
In favour of the formation of the postulated carbonium ion intermediate in the proposed mechanism is the fact that such reactions occured faster and with higher yields in case of ketones which gave the more stable tertiary carbonium ion. With formaldehyde, the reaction was found to be the lowest among the other aldehydes.

The 1,3-oxazine ring is responsible for a considerable bathochromic shift in the absorption spectra of such derivatives as compared with the starting 1-amino-2-(hydroxymethyl)anthraquinones. The IR spectra indicated the presence of NH absorption bands beside the methylene hydrogen (*cf.* Table 2).

The methylene group in the oxazine nucleus proved to be active and react with carbonyl compounds in the presence of anhydrous zinc chloride as a catalyst to give the corresponding 2-arylmethylene derivatives (**3**). The reaction can be represented as follows:

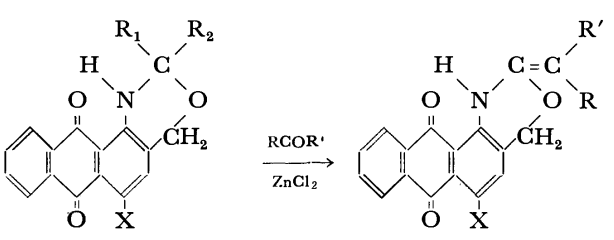

TABLE 1. (HYDROXYMETHYL)ANTHRAQUINONE DERIVATIVES (**1**)

X	Y	Z	Mp °C	Solvent of crystallization[a]	Yield %	Mol formula	N/%[b] Calcd	N/%[b] Found	λ_{max}^{EtOH}/nm (log ε)

tion of the amino group in the 6-position changes the colour of the molecule to the intense blue shade. The reaction is carried out by heating the bromo derivative of 1,3-oxazines (**2**) with the amine derivative in an alkaline solution and in the presence of a copper salt as catalyst to give anthraquinone disperse dyes (**4**) (*cf.* Table 4). Such amination can be carried on the brominated 1-amino-2-(hydroxymethyl)anthraquinone derivative and the oxazine ring can be further constructed by the action of carbonyl compounds.

As the previously prepared anthraquinone derivatives are water insoluble they were tested as disperse dyes for dyeing synthetic fibers in shades ranging from yellowish brown to intense blue. Samples of polyamide, polyester and acrylic fibers were dyed satisfactory using these derivatives. A comprehensive application program involving such disperse dyes is now in progress with the aim of investigating the relation between structure, fastness properties, and dyeing behaviour. This forthcoming study will include a comparison of the electron impact induced fragmentation patterns of these dyes with their lightfastness on polyester fibers.

Experimental

The infrared absorption spectra were determined with a Unicam SP 1200 spectrophotometer using the KBr wafer technique. Absorption spectra in visible region were determined with a Unicam SP 8000 ultraviolet recording spectrophotometer. All melting points are uncorrected.

(Hydroxymethyl)anthraquinone Derivatives (1). Dissolve (0.1 mol) of 1-amino(or 1-hydroxy)anthraquinone derivatives in about 160 ml (0.1 mol dm^{-3} KOH) and 150 ml ethanol, warm the solution and pass nitrogen gas through it for about 15 min. Add formaldehyde solution (40%, 0.1 mol), followed by addition of sodium dithionite solution (0.1 mol in about 40 ml 0.2 mol dm^{-3} KOH) and pass nitrogen gas for further 12 min. The reaction mixture was oxidized by air for about 30 min. The product was filtered, dried and crystallized from the proper solvent. The results are given in Table 1.

1,3-Oxazine Derivatives (2). A mixture of 1-amino-2-(hydroxymethyl)-4-bromo (or non-brominated) anthraquinone (0.1 mol) and the carbonyl compounds (0.1 mol) was dissolved in dioxane (80 ml) in presence of 10 ml HCl (1 mol dm^{-3}). The mixture was concentrated, cooled and then added to excess of cold water. The product was filtered, washed with water and dried, then crystallised from suitable solvent. The results are listed in Table 2.

2-Arylmethylene-1,3-oxazines (3). A mixture of 6-bromo-1,2-dihydroanthra[1,2-*d*][1,3]oxazine-7,12-dione (250 mg, 0.1 mol) and the carbonyl compound (0.1 mol) was fused for about 5 min in the presence of anhydrous zinc chloride (0.5 g). The melt was triturated with ethanol to dissolve the excess aldehyde, then filtered, washed with hot water and dried. The product was crystallized from the proper solvent. The results are given in Table 3. 2,2-Diformyl-1,2-dihydro-4*H*-anthra[1,2-*d*][1,3]oxazine-7,12-dione and its 6-bromo-analogue (**4c, d**) and the corresponding Schiff's bases (**5e—g**).

0.01 Mol of the dimethyl derivative (II, $R_1=R_2=CH_3$; X=H or Br) was dissolved in ethanol and the solution was added to a solution of SeO_2 (0.02 mol) in ethanol. The reaction mixture was boiled under reflux for 1.5 h. The solution was cooled and the precipitated selenium was eliminated by filteration. The filtrate was concentrated and cooled, then the product was collected and crystallized from ethanol.

4c; mp 95 °C; ν NH 3300, ν C–O 1110, and ν –COH 1730 cm^{-1}. Found: N, 3.99%. Calcd for $C_{18}H_{11}NO_5$: N, 4.36%.

4d; mp 112 °C; ν N–H 3280, ν C–O 1110, and ν –C–H 1730 cm^{-1}. Found: N, 2.99%. Calcd for $C_{18}H_{10}NO_5Br$: N, 3.50%.

0.1 Mol of the dialdehyde (**4d**) was condensed with 0.2 mol of *o*-phenylenediamine, *p*-aminophenol and *p*-anisidine by the usual way to give the corresponding Schiff's bases (**5e—g**) respectively.

5e; mp 105 °C; ν NH 3400, ν C–O 1100, and ν C=N 1550 cm^{-1}. Found: N, 7.92%. Calcd for $C_{24}H_{14}O_3N_3Br$: N, 8.26%.

5f; mp 120 °C; ν NH 3290, ν C–O 1080, and ν C=N 1550 cm^{-1}. Found: N, 8.12%. Calcd for $C_{30}H_{20}O_5N_3Br$: N, 8.35%.

5g; mp 118 °C; ν NH 3300, ν C–O 1150, and ν C=N 1550 cm^{-1}. Found: N, 7.41%. Calcd for $C_{32}H_{23}O_5N_3Br$: N, 7.92%.

Blue Anthra[1,2-d][1,3]*oxazine-7,12-dione Disperse Dyes.* A mixture of 6-bromo-1,3-oxazine derivative (0.02 mol) and the amine derivative (0.02 mol) was dissolved in ethanol (50 ml). The solution was turned alkaline by the addition of sodium carbonate. Copper carbonate (1 g) was added and the reaction mixture was refluxed for 4 h, whereby the brown colour was changed to deep blue. The mixture was filtered while hot and the filtrate was concentrated and diluted with cold water to give a blue precipitate. It was

filtered, washed with water and dried. The product was crystallized from dilute ethanol. The results are given in Table 4.

Application of the Prepared Anthraquinone Derivatives as Disperse Dyes. These derivatives could be used for colouring synthetic fibers, *e.g.* polyamide. This is done by immersing the textile material in a dyebath containing an aqueous dispersion of these dyes and an ionic surface-active reagent. The dyeing process was performed by boiling for 45 min. The fibers are soaped and rinsed with cold water then dried and tested for light and wash fastness.

Bulk Copolymerization of Acrylonitrile with α-Chloroacrylonitrile

Masao OKAMOTO* and Osamu ISHIZUKA

Department of Fiber and Polymer Engineering, Faculty of Engineering, Yamagata University, Jonan, Yonezawa 992

(Received April 18, 1980)

Synopsis. Copolymerization of acrylonitrile (M_1) with α-chloroacrylonitrile (M_2) was carried out at 60 °C using 4.3×10^{-2} mol% of α,α'-azobisisobutyronitrile. The four copolymers obtained were analyzed, their mole fractions of α-chloroacrylonitrile units being 0.196, 0.377, 0.532, and 0.722, and the monomer reactivity ratios r_1 and r_2 were found to be 0.31 and 3.25, respectively.

Copolymerization of acrylonitrile (M_1) with α-chloroacrylonitrile (CAN (M_2)) was carried out in order to obtain model compounds of chlorinated polyacrylonitrile. The monomer reactivity ratios r_1 and r_2 were evaluated by the Mayo-Lewis method.[1] So far the values have been reported only once.[2]

Experimental

Preparation of Copolymers. Commercial acrylonitrile and CAN were distilled in nitrogen atmosphere and then kept in a refrigerator. Both monomers were charged in the amounts given in Table 1 in the reaction vessel which was alternately evacuated with an oil pump and flushed with nitrogen. The bulk copolymerization was carried out at 60 °C in the presence of 4.3×10^{-2} mol% of α,α'-azobisisobutyronitrile (AIBN). The reaction vessel was sealed in order to prevent the loss of both monomers during the course of copolymerization, the reaction system being stirred magnetically. After the lapse of the required reaction time, hydroquinone was added in an amount equivalent to AIBN in order to terminate copolymerization. Copolymer was filtered, washed thoroughly with methanol, and finally dried in a vacuum at 30 °C to constant weight.

Chlorine Analysis. The method was reported in a previous work.[3]

Results and Discussion

The analytical data of products are summarized in Table 1. The mole fraction of CAN units in each copolymer was calculated by means of chlorine content. Figure 1 shows the relationship between the mole fraction obtained and that of CAN in monomer mixture at the start of reaction. Since the monomer concentrations, $[M_1]$ and $[M_2]$, at the time when polymerization ceased can be determined by means of the yield and the composition of copolymer, the lines on r_1-r_2 plots are obtained by means of Mayo-Lewis's integrated equation.[1] The lines have a common intersection near $r_1=0.31$, $r_2=3.25$, except for Experiments 6 and 7 in which light brown and brown products, respectively, were obtained. Coloration of the products in Experiments 2—5 was very faint. A side reaction would proceed simultaneously with copolymerization, being enhanced when the initial mole fraction of CAN is over 0.5.

Table 1. Copolymerization of acrylonitrile with CAN by AIBN at 60 °C

Expt No.	Reaction conditions: Acrylonitrile (M_1) / g	Reaction conditions: CAN (M_2) / g	Reaction conditions: Time / h	Analytical data of product: Yield / wt%	Analytical data of product: Chlorine content / wt%
1	20.15	0	0.25	4.7	0
2	18.13	2.75	10	22.0	11.60
3	16.12	5.39	24	9.7	20.25
4	14.10	8.25	48	4.8	26.40
5	10.07	13.76	19	2.9	32.85
6	8.06	16.51	24	4.3	33.45
7	4.03	22.02	24	4.6	33.37

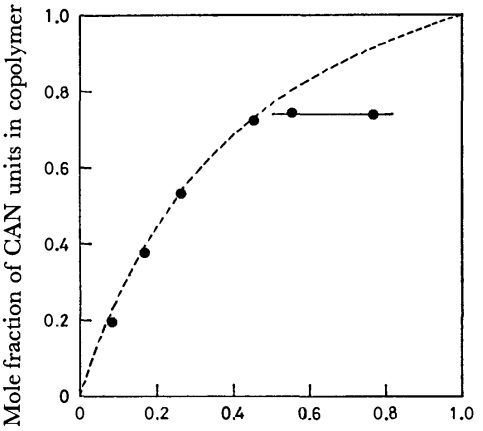

Fig. 1. Composition of copolymers.
A broken line is the initial copolymer composition curve for $r_1=0.31$, $r_2=3.25$.

In copolymers obtained in Experiments 2, 3, 4, and 5, the mole fractions of CAN units were 0.196, 0.377, 0.532, and 0.722, respectively. It seems that CAN units are distributed at random in the copolymer chain, since the reactivity ratio product (r_1r_2) is approximately equal to unity.

Interaction between Aromatics and Zinc Chloride. II. The Formation of σ-Complexes and Cation Radicals on Supported Zinc Chloride

Mikio MORITA,* Kunio HIROSAWA, Toshio SATO, and Koji OUCHI†

Government Industrial Development Laboratory, Hokkaido, 2-17 Tsukisamuhigashi, Toyohira-ku, Sapporo 061-01

†*Department of Applied Chemistry, Faculty of Engineering, Hokkaido University, Sapporo 060*

(Received June 11, 1979)

Synopsis. Anhydrous zinc chloride supported in the solid state was found to produce colored intermediates by reactions with aromatics (anthracene, naphthacene, pentacene, pyrene, pelyrene, and chrysene) at 60 °C. The measurements of their electronic absorption spectra and ESR spectra confirmed that these were the same aromatics–zinc chloride σ-complexes and aromatics cation radicals as those formed in molten zinc chloride.

It has been known that Lewis acids, such as boron trifluoride[1] and aluminum chloride,[2] react with aromatic hydrocarbons to form σ-complexes (electron donor–acceptor (EDA) complexes) and aromatics cation radicals. Our previous work revealed that molten zinc chloride also produced similar intermediates by means of reactions with aromatic hydrocarbons at higher temperatures.[3]

In order to advance further studies of the catalytic behavior of zinc chloride, we wish to confirm the reactivity of the aromatics–zinc chloride system with anhydrous zinc chloride supported on a porous Vycor glass at lower temperatures. Its high surface area and good transmission of light enabled us to measure better the electronic and ESR spectra.

The electronic absorption spectra of aromatics–zinc chloride colored complexes produced on the zinc chloride supported in the solid state were essentially similar to those of molten zinc chloride[3] and of aluminum chloride in the solid state.[2] Furthermore, the ESR signals were detected for the colored complexes. Based on these results, it was concluded that the zinc chloride supported in the solid state reacted directly with aromatic hydrocarbons to form the σ-complexes (EDA-complexes) and the cation radicals.

Experimental

Materials. The anthracene, naphthacene, pentacene, pyrene, perylene, chrysene, zinc metal, and silver chloride were all purchased and were all of a G. R. grade; they were used without further purification.

The rod of porous Vycor glass (Corning No. 7930) used as a support was ground to 100 mesh. The powdered Vycor glass was treated with a concd HNO_3 solution at room temperature overnight and washed with distilled water to remove foreign metal ions as impurities. Having been dried at 140 °C, it was heated in air at 600 °C for 6 h to burn off the organic contaminants. Its surface area was 154 m^2/g.

Preparation of Supported Zinc Chloride. Anhydrous zinc chloride was prepared by the reaction of zinc metal with siliver chloride at about 500 °C in a vacuum at 10^{-3} Torr and vaporized so as to be supported on the purified Vycor glass preliminarily heated at 500 °C for 4 h in a vacuum. The anhydrous zinc chloride content was 5—10 wt% in the present support.

Reaction. About 500 mg of the supported zinc chloride was transferred into a 1-mm-thick quartz cell in a vacuum and thoroughly mixed with 5 mg of an aromatic compound in the cell. After the cell had then been evacuated below 10^{-3} Torr, its neck was fused so as to seal it off. Then the cell was heated at a constant temperature above 60 °C. The formation of a colored product could be observed on the supported zinc chloride.

Electronic Spectra and ESR Signals. The electronic spectra of the colored products were measured at room temperature with a Hitachi 624 spectrometer equipped with an integrating sphere. The ESR signals were detected also at room temperature with a JES-ME-3X spectrometer for samples prepared in ESR tubes by a way similar to that described above.

Results and Discussion

The rate of the formation of aromatics–zinc chloride complexes was found to be depend on the aromatic hydrocarbon source. Under the present conditions, aromatic compounds with higher ionization potentials, such as benzene, naphthalene, and phenanthrene, could not be observed to form colored products. At higher temperatures and longer contact times, the transmittance of the samples gradually decreased and the characteristic absorption spectra of the complexes became obscure because of the formation of other compounds, such as condensed products of aromatics.

Figure 1 shows the absorption spectra of the colored products on the supported zinc chloride for anthracene, naphthacene, pentacene, pyrene, perylene, and chrysene; the positions of these absorption bands are summarized in Table 1 for comparison. These absorp-

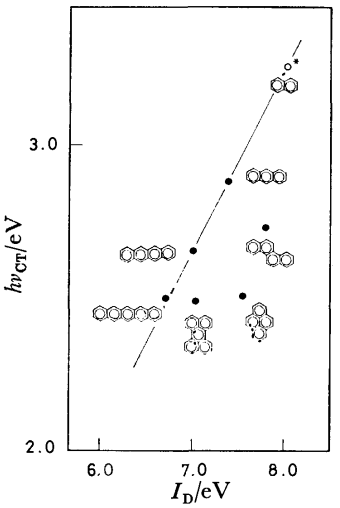
tion bands disappeared when the colored products were placed in contact with water vapor.

The supported zinc chloride itself did not give any absorption band within the entire wavelength region measured in this work. When anthracene came in contact with the supported zinc chloride at 60 °C, a broad absorption band at 430 nm appeared at first, and then another absorption band developed at 730 nm after prolonged contact time. Similarly, in the reaction with the supported zinc chloride at 100 °C for 30 min, naphthacene gave three weak and sharp absorption bands at 395, 755, and 775 nm, in addition to a strong, broad absorption band at 470 nm and a broad absorption band at 650 nm. Pentacene gave two broad absorption bands at 493 and 590 nm; pyrene gave two broad absorption bands at 495 nm and 650 nm; perylene gave a strong absorption band at 505 nm, a strong sharp absorption band at 545 nm and two weak absorption bands at 635 and 735 nm, and chrysene gave two absorption bands at 455 and 690 nm.

σ- or EDA-Complex Formation. As may be seen in Table 1, the absorption bands observed at 430 nm for anthracene, at 470 nm for naphthacene, at 493 nm for pentacene, and at 495 nm for pyrene on the supported zinc chloride were found to be almost the same as those at 420 nm, at 468 nm, at 440 nm, and at 481 nm respectively of the corresponding aromatics–aluminum chloride complexes in the solid state.[2)] Furthermore, the absorption bands seen at 430 nm for anthracene and at 470 nm for naphthacene were consistent with those at 425 nm and at 460 nm of the corresponding aromatics–molten zinc chloride complexes.[3)] The colored complexes on solid aluminum chloride or in molten zinc chloride are assigned to the σ-complexes (π, v-, or EDA-complexes), and the characteristic absorption bands, to the charge-transfer ones.[2,3)]

Figure 2 shows the linear correlation between the characteristic absorption energy of the present complexes, $h\nu_{CT}$, and the ionization potential, I_D, of the corresponding aromatics; although the absorption energy of the pyrene– and chrysene–zinc chloride complexes and the slope of the line deviate somewhat from the law of the charge-transfer complexes,[4)] these aromatics–zinc chloride complexes seem to be EDA-complexes, *i.e.*, σ-complexes (*cf.* Ref. 3).

Ion or Radical Formation. When the colored complexes on the supported zinc chloride were treated at higher temperatures, the spectra changed to those characteristic to cation radicals. Except for perylene,



* Cited from Ref. 3.

Fig. 2. Relation between the position of CT bands and ionization potentials of donors.

all the present samples also gave a broad singlet paramagnetic signal whose *g*-value was about 2.0036 for anthracene, 2.0037 for naphthacene, 2.0031 for pentacene, 2.0031 for pyrene, and 2.0032 for chrysene. The perylene on the supported zinc chloride gave the same ESR spectrum, split into seven signals with equal hyperfine splitting (0.3 mT), as was detected on silica–alumina.[7)] The *g*-value was about 2.0038.

These findings support the idea that aromatics–cation radicals can be formed in the aromatics–supported zinc chloride system, where the radical cations are supposedly produced by the ionization of the σ- or EDA-complexes.

The assignment of the electronic spectra for cation radicals of the aromatics is well established.[3,5,6)] The positions of the bands are also summarized in Table 1.

Anthracene in molten zinc chloride gave another electronic absorption band at 620 nm;[3)] this band is attributed to the dipositive ion[5,7)] or to a secondary σ- or π-complex produced by anthracene and the anthracene–zinc chloride σ-complex.[8)] This band did not appear in the anthracene–supported zinc chloride system; therefore, such intermediates cannot be considered for the supported zinc chloride under the present conditions.

Relative Electron-capture Efficiency of Disubstituted Benzene in γ-Irradiated MTHF Glass at 77 K

Toshinari SHIMOKAWA

Tokyo Metropolitan Isotope Research Center, 2-11-1 Fukazawa, Setagaya-ku, Tokyo 158

(Received December 28, 1979)

Synopsis. The relative electron-capture efficiencies of disubstituted benzenes were measured by a competitive method. It was found that the efficiencies of the disubstituted benzenes are correlated with the reactivity towards nucleophilic species as expressed by Hammett's substituent constant. The logarithmic values of the efficiency are roughly proportional to the polarographic half-wave reduction potentials and to the electron affinities.

A number of investigations aimed at determining the rate constant of the electrons ejected by the irradiation of ionizing radiation with various compounds in aqueous and organic solutions have been performed by the competitive-reaction or pulse-radiolysis technique. In a previous paper,[1] a study was made of electron-capture reactions by polychlorinated benzenes and halogenated benzenes in MTHF glass at 77 K by a competitive method, and the relationship between the reactivity and the electron affinity of these molecules was discussed.

In this paper, the electron-capture efficiencies of many disubstituted benzenes relative to that of biphenyl will be determined in the MTHF glass, and the effects of the substituents on the efficiency will be described.

Experimental

The disubstituted benzenes, except for *p*-chlorobenzonitrile (an Eastman reagent chemical), were of a guaranteed grade and were obtained from the Tokyo Kasei Kogyo Co., Ltd. These chemicals were used without further purification. The measurement of the relative electron-capture efficiency was carried out by the competitive method, biphenyl being used as the reference material (0.04 M).[1,2] The sample preparation, γ-irradiation, and other experimental conditions were described in a previous paper.[1] (1 M = 1 mol/dm³)

Results and Discussion

The relative electron-capture efficiency, K_s/K_{ϕ_2}, and the ratio to the parent compound, K/K_0, are summarized in Table 1.

In a chlorobenzene series, the substituents, NO_2, $COCH_3$, and CN, markedly increased the efficiency for electrons. This result is consistent with the inductive effect of these substituents. The substitution of halogen atoms also increased the efficiency. The order of efficiency for halogen substituents was Br>Cl≫F.

On the other hand, all the electron-donating groups such as OH decreased the efficiency for electron-capture except for *p*-chlorotoluene. The decrease in the efficiency is generally in the order of $OH>OCH_3>CH_3$. This result is probably due to the resonance effect of the substituent on the ring.

In the other series, the effect of the substituent on the electron-capture efficiency is compatible with that obtained from the chlorobenzene series except for the nitrobenzene series. In the case of the nitrobenzene series, the secondary substituent scarcely changed the efficiency of the parent molecule at all.

In order to examine the substitution effects in detail, we attempted to determine whether or not the Hammett linear relation was applicable to the electron-capture reaction in MTHF glass. In Fig. 1, the log K/K_0 for a

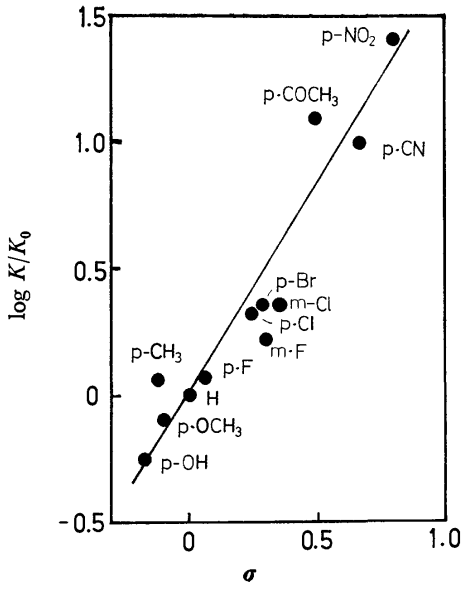

Fig. 1. Plot of log K/K_0 *vs.* Hammett substituent constant for a series of chlorobenzene.

series of chlorobenzene is plotted as a function of the Hammett substituent constant (σ).[3] A linear correlation between the log K/K_0 and σ was observed, and the reaction constant, ρ, was obtained as 1.58 from the slope. The Hammett linear relation also conforms to the electron-capture reactions of the other series except for the nitrobenzene and benzonitrile series. For the acetophenone, bromobenzene, and fluorobenzene series, the ρ values obtained in the same way are 0.49, 0.52, and 3.12 respectively. One can find that the ρ value decreases with an increase in the electron-capture efficiency of the parent molecule in the order of acetophenone, bromobenzene, chlorobenzene, and fluorobenzene.

In a previous paper,[1] it was found that the log $K_s/K_{\phi 2}$ of polychlorinated benzene correlated well with the polarographic half-wave reduction potential ($E_{1/2}$). In the forth column in Table 1, the $E_{1/2}$ values are also listed.[4-6] A good correlation between the log $K_s/K_{\phi 2}$ and the $E_{1/2}$ is observed in the case of disubstituted benzenes.

Streitwieser confirmed that the $E_{1/2}$ was well correlated to the electron affinity, A, for many aromatic hydrocarbons.[7] Therefore, it is possible to replace $E_{1/2}$ by A, and the plot of log $K_s/K_{\phi 2}$ against A was found to be roughly linear (Fig. 2). This linear correlation suggests that the initial process of the electron-capture is related to the lowest unoccupied orbitals of the molecule (LUMO), since the A value corresponds to the energy of LUMO.[8]

The correlation in Fig. 2 can be expressed by the following empirical equation:

$$\log K_s/K_{\phi_2} = 1.10A + 0.04 \quad (1)$$

However, the slope of the line in Fig. 2 greatly deviates from a predictable slope for a diffusional process in the gas phase.[1] In the case of the glassy state at low temperatures, a treatment similar to that in the gas phase may be inapplicable, for Kira and Imamura indicated that the electron-tunneling process is important in

MTHF glass at 77 K.[9]

Although the relative electron-capture efficiency does not directly correspond to the absolute rate constant, the relative magnitude of these values in Table 1 is a measure of the effects of the substituent on the parent molecule. The present results, however, do not provide sufficient data for discussing the nature of the electron-capture process in organic glasses.

The author is grateful to Dr. Takeshi Sawai for his valuable discussion.

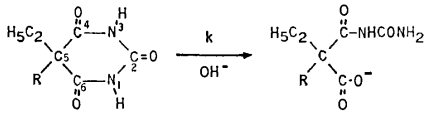
The Hydrolytic Rate of Barbituric Acid and the Extrathermodynamic Relationship

Shozo ASADA, Midori YAMAMOTO, and Jujiro NISHIJO*
Kobe Women's College of Pharmacy, Higashinada-ku, Kobe 658

(Received September 6, 1979)

Synopsis. The enthalpy-entropy relationship of activation was subjected to discussion in connection with the alkaline hydrolysis of 10 barbituric acids. The extrathermodynamic linear equation was derived by using several parameters; the dissociation constant (pK), the ^{13}C shift value [$\delta_c(5)$] at the 5-position of the ring, and/ or the molecular connectivity index (χ).

The alkaline hydrolysis of 5-substituted 5-ethylbarbituric acids (I) were investigated. It is known that Taft-type parameters can not be used to evaluate the substituent effects in this series of compounds.[1] Therefore, as physicochemical parameters which might reflect the electronic or steric effect of the substituent, the acid-dissociation constant (pK),[2] the value of the ^{13}C chemical shift [$\delta_C(5)$] at the 5-position,[3] and the molecular connectivity index (χ) given in the literature[4] were used to discuss them.



(I)

Experimental

Materials. Ten barbituric acids (I) described previously[5] were used; they are listed in Table 1. All the other chemicals were of an analytical grade.

Hydrolysis Procedures. An appropriate quantity of (I) was weighed in a volumetric flask, dissolved, and diluted with 0.4 mol dm^{-3} NaOH to produce 1×10^{-3} mol dm^{-3}. This flask was placed in a thermostatic water bath at 30, 40, or 50 $\pm$ 0.1 °C. Samples were withdrawn periodically and diluted with 0.4 mol dm^{-3} NaOH to produce a final barbiturate concentration of about 8×10^{-5} mol dm^{-3}. Spectrophotometric readings (A) at the absorption maximum (255 nm) were taken with a Hitachi Model UV-200 spectrophotometer. Plots of $\log(A-A_\infty/A_0-A_\infty)$ *vs.* the time were reasonably linear for each compound, where A_0 or A_∞ is the initial or the final asymptotic absorbance respectively. The apparent first-order rate constant (k) was obtained from the slope.

Calculation of the Molecular Connectivity Index (χ). The χ values were calculated using the previously reported method.[4] In the case of a double-bond structure, twice the value calculated as a double bond was taken into account. These values are listed in Table 2.

Results and Discussion

Relationship between Enthalpy and Entropy of Activation. According to the absolute rate theory, the enthalpy (ΔH^*) and entropy (ΔS^*) of activation[6] may be expressed by Eq. 1:

$$\log(k/T) = -(\Delta H^*/2.303RT) + (\Delta S^*/2.303R) + \log(k_B/h), \quad (1)$$

Table 1. Rate constants, k in h^{-1}, at three different temperatures in 0.4 mol dm^{-3} NaOH, and activation parameters for the hydrolyses of barbituric acids (I)

a) The apparent second acid-dissociation constants were determined by spectrophotometry at 20 °C for the ionic strength of 0.75. b) These values were reported previously.[5] c) The values are computed from the partial structure:

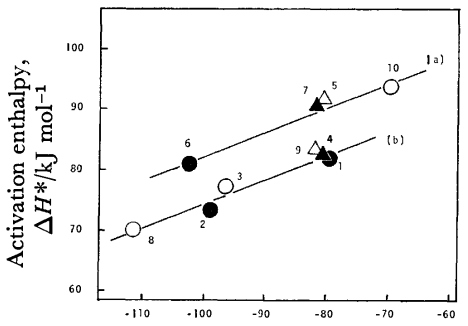

Fig. 1. Plots of the compensation effect of activation parameters.
Numbers adjacent to the marks indicate the compound numbers listed in Table 1.
Line (**a**): $\Delta H^* \times 10^3 = 122.3(\pm 5.9) \times 10^3 + 398(\pm 69)\Delta S^*$, $n=4$, $\gamma=0.971$; Line (**b**): $\Delta H^* \times 10^3 = 114.5(\pm 3.8) \times 10^3 + 401(\pm 39)\Delta S^*$, $n=6$, $\gamma=0.981$.

where k_B is the Boltzmann constant and where h is the Planck constant. Plots of log (k/T) *vs.* T^{-1} are drawn; ΔH^* was calculated from the slope, and ΔS^* was calculated by means of Eq. 1 at 50 °C, the results being given in Table 1. The ΔH^*-ΔS^* relation is shown in Fig. 1. The linear relationship between ΔH^* and ΔS^* is well known as the isokinetic relationship or the compensation effects.[7] It is possible to draw two isokinetic lines for the plots in Fig. 1. The **a** line is applied for 4 compounds (**5**, **6**, **7**, and **10**) which have a branched substituent group at the α-position, the isokinetic temperature being 398 K. The **b** line is for the other 6 compounds (**1**, **2**, **3**, **4**, **8**, and **9**), the isokinetic temperature being 401 K.

General Structure-Hydrolytic Reactivity Correlation. The extrathermodynamic linear Eq. 2 was proposed to express the relation between the hydrolytic rate constant (k) and the parameters, pK, $\delta_C(5)$, and χ. Regression analysis was then applied to this equation.

$$\log (k/k_0) = b_1[\mathrm{p}K - \mathrm{p}K_0] + b_2[\delta_c(5) - \delta_c(5)_0] + b_3[\chi - \chi_0] \quad (2)$$

or

$$\log k = b_0 + b_1\mathrm{p}K + b_2\delta_c(5) + b_3\chi = b_0 + b_1x_1 + b_2x_2 + b_3x_3, \quad (3)$$

where the subscript zero refers to the values of the standard compound, where b_i (i=0, 1, 2, and 3) are constants, and where x_1, x_2, and x_3 are predictor variables equivalent to pK, $\delta_C(5)$, and χ respectively. The correlation matrix is shown in Table 3. The smallest correlation exists between x_1 and x_2; therefore, both the variables make nearly independent contributions to log k. The regression between log k and each of the predictor variables is given by Eqs. 4—6 (Table 4). The regression including all the variables is also given by Eq. 7; its F-value is significant at the 1% level. When the variable x_3, which has the smallest t-value for the regression coefficient, is eliminated from Eq. 7, Eq. 8 is obtained and the contribution ratio of 86% is obtained. The F-value for Eq. 8 is 21.2, which is not greatly different from that obtained for Eq. 7. Therefore, no further elimination of variables was carried out. Thus, it is found that, among the parameters which may reflect the substituent effect, the combination of pK and $\delta_C(5)$ shows a good correlation with log k in the case of the compounds examined here.

Table 3. Correlation matrix for each combination of variables

	pK	$\delta_c(5)$	χ	log k
pK	1.000			
$\delta_c(5)$	0.034	1.000		
χ	0.301	0.720*	1.000	
log k	−0.691*	−0.639*	−0.490	1.000

The Solvent Effects of Water-Dimethyl Sulfoxide Mixtures on the Keto-Enol Tautomerization Rate of Di-*n*-alkyl β-Diketones

Hitoshi WATARAI

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

(Received November 21, 1979)

Synopsis. The kinetic solvent effects of water–dimethyl sulfoxide (DMSO) mixtures on the ketonization and the enolization rate constants of eight di-*n*-alkyl β-diketones were analyzed in terms of the group-transfer free energy from water to the mixed solvents. The transfer free energy of the transition state, as calculated from the rate constant and the partition coefficient of the keto or enol form, is found to be divided into three contributions: the two group-transfer free energies of the "transition state skeleton" and the methylene group, and the transfer free energy change due to the inductive effect of the *n*-alkyl group.

In the course of our study aimed at elucidating the kinetic behavior of β-diketones in a liquid-liquid partition system, it was found that the partition rate is controlled by the keto-enol tautomerization in the aqueous phase[1] and the important kinetic influence of aqueous solvent on the reaction was demonstrated.[2] Although it is well recognized that a kinetic solvent effect results from the difference in solvent effects on the reactant state and on the transition state, there have been only a few studies aimed at assessing the solvent effect on the two states individually. Previously, we ourselves demonstrated that a kinetic solvent effect can be experimentally assessed in terms of the free energies of transfer for a reactant and a transition state from a standard solvent to others, as calculated from the liquid-liquid partition coefficient and the rate constant.[2,3]

The purpose of this study is to elucidate the solvent effect and the substituent effect in the keto-enol tautomerization of di-*n*-alkyl β-diketones in a water–DMSO mixed solvent in terms of the transfer free energy.

Experimental

Chemicals. The acetylacetone and eight β-diketones were obtained from the same sources described elsewhere.[1] The solvents used were purified by the ordinary method. The mixed solvents were prepared by weight at the desired mole fraction of DMSO within ±0.0005.

Measurement of the Tautomerization Rate. The tautomerization rate constants were obtained from the absorption decreases of the enol form in 3 ml of a solution contained in quartz cell thermostated at 25±0.1 °C. The tautomerization reaction was initiated by the vapor injection method[2] for 2,3-hexanedione as well as for acetylacetone. For the other β-diketones, a minute quantity of pure liquid of β-diketone was quickly dissolved into a mixed solvent by means of a Teflon spatula designed to mix the solution effectively. Since the enol fraction in the pure liquid state of β-diketone is about 0.8, an enol-rich solution which shows an intense absorbance at 273 nm is produced by the dissolution procedure. First-order analysis of the absorbance change gave the tautomerization rate constant, $k_{obsd}(s^{-1})$. Measurements were repeated from two to five times.

TABLE 1. TAUTOMERIZATION RATE CONSTANTS OF DI-*n*-ALKYL β-DIKETONES IN WATER–DMSO MIXED SOLVENTS AT 25 °C

No.	β-Diketone	$k_{obsd}\times10^3/s^{-1}$

8	2,4-Nonanedione	7.17	4.42	3.08	1.75	0.892	0.415

Results

The observed rate constants are listed in Table 1. The ketonization and enolization rate constants, k_k and k_e, were calculated from the following equations:

$$k_k = (1-f)k_{obsd}, \quad k_e = fk_{obsd}, \tag{1}$$

where f is the enol fraction in the mixed solvent determined previously.[4]

The transfer free energies (kcal mol^{-1}) of the keto form, the enol form, and the transition state from water to mixed solvents were calculated by means of following equations,[3]

$$\delta\Delta G_K = 0.592 \ln\left(\frac{P}{P_o}\frac{1-f_o}{1-f}\right),$$

$$\delta\Delta G_E = 0.592 \ln\left(\frac{P}{P_o}\frac{f_o}{f}\right), \tag{2}$$

$$\delta\Delta G_x = 0.592 \ln\left(\frac{P}{P_o}\frac{1-f_o}{1-f}\frac{f_o}{f}\frac{k_{obsd,o}}{k_{obsd}}\right),$$

where P is the apparent partition coefficient of β-diketone in the heptane/water–DMSO system and where the subscript O refers to water as the standard solvent. The data of the partition coefficient were reported previously.[4] The calculated results are listed in Table 2, where the partition coefficient for 2,4-nonanedione was assumed to be equal to that of 4,6-nonanedione. The error in the calculation is less than 0.05 kcal mol^{-1}.

Discussion

Solvent Composition Dependence of Transfer Free Energies. In Table 2, $\delta\Delta G_E$ is a negative value in all systems, while $\delta\Delta G_x$ is positive for the smaller β-diketone and slightly negative for the larger β-diketone. $\delta\Delta G_K$ takes medium values between $\delta\Delta G_E$ and $\delta\Delta G_x$. When we recall that the activation energy changes are represented by $\delta\Delta G_x-\delta\Delta G_K$ or $\delta\Delta G_x-\delta\Delta G_E$, the variation in the tautomerization rate with the solvent composition is found to be primarily governed by those in $\delta\Delta G_K$ and $\delta\Delta G_E$, because the variation in $\delta\Delta G_x$ is smaller than the two others.

Recently, we proposed a new solvent parameter for a mixed solvent, $-(P_i/\alpha T)\ (v^E/v)$, where P_i, α, v^E, and v correspond to the internal pressure, the coefficient of

a) The numbers correspond to those in Table 1.

the thermal expansion, the excess molar volume, and the mean molar volume of the mixed solvent respectively.[5] For the transfer free energy, we can derive the following relation:

$$\delta\Delta G - \phi_s\delta\Delta G_1 = -q(r)\frac{P_1}{\alpha T}\left(\frac{v^E}{v}\right), \quad (3)$$

where $\delta\Delta G_1$ is the transfer free energy from water to DMSO and where $q(r)$ is a correction factor depending on the molar volumes of the solute and the solvent.[4] The plot of $\delta\Delta G-\phi_s\delta\Delta G_1$ against the pressure factor gave a linear relationship for $\delta\Delta G_K$ and $\delta\Delta G_E$ (the figure is not shown). This suggests that the variation in the solvent-solvent interaction energy in a water–DMSO mixture is an important factor govering the solvent-composition dependence of the tautomerization rate.

Substituent Effect. The relationship between $\delta\Delta G$ and the total number of carbon atoms, n, in β-diketones is summarized as follows:

(i) $\delta\Delta G_K$ and $\delta\Delta G_E$ decrease in proportion to n, *i.e.*,

$$\delta\Delta G_K = \delta\Delta G(\text{-COCH}_2\text{CO-}) + n\delta\Delta G(\text{-CH}_2\text{-}), \quad (4)$$
$$\delta\Delta G_E = \delta\Delta G(\text{-COCHCOH-}) + n\delta\Delta G(\text{-CH}_2\text{-}),$$

where $\delta\Delta G$(-COCH$_2$CO-), $\delta\Delta G$(-COCHCOH-), and $\delta\Delta G$(-CH$_2$-) are the transfer free energies of the diketone skeleton, the enol skeleton, and the methylene group.

(ii) $\delta\Delta G_X$ does not show a simple linear relationship with n, but it can be represented by the next equation:

$$\delta\Delta G_X = \delta\Delta G(\bar{X}) + \delta\Delta G(x) + n\delta\Delta G(\text{-CH}_2\text{-}), \quad (5)$$

where $\delta\Delta G(\bar{X})$ is the transfer free energy of the transition-state skeleton, calculated by subtracting $2\delta\Delta G$(-CH$_2$-) from the $\delta\Delta G_X$ of acetylacetone, and where $\delta\Delta G(x)$ is an increment in $\delta\Delta G(\bar{X})$ induced by an alkyl group other than the methyl group. For methyl group, $\delta\Delta G(x)$ is equal to zero, from the definition. Since the charge distribution in the transition state is expected to be highly delocalized, $\delta\Delta G(x)$ may be sensitive to the electronic property of the alkyl substituent. Therefore, we tested the correlation between $\delta\Delta G(x)$ and the

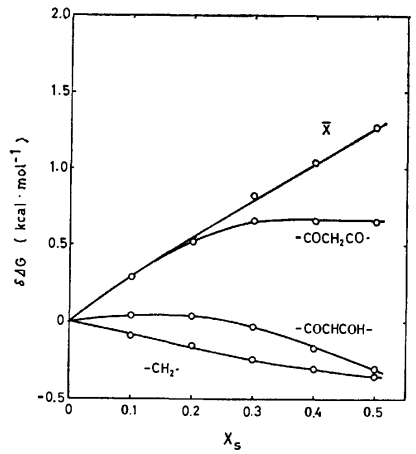

Fig. 1. Variation of the group transfer free energies with mole fraction of DMSO.

inductive parameter of the substituent proposed by Taft.[6] The plot of $\delta\Delta G(x)$ calculated from Eq. 5 against the sum of Taft σ^* (*vide infra*) for two alkyl groups of

n-Alkyl group	CH_3	C_2H_5	C_3H_7	C_4H_9
Taft's σ^*	0 000	−0 100	−0 115	−0.130

R_1 and R_2, $(\sigma_1^*+\sigma_2^*)$, in R_1-COCH$_2$COR$_2$ showed a linear relationship. Therefore, Eq. 5 can be rewritten as:

$$\delta\Delta G_x = \delta\Delta G(\bar{X}) + \rho(x_s)(\sigma_1^*+\sigma_2^*) + n\delta\Delta G(\text{-CH}_2\text{-}), \quad (6)$$

where $\rho(x_s)$ is a characteristic coefficient depending on the solvent composition. Because of the repulsive property of the interaction energy between DMSO and the anion,[7] $\delta\Delta G(\bar{X})$ is expected to be large and positive when Taft's σ^* value of the substituent is large and negative. Hence, the apparent proportionality between the tautomerization rate constant and the number of the methyl group can be ascribed to the large difference between the Taft σ^* values of the methyl group and those of the other substituents.

The group transfer free energies obtained on the basis of Eqs. 4 and 5 are shown in Fig. 1 as a function of the mole fraction of DMSO. The decreasing order of $\delta\Delta G(\bar{X})>\delta\Delta G$(-COCH$_2$CO-)$>\delta\Delta G$(-COCHCOH-)$>\delta\Delta G$(-CH$_2$-) may correspond to the decreasing order of the extent of charge delocalization. It is noticeable that the inductive effect has been clearly shown to be effective only in the transition state.

The author thanks Professor Nobuo Suzuki of Tohoku University for his helpful advice.

Mössbauer Effect in Fluorotrimethyltin(IV)

Hisao NEGITA,* Ryukei BOKU, Masahiro SUGIYA, and Sumio ICHIBA
Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730
(Received January 10, 1980)

Synopsis. The angular dependent Mössbauer spectra of ^{119}Sn in needle crystals of fluorotrimethyltin(IV) were studied at 110 K. The principal axis of the electric-field gradient was observed at about 20° from the a axis. ^{19}F NMR spectra of the solid were also studied. From the temperature dependence of the linewidth, the activation energy for the motion of the F atom was estimated to be 6.7±1.3 kJ mol^{-1}.

The X-ray diffraction[1] of fluorotrimethyltin(IV), Me_3SnF, showed that the molecule consists of Me_3Sn groups and F atoms arranged alternately in a chain-like manner along the a axis. Yasuda *et al.*[2] proposed a structure for Me_3SnF on the basis of the X-ray diffraction study. Mössbauer studies[3,4] confirmed a trigonal bipyramidal configuration of the tin atom, and related the intensity asymmetry of the doublet resonance spectrum to the intermolecular bonding, F–Sn···F. ^{1}H NMR study[5] supported the proposed structure from the viewpoint of motions of the Me_3Sn group. The purpose of the present study is to examine the validity of the proposed structure in more detail by means of the angular dependent Mössbauer spectra and ^{19}F NMR of the solid.

Experimental

The angular dependent Mössbauer spectra were obtained from 4—6 mm long needle crystals which were attached in the same direction with nail enamel on an absorber holder and kept at 110 K in a cryostat.

The measurement of the ^{19}F NMR was made at 13.00 MHz by a broad line NMR spectrometer (Japan Electron Optics Lab. Co., Ltd.). The linewidth was measured between maximum and minimum deflection points of the derivative tracing, using an amplitude which was narrow compared to the linewidth. The scanning rate was set to 0.8—2.0 G per second to avoid the saturation broadening.

Results and Discussion

Me_3SnF is an orthorombic crystal, space group Pmcn, with four molecules in a unit cell.[1] If the space group is reasonable, the unit cell comprises two equivalent sites and a 180° rotation about the a axis transforms one into the other. If the areas of the $\sigma(\pm1/2\rightarrow\pm1/2)$ and $\pi(\pm1/2\rightarrow\pm3/2)$ transitions are expressed by A_σ and A_π, and the recoilless fraction is assumed to be isotropic in the first approximation,[6] then, for a single-crystal absorber, the area ratio after Zory[7] is given by Eq. 1 as a function of the polar and azimuthal angles, Θ and Φ, of the incident γ-ray with respect to the crystal axes system O_{bca} (see Fig. 2).

$$\frac{A_\sigma}{A_\pi}=\frac{4\left(1+\frac{1}{3}\eta^2\right)^{1/2}-(3K-1+\eta K')}{4\left(1+\frac{1}{3}\eta^2\right)^{1/2}+(3K-1+\eta K')}, \quad (1)$$

where

$$K=(Z_b^2\cos^2\Phi+Z_c^2\sin^2\Phi)\sin^2\Theta+Z_a^2\cos^2\Theta+Z_bZ_c\sin^2\Theta\sin2\Phi,$$

$$K'=[(X_b^2-Y_b^2)\cos^2\Phi+(X_c^2-Y_c^2)\sin^2\Phi]\sin^2\Theta+(X_a^2-Y_a^2)\cos^2\Theta+(X_bX_c-Y_bY_c)\sin^2\Theta\sin2\Phi.$$

The symbol X_a, for instance, stands for the direction cosine of the angle between the axis of the electric-field gradient (EFG) and the corresponding crystal axis. In the case of needle crystals grown along the a axis, the area ratio is given by integrating Eq. 1 from 0 to 2π on Φ. Expressing each of the direction cosines as a function of the Euler angles (α, β, γ), the resulting area ratio is:

$$\frac{A_\sigma}{A_\pi}=\frac{8\left(1+\frac{1}{3}\eta^2\right)^{1/2}-(3I-2+\eta I')}{8\left(1+\frac{1}{3}\eta^2\right)^{1/2}+(3I-2+\eta I')}, \quad (2)$$

where

$$I=2\cos^2\beta\cos^2\Theta+\sin^2\beta\sin^2\Theta,$$

$$I'=\sin^2\beta\cos2\gamma(2\cos^2\Theta-\sin^2\Theta).$$

In the case of $\eta=0$, this equation becomes equal to that[8] obtained by integrating the transition probabilities.

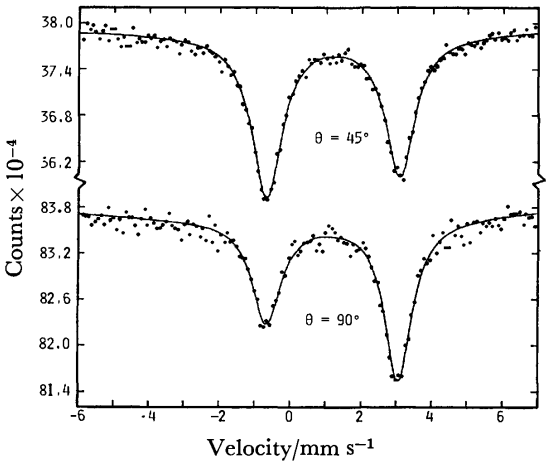

Fig. 1. The Mössbauer absorption spectra of Me_3SnF needle crystals at 110 K.

Figure 1 shows two typical spectra obtained for the γ-ray propagation direction at angles of 45° and 90° from the needle axis. In Fig. 2, the experimental values of the ratio of the high-energy absorption area to the low, A_H/A_L, are plotted against the angle Θ along with the theoretical curves calculated from Eq. 2, assuming that the molecule has C_{3v} symmetry, *i.e.*, $\eta=0$. The experimental points fit closely to the curve of $\beta=20°$.

Figure 3 shows the crystal structure proposed by Yasuda *et al.*[2] The Me_3Sn group forms a planar equilateral triangular structure and is inclined by 21° to the plane perpendicular to the a axis, and the Me_3Sn

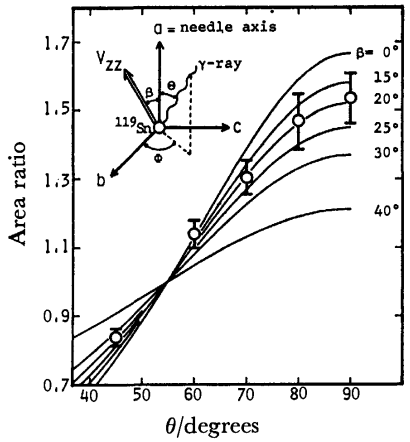

Fig. 2. The angular dependence of the area ratio for Me_3SnF needle crystals at 110 K.

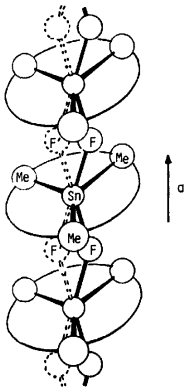

Fig. 3. Arrangement of Me_3SnF molecules.[2] F and F′ indicate the two possible possitions of the fluorine atom.

groups and F atoms are arranged alternately along the a axis. According to this structure, the molecular symmetry about the tin atom is not C_{3v}. However, it is expected that the departure from C_{3v} is not very great, and hence V_{zz} is approximately perpendicular to the plane of the Me_3Sn group, *i.e.*, the angle β is estimated to be about 21°. The value agrees well with our result, and the fact that A_H/A_L is equal to A_σ/A_π means that the σ transition lies at a higher energy than the π transition, *i.e.*, the sign of the principal component of the EFG tensor is positive, $V_{zz}>0$.

In order to explain the anomaly[1] in the electron-density distribution of the F atom, Yasuda *et al.*[2] predicted that the F atom would occupy two positions of minimum potential energy at room temperature, as

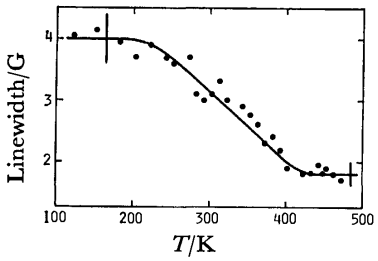

Fig. 4. The ^{19}F NMR linewidth as a function of temperature for Me_3SnF.

seen in Fig. 3. To examine the question of the motion of the F atom, ^{19}F NMR spectra were investigated in the temperature range 123—473 K. The linewidth is plotted as a function of temperature in Fig. 4. Limits of experimental error are shown at low and high temperatures by error bars in the figure. At low temperature the linewidth is constant at 4.0 G, presumably due to the rigid-lattice value. At temperatures around 450 K, the linewidth decreases to 1.8 G. The reduction of the linewidth seems likely to be caused by the switching motion of the F atoms. Accordingly, the molecular symmetry at the tin atom is expected to approach to C_{3v} by such motion. This is reflected also at the IR spectra[4] of the compound: the Sn–C asymmetric streching vibration occurs as a nearly singlet peak in the room-temperature spectrum, whereas in the liquid-nitrogen spectrum it is resolved into a doublet. The activation energy for the motion of the F atom was estimated to be 6.7 ± 1.3 kJ mol^{-1} on the basis of the theory[9] relating linewidth and correlation frequency.

(Received February 9, 1980)

Synopsis. When pyridine is added to the reaction system of the electron transfer between Fe(II) and Fe(III) in aqueous solution at constant $[HClO_4]_o$, the apparent rate constant k grows rapidly with $[Py]_o$ at $[Py]_o<[HClO_4]_o$, while k suddenly diminishes to a small and constant value at $[Py]_o>[HClO_4]_o$. The predominant paths of the reaction will be discussed.

We have been investigating the reaction mechanisms of the electron transfer between iron(II) and iron(III) complexes Fe(II)+*Fe(III)→Fe(III)+*Fe(II) in various solutions.[1] In this note, we will report on an interesting phenomenon observed in the case that pyridine(Py) is added to the reaction system. Namely, when the total concentration of pyridine $[Py]_o$ is increased in aqueous solutions of iron(II) and iron(III) at a constant concentration of perchloric acid $[HClO_4]_o$, the apparent rate constant of the electron transfer reaction k grows rapidly at first, and becomes almost infinitely large until $[Py]_o$ reaches to values closely equal to $[HClO_4]_o$. After that, nevertheless, it suddenly diminishes to a constant value as small as $k=4.5\pm1.6$ $M^{-1}s^{-1}$ (1 M=1 mol dm^{-3}) indifferent to both $[Py]_o$ and $[HClO_4]_o$. A few cases of the phenomenon are shown in Fig. 1, in which k is plotted against $[Py]_o$ when $[HClO_4]_o$ is kept at 0.05, 0.10, and 0.20 M respectively, at $\mu=0.2$ M and 25 °C.

The apparent rate constant k was determined by the method using radioactive tracer Fe-59, as described elsewhere.[2,3]

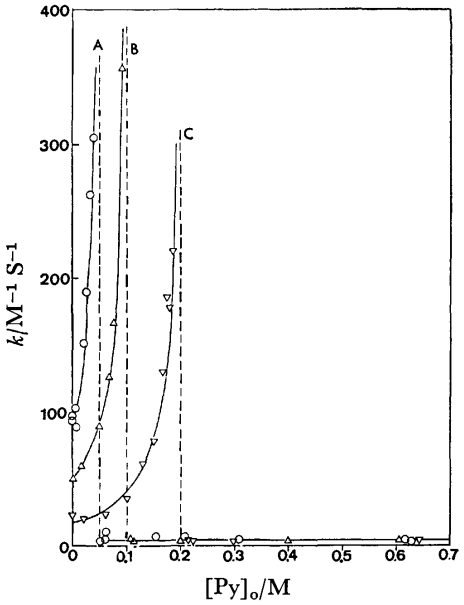

Fig. 1. The variation of k with $[Py]_o$ at $[HClO_4]_o=0.05$ M (a), 0.10 M (b), and 0.20 M (c).

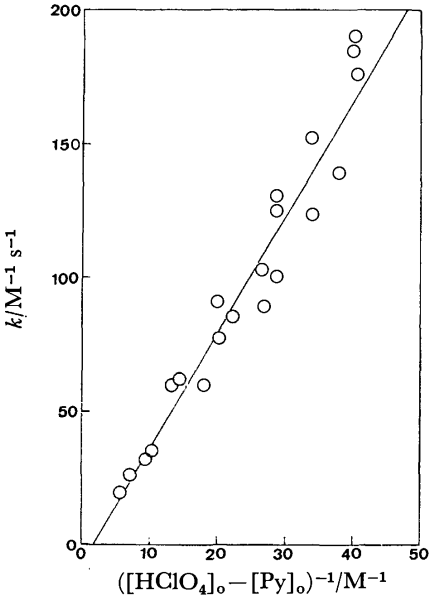

Fig. 2. The linear relationship of k with $([HClO_4]_o-[Py]_o)^{-1}$ at $[Py]_o<[HClO_4]_o$.

The observed fact that k varies peculiarly with the increase in $[Py]_o$ at a constant $[HClO_4]_o$ should be reasonably understood by the following consideration. At the concentration range of $[Py]_o<[HClO_4]_o$, the concentration of hydrogen ion $[H^+]$ becomes smaller by as much as $[Py]_o$ than $[HClO_4]_o$, because pyridine is a considerably strong base with a basicity constant $K_b=2.8\times10^5$ M^{-1} at $\mu=0.5$ M and 25 °C where $K_b=[PyH^+]/[Py][H^+]$.[4,5] Therefore, the actual value of the hydrogen ion concentration in the reaction system is approximately equal to $[HClO_4]_o-[Py]_o$. Consequently, when k is plotted against $([HClO_4]_o-[Py]_o)^{-1}$ instead of plotting against $[HClO_4]_o^{-1}$, a single straight line is obtained as is shown in Fig. 2. This indicates that k can be expressed by the following equation:

$$k = k_o + \frac{k_H K_H}{[HClO_4]_o - [Py]_o}$$

where k_o and k_H denote the reaction rate constants of the electron transfer Fe^{2+}/Fe^{3+} and $Fe^{2+}/FeOH^{2+}$ respectively, and K_H the hydrolysis constant of Fe^{3+}, $K_H=[FeOH^{2+}][H^+]/[Fe^{3+}]$.

The slope of the straight line is found to be 4.4 s^{-1} which is fairly close to the value $k_HK_H=6.0$ s^{-1} observed in aqueous solutions, using the value $K_H=2.2\times10^{-3}$ M.[6] Therefore, the equation suggests that the reaction path between Fe^{2+} and $FeOH^{2+}$ (Path B) takes an important part in parallel with the reaction path between Fe^{2+} and Fe^{3+} (Path A) in the electron transfer

reaction in the present system, the asterisked iron *Fe expressing the species labelled by radiotracer.

$$Fe^{2+} + *Fe^{3+} \longrightarrow Fe^{3+} + *Fe^{2+} \quad (A)$$

$$Fe^{2+} + *FeOH^{2+} \longrightarrow FeOH^{2+} + *Fe^{2+} \quad (B)$$

When $[Py]_o$ becomes larger than $[HClO_4]_o$, the apparent rate constant k suddenly diminishes and keeps almost constant value, as shown in Fig. 1. In this concentration range of $[Py]_o > [HClO_4]_o$, a part of pyridine is protonated with H^+ to be pyridinium ion and the rest of pyridine coordinates to Fe^{2+} to be $Fe(Py)_n^{2+}$.[7] Since $[H^+]$ decreases to a considerable extent due to the protonation of pyridine, Fe^{3+} is forced to be hydrolyzed to give $FeOH^{2+}$. Consequently, each of the equilibria of the following three reactions declines towards the right-hand side.

$$Py + H^+ \rightleftharpoons PyH^+$$

$$Fe^{2+} + nPy \rightleftharpoons Fe(Py)_n^{2+}$$

$$Fe^{3+} \rightleftharpoons FeOH^{2+} + H^+$$

Thus, the main path of the electron transfer reaction should be the reaction between $Fe(Py)_n^{2+}$ and $FeOH^{2+}$ (Path C),

$$Fe(Py)_n^{2+} + *FeOH^{2+} \longrightarrow \text{Products}, \quad (C)$$

the rate constant of which may be approximately equal to the apparent rate constant observed after $[Py]_o$ surpasses $[HClO_4]_o$. Although pyridine may be supposed to coordinate to $FeOH^{2+}$, the occurrence of the coordinated species has not been ascertained yet as far as the spectrophotometric observation was performed.

A.c. Polarographic Determination of Cyanide Ion after Conversion to Mercury(II) Cyanide by Use of Hg-form Resin

Goro HANAGATA,** Kunio OHZEKI, and Tomihito KAMBARA*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
***Division of Environmental Conservation, Graduate School of Environmental Science, Hokkaido University, Sapporo 060*

(Received April 11, 1980)

Synopsis. Cyanide ion was converted to mercury(II) cyanide by shaking with Hg(II)-form resin and determined by a.c. polarography at pH 9.0. The recovery was 80.5%. A linear calibration curve was obtained in the cyanide concentrations ranging from 10^{-4} to 10^{-3} M (1 M=1 mol dm^{-3}).

As to the polarographic determination of cyanide ion, several methods have been reported,[1-4] which were mainly based on the anodic oxidation of mercury in the presence of cyanide. As early as 1937 the reduction of mercury(II) cyanide was studied in detail by Tomes.[5]

Experimental

Reagents. All chemicals used were of analytical reagent grade. A 10^{-2} M nickel(II) solution was prepared from sulfate and standardized against EDTA. A 10^{-2} M potassium cyanide solution was standardized against the nickel(II) solution. The solution of other metal ions was prepared from sulfate or nitrate and standardized against EDTA. A stock solution of mercury(II) cyanide was prepared by mixing the mercury(II) nitrate and potassium cyanide in the stoichiometric ratio. Buffer solutions used were 0.2 M boric acid —0.2 M sodium hydroxide (pH=8.0—11.0).

A cation exchanger Dowex 50 W-X8 (100—200 mesh) was washed as usual, converted into H-form and then air-dried. Five grams of the resin (2.79 meq/g) were treated with mercury (II) nitrate. The Hg-form resin was then washed with water and finally dispersed in water to give a suspension of 500-ml volume. The mixture was stirred each time before pipetting out.

Apparatus. The polarograph used was a Yanagimoto product, type P-8. Characteristics of the dropping mercury electrode were: m=1.88 mg s^{-1} and t=3.97 s in 0.5 M potassium nitrate solution containing the borate buffer in 0.02 M (pH=9.0) at an open circuit with a mercury column height of 72.5 cm. Polarograms were recoded at 25±0.1 °C. A Hitachi-Horiba glass electrode pH-meter, F-5 was used.

General Procedure. A 20-ml portion of smaple solution containing cyanide ion in the concentrations ranging from 10^{-4} to 10^{-3} M was taken into a separatory funnel and 5 ml of the Hg-form resin suspension was added. The mixture was shaken for 5 min at a room temperature. The resin was then separated by filtration through glass wool, and washed with about 10 ml of water. The filtrate and washings were transferred into a 50-ml volumetric flask containing 10 ml of 2.5 M potassium nitrate and 5 ml of the borate buffer (pH=9.0). The volume was adjusted to mark with water. A part of the solution was taken into a cell and oxygen was purged by passing nitrogen gas for 5 min. The dissolved oxygen interfered slightly when the concentration of mercury(II) cyanide is low. The a.c. polarograms were recorded succssively three times and the average peak current was measured.

Results and Discussion

Polarographic Behavior of Mercury(II) Cyanide. The direct current polarographic reduction of mercury(II) cyanide has been studied by Tomes[5] and Newman *et al.*[6] In the pH range 6.0—9.5 was found a reversible wave corresponding to the over-all electrode reaction

$$Hg(CN)_2 + 2H^+ + 2e \longrightarrow Hg + 2HCN. \quad (1)$$

In alkaline solution $Hg(CN)_3^-$ and $Hg(CN)_4^{2-}$ are also reducible at the dropping mercury electrode.[6]

A well-defined a.c. polarogram with a stable and constant peak height was obtained in the pH range of 8.8 to 9.3, while the peak potential was shifted from —354 to —339 mV *vs.* Hg-pool. When mercury(II) ion is added in excess, however, precipitation of mercury(II) hydroxide takes place which causes the erroneous results. From the practical viewpoint, it is necessary to convert cyanide ion completely into mercury(II) cyanide without addition of excess mercury(II) ion.

Use of Hg-form Resin. The mercury(II) cyanide being strongly stable,[7] it is expected that when cyanide ion is mixed with Hg-form resin mercury(II) ion is expelled form the resin into the solution forming mercury(II) cyanide as follows:

$$(RSO_3)_2Hg + 2KCN \longrightarrow 2RSO_3K + Hg(CN)_2, \quad (2)$$

where R denotes the resin matrix.

A 20-ml portion of sample solution containing 237 μg of cyanide was converted to mercury(II) cyanide and determined according to the above-stated general procedure. The procedure was repeated five times. The average peak current was 140 μS and relative

Table 1. Recovery of cyanide ion

Metal-cyano complex[a]	Temperature (°C)	Shaking time (min)	Conversion to $Hg(CN)_2$ (%)
KCN	room temp[b]	5	80.5
$K[Ag(CN)_2]$	room temp	5	81.1
$K_2[Ni(CN)_4]$	room temp	5	31.6
	room temp	60	81.0

$K_3[Fe(CN)_6]$	room temp	5	8.6
	room temp	60	81.1

a) Total cyanide ion concentration in the electrolysis solution was 4×10^{-4} M. Cyano complex was prepared by mixing the metal ion in small excess to the stoichiometric ratio. b) 17±2 °C.

standard deviation was 4.0%. On the other hand, the corresponding sample solution prepared from the stoichiometric mixture of cyanide and mercury(II) gave peak current of 174 μS ($n=3$). The conversion ratio was calculated to be 80.5%. The prolonged shaking time and the increased amount of resin have no effect on the improvement of recovery. The loss is not clearly explained, while the incomplete recovery is partly attributable to the formation of $Hg(CN)^+$.

A linear calibration curve of good proportionality was obtained in the cyanide ion concentrations ranging from 10^{-4} to 10^{-3} M. This means that the conversion ratio is constant in the above concentration range.

Silver(I) and cadmium(II) do not interfere with the formation of mercury(II) cyanide as shown in Table 1. In the presence of niekel(II) and iron(III) a prolonged shaking time or an elevated temperature is effective. Cobalt(III) combining with cyanide ion stronger than mercury(II) reduces the recovery seriously. Copper(II) and iron(II) also interfere.

When the concentration of chloride or thiocyanate exceeds twice that of cyanide, the recovery begins to decrease. An equimolar amount of sulfide interferes seriously.

Halogenation of Alkyl *p*-Tolyl Sulfones with Carbon Tetrahalides. Application to the Synthesis of Aromatic Ketones

Hiroshi KOTAKE, Katsuhiko INOMATA,* Hideki KINOSHITA,
Yasuko SAKAMOTO, and Yoko KANETO
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received April 11, 1980)

Synopsis. Carbanions of alkyl *p*-tolyl sulfones reacted with carbon tetrahalides to give the corresponding polyhalogenated products in good yields. Some chlorinated sulfones were converted to unsymmetrical ketones by treatment with silver perchlorate in trifluoroacetic acid.

Arnold and Kulenovic have reported that carbanions of esters reacted with carbon tetrahalides to give the corresponding α-monohalo esters.[1)]

a) Tenfold molar quantity of CCl_4 was used. b) Isolated yields by preparative TLC.

In connection with our continuing interest to extend the synthetic utility of sulfones,[2)] we have tried a similar halogenation reaction to sulfones. When an alkyl *p*-tolyl sulfone (**1**) was lithiated with an equimolar amount of butyllithium in THF at −78 °C followed by addition of tenfold molar quantity of carbon tetrachloride, the corresponding polychlorinated sulfone (**2**) was obtained (Table 1), being in contrast with the report mentioned above.[1)]

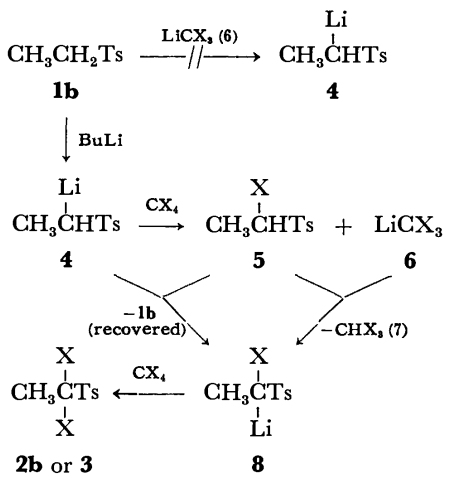
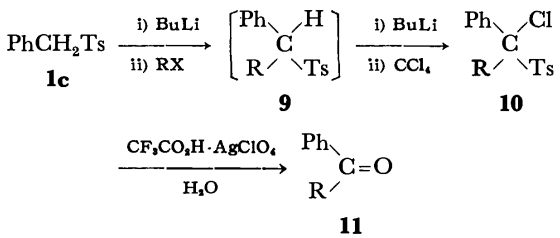
1	*ca.* 0.1	10 (X=Cl)	**2b**, 12	82
1	1	1 (X=Cl)	**2b**, 51	38
1	1	10 (X=Br)	**3**, 54	41

The result of halogenation of ethyl *p*-tolyl sulfone (**1b**) under the various conditions (Table 2) suggested that the polyhalogenation proceeds through the following scheme[3)] and that the order of acidities are $CH_3CHClTs$ (**5**)>$HCCl_3$ (**7**)>CH_2CH_2Ts (**1b**).



The halogenation of alkyl *p*-tolyl sulfone with carbon tetrahalide was successfully applied to the synthesis of unsymmetrical aromatic ketones as illustrated in the following scheme: the alkylated intermediate (**9**),



without isolation, was lithiated again with butyllithium followed by the addition of carbon tetrachloride to give the chlorinated sulfone (**10**) in good yield (Table 3). The chloro sulfone (**10**) was treated with silver perchlorate in refluxing trifluoroacetic acid containing a small amount of water to afford the corresponding aromatic ketone (**11**) in good yield (Table 3).[5)]

Experimental

All the melting points are uncorrected. The NMR and IR spectra were recorded on JEOL JNM/MH-60 and JASCO IRA-1 spectrometers, respectively.

Materials. Freshly distilled THF with lithium aluminum hydride under nitrogen was used. Thin-layer chromatography (TLC) was performed on Merck's Silicagel 60 PF_{254} (Type 7749).

Alkyl p-*Tolyl Sulfones (1a—f).* All of them were readily prepared from equimolar amounts of alkyl halides and sodium *p*-toluenesulfinate tetrahydrate by refluxing in methanol for 8—19 h except **1e** previously described.[4] 2-Phenylethyl *p*-tolyl sulfone (**1d**) is an only new compound. Mp 73.0—73.5 °C. Found: C, 69.23; H, 6.14%. Calcd for $C_{15}H_{16}O_2S$: C, 69.23; H, 6.15%.

1,1-Dichloroethyl p-*Tolyl Sulfone (2b).* Ethyl *p*-tolyl sulfone (**1b**, 184 mg, 1 mmol) was lithiated by stirring with an equimolar amount of butyllithium in THF (10 ml) at −78 °C for 15 min under nitrogen. After addition of carbon tetrachloride (1.538 g, 10 mmol), the reaction mixture was allowed to warm to room temperature and then stirred for 15 min at room temperature. After evaporation of the solvent, the resulting residue was treated with pH 7 buffer solution followed by extraction with ethyl acetate. The crude residue obtained by concentration of the extract was subjected to preparative TLC (hexane–ether 5 : 4 v/v) to give **2b** (229 mg, 91%, mp 100—105 °C). NMR ($CDCl_3$) δ 2.39 (s, 3H), 2.45 (s, 3H), 7.29 (d, 2H, J=9 Hz), 7.82 (d, 2H, J=9 Hz). Recrystallization from heptane gave the pure substance (187 mg, 74%, mp 106—108.0 °C) for elemental analysis. Found: C, 42.81; H, 3.92%. Calcd for $C_9H_{10}Cl_2O_2S$: C, 42.69; H, 3.95%.

In a silmilar manner, **2a,c—f** and **3** were prepared from the corresponding alkyl *p*-tolyl sulfones (Tables 1 and 2).

CCl_3Ts (2a): Found: C, 35.40; H, 2.54%. Calcd for $C_8H_7Cl_3O_2S$: C, 35.10; H, 2.56%.

$PhCCl_2Ts$ (2c): Found: C, 53.39; H, 3.73%. Calcd for $C_{14}H_{12}Cl_2O_2S$: C, 53.33; H, 3.81%.

$PhCH_2CCl_2Ts$ (2d): NMR ($CDCl_3$) δ 2.44 (s, 3H), 3.71 (s, 2H), 7.25 (s, 5H), 7.30 (d, 2H, J=9 Hz), 7.83 (d, 2H, J=9 Hz). Found: C, 54.90; H, 4.24%. Calcd for $C_{15}H_{14}Cl_2O_2S$: C, 54.71; H, 4.26%.

$CHCH_2CCl_2Ts$ (2e): NMR ($CDCl_3$) δ 2.45 (s, 3H), 2.82 (d, 2H, J=4 Hz), 3.91 (broad, 4H), 5.32 (t, 1H, J=4 Hz), 7.34 (d, 2H, J=9 Hz), 7.87 (d, 2H, J=9 Hz). Found: C, 44.41; H, 4.39%. Calcd for $C_{12}H_{14}Cl_2O_4S$: C, 44.31; H, 4.31%.

$(CH_3)_2CClTs$ (2f): Found: C, 51.76; H, 5.53%. Calcd for $C_{10}H_{13}ClO_2S$: C, 51.61; H, 5.59%.

CH_3CBr_2Ts (3): Mp 121—122 °C (recrystallized from heptane). NMR ($CDCl_3$) δ 2.45 (s, 3H), 2.65 (s, 3H), 7.31 (d, 2H, J=9 Hz), 7.87 (d, 2H, J=9 Hz). Found: C, 31.78; H, 2.88%. Calcd for $C_9H_{10}Br_2O_2S$: C, 31.58; H, 2.92%.

1-Chloro-1,2-diphenylethyl p-*Tolyl Sulfone (10, R=CH_2Ph).* Benzyl *p*-tolyl sulfone (**1c**, 246 mg, 1 mmol) was lithiated by stirring with an equimolar amount of butyllithium in THF (20 ml) at −78 °C for 20 min and then at room temperature for 20 min under nitrogen. After cooling to −78 °C, a THF (2 ml) solution of benzyl bromide (171 mg, 1 mmol) was added. The reaction mixture was allowed to warm to room temperature to complete the alkylation and then cooled again to −78 °C followed by the addition of carbon tetrachloride (1.538 g, 10 mmol). After stirring for 20 min, the mixture was treated with 1 mol dm^{-3} HCl–MeOH at −78 °C and partitioned between ether and water. The organic layer was dried over Na_2SO_4 followed by evaporation of the solvent under reduced pressure. The resulting residue was subjected to preparative TLC (hexane–ethyl acetate 5 : 1 v/v) to give **10** (322 mg, 87%, mp 133 °C). NMR ($CDCl_3$) δ 2.35 (s, 3H), 3.82 (d, 1H, J=15 Hz), 4.30 (d, 1H, J=15 Hz), 6.85—7.65 (m, 14H). Recrystallization from heptane gave the pure substance (mp 136—137 °C) for elemental analysis. Found: C, 67.89; H, 5.00%. Calcd for $C_{21}H_{19}ClO_2S$: C, 68.01; H, 5.16%.

In a similar manner, other chlorinated sulfones (**10**, R=CH_2CH_2Ph, $(CH_2)_4CH_3$ and **12**) were prepared.

$PhCH_2CH_2CPhClTs$: Mp 114—115 °C (recrystallized from cyclohexane). NMR ($CDCl_3$) δ 2.32 (s, 3H), 2.4—3.2 (m, 4H), 6.8—7.6 (m, 14H). Found: C, 68.51; H, 5.44%. Calcd for $C_{22}H_{21}ClO_2S$: C, 68.66; H, 5.46%.

$CH_3(CH_2)_4CPhClTs$: Mp 66—67 °C (recrystallized from hexane). NMR ($CDCl_3$) δ 0.6—1.6 (m, 9H), 2.36 (s, 3H), 2.15—3.20 (m, 2H), 7.07 (d, 2H, J=9 Hz), 7.1—7.5 (m, 5H), 7.35 (d, 2H, J=9 Hz). Found: C, 65.09; H, 6.57%. Calcd for $C_{19}H_{23}ClO_2S$: C, 65.05; H, 6.56%.

$CH_3(CH_2)_4(CH_2Ph)ClTs$: Oil. NMR ($CDCl_3$) δ 0.82 (t, 3H, J=5 Hz), 0.95—2.25 (m, 8H), 2.39 (s, 3H), 3.17 (d, 1H, J=14 Hz), 3.53 (d, 1H, J=14 Hz), 7.14 (s, 5H), 7.23 (d, 2H, J=8 Hz), 7.77 (d, 2H, J=8 Hz).

1,2-Diphenylethanone (11, R=CH_2Ph). To a solution of **10** (100 mg, 0.27 mmol) in trifluoroacetic acid (2 ml) were added silver perchlorate (112 mg, 0.54 mmol) and water (0.5 ml). After refluxing for 1 h, the reaction mixture was diluted with ether, neutralized with a saturated $NaHCO_3$ solution, washed with water, and dried over Na_2SO_4. The crude residue obtained by evaporation of ether was subjected to preparative TLC (hexane–ethyl acetate 5 : 1 v/v) to give **11** (45 mg, 85%, mp 50—54 °C (lit, 55—56 °C)). IR and NMR spectra were in accordance with those of authentic sample.

In a similar way, other aromatic ketones (**11**, R=CH_2CH_2-Ph, $(CH_2)_4CH_3$) were obtained as shown in Table 3.

Evidence for Electron-transfer Process in Abnormal Grignard Reactions. Enolization and α-Diketone Formation

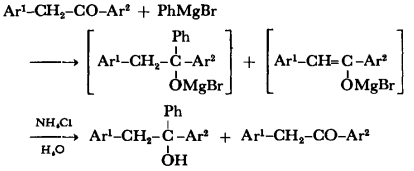
Masao Ōkubo,* Yoshiaki Morigami, and Reiko Suenaga

Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjō-machi, Saga 840

(Received January 30, 1980)

Synopsis. The effect of 2,6-dimethyl groups on enolization *vs.* addition in the reaction of PhMgBr with $PhCH_2COPh$, and also the formation of α-diketone from $2,4,6\text{-}Me_3C_6H_2COCl$ by the treatment with MeMgX and *i*-PrMgX in the presence of $CoCl_2$, were studied. The results were discussed on the basis of electron-transfer mechanism.

In Grignard reaction of carbonyl compounds, steric hindrance affects greatly the concentration as well as the spin distribution of initially formed ketyl radicals and consequently the course of reaction.[1,2] Correlation between the spin density and the product distribution was discussed in the studies on aromatic substitution,[1] replacement of anionoid substituents,[2] and conjugate addition.[2] Among representative abnormal Grignard reactions, enolization of ketones[3] and α-diketone formation from hindered aroyl chloride[4] remanined to be studied on the same basis. Some results obtained in these reactions will be reported and discussed in this paper.

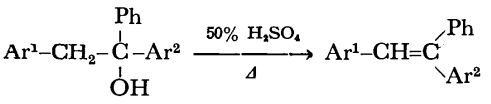


Scheme 1.

Enolizable ketones studied are benzyl phenyl ketone and its *o*-methyl derivatives (Table 1, **1**, **2**, **3**, and **4**), the reaction with PhMgBr being shown in Scheme 1. The reaction was carried out in tetrahydrofuran (THF) under nitrogen atmosphere, the reaction mixture being heated at 50 °C for 30 min. The cooled reaction mixture was quenched with saturated aqueous NH_4Cl. A mixture of products obtained after removal of solvent was heated with 50% H_2SO_4 to convert the alcohols (normal adducts) into the corresponding triarylethylenes (Scheme 2). The product mixtures were finally submitted to GLC analysis. The product distributions thus determined are summarized in Table 1.

Table 1. Product distribution in the reaction of hindered benzyl phenyl ketones

No.	$Ar^1\text{-}CH_2\text{-}CO\text{-}Ar^2$ structure	[PhMgBr]/[Ketone]	Product distribution (%) Recovered ketone	Product distribution (%) $Ar^1\text{-}CH\text{=}C(Ar^2)Ph$
1		1	36	64
		1.5	27	73
		2	3	97
		3	2	98
2		1	78	22
		5	66	34
		10	54	46
3		10	100	0
4		10	100	0



Scheme 2.

The results show that the presence of 2,6-dimethyl groups affect remarkably the product distribution: the groups on the benzoyl moiety do much more greatly than those on the benzyl moiety, thus inhibiting normal addition completely. In order to estimate the extent of enolization, the reaction mixtures of **3** and **4** were quenched with $D_2O\text{–}D_2SO_4$. Analyses of the NMR spectra show that the recovered **3** has been enolized quantitatively while **4** to *ca.* 60%.

ESR signals were detected in the reactions of **3** and **4** at room temperature. Failure to detect ESR signals in the cases of **1** and **2** is quite reasonable, since it is known that ketones having α-hydrogen atom cannot give stable metal ketyls due to rapid decomposition.[5,6] Existence of the initial electron-transfer step from Grignard reagent to substrates is generally accepted on the basis of recent mechanistic studies.[7,8] The failure to detect ESR signals in the cases of **1** and **2** is thus ascribable to the rapid subsequent processes: enolization and addition.

ESR signal observed in the case of **3** ($a_{\alpha\text{-H}}=2.6$) disappeared completely after heating the reaction mixture at 50 °C for 30 min, whereas that in the case of **4** ($a_{\alpha\text{-H}}=7.5$[9]) did not. In spite of the expected high spin density on the carbonyl carbon atom due to the sterically suppressed spin delocalization on the hindered phenyl group, the fair stability of these ketyls at room temperature could be ascribed to their conformation (Fig. 1): the direction of the $C_\alpha\text{–}H_\alpha$ bond is not in trans to that of the free spin orbital and the free spin may be stabilized by the spatial assistance of the π-electrons of the aryl group on the benzyl moiety (**3a** and **4a**). Predominance of these eclipsed conformations is rationalized since at least two THF molecules affect greatly the bulkiness of the –OMgBr group. By heating the reaction mixture of **3**, however, the conformational rotation to the staggered form (**3b**) occurs, allowing the direction of the $C_\alpha\text{–}H_\alpha$ bond to be in full trans to

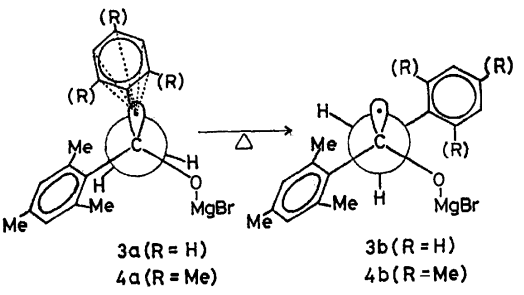


Fig. 1. Conformation of the ketyl radicals of **3** and **4**.

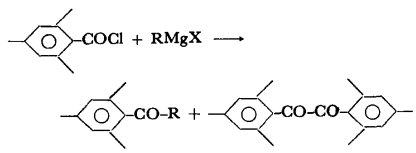
that of the free spin orbital. This conformation is responsible for the β-scission of the α-hydrogen atom, the original ketone **3** being thus enolized. The great stability of the ketyl of **4** is thus ascribed to the sterically retarded conformational change from **4a** to **4b** (Fig. 1) caused by the hindered aryl group of the benzyl moiety. It should be noted that the electron-transfer process was confirmed for the first time in the reaction of enolizable ketones.

The formation of α-diketone(2,2′,4,4′,6,6′-hexamethylbenzil) from hindered 2,4,6-trimethylbenzoyl chloride by the treatment with Grignard reagents (Scheme 3; R=Me, X=Br and I) in the presence of a catalytic amount of $CoCl_2$ was reported.[4] If isopropylmagnesium halide (Scheme 3; R=*i*-Pr, X=Cl, Br, and I) is used, the bulkier isopropyl group is expected to raise the yield of α-diketone.



Scheme 3.

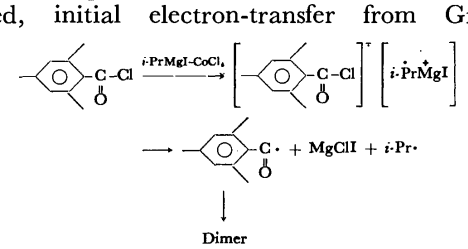
The reaction was carried out in diethyl ether to compare our result with the previous one.[4] A very high yield of the α-diketone was realized by the treatment with *i*-PrMgI (Table 2). This result, however, is explicable in terms of the electron-transfer ability of the reagent instead of ambiguous effect of bulkiness. The thermographic[10] and electrolytic[11] studies of Grignard reagents show that the isopropyl reagent is much more electron-donating than the methyl reagent. Iodide ion has an oxidation potential much lower than that of bromide ion,[12] and is favorable to the α-diketone formation as shown in Table 2. It is thus reasonable to consider that the combination of isopropyl group and iodide ion can transfer single electron to the aroyl chloride most effectively among the five reagents examined.

Table 2. Yields of the α-diketone

Grignard Reagent	Yield of  (%)
Me_2CHMgI	87
$Me_2CHMgBr$	38
$Me_2CHMgCl$	22
MeMgI	63[a]
MeMgBr	31[a]

a) The previous results[4] were reproducible.

Though volatile products[4] could result from *i*-Pr· as well as the equivocal role of $CoCl_2$ remains still to be examined, initial electron-transfer from Grignard reagent to the benzoyl chloride followed by releasing of chloride anion should be emphasized, consequently producing the hindered aroyl radical (Scheme 4) to dimerize to give the α-diketone.



Scheme 4.

Experimental

Materials. Melting points are uncorrected. Friedel-Crafts' method using phenylacetyl chloride was applied to prepare **1** and **3**; **1**: mp 57—59 °C, **3**: mp 101—103 °C. 2,4,6-Trimethylphenylacetyl chloride was used to prepare **2** and **4**; **2**: mp 164.5—165 °C, **4**: mp 181—182 °C. Anthydrous $CoCl_2$ was prepared from commercial hydrated salt.[4] Authentic sample of the α-diketone was prepared according to the reported method[4] using isopropylmagnesium iodide: mp 120.5—122 °C (lit,[4] mp 119—120 °C).

Procedures. PhMgBr (0.0276 mol) in 20 ml THF was prepared in the usual manner. The Grignard solution was cooled to 0 °C and the ketone **1** dissolved in 20 ml THF was added rapidly; the resulting mixture was heated at 50 °C for 30 min. The subsequent procedures were described in the text. The other ketones were treated similarly. The ketones **3** and **4** were recovered quantitatively even by the treatment with 10 molar equivalents of PhMgBr. The apparatus used for ESR measurements was reported previously.[13]

i-PrMgX (0.021 mol) was prepared in diethyl ether (25 ml). $CoCl_2$ (0.0002 mol) was added under N_2, and the resulting black solution was transferred under N_2 into a dropping funnel, the reaction with the aroyl chloride (0.007 mol) in diethyl ether (25 ml) being carried out in the manner of reverse addition.[4] The product mixtures obtained in the reactions of the respective Grignard reagents were submitted to high pressure liquid chromatography on silica gel by use of methyl alcohol–water (65 : 35) as eluent under the pressure of 30 kg/cm^2. The yield of the α-diketone was estimated by comparison with a straight calibration line obtained by injection of the authentic sample solutions in benzene.

A Convenient One-step Preparation of Oxacyclanes by Dehydration of Diols over Alumina

Yoshihisa INOUE,* Shokichiro DEGUCHI, and Tadao HAKUSHI

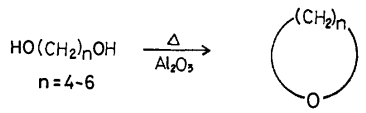
Department of Applied Chemistry, Himeji Institute of Technology, Shosha 2167, Himeji, Hyogo 671-22

(Received April 14, 1980)

Synopsis. Dehydration of 1,4-, 1,5-, or 1,6-alkanediols over alumina at 220—250 °C in a distillation apparatus gave the corresponding 5- to 7-membered oxacyclanes in good yield of 51—71%. Diethylene glycol also gave 1,4-dioxane in 49% yield, whereas attempted one-step synthesis of crown ethers from polyethylene glycols in a similar manner resulted in the predominant formation of 1,4-dioxane without any trace of crown ether.

Most aliphatic ethers are prepared by the removal of water from alcohol under acidic conditions.[1] However, this method has not been used extensively and is actually unsuccessful as a general method for the preparation of oxacyclanes from α,ω-alkanediols.[2,3] Oxacyclanes have been synthesized so far from diols *via* many steps.[4-6] Recently, the synthesis of oxacyclanes has been accomplished by the use of dimethyl sulfoxide,[7] sulforane,[8] or carbodiimide,[9] but these syntheses require the use of relatively inaccessible reagents and do not give satisfactory yield for the synthesis of larger-sized oxacyclanes. The use of alumina as a dehydrating agent appears to be well established for the preparation of tetrahydrofuran derivatives from 1,4-diols.[10,11] An attempted extension of the method to prepare smaller-sized oxacyclanes has been unsuccessful[11] and further attempts have not been made so far.

We wish now to present a convenient one-step method for preparing 5- to 7-membered oxacyclanes from diols and also an attempted one-step synthesis of crown ethers from polyethylene glycols. The use of alumina in liquid phase makes the method easy to use and gives good yields.



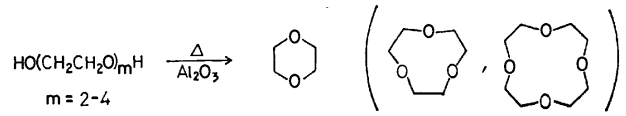
In a typical experiment, a diol was mixed with an equal weight of activated alumina and the mixture was heated up to 220—250 °C in a distillation apparatus fitted with a heating mantle until distillation ceased (*ca.* 5—30 h) to give a corresponding oxacyclane and water as an azeotropic distillate. Dehydration by alumina of 1,4-, 1,5-, or 1,6-alkanediol, *i.e.* **3**, **5**, **7**, or **9**, afforded the oxacyclane, *i.e.* **4**, **6**, **8**, or **10**, in 51—71% isolated yield, although 1,3-butanediol failed to give 2-methyloxetane in a satisfactory yield, probably due to the strain of the four-membered ring. The introduction of other functional group, *i.e.* an additional hydroxyl group or a double bond, resulted in diminished yield of 18—25%.

We also carried out the dehydration of polyethylene glycol by alumina, since this method seemed quite attractive as a simple method for preparing crown ethers. Although the reaction of diethylene glycol over alumina gave 1,4-dioxane in good yield, similar treatment with tri- or tetraethylene glycol resulted in the predominant formation of 1,4-dioxane without any trace of crown ether.

TABLE 1. DEHYDRATION OF DIOLS OVER ALUMINA AT 220—250 °C

Diol		Reaction time/h	Product		(% yield)	Bp/°C
1,4-Butanediol	**3**	20		**4**	(71)	65—66
2,5-Hexanediol	**5**	6	a)	**6**	(58)	92—94
1,5-Pentanediol	**7**	5		**8**	(52)	87—88
1,6-Hexanediol	**9**	18		**10**	(53)	112
1,2,6-Hexanetriol	**11**	30	OH	**12**	(18)	187
3-Hexene-2,5-diol	**13**	12	a)	**14**	(25)	73—75
1,3-Butanediol	**1**	20		**2**	(0.8)[b]	—
Diethylene glycol	**15**	21		**16**	(49)	98—100

a) From ^{13}C NMR spectrum, this ether is shown to be a 1:1 mixture of *cis*- and *trans*-isomers. b) Yield determined by GLC.



