \xrightarrow{-H_2O} [Ar\cdots N_2O\cdots CuX_2] + t\text{-BuS}\cdot \longrightarrow ArX + N_2O + CuX + \mathbf{5} + \mathbf{6} \quad (5) \\ \qquad\qquad\qquad\qquad\qquad\qquad \mathbf{4} \end{cases}$$

p-Aminophenol (**10**) did not give the corresponding halide with thionitrate **2** but gave N-(t-butylthio)-p-benzoquinone imine (**11**) in 40% yield. The reaction of p-hydroxyaniline **10** and thionitrate **2** without anhydrous copper(II) chloride also gave p-benzoquinone imine **11**, however, the corresponding S-t-butyl 2-methyl-2-propanethiosulfonate (**12**) was formed from thionitrate **2**, besides disulfide **5** and trisulfide **6**.



$$\mathbf{10} + \mathbf{2} \xrightarrow[25\,°C,\ 4\,h]{\text{in } CH_3CN} \mathbf{11} + \mathbf{5} + t\text{-BuSO}_2\text{S–Bu-}t$$

12

We have also found that the 2-aryl-1-haloethanes (**13**) were readily obtained in the Meerwein arylation when various arylamines **3** were stirred with thionitrite **1** or thionitrate **2** and anhydrous copper(II) halides in the presence of such olefins as acrylonitrile, styrene and acrylic acid as shown in Table 2. In this reaction,

Table 2. Deamination with thionitrite **1** or thionitrate **2** and anhydrous copper(II) halides in the presence of olefins

13 **4**

small amounts of corresponding aryl halides **4** were also formed. However, 2-aryl-1-haloethanes **13** were always the main products. Arylation of olefins proceeded more readily and gave the products in better yields with the thionitrate **2** than with the thionitrite **1**. The reaction of *p*-nitroaniline which has an electron-withdrawing nitro group proceeded readily giving the product nearly quantitatively, whereas, the reaction with *p*-methoxyaniline, which has an electron-donating methoxyl group, was somewhat anomalous and gave the adduct in a poor yield together with many uncharacterized substances. Thus thionitrite **1** and thionitrate **2** have now found to be excellent Meerwein type arylation reagents. Some of the compounds in Table 2 are quite useful compounds. For example, treatment of 2-bromo-3-phenylpropionic acid with aq. ammonia can give *dl*-phenylalanine,[7] while ethyl 2-chloro-3-(*p*-nitrophenyl)propionate could be used for the synthesis of chloramphenicol. Arylation of olefinic compounds is presumed to proceed *via* the Meerwein type arylation path which involves aryl radicals formed by the decomposition of diazonium salts as shown in Eq. 6.

$$Ar\cdot + CH_2{=}CHY \longrightarrow ArCH_2\dot{C}HY \xrightarrow{CuX_2} ArCH_2\underset{X}{CH}Y \quad (6)$$

p-Toluenesulfonyl nitrite (**14**), which is a new sulfonyl derivative prepared from the corresponding sulfinic acid with N_2O_4,[16] was also found to be an excellent deaminative reagent of arylamines. This reaction requires

$$\underset{\mathbf{14}}{p\text{-}TolSO_2NO} + \underset{\mathbf{3}}{ArNH_2} + CuX_2 \xrightarrow[25\,^\circ C,\,1\,h]{\text{in } CH_3CN}$$

X=Cl, Br

$$ArX + N_2 + \underset{\mathbf{15}}{(p\text{-}TolSO_2)_2NOH}$$

4

a larger amount of deaminative reagent **14** than thionitrite **1** or thionitrate **2** because of the formation of a nitrogen compound, *N,N'*-bis(*p*-tolylsulfonyl)hydroxylamine (**15**). When various arylamines **3** were treated with anhydrous copper(II) halides and excess sulfonyl nitrite **14** at room temperature, evolution of nitrogen gas was observed during the period of *ca.* 30 min and the corresponding aryl halides **4** were obtained in good yields. These results are listed in Table 1.

Experimental

All the melting points and boiling points were uncorrected. Elemental analysis of sulfur was carried out by Sagami Chemical Research Center and the analyses of other elements were carried out by the Chemical Analysis Center in our University. Analytical determinations by GLC were performed on a Hitachi 163 gas chromatograph fitted with the following column (3 mm o.d.×3 m): 10% SE-30 on Chromosorb W. ^{1}H-NMR spectra were taken at 60 MHz on a Hitachi R-24 A apparatus. IR spectra were recorded with a Hitachi 215 spectrometer. Mass spectra were recorded with a Hitachi RMU-6M spectrometer.

Synthesis of t*-Butyl Thionitrite (1).* Dinitrogen tetraoxide[1] (0.1 mol) in carbon tetrachloride (11 ml) was added to a stirred solution of *t*-BuSH 9.02 g (0.1 mol) in dry ether (100 ml) for a few minites at −70 °C. The solution was stirred further for several minutes and poured into the cold 5% $NaHCO_3$ aq. solution and extracted with ether. The ethereal extract was dried ($MgSO_4$) in dark at 0 °C, and the solvent was evaporated *in vacuo* giving almost pure thionitrite **1** 7.0 g (59%), which was pure enough for the reaction over several months at −20 °C with molecular sieves: bp 40—42 °C/55 mmHg (lit,[9] 36 °C/48 mmHg). IR (neat):

1490 (NO), 1360, 1298, and 1157 cm^{-1}. NMR (CCl_4): δ 1.85 (s).

Synthesis of t-*Butyl Thionitrate (2).* This reaction required a relatively large flask (2 l) fitted with a reflux condencer the end of which is open for air escape, since the reaction took place vigorously. Dinitrogen tetraoxide[1] (1.5 mol) in carbon tetrachloride (135 ml) was added dropwise to a stirred solution of *t*-BuSH 55.3 g (0.6 mol) in dry ether (500 ml) for over 30 min at the rate that ether slowly refluxed. After the addition was over, the solution was stirred further for *ca.* 30 min. The solution was washed with ice-cold water and dried ($MgSO_4$), concentrated, and distilled (with molecular sieves) giving 67.5 g (84%) of colorless oil which had a stimulating odor: bp 40—41 °C/6 mmHg (lit,[9] 55 °C/13 mmHg). IR (neat): 2950, 1520 (NO), 1300, 1263, 1155, and 825 cm^{-1}. NMR (CCl_4): δ 1.58 (s). Thionitrate **2** was pure enough for the reaction over several months at −20 °C with molecular sieves.

Reactions of t-*Butyl Thionitrite (1) and Primary Amines (3) with Anhydrous Copper(II) Halides.* The following is a typical run. After a solution of *t*-BuSNO 0.89 g (7.5 mmol) in dry acetonitrile (20 ml) was added onto well-dried anhydrous copper(II) chloride 0.85 g (6 mmol) under argon with vigorous stirring, *p*-nitroaniline 685 mg (5 mmol) was slowly added in a period of 5 min at 25 °C. The solution was stirred further for 2 h, and then hydrochloric acid solution (20%, 100 ml) was added. The solution, after saturated with NaCl, was extracted with ether. The extract was washed with water saturated with NaCl and dried ($MgSO_4$), concentrated. Recrystallization (from hexane) gave pure *p*-chloronitrobenzene 770 mg (quant.): mp 80—82 °C. IR and NMR spectra were identical with those of authentic samples. Other products were disulfide **5** (0.32 mmol) and trisulfide **6** (2.2 mmol). The amounts of these polysulfides were estimated by GLC and separated by distillation. Disulfide **5**: MS (70 eV), *m/e* 178 (M^+). IR spectrum was identical with that of authentic sample. Trisulfide **6**: mp 14—15 °C (lit,[10] 16.63 °C). IR (neat): 1450, 1360, and 1260 cm^{-1}; NMR (CCl_4): δ 1.36 (s) (lit.[11] δ 1.34). MS (70 eV), *m/e* 210 (M^+).

Reactions of t-*Butyl Thionitrate (2) and Primary Amines (3) with Copper(II) Halides.* The following is a typical run. Well-dried anhydrous copper(II) chloride 810 mg (6 mmol) and *p*-nitroaniline 682 mg (5 mmol) were treated with *t*-$BuSNO_2$, 1.02 g (7.5 mmol) under argon in a similar procedure to that of *t*-BuSNO, giving 780 mg (quant.) of *p*-chloronitrobenzene. Amounts of disulfide **5** (0.31 mmol) and trisulfide **6** (2.1 mmol) were also monitored by GLC and identified with IR, NMR, and MS spectral analyses after distillation.

Melting points, or boiling points, IR and NMR spectra of all halides in Table 1 were identical with those of authentic samples.

Reaction of t-*Butyl Thionitrate (2) and* p-*Aminophenol (10) with Copper(II) Chloride.* Anhydrous copper(II) chloride 810 mg (6 mmol) and *p*-aminophenol 546 mg (5 mmol) were treated with thionitrate **2** 1.02 g (7.5 mmol) for 1 h in a similar procedure to the former reaction. TLC (hexane: ether=10: 1) gave 390 mg (40%) of *N*-(*t*-butylthio)-*p*-benzoquinone imine as bright yellow crystals: mp 77—79 °C (recrystallized from hexane). Found: C, 61.38; H, 6.60; N, 7.13; S, 16.29%. Calcd for $C_{10}H_{13}NOS$: C, 61.51; H, 6.71; N, 7.17; S, 16.42%. IR (KBr): 1630 (C=O), 1475, 1450, 1360, 1143, 861, and 705 cm^{-1}. UV (hexane) max: 401 nm. NMR (CCl_4): δ 1.45 (s, 9H), 6.13—6.50 (m, 2H), and 6.75—7.35 (m, 2H). MS (70 eV), *m/e* (rel intensity): 195 (23, M^+), 138 (76, O=  =NS$^+$), and 57 (100, *t*-Bu^+).

TABLE 3. SPECTRAL DATA OF 2-ARYL-1-HALOETHANES

Compound	IR (neat, cm^{-1})	^{1}H-NMR (CCl_4, δ)	MS (70 eV), *m/e*, M^+

a) Spectral data were identical with those of literature.[8] b) Bp(bath temp) 160 °C/2 mmHg (lit,[14] 166—168 °C/4 mmHg). c) Bp (bath temp) 85—90 °C/20 mmHg (lit,[15] 85—89 °C/50 mmHg). d) Bp(bath temp) 100 °C/2 mmHg (lit,[12] 136—165 °C/15 mmHg). e) Bp (bath temp) 120 °C/2 mmHg (lit,[13] 176—177 °C/20 mmHg). f) Mp 45—47 °C (lit,[15] 48 °C).

Disulfide **5** (92 mg) and trisulfide **6** (250 mg) were also isolated by TLC and distillation.

Reaction of t-*Butyl Thionitrate (2) and* p-*Aminophenol (10) without Anhydrous Copper(II) Halide.* *p*-Aminophenol 109 mg (1 mmol) was added to a stirred solution of thionitrate **2** 202 mg (1.5 mmol) in dry acetonitrile (3 ml). The mixture was stirred further for 4 h. The amounts of the products were estimated by GLC: *p*-Benzoquinone imine **11** (0.43 mmol, 43%), disulfide **5** (0.19 mmol, 26%), thiosulfonic *S*-ester **12** (0.24 mmol, 33%). Thiosulfonic *S*-ester **12** was isolated by preparative GLC: mp 22—24 °C. IR (neat): 1290 and 1100 cm^{-1}. NMR (CCl_4): δ 1.40 (s) and 1.58 (s). MS (70 eV), *m/e* 210 (M^+). Found: C, 45.59; H, 8.61; S, 30.29%. Calcd for $C_8H_{18}O_2S_2$: C, 45.68; H, 8.62; S, 30.48%.

Reactions of t-*Butyl Thionitrite (1) or* t-*Butyl Thionitrate (2) and Arylamines (3) with Copper(II) Halides in the Presence of Olefins.* The following is a typical run. Thionitrate **2** 1.02 g (7.5 mmol) in acetonitrile (7 ml) and acrylonitrile (7 ml) were added to the well-dried anhydrous copper(II) chloride 810 mg (6 mmol). *p*-Nitroaniline 690 mg (5 mmol) in acetonitrile (5 ml) was added to the mixture in a period of 15 min with stirring. During this period, the flask was cooled by water. The mixture was kept stirring further for 30 min. Evolution of gas (110 ml) was observed during this period. Diluted aq. HCl solution (20%, 100 ml) was added to the mixture, which was then extracted with ethyl ether. The ethereal extract was dried ($MgSO_4$), and concentrated. TLC (hexane: ether=10: 1) gave 689 mg (65%) of 2-chloro-3-(*p*-nitrophenyl)propionitrile and 172 mg (22%) of *p*-chloronitrobenzene. Disulfide **5** 71 mg and trisulfide **6** 186 mg, were obtained directly by GLC.

Spectral data of the products were summarized in Table 3.

Reactions of p-*Toluenesulfonyl Nitrite (14) and Aryl Amines (3) with Copper(II) Halides.* The following is a typical run. Well-dried anhydrous copper(II) chloride 161 mg (1.2 mmol) and *p*-bromoaniline 191 mg (1.0 mmol) were treated with sulfonyl nitrite **14**[16] 444 mg (2.4 mmol) under argon in a similar procedure to that of thionitrite **1**, giving 177 mg (93% by GC) of *p*-bromochlorobenzene. Hydroxylamine **15** 340 mg (83%) was also isolated in this reaction: mp 124—125 °C (from ether), (lit,[17] 126 °C). IR spectrum of compound **15** was identical with that of an authentic sample prepared by the procedure described in the literature.[17]

Synthesis of Linear Pyranocoumarins: Xanthoxyletin, 4-Methylxanthyletin, and 4-Phenylxanthyletin

Vindo Kumar Ahluwalia,* Mrs. Krishna Bhat, Chandra Prakash, and Shashi Bala
Department of Chemistry, University of Delhi, Delhi 110007, India

(Received June 6, 1979)

A convenient synthesis of linear pyranocoumarins (2*H*,8*H*-benzo[1,2-b: 5,4-b']dipyran-2-ones), *viz.*, xanthoxyletin, 4-methylxanthyletin and 4-phenylxanthyletin is described which uses blocking the 8-position of appropriate 7-hydroxycoumarin derivatives with iodine and 1,1-dimethyl-2-propynylation followed by cyclisation.

The occurrence of linear pyranocoumarins (2*H*,8*H*-benzo[1,2-b: 5,4-b']dipyran-2-one derivatives), *viz.*, xanthyletin,[1-3] xanthoxyletin,[3-5] luvangetin,[1] dentatin,[6] roubustic acid,[7-10] robustin,[10] their methyl ethers,[10] lonchocarpic acid[9,11-13] and lonchocarpen[13] prompted us to devise a convenient method for their synthesis. A few syntheses of these coumarins are known[14-17] but these involve a number of steps and the overall yield is poor.

It has been shown[16,18,19] that 7-hydroxycoumarin derivatives react with 3-chloro-3-methyl-1-butyne in acetone to yield the 7-(1,1-dimethyl-2-propynyl) ethers, which on heating with *N,N*-dimethylaniline resulted[17-19] in the formation of angular pyrano coumarins (2*H*,8*H*-benzo[1,2-b: 3,4-b']dipyran-2-one derivatives) *i.e.* cyclization takes place at more reactive 8-position due to fixation of double bond. But if 8-position is substituted,[15,16] the cyclization takes place at 6-position and the corresponding 8-substituted linear pyranocoumarins are obtained. Thus linear pyranocoumarins having 8-position free could not be prepared by this method. However these coumarins have been synthesized by very tedious methods.[14-17] A convenient method has now been developed for the synthesis of linear pyranocoumarins by blocking the 8-position with an easily introducable and removable group like iodine, which is knocked out on heating with *N,N*-dimethylaniline and cyclization takes place at 6-position. The required intermediate 7-(1,1-dimethyl-2-propynyloxy)-8-iodocoumarin derivatives were prepared by iodination of corresponding 7-hydroxycoumarin with iodine and periodic acid, followed by reaction with 3-chloro-3-methyl-1-butyne in acetone in presence of potassium carbonate.

Using the above method, the synthesis of 5-methoxy-8,8-dimethyl-2*H*,8*H*-benzo[1,2-b: 5,4-b']dipyran-2-one (xanthoxyletin) (**1**), 4,8,8-trimethyl-2*H*,8*H*-benzo[1,2-b: 5,4-b']dipyran-2-one (4-methylxanthyletin) (**2**) and 8,8-dimethyl-4-phenyl-2*H*,8*H*-benzo[1,2-b: 5,4-b']dipyran-2-one (4-phenylxanthyletin) (**3**) has been carried out. The synthesis of **1** was effected as follows. Iodination of 7-hydroxy-5-methoxycoumarin[20] with iodine/periodic acid gave 7-hydroxy-8-iodo-5-methoxycoumarin (**4**), the structure of which was confirmed by the ^{1}H NMR spectrum of its acetate. Etherification of **4** with 3-chloro-3-methyl-1-butyne in acetone/K_2CO_3 yielded 7-(1,1-dimethyl-2-propynyloxy)-8-iodo-5-methoxycoumarin (**5**), which on heating with *N,N*-dimethylaniline afforded **1**. That the cyclization takes place at 6-position and iodine was knocked out in above reaction was shown by its NMR spectral data, and its disagreement with angular isomer, *viz.*, 5-methoxy-8,8-dimethyl-2*H*,8*H*-benzo[1,2-b: 3,4-b']dipyran-2-one.[21]

Similarly, iodination of 7-hydroxy-4-methylcoumarin[22] with iodine/periodic acid gave 7-hydroxy-8-iodo-4-methylcoumarin (**6**). Its structure was confirmed by the NMR spectral data of its acetate, which showed the presence of two doublets (J=9.5 Hz) for ortho-coupled H5 and H6 protons. Etherification of **6** with 3-chloro-3-methyl-1-butyne in acetone/K_2CO_3 yielded 7-(1,1-dimethyl-2-propynyloxy)-8-iodo-4-methylcoumarin (**7**), which on heating with *N,N*-dimethylaniline afforded **2**. Its structure was in agreement with the NMR spectral data which showed the presence of two singlets for para-coupled H5 and H10 protons, along with other usual signals.

Using the above method, 4-phenylxanthyletin (**3**) has also been synthesized starting from 7-(1,1-dimethyl-2-propynyloxy)-8-iodo-4-phenylcoumarin (**8**), which was prepared by the iodination of 7-hydroxy-4-phenylcoumarin[23] with iodine and periodic acid to 7-hydroxy-8-iodo-4-phenylcoumarin (**9**), followed by etherification with 3-chloro-3-methyl-1-butyne in acetone in presence of potassium carbonate. Compound **8** on heating with *N,N*-dimethylaniline yielded **3**. Its structure was in agreement with its ^{1}H-NMR spectral data.

Experimental

Melting points are uncorrected. Infrared spectra were recorded on a Perkin-Elmer Infra-cord spectrometer. The NMR spectra were recorded on Perkin Elmer R-32 instrument with TMS as internal standard.

*5-Methoxy-8,8-dimethyl-2*H*,8*H*-benzo[1,2-b: 5,4-b']dipyran-2-one (Xanthoxyletin) (1). (a) 7-Hydroxy-8-iodo-5-methoxycoumarin (4)*: 7-Hydroxy-5-methoxycoumarin[20] (2 g, 10.4 mmol) was dissolved in minimum amount of ethanol and to

this solution iodine (2.1 g) and periodic acid (0.5 g in water) were added. The mixture was stirred for 2 h at room temperature and then diluted with water to give the coumarin (**4**) (2.2 g, 6.91 mmol) (66.7%). It crystallized from ethanol as yellow needles mp 235—237 °C. Found: C, 37.6; H, 2.1%. Calcd for $C_{10}H_7O_4I$: C, 37.7; H, 2.2%. Its acetate (prepared by acetic anhydride–pyridine) melted at 205—207 °C. NMR (DMSO-d_6): δ 2.20 (s, 3H, 7-OAc); 3.75 (s, 3H, 5-OCH_3); 6.25 (d, 1H, J_0=9.5 Hz, H3); 6.85 (s, 1H, H6); 7.88 (d, 1H, J_0=9.5 Hz, H4).

(b) 7-(1,1-Dimethyl-2-propynyloxy)-8-iodo-5-methoxycoumarin (5): A solution of (**4**) (1 g, 3.14 mmol) in dry acetone (75 ml) was refluxed with 3-chloro-3-methyl-1-butyne (4 ml, 38.9 mmol) in presence of anhydrous potassium carbonate (3 g) and anhydrous potassium iodide (1.9 g) for 24 h. The solvent was distilled off and the residue was treated with ice. The separated solid was filtered, washed with a dilute solution of sodium carbonate and water and crystallized from benzene–petroleum ether to give (**5**) (0.62 g, 1.61 mmol) (51.7%) as yellow needles mp 178—179 °C. Found: C, 46.9; H, 3.5%. Calcd for $C_{15}H_{13}O_4I$: C, 46.8; H, 3.6%. NMR ($CDCl_3$) δ 1.62 (s, 6H, $-C(CH_3)_2$); 2.58 (s, 1H, $-C\equiv CH$); 3.82 (s, 3H, 5-OCH_3); 6.09 (d, 1H, J_0=9.5 Hz, H3); 6.88 (s, 1H, H6); 7.91 (d, 1H, J_0=9.5 Hz, H4).

(c) 5-Methoxy-8,8-dimethyl-2H,8H-benzo[1,2-b: 5,4-b']dipyran-2-one (Xanthoxyetin) (1): The above 1,1-dimethyl-2-propynyl ether (**5**) (0.1 g, 0.26 mmol), was refluxed with *N,N*-dimethylaniline (3 ml) for 12 h. The cooled reaction mixture was poured over ice-cold hydrochloric acid. The solution was extracted thrice with ethyl acetate (150 ml), washed with 5% HCl, 5% NaOH and finally with water and dried (Na_2SO_4). Distillation of ethyl acetate yielded **1** (50 mg, 0.19 mmol) (74.6%) which crystallized from benzene–petroleum ether as yellow needles, mp 132—133 °C (lit,[5] mp 132—133 °C). Found: C, 69.6; H, 5.5%. Calcd for $C_{15}H_{14}O_4$: C, 69.7; H, 5.4%. NMR ($CDCl_3$) δ 1.76 (s, 6H, $-C(CH_3)_2$); 4.16 (s, 3H, 5-OCH_3); 5.85 (d, 1H, J_0=9.5 Hz, H3); 6.32 (d, 1H, $J_{6,7}$=10 Hz, H6); 6.5 (s, 1H, H10); 7.08 (d, 1H, $J_{6,7}$=10 Hz, H7); 8.2 (d, 1H, J_0=9.5 Hz, H4). IR ν_{max} (KBr) (cm^{-1}) 1710 (C=O); 1610 and 1600 (C=C); 1350 and 1360 ($-C(CH_3)_2$).

4,8,8-Trimethyl-2H,8H-benzo[1,2-b: 5,4-b']dipyran-2-one (4-Methylxanthyletin) (2). (a) 7-Hydroxy-8-iodo-4-methylcoumarin (6): 7-Hydroxy-4-methylcoumarin[22] (2 g, 11.3 mmol) was dissolved in minimum amount of ethanol and to this solution iodine (2.31 g) and periodic acid (0.52 g in water) were added. The mixture was stirred for 2 h at room temperature and then diluted with water to give **6** (2.5 g, 8.27 mmol) (73.3%). It crystallized from ethanol as light yellow needles, mp 219—220 °C. Found: C, 39.6; H, 2.3%. Calcd for $C_{10}H_7O_3I$: C, 39.7; H, 2.3%. Its acetate (acetic anhydride-pyridine) melted at 180—181 °C. NMR ($CDCl_3$) δ 2.5 (bs, 6H, 4-CH_3 and 7-OAc); 6.48 (s, 1H, H3); 7.34 (d, 1H, J_0=9.5 Hz, H6); 7.85 (d, 1H, J_0=9.5 Hz, H5).

(b) 7-(1,1-Dimethyl-2-propynyloxy)-8-iodo-4-methylcoumarin (7): A solution of **6** (1 g, 3.31 mmol) in dry acetone (75 ml) was refluxed with 3-chloro-3-methyl-1-butyne (4 ml, 38.9 mmol) in presence of anhydrous potassium carbonate (3 g) and anhydrous potassium iodide (2.06 g) for 24 h. Working up of the reaction mixture yielded **7** (0.65 g, 1.76 mmol) (54.2%). It crystallized from benzene–petroleum ether as yellow needles, mp 185—186 °C. Found: C, 48.8; H, 3.4%. Calcd for $C_{15}H_{13}O_3I$: C, 48.9; H, 3.5%. NMR ($CDCl_3$) δ 1.81 (s, 6H, $-C(CH_3)_2$); 2.42 (s, 3H, 4-CH_3); 2.7 (s, 1H, $-C\equiv CH$); 6.15 (s, 1H, H3); 7.3 (d, 1H, J_0=9.5 Hz, H6); 7.55 (d, 1H, J_0=9.5 Hz, H5).

(c) 4,8,8-Trimethyl-2H,8H-benzo[1,2-b: 5,4-b']dipyran-2-one (4-Methylxanthyletin) (2): The above 1,1-dimethyl-2-propynyl ether (0.1 g, 0.27 mmol) was refluxed with *N,N*-dimethylaniline (3 ml) for 12 h. The cooled reaction mixture was poured over ice cold hydrochloric acid, worked up (as in the case of **1**) to yield **2** (50 mg, 0.20 mmol) (76.9%), which crystallized from benzene–petroleum ether as yellow needles, mp 237—238 °C. Found: C, 74.2; H, 5.8%. Calcd for $C_{15}H_{14}O_3$: C, 74.3; H, 5.7%. NMR ($CDCl_3$) δ 1.49 (s, 6H, $-C(CH_3)_2$); 2.35 (s, 3H, 4-CH_3); 5.65 (d, 1H, $J_{6,7}$=10 Hz, H6); 6.05 (s, 1H, H3); 6.26 (d, 1H, $J_{6,7}$=10 Hz, H7); 7.09 (s, 1H, H10); 7.22 (s, 1H, H5). IR ν_{max} (KBr) (cm^{-1}) 1710 (C=O); 1610 and 1600 (C=C); 1345 and 1360 ($-C(CH_3)_2$).

8,8-Dimethyl-4-phenyl-2H,8H-benzo[1,2-b: 5,4-b']dipyran-2-one (4-Phenylxanthyletin) (3). (a) 7-Hydroxy-8-iodo-4-phenylcoumarin (9): 7-Hydroxy-4-phenylcoumarin[23] (2 g, 8.40 mmol) was dissolved in minimum amount of ethanol and to this solution iodine (1.71 g) and periodic acid (0.39 g in water) were added. The mixture was stirred for 2 h at room temperature and then diluted with water to give coumarin (**9**) (2.5 g, 6.86 mmol) (80%). It crystallized from ethanol as light yellowish needles, mp 263—264 °C. Found: C, 49.3; H, 2.4%. Calcd for $C_{15}H_9O_3I$: C, 49.4; H, 2.5%. Its acetate (acetic anhydride–pyridine) melted at 178—179 °C. NMR ($CDCl_3$) δ 2.44 (s, 3H, 7-OAc); 6.38 (s, 1H, H3); 7.05 (d, 1H, J_0=9.5 Hz, H6); 7.32 (d, 1H, J_0=9.5 Hz, H5); 7.4 (bs, 5H, 4-Ph).

(b) 7-(1,1-Dimethyl-2-propynyloxy)-8-iodo-4-phenylcoumarin (8): A solution of **9** (1 g, 2.80 mmol) in dry acetone (75 ml) was refluxed with 3-chloro-3-methyl-1-butyne (4 ml, 38.9 mmol) in presence of anhydrous potassium carbonate (3 g) and anhydrous potassium iodide (1.5 g) for 24 h. Working up of the reaction mixture yielded (**8**) (0.7 g, 1.62 mmol) (63.6%) which crystallized from benzene–petroleum ether as brown needles mp 261—262 °C (Found: C, 55.7; H, 3.5%. Calcd for $C_{20}H_{15}O_3I$: C, 55.8; H, 3.4%). NMR ($CDCl_3$): δ 1.9 (s, 6H, $-C(CH_3)_2$); 2.76 (s, 1H, $-C\equiv CH$); 6.32 (s, 1H, H3); 7.32 (d, 1H, J_0=9.5 Hz, H6); 7.56 (s, 5H, 4-Ph); 7.66 (d, 1H, J_0=9.5 Hz, H5).

(c) 8,8-Dimethyl-4-phenyl-2H,8H-benzo[1,2-b: 5,4-b']dipyran-2-one (4-Phenylxanthyletin) (3). The above 1,1-dimethyl-2-propynyl ether (**8**) (0.1 g, 0.23 mmol) was refluxed with *N,N*-dimethylaniline (3 ml) for 6 h. The cooled reaction mixture was poured over ice cold hydrochloric acid and worked up (as in case of **1**) to yield **3** (45 mg, 0.14 mmol) (63.9%). It crystallized from benzene–petroleum ether as yellow needles, mp 181—182 °C. Found: C, 78.8; H, 5.3%. Calcd for $C_{20}H_{16}O_3$: C, 78.9; H, 5.2%. NMR ($CDCl_3$) δ 1.52 (s, 6H, $-C(CH_3)_2$); 5.62 (d, 1H, $J_{6,7}$=10 Hz, H6); 6.08 (s, 1H, H3); 6.18 (d, 1H, $J_{6,7}$=10 Hz, H7); 6.96 (s, 1H, H10); 7.3 (s, 5H, 4-Ph); 7.45 (s, 1H, H5). IR ν_{max} (KBr) (cm^{-1}) 1715 (C=O); 1615 and 1600 (C=C); 1345 and 1360 ($-C(CH_3)_2$).

The Cyclodextrin-accelerated Cleavage of Thiocarboxylic *S*-Esters

Makoto KOMIYAMA† and Myron Lee BENDER*

Departments of Chemistry and Biochemistry, Northwestern University, Evanston, IL 60201, USA

(Received January 10, 1979)

The effect of α- and β-cyclodextrins on the cleavage of the thiocarboxylic *S*-esters, *S*-*p*-nitrophenyl thioacetate (**1**) and *S*-ethyl *p*-nitrothiobenzoate (**3**), was compared with their effect on the cleavage of the corresponding oxygen esters, *p*-nitrophenyl acetate (**2**) and ethyl *p*-nitrobenzoate (**4**). The rate constants of α- or β-cyclodextrin-accelerated cleavage of **1** (1.5×10^{-2} or 4.8×10^{-2} s^{-1} at pH 10.5, 25 °C) were almost identical with the values of **2** (1.6×10^{-2} or 4.2×10^{-2} s^{-1}), definitely showing the rate-determining formation of tetrahedral intermediates. The cleavage of **3** was accelerated by α- and β-cyclodextrins, whereas the cleavage of **4** was decelerated by β-cyclodextrin but was not affected by α-cyclodextrin. The contrast in the effect of cyclodextrins on **3** and **4** was ascribed to the difference of the rate of breakdown of the tetrahedral intermediates to products, caused by different pK's of the leaving groups of **3** (10.5) and **4** (16.0). The formation of tetrahedral intermediates confirmed in the cyclodextrin-accelerated hydrolyses of esters further strengthened the previous proposal that cyclodextrin is an excellent model of serine proteases, since these intermediates are also formed in enzymatic reactions.

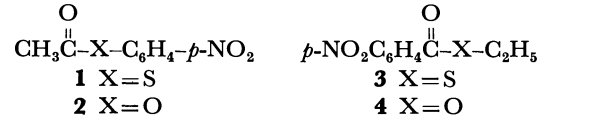
It is well known that cyclodextrins (CDs) affect the rates of many kinds of chemical reactions. The most important feature of reactions involving CDs as accelerating (or retarding) reagents is the formation of inclusion complexes of substrates with CD, which is followed by chemical reaction. Thus, CD chemistry provides a good example of a "guest-host" relationship and CDs have been used as models of enzymes (especially of hydrolytic enzymes).[1,2]

Much work has been done on the CD-accelerated cleavage of oxygen esters,[1-6] showing clear-cut differences of the effect of CD depending on the leaving groups. Thus, cleavage of phenyl esters are accelerated by CD, whereas cleavage of alkyl esters are decelerated by CD, which was attributed to either the high pK_a of the leaving group (alcohol) or non-productive binding.[1,4] Cleavage of phenyl esters is a nucleophilic reaction by the secondary hydroxyl group of CD, resulting in acyl-CD and phenol.

In spite of the multitude of information on the cleavage of oxygen esters, however, no report has been made about the effect of CD on the cleavage thiocarboxylic *S*-esters. This report describes the rate effect of α-cyclodextrin (α-CD) and β-cyclodextrin (β-CD) on the cleavage of *S*-*p*-nitrophenyl thioacetate (**1**), an *S*-phenyl thioester, and *S*-ethyl *p*-nitrothiobenzoate (**3**), an *S*-alkyl thioester. For purposes of comparison, the rate effect of α-CD and β-CD on the cleavage of the corresponding oxygen esters, *p*-nitrophenyl acetate (**2**) and ethyl *p*-nitrobenzoate (**4**) was also determined.

The comparison between **1** and **2** can be a good test to check whether or not the cleavage of these substrates proceeds *via* tetrahedral intermediates. If the cleavage involves formation of tetrahedral intermediates, the rate constant of the CD-accelerated cleavage of **1** should be (approximately) equal to that of **2**. Alternatively, in an S_N2 type reaction, an –SR group of **1** should be displaced at least 250 times faster than an –OR group of **2**.[7,8]

Furthermore, the effect of CD on the cleavage of **3** (whether acceleration or deceleration) can probe whether the high pK_a of the leaving group or non-productive binding is the important factor in the deceleration of the cleavage of alkyl esters by CD, since ethanethiol has smaller pK_a (10.5)[9] than the nucleophilic hydroxyl group of CD (around 12).[4,6]



1 X=S **2** X=O **3** X=S **4** X=O

Experimental

Materials. **1** was synthesized from acetyl chloride and thiophenol, and recrystallized from cyclohexane; mp 82 °C (lit, 82 °C,[10] 82.3—82.6 °C[11]). **2** was recrystallized from chloroform–hexane; mp 79.5 °C (lit, 79.5—80 °C[11]).

3 was synthesized from *p*-nitrobenzoyl chloride and ethanethiol, and purified by recrystallization from acidified aqueous ethanol; mp 70.0—70.2 °C (lit, 69.5—70 °C,[7] 67—68 °C[12]). **4** was recrystallized from aqueous ethanol; mp 56.5—57 °C (lit, 56.5—57 °C). α-CD and β-CD were purified by recrystallization from water. All water used for kinetic studies was doubly distilled.

Kinetics. The cleavage of **1**—**4** was carried out at 25 °C and was followed at 410 nm (**1** and **2**) and 300 nm (**3** and **4**) by a Cary 14 spectrophotometer. Reactions were initiated by addition of stock solution of **1**—**4** in acetonitrile to a thermostatted buffer solution. In the reactions of **3**, buffer solution was flushed with nitrogen before the addition of the sample stock solution, since an accelerating effect by oxygen was reported.[7]

The kinetic data (k_{obsd}) were treated based on the following reaction scheme and the corresponding Lineweaver-Burk plots:[1]

$$\text{Ester} + \text{CD} \underset{K_d}{\rightleftharpoons} \text{Complex} \xrightarrow{k_c} \text{Products};\quad \text{Complex} \xrightarrow{k_{un}} \text{CD}$$

$$1/(k_{obsd} - k_{un}) = K_d/(k_c/k_{un})[\text{CD}]_0 + 1/(k_c - k_{un}).$$

Results

Both α-CD and β-CD showed acceleration of the cleavage of **1** and **2**. The rate constants of the cleavage of **1** and **2** in the presence of CD (in large excess),

† Current address: Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo 113.

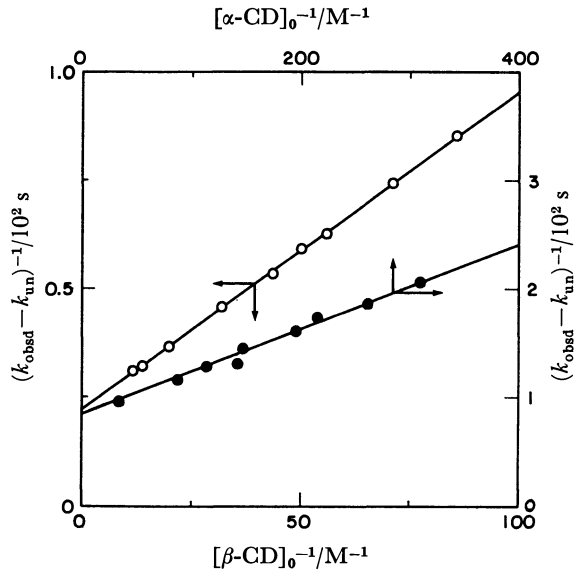


Fig. 1. Plot of $1/(k_{obsd}-k_{un})$ *versus* $1/[C]_0$ of the α-CD (●)- and β-CD (○)-accelerated cleavage of **1**. pH 10.5, I=0.2 M, 25 °C.

k_{obsd}, asymptotically approached a maximum value as $[CD]_0$ increased, showing the complex formation of CD with **1** and **2**. Thus, the rate constant of the cleavage of **1** and **2** complexed with CD, k_c, and the dissociation constant of the CD-**1** (or **2**) complex, K_d, were determined by plotting $1/(k_{obsd}-k_{un})$ *vs.* $1/[CD]_0$ as shown in Fig. 1. Here k_{un} is the rate constant in the absence of CD (see Experimental).

TABLE 1. VALUES OF k_c AND K_d FOR THE α-CD AND β-CD ACCELERATED CLEAVAGE OF **1** AND **2**[a,b]

Cyclodextrin	Substrate	k_c / 10^{-3} s^{-1}	K_d / 10^{-3} M
α-CD	**1**	15±1	4.8±0.3
	2	16±1	12±2
β-CD	**1**	48±3	3.0±0.4
	2	42±3	6.1±0.7

a) pH 10.5, I=0.2 M. b) k_{un}'s are 2.8×10^{-3} s^{-1} for **1** and 4.6×10^{-3} s^{-1} for **2**.

Table 1 lists the values of k_c and K_d for the CD-accelerated cleavage of **1** as well as those of **2**.

Significantly, k_c of **1** accelerated by α-CD is almost equal to that of **2** accelerated by α-CD. β-CD also gave almost identical values of k_c of **1** and **2**. Thus, *S*-phenyl thioester and phenyl ester are cleaved by CD at similar rates. This result shows that a rate-limiting step occurs before the hydroxyl or mercapto group partitions, since the cleavage of the *S*-phenyl thioester should be faster than that of the phenyl ester by at least 250 fold if breaking of the bond between the carbonyl atom and the sulfur atom (or oxygen atom) were rate-limiting.

The change of absorbance at 300 nm in the cleavage of **3** by CD did not follow first-order kinetics (Fig. 2). This result indicates a stepwise pathway (acylation of CD by **3**, followed by hydrolysis of acyl-CD, as shown

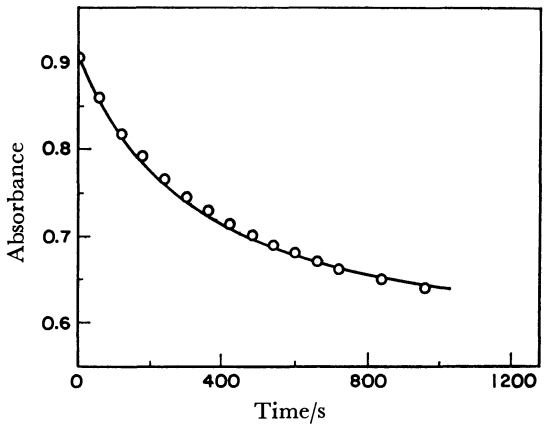

Fig. 2. Change of absorbance at 300 nm for the hydrolysis of **3** in the presence of 0.02 M α-CD at pH 10.5, 25 °C; blank circles are experimentally obtained, whereas the solid line is the theoretical line calculated by using $k_1=1.5\times10^{-3}$ s^{-1} and $k_2=7.5\times10^{-3}$ s^{-1} in Eq. 2.

by Eq. 1 which is consistent with CD-accelerated hydrolyses of phenyl esters.

$$\mathbf{3} + \mathrm{CD} \xrightarrow{k_1} p\text{-nitrobenzoyl-CD (}\mathbf{5}\text{)} + \text{ethanethiol}$$
$$\downarrow k_2 \qquad (1)$$
$$p\text{-nitrobenzoate (}\mathbf{6}\text{)} + \mathrm{CD} + \text{ethanethiol}$$

Of the species in Eq. 1, **3**, **5**, and **6** all absorb at 300 nm (molar absorption coefficients ε_3, ε_5,[13] and ε_6= 8.97×10^3, 2.04×10^3, and 5.84×10^3 M^{-1} cm^{-1}). When the rate constant of the hydrolysis of **5** (k_2) is comparable to that of the cleavage of **3** in the presence of CD (k_1) in magnitude, the intermediate **5** accumulates. Thus, k_1 was determined by fitting the observed absorbance at 300 nm (A) to the theoretical values calculated by Eq. 2.

$$A=\frac{A_0}{\varepsilon_3}\left[\varepsilon_3\exp(-k_1t)+\varepsilon_5\frac{k_1}{k_2-k_1}\{\exp(-k_1t)-\exp(-k_2t)\}\right.$$
$$\left.+\varepsilon_6\left\{1+\frac{k_2\exp(-k_1t)-k_1\exp(-k_2t)}{k_1-k_2}\right\}\right], \qquad (2)$$

where A_0 is the initial absorbance, and the first, second, and third terms of Eq. 2 correspond to the absorbance due to **3**, **5**, and **6**, respectively, in the reaction solution. k_2 was independently determined to be 7.5×10^{-3} s^{-1} at pH 10.5 using the change of absorbance at 260 nm in the hydrolysis of *m*-chlorophenyl *p*-nitrobenzoate in the presence of 0.02 M α-CD according to the previous paper.[4]

As shown in Fig. 2, the change of the absorbance at 300 nm in the hydrolysis of **3** in the presence of 0.02 M α-CD (blank circles) satisfactorily fits the theoretical line calculated from Eq. 2 by using $k_1=1.5\times10^{-3}$ s^{-1}.

Small deviations of the experimental results from the theoretical line are attributable to **3** alone not complexed with α-CD, being hydrolyzed by hydroxide ion without forming **5** as an intermediate. A rough estimate of the amount of complexed **3** was made by using the dependence of the initial slope of the absorbance change upon $[\alpha\text{-CD}]_0$, indicating that about 70% of **3** is complexed with α-CD when $[\alpha\text{-CD}]_0$ is 0.02 M. Similarly, k_1 of **3**

in the presence of 0.015 M β-CD, where about 80% of **3** is complexed with β-CD, was determined to be 5×10^{-4} s^{-1}.

On the other hand, the absorbance change at 300 nm in the hydrolysis of **4** in the presence of CD did not show any measurable deviation from first-order kinetics and the rate constant of its cleavage was determined by the usual first-order equation. This fact indicates that the cleavage of **4** does not follow Eq. 1 but rather proceeds by alkaline reaction, which is discussed later.

Table 2. Effects of α-CD and β-CD on the cleavage of **3** and **4**[a]

CD	Substrate	Observed rate constant (10^{-4} s^{-1})	Rate effect by CD[d]
α-CD[b]	**3**	15±2	6.5
	4	2.6±0.05	1.0
β-CD[c]	**3**	5±1	2.2
	4	1.5±0.03	0.57

a) pH 10.5, I=0.2 M, and 25 °C. b) 0.02 M. c) 0.015 M. d) The ratio of the rate of cleavage of **3** and **4** in the presence of CD to that in its absence.

Table 2 lists the rate constants of the cleavage of **3** and **4** in the presence of CD determined by the above method. It was found that 0.02 M α-CD and 0.015 M β-CD show 6.5 and 2.2 fold acceleration of the cleavage of **3**, an *S*-alkyl thioester. This is in contrast to (about 2 fold) deceleration by β-CD and virtually no effect by α-CD in the cleavage of **4**, an alkyl ester.

Discussion

The almost identical k_c's of **1** and **2** definitely showed the formation of tetrahedral intermediates in the CD-accelerated cleavage of esters. The change of leaving group from *p*-nitrophenol to *p*-nitrothiophenol does not produce a significant effect on k_c, since the formation of tetrahedral intermediates (rather than their breakdown to products) is rate-determining. This occurs because of the larger pK_a of the attacking secondary hydroxyl groups of the CD (around 12) than the pK_a's of the leaving groups (the pK_a's of *p*-nitrophenol and *p*-nitrothiophenol are 7.15[15] and 4.47[11]).

The formation of tetrahedral intermediates was also confirmed in the CD-accelerated cleavage of **3** by the deviation of the absorbance at 300 nm from first-order kinetics (Fig. 2). In the CD-accelerated cleavage of **1** and **2**, however, no deviation from first-order kinetics was observed in spite of the formation of tetrahedral intermediates, since spectroscopy directly followed the cleavage of **1** and **2** by release of *p*-nitrothiophenol and *p*-nitrophenol.

Now it is evident that formation of a tetrahedral intermediate is a common feature among serine protease-catalyzed[11,16] and CD-accelerated hydrolyses of esters (as well as alkaline hydrolyses of esters[17]).

The large difference of the effect of CD on the cleavage of **3** (acceleration by both α-CD and β-CD) from the effect on the cleavage of **4** (retardation by β-CD and no effect by α-CD) is mainly attributable to the difference of pK_a's of the leaving groups. Ethanethiol and ethanol have pK_a's of 10.5[9] and 16.0.[18] As the secondary hydroxyl group of CD has a pK_a around 12,[4,6] the formation of tetrahedral intermediate is rate-determining in the CD-accelerated cleavage of **3**, which can be facilitated by complexation. In the cleavage of **4**, however, reaction involving a tetrahedral intermediate produced by nucleophilic attack of CD is unlikely, since its breakdown to product is energetically unfavorable. Thus, the cleavage of **4** in the presence of CD proceeds largely *via* an alkaline reaction. Here, CD shows retardation because of steric hindrance (protection of the substrate by the wall of the CD) and electrostatic repulsion between two anions (the secondary hydroxide anion of CD and OH^-); with α-CD this effect is very small.

The above argument is consistent with the results of the aminolysis of **3** and **4**, showing no reaction of *n*-butylamine (pK_a 10.6[19]) with **4** as opposed to its considerable reaction with **3**.[7]

Non-productive binding can be partly responsible for the different effect of CD on **3** and **4**. Two structures of inclusion complexes are possible, *i.e.* structure A in which the *p*-nitrophenyl portion of **3** (or **4**) is included in the cavity of CD and the ethanol (or ethanethiol) portion protrudes from the secondary hydroxyl side of the cavity, and structure B in which the ethanol (or ethanethiol) portion is located inside the cavity and the rest is located outside. Of these two structures, only structure B is productive, whereas structure A is non-productive since cleavage the carbonyl carbon atom between and the ether oxygen (or sulfur) atom bond through nucleophilic attack by CD is sterically impossible as shown by CPK molecular models.

Since the sulfur atom is larger in size than the oxygen atom and is more apolar, thioester **3** assumes a structure (where the ethylthio portion is included in the apolar cavity of CD) more favorably than the oxygen ester **4** does (structure B). In other words, the proportion of structure B in the CD-**3** complex is larger than that in the CD-**4** complex. Since structure A is nonproductive and structure B is productive, as described above, the CD-**3** complex is more reactive than the CD-**4** complex.

In conclusion, it was found that CD accelerates the cleavage of *S*-phenyl thioester (**1**), *S*-alkyl thioester (**3**), and phenyl ester (**2**). However, the cleavage of the alkyl ester (**4**) was retarded by β-CD but was not affected by α-CD. The CD-accelerated cleavage of **1**—**3** proceeds *via* tetrahedral intermediates, which is consistent with serine protease-catalyzed reactions. Thus, the similarity between CD reactions and enzymatic reactions conforms to not only the overall pathway, as proposed before, but also the more detailed mechanism. The present finding shows that CD is an excellent model of serine proteases.

Spectrophotometric Study on the Complex Formation of Hydroperoxide with Tetraphenylporphyrin Cobalt(II)

Teruaki YAMADA and Yoshio KAMIYA*

Department of Reaction Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received January 27, 1979)

The rate constants, activation energies, activation entropies and equilibrium constants for the coordination of 1,2,3,4-tetrahydro-1-naphthyl hydroperoxide (THP), 1-methyl-1-phenylethyl hydroperoxide (CHP) and *t*-butyl hydroperoxide (BHP) to para-substituted tetraphenylporphyrin Co(II), Co(*p*-X)TPP (X=OCH_3, H, Cl) were obtained by the visible spectral method at 235—245 K. The rate constants of coordination were k=0.097—2.03×10^2 M^{-1} s^{-1}, the equilibrium constants being K=0.692—2.5×10^{-6} M^{-1}. As a *para*-substituent effect on k and K, the constants were found to increase with increase in the electron donating property of the substituent group. They also depend on the kind of hydroperoxide, the rate constants decreasing in the order $k_{THP}>k_{CHP}>k_{BHP}$, and the equilibrium constants in the order $K_{CHP}>K_{BHP}>K_{THP}$. Activation energies were 7.0—7.8 kcal mol^{-1} and activation entropies −21——25 cal K^{-1}. No spectral change by the addition of hydroperoxide to CuTPP and NiTPP was observed.

The decomposition reaction of hydroperoxide catalyzed by transition-metal ion proceeds by the redox reaction[1] of transition-metal ion which has two valences. The reaction seems to consist of three steps, (a) coordination of hydroperoxide molecule to a metal ion, (b) migration of electron from metal ion to hydroperoxide followed by the cleavage of O–O bond of hydroperoxide, and (c) release of the fragmentation products from a metal ion.

Formation of the hydroperoxide–metal ion complex has been anticipated in many kinetic studies[2-8] since George[9] *et al.* proposed its formation. Richardson[10] reported evidence of the formation for the first time using NMR and visible spectral methods. Some qualitative studies using spectral method had been reported until 1971 when Bulgakova *et al.*[11] Svitych *et al.*[12,13] worked out quantitative studies.[11-13] They reported equilibrium constants and enthalpy of formation of hydroperoxide–metal ion complex using NMR method at low temperature.

In this report, tetraphenylporphyrin metal(II) complex was chosen because of its intense absorbance at the Soret band 410—420 nm, being sensitive to the change of coordination number. The coordination reaction was followed by the decrease of the Soret band using the visible spectra method at 235—245 K. The kinetic and thermodynamic data were calculated from experimental data and the results discussed in terms of the effects of *para*-substituent group, hydroperoxide, and central metal ion.

Experimental

Materials. The *para*-substituted tetraphenylporphyrin free bases H_2(*p*-X)TPP (X=OCH_3, H, Cl),[14] Co(*p*-X)TPP and CuTPP,[15] and NiTPP[16] were prepared according to reported methods. The products were chromatographed on silica gel four or five times using chloroform in each step. The visible spectra of Co(*p*-X)TPP, CuTPP, and NiTPP were very similar to those reported. 1,2,3,4-Tetrahydro-1-naphthyl hydroperoxide (THP) was prepared by the autoxidation of tetralin and crystallized from heptane.[17] Reagent grade 1-methyl-1-phenylethyl hydroperoxide (CHP) and *t*-butyl hydroperoxide (BHP) (Nippon Oils and Fats Co.) were purified and spectral grade dichloromethane was dried before use.

Measurements. Spectrophotometric measurements were carried out on a JASCO-UVIDEC-1 spectrophotometer equipped with a cryostat (type DN-704, Oxford Instrument Co.) in which a quartz cell was set at prescribed temperature within ±0.05 °C with a controller. Both the solution of M(II)TPP (2 ml) in cell and that of hydroperoxide (0.5 ml) in an injector set above the solution of M(II)TPP were cooled to the reaction temperature. Reaction was started when the solution of hydroperoxide was poured into the cell, and followed by measuring the decrease in the Soret band of M(II)TPP. The solution in the cell was stirred throughout the reaction with a magnetic stirrer set under the cryostat.

Results and Discussion

Spectral Chenges. A typical spectral change of Co(*p*-H)TPP with the addition of 1,2,3,4-tetrahydro-1-naphthyl hydroperoxide is shown in Fig. 1. There are three patterns in spectral changes according to the

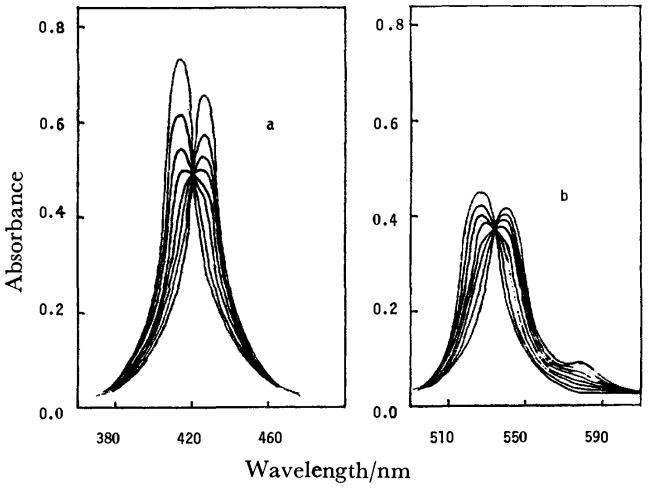

Fig. 1. Visible spectral change observed upon addition of THP to a solution of Co(*p*-H)TPP.
a) [Co(*p*-H)TPP]=2.1×10^{-6} M, [THP]=2.1×10^{-6} M, b) [Co(*p*-H)TPP]=5.0×10^{-5} M, [THP]=5.0×10^{-5} M in CH_2Cl_2 at 235 K.

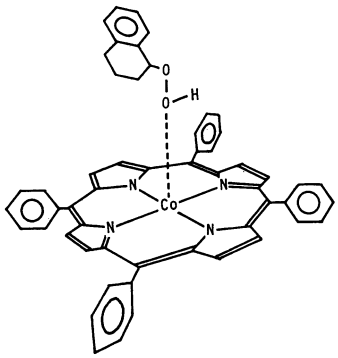

Fig. 2. Supposed structure of hydroperoxide–Co(*p*-H)-TPP complex.[24]

reaction temperatures. At 235 K, the Soret band (414 nm) of Co(*p*-H)TPP decreased with the addition of hydroperoxide, a new absorption band (427 nm) appearing. The isosbestic point at 417 nm is sharp, the decomposition reaction of hydroperoxide being negligible at this temperature. It can be assumed that the new absorption band (427 nm) results from the hydroperoxide–Co(*p*-H)TPP complex (Fig. 2). Similar spectral changes take place when pyridine or *t*-butyl alcohol is added to Co(*p*-H)TPP in line with the published data.[16,18] Absorption of the Q band (527 nm) also decreased, a new band (540 nm) appearing (Fig. 1). This spectrum is similar to that of Co(III)TPP.[21]

Rise in temperature from 250 K to 265 K gave rise to a new spectral change. A new absorption band (427 nm) decreased, accompanied by the temporary appearance of 414 nm band, giving a new absorption band (432 nm). Further rise in temperature from 265 K to 295 K made the absorption decrease and disappear.

Kinetic and Thermodynamic Data. Figure 3 shows the decay curve of the Soret band (414 nm) of

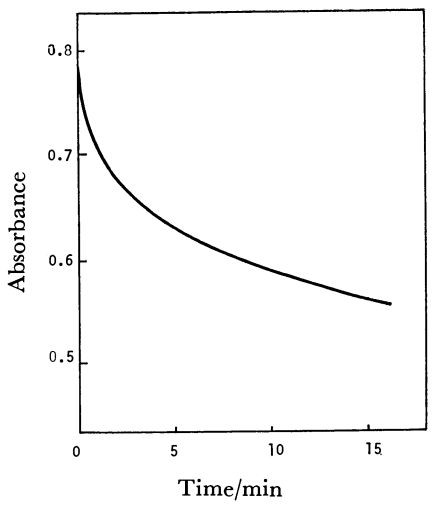

Fig. 3. Absorption decay curve of Co(*p*-H)TPP at 414 nm.
[Co(*p*-H)TPP]=2.1×10^{-6} M, [THP]=2.1×10^{-6} M, in CH_2Cl_2 at 235 K.

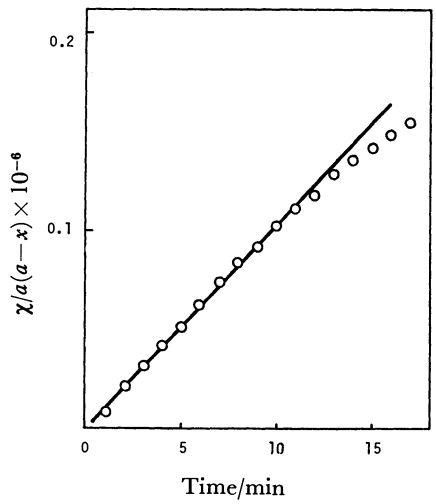

Fig. 4. Second-order plot for formation of Co(*p*-H)TPP–THP complex.
a=[Co(*p*-H)TPP]=2.1×10^{-6} M, [THP]=2.1×10^{-6} M in CH_2Cl_2 at 235 K.

Co(*p*-H)TPP caused by the addition of 1,2,3,4-tetrahydro-1-naphthyl hydroperoxide. The rate of decrease became slow, reaching an equilibrium state within 30 min after the reaction started. In the case of 1-methyl-1-phenylethyl hydroperoxide or *t*-butyl hydroperoxide, the initial rate was lower than that of 1,2,3,4-tetrahydro-1-naphthyl hydroperoxide, taking a long time to reach an equilibrium state. The results are plotted as a second-order reaction, the initial rate constant being calculated (Fig. 4). Activation energies were evaluated (Fig. 5) from the temperature dependance of the initial rate constant in the temperature range 235—245 K.

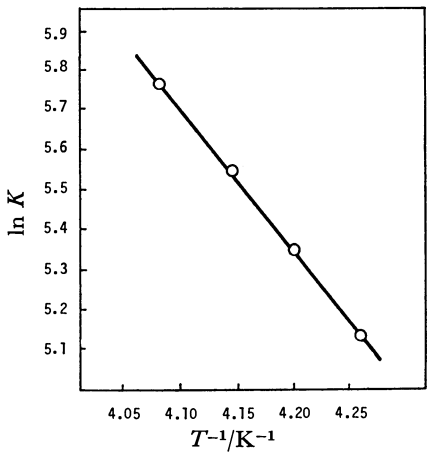

Fig. 5. Temperature dependence of rate constant for formation of Co(*p*-H)TPP–THP complex.
[Co(*p*-H)TPP]=2.1×10^{-6} M, [THP]=2.1×10^{-6} M.

The kinetic and thermodynamic data of the coordination of hydroperoxide to M(II)TPP are given in Table 1. The rate constants and equilibrium constants increased with the increase in electron donating property of substituent group of Co(*p*-X)TPP in all hydroperoxides.

Table 1. Rate constants, activation energies, activation entropies, and equilibrium constants for coordination of hydroperoxide to M(II)TPP

M(II)TPP	ROOH	k/M^{-1} s^{-1}	ΔE/kcal mol^{-1}	ΔS/cal K^{-1}	K/M^{-1}

a) Ref. 19. b) Ref. 21. c) [M(II)TPP]: [THP]=1: 1, 235 K.

Fairly good correlations are observed between the oxidation potentials[19] and the rate constants or the equilibrium constants of Co(*p*-H)TPP (Table 2). The oxidation potential of metal ion seems to be an important factor affecting the two constants. This substituent effect is similar to that found in Co(*p*-H)TPP·py+O_2⇄Co(*p*-H)TPP·py(O_2) system studied in detail by Walker *et al.*[20] In the case of NiTPP, its too large oxidation potential[21] would prevent the coordination of hydroperoxide molecules. CuTPP showed no spectral change because of difficulty for it to take the five-coordination structure as judged from its stability constant. No activity in the decomposition of hydroperoxide on NiTPP and CuTPP can be attributed to the difficulty in coordination.

The rate constants and equilibrium constants change with the kind of hydroperoxide (Table 1). The order of rate constant k is $k_{THP}>k_{CHP}>k_{BHP}$, and the order of equilibrium constant K is $K_{CHP}>K_{BHP}>K_{THP}$ in hydroperoxide–Co(*p*-X)TPP (X=OCH_3, H, Cl) systems. A comparison of the half-wave potential[22] of hydroperoxide with the rate constant or equilibrium constant is given in Table 3. Except for the case of 1,2,3,4-tetrahydro-1-naphthyl hydroperoxide having a larger k and a smaller K than those expected from its half-wave potential, the orders $k_{CHP}>k_{BHP}$ and $K_{CHP}>K_{BHP}$ can be explained by the order of half-wave potential of hydroperoxide, $E_{1/2}$(CHP)$>E_{1/2}$(BHP). The higher half-wave potential which indicates the energy level of LUMO (Lowest Unoccupied Molecular Orbital) of O–O bond in hydroperoxide[23] would give a larger rate constant or larger equilibrium constant. The steric factor is attributable to the deviation in the case of 1,2,3,4-tetrahydro-1-naphthyl hydroperoxide. A configuration of 1,2,3,4-tetrahydro-1-naphthyl hydroperoxide more favorable to Co(II) ion than that of other two hydroperoxides might bring forth a larger constant k. This is in line with the smallest activation entropy of this system. The activation energies for coordination reaction of hydroperoxide to Co(*p*-X)TPP are 7.0—7.8 kcal mol^{-1}, which is reasonable in view of the activation energy 15—25 kcal mol^{-1} of the decomposition reaction of hydroperoxide. The activation entropies are −21——25 cal K^{-1}, in line with the formation reaction hydroperoxide–Co(*p*-X)TPP complex.

Table 3. Comparison of half-wave potentials with rate constants and equilibrium constants for ROOH

ROOH	$E^{a)}_{1/2}$/V	k[b]/M^{-1} s^{-1}	K[b]/M^{-1}
BHP	−0.96	1.27×10	1.38×10^{6}
THP	−0.73	1.67×10^{2}	8.31×10^{5}
CHP	−0.68	3.20×10	2.09×10^{6}

a) Ref. 22. b) [Co(*p*-H)TPP]: [ROOH]=1: 1, 235 K.

It is difficult to obtain the rate constant and the activation energy in the decomposition reaction of 1,2,3,4-tetrahydro-1-naphthyl hydroperoxide by Co(*p*-X)TPP at a temperature above 10 °C since the reaction proceeds too fast and the catalytic activity decreases within 30 s, the colored solution of Co(*p*-X)-TPP preventing accurate iodometry.

The authors thank Mr. H. Ogata for the synthesis of CoTPP complexes.

Photochemical Transformations of 1,2-Diketones and Benzhydrylamine

Kailash Nath MEHROTRA and Ganesh Prasad PANDEY

Department of Chemistry, Banaras Hindu University, Varanasi 221005, India

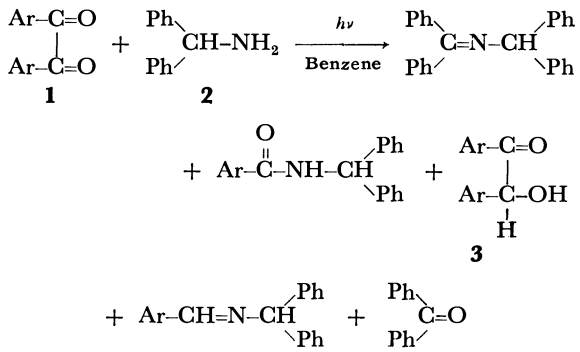
(Received April 28, 1979)

Photolysis of a mixture of substituted 1,2-diketones and benzhydrylamine (in 1:2 mole ratio) in benzene gave *N*-benzhydrylidenebenzhydrylamine, *N*-(diarylmethyl)benzamides, acyloins (**3**), *N*-(arylmethylene)benzhydrylamines, and benzophenone separated by fractional crystallization and column chromatography. The products have been characterised by analytical and spectral (IR, UV, and NMR) data and the structural assignments confirmed by the comparison (IR spectra and undepressed mixed mp) with authentic samples. Acyloins (**3**) are precursors for *N*-(diarylmethyl)benzamides and *N*-(arylmethylene)benzhydrylamines. A tentative mechanistic route for the formation of products has been suggested.

Irradiation of aromatic ketones and aliphatic amines (primary as well as secondary) in nonpolar media leads to a high yield of pinacols and substituted imines initiated by hydrogen abstraction from amine by the triplet-excited state of the ketone.[1] It has been observed that the presence of a hydrogen atom to the heteroatom in amine enhances its reactivity towards photoreduction of ketones.[2] Hydrogen abstraction by an excited state of benzil from 2-propanol and subsequent α-cleavage has been known to form benzoin, 2,3-dihydroxy-1,2,3,4-tetraphenyl-1,4-butanedione, small amount of benzoic acid, benzaldehyde, α-benzoylbenzylbenzoate, and 1,2-dibenzoyl-1,2-diphenylethylene dibenzoate.[3] Irradiation of benzil in butylamine has been reported to give *N*-butylbenzamide, deoxybenzoin, *dl* and *meso* forms of 1,2-dibenzyl-1,2-diphenyl-1,2-ethanediol and *N*-butylidine-2-butylamine.[4] In the present paper we describe the isolation of *N*-benzhydrylidenebenzhydrylamine, *N*-(diarylmethyl)benzamides, acyloins (**3**), *N*-(arylmethylene)benzhydrylamines, and benzophenone from the irradiation of 1,2-diketones and benzhydrylamine in benzene with UV light. The formation of *N*-(diarylmethyl)benzamides and *N*-(arylmethylene)-benzhydrylamines has been shown to occur through acyloins.

Results and Discussion

Irradiation of benzil (**1a**) and benzhydrylamine (**2**), in 1:2 mole ratio, in thiophene free benzene under nitrogen atmosphere by UV light for 32 h gave *N*-benzhydrylidenebenzhydrylamine, *N*-benzhydrylbenzamide, benzoin, *N*-benzylidenebenzhydrylamine, and benzophenone. These products were separated by fractional crystallization and column chromatography. The irradiated solution gave a positive Nessler's spot test for the presence of ammonia.[5] Similar results were obtained on irradiation (21—48 h) of a mixture of other diketones (**1b—d**) and benzhydrylamine. In each case the time of irradiation for complete disappearance of diketone (TLC) has been found to depend on the nature of substituents on the phenyl rings of the diketone (Table 1). It has been observed that the irradiation time increased and total yields of the products decreased as the diketone (**1**) was changed from **a** to **b** to **c**. The excited state reactivity of the diketones has been known to decrease with the presence of electron-donating groups on the *para* position of the phenyl rings of benzil,[6] the order of reactivity, H>CH_3>OCH_3, is in agreement with the observed behaviour of the diketones **1a—c** (Table 1). The reaction can be shown as



These products were not formed when a mixture of benzil and benzhydrylamine in benzene was heated to reflux for 24 h confirming the photochemical nature of the above reaction.

Irradiation of a mixture of benzoin and benzhydryl-

TABLE 1. PRODUCTS DISTRIBUTION OBTAINED ON IRRADIATION OF 1,2-DIKETONES AND BENZHYDRYLAMINE (in 1:2 mole ratio)

1,2-Diketones	Ar	Time of Irradiation / h	Ph(Ph)C=N-CH(Ph)Ph yield/%	Ar-C(=O)-NH-CH(Ph)Ph yield/%	Ph(Ph)C=O yield/%	Ar-CH=N-CH(Ph)Ph yield/%	Ar-CH(OH)-C(=O)-Ar yield/%
1a	C_6H_5	32	34	28	7	9	5
1b	C_6H_4·CH_3-*p*	36	30	19	10	9	4
1c	C_6H_4·OCH_3-*p*	48	21	15	8	11	6
1d		21	16	8	—	6	a)

a) Could not be isolated but its presence was detected by TLC.

amine (in 1 : 2 mole ratio) in benzene for 21 h in a similar manner as described above gave *N*-benzhydrylbenzamide and *N*-benzylidenebenzhydrylamine. This observation supports the view that acyloins (**3**) could be intermediates in the formation of *N*-(diarylmethyl)-benzamides and *N*-(arylmethylene)benzhydrylamines from the irradiation of diketones **1a—d**.

The photoreaction is initiated by an abstraction of a hydrogen α to the amino group in benzhydrylamine by an excited triplet state of the diketone leading to the α-aroyl-α-hydroxybenzyl radical (**a**) and α-aminobenzhydryl radical (**b**). This step is similar to the one given in the photoreduction of benzil in 2-propanol[3] and also in the photoreduction of benzophenone in primary amines[1,2] in which the initial step involves a hydrogen atom abstraction.

$$Ph_2C{=}O^{*3} + RR'CHNH_2 \longrightarrow Ph_2\dot{C}OH + RR\dot{C}NH_2$$

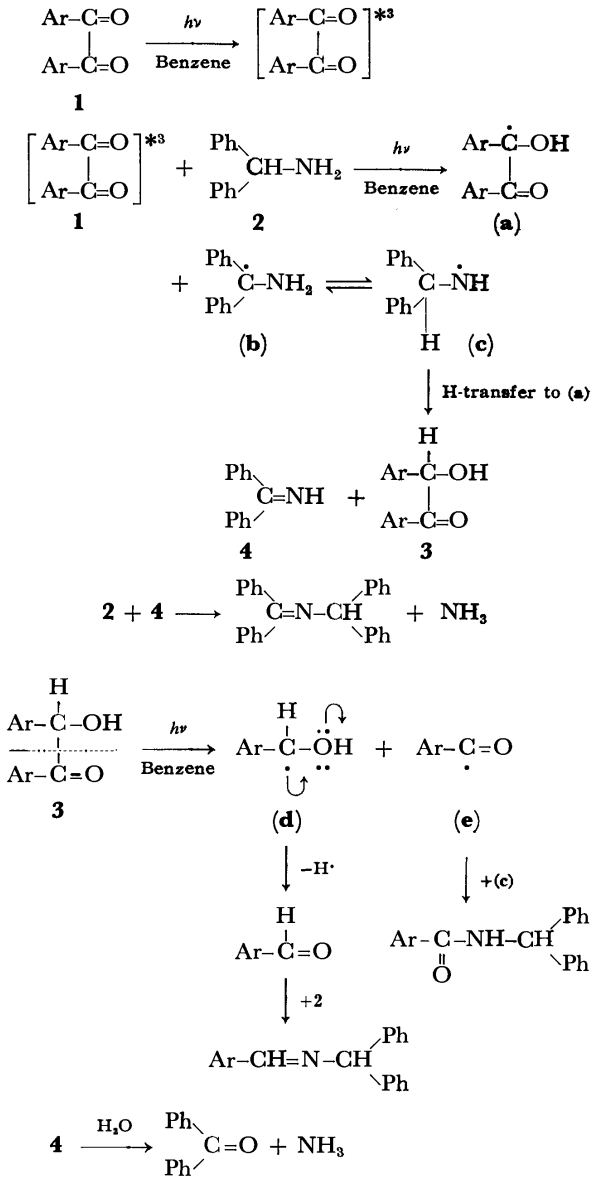
In deuterated amines, where electron release is more efficient, an electron transfer has been suggested to occur in the initial step.[2]

$$Ph_2C{=}O^{*3} + R_2CHND_2 \longrightarrow [Ph_2\dot{C}{-}O^- \quad R_2\overset{+}{C}H\dot{N}D_2]$$

Such electron transfer initiation has also been known to occur in photoreduction of aromatic ketones in tertiary amines.[7] Hydrogen abstraction by one of the carbonyl groups in 1,2-diketones[6] has been known to occur through an excited triplet state *via* a $^3(n\rightarrow\pi^*)$ excitation.[8] It has been observed that the presence of a hydrogen atom α to the amino group increases the hydrogen donating capability of amines in the photoreduction of ketones.[2] Rearrangement of **b** to **c** and subsequent hydrogen transfer to **a** may lead to the formation of acyloin (**3**) and diphenylmethanimine (**4**). The reaction between **4** and benzhydrylamine (**2**) may give rise to *N*-benzhydrylidenebenzhydrylamine and ammonia in a manner already reported.[9] The formation of *N*-benzhydrylidenebenzhydrylamine in each case, irrespective of the nature of the aryl group present in 1,2-diketones, strongly suggests that it must be arising from benzhydrylamine only which is in agreement with the step given in Scheme. The proposed Scheme also explains the requirement of two moles of benzhydrylamine per mole of the diketone in the reaction.

A photolytic carbon-carbon bond cleavage in acyloin (**3**) may give rise to radicals **d** and **e** in an analogous manner as proposed in the case of irradiation of benzoin ethers.[10] Recombination of the radicals **c** and **e** may form *N*-(diarylmethyl)benzamides and loss of hydrogen from radical **d** may lead to aldehydes which on reaction with benzhydrylamine form *N*-(arylmethylene)benzhydrylamines. Irradiation of benzoin with UV light has been known to give benzaldehyde.[11] Hydrolysis of diphenylmethanimine (**4**) may result in the formation of benzophenone and ammonia.

On the basis of the above observations a tentative mechanistic route can be shown as follows:



Experimental

General. Melting points have been determined in capillaries on Buchi melting point apparatus and are uncorrected. The IR spectra were measured in Nujol mull on a Perkin-Elmer 720 spectrophotometer and the UV in ethanol on a Cary-14 spectrophotometer. The NMR spectra were recorded on a Varian A-60 Hz spectrometer in $CDCl_3$ with TMS as the internal standard.

Materials. The 1,2-diketones were obtained from Ega Chemie, Germany and benzhydrylamine was prepared according to the reported method.[12]

General Irradiation Procedure. A solution containing 1,2-diketones (0.005 mol) and benzhydrylamine (0.010 mol) in 350 ml of benzene (thiophene free) was irradiated with UV light from a 200 W Hanovia lamp. Pre-purified nitrogen was bubbled into the solution prior to irradiation and a slow stream was continued during the course of photolysis. The progress of reaction was monitored by TLC. The irradiated solutions gave a positive Nessler's test for ammonia.[5] Irradiation was discontinued when the starting diketone had appreciably diminished. The solvent was evaporated under reduced pressure. The products were separated by fractional crystallization and column chromatography and were characterised on the basis of analytical and spectral (IR, UV, and NMR) data. The structural assignments were further confirmed by the comparison (IR spectrum and mixed mp) with authentic samples.

*Irradiation of Benzil (**1a**) and Benzhydrylamine.* Irradiation of a mixture of benzil and benzhydrylamine in benzene for 32 h and evaporation of the solvent gave a thick pasty mass which on treatment with ethanol afforded a white crystalline solid (34%), identified as *N*-benzhydrylidene benzhydrylamine, mp and mixed mp 149—151 °C (lit,[13] mp 152 °C); UV (EtOH, nm): 252; IR (Nujol, cm^{-1}): 1620 ($\nu_{C=N}$); NMR ($CDCl_3$, δ ppm): 5.60 (s, 1H, $CHPh_2$), 7.35 (m, 16H, arom.), and 7.90 (m, 4H, arom.). Found: C, 90.01; H, 6.20; N, 3.89%. Calcd for $C_{26}H_{21}N$: C, 89.91; H, 6.05; N, 4.03%.

Fractional crystallization of the mother liquor from benzene–hexane (1: 1) gave 28% of white needle shaped crystals which were shown to be *N*-benzhydrylbenzamide, mp and mixed mp 169—172 °C (lit,[14] mp 172—174 °C). UV (EtOH): end absorption; IR (Nujol, cm^{-1}): 3300 (ν_{NH}), 1640 ($\nu_{C=O}$); NMR ($CDCl_3$, δ ppm): 1.65 (bs, 1H, NH, exchangeable on deuteration), 6.39 and 6.53 (d, 1H, J=8.4 Hz, $CHPh_2$, doublet due to spin-spin coupling with NH[15]), 7.41 (m, 13H, arom.), and 7.75 (m, 2H, arom.). Found: C, 83.24; H, 5.51; N, 5.07%. Calcd for $C_{20}H_{17}NO$: C, 83.62; H, 5.92; N, 4.87%. The IR spectrum was superimposable with that of an authentic sample.[16]

The mother liquor was concentrated and subjected to column chromatography over neutral alumina (60 g, 2.5×45 cm) to give the following products by using hexane, hexane–benzene (7: 3), and hexane–benzene (1: 1) as eluants:

(*i*). Benzophenone (7%), identified as 2,4-dinitrophenylhydrazone derivative mp 229 °C.

(*ii*). *N*-Benzylidenebenzhydrylamine (9%), mp and mixed mp 98—99 °C (lit,[17] mp 98—100 °C). UV (EtOH, nm): 252; IR (Nujol, cm^{-1}): 1620 ($\nu_{C=N}$); NMR ($CDCl_3$, δ ppm): 5.58 (s, 1H, $CHPh_2$), 7.40 (m, 13H, arom.), 7.90 (m, 2H, arom.), and 8.34 (s, 1H, formyl). Found: C, 88.58; H, 6.35; N, 4.98%. Calcd for $C_{20}H_{17}N$: C, 88.56; H, 6.27; N, 5.17%.

(*iii*). Benzoin (5%), mp and mixed mp 136—138 °C. The IR spectrum was superimposable with that of an authentic sample.[18]

*Irradiation of 4,4′-Dimethylbenzil (**1b**) and Benzhydrylamine.* Irradiation of a mixture of 4,4′-dimethylbenzil (**1b**) and benzhydrylamine in benzene for 36 h and similar work up as described above gave the following products:

(*i*). *N*-Benzhydrylidenebenzhydrylamine (30%), mp and mixed mp 149—151 °C.

(*ii*). *N*-Benzhydryl-4-methylbenzamide (19%), mp and mixed mp 182—184 °C (lit,[14] mp 183—184 °C). UV (EtOH): end absorption; IR (Nujol, cm^{-1}): 3300 (ν_{NH}), 1640 ($\nu_{C=O}$); NMR ($CDCl_3$, δ ppm): 1.59 (bs, 1H, NH, exchangeable on deuteration), 2.30 (s, 3H, CH_3), 6.45 and 6.31 (d, 1H, J= 8.4 Hz, doublet due to spin-spin coupling with NH[15]), 7.26 (m, 12H, arom.), and 7.68 (m, 2H, arom.). Found: C, 83.78; H, 6.46; N, 4.72%. Calcd for $C_{21}H_{19}NO$: C, 83.85; H, 6.31; N, 4.65%. The IR spectrum was superimposable with that of an authentic sample.[16]

(*iii*). Benzophenone (10%), identified as 2,4-dinitrophenylhydrazone derivative, mp 229 °C.

(*iv*). *N*-(4-Methylbenzylidene)benzhydrylamine (9%), mp and mixed mp 103—105 °C. UV (EtOH, nm): 254; IR (Nujol, cm^{-1}): 1620 ($\nu_{C=N}$); NMR ($CDCl_3$, δ ppm): 2.40 (s, 3H, CH_3), 5.60 (s, 1H, $CHPh_2$), 7.38 (m, 12H, arom.), 7.80 (m, 2H, arom.), and 8.50 (s, 1H, formyl). Found: C, 88.52; H, 6.82; N, 5.01%. Calcd for $C_{21}H_{19}N$: C, 88.42; H, 6.66; N, 4.92%.

(*v*). 4,4′-Dimethylbenzoin (4%), mp and mixed mp 85—86 °C. The IR spectrum was superimposable with that of an authentic sample.[18]

*Irradiation of 4,4′-Dimethoxybenzil (**1c**) and Benzhydrylamine.* Irradiation of a mixture of 4,4′-dimethoxybenzil and benzhydrylamine in benzene for 48 h and separation of the components in a similar manner as described above gave the following products:

(*i*). *N*-Benzhydrylidenebenzhydrylamine (21%), mp and mixed mp 149—151 °C.

(*ii*). *N*-Benzhydryl-4-methoxybenzamide (15%), mp and mixed mp 198—199 °C (lit,[14] mp 198—200 °C). UV (EtOH, nm): 250; IR (Nujol, cm^{-1}): 3300 (ν_{NH}), 1640 ($\nu_{C=O}$); NMR ($CDCl_3$, δ ppm): 1.83 (bs, 1H, NH, exchangeable on deuteration), 3.76 (s, 3H, OCH_3), 6.53 and 6.39 (d, 1H, J= 8.4 Hz, $CHPh_2$, doublet due to spin-spin coupling with NH[15]), 6.83 (A_2B_2, 2H, J=9 Hz, arom.), 7.28 (m, 10H, arom.), and 7.75 (A_2B_2, 2H, J=9 Hz, arom.). Found: C, 79.43; H, 6.18; N, 4.51%. Calcd for $C_{21}H_{17}NO_2$: C, 79.49; H, 5.99; N, 4.41%. The IR spectrum was identical with that of an authentic sample.[16]

(*iii*). Benzophenone (8%), identified as 2,4-dinitrophenylhydrazone derivative mp 229 °C.

(*iv*). *N*-(4-Methoxybenzylidene)benzhydrylamine (11%), mp and mixed mp 108—110 °C (lit,[17] mp 110 °C). UV (EtOH, nm): 272; IR (Nujol, cm^{-1}): 1620 ($\nu_{C=N}$); NMR ($CDCl_3$, δ ppm): 3.70 (s, 3H, OCH_3), 5.43 (s, 1H, $CHPh_2$), 6.80 (A_2B_2, 2H, J=9 Hz, arom.), 7.23 (m, 10H, arom.), 7.70 (A_2B_2, 2H, J=9 Hz, arom.), and 8.27 (s, 1H, formyl). Found: C, 84.01; H, 6.52; N, 4.58%. Calcd for $C_{21}H_{19}NO$: C, 83.85; H, 6.30; N, 4.64%.

(*v*). 4,4′-Dimethoxybenzoin (6%), mp and mixed mp 115—117 °C. The IR spectrum was superimposable with that of an authentic sample.[18]

*Irradiation of 2,2′-Furil (**1d**) and Benzhydrylamine.* Irradiation of a solution containing 2,2′-furil and benzhydrylamine in benzene for 21 h and separation on a column packed with alumina gave the following products:

(*i*). *N*-Benzhydrylidenebenzhydrylamine (16%), mp and mixed mp 149—151 °C.

(*ii*). *N*-Benzhydryl-2-furamide (8%), mp and mixed mp 161—162 °C. UV (EtOH): end absorption; IR (Nujol, cm^{-1}): 3290 (ν_{NH}), 1650 ($\nu_{C=O}$); NMR ($CDCl_3$, δ ppm): 1.82 (bs, 1H, NH, exchangeable), 6.30 and 6.16 (d, 1H, J=8.4 Hz, $CHPh_2$[15]), and 6.25 (m, 13H, aromatic and 2-furoic). Found: C, 78.38; H, 5.32; N, 5.20%. Calcd for $C_{18}H_{15}NO_2$: C, 77.97; H, 5.41; N, 5.05%. The IR spectrum was superimposable with that of an authentic sample.[16]

(*iii*). *N*-(2-Furfurylidene)benzhydrylamine (6%), mp and mixed mp 104—106 °C. UV (EtOH, nm): 272; IR (Nujol, cm^{-1}): 1640 ($\nu_{C=O}$); NMR ($CDCl_3$, δ ppm): 5.58 (s, 1H, $CHPh_2$), 6.43 (m, 1H, furan CH_a), 6.46 (d, 1H, J=3 Hz, furan CH_b), 7.33 (m, 11H, 10 arom+1 furan CH_c), and 8.20 (s, 1H, formyl). Found: C, 83.03; H, 5.37; N, 5.45%. Calcd for $C_{18}H_{15}NO$: C, 82.75; H, 5.74; N, 5.36%. The IR spectrum was superimposable with that of an authentic sample prepared by following the method of Michaelis.[17]

In this case 2,2′-furoin could not be isolated although its presence was detected on TLC.

Irradiation of Benzoin and Benzhydrylamine. Irradiation of a mixture of benzoin and benzhydrylamine in a similar manner as described earlier gave *N*-benzhydrylbenzamide (28%) and *N*-benzylidenebenzhydrylamine (21%) identified on the basis of comparison (IR spectra and undepressed mixed mp) with authentic samples.

We are greatful to the University Grants Commission, New Delhi for financial support and to Professor O. P. Malhotra for encouragement and facilities.

Fluorination with Xenon Difluoride. XXII. The Role of Catalyst and Temperature on the Fluorination of Norbornene and Norbornadiene

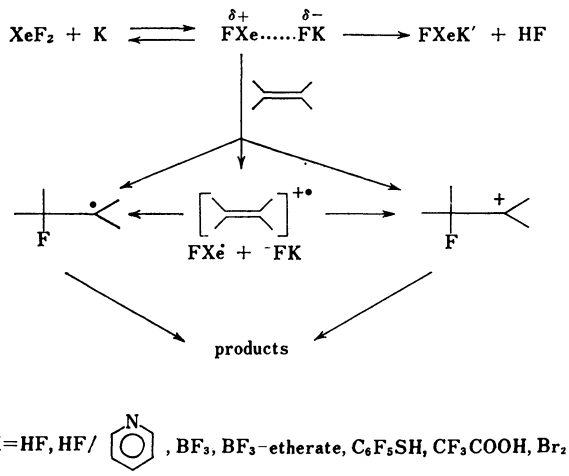
Ana GREGORČIČ and Marko ZUPAN*

Department of Chemistry and "Jožef Stefan" Institute, University of Ljubljana, Ljubljana, Yugoslavia

(Received June 20, 1979)

The reaction of norbornene was used as a mechanistic probe to elucidate the effect of catalyst (HF, HF–pyridine, BF_3, BF_3–etherate, and pentafluorothiophenol) and temperature (from −61 °C to 25 °C) on liquid phase fluorination with xenon difluoride, resulting in the formation of seven products, depending on the reaction conditions: fluoronortricyclane, 2-*endo*-3-*exo*-difluoronorbornane, 2-*exo*-7-*anti*-difluoronorbornane, 2-*endo*-5-*exo*-difluoronorbornane, 2-*exo*-5-*exo*-difluoronorbornane, 2-*exo*-3-*exo*-difluoronorbornane, and 2-*exo*-7-*syn*-difluoronorbornane. The catalyst has a significant effect on the reaction pathways, boron trifluoride etherate favouring the formation of 2-*endo*-5-*exo*- and 2-*exo*-5-*exo*-difluoronorbornane, while pentafluorothiophenol favoured the formation of fluoronortricyclane. The catalyst and temperature has much less effect on the reaction pathways in the case of norbornadiene, four products being formed: fluoronortricyclane, 3-*endo*-5-*exo*-difluoronortricyclane, 3-*exo*-5-*exo*-difluoronortricyclane, and 2-*exo*-7-*syn*-difluoro-5-norbornene. Pentafluorothiophenol as a catalyst, when used in a greater amount, favours the formation of fluoronortricyclane.

Xenon difluoride is a mild fluorinating agent for the fluorination of alkenes, acetylenes, aromatic and heteroaromatic compounds.[1] The mechanism of fluorine addition to olefins with xenon difluoride depends on structure of the olefin, the catalyst used, solvent polarity, and temperature. The formation of β-fluorocarbonium ions, free radical intermediates or ion radicals has been suggested (Scheme 1). The following substrates are convenient catalysts for the fluorination of olefins: hydrogen fluoride,[2] HF–pyridine,[3] trifluoroacetic acid,[4] bromine,[5] and boron trifluoride etherate.[6]

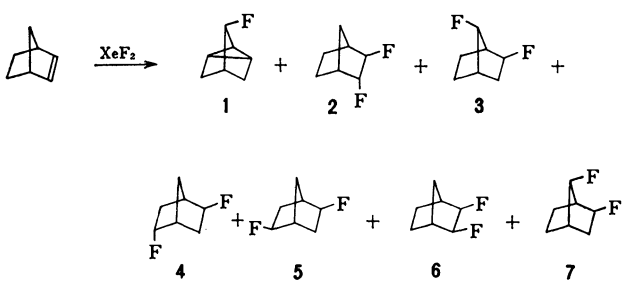


Scheme 1.

Recently it was found that boron trifluoride[7] is a convenient catalyst for the fluorination of less reactive organic compounds, while in the case of more sensitive organic compounds pentafluorothiophenol proved to be preferable to hydrogen fluoride, which causes acid catalyzed decomposition. The fluorination of norbornene with xenon difluoride in the presence of HF resulted in the formation of seven products. Besides the formation of carbonium ions free radical intermediates have also been observed.[8] Shackelford found that low temperature fluorination of norbornene, catalyzed by boron trifluoride etherate, gives only three products.[9] The reaction of norbornene has been used several times as a mechanistic device to elucidate the mechanism and stereochemistry of diverse reactions.[10] We have utilized the sensitivity of the reactions of norbornene to the reaction conditions for studying the effect of catalyst and temperature on the fluorination with xenon difluoride. The effect of catalyst and temperature on the fluorination of norbornadiene has also been studied.

Results and Discussion

The reaction of norbornene with xenon difluoride in dichloromethane at various temperatures and in the presence of various catalysts resulted in the formation of seven products (Scheme 2). Analysis of the reaction mixture by GLC gave the relative yields given in Table 1. The products of reaction were collected by preparative GLC. The structures of the compounds were determined on the basis of their mass, ^{19}F and ^{1}H NMR spectra and are in agreement with those reported.[8] The effect of catalysts, *i.e.* hydrogen fluoride, hydrogen fluoride–pyridine, boron trifluoride etherate, boron trifluoride, and pentafluorothiophenol, is most evident from the formation of fluoronortricyclane (**1**), 2-*endo*-3-*exo*-difluoronorbornane (**2**), 2-*exo*-3-*exo*-difluoronorbornane (**6**), and 2-*exo*-7-*syn*-difluoronorbornane (**7**).



Scheme 2.

We have established that the formation of products **2** and **6** can partly be ascribed to free radical intermediates. The great selectivity in the formation of

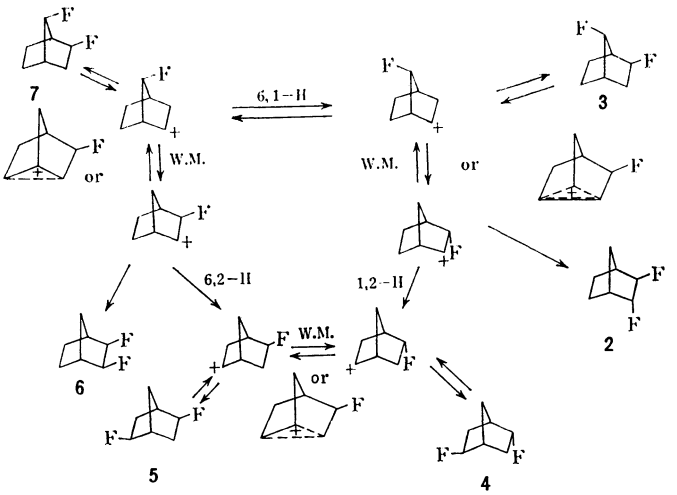
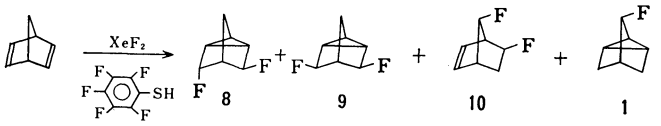
2-*endo*-5-*exo*-difluoronorbornane (**4**), and 2-*exo*-5-*exo*-difluoronorbornane (**5**), pointed out by Shackelford,[9] arises from secondary isomerisation of 2-*exo*-7-*anti*-difluoronorbornane (**3**). In order to clarify the primary formed products in the BF_3–etherate catalyzed reaction, we made a 10 min experiment at −61 °C and confirmed that five products are formed. Besides difluoronorbornanes **3**, **4**, and **5**, fluoronortricyclane (**1**) and 2-*exo*-7-*syn*-difluoronorbornane (**7**) were formed as well. The experiment performed under the same conditions as reported[9] (temperature from −61 °C to +25 °C) resulted in a similar product distribution, while small amounts of fluoronortricyclane (**1**) and 2-*exo*-7-*syn*-difluoronorbornane (**7**) were also detected. The effect of temperature on the reaction pathways in BF_3–etherate catalyzed fluoronations is given in Table 1.

BF_3-catalyzed fluorination of norbornene at room temperature resulted in the formation of seven products. The formation of fluoronortricyclane as the major prodyct in pentafluorothiophenol catalyzed reactions (Table 1) stimulated us to study the effect of the amount of catalyst on product distribution (Table 2). The increase in the amount of pentafluorothiophenol is reflected in the increased formation of fluoronortricyclane (**1**), while the experiment with equimolar amounts of catalyst and norbornene resulted in only trace amounts of difluoronorbornanes **3**, **4**, and **5**.

The formation of seven products resulting from the fluorination of norbornene under various conditions (catalyst, temperature) can be mainly ascribed to the intermediately formed β-fluorocarbonium ion, which further undergoes Wagner-Meerwein rearrangements and hydride shifts (Scheme **3**). The mechanism involves the irreversibile hydride shifts 6,2-H and 1,2-H, based on the observation of isomerization of the products in dichloromethane in the presence of hydrogen fluoride, where similar carbonium ions are formed.[8] The formation of 2-*exo*-3-*endo*-difluoronorbornane (**2**) and 2-*exo*-3-*exo*-difluoronorbornane (**6**) formed in room temperature fluorination catalyzed by BF_3–etherate and BF_3, can be partly ascribed to the formation of free



Scheme 3.



Scheme 4.

Table 3. Effects of catalyst and temperature on the addition of XeF_2 to norbornadiene

Catalyst	Temp °C	Time min	8	9	10

radical intermediates (Scheme 1). The effect of catalyst (HF, HF–pyridine, BF_3–etherate, BF_3, pentafluorothiophenol) on the reaction pathways is reflected most significantly in the amount of fluoronortricyclane formed.

The fluorination of norbornadiene resulted in the formation of four products, depending on the catalyst used (Scheme 4). It is evident that variation of catalyst, *i.e.* HF, HF–pyridine, BF_3–etherate, and temperature from −61 °C to 25 °C, has much less effect on the reaction pathways than in the case of norbornene (Table 3). However, in the pentafluorothiophenol catalyzed reaction, fluoronortricyclane (**1**) was formed besides[8] 3-*endo*-5-*exo*-difluoronortricyclane (**8**), 3-*exo*-5-*exo*-difluoronortricyclane (**9**), and 2-*exo*-7-*syn*-difluoronorbornene-5 (**10**). The effect of the amount of catalyst is shown diagramatically in Fig. 1. As in the case of norbornene, fluoronortricyclane became the main product when greater amounts of catalyst were used. An explanation for the formation of four products in the pentafluorothiophenol catalyzed reaction is given in Scheme 5. In the first step, polarization of XeF_2 by pentafluorothiophenol is suggested, which is then followed by the formation of two β-fluorocarbonium

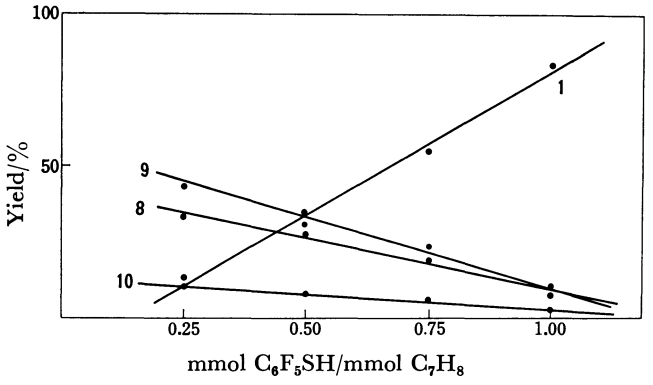

Fig. 1. Effect of the amount of pentafluorothiophenol on product distribution in fluorination of norbornadiene.

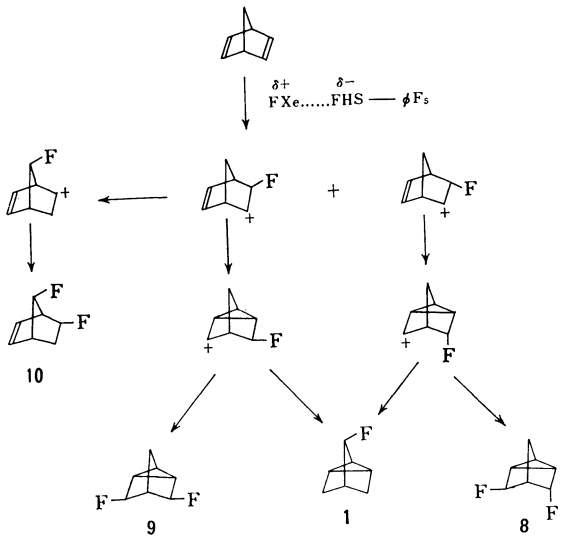

Scheme 5.

ions, giving two fluoronortricyclyl cations. The preferential *exo* attack[11] of the fluorine anion leads to the formation of difluoronortricyclane products (**8**, **9**), while reaction with pentafluorothiophenol results in the formation of fluoronortricyclane (**1**). In halofluorinations[11] of norbornadiene only the primary formed β-*exo*-fluorocarbonium ion undergoes Wagner-Meerwein rearrangement, leading to the formation of 2-*exo*-7-*syn*-5-norbornene (**10**).

Experimental

IR spectra were recorded with a Perkin Elmer 257 spectrometer and ^1H and ^{19}F NMR spectra with a JEOL JNM PS-100 from CCl_4 solution with Me_4Si and CCl_3F as internal references. Mass spectra were taken on a CEC 21-110 spectrometer. Gas-liquid partition chromatography was carried out on a Varian Aerograph Model 1800.

Materials. Norbornene, norbornadiene and pentafluorothiophenol were purified before use. Hydrogen fluoride and boron trifluoride of Fluka Purum quality were used without further purification. Dichloromethane and diethyl ether were purified and stored over molecular sieves.[12] Xenon difluoride was prepared by a photosynthetic method,[13] the purity being higher than 99.5%.

Addition and Isolation Procedures. To a solution of 1 mmol of olefin in dichloromethane (2 ml) in a Kel-F vessel was added 1 mmol of xenon difluoride at an appropriate temperature, the corresponding catalyst (HF, BF_3, BF_3–etherate, or pentafluorothiophenol) being introduced into the reaction mixture with stirring. The reactions were stopped by addition of dichloromethane (15 ml) and 10 ml of 5% $NaHCO_3$. The reaction mixture was washed with water, and dried over anhydrous sodium sulfate. The solvent was evaporated *in vacuo*. The crude reaction mixtures were analyzed by GLC, the products being isolated by preparative GLC. The

structures of the products were established by a comparison of their spectroscopic data with those published.[8] Each experiment was repeated several times, the average data being given in the tables; relative yields were determined by GLC (DDP-10%, Chromosorb Regular 100, 45—120 °C in the case of norbornene reaction, and Carbowax 20 M 25%, Varaport 30 70/80, 130 °C for norbornadiene). The maximum error between parallel experiments was ±1.5%.

We thank Prof. J. Slivnik for the xenon difluoride. Financial assistance of the Research Community of Slovenia is acknowledged.

(Received October 4, 1979)

Seven different crystalline bis(dienyl)magnesium·TMEDA complexes of open chain or cyclic structure were prepared by metal exchange reaction of corresponding potassium dienides. They are fluxional in solution due to the rapid 1,3-rearrangement. Terminally σ-bonded *trans* or (*E*) structure exists primarily in the open chain complexes while centrally σ-bonded *cis* structure in cyclic dienylmagnesium·TMEDA complexes. The former gave 1,3-dienes exclusively but the latter gave 1,4-dienes upon hydrolysis. Molecular structure of bis(2,4-dimethyl-2,4-pentadienyl)magnesium determined by X-ray crystallography showed that it has terminally σ-bonded structure. Addition of dienylmagnesium compounds to acetone followed by hydrolysis gave 1,4-diene derivatives regioselectively but that to diisopropyl ketone gave 1,3-diene derivatives selectively. Unsaturated alcohols with an elongated carbon chain were synthesized by thermal cracking of cyclic ether complexes. 1,3,7-Trienes can be obtained selectively by reaction of appropriate allyl halides in the presence of CuCl catalyst and regioselective dienylation occurred by using $TiCl_2(\eta^5\text{-}C_5H_5)_2$ as catalyst.

Allylic magnesium compounds have been utilized as an agent for introduction of olefin groups into various organic groups[1] or as a component of polymerization catalysts.[2] Stereoselective or regioselective introduction of the dienyl moiety into organic groups is also attractive especially for the synthesis of terpenoids or biologically active substances. Organic synthesis using dienylmetal compounds have been little developed due to the lack of suitable preparation methods though some diene syntheses catalyzed by transition metal compounds[3] and by Grignard type reaction[4] are recently reported. We present here a widely applicable novel route for the preparation of pure bis(dienyl)magnesium compounds, their structures, and some applications for organic synthesis. Bis(dienyl)magnesium compounds of five different linear dienes and of two cyclic dienes were prepared by transmetalation of dienyl anions with magnesium halides. All of these were isolated for the first time as crystals of *N,N,N',N'*-tetramethylethylenediamine (TMEDA) complexes. These dienylmagnesium compounds are fluxional in solution and their simple averaged ^{1}H-NMR spectra resemble well those of corresponding dienyl anions. Hence the fluxional structure is discussed in relation to the conformation[5] of the dienyl anions whose conformational stability was recently treated by extended Hückel MO calculations.[6]

Results and Discussion

Isolation of Crystalline Dienylmagnesium Compounds. Series of bis(dienyl)magnesium compounds and Grignard type dienylmagnesium halides were prepared by the metal exchange reaction. Bis(2,4-pentadienyl)-magnesium was synthesized by the 2:1 reaction of potassium pentadienide[7] with anhydrous magnesium halide in THF in 85—95% yield and was isolated as pure crystals of TMEDA complex **1**. Deuteriolysis of **1** gave two moles of pentadiene-1-*d* or -3-*d* and one mole of TMEDA as evidenced by GC of the resulting solution. Grignard type pentadienylmagnesium bromide can also be prepared by the 1:1 reaction of potassium

$$2\,C_5H_7K + MgX \xrightarrow{THF} (C_5H_7)_2Mg\cdot 2\,THF$$
$$\xrightarrow{TMEDA} (C_5H_7)_2Mg\cdot TMEDA$$
1

pentadienide with magnesium bromide. In the similar manner, TMEDA complexes of bis(2,4-hexadienyl)-magnesium **2** and hexadienylmagnesium bromide were prepared in 90% yield. The direct reaction of magnesium with 1-bromo-2,4-hexadiene in THF gave hexadienylmagnesium bromide in only 30% yield. The formation of homo coupling products, $C_{12}H_{18}$, (70% yield) was predominant in the latter case even when 1-bromo-2,4-hexadiene was added to an excess (10 equivalent)magnesium turnings very slowly. Thus, the present method is widely applicable and superior to the known method with regard to the yield and purity. This paper mainly deals with bis(dienyl)-magnesium compounds to avoid the complex problem arising from a Schlenk equilibrium observed for Grignard reagents. Other crystalline TMEDA complexes of bis(4-methyl-2,4-pentadien-1-yl)magnesium **3**, bis(3-methyl-2,4-pentadien-1-yl)magnesium **4**, bis(2,4-dimethyl-2,4-pentadien-1-yl)magnesium **5**, bis(2,6-cycloheptadien-1-yl)magnesium **6**, and bis(2,7-cyclooctadien-1-yl)magnesium **7** were prepared in essentially the same way as described for **1**. Their chemical characterization is given in Table 1. The molecular weights determined cryoscopically in benzene showed that they are all monomeric. Based on these facts, following formulae are given for **1**—**5** and **6**—**7**.

Population at Equilibria Existed in Bis(dienyl)magnesium. Monoalkyl substituted allylic Grignard reagents are known to be present in solution predominantly as γ-alkyl substituted species,[8] although it is equilibrating with the α-alkyl substituted one by rapid 1,3-rearrangement as evidenced by NMR spectroscopy and as deduced from structures of the products obtained by hydrolysis. The *cis*/*trans* ratio of the product decreased with an increase in bulkiness of the alkyl substituent,

Equilibria for the dienylmagnesium compounds are rather complex because dienyl group has three reactive carbon atoms, C_1, C_3, and C_5. For example, following eight species are possible for the hexadienylmagnesium compounds (Scheme 1). To get the information on the configuration of the diene group and on the position at which the magnesium atom is bonded, hydrolysis of the bis(dienyl)magnesium compounds was carried out (Table 2). Compounds **1** and **4** gave 1,3-dienes primarily but the cyclic dienylmagnesium compounds **6** and **7** gave 1,4-dienes exclusively in line with hydrolysis

data of the starting dienyl anions.[7] Other magnesium compounds **2**, **3**, and **5** gave nearly equal amounts of 1,3- and 1,4-dienes, although the corresponding dienyl anions gave only 1,3-dienes.[7] Thus dienylmagnesium compounds exist as an equilibrium mixture and the alkyl substitution on the pentadienyl group influences the ratio of resulting 1,3- to 1,4-dienes. Characteristic feature of the hydrolysis of **1**, **3**, and **4** is that *trans*(or *E*)-1,3-diene was produced in preference to *cis*(or *Z*)-1,3-diene. This result sharply contrasts to the hydrolysis of the corresponding potassium dienides which gave *cis*-1,3-diene selectively. In the case of **2**, nearly equal amounts of *trans,trans*- and *trans,cis*-2,4-hexadiene were produced upon hydrolysis. Two routes are possible for the production of *trans,cis*-2,4-hexadiene (from Ib and Ig in Scheme 1) but the route *via* Ib is more plausible. If Ig is equilibrating with Ia and the *trans,cis*-isomer is formed from Ig, other isomers (*i.e.*, 1,3-hexadiene derived from Id or Ie, *cis*-1,4-hexadiene from If and *cis,cis*-2,4-hexadiene from Ih) should be produced simultaneously but those yields were negligible. *Trans* configuration of 1,4-hexadiene obtained from **2** together with the configuration of above mentioned 2,4-hexadiene supports the postulate of equilibration between Ia and Ib. In contrast to the open chain dienylmagnesium compounds, cyclic dienylmagnesium compounds **6** and **7** gave *cis,cis*-1,4-dienes exclusively, indicating the negative charge being high on the C_3 atom.

The position of equilibrium was altered by change

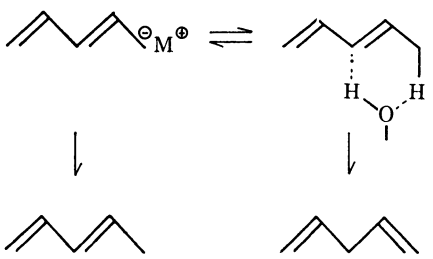
Pyrrolidine	95	5	0
Piperidine	96	4	0

a) Protonolysis was carried out in benzene at 10 °C.

of basicity of the protonolysis agents and of the ligands as shown in Table 3. The variation in distribution of the protonolysis products may be explained by considering both ionic species and covalent species which are equilibrating with each other as was described for magnesium–diene adducts;[9] *i.e.*, protonation with bases occurs at $C_1(C_5)$ position exclusively while that with acid occurs also at C_3 position. The former may be explained by the predominant cleavage of ionic Mg–C bond and the latter by the cleavage of covalent Mg–C bond presumably by a concerted mechanism. Based on this assumption, the effect of the ligand to the structure of the hydrolysis product was examined.



Coordination of strong donor such as 1,4,8,11-tetramethyl-1,4,8,11-tetraazatetradecane(tetramethylcyclam) and 1,4,7,10,13-pentaoxacyclopentadecane(15-crown-5) increases the ionic nature of the Mg–C bond and hence the dienyl group behaved similarly to the dienyl anion[7] giving 1,3-diene exclusively upon hydrolysis (Table 4). Linear polyethers bearing aromatic end groups are also being increasingly used for complexing the metal cations[10] but the polyethers shown in Table 4 have relatively little interaction with metal.

A typical example of the regioselective 1,4-diene formation is observed in hydrolysis of $K[(C_5H_7)_4Al]$ which was prepared by the 4: 1 reaction of potassium pentadienide with aluminium chloride (see experimental). It has terminaly-σ-bonded structure as evidenced by ^{1}H-NMR and it gave 1,4-pentadiene quantitatively (99%) upon hydrolysis. Thus, the complete conversion of a 1,3-diene to the thermally more unstable 1,4-diene was realized by the metalation of 1,3-diene with alkali metals, followed by the aluminium assisted reaction. Similar regioselectivity is found also for allylaluminium compounds and enediylaluminium compounds[11] obtained from endiylmagnesium compounds. The high regioselectivity should be ascribed to the larger covalent character of the Al–C bond compared to the Mg–C bond.