We may conclude this method offers a simple and convenient procedure especially for the preparation of 5- to 7-membered oxacyclanes and its alkyl derivatives.

Experimental

All the diols were commercially available and fractionally distilled prior to use. Commercial alumina for chromatography of 200 mesh (Nakarai Chimicals Co.) was used as a dehydration catalyst after dried for 10 h in an oven at 200 °C.

Dehydration of Diols ***1***, ***3***, ***5***, ***7***, ***9***, ***11***, *and* ***13***. Preparation of oxacyclanes, **2**, **4**, **6**, **8**, **10**, **12**, or **14**, was accomplished in a distillation apparatus by heating a diol with an equal weight of activated alumina at 220—250 °C. The product ether and water was distilled as an azeotropic mixture. The distillate was saturated with salt, and the organic layer was dried, filtered and then fractionally distilled to give the product oxacyclane. The isolated yield and boiling point of the

product are presented in Table. The product ethers (95—99% pure by GLC on polyethylene glycol-20M column) were identified by IR, ^{13}C NMR and, if needed, mass spectra and GLC comparison with the authentic samples.

1,4-Dioxane (16). Dehydration of diethylene glycol (20 g) over alumina (12 g) and the subsequent work-up gave 8.1 g (49%) of 1,4-dioxane. The IR and NMR spectra and GLC retention time were identical with those of the authentic dioxane.

Attempted Synthesis of Crown Ether. The facile preparation of 1,4-dioxane from diethylene glycol prompted us to the one-step synthesis of crown ethers from polythylene glycols. Dehydrations of tri- and tetraethylene glycols over alumina were performed merely to give 1,4-dioxane as a major dehydration product in both cases. Repeated attempts at a reduced pressure also gave dioxane; no cyclic polyethers, *e.g.* 9-crown-3 or 12-crown-4, were produced in any cases.

A New Synthesis of Allethrolone

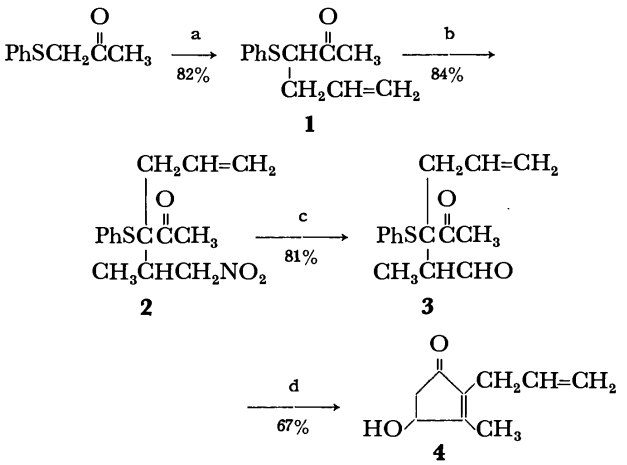
Noboru ONO,* Yo TANABE, Rikuhei TANIKAGA, Aritsune KAJI, and Takashi MATSUO**

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606
***Institute of Biological Science, Sumitomo Chemical Ind., Takarazuka, Hyogo 665*

(Received May 6, 1980)

Synopsis. A new synthesis of 2-allyl-4-hydroxy-3-methyl-2-cyclopenten-1-one, so called allethrolone is described, in which the Michael addition of 3-phenylthio-5-hexen-2-one to 1-nitro-1-propene followed by conversion of the nitromethyl group in the adduct to an aldehyde function is involved as the key step.

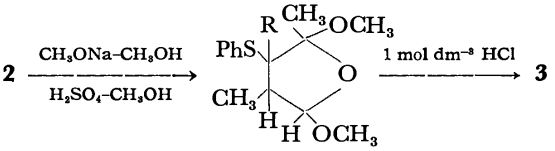
Allethrolone (**4**) is the alcohol component of the allethrine which is a commercially important synthetic homologue of natural occurring pyrethrines. Allethrolone is now prepared in industry by the method of Schechter, which starts from allyl chloride, methyl acetoacetate, and methylglyoxal.[1] Owing to low overall yield of this method, a new efficient method to prepare **4** is desired. Recently, some elegant methods have been devised by Büchi[2] or Schlessinger.[3] Though the yield has been greatly improved by these methods, they require rather expensive starting materials or reagents. This paper presents a new synthesis of **4** starting from readily available materials and by a simple procedure. This new method is outlined in Scheme 1.



a: CH_2=$CHCH_2Br$, 30% NaOH, b: NaH, CH_3CH=$CHNO_2$ in DMF, c: CH_3ONa-CH_3OH/H_2SO_4-CH_3OH, 1 mol dm^{-3} HCl, d: C_2H_5ONa-C_2H_5OH

Scheme 1. A new synthesis of allethrolone (**4**).

3-Phenylthio-5-hexen-2-one (**1**) was obtained in 82% yield by alkylation of α-(phenylthio)acetone with allyl bromide under phase transfer conditions. The Michael addition of **1** to 1-nitro-1-propene took place at 0 °C in DMF using sodium hydride as a base to give the adduct **2** in 84% yield. The key step of the new method is conversion of the nitromethyl group in **2** to an aldehyde function. In general, a Nef type reaction of 1-nitro-4-alkanones involves some difficulties due to formation of a stable cyclic intermediates.[4] After several unsuccessful trials,[5] **2** could be converted to γ-keto aldehydes (**3**) by treating the *aci*-nitro anion of **2** with sulfuric acid in methanol followed by hydrolysis of the crude product with 1 mol dm^{-3} hydrochloric acid. The conventional method to convert 1-nitro-4-alkanones to γ-keto aldehydes requires protection of the ketone function as an acetal before a Nef type reaction.[4] However, protection of the ketone function of **2** is not required in the present procedure, for the reaction proceeds *via* an intermediate **5** in which the ketone function is already protected.[6]



5 R= CH_2CH=CH_2

Finally, **4** was obtained in 67% yield on treatment of **3** with sodium ethoxide in ethanol.

The reactions devised here to prepare **4** can be applied to the synthesis of other related compounds: especially high reactivity of nitroolefins as Michael acceptors for ketone enolates and the simple method to prepare γ-keto aldehydes from 1-nitro-4-alkanones are of special use in organic synthesis.[7]

Experimental

NMR spectra were recorded on a JEOL PS-100 spectrometer. Chemical shift (δ) are given in ppm relative to an internal standard of TMS. IR spectra were recorded on a Hitachi 215 spectrometer, and MS on a Hitachi M-52 spectrometer with 20 eV.

3-Phenyltio-5-hexen-2-one (1). A mixture of α-(phenylthio)acetone[8] (10 g, 0.066 mol), allyl bromide (8.6 g, 0.072 mol), triethylbenzylammonium chloride (0.2 g) in 30% NaOH (100 ml) and benzene (100 ml) was stirred vigorously at 5—10 °C for 10 h. The reaction mixture was poured into water and worked up as usual. Distillation of the crude product afforded **1** (10.1 g, 82%), bp 120—121 °C/2 mmHg (1 mmHg=133.322 Pa); IR (neat) 1710 cm^{-1} (C=O); NMR (CCl_4) 2.20 (s, 3H), 2.4 (m, 2H), 3.60 (t, J=7.2 Hz, 1H), 4.9—5.2 (m, 2H), 5.5—6.0 (m, 1H), 7.5 (m, 5H). Found: C, 69.52; H, 6.82%. Calcd for $C_{12}H_{14}SO$: C, 69.86; H, 6.84%.

3-Allyl-4-methyl-5-nitro-3-phenylthio-2-pentanone (2). A solution of **1** (10 g, 0.048 mol) in 50 ml of DMF was added dropwise to a stirred suspension of NaH (0.05 mol, 50% dispersion in mineral oil) in 200 ml of DMF at room temperature, and the resulting mixture was kept stirring to cease evolution of hydrogen. A solution of 1-nitro-1-propene[9] (4.0 g, 0.048 mol) in 20 ml of DMF was added dropwise to the above DMF solution of the sodium salt of **1** under colling with an ice–salt bath (about −5 °C) and the resulting solution was stirred for 1 h at −5 °C, and then quenched with acetic acid (6 ml). After the usual work up, the crude product was subjected to column chromatography (sliica gel using benzene as an eluent) to give **2** (11.76 g, 84%): IR (neat)

1705 cm^{-1} (C=O), 1555, 1380 cm^{-1} (NO_2); NMR (CCl_4) 1.04, 1.14 (d, d, J=7.0 Hz, 3H), 2.30, 2.35 (s, s, 3H), 2.55 (m, 2H), 2.85 (m, 1H), 4.2—4.5 (m, 2H), 4.9—5.2 (m, 2H), 5.5—6.0 (m, 1H), 7.5 (m, 5H). The product was about 1: 1 mixture of two diasteroisomers and it was used for the next step without further purification.

3-Acetyl-2-methyl-3-phenylthio-5-hexenal (3). A solution of **2** (4.0 g, 0.014 mol) in 15 ml of methanol was added to a stirred solution of sodium methoxide (1 mol dm^{-3}, 16 ml) at −5 °C. The above solution of *aci*-nitro anion was added dropwise at a rate of one drop per second to a stirred solution of 30 ml of sulfuric acid in 120 ml of methanol at −5 °C. When the addition was complete the mixture was poured into 300 ml of dichloromethane and washed with ice water and dilute aqueous sodium hydroxide. The organic layer was dried over anhydrous magnesium sulfate and concentrated *in vacuo* to yield 3.9 g of the product **5**. The crude product was hydrolyzed with 1 mol dm^{-3} HCl (40 ml) at 50 °C for 1 h. After the usual work up, the crude product was subjected to column chromatography (silica gel using benzene as an eluent) to give **3** (2.9 g, 81%): IR (neat) 1720, 1700 cm^{-1} (C=O), NMR (CCl_4) 1.20, 1.38 (d, d, J=7.0 Hz, 3H), 2.40 (s, 3H), 2.55 (m, 2H), 2.8 (m, 1H), 4.9—5.1 (m, 2H), 5.8—6.0 (m, 1H), 7.3 (m, 5H), 9.55, 9.85 (s, s, 1H). The product was aboult 1: 1 mixture of two diastereoisomers.

Allethrolone (4). Compound **3** (2.62 g, 0.01 mol) was dissolved in 30 ml of ethanol which contained 0.01 mol sodium ethoxide. The resulting solution was stirred at room temperature for 1 h and quenched with 1 mol dm^{-3} HCl. After the usual work up, the crude product was subjected to column chromatography (silica gel using benzene–ether as an eluent) to give **4** (1.02 g, 67%); IR (neat) 3400 cm^{-1} (OH), 1720 cm^{-1} (C=O), 1650 cm^{-1} (C=C); NMR (CCl_4) 2.05 (s, 3H), 2.38 (m, 1H), 2.62 (m, 1H), 2.85 (m, 2H), 3.4 (s, 1H), 4.60 (m, 1H), 4.9—5.1 (m, 2H), 5.6—6.0 (m, 1H). MS m/e= 152 (M^+, 30), 137 (23), 124 (27), 123 (12), 111 (12), 109 (100). The spectral data of the product were identical in all respects with authetic allethrolone.

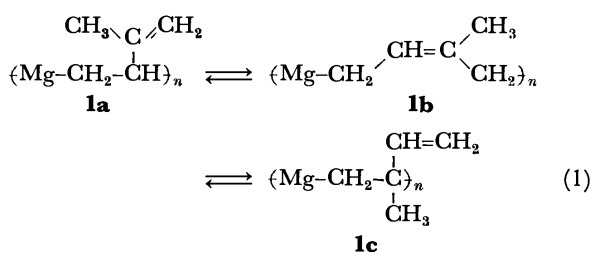
Department of Macromolecular Science, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received May 6, 1980)

Synopsis. A series of isoprene coupling dimers bonded at 1-2, 1-3, 1-4, 2-4, 3-4, or 4-4 position was prepared by regiocontrolled catalysis of trasition metals or without catalysts in the reaction of 2-methyl-2-butene-1,4-diylmagnesium or 3-methyl-2-butenylmagnesium chloride with C_5-alkenyl halides.

Organolithium-[1] or organomagnesium-[2] assisted terpenoid synthesis by insertion of isoprene to metal-carbon bond have recently been extensively studied and transition metal catalysts have been found to be effective for selective 1,4-addition of isoprene to these organometals. We have investigated the monoterpene synthesis using unique bifunctional 2-methyl-2-butene-1,4-diylmagnesium **1**, which is now readily obtainable by direct reaction of magnesium with isoprene.[3] The compound **1** is more reactive than the usual alkyl- or allylmagnesium compounds due to the higher ionicity of metal-carbon bond[3] and has four reactive sites, C_1, C_2, C_3, and C_4, arisen from the following rapid equilibrium, though the most part of it assumes the structure **1b** in tetrahydrofuran. This paper describes the selective synthesis of 1-4 (head to tail), 3-4, and 2-4 bonded isoprene dimers consisting of the same carbon skeleton as naturally occurring monoterpenoids by regiocontrolled catalysis in the reaction of **1** or 3-methyl-2-butenylmagnesium chloride.



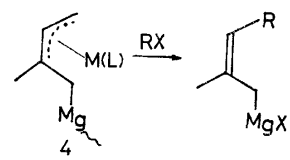
(1)

The 1:1 reaction of **1** with 1-chloro-3-methyl-2-butene in THF at 30 °C for 1 h followed by hydrolysis gave a 4-3 bonded isoprene dimer, 2,3,6-trimethyl-1,5-heptadiene **2** (78%), and a 4-4 bonded dimer, 2,7-dimethyl-1,6-octadiene **3** (22%) in 99% combined yield. Thus, C_3-carbon atom of **1** reacts predominantly. To realize the regioselective control of the various reaction sites in equilibrium, catalysis of Ni(II), Pd(II), and Ti(IV) complexes was examined since these are known as effective catalysts for regio- or stereoselective coupling of allyl halides with organomagnesium compounds.[2,4] The reaction required lower temperatures (0—5 °C) for the effective catalysis because **1** is reactive at 30 °C towards alkenyl halides without catalysts. As shown in Table 1, the addition of Ni(II) or Pd(II) complexes was effective for selective 4-4 coupling of the isoprene units and hydrolysis of the product with dilute aqueous (2 mol dm^{-3}) HCl gave **3** exclusively. This result may be explained by considering **4** as the intermediate. $TiCl_2(\eta^5\text{-}C_5H_5)_2$ and $ZrCl_2(\eta^5\text{-}C_5H_5)_2$ were not so effective for this system presumably due to the formation of catalytically inactive Cp_2M(isoprene) complexes.[5]

Table 1. Regioselection in reaction of **1** with 1-chloro-3-methyl-2-butene in THF[a]

Catalyst	% Ratio of regioisomer		Yield/%
	2	**3**	
None[b]	78	22	99
$NiCl_2(PPh_3)_2$	12	88	72
$NiCl_2$	29	71	65
$PdCl_2(PPh_3)_2$	6	94	75
$PdI_2(PPh_3)_2$	17	83	83

a) Reaction was carried out at 0 °C for 10 h in the presence of catalst (2 mol%) and the reaction mixture was hydrolyzed. b) Reacted at 30 °C for 5 h.



The successful control of the regioselectivity prompted us to prepare myrcene by reaction of **1** with 2-chloromethyl-1,3-butadiene using the Ni(II) catalysts. The reaction proceeds in good yield (75—78%) and myrcene **6** was obtained in 93—95% selectivity by hydrolysis (Table 2). The ratio of α-(**6a**) to β-myrcene **6b** was 8:2 but the ratio changed to 3:7 by protonation with piperidine or pyrrolidine depending on the basicity of protonolysis agents. Similar interconversion have been observed in the protonolysis of enediylmagnesium.[3] In the absence of catalyst, C_3-atom of **1** predom-

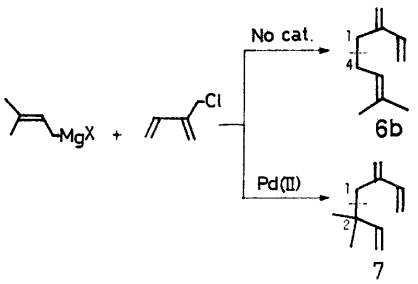
$PdCl_2(PPh_3)_2$	41	59	89
$(\eta^5\text{-}C_5H_5)_2TiCl_2$	73	27	62

a) The reaction mixture was hydrolyzed, after carrying out the reaction at 0 °C for 10 h in the presence of catalyst (2 mol%). b) Reaction was done at 30 °C for 1 h. c) 1,2-Bis(diphenylphosphino)ethane complex.

inantly was alkylated with 2-chloromethyl-1,3-butadiene to give a 1-3 bonded dimer, 2,3-dimethyl-5-vinyl-1,5-hexadiene **5**, consistent with the reaction shown in Eq. 1. The reaction of 3-methyl-2-butenylmagnesium chloride with 2-chloromethyl-1,3-butadiene also produced pure β-myrcene in 92% yield without catalyst. The addition of 2.0 mol% of $PdCl_2(PPh_3)_2$ catalyst caused the production of 2-1 bonded isoprene dimer **7**



in 80% regioselectivity (68% yield). If this Pd(II) catalyzed reaction is applicable also to the reaction of 3-methyl-2-butenylmagnesium chloride with 1-chloro-3-methyl-2-butene, the 2-4 bonded isoprene dimer whose carbon skeleton is identical with yomogi alcohol or artemisia alcohol should be formed. Actually the 2-4 bonded dimer formed but the selectivity was poor (25%) presumably due to the rapid reaction in the absence of catalyst to give a 4-4 bonded dimer even at 0 °C. The dimer **3** was obtained in 75% selectivity (70% yield) in this case.

One of the most important characteristics of the reaction shown in Eqs. 1 and 2 is that the products still retain the reactivity towards a further attack of dienes or electrophiles for preparation of various derivatives of sesqui- or diterpenes. The regioselectivity observed in the present Ni(II) or Pd(II)-catalyzed reaction is considered to be due to the combined steric and electronic effects of the $-CH_2MgCl$ substituent on the η^3-allyl moiety.

Experimental

2-Methyl-2-buten-1,4-diylmagnesium **1** was prepared as previously noted.[3)] 1-Chloro-3-methyl-2-butene prepared according to the method of Tanaka[6)] and 2-chloromethyl-1,3-butadiene by Alieva's method[7)] were purified by distillation after drying over calcium hydride. All the reaction products were characterized by ^1H NMR, IR, and MS in essentially the same way as described previously.[3)]

*Reaction of **1** with 1-Chloro-3-methyl-2-butene.* To the THF (40 ml) solution of **1** (1.0 g, 11 mmol) was added 1-chloro-3-methyl-2-butene (1.1 ml, 10 mmol) at −70 °C and then transition metal catalysts (2.0 mol% of **1**). The mixture was allowed to react at 0 °C for 10 h under magnetic stirring and was hydrolyzed with 2 mol dm^{-3} HCl after the addition of pentane (50 ml). The pentane fraction was distilled and the products were finally separated by gas chromatography. Resulting 2,3,6-trimethyl-1,5-heptadiene **2** and 2,7-dimethyl-1,6-octadiene **3** were identified with authentic samples obtained from **1** and isoprene.[3)]

*Reaction of **1** with 2-Chloromethyl-1,3-butadiene.* The reaction of **1** (1.0 g, 11 mmol) with 2-chloromethyl-1,3-butadiene (1.0 ml, 10 mmol) was carried out under the same reaction conditions as above mentioned reaction. Piperidine (2.0 ml, 20 mmol) or pyrrolidine (1.7 ml, 20 mmol) was added and the mixture was heated to 50 °C for 30 min for the complete protonation. Resulting α- and β-myrcene were identified with authentic samples purchased from Takasago Perfumary Co. with NMR and IR. Characterization of the 1-3 bonded isoprene dimer was made from the following data.

2,3-Dimethyl-5-vinyl-1,5-hexadiene: IR (neat) 1644, 1595, 992, 891 cm^{-1}; NMR($CDCl_3$) δ=6.38 (d of d, 1, J=10.3 and 16.9, CH), 5.23 and 5.00 (two d, 4, CH_2), 4.69 (d, 2, J_{gem}= 1.9, CH_2), 2.26 (d, 2, J=7.8, CH_2), 2.02 (m, 1, CH), 1.69 (s, 3, CH_3), 0.99 (d, 3, CH_3); M^+ 136. Calcd for $C_{10}H_{16}$; M, 136.

Reaction of 3-Methyl-2-butenylmagnesiumchloride with Alkenyl Halides. To the 3-methyl-2-butenylmagnesiumchloride (1.4 g, 11 mmol) in THF (40 ml) was added THF solution (5 ml) of 2-chloromethyl-1,3-butadiene (1.0 ml, 10 mmol) or 1-chloro-3-methyl-2-butene (1.1 ml, 10 mmol) at −70 °C. Reaction was carried out at 0 °C for 10 h. The reaction products were distilled, isolated with preparative GC and identified with authentic samples[3)] except the followings.

*3,3-Dimethyl-5-vinyl-1,5-heptadiene **7**.* IR (neat) 1640, 1593, 1415, 1382, 1366, 990, 895 cm^{-1}; NMR ($CDCl_3$) δ= 6.36 (d of d, 1, CH), 5.87 (d of d, 1, CH), 5.25 and 5.00 (two d, 2, CH_2), 5.03 and 4.85 (two d, 2, CH_2), 4.96 (bs, 2, CH_2), 2.21 (s, 2, CH_2), 1.01 (s, 6, CH_3); M^+, 136. Calcd for $C_{10}H_{16}$; M, 136.

3,3,6-Trimethyl-1,5-heptadiene(2-4 Bonded Dimer). IR (neat) 1674, 1643, 995, 908, 884, 830 cm^{-1}; NMR ($CDCl_3$) δ=5.80 (d of d, 1, CH), 5.51 (t, 1, CH), 4.68 and 4.91 (two d, 2, CH_2), 2.25 (d, 2, CH_2), 1.98 (bs, 12, CH_3); M^+, 138. Calcd for $C_{10}H_{18}$; M, 138.

ESR Studies of Abnormal Methyl Radicals on Various Solid Surfaces

Duro A. ODUWOLE* and Barrie WISEALL†

Department of Chemistry, Queen Mary College, Mile End Road, London, E1 4NS, U. K.

†*Department of Chemistry, City of London Polytechnic, Jewry Street, London, EC1N 2EY, U. K.*

(Received November 5, 1979)

Synopsis. Direct spectroscopic evidence is presented that strongly caged methyl iodide (or methane) molecules in *porous* surfaces are the precursors of abnormal methyl radicals. The implication of this result as concerns the nature of radical surface interaction is discussed in terms of a matrix effect.

The ESR spectra of methyl radicals trapped on solid surfaces are of interest because of their potential usefulness in surface studies. Previous independent studies using different surface types reported a number of inconsistent observations[1-3] and no collective study of these surfaces has appeared in literature. The most stable radical, the normal methyl radical (Me_n, a $\approx$2.3 mT) has been observed over a wide range of temperatures on different surfaces.[1,2,4] Interactions between the Me_n radical and surface silanol groups characterized by observable satellite lines, led to acceptable models of stabilization of this species. The formation of abnormal methyl radicals (Me_{ab}, a $\approx$1.9—2.1 mT) which are not commonly observed even at liquid nitrogen temperatures, is far less understood. Studies of this species on porous Vycor glass[1] and silica gel[2] surfaces suggested inconsistent mechanisms of stabilization. The present study of the formation of Me_{ab} radicals on various surfaces (Table 1) demonstrates a surface porosity dependence and shows for the first time, the stabilization of this species on a low temperature pretreated surface. A very low surface coverage of methyl iodide ($\approx$0.2%) is found necessary for their stabilization while larger coverages lead to complex radical kinetics which depend markedly on surface type, photolysis time and intensity since this radical is quickly swamped by the growth of Me_n radicals.

After the initial thermal pretreatment of the various silica surfaces under vacuum at specified temperatures (T_d) as generally described,[1-4] the surfaces were given an approximately 0.2% surface coating of methyl iodide which was left in contact for 1 h. The samples were then pumped under vacuum for 3 h at 373 K to remove physisorbed species. Studies showed that prolonged pumping at higher temperatures up to 500 K reduced only the yield of Me_n radicals but *not* the yield of Me_{ab} radicals on photolysis. Radicals were produced by UV photolysis with the full focussed radiation from a Hanovia medium pressure lamp.

A study of the yield as a function of pretreatment temperature shows enhanced yields on high T_d surfaces (Fig. 1), consistent with an expected decrease in the number of surface –OH groups. The relative yield

TABLE 2. THE HYPERFINE CONSTANTS AND LINE WIDTH PARAMETERS (ΔH_{pp}) OBSERVED FOR ABNORMAL METHYL RADICALS STABILIZED ON POROUS VYCOR GLASS AND SILICA GEL SURFACES AT 77 K

Surface type	Pretreatment temperature / K	$a_H \pm 0.005$ mT	$\Delta H_{pp} \pm 0.005$ mT (for lines to increasing field)			
Porous Vycor glass	673	1.925	0.170	0.106	0.183	0.306
	1073	1.930	0.171	0.127	0.172	0.333
Silica gels (normal porosity and macroporous)	673	2.050	0.195	0.110	0.112	0.207
	1073[a]	2.025[b]	0.155	0.060	0.042	0.115
		2.080[c]	0.140	0.060	0.054	0.082

a) Two types of the radical (Me_{ab_1} and Me_{ab_2}) are identified on the surfaces pretreated above 870 K. b) Me_{ab_1} radical. c) Me_{ab_2} radical.

of radicals $\frac{Me_{ab}}{Me_n}$ obtained after prolonged photolysis of identically prepared samples of the various surface types (Table 1) increases with the surface porosity. No evidence of Me_{ab} radical formation on non-porous surfaces was found under any condition of sample preparation; the absence of this species on B_2O_3 enriched glass throws some doubt on the impurity-stabilization mechanism previously suggested.[1] The results strongly suggest that caged methyl iodide molecules which were not removed by prolonged pumping under vacuum at temperatures up to 500 K are precursors of Me_{ab} radicals.

It has been shown previously[5] that Me_n radicals trapped on various silica surfaces exhibit identical spectral parameters (ignoring small distortions caused by second order effects). The parameters observed for Me_{ab} radicals (Table 2) however, depend markedly on surface type; these suggest that Me_{ab}, rather than Me_n radicals,[4] are more effective labels for surface studies. These spectral differences may be explained by a matrix effect[6] in which interactions between the radical and the matrix particles can restrict radical rotations (causing line broadening) and reduce the hyperfine constants as compared to the Me_n radical. Since porous Vycor glass also contains boron (^{11}B has $I=3/2$), coupling with the quadrupole moments could produce the additional line broadening observed for Me_{ab} radical on this surface. This interpretation is in accord with the work of Fujita *et al.*[7] who showed that the reduced hyperfine constants observed for Me_{ab} radicals on porous Vycor glass and other matrices represent charge transfer to their environments. It can thus be deduced from our data that the charge transfer effect is greater for porous Vycor glass than for silica gel surfaces.

Two species of the abnormal radical, namely Me_{ab_1} and Me_{ab_2} are identified on silica gel pretreated above 870 K (Table 2). It is suggested that Me_{ab_2} radical observed only on these surfaces interacts with siloxane bridges known to occur under these conditions. A variable temperature study shows that Me_{ab_2} is relatively unstable and is not observed even under continuous photolysis at 98 K. Previous authors[2] have suggested the presence of the Me_{ab_2} radical but their results have been open to various interpretations such as a further splitting of Me_{ab_1} spectrum by a nuclear spin $I=1/2$ which produces line separations increasing to high field due to second order effects. This is the first study to identify this radical unambiguously. Matrix effects probably preclude resolution of Me_{ab_2} radical on porous Vycor glass.

Fujieda *et al.*[3] previously reported that the ESR spectra of methyl radicals produced from one monolayer of methane adsorbed on alumina surfaces show a partially resolved sextet structure and deduced that the three methyl protons in this system are not equivalent, one or two interacting more strongly with the surface than the other. However, the present study shows that by pumping off weakly adsorbed CH_4 a well resolved quartet (a ≈ 2.0 mT) is observed. Thus the non-equivalence of the 3 methyl protons suggested by Fujieda arises from their experiment conditions and could be due to dipolar interactions and other secondary causes.

The Hydrothermal Activation of Silica–Alumina for Butene Isomerization. A Device to Prepare a Standard Sample

Shozo Furuyama,* Osamu Murashita,** Yuko Yukumoto, and Tetsuo Morimoto
Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700
(Received October 11, 1979)

Three kinds of silica–alumina catalysts were prepared by hydrothermal treatment (heating a sample in hot water) over the range of 25—250 °C for various periods. It was found that the hydrothermal treatment significantly increased its catalytic activity for butene isomerization. The dependencies of various surface properties (the production ratio of 2-butene isomers, the surface acidity, the surface area, the pore-size distribution, and the shape and size of the catalyst particle) on the hydrothermal conditions and the kind of starting catalyst sample were systematically investigated, too. It was concluded that the increase in the catalytic activity might be due to the progress of the Si/Al isomorphic substitution in the tetrahedral surface silica network. Hot water might serve as a solvent for the cations and facilitate their movements. Since the hydrothermal treatment can erase the effects of the blending method on the catalytic activity and other surface properties almost completely, this treatment can be used to prepare a standard sample.

Structural change in minerals is accelerated by the action of hot water.[1] Numerous minerals, including optically active quartz and various kind of zeolites, are synthesized using this action in the laboratory.[2,3] We have attempted similarly to use the action of hot water for the preparation and/or activation of various metal oxide catalysts.

Silica–alumina is a strong solid acid and is widely used as a catalyst for various reactions.[4] From the similarities to zeolite in composition, acidic nature, and other aspects, it has been accepted by many workers that the acid center of silica–alumina originates from the isomorphic substitution of a silicon atom by an aluminum atom in the tetrahedral silicate network.[4,5] To obtain an active catalyst, one must devise a method to promote the isomorphic substitution effectively. The action of hot water may be appropriately used for this purpose.

In the present paper, we will demonstrate that hydrothermal treatment (heating a sample in hot water) significantly increases the catalytic activity for butene isomerization. The reasons for this increase were studied by measuring systematically the variations in the surface acidity, the production ratio of 2-butne isomers, the surface area, *etc.* with the hydrothermal time and temperature. A systematic elucidation of the relationship between the structure of an acid site and its catalytic function for butene isomerization has been made elsewhere, using a catalyst prepared by means of the hydrothermal activation technique.[6]

Experimental

Materials. Three kinds of hydrothermally activated silica–alumina (SA) materials were prepared as follows. Silica hydrogel was prepared by the hydrolysis of one part of doubly distilled tetraethyl silicate by five parts of water at 100 °C under vigorous agitation.[7] Alumina hydrogel was prepared by the hydrolysis of vacuum-distilled aluminum isopropoxide by dropping water into it under vigorous agitation. To prepare the SA-25MHT sample, these two hydrogels were mixed thoroughly (alumina content: 25 wt%) and dried at 110 °C for 1 d. Then, the sample was calcined at 400 °C for 20 h and at 550 °C for 5 h in air, and finally exposed to wet air in a rotary kiln at 110 °C for 5 h. The silica–alumina dry gel (SA-25M) thus prepared was heated in hot water over the range of 25—250 °C in a Pyrex ampoule for various periods. To prepare the SA-*n*KHT sample, silica and alumina hydrogels were dried separately at 110 °C and then blended using an agate mortar and pestle for 30 min. (*n* denotes the alumina content, ranging from 0.1 to 50 wt%). The blended dry gel (SA-*n*K) was heated in hot water at 110 °C for various periods. To prepare the SA-*n*JHT sample, the silica and alumina hydrogels were mixed thoroughly (the alumina content, *n*, ranged from 0.1 to 50 wt%) and then heated in hot water in a Pyrex ampoule at 110 °C for 3 d. All these three kinds of samples were dried at 110 °C for 1 d before storage. Tokyo Kasei reagent-grade 1-butene was kept in a 3-L Pyrex bulb after having been passed through dry molecular sieves 3A. Nakarai reagent-grade butylamine was dried with sodium hydroxide and distilled before use. Nakarai reagent-grade color indicators (methyl red, dicinnamylideneacetone, and anthraquinone) were used without further purification.[8]

Procedure. A conventional vacuum apparatus equipped with a circulation reactor (240 ml) was used to measure the catalytic activity for the 1-butene isomerization. A catalyst (0.15 g) was degassed at 300 °C for 2 h and kept at 0 °C during the reaction. At appropriate intervals after the introduction of about 16×10^3 Pa of 1-butene, small portions of the reacting gas were withdrawn in sequence into gas samplers kept at 77 K. The composition of the reacting gas was analyzed by means of a gas chromatograph equipped with a 5-m dioctyl phthalate column kept at 0 °C. To measure the acidity, the catalyst (0.2 g) was degassed at 300 °C for 2 h. After having been cooled to room temperature, the catalyst was covered with 10 ml of dry benzene. The acidity was, then, determined by the conventional butylamine titration method.[9,10] The pore-size distribution of the catalyst was determined by applying the Cranston-Inkley method.[11] An electron microscopic photograph was taken by a Hitachi HU-11A with 11,000-times magnification. The X-ray powder pattern was measured by means of a Rigaku Geigerflex.

Results and Discussion

SA-25MHT Series. The variation in the catalytic activity for 1-butene isomerization was measured at 0 °C as functions of the hydrothermal time and the hydrothermal temperature. Since the isomeriza-

tion of 1-butene to 2-butenes could be approximated to a simple first-order reaction at the initial stage, the apparent rate constant, k_1, was obtained from Eq. 1:

$$k_1 = (1/t) \ln (P_0/P_t). \quad (1)$$

Here, P_0 and P_t are the partial pressures of 1-butene at times zero and t respectively. The results are shown in Fig. 1. The figure shows that the catalytic activity of SA-25MHT increased with the increase in the hydrothermal time at first, reached a maximum, and then gradually decreased. This variation became prominent with the increase in the hydrothermal temperature. For instance, it took 50 h at 100 °C to attain the maximum activity, while it took only 12 h at 150 °C.

To elucidate the reason for the increase in the catalytic activity, the changes in the "macroscopic" surface structure (surface area, pore-size distribution, and particle shape), the production ratio of *cis*-2-butene *vs.* *trans*-2-butene (c/t), and the surface acidity with the hydrothermal treatment were measured.

The BET surface area decreased with the increase in the hydrothermal time, as is shown in Fig. 2. Its rate of decrease became prominent with the increase in the hydrothermal temperature. For instance, the surface area decreased to one-third after 18 h at 250 °C, while it remained almost constant even after 15000 h (one year and eight months) at 25 °C. It

has been observed by several workers that the surface area of silica–alumina decreases significantly when exposed to hot water-vapor, too.[12] However, to attain the same effect as hot liquid-water, vapor needs a much higher temperature (480—950 °C).[12] The measurement of the pore-size distribution showed that the most probable size changed from 4 to 7 nm in diameter over a period of 14 d at 100 °C. Electron microscopic measurement showed that the shape of the elementary particle of the catalyst powder was quite thin and slender before the hydrothermal treatment, but became fat and thick after 14 d at 100 °C. These results clearly showed that the "macroscopic" surface structure changed significantly with the hydrothermal treatment.

The dependency of the c/t ratio upon the hydrothermal treatment is shown in Fig. 3. The value decreased from 1.8 to 0.9 with an increase in the hydrothermal time. It has been observed by many workers that the c/t ratio depends strongly upon the structure of the active site. For instance, the ratio was larger than 3.5 on dry active alumina, while it was around 1 on a typical silica–alumina catalyst.[13] It can be concluded that the hydrothermal treatment changed the structure of the active site ("microscopic" surface structure) from the active-alumina type to the typical silica–alumina type.

The acid amounts, as determined by the butylamine titration method using methyl red ($pK_a=4.8$), dicinnamylideneacetone ($pK_a=-3.0$), and anthraquinone ($pK_a=-8.2$), were 0.95, 0.55 and 0.35 meq g^{-1} respectively before the hydrothermal treatment, but became 0.60, 0.35, and 0.35 meq g^{-1} respectively after the hydrothermal treatment at 100 °C for 14 d. This means that the less active SA-25M had more numerous active sites than the more active SA-25MHT. It was, therefore, concluded that the increase in the catalytic activity with the hydrothermal treatment did not arise from the change in quantity, but resulted from the change in quality, of the active sites in the case of the SA-25MHT series.

The dependencies upon the degassing temperature of the catalytic activity and the c/t ratio for the butene isomerization, the numbers of the surface hydroxyl

group and acid sites, and the catalytic activity for the butene polymerization have been studied elsewhere.[6] It has been concluded that the structure of the acid site (*i.e.*, the active site for the butene isomerization) changed thus: (c)→(d)→(e)→(f) with an increase in the degassing temperature from 25 to 700 °C (Fig. 4).[6] The most active site is the (d) site, which has the most suitable structure for the occurrence of proton-donation-acception to promote the isomerization.[6] The (f) site lacks a proton, resulting in quite a low catalytic activity with a high c/t ratio for the isomerization.[6] However, the acid strength of both (d) and (f) sites are equivalent to, or higher than, 48 wt% of sulfuric acid.[6,8] The present results, when combined with those of a study made elsewhere (Ref. 6), can lead to the conclusion that the active site had a structure like (f) (the pseudo-active alumina type) before the hydrothermal treatment, but changed to the (d) site upon the action of hot water. That is, all results could be explained consistently by the assumption that the Si/Al isomorphic substitution was promoted by the hydrothermal treatment.

SA-10KHT Series. The effect of hot water in increasing the catalytic activity was more clearly demonstrated in the experiment using the SA-10KHT sample. Variations in the catalytic activity, the acid amount, and the surface area with the hydrothermal time at 100 °C are shown in Fig. 5. Figure 5a shows that the catalytic activity was negligibly low before the treatment, but increased gradually with the increase in time. It reached a maximum after 16 d and then started to decline. Although the rate of increase was very low (about one-eighth as low as that for the SA-25MHT series), the values of maximum activity did not differ much from each other. The c/t ratio was around 0.9, irrespective of the hydrothermal time.

Figure 5b shows that the acid amount, $A(H_0 \leq -3.0)$, as determined using dicinnamylideneacetone, also increased with the increase in the hydrothermal time.[14] The trend was quite similar to the trend of the catalytic activity.[15] Moreover, the maximum value was comparable with that of SA-25MHT, as in the case of the catalytic activity. As was noted in the experimental section, the SA-10K was prepared by a simple mechanical blending of dry silica and alumina gels only. It was unlikely that the active site originating from the Si/Al isomorphic substitution existed before the hydrothermal treatment. The appearances of the catalytic activity with a low c/t ratio and of the acid site ($H_0 \leq -3.0$) on SA-10KHT, therefore, may be proofs of the progress of the isomorphic substitution with the hydrothermal treatment.

The same conclusion was obtained from the trends of the variations in the surface area and the crystallinity of the silica, alumina, and SA-10K samples with the hydrothermal treatment. Figure 5c shows that the surface area of SA-10KHT decreased from 500 to 350 $m^2 g^{-1}$ upon the hydrothermal treatment at 110 °C for 16 d. The surface area of silica decreased very rapidly from 530 to 200 $m^2 g^{-1}$ while that of alumina remained almost constant (200 $m^2 g^{-1}$) during the same period. The combined surface areas of 90 wt% of silica and 10 wt% of alumina before and after the treatment were, therefore, 500 and 200 $m^2 g^{-1}$ respectively. This decrease (300 $m^2 g^{-1}$) was almost twice as large as the decrease for SA-10KHT (150 $m^2 g^{-1}$). The X-ray powder pattern showed that

silica and SA-10KHT kept their amorphous structures, while alumina was altered to boehmite during the hydrothermal treatment. These two facts may show that no pure silica and alumina surfaces were exposed on SA-10KHT.[16] During the hydrothermal treatment, either the Si and Al cations moved from the original particles to different particles and formed a new surface with an aluminosilicate network both on the parent silica and alumina particles.[16] This surface might be quite resistant to the action of hot water. Therefore, the surface area of SA-10KHT did not decrease so rapidly as that of silica,[17] and the boehmite phase was not formed in this sample.

Finally, we should discuss the mechanism of the effect of the hydrothermal process on the present silica–alumina samples. The kinetic behavior of the Si and Al cations in the solid and liquid phases was not paticularily explored in the present study. However, it may not be unrealistic to infer that Si and Al cations can be dissolved in hot water and move from surface to surface *via* the liquid phase (the liquid-phase mechanism). In other words, the role of hot water may be as a medium to take out the cations from the catalyst surface and transfer them to another surface. The idea that hot water is a solvent for metal cations is very common in studies of the hydrothermal syntheses of quartz and zeolite.[2,3] It is possible to imagine other mechanisms, for instance, that the metal cations move *via* surface and/or the bulk of a solid (the solid-phase mechanism). However, it is quite doubtful that those solid-phase mechanisms can account for the following facts more consistently than the liquid-phase mechanism can: (1) the Si/Al isomorphic substitution did occur, even in the SA-10KHT sample, in which Si and Al cations were originally separated in different particles, and (2) the "macroscopic" surface structure changed significantly and simultaneously with the isomorphic substitution. To attain the same effect with hot water-vapor (with which the solid-phase mechanisms actually work), a much higher temperature has been needed.[12] Therefore, the most reasonable conclusion may be that the isomorphic substitution mainly progressed through the liquid-phase mechanism, as far as the present study is concerned.

SA-nKHT and SA-nJHT Series. A series of SA-*n*KHT samples was prepared by hydrothermal treatment at 100 °C for 16 d, and their catalytic activity, surface acidity, and surface area were compared with those of the corresponding SA-*n*JHT samples. Figures 6a and b show that the dependencies of the catalytic activity and surface acidity upon the alumina content in the two series are quite similar to each other. Before the hydrothermal treatment, the catalytic activity and acid amount were about one-third as low as the maximum value in the SA-*n*JHT series, while they were quite low in the SA-*n*KHT series. The hydrothermal treatment could erase, easily and almost completely, the differences in the catalytic activity and surface acidity originating from the difference in the blending method. Thus, it may be concluded that the hydrothermal treatment can be a useful device for preparing a standard sample of the silica–alumina catalyst. The small but parallel difference between their surface areas shown in Fig. 6c may arise from the different hydrothermal times, 16 d for the SA-*n*KHT series and 3 d for the SA-*n*JHT series.

Catalysis by Mixed Oxide Perovskites. I. Hydrogenolysis of Ethylene and Ethane on $LaCoO_3$

Kenji Ichimura,* Yasunobu Inoue, and Iwao Yasumori
Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
(Received November 8, 1979)

Catalysis by a mixed oxide with a perovskite structure, $LaCoO_3$, was studied for the hydrogenolysis of ethylene and ethane at temperatures 300—600 K using the hydrogen-excess mixtures. The high and stable activity was obtained by evacuating $LaCoO_3$ at 600 K. Ethylene hydrogenolysis above 420 K proceeded consecutively *via* the intermediate, ethane, to produce methane, whereas only the hydrogenation to form ethane occurred below 420 K. Different temperature dependence of the rate was observed, *i.e.*, the activation energy of -19.3 kJ·mol^{-1} in the range 420—600 K and 33.6 kJ·mol^{-1} in the range 300—420 K. The mechanistic analysis and tracer study using D_2 showed that the slow step of the hydrogenation shifts, with increasing temperature, from the adsorption of hydrogen to the surface reaction between hydrogen atom and ethyl radical. The hydrogenolysis of ethane produced only methane and no ethylene was observed in gas phase; the reaction orders with respect to hydrogen and ethane pressures were, respectively, -0.5 and 1.0. In the reaction with D_2, methane [D_4] was the main product and an equilibrium among the formed H_2, HD, and D_2 was quickly established. The adsorption of ethane to undergo the rupture of the carbon-carbon bond and to form monocarbon species was proposed to be a slow step. The catalytic activities of the component oxides, La_2O_3 and Co_2O_3, were also examined for a comparison. The structure and electronic states of $LaCoO_3$ were investigated by means of X-ray diffraction and X-ray photoelectron spectroscopy in connection with the catalytic activity. It was proposed that the hydrogenation proceeded mainly on a pair of La^{3+} and O^{2-} ions, whereas the hydrogenolysis was accelerated by the Co^{3+} ion; the (110) plane is suggested to be the most favorable for the catalysis.

Recently, the mixed oxides which have a perovskite structure have been recognized as promising catalysts for the reactions involving hydrogen such as the equilibration between H_2 and D_2, the hydrogenation and isomerization of olefins and the hydrogenolysis of hydrocarbons and also as suitable ones for the fundamental research of catalytic activity because of their well-defined structures.[1-7] It has been theoretically shown that the valence band structures of some perovskites are similar to those of transition metals.[8-11] Among these perovskites, those containing the lanthanoid elements R, $RCoO_3$, were reported to be more active for the hydrogenolysis of *cis*-2-butene than several kinds of transition metals.[1] We have found that $LaCoO_3$ catalyzed the hydrogenolysis of ethylene and ethane to produce methane. The hydrogenolysis of the hydrocarbons on this perovskite, however, has not been studied in detail, and thus the function of the catalyst has not been revealed yet.

In the present work, being the first one in our series, the detailed kinetic study for the hydrogenolysis of ethylene and ethane was performed, and was supplemented by the analysis of deuterium distributions in the reaction with deuterium. The crystal and electronic structures of the oxide were examined by X-ray diffraction and X-ray photoelectron spectroscopy (XPS). On the basis of the obtained results, the structures of the active site for the hydrogenation and hydrogenolysis were discussed.

Experimental

Material. $LaCoO_3$ was prepared by calcining the mixed hydroxides of La and Co at 1170 K for 3 h and then 1370 K for more than 12 h. The hydroxides were coprecipitated from the mixture of equimolar solutions of $La(NO_3)_3 \cdot 6H_2O$ and $Co(NO_3)_2 \cdot 6H_2O$ by adding an aqueous solution of ammonia and the precipitate was washed with distilled water and dried at 330 K. The X-ray diffraction pattern of the calcined product coincided with that of $LaCoO_3$ reported by Askham *et al.*[12] and any other compounds were not detected. The surface area of the catalyst was estimated at 0.33 m^2·g^{-1} by BET method using Kr adsorption at 77 K.

X-Ray photoelectron spectra of the catalyst were recorded on a Hewlett-Packard 5950A ESCA spectrometer with monochromatized Al $K\alpha$ radiation (1486.6 eV) in an ultra high vacuum of 10^{-9} Torr (1 Torr = 133.3 Pa). An electron flood gun was used to compensate the charging-up shifts of the spectra due to photoelectron emission. The values of observed binding energies were corrected using that of C 1s, 284.7 eV, as a standard.

The property of synthesized $LaCoO_3$ was examined simultaneously by DTA and TGA using a Rigaku-Denki thermal analyser in air for the sample of 50 mg which was inserted in a platinum vessel together with the reference alumina. When the catalyst was heated from 300 to 1300 K and then cooled to 300 K at a rate of 10 K·min^{-1}, two weak endothermic peaks appeared around 610 and 910 K, accompanied by the respective decreases of 0.03 and 0.06% in weight. Further, a strong endothermic peak appearing around 1190 K with increasing temperature caused a decrease of 0.21% in weight. The endothermic change at 1190 K was reversible and attributed to the first order transformation of the crystal resulting in the elimination of oxygen. Before and after the DTA and TGA measurements, no change of X-ray diffraction pattern was observed. From the $LaCoO_3$ sample which was prepared in air by calcining at 1370 K, H_2O, CO, and CO_2 were desorbed on heating; H_2O appeared around 540 and 600 K, while CO and CO_2 desorbed around 410 and 590 K. Samples after cooling to 300 K *in vacuo* evolved scarcely any gas on the second heating up to 800 K.

Hydrogen (99.99% pure), deuterium (99.6%), methane (99.95%), ethylene (99.8%), ethane (99.7%), and *cis*-2-butene (99%) were purchased from Takachiho Chem. Ind., Ltd. and used without further purification.

Procedure. Kinetic studies were carried out in the reaction temperatures from 300 to 600 K using a closed circulation system connected to a high vacuum line. The catalyst sample, 100 to 300 mg in weight, was evacuated in a reaction tube at various temperatures between 300

and 800 K for 1 to 6 h. When the catalyst was evacuated at 600 K for 1 h before each run, the activity was satisfactorily reproduced in successive ten kinetic runs and remained constant on heating the catalyst up to 800 K under vacuum.

The partial pressures of hydrocarbons were changed from 5 to 15 Torr and those of hydrogen and deuterium from 50 to 150 Torr. The composition of the reaction products was determined gas-chromatographically for the sample taken out periodically from the reaction system during the course of reaction. In addition to the hydrogenolysis of ethylene and ethane, the same reactions with D_2, the exchange reaction between methane and D_2, the equilibration of H_2 and D_2 were also examined. These reaction mixtures were analyzed by means of a mass spectrometer, Hitachi RMU-7M, and a gas chromatograph was used to analyze the isotopic molecules of hydrogen, H_2, HD, and D_2.

A preliminary study on the reaction of *cis*-2-butene (10 Torr) with hydrogen (100 Torr) over $LaCoO_3$ at 573 K confirmed that the hydrogenolysis and isomerization of butene took place simultaneously to form the main product, methane and butene isomers, as previously reported by Pedersen and Libby.[1]

Results

Hydrogenolysis of Ethylene and Ethane. Figure 1 shows the change in the gas-phase composition with time in the reaction of ethylene with hydrogen at 573 K. Ethane and methane were produced during the course of hydrogenolysis. The solid lines in the figure are the simulated curves by assuming the consecutive reaction pathway from ethylene to methane *via* an intermediate, ethane, as is described later in detail. The reaction at temperatures lower than 420 K gave only ethane as the product. Figure 2 shows the change in the initial rate of ethylene consumption with reaction temperature. The maximum in the rate appeared at about 420 K. The apparent activation energy was estimated at 33.6 kJ·mol^{-1} below 420 K and −19.3 kJ·mol^{-1} above 420 K. The kinetics of the reaction was studied at 353 and 573 K to clarify the nature of the reaction in the respective temperature ranges above and below 420 K. The rates of ethylene consumption at 573 K and 353 K are respectively expressed as

$$R_{573} = kP_{C_2H_4}P_{H_2} \quad (1)$$

and

$$R_{353} = k'P^0_{C_2H_4}P_{H_2}, \quad (2)$$

where k and k' denote the rate constants and P_i represents the partial pressure of molecule i (i=C_2H_4 or H_2).

The kinetic study of the ethane hydrogenolysis was carried out at temperatures between 473 K and 573 K. Methane was the sole product of the hydrogenolysis, and ethylene was not detected during the course of reaction. The rate of ethane consumption was given by

$$R = k^*P_{C_2H_6}P_{H_2}^{-0.5}, \quad (3)$$

with the activation energy of 34.9 kJ·mol^{-1} as shown in Fig. 2.

Isotopic Exchange Reactions of Ethylene, Ethane, or Methane with Deuterium and Equilibration between Hydrogen and Deuterium. Reaction of ethylene with D_2 was investigated at 353 K and 573 K. The observed deuterium distributions are summarized in Table 1. In the reaction at 573 K, no significant kinetic isotope effect was observed. The deuterium atoms were quite widely distributed in ethylene, ethane, and methane, whereas the produced HD and H_2 were in equilibrium with D_2 during the course of reaction. On the other hand, in the reaction at 353 K, the normal isotope effect was observed; the rate of ethylene hydrogenation with H_2 was about twice as large as that with D_2. The composition among H_2, HD, and D_2 in the gas phase was far from an equilibrium value.

The reaction of ethane with D_2 at 573 K produced methane[D_4] as main product but a negligibly small amount of deuterium-exchanged ethane. A separate experiment showed that the exchange reaction between methane and D_2 was also negligible at this temperature.

The equilibration between H_2 and D_2 was also separately examined at temperatures between 170 K and 573 K, and was found to take place rapidly on $LaCoO_3$ with activation energy of 16.0 kJ·mol^{-1}. The rate of equilibration was about 100 times as large as that of ethylene hydrogenation at 573 K.

Catalytic behavior of Component Oxides, La_2O_3 and Co_2O_3. The catalytic activities of La_2O_3 and Co_2O_3 were also examined in order to compare with that of $LaCoO_3$. La_2O_3 showed neither hydrogenation nor hydrogenolysis activity after outgassing at temperatures below 773 K, but it became catalytically active only for the hydrogenation when heated *in vacuo* at temperature as high as 973 K. Ethylene hydrogenation on thus activated La_2O_3 exhibited a maximum in the reaction rate, 2.3×10^{14} molecule·s^{-1}·cm^{-2}, at around 548 K (P_{H_2}=98.4 Torr and $P_{C_2H_4}$=13.6 Torr), giving the activation energy of −33.1 kJ·mol^{-1} above 548 K and 16.2 kJ·mol^{-1} below this temperature. It should be noted that these reaction behavior quite resembled those for the hydrogenation on $LaCoO_3$. When Co_2O_3 was evacuated at 600 K for 1 h, the hydrogenolysis of ethylene took place at 573 K to produce ethane and methane. The catalytic activity of this oxide, however, was unstable, and this was due to the reduction of Co_2O_3 to metallic cobalt during the course of reaction, since H_2O was formed, and X-ray diffraction of the oxide employed for the reaction showed characteristic peaks associated with developed cobalt metal particles. For the initial stage of reaction, rough estimation gave a rate of ethane formation, 4×10^{11} molecules·s^{-1}·cm^{-2} at 573 K, and about 30% of reacted ethylene was consumed by the direct formation of methane *via* the adsorbed ethylene.

Structural and Chemical Changes of the Catalyst. In order to see the relationship between the structure and the activity of $LaCoO_3$, the fresh catalyst, (A), the 50% deactivated catalyst by repeated run of the reaction, (B), and the completely deactivated one (C) were examined by X-ray diffraction. Each X-ray diffraction peak of samples B and C splitted into two or three peaks which appeared at lower diffraction angles. These results suggest that the activity decreases as the lattice expands to some extent.

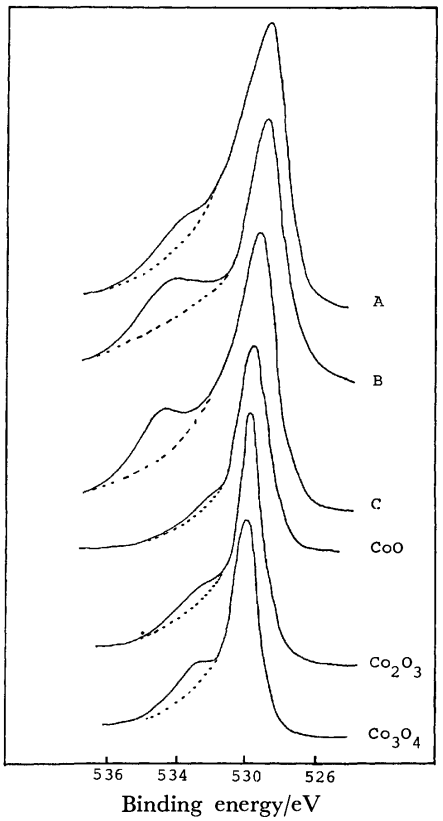

Fig. 3. X-Ray photoelectron spectra in O 1s region. Spectra A, B, and C denote the fresh $LaCoO_3$, the 50%-deactivated catalyst and the completely deactivated one, respectively.

The electronic states of samples A, B, and C were also inspected by means of XPS in comparison with those of CoO, Co_3O_4, and Co_2O_3. The O 1s spectra are illustrated in Fig. 3. The spectra of these $LaCoO_3$ samples evacuated at 300 K indicate the presence of two kinds of oxygen species; the O 1s peak of lower binding energy shifted to higher energy side with decreasing activity and the spectrum of sample became similar to those of cobalt oxides. The O 1s peak of higher binding energy diminished in intensity to the level shown by the dotted lines upon evacuation at 770 K. From the comparison with the spectra of Cu_2O, CuO, and NiO obtained by Robert *et al.*,[13] this peak was assigned to the adsorbed oxygen and the peak of lower binding energy to the lattice oxygen.

Figure 4 shows the spectral peaks from Co 2p levels. The values of spin-orbit splitting and FWHM for the fresh $LaCoO_3$ (A) are 15.3 eV and 3.2 eV, respectively, and the value of the splitting is simialr to that for Co_2O_3, 15.2 eV. However, the corresponding spectrum of catalyst C, in which the respective values are 15.9 eV and 4.7 eV, is almost the same as that of CoO with those values of 16.0 eV and 4.7 eV and is accompanied by the characteristic shake-up satellites. These differences can be used to distinguish the oxidation states of Co atoms, as reported

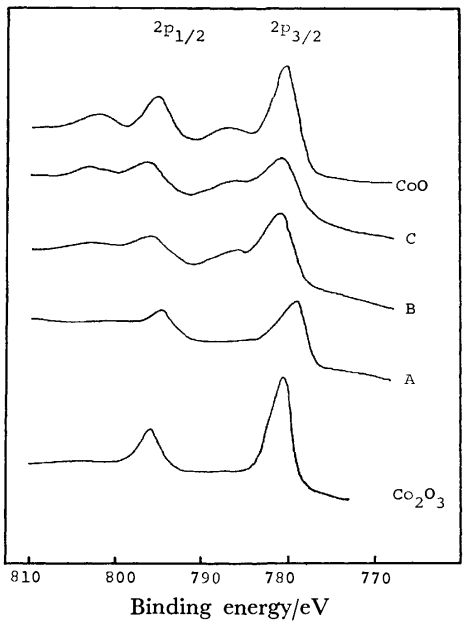

Fig. 4. X-Ray photoelectron spectra in Co 2p region. Spectra A, B, and C: see caption in Fig. 3.

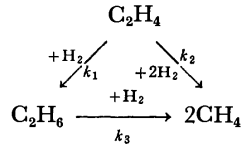
by several workes,[14-16] and lead to the conclusion that the reduction from a trivalent ion, Co^{3+}, to a bivalent ion, Co^{2+}, occurred, resulting in the structural change and the degradation of catalytic activity.

No significant change of La 3d spectra was observed for all the catalysts in comparison with that for La_2O_3.

The property of $LaCoO_3$ surface was inspected from the adsorption of H_2, C_2H_4 and CO at room temperature. All the adsorbed species were removed on heating at 600 K and, from the amounts for saturation, the number of adsorption sites was estimated at 4×10^{14} cm^{-2} which corresponds to about 40% of the total surface ions.

Discussion

Mechanism of Ethylene Hydrogenolysis. The hydrogenolysis of ethylene proceeds in the following sequence;



Since the observed hydrocarbon orders were unity for both the hydrogenation of ethylene and the hydrogenolysis of ethane in the high temperature range and the reacting system contained a large excess of hydrogen, the rates of ethylene and ethane consumption are expressed in the form of the pseudo-first order reaction,

$$\frac{d[C_2H_4]}{dt} = -(k_1+k_2)[C_2H_4], \quad (4)$$

$$\frac{d[C_2H_6]}{dt} = +k_1[C_2H_4] - k_3[C_2H_6], \quad (5)$$

$$\frac{d[CH_4]}{dt} = +2k_2[C_2H_4] + 2k_3[C_2H_6]. \quad (6)$$

The apparent rate constants, k_1, k_2, and k_3 as parameters, were determined by applying the nonlinear least square method to the experimental data. Estimated value of k_2, 0.014 h^{-1}, was smaller than k_1, 0.15 h^{-1}, which clearly indicates that the direct conversion of C_2H_4 to CH_4 gives a minor contribution to the entire reaction. The value of k_3, 0.12 h^{-1}, was found to coincide with the rate constant evaluated from the hydrogenolysis of ethane under the same conditions. By using these parameters, the changes in the partial pressures of reactants and products with time were calculated as shown in Fig. 1. A good agreement between the observed and calculated curves confirmed that the hydrogenolysis of ethylene proceeds consecutively, as shown in the sequence,

$$C_2H_4 \xrightarrow{+H_2} C_2H_6 \xrightarrow{+H_2} 2CH_4. \quad (7)$$

The reaction of ethylene with deuterium in the high temperature region showed wide deuterium distributions in ethylene and ethane as well as the nearly established equilibrium among gaseous H_2, HD, and D_2. Thus, these results lead to the associative mechanism which involves the following reaction steps:

$$H_2 \rightleftharpoons 2H(a) \quad (8)$$

$$C_2H_4 \rightleftharpoons C_2H_4(a) \quad (9)$$

$$C_2H_4(a) + H(a) \rightleftharpoons C_2H_5(a) \quad (10)$$

$$C_2H_5(a) + H(a) \longrightarrow C_2H_6 \quad (11)$$

where (a) denotes the adsorbed state. The above-mentioned deuterium distributions also indicate that Step 11 is a rate-determining process, and the reaction rate is given by

$$R_h = k_{11}\theta_{C_2H_5}\theta_H = \frac{k_{11}K_{10}K_eK_hP_{C_2H_4}P_{H_2}}{(1+K_eP_{C_2H_4}+\sqrt{K_hP_{H_2}}+K_{10}K_eP_{C_2H_4}\sqrt{K_hP_{H_2}})^2} \quad (12)$$

where θ_i represents the fraction of surface coverage of the i species on the hydrogenation site. Under the condition of

$$1 \gg K_eP_{C_2H_4} + \sqrt{K_hP_{H_2}} + K_{10}K_eP_{C_2H_4}\sqrt{K_hP_{H_2}}, \quad (13)$$

Eq. 12 is simplified to

$$R_h = k_{11}K_{10}K_eK_hP_{C_2H_4}P_{H_2} = k_hP_{C_2H_4}P_{H_2}. \quad (14)$$

In the low temperature region, the fraction of gaseous H_2 and HD was small in contrast to the wide deuterium distributions in the ethylene and ethane, which leads to the assumption that the adsorption of hydrogen in Step 8 is a slow step. Thus, the rate equation is expressed as

$$R_l = k_8P_{H_2}(1-\theta_{C_2H_4})^2 = \frac{k_8P_{H_2}}{(1+K_eP_{C_2H_4})^2}. \quad (15)$$

Under the condition of

$$1 \gg K_eP_{C_2H_4}, \quad (16)$$

Eq. 15 becomes

$$R_l = k_8P_{H_2}. \quad (17)$$

Equations 14 and 17 are in agreement with the observed pressure dependences in respective temperature regions.

It is of nessesity to assess this mechanism in con-

nection with that of ethylene and ethane hydrogenolysis. The striking features of catalysis by $LaCoO_3$ were the restriction imposed on the direct path from adsorbed ethylene to methane and were also the feasibility of ethane hydrogenolysis without producing ethylene in the gas phase. With this in mind, Step 10 in the associative mechanism would appear to contradict the behavior of the hydrogenolysis, if the available sites are the same for both reactions, since the intermediate described in Step 10 would rapidly undergo the rupture of carbon-carbon bond, which turned out to give a direct pathway for methane formation. Thus, it is suggested that the active sites for hydrogenation are different from those for the hydrogenolysis. A comparison of ethylene hydrogenation on La_2O_3 and $LaCoO_3$ indicated that the kinetic behavior was quite similar each other and that the catalytic acitivity was compatible when it was evaluated as the reaction rate per La^{3+} ion exposed at surface. On the contrary, Co_2O_3 exhibited a considerable selectivity to the hydrogenolysis of the adsorbed ethylene to methane but much lower activity for the hydrogenation. Therefore, these findings enable us to conclude that a pair of La and oxygen ions is mainly responsible for the hydrogenation activity of $LaCoO_3$. In this regard, it should be noted that the conditions, (13) and (16), are established for these sites of $LaCoO_3$ oxide.

Mechanism of Hydrogenolysis of Ethane. In the hydrogenolysis of ethane over transition metals, Sinfelt *et al.* proposed the mechanism involving the dissociative adsorption of ethane to produce ethyl radical which changed to hydrogen-deficient species and further to monocarbon surface fragments.[17] In the hydrogenolysis on $LaCoO_3$, however, emphasis should be put on the results that no ethylene is formed during the reaction. The facts that the hydrogenolysis of ethane is catalyzed by Co_2O_3 but not La_2O_3, and that the H_2-D_2 equilibration takes place on these oxides and $LaCoO_3$ suggest the co-functional role of component ions in the hydrogenolysis; Co^{3+} ion is mainly responsible for the C–C bond scission, while the other La^{3+} and O^{2-} ions contribute as the sites to supply the dissociatively adsorbed hydrogen. Thus, by taking the above-mentioned pathway of ethylene hydrogenation and these findings into consideration, we propose the following reaction mechanism.

$$H_2 \rightleftharpoons 2H(a) \tag{18}$$

$$C_2H_6 + H(a) \longrightarrow CH_3(a^*) + CH_3(a^*)\cdots H(a) \tag{19}$$

$$CH_3(a^*) \rightleftharpoons CH_2(a^*) + H(a) \tag{20}$$

$$CH_3(a^*) + H(a) \longrightarrow CH_4 \tag{21}$$

where (a*) represents the adsorbed state on Co^{3+} site and (a) denotes that on La^{3+} or O^{2-} site. Since methane[D_4] is the main species in the reaction of C_2H_6 with D_2, the hydrogenolysis comprise necessarily a rapid hydrogen exchange, as expressed in Eq. 20, between surface monocarbon species, *i.e.*, adsorbed carbene and methyl radicals. The absence of deuterium-exchanged ethane strongly suggests that the Step (19) is rate-determining, and the rate equation of hydrogenolysis is given by

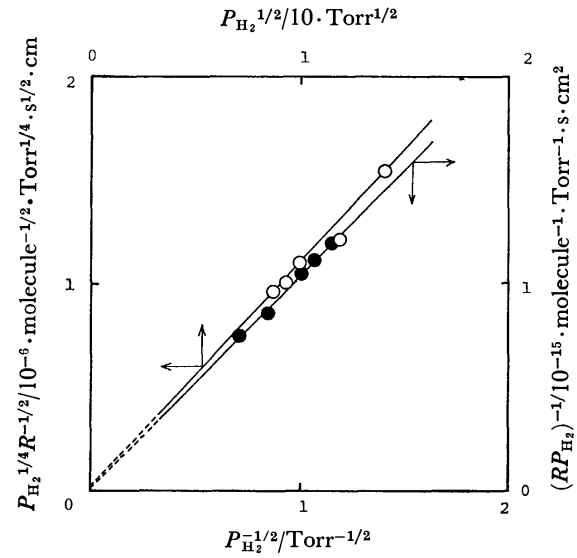


Fig. 5. Plots of $P_{H_2}^{1/4}R^{-1/2}$ *vs.* $P_{H_2}^{1/2}$ and $(RP_{H_2})^{-1}$ *vs.* $P_{H_2}^{-1/2}$. R and P_{H_2} represent the initial rate and the partial pressure, respectively.

$$R = k_{19}P_{C_2H_6}\theta_v^{*2}\theta_H \tag{22}$$

where θ_v^* denotes a fraction of vacant Co^{3+} sites and θ_H represents that of the other sites occupied by hydrogen atoms. These fractions are respectively described as

$$\theta_v^* = 1/(1+\sqrt{K_h^*P_{H_2}}) \text{ and } \theta_H = \sqrt{K_hP_{H_2}}/(1+\sqrt{K_hP_{H_2}}), \tag{23}$$

provided the fraction of sites covered with hydrocarbon species to be negligible. Under the condition of strong hydrogen adsorption on Co^{3+} sites, $1 \ll \sqrt{K_h^*P_{H_2}}$, the rate equation is rewritten into the form as,

$$\frac{1}{RP_{H_2}} = (K_h^*/k_{19}\sqrt{K_hP_{C_2H_6}})(\sqrt{K_h}+1/\sqrt{P_{H_2}}). \tag{24}$$

Under the condition of $1 \gg \sqrt{K_hP_{H_2}}$ as an approximation of weak adsorption on the other sites, on the other hand, the rate equation is recasted into the form

$$P_{H_2}^{1/4}/\sqrt{R} = (K_h^*/k_{19}\sqrt{K_hP_{C_2H_6}})^{1/2}(1/\sqrt{K_h^*}+\sqrt{P_{H_2}}). \tag{25}$$

Figure 5 shows good linear relationships for the plots of $(RP_{H_2})^{-1}$ *vs.* $P_{H_2}^{-1/2}$ on Eq. 24 and $P_{H_2}^{1/4}/\sqrt{R}$ *vs.* $\sqrt{P_{H_2}}$ on Eq. 25. Since the evaluated values of K_h and K_h^* at 573 K are 4×10^{-6} and 10, respectively, and P_{H_2} is 100 Torr, the relation

$$\sqrt{K_h^*P_{H_2}} \gg 1 \gg \sqrt{K_hP_{H_2}}$$

is held, which justifies the approximations used. By introducing these approximations, the rate equation (22) is finally simplified as

$$R = k_{19}\frac{\sqrt{K_h}}{K_h^*}P_{C_2H_6}P_{H_2}^{-0.5} \tag{26}$$

which accords with the observed partial pressure dependence.

It is interesting to compare the activity of $LaCoO_3$ for the hydrogenolysis of ethane with those of platinum and palladium; the specific rate for the hydrogenolysis over $LaCoO_3$ at 573 K is evaluated at 1×10^{13} molecule$\cdot s^{-1}\cdot cm^{-2}$ by using a reactant mixture of C_2H_6 (10 Torr) and H_2 (100 Torr). The values for Pt and

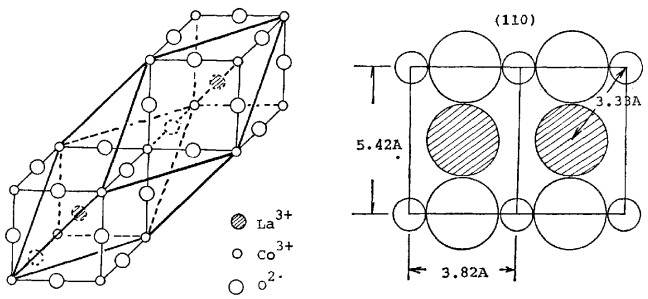

Fig. 6. Structure and geometry of $LaCoO_3$. $LaCoO_3$ have a perovskite structure, D^5_{3d}-$R\bar{3}m$, but the (110) plane is drawn as cubic structure for simplicity.

Pd catalysts are respectively 2×10^{11} and 4×10^{11} molecule$\cdot s^{-1}\cdot cm^{-2}$ which were obtained by correcting the Sinfelt's data[17] to the present reaction conditions. As the reaction temperature rises, the difference among these rates will be smaller because of large activation energy for Pt and Pd, *i.e.*, 227 and 244 kJ$\cdot$mol^{-1}, respectively.

Structure of Active Sites. At present, knowledge on $LaCoO_3$ catalyst has not been accumulated sufficiently to mention the nature of active sites for the hydrogenolysis in detail. We give here only a speculative description to their structure and behavior. The number of adsorption sites for hydrogen or ethylene on $LaCoO_3$ corresponds to about 40% of the total surface ions. These results predict that most of the exposed surface are available for the reaction and, especially, the (110) lattice plane as illustrated in Fig. 6 is likely the most favorable for the catalysis. Among the ion pairs of Co^{3+}–O^{2-} (1.91 Å), La^{3+}–O^{2-} (2.71 Å), and La^{3+}–Co^{3+} (3.16 Å), the former two pairs seem to be suited for the dissociative adsorption of hydrogen as seen in the case of transition metal oxides. As mentioned earlier, the hydrogenation mainly proceeds on the sites consisting of La and oxygen ions. It is likely that the Co^{3+} ion in $LaCoO_3$ somewhat affects the surface states of both ions in a way to provide the hydrogenation activity in accordance with a trend that a heat treatment at high temperature changed La_2O_3 to be catalytically active. For the hydrogenolysis, the geometric arrangement of the (110) plane substantiates the co-functional role in which the Co^{3+} ion ruptures the carbon-carbon bond, and the nearby La and oxygen ions supply hydrogen atoms to the resulting monocarbon species. These synergetic effect by the three component ions in $LaCoO_3$ was found to be pronounced in the hydrogenolysis of C_3 to C_5-alkanes with longer carbon chains.[18]

The thermal desorption and IR studies of adsorbed species on $LaCoO_3$ are in progress, and the obtained information will be useful in revealing the contributions of these species to the reaction and the function of active sites.

(Received November 16, 1979)

The adsorption of uranium from sea water with hydrous titanium(IV) oxide(HTO) was studied. HTO was prepared by mixing titanium(IV) chloride and aqueous ammonia at different pHs and temperatures. The fundamental property of HTO was investigated for apparent crystal size, specific surface area, and pore size. The uranium uptake of HTO was found to depend more strongly on the temperature than on the pH in the preparation. HTO prepared at higher temperatures exhibited larger pores and a higher uranium uptake. A kinetic study of the uranium adsorption revealed that the rate of adsorption was controlled by the particle diffusion. The diffusion coefficients were calculated.

There are a large number of elements dissolved in sea water. Though the concentration of uranium in sea water is very low (3 ppb), the total amount of uranium is estimated to be about 4×10^9 t. The recovery of uranium from sea water has been studied, and several techniques for the extraction have been proposed.[1-4] Among these techniques, the adsorption method has been considered most feasible.

Hydrous titanium(IV) oxide (HTO) may be the most suitable uranium adsorbent because of its higher selectivity and adsorption capacity. Ogata[5] has shown that the uranium uptake depends strongly on the method of the preparation of HTO. However, no systematic study has been reported of the relation between the physical properties and uranium adsorption of HTO.

In the present work, the relationship between the uranium adsorption and the physical properties of HTO, such as the apparent crystal size, the specific surface area, and the pore size, is investigated.

Experimental

Preparation of HTO. HTO was prepared by the addition of 7% aqueous ammonia to a solution of 0.6 mol dm^{-3} titanium(IV) chloride at different temperatures. The pH values at the end of precipitation was controlled between 3 and 9. The precipitate was filtered off, washed with distilled water, and finally dried at room temperature for about 10 d. The dried samples were crushed and sieved, a fraction of 150—200 mesh size being used in the following experiments.

Sample Solution. The sea water used in the present work was obtained at the seashore of Hitachi city. The uranium concentration was found to be 3.1 ppb, and the pH value, 8.1. In the adsorption experiments, the initial concentration of uranium was set as 10—30 ppb by the addition of uranyl(VI) chloride solution to the sea water.

Adsorption Experiment. The HTO samples of 0.04 g were introduced into 1000 ml of sea water at 25 °C. The solution was stirred by means of a vertical stirrer. The adsorption equilibrium was attained within 8 h under the present experimental conditions. The solution was filtered to separate the adsorbents, and the uranium in the solution was determined spectrophotometrically, with Arsenazo III as an indicator.[6]

Measurement of X-Ray Diffraction. The X-ray diffraction pattern of HTO was measured with a Rigaku Denki Geiger Flex X-Ray Diffractometer, filtered Cu $K\alpha$ being used. The apparent crystal size was calculated by the Sheller equation from a peak corresponding to the (101) plane of anatase.

Measurement of Specific Surface Area and Mean Pore Radius. The specific surface area and pore volume of HTO were measured by means of the N_2 adsorption at −195 °C. The mean pore radius, r, was calculated from the $r=2V/S$ equation, where V is the pore volume and S the specific surface area.

Results and Discussion

Uranium Uptakes of HTO Prepared at Different pHs, and Temperatures. The effects of the final preparation pH of HTO on the specific surface area and the uranium uptake are shown in Fig. 1. The specific surface area (about 400 $m^2\,g^{-1}$) of HTO is independent of the pH values of the preparation. It can be seen that uranium uptakes also do not depend on the pH values of the preparation.

The effect of the preparation of HTO on the uranium uptake was investigated as well. The uranium uptake

by HTO increased with an increase in the temperature of the preparation (Fig. 2). That is, HTO prepared at 20 °C and pH 5 had the uranium uptake of 40 μg g^{-1}; at 50 °C, 60 μg g^{-1}; at 70 °C, 73 μg g^{-1}, and at 90 °C, 82 μg g^{-1}. It is thus found that the uranium uptake depends strongly on the preparation temperature.

Physical Properties and Uranium Adsorption. In order to investigate the effect of the preparation temperature on the uranium uptake, the apparent crystal size, the specific surface area, and the mean pore radius of HTO were measured.

HTO prepared at 20 °C was found to be an amorphous structure, while that prepared above 50 °C showed some weak diffraction lines, indicating a crystal growth of an anatase type. The apparent crystal size of the anatase type is plotted against the temperature in Fig. 3. The crystal size of anatase increased with the temperature from about 28 Å at 50 °C to about 40 Å at 90 °C. The uranium uptake increased with the crystal growth of HTO under the present experimental conditions.

The specific surface area of HTO shows an inverse relationship with the pore radius and the crystal size (Fig. 3 and Fig. 4). The specific surface area decreased with the increase in the temperature from about 450 m^2 g^{-1} at 20 °C to about 220 m^2 g^{-1} at 90 °C. At the same time, the mean pore radius increased with the preparation temperature, *i.e.*, the values of the mean pore radius of the samples prepared at pH 5 were found to be 13.5 Å at 20 °C, 15.3 Å at 50 °C, 18.2 Å at 70 °C, and 21 Å at 90 °C. The preparation temperature thus had a large effect on the specific surface area and the mean pore radius of HTO.

The relation between the specific surface area and the uranium uptake of HTO is shown in Fig. 5. The uranium uptake decreased with the increase in the specific surface area, while it increased with the mean pore radius, as is shown in Fig. 6. The results show that the uranium uptake is low when the mean pore radius is small, despite the high specific surface area.

In consequence of the relatively high carbonate

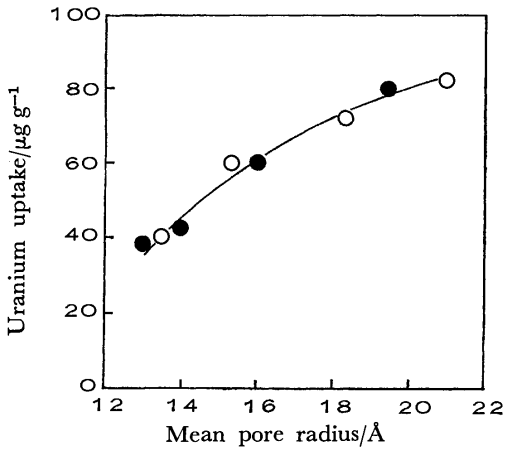

Fig. 6. Relation between uranium uptake and mean pore radius of hydrous titanium(IV) oxide.
○, ●: Same as Fig. 5.

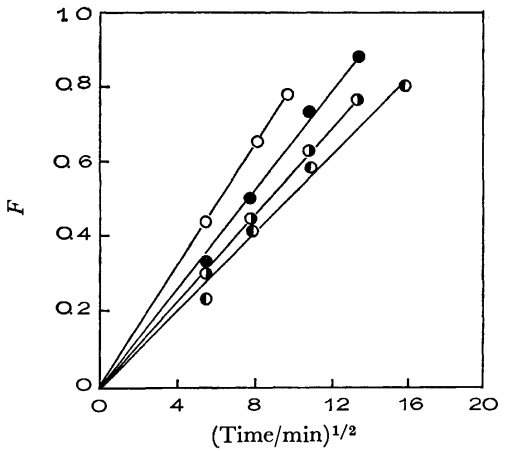

Fig. 7. Plot of F *vs.* $t^{1/2}$.
Uranium adsorption; concentration of uranium: 30 ppb, temperature: 25 °C.

concentration in sea water (2.3×10^{-3} mol dm^{-3}), uranium exists in the form of tris(carbonato)dioxouranate(VI) $[UO_2(CO_3)_3]^{4-}$.[7] The ionic radius of the ion is estimated to be more than 4.7 Å.[8] It is supposed that $[UO_2(CO_3)_3]^{4-}$ can easily enter the pores with a larger diameter of HTO. However, in the case of HTO prepared at a lower temperature, the entrance of $[UO_2(CO_3)_3]^{4-}$ into the small pores is difficult. Therefore, it is considered that HTO prepared at a higher temperature exhibits a higher uranium uptake.

Kinetic Studies. Kinetic measurements were made of the uranium adsorption by HTO. When the adsorption is controlled by the particle diffusion, the following equation holds:[9]

$$F=\frac{Q_t}{Q_\infty}=\frac{6}{R}\sqrt{\frac{D_1 t}{\pi}},$$

where F is the extent of adsorption, Q_t the uranium uptake in time t and Q_∞ the uranium uptake at equilibrium. R is the radius of the adsorbent, and D_1 the diffusion coefficient. A plot of F *versus* $t^{1/2}$ will be a straight line if the adsorption is controlled by the particle diffusion, and the diffusion coefficient can be obtained from the slope of the line.

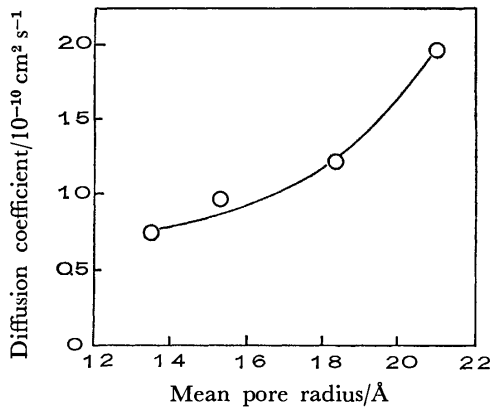

Fig. 8. Relation between diffusion coefficient and mean pore radius.

The rate of the uranium adsorption with HTO prepared at pH 5 and at 20—90 °C is shown in Fig. 7, which gives a linear relationship of F with $t^{1/2}$. The calculated diffusion coefficients are found to be 0.73×10^{-10} cm^2 s^{-1} for HTO prepared at 20 °C, 0.95×10^{-10} cm^2 s^{-1} at 50 °C, 1.24×10^{-10} cm^2 s^{-1} at 70 °C, and 1.98×10^{-10} cm^2 s^{-1} at 90 °C.

Figure 8 shows the relation between the diffusion coefficient and the mean pore radius of HTO prepared at 20—90 °C. It can be seen that the diffusion coefficients increase with the mean pore radius, *i.e.*, HTO prepared at a high temperature has larger pores and exhibits a higher uranium adsorption rate than that prepared at a low temperature. The diffusion coefficients in the present work are of the same magnitude as for the adsorption of methylene blue (with an ionic radius of about 4.5 Å) on the activated carbon (pore radius 10—30 Å, $D_1=1.1\times10^{-10}$ cm^2 s^{-1}).[10]

The rate of the uranium adsorption increased with the temperature of the solution. The diffusion coefficient for HTO prepared at 90 °C was found to be 2.53×10^{-10} cm^2 s^{-1} at 40 °C of the solution in the adsorption experiment shown in Fig. 7. The activation energy was calculated to be 12.6 kJ mol^{-1}. The relatively small activation energy indicates that the adsorption rate is controlled by the particle diffusion.

The authors wish to thank Professor Shosuke Imoto of Osaka University and Dr. Simpei Matsuda and Dr. Kazunori Fujita of the Hitachi Research Laboratory, Hitachi, Ltd., for their many helpful discussions and suggestions.

(Received November 27, 1979)

The Raman spectra of thin films of nematic liquid crystals, MBBA and NP-5A, have been measured for samples sandwiched between two glass (or quartz) plates, which had been pretreated in several ways. The intensities of the fundamental bands of the molecules and the polarization components of each band depend on the molecular orientation structures, such as the homogeneous and homeotropic alignments. The intensity ratio provides a semi-quantitative measure for the molecular orientation, and the Raman results are compared with those from polarizing microscopic observations and infrared spectra. The molecular orientation of the liquid crystals varies with the concentrations of surface-active agents as well as the materials used for the pretreatment of the plates. The molecular interactions, which give rise to the orientation structures, are briefly discussed.

The molecular orientation structures in nematic liquid crystals depend on the nature of the substrate surfaces resulting from previous treatment, and they can usually be distinguished by observation with a polarizing microscope.[1,2] They have, however, not always been clarified in molecular dimensions, because X-ray studies are not so effective for the thin films. Recently, the Raman spectra of liquid crystals have been actively studied,[3–7] but most of the work has been performed with bulk samples. For the vibrational spectra of liquid crystal films, we have reported a preliminary Raman result,[8] while some works on the far-infrared spectra have been reported[9–11] and the infrared ATR spectra on the In_2O_3 surface have been studied.[12] However, with the samples between glass or quartz plates, infrared measurement is not so useful. In order to obtain more precise information regarding the molecular orientation structures, the Raman spectra of thin films of nematic liquid crystals on glass or quartz surfaces have been studied in our present work.

Experimental

MBBA(*N*-(*p*-methoxybenzylidene)-*p*-butylaniline; Kodak and Tokyo Chem. Co.) and NP-5A (a mixture of 4-methoxy-4′-butylazoxybenzene with 4-methoxy-4′-ethylazoxybenzene; Merck) were used. Optically flat glass (or quartz) plates ($25 \times 75 \times 1$ mm) were cleaned by using a chromium trioxide solution and then treated by one of the following ways: (i) Silk treatment (rubbed with a silk cloth in the direction parallel to the long edges of the plate surface); (ii) HTAB treatment (dipped in an aqueous solution (0.007—1.4 mM; 1 M=1 mol dm^{-3}) of HTAB (hexadecyltrimethylammonium bromide; Wako Chem.) and then carefully dried); (iii) Lecithin treatment (dipped in an ethanol solution (0.001—1.0 mM) of lecithin (Wako 1st grade, extracted from eggs) and dried), or (iv) Silane treatment (dipped in a solution of 2 mM diphenyldichlorosilane (Wako Chem. special grade) in toluene and dried). A drop of MBBA or NP-5A was sandwiched by two pretreated plates, slightly pressed, and then fastened with a plastic tape along the edges. The thicknesses of the films were measured roughly by observing the interference fringes in the visible and infrared regions, 1—100 μm.

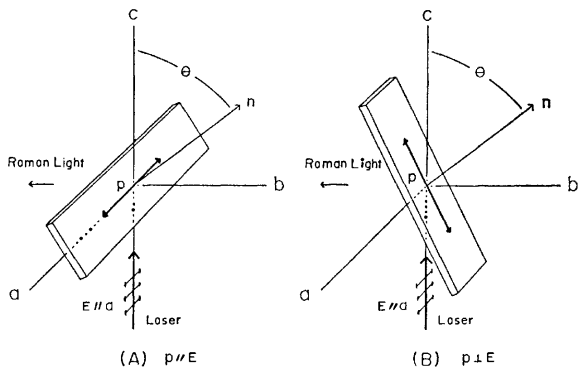

Fig. 1. Setting and irradiation of samples: (A) $\boldsymbol{p}//\boldsymbol{E}$, (B) $\boldsymbol{p} \perp \boldsymbol{E}$.

For polarizing microscopic observation, the samples were examined between crossed nicols under a Carl Zeiss photomicroscope (64 fold).

The Raman spectra were measured by means of a JASCO R-300 spectrophotometer with a JEOL-04 Ar ion laser. All the observations of the films were made in oblique settings, where the plane normal of the film, n, made an angle, θ, with the incident beam (θ=30°—80°). The laser beam irradiated the sample along the c axis (a, b, and c are the space fixed Cartesian coordinates, and n lies on the bc plane), and the scattered light was gathered in the b direction, as is shown in Fig. 1.

For the measurements of the polarization components of the Raman bands, a usual polarizer was inserted in front of the sample and an analyzer was placed near the entrance slit of the monochromator. The electric vector of the laser beam, $\boldsymbol{E}$, was taken as the a direction and could be rotated in the b direction by means of a $\lambda/2$ plate made of white mica.

The infrared spectra were measured with a JASCO DS-402G infrared spectrophotometer for the samples on quartz plates. The polarized spectra were measured with an AgCl polarizer which was located in front of the thermocouple detector.

Results and Discussion

Examination in a polarizing microscope showed different patterns for the samples, as is shown in Table 1. For example, the sample of MBBA on the glass treated with silk showed a characteristic thready texture parallel to the long edges, $\boldsymbol{p}$, and is called as a homogeneous sample, while the sample of MBBA on the glass treated with the 0.7 mM HTAB solution showed only dark stars and is designated as a homeotropic sample. In Table 1 the samples which showed colorful patterns (including texture) are classified as //, and the samples with dark stars, as ⊥. There can be seen

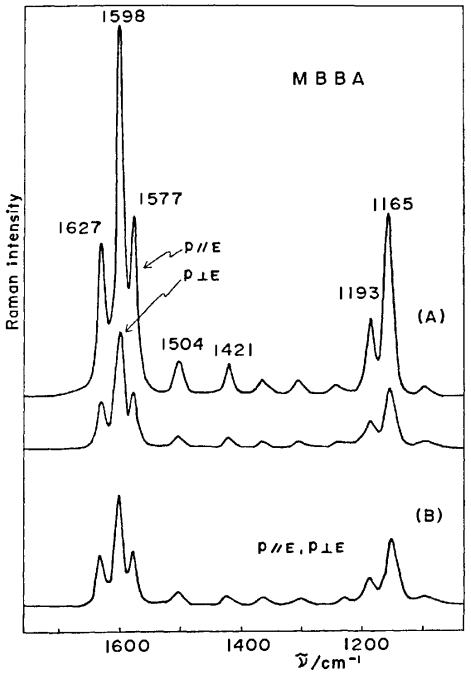

Fig. 2. Raman spectra of aligned thin (*ca.* 1 μm) films of MBBA.
(A): Homogeneous, (B) homeotropic samples.

only a very small difference in the observation between glass and quartz substrates. △ is used for the sample showing a dark colorful pattern.

The Raman spectra reported so far are for the films more than 25 μm thick. The oblique setting used here made it possible to measure the spectra of the thinner films. The Raman spectra for the MBBA thin (*ca.* 1 μm) film with a polarized incident light are shown in Fig. 2 ($\theta=60°$) for the 1700—1000 cm^{-1} region. (A) and (B) show the spectra for homogeneous (silk treatment) and homeotropic (0.7 mM HTAB treatment) samples respectively. For the homogeneous sample, the band intensities at 1598 cm^{-1} and 1577 cm^{-1} for $\boldsymbol{p}//\boldsymbol{E}$ are about three times larger than those for $\boldsymbol{p}\perp\boldsymbol{E}$, while for the homeotropic sample they are almost the same for $\boldsymbol{p}//\boldsymbol{E}$ and $\boldsymbol{p}\perp\boldsymbol{E}$, taking the electric vector of the incident light as $\boldsymbol{E}//\boldsymbol{a}$ and the long axis of the plate as $\boldsymbol{p}$. These spectra were independent of θ. The 1598 cm^{-1} and 1577 cm^{-1} bands are assigned to the benzene ring-vibrations,[3,4,12] the Raman-scattering tensors of which have the largest element $|\alpha'_{zz}|$ ($|\alpha'_{zz}| \gg |$other element$|$), taking z as the molecular long axis.

The Raman-scattering tensor (polarizability tensor derivative) is expressed by;

$$\alpha'_{mol} = \begin{pmatrix} \alpha'_{xx} & \alpha'_{xy} & \alpha'_{xz} \\ \alpha'_{yx} & \alpha'_{yy} & \alpha'_{yz} \\ \alpha'_{zx} & \alpha'_{zy} & \alpha'_{zz} \end{pmatrix}, \quad (1)$$

where x, y, and z are the principal molecular axes. Assuming an axial symmetry about the z axis resulting from the free rotation around the z axis, we obtain $\alpha'_{zz}=A$, $\alpha'_{zx}=\alpha'_{yz}=\alpha'_{zy}=\alpha'_{xz}=B$, $\alpha'_{xx}=\alpha'_{yy}=C$, and $\alpha'_{xy}=\alpha'_{yx}=D$; then,

$$\alpha'_{mol} = \begin{pmatrix} C & D & B \\ D & C & B \\ B & B & A \end{pmatrix}. \quad (2)$$

The Raman-scattering tensor in the laboratory coordinates (space fixed, a, b, c);

$$\alpha'_{lab} = \begin{pmatrix} \alpha'_{aa} & \alpha'_{ba} & \alpha'_{ac} \\ \alpha'_{ba} & \alpha'_{bb} & \alpha'_{bc} \\ \alpha'_{ac} & \alpha'_{bc} & \alpha'_{cc} \end{pmatrix} \quad (3)$$

is transformed from (1) or (2) using Euler's angles (α, β, γ).[19]

$$\begin{aligned}
\alpha'_{aa} &= (1/3)(2C+A) + (1/3)(A-C)(3\sin^2\beta\cos^2\alpha - 1) \\
&\quad - D[\sin 2\gamma(\cos^2\beta\cos^2\alpha - \sin^2\alpha) + \cos 2\gamma\cos\beta\sin 2\alpha] \\
&\quad + B\sin\beta(2\cos\gamma\cos\beta\cos^2\alpha - \sin\gamma\sin 2\alpha) \\
&\quad - B\sin\beta(2\sin\gamma\cos\beta\cos^2\alpha + \cos\gamma\sin 2\alpha). \\
\alpha'_{ac} &= (A-C)\sin\beta\cos\beta\cos\alpha \\
&\quad + D\sin\beta(\sin 2\gamma\cos\beta\cos\alpha + \cos 2\gamma\sin\alpha) \\
&\quad + B(\cos\gamma\cos 2\beta\cos\alpha - \sin\gamma\cos\beta\sin\alpha) \\
&\quad - B(\sin\gamma\cos 2\beta\cos\alpha + \cos\gamma\cos\beta\sin\alpha). \\
\alpha'_{bc} &= (A-C)\sin\beta\cos\beta\sin\alpha \\
&\quad + D\sin\beta(\sin 2\gamma\cos\beta\sin\alpha - \cos 2\gamma\cos\alpha) \\
&\quad + B(\cos\gamma\cos 2\beta\sin\alpha + \sin\gamma\cos\beta\cos\alpha) \\
&\quad - B(\sin\gamma\cos 2\beta\sin\alpha - \cos\gamma\cos\beta\cos\alpha). \\
\alpha'_{ba} &= (1/2)(A-C)\sin^2\beta\sin 2\alpha \\
&\quad - (D/2)[\sin 2\gamma(1+\cos^2\beta)\sin 2\alpha - 2\cos 2\gamma\cos\beta\cos 2\alpha] \\
&\quad + B\sin\beta(\cos\gamma\cos\beta\sin 2\alpha + \sin\gamma\cos 2\alpha) \\
&\quad - B\sin\beta(\sin\gamma\cos\beta\sin 2\alpha - \cos\gamma\cos 2\alpha).
\end{aligned}$$

α'_{bb} and α'_{cc} are omitted.

In our Raman measurements, shown in Fig. 1, we observe $(\alpha'_{aa})^2+(\alpha'_{ac})^2$ as the intensities. Assuming the molecular long axis, z, to be parallel to $\boldsymbol{p}$ for the homogeneous samples and perpendicular to $\boldsymbol{p}$ for the homeotropic samples, Euler's angles for the sample settings are given as follows:

$\alpha = 0°$, $\beta=90°$ for homogeneous $\boldsymbol{p}//\boldsymbol{E}$,

$\alpha = 270°$, $\beta = 30°$ for homogeneous $\boldsymbol{p}\perp\boldsymbol{E}$,

$\alpha = 90°$, $\beta = 60°$ for homeotropic $\boldsymbol{p}//\boldsymbol{E}$ and $\boldsymbol{p}\perp\boldsymbol{E}$.

The $(\alpha'_{aa})^2+(\alpha'_{ac})^2$ are calculated by averaging over $\gamma(0\rightarrow 2\pi)$

$$(\alpha'_{aa})^2 + (\alpha'_{ac})^2 = A^2 + B^2, \text{ for homogeneous } \boldsymbol{p}//\boldsymbol{E}$$
$$= (3/4)B^2 + C^2 + (5/8)D^2, \text{ for homogeneous } \boldsymbol{p}\perp\boldsymbol{E}$$
$$= (1/4)B^2 + C^2 + (7/8)D^2, \text{ for homeotropic } \boldsymbol{p}//\boldsymbol{E} \text{ and } \boldsymbol{p}\perp\boldsymbol{E}.$$

Since we have $|A_1| \gg |B_1|$ and negligibly small $|C_1|$ and $|D_1|$ values for the 1598 cm^{-1} band (using the suffix 1), the larger intensity observed for the homogeneous $\boldsymbol{p}//\boldsymbol{E}$ than that for the homogeneous $\boldsymbol{p}\perp\boldsymbol{E}$ can well be interpreted. The intensity ratio between 1598 cm^{-1} and 1577 cm^{-1} bands should be constant for all the sample settings, which is in harmony with the observation. The observed Raman spectra, therefore, certainly confirm the molecular alignments suggested by the observation by a polarizing microscope; the molecular long axis is parallel to $\boldsymbol{p}$ for the homogeneous sample and perpendicular to $\boldsymbol{p}$ for the homeotropic sample.

The observed peak intensity ratios between the 1627 cm^{-1} and 1598 cm^{-1} bands are given in Table 2 for

Table 2. Intensity ratios between 1627 cm^{-1} and 1598 cm^{-1} bands, $I(1627)/I(1598)$, of MBBA films

	Bulk Isotropic	Film	
		Homogeneous	Homeotropic
$\boldsymbol{p}//\boldsymbol{E}$	0.417	0.402	0.445
$\boldsymbol{p}\perp\boldsymbol{E}$		0.414	0.445

the MBBA thin films at $\theta=60°$, together with the value for the isotropic bulk (50 °C). If the 1627 cm^{-1} band is assigned to the C=N stretching vibration (using the suffix 2), $|B_2|$ and $|C_2|$ are quite large, though $|A_2|$ is the largest among $|A_2|$, $|B_2|$, $|C_2|$, $|D_2|$, because the C=N bond lies on the phenyl plane and makes an angle of 30° with the z axis.[12] The intensity ratio between the 1627 cm^{-1} and 1598 cm^{-1} bands, $I(1627)/I(1598)$, therefore, should vary with the molecular orientation, having the largest value for the homeotropic sample ($\boldsymbol{p}//\boldsymbol{E}$ and $\boldsymbol{p}\perp\boldsymbol{E}$). Based on the expressions for $(\alpha'_{aa})^2+(\alpha'_{ac})^2$ and the observed relation $|A_1|>|A_2|$, the following relation for the intensity ratio, $I(1627)/I(1598)$, can be derived:

(homogeneous $\boldsymbol{p}//\boldsymbol{E}$) < (homogeneous $\boldsymbol{p}\perp\boldsymbol{E}$) < (homeotropic $\boldsymbol{p}//\boldsymbol{E}$ and $\boldsymbol{p}\perp\boldsymbol{E}$).

The relation derived above is in good agreement with the observed values in Table 2. This fact also confirms that the 1627 cm^{-1} band is to be assigned to the C=N stretching vibration, though there may be some vibrational coupling with the benzene-ring vibration. The treatment described above is rather rough, and we have neglected the molecular precessional motion[5,12] around the optic axis.

The molecular orientation of the liquid crystals depends on the concentrations of HTAB or lecithin solutions as well as on the materials used for the pretreatment of the plates, as has been reported by Proust and Ter-Minassian-Saraga.[13] The Raman intensity ratios, $I(1627)/I(1598)$, observed for the samples treated with various concentrations of HTAB and lecithin are shown in Table 3. For the sample treated with

Table 3. Relation between Raman intensity ratios of MBBA films and concentrations of HTAB and lecithin

Treatment	Concentration	$\frac{I(1627)}{I(1598)}$	Microscopic observation

	0.070	0.44_1	⊥
	0.70	0.445	⊥
	1.4	0.44_5	⊥
Lecithin (C_2H_5OH soln)	0.0010 mM	0.39_7	∥
	0.010	0.40_1	∥
	0.10	0.43_2	⊥
	1.0	0.43_8	⊥

Table 4. Polarization components of 1598 cm^{-1} band of MBBA films (relative values)

	Homogeneous $\boldsymbol{p}//\boldsymbol{E}$	Homeotropic $\boldsymbol{p}//\boldsymbol{E}$, $\boldsymbol{p}\perp\boldsymbol{E}$
(aa)	1.0	1.0
(ac)	0.37	0.90
(bc)	0.29	1.6
(ba)	0.59	1.3

0.7 mM HTAB, the measurements were made for a number of samples, while for the other cases several samples were measured for each concentration. With the HTAB treatments the MBBA molecules were almost perpendicular to the plate surface, but with the lecithin treatments they were perpendicular only if a concentration of lecithin larger than 0.1 mM was used. Moreover, with 0.01 or 0.001 mM lecithin treatment the MBBA molecules were parallel to the plate surface. With low concentrations, the amount of the adsorbed HTAB or lecithin must be small, giving rise to an incomplete surface treatment.

Thus, the intensity ratio provides a semi-quantitative measure of the molecular orientation. It was, however, found that the Raman results did not always coincide with those suggested by the polarizing microscopic observations. For example, the MBBA sample treated with 0.007 mM HTAB showed the Raman intensity ratio of 0.436, corresponding to the almost perpendicular orientation structure, though the examination by the polarizing microscope did not enable us to distinguish the molecular orientation.

The Raman intensity ratio varies with the change in the thickness of the samples. For the MBBA samples treated with 0.7 mM HTAB, the intensity ratio $I(1627)/I(1598)$ was 0.445 for the *ca.* 1 μm film and 0.427 for the 25—100 μm films ($\boldsymbol{p}//\boldsymbol{E}$, $\theta=60°$), showing that the molecular orientations were incomplete with the thicker films, because the ratio becomes largest when the molecules are perpendicular to the plate surface. On the other hand, the samples treated with silk did not show any appreciable change in the intensity ratio for 1—100 μm films.

The polarization components were measured for (aa), (ac), (bc), and (ba), where (ac) means the spectrum observed with a incident and c scattered components. The relative intensities of the 1598 cm^{-1} band observed among the polarization components

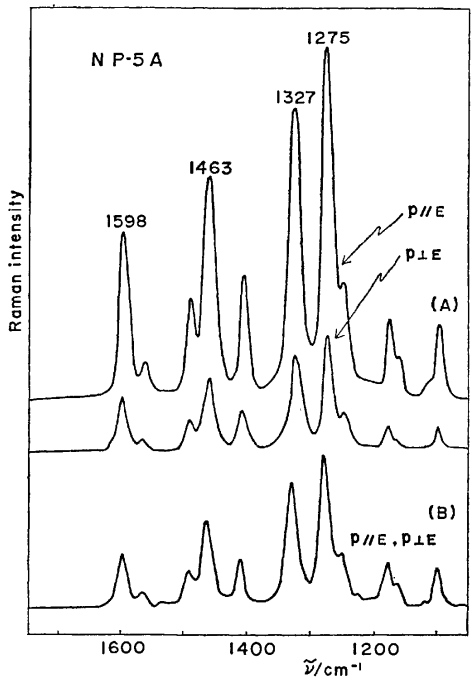

Fig. 3. Raman spectra of aligned thin (*ca.* 1 μm) films of NP-5A.
(A): Homogeneous, (B) homeotropic samples.

for $\theta=60°$ are shown in Table 4. The polarization components are calculated from the elements of α'_{ab} derived above. For homogeneous $\boldsymbol{p}//\boldsymbol{E}$, $(\alpha'_{bc})^2=D_1^2/2$ and $(\alpha'_{ba})^2=B_1^2$ while for homeotropic $\boldsymbol{p}//\boldsymbol{E}$ and $\boldsymbol{p}\perp\boldsymbol{E}$,

$$(\alpha'_{bc})^2 = (3/16)A_1^2 + (1/4)B_1^2 + (3/16)C_1^2 + (3/32)D_1^2$$

$$(\alpha'_{ba})^2 = (3/4)B_1^2 + (1/8)D_1^2.$$

Then, for the 1598 cm^{-1} band, the following relations can be derived theoretically:

$(\alpha'_{bc})^2 < (\alpha'_{ba})^2$ for homogeneous $\boldsymbol{p}//\boldsymbol{E}$, and

$(\alpha'_{bc})^2 > (\alpha'_{ba})^2$ for homeotropic $\boldsymbol{p}//\boldsymbol{E}$ and $\boldsymbol{p}\perp\boldsymbol{E}$.

These relations are in harmony with the observed relations:

$I(\mathrm{bc}) < I(\mathrm{ba})$ for homogeneous $\boldsymbol{p}//\boldsymbol{E}$, and

$I(\mathrm{bc}) > I(\mathrm{ba})$ for homeotropic $\boldsymbol{p}//\boldsymbol{E}$ and $\boldsymbol{p}\perp\boldsymbol{E}$.

In this case, the values depend on θ. These results also confirm the molecular arrangements described above.

The results obtained for the NP-5A film samples are shown in Fig. 3 and Tables 5 and 6. For the NP-5A film, the Raman bands have not yet been assigned to the normal vibrations of the molecules. However, as is shown in Fig. 3 for the homogeneous sample treated with silk, the Raman intensities of the 1598, 1463, 1327, and 1275 cm^{-1} bands were much stronger for $\boldsymbol{p}//\boldsymbol{E}$ than those for $\boldsymbol{p}\perp\boldsymbol{E}$, while no appreciable intensity changes in these Raman bands could be observed for the homeotropic sample treated with 0.1 mM lecithin. The strong bands observed for the $\boldsymbol{p}//\boldsymbol{E}$ of the homogeneous sample can be assigned to the vibrations, of which the Raman-scattering tensors have the largest $|\alpha'_{zz}|$ values. This homogeneous sample showed a colorful texture in the polarizing microscopic examination and had its molecular

Table 5. Intensity ratios for NP-5A films

Table 6. Polarization components of 1275 cm^{-1} band of NP-5A films (relative values)

	Homogeneous (silk) $\boldsymbol{p}//\boldsymbol{E}$	Homeotropic (lecithin) $\boldsymbol{p}//\boldsymbol{E}$, $\boldsymbol{p}\perp\boldsymbol{E}$
(aa)	1.0	1.0
(ac)	0.6	0.8
(bc)	0.4	1.0
(ba)	0.6	0.7

axes parallel to $\boldsymbol{p}$. The sample treated with 0.7 mM HTAB also showed a colorful pattern, but not a colorful texture, and it was a kind of homogeneous sample where the molecular long axes must be randomly oriented on the plane parallel to the plate surface. In the homogeneous (texture) sample, the Raman intensity ratios are different for $\boldsymbol{p}//\boldsymbol{E}$ and $\boldsymbol{p}\perp\boldsymbol{E}$, while they are the same in the other cases, as is shown in Table 5.

The polarization components of the 1275 cm^{-1} band are shown in Table 6. $I(\mathrm{ba})>I(\mathrm{bc})$ was observed for the homogeneous sample and $I(\mathrm{bc})>I(\mathrm{ba})$ for the homeotropic sample, similar to those for the 1598 cm^{-1} band of MBBA films, confirming the molecular orientations suggested by the polarizing microscopic observations.

The infrared transmission spectra were observed at normal incidence for the MBBA films between quartz windows, but only in the C–H stretching region. They are shown in Fig. 4. The bands at 3022 and 3000 cm^{-1} can be assigned to the C–H stretching vibrations in =C–H or aromatic C–H groups. These bands have their transition moments on the molecular plane, because the C–H bands must be on the plane which approximately coincides with the benzene-ring planes. These bands are stronger for the homogeneous sample than for the homeotropic sample, as is shown in Fig. 4(A). The dichroic spectra for the homogeneous sample are observed to be as in Fig. 4(B), where these bands are stronger for $\boldsymbol{p}\perp\boldsymbol{E}$ than for $\boldsymbol{p}//\boldsymbol{E}$, taking the electric vector as $\boldsymbol{E}$. Bulkin and Lok, after measuring the far-infrared spectra of aligned films of MBBA, reported that the spectra of the homogeneous and homeotropic samples did not show any measurable difference in the intensity of the intermolecular mode.[9] However, the present infrared results for the intramolecular modes can confirm the molecular orientations described above.

It may thus be considered that the Raman spectra certainly give information on molecular orientation

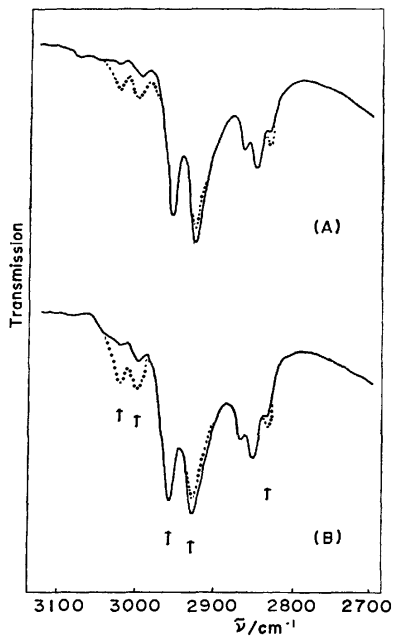

Fig. 4. Infrared spectra of aligned thin (*ca.* 1 μm) films of MBBA.
(A): Homeotropic —— and homogeneous ---- samples, (B): dichroism of homogeneous sample; $p//E$ ——, $p \perp E$ ----.

structures semiquantitatively. For the completely oriented structures, perpendicular or parallel, the Raman results agree well with the suggestions of the polarizing microscopic observations. Although the examination by a polarizing microscope is a simple and convenient method for distinguishing the orientations, it can not always be used, especially for the intermediate orientations. On the other hand, the Raman intensities measured can serve as a degree of alignment for the structural study of liquid crystal films. Furthermore, measurements of the thinner layers, more specific for the surface species, can be performed by observing the resonance Raman spectra, since the resonance Raman effect has been effectively used in the studies of small amounts of surface species.[14-17] Moreover, some theoretical work which assumes the molecular model parameters, such as the order parameter, developed by Pershan *et al.*[5] and Hatta,[12] will be able to quicken progress in studying the structures in their molecular dimensions.

Lastly, let us add some consideration of the mechanism of the formation of the two types of molecular orientation structures, homogeneous and homeotropic. The homogeneous structures appeared in thin films between two silk-treated clean plates, while the homeotropic structures appeared in thin films between plates previously treated with HTAB or lecithin solutions of certain concentration ranges. In the former case, it is supposed that the long molecules of liquid crystals with dipoles whose moment vectors being considered are in the direction of their long axes will be attracted to the plate surface mainly by the electrostatic forces between their dipoles and induced dipoles at the surface, and that they will also be oriented parallel to the surface in the inner part of the films by means of the dipole-dipole interactions, so that they will realize the homogeneous structures. On the other hand, in the latter case, where the plates are pretreated with HTAB or lecithin, whose molecules are amphiphilic in nature, the plate surfaces will be covered by these molecules anchored by their polar groups and will, accordingly, become hydrophobic because of the hydrocarbon chains oriented outside. Then, the liquid-crystal molecules with also hydrophobic groups (hydrocarbon chains at the end of their long molecules) will be attracted to the hydrophobic surfaces by the London-van der Waals attraction forces,[18] so that they will be oriented perpendicular to the surface to form homeotropic structures. However, if the concentration of the HTAB or lecithin solution used for pretreatment is too low, the surface density of the adsorbed molecules will be too small to realize the favorable orientation of the homeotropic alignment of the liquid-crystal molecules. Moreover, the difference observed between HTAB and lecithin in the concentration ranges (0.01 mM<for HTAB, 0.1 mM< for lecithin) required for the homeotropic alignment may be considered to be due to the difference in their molecular structures regarding the possibility of taking favorable orientations at the solid surface.

A New Assisted Reaction in the Photodecomposition Reaction of Dibenzoyl Peroxide

Yoshio SAKAGUCHI, Hisaharu HAYASHI,† and Saburo NAGAKURA*

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato, Tokyo 106

† *The Institute of Physical and Chemical Research, Wako, Saitama 351*

(Received February 2, 1980)

2,2′-, 2,3′-, and 3,3′-Dimethylbiphenyls were found in the photodecomposition reaction of dibenzoyl peroxide using toluene as solvent. We carried out the experiments to study the external magnetic field, oxygen scavenging, and excitation light intensity effects on their yields. It is concluded that they are produced through the dimerization of (benzoyloxy)methylcyclohexadienyl radicals. This is a new case of the assisted reaction by benzoyloxyl radical. The yields of dimethylbiphenyls were found to be affected remarkably by the small variation of the concentration of benzoyloxyl radical through the three experiments.

The external magnetic field effect upon chemical reactions is one of the most challenging subjects of modern chemistry. We have studied the magnetic field effects upon the photolysis of dibenzoyl peroxide, and have found that the yields of some products in the reaction are dependent upon external magnetic field,[1,2] particularly the yields of newly found products of the reaction, dimethylbiphenyls, show very large magnetic field dependence.[3] In the present paper, the identification and formation mechanism of the newly found products will be discussed in detail, special attention being paid to the scavenger and the excitation light intensity effects on the product yields of this reaction.

During the study of the magnetic field effects upon the photolysis of dibenzoyl peroxide, we found that the yields of some products were sensitive to excitation light intensity. Therefore we have constructed a stabilized light source necessary for excitation and have measured the yields under constant light intensity.

Experimental

The toluene solution (0.5 ml) of dibenzoyl peroxide (**1**) (0.04 mol dm^{-3}) containing chrysene (**2**) (0.002 mol dm^{-3}) as a singlet sensitizer[4] in a Pyrex cell was degassed with the freeze-thaw technique, and was sealed under a nitrogen atmosphere. The irradiation system used in this study is shown in Fig. 1. The cell was set in a water bath with a quartz window. The temperature of the bath was kept 16.5±0.3 °C. The solution was irradiated with an ORC CHM-506-15 1 kW super high pressure mercury lamp through a water filter with Pyrex windows. In order to stabilize the excitation light intensity, we made a feed-back power supply. The light intensity was monitored by a Toshiba TPS 601 phototransister and its signal was returned to the power supply of the lamp. The response time of the feed-back system was about 1 s. The fluctuation of the light intensity was less than ±1.5% and its drift was less than ±2.5% per hour. The excitation light intensity was reduced by placing a copper mesh in front of the sample.

The decrease of **1** was monitored by iodometric titration. In order to decompose **1** almost completely, the irradiation time was set fivefold of the half life time of its disappearance.

The photodecomposition products with molecular weights less than 214 were identified with a Shimadzu 4CMPF gaschromatograph and a Hitachi RMU-6MG gaschromatograph-mass spectrometer. For the former, a 3 mm diameter×1 m PEG 20 M and Silicone OV-1 columns and 3 mm diameter×2 m Apiezone L, Polyphenylether 6-ring,

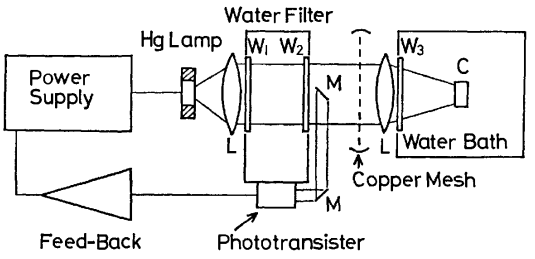

Fig. 1. Reaction apparatus of photodecomposition reaction.
C: Sample cell, L: quartz lens, M: mirror, W_1, W_2: Pyrex windows, W_3: quartz window.

Silicone OV-17, and Bentone 34 columns were used. For the latter, 3 mm diameter×1 m Silicone OV-1 column was used.

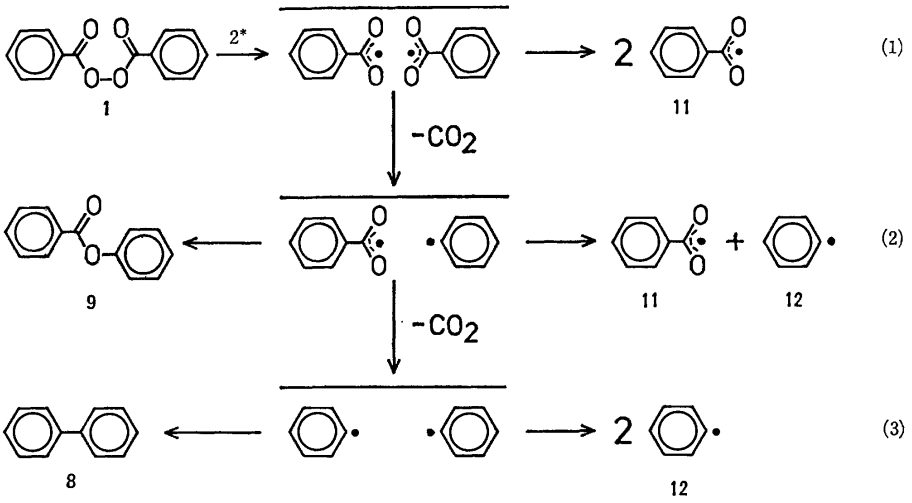
In addition to the established authentic samples[5,6] (biphenyl, 1,2-diphenylethane, diphenylmethane, *o*-, *m*-, and *p*-methylbiphenyls, phenyl benzoate, and *o*-, *m*-, and *p*-tolyl benzoates), 2,2′-, 2,3′-, 2,4′-, 3,3′-, 3,4′-, and 4,4′-dimethylbiphenyls, 2-, 3-, and 4-methyldiphenylmethanes, and benzyl benzoate were prepared for the authentic samples in the present study. Dimethylbiphenyls except for 4,4′-one (Tokyo Kasei) were synthesized after the method described in the literature.[7] 3- and 4-Methyldiphenylmethane were made by Wolff-Kishner reduction of the corresponding ketones.[8] 2-Methyldiphenylmethane was given by Dr. Sakuragi, The University of Tsukuba.[9] Benzyl benzoate was prepared from benzyl alcohol and benzoyl chloride.

The yields were measured by the gaschromatograph with a 3 mm diameter×1 m PEG 20 M column, terephthalonitrile being used as an external standard. The respective peaks were integrated by a Shimadzu chromatopac EIA integrator and these data were treated statistically using a YHP 9825A desktop computer.

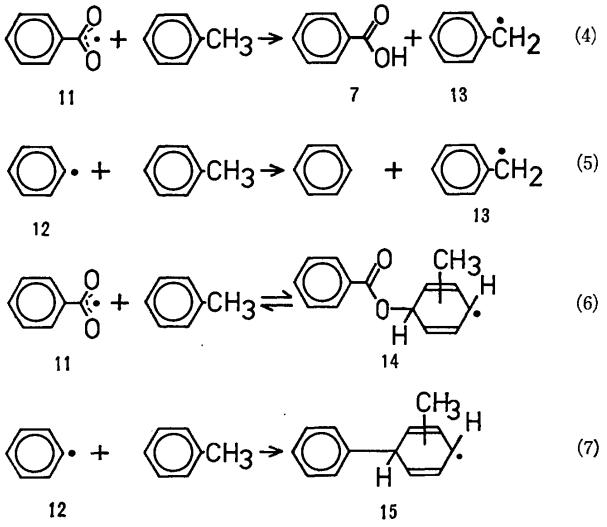
Results and Discussion

In this study, we identified 14 products with molecular weights less than 212.[3] They are listed in Table 1 together with their yields under the high and low excitation light intensities. At first, our consideration will be confined to the case of high intensity excitation. Among the products given in Table 1, dimethylbiphenyls (**3**'s) and benzyl benzoate (**10**) were found for the first time in the present study, while the others have already been identified.[5,6]

The photolysis of **1** proceeds as follows:[5]



As is seen in Eq. 1, the O–O bond of **1** is dissociated to produce a benzoyloxy-benzoyloxy radical pair ($\overline{PhCO_2\cdot\ PhCO_2\cdot}$). It releases carbon dioxide and produces benzoyloxy-phenyl and phenyl-phenyl radical pairs.(See Eqs. 2 and 3.) By the recombination within the cages, **8** and **9** are formed as cage products. The pair which retains from recombination, dissociates to escaping radicals. The escaping benzoyloxy (**11**) and phenyl (**12**) radicals react with solvent (toluene) and form new radicals as shown in the following equations.



The existence of benzyl radical (**13**) was proved by the formation of 1,2-diphenylethane (**5**).[10] Beside the formation of **13**, the cyclohexadienyl radicals (**14** and **15**) are formed as is shown in Eqs. 6 and 7. Their existences were proved by the formation of tolyl benzoates (**6**'s) and methylbiphenyls (**4**'s).[5,11-13] It is worth while to point out that diphenylmethane was not found under the present experimental conditions.[6] This suggests that the reactions of Eqs. 5 and 7 are very fast and the back reaction of Eq. 7 can be disregarded.[13] On the other hand, **11** can be supplied not only by the escaping from the cage but also by the back reaction of Eq. 6.[13]

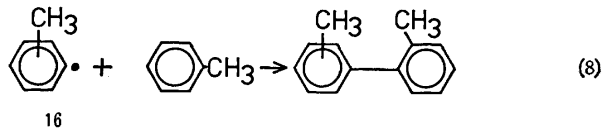
TABLE 1. PRODUCT YIELDS AND THEIR DEPENDENCES ON THE EXCITATION LIGHT INTENSITY[a]

Products		I_0	$1/3.5\,I_0$	
2,2'-Dimethylbiphenyl	(2,2'-**3**)	0.2 %	0.1 %	
2,3'-Dimethylbiphenyl	(2,3'-**3**)	2.36	1.44	(61)
3,3'-Dimethylbiphenyl	(3,3'-**3**)	3.56	2.23	(63)
2-Methylbiphenyl	(2-**4**)	6.21	6.86	(110)
Mixture[b]		23.22	24.30	(105)
o-Tolyl benzoate	(*o*-**6**)	4.09	3.26	(80)
Benzoic acid	(**7**)	102.10[c]	97.00[c]	(95)
Biphenyl	(**8**)	1.19	1.22	(103)
Phenyl benzoate	(**9**)	16.13	15.73	(98)
m-Tolyl benzoate	(*m*-**6**)	—[d]		
p-Tolyl benzoate	(*p*-**6**)	—[d]		
Benzyl benzoate	(**10**)	—[d]		

a) The yields are presented in mole percent taking benzoyl peroxide as reference. Values in the parentheses are the percentages of the yields under $1/3.5\,I_0$ divided by those under I_0. The experimental errors are less than 5% of respective values for dimethylbiphenyls and biphenyl and less than 3% of those for the others. b) Given value is the sum of the yields of 3- and 4-methylbiphenyls (3- and 4-**4**'s) and 1,2-diphenylethane (1,2-**5**) because of incomplete separation under our VPC conditions. c) The absolute yield of benzoic acid is not so precise as others owing to the VPC conditions, but the relative value in the parentheses are as precise as others. d) These products were identified but their yields were not measured because of their low yields and the incomplete separation between them under our VPC conditions.

Concerning **3**'s six isomers (2,2'-, 2,3'-, 2,4'-, 3,3'-, 3,4'-, and 4,4'-**3**'s) may be expected to exist. But actually, the only three isomers (2,2'-, 2,3'-, and 3,3'-**3**'s) were detected in the present experiment and no para-substituted compounds (2,4'-, 3,4'-, and 4,4'-**3**'s) could be found. The observed ratio of the detected isomers is; 2,2'-**3**:2,3'-**3**:3,3'-**3**=6.8:60.2:100, showing that the yields of the meta-isomers are larger than those of the ortho-isomers.

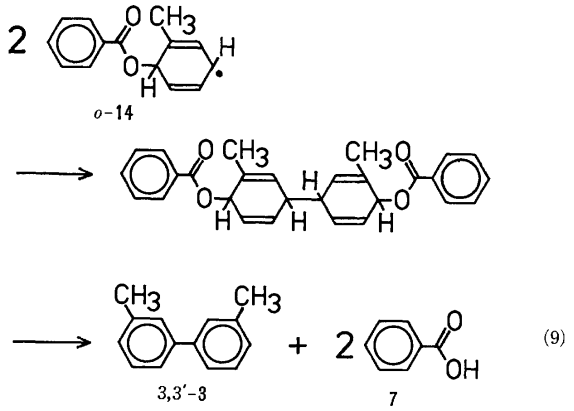
The most intuitive path for formation of **3**'s is the addition of the methylphenyl (tolyl) radical (**16**) to toluene as follows:[14]



(8)

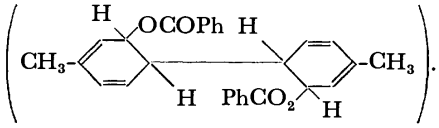
The consideration on the partial rate factors of tolylation, however, rejects the application of this mechanism to formation of **3**'s. The partial rate factors of the reaction shown by Eq. 8 can safely be considered to be similar to those of phenylation of toluene (f_t), the ratio of which was measured to be $f_o:f_m:f_p=3.3:1.1:1.3$.[15] Thus this mechanism predicts that the yield of 2,x'-**3** should be larger than that of 3,x'-**3**. This prediction contradicts the observed ratio. Therefore, the direct tolylation mechanism is disregarded.

Another possible mechanism for formation of **3**'s is an assisted reaction mechanism which have been applied to formation of tetraarylmethanes[16] and *N*-aryldiphenylmethanimines[17] by **11**. For example, 3,3'-**3** can be formed through the 4-benzoyloxy-3-methyl-2,5-cyclohexadienyl radical (*o*-**14**) as follows:



(9)

The benzoyloxylation of toluene preferably occurs on the *o*-position through the hyperconjugation of the methyl group. The steric hindrance of the methyl group may block benzoyloxylation on the methylsubstituted ring carbon atom leading to  . Furthermore, the steric hindrance of benzoyloxy residue in **14** is considered to disturb the dimerization reaction at its ortho-position



The above consideration on steric hindrance can explain the fact that formation of the **3**'s with a methyl group on the 4-position (2,4'-, 3,4'-, and 4,4'-**3**'s) is prohibited. Thus the assisted reaction scheme explains the observed yields of **3**'s. According to this mechanism, **3**'s are escape products.

In order to prove this assisted reaction scheme, we have studied the following effects on the reaction yields.

1) The effect of external magnetic field.
2) The effect of oxygen scavenging.
3) The effect of excitation light intensity.

The yields of **3**'s were decreased and increased by the application of the low (9.75 and 78 mT) and high (4.3 T) magnetic field, respectively.[3] Since this reaction occurs through a singlet precursor in which two radicals in the benzoyloxy-benzoyloxy, benzoyloxy-phenyl, or phenyl-phenyl radical pair have the anti-parallel unpaired electron spins, the observed magnetic field dependence corresponds to that of the escape product belonging to the (a-3) type of the theoretical classification.[2,3] Therefore, from the magnetic field effect, **3**'s are proved to be escape products in accordance with the above mentioned assisted reaction mechanism.

Table 2. Oxygen scavenging effect on the yields of the products[a]

Products		Degassed	Aerated	
2,3'-Dimethylbiphenyl	(2,3'-**3**)	2.26%	1.45%	(64)
3,3'-Dimethylbiphenyl	(3,3'-**3**)	3.47	2.37	(68)
2-Methylbiphenyl	(2-**4**)	5.68	9.34	(165)
Mixture[b]		20.06	13.92	(68)
o-Tolyl benzoate	(*o*-**6**)	3.24	9.57	(296)
Benzoic acid	(**7**)	81.27[c]	84.80[c]	(104)
Biphenyl	(**8**)	1.23	1.12	(91)
Phenyl benzoate	(**9**)	16.28	15.50	(95)

a) The yields and the values in the parentheses have similar meanings as those in Table 1. The experimental errors are the same as those in Table 1. b) Given value is the sum of the yields of 3- and 4-methylbiphenyls (3- and 4-**4**'s) and 1,2-diphenylethane (1,2-**5**) because of incomplete separation under our VPC conditions. c) Same as the note c) in Table 1.

Next, we tried to scavenge escaping radicals. Because this reaction yields various kinds of products, organic scavenger may disturb analysis of the products. So the dissolved oxygen in the solution was used as a radical scavenger. The product yields from the samples with and without degassing are listed in Table 2.[18] The excitation light intensity was kept constant during the two series of the experiments. The reaction time was 30 min for these experiments. We can see from Table 2 that the yields of 2,3'- and 3,3'-**3**'s were decreased by the dissolved oxygen. This decrease and the increase of the yield of *o*-**6** seem to indicate that **14**'s react with oxygen forming **6**'s and the dimerization reaction of **14**'s to form **3**'s are inhibited by the oxidation. **15**'s are also oxidized forming **4**'s. The increase of 2-**4** is remarkable as is shown in Table 2. But the sum of the yields for 3- and 4-**4** and 1,2-**5** is decreased by oxygen, because **13** is oxidized forming benzyl alcohol and benzaldehyde as final products[19] and like the case of **14**'s, the dimerization of **13** is also inhibited. On the other hand, the yields of **8** and **9** were not so much changed by oxygen. Therefore, the yields of cage products can be considered to be nearly insensitive to dissolved oxygen. This is also one of the proofs of the fact that **3**'s are escape products.

In order to determine whether **3**'s are formed through the dimerization of **14**'s, we studied the excitation light intensity dependence of their yields. On the assumption that **1** decomposes exponentially and the concentration of radical **n**, [**n**], is proportional to the decomposition rate of **1**, then the yield of the products coming from **n** has the following excitation light intensity dependence.[20] When the formation rate of the product has a first order dependence on [**n**], the product yield does not depend on the excitation light intensity. When the rate has a second order dependence on [**n**], the product yield depends linearly on the excitation light intensity. The above-mentioned excitation light intensity dependence is calculated through an oversimplified model. Thus the actual dependence may be more complex than the above prediction. But it can be used for a qualitative argument.

On the second column of Table 1 are listed the yields in the low excitation light intensity experiment in which the light intensity was reduced to 1/3.5 of that in the high intensity experiment and the reaction time was increased to 70 min from 20 min in the high intensity experiment. We can see from Table 1 that the yields of **3**'s are reduced by lowering the excitation light intensity. The yield of *o*-**6** is also somewhat decreased. These findings may be explained by the following consideration. Owing to the elongation of reaction time, the concentrations of the initially prepared benzoyloxy and phenyl radicals decrease. Thus bimolecular termination reactions between escaping radicals are retarded and the probability of the decomposition of **11** to **12**, which is an unimolecular reaction, increases relatively. This means that the yields of **3**'s and *o*-**6** coming from **11** decrease. Table 1 shows that the decrement is much larger for **3**'s than *o*-**6** which is considered to be produced depending linearly on the concentration of **14**. Therefore it is most probable that the formation rates of **3**'s are nearly proportional to the square of the concentration of **14**. This supports the mechanism that **3**'s are formed by the dimerization of **14**.

The decrease in the yields of the products which come from **11** reflected on the increase in the yields of the products coming from **12**. As is shown in Table 1, by lowering the excitation light intensity the yield of 2-**4** increased a little and the sum of the yields of 3- and 4-**4** and 1,2-**5** increased slightly. The yields of **8** and **9** are not affected so much by the change of the excitation light intensity. This can be interpreted by the fact that they are cage products.

The above-mentioned three experiments show that dimethylbiphenyls are escape products which are formed through the dimerization of (benzoyloxy)methylcyclohexadienyl radicals. This shows the rationality of the assumed assisted dimerization scheme.

This is a new assisted reaction by the benzoyloxy radical. The other cases which have hitherto been studied are formation of tetraarylmethane through the reaction with the triphenylmethyl radical[16] and formation of *N*-aryldiphenylmethanimine through the reaction with the diphenylmethaniminyl radical.[17] Compared with these two cases, the present process is more essential, because **3**'s are produced from two **14**'s and their formation does not need the other radicals.

The excitation light dependence of the radical reaction induced by photodecomposition can be anticipated as the possibility to elucidate the mechanism, although the experiments concerning the change in the excitation light intensity have not been preferred because it can provoke complexities in the reaction by the change in the radical concentrations. The present study shows that the experiment of light intensity dependence is useful for the classification of reaction mechanisms.

The authors wish to express their sincere thanks to Professor Katsumi Tokumaru and Dr. Hirochika Sakuragi, The University of Tsukuba, and Professor Masayuki Yoshida, The University of Tokyo, for helpful discussion and for supplying some of the authentic samples.

18) The values in the left columns in Tables 1 and 2 except for **7** are somewhat different from each other. This is due to the difference in the excitation light intensity. The fairly large discrepancy of the yield of **7** comes from the VPC conditions. However the values presented in left and right columns within each table do not have such discrepancies between them, because they were obtained under

the same experimental conditions.

19) We identified them under the existence of oxygen but we did not measure their yields.

20) The concentration of **1**, [**1**], decays as follows:

$$[\mathbf{1}](t)=[\mathbf{1}](0)\exp(-\alpha It),$$

here [**1**](0) is its initial concentration. I is the excitation light intensity, and α is the decomposition rate constant. When **n** is formed in proportion to [**1**], [**n**] can be given as follows:

$$[\mathbf{n}](t)=C_{\mathbf{n}}\left(-\frac{\mathrm{d}[\mathbf{1}](t)}{\mathrm{d}t}\right)=C_{\mathbf{n}}\alpha I\exp(-\alpha It),$$

here $C_{\mathbf{n}}$ is the fractional coefficient. If a product is produced in proportion to [**n**] or to the square of [**n**], the yield, ${}^{1\text{ or }2}Y$ is given respectively as follows:

$${}^{1}Y=\lambda_1\int_0^\infty[\mathbf{n}](t)\mathrm{d}t=\lambda_1C_{\mathbf{n}}$$

$${}^{2}Y=\lambda_2\int_0^\infty([\mathbf{n}](t))^2\mathrm{d}t=\lambda_2C_{\mathbf{n}}^2\frac{I}{2},$$

here λ_t is the reaction probability.

Thus ${}^{1}Y$ is independent of I, and ${}^{2}Y$ is linearly dependent on I.

CNDO and INDO Calculations of the Magnetic Circular Dichroism of Several Purine Derivatives

Akira KAITO and Masahiro HATANO*

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Sendai 980

(Received February 4, 1980)

Calculations of the magnetic circular dichroism(MCD) of methylpurines and methyladenines were carried out not only by the CNDO/S-CI procedure, but also by the INDO/S-CI procedure. The CNDO/S-CI procedure correctly predicted the signs and magnitudes of the MCD spectra of 1-, 3-, and 7-methylpurines and of 9-methyladenine which cannot be improved by the parameter adjustment. On the other hand, the signs of the MCD spectra and transition energies of all these purine derivatives were clearly explained by the INDO/S-CI procedure.

The magnetic circular dichroism (MCD) spectra of purine derivatives have been extensively studied by many investigators because the MCD spectra give valuable information on the electronic structure of these compounds.[1-3] By MCD the electronic absorption bands which overlap with each other have been resolved, and the presence of several electronic transitions in the ultraviolet region has been clarified.

On the other hand, there have been many attempts to calculate the Faraday parameters of the organic aromatic compounds by means of quantum mechanical SCF-MO calculations. The Pariser-Parr-Pople(PPP) procedure[4] has been successfully applied to explaining the signs of the MCD spectra of the derivatives and hetero atom analogues of alternant and nonalternant aromatic hydrocarbons.[5] The complete neglect of the differential overlap (CNDO) method,[6,7] an SCF-MO procedure for all valence electrons, has also predicted the correct signs of the MCD spectra of indole,[8] azines,[9] substituted benzenes,[10,11] some alternant hydrocarbons,[12] and azanaphthalenes.[13]

However, the original CNDO/S-CI procedure[7] proposed by Jaffé and his co-workers has failed to reproduce the MCD spectra of methyladenines and some 8-azapurines.[3] In order to overcome the difficulty, Djerassi and his co-workers have set the scaling constant, κ, for the π-type overlap integrals back to unity, as in the CNDO/2 method, and scaled the state energies and all the quantities derived from energies by means of an adjustable parameter, κ', after the CI calculation had been performed.[3] Although the new method, labeled the CNDO/S' method, has correctly predicted the signs of the MCD spectra of methyladenines and 8-azapurines, it cannot give wavefunctions which take account of the transition energies as well as the sign of the MCD spectra.

In this work, we calculate the transition energies and the Faraday B terms of purine, methylpurines, and methyl adenines not only by means of the CNDO procedure, but also by means of the intermediate neglect of the differential overlap(INDO) approximation,[14,15] and compare the results with the experimental data which have appeared in the literature.

Theoretical

The Faraday B terms were calculated using wavefunctions obtained from the INDO/S-CI approximation. The one-center core integrals and one-center electron repulsion integrals were evaluated from the valuence-state energy data[16] and the experimental Slater-Condon parameters.[17] The two-center electron repulsion integrals were calculated by means of the Nishimoto-Mataga equation.[18] The resonance integrals, $\beta_{\mu\nu}$, between atomic orbitals, μ and ν, were evaluated by means of the following equation:

$$\beta_{\mu\nu} = \frac{1}{2}(\beta_A + \beta_B)\bar{S}_{\mu\nu}, \quad (1)$$

where β_A is a bonding parameter of the atom, A, to which the atomic orbital, μ, belongs and where $\bar{S}_{\mu\nu}$ is an overlap integral obtained as follows:

$$\bar{S}^{ss}_{\mu\nu} = S^{ss}_{\mu\nu}, \quad (2)$$

$$\bar{S}^{sp}_{\mu\nu} = S^{sp}_{\mu\nu} \quad (3)$$

$$\bar{S}^{pp}_{\mu\nu} = S^{\sigma\sigma}_{\mu\nu} g^{\sigma\sigma}_{\mu\nu} \kappa_{\sigma\sigma} + S^{\pi\pi}_{\mu\nu} g^{\pi\pi}_{\mu\nu} \kappa_{\pi\pi}, \quad (4)$$

where $g^{\sigma\sigma}_{\mu\nu}$ and $g^{\pi\pi}_{\mu\nu}$ are the geometric factors and where $\kappa_{\sigma\sigma}$ and $\kappa_{\pi\pi}$ are the semiempirical scaling factors. The bonding parameters, β, and the scaling factors are determined so that the ionization potentials and transition energies of benzene and pyridine are well reproduced ($\beta_H = -6.6$ eV, $\beta_C = -15.4$ eV, $\beta_N = -23$ eV, $\kappa_{\sigma\sigma} = 1.23$, $\kappa_{\pi\pi} = 0.67$). The configuration interaction(CI) among singly excited configurations below 10 eV was taken into account.

We also calculated the Faraday B terms of the purine derivatives within the framework of the CNDO/S-CI approximation. The one-center repulsion integrals and one-center core parameters were taken from the values determined by Sichel and Whitehead.[19] The two-center electron integrals were evaluated by the Nishimoto-Mataga equation.[18] The bonding parameter, β, and the scaling factor for the π-type overlap integrals, κ, were empirically chosen in the same way as the INDO/S calculation ($\beta_H = -6.6$ eV, $\beta_C = -17.8$ eV, $\beta_N = -28$ eV, $\kappa_{\sigma\sigma} = 1.0$, $\kappa_{\pi\pi} = 0.59$).

The molecular structures of 7*H*-purine[20] and 9-methyladenine[21] have been clarified by X-ray crystal analysis. However, no experimental data for the structures of the remaining compounds have been reported. The bond lengths and the bond angles of the 7*H*-purine ring of 7-methylpurine and 7-methyladenine were taken from those of 7*H*-purine. The molecular structure of the 9*H*-purine ring of 9-methylpurine was set equal to those of 9-methyladenine. The geometries of 1- and 3-methylpurines were assumed to be the combinations of the geometry of the tautomeric forms of isocytosine[22] for the pyrimi-

a) The experimental data of the methylpurines are taken from Ref. 2.

dine ring with that of 7*H*-purine for the imidazole ring. The bond lengths and bond angles of the methyl and amino groups were assumed to be the same as those of 9-methyladenine.

The Faraday B term of a transition from the ground state, a, to the excited state, j, is given by:[23]

$$B_{j\leftarrow a} = \sum_{k\neq a,j} B_{j,k} + \sum_{k\neq a,j} B_{k,a} + B_{j,a} \quad (5)$$

$$B_{j,k} = \mathrm{Im}\langle j|\boldsymbol{\mu}|k\rangle\cdot\langle a|\boldsymbol{m}|j\rangle \times \langle k|\boldsymbol{m}|a\rangle/(E_k-E_j) \quad (6)$$

$$B_{k,a} = \mathrm{Im}\langle k|\boldsymbol{\mu}|a\rangle\cdot\langle a|\boldsymbol{m}|j\rangle \times \langle j|\boldsymbol{m}|k\rangle/(E_k-E_a) \quad (7)$$

$$B_{j,a} = \mathrm{Im}\langle j|\boldsymbol{\mu}|a\rangle\cdot\langle a|\boldsymbol{m}|j\rangle \times (\langle j|\boldsymbol{m}|j\rangle-\langle a|\boldsymbol{m}|a\rangle)/(E_j-E_a) \quad (8)$$

In Eqs. 6—8, $\boldsymbol{m}$ and $\boldsymbol{\mu}$ are the electric and magnetic moment operators respectively, and E_a, E_j, and E_k are energies of the a, j, and k states respectively. $B_{j,k}$ stands for the magnetic mixing of the k state with the excited state, j, and $B_{k,a}$ represents the coupling of the k state to the ground state, a. $B_{j,a}$ arises from the magnetic mixing between the ground state, a, and the excited state, j.

The electric transition moments were evaluated by the dipole length method. The LCAO-MO coefficients regarding the orthogonalized INDO atomic orbital basis were deorthogonalized by the inverse Löwdin transformation[24], and the atomic integrals

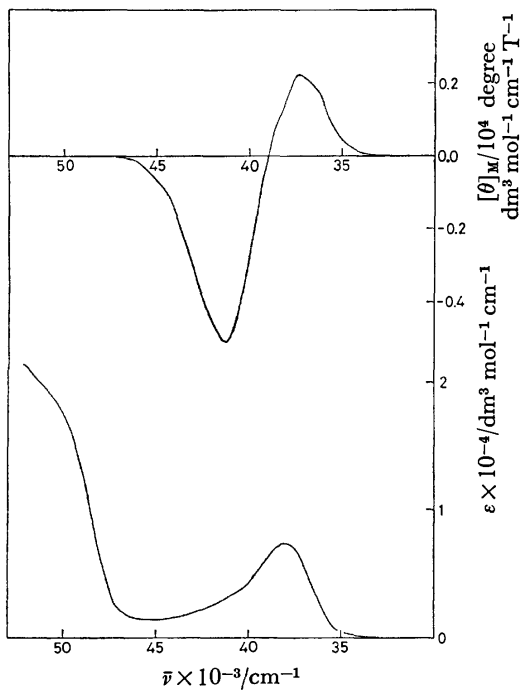

Fig. 1. MCD (upper) and absorption (lower) spectra of purine in aqueous solution (pH 7) at room temperature.

were calculated using Slater atomic orbitals,[25] in accordance with the description of Refs. 26 and 27.

The Faraday B terms calculated for non-centric molecules using a limited basis set are origin-dependent.[28,29] In this work, the origin was placed at the center of the electron cloud in the molecule, according to the theoretical argument of Caldwell and Eyring.[29]

Computations were carried out using an ACOS 700 computer in the computer center of Tohoku University.

Results and Discussion

The MCD and absorption spectra of purine are presented in Fig. 1. The molar ellipticity $[\theta]_M$ per unit of magnetic field is shown in degree dm^3 mol^{-1} cm^{-1} T^{-1}. The intense absorption band observed at 38100 cm^{-1} is resolved into two in the MCD spectrum. The positive MCD band is assigned to the lowest $\pi^*\leftarrow\pi$ transition, and the negative one, to the second $\pi^*\leftarrow\pi$ transition.

The results calculated for purine and methylpurines are given in Table 1, along with the experimental data. The experimental values of the Faraday B terms of purine were obtained by a gaussian curve-fitting procedure. The experimental data for methylpurines were taken from the spectra reported by Townsend *et al.*[2] The sign pattern of the MCD of methylpurines is the same as that of purin itself. The transition energies of 7-methylpurine and 9-methylpurine are close to those of purine, whereas the MCD bands of 1-methylpurine and 3-methylpurine are shifted to a lower wavenumber region relative to purine. For purine, 1-methylpurine, 3-methylpurine, and 7-methylpurine, both INDO/S-CI and CNDO/S-CI procedures correctly predict the sign of the MCD spectra and the band positions of these compounds. On the other hand, a remarkable difference between the INDO/S-CI result and the CNDO/S-CI result is found for 9-methylpurine. Although the INDO/S-CI procedure explains the sign of the MCD of 9-methylpurine well, the sign of the MCD of 9-methylpurine calculated by the CNDO/S-CI procedure is the opposite of that of the experiments.

In the lowest wavenumber region, two $\pi^*\leftarrow$n transitions with A″ symmetry are predicted. In the MCD and absorption spectra, $\pi^*\leftarrow$n transitions are hidden behind the stronger $\pi^*\leftarrow\pi$ transitions, and none of them is observed separately. However, 7-ribosyl purine exhibits a negative CD band, at 35200 cm^{-1}, which arises from the $\pi^*\leftarrow$n transition.[30] A weak out-of-plane polarized band was observed at 34000 cm^{-1} in the polarized absorption spectrum of the crystal of 7-methylpurine and assigned to the $\pi^*\leftarrow$n transition.[31] The calculated transition energy of the lowest $\pi^*\leftarrow$n transition agrees fairly well with these experimental findings.

The magnitudes of the calculated Faraday B terms of the $\pi^*\leftarrow$n transitions are smaller than those of the $\pi^*\leftarrow\pi$ transitions, except for the fourth $\pi^*\leftarrow$n transition of 1-methylpurine and the second $\pi^*\leftarrow$n transition of 3-methylpurine. The relatively large B terms of the $\pi^*\leftarrow$n transitions of 1- and 3-methylpurines are interpreted as mainly arising from the magnetic coupling of the neighbouring $\pi^*\leftarrow\pi$ state with the $\pi^*\leftarrow$n state.

The experimental and theoretical results for methyladenines are shown in Table 2. The experimental transition energies and Faraday B terms are taken from Ref. 3. The substitution of the amino group on the purine ring reverses the sign of the MCD spectra and causes a slight red shift. The INDO/S-CI procedure takes good account of the sign of the MCD spectra of these methyladenines, except for the lowest $\pi^*\leftarrow\pi$ transition of 7-methyladenine. The CNDO/S-CI method cannot reproduce the sign of three lowest MCD bands of 7-methyladenine.

The effects of the bonding parameter of the nitrogen atom, β_N, on the B terms calculated by the INDO/S-CI procedure are given in Table 3. In the INDO/S-CI calculation, the signs of the Faraday B term of 7-methyladenine are sensitive to the bonding parameter of the nitrogen atom, β_N. The unsatisfactory results for the sign of the lowest MCD band of 7-methyladenine are improved by increasing the value of $|\beta_N|$. We have also calculated the B terms of 7-methyladenine and 9-methylpurine by the CNDO/S-CI method with $\beta_N=-20$ eV and -35 eV. However, the calculated signs of the B terms of these compounds were not improved.

Recently Michl has shown that the sign of the Faraday B term of $\pi^*\leftarrow\pi$ transitions in cyclic π-systems with $(4N+2)\pi$ electrons can be predicted by a simple rule.[5] The sign of the B term of the lowest $\pi^*\leftarrow\pi$ transition is the same sign as the difference in the energy gap of the two lowest unoccupied molecular orbitals (ΔLUMO) from that of the two highest occupied molecular orbitals (ΔHOMO), (ΔHOMO—

a) Ref. 3.

ΔLUMO). Although the purine derivatives may deviate somewhat from the weakly perturbed 10 electron annulenes, it is a fact that the energy of the frontier molecular orbitals is an important factor in determining the sign of the MCD spectra. The values of (ΔHOMO−ΔLUMO) calculated by the INDO/S-CI method are negative or almost zero for methylpurines and positive for methyladenines. However, the CNDO/S-CI method predicts a large positive value for the difference, (ΔHOMO−ΔLUMO), of 9-methylpurine, leading to the positive B value for the lowest $\pi^*\leftarrow\pi$ transition.

The two LUMO's and the two HOMO's of 9-methylpurine obtained from the INDO/S calculation are shown in Fig. 2. The LCAO-MO coefficients obtained by the CNDO/S method are analogous to

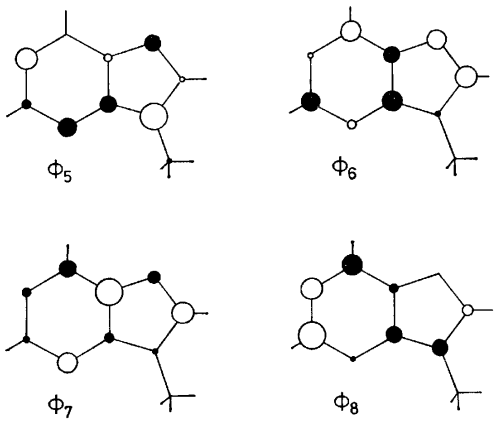

Fig. 2. LCAO-MO coefficients of the highest occupied π molecular orbitals, ϕ_5 and ϕ_6, and the lowest unoccupied π molecular orbitals, ϕ_7 and ϕ_8 of 9-methylpurine. White and black circles represent positive and negative signs, respectively.

those obtained by the INDO/S method and so are not shown here. The orbital energies of the HOMO, ϕ_6, and the LUMO's, ϕ_7 and ϕ_8, calculated by the CNDO/S method are almost the same as those calculated by the INDO/S method, whereas the CNDO/S method predicts the energy of the molecular orbital, ϕ_5, to be lower by 0.53 eV than that calculated by the INDO/S method. This is because the CNDO/S method does not discriminate the energy of one π-electron in the pyrrole-type nitrogen atom having two π-electrons from that in the pyridine-type nitrogen atom with one π-electron, and gives poor results for the energy of the molecular orbital, ϕ_5, in which the LCAO-MO coefficients of the nitrogen atoms are larger than in other molecular orbitals; although the semi-empirical valence-state ionization potentials, $I_p\{N(SP^2PP)\rightarrow N(SPPP)\}$ and $I_p\{N(SP^2PP)\rightarrow N(SP^2P)\}$, are 12.48 eV and 14.42 eV respectively,[16] the CNDO/S method does not distinguish between them.

The INDO/S-CI procedure is superior to the CNDO/S-CI procedure in that the former can discriminate the ionization potential of the pyrrole-type nitrogen atom from that of the pyridine-type nitrogen atom, and predicts correct signs of the Faraday B terms of 9-methylpurine and 7-methyladenine.

This work was supported in part by a grant from the Japan Society for the Promotion of Science.

Studies of the Magnetic Circular Dichroism and Tautomerism of Pyridinols (Pyridinones) and Pyrimidinols (Pyrimidinones)

Akira KAITO and Masahiro HATANO*

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Sendai 980

(Received February 4, 1980)

The magnetic circular dichroism(MCD) spectra of pyridinols (pyridinones) and pyrimidinols (pyrimidinones) were measured in the wavenumber region of 27000—50000 cm^{-1}. The transition energies, the oscillator strengths, and the Faraday B terms were calculated within the framework of the INDO/S-CI approximation. The calculated results for the $\pi^* \leftarrow \pi$ transitions were in good agreement with the experimental results. The lactim-lactam tautomerism of 3-pyridinol(3(1H)-pyridinone) and 2-pyrimidinol (2-pyrimidinone) was discussed.

The electronic structures of the derivatives of pyridine and pyrimidine have been extensively studied by many investigators.[1-11] In particular, some of these compounds, such as uracil, cytosine, thymine, and vitamin B_6, have attracted special interest because of their biological importance. The ultraviolet spectra of the pyridine and pyrimidine derivatives have been interpreted[2-5, 7-10] by means of SCF-MO calculations of the Pariser-Parr-Pople(PPP) procedure[12] and the complete neglect of the differential overlap (CNDO) method.[13,14]

Considerable attention has also been paid to the problem of tautomerism between lactam and lactim forms, which can be expected in these heterocyclic compounds because of the presence of labile hydrogen atoms. Mason and his co-workers have investigated pyridinol-pyridinone and pyrimidinol-pyrimidinone tautomerism in aqueous solutions by the measurements of the UV-absorption spectra.[1] The measurements of the UV and IR spectra have suggested that some of the hydroxy derivatives of pyrimidine favor the lactam-pyrimidinone forms.[15] The tautomerism of 4-pyrimidinol(4-pyrimidinone) and 4,6-pyrimidinediol(6-hydroxy-4-pyrimidinone, *etc.*) has been investigated by NMR spectroscopy.[16,17] The tautomeric stability of substituted pyridines and pyrimidines has been discussed on the basis of the SCF-MO calculation in the CNDO/2 approximation.[11]

On the other hand, magnetic circular dichroism (MCD) spectroscopy has made remarkable progress in providing valuable information on the electronic structures of ions and molecules.[18,19] The MCD spectra of derivatives of pyrimidine and purine and other heterocyclic compounds have been reported, and the electronic and molecular structures of these compounds studied.[20-26] In addition, the signs and magnitudes of the MCD spectra of azines,[22] azanaphthalenes,[23] aza-replaced alternant hydrocarbons,[24] indole,[25] and purine derivatives[26,27] have been calculated by the quantum mechanical SCF-MO procedures.

More recently, Jonas and Michl have reported the MCD spectra of pyridinones and pyrimidinones and interpreted them in terms of the π-electron theory.[28] Although the present work partially overlaps with their work, they have investigated mainly the keto forms of these compounds in acetonitrile solutions.

In this work we measured the MCD spectra of 2- and 4-pyridinols(2- and 4-pyridones), 3-pyridinol(3-(1H)-pyridinone), 2- and 4-pyrimidinols(2- and 4-pyrimidinones), and uracil, both in aqueous and in relatively nonpolar solvents. We also calculated the signs and the magnitudes of the MCD of the tautomers of these pyridine and pyrimidine derivatives within the framework of the intermediate neglect of the differential overlap (INDO) procedure.[29,30] The lactam-lactim tautomerism of these heterocyclic compounds is also discussed.

Experimental

The 2-pyridinol(2-pyridone), 3-pyridinol(3(1H)-pyridinone), and 4-pyrimidinol(4-pyrimidinone) were purified by recrystallization from benzene. The 4-pyridinol(4-pyridone) and uracil were also recrystallized from water. The 2-pyrimidinol(2-pyridone) was liberated with sodium hydroxide from its hydrochloride and was purified by vacuum sublimation and recrystallization from ethanol. Spectro-grade dioxane, heptane–dioxane (7:3 in volume), ethanol, and a phosphate buffer solution (pH 6—7) were used as solvents.

The MCD spectra were recorded with a JASCO J-20A recording circular dichrometer equipped with a 1.25 T electromagnet. The absorption spectra were measured on a Hitachi EPS-3T recording spectrophotometer.

The experimental values of the Faraday B terms were obtained from the MCD spectra by the use of the method of moments,[18] after the overlapping bands had been resolved by the Gaussian curve-fitting procedure.

Theoretical

The wavefunctions obtained from the INDO/S-CI approximation were used for calculating the Faraday B terms. The bonding parameter for the oxygen atom was determined so that the transition energies of some ketones are well reproduced ($\beta_0 = -31$ eV). The other parameters of the INDO/S calculation are the same as those of the previous work.[27] The configuration interaction among singly excited configurations below 12 eV was taken into consideration.

The molecular structures of uracil and 2-pyrimidinone were taken from the experimental data[31,32] obtained by the X-ray crystal analysis. However, no experimental data have been reported for the remaining compounds. The bond lengths and bond angles of pyridinones and 4-pyrimidinone were taken from those of 2-pyrimidinone.[32] The molecular structures of 3-pyridinol and 2-pyrimidinol were estimated from those of pyridine, pyrimidine, and phenol.

The Faraday B terms were calculated according to the expression derived by Buckingham and Stephens.[18]

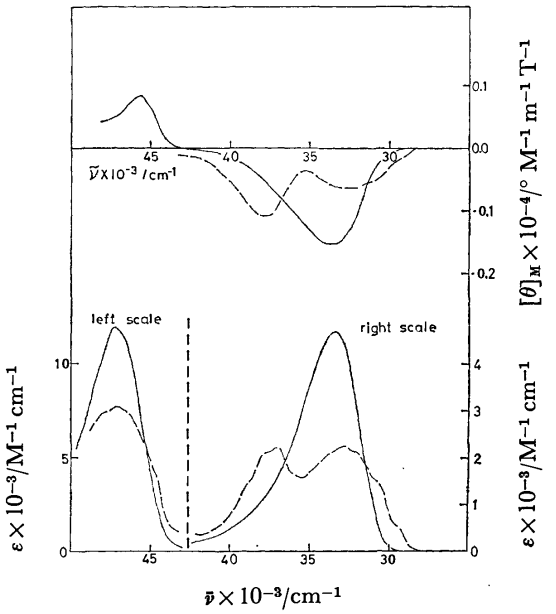

Fig. 2. MCD (upper) and absorption (lower) spectra of 2-pyrimidinol (2-pyrimidinone) in aqueous (——) and heptane-dioxane (7:3 in volume) (----) solutions.

The details of the calculation of the *B*-terms were reported in a previous paper.[27]

Results and Discussion

The experimental MCD and absorption spectra of 3-pyridinol(3(1*H*)-pyridinone) are presented in Fig. 1. The molar ellipticity $[\theta]_M$ per unit of magnetic field is shown in ° M^{-1} m^{-1} T^{-1}, and the molar extinction coefficient, ε, in M^{-1} cm^{-1} (1 M=1 mol dm^{-3}).

Four electronic transitions are identified in the MCD and absorption spectra of 3-pyridinol (3(1*H*)-pyridinone) in an aqueous solution, while only two bands are observed in an ethanol solution. The lactim 3-pyridinol and lactam 3(1*H*)-pyridinone forms have been shown to exist in equilibrium in an aqueous solution.[1] The two MCD bands observed at 36400 cm^{-1} and 45800 cm^{-1} in an ethanol solution are assigned to the $\pi^*\leftarrow\pi$ transitions of the lactim 3-pyridinol form. On the other hand, the two MCD bands at 32000 cm^{-1} and 41100 cm^{-1} which appear in an aqueous solution are attributable to the $\pi^*\leftarrow\pi$ transitions of the lactam 3(1*H*)-pyridinone form.

The MCD and absorption spectra of 2-pyrimidinol (2-pyrimidinone) are presented in Fig. 2. 2-Pyrimidinol (2-pyrimidinone) exhibits positive and negative MCD bands at 34300 cm^{-1} and 47400 cm^{-1} respectively in an aqueous solution. It has been shown by a UV spectrographic comparison with 1-methyl-2-pyrimidinone that 2-pyrimidinol (2-pyrimidinone) predominantly exists in the lactam 2-pyrimidinone form in an aqueous solution.[1] On the other hand, in a heptane-dioxane (7:3 in volume) solution the lowest MCD bands decrease in intensity, and a new negative MCD band appears at 37400 cm^{-1} (Fig. 2), This band can reasonably be assigned to the lowest $\pi^*\leftarrow\pi$ transitions of the lactim 2-pyrimidinol form, which is in equilibrium with the lactam 2-pyrimidinone form in heptane–dioxane (7:3 in volume).

The MCD spectra of the remaining compounds were in agreement with those reported by Jonas and Michl.[28]

The experimental and calculated results are summarized in Table 1. The calculated transition energies of 3(1*H*)-pyridinone are much smaller than the experimental ones. A similar difficulty has been met with in the CNDO/S-CI calculation reported by Cignitti and Paoloni.[8] They have also reported that the lowest absorption band of 3(1*H*)-pyridinone, observed at 32000 cm^{-1} in an aqueous solution, shows a large hypsochromic shift in a saturated cyclohexane solution.[8] The solvent shift can be explained by the fact that ground state has a larger dipole moment than the low-lying excited states and is stabilized by the dipole-dipole interaction with the polar solvent. However, the calculated results for the $\pi^*\leftarrow\pi$ transitions of the remaining compounds are in satisfactory agreement with the experimental data. In particular, the calculated signs of the Faraday *B* terms agree perfectly with the experimental results. The signs of the Faraday *B* terms of the first and second $\pi^*\leftarrow\pi$ transitions are positive and negative respectively, both for the lactam form and for the lactim form.

On the other hand, several $\pi^*\leftarrow$n transitions are predicted in the ultraviolet region. The lowest $\pi^*\leftarrow$n transition of pyridinones and pyrimidinones is characterized by the transition from the nonbonding 2p orbital of oxygen to the unoccupied π orbitals. The second $\pi^*\leftarrow$n transition of pyrimidinones and the low-lying $\pi^*\leftarrow$n transitions of 3-pyridinol and 2-pyrimidinol correspond to the transition from the nonbonding orbital of the aza nitrogen atom to unoccupied π orbitals.

Although the first $\pi^*\leftarrow$n transition of pyridinone and pyrimidinone is predicted in the wavenumber

region of 21000—27000 cm^{-1}, no distinct MCD or absorption band is found in this spectral region. The first $\pi^*\leftarrow$n transition is probably hidden behind the tail of the lowest absorption band; otherwise, it has too small an intensity to be observed. It should be noted that the calculated transition energy of the lowest $\pi^*\leftarrow$n transition of these compounds is not very reliable, because it has been shown to be sensitive to the choice of the two-center electron repulsion integrals.[8)]

We have calculated the magnetic mixing among excited electronic states caused by the external magnetic field. The Faraday B terms of the two lowest $\pi^*\leftarrow\pi$ transitions proved to be mainly induced by the magnetic mixing between the two lowest $\pi^*\leftarrow\pi$ states, leading to the opposite sign of the B terms of these transitions. The magnetic mixing between the $\pi^*\leftarrow\pi$ state and the $\pi^*\leftarrow$n state is small except when the energy separation of the two states is very small, and it does not make a large contribution to the MCD spectrum.

The Application of Magnetic Circular Dichroism to the Study of the Tautomerism of Cytosine and Isocytosine

Akita KAITO, Masahiro HATANO,* Toru UEDA,** and Susumu SHIBUYA**

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Sendai 980

*** Faculty of Pharmaceutical Science, Hokkaido University, Sapporo 060*

(Received March 5, 1980)

The MCD and absorption spectra of cytosine and isocytosine and their *N*-substituted derivatives were measured in the wave-number region of 30000—50000 cm^{-1}. On the basis of the experimental results, the tautomerism of cytosine and isocytosine was discussed. The transition energies, the oscillator strengths, and the Faraday *B* terms of the tautomeric forms of cytosine and isocytosine were calculated within the framework of the intermediate neglect of the differential overlap(INDO) approximation. The calculated results are in good agreement with the experimental data.

The magnetic circular dichroism (MCD) spectra of purine and pyrimidine derivatives, which are the constituents of nucleic acids, have been extensively studied by many investigators.[1-4] Some overlapping absorption bands have been resolved in the MCD spectra, and valuable information about the electronic structure of these compounds has been obtained. Recently, also quantum mechanical calculations of the MCD of some purine derivatives[4,5] and pyrimidine derivatives[6] have been reported.

On the other hand, the minor tautomers of nucleic acid bases are biological interest because they have been considered to be a source of the imperfect base pairing which leads to genetic mutations.[7] The tautomerism of cytosine in solution has been studied by the aid of the electronic absorption spectra.[8-10] Morita and Nagakura[10] have shown that, in an aqueous solution, cytosine takes the [1*H*]-2-keto 4-amino form(I) at room temperature, but with a rise in the temperature the 2-keto 4-imino form(II) coexists with Form I, while cytosine takes Form I and Form II in trimethyl phosphate and in acetonitrile respectively. It has been proposed from the unusual line broadening of the NMR spectra of the H5 proton of cytosine that Form II coexists with Form I to the extent of 15±3% at room temperature in a neutral aqueous solution of cytosine.[11] However, Wong[12] has shown that the line broadening is caused by the paramagnetic impurities, and this has raised questions about the existence of 15% of the minor tautomer of cytosine, Form II, at room temperature in a neutral aqueous solution.

The tautomerism of isocytosine has also been extensively studied by measurements of the electronic absorption spectra.[9,10,13] It has been shown that isocytosine takes the [3*H*]-2-amino 4-keto form(IV) in ethanol and in a diethyl ether solution, but in an aqueous solution, the [1*H*]-2-amino 4-keto form(V) coexists with Form IV.[9,10,13]

The tautomeric forms of cytosine and isocytosine in the crystalline state are of interest. X-Ray crystal analysis studies have shown that cytosine takes Form I in crystals,[14] while Forms IV and V coexist at a ratio of 1:1 in the isocytosine crystal.[15]

In this work, we measure the MCD spectra of cytosine, isocytosine, and their derivatives and discuss the tautomerism of cytosine and isocytosine on the basis of the MCD spectra. We also calculate the Faraday *B* terms of three tautomers of cytosine and two tautomers of isocytosine, which are shown in Fig. 1, using wavefunctions obtained by the intermediate neglect of the differential overlap (INDO) procedure.[16,17]

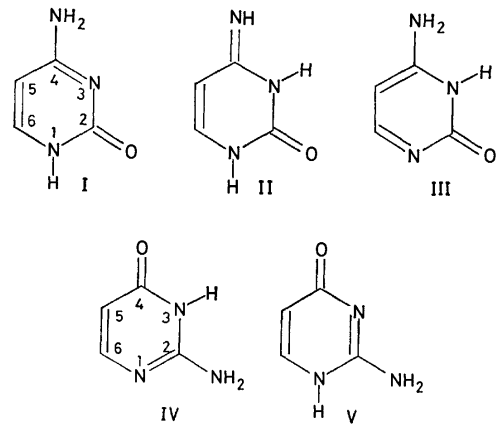

Fig. 1. Tautomeric forms of cytosine and isocytosine.

Experimental

Cytosine and isocytosine were purified by recrystallization from water. 3-Methylcytosine and 3-methylcytidine methosulfate were also recrystallized from a methanol-ethyl acetate solution. 3-Methylisocytosine was prepared according to the procedure by Angier and Curran.[18] Isocytosine was synthesized by the ammonolysis of 2,5′-cyclouridine.[19]

Acetonitrile, ethanol, a Na_2HPO_4–KH_2PO_4 buffer solution(pH 7), and a NaOH–Na_2HPO_4 buffer solution(pH 11) were used as solvents. The pH values of the buffer solutions were controlled so that the neutral form was dominant.

The MCD spectra were recorded with a JASCO J-20A recording circular dichrometer equipped with a 12.5 kG electromagnet. The absorption spectra were measured on a Hitachi EPS-3T recording spectrophotometer.

The experimental values of the Faraday *B* terms were obtained by the gaussian curve-fitting procedure or the method of moments.

Theoretical

The Faraday *B* terms were calculated using wavefunctions obtained by the INDO/S-CI approximation.[16,17] The bonding parameter of the oxygen atom, β_0, was determined so that the transition energies of the $\pi^* \leftarrow \pi$ transitions of some ketones were well reproduced ($\beta_0 = -31$ eV). The other parameters in

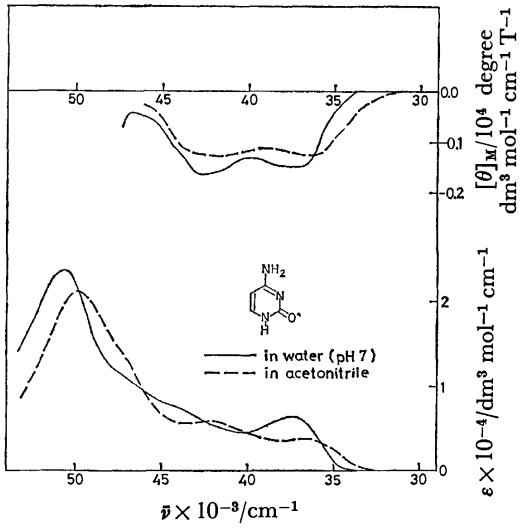

Fig. 2. MCD (upper) and absorption (lower) spectra of cytosine in aqueous solution (pH 7) (——) and in acetonitrile (– – –) at room temperature.

the calculation were described in a previous paper.[5]

The molecular structures of Form I of cytosine and Forms IV and V of isocytosine were taken from the experimental data obtained by X-ray crystal analysis.[14,15] The bond lengths and bond angles of Forms II and III of cytosine were estimated from the experimental values of Forms I, IV, and V.[14,15]

The configuration interaction among singly excited configurations below 12 eV was taken into account.

The Faraday B terms were calculated according to the expression derived by Buckingham and Stephens.[20] The procedures of the calculation of the Faraday B terms have been reported in the previous paper.[5]

Results and Discussion

The MCD and absorption spectra of cytosine are shown in Fig. 2. The molar ellipticity per unit of the magnetic field, $[\theta]_M$, is expressed by 10^4 degree dm^3 mol^{-1} cm^{-1} T^{-1} unit, and the extinction coefficient, ε, by dm^3 mol^{-1} cm^{-1} unit. The spectra in the aqueous solution are in agreement with those measured by Voelter *et al.*[1] In the wavenumber region of 32000—46000 cm^{-1}, two negative MCD bands are observed. In the absorption spectrum, we can observe an intense peak and a shoulder at 50700 cm^{-1} and at about 47000 cm^{-1} respectively, while no distinct MCD band is detected in the wavenumber region of 47000—50000 cm^{-1}. The MCD and absorption spectra in an acetonitrile solution are red-shifted and decrease in intensity relative to the spectra in an aqueous solution.

The MCD, CD, and absorption spectra of 3-methylcytidine methosulfate in an aqueous solution (pH 11) are presented in Fig. 3. 3-Methylcytidine shows a negative MCD band and a positive MCD band at 37400 cm^{-1} and at 43400 cm^{-1} respectively.

On the other hand, Morita and Nagakura[10] have concluded that the most stable form of cytosine in acetonitrile is Form II. The MCD and absorption

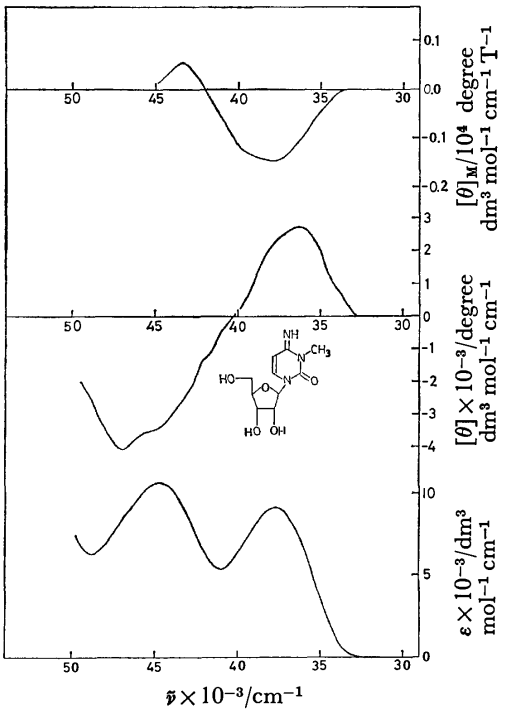

Fig. 3. MCD (top), CD (middle), and absorption (bottom) spectra of 3-methylcytidine in aqueous solution (pH 11) at room temperature.

spectra of Form II should resemble those of 3-methylcytidine, because the tautomeric form of 3-methylcytidine is fixed to Form II. However, the sign of the second MCD band of cytosine in acetonitrile is the opposite of that of 3-methylcytidine. In addition, the absorption spectrum of cytosine in acetonitrile is not very similar to that of 3-methylcytidine with respect to the absorption intensity and the position of the absorption peak observed in the wavenumber region higher than 40000 cm^{-1}. The MCD spectrum of cytosine in acetonitrile resembles that of cytosine in an aqueous solution rather than the MCD spectrum of 3-methylcytidine.

These results suggest that the most stable tautomer of cytosine is Form I, not only in a neutral aqueous solution, but also in acetonitrile. We can consider several reasons for the solvent dependence of the MCD and absorption spectra of cytosine: a change in the polarity of the solvent, the specific interaction of the cytosine molecule with the solvent molecules, such as the formation of hydrogen bonding, the association of cytosine molecules, or the contamination of small amount of minor tautomers.

The MCD and absorption spectra of 3-methylcytosine, whose tautomeric form is fixed to Form III,[21] are shown in Fig. 4. Morita and Nagakura[10] have reported that Form III coexists with Forms I and II, to a much smaller extent, in an acetonitrile solution of cytosine at a higher temperature. The sign pattern of the MCD spectrum of 3-methylcytosine is the same as that of 3-methylcytidine (Form II), while the lowest MCD and absorption bands lie at lower wavenumbers than those of cytosine (Form I) and 3-methylcytidine (Form II). The presence of

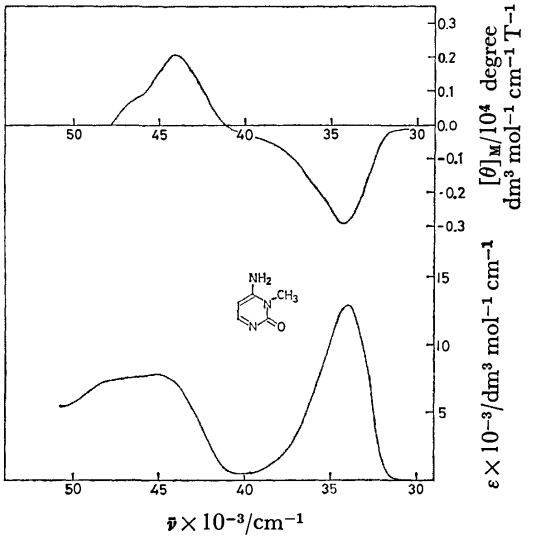

Fig. 4. MCD (upper) and absorption (lower) spectra of 3-methylcytosine in aqueous solution (pH 11) at room temperature.

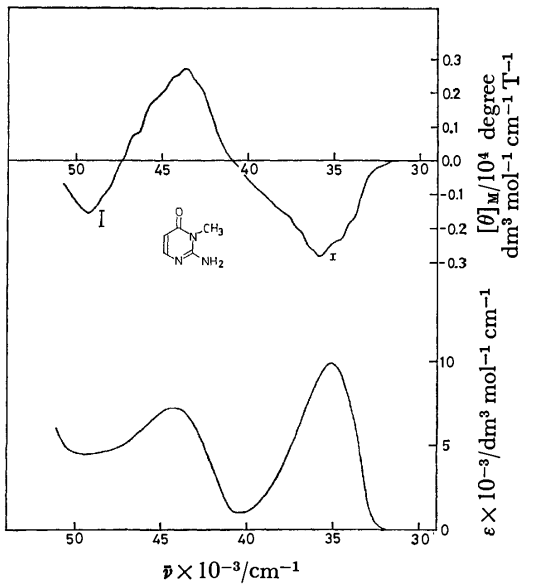

Fig. 5. MCD (upper) and absorption (lower) spectra of 3-methylisocytosine in aqueous solution (pH 7) at room temperature.

Form III in cytosine is not confirmed by the results of this work.

The MCD and absorption spectra of 3-methylisocytosine, whose tautomeric form is fixed to Form IV, are exhibited in Fig. 5. The MCD and absorption spectra of 3-methylisocytosine are very similar to those of 3-methylcytosine, because these two compounds have the same valence-bond structure.

The MCD, CD, and absorption spectra of isocytidine, whose tautomeric form is fixed to Form V, are shown in Fig. 6. Although the lowest negative MCD band almost corresponds to the lowest absorption band at 39100 cm^{-1}, the second negative MCD band lies intermediate between the absorption peak at 48500 cm^{-1} and a shoulder at 43600 cm^{-1}.

The MCD and absorption spectra of isocytosine in

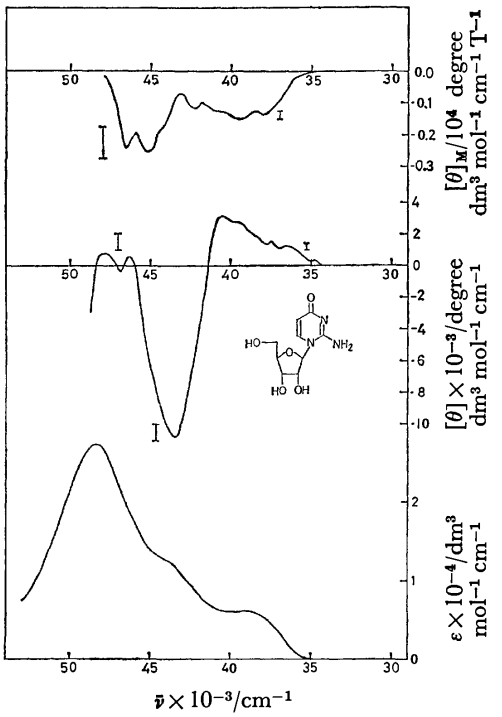

Fig. 6. MCD (top), CD (middle), and absorption (bottom) spectra of isocytidine in aqueous solution (pH 7) at room temperature.

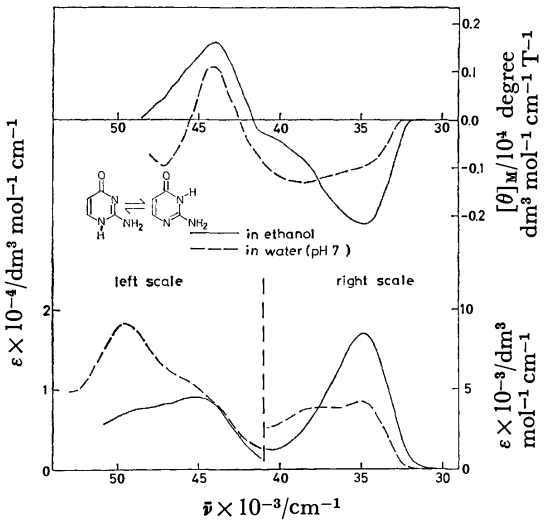

Fig. 7. MCD (upper) and absorption (lower) spectra of isocytosine in aqueous solution (pH 7) (– – –) and in ethanol (——) at room temperature.

an ethanol and in an aqueous solution (pH 7) are shown in Fig. 7. In the ethanol solution, negative and positive MCD bands are observed at 35400 cm^{-1} and at 44500 cm^{-1} respectively. The MCD and absorption spectra of isocytosine in ethanol resemble those of 3-methylisocytosine, suggesting that the prevailing tautomeric form of isocytosine in ethanol is Form IV. In the aqueous solution, the two MCD bands at 35400 cm^{-1} and at 44500 cm^{-1} decrease in intensity, and two negative MCD bands appear at about 38700 cm^{-1} and at 47200 cm^{-1}. These MCD bands appearing in the aqueous solution are analogous to the MCD bands of isocytidine, and they can rea-

sonably be assigned to the MCD bands of Form V. Thus, the MCD spectrum of isocytosine in an aqueous solution can be well interpreted by assuming that Form V is in equilibrium with Form IV in an aqueous solution of isocytosine.

The calculated transition energies, oscillator strengths, and Faraday B terms of Forms I—V are listed in Table 1, along with the experimental values. It should be noted that the positive B terms give negative MCD bands. In the ultraviolet region, the present calculation predicts three or four $\pi^* \leftarrow \pi$ transitions for Forms I—V; these transitions can reasonably be assigned to the peaks and the shoulder observed in the absorption and MCD spectra. On the other hand, several transitions with A″ symmetry are predicted below 50000 cm^{-1}. Most of them are characterized by a transition from the nonbonding orbitals of carbonyl oxygen and azanitrogen to the unoccupied π orbitals. Although the lowest $\pi^* \leftarrow$n transition of Form V is predicted at a much lower wavenumber than the lowest $\pi^* \leftarrow \pi$, no MCD or absorption band assignable to the lowest $\pi^* \leftarrow$n transition is identified.

A large B value is predicted for the second $\pi^* \leftarrow$n transition of Form III, whose oscillator strength is much smaller than that of the $\pi^* \leftarrow \pi$ transitions. The large B term of the second $\pi^* \leftarrow$n transition is mainly induced by the magnetic mixing of the second $\pi^* \leftarrow$n state with the first $\pi^* \leftarrow \pi$ state, which lies close to the second $\pi^* \leftarrow$n state, and this large B term is partially cancelled out by the negative B term of the first $\pi^* \leftarrow \pi$ transition in the MCD spectrum; the net contribution to the MCD spectrum from these two electronic transitions is about $+12.2 \times 10^{-4}$ βD^2 cm.

The calculated values of the transition energies and the oscillator strengths of the $\pi^* \leftarrow \pi$ transitions of Forms I—V are in good agreement with the experimental values. The magnitudes of the experimental B terms of the second MCD band of cytosine are larger than the theoretical B values of the electronic transitions predicted in the spectral region of 42000—45000 cm^{-1}. The second $\pi^* \leftarrow \pi$ transition of Form V, whose B term is predicted to be negative and large, is not identified in the MCD spectrum of isocytidine. However, the agreement between the calculation and the experiment is satisfactory as a whole.

In order to study the effect of the methylation at the nitrogen atom on the calculated results, we have carried out a similar calculation for 3-methyl-4-imino-2-pyrimidinone (the N-methylated derivative of Form II) and for 3-methylisocytosine (the N-methylated derivative of Form IV); the results are shown in Table 2. The calculated transition energies of the N-methylated compounds tend to be slightly smaller than those of Form II and Form IV themselves. The calculated energy difference between the second and the third $\pi^* \leftarrow \pi$ transitions of Form II becomes smaller upon N-methylation, which increases the magnetic mixing between the second and the third $\pi^* \leftarrow \pi$ states. However, the calculation shows that the spectral features of Form II and Form IV are not much affected by the N-methylation.