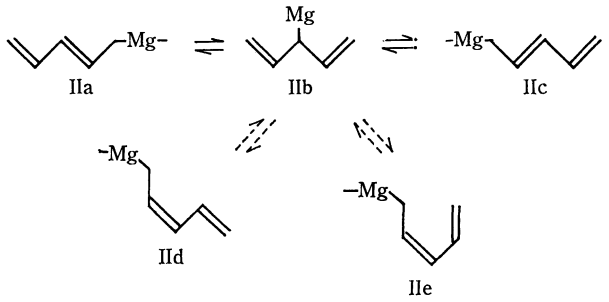
Nuclear Magnetic Resonance Studies. ^{1}H-NMR spectra of TMEDA complexes **1**—**7** are collected to know the correlation between the population at equilibrium obtained by hydrolysis and the structure of the complexes in solution (Table 5). The values of chemical shifts of **1** clearly shows that the terminally σ-bonded structure (IIa and IIc) exists predominantly,



although it is equilibrating rapidly with IId or IIe *via* IIb the presence of which was not detected on the NMR time scale, a simple averaged A_2BX type spectrum being observed. Proton-proton coupling constant J_{23} (or J_{34}), of 11.7 Hz corresponds to the J_{23} of internal olefin protons of pentadienyl anions (11.5—13.5 Hz)[12] whose conformation is W-form (*trans* configuration). The coupling constant J_{23} for dienyl anions having *cis*-configuration is known to be 7—9 Hz.[13] The *cis*/*trans* ratio of **1** calculated from the magnitude of the coupling constant (assuming *trans* $J_{H,H}$ to be 12.5 Hz and *cis* $J_{H,H}$ to be 7.0 Hz) with a linear equation is 0.21 in line with the hydrolysis data (0.22). Thus **1** was concluded to be in equilibrium between IIa and IIc keeping *trans* configuration. The rapid equilibrating structure may be correlated to the W-form of the pentadienyl anion which also shows A_2BX spectrum. Based on the coupling constant, we may conclude that sickle(IId) and U(IIe) formed compounds which result by the rotation around the C_2–C_3 or C_3–C_4 bond have minor populations at equilibrium. Assignment of the signals of **2** was made in part from a decoupled spectrum and **2** was concluded to be terminally-σ-bonded structure. The value of proton-proton coupling of J_{45}, 13.1 Hz, indicates that C_4H=C_5H group assumes *trans* structure while that of J_{23} shows C_2H=C_3H group being in equilibrium between *trans* and *cis* structure (*cis*/*trans*=0.41). The higher field shift of C_1-proton

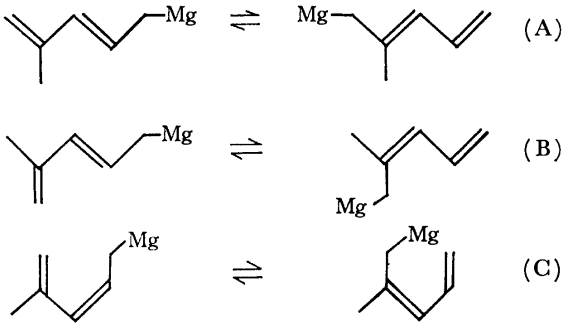
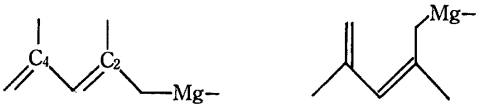
a) Calibrated using benzene as internal standard (benzene peak, 7.20 ppm downfield from external TMS). Data were collected at 38 °C in C_6D_6. b) Bis(pentadienyl)magnesium-15-crown-5 complex at −60 °C in THF-d_8.

and lower field shift of C_5-proton compared to the values of **1**, suggest that the equilibrium in Scheme 1 are shifted to Ia and Ib in line with the hydrolysis data. The spectrum of **3** was composed of both A_2BX pattern signals and broad singlet assignable to the terminal CH_2 group. Magnitude of J_{23} corresponds to that of *trans* structure. Protons attached to C_1 and C_5 carbon atoms shifted to higher field by 1.9—2.1 ppm from C_1 and C_5-protons of the starting diene showing the presence of the equilibrium. Therefore, the following equilibria (A) and/or (B) which include *trans* configuration are considered for **3**. Equilibrium (C) including *cis* configuration may exist in only minor population, if any.



Although ^{1}H-NMR data of **4** gave no information about the configuration, it is possible to conclude based on chemical shift value that **4** has also terminally σ-bonded structure primarily. Hydrolysis data of **4** (exclusive production of (*E*)-3-methyl-1,3-pentadiene) strongly suggest that rapid 1,3-rearrangement occurs in solution keeping (*E*)-structure. If the conformation changes from (*E*) to (*Z*) during the rearrangement, (*Z*)-3-methyl-1,3-pentadiene should be produced in lager amounts.

In contrast to **1**—**4**, (*Z*)-configuration is most plausible for 2,4-dimethylpentadienylmagnesium **5** due to the steric repulsion between the two methyl groups. The double bonds in (*E*)-2,4-dimethylpentadienyl group can not be coplanar since the van der Waals radius of methyl group (*ca.* 2.0 Å) is much larger than the C_2–C_4 carbon distance (1.3 Å). The X-ray analysis of bis(2,4-dimethylpentadienyl)magnesium·TMEDA **5**, actually, showed that it has (*Z*)-configuration (details are given later in this paper). Chemical shift of **5** shows that it has terminally σ-bonded structure also in solution.



5 (*E*) **5** (*Z*)

Thus, (*E*)- and (*Z*)-pentadienylmagnesium compounds of open chain structure were realized. This finding prompted further interest in comparison of electron density distribution of **5** with that of (*Z*)-pentadienylmagnesium compounds of cyclic structure. Proton-proton coupling constants, J_{23} (7.4 Hz for **6** and 6.5 Hz for **7**) show that cyclic dienylmagnesium **6** and **7** have (*Z*)-structure as expected. The increased coupling constants of J_{12} (9.7 Hz for **6** and 9.3 Hz for **7**) may be explained by the torsion around the C_1–C_2 carbon bond derived from the nonplanar structure[14)] rather than the equilibrium between *cis* and *trans* structure because *cis,trans* (or *trans,trans*) conformation is much higher in energy than the *cis,cis* conformation in a ring system,[15)] especially for 1,3-cycloheptadiene.

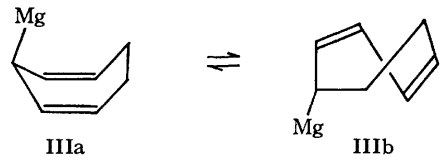
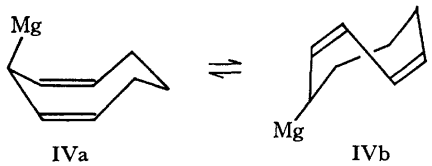
a) In ppm downfield from external TMS (calibrated using benzene peak, assumed to be 128.0 ppm). b) Measured at 38 °C in C_6D_6.

The most striking feature in the spectra of **6** (Fig. 1) and **7** is that the signals of the proton attached to the central C_3-carbon atom appeared at higher field than that of C_1 and C_5 carbon stoms. This means that centrally bonded 1,4-diene type structure exists primarilly in **6** and **7** and the electron density on the C_3 carbon atom is higher than those on the C_1 and C_5 carbon atoms. Based on these facts, structure IIIa is considered for **6** as the abundant species although it is in equilibrium with the minor species IIIb of 1,3-dienyl type structure. For the structure IIIb, twisted structure is most plausible from view of the conformational stability.[16] Stereochemistry around the Mg–C bond in IIIa and IIIb could not be determined by spectral data. Since the



IIIa IIIb

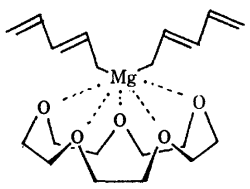


IVa IVb

boat-chair conformation[17] is known for 1,4-cyclooctadiene to be much more stable than the boat-boat conformation, structure IVa is reasonably considered as the predominant species for **7**. The minor species IVb which is equilibrating with IVa should have also nonplanar 1,3-diene structure because double bonds in 1,3-cyclooctadiene can not be coplanar.[18] Thus, a sharp contrast in electron density (or the position at which the metal bonds to a carbon atom) was observed between acyclic dienylmagnesium compound and cyclic dienylmagnesium compounds with (*Z*) structures. That is, the former has high electron density on the terminal carbon atoms while the latter on the central carbon atom.

^{13}C-NMR chemical shifts for dienyl anions have been reported[19] and provide the best measure of electron density distribution and the configuration of dienyl anions. ^{13}C-NMR spectral data of bis(dienyl)magnesium were collected in this view as shown in Table 6. Assignment of the spectrum was done with nondecoupled spectrum and by partial decoupling. The striking feature of these data is that signals of C_1 and C_5 atoms of linear dienylmagnesium compounds **1**—**5** appeared in higher field than that of C_3 atom, while those of cyclic compound **6** and **7** appeared in lower field than the signal of C_3 carbon atoms consistent to the ^{1}H-NMR data. The values of the carbon-proton coupling constant were useless for the determination of the configuration. Based on ^{13}C-NMR, ^{1}H-NMR, and hydrolysis data, it is reasonable to conclude that bis(dienyl)magnesium of open chain structure except **5** assume primarily the terminally σ-bonded (*E*) structure but those of cyclic dienyl structure assume the centrally σ-bended (*Z*) structure.

Although no appreciable change in chemical shift was observed for **1**—**7** over a 100 °C temperature (−80—50 °C) within 10 Hz and no limiting structure was realized even at −100 °C, freezing of the dynamic equilibrium was realized by coordination of a bulky ligand such as 15-crown-5 or 1,4,7,10,13,16-hexaoxacyclooctadecane (18-crown-6). ^{1}H-NMR spectrum of 1 : 1 complex of 15-crown-5 or 18-crown-6 showed A_2BX pattern at 0—30 °C but it showed the limiting structure (see Table 5) below −40 °C. Chemical shift and relative intensity of the signals observed at −60 °C are characteristic of the terminally σ-bonded structure and resemble well to that of bis(pentadienyl)zinc·TMEDA complex.[20] This is the first example of freezing out of the equilibrium of allylic type magnesium compound. The complete equilibrium shift may be attained by the steric repulsion between the crown ether and the pentadienyl group. Examination of models which permits the 1,3-rearrangement showed the following structure to be the most plausible for this complex.



Solubility of the 1 : 1 crown ether complex in benzene becomes less than 1/5 of that of THF complex due to the increase in ionic character, being different from the behavior of the usual crown ether complexes.[21] Linear polyethers had no ability to freeze out the equilibrium even at −80 °C. Coordination of strong coordinating

ligand, trimethylamine oxide, was unable to shift the equilibrium and no significant changes in chemical shift were observed over a temperature range from 50 °C to −80 °C. Thus, steric factor rather than the donor property was considered to be dominant to bring about the complete shift of the equilibrium.

X-Ray Structural Studies of Bis(2,4-dimethyl-2,4-pentadienyl)magnesium·TMEDA. The molecular structure of **5** is given in Fig. 2. Bond lengths and bond angles are listed in Table 7. The molecules has a two-fold symmetry. The magnesium atom lies on a crystallographic two-fold axis parallel to the b axis, and is tetrahedrally coordinated by the two carbon atoms from two pentadienyl groups and two nitrogen atoms from the TMEDA. The dihedral angle between planes defined by Mg, C(1), and C(1′) and Mg, N, and N′ is 83.6°.

The remarkable feature of the structure is that the 2,4-dimethylpentadienyl group is terminally σ-bonded (1-η-C_7H_{11} structure) to the magnesium atom by the C(1) atom and has the (*Z*)-configuration (U-shape) but not the (*E*)-configuration (W-shape) like that observed for **1**—**4** in solutions by ^{1}H-NMR. The Mg–C(1) distance [2.179(15) Å] is the reasonable value. The Mg–C distances in $C_2H_5MgBr\cdot 2C_4H_{10}O$,[22] $[C_2H_5MgBr\cdot N(C_2H_5)_3]_2$,[23] $[C_2H_5Mg_2Cl_3\cdot(C_4H_8O)_3]_2$,[24] and $[(C_2H_5)_2Mg]_\infty$[25] are 2.15(2) Å, 2.18(2) Å, 2.19(3) Å, and 2.2$_6$ Å, respectively. Expected Mg–C covalent bond length for $C_6H_5MgBr\cdot 2C_4H_{10}O$[26] is 2.17 Å. Two double bonds in the dimethylpentadienyl group is not coplanar, the plane defined by the C(1), C(2), C(3), and C(6) atoms makes an angle of 22.6° with the plane made by C(3), C(4), C(5), and C(7). This is probably due to the steric repulsion between two methyl groups as mentioned before. In the pentadienyl moiety the bond alternation in bond length is observed, C(1)–C(2)=1.467(20), C(2)–C(3)=1.402(19), C(3)–C(4)=1.466(20), and C(4)–C(5)=1.356(22) Å. The C(2)–C(3) and C(4)–C(5) bond lengths are significantly smaller than the C–C bond(1.43 Å) of η^5-cyclopentadienyl group in $C_5H_5MgBr\cdot(C_2H_5)_2N(CH_2)_2N(C_2H_5)_2$.[27]

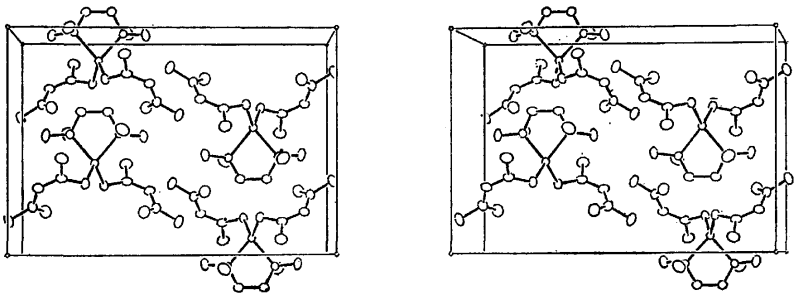

Fig. 3. A stereoscopic drawing of the crystal structure of $Mg(C_7H_{11})_2 \cdot TMEDA$.

The TMEDA coordinates to the magnesium atom by two nitrogen atom [Mg–N=2.202(12) Å]. The N–Mg–N′ angle[84.2(5) Å] largely deviates from tetrahedral angle and is comparable to that of $C_5H_5MgBr \cdot (C_2H_5)_2N(CH_2)_2N(C_2H_5)_2$ (82.5±0.5°) and that of $Li[(CH_3)_2N(CH_2)_2N(CH_3)_2]_2C_{10}H_8$(85.2°).[28] The Mg–N–C(8) angle[104.4(11)°] is also slightly smaller than the tetrahedral angle.

The crystal structure is shown in Fig. 3. No close intermolecular atomic contact less than the van der Waals distance(3.6 Å) was observed.

Regioselective Dienylation of Carbonyl Compounds. Addition of bis(dienyl)magnesium to carbonyl compounds was examined to check whether the abundancy of the solution species of **1**—**7** reflects the structure of the addition products. The result of the reaction with a simple ketone, acetone, is given in Table 8.

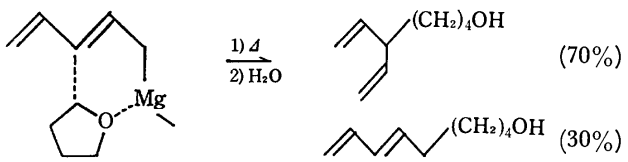
Table 8. Addition of ketones on the C_1 and C_3 carbon atoms of bis(dienyl)magnesium·TMEDA complexes[a]

Complex	Acetone		DIPK	
	C_1/%	C_3/%	C_1/%	C_3/%
1	2	98	100	0
2	2	98	100	0
3	5	95	65 35[b]	0
4	1	99	95	5
5	5	95	100	0
6	1	99	8	92
7	20	80	25	75

a) Reaction was carried out at 10 °C for 2 h in benzene. b) 2,5-Dimethyl-3-isopropyl-5,7-octadien-3-ol.

Regioselective addition occurred for **1**—**7**. The regioselectivity also depends on the ligand property. For example, compound **1** coordinated with THF, 1,2-dimethoxyethane, $CH_3O(CH_2CH_2O)_2CH_3$, $CH_3O(CH_2CH_2O)_3CH_3$, and $CH_3O(CH_2CH_2O)_4CH_3$ reacted with acetone on the C_3 carbon atom in 67, 81, 83, 78, and 77% conversion respectively in line with the hydrolysis data. The regioselectivity increased up to 99—100% by using 15-crown-5,18-crown-6, and tetramethylcyclam. The behavior to acetaldehyde was the same with that to acetone. In contrast to above, the reaction of **1**—**5** with a bulky ketone, diisopropyl ketone, gave 1,3-diene derivatives selectively presumably due to the steric repulsion between the isopropyl group and the diene moiety. The configuration of the dienyl group of the products obtained from **1**—**3** was trans. Similar behavior of the bulky ketone was found for the reaction with allylmagnesium compounds and is explained by S_E2' mechanism based on the kinetic studies.[29] Cyclic dienylmagnesium compounds also allow the selective reaction in this case.

Formation of Unsaturated Alcohols by Thermal Cracking of Bis(dienyl)magnesium·Cyclic Ether Complexes. Thermal cracking of bis(dienyl)magnesium·THF adduct followed by hydrolysis provided a novel route for the synthesis of unsaturated alcohols. Heating of THF complex of **1** in toluene at 120 °C for 3 h and hydrolysis of the reaction mixture gave 6,8-nonadien-1-ol (30%) and 5-vinyl-6-hepten-1-ol (70%) in 40—60% yield.



THF molecule was cleaved. By taking advantage of this reaction, synthesis of a precursor of an insect pheromone for *carpocapsa pomonella*[30] was attempted. Thermal cracking of oxepane complex of **2** gave 7-vinyl-8-decen-1-ol(63%) and its isomer, 8,10-dodecadien-1-ol in 6% yield. Thus, this reaction has an extensive utility in the synthesis of unsaturated alcohols with an elongated carbon chain. The order in reactivity of cyclic ethers followed that described for acid-catalyzed cleavage of cyclic ethers.[31]

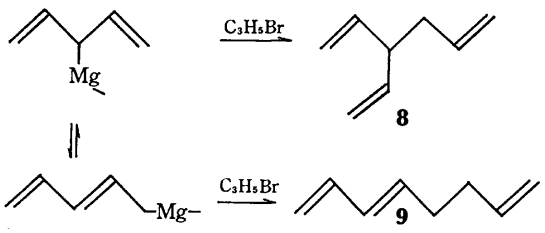
Selective Synthesis of Trienes. Though transition

Table 9. Coupling reaction of allyl bromide with $(C_5H_7)_2$ Mg·2THF catalyzed by transition metal compounds[a]

Catalyst	Products/%	
	8	**9**
None	10	90
CuCl	1	99
$TiCl_2(\eta^5\text{-}C_5H_5)_2$	92	8
$ZrCl_2(\eta^5\text{-}C_5H_5)_2$	88	12
$NbCl_2(\eta^5\text{-}C_5H_5)_2$	60	40

a)Reaction conditions; 0 °C, 20 h in benzene, catalyst; 2 mol% for the magnesium compound. b) Reaction was carried out at 30 °C for 2 h.

metal-catalyzed triene synthesis are known for several conjugated dienes,[32] novel triene synthesis by the coupling reaction of dienylmagnesium compound with allyl halides is attractive since it has wider applicability. As a typical example, the reaction of pentadienylmagnesium bromide with allyl bromide catalyzed by transition metal compounds was examined (Table 9). The reaction catalyzed by $MX_2(\eta^5\text{-}C_5H_5)_2$(M=Zr,[33] Ti[34]) gave 3-vinyl-1,5-hexadiene **8** regioselectively while with copper(I) chloride catalyst it gave 1,3,7-octatriene **9** selectively. The poor selectivity by $NbCl_2(\eta^5\text{-}C_5H_5)_2$[35] may be due to its poor solubility. This type of reaction will be useful for obtaining desired trienes by an appropriate combination of dienylmegnesium compounds with allyl halides. The selectivity by Ni(II) chloride, Co(II) chloride, or $NiBr_2(PPh_3)_2$ catalyzed reaction was low while these were active for selective synthesis of linear tetraenes from dienyl anions.[7]



Experimental

Anhydrous magnesium bromide and magnesium chloride were prepared by the reaction of magnesium (1.0 mol) with 1,2-dibromoethane (1.0 mol) or 1,2-dichloroethane (1.0 mol) in ether at 0 °C and were stored in argon.[36] Commercial anhydrous magnesium halides were unsuitable for this examination because they include hydrates. All ethers were dried over Na/K alloy and distilled. Crown ethers (Nisso Chem. Corp.) were used without further purification or drying. TMEDA was dried over calcium hydride and distilled. Trimethylamine oxide was prepared according to the method of Meisenheimer[37] and was sublimed (140 °C/10^{-4} mmHg). Tetramethylcyclam was synthesized by the known method.[38] 1-Bromo-2,4-hexadiene was prepared from sorbic acid[39] in the usual manner. Potassium dienides were prepared by the procedure previously reported.[7] Melting points were measured in a sealed tube and were uncorrected. GC analysis and the separation of the reaction products were made with a Hitachi Model 163 gas chromatograph using a capillary column OV-1 or HB 2000 and a Varian-Aerograph Model 700 gas chromatograph using a column packed with Silicone DC-550. NMR spectra were recorded on a Varian XL-100 instrument with a VFT-100-620L Fourier transform accessory. IR spectra were recorded on a Hitachi EPI-2 spectrometer. All the procedures were conducted in an argon atomosphere by using flow system. Elemental analysis was carried out for the key substances with Yanagimoto Model MT-2 CHN-analyzer.

Preparation of Bis(pentadienyl)magnesium·TMEDA Complex **1**. A THF solution (40 ml) of anhydrous magnesium bromide (6.4 g, 35 mmol) was added over a 20 min period to potassium pentadienide (6.4 g, 60 mmol) dispersed in THF (100 ml) in a 300 ml Schlenk tube with stirring at 0—5 °C. The magnetic stirring continued for 3 h at 10 °C and the orange color of the solution changed to pale yellow. After the addition of pentane (100 ml), the resulting precipitate of magnesium bromide was separated by centrifugation with the use of a two-necked glass tube fitted with rubber stoppers. The supernatant liquid was evaporated to dryness and a mixture of diethyl ether (100 ml) and pentane (50 ml) was added to the residue for complete separation of the salt. Evaporation of the ether–pentane soluble fraction gave $(C_5H_7)_2Mg\cdot 2THF$ as pale yellow oil. Yield; 70—80% (6.3—7.2 g). Toluene solution of this complex gave pentadiene and THF in a 1:1 molar ratio upon hydrolysis as evidenced by GC. TMEDA complex was prepared by the addition of TMEDA (7.5 ml, 50 mmol) dissolved in pentane (40 ml) to the THF complex (6.0 g, 20 mmol) in THF (10 ml), stirring the mixture for 2 h at room temperature and then cooling to −20 °C to induce the crystallization. Yield; 85% (5.2 g). Concentration by evaporation and cooling of the supernatant solution further gave TMEDA complex (0.6 g). Recrystallization was made in 5:1 hexane–THF at −20 °C.

Preparation of Bis(pentadienyl)magnesium·diethyl ether Complex. Diethyl ether (150 ml) was added to the THF-free potassium pentadienide (5.3 g, 50 mmol) in 300 ml Schlenk tube cooled with ice–water (addition of potassium pentadienide to ether should be avoided since the THF-free potassium dienide is very explosive in the air). Anhydrous magnesium bromide (5.2 g, 28 mol) was added at once and magnetic stirring was continued for 10 h at 30 °C until the yellow solid changes to a white powder. The supernatant pale yellow solution was evaporated and the resulting oily ether complex was washed with two portions of pentane (30 ml) at −78 °C. Yield; 60% (4.7 g) based on potassium dienide. This ether complex can not be prepared from the THF complex **1** by ligand exchange reaction.

Preparation of Bis(pentadienyl)magnesium·15-crown-5 ether Complex. A solution of 15-crown-5 (2.2 g, 10 mmol) in benzene (10 ml) was added to bis(pentadienyl)magnesium·ethyl ether complex (3.2 g, 10 mmol) dissolved in benzene (20 ml) at room temperature with magnetic stirring, crystals of the complex being precipitated instantly. The precipitate was washed with two portions of pentane (20 ml) and recrystallized in toluene. Yield; 98%. The relative signal intensity ratio in ^{1}H-NMR spectrum showed the formation of 1:1 complex.

Preparation of Pentadienylmagnesium Bromide. In the same reaction conditions and the same procedures to the preparation of **1**, Grignard type dienylmagnesium bromide can be prepared by 1:1 reaction of a dienyl anion and magnesium bromide. For example, the reaction of potassium pentadienide (5.3 g, 50 mmol) with magnesium bromide (10.1 g, 55 mmol) in THF at 30 °C for 3 h gave pentadienylmagnesium bromide coordinated with two moles of THF as an oily substance. Yield; 90% (9.9 g). The reaction of the resulting THF complex (6.6 g, 30 mmol) with TMEDA (6 ml, 40 mmol) gave TMEDA complex having mp 122 °C quantitatively.

Preparation of Bis(dienyl)magnesium·TMEDA Complexes **2**—**7**. In essentially the same way to the preparation of **1**, crystals of TMEDA complexes of **2**—**7** were prepared. Recrystallization of **4** and **7** were done in a mixture of toluene and pentane (1:10) at 0 °C.

Crystal Data and Structure Determination of Bis(2,4-dimethylpentadienyl)magnesium·TMEDA. $C_{20}H_{38}N_2Mg$, *F.W.* 330.9, orthorhombic, space group Pbcn (No. 60), (20 °C) a=10.145(2), b=12.486(2), c=17.587(2) Å, V=2227.8(5) Å^3, D_C=0.987 g cm^{-3} for Z=4; (−60 °C) a=10.105(6), b=12.325(6), c=17.580(9) Å, V=2189.6(21) Å^3, D_C=1.004 g cm^{-3} for Z=4.

As the crystals are unstable in air, a crystal with suitable

size was selected and sealed in a thin-walled glass capillary tube. In spite of the repeated recrystallizations and the very careful sealing only a few crystals were found useful for the X-ray analysis. Preliminary X-ray photographic study determined the corresponding space group as Pbcn (systematic absence of reflections, $0kl$: $k=2n+1$, $h0l$: $l=2n+1$, $hk0$: $h+k=2n+1$).

Unit-cell dimensions and reflection intensities were measured on a Rigaku automated, four-circle diffractometer. Zirconium-filtered Mo $K\alpha$ radiation was used. The θ-2θ scan technique was applied. The scan rate was 4° min^{-1} and the scan range for each reflection was $\Delta 2\theta=(2.0+0.70\tan\theta)°$. Background of 5 s were measured before and after each scan. Intensity data were first collected at 20 °C, but the higher angle reflections were too weak to be observed and the structure determined was not sufficiently accurate. Intensity data were therefore collected again at −60 °C, a total of 1185 (714 non-zero) reflections being observed ($2\theta\leqq 42°$). But the number of unobserved reflections was still large. Low temperature was attained by the gas flow method of liquid nitrogen. However, as the crystal was sealed in the glass-capillaly tube, the deposition of the frost on the glass due to the moisture in air was much easier than the crystal without sealing in the glass capillary. The lowest temperature attained without the frost was only −60 °C. The intensity data were corrected for usual Lorentz and polarization effects but not for absorption [μ(Mo $K\alpha$)=0.88 cm^{-1}].

Since the space group is Pbcn and four molecules are contained per unit-cell, the molecule must lie on a special position, two-fold axis or center of symmetry.

The structure was solved by the heavy atom method, and refined isotropically by the block-diagonal least-squares procedure (*HBLS V*).[40] The room temperature structure was first determined, but the convergence of the refinement was insufficient (R=0.185 for 807 non-zero reflections). The structure was, therefore, refined using the intensity data obtained at −60 °C. After the R value decreased to 0.162, the refinement was carried out anisotropically with unit weight, and the final R value was rather high as 0.135 for 714 non-zero reflections. This limits the accuracy of the result. Atomic scattering factors were taken from the International Tables for X-Ray Crystallography, Vo. IV.[41] Calculations were done on an ACOS series 77 system 700 computer at Osaka University.[42] The final atomic positional and thermal parameters are listed in Table 10.[43]

Preparation of Pentadienylaluminium Compounds. Granules of anhydrous aluminium chloride (2.7 g, 20 mmol) was added to the potassium pentadienide (2.1 g, 20 mmol) dissolved in THF (60 ml) at 0 °C with stirring. After refluxing the solution for 30 min, the solution was reduced to *ca.* 30 ml by evaporation and then hexane (50 ml) was added to induce the precipitation of the salt. The supernatant liquid separated by centrifugation was evaporated to dryness and washed with hexane (50 ml) to give potassium tetrakis(pentadienyl) aluminium·THF complex as an oily material. Yield: 92% (7.4 g). ^{1}H-NMR (C_6D_6) δ=6.10, 6.30 (m, 8, CH=), 5.93 (d of t, 4, CH–), 4.90 (d of d, 4, J=14.0, *trans* CH_2=), 4.72 (d of d, 4, J=9.0, *cis* CH_2=), 3.65 (m, 4, CH_2O of THF), 1.40 (m, 4, CH_2 of THF), 0.16 (d, 8, CH_2).

In the similar manner, the 2:1 reaction of $(CH_3)_2AlCl$ with potassium pentadienide gave potassium dimethyldipentadienylaluminium in 70% yield. No tripentadienylaluminium corresponding to bis(pentadienyl)magnesium was obtained as evidenced by distillation of the whole reaction products in high vacuum. ^{1}H-NMR (C_6D_6) δ=6.14—6.33 (m, 4, CH), 5.60 (d of t, 2, J=14.0, CH–CH_2), 4.78, 4.72 (d of d, 8, CH_2=), 3.53 (m, 4, CH_2O of THF), 1.60 (m, 4, CH_2 of THF), 0.90 (d, 4, CH_2), −0.12 (s, 6, CH_3). Hydrolysis of $K[(C_5H_7)_4Al]$

and $K[(C_5H_7)_2(CH_3)_2Al]$ in toluene produced 1,4-pentadiene exclusively (99%) in 98% GC yield. Reaction of acetaldehyde and acetone, followed by hydrolysis gave 1,4-diene derivatives (purity, 99%) in 90% yield in both cases (spectral data of the products are given later in this section).

Dienylation of Carbonyl Compounds with **1**—**7**. To the benzene solution (60 ml) of bis(dienyl)magnesium **1**—**7** (20 mmol) was added acetone (2.9 ml, 40 mmol) dropwise at 5 °C. The reaction mixture was stirred for 2 h at 30 °C and hydrolyzed with 2 mol dm^{-3} HCl at 5 °C. After filtration, benzene fraction was distilled under reduced pressure. The reaction of bis(dienyl)magnesium with acetaldehyde was carried out in the same manner but with diisopropyl ketone at 50 °C for 3 h.

Dienylation of Acetone. *2-Methyl-3-vinyl-4-penten-2-ol from* **1**: IR (neat) 3440 (OH), 1638 (C=C), 1015, 915 cm^{-1} (CH=CH_2); ^{1}H-NMR ($CDCl_3$) δ=5.94 (d of d of d, 2, CH=), 5.15 (d of d, 2, J=16.5, *trans* CH_2=), 5.02 (d of d, 2, J=10.2, *cis* CH_2=), 2.75 (t, 1, J=8.0, CH), 1.98 (s, 1, OH), 1.18 (s, 6, CH_3); Found: C, 76.07; H, 11.4%; M^+-1, 125. Calcd for $C_8H_{14}O$: C, 76.19; H, 11.1%; M, 126.

trans-*2-Methyl-3-vinyl-4-hexen-2-ol from* **2**: IR (neat) 3450, 1635, 990, 912 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=5.71 (d of d of d, 1, CH), 5.53 (d of d, 1, J=13.7 *trans* CH=CHCH$_3$), 5.53 (d of q, 1, CH), 5.12 (d of d, 1, J=10.3 *cis* CH_2), 5.07 (d of d, 1, J=16.5 *trans* CH_2), 3.14 (d of d, J=8.1, CH), 2.09 (s, 1, OH), 1.75 (d, 3, CH_3), 1.15 (s, 6, CH_3).

cis-*2-Methyl-3-vinyl-4-hexen-2-ol from* **2**: IR (neat) 3450, 1635, 990, 719 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=5.71 (d of d of d, 1, CH), 5.53 (d of d, 1, J=9.2, *cis* CH=CHCH$_3$), 5.53 (d of q, 1, CH=), 5.08, 5.16 (m, 2, CH_2), 2.72 (d of d, J=8.0, CH), 2.09 (s, 1, OH), 1.87 (d, 3, CH_3), 1.15 (s, 6, CH_3).

2,4-Dimethyl-3-vinyl-4-penten-2-ol from **3**: IR (neat) 3490, 1635, 1000, 915 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=6.10 (d of d of d, 1, CH), 5.15 (d of d, 1, J=10.4, for *cis* CH_2=), 5.02 (d, 2, J=2.2, CH_2), 5.00 (d of d, 1, CH_2), 2.75 (d, 1, CH), 1.87 (s, 3, CH_3), 1.73 (s, 1, OH), 1.25 (s, 6, CH_3).

2,3-Dimethyl-3-vinyl-4-penten-2-ol from **4**: ^{1}H-NMR ($CDCl_3$) δ=5.82 (d of d, 2, CH), 5.14 (d of d, 2, J=10.4 for *cis* CH_2, J=2.8 for gem H), 4.99 (d of d, 2, J=16.5, *trans* CH_2), 1.73 (s, 1, OH), 1.25 (s, 3, CH_3), 1.24 (s, 6, CH_3); MS, Found: M^+-1, 139.

2,4-Dimethyl-3-isopropenyl-4-penten-2-ol from **5**: IR (neat) 3500, 1643, 1020, 890 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=4.91 (d, 4, J=2.9, CH_2), 2.54 (s, 1, CH), 2.24 (s, 1, OH), 1.72 (s, 6, CH_3), 1.16 (s, 6, CH_3); Found: C, 77.9; H, 11.5%; M^+-1, 153. Calcd for $C_{10}H_{18}O$; C, 77.86; H, 11.76%; M, 154.

2-(2,6-Cycloheptadienyl)-2-propanol from **6**: ^{1}H-NMR ($CDCl_3$) δ=5.81 (d of t, 2, J=12.2, CH_2CH=), 5.68 (d of d, 2, CH), 3.20 (d of d, 1, CH), 2.27 (m, 4, CH_2), 1.52 (s, 1, OH), 1.27 (s, 6, CH_3).

2-(2,7-Cyclooctadienyl)-2-propanol from **7**: IR (neat) 3510, 1638, 1075 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=5.90 (d of d, 2, J=12.2, CH), 5.49 (d of t, 2, CH), 3.30 (d of d, 1, J=6.6, CH), 2.18 (m, 4, CH_2), 2.00 (s, 1, OH), 1.35 (m, 2, CH_2), 1.16 (s, 6, CH_3); Found: C, 79.46; H, 10.92%; M^+-1, 165. Calcd for $C_{11}H_{18}O$: C, 79.47; H, 10.91%; M, 166.

Dienylation of Acetaldehyde. *3-Vinyl-4-penten-2-ol from* **1**: IR (neat) 3380, 1637, 999, 915 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=5.89 (d of d of d, 2, CH), 5.15 (d of d, 2, J=10.0, CH_2), 5.03 (d of d, 2, J=16.2, CH_2), 3.76 (d of d, 1, J=6.0, C<u>H</u>–CH_3), 2.82 (bt, 1, CH), 1.98 (s, 1, OH), 1.20 (d, 3, J=6.2, CH_3); MS, Found: M^+-1, 111.

1-(2,7-Cyclooctadienyl)ethanol from **7**: IR (neat) 3420, 1635, 1070 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=5.65 (d of t, 2, CH), 5.62 (d of d, 2, J=11.8, CH), 3.82 (d of q, 1, CH), 3.25 (bt, J=6.5, CH), 2.30 (m, 4, CH_2), 1.98 (s, 1, OH), 1.47 (m, 2, CH_2), 1.20 (d, 3, J=6.8, CH_3); MS, Found: M^+-1, 151.

Dienylation of Diisopropyl Ketone. *2-Methyl-3-isopropyl-5,7-octadien-3-ol from* **1**: IR (neat) 3500, 1640, 1605, 988, 830, 784 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=6.35 (d of d of d, 1, CH), 5.95 (d of t, 1, J=15.5, CH), 5.92 (d of d, 1, J=9.5, CH), 5.12 (d of d, 1, J=16.5, *trans* CH_2=CH), 5.02 (d of d, 1, J=10.2, *cis* CH_2=CH), 2.38 (d, 2, J=7.0, CH_2), 1.88 [m, 2, C<u>H</u>(CH_3)$_2$], 1.30 (s, 1, OH), 0.98 (d, 12, J=7.3, CH_3); Found: C, 78.85; H, 12.25%; M^+-1, 181. Calcd for $C_{12}H_{22}O$: C, 79.06; H, 12.16%; M, 182.

2-Methyl-3-isopropyl-5,7-nonadien-3-ol from **2**: IR (neat) 3500, 988, 950 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=6.12 (d of d, 1, J=15.5, CH), 5.90 (d of d, 1, J=15.6, C<u>H</u>=CHCH$_2$), 5.52 (d of q, 1, CH), 5.48 (d of t, 1, CH), 2.30 (d, 2, J=7.5, CH_2), 1.92 [m, 2, C<u>H</u>(CH_3)$_2$], 1.73 (d, 3, J=6.5, CH_3), 1.40 (s, 1, OH), 0.95 (d, 12, J=7.5, CH_3).

2,5-Dimethyl-3-isopropyl-5,7-octadien-3-ol from **3**: IR (neat) 3510, 1644, 1610, 995, 898 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=6.45 (d of d of d, 1, CH), 6.01 (d, 1, J=10.2, CH), 5.12 (d of d, 1, J=16.7, CH_2=), 5.00 (d of d, 1, J=10.2, CH_2=CH), 2.28 (s, 2, CH_2), 1.89 (m, 2, C<u>H</u>–CH_3), 1.59 (s, 1, OH), 0.98 (d, 12, CH_3).

*2,7-Dimethyl-3-isopropyl-5,7-octadien-3-ol from***3** : IR (neat) 3510, 1640, 905 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=6.20 (d, 1, J=15.2, CH), 5.74 (d of t, 1, CH), 4.88 (d, 2, CH_2=), 2.34 (d, 2, J=8.4, CH_2), 1.89 (m, 2, C<u>H</u>–CH_3), 1.59 (s, 1, OH), 0.98 (d of d, 12, J=7.0 and 2.8, CH_3).

2,6-Dimethyl-3-isopropyl-5,7-octadien-3-ol from **4**: IR (neat) 3500, 1640, 1608, 990, 894 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=6.43 (d of d, 1, CH), 5.64 (t, 1, CH), 5.13 (d of d, 1, J=17.0, CH_2=CH), 4.99 (d of d, 1, J=10.8, CH_2=CH), 2.42 (d, 2, J=7.8, CH_2), 1.89 (m, 2, C<u>H</u>CH_3), 1.78 (s, 3, CH_3), 1.28 (s, 1, OH), 0.97 (d, 12, J=7.5 and 2.8, CH_3); MS, Found: M^+-1, 195.

2,5,7-Trimethyl-3-isopropyl-5,7-octadien-3-ol from **5**: IR (neat) 3570, 1635, 894 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=5.81 (s, 1, CH), 5.01, 4.85 (d, 2, J=2.5, CH_2=), 2.33 (s, 2, CH_2), 1.98, 1.85 (two s, 6, CH_3), 1.93 (m, 2, C<u>H</u>–CH_3), 1.35 (s, 1, OH), 0.98 (d, 12, CH_3); Found: C, 79.95; H, 12.25%; M^+-1, 209. Calcd for $C_{14}H_{26}O$: C, 79.93; H, 12.46%; M, 210.

3-(2,6-Cycloheptadienyl)-2,4-dimethyl-3-pentanol from **6**: IR (neat) 3510, 1665, 1641 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=6.10 (d of d, 2, J=11.5, CH), 5.56 (d of t, 2, CH), 3.20 (bt, 1, CH), 2.30 (m, 4, CH_2), 1.90 (m, 2, CH), 1.60 (s, 1, OH), 1.00 (d, 12, CH_3); Found: C, 80.71; H, 11.60%; M^+-1, 207. Calcd for $C_{14}H_{24}O$: C, 80.70; H, 11.62%; M, 208.

3-(2,7-Cyclooctadienyl)-2,4-dimethyl-3-pentanol from **7**: IR (neat) 3370, 1658, 1080 cm^{-1}; PMR ($CDCl_3$) δ=5.3—5.8 (m, 4, CH), 3.58 (t, 1, CH), 2.38 (m, 4, CH_2), 2.30 (s, 1, OH), 1.90 (m, 2, CH), 1.40 (m, 2, CH_2), 1.00 (d, 12, CH_3).

Thermal Cracking of Pentadienylmagnesium·THF Complexes. Bis(pentadienyl)magnesium·THF complex (4.0 g) dissolved in toluene (50 ml) which contains 5 mol equivalent of THF was heated to 120 °C for 3 h in a sealed tube, gray precipitates of degradation products being formed. Resulting mixture was hydrolyzed with 2 mol dm^{-3} HCl and the toluene soluble fraction was distilled. The ratio of 6,8-nonadien-1-ol to 5-vinyl-6-hepten-1-ol was 3:7. Yield, 40%. In the same way, thermal cracking of pentadienylmagnesium bromide·THF complex was carried out at 130 °C for 4 h, the same products being obtained in a 7:3 ratio in 60% yield.

6,8-Nonadien-1-ol: IR (neat) 3450, 1642, 1605, 987, 905 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=6.5—6.6 (m, 2, CH), 5.62 (d of t, 1, J=15.5, CH), 5.00, 5.12 (m, 2, CH_2=), 3.68 (t, 2, CH_2), 2.16 (d of t, 2, CH_2), 2.20 (s, 1, OH), 1.45 (m, 6, CH_2); M^+, 140. Calcd for $C_9H_{16}O$: M, 140.

5-Vinyl-6-hepten-1-ol: IR (neat) 3500, 1635, 995, 912 cm^{-1}; ^1H-NMR ($CDCl_3$) δ=5.78 (m, 2, CH), 5.00 (d of d, 2, J=10.2, *cis* CH_2=CH), 4.95 (d of d, 2, J=17.2, *trans* CH_2=CH), 3.62 (bt, 2, J=6.9, CH_2), 2.69 (m, 1, J=9.2, CH), 2.35 (s, 1, OH), 1.44 (m, 6, CH_2); Found: C, 77.85; H, 10.91%; M^+-1, 139. Calcd for $C_9H_{15}O$: C, 77.66; H, 10.85%; M, 140.

Thermal Cracking of Bis(hexadienyl)magnesium·oxepane Compound. Oxepane complex of bis(hexadienyl)magnesium was prepared by 2:1 reaction of THF free potassium hexadienide (2.4 g, 20 mmol) with magnesium bromide (1.8 g, 10 mmol) in oxepane (30 ml). After evaporation of oxepane in vacuum, oxepane complex was extracted from the residue with diethyl ether (100 ml). Bis(hexadienyl)magnesium·oxepane complex was obtained as an oily substance by evaporation of diethyl ether. Thermal craking was carried out in toluene at 120 °C for 5 h after the addition of 10 mol equivalent of oxepane. Yield, 40%.

8,10-Dodecadien-1-ol: IR (neat) 3510, 1640, 1602, 987, 910 cm^{-1}; ^1H-NMR ($CDCl_3$) δ=6.4—6.5 (m, 2, CH), 5.50 (d of t, 1, J=16.0, CH), 5.40 (d of q, 1, J=15.5, CH), 3.68 (bt, 2, J=6.9, CH_2), 2.10 (d of t, 2, CH_2), 2.20 (s, 1, OH), 1.68 (d, 3, CH_3), 1.49 (m, 10, CH_2), M^+-1, 181. Calcd for $C_{12}H_{22}O$: M, 182.

7-Vinyl-8-decen-1-ol: IR (neat) 3505, 1636, 995, 911 cm^{-1}; ^1H-MNR ($CDCl_3$) δ=5.81 (m, 1, CH), 5.62 (d of d, 1, J=15.2, CH), 5.50 (d of q, 1, CH), 5.00 (m, 2, CH_2), 3.65 (bt, 2, CH_2), 2.75 (m, 1, CH), 1.65 (d, 2, CH_3), 1.49—1.52 (m, 10, CH_2); Found: C, 79.53; H, 12.05%; M^+-1, 181. Calcd for $C_{12}H_{22}O$: C, 79.04; H, 12.18%; M, 182.

Preparation of Trienes: Catalysts, MCl_2 (η^5-C_5H_5)$_2$ (M=Ti, Zr, Nb, 2 mol%) or CuCl (0.12 g, 5 mol% to magnesium compounds), was added to the diethyl ether solution (100 ml) of pentadienylmagnesium bromide·2THF (7.9 g, 25 mmol) cooled to 0 °C and then 3-bromopropene (3.5 ml, 40 mmol) was added dropwise with vigorous stirring. The mixture was stirred for 20 h at 0 °C, then warmed to 30 °C for 1 h and quenched with 2 mol dm^{-3} HCl. Diethyl ether fraction was distilled. Typical yield: 90% based on 3-bromopropene.

3-Vinyl-1,5-hexadiene: IR (neat) 1650, 1635 cm^{-1}; ^1H-NMR ($CDCl_3$) δ=5.84 (d of d of d, 2, CH), 5.80 (d of d of d, 1, CH), 5.02 (d of d, 2, J=10.2, CH_2=CH), 4.98 (d of d, 2, J=16.0, CH_2=CH), 5.01, 4.98 (m, 2, CH_2=), 2.83 (m, 1, J=6.2, C<u>H</u>CH_2), 2.21 (d of d, 2, J=6.4, C<u>H</u>$_2$CH=); M^+, 108. Calcd for C_8H_{12}: M, 108.

(Received October 4, 1979)

A series of bis(dienyl)beryllium and bis(dienyl)zinc compounds were prepared by metal exchange reaction from seven different dienyl anions and were isolated as crystals of TMEDA complexes. Bis(dienyl)beryllium compounds of open chain structure obtained from pentadienyl, 2-methylpentadienyl, and 3-methylpentadienyl anions assume the terminally σ-bonded (*E*)-2,4-pentadienyl structure in solution as evidenced by ^{1}H-NMR and ^{13}C-NMR spectroscopies. Hydrolysis of these compounds gave 1,4-dienes regioselectively. The corresponding bis(dienyl)zinc compounds exist as a (*Z*), (*E*) mixture of teminally σ-bonded structures. An X-ray analysis of pentadienylzinc chloride·TMEDA complex showed that it had terminally σ-bonded (*E*)-2,4-pentadienyl structure with *s-trans* conformation. Steric effect of two methyl substituents in bis(2,4-dimethylpentadienyl)zinc induces the (*Z*) configuration which leads to the fluxional behavior by rapid 1,5-rearrangement above −80 °C.

In the previous paper, synthesis and chemical reaction of seven different bis(dienyl)magnesium compounds having fluxional structures in solution were reported.[1] A rapid 1,3-rearrangement (1,3-shift) between the magnesium-terminal C-1 (or C-5) and magnesium-central C-3 carbon bonds explains the fluxional behavior assisted by the ionic character of the Mg–C bonds. Substitution of the magnesium atom with more electro-negative metals, beryllium or zinc, may freeze the rapid equilibrium since the covalency of the M–C bonds does not favor suprafacial 1,3-sigmatropic shift which is thermally forbidden when covalency of the bond is complete. The position of the metal-carbon bond may be fixed to either C-1, C-3, or C-5 carbon atoms of the dienyl group reflecting the radius and the electronegativity of the metals. The position of the metal-carbon bond should also be influenced by a change in bulkiness of the substituents on the pentadienyl group because no remarkable difference in electron density was observed by CNDO-II calculations[2] among C-1, C-3, and C-5 of lithium pentadienide. Since the ionic radius of Zn (0.74 Å) is significantly larger than that of Be (0.41 Å), comparative studies on the structure of bis(dienyl)beryllium and bis(dienyl)zinc compounds will provide informations on the steric effect of the metal on the configuration or conformation of the dienyl group. Unique chemical behaviors of beryllium compounds resulting from its small ionic radius[3] are of interest but no compounds related to this work are reported.

Understanding the difference in the position of the metal-carbon bond, configuration of dienyl group, process for the rearrangement and chemical reactivity between dienylmetal compounds of Be, Mg, and Zn will be essential for selective dienylation of organic groups using these reagents. Like some organozinc compounds used for addition to olefins,[4] dienylzinc compounds reported here will be useful as the selective reagents for introducing a dienyl group to carbonyl compounds and olefins.

Results and Discussion

Preparation and Properties of Bis(dienyl)beryllium and -zinc Compounds. Bis(pentadienyl)beryllium and bis(pentadienyl)zinc compounds were prepared by the 2:1 reaction of potassium pentadienide[5] with anhydrous beryllium chloride and zinc chloride, respectively, in THF. Zinc chloride readily reacts with dienyl anions at 0 °C while beryllium chloride requires higher temperatures (>40 °C). The resulting dienylmetal compounds are coordinated by two moles of THF as evidenced by NMR and by GC of the hydrolyzate. The 1:1 reaction of pentadienyl potassium with zinc chloride gave $C_5H_7ZnCl\cdot 2THF$ similar to $C_5H_7MgBr\cdot 2THF$ but that with beryllium chloride gave

$$KC_5H_7 + MX_2 \xrightarrow{THF} C_5H_7MX\cdot 2THF \xrightarrow{KC_5H_7} (C_5H_7)_2M\cdot 2THF$$
$$M=Be,\ Zn$$

mainly $(C_5H_7)_2Be\cdot 2THF$ presumably due to the instability of RMX type structure.[6] Dienylzinc compounds are thermally the least stable among the Be, Zn, and Mg compounds. For example, bis(pentadienyl)zinc·2THF or bis(pentadienyl)zinc·$2N(C_2H_5)_3$ began to decompose at 10 °C giving metallic zinc and coupling dimers, $C_{10}H_{14}$.[7] The corresponding magnesium compound, $(C_5H_7)_2Mg\cdot 2THF$, decomposed at 80—90 °C and the ring cleavage of the coordinated THF occurred to afford unsaturated alcohols with an elongated carbon chain[1] while $(C_5H_7)_2Be\cdot 2THF$ was stable up to 100 °C in toluene. Remarkable difference in thermal stability was observed also for bis(cyclooctadienyl)metal compounds. The zinc compound was decomposed even at −20 °C but the magnesium and the beryllium compounds were stable at 50—60 °C. ^{1}H-NMR spectra of all the pentadienylmetal–THF complexes showed simple averaged AB_2X pattern signals (Table 1) due to the rapid 1,3-rearrangement as was observed for dienylmagnesium, allylmagnesium,[8] and allylaluminium[9] compounds. The chemical shifts (δ-values) of the protons at C-1 and C-3 increased with increasing covalent character of the M–C bond in the order Zn–C>Be–C>Mg–C.

The fluxionality can be frozen at room temperature by addition of bifunctional chelating ligands, *N,N,N',N'*-tetramethylethylenediamine (TMEDA) or *N,N,N',*

TABLE 1. CHEMICAL SHIFTS(δ-VALUES) AND COUPLING CONSTANTS OF FLUXIONAL PENTADIENYLMETAL COMPOUNDS[a)]

	C_1-H(C_5-H)	C_2-H(C_4-H)	C_3-H

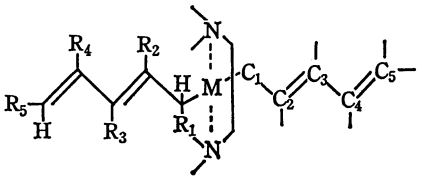
N'-tetramethyl-1,3-propanediamine (TMPDA) and a series of bis(dienyl)beryllium and bis(dienyl)zinc complexes which show the limiting structure in solution were isolated as crystals. They exist in monomeric form in benzene and the following formula are given for these complexes. Hydrolysis data are given in

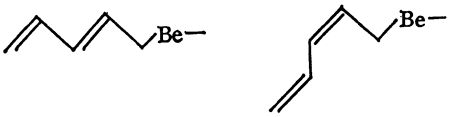


M; Be Zn

1	**8**	$R_1=R_2=R_3=R_4=R_5=H$
2	**9**	$R_3=CH_3$, $R_1=R_2=R_4=R_5=H$
3	**10**	$R_4=CH_3$, $R_1=R_2=R_3=R_5=H$
4	**11**	$R_5=CH_3$, $R_1=R_2=R_3=R_4=H$
5	**12**	$R_2=R_4=CH_3$, $R_1=R_3=R_5=H$

Tables 2 and 3. Formation of 1,4-dienes is remarkable as compared with that of 1,3-dienes especially for the beryllium compound. With respect to the 1,3-dienes, (*E*) structure predominated over (*Z*) structure for **1**—**4** and **8**—**10**. No information on the configuration of **5** and **12** was obtained by hydrolysis. If hydrolysis undergoes mainly through cyclic transition state[10] and partially by direct cleavage just as found for hydrolysis mechanism of allylic magnesium compounds,[1] terminally σ-bonded (*E*) structure is most plausible for **1**—**4** and **8**—**10**.

Nuclear Magnetic Resonance Studies on Bis(dienyl)beryllium Compounds. ^{1}H-NMR spectral data of seven different bis(dienyl)beryllium were measured and collected in Table 4. The assignment was done based on the values of chemical shift, relative intensities of the proton signals and the decoupling from the neighboring protons. It is clear that bis(pentadienyl)-beryllium·TMEDA complex **1** obtained from potassium pentadienide assumes terminally σ-bonded structure **1a** with (*E*) configuration ($J_{2,3}$=14.6 Hz). However, the TMEDA complex obtained from the reaction of $(C_5H_7)_2Mg\cdot 2THF$ with $BeCl_2$ comprises two species, (*E*) (**1a**) and (*Z*) (**1b**) isomers in an 8:1 ratio. The signals of major species are concordant in chemical shift with those of **1a** obtained from pentadienyl anion. Proton-proton coupling constant of $J_{2,3}$, 9.5 Hz, of minor signals corresponds to that of (*Z*) configuration.[11] Any signals derived from the



1a (*E*) **1b** (*Z*)

Be–C_3 carbon bond was not detected in the spectrum, although simple Hückel MO calculation suggests that the electron density of the pentadienyl anion is the highest on the C-3.[12] Therefore, the regioselective 1,4-diene formation is rationalized by concerted mechanism as described for allylic magnesium compounds[1] and the formation of 1,3-diene by direct cleavage of solvent-separated ionic species.[13] Proton signals attached to C-2 and C-4 unfortunately overlap with each other. Therefore, the correct assignment was made from the decoupled spectra with reference to the spectrum of bis(2,4-pentadienyl-1,1,5,5-d_4)-beryllium·TMEDA complex (Fig. 1) which was prepared by the reaction of beryllium chloride with potassium penta-

8	20.5	147.1	118.2	141.0	105.0

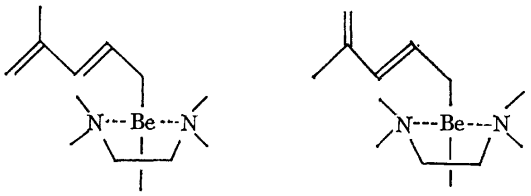
a) Calibrated using internal benzene peak, assumed to be 128.0 ppm downfield from external TMS. Data were collected at 38 °C in C_6D_6 and assignment was made by the partial decoupling method.

showed only five signals of (*E*) species consistent with the ^{1}H-NMR spectral data. Carbon-proton coupling constants obtained from non-decoupled spectra show no significant difference between (*Z*) and (*E*) structure.

The TMEDA complex of bis(3-methylpentadienyl)-beryllium **2** had simple ^{1}H-NMR pattern which was readily attributed to the terminally σ-bonded structure and the ^{13}C-NMR spectrum showed expected six signals derived from either (*E*) or (*Z*) isomer. With reference to the exclusive production of (*E*)-3-methyl-1,3-pentadiene[5] and 3-methyl-1,4-pentadiene upon hydrolysis

of **2**, one can conclude that **2** assumes solely terminally σ-bonded structure with (*E*)-configuration.

Two different structures, bis(2-methyl-2,4-pentadienyl)beryllium and bis(4-methyl-2,4-pentadienyl)beryllium, are possible for the compound obtained from potassium 2-methylpentadienide. In the case of the corresponding magnesium compound hydrolysis gave nearly equal amounts of 2-methyl-1,3-pentadiene and 4-methyl-1,3-pentadiene. However, the relative intensities of the signals of ^{1}H-NMR spectrum and the chemical shift values clearly show that bis[(*E*)-2-methyl-1,3-pentadienyl]beryllium **3** exists predominantly (95%) in the solution. It gave a 1,4-diene regioselectively by hydrolysis. Although a small amount of 4-methyl-1,3-pentadiene (2.6%) was formed by hydrolysis, their ^{1}H-NMR signals were too weak for making the correct assignment. All the expected six signals were observed also in the ^{13}C-NMR spectrum and their assignment was done by the partial decoupling method. Among the six signals, only that of C-2 splits into two peaks with a 1:1 intensity. Difference in chemical shift between the two signals (0.3 ppm) is too small to attribute them to (*E*) and (*Z*) isomers. Chemical shift difference between (*Z*) and (*E*) species observed for **1** is 3.4 ppm. Such predominance of (*Z*) isomer is ruled out in the present case by the hydrolysis data and the ^{1}H-NMR spectrum. Most plausible explanation is that those signals have arisen from the following two conformations (*s-cis* and *s-trans*). Free rotation around the C_3–C_4 bond would be hindered by the steric effect of the methyl group toward the TMEDA ligand. Thus. beryllium compounds **1**. **2**, and **3** assume *trans*-



3 (*s-trans*) **3** (*s-cis*)

or (*E*)-structure. For the compounds obtained by reaction of potassium 2,4-hexadienide with beryllium chloride, many isomers are to be considered but the abundant species (80%) was found to be bis-[(*E*,*E*)-2,4-hexadienyl]beryllium·TMEDA complex **4** and minor species (20%) to be bis[(*E*.*Z*)-2,4-hexadienyl]beryllium. The results of hydrolysis of **4** [exclusive production of (*E*)-1,4-hexadiene and (*E*,*E*)-2,4-hexadiene] are concordant to the ^{1}H-NMR spectral data. Decoupled spectrum of **4** showed that the proton-proton coupling constants of $J_{2,3}$ and $J_{4,5}$ for (*E*,*E*)-isomer are 13.9 and 14.0 Hz and those for (*E*,*Z*)-isomer are 13.9 and 9.8 Hz, respectively. These coupling constants are in accord with the known values.[11,14] No methylene signals (CH_2=C) ascribable to C-3 or C-5 metalated species was detected.

NMR Studies on Crystalline Bis(dienyl)zinc Compounds of Open Chain Structure. For comparison with magnesium and beryllium compounds, the corresponding bis(dienyl)zinc·TMEDA complexes were prepared by the same method. The striking feature of the zinc compounds is that those are thermally unstable. For example, half-lives of bis(pentadienyl)zinc·2THF and bis(pentadienyl)zinc·2N(C_2H_5)$_3$ complexes at 30 °C were 10 and 15 min respectively in benzene as evidenced by ^{1}H-NMR and by gas chromatographic analysis of the hydrolyzate. These gave a 1:1 mixture of 1,3,7,9-dodecatetraene and 5-vinyl-1,3,7-octatriene quantitatively precipitating metallic zinc by raising the temperature to 80 °C. Radical coupling mechanism is most probable for this reaction. Indeed, CIDNP (chemically induced dynamic nuclear polarization) was detected on the ^{1}H-NMR spectrum at 38 °C. The two sets of resonances at 6.58, 5.12, 3.67 ppm and 6.02, 5.12, 2.78 ppm show A/E multiple polarizations[15] and are assigned to the pair of 1,4-pentadiene radicals and the pair of 1,4- and 1,3-pentadiene radicals respectively. Similar CIDNP has been reported for some organometallic compounds[16] and was recently detected for an allylzinc system[17] at higher temperatures (153 °C). By coordination with two moles of a strong donor, trimethylamine oxide, the thermal stability of bis(pentadienyl)zinc increased up to 100 °C but the rapid 1,3-rearrangement cannot be frozen even at −70 °C. The use of a chelating ligand such as TMEDA or TMPDA was essential to get the limiting structure. Another characteristic of bis(dienyl)zinc·TMEDA complex is that they comprise two or more isomeric species. The low mp of zinc compounds compared to beryllium compounds might be due to the contamination of the isomers.

Assignments of proton signals of the isomers were done by reference to the spectra of beryllium compounds (Table 6). Bis(pentadienyl)zinc·TMEDA **8** exists as a mixture of (*E*) and (*Z*) isomers in a 4:1 ratio, but C_5H_7ZnCl·TMEDA **8'** has solely (*E*) structure in solution below 80 °C. The importance of this finding prompted the determination of the crystal structure of C_5H_7ZnCl·TMEDA as the typical example of the pentadienyl metal compounds for the present work. While complex **8** decomposed at 70 °C, C_5H_7ZnCl·TMEDA was thermally more stable and it displayed fluxional behavior at 90—120 °C (*i.e.*, simple averaged spectrum was obtained) and finally decomposed at 125 °C.

Bis(3-methylpentadienyl)zinc·TMEDA **9** obtained from potassium 3-methylpentadienide also comprises (*E*) and (*Z*) isomers in a 4:1 ratio.

In sharp contrast with **3**, zinc complex **10** prepared from potassium 2-methylpentadienide are composed of three isomeric species, (*E*)-4-methyl-2,4-pentadienyl-(45%), (*Z*)-4-methyl-2,4-pentadienyl-(5%), and 2-methyl-2,4-pentadienylzinc (50%) species. Their assignments shown in Table 6 could be made with a decoupled spectrum by reference to the spectrum of beryllium compound **3**. It could not be determined

11(2*E*, 4*E*)	1.48 (d, 8.7)	6.09 (d of t)	5.64 (d of d, 9.8)	6.18 (d of d, 11.1)	5.29 (d of q, 14.0)
11(2*Z*, 4*E*)	1.57 (d, 8.7)	6.18 (d of t)	5.15 (d of d, 14.0)	6.17 (d of d, 11.1)	5.29 (d of q, 13.8)
12a	5.01(bs)	—	5.76(s)	—	1.48(bs)
12c	3.45(bs)	—	5.37(s)	—	3.45(s)

a) Data were collected at 38 °C in C_6D_6 and assignments were made from decoupled spectra by reference to the spectrum of the corresponding beryllium compound. b) Major signals were tentatively assigned to 9(*E*) based on the hydrolysis data.

from NMR data at hand whether **10** was composed of an asymmetric species of the type RZnR′,[18] 2-methylpentadienyl-4-methylpentadienylzinc, or a mixture of equal amounts of symmetric bis(4-methylpentadienyl)zinc (**10a**) and bis(2-methylpentadienyl)-zinc complex (**10b**)

Decoupled spectrum of bis(hexadienyl)zinc·TMEDA complex **11** showed that bis[(*E*,*E*)-2,4-hexadienyl]zinc (50%), bis[(*Z*,*E*)-2,4-hexadienyl]zinc (40%) and the other dienyl compound of unknown structure [10%, presumably (*E*,*Z*)-isomer] existed in the system. Thus, selective formation of the dienylmetal compound was not observed in cases of **10** and **11**. The poor selectivity should be ascribed to the large ionic radius of zinc atom compared to beryllium. Similar size effect of metal is known for the alkali-metal-catalyzed stereospecific polymerization of isoprene, Li favoring over Na or K for stereoregulation.[19] Thus, the use of beryllium is suitable for selective formation of one particular isomer of the dienylmetal compound.

The predominant formation of the (*E*) species observed for dienylberyllium compounds **1**—**4** and dienylzinc compounds **8**—**9** may be ascribed to the covalency in the M–C bonding. Similar behavior is also known for allylic metal compounds; *i.e.*, 2-butenylaluminium compounds assumes (*E*) structure[9] while more ionic allylic magnesium compounds[20] prefer the (*Z*) structure.

X-Ray Structural Study of Pentadienylzinc Chloride·TMEDA. TMEDA complexes of bis(pentadienyl)beryllium, bis(pentadienyl)zinc, and pentadienylzinc chloride have (*E*)-structure in solution as evidenced by ^{1}H-NMR spectroscopy. ^{1}H-NMR spectrum of the fluxional bis(pentadienyl)magnesium indicated that the rapid 1,3-shift occurs keeping *s-trans*-(*E*) conformation.[1] To determine whether they assume *s-trans*-(*E*) or *s-cis*-(*E*)-conformation (which corresponds to W-shaped or sickle-shaped structure for the pentadienyl anion[5]), X-ray analysis of C_5H_7ZnCl·TMEDA was done since it showed much more reflections compared to $(C_5H_7)_2$-Zn·TMEDA and $(C_5H_7)_2$Be·TMEDA. The molecular structure is given in Fig. 2. Bond lengths and bond angles are listed in Table 7. The coordination geometry around the zinc atom is essentially tetrahedral and the C(1)–Zn–Cl angle is slightly deviated [118.8(4)°] from the standard tetrahedral angle.

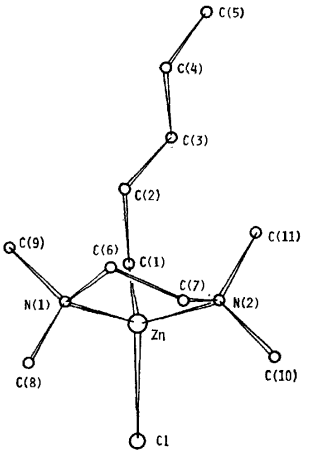

Fig. 2. Molecular structure of $ZnCl(C_5H_7)$·TMEDA.

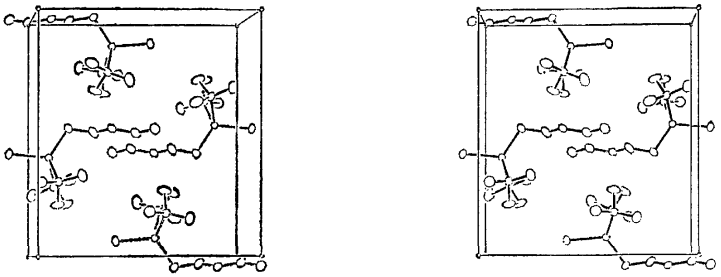

Fig. 3. A stereoscopic drawing[36] of the crystal strcuture of $ZnCl(C_5H_7)\cdot TMEDA$.

Table 7. Bond lengths [l/Å] and bond angles [ϕ/°] in $ZnCl(C_5H_7)\cdot TMEDA$
Estimated standard deviations in parentheses

Bond lengths			
Zn-Cl	2.263(3)	N(1)-C(6)	1.480(12)
Zn-N(1)	2.161(6)	N(1)-C(8)	1.482(13)
Zn-N(2)	2.151(6)	N(1)-C(9)	1.506(13)
Zn-C(1)	2.03(12)	N(2)-C(7)	1.460(12)
C(1)-C(2)	1.460(17)	N(2)-C(10)	1.509(11)
C(2)-C(3)	1.293(15)	N(2)-C(11)	1.482(12)
C(3)-C(4)	1.399(13)	C(6)-C(7)	1.498(15)
C(4)-C(5)	1.273(15)		
Bond angles			
Cl-Zn-C(1)	118.8(4)	Zn-N(1)-C(6)	104.7(6)
Cl-Zn-N(1)	105.04(17)	Zn-N(1)-C(8)	112.9(6)
Cl-Zn-N(2)	104.59(17)	Zn-N(1)-C(9)	111.6(6)
N(1)-Zn-N(2)	84.5(3)	C(6)-N(1)-C(8)	111.4(8)
N(1)-Zn-C(1)	118.2(4)	C(6)-N(1)-C(9)	107.6(8)
N(2)-Zn-C(1)	120.0(4)	C(8)-N(1)-C(9)	108.4(8)
Zn-C(1)-C(2)	114.9(9)	Zn-N(2)-C(7)	105.6(6)
C(1)-C(2)-C(3)	132.8(9)	Zn-N(2)-C(10)	113.3(5)
C(2)-C(3)-C(4)	132.3(10)	Zn-N(2)-C(11)	111.1(5)
C(3)-C(4)-C(5)	137.2(11)	C(7)-N(2)-C(10)	107.0(7)
N(1)-C(6)-C(7)	112.8(9)	C(7)-N(2)-C(11)	113.9(7)
N(2)-C(7)-C(6)	112.8(9)	C(10)-N(2)-C(11)	106.0(7)

The N(1)–Zn–N(2) angle [84.5(3)°] which is equal to the corresponding angle in $(C_7H_{11})_2Mg\cdot TMEDA$ [84.2(5)°][1] is largely deviated from the tetrahedral angle. The N–Zn–N angle in $ZnCl_2\cdot TMEDA$ is 87.9°.[21]

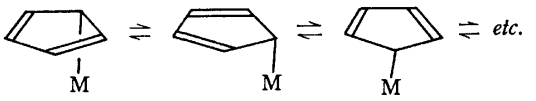
The remarkable feature of the molecular structure is that the pentadienyl group is σ-bonded to the zinc atom by the terminal C(1) [Zn–C(1)=2.031(12) Å] similar to the dimethylpentadienyl group in $(C_7H_{11})_2$-Mg·TMEDA, but the pentadienyl group in the present complex has the *s-trans*-(*E*) conformation (W-shaped structure). The Zn–C bond length is nearly equal to those of EtZnI(1.95 Å),[22] $(MeZnOMe)_4$ (1.94 Å),[23] $LiZn(CH_3)_4$(2.07 Å),[24] but shorter than the bond length of Zn–C(Cp) in $(C_5H_5)ZnCH_3$(2.28 Å).[25] The bond lengths in the pentadienyl group show the bond alternation, C(1)–C(2)=1.460(17), C(2)–C(3)=1.293 (15), C(3)–C(4)=1.399(13) and C(4)–C(5)=1.273(15) Å. Thus, C(2)–C(3) and C(4)–C(5) double bond and C(3)–C(4) single bond lengths are slightly shorter than the ordinary C–C bond (1.33 Å for C–C double bond and 1.5 Å for single bond). All the bond angles are more than 10° larger than that of the C(sp^2) bond angle. The pentadienyl group is planar within ±0.02 Å and the dihedral angle between this plane and the plane defined by the Zn, Cl, and C(1) is 71.2°. The bond length of Zn–Cl [2.263(3) Å] is reasonable value. The Zn–Cl bond length for $ZnCl_2(CH_3CN)_2$[26] and $ZnCl_2\cdot TMEDA$[21] are 2.17 and 2.208(4)Å, respectively.

The TMEDA coordinates to the zinc atom by two nitrogen atoms. The two Zn–N lengths are almost equal [Zn–N (1)=2.161 (6) and Zn–N (2)=2.151 (6) Å]. The TMEDA moiety has the similar structure as that in $(C_7H_{11})_2Mg\cdot TMEDA$ except the two-fold symmetry.

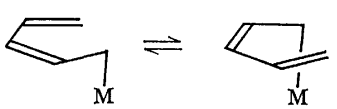
The crystal structure is shown in Fig. 3. No close intermolecular atomic contacts less than the van der Waals distance is observed.

1,5-Metallotropic Rearrangement Induced by σ-π Conjugation. The pathway of the metallotropic rearrangement of η^1-cyclopentadienylmetal compounds has been described as 1,2-shift,[27] although the equivalent pathway, 1,5-shift is prefered on the ground of orbital symmetry rules (*i.e.*, suprafacial 1,5-sigmatropic rearrangement).[28] If the stereochemistry required for the 1,5-shift is realized using dienylmetal compound of open chain structure (see Scheme 1), the 1,5-shift should be observable at a reasonable rate. Taking advantage of steric effect of two methyl substituents on C-2 and C-4 positions, we could realize the required geometry in bis(2,4-dimethyl-2,4-pentadienyl)zinc·TMEDA **12** as described below.

1,2- or 1,5-Metallotropic rearrangement in η^1-cyclopentadienyl compd.



1,5-Metallotropic rearrangement in (*Z*)-2,4-dimethylpentadienylmetal compd.



Scheme 1.

In the spectrum of **12**, two sets of signals (10:9 ratio) were observed. The similar ratio (10:7) was also observed for monodienyl substituted zinc compound, $C_7H_{11}ZnCl\cdot TMEDA$. One is very close in shape and in chemical shift values to bis(2,4-dimethylpentadienyl)magnesium compound of fluxional

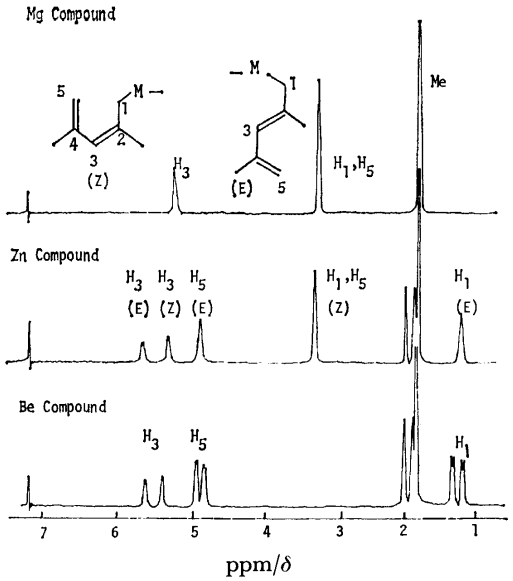


Fig. 4. ^{1}H-NMR spectra of bis(2,4-dimethylpentadienyl)metal·TMEDA complexes of Mg, Zn, and Be in benzene-d_6 at 10 °C (proton signals of TMEDA were neglected).

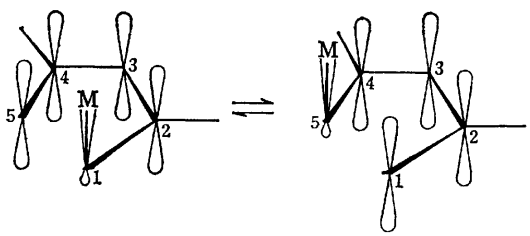
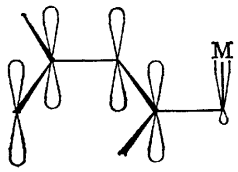
structure and the other corresponds to the terminally σ-bonded structure observed for bis(2,4-dimethylpentadienyl)beryllium·TMEDA (Fig. 4). Chemical shift values and the relative proton signal intensity ratio were independent of the concentration and temperature (−70—50 °C). Possibility of the equilibrium mixture is thus excluded. The effect of aggregation is negligible because **12** is monomeric in benzene independent of the concentration of the solution. Therefore, above two sets of signals can reasonably be assinged to independent (*Z*) and (*E*) species. Based on these facts, fluxional proton signals can be assigned to the (*Z*) species of **12** and are explained by rapid 1,5-rearrangement between **12a** and **12b**.



12a **12b**

The U-shaped geometry is also found for bis(2,4-dimethylpentadienyl)magnesium in solid state.[1] The polarized σ-bond M–C_1 or M–C_5 is in σ-π conjugation[29] with the p-orbital of C-2 or C-4 atom and hence the metal attached to the C-1 in **12a** can easily move to C-5 by least motion. In contrast, the stereochemistry of the (*E*) species **12c** does not allow such a facile rearrangement since the metal is far apart from C-5. The (*E*) structure is limited to the following sickle-shaped structure due to the steric repulsion between two methyl groups.

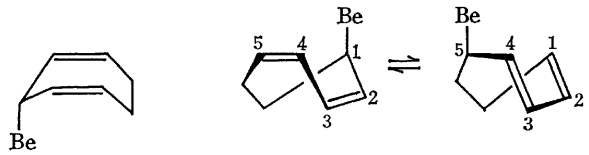


12c

If rapid 1,3-rearrangement occurs, the species **12c** should be in equilibrium also with **12a** to give a simple averaged spectrum as was found for dienylmagnesium compounds.

Bis(2,4-dimethylpentadienyl)beryllium·TMEDA **5** is not fluxional and two sets of resonances (7:5 ratio) attributable to (*Z*) and (*E*) terminally σ-bonded species were observed. Chemical shift values of ^{13}C-NMR spectrum support this explanation. Resonances appearing at lower field may be assigned to those of (*E*) species of **5** by reference to the chemical shift of **12**. The relatively small ionic radius of beryllium atom may be inadequate for 1,5-rearrangement at room temperature. At 80 °C, **5** displays the fluxional behavior similar to **12**.

This guide line appears to be generally applicable and unexpected simple ^{1}H-NMR spectral pattern of bis(cycloheptadienyl)beryllium·TMEDA **6** and bis(cyclooctadienyl)beryllium·TMEDA **7** complexes may be explained by the predominant occurrence of the 1,5-pathway. As previously noted, electron density of cycloheptadienyl and cyclooctadienyl metal compound of Mg[1] and alkali metals[5] is highest on the central C-3. Considering the distribution of the electron density, the centrally σ-bonded structure **6a** may be preferred for **6**. However, chemical shifts of **6** (Fig. 5)



6a **6b**

indicate that it assumes (*Z*)-2,4-dienylmetal type structure **6b** at room temperature contrary to the prediction. Since 1,3-cycloheptadiene[30] and 1,3-cyclooctadiene are known to have twisted structure[31], C-1 atom is close to C-5 to allow the direct 1,5-shift by transannular interaction rather than sequential 1,2- or 1,3-shift observed for η^1-cyclopentadienylmetal compounds or dienylmagnesium compounds.

If this consideration is correct, the negative charge density on C-1 and C-5 should increase by the effect of metal in sharp contrast with the negative charge distribution of the magnesium compound. Thus, simple averaged spectra of **6** (at 90 °C) and that of bis(cycloheptadienyl)beryllium·2THF are measured. Indeed, a remarkable difference in chemical shifts between proton signals of the beryllim compound and magnesium compound (Table 8) was observed. Proton at C_1 and C_5 of beryllium compound appeared at 3.9 ppm and C_3-H at 5.1 ppm while the C_1-H

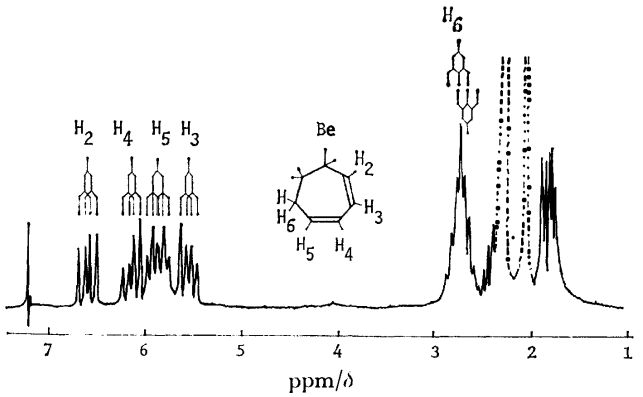


Fig. 5. ^{1}H-NMR spectrum of bis(cycloheptadienyl)-beryllium·TMEDA complex in benzene-d_6 at 38 °C.

and C_5-H signals of the magnesium compound appeared at 4.6 ppm and C_3–H signal at 3.5—3.9 ppm. Negative charge density is thus highest on the C-1 and C-5 for the beryllium compound **6** but highest on the C-3 for the magnesium compound. Bis(cyclooctadienyl)beryllium·TMEDA **7** also has the highest negative charge density on C-1 and C-5 atoms and is fluxional at room temperatures (see Table 4). Conformation of **7** will be more suited for the rapid rearrangement than that of **6**. Thus, the remarkably high chemical shift values of C_1- and C_5-protons of cyclic dienylberyllium compounds and their fluxionality can be explained by the rapid transannular 1,5-rearrangement induced by σ-π conjugation. Rearrangement observed for the magnesium compound should occur by the 1,3-pathway induced by dπ-pπ conjugation[32] due to the higher ionicity of the Mg–C bond. Bis(cycloheptadienyl)zinc·2THF also showed similar chemical shift values at −20 °C to that of the beryllium compound. The information on the conformation of the crystalline TMEDA complexes of bis(cycloheptadienyl)zinc **13** and bis(cyclooctadienyl)zinc **14** cannot be obtained at present due to their thermal instability. However, the location of the metal on the cyclooctadienyl group can be inferred by the reaction with carbonyl compounds. That is, reaction of **14** with acetone or acetaldehyde gave regioselectively 2-(2,7-cyclooctadienyl)-2-propanol or 1-(2,7-cyclooctadienyl)ethanol respectively at −30 °C (regioselectivity, 98% in both cases). Since six-membered cyclic transition state is generally assumed for this type of reaction, the above result indicates that the metal–C_1 bond is involved in the compound **14**. Corresponding beryllium compound **7** also reacted with acetone regioselectively. Regioselectivity of bis(dienyl)metal compounds of open chain structure **1**—**5**, **8**—**12** toward acetone is as high as that of cyclic dienylmetal compounds (Table 9). It is noteworthy that regioselectivity of **10** is high since **10a** and **10b** gave the same products. Chemical characterization of these addition compounds were reported in Ref. 1.

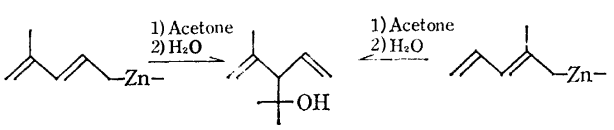

Table 8. Chemical shifts(δ-values) and coupling constants(Hz) of fluxional bis(cycloheptadienyl)metal compounds[a]

Compound	C_1-H(C_5-H) ($J_{1,2}$)	C_2-H(C_4-H)	C_3-H ($J_{2,3}$)
$(C_7H_9)_2$Be·2THF	3.85	6.26	5.12

5	98	**12**	97
6	98	**13**	98
7	99	**14**	98

a) In benzene at 5 °C.

In summary, unambiguous evidence for symmetry-allowed 1,5-shift was obtained for covalently-bonded linear dienylmetal compounds. The absence of the corresponding 1,3-shift also indicated the unimportance of ionic character and d-orbital participation in the zinc-dienyl bonding. The covalency in the bonding in dienylberyllium or dienylzinc compounds thus dictates terminally bonded structure which in turn induces regioselective reaction of the dienyl group.

Experimental

Anhydrous zinc chloride and zinc bromide (Wako Pure Chem.) were used after drying at 140—150 °C for 20 h *in vacuo*. Anhydrous beryllium chloride was purified by dissolution of the commercial sample (needle crystals, Kishida Chem. Co.) in diethyl ether and then evaporation of the ether soluble fraction. Hydrates of beryllium chloride was thus removed. Benzene-d_6 (99.5%, Merck Co.) and toluene-d_8 (99%, Merck Co.) were dried over sodium/potassium alloy and distilled. All the procedures were done in an argon atmosphere with the high vacuum technique. ^{1}H-NMR spectra were recorded at 100 MHz and ^{13}C-NMR spectra at 25.2 MHz on a Varian XL-100 instrument with a VFT-100-620L Fourier transform accessory. All the other in-

strumental analyses were done as previously reported.[1] Melting points were measured in a sealed tube and were uncorrected.

Preparation of Bis(2,4-pentadienyl)beryllium·TMEDA **1**. To a chilled solution of beryllium chloride·diethyl ether complex (2.3 g, 10 mmol) in THF (30 ml) was added a THF solution (40 ml) of potassium pentadienide (2.2 g, 20 mmol) using a syringe over a 20 min period at 5—10 °C with vigorous stirring. The mixture was allowed to react at 50 °C for 1 h and pentane (100 ml) was added at 10 °C to induce the precipitation of the salt. The supernatant liquid was separated from the salt by centrifugation using a two-necked glass tube protected with plastic cover and equipped with two small rubber stoppers and then it was evaporated *in vacuo*. Extraction of the residue with a mixture of diethyl ether (100 ml) and pentane (30 ml) followed by evaporation gave bis(pentadienyl)beryllium·2 THF as a pale yellow oil. Typical yield: 80% (2.3 g). TMEDA complex **1** was prepared by the addition of TMEDA (2.2 ml, 15 mmol) to the THF complex (2.8 g, 10 mmol) in diethyl ether (10 ml) at 20 °C. After the addition of pentane (30 ml), the mixture was cooled to −20 °C to induce the precipitation of colorless needle crystals. Yield: 92% (2.2 g) based on the THF complex. Recrystallization was carried out in 1:3 ether–pentane solution. Found: pentadiene, 53.0%; TMEDA, 43.2% (by GC); Be, 3.10% by beryllium oxide method. Calcd for $BeC_{16}H_{22}N_2$, pentadiene, 53.39%; TMEDA, 43.03%; Be, 3.58%.

Preparation of Bis(2,4-pentadienyl-1,1,5,5-d_4)beryllium·TMEDA. In essentially the same way as **1**, bis(pentadienyl-1,1,5,5-d_4)beryllium·TMEDA was prepared by reaction of potassium pentadienide-1,1,5,5-d_4($KC_5H_3D_4$) with beryllium chloride. Preparation of $KC_5H_3D_4$ is as follows. A solution of dimethyl glutarate (32 g, 0.2 mol) in diethyl ether (50 ml) was added dropwise to the suspension of $LiAlD_4$ (10 g, 0.24 mol, Merck Co.) in ether (300 ml) at 0 °C. After stirring for 5 h at 0 °C, the mixture was hydrolyzed with 2M HCl and distilled to give 1,5-pentanediol-1,1,5,5-d_4 (110 °C/1 mmHg, 20.5 g, 95% yield). Resulting pentanediol was esterified with acetic anhydride by the known method and then pyrolysis of the 1,5-pentanediyl diacetate was carried out by passing it through a Pyrex tube heated to 575± 5 °C to produce 1,4-pentadiene-1,1,5,5-d_4. Yield: 57% based on diol (8 g). After purification by distillation and drying over calcium hydride, resulting deuterated 1,4-diene (4 g, 6 mmol) was allowed to react with metallic potassium (1.2 g, 3 mmol) in THF (7 ml) in the presence of triethylamine (5 ml) at 10 °C to give $KC_5H_3D_4$.

Preparation of Bis(dienyl)beryllium·TMEDA Complex **2**—**7**. In essentially the same way as described above, a series of bis(dienyl)beryllium·TMEDA complexes were prepared from the corresponding potassium dienide. Yield: 75—85%.

Preparation of Bis(2,4-pentadienyl)zinc·TMEDA **8**. To a solution of potassium pentadienide (2.2 g, 20 mmol) in THF (40 ml) cooled by ice–water was added powdered zinc chloride (1.4 g, 10 mmol) over a 30 min period with stirring. The mixture was stirred at 5 °C for 1 h and then the volume of the solution was reduced to 1/5 by evaporation. Pentane (80 ml) was added to the residue for complete precipitation of the salt, which was then separated by quick filtration with a glass filter or by centrifugation at 5—15 °C for 10 min. All the procedures were done below 15 °C to prevent thermal decomposition. The supernatant liquid was evaporated and washed with a small portion of pentane (10 ml) at −70 °C to give bis(pentadienyl)zinc·2THF as oily substance. Yield: 84% (2.9 g). Bis(pentadienyl)zinc·TMEDA **8** was prepared by the addition of TMEDA (2.2 ml, 15 mmol) to bis(pentadienyl)zinc·2THF (2.7 g, 8 mmol) in ether (8 ml) at 0 °C. After stirring for 30 min at 30 °C, pentane (15 ml) was added and the solution was allowed to stand at −20 °C to induce the precipitation of the crystals. Yield: 98% based on the THF complex (2.3 g). Recrystallization was carried out at −20 °C from THF–pentane (1:10 vol ratio).

The other complexes of triethylamine, TMPDA, and trimethylamine oxide were prepared in the same procedure as that for the THF complex and were recrystallized from pentane at −40 °C, ether–pentane at −20 °C, and toluene at 0 °C, respectively.

Preparation of Bis(dienyl)zinc·TMEDA **9**—**12**. A series of bis(dienyl)zinc·TMEDA complexes were prepared in the same procedure described for **8** from corresponding potassium dienides. The reaction of potassium 2,4-dimethylpentadienide with zinc chloride gave THF free bis(2,4-dimethylpentadienyl)zinc as evidenced by ^{1}H-NMR while the reaction of potassium 2-methylpentadienide, 3-methylpentadienide, and hexadienide gave the complexes coordinated with 2 moles of THF.

Preparation of Pentadienylzinc Chloride·TMEDA Complex. The sample for X-ray structural analysis was prepared as follows. A solution of potassium pentadienide (2.2 g, 20 mmol) in THF (40 ml) was added with a syringe over a 30 min period to a stirred solution of anhydrous zinc chloride (2.88 g, 20 mmol) in THF (30 ml) at 5 °C. The mixture was stirred for additional 1 h at 30 °C and then the salt was separated by centrifugation. THF fraction was evaporated to give $C_5H_7ZnCl·2THF$ as semi-solid, which was then extracted with two portions of toluene (20 ml). Addition of a mixture of TMEDA (3.3 ml, 22 mmol) and pentane (80 ml) to the toluene solution followed by cooling to −20 °C produced $C_5H_7ZnCl·TMEDA$ quantitatively as needle crystals; mp, 77 °C. Yield: 85% based on zinc chloride (4.6 g).

Dienylation of Acetaldehyde and Acetone. To the solution of **1**—**12** (5 mmol) in benzene (8 ml) was added a solution of acetaldehyde (0.6 ml, 12 mmol) or acetone (0.8 ml, 12 mmol) in benzene (3 ml) at 5 °C. Resulting mixture was hydrolyzed at 0 °C and distilled *in vacuo*. In cases of **13** and **14**, corresponding reaction was carried out in THF at −30 °C without isolating the complex. After the mixture was allowed to stand at 0 °C for 1 h it was quenched with 2 M HCl. Resulting alcohols were analyzed by GC using authentic samples (chemical characterization was previously reported. see Ref. 1). Yield by GC: 98%. Both acetaldehyde and acetone attacked the C-3 atom of dienyl group regioselectively in all cases.

Crystal Data and Structure Determination of Pentadienylzinc Chloride·TMEDA. $C_{11}H_{19}N_2ClZn$, *F. W.* 280.1, monoclinic, space group $P2_1/c$, a=8.935(2), b=13.587(2), c=12.096(2) Å, β=95.50(2)°. V=1461.7(5) Å^3, D_c=1.272 g cm^{-3} for Z=4.

Unit-cell dimensions and reflection intensities were measured on a Rigaku automated, four-circle diffractometer using graphite monochromatized Mo $K\alpha$ radiation. The θ-2θ scan technique was applied at a 2θ scan rate of 4°min^{-1}. The scan width was $\Delta 2\theta=(2.0+0.7\tan\theta)°$. Backgrounds were counted for 5 s before and after the scan of each peak. Intensities of three standard reflections were measured after every 60 reflections. A total of 2296 (1852 non-zero) reflections was collected up to $\Delta 2\theta$=48°. Usual Lorentz and polarization corrections were applied but no absorption correction was made [μ(Mo $K\alpha$)=17.1 cm^{-1}].

The structure was established by the heavy atom method and refined isotropically by the block-diagonal least-squares procedure (HBLS V).[33] After the R value decreased to 0.15, anisotropic refinements were carried out. Final R

value was 0.068 for non-zero reflections. Atomic scattering factors were taken from International Tables for X-Ray Crystallography, Vol. IV.[34] The weighting schemes used in the final refinement were $w=[\sigma^2(F_o)+a|F_o|+b|F_o|^2]^{-1}$ for $|F_o|>0$ and $w=c$ for $|F_o|=0$, where, $a=0.0067$, $b=0.002$, and $c=0.111$. The final atomic positional and thermal parameters are listed in Table 10. Calculations were done on an ACOS series 77 NEAC system 700 computer at Osaka University.[35]

Vinyl Polymerization. 394.[1] Radical Polymerization of Methyl Methacrylate Initiated with *Saccharomyces Cerevisiae*

Minoru Imoto,* Tatsuro Ouchi, Eijiro Morita, Minoru Yamada, Tai Tokuyama,†† and Hitoshi Obata

Laboratry of Synthetic High Polymers, Faculty of Engineering, Kansai University, Suita, Osaka 564

†† *Laboratory of Applied Biochemistry, Faculty of Engineering, Kansai University, Suita, Osaka 564*

(Received October 4, 1979)

The polymerization of methyl methacrylate with *Saccharomyces cerevisiae* was carried out in water, the reaction being found to proceed through a radical mechanism. The effect of the mass of reagent on the rate of polymerization and selectivity of vinyl monomer were studied. The isolated cell wall showed remarkable activity for polymerization. The change of surface of the polymerization system was observed with a scanning electron microscope.

Recently, it was reported[2] that the cell of yeast, *Saccharomyces cerevisiae*, can initiate the polymerization of methyl methacrylate (MMA) in the presence of Cu(II) ion. The polymerization was found to proceed on the exterior and interior of the cell, particularly on the cell wall. The present paper deals with a precise study of the polymerization. The radical mechanism is confirmed, effects of the mass of reactant on the conversion of MMA, selectivity of the vinyl monomer and polymerization by the cell wall isolated from the cells being given.

Experimental

Materials. Dry yeast *Saccharomyces cerevisiae* (SC-1, Oriental Yeast Co.) was used. MMA and other monomers were purified by the usual methods. Copper(II) chloride (special grade) was used without further purification. The water was ion-exchanged and distilled.

Procedures. MMA, water, and other reagents were placed in a tube which was then sealed in a vacuum after thawing with nitrogen and incubated at 30 or 85 °C with shaking or by being left to stand. After a certain time, the contents of the tube were poured into a large amount of methanol in order to precipitate the polymer formed. After filtration, the product was thoroughly washed with methanol, dried in a vacuum, and then weighed. The conversion of MMA was calculated by the following equation:

$$\text{Conversion}(\%) = \frac{\text{Wt. of products(g)} - \text{Initial wt. of cells(g)}}{\text{Wt. of MMA in the feed(g)}} \times 100$$

It was confirmed by turbidimetry that no multiplication of cell was observed during the course of polymerization at 30 °C for 10 d. The mode of the polymerization system was observed with a scanning electron microscope (SEM).[2] The number-average degree of polymerization (P_n) of poly(MMA) produced was estimated from the viscosity determined in benzene at 30 °C, using Welch's equation.[3]

Results and Discussion

Confirmation of Radical Mechanism. Copolymerization of MMA with Styrene (St) was carried out (Fig. 1), a radical mechanism being confirmed.

Selectivity of Vinyl Monomer. Polymerization of various monomers was carried out with the system SC-1, Cu(II) ion, and water. The results are given in Table 1.

The conversion of St and acrylonitrile (AN) was in the range of thermal polymerization or experimental errors. Thus, no initiating ability of the present initiator system for St and AN was observed. On the other hand, MMA, ethyl methacrylate (EMA), and methacrylic acid (MAA) were found to be polymerized.

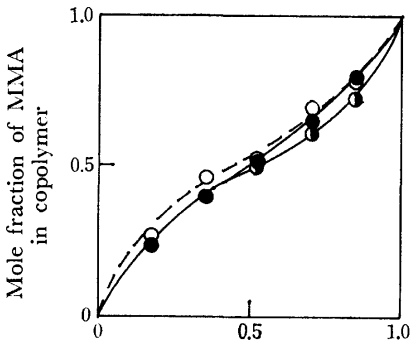

Fig. 1. Copolymerization of MMA and St. (MMA+St) 3 cm³, H_2O 10 cm³, SC-1 0.1 g, $CuCl_2 \cdot 2H_2O$ 1×10^{-3} g. ●(A), Copolymer produced at 85 °C after 3 h with shaking, including both copolymers produced in the water phase and monomer layer. ◗(B), Copolymer produced in the water layer at 30 °C after 10 d on standing. ○(C), Copolymer produced in the monomer layer at 30 °C after 10 d on standing.

Table 1. Polymerization of vinyl monomers[a]

SC-1/g	$CuCl_2 \cdot 2H_2O$/g	Conversion/%				
		MMA	St	AN	MAA	EMA
0	0	0	1.14	0	0	3.08
0.1	0	0	0.89	0	1.99	0.39
0	1×10^{-3}	0	1.43	0	0	0
0.1	1×10^{-3}	8.63	2.15	0.66	7.25	5.90

a) Monomer 3 cm³, H_2O 10 cm³; 30 °C, 10 d, with shaking.

AN: acrylonitrile, MAA: methacrylic acid, EMA: ethyl methacrylate, St: styrene, MMA: methyl methacrylate.

Effect of the Mass of Cu(II) Ion on the Polymerization of MMA. The effect of the mass of Cu(II) ion on the conversion of MMA was obtained for polymerization at 85 °C with shaking (Fig. 2) and on standing

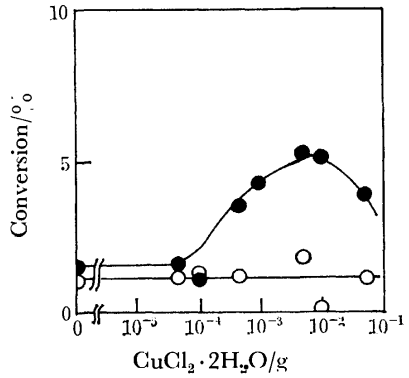

Fig. 2. Conversion of MMA with shaking *vs.* mass of $CuCl_2 \cdot 2H_2O$. MMA 3 cm³, ● SC-1 0.1 g, ○ SC-1 0 g, H_2O 10 cm³; 85 °C, 5 h.

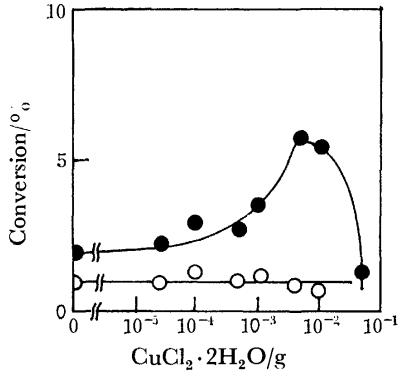

Fig. 3. Conversion of MMA on standing *vs.* mass of $CuCl_2 \cdot 2H_2O$. MMA 3 cm³, ● SC-1 0.1 g, ○ SC-1 0 g, H_2O 10 cm³; 85 °C, 5 h.

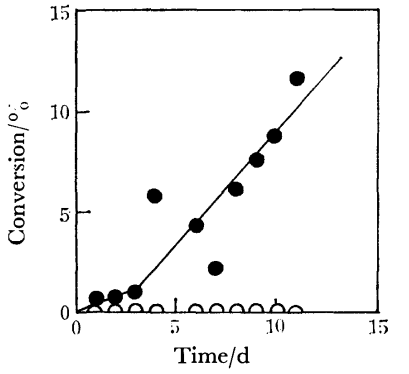

Fig. 4. Time-conversion curve.
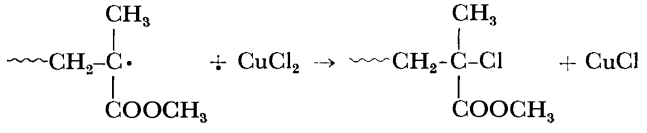
MMA 3 cm³, ● SC-1 0.1 g, ○ SC-1 0 g, H_2O 10 cm³, $CuCl_2 \cdot 2H_2O$ 1×10^{-3}g; 30 °C, with shaking.

(Fig. 3). In both cases, the maximum conversion was observed at 5×10^{-2} g of $CuCl_2 \cdot 2H_2O$. The decrease in the conversion of MMA by excess Cu(II) ion was due to the following inhibition reaction of the propagating radical with Cu(II) ion:



It should be noted that both conversion curves are similar to each other. The time-conversion curve of the polymerization of MMA is shown in Fig. 4. The white and black circles indicate the conversion of MMA in the absence and presence, respectively, of SC-1. There is an induction period of about 2 d.

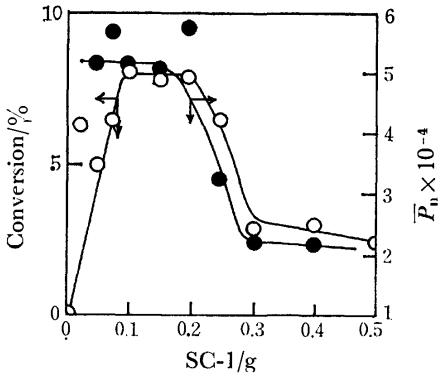


Fig. 5. Conversion of MMA or $\bar{P}_n$ of poly-(MMA) *vs.* mass of SC-1. MMA 3 cm³, H_2O 10 cm³, $CuCl_2 \cdot 2H_2O$ 1×10^{-3}g; 30 °C, 10 d, with shaking, ○ conversion. ● $\bar{P}_n$.

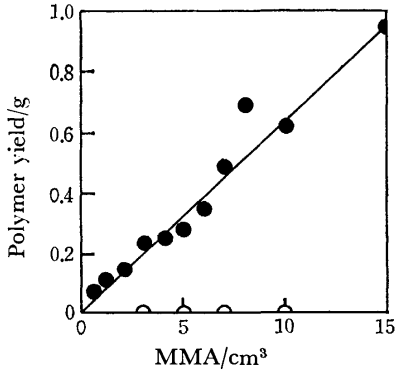

Fig. 6. Polymer yield *vs.* mass of MMA.
● SC-1 0.1 g, ○ SC-1 0 g, H_2O 10 cm³, $CuCl_2 \cdot 2H_2O$ 1×10^{-3}g; 30 °C, 10 d, with shaking.

Effect of the Mass of SC-1 on the Polymerization of MMA. Varying the mass of SC-1 and keeping that of Cu(II)-ion, MMA, and water constant, we carried out polymerization at 30 °C for 10 d with shaking. The results on the conversion of MMA and $\bar{P}_n$ of poly-(MMA) are shown in Fig. 5.

The conversion increased with the mass of SC-1, reaching maximum immediately and then decreasing. This was confirmed by repeated experiments. $\bar{P}_n$ also decreased with the mass of SC-1.

The only assumption to explain the behavior is as follows: the contents of some unknown free-radical other than the propagating poly-(MMA) radicals increase with the mass of SC-1 in the feed. The free-radicals could be produced by the chain transfer reactions of the propagating poly-(MMA) radicals with the vital macromolecules in the cell, and could scavenge the propagating poly-(MMA) radicals. Thus, above a certain amount of SC-1, the conversion of MMA and $\bar{P}_n$ of poly-(MMA) decreases. This was supported by the results of experimental studies on the chain-transfer reaction of poly-(MMA) radicals with nucleic acid bases and nucleosides.[4]

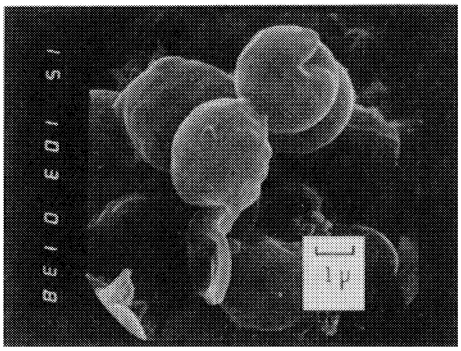

Fig. 7(a). Surface view of the SC-1.

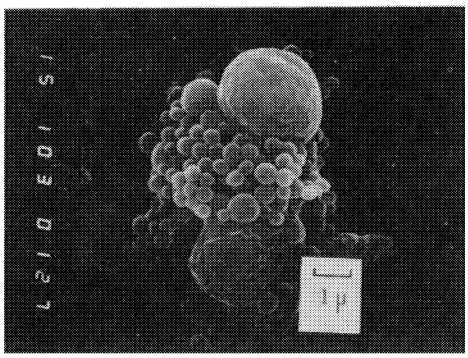

Fig. 7(b). Surface view of the polymerized system (SC-1, 0.1 g; MMA, 3 cm³; $CuCl_2 \cdot 2H_2O$, 1×10^{-3}g; H_2O, 10 cm³; 30 °C, 10 d, on standing; Conversion of MMA, 8.8%).

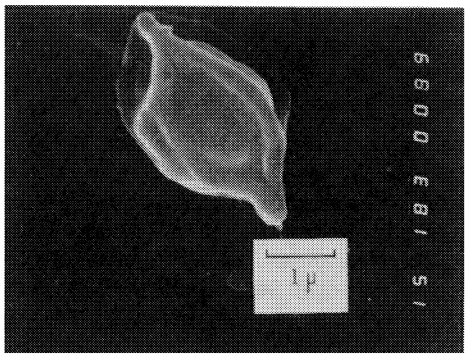

Fig. 7(c). Surface view of the polymerized system. After the polymerization, the product was washed under reflux with benzene for 50 h.

Effects of the Mass of MMA on Polymerization. The masses of SC-1, Cu(II) ion, and H_2O were kept constant. The polymerization was carried out at 30 °C for 10 d with shaking. The results are shown in Fig. 6. The polymer yield in g increased linearly with the amount of MMA.

Scanning Electron Microscopy (SEM). It was observed by transmission electron microscopy that the cell wall is disintegrated at a 3.1% conversion of MMA.[1] This is due to the particular easiness of the polymerization of MMA in the cell wall. When the conversion of MMA was only 2.1%, the cell wall became somewhat larger. We have treated the case in which the conversion of MMA reached 8.8%. The results of SEM are shown in Figs. 7(a), (b), and (c). Since the conversion was 8.8%, it seems that the wall was already disintegrated, thus becoming the active center for the polymerization of MMA. The propagating chain radicals were brought into the water phase. A similar polymerization to suspension polymerization takes place. Figure 7(b) is in line with the consideration. The small round particles near the cell are poly-(MMA) produced formed in the water phase. After washing with benzene for 50 h (Fig. 7(c)), the particles of poly-(MMA) produced in the water phase disappeared, only the cell containing poly-(MMA) produced in the interior being observed.

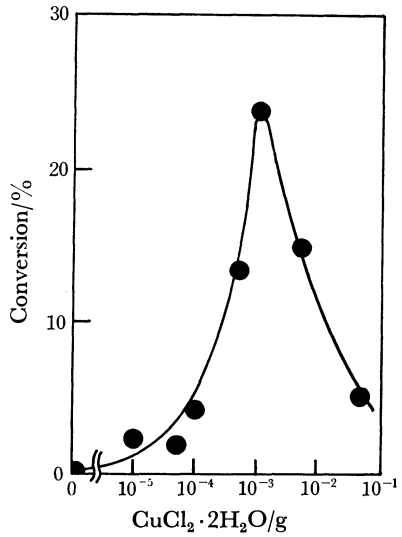

Fig. 8. The polymerization of MMA initiated by the cell wall of SC-1. MMA 3 cm³, cell wall 0.1 g, H_2O 10 cm³; 30 °C, 10 d, with shaking.

Polymerization of MMA Initiated with Cell Wall. The cell wall which is particularly active was isolated as follows. SC-1 was disrupted by means of an X-press. The cell wall was separated by centrifugation at 12000 rpm for 60 min, washed twice with cold distilled water and lyophilized, polymerization of MMA then being carried out. The results are shown in Fig. 8. The activity for polymerization of the cell wall became *ca.* 3 times higher than the original SC-1.

(Received October 5, 1979)

Pyrano[2,3-*b*]indolizinone derivatives were formed in 18—98% yields by the reactions of 3-[bis(alkylthio)-methylene]-2,3-dihydroindolizin-2-ones with various acetates in the presence of alkali. Dihydroindolizinones were readily obtained by the alkaline treatment of 1-[2,2-bis(alkylthio)-1-ethoxycarbonylvinyl]-2-ethylpyridinium iodides and -2-methylpyridinium iodides or by the *S*-alkylation of 3-[(alkylthio)mercaptomethylene]-1-phenyl-2,3-dihydroindolizin-2-ones with alkyliodides.

In a previous paper a report was given on the unexpected formation of 3-[bis(ethylthio)methylene]-1-methyl-2,3-dihydroindolizin-2-one in the reaction of 1-[1-ethoxycarbonyl-2,2-bis(ethylthio)vinyl]-2-ethylpyridinium iodide with alkali.[1] The compound is a quite new indolizine with an interesting structure: a) dihydroaromatic: b) enone and ketene dithioacetal: c) 2-methylene-1,2-dihydropyridine. We thus assumed that, if the structural contribution such as (C) (Fig. 1) for this 3-methylene-2,3-dihydroindolizin-2-one is present, the reaction of this molecule with a bifunctional reagent may lead to the condensed indolizine derivative. This was found to be the case, pyrano[2,3-*b*]indolizinone derivative being formed by the reaction with ethyl cyanoacetate under basic conditions. In this paper we wish to report the synthesis of some 3-methylene-2,3-dihydroindolizin-2-ones and their facile transformations into pyrano[2,3-*b*]indolizinone derivatives.

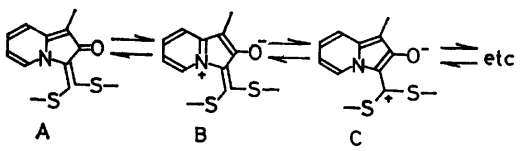

Fig. 1.

Results and Discussion

Preparation of 3-Methylene-2,3-dihydroindolizin-2-ones. The reactions of 1-[2,2-bis(alkylthio)-1-ethoxycarbonylvinyl]-2-ethylpyridinium iodides (**8** and **9**) and -2-methylpyridinium iodides (**10** and **11**), readily obtained from 1-(ethoxycarbonylmethyl)-2-ethylpyridinium bromide (**1**) and -2-methylpyridinium chloride (**2**) *via* the corresponding pyridinium ylides (**4**—**7**) (Scheme 1),[2] with alkali gave 3-[bis(alkylthio)methylene]-2,3-dihydroindolizin-2-one derivatives (**15**—**18**) as dark green prisms or oils in over 90% yields. In contrast with **10** and **11**,[3] alkaline treatment of 2-ethylpyridinium salts (**8** and **9**) in the presence of an activated ethoxymethylene compound such as ethyl (ethoxymethylene)cyanoacetate (**12**) afforded only 3-methylene-2,3-dihydroindolizin-2-ones (**15** and **16**) in comparable yields, and not the expected 2-allylidene-1,2-dihydropyridines (**13** and **14**). On the other hand, treatment of 2-benzyl-1-(ethoxycarbonylmethyl)pyridinium bromide (**3**) with carbon disulfide and then dialkyl sulfate in the presence of potassium hydroxide afforded 3-[(alkylthio)mercaptomethylene]-1-phenyl-2,3-dihydroindolizin-2-ones (**21** and **22**) as orange needles in 88 and 79% yields, respectively. *S*-Alkylation of the mercapto derivatives (**21** and **22**) with methyl and ethyl iodide in the presence of potassium carbonate in chloroform gave 3-[bis(alkylthio)methylene]-1-phenyl-2,3-dihydroindolizin-2-ones (**19** and **20**) in 96 and 91% yields, respectively.

The 3-methylene-2,3-dihydroindolizin-2-one derivatives (**15**, **16**, and **19**—**22**) were very stable under the usual conditions (below 80 °C), while the 1-unsubstituted derivatives (**17** and **18**) were considerably unstable even at room temperature and, in particular, very sensitive to column separation (alumina).