Liquid Crystal Formation in Binary Systems. II. Induction of Nematic and Smectic Phases by Electron Donor-Acceptor Interaction between the *p*-Dimethylamino and *p*-Nitro Derivatives of *N*-Benzylideneaniline

Kotaro Araya and Yoshio Matsunaga*

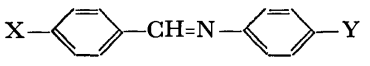
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received February 28, 1980)

The formation of solid molecular complexes and the induction of nematic and smectic phases have been demonstrated with a number of binary mixtures of potentially-mesomorphic electron donors and acceptors of the type *N*-(*p*-X-benzylidene)-*p*-Y-aniline. One of the components contains a dimethylamino group as X or Y, and the other a nitro group as X or Y. The remaining substituents are methoxyl, ethoxyl, or propoxyl groups. The maximum temperature of the nematic phase induced in these electron donor-acceptor systems is higher by 23 to 45 °C than the straight line joining the latent transition temperatures of the two components. The tendency to form a solid complex and that to induce a nematic phase are both shown to a large extent by the propoxy derivatives, to a lesser extent by the methoxy derivatives, and least by the ethoxy derivatives. All the solid molecular complexes are reddish brown and exhibit an additional electronic absorption band located at about 500 nm. The mesophases are similarly colored. The enhanced thermal stability of the nematic and smectic phases in these binary mixtures is ascribed to the complex formation by an electron donor-acceptor interaction.

The liquid crystalline state is a state of matter intermediate between crystalline solids and isotropic liquids. Intermolecular attractions are supposed to be essential for producing the parallel molecular arrangement characteristic of such a state. If the interactions are not strong enough to produce the orientation, the compound may be monotropically mesomorphic. Upon heating such a compound, the crystalline solid melts to an isotropic liquid but the latter may undergo the transition to a liquid crystal if it is sufficiently supercooled. Even when the expected metastable liquid crystalline state is not achieved, the compound may be considered to be potentially mesomorphic. This paper deals mostly with the compounds of the last category. It seemed likely to us that the parallel molecular arrangement required by liquid crystal formation should become observable in the binary systems consisting of potentially mesomorphic compounds if the orientational cohesive forces were supplemented by an electron donor-acceptor interaction. This sort of intermolecular force may particularly suit the alignment of the planar component molecules. The enhancement of nematic-phase stability found by Park *et al.* with the binary system of *N*-(*p*-methoxybenzylidene)-*p*-butylaniline and 4-cyano-4′-pentylbiphenyl and several other, closely related systems is apparently in support of our postulate.[2,3] They have attributed the increased thermal stability to molecular complexing by a weak electron donor-acceptor interaction. A similar observation has been made by us with the azoxydianisole-*N*-(*p*-nitrobenzylidene)-*p*-anisidine mixtures.[1] It must be noted that both or one of the component compounds in these systems are enantiotropically mesomorphic, in contrast to those to be described in this paper.

Because of the simplicity of molecular structure and the ease of preparations, *N*-(*p*-X-benzylidene)-*p*-Y-aniline



lines were chosen for the present study. In order to maximize the proposed intermolecular attraction, a dimethylamino group was introduced to one of the components, which is regarded as the electron donor, and a nitro group to the other, which is regarded as the electron acceptor. The remaining terminal groups were selected from short alkoxyl groups: namely, methoxyl, ethoxyl, and propoxyl groups, to avoid making the component compounds themselves mesomorphic.

Experimental

Materials. The *N*-benzylideneanilines listed in Table 1 were prepared by a condensation reaction between a *p*-X derivative of benzaldehyde and a *p*-Y derivative of aniline, and were purified by repeated recrystallization from a suitable solvent and by sublimation in a vacuum if necessary. Hereafter, the compounds are represented by their terminal groups (X,Y). Binary mixtures in known proportions were melted in small test tubes, shaken well to insure homogeneity, and then rapidly cooled.

Measurements. The calorimetric curves were recorded on a Rigaku Thermoflex differential scanning calorimeter during the processes of heating and cooling. The heating rate in this work was 2.5 °C min^{-1}. The temperature was calibrated as described in a previous paper.[1] The induced mesophases were identified by examining the texture with the aid of a polarizing microscope and/or by studying the continuous miscibility with a reference mesophase. The diffuse reflectance of the solid component compounds and molecular complexes was measured by means of a Beckman DK 2A spectroreflectometer. The spectrum was then plotted using the Kubelka-Munk function.

Results and Discussion

Methoxy Derivatives. The phase diagrams of all the possible electron donor-acceptor combinations of the methoxy derivatives are presented in Fig. 1. The open and shaded circles indicate the transitions found during the processes of heating and cooling respectively. Therefore, the phase appearing below the transition, indicated solely by shaded circles, is metastable. The shaded circles are omitted when they coincide exactly with the open circles. The systems of (dimethylamino, methoxy) with (nitro, methoxy) and also of (methoxy,

Phase diagrams of (a) the *N*-[*p*-(dimethylamino) benzylidene]-*p*-anisidine–*N*-(*p*-nitrobenzylidene)-*p*-anisidine, (b) *N*-(*p*-methoxybenzylidene)-*p*-(dimethylamino)aniline–*N*-(*p*-nitrobenzylidene)-*p*-anisidine, (c) *N*-[*p*-(dimethylamino)benzylidene]-*p*-anisidine–*N*-(*p*-methoxybenzylidene)-*p*-nitroaniline, and (d) *N*-(*p*-methoxybenzylidene)-*p*-(dimethylamino)aniline–*N*-(*p*-methoxybenzylidene)-*p*-nitroaniline systems. The open and shaded circles are transitions observed in the processes of heating and cooling respectively.

dimethylamino) with (nitro, methoxy) yield only solid 1:1 molecular complexes (see Figs. 1a and 1b). The eutectic points in the former system are located at 128 °C and 18.5 mol% and at 123 °C and 84.5 mol% of the acceptor component. The melting point of the complex is 138.5 °C; this is a few degrees higher than the mean value of those of the components. In the latter system, the eutectic points are found at 125 °C and 26 mol% and at 115.5 °C and 77 mol%. The complex melts congruently at 131 °C. This temperature is several degrees below the straight line joining the melting points of the components. Disregarding small variations in the melting point of the component compounds, one may say that the higher the melting point and the wider the region of the existence of the solid complex (the composition difference between the two eutectics), the more stable is the complex.[9] Therefore, the solid complexes formed in the (dimethylamino, methoxy)–(methoxy, nitro) and (methoxy, dimethylamino)–(methoxy, nitro) systems shown in Figs. 1c and 1d are of considerably lower stability. Note that the composition of the complex in the last system is not 1:1 but 3:2. When the melts of these two systems are supercooled, the isotropic liquid-nematic liquid crystal (I-N) transition curves are partially observable. Since the latent I-N transition temperatures of (dimethylamino, methoxy) and (methoxy, nitro) were estimated as 55 °C and 82 °C respectively by the method to be mentioned in the last paragraph of this paper, the maximum deviation from linearity in the transition temperature is as much as 30 °C at 50 mol%. The corresponding value in the (methoxy, dimethylamino)–(methoxy, nitro) system is not available, but the deviation at 60 mol% is 25 °C. The flat maximum is indicative of a high degree of dissociation of molecular complex in the isotropic liquid phase. The I-N transition curve is observable only in the high mol% range of the acceptor compound. The large temperature difference between the freezing point curve and the metastable I-N transition curve may account for the solidification of supercooled melts without reaching the latter in the left half of the diagram.

Ethoxy Derivatives. As is shown in Fig. 2, all the combinations of the ethoxy derivatives can produce nematic phases. The I-N transition is monotropic in the system of (dimethylamino, ethoxy) with (nitro, ethoxy) but enantiotropic in the other three. The nematic liquid crystals are stable in the hatched areas in Figs. 2b, 2c, and 2d. The I-N transition curves are very much alike. The maximum is located near a 1:1 mole ratio, and is a little above 120 °C in the two systems with (nitro, ethoxy), but a little below 120 °C in the two systems with (ethoxy, nitro). One factor that should not be ignored is the fact that the latent I-N transition in the donor compound occurs at an appreciably higher temperature than that of the corresponding methoxy compounds. The thermal stability enhancement by mixing of the donor and acceptor compounds is therefore not large; it ranges from 23 to 32 °C.

It must be added that the system (dimethylamino,

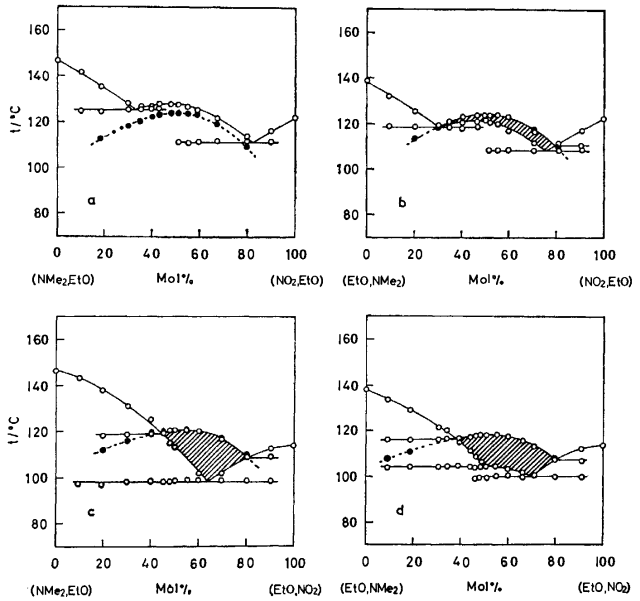

Fig. 2. Phase diagrams of (a) the *N*-[*p*-(dimethylamino)benzylidene]-*p*-phenetidine–*N*-(*p*-nitrobenzylidene)-*p*-phenetidine, (b) *N*-(*p*-ethoxybenzylidene)-*p*-(dimethylamino)aniline – *N*-(*p*-nitrobenzylidene)-*p*-phenetidine, (c) *N*-[*p*-(dimethylamino)benzylidene]-*p*-phenetidine–*N*-(*p*-ethoxybenzylidene)-*p*-nitroaniline, and (d) *N*-(*p*-ethoxybenzylidene)-*p*-(dimethylamino)-aniline–*N*-(*p*-ethoxybenzylidene)-*p*-nitroaniline systems. In the hatched area, the nematic phase is stable. As to the open and shaded circles, see the caption of Fig. 1.

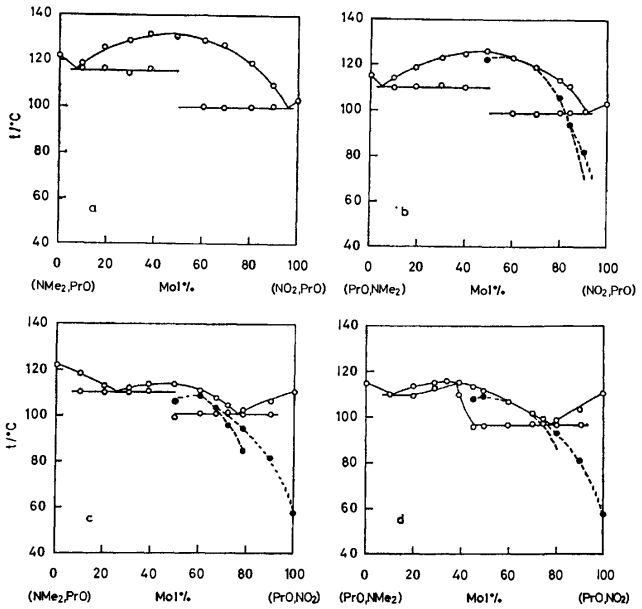

Fig. 3. Phase diagrams of (a) the *N*-[*p*-(dimethylamino)benzylidene]-*p*-propoxyaniline – *N*-(*p*-nitrobenzylidene)-*p*-propoxyaniline, (b) *N*-(*p*-propoxybenzylidene)-*p*-(dimethylamino)aniline – *N*-(*p*-nitrobenzylidene)-*p*-propoxyaniline, (c) *N*-[*p*-(dimethylamino)-benzylidene]-*p*-propoxyaniline – *N*-(*p*-propoxybenzylidene)-*p*-nitroaniline, and (d) *N*-(*p*-propoxybenzylidene)-*p*-(dimethylamino)aniline–*N*-(*p*-propoxybenzylidene)-*p*-nitroaniline systems. As to the open and shaded circles, see the caption of Fig. 1.

ethoxy)–(nitro, ethoxy) shown in Fig. 2a has been studied by Lohar.[8] The agreement in the melting points of the component compounds is good and that in the freezing point curve above 60 mol% of the acceptor compound is fair. He has located a eutectic at 114.5 °C and 83 mol%. These values compare well with ours: namely, 111.5 °C and 82.5 mol%. However, Lohar's freezing point curve below 60 mol% is at significantly higher temperatures. The eutectic we found at 125.5 °C and 33 mol% is missing in his result. In addition, the metastable nematic phase has not been detected at all.

The tendency to form a solid complex is markedly diminished compared with that of the methoxy derivatives. While the region of the existence of the solid complex in the system of (dimethylamino, ethoxy) with (nitro, ethoxy) is 49.5 mol%, that in the system of the corresponding methoxy compounds extends over 66 mol% (compare Figs. 1a and 2a). The fact that the melting point of the complex, 127 °C, is several degrees below the mean value of those of the components reflects also a decreased stability of the solid complex. This tendency is shown most when (dimethylamino, ethoxy) is mixed with (ethoxy, nitro), as is illustrated in Fig. 2c. The resulting phase diagram is of the eutectic type, no solid complex being formed. The complex in the (ethoxy, dimethylamino)–(ethoxy, nitro) system shown in Fig. 2d is also not of high stability. It melts incongruently at 104 °C. Here again, the composition does not appear to be a 1:1 mole ratio.

Propoxy Derivatives. Among the examined alkoxyl groups, the propoxyl group is the substituent which best stabilizes a solid complex. The diagrams illustrated in Fig. 3 indicate the formation of a congruently melting molecular complex in all the systems. The one formed in the (dimethylamino, propoxy)–(nitro, propoxy) system is the most stable, melting at 132 °C (see Fig. 3a). While this value is lower than the melting point of the complex formed in the (dimethylamino, methoxy)–(nitro, methoxy) system shown in Fig. 1a, it is higher by 17 °C than the mean value of those of the components. The eutectic points are at 115.5 °C and 7 mol% and at 100 °C and 96 mol%. As the result, the freezing point curve of the complex occupies a large part of the diagram. No liquid crystalline phase is observed in this system, while the other three systems yield not only nematic but also smectic phases. The difference between the latent I-N transition temperature and the melting point in the acceptor compound is larger than that in the donor compound; nevertheless, the mesophases were found solely on the nitro derivative-rich side. (Propoxy, nitro) is the only compound in this work whose liquid phase could be cooled to the I-N transition temperature without solidification occurring. The melt, which is relatively rich in the donor component, is directly transformed into the smectic phase. In other words, only the isotropic liquid-smectic liquid crystal (I-S) transition curve is observable in such a composition range. The maximum temperatures of nematic and smectic phases in the system containing

(propoxy, nitro) as the acceptor component do not differ much from each other (see Figs. 3c and 3d). These nematic phases are stabilized as much as 40 °C near the maximum with respect to the ideal linear relationship. The latent nematic liquid crystal-smectic liquid crystal (N-S) transition temperatures of the component compounds are not known, but they are certainly located below the I-N transition temperatures. The extrapolation of the N-S transition curve in Fig. 3c to 100 mol% of (propoxy, nitro) suggests that the latent transition temperature of this acceptor compound is not higher than 20 °C.

The thermal stability enhancement of a smectic phase has been reported by several workers in binary mixtures in which both or one of the components give stable nematic liquid crystals.[6,10-12] For example, a paper by Schroeder and Schroeder has referred to the appearance of a smectic phase by mixing of mesomorphic 4,4'-bis(hexyloxy)azoxybenzene and non-mesomorphic (methoxy, nitro).[6] Engelen *et al.* have proposed that such phases be called induced smectic phases.[11] They have concluded that mixtures of terminal polar with terminal nonpolar nematic liquid crystals usually induce smectic phases. While nitro and cyano derivatives are considered to be polar, the derivatives carrying only alkyl and alkoxyl groups are nonpolar. Contrary to these authors' conclusion, Domon and Billard have shown recently that the existence of a strong terminal dipole for only one of the components is not always correlated with the induction of smectic phases.[12] Among the twenty-eight systems listed by them, over ten have been shown to yield an induced smectic phase without a terminal polar compound. Our systems are entirely different from theirs; that is, all our component molecules bear a dimethylamino or nitro group and are strongly polar. Secondly, the nematic phases of the components are metastable with respect to the crystalline phases at any temperature.

General Remarks. As the whole, the tendency of a solid complex formation decreases in the following order:

(dimethylamino, alkoxy)-(nitro, alkoxy) > (alkoxy, dimethylamino)-(nitro, alkoxy) > (alkoxy, dimethylamino)-(alkoxy, nitro) > (dimethylamino, alkoxy)-(alkoxy, nitro).

Among the compounds examined, this tendency is shown to a large extent by the propoxy derivatives, to a lesser extent by the methoxy derivatives, and least by the ethoxy derivatives.

The latent I-N transition temperatures of the ethoxy derivatives are higher than those of the methoxy and propoxy derivatives, thus making the observation of the induced mesophases easiest. The effects of dimethylamino and nitro groups on the transition temperature are also appreciable. Consequently, the order is ethoxy > propoxy > methoxy for the donor compounds, while ethoxy > methoxy > propoxy for the acceptor compounds.

The observations made with the ethoxy derivatives suggest that the thermal stability enhancement of nematic phases is larger in the first two combinations of the donor and acceptor compounds: namely, (dimethylamino, alkoxy)-(nitro, alkoxy) and (alkoxy, dimethylamino)-(nitro, alkoxy). Concerning the effects of alkoxyl groups, the comparison is possible with the other two combinations, as listed in Table 2. The order of the alkoxy derivatives in the thermal stability enhancement of nematic phases agrees exactly with that of the tendency of a solid complex formation: that is,

propoxy > methoxy > ethoxy.

Qualitatively speaking, therefore, the effects of substituents on the formation of a solid complex and the induction of mesophases are dependent on each other. The special feature of smectic phase is its stratification. This structure makes the phase to be much closer to the crystalline state than is the nematic phase. The appearance of smectic phase in the mixtures of the propoxy derivatives seems to be correlated with the fact that the tendencies to form a solid complex and to induce a mesophase are both high.

Table 2. Thermal stability enhancement of nematic phases: the deviation at 50 mol% from a linear relationship between the transition temperatures of the component compounds

(The values in parentheses were estimated by the extrapolation of the I-N transition curves.)

Combination	Methoxy deriv.	Ethoxy deriv.	Propoxy deriv.
(Dimethylamino, alkoxy) + (nitro, alkoxy)	(33 °C)	32 °C	(45 °C)
(Alkoxy, dimethylamino) + (nitro, alkoxy)	(32 °C)	31 °C	(40—45 °C)
(Dimethylamino, alkoxy) + (alkoxy, nitro)	30 °C	27 °C	(40 °C)
(Alkoxy, dimethylamino) + (alkoxy, nitro)	(27 °C)	23 °C	(40 °C)

The solid molecular complexes are reddish brown, while the component compounds are yellow. A study of the diffuse reflection spectra has revealed the appearance of an additional electronic absorption band due to complexing. As is exemplified by the combination of (dimethylamino, ethoxy) and (nitro, ethoxy) in Fig. 4, the maximum is located around 20×10^3 cm^{-1} (500 nm). This band is assigned to the charge-transfer transition associated with the electron donor-acceptor pairs. The persistence of color in mesophases is considered as the evidence that the molecular complexing in them is also of the electron donor-acceptor type. Naturally, the loss of color is seen when the separation of donor and acceptor molecules into two phases occurs by the solidification.

Estimation of Latent Transition Temperatures. The failure to observe mesophases in the systems (dimethylamino, methoxy)-(nitro, methoxy), (methoxy, dimethylamino)-(nitro, methoxy), and (dimethylamino, propoxy)-(nitro, propoxy), shown in Figs. 1a, 1b, and 3a respectively, must be attributed to the strong tendency to form a crystalline solid, which overshadows the transformation of the melt to a metastable mesophase. The existence of such a induced mesophase has been confirmed by a study of the phase diagram of

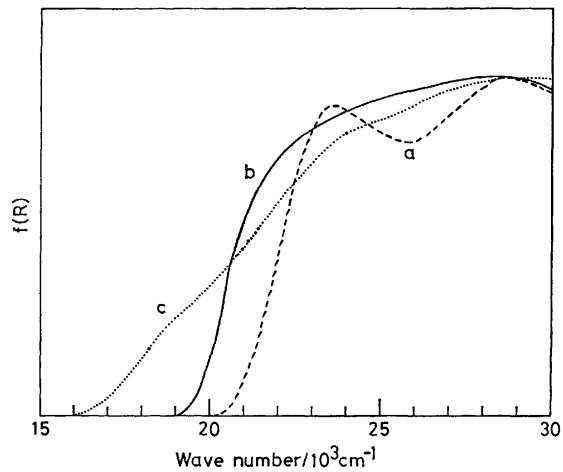

Fig. 4. Diffuse reflection spectra of (a) *N*-[*p*-(dimethylamino)benzylidene]-*p*-phenetidine, (b) *N*-(*p*-nitrobenzylidene)-*p*-phenetidine, and (c) their 1:1 complex.

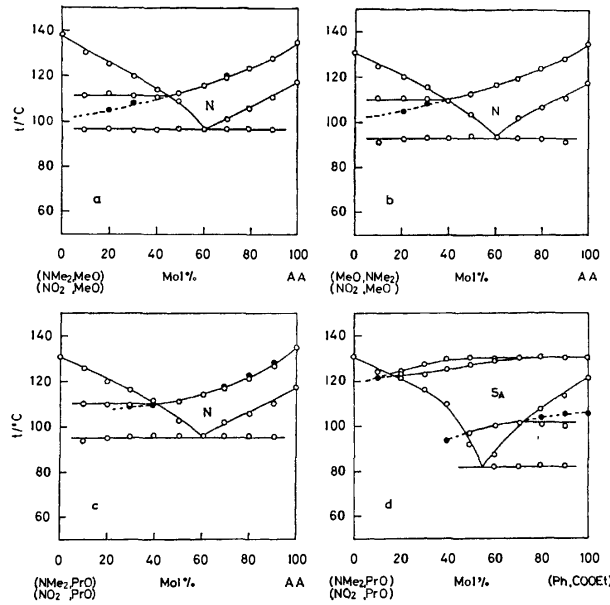

Fig. 5. Phase diagrams of (a) the system consisting of the *N*-[*p*-(dimethylamino)benzylidene]-*p*-anisidine–*N*-(*p*-nitrobenzylidene)-*p*-anisidine (1:1) complex and azoxydianisole, (b) the system consisting of the *N*-(*p*-methoxybenzylidene)-*p*-(dimethylamino)aniline–*N*-(*p*-nitrobenzylidene)-*p*-anisidine (1:1) complex and azoxydianisole, (c) the system consisting of the *N*-[*p*-(dimethylamino)benzylidene]-*p*-propoxyaniline – *N*-(*p*-nitrobenzylidene)-*p*-propoxyaniline (1:1) complex and azoxydianisole, and (d) the system consisting of the *N*-[*p*-(dimethylamino)benzylidene]-*p*-propoxyaniline–*N*-(*p*-nitrobenzylidene)-*p*-propoxyaniline (1:1) complex and *N*-(*p*-phenylbenzylidene)-*p*-ethoxycarbonylaniline. As to the open and shaded circles, see the caption of Fig. 1.

the pseudo-binary system consisting of the 1:1 complex and a mesomorphic compound. We employed for this purpose azoxydianisole (AA), which exhibits a nematic phase stable between 117.5 and 135 °C, and *N*-(*p*-phenylbenzylidene)-*p*-ethoxycarbonylaniline (phenyl, ethoxycarbonyl), which exhibits a smectic phase stable between 121.6 and 131.0 °C.[13] The diagrams displayed in Fig. 5 are of the eutectic type and clearly prove the latent induction of mesophases in all the three systems. The I-N transition temperature in the (dimethylamino, methoxy)–(nitro, methoxy) complex is estimated by the extrapolation of the transition curve to 0 mol% of AA to be 101 °C (see Fig. 5a). This temperature is higher by 33 °C than the straight line joining the latent transition temperatures of the two components of the complex. As the matter of fact, the molten complex solidifies at 112.5 °C, thus making the I-N transition not detectable. In the case of the (methoxy, dimethylamino)–(nitro, methoxy) complex shown in Fig. 5b, the I-N transition temperature obtained by the extrapolation is 102 °C, which is 32 °C above the mean value of those of the two components. It must be emphasized that the thermal stability enhancement in these two complexes is larger than that in the other two systems of the methoxy derivatives, in agreement with the order of tendency of a solid-complex formation.

The (dimethylamino, propoxy)–(nitro, propoxy) complex is expected to have latent I-N and I-S transition temperatures. The former temperature is located at about 107 °C by the diagram with AA and the latter at 119 °C by the diagram with (phenyl, ethoxycarbonyl), as are shown in Figs. 5c and 5d. The stability enhancement of the nematic phase is about 45 °C, the largest among all the examined combinations. The diagram shows that the induced mesophase is of the type smectic A. When the smectic A phase of (phenyl, ethoxycarbonyl) is supercooled, another smectic phase appears at 106 °C (see Fig. 5d). The eutectic point of this pseudo-binary system is considerably lower than this transition curve; therefore, the new smectic phase becomes enantiotropic in the range of 50 to 70 mol% of (phenyl, ethoxycarbonyl).

With the exception of (propoxy, nitro), the I-N transition of the component compounds could not be observed by supercooling of the melt. Consequently, the transition temperatures listed in Table 1 have been deduced by the extrapolation of the transition curves observed in the binary systems with mesomorphic AA. Such systems have been extensively studied by Dave and Lohar and the diagrams with the following five compounds can be reproduced from their data:[4,5] (dimethylamino, methoxy), (nitro, methoxy), (methoxy, dimethylamino), (dimethylamino, ethoxy), and (nitro, ethoxy). Especially for the last two, the transition temperatures have been estimated by Lohar to be 97.5 °C and 85 °C respectively.[8] We have worked on all the other systems. The diagrams are of the eutectic type. When the Schiff base is a dimethylamino derivative, the I-N transition curve deviates negatively from the ideal linear relationship. In other words, the curve is slightly concave upwards. On the other hand, the transition curve is markedly convex upwards with the nitro derivative, indicating the attractive interaction between the Schiff base and AA molecules. The I-N and solid-liquid transition temperatures read from the phase diagrams are summarized in Table 3

Table 3. Isotropic liquid-nematic liquid crystal transition temperatures in the binary systems with azoxydianisole

(Monotropic transitions are given in parentheses.)

and 4 respectively. The latent I-N transition temperatures of the Schiff bases presented in Table 1 were obtained by the extrapolation of the transition curves to 0 mol% of AA. They are in good agreement with those located from the phase diagrams of the binary mixtures of the Schiff bases given in Figs. 1, 2, and 3.

Charge Transfer and Proton Transfer in the Formation of Molecular Complexes. XII.[1] *o*-Aminobenzoic Acid–Picric Acid and Related Complexes

Yoshio MATSUNAGA* and Reiko USUI

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received April 9, 1980)

The combination of *o*-aminobenzoic acid and picric acid was found to yield four kinds of adducts. These were a stable yellow (1:1) salt, formed by the proton transfer from the picric acid to the *o*-aminobenzoic acid molecule, two red (1:1) molecular complexes of markedly different stability, and a red (2:1) complex consisting of the *o*-aminobenzoic acid molecule, its protonated ion, and the picrate ion. The enthalpy change and the activation energy for the isomerization from the salt to the charge-transfer complex by a solid-solid transformation were shown to decrease during storage. The 1,3,5-trinitrobenzene complexes with *o*-(methylamino)benzoic acid, *o*-, *m*-, and *p*-(dimethylamino)benzoic acids, and their sodium and potassium salts were prepared. Their electronic spectra were measured, along with those of the complexes with *o*- and *p*-aminobenzoic acids and their salts presented in the work of Sudborough and Beard. The displacement of the charge-transfer absorption maxima to the lower wavenumber side by the salt formation is 2×10^3 cm^{-1} on the average and seems to be consistent with our proposition that the picrate ion acts as an electron acceptor in aromatic amine-picric acid (2:1) complexes.

One of the most striking properties of *o*-aminobenzoic acid is the formation of both a yellow salt and a red molecular complex with picric acid;[2] and another is the formation of the 1,3,5-trinitrobenzene complexes of the potassium salt as well as of the acid itself.[3] They have received no further attention, however. When picric acid is combined with an aromatic amine, the acid-base interaction generally predominates in the solid state. With this acid, only three other anilines and three naphthylamines are known to exhibit the phenomenon of complex isomerism: that is, the formation of both a salt and a charge-transfer complex.[4,5] In some cases, the two forms are enantiotropically related to each other, while in the others, the molecular complex is metastable with respect to the salt at every temperature. One of the aims of the present work was to clarify the relation between the two forms of the *o*-aminobenzoic acid–picric acid reported by Issa and El-Essawey.[2]

1-Naphthylamine was shown by Kofler to form the yellow 1:1 and red 2:1 adducts with picric acid.[6] The former is a simple salt, while the latter consists of naphthylamine molecule, naphthylammonium cation, and picrate anion.[7] The red color presumably arises from the charge-transfer interaction between the amine molecule and the picrate ion. We assumed that the electron acceptor in this 2:1 adduct is the picrate ion. Our proposition that the acceptor strength of picric acid is not much affected by the salt formation seems to be consistent with numerous examples subsequently accumulated by us; however, this is in serious conflict with Tanaka's recent theoretical view.[8] On the basis of his molecular orbital calculations, he suggested that the picrate anion is a donor and the indole moiety an acceptor in the tryptophan picrate. If so, the change in the electronic structure of picric acid by salt formation must be substantial, because indole is known to act as a donor in the complex formation with picric acid.[9] The second aim of the present work was to find out experimentally how large the change in the donor strength of aminobenzoic acid by salt formation is. The spectral measurements of the trinitrobenzene complexes of *o*- and *p*-aminobenzoic acids and their potassium salts originally prepared by Sudborough and Beard will provide the means of giving a certain answer to this question. Both the acids and the salts undoubtedly function as electron donors in forming the complexes. If the energy differences in the charge-transfer absorption maxima observed with them are significantly smaller than the magnitude predicted by Tanaka for picric acid, our proposition becomes more likely than his.

Experimental

Materials. The *o*- and *p*-aminobenzoic acids, *m*- and *p*-(dimethylamino)benzoic acids, and picric acid were obtained from commercial sources. The methylation of *o*-aminobenzoic acid with a calculated amount of dimethyl sulfate yields the *N*-methyl derivative, while that with an excess of methyl iodide yields the *N,N*-dimethyl derivative.[10] The latter was isolated as the polyiodide. After removing iodine by steam distillation, the acid was freed from hydrogen iodide by the treatment with silver oxide. The *o*-(dimethylamino)benzoic acid thus separated was purified by the precipitation from a methanol solution by the addition of diethyl ether. The synthesis of 1,3,5-trinitrobenzene was carried out starting from 2,4,6-trinitrotoluene, Eastman yellow label, through 2,4,6-trinitrobenzoic acid.[11] The alkali-metal salts of the aminobenzoic acids were obtained by dissolving equimolar amounts of the acid and the hydroxide in water and then evaporating to dryness. The use of an excess of the latter reagent must be carefully avoided; otherwise, a small amount of Meisenheimer complex is formed in the step of the trinitrobenzene-complex preparation and interferes with the measurements of the electronic spectra. The complexes were isolated by concentration or by evaporation of a solution containing equimolar amounts of the components in an appropriate solvent.

Measurements. The spectroscopic, calorimetric, and X-ray measurements were made using the procedures reported in a previous paper of this series.[12] As the red form of *o*-aminobenzoic acid–picric acid is too unstable to be ground, the thin layers of the complex were prepared by evaporating the warm solution on sodium chloride or quartz plates for the spectroscopic measurements.

Results and Discussion

When a hot methanol solution of equimolar amounts of *o*-aminobenzoic acid and picric acid is concentrated, red crystals appear. They are not stable at room temperature and are gradually transformed into yellow crystals. Found: C, 43.13; H, 2.78; N, 15.00%. Calcd for $C_7H_7NO_2$–$C_6H_3N_3O_7$: C, 42.63; H, 2.75; N, 15.30%. In agreement with the observation made by Issa and El-Essawey, the former form exhibits an asymmetric N–H stretching band and a symmetric one at 3485 and 3375 cm^{-1} respectively, while the latter shows broad bands covering the region from 2925 to 2625 cm^{-1}, to be assigned to the NH_3^+ group. The red form deposited on a quartz plate shows an electronic absorption band which is not present in either of the components. The maximum is hidden under a strong higher-energy band, but is possibly at about 22×10^3 cm^{-1}. This wavenumber is not far from that of the charge-transfer absorption band in the orange-yellow *o*-aminobenzoic acid–trinitrobenzene complex, about 24×10^3 cm^{-1}. As the acceptor strength of picric acid is known to be comparable with that of 1,3,5-trinitrobenzene, the band may be ascribed to the charge-transfer transition from the *o*-aminobenzoic acid molecule to the picric acid molecule.

Upon heating the yellow crystals at a scanning rate of 2.5 °C min^{-1}, an endothermic peak extending from 156 to 171 °C is observed on the calorimetric curve. Above this temperature range, the red form produced by the phase transition starts to decompose exothermally. The enthalpy change of the transition from the yellow salt to the red molecular complex decreases during storage. The fresh samples give a value of 10.2 kJ mol^{-1}. On the other hand, the value obtained after one-month storage at room temperature is 6.6 kJ mol^{-1}. These enthalpy changes are rather small compared to those so far examined. The values recorded earlier range from 9.2 kJ mol^{-1} of *o*-chloroaniline-2,4,6-trinitrobenzoic acid to 34 kJ mol^{-1} of 1-bromo-2-naphthylamine-picric acid.[1,12] It is apparent that these isomeric forms are enantiotropically related to each other. Previously we showed that the picrates of all the anilines with pK_a values of less than 3 isomerize into charge-transfer complexes upon melting, if they do not isomerize by an enantiotropic solid-solid transition.[13] The pK_a value reported by Schwarzenbach *et al.* for *o*-aminobenzoic acid is 2.09,[14] and nicely fits into the range where complex isomerization is expected to occur.

The endothermic peak due to the transformation covers a temperature range as wide as 15 °C and is asymmetric, in contrast to those of Hertel's picric acid complexes described earlier.[1] The slope changes very gently on the lower-temperature side and sharply on the other side. Up to near the maximum, the curve is characteristic of a transition whose extent increases linearly with time under isothermal conditions. In other words, the rate constant, k, is given by

$$k=B(dH/dt),$$

where B is a constant and where (dH/dt) is the rate of change of enthalpy with time and is proportional to the departure of the peak from the baseline at the associated temperature.[15] The activation energy of such a transition can be estimated by a plot of log (dH/dt) *versus* $1/T$. The energy given by the fresh samples is relatively large and is scattered in a wide range. At the heating rate of 2.5 °C min^{-1}, six independently-prepared samples gave 449, 600, 640, 719, 879, and 931 kJ mol^{-1} (see Plots a and b in Fig. 1). This energy decreases during storage at room temperature and becomes more reproducible. After one month, the six runs performed at the scanning rates of 2.5, 5, 10, and 20 °C min^{-1} yielded the mean value of 306 ± 15 kJ mol^{-1} (see Plots c and d in Fig. 1). The over-all activation energy of a solid-solid transformation depends mostly upon the kinetics of the nucleation, which takes place heterogeneously and preferentially at grain boundaries.[16] When the red charge-transfer complex is transformed into the yellow salt below the transition temperature, the initially-formed crystals are supposed to be highly strained because of the change of molecular arrangement. Upon storage, such a stress may be largely reduced by the spontaneous growth of the grain boundaries. The relatively large and markedly scattered activation energies observed with the fresh samples suggest that the growth of the grain boundaries proceeds rather slowly and irregularly. This postulate seems to be in accordance with the observations made earlier with some Hertel's picric acid complexes that the endothermic peak due to the transformation from the salt to the charge-transfer complex is appreciably broadened and weakened by the grinding of the crystals.[1]

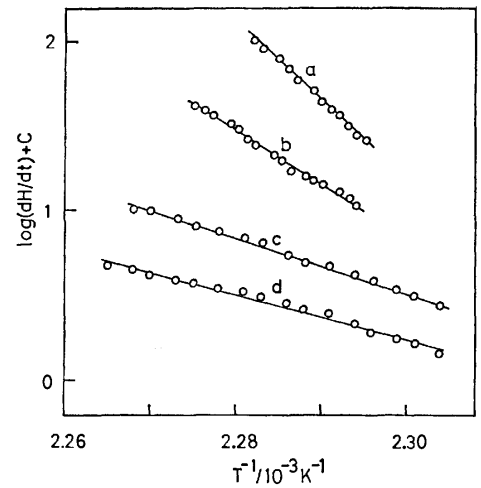

Fig. 1. Arrhenius plots constructed from the endothermic peak due to the isomerization from the yellow salt to the red molecular complex of the *o*-aminobenzoic acid–picric acid (1:1). a) and b), fresh samples at a heating rate of 2.5 °C min^{-1}. The estimated activation energies are 931 and 600 kJ mol^{-1} respectively. c) and d), samples stored for one month at room temperature. The heating rates are 10 and 5 °C min^{-1}, and the activation energies are 275 and 271 kJ mol^{-1} respectively.

The vermillion crystals deposited from a chloroform solution are also of the 1:1 mole ratio. Found: C,

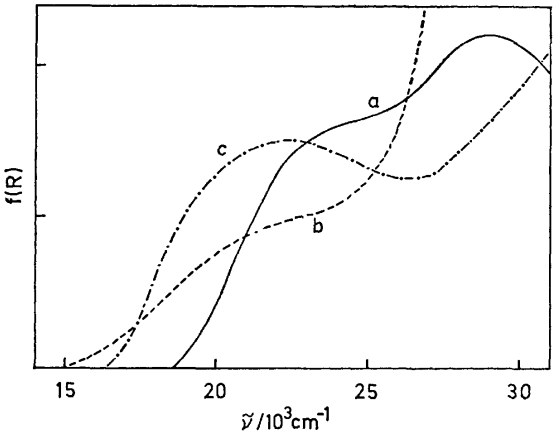

Fig. 2. Kubelka-Munk plots of diffuse reflectance of the 1,3,5-trinitrobenzene complexes with a) *o*-aminobenzoic acid, b) the sodium salt, and c) the potassium salt.

42.62, 42.49; H, 2.71, 2.70; N, 15.25, 15.32%. Contrary to the red-colored form from a methanol solution, the crystals could be kept at room temperature over several months without the transformation to the yellow salt. However, they are easily transformed into yellow powder by crushing. A comparison of the X-ray diffraction patterns revealed that the molecular complex is polymorphic. The N–H stretching bands are found at 3500 and 3380 cm^{-1}. The maximum of the charge-transfer absorption band in the second form of the molecular complex is not separable from a strong higher-energy band, but is possibly located around 21×10^3 cm^{-1}.

Stable scarlet crystals can also be obtained from a methanol solution if *o*-aminobenzoic acid is dissolved in excess. The compound is of the 2:1 mole ratio. Found: C, 47.61; H, 3.41; N, 13.99%. Calcd for $(C_7H_7NO_2)_2$–$C_6H_3N_3O_7$: C, 47.72; H, 3.40; N, 13.91%. The vibrational bands due to the NH_2 group, 3475 and 3375 cm^{-1}, and also the pattern characteristic of the NH_3^+ group in the range from 2875 to 2625 cm^{-1} are found in the infrared spectrum. Without doubt, the proton-transfer and charge-transfer interactions operate simultaneously in this solid. The electronic absorption band appearing as a shoulder at about 20×10^3 cm^{-1} is assigned to the charge-transfer transition between the *o*-aminobenzoic acid molecule and the picrate ion. Following our earlier view,[7] we tentatively suppose that the latter species acts as an electron acceptor in this complex. This point will be discussed in detail later.

Sudborough and Beard noted that the trinitrobenzene complex of *o*-aminobenzoic acid is orange yellow and that of its potassium salt is deep red.[3] Their electronic spectra are presented in Fig. 2, which includes the spectrum of the complex formed with the sodium salt. The charge-transfer absorption maximum of the potassium-salt complex is seen at 22.3×10^3 cm^{-1}. In the other two, the absorption maximum is not explicit because of overlapping with a stronger absorption band; nevertheless, it is very likely that the sodium-salt complex gives a maximum at the same wavenumber as that of the potassium-salt complex. The maximum in the *o*-aminobenzoic acid complex is probably at about 24×10^3 cm^{-1}. Thus, the difference which should reflect the relative ionization potentials of the acid and its salts is only about 2×10^3 cm^{-1} or 0.2 eV. Some additional spectral measurements were made in which the *N*-methyl and *N,N*-dimethyl derivatives were employed as donors. Here again, no large shift due to salt formation can be found. The observed wavenumbers are listed in Table 1.

Table 1. The wavenumbers of the charge-transfer absorption maxima in the solid trinitrobenzene complexes

Donor	Wavenumber /10^3 cm^{-1}	Color
o-Aminobenzoic acid	24	yellowish orange
Sodium *o*-aminobenzoate	22	dull red brown
Potassium *o*-aminobenzoate	22.3	scarlet
o-(Methylamino)benzoic acid	23	orange
Sodium *o*-(methylamino)-benzoate	21.2	brown carmine
Potassium *o*-(methylamino)-benzoate	21.2	brown carmine
o-(Dimethylamino)benzoic acid	23.5	orange brown
Potassium *o*-(dimethylamino)-benzoate	23	violet black
m-(Dimethylamino)benzoic acid	21.5	violet black
Sodium *m*-(dimethylamino)-benzoate	19.5	blackish violet
Potassium *m*-(dimethylamino)-benzoate	20.5	violet black
p-Aminobenzoic acid	25	orange
Sodium *p*-aminobenzoate	22.0	violet brown
Potassium *p*-aminobenzoate	24	brown orange
p-(Dimethylamino)benzoic acid	21.5	deep carmine
Sodium *p*-(dimethylamino)-benzoate	21.3	dark violet red
Potassium *p*-(dimethylamino)-benzoate	21.0	violet black

Although *m*-aminobenzoic acid does not form a molecular complex with trinitrobenzene, the potassium salt is known to give a dark reddish brown complex.[3] With the *N,N*-dimethyl derivative, however, both the acid and the salts yield the complexes. Sudborough and Beard have isolated the trinitrobenzene complexes of *p*-aminobenzoic acid and its potassium salt. The former is red and the latter dark red. The *N,N*-dimethyl derivative and its salts form more deeply colored complexes. Their spectral data are also given in Table 1. In all cases, the charge-transfer absorption maxima of the salt complexes are consistently displaced to the lower wavenumber side, but only by 2×10^3 cm^{-1} on the average, compared to those of the corresponding acid complexes. The results may be understood from the fact that the ionization potentials of the salts are lower than those of the acids by the same magnitude.

Tanaka has presented the location of the highest occupied molecular orbital (HOMO) of picrate anion and that of the lowest unoccupied molecular orbital (LUMO) of the indole moiety of tryptophan as the

criteria of electron donor and acceptor strength.[8] His conjecture of the donor character of the picrate anion comes from the calculations that its HOMO is located 3.78 eV above the HOMO of the indole moiety and its LUMO is 2.30 eV above the LUMO of the latter. However, the charge-transfer absorption in the tryptophan picrate appears in the same region as that of the indole–picric acid.[9] Furthermore, indole is well-known to behave as an electron donor in forming molecular complexes with a number of compounds including picric acid.[9,17] If it is assumed that picric acid is an acceptor but its anion is a donor with respect to essentially the same species, then the relative locations between the HOMO of indole and the LUMO of picric acid must resemble those between the HOMO of picrate ion and the LUMO of indole moiety calculated by Tanaka. As a consequence, the LUMO of picrate ion should be located at an energy higher by about 6 eV than the LUMO of the acid. If so, the HOMO of picrate ion should be also higher to a similar extent than the HOMO of picric acid. Analogously, one may expect a considerable difference, presumably of the order of 1 eV, in the location of the HOMO between an aminobenzoic acid and its anion. The experimental results summarized in Table 1 are definitely not in accord with the assumption made above. Thus, an alternative explanation that the picrate anion is not an electron donor but an electron acceptor in the tryptophan picrate and also in the *o*-aminobenzoic acid–picric acid (2:1) complex appears to be more likely. In this regard, it should be noted that the picrate anion in the solid complex is under the strong influence of the counter ion.[18] The charge on the anion in such solids may be largely localized by the polarizing power of the cation. The resultant situation would be more or less similar to the electronic structure of a picric acid molecule. Therefore, we feel that Tanaka's theoretical work on either an isolated picrate anion or a composite molecule does not reflect the situation in the solid salt complexes.

The authors wish to express their thanks to Dr. Jun-ichi Aihara for his helpful discussion.

A Study of the Ligand Exchange of Bromo(*o*-tolyl)bis(triphenylphosphine)nickel(II) with Amine by Means of ^{31}P- and ^{13}C-NMR Spectroscopy

Yoshiyuki NAKAMURA,* Ken-ichi MARUYA, and Tsutomu MIZOROKI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received March 21, 1980)

The amine substitution of bromo(*o*-tolyl)bis(triphenylphosphine)nickel(II) was investigated by the use of ^{31}P- and ^{13}C-NMR. The triphenylphosphine ligands are readily replaced by sterically less crowded amines, such as primary amines, secondary amines, pyridine, and *γ*-picoline, at room temperature in chlorobenzene, while no replacement at all takes place with tertiary amines. The equilibrium constants with *γ*-picoline, pyridine, or dibutylamine, as defined by Eq. 2, show that the entropy change contributes predominantly to the constant. The substitution with pyrrolidine, as monitored by means of ^{13}C-NMR, indicates that the amine coordinates to the nickel(II) atom.

It is well known that organo transition-metal complexes are stabilized by the coordination of the tertiary phosphine ligand to the metal atoms. For example, halogeno(aryl)bis(triphenylphosphine)nickel(II), first prepared by Chatt[1] twenty years ago, is quite stable in organic solvents. This compound acts as a precursor to an active catalyst for the selective dimerization and codimerization of olefin[2-4] and gives a cationic nickel(II) complex with an amine ligand on treatment with $AgClO_4$.[5] Little attention has, however, been paid to organo transition-metal complexes with amine ligands, presumably because they are too unstable to be easily isolated and characterized. Little information is, accordingly, available with respect to the coordination states of amines, although amine is expected to behave much like phosphine.

Triphenylphosphine ligands on bromo(*o*-tolyl)bis(triphenylphosphine)nickel(II) are readily replaced by other tertiary phosphines, with the driving force for the replacement being steric in nature.[6] The same procedure may be extended to the substitution of amine for phosphine. Thus, the substitution reactions of various amines, as represented by:

$$[NiBr(o\text{-tolyl})(PPh_3)_2] \underset{PPh_3}{\overset{amine}{\rightleftharpoons}} [NiBr(o\text{-tolyl})(amine)(PPh_3)] \underset{PPh_3}{\overset{amine}{\rightleftharpoons}} [NiBr(o\text{-tolyl})(amine)_2] \quad (1)$$

have been investigated in order to elucidate the nature of the amine coordination.

Experimental

Materials. Bromo(*o*-toly)bis(triphenylphosphine)nickel(II) was prepared by the oxidative addition of *o*-bromotoluene to tetrakis(triphenylphosphine)nickel(0) according to the literature.[7]

All the experiments were conducted under a nitrogen atmosphere. Chlorobenzene which has been dried by P_2O_5 before distillation was used as the solvent. No reaction of chlorobenzene with amines was observed under the present experimental conditions. The pyridine, *γ*-picoline, pyrrolidine, piperidine, butylamine, and dibutylamine were dried by CaH_2 before distillation. The other amines, such as quinoline, 4-methoxyaniline, 3,4-dimethylaniline, 4-methylaniline, aniline, 4-chloroaniline, *N*-methylpyrrolidine, *N*-methylpiperidine, tributylamine, t-butylamine, propylamine, dipropylamine, and *N,N,N',N'*,-tetramethylethylenediamine, obtained from commerical sources, were used without further purification.

Procedures. All the samples were prepared under a nitrogen atmosphere. To bromo(*o*-tolyl)bis(triphenylphosphine)nickel(II) (50 mg) placed in a two-necked flask (20 ml) are added chlorobenzene (5.00 ml) containing a known amount of an amine, the solution was then stirred at room temperature for about 1 h before ampouling the solution with C_6D_6 (D-lock) and TMS into a NMR tube (10 mm. O.D.).

The ^{31}P- and ^{13}C-NMR spectra were obtained on a Japan Electron Optics Laboratory FX-100 spectrometer operating the pulsed Fourier transform mode at 40.26 and 25.00 MHz, the repetitions being 6 s (^{31}P-; 400—1000 pulses) and 2 s (^{13}C-; 10000—35000 pulses). The ^{31}P-NMR spectra were taken without proton-decoupling, if necessary. The ^{31}P- and ^{13}C-NMR chemical shifts were reported in ppm, downfield from internal triphenylphosphine (−5.86 ppm from H_3PO_4) and TMS respectively.

Results and Discussion

General Features of the Substitution. Figure 1 shows the ^{31}P-{^{1}H}NMR spectra of the chlorobenzene solutions of *trans*-[NiBr(*o*-tolyl)$(PPh_3)_2$] (to be denoted by the M-complex here after) and pyridine (pK_b= 8.8) at −20 °C. The increase in the molar ratio of pyridine to the nickel complex results in a decrease in the intensity of resonance, S_0, at 29.4 ppm due to the M-complex, accompanied by an increase in that of the resonance, L_p, at 0 ppm due to free triphenylphosphine. The resonance, S_1, at 36.9 ppm can be attributed to the monosubstituted M-complex with pyridine, [NiBr(*o*-tolyl)(pyridine)(PPh_3)].

The degree of amine coordination to nickel is represented by the relative intensities, h_p and h_1, of L_p and S_1 the resonances:

$$h_p = \frac{h(L)_p}{h(L_p)+h(S_0)+h(S_1)}, \quad h_1 = \frac{h(S_1)}{h(L_p)+h(S_0)+h(S_1)},$$

where $h(L_p)$, $h(S_0)$, and $h(S_1)$ are the peak heights of the resonances for free triphenylphosphine, the M-complex, and the monosubstituted M-complex respectively.

With respect to the amines with a pyridine ring, the following coordination sequence may be deduced from

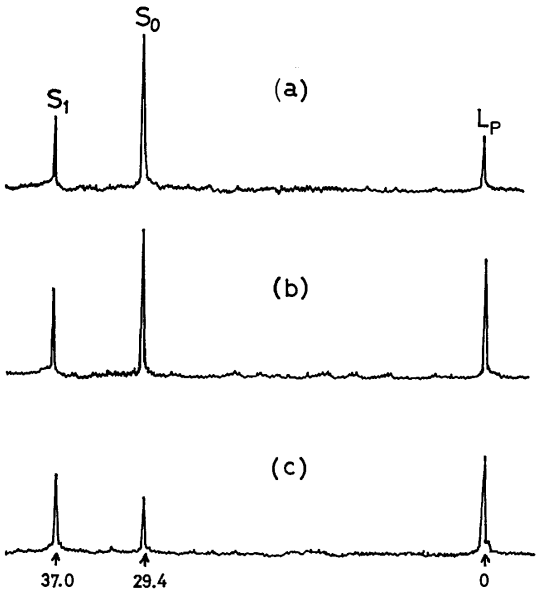

Fig. 1. ^{31}P-{^1H} NMR spectra in the substitution of M-complex with pyridine at −20 °C at the molar ratio of $[pyridine]_0/[M]_0=5$(a), 10(b), or 20(c).

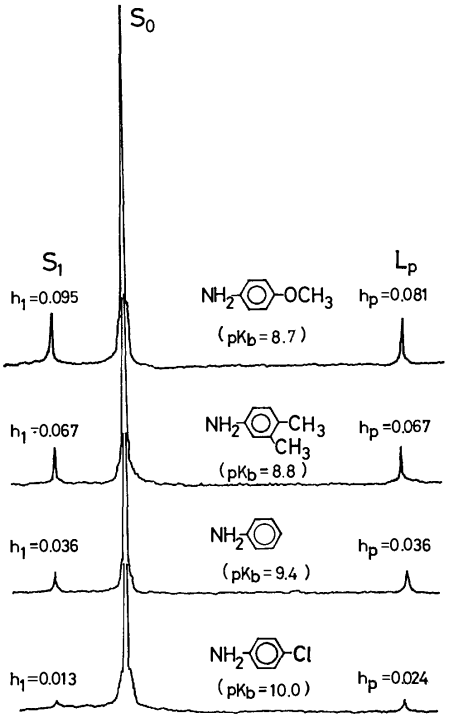

Fig. 2. ^{31}P-{^1H} NMR spectra in the substitution of M-complex with substituted aniline at the molar ratio of $[aniline]_0/[M]_0=20$ at −20 °C.

the relative intensities at −20 °C;

$$\gamma\text{-picoline} > \text{pyridine} \gg \text{quinoline}$$
$$(pK_b=7.9) \quad (pK_b=8.8) \quad (pK_b=9.2)$$

where the molar ratio of the amine to the M-complex is 10. This sequence appears to imply that the more basic the amine, the stronger the coordination. In order to confirm this tendency, *p*-substituted anilines with equal steric crowding were chosen as the substitutes.

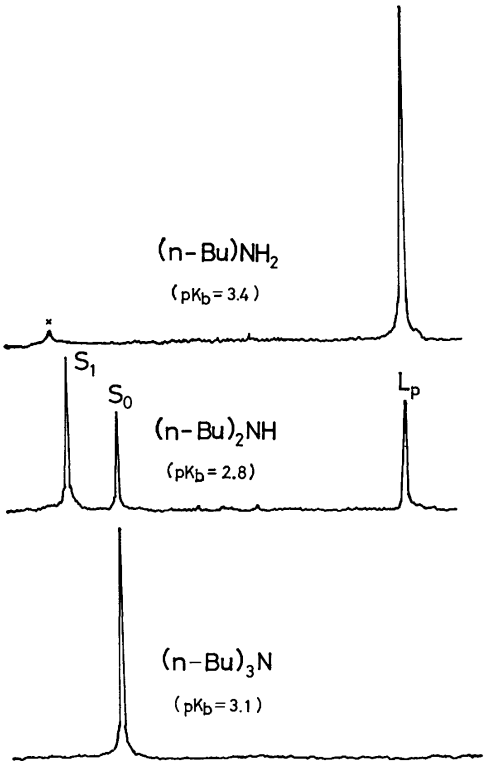

Fig. 3. ^{31}P-{^1H} NMR spectra in the substitution with $NH_{3-n}(n\text{-Butyl})_n$($n$=1, 2, and 3) at molar ratio of $[amine]_0/[M]_0=6$ at −20 °C.

The ^{31}P-{^1H} NMR spectra of the M-complex p-substituted aniline system are shown in Fig. 2. The stronger electron donor results in the higher relative intensities, h_p and h_1, of the free triphenylphosphine and the monosubstituted M-complex.

On the other hand, most of the triphenylphosphine on M-complex is replaced by butylamine ($pK_b=3.4$) at the molar ratio of [butylamine]/[M]=6, while no replacement by tributylamine ($pK_b=3.1$) takes place at all, as is shown in Fig. 3. Essentially the same sequence was observed with mono-, di-, and tri-propylamines. Other sterically crowded amines, such as *N*,*N*-dimethylaniline, *N*-methylpyrrolidine, and *N*-methylpiperidine, gave neither the resonance due to free triphenylphosphine nor that due to the mono-substituted M-complex. From comparisons of the ^{31}P-NMR spectra (Fig. 1) with pyridine ($pK_b=8.8$) and (Fig. 3) with butylamine ($pK_b=3.4$), it seems that the triphenylphosphine on the M-complex is replaced more readily by a strong amine base. Figure 3 clearly shows that the steric factor is predominant in the substitution with amine, as well as with other tertiary phosphine ligands.[6]

When *N*,*N*,*N*′,*N*′,-tetramethylethylenediamine was used, both L_p and S_0 resonances were observed, while no S_1 resonance corresponding to the monosubstituted M-complex was detected, suggesting some chelation of the diamine, although no further study was done.

The ^{31}P- chemical shifts (S_1) of the monosubstituted M-complex with various amines, [NiBr(*o*-tolyl)(amine)(PPh_3)], were almost the same (independent of the strength of the amine base): 34.7 ppm ($NH(n\text{-Pr})_2$),

TAELB 1. EQUILIBRIUM CONSTANTS WITH AMINE; $K_1=\frac{[S_1][L_p]}{[S_0][L_N]}$

Amine	$[N]_0/[M]_0$	K_1 24 °C	10 °C	0 °C	−10 °C	−20 °C
NH(*n*-Bu)$_2$	1.53	0.71	—	0.48	—	0.48
	3.07	0.80	0.60	0.55	0.59	0.55
	mean	0.75	0.60	0.51	0.59	0.51
Pyridine	5.0	0.21	0.23	0.24	0.27	—
	10.0	0.24	0.22	0.19	—	—
	mean	0.23	0.23	0.22	0.27	—
γ-Picoline	3.0	0.85	0.78	0.69	0.51	—
	6.0	0·79	0.72	0.61	0.61	—
	mean	0.82	0.75	0.65	0.57	—

34.4 ppm (NH(*n*-Bu)$_2$), 36.5 ppm (pyrrolidine), 36.7 ppm (piperidine), 37.2 ppm (γ-picoline), and 36.9 ppm (pyridine).

Evaluation of Equilibrium Constant. Since substituted M-complexes with amines were too unstable to be isolated, we attempted to evaluate the equilibrium constants of Eq. 2 using pyridine, γ-picoline, or dibutylamine in order to confirm Eq. 2.

The concentrations of free triphenylphosphine, the M-complex, and the monosubstituted M-complex at equilibrium can be calculated from the relative peak areas of ^{31}P-NMR (without ^{1}H-decoupling) and from the initial concentrations of the M-complex and the amine, because they are proportional to the concentrations (mol/l), $[L_p]$, $[S_0]$, and $[S_1]$. The relative peak areas are as follows:

$$\underset{[S_0]}{[NiBr(o\text{-tolyl})(PPh_3)_2]} + \underset{[L_N]}{Amine} \underset{\text{in } C_6H_5Cl}{\overset{K_1}{\rightleftarrows}} \underset{(cis \text{ and } trans)}{\underset{[S_1]}{[NiBr(o\text{-tolyl})(amine)(PPh_3)]}} + \underset{[L_p]}{PPh_3} \quad (2)$$

$HL_p=H(L_p)/(H(S_0)+H(S_1)+H(L_p))$, $HS_0=H(S_0)/(H(S_0)+H(S_1)+H(L_p))$, and $HS_1=H(S_1)/(H(S_0)+H(S_1)+H(L_p))$, where $H(L_p)$, $H(S_0)$, and $H(S_1)$ are the peak areas of the resonances of L_p, S_0, and S_1 recorded on ^{31}P-NMR charts. Each concentration is a function of HL_p, HS_1, or HS_0, as represented by Eqs. 3—7.

$$[L_p] = 2[M]_0 \times HL_p \quad (3)$$

$$[S_0] = [M]_0 \times HS_0 \quad (4)$$

$$[S_1] = 2[M]_0 \times HS_1 \quad (5)$$

$$[S_2] = [M]_0 - [S_0] - [S_1] \quad (6)$$

$$[L_N] = [N]_0 - 2[S_2] - [S_1] \quad (7)$$

$[M]_0$ is the total concentration of nickel(II) complex and is given by the amount of M-complex initially charged, and $[N]_0$ is the concentration of amine initially charged. $[S_2]$ and $[L_N]$ are the concentrations of the disubstituted M-complex and the free amine at equilibrium respectively.

The equilibrium constants $K_1=\left(\frac{[S_1][L_p]}{[S_0][L_N]}\right)$ thus obtained at different values of $[N]_0/[M]_0$ are summarized in Table 1. Despite the two-fold change in $[N]_0/[M]_0$ the values of K_1 are almost constant at any temperature, as was expected.

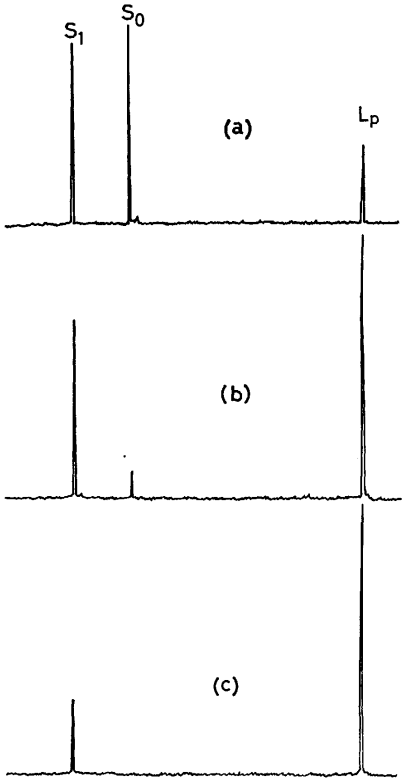

Fig. 4. ^{31}P-{^{1}H} NMR spectra in the substitution of M-complex with pyrrolidine at the molar ratio of 1(a), 2(b), or 4(c) at −24 °C.

It is notable that the effect of the temperature on K_1 is very small, indicating that the entropy change is the predominant factor in the equilibrium constant. This feature is in accord with the fact that bulky amines do not result in the substitution. On the other hand, the equilibrium constants for sterically less crowded amines, such as propylamine, butylamine, pyrrolidine, and piperidine, appear to be too large, rendering the evaluation difficult because of the difficulty in evaluating the value of $[L_N]$, even in a system with added PPh_3. They are, however, presumably one order of magnitude larger than that for γ-picoline. It may be imagined that more than two molecules of a sterically less crowded amine coordinate to the nickel(II) atom, whereas no new resonance in ^{31}P-{^{1}H} NMR was observed in addition to the S_0, S_1, and L_p resonances,

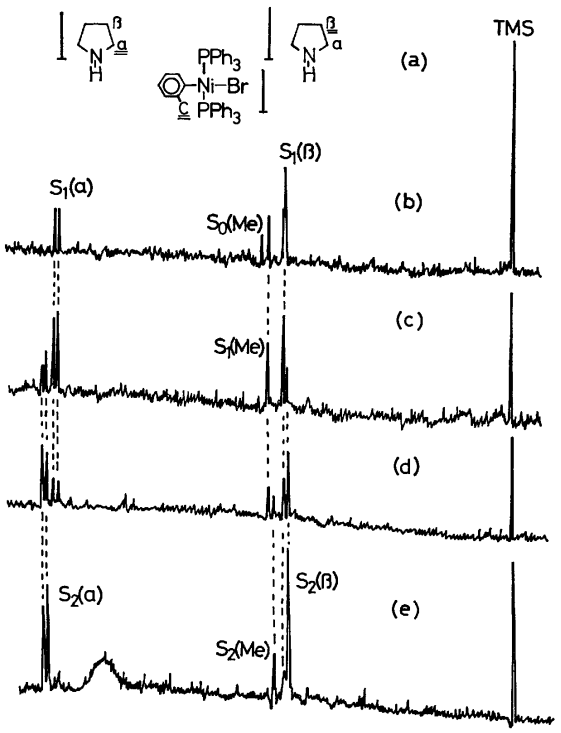

Fig. 5. ^{13}C-{^1H} NMR spectra in the substitution of M-complex with pyrrolidine at the molar ratio of 1(b), 2(c), 4(d), and 8(e), and free pyrrolidine(a) at −20 °C.

as is shown in Figs. 1—4, giving no indication of such coordination.

Evidence of Amine Coordination Obtained by Means of ^{13}C-{^1H} NMR. More direct evidence for the coordination of amine to the nickel(II) atom will be provided by ^{13}C-{^1H} NMR. Pyrrolidine was selected as the candidate amine, because it has only two kinds of carbon atoms exhibiting a strong coordination ability to the nickel(II) atom, thus making the ^{13}C-{^1H} NMR analysis simpler. The results are shown in Fig. 5. The methyl carbon (26.27 ppm, S_0(Me)) of the M-complex and the α-carbon (47.12 ppm, $L_N(\alpha)$) and the β-carbon (25.78 ppm, $L_N(\beta)$) of free pyrrolidine are observed in the range of 0—50 ppm, as is shown Fig. 5(a).

In Fig. 5(b) for $[N]_0/[M]_0=1$, the α-carbon of the pyrrolidine ligand of the monosubstituted M-complex is split into two resonances (47.56 ppm and 48.00 ppm, $S_1(\alpha)$), while the β-carbon is shifted to 23.98 ppm (broad)($S_1(\beta)$), and the methyl carbon, to 25.58 ppm (S_1(Me)). In Fig. 5(c) for $[N]_0/[M]_0=2$, three new resonances are observed. The two resonances at 49.17 ppm and at 48.82 ppm ($S_2(\alpha)$) are due to the α-carbon of pyrrolidine of the disubstituted M-complex, while the other at 23.54 ppm (broad)($S_2(\beta)$), is that of the β-carbon.

It should be noticed that the resonance at 26.27 ppm (S_0(Me)) observed in Fig. 5(b) mostly disappears in Fig. 5(c). In Fig. 5(d) for $[N]_0/[M]_0=4$, one new resonance (25.00 ppm, S_2(Me)) is detected; it can be assigned to the methyl carbon of the disubstituted M-complex. The relative intensities of the $S_2(\alpha)$ and $S_2(\beta)$ resonances are larger than those in Fig. 5(d).

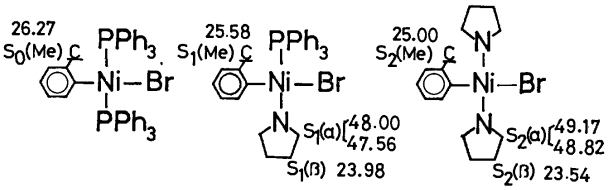

Fig. 6. Assignment of ^{13}C-{^1H} NMR.

This change in the ^{13}C-NMR spectra with the amine concentration is in accord with the results for ^{31}P-{^1H} NMR shown in Fig. 4.

The assignment of these ^{13}C-{^1H} NMR resonances is summarized in Fig. 6. The assignment is based on the following facts; 1) three resonances (S_0(Me), S_1(Me), and S_2(Me)) are observed, with their relative intensities depending reasonably on the molar ratio of pyrrolidine, and 2) the intensities of $S_2(\alpha)$ and $S_2(\beta)$ relative to $S_1(\alpha)$ and $S_1(\beta)$ increase with the increase in the molar ratio of pyrrolidine. Since the ^{13}C-resonances ($S_1(\alpha)$ and $S_2(\alpha)$) of the α-carbons of pyrrolidine are observed to split into two peaks upon coordination to nickel(II), it may be suggested that this is a mixture of *cis-* and *trans-* forms of mono- and disubstituted M-complexes, although only one resonance of the ^{31}P-{^1H} NMR spectra is observed with the monosubstituted M-complex (Fig. 4). It is also possible that no rotation is allowed about the N–Ni bonds of the substituted M-complexes, thus resulting in the split. No clear explanation of the split can, however, be made at present.

At a high molar ratio of pyrrolidine (Figs. 5(d) and 5(e)), no resonance due to free pyrrolidine (25.78 ppm (α) and 47.12 ppm (β)) is detected, while a broad resonance is observed in the range from 39 to 45 ppm (Fig. 5(e)). This resonance remains unclarified. Free pyrrolidine is possibly polymerized during the ^{13}C-{^1H} NMR measurements (about 10 hours at room temperature for each measurement) because of its reactivity is higher than that of the coordinated pyrrolidine.

It may be concluded at least that the driving force for the substitution is predominantly the steric factor of amine rather than the electronic factor, as is the case with the substitution of triphenylphosphine ligands with other tertiary phosphines.

Thermal Decomposition of Graphite Fluoride. II. Kinetics of Thermal Decomposition of $(CF)_n$ in a Vacuum

Nobuatsu WATANABE* and Satoshi KOYAMA

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received April 3, 1980)

The rate of thermal decomposition of $(CF)_n$ prepared under several reaction conditions was measured in a vacuum. The rate was expressed by Avrami-Erofeyev's equation of second-order for highly oriented sample and of first-order for disordered one. The apparent activation energies of the decomposition reaction were about 50 kcal/mol (1 cal=4.184 J) for the former, and about 14 kcal/mol in higher temperature region and about 100 kcal/mol in lower temperature region for the latter. Thermal decomposition of $(CF)_n$ proceeds two-dimensionally around a nucleus of carbon which is formed at the initial stage of decomposition. The rate of thermal decomposition of various samples is dependent on the number of the nucleus forming sites. The nucleation of carbon takes place on a grain boundary between two small crystallites of $(CF)_n$. The rate of the growth of the nucleus is fast along the grain boundary but slow in other directions. The activation energy was estimated to be about 100 kcal/mol for the former and almost 0 kcal/mol for the latter.

It is well-established that the physicochemical properties of graphite fluoride depend both on those of original carbon materials and fluorination conditions.[1,2] DTA studies revealed that decomposition temperature of $(CF)_n$ samples varied widely between 320 and 610 °C. Detailed analyses of the decomposition products of $(CF)_n$ in a vacuum have also been made, and it was found that thermal decomposition can be expressed by the following equation,[3]

$$2(CF)_n \longrightarrow nC^* + XCF_2 + YC_2F_4, \quad (1)$$

where $X+2Y=n$ and C* is amorphous carbon. Then, these gaseous products give various compounds such as CF_4, C_2F_6, C_3F_8, *etc.*

Recently this reaction was also studied by Kamarchik and Margrave.[4] They have used Avrami-Erofeyev's equation to analyze their kinetic data.

$$-\ln(1-\alpha) = (kt)^n, \quad (2)$$

where α is the fraction decomposed, k is the rate constant, and n is the dimension of the nucleus growth. The value of n was found to be 2. This result suggests that the decomposition proceeds two-dimensionally around an active site or a nucleus, and the reaction is of an auto-catalytic type. However, they could not make clear the reason why the rate of thermal decomposition of $(CF)_n$ samples varied with their formation conditions.

In this work, thermal decomposition of $(CF)_n$ prepared from various carbon materials was investigated in more detail. Based on the kinetic studies, we will discuss how the reaction (Eq. 1) proceeds in a particle or crystal of $(CF)_n$, and why the thermal behavior of samples differs from each other. In addition, microscopic observation has been made with $(CF)_n$ before and after the decomposition, and we also discuss where the decomposition begins, and how the nucleus grows.

Experimental

Preparation and Some Properties of $(CF)_n$ Samples. The samples used for the measurement of decomposition rate were prepared from (I) flaky natural graphite whose grain size was 279—840 μm, (II) powdery natural graphite whose grain size was 46—62 μm, and (III) petroleum coke (<37 μm).

The samples I and II were prepared by using a rotary reactor for fluorination.[5] Table 1 shows some properties and formation conditions of these samples. Crystallinity was measured by means of X-ray diffractometry. The crystallinity of the samples increases in the order of I>II>III. While the fluorine/carbon atomic ratio (F/C) of sample III is the highest. This is due to the presence of CF_2 or CF_3 groups on the particle surface of this $(CF)_n$ sample.[6]

In addition to the samples described in Table 1, another $(CF)_n$ sample has been prepared for microscopic observation in the following manner. A grain of flaky natural graphite of 2 mm in diameter was directly fluorinated in a thermo-balance type apparatus at 610 °C, for 48 h. Fluorine pressure was 26.6 kPa. The sample of $(CF)_n$ thus prepared was of flaky type. The size was about 2 mm in diameter (a and b axes) and about 0.5 mm in thickness (c axis), respectively.

Measurement of the Decomposition Rate and Microscopic Observation. A thermo-balance was used to measure the weight loss *vs.* time curve. The apparatus has been described in detail previously.[7] About 30 mg of $(CF)_n$ sample on a nickel boat was placed in the reaction tube of the apparatus. A pressure of 0.13 Pa was kept throughout the decomposition.

TABLE 1. PREPARATION CONDITION AND SOME PROPERTIES OF GRAPHITE FLUORIDE SAMPLE

Sample	Starting materials	Preparation condition		Crystallinity		F/C ratio	Color
		Temp/°C	t/h	d_{001}/Å	β_{001}/°		
I	Natural graphite (279—840 μm)	600	24	5.84	1.4	0.93	White
II	Natural graphite (46—62 μm)	600	11	6.00	2.5	0.94	Gray

The sample for microscopic observation was cleaved vertically along c axis. To do this, two fine rods of steel were sticked on both basal planes of a particle, then they were pulled off. These procedures were continued until the sample became sufficiently transparent. The sample thus formed was about 0.05 mm in thickness. The microscopic observation was carried out through this thin flake by means of either transmitted or reflected light, and in some cases, polarized light was used. The distribution of fluorine and carbon atoms in $(CF)_n$ sample was determined by X-ray microanalyzer.

Results and Discussion

Figure 1 shows TG curves for the decomposition of $(CF)_n$ sample given in Table 1 and of a sample from natural graphite of 62—74 μm. The heating rate was 5 °C/min. The decomposition of sample III which has a low crystallinity begins at lower temperature. However, the decomposition ended at the same temperature for all the samples, and their final weight loss was also constant value of about 70%. In the following discussion, the fraction decomposed, α is defined by $\alpha=w/w_f$, where w is the weight loss and w_f is the final weight loss. Since the final weight loss was 70%, α was given by $\alpha=w/0.7$.

Decomposition Rate of Samples I and II. Figure 2 shows the weight loss *vs.* time curves for the decomposition of sample I. Each curve has induction period, followed by acceleratory period and deceleratory period, that is, the curves are of sigmoid type. These curves are characteristic of the thermal decomposition of solids such as magnesite,[8] barium azide,[9] and other ionic crystals. The presence of induction and acceleratory periods shows that the reaction proceeds heterogeneously,[10] namely, a nucleus of the decomposition product is formed at a specific point in the crystal and spreads around the point.[11] In heterogeneous reactions, it is known that the rate equation for the decomposition of various kinds of compound is expressed by

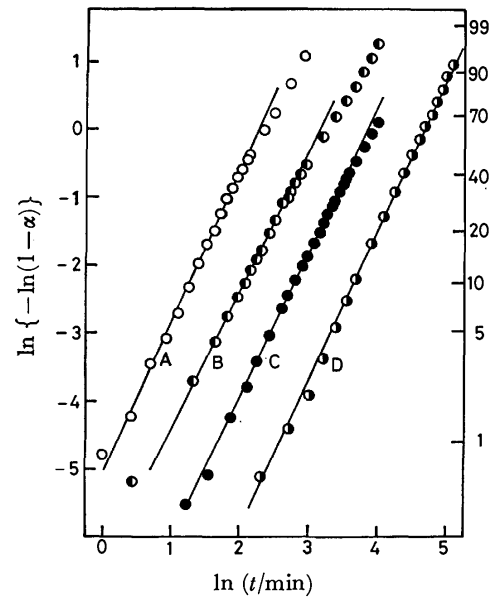

Fig. 3. $\ln\{-\ln(1-\alpha)\}$ *vs.* $\ln t$ plots for thermal decomposition of graphite fluoride (sample I).
A: 668 °C (n=2.24), B: 654 °C (n=2.05), C: 616 °C (n=2.12), D: 599 °C (n=2.18).

$$\alpha = \frac{\sigma N_0}{V_0}(k_1 t)^n, \tag{3}$$

or

$$-\ln(1-\alpha) = \frac{\sigma N_0}{V_0}(k_1 t)^n, \tag{4}$$

where α is the fraction decomposed, σ is the shape factor of a nucleus, N_0 is the number of nucleus forming sites, V_0 is the final volume of the reaction products, k_1 is the linear rate constant of the growth of the nucleus and n is the dimension of the growth of nucleus. The curves shown in Fig. 2 could be expressed by Eq. 3 only for the region that the weight loss is less than 20%. However, the n value was varied from 1.5 to 2.1. This is because the overlapping of nuclei is not taken into account, and it becomes difficult to neglect the effect of overlapping as the nucleus grows. Equation 4 was derived by Avrami considering this effect.[12]

Then Eq. 4 was applied to the decomposition of $(CF)_n$, and $\ln\{-\ln(1-\alpha)\}$ was plotted against $\ln t$ in Fig. 3, in order to obtaine the n value. The plot gives a straight line for the region that α is less than 40% for samples I and II. For sample I, values in the range from 2.05 to 2.24 were obtained from the

slopes of these plots as the dimension of the nucleus growth. This result suggests that the rate of the nucleation is sufficiently fast and that the dimension of the growth of nucleus is 2. Then $\sqrt{-\ln(1-\alpha)}$ was plotted against time in order to obtain the apparent rate constant in Fig. 4. This plot gives a straight line in the range of α=0—40% for sample I. The same plot for sample II also gives a straight line in the same range and the rate constant can be obtained from the slope. Figure 5 shows the Arrhenius plots for these two samples. The activation energy was 52.8 kcal/mol for sample II and 49.7 kcal/mol for sample I. The intercept to the ordinate $1/T$=0 was 26.8 and 24.0 for sample II and I, respectively. These values are given by $\ln A\sqrt{\sigma N_0/V_0}$, where A is the frequency factor of k_1. Since A, σ, and V_0 can be regarded as constant for these samples, the difference in the intercepts and the apparent reaction rate between the samples are due to the difference in N_0. It was found from the value of 26.8 and 24.0 that the number of nucleus forming site in sample II was about 300 times that in sample I.

It was found that the dimension of the nucleus growth is two and that the number of nucleus forming sites is different in each sample. These results suggest that the decomposition is initiated at CF_2 and CF_3 groups on the surface of $(CF)_n$ crystal or at a point on the region which is highly strained as reported on the decomposition by γ-ray[13] and by heat.[14] They also suggest that the nuclei formed spread two-dimensionally in parallel with the layer plane.

Decomposition Rate of Samples II and III. In contrast to the samples I and II, smaple III is a fine powdery sample prepared from petroleum coke. The weight loss *vs.* time curve for this sample has almost no acceleratory period and exhibits deceleratory curve from the beginning since the overlapping will take place as soon as the decomposition starts. The reaction rate is then expressed by the first-order equation:

$$-\ln(1-\alpha) = kt, \qquad (5)$$

where k is the apparent rate constant. Figure 6 shows $\ln(1-\alpha)$ *vs.* time plots for this sample. The same plots for sample II also gave straight lines in the region where the weight loss is more than 20% (see Fig. 7). The Arrhenius plots for sample III at 480 °C or above can be approximated by a straight line (see Fig. 8), and the activation energy was calculated to be about 14 kcal/mol. On the other hand, it was about 100 kcal/mol below this temperature. This fact suggests that the rate-determining step at higher temperatures differs from that at lower tem-

peratures. For sample II the activation energy was calculated to be about 100 kcal/mol. The same plot for sample I did not give a straight line. The results obtained above are summarized in Table 2.

Microscopic Observation of the Formation and Growth of Nucleus. Graphite fluoride belongs to optically uniaxial crystals and its optic character is negative. The principal refractive index, ω is 1.543—1.544.[15] In the following observation, since sample was exposed with the light in parallel with the optic axis (or crystallographical c axis) of $(CF)_n$, it apparently looks optically isotropic. Therefore, it looks always dark in the observation between crossed nicols. Figure 9 shows the photomicrographs of the sample before decomposition. The bright lines in Fig. 9B showed double refraction and were extinguished in the rotation of the sample by 90°. A bright line showing double refraction corresponds to the black line in Fig. 9A, and is regarded as grain boundary in $(CF)_n$ crystal.

The sample was heated up to 400 °C in a vacuum with a heating rate of 10 °C/min, and it was then quenched to room temperature. Photomicrographs of the sample after these treatments are shown in Fig. 10. In the case of observation with transmitted light, the black lines in Fig. 10A were widened, and light lines in Fig. 10B were darkened in the observation between crossed nicols. These results suggest that the decomposition nucleus of carbon is formed on the grain boundary.

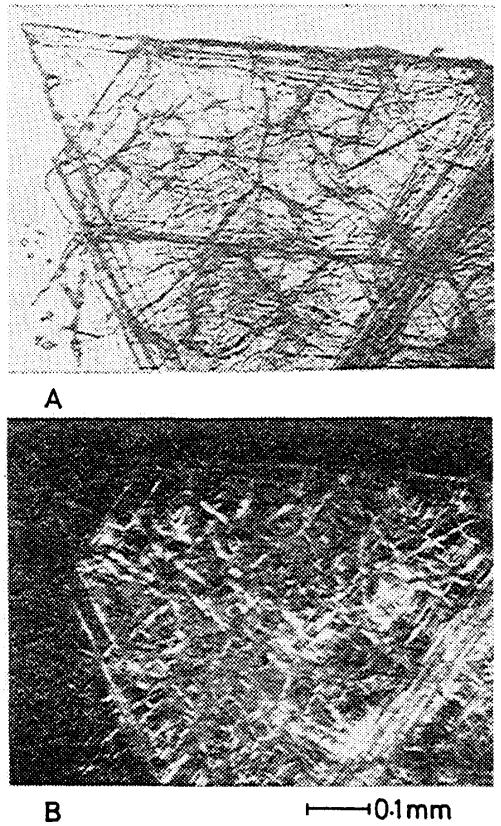

Fig. 9. Photomicrographs of graphite fluoride thin flake.
A: Transmission, B: reflection between crossed nicols.

Figure 11 shows the shape of the nucleus. The main part of the photomicrograph is sketched; the solid line shows the outline of a nucleus, and the broken line shows a grain boudary. Nuclei spread long along the grain boundary, and is anisotropic in shape. Therefore, a nucleus should be formed at a point on a grain boundary and then grow along the grain boundary. The growth of the nucleus is not isotropic, that is, fast along the grain boundary and slow in other directions. Figure 12 shows a scanning electron micrograph and changes in composition of carbon

and fluorine atoms determined by means of the X-ray microanalysis. The straight line shows the place where the analysis is done. Two curves above the straight line show the distribution of carbon and fluorine atoms. Fluorine concentration near the grain boundary is low and carbon concentration is high as compared with other parts. No such a change was observed for the original graphite fluoride.

It should be due to the strain energy[15] that the decomposition begins at a point on the grain boundary. This region is energetically activated. The nucleation takes place at the point to which extremely high stress is applied. When the layer plane of $(CF)_n$ is decomposed to that of graphite, the C–C bond length decreases from 1.54 to 1.42 Å, and the plane shrinks.[2] Therefore, the stress applied to the point where the decomposition occurs is relaxed. Next the stress remains in the vicinity along the grain boundary, and then the vicinity will decompose in turn. Thus the nucleus grows along the grain boundary. Because of the relaxation of the stress which expands the layer spacing, the crystallinity of $(CF)_n$ is improved as described in the preceding paper.[3]

Kinetics of Thermal Decomposition of $(CF)_n$. The rate of thermal decomposition of highly oriented $(CF)_n$ is expressed by Eq. 4 with $n=2$. In this equation, it is assumed that the volume $V(t)$ of the nucleus at time t is given by:

$$V(t) = \sigma(k_1 t)^2 \qquad (6)$$

This equation also involves the assumption that the growth of the nucleus is isotropic. When the nucleus grows anisotropically, the volume should not be given by this equation. Figure 13 shows a model of the nucleus shape in $(CF)_n$. A nucleus formed at A at time 0 grows at a rate of k_a along the grain boundary and at a rate of k_b in other directions, where $k_a > k_b$. At time y ($y<t$), the growth of the nucleus reaches to B. At time t, the front of the nucleus spreads by $k_b(t-y)$ from B and by $k_b \cdot t$ from A in other directions than grain boundary. Therefore, the shape of the nucleus

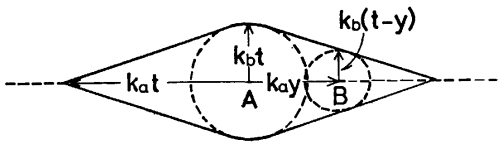

Fig. 13. Schematic model of a nucleus at time t, which was formed at $t=0$.
Broken line: grain boundary.

at time t is rhomb-like as given by the solid line in Fig. 13. The volume of the nucleus having this shape is given by:

$$V(t) = 2\sigma k_a k_b t^2, \qquad (k_a \gg k_b). \tag{7}$$

Then Eq. 4 can be rewritten as[10]

$$-\ln(1-\alpha) = \frac{2\sigma N_0 k_a k_b}{V_0} \cdot t^2. \tag{8}$$

The apparent rate constant, k_1 in Eq. 4 is given by:

$$k_1 = \sqrt{k_a k_b} = A\{\exp(E_{aa}+E_{ab})/2RT\}, \tag{9}$$

where E_{aa} and E_{ab} are the value of activation energy involved in k_a and k_b, respectively. The apparent activation energy according to Eq. 4 is about 50 kcal/mol, that is,

$$E_{aa}/2 + E_{aa}/2 \simeq 50 \text{ (kcal/mol)}. \tag{10}$$

The degree of the nuclei overlapping on the grain boundary becomes larger as the decomposition proceeds because the nucleus forming sites are distributed on the grain boundary. In Avrami-Erofeyev's equation, the overlapping of nuclei has been taken into account.[10] However, Eq. 7 is not applicable if nuclei overlap only on the grain boundary. The number of nucleus forming sites, N_0 of the sample II is greater than that of sample I. The shape of a nucleus of the sample with a large number of nucleus forming sites is shown in Fig. 14. The nuclei overlapping on the grain boundary is negligible in an earlier part of the decomposition as shown in Fig. 14A. On the other hand, it becomes nonnegligible in the later part of the decomposition as shown in Fig. 14B. If the length L of the grain boundary is sufficiently large, the nucleus shown in Fig. 14B is given by:

$$V(t) = 2L\sigma k_b t. \tag{11}$$

Then the rate equation can be written as:

$$-\ln(1-\alpha) = \frac{2L\sigma N_0 k_b}{V_0} \cdot t. \tag{12}$$

This equation has the same form as Eq. 5 and has been applied to the decomposition of sample II (decomposed above 30%) and sample III (decomposed above several percent). The activation energy according to this equation has been obtained to be about 100 kcal/mol, which means $E_{ab} \simeq 100$ kcal/mol. Substituting this value into Eq. 10, a value of almost 0 kcal/mol is obtained as the activation energy for the growth of the nucleus along the grain boundary, that is, $E_{aa} \simeq 0$ kcal/mol.

Characteristics of thermal decomposition of $(CF)_n$. Graphite fluoride, $(CF)_n$ can be regarded as a two-dimensional sheet-like ploymer, and carbon atoms are bonded to fluorine atoms covalently. Chain polymers are generally depolymerized by heat treatment, and

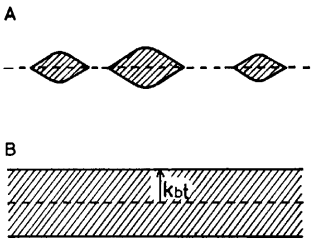

Fig. 14. Schematic illustration of nucleus when the sample has a large number of nucleus forming sites, N_0.
A: Overlapping of nuclei along grain boundary can be neglected, B: grain boundary has perfectly nucleated.

release their corresponding monomer. It seems strange that the decomposition reaction of $(CF)_n$ is heterogeneous as known about magnesite, barium azide, and other ionic crystals.

"Cage effect" is one of the most important phenomena which take place during γ-ray irradiation on some polymers.[16] This effect is essentially the trapping of radicals or molecules formed by the rupture of the polymer chain in polymer molecules. Then these are to recombine with the polymer radicals resulting from the rupture. This is also the case for thermal decomposition of $(CF)_n$. Carbon atoms in the layer is hardly released because they are bonded to neighboring three carbon atoms. Even if one C–C bond is ruptured, the remaining two bonds hold the carbon atom. The probability of recombination should increase, and the decomposition takes place preferentially at the interface between the nucleus and reactant. In fact, decomposition is also initiated on the surface of the crystal and proceeds to the inner part when γ-ray is irradiated on $(CF)_n$.[13] In the case of $(CF)_n$, this effect should be called as "chain effect" rather than "cage effect."

It is due to the strong stress to the grain boundary that thermal decomposition of $(CF)_n$ is initiated at grain boundary. The strain in grain boundary also leads to the decomposition at such a low temperature as 400 °C and zero activation energy E_{aa}. The strain energy remains in the vicinity, and the nucleus grows along the grain boundary.

The actual decomposition mechanism might be more complicated because the grain boundary does not have regular form, and therefore, the shape of the nucleus must change with that of the grain boundary. Consequently, it is not enough to consider only the simple model shown in Fig. 13 for the explanation of the whole reaction. Both Eqs. 8 and 12 could not be applied in the region $\alpha=40$—100% for sample I.

Conclusion

Thermal decomposition of $(CF)_n$ is initiated at a point on a grain boundary or at CF_2 or CF_3 group on the surface of a particle. The nucleus of carbon formed spreads two-dimensionally but anisotropically; the rate of the nucleus growth is larger along the grain boundary than in other directions. As a result,

the shape of nucleus varies with the degree of nucleus overlapping along grain boundary, and the reaction is expressed by either of two different equations. The apparent rate of thermal decomposition is determined by the number of nucleus forming sites in $(CF)_n$ sample.

Thermal Decomposition of Graphite Fluoride. III. Thermal Decomposition of $(CF)_n$ in Oxygen Atmosphere

Nobuatsu WATANABE,* Toshihiko KAWAMURA, and Satoshi KOYAMA
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606
(Received April 3, 1980)

Thermal decomposition of $(CF)_n$ was carried out under an oxygen atmosphere. The decomposition temperature was found to be a decisive factor to control the decomposition mechanism and the structure of residual substances. The decomposition reaction proceeded faster in oxygen than in a vacuum at temperatures higher than 588 °C. However, it was reversed below 588 °C. The decomposition mechanism in high temperature region was similar to that in a vacuum. The ESCA spectra of residual substances prepared above 588 °C indicated the presence of carbon atoms which were not bonded with fluorine, namely the nuclei comprised of carbon still remained even in oxygen. The rate of the weight decrease was larger in oxygen than in a vacuum because of the reaction of carbon nuclei, which was formed by thermal decomposition, with oxygen. On the other hand, it considerably decreased below 588 °C, where no nuclei was found for any sample.