The structural assignment of the 2,3-dihydroindolizin-2-one derivatives (**15**—**22**) was accomplished mainly from physical and spectral data. For example, elementary analyses of the crystalline compounds (**15**, **19**, **21**, and **22**) were in good accord with the proposed structures. The IR spectra of **15**—**22** showed a strongly lowered carbonyl absorption near 1600 cm^{-1}, indicating the presence of the contribution of the polarized structure as observed in 2-methylene-1,2-dihydropyridine derivative,[4] and those of **21** and **22** exhibited also a weak mercapto absorption near 2500 cm^{-1} but no hydroxyl absorption over 3000 cm^{-1}. The IR spectra of **21** and **22** excluded the possibility of the 2-hydroxyindolizine structure. The NMR spectra (Table 1) of compounds **15**—**20**, and **21** and **22** are similar to each other, and the considerable low values of the skeletal protons in **15**—**20** in comparison with those of aromatic indolizines[5] strongly supported their dihydroindolizine structure. Furthermore, signals appearing at near δ 13 ppm in the NMR spectra of **21** and **22** should be due to the mercapto group hydrogen-bonding to the 2-carbonyl oxygen. The considerably high values of the chemical shifts of **21** and **22** as compared with those of **15**—**20** can be explained by the promoted aromatic character owing to the hydrogen-bonding.

Reactions of 3-Methylene-2,3-dihydroindolizin-2-ones with Various Acetates in the Presence of Alkali. In order to achieve transformation of these dihydroaromatic compounds (**15**—**20**) into condensed aromatic indolizine derivatives, we carried out their reactions with bifunctional reagents in the light of ketene dithioacetal chemistry.[6] We chose activated acetate derivatives, which can easily generate the nucleophilic carbanion under basic conditions and also have an electrophilic carbonyl carbon. When 3-methylene-2,3-dihydroindo-

lizin-2-ones (**15**—**20**) were allowed to react with ethyl cyanoacetate (**23**) in benzene in the presence of triethylamine under reflux, smooth evolution of methanethiol or ethanethiol was observed, separation of the reaction solutions giving crystalline 4-alkylthio-3-cyano-2*H*-pyrano[2,3-*b*]indolizin-2-one derivatives (**24**—**29**). 4-Ethoxy derivatives **30** and **32** were also obtained in the reactions of **15** and **20** (Scheme 2). Furthermore, the respective replacement of the solvent and the base, benzene by ethanol and triethylamine by potassium *t*-butoxide, in the reactions of **15**, **16**, and **19** with **23** gave rise to increased formation of 4-ethoxypyranoindolizinones (**30** and **32**).

On the other hand, similar reactions of **15**—**20** with ethyl benzoylacetate (**33**), diethyl malonate (**34**), ethyl acetoacetate (**35**), and ethyl phenylacetate (**36**) in the presence of potassium *t*-butoxide gave only 4-alkylthio-2*H*-pyrano[2,3-*b*]indolizin-2-one derivatives (**37**—**60**) in 18—98% yields with the evolution of methanethiol or ethanethiol (Scheme 3). The use of triethylamine as a base in the above reactions did

not give satisfactory results because of their diminished yields of pyranoindolizinones.

All the pyrano[2,3-*b*]indolizinones (**24**—**30**, **32**, and **37**—**60**) were very stable crystalline compounds with strong fluorescence. Elementary analyses of compounds **25**—**29** and **37**—**60** were in good accord with the postulated structures, the IR spectra always showing a strong absorption at 1670—1700 cm^{-1} due to the 2-pyrone carbonyl group (Table 4). As compared with 3-methylene-2,3-dihydroindolizin-2-ones (**15**—**22**), the NMR spectra of the pyranoindolizinones (**24**—**30**, **32**, and **37**—**60**) (Table 2) exhibited signals at a fairly low field attributable to the skeletal protons, whose values coincided with those of known aromatic indolizine derivatives.[5] For example, the NMR spectrum of **39** showed skeletal proton signals at δ 6.82 (1H, dt, J=7.0, 7.0, and 2.0 Hz, C_7–H), 7.34 (1H, br t, J=8.0 and 7.0 Hz, C_8–H), 7.49 (1H, br d, J=8.0 Hz, C_9–H), and 9.28 (1H, d, J=7.0 Hz, C_6–H), and methyl signals at δ 2.30 (3H, s, C_{10}–Me), 2.46 (3H, s, SMe), and 2.65 (3H, s, COMe), and the chemical shifts of the skeletal protons (δ 6.82—9.28) and of the C_{10}–Me protons (δ 2.30) were in line with those of 3-acylindolizines (δ 6.50—9.40)[3] and 1-methylindolizine (δ 2.27).[7] On the other hand, the NMR spectra of **30** and **32** were almost the same as those of 4-alkylthiopyrano[2,3-*b*]indolizin-2-ones (**24**—**29** and **37**—**60**)

except for the absence of the alkylthio signals and the presence of an ethoxyl signals (δ near 1.7 (3H, t, J=7.0 Hz) and near 5.1 (2H, q, J=7.0 Hz)). From the results and mechanistic consideration, the products **24**—**29** and **37**—**60**, and **30** and **32** were concluded to be 4-alkylthio-2*H*-pyrano[2,3-*b*]indolizin-2-one derivatives and the 4-ethoxy isomers, respectively.

Reaction Mechanism. The formation of pyranoindolizinones (**24**—**29** and **37**—**60**) is explained by the nucleophilic substitution with the carbanion (**61**), generated *in situ* by the treatment of acetates with base, at the 3-methylene position of 2,3-dihydroindolizin-2-ones (**15**—**20**), followed by the hydrogen abstraction from the resulting product (**62**) by a base catalyst and then the intramolecular nucleophilic cyclization of the anion (**64**) (*via* the primary carbanion (**63**)) with the elimination of an ethoxide ion. The fact that the primary substitution compound (**62**) was not isolated at all suggests a very fast progress of steps **62**→**63**→**64**→**24**—**29** and **37**—**60**. On the other hand, 4-ethoxypyranoindolizinones such as **30**—**32** should be formed *via* the nucleophilic substitution of 4-alkylthio-3-cyanopyranoindolizinones by the ethoxide ion generated *in situ* in these reaction systems, since, if similar substitution for 3-methylene-2,3-dihydroindolizin-2-ones (**15**—**20**) could occour initially, other 4-ethoxypyranoindolizinone derivatives should be formed together with **30** and **32**. In these reactions the reason for only the formation of 4-ethoxy-3-cyano-2*H*-pyrano[2,3-*b*]indolizin-2-ones (**30** and **32**) is not clear, but it may be related to the strong electron-withdrawing effect and the smaller hindrance of the cyano group. The mechanisms are summarized in Scheme 4.

Experimental

Melting points were measured with a Yanagimoto micro-melting point appratus and are uncorrected. Microanalyses were carried out on a Perkin-Elmer 240 Elemental Analyzer. The NMR spectra were determined with a Varian EM360A NMR Spectrometer in deuteriochloroform with tetramethylsilane as an internal standard. The chemical shifts are expressed in δ values. The IR spectra were taken with a Hitachi 260-10 Infrared Spectrophotometer.

*Preparation of Pyridinium Salts (**8**—**11**).* All the 1-[2,2-bis(alkylthio)-1-ethoxycarbonylvinyl]-2-ethylpyridinium iodides (**8** and **9**) and -2-methylpyridinium iodides (**10** and **11**)[2,3] were prepared from 1-(ethoxycarbonylmethyl)-2-ethylpyridinium bromide (**1**) and -2-methylpyridinium chloride (**2**) according to the procedure of Tominaga *et al.*[2] The results and some properties of new compounds (**4**, **5**, **8**, and **9**) are as follows: (**4**), 56%, yellow needles, mp 146—149 °C, Found: C, 54.86; H, 6.05; N, 4.90%. Calcd for $C_{13}H_{17}NO_2S_2$: C, 55.09; H, 6.05; N, 4.92%. (**5**), 38%, yellow needles, mp 103—106 °C, Found: C, 39.48; H, 4.78; N, 3.30%. Calcd for $C_{14}H_{20}NO_2S_2I$: C, 39.52; H, 4.74; N, 3.29%. (**8**), 91%, pale yellow prisms, mp 109—112 °C, Found: C, 56.61; H, 6.42; N, 4.63%. Calcd for $C_{14}H_{19}NO_2S_2$: C, 56.53; H, 6.44; N, 4.71%. (**9**), 86%, pale yellow prisms, mp 117—120 °C, Found: C, 42.36; H, 5.31; N, 3.22%. Calcd for $C_{16}H_{24}NO_2S_2I$: C, 42.38; H, 5.34; N, 3.09%.

*Preparation of 3-Methylene-2,3-dihydroindolizin-2-ones (**15**—**18**). General Method*: A chloroform solution (50 ml) of pyridinium salt (1 or 2 mmol) was treated with potassium carbonate (5 or 10 g) at room temperature until the TLC spot of the

salt disappeared (*ca.* 10—15 h). Insoluble inorganic substances were removed from the reaction solution by filtration and the filtrate was concentrated at reduced pressure. The residues were separated by column chromatography (alumina) using ether-chloroform as an eluent in the cases of 1-methyl-3-methylene-2,3-dihydroindolizin-2-ones (**15** and **16**). However, the column separation of 1-unsubstituted 3-methylene-2,3-dihydroindolizin-2-ones (**17** and **18**) was unsuccessful because of their instability. The results and properties are given in Table 3.

*Preparation of 3-[(alkylthio)mercaptomethylene]-1-phenyl-2,3-dihydroindolizin-2-ones (**21** and **22**).* To an ethanol solution (100 ml) of 2-benzyl-1-(ethoxycarbonylmethyl)pyridinium bromide (**3**, 10 mmol) and carbon disulfide (1.1 g, 15 mmol) aq potassium hydroxide (KOH (2.8 g, 50 mmol) in 5 ml water) was added dropwise at room temperature. After the reaction mixture had been stirred for 1 h, ice water (200 ml) and then dialkyl sulfate (12 mmol) were added. The crude 3-[(alkylthio)mercaptomethylene]-1-phenyl-2,3-dihydroindolizin-2-one (**21** or **22**) precipitated was collected by filtration, dried, and recrystallized from chloroform. The results are summarized in Table 3.

*Preparation of 3-Methylene-2,3-dihydroindolizin-2-ones (**19** and **20**).* *General Method*: A chloroform solution (50 ml) of mercapto derivative (3 mmol) was treated with potassium carbonate (10 g) and methyl or ethyl iodide (4 mmol) at room temperature for 1—2 d, and the reaction mixture was filtered in order to remove insoluble substances. The filtrate was concentrated, and the residual oil was separated by column chromatography (alumina) using ether–chloroform as an eluent. The data are given in Table 3.

*Preparations of Pyrano[2,3-b]indolizinones (**24—30**, **32**, and **37—60**).* *Method A*: A benzene solution (30 ml) of 3-methylene-2,3-dihydroindolizin-2-one (1 mmol), ethyl cyanoacetate (**23**, 0.34 g, 3 mmol), and triethylamine (2 g) was allowed to react under reflux for 6—12 h. The reaction mixture was concentrated at reduced pressure, and the residual oil was separated by column chromatography (alumina). Recrystallization from chloroform–ether gave the corresponding 4-alkylthio-3-cyano-2*H*-pyrano[2,3-*b*]indolizin-2-ones (**24—29**) and the 4-ethoxy derivatives (**30** and **32**).

Method B: A benzene solution (30 ml) of 3-methylene-2,3-dihydroindolizin-2-one (1 mmol), the acetate (3—5 mmol), and potassium *t*-butoxide (1.5—2 mmol) was allowed to react under reflux until the TLC spot of 3-methylene-2,3-dihydroindolizin-2-one disappeared (3 h—3 d). The reaction mixture was then filtered in order to remove insoluble inorganic substances and the filtrate was concentrated at reduced pressure. The usual separation of the residual oils gave the corresponding 4-alkylthio-2*H*-pyrano[2,3-*b*]indolizin-2-one derivatives (**37—60**).

In the reactions of **15**, **16**, and **19** with **23**, the replacement of the solvent and base, benzene by ethanol and triethylamine by potassium *t*-butoxide, gave rise to increased formation of 4-ethoxypyranoindolizinones (**30** and **32**).

In the reactions with various acetates (**23** and **33—36**), 1-unsubstituted 3-methylene-2,3-dihydroindolizin-2-ones (**17** and **18**) were used without purification, the yields of pyranoindolizinones (**26**, **27**, and **45—52**) being estimated from the corresponding pyridinium salts (**10** and **11**).

The results and properties are summarized in Table 4.

Pseudo-sugars. VI. Synthesis of Six Isomers of 5-Hydroxymethyl-1,2,3,4-cyclohexanetetrol (Pseudo-hexopyranose) and Their Derivatives[1]

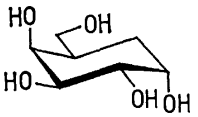
Seiichiro Ogawa,* Masayasu Ara, Takashi Kondoh, Michio Saitoh, Reiko Masuda, Tatsushi Toyokuni, and Tetsuo Suami

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 223

(Received October 15, 1979)

Six isomers of 5-hydroxymethyl-1,2,3,4-cyclohexanetetrol, including naturally occurring (1,2/3,4,5)-isomer, and their several derivatives were synthesized from the *exo*-2-substituted *endo*-3-acetoxy-*endo*-5-acetoxymethyl-7-oxabicyclo[2.2.1]heptane compounds.

The isolation of an antibacterial substance, (+)-(1,2/3,4,5)-5-hydroxymethyl-1,2,3,4-cyclohexanetetrol (pseudo-α-D-galactopyranose) (**1**)[2] in fermentation broth of *actinomyces Streptomyces* sp. MA-4145[3] prompted us to investigate a structure-activity relationship of stereoisomers of (hydroxymethyl)cyclohexanetetrol (pseudo-hexopyranose) and its related substances. In the present paper, we wish to report a synthesis of two isomeric pseudo-hexopyranoses (**1**, racemate, and **14**) and their derivatives by acetolysis of *exo*-2-substituted *endo*-3-acetoxy-*endo*-5-acetoxymethyl-7-oxabicyclo[2.2.1]heptane compounds (**2**—**5**). In addition, nucleophilic substitution reaction of bromo(hydroxymethyl)cyclohexanetriols (**8** and **16**) thus obtained from **4** led to the other four isomers (**20**, **24**, **28**, and **32**) and their amino deoxy derivatives.



(+)-(1,2/3,4,5)-5-Hydroxymethyl-1,2,3,4-cyclohexanetetrol (**1**)

Treatment of *exo*-2, *endo*-3-diacetoxy-*endo*-5-acetoxymethyl-7-oxabicyclo[2.2.1]heptane (**2**)[4] with a mixture of acetic acid and acetic anhydride containing sulfuric acid in a sealed tube at 80 °C overnight resulted in cleavage of the anhydro ring giving rise to a mixture of products, from which on fractional crystallization penta-*O*-acetyl-5-hydroxymethyl-1,2,3,4-cyclohexanetetrols (**6**, 19%) and (**13**, 18%) were isolated. As expected, **6** and **13** were shown to be identical with authentic samples with (1,2/3,4,5)-[5] and (1,3,5/2,4)-configurations,[4] respectively. Compounds **6** and **13** were converted into the corresponding pentols (**1**, racemate) and (**14**) by treatment with methanolic sodium methoxide.

A similar procedure was used for the acetolysis of **3**,[6] **4**,[7] and **5**.[7] Compound **3** gave 2-*O*-methyl-(1,2/3,4,5)- (**7**) and 2-*O*-methyl-(1,3,5/2,4)-5-hydroxymethyl-1,2,3,4-cyclohexanetetrol tetraacetates (**15**) in 28 and 12% yields, respectively. In the ^{1}H NMR spectra of **7** and **15**, signals due to the protons on the carbon atoms attached to methoxyl groups appeared as a one-proton doublet of doublets with 3 and 11-Hz splittings at δ 4.30 and a one-proton triplet with 11-Hz splitting at δ 3.90, respectively, confirming the assigned structures. Similarly, the structures of tetra-*O*-acetyl-2-bromo-5-hydroxymethyl-1,3,4-cyclohexanetriols (**8**, 31%) and (**16**, 13%) obtained by acetolysis of **4** were assigned to possess (1,2/3,4,5)- and (1,3,5/2,4)-configurations, respectively, by the ^{1}H NMR signal due to the proton on the carbon atom attached to the bromo group.

On the other hand, acetolysis of **5** gave a sole crystalline tetra-*O*-acetyl(hydroxymethyl)cyclohexanetriol (**17**) in 58% yield. In order to establish the structure, **8** and **16** were subjected to hydrogenolysis with Raney nickel T-4[8] in the presence of Amberlite IR-45 (OH^-) to give the corresponding debromo compounds (**9**, 62%) and (**17**, 36%),[9] respectively. Compounds **9** and **17** were therefore assigned to tetraacetates of (1/3,4,5)- and (1,3,5/4)-5-hydroxymethyl-1,3,4-cyclohexanetriols, respectively. In the case of **5**, the anhydro ring was opened preferentially at C-1 by an acetate ion.

To prepare the other isomers of pseudo-hexopyranose and their derivatives, nucleophilic substitution reaction of **8** and **16** with an acetate or azide ion was studied. Treatment of **8** with an excess of sodium acetate in 90% aqueous 2-methoxyethanol at boiling temperature for 2 days gave, after acetylation, **6** (10%) and the hitherto unknown isomer (**19**, 31%). of **6** suggested that the reaction involved the intermediary 2,3-cyclic acetoxonium ion *via* an anchimeric assistance of the C-3 acetoxyl group, **19** was tentatively assigned to have (1,3/2,4,5)-configuration, resulting from the back side attack of an acetate ion at C-3.

The similar treatment of **16** with an acetate ion gave new isomers (**23**, 29%) and (**27**, 27%). When **16** was treated with sodium benzoate in dimethyl sulfoxide at 120 °C for 2 days, direct S_N2 reaction occurred to give 2-*O*-benzoyl-(1,2,3,5/4)-5-hydroxymethyl-1,2,3,4-cyclohexanetetrol tetraacetate (**31**) in 49% yield. The assigned structure was supported by appearance of a one-proton triplet (J=2.5 Hz, H-2) at δ 5.78 together with a one-proton triplet (J=10 Hz, H-4) at δ 5.40 and a one-proton doublet of doublets (J=2.5 and 10 Hz, H-3) at δ 5.04 in the ^{1}H-NMR spectrum.

O-Deacylation of **19**, **23**, **27**, and **31** in the usual way gave the corresponding pentols (**20**), (**24**), (**28**), and (**32**), respectively. Compound **32** was further characterized as the pentaacetate (**33**), which was found not to be identical with either **23** or **27**.

In order to determine the structures of **23** and **27**, the following sequence of the reactions was carried out. Treatment of **24** with 2,2-dimethoxypropane in *N*,*N*-dimethylformamide in the presence of *p*-toluenesulfonic acid gave a sole crystalline di-*O*-isopropylidene derivative (**36**) in 71% yield. Oxidation with ruthenium tetraoxide in a mixture of chloroform–water in the presence of sodium metaperiodate gave a ketone (**37**) in 61% yield, the structure of which was supported by ^{1}H NMR spectroscopy. Hydrogenation with platinum oxide in ethyl acetate gave a syrupy di-*O*-isopropylidene derivative (**38**) of pentol different from **36**. Compound **38** was then converted into a pentol identical with **32** in all respects. Three isomers with (1,3,5/2,4)-, (1,4/2,3,5)-, and (1,2,5/3,4)-configurations were considered to be formed from **16** by the anchimeric reaction involving the cyclic acetoxonium ions between C-1 and C-2, and/or C-2 and C-3. Therefore, these results showed that **23** was C-1 epimer of **32**, possessing (1,4/2,3,5)-configuration, and then **27** was tentatively assigned to the (1,2,5/3,4)-isomer.

Treatment of **8** with an excess of sodium azide in aqueous 2-methoxyethanol at boiling temperature for 2 days, followed by acetylation, gave two azides (**11**, 15%) and (**21**, *ca.* 80%). By analogy to the reaction with an acetate ion, two compounds were presumed to be tetra-*O*-acetyl-(1,2/3,4,5)-2-azido-5-hydroxymethyl-1,3,4- and tetra-*O*-acetyl-(1,3/2,4,5)-3-azido-5-hydroxymethyl-1,2,4-cyclohexanetriols. The ^{1}H NMR spectrum of **11** was fully interpreted by first-order method, being consistent with the former structure. In the spectrum of **21**, appearance of a one-proton triplet (J=10 Hz) due to the proton on a carbon atom attaching to the azido group showed that **21** had the latter structure, all the substituent except for the acetoxymethyl group locating in equatorial positions in the favored conformation. Hydrogenation of **11** and **21** with Raney nickel T-4 in methanol containing acetic anhydride gave the corresponding tetra-*O*-acetyl-(acetamido)(hydroxymethyl)cyclohexanetriols (**12**) and (**22**), respectively.

The similar azidolysis of **16** followed by acetylation gave, after fractionation by a silica gel column, two syrupy azides (**25**, 48%) and (**29**, 54%).[10] On hydrogenation and acetylation in the usual way, **25** and **29** were converted into the corresponding amino alcohol pentaacetates (**26**) and (**30**). Their structures were deduced by analogy to those of **23** and **27** obtained by the similar reaction with an acetate ion, and finally confirmed by ^{1}H NMR spectroscopy. Judging from the patterns of the signals due to C-7 methylene protons, the structures of **25** and **29** might be able to correlate with those of **23** and **27**, respectively. Further evidence was obtained by the spectrum of **26**, which showed after deuteration a one-proton narrow quartet (J= 3.5 Hz, H-4) at δ 4.18. Therefore, **26** and **30** were assigned to possess (1,4*N*/2,3,6)- and (1,2,5/3*N*,4)-configurations, respectively, as shown in the Scheme.

When dimethyl sulfoxide was used as the reaction solvent in the azidolysis of **16**, direct S_N2 reaction occurred to give an azide (**34**) with the inversion of the configuration at C-2. In the ^{1}H NMR spectrum, a narrow triplet (J=2.5 Hz, H-2) at δ 4.20 clearly supported the axial-equatorial-axial conformation for H-1, H-2, and H-3. Hydrogenation of **34** followed by acetylation gave tetra-*O*-acetyl-(1,2,3,5/4)-2-acetamido-5-hydroxymethyl-1,3,4-cyclohexanetriol (**35**).

Compounds **12** and **35** are considered to be carbocyclic analogs of 2-amino-2-deoxy-α-DL-galactopyranose and β-DL-mannopyranose. Biochemical and biological studies of pseudo-hexopyranoses and their amino deoxy derivatives obtained in this work are on the way.

Experimental

Unless otherwise stated, melting points were determined on a Büchi 510 capillary melting point apparatus and are uncorrected. Solutions were evaporated under reduced pressure at 40—50 °C. IR spectra were recorded on a Hitachi

225 spectrometer in potassium bromide pellets. ^{1}H NMR spectra were taken on a Varian EM-360A (60 MHz) in deuteriochloroform with reference to tetramethylsilane as an internal standard and the peak positions are given in terms of δ-values. Values given for coupling constants are of first-order. TLC was performed on precoated silica gel 60 F-254 plaques (Merck, Darmstadt; 0.25 mm thickness). The silica gel used for a column chromatography was Wakogel C-300 (Wako Pure Chemical Industries, Ltd.).

Acetolysis of exo-*2*, endo-*3-Diacetoxy*-endo-*5-acetoxymethyl-7-oxabicyclo[2.2.1]heptane (**2**).*[4] A mixture of **2** (4 g), acetic acid (12 ml), acetic anhydride (7 ml), and concentrated sulfuric acid (0.7 ml) was sealed in a glass tube and heated at 80—85 °C for 20 h in an oil bath. The brown reaction mixture was poured into ice–water (200 ml), and the solution was neutralized with sodium hydrogencarbonate and extracted with ethyl acetate (3×30 ml). The extracts were washed with water thoroughly, dried over anhydrous sodium sulfate, filtered through a short column of alumina and concentrated. The syrupy residue was crystallized from a small amount of ethanol to give penta-*O*-acetyl-(1,2/3,4,5)-5-hydroxymethyl-1,2,3,4-cyclohexanetetrol (**6**, 1.2 g, 19%) as crystals: mp 137—138 °C, 144.5—145 °C (hot-stage) [lit,[5] 147—148 °C (hot-stage)]. The ^{1}H NMR spectrum ($CDCl_3$) was superimposable on that of an authentic sample reported.[5] (Found: C, 52.57; H, 6.22%).

The mother liquor from **6** was concentrated to a small volume and kept in a refrigerator for a week to give penta-*O*-acetyl-(1,3,5/2,4)-5-hydroxymethyl-1,2,3,4-cyclohexanetetrol (**13**, 1.15 g, 18%) as practically pure crystals: mp 109.5—111 °C. Recrystallization from ethanol gave a pure sample: mp 111.5—112.5 °C (lit,[4] 111—112 °C), which was identified with an authentic sample by comparison with IR and ^{1}H NMR spectra.

Compound **6** (1 g) was treated with 1 M methanolic sodium methoxide (1.1 ml) in methanol (50 ml) at reflux temperature for 0.5 h. After cooling, the solution was neutralized with Amberlite IR-120 (H^+) and concentrated to give a crystalline residue, which was crystallized from ethanol to give racemic (1,2/3,4,5)-5-hydroxymethyl-1,2,3,4-cyclohexanetetrol (**1**, 0.44 g, 96%) as crystals: mp 167—168 °C [lit,[5] 173—174 °C (hot-stage)] (Found: C, 47.04; H, 7.92%).

Compound **13** was *O*-deacetylated as described above to give (1,3,5/2,4)-5-hydroxymethyl-1,2,3,4-cyclohexanetetrol (**14**) as a homogeneous syrup, identical with an authentic sample[4] in all respects.

Acetolysis of 3-endo-*Acetoxy-5*-endo-*acetoxymethyl-2*-exo-*methoxy-7-oxabicyclo[2.2.1]heptane (**3**).*[6] A mixture of **3** (3 g), acetic acid (9 ml), acetic anhydride (4 ml), and concentrated sulfuric acid (0.4 ml) was heated in a glass sealed tube at 90—95 °C overnight. The mixture was poured into ice–water (150 ml) and the solution was extracted with chloroform (3×30 ml). The extracts were washed thoroughly with aqueous sodium hydrogencarbonate and water, successively, dried, and filtered through a short column of alumina. Evaporation of the solvent gave a crystalline mixture of products (2.45 g, 59%), which was fractionally crystallized from ethanol to give first 1,3,4,7-tetra-*O*-acetyl-2-*O*-methyl-(1,2/3,4,5)-5-hydroxymethyl-1,2,3,4-cyclohexanetetrol (**7**, 0.49 g, 12%) as plates: mp 144.5—145 °C. ^{1}H NMR ($CDCl_3$) δ=2.04 (6H, s) and 2.10 (6H, s) (OAc), 3.36 (3H, s, OMe), 3.48 (1H, dd, J=3 and 10 Hz, H-2), 3.8—4.0 (2H, m, C<u>H</u>$_2$OAc), 5.06 (1H, dd, J=3 and 10 Hz, H-3), 5.50 (2H, m, H-1 and H-4).

From the mother liquor of **7**, 1,3,4,7-tetra-*O*-acetyl-2-*O*-methyl-(1,3,5/2,4)-5-hydroxymethyl-1,2,3,4-cyclohexanetetrol (**15**, 1.15 g, 28%) was obtained as prisms: mp 80—81.5 °C. ^{1}H NMR ($CDCl_3$) δ=2.05 (6H, s), 2.07 (3H, s) and 2.10 (3H, s), 3.30 (1H, t, J=10 Hz, H-2), 3.44 (3H, s, OMe), 3.9—4.2 (2H, m, C<u>H</u>$_2$OAc), 4.6—5.1 (3H, m, H-1, H-3, and H-4).

Found for **7**: C, 53.47; H, 6.67%; and for **15**: C, 53.27; H, 6.72%. Calcd for $C_{16}H_{24}O_9$: C, 53.33; H, 6.71%.

Acetolysis of endo-*3-Acetoxy*-endo-*5-acetoxymethyl*-exo-*2-bromo-7-oxabicyclo[2.2.1]heptane (**4**).* A mixture of **4** (4 g), acetic acid (12 ml), acetic anhydride (8 ml), and concentrated sulfuric acid (0.5 ml) was heated in a sealed tube at 90—95 °C overnight. The brown mixture was poured into ice–water (200 ml) and the resulting crystals were collected by filtration and washed with water. The product was dissolved in hot ethanol, treated with active carbon, and crystallized to give a mixture of crystals (3.7 g, 64%). Fractional crystallization from ethanol first gave tetra-*O*-acetyl-(1,2/3,4,5)-2-bromo-5-hydroxymethyl-1,3,4-cyclohexanetriol (**8**, 1.6 g, 31%) as prisms or plates: mp 161.5—162.5 °C. ^{1}H NMR ($CDCl_3$) δ=2.03 (3H, s), 2.06 (3H, s), 2.12 (3H, s), and 2.17 (3H, s) (OAc), 3.85—4.0 (2H, m, C<u>H</u>$_2$OAc), 4.30 (1H, dd, J=3 and 11 Hz, H-2), 5.27 (1H, dd, J=3 and 11 Hz, H-3), 5.38 (1H, t, J=3 Hz, H-4), 5.52 (1H, q, J=3 Hz, H-1).

From the mother liquor of **8**, tetra-*O*-acetyl-(1,3,5/2,4)-2-bromo-5-hydroxymethyl-1,3,4-cyclohexanetriol (**16**, 0.7 g, 13%) was obtained as thin plates: mp 145—146 °C. ^{1}H NMR ($CDCl_3$) δ=2.03 (6H, s), 2.07 (3H, s), and 2.10 (3H, s) (OAc), 3.9—4.1 (2H, m, C<u>H</u>$_2$OAc), 3.90 (1H, t, J=11 Hz, H-2), 4.88 (1H, t, J=11 Hz, H-3), 4.92 (1H, m, H-1), 5.23 (1H, t, J=11 Hz, H-4).

Found for **8**: C, 44.25; H, 5.11; Br, 19.20%; and for **14**: C, 44.06; H, 5.08; Br, 19.50%. Calcd for $C_{15}H_{21}O_8Br$: C, 44.02; H, 5.17; Br, 19.53%.

Acetolysis of 2-endo-*Acetoxy-6*-endo-*acetoxymethyl-7-oxabicyclo-[2.2.1]heptane (**5**).*[6] a) A mixture of **5** (4 g), acetic acid (12 ml), acetic anhydride (8 ml), and concentrated sulfuric acid (0.5 ml) was heated in a sealed tube at 90—95 °C overnight. The reaction mixture was poured into ice–water (100 ml) and the resulting precipitates were collected by filtration. The aqueous filtrate was extracted with chloroform and the extracts were worked up in the usual manner to give an additional crop of crystals. Recrystallization of the combined crude crystals from ethanol gave tetra-*O*-acetyl-(1,3,5/2)-3-hydroxymethyl-1,2,5-cyclohexanetriol (**17**, 3.42 g, 58.4%) as needles: mp 104—105 °C. ^{1}H NMR ($CDCl_3$) δ=1.97 (3H, s), 2.01 (3H, s), and 2.04 (6H, s) (OAc).

Found: C, 54.39; H, 6.55%. Calcd for $C_{15}H_{22}O_8$: C, 54.53; H, 6.73%.

b) A solution of **16** (0.88 g) in ethyl acetate (10 ml) was hydrogenated (Parr shaker apparatus) in the presence of Raney nickel T-4[8] (3 ml) and Amberlite IR-45 (OH^-) in the initial hydrogen pressure of 3.4 kg cm^{-2} at ambient temperature overnight. The catalyst and resin were filtered off and the filtrate was concentrated. The residue was recrystallized from ethanol to give **17** (0.24 g, 36%) as needles, which was identical with the compound obtained from **5** in all respects.

*(1,3,5/2,4)-3-hydroxymethyl-1,2,5-cyclohexanetriol (**18**).* To a solution of **17** (4 g) in methanol (200 ml) was added 1 M methanolic sodium methoxide (12 ml) and the mixture was refluxed for 1.5 h. The mixture was processed in the usual manner to give a product, which was crystallized from ethanol to give **18** (1.9 g, 96%) as needles: mp 125—127 °C.

Found: C, 51.68; H, 8.60%. Calcd for $C_7H_{14}O_5$: C, 51.84; H, 8.70%.

*Tetra-O-acetyl-(1,2,3/5)-3-hydroxymethyl-1,2,5-cyclohexanetriol (**9**).* A solution of **8** (3 g) in ethyl acetate (20 ml) was hydrogenated similarly as described in the preparation of **17**. The crude product was recrystallized from ethanol to give **9** (1.5 g, 62%) as needles: mp 98—99 °C. ^{1}H NMR ($CDCl_3$) δ=1.99 (3H, s), 2.05 (3H, s), 2.09 (3H, s), and 2.11 (3H, s) (OAc), 3.8—4.1 (2H, m, C$\underline{H}_2$OAc). 5.01 (1H, dd, J=2.5 and 9 Hz. H-1), 5.24 (1H, t, J=2.5 Hz, H-5), 5.46 (1H, t, J=2.5 Hz, H-2).

Found: C, 54.52; H, 6.70%. Calcd for $C_{15}H_{22}O_8$: C, 54.53; H, 6.73%.

*(1,2,3/5)-3-Hydroxymethyl-1,2,5-cyclohexanetriol (**10**).* Compound **9** (0.3 g) was *O*-deacetylated in methanol (20 ml) containing 1 M methanolic sodium methoxide (0.5 ml) similarly as described in the preparation of **1**. The crude product was purified by a silica gel column with methanol to give a homogeneous syrup (0.15 g, 98%).

Found: C, 52.12; H, 8.42%. Calcd for $C_7H_{14}O_4$: C, 51.84; H, 8.70%.

*Reaction of **8** with Sodium Acetate.* A mixture of **8** (2.9 g), anhydrous sodium acetate (3 g), and 90% aqueous 2-methoxyethanol (70 ml) was refluxed for three days and concentrated under reduced pressure. The solid residue was dried by coevaporation with toluene and then treated with acetic anhydride (10 ml) and pyridine (15 ml) at ambient temperature overnight. An insoluble material was removed by filtration and the filtrate was concentrated. The syrup was dissolved in chloroform and filtered through a short column of alumina. Removal of the solvent and crystallization from ethanol gave **6** (0.26 g, 10%) as prisms: mp 136—137 °C, identical with the compound obtained from **2**. The mother liquor of **6** was kept in a refrigerator for a week to give penta-*O*-acetyl-(1,3/2,4,5)-5-hydroxymethyl-1,2,3,4-cyclohexanetetrol (**19**, 0.8 g, 31%) as plates: mp 106—107 °C. ^{1}H NMR ($CDCl_3$) δ=2.00 (12H, s) and 2.12 (3H, s) (OAc), 4.18 (2H, d, J=6 Hz, C$\underline{H}_2$OAc).

Found: C, 52.81; H, 6.22%. Calcd for $C_{17}H_{24}O_{10}$: C, 52.57; H, 6.23%.

O-Deacetylation of **19** (0.5 g) with methanolic sodium methoxide in the usual manner to give a crystalline pentol (**20**, 0.17 g, 75%), which was recrystallized from ethanol to give an analytical sample: mp 154.5—156 °C.

Found: C, 46.95; H. 7.75%. Calcd for $C_7H_{14}O_5$: C, 47.18; H, 7.92%.

*Reaction of **16** with Sodium Acetate.* A mixture of **16** (2 g), anhydrous sodium acetate (2.9 g), and 90% aqueous 2-methoxyethanol was refluxed for 43 h and concentrated under reduced pressure. The reaction mixture was processed similarly as described in the reaction of **6**. A crystalline mixture of products (1.5 g) was fractionally crystallized from ethanol. The first crop of crystals (0.6 g) was recrystallized twice to give penta-*O*-acetyl-(1,4/2,3,5)-5-hydroxymethyl-1,2,3,4-cyclohexanetetrol (**23**, 0.27 g, 14%) as prisms: mp 99.5—100 °C. ^{1}H NMR ($CDCl_3$) δ=1.99 (3H, s), 2.04 (3H, s), 2.06 (3H, s), 2.12 (3H, s), and 2.13 (3H, s) (OAc), 3.98—4.15 (2H, m, C$\underline{H}_2$OAc), 4.98 (1H, q, J=3 Hz, H-1), 5.0—5.5 (3H, m, H-2, H-3, and H-4).

The second crop of crystals (0.9 g) was fractionally crystallized from ethanol to give practically pure **23** (0.3 g, total yield 29%) and penta-*O*-acetyl-(1,2,5/3,4)-5-hydroxymethyl-1,2,3,4-cyclohexanetetrol (**27**, 0.51 g, 27%) as prisms: mp 106—107 °C. ^{1}H NMR ($CDCl_3$) δ=2.01 (6H, s), 2.06 (3H, s), 2.10 (3H, s), and 2.13 (3H, s) (OAc), 4.05 (2H, d, J=5 Hz, C$\underline{H}_2$OAc), 4.9—5.35 (4H, m, H-1, H-2, H-3, and H-4).

Found for **23**: C, 52.71; H, 6.21%, and for **27**: C, 52.32; H, 6.11%. Calcd for $C_{17}H_{24}O_{10}$: C, 52.57; H, 6.23%.

O-Deacetylation of **23** (0.25 g) in the usual manner gave the pentol (**24**, 0.10 g, 84%) as a homogenous syrup.

O-Deacetylation of **27** (0.25 g) in the usual manner gave a crystalline pentol (**28**, 0.075 g, 65%), which was recrystallized from ethanol to give prisms: mp 143.5—144.5 °C.

Found for **24**: C, 47.34; H, 7.74%, and for **28**: C, 46.96; H, 7.74%. Calcd for $C_7H_{14}O_5$: C, 47.18; H, 7.92%.

*1,3,4,7-Tetra-O-acetyl-2-O-benzoyl-(1,2,3,5/4)-5-hydroxymethyl-1,2,3,4-cyclohexanetetrol (**31**).* A stirred mixture of **16** (1.24 g), sodium benzoate (1.2 g), 18-crown-6 (0.4 g) in dimethyl sulfoxide (30 ml) was heated at 115—120 °C for 2 d. After cooling, the reaction mixture was diluted with ethyl acetate (100 ml) and the solution was washed well with water. The organic layer was dried and filtered through a short column of alumina. The filtrate was concentrated and the residue was crystallized from ethanol to give **31** (0.67 g, 49%) as prisms: mp 134—135 °C. ^{1}H NMR ($CDCl_3$) δ=1.94 (3H, s), 1.96 (3H, s), 2.03 (3H, s), and 2.10 (3H, s) (OAc), 4.06 (2H, broad s, C$\underline{H}_2$OAc), 5.05 (1H, dd, J=2.5 and 10 Hz, H-3), 5.40 (1H, t, J=10 Hz, H-4), 5.79 (1H, t, J=2.5 Hz, H-2), 7.45 (3H, m) and 8.05 (2H, m) (phenyl).

Found: C, 58.79; H, 5.91%. Calcd for $C_{22}H_{26}O_{10}$: C, 58.66; H, 5.82%.

O-Deacylation of **31** (0.23 g) in the usual manner gave a crystalline pentol (**32**), which was recrystallized from ethanol–water to give needles: mp 198—199 °C.

Found: C, 47.16; H, 7.76%. Calcd for $C_7H_{14}O_5$: C, 47.18; H, 7.92%.

Acetylation of **32** (0.05 g) with acetic anhydride and pyridine in the usual manner gave, after crystallization from ethanol, a pentaacetate (**33**, 0.1 g, 90%) as prisms: mp 123—125 °C. ^{1}H NMR ($CDCl_3$) δ=1.98 (3H, s), 2.02 (3H, s), 2.06 (3H, s), and 2.20 (3H, s) (OAc), 4.01 (2H, broad d, J=4 Hz, C$\underline{H}_2$OAc), 4.91 (1H, dd, J=2.5 and 10 Hz, H-3), 5.23 (1H, t, J=10 Hz, H-4), 5.56 (1H, t, J=2.5 Hz, H-2).

Found: C, 52.69; H, 6.33%. Calcd for $C_{17}H_{24}O_{10}$: C, 52.57; H, 6.23%.

*2,3:4,7-Di-O-isopropylidene-(1,4/2,3,5)-5-hydroxymethyl-1,2,3,4-cyclohexanetetrol (**36**).* The crude **24** obtained from **23** (0.8 g) in the usual manner was heated with 2,2-dimethoxypropane (4 ml) in *N,N*-dimethylformamide (10 ml) in the presence of *p*-toluenesulfonic acid (15 mg) at 60 °C for 1 h. After cooling, the mixture was treated with Amberlite IRA-400 (OH^-) and concentrated. The residue was crystallized from ethanol to give **36** (0.36 g, 71%) as crystals: mp 147.5—148.5 °C. ^{1}H NMR ($CDCl_3$) δ=1.35 (3H, s), 1.41 (3H, s), 1.50 (3H, s), and 1.52 (3H, s) (isopropylidene), 3.61 (1H, d) and 3.80 (1H, broad d) (J=5 Hz, H-7 and H-7'), 4.10 (3H, broad s, H-2, H-3, and, H-4).

Found: C, 60.50; H, 8.60%. Calcd for $C_{13}H_{22}O_5$: C, 60.43; H, 8.60%.

The acetate was prepared in the conventional way. The crude product was recrystallized from ethanol to give prisms: mp 140.5—141 °C. ^{1}H NMR ($CDCl_3$) δ=1.37 (3H, s), 1.45 (3H, s), 1.49 (3H, s), and 1.51 (3H, s) (isopropylidene), 3.69 (2H, AB-quartet, H-7 and H-7'), 3.9—4.2 (2H, m, H-2 and H-3), 5.25 (1H, broad q, J=3 Hz, H-1).

Found: C, 59.72; H, 7.70%. Calcd for $C_{15}H_{24}O_6$: C, 59.98; H, 8.05%.

The tosylate was prepared by treatment with *p*-toluenesulfonyl chloride in pyridine. The crude product was crystallized from 2-propanol to give crystals: mp 137—138 °C.

Found: C, 58.46; H, 6.77; S, 7.52%. Calcd for $C_{20}H_{28}O_7S$: C, 58.22; H, 6.86; S, 7.77%.

2,3:4,7-Di-O-isopropylidene-(2,3,5/4)-2,3,4-trihydroxy-5-(hy-

*droxymethyl)cyclohexanone (**37**).* Compound **36** (0.5 g) was dissolved in ethanol-free chloroform (10 ml), and a catalytic amount of ruthenium dioxide and aqueous sodium hydrogencarbonate were added. A 5% aqueous sodium metaperiodate (10 ml) was added to the mixture during 20 min under ice cooling with vigorous agitation. After 2.5 h, an excess of periodate and ruthenium tetraoxide were destroyed with 2-propanol, and black precipitates were removed by filtration. The organic layer was separated, washed with water thoroughly, and dried. Removal of the solvent gave a crystalline residue which was recrystallized from ethanol to give **37** (0.3 g, 61%) as crystals: mp 124 °C (after sintering at 119 °C). ^{1}H NMR ($CDCl_3$) δ=1.40 (3H, s), 1.48 (3H, s), and 1.50 (6H, s) (isopropylidene), 1.8—2.6 (3H, m, H-5, H-6, and H-6'), 3.3—4.0 (3H, m, H-4, H-7, and H-7'), 4.4—4.6 (2H, m, H-2 and H-3).

Found: C, 61.01; H, 7.77%. Calcd for $C_{13}H_{20}O_5$: C, 60.92; H, 7.87%.

Compound **37** (0.13 g) was hydrogenated in ethyl acetate (5 ml) in the presence of platinum oxide in the usual manner to give a homogeneous syrup of 2,3:4,7-di-*O*-isopropylidene-(1,2,3,5/4)-5-hydroxymethyl-1,2,3,4-cyclohexanetetrol (**38**, 0.12 g), which was not identical with **36** in all respects. Crude **38** was directly treated with 80% aqueous acetic acid (5 ml) at 80 °C for 1 h. The reaction mixture was concentrated and the residue was recrystallized from ethanol–water to give **32** (83 mg, 92%): mp 196—197 °C, identical with the compound obtained from **31**.

*Reaction of **8** with Sodium Azide.* A mixture of **8** (5.7 g), sodium azide (6 g), and 90% aqueous 2-methoxyethanol (120 ml) was refluxed for 44 h and concentrated under reduced pressure. The residue was dried by coevaporation with toluene several times and then treated with acetic anhydride (20 ml) and pyridine (30 ml) at ambient temperature overnight. An insoluble material was removed by filtration and the filtrate was concentrated. The residue was dissolved in ethyl acetate (50 ml) and filtered through a short column of alumina (20 g). The filtrate was concentrated and the syrupy residue was crystallized from ethanol to give tetra-*O*-acetyl-(1,2/3,4,5)-2-azido-5-hydroxymethyl-1,3,4-cyclohexanetriol (**11**, 0.79 g, 15%) as prisms: mp 145—147 °C. ^{1}H NMR ($CDCl_3$) δ=2.03 (3H, s), 2.07 (3H, s), and 2.13 (6H, s) (OAc), 3.6—4.0 (2H, m, C<u>H</u>$_2$OAc), 3.75 (1H, dd, J=3 and 11 Hz, H-2), 5.17 (1H, dd, J=3 and 11 Hz, H-3), 5.40 (1H, q, J=3 Hz, H-1), 5.53 (1H, t, J=3 Hz, H-4).

Found: C, 48.67; H, 5.72; N, 11.11%. Calcd for $C_{15}H_{21}N_3O_8$: C, 48.52; H, 5.70; N, 11.32%.

The mother liquor of **11** was concentrated to give a syrup which consisted mainly of tetra-*O*-acetyl-(1,3/2,4,5)-3-azido-5-hydroxymethyl-1,2,4-cyclohexanetriol (**21**, 5.1 g). ^{1}H NMR ($CDCl_3$) δ=2.02 (3H, s), 2.09 (3H, s), 2.11 (3H, s), and 2.13 (3H, s) (OAc), 3.79 (1H, t, J=10 Hz, H-3), 4.8—5.2 (3H, m, H-1, H-2, and H-4). Purification of **21** was not attempted because its mobility on TLC was similar to that of **11** in various solvent systems.

*Tetra-O-acetyl-(1,2/3,4,5)-2-acetamido-5-hydroxymethyl-1,3,4-cyclohexanetriol (**12**).* A solution of **11** (0.6 g) in ethanol (35 ml), acetic anhydride (0.8 ml), and Raney nickel T-4 (one-spoonful) was hydrogenated with 3.4 kg cm^{-2} starting pressure of hydrogen gas at ambient temperature overnight in a Parr hydrogenation apparatus. The catalyst was removed by filtration and the filtrate was concentrated. Recrystallization of the crude product from ethanol gave **12** (0.48 g, 82%) as needles: mp 184—185.5 °C. ^{1}H NMR ($CDCl_3$) δ=1.83 (3H, s, NAc), 1.95 (3H, s), 2.02 (3H, s), and 2.13 (3H, s) (OAc), 3.85—4.0 (2H, m, C<u>H</u>$_2$OAc), 4.52 (1H, ddd, J=3, 9, and 11 Hz, H-2), 5.12 (1H, dd, J=3 and 11 Hz, H-3), 5.25 (1H, t, J=3 Hz, H-4), 5.53 (1H, q, J=3 Hz, H-1), 5.70 (1H, d, J=9 Hz, N<u>H</u>).

Found: C, 52.54; H, 6.41; N, 3.70%. Calcd for $C_{17}H_{25}NO_9$: C, 52.71; H, 6.51; N, 3.62%.

*Tetra-O-acetyl-(1,3/2,4,5)-3-acetamido-5-hydroxymethyl-1,2,4-cyclohexanetriol (**22**).* The crude **21** (5 g) was hydrogenated similarly as described in the preparation of **12**. The crude product was recrystallized from ethanol–ether to give **22** (2.7 g, 51% yield based on **8** used) as needles: mp 159—160 °C. ^{1}H NMR ($CDCl_3$) δ=1.91 (3H, s, NAc), 2.03 (6H, s), 2.07 (3H, s), and 2.13 (3H, s) (OAc), 4.2—4.3 (2H, m, C<u>H</u>$_2$OAc), 5.71 (1H, d, J=9 Hz, N<u>H</u>).

Found: C, 52.64; H, 6.45; N, 3.76%. Calcd for $C_{17}H_{25}NO_9$: C, 52.71; H, 6.51; N, 3.62%.

*Reaction of **16** with Sodium Azide.* A mixture of **16** (3 g), sodium azide (3.4 g), and 90% aqueous 2-methoxyethanol (70 ml) was refluxed for 40 h. The reaction mixture was processed and acetylated similarly as described in the reaction of **8**. The syrupy mixture (3.2 g) of azides obtained was chromatographed on a silica-gel column (70 g) with butanone–toluene (1:6, v/v) as an eluent to give tetra-*O*-acetyl-(1,4/2,3,6)-4-azido-6-hydroxymethyl-1,2,3-cyclohexanetriol (**25**, 1.3 g, 48%) as a homogeneous syrup, which crystallized on standing in a refrigerator for two months: mp 84—84.5 °C, and tetra-*O*-acetyl-(1,2,5/3,4)-3-azido-5-hydroxymethyl-1,2,4-cyclohexanetriol (**29**, 1.5 g, 54%) as a homogeneous syrup, which also crystallized on standing in a refrigerator for two months: mp 66—67 °C. ^{1}H NMR ($CDCl_3$) data for **25**: δ=1.99 (3H, s), 2.02 (3H, s), 2.05 (3H, s), and 2.12 (3H, s) (OAc), 3.8—4.1 (3H, m, H-4 and C<u>H</u>$_2$OAc), 5.0—5.3 (3H, m, H-1, H-2, and H-3), and for **29**: 2.00 (3H, s), 2.07 (3H, s), 2.12 (3H, s), and 2.14 (3H, s) (OAc), 4.0—4.1 (3H, m, H-3 and C<u>H</u>$_2$OAc), 4.9—5.3 (3H, m, H-1, H-2, and H-4).

Found for **25**: C, 48.31; H, 5.62; N, 11.11%, and for **29**: C, 48.51; H, 5.67; N, 11.17%. Calcd for $C_{15}H_{21}N_3O_8$: C, 48.52; H, 5.70; N, 11.32%.

*Tetra-O-acetyl-(1,4/2,3,6)-4-acetamido-6-hydroxymethyl-1,2,3-cyclohexanetriol (**26**).* The crude syrupy **25** (0.35 g) was hydrogenated similarly as described in the preparation of **12**. The crude crystalline product was recrystallized from ethanol–ether to give **26** (0.16 g, 44%) as prisms: mp 181—182 °C. The overall yield from **16** was 24%. ^{1}H NMR ($CDCl_3$) δ=1.99 (6H, s), 2.03 (3H, s), 2.06 (3H, s), and 2.10 (3H, s) (NAc and four OAc), 4.05 (2H, broad d, C<u>H</u>$_2$OAc), 4.18 (1H, m, H-4, the signal changes to a quartet with 3.5 Hz splitting on deuteration), 5.1—5.3 (3H, m, H-1. H-2, and H-3), 6.70 (1H, J=8 Hz, N<u>H</u>).

Found: C, 52.99; H, 6.57; N, 3.64%. Calcd for $C_{17}H_{25}NO_9$: C, 52.71; H, 6.51; N, 3.62%.

A mixture of **25** and **29** obtained from **16** (2.7 g) was without separation directly hydrogenated followed by acetylation to give **26** (0.12 g, 24%): mp 179—180 °C, cleanly crystallized out of the mixture of products.

*Tetra-O-acetyl-(1,2,5/3,4)-3-acetamido-5-hydroxymethyl-1,2,4-cyclohexanetriol (**30**).* The crude syrupy **29** (0.47 g) was hydrogenated and acetylated similarly as described in the preparation of **12**. The syrupy product (0.41 g, 84%) was purified by a silica gel column with chloroform–ethyl acetate (5:1, v/v) as an eluent to give **30** as a homogeneous syrup. ^{1}H NMR ($CDCl_3$) δ=1.96 (3H, s) and 2.05 (12H, s) (NAc and four OAc), 4.41 (2H, d, J=6 Hz, C<u>H</u>$_2$OAc), 4.62 (1H, broad td, J=4 Hz, H-3), 5.0—5.25 (3H, m, H-1, H-2, and H-4), 6.60 (1H, d, J=9 Hz, N<u>H</u>).

Found: C, 52.47; H, 6.38; N, 3.53%. Calcd for $C_{17}H_{25}NO_9$: C, 52.71; H, 6.51; N, 3.62%.

Tetra-O-acetyl-(1,2,3,5/4)-2-acetamido-5-hydroxymethyl-1,3,4-

*cyclohexanetriol (**35**).* A stirred mixture of **16** (2 g), sodium azide (2 g), and dimethyl sulfoxide (35 ml) was heated at 110 °C for 10 h. The reaction mixture was diluted with water (100 ml) and the solution was extracted with ethyl acetate (3×50 ml). The extracts were washed with water, dried, and filtered through a short column of alumina (10 g). The filtrate was concentrated to give tetra-*O*-acetyl-(1,2,3,5/4)-2-azido-5-hydroxymethyl-1,3,4-cyclohexanetriol (**34**, 1 g, 51%) as a chromatographically homogeneous syrup: ^{1}H NMR ($CDCl_3$) δ=2.07 (3H, s), 2.09 (3H, s), 2.11 (3H, s), and 2.13 (3H, s) (OAc), 3.93 (2H, broad s, C$\underline{H}_2$OAc), 4.20 (1H, t, J=2.5 Hz, H-2), 4.75—5.2 (3H, m, H-1, H-3, and H-4).

The crude syrup was directly hydrogenated and acetylated similarly as described in the preparation of **12**. The crude product was recrystallized from chloroform–ether to give **35** (0.6 g, 31% yield based on **16** used) as needles: mp 177—179 °C. ^{1}H NMR ($CDCl_3$) δ=1.97 (3H, s), 2.00 (3H, s), and 2.05 (9H, s) (NAc and four OAc), 4.02 (2H, AB quartet, C$\underline{H}_2$OAc), 4.8—5.2 (3H, m, H-1, H-3, and H-4), 6.10 (1H, J=8 Hz, N$\underline{H}$).

Found: C, 52.47; H, 6.45; N, 3.55%. Calcd for $C_{17}H_{25}NO_9$: C, 52.71; H, 6.51; N, 3.62%.

The present work was partially supported by a Grand-in-Aid for Scientific Research No. 355376 from the Ministry of Education, Science and Culture. The authors wish to express their thanks to Mr. Saburo Nakada for elemental analyses.

The Benzannelated Annulenes. Dibenzo[*d,j*]-6,8-bisdehydrothia[13]-, [15]-, and Dibenzo[*f,l*]-8,10-bisdehydrothia[17]annulene

Jūro Ojima,* Kiyomi Kusaki, Kazuyo Wada, and Yukiko Nakagawa
Department of Chemistry, Faculty of Science, Toyama University, Gofuku, Toyama 930
(Received October 18, 1979)

The title compounds have been synthesized by the double Wittig reaction of bis[(triphenylphosphonio)-methyl] sulfide dibromide with *o*-ethynylbenzaldehyde and/or *o*-ethynylcinnamaldehyde, followed by the oxidative coupling. The ^{1}H-NMR spectra of these compounds gave no evidence for a ring current.

Replacement of one of the double bonds of $(4n+2)$ or $(4n)\pi$ electron annulene with a sulfur atom which possesses a lone pair of electrons will lead to the potentially diatropic or paratropic system, respectively.

In connection with the studies to confirm the prediction Sondheimer *et al.* have synthesized dimethylbis-dehydrothia[13]- **1**,[1a] [15]- **2**,[1b] and [17]annulene **3**[1c] as well as their bis(cyclohexene)-annelated ones[1a,b,d] in which the sulfur atom is flanked by ethylenic bond on both sides.

The method consists in employing a double Wittig condensation of bis[(triphenylphosphonio)methyl] sulfide dibromide **4**[2] with an appropriate aldehyde containing terminal acetylene group, followed an intramolecular oxidative coupling of the resulting acyclic compound.

As an extension of our works on benzannelated annulenes,[3] we have now applied with advantage the method to the synthesis of benzannelated bisdehydrothiaannulenes by using *o*-ethynylbenzaldehyde **5**[3a] and/or *o*-ethynylcinnamaldehyde **10**[4] as the starting material and by the essentially same approach as that of Sondheimer *et al.*[1] We now describe the syntheses of the title compounds, *i.e.*, dibenzo[*d,j*]-6,8-bisdehydrothia[13]- **9**, -[15]annulene **14**, and dibenzo[*f,l*]-8,10-bisdehydrothia[17]annulene **12**.

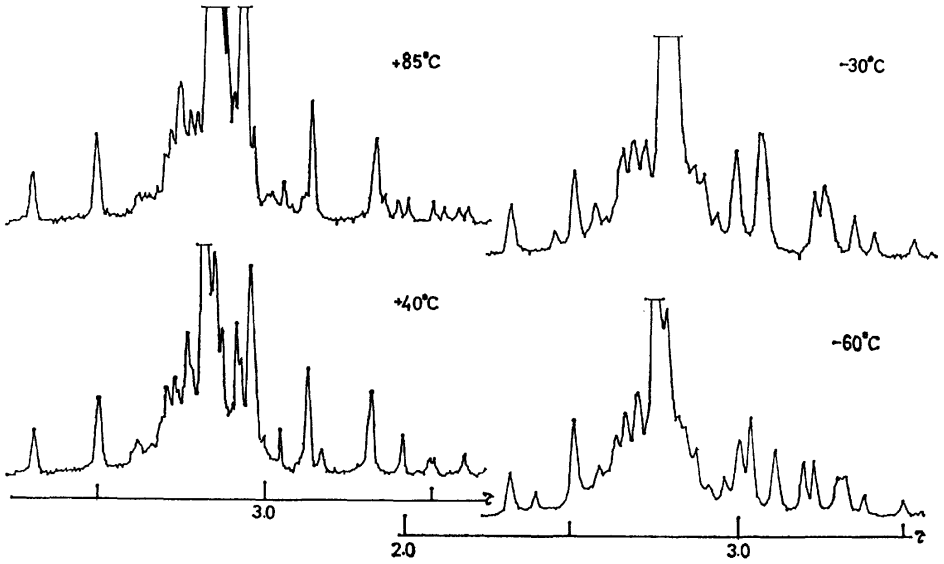

Fig. 1. ^{1}H-NMR FT spectra of **14** in $CDCl_3$ at 80 MHz (Internal Standard, TMS).

The double Wittig reaction of 2 molar equivalents of *o*-ethynylbenzaldehyde **5**[3a] and 1 molar equivalent of bis[(triphenylphosphonio)methyl] sulfide dibromide **4**[2] in *N,N*-dimethylformamide with ethanolic lithium ethoxide at 80 °C yielded an acyclic stereoisomeric mixture in a good yield, from which *trans-trans* isomer **6** (1%), *cis-trans* isomer **7** (21%), and *cis-cis* isomer **8** (25%) were isolated; only **8** was obtained as crystals. Configuration of each isomer was confirmed by IR and NMR spectra. Oxidative coupling of the mixture of **6**—**8** was carried out with anhydrous copper(II) acetate in pyridine and dry ether at 50 °C as reported by Darby *et al.*[5] Column chromatography of the product on alumina gave the cyclic compounds, from which we could isolate *trans-trans* isomer **9** as crystals in a 17% yield. Similarly, the reaction of the salt **4** with *o*-ethynylcinnamaldehyde **10**[4] gave a very unstable stereoisomeric mixture in a 35% yield, from which only mono-*cis* isomer **11** was isolated as bright yellow crystals. Coupling of the unstable mixture as before gave only di-*cis* isomer **12** in a 20% yield, although several isomers were obtained for both dimethyl-[1e] and bis(cyclohexene)-annelated [17]annulene.[1d] The double Wittig reaction between the salt **4** and each 1 molar equivalent of **5** and **10** was carried out at 70 °C in *N,N*-dimethylformamide. Column chromatography of the product afforded the desired acyclic compound of [15]annulene in an 18% yield along with analogues of [13]- and [17]annulenes. We isolated all-*trans* isomer **13** as yellow crystals by further purification. Oxidative coupling of the acyclic mixture containing **13** gave the mixture of the cyclic compounds, from which we could isolate all-*trans* isomer **14** in a 15% yield. The assignment of the structure of these compounds was made on the basis of their spectral properties as well as elemental analyses for the crystalline compounds, and the assigned conformations were given to these compounds in analogy with the dimethylthiaannulenes **1**—**3**, which were shown to have the conformations based on ^{1}H-NMR spectroscopy of the corresponding dideuterio compounds.[1] The dibenzo[*d,j*]-6,8-bisdehydrothia[13]annulene **9**, -[15]annulene **14**, and dibenzo[*f,l*]-8,10-bisdehydrothia-[17]annulene **12** formed light yellow needles (164 °C (dec)), yellow needles (141 °C (dec)), yellow needles (196 °C (dec)), respectively; all these compounds ap-

pear to be considerably stable.

The ^{1}H-NMR spectral data of the protons of **9**, **12**, and **14**, altogether with those of **1**—**3** reported by Sondheimer *et al.*[1] are summarized in Table 1. The individual assignments were made on the basis of the multiplicity, coupling constants, and the data of the closely related compounds.[1] The signals of all olefinic protons could not be located precisely, because the signals due to benzenoid protons were also observed in almost the same region as those of olefinic protons. Comparison of the chemical shifts of the olefinic protons of the dibenzannelated annulene with those of the corresponding dimethylthiaannulene **1**—**3** shows that the dibenzothiaannulenes **9**, **12**, **14** are atropic, reflecting that annelation of two benzene rings eliminate the ring current observed for **1**—**3**. The NMR spectra of [13]- **9** and [17]annulene **12** proved to be temperature-independent in the range of −60 to 60 °C, in contrast to the cases for dimethylthia-[13]- **1** and [17]annulene **3**.[1a,c] On the other hand, the spectra of [15]annulene **14** which are illustrated in Fig. 1, are temperature-dependent, though the dimethylthia[15]annulene **2** being a rigid molecule. As seen from Fig. 1, the signals become more complex from +85 °C to −60 °C, especially in the τ 3.0—3.5 region. The change of the band is not understandable by taking for a rotation about a *trans* double bond. Thus, although this behavior is not understood, similar type of NMR temperature dependence has been observed in the case of the spectra of monodehydro-[14]annulene.[6] However, a possible explanation is the increase of the anisotropic effect of the fused benzene rings on cooling, reflecting that the macrocyclic ring becomes more planar.[7]

The electronic spectra of **9**, **12**, **14** are illustrated in Fig. 2. It is recognized that the electronic spectra of carbocyclic annulenes and dehydroannulenes have been shown to alternate, the main maxima of $(4n+2)\pi$-electron systems being at higher wavelength than those of $4n$ systems.[8] However, this trend is not exhibited for the electronic spectra of these benzothiaannulene series, reflecting that the compounds **9**, **12**, **14** are atropic.

Experimental

All melting points are uncorrected. Brockmann Alumina (Act. II—III) wasused for column chromatography. The IR spectra were measured on a Hitachi EPI-S2 spectrophotometer. The UV spectra were taken on a Hitachi 124 spectrophotometer and refer to tetrahydrofuran solution. Shoulders in UV spectra are indicated by sh. The NMR

measurements were made with a Varian EM-390, a Hitachi R-900 at 90 MHz or a Varian FT-80A spectrometer at 80 MHz in $CDCl_3$ using tetramethylsilane as an internal standard and recorded in τ-values. The mass spectra were obtained on a JEOL JMS-OI-SG-2 or JEOL JMS-D 100 spectrometer at 75 eV using direct insertion technique. Evaporation of solvents was carried out at water aspirator pressure.

Bis[2-(o-ethynylphenyl)vinyl] Sulfides **6**, **7**, *and* **8**. Lithium ethoxide prepared from lithium (0.33 g, 0.047 gatm) in ethanol (112 ml) was added dropwise with stirring under nitrogen atmosphere at 80—86 °C over a period of 1.5 h to a mixture of *o*-ethynylbenzaldehyde **5**[3a] (5.8 g, 0.045 mol) and bis[(triphenylphosphonio)methyl] sulfide dibromide **4**[2] (13.2 g, 0.0177 mol) in *N,N*-dimethylformamide (446 ml). After further 2 h of stirring at the same temperature, the mixture was then poured into water (500 ml) and extracted thoroughly with benzene. The extracts were washed with dilute hydrochloric acid, aq sodium hydrogencarbonate and saturated sodium chloride solution successively, dried over sodium sulfate, and evaporated to give a dark brown semisolid. Chromatography over a column of alumina (160 g) with hexane-ether (95:5—85:15) as eluent gave a mixture of acyclic compound. The mixture was again taken up in ether and absorbed on alumina (120 g). Careful elution with hexane-ether (98:2) resulted in separation of three isomers. Early eluents gave *trans-trans* isomer **6** (0.05 g, 1.0%) as a light yellow liquid, MS: *m/e* 286 (M^+, 100); mol wt, 286.3; IR (neat): 3300 (-C≡CH), 2100 (-C≡C-), 1585 (C=C), 960, 950 cm^{-1} (*trans* C=C); UV: λ_{max}225 (35100), 252 (25400), 337 nm (27300); NMR: *ca.* 2.4—2.9 (m, 10H, H^B and benzenoid H), 3.00 (d, J=16, 2H, H^A), 6.65 (s, 2H, -C≡CH). The following eluents gave *cis-trans* isomer **7** (1.05 g, 21%) as a light yellow liquid, MS: *m/e* 286 (M^+, 100); mol wt, 286.3; IR (neat): 3300 (-C≡CH), 2100 (-C≡C-), 1597 (C=C), 960, 945 (*trans* C=C), 712, 704 cm^{-1} (*cis* C=C); UV: λ_{max} 226 (37200), 250 (26200), 332 nm (31700); NMR: *ca.* 2.2—3.0 (m, 10H, H^B, $H^{B'}$, and benzenoid H), 3.10 (d, J=16, 1H, H^A), 3.42 (d, J=11, 1H, $H^{A'}$), 6.66 (s, 1H, -C≡CH), 6.67 (s, 1H, -C≡CH). The last eluents gave *cis-cis* isomer **8** (1.27 g, 25%) as solid, which was recrystallized from hexane-benzene to give colorless needles, mp 86—88 °C, MS: *m/e* 286 (M^+, 100); mol wt, 286.3; IR (KBr): 3300 (-C≡CH), 2100 (-C≡C-), 1590 (C=C), 706 cm^{-1} (*cis* C=C); UV: λ_{max}227 (27500), 248 sh (19600), 326 nm (21300); NMR: 2.2—2.9 (m, 8H, benzenoid H), 2.93 (d, J=11, 2H, H^B), 3.47 (d, J=11, 2H, H^A), 6.65 (s, 2H, -C≡CH).

Dibenzo[d,j]-*6,8-bisdehydrothia*[*13*]*annulene* **9**. A solution of a mixture of **6**, **7**, and **8** (2.37 g, 8.3 mmol) in pyridine (141 ml) and dry ether (47 ml) was added dropwise to a stirred solution of anhydrous copper(II) acetate (10.6 g) in pyridine (303 ml) and dry ether (101 ml) during 2 h at 45—50 °C and the reaction mixture was stirred for further 1.5 h at the same temperature. After cooling, the mixture was diluted with benzene (500 ml) and filtered through Hyflo Super-Cel. The precipitates formed were washed with benzene (50 ml×2). The filtrate was then poured into 7% hydrochloric acid (1000 ml), and the aq layer was further extracted with benzene. The combined organic layer was washed with 7% hydrochloric acid, water, aq sodium hydrogencarbonate, saturated sodium chloride solution successively, and dried over sodium sulfate. A dark brown liquid obtained by solvent removal was chromatographed on alumina (120 g) with hexane as eluent. Early fractions gave a very unstable liquid which was turned to brownish amorphous on dryness and exposed to air. The following fractions gave *trans-trans* isomer **9** (0.045 g, 17%) as relatively stable crystals. Recrystallization from hexane–benzene afforded light yellow needles, mp 164 °C (dec); MS: *m/e* 284 (M^+, 100); mol wt, 284.3; IR (KBr): 2200 (-C≡C-), 1595 (C=C), 940 cm^{-1} (*trans* C=C); UV: λ_{max} 218 (40900), 227 sh (38300), 247 (19400), 261 (17900), 308 (34500), 346 (10600), 360 sh (8700), 388 sh nm (3100); NMR: see Table 1.

Bis[4-(o-ethynylphenyl)-1,3-butadienyl] Sulfide **11**. Lithium ethoxide prepared from lithium (0.32 g, 0.046 gatm) in ethanol (106 ml) was added dropwise with stirring under nitrogen atmosphere at 70—75 °C during 2 h to a mixture of *o*-ethynylcinnamaldehyde **10**[4] (6.3 g, 0.040 mol) and the salt **4** (13.5 g, 0.018 mol) in *N,N*-dimethylformamide (422 ml). The reaction mixture was stirred for further 1.5 h under an atmosphere of nitrogen at the same temperature. After work up as described for the isolation of **8**, a dark red semisolid obtained was chromatographed on alumina (160 g). The fractions eluted with hexane–ether (98:2—96:4) gave the stereoisomeric mixture of acyclic compound as very unstable liquid (2.14 g, 35%). After the liquid was passed through a short column of alumina (30 g) with hexane–ether, the crystals (1.50 g, 25%) obtained was recrystallized from hexane–ether, giving mono-*cis* isomer **11** as light yellow needles, mp 134—136 °C, MS: *m/e* 338 (M^+, 100); mol wt, 338.4; IR (KBr): 3280 (-C≡CH), 2150 (-C≡C-), 1680, 1623 (C=C), 970 (*trans* C=C), 710, 700 cm^{-1} (*cis* C=C); UV: λ_{max} 233 (27500), 258 sh (20200), 267 (21500), 283 (19400), 365 nm (31100); NMR: 2.2—2.8 (m, 12H, H^C, $H^{C'}$, H^D, $H^{D'}$, and benzenoid H), 3.40—3.78 (m, 4H, H^A, $H^{A'}$, H^B, and $H^{B'}$), 6.60 (s, 2H, -C≡CH).

Found: C, 85.39; H, 5.08%. Calcd for $C_{24}H_{18}S$: C, 85.17; H, 5.36%.

Dibenzo[f,l]-*8,10-bisdehydrothia*[*17*]*annulene* **12**. A solution of the isomeric mixture containing **11** (0.57 g, 16.8 mmol) in pyridine (30 ml) and dry ether (10 ml) was added dropwise to a stirred solution of anhydrous copper(II) acetate (2.17 g) in pyridine (64 ml) and dry ether (21 ml) for 1.5 h at 50—55 °C and the reaction mixture was stirred for further 1 h at the same temperature. After work up as described for the isolation of **9**, a dark red brown liquid obtained was chromatographed on alumina (130 g). The fractions eluted with hexane-ether (97:3) gave di-*cis* isomer **12** (111 mg, 20%) as solid. Recrystallization from hexane-ether afforded pure **12** as yellow needles, mp 196 °C (dec), MS: *m/e* 336 (M^+, 100); mol wt, 336.4; IR (KBr): 2235, 2185 (-C≡C-), 1620 (C=C), 965 (*trans* C=C), 700, 680 cm^{-1} (*cis* C=C); UV: λ_{max} 226 (38300), 272 (41200), 286 (46300), 332 (44200), 348 (39400), 375 sh (16100), 404 sh nm (9720); NMR: see Table 1.

Found: C, 85.50; H, 4.51%. Calcd for $C_{24}H_{16}S$: C, 85.68; H, 4.79%.

2-(o-Ethynylphenyl)vinyl 4-(o-Ethynylphenyl)-1,3-butadienyl Sulfide **13**. Lithium ethoxide prepared from lithium (0.19 g, 0.027 gatm) in ethanol (46 ml) was added dropwise with stirring under nitrogen atmosphere at 69—71 °C over a period of 1 h to a mixture of *o*-ethynylbenzaldehyde **5** (1.39 g, 0.011 mol), *o*-ethynylcinnamaldehyde **10** (1.67 g, 0.011 mol), and the salt **4** (7.93 g, 0.011 mol) in *N,N*-dimethylformamide (249 ml). After further 2 h of stirring at the same temperature under nitrogen atmosphere, the mixture was poured into water (500 ml). After work up as described for the isolation of **8**, a dark brown semisolid was passed through a short column of alumina (40 g) with hexane–

ether to remove polymeric products. A dark red liquid obtained by evaporation of solvents was cautiously chromatographed on alumina (140 g) with hexane-ether (96:4). The early eluents gave a mixture of acyclic compound of [13]annulene (0.941 g). The following eluents afforded an unstable red liquid of a mixture of acyclic compound of the desired [15]annulene (0.609 g, 18%). The last fractions gave a mixture of acyclic compound of [17]annulene (0.171 g). The unstable red liquid of the acyclic mixture of [15]-annulene was passed through a short column of alumina (30 g). The eluents with hexane gave solid (0.203 g, 6.0%) which was recrystallized from hexane–ether to afford all-*trans* isomer **13** as light yellow needles, mp 117—118 °C, MS: *m/e* 312 (M^+, 100); mol wt, 312.4; IR (KBr): 3300 (-C≡CH), 2180 (-C≡C-), 1620, 1590, 1585 (C=C), 965 cm^{-1} (*trans* C=C); UV: λ_{max} 227 (33900), 237 sh (29300), 255 (25300), 290 (14100), 349 nm (33100); NMR: 2.17—3.03 (m, 11H, H^B, $H^{B'}$ or $H^{C'}$, $H^{D'}$, and benzenoid H), 3.49 (d, J=14, 1H, H^A or $H^{A'}$), 3.60 (d, J=14, H^A or $H^{A'}$), 3.65 (dd, J=14, 10, 1H, $H^{B'}$ or $H^{C'}$), 6.65 (s, 2H, -C≡CH).

Found: C, 84.31; H, 4.92%. Calcd for $C_{22}H_{16}S$: C, 84.57; H, 5.16%.

Dibenzo[d, j]-*6,8-bisdehydrothia*[*15*]*annulene* ***14***. A solution of the acyclic mixture containing **13** (1.92 g, 6.15 mmol) in pyridine (106 ml) and dry ether (35 ml) was added dropwise to a stirred solution of anhydrous copper(II) acetate (7.84 g) in pyridine (231 ml) and dry ether (77 ml) during 2 h at 46—50 °C. The mixture was stirred at the same temperature for further 2 h. After work up as in the isolation of **9**, the red liquid obtained was chromatographed on alumina (100 g). The all-*trans* isomer **14** (0.41 g, 21%) was obtained from fractions eluted with hexane–ether (98:2) as solid. Recrystallization from hexane–ether gave pure **14** as yellow needles, mp 141 °C (dec); MS: *m/e* 310 (M^+, 64%), 309 (100); mol wt, 310.4, IR (KBr): 2180 (-C≡C-), 1630, 1600, 1590 (C=C), 985 cm^{-1} (*trans* C=C); UV: λ_{max} 222 (40400), 283 sh (37000), 300 sh (46100), 313 (49800), 375 sh (4020); NMR: see Table 1.

Found: C, 84.83; H, 4.34%. Calcd for $C_{22}H_{14}S$: C, 85.12; H, 4.55%.

The authors wish to thank Professor F. Sondheimer and Dr. J. E. Anderson, University College London, for helpful suggestions and Dr. Akio Yasuhara, National Institute for Environmental Studies, for measurement of the mass spectra. One of the authors (J. O.) is grateful to the Ministry of Education for financial support of this investigation through a Grant-in-Aid (054103, 1975) for Scientific Research.

Modification of (*S*)-*N*,*N*-Dimethyl-1-[(*R*)-1′,2-bis(diphenylphosphino)-ferrocenyl]ethylamine (BPPFA) as a Ligand for Asymmetric Hydrogenation of Olefins Catalyzed by a Chiral Rhodium(I) Complex†

Keiji YAMAMOTO,* Junya WAKATSUKI, and Ryuichi SUGIMOTO
Department of Chemical Engineering, Tokyo Institute of Technology, Meguro, Tokyo 152

(Received October 6, 1979)

Asymmetric homogeneous hydrogenation of prochiral olefins catalyzed by chiral rhodium(I) complexes was carried out by using several ferrocenylphosphines as ligands which play a key role of the chiral recognition. Modifications of BPPFA were made in order to examine a steric effect of the given substutient at the asymmetric center on the efficiency of the chiral ligands, indicating the parent BPPFA to be superior to the others examined for the asymmetric hydrogenation of highly functionalized olefins.

Rapid development in asymmetric homogeneous hydrogenation of olefins catalyzed by chiral rhodium(I) complexes has encouraged significant efforts in the preparation of chiral phosphines for some years.

Although the choice of the chiral ligand for this purpose is still empirical at the present time, there are several efficient bisphosphine ligands which enable the catalyst for hydrogenation of certain functionalized prochiral olefins, *e.g.* α-(acylamino)acrylic acid, to attain 80—100% in enantioselectivity.[1] Among such ligands, (2*R*, 3*R*)-2,3-*O*-isopropylidene-2,3-dihydroxy-1,4-bis(diphenylphosphino)butane(DIOP),[2] (1*R*,2*R*)-bis[(*o*-methoxyphenyl)phenylphosphino]ethane (DIPAMP),[3] and (2*S*,3*S*)-2,3-bis(diphenylphosphino)-butane (CHIRAPHOS)[4] have equivalent diarylphosphino groups in the molecule, forming more or less rigid chelates with the metal atom. (2*R*)-1,2-Bis(diphenylphosphino)propane(PROPHOS)[5] and (1*S*)-1,2-bis(diphenylphosphino)-1-phenylethane[6] may also be included in this class of ligands.

The most convincing explanation for the existing effective chiral recognition by these chelate ligands is that the four phenyl (aryl) groups on the phosphorus atoms are arranged around the rhodium metal in an alternating 'edge-face' manner, which is dictated by the chiral centers present in the ligand molecule.[3,4]

On the other hand, (2*S*,4*S*)-*N*-*t*-butoxycarbonyl-2-[(diphenylphosphino)methyl]-4-(diphenylphosphino)-pyrrolidine (BPPM),[7] and (*S*)-*N*,*N*-dimethyl-1-[(*R*)-1′,2-bis(diphenylphosphino)ferrocenyl]ethylamine (BPPFA)[8] contain sterically non-equivalent phsophorus atoms and clear modelling of the 'edge-face' conformation is rather difficult. However, (*S*)-(*R*)-BPPFA is unique in that it has planar element of chirality which arises from introducing the phosphino groups into the optically pure *N*,*N*-dimethyl-1-ferrocenylethylamine.[9]

We describe here some modifications of BPPFA by changing a methyl group bound to the asymmetric carbon atom with an isopropyl or a phenyl group in order to examine a steric effect of the asymmetric center on the conformation of the chelate and thus the efficiency of the chiral ligands: They were used for the rhodium(I) complex-catalyzed hydrogenation of a variety of olefinic substrates.

† Presented in part at the 37th National Meeting of the Chemical Society of Japan, Tokyo, April 1978, Abstr. 4L12.

There has been another approach to the modification of BPPFA, which involves retentive substitution of a dimethylamino group with higher dialkylamino groups or a hydroxyl group, indicating a remarkable participation of these functional groups to the asymmetrically catalyzed reactions.[10,11]

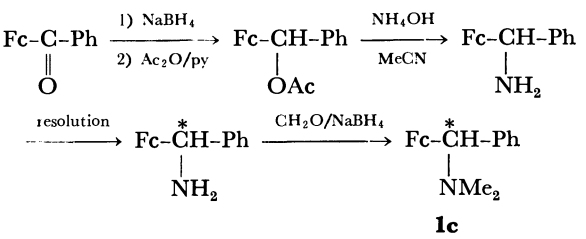
Results and Discussion

Preparation of Analogs of BPPFA. *N*,*N*-Dimethyl-1-ferrocenyl-2-methylpropylamine (**1b**) was obtained by a similar procedure to the preparation of *N*,*N*-dimethyl-1-ferrocenylethylamine (**1a**)[9] (Eq. 1), and was resolved by crystallization of the tartrates from aqueous acetone.

$$\underset{\text{(Fc = ferrocenyl)}}{\text{Fc-CH(CN)NMe}_2} + \text{RMgX} \rightarrow \underset{\begin{array}{l}\textbf{1a},\ \text{R=Me}\\ \textbf{1b},\ \text{R=}i\text{-Pr}\end{array}}{\text{Fc-CHRNMe}_2} \qquad (1)$$

It was noted that the reaction with isopropylmagnesium chloride gave not only **1b**, but a ketone which came from an attack of the Grignard reagent on the nitrile group. Ugi *et al.*[12] have recently reported the preparation of optically active **1b**.

Optically pure *N*,*N*-dimethyl-α-ferrocenylbenzylamine (**1c**) (absolute configuration unknown) was prepared according to Scheme 1. Resolution of the



Scheme 1.

primary amine[13] was carried out by crystallization of the hydrogen dibenzoyltartrate from ethanol by a reported procedure.[14] The absolute configuration of (−)-**1c** was most likely estimated to be *S* by correlating CD spectra of BPPFA analogs (*vide infra*).

Chiral ferrocenylphosphines were prepared by way of stereoselective lithiation[9] of optically active ferrocenyl-substituted amines (**1a**—**c**). Thus, stepwise lithiation of **1a**—**c** with butyllithium in ether and with butyllithium / *N*, *N*, *N*′, *N*′ - tetramethylethylenediamine

Physical properties of ferrocenylphosphines (**2** and **3**) were given in Table 1 and NMR and IR spectral data of **2** and **3** were summarized in Table 2. The circular dichroism (CD) spectra of **2a—c** were shown in Fig. 1. Since the enantiomeric property of (*R*)-(*S*)-**2b** as compared with (*S*)-(*R*)-**2a** is obvious from the CD spectra, it is most probable that the absolute configuration of (−)-**2c** with a positive Cotton effect is (*S*)-(*R*), and in turn that of (−)-**1c** is *S*.

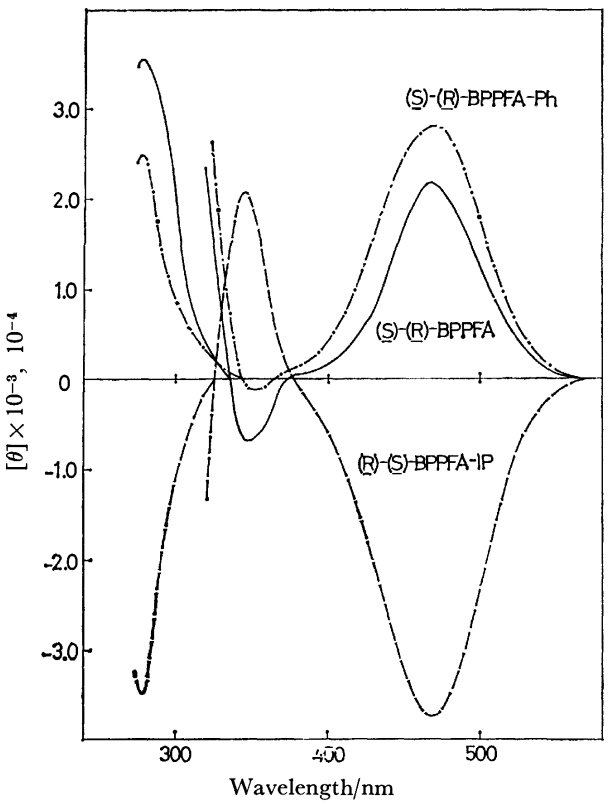

Fig. 1. Circular dichroism (CD) spectra of BPPFA (**2a—c**).

Asymmetric Hydrogenation of α-(Acylamino)acrylic Acids Using BPPFA Rhodium(I) Catalyst. We are primarily concerned with the modification of (*S*)-(*R*)-BPPFA (**2a**) which has been found to exert an effective chiral influence in the rhodium(I) complex-catalyzed hydrogenation of α-acetamidocinnamic acid.[8b] Kagan, *et al.*[15] have previously reported that the geometry of the olefinic acids and esters has a marked effect on the optical yield of phenylalanine derivatives obtained by asymmetric hydrogenation catalyzed by Rh(I)–DIOP system. Therefore, we have also carried out the hydrogenation of (*Z*)-α-acetamido- and (*Z*)- and (*E*)- α-benzamidocinnamic acid and their methyl esters using Rh(I)–BPPFA as catalyst under the standard conditions where complete hydrogenation of each substrate is confirmed. (details in Experimental)

TABLE 3. DEPENDENCE OF THE OPTICAL YIELDS ON THE GEOMETRY OF SUBSTRATES IN THE ASYMMETRIC HYDROGENATION CATALYZED BY Rh(I)-BPPFA

Substrate	Optical yield (% e.e.)[a]	
	(*S*)-(*R*)-BPPFA	(+)-DIOP[b]
Ph, H, NHAc, CO_2H	86	82
Ph, H, NHAc, CO_2Me	69	74
Ph, H, NHBz, CO_2H	37	70
Ph, H, NHBz, CO_2Me	35	38
Ph, H, CO_2H, NHBz	4	25
Ph, H, CO_2Me, NHBz	*nil*	5

a) (*S*)-Phenylalanine derivatives obtained. Optical yields are calculated with respect to the following values of the optically pure compounds: *N*-Acetylphenylalanine, $[\alpha]_D^{25}$ +46.8° (*c* 1.06, 95% EtOH).[15] Methyl ester, $[\alpha]_D^{25}$ +15.9° (*c* 2.0, MeOH): R. Glazer, *J. Organomet. Chem.*, **121**, 249 (1976). *N*-Benzoylphenylalanine, $[\alpha]_D^{25}$ −19.8° (*c* 8.8, 0.4 M NaOH).[2] Methyl ester, $[\alpha]_D^{25}$ −45.3° (*c* 1.325, 95% EtOH).[15] b) Lit.[15]

Table 3 shows the results together with the corresponding data reported by Kagan *et al.*[15] Dependence of the optical yield on the geometry of substrates is evident, deficiency of the optical yields starting from (*E*)-α-benzamidocinnamic acid and its ester being stronger in BPPFA than in DIOP. The results show that the same basis of the chiral recognition as mentioned above can be applied for these chelate ligands. Intrinsic low enantioselectivity with (*E*)-α-benzamidocinnamic acid has recently been discussed in terms of an inferior matching of the substrate with the catalyst in addition to a partial isomerization into the (*Z*)-isomer.[16,17]

BPPFA (**2a**—**c**) were examined as ligands in Rh(I) complex-catalyzed hydrogenation of (*Z*)-α-acetamidocinnamic acid and α-acetamidoacrylic acid, respectively. Results obtained were given in Table 4.

As is seen in Table 4, the parent BPPFA (**2a**) is much superior in asymmetric hydrogenation of these two amino acid precursors to the analogs **2b** and **2c**. Also PPFA–Ph (**3c**) is not effective as compared with **3a**, preferred configuration being inverted from *S* with bisphosphines **2** to *R* with monophosphines **3**. The fact that inverse enantioselectivity was observed between **2c** and **3c** as well as **2a** and **3a** despite the identical absolute configuration of these chiral ligands may well be explained by the different conformation of bisphosphine chelate of **2c** and **2a** from that of P–N chelate of **3c** and **3a**, respectively.

Although change in the structure at asymmetric carbon atom of BPPFA (**2a**) or PPFA (**3a**) so far deteriorated the enantioselective hydrogenation of the amino acid precursors, it does not appear to be true that the parent BPPFA (**2a**) is of sole choice of these chiral ferrocenylphosphines for the catalyzed asymmetric hydrogenation of various olefin substrates.

Asymmetric Hydrogenation of Itaconic Acid, Atropic Acid, and α-Ethylstyrene. These substrate were chosen

(*R*)-2-Phenylbutane, $[\alpha]_D^{25}$ −27.3° (neat): W. A. Bonner and T. W. Greenlee, *J. Am. Chem. Soc.*, **81**, 3336 (1959).

because they lack any attractive interaction as is expected for α-(acylamino)acrylic acids which coordinate with both the olefin bond and the amido carbonyl group to the rhodium. We have reported the preparation of (*S*)-*N*,*N*-dimethyl-1-[2-(diphenylphosphino)-1-naphthyl]ethylamine (1,2-DPNEA),[19] which was used as ligand in the rhodium complex-catalyzed asymmetric hydrogenation of itaconic acid. The optical yield of α-methylsuccinic acid obtained was up to 54% e.e. with added triethylamine. Lately, rhodium(I)–BPPM system has been found to give rise to an exceedingly high optical yield in the hydrogenation of itaconic acid.[20,20a]

As simple olefinic acids, itaconic acid and atropic acid were readily hydrogenated under standard conditions employed with Rh(I)–BPPFA catalyst system, but only moderate to low optical yields for these substrates were observed (Table 5).

It is of interest, however, to note that three BPPFAs exert no significant difference in the extent of enantioselective hydrogenation of itaconic acid, whereas a marked dependence on these ligands was observed for α-acetamidocinnamic acid. Furthermore, atropic acid undergoes hydrogenation with no coincidence between the observed configuration of product and absolute configuration of BPPFAs used.

Finally, asymmetric hydrogenation of α-ethylstyrene, one of the simplest hydrocarbon prochiral olefins, was examined using Rh(I)–BPPFAs as catalyst. Results are given in Table 5. Although the low enantioselection by Rh(I)–BPPFAs is again due to the simple structure of nonfunctionalized olefin substrate, BPPFA–Ph (**2c**) gave much higher optical yield of *s*-butylbenzene than the other two. Thus, it is encouraging to find that the simpler the structure of substrate olefin is, the more efficient would be the steric effect at the asymmetric carbon in BPPFAs. On the other hand, the uniformyl low ability of BPPFA–IP (**2b**) in the present asymmetric hydrogenation is presumably explained by the fact that an isopropyl group is of the same steric bulk as the dimethylamino group, and rather interferes in the proper conformation of the chelate present in the parent BPPFA (**2a**).

Experimental

Preparation of N,N-*Dimethyl-1-ferrocenyl-2-methylpropylamine (**1b**).* To an ether solution of isopropylmagnesium chloride, prepared from isopropyl chloride (14.5 g, 0.185 mol) and magnesium turnings (4.5 g) in anhydrous ether (80 ml), was added α-ferrocenyl-α-dimethylaminoacetonitrile[9] (24.8 g, 0.092 mol) dissolved in ether (150 ml) at room temperature. The mixture was stirred for 4.5 h, and hydrolyzed with 10% aqueous ammonium chloride solution. The organic layer was separated and the aqueous layer was extracted with three 50 ml portions of ether. The combined organic layer and extracts were washed with brine and the solvent was removed by evaporation to give 28.8 g of crude product. This was taken up in benzene, extracted with aqueous phosphoric acid (30 g in 400 ml water). The extract was washed with benzene and neutralized with 10% sodium carbonate solution. The organic layer separated was extracted with benzene, and the benzene solution was dried ($MgSO_4$) and evaporated to give 21.1 g, of a mixture of **1b** and a ketone which was separated by distillation.

1b (17.5 g, 65% yield): bp 106—109 °C/0.05 Torr; mp 20—21 °C; NMR ($CDCl_3$, TMS): δ 1.10, 1.24 (dd, *J*= 6.8 Hz, CHMe), 1.81—2.48 (m, CHMe), 2.11 (s, NMe_2), 3.20 (d, *J*=6.0 Hz, Fc-CH), and 4.14 ppm (s, $C_5H_5FcC_5H_4$); IR: 3050 (m), 2900(s), 2800(m), 1448(m), 1100(s), 1020 (m), 1009(s), 1000(m), 810(s), and 730(m) cm^{-1}. The ketone (4.3 g, 15% yield, mp 81—82 °C) was found by its NMR and IR spectrum to be 1-ferrocenyl-1-dimethylamino-3-methyl-2-butanone. NMR ($CDCl_3$): δ 1.17 (d, *J*=7.2 Hz, $CHMe_2$), 2.10 (s, NMe_2), 3.15 (m, *J*=3.3 Hz, CHMe), 4.06 (s, C_5H_5), 4.15 (C_5H_4), and 4.45 ppm (m, CHN); IR (KBr): 1705 cm^{-1} (C=O).

*Resolution of **1b**.* Crude **1b** (23.75 g, 83 mmol) dissolved in acetone (30 ml) was added to a solution of (*R*,*R*)-tartaric acid (12.4 g, 83 mmol) in 85% aqueous acetone (35 ml). Crystals of the hydrogen tartrate formed (28.3 g, 65 mmol) were extracted with hot acetone to leave yellow crystals (11.4 g), while the acetone extract gave orange crystals (10.7 g) after evaporation. From these salts (+)-**1b** (7.79 g, 27.3 mmol, 42%), $[\alpha]_D^{20}$ +135.8° ($CHCl_3$), and (−)-**1b** (7.44 g, 26.0 mmol, 40%), $[\alpha]_D^{20}$ −125.3° ($CHCl_3$), were recovered, respectively. The procedure was repeated five times for further resolution to the highest and constant rotation:

(*S*)-**1b** (4.30 g, 24%), $[\alpha]_D^{20}$ +158.9° (*c* 1.00, $CHCl_3$)
$[\alpha]_D^{20}$ +190.0° (*c* 1.00, benzene)

(*R*)-**1b** (4.00 g, 21%), $[\alpha]_D^{20}$ −160.6° (*c* 1.00, $CHCl_3$)
$[\alpha]_D^{20}$ −192.0° (*c* 1.00, benzene)

The reported maximum rotation is $[\alpha]_D^{20}$ +192.8° (*c* 1, benzene).[12] It should be noted that (−)-**1b**-tartrate as orange crystals is more soluble in hot acetone than the (+)-**1b** salt, though the rate of formation of the latter is faster than that of the former. In addition, (−)-**1b**-tartrate was better purified at the later stage of resolution by washing with diethyl ether.

Preparation of N,N-*Dimethyl-α-ferrocenylbenzylamine (**1c**).*
α-Ferrocenylbenzylamine. To a stirred solution of α-fer-

rocenylbenzyl acetate[21] (8.0 g, 24 mmol) in acetonitrile (150 ml) was added 38% ammonia solution (35 ml), and the mixture was allowed to stand overnight at room temperature. (Methanol cannot be used as a solvent contrary to the reaction of 1-ferrocenylethyl acetate.[13])

The reaction mixture was evaporated to the minimum volume, and the residue was dissolved in ether (50 ml). The resulting solution was extracted with 8.5% phosphoric acid. The extract was washed with ether and an amine was set free by adding excess 20% sodium hydroxide solution. After usual work up, there obtained α-ferrocenylbenzylamine (4.35 g, 62%): mp 47—49 °C; NMR ($CDCl_3$): δ 1.87 (br.s, $-NH_2$), 4.00—4.32 (m, C_5H_4); 4.12 (s, C_5H_5), 4.81 (s, Fc–CH), and 7.10—7.40 ppm (m, C_6H_5); IR (KBr): 3080, 1600, 1490, 1100, 1000, 810, 720, 700 cm^{-1}.

Resolution of α-Ferrocenylbenzylamine. According to the procedure by Allenmark,[14] a hot solution of (*R*,*R*)-*O*,*O*′-dibenzoyltartaric acid monohydrate (6.48 g, 17.2 mmol) in ethanol (69.5 ml) was added to a hot solution of the racemic amine (5.01 g, 17.2 mmol). After the solution was cooled, an yellow salt precipitated was collected (6.88 g, 59.9%), $[\alpha]_D^{25}$ −87.6° (*c*, 0.502, MeOH). The mother liquor was evaporated to dryness to leave another salt (4.31 g, 37.5%), $[\alpha]_D^{25}$ −41.2° (*c* 0.712, MeOH). Further resolution of the yellow salt was carried out by successive extraction with hot ethanol (180 ml and 85 ml) to give 3.25 g (29.1%) of the purified salt, $[\alpha]_D^{20}$ −107.6° (*c* 0.392, MeOH) (lit,[14] $[\alpha]_D^{25}$ −107°). From this salt the pure (−)-amine was obtained (1.40 g, 96% recovery), mp 80—83 °C, $[\alpha]^{25}$ −27.3° (*c* 0.504, MeOH) (lit,[14] $[\alpha]_D^{25}$ −26.1°).

*(−)-N,N-Dimethyl-α-ferrocenylbenzylamine (**1c**).* To a solution of (−)-amine (1.87 g, 6.42 mmol, 94% optical purity) in methanol (80 ml) was added 37% aqueous formaldehyde (21 ml) in an ice–water bath. To the cooled solution was added sodium borohydride (4.01 g) portionwise, and the mixture was stirred at room temperature overnight. After usual work up and purification, there obtained pure dimethylated amine (1.51 g, 74%), mp 62—64 °C, $[\alpha]_D^{25}$ −106.9° (*c*, 0.350, MeOH). (lit,[14] $[\alpha]_D^{25}$ −109°).

NMR ($CDCl_3$): δ 2.03 (s, NMe_2), 3.68 (s, C_5H_5), 3.73 (s, Fc–CH), 3.98—4.20 (m, C_5H_4), and 7.13—7.50 ppm (m, C_6H_5). IR (KBr): 1450, 1110, 1005, 820, 740, 705 cm^{-1}. In the same procedure as above, optically pure (−)-amine was dimethylated, $[\alpha]_D^{25}$ −112° (MeOH).

*Preparation of BPPFA-IP (**2b**), PPFA-IP (**3b**), BPPFA-Ph (**2c**), and PPFA-Ph (**3c**).* The procedures were the same as those reported by Kumada and coworkers,[8] the following is typical: To a stirred solution of (*R*)-**1b** (2.02 g, 7.1 mmol), $[\alpha]_D^{20}$ −192° (benzene), in anhydrous ether (2 ml) cooled in an ice–water bath was added dropwise butyllithium (2.32 M in hexane, 3.3 ml, 7.7 mmol) under a nitrogen atmosphere. Stirring was continued for 1.5 h at room temperature. To the mixture was added dropwise a mixture of butyllithium (3.3 ml) and TMEDA (0.945 g, 8.1 mmol) with cooling. The resulting mixture was stirred for 4.5 h at room temperature, followed by addition of diphenylphosphinous chloride (4.65 g, 21.0 mmol) in ether. After the reaction mixture was stirred overnight, 5% sodium hydrogencarbonate solution (50 ml) was added. Usual work up and column chromatographic purification (silica gel, hexane–benzene–ethyl acetate) to give (*R*)-(*S*)-**2b** (1.53 g, 33% yield): mp 80—82 °C (ethanol). Similarly, using (−)-**1c** (0.874 g, 2.65 mmol) was obtained (*S*)-(*R*)-**2c** (0.564 g, 30%).

In the same manner as above but with single lithiation, (*R*)-(*S*)-**3b** (38%) and (*S*)-(*R*)-**3c** (35%; 95% optical purity) were prepared. Physical, analytical, and spectral data for these ferrocenylphosphines are given in Tables 1 and 2, respectively. CD spectra of BPPFAs (**2a—c**) were shown in Fig. 1. The molecular ellipticity [θ] of ferrocenylphosphines newly prepared were given in Table 6.

Assymmetric Hydrogenation of Olefins Using BPPFAs-Rh(I) Catalyst. Materials: (*Z*)-α-Acetamidocinnamic acid, its methyl ester,[15] (*E*)- and (*Z*)-α-benzamidocinnamic acid,[22] and their methyl esters were prepared by the known procedures. Atropic acid and α-ethylstyrene were also prepared from hydrolysis of ethyl atropate[23] and thermolysis of 2-phenylbutyl acetate,[24] respectively. Commercially available itaconic acid was used as received.

All solvents used were dried and distilled.

General Procedure of Hydrogenation. The following is chosen as standard conditions.

In a 50 ml microautoclave fitted with a glass tube were placed $[RhCl(C_6H_{10})]_2$ (5.5 mg, 1.25×10^{-2} mmol), BPPFA (**2**) (2.50×10^{-2} mmol), and a substrate olefin (5.00 mmol) under a nitrogen atmosphere. Benzene–methanol (10 ml, 1:3 v/v) previously deoxygenated was added to the mixture and hydrogen was then introduced after three successive substitution of nitrogen with hydrogen (20 atm). Reactions were carried out at 20 atm of initial hydrogen pressure and at room temperature with magnetical stirring for an appropriate period of time to ensure 100% conversion. The extent of reaction was monitored by approximately 3 atm of hydrogen uptake and was checked by NMR spectrum of the final products which were purified by a known procedure.

When a cationic rhodium(I) catalyst, $[Rh(COD)BPPFA]^+ClO_4^-$ or $[Rh(COD)PPFA]^+ClO_4^-$, was used, the concentration of the catalyst was also 2.5 mM and that of the substrate 0.50 M.

Tables 3—5 show all results obtained for the catalyzed asymmetric hydrogenation of a variety of olefins examined.

The authors are grateful to Prof. J. Tsuji for valuable suggestions. We thank Mr. T. Takakuwa of JASCO for the measurments of ORD and CD spectra. We owe to Dr. N. Morita for the preparation and resolution of **1b**. The present work was supported by a Grant-in-Aid for Scientific Research (155328) from the Ministry of Education.

(Received October 22, 1979)

As chiral ligands for transition metal complex catalyzed asymmetric reactions, various kinds of chiral ferrocenylphosphines, which have planar chirality due to 1,2-unsymmetrically substituted ferrocene structure and also have a functional group on the side chain of the ferrocene nucleus, were prepared. (*S*)-*N*,*N*-dimethyl-1-[(*R*)-2-(diphenylphosphino)ferrocenyl]ethylamine [(*S*)-(*R*)-PPFA], (*S*)-*N*,*N*-dimethyl-1-[(*R*)-1′,2-bis(diphenylphosphino)ferrocenyl]ethylamine [(*S*)-(*R*)-BPPFA], and their dimethylphosphino derivatives were prepared by way of lithiation of optically resolved *N*,*N*-dimethyl-1-ferrocenylethylamine. The 1-(dimethylamino)ethyl group on the ferrocenylphosphines was converted stereospecifically by nucleophilic substitution reactions into 1-methoxy-, 1-hydroxy-, 1-diphenylphosphino-, and several 1-(dialkylamino)ethyl groups. 1-Diphenylphosphino-2-(dimethylaminomethyl)ferrocene (FcPN) was optically resolved *via* its phosphine sulfide dibenzoyltartaric acid salt. The relationship between CD spectra of the chrial ferrocenylphosphines and the configuration of their planar chirality is discussed.

There has been intense interest and activity recently in asymmetric synthesis catalyzed by transition metal complexes with chiral ligands.[1,2] This has resulted in so great a success in asymmetric homogeneous hydrogenation by chiral phosphine rhodium complexes as to produce α-amino acids with over 90% optical purity.[3] One of the most significant problems in studies on the catalytic asymmetric synthesis is how to develop a chiral ligand which will enable the catalyst for a given reaction to be as efficient in stereoselectivity as possible, and considerable efforts have been devoted to searching for new chiral phosphine ligands. These chiral phosphines may be classified into two classes: (A) phosphines bearing an asymmetric center at the phosphorus atom and (B) phosphines whose chirality is due to asymmetric carbons in groups bonded to phosphorus.

Methylphenylpropylphosphine[4] was used by Horner *et al.*[5] and Knowles *et al.*[6] in their early studies on catalytic asymmetric hydrogenation. Many optically active tertiary phosphines have been prepared since Mislow *et al.* developed a new synthetic method for the chiral phosphines in 1967,[7] and some of them have been reported to be effective ligands for catalytic asymmetric reactions. (*o*-Methoxyphenyl)cyclohexylmethylphosphine (CAMP)[8] and 1,2-bis[(*o*-methoxyphenyl)phenylphosphino]ethane (diPAMP)[9] by Knowles *et al.* gave, when complexed with rhodium, optical yields of over 90% in the hydrogenation of α-(acylamino)acrylic acids.

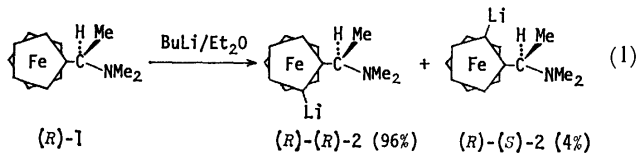
Phosphines containing asymmetric alkyl groups were usually derived from optically active natural compounds. Kagan *et al.* have achieved a great success with 2,3-*O*-isopropylidene-1,4-bis(diphenylphosphino)-2,3-butanediol (DIOP),[10] prepared relatively easily from tartaric acid. The DIOP has been successfully applied in various kinds of catalytic asymmetric synthesis, *e.g.*, hydrogenation of olefins[11-15] and ketones,[16,17] hydrosilylation of ketones[18-21] and imines,[11a] hydroformylation,[22-24] Grignard cross-coupling,[25,26] and allylic alkylation.[27] Neomenthyldiphenylphosphine (NMDPP)[28,29] and its diastereomeric isomer (MDPP),[29] prepared by Morrison *et al.*, have been used for the hydrogenation of acrylic acids to give up to 62% optical yield.[3,28] They have also studied a bisphosphine ligand (CAMPHOS) derived from camphoric acid.[3] Dimenthylphosphines have been synthesized and used as chiral ligands for a nickel catalyzed cooligomerization of olefins.[30] Optically active amino acids, proline and hydroxyproline, have been employed as chiral sources of phosphine ligands. They are (*S*)-2-(diphenylphosphinomethyl)pyrrolidines[31] and (2*S*, 4*S*)-4-diphenylphosphino-2-(diphenylphosphinomethyl)pyrrolidines,[32] respectively, the latter affording enantiomeric excess of 83—91% in the hydrogenation of α-(acylamino)cinnamic acids. Mono- and diphosphines derived from sugars have been reported to be effective for the asymmetric hydrogenation.[33] (*S*,*S*)-2,3-bis(diphenylphosphino)butane (chiraphos) and (*R*)-1,2-bis(diphenylphosphino)propane (prophos) developed by Fryzuk and Bosnich[34] are among the best ligands for the synthesis of optically active amino acids by the rhodium complex catalyzed hydrogenation. 2,2′-Bis(diphenylphosphinomethyl)-1,1′-binaphthyl (NAPHOS),[35] whose chirality is due to binaphthyl axial chirality, has been prepared and used as a ligand in several catalytic asymmetric reactions.

Chiral ferrocenylphosphines, which have planar chirality due to 1,2-unsymmetrically substituted ferrocene structure[36] and also have various functional groups such as an amino or a hydroxyl group, have been found to give rise to a high asymmetric induction in several transition metal catalyzed asymmetric reactions, *viz.*, hydrogenation of olefins,[37,38] ketones,[39] and imines[40] catalyzed by rhodium complexes, hydrosilylation of ketones by rhodium complexes[41] and of olefins by palladium complexes,[42] Grignard cross-coupling by nickel[43] and palladium[44] complexes, and isomerization of allylamines to enamines by cobalt complexes.[45] In this paper, we wish to describe in detail the preparation of the chiral ferrocenylphosphines.

† Present address: Department of Chemical Engineering, Tokyo Institute of Technology, Meguro-ku, Tokyo 152.

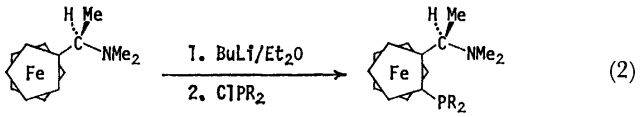
Results and Discussion

Introduction of Phosphino Groups into N,N-*Dimethyl-1-ferrocenylethylamine.* Chiral ferrocenylphosphines are readily prepared by way of lithiation of optically resolved *N,N*-dimethyl-1-ferrocenylethylamine (**1**). The lithiation of (*R*)-**1** with butyllithium was previously reported by Ugi and coworkers[36] to proceed with high stereoselectivity to give preferentially (*R*)-*N,N*-dimethyl-1-[(*R*)-2-lithioferrocenyl]ethylamine[(*R*)-(*R*)-**2**] (Eq. 1).



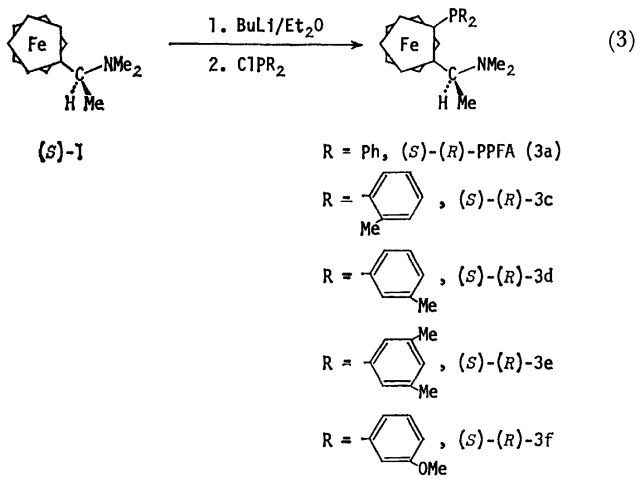
(1)

In our studies, (*R*)-**1** was lithiated, after the Ugi's procedures, with a slight excess of butyllithium in ether, and the lithiated ferrocene was then treated with chlorodiphenylphosphine. (*R*)-*N,N*-dimethyl-1-[(*S*)-2-(diphenylphosphino)ferrocenyl]ethylamine [(*R*)-(*S*)-PPFA] (**3a**), formed *via* (*R*)-(*R*)-**2**, was obtained in 55% isolated yield (Eq. 2). A small amount of



(2)

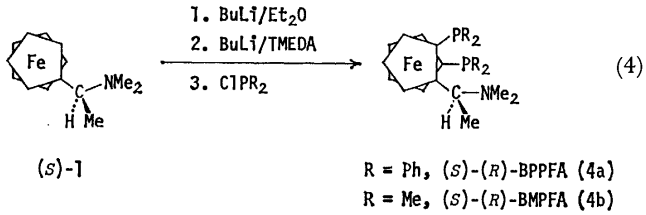
diastereomeric by-product (*R*)-(*R*)-PPFA (**3a**), formed *via* (*R*)-(*S*)-**2**, was readily removed by recrystallization. (*S*)-(*R*)-PPFA, which is an enantiomer of (*R*)-(*S*)-PPFA, was also prepared from (*S*)-**1** (Eq. 3). Simi-



(3)

larly, (*R*)-*N,N*-dimethyl-1-[(*S*)-2-(dimethylphosphino)-ferrocenyl]ethylamine [(*R*)-(*S*)-MPFA] (**3b**) was prepared in 31% yield starting with (*R*)-**1** and with chlorodimethylphosphine. Several bis(substituted phenyl)phosphino groups, such as bis(2-methylphenyl)phosphino, bis(3-methylphenyl)phosphino, bis(3,5-dimethylphenyl)phosphino, and bis(3-methoxyphenyl)phosphino groups, were introduced into (*S*)-**1** in a similar manner using the corresponding chlorodiarylphosphines (Eq. 3).

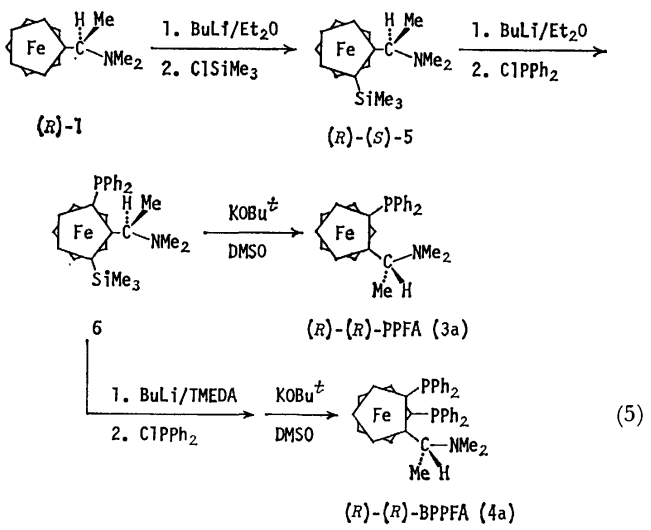
Lithiation of ferrocene in the presence of *N,N,N',N'*-tetramethylethylenediamine (TMEDA) is known[46] to produce 1,1'-dilithioferrocene, and it was expected that chiral ferrocenylphosphines bearing two phosphino groups could be prepared by the dilithiation of **1**; indeed, the stepwise lithiation of (*S*)-**1** with butyllithium in ether and then with butyllithium/TMEDA in the same solvent followed by diphenylphosphination with chlorodiphenylphosphine led to the introduction of two diphenylphosphino groups, one onto each of the cyclopentadienyl rings to give (*S*)-*N,N*-dimethyl-1-[(*R*)-1',2-bis(diphenylphosphino)ferrocenyl]ethylamine [(*S*)-(*R*)-BPPFA] (**4a**) in 58% yield (Eq. 4). The analogous bis(dimethylphosphino) derivative [(*S*)-(*R*)-BMPFA] (**4b**) was also prepared. The lithiation of PPFA (**3a**) with butyllithium followed by phosphination with chlorodiphenylphosphine resulted in the formation of *N,N*-dimethyl-1-[2,5-bis(diphenylphosphino)ferrocenyl]ethylamine, and BPPFA (**4a**) was not formed in any noticeable amounts.



(4)

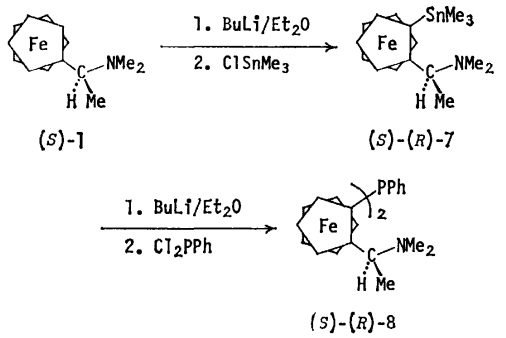
Although the ferrocenylphosphines with (*S*)-(*R*) or (*R*)-(*S*) configuration were readily obtained in good yields as shown in Eqs. 2—4, it was difficult to obtain pure (*R*)-(*R*) or (*S*)-(*S*) isomers in quantity by the lithiation-phosphination of **1**, since the lithioferrocene **2** which leads to (*R*)-(*R*) or (*S*)-(*S*) ferrocenylphosphine is produced only in small quantities from the highly stereoselective lithiation of **1** (see Eq. 1). This difficulty was solved by first protecting the ring hydrogen liable to lithiation with a trimethylsilyl group, then metalating the other lower reactive hydrogen, vicinal to the 1-(dimethylamino)ethyl group, followed by treating with chlorodiphenylphosphine, and finally desilylating. Thus, (*R*)-*N,N*-dimethyl-1-[(*S*)-2-(trimethylsilyl)ferrocenyl]ethylamine (**5**)[36] obtained by trimethylsilylation of (*R*)-**1** with butyllithium and chlorotrimethylsilane, was diphenylphosphinated with butyllithium and chlorodiphenylphosphine to give regioselectively (*R*)-*N,N*-dimethyl-[2-trimethylsilyl-5-(diphenylphosphino)ferrocenyl]ethylamine (**6**). Desilylation of **6** to (*R*)-(*R*)-PPFA was effected by treatment with potassium *t*-butoxide in dimethyl sulfoxide after Price's techniques.[47] Usual protodesilylation methods were not successful in this special case. Desilylation after introduction of the second diphenylphosphino group into **6** gave (*R*)-(*R*)-BPPFA.

Attempts to prepare bis[2-[1-(dimethylamino)ethyl]-ferrocenyl]phenylphosphine (**8**) by the lithiation of **1** with butyllithium and then addition of dichlorophenylphosphine failed, probably due to the low conversion (≈60%) of **1** into the lithioferrocene **2**. Main products were dibutylphenylphosphine and a phenyl-



(5)

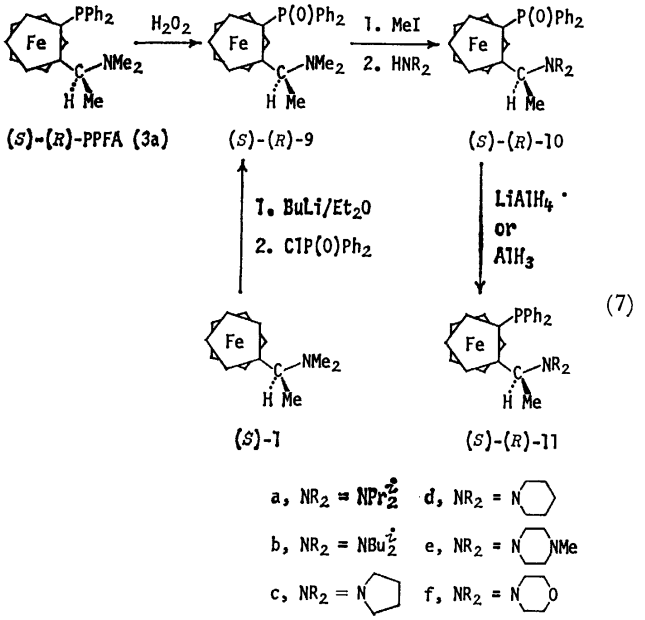
butylphosphinoferrocene derivative, formed by the reaction of chlorophosphines with unreacted butyllithium. The preparation of (*S*)-(*R*)-**8** was achieved *via* transmetalation of (*S*)-*N*,*N*-dimethyl-1-[(*R*)-2-(trimethylstannyl)ferrocenyl]ethylamine (**7**) which had been once isolated as a precursor of lithioferrocene (*S*)-(*S*)-**2** (Eq. 6).[48]



(6)

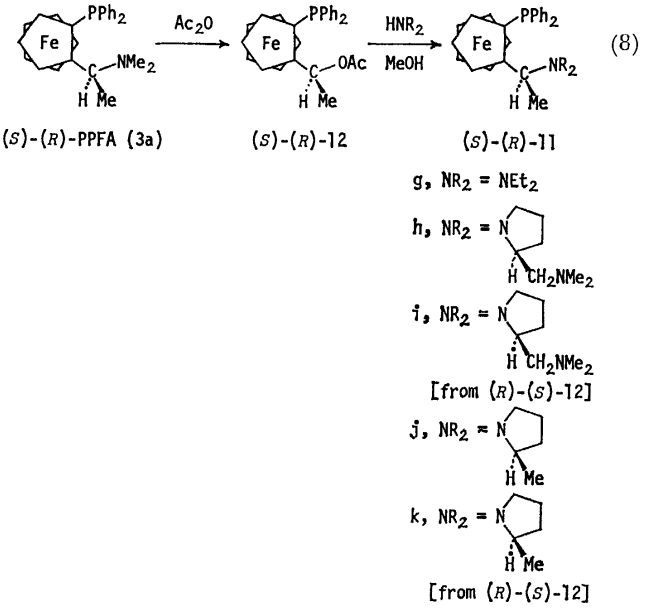
Modification of the Side Chain of Chiral Ferrocenylphosphines. Ferrocenylethane derivatives with a suitable leaving group such as trimethylammonium or acetate in the α-position have been reported[36,49] to undergo nucleophilic substitutions generally with complete retention of configuration.

Attempts to replace the dimethylamino group in (*S*)-(*R*)-PPFA (**3a**) by other dialkylamino groups by treating **3a** with methyl iodide and then with dialkylamines were not successful. The reaction of **3a** with methyl iodide formed preferentially the phosphonium salt rather than the desired ammonium salt. Protection of the diphenylphosphino group against the formation of phosphonium salt enabled the nucleophilic substitution to occur on the side chain. Thus, the preparation of several (*R*)-[(*S*)-1-(diaklylamino)-ethyl]ferrocenylphosphines (**11**) could be achieved first by converting (*S*)-(*R*)-**3a** into the phosphine oxide (**9**), then quaternization of the dimethylamino group, treatment with a dialkylamine and finally by reduction with lithium aluminum hydride or alane (Eq. 7). The diisopropylamino (**11a**), diisobutylamino (**11b**), 1-pyrrolidinyl (**11c**), piperidino (**11d**), 4-methyl-1-piperazinyl (**11e**), and morpholino (**11f**) derivatives were obtained in 30–60% overall yields. The phosphine oxide (*S*)-(*R*)-**9** could also be obtained by the reaction of lithioferrocene **2** with diphenylphosphinyl chloride in a similar way to the preparation of (*S*)-(*R*)-**3a**.



(7)

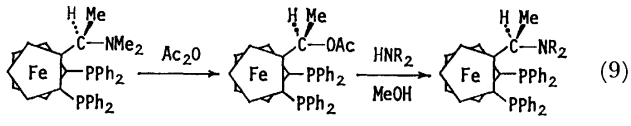
The dimethylamino group in (*S*)-(*R*)-PPFA (**3a**) was found to be substituted by other amino groups more conveniently by way of (*S*)-1-[(*R*)-2-(diphenylphosphino)ferrocenyl]ethyl acetate (**12**) (Eq. 8). (*S*)-(*R*)-PPFA (**3a**) was treated with an excess of acetic anhydride at 100 °C employing a modification of Nesmeyanov's procedure[50] to give the acetate (*S*)-(*R*)-**12** in the epimeric pure form in almost quantitative yield. The configuration *S* of the carbon central chirality of **12** was inferred from the result that the same substitution reaction on [1-(dimethylamino)-ethyl]ferrocene proceeded with nearly complete retention of configuration. (*S*)-(*R*)-**12** was then allowed to react with a dialkylamine in refluxing methanol to give (*S*)-(*R*)-**11f—k** in a high yield.



(8)

Replacement of the dimethylamino group in (*R*)-(*S*)-

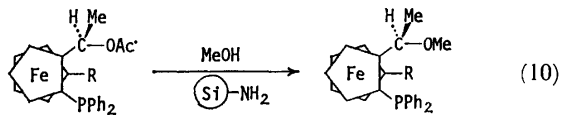
BPPFA (**4a**) by other amino groups was also carried out *via* its acetate derivative (**13**) in a similar manner to the preparation of **11** (Eq. 9).



(9)

a, $NR_2 = NH_2$ f, $NR_2 = NMeCH_2CH{=}CH_2$
b, $NR_2 = NEt_2$ g, $NR_2 = NMeCH_2CH_2NMe_2$
c, NR_2 = N⬠ h, $NR_2 = NMeCH_2CH_2NHMe$
d, NR_2 = N⬡ i, $NR_2 = NMeCH_2CH_2OH$
e, NR_2 = N⬡NMe j, $NR_2 = N(CH_2CH_2OH)_2$

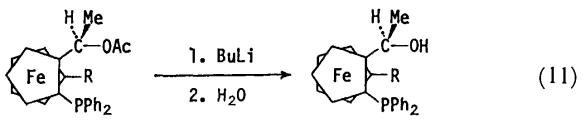
A methoxyl group also was introduced into the side chain of the chiral ferrocenylphosphines by treatment of the acetate (*R*)-(*S*)-**12** or (*R*)-(*S*)-**13** with refluxing methanol in the presence of 3-aminopropylated silica gel[51] (Eq. 10). (*R*)-(*S*)-**16** was also found to be formed by the reaction of (*R*)-(*S*)-**13** with sodium methoxide in methanol.



(10)

R = H, (*R*)-(*S*)-12 (*R*)-(*S*)-15
R = PPh_2, (*R*)-(*S*)-13 (*R*)-(*S*)-16

The acetate (*R*)-(*S*)-**13** was converted quantitatively into a ferrocenylphosphine with the hydroxyl group, (*R*)-1-[(*S*)-1′,2-bis(diphenylphosphino)ferrocenyl]ethanol (BPPFOH) (**18**) by treatment with an excess of butyllithium in ether followed by hydrolysis (Eq. 11). Direct acid or base hydrolysis of the acetate in the usual way gave only lower yields.

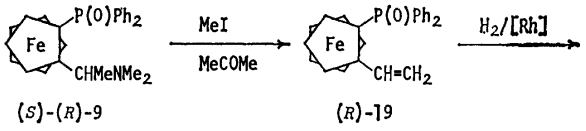


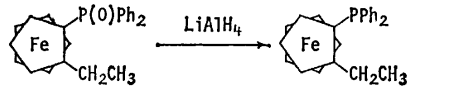
(11)

R = H, (*R*)-(*S*)-12 (*R*)-(*S*)-PPFOH (17)
R = PPh_2, (*R*)-(*S*)-13 (*R*)-(*S*)-BPPFOH (18)

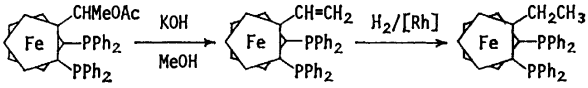
The chiral ferrocenylphosphines mentioned above all contain both planar and central elements of chirality and also a functional group such as the amino, hydroxyl, or methoxyl. Ferrocenylphosphines, (*R*)-1-diphenylphosphino-2-ethylferrocene (PPEF) (**21**) and (*S*)-1′,2-bis(diphenylphosphino)-2-ethylferrocene (BPPEF) (**23**), having only a planar element of chirality, were prepared by a sequence of reactions as shown in Eqs. 12 and 13. (*S*)-(*R*)-**9** was subjected to Hofmann elimination to give a vinylferrocene (*R*)-**19**. Hydrogenation of (*R*)-**19** in the presence of chlorotris(triphenylphosphine)rhodium(I) to (*R*)-**20** followed by reduction with lithium aluminum hydride gave (*R*)-PPEF (**21**).

Treatment of (*R*)-(*S*)-**13** with potassium hydroxide in methanol gave elimination product (*S*)-**22** in 34% yield together with substitution product (*R*)-(*S*)-**18** (39%). (*S*)-**22** was then converted into (*S*)-BPPEF (**23**) by the rhodium catalyzed hydrogenation.



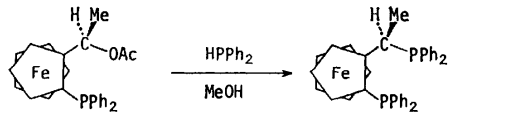


(12)



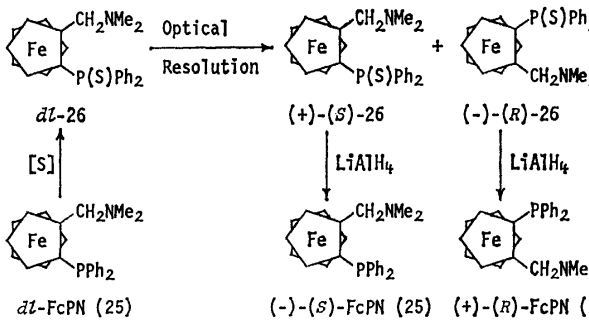
(13)

Finally, a new type of bisphosphine [(*R*)-1-[(*S*)-2-(diphenylphosphino)ferrocenyl]ethyl]diphenylphosphine (**24**) was prepared from (*R*)-(*S*)-**12** by substitution reaction with diphenylphosphine in methanol (Eq. 14).



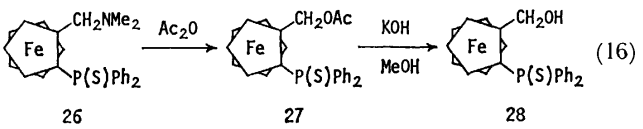
(14)

Preparation of Optically Active 1-Dimethylaminomethyl-2-(diphenylphosphino)ferrocene (FcPN). 1-Dimethylaminomethyl-2-(diphenylphosphino)ferrocene (FcPN)[52] (**25**), which is analogous to **3a** but lacks carbon central chirality, was optically resolved *via* its phosphine sulfide dibenzoyltartaric acid salt (Eq. 15). Attempted resolution of *dl*-**25** directly *via* its ammonium salts with optically active acids, such as tartaric acid, dibenzoyltartaric acid, or camphor-10-sulfonic acid, was not successful. Alkaline hydrolysis of one of the diastereoisomers, which were separated as crystals in the fractional recrystallization of the ammonium salts consisting of the *dl*-phosphine sulfide **26** and dibenzoyl-*d*-tartaric acid in methanol, gave (+)-isomer of **26**,



(15)

which was converted into (−)-**25** by reduction with lithium aluminum hydride in dioxane. The configuration of (−)-**25** was inferred to be *S* by comparison of its CD spectrum with that of other ferrocenylphosphines of definite configuration (*vide infra*). The phosphine sulfide **26** was converted into the hydroxy derivative **28** (Eq. 16), and the enantiomeric purity

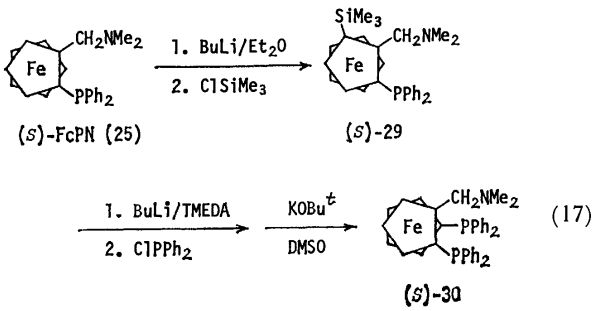


(16)

26 27 28

was determined by NMR spectroscopy using a chiral lanthanoid shift reagent,[53] tris(3-trifluoroacetyl-*d*-camphorato)europium(III) [Eu(facam)$_3$]. **26** of $[\alpha]_{545}^{25}$ ±50.5° (chloroform) turned out to be optically pure.

The bisphosphine (*S*)-**30** analogous to FcPN (**25**) was also prepared from the optically active **25** using the protecting method with the trimethylsilyl group (Eq. 17).



(17)

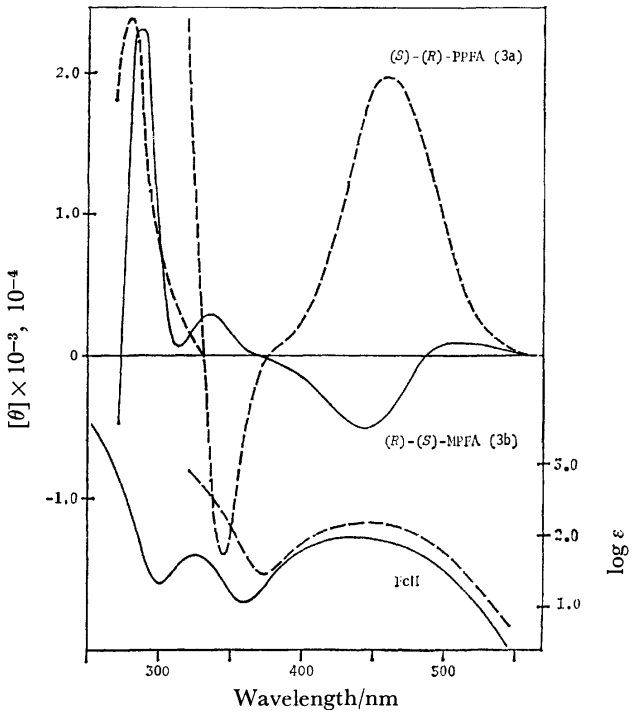


Fig. 1. CD and UV spectra of (*S*)-(*R*)-PPFA (**3a**) and (*R*)-(*S*)-MPFA (**3b**) in chloroform.

Physical Properties of Chiral Ferrocenylphosphines. Melting points, specific rotations, and analytical data for the chiral ferrocenylphosphines are summarized in Table 1. The absorption and CD spectra of PPFA (**3a**), MPFA (**3b**), BPPFA (**4a**), PPEF (**21**), and FcPN (**25**) are shown in Figs. 1, 2, and 3. The absorption spectrum of ferrocene has two long wavelength bands at 440 and 325 nm assignable to d-d type transition.[54] The CD spectra of chiral ferrocenylphosphines reveal optical activity arising from

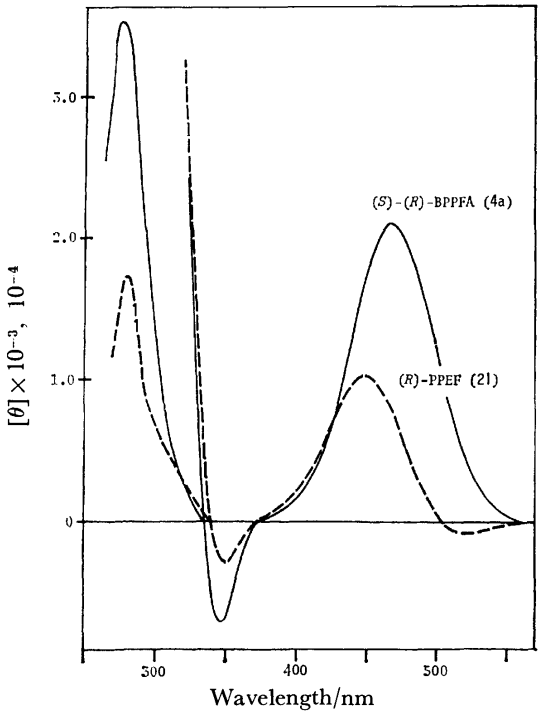

Fig. 2. CD spectra of (*S*)-(*R*)-BPPFA (**4a**) and (*R*)-PPEF (**21**) in chloroform.

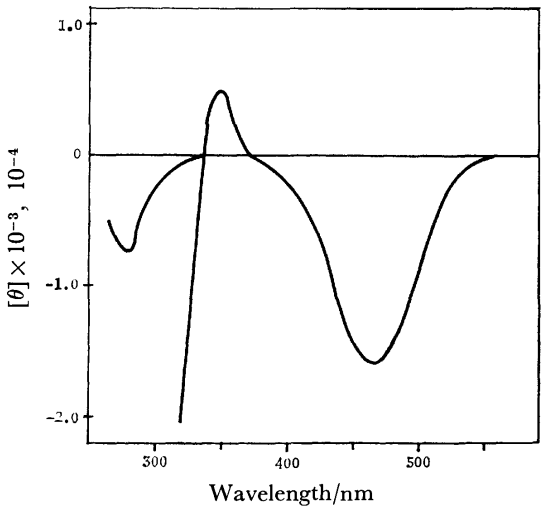

Fig. 3. CD spectrum of (*S*)-FcPN (**25**) in chloroform.

the planar chirality around these two absorption bands. The ferrocenylphosphines with planar chirality of *R* configuration, (*S*)-(*R*)-PPFA (**3a**), (*S*)-(*R*)-BPPFA (**4a**), and (*R*)-PPEF (**21**), all have positive Cotton effects around 450—470 and negative ones around 340—350 nm, whereas opposite Cotton effects are observed in the case of (*R*)-(*S*)-MPFA (**3b**) whose planar chirality is *S*. The negative and positive Cotton effects around 450—470 and 340—350 nm respectively observed in the CD spectrum of (—)-FcPN (**25**) shows that the absolute configuration of (—)-FcPN is *S*.

Conclusions. In conclusion we summarize some unique and significant features of the chiral ferrocenylphosphine ligands. (1) They all contain planar element of chirality due to 1,2-unsymmetrically substituted ferrocene structure, which must be highly asym-

metric enough to bring about high stereoselectivity in the catalytic asymmetric reactions. (2) Phosphines having either of the two configurations (*R* and *S*) of the carbon central chirality on the side chain of ferrocene and also those lacking this central chirality can be prepared: examples are (*S*)-(*R*)-**3a**, (*R*)-(*R*)-**3a**, and (*R*)-**25**. (3) Various kinds of functional groups such as an amino, alkoxyl, or hydroxyl can be introduced into the ferrocene side chain by nucleophilic substitution reactions, which proceed stereospecifically without any racemization or epimerization. (4) Both mono- and bisphosphines can be prepared from the same chiral source. They will coordinate with a transition metal as monodentate and bidentate ligands, respectively. The monophosphines with an amino group may possibly be a new type of chiral ligands that are capable of coordinating at both the phosphorus and nitrogen atoms.

The chiral ferrocenylphosphines have aforementioned advantages over other chiral phosphines, and they indeed gave rise to a high asymmetric induction in several transition metal complex catalyzed asymmetric reactions.[37-44] The high ability of the chiral ferrocenylphosphines is ascribed mainly to the attractive interactions between functional groups on a substrate and on the chiral ligand coordinated to a transition metal catalyst. The catalytic asymmetric reactions will be fully described elsewhere.

Experimental

All melting points are uncorrected. ^{1}H NMR spectra were recorded with a JEOL MH-100 or Varian EM-360 spectrometer, using tetramethylsilane as an internal standard in chloroform-*d*. The notations s, d, t, q, m, dd, and cm indicate singlet, doublet, triplet, quartet, multiplet, doublet of doublets, and complex multiplet, respectively. A letter b before these letters indicates broad. Infrared spectra were recorded with a Hitachi EPI-G3 grating spectrophotometer, UV spectra with a Hitachi EPS-3T spectrophotometer, and optical rotations were measured with a Yanagimoto OR-50 automatic polarimeter. ORD and CD spectra were obtained on a JASCO J-20 automatic recording spectropolarimeter. Wakogel (Silica gel) C-200 and Alumina Activated 200 (Nakarai) for column chromatography, and Alumina PF_{254} (Merck) and Silica gel 60 PF_{254} (Merck) for preparative TLC were used for the isolation and purification of the products.

dl-*N*,*N*-dimethyl-1-ferrocenylethylamine (**1**) was prepared by literature methods,[55,56] and optically resolved according to the reported procedure.[36]

Preparation of Chiral Ferrocenylphosphines. All manipulations for preparing phosphines were carried out in an oxygen-free dry nitrogen atmosphere. Melting points, optical rotations, and analytical data for the phosphines are summarized in Table 1.

*(S)-N,N-Dimethyl-1-[(R)-2-(diphenylphosphino)ferrocenyl]ethylamine [(S)-(R)-PPFA (**3a**)].* According to the procedure reported by Ugi *et al.*[36] for stereoselective lithiation of resolved *N*,*N*-dimethyl-1-ferrocenylethylamine (**1**), 12.4 ml of 1.4 M butyllithium in hexane was added to a solution of 3.60 g (14 mmol) of (*S*)-**1** ($[\alpha]_D^{24}$ −13.8° (*c* 1.5, ethanol)) in 20 ml of dry ether at 25—27 °C over a period of 20 min. The mixture was stirred at room temperature for 1.5 h and then 6.2 g (28 mmol) of chlorodiphenylphosphine in 10 ml of ether was added with heating under gentle reflux in the course of 45 min. After 4 h reflux aqueous sodium hydrogencarbonate was slowly added with cooling in an ice-bath. The resulting organic layer and benzene extracts from the aqueous layer were combined, washed with water, dried over anhydrous sodium sulfate, and concentrated *in vacuo* to afford a red oil. The oil was chromatographed on alumina (eluent: hexane/benzene, 3/1), and evaporated to give a crude product as orange crystals. The product was purified by recrystallization from ethanol to give 3.11 g (50% yield) of (*S*)-(*R*)-PPFA (**3a**), UV: λ_{max} ($CHCl_3$) 447 nm (ε 150), NMR: δ 1.19 (d, 3H, *J*=7 Hz, $CHC\underline{H}_3$), 1.77 (s, 6H, $NC\underline{H}_3$), 3.90 (s, 5H, $FeC_5\underline{H}_5$), 3.56—4.39 (m, 4H, $FeC_5\underline{H}_3C\underline{H}$), and 6.88—7.71 (cm 10H, $C_6\underline{H}_5$). The IR spectrum indicated the presence of the unsubstituted cyclopentadienyl ring (1105 and 1001 cm^{-1}) and phenyl groups (745 and 698 cm^{-1}). ORD (*c* 0.11 and 0.004, chloroform): $[\Phi]_{589}$ +1520°, $[\Phi]_{495}$ +3140° (pk), $[\Phi]_{434}$ +1590° (tr), and $[\Phi]_{294}$ +21900° (pk). The CD spectrum is shown in Fig. 1.

(*R*)-(*S*)-PPFA (**3a**) was prepared from (*R*)-**1** in a similar manner.

*(R)-N,N-Dimethyl-1-[(S)-2-(dimethylphosphino)ferrocenyl]ethylamine [(R)-(S)-MPFA (**3b**)].* At 27 °C, 3.14 g (12.2 mmol) of (*R*)-**1** ($[\alpha]_D^{24}$ +14.1° (*c* 1.6, ethanol)) was lithiated as described above. To the solution, 1.59 g (15.5 mmol) of chlorodimethylphosphine was added dropwise with stirring. A vigorous reaction occurred and the chlorodimethylphosphine was added at such a rate as to maintain boiling. The resulting mixture was heated under reflux for 3 h. Benzene/ether (1/1) (50 ml) and dilute sodium hydroxide solution (20 ml) were then added to the cooled reaction mixture. The organic layer was separated, dried over anhydrous sodium sulfate, and concentrated *in vacuo*. The residue was chromatographed on alumina (benzene) to give 1.10 g (31% yield) of (*R*)-(*S*)-MPFA (**3b**) as a red oil, UV: λ_{max} ($CHCl_3$) 446 nm (ε 131); NMR: δ 1.08 and 1.31 (a pair of d, 6H, *J*=2.6 Hz, $P(C\underline{H}_3)_2$), 1.34 (d, 3H, *J*=5.6 Hz, $CHC\underline{H}_3$), 2.14 (s, 6H, $NC\underline{H}_3$), 4.09 (s, 5H, $FeC_5\underline{H}_5$), 3.8—4.4 (cm, 3H, $FeC_5\underline{H}_3$). Methine proton resonances may lie under the cyclopentadienyl proton resonances. The IR spectrum indicated the presence of the unsubstituted cyclopentadienyl ring (1106 and 1000 cm^{-1}) and dimethylphosphino group (928 cm^{-1}). ORD (*c* 0.11 and 0.01, chloroform): $[\Phi]_{589}$ −425°, $[\Phi]_{473}$ −1120° (tr), $[\Phi]_{415}$ −615° (pk), $[\Phi]_{328}$ −1580° (tr), $[\Phi]_{304}$ −990° (pk), and $[\Phi]_{273}$ −8290° (tr). The CD spectrum is shown in Fig. 1.

*(S)-N,N-Dimethyl-1-[(R)-2-[bis(2-methylphenyl)phosphino]ferrocenyl]ethylamine [(S)-(R)-**3c**].* (*S*)-(*R*)-**3c** was prepared in a similar manner to that for the preparation of (*S*)-(*R*)-**3a** starting with (*S*)-**1** and with chlorobis(2-methylphenyl)phosphine;[57a] recrystallized from methanol, 30% yield; NMR: δ 1.35 (d, 3H, *J*=7.5 Hz, $CHC\underline{H}_3$), 1.82 (s, 6H, $NC\underline{H}_3$) 2.15 and 2.96 (a pair of s, 6H, $C_6H_4C\underline{H}_3$), 3.88 (s, 5H, $FeC_5\underline{H}_5$), 3.75—4.48 (m, 4H, $C_5\underline{H}_3C\underline{H}$), 6.9—7.3 (cm, 8H, $PC_6\underline{H}_4$).

*(R)-N,N-Dimethyl-1-[(S)-2-[bis(3-methylphenyl)phosphino]ferrocenyl]ethylamine [(R)-(S)-**3d**].* Prepared from (*R*)-**1** and chlorobis(3-methylphenyl)phosphine,[57b] 35% yield; NMR: δ 1.28 (d, 3H, *J*=7.5 Hz, $CHC\underline{H}_3$), 1.80 (s, 6H, $NC\underline{H}_3$), 2.25 and 2.40 (a pair of s, 6H, $C_6H_4C\underline{H}_3$), 3.96 (s, 5H, $FeC_5\underline{H}_5$), 3.84—4.42 (m, 4H, $FeC_5\underline{H}_3C\underline{H}$), 6.90—7.63 (cm, 8H, $PC_6\underline{H}_4$).

*(S)-N,N-Dimethyl-1-[(R)-2-[bis(3,5-dimethylphenyl)phosphino]ferrocenyl]ethylamine [(S)-(R)-**3e**].* Prepared from (*S*)-**1** and c lorobis(3,5-dimethylphenyl)phosphine (115—135 °C/0.015 mmHg, prepared by Yudina's method[57b]), 28% yield; NMR: δ 1.26 (d, 3H, *J*=7 Hz, $CHC\underline{H}_3$), 1.84 (s,

a) Specific rotation in ethanol. b) Bp 157 °C/0.03 mmHg. c) Decomposition. d) $[\alpha]_{545}^{25}$ ($CHCl_3$).

6H, NC$\underline{H}_3$), 2.18 and 2.32 (a pair of s, 12H, $C_6H_3(C\underline{H}_3)_2$), 3.94 (s, 5H, $C_5\underline{H}_5$), 3.8—4.4 (m, 4H, $FeC_5\underline{H}_3C\underline{H}$), 6.7—7.3 (m, 6H, $PC_6\underline{H}_3$).

(S)-N,N-Dimethyl-1-[(R)-2-[bis(3-methoxyphenyl)phosphino]-ferrocenyl]ethylamine [*(S)-(R)-**3f***]. Prepared from (*S*)-**1** and chlorobis(3-methoxyphenyl)phosphine,[57b] 34% yield, recrystallized from hexane; NMR: δ 1.25 (d, 3H, J=7 Hz, C$H\underline{C}\underline{H}_3$), 1.78 (s, 6H, NC$\underline{H}_3$), 3.66 and 3.76 (a pair of s, 6H, OC$\underline{H}_3$), 3.95 (s, 5H, $FeC_5\underline{H}_5$), 3.8—4.4 (m, 4H, $FeC_5\underline{H}_3C\underline{H}$), 6.6—7.3 (cm, 8H, $PC_6\underline{H}_4$).

(S)-N,N-Dimethyl-1-[(R)-1',2-bis(diphenylphosphino)ferrocenyl]-ethylamine [*(S)-(R)-BPPFA (**4a**)*]. To a solution of 3.6 g (14 mmol) of (*S*)-**1** in 22 ml of dry ether, 12.0 ml of 1.4 M butyllithium in hexane was added at 27 °C over a period of 20 min. The mixture was stirred at room temperature for 1 h and then a mixture of 1.9 g (16 mmol) of freshly distilled TMEDA and 13.0 ml of 1.4 M butyllithium in hexane was added in 15 min. After 5 h stirring at room temperature, 9.3 g (42 mmol) of chlorodiphenylphosphine was added to the cooled reaction mixture. After standing overnight it was hydrolyzed with aqueous sodium hydrogencarbonate. The resulting organic layer and extracts (benzene 50 ml) from the aqueous layer were combined, dried over anhydrous sodium sulfate, and concentrated *in vacuo*. The residue was chromatographed on alumina (hexane/benzene 2/1) to give the crude product, which was recrystallized from ethanol to give 5.08 g (58% yield) of pure (*S*)-(*R*)-**4a**; UV: λ_{max} ($CHCl_3$) 443 nm (ε 194); NMR: δ 1.12 (d, 3H, J=7 Hz, C$H\underline{C}\underline{H}_3$), 1.75 (s, 6H, NC$\underline{H}_3$), 3.41—4.42 (m, 8H, $C_5\underline{H}_4FeC_5\underline{H}_3C\underline{H}$), 6.87—7.66 (cm, 20H, $PC_6\underline{H}_5$). The IR spectrum did not exhibit absorptions near 1100 and 1000 cm^{-1}, indicating the absence of the unsubstituted cyclopentadienyl ring. ORD (*c* 0.10 and 0.004, chloroform): $[\Phi]_{589}$ +2160°, $[\Phi]_{499}$ +3890° (pk), $[\Phi]_{446}$ +2680° (tr), and $[\Phi]_{299}$ +30,300° (pk). The CD spectrum is shown in Fig. 2.

(S)-N,N-Dimethyl-1-[(R)-1',2-bis(dimethylphosphino)ferrocenyl]-ethylamine [*(S)-(R)-BMPFA (**4b**)*]. (*S*)-**1** (14.0 g. 54.6 mmol) was lithiated first with 48 ml of 1.4 M butyllithium and then with 62 ml of 1.4 M butyllithium and 10.0 ml (66.8 mmol) of TMEDA as described in the preparation of (*S*)-(*R*)-BPPFA (**4a**). To the solution was added 16.0 ml (187 mmol) of chlorodimethylphosphine at 0 °C. After stirring at room temperature overnight, the reaction mixture was hydrolyzed with 100 ml of 2 M sodium hydroxide. The resulting solution was extracted with benzene (2 × 100 ml). Evaporation of the solvent gave a red oil, which was distilled to give 19.5 g of a mixture of (*S*)-(*R*)-MPFA (**3b**) and (*S*)-(*R*)-BMPFA (**4b**) (1:2 mixture, 120—157 °C/0.03 mmHg) and 2.5 g (12% isolated yield) of pure (*S*)-(*R*)-BMPFA (**4b**) (157 °C/0.03 mmHg); NMR: δ 1.00—1.43 (cm, 12H, PC$\underline{H}_3$), 1.50 (d, 3H, J=7 Hz, C$H\underline{C}\underline{H}_3$), 2.04 (s, 6H, NC$\underline{H}_3$), 3.58 (q, 1H, C$\underline{H}C\underline{H}_3$), 3.8—4.4 (cm, 7H, $C_5\underline{H}_4FeC_5\underline{H}_3$).

(R)-N,N-dimethyl-1-[(R)-2-(diphenylphosphino)ferrocenyl]ethylamine [*(R)-(R)-PPFA (**3a**)*]. To a solution of 1.47 g (4.47 mmol) of (*R*)-α-[(*S*)-2-trimethylsilylferrocenyl]ethyldimethylamine[36] [(*R*)-(*S*)-**5**] in 15 ml of dry ether was added 5.3 ml of 1.27 M butyllithium in hexane at room temperature. After stirring at 30 °C for 2 h, 2.0 g (9.0 mmol) of chlorodiphenylphosphine was added. The reaction mixture was refluxed for 2 h, and then hydrolyzed with 30% sodium hydroxide at 0 °C. The resulting mixture was extracted with benzene (2 × 50 ml). The benzene solution was washed with brine, dried over anhydrous sodium sulfate, and the solvent was removed under reduced pressure. The NMR spectrum of the residue indicated that about 50% of **5** was phosphinated. Preparative TLC (alumina, hexane/benzene 2/1) gave 0.65 g of recovered (*R*)-(*S*)-**5** (R_f 0.4) and 1.03 g (45% yield) of (*R*)-*N*,*N*-dimethyl-1-[2-trimethylsilyl-5-(diphenylphosphino)ferrocenyl]ethylamine (**6**) (R_f 0.6). NMR of (*R*)-**6**: δ 0.27 (s, 9H, SiC$\underline{H}_3$), 1.68 (s, 6H, NC$\underline{H}_3$), 1.83 (d, 3H, J=7 Hz, C$H\underline{C}\underline{H}_3$), 3.27 (q, 1H, C$\underline{H}C\underline{H}_3$), 3.92 (s. 6H, $C_5\underline{H}_5FeC_5\underline{H}$), 4.18 (d. 1H, J=3.2 Hz. $FeC_5\underline{H}$), 7.08—7.72 (m, 10H. $PC_6\underline{H}_5$).

A solution of 0.296 g (0.58 mmol) of (*R*)-**6** and 0.067 g (0.63 mmol) of potassium *t*-butoxide in 10 ml of dry dimethyl sulfoxide was warmed at 43 °C for 20 min. Benzene (20 ml) was added and the benzene solution was washed with brine, dried over anhydrous sodium sulfate. and evaporated. Column chromatography (alumina, ether) gave 0.111 g (44%) of crude (*R*)-(*R*)-**3a** containing 10% of epimerized ferrocenylphosphine, (*S*)-(*R*)-**3a**. The latter was removed as follows: The crude (*R*)-(*R*)-**3a** was dissolved in pentane. and the pentane was evaporated slowly until small amounts of crystals appeared. The crystals which consisted of *ca.* 1:1 mixture of (*S*)-(*R*)-**3a** and (*R*)-(*R*)-**3a** were removed by filtration, and the filtrate was evaporated to give almost pure (*R*)-(*R*)-**3a** (0.093 g, 37% yield) as a red oil; NMR: δ 1.35 (d, 3H, J=7.5 Hz, C$H\underline{C}\underline{H}_3$), 2.14 (s, 6H. NC$\underline{H}_3$), 3.60 (q, 1H, C$\underline{H}C\underline{H}_3$), 3.98 (s, 5H. $FeC_5\underline{H}_5$), 3.71, 4.24, 4.35 (m, 3H, $FeC_5\underline{H}_3$), 7.15—7.65 (cm, 10H, $PC_6\underline{H}_5$).

(R)-N,N-Dimethyl-1-[(R)-1',2-bis(diphenylphosphino)ferrocenyl]-ethylamine [*(R)-(R)-BPPFA (**4a**)*]. To a solution of 0.738 g (1.45 mmol) of (*R*)-**6** in 25 ml of dry ether was added dropwise with stirring 2.1 ml (13.5 mmol) of TMEDA and 11.5 ml (13.5 mmol) of 1.25 M butyllithium in hexane succesively at 0 °C. After stirring at room temperature, a solution of 2.9 ml (15 mmol) of chlorodiphenylphosphine in 10 ml of ether was added at 0 °C. The mixture was refluxed for 1 h, and then hydrolyzed with 30% sodium hydroxide (50 ml). The mixture was extracted with benzene. The organic phase was washed with water, dried over anhydrous sodium sulfate, and evaporated. The residue was chromatographed on alumina (benzene/ether 1/1). An orange band was collected. The NMR spectrum showed that *ca.* 20% of (*R*)-**6** was converted to the bisphosphine derivative. This mixture was used for the desilylation without further purification.

To the mixture thus obtained was added 0.15 g (1.35 mmol) of potassium *t*-butoxide and 10 ml of dry dimethyl sulfoxide. The mixture was warmed with stirring at 40 °C for 20 min. After usual work up. preparative TLC (silica gel, benzene/ether 1/1) gave (*R*)-(*R*)-PPFA (**3a**) (R_f 0.3) and 0.080 g (9% yield) of (*R*)-(*R*)-BPPFA (**4a**) (R_f 0.6). For (*R*)-(*R*)-**4a**, NMR: δ 1.35 (d, 3H, J=7 Hz, C$H\underline{C}\underline{H}_3$), 2.07 (s, 6H, NC$\underline{H}_3$), 3.32—4.48 (m, 8H, $C_5\underline{H}_4FeC_5\underline{H}_3C\underline{H}$), 7.00—7.55 (cm, 20H, $PC_6\underline{H}_5$).

(S)-N,N-Dimethyl-1-[(R)-2-(trimethylstannyl)ferrocenyl]ethylamine [*(S)-(R)-**7***]. (*S*)-**1** (5.0 g. 19.5 mmol) was lithiated as described above. To the solution was added a solution of 5.84 g (29.3 mmol) of trimethyltin chloride in 10 ml of dry ether over a period of 8 min. After refluxing for 2 h. the reaction mixture was hydrolyzed with aqueous sodium hydrogencarbonate at 0 °C. The organic layer was separated and extracted with dilute phosphoric acid. The aqueous solution was made alkaline with sodium carbonate and extracted with ether. The ether solution was washed with brine, dried over anhydrous magnesium sulfate, and evaporated under reduced pressure. The residue was chromatographed on alumina (benzene) to give 3.48 g (43% yield) of (*S*)-(*R*)-**7** as a red oil; NMR: δ 0.21 (s and d, 9H, J_{H-Sn}=37.7 Hz, SnC$\underline{H}_3$), 1.18 (d, 3H, J=6 Hz. C$H\underline{C}\underline{H}_3$). 1.99 (s, 6H, NC$\underline{H}_3$), 3.82 (q, 1H, C$\underline{H}C\underline{H}_3$), 4.00 (s, 5H,

$FeC_5\underline{H}_5$), 4.00 and 4.23 (m, 1H and 2H, $FeC_5\underline{H}_3$).

*Bis[(R)-2-[(S)-1-(dimethylamino)ethyl]ferrocenyl]phenylphosphine [(S)-(R)-**8**].* To a solution of 0.88 g (2.1 mmol) of (*S*)-(*R*)-**7** in 5 ml of dry ether was added 1.47 ml (2.2 mmol) of butyllithium in hexane (1.5 M) over a period of 10 min at 0 °C. After stirring at 0 °C for 30 min, 0.19 g (1.1 mmol) of dichlorophenylphosphine was slowly added (5 min). The reaction mixture was refluxed for 1 h and then hydrolyzed with aqueous sodium hydrogencarbonate at 0 °C. The resulting organic layer and ether extracts from the aqueous layer were combined and extracted with 10% phosphoric acid. The aqueous layer was made alkaline with sodium carbonate, and extracted with ether. The ether solution was washed with brine, dried over anhydrous sodium sulfate, evaporated under reduced pressure to give a red oil. The oil was chromatographed on alumina (benzene/ether 1/1) to give 0.157 g (21% yield) of (*S*)-(*R*)-**8**. A pure sample was obtained by recrystallization from pentane; NMR: δ 1.24 and 1.48 (a pair of d, 6H, J=6.3 Hz, $CHC\underline{H}_3$), 1.64 and 2.30 (a pair of s, 12H, $NC\underline{H}_3$), 3.57 and 3.96 (a pair of s, 10H, $FeC_5\underline{H}_5$), 3.9—4.6 (m, 8H, $FeC_5\underline{H}_3C\underline{H}$), 7.13—7.76 (m, 5H, $PC_6\underline{H}_5$).

*(S)-N,N-Dimethyl-1-[(R)-2-(diphenylphosphinyl)ferrocenyl]ethylamine [(S)-(R)-**9**].* (a) A solution of 8.8 g (37 mmol) of diphenylphosphinic chloride in 30 ml of ether was added in 15 min to the refluxing solution of 5.08 g (19.8 mmol) of (*S*)-**1** which had been lithiated as described in the preparation of (*S*)-(*R*)-**3a**. The mixture was refluxed for 9 h, and then hydrolyzed with aqueous sodium hydroxide. The resulting organic layer and benzene extracts from the aqueous layer were combined, dried over anhydrous sodium sulfate, and concentrated *in vacuo* to a minimum volume. The residue was chromatographed on alumina. Elution with benzene gave 2.5 g of starting amine (*S*)-**1**. Elution with benzene/ethyl acetate (1/1) gave the crude product. The product was purified by recrystallization from dichloromethane/light petroleum ether (1/4) to give 2.74 g (30% yield) of (*S*)-(*R*)-**9** which gave brown crystals; UV: λ_{max} ($CHCl_3$) 446 nm (ε 145); NMR: δ 1.12 (d, 3H, J=6 Hz, $CHC\underline{H}_3$), 1.61 (s, 6H, $NC\underline{H}_3$), 4.13 (s, 5H, $FeC_5\underline{H}_5$), 3.76—4.51 (m, 4H, $FeC_5\underline{H}_3C\underline{H}$), 7.13—8.02 (m, 10H, $PC_6\underline{H}_5$); IR (KBr): 1192 (P→O) and 1107, 1010 cm^{-1} (FeC_5H_5).

(b) To a solution of 3.29 g (7.44 mmol) of (*S*)-(*R*)-**3a** in 60 ml of acetone was added dropwise 3 ml of 30% hydrogen peroxide. After 30 min at room temperature, aqueous sodium thiosulfate was added to decompose an excess of the hydrogen peroxide. The reaction mixture was extracted with dichloromethane. The extract was washed with water, dried over anhydrous sodium sulfate, and then evaporated. Purification of the residue by short-column chromatography (alumina. ethyl acetate) gave 3.31 g (97% yield) of (*S*)-(*R*)-**9**.

*(S)-1-[(R)-2-(Diphenylphosphinyl)ferrocenyl]ethylamines [(S)-(R)-**10**].* The following procedure for the preparation of (*S*)-(*R*)-**10a** is typical. To a solution of 0.50 g (1.1 mmol) of (*S*)-(*R*)-**9** in 6 ml of acetonitrile was added 4 ml (64 mmol) of methyl iodide, and the mixture was stirred at room temperature for 1 h, then evaporated to *ca.* 2 ml. To the residue, 4 ml of acetonitrile and 4 ml (29 mmol) of diisopropylamine were added. The reaction mixture was kept stirring overnight, and the solvent was removed under reduced pressure. The product was extracted with dichloromethane, and the extract was washed with brine, dried over anhydrous magnesium sulfate, and evaporated. The residue was purified by column chromatography (alumina, ethyl acetate) to give 0.47 g (82% yield) of (*S*)-(*R*)-**10a**, which was recrystallized from ethanol; NMR: δ 0.60 and 0.94 (a pair of d, 12H, J=7 Hz, $N(CH(C\underline{H}_3)_2)_2$), 1.50 (d, 3H, J=7.5 Hz, C_5H_3-$CHC\underline{H}_3$), 3.05 (7, 2H, $NC\underline{H}$), 4.12 (s, 5H, $FeC_5\underline{H}_5$), 3.87—4.62 (m, 4H, $FeC_5\underline{H}_3C\underline{H}$), 7.20—7.92 (m, 10H, $PC_6\underline{H}_5$).

*(S)-(R)-**10b**.* Prepared from (*S*)-(*R*)-**9** and diisobutylamine in 60% yield; NMR: δ 0.50 and 0.67 (a pair of d, 12H, J=7 Hz, $N(CH_2CH(C\underline{H}_3)_2)_2$), 1.49 (d, 3H, J=7.5 Hz, $C_5H_3CHC\underline{H}_3$), 1.20—1.60 (m, 2H, $N(CH_2C\underline{H}$-$Me_2)_2$), 1.85—2.16 (m, 4H, $NC\underline{H}_2$), 4.02 (s, 5H, $FeC_5\underline{H}_5$), 4.00—4.59 (m, 4H, $FeC_5\underline{H}_3C\underline{H}$), 7.20—7.92 (cm, 10H, $PC_6\underline{H}_5$).

*(S)-(R)-**10c**.* Prepared from (*S*)-(*R*)-**9** and pyrrolidine in 55% yield, and recrystallized from hexane; NMR: δ 0.96—1.15 and 1.96—2.41 (bm, 4H and 4H, 1-pyrrolidinyl), 1.32 (d, 3H, J=7.5 Hz, $C\underline{H}_3$), 4.18 (s, 5H, $FeC_5\underline{H}_5$), 3.88—4.56 (m, 4H, $FeC_5\underline{H}_3C\underline{H}$), 7.25—7.93 (m, 10H, $PC_6\underline{H}_5$).

*(S)-(R)-**10d**.* Prepared from (*S*)-(*R*)-**9** and piperidine in 86% yield; NMR: δ 0.65—1.18 and 2.20 (b and deformed t, 6H and 4H, respectively, piperidino), 1.22 (d, 3H, J=7 Hz, $C\underline{H}_3$), 4.12 (s, 5H, $FeC_5\underline{H}_5$), 3.90—4.48 (m, 4H, $FeC_5\underline{H}_3C\underline{H}$), 7.12—7.93 (cm, 10H, $PC_6\underline{H}_5$).

*(S)-(R)-**10e**.* Prepared from (*S*)-(*R*)-**9** and *N*-methylpiperazine in 81% yield; NMR: δ 1.24 (d, 3H, J=7 Hz, $CHC\underline{H}_3$), 1.45—1.80 (bm, 4H, $MeNC\underline{H}_2$), 1.89 (s, 3H, $NC\underline{H}_3$), 2.24—2.44 (m, 4H, $CHNC\underline{H}_2$), 4.12 (s, 5H, $FeC_5\underline{H}_5$), 3.93—4.58 (m, 4H, $FeC_5\underline{H}_3C\underline{H}$), 7.30—7.89 (m, 10H, $PC_6\underline{H}_5$).

*(S)-(R)-**10f**.* Prepared from (*S*)-(*R*)-**9** and morpholine in 92% yield; NMR: δ 1.25 (d, 3H, J=7 Hz, $C\underline{H}_3$), 2.12—2.48 (m, 4H, $NC\underline{H}_2$), 2.68—3.04 (m, 4H, $OC\underline{H}_2$), 4.13 (s, 5H, $FeC_5\underline{H}_5$), 3.93—4.60 (m, 4H, $FeC_5\underline{H}_3C\underline{H}$), 7.25—7.92 (m, 10H, $PC_6\underline{H}_5$).

*(S)-1-[(R)-2-(Diphenylphosphino)ferrocenyl]ethyl Acetate [(S)-(R)-**12**].* In a degassed sealed glass tube, a mixture of 701 mg (1.59 mmol) of (*S*)-(*R*)-PPFA (**3a**) and 1.0 ml of acetic anhydride was heated at 100 °C for 2 h. It was then cooled in a refrigerator overnight and orange crystals formed were collected on a glass filter, washed with cold methanol, and dried *in vacuo* to give 646 mg (89% yield) of (*S*)-(*R*)-**12**; NMR: δ 1.20 (s, 3H, $COC\underline{H}_3$), 1.64 (d, 3H, J=7 Hz, $CHC\underline{H}_3$), 4.04 (s, 5H, $FeC_5\underline{H}_5$), 3.80, 4.35, 4.56 (bm, 3H, $FeC_5\underline{H}_3$), 6.18 (dq, 1H, J_{H-P}=3 Hz, $C\underline{H}CH_3$), 7.05—7.65 (m, 10H, $PC_6\underline{H}_5$).

(*R*)-(*S*)-**12** was also prepared starting with (*R*)-(*S*)-**3a** in a similar manner.

*(S)-1-[(R)-2-(Diphenylphosphino)ferrocenyl]ethylamines [(S)-(R)-**11**].*

*(S)-(R)-**11a**.* To a solution of 0.175 g (4.6 mmol) of lithium aluminum hydride in 15 ml of dry dibutyl ether and 10 ml of dry benzene, was added with stirring 0.121 g (0.236 mmol) of (*S*)-(*R*)-**10a**. The mixture was kept at 75 °C for 6 h, and then hydrolyzed by successive addition of water and 10% aqueous sodium hydroxide. The product was extracted with benzene, and the benzene solution was washed with brine and water, dried over anhydrous sodium sulfate, and evaporated to give a red oil. It was chromatographed (alumina, benzene) to give 83 mg (71% yield) of (*S*)-(*R*)-**11a**, which was purified by recrystallization from ethanol; NMR: δ 0.74 and 1.01 (a pair of d, 12H, J=7 Hz, $CH(C\underline{H}_3)_2$), 1.59 (d, 3H, J=7.5 Hz, $C_5H_5CHC\underline{H}_3$), 3.10 (7, 2H, $C\underline{H}Me_2$), 3.87 (s, 5H, $FeC_5\underline{H}_5$), 4.00—4.55 (m, 4H, $FeC_5\underline{H}_3C\underline{H}$), 7.08—7.68 (m, 10H, $PC_6\underline{H}_5$).

(*S*)-(*R*)-**11b**, **11c**, **11d**, and **11f** were prepared in a similar manner to that for the preparation of (*S*)-(*R*)-**11a**, starting with (*S*)-(*R*)-**10b**, **10c**, **10d**, and **10f**, respectively.

*(S)-(R)-**11b**:* 66% yield; NMR: δ 0.55 and 0.73 (a pair of d, 12H, J=7 Hz, $CH(C\underline{H}_3)_2$), 1.50 (d, 3H, J=7.5 Hz, $C_5H_3CHC\underline{H}_3$), 1.26—1.66 (m, 2H, $CH_2C\underline{H}(CH_3)_2$), 1.92 (d, 4H, $C\underline{H}_2CH(CH_3)_2$), 3.77 (s, 5H, $FeC_5\underline{H}_5$), 4.03—

4.40 (m, 4H, $FeC_5\underline{H}_3C\underline{H}$), 7.03—7.70 (m, 10H, $PC_6\underline{H}_5$).

*(S)-(R)-**11c***: 87% yield; NMR: δ 1.04—1.25 and 2.03—2.43 (m and m, 4H and 4H, respectively, 1-pyrrolidinyl), 1.40 (d, 3H, J=7.5 Hz, $C\underline{H}_3$), 3.90 (s, 5H, $FeC_5\underline{H}_5$), 3.82—4.42 (m, 4H, $FeC_5\underline{H}_3C\underline{H}$), 7.11—7.66 (m, 10H, $PC_6\underline{H}_5$).

*(S)-(R)-**11d***: 69% yield; NMR: δ 0.6—1.2 and 2.24 (bm and deformed t, 6H and 4H, respectively, piperidino), 1.27 (d, 3H, J=7 Hz, $C\underline{H}_3$), 3.89 (s, 5H, $FeC_5\underline{H}_5$), 3.85—4.41 (m, 4H, $FeC_5\underline{H}_3C\underline{H}$), 7.1—7.7 (m, 10H, $PC_6\underline{H}_5$).

*(S)-(R)-**11f***: 29% yield; NMR: δ 1.30 (d, 3H, J= 7 Hz, $C\underline{H}_3$), 2.10—2.46 (m, 4H, $NC\underline{H}_2$), 2.67—3.13 (m, 4H, $OC\underline{H}_2$), 3.92 (s, 5H, $FeC_5\underline{H}_5$), 3.86—4.42 (m, 4H, $FeC_5\underline{H}_3C\underline{H}$), 7.14—7.66 (m, 10H, $PC_6\underline{H}_5$).

*(S)-(R)-**11f*** was also prepared from *(S)-(R)-**12*** (*vide infra*).

*(S)-(R)-**11e***. To a solution of 0.57 g (1.11 mmol) of *(S)-(R)-**10e*** in 5 ml of benzene and 10 ml of dibutyl ether, a large excess of aluminum hydride, prepared from lithium aluminum hydride and aluminum chloride in ether, was added. The mixture was refluxed for 4 h, and then hydrolyzed with 20% aqueous sodium hydroxide at 0 °C. The organic layer was separated and the water layer was extracted with ether. The combined organic layer was washed with brine, dried over anhydrous sodium sulfate, and evaporated. The residue was purified by column chromatography (alumina, ether) to give 0.31 g (57% yield) of *(S)-(R)-**11e***; NMR: δ 1.25 (d, 3H, J=7 Hz, $CHC\underline{H}_3$), 1.4—1.9 (bm, 4H, $CH_3NC\underline{H}_2$), 1.88 (s, 3H, $NC\underline{H}_3$), 2.18—2.50 (m, 4H, $CHNC\underline{H}_2$), 3.90 (s, 5H, $FeC_5\underline{H}_5$), 3.84—4.42 (m, 4H, $FeC_5\underline{H}_3C\underline{H}$), 7.12—7.71 (m, 10H, $PC_6\underline{H}_5$).

*(S)-(R)-**11f***. A solution of 60 mg (0.13 mmol) of *(S)-(R)-**12*** and 0.6 ml of morpholine in 2.0 ml of methanol was refluxed for 5 h. Then the solvent was removed under reduced pressure, and 5 ml of benzene was added. The solution was washed with brine, dried over anhydrous sodium sulfate, and evaporated. The resulting red oil was column chromatographed (alumina, ether) to give 61.5 mg (98% yield) of *(S)-(R)-**11f***.

*(S)-(R)-**11g***. Prepared from *(S)-(R)-**12*** and diethylamine in 95% yield, recrystallized from dichloromethane/methanol; NMR: δ 0.65 (t, 6H, J=7 Hz, $NCH_2C\underline{H}_3$), 1.30 (d, 3H, J=7 Hz, $CHC\underline{H}_3$), 2.07—2.48 (cm, 4H, $NC\underline{H}_2$), 3.92 (s, 5H, $FeC_5\underline{H}_5$), 3.85—3.93, 4.19—4.52 (m, 4H, $FeC_5\underline{H}_3C\underline{H}$), 7.10—7.73 (m, 10H, $PC_6\underline{H}_5$).

*(S)-(R)-**11h***. Prepared from *(S)-(R)-**12*** and *(S)*-2-(dimethylaminomethyl)pyrrolidine[58] in 70% yield; NMR: δ 1.26 (m, 4H, $CH_2C\underline{H}_2C\underline{H}_2CH$), 1.49 (d, 3H, J=7 Hz, $CHC\underline{H}_3$), 1.6—1.7 (m, 2H, $C\underline{H}_2NMe_2$), 2.06 (s, 6H, $NC\underline{H}_3$), 2.2—2.9 (m, 3H, $C\underline{H}_2NC\underline{H}$), 3.91 (s, 5H, $FeC_5\underline{H}_5$), 3.96—4.45 (m, 4H, $FeC_5\underline{H}_3C\underline{H}$), 7.10—7.75 (m, 10H, $PC_6\underline{H}_5$).

*(R)-(S)-**11i***. Prepared from *(R)-(S)-**12*** and *(S)*-2-(dimethylaminomethyl)pyrrolidine[58] in 88% yield, recrystallized from ethanol; NMR: δ 1.30 (d, 3H, J=7 Hz, $CHC\underline{H}_3$), 2.18 (s, 6H, $NC\underline{H}_3$), 0.5—2.9 (m, 9H), 3.96 (s, 5H, $FeC_5\underline{H}_5$), 3.75, 4.22, 4.37 (m, 3H, $FeC_5\underline{H}_3$), 4.50 (m, 1H, $FeC_5H_3C\underline{H}$), 7.10—7.70 (m, 10H, $PC_6\underline{H}_5$).

*(S)-(R)-**11j***. Prepared from *(S)-(R)-**12*** and *(R)*-2-methylpyrrolidine[59] (contaminated with 30% of piperidine), purified by preparative TLC (alumina, benzene R_f 0.5), 36% yield, recrystallized from ethanol; NMR: δ 0.17 (d, 3H, J=6 Hz, $CH_2CHC\underline{H}_3$), 1.1—1.4 (m, 4H, $CH_2C\underline{H}_2C\underline{H}_2CH$), 1.55 (d, 3H, J=7 Hz, $C_5H_3CHC\underline{H}_3$), 2.1—2.7 (m, 2H, $NC\underline{H}_2$), 2.70—2.95 (m, 1H, $NC\underline{H}CH_2$), 3.88 (s, 5H, $FeC_5\underline{H}_5$), 4.00, 4.2—4.5 (m, 4H, $FeC_5\underline{H}_3C\underline{H}$), 7.1—7.7 (m, 10H, $PC_6\underline{H}_5$).

*(R)-(S)-**11k***. Prepared from *(R)-(S)-**12*** and *(R)*-2-methylpyrrolidine[59] (contaminated with 30% of piperidine) in 50% yield. The *(R)-(S)-**11k*** contained 25% of *(R)-(S)-**11d***, which could not be removed. NMR: δ 0.98 (d, 3H, J=6 Hz, $CH_2CHC\underline{H}_3$), 1.24 (d, 3H, J=7 Hz, $C_5H_3CHC\underline{H}_3$), 0.4—1.6 (m, 4H, $CH_2C\underline{H}_2C\underline{H}_2CH$), 1.9—2.3 (m, 2H, $NC\underline{H}_2$), 2.49 (6, 1H, $NC\underline{H}CH_2$), 3.96 (s, 5H, $FeC_5\underline{H}_5$). 3.75, 4.20, 4.35 (m, 3H, $FeC_5\underline{H}_3$), 4.49 (double q, 1H, J_{H-P}= 3 Hz, $C_5H_3C\underline{H}$), 7.05—7.65 (m, 10H, $PC_6\underline{H}_5$).

(R)-1-[(S)-1',2-Bis(diphenylphosphino)ferrocenyl]ethyl acetate [*(R)-(S)-**13***]. A mixture of 0.626 g (1.0 mmol) of *(R)-(S)*-BPPFA (**4a**) and 3 ml of acetic anhydride was heated at 100 °C for 1 h in a degassed sealed glass tube. After cooling the reaction mixture to room temperature, orange crystals formed were collected on a glass filter. and dried *in vacuo*. The crystals (0.576 g, 90% yield) were pure *(R)-(S)-**13***; NMR: δ 1.16 (s, 3H, $COC\underline{H}_3$), 1.49 (d, 3H. J= 6.5 Hz, $CHC\underline{H}_3$), 3.60—4.56 (m, 7H, $C_5\underline{H}_4FeC_5\underline{H}_3$), 6.12 (double q, J=6.4 Hz and 2.4 Hz, 1H, $C\underline{H}CH_3$), 7.00—7.56 (m, 20H, $PC_6\underline{H}_5$). IR (KBr): 1734, 1372, and 1240 cm^{-1} (CH_3COO).

(R)-1-[(S)-1',2-Bis(diphenylphosphino)ferrocenyl]ethylamine [*(R)-(S)-**14a***]. A mixture of 0.71 g (1.11 mmol) of *(R)-(S)-**13*** in 5 ml of saturated ammonia–methanol was heated at 100 °C for 7 h in a microautoclave. Benzene (20 ml) was added, and the solution was washed with dilute aqueous sodium hydroxide, dried over anhydrous sodium sulfate, and evaporated. The residue was chromatographed on alumina (ether/ethyl acetate 2/1) to give 0.57 g (86% yield) of *(R)-(S)-**14a***, which was recrystallized from hexane/dichloromethane; NMR: δ 1.30 (d, J=7 Hz, $C\underline{H}_3$), 1.27—1.41 (bs, 2H, $N\underline{H}_2$), 3.63, 4.10, 4.39 (m, 8H, $C_5\underline{H}_4FeC_5\underline{H}_3C\underline{H}$), 7.14—7.63 (m, 20H, $PC_6\underline{H}_5$).

*(S)-(R)-**14b***—**e** and *(R)-(S)-**14f***—**j** were prepared by the reaction of **13** with the corresponding dialkylamine in methanol. The following procedure for the preparation of *(S)-(R)-**14c*** is typical.

*(S)-(R)-**14c***. A solution of 0.450 g (0.70 mmol) of *(S)-(R)-**13*** and 4 ml of pyrrolidine in 15 ml of methanol was refluxed for 8 h. The solvent was removed under reduced pressure, and benzene was added. The solution was washed with brine, dried over anhydrous sodium sulfate, and evaporated. The residue was purified by column chromatography (alumina, ether) to give 0.368 g (81% yield) of *(S)-(R)-**14c***, which was recrystallized from ethanol; NMR: δ 0.86—1.24 and 1.98—2.44 (bm, 4H and 4H, pyrrolidino), 1.26 (d, 3H, J=7 Hz, $C\underline{H}_3$), 3.46—4.46 (m, 8H, $C_5\underline{H}_4FeC_5\underline{H}_3C\underline{H}$), 7.03—7.61 (m, 20H, $PC_6\underline{H}_5$).

*(S)-(R)-**14b***. Prepared from *(S)-(R)-**13*** and diethylamine in 62% yield, recrystallized from benzene/hexane; NMR: δ 0.63 (t, 6H, J=7.5 Hz, $NCH_2C\underline{H}_3$), 1.20 (d, 3H, J=7.5 Hz, $CHC\underline{H}_3$), 2.22 (m, 4H, $NC\underline{H}_2$), 3.40—4.60 (m, 8H, $C_5\underline{H}_4FeC_5\underline{H}_3C\underline{H}$), 7.00—7.70 (m, 20H, $PC_6\underline{H}_5$).

*(S)-(R)-**14d***. Prepared from *(S)-(R)-**13*** and piperidine in 88% yield, recrystallized from benzene/hexane; NMR: δ 0.66—1.20 and 2.03—2.40 (bm, 6H and 4H, respectively, piperidino), 1.19 (d, 3H, J=7.5 Hz, $C\underline{H}_3$), 3.40—4.40 (m, 8H, $C_5\underline{H}_4FeC_5\underline{H}_3C\underline{H}$), 6.98—7.60 (m, 20H, $PC_6\underline{H}_5$).

*(S)-(R)-**14e***. Prepared from *(S)-(R)-**13*** and *N*-methylpiperazine in 62% yield; NMR: δ 1.12 (d, 3H, J=7.5 Hz, $CHC\underline{H}_3$), 1.23—1.90 (bs, 4H, $C\underline{H}_2NMeC\underline{H}_2$), 1.78 (s, 3H, $NC\underline{H}_3$), 2.02—2.46 (bs, 4H, $C\underline{H}_2N(CH)C\underline{H}_2$), 3.36—4.38 (m, 8H, $C_5\underline{H}_4FeC_5\underline{H}_3C\underline{H}$), 6.95—7.50 (m, 20H, $PC_6\underline{H}_5$).

*(R)-(S)-**14f***. Prepared from *(R)-(S)-**13*** and *N*-methylallylamine, recrystallized from hexane, 81% yield; NMR: δ 1.15 (d, 3H, J=7.5 Hz, $CHC\underline{H}_3$), 1.66 (s, 3H, $NC\underline{H}_3$), 2.60—3.05 (m, 2H, $NC\underline{H}_2$), 3.52, 3.67, 3.97, 4.08, and 4.36 (m, 1H, 1H, 1H, 2H, and 2H, $C_5\underline{H}_4FeC_5\underline{H}_3$), 4.23 (m, 1H, $C\underline{H}CH_3$), 4.62—5.15 (m, 3H, $C\underline{H}$ $C\underline{H}_2$),

7.07—7.37 (m, 20H, $PC_6\underline{H}_5$).

*(R)-(S)-**14g***. Prepared from (*R*)-(*S*)-**13** and *N,N,N'*-trimethylethylenediamine in 74% yield; NMR: δ 1.07 (3H, J=7 Hz, $CHC\underline{H}_3$), 1.60 (s, 3H, $CHNC\underline{H}_3$), 1.45—1.70 and 2.07—2.41 (m, 4H, $NC\underline{H}_2C\underline{H}_2N$), 1.90 (s, 6H, $N(C\underline{H}_3)_2$), 3.37—4.30 (m, 8H, $C_5\underline{H}_4FeC_5\underline{H}_3C\underline{H}$), 6.80—7.50 (m, 20H, $PC_6\underline{H}_5$).

*(R)-(S)-**14h***. Prepared from (*R*)-(*S*)-**13** and *N,N'*-dimethylethylenediamine, recrystallized from hexane, 91% yield; NMR: δ 1.18 (d, 3H, J=7.5 Hz, $CHC\underline{H}_3$), 1.68 and 1.96 (s and s, 3H and 3H, $NC\underline{H}_3$), 2.12—2.86 (m, 5H, $NC\underline{H}_2C\underline{H}_2N\underline{H}$), 3.75, 3.86, 4.09, 4.34, and 4.42 (m, 1H, 1H, 1H, 2H, and 2H, respectively, $C_5\underline{H}_4FeC_5\underline{H}_3$), 4.22 (m, 1H, $C\underline{H}CH_3$), 7.10—7.40 (m, 20H, $PC_6\underline{H}_5$).

*(R)-(S)-**14i***. Prepared from (*R*)-(*S*)-**13** and 2-(methylamino)ethanol, recrystallized from ethanol, 88% yield; NMR: δ 1.18 (d, 3H, J=7.5 Hz, $CHC\underline{H}_3$), 1.62 (s, 3H, $NC\underline{H}_3$), 2.18—2.74 (m, 3H, $NC\underline{H}_2$ and $O\underline{H}$), 3.06—3.40 (m, 2H, $OC\underline{H}_2$), 3.47, 3.76, 3.90, 4.02—4.19, 4.34, and 4.43 (m, 1H, 1H, 1H, 2H, 1H, and 1H, respectively, $C_5\underline{H}_4FeC_5\underline{H}_3$), 4.26 (m, 1H, $C\underline{H}CH_3$), 7.10—7.38 (m, 20H, $PC_6\underline{H}_5$).

*(R)-(S)-**14j***. Prepared from (*R*)-(*S*)-**13** and di(2-hydroxyethyl)amine in 82% yield, recrystallized from hexane/methanol; NMR: δ 1.33 (d, 3H, J=7.5 Hz, $C\underline{H}_3$), 2.47 (t, 4H, J=5.5 Hz, $NC\underline{H}_2$), 3.16—3.38 (m, 4H, $OC\underline{H}_2$), 3.43, 3.71, 4.02, 4.05, and 4.18—5.03 (m, 1H, 1H, 1H, 1H, and 4H, $C_5\underline{H}_4FeC_5\underline{H}_3C\underline{H}$), 7.10—7.40 (m, 20H, $PC_6\underline{H}_5$).

(R)-1-[(S)-2-(Diphenylphosphino)ferrocenyl]ethyl methyl ether [*(R)-(S)-**15***]. A mixture of 92 mg (0.20 mmol) of (*R*)-(*S*)-**12** and 1.60 g of 3-aminopropylated silica gel[51] (0.236 meq/g nitrogen) in 10 ml of dry methanol was refluxed for 10 h. Methanol was evaporated, and 10 ml of ether was added. The silica gel was removed by short alumina column. Evaporation of the solvent gave crude (*R*)-(*S*)-**15**, which was recrystallized from methanol, 58% yield; NMR: δ 1.57 (d, 3H, J=7 Hz, $CHC\underline{H}_3$), 2.90 (s, 3H, $OC\underline{H}_3$), 3.98 (s, 5H, $FeC_5\underline{H}_5$), 3.83, 4.29, and 4.50 (bm, 3H, $FeC_5\underline{H}_3$), 4.45—4.75 (m, 1H, $C\underline{H}CH_3$), 7.1—7.7 (m, 10H, $PC_6\underline{H}_5$).

(R)-1-[(S)-1',2-Bis(diphenylphosphino)ferrocenyl]ethyl methyl ether [*(R)-(S)-**16***]. (a) A mixture of 72 mg (0.112 mmol) of (*R*)-(*S*)-**13** and 95 mg of 3-aminopropylated silica gel[51] (0.236 meq/g nitrogen), prepared from (3-aminopropyl)-triethoxysilane and activated silica gel, in 5 ml of methanol was refluxed for 29 h. The silica gel was filtered off. The filtrate was evaporated to give a quantitative yield of crude (*R*)-(*S*)-**16**, which was recrystallized from ethanol, 58 mg (85% yield).

(b) A solution of 81 mg (0.126 mmol) of (*R*)-(*S*)-**13** and 6.9 mg (0.128 mmol) of sodium methoxide in 10 ml of methanol was refluxed for 3 h, and then evaporated. The residue was passed through a short alumina column (ether/benzene) to give 67 mg (87% yield) of (*R*)-(*S*)-**16**; NMR: δ 1.45 (d, 3H, J=7.5 Hz, $CHC\underline{H}_3$), 2.88 (s, 3H, $OC\underline{H}_3$), 3.65, 3.95—4.20, 4.38, and 4.45 (m, 2H, 3H, 1H, and 1H, respectively, $C_5\underline{H}_3FeC_5\underline{H}_4$), 4.55 (m, 1H, $C\underline{H}CH_3$), 7.10—7.38 (m, 20H, $PC_6\underline{H}_5$).

(R)-1-[(S)-2-(Diphenylphosphino)ferrocenyl]ethanol [*(R)-(S)-**PPFOH (17)***]. To a solution of 60 mg (0.13 mmol) of (*R*)-(*S*)-**12** in 5 ml of dry ether was added 1.0 ml (1.25 mmol) of 1.25 M butyllithium in hexane. The mixture was kept stirring at room temperature for 1 h, and then hydrolyzed with water at 0 °C. Usual work up and column chromatography (alumina, ethyl acetate) gave 50 mg (92% yield) of (*R*)-(*S*)-**17**; NMR: δ 1.42 (d, 3H, J=7 Hz, $CHC\underline{H}_3$), 1.65 (bs, 1H, $O\underline{H}$), 3.95 (s, 5H, $FeC_5\underline{H}_5$), 3.71, 4.21, and 4.42 (m, 3H, $FeC_5\underline{H}_3$), 4.90 (dq, 1H, J_{H-P}=3 Hz, $C\underline{H}CH_3$), 7.05—7.55 (m, 10H, $PC_6\underline{H}_5$).

(R)-1-[(S)-1',2-Bis(diphenylphosphino)ferrocenyl]ethanol [*(R)-(S)-**BPPFOH (18)***]. To a suspension of 0.576 g (0.90 mmol) of (*R*)-(*S*)-**13** in 20 ml of dry ether, 1.7 ml of 1.27 M butyllithium in hexane was added at 0 °C. The resulting red solution was kept stirring at room temperature for 2 h, and hydrolyzed with water at 0 °C. The product was extracted with ether, and the ether solution was washed with water, dried over anhydrous sodium sulfate, and evaporated. The residue was chromatographed (alumina, ethyl acetate) to give 0.512 g (95% yield) of (*R*)-(*S*)-**18**. An analytically pure sample was obtained by recrystallization from ethanol; NMR: δ 1.38 (d, 3H, J=6.5 Hz, $CHC\underline{H}_3$), 1.78—1.98 (bs, 1H, $O\underline{H}$), 3.58—4.54 (m, 7H, $C_5\underline{H}_4FeC_5\underline{H}_3$), 4.88 (q, 1H, $C\underline{H}CH_3$), 6.94—7.70 (m, 20H, $PC_6\underline{H}_5$). IR (CCl_4): 3570 cm^{-1} (OH).

(R)-1-Diphenylphosphinyl-2-ethylferrocene [*(R)-**20***]. To a solution of 0.93 g (2.03 mmol) of (*S*)-(*R*)-**9** in 45 ml of acetone, 5.0 ml of methyl iodide was added at room temperature. The solution was refluxed for 15 min and concentrated *in vacuo* to *ca.* 15 ml. The residue was diluted with 30 ml of benzene, washed with 50 ml of 8.5% aqueous phosphoric acid and 50 ml of 10% aqueous sodium hydroxide, and dried over anhydrous sodium sulfate. After evaporation of the solvents, the residue was chromatographed on silica gel (benzene/ethyl acetate, 3/1) to give 0.61 g (73%) of crude (*R*)-1-diphenylphosphinyl-2-vinylferrocene (**19**) as a reddish-brown viscous oil; NMR: δ 4.12 (s, 3H, $FeC_5\underline{H}_3$), 4.22 (s, 5H, $FeC_5\underline{H}_5$), 4.7—5.5 (m, 2H, $CH{=}C\underline{H}_2$), 5.9—6.7 (m, 1H, $C\underline{H}{=}CH_2$), 7.1—7.9 (m, 10H, $PC_6\underline{H}_5$). IR: 1625 (vinyl), 1193 (P=O), and 1108 and 1002 cm^{-1} (FeC_5H_5).

The crude vinylferrocene (*R*)-**19** (0.57 g) in 5 ml of benzene solution was hydrogenated in a 50-ml steel autoclave at 130 kg/cm^2 of hydrogen in the presence of 10 mg of chlorotris(triphenylphosphine)rhodium to give, after chromatography on alumina (benzene/ethyl acetate 2/1), 0.29 g of (*R*)-**20**; NMR: δ 0.95 (t, 3H, J=7 Hz, $C\underline{H}_3$), 2.26—2.77 (cm, 2H, $C\underline{H}_2$), 4.25 (s, 5H, $FeC_5\underline{H}_5$), 3.72, 4.17, and 4.32 (m, 3H, $FeC_5\underline{H}_3$), 7.22—7.96 (m, 10H, $PC_6\underline{H}_5$).

(R)-1-Diphenylphosphino-2-ethylferrocene [*(R)-**PPEF (21)***]. A solution of 0.23 g (0.55 mmol) of (*R*)-**20** in 5 ml of benzene was added at room temperature to a solution of 0.1 g of lithium aluminum hydride in 4 ml of dry dibutyl ether over a period of 10 min. The reaction mixture was heated at 80—85 °C for 4.5 h. After work up in the usual way, chromatography on alumina using benzene as an eluent gave 0.17 g (78% yield) of (*R*)-**21**; UV: λ_{max} ($CHCl_3$) 446 nm (ε 155); NMR: δ 1.01 (t, 3H, J=7 Hz, $C\underline{H}_3$), 2.19—2.71 (m, 2H, $C\underline{H}_2$), 3.94 (s, 5H, $FeC_5\underline{H}_5$), 3.56, 4.10, and 4.27 (m, 3H, $FeC_5\underline{H}_3$), 6.76—7.62 (m, 10H, $PC_6\underline{H}_5$). ORD (*c* 0.12 and 0.005, chloroform): $[\Phi]_{589}$ +1080°, $[\Phi]_{474}$ +2450° (pk), $[\Phi]_{428}$ +1880° (tr), and $[\Phi]_{294}$ +14400° (pk). The CD spectrum is shown in Fig. 2.

(S)-1,1'-Bis(diphenylphosphino)-2-vinylferrocene [*(S)-**22***]. A solution of 1.17 g (1.83 mmol) of (*R*)-(*S*)-**13** in 10 ml of 10% potassium hydroxide in methanol was refluxed for 1 h. After usual work up, column chromatography (alumina) gave 0.360 g (34% yield) of (*S*)-**22** (benzene elution) and 0.431 g (39% yield) of (*R*)-(*S*)-**18** (ethyl acetate elution). (*S*)-**22**; NMR: δ 3.57, 3.68, 4.12, 4.23, 4.33, and 4.68 (m, 1H, 1H, 1H, 2H, 1H, 1H, respectively, $C_5\underline{H}_4FeC_5\underline{H}_3$), 4.95—5.40 (m, 2H, $CH{=}C\underline{H}_2$), 6.48—6.94 (m, 1H, $C\underline{H}{=}CH_2$), 7.0—7.6 (m, 20H, $PC_6\underline{H}_5$).

(S)-1,1'-Bis(diphenylphosphino)-2-ethylferrocene [*(S)-**BPPEF (23)***]. A solution of 85 mg (0.15 mmol) of (*S*)-**22** and 7 mg (0.015 mmol) of chlorotris(triphenylphosphine)-rhodium in 5 ml of benzene was placed in a microautoclave, and magnetically stirred with hydrogen at 50 atm for 18 h.

Column chromatography (alumina, benzene) gave 50 mg (57% yield) of (*S*)-**23**; NMR: δ 0.93 (t, 3H, J=7.5 Hz, $CH_2C\underline{H}_3$), 2.37 (q, 2H, $C\underline{H}_2CH_3$), 3.30—3.55, 3.55—3.75, 3.85—4.17, and 4.20—4.40 (bm, 1H, 1H, 3H, and 2H, respectively, $C_5\underline{H}_4FeC_5\underline{H}_3$), 6.8—7.6 (m, 20H, $PC_6\underline{H}_5$).

[(R)-1-[(S)-2-(Diphenylphosphino)ferrocenyl]ethyl]diphenylphosphine [(R)-(S)-**24**]. A solution of 69.2 mg (0.15 mmol) of (*R*)-(*S*)-**12** and 280 mg (1.5 mmol) of diphenylphosphine in 4.5 ml of methanol was refluxed under argon for 7 h. The solvent was removed under reduced pressure, and the residue was chromatographed on alumina (benzene) to give 74 mg (85% yield) of (*R*)-(*S*)-**24** as a red oil; NMR: δ 1.51 (dd, 3H, J_{H-H}=7.2 Hz, J_{H-P}=5.8 Hz, $PCHC\underline{H}_3$), 3.97 (s, 5H, $FeC_5\underline{H}_5$), 3.75—4.44 (m, 4H, $FeC_5\underline{H}_3C\underline{H}$), 7.31—7.95 (m, 20H, $PC_6\underline{H}_5$).

dl-1-Diphenylphosphino-2-(dimethylaminomethyl)ferrocene [dl-*FcPN* (**25**)]. *dl*-**25** was prepared according to the reported procedure,[52] mp 101.5—102 °C; NMR: δ 2.01 (s, 6H, $NC\underline{H}_3$), 3.48 (deformed AB, 2H, J=14 Hz, $\Delta\nu$=17 Hz, $C\underline{H}_2$), 3.94 (s, 5H, $FeC_5\underline{H}_5$), 3.87, 4.29, and 4.52 (m, 3H, $FeC_5\underline{H}_3$), 7.15—7.71 (m, 10H, $PC_6\underline{H}_5$).

dl-1-Diphenylthiophosphinyl-2-(dimethylaminomethyl)ferrocene [dl-**26**]. A solution of 26.9 g (62.9 mmol) of *dl*-**25** and 2.22 g (69.2 mmol) of sulfur in 60 ml of benzene was refluxed for 1 h. The solvent was removed under reduced pressure and the residue was purified by short-column chromatography (alumina) to give 25.8 g (89% yield) of *dl*-**26**, mp 166 °C; NMR: δ 1.92 (s, 6H, $NC\underline{H}_3$), 3.52 (AB, 2H, J=13 Hz, $\Delta\nu$=67 Hz, $C\underline{H}_2$), 4.27 (s, 6H, $FeC_5\underline{H}_5$ and one of $FeC_5\underline{H}_3$), 3.82 and 4.60 (m, 2H, $FeC_5\underline{H}_3$), 7.25—7.96 (m, 10H, $PC_6\underline{H}_5$).

(S)- and (R)-26. *dl*-**26** (5.72 g, 12.4 mmol) dissolved in 20 ml of hot benzene was added to a hot benzene (20 ml) solution of 4.68 g (12.4 mmol) of dibenzoyl-*d*-tartaric acid.[60] The benzene was removed by evaporation under reduced pressure to give ammonium salts as an orange powder. The ammonium salts were dissolved in 100 ml of warm (40 °C) ethanol. Very soon orange crystals started to separate out. After 8 h the crystals were collected and set free with aqueous sodium carbonate. The partially optically active **26** (2.05 g) obtained and 1.58 g of dibenzoyl-*d*-tartaric acid were mixed in 7 ml of dichloromethane. Ethanol (50 ml) was added, and the solution was kept at 50 °C. As dichloromethane was evaporated, orange needle crystals were formed. After 8 h 2.90 g of the crystals ($[\alpha]_D^{25}$ +12° (*c* 0.4, chloroform)) were obtained; this was converted with aqueous sodium carbonate to **26**, which was purified by a short alumina column (ether) to give 1.63 g (57% yield) of optically pure (*S*)-**26**; $[\alpha]_{545}^{25}$ +50.2° (*c* 0.5, chloroform). From the mother liquor of the first crystallization, was recovered 3.15 g of *R*-rich **26**, which was fractionally recrystallized using dibenzoyl-*l*-tartaric acid to give 1.50 g (52% yield) of (*R*)-**26**; $[\alpha]_{545}^{25}$ −50.5° (*c* 0.5, chloroform).

(S)-FcPN (**25**). To a solution of 1.38 g (3.0 mmol) of (*S*)-**26** in 20 ml of dry dioxane was added 0.6 g of lithium aluminum hydride, and the mixture was refluxed for 22 h. It was hydrolyzed with 10% aqueous sodium hydroxide, and then extracted with benzene. Column chromatography (alumina, ether) gave 1.06 g (83% yield) of crude (*S*)-**25**. Recrystallization from pentane (4 ml) gave 0.77 g of pure (*S*)-**25** as red cubic crystals. The CD spectrum is shown in Fig. 3.

In the same manner, (*R*)-**25** was obtained from (*R*)-**26** in 80% yield.

(S)-1-Diphenylthiophosphinyl-2-(acetoxymethyl)ferrocene [(S)-**27**]. In a degassed sealed glass tube, a mixture of 0.23 g (0.50 mmol) of (*S*)-**26** and 2.0 ml of acetic anhydride was heated at 100 °C for 20 h. Benzene (5 ml) was added and the benzene solution was washed with aqueous sodium hydroxide and water, dried over anhydrous sodium sulfate, and evaporated. Column chromatography (alumina, ethyl acetate) gave 0.20 g (84% yield) of (*S*)-**27**, $[\alpha]_{545}^{25}$ +59° (*c* 0.5, chloroform), mp 190—193° (decomp); NMR: δ 1.56 (s, 3H, $COC\underline{H}_3$), 4.35 (s, 6H, $FeC_5\underline{H}_5$ and one of $FeC_5\underline{H}_3$), 3.81 and 4.59 (m, 2H, $FeC_5\underline{H}_3$), 5.24 (AB, 2H, J=12 Hz, $\Delta\nu$=45 Hz, $C\underline{H}_2$), 7.22—7.90 (m, 10H, $PC_6\underline{H}_5$).

(S)-1-Diphenylthiophosphinyl-2-(hydroxymethyl)ferrocene [(S)-**28**]. A solution of 0.20 g (0.42 mmol) of (*S*)-**27** in 8 ml of 3 M aqueous potassium hydroxide and 18 ml of methanol was refluxed for 1 h. The solvent was removed, and 10 ml of benzene was added. The benzene solution was washed with water, dried over anhydrous sodium sulfate, and evaporated. The product was purified by column chromatography (alumina, chloroform/methanol 15/1) to give 0.16 g (88% yield) of (*S*)-**28**, mp 192—194 °C (decomp); NMR: δ 3.34 (dd, 1H, J=6 and 8 Hz, $O\underline{H}$), 4.31 (s, 5H, $FeC_5\underline{H}_5$), 3.70—4.78 (m, 5H, $FeC_5\underline{H}_3C\underline{H}_2$), 7.21—7.95 (m, 10H, $PC_6\underline{H}_5$).

dl-**28** was also prepared from *dl*-**26**; NMR of *dl*-**28** in the presence of 30 mol% of $Eu(facam)_3$: δ 5.30 and 5.88 (a pair of s, $FeC_5\underline{H}_5$).

(S)-1,1'-Bis(diphenylphosphino)-2-(dimethylaminomethyl)ferrocene [(S)-**30**]. To a solution of 1.02 g (2.4 mmol) of (*S*)-**25** in 25 ml of dry ether was added a solution of butyllithium in hexane (4.0 ml of a 1.25 M solution). After stirring at room temperature for 1.5 h, 1.5 ml (12 mmol) of chlorotrimethylsilane was added with heating under gentle reflux. The reaction mixture was refluxed for 2 h, hydrolyzed with 10 ml of water and 10 ml of 30% aqueous sodium hydroxide, and then extracted with benzene (2×40 ml). The combined benzene extracts were washed with brine and dried over anhydrous sodium sulfate. Evaporation of the solvent followed by column chromatography (alumina, benzene/ether 1/1) gave 1.02 g (85% yield) of 1-diphenylphosphino-2-dimethylaminomethyl-3-(trimethylsilyl)ferrocene [(*S*)-**29**]. Elution with ethyl acetate gave 0.15 g of recovered (*S*)-**25**. NMR of (*S*)-**29**: δ 0.28 (s, 9H, $SiC\underline{H}_3$), 1.78 (s, 6H, $NC\underline{H}_3$), 3.47 (ABX, 2H, $J_{H_A-H_B}$=13 Hz, J_{H_A-P}=3 Hz, J_{H_B-P}=0 Hz, $\Delta\nu$=16 Hz, $C\underline{H}_2$), 3.90 (s, 5H, $FeC_5\underline{H}_5$), 3.97 (d, 1H, J=3 Hz, one of $FeC_5\underline{H}_2$), 4.20 (d, 1H, one of $FeC_5\underline{H}_2$), 7.12—7.72 (m, 10H, $PC_6\underline{H}_5$).

(*S*)-**29** (1.02 g, 2.04 mmol) was lithiated with butyllithium (4.9 ml of 1.25 M hexane solution) and TMEDA (0.92 ml, 6.13 mmol). To the solution was added with stirring 1.5 ml (7.96 mmol) of chlorodiphenylphosphine at 0 °C. The reaction mixture was refluxed for 1.5 h, hydrolyzed with 30% aqueous sodium hydroxide at 0 °C, and extracted with benzene (2×30 ml). The benzene extracts were washed with brine, dried over anhydrous sodium sulfate, and evaporated. Column chromatography (alumina, hexane/benzene 1/1) gave 0.747 g of recovered (*S*)-**29** and 0.393 g of a mixture of recovered (*S*)-**29** and the desired phosphinated product (3:7).

The above-obtained mixture (0.318 g) was desilylated by treatment with 0.052 g (0.46 mmol) of potassium *t*-butoxide in 10 ml of dimethyl sulfoxide. Usual work up and preparative TLC (silica gel, benzene/acetone 1/1) gave 0.160 g of (*S*)-**30** (R_f 0.65); NMR: δ 1.94 (s, 6H, $NC\underline{H}_3$), 3.11, 3.14, 3.47, 3.57, 3.71, 3.99, 4.09, 4.16, 4.27, and 4.52 (m, 9H, $C_5\underline{H}_4FeC_5\underline{H}_3C\underline{H}_2$), 7.0—7.7 (m, 20H, $PC_6\underline{H}_5$).

The reaction of (R)-1 with Acetic Anhydride. A solution of 0.186 g (0.726 mmol) of (*R*)-(+)-**1** ($[\alpha]_D^{25}$ +14.1° (*c* 1.7, ethanol)) in 0.3 ml of acetic anhydride was heated at 100 °C for 2 h. Saturated aqueous sodium hydrogencarbonate was added at room temperature, and the product

was extracted with ether. The ether solution was washed with brine, dried over anhydrous sodium sulfate, and evaporated *in vacuo* to give 0.192 g (97% yield) of 1-ferrocenylethyl acetate, $[\alpha]_D^{25}$ −26.6° (*c* 1.0, ethanol), (lit,[49] (*R*)-1-ferrocenylethyl acetate, $[\alpha]_D^{25}$ −28.5° (*c* 1.4, ethanol)).

We thank the Ministry of Education for Grant-in-Aid (No. 235053, 303523, 311709, 355370) and the Asahi Glass Foundation for the Contribution to Industrial Technology for financial support of this work. We are indebted to Professor Y. Imanishi, Department of Polymer Chemistry, Kyoto University, for CD measurements.

Cyclotrimerization of Phenylacetylene Catalyzed by Halides of Niobium and Tantalum

Toshio MASUDA,* Taizo MOURI, and Toshinobu HIGASHIMURA
Department of Polymer Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606
(Received November 8, 1979)

Halides of niobium and tantalum (NbX_5, TaX_5; X=Cl, Br, F) catalyzed the cyclotrimerization of phenylacetylene in hydrocarbon and chlorinated hydrocarbon solvents at 0—90 °C. When $NbCl_5$ and $TaCl_5$ were used as catalysts, two cyclic trimers, 1,2,4- and 1,3,5-triphenylbenzenes were exclusively formed, and their ratio varied from 17:83 to 94:6 depending on reaction conditions. The cyclotrimerization was more selective than those by other known catalysts. The cyclotrimerization by $NbBr_5$ and $TaBr_5$ occurred in a similar manner, but the reaction was less selective than that catalyzed by $NbCl_5$ and $TaCl_5$. Not only cyclotrimerization but also linear oligomerization proceeded by NbF_5 and TaF_5 as catalysts. The results obtained were discussed together with the linear polymerization of phenylacetylene catalyzed by $MoCl_5$ and WCl_6.

The cyclotrimerization of acetylenes is catalyzed by various transition-metal complexes to give benzene derivatives.[1] The best known catalysts for this reaction are Ziegler-type catalysts and Ni(0) complexes. The catalysts for the cyclotrimerization of acetylenes are usually either mixtures of a transition-metal compound and a reducing agent, or organo-transition metal complexes in which the metals are in a reduced state.

The cyclotrimerization of phenylacetylene by Ziegler-type catalysts gives a mixture of comparable amounts of 1,2,4- and 1,3,5-triphenylbenzene (1,2,4- and 1,3,5-TPB's).[2] The reaction catalyzed by Ni(0) complexes mainly provides a mixture of 1,2,4-TPB and linear oligomers.[3] A cobalt complex is reported to afford mainly 1,2,4-TPB in high yield.[4] In general, most catalysts so far reported for the cyclotrimerization of phenylacetylene show no high selectivity with respect to both cyclization and substituent position. Pure 1,3,5-TPB has been obtained by the acid-catalyzed condensation of acetophenone,[5] and pure 1,2,4-TPB by the reaction of 2,5-diphenylthiophene 1,1-dioxide with phenylacetylene.[6]

There has been a patent on the cyclotrimerization of acetylene and 1-alkyne by use of $NbCl_5$ and $TaCl_5$. The selectivity, however, has not been examined in detail.[7]

We have found that phenylacetylene is polymerized by the chlorides of molybdenum and tungsten to give selectively a linear high polymer (*MW* 5000—15000).[8] From this point of view, it is of great interest what reactions of phenylacetylene take place in the presence of the halides of niobium and tantalum.

The present paper describes the cyclotrimerization and linear oligomerization of phenylacetylene catalyzed by halides of niobium and tantalum (NbX_5, TaX_5; X=Cl, Br, F).

Experimental

Reagents. Phenylacetylene was prepared by the bromination of styrene and the subsequent dehydrobromination, according to the literature method.[9] The halides of niobium and tantalum (Alfa-Ventron, purity >99%) were used without further purification. Solvents were purified by the usual methods.

Procedures. Cyclotrimerization was carried out under a dry nitrogen atmosphere in a 30 ml Erlenmeyer flask equipped with a three-way stopcock, at $[PA]_0=1.0$ mol dm^{-3} and [Cat]=10 mmol dm^{-3} (PA: phenylacetylene, Cat: catalyst). The reaction was started by adding the monomer solution to the catalyst solution at a given temperature, and terminated by adding ammoniacal methanol. The consumption of monomer was determined by gas chromatography. The catalyst residue was removed by washing the reaction mixture with aqueous hydrochloric acid and water, and volatile materials were evaporated. The product obtained was dried under vacuum.

The number-average molecular weight of the products was measured on a Hitachi 117 molecular weight apparatus. The gel permeation chromatograms of the products were observed on a JASCO FLC-A700 chromatograph (column JSP 101, polystyrene gel, xl; eluent $CHCl_3$). The IR spectra of the produts were measured on a Shimadzu IR 27G spectrophotometer in KBr disks. The ratio of 1,2,4-TPB to 1,3,5-TPB in the products was determined from the ratios of D_{1600}/D_{1070}, D_{1495}/D_{1070}; and D_{1475}/D_{1070} in the IR spectra. Here, the absorption at 1070 cm^{-1} appears commonly in both 1,2,4- and 1,3,5-TPB's, while the absorptions at 1600, 1495, and 1475 cm^{-1} are characteristic of either 1,2,4- or 1,3,5-TPB. The ^{1}H NMR spectra were recorded on a JEOL JNM-MH 60 spectrometer.

Results and Discussion

Cyclotrimerization of Phenylacetylene Catalyzed by $NbCl_5$ and $TaCl_5$. The cyclotrimerization of phenylacetylene was performed with $NbCl_5$ and $TaCl_5$ in hydrocarbon and halogenated hydrocarbon solvents at 60 °C for 1 h ($[PA]_0=1.0$ mol dm^{-3}, [Cat]=10 mmol dm^{-3}). The reaction was fast and exothermic, and usually proceeded quantitatively. No reaction took place in such solvents as 2-butanone, acetonitrile, ethyl acetate, 1,4-dioxane and nitrobenzene.

The gel permeation chromatogram of the product showed only a peak at the position corresponding to the cyclic trimers. The number-average molecular weight of the product obtained agreed to the value for the trimers (306.4) within an error of 2%. These results indicate that no product other than the trimers was formed. Further, the IR, UV, and ^{1}H NMR spectra of the product were compared with those of authentic 1,2,4- and 1,3,5-TPB's, which revealed that the product was exclusively a mixture of 1,2,4- and 1,3,5-TPB's.

$[PA]_0 = 1.0$ mol dm^{-3}, $[Cat] = 10$ mmol dm^{-3}.

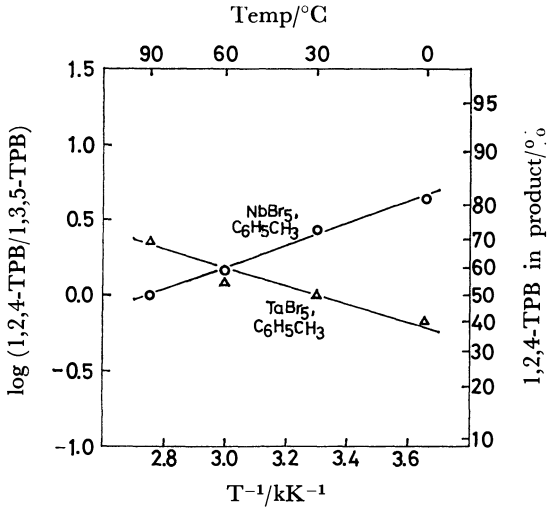

Fig. 2. Arrhenius plots of the ratio of 1,2,4-TPB to 1,3,5-TPB in the cyclotrimerization of phenylacetylene catalyzed by $NbBr_5$ and $TaBr_5$.
$[PA]_0 = 1.0$ mol dm^{-3}, $[Cat] = 10$ mmol dm^{-3}.

Table 1 shows the 1,2,4-TPB content of product expressed in %. In general, $NbCl_5$ gave a product containing more 1,2,4-TPB than $TaCl_5$ did. With regard to solvent, benzene gave a product having the highest 1,2,4-TPB content with both catalyst. On the other hand, 1,2,4-TPB was the least in carbon tetrachloride and in chloroform as solvents. This solvent effect on the product composition is not simply explained, for example in terms of solvent polarity. As seen in Table 1, the 1,2,4-TPB content varied in a range of 40—90% depending on the types of catalyst and solvent.

The dependence of the product composition on reaction temperature was investigated. Toluene and carbon tetrachloride were employed as two different types of solvents. As seen in Fig. 1, good linear relationships were observed in the Arrhenius plots. When $NbCl_5$ was used as a catalyst, the 1,2,4-TPB content of product increased with decreasing reaction temperature. For instance, it was 94% at 0 °C in toluene. $NbCl_5$ is thus an excellent catalyst for the synthesis of 1,2,4-TPB, especially when used at low temperature. On the other hand, the lower the temperature, the less the 1,2,4-TPB content when the $TaCl_5$ catalyst was used. For example, 1,2,4-TPB was 17% at 30 °C in carbon tetrachloride. Thus, the present cyclotrimerizations at low temperature are much more selective than those so far reported. Especially, the cyclotrimerization by $NbCl_5$ at low temperature seems to be a useful method of synthesizing 1,2,4-TPB, though 1,3,5-TPB can be easily prepared by the acid-catalyzed condensation of acetophenone.[5)]

It was confirmed by the following two ways that the product composition in the present cyclotrimerization is kinetically controlled: i) The product composition did not depend on the conversion with both $NbCl_5$ and $TaCl_5$ as catalysts, and ii) 1,2,4-TPB did not isomerize to 1,3,5-TPB in the presence of $TaCl_5$ under the same conditions as those of cyclotrimerization, and *vice versa* with $NbCl_5$.

Cyclotrimerization of Phenylacetylene Catalyzed by $NbBr_5$ and $TaBr_5$. Cyclotrimerization of phenylacetylene was performed with $NbBr_5$ and $TaBr_5$ as catalysts in hydrocarbons and halogenated hydrocarbons. The reaction was usually quantitative within 1 h; the reac-

tion rate was similar to or a little slower than that catalyzed by $NbCl_5$ and $TaCl_5$. It was confirmed in the same way as in the case of the chloride catalysts that the product comprised only the two cyclic trimers.

The 1,2,4-TPB content of product is listed in Table 2. Usually $NbBr_5$ produced more 1,2,4-TPB than $TaBr_5$ did. This is the same tendency as observed in the reaction by the chloride catalysts, but the difference in the compositions with $NbBr_5$ and $TaBr_5$ was smaller. The 1,2,4-TPB content only varied in a range of 49—71% in various solvents examined, when $NbBr_5$ and $TaBr_5$ were used.

Figure 2 shows the dependence of the product composition on temperature. As in the chloride-catalyzed reaction, good linear relationships held in the Arrhenius plots. The 1,2,4-TPB content of product obtained with $NbBr_5$ increased with decreasing temperature, whereas the opposite trend was observed with $TaBr_5$. This tendency is also the same as that found in the chloride catalyst systems.

Thus the bromide catalysts behave in a similar manner to the chloride catalysts. The effects of catalyst metal and solvent on the product composition, however, are smaller in the bromide-catalyzed reaction.

Cyclotrimerization and Linear Oligomerization of Phenylacetylene Catalyzed by NbF_5 and TaF_5. The gel permeation chromatogram of the product obtained with NbF_5 and TaF_5 showed many peaks due to oligomers as well as a peak due to the cyclic trimers. Since the molecular weights of these oligomers ranged from 204 (dimer) to several thousands and they are colored dark red, their structure seems to be linear. The ^1H NMR and IR spectra also indicated the formation of not only the cyclic trimers but also of compounds whose structure was similar to that of the linear polymer produced with WCl_6. Consequently, it is concluded that NbF_5 and TaF_5 catalyze not only cyclotrimerization but also linear oligomerization.

The ratio of the linear oligomers to the cyclic trimers in the product was tentatively determined from peak areas in the gel permeation chromatogram measured with a refractive index detector. As shown in Table 3, the linear oligomer content of product was higher in halogenated hydrocarbons than in paraffinic hydrocarbons. TaF_5 gave a product containing more linear oligomers than NbF_5 did. The conversion ranged from 45 to 100% under the reaction conditions shown in Table 3.

The product obtained with TaF_5 in ethylene dichloride virtually consisted of the linear oligomers. The ^1H NMR and IR spectra of the linear oligomers resembled those of a linear high polymer obtained with

TABLE 3. LINEAR OLIGOMER CONTENT (%) OF PRODUCT IN THE REACTION OF PHENYLACETYLENE CATALYZED BY NbF_5 AND TaF_5[a)]

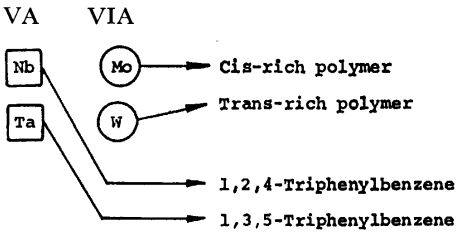

Scheme 1.

WCl_6. The number-average molecular weight was 1400.

When benzene and toluene were used as solvents, the yield of product did not agree with the consumption of reactant, but the former exceeded the latter. The product from a toluene solution proved to have tolyl group according to its ^1H NMR spectrum. These findings indicate that solvent-incorporated linear oligomers were formed. These oligomers seem to have been produced by the Friedel-Crafts alkylation, which suggests that the linear oligomerization proceeds *via* a cationic species. This is expected because the fluorides of niobium and tantalum are stronger Lewis acids than their chlorides and bromides are.

Characteristics of the Present Cyclotrimerization. Two characteristics are pointed out for the present cyclotrimerization.

One is that no reducing agent has to be added though the metals of NbX_5 and TaX_5 are in their highest oxidation state. This contrasts with the case of Ziegler-type catalysts, in which a reducing agent such as triethylaluminum is required for an active species to be formed. The metals of some metal halides such as $NbCl_5$, $MoCl_5$, and WCl_6 can be reduced by olefins and acetylenes.[10)] This reduction occurs through the halogenation of olefins and acetylenes. Thus, it is assumed that NbX_5 and TaX_5 are at first reduced by phenylacetylene in the present reaction.

The second characteristic is the striking contrast to the linear polymerization of phenylacetylene catalyzed by $MoCl_5$ and WCl_6. The relationships between catalyst metals and products (exclusive or principal) are shown in Scheme 1: The chlorides of niobium and tantalum brought about only cyclotrimerization. Further, there was a tendency for $NbCl_5$ to give 1,2,4-TPB as the major product and for $TaCl_5$ to give 1,3,5-TPB. On the other hand, $MoCl_5$ and WCl_6 polymerize phenylacetylene very effectively to give linear high polymers.[8)] The $MoCl_5$ catalyst provides a *cis*-rich polymer, while WCl_6 gives a *trans*-rich polymer. No cyclic trimer is formed in this polymerization at all. It is of great interest that the kind and structure of the product critically depend on the group and period of the metal in these reactions. On the other hand, Ziegler-type catalysts and Ni(0) complexes can catalyze both cyclotrimerization and linear polymerization, and it is often difficult to selectively bring about either of the two reactions with these catalysts.

It has been clarified that the cobalt-catalyzed cyclotrimerization of acetylenes proceeds *via* a metallo-

cyclopentadiene (metallole).[11,12] Since the present cyclotrimerization is also a coordination reaction and behaves in some respects similarly to the cobalt-catalyzed reaction, the present reaction might proceed by a similar mechanism. A further study on reaction behavior, mechanism, and intermediates is in progress.