A high temperature reaction of graphite fluoride with elemental fluorine gives the $(CF)_n$ type graphite fluoride having a layered structure of hexagonal network. The low surface energy is the most characteristic nature of the product.[1] Therefore, while it is useful as a solid lubricant on one hand, it is on the other hand a troublesome substance which brings about the anode effect in the electrolysis of molten fluorides. Currently, there is a necessity of studying the decomposition of $(CF)_n$ in order to produce in good yield and to elucidate the phenomenon of anode effect. Graphite fluoride, $(CF)_n$, decomposes in a vacuum at high temperature to form several kinds of volatile fluorocarbons and amorphous carbon.[2] Previous studies revealed that the Avrami-Erofeyev equation could be applied to the isothermal TG curves for the decomposition of $(CF)_n$ in a vacuum, and that fluorine and carbon atoms were eliminated from $(CF)_n$ in the ratio of 2 to 1 during the decomposition.[3-5] In this study, thermal decomposition of $(CF)_n$ was performed under oxygen atmosphere and comparison was made with the decomposition behavior in a vacuum.

Experimental

The starting material was natural graphite from Madagascar, whose particle size was 46—62 μm, and the purity was 99.5% from ash treatment. Graphite fluoride, $(CF)_n$, was prepared by the fluorination of natural graphite at 600 °C for 10 h (sample I) or for 15 h (sample II) under the stream of mixed gas of fluorine (5.1×10^4 Pa) and argon (5.1×10^4 Pa). Some properties of these samples were summarized in Table 1. Sample I was used for the measurement of TG and DTA, and sample II was used for X-ray diffractometry, elementary analysis, photoelectron and infrared spectroscopy.

Isothermal TG curves for thermal decomposition of $(CF)_n$ were measured with a thermobalance under oxygen flow. The flow rate was between 15 and 20 ml/min. The residual substances were obtained from the partially decomposed $(CF)_n$. They were analyzed with the methods mentioned above. DTA was carried out under reduced pressure of 6.7×10^2 Pa, using α-Al_2O_3 as a reference material. Infrared spectra were taken with the KBr disc method. The fluorine content of residual substance was determined with the oxygen flask method.

TABLE 1. SAMPLES USED FOR THE EXPERIMENT

Sample	Fluorine content/%	Crystallinity		Color
		d_{001}/Å	β_{001}/°	
I	56.3	6.02	2.40	Gray
II	59.7	5.97	1.67	Gray

Results

Isothermal TG Curves for Thermal Decomposition of $(CF)_n$ in Oxygen. Figure 1 shows isothermal TG curves both in oxygen and in a vacuum at several temperatures. The final weight loss was about 75% in a vacuum, whereas it was almost 100% in oxygen at temperatures above 588 °C. The Arrhenius plot for the TG curves in oxygen is given in Fig. 2. The rate constant was defined to be the slope at the inflexion point of the TG curve. As shown in the figure, it has a distinct break point at 588 °C. This means that the mechanism of thermal decomposition is different from each other in the two regions divided at this tempera-

ture. As seen in Fig. 1, the decomposition proceeds faster in oxygen than in a vacuum at temperatures higher than 588 °C, though the reverse is ture below 588 °C.

The thermal decomposition of $(CF)_n$ has been studied under vacuum previously,[3-5] and the Avrami-Erofeyev equation[6]

$$-\ln(1-\alpha) = (kt)^n$$

is applied to the isothermal TG curves. Here α is the fraction decomposed, k is the rate constant and n is the dimension of nucleus growth. The mechanism shown in Fig. 3 is suggested for the structural changes during the decomposition from the facts that n is equal to 2 and $(CF)_n$ has a layered structure.[7] The above equation can also be applied to the isothermal TG curves in oxygen. The result is shown in Fig. 4, where straight lines are obtained at temperatures above 588 °C. This means that the decomposition at higher temperatures is also due to the formation and growth of nuclei. No such plots can be obtained at temperatures below 588 °C, because the decomposition rates are too small to measure the final weight loss.

Structural Analysis of Residual Substance. In order to elucidate the difference in the mechanism of the thermal decomposition due to a temperature, the residual substance was analyzed by several methods. The sample were those prepared by the thermal decomposition of $(CF)_n$ in oxygen at 560 and 610 °C.

Table 2 shows the fluorine contents and color of the residual substance. The fluorine contents are

	59.4	57.9	Black
Before decomposition		59.7	Gray

almost constant and independent of decomposition temperature or weight loss. This fact indicates that fluorine and carbon atoms are eliminated in the ratio of 1 to 1 during the decomposition in oxygen. In addition, it was observed that $(CF)_n$ turned black as soon as the decomposition started at 610 °C and this color did not change during the decomposition as observed in a vacuum.[4] On the other hand, $(CF)_n$ gradually turned white at 560 °C as the decomposition

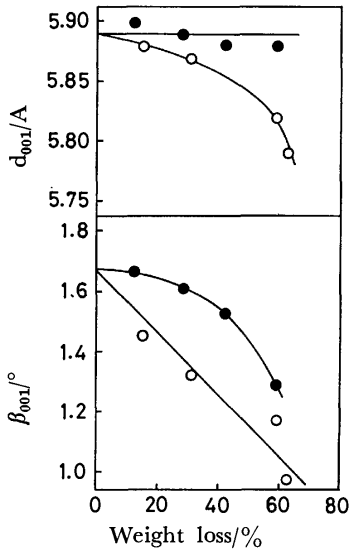

Fig. 6. Change in crystallinity of residual substance formed in oxygen.
●: 610 °C, ○: 560 °C.

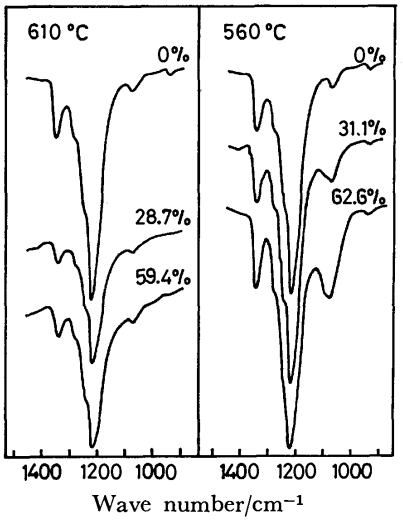

Fig. 7. IR spectra of residual substance formed in oxygen. Numerical value for each spectrum indicates the weight loss of residual substance.

proceeded.

The DTA curves are shown in Fig. 5, where the residual substance formed at 610 °C is thermally less stable than that formed at 560 °C.

Figure 6 shows the results obtained from X-ray diffractometry. Only the lines correspond to $(CF)_n$ can be observed and those of carbon are not observed at both temperatures. The interlayer spacing and half width were calculated from the diffraction profile of the 001 line of $(CF)_n$. The decrease in the half width means that the strain of $(CF)_n$ is removed. The rate at 560 °C is larger than that at 610 °C.

Figure 7 shows the IR spectra of residual substances. The pattern of the peak at 1075 cm^{-1} for the sample prepared at 560 °C varies with the decrease in weight, whereas the pattern is hardly changed by heating at 610 °C. However, there is no peak for carbonyl group as observed in graphitic oxide.[8]

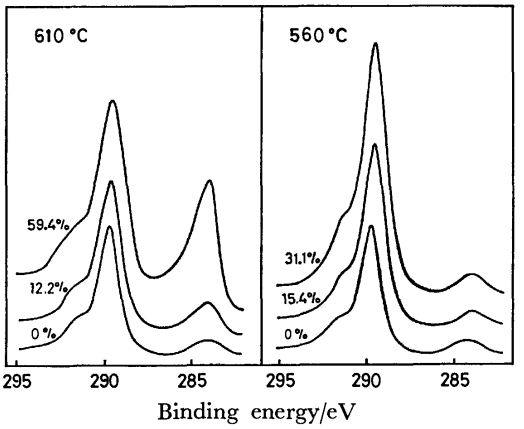

Fig. 8. C_{1s} ESCA spectra of residual substance formed in oxygen. Numerical value for each spectrum indicates the weight loss of residual substance.

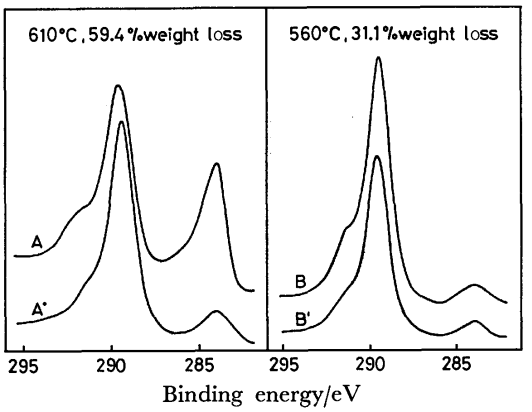

Fig. 9. C_{1s} ESCA spectra of residual substance formed in oxygen.
A,B: Before grinding, A',B': after grinding.

The ESCA spectra of the residual substances are shown in Fig. 8, where two peaks are observed at 284 and 289.5 eV. The former is due to C_{1s} electrons of graphite or hydrocarbons, and the latter is due to those of tertiary C–F group.[9,10] No changes are observed in the spectra of the residual substances formed at low temperature, whereas in the case of the sample prepared at high temperature, the intensity of the peak at 284 eV increases as the decomposition proceeds. Figure 9 shows the change in the C_{1s} ESCA spectra for samples ground with an agate mortar. For the sample prepared at 610 °C, there is a decrease in the intensity of the peak at 284 eV. In general, the information obtained from ESCA is limited to the surface layer of the sample. Therefore, the ESCA spectra show that carbon atoms having no bond with fluorine atoms are present only on the surface of the residual substance formed at 610 °C. However, since the amount of such carbon atoms is regarded to be negligible compared with that of carbon bonded with fluorine, the fluorine contents are not dependent on the weight loss, as shown in Table 2. For the sample formed at 560 °C, no such carbon atoms are found. This is consistent with the result of the elementary analysis.

All the evidences shown above indicate that the

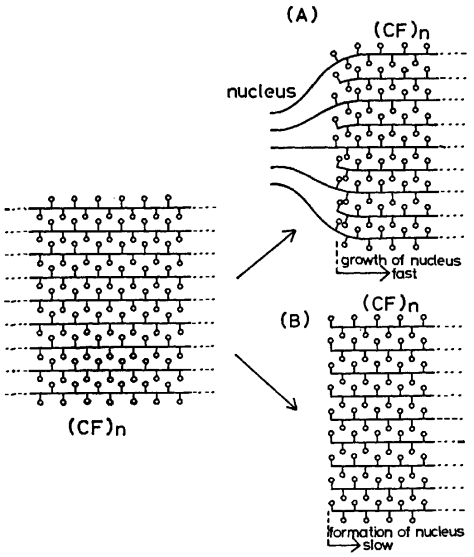

Fig. 10. Schematic illustration of thermal decomposition of $(CF)_n$ in oxygen.
(A): Residual substance formed in high temperature region, (B): residual substance formed in low temperature region.

mechanism of the thermal decomposition of $(CF)_n$ in oxygen at temperatures higher than 588 °C is different from that below this temperature as suggested from the Arrhenius plot.

Discussion

Mechanism of Thermal Decomposition of $(CF)_n$ in Oxygen. From the results described above, the mechanism shown in Fig. 10 is suggested for the thermal decomposition in oxygen. The decomposition is initiated by the nucleus formation at the edge plane or strained regions of $(CF)_n$ as is discussed in the study under vacuum.[4] The result of X-ray diffractometry supports the above view. The nucleus consists of carbon atoms. Since fluorine and carbon atoms are eliminated in the ratio of 2 to 1 during the decomposition in a vacuum, the ratio of carbon atoms in the residual substance increases as the decomposition proceeds. In the presence of oxygen, it is expected that the decomposition rate in oxygen is larger than that in a vacuum because of the reaction of carbon with oxygen. This inference seems to be reasonable because no peak due to carbonyl group is observed in the IR spectra and fluorine and carbon atoms are eliminated in the ratio of 1 to 1. However, since the decomposition in a vacuum proceeds faster than that in oxygen at 575 °C as shown in Fig. 1, the inference is not valid for the decomposition at low temperatures.

In the case of the thermal decomposition in oxygen at high temperatures, the mechanism is considered to be similar to that in a vacuum from the following results; (i) the decomposition proceeds faster in oxygen than in a vacuum, (ii) the isothermal TG curves are fit to the Avrami-Erofeyev equation, (iii) the change in the color of residual substances in oxygen is similar to that in a vacuum and (iv) carbonaceous parts are present on the surface of residual substances. If the nuclei grow at a rate larger than that of the reaction of carbon with oxygen, they will still remain even in the presence of oxygen. Therefore, the weight loss in oxygen is almost equal to a sum of that in a vacuum and that by the elimination of carbon dioxide. and the rate of the weight loss in oxygen is larger than that in a vacuum.

On the other hand, in the low temperature region, the nuclei grow at a rate smaller than that of the reaction of carbon with oxygen. That is, since the nuclei are consumed as soon as they are formed, the rate of weight loss is smaller than that in a vacuum. From this reason, the ESCA spectra of residual substances formed at 560 °C show no peak corresponding to the carbon atoms which are not bonded with fluorine atoms.

Structural Aspect of Residual Substance. The differences in the properties of the residual substances formed at 560 °C and 610 °C are discussed in relation to the nucleus described above. The residual substances formed at 610 °C have carbonaceous parts which can change to nuclei, whereas those formed at 560 °C have no such parts. The strain energy produced by the difference in the crystal structure between reactant and product is one of the sources for the activation of nucleus in the thermal decomposition of solids.[11] Since the residual substances formed at 610 °C have such strain energy in the particle, their crystallinity is inferior to that of the residual substances formed at 560 °C, and the former is thermally less stable than the latter.

6) The Avrami-Erofeyev equation is derived on the assumption that the reaction in question is initiated by the formation of nucleus which grows either n-dimensionally or $(n-1)$-dimensionally. The nucleus is the fragment of the product.
7) Nuclei are formed at the edge of layers or at the strained parts of $(CF)_n$ when the rupture of C–C bond occurs, and at the same time, fluorocarbon radical (*i.e.* CF_2) or fluorocarbon molecule (*i.e.* C_2F_4) are formed. The nuclei mainly consist of carbon atoms. Since the interface between $(CF)_n$ and nuclei is more reactive than the bulk of $(CF)_n$, it is more likely that the decomposition proceeds by two dimensional growth of the nuclei in the layers. From another experiment, it was found that the rupture of C–C bond takes place at every second layer of $(CF)_n$.

(Received April 11, 1980)

Fortamine dihydrochloride, $C_8H_{18}N_2O_4 \cdot 2HCl$, is obtained by the hydrolysis of fortimicin B with hydrochloric acid. The space group is *C2* with $a=16.109(2)$, $b=10.047(1)$, $c=8.603(1)$ Å, $\beta=108.69(1)°$, and $Z=4$. The structure was solved by the heavy atom method, and least-squares refinement using 1564 reflexions led to the final R value of 0.030. The ring conformation of fortamine dihydrochloride is an inversed chair form of fortamine. The chair form is significantly compressed to relax the non-bonded interactions between axial substituents.

In the studies on the structures of fortimicins, potent aminocyclitol antibiotics, Egan *et al.* have reported that the ring conformation of 1,4-diaminocyclitol in fortimicin B must be inversed when its amino groups are protonated in its sulfate.[1] Similar unusual conformational inversion occurs in fortimicin A (4-*N*-glycylfortimicin B).[1] We have achieved X-ray analyses of fortimicin B[2] and fortamine,[3] and found that 1,4-diaminocyclitol rings take a normal conformation as shown in Fig. 1. We will denote this conformation as 'B' type and inversed one as 'A' type. Because of the inherent 1,3-diaxial interactions, 'A' type conformation seems to be unstable and it is necessary to examine the validity of the assignment by Egan *et al.*[1] Unfortunately, attempts to crystallize fortimicin B sulfate and fortimicin A were unsuccessful, but crystals of fortamine dihydrochloride were obtained. Its structure determination would throw light on the effect of protonation on the ring conformation.

Experimental and Structure Determination

Fortamine dihydrochloride was obtained by the hydrolysis of fortimicin B with hydrochloric acid. The prismatic crystals were grown from a methanol solution. A crystal of $0.5 \times 0.4 \times 0.3$ mm^3 sealed in a glass capillary was used for data collection on a Rigaku four-circle automated diffractometer with graphite monochromated Mo $K\alpha$ radiation ($\lambda=0.71069$ Å). Preliminary unit-cell dimensions and space group were obtained from photographs. The space group was determined from the systematic absences (*hkl* for $h+k=2n+1$). Accurate cell dimensions were determined by least-squares calculation with the 2θ values of 15 high angle reflexions measured on the diffractometer. Crystal data are summarized in Table 1. All reflexions within the range of $2\theta \leqq 55°$ were collected by the use of the ω-2θ scan mode with a scanning rate of $4°(2\theta)$ min^{-1}. Stationary background counts were accumulated for 10 s before and after each scan. Periodic checks of the intensity values of three standard reflexions did not reveal any significant X-ray damage or crystal decay. Any corrections for absorption or extinction were not applied. A total of 1610 independent reflexions were obtained, of which 1564 ($|F_o| \geqq 3.0\sigma(|F_o|)$) were considered as observed.

The structure was solved by the heavy atom methods and refined by the block-diagonal least-squares methods with the modified HBLS program. All the hydrogen atoms were found by the difference Fourier synthesis. Refinement was brought to completion using anisotropic and isotropic thermal parameters for the non-hydrogen and hydrogen atoms, respectively. In the later stage of the refinement, the following weighting system was adopted;
$w=0.3$ for $|F_o|<3.72$ and $|F_o|>37.16$, and

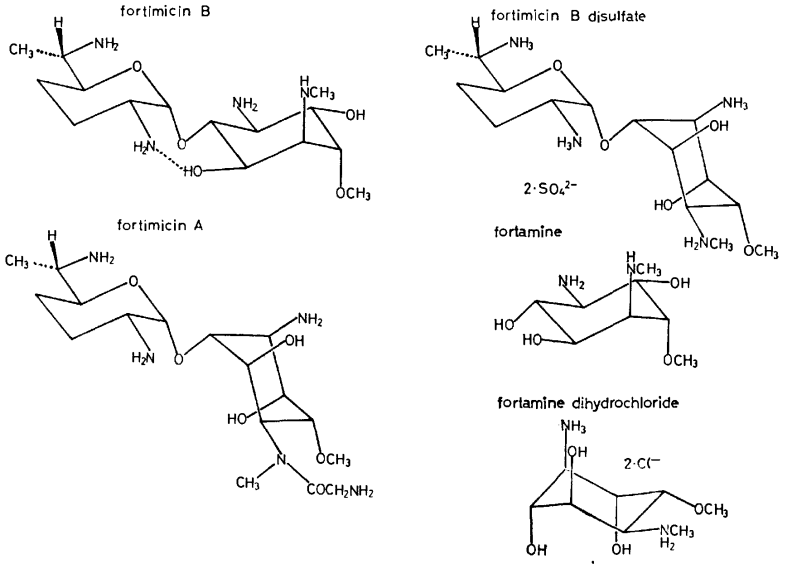

Fig. 1. Structures of fortimicins and fortamines.

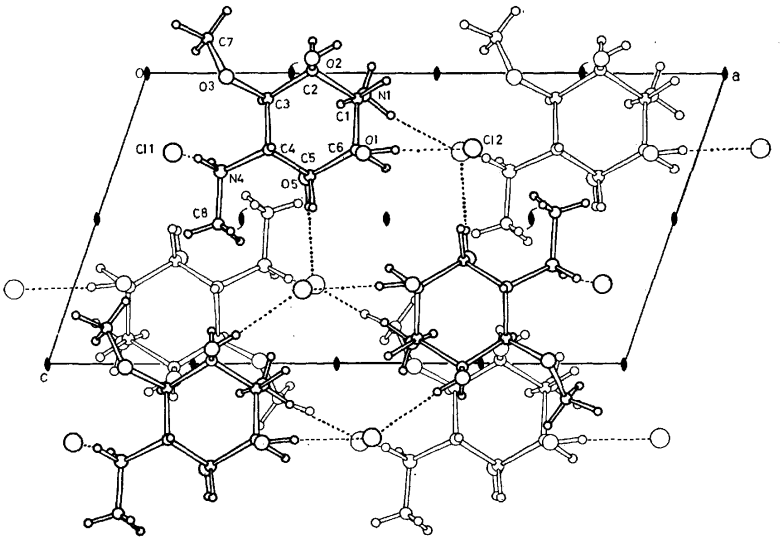

Fig. 2. The crystal structure projected along the b axis.

Table 1. Crystal data

$C_8H_{20}N_2O_4Cl_2$	$b=10.047(1)$
M.W.=277.15	$c=8.603(1)$ Å
C2	$\beta=108.69(1)°$
$Z=4$	$D_x=1.396$ g cm^{-3}
$a=16.109(2)$	μ(Mo $K\alpha$)=4.961 cm^{-1}

$w=(0.00833(F_o)^2-0.34114|F_o|+4.48559)^{-1}$ for $3.72\leqq|F_o|\leqq37.16$. The final R value was 0.030. Atomic scattering factors were taken from "International Tables for X-Ray Crystallography."[4] Differences in the intensities of six Friedel pairs of reflexions measured on a diffractometer using Cu $K\alpha$ radiation confirmed the absolute configuration previously determined by CD measurements.[1] The final positional and thermal parameters are given in Table 2. A list of the observed and calculated structure factors is kept as Document No. 8035 at the Chemical Society of Japan.

Results

Hydrogen Bond and Crystal Structure. The crystal structure viewed along the b axis is shown in Fig. 2. Hydrogen bond lengths and angles are listed in Table 3. All functional groups are involved in intermolecular hydrogen bonds with the chloride anions, but there is no hydrogen bond between functional groups. The N(4) atom makes bifurcated hydrogen bonds with Cl(1) and Cl(2). Two short contacts are found between O(5) and N(1), and between O(3) and N(4); O(5)···N(1) and O(3)···N(4) distances being 2.802 and 2.703 Å, and O(5)···H–N(1) and O(3)···H–N(4) angles 109.2 and 97.8°, respectively. Judging from these geometries, it is not plausible to assign hydrogen bonding to these interactions.

Bond Lengths and Angles. The bond lengths and angles are shown in Table 4, in which corresponding values of fortamine are also given. The average endocyclic C–C bond length of 1.527 Å in the dihydrochloride is essentially equal to that of 1.524 Å in fortamine. This indicates that protonation at the amino groups hardly affects the endocyclic C–C bond lengths. Although the C(1)–C(2) length of fortamine is significantly short (1.505 Å), that of the dihydrochloride (1.542 Å) is notably long. The C(1)–N(1), C(4)–N(4) and N(4)–C(8) bond lengths of the dihydrochloride becomes longer than those of fortamine under the influence of protonation. All C–O (hydroxyl) bond lengths except C(5)–O(5) are significantly shorter than those of fortamine. The C(2)–O(2) bond length (1.411 Å) is particularly short.

The average endocyclic C–C–C bond angles is 112.1°. This value is larger than 111.4° of fortamine. The effect of protonation is seen in the endocyclic bond angles, too. In epi-inositol, the C–C–C angle between 1,3-diaxial hydroxyl group is 114.7°.[5] Similar 1,3-diaxial interaction between O(1) and O(2) (O(1)···O(2) distance being 3.01 Å) in the present molecule widen the C(6)–C(1)–C(2) angle to 114.3°. On the contrary, the C(1)–C(6)–C(5) angle of 112.4(2)° is not so large and does not seem to suffer from the N(1)···O(5) non-bonded interaction, although the N(1)···O(5) distance is shorter (2.820 Å).

All of the exocyclic bond angles except O(3)–C(3)–C(4) and C(7)–O(3)–C(3) in the dihydrochloride are significantly different from those in the free base, fortamine. The bond angles around N(4)–C(4) and O(3)–C(3) are remarkably asymmetrical. This seems to indicate that there is some attractive force between N(4) and O(3).

Conformation of the Molecule. The ring conformation of fortamine dihydrochloride, as shown in Fig. 3, is inverse of the free base conformation. The signs of torsional angles listed in Table 5 also represent the ring inversion. Figure 4 shows the important torsional angles between substituents and the *d* values, defined by deviations of the two atoms from the least-squares plane through other four atoms consisting of the seat of a chair. The average C–C–C–C torsional angles in the ring is 52.7° and average *d* is 0.627 Å. Both of these values are smaller than those of the free base, 54.9° and 0.655 Å, respectively. The ring of the dihydrochloride is flattened to some extent

from the free base. As seen from the d values, C(4) and C(5) are puckered and C(1) and C(2) flattened. Small C(5)–C(4)–N(4)–C(8) torsional angle of 44.8° is probably due to the bifurcated hydrogen bond of N(4). Some exocyclic torsional angles between axial substituents in the dihydrochloride are fairly larger than those in the free base. This indicates the exocyclic torsional angles also suffer from 1,3-diaxial interaction to a large extent. Therefore, the smallest exocyclic O(2)–C(2)–C(3)–O(3) torsional angle of 46.5° is due to the O(1)···O(2) repulsion.

Discussion

Fortamine dihydrochloride takes the 'A' type conformation in the crystal structure. This result shows that the protonation at the two nitrogen atoms makes

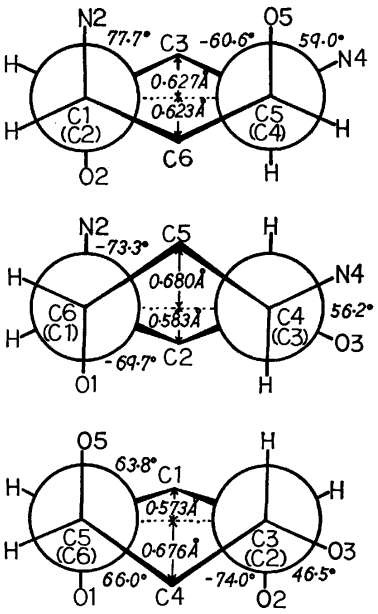

Fig. 4. Schematic drawings of chair forms of fortamine and fortamine dihydrochloride.

the 'B' type conformation unstable and inverse the fortamine ring into the 'A' type conformation. It seems that the electrostatic repulsion between the charge at the amino groups is responsible for the ring inversion. We calculated the electrostatic repulsion energies of the fortamine dihydrochloride in the 'A' type and in the 'B' type conformations. To simplify the treatment 1 e.s.u. charge due to protonation is assumed to be localized at each nitrogen atom. The geometry of the 'B' type dihydrochloride is taken as that of fortamine except the C–N distances which are replaced by the values observed in fortamine dihydrochloride. The calculation indicates that the electrostatic repulsion energy in the 'B' type conformation is 0.50 kcal/mol higher than that in the 'A' type conformation.

In the 'A' type conformation, however, the non-bonded interactions between the axial substituents seem to be more crucial than those in the 'B' type conformation. We estimated them by calculating the non-bonded interaction energy between the axial substituents. Giglio's potentials[6] were used and the effect of axial hydrogen atoms were also included. The value obtained was 1.19 kcal/mol. This is not so high; in other words, the non-bonded interactions between the axial substituents in the 'A' type conformation are fully relaxed by deforming the endocyclic angles and torsional angles as described in the previous section. Although further studies on the energy of molecular deformation would be required, it is most probable that the electrostatic force is ineviatble to stabilize fortamine dihydrochloride molecule in the 'A' type conformation. The inversed chair form significantly compressed to relax the 1,3-diaxial interactions would serve the basis to construct the structure of fortimicin A.

Electronic Spectra of Single Crystals of 1,1′-Diethyl-2,2′-Cyanine Iodide, Bromide, and Chloride

Jiro TANAKA,* Masashi TANAKA, and Masuo HAYAKAWA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received April 18, 1980)

Reflection spectra of single crystals of 1,1′-diethyl-2,2′-cyanine iodide, bromide and chloride were measured in order to find the origin of the J band. The spectra were obtained by the Kramers-Kronig transformation of reflectivity. The positions of absorption peaks and the shapes of vibronic envelope for each crystalline faces are explained by a calculation of surface exciton splitting with a weak coupling model. The intensity of each bands is interpreted by the oriented gas model, however, a peculiar anomalous band shape characteristic of J band is explained by the charge resonance (CR) and the molecular exciton interaction. The J band is found along particular crystalline direction, in which the dye molecules are stacked face to face, showing importance of interplanar π electron interaction. The molecular exciton band shape is changed significantly to give a J band because the higher vibronic bands are blurred off by the enhanced relaxation mechanism of the CR interaction.

Jelly[1] and Scheibe[2] found a sharp electronic absorption band of cyanine dye on a concentrated solution of 1,1′-diethyl-2,2′-cyanine, and it has been called J band. The J band shows several peculiar spectral characteristics; the band appears only in an aggregate system and it is unusually sharp as an electronic transition of organic molecule modified by association. The emission spectra of the aggregate is also sharp without Stokes shift. The spectra and physico-chemical properties of cyanine dye aggregate system have been investigated by many people, particularly by Scheibe and his coworkers[3] in view of finding the relation between the structure and the spectra and the mechanism of spectral sensitization for silver halide crystals. Cooper[4] investigated the aggregate state in solution at low temperature and found a doublet structure in the J band and a sharp emission band. Daltrozzo *et al.*[5] studied the condition of J-aggregation in solution and proposed a model of the aggregate.

Theoretical investigation on the band shift of the aggregate was first presented by McRae and Kasha[6] based on a molecular exciton theory, and further development was proceeded by Norland, Bird and their group[7] and Kuhn and his group.[8] These authors suggested that a lateral displacement of adjacent dye molecules shifts a monomer absorption band (M band) to red and produces the J band, while a pairwise stacking of the dye causes a hypsochromic H band. A theory of the band shape of the J band was developed by Briggs and Herzenberg[9] with coherent exciton scattering (CES) method and it has been suggested that the band will be sharp when the exciton interaction is much stronger than the coupling with the molecular vibration. Sumi[10] extended a model calculation with coherent potential approximation (CPA) including several coupling parameters and obtained a band shape which looks like the J band. A similar calculation was carried out by Ito *et al.*[11]

In order to study the nature of the electronic transitions of the J aggregate, spectral measurement of the single crystals of these dyes will be particularly useful, because the directional properties of the electronic transition may be clearly demonstrated and a peculiar characteristics of the J band may be found. Several years ago Dr. Jörg Preuss in Münich suggested to one of the authors (J. T.) that a sharp J type absorption band could be found in the crystal of 1,1′-diethyl-2,2′-cyanine chloride along the stacking axis of the molecules. Recently Marchetti *et al.*[12] reported the crystalline spectra of the same dye iodide and chloride and correlated the J band in solution to the crystalline exciton state.

In this paper the spectra of the above dye iodide, bromide and chloride are presented with a theoretical consideration of the band splitting and the band shape, together with assignments of each band. A particular emphasis will be given on the importance of the charge resonance (CR) interaction between the dye molecules in the crystals.

Experimental

Materials. 1,1′-Diethyl-2,2′-cyanine iodide (dye iodide) was a product of Japanese Research Institute for Photosensitizing Dyes Co. (Okayama). The crystals of the dye iodide were obtained by recrystallization from methanol solution. The crystals of the dye bromide and the chloride were obtained by metathesis with potassium bromide or chloride after precipitation of the iodide by silver nitrate as silver iodide. The crystalline forms and faces were confirmed by taking X-ray photographs on Weissenberg camera and compared with the published X-ray data.[13–15] The shape of the crystalline forms are sketched as shown in Fig. 1.

Measurements. The reflection spectra were measured with a microscopic spectrophotometer constructed in this laboratory. It consists of an Olympus microscope, a Carl Zeiss Ultrafluar lens (×10), a Nikon crystal mount, a HTV 928 photomultiplier tube as detecting device and an Intel 8080 microcomputer for data processing. The reflectivities were converted to molar absorption coefficients by using Kramers-Kronig transformation on a FACOM 230-60 and 230-75 computers of Nagoya University Computation Center.

The spectra in a ethyleneglycol–water (EGW) solution at room temperature and 77 K were measured with a Cary 16 spectrophotometer equipped with a Cryo-tip refrigerator (Fig. 2).

Theoretical Considerations on Crystalline Excited States

Molecular Orbital and the Excited State of the Dye Molecule. The molecular orbitals of π electron system of the dye were calculated by Pariser-Parr-Pople[16] method with Nishimoto-Mataga[17] potential. The atomic coordinates determined by the X-ray crystal structure analyses were used for the calculation, and the results were nearly the same for the molecules in the iodide, bromide and chloride crystals. Two quinoline rings are twisted, hence the directions of π electron envelopes were settled along the direction perpendicular to one of the quinoline ring plane, another quinoline ring plane and the plane composed of the central carbon and the adjacent carbons of the quinoline rings. By this choice a pseudo-two-fold symmetry of the MO was conserved.

The highest occupied orbital (orbital 11, HOMO) and the lowest unoccupied orbital (orbital 12, LUMO) have a pseudo-symmetry of S_y and A_y, respectively, where the y axis is the short molecular axis, and the charge density spreads over the whole molecule. The second and the third HOMO are nearly degenerate, and the charge densities are localized on either one of quinoline rings.

The energy of the lowest allowed transition, which is composed of mainly one electron transition from the HOMO to LUMO, was calculated at 18600 cm^{-1} (2.30 eV) and the polarization is along the long axis of the molecule. The calculated value is nearly in agreement with the value found in solution spectra (*cf.* Fig. 2, peak at 19000 cm^{-1}). We consider only this transition in this paper because other bands are weak and locate at higher energy region.

Molecular Exciton States and Intermolecular Exciton Interaction. The crystals treated in this paper are all monoclinic with space groups and lattice constants as shown in Table 1 and they contain four molecules per unit cell. The molecular exciton (MX) state in the crystal, one of them is allowed along the monoclinic axis (A_u state) and another is allowed perpendicular to it (B_u state), are written as

$$\left.\begin{aligned} A_u:\ \Psi_b &= \frac{1}{\sqrt{N}}(\Psi_{1i}-\Psi_{2i}+\Psi_{3i}-\Psi_{4i})e^{ik\cdot R_i} \\ B_u:\ \Psi_{ac} &= \frac{1}{\sqrt{N}}(\Psi_{1i}-\Psi_{2i}-\Psi_{3i}+\Psi_{4i})e^{ik\cdot R_i} \end{aligned}\right\}, \quad (1)$$

where N is the number of molecules in the crystal under consideration, i is the numbering of unit cell and 1, 2, 3, and 4 designate the molecular site. Ψ_{1i} means the original site of the i-th cell is excited and others are in the ground state. Ψ_{2i}, Ψ_{3i}, and Ψ_{4i} are the wavefunction in which the excitation occurs at sites related by the crystal symmetries of inversion, screw-axis rotation and glide-reflection, respectively. The exponential factor shows the translational symmetry of the crystal, and if we consider N molecules with a spacing of a, then $k=2\pi n/Na$ where $n=0,1,2,\cdots N$.

The most significant term of the interaction Hamiltonian is the dipole-dipole type between the transition moment on different molecules. If we denote the HOMO by ϕ_m and LUMO by ϕ_n, the excitation transfer matrix element between the i-th and the j-th molecules will be written as

$$\begin{aligned} b_{ij} &= \int \phi^*_{jn}(r_j)\phi^*_{im}(r_i)\frac{e^2}{r_{ij}}\phi_{jm}(r_j)\phi_{in}(r_i)\,dv_i dv_j \\ &= \frac{1}{R^3_{ij}}\left(\boldsymbol{p}_i\cdot\boldsymbol{p}_j-\frac{3(\boldsymbol{p}_i\cdot\boldsymbol{R}_{ij})(\boldsymbol{p}_j\cdot\boldsymbol{R}_{ij})}{R^2_{ij}}\right) \end{aligned} \quad (2)$$

Here $\boldsymbol{R}_{ij}$ is the vector connecting between the i-th and the j-th molecules, $\boldsymbol{p}_i$ and $\boldsymbol{p}_j$ are the transition moments of these transitions, respectively.

For the strong molecular transition of the dye in the crystal, the dipole interaction is most significant, and the calculation of surface exciton states by a slab sum method is appropriate for the present analysis.[18] Marchetti *et al.*[12] calculated the surface exciton state of the dye iodide to explain the spectral shifts. We have calculated the surface exciton energies for the measured crystalline faces of the dye iodide and bromide and the results of calculation are shown in Table 2. Because the measured crystalline spectra showed a weak coupling type, the estimation of exciton band

energies were presented for each vibronic band. The listed values B_n for each vibronic levels were obtained by using $\boldsymbol{p}$ values estimated from the oscillator strength for each vibronic band.

The summation of molecules was taken for the limited radius of sphere (100—200 Å) or the finite depth (10—20 Å) of the slab which gave a convergent result. The energy band structure for each exciton levels is illustrated in Fig. 3. The state density for the single exciton level will be given by $N/2B_n$, but when the higher vibronic exciton band overlaps with the lower ones, the density will be increased in the superposed region.

Charge Resonance State. When molecules in the crystals strongly overlap with neighboring ones, the charge transfer (CT) state becomes important. The crystals now considering are composed of same species, and the CT should occur between each other, hence the CT state should be called as the charge resonance (CR) state. The CR effect in molecular crystal will be two or three-fold; one is for the ground state to stabilize the stacked structure and others are an appearance of the CR exciton band and the modification of the molecular exciton bands.

The CR transition in a neat molecular crystal is not so frequently found; the out of plane transition

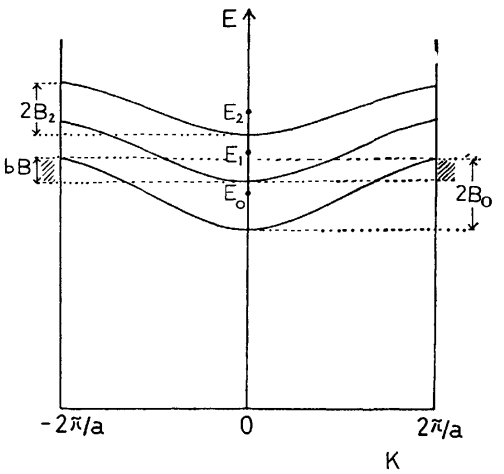

Fig. 3. Molecular exciton (MX) band structure with vibronic exciton splittings.

of the α form crystal of 9,10-dichloroanthracene[19–21] is known to be the case. In anthracenophane molecules where the interplanar distances are very close, the CR absorptions are found but they are rather weak and broad.[22] Apparently the CR transitions are found in cases where a peculiar polarization is

TABLE 3. ENERGY LEVELS OF CHARGE RESONANCE STATE

Dye halide crystals	Axis relating stacked molecules	Energy levels of CR states without polarization correction
Dye iodide	b-axis	3.33 eV
	c-axis	3.36
Dye bromide	a-axis	3.32
	b-axis	3.43
Dye chloride	a-axis	3.20
	c-axis	3.44

expected or a borrowing of intensity from nearby strong allowed transition is accessible. In the present crystals the intermolecular overlap is appreciably large along one-dimensional chain and the CR effect may be found on particular crystalline directions.

The energy level of the CR state is estimated by using the calculated MO and Nishimoto-Mataga[17] potential as shown in Table 3. The potential may underestimate the Coulomb term between molecules, hence the estimated levels may be too high. Moreover the CR state will be stabilized by a polarization force in a highly polarizable crystal as much as 1—2 eV.[23] Therefore the CR level may be at about 2.3 eV and they will be close to or coincident with the molecular exciton levels.

The mixing of the CR state wavefunction Φ to the ground state wavefunction Ψ_0 can be described by the wavefunction of the stabilized ground state as

$$\Psi_G = \Psi_0 + \frac{\langle \Psi_0 | H' | \Phi \rangle}{E_{CR} - E_0} \Phi. \tag{3}$$

The CR matrix element between the stacked molecules will be related to the transfer integral t and it is actually estimated by the overlap integrals between the π electrons of stacked molecules. Namely, the charge transfer matrix will be written, for example, between the HOMO of the i-th molecule and the LUMO of the j-th molecule as $t_{im,jn}$ or simply as t_{mn}. The calculated results of overlap integrals between the neighboring molecules are shown in Table 4, where a single exponent AO and four term expanded AO[24] were used for the calculation and compared in the Table. The empirical values of energy of t integrals are given by

$$t = kS, \tag{4}$$

where the proportional constant k is about $k = -10$ eV for S evaluated by the four term expanded AO and $k = -15$ eV for S obtained by single exponent AO. Referring to Table 2 the largest value is about -0.10—0.15 eV between the HOMO (t_{mm}) and about -0.10 eV between the HOMO and LUMO (t_{mn}). These values are fairly large as the intermolecular interaction in molecular crystal between the same species. The matrix element in Eq. 3 is relevant for t_{mn} and the coefficient of the CR configuration in the ground state is estimated as about 0.1.

The wavefunctions for the optically allowed CR exciton states are written as

$$\left.\begin{aligned} A_u:\ \Phi_b &= \frac{1}{\sqrt{N}} \sum_i (\Phi_{1i} - \Phi_{2i} + \Phi_{3i} - \Phi_{4i}) e^{ik \cdot R_i} \\ B_u:\ \Phi_{ac} &= \frac{1}{\sqrt{N}} \sum_i (\Phi_{1i} - \Phi_{2i} - \Phi_{3i} + \Phi_{4i}) e^{ik \cdot R_i} \end{aligned}\right\}. \tag{5}$$

Here Φ_{1i} implies that an electron in the 1st site of the i-th cell is transferred to the adjacent molecules. The CR exciton band width is estimated with these wavefunctions and only the nearest neighbor interactions are taken into account to give

$$C = b_{CR} + S_{mm} t_{nn} + S_{nn} t_{mm}. \tag{6}$$

Here b_{CR} is the dipole-dipole interaction between the CR transitions on different sites and it is much less as compared to the values of strong molecular HOMO to LUMO transition. The terms $S_{mm}t_{nn}$ are second order to the electron overlap, therefore the CR exciton band width C will be one or two order of magnitudes smaller than B. On this ground the CR exciton band will be much narrow than the MX band. When they are mixed the CR band will be wider than before the interaction.

Mixing of the CR State with Molecular Exciton States. When the CR level is located nearby the MX level, the interaction between the two states will be significant and it may modify the shape of MX band. The wavefunction for the mixed exciton states will be given for A_u state as

$$\left.\begin{aligned} &\Psi_b + \frac{\langle \Psi_b | H' | \Phi_b \rangle}{E_{CR} - E_{MX}} \Phi_b \\ \text{and} \\ &\Phi_b + \frac{\langle \Phi_b | H' | \Psi_b \rangle}{E_{MX} - E_{CR}} \Psi_b \end{aligned}\right\}. \tag{7}$$

The off-diagonal matrix elements between the CR and the MX states include both the dipole interaction and the transfer terms and they will be written as

$$b_{MC} + \sum_{ij} (t_{in,jn} - t_{im,jm}), \tag{8}$$

where b_{MC} is the dipole interaction between the molecular and CR exciton transitions of A_u symmetry and the transfer integrals may be taken over i and j molecules related by translation, inversion, screw-axis and glide reflection, respectively, but actually the transfer interaction between the nearest neighbors is much larger than for other type. This is one of the reason why the mixing occurs anisotropically; the electron overlap between the stacked molecules is significant along particular direction. The dipole-dipole interaction between the two type of transitions may be another probable source of the anisotropy of mixing. The b-axis of the dye iodide and bromide and the c-axis of the dye chloride are the direction along which the CR effect seems important because t_{nm} is large between the molecules stacked along these directions, hence the ground state will have an anisotropic CR character by this mechanism. The intrinsic CR band will be stronger along this direction than others, therefore the mixing through b_{MC} term will be larger along this particular crystalline directions than others.

One of the consequence of the CR and the MX mixing will appear in the exciton band structure. The CR exciton band is narrow and flat, and the

Table 4. Overlap integrals between the MO of stacked dye molecules

state density may be greatly modified around the interacting region. For instance the energy levels in Fig. 4 show that the CR exciton level exists on the top region of the MX 0-0 band, and after the interaction, by non-crossing rule, the energy curves become plateu and the state density increases greatly in this range. If the 0-1 exciton level is located close to it, the radiationless exciton scattering may be enhanced and the higher vibronic band shape will be broadened significantly by the radiationless transitions.

One of another consequence of the CR and MX mixing may be an appearance of Fano's effect[25] in the begining of the absorption band. An interference which produces a dip or sharpening of the absorption band may be an indication of such interaction.

Band Splitting and Band Shape Analysis of Exciton States. Electronic transitions of large oscillator strength exhibit directional dispersion in anisotropic crystals. Weiser *et al.*[26] analysed the spectra of pentamethine cyanine dye crystal showing that the band shift is changed with the direction of the propagation of light to the crystalline face, however, this method is applicable only for uniaxial crystal.

For the present crystals the surface exciton state is calculated by a slab sum method.[18] The vibrational pattern of the monomer absorption band of the dye is simulated by a Lorentzian type shape function as

$$\left.\begin{aligned} \langle g\rangle &= \sum_{n=0}^{2}\langle g\rangle_n \\ \langle g\rangle_n &= Im\frac{|\boldsymbol{p}_n|^2}{E-E_0-n\lambda-i\gamma_n} \end{aligned}\right\}, \qquad (9)$$

where E_0 is the transition energy of the monomer dye, λ is the vibrational quanta of the coupled normal vibration and γ_n is the half-width of each band. The band width γ_n manifests the coupling of each vibronic level with other low frequency intramolecular and solvent modes. The present monomer spectrum was simulated by using $E_0=19000\ \mathrm{cm^{-1}}$, $\lambda=1300\ \mathrm{cm^{-1}}$ and $\gamma_n=500\ \mathrm{cm^{-1}}$. We took the square of the transition moment $|\boldsymbol{p}_n|^2$ as proportional to the observed vibronic band intensities. Actually each absorption band has a Gaussian shape, but it was approximated by a Lorentzian shape. In the molecular exciton states, following a weak coupling model, each band peak is expected to shift as proportional to the vibronic band intensity and the shift is given by B_n, where the CR effect is not taken into account. Then the absorption shape of the molecular surface exciton states is written as follows.

$$\langle G\rangle = \sum_{n=0}^{2} Im\frac{|\boldsymbol{p}_n|^2}{E-E_0-n\lambda-B_n-i\Gamma_n} \qquad (10)$$

Here Γ_n is the half-width for the n-th vibronic level. The band shapes are simulated for several crystalline faces of the dye bromide and iodide and the results are shown in Fig. 5, where the crystalline Γ_n is taken equal to γ_n of solution spectra.

Results of this simulation may be summarized as follows. (1) When B_n is negative and large, the red shift of the split band is accompanied with increasing separation of the vibrational progressions. The band intensities are distributed among each vibronic levels as in solution spectra. (2) When B_n is positive and large, the blue-shifted vibronic levels are overlapped and converged into a single peak. Some of the measured spectra shown in the following section are consistent with this theoretical band shape analysis, but the J type band is different from this calculation. As regard to the sharpness of the J band, Briggs and Herzenberg[9] and also Sumi[10] attributed it solely to the increased exciton band shift, B, and B/λ was taken as a measure of the interaction, however, actually the same B/λ value does not give the same band shape. The J type absorption shape is found when the higher vibronic transitions lose intensity

and the 0-0 vibronic transition becomes sharp. In fact the J type absorption band appears when the CR level is coincident or close to the MX 0-0 band and the interaction is significant.

The CR band shape is not explained in the above treatment. Apparently extra absorption bands are found in the present crystals in addition to the MX bands, because the electron overlap is appreciably large. They are regarded as the CR bands. Normally the CR transition is rather broad in many molecular crystals, but it is found to be sharp when the CR exciton band width is increased by the mixing with the MX band. Toyozawa[27] pointed out that the half-band width of the exciton absorption band is given by an exciton scattering mechanism and is proportional to the state density of the exciton band. For the localized CR exciton state the band width will be given by

$$\gamma_{CR} = \frac{2\pi}{\hbar} \sum d_{CR}^2 / \Delta_{CR}, \tag{11}$$

where d_{CR} is the matrix element with phonon and Δ_{CR} is the energy of the coupled phonon modes. When the CR level is below the MX 0-0 level and they interact each other, the mixed CR+MX states are formed, and the exciton band-width of CR state may be increased as aB_0, and γ_{CR} will be reduced significantly. The localized CR state is changed into the mobile molecular coupled exciton state. The band-width Γ_{CR} will be narrowed because $aB_0 > \Delta_{CR}$ and $d_{kk'} < d_{CR}$ where $d_{kk'}$ is the exciton scattering matrix. The band-width will be given by

$$\Gamma_{CR} = \frac{2\pi}{\hbar} \sum d_{kk'}^2 / aB_0. \tag{12}$$

The intensity of the mixed transitions is mostly due to the MX 0-0 band, and the absorption appears as a single band or separate bands depending on the coupling of the CR and MX transition dipoles.

The band-width of the MX 0-0 level may be reduced from its original molecular band-width γ_0 by several mechanisms. One is discussed by Toyozawa[27] that when B_0 is large the state density is reduced and Γ_0 will be decreased as

$$\Gamma_0 = \frac{2\pi}{\hbar} \sum d_{kk'}^2 / B_0. \tag{13}$$

For the higher vibronic MX levels, when $B_0 > \lambda$, the 0-0 exciton band will overlap with the 0-1 level, and additional scattering route may be provided through the inter-band scattering and the absorption band-width may be increased as

$$\Gamma_1 = \frac{2\pi}{\hbar} \{ \sum d_{kk'}^2 / B_1 + \sum d_{kk_0}^2 / bB_0 \} \tag{14}$$

The increase of Γ_1 is contrast to the decrease of Γ_0, thus the narrowing of the MX 0-0 band may be interpreted by the exciton band scattering mechanism and the peak intensities of higher vibronic bands will be suppressed by the increase of Γ_1.

However, as is described previously, the CR interaction with the MX band may change the exciton band structure. If the exciton band becomes flat by the CR mixing, the inter-band scattering will be enhanced because the state density is increased around

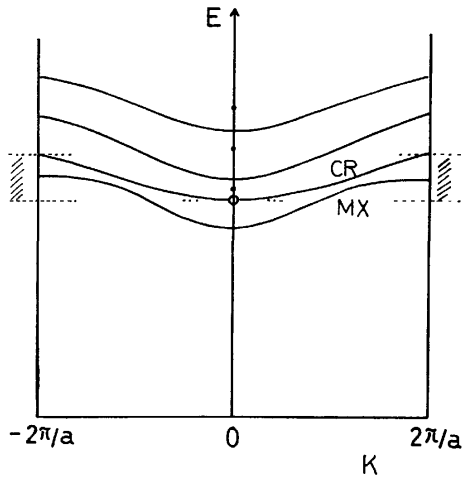

Fig. 4. Mixing of the CR and MX levels and band structures.

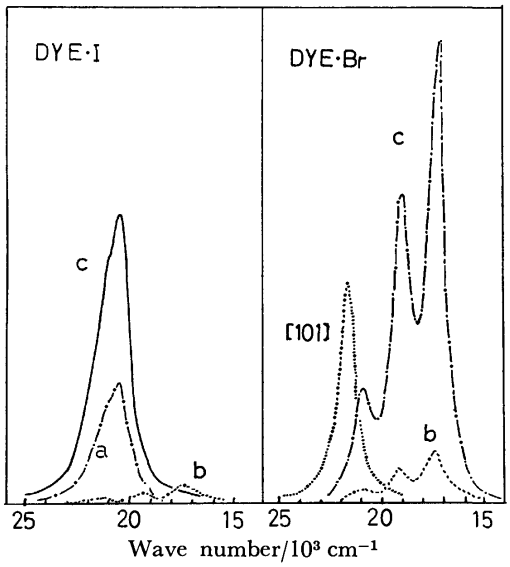

Fig. 5. Simulated absorption spectra of the dye iodide and the dye bromide. The ordinate is absorption coefficient in arbitrary unit.

the interacting region and higher vibronic band has additional decay terms represented by

$$\Gamma_n = \frac{2\pi}{\hbar} \sum t_{CR,MX}^2 / \delta_n,$$

where $t_{CR,MX}$ is the inter-band scattering matrix between the CR and MX states and δ_n is a small energy difference of two levels of nearly iso-energetic condition. The increased Γ_n will make the higher vibronic exciton band very broad and the absorption intensity will be lost except the mixed MX 0-0 band. Moreover the band-width of the MX 0-0 band may be sharpened by the following CR interaction mechanism. When the CR level is above and close to the MX 0-0 band, another mechanism is conceivable as follows. Suppose some phonon coupled 0-0 band may have energy of $E_0 + \Delta_n$, and it is equal to that of the CR level. The mixing with the CR level will take place, and the band-width will be broadened by the inter-band scattering mechanism as is discussed above. Then the MX 0-0 band will be sharper

because some phonon coupled modes lose the peak intensity. These arguments may throw some light on the peculiar band shape of the J band.

Results and Discussion

Crystalline Spectra of the Dye Iodide. The crystals obtained from methanol solution were used for the reflectivity measurement with crystalline faces, (100), (011), and (01$\bar{1}$) as shown in Fig. 1. The projection of molecules onto the (100) plane is shown in Fig. 6 according to the X-ray crystal analysis of Nakatsu *et al.*[15] Two quinoline rings of the dye molecule are twisted each other, and each ring stacks with another quinoline ring of the adjacent molecules. The double array of molecules extend along [101].

The reflection spectra with (100), (011), and (0$\bar{1}\bar{1}$) faces are shown in Fig. 7. The Kramers-Kronig transformation of the reflectivity gives the absorption spectra as shown in Fig. 8. The spectra along the [011] axis is similar to that of along the [01$\bar{1}$]. The absolute values of reflectivity and hence the molar absorption coefficients are dependent on the quality of surface of crystal, therefore the comparison of intensities with different crystalline faces may be less accurate than to obtain the dichroic ratio with the same face.

The spectra with the (100) face (Fig. 8(a)) showed a strong dichroism; the intensity is much stronger along the c-axis than along the b-axis. Actually the intensity along the b-axis is much intensified than the value expected from the oriented gas model; and it may be due to the influence of the CR state which may exist around the 17000—19000 cm^{-1} region. The exciton splitting for the (100) face is calculated as shown in Table 2; the red shift for the b-axis is well explained and the blue shift of the c-axis will be right if we take the 20350 cm^{-1} band along the c-axis as the 0-0 band because it should be fairly strong as compared to other bands. Then the band at 17400 and 18600 cm^{-1} along the c-axis is regarded as the CR band. The broad absorption bands in the 18000—26000 cm^{-1} region appeared along the b-axis are regarded as the mixed band of the CR and MX states, because an enhancement of the intensity and the

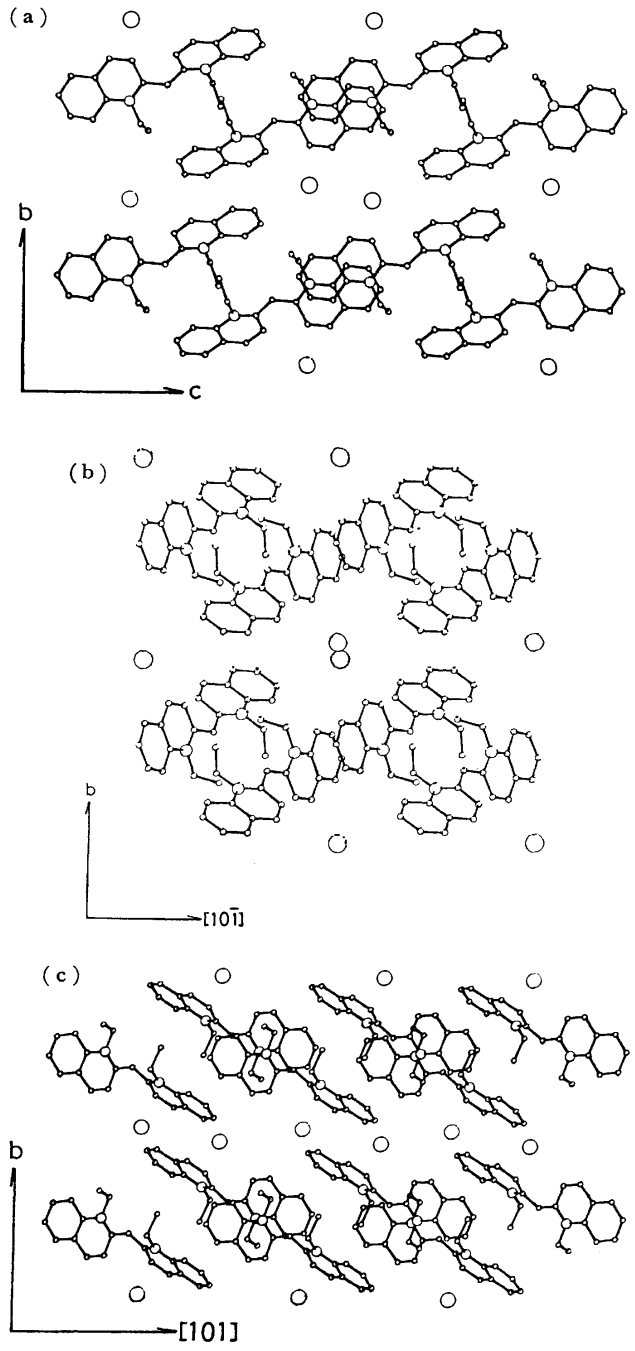

Fig. 9. Projection of molecules onto the developed crystalline faces of the dye bromide.
(a) (100) face, (b) (101) face, and (c) (10$\bar{1}$) face.

sharpening of the 0-0 band may be explained by the interaction between the CR and MX states as is discussed previously.

The spectra with the (011) face is shown in Fig. 8(b). The absorption band along the a-axis is similar to the c-axis band, and the weak humps at 17500 and 18600 cm^{-1} are regarded as the CR band. Along the [01$\bar{1}$] direction both the A_u and the B_u transitions are allowed, the peak at 17400 cm^{-1} is ascribed to the A_u type, while peaks at 18700, 20100, and 21100 cm^{-1} are ascribed to the B_u type transitions. The calculated splittings for the MX bands are approxi-

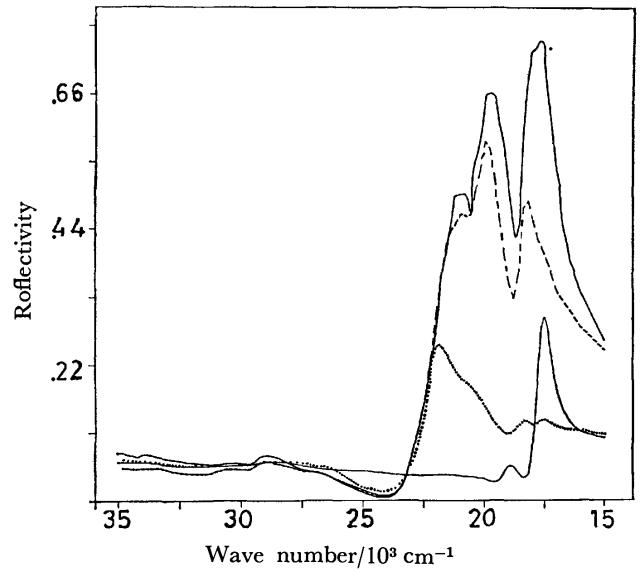

Fig. 10. Reflection spectra of the dye bromide measured with (100) face —— c-axis, —— b-axis, and (10$\bar{1}$) face---- [101] direction (101) face····· [10$\bar{1}$] direction.

mately in agreement with the observed spectral tendency.

The simulated absorption curve by Eq. 10 for the MX vibronic band is shown in Fig. 5, where the intensity is taken as proportional to the oriented gas value. We took the values of B_0 as -1500 cm^{-1} for the b-axis and 1500 cm^{-1} for the c-axis. The calculated curve is in agreement with the observed spectra except that the CR effect is seen along the b-axis and the CR bands are seen along other axes as extra bands. The original CR band starts at about 17000 cm^{-1} and appears in the range of 17500—27000 cm^{-1} as a broad band. Along the b-axis the CR state interacts strongly with the MX state in the 17000—19000 cm^{-1} region and a sharp mixed band is observed, because the electron overlap is largest along this direction. Examination of these spectra shows that the J-type sharp absorption can be found only along the b-axis. It means an importance of CR effect through the electron overlap, since the calculated overlap integrals given in Table 4 show that the b-axis value is larger than for the c-axis and the obtained value is large enough to give effective interaction between molecules.

Crystalline Spectra of the Dye Bromide. The projection of molecules onto the measured crystalline faces are shown in Fig. 9 according to the X-ray structural result of Nakatsu *et al.*[14] The crystalline reflection spectra were measured with (100), (101) and (10$\bar{1}$) faces as shown in Fig. 10 and the absorption spectra calculated by the Kramers-Kronig transformation are shown in Fig. 11. The simulated absorption curve (Fig. 5) is obtained with the reduced surface exciton shift of -1000 cm^{-1} and the 0-0 band origin assumed at 18500 cm^{-1}.

The transition to the A_u excited state, which is allowed along the b-axis, appears at the same position for all measured faces and the calculated value is

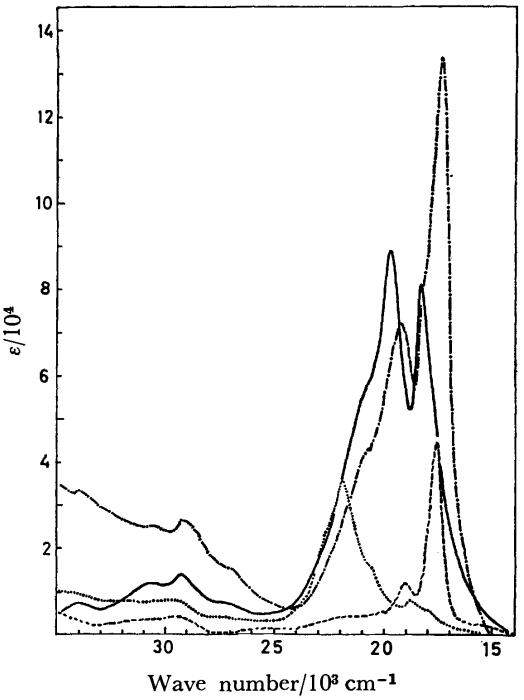

Fig. 11. Absorption spectra of the dye bromide obtained with (100) face —·—·— c-axis, ---- b-axis, (10$\bar{1}$) face —— [101] direction, and (101) face ····· [10$\bar{1}$] direction.

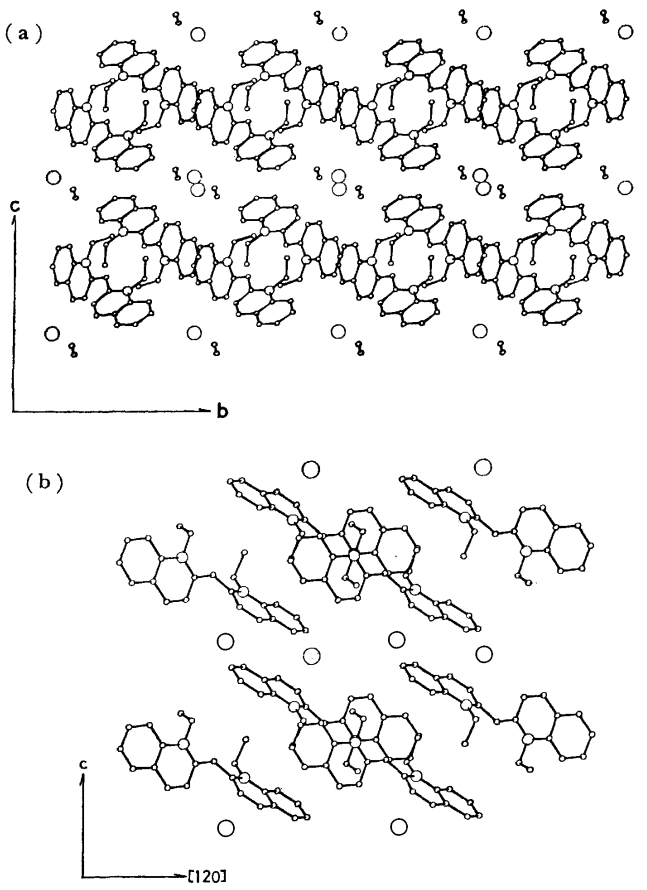

Fig. 12. Projection of molecules onto the developed crystalline faces of the dye chloride (a) (100) plane, (b) (1$\bar{2}$0) plane.

$-1590\ cm^{-1}$, while the observed shift is about $-1000\ cm^{-1}$. Comparison of the intensity of simulated spectra with the observed spectra showed that the 0-0 band is intensified and sharpened. The CR state may exist in this region and the enhancement and the sharpening of the b-axis transition may be due to the interaction of the CR and MX states. The band shape along the b-axis is a typical of J band that the intensity is concentrated around the 0-0 transition and higher vibronic bands are broad and weak.

The transition to the B_u state on the (100) face is allowed along the c-axis, and it shows vibronic structures starting 0-0 at $17460\ cm^{-1}$. Although the exciton shift B_0 is almost same for b and c-axes, the band shape is different. The simulated spectra with a shift of $-1000\ cm^{-1}$ shown in Fig. 5 is in good agreement with the observed spectra, except that the 0-0 band is actually much sharp and intense than the simulated spectra. For the c-axis the mixing of the CR and MX states seems smaller than for the b-axis, presumably because the electron overlap is smaller along this direction.

The B_u type transition on the (10$\bar{1}$) face showed peaks at 18300 and $19700\ cm^{-1}$ and a shoulder at $21000\ cm^{-1}$. We may assign the $18300\ cm^{-1}$ band as the 0-0 band and the $19700\ cm^{-1}$ band as the 0-1 band, because the calculated shift for the 0-0 band is $-260\ cm^{-1}$, but the band progression is not normal as compared to other directions. An alternative plausible interpretation may be that the 18300 cm^{-1} band is the CR mixed band and the MX 0-0 band is shifted to $19700\ cm^{-1}$. The vibronic pattern is normal by this choice, and the CR band is fairly strong because of borrowing intensity from the MX 0-0 band.

With the (101) face along the [10$\bar{1}$] direction a peak is found at $21800\ cm^{-1}$, a shoulder at $20800\ cm^{-1}$ and weak humps around $18800\ cm^{-1}$. The simulated absorption spectra (Fig. 5) is in agreement if we take a shift of $+3000\ cm^{-1}$, but actually the calculated shift is $+1880\ cm^{-1}$ for the 0-0 band. A shoulder at $20800\ cm^{-1}$ may be the shifted 0-0 band. Thus a calculated tendency of overlap of peaks for the blue-shifted bands is actually exemplified. The weak humps around $18500\ cm^{-1}$ region may be the CR band, and it will be weak because the strong MX band shifts to blue and does not mix with it.

In this spectra again the value of B/λ does not show a good correlation with the observed spectral bandwidth. Moreover the directional property of the J band will show the detailed mechanism of the CR and MX mixing that the electron overlap and the dipole interaction anisotropy are important.

Crystalline Spectra of the Dye Chloride. The crystalline structure of the dye chloride was analysed by Dammeier and Hoppe[13] although the crystalline axes were chosen differently from other crystals. The crystal structure is isomorphous with the dye bromide, and the c-axis of the chloride corresponds to the b-axis of the bromide. The [120] and b-axes of the chloride are correlated to the [101] and [10$\bar{1}$] axes of the bromide. The projection of molecules onto the measured

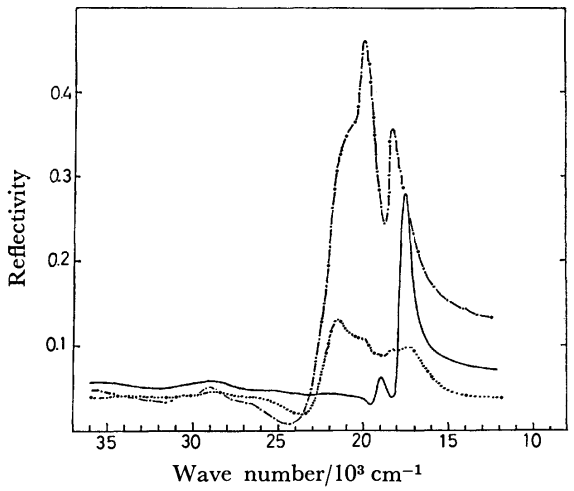

Fig. 13. Reflection spectra of the dye chloride measured with (100) face ····· b-axis, —— c-axis and (1$\bar{2}$0) face —·—·— [120] direction.

faces are shown in Fig. 12. The reflection spectra were measured with the (1$\bar{2}$0) and (100) faces as shown in Fig. 13.

The absorption spectra obtained by the Kramers-Kronig transformation look like the bromide spectra (Fig. 14). The surface exciton splitting on (100) and (1$\bar{2}$0) faces were calculated as shown in Table 2. If we take the molecular 0-0 transition at 19000 cm^{-1} the agreement between the calculated and the experimental values of the shift is quite satisfactory.

The transition along the c-axis is red shifted and the sharp J band appears by the interaction of the CR and the MX states, because the electron overlap is significantly large along the c-axis (Table 4). The band along the [120] axis showed several peaks and a plausible explanation for this pattern may be that the 18400 cm^{-1} band is the mixed CR state and the 19800 cm^{-1} band is the MX 0-0 vibronic transition. The spectra along the b-axis is blue-shifted at 21400 cm^{-1}, and the calculated shift is in reasonable agreement with the observed value. A single peak is appeared because the large blue-shifted vibronic transitions are overlapped as is discussed previously. Another weak shoulder around 18400 cm^{-1} may be due to the CR band. Thus the observed spectra showed a similarity with the bromide spectra reflecting isomorphous crystalline structure.

Spectra of the Dye Iodide in Solution. The J band in solution may be compared with the crystalline spectra in order to find the structure of the J aggregate in solution. The spectra of the dye iodide in a 1:1 ethyleneglycol water (EGW) solution shown in Fig. 2 are nearly in agreement with the earlier results of Zimmerman and Scheibe[3] and Cooper;[4] the J band appears at 77 K. However, the detail of the spectra is slightly different between independent studies and it may be due to the difference in experimental conditions such as the kind of solvent and the concentration of counter ions. For instance the intensity of the J band is varied case by case; it is strongest in water with chloride ion[3] and is weak in ethanol with

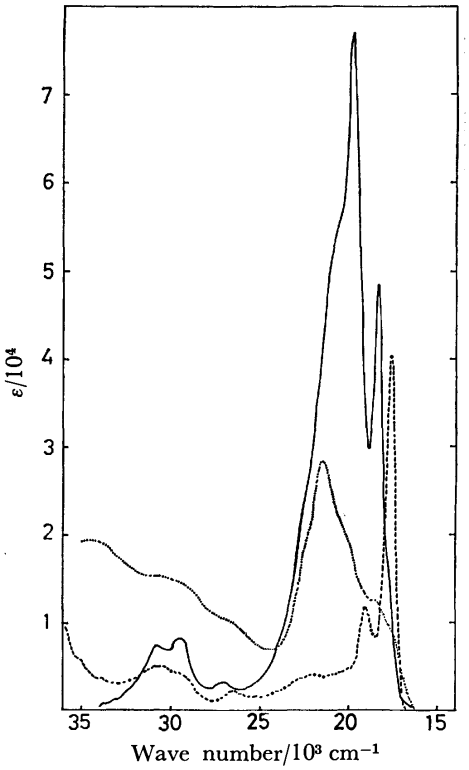

Fig. 14. Absorption spectra of the dye chloride with (100) face ····· b-axis, ---- c-axis and (1$\bar{2}$0) face —— [120] direction.

iodide ion[12] and is intermediate in EGW solution. Cooper[4] observed a doublet structure of the J band on the dye bromide in EGW at 77 K, but we found a weak doublet in dye iodide in the same solution at 77 K. It appears that the change of spectra reflects a variation of the fine structure of the aggregate. Marchetti *et al.*[12] did not report the doublet presumably because their solution contained 0.1 M KI and they proposed that the spectra resemble to the crystalline spectra of the dye iodide, hence the J aggregate will have a similar structure of the iodide crystals. Our results showed that the positions of the aggregate band are very close to the bands found in the iodide crystal rather than that of the bromide, but the intensity of the J band at 17400 cm^{-1} in solution is much stronger than in the crystal. We agree with their opinion that the aggregate in solution may have a similar structure of the iodide crystal.

We have estimated how many molecules might be involved in the aggregate by calculating the band splitting using the same arrangement of molecules in the crystal of the dye iodide. The splitting for the A_u and B_u transitions were calculated for the spherical assemblies of molecules of radius 10—18 Å, which includes 4 to 50 molecules inside. The results of the calculation showed that the sphere of the radius 16 Å containing 36 molecules gives a maximum splitting, the red shift of −1220 cm^{-1} and the blue shift of 1640 cm^{-1}. In solution the splitting of the J band and the blue-shifted 0-0 vibronic band is 3400 cm^{-1}, hence the calculated valuc is smaller than the observed value, but the agreement is not so bad. If we use the crys-

talline data of the dye bromide or chloride, the result is much smaller than for iodide. Although the agreement is not in perfect, but the similarity of the band shape supports the iodide structure and it may be inferred that the J-aggregate of 2,2'-cyanine in solution is conformed of at least 30 molecules assembled like the dye iodide crystal. Scheibe and his coworkers[3,5] discussed the minimum size of the J-aggregate and suggested that it might include at least 7 molecules. Further studies will be required to clarify these points.

Summary of the J Band of 2,2'-Cyanine Dye Crystals. The results of spectral investigation on 2,2'-cyanine dye iodide, bromide, and chloride crystals are summarized as follows. (1) Molecular electronic transition of the dye is split on crystalline surfaces by the exciton interaction. The splittings on the developed crystalline faces are reasonably explained by the dipole-dipole interaction with a slab sum method. The vibronic band shapes are well simulated by a weak coupling model; each vibronic level interacts individually. A red shifted band shows expanded vibronic intervals while a blue shifted one converges into a single peak. In addition, extra bands, which are not found in solution spectra, appear because of the electron overlap effect, that is the CR band.

(2) The J type band is found with particular crystalline directions of specific surfaces. A characteristic of the crystalline J band may be a sharpened 0-0 band and diminished higher vibronic bands. It appears when the CR state is mixed with the split MX state. An extensive electron overlap between the neighbor molecules is an important necessary condition for the appearance of the J band. A coincidence of the MX and CR state is another requisite for the sharp J band. It may be said that the sharp J band will be found only when these several dominating conditions are satisfied, but a widely used nomenclature for the J band may infere the red shifted strong transition with exciton sharpening without the CR mixing. We believe our view is more extensive.

Anyhow, several conditions, a lateral displacement of molecules, which is necessary for a large red shift, an extensive stacking of molecules to give a strong electron overlap, and a coincidence of the MX and CR levels, are satisfied only for rare cases. Therefore the appearance of the J band may be an unusual spectral phenomena associated with specific aggregation of cyanine dyes.

The authors thank to Profs. K. Nakatsu, Y. Toyozawa, and Dr. H. Sumi for helpful information and kind discussions. This research was supported from the Grant-in-Aid of the Ministry of Education, Science and Culture (No. 254144, 1977).

The J-aggregate 5,5′,6,6′-Tetrachloro-1,1′-diethyl-3,3′-bis(4-sulfobutyl)-benzimidazolocarbocyanine Sodium Salt in Aqueous Solution

Shigetoshi Makio, Nobuaki Kanamaru, and Jiro Tanaka*

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received April 18, 1980)

The aggregation of the title dye in a dilute alkaline aqueous solution is investigated at 283—303 K by measuring the electronic absorption spectra. The association number is estimated to be 8, the heat of formation and the entropy change for the association are found as $\Delta H = -91.5$ kcal mol^{-1} (1 cal=4.184 J) and $\Delta S = -139.3$ cal K^{-1} mol^{-1}, respectively. The structure of the octamer is discussed from a view of spectral shift, intermolecular force and the crystalline structural data. The lifetimes, quantum yields and polarization of fluorescence are investigated on the monomeric and the J-aggregate state of the dye. The energy transfer between several J-aggregate units is indicated in the excited state.

The appearance of the J band is an extraordinary spectral phenomenon caused by molecular association. Since Jelly[1] and Scheibe[2] found the J band, its origin has been discussed by many people. Herz[3] has reviewed the aggregation of organic dyes in solution, but only a few dyes are known to form the J-aggregate in solution. The aggregation number of the J-aggregate is not firmly fixed; different numbers, $n=3$—7, have been proposed for 2,2′-cyanine chloride[4,5] and $n=4$ for the dye discussed in this paper.[3] 5,5′,6,6′-Tetrachloro-1,1′-diethyl-3,3′-bis(4-sulfobutyl)benzimidazolocarbocyanine sodium salt is a good sensitizer for silver halide crystals and easily forms the J-aggregate in aqueous solution,[3] in a monomolecular film and on silver halide crystals.[6] We have investigated the equilibrium of the dye in a dilute alkaline aqueous solution and obtained the aggregation number, the equilibrium constant and the heat of formation. A model of the aggregate is suggested based on the crystal structural data and a theoretical calculation of the molecular interaction.

Experimental

The dyes used were gifted from Fuji Film Co. and were used without further purification. The water used for the solvent was twice distilled with potassium permanganate to remove oxidant and carbon dioxide. The dilute NaOH aqueous solution was prepared by carefully adjusting the pH of solution at 11.0. The dyes were dissolved immediately before experiment into the prepared solvent to attain the concentration to be measured. The temperature of the dye solution was kept constant with an accuracy of ±0.04 °C by circulating thermostated water around the cell compartment. The temperature was measured with a copper-constantan thermocouple by a Hewlett-Packard type 3465 B digital multimeter. The visible absorption spectra were recorded with a Cary 16 spectrophotometer. The fluorescence, the fluorescence excitation, and polarization spectra were measured with a Shimadzu spectrofluorometer RF-501. The band-width of the fluorescence was measured with a Spex double spectrometer under a narrow band excitation of the dye laser, Spectra Physics model 375 at the Institute of Molecular Science. The lifetime of fluorescence was measured by a HTV streak camera excited with a p s pulse of the second harmonics of YAG laser at the Institute of Molecular Science. The condition for the aggregation is dependent on several unexpected factors: *e.g.* a careful removal of the oxidant from the water is essential and the stability of the dye solution must be checked before each measurement.

Results and Discussion

A typical spectral change by the dye aggregation is shown in Fig. 1 for the concentration range of 10^{-7}—10^{-3} mol/dm^3 at 293 K. The monomer absorption peak was found at 19490 cm^{-1}, and a shoulder was observed at 20900 cm^{-1}. The peak of the J absorption band was observed at 17040 cm^{-1} with a half-band width of 240 cm^{-1}. An isosbestic point was found at 18590 cm^{-1}, and the tail of the absorption of the J-aggregate extended to 21000 cm^{-1} region (curve 9 of Fig. 1).

The equilibrium between the monomer and the J-aggregate is described as

$$nM \rightleftharpoons J, \tag{1}$$

where the equilibrium constant, K, is given by

$$K = \frac{C_J}{(C_M)^n}. \tag{2}$$

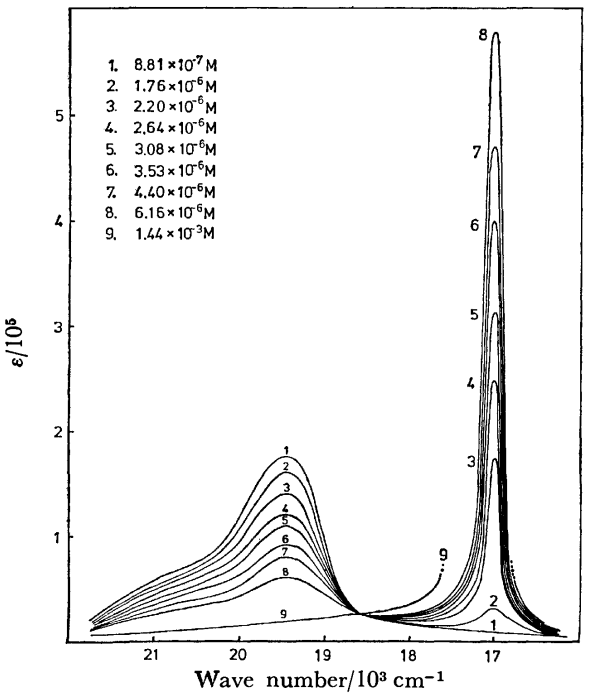

Fig. 1. Change of electronic absorption spectra with the concentration of the dye in a dilute alkaline aqueous solution (pH=11.0). (The concentrations are given in unit of monomer.)

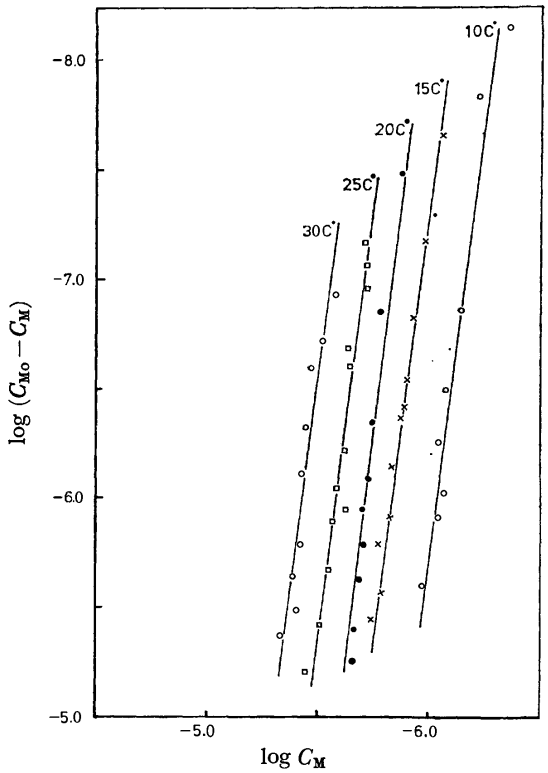

Fig. 2. Plots of $\log(C_{Mo}-C_M)$ against $\log C_M$.

Here C_J and C_M are the concentrations of the J-aggregate and the monomer, respectively. If the nominal concentration of the dye is shown by C_{Mo}, then

$$C_{Mo} = C_M + nC_J = C_M + nK(C_M)^n. \quad (3)$$

By taking the logarithms we obtain

$$\log(C_{Mo}-C_M) = n\log C_M + \log(nK). \quad (4)$$

We have carefully measured C_M by using the monomer's molar absorption coefficient, $\varepsilon_M=175000$, at 19490 cm^{-1} and used them to obtain constants in Eq. 4. A plot of $\log(C_{Mo}-C_M)$ *versus* $\log C_M$ is shown in Fig. 2, where the contribution of the tail of the J-band to the absorption at 19490 cm^{-1} is estimated by the absorption spectrum of a high concentration solution, which indicated a slight absorption of the J-band as shown in curve (9) of Fig. 1. Although Herz[3] plotted $\log(nC_J)$ *versus* $\log C_M$ in his analysis, we used $(C_{Mo}-C_M)$ instead of nC_J, because the concentration of the J-aggregate at the initial stage of the aggregation is liable to experimental artifact. When we use the intensity of the J band for equilibrium measurements, the results were not quantitatively reproducible for small absorbance. It appears that the concentration of the residual monomer which does not aggregate in solution is more precisely determined than that of the aggregate in the early stage of aggregation.

The gradient of the straight lines drawn for these plots gives the association number $n=8$, which is different from the value $n=4$ reported by Herz.[3] Since the present experiment covers wider temperature and concentration ranges, we believe that 8 is more reliable. Actually the gradient of the plot is easily influenced by uncertain experimental conditions, and it has tendency to give rather larger value more than 8.

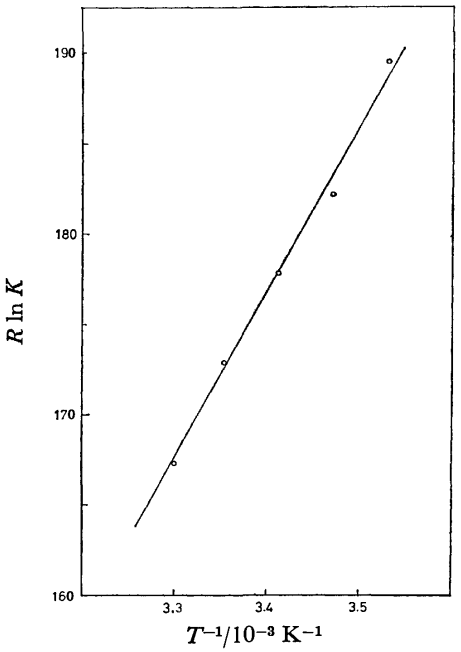

Fig. 3. A plot of $R\ln K$ against T^{-1}.

Table 1. Equilibrium constants and free energies of association

Temp K	Association number	$10^{-4}\varepsilon_J/8$	$\log K$	$-\Delta G$ (kcal mol^{-1})
283	8	85.3	41.4	53.7
288	8	85.3	39.8	52.5
293	8	85.2	38.8	52.0
298	8	78.7	37.8	51.5
303	8	75.9	36.6	50.7

By using this number, the equilibrium constants K were determined at several temperatures (Table 1). In the Table the molar absorption coefficients of the octamer are shown confirming that the values are reasonably constant. The plot of $R\ln K$ against $1/T$ gives the heat of formation and entropy change for the aggregation. The values are $\Delta H=-91.5$ kcal mol^{-1} and $\Delta S=-139.3$ cal K^{-1} mol^{-1} for the octamer. These values are much larger than those of dimerization ($\Delta H=-3$——-8 kcal mol^{-1}, $\Delta S=-10$ cal K^{-1} mol^{-1})[7-11] and of trimerization ($\Delta H=-11$ kcal mol^{-1})[11] for other dyes. This result indicates that the octamer is formed concertedly without an intermediate stage as is consistent with the appearance of the isosbestic point in Fig. 1.

The J type absorption band was found in the crystal of5,5′,6,6′-tetrachloro-1,1′,3,3′-tetraethylbenzimidazolocarbocyanine iodide solvated with two molecules of methanol,[12] and it was realized that the intermolecular arrangement and contact is very important for the appearance of the J band. It seems certain that the J-aggregate in solution takes a similar conformation as was seen in the crystal structure determined by Smith and Luss.[13]

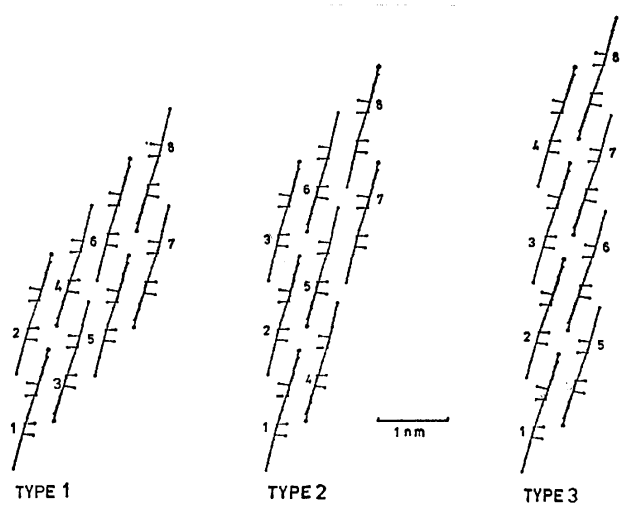

Fig. 4. Three types of model of J-aggregate

We have tried to correlate the observed J band shift with the calculated band shift in the models of the octamer. The calculation is not merely to evaluate the spectral shift by a theoretical calculation, but to estimate the magnitude of the intermolecular attraction by a dispersive and charge transfer forces.

Now we assume three models of the J-aggregate as shown in Fig. 4, where the dyes are placed face to face on a sheet as in the crystal of the dye solvated with two methanol molecules.[13] Eight dye molecules are arranged as in the crystalline bc plane; the choices of lateral displacement are different for three kinds of models. The exciton states are presumed for the octamer; the wavefunction of the ground and the excited states are written as

$$\Phi_G = \prod_{i=1}^{8} \phi_i^\circ$$
$$\Phi_E = \sum_{j=1}^{8} \left(\prod_{i \neq j}^{8} \phi_i^\circ \right) \phi_j^e \qquad (5)$$

where ϕ_i° and ϕ_j^e mean the ground and the excited states of the i-th and the j-th molecules. The calculation of the energy shift is carried out for the allowed in phase state given by Eq. 5 by a dipole-dipole approximation and by a somewhat rigorous transition density method.[14] In the dipole-dipole approximation the length of the transition dipole was estimated as 2.42 Å from the solution spectral oscillator strength of the monomer absorption band. Here we take the strong coupling model for the aggregate, in which all transition intensities are concentrated in the 0-0 band. In the transition density model we take it as $\pm 0.32\,e$ charges separated by 7.54 Å in the molecular plane based on the MO calculation. The results of calculation is shown in Table 2, and it is found that the type 1 model gives the largest stabilization of the excited state and the two methods give identical results. Experimentally the observed shift is $-2460\ \mathrm{cm}^{-1}$, hence the magnitude of the shift is well explained by these models. So far no rigorous proof for the in-phase Φ_E to be real eigenstate of the system is given. However, the 8-th order eigenvalue problem was solved for the type 1 model, and the result gave practically the same energy ($-2950\ \mathrm{cm}^{-1}$) and the intensity of 84% as given by in-phase Φ_E. The lowest energy state has the largest transition dipole, and the wavefunction shows that the excitation distributes more in the middle of the aggregate.

Table 2. Shift of absorption spectra calculated by exciton type interactions

Model	Dipole-dipole approximation	Transition density method
1	$-3000\ (\mathrm{cm}^{-1})$	$-2800\ (\mathrm{cm}^{-1})$
2	-2700	-2650
3	-2500	-2400

Table 3. Overlap integrals between dye molecules

Overlap types	A	B	C
Overlap integrals S	-0.0003	-0.0036	0.0074

Table 4. Comparison of overlap index

Model	Overlap index
1	24.6×10^{-5}
2	19.1×10^{-5}
3	22.0×10^{-5}

The stabilization energy of the aggregate by the dispersion force in the ground state may be estimated by the perturbation theory as follows. The van der Waals force (dispersion force) for the pair-wise molecules i and j will be given by

$$E_{v.d.w} = \sum_e \frac{|\langle \phi_i^e \phi_j^e | V | \phi_i^\circ \phi_j^\circ \rangle|^2}{E_{ei} + E_{ej} - E_{oi} - E_{oj}} \qquad (6)$$

where the values of matrix element are the same for the calculated ones given in Table 2. Therefore the larger the shift the greater will be the dispersion force, and the type 1 model seems to be most stable from this point of view.