Potentiometric Determination of the Concentration of Aggressive Anions That Can Be Tolerated by a Certain Passivator

Salah Mohamed Abd El Haleem and Ali Abd El Aal
Faculty of Science, Zagazig University, Zagazig, Egypt
(Received January 18, 1979)

The effect of various additives of Cl^-, Br^-, and I^- on the potential of a passivated steel electrode was established. In solutions of Na_2CrO_4, Na_2HPO_4, and Na_2WO_4, S-shaped relations were obtained between the steady-state potential and the quantity of the aggressive salt added. The resulting active potentials were established after an induction period which decreases with increase in the concentration of the attacking ions and/or decrease in that of the inhibiting anions. The concentration, C_{agg}, that can be tolerated by a certain concentration of the inhibiting anion, C_{inh}, is given by $\log C_{inh}=K+n \log C_{agg}$, where K and n are constants. The equation was derived theoretically on the basis of the changes produced in the structure of the double layer caused by specific adsorption of both aggressive and passivating ions. In solutions of $KMnO_4$, $NaNO_2$, and $K_3[(Fe(CN)_6)]$, the passivating film could not withstand the corroding action of the halide ions.

The minimum concentration of a certain passivator that can withstand the corroding action of a particular aggressive ion is of importance from theoretical as well as practical points of view.[1-9] The concentration was determined under certain conditions.[2-5,10-14] Only a few fundamental studies being carried out.[6-9,15] Some of the studies are based on time consuming measurements, such as weight loss or visual methods,[6-9,15-17] or on accelerated polarization techniques not in line with natural corrosion conditions.[18-20] It is desirable to establish a simple method to determine such a concentration, in a relatively short time and under natural corrosion conditions.

We have studied the variation of potential of a steel electrode under open circuit conditions, in order to establish the mode which the potential of an electrode, previously equilibrated in a certain passivator, would follow when increasing amounts of a corroding anion such as Cl^-, Br^-, and I^- were added to the solution, and to find a relation between the concentrations of the two counteracting anions. The type of corrosion that occurs always under these conditions is the localized type of attack, the extreme of which is pitting corrosion.[1,9]

Experimental Method and Materials

The steel electrodes (Delta steel Mill company, Cairo) have the same chemical composition as those used:[21,22]

C	Mn	S	P	Si
0.40	0.78	0.045	0.06	0.23%

The metal was machined in the form of short rods; length 2,4 cm, dia. 1 cm. This was fixed to Pyrex glass tubings with neutral wax. Electrical contact was achieved through thick copper wires soldered to the ends of the rods, not exposed to the solution. The electrodes were polished and abraded with the finest grade emery paper. They were then degreased with acetone and washed with triple-distilled water.

Two procedures were followed to achieve the variation of potential of the steel electrode.

Procedure A. The electrode was first equilibrated in a definite volume of the passivating (inhibiting) agent until a constant potential was established. Enough corrosive agent was then introduced into the solution to attain a definite concentration, and the change in potential was again followed with time. The effect of other quantities of the aggressive anions was examined in the same manner, starting always with a fresh solution of the inhibitor and with a newly polished electrode.

Procedure B. Increasing amounts of the aggressive salts were added to the same solution, allowing sufficient time for the establishment of constant potential.

Passivation (inhibition) of the steel electrode was carried out in solutions of different concentrations of Na_2CrO_4, Na_2HPO_4, Na_2WO_4, $KMnO_4$, $NaNO_2$, and $K_3[(Fe(CN)_6)]$. The concentration of the test solution was chosen to induce passivity rather than cause corrosion.[7,8,23,24] NaCl, NaBr and NaI (analytical grade) were used to introduce aggressive anion.

The potential of the steel electrode was measured, to the nearest mV, on Electronic Potentiometer (Metrohm pH meter type 512) relative to a saturated calomel electrode (SCE). This was separated from the main electrolyte by two salt bridges filled with the same passivating solution in order to prevent contamination with Cl^- ion. The steady-state potentials were considered valid when values were obtained, not changing more than 1 mV in 5 min. The electrolyte was stirred, a stream of oxygen, (2—3) bubbles/s) being passed during the course of experiment. Measurements were carried out at 25 ± 1 °C.

Results and Discussion

The curves with black circles in Fig. 1 represent the variation of the potential of the steel electrode with time in solutions of 0.1 M and 0.2 M Na_2CrO_4. The potential shifted towards positive values showing the occurrance of passivity,[23,24] and attained constancy after 160—180 min, following the immersion of the electrode in solution.

When a very small amount of Cl^- ion is introduced into the solution following passivation, the steady state potential remains more or less constant. Low Cl^- ion concentrations have no effect on the dissolution kinetics of the passive film already formed on the electrode surface.[22,25,26]

When the concentration of the Cl^- ion in solution is further increased, a state is soon reached where the Cl^- ion concentration is sufficent to undermine the protective film on the metal surface, causing the potentials of the electrode to change in the negative direction.

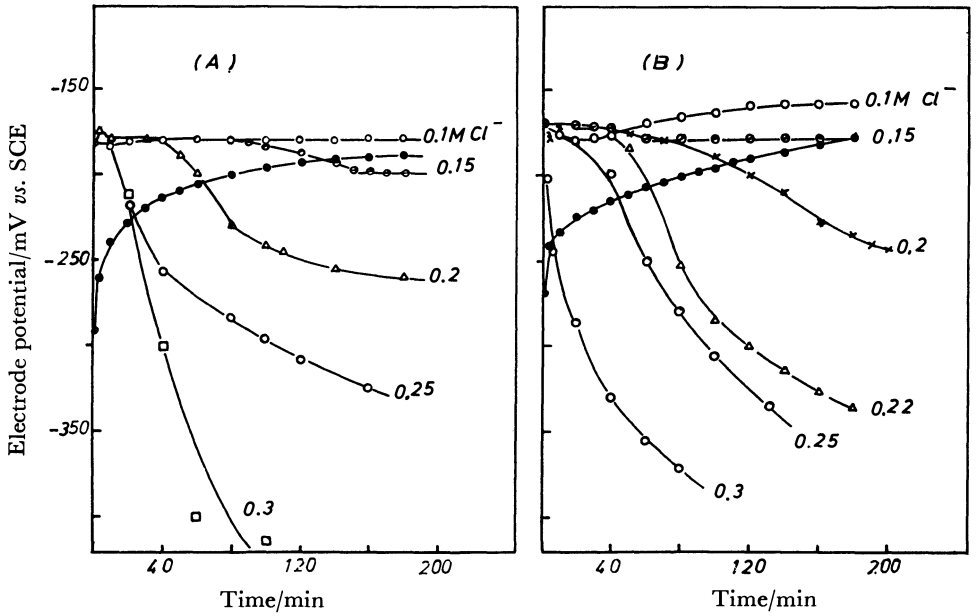

Fig. 1. Variation of the steel electrode potential with time in (A) 0.1 M and (B) 0.2 M Na_2CrO_4 in the presence of different NaCl additions.

Cl^- ions do not attack the passive electrode directly (cuves A and B, Fig. 1). A certain length of time elapses before the potential of the steel electrode changes from that measured in the Cl^--free solution. This is identified as the induction period[18,27] for pitting corrosion to occur. It decreases with the increase of the concentration of the aggressive anion.[18,27] In relatively concentrated Cl^- media, the induction period is too short to be recorded.

In the presence of Cl^- ions, the steel electrode acquires new steady state potentials. For a certain chromate concentration, these potentials become more negative the higher the Cl^- ion content. On the other hand, the potentials developed in equimolar solutions of Cl^- ion depend on the concentration of the passivating ion, being more positive the higher the chromate content.

The curves in Fig. 2 show the variation of the steady state potential of the passive steel electrode with the amount of NaCl, NaBr, and NaI in solutions of Na_2CrO_4 in the range 0.05—0.5 M using procedure (B) for measurements. Figures 3 and 4 represent the same behavior in Na_2HPO_4 and Na_2WO_4 solutions of different concentrations. They are sigmoid, showing normal mode of potentiometric titration, which may be used

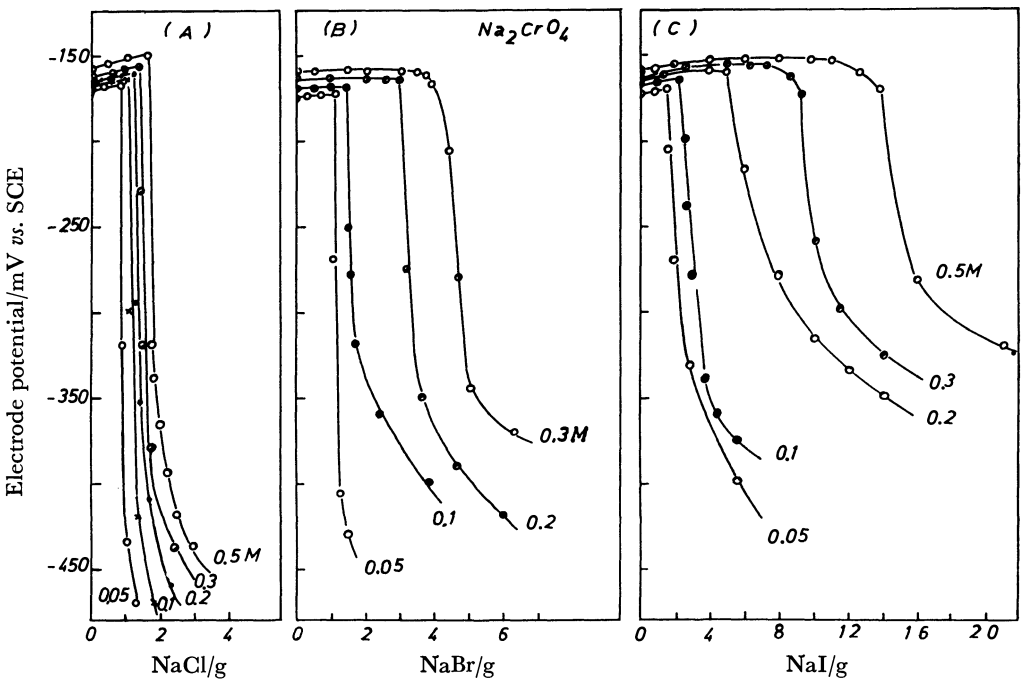

Fig. 2. Variation of the potential of the steel electrode previously passivated in different concentrations of Na_2CrO_4, with additions of NaCl, NaBr, and NaI.

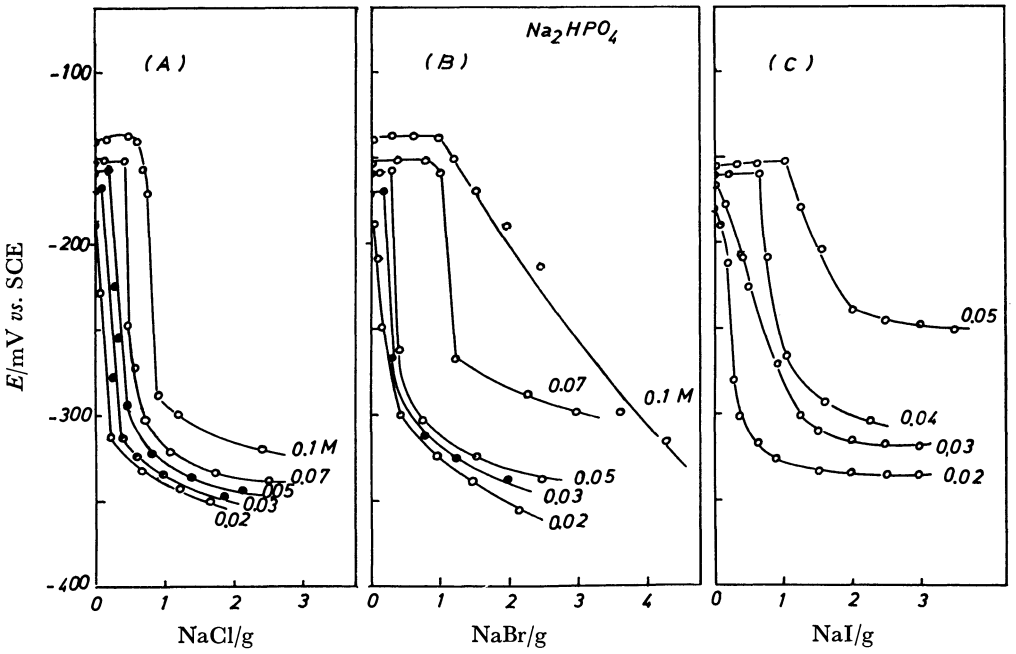

Fig. 3. Variation of the potential of the steel electrode previously passivated in different concentrations of Na_2HPO_4 with additions of NaCl, NaBr, and NaI.

to determine the concentration of an inhibitor that can withstand a certain concentration of the aggressive ions. The starting potentials, measured in aggressive-free media, become more positive the higher the concentration of the inhibitor in solution. The rate of potential change at the inflexion point of the curves is inversely proportional to the same parameter. This is to be expected since it is easier to initiate pitting corrosion, which is the type of attack occurring under these conditions, in dilute passivating solutions than in concentrated ones. It appears that as the concentration of the inhibiting agent in solution is raised, more aggressive anion is needed to destroy the protective film on the metal surface and induce pitting corrosion.

The curves in Fig. 5 (A, B, and C) represent the effect of adding Cl^- ions of increasing concentrations

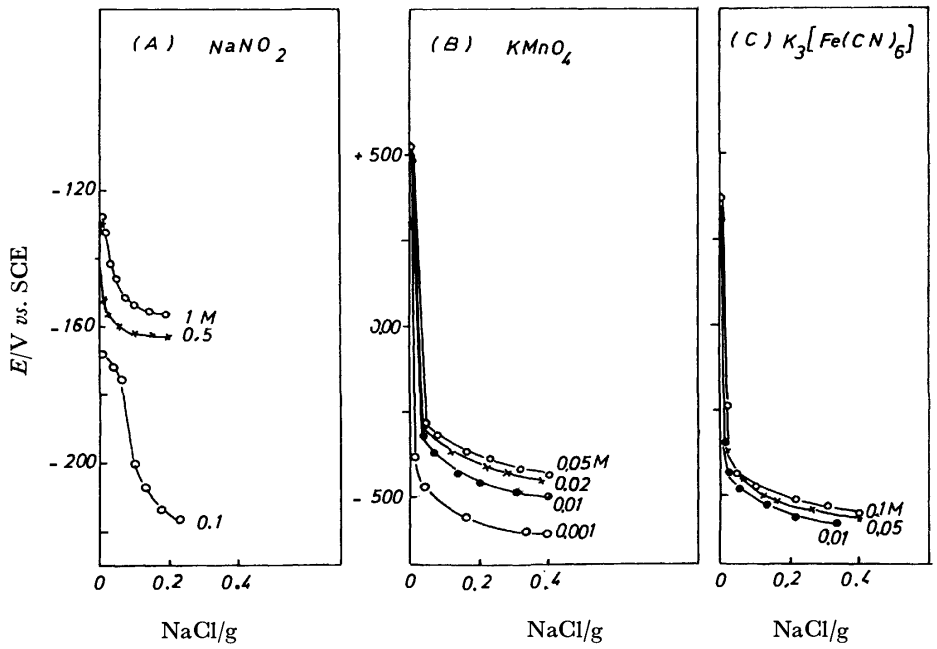

Fig. 5. Variation of the potential of the steel electrode previously passivated in different concentrations of (A) $NaNO_2$, (B) $KMnO_4$, and (C) $K_3Fe(CN)_6$, with the additions of NaCl.

to solutions of $NaNO_2$, $KMnO_4$, and $K_3[(Fe(CN)_6)]$, respectively. Despite the fact that the initial steady state potentials of the steel electrode in these media are equal to or higher than those measured in chromate, phosphate or tungestate solutions of the same concentration, the addition of Cl^- ions to the former solutions causes the potential to shift directly towards more negative values. Apparently treatment of the steel electrode in solutions of these oxidizing agents produces no permenant state of passivity.[1] This shows that the function of a certain passivator does not depend primarily on its redox-potential as much as on its ability to form an adhering and stable film on the metal surface. This is not the case with NO_2^-, MnO_4^-, and $[Fe(CN)_6]^{3-}$ anions, the reduction of which at the cathodic sites produces soluble corrosion products. Similar results were obtained in the case of zinc.[1]

Inflexion occurs in the potential of the steel electrode when enough aggressive salt is added to the inhibitive solution (Figs. 2—4). The inflexion indicates that the inhibiting film is being destroyed by the aggressive anions. Concentrated solutions of the passivator consume more attacking agent before the potential tends towards more negative values. The relation between the two variables is not linear.[1] There is no definite potential,[19,27] above which the metal withstands attack, and below which it undergoes corrosion. The choice of such a potential, to be taken as a basis for comparison, is thus arbitrary. Since the initial potential of the steel electrode in aggressive-free media depends on the ambient concentration of the passivator, choice of one and the same potential for all the solutions will not be free from error. It is more plausible, however, to relate this potential to that of the initial value in such a manner that it is common to all curves. Shams El Din and Abd El Haleem[1] assumed that the localized type of attack (pitting) is operative to the same extent in all solutions when enough of the aggressive anion is present to displace the initial potential to the negative direction by a constant value. The relation between C_{agg} and C_{inh} is considered at the point of inflexion (0 mV displacement), as well as at some other potentials (more negative to the starting potentials). The plot of the two variables on a double logarithmic scale for chromate solutions is given in Fig. 6. Similar results were obtained with phosphate and tungestate solutions. Parallel straight lines are obtained satisfying the relationship:

$$\log C_{inh} = K + n \log C_{agg}, \qquad (1)$$

where K and n are constants.

The values of the exponent n for solutions of Na_2CrO_4, Na_2HPO_4, and Na_2WO_4 containing the aggressive anion Cl^-, Br^-, and I^- are given in Table 1.

Table 1. Values of the exponent n in Eq. 1 for different inhibiting-aggressive pairs

Inhibitor	Na_2CrO_4			Na_2HPO_4			Na_2WO_4		
Aggressive	Cl^-	Br^-	I^-	Cl^-	Br^-	I^-	Cl^-	Br^-	I^-
n	3.25	1.2	0.93	0.72	0.6	0.45	1.0	0.97	0.33

It appears that (Fig. 1 and Table 1)
(1) n is independent of the potential at which it is determined, (2) n depends primarily on the type of the inhibitor, decreasing in the order $Cl^- > Br^- > I^-$, (3) the values of n in Na_2CrO_4 solution is significantly greater than that of the other two inhibitors.

Equation 1 was also obtained by other workers,[6-9,15,20] Matsuda and Uhlig[15] derived it by assuming the occurrence of competitive adsorption between the aggressive and the inhibiting anions. Brasher *et al.*,[9] on the other hand derived it by conferring

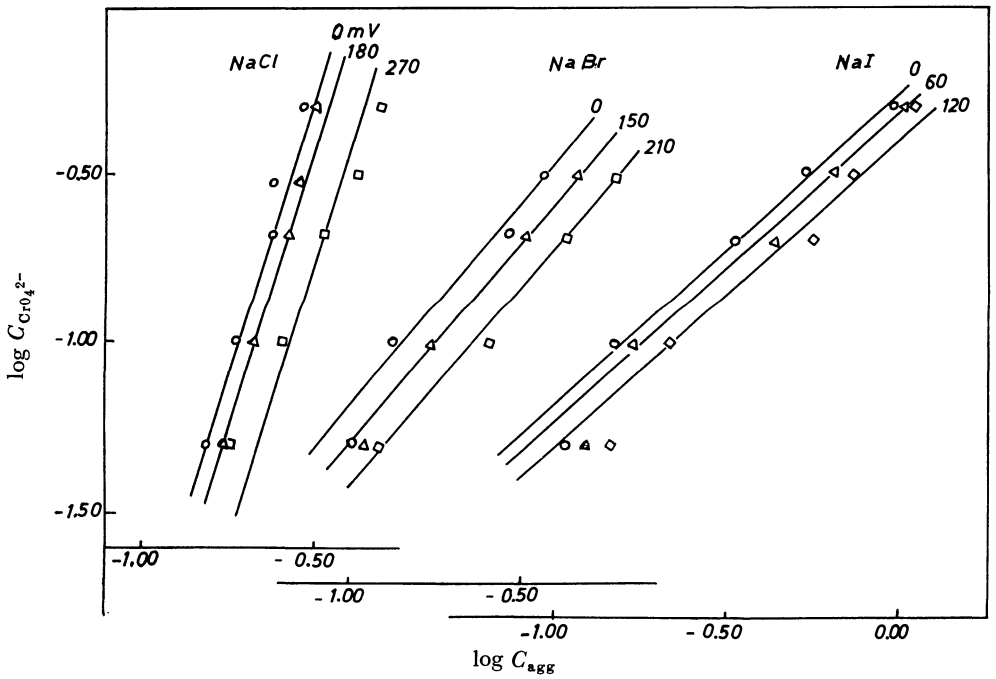

Fig. 6. log $C_{CrO_4^{2-}}$ – log C_{agg} plots at different potentials.

anion exchange properties to the oxide film formed on the metal surface. Selectivity for one or the other of two anions present in solutions was considered to depend on its nature as well as on its concentration. Anderson and Hocking[20] expressed a similar view.

In the present study, Eq. 1 is derived on the basis of the effect produced by both the inhibiting and corrosive anions, when specifically adsorbed on the metal surface, on the structure of the double layer at the metal/solution interface. The derivation is based on the following considerations: (a) In neutral solutions, the corrosive anions attack the passivating oxide film on the metal surface through specific adsorption of the anion,[28-30] their peptizing action on the metal oxide[31] and/or the creation of electrostatic fields through the oxide between opposite charges.[32] One or more of these processes is associated with decrease in the free energy of the system. (b) Inhibiting anions, on the other hand, play their role either by film repair as in the case of CrO_4^{2-} and NO_2^-,[6,7] or by blocking the active sites on the metal surface (benzoate).[8] Both effects involve a decrease in free energy at the metal/solution interface. (c) In solutions containing both the inhibiting and the corrosive anions, the process occurring depends primarily upon which of the two reactions is associated with a larger decrease in free energy. This, in turn, involves a number of associated features such as the concentration and charge of the ions, as well as their adsorbability on the oxide film. (d) The aggressive or the inhibiting anions should be adsorbed on the surface before reacting with the metal. Such adsorption affects both the structure of the double layer at the metal/solution interface, as well as the effective potential necessary for the electrochemical reaction. Figure 7 is a schematic presentation of the structure of the double layer, in which the specifically adsorbed anions occupy the inner Helmholtz plane (IHP), causing a potantial

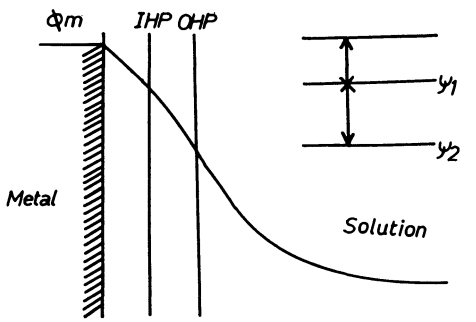

Fig. 7. Schematic presentation of the structure of the double layer at the metal/solution interface.

drop ϕ'. Anions bound only by electrostatic forces occupy the outer plane of the double layer (OHP) with a potential ϕ''. The diffuse double layer consisting of ions is dispersed in the direction of solution.

The relation between the surface concentration, C_s, and the bulk concentration, C_b, of a certain ionic species is given by[1]

$$C_s = C_b \exp(-\Delta G^\circ/RT), \quad (2)$$

where ΔG° is the standard electrochemical free energy change of adsorption, its value depending on the nature of interaction between the ions and the surface as well as their ionic charge, Z. In absence of specific adsorption, we have

$$\Delta \bar{G}^\circ = \pm ZF\phi''. \quad (3)$$

The positive and negative signs in Eq. 3 refer to whether adsorption of anions takes place on the negative or the positive side of the potential of the zero charge of the metal. On the other hand, for anions that are specifically adsorbed we have

$$\Delta \bar{G}^\circ = \Delta G^\circ \pm ZF\phi', \quad (4)$$

where ΔG° represents the standard chemical free energy of adsorption. The surface coverage, θ, with specifically adsorbed anions is given by

$$\theta = X \exp(-\Delta\bar{G}^\circ/RT), \quad (5)$$

where X is the mole fraction of the anion in the bulk of solution. However, in solutions of fixed concentration (x), θ is constant and ψ' is given by

$$\psi' = \pm\frac{RT}{ZF}\ln x + \text{constant}. \quad (6)$$

For a metal like iron immersed in a solution of an inhibiting anion (Z_1, X_1), until the establishment of the steady-state potential, a definite fraction of the metal surface is covered by specifically adsorbed anions, adsorbed either on the bare metal surface or on the oxide covering the metal. In this case, ψ_1' at the (IHP) is given by

$$\psi_1' = \pm\frac{RT}{Z_1F}\ln x_1 + \text{const}_1. \quad (7)$$

When an aggressive anion (Z_2) is added in a small amount after the establishment of the steady-state potential in an inhibiting solution, it will first be adsorbed on the free fraction of the surface. On gradual increase in the concentration of the aggressive ion, it will compete with the inhibiting anions for the sites occupied by the latter. Displacement of the inhibiting anions occurs by virtue of the smaller size of the aggressive ions (large charge density) and/or a large drop in the free energy of adsorption. When the concentration of the aggressive anions becomes equal to (X_2), *i.e.* at the end of the horizontal segments (curves, Figs. 2—4), it will represent the maximum amount of the aggressive anion that can be tolerated by the concentration X_1 of the inhibitor. The magnitude of ψ_2' corresponding to the aggressive anion at the (IHP) is given by

$$\psi_2' = \pm\frac{RT}{Z_2F}\ln x_2 + \text{const}_2. \quad (8)$$

Since $\psi_1'=\psi_2'$ apparently at the point of inflexion (Figs. 2—4), we have

$$\frac{RT}{Z_1F}\ln x_1 + \text{const}_1 = \frac{RT}{Z_2F}\ln x_2 + \text{const}_2 \quad (9)$$

or

$$\log X_1 = \frac{Z_1}{Z_2}\log X_2 + \text{constant}. \quad (10)$$

Equation 10 has the same form as that obtained experimentally or derived theoretically.[9,15] From the equation as well as the values of the exponent n (Table 1), we can draw the following conclusions:

1. Equation 10 is based on the idea of competitive adsorption, but unlike the treatment of Matsuda and Uhlig[15] and Brasher *et al.*,[9] it presumes no particular type of adsorption isotherms.

2. The potential of the working electrode remains practically constant until the ψ-potential for the electrode in the inhibiting medium starts to decrease as a result of excessive adsorption of the aggressive anion. The curves (Figs. 2—4) reveal that this is actually the case.

3. The exponent n of Eq. 1 is given here as the ratio of the electrical charges of the inhibiting/aggressive anions. Similar findings were suggested by Brasher *et al.*[9] The values (Table 1) show that this state of affairs is nearly fulfilled when HPO_4^{2-} and WO_4^{2-} are used as inhibitors. An exception is the WO_4^{2-}/I^- system, in which inhibition involves the reduction of the inhibitor with the probable formation of the iodocomplexes of the lower valent W. Concerning the CrO_4^{2-} ions, however, the value of n is almost twice that determined for the other two inhibitors. This is explained on the basis that CrO_4^{2-} reacts preferentially either in the $HCrO_4^-$ or the $Cr_2O_7^{2-}$ forms.[7]

4. Equation 1 holds not only at the inflexion points but also at other more active (negative) potentials, as long as they are referred to the starting potential measured in the aggressive-free media.

5. From the curves (Figs. 2—4) and Eq. 1, we can determine the concentration of the aggressive anion that can be tolerated by a certain concentration of the inhibiting anion, using a simple potentiometric method.

Exact Relationship between Resonance Energies and Ring Currents of Aromatic Annulenes

Jun-ichi AIHARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received June 4, 1979)

Synopsis. Haddon's analytical relationship between the resonance energies and the ring currents of $(4n+2)\pi$-electron annulenes was decidedly improved by means of the graph theory of aromaticity.

An NMR criterion of aromaticity has widely been accepted according to which diamagnetic ring currents indicate aromaticity while paramagnetic ring currents indicate antiaromaticity.[1-2] However, it had not been clear that this magnetic criterion is equivalent to the energetic definition of aromaticity[3] until we previously proved that the diamagnetic susceptibility of a cyclic conjugated system[4,5] strongly reflects its conjugative stabilization.[6] In the case of annulenes, the sign of the susceptibility exactly accords with that of the resonance energy due to aromaticity.[7-10]

Recently, Haddon reported an analytical relationship between the resonance energies (*RE*s) and the reduced ring currents (*RC*s) of $(4n+2)\pi$-electron annulenes.[11] He adopted my former method (denoted by A-I)[7,8] to estimate the resonance energies, and found that the relationship takes the form

$$RE = \frac{\pi^2}{3S}RC, \tag{1}$$

where S is the area of the annulene ring, and RC the reduced ring current related linearly to the ring current intensity, I, in this manner:

$$I = \left[8\pi^2 c\left(\frac{e}{hc}\right)^2 H\right]RC. \tag{2}$$

Here, H is the applied magnetic field (taken perpendicular to the molecular plane), and the other symbols have their usual meaning.

The A-I method is one of the analytical methods for estimating the resonance energy of a cyclic conjugated system.[7,8] The π-bond energy of an infinitely large cyclic polyene is therein utilized in the definition of an olefinic reference structure. However, I have not been using this method since another method (denoted by A-II) was devised by means of graph theory.[8] At present, the A-II method appears to be physically much more sound and meaningful.[6,8-10] Accordingly, Haddon's treatment of ring currents[11] can naturally be improved on the basis of the A-II method. This is shown below.

Theory and Discussion

According to the A-II method,[8-10] a characteristic polynomial for an olefinic reference structure of a conjugated hydrocarbon can be written as

$$R(X) = X^N + \sum_{k=1}^{[N/2]} (-1)^k p(k) X^{N-2k}, \tag{3}$$

where N is the number of sp^2-carbon atoms in a conjugated system, $p(k)$ the number of ways of choosing k disjoint π bonds from the conjugated system,[12] and $[N/2]$ the maximum integer not larger than $N/2$. The resonance energy can be defined as the difference between the total π-electron energy of a conjugated system and that of its reference structure given by Eq. 3, and this is termed the A-II resonance energy.[8]

There are five kinds of $(4n+2)\pi$-electron annulenes; [4n+2]annulenes, $[4n]^{2+,2-}$annulenes, $[4n+1]^-$annulenes, and $[4n+3]^+$annulenes. These are all aromatic.[8-10] Fortunately, A-II resonance energies (*RE**) of these annulenes can be expressed analytically in the form[10]

$$RE^* = \frac{4(1-\cos\theta)\beta}{\sin 2\theta} \quad ([4n+2]\text{annulenes}) \tag{4a}$$

$$= \frac{4(1-\cos\theta)\beta}{\tan 2\theta} \quad ([4n]^{2+,2-}\text{annulenes}) \tag{4b}$$

$$= \frac{2(1-\cos\theta)\beta}{\sin\theta} \quad \begin{matrix}([4n+1]^-\text{annulenes and}\\ [4n+3]^+\text{annulenes}).\end{matrix} \tag{4c}$$

Here, $\theta=\pi/2N$. On the other hand, the reduced ring currents are given by[11,13]

$$RC = \frac{2S\beta}{N^2 \sin 2\theta} \quad ([4n+2]\text{annulenes}) \tag{5a}$$

$$= \frac{2S\beta}{N^2 \tan 2\theta} \quad ([4n]^{2+,2-}\text{annulenes}) \tag{5b}$$

$$= \frac{S\beta}{N^2 \sin\theta} \quad \begin{matrix}([4n+1]^-\text{annulenes and}\\ [4n+3]^+\text{annulenes}).\end{matrix} \tag{5c}$$

Combining Eq. 4 with Eq. 5, we obtain

$$RE^* = \frac{2N^2 RC}{S}(1-\cos\theta), \tag{6}$$

for all kinds of $(4n+2)\pi$-electron annulenes. It should be stressed that this is a single exact relationship found between the A-II resonance energies and the ring currents of aromatic annulenes.

In order to visualize the physical image of this relationship, let us expand the cosine in it into a corresponding power series as follows:

$$RE^* = \frac{\pi^2}{4S}RC\left(1-\frac{\pi^2}{48N^2}+\frac{\pi^4}{5760N^4}-\cdots\right). \tag{7}$$

Cleraly for large N it is possible to truncate Eq. 7 at the first term. Even for benzene ($N=6$), the error due to such truncation is less than one percent. Adopting this simplification, we obtain for the A-II resonance energy

$$RE^* = \frac{\pi^2}{4S}RC. \tag{8}$$

This expression is quite similar to Haddon's one (Eq. 1), but the proportionality constant is reduced to three-fourths. This is due to the fact that the A-I resonance energy is about 33 percent larger than the

A-II resonance energy for all aromatic annulenes, both neutral and ionic.[8] However, this difference is never a triviality. Considering that the A-II resonance energy only is closely related to the magnetic property of a cyclic conjugated system,[6] it will be evident that Eq. 8 is much more preferable to Eq. 1. In other words, Eq. 8 represents a more realistic relationship between the resonance energies and the ring currents of $(4n+2)\pi$-electron annulenes.

By the way, the diamagnetic susceptibility(χ_π) of an annulene conjugated system[5] is given by

$$\chi_\pi = \frac{SI}{cH}. \tag{9}$$

The following relationship then holds for aromatic annulenes:

$$\chi_\pi = 32\left(\frac{e}{hc}\right)^2 S^2 RE^*. \tag{10}$$

This expression indicates that the susceptibility is proportional both to the resonance energy and to the area of the annulene ring squared.

Concluding Remarks

The behavior of the ring current in relation to the A-II resonance energy has been considered above in the hypothetically bond-equalized case. The entire analysis has been simple and exact. As pointed out by Haddon,[11] encouraging evidence for Eqs. 1 and 8 has already been published in the case of aromatic bisdehydroannulenes,[14] for which proton chemical shifts nicely correlate with Hess-Schaad resonance energies.[15] However, any analytical relationship between resonance energies and ring currents cannot be obtained for antiaromatic annulenes, because bond alternation plays a crucial role in these compounds.[16]

Finally, it must be noted that Eq. 8 does not imply that a theoretical relationship must exist between the resonance energies and the ring currents of $(4n+2)\pi$-electron annulenes. It simply indicates the A-II resonance energy evaluated relative to the magnitude of the ring current. The close relationship found between these two quantities might have been regarded as superficial if a theoretical relationship between aromaticity and diamagnetism has not been established.[6]

Addendum. The realness of the roots of the same polynomial as Eq. 3 has already been proved by Heilmann and Lieb.[17] This proof warrants the realness of the A-II resonance energy. Professor L. J. Schaad kindly brought my attention to the Heilmann-Lieb paper.

Thermodynamic Relation of Interfacial Tensions in Three Fluid Phases

Kazuo TAJIMA,* Takao TSUTSUI, and Hiroshi MURATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo 158

(Received June 4, 1979)

Synopsis. The thermodynamic relation was derived for the interfacial tensions at the three interfaces of two immiscible solutions and their vapor phase at a constant temperature. The relation obtained was experimentally tested by measuring each interfacial tension of systems which consisted of organic (alcohols(C_4—C_{10}), triolein, and hexadecane) and aqueous phases. The relation of the interfacial tensions was valid for the polar oil–water systems. but not for the hexadecane–water system unless a surfactant was added.

It is well known as the so-called Antonoff rule that the interfacial tension at two liquid phases can be expressed by the difference in each surface tension at the vapor–solution interfaces. The validity of Antonoff rule, introduced without any theoretical proof,[1] has been tested by many investigators. The crucial conclusion, however, has not yet been drawn.[2–6]

The present work attempts to establish the thermodynamic relation between each surface tension at the three interfaces (*e.g.*, vapor–water, vapor–oil, and oil–water) of the vapor and the two liquid phases, which are mutually saturated. The relation derived will be verified by experiments.

Theoretical

The system taken is that in which the two liquid phases, which are mutually saturated, are equilibrated with the vapor phase at a constant temperature and pressure. Let us consider what relation is established in these interfacial tensions when the system is altered in an isothermal and reversible change, as is shown in Fig. 1, at a constant total volume and mass. We assume that the internal energy for the whole system, U, is completely defined by the variables of the following function:

$$U = U(T,\ V,\ \sum_{\theta} A^{\theta},\ N) \tag{1}$$

where T is the absolute temperature; V, the total volume of the system; A^{θ}, the interfacial area at the interface, θ, and N, the total number of moles of the species in the system. The interfacial total excess volume, V^e, is defined and assumed by the Gibbs convention as follows:

$$V^e = V - \sum_{j} V^j = 0 \tag{2}$$

Therefore, N is related to:

$$N = \sum_{ij} n_i^j + \sum_{i\theta} \Gamma_i^{\theta} A^{\theta} \tag{3}$$

where n_i^j is the mole numbers of the component i in the homogeneous bulk phase, j; Γ_i^{θ}, the mole numbers of the component i per unit area at the interface, θ; the summations of j and θ are taken over the three bulk (k, l, and m) and interfacial (α, β, and γ) phases, and i is taken for the binary components (1 and 2). The total excess internal energy of the interface, U^e,

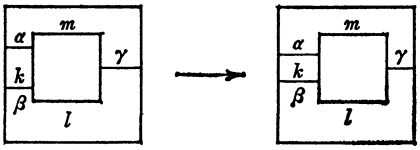

Fig. 1. Isothermal changes in interfacial area at constant total volume and mass. The phases, k, l, m show two immiscible solutions and their vapor, and α, β, γ three interfaces.

is defined as:

$$U^e = U - \sum_{j} U^j = \sum_{\theta} U^{\theta} \tag{4}$$

where U^j and U^{θ} denote the internal energies of the bulk phases, j, and the interfacial phase, θ, defined as follows:

$$\left.\begin{aligned} U^j &= U^j(T,\ V^j,\ \sum_i n_i^j) \\ \text{and:}\quad U^{\theta} &= U^{\theta}(T,\ A^{\theta},\ \sum_i \Gamma_i^{\theta}) \end{aligned}\right\} \tag{5}$$

Since, from the definition of Eq. 2, Γ_1^{θ} is equal to zero, for the infinitesimal changes of U^e we obtain:[7]

$$dU^e = \sum_{\theta}\left[\left(\frac{\partial U^{\theta}}{\partial T}\right)_{A,\Gamma} dT + \left(\frac{\partial U^{\theta}}{\partial A^{\theta}}\right)_{T,\Gamma} dA^{\theta} + \left(\frac{\partial U^{\theta}}{\partial \Gamma_2^{\theta}}\right)_{T,A} d\Gamma_2^{\theta}\right] \tag{6}$$

and:

$$\left(\frac{\partial U^{\theta}}{\partial A^{\theta}}\right)_{T,\Gamma} = \sigma^{\theta} + b^{\theta}$$

where σ^{θ} is the interfacial tension at the interface, θ, and b^{θ} is the heat of expansion of the interface, θ. Usually this term can not be neglected in the adiabatic expansion for the thin film surfaces, but it is customarily considered to be approximately zero for the adsorbed films. If the variation in the surface area does not affect any thermodynamic stabilities of the system under the conditions considered, we obtain:

$$dU^e = \sum_{\theta} (\sigma^{\theta} + b^{\theta}) dA \tag{7}$$

Furthermore, the changes in the surface area at each interface, according to the process shown in Fig. 1, are related to:

$$dA^{\alpha} = dA^{\beta} = -dA^{\gamma} = dA \neq 0 \tag{8}$$

This equiarea change at a constant total area establishes the trivial nature of the contribution of the b^{θ} term to the internal energy change of the system as a whole, because the dissipation of the surface at the γ interface and the creation of new surfaces at the α and β interfaces occur simultaneously. Thus, if the total b^{θ} terms are compensated for, the interfacial systems can be changed isothermally. Therefore, substituting Eq. 8 into 7, we obtain finally:

$$\sigma^{\alpha} + \sigma^{\beta} = \sigma^{\gamma} \tag{9}$$

Consequently, Eq. 9, the so-called Antonoff relation,

Table 1. Interfacial tensions in the vapor-oil-water interfaces

Substance	Temp °C	$\sigma^{v/w}$ mN m^{-1}	$\sigma^{v/o}$ mN m^{-1}	$\sigma^{o/w}$ mN m^{-1}	$\sigma^{o/w}_{cal}$ mN m^{-1} from Eq. 9[a]

a) α=v/o, β=o/w, γ=v/w. b) *N*-Dodecyl-β-alanine was added as a surfactant.

is derived thermodynamically for a system which is composed of the vapor and two liquid phases, which are mutually saturated at a constant temperature and pressure. The validity of Eq. 9 can be tested experimentally.

Experimental

Normal alcohols with carbon atoms of 4, 6, 8, and 10, triolein and hexadecane were used as one liquid phase, while the other was water. The organic and aqueous phases were mutually saturated by letting stand them for 10 days with occasional shaking. The surface tensions of the three interfaces were measured by the Wilhelmy plate method. When the tension of the oil–water interface was measured, particular attention was paid to the wetting and the correction of buoyancy for the plate.[8] The interfacial tension was measured within an experimental error of $\pm$0.3 mN m^{-1}. The temperature of the system was controlled by circulating the thermostatic water.

Results and Discussion

The results are shown in Table 1. It may be seen that Eq. 9 was valid for the alcohol–water and triolein–water systems, but not for the hexadecane–water system. The inconsistency of Eq. 9 with the experimental results for the hexadecane–water system was mainly considered to be the result of the incompleteness of the mutual solubilities.[9] The hexadecane–water system, however, to which a surfactant soluble in both liquid phases was added, obeyed the relation of Eq. 9. The use of such a surfactant is considered to promote the increasing mutual solubilities of the system and to favor the formation of stable films at each interface, as in the polar oil–water system.

In conclusion, if the system is allowed to reach the thermodynamic equilibrium, and if the equilibrium interfacial tensions are measured, Eq. 9 can be used to explain the correlation between the interfacial tensions of the three fluid phases, especially for the systems composed of the two polar liquid phases with high mutual solubilities.

The Solvent Extraction Study of a Dibenzo-18-crown-6 Complex with Silver Picrate

Yasuyuki TAKEDA* and Fujio TAKAHASHI

Department of Chemistry, Faculty of Science, Chiba University, Yayoi-chō, Chiba 260

(Received September 5, 1979)

Synopsis. The extraction constant of the silver ion–dibenzo-18-crown-6 (DB18C6) complex between benzene and water and the complex-formation constant of DB18C6 with silver picrate in benzene were determined at 25 °C. The Ag^+–DB18C6 complex is much more extractable than the Ag^+–18-crown-6 one. The Ag^+–DB18C6 complex is much more stable for benzene than for aqueous solutions.

The solvent extractions of uni- and bivalent metal ions with crown ethers to date have been investigated; these data show that the crown ethers form stoichiometrically stable complexes with the metal ions.[1] In some of these studies, the overall extraction equilibria have been analyzed by means of the constituent equilibria, and the extractability of the metal cation–crown ether complex as well as that of the metal cation have been discussed in detail.[1a–1d]

In the present study, the extraction constant values of the silver picrate and the silver picrate–dibenzo-18-crown-6 (DB18C6) systems have been determined between benzene and water, the overall extraction equilibrium of the latter system has been analyzed by means of the constituent equilibria, and the complex-formation constant values of DB18C6, 15-crown-5 (15C5), 18-crown-6 (18C6), and dibenzo-24-crown-8 (DB24C8) with the silver picrates in a benzene solution have been calculated using the extraction constant value of the silver picrate.

Experimental

The DB18C6 was obtained from the Aldrich Chemical Co., Inc. The $AgNO_3$ and picric acid were of an analytical grade and were from the Koso Chemical Co., Ltd. The method of the purification of DB18C6[2] and the determinations of the concentrations of $AgNO_3$ and the picric acid solutions[1d] have been described in the literature. Analytical-grade benzene (Wako-Pure Chemicals, Ltd.) was washed twice with distilled water. The benzene or the benzene solution of DB18C6 (4.0×10^{-4}—4.1×10^{-3} M; 1M=1 mol dm^{-3}) and the aqueous solution of $AgNO_3$ (3.0×10^{-3}—6.0×10^{-3} M) and the picric acid (1.9×10^{-3}—8.0×10^{-3} M) in stoppered 30-ml glass tubes were shaken in a thermostated water bath for approx. 30 min at 25±0.2 °C and then centrifuged. The initial volume of each phase was 10 ml in all cases. All the extractions were conducted in the pH range of 2.2—2.5. The Ag in the organic phase was back-extracted into a 1M nitric acid aqueous solution (8 ml), and the Ag concentration in the aqueous phase was determined by the use of a Seiko SAS-725 atomic absorption spectrophotometer.

Results

In an equilibrium between an aqueous solution of a univalent metal ion, M^+, a picrate ion, A^-, and benzene, and its solution of a crown ether, L, the equilibrium constants may be defined by the following equations:

$$K_{ex}(1) = [MA]_o[H^+]/[M^+][HA]_o \quad (1)$$

$$K_{ex}(2) = [MLA]_o[H^+]/[M^+][L]_o[HA]_o \quad (2)$$

$$K_{D,L} = [L]_o/[L] (K_{D,L} = 800 \text{ for DB18C6}^{1a)}) \quad (3)$$

$$K_{ex}(HA) = [HA]_o/[H^+][A^-] \quad (4)$$

$$K_{ML} = [ML^+]/[M^+][L] \quad (5)$$

$$K_{ex}(3) = [MLA]_o/[ML^+][A^-] \quad (6)$$

where the subscript "o" and the lack of subscript designate the organic phase and the aqueous phase respectively; square brackets indicate the molar concentrations. Thus, $K_{ex}(2)$ can be written as follows:

$$K_{ex}(2) = K_{D,L}^{-1}K_{ex}(HA)^{-1}K_{ML}K_{ex}(3) \quad (7)$$

In the absence of crown ether, the distribution ratio of the metal may be represented by:

$$D_M = [MA]_o/[M^+] \quad (8)$$

The substitution of Eqs. 1 and 4 into Eq. 8 gives:

$$D_M = K_{ex}(1)K_{ex}(HA)[A^-] \quad (9)$$

The $\log D_M$ *vs.* $\log[A^-]$ plot for Ag^+ in Fig. 1 shows a linear relationship with a slope of 1, indicating that the $K_{ex}(1)$ in the present study can be described by Eq. 1. The value of $[A^-]$ in Eq. 9 was calculated from Eq. 10:

$$[A^-] = ([HA]_t - [MA]_o)/\{1+(K_{HA}+K_{ex}(HA))[H^+]\} \quad (10)$$

where the subscript "t" denotes the total concentration. The value of $K_{ex}(HA)$ was spectrophotometrically determined to be 247 by using the association constant of picric acid ($K_{HA}=1.9_5$[3]). When a crown ether exists in the extraction system, D_M may be represented by:

$$D_M = [MLA]_o/([M^+]+[ML^+]) \quad (11)$$

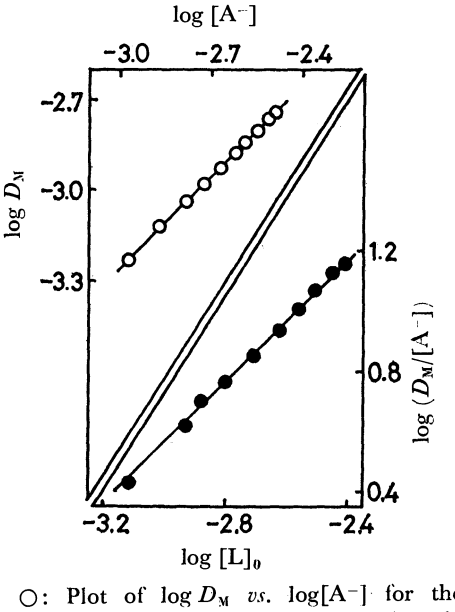

Fig. 1. ○: Plot of $\log D_M$ *vs.* $\log[A^-]$ for the Ag^+ system at 25 °C. ●: Plot of $\log(D_M/[A^-])$ *vs.* $\log[L]_o$ for the Ag^+–DB18C6 system at 25 °C.

Table 1. $\log K_{ML}$ and $\log\{K_{ex}(2)/K_{ex}(1)\}$ values for Ag^+-crown ether systems at 25 °C

Crown ether	$\log K_{ML}$	$\log\{K_{ex}(2)/K_{ex}(1)\}$
15C5	0.94[4]	4.71[a]
18C6	1.50[4]	4.70[a]
DB18C6	1.41[5]	3.82
DB24C8	—	3.35[b]

a) The $\log K_{ex}(2)$ values for 15C5 and 18C6 are 2.06 and 2.05 respectively.[1d] b) $\log K_{ex}(2) = 0.70$.[1e]

In the case of $[M^+] \gg [ML^+]$, Eq. 11 becomes:

$$D_M = K_{ex}(2)K_{ex}(HA)[A^-][L]_o \quad (12)$$

The $\log(D_M/[A^-])$ *vs.* $\log[L]_o$ curve in Fig. 1 is linear, with a slope of 1, indicating that DB18C6 forms a 1:1 complex with the Ag^+ ion. The values of $[A^-]$ and $[L]_o$ in Eq. 12 were calculated from Eqs. 13 and 14 respectively:

$$[A^-] = ([HA]_t - [MLA]_o)/\{1 + (K_{HA} + K_{ex}(HA))[H^+]\} \quad (13)$$

$$[L]_o = [L]_t - [MLA]_o \quad (14)$$

The values of $\log K_{ex}(1)$ and $\log K_{ex}(2)$ for the Ag^+ and the Ag^+–DB18C6 systems, as calculated from the data of Fig. 1, are −2.65 and 1.17 respectively.

Discussion

$K_{ex}(2)/K_{ex}(1)$ in Table 1 represents the formation constant for the 1:1:1 complex of the crown ether with the silver picrate in a benzene solution. Table 1 shows that the complex-formation constants are very much larger for benzene than for aqueous solutions. The stability of the 15C5 complex is the highest of all the crown ether complexes in a benzene solution; on the contrary, it is the lowest in an aqueous solution. The difference in the complex-formation constant values between 18C6 and DB18C6 considerably increases in going from water to benzene. The $\log\{K_{ex}(2)/K_{ex}(1)\}$ value of DB24C8 is the smallest, although it has the most donor oxygen atoms (eight) of all these crown ethers. The picrate anion was used as the only counter ion in this work. However, the anion effect on the complex-formation reaction in a low polar solvent may be very important, since an ion-pair complex-formation reaction, *e.g.*, $AgA + L \rightleftharpoons AgLA$ in the present study, occurs in a solvent with a low dielectric constant.

As may be seen from Table 2, in the cases of both 18C6 and DB18C6, the $\log K_{ex}(3)$ values of K^+ and Tl^+, which have very much smaller $-\Delta G_h^\circ$ values and much more optimum sizes for the 18C6 and DB18C6 cavities (radius: 1.3—1.6 Å[1c]) than does Ag^+, are larger than that of Ag^+; the $\log K_{ex}(3)$ values of Rb^+ and Cs^+, which have very much smaller $-\Delta G_h^\circ$ values than Ag^+ and no more optimum sizes for the 18C6 and DB18C6 cavities than Ag^+ has, are larger than that of Ag^+; the $\log K_{ex}(3)$ value of Ag^+, which fits more closely into the 18C6 and DB18C6 cavities than Na^+, is larger than that of Na^+, although the $-\Delta G_h^\circ$ value of Ag^+ is much greater than that of Na^+. It has been found that the structure of the crown ether complex with the cation in the center of the crown ether ring does not require the stripping of the entire solvation shell of the ion, since solvent contacts are still possible in the direction perpendicular to the plane of the ring.[8] It thus appears that the extractability of the univalent metal ion complex with the same crown ether in this work is determined primarily by both the ratio of the ionic size to the cavity size of 18C6 and the interaction of the metal ion trapped in the cavity with water molecules. The remarkable substituent effect of the two benzo groups attached to 18C6 on the extractability of the Ag^+ complex can be seen in Table 2; *i.e.*, the difference in the $\log K_{ex}(3)$ values of Ag^+ and Na^+ markedly increases from 18C6 to DB18C6, while, on the contrary, that of Ag^+ and each of the others decreases and the Ag^+–DB18C6 complex, whose molar volume is much larger than that of the Ag^+–18C6 complex, is much more extractable than the Ag^+–18C6 one.

Spin-trapping Reactions in γ-Irradiated Benzene Solutions. Generation of Authentic Spin-adduct Radicals

Tsuneki ICHIKAWA* and Hiroshi YOSHIDA
Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060
(Received September 12, 1979)

Synopsis. Spin-trapping in γ-irradiated solutions of chlorinated hydrocarbons in benzene by using 2,4,6-tri-*t*-butylnitrosobenzene revealed that transient free radicals are generated almost exclusively by the dissociative electron attachment to the solutes. This provides a simple, useful method for preparing the authentic spin-adducts of hydrocarbon radicals.

The spin-trapping technique has been utilized for the detection of short-lived free radicals involved in chemical reactions. The technique comprises the conversion of the short-lived radicals into the stable nitroxide radicals (spin-adducts) by the reaction with nitroso or nitrone compounds (spin-traps) and the observation of the latter radicals by means of the conventional ESR method. The ESR spectra of authentic spin-adducts are essential for the identification of the spin-trapped short-lived radicals. The authentic spin-adducts have been generated by several methods.[1-4] We wish to report a simple radiation-chemical method which is applicable in spin-trapping studies.

The free radicals were generated by the dissociative electron attachment, $RCl+e^- \rightarrow R\cdot + Cl^-$, to chlorinated hydrocarbons in γ-irradiated benzene solutions. Benzene was chosen as solvent because the radiation-chemical yield of the free radicals from neat benzene (per 100 eV radiation energy absorbed, *G*-value) is as low as 0.4.[5] In contrast, the yield is generally as high as 3 in saturated hydrocarbons, so that the spin-adducts of the solvent radicals sometimes prevent detection of free radicals from solutes in saturated hydrocarbon solvents by the spin-trapping technique.

Experimental

Benzene of spectrograde was used. Reagent grade chlorinated hydrocarbons were used as solutes without further purification. The spin-trap, 2,4,6-tri-*t*-butylnitrosobenzene,[6] was supplied by Dr. Masahiro Tabata, Hokkaido University. The sample solutions were degassed by freeze-pump-thaw cycles, sealed in ESR tubes at 10^{-3} Pa irradiated with ^{60}Co γ-rays, and subjected to measurements with an ESR spectrometer (JEOL, JES-ME-2X). The yield of the spin-adducts was determined by using the DPPH solution in benzene as a standard. All the experimental procedures were carried out at ambient temperture (20±2 °C).

Results and Discussion

The ESR spectrum recorded from benzene containing only the spin-trap is predominantly due to the spin-adduct of phenyl radical[2] (Fig. 1A). The spectral lines indicated by arrows show a minor contribution from unidentified free radicals. The generation of phenyl radical from benzene is necessarily accompanied by the formation of hydrogen atoms. However, they cannot be observed by the spin-trapping technique.

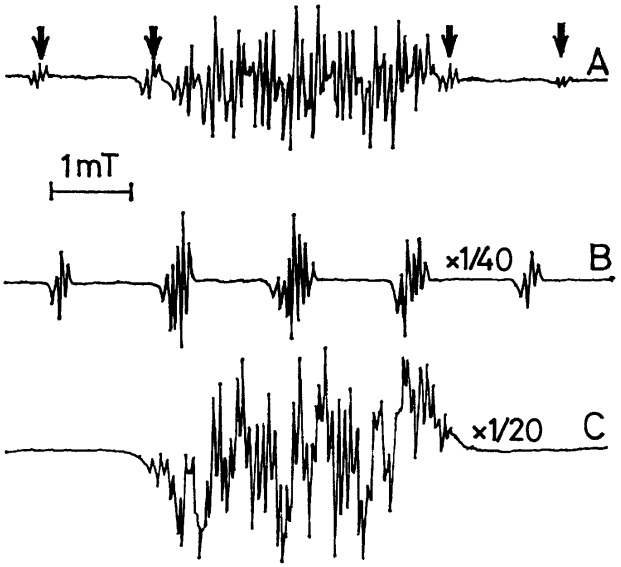

Fig. 1. ESR spectra of spin-adducts generated in benzene containing the 0.01 mol/dm³ spin-trap (A) with no other solute, (B) with benzyl chloride and (C) with *o*-chlorotoluene, γ-irradiated to the dose of 1×10^{19} eV/g.
The concentration of the chlorinated hydrocarbons is 0.2 mol/dm³ for all the samples. Arrows indicate the spectrum due to an unidentified spin-adduct. Relative sensitivity in the ESR measurements is shown in the figure.

Probably they readily react with benzene to form cyclohexadienyl radicals, which are too stable due to the π-conjugation to react with the spin-trap. The *G*-value of the spin-adduct of the phenyl radical is only 0.01 at 0.01 mol/dm³ of the spin-trap.

Effects of the addition of solutes to the solution are summarized as follows. No change observed in the spectrum on addition of 0.2 mol/dm³ toluene. The yield of the spin-adduct of phenyl radical increases by four times on addition of 0.2 mol/dm³ chlorobenzene. A spectrum almost exclusively due to the spin-adduct of benzyl radical (Fig. 1B) was observed on addition of 0.2 mol/dm³ benzyl chloride. In contrast, the spin-adduct of a phenyl-type radical (very probably *o*-methylphenyl radical) was observed on addition of *o*-chlorotoluene, but no formation of the benzyl-type radical.

The results indicate that short-lived free radicals are generated by the dissociative attachment of the electrons released by γ-rays to the chlorinated compounds and converted into the stable nitroxide radicals by the spin-trap. An alternative mechanism in which the free radicals are generated by the dissociation of the excited solutes resulting from the energy transfer from the solvent is excluded by the formation of the

phenyl-type radical from *o*-chlorotoluene. The bond energy for the benzyl–hydrogen bond (3.7 eV) is smaller than that for the phenyl–chlorine bond (4.1 eV),[7] so that the benzyl-type radical should be generated from the excited *o*-chlorotoluene.

The total energy for the dissociative electron attachment reaction is given by

$$E = BE(\text{R-Cl}) - EA(\text{Cl}) - E_s(\text{Cl}^-) - E(\text{e}^-), \quad (1)$$

where BE(R–Cl) denotes the C–Cl bond energy, and EA(Cl) the electron affinity of the chlorine atom, 3.6 eV.[7] The solvation energy of the chloride ion, $E_s(\text{Cl}^-)$, can be estimated to be 2.2 eV by the Born formula and from the ionic radius, 1.81 A,[7] and the dielectric constant of benzene, 2.28.[7] The energy of electron in benzene, $E(\text{e}^-)$, is −0.5 eV.[8] Thus eq. 1 is reduced to $E=BE(\text{R-Cl})-5.3$ eV. Since the C–Cl bond energy is generally smaller than 5.3 eV, the reaction is exothermic. Thus, the dissociative electron attachment readily occurs to give free radicals from chlorinated hydrocarbon solutes.

Propyl, butyl, α-methylbenzyl, and phenylethyl radicals can actually be generated by the dissociative electron attachment to the corresponding chlorides, and are detected by means of the spin-trapping technique. The hyperfine couplings of spin-adducts thus formed are in good agreement with those reported. The coupling constants for the spin-adduct of benzyl radical, 1.32 mT (two protons), 0.08 mT (two protons), and 1.48 mT (a nitrogen nucleus), differ slightly from the coupling constants observed in toluene solution, 1.362 mT, 0.083 mT, and 1.475 mT.[2] The solvent effect on the coupling constants is appreciable even between benzene and toluene.

Figure 2 shows the relation between radiation dose and the yield of the spin-adduct of butyl radical generated from butyl chloride. No influence of the dose rate indicates that the bimolecular recombination of butyl radicals is practically absent. The gradual decrease in the rate of formation of the spin-adduct with the radiation dose indicates that butyl radicals react competitively with the spin-traps and the spin-adducts. The latter reaction is generally found in spin-trapping studies and is important in the kinetic analysis of the spin-trapping reactions.[3,9]

The yield of the butyl radical spin-adduct is proportional to the concentration of the added butyl chloride: [spin-adduct]$=1.8\times10^{-5}$ [butyl chloride] has been obtained for the spin-trap concentration of 0.01 mol/dm^3, the butyl chloride concentration lower than 0.4 mol/dm^3, and the radiation dose of 1×10^{19} eV g^{-1}.

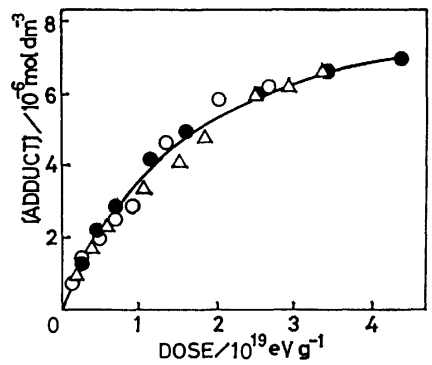

Fig. 2. Effect of dose and dose rate on the yield of the spin-adduct of butyl radical generated in the benzene solution containing the 0.01 mol/dm^3 spin-trap and 0.2 mol/dm^3 butyl chloride.
Key to the dose rate; ○, 3.6×10^{15} eV/g·s; ●, 7.6×10^{15} eV/g·s; △, 15.8×10^{15} eV/g·s.

The linear dependence suggests that the electrons disappear mostly in recombining with cations and only a small fraction of them react with butyl chloride. This is in line with a low *G*-value of the spin-adduct, 0.04, determined from the initial slope of the curve.

In conclusion, the spin-adducts of various free radicals can be authentically generated by the γ-irradiation of the benzene solutions, when the corresponding chlorinated compounds are available. The advantage of the present method lies in the fact that the ESR spectra of the spin-adducts can be recorded without interference of the spectra due to the by-product spin-adducts.

Reactions of Imidoyl-palladium(II) Complexes with Electrophiles

Katsuma HIRAKI,* Yoshio FUCHITA,* and Toyohiko MASUMOTO

Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Bunkyo-machi, Nagasaki 852

(Received September 4, 1979)

Synopsis. Imidoyl-palladium(II) complexes, derived from the reactions between imidoyl chlorides and tetrakis(triphenylphosphine)palladium(0), react with perchloric acid or triethyloxonium tetrafluoroborate to give new aminocarbene-palladium(II) complexes.

Tanaka and Alper[1] prepared several (*N*-arylimidoyl)chlorobis(triphenylphosphine)palladium(II) complexes with an oxidative addition of the corresponding imidoyl chlorides to tetrakis(triphenylphosphine)palladium(0). It has been reported that *N*-alkylbenzimidoyl chloride reacts with tetrakis(triphenylphosphine)platinum(0) and gives a few products, which are very difficult to be isolated.[2] This note deals with the preparation of chloro[*N*-(*p*-nitrobenzyl)-*p*-methylbenzimidoyl]bis(triphenylphosphine)palladium(II) (**1a**) and the corresponding *N*-(*p*-nitrophenyl)-*p*-methylbenzimidoyl complex (**1b**) and with the reactions of these imidoyl-palladium(II) complexes toward a few electrophiles. Crociani *et al.*[3] obtained a neutral and a cationic carbene complexes from reactions of chloro(*N*-phenylbenzimidoyl)bis(triphenylphosphine)palladium(II) with HCl and $HClO_4$, respectively.

Experimental

General Procedures. Tetrakis(triphenylphosphine)palladium(0)[4] and chloro[*N*-(*p*-tolyl)benzimidoyl]bis(triphenylphosphine)palladium(II) (**1c**)[1] were prepared according to the published methods. Imidoyl chlorides[5,6] and triethyloxonium tetrafluoroborate[7] were also synthesized according to the reported procedures. IR and ^{1}H-NMR spectra, conductivities and melting points were measured according to the previous paper.[8]

*Preparations of the Imidoyl-palladium(II) Complexes, **1a** and **1b**.* Slight excess imidoyl chloride (0.48 mmol) in benzene solution (10 ml) was added to a benzene solution (20 ml) of [Pd(pph$_3$)$_4$] (0.43 mmol), and the reaction mixture was stirred for 1 d at room temperature and concentrated. Addition of hexane to the concentrated reaction mixture gave yellow precipitates. Recrystallization from benzene and hexane yielded the imidoyl-palladium(II) complexes, **1a** and **1b**.

*Reaction of **1a**, **1b**, or **1c** with Perchloric Acid.* To a benzene solution (35 ml) of the imidoyl complex (0.22 mmol) was added perchloric acid (0.24 mmol) in 10 ml of diethyl ether. Off white precipitates formed immediately, which was filtered after stirring for 3 h at room temperature. Recrystallization from dichloromethane and hexane gave the aminocarbene-palladium(II) complex, **2a**, **2b**, or **2c**.

*Reaction of **1a** or **1c** with Triethyloxonium Tetrafluoroborate.* The mixture of **1a** or **1c** (0.29 mmol) and triethyloxonium tetrafluoroborate (0.32 mmol) in dichloromethane (25 ml) was stirred for 1 d at room temperature. Addition of diethyl ether to the concentrated reaction mixture gave the aminocarbene-palladium(II) complex, **3a** or **3c**.

Results and Discussion

N-(*p*-Nitrobenzyl)-*p*-methylbenzimidoyl chloride reacted with equimolar amount of tetrakis(triphenylphosphine)palladium(0) in benzene at room temperature to afford *trans*-chloro[*N*-(*p*-nitrobenzyl)-*p*-methylbenzimidoyl]bis(triphenylphosphine)palladium(II) (**1a**) in good yield, similar to the case of *N*-(*p*-nitrophenyl)-*p*-methylbenzimidoyl chloride and other *N*-arylimidoyl chlorides.[1] Although Tanaka and Alper[1] used two equivalents of the imidoyl chloride, a slightly excess amount of the imidoyl chloride was enough to obtain the imidoyl-palladium(II) complexes in good yield.

Reactions of **1a**, **1b**, and **1c** with perchloric acid gave stable off white crystals **2a**, **2b**, and **2c**, respectively, which contained a half mole of dichloromethane as solvent of crystallization. Complex **1a** and **1c** also reacted with triethyloxonium tetrafluoroborate in dichloromethane to produce **3a** and **3c**, respectively. Elemental analyses, IR and ^{1}H-NMR spectra together with some properties of the complexes prepared in this study are summarized in Tables 1 and 2.

N-(*p*-Nitrobenzyl)imidoyl complex **1a** is fairly unstable and turns pink within a week even under dry nitrogen atmosphere, whereas *N*-arylimidoyl complexes **1b** and **1c** are considerably stable in the same conditions. Trans configurations of **1a** and **1b** were inferred by the similarity of the structures to the complexes of Tanaka and Alper,[1] and ν(Pd–Cl) frequencies of **1a** and **1b** are reasonable (see Table 2).

On the basis of molar conductivities, elemental analyses, IR and ^{1}H-NMR spectra, complexes **2a**—**2c**, **3a**, and **3c** were assigned to new cationic aminocarbene-palladium(II) complexes, which were formed by an addition of a proton or an ethyl group to the secondary

nitrogen atom on the imidoyl ligand. The ^{1}H-NMR spectrum of **2c** showed two singlets at δ 2.43 and 2.47, assignable to two magnetically nonequivalent methyl protons in two isomers as shown in Fig. 1. Complex **3a** also exhibited nonequivalent two methylene resonances of *N*-(*p*-nitrobenzyl) group at δ 4.99 and 5.04. These isomers were caused by the restricted rotation around the C–N bond. Analogous isomerism probably exists in other aminocarbene complexes, in consideration of two ν(Pd–Cl) frequencies in their Far-IR spectra.

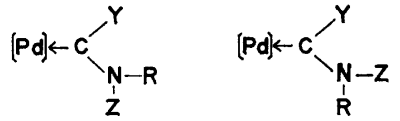

Fig. 1. Isomers for **2**(R=H) and **3**(R=Et).

The ν(Pd–Cl) frequency of the aminocarbene complexes is shifted to a higher wave number relative to that of the corresponding imidoyl complexes. These results indicate that the aminocarbene ligand has a weaker trans influence than the imidoyl one has.[9] On the other hand, the ν(C–N) frequency of the former complexes is lower than the ν(C=N) of the corresponding latter complexes. This is attributable to a decreased carbon–nitrogen bond order in the aminocarbene moiety.

Dimethyl sulfate reacted with **1c**, but gave no isolatable pure product. Other alkylating reagents such as methyl iodide and allyl iodide did not react with the imidoyl complex, and only the starting materials were recovered. This paper presents the first example of ethylation onto the nitrogen atom of an imidoyl ligand.

The Partial Molar Quantity of the Sulfur of the Compounds in the Fe–V–S System

Hiroaki WADA

National Institute for Researches in Inorganic Materials, Namiki 1-1, Sakura-Mura, Niihari-Gun, Ibaraki 305

(Received September 25, 1979)

Synopsis. An equilibrium study of the Fe–V–S system was carried out under controlled sulfur-pressure conditions. Partial molar enthalpies of the sulfur of the compounds in the Fe–V–S system were calculated on the basis of the P_{S_2}–T–X relations, which were established at temperatures between 520 and 814 °C.

The phase relations in the portion of the FeS–VS–S composition triangle have recently been clarified.[1-4] It has been found that the Fe–V–S system has extensive solid-solution phases, such as $(Fe,V)_{1-x}S$ and $(Fe,V)_3S_4$, which have a lattice intermediate between the NiAs-type and the $Cd(OH)_2$ lattice. However, no thermodynamic data on the ternary compounds of Fe–V–S have yet been reported. This note will be concerned with the partial molar enthalpy of sulfur, $\Delta\bar{H}_s$, which can be derived from the thermochemical data of compounds in the Fe–V–S system.

Experimental

The sulfide samples with the desired atomic Fe:V ratios were synthesized by heating mechanical mixtures of reagent-grade $VOSO_4 \cdot 3H_2O$ and $FeSO_4 \cdot (NH_4)_2SO_4 \cdot 6H_2O$ in an H_2S atmosphere at 1050 °C for 4 h; they were then used as the starting materials. The equilibrium study was carried out by means of thermogravimetry, using a quartz spring balance. The general experimental procedures, the apparatus, and the chemical analyses are the same as those described in the previous paper.[1]

Results and Discussion

The experimentally determined P_{S_2} (equilibrium sulfur pressure)–T(temperature)–X(composition) relations, which had been reported in three preceding publications,[1,3,4] were used in the computation of the activities and the partial molar enthalpies.

Under the experimental conditions employed, the vapor phase in equilibrium with iron vanadium sulfides contains various molecular species of sulfur from S_2 to S_8. In such a case, according to Geffken *et al.*,[5] the activity of sulfur, a_s, can be given by

$$a_s = \left(\frac{P_{S_n}}{P_{S_n}^{\circ}}\right)^{1/n}, \quad (1)$$

where the subscript, n, indicates the number of atoms in a molecule. If the reference state of sulfur is chosen as 0.5 S_2 (g), where the S_2 (g) is considered to be an ideal gas at a pressure of 1 atm at the given temper-

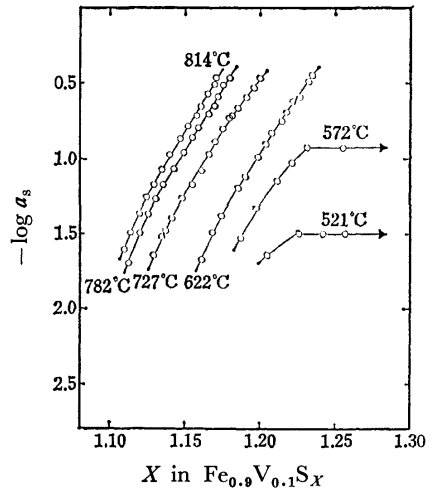

Fig. 1. The relation of log a_s with composition, X in $Fe_{0.90}V_{0.10}S_X$.

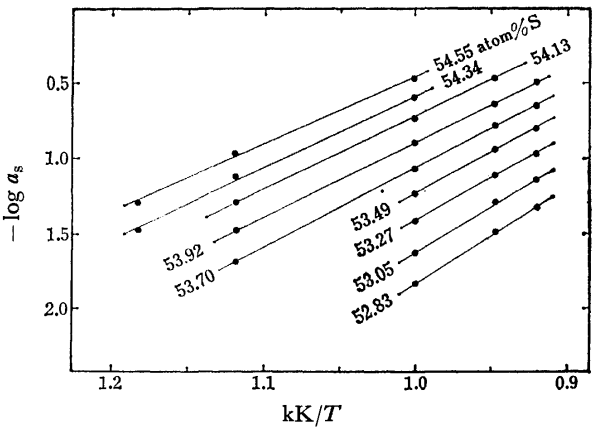

Fig. 2. The relation of log a_s with $1/(T/\mathrm{K})$.

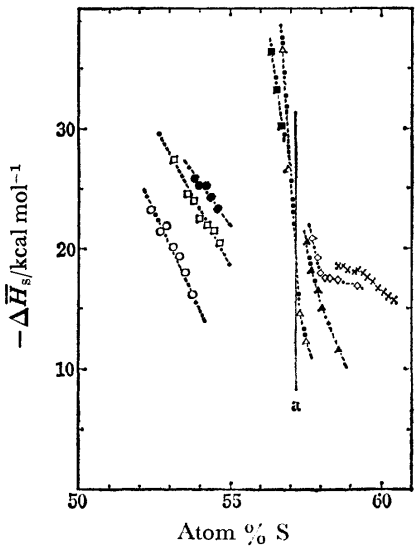

Fig. 3. $\Delta\bar{H}_s$ of compounds in the Fe–V–S system as function of composition. The stoichiometric Fe+V:S=3:4 composition is designated as the symbol a. ○: Fe:V=1:0, □: Fe:V=9:1, ●: Fe:V=4:1, ■: Fe:V=3:2, △: Fe:V=1:1, ▲: Fe:V=7:13, ◇: Fe:V=13:37, ×: Fe:V=1:19.

ature,[6] the activity of sulfur is expressed by:

$$\log a_s = 0.5 \log P_{s_2}. \quad (2)$$

The partial molar enthalpies can be computed from the Gibbs-Helmholtz equation[7] by using the activity data as follows:

$$\Delta\overline{H}_s = -4.574\, T^2 \frac{d \log a_s}{dT}. \quad (3)$$

Figure 1 shows a typical example of the isotherms of $Fe_{0.90}V_{0.10}S_x$, where the activity of sulfur is calculated according to Eq. 1. Figure 2 represents the log a_s versus the reciprocal temperature relations, which are derived from the experimental data shown in Fig. 1. It is found that the data points lie on a straight line for a given composition in the range from 52.8 to 54.5 atom% S. This suggests that the Gibbs-Helmholtz equation holds in the relation of log a_s with $1/T$ under the experimental temperature conditions. From the slopes of these straight lines, the partial molar enthalpies of the sulfur of $Fe_{0.90}V_{0.10}S_x$ were calculated by the least-squares method. The calculated partial molar enthalpies are plotted in Fig. 3 as a function of the composition, together with those of other samples. The $\Delta\overline{H}_s$ of $Fe_{0.90}V_{0.10}S_x$ increases linearly from -27.5 to -20.5 kcal/mol (1 cal=4.184 J) in the compositional range from 53.1 to 54.6 atom% S.

As is evident in Fig. 3, $\Delta\overline{H}_s$ varies with the composition of the iron vanadium sulfides. It can be concluded that (1) $\Delta\overline{H}_s$ decreases with an increase in the V/Fe ratio when the sulfur content is held constant and (2) $\Delta\overline{H}_s$ increases with an increase in the sulfur content when the V/Fe ratio is held constant.

Studies on Bromites. III. Isolation and Characterization of Quaternary Ammonium Bromites

Toshifumi KAGEYAMA* and Tamotsu YAMAMOTO
Industrial Chemistry, Faculty of Engineering, Kanto Gakuin University, Mutsuura, Kanazawa-ku, Yokohama 236
(Received October 12, 1979)

Synopsis. Bromite, BrO_2^-, could be easily stabilized and isolated as quaternary ammonium salts by the reaction of sodium bromite with the corresponding ammonium halides. The bromites are more stable and non-hygroscopic in comparison to sodium bromite. The stability of the ammonium bromites depends a great deal on the structure of the ammonium groups.

Sodium bromite (**1**) (in aqueous solution) has been used as an oxidative desizing agent for textiles because of its mild oxidizing property.[1] The aqueous solution of **1** (*ca.* 4%) can be easily prepared by the reaction of sodium hydroxide with bromine, followed by dispropotionation.[2,3] However, troublesome operations such as concentration and purification at low temperature are necessary for the isolation of pure **1** from dilute solution.[4,5] Sodium bromite thus obtained contains small amounts of impurities, NaBr, $NaBrO_3$, and NaOH, even the most purified product being hygroscopic and unstable.

For studies on physical and chemical properties of BrO_2^-, stability of the compound is required. We could isolate an extremely stable bromite, tetrabutylammonium bromite (**3a**), during the course of the oxidation reaction using **1** in the presence of phase transfer catalyst, tetrabutylammonium chloride (**2**). In the present paper, we wish to describe the isolation and characterization of the quaternary ammonium bromites containing **3a**.

Isolation of the bromites **3** is very simple as shown in the following. An equimolar amount of **1** in water

$$\underset{\mathbf{1}}{NaBrO_2} + \underset{\mathbf{2}}{R^1{}_3R^2N^+\,Cl^-} \longrightarrow \underset{\mathbf{3}}{R^1{}_3R^2N^+\,BrO_2^-}$$

and tetrabutylammonium chloride **2** were mixed in water. The pH of the resulting solution was so adjusted with acetic acid that an orange crystal of **3a** almost insoluble in water was precipitated. The structure of **3a** was confirmed by means of IR and NMR spectra (in the presence of tetrabutylammonium) and analytical data of Br (total) and BrO_2^- obtained by titration with sodium arsenite[6] after dissolution in alkaline solution.

$$R^1{}_3R^2N^+\,BrO_2^- + NaOH \xrightarrow[\text{in } H_2O]{} NaBrO_2 + R^1{}_3R^2N^+\,OH^-$$

Other quaternary ammonium bromites, tetraethylammonium (**3c**), dodecyltrimethylammonium (**3d**), octadecyltrimethylammonium (**3e**) and benzyltrimethylammonium bromite (**3f**), were prepared in a similar way. However, tetramethylammonium bromite (**3b**) was not isolated because of decomposition with time. The results are given in Tables 1 and 2.

Most of the bromites **3** obtained have definite melting points and are stable and non-hygroscopic enough to be kept at room temperature for over half a year.

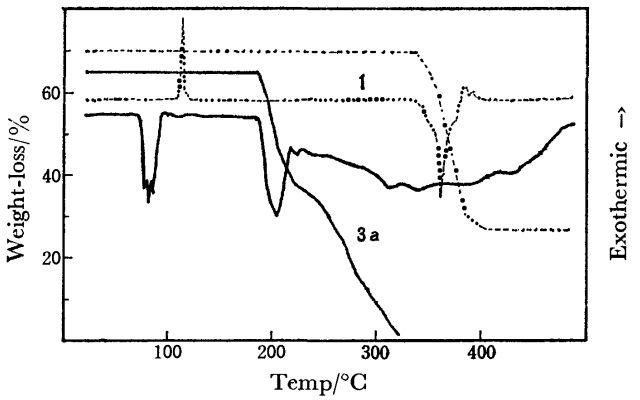

Fig. 1. DTA and TG curves of **1** and **3a**.

The instability seems to depend remarkably on the structure of the cation. The bromites having large and bulky groups on nitrogen are more stable than those containing no such groups, the order of stability being **3a**>**3c**≫**3b** in bulkiness and **3e**>**3d**≫**3b** in size of group.

The same tendency was observed quantitatively by means of thermal analysis. In the DTA curve of **3a** (Fig. 1) two peaks were observed at 74 and 188 °C. The former might correspond to melting point and the latter to decomposition temperature on the basis of thermogravimetry. The DTA curves of the other bromites showed the same pattern. The decomposition temperatures obtained from their curves are 115 (**3c**), 110 (**3d**), 167 (**3e**), and 115 °C (**3f**) and can be arranged in the order mentioned above.

The DTA curve of sodium bromite (dotted line, Fig. 1) has two peaks at 109 °C (exothermic, on the basis of dispropotionation) and at 359 °C (endothermic, on the basis of decomposition of sodium bromate).[5a] There is a remarkable difference between the curves of the bromites **3** and **1**, which seems to be due to the difference in their decomposition patterns.

The isolation of the quaternary ammonium bromites **3** is of importance not only as regards the stabilization of BrO_2^- but also because of their use in oxidation reactions in an organic medium, since **3** is soluble in benzene, dichloromethane, and chloroform.

Experimental

The IR spectra were recorded on a Hitachi 285 spectrophotometer and NMR spectra on a JNM-C-100 spectrometer (Japan Electron Optics Lab.), the thermal analysis being carried out on a DTA-TG apparatus 8055-EI, Rigaku Denki Co. Ltd.

Determination of BrO_2^- was carried out after dissolution in alkaline solution containing two fold amount of NaOH (in mol) to sample **3**.

Materials. Sodium bromite was prepared by the method described in a previous paper.[5a] Quaternary am-

monium bromides and chlorides of reagent grade were used.

Isolative Preparation of Quaternary Ammonium Bromites **3**. *General Procedure*: To an aqueous solution (18%) of 10 mmol of sodium bromite was added 10 mmol of quaternary ammonium halide. After stirring for 30 min, the pH of the resulting solution was adjusted to 8—9 by the addition of acetic acid, stirring being continued for 60 min. An orange crystal of quaternary ammonium bromite **3** deposited. The crystal was dissolved in CH_2Cl_2 without filtration and the solution was extracted with CH_2Cl_2 (15 cm^3×3). The combined extracts were dried over anhydrous sodium sulfate and evaporated to dryness *in vacuo* to give an orange crystal of **3** which was purified by reprecipitation from CH_2Cl_2–Et_2O. The results are given in Tables 1 and 2.

We wish to thank Prof. M. Okawara, for advice and Mr. Y. Nakamura, for measuring NMR spectra (Tokyo Institute of Technology).

A New Reaction of a 7,7-Diethoxybicyclo[4.2.0]octan-2-one Derivative. The Formation of the Bicyclo[3.2.1]octane Skeleton

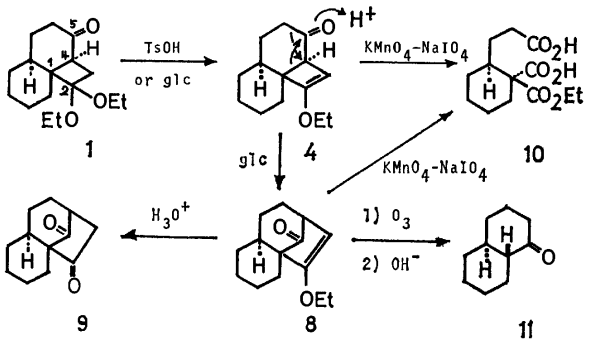
Mitsutoshi YANAGIYA, Takamasa TOMITA, and Takeshi MATSUMOTO*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received June 7, 1979)

Synopsis. 2,2-Diethoxytricyclo[6.4.0.0^{1,4}]dodecan-5-one was rearranged to 11-ethoxytricyclo[7.2.1.0^{1,6}]dodec-10-en-12-one under GLC conditions (Thermol-3 on Shimalite, 200 °C) in an 87% yield.

A bicyclo[3.2.1]oct-7-en-8-one derivative (**8**) was obtained in one step by an acid-catalyzed rearrangement of a 7,7-diethoxybicyclo[4.2.0]octane derivative (**1**) under GLC conditions. Since compounds of type **1** are readily obtainable through photocycloaddition, and since compounds with the bicyclo[3.2.1]octane skeleton are frequently found among natural products, the present reaction may be of some interest for the synthesis of such compounds as terpenoid.

The irradiation of a solution of 4,4a,5,6,7,8-hexahydro-2(3*H*)-naphthalenone in an excess of 1,1-diethoxyethylene afforded three stereoisomers: 2,2-diethoxytricyclo[6.4.0.0^{1,4}]dodecan-5-one **1** (60%), (**2**) (the C-1, C-4 epimer of **1**, 4.8%), and (**3**) (the C-4 epimer of **1**, 13.6%). The stereostructure of these compounds were determined as follows. On treatment with basic alumina, **3** was completely converted to **1**. The treatment of **1** with a catalytic amount of *p*-toluensulfonic acid afforded an enol ether (**4**) in a quantitative yield, this ether was then ozonized to give ethyl *trans*-decahydro-4-hydroxymethylene-3-oxo-4a-naphthalenecarboxylate (**5**) and *trans*-decahydro-4a-ethoxycarbonyl-3-oxo-4-naphthalenecarboxylic acid (**6**) in 22% and 66% yields respectively. Both **5** and **6** were treated with a refluxing aq alkaline solution to give *trans*-decahydro-3-oxo-4a-naphthalenecarboxylic acid (**7**).[1,2] The stereochemistry of **2** was confirmed by leading it to the *cis*-keto acid[2] in an analogous manner.



Passing the acetal ketone **1** through a column (Thermol-3 on Shimalite[3]) in a stream of helium gave 11-ethoxytricyclo[7.2.1.0^{1,6}]dodec-10-en-12-one (**8**) in an 87% yield. Compound **8** exhibited an IR absorption at 1759 cm^{-1}, and an olefinic structure was evidenced in its IR (1630 cm^{-1}) and NMR (1H, d, δ=4.75) spectra. The hydrolysis of **8** with dil acid afforded a bridged 1,3-diketone (**9**). The degradation of **8** with ozone, followed by an alkaline treatment, gave *trans*-1-decalone (**11**) (86% yield). On the other hand, the oxidation of **8** (and **4**) by the method of Lemieux-von Rudloff[4] afforded a dicarboxylic acid (**10**). Therefore, the structure of the new enol ether is represented by Formula **8**.

The rearrangement **1**→**8** probably proceeds through the bicyclo[4.2.0]oct-7-en-2-one intermediate **4**, since the treatment of **4** under similar GLC conditions afforded **8** in an almost quantitative yield. An analogous skeletal transformation of bicyclo[4.2.0]oct-7-en-2-one using acid washed alumina has been described by Cargill and Crawford.[5]

Experimental

Photocycloaddition of 4,4a,5,6,7,8-Hexahydro-2-(3H)-naphthalenone with 1,1-Diethoxyethylene. A solution of 4,4a,5,6,7,8-hexahydro-2(3*H*)-naphthalenone (1.48 g, 9.3 mmol) and 1,1-diethoxyethylene (16.8 g. 144 mmol) in 60 ml of hexane was irradiated using a 75 W high-pressure Hg lamp (Pyrex filter, −78 °C, 5 h, N_2 bubbling). The subsequent distillation of the product yielded a pale yellow oil (2.54 g, bp 103—122 °C/2 mmHg, 1 mmHg≃133.3 Pa). Three products, **1** (t_R=2.50, relative to the starting enone), **2** (t_R=3.26), and **3** (t_R=4.19), were separated by GLC (DGSP. 200 °C). Adduct **1** solidified on standing and was recrystallized from hexane at −78 °C. Adduct **3** (31 mg) was passed through basic alumina (2 g, benzene) to give **1** (29 mg). Adduct **1** (1.57 g, 60% yield): bp 110—112 °C/3 mmHg: mp 61—63 °C; IR (nujol) 1705, 1058 cm^{-1}; NMR (CCl_4) δ=3.55 (2H, q, J=8 Hz), 3.40 (2H, q. J=8 Hz), 2.62—2.30 (3H, m), 1.20 (3H, t, J=8 Hz), 1.15 (3H, t, J=8 Hz), 2.2—1.0 (13H, m). Found: C, 71.99: H, 9.78%. Calcd for $C_{16}H_{26}O_3$: C, 72.14; H, 9.84%. Adduct **2** (0.125 g, 4.8%): bp 110—112 °C/3 mmHg; IR (neat) 1705, 1055 cm^{-1}; NMR (CCl_4) δ=3.54 (2H, q, J=8 Hz), 3.49 (2H, q. J=8 Hz), 2.25 (3H, m), 1.20 (6H, t, J=8 Hz), 2.2—1.1 (13H, m). Found: C, 72.07; H, 9.75%. Adduct **3** (0.365 g, 13.6%): bp 120—122 °C/3 mmHg; IR (neat) 1730, 1055 cm^{-1}; NMR (CCl_4) δ=3.35 (2H, q, J=8 Hz), 3.40 (2H, q, J=8 Hz), 2.25 (3H, m), 1.12 (6H, t, J=8 Hz), 2.2—1.0 (13H, m). Found: C, 72.22; H, 9.80%.

Formation of the Enol Ether 4 from 1. A mixture of **1** (0.246 g, 0.923 mmol) and anhyd *p*-TsOH (1 mg) was heated to 120 °C (15 mmHg, 10 min), when the evolution of gas subsided. The subsequent distillation of the residue gave 0.199 g (98%) of **4**: bp 100—102 °C/2 mmHg; IR (neat) 1692, 1630 cm^{-1}; NMR (CCl_4) δ=4.44 (1H, s), 3.90 (2H, q, J=8 Hz), 2.60 (1H, S), 2.42 (1H, S), 2.7—2.2 (2H, b), 1.39 (3H, t, J=8 Hz), 2.2—1.0 (11H, m). Found: C, 76.36; H, 9.15%. Calcd for $C_{14}H_{20}O_2$: C, 76.32; H, 9.15%.

Oxidative Cleavage of 4 to 7. A solution of **4** (199 mg, 0.905 mmol) in hexane (10 ml) was treated with ozone (−78 °C, 0.5 h). After the excess ozone has been expelled, the solution was diluted with a mixture of MeOH–H_2O (1:1, 20 ml) and stirred for 24 h at r.t. Work up of the product gave an oil (253 mg), which was then chromatographed on silica gel (5 g, benzene) to give 52 mg (22%) of **5**: oil; IR (neat) 1730, 1630, 1590 cm^{-1}; NMR (CCl_4) δ=15.58 (1H, d, J=3 Hz), 9.15 (1H, d, J=3 Hz), 4.17

(2H, q, J=8 Hz), 2.45 (2H, m), 1.27 (3H, t, J=8 Hz), 2.1—1.0 (11H, m), and 163 mg (66%) of **6**: oil; IR (neat) 1730, 1710 cm^{-1}; NMR ($CDCl_3$) δ=12.8 (1H, b), 6.20 and 6.15 (1:4, 2H, each q, J=7 Hz), 3.74 and 3.60 (1:4, 1H, s), 2.48 (2H, m), 2.3—0.8 (11H, m). A solution of **5** (37 mg) in 10% aq KOH was refluxed for 2 h. The solution was acidified with HCl, and the product was taken up into ether. Evaporation of the ether yielded 25.5 mg (89.5%) of the keto acid **7**,[2] mp 116—118 °C, after recrystallization from $CHCl_3$–hexane. Similarly, the keto acid **6** (54 mg) was treated with the KOH solution (reflux, 2 h) to give the same *trans*-keto acid **7** (34 mg, 86%). The *cis*-adduct **2** was converted to the *cis*-keto acid, which was found to be identical (IR, NMR, TLC) with an authentic sample derived from *cis*-9-cyano-2-decalone.[2]

*Rearrangement of **1** (and **4**) to the Keto Enol Ether **8**.* This rearrangement was carried out at 180—220 °C using a Varian A-700 gas chromatograph equipped with a column packed with 15% Thermol-3 coated on Shimalite (3/8″×6 ft). Helium was used as the carrier gas (100 ml/min). In a typical run, an ethereal solution of **1** (330 mg in 1 ml) was used. After the elution of the solvent, the eliminated ethanol was eluted slowly (t_R=2 min) and **4** was eluted as pale yellow oil (t_R=10.5, 237 mg, 87% yield). The products were collected on granular anhyd Na_2SO_4 placed in a short glass tube fitted to the outlet. An analytical sample was obtained by distillation. Bp 100—105 °C/3 mmHg; IR (neat) 1759, 1613 cm^{-1}; NMR (CCl_4) δ=4.75 (1H, d, J=4 Hz, =C–**H**), 3.94 (2H, q, J=8 Hz), 2.77 (1H, m, =C–C–**H**), 1.40 (3H, t, J=8 Hz), 2.3—0.9 (13H, m); MS *m/e* 220 (M^+). Found: C, 76.34; H, 9.16%. Calcd for $C_{14}H_{20}O_2$: C, 76.32; H, 9.15%.

*Hydrolysis of **8**, Formation of the Diketone **9**.* To a solution of **8** (70 mg) in dioxane–H_2O (2:1, 3 ml), was added 0.1 ml of conc HCl with stirring. White crystals (60 mg, 97%) were immediately precipitated. Recrystallization from ether gave pure **9**: mp 117—118 °C, IR (nujol) 1760, 1720 cm^{-1}; NMR ($CDCl_3$) δ=3.1—2.45 (3H, m), 2.4—1.9 (2H, m), 1.9—0.9 (11H, m). Found: C, 75.12; H, 8.36%. Calcd for $C_{12}H_{16}O_2$: C, 74.97; H, 8.39%.

*Oxidation of **8** (and **4**) to Dicarboxylic Acid, **10**.* Following the method of Lemieux-von Rudloff,[4] **8** (51 mg, 0.23 mmol) was oxidized with 220 mg (0.125 mmol) of $KMnO_4$ and 486 mg (2.2 mmol) of $NaIO_4$ in *t*-BuOH–H_2O (3:1, 4 ml) to give **10**: mp 161—163 °C; IR (nujol) 1742, 1710 cm^{-1}. Found: C, 57.01; H, 7.40%. Calcd for $C_{13}H_{20}O_6$: C, 57.34; H, 7.40%.

Methyl Ester: Bp 135 °C (bath temp)/2 mmHg; IR (neat) 1735 cm^{-1}; NMR (CCl_4) δ=4.20 (2H, q, J=7 Hz), 3.72 (3H, s), 3.65 (3H, s), 2.28 (2H, t, J=6 Hz), 1.29 (3H, t, J=7 Hz), 2.5—1.0 (11H, m); MS *m/e* 300 (M^+). A similar treatment of **4** (141 mg) with $KMnO_4$ (60 mg)–$NaIO_4$ (1.2 g) gave a dicarboxylic acid which was completely identical with the **10** obtained from **8**.

*Degradation of **8** to **11**.* A solution of **8** (110 mg) in AcOEt (5 ml) was treated successively with an excess of ozone (−78 °C), KI (0.5 g) in MeOH–H_2O (1:1, 5 ml, 2 h), and $Na_2S_2O_3$. The product, obtained in the usual way, was heated in a mixture of aq 10% NaOH (2 ml) and EtOH (2 ml) for 6 h. The ethereal extract boiling at 105 °C/14 mmHg (66 mg) was identical with the authentic **11**.

Some Reactions on 4*H*-Cyclopenta[*def*]phenanthrene-8,9-dione

Masaaki Yoshida, Atsushi Kadokura,† Masahiro Minabe,* and Kazuo Suzuki

Department of Industrial Chemistry, Faculty of Engineering, Utsunomiya University, Ishiicho, Utsunomiya 321-31

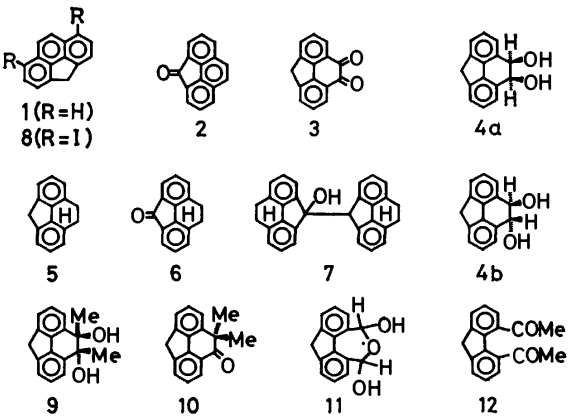
(Received June 18, 1979)

Synopsis. The oxidation of 8,9-dihydro-4*H*-cyclopenta[*def*]phenanthrene gave the 4-ketone by treatment with Triton B-oxygen, and afforded 8,9-diketone by the action of chromium (III) salt. The reduction of the quinone yielded the corresponding *meso*- and *dl*-diols.

The oxidation of 4*H*-cyclopenta[*def*]phenanthrene (**1**) has already been reported to give cyclopenta[*def*]phenanthren-4-one (**2**), 4*H*-cyclopenta[*def*]phenanthrene-8,9-dione (**3**), and other substances.[1,2] *meso*-8,9-Dihydro-4*H*-cyclopenta[*def*]phenanthrene-8,9-diol (**4a**) was obtained from **1** by treatment with osmium tetraoxide.[3] The quinone, **3**, has been prepared by the oxidation of **1** with iodic acid.[4]

The present paper will deal with another route to form **3** and some related reactions.

The air-oxidation of 8,9-dihydro-4*H*-cyclopenta[*def*]-phenanthrene (**5**)[5] gave the expected 8,9-dihydrocyclopenta[*def*]phenanthren-4-one (**6**) in a moderate yield, accompanied by the formation of 8,8′,9,9′-tetrahydro-4,4′-bi(4*H*-cyclopenta[*def*]phenanthren)-4-ol (**7**). This reaction may be initiated by the dissociation of more acidic protons on the active 4-methylene[6] than the 8,9-protons.



Scheme 1.

The reexamination of the oxidation of **1** using iodic acid resulted in **2**, **3**, and 1,7-diiodo-4*H*-cyclopenta-[*def*]phenanthrene (**8**).[4] Pure **3** was also isolated easily by the reaction of **5** with sodium dichromate, in spite of the dominant formation of **2**, which can be converted into **5**.

The reduction of **3** with lithium aluminium hydride afforded two isomeric diols, **4a**[3] and *dl*-8,9-dihydro-4*H*-cyclopenta[*def*]phenanthrene-8,9-diol (**4b**). The treatment of **3** with a large excess of methylmagnesium iodide gave only a single isomer, 8,9-dimethyl-4*H*-cyclopenta[*def*]phenanthrene-8,9-diol (**9**), of the expected diastereomeric diols. An inspection of the molecular model suggests that the attack of the second molecule of the Grignard reagent from the same side as in the first attack would be sterically hindered; hence, a *dl*-structure is tentatively assigned to **9**.

The pinacol-pinacolone rearrangement of **9** gave the expected 9,9-dimethyl-4*H*-cyclopenta[*def*]phenanthren-8-one (**10**). A similar transformation of **4a** and **4b** yielded only **3**. The oxidative cleavage of **4a** and **4b** afforded 6,10-dihydro-4*H*-fluoreno[4,5-*cde*]oxepin-4,6-diol (**11**),[7] and **9** was also converted into 4,5-diacetylfluorene (**12**). The UV absorbance at the characteristic maximum of **4a** (307 nm) is greater than those of **4b** (308 nm) and **9** (305 nm). This may result from the steric factor of the 8,9-substituents.

The reactivities of **4a** and **4b** towards periodic acid were compared to each other at 50 °C by measurements of the disappearance of the maximum at *ca.* 307 nm caused by the diol and the appearance of the peak at 298 nm of **11**. The reaction time of **4b** was twice that of **4a**. This difference in the reactivity is consistent with the assignments of the *meso*- and *dl*-configurations to **4a** and **4b** respectively.[8]

Experimental

All the melting points are uncorrected. The instruments used in this experiment were the same with those described elsewhere.[7]

Air-oxidation of 8,9-Dihydro-4H-cyclopenta[def]*phenanthrene (5).* Air was introduced into a solution of **5** (960 mg, 5 mmol) in pyridine (25 ml) containing Triton B (40%, 0.25 ml) at 17—19 °C for 20 h. After PhH (50 ml) has then been added, the reaction mixture was extracted with HCl (2 mol/l, 90 ml), and the PhH solution was washed with aqueous NaCl, dried over Na_2SO_4, and chromatographed on an alumina column, with PhH as the eluent. The first eluate was evaporated to dryness, and the residue was recrystallized from hexane to give 125 mg (13%) of **5**: mp 141—142 °C.

The second orange eluate afforded 714 mg (69%) of **6**: mp 141—143 °C (from HOEt); IR 1700 cm^{-1} (C=O); NMR ($CDCl_3$) δ 3.03 (4H, s) and 6.91—7.39 (6H, m); MS, *m/e*, 206 (M^+). Found: C, 87.29: H, 4.82%. Calcd for $C_{15}H_{10}O$: C, 87.35; H, 4.89%.

The colorless portion of the alumina yielded 39 mg (4%) of **7**: mp 219—221 °C (dec) (from cyclohexane); IR 3335 cm^{-1} (OH); NMR ($CDCl_3$) δ 2.01 (1H, s, OH), 2.93 (4H, s), 2.97 (4H, s), 4.88 (1H, s), and 6.71—7.03 (12H, m); MS, *m/e*, 398 (M^+), 207, and 191. Found: C, 90.50; H, 5.31%. Calcd for $C_{30}H_{22}O$: C, 90.42; H, 5.57%.

Oxidation of 4H-Cyclopenta[def]*phenanthrene (1) with HIO_3.* The hydrocarbon **1** (1.0 g, 5.3 mmol) was treated with HIO_3 (4.3 g), H_2O (25 ml), and HOAc (30 ml) in dioxane (270 ml) by a method similar to that described elsewhere:[4] 407 mg (41%) of **1** was recovered by sublimation *in vacuo*: mp 114—115 °C. Upon separation by column chromatography, 62 mg (6%) of **2** (mp 169.5—170.0 °C; lit,[1] mp 170 °C) and 272 mg (24%) of **3** (mp 256 °C, dec: lit,[4] mp 260 °C, dec)

† Present address: Tama Kagaku Kogyo, Ltd., Shinmachi, Yashio 340.

were obtained.

In addition, a 50-mg portion (2%) of **8** was isolated: mp 216—217 °C (from cyclohexane); NMR (CS_2) δ 4.20 (2H, s, H_4), 7.39 (2H, d, J=7.8 Hz, H_3, H_5), 7.75 (2H, s, H_8, H_9), and 8.00 (2H, d, H_2, H_6); MS, *m/e*, 442 (M^+), 315, and 188. Found: C, 40.98; H, 2.15%. Calcd for $C_{15}H_8I_2$: C, 40.76; H, 1.82%.

4H-Cyclopenta[def]*phenanthrene-8,9-dione (**3**).* A solution of **5** (2.40 g, 12.5 mmol) in HOAc (200 ml) was refluxed with $Na_2Cr_2O_7 \cdot 2H_2O$ (5.0 g) for 45 min. Upon treatment with PhH and H_2O, the PhH solution of the resulting precipitate was chromatographed on a silica-gel column, with PhH as the eluent; the first eluate gave 0.43 g (18%) of **1**. The lower yellow band on the column was extracted with HOEt, giving 1.43 g (56%) of **2**.

The upper orange-red band was extracted with EtOAc to give 0.54 g (20%) of **3**.

meso- *(**4a**) and* dl-*8,9-Dihydro-4H-cyclopenta*[def]*phenanthrene-8,9-diols (**4b**).* Quinone, **3** (440 mg, 2 mmol), in ether (80 ml) was added to a suspension of $LiAlH_4$ (304 mg, 8 mmol) in ether (20 ml) at 0 °C, after which the mixture was stirred for 10 h at room temperature. Upon decomposition with aqueous NaCl and the evaporation of the ether, the residue was purified by fractional recrystallization from CH_2Cl_2 to give 244 mg (55%) of **4b**: mp 200.0—200.5 °C (dec); IR 3240 cm^{-1} (OH); UV_{max} (HOEt) 270 (log ε 4.10), 296 (3.45), and 308 nm (3.30); NMR ($CDCl_3$) δ 1.76 (2H, s, OH), 3.94 (2H, s), 5.18 (2H, s), and 7.17—7.49 (6H, m); MS, *m/e*, 224 (M^+), 206, and 178. Found: C, 80.40; H, 5.31%. Calcd for $C_{15}H_{12}O_2$: C, 80.33; H, 5.39%.

In addition, 20 mg (5%) of **4a** was isolated; it was identical in all respects with the specimen obtained by the oxidation of **1** with OsO_4;[3] mp 183.5—184.5 °C (dec) (lit,[3] mp 180 °C, dec); IR 3395 and 3305 cm^{-1} (OH); UV_{max} (HOEt) 268 (log ε 4.14), 295 (3.40), and 307 nm (3.41); NMR ($CDCl_3$) δ 2.15 (2H, s, OH), 3.93 (2H, s), 5.08 (2H, s), and 7.28—7.62 (6H, m); MS, *m/e*, 224 (M^+), 206, and 178.

8,9-Dimethyl-4H-cyclopenta[def]*phenanthrene-8,9-diol (**9**).* A solution of **3** (550 mg, 2.5 mmol) in PhH (100 ml) was added to a mixture of MeMgI (prepared from MeI (1.2 ml, 20 mmol) and Mg) in ether at 15—20 °C, after which the new mixture was refluxed for an additional 5 h. Upon treatment with aqueous NH_4Cl, the resulting mixture was separated by means of a silica-gel column with PhH–EtOAc (95/5). The orange-red band on the column gave 72 mg (13%) of **3**. The upper light yellow band afforded 361 mg (57%) of **9**: mp 167.5—168.5 °C; IR 3470 cm^{-1} (OH); UV_{max} (HOEt) 273 (log ε 4.06), 294 (3.80), and 305 nm (3.16); NMR ($CDCl_3$) δ 1.50 (6H, s), 2.28 (2H, s, OH), 3.92 (2H, s), and 7.25—7.50 (6H, m); MS, *m/e*, 252 (M^+), 234, 189, and 165. Found: C, 80.55; H, 6.77%. Calcd for $C_{17}H_{16}O_2$: C, 80.92; H, 6.39%.

Pinacol-Pinacolone Rearrangement of Diols. a) 9,9-Dimethyl-4H-cyclopenta[def]*phenanthren-8-one (**10**):* A mixture of **9** (252 mg, 1 mmol) in HOAc (50 ml) containing H_2SO_4 (0.35 ml) was refluxed for 3 h to afford 132 mg (56%) of **10**: mp 99—100 °C (from aqueous DMF); IR 1662 cm^{-1} (C=O); NMR ($CDCl_3$) δ 1.57 (6H, s), 4.02 (2H, s), and 7.28—7.93 (6H, m); MS, *m/e*, 234 (M^+) and 219. Found: C, 87.20; H, 6.16%. Calcd for $C_{17}H_{14}O$: C, 87.15; H, 6.02%.

b): A solution of **4a** (112 mg, 0.5 mmol) in HOAc (10 ml) was refluxed with H_2SO_4 (0.1 ml) for 10 min, giving 37 mg (34%) of **3**. Similarly, **4b** (112 mg, 0.5 mmol) gave 48 mg (43%) of **3**.

*4,5-Diacetylfluorene (**12**).* The diol **9** (252 mg, 1 mmol) was treated with $Pb(OAc)_4$ (0.5 g) in PhH (50 ml) at room temperature for 5 h to yield 148 mg (59%) of **12**: mp 167—168 °C; IR 1670 cm^{-1} (C=O); UV_{max} (HOEt) 246 (log ε 4.36), 275 (3,52), and 322 nm (3.86); NMR ($CDCl_3$) δ 2.67 (6H, s), 3.90 (2H, s), and 7.13—7.64 (6H, m); MS, *m/e*, 250 (M^+), 235, 207, 193, and 165. Found: C, 81.28; H, 5.84%. Calcd for $C_{17}H_{14}O_2$: C, 81.58; H, 5.64%.

In addition, 30 mg (12%) of **9** were recovered.

Glycol Scission of Diols. A solution of **4a** (1.34×10^{-4} mol/l HOEt, 4.00 ml) was mixed with an aqueous solution of H_5IO_6 (5.07×10^{-3} mol/l, 0.11 ml) in a quartz cell, which was maintained at 50±1 °C. After the prescribed times, the UV spectra were measured in the range from 290 to 340 nm. The spectrum after 120 min was identical with that of **11**:[7] UV_{max} (HOEt) 265 (log ε 4.16), 287 (3.66), and 298 (3.74).

Two solutions of **4b** and H_5IO_6 were treated as a manner similar to that described above; the end point of the reaction was observed after 240 min.

The similar treatment of **9** showed no significant change after 24 h.

A Convenient Method for the Preparation of Highly Pure *t*-Alkyl Bromides and Iodides

Hiromitsu MASADA* and Yoshiharu MUROTANI

Department of Industrial Chemistry, Faculty of Engineering, Kanazawa University, Kanazawa 920

(Received June 25, 1979)

Synopsis. Highly pure (99—100%) *t*-butyl and *t*-pentyl bromides and iodides, and 3-bromo-3-ethylpentane were readily prepared in 83—95% yields by the reactions of the corresponding alcohols with hydrobromic or hydroiodic acid, using lithium or calcium halide. The metal halides remarkably increased the yield and the purity of the products.

t-Alkyl bromides have been commonly prepared by the addition of hydrogen bromide to olefins[1] and by the reactions of *t*-alkyl alcohols with phosphorus(III) bromide,[2] hydrobromic acid,[3,4] or bromine and triphenylphosphine.[5] *t*-Alkyl iodides have been prepared by the reactions of the corresponding alcohols with potassium iodide and phosphoric acid,[6] or with trimethylsilyl iodide,[7] and by the iodination of *t*-alkyl chlorides.[8] However, the above preparations are not always satisfactory with regard to the purity and the yield of the product and the reaction conditions. The commercially available *t*-butyl bromide and iodide are contaminated by impurities (4—5%) which can not be readily removed.

We wish now to report a convenient and selective method of preparing highly pure *t*-alkyl bromides and iodides under very mild conditions, using lithium and calcium halides.

Results and Discussion

Table 1 shows the brominations of *t*-alkyl alcohols. The reactions of *t*-butyl alcohol with two and five molar equivalents of hydrobromic acid were carried out in the absence of the metal bromides at 0 °C to give *t*-butyl bromide in yields of only 9 and 43% respectively. By contrast, the yield of the bromide was increased up to 85% in the reaction of *t*-butyl alcohol with hydrobromic acid and metal bromide (molar ratio 1:2:1.5). A further excess of hydrobromic acid or metal bromide did not, though, improve the yield significantly. The product after simply being washed with ethylene glycol was 99.7—99.8% pure, with the only impurity being 0.2—0.3% of 2-methylpropene. Sodium and magnesium bromides were not effective for use in the preparation because of their poor solubility in hydrobromic acid. Similar brominations of *t*-pentyl alcohol and 3-ethyl-3-pentanol using metal bromides were also carried out to give the corresponding bromides of a high purity in 91 and 93% yields respectively.