The charge transfer force between the dye pair may be estimated by the following formula

$$E_{CR} = \frac{4\beta_{ij}^2}{E_{CT} - E_o} = \frac{4(kS_{ij})^2}{E_{CT} - E_o} \qquad (7)$$

where the dye molecules are presumed to play roles of both the electron donor and acceptor. Here β_{ij} is Mulliken's charge transfer integral approximated by the overlap integral between the HOMO and LUMO of the paired dye molecules, i and j. There are three types of overlap of dye molecules, A, B, and C in the order of increasing overlap integrals in the crystal of the dye with two methanol molecules.[13,15] The numerical calculation of the overlap integrals will be published in a separate paper and only the values are shown in Table 3. For three types of models we evaluate the overlap index given by $\sum_{ij} S_{ij}^2$ as shown in Table 4. The result of the calculation shows that type 1 is most stable from a view of the charge resonance interaction.

One more important force for the molecular association in aqueous solution is hydrophobic force which is produced by the surface tension of water.[16]

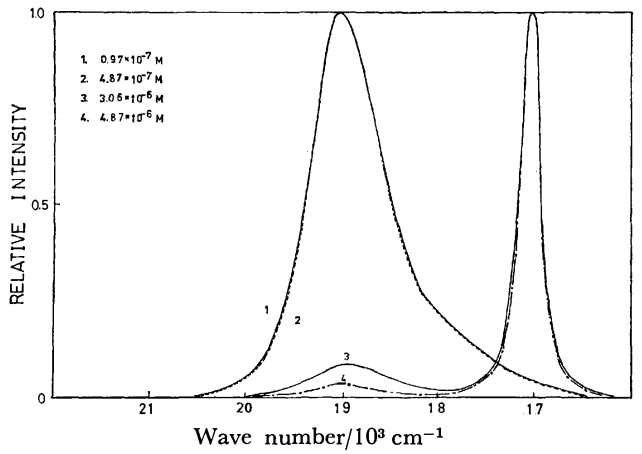

Fig. 5. Change of fluorescence spectra with the concentration of the dye.

The force will be greatest if the surface area of the aggregate is smallest and the type 1 model is most favorable from this point. On these grounds we may guess that the shape of the J-aggregate in aqueous solution correspond to type 1 model.

Fluorescence Spectra. The fluorescence spectra at various concentration of the dye measured by the excitation at 21740 cm^{-1} is shown in Fig. 5. The monomer fluorescence band shows a Stokes shift of 620 cm^{-1}, while the sharp J-band emission shows no Stokes shift. The band shape of the J-emission band was measured by a sharp dye laser excitation at 17340 cm^{-1} and 17182 cm^{-1} for the solution of 2.14×10^{-6} mol/dm^3, but it did not show any shift or broadening by changing the excitation energy. The band-width of the emission was only 150 cm^{-1}, which is smaller than the absorption band-width. Anomalous sharpening and zero-Stokes shift by aggregation are quite unusual as a complex organic molecule. An importance of charge resonance effect on the excitation transfer is discussed on various crystals as is discussed in separate papers.[12]

The excitation spectra for this sharp fluorescence band was in perfect agreement with the absorption spectra of the J-aggregate, and a long tail of absorption extended into the 22000 cm^{-1} region. The excitation profile of the J-emission was completely different from that of the monomer emission, therefore a possibility of energy transfer from the monomer to the J-aggregate may be rejected.

The quantum yields of fluorescence were measured relative to that of rhodamine B (0.97) in ethanol:

Monomer $\Phi^M = 0.03 \pm 0.006$

Aggregate $\Phi^J = 0.25 \pm 0.05$.

The lifetimes were measured at ambient temperature by a p s YAG laser as follows;

Monomer $\tau^M = 0.12 \pm 0.03$ ns

Aggregate $\tau^J = 0.062 \pm 0.01$ ns.

The lifetime of emission is correlated to the absorption oscillator strength f and fluorescence quantum yield. The natural lifetime is approximately given as

$$\tau_0 = 1.500/\bar{\nu}^2 f$$

and the fluorescence lifetimes are

$$\tau^M = \Phi^M \cdot \tau_0(M)$$
$$\tau^J = \Phi^J \cdot \tau_0(J).$$

The oscillator strength of the aggregate absorption is conserved as compared to the monomer absorption, *i.e.* $f(M)=1.02$ and $f(J)=8.16$, from these and observed quantum yields we obtain $\tau^M=0.12$ ns and $\tau^J=0.16$ ns as calculated values. The agreement is excellent for the monomer and is not good for the J-aggregate.

The radiative (k_r) and non-radiative (k_{nr}) decay rates of the excited state are related to the quantum yield of fluorescence Φ and fluorescence life time τ as follows.

$$\Phi = \frac{k_r}{k_r+k_{nr}}$$
$$\tau = \frac{1}{k_r+k_{nr}}.$$

By using the observed values, these rates are evaluated for the monomer and the J-aggregate as

	$k_r[s^{-1}]$	$k_{nr}[s^{-1}]$
Monomer	2.5×10^8	8.1×10^9
Aggregate	4.0×10^9	1.2×10^{10}.

It is apparent that the J-aggregate has 16 times larger radiative rate as compared to the monomer. A most plausible explanation for this enhancement is that the fast excitation transfer takes place between more than two J-aggregate units within the life time of the excited state, and the coherent excited state has a larger radiative transition probability than the value expected for the octamer ($f(J)=8.16$). The extent of the excitation transfer might be more than two units, because two is an ideal number expected for the parallel arrangement which will be never realized in solution. Therefore the delocalization of the excited energy between several J-aggregate is the most acceptable reason for the discrepancy between τ^J (calcd) and τ^J (obsd).

Further support for the fast excitation transfer between the J-aggregate is given by the polarization measurement. The polarization of the emission bands were measured at different temperatures; the p-values were

p(monomer) $= 0.40\pm0.04$ for 275—303 K

p(aggregate) $= 0.20\pm0.02$ at 303 K

p(aggregate) $= 0.23\pm0.02$ at 275 K

in dilute alkaline solution. The relation given by Perrin[17,18] on the rotational relaxation of the chromophore and the p-value is

$$p = p_0\left[1+\left(1-\frac{p_0}{3}\right)\left(\frac{\tau_{fl}}{\tau_{rot}}\right)\right]^{-1}$$

where p_0 is an ideal polarization value for rigid chromophore, τ_{fl} and τ_{rot} are the fluorescence and rotational relaxation lifetimes. From this equation and putting $p_0=0.45$ we may estimate the rotational relaxation times for the monomer to be 1.18 ns, while that of the J-aggregate is 0.04 ns. If we assume the excitation of the J-aggregate is confined within octamer, this result is quite unreasonable since the large aggregate

has a much shorter rotational time constant than a small monomer. If the energy transfer between several J-aggregate is very efficient, the low p-value is reasonably accepted as a polarization quenching by a fast energy transfer.

The authors thank to Profs. E. Hirota and K. Yoshihara of the Institute for Molecular Science for the use of the dye and YAG lasers. This research was supported in part from the Grant-in-Aid of the Ministry of Education, Science and Culture (No. 254144, 1977).

Behavior of Sulfate Ions during Formation of Anodic Oxide Film on Aluminium

Yoshio FUKUDA* and Toshiro FUKUSHIMA

Corrosion Division, National Research Institute for Metals, 2-3-12, Nakameguro, Meguro-ku, Tokyo 153

(Received April 21, 1980)

The incorporation of sulfate into anodic film formed on aluminium in an H_2SO_4–$MgSO_4$ solution was investigated by infrared spectroanalysis using the compensation method. The sulfate content of the film was very small at the initial stage of anodizing, but increased with time to a nearly constant value. This result is explained in terms of the variation of strength of electric field and the mobility of each anion in the barrier layer. The distribution of sulfate across the cell wall also was examined. The sulfate content was relatively small near the wall/solution interface, but increased with the distance across the wall from the surface, reached a maximum value on the intermediate layer between the wall/solution interface and the cell boundary, and decreased gradually. Such distribution is considered to be similar to that across the barrier layer. The SO_4 distribution and the transfer of anions from the barrier layer to the porous layer are explained.

When aluminium is anodized in an aqueous solution of an acid such as sulfuric or oxalic acid, porous-type films are formed. These films consist of hexagonal columnar cells, each of which contains a cylindrical pore. At the bottom of the pore there is a thin layer, called the "barrier layer."[1] Probably only the barrier layer forms immediately after the start of electrolysis, but in a short time pores are developed by the solvent action of the electrolyte on the layer, and then close-packed cells are established. While the formation and dissolution of the barrier layer occur simultaneously, the porous layer grows toward the metal. Accordingly, the initially formed film is located near the outer surface. Such porous-type films contain more electrolyte anions than barrier-type films which are formed in neutral salt solutions.[2] This fact suggests that the anions involved in the film affect the dissolution behavior of the film and determine the type of the film. Therefore, a study of the anodic behavior of electrolyte anions during the pore development is important to understand the pore-formation process and the properties of the films. From this point of view, the time dependence and distribution of the oxalate content of the film formed in oxalic acid were elucidated in a previous paper.[3] The distribution of anions in the film formed with phosphoric acid also has been described.[4,5]

Although the incorporation of sulfate into the initially formed film has been studied by Brace and Baker[6] using ^{35}S as a radioactive tracer, the time dependence and distribution of sulfur content of the film are not obvious. Whether or not the behavior of anions at a constant current density is different from that of anions at a constant voltage also is not obvious.

The time dependence of sulfate content of the film during anodization in an H_2SO_4–$MgSO_4$ solution at a constant current density or a constant voltage was examined by infrared spectroanalysis using the compensation method. The anion distribution across the cell wall was examined by gravimetric analysis and the manner of transfer of anions from the barrier layer to the porous layer was speculated about.

Experimental

Foil specimens of 99.99% aluminium (annealed, 150 mm × 70 mm × 0.1 mm or 150 mm × 35 mm × 0.1 mm) were treated with a hot solution of mixture of phosphoric acid and chromic acid to remove natural oxide film, and then were anodized. For Auger electron spectroscopy and electron microscopic observation, electropolished aluminium sheets (25 mm × 10 mm × 0.5 mm) of the same purity were used. A 3 dm^3 beaker was used as an electrolytic cell, the cathodes being made of two plates of carbon (200 mm × 45 mm × 10 mm).

Anodizing was carried out in a mixed solution of 0.6 mol dm^{-3} H_2SO_4 and 0.4 mol dm^{-3} $MgSO_4$ at 30 °C for 3 s—30 min by applying a constant current density of 1 A dm^{-2} or a constant bath voltage of 18 V while the solution was stirred at a nearly constant rate. In every process, after the steady state was reached, the current density was 1 A dm^{-2} and the bath voltage was 18 V. Magnesium sulfate was added to sulfuric acid in order to retard the arrival at the critical point ('c' in Figs. 6 and 7) by suppression of the dissolution of the film.[7] Since the Mg content of the film was extremely small and the sulfate content of the film was nearly the same as that of sulfuric acid film,[7] the film-forming characteristics of this mixture are considered to be essentially the same as those of sulfuric acid alone.

After the anodized specimens were rinsed in running water for 10 min,[6] the films were isolated by the mercury (II) chloride method. The films were rinsed, dried, and fully crushed. Thereafter, the SO_4 content of the films was determined by gravimetric analysis ($BaSO_4$) and by infrared spectroanalysis (KBr disk; sample = 3.5 mg, KBr = 800 mg). The chemical composition of the film near the surface and the film/metal interface were analyzed by a PHI Auger spectrometer during or after Ar^+ ion sputtering (E_p = 3 kV). The thin films isolated were observed directly with a transmission electron microscope at an accelerated voltage of 50 or 100 kV.

Results

Electron Microscopic Observation. At the constant current density, numerous pores of small radii were observed in the 3 s-film (Fig. 1). The radii of some pores increased with time and the number (surface density) of pores decreased (Fig. 2). The total area of pores decreased with time to a nearly constant value after 20 s.

At the constant bath voltage, the average radius of the pores and its variation with time were nearly the same as those obtained by the constant current process. Altough the number of pores in the 3 s and 10 s films was smaller than that obtained by the constant current process, the number decreased with time,

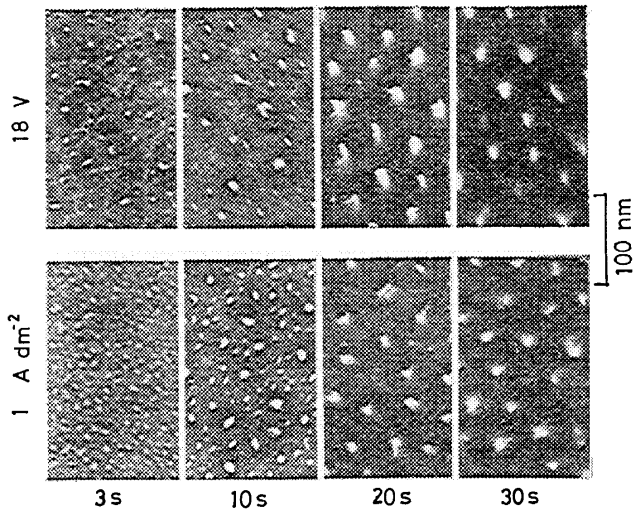

Fig. 1. Transmission electronmicro-photos showing the growth of pores at the initial stage of anodizing in 0.6 mol dm^{-3} H_2SO_4–0.4 mol dm^{-3} $MgSO_4$ at 30 °C (accelerated voltage=50 kV).

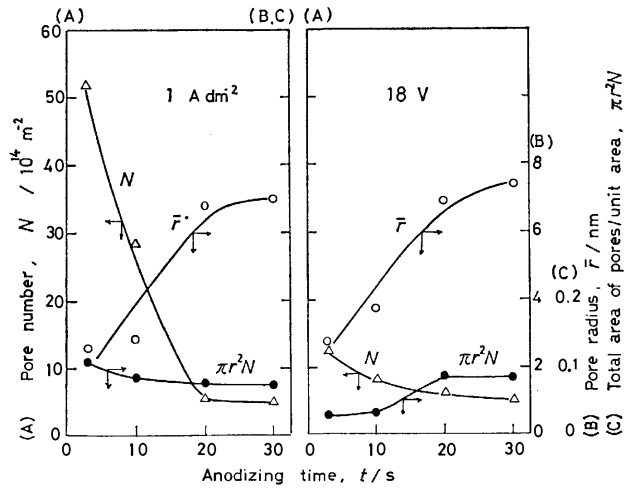

Fig. 2. Time dependence of the number, radius, and total area of pores (0.6 mol dm^{-3} H_2SO_4–0.4 mol dm^{-3} $MgSO_4$, 30 °C).

reaching nearly the same value as that obtained by the constant current process. From these results, it was found that near the outer surface of the film there were smaller pores than in the inner part of the film.

Further, the number of pores in 30 s-films was smaller than that reported[1,8] previously. This is probably due to the low ability of transmission of the electron beam at 50 kV. Therefore, the values of the dissolution rate shown in Fig. 10 were calculated by using the data ($r=7$ nm, $N=9.2\times10^{14}$ m^{-2}) obtained with 100 kV-observation on the films formed for 80 s.

Infrared Spectra of the Films. Curve 1 in Fig. 3 shows a spectrum of a film formed in sulfuric acid, obtained by using KBr as reference. The absorption band 1150 cm^{-1} is considered to be due to sulfate, because it also exists in the spectrum of $Al_2(SO_4)_3$ (broken line). Dorsey[9] also assigned such bands to sulfate. However, the determination of the SO_4 content of the film using this band was difficult, because

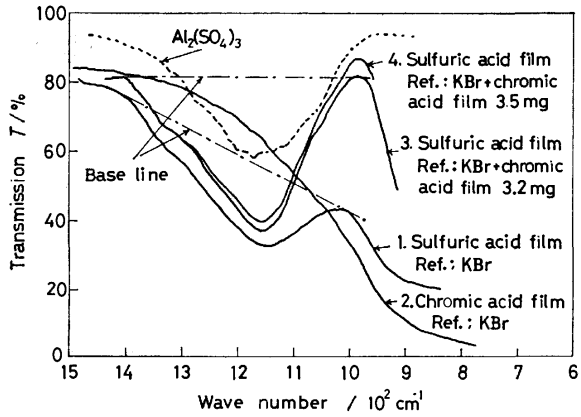

Fig. 3. Infrared spectra obtained by the compensation method.

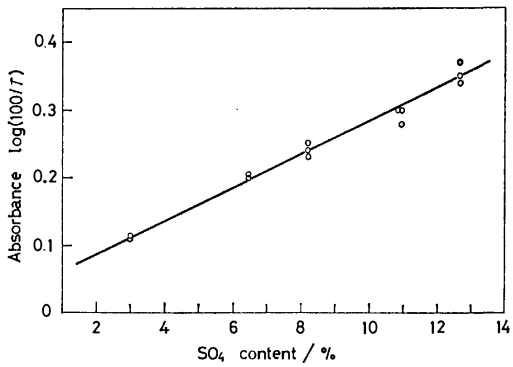

Fig. 4. Calibration of absorbance at 1150 cm^{-1} in IR spectra against the SO_4 content determined by gravimetric analysis ($BaSO_4$).

not only was its band weak, but also a strong and wide absorption band due to Al-OAl (stretching) was present below 900 cm^{-1}.[10] Therefore, the appropriate amount (1—3.5 mg) of the film formed in chromic acid, which did not absorb infrared rays over the 1400—1000 cm^{-1} region (curve 2), was added to the KBr reference so as to make the base line of the spectrum nearly horizontal, as shown by the curve 3, compensating the absorption by Al-OAl. When the amount of the film formed in chromic acid was in excess, such spectra as the curve 4 were obtained. However, the slight deviation of the base line from the horizontal did not appreciably change the absorbance at 1150 cm^{-1}. By such a compensation method, the IR spectra of the films whose SO_4 content had been already determined by gravimetric analysis were obtained. The absorbance at 1150 cm^{-1} was then calibrated against the SO_4 content of the film (Fig. 4). By using this relation, the SO_4 content of the film could be determined with errors below 10%.

Time Dependence of the SO_4 Content. Figure 5 shows the IR spectra of the films formed at 1 A dm^{-2} for 5 s—30 min. Nearly the same spectra were obtained in the case of 18 V-anodizing. The time dependence of the SO_4 content obtained from these spectra is shown in Figs. 6 and 7. At the initial stage of every anodizing process, the SO_4 content was very small, but it increased with time to a nearly

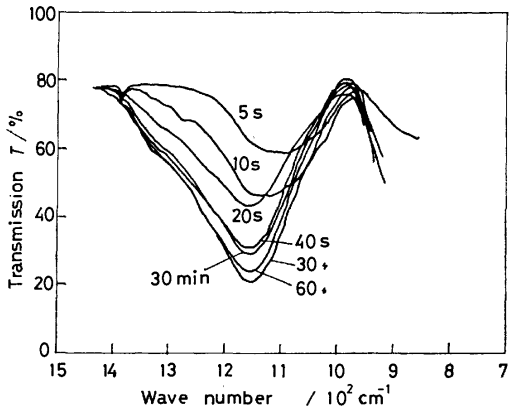

Fig. 5. Infrared spectra of films formed in 0.6 mol dm^{-3} H_2SO_4–0.4 mol dm^{-3} $MgSO_4$ at 30 °C and 1 A dm^{-2} for various times (Ref.; KBr+chromic acid film).

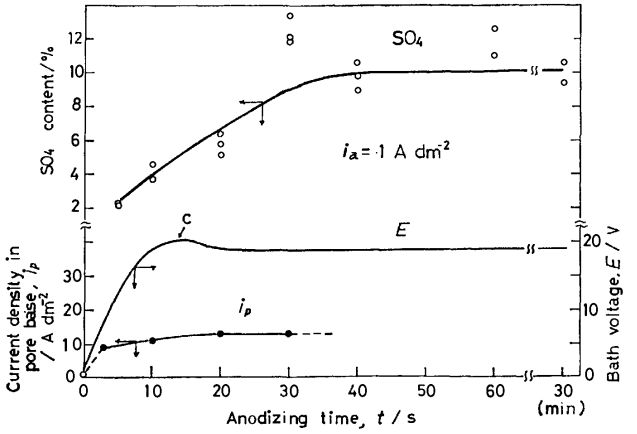

Fig. 6. Time dependence of the SO_4 content, current density in pore base, and bath voltage during constant current anodizing (0.6 mol dm^{-3} H_2SO_4–0.4 mol dm^{-3} $MgSO_4$, 30 °C).

constant value after 30 s at 1 A dm^{-2} and after 10 s at 18 V, respectively. These results were similar to those obtained with oxalic acid. However, in the case of 5 s and 10 s-films, the band due to sulfate shifted to a lower wave number. Perhaps the binding state of sulfate to the film is different. Therefore, strictly speaking, the relation between the absorbance at such a lower wave number and the SO_4 content may be different to some extent from that shown in Fig. 4. However, the results shown in Figs. 6 and 7 were consistent with the fact (Fig. 8) that the Auger peak to peak height of sulfur in the film near the outer surface, which was formed initially, was smaller than that of sulfur in the inner part of the film, which was formed later.

Anion Distribution across the Cell Wall. The distribution of electrolyte anions across the cell wall was examined in the same way as in the previous paper. Namely, after the specimen was anodized for 30 min, it was immersed in 1 mol dm^{-3} H_2SO_4, keeping the temperature at 30 °C. Then the time dependences of both the amount of the dissolved film and the SO_4 content of the remaining film were determined by

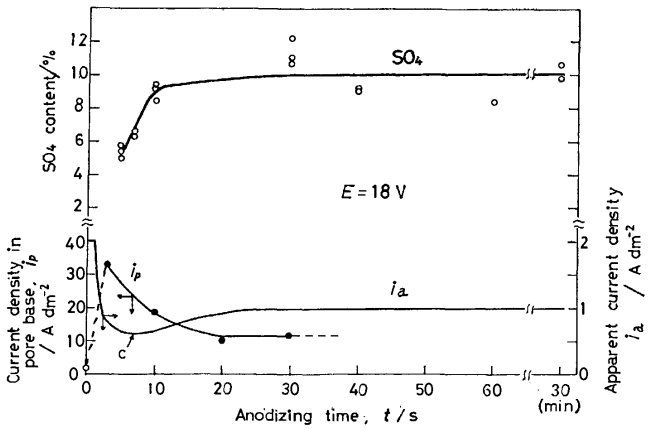

Fig. 7. Time dependence of the SO_4 content, current density in pore base, and apparent current density during constant voltage anodizing (0.6 mol dm^{-3} H_2SO_4–0.4 mol dm^{-3} $MgSO_4$, 30 °C).

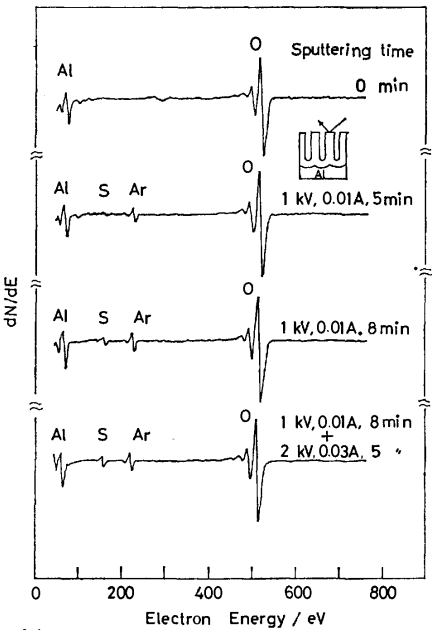

Fig. 8. Auger spectra obtained during Ar^+ ion sputtering from the surface of the film (0.6 mol dm^{-3} H_2SO_4–0.4 mol dm^{-3} $MgSO_4$, 30 °C, 1 A dm^{-2}, 30 s).

weight measurement and gravimetric analysis, respectively (Fig. 9). From these results, the SO_4 content of the film dissolved for a certain period was calculated. Further, the rate of chemical dissolution of the film was calculated every 10 min with reference to the method by Nagayama and Tamura[11] and the thickness of the wall consumed was thereby determined. The SO_4 content and chemical dissolution rate of the film for a certain period were plotted against the mean distance from the surface of the wall (Fig. 10).

The SO_4 content was relatively small near the wall/solution interface, but increased with the distance across the wall from the surface, reached a maximum value on the intermediate layer between the wall/solution interface and the cell boundary, and decreased gradually. This result is similar to that obtained with phosphoric acid[4] or oxalic acid.[3]

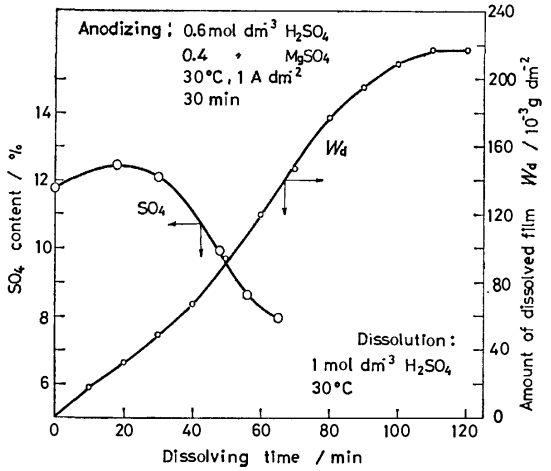

Fig. 9. Variation of the amount of the dissolved film and the SO_4 content of the remaining film with dissolving time.

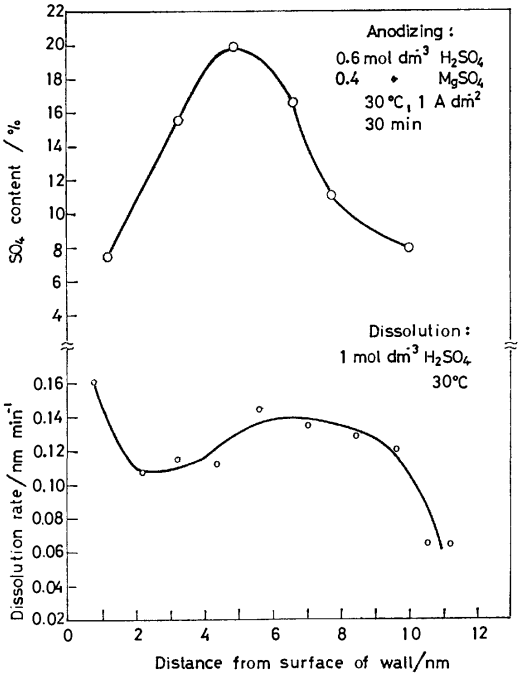

Fig. 10. Distribution of anions across the cell wall (upper) and the variation of dissolution rate of the film with the distance from the surface of the wall (lower).

As shown in Fig. 10 (lower), the chemical dissolution rate of the wall was highest near the surface, decreased with the distance from the surface, increased slightly, and decreased again near the boundary of the cells.

Little sulfur was detected near the barrier layer/metal interface (Fig. 11). The rate of sputtering of the film near the barrier layer/metal interface was lower than that of the bulk of the film.

Discussion

Mobility of Electrolyte Anions. It is impossible that the sulfate ions enter from the surface of the cell wall to which no electric field is applied. It is considered that the anions are pulled under the electric field from the surface of the barrier layer into the bulk of the layer, migrate through the layer, and remain in the porous layer by being released from the electric field.

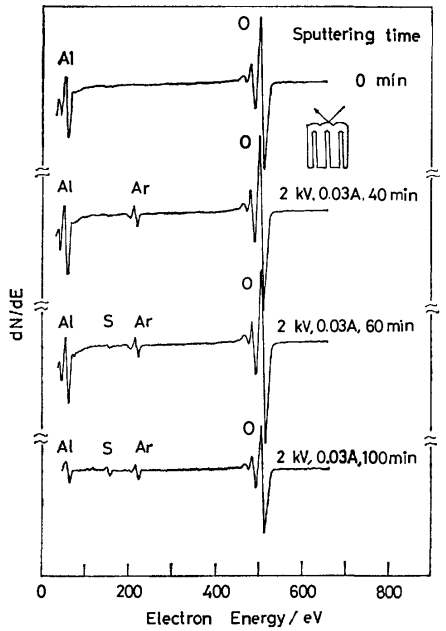

Fig. 11. Auger spectra obtained after Ar^+ ion sputtering from the barrier layer/metal interface (0.6 mol dm^{-3} H_2SO_4–0.4 mol dm^{-3} $MgSO_4$, 30 °C, 18 V, 30 min).

Although the mechanism of movement of electrolyte anions is not known well, if the anions are mobile, the anion content of the film would increase with the strength of the electric field. This seems to be reasonable on the basis of the following two facts. (1) According to Hoar and Yahalom,[12] the electrical properties of the barrier layer formed in sulfuric acid and sulfate solutions are similar to those of the barrier layer formed in neutral borate solution, and the relation, $\log i$ (A m^{-2}) $\propto E/y$ (V m^{-1}), is not changed remarkably for different incorporated anions. In other words, as the current density becomes higher, the strength of the electric field increases. (2) According to Mason,[13] the SO_3 content of the film increases with the current density. Therefore, it can be said that the stronger electric field at the higher current density causes the increased SO_3 content of the film.

Time Dependence of the SO_4 Content. In this experiment, even if the apparent current density (i_a) is constant, the real current density varied with the pore development at the initial stage (Fig. 6). Namely, when the anodizing is started, pores should not be present, so the current density is 1 A dm^{-2}. However, as pores were developed with time (3—20 s), the current density in the pore base (i_p) increased to a nearly constant value after 20 s (Fig. 6). Therefore, the strength of electric field would be small immediately after the start of anodizing, so that the SO_4 content is very small. Probably, this is due to small mobilities of HSO_4^- and SO_4^{2-} compared with

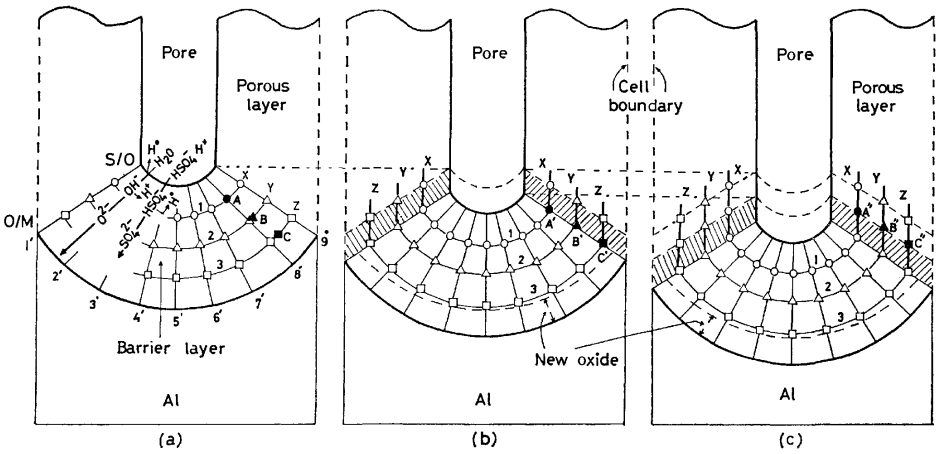

Fig. 12. Schematic representation of the transfer of anions from the barrier layer to the porous layer.

those of OH^- and O^{2-}. However, as pores are developed (3—20 s), the i_p increases and the strength of the electric field would increase, causing the increase of the SO_4 content. After 20 s, the i_p value is nearly constant. Therefore, it is considered that the film containing about 10% SO_4 (sulfate content of the 30 min-film) grows beneath the 20 s-film at a constant rate. The proportion of the initially formed film (outer layer) to the total film decreases with time so that the value of SO_4 content of the film, which was about 6% at 20 s, would approach with time to 10% as follows: $(6\%\times20+10\%\times10)/30=7.3\%$ at 30 s, $(6\%\times20+10\%\times40)/60=8.7\%$ at 60 s, and $(6\%\times20+10\%\times100)/120=9.3\%$ at 2 min. This is in fairly good agreement with the experimental result (Fig. 6).

In the case of constant voltage (Fig. 7), the i_a stayed at about 2 A dm^{-2} for the first 2 s, then abruptly decreased to a minimum value, and afterwards increased slightly to a constant value. For the first 2 s, the current density is low and the strength of electric field would be small, so that the SO_4 content of the film is small at the initial stage of anodizing. However, the i_p increases and the strength of the electric field would increase, so that the SO_4 content increases with time. In this case, the time to saturation of the SO_4 content was shorter than in the constant current process. This is due to the higher current density in the pore base at the initial stage of anodizing.

Anion Distribution across the Cell Wall. In steady state, the barrier layer, of constant thickness, moves toward the metal while it is renewed continuously. According to Siejka and Ortega,[14] the new oxide is formed at the oxide/metal (O/M) interface by the migration of oxygenated anions (O^{2-}, SO_4^{2-}), while at the solution/oxide (S/O, pore base), only the dissolution of the film occurs and there the oxide is not formed by the migration of cations.

Figure 12a shows the cross section of the barrier layer and its neighborhood in steady state. The curves 1, 2, and 3 show isopotential planes,[15] the lines of 1′—9′ show the current flow (the direction of the electric field). The anion content is the same everywhere on a certain isopotential plane. Since the current density in the barrier layer decreases with the distance from the surface of the layer, the strength of the electric field is considered to decrease with the distance from the surface.

In the steady state, OH^- (by decomposition of H_2O) and HSO_4^- ions are supplied from the solution into the barrier layer. The former is dissociated into O^{2-} and the latter is dissociated into SO_4^{2-} by releasing H^+, and then they migrate into the barrier layer. However, SO_4^{2-}, which is larger than O^{2-}, becomes gradually immobile since the strength of electric field decreases with the distance from the surface. On the intermediate layer between the interfaces of O/M and S/O, the strength of electric field is probably so small that SO_4^{2-} ions are delayed and accumulated there. On the contrary, O^{2-} ions migrate farther inward, so that the film with a very small SO_4 content is formed near the O/M interface (Fig. 11).

When the electrolysis is continued, the interfaces of S/O and O/M move gradually, while the distance between these interfaces is kept constant and the shaded portions become porous, as shown in Figs. 12b and 12c. During this period, the direction and strength of electric field applied to the anions at the position of A turn to the cell boundary and increase, so that the anions migrate toward the cell boundary and the metal, resulting in the movement on the isopotential plane 1 to A′ in Fig. 12b. Al^{3+} ions which take part in the formation of the film are replaced continuously by new cations transported from the metal. Most anions located at A may be transferred to A′; however, some anions may migrate inward further than the isopotential plane 1 and some anions may be supplied from the solution. The SO_4 content on the plane 1 is always kept constant. Thereafter, the anions at A′ remain in the porous layer by being released from the electric field, as shown by A″ in Fig. 12c. In the same manner, most anions located at the positions B and C in Fig. 12a are transferred to B′ and C′ in Fig. 12b, and remain in the porous layer as B″ and C″ in Fig. 12c, respectively. Accordingly, the anions located nearer to the surface of the barrier layer and farther from the center (5′

in Fig. 12a) of the layer are more rapidly transferred to the porous layer. The SO_4 contents on the planes X, Y, and Z in the porous layer are the same as those on the planes 1, 2, and 3 in the barrier layer, respectively. The composition of the wall surface is the same as that of the barrier layer surface.

The surface of the wall is soluble, since HSO_4^- ions would be incorporated into the oxide. The chemical dissolution rate of the wall decreases with the distance from the surface of the wall as the number of HSO_4^- ions became fewer, increases owing to the increase in the SO_4 content of the film, and decreases again near the cell boundary owing to the decrease in the SO_4 content.

Thus, the distribution of anions across the cell wall is considered to be similar to that established in the barrier layer.

Conclusions

The time dependence and distribution of SO_4 content of the anodic oxide film formed on aluminium in an H_2SO_4–$MgSO_4$ solution were the same as those of the film formed in oxalic acid and in phosphoric acid. From these results, it is speculated that the behavior of sulfate ions during anodizing was as follows.

(1) Immediately after the start of anodizing, a film containing a number of micropores and a small quantity of SO_4 was formed, and then the number of pores decreased. During this period, the current density in the pore base increased and the strength of electric field increased so that the SO_4 content of the film increased. When the current and voltage were in steady state, the SO_4 content of the film became constant.

(2) Under the electric field, HSO_4^- ions were pulled from the surface of the barrier layer into the layer, were dissociated into SO_4^{2-} by releasing H^+, and then migrated into the layer. However, since the strength of electric field was smaller with the distance from the surface of the barrier layer, SO_4^{2-} ions gradually became immobile and accumulated. Therefore, the SO_4 content of the film reached a maximum value on the intermediate layer between the pore base and the barrier layer/metal interface. When the barrier layer became porous by being released from the electric field, the distribution of anions across the barrier layer remained in the porous layer across the cell wall.

(3) The surface of the wall was soluble since HSO_4^- ions would be incorporated into the oxide. The chemical dissolution rate of the wall decreased with the distance from the surface of the wall as the number of HSO_4^- ions became fewer, increased owing to the increase in the SO_4 content of the film, and decreased again near the cell boundary owing to the decrease in the SO_4 content.

The authors are indebted to Dr. Kazuhiro Yoshihara and Dr. Masayasu Kurahashi of this institute for the performance of the Auger electron spectroscopy.

Raman Scattering Study on Coordination Structures of Cu(II)–L-Histidine(1 : 2) in Aqueous Solutions

Masao ITABASHI* and Koichi ITOH

Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo 160

(Received April 30, 1980)

The pH and pD dependences of the Raman spectra of Cu(II)–L-histidine (1:2) and Cu(II)–L-histidine-d_{3-5} (1:2) were analyzed based on the pH titration data. Several ring vibrations of the imidazolyl group with cationic, neutral and anionic forms, the out-of-plane bending vibration of the bound carboxylate, and the Cu(II)–N stretching vibrations of the bound amino groups are used to study the chelation structures of the species taken by the solutions. From the results it was concluded that MHA^{2+}, the major species below pH 3, assumes a glycine-like chelation structure with an unbound imidazolium cation. The results also indicate that the species MHA_2^+, which is prominent in the pH region 4.0—4.5, takes a mixed-type structure, in which one histidine molecule coordinates to Cu(II) as a terdentate ligand and another binds as a substituted glycine. MA_2, the major species around pH 7, is determined to have the chelation structure in which two nitrogen atoms of the amino groups and two nitrogen atoms of the imidazole rings are bound to the Cu(II) ion in the square-planar trans position and at least one carboxyl group in the axial position.

The imidazolyl group, as a histidine moiety, functions as a ligand toward transition metal ions in a variety of metalloproteins including carbonic anhydrase,[1] carboxypeptidase,[2] and thermolysine.[3] Yoshida *et al.*[4] and Salama and Spiro[5] measured the Raman spectra of cobalt(II)–imidazole and cobalt(II)–L-histidine complexes as model compounds of metalloproteins and studied the relationship between the spectra and the coordination geometries of the complexes. Recently we also analyzed the Raman spectra of hexakis(4-methylimidazole)cobalt(II) complex, $Co(4MeImH)_6^{2+}$, and bis(L-histidinato) metal complexes, M(L-His)$_2$ (M=Ni(II), Zn(II)), in solid state.[6] From this study we concluded that some vibrational modes of the bound imidazolyl group clearly reflect the coordination site of this group to central metal ions. We also mentioned the possibility of elucidating the coordination geometries of the above-mentioned metalloproteins by means of Raman spectroscopy.

In this paper we measured Raman spectra and studied the coordination structures of Cu(II)–L-histidine(1:2) in aqueous solutions. Physiological studies suggest that a fraction of Cu(II) ions in human plasma is bound to human serum albumin and at the same time bound to amino acids consisting mostly of L-histidine.[7,8] Therefore, many physicochemical methods have been applied to Cu(II)–L-histidine(1:2) in aqueous solutions. Several pH-titration studies indicate that the solution contains MHA^{2+}, MA^+, MHA_2^+ and MA_2 as major species near and below the physiological pH[9,10] (Cu(II) abbreviated to M^{2+} and anionic histidine to A^-). The precise structures of these species, however, are still uncertain because the physical parameters obtained for the system (*e.g.*, formation constants, absorption maxima, and circular dichroism extrema) give only indirect informations about the coordination geometries. The use of ^{1}H-NMR spectroscopy is restricted only to the Cu(II)–L-histidine system with the ligand to metal ion ratio greater than 10^3 because the long electron spin relaxation time of Cu(II) ion causes too large line broadening of ligand resonances to permit their observation at stoichiometric concentration ratios.[11,12] The analysis of the Raman spectra provide us with some new and direct informations about the coordination structures of several species. The results clearly show that Raman spectroscopy is one of the powerful method for the structural study of coordination compounds containing L-histidine molecules and L-histidine residues as ligands.

Experimental

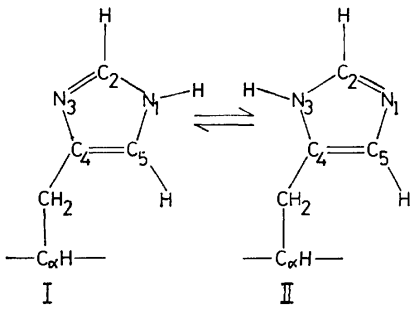
Materials. L-Histidine monohydrochloride monohydrate and $CuCl_2 \cdot H_2O$ were of reagent grade and obtained from Kanto Chemical Co., Inc. D_2O (99.75%), and concentrated D_2O solutions of NaOD (40%), and DCl (37%) were from E. Merck AG, Darmstadt. The measurement of the Raman spectra was made on the aqueous solutions of L-histidine and those containing L-histidine (0.4 M†) and $CuCl_2$ (0.2 M). The measurement was also performed on the D_2O solutions of L-histidine-d_{3-5} and those containing L-histidine-d_{3-5} (0.4 M) and $CuCl_2$ (0.2 M). L-Histidine-d_{3-5} and $CuCl_2 \cdot D_2O$ were prepared by Iyophilizing two times the D_2O solutions of L-histidine and $CuCl_2 \cdot H_2O$. The pH and pD values of the sample solutions were adjusted with 2—5 M NaOH and HCl and 2—5 M NaOD and DCl, respectively.

Measurement of Raman Spectra. All the spectra were taken by using a JEOL 400D Raman spectrophotometer equipped with a Spectra Physics model 164 argon ion laser. The 488.0 nm emission line was used as an excitation source. A spinning cell or a flow technique was used for the measurement.

Results and Discussion

Species Distribution of Cu(II)–L-Histidine (1:2) in Aqueous Solutions. A histidine molecule is considered to have three potential coordination sites in aqueous solutions. As pH rises, the carboxyl oxygen (pK_a=1.9), the imidazole nitrogen (pK_a=6.1) and the amino nitrogen (pK_a=9.1) become available for coordination to a metal ion.[10,13] The neutral imidazolyl group exists in the tautomeric equilibrium between the N(1) protonated form and the N(3) protonated one (Scheme 1).[14] Either one of these nitrogens

† 1 M=1 mol dm^{-3}.

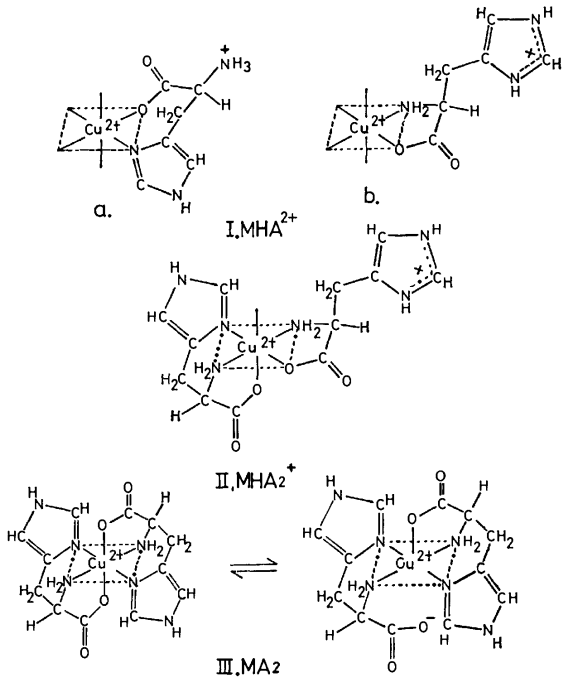


Scheme 1.

forms the chelation site.

In order to analyze the Raman spectra of Cu(II)–L-histidine complexes in aqueous solutions, it is first necessary to know the type of species which appears in various pH values of the solutions. As mentioned in the previous section, the solutions possess the predominant species, MHA^{2+}, MA^{+}, MHA_2^{+}, and MA_2. Below pH 3 the only major species is MHA^{2+} with a frequency approaching 50%. Just above pH 3, the solution contains the species MA^{+} in its maximum amount where about 25% of the Cu(II) ion is so bound. The species MHA_2^{+} appears to the extent of 90% from pH 4 to 4.5, and its deprotonation leads to MA_2 with $pK_a=5.5$. From pH 7 to 8 the species MA_2 is the most stable and its existence ratio approaches to 100%. In a pH region higher than 9, the formation of species $MH_{-1}A_2^{-}$, $MH_{-1}A$, and $M_2H_{-2}A_2$ are possible due either to hydroxylation or pyrrole hydrogen ionization ($pK_a=11.7$).[15,16]

It is known that a Cu(II) ion prefers a square-planar or a grossly distorted octahedral geometry to bind a maximum of two amino acid ligands. For a steric reason the three donor atoms of a terdentate histidine anion (A^{-}) cannot all occupy a planar site simultaneously, and these atoms have the equal possibility of being bound to the Cu(II) ion in the axial position. It has been strongly favored that the species MA^{+} involves the amino and imidazolyl groups in the square plane (histamine-like) with the carboxyl group in an apical position.[17] In contrasts, the site of protonation in MHA^{2+} is more controversial. The most popular view has been that the Cu(II) ion is bonded through an imidazole nitrogen and a carboxyl oxygen, while the amino nitrogen is protonated (Scheme 2 Ia).[9,18–20] The imidazole-carboxylate chelation, however, forms an unstable 7-membered ring and the binding at the glycine locus with an unbound protonated imidazolium cation has also been suggested to MHA^{2+} (Scheme 2 Ib).[17] Scheme 2 II shows one of the structures proposed to the species MHA_2^{+}, in which one histidine molecule coordinates to the Cu(II) ion as a terdentate ligand while another binds as a substituted glycine with an unbound imidazolium cation (mixed type).[15] The structure of the species MA_2 has so far received the most attention as a model for the transport form of Cu(II) ions in human blood. Great controversy, however, has been centered around its structure and several different proposals have been made to it.[17,21–23] The structure shown in Scheme 2 III is one of the proposals.[15]



Scheme 2.

Raman Spectra of L-*Histidine and Cu(II)–*L-*Histidine (1:2) in H_2O.* Figure 1 shows the Raman spectra of L-histidine in H_2O at the pH values of 3.90(A), 8.15(B), and 11.98(C). Ashikawa and Itoh analyzed the pH dependence of Raman spectra of L-histidine.[24] On the basis of the normal coordinate treatment they assigned the bands observed at 1627, 1264, and 994 cm^{-1} in Fig. 1(A) to the C=C stretching, the ring breathing, and the C–H in-plane bending vibrations of the protonated imidazolium cation, respectively. They also stated that the doublet bands around 1580, 1270, and 990 cm^{-1} observed in Fig. 1(C) reflect the tautomerism of the neutral imidazolyl group of L-histidine, the 1570-, 1285-, and 988-cm^{-1} components corresponding to the tautomer I and the 1585-, 1262-, and 1004-cm^{-1} to the tautomer II (Scheme 1). At pH 8.15, where the tautomer I is predominant, the spectrum shown in Fig. 1(B) gives rise to the strong and sharp bands at 1570, 1282, and 988 cm^{-1}. These results are useful for monitoring the coordination mode of each species assumed by the Cu(II)–L-histidine (1:2) system.

Figure 2 shows the Raman spectra of the Cu(II)–L-histidine(1:2) aqueous solutions with various pH values. The spectrum observed at pH 2.48 (Fig. 2(F)), where the species MHA^{2+} is predominant, shows the prominent bands at 1628, 1483, 1268, 1189, 990, and 629 cm^{-1}. The spectrum is quite similar to that of the ligand containing a protonated imidazolium cation (Fig. 1(A)) with the exception that a well-defined band at 561 cm^{-1} is observed in Fig. 2(F). The 561-cm^{-1} band is observed throughout the pH range 2.48—7.23 (Figs. 2(C)—(F)), where the carboxyl group of the ligand is bound to the Cu(II) ion. This band can be assigned to the out-of-plane bending mode of the bound carboxylate by comparing with the same vibrational mode observed at 570 cm^{-1} for bis-

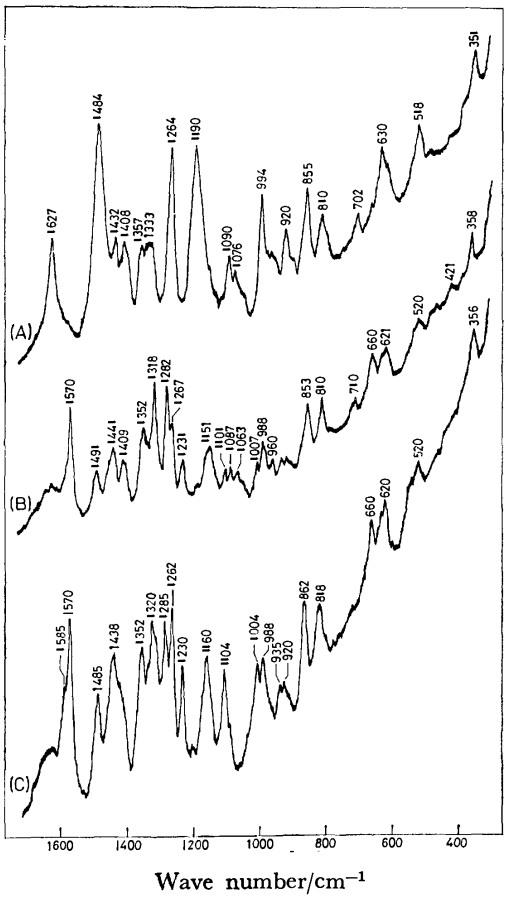


Fig. 1. Raman spectra of L-histidine in aqueous solutions (*ca.* 10 wt%) at a room-temperature: (A) pH= 3.90, (B) 8.15, (C) 11.98.

(glycino) complex of Cu(II).[25] From these results it is clear that in the species MHA^{2+} the Cu(II) ion is bound through an amino nitrogen and a carboxyl oxygen (glycine-like chelation), while the protonated imidazolium cation is not involved in the coordination. Therefore, the structure of this species is concluded to be the one shown in Scheme 2 Ib.

On raising the pH values (Figs. 2(D) and (E)) the band at 1628 cm^{-1} decreases its intensity and another band begins to appear at about 1585 cm^{-1} (the C=C stretching vibration of the neutral imidazole ring). The latter band is attributable to the bound imidazolyl group because the group with the pK_a value of 6.1 cannot exist as a free and neutral form at pH 4.55 and 3.72. One of the pH titration studies[10] reports that at pH 3.72 there exist appreciable amounts of three species, MA^+, MHA^{2+}, and MHA_2^+ in the Cu(II)-L-histidine(1:2) system. Therefore, it is difficult to assign each Raman scattering band in Fig. 2(E) to either one of the species. At pH 4.55, MHA_2^+ is the only major species. As Fig. 2(D) shows, the intensities of the two C=C stretching bands at 1628 and 1583 cm^{-1} are almost identical with each other, which is consistent with the mixed-type chelation structure shown in Scheme 2 II.

The Raman spectrum measured at pH 7.23 (Fig. 2(C)), where the species MA_2 exists almost exclusively, exhibits the vibrational modes of the neutral imidazole

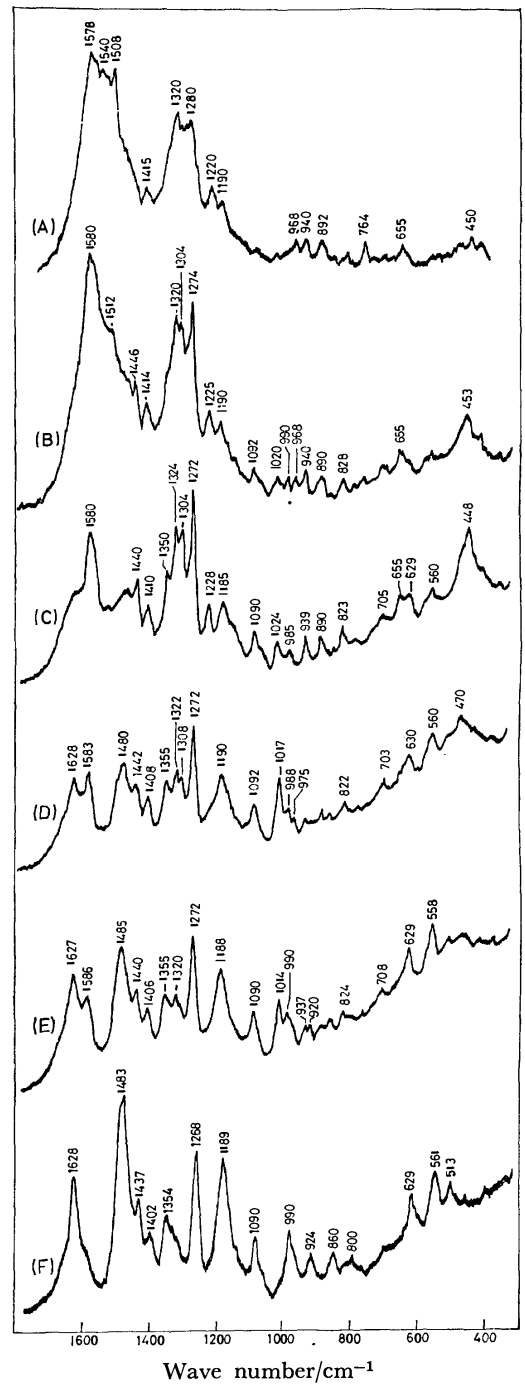

Fig. 2. Raman spectra of Cu(II)-L-histidine(1:2) in aqueous solutions (0.2 M) at a room-temperature: (A) pH=11.12, (B) 9.52, (C) 7.23, (D), 4.55, (E) 3.72, (F) 2.48.

ring (1580 and 1272 cm^{-1}, *etc.*). As already mentioned, the free imidazolyl group of L-histidine in a basic aqueous solution (Fig. 1(C)) gives rise to the doublets near 1580, 1270, and 990 cm^{-1}. The singlet bands observed at 1580 and 1272 cm^{-1} in Fig. 2(C) indicates that the imidazolyl group of the species MA_2 takes either one of the two tautomeric forms shown is Scheme 1. The strong band at 448 cm^{-1} in Fig. 2(C) can be ascribed to one of Cu(II)-ligand stretching vibrations because the free L-histidine with

the neutral imidazolyl group does not show any band in this region (Figs. 1(B) and (C)). This band shifts down to 432 cm^{-1} in D_2O (see the next section and Fig. 4(B)), suggesting that the 448 cm^{-1} band can be assigned to the Cu(II)–N stretching vibration of the bound amino groups. Generally two amino groups coordinated to the central Cu(II) ion with cis position show two Cu–N stretching bands (symmetric and asymmetric) while the amino groups occupying the trans position give only one Cu–N symmetric stretching vibration. This is supported by the observations that *trans*-Cu(II)(glycine)$_2 \cdot 2H_2O$ gives rise to only one Cu(II)–N stretching mode at 462 cm^{-1} while *cis*-Cu(II)(glycine)$_2 \cdot H_2O$ shows two Cu(II)–N stretching bands at 477 cm^{-1} (asymmetric) and 455 cm^{-1} (symmetric).[25] In Fig. 2(C) the only one Cu(II)–N stretching band appears at 448 cm^{-1} indicating that the trans position to the central Cu(II) ion is taken by the bound amino groups. The band at 560 cm^{-1} in Fig. 2(C), the intensity of which is a little weaker than that of the corresponding band in Fig. 2(D), can be assigned to the out-of-plane bending vibration of the bound carboxylato group. From the above-mentioned results it can be concluded that the coordination structure of the species MA_2 is similar to that proposed by Kruck and Sarkar,[15] in which two nitrogen atoms of the amino groups and two nitrogen atoms of the imidazole rings are bound to the Cu(II) ion in square-planar trans position and at least one, if not both, carboxyl group is bound in the axial position (Scheme 2 III).

Salama and Spiro have measured the Raman spectrum of octahedral Co(L-histidinato)$_2$ complex in H_2O with a UV excitation (363.8 nm).[5] They observed a band at 1574 cm^{-1}, which corresponds to the one observed at 1580 cm^{-1} in Fig. 2(C), and assigned it to the bound carboxylate mode. Cu(II)–histamine (1:2) in the aqueous solution with the pH values where the imidazolyl group of the ligand has the neutral form[26] and Co(4MeImH)$_6^{2+}$ complex[6] also show a well-defined peak in the region from 1590 to 1570 cm^{-1}. These results exclude the assignment made by Salama and Spiro and confirm that the 1580-cm^{-1} band in Fig. 2(C) are due to the C=C stretching vibration of the bound imidazolyl group.

At pH 9.52 (Fig. 2(B)) the 1580-cm^{-1} band is remarkably enhanced with a shoulder at 1512 cm^{-1} and, as the pH value is increased further (pH 11.12, Fig. 2(A)), a broad band centered around 1540 cm^{-1} begins to appear. The Raman spectrum of histidine with the imidazolide anion gives rise to the C=C stretching vibration of the group at 1527 cm^{-1}, which corresponds to the 1540-cm^{-1} band in Fig. 2(A). The shift to the higher frequency ($\Delta\nu = 13$ cm^{-1}) can be ascribed to the chelation of the anionic group in the Cu(II)–L-histidine(1:2) system. Salama and Spiro[5] also measured the Raman spectrum of tetrahedral Co(L-histidinato)$_2^{2-}$ complex and observed the scattering peak at 1545 cm^{-1}, to which they assigned the anti-symmetric mode of the free carboxylate anion. The frequency of 1545 cm^{-1} is too low to be assigned to the free carboxylate mode because the infrared spectra of L-histidine and Cu(II)–L-histidine(1:2) in

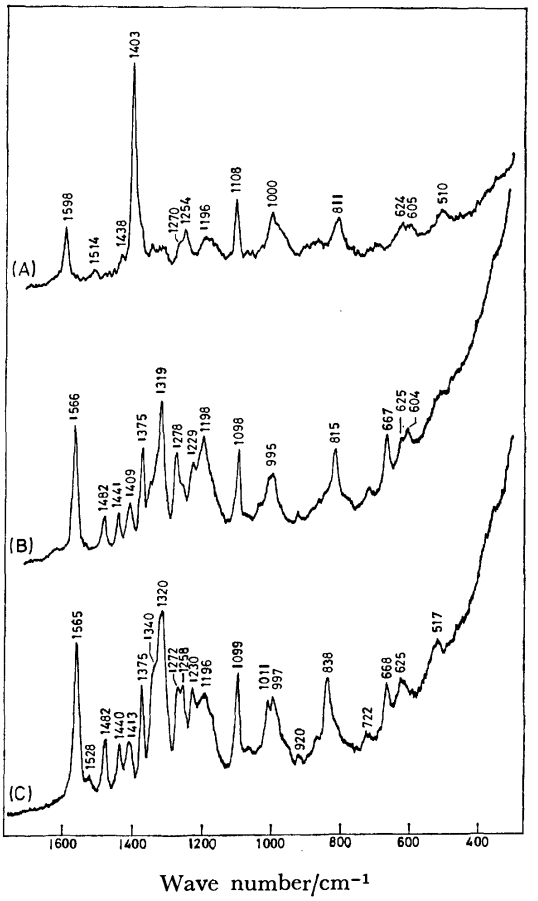

Fig. 3. Raman spectra of L-histidine-d_{3-5} in D_2O (*ca.* 10 wt%) at a room-temperature: (A) pD=2.80, (B) 8.34, (C) 13.20.

D_2O solutions show the free and the bound carboxylate mode at 1578 and 1590 cm^{-1}, respectively.[15] The appearance of the 1540-cm^{-1} band in Fig. 2(A) is accompanied by the shift and disappearance of several bands in Fig. 2(C). The bands observed at 1272 and 985 cm^{-1} in Fig. 2(C) shift to 1280 and 968 cm^{-1}, respectively. The 1090- and 1024-cm^{-1} bands in Fig. 2(C) almost disappear in Fig. 2(A). These results can be ascribed to the change in the chelation structure caused by the deprotonation of the imidazolyl group. Above pH 8, however, the Cu(II)–L-histidine(1:2) system becomes unstable (sometimes we observed a slight precipitation just above pH 9 presumably due to the copper(II) hydroxide formation) and we could not make a detailed analysis of the Raman spectra of Cu(II)–L-histidine (1:2) in which all the imidazolyl groups have the anionic form.

Raman Spectra of L-*Histidine*-d_{3-5} *and Cu(II)–*L-*Histidine*-d_{3-5} *(1:2) in* D_2O. Figure 3 shows the Raman spectra of L-histidine-d_{3-5} in D_2O at the pD values of 2.80(A), 8.34(B), and 13.20(C). The spectrum observed at pD 2.80 shows the bands at 1598, 1403, 1254, and 1000 cm^{-1}. They correspond to the 1627-, 1484-, 1264-, and 994-cm^{-1} bands in Fig. 1(A) and are assigned to the C=C stretching, the N–D in-plane bending, the ring breathing, and the C–H in-plane bending vibrations of the imidazolyl group,

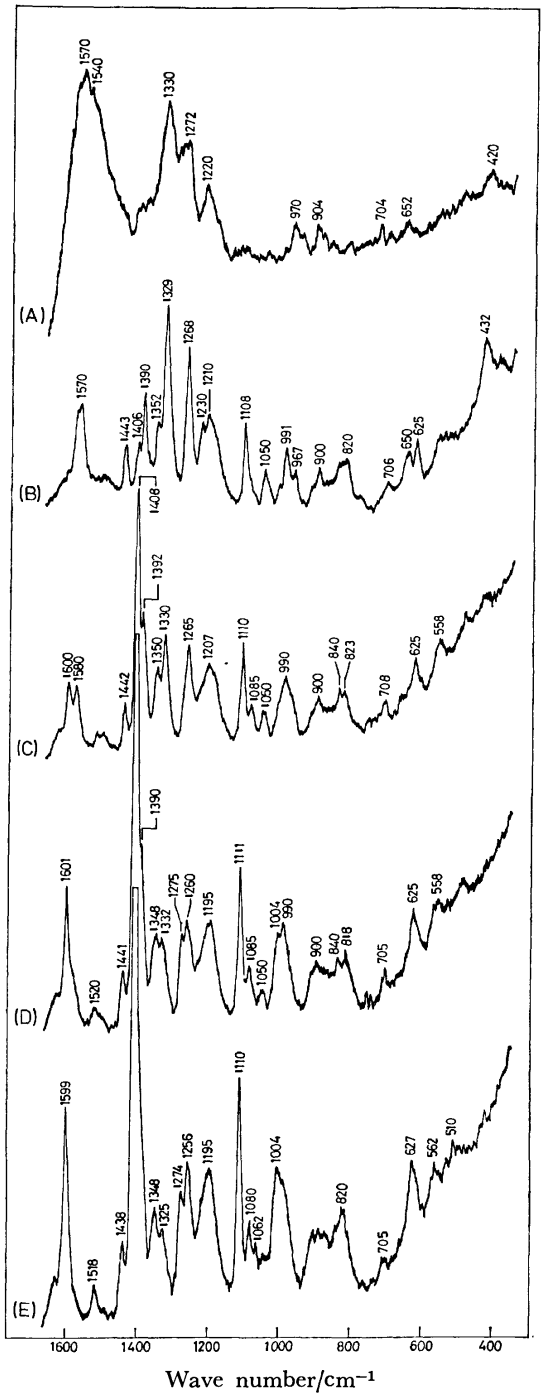

Fig. 4. Raman spectra of Cu(II)–L-histidine-d_{3-5} (1:2) in D_2O at a room-temperature: (A) pD=10.6, (B) 7.7, (C) 4.4, (D) 3.3, (E) 2.5.

respectively. At pD 8.34, where the neutral imidazolyl group favors the tautomeric form I, the spectrum (Fig. 3(B)) gives rise to the bands at 1566, 1278, and 995 cm^{-1} which are due to the C=C stretching, the breathing and the C–H in-plane bending modes of the neutral imidazolyl group with the tautomeric form I. On raising the pD value to 13.2, where both the tautomers I and II coexist, the Raman spectrum (Fig. 3(C)) shows the 1258- and 1011-cm^{-1} bands ascribable to the tautomer II in addition to the 1272- and 997-cm^{-1} bands due to the tautomer I. In the D_2O solution the tautomer I has the C=C stretching vibration with the frequency virtually identical with that of the tautomer II, giving rise to a sharp and strong band at 1565 cm^{-1} in Fig. 3(C).

Figures 4(A)—(E) show the Raman spectra of Cu(II)–L-histidine-d_{3-5}(1:2) in D_2O measured at pD values from 2.5 to 10.6. The bands at 1599, 1408, 1256, 1110, and 1004 cm^{-1} in Fig. 4(E) correspond to those at 1598, 1403, 1254, 1108, and 1000 cm^{-1} in Fig. 3(A), all of which are assigned to a protonated imidazolium cation. The out-of-plane bending vibration of the bound carboxylato group is observed at about 560 cm^{-1} in Fig. 4(E). Therefore, the Raman spectrum shown in Fig. 4(E) also confirms that the glycine-like binding occurs in MHA^{2+} which is the major species at pD 2.5.

In Fig. 4(D) the 1601- and 1408 cm^{-1} bands decrease their intensities, and there appear a shoulder band near 1580 cm^{-1} and a band at 990 cm^{-1}. The latter two bands can be ascribed to the bound neutral imidazolyl group. This is consistent with the result of the pH titration study[10] which brought the conclusion that in the pH region just above 3 there exist appreciable amounts of multiple species consisting of MHA^{2+} (Scheme 2 Ib), MHA_2^+ (Scheme 2 II) and MA^+ in which an L-histidine molecule is bound to Cu(II) as a terdentate anion.

At pD 4.4 (Fig. 4(C)), the intensity of the C=C stretching vibration observed at 1600 cm^{-1} (ascribed to the protonated imidazolium cation) is almost the same as that of the 1580-cm^{-1} band (assignable to the bound neutral imidazolyl group). This is consistent with the mixed-type structure (Scheme 2 II) proposed to MHA_2^+ which is the major species at pD 4.4.

The spectrum observed at pD 7.7 (Fig. 4(B)) also confirms the structure (Scheme 2 III) which was proposed to MA_2, the major species at pD 7.7. First, well-defined bands at 1570, 1268, and 991 cm^{-1} indicate that the species contains the neutral imidazolyl group with the tautomeric form I and the N(3) atom is bound to the Cu(II) ion. Second, the band near 560 cm^{-1} shows that in the species MA_2 at least one carboxylato group is bound to the central ion. Third, the sharp band at 432 cm^{-1} can be ascribed to the symmetric Cu(II)–N stretching vibration of the bound amino groups occupying the trans position to the Cu(II) ion. In Fig. 4(B) we cannot find the band which corresponds to the sharp band at 1482 cm^{-1} in Fig. 3(C). L-Histidine in a basic aqueous solution (Fig. 1(C)) also gives rise to a sharp band at 1485 cm^{-1} which reduces its intensity appreciably or almost disappears in Fig. 2(C). The 1482-cm^{-1} band in Fig. 3(C) (and the 1485 cm^{-1} in Fig. 1(C)) is presumably ascribed to one of the imidazole ring vibrations,[27] to which the N(3)=C(2) stretching mode contributes. On coordination of the imidazolyl group *via.* the N(3) atom, this band either shifts or decreases its intensity. The 1375-cm^{-1} band observed for the free ligand in D_2O (Fig. 3(C)) shifts to 1390 cm^{-1} in Fig. 4(B). The frequency shift can also be used to monitor the chelation of the imidazolyl group in D_2O.

In a higher pD region (Fig. 4(A)), there appears

Table 1. Obsd Raman frequencies of L-His and Cu(II)-L-His(1:2) system (1600—300 cm^{-1})

a strong and broad band around 1540 cm^{-1}, giving a large background in the frequency range from 1600 to 1500 cm^{-1}. This band corresponds to the one at 1540 cm^{-1} in Fig. 2(A) and it can be assigned to the C=C stretching vibration of the bound imidazolide anion. As is the case with the Raman spectrum observed for the H_2O solution at a high pH value (Fig. 2(A)), the spectral features of Fig. 4(A) are different from those of Fig. 4(B) in several respects. The bands at 1268, 991, and 432 cm^{-1} in Fig. 4(B) shift to 1272, 970, and 420 cm^{-1} in Fig. 4(A), respectively. The bands observed at 1108 and 1050 cm^{-1} in Fig. 4(B) almost disappear in Fig. 4(A). Although these results clearly reflect the change in the coordination mode of the sample, the clear-cut explanation to these changes based on the assumed species (*i.e.*, $MH_{-1}A_2^-$, $MH_{-1}A$, and $M_2H_{-2}A_2$) could not be made because of the same reason given to the H_2O solution with a high pH value.[15] Sometimes the sample forms a dark-colored precipitation above pD 8.

Conclusions

The frequencies and tentative assignments of the Raman bands observed for L-histidine and Cu(II)–L-histidine(1:2) in H_2O and L-histidine-d_{3-5} and Cu(II)–L-histidine-d_{3-5}(1:2) in D_2O are listed in Table 1. As mentioned above, the C=C stretching and the breathing vibrations of the free and bound imidazolyl groups, the out-of-plane bending vibration of the bound carboxylato group, and the Cu(II)–N stretching vibrations of the bound amino groups can be used to determine the chelation structures of the species taken by the Cu(II)–L-histidine(1:2) system. The following are the conclusions. (1) The species MHA^{2+}, the major one below pH 3, assumes the structure shown in Scheme 2 Ib. The results obtained from the Raman spectra are incompatible with the structure shown in Scheme 2 Ia, which has been one of the most popular structures proposed to MHA^{2+}. (2) The Raman spectra measured at pH 4.55 and pD 4.4 (Figs. 2(D) and 4(C)) correspond quite well to the mixed-type chelation structure shown in Scheme 2 II, which is proposed to MHA_2^+, the major species in the pH region from 4 to 4.5. (3) From the Raman spectra measured at pH 7.23 and pD 7.7, where the species MA_2 is present almost to the extent of 100%,

it is concluded that the species assumes the chelation structure shown in Scheme 2 III. The intensity of out-of-plane bending vibration of the bound carboxylato group observed at 560 cm^{-1} in Fig. 2(C) is smaller than that of the corresponding band in Fig. 2(D), which suggests that one of the carboxylato groups exists in the equilibrium between the bound and free states.

We wish to express our sincere thanks to Professor M. Tasumi, Faculty of Science, The University of Tokyo, and Mr. S. Muraishi, JEOL Co. Ltd., for allowing us to use their Raman spectrophotometers.

Possible Role of Denatured Albumin in Formation of "Heat-resistant" Serum Albumin

Hiroshi TERADA,* Kazuhiko WATANABE, and Fujio KAMETANI
Faculty of Pharmaceutical Sciences, University of Tokushima, Shomachi-1, Tokushima 770

(Received May 8, 1980)

Studies with the probe dye 2-(4-hydroxyphenylazo)benzoic acid, which can detect small conformational differences in serum albumin, showed that the conformation of "heat-resistant" serum albumin (form N') was not constant, but depended on the heating temperature, becoming similar to that of the denatured monomer as the heating temperature was increased from 55 °C to 70 °C in buffer of pH 7.0. Denatured albumin was suggested to protect native serum albumin from full denaturation. In the presence of denatured albumin, native albumin was found to undergo only a slight conformational change to give the N' form. This protective effect may explain why a constant amount of serum albumin remains as "heat-resistant" serum albumin even after prolonged heating.

From studies on changes in the solubility and sedimentation velocity of serum albumin on denaturation, Levy and Warner[1,2] concluded that a certain amount of serum albumin remains undenatured even after prolonged heating at 65 °C in solutions of various pH values, and that denatured albumin consists of monomer, dimer and higher aggregates. These findings have been confirmed by electrophoresis of albumin heat denatured between 65 °C and 75 °C.[3-5] The presence of an undenatured, heat-stable fraction in heat-treated albumin has been interpreted as due to the existence of "heat-resistant" serum albumin, and it has sometimes been taken as support for the concept of the heterogeneity of serum albumin.[6,7]

In studies using probe dyes, such as 2-(4-hydroxyphenylazo)benzoic acid (HABA), Bromcresol Green and 8-anilinonaphthalene-1-sulfonate,[8-10] we found that there are at least two forms, N and N', in the native fraction of heat-treated serum albumin, and that during heating N' is formed from N by slight conformational modification. The N' form is "heat-resistant" albumin itself. Although "heat-resistant" albumin (N' form) is very similar to N in properties, such as its helical content, electrophoretical mobility and absorption spectrum in the ultraviolet region,[5] it can be distinguished from N with these probe dyes. Among the probe dyes examined, HABA is the most useful, since it shows a new spectral band at about 480 nm with N or N', but not with denatured albumin.[8,11] The affinity of HABA for N', determined from the absorbance of the dye at about 480 nm, was found to be about 60% of that of N in heat-treated albumin at 65 °C in buffer of pH 7.0 or pH 9.0.[8]

Since heat denaturation of serum albumin is characterized by the presence of "heat-resistant" serum albumin and the formation of aggregated albumin, it is very important for understanding the mechanism of heat denaturation of albumin to determine various properties of these molecular species, and especially of "heat-resistant" albumin. This paper deals with the effect of the heating temperature of the properties of "heat-resistant" serum albumin, and the effect of denatured albumin on formation of "heat-resistant" albumin, examined by electrophoresis and with the probe dye HABA. The importance of denatured albumin in formation of "heat-resistant" albumin is suggested.

Experimental

Materials. Bovine serum albumin (Armour, crystalline, Lot no. H72803 and H72009) was used without further purification. Its molecular weight was assumed to be 6.6×10^4. The concentration of albumin in solution in 0.1 mol/dm^3 potassium phosphate buffer, prepared just before use, was determined spectrophotometrically as described previously.[8] The concentration of denatured albumin was expressed in terms of monomer. HABA was obtained from Wako Chemical Co., Osaka (Japan). The other reagents used were standard commercial products.

Method. Heat denaturation was carried out at pH 7.0 as described previously.[8] Acrylamide gel electrophoresis (gel concentration: 7.5%) was conducted at pH 8.3, and quantitative analysis of protein bands of heat-treated albumin, stained with Amidoblack 10B, was carried out in a Shimadzu dual-wavelength TLC scanner, model CS-900, using a wavelength pair of 590 and 700 nm.[10] The absorption spectrum of HABA was recorded at pH 7.0 and 25 °C in a Union spectrophotometer, model SM 4012.

Results

Effect of Temperature on Properties of N'. Figure 1 shows the time-course of heat-denaturation of 1.5×10^{-4} mol/dm^3 bovine serum albumin at various temperatures at pH 7.0, determined by acrylamide gel electrophoresis. At all temperatures, denaturation was first rapid and then slowed down, finally reaching a steady level. The existence of an undenatured fraction of serum albumin after prolonged heating is regarded as due to the formation of modified native albumin N' ("heat-resistant" albumin) from native albumin.[8] The results in Fig. 1 indicate that the amount of N' decreases as the heating temperature increases; at 55 °C, 92% of native albumin (N) changes to N', whereas at 70 °C, only 20% changes to N' and 80% is denatured. At 80 °C all the native albumin is denatured (Table 1). This temperature-dependent denaturation is essentially the same as that at pH 8.9.[4] However, denaturation proceeded more rapidly at pH 8.9, probably because the exchange of disulfide bonds associated with denaturation of serum albumin was greater due to the higher concentration of OH^- (Refs. 5 and 12).

As reported previously, the spectrum of the probe dye HABA shows a new spectral band at about 480

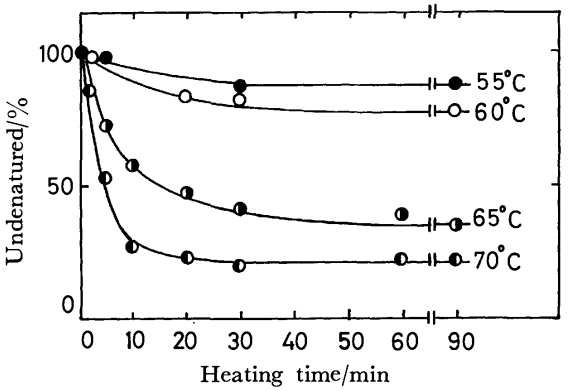

Fig. 1. Time course of heat denaturation of serum albumin at various temperatures determined by acrylamide gel electrophoresis.

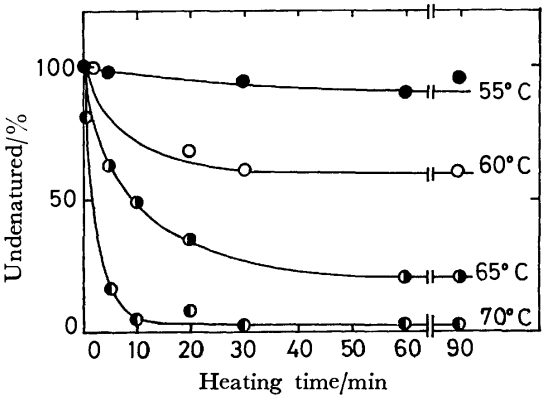

Fig. 2. Time course of heat denaturation of serum albumin at various temperatures determined from the absorbance of HABA.

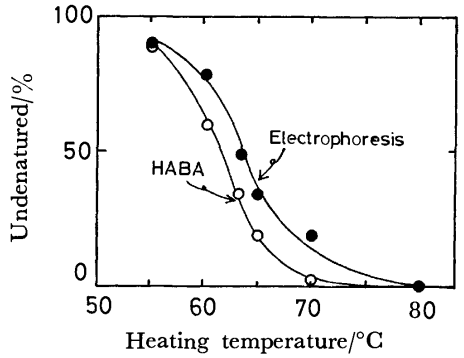

Fig. 3. Temperature-dependence of change in amount of undenatured albumin after heating for 90 min, determined by electrophoresis and from the absorbance of HABA.

nm on binding with undenatured albumin (N and N').[8] Using the same heat-treated albumin as for the experiments in Fig. 1, the absorbance of 10^{-3} mol/dm^3 HABA at 480 nm was measured. The relative absorbance of HABA induced by 10^{-5} mol/dm^3 heat-treated albumin to that induced by the same concentration of unheated albumin was taken as the relative amount of undenatured albumin remaining during heat-treatment, and is plotted as a function of the heating period at various temperatures in Fig. 2. The results in Fig. 2 are very similar to those in Fig. 1 determined by acrylamide gel electrophoresis, but the changes are more rapid.

Table 1. Relative amount of N' formed after prolonged heating

Heating temp/°C	Relative amount of N'/%		Ratio (A/B)
	From absorbance of HABA (A)	By electrophoresis (B)	
55	89	92	0.97
60	60	79	0.76
63	35	50	0.70
65	20	35	0.57
70	3	20	0.15
80	0	0	—

Figure 3 shows the temperature dependences of the relative amount of N' after heating for 90 min, determined by electrophoresis and from the absorbance of HABA. These values and the ratio of the relative amount of N' determined with HABA to that determined by electrophoresis are listed in Table 1. Values for the relative amount of N' determined by the two methods decreased similarly with the heating temperature, but the value determined with HABA was always smaller than that determined by electrophoresis, because the molar extinction coefficient of HABA induced by N' is smaller than that induced by N.[8] If the conformation of N' around the binding sites for HABA is the same in N' formed at all temperatures, the ratio of N' determined with HABA to that determined by electrophoresis should be the same between 55 °C and 70 °C, even though the relative amount of N' determined by the two methods changes with the heating temperature. However, the results in Table 1 show that this ratio becomes smaller with increase in the heating temperature, indicating that the structure of N' is not the same at different heating temperatures, and that the affinity of N' to HABA becomes smaller as the denaturating temperature increases.

Effect of Denatured Albumin on Denaturation. Figure 4 shows the time course of denaturation of serum albumin at 65 °C monitored by measuring the absorbance of HABA at 480 nm; the relative absorbance of HABA induced by heat-treated albumin to that induced by unheated albumin is plotted against the heating time. In this experiment, solutions containing various amounts of denatured albumin (final concentration, D_0) and native albumin (final concentration, N_0) at a constant total protein concentration of 5.0×10^{-5} mol/dm^3 were heated. The denatured albumin used was obtained by heating serum albumin at 80 °C for 15 min in buffer of pH 7.0 to denature it completely. It is apparent from the figure that the extent of denaturation decreases with increase in the amount of denatured albumin; with solutions containing 75% and 50% $D_0(N_0/(N_0+D_0)=$ 0.25 and 0.50, respectively) before heating, the absorbance of HABA due to the undenatured fraction ($N+N'$) after heating for 25 min is decreased to 43%

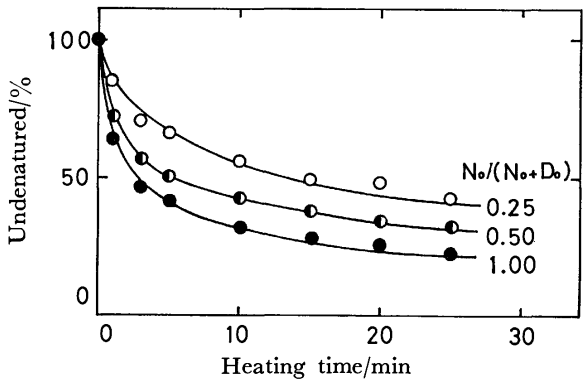

Fig. 4. Time course of heat denaturation of serum albumin at 65 °C and pH 7.0 in the presence of various amounts of heat denatured albumin. Denaturation was monitored by the absorbance of 10^{-4} mol/dm^3 HABA.
N_0: Initial concentration of native albumin, D_0: initial concentration of heat-denatured albumin.

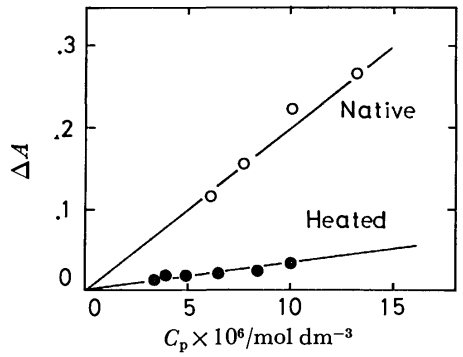

Fig. 5. Concentration dependence of heat denaturation of serum albumin at 65 °C and pH 7.0. The denaturation was monitored as the absorbance of 5.0×10^{-4} mol/dm^3 HABA induced by 10-fold diluted samples of heat-treated albumin. The concentrations of heat-denatured albumin(C_p) shown in the figure are those at the time of measuring the absorbance of HABA, and the C_p values during heat-denaturation were 10 times greater. The absorbance of HABA induced by native albumin is also shown.

and 32%, respectively, while in the absence of denatured albumin ($N_0/(N_0+D_0)=1$) it is decreased to 23%. The addition of denatured albumin before heating seems to inhibit denaturation. However, in this experiment the decrease in denaturation could be due to an effect of concentration on denaturation of serum albumin, since the experiments were carried out keeping N_0+D_0 constant and thus N_0 decreased with increase in D_0.

For examination of this possibility, we measured the heat denaturation at 65 °C of solutions of serum albumin at concentrations of 3.0×10^{-5} mol/dm^3 to 10^{-4} mol/dm^3. The solutions were heated for 100 min, and then mixed with a solution of HABA and the absorbance of HABA was measured at 480 nm. The absorbance induced by various concentrations of native albumin was also measured. As shown in Fig. 5, the absorbance of HABA increased linearly with increase in concentration of the heat-treated albumin,

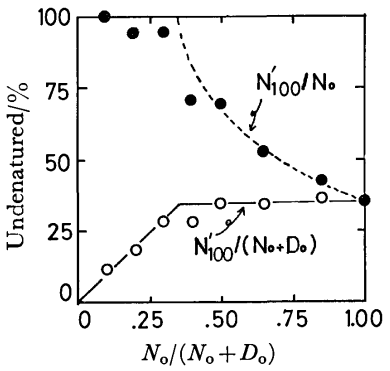

Fig. 6. Effect of heat-denatured albumin on denaturation of serum albumin at 65 °C and pH 7.0.
D_0: Initial concentration of heat-denatured albumin, N_0: initial concentration of native albumin, N'_{100}: concentration of N' after heating for 100 min.

indicating that denaturation does not depend on the concentration of albumin under these experimental conditions. The ratio of the slope of the straight line obtained with denatured albuimn to that with native albumin was 0.18, coinciding well with the value of 0.20 obtained on denaturation of 1.5×10^{-4} mol/dm^3 serum albumin for 90 min at 65 °C (*cf.* Table 1). Thus the decreased denaturation of native albumin in the presence of denatured albumin shown in Fig. 4 could be due to an inhibitory effect of denatured albumin, not to dilution of the native albumin. Thus the effect of denatured albumin on denaturation was next studied in more detail.

Various amounts of native albumin(N) were mixed with denatured albumin(D), obtained by heat-treatment at 80 °C for 10 min, keeping the total albumin concentration at 1.5×10^{-4} mol/dm^3. The mixtures were heated at 60 °C or 65 °C for 100 min, where the albumin remaining undenatured was N' form. Then they were subjected to polyacrylamide gel electrophoresis and the amount of undenatured albumin (N'_{100}) was determined from the absorbance of the stained Amidoblack 10B. The ratio N'_{100}/N_0 (the amount of undenatured albumin as a percentage of that before heating), and the ratio $N'_{100}/(N_0+D_0)$ (the amount of undenatured albumin as a percentage of the total concentration of albumin) are plotted as functions of $N_0/(N_0+D_0)$ (=the relative amount of native albumin before heat-treatment) in Figs. 6 and 7.

On heating at 65 °C (Fig. 6), the value of N'_{100}/N_0 became greater as the value $N_0/(N_0+D_0)$ decreased; in the absence of denatured albumin before heat-treatment ($N_0/(N_0+D_0)=1.00$) N'_{100}/N_0 was 35%, whereas when the albumin solution contained more than 65% denatured albumin ($N_0/(N_0+D_0)\leq0.35$) N'_{100}/N_0 was almost 100%. However, when the percentage of undenatured albumin was expressed in terms of the total albumin content, $N'_{100}/(N_0+D_0)$, 35% of the albumin consistently remained undenatured in the region where the content of the original native albumin was greater than 35% ($N_0/(N_0+D_0)\geq0.35$). Moreover, in the region where $N_0/(N_0+D_0)$ was less than 0.35, the plot of change in the percentage of undenatured albumin after heating for 100 min

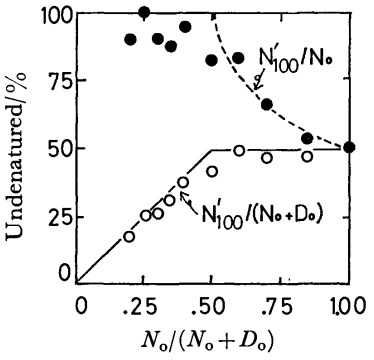

Fig. 7. Effect of heat-denatured albumin on the denaturation of serum albumin at 63 °C and pH 7.0. Experimental conditions were similar to those in Fig. 6, except heating temperature.

against $N_0/(N_0+D_0)$ was linear with a slope of one; that is, the percentage of undenatured albumin was the same as before heat-treatment, since no denaturation took place. In the figure, the solid and dotted lines were drawn assuming that at less than 0.35 $N_0/(N_0+D_0)$, the serum albumin was not denatured.

On denaturation at 63 °C, results were similar to those on denaturation at 65 °C, as shown in Fig. 7, and about 50% of the albumin was denatured when no denatured albumin was added before heat-treatment (the solid and dotted lines in the figure were drawn assuming that at less than 0.50 $N_0/(N_0+D_0)$, the serum albumin was not denatured.). The scatter of experimental results on denaturation at both temperatures in the region of small values of $N_0/(N_0+D_0)$ is due to the difficulty in determining the exact amount of undenatured albumin, since before heating the sample contained only a small amount of native albumin.

Discussion

The results of Figs. 1 and 2, and Table 1 show that form N' ("heat-resistant" serum albumin) remaining in heat-treated albumin after prolonged heating changes in conformation and loses affinity for HABA with increase in the heating temperature. Under the experimental conditions for Fig. 2, where the concentration of the probe dye HABA was much greater than that of the protein, the change in affinity of the protein for the dye reflects change in the number of binding sites for the dye.[8,10] Thus decrease in the affinity of N' for HABA with increase in heating temperature from 55 °C to 70 °C indicates that the number of binding sites on N' became smaller as the heating temperature increased. Since the denatured monomer did not have any binding sites for HABA that induced the characteristic absorption band of the dye, it can be concluded that the conformation of N' became similar to that of the denatured monomer, at least with regard to the microenvironment around the binding site for HABA, with increase in the heating temperature. As reported previously,[9] heat-treatment of native albumin(N) first causes formation of N' and denatured monomer. There must be some regulatory effect determining the amounts of denatured monomer and N' formed from N. Thus the mechanism of formation of N' from N is important for understanding the mechanism of heat-denaturation of serum albumin.

The results of this study, especially those in Figs. 6 and 7, indicate that denatured albumin has a protective effect on heat-denaturation of serum albumin, and that the denaturation proceeds until the ratio of the amount of native albumin to denatured albumin attains a certain value depending on the heating temperature; at 65 °C, 35% was native and 65% denatured, whereas at 63 °C, 50% was native and 50% denatured. Kratochvil *et al.*[13] reported that albumin that had been heated at 65 °C retarded the aggregation of serum albumin induced by heating at 75 °C. This report and our results suggest that denatured albumin stabilizes native albumin, preventing the latter from complete denaturation.

Some biopolymers are known to be stable in solution containing protein or starch.[14] Recently, Martinek *et al.*[15] reported that α-chymotrypsin and trypsin became stable against thermo-inactivation, when they interacted non-covalently with polyacrylamide gel. Similarly, our preliminary experiments showed that the presence of polyvinylpyrrolidone reduced the rate of heat-denaturation of serum albumin. In view of these findings, it is suggested that denatured albumin (D) which mainly consists of aggregated albumin protects native albumin(N) from heat-denaturation probably by a certain non-covalent interaction between D and N, but this "interaction" is not strong enough to prevent the denaturation completely and thus N changes slightly in conformation to form N'. With increase in the heating temperature, the "interaction" between D and N will become weaker, and thus the conformational change of N' will increase, the conformation of N' finally becoming similar to that of the denatured monomer, as indicated by the results in Table 1.