Table 2 shows the iodinations of *t*-alkyl alcohols. The iodinations of *t*-butyl and *t*-pentyl alcohols with two equivalents of hydroiodic acid gave the corresponding iodides in only 21 and 35% yields respectively. The addition of 1—1.5 molar equivalents of lithium or calcium iodide to the system afforded highly pure *t*-butyl and *t*-pentyl iodides in 80—84% yields. Furthermore, the pure iodides could be readily obtained by the vacuum distillation of these highly pure products at room temperature.

On the whole, the metal halides in the reaction system remarkably increased the yield and the purity of the product. The hindered *t*-pentyl halides and 3-bromo-3-ethylpentane were more readily prepared than *t*-butyl halides. The hydrolysis of *t*-alkyl halides was much retarded by the addition of metal halides. Therefore, the halogenation of *t*-alkyl alcohols is in equilibrium with the hydrolysis, and the equilibrium is shifted very far to the right by these metal halides:

$$t\text{-ROH} + \text{HX(aq)} \underset{}{\overset{\text{MX}_n}{\rightleftharpoons}} t\text{-RX} + \text{H}_2\text{O}$$

a) A 0.1-mol quantity of *t*-alkyl alcohol was used. b) Isolated yield of *t*-alkyl iodide based on *t*-alkyl alcohol. c) Determined by titration with 0.1 M aqueous sodium hydroxide.

Experimental

The purity of the *t*-alkyl bromides and iodides was confirmed by GLPC and by titration with 0.1 M aqueous sodium hydroxide.[9] GLPC analyses were performed on a 3 m×3 mm column packed with 5% Silicone DC 550 or 5% Didecyl phthalate, at 50—60 °C and at the carrier gas (helium) flow rate of 60—80 cm^3/min. NMR spectra were recorded on a Hitachi NMR R-24B spectrometer operating at 60 MHz. Chemical shifts are reported in δ units, with tetramethylsilane as an internal standard.

Materials and Preparation. Lithium and calcium halides were of a commercial grade and were used without further purification. Hydrobromic acid (47%) and hydroiodic acid (55%) were GR grade reagents obtained from Nakarai Chemicals Co. *t*-Butyl and *t*-pentyl alcohols were distilled from sodium. 3-Ethyl-3-pentanol was prepared from diethyl ketone and ethylmagnesium bromide.

t-*Butyl Bromide*: Hydrobromic acid (23.2 cm^3, 0.2 mol) was added, drop by drop, to a mixture of lithium bromide (13.03 g, 0.15 mol) and *t*-butyl alcohol (7.412 g, 0.1 mol) at 0 °C in a 100-cm^3 Erlenmeyer flask. The mixture was then stirred magnetically for 2 h. The upper organic layer was separated and washed with ethylene glycol (10 cm^3×3) to remove the hydrobromic acid and the remaining *t*-butyl alcohol, and was then dried over anhydrous sodium sulfate, giving 11.72 g (85%) of 99.8% pure *t*-butyl bromide; this was later distilled *in vacuo* to give the pure bromide as a colorless liquid: bp 73.1 °C; NMR ($CDCl_3$) δ=1.78 (9H, s, *t*-Bu).

t-*Pentyl Bromide*: Yield, 91%; bp 107.4 °C; NMR ($CDCl_3$) δ=1.09 (3H, t, J=7.2 Hz, CH_2CH_3), 1.78 (6H, s, *gem*-CH_3), and 1.82 (2H, q, J=7.2 Hz, CH_2).

3-Bromo-3-ethylpentane: Yield, 93%; bp 55 °C/15 Torr;† NMR ($CDCl_3$) δ=0.99 (9H, t, J=7.2 Hz, CH_3) and 1.90 (6H, q, J=7.2 Hz, CH_2).

t-*Butyl Iodide*: Yield, 83%; bp 26 °C/50 Torr; NMR ($CDCl_3$) δ=1.95 (9H, s, *t*-Bu).

t-*Pentyl Iodide*: Yield, 84% bp 25 °C/15 Torr; NMR ($CDCl_3$) δ=1.06 (3H, t, J=6 Hz, CH_2CH_3), 1.66 (2H, q, J=7 Hz, CH_2), and 1.91 (6H, s, *gem*-CH_3).

Reactions of Enamino Ketones. VII. The Photochemical Reaction of 4-Methylamino-3-penten-2-one and 2,4-Pentanedione with Benzophenone

Takao Tokumitsu* and Takayuki Hayashi

Department of Chemistry, Faculty of Science, Yamaguchi University, Yoshida, Yamaguchi 753

(Received July 4, 1979)

Synopsis. The photochemical reaction of 4-methylamino-3-penten-2-one with benzophenone gave *N*-(2,2-dipenyl-2-hydroxyethyl)-4-amino-3-penten-2-one. The reaction of 2,4-pentanedione gave oxetane, resulting from the cycloaddition of benzophenone to the double bond of the enol form.

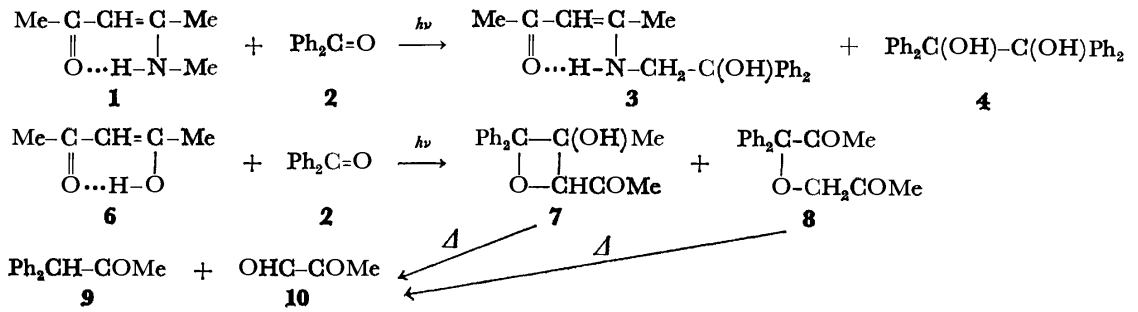
The photochemical reactions of enamines,[1] ketenimines,[2] and *N*-acyl enamines[3] with benzophenone (**2**) have been widely investigated. In general, the reactions of their compounds with **2** give diphenylmethylation products and/or oxetanes by the photocycloaddition of **2** to the carbon-carbon double bond. We have now investigated the photochemical reaction of **2** with secondary enamino ketones and β-diketones containing an analogous chelated structure.

The irradiation of a benzene solution containing an equimolar mixture of 4-methylamino-3-penten-2-one (**1**) and **2** for 48 h afforded *N*-(2,2-diphenyl-2-hydroxyethyl)-4-amino-3-penten-2-one (**3**) in a 17% yield, accompanied by benzopinacol (**4**). The structure of **3** was confirmed by the spectral data, and the regeneration, by the condensation of 2,4-pentanedione (**6**) with 2-amino-1,1-diphenylethanol (**5**),[4] which had been obtained by the acid hydrolysis of **3**. In this reaction, the light energy was absorbed exclusively by **2**. However, no oxetane, benzhydrol, and dimer of **1** was obtained. The reaction was also completely inhibited in the presence of 1,3-pentadiene, an efficient triplet quencher of **2**.[5] The hydrogen-source for the formation of **4** is presumed to be the amine part of **1** and the resinous by-products, which are produced in quantity in the reaction.[1]

The photochemical reaction of **2** with 4-anilino-3-penten-2-one (**11**) and 3-methylamino-1-phenyl-2-buten-1-one (**12**) containing the intramolecular hydrogen bonding did not give any photoadduct, the starting materials being recovered. This may be attributed to the circumstance that 95%< of the light energy was absorbed by **11** (at 365 nm ε *ca.* 2000) or **12** (at 365 nm ε *ca.* 8600) under the present reaction conditions. In contrast, 4-dimethylamino-3-penten-2-one (**13**), which can not form a chelate ring, gave, under similar conditions and in addition to **4**, *N*-(2,2-diphenyl-2-hydroxyethyl)-*N*-methylacetamide (**14**) in a 6% yield. The structure of **14** was also assigned on the basis of the spectral data and by elemental analysis. The formation of the amide **14** can be explained by assuming the formation of diphenylhydroxymethylation of **13**, which is oxidative-decomposed to yield the amide during the chromatographic treatment.

In the photochemical reaction of **2** with enamino ketones with a hydrogen atom at the α-position to the nitrogen, the diphenylhydroxymethylation exclusively occurs at this position, since its proton is easily abstracted by excited **2**.[1,3,6,7] Consequently, it appears that the intramolecular hydrogen bonding contributes only to the stability of the substrates and the products.

The irradiation of 2,4-pentanedione (**6**) with **2** for 72 h afforded 1:1 adducts, 2-acetyl-3-hydroxy-3-methyl-2,2-diphenyloxetane (**7**) in a 43.5% yield and acetonyl α,α-diphenylacetonyl ether (**8**) in a 44% yield. The structure of an adduct, **7**, was assigned to the oxetane on the basis of the spectral data and the elemental analysis. The IR absorptions at 3400 and 1704 cm^{-1} of **7** show the presence of an intramolecular hydrogen-bonded hydroxyl and carbonyl group. Furthermore, **7** reacts with 2,4-dinitrophenylhydrazine to give a single 2,4-dinitrophenylhydrazone. These results suggest that the methyl and acetyl groups on the oxetane ring have a *trans*-configuration. The oxetane, **7**, was cleaved to an ether, **8**, by boiling it with a solvent, such as benzene or ethanol, or by column chromatography. These conditions define the stability of the β-hydroxy ketone, since the dealdolization may involve a thermal process.[8] Consequently, it is considered that the ether, **8**, was produced by the cleavage of the oxetane, **7**, during the separation, by analogy with the photoadducts of cycloalkene and β-diketones.[8,9] **7** and **8** also afforded 1,1-diphenyl-2-propanone (**9**)[10] and methylglyoxal (**10**)[11] respectively by thermal cleavage under a nitrogen atmosphere. In this photoreaction, the light energy was absorbed exclusively by **2**; the reaction was also inhibited com-



pletely in the presence of 1,3-pentadiene.[5] The photodimerization of enones is sensitized by **2**,[12] but no cross-coupling reaction of these compounds has been known. The formation of the oxetane, **7**, can easily be interpreted by assuming the attack of **2** in the triplet state on the double bond of the enolated **6**. An electron-deficient oxygen of the excited **2** can attack the more negative center at the 3-position of **6** to give the more stable intermediate diradical, followed by cyclization to form an oxetane. This consideration clearly explains the orientation mode in the formation of the oxetane, **7**.

The photochemical reaction of **2** with ethyl acetoacetate (**15**) and benzoylacetone (**16**) did not give a photoadduct such as oxetane. This may be attributed to the facts that the former has a low enol content and that the latter absorbs most of the light energy under the present reaction conditions.

The difference in the photochemical reactivity of **1** and enolated **6** with **2** may be attributed to the presence or absence of an α-hydrogen atom, which is easily abstracted by excited **2**.

Experimental

The enamino ketones were prepared from the corresponding β-diketones and amines. The **2**, benzene, and the other materials were purified in the usual way. The IR, NMR, and UV spectra were recorded with JASCO IRG, Hitachi R24B, and Hitachi 124 spectrometers respectively. The MS spectra were determined with a CEC21-110B mass spectrometer.

The irradiations were performed under a nitrogen atmosphere with a 100-W high pressure mercury lamp which had been lowered into a water-cooled Pyrex immersion well. The yields are based on the consumed **2**. All the melting points are uncorrected.

*Photochemical Reaction of **1** with **2***: A solution containing 7.9 g (70 mmol) of **1** and 12.7 g (70 mmol) of **2** in 400 ml of benzene was irradiated for 48 h. The reaction mixture was then concentrated *in vacuo* to *ca.* 30 ml, the residual solid was removed by filtration, and the filtrate was chromatographed on silica gel. Elution with benzene gave **4** (5.9 g, 75%) and **2** (4.9 g, 39% recovery). Elution with benzene–acetone (10:1) gave **1** (1.3 g, 17% recovery). Further elution with acetone gave a resinous substance. The collected solid was recrystallized with chloroform to give 2.1 g (17%) of **3** as colorless prisms; mp 223—224 °C. MS *m/e*: 295 (M^+). IR($CHCl_3$): 3570, 1610, and 1570 cm^{-1}. NMR (DMSO-d_6) δ=1.85 (3H, s), 1.89 (3H, s), 4.23 (2H, d, J=6 Hz), 5.02 (1H, s), 6.26 (1H, s), 7.5—7.9 (10H, m), and 11.12 (1H, s). UVmax (EtOH): 312.5 (ε 18000) and 318^{sh} nm (17000). Found: C, 76.98; H, 6.99; N, 4.72%. Calcd for $C_{19}H_{21}NO_2$: C, 77.25: H, 7.13; N, 4.74%. Hydrolysis of **3** by dil-HCl yielded **5** and **6**.

*Photochemical Reaction of **13** with **2***: A solution containing 8.9 g (70 mmol) of **13** and 12.8 g (70 mmol) of **2** in bezene (400 ml) was irradiated for 72 h. The solution was then removed, and the residue was chromatographed on silica gel. From the benzene eluents, 3.0 g (35%) of **4** were isolated; 4.2 g (33%) of **2** were also recovered. Further elution with benzene-methanol (5:1) gave a brown viscous oil, which was separated by carbon tetrachloride-hexane (1:1) to give 0.7 g of **14**; mp 138—139 °C. MS *m/e* 269 (M^+). IR ($CHCl_3$): 3280 (O–H), and 1620 cm^{-1} (C=O). NMR ($CDCl_3$) δ=2.03 (3H, s), 2.47 (3H, s), 4.22 (2H, s), 5.38 (1H, s), and 7.1—7.6 (10H, m). Found: C, 75.57; H, 7.06; N, 5.11%. Calcd for $C_{17}H_{19}NO_2$: C, 75.74; H, 7.11; N, 5.20%.

*Photochemical Reaction of **6** with **2***: A solution containing 8.0 g (80 mmol) of **6** and 14.5 g (80 mmol) of **2** in 400 ml of benzene was irradiated for 72 h. The reaction mixture was then concentrated *in vacuo* to *ca.* 30 ml, the crystals of the oxetane, **7**, were removed by filtration, and the filtrate was chromatographed on silica gel. From the benzene eluent, 0.5 g (12%) of **4** was isolated, while 10.5 g (72%) of **2** and 5 g (62%) of **6** were recovered. From the benzene–acetone (10:1) eluent we obtained 2.7 g (44%) of **8** as a viscous liquid; IR ($CHCl_3$): 1714, 1598, 1354, and 1098 cm^{-1}. NMR ($CDCl_3$) δ=2.11 (3H, s), 2.21 (3H, s), 3.35 (2H, s), and 7.3 (10H, s). Found: C, 76.40; H, 6.50%. Calcd for $C_{18}H_{18}O_3$: C, 76.57; H, 6.45%. The product, **8**, gave a mixture of 2,4-dinitrophenylhydrazones of **9** and **10** in ethanol. The former had a mp of 141—142 °C (from EtOH), undepressed on admixture with an independently synthesized authentic specimen with the same melting point.[10] The latter had a mp of 299—300 °C (from DMF) (Lit,[11] mp 299—300 °C). The oxetane, **7**, was washed with benzene; 2.7 g (43.5%); mp 141—142 °C (dec). IR ($CHCl_3$): 3550, 3400, 1721, 1704, 995, and 977 cm^{-1}. NMR ($CDCl_3$) δ=1.35 (3H, s), 2.13 (3H, s), 2.63 (1H, s), 4.90 (1H, s), and 7.3—7.7 (10H. m). UVmax (EtOH): 224 (ε 20000), 259 (3500), and 290^{sh} nm (1300). Found: C, 76.62; H, 6.48%. Calcd for $C_{18}H_{18}O_3$: C, 76.57; H, 6.45%. 2,4-Dinitrophenylhydrazone of **7** had mp 161—162 °C (from EtOH); IR (Nujol): 3550 (O–H), 3300 (N–H), and 995 cm^{-1} (C–O–C). Found: C, 62.41; H, 4.71; N, 12.14%.

Other Photochemical Reactions: The irradiation of a benzene solution containing 1,3-pentadiene, **1** or **6**, and **2** caused the unreacted starting materials to be recovered. The reaction of **15** with **2** in benzene for 48 h gave **4** (92%) and a resinous substance, while **2** (47%) and **15** (46%) were recovered. The irradiations of **11**, **12**, and **16** with **2**, a benzene solution containing only **1** and/or **6**, and a cyclohexene solution of **1** caused the unreacted starting materials to be recovered quantitatively.

The Synthesis of 2-Imino-2,3-dihydro-1,3,4-selenadiazole Derivatives

Masahiko TAKAHASHI* and Michiyoshi KUROSAWA

Department of Industrial Chemistry, Faculty of Engineering, Ibaraki University, Hitachi, Ibaraki 316

(Received August 1, 1979)

Synopsis. The reaction of phenacyl selenocyanate with arenediazonium chlorides afforded 3-aryl-5-benzoyl-2-imino-2,3-dihydro-1,3,4-selenadiazoles, which were then acetylated and nitrosated to give the corresponding 2-acetylimino and 2-nitrosoimino derivatives respectively.

As compared with the chemistry of 1,3,4-thiadiazole,[1] that of 1,3,4-selenadiazole is less known, it has been studied intensively for only the last 10 years.[2] A few 1,3,4-selenadiazole derivatives have been shown to have significant antibacterial activity.[3] Recently it has been reported by Shawali *et al.*[4] that the diazonium coupling reaction of phenacyl thiocyanate (**1**) is a convenient route to 2-imino-2,3-dihydro-1,3,4-thiadiazoles (**2**). Similarly, the reaction of 3-thiocyanatopentane-2,4-dione (**3**) led to the one-step synthesis of **2**.[5] Accordingly, it appears possible to obtain 2-imino-2,3-dihydro-1,3,4-selenodiazoles by reacting phenacyl selenocyanate (**4**) with arenediazonium chlorides. We thus obtained the expected compound from readily-available starting material, **4**, in one step, although the yields were rather low. The direct synthesis of 2,3-dihydro-1,3,4-selenadiazoles has so far been known in only one case, *i.e.*, the reaction of hydrazonyl halides with potassium selenocyanate,[6] while several derivatives have been prepared indirectly from 2-amino-1,3,4-selenadiazoles.[7]

The treatment of **4** with arenediazonium chlorides at 0—5 °C gave precipitates. These precipitates contained a significant amount of tars; attempts to obtain analytical pure samples by recrystallization were unsuccesful. Crude products which showed only one spot on a thin-layer chromatogram were, however, obtained by repeating the precipitation with ether from a hot solution of acetic acid. In the IR spectra of these crude products, the selenocyanato absorption (2160 cm^{-1}) presented in **4** disappeared, and new imino absorptions were observed in the region of 2950—2860 cm^{-1} (Table 1). Although these IR spectra suggested the cyclization to the expected 3-aryl-5-benzoyl-2-imino-2,3-dihydro-1,3,4-selenadiazoles (**5**), the structure of **5** were not confirmed ultimately until their acetylation and nitrosation, since the elemental analyses of **5** were unsatisfactory because of the difficulties in purification.

The reflux of **5** in acetic anhydride afforded the acetate (**6**) in good yields (Table 2). The IR spectra of **6** showed no NH absorption, but exhibited two carbonyl absorptions in the regions of 1650—1621 cm^{-1} and 1636—1615 cm^{-1}, which were assigned to benzoyl carbonyls and acetyl carbonyls respectively. The meth-

yl proton resonances were observed at δ 2.30—2.39 ppm in the NMR spectra. These spectral data and the satisfactory elemental analyses were consistent with the 2-acetylimino-3-aryl-5-benzoyl-2,3-dihydro-1,3,4-selenadiazole structures (**6**).

The treatment of **5** with sodium nitrite in acetic acid at room temperature gave the nitrosoimino derivatives (**7**), red to orange, in good yields (Table 2). The IR spectra of **7** showed no NH absorption, but did display carbonyl absorptions in the region of 1645—1632 cm^{-1}. The structures of 3-aryl-5-benzoyl-2-nitrosoimino-2,3-dihydro-1,3,4-selenadiazoles (**7**) were also supported by the NMR and analytical data.

Experimental

The IR and NMR spectra were taken on a JASCO IRA-2 spectrometer and a JEOL-PMX 60 spectrometer respectively. The elemental analyses were performed on a Shimadzu UM-3B apparatus.

*Reaction of **4** with Arenediazonium Chlorides.* To a stirred and ice-cooled solution of **4**[8] (2.2 g, 10 mmol) and sodium acetate (2.5 g) in MeOH (50 ml), an aqueous arenediazonium chloride solution (19 ml) prepared from arylamine (15 mmol) in the usual manner was added, drop by drop, below 5 °C. After stirring below 5 °C for 5 h, the separated solids were collected by filtration and rinsed with ether. They were dissolved into hot acetic acid, and then the solution was poured into ether. The collection of the resulting precipitates gave, as the crude products, **5a—e**.

*Acetylation of **5**.* A solution of **5** (1.0 mmol) in acetic anhydride (5 ml) was refluxed for 1 h. The subsequent evaporation of the solvent, rinsing of the residue with ether, and recrystallization gave the pure acetates (**6a—e**).

*Nitrosation of **5**.* To a stirred solution of **5** (1.0 mmol) in acetic acid (5 ml), an aqueous solution (2 ml) of sodium nitrite (140 mg, 2.0 mmol) was added, drop by drop, at room temperature. After 1 h, a small amount of water was added to the red solution, and the precipitates thus formed were collected by filtration. The subsequent rinsing of the precipitates with water, followed by recrystallization, afforded the pure nitroso derivatives (**7a—e**).

Facile Synthesis of 2,5-Diacylthiophenes. II. The Reaction of Diketo Sulfides with 1,2-Diketones

Yuji MIYAHARA,* Takahiko INAZU, and Tamotsu YOSHINO

Department of Chemistry, Faculty of Science, Kyushu University 33, *Hakozaki, Higashi-ku, Fukuoka 812*

(Received August 7, 1979)

Synopsis. The base-catalyzed reaction of diketo sulfides $(RCOCH_2)_2S$ (R=phenyl, *p*-tolyl) with biacetyl or benzil have provided high yields of 2,5-diacyltetrahydrothiophene-3,4-diol derivatives rather than the expected 2,5-diacylthiophenes. The diols have been transformed cleanly into the corresponding 2,5-diacylthiophenes by treatment with thionyl chloride–pyridine. In contrast, the reaction of the diketo sulfide (R=*p*-tolyl) with phenylglyoxal afforded a 2,5-diacylthiophene directly in good yield.

We have recently demonstrated that the extension of the Hinsberg thiophene synthesis to the diketo sulfides of the type $(RCOCH_2)_2S$, affording 2,5-diacylthiophenes, is very successful when glyoxal is used as the 1,2-dicarbonyl compound and when the reaction is conducted under mild conditions.[1] An obvious extension of the thiophene synthesis is the condensation with 1,2-diketones such as biacetyl and benzil, which have been frequently used in the Hinsberg reaction.[2] When the reaction of α,α′-thiodiacetophenone (**1a**) with biacetyl was conducted under the usual Hinsberg conditions (a rather high concentration of sodium alkoxide), only an intractable tar was obtained. On addition of a dilute methanolic solution of sodium methoxide to a solution of **1a** and biacetyl in methanol at room temperature, a white crystalline precipitate started to separate in a few minutes, in a manner similar to the condensation with glyoxal yielding 2,5-diacylthiophenes. The product isolated at this stage was, however, not the expected thiophene derivative **4a** but an intermediate adduct 2,5-dibenzoyl-3,4-dimethyltetrahydrothiophene-3,4-diol (**2a**). Further addition of the base solution gradually dissolved the precipitate. The resultant dark homogeneous solution gave no crystalline substance. Similar results were obtained for the reactions of **1a** with benzil and **1b** with biacetyl or benzil. On the other hand, the reactions of aliphatic diketo sulfides (R=*t*-butyl, nonyl) gave dark tars with recovery of the starting materials. The yields of the diols **2a**, **2b**, **3a**, and **3b** were very variable, maybe because of the reversibility of the reaction and the complex condensation reactions of the regenerated diketo sulfides. In fact, reproducible high yields could be realized under conditions in which the less soluble diols crystallized out almost completely. The yields and the properties of the diols are summarized in Table 1. The diols thus obtained were pure, judging from their sharp melting points (with decomposition), IR and NMR spectral data, and TLC behavior. Each of them must, therefore,

be one of the seven possible isomers, but the configurations could not be determined on the basis of the available data.[3] The most striking feature of the diols is the sterically hindered nature of the hydroxyl groups, which is evidenced by the unusually slow deuterium exchange of the hydroxyl protons in the diols, especially the bulky phenyl-substituted **3a** and **3b**, and the unexpectedly high Rf values on TLC (silica gel, benzene; 0.29 and 0.71 for **2a** and **3a**, respectively, compared with 0.27 for **1a**).

Although all the attempted dehydrations of the diols under basic (sodium alkoxide/alcohol) or acidic conditions (*p*-toluenesulfonic acid/benzene, phosphorus pentaoxide/benzene, acetic anhydride[3]) gave complex mixtures of products containing the original diketo sulfides and diketones, treatment with thionyl chloride–pyridine at room temperature readily effected the desired conversion to 2,5-diacylthiophenes in high yields, as shown in Table 1. Thus, the condensation of the diketo sulfides with 1,2-diketones was realized in two steps in good overall yields.

The marked difference in reactivity between glyoxal and 1,2-diketones in the reaction with the diketo sulfides led us to investigate the reaction of phenylglyoxal as an intermediate case. The reaction of **1b** with phenylglyoxal under conditions similar to those used for the reaction with 1,2-diketones provided 2,5-di-*p*-toluoyl-3-phenylthiophene (**6**), directly but less efficiently than that with glyoxal.[1]

The resistance of the diols to dehydration, therefore, may be associated with the steric crowding in the diols and the corresponding 2,5-diacylthiophenes. The successful Hinsberg condensation of thiodiacetate esters with 1,2-diketones, in contrast to the present reaction of diketo sulfides, must be ascribed to the neighboring-group assistance by the formation of a δ-lactone intermediate (a Stobbe-type condensation).[4]

Experimental

All the melting points were determined in capillary tubes and are uncorrected. The NMR spectra were recorded on a Hitachi R-20B spectrometer at 60 MHz in deuteriochloroform, with tetramethylsilane as an internal standard. The IR spectra were obtained on a Hitachi 215 spectrophotometer in KBr disks and were calibrated carefully with a polystyrene film.

Reaction of Diketo Sulfides with 1,2-Diketones. The reaction of **1a** with biacetyl yielding **2a** was best carried out as follows. To a stirred solution of **1a** (2.70 g, 10 mmol) and biacetyl (freshly opened, 1.00 g, 11.6 mmol) in 40 ml of methanol was added 0.5 ml of a solution of sodium methoxide (0.5 g of sodium dissolved in 100 ml of methanol) at *ca.* 40 °C. The precipitation of crystals occurred immediately with evolution of heat. After stirring for 1 h, the product was collected by filtration and washed with methanol. To the filtrate, biacetyl (0.5 g) and the base solution (0.5 ml) were added to give, after standing overnight, a small additional amount of the product. The yield of the colorless needles of **2a** amounted to 3.26 g (91.6%); mp 201—202 °C (decomposed with evolution of a gas), recrystallized from chloroform.

Other diols **2b**, **3a**, and **3b** were obtained similarly by the reaction of the diketo sulfides **1a** and **1b** with biacetyl or benzil as shown in Table 1. To be noted is the very slow deuterium exchange of the hydroxyl protons. The hydroxyl and the methine protons appeared close together as singlets in the NMR spectra. In order to make assignments the sample solutions were shaken with a drop of deuterium oxide. The procedure resulted in a slight decrease in the intensities of the hydroxyl peaks of **2a** and **2b** and almost no change in the case of **3a** and **3b**. In order to reduce the intensities of the hydroxyl peaks of **3a** and **3b** appreciably, it was necessary to heat and shake repeatedly.

*Dehydration of the Diols **2a**, **2b**, **3a**, and **3b**.* To a suspension of the diol (4.0 mmol) in 30 ml of chloroform and 4.0 ml of pyridine cooled in an ice bath, was added 4.0 ml of thionyl chloride. The resultant clear yellow solution was stirred at room temperature for 1 h. Then, the solution was poured into ice and water containing hydrochloric acid, and extracted with chloroform. After washing with water, the extracts were dried over magnesium sulfate and filtered through a short column of silica gel. After solvent evaporation, the residue was crystallized from methanol.

*Condensation of **1b** with Phenylglyoxal.* To a stirred, warm solution of **1b** (1.492 g, 5.0 mmol) and phenylglyoxal (freshly prepared,[5] 740 mg, 5.5 mmol) in 10 ml of methanol was added a solution of sodium methoxide (0.5 g of sodium dissolved in 100 ml of methanol, 10 ml) over a 10-min period. Crystals started to separate slowly. After it had been stirred for 30 min, the solution was allowed to stand for 2 d. The product was collected by filtration and washed well with methanol. **6** was obtained as pale yellow granules in 67.8% yield (1.345 g); recrystallized from benzene–methanol; mp 129—130 °C.

Reaction of Ethyl Azidoformate with Morpholines

Teruko Tsuchida,* Kikuhiko Koyama, Michiharu Mitani, and Hiroshi Takeuchi

Department of Synthetic Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano 380

(Received August 11, 1979)

Synopsis. Ethyl azidoformate (**1**) reacts rapidly with morpholine to give morpholinium azide and 4-(ethoxycarbonyl)morpholine in good yields. With 4-methylmorpholine (**3**), however, the azide **1** reacts at 115 °C with evolution of nitrogen to give formal nitrene-insertion products, 4-methyl-3-(ethoxycarbonylamino)morpholine and 4-(ethoxycarbonylaminomethyl)morpholine. There has not been found any product which might arise from the nitrene-insertion into C–H bond adjacent ot oxygen of **3**. These results can be accounted for on the basis of the n-donor abilities of heteroatoms, O and N.

Ethoxycarbonylnitrene generated photochemically or thermally from ethyl azidoformate inserts exclusively into C–H bonds adjacent to oxygen of cyclic and open-chain ethers.[1-3] The nitrene also exclusively reacts with CH_3 groups of *N,N*-dimethylaniline to give formal insertion product.[4]

The exclusive reactions at these activated C–H bonds have been considered to proceed with the initial formation of O–N or N–N ylids by coordinative attack of the electron-deficient nitrene on the heteroatoms with nonbonded electron pair, followed by the rearrangement to give formal insertion products.

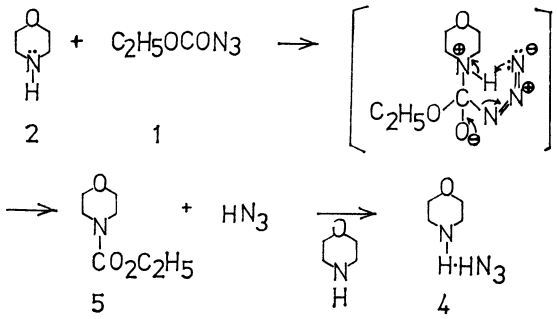
Morpholine and its *N*-substituted derivatives are, therefore, particularly interesting in connection with the possibility of intervention of such ylid intermediates, because of bearing two kinds of C–H bonds activated by the adjacent oxygen and nitrogen atoms, respectively.

Results and Discussion

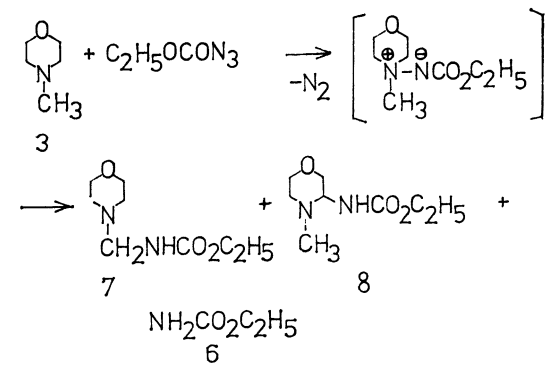
The reaction of ethyl azidoformate (**1**) with morpholine (**2**) was conducted by adding the azide **1** to **2** at room temperature and heating the solution to 120 °C for 2 h with stirring. A white solid formed immediately at the stage of the addition was separated by filtration, and proved to be morpholinium azide (**4**, 86% yield) on the basis of its spectral data. In addition, 4-(ethoxycarbonyl)morpholine (**5**) was obtained in 57% yield from the filtrate by the vacuum distillation. The structure of **5** was characterized by comparison with the authentic sample.

The result described above clearly indicates that the products **4** and **5** were formed by a simple displacement of azide ion[5] from **1** with **2**, which is a strong nucleophile[6] with mobile hydrogen atom on nitrogen, but via neither nitrene nor ylid intermediate, as shown in Scheme 1.

The thermolysis of the azide **1**, however, smoothly proceeded in 4-methylmorpholine (**3**) with evolution of nitrogen at 115 °C. After usual workup involving removal of unchanged **3**, three major products isolated by preparative VPC from a residual oil were identified as ethyl carbamate (**6**), 4-(ethoxycarbonylaminomethyl)morpholine (**7**) and 4-methyl-3-(ethoxycarbonylamino)morpholine (**8**), respectively. The structural assignment of these products, **6**, **7** and **8**, was based on their ^1H NMR and mass spectral data. The product distribution in the oily residue has tentatively been determined as 61.1% of **6**, 13.4% of **7**, 2.5% of **8** and 23% (total) of three unidentified products, instead of their exact yields, on the basis of their VPC peak areas. A further examination of the reaction mixture gave no evidence for the presence of any product which might arise from the reaction at C–H bond activated by the adjacent oxygen.



Scheme 1.



Scheme 2.

Of interest is the fact that the reaction occurs exclusively at C–H bonds adjacent to nitrogen. This can be rationalized in terms of the mechanism in which the N–N ylid is involved as an intermediate. Since nitrogen is a much stronger n-electron donor than oxygen and the N–N ylid is more stable than the O–N ylid, the electron-deficient nitrene attacks preferentially nitrogen over oxygen to give a more stable ylid followed by rearrangement leading to formal nitrene-insertion products, **7** and **8**, even though the detailed mechanism for the rearrangement has not been clear yet.

Experimental

IR spectra were recorded on a Hitachi Model EPI-G3 and ^1H NMR spectra on a JEOL JNM 4H 100 spectrometer.

Mass spectra were obtained by JEOL JMC OlSG-2 spectrometer.

Commercially available morpholine and 4-methylmorpholine were used after distillation. Ethyl azidoformate was prepared according to the method of Lwowski and Mattingly.[7]

Authentic 4-(ethoxycarbonyl)morpholine was prepared from morpholine and ethyl chloroformate by usual procedures.[7]

*Reaction of Ethyl Azidoformate (**1**) with Morpholine (**2**).* The azide **1** (2.0 g; 0.017 mol) was added at room temperature to **2** (7.5 g; 0.087 mol) with stirring. During the addition, a white solid rapidly separated without any evolution of gases. The mixture was then heated to 120 °C and kept at that temperature for 2 h. After cooling to room temperature the resulting solid was separated on a filter, washed with ether, dried *in vacuo* and recrystallized from hot methanol to give **4** as white needles, mp 129.2—130.2 °C (yield; 1.89 g; 86.1%). Soluble in water but insoluble in ether and benzene. IR (KBr) 2450 ($\overset{+}{N}H_2$), 2030 (N_3^-) and 1590 cm^{-1} ($\overset{+}{N}H_2$); ^1H NMR ($(CD_3)_2SO$) $\delta=3.15$ (4H, m, N-CH_2), 3.8 (4H, m, O-CH_2) and 7.35 (2H, br, NH_2, disappered by treatment with D_2O); MS *m/e*: 87 (M−HN_3) and 43 (HN_3); Found: C, 36.82; H, 7.58; N, 43.20%. Calcd for $C_4H_{10}ON_4$: C, 36.91; H, 7.74; N, 43.50%.

The filtrate was fractionally distilled *in vacuo* to give **5** (yield; 1.53 g; 57%): bp 111.2 °C/25 mmHg: IR (neat) 2950 (-CH_3), 1700 (C=O) and 1240 cm^{-1} (=C-O-C); ^1H NMR (CCl_4) $\delta=1.29$ (3H, t, CH_3-), 3.36—3.8 (8H, m, ring proton) and 4.1 (2H, q, -CH_2-); MS *m/e*: 159 (M); Found: C, 52.60; H, 8.49; N, 8.61%. Calcd for $C_7H_{13}O_3N$: C, 52,82; H, 8.23; N, 8.80%. IR spectrum of **5** was identical in all respects with that of an authentic sample.

*Thermolysis of **1** in 4-Methylmorpholine (**3**).* A stirred solution of **1** (2.3 g; 0.02 mol) in **3** (10.1 g; 0.1 mol) was heated to 115 °C and kept at this temperature for 3 h during which time nitrogen was smoothyl evolved. After the nitrogen evolution has ceased, removal of the excess **3** from the reaction mixture *in vacuo* left a residual oil (4.2 g). The residual oil was subjected to preparative VPC on a column (8 mm×2 m) packed with 5% Silicone OV-22 on 60/80 Uniport KS (oven temperature, initial: 110 °C, final: 230 °C, rate: 10 °C/min) to separate four components. Among them, three major components were identified as ethyl carbamate (**6**), 4-(ethoxycarbonylaminomethyl)morpholine (**7**) and 4-methyl-3-(ethoxycarbonylamino)morpholine (**8**), respectively. The product **6** was characterized by comparison of its VPC retention time and IR spectra with those of the authentic sample. The structural assignment of the components **7** and **8** was performed on the basis of their IR, ^1H NMR and mass spectral data. Analytical data for **7**: IR (neat) 3400 (NH), 1720 (C=O) and 1250 cm^{-1} (=C-O-C); ^1H NMR ($CDCl_3$) $\delta=1.28$ (3H, t, CH_3-), 2.05—3.08 (2H, m, N-CH_2), 3.5 (4H, m, H_2C-N-CH_2), 3.71 (4H, m, H_2C-O-CH_2) and 4.2 (2H, q, -CH_2-); MS *m/e* (rel intensity): 159 (M−C_2H_5 24.1), 115 (M−$CO_2C_2H_5$ 7.4), 100 (M−$NHCO_2C_2H_5$ 29.2) and 86 (M−$CH_2NHCO_2C_2H_5$ 30.7). Analytical data for **8**: IR (neat) 3325 (NH), 2800 (N-CH_3) and 1710 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) $\delta=1.25$ (3H, t, CH_3-), 2.3 (3H, s, N-CH_3), 2.4—2.9 (3H, m, HC-N-CH_2), 3.3—3.85 (4H, m, H_2C-O-CH_2), 4.12 (2H, q, -CH_2) and 5.6 (1H, br, -NH-); MS *m/e* (rel intensity): 188 (M 45.5), 173 (M−CH_3 5.4), 159 (M−C_2H_5 69.7), 115 (M−$CO_2C_2H_5$ 17.2) and 100 (M−$NHCO_2C_2H_5$ 72.9).

The fourth component collected by preparative VPC was failed in its structural determination, although ^1H NMR spectra showed no peaks assignable to CH_3-, CH_2- or CH- adjacent to N.

Chemical Studies on Tuberactinomycin. XVII.[1] Synthesis of *threo*-γ-Hydroxy-L-β-lysine, Constituent Amino Acid of Tuberactinomycin A and N

Tadashi TESHIMA, Toshihiko ANDO, and Tetsuo SHIBA*

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received August 17, 1979)

Synopsis. *threo*-γ-Hydroxy-L-β-lysine which is a constituent amino acid of antibiotics tuberactinomycin A and N, was synthesized from *threo*-β-hydroxy-L-ornithine derivative by the Arndt-Eistert reaction. The synthetic amino acid was identical with the natural sample in all respects. Furthermore, a route was established to prepare a protected γ-hydroxy-β-lysine derivative useful for the peptide synthesis.

γ-Hydroxy-β-lysine is a constituent amino acid of peptide antibiotics, tuberactinomycin A and N.[2] Either *threo* or *erythro* isomer of this amino acid was obtained from both tuberactinomycin A and N depending on the hydrolysis conditions. Thus, *threo* isomer was obtained from a hydrolyzate with 6 M hydrochloric acid, whereas *erythro* isomer from that with concentrated sulfuric acid.[2] An intact configuration of the amino acid in the original antibiotics was supposed to be of *threo* form from an assumption of the reaction mechanisms in the acidolysis.[3-5]

Racemic *threo* and *erythro* forms of γ-hydroxy-β-lysine were synthesized from a key intermediate, β-methoxyornithine derivative, resulting in a confirmation of the structure of this amino acid.[6] In the present study, a genuine stereoisomer of the natural amino acid, *i.e.*, *threo*-γ-hydroxy-L-β-lysine, was synthesized via *threo*-β-hydroxy-L-ornithine according to a scheme shown in Fig. 1. An intermediate in the synthetic route, N^{β},N^{ϵ}-bis(benzyloxycarbonyl)-*O*-*t*-butyl-γ-hydroxy-L-β-lysine, was successfully used to the total synthesis of tuberactinomycin N, which will be reported elsewhere.[1]

In the Arndt-Eistert reaction for an elongation of the carbon chain, hydroxyl group must be blocked anyhow. Moreover, it was found in our previous study that γ-hydroxy-β-lysine was very liable to be lactonized.[2] Therefore, a protection of the hydroxyl group was necessary particularly for the purpose of the peptide synthesis. *t*-Butyl group was chosen as the protecting group because of a mildness in the introducing reaction. N^{δ}-Benzyloxycarbonyl-*threo*-β-hydroxy-L-ornithine (**1**) was obtained by a coupling of β-(benzyloxycarbonylamino)propionaldehyde with aqua[*N*-(1-carboxylatoethylidene)glycinato]copper(II) followed by a diastereomeric separation and then an optical resolution enzymatically according to the method reported previously.[7] The compound **1** was converted to bis(benzyloxycarbonyl) derivative **2**, and then to its methyl ester **3**. It was treated with isobutylene in the presence of an acid catalyst to give a fully protected derivative **4**. Saponification of **4** produced a free carboxylic acid **5**, which was treated with ethyl chloroformate and then diazomethane to afford a diazo ketone. Wolff rearrangement for the diazo ketone was carried out in the presence of silver benzoate in methanol. Hydrolysis of the product with 6 M hydrochloric acid gave *threo*-γ-hydroxy-L-β-lysine lactone dihydrochloride (**7**). The lactone dihydrochloride **7** thus synthesized was completely identical with the natural specimen obtained from the hydrochloric acid hydrolyzate of tuberactinomycin N[2] in all respects (Table 1). This is the first synthesis of the natural form of γ-hydroxy-β-lysine, and gave a confirmative conclusion for the supposed configurations of this natural amino acid.

a) R_f value on developing solvent: phenol-water-28% ammonia (30: 10: 1). b) Migration distance toward cathode. Buffer solution: pyridine-acetic acid-water (30: 4: 966).

Experimental

All melting points are uncorrected. NMR spectra were obtained with a Varian XL-100-15 spectrometer using sodium 2,2-dimethyl-2-silapentane-5-sulfonate as an internal standard. The optical rotations were measured with a Perkin-Elmer 141 polarimeter. IR spectra were obtained with a Hitachi EPI-G2 Grating Infrared Spectrophotometer. Thin-layer chromatographies were carried out by the ascending method on silica gel 60 F_{254} using developing solvent, phenol-water-28% ammonia (30:10:1). Paper electrophoreses were carried out at 750 V and 1 mA/cm 1 h on Toyo Roshi No. 51 paper using a buffer solution of pyridine–acetic acid–water (30:4:966).

N^{α}, N^{δ}-*Bis(benzyloxycarbonyl)*-threo-β-*hydroxy*-L-*ornithine* (**2**). To a suspension of N^{δ}-benzyloxycarbonyl-*threo*-β-hydroxy-L-ornithine (**1**)[7] (1.00 g, 3.55 mmol) and triethylamine (1.15 ml, 8.24 mmol) in 300 ml of water–tetrahydrofuran (2:1), was added benzyloxycarbonyl chloride (800 mg, 4.69 mmol) in 4 ml of tetrahydrofuran portionwise with stirring under ice cooling for 2.5 h. After the usual work up for

benzyloxycarbonylation, crystals of the product were obtained: yield 1.32 g (89.2%). It was recrystallized from ethyl acetate–hexane: yield 1.23 g (83.1%), mp 141.5—143 °C, $[\alpha]_D^{20}$+13.8° (c 1.04, CH_3OH).

Found: C, 60.80; H, 5.83: N, 6.62%. Calcd for $C_{21}H_{24}N_2O_7$: C, 60.57; H, 5.81; N, 6.73%.

N^{α},N^{δ} - *Bis(benzyloxycarbonyl)* - threo - *β* - *hydroxy* - L - *ornithine Methyl Ester* (**3**). To a solution of N^{α},N^{δ}-bis(benzyloxycarbonyl)-*threo*-*β*-hydroxy-L-ornithine (**2**) (1.20 g, 2.88 mmol) in 20 ml of methanol, a solution of diazomethane in ether was added until its yellow color remained. After excess diazomethane was decomposed with acetic acid, the reaction mixture was concentrated *in vacuo*. The oily residue was triturated with hexane to give crystals: yield 1.22 g (98.5%). It was recrystallized from ethyl acetate–hexane: yield 1.19 g (95.9%), mp 85—88 °C, $[\alpha]_D^{18}$+5.42° (*c* 1.02, CH_3OH).

Found: C, 61.40; H, 6.31; N, 6.28%. Calcd for $C_{22}H_{26}N_2O_7$: C, 61.38; H, 6.09; N, 6.51%.

N^{α},N^{δ}-*Bis(benzyloxycarbonyl)*-O - t - *butyl* - threo - *β*-*hydroxy*-L-*ornithine* (**5**). To a solution of N^{α},N^{δ}-bis(benzyloxycarbonyl)-*threo*-*β*-hydroxy-L-ornithine methyl ester (**3**) (1.00 g, 2.33 mmol) in 100 ml of dichloromethane and 300 ml of liquid isobutylene in a pressure bottle, 0.2 ml of concentrated sulfuric acid was added under cooling. The mixture was shaken at 37 °C for 11 d and then neutralized with triethylamine. The solution was concentrated *in vacuo*, and the oily residue was purified by silica gel column chromatography using a developing solvent of benzene–ethyl acetate (9:1); yield 910 mg (80.5%), a pale yellow oil. *O*-*t*-Butyl methyl ester (**4**) thus obtained was saponified with 2.81 ml of 1 M sodium hydroxide in 5 ml of *N*,*N*-dimethylformamide at 0 °C. After the usual work up, crystals of the carboxylic acid was obtained: yield 633 mg (71.6%). It was recrystallized from ethyl acetate–ether–hexane; yield 567 mg (64.1%), mp 92—95 °C, $[\alpha]_D^{21}$ −2.07° (*c* 5.07, CH_3OH).

Found: C, 63.65; H, 6.83; N, 5.92%. Calcd for $C_{25}H_{32}N_2O_7$: C, 63.55; H, 6.83; N, 5.93%.

threo-*γ*-*Hydroxy*-L-*β*-*lysine Lactone Dihydrochloride* (**7**). To a solution of N^{α},N^{δ}-bis(benzyloxycarbonyl)-*O*-*t*-butyl-*threo*-*β*-hydroxy-L-ornithine (**5**) (420 mg, 0.890 mmol) in 4 ml of ethyl acetate, *N*-methylmorpholine (0.100 ml, 0.890 mmol) and ethyl chloroformate (0.085 ml, 0.89 mmol) were added at −20 °C with stirring. The reaction mixture was stirred for 1 h, and insoluble material was filtered off. To the filtrate, excess diazomethane in ether was added at −20 °C with stirring. The reaction mixture was stirred at this temperature for 1 h and then at room temperature overnight. Insoluble material was filtered off and the filtrate was concentrated *in vacuo*. A diazo ketone was obtained as a yellow oil.

To a solution of this oily residue in 4 ml of methanol, silver benzoate (70 mg, 0.306 mmol) in 0.7 ml of triethylamine was added and the mixture was stirred at room temperature in the dark for 4 h and then concentrated *in vacuo*. After the residue was dissolved in ethyl acetate, insoluble inorganic material was filtered off. The filtrate was washed with 10% citric aicd, saturated sodium hydrogencarbonate, and water. Organic layer was dried over anhydrous magnesium sulfate and concentrated *in vacuo* to give a methyl ester **6**.

A suspension of **6** in 25 ml of hydrochloric acid was heated under reflux for 3 h, and concentrated *in vacuo*. The residue was triturated with ethanol and ether to give crystals: yield 58.1 mg (30.1%). It was recrystallized from ethanol–ether: yield 45 mg (23%), mp 252—255 °C (dec), $[\alpha]_D^{21}$ +63° (*c* 0.5, H_2O).

Found: C, 32.97; H, 6.59; N, 12.79; Cl, 32.33%. Cacld for $C_6H_{14}N_2O_2Cl_2$: C, 33.20; H, 6.50; N, 12.90; Cl, 32.66%.

Reaction of Dibenzyl Disulfide and Analogues with Na_2S_x–NaOH[1] Supplementary Data for Mechanism for Reaction of *p*-Nitrotoluene with Na_2S_x[2]

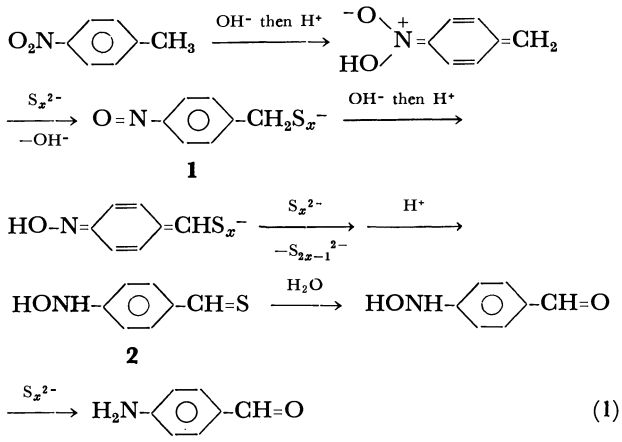
Yoshiro OGATA* and Yoshiaki NAKAGAWA

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received August 31, 1979)

Synopsis. Reaction of dibenzyl disulfide with aquoethanolic NaOH gave benzaldehyde and α-toluenethiol. On the other hand, the reaction of dibenzyl disulfide with Na_2S_x in the presence of NaOH gave preferentially benzaldehyde alone. These facts are explained by the further reaction of α-toluenethiol with Na_2S_x giving benzaldehyde and support our mechanism proposed previously for the reaction of *p*-nitrotoluene with Na_2S_x.

In the previous article,[2] we reported the mechanism for the reaction of *p*-nitrotoluene with Na_2S_x. The mechanism involves a benzyl polysulfide derivative as one of the intermediates to give *p*-aminobenzaldehyde.



Among steps in this mechanism, there is no literature on the step for the formation of thioaldehyde (**2**) from benzyl polysulfide derivative (**1**) and, in the reaction path, there may be dibenzyl polysulfide derivatives produced from **1**. It has been reported that, for example, dithiodiacetic acid[3,4] or its ester[5] which has electron-withdrawing groups on the α-carbon to the dithio group decomposes by OH^- to give thioaldehyde and thiol, but the reaction of dibenzyl disulfide with OH^- is unknown. Hence dibenzyl disulfide and bis(*p*-nitrobenzyl) disulfide were selected as model compounds, and they were allowed to react with NaOH or Na_2S_x–NaOH. Further, the reaction of α-toluenethiol with Na_2S_x–NaOH was also examined.

TABLE 1. YIELDS OF PRODUCTS FROM A REACTION OF DIBENZYL DISULFIDE WITH NaOH OR Na_2S_x–NaOH IN H_2O–EtOH (2: 1) BY REFLUXING FOR 1 h

Products	Yield (%)	
	with NaOH[a]	with Na_2S_x–NaOH[b]
PhCHO	24.0	49.0
$PhCH_2SH$	24.4	trace
PhCOOH	3.1	4.5
$PhCH_2OH$	3.3	0.8

a) $[NaOH]_0 = 0.74$ M. b) $[NaOH]_0 = 0.70$ M, $[Na_2S \cdot 9H_2O]_0 = 0.17$ M, $[S]_0 = 0.65$ M; A mixture of Na_2S and S can form Na_2S_x ($x = 1$—5), its initial concentration being *ca.* 0.17 M as Na_2S_4.

Results and Discussion

Reaction with NaOH. The reaction of dibenzyl disulfide with aquoethanolic NaOH gave benzaldehyde, α-toluenethiol and a small amount of benzoic acid and benzyl alcohol. Yields of products are listed in Table 1.

$$PhCH_2SSCH_2Ph \xrightarrow{NaOH} PhCHO + PhCH_2SH + PhCOOH + PhCH_2OH \quad (2)$$

This type of reaction is expected from the alkaline decomposition of dithiodiacetic acid[3,4] or its ester[5] which gives $HSCH_2COOH$ and OHCCOOH.

Benzoic acid and benzyl alcohol appearing in Eq. 2 may be the products of Cannizzaro reaction of benzaldehyde.

Reaction with Na_2S_x–NaOH. The reaction of dibenzyl disulfide with aquoethanolic Na_2S_x, which was prepared from Na_2S and S *in situ* (see Experimental Section), in the presence of NaOH gave benzaldehyde and a small amount of benzoic acid and benzyl alcohol along with a trace amount of α-toluenethiol (Table 1). The yield of benzaldehyde (49%) in the reaction of dibenzyl disulfide with Na_2S_x–NaOH is nearly equal to the sum of yields of benzaldehyde (24%) and α-toluenethiol (24%) in the reaction with NaOH. Hence, the produced α-toluenethiolate ion may react further with Na_2S_x to give benzyl polysulfide ion, and then deprotonation occurs to facilitate the S–S bond fission as observed with other disulfide compounds such as dibenzyl disulfide (Eq. 3).

$$PhCH_2S^- \xrightarrow[-S^{2-}]{S_{x+1}^{2-}} PhCH_2S\text{-}S_x^- \xrightarrow{OH^-} \bar{P}hCH\text{-}S\text{-}S_x^- \quad (3a)$$

$$\bar{P}hCHS\text{-}S_x^- \xrightarrow{-S_x^{2-}} PhCH{=}S \xrightarrow{H_2O} PhCH{=}O \quad (3b)$$

Thiobenzaldehyde is easily hydrolyzed as reported previously by King[6] (Eq. 3b).

The reaction of *α-toluenethiol* with aquoethanolic Na_2S_x in the presence of NaOH gave mainly benzaldehyde, but no reaction occurred with NaOH. This fact supports the above mechanism, *i.e.*, polysulfide ion is necessary for the oxidation of thiol to the corresponding aldehyde.

In the reaction of *bis(p-nitrobenzyl) disulfide*, *p*-aminobenzaldehyde was identified by means of NMR as one of the products, which suggests that the analogous mechanism involving S–S cleavage followed by the

hydrolysis of thioaldehyde would operate.

These results suggest that the benzyl polysulfide derivatives or dibenzyl polysulfide derivatives, if produced during the reaction of *p*-nitrotoluene with Na_2S_x, should be easily converted into benzaldehyde derivatives by NaOH and Na_2S_x, so that the results support our mechanism previously postulated.

Experimental

Melting points were measured by a Yanagimoto micro melting point apparatus and were not corrected. NMR spectra were recorded on a Hitachi R-24B NMR spectrometer using Me_4Si as an internal standard. The GLC analysis was performed with a Yanagimoto G 180 gas chromatograph with a flame ionization detector.

Materials. Dibenzyl disulfide was prepared by the method of Minoura;[7] mp 69—70 °C (lit,[7] 71 °C); NMR ($CDCl_3$): δ 3.59 (s, 4H, CH_2), 7.24 (s, 10H, ArH). Bis(*p*-nitrobenzyl) disulfide was prepared according to Price;[8] mp 124.5—126 °C (lit,[8] 126.5 °C); NMR ($CDCl_3$): δ 3.69 (s, 4H, CH_2), 7.4 (d, 4H, ArH, J=9 Hz), 8.2 (d, 4H, ArH, J=9 Hz).

Reaction of Dibenzyl Disulfide with NaOH. A hot solution (14 ml) of NaOH (0.65 g, 16 mmol) was poured into a 100 ml round-bottomed flask containing a hot ethanolic solution (7 ml) of dibenzyl disulfide (1.00 g, 4.1 mmol). The mixture was heated under reflux for 1 h. Most of the products were extracted with diethyl ether from the alkaline solution and then the aqueous solution was acidified with dil. H_2SO_4. The acidic solution was also extracted with diethyl ether and the extract containing benzoic acid was esterified by diazomethane. Both extracts from alkaline and acidic solutions were analyzed by GLC, using two sorts of columns (2.5 mm × 1 m), PEG 20 M and Silicone OV 17, at 100—250 °C. Biphenyl was used as an internal standard.

Reaction of Dibenzyl Disulfide with Na_2S_x–NaOH. The analogous reaction of dibenzyl disulfide was done with a mixture of dibenzyl disulfide (1.00 g, 4.1 mmol), $Na_2S_x \cdot 9H_2O$ (0.83 g, 3.5 mmol), S (0.39 g, 1.2×10^{-2} g atom) and NaOH (0.65 g, 16 mmol). The products and their yields were listed in Table 1. All products were identified by comparison of GLC peaks with those authentic specimens.

Synthesis of 3-Carbamoyl-4-[(β-D-ribofuranosyl)methyl]pyrazole, a Pyrazole Homo-*C*-nucleoside[1]

Tsuneo SATO and Ryoji NOYORI*

Department of Chemistry, Nagoya University, Chikusa, Nagoya 464

(Received September 17, 1979)

Synopsis. A facile, stereocontrolled synthesis of the title pyrazole homo-*C*-nucleoside is described.

Recently we have developed efficient routes to a variety of natural[2] and unnatural *C*-nucleosides.[3] Significant biological activities displayed by pyrazole nucleosides[4] have prompted us to make the related *C*-nucleoside analogues. Outlined herein is the stereospecific synthesis of a pyrazole homo-*C*-nucleoside.[5]

The readily accessible chiral lactone **1** was converted to **2**. The ester **2** was then reduced with diisobutylaluminum hydride[6] to give the corresponding aldehyde in a high yield, which in turn was condensed with methoxycarbonylmethylenetriphenylphosphorane[7] to produce **3**. 1,3-Dipolar cycloaddition across the electron-deficient double bond was effected by diazomethane and the resulting cycloadduct was aromatized by treating with bromine, giving rise to **4**. Ammonolysis of the ester function, giving **5**, and removal of the protective groups led to the desired homo-*C*-nucleoside **6**.

Experimental

General. All melting points are uncorrected. IR spectra were recorded on a JASCO IRA-1 spectrometer. ^1H and ^{13}C NMR spectra were obtained using a Varian HA-100D spectrometer and a Varian CFT-20 spectrometer, respectively. The chemical shifts are recorded in parts per million relative to tetramethylsilane as an internal standard. UV spectra were recorded on a Hitachi 323 recording spectrophotometer. Optical rotations were measured with a JASCO DIP-SL automatic polarimeter. Analytical thin-layer chromatography (TLC) was done using 0.25-mm layers of silica gel 60 PF_{254} (E. Merck) and preparative TLC was performed using 20×20 cm glass plates coated with a 1.0 mm layer of silica gel 60 PF_{254}. The position of spots is shown by R_f values. For column chromatography E. Merck Kiesergel 60 (70—230 mesh) was used.

6 R = R' = H

Methyl 2-(2,3-O-Isopropylidene-5-O-t-butyldimethylsilyl-β-D-ribofuranosyl)acetate (2). A mixture of methyl 2-(2,3-*O*-isopropylidene-β-D-ribofuranosyl)acetate[8,11a] (5.72 g, 23.3 mmol), *t*-butyldimethylsilyl chloride (5.41 g, 34.9 mmol), and imidazole (4.76 g, 69.8 mmol)[9] in 40 ml of dry DMF was stirred at 25 °C for 12 h, and then evaporated *in vacuo*. The residue was partitioned between ethyl acetate (100 ml) and brine (20 ml), and organic phase was filtered, dried (Na_2SO_4), and evaporated, leaving a syrup. Chromatography on a silica gel column using hexane–ethyl acetate (5:1) as an eluent gave 8.51 g (100%) of **2** as a colorless syrup. R_f=0.46 (hexane–ethyl acetate (2:1)); $[\alpha]_D^{21}$ −13.6° (*c* 1.62, $CHCl_3$); IR (neat) 1738 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 0.02 (s, CH_3), 0.85 (s, *t*-C_4H_9), 1.29 and 1.46 (s, isopropylidene CH_3), 2.58 (d-like, *J*=6.1 Hz, CH_2CO-OCH_3), 3.84 (s, OCH_3), 3.66 (d-like, *J*=3 Hz, $H_{5'}$), 4.02 (m, $H_{4'}$), 4.28 (m, $H_{1'}$), 4.38 (dd, *J*=4.1, 6.1 Hz, $H_{2'}$), 4.63 (dd, *J*=3.0, 6.1 Hz, $H_{3'}$); ^{13}C NMR ($CDCl_3$) δ 17.89, 25.52, 25.82, 27.36, 38.62, 51.34, 63.79, 81.18, 82.06, 84.66, 84.97, 113.74, 170.74.

Methyl 4-(2,3-O-Isopropylidene-5-O-t-butyldimethylsilyl-β-D-ribofuranosyl)crotonate (3). A freshly prepared solution of diisobutylaluminum hydride[6] in toluene (1.6 M, 17.0 ml, 27.1 mmol) was added dropwise over a period of 10 min to a slution of **2** (7.51 g, 20.9 mmol) in toluene (30 ml) at −78 °C under argon. The reaction mixture was then stirred at this temperature for additional 1 h. The mixture was diluted with ether (30 ml) and then saturated NH_4Cl solution (5 ml) was carefully added. The mixture was warmed to room temperature and filtered with a Celite 545 pad. The filtrate was evaporated under reduced pressure to give 2-(2,3-*O*-isopropylidene-5-*O*-*t*-butyldimethylsilyl-β-D-ribofuranosyl)acetaldehyde (6.32 g, 92%) as a colorless syrup. This material was subjected to the next reaction without purification. A mixture of this aldehyde (6.32 g, 19.2 mmol) and methoxycarbonylmethylenetriphenylphosphorane[7] (20.9 g, 65.6 mmol) in dry dichloromethane (60 ml) was stirred for 12 h at 25 °C. The reaction mixture was evaporated and the residue was chromatographed on a silica gel column using hexane–ethyl acetate (10:1) as an eluent. The resulting product was evaporated, leaving 3.98 g (54%) of **3** as a colorless syrup. In addition, the starting aldehyde was recovered (2.28 g, 36%). R_f=0.53 (hexane–ethyl acetate (2:1)); $[\alpha]_D^{21}$ −28° (*c* 0.62, $CHCl_3$); IR (neat) 1724 (C=O), 1660 cm^{-1} (C=C); ^1H NMR ($CDCl_3$) δ 0.03 and 0.83 (s, *t*-C_4H_9, $(CH_3)_2$), 1.26 and 1.45 (s, isopropylidene CH_3), 2.44 (m, CH_2CH=CH), 3.66 (d-like, *J*=3 Hz, $H_{5'}$), 3.66 (s, OCH_3), 3.94 (m, $H_{1'}$ and $H_{4'}$), 4.24 (dd, *J*=5.0, 6.3 Hz, $H_{2'}$), 4.58 (dd, *J*=4.0, 6.3 Hz, $H_{3'}$), 5.86 (dt, *J*=1.4, 16.0 Hz, CH=C<u>H</u>$COOCH_3$), 6.90 (dt, *J*=7.0, 16.0 Hz, C<u>H</u>=$CHCOOCH_3$); ^{13}C NMR ($CDCl_3$) δ 18.32, 25.57, 25.88, 27.47, 36.32, 51.16, 63.67, 81.99, 83.19, 84.53, 84.77, 114.08, 123.41, 144.30, 166.46. Found: *m/e* 371.1873. Calcd for $C_{18}H_{31}O_6Si$: (M−CH_3), 371.1890.

3-Methoxycarbonyl-4-[(2,3-O-isopropylidene-5-O-t-butyldimethylsilyl-β-D-ribofuranosyl)methyl]pyrazole (4). A solution of **3** (3.83 g, 9.92 mmol) in 10 ml of ether was cooled at 0 °C and to this was added a solution of diazomethane (49.6 mmol) in ether (50 ml). The resulting yellow solution was stirred at 25 °C for 12 h and then evaporated to dryness leaving 4.25 g (100%) of 3-methoxycarbonyl-4-[(2,3-*O*-isopropylidene-5-*O*-*t*-butyldimethylsilyl-β-D-ribofuranosyl)methyl]-2-pyrazoline as a yellow syrup. This material was not further purified. To the mixture of the pyrazoline (4.25 g, 9.92 mmol) and dry $NaHCO_3$ (4.17 g, 49.6 mmol) in dry chloroform (50 ml) was added drowpise a solution of bromine in chloroform (1.0 M solution, 16.9 mmol). The reaction mixture was stirred at 0 °C for 1 h. A solution of 10% sodium thiosulfate (30 ml) was added and the solution was stirred for additional 20 min. The organic phase was separated and the aqueous layer was extracted with ethyl acetate (3×20 ml). The combined extracts were dried (Na_2SO_4) and evaporated. The residue was chromatographed on a silica gel column using hexane–ethyl acetate (1:1) as an eluent. The pyrazole **4** was obtained as a colorless syrup (1.27 g, 30%). R_f=0.29 (hexane–ethyl acetate (1:1)); $[\alpha]_D^{21}$ −25° (*c* 1.5, $CHCl_3$); IR ($CHCl_3$) 3460 (NH), 1728 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 0.03 and 0.90 (s, *t*-C_4H_9, $(CH_3)_2$), 1.32 and 1.52 (s, isopropylidene CH_3), 3.10 (m, CH_2-pyrazole), 3.74 (d-like, *J*=4.0 Hz, $H_{5'}$), 3.94 (s, OCH_3), 4.0—4.3 (m, $H_{1'}$ and $H_{4'}$), 4.40 (dd, *J*=4.1, 6.1 Hz, $H_{2'}$), 4.66 (dd, *J*=3.8, 6.1 Hz, $H_{3'}$), 7.70 (br s, H_5); ^{13}C NMR ($CDCl_3$) δ 18.20, 25.53, 25.78, 27.37, 28.72, 51.30, 63.78, 82.05, 84.26, 84.67, 113.67, 120.02, 132.51, 138.26, 162.67; UV λ_{max} (CH_3OH) 221 nm (ε 7350). Found: *m/e* 426.2181. Calcd for $C_{20}H_{34}O_6N_2Si$: M, 426.2186. The NMR data of **4** are consistent with the assigned β structure. The signals due to the isopropylidene methyls occur at δ 1.32 and 1.52 in the ^1H spectrum (Δδ 0.20 ppm)[10] and δ 25.53 and 27.37 in the ^{13}C spectrum (Δδ 1.84 ppm),[11] and the observed chemical shift differences are apparently in the β range.

3-Carbamoyl-4-[(β-D-ribofuranosyl)methyl]pyrazole (6). A solution of the pyrazole **4** (1.00 g. 2.35 mmol) in methanol (50 ml) was saturated with ammonia at 0 °C and stirred at 25 °C for 4 d. Evaporation of the solvent gave yellow powder. Purification on silica gel plates eluting with hexane–ethyl acetate (1:2) gave 3-carbamoyl-4-[(2,3-*O*-isopropylidene-5-*O*-*t*-butyldimethylsilyl-β-D-ribofuranosyl)methyl]-pyrazole (**5**) (313 mg. 32%) as a white powder. This compound was recrystallized from ethyl acetate, mp 202—204 °C. In addition, unreacted **4** was recovered (630 mg, 63%). R_f=0.15 (hexane–ethyl acetate (1:1)); $[\alpha]_D^{20}$ −15° (*c* 0.15, CH_3OH); IR ($CHCl_3$) 3200—3540 (NH and NH_2). 1678 cm^{-1} (C=O); ^1H NMR (acetone-d_6) δ 0.05 and 0.91 (s, *t*-C_4H_9, $(CH_3)_2$), 1.15 and 1.33 (s, isopropylidene CH_3), 3.00 (m, CH_2–pyrazole), 3.64 (m, $H_{5'}$), 3.82 (m, $H_{1'}$), 4.08 (m, $H_{4'}$), 4.40 (dd, *J*=3.5, 6.5 Hz, $H_{2'}$), 4.55 (dd, *J*=3.2, 6.5 Hz, $H_{3'}$), 6.30 and 6.98 (br, NH_2), 7.60 (m, H_5), 11.10 (br, NH); ^{13}C NMR (dimethyl-d_6 sulfoxide) δ 17.96, 25.41, 25.79, 27.25, 28.31, 63.74, 81.71, 84.02, 84.15, 84.36, 112.78, 117.27, 130.52, 130.63, 164.55; UV λ_{max} (CH_3OH) 221 nm (ε 7800). Found: C, 55.69; H, 8.22; N, 10.14%. Calcd for $C_{19}H_{33}O_5N_3Si$: C, 55.45; H, 8.08; N, 10.21%.

The amide **5** (300 mg, 0.730 mmol) was stirred in 3 ml of 90% aqueous trifluoroacetic acid at 25 °C for 10 min and the mixture was evaporated to dryness *in vacuo*. The crude product was triturated with ether (3×3 ml). Compound **6** was obtained as a hygroscopic white powder (159 mg, 85%). ^1H NMR (dimethyl-d_6 sulfoxide) δ 2.92 (m, CH_2–pyrazole), 3.21 (m, $H_{5'}$), 3.64 (m, $H_{1'}$, $H_{2'}$, $H_{3'}$, and $H_{4'}$), 4.4—5.8 (br, OH), 7.10 (m, H_5), 7.10 and 7.64 (br, NH_2); ^{13}C NMR (dimethyl-d_6 sulfoxide) δ 29.18 (CH_2-pyrazole), 62.76 ($C_{5'}$), 72.34, 75.09, 84.02, 85.14 ($C_{1'}$–$C_{4'}$ of ribose), 119.38, 132.02, 132.15, 165.84; UV λ_{max} (CH_3OH) 222 nm.

This work was supported in part by the Ministry of Education, Japanese Government (Grant-in-Aid, No. 401538). We express our thanks to Fujisawa Pharmaceutical Co. for performing the elemental analysis and Ono Pharmaceutical Co. for obtaining the exact mass spectra.

The Kinetics of the Darzens Reaction of *p*-Substituted Benzaldehydes and Phenacyl Chloride

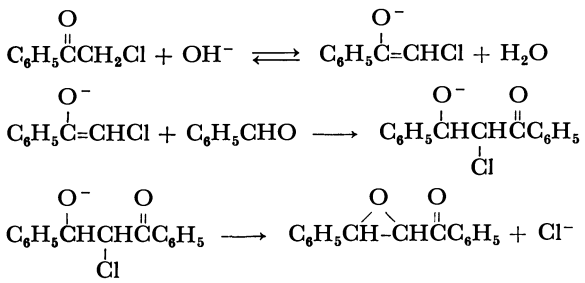
Raj Kumar BANSAL* and Miss Kanta SETHI

9 *Department of Chemistry, Indian Institute of Technology, New Delhi, India*

(Received June 23, 1979)

Synopsis. The rate constants for the base-catalyzed Darzens reaction of *p*-substituted benzaldehydes and phenacyl chloride have been measured at two temperatures in aqueous dioxane. Enthalpies and entropies of activation have been evaluated. The reactivity of the *p*-substituted benzaldehydes was found to follow the order *p*-NO_2>*p*-Cl>*p*-Br>H>*p*-CH_3>*p*-OCH_3. The kinetic data can be correlated with ρ values according to the Hammett equation.

The Darzens reaction often involves the condensation between aldehyde or ketone and α-halogenomethylene compound to produce an oxirane containing derivative. The mechanism of the reaction between benzaldehyde and phenacyl chloride catalyzed by sodium hydroxide to form an epoxy ketone appears to be established from the work of Bartlett.[1] It is generally agreed that the following sequence of reactions is involved:



Furthermore, it is argued from non-kinetic methods that the second step is the rate-determining step of the reaction.[2]

A brief study of the methoxide ion catalyzed reaction between benzaldehyde and substituted phenacyl chlorides was made[3] to evaluate the effect of substituents on rate. There is no kinetic investigation, however, on the rate of the reaction when the substituents are located on benzaldehyde. In our continuing study[4] of the various aspects of the Darzens reaction we have measured the rates of the reaction between *p*-substituted benzaldehydes and phenacyl chloride using sodium hydroxide in dioxane–water solvent mixture. We have also examined the application of the Hammett equation in this reaction.

Experimental

Materials. All liquid aldehydes were purified by fractional distillation and stored under nitrogen: benzaldehyde, bp 62—62.5 °C/10 mmHg, *p*-methoxybenzaldehyde, (E. Merck), bp 88—89 °C/2 mmHg, *p*-methylbenzaldehyde (Fluka, A. G.), bp 72—73 °C/3 mmHg. *p*-Nitrobenzaldehyde (BDH) mp 105.5—106 °C (hexane), *p*-bromobenzaldehyde mp 67—67.5 °C (aq ethanol), phenacyl chloride (Fluka, A. G.), mp 56—57 °C (petroleum ether) were all purified by recrystallization. Analar grade dioxane was purified by refluxing with sodium metal followed by distillation.[5]

Experimental Procedure. From several initial preliminary runs it was established that the rate could be conveniently measured in 40% aq dioxane at 15 °C and 25 °C. Appropriate volumes of solutions of the components except phenacyl chloride were transferred to a nitrogen flushed, round bottomed flask fitted with a rubber septum and brought to the desired temperature. The reaction was initiated by injecting a required amount of concentrated solution of phenacyl chloride in dioxane with the help of a hypodermic syringe. The self-condensation of phenacyl chloride was precluded by using 9—15 fold excess of benzaldehyde. Five ml aliquots were withdrawn with the aid of a syringe and run into cold standard sulfuric acid. The remaining sulfuric acid was back-titrated against sodium hydroxide of known strength. The final reading was taken after the reaction flask was allowed to stand for 70 h. The rate constants were calculated from linear plots obtained by using the standard third order equation.[6]

Results and Discussion

All the runs were made at 15 °C and 25 °C in 40% aqueous dioxane (v/v). Sodium perchlorate of 0.01 M strength was employed to maintain a constant ionic strength. Duplicate runs were made in each case. The runs were carried out to about 60—70% completion, the reaction complies to a third order kinetics being first order in the concentration of each reactant. Rate constants were calculated from linear third order plots. Appropriate data are summarized in Table 1.

Table 1. Third order rate constants and activation parameters of base-catalysed condensation between *p*-substituted benzaldehydes and phenacyl chloride in aqueous dioxane

Compound	*p*-Substituent	$10^{-1}k/l^2$ mol^{-2} s^{-1} 15C°	25°C	ΔH / kcal mol^{-1}	$-\Delta S^*$ / e.u.
I	OCH_3	0.600±0.012	1.296±0.012	12.56±0.191	11.30±0.466
II	CH_3	0.676±0.017	1.397±0.029	11.76±0.249	13.97±0.838
III	H	0.764±0.012	1.484±0.010	10.98±0.134	16.33±0.418
IV	Br	0.965±0.019	1.854±0.026	10.47±0.046	17.58±0.150
V	Cl	0.989±0.016	1.878±0.028	10.28±0.070	18.20±0.222
VI	NO_2	1.768±0.015	2.890±0.033	7.74±0.042	25.88±0.141

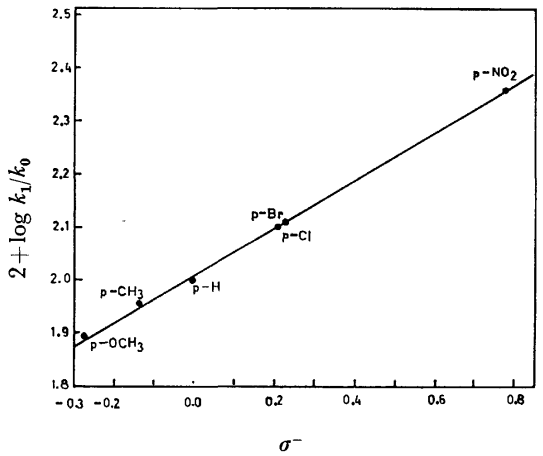


Fig. 1. Hammett plot of condensation of *p*-substituted benzaldehydes with phenacyl chloride.

There is a regular variation in the rates with the nature of the *p*-substituents. The order of reactivity being $NO_2 > Cl > Br > H > CH_3 > OCH_3$ *i.e.* electron-withdrawing groups increase while electron-donating groups decrease the rate. This fact is also borne out by the enthalpies of activation (ΔH^*) values calculated for these reactions which are 7.8 kcal/mol for the *p*-NO_2 and 12.56 kcal/mol for the *p*-OCH_3 groups.

The sign and magnitude of the reaction constant, ρ in the Hammett equation are often evaluated to assess the charge type of the transition state. The ρ value from the Hammett plot (Fig. 1) has been found to be $+0.446$ ($r=0.998$) by least squares method. The small value reflects a weak interaction between the substituent and the reaction site. It, however, does indicate the transition state has a negative character.

Adsorptive Mechanism on Activated Carbon in the Liquid Phase. III. The Relationship between the Physical Constants of Organic Compounds and Their Adsorbabilities on Activated Carbon from an Aqueous Solution[1)]

Ikuo Abe,* Katsumi Hayashi, Mutsuo Kitagawa,** and Toshihiro Urahata

Osaka Municipal Technical Research Institute, Ogimachi, Kita-ku, Osaka 530

(Received January 30, 1979)

In order to evaluate the adsorbability for a given activated carbon from a knowledge of the physical properties of the adsorbate, the partition coefficients (α) of 93 organic compounds between the solution and the adsorbed phases at an infinite dilution have been calculated and correlated with the various physical constants. For aliphatic monofunctional compounds, a good linear relationship is obtained between log α and the following physical constants: molecular weight, molar attraction constant, and modified organicity/inorganicity value. This indicates that these physical constants are useful for predicting the adsorbability of aliphatic monofunctional compounds and that a straight line represents the adsorption characteristics of a given activated carbon. The correlation coefficient between the log α value and the physical constants for multifunctional compounds is lower than that for monofunctional compounds. The adsorptive mechanism on activated carbon in an aqueous solution is discussed on the basis of the conclusion obtained in the previous paper.

The ability to predict the adsorbability for a given adsorbent from a knowledge of the physical properties of the adsorbate has long been an important objective in adsorbent-adsorbate interaction research. In gas-phase adsorption, the decisive component of the adsorption forces on an activated carbon surface is the dispersion component of the Van der Waals forces. Therefore, the adsorptive interaction is strongly dependent on the polarizability of the molecules. Since the polarizability of a molecule is approximately proportional to the volume of a molecule or molar volume, the adsorbability can also be evaluated in terms of the molar volume[2)] or the parachors.[3)] Reucroft *et al.*[4)] studied the relationship between the adsorbability and various physical constants and concluded that the molar refraction gives a good correlation. However, no similar investigation in liquid-phase adsorption has been thoroughly undertaken in contrast to that in the gas phase. A brief survey of adsorption from the liquid phase was, though, made by Hassler.[5)] He listed all the factors influencing adsorption at the carbon-liquid interface and noted that such physical properties as the molecular weight and the solubility significantly influenced the adsorbability. The significance of these factors has also been pointed out by numerous other investigators.[6–14)] Pouchly and Vavruch[15)] noted that the main factor was the general rule of the mutual affinity of substances with similar polarities. From this rule, it is expected that nonpolar substances will be more readily adsorbed on activated carbon, a nonpolar adsorbent, than polar substances. Wohleber and Manes[16)] presented a method for estimating the adsorbability of a partially miscible organic liquid from a water solution on an activated carbon by the knowledge of the adsorbability of the vapors of the solute and the solvent. The method, which is based on the Polanyi adsorption potential theory,[17)] suggests that the adsorbability in the liquid phase can be estimated from the molar volume, the parachor, or the molar refraction, which are used as the criteria of adsorbability in the gas phase. Abe *et al.*[18)] reported that the adsorption process of aliphatic monofunctional compounds is energetically similar to the precipitation process of the hydrocarbon portion of the solute. This suggests that the adsorbability can be estimated from the volume of the hydrocarbon portion of the solute. These discussions of the relationship between the adsorbability in the liquid-phase adsorption and the physical constants have been so far done almost always qualitatively, because they are based on limited data for a small number of compounds. Therefore, it is desirable to relate quantitatively the adsorbability to the physical constants for a large number of compounds. Giusti *et al.*[11)] have measured the amounts of adsorption of 90 organic compounds on an activated carbon, but have not discussed the subject thoroughly. Since a good correlation has been obtained between our adsorption data in the previous paper[18)] and Giusti's data, in this paper we have related the adsorbability to the physical constants quantitatively by using both sets of data. Furthermore, in order to find a physical constant with a good correlation with the adsorbability, we have also examined the physical constants which have been used for the prediction of the adsorbability on the other adsorption systems. For example, the inorganicity/organicity value has been used for predicting the affinity of dyes on fibers.[19,20)] The partition coefficient between water and 1-octanol has been used for estimating the affinity of organic compounds in the hydrophobic region in a protein molecule.[21,22)] The molar attraction constant, which gives a quantitative measure of the relative mutual attraction of organic molecules to one another as a result of dispersion forces, has been used as a physicochemical criterion for the sorption at the membrane-solution interface in reverse osmosis.[23)]

In this paper we have examined the correlation between the adsorbabilities of 93 organic compounds and these physical constants for predicting the adsorbability in terms of the physical constant. Furthermore, we have examined whether or not these results can be successfully explained by the adsorptive mechanism proposed in the previous paper.[18)]

a) Our data.[18] b) Giusti's data.[11] c) Calculated from Eq. 2.

Procedure

In a previous paper[18] the adsorption isotherms of 22 aliphatic monofunctional compounds from an aqueous solution on Pittsburgh Activated Carbon-grade CAL activated carbon have been determined, and the adsorbabilities of the solutes at an infinite dilution have been calculated. The adsorbability (α) has been defined as follows:

$$\alpha \equiv \lim_{C \to 0} \frac{X}{C}, \tag{1}$$

where X is the amount of adsorbed solute on carbon (mg/g) and C is the equilibrium concentration of the solute (mg/l). The constant, α, represents the partition coefficient between the solution and the adsorbed phases at an infinite dilution. The values of α for the 22 compounds are presented in Table 1. Giusti *et al.*[11] have reported the adsorption data for 90 compounds on Westvaco Nuchar Activated Carbon-grade WV-G activated carbon. They determined the adsorbability for each compound by measuring the amount of adsorption at an equilibrium concentration under the following conditions: a concentration of activated carbon of 5000 mg/l, and an initial concentration of the solute (C_0) of 1000 mg/l. We have calculated the value of $(C_0-C)/C$, which represents the partition coefficient at the equilibrium concentration, C, from their data.

Figure 1 shows the relationship between the value of $\log \alpha$ in our data and the values of $\log\{(C_0-C)/C\}$ calculated from Giusti's data for the common 19 compounds included in both sets of data. It can be seen from Fig. 1 that $\log \alpha$ is related to $\log\{(C_0-C)/C\}$ by the following equation:

$$\log \alpha = 1.21 \log \frac{C_0-C}{C} - 0.195. \tag{2}$$

The correlation coefficient (r) between $\log \alpha$ and $\log\{(C_0-C)/C\}$ obtained by the regression analysis was high, $r=0.957$, in spite of the difference in the carbon used. Assuming that Eq. 2 was applicable to the other 71 compounds, the α values for the 71 compounds were calculated from Eq. 2. These values are also tabulated in Table 1. In this manner, the values of α for all 93 organic compounds were determined.

The correlation between the adsorbabilities (α) and physical constants (x) were tested by means of the following linear relation:

$$\log \alpha = ax+b, \tag{3}$$

where a and b are constants. By regression analysis, the correlation coefficient (r) and the a and b constants were determined.

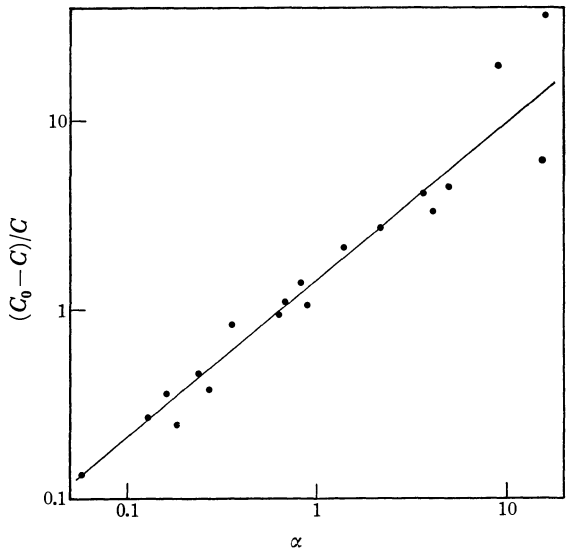

Fig. 1. Relationship between α in our data and $(C_0-C)/C$ calculated from Giusti's data.

Results

Molecular-size Parameters. The relationship between the molecular weight (M) and $\log \alpha$ is given in Fig. 2, while the results of the regression analysis are given in Table 2. The correlation coefficient was very high for the aliphatic monofunctional compounds and for all the aromatics except benzene, but for the aliphatic multifunctional compounds it was low. It can be seen from Table 2 or Fig. 2 that the α value for the aliphatic monofunctional compounds is approximately doubled for each rise of 10 in the molecular weight. As can be seen from Table 2, the correlation coefficient between the molar volume (V) and $\log \alpha$ was also high for aliphatic monofunctional compounds, and the correlation with the carbon number (N) of compound was good for all the compounds.

Aqueous Solubility (C_s). Figure 3 shows the relationship between $\log C_s$ and $\log \alpha$. The correlation

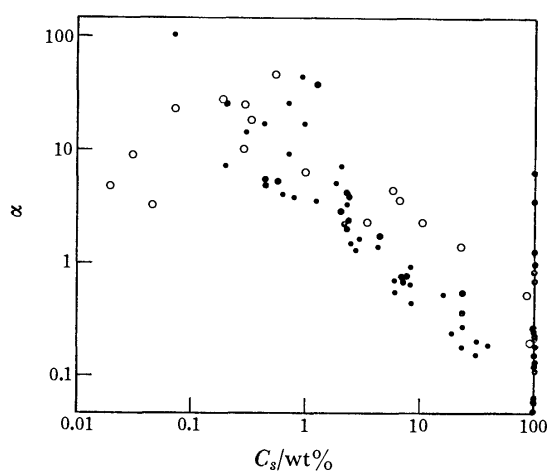

Fig. 3. Relationship between α and aqueous solubility.

coefficient was very high for the 15 linear aliphatic monofunctional compounds in our work. The value of a for these compounds was about −1, which suggests the following relationship;

$$\alpha \cdot C_s = \text{const.} \quad (4)$$

However, the correlation coefficient for all aliphatic monofunctional compounds was low because the compounds with 100 weight % aqueous solubility revealed a wide range of adsorbability.

Molar-attraction Constant (F). The concept of the cohesive energy of a liquid has been discussed extensively in the literature.[24,25] The molar cohesive energy, E, is given by this expression:

$$E \fallingdotseq \Delta H - RT \quad (5)$$

where ΔH is the heat of vaporization; R, the gas constant, and T, the absolute temperature. When the cohesion between molecules is due to dispersion forces, as is essentially the case with nonpolar molecules, E is related to the heat of mixing per cc (ΔH_{cc}) by Scatchard's[26] semi-empirical relation:

$$\Delta H_{cc} = \phi_1\phi_2\{(E_1/V_1)^{1/2} - (E_2/V_2)^{1/2}\}^2, \quad (6)$$

where ϕ is the volume ratio and the subscripts 1 and 2 represent a set of two dissimilar molecules. Equation 6 is equivalent to the statement that the cohesive energy, E, of a mixture of n_1 mol of Liquid 1 and n_2 mol of Liquid 2 can be given by this expression:

$$E^{1/2}(n_1V_1 + n_2V_2)^{1/2} = n_1(E_1V_1)^{1/2} + n_2(E_2V_2)^{1/2}, \quad (7)$$

which shows that $(EV)^{1/2}$ is an additive property. Assuming that this property might hold for the atoms

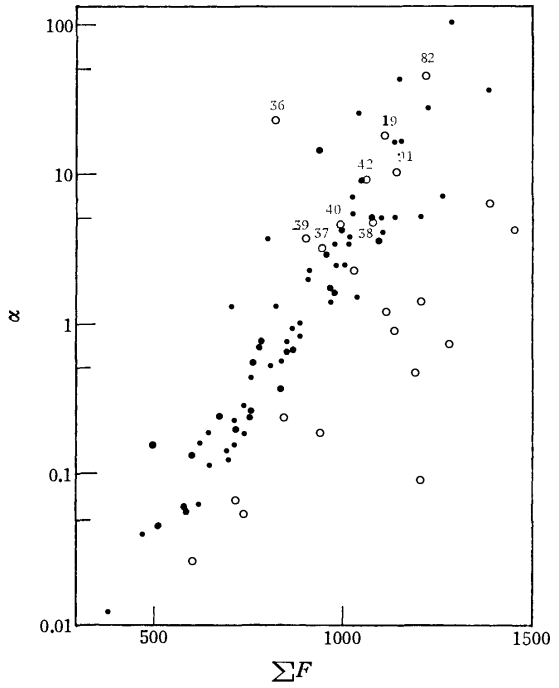

Fig. 4. Relationship between α and molar-attraction constant.

or groups constituting a molecule, Small[24] derived a set of additive constants for the common groups of organic molecules. These constants are called molar-attraction constants and are denoted by the symbol F. Then, ΣF summed over the present groups gives the value of $(EV)^{1/2}$ for 1 mol of the substance concerned.

Figure 4 shows the relationship between the ΣF values calculated from Small's F values for the compounds in Table 1 and log α. The correlation for the aliphatic monofunctional compounds and aromatics except benzene was very high, while that for aliphatic multifunctional compounds was low. This tendency is analogous to that of the molecular weight.

Organicity and Inorganicity. In order to estimate the solubility of organic compounds, Fujita[27] proposed the concept of organicity and inorganicity, where it is assumed that the organicity value per carbon atom is 20 and that inorganicity value for a hydroxyl group is 100. The inorganicity values for the other functional groups are determined in values relative to that for the hydroxyl group; they are given in Table 3. Since the organicity/inorganicity value (O/IO) is a criterion of the solubility, the value can also be used as a criterion of adsorbability. There existed a linear relationsihp between O/IO and log α for a homologous series of solutes, but the correlation coefficient for all the compounds in Table 1 was very low. This suggests that Fujita's IO value cannot be used as a criterion of adsorbability. In order to improve the correlation between the O/IO value and log α, the IO values for the functional groups were redetermined so as to fit the O/IO *vs.* log α plots of all the compounds to the straight line obtained for alcohols. These values are given in Table 3. Figure 5 shows the relationship between log α and the modified O/IO values calculated from the redetermined IO values and Fujita's O values. The correlation coefficient was very high for aliphatic monofunctional compounds.

Table 3. Inorganicity values for functional groups

Functional group		Inorganicity value	
		Fujita[10]	This work

Carboxylic aicds	-COOH	150	93
Ketones	>CO	65	109
Ethers	-O-	20	103
Esters	-COOR	60	93
Aldehydes	-CHO	65	98

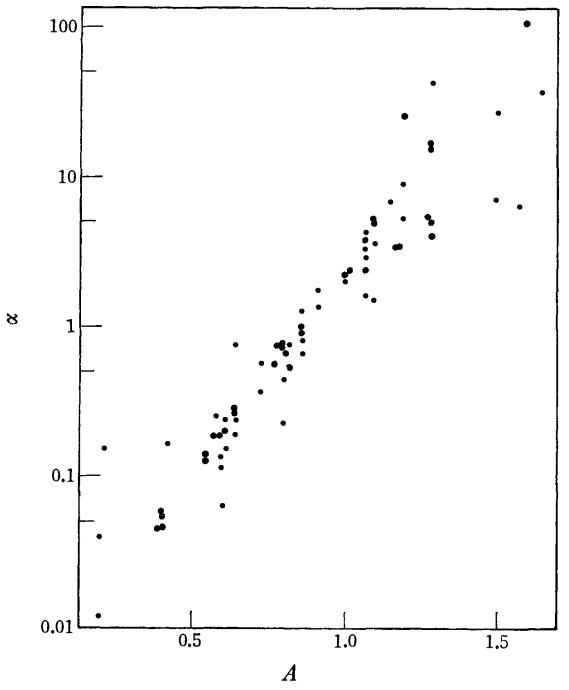

Fig. 5. Relationship between α and modified organicity/inorganicity.

Partition Coefficient between Water and 1-Octanol (P_{oct}). Assuming that the adsorption process is identical with the partition process between water and adsorbed phases, and that the polarity of the adsorbed phase is similar to that of 1-octanol, a high correlation between P_{oct} and α can be expected. Figure 6 shows the relationship between the log P_{oct} values calculated from Hansch's data[28] and log α. The correlation coefficient was high for aliphatic monofunctional compounds.

Polarity Parameters. The following empirical polarity parameters of organic compounds, among others, have been proposed by earlier investigators: $(D-1)/(2D+1)$ (D: dielectric constant, Kirkwood[29]), the E_T-values (Dimroth, Reichardt[30]), the Y-values (Winstein, Grunwald[31]), the Ω-values (Berson, Hamlet, Mueller[32]), the Z-values (Kosower[33]), and the S-values (Brownstein[34]). The relationship between the polarity parameters and log α were all similar in tendency, and the correlation coefficients were low.

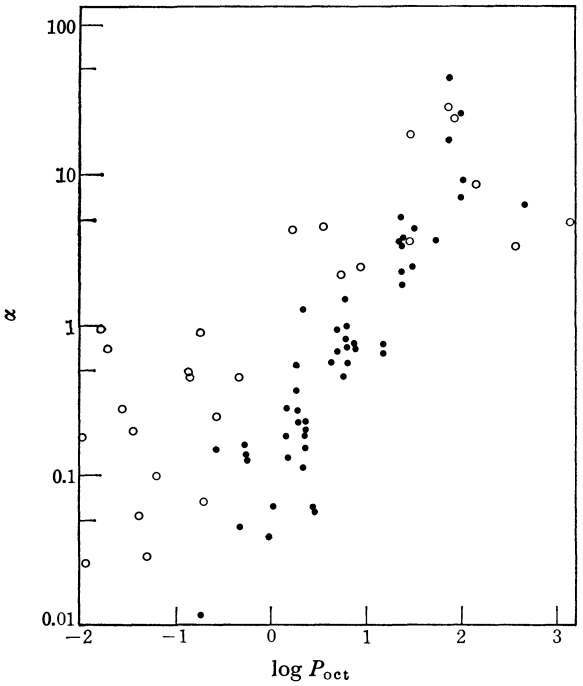

Fig. 6. Relationship between α and partition coefficient.

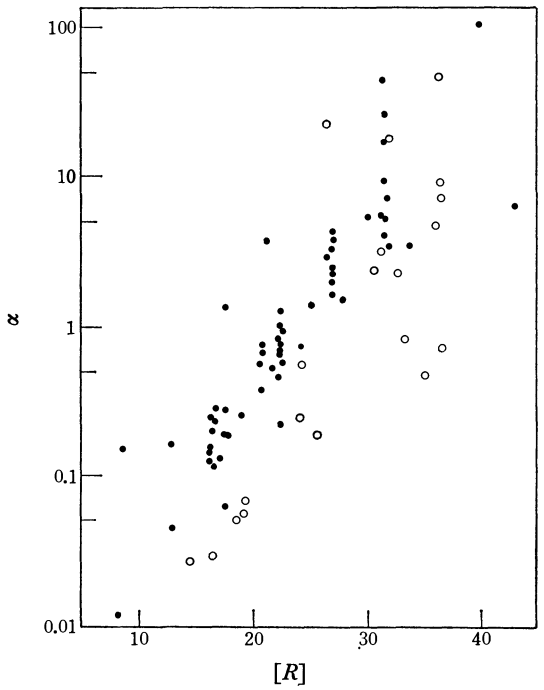

Fig. 7. Relationship between α and molar refraction.

Molar Refraction ([R]). The molar refraction is obtained from the Lorenz-Lorentz equation using the following form:

$$[R] = \frac{n^2-1}{n^2+2}\frac{M}{\rho} \tag{8}$$

where n is the refractive index and ρ is the density. Figure 7 shows the relationship between [R] and log α. The correlation coefficient for the 61 aliphatic monofunctional compounds was 0.898. In gas-phase adsorption, Reucroft *et al.*[4] obtained the high correlation coefficient of 0.94 for 15 organic vapors.

Parachor ([P]). Parachor is obtained approximately by the use of the following equation:

$$[P] = \frac{M}{\rho}\cdot\gamma^{1/4} \tag{9}$$

where γ is the surface tension. It can be seen from Table 2 that the correlation coefficient between [P] and log α is high, 0.889, for 45 aliphatic monofunctional compounds. In gas-phase adsorption, the value was 0.90 for 15 organic vapors.[4]

Discussion

In this work, the relationship between the adsorbability and various physical constants was examined for a large number of organic compounds, and it was found that, for aliphatic monofunctional compounds, there existed a good linear relationship between log α and the following physical constants: the molecular weight, the molar-attraction constant, and the modified *O/IO* value. This indicates that these physical constants are useful for predicting the adsorbability of aliphatic monofunctional compounds on activated carbon from an aqueous solution and that the *a* and *b* constants in Eq. 3 are useful for characterizing the adsorptive power of activated carbon. If the *a* and *b* constants are determined from the adsorption data of several compounds, the adsorbability for many other compounds can be predicted from only the physical constant. On the other hand, the adsorbability of multifunctional compounds could not be predicted from the physical constant and Eq. 3. The possibility of the prediction for aromatic compounds could not be ascertained because of the small number of compounds studied.

We will now consider the adsorptive mechanism on activated carbon in the water phase. In a previous paper[18] the free energy change of the adsorption process of 22 aliphatic monofunctional compounds on CAL activated carbon from aqueous solution was compared with the free energy of the precipitation process of the same compound from water to the pure liquid solute; the following results were obtained. 1) The adsorption process of the hydrocarbon portion of a solute molecule is analogous to the precipitation process of the portion. 2) The functional group situated in the terminal position of a solute molecule is appreciably hydrated, even in the adsorbed phase. 3) The functional group situated inside a solute molecule is not appreciably hydrated in the adsorbed phase. These results suggest that the adsorption of the solute takes place by means of the precipitation of the hydrocarbon portion of the solute from the aqueous solution and that the adsorbability depends mainly on the volume of the hydrocarbon. Since the free energy change for the precipitation process of the hydrocarbon is negative, the adsorbability increases with an increase in the volume of the hydrocarbon portion in a solute molecule. The fact that, for aliphatic monofunctional compounds, a high correlation coefficient was obtained between the adsorbability and the molecular weight, the molar volume, and the

modified O/IO value can be explained by the fact that the increase in these physical constants is approximately equal to the increase in the volume of the hydrocabon portion of a solute molecule. The high correlation with the molar-attraction constant, the molar refraction, and the parachor can also be accounted for by the fact that these physical constants are functions of the molar volume. Furthermore, the result that the correlation coefficient with the carbon atom number was high in spite of the variety of compounds suggests that the volume of the hydrocarbon was a dominant factor governing the adsorption. It can be seen from the modified IO values in Table 3 that the adsorbability does not appreciably depend on the kind of functional group.

The adsorbability of the multifunctional compounds was lower than that of the monofunctional compounds. This result can be explained by the facts that the functional group situated inside a solute molecule is somewhat dehydrated in the adsorbed phase and that the free energy change for the dehydration of the functional group is positive. In addition, the somewhat hydrated functional group may be considered to interfere with the dehydration of the adjacent hydrocarbon portion.

The low correlation with the polarity parameters suggests that the polarity is not the principal factor controlling the adsorbability on activated carbon and that the volume of the hydrocarbon portion of a solute molecule is not the principal factor controlling the polarity. Actually, the polarity is greatly influenced by the functional group.

Although, in this paper, we did not discuss the influence of the difference in activated carbon on the adsorbability of organic compounds, in a subsequent investigation[35] we obtained a similar result for a large number of activated carbons. It should be remembered, however, that surface oxides influence the adsorption of organic compounds.[5,7,11,36,37] In particular, the adsorption of strongly ionized low-molecular-weight compounds may be greatly influenced by surface oxides in a low or high pH solution.

The authors wish to express their thanks to Professor Nobuhiko Kuroki and Associate Professor Joichi Koga, the University of Osaka Prefecture, for their helpful discussions.

Surface Composition of SnO_2–ZrO_2 Binary Oxide Catalyst and Its Selectivity for C_3H_6–NO Reaction

Toshinobu Imanaka, Takeshi Hashimoto, Katsumi Sakurai, Yasuaki Okamoto, and Shiichiro Teranishi*

Department of Chemical Engineering, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received June 12, 1979)

The relation between the composition of outermost surface layer on SnO_2–ZrO_2 binary oxide catalyst and catalytic selectivity in the C_3H_6–NO reaction has been investigated by XPS technique. The composition of outermost surface layer was estimated from a comparison of the intensity ratios of X-ray induced Auger peak or XPS peak of Sn to XPS peak of Zr. A superficial enrichment of Zr was observed in these catalysts calcined at 600 °C in the air, while surface enrichment of Sn took place during the course of evacuation at 450 °C. The catalytic selectivity for formation of acrylonitrile showed a maximum with the catalyst containing Sn and Zr in the same concentration at the outermost surface layer of catalyst.

Enrichment of one component of a binary alloy occurs when the alloy is prepared in the air or reactive gases.[1,2] Knowledge of the surface composition of a binary catalyst is necessary for the clarification of heterogeneous catalytic reactions. Only a little evidence of the difference in surface and bulk compositions in cases of multicomponent oxide catalysts has been obtained.[3–6]

Studies with some binary oxide catalysts were carried out by means of X-ray photoelectron spectroscopy (XPS) in order to show the considerable difference occuring in the surface composition from the bulk composition of binary oxide catalysts such as SnO_2–MoO_3 and CoO–MoO_3 binary systems.[7–9] Only a few studies have been made to elucidate the influence of surface composition of solid catalysts on catalytic activity or selectivity.[7]

In the present work, the relation between the surface composition of some SnO_2–ZrO_2 binary oxide catalysts and the catalytic activity or selectivity for the C_3H_6–NO reaction has been studied. Special attention was attached to the role of the outermost surface layer of catalysts on catalytic activity and selectivity.

Experimental

The SnO_2–ZrO_2 binary oxide catalysts were prepared by impregnation and coprecipitation. The impregnated catalysts were prepared as follows: Powder of SnO_2 or ZrO_2 as a support was immersed in aqueous solutions of $ZrO(NO_3)_2$, $ZrOCl_2$, or $SnCl_2$ respectively, followed by evaporation to dryness at 100 °C and calcination in the air at 600 °C for 8 h. The SnO_2/ZrO_2 catalyst represents the SnO_2 supported on ZrO_2, the ZrO_2/SnO_2 catalysts representing the ZrO_2 supported on SnO_2.

Coprecipitated SnO_2–ZrO_2 catalysts were prepared by precipitation at pH~5 from a solution of $SnCl_2$ and $ZrO(NO_3)_2$ or $ZrOCl_2$ with dilute NH_4OH. The precipitates were washed, dried at 100 °C and then calcined in the air at 600 °C for 8 h. $SnCl_2 \cdot 2H_2O$, $ZrO(NO_3)_2 \cdot 2H_2O$, ZrO_2 (Nakarai Chemical Co.), $ZrOCl_2$, SnO_2, and a solution of NH_3 (Wako Pure Chem. Co.) were used.

Procedures

XPS spectra were measured on a Hitachi 507 photoelectron spectrometer equipped with a cylindrical mirror analyzer using Al $K\alpha_{1,2}$ radiation. The catalysts were mounted on a sample holder made of stainless steel. All binding energies were referred to the contaminant carbon [C 1s=285.0 eV]. The peak area intensities of Sn $3d_{5/2}$ and Zr 3d were used to obtain the Sn/Zr intensity ratio. The peak of Sn $3d_{5/2}$ (binding energy, *B.E.*, 486.6±0.2 eV) and Sn Auger (LMM, Kinetic energy; *K.E.*, 420 eV) were also used for obtaining information on depth profiles from the surface to the bulk of the catalysts. The surface compositions were determined by the intensity ratio Sn $3d_{5/2}$: Zr 3d or Sn Auger: Zr 3d using the calibration curve obtained by using mixtures of SnO_2 and ZrO_2 powder.

The reaction of C_3H_6–NO was studied over the SnO_2–ZrO_2 catalysts by using a reaction mixture, C_3H_6/NO=1/1, in a circulating system under 2.533×10^4 Pa (190 Torr) total pressure at 530 °C. Products were analyzed by GLC after 3 h.

Results and Discussion

Figure 1 shows the correlation between the content of Sn at the surface and that in bulk of SnO_2–ZrO_2 binary oxide catalysts prepared by coprecipitation.

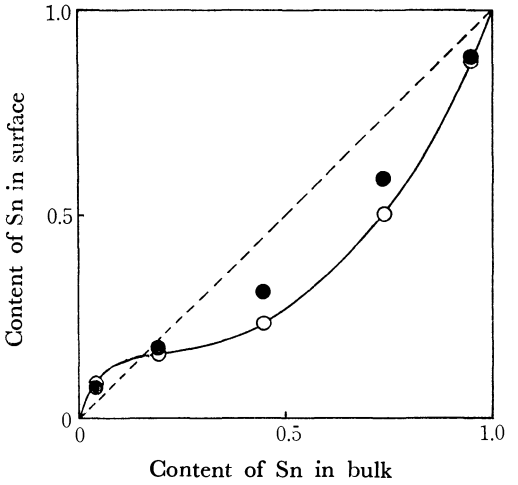

Fig. 1. Correlation between content of Sn in surface and that in bulk for coprecipitated SnO_2–ZrO_2 catalysts.
○: After calcination, ●: after evacuation at 450 °C for 2 h.

The value of surface composition was calculated from the intensity ratio of Sn Auger peak to Zr XPS peak, Zr 3d (*B.E.* 181.8±0.2 eV). The dotted straight line corresponds to the surface composition equal to bulk composition. A superficial enrichment of Zr was observed in these catalysts calcined in the air except for a small content of Sn (Sn/(Sn+Zr)<0.15 molar fraction). It is accepted that the surface is enriched by the constituent which has the lowest free energy under a surrounding gas. The surface enrichment of Zr during the course of preparation in the air would be due to the fact that the heat of formation of ZrO_2, 1079.5 kJ mol^{-1}, is larger than that of SnO_2, 574.9 kJ mol^{-1}. If the surface enrichment of Zr can be ascribed to the process in the formation of precipitate, the solubility product constant K_{sp} of $Sn(OH)_2$ should be smaller than that of $Zr(OH)_4$. However, the K_{sp} values of $Sn(OH)_2$[10] and $Zr(OH)_4$[11] are 1.8×10^{-15} and 8×10^{-52}, respectively, at 25 °C. The surface enrichment of Zr cannot be attributed to the difference of solubility in the formation of precipitates. A slight Sn enrichment was observed in the region less than 0.15 mole fraction of Sn in bulk. This might be due to the exclusion of Sn from the bulk of the catalyst by the crystallization of SnO_2. When evacuated at 450 °C for 2 h, the atomic intensity ratio Sn/(Sn+Zr) increased (Fig. 1), indicating that surface enrichment of Sn occurs during the course of evacuation.

The correlations between the content of Sn in surface and that in bulk of SnO_2–ZrO_2 binary catalysts prepared by the impregnation methods are shown in Fig. 2. As expected, the surface enrichment of Sn and Zr was observed in the SnO_2/ZrO_2 and ZrO_2/SnO_2 catalysts, respectively. After evacuation at 450 °C for 2 h, the surface enrichment of Sn was observed in both catalysts.

The surface is enriched by the constituent which has the lowest surface free energy, the surface composition being correlated with the surface tension of solids. Oresbury *et al.*[3] pointed out that the surface tension

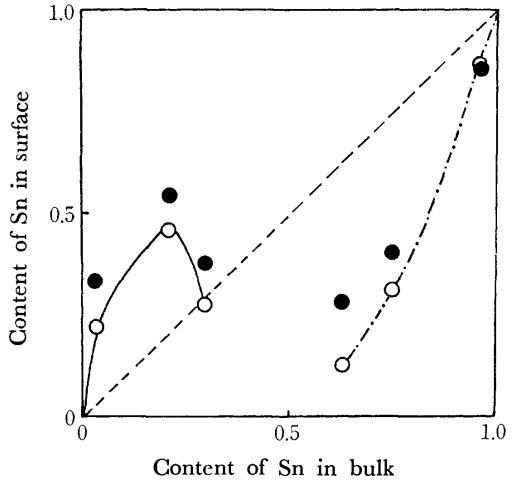

Fig. 2. Correlation between content of Sn in surface and that in bulk for impregnated SnO_2–ZrO_2 catalysts.
○: After calcination, ●: after evacuation at 450 °C for 2 h. ——: SnO_2/ZrO_2, —·—: ZrO_2/SnO_2.

of metals can be estimated from the heat of vaporization and sublimation, the surface tension of metals increasing with increase in the heat of vaporization and sublimation. The heat of vaporization of metals is correlated with the melting point of metals, the melting point increasing with increase in the heat of vaporization (*cf.* Zr: 581.6 kJ mol^{-1}, Sn: 290.4 kJ mol^{-1}). This relation might be applied to binary oxide catalysts. In the case of SnO_2–ZrO_2 binary catalysts, the surface enrichment of Sn seems to be due to the fact that the melting point of SnO_2, 1127 °C, is lower than that of ZrO_2, 2700 °C.[12] It might also be due to the fact that SnO_2 of the surface is reduced more easily than ZrO_2 since the heat of formation of SnO_2 is lower than that of ZrO_2.

It is necessary to estimate the composition of the outermost surface layer in relation to heterogeneous catalysis. The escape depth increases a great deal with increase in electron energy, characteristic of scattering length determined by electron-electron interactions.[13] The values for the escape depth is evaluated by using samples consisting of homogeneous films having uniform thickness.[14] The intensity, $I(d)$, of photoelectrons with a certain energy, expelled from a film of effective thickness d is given by $I(d)=I_\infty[1-\exp(-d/\lambda)]$, where λ is the electron escape depth in the film material and I_∞ the intensity of electrons expelled from a thick sample of the film material.

The energy dependence for the electron escape depth in the energy region of some kilovolts is expressed by the following relation obtained by Brundle,[13]

$$\lambda(E) \propto E^n$$

where n is 0.5±0.1[15] and E the kinetic energy, eV. Accordingly, the value of escape depth of the Sn Auger peak (kinetic energy: 420 eV) is *ca.* 8 Å, while the Sn XPS peak (kinetic energy: 1000 eV) is estimated to be *ca.* 12 Å. Thus, information on depth profiles is obtained from a comparison of both peak intensities.

A comparison of surface composition calculated from the intensity ratio of Sn Auger/Zr 3d to that of Sn 3d/Zr 3d is given in Fig. 3. The content of Sn obtained by using Sn Auger peak intensity is represented by r_1, and the content of Sn determined by Sn $3d_{5/2}$ by r_2. The surface layer in the impregnated and coprecipitated catalysts seems to be homogeneous. However, after evacuation at 450 °C, the surface enrichment of Sn is observed as shown in Figs. 1 and 2. The results indicate that the surface enrichment of Sn occurs in the surface layer of the SnO_2–ZrO_2 binary oxide catalysts during the course of evacuation at 450 °C.

In the presence of SnO_2–ZrO_2 catalysts, propylene reacts with NO to give CH_2=CHCN, CH_3CN, and CO_2. We have examined the relation between the composition of the outermost surface layer of the catalyst and the catalytic selectivity in this reaction (C_3H_6–NO).

Figure 4 shows the dependence of catalytic selectivity for the C_3H_6–NO reaction on the surface composition of the catalysts. In the catalysts prepared by both methods, the change in surface composition obtained from the intensity ratio Sn Auger/Zr 3d was not observed during contact with C_3H_6, NO, and

mixtures of C_3H_6 and NO. The selectivity for the formation of CH_2=CHCN becomes maximum at the atomic ratio, Sn/Zr=0.6, indicating that the catalytic selectivity is a function of surface composition of the catalyst irrespective of the method of preparation. The atomic ratios were estimated from the peak intensities of Sn Auger and Zr XPS, escape depths being 8 Å and 14 Å, respectively. The atomic ratio of Sn to that of Zr in the region near 3 Å from the outermost surface layer, $(Sn/Zr)_d$, was estimated by using the escape depths of Sn and Zr as follows.

$$(Sn/Zr)_d = f(I_{Sn}/I_{Zr})_d$$
$$= f(I_{Sn}/I_{Zr})_\infty[1-\exp(-d/\lambda_{Sn})]/[1-\exp(-d/\lambda_{Zr})]$$

where d=3 Å, λ_{Sn}=8 Å, λ_{Zr}=14 Å, and f is a constant.

The value of atomic ratio in the region near 3 Å from outermost surface layer can thus be estimated by

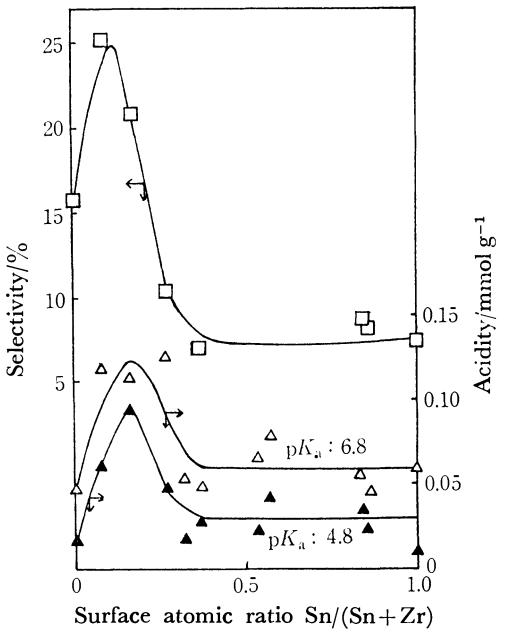

Fig. 5. Correlation between the selectivity for the formation CH_3CN as a function of the atomic ratio on the surface layer of the catalyst and its surface acidity.
□: Selectivity (%), △: pK_a: 6.8, ▲: pK_a: 4.8.

$(Sn/Zr)_{3Å}=0.96\simeq 1$.

This indicates that the catalytic selectivity for the formation of CH_2=CHCN becomes maximum with the same concentration of Sn and Zr of outermost surface layer on the catalyst.

On the other hand, the selectivity for the formation of CH_3CN becomes maximum near the atomic ratio 0.07 (Fig. 4). The results of acidity (amount of acid mmol/g) measured at pK_a=6.8 and 4.8 and the selectivity for formation of CH_3CN are shown in Fig. 5 as a function of the atomic ratio on the surface layer of the catalyst. The maximum selectivity agrees with that of acidity, indicating that the presence of acid sites on the surface of the catalysts results in the formation of CH_3CN produced by cracking reactions.

Effect of Hydrogen Chloride on the Pyrolysis of Acetylene as Studied with a Single-pulse Shock Tube

Hiroo OGURA

Institute of Space and Aeronautical Science, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153

(Received June 27, 1979)

The pyrolysis of acetylene in the presence of hydrogen chloride was investigated with a single-pulse shock tube in the temperature range 1100—1680 K. The hydrocarbons produced in the C_2H_2–HCl system were quite the same as those obtained in the C_2H_2–Ar system. The formation rate of the main pyrolysis product, 1-buten-3-yne, was reduced remarkably by the addition of hydrogen chloride, being of third-order and of inverse first-order with respect to the concentrations of acetylene and hydrogen chloride, respectively. The overall second-order rate constant obtained was

$$k(\mathrm{cm^3\ mol^{-1}\ s^{-1}}) = 2.9\times10^{12}\exp(-45800/RT).$$

As the chlorine atom containing product, only chloroacetylene was found in small amounts, its formation rate being of second-order with respect to acetylene. The inhibitory effect of hydrogen chloride on the 1-buten-3-yne formation rate was interpreted in terms of the change in the termination from the recombination reaction of 2-ethynylvinyl radical to the reaction of 2-ethynylvinyl radical with hydrogen chloride.

Hydrogen chloride has been used as an additive that may scavenge the chain carrier radicals in the system of decomposing hydrocarbons. Cullis *et al.*[1] studied the pyrolysis of acetylene in the presnece of hydrogen chloride at temperatures below 800 K, reporting that it may inhibit the pyrolysis of acetylene by a different mechanism from that of nitrogen monoxide. On the other hand, using a shock tube Bopp and Kern found that hydrogen chloride has no appreciable effect on the pyrolysis of acetylene at temperatures above 1650 K.[2]

A shock tube study on the pyrolysis of acetylene in the presence of nitrogen monoxide at intermediate temperatures showed that the nitrogen monoxide ceases to be an inhibitor with rise in temperature.[3] Analyses of both the yield-temperature plots of the pyrolysis products and the reaction products containing chlorine atom would be useful for a mechanistic study of the inhibitory effect of hydrogen chloride, as was found in the case of the C_2H_2–NO system.

Experimental

Apparatus and Procedure. The apparatus and procedure were the same as those described previously.[3] A 4-cm single-pulse shock tube was used, the driven section being 277 cm and the driver section 128.5 cm in length. Helium was used as a driver gas. The shocks were fired within 5 min after the test gases had been introduced into the driven section.

Materials. Four mixtures were prepared in a glass vessel of 10-l volume with the ratios of C_2H_2/HCl/Ar = 10/2/88; 10/0.5/89.5; 5/1/94; and 10/0/90. The test mixtures were stirred with a glass fan for 4 h. The mixing and storage time periods were kept constant for the three mixtures with hydrogen chloride, since too long storage resulted in the formation of vinyl chloride in a considerable amount. One mixture completely mixed was shock-heated within 2 d, the vinyl chloride formation being negligible.

Hydrogen chloride (Matheson Co.) was purified by bulb-to-bulb distillation. Argon and acetylene were purified according to the method reported.[3] The standard gas mixtures for the calibration of gas-chromatography were the same as those used previously.[3]

Chloroacetylene was synthesized from 1,2-dichloroethylene by the method of Bashford *et al.*[4] The chloroacetylene was purified by bulb-to-bulb distillation. The gas-chromatographic and mass spectrometric analyses showed that no detectable impurities were found. The purified chloroacetylene was diluted with a large amount of argon, and used as a gas-chromatographic standard gas.

Analytical. The reaction products were analyzed by gas-chromatography. The details of the hydrocarbon analysis were described elsewhere.[3] Chloroacetylene and vinyl chloride were analyzed in the same way as the hydrocarbons on a Porapak N column at 140 °C. The order of elution was CH_4, C_2H_6, C_2H_4, allene, propyne, chloroacetylene, vinyl chloride, 1,3-butadiene, 1-buten-3-yne, 1,3-butadiyne, and benzene. Hydrogen was analyzed at room temperature with a thermal conductivity cell on a 1.2 m column packed with molecular sieve 13X(80—100 mesh), argon being used as a carrier gas.

Results

The mixtures were subjected to shock-heating in the temperature range 1100—1680 K. The total densities behind the reflected shock waves were *ca.* 2.68×10^{-5} mol/cm^3, the reaction times being *ca.* 990 μs. The shock-heated samples were extracted into pre-evacuated bulbs of 60-ml volume, and analyzed by gas-chromatography.

Product analysis showed that the hydrocarbons produced with and without hydrogen chloride were the same; CH_4, C_2H_4, C_2H_6, allene, propyne, 1,3-butadiene, 1-buten-3-yne, 1,3-butadiyne, and benzene being formed. The major products were also 1-buten-3-yne, 1,3-butadiyne, and hydrogen in the presence of hydrogen chloride. The minor products were CH_4, C_2H_4, allene, propyne, and benzene, trace products being C_2H_6 and 1,3-butadiene as in the case of acetylene.

Chloroacetylene was produced in a small amount as a product containing chlorine atom. The chloroacetylene was identified by both gas-chromatographic and mass spectrometric comparison with the synthesized gas. Substances condensible at liquid nitrogen temperature in several runs at higher reaction temperatures were used for identification. No products which might contain chlorine atoms were detected in the substances condensible at liquid nitrogen temperature.

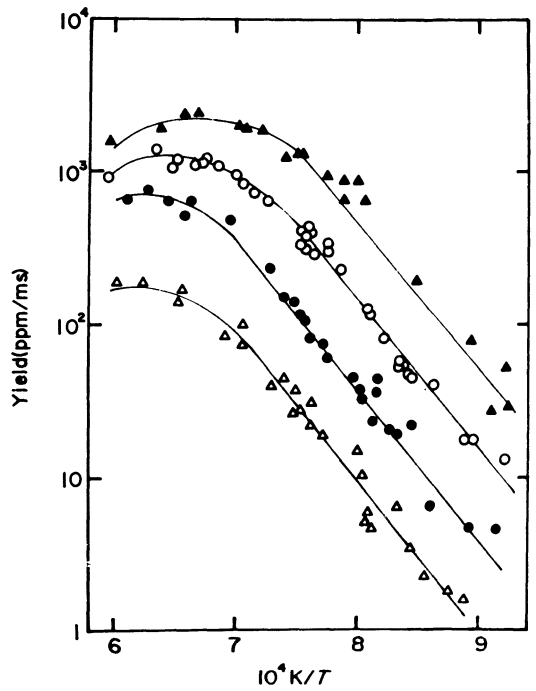

Fig. 1. Yield-temperature plots of 1-buten-3-yne formation.
●; C_2H_2/HCl/Ar=10/2/88, ○; C_2H_2/HCl/Ar=10/0.5/89.5, △; C_2H_2/HCl/Ar=5/1/94, ▲; C_2H_2/HCl/Ar=10/0/90.

Inhibited Rate of 1-Buten-3-yne Formation. The yields of 1-buten-3-yne(ppm/ms) for four mixtures with different composition of C_2H_2 and HCl are plotted as a function of temperature in Fig. 1. The yield-temperature plots show that the yields of 1-buten-3-yne are markedly decreased by the addition of hydrogen chloride at lower temperatures, and that they are significantly dependent on the amount of hydrogen chloride added. The rates of 1-buten-3-yne formation at temperatures below 1350 K are nearly of third order with respect to acetylene and of inverse first order with respect to hydrogen chloride. Apparent overall second-order rate constants for the inhibited 1-buten-3-yne formation at temperatures below 1350 K (58 experiments) are plotted in the Arrhenius form in Fig. 2. The best fit rate constant expression was obtained by the least-squares method as[5]

$$k_1(\mathrm{cm^3\ mol^{-1}\ s^{-1}}) = 2.9 \times 10^{12} \exp(-45800/RT)^*. \quad (1)$$

Formation Rate of Chloroacetylene. The formation of chloroacetylene was expected to have something to do with the reduction of 1-buten-3-yne yields. In order to determine the concentration dependence of the rate of chloroacetylene formation on acetylene and hydrogen chloride, the yields of chloroacetylene are plotted as a function of temperature in Fig. 3. We see that the rates of chloroacetylene formation are approximately of second-order with respect to acetylene and are little dependent on the hydrogen chloride concentration. Apparent second-order rate constants of 43 experiments are shown in the Arrhenius form in Fig. 4. The least-squares treatment of the data gives the best fit rate constant as[5]

$$k_2(\mathrm{cm^3\ mol^{-1}\ s^{-1}}) = 1.0 \times 10^{16} \exp(-67200/RT). \quad (2)$$

Only the data obtained at temperatures below 1350 K were adopted, since the yields of chloroacetylene decreased at higher temperatures and the temperatures where the yields began to decrease differed for the three mixtures with hydrogen chloride.

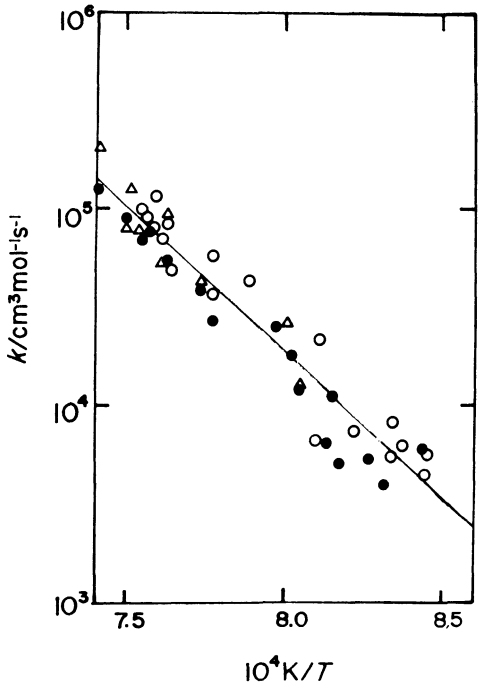

Fig. 4. Arrhenius plots of the second-order rate constants for chloroacetylene formation.
Symbols are the same as in Fig. 1.

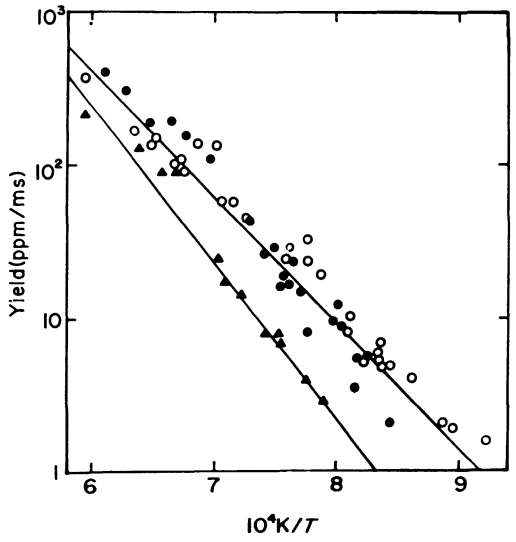

Fig. 5. Effect of hydrogen chloride on the yields of ethylene. Symbols are the same as in Fig. 1.

Effects on Other Products. Hydrogen chloride affects the yields of other products in two different ways: (a) in the case of 1,3-butadiyne, hydrogen, and ethylene, the yields increase considerably at lower temperatures, and at higher temperatures are little influenced by the concentration of hydrogen chloride added (Fig. 5); (b) in the case of allene, propyne, and benzene, the yields decrease significantly at lower temperatures, the decrease becoming smaller with rise in temperature.

Discussion

The hydrocarbons produced in the C_2H_2–HCl system are the same as those in the pyrolysis of acetylene. Although their yields are affected by the addition of hydrogen chloride, the forms of yield-temperature plots are similar to those in the absence of hydrogen chloride. This suggests that a mechanism similar to that of the pyrolysis alone is operative in the C_2H_2–HCl system. A pyrolysis mechanism for acetylene has been proposed from a thermochemical point of view,[6] and tested by the addition of nitrogen monoxide.[3] The mechanism is as follows:

$$2C_2H_2 \longrightarrow C_4H_3(1) + H \qquad \Delta H^\circ = 46.2 \quad (3)$$

$$C_4H_3(1) + C_2H_2 \longrightarrow C_6H_5 \qquad \Delta H^\circ = -20.5 \quad (4)$$

$$C_6H_5 \longrightarrow C_4H_4 + C_2H \qquad \Delta H^\circ = 53.1 \quad (5)$$

$$C_2H + C_2H_2 \longrightarrow C_4H_3(2) \qquad \Delta H^\circ = -44.8 \quad (6)$$

$$C_4H_3(2) + C_2H_2 \longrightarrow C_4H_4 + C_2H \qquad \Delta H^\circ = 11.7 \quad (7)$$

$$2C_4H_3(2) \longrightarrow \text{termination} \quad (8)$$

C_4H_3 (1) and C_4H_3 (2) stand for 1-ethynylvinyl and 2-ethynylvinyl radicals, respectively.

Inhibitory Effect of Hydrogen Chloride. A free-radical chain mechanism for the inhibited formation of 1-buten-3-yne could be constructed in line with that for the pyrolysis of acetylene. The inhibitory effect of hydrogen chloride can be interpreted by the reactions with the radicals present in the pyrolysis system of acetylene alone:[7]

$$C_4H_3(1) + HCl \longrightarrow C_4H_4 + Cl \qquad \Delta H^\circ = 23.8 \quad (9')$$

$$\longrightarrow C_4H_3(1)Cl + H \quad (9'')$$

$$C_2H + HCl \longrightarrow C_2H_2 + Cl \qquad \Delta H^\circ = -8.8 \quad (10')$$

$$\longrightarrow C_2HCl + H \qquad \Delta H^\circ = 11.3 \quad (10'')$$

$$C_4H_3(2) + HCl \longrightarrow C_4H_4 + Cl \qquad \Delta H^\circ = 2.0 \quad (11')$$

$$\longrightarrow C_4H_3(2)Cl + H \qquad \Delta H^\circ = 19.8 \quad (11'')$$

The reaction of C_6H_5 radical with HCl can be neglected, since the bimolecular reaction would be too slow to be competitive with the unimolecular decomposition of C_6H_5 radical (Reaction 5). The mechanism for the inhibited pyrolysis consists of three sets of competitive reactions of the radicals with C_2H_2 and HCl. The reaction of C_4H_3 (1) radical with HCl (Reactions 9′ and 9″) is referred to hereafter as Reaction 9.

The characteristic feature of the 1-buten-3-yne formation rates in the C_2H_2–HCl system is their concentration dependence on C_2H_2 and HCl. The formation rates are inversely proportional to the concentration of HCl. The inverse first-order dependence on an additive is observed when the termination reaction in its absence is replaced by a reaction of the predominant radical with the additive.[8] Thus Reaction 8, the major termination in the reaction C_2H_2–Ar system, would become a minor one in the C_2H_2–HCl system.

Assuming the steady-state concentrations of C_4H_3 (1), C_2H, C_6H_5, and C_4H_3 (2) radicals in Reactions 3—11, we get

$$R_3 = 2R_8^{HCl} + R_9 + R_{10} + R_{11}. \quad (12)$$

Since the contribution of Reaction 8 to the termination would be small, $2R_8^{HCl}$, R_8^{HCl} denoting the rate of Reaction 8 in the presence of HCl, can be neglected:

$$R_3 \simeq R_9 + R_{10} + R_{11}. \quad (12')$$

In the absence of hydrogen chloride, the steady-state concentrations of the radicals are expressed as follows:

$$[C_4H_3(1)]_{ss} = (k_3/k_4)[C_2H_2] \quad (13)$$

$$= 56 \exp(-40900/RT)[C_2H_2] \quad (13')$$

$$[C_2H]_{ss} = [C_4H_3(1)]_{ss} + (k_7/k_6)[C_4H_3(2)]_{ss} \quad (14)$$

$$\simeq 3.8 \times 10^2 \exp(-30900/RT)[C_2H_2] \quad (14')$$

$$[C_4H_3(2)]_{ss} = (k_3/2k_8)^{1/2}[C_2H_2] \quad (15)$$

$$= 3.0 \exp(-23700/RT)[C_2H_2] \quad (15')$$

The rate constants used in the above estimation are those adopted previously:[3]

$$k_3(\mathrm{cm^3\,mol^{-1}\,s^{-1}}) = 3.5\times10^{13} \exp(-47400/RT) \quad (16)$$

$$k_6(\mathrm{cm^3\,mol^{-1}\,s^{-1}}) = 6.5\times10^{11} \exp(-6500/RT) \simeq k_4 \quad (17)$$

$$k_7(\mathrm{cm^3\,mol^{-1}\,s^{-1}}) = 7.9\times10^{13} \exp(-22600/RT) \quad (18)$$

$$k_8(\mathrm{cm^3\,mol^{-1}\,s^{-1}}) = 2.0\times10^{12}. \quad (19)$$

From Eqs. 13′, 14′, and 15′, C_4H_3 (1) and C_4H_3 (2) are found to be the least and most abundant radicals in the C_2H_2–Ar system, respectively.

Although the change of concentration dependence of 1-buten-3-yne formation rate upon the addition of HCl might indicate that the hydrogen chloride added decreases the steady-state concentrations of the radicals in the C_2H_2–HCl system considerably, the C_4H_3 (2) radical would be the most predominant chain carrier radical even in the C_2H_2–HCl system. Neglecting the contribution of Reactions 9 and 10 to the termination, Eq. 12′ can be approximated by

$$R_3 = k_3[C_2H_2]^2 \simeq k_{11}[C_4H_3(2)]_{ss}^{HCl} = R_{11} \quad (12'')$$

from which we get the steady-state concentration of $C_4H_3(2)$ in the presence of HCl, $[C_4H_3(2)]_{ss}^{HCl}$:

$$[C_4H_3(2)]_{ss}^{HCl} \simeq (k_3/k_{11})[C_2H_2]^2/[HCl] \quad (20)$$

In the present mechanism 1-buten-3-yne is formed mainly by Reaction 7.

$$R_{C_4H_4}^{HCl} \simeq R_7^{HCl} \simeq k_7(k_4/k_{11})[C_2H_2]^3/[HCl], \quad (21)$$

where the formation rate of 1-buten-3-yne in the presence of HCl is denoted by $R_{C_4H_4}^{HCl}$. The formation rate derived from the present mechanism is in line with the observed one as regards concentration dependence.

Since no rate constants, estimated or observed, are available, k_{11} is calculated by a comparison with the observed (Eq. 1) and estimated (Eq. 21) rates for 1-buten-3-yne formation to be

$$k_{11}(\mathrm{cm^3\,mol^{-1}\,s^{-1}}) \simeq k_3k_7/k_1, \quad (22)$$

$$= 9.5\times10^{14} \exp(-24200/RT). \quad (22')$$

The rate constant estimated in Eq. 22′ is a representative one for both Reactions 11′ and 11″, its activation energy being greater than their heats of reaction. In view of the heat of reaction, the activation energy of Reaction 11″ is expected to be greater than that of Reaction 11′. When the activation energy of k_{11} is attributed to Reaction 11″, the activation energy for the inverse Reaction 11″ is estimated to be 4.4 kcal/mol from the heat of reaction. In the case of CH_3 radical reactions with HCl, the activation energies for the inverse reactions are obtained experimentally to be 4.6 kcal/mol for $H+CH_3Cl$ and 2.5 kcal/mol for $Cl+CH_4$.[9-11]

No detectable amount of chlorine atom containing products except for C_2HCl was found. $C_4H_3(2)Cl$ would undergo a unimolecular decomposition at temperatures above 1100 K as in the case of C_2H_3Cl.[12]

$$C_4H_3(2)Cl \longrightarrow C_4H_2 + HCl \qquad \Delta H^\circ = 20.4 \quad (23)$$

By this reaction the yields of C_4H_2 should increase upon addition of HCl, this being in line with the experimental results, In the present free-radical mechanism HCl catalizes the decomposition of the $C_4H_3(2)$ radical at temperatures above 1100 K.

The formation rate of 1-buten-3-yne in the absence of HCl has been reported:[6]

$$R_{C_4H_4} = 2.4\times10^{14} \exp(-46400/RT)[C_2H_2]^2. \quad (24)$$

In the present mechanism the steady-state concentrations of the $C_4H_3(2)$ radical with and without HCl are related to the observed 1-buten-3-yne formation rates as follows:

$$[C_4H_3(2)]_{ss}^{HCl}/[C_4H_3(2)]_{ss} = R_7^{HCl}/R_7 = R_{C_4H_4}^{HCl}/R_{C_4H_4} \quad (25)$$

$$= 1.2 \times 10^{-2} \exp(600/RT)[C_2H_2]/[HCl]. \quad (25')$$

In the presence of HCl the steady-state concentration of $C_4H_3(2)$ radical is reduced by a factor 0.1—0.3 of that in its absence (1100—1350 K and $[C_2H_2]/[HCl]=5$—20). The chain length of 1-buten-3-yne formation rate in the C_2H_2–Ar system is given by

$$R_{C_4H_4}/R_3 = R_{C_4H_4}/R_8 = 7.1 \exp(1000/RT), \quad (26)$$

$$\simeq 10(1100\text{—}1350\,\mathrm{K}). \quad (26')$$

The chain length in the C_2H_2–HCl system is shortened to *ca.* 1—3 under the present experimental conditions, since the 1-buten-3-yne formation rate is proportional to the steady-state concentration of C_4H_3 (2) radical. In the system with the composition of $[C_2H_2]/[HCl]=5$, the chain length is *ca.* 1.0 at temperatures 1100—1350 K, the chain being almost completely stopped.

The contribution of Reaction 8 to the termination in the C_2H_2–HCl system is estimated by means of Eqs. 12″ and 25.

$$R_8^{HCl} \simeq (1/10\text{—}1/100)R_8 \simeq (1/10\text{—}1/100)R_{11}.$$

As assumed in the derivation of Eq. 12″, Reaction 8 in the C_2H_2–HCl system is found to be an insignificant termination.

Formation Rate of Chloroacetylene. The steady-state approximation made in the derivation of Eq. 12 also gives the equation

$$R_8^{HCl} = R_7^{HCl} + R_{11} \quad (27)$$

from which the steady-state concentration of C_2H radical is obtained as

$$[C_2H]_{ss}^{HCl} = (1/k_6)(k_7+k_{11}[HCl]/[C_2H_2])[C_4H_3(2)]_{ss}^{HCl}. \quad (28)$$

In the present mechanism the chloroacetylene is formed by Reaction 10″. The formation rate is then expressed by

$$R_{C_2HCl} = (k_3k_{10''}/k_6k_{11})(k_7[C_2H_2]^2 + k_{11}[C_2H_2[HCl]), \quad (29)$$

$$= (k_3k_7/k_6)(k_{10''}/k_{11})[C_2H_2]^2(1+R_{11}/R_7^{HCl}). \quad (29')$$

Since the formation rate of chloroacetylene is little dependent on the hydrogen chloride concentration in the present experiments, to be compatible with the observed rate, Eq. 29′ can be approximated by

$$R_{C_2HCl} \simeq (k_3k_7/k_6)(k_{10}''/k_{11})[C_2H_2]^2. \quad (29'')$$

By a comparison of the estimated second-order rate constant with the observed one (Eq. 2), we obtain

$$k_{10}''/k_{11} = 2.3 \exp(-3700/RT), \quad (30)$$

$$\simeq 0.4—0.6\,(1100—1350\,K). \quad (30')$$

The rate constant k_{10}'' is then obtained from Eqs. 22' and 30:

$$k_{10}''(cm^3\,mol^{-1}\,s^{-1}) = 2.2\times10^{15}\exp(-27900/RT) \quad (31)$$

The frequency factors of k_{10}'' and k_{11} seem to be somewhat greater than that of the usual abstraction reaction, *i.e.*, 10^{13}—10^{14}. However, they might be reasonable as considered from the assumptions made in their derivation. The effective rate constants for Reactions 10 and 11 might be of comparable order of magnitude, since these reactions are of a similar type. This may be supported by Eq. 30'.

Using the estimated rate constants k_{10}'' and k_{11}' we can evaluate the relative importance of the competitive reactions of the radicals with C_2H_2 and HCl. The contribution of k_{10}' to k_{10} can be neglected in analogy with Reaction 11.

$$R_{10}/R_6^{HCl} \simeq (k_{10}''/k_6)[HCl]/[C_2H_2],$$
$$= 3.4\times10^3\exp(-21400/RT)[HCl]/[C_2H_2],$$
$$R_{11}/R_7^{HCl} = (k_{11}/k_7)[HCl]/[C_2H_2],$$
$$= 12\exp(-1600/RT)[HCl]/[C_2H_2],$$
$$(R_{10}/R_6^{HCl})/(R_{11}/R_7^{HCl}) \simeq (k_7/k_6)(k_{10}''/k_{11}),$$
$$= 3.0\times10^2\exp(-19800/RT),$$
$$\simeq 0.04—0.2(1100—1350\,K).$$

The equations show that the scavenging of C_2H radical by HCl molecule is less important than that of $C_4H_3(2)$ radical. This is in line with the assumption made in the derivation of 1-buten-3-yne formation rate.

Reactions of Other Radicals. In the absence of HCl, C_2H_4 is formed by the following reaction.[6]

$$H + C_2H_2 \longrightarrow C_2H_3, \quad \Delta H^\circ = -46.7 \quad (32)$$

$$C_2H_3 + C_2H_2 \longrightarrow C_2H_4 + C_2H, \quad \Delta H^\circ = 12.7. \quad (33)$$

In the presence of HCl, the C_2H_3 radical will react with HCl.

$$C_2H_3 + HCl \longrightarrow C_2H_4 + Cl, \quad \Delta H^\circ = 3.9 \quad (34')$$

$$\longrightarrow C_2H_3Cl + H, \quad \Delta H^\circ = 19.6 \quad (34'')$$

$$C_2H_3Cl \longrightarrow C_2H_2 + HCl. \quad \Delta H^\circ = 27.1 \quad (35)$$

As in the case of Reaction 11, the activation energy of Reaction 34' would be smaller than that of Reaction 34''. In view of the heat of reaction the activation energy of Reaction 34' would be smaller than that of Reaction 33, the yields of C_2H_4 thus increasing with the reaction of HCl at lower temperatures.

The C_2H_3 radical becomes a radical of greater molecular weight by successive reactions with C_2H_2 molecules. Its growth is suppressed considerably by Reaction 34 in the C_2H_2–HCl system, the yields of allene, propyne, and benzene decreasing.

$$C_2H_3 + C_2H_2 \longrightarrow C_4H_5 \xrightarrow{C_2H_2} C_6H_7,$$

$$C_6H_7 \longrightarrow C_3H_3 \xrightarrow{C_2H_2} C_3H_4,$$

$$\longrightarrow C_6H_6.$$

The reactions with HCl would produce excess atoms than in its absence. The yields of hydrogen will increase by

$$H + C_2H_2 \longrightarrow H_2 + C_2H.$$

Apparently a different effect of hydrogen chloride on the two groups would result from the same radical scavenging by hydrogen chloride. The main and characteristic features of acetylene pyrolysis inhibited by hydrogen chloride can be explained by the free-radical mechanism.

Comparison with Other Inhibitors. The small inhibitory effect of nitrogen monoxide was interpreted in terms of the scavenging and partial revival of the chain carrier radical.[3]

$$C_4H_4(2) + NO \longrightarrow C_2HCHO + HCN, \quad (36)$$

$$C_2HCHO \longrightarrow C_2H + CHO. \quad (37)$$

By a comparison with the estimated rate constants for Reactions 11 and 36, we get

$$k_{36}/k_{11} = 2.4\times10^{-2}\exp(9300/RT). \quad (38)$$

In the temperature range 1100—1350 K, the above values are 0.1—0.3, the scavenging effect of nitrogen monoxide being much smaller than that of hydrogen chloride. In the C_2H_2–NO system the steady-state concentration of $C_4H_3(2)$ radical is less reduced by Reaction 36, Reaction 8 being the predominant termination reaction.

The consumption rate of acetylene at temperatures below 800 K is inversely proportional to the hydrogen bromide concentration, while it is less dependent on the concentration of hydrogen chloride.[1] The activation energy of Reaction 11 is much greater than that of Reaction 8 (recombination reaction). Thus Reaction 8 can be faster than Reaction 11 at temperatures below 800 K, the scavenging effect of Reaction 11 being smaller. When hydrogen chloride is added in much smaller amounts than those in the present experiments. Reaction 8 predominates over Reaction 11 even at temperatures 1100—1350 K. In this case the inhibitory effect of hydrogen chloride would be similar to that reported.[1]

The author would like to express his gratitude to Prof. Kenji Kuratani, University of Tokyo, for his interest and valuable discussions.

11) In analogy with the reaction of CH_3+HCl, the activation energy of Reaction 11′ would be estimated as 5.4 kcal/mol from the heat of reaction. If the contribution of Reaction 11′ to the rate of Reaction 11 is far greater than that of Reaction 11′, the activation energy of Reaction 11 would be close to that of Reaction 11′. In the product analysis no detectable amount of chlorine atom containing products except for C_2HCl was found. This might indicate the minor role of reactions with Cl atom in spite of their smaller heats of reaction.

Photoelectron Angular Distribution Measurements for Some Aliphatic Alcohols, Amines, and Halides

Chikatoshi UTSUNOMIYA,† Tsunetoshi KOBAYASHI,†† and Saburo NAGAKURA*,†,††

† *The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato, Tokyo 106*

†† *The Institute of Physical and Chemical Research, Wako, Saitama 351*

(Received July 9, 1979)

The angular distributions for the He I photoelectron spectra of some aliphatic alcohols, amines, and halides were measured in order to reexamine the assignments of the so-called p-type photoelectron spectral bands in the He I region of these molecules. The second band of methanol and the third band of ethanol were assigned to the in-plane n orbitals localized mainly on the oxygen atom. Furthermore, it was found that the angular distributions of photoelectrons were useful for the conformational analysis of molecules and that the sum of β values was conserved for these compounds.

The photoelectron differential cross-section ($d\sigma/d\Omega$) for an unpolarized light and an ensemble of randomly oriented molecules or atoms is given by

$$d\sigma/d\Omega \propto 1 + 0.5\beta(1.5\sin^2\theta - 1) \quad (1)$$

where β is an asymmetry parameter, and θ is the angle between the direction of an ejected photoelectron and that of an incoming photon.[1,2] The β value depends on the kinetic energy of the photoelectron and the character of the molecular orbital from which the photoelectron is ejected. Therefore, the β value is expected to be useful for the interpretation of photoelectron spectra. Actually, using the β values, we solved the problems of the photoelectron spectral band assignments of benzene[3] and pyridine[4] about which there had been disputes.

He I/II photoelectron spectra have been studied by a number of workers with methanol and ethanol[5-11] and also with methylamine and ethylamine.[5,9,11] However, studies of the assignments of all the bands in the He I region are few. Katsumata and coworkers[11] proposed the assignments of all the p-type bands in the He I region of these alcohols and amines on the basis of the sum rule.[12] As for methanol, Robin and Kuebler[10] assigned all the photoelectron spectral bands with the aid of an *ab initio* MO calculation.

Many photoelectron spectral studies have been made with alkyl halides.[8,12-19] Kimura and coworkers[12] studied systematically the photoelectron spectra of alkyl halides covering the higher alkyl chlorides, bromides, and iodides, and assigned all the p-type bands in the He I region with the aid of the sum rule.

In the present study, the photoelectron angular distributions have been measured for aliphatic amines, alcohols, and halides, and the band assignments have been reexamined from the standpoint of the photoelectron angular distributions. The correlation between the β value and the character of the orbital from which the photoelectron is ejected, and the existence of the sum rule for the β values are discussed.

Experimental

The details of a photoelectron spectrometer used for the angular distribution measurements in the present study were described in a previous paper.[3] The β values were obtained according to formula (1) using the intensities measured at two angles, $\theta=45°$ and 90°. The measurements were carried out at room temperature, and the vapor pressure of the samples was kept at 4×10^{-4} Torr.

Results and Discussion

Aliphatic Alcohols and Amines. The photoelectron spectra of methanol and ethanol are shown in Fig. 1, and those of methylamine and ethylamine in Fig. 2. The vertical ionization potentials (I_v) and the β values of methanol and ethanol are summarized in Table 1 together with the band assignments. It is known that ethanol and ethylamine take the *trans* and *gauche* forms in the gaseous state, the *trans* form being predominant for both compounds.[20,21]

The first band of methanol or ethanol is assigned to the out-of-plane n orbital (a″n′(O)) which is localized mainly on the oxygen atom.[6-8,10,11] As is seen in Table 1, the β values of these orbitals are nearly equal to each other. The second band of methanol was ascribed to the a′π(CH_3) orbital by Katsumata and coworkers[11] from the sum rule. However, from the comparative consideration of the second bands of methanol, water, and dimethyl ether, it is derived

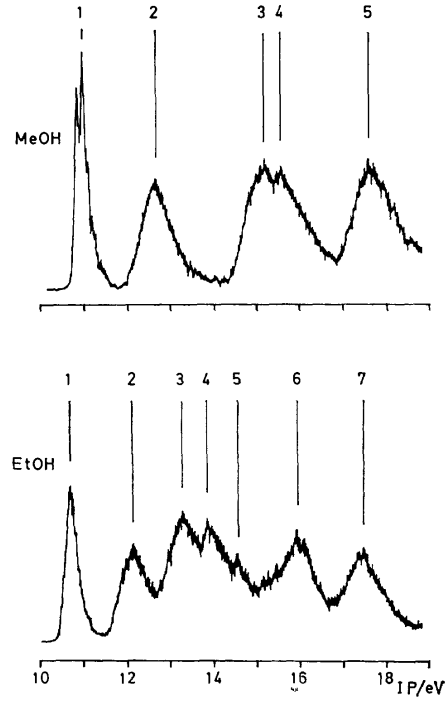

Fig. 1. Photoelectron spectra of methanol and ethanol.

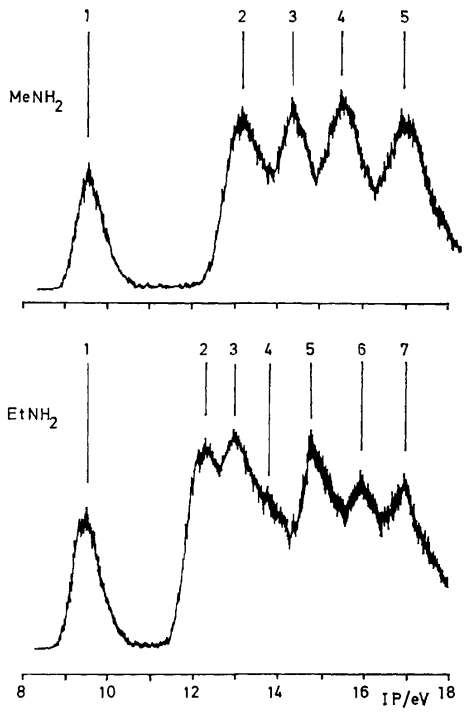

Fig. 2. Photoelectron spectra of methylamine and ethylamine.

that the band is assigned to the in-plane n orbital (a'n(O)) localized mainly on the oxygen atom. The second bands of water[13] and dimethyl ether[22] are assigned to the in-plane n(O) orbitals experimentally. The *ab initio* MO calculations of water[23] and dimethyl ether[24] also support the assignment. The β values and the ionization potentials of the second bands of water, methanol, and dimethyl ether are shown in Table 2. We can see from this table that the β value and ionization potential of the second band of methanol are intermediate between the corresponding values of water[25] and dimethyl ether. This shows that the second band of methanol is also assigned to the in-plane n(O) orbital. The MO calculation[26] is consistent with this assignment. The third, fourth, and fifth bands of methanol are assigned to the $a'\sigma(CO)$, $a''\pi'(CH_3)$, and $a'\pi(CH_3)$ orbitals, respectively, with the aid of the MO calculation.[26] As described later, these assignments are reasonable from the consideration of the β values and are consistent with Robin and Kuebler's result.[10]

As is seen in Table 1, the β values of the second and third bands of ethanol are 0.30 and 0.56, respectively. On the other hand, the β value of the $a'\sigma(CC)$ orbital of ethylamine is <0.37 (see the later discussion), and that of the in-plane n(O) orbital is 0.45 for methanol and 0.64 for dimethyl ether (Table 2). Therefore, the second band of ethanol should be assigned to the $a'\sigma(CC)$ orbital, and the third band to the in-plane n(O) orbital.

The fourth, fifth, and sixth bands of ethanol were assigned by Katsumata *et al.*[11] to the $a'\sigma(CO)$, $a''\pi^-(C_2H_5)$, and $a''\pi^+(C_2H_5)$ orbitals. These assignments are supported by the observed β values. Since the MO calculation of methanol[26] suggests that the energy of the $a'\pi(CH_3)$ orbital is higher than that of the $a'\sigma(OH)$ orbital, the seventh band of ethanol is preferably assigned to the $a'\pi(CH_3)$ orbital.

The band positions, β values, and assignments of the photoelectron spectra of methylamine and ethylamine are given in Table 3. The observed bands are assigned by considering the β values, the sum rule, and the MO's calculated with methylamine.[27]

According to the assignments given in Table 3, the β values of the pseudo π orbitals of the methyl group of methanol correspond to those of methylamine. This is also the case for the pseudo π orbitals of the ethyl groups of ethanol and ethylamine. The β value of the third band of ethylamine ($a'\sigma(CC)$) is 0.46 at the band maximum. This value, however, may conceivably be higher than the real value because this band is largely overlapped by the second band with the larger β value. The observed β value shows the energy dependence; 0.46 at 13.08 eV, 0.39 at

	Assign. (this work)	a''n'(O)	$a'\sigma(CC)$	a'n(O)	$a'\sigma(CO)$	$a''\pi^-(C_2H_5)$	$a''\pi^+(C_2H_5)$	$a'\pi(CH_3)$

a) These numbers correspond to those shown in Fig. 1. b) The error of the β value denotes the mean square error. c) Ref. 11. d) The underlined orbitals of the *gauche* form are a'' like out-of-plane orbitals because ethanol has no symmetry in the *gauche* form. e) The π^+ and π^- denote the bonding and antibonding types of combinations of the methyl pseudo π and methylene pseudo π orbitals, respectively.

13.18 eV, and 0.37 at 13.28 eV. The band overlap decreases with increasing *IP*. This means that the real β value of the third band of ethylamine is smaller than 0.37 and corresponds well to the β value of the a'σ(CC) band of ethanol (0.3). Thus, the present band assignments of alcohols and amines given in Tables 1 and 3 are supported by the consistency of the β values determined for the corresponding bands.

From the above-mentioned consistency of β values, we can discuss the conformation of ethylamine as an example. On the assumption of the *gauche* form as the predominant conformation, the second band of ethylamine is assigned to the σ(CC) orbital (see Table 3) and its β value may be expected to be $\sim$0.3, being inconsistent with the observed value, 0.54. This seems to support the *trans* form as the predominant conformation.

From the comparison of the band assignments made by the present authors with those made by Katsumata *et al.* with the aid of the sum rule, we can see that

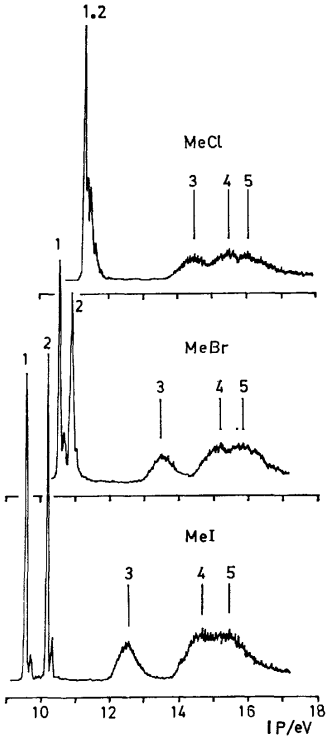

Fig. 3. Photoelectron spectra of methyl chloride, bromide, and iodide.

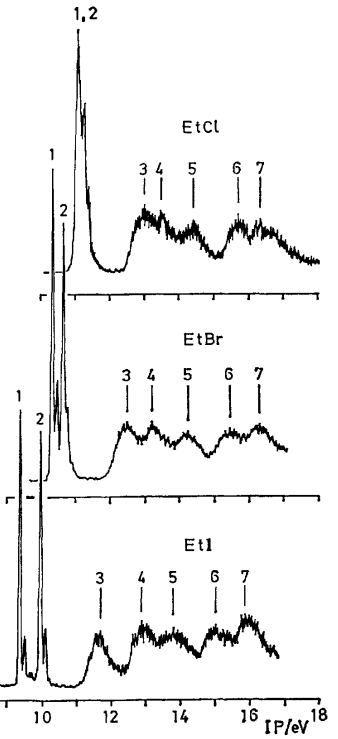

Fig. 4. Photoelectron spectra of ethyl chloride, bromide, and iodide.

the agreement is satisfactory for amines but some discrepancies due to the unreasonable assignments based on the sum rule are found for alcohols. This may be caused by the inadequate choice of parameters of the sum rule for the localized orbitals concerning the oxygen atom.

Alkyl Halides. The photoelectron spectra of methyl chloride, bromide, and iodide are shown in Fig. 3, and those of ethyl chloride, bromide, and iodide are in Fig. 4. The I_v's and the β values of these compounds are summarized in Table 4 together with the assignments made so far by other authors.[12-15,19] The β values of methyl halides were reported by Carlson and coworkers[25], and their values are consistent with ours. As is seen in Table 4, the consistency of β values among the related molecules is satisfied for the n(Cl), n(Br), n(I), σ(CCl), σ(CBr), and σ(CI) orbitals. This is also the case for the σ(CC) orbitals and the pseudo π orbitals of methyl and ethyl groups. These reasonable correspondences of the β values support the former assignments. The first and second bands of the bromides and iodides are caused by the spin-orbit splitting, and the fourth and fifth bands of the methyl halides are by the Jahn-Teller effect. The β values change scarcely by the splittings for the compounds.

Sum of β Values. The sums of the β values ($\sum\beta$) of all the p-type bands are shown in Table 5 for the alcohols, amines, and halides. The difference between the sum for methyl and ethyl derivatives ($\Delta\sum\beta$, see Table 5) is regarded to be the sum of the β values of the σ(CC) and $\pi(CH_2)$ orbitals. We can see from

Table 5. Sums of β values and their differences for aliphatic alcohols, amines, and halides

Compounds	$\sum\beta$[a]	$\Delta\sum\beta$[b]
MeOH	2.73±0.08	1.15±0.13
EtOH	3.88±0.10	
$MeNH_2$	3.11±0.08	1.14±0.11
$EtNH_2$	4.25±0.08	
MeCl	4.22±0.06	0.87±0.14
EtCl	5.09±0.12	
MeBr	4.76±0.09	0.86±0.15
EtBr	5.62±0.12	
MeI	5.51±0.07	0.89±0.11
EtI	6.40±0.08	

a), b) The errors for $\sum\beta$ and $\Delta\sum\beta$ denote mean square errors.

Table 5 that the values for the alcohols and the amines correspond well to each other. The values for the halides correspond well to one another and are equal to those for the alcohols and amines within the limits of experimental error as shown in Table 5. These results indicate that the sum of the β values is conserved for these molecules.

Finally, the β values of various orbitals of the molecules under consideration are summarized in Table 6. We can see from this table that a fluctuation of the β value from one molecule to another is small for the respective orbitals under consideration except for the $\pi(CH_3)$ orbital. Particularly the consistency of the β values is satisfied for the respective n orbitals.

From the above discussion, it is concluded that the photoelectron spectral bands can be assigned effectively with the aid of photoelectron angular distributions.

The Syntheses, Electrical Resistivities, and Electronic Absorption Spectra of Cation-TCNQ-Crown Ether Complexes

Minoru Morinaga, Takashi Nogami,* Yasuhiro Kanda, Tsuruyoshi Matsumoto, Katsumi Matsuoka, and Hiroshi Mikawa

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received July 23, 1979)

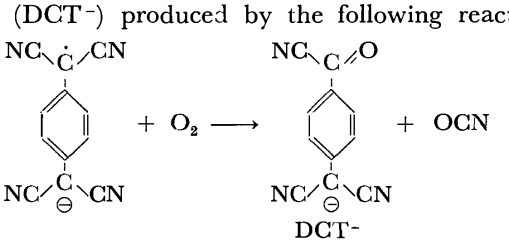
Crown ether complexes with alkali-metal–, ammonium–, and barium–TCNQ salts were isolated. Their electrical resistivities and electronic absorption spectra were measured. The simple salts, (crown ether)$_m$(M^+-$TCNQ^-$)$_n$, were almost all insulators with resistivities greater than 10^7 Ω cm. However, the complex salts, (Crown ether)$_m$(M^+TCNQ^-)$_n$(TCNQ), were much more conductive than simple salts with resistivities of 10^2—10^4 Ω cm. Three types of electronic-absorption spectra were observed for the simple salts. The simple salts with charge-transfer absorption bands were much more conductive than those without charge-transfer absorption bands.

Since tetracyanoquinodimethane (TCNQ) has been synthesized,[1] much attention has been paid to the high electrical conductivities and characteristic magnetic, optical, and structural properties of TCNQ complexes.[2] It has been clarified that a structure with segregated stacks of donor and acceptor molecules in the crystal greatly influences the physical properties. The modification of the crystal structure might, therefore, induce interesting properties. In order to confirm this, we chose to study metal-cation– and ammonium–TCNQ salts and have tried to surround the cation with crown ethers.[3] Surrounding the cation with crown ethers will weaken the interaction between the cation and TCNQ anion radicals,[4] leading to a change in the physical properties. We have isolated the complexes of alkali-metal–, ammonium–, and barium–TCNQ salts with crown ethers and cryptand, and have measured their electrical resistivities and electronic-absorption spectra.[5]

Results and Discussion

Isolation of Alkali-Metal–, Ammonium–, and Barium–TCNQ–Crown Ether Complexes. The following crown ethers, cryptand, and TCNQ salts were used for the preparation of the complexes: 12-crown-4 (**1**), 15-crown-5 (**2**), 18-crown-6 (**3**), dibenzo-18-crown-6 (**4**), dicyclohexyl-18-crown-6 (**5**), dibenzo-24-crown-8 (**6**), cryptand [2,2,2] (**7**), Li^+TCNQ^- (**8**), Na^+TCNQ^- (**9**), K^+TCNQ^- (**10**), Rb^+TCNQ^- (**11**), Cs^+TCNQ^- (**12**), $NH_4^+TCNQ^-$ (**13**), and $Ba^{2+}(TCNQ^-)_2$ (**14**). We have isolated two types of complexes *i.e.*, simple salts, expressed as (crown ether)$_m$(M^+TCNQ^-)$_n$, and complex salts, expressed as (crown ether)$_m$ (M^+-$TCNQ^-$)$_n$(TCNQ).[6] Table 1 lists the complexes isolated and their yields, melting points, stoichiometries, and analytical data, with some remarks. Most of the complexes were obtained as crystals. A variety of crystal colors were found for simple salts. As expected, the stoichiometry of a simple salt has a tendency for the crown ether with a cavity comparable to or larger than the cation size to have a one-to-one stoichiometry, while the crown ether with a cavity smaller than the cation size has a two-to-one stoichiometry arising from the cation sandwiched by crown ethers.[4] In spite of the above tendency, however, several exceptions to these rules exist for simple salts; 18-crown-6 and substituted 18-crown-6 make complexes of different stoichiometries with the same cation, as has been shown for Rb-cation complexes with **3**, **4**, and **5**, and Cs-cation complexes with **3**, **4**, and **5**. Most of the complex salts have the stoichiometry to be expected from those of simple salts. However, there are some exceptions, such as **2–11–15**, **3–12–15**, and **4–12–15**. In the case of the system with 15-crown-5 and Cs^+TCNQ^-, we could not isolate the simple salt, while the complex salt could be isolated easily. In this connection, we could isolate the complex salts of sodium and potassium cations, *i.e.*, **2–10–15**, **3–9–15**, **3–10–15**, and **4–10–15**, while the corresponding original complex salts, Na^+-$TCNQ^-$TCNQ and K^+TCNQ^-TCNQ, have not been obtained thus far. Besides the complexes in Table 1, we tried to obtain the following simple salts and complex salts: **2–13**, **6–13**, **4–14**, **2–9–15**, **4–9–15**, **7–9–15**, **3–10–15**, **7–10–15**, **4–11–15**, **7–11–15**, **7–12–15**, **2–13–15**, **6–13–15**, and **4–14–15**. However, the existence of these salts could not be verified.

The simple salts of purple, violet, and blue colors and all the complex salts were found to be stable in the air for several months. However, the greenish yellow, yellow, and green complexes were unstable, and the surfaces of the solids became brown in the air or in an oxygen atmosphere for several hours. They were stable in a vacuum or in an argon atmosphere. The change in the diffuse reflectance spectra of these complexes with time in the air showed the gradual disappearence of the absorption band in the near-infrared region and the appearence of the absorption band at 480 nm. The 480 nm band may be due to the α,α-dicyano-*p*-(cyanocarbonyl)-α-toluenide anion (DCT^-) produced by the following reaction:[7]



Electrical Resistivities. The electrical resistivities of the simple salts and complex salts measured with compressed samples are shown in Table 2. Table 3 shows the reported electrical resistivities, together with our measurements of the original TCNQ salts

a) Unless specified, the yield is less than 10%. b) Unless specified, the melting point is higher than 300 °C. c) Crown ether: $M^{n+}(TCNQ^-)_n$ for simple salts. Crown ether: $M^{n+}(TCNQ^-)_n$: TCNQ for complex salts. d) The upper analytical data were obtained for the samples using the one-step method, and the lower ones, for the samples using two-step method. The other analytical data were obtained for the samples with the one-step method.

for the sake of comparison. Table 2 shows that the electrical resistivities of the simple salts are greater than 10^7 Ωcm. On the other hand, the complex salts are much more conductive than the corresponding simple salts, having electrical resistivities of 10^2—10^1 Ωcm. When we compare the values of Table 2 with those of Table 3, it is clear that simple salts are much less conductive than the corresponding original TCNQ salts. On the other hand, the electrical resistivities of the complex salts are of almost the same order as those of the original TCNQ salts. It is noteworthy that **3–9–15** and **3–13–15** are much more conductive than **9** and **13** respectively. Considering the fact that the complex salt can be easily produced for cation–TCNQ–crown ether complexes, these complexes may be expected to be good candidates for highly conductive organic materials.

We have found that a close correlation exists between the colors of the simple salts and their electrical resistivities. All the yellow or greenish-yellow complexes[8] have electrical resistivities greater than 10^{14} Ωcm.[9] On the other hand, blue, purple, violet, or green complexes[10] are much more conductive than the yellow or greenish-yellow complexes with the electrical resistivities of 10^7—10^{11} Ωcm. This is probably because of the difference in the strength of the interaction between adjacent TCNQ anion radicals in the crystal. The TCNQ anion radicals in the yellow or greenish-yellow crystals are almost completely isolated from each other. On the other hand, the overlap of the π-molecular orbitals of the neighboring TCNQ anion radicals occurs to some extent in the other simple salts.

We have also found evidence of complex-salt formation by only grinding a mixture of a simple salt and neutral TCNQ in an agate bowl. Figure 1 shows the plot of the electrical resistivities of the mixture against the initial neutral TCNQ molar fraction in **3–10** and **15** mixtures. The electrical resistivity drops about four orders of magnitude at the TCNQ molar fraction of *ca.* 0.7. The attained minimum electrical resistivities are one order of magnitude greater than in the pure complex salt, thus showing the complex-salt formation.

Electronic Absorption Measurements. The electronic absorption spectra were measured by the nujol-mull method. Figure 2 shows the electronic absorption spectra of **10** in an acetonitrile solution and in nujol mull. The absorption band at 7×10^3 cm^{-1} for the nujol-mull spectrum is ascribed to the charge-transfer (CT) transition between TCNQ anion radicals.[11] Table 2 summarizes the absorption-peak positions of the cation–TCNQ–crown ether complexes. Three types of absorption spectra were observed for the simple salts: Type A, purple, violet, or blue complexes with two absorption bands with comparable intensities below 20×10^3 cm^{-1}; Type B, yellow or greenish-yellow complexes with a sharp absorption peak around 12×10^3

Table 2. Electrical resistivities and electronic-absorption peak positions of cation-TCNQ-crown ether complexes

cm^{-1} and no or weak absorption below 12×10^3 cm^{-1}, and Type C, green complexes with a sharp absorption peak around 12×10^3 cm^{-1} and a relatively strong absorption peak below 12×10^3 cm^{-1}. All the complex salts have a characteristic absorption below 5×10^3 cm^{-1}. Figures 3, 4, and 5 show the electronic absorption spectra of several simple salts of Types A, B, and C respectively as typical examples. Figure 6 shows the electronic absorption spectra of three complex salts.

Although crystallographic study and the polarized absorption spectra are needed for the assignment of the absorption bands, the most probable assignment for the Type A complex is that the lowest-energy

band is due to the charge-transfer transition between TCNQ anion radicals, and the second band, to the local excitation within TCNQ anion radical. It is interesting to note that the absorption-peak positions

of the lowest-energy band of the Type A complexes vary from complex to complex, ranging from 7.0×10^3 cm^{-1} to 11.8×10^3 cm^{-1}. If these bands are ascribed to the charge-transfer absorption, this fact will reflect the difference in the strength of the interaction between TCNQ anion radicals in Type A complexes. More exactly, the peak position of this band is affected by the crown ethers in the following order: 12-crown-4 complexes (7.0×10^3 cm^{-1})<cryptand [2,2,2]-complexes ($8.1—8.3\times10^3$ cm^{-1})<15-crown-5-complexes ($9.3—10.6\times10^3$ cm^{-1})<dicyclohexyl-18-crown-6-complexes ($10.4—11.2\times10^3$ cm^{-1})<18-crown-6-complexes ($11.6—11.8\times10^3$ cm^{-1}). In the 15-crown-5-complexes, an increase in the cation size results in a shift of the peak position to the higher-energy region, *i.e.*, 9.3×10^3 cm^{-1} for Na^+TCNQ^- ($R_{Na^+}=1.90$ Å)< 9.6×10^3 cm^{-1} for K^+TCNQ^- ($R_{K^+}=2.66$ Å)<10.5×10^3 cm^{-1} for Rb^+TCNQ^- ($R_{Rb^+}=2.96$ Å)<10.6×10^3 cm^{-1} for $NH_4^+TCNQ^-$ ($R_{HN_4^+}=2.84$ Å) Here, R_{M^+} indicates the ionic diameter of the M^+ cation. Contrary to this, a reverse order was found for the dicyclo-

hexyl-18-crown-6-complexes, *i.e.*, 11.2×10^3 cm^{-1} for Na$^+$TCNQ$^-$ > 10.8×10^3 cm^{-1} for K$^+$TCNQ$^-$ > 10.4×10^3 cm^{-1} for NH_4^+TCNQ$^-$. Although these clear correlations between the peak positions of the CT-bands and the molecular structures of the complexes are noteworthy, we can not discuss these characteristics any more without crystallographic data.

Type B complexes have almost the same absorption peaks, which resemble the absorption spectrum of TCNQ anion radical in shape and peak position (see Fig. 2). This fact suggests that TCNQ anion radicals are isolated in the Type B complexes. The unstable properties of these complexes in the air or in the oxygen atmosphere described before may also arise from the isolated structure of the TCNQ anion radical in the crystal.

The absorption spectra of the Type C complexes show an intermediate character between those of the Types A and B complexes, having a charge-transfer band and an isolated TCNQ$^-$ band.

All the complex salts have absorption bands below 5×10^3 cm^{-1}, as is evident from Fig. 6. These absorptions are to be ascribed to the charge-transfer transition from the TCNQ anion radical to neutral TCNQ.[11]

Correspondence between the Electrical Resistivities of the Complexes and Their Electronic Absorption Spectra. It has been clarified that the semi-conducting and, in some cases, metallic properties of several TCNQ complexes arise from the crystal structure with one-dimensional TCNQ columns, thereby having a large overlap of the π-electron clouds between adjacent TCNQ molecules.[2] The electronic absorption spectra of such complexes showed charge-transfer absorption bands between the adjacent TCNQ anion radicals[11] in the infrared region, reflecting the strong electronic interaction between TCNQ molecules.

We have found that simple salts may be divided into two groups from the viewpoint of the electrical resistivity, *i.e.*, the relatively conducting Types A and C complexes, and the insulating Type B complexes. Types A and C complexes have charge-transfer absorption bands showing an overlap of the π-electron clouds between TCNQ anion radicals. Thus, an electron can move through the overlap of the π-electron clouds in these complexes. On the other hand, the TCNQ anion radical is considered to be isolated in the Type B complexes, judging from their electronic absorption spectra. Thus, the π-electron on a TCNQ$^-$ can hardly move to the neighboring TCNQ, resulting in the insulating properties of Type B complexes.

The complex salts were much more conductive than simple salts. The observation of the charge-transfer absorption bands also shows a large overlap of the π-electron clouds between adjacent TCNQ molecules. Moreover, the Coulomb repulsion between the mobile electrons is much more reduced in the complex salt, resulting in much higher conductivities than in simple salts.

Experimental

Materials. All the crown ethers and cryptand were purchased from Nakarai Chemicals, Ltd. TCNQ and its cation salts were synthesized according to the literature.[12]

Isolation of Simple Salts. Most of the simple salts, (crown ether)$_m$(M$^+$TCNQ$^-$)$_n$, were isolated as follows. A cation-TCNQ salt and crown ether (1.2—2 molar ratio)[13] were dissolved in hot methanol and refluxed for 15 min with stirring, after which the hot solution was filtered. The filtrate was allowed to stand at room temperature, and then it was cooled at 0 °C for several hours. Crystals thus precipitated were collected, washed with a small amount of methanol, and dried in a vacuum. When crystals did not come out, the solution was cooled to −15 °C, or to 0 °C after being concentrated. In addition to the above general techniques, we used the following procedures if necessary: (i) In the case of cryptand [2,2,2], we used acetone as a solvent instead of methanol. (ii) After collecting the complexes of dibenzo-18-crown-6 and dibenzo-24-crown-8, they were washed first with benzene and then with methanol. (iii) Because the solubility of dibenzo-18-crown-6 and dibenzo-24-crown-8 is smaller than that of the other crown ethers, we used much more solvent. (iv) When the starting materials were recovered, we used more crown ether and less solvent the next time.

Isolation of Complex Salts. Complex salts, (crown ether)$_m$(M$^+$TCNQ$^-$)$_n$(TCNQ), were isolated by either a one-step method or a two-step method. In the one-step method, methanol containing cation-TCNQ salt and crown ether was mixed with an acetonitrile solution of neutral TCNQ (0.5—1.0 molar ratio),[14] after which the solution was refluxed with stirring for 15 min. The hot solution was filtered, allowed to stand at room temperature, and then cooled to 0 °C. The crystals thus precipitated were collected, washed with a small amount of methanol, and dried in a vacuum. In the two-step method, simple salt was first synthesized, and then the methanol solution of the simple salt was mixed with an acetonitrile solution of neutral TCNQ (0.5—1.0 molar ratio).[14] The solution was refluxed with stirring for 15 min, after which the hot solution was filtered. The filtrate was allowed to stand at room temperature and then cooled to 0 °C. The crystals thus precipitated were collected, washed with a small amount of methanol, and dried in a vacuum. In addition to the above techniques, we used the following procedures if necessary: (i) Crystallization should be done as slowly as possible. (ii) When neutral TCNQ came out initially, the crystallized TCNQ was filtered off, and then the solution was cooled again. (iii) When neutral TCNQ and complex salt came out together, we used either of two methods: (a) we separated the two materials by the use of spatula, or (b) if we could not separate them by the use of a spatula, we used more solvent and added either simple salt or crown ether and original TCNQ salt (M$^+$TCNQ$^-$). (iv) When complex salt and simple salt came out together, we added more solvent, or we added more solvent and a small amount of TCNQ.

Typical examples are shown below.

*Preparation of 18-Crown-6–K$^+$TCNQ$^-$, (**3**—**10**).* K$^+$-TCNQ$^-$ (150 mg) and 18-crown-6 (175 mg) were added to methanol (120 ml), after which solution was refluxed for 15 min. The hot solution was filtered, allowed to stand at room temperature, and then cooled to 0 °C overnight. The crystals were collected, washed with a small amount of methanol, and dried in a vacuum.

*Preparation of Dibenzo-18-crown-6–Na$^+$TCNQ$^-$, (**4**—**9**).* Na$^+$TCNQ$^-$ (100 mg) and dibenzo-18-crown-6 (165 mg) were added to methanol (200 ml), after which the solution was refluxed for 15 min. The hot solution was filtered, allowed to stand at room temperature, and then cooled to 0 °C overnight. The crystals were collected, washed

with a large amount of benzene and a small amount of methanol, and dried in a vacuum.

*Preparation of Cryptand [2,2,2]-Rb$^+$TCNQ$^-$, (**7—11**).* Rb$^+$TCNQ$^-$ (150 mg) and cryptand [2,2,2] (190 mg) were added to acetone (120 ml), after which the solution was refluxed for 15 min. The homogeneous solution was concentrated to about 30 ml by rotary evaporator and then filtered. The solution was allowed to stand at room temperature and then cooled to −15 °C overnight. The crystals were collected, washed with a small amount of acetone, and dried in a vacuum.

*Preparation of (18-Crown-6)$_2$(Cs$^+$TCNQ$^-$) (TCNQ), (**3—12—15**).* Cs$^+$TCNQ$^-$ (200 mg) and 18-crown-6 (300 mg) were added to methanol (160 ml), after which the solution was mixed with an acetonitrile solution (40 ml) of TCNQ (120 mg). The solution was refluxed for 15 min, and the hot solution was filtered. The solution was allowed to stand at room temperature and then cooled to 0 °C overnight. The crystals were collected, washed with a small amount of acetonitrile and methanol, and dried in a vacuum.

*Preparation of (18-Crown-6)$_2$(Rb$^+$TCNQ$^-$) (TCNQ), (**3—11—15**).* Rb$^+$TCNQ$^-$(18-crown-6)$_2$ (111 mg) in 80 ml of methanol was mixed with an acetonitrile solution (20 ml) of TCNQ (50 mg). The procedures were the same as in the preparation of **3—12—15**.

Measurement of Electrical Resistivity. A sample (150 mg) ground in an agate bowl was compressed at 2.2 t/cm^2 to obtain a pellet with a diameter of 13 mm and a thickness of about 0.8—0.9 mm. Silver paste was painted onto both surfaces of the pellet as electrodes, and the electrode area was measured by tracing the electrode shape on a section paper. The electrode area was usually about 50 mm^2. Copper wires were then attached to the electrodes by means of the silver paste. The electrical current was measured by means of Takeda-Riken TR-8651 Electrometer.

Electronic-absorption Measurements. The electronic-absorption spectra were measured by means of a Hitachi ESP-3T spectrometer. The nujol mull sample was sandwiched between the plates of two quartz cells.

We are grateful to Dr. Shinobu Ikeno, Research Division, Matsushita Electric Works Co., Ltd., for his helpful discussion. We are also grateful to Miss Junko Maenaka, Mr. Kazuaki Muneishi, and Miss Yuriko Sako, Faculty of Engineering, Osaka University, for the elementary analysis.

13) When we used too much crown ether (more than a 2 molar ratio), we also got good crystals.

14) In the case of TCNQ molar ratios of greater than 1.0, complex salt was mixed with neutral TCNQ. In the case of TCNQ molar ratios of less than 0.5, however, the yield of the complex was reduced markedly.

Topological Index and Thermodynamic Properties. II.† Analysis of the Topological Factors on the Absolute Entropy of Acyclic Saturated Hydrocarbons

Hideyuki NARUMI and Haruo HOSOYA*,††

Department of Chemistry, Hokkaido University, Sapporo 060

(Received September 11, 1979)

The absolute entropy of acyclic saturated hydrocarbons is found to be well correlated linearly with the logarithm of the topological index (Z_G) of the graph of the carbon atom skeleton as, $S^\circ = a \log Z_G + b$, excpet for sterically overcrowded and highly symmetrical molecules. This relation is improved by taking the symmetry factor σ into account as, $S^\circ = a \log Z_G + b + c \log \sigma$. The physical meaning of these relations is clarified by analyzing the mathematical properties of Z_G and the rotational partition function proposed by Pitzer.

Recently importance of the topological or graph-theoretical aspects of molecules has been recognized and detailed analyses have been developed by many authors.[1-4] The problems discussed are, for example, enumeration of the number of the structural isomers,[1] analysis of the stability and the electronic distribution on π-electron networks,[5-7] coding and classification of the structures of molecules,[8,9] and interpretation of empirical rules on the thermodynamic properties of organic molecules.[10-12] Concerning the last problem one of the present authors has proposed the topological index[13] (Z_G) for the carbon atom skeleton of a saturated hydrocarbon and has shown that several empirical rules on the boiling point (bp) are interrelated to each other by assuming the relation

$$\text{bp} = a \log Z_G + b.^{12} \quad (1)$$

However, physical interpretation of Eq. 1 is not yet fully given.

It is practically very difficult to estimate the value of the boiling point of a compound from purely theoretical calculations based on an *a priori* model for the motions of molecular aggregates. Then a clue for solving this problem might be obtained by analyzing the topological aspects of other quantities, such as the entropy, critical pressure and volume, *etc.*, whose behaviors are similar to that of the boiling point but are more interpretable by the molecular theory.[14]

According to the theory developed by Pitzer,[15] the observed values of the absolute entropy S° of small acyclic saturated hydrocarbons can accurately be reproduced from the partition function obtained solely by the atomic and molecular constants and temperature.[15-19] However, from this theory and numerical calculations, it is difficult to draw generalized rules and their physical interpretation for the topological dependence of S°. Namely, so many different factors especially on the rotational conformations are entangled in the Pitzer's theory that practically the calculation of S° values is limited to small alkanes, say, with fewer than ten carbon atoms.

On the contrary, the topological index has been known to reflect the topological characteristics of the zig-zag chain especially on the degree of rotational freedom and to have a number of mathematically interesting properties. Namely, we have found that S° of saturated hydrocarbons is also related to the topological index as

$$S^\circ = a \log Z_G + b. \quad (2)$$

The purposes of the present paper are to obtain logical bases for the empirical relation 2 in terms of the Pitzer's partition function for clarifying the topological nature of the absolute entropy of van der Waals gases.

In Section I the mathematical properties of the topological index for tree graphs are reviewed with particular emphasis on the effect of branching including some additivity relationship. In Section II parallelism between the observed and calculated (by the topological index, Pitzer's partition function, and an empirical formula) entropies of small alkanes is presented and several important features of the branching effect on S° are exposed. It is also demonstrated that as the increase of the size of the molecule, to the extent where the Pitzer's theory cannot follow, the relation between $\log Z_G$ and observed S° gets better. In Section III by analyzing the relation between Z_G and the partition function the empirical relation 2 is justified.

I. Topological Index

Definition.[13] A graph G is composed of points and lines, or carbon atoms and C–C bonds of the carbon atom skeleton of a saturated hydrocarbon molecule. The non-adjacent number $p(G,k)$ for G is defined as the number of ways for choosing k ($0 \sim m$) disjoint lines, with $p(G,0)$ being defined as unity. The topological index Z_G is the sum of the $p(G,k)$'s,

$$Z_G = \sum_{k=0}^{m} p(G,k). \quad (3)$$

For a tree graph, or an acyclic hydrocarbon, $p(G,k)$ is nothing else but the coefficient of the characteristic polynomial of G

$$P_G(X) = (-1)^n \det(\boldsymbol{A} - X\boldsymbol{E}) = \sum_{k=0}^{n} a_k X^{n-k} = \sum_{k=0}^{[n/2]} (-1)^k p(G,k) X^{n-2k}, \quad (4)$$

where $\boldsymbol{A}$ is the adjacency matrix of G with elements

† Part I, *Bull. Chem. Soc. Jpn.*, **45**, 3415 (1972).

$$A_{rs} = \begin{cases} 1 & \text{if points r and s are neighbors} \\ 0 & \text{otherwise,} \end{cases} \quad (5)$$

$\boldsymbol{E}$ is the unit matrix of the same order n (the number of points in G) as $\boldsymbol{A}$, and det stands for a determinant. From Eqs. 3 and 4 one gets

$$Z_G = (-i)^n P_G(i) \quad (6)$$

for a tree graph.

Recursion Formulas.[13,20] The Z_G values for small tree graphs are given in Table 1, where the observed and calculated absolute entropy of the corresponding alkanes are compared for the later discussion.[21] For larger graphs, Z_G can easily be obtained from the values of smaller subgraphs by using the recursive relations described below.

Suppose that a graph G is obtained from graphs A and B by joining them with line l as in Fig. 1. The topological index Z_G of G can be given as

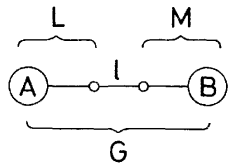
$$Z_G = Z_L \cdot Z_M + Z_A \cdot Z_B, \quad (7)$$

where L and M are the subgraphs obtained by deleting line l from G.

Suppose that a graph G is obtained from graphs A and B by joining them with point p as in Fig. 2. Graphs L and M which are obtained by adding point p to A and B, respectively, are the same as in Fig. 1. The topological index Z_G of G can be obtained by

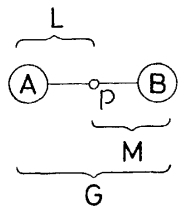
$$Z_G = Z_L \cdot Z_B + Z_A \cdot Z_M - Z_A \cdot Z_B. \quad (8)$$

Branching Properties.[12] The topological indices of the various series of branched alkanes have a number of interesting mathematical properties which are in parallel with the experimentally known features of the absolute entropy. It is remarkable that these properties are maintained up to an infinitely large system. In the following discussion the carbon atom skeleton of an acyclic alkane is represented by a tree graph.



$$Z_G = Z_L \cdot Z_M + Z_A \cdot Z_B$$

Fig. 1. Recursion formula 1.



$$Z_G = Z_L \cdot Z_B + Z_A \cdot Z_M - Z_A \cdot Z_B$$

Fig. 2. Recursion formula 2.

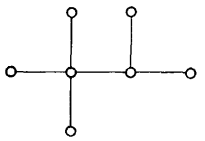
Given a tree graph



$Q_7 = R_7 = S_7$

and try to enlarge it to form a series of graphs with similar mode of branching by inserting points one by one in between certain prescribed lines. As in Fig. 3 there are three possible ways for doing so, since Q_7 has three topologically different types of lines.

In this way one gets three series of graphs, Q, R, and S. The original graph is turned out to be the smallest and the common member of the series Q, R, and S. As expected from this procedure, an infinite number of topologically different series of graphs are derived. In Table 2 are given twenty fundamental series of graphs with different modes of branching. They are subdivided into several classes with respect to the number of tertiary (n_Y) and quarternary (n_X) carbon atoms.

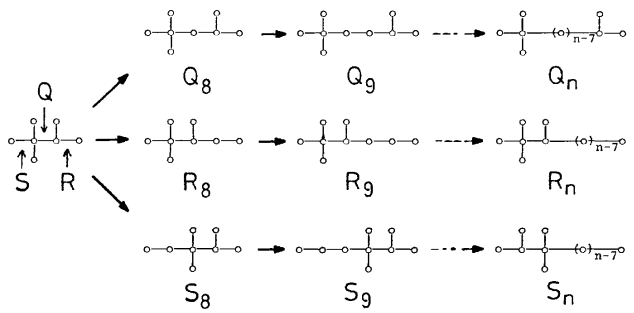


Fig. 3. Generation of different series of graphs from a parent graph.

Consider a series of graphs A-i-B composed of subgraphs A and B and i consecutive line of points. Successive application of Eqs. 7 and 8 gives the following recursive relation for the topological indices of these graphs.

A-i-B $(i \geq 0)$

$$Z_{A-(i+2)-B} = Z_{A-(i+1)-B} + Z_{A-i-B}. \quad (9)$$

Therefore, if the topological index of any series of graph G_n with n points as given in Table 2 is denoted by Z_n, a recursive relation similar to Eq. 9 can be written as

$$Z_{n+2} = Z_{n+1} + Z_n. \quad (10)$$

Although graph A-i-B has been defined for non-negative integers of i, the recursive relation 10 can formally be extended down to as small integers as one wishes irrespective of the existence of the corresponding graph. In Table 2 are given the Z_1 and Z_2 values for all the series of molecules studied. Although from these values the topological index Z_n for graph G_n can be obtained by the successive application of Eq. 10, one can obtain the closed and asymptotic forms of Z_n as in the following discussion.

It is known that if a series of numbers Z_n obey a recursive relation as 10, Z_n can be expressed explicitly by

$$Z_n = a\alpha^n + b\beta^n,^{23,24)} \quad (11)$$

where α and β are the roots of the equation

$$x^2 - x - 1 = 0,$$

namely,

$$\alpha = (1+\sqrt{5})/2 \text{ and } \beta = (1-\sqrt{5})/2. \quad (12)$$

The constants a and b are obtained if two of the members of the series $\{Z_n\}$ are given. Here by putting $n=1$ and 2 one gets

$$\begin{aligned} a &= (Z_1+\alpha Z_2)/(1+3\alpha) \\ b &= (Z_1+\beta Z_2)/(1+3\beta), \end{aligned} \quad (13)$$

which enables the calculation of any member of Z_n with Eq. 11. The values of a and b differ from series to series as in Table 2 and may be called as the structural factors.

For larger n the second term of Eq. 11 vanishes because of the relation $\alpha>1>|\beta|$. Then one gets

$$Z_n \rightarrow a\alpha^n \quad (14)$$

or

$$\log Z_n \rightarrow \log a + n \log \alpha. \quad (15)$$

The ratio Z_{n+1}/Z_n approaches to a constant value α for all the series of graphs,

$$Z_{n+1}/Z_n \rightarrow \alpha. \quad (16)$$

It is found from Table 2 that the value of a_G (a for a series G) is the largest for normal alkanes (series N) and is roughly determined by the number and mode of branching, whereas the value of b_G is scattered from series to series. This feature will be clarified if the value $\delta_G=\log(a_N/a_G)$ is compared with each other. Note that

$$\log Z_N - \log Z_G \rightarrow \log a_N - \log a_G = \delta_G. \quad (17)$$

As is evident from Table 2 the $\overline{\delta_G}$ averaged over a group of series with the same values of n_Y and n_X is roughly given by

$$100\,\bar{\delta}_G \fallingdotseq 5(n_Y+3n_X). \quad (18)$$

This means that the decrement of the logarithm of the topological index Z_G of a given graph from that of the linear graph with the same number of points is roughly determined by the number of the tertiary and quarternary carbon atoms in a simple manner as in Eq. 18. Recall that the effect of n_X on the lowering of the p(G, 2) number is three times as large as that of n_Y. See Eq. 12 of Ref. 13.

The effect of the quarternary carbon atom δ_X is three times larger than that of the tertiary carbon atom δ_Y. Namely,

$$\delta_L = 2.5\delta_A, \quad \delta_M = 3.2\delta_B, \quad \delta_O = 2.8\delta_C \quad (19)$$

or simply as

$$\delta_X \fallingdotseq 3\delta_Y. \quad (20)$$

Further inspection of the δ_X values reveals interesting additivity relationships. Namely, we have rigorous equalities as

$$\begin{aligned} \delta_E &= 2\delta_A \\ \delta_T &= 2\delta_L \\ \delta_Q &= \delta_A + \delta_L \ . \end{aligned} \quad (21)$$

That is, the value of δ for a graph with two branches is the sum of the δ values for the two graphs each with a single component branch, if the two roots of the branching are separated at least by one point, *i.e.*, one CH_2 unit. In Appendix I a general proof of this property of the δ value is given.

If two branches are adjacent the δ value is always smaller than the sum of the δ values for the component structures. For example, we can see

$$\begin{aligned} \delta_H &< \delta_A + \delta_B, \\ \delta_I &< \delta_B + \delta_C, \\ \delta_J &< \delta_A + \delta_D. \end{aligned} \quad (22)$$

Longer branching causes much smaller decrement in δ value than a shorter branching at the same root, for example,

$$\delta_D < \delta_B. \quad (23)$$

Finally the relations

$$\begin{aligned} &\delta_A > \delta_C > \delta_B, \\ \text{and} \quad &\delta_L > \delta_O > \delta_M \end{aligned} \quad (24)$$

show a zig-zag effect of the branching in going from the terminal to the center. All these properties can be deduced mathematically as in the case of the relation 20.

II. Relation between S° and Topological Quantities**

In Fig. 4 are shown the relations between the Z_G values and the observed absolute entropy S° of smaller ($n\leq 7$) acyclic saturated hydrocarbons. Similar plots are extended as in Fig. 5 for larger members of several series (normal (●), 3-methyl (△), 2,2-dimethyl (○), 2,3-dimethyl (+), and 2,4-dimethyl (□) alkanes) of saturated hydrocarbons. These two plots indicate several important aspects of the relation 2. Namely, Fig. 4 shows that the more the branching the smaller the value of S° as does Z_G. Introduction of a quarternary carbon atom causes much larger effect than that of two tertiary carbon atoms. It should also be noted here that as in the case of the boiling point 2-methyl substitution causes larger decrease in S° than does 3-methyl substitution in parallel with the behavior of Z_G. Inspection of the correlation

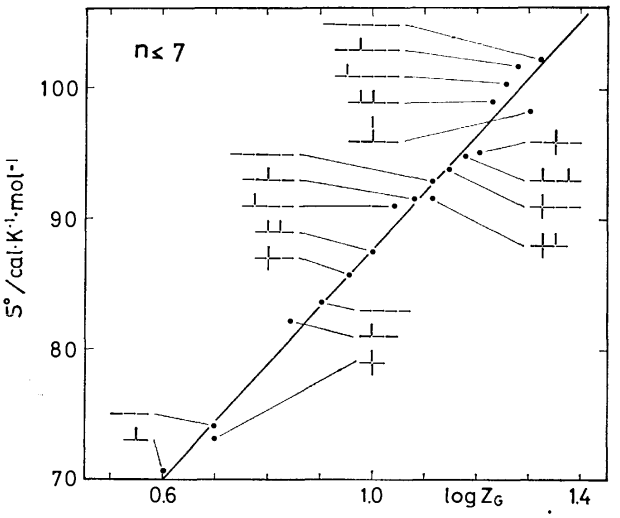

Fig. 4. $\log Z_G$—S° plot for smaller alkanes ($n\leq 7$).

** 1 cal=4.184 J.

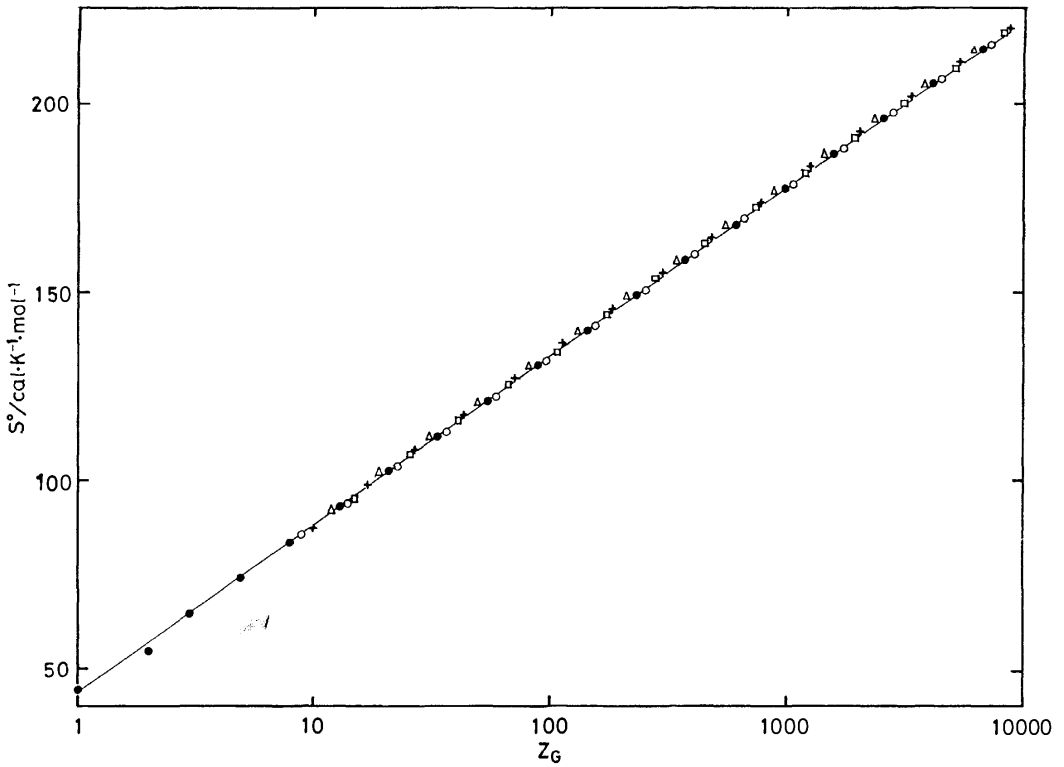

Fig. 5. log Z_G—$S°$ plot for larger members ($n \leq 20$) of several series of alkanes.

between the topological structure of alkane and entropy reveals that the effect of the tertiary and/or quarternary carbon atoms in lowering the $S°$ value is additive if there is at least a secondary (CH_2) carbon atom between these branching sites. Further, it is observed that the higher the symmetry, the smaller the $S°$ value. However, Z_G has nothing to do with the symmetry of a graph. The remarkably good linear relation between $S°$ and log Z_G, especially within each series, in Fig. 5 demonstrates that the growth of the chain length by one CC bond in eash series contributes the same amount (9.38 cal·K^{-1}·mol^{-1}) of increase in the entropy and that log Z_G has just the same property as has been shown above.

Although a number of empirical relations have been proposed for the topological dependence of the absolute entropy or the related quantities of branched compounds, especially of the saturated hydrocarbons, in this paper, we will discuss only three of them, namely, the relations proposed by the present author (topological index[12,13]), by Pitzer (partition function[15]), and by Pitzer and Scott (purely empirical one[18]), since the parameters involved in other theories do not seem to be easily interpretable.[4,10,11]

Pitzer has derived the expression of $S°$ of acyclic saturated hydrocarbons in terms of the molecular constants by enumerating the partition functions for the molecular motions. His original expression can be transformed into as

$$S° = C_0 + C_1 n + C_2 n_Y + C_3 n_X + \Delta, \tag{25}$$

$$\Delta = R(\ln Q + Q'/Q - \ln \sigma), \tag{26}$$

$$Q = \sum_{i}^{\text{conformations}} \exp(-\Delta\varepsilon_i/kT) = \sum_{j} g_j \exp(-\Delta\varepsilon_j/kT), \tag{27}$$

$$Q' = \sum_{i}^{\text{conformations}} \frac{\Delta\varepsilon_i}{kT} \exp(-\Delta\varepsilon_i/kT)$$

$$= \frac{a}{kT} \sum_{j} g_j \exp(-\Delta\varepsilon_j/kT), \tag{28}$$

$\Delta\varepsilon_i$=relative energy of i-th conformation
g_j=number of conformations with j excess *gauche* pairs relative to the conformation with the lowest energy, $\Delta\varepsilon_j$ being approximated as ja (a is the energy of a *gauche* form relative to the *trans* form)
σ=symmetry number=$\sigma_e \cdot \sigma_1 / I$
σ_e=symmetry number for external rotation
σ_1=symmetry number for internal rotation
I=number of racemic isomers (2 for racemic mixture, 1 for otherwise)
n=number of carbon atoms
n_Y=number of tertiary carbon atoms
n_X=number of quarternary carbon atoms.

The derivation of Eq. 25 will be given in Appendix II.

The numerical values of C_0, C_1, C_2, and C_3 for $S°$ at 298.15 K given in Table 1 are obtained from the paper by Person and Pimentel[16] and the book by Janz,[17] both of whom refined the Pitzer's original values.[25] Then Eq. 25 is expressed in the unit of cal·K^{-1}·mol^{-1} as

$$S°_{\text{thm}} = 43.012 + 7.679n - R\ln\sigma - 1.068\, n_Y - 3.425\, n_X + R(\ln Q + Q'/Q). \tag{29}$$

The data for calculating the values of σ, Q, and Q'

are given in Table 3, where the g_j numbers have been obtained by the method of Balaban with 4-digit codes representing the direction of the C–C bond in the diamond lattice.[26,27]

Although Eq. 29 gives fairly good results (See Table 1) for the lower members of saturated hydrocarbons, it is a formidable task to get the g_j numbers for larger molecules. Then Pitzer and Scott have proposed the empirical formula

$$S^\circ_{emp} = 39.00 + 9.13n - R\ln\sigma - 3.5B \qquad (30)$$

where the value B is the number of branches.[18]

If one compares Eqs. 29 and 30 by noting that $B=n_Y+2n_X$, it is found that Eq. 30 does not properly take into account the effect of branching and also the rotational partition function. The effect of the site of the branching as discussed in Section I is completely neglected in Eq. 30.

The three different sets of calculated entropies, Eqs. 2, 29, and 30 are compared with the observed values in Table 1. As judged from the standard deviations (s) and the correlation coefficients (r) for the three different sets of calculations, the thermodynamic formula 29 gives the best and the topological formula 2 the worst agreement with experiments. Deviation of the plot of Z_G—S°_{top} from linearity in Fig. 4 is seen mostly for molecules with high symmetry.

In Figs. 6 and 7 the log Z_G—S°_{top} plots are also given for hydrocarbons with $n=8$ and 9, respectively,

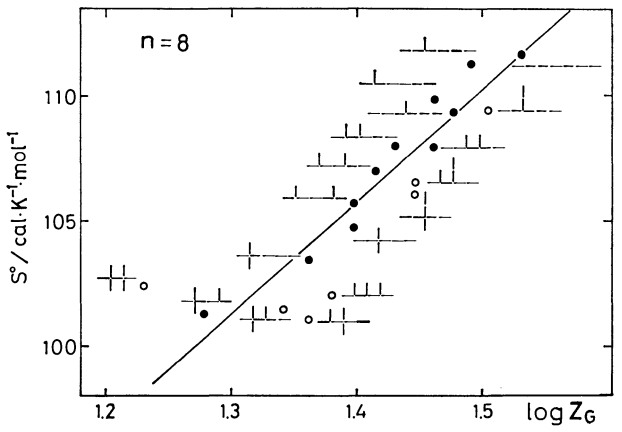

Fig. 6. log Z_G—S° plot for octane isomers.

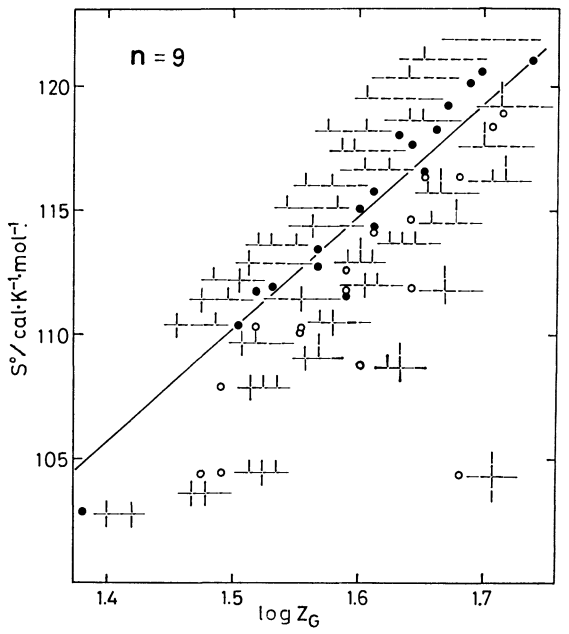

Fig. 7. log Z_G—S° plot for nonane isomers.

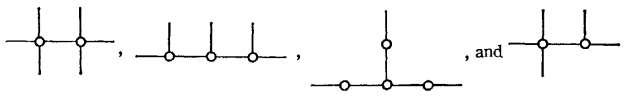
where those hydrocarbons containing skeletons



are marked with open circles, which tend to be scattered beneath the correlation line given in Fig. 5. Note that most of the rest of the molecules marked with filled circles are still on the straight line except for several melecules. Then as long as we are concerned with the fundamental analysis of the effect of branching and extension of the chain unit on the entropy, the topological index is found to be fairly effective, whereas the Pitzer's theory fails to be applied to larger molecules owing to the infeasibility of the enumeration of the steric factors.

III. Analysis of the Topological Dependence of the Entropy

As is found above, sterically overcrowded and/or highly symmetrical acyclic hydrocarbons are beyond the limit of the estimation of the absolute entropy by the use of only the topological index. If the symmetry factor σ is taken into consideration by adding the correction term to Eq. 2 for the set of data in Table 1, one gets

$$S^\circ_{top} = 46.453 + 42.100 \log Z_G - 2.9630 \log \sigma \qquad (31)$$

where the coefficients were obtained by the least squares calculation. The values of s=0.744 and r= 0.9970 show fair improvement from Eq. 2. In both of Eqs. 29 and 30, the contribution of the symmetry factor σ is given by $-R \ln \sigma = -4.576 \log \sigma$, which is 50 per cent larger than the corresponding term in Eq. 31. This means that the higher the symmetry of the molecule the smaller the topological index as the result of branching, but that this tendency of Z_G is not large enough for explaining the symmetry dependence of entropy completely.

With the above discussion in mind let us make term-to-term comparison of Eqs. 29 and 31 for larger alkanes. According to Relation 15, n can be substituted by

$$n = (\log Z_G - \log a)/\log \alpha. \qquad (32)$$

Equation 25 or 29 is then transformed as

$$S^\circ_{thm} = 43.012 + 36.744 \log Z_G - 4.5757 \log \sigma - (36.744 \log a + 1.068\, n_Y + 3.425\, n_X) + 1.9872\, (\ln Q + Q'/Q). \qquad (33)$$

There are observed small discrepancy between the corresponding coefficients of the first three terms of S°_{thm} and S°_{top}. Let us examine the relation between these discrepancies and the last two terms in S°_{thm}, which are missing from the expression of S°_{top}. As seen from Table 2 the fourth term is found to be constant as

$$-(36.744 \log a + 1.068\, n_Y + 3.425 n_X) = 6.9 \pm 1.4 \qquad (34)$$

throughout all the series studied. On the other hand, the last term seems to increase with n or $\log Z_G$ but with a few exceptions at least for small members of alkanes (See Table 3). Person and Pimentel[16] have noticed the linear increase of this term with respect to n for n-alkanes. One may then expect a rough estimate of this term as

$$R(\ln Q + Q'/Q) = 6.5 \log Z_G - 3.9 \pm 1.0 \qquad (35)$$

for larger alkanes. Now substitution of these two relations into Eq. 33 yields

$$S^\circ_{thm} = 46.0 + 43.2 \log Z_G - 4.6 \log \sigma \pm 2.4 \qquad (36)$$

which is turned out to be very close to the round-off experssion of Eq. 31 as

$$S^\circ_{top} = 46.5 + 42.1 \log Z_G - 3.0 \log \sigma. \qquad (37)$$

Large deviation from Eq. 34 is not expected, since the components in Eq. 34 are related with each other as in Eqs. 17 and 18. Although at the present stage we cannot draw any quantitative conclusion on Relation 35, this is qualitatively approved by the following discussion. The branching of the carbon atom skeleton diminishes the rotational degree of freedom mainly and additional decrement in the partition function is brought about by the increase of the overcrowded conformations. The above analysis shows that both the effects are reflected well in (the logarithm of) the topological index; the latter effect contributing by the amount of as large as fifteen per cent. The symmetry factor for a molecule with higher symmetry lowers further the entropy as much as a few per cent for each of additional symmetry operations.

One may well say that the above argument is based on superficial comparison of figures between experiments and models. However, the parallelism between the mathematical properties of S° and Z_G as discussed in Sections I and II ensures that these relations obtained in this paper can be used as the start for further analysis of the thermodynamic properties of van der Waals fluids.

Appendix I

Proof of Eq. 21

Consider four series of graphs, N, X, Y, and XY, as shown in Fig. A. Graph N_k is a path progression with k $(=l+m+n)$ points. Graph X_k, which is a member of the series X with k points, is composed of the root Ⓧ with l points and a path progression N_{m+n} $(m+n>0)$. Graph Y_k is composed of the root Ⓨ with m points and a path progression N_{l+m} $(l+m>0)$. The roots Ⓧ and Ⓨ characterize graphs X_k and Y_k, respectively, by their modes of branching. Graph XY_k is composed of the roots Ⓧ and Ⓨ and a path progression

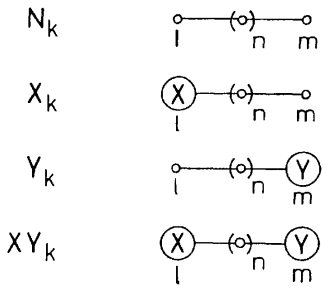


Fig. A. Four different series of graphs. The total number of points is $k=l+m+n$.

N_n ($n>0$).

If the topological indices of these graphs are denoted respectively as N_k, X_k, Y_k, and XY_k, these values can be expressed by using Eq. 8 as follows:

$$\begin{aligned} N_k &= N_{l+n}\cdot N_m + N_{l+n-1}\cdot N_{m+1} - N_{l+n-1}\cdot N_m \\ X_k &= X_{l+n}\cdot N_m + X_{l+n-1}\cdot N_{m+1} - X_{l+n-1}\cdot N_m \\ Y_k &= N_{l+n}\cdot Y_m + N_{l+n-1}\cdot Y_{m+1} - N_{l+n-1}\cdot Y_m \\ XY_k &= X_{l+n}\cdot Y_m + X_{l+n-1}\cdot Y_{m+1} - X_{l+n-1}\cdot Y_m. \end{aligned} \quad (A1)$$

Note that these relations are valid for the case with $n>0$, since graphs X_k and Y_k are defined, respectively, for the cases with $k\geq l$ and $k\geq m$. By combining these equations one gets

$$XY_k\cdot N_k - X_k\cdot Y_k = (X_{l+n}\cdot N_{l+n-1} - X_{l+n-1}\cdot N_{l+n}) \times (Y_m\cdot N_{m+1} - Y_{m+1}\cdot N_m). \quad (A2)$$

Division of the both sides of Eq. A2 by N_k^2 gives

$$\begin{aligned} \frac{XY_k}{N_k} - \frac{X_k}{N_k}\cdot\frac{Y_k}{N_k} &= \frac{X_{l+n}\cdot Y_m\cdot N_{l+n}\cdot N_m}{N_k^2} \\ &\times\left(\frac{N_{l+n-1}}{N_{l+n}} - \frac{X_{l+n-1}}{X_{l+n}}\right)\left(\frac{N_{m+1}}{N_m} - \frac{Y_{m+1}}{Y_m}\right) \\ &< \frac{X_{l+n}}{N_{l+n}}\cdot\frac{Y_m}{N_m}\left(\frac{N_{l+n-1}}{N_{l+n}} - \frac{X_{l+n-1}}{X_{l+n}}\right) \\ &\times\left(\frac{N_{m+1}}{N_m} - \frac{Y_{m+1}}{Y_m}\right). \end{aligned} \quad (A3)$$

The last inequality is obtained by using the relation

$$N_k > N_{l+n}\cdot N_m \quad \text{(from Eq. 7)}. \quad (A4)$$

Since the topological index of the path progression N_k is the largest among the isomeric graphs with the same number of points, we have

$$\frac{X_{l+n}}{N_{l+n}},\ \frac{Y_m}{N_m} < 1.$$

As k increases the remaining two terms in the parentheses individually approach to zero because of the asymptotic relation 14. Now Eq. A3 sharply converges to zero with increasing the size of the graph, or

$$\frac{XY_k}{N_k} \to \frac{X_k}{N_k}\cdot\frac{Y_k}{N_k}. \quad (A5)$$

With respect to the coefficient a defined in Eq. 11, a rigorous relation

$$\frac{a_{XY}}{a_N} = \frac{a_X}{a_N}\cdot\frac{a_Y}{a_N} \quad (A6)$$

holds, which completes the proof of Eq. 21.

Appendix II

Derivation of Eq. 25

According to Pitzer[15] the absolute entropy of an alkane is expressed as

$$S^\circ = f_0 + \sum_{i=1}^{7} f_i n_i + \Delta \quad (A7)$$

with

n_1=number of C–C stretching modes
n_2=number of C-C-C bending modes
n_3=number of internal rotations (C-C-C-C)
n_4=number of CH_3 groups
n_5=number of $-CH_2-$ groups
n_6=number of $-\overset{|}{C}H-$ groups$=n_Y$
n_7=number of $-\overset{|}{\underset{|}{C}}-$ atoms$=n_X$.

Δ is defined as Eq. 26. Person and Pimentel[16] give the coefficients f_i ($i=0\sim7$) for various temperatures. The values for $T=298.15$ K are:

$$f_0=57.473,\ f_1=0.792,\ f_2=2.173,$$
$$f_3=4.523,\ f_4=2.314,\ f_5=0.191,$$
$$f_6=-0.65,\ \text{and}\ f_7=-2.78$$

in units of cal·K^{-1}·mol^{-1}.

A simple combinatorial consideration on tree graphs gives the following relations among $n_1\sim n_7$ and n (the number of the carbon atoms),

$$\begin{aligned} n_1 &= n - 1 \\ n_2 &= n - 2 + n_6 + 2n_7 \\ n_3 &= n - 3 - n_6 - 2n_7 \\ n_4 &= 2 + n_6 + 2n_7 \\ n_5 &= n - 2 - 2n_6 - 3n_7. \end{aligned} \quad (A8)$$

By putting Relations A8 into Eq. A7 one gets Eq. 25 with

$$C_0=f_0-f_1-2f_2-3f_3+2f_4-2f_5=43.012$$
$$C_1=f_1+f_2+f_3+f_5=7.679$$
$$C_2=f_2-f_3+f_4-2f_5+f_6=-1.068$$
$$C_3=2f_2-2f_3+2f_4-3f_5+f_7=-3.425.$$

Field Theoretical Treatment of the Proton hfs in Aromatic Ion Radicals

Shigeyuki Aono,* Kiyoshi Nishikawa, and Kisaburo Deguchi
Department of Chemistry, Faculty of Science, Kanazawa University, Marunouchi, Kanazawa 920
(Received September 13, 1979)

Field theoretical method to estimate the proton hfs in aromatic ion radicals is presented, and applied to explain why the proton hfs of the positive ion is larger than that of the negative ion of the same molecule. Since the Hartree-Fock orbitals of the neutral molecule are adequate for describing the negative ion state of this molecule, but not for the positive ion state, the correlation effect in the latter should be effectively taken into account, so that the particle propagators in the positive ion are renormalized. The hyperfine energy consists of two terms, the hyperfine self-energy term and the pole strength which is interpreted as the existence probability of the state under investigation. The electron correlation affects these differently between positive and negative ions.

It has been observed in aromatic compounds that absolute values of the proton hfs constants of the positive ions are larger than those of the corresponding negative ions.[1] Usually we adopt the simple relation that the hfs constant a_N is proportional to the spin density at the nucleus N;

$$a_N = Q\rho_N, \tag{1}$$

where Q is the proportionality constant, being estimated to be about -23 G. If we estimate ρ_N by means of the Hückel method or the PPP (Pariser-Parr-Pople) method, we can obtain

$$\rho_N^{(+)} = \rho_N^{(-)}. \tag{2}$$

That is, the spin density of the positive ion at the nucleus N, $\rho_N^{(+)}$ is equal to that of the negative ion, $\rho_N^{(-)}$. This relation is one of pairing properties widely found in the alternant hydrocarbons.[2]

Higuchi[3] tried a careful calculation taking into account the excess (shortage) of charge in the negative (positive) ion, and obtain the result reverse to the observation. Bolton[4] treated this problem from a intuitive aspect. His idea is that the orbital exponent of the wave function is larger (in absolute value) in the positive ion than in the negative ion, since there is an excessive nuclear attraction in the former.

It seems true that any theoretical effort to explain this problem would be in vain, so long as symmetrical character be kept in the alternant hydrocarbons. However, we should like to insist that it is preferable to treat both ions with common reference orbitals which are evaluated in the neutral molecule.

General

As is well known, the origin of the proton hfs in aromatic radicals is spin polarization due to the electron correlation at the nucleus in question. A little spin density produces magnetic energy due to the coupling between electron and nuclear spins.

A nice way to take the electron correlation effect into account in the spin polarization was introduced by Cederbaum.[5] This method will be briefly presented in the following.

We note that energy responsible for the proton hfs is a tiny part of the entire electron energy. In this sense, we wish to obtain the electron Green's function of which self-energy part contains the hyperfine energy. The total Hamiltonian of the system in question is written symbolically as

$$H = H_0 + H_V + H_{hf} \tag{3}$$

where H_0 is the HF (Hartree-Fock) Hamiltonian, H_V the electron correlation term and H_{hf} the hyperfine interaction between electron and nuclear spins.

Let us assume that we have already obtained in the HF approximation a set of one-particle orbitals, $\{\phi_n\}$ and that of orbital energies, $\{\varepsilon_n\}$. The Green's function in this approximation is

$$G^0_{ij}(\omega) = \frac{\delta_{ij}}{\omega - \varepsilon_i + i\eta \text{ sign } \varepsilon_i}, \tag{4}$$

where the orbital energy ε_i is counted from the chemical potential which is set at the mid-point between occupied and vacant orbital energies, and η the positive infinitesimal.

The Green's function for the total Hamiltonian (3) is written in matrix form as

$$G(\omega) = [G^0(\omega)^{-1} - \Sigma(\omega)]^{-1}, \tag{5}$$

and that for the first two terms of (3) is

$$G^V(\omega) = [G^0(\omega)^{-1} - \Sigma^V(\omega)]^{-1}, \tag{6}$$

where $\Sigma(\omega)$ and $\Sigma^V(\omega)$ are self-energy terms. It is obvious that

$$\Sigma(\omega) = \Sigma^V(\omega) + \Sigma^{hf}(\omega), \tag{7}$$

in which $\Sigma^{hf}(\omega)$ is the self-energy term concerning to the hyperfine interaction. $\Sigma^{hf}(\omega)$ arises in two ways: If the unpaired electron has finite density at the nucleus in question (the case of s electron), the electron spin directly couples with nuclear spin, while if not (the case of π electron, for example) the coupling takes place indirectly through intermediate states. In the latter case the electron correlation effect is especially important. However, even in the first case, we can show a correlation effect which is not given by current theories, but is given by the following field theoretical treatment.

Using relations (5) and (6) in (7), we obtain

$$G^V(\omega)^{-1} - G(\omega)^{-1} = \Sigma^{hf}(\omega). \tag{8}$$

Let $G^V(\omega)$ is diagonalized in the form

$$G^V_{ii}(\omega) = \frac{p(E^V_i)}{\omega - E^V_i}. \tag{9}$$

In the above, E^V_i is determined from

$$\det|G^V(\omega)| = 0, \tag{10}$$

and $p(E_i^{\mathrm{v}})$ is called the pole strength which is approximately evaluated as follows. Neglecting the off-diagonal terms in $G^{\mathrm{v}}(\omega)$, we obtain

$$G_{ii}^{\mathrm{v}}(\omega) = [\omega - \varepsilon_i - \Sigma_{ii}^{\mathrm{v}}(\omega)]^{-1}. \tag{11}$$

Then we set

$$\omega - \varepsilon_i - \Sigma_{ii}^{\mathrm{v}}(\omega) = (\omega - E_i^{\mathrm{v}})p(\omega)^{-1} \tag{12}$$

and differentiate both sides with respect to ω, and finally put $\omega = E_i^{\mathrm{v}}$. Thus it follows that

$$p(E_i^{\mathrm{v}}) = \left\{1 - \left.\frac{\partial \Sigma_{ii}^{\mathrm{v}}(\omega)}{\partial \omega}\right|_{\omega = E_i^{\mathrm{v}}}\right\}^{-1}. \tag{13}$$

Similarly we obtain

$$G_{ii}(\omega) = \frac{p(E_i)}{\omega - E_i}, \tag{14}$$

$$p(E_i) = \left\{1 - \left.\frac{\partial \Sigma_{ii}(\omega)}{\partial \omega}\right|_{\omega = E_i}\right\}^{-1}. \tag{15}$$

It should be stressed that the pole strength $p(E_i)$ is the probability that the state with an unpaired electron of which energy is E_i can exist.