Though it is not clear at present how denatured albumin protects native albumin from denaturation, the stabilizing effect of denatured albumin could be one of the decisive reasons why serum albumin is not completely denatured and "heat-resistant" serum albumin (form N') exists between 55 °C and 70 °C. Since our recent results[10] have suggested that fatty acids also influence the process of heat-denaturation of serum albumin, further studies are necessary on the mechanism of formation of N' during heat-denaturation of serum albumin.

The authors thank Miss Yukari Maeda for technical assistance. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 167273 from the Ministry of Education, Science and Culture.

The Kinetics of Oxygen-exchange Reaction between Chromate Ions and Water

Akiko Okumura,* Mie Kitani, Yuiko Toyomi, and Nobukazu Okazaki

Department of Chemistry, Nara Women's University, Nara 630

(Received January 5, 1980)

The oxygen-exchange reaction between chromate ions and water has been studied under the following conditions: 25 °C, pH=7—12, [Cr(VI)]=0.075 mol dm^{-3}, I=0.2 and 1 mol dm^{-3}. The rate law of the exchange reaction has been found to be:

$$R = k_1[CrO_4^{2-}] + k_2[HCrO_4^-] + k_3[H^+][HCrO_4^-] + k_4[HCrO_4^-][CrO_4^{2-}] + k_5[HCrO_4^-]^2.$$

The exchange rate has been analyzed in terms of this rate law to obtain the values of k_1—k_5. The presence of the third-order rate term in [Cr(VI)] has been suggested. The activation energy of the overall exchange reaction (I=1 mol dm^{-3}) is (25.5±0.7) kJ/mol at pH 7.4 and (98.9±1.0) kJ/mol at pH 11.0. The salt effect is negative at pH<10.5 and absent at pH>10.5.

In a series of papers on the oxoanion catalysis of the oxygen-exchange reaction of arsenate ions,[1,2] it has been suggested that a study of the oxygen-exchange reaction of an oxoanion in the presence of a catalytic amount of another oxoanion may provide a means of elucidating the interactions of these two oxoanions. As a preliminary to a study of the interaction of chromate ions with another oxoanion by the oxygen-exchange reaction,[3] we have examined the oxygen exchange of chromate ions with water.

This reaction has been studied by several authors.[4–6] Holyer and Baldwin[5] have interpreted the exchange reaction (pH 6.7—12, [Cr(VI)]=0.64—2.7 M,** 25 °C) in terms of these reactions:

$$HCrO_4^- + CrO_4^{2-} \rightleftharpoons Cr_2O_7^{2-} + OH^-,$$

$$HCrO_4^- + HCrO_4^- \rightleftharpoons Cr_2O_7^{2-} + H_2O,$$

and $$CrO_4^{2-} + H_2{}^{18}O \rightleftharpoons CrO_3{}^{18}O^{2-} + H_2O.$$

Mak[6] has extended the study up to pH 4.5 ([Cr(VI)]= 0.1 and 0.2 M, 25 °C), and proposed these exchange paths:

$$Cr_2O_7^{2-} + HCrO_4^- \rightleftharpoons Cr_3O_{10}^{2-} + OH^-,$$

and $$HCr_2O_7^- + HCrO_4^- \rightleftharpoons Cr_3O_{10}^{2-} + H_2O,$$

the former being important at pH 6.7—7.6, and the latter, at pH<6.0. The chloride-ion catalysis of the oxygen-exchange reaction of chromate ions has been noted by this author at pH>6.8. The absence of the salt effect on the exchange reaction has been claimed in these papers.

In the present paper, the uncatalyzed and acid-catalyzed oxygen exchanges of hydrogenchromate ions with water have been proposed as additional exchange paths, the presence of the third-order rate term in [Cr(VI)] has been suggested, and the salt effect on the exchange reaction has been established.

Experimental

Materials. The sodium chromate tetrahydrate (guaranteed reagent, Merck), sodium chloride (guaranteed reagent JIS), and other chemicals (guaranteed reagent JIS) were used without further purification. Sodium chromate enriched in oxygen-18 was prepared by the exchange reaction of sodium chromate with $H_2{}^{18}O$ at 100 °C for 2 h.

** 1 M=1 mol dm^{-3}.

Procedure. The procedures were almost the same as those previously reported.[7] The exchange reaction was initiated by dissolving a weighed amount of the enriched sodium chromate in normal water. The normal water was boiled before use to expel the dissolved carbon dioxide. The pH of the solution was fixed by adding a small amount of a hydrochloric acid or sodium hydroxide solution. The pH of the solution was measured with a Hitachi-Horiba pH-meter (Model F-7) or with a Radiometer PHM-26 pH-meter equipped with a glass electrode (Type 202 C) and a reference electrode (Type K 401). The ionic strength was adjusted to 1 M by the addition of sodium chloride. The ionic strength of 0.2 was maintained by means of the chromate. The reactions were carried out at 25 °C. At appropriate intervals, aliquots were drawn and the chromate ion was precipitated as barium chromate by adding a solution of barium chloride. The above series of operations were carried out under an atmosphere of nitrogen.

To avoid the precipitation-induced oxygen exchange of the chromate ion, which becomes appreciable at pH values smaller than 8, the pH of the solution was, when necessary, brought to ≈9 before the addition of the precipitant by adding an appropriate amount of a sodium hydroxide solution.

The precipitate was separated by means of a centrifuge, washed three times with absolute ethanol, dried in an oven at 110 °C, and converted into carbon dioxide by the guadinium-chloride method.[8] The isotopic analysis of the carbon dioxide was done on a Hitachi RMS-I-type mass spectrometer.

The rate of the oxygen exchange was calculated by means of this formula:

$$R = -\frac{1}{t}\cdot\frac{[Cr(VI)][H_2O]}{4[Cr(VI)]+[H_2O]}\cdot\ln\left(1-\frac{O_0-O_t}{O_0-O_\infty}\right),$$

where O_0, O_t, and O_∞ are the oxygen-18 contents of the chromate at the times 0, t, and infinity respectively, and where [Cr(VI)] and [H_2O] are the molar concentrations of the chromate and water respectively.

Dissociation and Condensation Constants of Hydrogenchromate Ions. The values of the equilibrium constants, K_1 and K_d, defined by:

$$K_1 = [HCrO_4^-]/a_{H^+}[CrO_4^{2-}],$$

and $$K_d = [Cr_2O_7^{2-}]/[HCrO_4^-]^2,$$

were obtained as follows. The values at I=0.2 M and 25 °C were interpolated from the literature values[9] by means of the Debye-Hückel equation. The literature values at 20 °C were corrected to 25 °C and used in the interpolation. The results are $\log(K_1/M)=6.03$ and $\log(K_d/M)=1.75$.

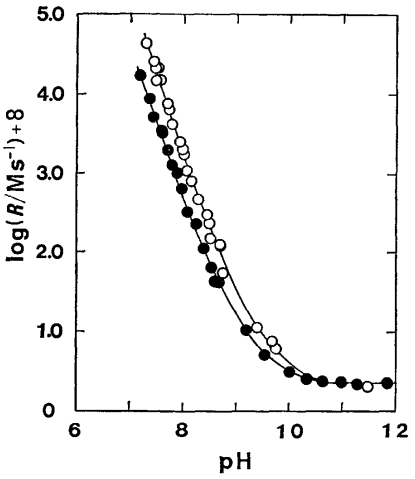

Fig. 1. The rate of oxygen exchange reaction of chromate ions with water *versus* pH.
([Cr(VI)]=0.075 M, 25 °C)
○: I=0.2 M, ●: I(NaCl)=1.0 M.

The values at I(NaCl)=1.0 M and 25 °C were determined by means of potentiometric titrations with a glass electrode. Solutions of sodium chromate of known concentrations and a unit ionic strength were titrated with standardized hydrochloric acid. Seven series of titrations were carried out with chromate solutions of varied concentrations, ranging from 1.157×10^{-3} M to 6.198×10^{-2} M. The titration curves were treated by the method of Sillén[10] and Sasaki[11] to obtain the values of K_1 and K_d. The value of the activity coefficient of the hydrogen ion in the medium of I(NaCl)=1.0 M necessary for the treatment was obtained by the potentiometric titration of a 1 M NaCl solution with standardized hydrochloric acid. The results are $\log(K_1/M)=5.73$ and $\log(K_d/M)=2.14$.

Results and Discussion

pH *Dependence of the Exchange Rate.* The dependence of the exchange rate on the pH was studied at I=1.0 and 0.2 M, the concentration of Cr(VI) being kept at ≈0.075 M. The rate-pH profiles are shown in Fig. 1. In the pH region smaller than 8.7, $\log(R/M\ s^{-1})$ decreases linearly with the increase in pH. The slopes of the lines obtained by the method of the least-squares are -1.89 ± 0.04 (I=0.2 M) and -1.82 ± 0.03 (I=1.0 M). From pH=8.7 upwards, the rate decreases increasingly less rapidly, and above pH=10.5, where CrO_4^{2-} is the predominating ionic species, it becomes independent of the pH. The exchange rate in this region is so slow (half-life=*ca.* 25 d) that it was difficult to follow the reaction for more than a half-period without the interference of the atmospheric carbon dioxide. In these runs, the final values were borrowed from the runs under more acidic conditions.

[*Cr(VI)*] *Dependence of the Exchange Rate.* This was studied at four different pH's: 7.2, 7.4, 7.7, and 8.0 (25 °C, I=1.0 M). The concentration of Cr(VI) was varied from 0.036 to 0.14 M at pH=7.2, 7.7, and 8.0, and from 0.010 to 0.14 M at pH=7.4. Plots of $\log(R/M\ s^{-1})$ against log([Cr(VI)]/M) are shown in Fig. 2. The slopes of the four straight lines through

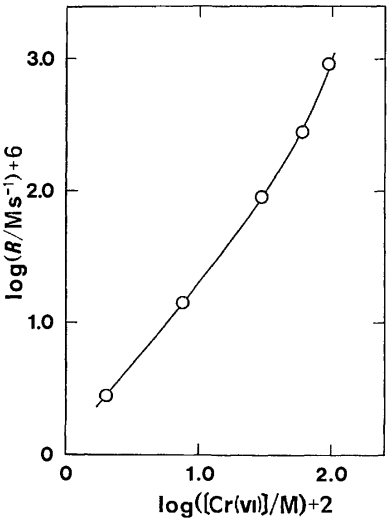

Fig. 3. Dependence of the exchange rate on [Cr(VI)].
[Cr(VI)]=0.02—0.96 M, I(NaCl)=4 M, pH=7.5, 25 °C.

each set of plotted points are 1.23 ± 0.02 (pH: 7.2), 1.05 ± 0.03 (pH: 7.4), 1.17 ± 0.02 (pH: 7.7), and 0.93 ± 0.01 (pH: 8.0). It may be inferred that the order of the exchange reaction with respect to [Cr(VI)] tends to the value of unity with the increase in the pH.

Holyer and Baldwin[5] have reported a value of 1.98 ± 0.07 for the corresponding slope at pH=7.5 with Cr(VI) concentrations ranging from 0.15 to 2.7 M. In order to explain the apparent discrepancy between this and the present results, we have studied the [Cr(VI)] dependence over a wider range of Cr(VI) concentrations (0.02—0.96 M, I(NaCl)=4.0 M). The logarithmic plot of R against [Cr(VI)] gives a curve concave upwards (Fig. 3), the slope of the curve in-

Table 1. Effect of the supporting electrolytes on the rate of the oxygen exchange of chromate ions

[Cr(VI)] / M	pH[a]	Supporting electrolyte (I=1.0 M)	$R/10^{-5}$ M s^{-1}
0.0721	7.60	$NaClO_4$	0.828±0.006
0.0739	7.60	NaCl	0.792±0.006
0.0720	7.51	$NaClO_4$	1.83±0.06
0.0741	7.51	NaCl	1.75±0.05

a) In measuring the pH, the inner solution of the reference electrode was replaced by 4 M NaCl.

creasing from unity to 2.6 with the increase in the concentration of Cr(VI). It appears that the observed [Cr(VI)] dependence of the exchange reaction is dependent on the value of [Cr(VI)]. The kinetics of the oxygen exchange of chromate ions involves both the first-order and the higher-order rate terms in [Cr(VI)]. At lower concentrations of Cr(VI), the first-order term predominates, while at higher concentrations the second- and third-order terms come into play.

Effect of Chloride Ions on the Exchange Rate. Since hydrogenchromate ions react with chloride ions to form trioxochlorochromate(VI) ions in acidic aqueous solutions,[12,13] it may be suspected that the $HCrO_4^- + Cl^- + H^+ \rightleftharpoons CrO_3Cl^- + H_2O$ reaction might contribute to the oxygen exchange of chromate ions. Perlmutter-Hayman and Wolff[14] have noted the absence of chloride-ion catalysis of the hydrolysis of dichromate ions.

In order to examine the possibility of nucleophilic catalysis by chloride ions, the exchange rate was studied in the perchlorate media and compared with the rate in NaCl media (Table 1). The results indicate that the catalysis of the oxygen exchange of chromate ions by chloride ions is absent, at least under the present experimental conditions.

Mechanism of the Oxygen-exchange Reaction. The above results may be summarized as follows:

pH: 7.2—8.7 $R \propto [H^+]^{1.8}[Cr(VI)]^{1.2-1.0}$,

pH: 8.7—10.5 $R \propto [H^+]^{1.8-0}[Cr(VI)]$,

pH: >10.5 $R \propto [H^+]^0[Cr(VI)]$.

In the pH region greater than 10.5, the exchange reaction may be interpreted in terms of the process:

$$CrO_4^{2-} + H_2{}^{18}O \rightleftharpoons CrO_3{}^{18}O^{2-} + H_2O. \quad (1)$$

Since the more acidic species of an oxoanion is usually more reactive in the oxygen-exchange reaction, it is natural to assume the exchange mechanism:

$$HCrO_4^- + H_2{}^{18}O \rightleftharpoons HCrO_3{}^{18}O^- + H_2O, \quad (2)$$

along with Reaction 1.

The nearly first-order dependence on [Cr(VI)] (see Fig. 2, [Cr(VI)]<0.14 M) and the nearly second-order dependence on [H$^+$] observed at pH<8.7 suggest that the acid-catalyzed oxygen exchange of hydrogenchromate ions with water:

$$CrO_4^{2-} + H^+ \rightleftharpoons HCrO_4^-,$$

$$HCrO_4^- + H_2{}^{18}O + H^+ \rightleftharpoons HCrO_3{}^{18}O^- + H_2O + H^+, \quad (3)$$

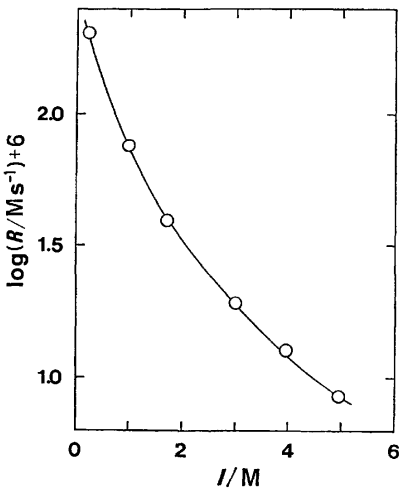

Fig. 4. The effect of ionic strength on the exchange rate.
I=0.2—5 M, [Cr(VI)]=0.075 M, pH=7.5, 25 °C.

plays a dominant role in this pH region.

The order of the exchange reaction with respect to [Cr(VI)] is definitely greater than unity at pH<7.7. This fact suggests that there is some contribution of the two dimerization mechanisms, 4 and 5, to the exchange reaction:

$$HCrO_4^- + CrO_4^{2-} \rightleftharpoons Cr_2O_7^{2-} + OH^-, \quad (4)$$

$$HCrO_4^- + HCrO_4^- \rightleftharpoons Cr_2O_7^{2-} + H_2O. \quad (5)$$

The rate law of the oxygen exchange of chromate ions with water may now be written as:

$$R = R_1 + R_2 + R_3 + R_4 + R_5$$
$$= k_1[CrO_4^{2-}] + k_2[HCrO_4^-] + k_3[H^+][HCrO_4^-] + k_4[HCrO_4^-][CrO_4^{2-}] + k_5[HCrO_4^-]^2. \quad (6)$$

Salt Effect. The effect of the ionic strength on the exchange rate can be seen from Fig. 1. The salt effect is negative at pH<10.5 and is absent above pH=10.5. The salt effect at pH=7.50 has been studied over a wider range of ionic strength (I(NaCl)= 0.2—5.0 M) (Fig. 4), [Cr(VI)] being kept at 0.075 M. The exchange rate decreases with the increase in the ionic strength.

At pH 7.50, the exchange reaction proceeds for the most part through the k_3 and k_5 paths (*ca.* 65% and 30% respectively). The kinetic salt effect on the k_3 path may be expected to be negative, and that on the k_5 path, to be positive. The equilibrium salt effect on K_1 and K_d reduces the concentration of $HCrO_4^-$, which is the more active species in the oxygen exchange of chromate ions. The observed salt effect is a result of these effects.

Temperature Dependence of the Exchange Rate. This has been studied at pH 7.38 (0 °C, 15 °C, and 25 °C) and at pH 11.0 (25 °C, 35 °C, and 45 °C). The concentration of chromium(VI) was kept at 0.075 M, the ionic strength being fixed at 1.0 M. The Arrhenius plots are shown in Fig. 5. The activation energies are (25.5±0.7) kJ/mol at pH 7.38 and (98.9±1.0) kJ/mol at pH 11.0.

Since the oxygen exchange proceeds exclusively through the k_1 path at pH=11.0, the value obtained

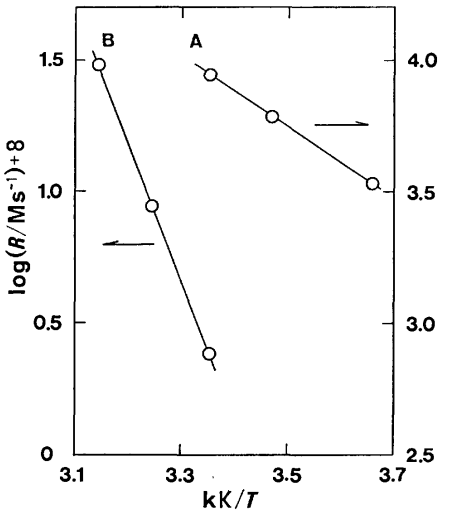

Fig. 5. Temperature dependence of the exchange rate at pH=7.4(A) and pH=11.0(B). ([Cr(VI)]=0.075 M, I(NaCl)=1 M).

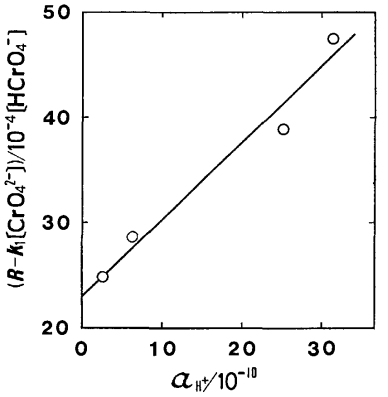

Fig. 6. A plot of $(R-k_1[CrO_4^{2-}])/[HCrO_4^-]$ against a_{H^+}. 25 °C, [Cr(VI)]=0.075 M, I(NaCl)=1 M, pH=8.5—9.6.

above (98.9 kJ/mol) may be interpreted as the energy of activation of this path. The entropy of activation of this path, ΔS^*_1 (298 K), is calculated to be (-45.1 ± 3.3) J/K mol, assuming the first-order dependence on $[H_2O]$.

Analysis of the Exchange Rate. The exchange rates plotted in Fig. 1 were analyzed as follows. The concentrations of the ionic species of Cr(VI) were calculated by the relations:

$$[Cr(VI)] = [HCrO_4^-] + [CrO_4^{2-}] + 2[Cr_2O_7^{2-}],$$

$$K_1 = [HCrO_4^-]/a_{H^+}\cdot[CrO_4^{2-}],$$

$$K_d = [Cr_2O_7^{2-}]/[HCrO_4^-]^2.$$

In the pH region greater than 10.5, the exchange reaction proceeds exclusively through the k_1 path. The appropriate rate law is:

$$R = k_1[CrO_4^{2-}].$$

The average of five values of k_1, calculated from the data in Fig. 1, pH>10.5, is:

$$k_1 = (3.2\pm 0.2)\times 10^{-7}\ s^{-1}.$$

Since the order of the exchange reaction with respect to [Cr(VI)] is 0.93 at pH=8.0, the contribution of the condensation mechanism (k_4 and k_5 paths) may be ignored in the pH region greater than 8.0. The rate law (6) then reduces to:

$$R = k_1[CrO_4^{2-}] + k_2[HCrO_4^-] + k_3[H^+][HCrO_4^-],$$

or $$(R-k_1[CrO_4^{2-}])/[HCrO_4^-] = k_2 + k_3[H^+].$$

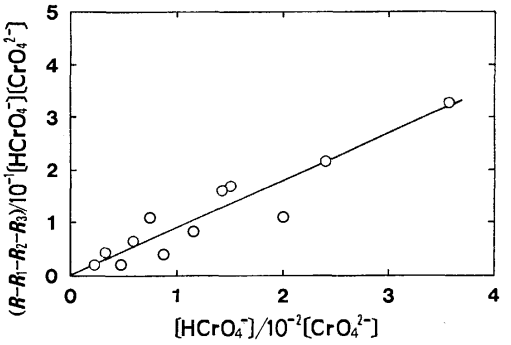

Fig. 7. $(R-R_1-R_2-R_3)/[HCrO_4^-][CrO_4^{2-}]$ as a function of $[HCrO_4^-]/[CrO_4^{2-}]$.
25 °C, [Cr(VI)]=0.075 M, I(NaCl)=1 M, pH=7.2—8.5.

In Fig. 6, the left-hand side of the equation is plotted against a_{H^+} for the runs at pH 8.5—9.57 and I=1.0 M. The least-squares treatment of the plot yields the values:

$$k_2 = (2.30\pm 0.19)\times 10^{-3}\ s^{-1},$$

and $$k_3 = (0.37\pm 0.09)\times 10^{6}\ M^{-1}\ s^{-1}.$$

The rate law (6) may then be written as:

$$\frac{R-k_1[CrO_4^{2-}]-k_2[HCrO_4^-]-k_3[H^+][HCrO_4^-]}{[HCrO_4^-][CrO_4^{2-}]} = k_4 + k_5[HCrO_4^-]/[CrO_4^{2-}]. \quad (7)$$

The left-hand side of the equation was calculated by using the values of k_1, k_2, and k_3 obtained above; in Fig. 7 it is plotted against $[HCrO_4^-]/[CrO_4^{2-}]$ for the runs at pH 7.2—8.5 and I=1.0 M. From the intercept and the slope of the straight line, the values of k_4 and k_5 are found to be $(0.8\pm 17)\times 10^{-3}\ M^{-1}\ s^{-1}$ and $(9.0\pm 1.1)\ M^{-1}\ s^{-1}$ respectively.

The runs at I=0.2 M were treated similarly. The values of the rate constants thus obtained are summarized in Table 2. The sign of the salt effect for each of these rate constants is as would be expected for the charge type of each reaction. In Fig. 1 the curves show the exchange rates calculated by using the rate constants obtained above. The agreement with the experimental values is satisfactory.

Our values of k_1 and k_4 agree satisfactorily with those of the earlier works.[5,15,16] Table 3 shows the value of k_5 obtained by various methods. The values of k_5 obtained in this study are larger by one order of magnitude than those determined by the methods other than oxygen-exchange. We have obtained a k_5 value of a similar magnitude (k_5=8.4 $M^{-1}\ s^{-1}$, at I=1.0 M and 25 °C) in the KCl medium. The discrepancy must be due to the occurrence of the third-order rate terms, $k_a[HCrO_4^-]^3$ and/or $k_b[HCrO_4^-]^2[CrO_4^{2-}]$, which increase in importance as the total concentration increases. It has been noted above that

Table 2. Rate constants of the oxygen-exchange reaction of chromate ions with water at 25 °C

I(NaCl)/M	k_1/s^{-1}	k_2/s^{-1}	k_3/$M^{-1}s^{-1}$	k_4/$M^{-1}s^{-1}$	k_5/$M^{-1}s^{-1}$
0.2	$(3.2\pm0.2)\times10^{-7}$	$(2.4\pm0.9)\times10^{-3}$	$(1.9\pm0.2)\times10^{6}$	$\approx10^{-3}$	5.0 ± 1.1
1.0		$(2.3\pm0.2)\times10^{-3}$	$(0.73\pm0.09)\times10^{6}$	$\approx10^{-3}$	9.0 ± 1.1

Table 3. Rate constants of the dimerization of hydrogenchromate ions at 25 °C

k_5/$M^{-1}s^{-1}$ a)	[Cr(VI)]/M	I/M	Reference
9.0	0.075	1.0(NaCl)	This work b)
5.0	0.075	0.2	This work b)
1.3	1—2.7	Not controlled 2.5—6.0	5 b)
5.5	0.1, 0.2	0.15, 0.45	6 b)
0.45 c)	0.02	0.1(KNO_3)	17
0.25	$(3—4)\times10^{-4}$	0.2($NaNO_3$)	18
0.38	0.002	0.1(KNO_3)	15

a) While the value of k_5 obtained by the oxygen-exchange method usually refers to the transfer of four oxygen atoms between chromate ions and water, the rate constant of the $2HCrO_4^- \rightleftharpoons Cr_2O_7^{2-} + H_2O$ reaction corresponds to the transfer of one atom of oxygen. In this column, the rate constants obtained by other methods are divided by 4 for comparison. b) Oxygen-exchange method. c) 23 °C.

the order of the exchange reaction in [Cr(VI)] increases above 2 with the increase in [Cr(VI)].

Perlmutter-Hayman *et al.*[14,19] have noted the general acid and base catalyses of the hydrolysis of dichromate ions. From the catalytic constants of other acids, Pladziewicz and Espenson[20] estimated the value of the rate constant of the hydrogenchromate-catalyzed hydrolysis of dichromate ions to be 0.1 $M^{-1}s^{-1}$. This value is, however, too small to account for the discrepancy noted above.

Mak[6] has determined the rate constant of the reaction:

$$HCrO_4^- + Cr_2O_7^{2-} \rightleftharpoons Cr_3O_{10}^{2-} + OH^-,$$

to be 13.6 $M^{-1}s^{-1}$ at 25 °C. This reaction might explain a part of the discrepancy.

The remaining possibility is the chromate-ion catalysis of the dimerization of hydrogenchromate ions:

$$2HCrO_4^- + CrO_4^{2-} \rightleftharpoons Cr_2O_7^{2-} + H_2O + CrO_4^{2-}.$$

On the assumption that the discrepancy is due entirely to the general-base catalysis, Eq. 7 may be written as:

$$\frac{R-(R_1+R_2+R_3)}{[HCrO_4^-][CrO_4^{2-}]} = k_4 + (k_5+k_b[CrO_4^{2-}])\frac{[HCrO_4^-]}{[CrO_4^{2-}]}.$$

Under the present experimental conditions, the dominating ionic species of Cr(VI) is CrO_4^{2-} (>95%), and $[CrO_4^{2-}]$ may be regarded as nearly constant. The plot of $(R-(R_1+R_2+R_3))/[HCrO_4^-][CrO_4^{2-}]$ against $[HCrO_4^-]/[CrO_4^{2-}]$ (Fig. 7) remains linear. Using 0.36 (the average of the last three values in Table 3) as the value of k_5, the upper limit of the value of k_b may be calculated as 65 $M^{-2}s^{-1}$, or 2.6×10^2 $M^{-2}s^{-1}$ (referred to the transfer of 1 atom of oxygen)

Table 4. Effect of protonation on the reactivity of oxoanions towards water

Reaction	Rate constants/s^{-1}	Temp/°C	I/M	Reference
$HCrO_4^- + H_2O \rightarrow$	2.4×10^{-3}	25	1.0, 0.2	This work
$CrO_4^{2-} + H_2O \rightarrow$	3.2×10^{-7}	25	1.0, 0.2	This work
$H_2AsO_4^- + H_2O \rightarrow$	1×10^{-4}	30	0.55	7
$HAsO_4^{2-} + H_2O \rightarrow$	1.2×10^{-5}	30	0.55	7
$AsO_4^{3-} + H_2O \rightarrow$	1.5×10^{-6}	30	0.55	7
$HSeO_3^- + H_2O \rightarrow$	2×10^{-4}	0	0.16	21
$SeO_3^{2-} + H_2O \rightarrow$	1.5×10^{-4}	0	0.16	21

(I=0.2 M).

On the contrary, if it is assumed that the rate term, $k_a[HCrO_4^-]^3$, accounts for all of the discrepancy, Eq. 7 becomes:

$$\frac{R-(R_1+R_2+R_3)}{[HCrO_4^-][CrO_4^{2-}]} = k_4 + (k_5+k_a[HCrO_4^-])\frac{[HCrO_4^-]}{[CrO_4^{2-}]}.$$

As $[HCrO_4^-]$ changes 20-fold between pH=7.2 and 8.5, the plot of $(R-(R_1+R_2+R_3))/[HCrO_4^-][CrO_4^{2-}]$ against $[HCrO_4^-]/[CrO_4^{2-}]$ should be a concave curve upwards. Figure 7 does not show such a trend.

The rate-determining step of the nucleophilic catalysis of the dimerization of hydrogenchromate ions[15] is the attack of a nucleophile on the hydrogenchromate ion. In the case of chromate ions as the nucleophile this is nothing but the dimerization of chromate ions and does not result in the acceleration of the rate of oxygen exchange between chromate ions and water. The analysis of the third-order rate terms is beyond the scope of this work.

The hydrogen-ion-catalyzed oxygen exchange of hydrogenchromate ions with water which has been found in this work may be formulated as:

$$H^+ + HCrO_4^- \rightleftharpoons H_2CrO_4,$$

$$H_2CrO_4 + H_2{}^{18}O \rightleftharpoons H_2CrO_3{}^{18}O + H_2O.$$

The dissociative mechanism seems unlikely because of the small activation energy (25.5 kJ/mol) at pH=7.38.

$$H_2CrO_4 \rightleftharpoons H_2O + CrO_3.$$

Table 4 shows the effect of protonation on the reactivity of oxoanions towards water. The enhanced reactivity of hydrogenchromate ions as compared with that of chromate ions is noteworthy. Since the role of a proton in facilitating the oxygen exchange of oxoanions probably consists in the polarization of the bond between the oxygen and the central atom, this bond seems to be more polarizable in chromate ions than in arsenate and selenite ions.

Restricted SCF and MC-SCF Study of the Σ and Π States of the Formyloxyl and Formylaminyl Radicals

Osamu KIKUCHI

Department of Chemistry, The University of Tsukuba, Sakura-mura, Ibaraki 305

(Received February 22, 1980)

Open-shell restricted SCF and MC-SCF methods with the semi-empirical MINDO/3 approximation have been applied to the Σ and Π states of the formyloxyl and formylaminyl radicals. In the MC-SCF formalism, the $\pi\rightarrow\pi^*$ singly- and doubly-excited configurations are included. The optimized molecular structures and spin distributions predicted by the SCF and MC-SCF methods are compared. For the Π state of formyloxyl, the restricted SCF method gives a distorted C_s structure as the most stable Π structure, while the MC-SCF gives a symmetric C_{2v} structure. The use of the MC wavefunctions is recommended for the evaluation of the molecular and electronic structures of these radicals, in which a doublet instability of the restricted SCF solution is expected to occur.

Aminyl radicals[1] are unique in that the central nitrogen atom possesses both an unpaired electron and a lone pair of electrons in its pure $2p_z$ AO and hybrid σ AO; they are, therefore, capable of existing in either a Π or Σ ground electronic state. Since the σ hybrid AO is lower in energy than the pure $2p_z$ AO, the Π state is the ground state of alkylaminyl radicals.[1]

Π Σ

When one of the alkyl groups is replaced by a carbonyl group, an electron-withdrawing group, the $2p_z$ AO is stabilized by the carbonyl π^* orbital. Thus, the Π and Σ states of the acylaminyl radicals[2] may be expected to lie very close to each other, and their ground state can not easily be predicted. The same Σ-Π problem occurs in the acyloxyl radicals,[3,4] which are important intermediates in the thermal and photochemical decompositions of acyl peroxides.

Several semi-empirical and *ab initio* calculations have been reported for solving the Σ-Π problem for the acylaminyl[5,6] and acyloxyl[7-9] radicals. One theoretical problem involved in these radicals is the doublet instability expected in the RHF wavefunction for the three-electron π system. It has been pointed out[10-12] for the allyl radical that the doublet instability occurs in its π system for some region of its geometrical space, and this instability does not depend upon the approximation employed in the semi-empirical or *ab initio* RHF methods.[12] In this study, a multi-configuration(MC)-SCF formalism for the doublet states is applied to the formylaminyl and formyloxyl radicals in the hope of obtaining molecular and electronic structures which are not disturbed by the doublet instability of three-electron π system. The Π and Σ states of these radicals are calculated by a three-configuration MC-SCF equation with the semi-empirical MINDO/3 approximation.[13] Since the energy difference between the Π and Σ states of these radicals is expected to be very small,[5-9] it is difficult to derive any ultimate conclusion about the Σ-Π problem of these radicals by the present semi-empirical approximation. Attention is paid especially to the molecular and electronic structures of these radicals, obtained by both the open-shell restricted SCF and the MC-SCF methods.

Procedure

The distortion of the nuclear framework of the allyl radical leads to a further lowering of the RHF energy,[11,14] which is inconsistent with the ESR experimental evidence.[15] This instability of the RHF solution seems to be general in three-electron π systems.[12] The instability problem which appears in the three-electron system has been examined in detail for the H_3 system by Yamaguchi and Fukutome.[16] They showed that the RHF solution is stable in only a small region of the geometrical space of the H_3 system. The CCC angle of the allyl radical, and also the corresponding angles of formylaminyl and formyloxyl, are expected to be $\approx 120°$. The UHF solution of the H_3 system[16] indicates that the correct wavefunction of this region has the ASDW configuration, which is expressed in terms of the RHF orbitals by a mixture of three electron configurations. In the present formylaminyl and formyloxyl systems, these three configurations correspond to the ground configuration and the $\pi\rightarrow\pi^*$ singly- and doubly-excited configurations. Thus, the following four configuration functions are taken into account in the present MC-SCF formalism:

$$^2\Psi_g = |\cdots i\bar{i}\cdots m|$$

$$^2\Psi_i^k(1) = \frac{1}{\sqrt{2}}\{|\cdots i\bar{k}\cdots m| + |\cdots k\bar{i}\cdots m|\}$$

$$^2\Psi_i^k(2) = \frac{1}{\sqrt{6}}\{|\cdots i\bar{k}\cdots m| - |\cdots k\bar{i}\cdots m| - 2|\cdots ik\cdots \bar{m}|\}$$

$$^2\Psi_{\bar{i}}^{k} = |\cdots k\bar{k}\cdots m|,$$

and the wavefunction is expressed by:

$$^2\Phi = C_0\Psi_g + C_1\Psi_i^k(1) + C_2\Psi_i^k(2) + C_3\Psi_{\bar{i}}^{k}. \quad (1)$$

The electronic energy of Eq. 1 is written as:

$$E_{\mathrm{elec}} = E_g + \sum_{p,q} A_{pq}L_{pq} + \sum_{p,q,r,s} B_{pqrs}\langle pq|rs\rangle, \quad (2)$$

where p, q, r, and s run over the i, m, and k orbitals, and where A_{pq} and B_{pqrs} are expressed by the configuration expansion coefficients (they are given in the Appendix). Also,

$$E_g = \sum_{p=1}^{m-1} 2H_{pp} + \sum_{p,q}^{m-1}(2J_{pq} - K_{pq}) + H_{mm} + \sum_{p}^{m-1}(2J_{pm} - K_{pm})$$

$$L_{pq} = H_{pq} + \sum_{r}^{m-1}\{2\langle rr|pq\rangle - \langle rq|pr\rangle\} + \frac{1}{2}\{2\langle mm|pq\rangle - \langle mq|pm\rangle\},$$

$$I_{pq} = \int \phi_p^*(1) H_{\mathrm{core}}(1)\phi_q(1)d\tau$$

$$\langle rs|tu\rangle = \int \phi_r^*(1)\phi_s(1)\frac{1}{r_{12}}\phi_t^*(2)\phi_u^*(2)d\tau_1 d\tau_2.$$

A troublesome aspect of implementing the MC-SCF formalism involves the handling of the off-diagonal Lagrangian multipliers, which insure orthonormality between open- and closed-shell orbitals of the same symmetry.[17] Segal[18] has put forward the "partitioning basis-set" technique, which simplifies the calculation of the wavefunctions of the excited states of molecules. His method corresponds to a partial variation method, in which the variations of open-shell orbitals are expanded by virtual orbitals. Thus, the MO's obtained by this method are not optimum ones. However, its simplicity makes it possible to obtain many types of MC-SCF wavefunctions easily. This technique, which has been applied to the calculation of MC-SCF wavefunctions by Basch[19] and also by the present author,[20] was used in the present study. After treatment the same as that described previously,[20] Fock-type eigenvalue equations are obtained:

$$\left.\begin{aligned} &F_\lambda|\phi_\lambda\rangle = \varepsilon_\lambda|\phi_\lambda\rangle \quad (\lambda=1,2,\cdots,m-1;\ \neq i)\\ &F_i|\phi_i\rangle = \varepsilon_i|\phi_i\rangle\\ &F_m|\phi_m\rangle = \varepsilon_m|\phi_m\rangle\\ &F_k|\phi_k\rangle = \varepsilon_k|\phi_k\rangle. \end{aligned}\right\} \quad (3)$$

The operators, F_λ F_i, F_m, and F_k, are given by:

$$F_\lambda = F_c + \sum_{r,s}^{i,k}\frac{1}{2}A_{rs}(2f_{rs}-g_{rs})$$

$$F_c = H_{\mathrm{core}} + \sum_{p=1}^{m-1}(2J_p - K_p) + \frac{1}{2}(2J_m - K_m)$$

$$F_m = \frac{1}{2}F_\lambda - \frac{1}{4}(2J_m - K_m) + B_{miim}g_{ii} + B_{mkkm}g_{kk} + \frac{1}{2}B_{mikm}(g_{ik}+g_{ki})$$

$$F_i = F_{ii} + F_{ik}|\phi_k\rangle\langle\phi_i| + |\phi_i\rangle\langle\phi_k|F_{ki}$$

$$F_k = F_{kk} + F_{ki}|\phi_i\rangle\langle\phi_k| + |\phi_k\rangle\langle\phi_i|F_{ik}$$

$$F_{ii} = F_\lambda + \frac{1}{2}A_{ii}F_c + B_{iiii}f_{ii} + \frac{1}{2}B_{iikk}f_{kk} + \frac{1}{2}B_{iiki}(f_{ik}+f_{ki}) + \frac{1}{2}B_{ikki}g_{kk} + B_{miim}g_{mm}$$

$$F_{kk} = \frac{1}{2}A_{kk}F_c + B_{kkkk}f_{kk} + \frac{1}{2}B_{iikk}f_{ii} + \frac{1}{2}B_{ikkk}(f_{ik}+f_{ki}) + \frac{1}{2}B_{ikki}g_{ii} + B_{mkkm}g_{mm}$$

$$F_{ik} = \frac{1}{2}A_{ik}F_c + \frac{1}{2}B_{mikm}g_{mm} + \frac{1}{2}B_{iiki}f_{ii} + \frac{1}{2}B_{ikkk}f_{kk} + B_{ikik}f_{ik}$$

$$F_{ki} = \frac{1}{2}A_{ki}F_c + \frac{1}{2}B_{mikm}g_{mm} + \frac{1}{2}B_{kiii}f_{ii} + \frac{1}{2}B_{kiki}f_{kk} + B_{kiki}f_{ki},$$

where r and s run over two orbitals, i and k, and where p runs over orbitals which are doubly occupied in the Ψ_g configuration. The J_p, K_p, and H_{core} operators have their usual meanings, and the f_{rs} and g_{rs} operators are defined by:

$$f_{rs}(1)\phi_t(1) = \left(\int\frac{1}{r_{12}}\phi_r(2)\phi_s(2)d\tau_2\right)\phi_t(1)$$

$$g_{rs}(1)\phi_t(1) = \left(\int\frac{1}{r_{12}}\phi_r(2)\phi_t(2)d\tau_2\right)\phi_s(1).$$

If the variation method is applied so as to minimize the E_{elec} with respect to the LCAO coefficients, $\mathbf{c}$, of:

$$\phi_r = \chi c_r,$$

equations equivalent to Eq. 3 are obtained:

$$\left.\begin{aligned} &\boldsymbol{F}_\lambda\boldsymbol{c}_\lambda = \boldsymbol{c}_\lambda\boldsymbol{\varepsilon}_\lambda\\ &\boldsymbol{F}_i\boldsymbol{c}_i = \boldsymbol{c}_i\boldsymbol{\varepsilon}_i\\ &\boldsymbol{F}_m\boldsymbol{c}_m = \boldsymbol{c}_m\boldsymbol{\varepsilon}_m\\ &\boldsymbol{F}_k\boldsymbol{c}_k = \boldsymbol{c}_k\boldsymbol{\varepsilon}_k, \end{aligned}\right\} \quad (4)$$

where the matrices, $\boldsymbol{F}_\lambda$, $\boldsymbol{F}_i$, $\boldsymbol{F}_m$, and $\boldsymbol{F}_k$, are evaluated with the corresponding operator and the set of AO's. The configuration expansion coefficients and the orbital expansion coefficients are determined by an iterative procedure described elsewhere.[20] The spin density at the rth AO is obtained by means of:[21]

$$\rho_r = \left(1-\frac{4}{3}C_2^2\right)c_{rm}^2 + \left(\frac{2}{3}C_2^2 + \frac{2}{\sqrt{3}}C_1C_2\right)c_{ri}^2 + \left(\frac{2}{3}C_2^2 - \frac{2}{\sqrt{3}}C_1C_2\right)c_{rk}^2 + \frac{4}{\sqrt{6}}(C_2C_3 - C_0C_2)c_{ri}c_{rk}.$$

The open-shell restricted SCF solutions, which are being compared with the MC-SCF results, are obtained by the repeated diagonalization of the correct general SCF operator for the doublet state given by Hirao and Nakatsuji.[22] This gives correct converged solutions even when the usual Roothaan open-shell treatment diverges.

The semi-empirical MINDO/3 approximation[13] is used to evaluate the matrix elements. The calculation of the simplest nitrogen-center radical, NH_2, by this approximation gives satisfactory results for both the molecular structures of the Π_N and Σ_N states and the energy separation between these two states.[24]

Results and Discussion

Formyloxyl Radical. Formyloxyl has the possibility of existing in the symmetric C_{2v} structure and is a good example for use in examining the difference between the results obtained by the SCF and MC-SCF methods. In the Ψ_g configuration for the Π state of formyloxyl, the lowest π MO(π), the second π MO(π^0), and the highest π MO(π^*) are doubly-occupied, singly-occupied, and unoccupied MO's respectively. In the MC-SCF formalism, the π, π^0, and π^* MO's are assigned to the i, m, and k MO's of Eq. 1 respectively. In the calculation of the $\Sigma(B_2)$ state, the π^0, $\sigma(b_2)$, and π^* MO's are assigned to the i, m,

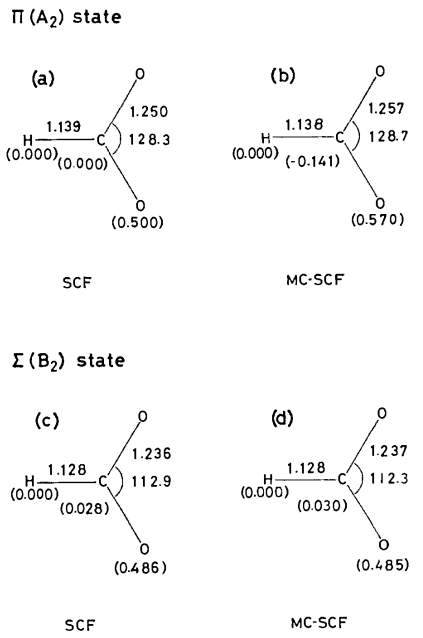

Fig. 1. The structures and spin distributions of the Π and $\sum$ states of the C_{2v} formyloxyl radical. Atomic spin densities are in parentheses. Bond lengths are in Å, and bond angles in degrees.

and k MO's respectively.[25] The optimized[26] molecular structures and spin distributions for the C_{2v} Π and $\sum$ states are shown in Fig. 1. The SCF and MC-SCF methods predict a very similar molecular structure for the $\Pi(A_2)$ state and also for the $\Sigma(B_2)$ state. The spin distribution of the $\Sigma(B_2)$ state by SCF and MC-SCF also resemble each other. The negative spin density appears at the central carbon atom in the MC-SCF Π state. Although the molecular structure and spin distribution of the C_{2v} formyloxyl are not greatly afected by the inclusion of the excited configurations, the relative energy between the $\Sigma(B_2)$ and $\Pi(A_2)$ states is greatly reduced by the MC-SCF formalism (Table 1).

The SCF calculation gives a stable Π(A″) structure for the distorted C_s formyloxyl.[27] This is shown in Fig. 2. This distorted C_s structure is 19.6 kJ mol^{-1} more stable than the SCF C_{2v} $\Pi(A_2)$ state, and the unpaired electron is located mostly (90%) at one of the oxygen atoms in this structure. These results indicate that the SCF calculation predicts the distorted C_s structure instead of the symmetric C_{2v} one, as the most stable Π state. The C_{2v} structure of the allyl π radical has been determined from the experimental ESR coupling constants of allyl.[15] When the open-shell restricted SCF procedure is applied to the allyl radical, the distorted C_s structure is obtained, while the MC-SCF MINDO/3 procedure presented here gives the C_{2v} structure,[14] which is consistent with the experimental evidence for the allyl radical. Thus, the C_s(Π) structure of the acyloxyl radical predicted by the present SCF calculation may not be correct for the Π state of acyloxyl.

When the MC-SCF optimization of the nuclear framework, using the C_s structure in Fig. 2 as the initial structure, was carried out for the Π state, the

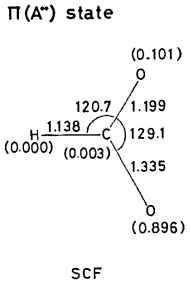

Fig. 2. The optimized structure and spin distribution (in parentheses) of the Π(A″) state of the distorted C_s formyloxyl radical. The MC-SCF formalism does not give the stable structure for the distorted form.

Table 1. Relative energies (kJ mol^{-1}) of the $\sum$ and Π states of the formyloxyl radical

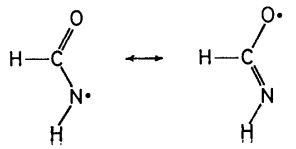
	SCF	MC-SCF
$\Sigma(B_2)$	0.0	0.0
$\Pi(A_2)$	59.8	9.2
Π(A″)	40.2	—

symmetric Π structure shown in Fig. 1-(b) was obtained as the optimized one. It may be concluded that the stable C_s Π structure of formyloxyl predicted by the SCF calculation results from the doublet instability expected in the RHF solution for the C_{2v} structure of the three-electron π system, and that this instability is removed by the MC-SCF treatment. The wavefunction of the C_{2v} $\Pi(A_2)$ state, Fig. 1-(b), is:

$$0.974\Psi_g + 0.039\Psi_i^k(1) + 0.210\Psi_i^k(2) - 0.081\Psi_{ii}^{kk}$$

The contribution of the doubly-excited configuration, Ψ_{ii}^{kk}, to this state is small. It was found that the exclusion of the doubly-excited configuration from the present MC-SCF formalism also gives the $C_{2v}(A_2)$ structure, instead of the C_s(A″) one, as the most stable Π state. Thus, the inclusion of the singly-excited configuration in the MC-SCF formalism appears to be sufficient to remove the doublet instability expected in the RHF solution of C_{2v} three-electron radicals. It should be noted that, if the symmetry of formyloxyl is restricted to C_{2v}, a reliable structure for the Π state is obtained by the restricted SCF calculation, since the SCF and MC-SCF structures of the Π states (Fig. 1) closely resemble each other. The reliable spin distribution can be obtained by the SCF calculation, followed by the CI calculation.

Formylaminyl Radical. The optimized structures and spin distribution for the Π and $\sum$ states of formylaminyl are shown in Fig. 3. The difference in the molecular structures between the SCF and MC-SCF Π states is not very large, but it is important; the lengthening of the CO bond and the shortening of the CN bond are more obvious in the MC-SCF structure than in the SCF structure. This indicates



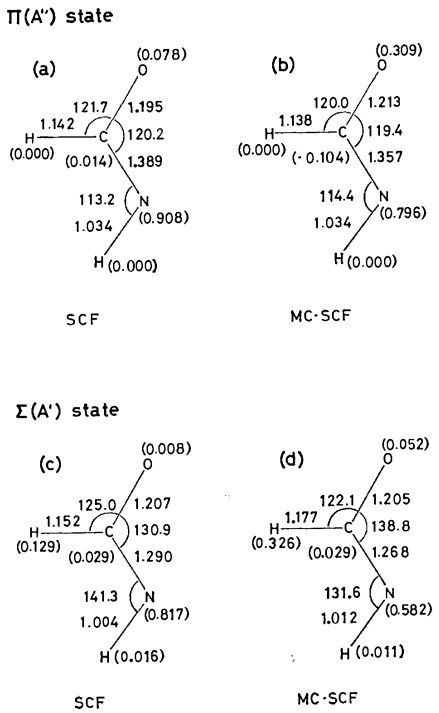


Fig. 3. The structures and spin distribution of the Π and Σ states of the formylaminyl radicals. Atomic spin densities are in parentheses. Bond lengths are in Å, and bond angles in degrees.

that the single-determinant SCF calculation overestimates the contribution of one of the canonical structures to the Π electronic state of this radical. This trend also appears in the calculated spin distribution; the larger spin density on the oxygen atom is obtained in the MC-SCF structure. As is to be expected from the analysis of the formyloxyl radical, the difference between the SCF and MC-SCF structures for the Π state of the acylaminyl radical may result mainly from the unstable nature of the restricted SCF method for this radical. A large difference is observed in the SCF and MC-SCF spin distributions in the Σ(A') state (Figs. 3c and 3d). This may come from the difference between the SCF and MC-SCF structures. The decrease in the HCN and CNH angles causes a larger interaction between the 1s AO of the H–C hydrogen atom and the hybrid odd-electron AO of the nitrogen atom, and the spin delocalization occurs from the nitrogen to the hydrogen atom. A similar trend has been observed in the spin distributions in the SCF Σ(A') state, which are calculated as functions of the CNH angle.

The ESR spectra of several acylaminyl radicals have been obtained.[1,5] The nitrogen splittings are ≈15 G (1 G=10^{-4} T), and the N–CH_3 proton splittings are ≈29 G. These values are very similar to those of the dialkylamino radicals,[1,5] whose ground state is of the π-type, and also indicate that the odd-electron AO at the nitrogen atom is not the sp hybrid AO, but almost pure 2p AO. These ESR results support the Π_N ground state for the acylaminyl radical, although it is not possible absolutely to exclude a Σ_N structure with the CNC angle of ≈180°. The MC-SCF results

Table 2. Relative energies (kJ mol^{-1}) of the Σ and Π states of the formylaminyl radical

	SCF	MC-SCF
Σ(A')	0.0	7.1
Π(A'')	26.4	0.0

in Table 2 indicate that the ground state of formylaminyl is of the Π(A'') type, which is consistent with the results of the ESR experiments. However, the energy difference between Σ and Π is very small.

The *ab initio* STO-3 G and 4-31G calculations by Baird and Kathpal[6] show that the Σ_N state is much (>40 kJ mol^{-1}) higher than the Π state, while the present results predict they will lie very close to one another. In their calculations of the formylaminyl radical, all the bond angles around the carbon atom were assumed to be 120°. As may be seen from Fig. 3, the bond angles around the carbon atom deviate greatly from 120°; the optimization of these angles is important in estimating the relative energy between the Π and Σ states.

Significant differences have been observed between the SCF and MC-SCF molecular electronic structures for the formyloxyl and formylaminyl radicals. They come mainly from the doublet instability of the restricted SCF solutions for the 3π-electron radicals. The allyl 3π-electron system is described correctly by the present MC-SCF procedure;[14] the use of the multi-configuration wavefunction is recommended for the evaluation of the molecular and electronic structures for the lower-lying Π and Σ states of acyloxyl and acylaminyl radicals.

Appendix

A_{pq} and B_{pqrs} in Eq. 2 are expressed by the following configuration expansion coefficients; all the other values are zero.

$$A_{ii} = -C_1^2 - C_2^2 - 2C_3^2$$
$$A_{kk} = C_1^2 + C_2^2 + 2C_3^2$$
$$A_{ik} = A_{ki} = \sqrt{2}\,(C_0C_1 + C_1C_3)$$
$$B_{iiii} = B_{kkkk} = C_3^2$$
$$B_{iikk} = -C_1^2 - C_2^2 - 4C_3^2$$
$$B_{miim} = B_{immi} = \frac{1}{2}(C_2^2 - \sqrt{3}\,C_1C_2)$$
$$B_{mkkm} = B_{kmmk} = \frac{1}{2}(C_2^2 + \sqrt{3}\,C_1C_2)$$
$$B_{mikm} = B_{immk} = \frac{\sqrt{6}}{2}(C_0C_2 - C_2C_3)$$
$$B_{ikii} = B_{kiii} = -\sqrt{2}\,C_1C_3$$
$$B_{ikkk} = B_{kikk} = \sqrt{2}\,C_1C_3$$
$$B_{ikik} = B_{kiki} = C_0C_3$$
$$B_{ikki} = 2(C_1^2 + C_3^2).$$

24) The HNH angle of the NH_2 radical estimated by MINDO/3 is 102° for the Π state and 136° for the $\sum$ state, and the energy difference between these states is estimated to be 24 kcal/mol. The corresponding experimental values[6] are 103°, 144°, and 31 kcal/mol respectively.
25) In the $\sum$ state of formyloxyl and formylaminyl, four electrons occupy the π orbitals, and the doublet instability may not occur. When the OCO or OCN angle becomes small, the energy difference between the π^0 and π^* levels decreases and the doubly-excited configuration from π^0 to π^* becomes important to the $\sum$ state. Moreover, the preliminary CI calculations showed that the singly-excited $\pi \rightarrow \pi^*$ configuration is important for the acylaminyl radical. For the above reasons, the π^0 and π^* MO's are assigned to the i and k orbitals in Eq. 1 for the $\sum$ state of the acyloxyl and acylaminyl radicals.
26) The variable metric method proposed by Fletcher was employed; R. Fletcher, *Computer J.*, **13**, 317 (1970).
27) The SCF MINDO/3 energies of $\sum(A_1)$ and the distorted $\sum(A')$ states are lower than those of the $\sum(B_2)$ and $\Pi(A_2)$ states. In these states, the CH distance is >1.2 Å and the OCO angle is $>150°$. These are, thus, transient states dissociative to $H+CO_2$.

Hydrogenation Activity and Selectivity of Cobalt Boride and Cobalt Nickel Binary Boride Catalysts

Yuriko NITTA, Toshinobu IMANAKA, and Shiichiro TERANISHI*

Department of Chemical Engineering, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received March 10, 1980)

Co–B catalyst has higher selectivity than Ni–B catalyst for the formation of α,β-unsaturated alcohols from α,β-unsaturated aldehydes and lower selectivity for the formation of olefins from acetylenes. The differences between the two catalysts can be ascribed to the differences in the adsorption strength of reactants on Co and Ni metals. The hydrogenation activities of the Co–Ni–B catalysts vary through a maximum, but the selectivities vary monotonously with nickel content. These features are explained in terms of the surface composition measured by XPS and of the surface area of the catalysts. The enrichment of nickel on the surface and the increase of the surface area are observed for the Co–Ni–B catalysts. Co–B catalysts modified by a small amount of metal salts (Fe, Cr, Cu, *etc.*) are more effective for the selective hydrogenation of α,β-unsaturated aldehydes than co-precipitated binary boride catalysts.

Paul *et al.* reported in 1951[1] that cobalt boride (Co–B) prepared by the liquid-phase reduction of cobalt salt with sodium tetrahydroborate has catalytic activity for the hydrogenation of safrole. Since then, the Co–B catalyst has been used in several reactions, such as in selective hydrogenation of nitriles to primary amines,[2] in the reduction of nitro compounds[3] and carbon monoxide,[4] and in hydrogenolysis of hydrogen peroxide.[5] With regards to the hydrogenation of olefins, aldehydes and ketones on Co–B catalyst, however, there have been only a few reports, probably because the activity of the Co–B catalysts is much lower than that of the Ni–B catalyst.

On the other hand, there have been some reports showing the difference between nickel and cobalt catalysts in the activity and selectivity for hydrogenations of various compounds.[6] We have reported the surface state of Ni–B catalyst and its catalytic activity and selectivity for hydrogenation reactions in comparison to other nickel catalysts.[7] In this work, we studied the selective hydrogenation of α,β-unsaturated aldehydes to unsaturated alcohols and that of acetylenes to olefins on the Co–B catalyst, which might exhibit higher selectivity than the Ni–B catalyst.

Furthermore, although a small amount of a metal such as Mo, W, Cr, or Rh, added to the Co–B or Ni–B catalyst is known to promote the catalytic activity,[1,5,8] there has been no detailed report on the catalytic activity and selectivity of binary boride catalysts with various compositions. In the present work, a series of co-precipitated cobalt nickel boride (Co–Ni–B) catalysts was examined in order to elucidate the relation between the catalytic activity or selectivity and the surface state of the binary boride catalysts. The effects of metal salt additives to the Co–B and Ni–B catalysts on their selectivities were also studied in order to reveal the influence of preparation methods of binary boride catalysts and to find a more effective catalyst for the selective hydrogenation of α,β-unsaturated aldehydes to unsaturated alcohols.

Experimental

Catalysts. Co–B catalyst was prepared by reducing cobalt(II) acetate with sodium tetrahydroborate in water at 30 °C according to the method described previoursly.[7e] Co–Ni–B catalysts were prepared in a similar way from mixtures of measured amounts of cobalt acetate and nickel acetate. The total weight of reduced metal was held constant. A freshly prepared catalyst was used for each experiment, immediately after washing with water and ethanol. The modification of Co–B or Ni–B catalyst by metal salts was carried out by stirring the washed catalyst with a measured amount of metal acetate or chloride in 20 cm^3 of ethanol for 20 min under a hydrogen atmosphere prior to the hydrogenation reaction.

BET surface areas of the catalysts were measured by N_2 adsorption at 77 K after they were washed with acetone and after evacuation by a diffusion pump for 4 h at ambient temperature. The surface areas of several catalysts were also measured after heating at 300 °C for 2 h *in vacuo*.

Apparatus, Procedure, and Materials. The hydrogenation reactions of acetone (2 cm^3), crotonaldehyde, cinnamaldehyde, and acetylenes (0.5 cm^3 for each) were carried out at 30 °C in 20 cm^3 of 99% ethanol under atmospheric pressure of hydrogen by using an apparatus similar to that described previously.[9] A sufficient amount of hydrogen was adsorbed on each catalyst prior to the hydrogenation reactions. The amount of catalyst used was 0.2 g of metal for the hydrogenation of crotonaldehyde and acetylenes, and 0.5 g for that of acetone and cinnamaldehyde. The reaction rates were found not to be controlled by diffusion under these reaction conditions.

The initial hydrogenation rates were measured manometrically by the uptake of hydrogen in the initial stage of the reaction. The decomposition rate of hydrogen peroxide was also measured for comparison from the volume of oxygen evolved on 0.2 g of catalyst at 0 °C in 20 cm^3 of ethanol.

The selectivity of a catalyst for the hydrogenation of α,β-unsaturated aldehydes (S_1) was determined as the ratio of the yield of unsaturated alcohols to the total yield of the products based on GLC analysis at about 50% conversion. With the hydrogenation of acetylenes, the olefin selectivity (S_2) of a catalyst was defined as the molar ratio of olefin in olefin plus paraffin.

All reactants and solvent used for the hydrogenation reactions were dried and distilled before use. Metal salts and $NaBH_4$ were commercially obtained guaranteed or extra pure grade reagents (Nakarai Chemicals) and were used without further purification.

Analysis. Analysis of the reaction products was carried out by GLC using a Shimadzu 4APT gas chromatograph with a 2 m column of 20% PEG 20 M on Celite 545,

○: Cinnamaldehyde, ◑: 3-phenylpropionaldehyde,
◎: cinnamyl alcohol, ●: 3-phenyl-1-propanol.

X-Ray photoelectron spectra(XPS) of some of the Co–Ni–B catalysts were measured to estimate the surface composition of the catalysts by using a Hitachi 507 photoelectron spectrometer. The detailed procedures were reported elsewhere.[7e] The surface concentration of nickel in a Co–Ni–B catalyst was estimated from the relative peak area intensities of Ni $2p_{3/2}$ and Co $2p_{3/2}$ and from the relative atomic sensitivities obtained by measuring the X-ray induced spectra of $NiSO_4$ and $CoSO_4$.

Results

Co–B Catalyst. The Co–B catalyst prepared from cobalt(II) acetate is a fine, nonpyrophoric, and nonferromagnetic precipitate, and appears amorphous from the X-ray diffraction pattern. These properties of Co–B catalyst are similar to those of the Ni–B catalyst reported previously.[1,7] The Co–B catalyst prepared from cobalt(II) chloride is, however, ferromagnetic and has a little lower activity for hydrogenation reactions than the one prepared from cobalt(II) acetate. Although the BET surface area of the Co–B catalyst is 38 m^2/g, twice as large as that of the Ni–B catalyst, the catalytic activity of the Co–B catalyst for hydrogenation reactions is considerably lower than that of the Ni–B catalyst. For example, the relative specific hydrogenation rates over the Co–B catalyst to that over the Ni–B catalyst are 1/3 for acetone, 1/15 for cinnamaldehyde, and 1/35 for crotonaldehyde. The low hydrogenation activity and the low resistivity to fatigue of cobalt catalyst may be partly attributed to the strong affinity of cobalt metal for oxygen,[10] as is expected from the following result of the decomposition reaction of hydrogen peroxide.

The hydrogenation profiles of cinnamaldehyde on the Co–B and Ni–B catalysts are shown in Fig. 1. A considerable amount of unsaturated alcohol, *i.e.*, cinnamyl alcohol, was produced together with much smaller amounts of saturated aldehyde and saturated alcohol from the initial to the middle of the reaction stage on the Co–B catalyst, whereas no unsaturated alcohol was detected at all for the reaction on the Ni–B catalyst. In the case of crotonaldehyde, we also

Table 1. Hydrogenation of acetylenes on cobalt and nickel catalysts

Reactant	Catalyst	Hydrogenation rate r/H_2-ccSTP $min^{-1}\cdot g^{-1}$	Olefin selectivity $S_2/\%$

obtained crotyl alcohol with 21% of selectivity on the Co–B catalyst as well as on the platinum boride catalyst modified by copper(II) salt or iron(II) salt, as reported in our previous paper.[11]

On the other hand, the selectivities to olefins(S_2) in the hydrogenation of acetylenes on the Co–B catalyst were somewhat lower than those on the Ni–B catalyst, while somewhat higher than those on Raney cobalt(R-Co) catalyst (Table 1). With regards to the hydrogenation rate of acetylenes, the Co–B catalyst showed considerably high activity, while the R-Co catalyst showed very low activity.

Co–Ni–B Catalysts. Figure 2 shows the initial hydrogenation rates (r_H) of acetone and crotonaldehyde and the initial decomposition rate(r_D) of hydrogen peroxide on the Co–Ni–B catalysts against nickel content (x=Ni/Co+Ni) in the catalyst. A maximum activity for hydrogenation reactions was obtained with a catalyst containing nickel in a concentration around x=0.5; however the shape of maximum was not sharp. X-Ray diffraction analysis showed that no crystalline phase existed in any of the Co–Ni–B catalysts used.

With respect to the decomposition reaction of hydrogen peroxide, however, the Co–B catalyst has the maximum activity, while a catalyst containing more nickel shows much lower activity. This feature cannot

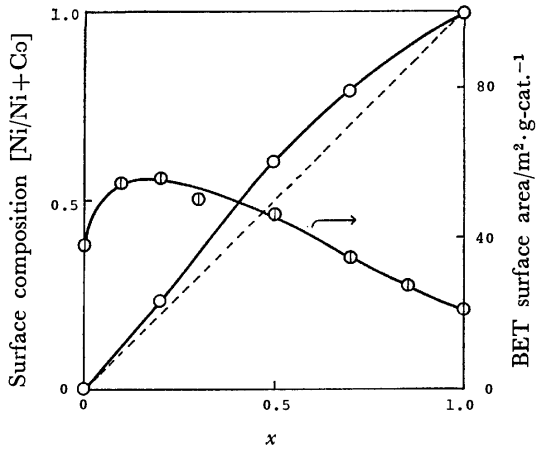

Fig. 3. Surface composition and BET surface area of Co–Ni–B catalyst as a function of nickel content x.

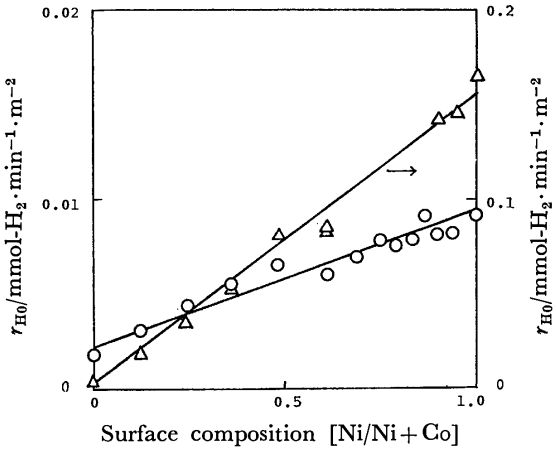

Fig. 4. Intrinsic hydrogenation activity r_{H0} of Co–Ni–B catalyst for acetone(○) and crotonaldehyde(△) as a function of surface composition.

be explained only by the increase of surface area of Co–Ni–B catalysts. It can be seen from Fig. 2 that the degree of variation in activity with nickel content is larger for the catalysts containing less nickel.

In Fig. 3, surface compositions of some Co–Ni–B catalysts obtained by XPS measurement are plotted, together with the BET surface areas of the catalysts, against nickel content in the bulk. The nickel content on the catalyst surface was found to be larger than that in the bulk.

Since the catalytic activities should be compared with the surface states of the catalysts, the intrinsic hydrogenation activities(r_{H0}) of Co–Ni–B catalysts per unit surface area were calculated based on the data in Fig. 2 and Fig. 3, and are plotted against the nickel content on the surface of the catalyst (Fig. 4).

The catalytic selectivities of the Co–Ni–B catalysts for the hydrogenations of α,β-unsaturated aldehydes(S_1) and phenylacetylene(S_2) are also plotted against nickel content(x) in Fig. 5. Both selectivities (S_1 and S_2) vary monotonously with nickel content in the catalysts. Each selectivity, S_1 or S_2, of the Co–Ni–B catalysts is lower than that of the Co–B or the Ni–B catalyst. The degree of variation in these selectivities with nickel content is also larger for the catalysts containing less

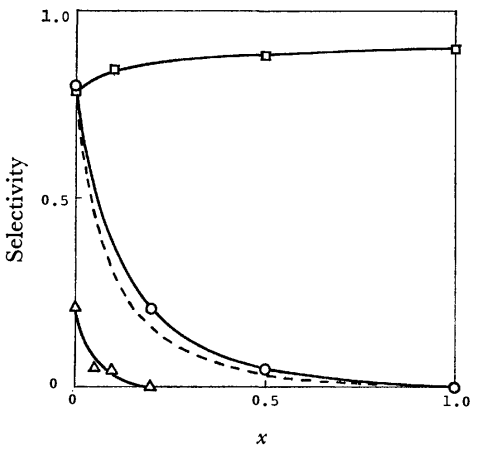

Fig. 5. Selectivity of Co–Ni–B catalyst as a function of nickel content x.

nickel.

In addition, the resistivity against sintering of the Co–Ni–B catalysts was studied by measuring the BET surface areas of the catalysts heated at 300 °C for 2 h *in vacuo*. The resistivity to the fatigue due to oxidation of the catalyst surface was also evaluated by measuring the decomposition rate of hydrogen peroxide repeatedly on once-used catalyst. Both resistivities increased rapidly with the increase of nickel content.

Co–B Catalyst Modified with Metal Salt. Table 2 lists the products distribution for the hydrogenation of crotonaldehyde and cinnamaldehyde on Co–B catalysts modified by various metal salts (0.17 mmol/g-Co). The addition of certain metal salts was found to increase the yield of unsaturated alcohols(UA) on the Co–B catalyst, as reported on R-Co catalyst,[12] while it was not effective at all in the case of the Ni–B catalyst. The effectiveness of metal salts added to the Co–B catalyst decreased in the order: Fe≃Cr>Cu>Cd>Zn>Ru>Co.

When the amount of the metal salts added was more than 0.17 mmol/g-Co (1 mol% of the amount of the Co–B catalyst), it was less effective. In the case that metal salts were added to the aqueous solution of cobalt acetate prior to the reduction with $NaBH_4$, the resulting coprecipitated binary boride catalysts, even Co–Ni–B or Co–Cr–B catalyst, were not so selective as the modified cobalt boride catalyst.

Discussion

From the fact that the plots in Fig. 4 give a straight line, the variation of the specific activity of the Co–Ni–B catalysts with nickel content shown in Fig. 2 is evidently explained in terms of the surface area and the surface composition of the catalysts. In other words, the maximum hydrogenation activity of the Co–Ni–B catalyst containing nickel in concentrations around x=0.5 is due not only to the increase of the

surface area but also to the enrichment of nickel on the surface of the catalyst.

The features of the dependence of the selectivities (S_1 and S_2) on nickel content mentioned before (Fig. 5) are also explicable by the enrichment of nickel on the catalyst surface and by the higher hydrogenation activity of Ni metal than that of Co metal in the catalyst. The dashed line in Fig. 5 represents the variation of the calculated selectivity with nickel content for the hydrogenation of cinnamaldehyde, based on the surface composition of the catalysts and the values of selectivities and activities of Co–B and Ni–B catalysts.

The rapid increase in the resistivities against sintering or the fatigue with the increase of nickel content in Co–Ni–B catalysts can also be understood as a result of the enrichment of nickel on the surface of the catalysts, because the Ni–B catalyst is well known to have high resistivities against sintering or fatigue.

An advantage of the coprecipitated binary boride catalyst, Co–Ni–B, is the increase of hydrogenation activity. As for the catalytic selectivity, these binary boride catalysts were found to be ineffective. On the other hand, another type of binary boride catalysts, prepared by the modification of the Co–B catalyst with a small amount of metal salt, has an increased selectivity for the hydrogenation of α,β-unsaturated aldehydes. In this case, since the added metal cations interact with cobalt metal only on the surface of the catalyst, the addition of only small amounts of metal salt was more effective, compared to the case of the coprecipitated binary boride catalyst. It can be concluded, therefore, that the coprecipitated binary boride catalysts are effective for the increase of hydrogenation activity but that the modified binary boride catalysts are effective for the increase of the catalytic selectivity.

As can be seen from Fig. 5, the variations of the catalytic selectivities, S_1 and S_2, with nickel content of the catalysts are quite different; S_1 is the largest for the Co–B catalyst, whereas S_2 is the largest for the Ni–B catalyst. In the competitive hydrogenation of acetophenones over Ni and Co catalysts, Kajitani *et al.* reported that the characteristic difference in the susceptibility to the effects of substituent groups and solvents between R-Ni and R-Co catalysts can be mainly attributed to the differences between nickel and cobalt metals.[6c] In the previous work, we reported that the hydrogenation activities and selectivities over various nickel catalysts, as well as the high resistivity of the Ni–B catalyst to poisoning,[7f] are explained in terms of the surface *d*-electron density of the catalyst.[7g] The characteristic differences in the hydrogenation activities and selectivities between the Co–B and Ni–B catalysts may, therefore, be due to the difference in the surface *d*-electron density of the two metals; the surface *d*-electron density of Co is smaller than that of Ni. That is to say, the reactants are adsorbed more strongly on the Co–B catalyst than on the Ni–B catalyst, resulting in lower hydrogenation rates on the Co–B catalyst than on the Ni–B catalyst. This is consistent with the results reported previously.[7g] Blyholder and Shihabi pointed out in their study of IR spectra that a metal-oxygen bond rather than a metal-carbon bond is responsible for the bonding between acetone and the metal surface of silica-supported nickel and cobalt.[13] Moreover, cobalt has stronger affinity for oxygen than nickel, as mentioned earlier. Therefore, the carbonyl group of α,β-unsaturated aldehydes will be adsorbed as strongly as the carbon-carbon double bond on the Co–B catalyst. This will relatively favor the hydrogenation of the carbonyl group on the Co–B catalyst, since the stronger adsorbate has an advantage in competitive hydrogenations. Especially for the hydrogenation of cinnamaldehyde, which has a large steric hindrance around the carbon-carbon double bond, the carbonyl group will be hydrogenated much more easily than the carbon-carbon double bond. On the Ni–B catalyst, however, the carbonyl group is adsorbed too weakly to be hydrogenated prior to the hydrogenation of the carbon-carbon double bond.

With regard to the hydrogenation of acetylenes, since a carbon-carbon triple bond is adsorbed on

metal much more strongly than the double bond, the hydrogenation of an acetylenic bond will be much more difficult than that of an olefinic bond on the Co–B catalyst, as compared with those on the Ni–B catalyst. Moreover, the olefinic bond is also adsorbed too strongly on the Co–B catalyst to desorb before being hydrogenated to the single bond. This will favor the hydrogenation of an olefinic bond formed by the hydrogenation of an acetylenic bond, resulting in the lower olefin selectivity(S_2) on the Co–B catalyst than on the Ni–B catalyst. This idea is supported by the fact that the olefin selectivities(S_2) for the hydrogenation of 1-heptyne, which is comfirmed to be adsorbed on catalysts more strongly than 2-heptyne by the result of competitive hydrogenation of 1-heptyne and 2-heptyne, are lower than those for the hydrogenation of 2-heptyne, as shown in Table 1.

We wish to thank Dr. Yasuaki Okamoto for his advice concerning the XPS measurement and for his valuable discussion. We also thank Miss Akiko Ohara for her technical assistance.

The Rate Constants of the Reactions of the Metastable Nitrogen Atoms, ^2D and ^2P, and the Reactions of $N(^4S)+NO\rightarrow N_2+O(^3P)$ and $O(^3P)+NO+M\rightarrow NO_2+M$

Ko-ichi SUGAWARA, Yo-ichi ISHIKAWA, and Shin SATO*

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received March 29, 1980)

The pulse-radiolysis technique was used for the measurement of the quenching rates of the metastable nitrogen atoms, ^2D and ^2P, both in nitrogen and in helium. The rate constants obtained for $N(^2D)$ were $(1.3\pm0.2)\times10^{-14}$ cm^3 molecule^{-1} s^{-1} (1 cm^3 molecule^{-1} s^{-1} = 6.022×10^{17} m^3 mol^{-1} s^{-1}) in nitrogen and $(4.6\pm0.4)\times10^{-17}$ in helium; these values were larger than those for the higher energy metastable nitrogen atoms, $N(^2P)$, $(3.3\pm0.3)\times10^{-17}$ in nitrogen and $(4.2\pm1.3)\times10^{-18}$ in helium. The room temperature rate constants of the reactions of these atoms with nitrogen monoxide and with ethylene were also measured. All of these rate constants were found to be of the order of 3×10^{-11} cm^3 molecule^{-1} s^{-1}. The rate constants of the reactions, $N(^4S)+NO\rightarrow N_2+O(^3P)$ and $O(^3P)+NO+M\rightarrow NO_2+M$, were also measured and compared with literature values.

Recently we used a pulse-radiolysis technique combined with the resonance absorption method for the measurement of the rate constants of the reactions of the ground state-nitrogen atoms with several olefins.[1] In that experiment, we recognized that the metastable nitrogen atoms, ^2D and ^2P, generated together with the ground state-nitrogen atoms, ^4S, decayed very rapidly in a high pressure nitrogen gas. Since then, our technique was improved, so that the measurement of the reactions of these metastable atoms could be attempted.

The quenching of the metastable nitrogen atoms by simple molecules and atoms is attracting the attention of many researchers. This is not only because of their occurrence in discharge systems, but also because of the significant roles which these atoms play in the chemistry of the upper atmosphere.[2-7]

A number of investigations have been reported on the reaction of the NO-titration for $N(^4S)$ atoms.[8-22] Since our apparatus can easily be applied for the measurement of this reaction, we have measured the rate constants of the reactions of $N(^4S)+NO\rightarrow N_2+O(^3P)$ and $O(^3P)+NO+M\rightarrow NO_2+M$, where M stands for N_2 or He.

Experimental

The apparatus, the set-up of which is shown schematically in Fig. 1, has been described previously.[23] To measure the time dependence of the concentration of $N(^2D)$ and $N(^2P)$ atoms, the emission lines at around 149.3 and 174.3 nm, respectively, were used; these were excited in flowing He containing a trace of N_2. Although both lines consisted of fine structures (149.262, 149.267, and 149.467 for the $^2P_J\rightarrow{}^2D$ transition and 174.272, 174.273, 174.526, and 174.527 for the $^2P_J\rightarrow{}^2P$ transition), they were not resolved for the measurement of the concentration of the atoms. For $N(^4S)$ and $O(^3P)$ atoms, the resonace lines were used.[1,23]

Figures 2, 3, and 4 show the optical densities for $N(^2D)$, $N(^2P)$, and $N(^4S)$ atoms generated immediately after the irradiation of the high-energy electrons, the peak energy

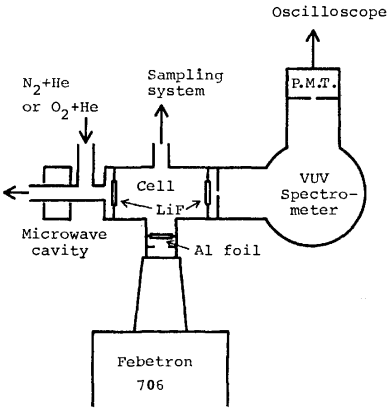

Fig. 1. Schematic diagram of the experimental apparatus. P.M.T., Photomultiplier.

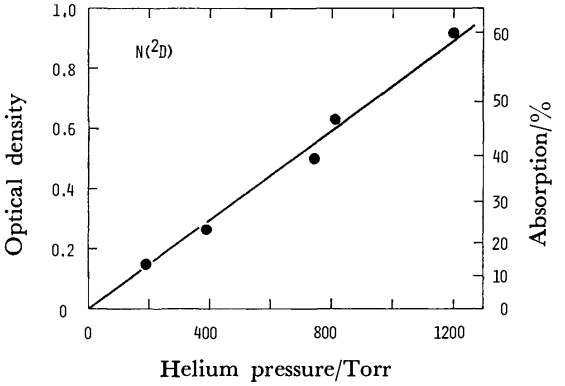

Fig. 2. The optical densities of $N(^2D)$ atoms generated immediately after the electron irradiation in the mixture of 2.0 Torr N_2 and He as a function of the He pressure.

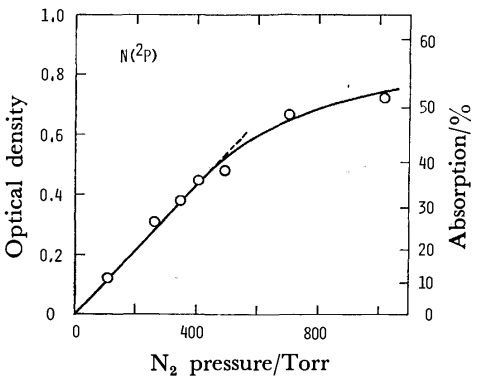

Fig. 3. The optical densities of $N(^2P)$ atoms generated immediately after the electron irradiation in N_2 as a function of the N_2 pressure.

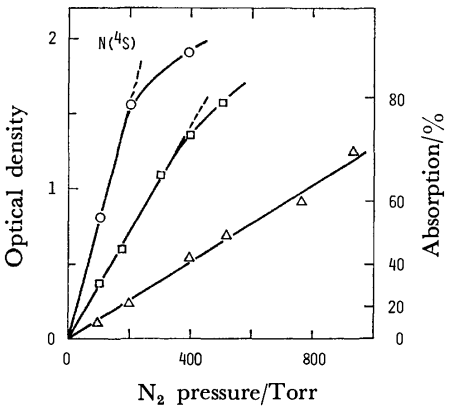

Fig. 4. The optical densities of N(⁴S) atoms generated immediately after the electron irradiation in N_2 as a function of the N_2 pressure. The d.c. charging voltages of Febetron 706 were set at 20 (△), 25 (□), and 28 (○) kV.

being 600 keV, from Febetron 706 as functions of the pressure of nitrogen or helium in the reaction cell. Since the penetration length of 600 keV-electrons is longer than 1 m in the atmosphere, probably most of the electrons ejected from Febetron 706 discharge at the wall of the reaction cell after having penetrated the reactant gas. Consequently, the energy transfer from the electrons to the gas should be proportional to the pressure of the gas in the cell.

The spectral lines used for the measurement of the optical densities of N(²P) and N(⁴S) atoms are not completely isolated from other spectral lines; therefore, some contamination could not be avoided. This is probably the reason for the apparent saturation of the optical densities for N(²P) and N(⁴S) atoms shown in Figs. 3 and 4. In the present experiments, optical densities less than 0.5 were always used for the measurement of the relative concentrations of atoms. Even if the light intensity of the contaminated spectral lines is 40%, the errors introduced in the estimation of the decay rate do not exceed 10%, since the first-order decay plots are always made in the optical density of 0.5—0.05.

The high-purity dried He (Nihon Helium Co.) and N_2 (Nihon Sanso Co.) were passed through traps filled with molecular sieve 4A at 77 K before use. The research grade NO and C_2H_4 (Takachiho Shoji Co.) were used without further purification.

Results

Figure 5 shows a typical example of the oscillograms obtained for the decay of N(²D) atoms in the mixture of He and N_2. The decay rate may be expressed as follows:

$$k = k_{He}[He] + k_{N_2}[N_2] + k_{dif}.$$

Here, k is the apparent decay rate, k_{He} and k_{N_2} are the rate constants of the quenching by He and N_2, and k_{dif} is the decay rate due to the diffusion of N(²D) atoms from the optical path. The last term may be ignored in the present experiment, since the k_{dif} value of the ground-state N(⁴S) atoms in N_2 at one atmosphere is only 0.3 s^{-1},[1] and k_{dif} is known to be roughly proportional to the reciprocal of the pressure of the solvent gas. In Fig. 6, the apparent decay rates are plotted as a function of the nitrogen pressure. The slope

that the ^2P state, which is higher than the ^2D state by 1.20 eV, is quenched more slowly than the ^2D state. Since the energy level of the ^2P state is higher than that of the ^2D state, the quenching of the ^2P state might produce the ^2D state; therefore, we carefully observed the decay of the ^2D state in the long time-range. But no indication of the production of the ^2D state by the quenching of the ^2P state could be observed in any case.

When a small amount of NO or C_2H_4 was added in the systems studied above, the rapid decays of both metastable states could be observed. The experimental results are shown in Figs. 8 and 9, and the quenching rate constants calculated from these figures are summarized in Table 2. The four rate constants are all of the order of 3×10^{-11} cm³ molecule⁻¹ s⁻¹. About a quarter of all collisions are efficient for the quenching.

Among the reactions of the ground state-nitrogen atoms with molecules, the reaction with nitrogen monoxide has been well established. In order to ascertain whether our apparatus works properly, we have measured the rate constant of this reaction. Figure 10 shows one of the combined oscillograms; one of the traces is for the decay of $N(^4S)$ atoms and the other for the formation and decay of $O(^3P)$ atoms. The measurement of the concentration of the $O(^3P)$

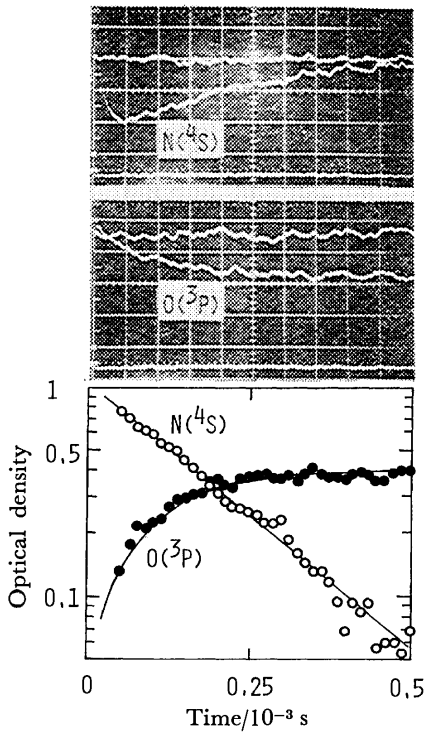

Fig. 10. The oscillograms and the plots of the logarithm of the optical densities for the decay of $N(^4S)$ atoms and for the formation and decay of $O(^3P)$ atoms. The NO pressure is 10.5 mTorr and the N_2 pressure, 198 Torr.

atoms has been discussed previously.[23] These traces correspond to the following reactions:

$$N(^4S) + NO \longrightarrow N_2 + O(^3P), \quad (1)$$

$$O(^3P) + NO + N_2 \longrightarrow NO_2 + N_2. \quad (2)$$

The solid curve for the time dependence of the concentration of $O(^3P)$ atoms was calculated by using the rate constants obtained below.

According to Reactions 1 and 2, the time dependence of the concentration of $O(^3P)$ atoms should be expressed as follows:

$$I_t = I_0[\exp(-k_2[NO][N_2]t) - \exp(-k_1[NO]t)].$$

Here, I_t is the time dependent variable proportional to the concentration of $O(^3P)$ atoms, I_0 is a constant, k_1 and k_2 are the rate constants of Reactions 1 and 2, and [NO] and $[N_2]$ are the concentrations of NO and N_2. When the solid curve for the $O(^3P)$ atoms shown in Fig. 10 was drawn by substituting the rate constants into the above equation, the constant I_0 was adjusted so as to fit the plot obtained at 0.50 ms.

Figure 11 shows the decay rates of $N(^4S)$ atoms as a function of the NO pressure. Here, three different nitrogen pressures and two different charging voltages of Febetron 706 were used; however, as shown in Fig. 11, all the decay rates obtained gave a consistent value. From this linear plot, the rate constant of Reaction 1 was estimated. In this estimation, the reaction of $N(^4S)$ atoms with NO_2, which is the product of Reaction 2, was ignored, since the reaction of N+NO_2 is known to be slower than that of N+NO ($k(N+NO_2) = (1.4\pm0.2)\times10^{-12}$ cm^3 molecule^{-1} s^{-1}),[13] and the concentration of NO_2 produced does not exceed 5% of that of NO. Table 3 compares the present result with those previously reported.

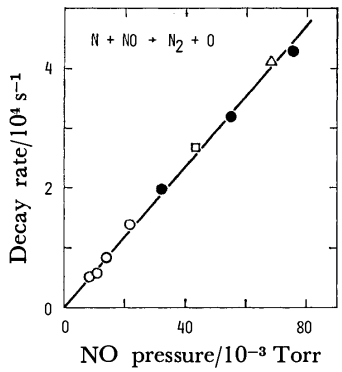

Fig. 11. The decay rates of $N(^4S)$ atoms as a function of the NO pressure. The N_2 pressures are 200 (□), 600 (○,●), and 1000 (△) Torr. The filled symbols denote 20 kV for the d.c. charging voltage of Febetron 706, while the open symbols, 25 kV.

Since Reactions 2 and 3 were much slower than Reaction 1 under the conditions of the present experiments,

$$O(^3P) + NO + He \longrightarrow NO_2 + He, \quad (3)$$

the concentration of NO was increased in the measurement of the rate constants of Reactions 2 and 3. In the time-range used for the measurement of the data shown in Figs. 12 and 13, Reaction 1 is already finished.

Figure 12 shows the decay rates of $O(^3P)$ atoms as functions of the pressures of NO and N_2. From these two linear relations, the rate constant of Reaction 2 can be derived. It is known that the rate constant of the reaction between $O(^3P)$ and NO_2 is comparable to that of Reaction 1 ($k(O+NO_2) = (9.5\pm1.1)\times10^{-12}$ cm^3 molecule^{-1} s^{-1}).[24] Consequently, the NO_2 produced in Reaction 2 might disturb the estimation of the rate constant of Reaction 2. However, as will be shown later, the concentration of NO_2 produced cannot exceed 2×10^{13} molecules cm^{-3}; therefore, the

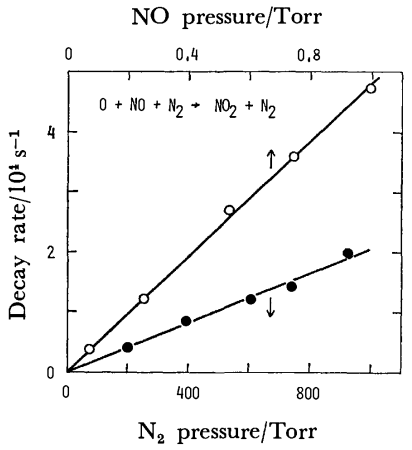

Fig. 12. The decay rates of $O(^3P)$ atoms as functions of the NO (○) or N_2 (●) pressure. When the NO pressure was varied, the N_2 pressure was fixed at 600 Torr, while when the N_2 pressure was varied, the NO pressure was fixed at 0.25 Torr.

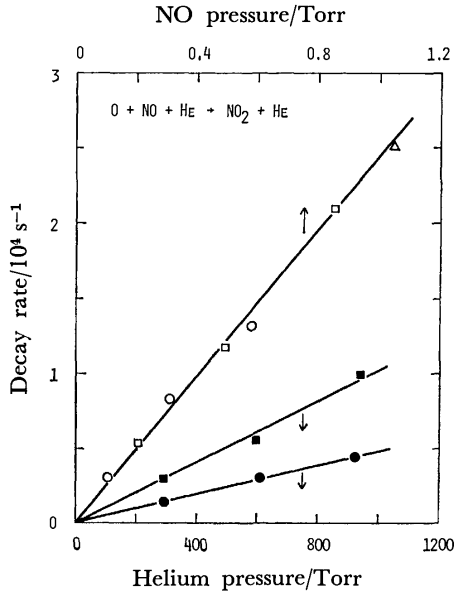

Fig. 13. The decay rates of $O(^3P)$ atoms as functions of the NO or He pressure. The open symbols denote that the He pressure is 600 Torr, while the filled ones denote that the NO pressures are fixed at 0.10 (●) and 0.20 (■) Torr.

disappearance of $O(^3P)$ atoms due to the reaction with NO_2 is less than 10% of that due to Reaction 2, even if the reactant gas consists of 0.25 Torr NO and 200 Torr N_2.