The electron energy E_i consists of the energy containing up to the correlation effect, E_i^{v} and the hyperfine energy, Δ_i;

$$E_i = E_i^{\mathrm{v}} + \Delta_i. \tag{16}$$

Using (9) and (14) in (8), we get

$$\frac{\omega - E_i^{\mathrm{v}}}{p(E_i^{\mathrm{v}})} - \frac{\omega - E_i}{p(E_i)} = \Sigma_{ii}^{\mathrm{hf}}(\omega). \tag{17}$$

Here putting $\omega = E_i$, we have the result,

$$\Delta_i = p(E_i^{\mathrm{v}})\,\Sigma_{ii}^{\mathrm{hf}}(E_i). \tag{18}$$

Considering that $p(\omega)$ and $\Sigma_{ii}^{\mathrm{hf}}(\omega)$ are smooth and slowly varying function of energy parameter, we may be allowed to approximate as

$$\Delta_i \simeq p(\varepsilon_i)\,\Sigma_{ii}^{\mathrm{hf}}(\varepsilon_i). \tag{19}$$

This result shows us that the hyperfine energy is given by a product of two terms; the first is the pole strength which concerns electronic structure of the whole system, and the second is the hyperfine self-energy term which is determined from a rather local structure giving the hyperfine interaction. Therefore we can say that even if the hyperfine interaction is simple as in the case with an unpaired electron in the s orbital, the correlation effect is taken into account *via* the pole strength.

Case of Aromatic Ion Radicals

In order to discuss the difference of the proton hfs values between aromatic positive and negative ion radicals in terms of the pole strength and the hyperfine self-energy term as in (19), let us define:

$$\delta p = (p^{+} - p^{-})/p^{-},$$
$$\delta\Sigma^{\mathrm{hf}} = (\Sigma^{\mathrm{hf}+} - \Sigma^{\mathrm{hf}-})/\Sigma^{\mathrm{hf}-},$$

where + and − are added to clearly indicate positive and negative ions, respectively. Then it is found that

$$\delta\Delta \equiv (\Delta^{+} - \Delta^{-})/\Delta^{-} \simeq \delta p + \delta\Sigma^{\mathrm{hf}}, \tag{20}$$

neglecting the second order terms with respect to δp and $\delta\Sigma^{\mathrm{hf}}$.

Now we evaluate the hyperfine self-energy term. The current treatments in evaluating the hyperfine energy have been carried out under the condition that $p(\varepsilon_i) = 1$, so that the hyperfine self-energy term itself is the hyperfine energy. Since the π-orbital with an unpaired electron has a nodal plane on which the proton is, an exchange type interaction shown in Fig. 1a is invoked to cause the spin polarization at the proton. The magnetic interaction represented by a dotted line creates a particle-hole pair, then the hole propagator of it annihilates combined with the incomming particle propagator, i, while the particle propagator of the pair is scattered to i with the electronic interaction. This mechanism is called the σ-π exchange interaction. However, the direct type interaction in Fig. 1b has vanishing result to the spin polarization due to the possibility of arbitrary choice of spin directions of the polarization part.

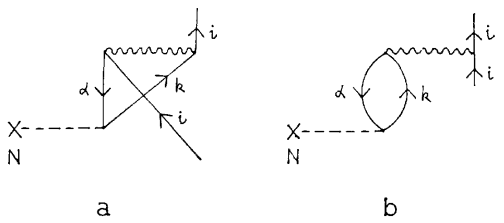

Fig. 1. Hyperfine self-energy terms.
a: Exchange type, b: direct type.

Observing the Fig. 1a, we can immediately obtain

$$\Sigma_{ii}^{\mathrm{hf}-}(\varepsilon_i) = -\sum_{k\alpha}(\mathrm{N};\ k\alpha)(ki;\ i\alpha)/\varepsilon_{\alpha k}, \tag{21}$$

$$\varepsilon_{\alpha k} = \varepsilon_\alpha - \varepsilon_k, \tag{21a}$$

where indices k and α denote the particle and hole states respectively, and

$$(\mathrm{N};\ k\alpha) = \int \mathrm{N}(\boldsymbol{r})\phi_k(\boldsymbol{r})\phi_\alpha(\boldsymbol{r})\mathrm{d}\boldsymbol{r}. \tag{22}$$

refering the magnetic interaction, and further

$$(ki;\ i\alpha) = \int \phi_k(\boldsymbol{r}_1)\phi_i(\boldsymbol{r}_1)\frac{1}{r_{12}}\phi_i(\boldsymbol{r}_2)\phi_\alpha(\boldsymbol{r}_2)\mathrm{d}\boldsymbol{r}_1\mathrm{d}\boldsymbol{r}_2. \tag{23}$$

In the above, the one-electron orbitals are assumed to be real without loss of generality.

We suppose the expression (21) refers to the negative ion, that is, an unpaired electron is in the lowest vacant orbital i. If we consider the positive ion in which an unpaired electron is in the highest occupied orbital η, we get a similar result,

$$\Sigma_{\eta\eta}^{\mathrm{hf}+}(\varepsilon_\eta) = -\sum_{k\alpha}(\mathrm{N};\ k\alpha)(k\eta;\ \eta\alpha)/\varepsilon_{\alpha k}. \tag{24}$$

In the corresponding diagram which leads to the above result, the direction of every line in Fig. 1a is reversed (see Fig. 2), and i is replaced by η.

Then using one of the pairing properties of the alternant hydrocarbons

$$(ki;\ i\alpha) = (k\eta;\ \eta\alpha) \tag{25}$$

we get

$$\Sigma_{ii}^{\mathrm{hf}-}(\varepsilon_i) = \Sigma_{\eta\eta}^{\mathrm{hf}+}(\varepsilon_\eta). \tag{26}$$

This is nothing but to reformulate the Mclachlan's result.[2]

To make steps further, a physical intuition is needed. Remember how to determine the HF orbitals. The HF functions of the particle state are determined for the state in which hole levels are already doubly occupied, then an extra electron is introduced. Therefore we can say that the HF functions are considerably suitable for describing the negative ion state. If we get a same order of approximation to the positive ion, we have to use the HF functions determined in the reference system which is the doubly ionized positive ion. Such consideration makes us use a different basis set for the positive ion from that for the negative ion. This is the Bolton's idea. However in the present treatment, we do not follow this, but want to use the identical basis set for both ions.

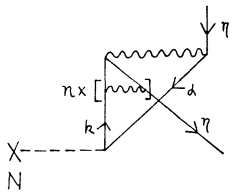

Fig. 2. Renormalization of the particle propagator in the hyperfine self-energy term of the positive ion.

When the basis set determined in the neutral molecule is employed, it is probable that the positive ion is more s nsitive to the electron correlation than the negative ion is. An extra positive charge in the positve ion works to decrease the virtual excitation energies, that is, the particle propagator should be renormalized with an extra hole propagator which arises only in the positive ion. To this end, in Fig. 2 the ladder type of particle-hole interactions are inserted n times (n tends to ∞). Combining this diagram and the corresponding exchange one, we can obtain

$$\begin{aligned}\Sigma_{\eta\eta}^{\mathrm{hf}+}(\varepsilon_\eta) &= -\sum_{k\alpha}(\mathrm{N};\, k\alpha)(k\eta;\, \eta\alpha)[\varepsilon_{\alpha k}+(\eta\eta;\, kk)-(\eta k;\, k\eta)]^{-1} \\ &= -\sum_{k\alpha}(\mathrm{N};\, k\alpha)(ki;\, i\alpha)[\varepsilon_{\alpha k}+(ii;\, kk)-(ik;\, ki)]^{-1},\end{aligned} \tag{27}$$

following the Kelly's technique to shift the energy denominator,[6] and using the pairing property to obtain the second equality. This is same as the expression of (21) for the negative ion except for the energy-shift terms of the denominator.

If we employ the CH fragment to estimate Σ^{hf}, the orbitals α and k are as usual restricted to the CH bonding and anti-bonding orbitals, respectively, so that we can remove the summation symbol. Consequently the second term of (20) becomes

$$\delta\Sigma^{\mathrm{hf}} = \{1+[(ii;\, kk)-(ik;\, ki)]/\varepsilon_{\alpha k}\}^{-1} - 1. \tag{28}$$

Since $\varepsilon_{\alpha k}$ is negative, it is obvious that the sign of (28) is positive, that is, at this stage the hfs value of the positive ion always larger than that of the negative ion.

We turn to evaluation of the pole strength, following

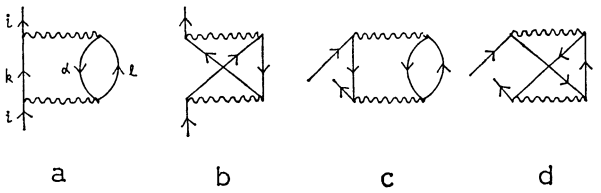

Fig. 3. Second order diagrams for the electron correlation (negative ion).

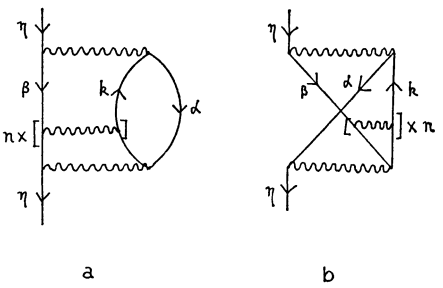

Fig. 4. Renormalization of the particle propagator in the electron correlation diagram (positive ion).

the spirit previously mentioned. To do so, the self-energy terms for the electron correlation will be calculated. Since we are using the HF orbitals, the first order diagrams are already included to infinite order. For the negative ion we are satisfied with an approximation displayed by Fig. 3, but the Fig. 3c and 3d can be neglected due to their small contributions (because of the large energy denominator). Therefore the second order correction in the negative ion becomes

$$\Sigma_{ii}^{\mathrm{V}}(\omega) = \sum_{\alpha kl} g(il;\, l\alpha)/(\omega+\varepsilon_\alpha-\varepsilon_k-\varepsilon_l), \tag{29}$$

$$g(ik;\, la) = 2(ik;\, l\alpha)(ki;\, \alpha l)-(ik;\, l\alpha)(k\alpha;\, li). \tag{29a}$$

In the case of the positive ion, the diagrams shown in Figs. 4a, 4b, and the corresponding exchange diagrams yield

$$\begin{aligned}\Sigma_{\eta\eta}^{\mathrm{V}}(\omega) = \sum_{\alpha\beta l} & g(\eta\beta;\, l\alpha)/[\omega+\varepsilon_l-\varepsilon_\alpha-\varepsilon_\beta-(\beta\beta;\, ll) \\ & +(\beta l;\, l\beta)].\end{aligned} \tag{30}$$

Then we get

$$\frac{\partial}{\partial\omega}\Sigma_{ii}^{\mathrm{V}}(\omega)\Big|_{\omega=\varepsilon_i} = -\sum_{\alpha kl} g(ik;\, l\alpha)/(\varepsilon_i+\varepsilon_\alpha-\varepsilon_k-\varepsilon_l)^2, \tag{31}$$

$$\begin{aligned}\frac{\partial}{\partial\omega}\Sigma_{\eta\eta}^{\mathrm{V}}(\omega)\Big|_{\omega=\varepsilon_\eta} &= -\sum_{\alpha\beta l} g(\eta\beta;\, l\alpha)/[\varepsilon_\eta-\varepsilon_\alpha-\varepsilon_\beta+\varepsilon_l \\ &\quad -(\beta\beta;\, ll)+(\beta l;\, l\beta)]^2 \\ &= -\sum_{\alpha kl} g(ik;\, l\alpha)/[\varepsilon_i+\varepsilon_\alpha-\varepsilon_k-\varepsilon_l \\ &\quad +(kk;\, ll)-(kl;\, lk)]^2,\end{aligned} \tag{32}$$

for the negative and positive ions, respectively. In obtaining the second equality of (32), use was made of the pairing properties,

$$\varepsilon_\eta = -\varepsilon_i, \qquad g(\eta\beta;\, l\alpha) = g(ik;\, l\alpha). \tag{33}$$

The expression of (32) is same as that of (31) except for additional terms in the denominator.

Using (31) and (32) in (15), we get δp of (20) as

Table 1. Proton hfs values of aromatic ion radicals. Experimental and theoretical results

		Experimental hf value/G			Theoretical		
		+ion	−ion	$\delta\Delta$	δp	$\delta\sum^{hf}$	$\delta\Delta$
	α	6.65	5.41	0.23	−0.051	0.340	0.189
	β	3.12	2.76	0.13	−0.051	0.107	0.056
	γ	1.40	1.53	−0.085	−0.051	0.051	0.
	α	5.17	4.25	0.22	−0.060	0.173	0.113
	β	1.72	1.55	0.11	−0.060	0.060	0.
	γ	1.06	1.15	−0.078	−0.060	0.035	−0.025
	α	4.10	3.53	0.16	−0.066	0.121	0.055
	β	3.10	3.08	0.0065	−0.066	0.091	0.025
	γ	0.46	0.46	0.	−0.066	0.013	−0.053

$$\delta p \simeq \left.\frac{\partial\sum^{v}_{\eta\eta}(\omega)}{\partial\omega}\right|_{\omega=\varepsilon_\eta} - \left.\frac{\partial\sum^{v}_{ii}(\omega)}{\partial\omega}\right|_{\omega=\varepsilon_i}$$

$$= -\sum_{\alpha kl} g(ik;\, l\alpha)\{[\varepsilon_{i\alpha kl}+(kk;\, ll)-(kl;\, lk)]^{-2}-\varepsilon^{-2}_{i\alpha kl}\} \tag{34}$$

with

$$\varepsilon_{i\alpha kl} = \varepsilon_i+\varepsilon_\alpha-\varepsilon_k-\varepsilon_l. \tag{34a}$$

As $\varepsilon_{i\alpha kl}$ is negative, it is found that δp has the positive sign.

Comming back to (20), we discuss effects of two terms constructing the hyperfine energy difference between positive and negative ions: the first is δp which is negative and relates with the electron correlation of the whole system, and the second is $\delta\sum^{hf}$ which is positive, strongly depending upon the local situation where the magnetic nucleus under consideration is.

Numerical Results and Discussion

The present theory being semi-qualitative, the numerical procedure is simplified to save computer time. The π electron orbitals which are involved in our calculation are obtained by the Hückel method, and are regarded as the self-consistent HF orbitals in the PPP approximation. Then the electron-electron interactions are introduced with the Nishimoto-Mataga parametrization.[7] Therefore the orbital energies in (34a) are not Hückel ones, but are regarded as the HF orbital energies in the PPP approximation.

In evaluating the hyperfine self-energy term employing the CH fragment, the energy separation between the CH bonding and antibonding orbitals is needed. This is approximately estimated in the semi-empirical theory as $\varepsilon_{ak}\simeq -10$ eV. As to the electron repulsion terms, the exchange integral, $(ik;ki)$ is negligibly small, and the direct term, $(ii;kk)$ may be a little smaller than the one-center coulomb repulsion integral multiplied by the unpaired electron density at the carbon atom, ρ_{Ci}: $(ii;kk)\simeq 10\rho_{Ci}$ eV. These energy parametrizations make $\delta\sum^{hf}$ given by (28) simple as

$$\delta\sum^{hf} = (1-\rho_{Ci})^{-1} - 1 \tag{35}$$

We tabulate observations and theoretical results of a few species as explanational examples. In table we have given values of δp and $\delta\sum^{hf}$; for example in the case of anthracene radical, the negative value of δp is independent of sites, while values of $\delta\sum^{hf}$ which are positive rapidly decrease in order of α, β, and γ. The overall value at each site agrees qualitatively with observation. In other species, we can get the negative values at γ positions, which were never explained by the current theories.

Somebody will be suspicious of our theoretical result, claiming that parametrizations in the present treatment mask the reliability. However, we think that a theory would be successful, if it present any possibility to explain the observed values under reasonable (to some extent) assumptions.

Hiroshi TAKAHASHI, and Yasukazu SAITO*

Institute of Industrial Science, The University of Tokyo, 22-1, Roppongi 7-Chome, Minato-ku, Tokyo 106

(Received September 26, 1979)

Mesoporous silica gel with a narrow pore-size distribution at the pore diameter of 200 Å has been prepared upon gelation in the presence of starch. Taking into account the effects on the geometrical properties of its surface, two typical surface-modifying procedures that utilize organoalkoxysilane were characterized. Procedure I retains the mesoporous structure, although the fixed amount of the organofunctional group is rather small. Procedure II introduces a large amount of the organofunctional group to the surface, but is accompanied by a pronounced reduction in both the B.E.T. surface area and the specific pore volume. The observed range of the apparent surface concentration of the organofunctional group and the scanning electron micrographs suggest that the surface is coated with highly crosslinked organosiloxane polymers in the latter case. Despite the contrasts between the two modified surfaces, the similarity of C-13 NMR line shapes, chemical shifts, and spin-lattice relaxation times between the respective surface organofunctional groups indicates that their microenvironment and mobility resemble each other.

The modification of the surface of porous adsorbents *via* the chemical bonding of the organofunctional group is now a common procedure to improve them for use as a stationary phase in liquid chromatography[1] or as a support of soluble complex catalysts.[2] A surface reaction with organoalkoxysilane is one of the most popular methods for this purpose, but scarcely physicochemical investigation has been undertaken to examine how the surface is actually "modified" by such a treatment.[1,3]

Since such geometrical properties as the specific pore volume and pore-size distribution govern the efficiency of chromatographic separations[4-6] and the activity and/or selectivity of catalytic reactions,[7] it is especially important to characterize appropriately the effect of the surface modification. From this viewpoint, we prepared mesoporous silica gel with a narrow pore-size distribution at the 200 Å pore diameter, and investigated the change in the geometrical properties associated with the coupling treatment with organoalkoxysilane. In an attempt to characterize the fixed organofunctional groups spectroscopically, C-13 NMR (CMR) spectroscopy was applied to them. Two typical procedures for fixation[8-11] were adopted, and the advantage of each procedure is discussed.

Experimental

Preparation of Mesoporous Silica Gel. Starch (15 g) was dissolved in warm water (500 cm^3), and the resulting solution was mixed with an aqueous solution of colloidal silica (Nissan Chem. Ind., Ltd.; Snowtex-30: SiO_2 content 30—31%; particle diameter 10—20 nm; pH 9.5—10.5; 500 cm^3). The mixed solution was poured into acetone (2.5 dm^3) with stirring and allowed to stand for 4 d with occasional stirring. During this procedure silica gel was precipitated, and the supernatant solution was replaced by acetone (2.5 dm^3) once a day. The silica gel thus formed was filtered, air-dried, milled in an α-alumina mortar, and calcined in air (120 °C, 24 h). After calcination, the color of the silica gel changed from white into light brown. It was decolorized by repeated washing with water, and then boiled three times. After cooling, the water was decanted and acid (concd HNO_3–concd H_2SO_4 150 cm^3; 9/1 Vol.) was added to the residual suspension of silica gel, which was then permitted to stand for 24 h. The treatment with acid was done twice. The sample was washed with water untill the solution became neutral and then dried in a drying oven. Silica gel was evacuated at 200 °C (4 h) immediately before the succeeding fixation treatment.

Procedure for the Fixation of Organofunctional Groups. The fixation of 3-aminopropyl or *N*-(2-aminoethyl)-3-aminopropyl groups to silica gel was effected in two ways. Procedure I: To a toluene solution (100 cm^3) of silane ($NH_2CH_2CH_2CH_2Si(OEt)_3$: Shin-Etsu Chem. Ind., Ltd.; 15.6 g), silica gel (10 g) was added with stirring, after which the suspended solution was refluxed for 24 h. The sample was then transferred to a Soxhlet apparatus, extracted with benzene for 24 h, and dried *in vacuo* (130 °C, 4 h). The fixation procedure for $NH_2CH_2CH_2NHCH_2CH_2CH_2Si(OMe)_3$ (Shin-Etsu Chem. Ind., Ltd.) was performed similarly using the following amounts of reagents: silane, 20.8 g; toluene, 100 cm^3, and silica gel, 15.0 g. Procedure II was the same as Procedure I except that water, in an amount equivalent to that necessary for hydrolyzing the alkoxyl group of the silane, was introduced into the toluene before the addition of silane. In Procedures I and II, about 20 and 70% of the added silane were consumed for fixation respectively.

Characterization of Silica Gels. The B.E.T. surface area (s_{BET}) was determined using the B.E.T. procedure (a_m (N_2) = 16.2 $Å^2$ $molecule^{-1}$). The specific pore volume (v_p) and the pore-size distribution were calculated from the nitrogen adsorption (or desorption) measurements at 77 K, based on the method of Cranston and Inkley,[12] or by means of mercury porosimetry (American Instrument Co., Ltd.; 60000 psi). The amounts of the fixed organofunctional groups were evaluated from the carbon and nitrogen contents of the modified silica gel, as determined from the elemental analysis. In the evaluation, alkoxyl carbons were omitted (*vide infra*), and the two values, coinciding within a 10% deviation, were averaged. Scanning electron micrographs were taken using a Hitachi HHS-2R SEM apparatus. CMR spectra were obtained with noise-modulated proton decoupling on a Fourier-transform pulsed NMR spectrometer (JEOL JNM-FX60), operating at 15.04 MHz.

Results and Discussion

Geometrical Properties of the Surfaces. The prepared silica gel (original silica gel) has the values of 148 $m^2 g^{-1}$ for s_{BET} and 0.792 $cm^3 g^{-1}$ for v_p (calculated at the saturated vapor pressure). In particular, as revealed by mercury porosimetry, it has a maximum abundance of mesopores, amounting to 0.45 $cm^3 g^{-1}$, with an (entrance) pore diameter of about 200 Å (Fig. 1). This feature is probably derived from the effect of the incorporation of starch upon gelation.[13,14] The nitrogen adsorption and desorption isotherms on the silica gel showed hysteresis. The analysis of the isotherms gave the pore-size distributions depicted in Fig. 2. The cumulative pore volumes below 300 Å were 0.427 and 0.653 $cm^3 g^{-1}$ respectively. Since a distinctive peak with a maximum abundance at a pore diameter of about 200 Å appears only in the case of desorption, the mesopores with that pore diameter may be formed with various bottlenecks.

After the modification with Procedure I, the corresponding values became 0.332 $cm^3 g^{-1}$ (nitrogen adsorption), 0.483 $cm^3 g^{-1}$ (nitrogen desorption), and 0.46 $cm^3 g^{-1}$ (mercury porosimetry). As far as the 200 Å-mesopores are concerned, both the mercury porosimetry (Fig. 1) and the nitrogen desorption experiment (Fig. 2) showed distribution patterns similar to those of the original silica gel around this range, and their abundance, evaluated by the mercury porosimetry, was actually hardly affected at all. The application of the V_a-t plot,[15,16] however, showed that the micropores (<7 Å) present on the original silica gel with the surface area of 12 $m^2 g^{-1}$, where S_{total} was evaluated to be 151 $m^2 g^{-1}$, were lost after this modification. It can be said that Procedure I caused little change in the mesopore structure, although it disrupted most of the micropores.

It was found that Procedure II exerted a further influence on the surface geometrical properties because of the presence of water in the fixation treatment. Figure 1 shows that a large amount of mesopores of the original silica gel disappeared during the treatment. The cumulative pore volume below 300 Å was decreased as low as 0.082 $cm^3 g^{-1}$, and the V_a-t plot indicated that the micropores vanished also in this case. For reference, the result for the Aerosil 380 (Degussa) modified with Procedure II is shown in Fig. 1. Naturally, it exhibits no population in the mesopore range of about 200 Å. The distribution in the pore-size range around tens of thousands ång-

stroms, which was observed in all the cases in Fig. 1, may correspond to the interstitial volume of agglomerated particles.

Table 1 presents the amount of the fixed organofunctional group, together with the values of s_{BET} and v_p, for the silica gels modified by the use of Procedure I or II in repeated runs. It is seen that Procedure II caused a pronounced reduction in both s_{BET} and v_p, but introduced an appreciable amount of organofunctional groups to the surface in comparison with Procedure I. The characteristic mesopores of the original silica gel are retained in Procedure I, whereas in Procedure II they are limited in return for the large amount of fixation. From this viewpoint, the trend shown in Table 1 is consistent with the data of the pore-size distribution.

The influence of these fixation procedures may be noticed plainly in the apparent surface concentration of the fixed organofunctional group (Table 1). In the case of Procedure I, the values have the same order of magnitude as the ordinary surface concentration of hydroxyl groups on silica gels (about 4.8 hydroxyl groups per 100 Å^2).[17] In contrast, Procedure II gave values far exceeding this value.

Scanning Electron Micrographs. Some representative scanning electron micrographs (SEM) of the original and modified silica gels are shown in Fig. 3. A remarkable feature is that the spherical shape of Aerosil 380 is completely lost by the modification with Procedure II. It appears that a number of Aerosil particles were combined and coated with a polymer-like substance, possibly an organosiloxane polymer. The marked decrease in s_{BET} (from 380 to 36 m^2 g^{-1}) seems to support this view. The SEM of the mesoporous silica gel modified with Procedure II also appears to indicate a similar surface coating. The observed range of the apparent surface concentration suggests that highly crosslinked organosiloxane polymers were formed as a result of the trifunctionality of the modifiers. The resemblance between the two silica gels, original and modified with Procedure I, is reasonable in view of the rather small change in the surface characteristics by this modification. It has been suggested that organoalkoxysilane molecules are fixed on silica surfaces in the monomeric form when the amount of physically adsorbed water is small.[1]

CMR Properties. The C-13 nuclear magnetic resonance of the fixed organofunctional group is detectable with high resolution if the solvent used to suspend the modified silica gel is properly chosen.[18] The CMR spectra of the fixed 3-aminopropyl groups are shown in Fig. 4. The absence of ethoxyl carbon resonances confirms that the ethoxyl groups were completely removed in the course of the fixation treatment. It is apparent that the two modified silica gels gave essentially identical spectra despite the salient contrasts between the geometrical properties of their surfaces. The situation was unaltered for the *N*-(2-aminoethyl)-3-aminopropyl group. The chemical shift data are tabulated in Table 2. The observed substantial low-field shift of the C_1 carbon atom seems reasonable in view of the fact that 2-butenes[19] and toluene[20] adsorbed on silica gel or Zeolite show low-field shifts for the carbon atoms pertinent to adsorption.

For the same samples, the spin-lattice relaxation times (T_1) of the carbon atoms were determined by the inversion-recovery method.[21] Table 3 shows that fixation caused a considerable reduction in T_1 values; here, too, there is no distiguishing difference between the two procedures.

The effect of possible paramagnetic impurities in the silica gel on the spin-lattice relaxation is small for the following reasons: (i) for both modified silica gels, the T_1 values of the C_1 carbon atom are significantly different between the two kinds of organofunctional groups, and (ii) the values of the ^{13}C–^1H nuclear Overhauser effect were determined to be 1.3 (C_1) and 1.6 (C_2) for the *N*-(2-aminoethyl)-3-amino-

propyl group (fixed with Procedure II; $CDCl_3$ solvent), values which are close to the maximum value of this effect (1.988) and which indicate the predominance of ^{13}C–^{1}H dipole-dipole interactions in the relaxation of these carbon atoms.[21] We consider that the observed enhancement of relaxation rates is ascribable to the decrease in the freedom of motion of the organofunctional groups resulting from the anchoring of the silicon atom. The magnitude of T_1 is reasonable for the aliphatic carbon chain, whose translational motion is hindered, but whose internal rotation is almost free, when compared with those for the butyl group anchored in poly(butyl methacrylate) (T_1 in s: C_1 0.12, C_2 0.13, *etc.*).[22] The increase in T_1 from C_1 to C_2 to C_3 reflects the ease of motion, in that order.

It should be noted that the resemblance of line shapes between the spectra suggests that the fixed organofunctional groups obtained with Procedure II have a homogeneity similar to those obtained with Procedure I. This similarity seems noticeable in view of the high crosslinkage of organosiloxane polymers, which was suggested for the former case. Based on the CMR properties reported above, it may be concluded that the microenvironment and the mobility of the fixed organofunctional groups resemble each other in the D_2O solvent, irrespective of the difference in the method of surface modification.

Comparison of the Two Surface-modifying Procedures. The two procedures for surface modification have thus been characterized. In the case of Procedure

II, pores of silica gel as large as 200 Å in pore diameter are covered with organosiloxane polymers, but this procedure has the merit of producing a large quantity of fixation. This may be advantageous for its use as a silica support for preconcentration of trace metals,[23] affinity chromatography, or the immobilization of soluble complex catalysts with high density of active sites.

In contrast, modification with Procedure I retains the mesoporous structure of the silica gel surface. In this case, the ability to separate substances or to select substrates, through differentiating their molecular sizes, can be expected. If this characteristics is employed properly, the utility of the surface organofunctional groups may be enlarged.

The authors whish to thank Mr. Tatsuro Tsuru for the nitrogen adsorption and desorption measurements.

Synthesis and Electrical Properties of TCNQ Radical Anion Salts with *N,N'*-Ethylenedi(1,3-dithiolan-2-iminium) Dication and Related Dications

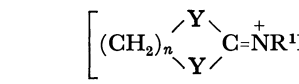
Yoshiji Yumoto, Ryoji Nishioka, and Toshio Tanaka*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

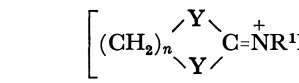
(Received September 27, 1979)

Simple and complex salts of the $TCNQ^{-}$ radical anion with *N,N'*-ethylenedi(1,3-dithiolan-2-iminium) dication and related dications,  $(TCNQ)_m^{2-}$ (R=H, Me; n=2, 6; m=2, 3, or 4) and  $(TCNQ)_m^{2-}$ (m=2, 3) were synthesized. All the salts as compacted samples display semiconducting behaviors in the 77—300 K range. Electrical resistivities of the simple salts are in the range of 1.8×10^{5}—9.8×10^{7} Ω cm at 25 °C. Electronic absorption spectra and magnetic susceptibilities suggest that the simple salts in the solid state involve $(TCNQ)_2^{2-}$ dimer. The 1 : 3 complex salt of *N,N'*-dimethyl-*N,N'*-ethylenedi(1,3-dithiolan-2-iminium) with TCNQ,  $(TCNQ)_3^{2-}$, exhibits a lower electrical resistivity (3.4 Ω cm) than other four complex salts (2.4×10—2.5×10^{3} Ω cm). Electronic absorption spectra and magnetic susceptibilities of the both 1 : 3 and 1 : 4 complex salts are interpreted in terms of the interaction between the TCNQ moieties.

According to the molecular requirements for obtaining highly conducting 7,7,8,8-tetracyanoquinodimethane (TCNQ) salts, for example, planar structure and high polarizability of the cation moiety, one of the authors recently prepared some simple and complex salts formed between *N,N*-dialkyl-1,3-dichalcogenacycloalkan-2-iminium cations and $TCNQ^{-}$ radical anion;

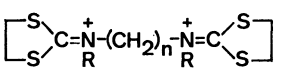


and



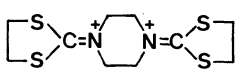
(n=2 or 3; Y=S or Se; R^1=R^2=Me, Et, *n*-Pr, *n*-Bu, *n*-C_6H_{13}, *n*-C_8H_{17}, *n*-$C_{10}H_{21}$, and Ph; R^1=Me and R^2=Ph).[1,2] All of these salts showed semiconducting behaviors. Electrical resistivities of the complex salts as compacted samples fell in the 2.4—90 Ω cm range at 25 °C with activation energies of 0.018—0.12 eV, whereas the simple salts exhibited the electrical resistivities of 4.4×10^{3}—1.3×10^{9} Ω cm with activation energies of 0.16—1.3 eV.

Thus, the iminium cations may be useful as cation sources in the synthesis of electrical conducting organic crystals. In this study, we have taken up di(1,3-dithiolan-2-iminium) dications, **A** and **B**, as the cation moieties of $TCNQ^{-}$ salts.



A

R= H, Me; n=2, 6



B

These dications are expected to have potential possibility of the formation of unusual stoichiometric $TCNQ^{-}$ salts with interesting electrical and magnetic properties. In fact, the stoichiometries of diquarternized 1,2-di(4-pyridyl)ethane and 1,2-di(4-pyridyl)-ethylene salts with TCNQ are 1:3,[3] 1:4,[4] 1:5,[5] and 2:5,[6] and the 1:4 complex salt of 1,2-bis(1-ethylpyridinim-4-yl)ethylene dication with the $TCNQ^{-}$ radical anion exhibit a metallic behavior below room temperature.[7]

This paper reports the preparation and electrical resistivity of some simple and complex salts of $TCNQ^{-}$ with the iminium dications. Electronic absorption spectra and magnetic susceptibilities of these salts are discussed in terms of the interaction between the TCNQ moieties.

Experimental

Disodium polymethylenebis(dithiocarbamate) (**1a—d**) were prepared as described in the literature.[8] Bis(triethylammonium) 1,4-piperazinebis(carbodithioate) (**2**) were obtained similarly by the reaction of piperazine in ethanol with triethylamine, followed by the addition of carbondisulfide.

N,N'-Ethylene-, *N,N'-Dimethyl-N,N'-ethylene-*, *N,N'-Hexamethylene-*, *N,N'-Dimethyl-N,N'-hexamethylenedi(1,3-dithiolan-2-iminium) and N,N'-Bis(1,3-dithiolan-2-ylidene)piperazine-1,4-dium Salts (**3a—d** and **4**).* To a suspension of **1a** (3.0 g, 12 mmol) in ethanol (20 ml) was added large excess 1,2-dibromoethane (5.1 g). The mixture was refluxed for 6 h, during which time white color of the suspension turned to yellow. A floating solid material in the suspension was collected by filtration and recrystallized from water to give white needles of *N,N'*-ethylenedi(1,3-dithiolan-2-iminium) dibromide (**3a**) in a 40% yield; mp 210—212 °C. Found: C, 22.26; H, 3.35; N, 6.60%. Calcd for $C_8H_{14}N_2S_4Br_2$: C, 22.54; H, 3.32; N, 6.57%. Similarly four other iminium dications were obtained as hexafluorophosphate or tetraphenylborate in 40—55% yields by the reaction of **1b—d** or **2** with excess 1,2-dibromoethane in ethanol, followed by the addition of ammonium hexafluorophosphate or sodium

tetraphenylborate. *N,N'*-Dimethyl-*N,N'*-ethylenedi(1,3-dithiolan-2-iminium) bis(hexafluorophosphate) (**3b**), mp 280—281 °C. Found: C, 20.26; H, 3.05; N, 4.68%. Calcd for $C_{10}H_{18}N_2S_4P_2F_{12}$: C, 20.55; H, 3.10; N, 4.79%. *N,N'*-Hexamethylenedi(1,3-dithiolan-2-iminium) bis(hexafluorophosphate) (**3c**), mp 198—200 °C. Found: C, 23.27; H, 3.58; N, 4.63%. Calcd for $C_{12}H_{22}N_2S_4P_2F_{12}$: C, 23.53; H, 3.62; N, 4.57%. *N,N'*-Dimethyl-*N,N'*-hexamethylenedi(1,3-dithiolan-2-iminium) bis(hexafluorophosphate) (**3d**), mp 225—227 °C. Found: C, 26.03; H, 4.02; N, 4.25%. Calcd for $C_{14}H_{26}N_2S_4P_2F_{12}$: C, 26.25; H, 4.09; N, 4.37%. *N,N'*-Bis(1,3-dithiolan-2-ylidene)piperazine-1,4-diium bis(tetraphenylborate) (**4**), mp 260—262 °C. Found: C, 74.10; H, 6.13; N, 3.23%. Calcd for $C_{53}H_{56}N_2S_4B_2$: C, 74.83; H, 6.06; N, 3.01%.

N,N'-Ethylene-, *N,N'-Dimethyl-N,N'-ethylene-*, *N,N'-Hexamethylene-*, *N,N'-Dimethyl-N,N'-hexamethylenedi(1,3-dithiolan-2-iminium) and N,N'-Bis(1,3-dithiolan-2-ylidene)piperazine-1,4-diium-TCNQ Simple Salts (5—9).* To a boiling ethanol (20 ml) solution of $Li^+TCNQ^{\cdot-}$ (0.50 g, 2.4 mmol) was added a hot aqueous (10 ml) solution of **3a** (0.50 g, 1.2 mmol). The mixture was allowed to stand in a refrigerator overnight. The resulting precipitate was recrystallized from acetonitrile to give **5** in a 71% yield. Other four simple salts **6—9** were prepared similarly by the equimolar reaction of $TCNQ^{\cdot-}$ in ethanol with the appropriate iminium dications in an acetonitrile/ethanol mixture (2:1 v/v), 67—85% yields.

N,N'-Ethylene-, *N,N'-Dimethyl-N,N'-ethylene-*, *N,N'-Haxamethylene-*, *N,N'-Dimethyl-N,N'-hexamethylenedi(1,3-dithiolan-2-iminium) and N,N'-Bis(1,3-dithiolan-2-ylidene)piperazine-1,4-diium-TCNQ Complex Salts (10—14).* To a boiling acetonitrile (50 ml) solution of the simple salt **5** (0.53 g, 0.78 mmol) was added two equivalent amounts of neutral TCNQ (0.32 g, 1.6 mmol) in boiling acetonitrile (25 ml). The mixture was allowed to stand at room temperature to afford **10** in a 75% yield. Similarly other complex salts **11—14** were prepared by the reactions of **6—9** with neutral TCNQ at the mole ratio of 1:2 in acetonitrile, respectively, 64—71% yields.

Physical Measurements. Electrical resistivities were measured as described previously,[1] in the 286—370 K range (for **5**—**9** and **12**) or using a OXFORD CF 104 cryostat equipped with digital temperature controller DTC-2 in the 77—300 K range (for **10**, **11**, **13**, and **14**). Electronic spectra were recorded on a HITACHI 340 spectrophotometer (3900—16700 cm^{-1}) and a UNION GIKEN SM 401 spectrophotometer (11100—50000 cm^{-1}). Infrared spectra were measured on a HITACHI 215 infrared spectrophotometer. Magnetic susceptibilities were measured for microcrystalline materials by a SHIMADZU MB-11 magnetic balance in the range of 77—300 K.

Results and Discussion

Synthesis and Characterization. Five *N,N'*-polymethylenedi(1,3-dithiolan-2-iminium) dications reacted with TCNQ$^{\cdot-}$ radical anion to give simple salts **5**—**9** with the composition of 1:2. Simple salts **5**, **6**, and **9** further reacted with neutral TCNQ in acetonitrile to afford the 1:3 complex salt, irrespective of the mole ratio of the reactants. On the other hand, the reactions of simple salts **7** and **8** with neutral TCNQ yield the 1:4 complex salts. This variation in compositions of the complex salts may reflect the distance between two cation sites in a given iminium dication.

The ratios of the TCNQ$^{\cdot-}$ radical anion to neutral TCNQ in these complex salts (Table 1) were determined by the absorbances at 395 and 842 nm in acetonitrile,[9] where the absorbance at 395 nm is a sum of those for the TCNQ$^{\cdot-}$ radical anion and neutral TCNQ and the absorbance at 842 nm is due to only the TCNQ$^{\cdot-}$ radical anion.

Electrical Properties. Temperature dependence of electrical resistivities for the simple and complex salts are illustrated in Fig. 1. The electrical resistivities (ρ) of simple and complex salts at 25 °C and the activation energies (E_a) calculated from the Arrhenius plots based on the equation, $\rho=\rho_0\exp(E_a/kT)$, are listed in Table 2, where ρ_0 is the constant value and k is the Boltzmann's constant. All the simple and complex salts showed typical semiconducting behaviors in the temperature range measured. The ρ values of simple salts **5**—**9** are in the same range as those of *N,N*-dialkyl-1,3-dithiolan-2-iminium-TCNQ$^{\cdot-}$ simple salts,  (R=Me, *n*-Pr, *n*-C_6H_{13}; $2.2\times10^5-1.3\times10^7$ Ω cm).[1,2] The ρ values shown in Table 2 indicate that the substitution of methyl group on the iminium nitrogen is more or less effective for obtaining organic salts with low electrical resistivities (compare **6**, **8**, **11**, and **13** with **5**, **7**, **10**, and **12**, respectively). On the other hand, the ρ values do not seem to be rationalized in terms of the methylene chain lengths (for instance, compare **12** and **13** with **10** and **11**, respectively), though more methylene groups between the two cation sites in a given iminium dications is possible to result in lowering planarity of the iminium dications. It should be noted that complex salt **11** exhibits a small ρ value, which is compared with those of *N,N*-dimethyl- and *N,N*-diethyl-1,3-dithiolan-2-iminium–TCNQ$^{\cdot-}$ complex salts, (3.8 and 3.3 Ω cm for R=Me and Et, respectively).[1] The resistivity, however, is larger by one order of magnitude than that of the highest conducting complex salt, quinolinium(TCNQ)$_2^{\cdot-}$ (0.5 Ωcm as compacted sample).[10]

Electronic Spectra and Magnetic Properties. Figure 2 illustrates the electronic absorption spectra of **6**, **11**, and **13** in the solid state. Simple salt **6** exhibits three absorption bands in the range of 4000—32000 cm^{-1}, of which the lowest energy band is assigned to the charge-transfer (CT) transition between the TCNQ$^{\cdot-}$ radical anions and the remaining two bands to the (TCNQ)$_2^{2-}$ dimer.[11] The presence of the (TCNQ)$_2^{2-}$ dimer in **6** is supported also from its diamagnetic property in the solid state at room temperature (χ_M=

a) Shoulders in parentheses.

-3.0×10^{-4} emu mol^{-1}). Other four simple salts **5**, **7**, **8**, and **9** in the solid state showed electronic absorption spectra similar to that of **6**, as listed in Table 3. They also exhibited diamagentic properties at room temperature, which suggest that two $TCNQ^{\cdot-}$ radical anions are coupled completely with each other, resulting in the formation of the $(TCNQ)_2^{2-}$ dimer pair in solid **5**, **7**, **8**, and **9**.

The spectrum of **11** showed four absorption maxima in the 4000—32000 cm^{-1} range, of which the lowest energy band may be due to the CT transition between the $TCNQ^{\cdot-}$ radical anion and neutral TCNQ,[11] whereas the spectral appearance of the remaining three bands roughly resembles that of simple salt **6**, suggesting that the $TCNQ^{\cdot-}$ radical anions more or less interact with each other regardless of the additional TCNQ in neutral form. This is consistent with the diamagnetic property of **11** at room temperature ($\chi_M=-1.2\times10^{-4}$ emu mol^{-1}). In addition, the spectral features of **11** are very similar to those of $(Cs^+)_2(TCNQ)_3^{2\cdot-}$,[11] (morpholinium$^+$)$_2$(TCNQ)$_3^{2\cdot-}$,[11] and $\left[(CH_2)_2\begin{smallmatrix}S\\S\end{smallmatrix}C{=}\overset{+}{N}(n\text{-}C_{10}H_{21})_2\right]_2(TCNQ)_3^{2\cdot-}$.[2] Complex salt **11** is, therefore, suggested to have a stacking of TCNQ moieties similar to these 2:3 complex salts, where exists the unit consisting of two $TCNQ^{\cdot-}$ radical anions and one neutral TCNQ. The same conclusion can be drawn for **10** and **14** on the basis of their electronic spectra similar to that of **11** and diamagnetisms at room temperature.

The 1:4 complex salt **13** exhibits a spectrum similar to those of the 1:2 complex salts of *N*,*N*-dialkyl-1,3-dithiolan-2-iminium cations, $\left[(CH_2)_2\begin{smallmatrix}S\\S\end{smallmatrix}C{=}\overset{+}{N}R_2\right]$-$(TCNQ)_2^{\cdot-}$ (R= *n*-Pr, *n*-Bu, and Ph);[2] the intense absorption around 26000 cm^{-1} may be contributed from both the LE_2 state of the $TCNQ^{\cdot-}$ radical anion and the excited state of neutral TCNQ.[11] The band around 10000 cm^{-1} may be assigned to a transition to the LE_1 state[11] of the $TCNQ^{\cdot-}$ radical anion. The presence of monomeric $TCNQ^{\cdot-}$ is consistent with the fact that **13** showed a paramagnetism at room temperature ($\chi_M=6.6\times10^{-4}$ emu mol^{-1}). Another 1:4 complex salt **12** also exhibited essentially the same spectrum as **13** in the solid satte (Table 3). In addition, **12** and **13** showed a very broad band ranging from 4000 to 2500 cm^{-1}, which was never seen in the spectra of simple salts **5**—**9**. This band is assigned to the CT transition between $TCNQ^{\cdot-}$ and neutral TCNQ.[11]

Temperature dependence of the paramagnetic terms (χ_P) for complex salts **11** and **13** are illustrated in Fig. 3. The susceptibilities were obtained by subtracting the diamagnetic term calculated from Pascal's constants from the observed molar susceptibilities χ_M. Complex salt **11** obeys the Curie-Weiss' law. On the other hand, **13** shows a maximum near 160 K and its paramagnetic susceptibility increases as the temperature increases above 190 K. This behavior may indicate that the interaction between the unpaired electrons is changing irregularly with temperature. Whether the interaction is due to antiferromagnetic interaction, or the singlet-triplet equilibrium which

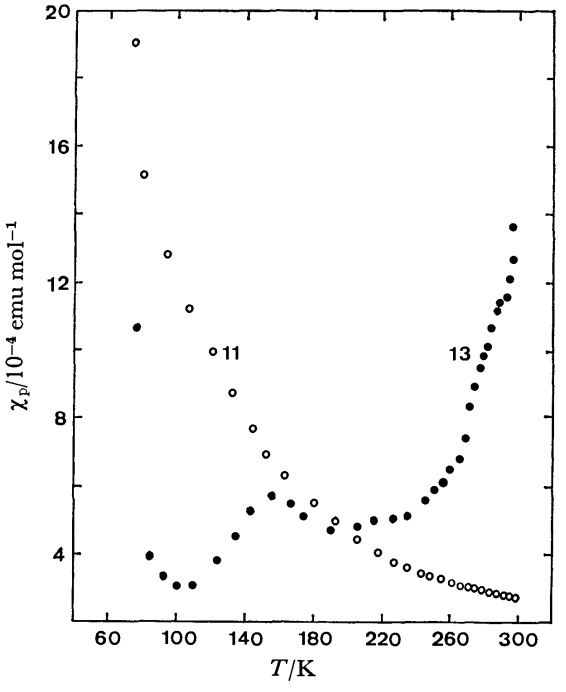

Fig. 3. Temperature dependence of paramagnetic susceptibilities of **11** and **13**.

has been reported in intermediate conductive 1:2 complex salts such as $Et_3\overset{+}{N}H(TCNQ)_2^{\cdot-}$,[12] is not clear in the present work. However, it is noted that the degree of the localization of the unpaired electrons (or spins) may be somewhat larger in **13** than **11**. This assumption may be correlated with the fact that **13** has a larger ρ value by one order of magnitude than **11**.

The authors wish to express their thanks to the Central Research Institute, Matsushita Electric Industrial Co., Ltd. for supplying a sample of TCNQ. They also would like to thank Professor Jiro Shiokawa of Osaka University for giving them the opportunity to use a magnetic balance. This work was carried out with a Grant-in-Aid for Scientific Research No. 347066 from the Ministry of Education, Science and Culture.

(Received September 29, 1979)

We have investigated the ESR spectrum of anion radical of purine generated electrochemically using a helical electrode cell for low-temperature ESR measurements. The assignment of the hfcc was made with the aid of partial deuteration and MO calculations. The most notable observation is that about 45% of the spin density is localized at position 6. This correlates well with the preferential hydrogenation at this position. The McLachlan method reproduces the observed spin distribution well with $\beta_{N9C}/\beta_{CC}=1.0$, which indicates that the bonding between the nitrogen at 9 and carbons at 4 and 8 have large double bond characters. The INDO-MO calculations based on the two molecular geometries for 9*H*-purine also agree well with the experimental data. Finally the effect of tautomerism of purine on the spectrum is discussed.

Since Pullman-Pullman's first theoretical work[1] a wide variety of experimental and theoretical investigations[2] have been made on biologically important purine bases in order to elucidate their electronic strucutres. For example, the lowest excited singlet state has been identified as a $n\pi^*$ state from the electronic absorption spectrum of purine(I).[3] Nuclear magnetic resonance (NMR) spectroscopy of H, ^{13}C and ^{15}N in purines[4,5] has given useful information regarding their tautomeric behavior of the labile protons. Theoretical calculations using different methods have been made on excited state energies,[3,6] electron distribution,[2,7,8] dipole moments,[7,8] and zero field splittings in triplet states.[9,10]

In order to evaluate the results of various theoretical calculations it is important to have experimental data on the details of electronic wave functions, but such data have not been available on purines so far. Electron spin resonance (ESR) spectroscopy in solution is capable of providing the most direct information on the wave functions of π electrons through hyperfine studies, but their radical species in solution have not been detected before, presumably because of their instabilities. In 1974 Yao and Musha investigated the electrochemical reduction of I in nonaqueous solvents and reported an ESR spectrum which they ascribed to the purine anion radical($I^{\cdot-}$),[11] but this is questionable because of its unusually large hyperfine coupling constants.

One of the present authors (H. O.) recently developed a two-electrode electrolysis cell using a helix for low-temperature ESR measurements which has several advantages over the commonly used electrolysis cell for ESR in obtaining the spectra of unstable anion radicals.[12] Using this cell we have succeeded in obtaining an ESR spectrum which is assigned to $I^{\cdot-}$ with reasonable certainty. In this paper we first report the ESR spectra of the anion radicals of I, 8-deuteriopurine(I-*d*) and 6,8-dideuteriopurine(I-d_2) produced electrochemically at low temperatures and analyze them using the computer simulations. Secondly the hyperfine coupling constants (hfcc) obtained are compared with those calculated by McLachlan's method and INDO-MO method established by Pople and Beveridge.[13] Both calculations are carried out based on the two tautomeric forms, 7*H*- and 9*H*-purines. Thirdly we discuss the effect of tautomerism of I in relation to the NMR results.[4]

Experimental

Purine(Aldrich) was normally used without further purifications. Identical results were obtained by using purine purified by vacuum sublimation. I-*d* and I-d_2 were synthesized by heating purine in refluxing D_2O for 4 h and 72 h, respectively, according to the method by Schweizer *et al.*[14] From the proton NMR spectra it was shown that I-*d* was produced completely, but I-d_2 sample was found to contain I-*d* by 35%. Acetonitrile(AN) and butyronitrile(BN) were purified according to the method of Van Duyne and Reilly.[15] After being dried with molecular sieve 4A, *N*,*N*-dimethylformamide(DMF) was distilled over fresh molecular sieve 4A. Just before the preparation of the sample solution DMF was shaken with Na_2SO_4 to ensure complete dryness of the solvent and was transferred to the electrolysis cell with a pipet in an atmosphere of dry nitrogen gas. This process was effective of prolong the lifetime of the purine anion radical. As the supporting electrolyte tetrabutylammonium perchlorate(TBAP) or tetrabutylammonium tetrafluoroborate-(TBFB) (Nakarai Chemical Ltd., SP grade for polarography) was used without further purifications. Electrochemical reduction of I, I-*d* and I-d_2 were carried out inside the cavity using the cell consisting of a helix and a gold wire going through inside the helix. The details of the cell construction were given previously,[12] ESR spectra were taken with a JEOL PE-3 spectrometer equipped with a temperature controller.

Results and Discussion

ESR Spectra. After the temperature of the solution was decreased as low as −50 °C the voltage applied between the two electrodes was increased until the ESR signal could be observed on an oscilloscope or a recorder with the modulation amplitude of 1.0×10^{-4} T. As the voltage reached −6.0 V an ESR signal with hyperfine structures appeared. In view of the results of a electrochemical study of purine by Yao and Musha[11] the observed ESR spectrum is

† Also Department of Chemistry, State University of New York at Stony Brook, Stony Brook, N. Y. 11794, U.S.A.

most likely due to $I^{\cdot-}$. This appearance voltage(V_a) is appreciably lower than twice the half-wave reduction potential ($E^r_{1/2}$) of I measured by Yao and Musha (−2.30 V). However, the previous work[12] has shown that V_a is considerably lower than twice $E^r_{1/2}$, when the produced anion radical is unstable. Hence $I^{\cdot-}$ is likely to be highly reactive. For the observation of high resolution spectra a voltage of −7.0 V or lower was applied during the ESR measurements. ESR measurements were made with low modulation amplitude of the order of 0.1×10^{-4} T. The spectrum intensity reached its maximum in several minutes and disappeared at most in 20 minutes.

A typical example of the spectrum taken with the modulation amplitude of 10^{-5} T is shown in Fig. 1a. It can be satisfactorily interpreted in terms of the three doublet splittings of 10.46, 4.80 and 1.75×10^{-4} T due to protons, and the three triplet splittings of 4.47, 1.14 and 0.28×10^{-4} T due to nitrogen nuclei. This interpretation of the spectrum was confirmed by the computer simulation made by using these splittings and the linewidths of 0.45×10^{-4} T (Fig. 1b). It should be noticed that the observed spectrum consists of the hyperfine splittings due to only one species.

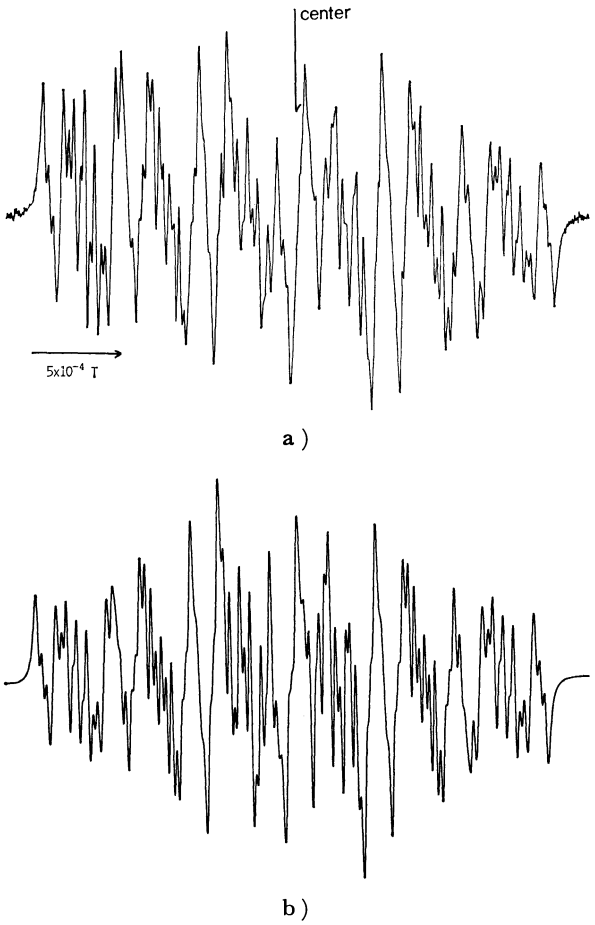

Fig. 1. a) ESR spectrum of $I^{\cdot-}$ generated electrochemically in DMF with 0.1 M TBAP at −50 °C, the applied voltage between two electrodes being −7.0 V. b) The simulation spectrum based on the data in Table 1. Total width: 28.79×10^{-4} T, line width: 0.450×10^{-4} T.

Recent evidence based on ^{13}C NMR indicates that I in dimethyl sulfoxide (DMSO) is in an equilibrium between 7*H*- and 9*H*-purine at room temperature, the ratio of the former to the latter being 4:6.[4] We have not detected so far any evidence for the existence of such tautomerism in our system. The experimental conditions, such as temperature, solvent used, supporting reagent, purification steps of I, have been altered, but the same spectrum was observed. The *g*-value of the spectrum was 2.0028, being close to that of free electron.

In order to ascertain the identification of the anion radical and to assign the proton hfcc, we have also taken the ESR spectra of I-$d^{\cdot-}$ and I-$d_2^{\cdot-}$ in DMF at −50 °C. Their spectra were resolved well enough to allow the analysis of hfcc (Fig. 2 and 3), though the spectrum of I-d_2 was superposed with the spectrum due to 35% of I-*d*. In table 1 the observed hfcc are summarized with those calculated by Hückel molecular orbital (HMO) modified with McLachlan's method.[16] From the comparison of the coupling constants of $I^{\cdot-}$ with those of I-$d^{\cdot-}$ and I-$d_2^{\cdot-}$ two coupling constants, 10.46 and 4.80G can be assigned unequivocally to positions 6 and 8, respectively. The others cannot be assigned experimentally but are tentatively assigned to the particular positions in the molecule

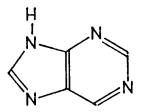
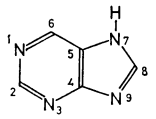
from the comparison of the experimental data with those obtained by the MO calculations (Table 1).

Comparison with Molecular Orbital Calculations. The molecule of I is usually represented by the form in which the labile proton is attached to the N(9) nitrogen: 9*H*-purine. However, the chemical shift values in ^{13}C NMR spectra of I and its methyl derivatives in DMSO indicates that I in DMSO is a tautomeric mixture of 60% 9*H*-purine and 40% 7*H*-purine. It is necessary, therefore, to take these tautomers into account when we compare the experimental data with the calculated ones. We have calculated spin densities of these tautomers by McLachlan's methods, using the parameters derived empirically in pyridines and diazines by Talcot and Myers[17], except



7*H*-purine



9*H*-purine

for the nitrogen to which the labile hydrogen atom is attached. The Coulomb integral of the nitrogen (α_N) in the NH fragment was estimated as $\alpha_N=\alpha_C+1.2\,\beta_{CC}$, based on the analysis of hfcc of radical cations of the dihydro derivatives of some diaza-aromatic compounds[18]. The resonance integrals between the nitrogen atom in this fragment and the adjacent carbon atoms (β_{NC}) were adjusted so as to fit to the experimental data. Spin densities of the 9*H*-purine anion radical were calculated by changing $\delta=\beta_{NC}/\beta_{CC}$ and the hfcc were calculated using $Q_N^N=27.3$, $Q_{NC}=-1.7$ and $Q_H=-42.5$G.[17] The obtained hfcc are given in Fig. 4 as functions of δ. Here $\delta=0.5$ corresponds to a model in which the NH fragment can be regarded as a secondary amine group. Then I is adequately described as 4,5-disubstituted pyrimidine with a strongly mesomeric substituent at position 5. This model is characterized by the largest spin density (48%) at position 8, followed by the next largest (26%) at position 6. As δ increases, spin densities at positions 6 and 3 increase appreciably accompanied by the decreases at positions 8 and 2. The best fit to the experimental results, shown by the dotted lines in Fig. 4, is obtained at $\delta=1.0$, which means that the

electronic structure of $I^{\overline{\cdot}}$ should be regarded as one of a 10π-electron heterocyclic aromatics rather than that of a substituted pyrimidine with a strongly mesomeric substituent. In other words, the bonding between the nitrogen at 9 and carbons at 4 and 8 have double bond characters as much as an aromatic –C–C– bonding. This choice of δ is also supported by the result of the X-ray study by Watson *et al.*,[19] which showed that the bond lengths between N(9) and C(4), and N(9) and C(8) are 1.37 and 1.31 A, respectively, indicating double bond characters of these bonds. The hfcc of 7*H*-purine anion radical was also calculated using the same parameters as in the case of 9*H*-purine, which are also shown in Table 1. It should be noticed in Table 1 that the calculated coupling constants of two tautomers are quite similar to each other and are in good agreement with the experimental results except for that of the labile proton.

In order to further compare the experimentally determined hfcc with those calculated by MO methods we have also made INDO calculations. As is well known, the results of the calculations carried out by this method depends on the geometries adopted. Here we used the same geometries as those adopted by Pullman *et al.*;[7] Watson and inverted Spencer geometries for 7*H*-purine, and inverted Watson and Spencer geometries for 9*H*-purine. The Watson geometry was derived from the crystallographic data of purine which has 7*H*-form in crystal.[19] The Spencer geometry means the structure established by Spencer on the basis of a general study of purine derivatives which are in 9*H* forms.[20] The inverted Watson and the inverted Spencer geometries were obtained by inverting the lengths of the 7–8 and 8–9 bonds, those of the 5–7 and 4–9 bonds, and the corrsepond-ing angles, respectively. The hfcc of $I^{\overline{\cdot}}$ calculated with these geometries are listed in Table 2.

It is seen from the table that the calculated hfcc for 9*H*-purine are rather different from those for 7*H*-purine and are in better agreement with the experimental hfcc. The best agreement between the experimental and the calculated hfcc seems to be obtained in the case of Spencer geometry of 9*H*-purine. The inverted Watson model can predict a large hfcc for H6, but the agreement with the experimental results is somewhat poorer. The total width of the ESR spectrum calculated for 9*H*-purine also agrees reasonably well with the observed total width. On the other hand, the hfcc calculated for 7*H*-purine do not reproduce the observed features of hfcc. The total width of the spectra calculated are much larger than the observed one. Thus the results of the INDO

calculations seem to be in favor of the 9*H*-form for I^-.

The most remarkable feature of the spin distribution of the purine anion is that about 45% of the spin density is localized at position 6. Such a large localized spin density is very rare in a π electron system of the size of I and should have an important implication to its chemical reactivity. It is known that the reaction such as hydrogenation takes place preferentially at position 6.[11] This was rationalized from the result of MO calculation.[21] According to Fukui's frontier electron theory[22] such a reaction should take place at the position where the frontier electron density is the largest. Our result clearly shows a large electron density in the frontier orbital (LUMO) at position 6.

It is interesting to compare the unpaired electron spin distribution in LUMO of I with that of indole. Although its electron spin distribution is not known experimentally, the result of a semiempirical calculation[23] may be used for comparison. The spin densities at positions 2, 3, 6, and 8 of indole, the position numbers of which correspond to those of I, are 0.136, 0.220, 0.212 and 0.155, respectively. From the comparison with the data of I it may be deduced that aza-substitution to the particular ring carbons enhances the localization of the spin density to position 6.

Tautomerism of Purine. Sometimes in the ESR spectra the dynamic behaviors of radical species can be revealed from line-width alternation, or line-width variation which can be related to the lifetimes of the radical species under consideration. If we take into account the difference in the calculated coupling constants between two stable tautomers, two possibilities can be considered from the observed spectrum: one is the case that the anion radical formation stabilizes one of the two tautomers (7*H*- or 9*H*-purine) at the temperatures around -50 °C, and the other is that the exchange of the labile proton between the two tautomers is very rapid compared with the ESR time scale, 10^6 Hz s^{-1}. It is difficult at present, to say definitely which is appropriate for the interpretation of the observed spectrum, but the former case is more likely when we take into account the ^{15}N NMR result that only one very broad signal for N7 and N9 could be observed because of slow hydrogen exchange of the order of 10^2 Hz sec^{-1}.

Effect of a Polar Solvent on the $^1J_{CH}$ Spin-coupling Constants in Chlorine-substituted Ethanes

Shosuke WATANABE* and Isao ANDO†

Minato High School of Technology, 18-13, Nishi-shinbashi 3-chome, Minato-ku, Tokyo 105

† *Department of Polymer Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152*

(Received October 11, 1979)

The directly-bonded ^{13}C–H spin-coupling constants ($^1J_{CH}$) for two chlorine-substituted ethanes, $CHCl_2CHCl_2$ and $CHCl_2CH_2Cl$, have been measured in various solvents with a wide range of dielectric constants and/or as a function of the temperature. Also, these two effects were estimated by the finite perturbation theory based on the CNDO/2 approximation with the solvaton theory. Both experimentally and theoretically, the dielectric constant of a solvent affects the $^1J_{CH}$ more than the temperature. It is shown that the solvent effect on the $^1J_{CH}$ spin couplings in $CHCl_2CHCl_2$ and $CHCl_2CH_2Cl$ arises mainly from electronic changes in the solute molecules caused by intermolecular solute-solvent interaction, more than from the change in the population of the rotational isomers.

The effects of solvents on spin-coupling constants have been widely studied by many authors. Some excellent reviews[1] have been presented on these effects.

In a previous paper,[2] we have ourselves treated numerically the effect of a polar solvent on directly-bonded ^{13}C–H spin-coupling constants for molecules in which unsaturated bonds fix the relative spatial positions of the atoms with each other (*e.g.*, CH_2=CHCN), and for halomethanes, with the aid of the finite perturbation theory[3] (hereafter, an acronym FPT will be used) with the solvaton model.[4] This approach successfully provided a quantitative description of the solvent effects on $^1J_{CH}$, following the Johnston-Barfield approaches, the reaction field model,[5] the cluster model[6] and the rotating-point dipole model.[7]

There is another category of solvent effects of coupling constants, namely, the solvent effects of the coupling constants of molecules which can take into account two or more conformations. In this case, we must consider two effects on the coupling constants; one is due to solvent-induced electronic changes in the solute molecules, and the other, to the change in the relative populations between the isomers because of intermolecular solute-solvent interaction. Barfield and Johnston[1a] calculated the vicinal H-F coupling constants in 1,1,1-trifluoroethane using the reaction-field model and concluded that the contribution from the solvent-induced electronic changes on the observed solvent effect is by no means negligible. The purpose of the present work is to separate the above two effects both experimentally and theoretically, and to discuss the mechanism of the solvent effect on the $^1J_{CH}$'s of molecules with rotational isomerism. We will analyze this problem with the term of FPT considering the effect of the aprotic polar solvent on the $^1J_{CH}$ coupling constants in chlorine-substituted ethanes, $CHCl_2CHCl_2$ and $CHCl_2CH_2Cl$.

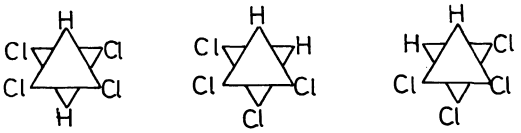
Experimental

The ^{13}C NMR spectra were measured by means of a JEOL PS-100 spectrometer with the PFT-100 Fourier transform system operating at 25.15 MHz. The Fourier-transformed spectra contain 4096 data points within spectra width of 1000 Hz. This indicates a limit of 0.25 Hz on the resolution. The temperatures are considered to be controlled within ±1 °C. The NMR tube used was 8 mm in diameter. The concentration of the sample in solution is 10% v/v.

The chlorine-substituted ethanes and solvents were obtained from the Tokyo Kasei Co. and were used without further purification.

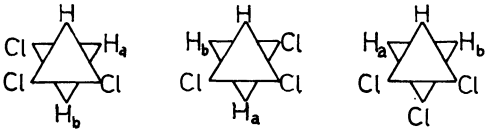
Theoretical

Rotational Isomerism. Both $CHCl_2CHCl_2$ and $CHCl_2CH_2Cl$ take the three energetically-preferred isomeric states as follows;[8] $CHCl_2CHCl_2$:



1-I 1-II 1-III

$CHCl_2CH_2Cl$:



2-I 2-II 2-III

The observed coupling constant is given by[9]

$$\langle J_{CH}\rangle = X_I J^I_{CH} + X_{II} J^{II}_{CH} + X_{III} J^{III}_{CH}, \quad (1)$$

when the exchange rate is sufficiently larger than the difference between J_{CH}'s, where X_I, X_{II}, and X_{III} are the molar fractions of the three isomers, I—III, respectively. Each of the molar fractions can be expressed in terms of the relative energy, ΔE, of the isomer with respect to that of the reference conformer, III. Equation 1 can be reduced into the following forms if the coupling constants are assumed to be temperature-independent;[10]

$CHCl_2CHCl_2$:

$$\langle J_{CH}\rangle = [2J^{II}_{CH} + J^{I}_{CH}\exp(-\Delta E/RT)]/[2+\exp(-\Delta E/RT)] \quad (2)$$

$CHCl_2CH_2Cl$:

$$\langle J_{CH}\rangle = \frac{1}{2}[(J^{III}_{CH_a} + J^{III}_{CH_b}) + 2(J^{I}_{CH_a} + J^{I}_{CH_b})\exp(-\Delta E/RT)]/[1+2\exp(-\Delta E/RT)] \quad (3)$$

We can evaluate, in principle, the relative energies,

ΔE's of the isomers and the coupling constants, J_{CH}^{i}'s, from the temperature dependence of $\langle J_{CH}\rangle$'s. It is, however, hard to determine them because of the small change in $\langle J_{CH}\rangle$'s. Gutowsky *et al.*[9] have estimated the relative energies of the isomers through the temperature dependence of the vicinal proton-proton spin couplings in halogen-substituted ethanes by means of a least squares method with a computer. In our previous work, the values of the relative energies of the isomers were estimated by Gutowsky's treatment[9] from the temperature dependence of the vicinal proton-proton spin coupling[11] in calculating Eqs. 2 and 3.

$^1J_{CH}$ Spin-coupling Constant. In previous papers,[2,12] we have applied the solvaton model to interaction with a solvent with the aid of semi-empirical SCF calculations. The "solvaton" is convenient for the description of the distribution of the oriented solvent around each atom in a molecule. Only a few important basic assumptions are introduced there: i) A counter charge (the solvaton) is induced on the surface of the solute molecules upon the addition of the solute to an aprotic polar solvent: (ii) each solvaton is associated individually with each atom of the solute, and the charge is equal in magnitude, but opposite in sign, to that of the associated atom: (iii) there are no interactions between the solvatons themselves, and (iv) the solvent-solute interaction is approximated by the Born equation,[13] which describes the energy of the solvaton of an ion in a dielectric continuum.

We will calculate $^1J_{CH}$ coupling constants as a function of the dielectric constant(ε) with the aid of the CNDO/2 approximation[14] in consideration of the above-mentioned solvent-solute interaction using the FPT theory. In this calculation, we will consider only the Fermi contact interaction, which seems to be predominant in $^1J_{CH}$ coupling constants.

The spin-unrestricted SCF equations on the Fock matrices, $F_{\mu\nu}^{\alpha}$ and $F_{\mu\nu}^{\beta}$, for α and β electrons are given by

$$F_{\mu\nu}^{\alpha} = H_{\mu\nu}^{core} + \sum_{\lambda\sigma}[P_{\lambda\sigma}(\mu\nu|\lambda\sigma) - P_{\lambda\sigma}^{\alpha}(\mu\sigma|\lambda\nu)] + \frac{\varepsilon-1}{\varepsilon}\int\phi_{\mu}\left(\sum_{s}^{N}\frac{Q_s}{r_{s1}}\right)d\tau + \frac{8}{3}\pi\beta\mu\int\phi_{\mu}\delta(r_B)\phi_{\nu}d\tau \quad (4\text{-}1)$$

$$F_{\mu\nu}^{\beta} = H_{\mu\nu}^{core} + \sum_{\lambda\sigma}[P_{\lambda\sigma}(\mu\nu|\lambda\sigma) - P_{\lambda\sigma}^{\beta}(\mu\sigma|\lambda\nu)] + \frac{\varepsilon-1}{\varepsilon}\int\phi_{\mu}\left(\sum_{s}^{N}\frac{Q_s}{r_{s1}}\right)d\tau - \frac{8}{3}\pi\beta\mu\int\phi_{\mu}\delta(r_B)\phi_{\nu}d\tau \quad (4\text{-}2)$$

if the Fermi contact interaction[3] and the solvent-solute interaction are taken into account. The third terms including ε correspond to the solvent-solute interaction given by the solvaton theory, while the final terms in both equations correspond to the Fermi contact interaction. μ denotes the magnetic moment of the nucleus B, and $\delta(r_B)$, the Dirac delta function for the contact term between the electron and the nucleus B. The other symbols are used in the usual manner. The charge, Q_s, is defined by the (i) assumption. In a previous paper,[2] we assumed an inequality between Q^{α} and Q^{β} in the solvaton, but this assumption tends to overestimate the values of the $^1J_{CH}$ coupling constant. Thus, in this work, we modified this assumption by terms including ε in Eq. (4): that is, Q_s is handled without being separated into Q_s^{α} and Q_s^{β}. Further, r_{s1} is the solvaton-electron distance and is estimated as follows: (i) if the AO's and solvatons are associated with the same atomic center, the van der Waals' radius, r_v, of the corresponding atom can be used for the solvaton-electron distance, and (ii) if the AO's and solvatons are associated with different atomic centers with a separation of r_R, r_{s1} is approximated by:

$$\sqrt{r_v^2 + r_R^2}.$$

The expression for the coupling constant between A and B becomes:

$$J_{AB} = \frac{16}{9}h\gamma_A\gamma_B\beta^2 s_A^2(0)s_B^2(0)\left[\frac{\partial}{\partial h_B}\rho_{s_As_A}^{spin}(h_B)\right]_{h_B=0} \quad (5)$$

using the FPT theory, where:

$$h_B = \frac{8}{3}\pi\beta\mu_B s_B^2(0)$$

Here, γ is the gyromagnetic ratio, $s_B^2(0)$ is the density at the nucleus of the valence s orbital of the B atom, and $\rho_{s_As_A}^{spin}(h_B)$ is the spin-density matrix corresponding to the valence s orbital of the A atom.

In calculation, the bond lengths and bond angles used are the standard values proposed by Pople and Gordon[15] except for the C–Cl bond length, the value of the C–Cl is not given there. Instead, 1.71 Å, which appears elsewhere, is adopted.[16] The values used for the effective van der Waals' radii are 1.20, 1.59, and 1.8 Å in hydrogen, carbon, and chlorine atoms respectively.[17] All the calculations were carried out with the HITAC-M180 computer at the Tokyo Institute of Technology.

Results and Discussion

In Table 1 are shown the observed $^1J_{CH}$ values of $CHCl_2CHCl_2$ and $CHCl_2CH_2Cl$ in solvents with various dielectric constants. From these data, it is found that the $^1J_{CH}$ values increase with an increase in ε. The ε dependence of $^1J_{CH}$ in $CHCl_2CHCl_2$ is nearly equal to that in $CHCl_2CH_2Cl$. Also in $CHCl_2CH_2Cl$ the ε dependence of $^1J_{CH}$ for CH is larger than that for CH_2. In a previous paper[2] we have reported that the observed and calculated $^1J_{CH}$ values can be approximated by:

$$^1J_{CH} = a\left(\frac{\varepsilon-1}{\varepsilon}\right) + b\left(\frac{\varepsilon-1}{\varepsilon}\right)^2 + c \quad (7)$$

From the plot of $^1J_{CH}$ against $(\varepsilon-1)/\varepsilon$, the values of the a, b, and c parameters were obtained, they are tabulated in Table 2. The c parameter means the $^1J_{CH}$ value at $\varepsilon=1$, that is, for an isolated molecule. The a and b parameters provide measures of the magnitude of the solvent effect of $^1J_{CH}$ coupling. In the case of chlorine-substituted methanes,[2] the b parameter is nearly equal to zero. However, in $CHCl_2CHCl_2$

Table 2. The values of the a, b, and c parameters in Eq. 7 for $CHCl_2CHCl_2$ and $CHCl_2CH_2Cl$

Parameter	$CHCl_2CHCl_2$	$CHCl_2CH_2Cl$	
	CH (Hz)	CH_2 (Hz)	CH (Hz)
a	3.5	0.5	2.0
b	4.0	1.3	3.0
c	178.3	154.9	180.3

Table 3. Temperature dependence of the $^1J_{CH}$ spin coupling constants of $CHCl_2CHCl_2$ and $CHCl_2CH_2Cl$ in neat liquid

Temp °C	$^1J_{CH}$/Hz		
	$CHCl_2CHCl_2$	$CHCl_2CH_2Cl$	
	CH	CH_2	CH
25	181.15	155.64	181.98
40	181.15	155.81	181.88
60	181.15	155.52	181.84
70	181.16	155.55	181.81
80	181.15	155.64	181.75
90	181.15	155.54	181.70
100	181.15	155.52	181.69

and $CHCl_2CH_2Cl$ the b parameter is finite, but larger than the value of the a parameter. The values of these parameters for CH are larger than those for CH_2. This fact coincides with the results for chlorine-substituted methanes,[2] in which an increase in the number of chlorine atoms induces an increase in the solvent effect.

Table 3 shows the temperature dependences of the $^1J_{CH}$ values of neat $CHCl_2CHCl_2$ and $CHCl_2CH_2Cl$. The $^1J_{CH}$ coupling is hardly dependent at all on the temperature. Thus, the temperature dependence for $^1J_{CH}$ is much smaller than the dependence on the polarity of the solvents. The difference in the $^1J_{CH}$ values in various solvents may not be the result of the difference in the populations of rotational isomers, but of the difference in electronic states in the molecules induced by the difference in solvent species. We will consider which difference is predominant through the calculation of the $^1J_{CH}$ couplings for a wide variety of dielectric constants and examples of rotational isomerism.

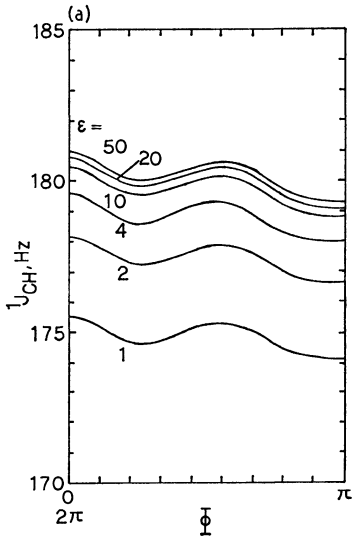
Before the numerical calculation, however, it is important to specify at the amounts of integral products, $s_C^2(0)s_H^2(0)$, chosen according to the FPT theory. The values will not only reflect the difference between the atomic or molecular environments of the nuclei, but will also be affected by the order of approximation in the molecular orbital theory. Thus, these values have often been proposed to coincide satisfactorily with the experimental results. Different values for the integral products seem to be different approximations inherent in the finite, self-consistent, and sum-over-states perturbation approximations. Two kinds of values will be used in this work: (i) Pople's value ($s_C^2(0)s_H^2(0)=1.5014$ a.u.),[3] and (ii) the ($s_C^2(0)s_H^2(0)=1.644$ a.u.) value, which gives the best agreement between the experimental results and our calculations. Table IV shows the calculated ε dependence of the $^1J_{CH}$ coupling constants of $CHCl_2CHCl_2$ and $CHCl_2CH_2Cl$ in *trans* and *gauche* conformations, using both values of the integral products. It is clear that the choice of the larger value (1.644 a.u.) for $s_C^2(0)s_H^2(0)$ decreases the difference between the calculated and experimental values. The dependence of the $^1J_{CH}$ coupling upon the dihedral angle, ϕ, is calculated at intervals of 10° as a function of ε, they are plotted in Fig. 1. The $^1J_{CH}$ value shows the dihedral-angle dependence as well as that of the coupling through three bonds. However, its dependence is very small compared with the latter case. Each of the dihedral-angle dependences for CH in $CHCl_2CHCl_2$ and $CHCl_2CH_2Cl$ have three minima and three maxima, while that for CH_2 in $CHCl_2CH_2Cl$ has two minima and two maxima. These positions are different in each case. The $^1J_{CH}$ values are not very much affected by $\phi(|^1J_{CH}(trans)-{}^1J_{CH}(gauche)|<0.5$ Hz). The $^1J_{CH}$ values in the *trans* and *gauche* positions are close to each other. From this, the temperature independence of the $^1J_{CH}$ couplings can be expected. On the other

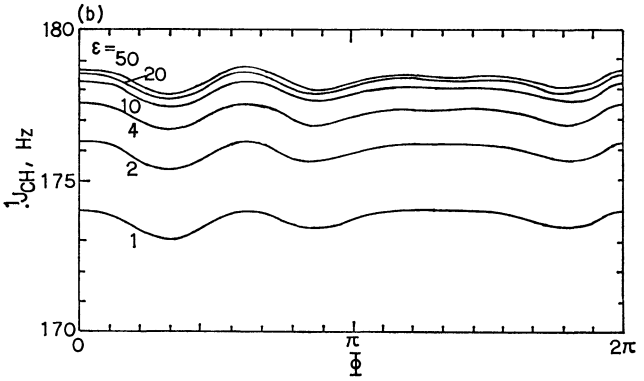
hand, the ε dependence can be expected to be large.

The temperature dependences of $\langle {}^1J_{CH} \rangle$ were obtained using the calculated ${}^1J_{CH}$ couplings of *trans* and *gauche* conformations tabulated in Table 4, and Eqs. 2 and 3. In these equations the energy differences (ΔE) between the conformers in various solvents were determined with Gutowsky's treatment on vicinal proton-proton spin coupling:[11]

$CHCl_2CHCl_2$: 889 (in CCl_4), 919 (neat liquid), 1165 (in acetone) and 1352 cal/mol (in dimethylsulfoxide), while

$CHCl_2CH_2Cl$: 160 (in CCl_4), 200 (neat liquid), 217 (in acetone) and 504 cal/mol (in dimethylsulfoxide).





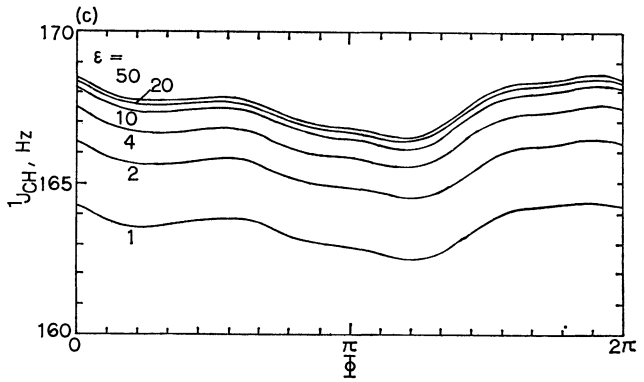


Fig. 1. The dihedral angle(Φ) dependences of the calculated ${}^1J_{CH}$ coupling constants of CH (a) in $CHCl_2$-$CHCl_2$ and CH (b) and CH_2 (c) in $CHCl_2CH_2Cl$ as a function of dielectric constant.

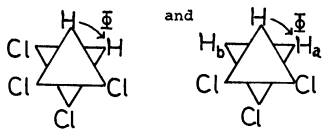
a) The definition of the dihedral angle, Φ, is as follows:



The results for $^1J_{CH}$ are shown in Table 5. The temperature dependence of the dielectric constants of the solvents is taken into account in Table 5 by the use of:

$$(\varepsilon+1)\cdot T \propto \text{constant} \quad (8)$$

after Wyman's study[18] of large classes of polar liquids. The calculated $\langle^1J_{CH}\rangle$ values are almost independent of the temperatures and can interpret the observed values qualitatively.

In order to obtain the calculated effect of the ε dependences of the $^1J_{CH}$, Eqs. 2 and 3 were used as well as the calculation of the temperature dependence. These results are shown in Table 6.

Table 5. Temperature dependences of the calculated $^1J_{CH}$ coupling constants of $CHCl_2CHCl_2$ and $CHCl_2CH_2Cl$ in neat liquid

100	177.25	167.00	178.75

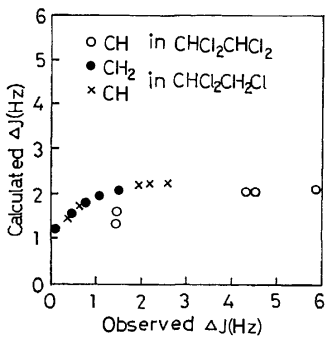

Fig. 2. The plots of calculated ΔJ against observed ΔJ.

For a further comparison of the calculated and experimental results, the differences, ΔJ, between the coupling constants in the indicated solvents and in hexane are shown in the table and also in Fig. 2. The calculated trends reproduce the observed ones in the solvent effect. However, the calculated values in the high-value range in ΔJ are underestimated. This seems to be a result of the exclusion of the one-center exchange integral in our calculation, because the inclusion of its integral leads to an increase in the magnitude of the directly-bonded coupling constant, as has been reported by Pople *et al.*[3]

As these results shows, the ε dependence is very large compared with the temperature dependence. This large dependence on ε is a proof of the larger contribution of the solvent-induced electronic changes of the solute molecules to the solvent effect on the $^1J_{CH}$, resulting from intermolecular solute-solvent interaction.

It can be concluded that there are good gross trends of agreement between the observed and calculated results. This would suggest a potential applicability of the solvaton theory in interpreting solvent effects in dipolar media.

The authors wish to thank Associate Professor R. Chûjô of our department for his many helpful suggestions and discussions.

The Crystal and Molecular Structure of Epoxyisoacoragermacrone

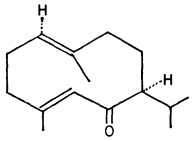
Hideo UEDA,† Chuji KATAYAMA, and Jiro TANAKA*

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

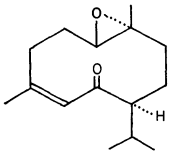
(Received October 15, 1979)

The crystal and molecular structure of epoxyisoacoragermacrone, which is an important derivative of acoragermacrone isolated from *Acorus calamus* L. for the study of the structural organic chemistry and biogenetic reactions, has been determined by the X-ray method. The crystal is orthorhombic, $P2_12_12_1$, with lattice parameters $a=7.425(2)$, $b=26.604(8)$, and $c=7.150(2)$ Å. The ten-membered ring is in a boat-chair conformation similar to the highly strained *cis*, *trans*-germacradiene system. The methyl groups take the axial and *syn* arrangement, and are on the β-face of the medium ring.

Recently, many germacrane-type sesquiterpenes isolated from the plants have been investigated by X-ray analysis. The structures of these sesquiterpenes were discussed from a viewpoint of biogenetic reactions,[1-3] pharmacological activities,[4-8] and conformations of ten-membered ring skeleton.[9-14] As a series of studies on sesquiterpenes separated from sweet flag oil,[15b] Yamamura and his coworkers[15] isolated many sesquiterpenes from *Acorus calamus* L. (Japanese name "Shyobu") and determined the structures by chemical and spectroscopic methods. They reported that acoragermacrone (**1**), which had a ten-membered skeleton, is one of the most important precursor of sesquiterpenes in Shyobu, and in fact, germacrones and epoxides derived from **1** are sesquiterpenes having selenane-, cadinane-, guaiane-, and elemene-types by cyclization reactions.[15c,d]



1



2

Epoxyisoacoragermacrone (**2**), 6,7-epoxy-10-isopropyl-3,7-dimethyl-2-cyclodecen-1-one derived from **1**, seems to be an important model compound for the biogenetic model reactions,[15d] and we undertook its X-ray crystal structure analysis.

Experimental

The crystals are of transparent prismatic forms. The space group was determined as $P2_12_12_1$ from the systematic absences observed on the oscillation and Weissenberg photographs. The unit-cell parameters were determined by the least-squares method, using twelve reflections measured on a Hilger & Watts four circle diffractometer with Ni-filtered Cu $K\alpha$ radiation ($\lambda=1.5418$ Å) The intensity data were collected on the diffractometer with the 2θ-ω scanning mode ($2\theta\leqq144°$) using the crystal of $0.3\times0.2\times0.3$ mm sealed in a glass capillary. The intensities of three standard reflections were monitored after every 100 reflections. The standard reflections were stable within 1% fluctuation from their mean values. Neither absorption nor extinction correction was made. The crystal data are given in Table 1.

TABLE 1. CRYSTAL DATA

M.W.:	236.36
Space group:	$P2_12_12_1$; $Z=4$
	$a=7.425(2)$, $b=26.604(8)$, $c=7.150(2)$ Å
D_c	$=1.111$ g cm^{-3}
μ	$=5.67$ cm^{-1} (for Cu $K\alpha$ radiation)

Determination and Refinement of the Structure

The structure was determined by the direct method with the program MULTAN[16] using 128 reflections with $|E|\geqq1.40$. An E map computed from the phase set with the highest figure of merit ($FOM=1.43$) revealed the locations of all non-hydrogen atoms. Hydrogen atoms were found on the difference Fourier map. The refinement was performed by the block-diagonal least-squares method with 960 independent reflections of $|F_o|\geqq3\sigma$. R-index converged to 0.060 with an equal weight for each reflection. The atomic scattering factors were taken from "International Tables for X-Ray Crystallography."[17] The least-squares program used for the refinement was written by Katayama, one of the authors. The program ORTEP[18] was used for drawing of Figs. 1—3. A part of the computation was performed at the Nagoya University Computation

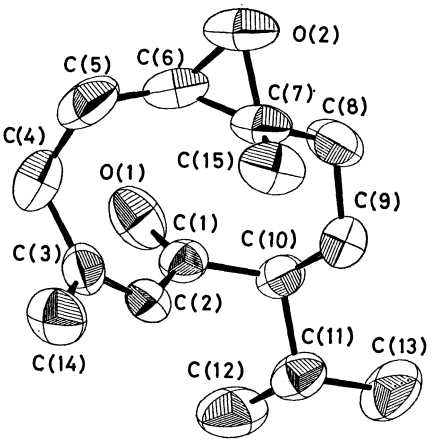

Fig. 1. The atomic numbering of **2**. Carbon and oxygen atoms are represented as thermal ellipsoids of a size such that the vibrating atoms have a 50% probability of being found them. The absolute configuration of the molecule was drawn to be in conformity with the established configuration by a chemical correlation method.

Center. The observed and calculated structure factors are given in Table 2.[19]

Results and Discussion

The molecular structure with atomic numberings is shown in Fig. 1, where each atom is represented by thermal ellipsoid as having 50% probability. The positional and thermal parameters of non-hydrogen atoms with their standard deviations are given in Tables 3 and 4, respectively. The coordinates and isotropic thermal parameters of hydrogen atoms are given in Table 5. The bond lengths and angles with their standard deviations are listed in Tables 6 and 7, respectively.

The molecule takes a "boat-chair" conformation. An α,β-unsaturated ketone chromophore takes a cisoid configuration, which is not planar, the torsion angle around C(1)–C(2) bond being 33°. The double bond C(2)=C(3) and epoxide group, equivalent to a double bond, are *cis* and *trans* configuration, respectively.

The methyl groups of germacradiene-type sesquiterpenes including *cis*, *trans*-double bonds are *anti* arrangement,[6] and of other ten-membered ring sesquiterpenes, shiromodiol[9] and pregeijerene[10] containing *trans,trans*-double bonds are *syn*, while those of melampodin[6] and haliangine,[14] *cis,trans*-double bonds, are *anti* arrangement. On the other hand, the conformations of the substituents of **2**, the epoxy and isopropyl groups, are semi equatorial and the two methyl groups are axial, *syn* arrangement, and β-orientation.

Ōsawa *et al.*[20] estimated the ground state conformation for all possible geometrical isomers of hedycaryol, one of the germacradiene-type sesquiterpenes, by the molecular mechanics calculations, and proposed that all the isomer might have more than two stable conformations. Takeda *et al.*[21] reported that several conformations of the ten-membered ring sesquiterpene should be considered in solution by temperature dependent NMR and NOE measurements. Yamamura *et al.*[15d] reported the C_{14} methyl group in **2** and in a reaction product of **2** by thiophenol protrudes into α-face of the macrocycle, which is contrary to our results. Therefore, it seems likely that the molecule

can take many conformations in solution.[21] The conformation of the medium ring of **2** is same as a less stable geometrical isomer of hedycaryol.[20]

Dunitz[22] distinguished between the conformers of ten-membered ring in terms of the endocyclic torsion angles. The torsion angles of some compounds having ten-membered ring are shown in Table 8. Each torsion angle of **2** is very similar to that of melampodin[6] and enhydrin,[8] which belongs to a highly strained *cis,trans*-germacradiene system. In dihydromikanolide[3] and pregeijerene,[10] however, several bonds are distorted in the opposite directions by about same magnitude compared with **2**.

The bond lengths are all normal except the C(6)–C(7) bond in the epoxide ring being significantly shorter than a normal single bond and the bond angle C(5)–C(6)–C(7), 123.3(6)°, indicates a remarkable deformation due to the epoxide ring formation. The similar distortion of the endocyclic bond angle was found in the other ten-membered ring epoxide, agerol diepoxide (127.2(6) and 125.0(5)),[1] dihydromikanolide (122.4(4)),[3] and elephantol *p*-bromobenzoate (124(1)°).[5]

Some of the non-bonded intramolecular distances are somewhat short, O(1)···C(6) being 3.199(8), C(1)···C(6), 3.094(9), C(1)···C(7), 3.206(9), C(2)···C(6), 3.240(9), and C(2)···C(7), 3.276(9)Å. A stereoview of the molecule is shown in Fig. 2, and the molecular packing in the crystal in Fig. 3. All intermolecular contacts are normal.

Polymer-protected Colloidal Nickel Boride in Ethanol and Its Catalytic Activity for Hydrogenation

Yukimichi NAKAO* and Shoei FUJISHIGE

Research Institute for Polymers and Textiles, Yatabe-Higashi, Tsukuba-gun, Ibaraki 305

(Received October 26, 1979)

Colloidal nickel borides were prepared in ethanol from nickel(II) chloride and sodium borohydride using a polymer as a protective colloid. For atmospheric hydrogenation of olefins such as acrylamide at 30 °C, the colloid prepared by using poly(vinylpyrrolidone) exhibited catalytic activity 15—60 times that of the usual nickel boride prepared without using a polymer. The high activity of colloidal nickel borides was found to be due to the polymers, soluble nylon being the most effective. The colloids are stable under oxygen-free hydrogen, decomposing immediately on exposure to air.

Reduction of nickel(II) chloride ($NiCl_2 \cdot 6H_2O$) with sodium borohydride ($NaBH_4$) in aqueous solutions gives a black precipitate of nickel boride which is catalytically active for the hydrogenation of olefinic compounds[1] and the hydrolysis of $NaBH_4$.[2] Many variations for the preparation of nickel boride have been reported.[3] Although the form of precipitated nickel boride varies according to the mode of preparation, most of them consist of a common unit Ni_2B.[3] In general, the activity of a solid catalyst such as nickel boride is primarily controlled by its effective surface area which is dependent upon both particle size and dispersion state. A number of reports[4] have appeared on the colloidal noble metals prepared from the corresponding metal salts by treatment with a reductant such as molecular hydrogen in aqueous solution. The coagulation of colloidal metals can be prevented by the presence of a polymer.

Hydrosol of nickel boride was prepared by the reduction of nickel(II) nitrate with potassium borohydride in the presence of a fairly large amount (5%) of a polymer such as acid gelatin and poly(vinyl alcohol).[5] Sols of metals in alcohol have been prepared in a similar manner.[6] An extremely fine colloid of rhodium (9 Å in diameter) was prepared from a methanolic solution of rhodium(III) chloride by treatment with sodium hydroxide in the presence of poly(vinylpyrrolidone) as a protective colloid. The colloidal rhodium was a very effective catalyst especially for the atmospheric hydrogenation of internal olefins. A clear nickel boride sol was prepared by the reduction of $NiCl_2 \cdot 6H_2O$ with $NaBH_4$ in ethanol under hydrogen in the presence of a small amount (0.01%) of poly(vinylpyrrolidone).[7] It exhibited a much higher activity for the hydrogenation of olefins such as acrylamide than that of the nickel boride precipitate prepared without using polymers. In the present paper, the effects of materials and the mode of preparation on the colloidal nickel boride as regards its catalytic activity and stability against oxygen are described.

Experimental

Chemicals. Hydrogen was of 99.999% purity. Liquid chemicals (reagent grade) for reaction medium were degassed by refluxing under argon before use. Solid chemicals (reagent grade) were used without further purification.

Preparation of Colloidal Nickel Boride. A typical procedure for the preparation of colloidal nickel boride is as follows. Nickel(II) chloride ($NiCl_2 \cdot 6H_2O$, 0.020 mmol) and poly(vinylpyrrolidone) (PVP-K30, degree of polymerization 360, 2.0 mg) were dissolved in ethanol (18 ml) under hydrogen. To the solution was added an ethanolic solution (1 ml) of sodium borohydride ($NaBH_4$, 0.040 mmol) prepared under argon with stirring at 30.0 °C and atmospheric pressure of hydrogen. Dark brown sol (19 ml) of nickel boride was obtained. The formation was followed by hydrogen evolution which ceased within 15 min.

Hydrogenation of Acrylamide. An ethanolic solution (1 ml) of acrylamide (0.25 mmol) prepared under argon was added to the nickel boride sol (19 ml) with stirring at 30.0 °C and atmospheric pressure of hydrogen, hydrogen uptake starting. The progress of hydrogenation was followed by means of the uptake volume of hydrogen. The hydrogenation product was found to be propionamide by means of infrared spectra.

Results

Formation of Colloidal Nickel Boride. Addition of an ethanolic solutions of $NaBH_4$ (0.040 mmol) to ethanolic solutions of $NiCl_2 \cdot 6H_2O$ (0.020 mmol) and PVP-K30 at 30 °C under hydrogen resulted in the formation of colloidal nickel boride. On adding $NaBH_4$, a short induction period of 1—2 s ended with the formation of a colloid. Colloidal nickel borides were obtained at 0 °C and −20 °C with induction periods 5 s and 25 s, respectively. Hydrogen evolution began immediately after the colloid formation, ceasing in 15 min. The total evolution volume was 2.55 ml (0.104 mmol).

Catalytic Activity for Hydrogenation. Addition of acrylamide[8] to colloidal nickel boride resulted in hydrogen uptake. Figure 1 shows the time-course of the hydrogen uptake. Equimolar amount of hydrogen with acrylamide was taken up until the hydrogenation was completed in 4 min. The initial rate of hydrogen uptake (r_1(acam)) was determined from the curve to be 167 H_2 mmol/Ni_2B mol s,[9] giving a measure of the catalytic activity of colloid.

Available Materials. Various nickel(II) salts, borohydrides, and solvents were examined for the preparation of colloidal nickel boride using PVP-K30. The results are given in Table 1. Nickel(II) sulfate and nickel(II) acetate also give colloidal nickel borides with an almost equal activity to that from $NiCl_2 \cdot 6H_2O$. On the contrary, a black colloidal solution from nickel(II) nitrate exhibits a much lower activity.

The use of water as a solvent gives a gray turbid solution which is not so effective as the clear sol pre-

pared in ethanol. Potassium borohydride (KBH_4) is almost insoluble in ethanol, but soluble in methanol. A sol prepared in methanol with KBH_4 is more effective than that prepared with $NaBH_4$.

Borohydride salts are known to react with methanol.[10)] Ethanolic and methanolic solutions of $NaBH_4$ were examined for their ability to produce active colloidal nickel boride. The dependence of the ability of both $NaBH_4$ solutions upon time after $NaBH_4$ dissolution at 17 °C is shown in Fig. 2. Ethanolic $NaBH_4$ is still able to produce a colloid after being left to stand for 18 h, the ability of methanolic $NaBH_4$ being completely lost within 1 h. When methanolic $NaBH_4$ was added to $NiCl_2 \cdot 6H_2O$–PVP-K30 solutions 20 min after its dissolution, a highly active colloid was obtained. KBH_4 reacted with methanol more slowly than $NaBH_4$.

A series of ethanol-soluble polymers were examined as a protective colloid using $NiCl_2 \cdot 6H_2O$, $NaBH_4$, and ethanol. Poly(vinylpyrrolidone)s, soluble nylon, and poly(vinyl alcohol) gave dark brown colloids, while poly(methyl vinyl ether) and ethyl hydroxyethyl cellulose gave black colloids. The catalytic activity of these colloids is shown in Table 2. Poly(vinylpyrrolidone)s of degree of polymerization 90 (PVP-K15) and 3250 (PVP-K90) give dark brown colloids with a nearly equal activity to that prepared with PVP-K30. The catalytic activity of colloid varies with the kind of polymer. Colloidal nickel boride with soluble nylon is the most active among those listed in Table 2, exhibiting about five times the activity of that with poly(methyl vinyl ether). *N*-methylpyrrolidone, a monomeric compound having the same functional group as poly(vinylpyrrolidone), gave no colloid but a black precipitate. Absence of a polymer also resulted in the precipitation of nickel boride.

Effect of $NaBH_4$ to $NiCl_2 \cdot 6H_2O$ Ratio. Colloidal nickel borides were prepared in ethanol with varying amounts of $NaBH_4$, and used as a catalyst after being stirred under hydrogen for 15 min. Figure 3 (solid line) shows the dependence of catalytic activity of colloidal nickel boride upon the molar ratio of $NaBH_4$ to $NiCl_2 \cdot 6H_2O$ (B/Ni). When less than equimolar $NaBH_4$ with $NiCl_2 \cdot 6H_2O$ (B/Ni<1) was used, only unstable colloids were obtained. Thus, colloidal nickel boride, once formed on addition of $NaBH_4$, was gradually inactivated under hydrogen with fading of coloration during 15 min stirring. The catalytic activity of colloid increases remarkably with increase in the amount of $NaBH_4$ in the range of B/Ni ratio between 1 and 2, the dark brown coloration of the original solution remaining unchanged. By using not less than double molar $NaBH_4$ with $NiCl_2 \cdot 6H_2O$ (B/Ni≧2), a colloid with an almost constant activity was obtained.

Reduction of $NiCl_2 \cdot 6H_2O$ with $NaBH_4$ in ethanol in the absence of a polymer gave a suspension containing visible particles of precipitated nickel boride. Suspen-

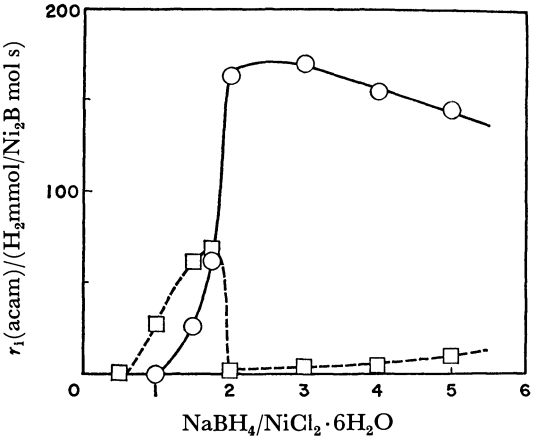

Fig. 3. Dependence upon $NaBH_4/NiCl_2 \cdot 6H_2O$ ratio of the catalytic activity of colloidal (○) and precipitated (□) nickel borides.

sions prepared with varying amounts of $NaBH_4$ were examined for their catalytic activity. The dependence of the catalytic activity of precipitated nickel boride upon B/Ni ratio (Fig. 3, broken line), is compared with that of colloidal nickel boride. Maximal activity is obtained with B/Ni ratio in the region 1.5—1.7, in which fine particles of nickel boride appear. On the other hand, the use of not less than double molar $NaBH_4$ with $NiCl_2 \cdot 6H_2O$ (B/Ni≧2) gives only a coagulated mass with a much lower activity. In this range of B/Ni ratio, colloidal nickel boride showed 15—60 times the catalytic activity of the precipitate.

Effect of the Amount of PVP-K30. The reduction of $NiCl_2 \cdot 6H_2O$ with $NaBH_4$ was carried out in ethanol in the presence of varying amounts of PVP-K30. As shown in Fig. 4, the presence of more than 0.5 mg (25 ppm) of PVP-K30 is important for obtaining colloidal nickel boride, otherwise a precipitate of nickel boride with a low activity is formed. The catalytic activity of colloidal nickel boride is nearly constant in the range of amount of PVP-K30 2—80 mg.

Decomposition by Oxygen. On exposure to the air, a dark brown solution of colloidal nickel boride was immediately converted into a light yellow inactive solution. In contrast, the colloid was stable under hydrogen and could be stored for 110 h with no change in coloration. The stored colloid exhibited 1.29 times the catalytic activity of the initial. Colloidal nickel boride was obtained under oxygen-free argon as well. Hydrogen was evolved by the hydrolysis of $NaBH_4$. So long as more than 4 vol% of evolved hydrogen was present in the atmosphere, the colloid was stable for a long period, exhibiting a considerable activity (r_i(acam)=150 H_2 mmol/Ni_2B mol s). Under argon containing less than 0.1 vol% of hydrogen, the colloidal nickel boride catalyst was completely inactivated within 1 h.

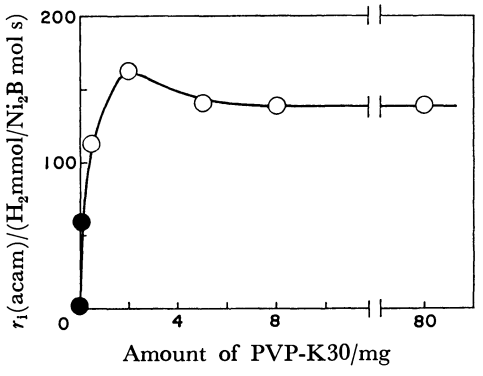

Fig. 4. Dependence upon the amount of PVP-K30 of the catalytic activity of nickel boride (○, colloidal; ●, precipitated).

Colloidal nickel borides prepared under hydrogen with 2 mg and 80 mg of PVP-K30 were exposed to the air at room temperature (20 °C). Decomposition of the colloids was followed by decrease in optical density at 750 nm of the colloidal solutions. The colloid with 80 mg of PVP-K30 always decomposed at a faster rate than that with 2 mg of PVP-K30.

Hydrogenation of acrylamide catalyzed by colloidal nickel borides with 2 mg and 80 mg of PVP-K30 was carried out in the presence of varying amounts of additional oxygen. The colloidal catalyst with 80 mg of PVP-K30 was inhibited more strongly than that with 2 mg of PVP-K30, the former being more sensitive to oxygen than the latter.

Discussion

The following stoichiometry was proposed for the progress of reduction of nickel(II) chloride with $NaBH_4$ in aqueous solution.[11]

$$NiCl_2 + 2NaBH_4 + 4.5H_2O \longrightarrow 0.5Ni_2B + 1.5H_3BO_3 + 6.25H_2 + 2NaCl \quad (1)$$

A similar process performed in ethanol under nitrogen gave a nickel boride precipitate having the formula $(Ni_2B)_2 \cdot H_3$.[12] It seems that colloidal nickel borides prepared in ethanol under hydrogen in the presence of a polymer contains a common structural unit Ni_2B. In the present case, the molar ratio of evolved hydrogen to $NiCl_2 \cdot 6H_2O$ charged was calculated to be 5.2, being smaller than that expected from Eq. 1. This gap between observed and theoretical amounts of evolved hydrogen is caused by the adsorption of hydrogen on the surface of colloidal nickel boride. Colloidal nickel borides were stable only in an oxygen-free atmosphere containing hydrogen. This indicates that the adsorption of hydrogen on the colloid surface might take part in the stability of the colloid. A black colloid prepared from nickel(II) nitrate was almost inactive (Table 1). On the other hand, colloidal nickel boride from $NiCl_2 \cdot 6H_2O$ was gradually inactivated when an alternative nitrate salt such as ammonium nitrate was added. In both cases, the inactivation process might be attributed to the loss of adsorbed hydrogen by oxidation with nitrate ion.

A reaction scheme involving $Ni(BH_4)_2$ intermediate was proposed for the process of nickel boride formation in aqueous solution.[11] During the induction period preceeding the formation of colloidal nickel boride, the conversion of $NiCl_2 \cdot 6H_2O$ into $Ni(BH_4)_2$ might occur.

In aqueous solution, nickel(II) hydroxide may be

formed in preference to nickel boride on account of the considerable basicity of the $NaBH_4$ solution. White turbidity appearing in the process using aqueous media (Table 1) might be due to polymeric nickel(II) hydroxide. However, nickel boride was predominantly produced in aqueous media when the reaction was carried out at low temperature (0 °C)[11] or in the presence of a large amount of polymers such as poly(vinyl alcohol)[5] owing to suppression of the formation of polymeric nickel(II) hydroxide.

The particle size of a colloidal catalyst is essential for the estimation of its turnover frequency. However, colloidal nickel boride was so unstable in a high vacuum as well as under hydrogen-free argon that the particle size of the colloid could not be determined by electron microscopy.

A precipitated nickel boride catalyst prepared without using polymers (B/Ni=1.5) was *ca.* 50% inhibited by the addition of 80 mg of PVP-K30. It seems that PVP-K30 acts as an inhibitor through locating on the catalytic surface of precipitated nickel boride. Polymers such as PVP-K30 existing in the solution of colloidal nickel boride are assumed to act as a protective colloid through covering the surface of colloidal particles.[13] Polymers existing in the solution of colloidal nickel boride are presumed to lower the catalytic activity to some extent. The widely varied activities of colloids prepared with a variety of polymers (Table 2) can be explained in terms of inhibition by polymers.

The degree of inhibition of a precipitated nickel boride catalyst increased with increase in the amount of PVP-K30. In contrary, the catalytic activity of colloidal nickel boride was independent of the amount of PVP-K30 (Fig. 4). A similar relationship was observed in the case of colloidal rhodium prepared by using poly(vinyl alcohol).[14] The discrepancy might be attributed to the variation of the size of colloidal particles with the amount of the polymer used.

The well-dispersed state of colloidal nickel boride due to the presence of PVP-K30 as a protective colloid is primarily responsible for its high activity. On the other hand, precipitated nickel boride formed with more than double molar $NaBH_4$ with $NiCl_2 \cdot 6H_2O$ gradually coagulated into a black mass with a very low activity. Well-dispersed suspension of precipitated nickel boride (B/Ni=1.5) coagulated on further addition of $NaBH_4$. Nickel borides were found to be very active catalysts for the hydrolysis of $NaBH_4$.[2]

$$NaBH_4 + 2H_2O \xrightarrow{Ni_2B} NaBO_2 + 4H_2 \quad (2)$$

It seems that excess or additional $NaBH_4$ is hydrolyzed to yield $NaBO_2$ which causes the coagulation of nickel boride precipitates.

Colloidal nickel borides prepared by using less than double molar $NaBH_4$ with $NiCl_2 \cdot 6H_2O$ exhibited a considerable activity when used immediately after preparation. Thus, acrylamide was hydrogenated at an initial rate of 46 H_2 mmol/Ni_2B mol s with the colloid which had been prepared 1 min before its use by using equimolar $NaBH_4$ with $NiCl_2 \cdot 6H_2O$. However, the colloid once formed was completely inactivated in 15 min with stirring under hydrogen (Fig. 3). The inactivation mechanism of the colloid under hydrogen has not been clarified.