Figure 13 shows the experimental results which can be used for the estimation of the rate constant of Reaction 3. In order to establish the rate constant, various experimental conditions were used, as stated in the figure caption. In six measurements, oxygen was used as the source of oxygen atoms. Since NO is reactive with O_2, the experiments were performed immediately after the mixture of O_2 and He was introduced in the reaction cell containing a known amount of NO.

The apparent decay rate of $O(^3P)$ atoms in this case may be expressed as follows:

$$k = k_{NO}[NO][M] + k_{O_2}[O_2][M].$$

Here, k_{NO} and k_{O_2} are the rate constants of the third-order reactions for the disappearance of $O(^3P)$ atoms, and $[M]=[He]+[NO]+[O_2]$. Since the He pressure is much higher than those of NO and O_2, the following equations may hold: $[M]=[He]$, $k_{NO}=k_3$, and $k_{O_2}=k_4$.

$$O(^3P) + O_2 + He \longrightarrow O_3 + He. \quad (4)$$

Using the rate constant of Reaction 4, which was determined in the previous paper,[23] the decay rate due to Reaction 3 can be estimated. These calculated results are plotted in Fig. 13. All the data obtained under different experimental conditions were found to be consistent with each other. The rate constants calculated from the slopes of the linear relations shown in Figs. 12 and 13 are compared with previous measurements in Table 4.

Discussion

In the previous paper,[23] we estimated the initial concentration of oxygen atoms generated in the mixture of 3 Torr oxygen and 900 Torr He to be about 3×10^{13} molecules cm^{-3}, when the d.c. charging voltage of Febetron 706 was set at 25 kV. In that calculation, the G-value of oxygen atoms was assumed to be 12.8. According to a theoretical calculation,[25] the G-value of nitrogen atoms under similar conditions is about 9; therefore, the initial concentration of nitrogen atoms at 25 kV of the d.c. charging voltage may be in the order of 2×10^{13} molecules cm^{-3}. The concentration of nitrogen atoms is not so high that the quenching of the metastable $N(^2D)$ and $N(^2P)$ atoms by $N(^4S)$

atoms may be ignored. If the quenching by $N(^4S)$ atoms is an important process, the decay rates shown in Figs. 6 and 7 should not be linearly dependent upon the pressure of the solvent gas.

As Table 1 shows, the $N(^2D)$ atoms are quenched by N_2 or He more easily than the higher state $N(^2P)$ atoms, while it is known that the radiative lifetime of $N(^2D)$ is longer than that of $N(^2P)$.[26] Such a reverse order can also be found between $O(^1D)$ and $O(^1S)$ atoms.[27] The quenching rate constants for the metastable oxygen atoms, however, are generally much larger than those for the metastable nitrogen atoms.

The rate constants of the reactions of $N(^2D)$ and $N(^2P)$ with NO and C_2H_4 obtained in the present experiments are a little smaller than those reported previously. One possible reason is that some other reactions contaminate the process; they might participate in the formation of $N(^2D)$ and $N(^2P)$ atoms in the present system. The neutralization reactions such as $N^+ + e^- + M \rightarrow N(^2D \text{ or } ^2P) + M$, however, may be ignored, since the time-range used for the measurement of $N(^2D)$ and $N(^2P)$ atoms is 20 μs–10 ms, while it is believed that the neutralization is completed within 10 μs.[28] If the metastable states higher than ^2P state are produced and if they are quenched to the ^2D and ^2P states in the time-range of ms, the discrepancy stated above may be explained, but it is difficult to imagine that the irradiation of high energy electrons is considerably different from the microwave discharge, which was used by previous investigations in producing the metastable atoms.

The rate constant obtained for the reaction $N(^4S) + NO \rightarrow N_2 + O(^3P)$ is in good agreement with the literature value. Since the rate constant of this reaction is comparable to those of the quenching reactions of $N(^2D)$ and $N(^2P)$ atoms by NO, the following reactions might affect the estimation of k_1:

$$N(^2D \text{ or } ^2P) + NO \longrightarrow N_2 + O \quad (5)$$

$$\longrightarrow N(^4S) + NO. \quad (6)$$

In the present experiments, we can measure only the time dependence of the relative concentrations of N or O atoms, but not the absolute concentrations; therefore, we cannot eliminate the possibility of the participation of Reaction 6 in the formation of $N(^4S)$ atoms. If Reaction 6 is a predominant process compared to Reaction 5, the data shown in Table 3, probably including the results reported from other investigations, need serious corrections. Further studies are obviously necessary.

As Fig. 11 shows, the initial concentration of $N(^4S)$ atoms, which is controlled by the charging voltage of Febetron 706, does not affect the observed rate constant; this fact seems to suggest that the active species such as $N_2(^3\Sigma_u^+)$ state produced by the pulse-irradiation have no effect on the reaction between $N(^4S)$ and NO.

The reaction between $O(^3P)$ atoms and NO is important in the chemistry of the atmosphere. So far, the rate constant of this famous third-order reaction has been measured mainly at low pressures. It may be worthwhile to mention that the present result, which was obtained at higher pressures, is in good agreement with the values obtained at low pressures. In other words, the reaction between $O(^3P)$ atoms and NO does not reach its high pressure limit even at 1000 Torr.

Interaction of 9-Aminoacridinium and 10-Methylacridinium Cations with Polyelectrolytes, with Emphasis on the Bound-dye Spectra[1)]

Kiwamu YAMAOKA,* Mineo TAKATSUKI, and Kinya NAKATA

Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received April 7, 1980)

Visible and UV absorption spectra of two dyes, 9-aminoacridinium (AA) and 10-methylacridinium (MeA) cations, were measured at 25 °C in the presence of three different polyelectrolytes—sodium salts of poly(*p*-styrenesulfonate) (NaPSS), polyphosphate (NaPP), and polyacrylate (NaPA)—for polymer residue-to-dye ratios from zero to near unity. The optical titration curves of AA–polyanion systems showed a slightly sigmoidal curvature. The method of extended principal component analysis was applied to the experimental spectra of the AA–NaPSS, –NaPP, –NaPA and MeA–NaPSS systems. Only two absorbing component dyes, *i.e.*, bound and unbound, were verified to exist in each system. The equilibrium constant of the binding between dye and polyanion, the pure spectrum of bound dye, and the adjustable parameter α, by which the sigmoidal titration curve is characterized, were determined. In each of the above systems, the bound-dye spectrum behaves in opposition to the common notion of "metachromasy," showing a bathochromic shift without any new band. The spectra of MeA changed only moderately by the addition of NaPSS. The ultrafiltration of the MeA–NaPP and –NaPA solutions confirmed that most of the MeA cations remain unbound.

Although the physicochemical basis of metachromasy still remains to be clarified becasue of its extraordinary complexity, it has become apparent that the metachromatic behavior of a cationic dye depends on the combination between its chemical structure and the charged functional group and conformation of the associated polyelectrolyte.[2–4)] The metachromasy of acridine dyes is known to be most marked in the presence of charged polyanions of various types when the dyes possess the exonuclear amino or disubstituted amino groups at the 3- and 6-positions.[5)] Indeed, the symmetric 3,6-substituted aminoacridines and their derivatives such as Proflavine (PF),[6)] Trypaflavine (TF),[2–4,7)] and Acridine Orange (AO)[6,8)] have been most extensively documented. Their interactions with both natural and synthetic polyanions have been studied theoretically and experimentally from two points of view: metachromatic changes of absorption spectra[8)] and binding reactions.[10)]

By means of the extended principal component analysis (the EPCA procedure), the interactions between TF, one of the most typical 3,6-diaminoacridines, and various polyanions were recently studied to extract the bound-dye spectrum out of a family of experimental spectra.[2)] The result is surprising in that each unmasked spectrum of bound TF always shows two broad but distinct bands whose maxima are located on both the longer- and shorter-wavelength sides of the original peak of TF without polymer. This finding requires some modifications to be made in the concept of metachromasy, which has been defined as the hypsochromic and hypochromic changes in color.[11)] The complexity of spectral changes of the dye–polymer systems is mainly associated with the elusive behavior of the visible absorption spectra of the above dyes, which belong to the C_{2v} point symmetry group and should, therefore, have two orthogonally polarized transition moments. A recent work on the film dichroism of those dyes ascertained beyond doubt that both the short-axis polarized band (the ^1L_a band) and the long-axis polarized band (the ^1L_b band) are involved in the seemingly simple absorption band.[12,13)]

It is now clear that use of some acridine dyes optically simpler than TF will help to understand the physical basis of metachromasy and, possibly, the binding mechanism. Both 9-aminoacridinium (AA) and 10-methylacridinium (MeA) cations are suited to this purpose. Each absorption spectrum shows two unequivocally assigned bands (the ^1L_a and ^1L_b bands) which are widely separated, so that the observed spectral changes may be related to each transition.[12–14)] Furthermore, both AA and MeA have been shown to bind to DNA and other polyelectrolytes.[15–21)] In this work, the observed absorption spectra of these dyes in the presence of three different polyanions were treated by the EPCA procedure to extract the spectra of AA and MeA bound to the polymers; the polymer residue-to-dye mixing ratios from zero to near unity were investigated. The optical titration data were analyzed to evaluate the apparent equilibrium constant and the molar fraction of the bound dye species.

Experimental

Materials. The three polymer and two dye samples used in this work are sodium poly(*p*-styrenesulfonate) (NaPSS, the degree of polymerization DP=1360),[2)] sodium polyphosphate (NaPP, DP=154),[2)] sodium polyacrylate (NaPA, DP=7700),[2)] 9-aminoacridinium chloride (denoted simply as AA),[4,20)] and 10-methylacridinium chloride (denoted as MeA).[12,20,21)]

Preparations of Sample Solutions. The dye concentration was determined by the use of the molar absorption coefficients, ε in $M^{-1}cm^{-1}$ (1 M=1 mol dm^{-3}), 10500 at 401 nm for AA and 21000 at 357 nm for MeA. The absorption of the dye–polymer solution was expressed with the apparent ε of the dye present in the solution, unless otherwise stated. The dye–polymer solution contained neither extra neutral salts nor buffer salts to avoid any side effects.[7)] A concentrated polymer solution (*ca.* 2 mM) was delivered dropwise to a dye solution (7 or 14 ml) in an optical cell (either 2 cm or 5 cm in path length) through a microburet (20 μl in each portion). The mixture was stirred for a few minutes before measuring each absorption spectrum. The molar mixing ratio of polymer residues to dye (P/D) was thus varied from zero to slightly over unity without appreciable volume increase. The volume correction for the observed absorbance was always made according to the procedure given in Ref. 2.

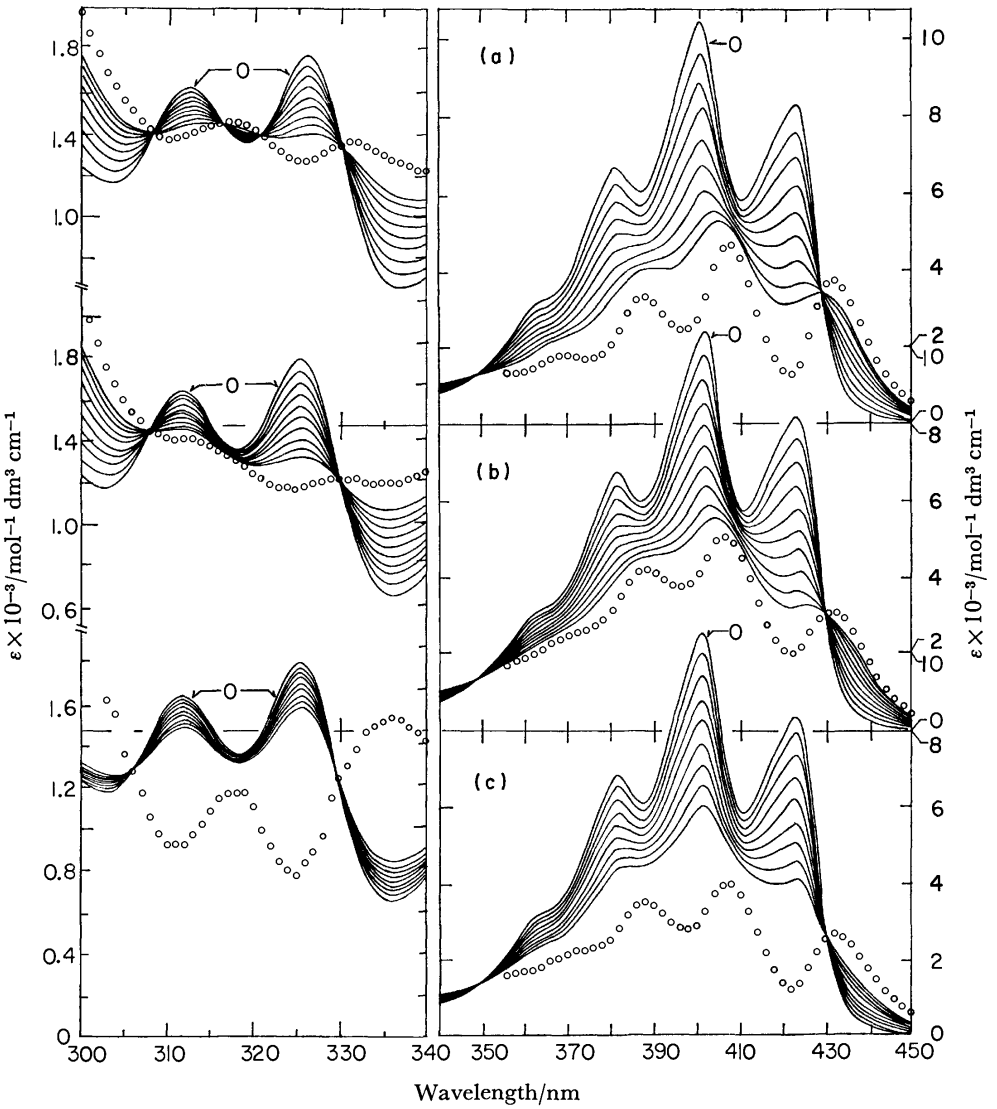

Fig. 1. The observed visible and UV absorption spectra of AA in the presence of (a) NaPSS, (b) NaPP, and (c) NaPA in the *P/D* range between 0 and nearly unity as specified below, together with the corresponding bound-dye spectra (circles).
The dye concentrations in mol/dm³ are: (a) 3.83×10^{-5}, (b) 4.43×10^{-5}, and (c) 3.78×10^{-5}. The pH values of the dye-polyanion systems are in the range of 6—7. In each family of spectra, the *P/D* values are in the following order which corresponds to the decrease in absorptions at 401 and 326 nm: (a) 0, 0.122, 0.243, 0.365, 0.486, 0.608, 0.730, 0.851, 0.973; (b) 0, 0.113, 0.226, 0.339, 0.451, 0.564, 0.677, 0.789, 0.902, 1.015; (c) 0, 0.160, 0.320, 0.481, 0.641, 0.801, 0.961, 1.120, 1.280. The isosbestic points in nm are: (a) 429, 349, 330, 320.6, 316, 308.3; (b) 429, 351, 330, 308; (c) 430, 351, 330, 306.

Ultrafiltration. Filtration experiments were performed, whenever needed, to detect the presence of unbound dye in the dye–polymer solutions in a manner similar to a previous case.[7]

Measurements. The absorption spectra were measured at 25 °C in the same manner as before.[2-4] The 5 cm and 2 cm cells were used for the visible and UV regions, respectively.

Data Analysis by the EPCA Procedure. The EPCA method utilized in this work has been described in detail elsewhere.[2-4,22] Since the number of the absorbing components involved in the present dye–polymer system was determined to be two (*vide post*), a generalized empirical expression (Eq. 1) was employed to describe the binding equilibrium between a dye D and a dye–polymer complex PD*:

$$K = \frac{[DP^*]}{[D][P]^{\alpha}}, \qquad (1)$$

where the notations have the same meaning as before.[2] The α is an empirical, adjustable parameter.

Results and Discussion

Visible and UV Absorption Spectra of the AA–Polymer Systems. The observed visible and UV spectra of AA in the presence of NaPSS, NaPP, and NaPA are shown over a *P/D* range of 0—1 in Figs. 1(a)—(c). The longest-wavelength band of AA in the 450—350 nm region is the short-axis polarized transition (the

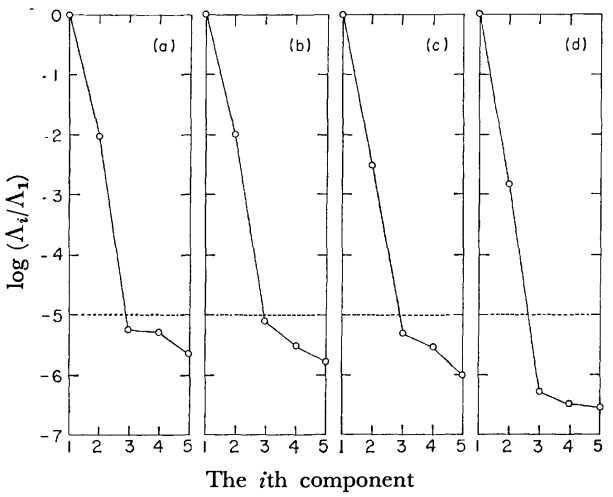

Fig. 2. Variations in the eigenvalue Λ_i (i=1, 5) with the ith absorbing component for three AA–polyanion systems [(a) NaPSS, (b) NaPP, and (c) NaPA] and for the MeA–NaPSS systems (d).

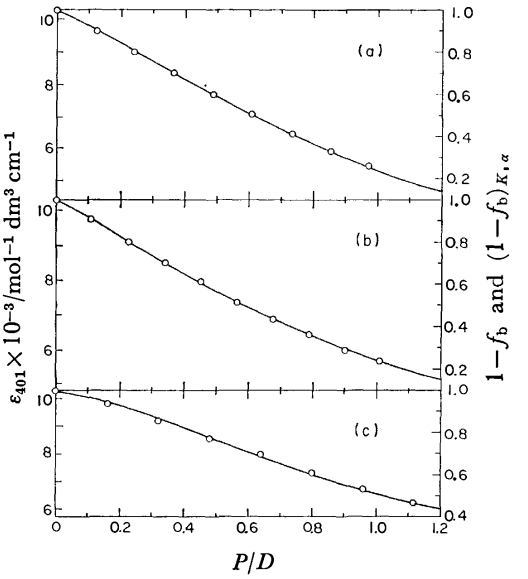

Fig. 3. Optical titration data of three AA–polyanion systems [(a) NaPSS, (b) NaPP, and (c) NaPA] and the fraction of bound AA.
The titration data (open circles) are plotted in terms of ε_{401} (left ordinate) against P/D. The fractions of unbound dye are also plotted against P/D (right ordinate). They were calculated by two different methods; $(1-f_b)_{K,\alpha}$ from the values of K and α according to Eq. 2 of Ref. 3 (it is drawn with the solid curve) and $(1-f_b)$ directly from the EPCA procedure with the aid of Eq. 4 of Ref. 3 (it is actually undistinguishable with the circle).

^1L_a band), *i.e.*, the axis is in the direction bisecting the 10-nitrogen and 9-carbon atoms of the acridine nucleus, while the short-wavelength band in the 340–300 nm region is the long-axis polarized band (the ^1L_b band), *i.e.*, the axis is perpendicular to the short axis in the molecular plane.[14] The ^1L_a band of AA with a vibrational structure and the ^1L_b band both decreased batho- and hypochromically by the dropwise addition of any of the three different polyanions. The peaks and shoulders of these bands were shifted toward the long wavelengths, but all fine structure was clearly retained. These spectral changes are contrary to the previous results for the 3,6-disubstituted acridine dye-polymer systems for which the hypso- and hypochromic effects were noted in a P/D range below unity.[2,3,6,8–10,23]

In each family of the spectra in Fig. 1, the isosbestic points (*cf.* the caption of Fig. 1) exist for both the ^1L_a and ^1L_b bands. The existence of these isosbestic points strongly indicates that two dye species, *i.e.*, unbound and bound, are present in each dye–polymer system.[2,3] Comparison of these points between three AA–polymer systems also indicates that the spectral profiles of AA bound to three polyanions are similar to one another, in spite of the marked differences in their ionized monomer units and molecular weights. In order to ascertain the number of absorbing species in each system, the PCA procedure was applied to the data spectra given in Fig. 1.

The Number of Absorbing Species in the AA–Polyanion Systems. In each system, the data matrix $\boldsymbol{D}$ was constructed with a set of absorbances at 48 selected wavelengths, at 2 nm intervals, between 356 nm and 450 nm and with a set of ten or nine experimentally obtained absorption spectra. The variation of the ith eigenvalue, Λ_i, with the ith component is shown in Fig. 2, where the ratios of Λ_i to Λ_1 are plotted on a logarithmic scale against components. It is clear from Figs. 2(a)—(c) that a large gap in eigenvalues exists between the second and third components (i=2 and 3) for each AA–polyanion system. In addition, the ratio of the eigenvalue of the third component Λ_3 to that of the first component is at most 1×10^{-5} (the dotted lines), which does not fulfill the criterion previously set for a genuine component.[2,22] These results can be taken as evidence that there are indeed two light-absorbing species in each system, *i.e.*, bound and unbound AA.

Optical Titration Curves and the Fraction of Bound AA. The optical titration curves of the AA–polyanion systems are shown in Fig. 3, where the apparent ε values at 401 nm, the peak position of free AA, were plotted against P/D. The ε values decrease with a slightly sigmoidal curvature with the increase in P/D, as was already noted for other dye–polymer systems.[2,3] To reproduce these titration data, the EPCA procedure was applied to the visible absorption spectra of each system shown in Fig. 1 with the aid of Eq. 1. The values of the parameter α and the equilibrium constant K were evaluated and are given in Table 1. The α values are larger than unity, as is expected from the sigmoidal curvature of the titration data.[2,3] The K' value at P/D=1 is a measure which can be compared with the commonly used equilibrium constant for a binding reaction, *viz.*, $K'=[DP^*]([D]\cdot[P])^{-1}=K[P]^{\alpha-1}$. The K' values are of the same order of magnitude as those obtained for other acridine dye–polyanion systems, indicative of a high binding ability of AA.[2]

The molar fraction of bound dye, f_b, is defined as the ratio of the concentration of bound dye to the

sum total of the concentrations of bound and free dyes in solution. The values of $(1-f_b)$ were calculated by two different methods, which are described in detail in Ref. 3 (*cf.* Eqs. 2 and 4 given therein). The calculated $(1-f_b)$ curves are shown for three AA–polyanion systems in Fig. 3. It is clear from Fig. 3 that AA binds to these polyanions by 50% or more at a P/D of unity in spite that AA is rather simple and small in molecular size as compared with TF.[2)]

Visible and UV Spectra of Bound AA. A major advantage of the EPCA method is the simultaneous determination of the bound-dye spectrum and the equilibrium constant for a given dye–polymer system.[2–4,22)] The pure spectra of bound AA in three AA–polyanion systems, extracted from the observed absorption spectra in the visible region, are shown by open circles in Figs. 1(a)—(c). Since the changes in the observed UV spectra of the same systems are not large enough for the EPCA method to be applied with high accuracy, the bound-AA spectra in the UV region were calculated by the use of the value of f_b, which was obtained from the binding curve $(1-f_b)$, and the observed ε_λ at a given wavelength λ. The molar absorption coefficient of the bound dye, ε^b_λ, at the same wavelength can be expressed as

$$\varepsilon^b_\lambda = \varepsilon^f_\lambda + \frac{\varepsilon_\lambda - \varepsilon^f_\lambda}{f_b}, \qquad (2)$$

where ε^f_λ is the molar absorption coefficient of the unbound dye at λ.

The unmasked bound-AA spectra reveal a number of interesting points. First, they all show a large bathochromic, but not hypsochromic, shift. As the spectral data in Table 2 indicate, the ^1L_a bands are shifted by 10 nm toward the red. Secondly, both ^1L_a and ^1L_b bands of the bound spectra retain the spectral profile of the original AA as regards the vibrational structure and the separation of successive subbands. In particular, no new band appears in the bound-AA spectra. Thirdly, the ^1L_a and ^1L_b bands of the bound spectra are both hypochromic, *i.e.*, the intensity of AA is decreased tremendously by its binding to a polymer site. The first and second features are in contrast with the definition of metachromasy[11)] and also with the observed metachromatic behavior of the 3,6-diaminoacridine and its derivatives which

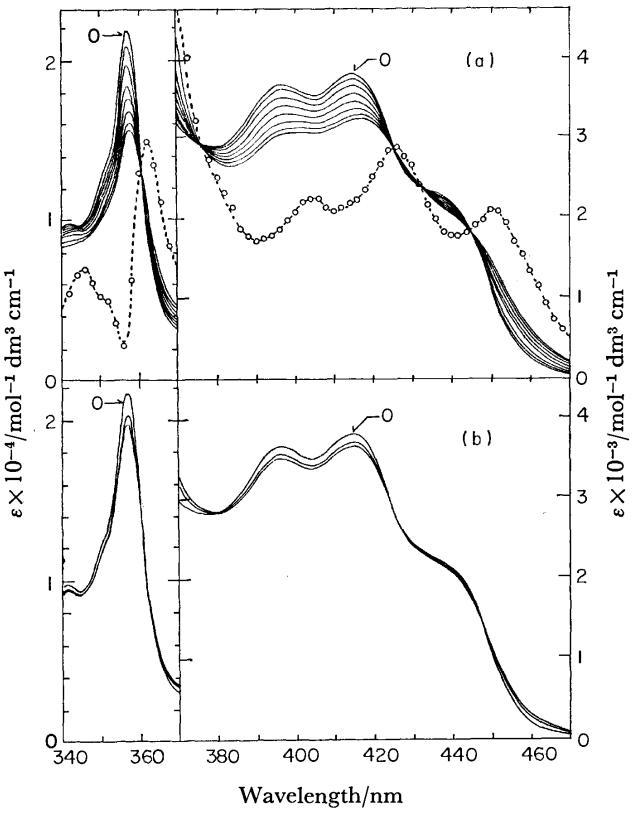

Fig. 4. The observed visible and UV absorption spectra of MeA in the presence of (a) NaPSS and (b) NaPP in the *P/D* range between 0 and nearly unity as specified below, together with the corresponding bound-dye spectrum (circles).
The dye concentrations are 2.20×10^{-5} mol dm^{-3} for both (a) and (b). The isosbestic points in nm are 445, 430.5, 426, 376.5, 360.5 in (a). The *P/D* values are in the following order which corresponds to the decrease in absorptions at 357 and 415 nm: (a) 0, 0.171, 0.342, 0.513, 0.685, 0.856, 1.027, 1.20.

are bound to synthetic polyelectrolytes in the low *P/D* range.[2,3,24]

Visible and UV Absorption Spectra of the MeA–Polyanion Systems. The observed visible and UV absorption spectra of MeA in the presence of NaPSS and NaPP are shown in Figs. 4(a) and (b), respectively. The absorption band of MeA in the 470—370 nm region is the short-axis polarized transition (^1L_a), while the band in the 370—340 nm region is the ^1L_b band.[12,13] In contrast with the cases of AA, the spectra of MeA changed only moderately by the dropwise addition of NaPSS and only silghtly with NaPP. It should be noted that the spectra of the MeA–NaPA system changed less than 10% in the *P/D* range between 0 and near 2. This trend is peculiar in the sense that all three polymers can be bound to AA in very favorable proportions and that the chemical structure of MeA does not seem to differ from that of AA. Thus, it appears that the observed discrepancy should be accounted for by some other reasons.

The ultrafiltration of both the MeA–NaPP and –NaPA solutions at a *P/D* value near 3 was performed. The filtrated solutions all showed the absorption spectrum characteristic of MeA free from either NaPP or

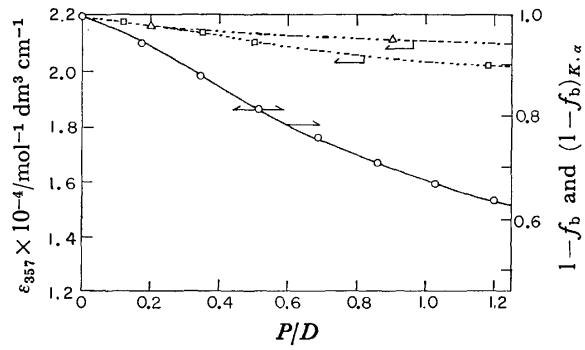

Fig. 5. Optical titration and the fraction of bound MeA.
The titration data (open symbols) are plotted with ε_{357} (left ordinate) against *P/D*.
(○) NaPSS, (□) NaPP, (△) NaPA. The fraction of unbound MeA was calculated only for the MeA–NaPSS system in the same manner as noted in Fig. 3.

NaPA. This result thus leads to the conclusion that most of the MeA cations in the NaPP or NaPA solution remain unbound and are filterable through a semipermeable membrane. Under considerations of the degree of polymerization of these polymers (see Experimental), this conclusion can not be explained by the size (or chain length) effect. Hence, it is most reasonable to attribute the difference in binding abilities to the geometry and the chemical properties of the ionized binding site of the polymer (sulfonate *versus* phosphate and carboxylate residues).

The experimental spectra of MeA–NaPSS system are, however, sufficient to reveal the spectral behavior of the bound MeA. As the *P/D* values increase, the intensity of both the ^1L_a and ^1L_b bands of MeA decreases with a concomitant shift toward the red, similarly to the case of the AA–NaPSS system. The result of the PCA treatment is shown in Fig. 2(d), where a large gap exists between the second and third components. Hence, the MeA–NaPSS system is indeed verified to contain two absorbing species, bound and unbound MeA.

Optical Titration, Fraction, and Spectrum of MeA Bound to NaPSS. The optical titration data of the MeA–polyanion systems are shown in Fig. 5, where the apparent ε values at 357 nm, a peak wavelength of free MeA, were plotted against *P/D*. The ε values of MeA in the presence of NaPSS decrease sigmoidally, which is in accord with an α value larger than unity. The fractions of MeA bound to NaPSS, $(1-f_b)_{K,\alpha}$, were calculated with the values of α and K given in Table 1. It is clear from Fig. 5 that more than 30% of MeA are bound to NaPSS at $P/D=1$ and that the calculated curve agrees well with the observed ε values. This latter result assures us that the EPCA procedure was applied properly. As are shown in Fig. 5, the changes in ε values with *P/D* are very small for the MeA–NaPP and –NaPA systems; for these, therefore, the α and K values could not be evaluated by the EPCA method.

The visible spectrum of MeA bound to NaPSS was extracted from the observed spectra, while the UV spectrum of the bound MeA was calculated with Eq.

2 from the f_b values in Fig. 5. The bound spectrum of MeA (circles in Fig. 4) is again, as in the case of bound AA, bathochromic and hypochromic relative to the unbound MeA. The optical data are given in Table 2, which shows that the separations of the successive peaks of the visible band (^1L_a) remain nearly constant for each of the unbound and bound MeA species. Thus, it can be concluded that the bound MeA retains the spectral features of unbound MeA itself showing neither a new "metachromasy band" nor metachromatic behavior, *viz.*, the blue shift of the absorption bands, in the presence of NaPSS.

Closing Remarks on Bound-dye Spectra and Binding Ability of AA and MeA. The bound-AA and -MeA spectra should result from the dyes which are bound to polymer sites to a maximal extent, since they are extracted in the P/D range between 0 and near unity. Yet, the AA and MeA spectra bound to various synthetic polyanions show the bathochromic and hypochromic changes, *i.e.*, both the short-axis and long-axis polarized bands shift toward the red rather than the blue. This trend is evidently opposite to the previous results obtained for 3,6-diaminoacridines, TF[2] and AO,[23] and contradicts the widely prevailing notion of metachromasy, *i.e.*, the shift of the visible absorption maximum toward the blue with a concomitant decrease in its intensity.[11] The spectrum of MeA bound to NaPSS (Fig. 4) is surprisingly close to that of MeA bound to DNA, in spite of a vast difference in their primary and secondary structures.[21] Hence, the bound-AA and -MeA spectra are rather insensitive to the structure of the ionizable groups of polymers and their overall conformations. The apparent equilibrium constants are in the order of NaPSS>NaPP>NaPA for AA, and NaPSS>NaPP≈NaPA for MeA. As regards the dye species, the fraction of bound AA is about equal to that of previously reported TF[2] at a P/D value of unity, but much higher than that of MeA, which is the simplest of all acridine dyes. The binding reactions between both AA and MeA and three polyanions seem to resemble the previous cases in which TF and Crystal Violet were employed,[2,3] although spectral changes of the former differ from those of the latter. Hence, it may be inferred that the binding mechanism formally expressed by Eq. 1 prevails in many dye–polymer combinations.

Singlet Energy Transfer in *p*-Terphenyl Crystal Doped with Tetracene

Hiroyuki SHINOHARA and Masahiro KOTANI*

Faculty of Science, Gakushuin University, Mejiro, Toshima-ku, Tokyo 171

(Received April 21, 1980)

The transfer of singlet energy in *p*-terphenyl crystal was measured as a function of the dopant (tetracene) concentration and the temperature. The simple hopping model yields a value of 3×10^{-14} s. This value is believed to be correct within a factor of 5. In the low temperature phase of the crystal, the energy transfer is temperature dependent with an activation energy of 66 cm^{-1} in undeuterated *p*-terphenyl and 90 cm^{-1} in perdeuterated *p*-terphenyl. It seems probable that in the low temperature phase the freedom of the conformational change of the molecule plays an important role in the energy migration.

p-Terphenyl is known as one of the fastest scintillators. Its short fluorescence lifetime (5 ns in the crystalline state) and the consequent excellent pulse pair separation makes the measurement of very high count-rates possible. The energy migration in *p*-terphenyl crystal is interesting because the molecule has some freedom of conformational change. There is some evidence that the three benzene rings of the free molecule are not coplanar in the electronic ground state, whereas the molecule tends to be planar in its electronic excited states.[1] Thus it is possible that the migration of the electronic excitation energy is accompanied by some molecular deformation. The energy migration in *p*-terphenyl crystal, however, has not been well investigated, seemingly just because the short lifetime makes the detailed investigation difficult.

Long range migration of excitation energy in organic crystals has been commonly studied with either of the two experimental approaches. One is based on the observation of sensitized luminescence from doped crystals, wherein guest molecules act as emission centers. The intensity[2] or the lifetime[3-5] of the host and the guest emission is measured as a function of the guest concentration. A bimolecular reaction between a singlet exciton which migrates over the host lattice and a guest molecule is thought to give rise to the guest emission. The other involves the analysis of the bimolecular annihilation of two singlet excitons.[6-9] This approach is superior to the former in the sense that doping is not necessary and the possible complications therefrom need not be considered. However, the precise knowledge of the initial concentration and the temporal behavior of the excitons which is needed limits the application of this method to materials with relatively long lifetimes.

In the present work the singlet energy migration in *p*-terphenyl crystal doped with tetracene was investigated with the steady state excitation. This system is ideal in that the solubility of tetracene in *p*-terphenyl crystal is very high. This makes the segregation of microcrystals of the dopant improbable, which is the major difficulty when data for a wide range of dopant concentration is needed. It also means that the distortion of the host lattice caused by the doping will be minimal. Another advantage of the system is the small overlap of the absorption and the emission spectra of *p*-terphenyl crystal. This feature makes the reabsorption of the fluorescence unimportant. It is to be noted also that the host and the guest fluorescence are well separated. The correction for the overlap of the respective fluorescence and for the absorption are accordingly unimportant and hence the quantitative determination of the relative intensity is possible.

Experimental

p-Terphenyl (GR grade, Tokyo Kasei Co.) was purified by column chromatography with activated alumina and by zone melting. The trace amount of tetracene in the starting material was removed by refluxing with maleic anhydried. Perdeuterated *p*-terphenyl (Merck Sharp and Dohme) was purified by chromatography and by zone melting. After extensive zone melting the crystal gave the same fluorescence spectrum as that of the undeuterated compound. The tetracence (Eastman) used as dopant was sublimed *in vacuo*. "Pure" *p*-terphenyl showed no detectable sensitized fluorescence and had a triplet lifetime of $\approx$100 ms. A weighed amount of tetracence was added to the "pure" *p*-terphenyl to give a sample with a dopant concentration of 10^{-2} mol/mol. Doped crystals of various concentrations were made by successively diluting this highly doped sample with the "pure" *p*-terphenyl. This procedure may be justified because the solubility of tetracene in *p*-terphenyl is practically unlimited, as described below. Crystals with tetracene concentration of 10^{-7} mol/mol prepared with this procedure exhibit faint sensitized fluorescence, whereas the "pure" sample showed no detectable guest fluorescence. This observation eventually showed that the concentration of tetracence in the "pure" sample was less than 10^{-7} mol/mol.

Melting point of doped crystals were measured in a stirred silicone oil bath and were observed visually.

Emission spectra were measured with a fluorescence spectrophotometer (Hitachi, MPF 2A). Temperature was controlled either by flowing cold nitrogen gas in a quartz cryostat or by thermal conduction using liquid nitrogen. The fluorescence lifetime was measured with the single photon counting technique with an air gap spark (pulse width 6 ns) as the excitation light source.

Results

Melting points for the samples with tetracene concentration up to 30 mol% were measured (Fig. 1). The fluorescence spectra of *p*-terphenyl crystal and of tetracene doped in *p*-terphenyl crystal are shown in Fig. 2. Also shown in the figure are the absorption spectrum of *p*-terphenyl and the excitation spectrum of the fluorescence of tetracene doped in *p*-terphenyl monitored at 530 nm. Figure 3 shows the concentration dependence of the ratio I_G/I_H, the intensity of the guest fluorescence observed at 570 nm

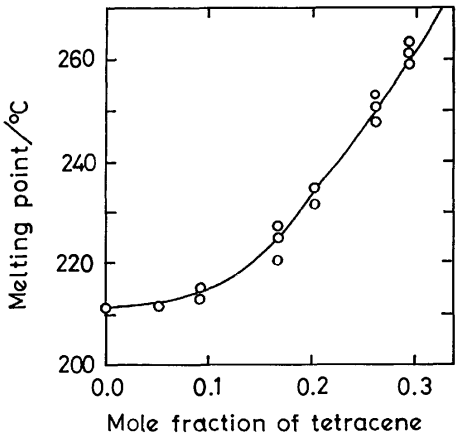

Fig. 1. Melting point of *p*-terphenyl doped with tetracene. The melting point goes up with the concentration of tetracene, indicating that *p*-terphenyl forms a solid solution in this concentration range.

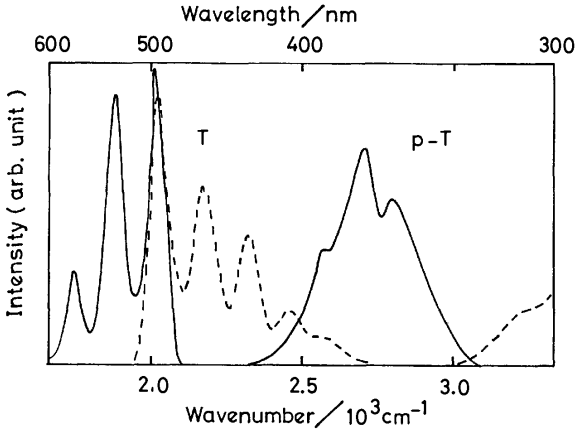

Fig. 2. Full lines (——) show the fluorescence spectra of *p*-terphenyl crystal (*p*-T) and of tetracene (T) doped in *p*-terphenyl. Dashed lines (----) show the absorption spectrum of *p*-terphenyl crystal and the excitation spectrum of the fluorescence of tetracene (as doped in *p*-terphenyl) monitored at 530 nm. The radiative transfer is not important in the system *p*-terphenyl doped with tetracene. The reabsorption of the fluorescence of *p*-terphenyl by *p*-terphenyl itself is also small.

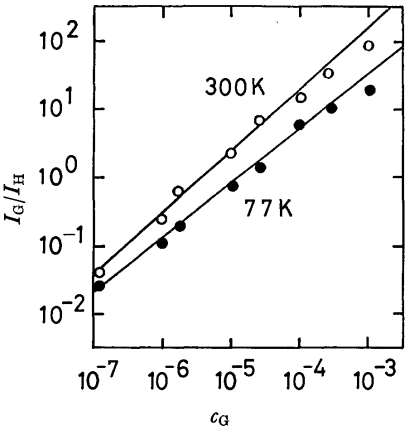

Fig. 3. The relative intensity of the guest fluorescence (I_G) over the host fluorescence (I_H) as a function of the mole fraction of tetracene (c_G).
The intensities are coreected for the detector sensitivity. ○; 300 K, ●; 77 K.

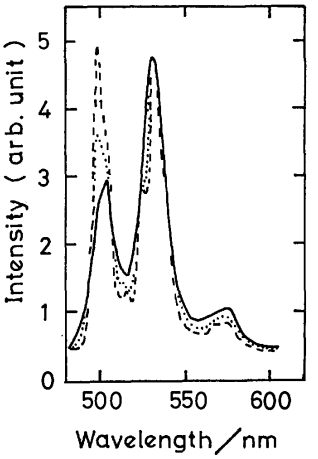

Fig. 4. Fluorescence spectra of tetracene doped in *p*-terphenyl (not corrected) showing the effect of reabsorption at different temperatures. The fluorescence was excited with 460 nm light (direct excitation of the guest).
---- 77 K, ····· 135 K, —— 300 K. $c_G = 1 \times 10^{-3}$ mol/mol. The intensity of the guest fluorescence (I_G) throughout this work was monitored at 530 nm.

over that of the host fluorescence observed at 370 nm, each corrected for the spectrometer sensitivity and expressed in a unit proportional to photons/s. The result is best fitted by

$$I_G/I_H = Ac_G^n, \quad (1)$$

with

$$A = 5.6 \times 10^5,\ n = 0.91 \pm 0.1,$$

for 300 K and

$$A = 9.4 \times 10^3,\ n = 0.81 \pm 0.1,$$

for 77 K; c_G is the mole fraction of the guest. The above wavelengths were chosen in order to minimize the effect of reabsorption. Figure 4 shows an effect of the reabsorption. It shows the emission spectra of the guest at different temperatures, excited at 460 nm (direct excitation of tetracene). The intensity of 570 nm peak relative to that at 530 nm is constant, whereas the relative intensity at 500 nm decreases with rising temperature. This is caused by the reabsorption of emitted fluorescence by tetracene itself. Reabsorption is significant at higher temperatures. Figure 5(a) shows the temperature dependence of I_H for an "pure" sample. Figure 5(b) shows the variation of I_H and I_G with temperature for a sample with the guest concentration of 10^{-5} mol/mol. The temperature dependence of I_G/I_H is shown in Fig. 6. Activation energies of 66 cm^{-1} for undeuterated *p*-terphenyl (*p*-T-h_{14}) and 90 cm^{-1} for perdeuterated *p*-terphenyl (*p*-T-d_{14}) were obtained from the slope of the straight parts of the figures corresponding to temperatures lower than 200 K.

Discussion

Solubility. *p*-Terphenyl exhibits a higher melt-

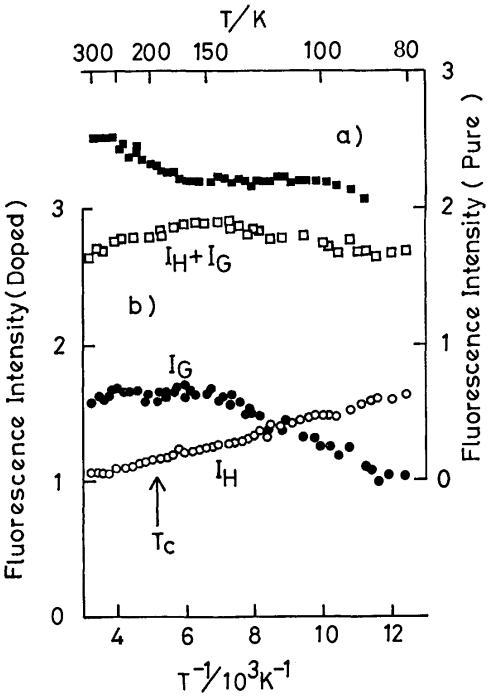

Fig. 5. (a) Temperature dependence of the fluorescence intensity (right ordinate) of an undoped *p*-terphenyl crystal. It is seen that the fluorescence quantum yield is constant within 15%. (b) Temperature dependence of the host (I_H) and the guest (I_G) fluorescence intensity of a doped crystal (left ordinate). Note that the sum (I_H+I_G) is nearly independent of temperature, showing that the radiationless decay is not important. T_c denotes the phase transition temperature.

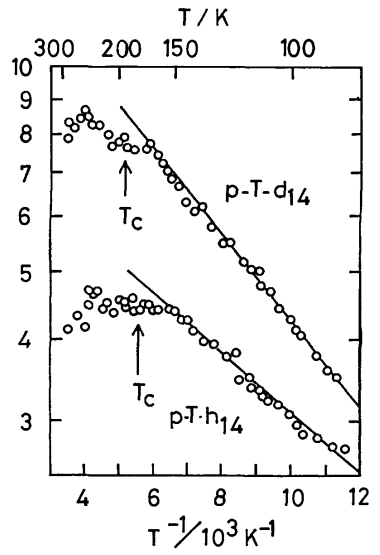

Fig. 6. Temperature dependence of the relative fluorescence intensity (I_G/I_H). Activation energies are 66 cm^{-1} for *p*-T-h_{14} and 90 cm^{-1} for *p*-T-d_{14}. T_c denotes the phase transition temperature.

ing point when it is doped with tetracene (Fig. 1). During zone refining it was noticed that the distribution coefficient k (concentration in the solid phase/concentration in the liquid phase) is larger than unity; tetracene accumulated at the top of the zone refining tube. These facts indicate that the solubility of tetracene in *p*-terphenyl crystal is very high. In this respect this system is basically different from the classical system of tetracene in anthracene, in which the solubility of tetracene is reported to be $\approx 10^{-5}$ mol/mol.[10] *p*-Terphenyl crystallizes in monoclinic form and tetracene has a triclinic lattice, so they are not isomorphic. Accordingly, they can not form a solid solution for the entire concentration range. However, the similar size and shape of the molecules of the two compounds seem to make possible the formation of the solid solution in a rather wide concentration range.

Kinetics. If a *p*-terphenyl crystal (host, hereafter with subscript H) doped with tetracene (guest, hereafter with subscript G) is illuminated with light of intensity I, the rate equations for the concentrations of the host and the guest singlet excited states are[2]

$$dS_H/dt = \alpha I - k_H S_H - k_{HG} S_H, \quad (2)$$

and

$$dS_G/dt = k_{HG} S_H - k_G S_G, \quad (3)$$

where α is the absorption coefficient, k_H and k_G are the monomolecular decay constants, and k_{HG} is the rate constant of the energy transfer. In the steady state condition

$$dS_H/dt = dS_G/dt = 0,$$

and the ratio of the fluorescence intensity I_G/I_H is given by

$$I_G/I_H = k_G^* S_G/k_H^* S_H = k_G k_{HG}/k_H^* k_G = \eta_G k_{HG}/\eta_H k_H, \quad (4)$$

where k^*'s are the radiative rate constants and η's are the fluorescence quantum yields.

The observed concentration dependence of I_G/I_H (Fig. 3) comes from the concentration dependence of k_{HG}, if η_G is constant. This is likely for the low concentration range of concern (10^{-7} to 10^{-3} mol/mol), where the trap-trap interaction must be negligible. If it is assumed that k_{HG} is proportional to the guest concentration, *i.e.*, $k_{HG}=c_G/t_h$, where t_h is the hopping time of the exciton,

$$I_G/I_H = \eta_G c_G/t_h \eta_H k_H. \quad (5)$$

From the fact that I_G/I_H is unity at the concentration of 5×10^{-6} mol/mol and the observed fluorescence decay time of 5.3 ns ($=1/k_H$) the hopping time, t_h, of an exciton on a lattice site is obtained to be 3×10^{-14} s (300 K) or 6×10^{-14} s (77 K), with an assumption $\eta_G/\eta_H=1$. It is possible that, with this assumption, we underestimate t_h by a factor of 3—5. The hopping time is shorter than that in anthracene, which is in accord with the result by Belitz, who measured the effect of doping on the fluorescence lifetime by using the phase method.[10] The spectral overlap of the host fluorescence and the guest absorption, which is the key factor in determining the host-guest energy transfer efficiency, is larger in anthracene–tetracene mixed crystal than in *p*-terphenyl–tetracene system. In the above analysis we have assumed that the last step of the energy migration, namely the transfer of the excitation energy to the guest molecule, is diffusion-limited. If it is not diffusion-limited, the result in Fig. 3 implies that t_h is even smaller than that given above.

The hyperlinear concentration dependence, *i.e.*, $n<1$ in Eq. 1, has been observed in several materials.[11-14] The deviation is small, but definitely present. It introduces an uncertainty of a factor of 2 in determining the value of k_{HG}. The attempt to explain it by a simple diffusion theory or by random walk consideration has not been successful so far.[15] In this work we analyze the result in terms of the simple hopping model, although the fact $n<1$ is not compatible with the assumption $k_{HG}=c_G/t_h$, at least in principle. The understanding of this feature awaits further investigation. It is interesting that Auweter *et al.* have found that the time dependent part of k_{HG} in naphthalene crystal is important for low dopant (anthracene) concentrations and that it is not simply proportional to the guest concentration.[9] It is to be noted that the hyperlinear dependence has been observed only for singlet energy transfer, but not for triplet.

Temperature Dependence of the Energy Transfer. The temperature dependence is quite different from that for anthracene and for naphthalene. In anthracene crystal the rate constant for the bimolecular annihilation, γ_{ss}, has been found to be proportional to $T^{-1/2}$; this has been explained in terms of the scattering of excitons by phonons.[16] In naphthalene, γ_{ss} is almost temperature independent.[9] Figure 4 shows that the fluorescence quantum yield of tetracene in *p*-terphenyl lattice, when corrected for the reabsorption, is independent of temperature. It is shown in Fig. 5(b) that I_G and I_H change with temperature, whereas the sum, I_H+I_G, shows only a slight variation in the temperature range 85—300 K. This shows that the quantum yield of the total fluorescence from the mixed crystal does not change within this temperature range and indicates that the effect of the traps for singlet excitons that may act as quenchers is not significant. Thus it seems reasonable to assume that the observed temperature dependence of I_G/I_H (Fig. 6) corresponds to that of k_{HG}. We may thus conclude that the energy transfer in *p*-terphenyl crystal is almost temperature independent in the temperature range 300—160 K (*p*-T-h_{14}) or 300—170 K (*p*-T-d_{14}) and that at lower temperatures the temperature dependence changes to that with an activation energy.

p-Terphenyl undergoes a phase transition around 190 K.[17-20] In the high temperature phase the molecules are planar. However, the amplitude of the rotational vibration of the central benzene ring about the molecular long axis is large and is better analyzed with the model in which the rotational vibration has a double well potential.[21] The sign of the resulting tilt of the central ring is random and no long range order is present. Below the transition temperature, however, the tilt of the central ring occurs in an ordered fashion, similar to the spins in antiferromagnetic materials. It has been observed that the order parameter grows as the temperature goes down. Hence the transition is thought to be of the order-disorder type.[22,23] It is proposed that a *p*-terphenyl molecule in its electronic ground state is non-planar, whereas in the excited state it is planar. This is based on the observation that the absorption spectrum of the compound in the solution lacks any vibrational structure, whereas its fluorescence spectrum is clearly structured.[1] It is also known that the absorption spectrum becomes more structured when the molecule in a viscous solution is excited to higher excited states.[24] In view of this conformational change accompanying the electronic excitation, the following mechanism of the energy transfer seems to be probable. A *p*-terphenyl molecule in a crystal takes the planar conformation when it is excited. Energy transfer to a neighboring molecule takes place equienergetically only when the latter takes the planar conformation. In this simplified model the energy barrier for the rotation of the central ring is expected to manifest itself in the temperature dependence of the energy transfer. When the four hydrogen atoms attached to the central benzene ring are replaced by four deuterium atoms, the moment of inertia about the molecular long axis increases by some 20% and the zero point energy becomes correspondingly lower. Accordingly, the activation energy ΔE is expected to be larger in *p*-T-d_{14} compared to *p*-T-h_{14} (Fig. 7), which is consistent with our observation. One could argue that the temperature dependence is caused by the presence of traps for excitons and the observed activation energies correspond to the trap depth. This possibility is denied by estimating the number of traps. Let us assume that the fraction x of the molecular sites is occupied by traps (impurities or displaced molecules), the depth of which is ΔE. The fraction 1-x is thus occupied by normal host molecules. An exciton migrates with occasional trapping. Detrapping is possible because ΔE (66 cm^{-1} or 90 cm^{-1}) is comparable to, or smaller than, kT for the temperature range investigated. The average hopping time of an exciton will be

$$t_h = (1-x)t_h^0 + xt_h^0\exp(-\Delta E/kT), \quad (6)$$

where t_h^0 is the hopping time between two normal

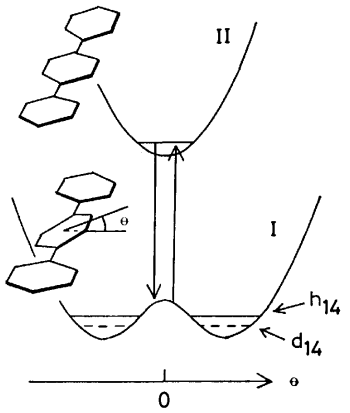

Fig. 7. A model for the intermolecular energy transfer in *p*-terphenyl crystal. In the electronic ground state (I) the molecule has a double well potential as regards the rotation of the central ring around the molecular long axis (θ). A molecule in the excited state (II) transfers its energy to a neighboring molecule equienergetically when the latter takes the planar conformation. The difference in the librational zero point energy of *p*-T-h_{14} and of *p*-T-d_{14} may account for the difference in the activation energies.

molecules. The observed temperature dependence of I_G/I_H could not be fitted with this model with x smaller than 0.8. This obviously contradicts the idea that a very low concentration of unidentified impurity is affecting the results. The fact that the temperature below which the plot log (I_G/I_H) *vs.* $1/T$ is linear corresponds roughly, although not exactly, to the transition temperature also seems to support our view that the temperature dependence, as well as the effect of deuterium substitution, is not determined by impurities, but is intrinsic.

Ylide-Metal Complexes. IV. The Preparation and Properties of IIb-group Metel (Zn, Cd, Hg) Complexes of Alkylidenetriphenylphosphoranes

Yoshihisa YAMAMOTO* and Hideo SUGIMOTO†

Faculty of Pharmaceutical Sciences, Higashi Nippon Gakuen University, Ishikari, Tobetsu, Hokkaido 061-02

(Received December 3, 1979)

Ylide-IIb-group metal (Zn, Cd, Hg) complexes, bis(triphenylphosphonium alkylide)metal dichloride, $[(C_6H_5)_3\overset{+}{P}-\underset{R}{\underset{|}{CH}}-M-\underset{R}{\underset{|}{CH}}-\overset{+}{P}(C_6H_5)_3](Cl^-)_2$ (M: Zn, Cd, Hg), and chloro(triphenylphosphonium isobutylide)metal dichloride, $[(C_6H_5)_3\overset{+}{P}-\underset{CH(CH_3)_2}{\underset{|}{CH}}-M-Cl]Cl^-$ (M: Zn, Cd), have been obtained from alkylidenetriphenylphosphoranes, $(C_6H_5)_3P=CH-R$ (R: H, CH_3, $CH(CH_3)_2$), and $ZnCl_2$, $CdCl_2$, or $HgCl_2$. In these organometallic complexes, the alkylidenetriphenylphosphoranes are attached to the IIb-group metals atom through the carbanionic donor atom. They are thermally stable.

The complexes of alkylidenetriphenylphosphorane and IIb-group metals have been investigated by Schmidbaur[1-4] and some other researchers.[5-7] The complexes of alkylidenetriphenylphosphorane $(C_6H_5)_3P=CH-R$ (R: H, CH_3, $CH(CH_3)_2$), and $ZnCl_2$, $CdCl_2$, or $HgCl_2$ have, however, been the subject of little research.

Previous papers have been concerned with the preparation and physical properties of stable 2/1- and 1/1-gold(I), silver(I) and copper(I) complexes of alkylidenetriphenylphosphoranes[8] and arsoranes.[9] The present paper will deal with the preparation and ^1H- and ^{13}C-NMR measurements of bis(triphenylphosphoniumalkylide)metal dichloride, $[(C_6H_5)_3\overset{+}{P}-\underset{R}{\underset{|}{CH}}-M-\underset{R}{\underset{|}{CH}}-\overset{+}{P}(C_6H_5)_3](Cl^-)_2$ (M: Zn, Cd, Hg) and chloro(triphenylphosphonium isobutylide)metal chloride, $[(C_6H_5)_3\overset{+}{P}-\underset{CH(CH_3)_2}{\underset{|}{CH}}-M-Cl]Cl^-$ (M: Zn, Cd).

Results and Discussion

Synthesis and Properties. 2/1 complexes of bis(triphenylphosphonium alkylide)metal dichloride (**1a**—**1b**, **2a**—**2b**, and **3a**—**3c**) and 1/1 complexes of chloro(triphenylphosphonium isobutylide)metal dichloride (**1d** and **2d**) have been isolated from a reaction mixture of alkylidene triphenylphosphorane ($(C_6H_5)_3P=CH-R$, **La**; R=H, **Lb**; R=CH_3 and **Lc**; R=$CH(CH_3)_2$) and $ZnCl_2$, $CdCl_2$, or $HgCl_2$. Attempts to obtain the bis(triphenylphosphonium isobutylide)metal dichloride

from **Lc** and $ZnCl_2$ or $CdCl_2$ invariably resulted in the isolation of a 1/1 complex of **1d** or **2d** respectively.

All the complexes except **1a** and **2a** are insoluble in most organic solvents and change to the corresponding phosphonium salts, *i.e.*, $[(C_6H_5)_3PCH_2R]Cl$, in chloroform and dichloromethane at room temperature or at a low temperature. **1a** and **2a** change slowly to the corresponding phosphonium salt in dichloromethane, but they are stable at −40 °C. All the complexes are thermally stable in the solid state. The stability of these complexes and bis(triphenylphosphonium methylide)metal chloride, $[(C_6H_5)_3\overset{+}{P}-CH_2-\bar{M}-CH_2-\overset{+}{P}(C_6H_5)_3]Cl^-$ (M: Cu; **4**,[10] Ag; **5**[11] and Au; **6**[8]), in dichloromethane is **6**≫**1a**≈**2a**>**4**≈**5**≫**3a**. **5** is sensitive to light, but **2a** is stable.

Also, **3a'** was prepared from **La** and $HgBr_2$ by Seyferth and Grim.[12] Although they reported that the **3a'** was somewhat soluble in hot methanol, **3a** can be decomposed in that solvent (*cf.* the ^1H-NMR section).

NMR Spectra. The ^1H-NMR spectrum of **1a** showed a doublet signal for the CH_2P at 0.76 ppm and a multiplet signal for the phenyl groups at 7.5 ppm in a ratio of 2:15 at room temperature. The ^1H-NMR spectrum of **2a** showed satellites caused by the spin-spin coupling of the $^{111/113}Cd$ nuclei with CH_2 protons in the complex, in addition to a doublet signal for the CH_2P at 0.70 ppm and a multiplet signal for the phenyl groups at 7.5 ppm. The ^1H-NMR spectrum of **3a** could not be measured at −45 °C because it was not soluble in dichloromethane-d_2. The ^1H-NMR spectrum of **3a** showed a doublet signal (J_{HCP}: 13.5 Hz) at 3.3 ppm in dichloromethane-d_2 at room temperature or at 3.0 ppm in hot methanol-d_4 for the methyl group and a multiplet signal for the phenyl groups at 7.5 ppm in dichloromethane-d_2 or at 7.7 ppm in methanol-d_4 in a ratio of 3:15. The chemical shift (δ) and the coupling constant (J_{HCP}) of methyltriphenylphosphonium bromide in methanol-

Standard: ^{1}H-NMR; int-TMS (δ=0), ^{13}C-NMR; CD_2Cl_2 (δ=53.6 ppm). Solvent: CD_2Cl_2. M: $^{111/113}$Cd.

d_4 are 3.0 ppm and 13.5 Hz for the methyl group and a multiplet signal for the phenyl groups at 7.7 ppm.

The coupling constants (J_{HCP}) of **1a** and **2a** were larger than that (7.5 Hz) of **La**, and their proton signals shifted to a lower field than that (0.13 ppm) of **La**. These spectra are similar to those[8,10,11] of **4**—**6**. It seems that the alkylidenetriphenylphosphoranes are attached to the metal atom through the carbanionic donor atom.[8,11,12] The cadmium atom in **2a** is considered to have the *SP* configuration from the following facts: the coupling constant (J_{HCM}) of **2a** is larger than those (35.4,[13] 34.9 Hz[14]) of the ylide-complexes with a tetrahedral-configurational cadmium atom, and it is close to those (49.4 Hz for $J_{HC^{111}Cd}$, 51.2 Hz for $J_{HC^{113}Cd}$) of diethylcadmium,[15] while the equivalent conductance of **2a** is 15 S cm^2 in dichloromethane at −50 °C. The chemical shifts (CH_2P) of **1a** and **2a** are at a higher field than those[8,10,11] of **4**—**6**. The change in the chemical shifts of these complexes is similar to that of the chemical shifts of other ylide-Ib-group and -IIb-group metal complexes.[13,14]

The ^{13}C-NMR spectra of **1a** and **2a** were measured in dichloromethane-d_2 at −60 °C. The coupling constants (J_{PC}) of these complexes were much smaller than that[8] of **La**. This finding is also similar to those[8,10,11] in the cases of **4**—**6**. The chemical shifts (CH_2P) of these complexes are at a higher field than those of **4**—**6**. The ^{1}H- and ^{13}C-NMR data of **1a** and **2a** are summarized in Table 1.

Experimental

Measurements. The NMR spectra were measured with an FX-60 spectrometer (JEOL) for ^{13}C-NMR, and with a JNMOMX-60 (JEOL) spectrometer and an R-40 (Hitachi) spectrometer for ^{1}H-NMR. The equivalent conductance was measured with a CM-30 (Schimadzu) conductometer.

Starting Materials. The methylene-,[16] ethylidene-,[10,17] isobutylidenetriphenylphosphoranes[10] were prepared from the corresponding phosphonium bromides by the sodium-amide method.[8,9]

The reaction mole ratio, the yield, the decomposition temperature, and the analytical data of complexes are collected in Table 2.

*Preparation of 1/2 Complexes. Bis(triphenylphosphonium methylide)zinc Dichloride (**1a**), Bis(triphenylphosphonium methylide)cadmium Dichloride (**2a**), and Bis(triphenylphosphonium methylide)mercury Dichloride (**3a**)*: $ZnCl_2$, $CdCl_2$, or $HgCl_2$ was added to a dry THF (20 cm^3) solution of methylenetriphenylphosphorane at room temperature under nitrogen. The color of the methylenetriphenylphosphorane changed from yellow to colorless. The white complex thus precipitated was filtered under nitrogen, washed with THF, and pentane, and dried under a vacuum.

*Bis(triphenylphosphonium ethylide)zinc Dichloride (**1b**), Bis(triphenylphosphonium ethylide)cadmium Dichloride (**2b**), Bis(triphenylphosphonium ethylide)mercury Dichloride (**3b**), and Bis(triphenylphosphonium isobutylide)mercury Dichloride (**3c**)*: These complexes were prepared according to the procedure for complexes **1a**, **2a**, and **3a**.

*Chloro(triphenylphosphonium isobutylide)zinc Chloride (**1d**)*: A dry ether (30 cm^3) solution of isobutylidenetriphenylphosphorane was added to $ZnCl_2$ at room temperature under nitrogen. The white complex precipitated after 8 d was filtered under nitrogen, washed with ether, and then pentane, and dried under a vaccum.

*Chloro(triphenylphosphonium isobutylide)cadmium Chloride (**2d**)*: A dry THF (20 cm^3) solution of isobutylidenetriphenylphosphoranes was added to $CdCl_2$ at room temperature under nitrogen. After 4 d, the precipitated white complex was filtered under nitrogen, washed with THF and then pentane and dried under a vacuum.

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

The Temperature Dependence of the Mixed and Intervalence State in Mono-oxidized *trans*-μ-(*as*-Indacene)bis(cyclopentadienyliron)

Sei'ichiro IIJIMA,† Izumi MOTOYAMA, and Hirotoshi SANO*

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukasawa, Setagaya-ku, Tokyo 158

(Received January 18, 1980)

The temperature dependence first observed in the Mössbauer spectrum for mono-oxidized *trans*-μ-(*as*-indacene)bis(cyclopentadienyliron) was interpreted in terms of the increase in the rate of intervalence-electron transfer between two irons with an increase in the temperature. The cyclic voltammetric study of *trans*-μ-(*as*-indacene)bis(cyclopentadienyliron) indicates that the metal-metal interaction in the monocation of the compound is greater than that in the monocation of biferrocene at room temperature.

The so-called "mixed-valence" compounds have been extensively investigated in connection with the increased interest in superconductive materials and biological "mixed-valence" systems.[1–6] The monocation salts of binuclear ferrocenes, in which two kinds of iron atoms, formally Fe(II) and Fe(III), are simultaneously present, have attracted much attention in the field of "mixed-valence" chemistry and have been investigated by using several physico-chemical measurements.[7–19]

As is known by means of Mössbauer spectroscopy, some of the monocation salts of binuclear ferrocenes give two different valence states of irons, corresponding to bi- and trivalent irons, while the others give iron atoms in an intervalent state averaged between these two valence states. In the latter compounds, the "intervalence state" has been interpreted by assuming a thermal-electron transfer between the two iron atoms on a time scale shorter than the life-time of the excited Mössbauer nuclear level, *ca.* 10^{-7} s. There has, however, been no direct experimental proof for this speculative interpretation of the mechanism, because there has been no binuclear ferrocene derivatives' monocation which shows a typical temperature-dependent Mössbauer spectrum from an isolated mixed-valence state to a single averaged valence state.

It is known by means of Mössbauer spectroscopy that the mono-oxidized biferrocenylene(bis(μ-bicyclopentadienyl)-diiron(II)) gives iron atoms in an intervalent state[16,18] and the averaging has been speculated to proceed either through the cyclopentadienyl rings or directly through the overlapped *d*-orbitals of each iron atom. It was recently demonstrated, based on Mössbauer spectroscopic studies of the mono-oxidized salts of acetylene-bridged binuclear ferrocenes, that the π-conjugated system(s) between two ferrocenyl moieties plays an important role in the appearance of the intervalent state.[20,21]

During the process of verifying the role of the π-conjugated system bridged between two ferrocene moieties in the molecule which has a *trans*-conformation with respect to iron atoms, in contrast with biferrocenylene's and [2.2]ferrocenophane-1.13-diyne's monocation, a model compound of biferrocene derivatives with the conformation fixed in the *trans* form, *trans*-μ-(*as*-indacene)bis(cyclopentadienyliron), $(C_{12}H_8)Fe_2(C_5H_5)_2$ (**1**) and its monocation salt, $(C_{12}H_8)Fe_2(C_5H_5)_2{}^+I_3{}^-0.5I_2$ (**2**) were first synthesized.[22] The latter monocation salt (**2**) shows a trapped mixed-valence-type spectrum at 4.2 K and an intervalence-type spectrum at room temperature. The present paper will describe the temperature dependence of the valence state of the salt (**2**) as determined by means of Mössbauer spectroscopy. Cyclic voltammograms of the compound (**1**) will also be reported in order to elucidate the degree of the metal-metal interaction in the monocationic species.

Fig. 1. The structure of **1** and **2**.

Experimental

Materials. *trans*-μ-(*as*-Indacene)bis(cyclopentadienyliron) (**1**) was prepared by the reaction of iron(II) chloride with a mixture of lithium cyclopentadienide and dilithium *as*-indacenide prepared by the reaction of dihydro-*as*-indacene with *n*-butyllithium. To a solution of tetrahydrofuran containing 0.62 g (4 mmol) of dihydro-*as*-indacene and cooled to −70 °C, 2.64 g (40 mmol) of cyclopentadiene was added. 32 ml of solution of 1.5 M *n*-butyllithium in hexane was added in drops over a period of 15 min. The mixture was allowed to stand for about 15 min until the temperature rose to room temperature. After the mixture had then been left for another 10 min, it was poured, at room temperature, into a suspension of iron(II) chloride prepared immediately before use. After the mixture had been allowed to stand for 30 min under stirring, the solvent was evaporated off and the residues were extracted with hexane. The extract was rapidly separated from ferrocene by column chromatography on alumina. **1** was thus obtained in the form of reddish needles in a yield of 3%. Mp 210—211 °C. Found: C, 66.79; H. 4.73%. Calcd for $C_{22}H_{18}Fe_2$: C, 67.05; H, 4.60%.

Biferrocene	0.36	0.68	0.32
1′,1‴-Diacetylbiferrocene	0.62	0.92	0.30
1′,1‴-Diethylbiferrocene	0.28	0.63	0.35
2,2″-Dimethylbiferrocene[c]	0.37	0.63	0.26

a) Volts *vs.* Ag/AgCl electrode at 250 mm/s. b) $\Delta E_{1/2} = E_{1/2}(2) - E_{1/2}(1)$. c) Cited from Ref. 15, where CV was determined in CH_3CN containing Et_4NClO_4 (0.1 M) in volts *vs.* SCE at 100 mm/s.

The monocation salt, $(C_{12}H_8)Fe_2(C_5H_5)_2{+}I_3^- \cdot 0.5I_2$ (**2**), was prepared through the oxidation of **1** in benzene with iodine. Found: C, 29.23; H, 2.23%. Calcd for $C_{22}H_{18}Fe_2I_4$: C, 29.31; H, 2.06%.

Biferrocene derivatives,[23-26] polyethylferrocenes,[27] and aminoferrocene[38] were prepared according to the methods previously reported in the literature.

Measurements. The ^{57}Fe Mössbauer measurements were carried out by using a ^{57}Co(Pt) source moving in a constant acceleration mode. The isomer shifts are determined relative to metallic iron foil. The experimental errors of the isomer shifts and quadrupole splittings are ±0.05 mm/s for Compound **2** and ±0.02 mm/s for the other compounds.

Cyclic voltammograms of biferrocene, 1′,1‴-diacetyl- and 1′,1‴-diethylbiferrocene, and Compound **1** were obtained using a Hokuto Denki HB-107A function generator and a Hokuto Denki HA-201 potentiostat combined with a standard three-electrode configuration. The working electrode, a platinum button (Beckman), and the reference, an Ag/AgCl electrode, were connected *via* a salt bridge containing *n*-Bu_4NClO_4 (0.1 M) in CH_3CN. The half-wave potentials given in Table 1 were calculated from the peak potentials.

Results and Discussion

The half-wave potentials obtained by means of cyclic voltammetry for Compound **1** and related compounds are summarized in Table 1. The number of positions of substituents in biferrocenes shown in Table 1 are illustrated in Fig. 2. In the cyclic voltammograms of the compounds in CH_3CN solutions containing 0.1 M *n*-Bu_4NClO_4, two steps of the one-electron oxidation were observed. It is known that the difference in the half-wave potentials ($\Delta E_{1/2}$) can be used as the measure of the metal-metal interaction in a mono-oxidized binuclear ferrocene.[14] The larger value of $\Delta E_{1/2}$ in **1** (0.41 V) compared to that in biferrocene (0.32 V) suggests that the metal-metal interaction in the monocation of **1** is greater than that in the monocation of biferrocene. The $\Delta E_{1/2}$ of **1** is also somewhat greater than those of the substituted biferrocenes listed in Table 1, indicating that the large $\Delta E_{1/2}$ of **1** should be ascribed to the *trans*-conformation of the ferrocenyl moieties of **1** rather than to a simple substituent's effect of the fused ring in **1**. The values of $\Delta E_{1/2}$ reported for other substituted biferrocenes by LeVanda *et al.* are also lower than

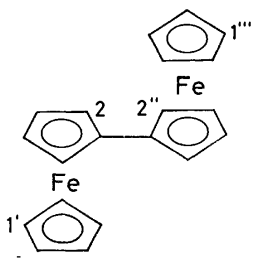

Fig. 2. The number of positions of substituents in the biferrocenes.

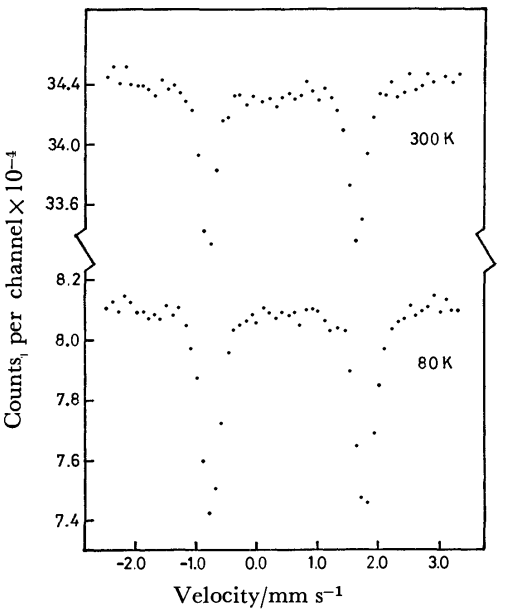

Fig. 3. Mössbauer spectra of $(C_{12}H_8)Fe_2(C_5H_5)_2$ (**1**) at 80 and 300 K.

that of **1**,[15] although their experimental conditions were a little different from those of the present studies. The small $\Delta E_{1/2}$ (0.26 V) found on 2,2″-dimethylbiferrocene[15] may be ascribed to the incomplete *trans*-conformation caused by the steric hindrance attributable to substituted rings. The results obtained for the compounds listed in Table 1 suggest that the two ferrocenyl moieties are twisted from a coplanar conformation with respect to the two combined cyclopentadienyl rings, except for **1**.

The Mössbauer parameters of Compound **1** and **2** are summarized in Table 2, with the data of biferrocene shown also for comparison. The neutral species (**1**) gives biferrocene-like spectral parameters, as may be seen in Fig. 3, although the quadrupole splitting (qs) is rather greater than that of biferrocene. This is similar to the relation between the qs of cyclopentadienyl(indenyl)iron(II) or bis(indenyl)iron(II) and that of biferrocene.[28,29] As may be seen in Table 3, it is found in the present studies that some ferrocene derivatives with electron-donating substituents give larger values of qs than that of ferrocene; that is, such a substituent increases the qs of ferrocene. On the other hand, it has been reported that the electron-attracting substituents decrease the qs of ferrocene.[30] Thus, the large qs of **1** is ascribable to the electron-donating effect of the fused ring in **1** to the ferrocenyl

Table 2. Mössbauer data for *trans*-μ-(*as*-indacene)-bis(cyclopentadienyliron) $(C_{12}H_8)Fe_2(C_5H_5)_2$ (**1**), its monocation salt, $(C_{12}H_8)Fe_2(C_5H_5)_2^+I_3^- 0.5I_2$ (**2**), and biferrocene

moieties.

The Mössbauer spectra of the monocation salt (**2**) were determined at 4.2, 100, 200, and 300 K. As is shown in Fig. 4, the shape of the spectrum of **2** greatly depends upon the temperature. The spectrum at 4.2 K consists of inner and outer doublets in nearly a 1:1 ratio; these doublets are ascribed to the ferrocenium-type and ferrocene-type irons (Fe(III) and Fe(II)) in **2** respectively. This is a typical trapped-valence type spectrum. On the other hand, only a single quadrupole doublet with a large half-line width (hlw) is observed in the spectrum at 300 K. The spectra at 100 and 200 K apparently consist of an intense "inner doublet" and a weak "outer doublet."

It is obvious that the results obtained for **2** cannot be interpreted essentially in terms of trapped-valence states with different spectral areas which are simply temperature-dependent. First of all, we cannot explain why the qs of the "inner doublet" increases considerably as the temperature increases (0.57 mm/s in qs from 4.2 to 300 K), despite the fact that qs slightly decreases as the temperature increases in most cases. Secondly, the anomalously large hlw of the "inner doublet" at higher temperatures cannot be explained either, because the hlw of ^{57}Fe absorption in most mono-oxidized binuclear ferrocenes has been reported to be in the range from *ca.* 0.3 to 0.4 mm/s, while the hlw of the "inner doublet" at 300 K is as large as 0.65 mm/s. Thirdly, such an extreme difference between the spectral areas in each component can only be explained by assuming a greatly different dependence in recoil-free fractions between the outer ferrocene-like and inner ferrocenium-like components, although a nearly equal recoil-free fraction for the two irons is to be expected from the point of view of the importance of the intermolecular interaction on the recoil-free fraction.[31]

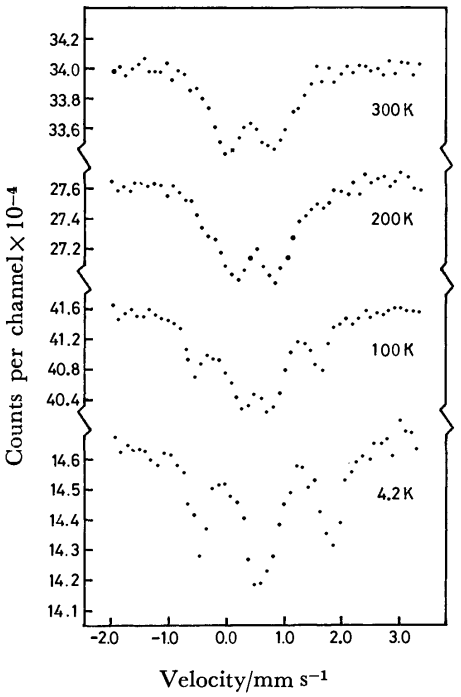

Fig. 4. Mössbauer spectra of $(C_{12}H_8)Fe_2(C_5H_5)_2^+$-$I_3^-$ 0.5I_2 (**2**) at 4.2, 100, 200, and 300 K.

On the other hand, the Mössbauer spectroscopic behaviour of some "mixed-valence" compounds (*e.g.*, Fe_3O_4,[32] $Fe_3(CH_3COO)_6 \cdot O \cdot 5H_2O$,[33] and Eu_3S_4[34]) has already been interpreted successfully in terms of an electron-hopping model. The temperature dependence of the Mössbauer spectra of the salt (**2**) was examined by applying this model to clarify the rate of thermal electron-transfer between two irons.

The shapes of the spectra of 100 and 200 K can well be described as the consequences of an increased electron-transfer rate with the increased temperature, which makes the qs values of the ferrocene-like and ferrocenium-like components closer to each other, causing the line to broaden on each component, while the rate of the electron-transfer is much smaller than *ca.* 10^7 s^{-1} at 4.2 K. The line components of the two

types of iron atoms virtually merge into a single resonance line at 300 K at a transfer rate larger than *ca.* 10^7 s^{-1}. The broadened line shape of the spectrum at 300 K can be explained in terms of the remaining relaxation effects caused by electron-hopping. The qs value at this temperature is slightly smaller than the average of the qs values of the two doublets at 4.2 K. This inconsistency can probably be ascribed to the simplicity of the model, since essentially no temperature-dependence is assumed for the basic electronic configurations of the pure ferrocene-like and ferrocenium-like components.

The general formula given by Wickman for the relaxation Mössbauer spectrum[35] has been applied to the explanation of the electron-hopping mechanism in Eu_3S_4 by Berkooz *et al.*[34] Both the relations derived from Wickman's formula of the transfer-rate with the peak positions and the half-line width of the spectral line component,[36] were used in the present study for the estimation of the electron-transfer rate in **2**, based on the assumption that the transfer rate at 4.2 K is much less than *ca.* 10^7 s^{-1}. In the calculation of the transfer rate, it is also assumed that the magnetic quantum number (m_I) of the excited Mössbauer nucleus does not change during the relaxation processes, *i.e.*, the relaxation between ferrocene-like and ferrocenium-like iron atoms occurs independently in each transition, $m_I=\pm1/2\rightarrow\pm1/2$ and $m_I=\pm1/2\rightarrow\pm3/2$, in Compound **2**.

The sign of the electric-field gradient (efg) of the ferrocenium-like component, like that of the ferrocene-like component in **2**, is assumed to be positive, because the ferrocenium-like component in biferrocene monocation salt is known to have a positive sign of efg.[19]

The electron-transfer rates, κ, were estimated to be 1.4×10^7 s^{-1} and 2.0×10^8 s^{-1} at 100 K and 300 K respectively. The values of the transfer rate derived from each transition coincide with each other within the range of experimental error.

The activation energy, E_p, of the electron-hopping in **2** was evaluated to be roughly 1 kcal mol^{-1} (0.04 eV) by using the following equation, as in the case of Eu_3S_4;[34]

$$\kappa = \kappa_0\exp(-E_p/kT).$$

The rate of the intermolecular electron transfer was determined at various temperatures in the NMR studies between ferrocene and ferrocenium ions in solutions of acetonitrile and of methanol.[37] The E_p value for the intermolecular electron-transfer was estimated to be 5 kcal mol^{-1} in acetonitrile and 3 kcal mol^{-1}. The lower value of E_p estimated in the present work may be ascribed to the smaller intramolecular Fe–Fe distance of the salt (*ca.* 5.0 Å) than that of the ferrocene-ferrocenium association complex (*ca.* 7.8 Å) and also the intramolecular π-conjugated system in **2**.

Nitrogen Determination by Pyrolysis Using Steam. I.

Akira NOMURA,* Yazaemon MORITA, and Yukitoshi KOGURE
Department of Analytical Chemistry, National Chemical Laboratory for Industry, Yatabe, Ibaraki 305

(Received January 31, 1980)

Pyrolysis of nitrogen compounds with use of steam and $FeCl_3$–Al_2O_3 catalyst was investigated in detail in order to develop a new method for nitrogen determination. The catalyst was prepared by mixing an aqueous $FeCl_3$ solution and porous active Al_2O_3 for column chromatography and drying the mixture. A sample solution containing nitrogen was added to the catalyst in a boat and was then covered with an additional catalyst after removal of the solvent, leaving the sample adsorbed on the catalyst. The boat was then inserted into a pyrolysis tube, the sample being pyrolyzed in the presence of steam also used as carrier gas. The nitrogen in the sample converted into ammonia by the pyrolysis reaction was determined by titration after steam distillation under alkaline conditions. The nitrogen compounds except for N–O and N–N bonded compounds were converted quantitatively into ammonia by the pyrolysis under optimum conditions. The reaction was applied to the determination of nitrogen in various compounds.

Nitrogen determination of organic compounds was carried out mainly by the classical Kjeldahl, Dumas and ter Meulen method. Modification of their method has been investigated. Hozumi and Kirsten[1] reported the sealed tube method. Microcoulometry combined with hydrogenation of nitrogen compounds[2] and chemiluminescence measurement of nitrogen monoxide with ozone[3] were applied to nitrogen determination. Nitrogen in coke was determined by the semimicro gasification method[4] using steam as a carrier gas.

A new method for nitrogen determination of organic compounds is described in this paper. Its principle is based on the fact that nitrogen compounds are converted into ammonia by pyrolysis using $FeCl_3$–Al_2O_3 catalyst in the presence of steam.

Experimental

Materials. Porous active aluminium oxides (Al_2O_3) for column chromatography (Merck) were used. Methyl Red–Methylene Blue mixed indicator was used for acidimetric titration. Other reagents were of reagent grade.

Apparatus. The apparatus for pyrolysis is shown in Fig. 1. The nitrogen contents in the reagents were determined with a microcoulometric titrating system (Model TN-01, Mitsubishi Chemical Industrial Co. Ltd.) or a Kjeldahl digestion and distillation apparatus.

Ammonia converted from the nitrogen compounds by pyrolysis was identified by gas chromatography (Shimadzu GC-4CMPF) with a nitrogen-selective detector (Envirotech Corp., Dohmann Microcoulometric Titration System-10) based on the investigation by Martin.[2] A glass column, length 1 m, i.d. 3 mm, packed with 10% by weight PEG-20M (Gas Chro. Industrial Co. Ltd.) on Chromosorb-W precoated with 5% of KOH was used, argon being used as carrier gas at 40 ml/min. A glass precolumn (3 mm i.d. × 90 mm) installed in the sample inlet zone of the gas chromatograph was packed with soda lime and heated at 200 °C to release the basic compounds in the samples.

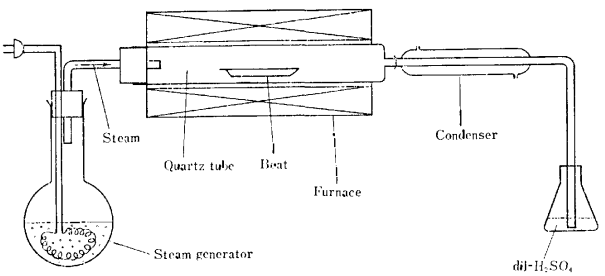

Fig. 1. Schematic diagram of apparatus for pyrolysis.

Preparation of Catalysts. Aqueous $FeCl_3$ solutions (50 ml) of various concentrations were added to Al_2O_3 (100 g), thoroughly mixed with a pestle and dried at 60 °C for 5 h. It is desirable to prepare the catalysts as required. Otherwise they should be stored in a desiccator containing silica gel.

Procedure. The catalyst (1.5 g) was uniformly distributed in an alumina boat (Japan Chemical Ceramic Co. Ltd., SSA-H5B). A sample solution of 0.5 ml containing approximately 1 mg of nitrogen dissolved with a suitable solvent was added to the catalyst with a micro pipette (Toa Medical Electronic Co. Ltd., Type 1058-F500) and dried at 60 °C in order to remove the solvent. The catalyst supporting the sample was covered uniformly with an additional catalyst (2.0 g). The boat was pushed with a stainless steel wire attached to the tail of the boat into a quartz pyrolysis tube (28.5ϕ × 475 mm), heated at 700—1000 °C in a furnace. Steam of 2.5 g/min, regulated with a Slidac, was immediately supplied from a steam generator for 10 min by connecting a hose to the open end of the pyrolysis tube. The pyrolyzed products were carried by the steam through a condenser to a flask containing dilute H_2SO_4 for absorption of ammonia in the reaction products. Ammonia was determined by the conventional titration method after steam distillation under alkaline conditions, since acidic materials such as HCl are produced during the course of pyrolysis by the decomposition of $FeCl_3$ and the sample. In order to obtain a blank value, the same procedure was carried out for the catalyst without sample.

Results and Discussion

Nitrogen compounds are classified into three types[5]—Type I: N–H and N–C bonded; Type II: N–O bonded; and Type III: N–N bonded. Ammonium sulfate, urea, pyridine, aniline, *p*-dinitrobenzene, and azobenzene were selected as typical compounds.

Identification of Ammonia by Gas Chromatography with Nitrogen-selective Detector. Since the method is based on the fact that nitrogen compounds are converted into ammonia by the pyrolysis reaction utilizing the $FeCl_3$–Al_2O_3 catalyst, the detection and identification of ammonia by gas chromatography with a nitrogen-selective detector would help confirm the validity of the method.

Samples for chromatographic analysis were prepared

Table 1. Effect of aluminium oxide properties on pyrolysis

No.	Properties of Al_2O_3			Concentration of $FeCl_3(Fe/Al_2O_3)$/wt%	Recovery of N/%			
	Activity[a]	Pore diameter/Å	Acidity		Pyridine	*p*-Dinitrobenzene	Azobenzene	Urea

a) Determined according to the method of Brockmann and Schodder.[6] b) End point not clear due to the presence of unreacted pyridine.

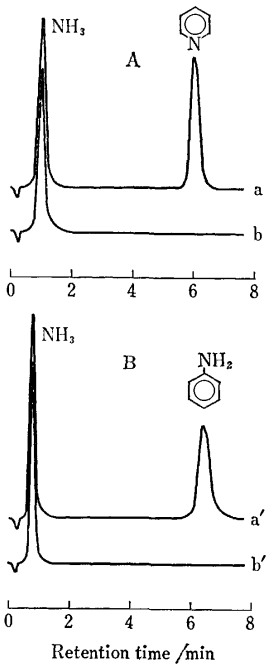

Fig. 2. Identification of ammonia by gas chromatography with nitrogen-selective detector.
A; Column temperature: 100 °C, a: standard sample (ammonium sulfate 100 ng N, pyridine 100 ng N), b: reaction products of pyridine at 800 °C, B; column temperature: 170 °C, a′: standard sample (ammonium sulfate 100 ng N, aniline 100 ng N), b′: reaction products of aniline at 800 °C.

as follows. The pyrolyzed products of 1 mg N of pyridine or aniline, absorbed in dilute H_2SO_4, were distilled. The distillate was neutralized with slight excess of acid (H_2SO_4) in an adaptor, then codensed to 10 ml. If the nitrogen in the pyridine or aniline is quantitatively recovered as ammonia, 100 ng/μl of nitrogen should be contained in the condensed solution.

The sample of 1 μl (100 ng N) was injected through the inlet of the gas chromatograph and the chromatogram obtained was compared with that of a standard sample (Fig. 2). Peaks of both pyridine and aniline (chromatograms A and B) disappeared, only that of ammonia appearing after the pyrolysis. The peak height of ammonia converted from pyridine or aniline was nearly the same as that of ammonia (100 ng N) in a standard sample.

The results indicate that both pyridine and aniline are converted into ammonia giving no other basic nitrogen compounds detectable with a nitrogen-selective detector. The conventional acidimetric titration is simpler and more precise for determination of ammonia as compared with chromatographic determination when only ammonia exists as a basic compounds.

Effect of Aluminium Oxide Properties. Aluminium oxides used were porous sorbents for column chromatography (particle size: 0.04—0.15 mm). The properties of aluminium oxides (Merck) are summarized in Table 1, together with catalytic efficiencies. The concentration of $FeCl_3$ supported on Al_2O_3 was in the range 1—6% of Fe/Al_2O_3. The temperature for the pyrolysis was 800 °C, the steam flow rate being 2.5 g/min.

TABLE 2. EFFECTS OF THE AMOUNT OF CATALYST AND THE HEATING TEMPERATURE ON PYROLYSIS

Compound	Amount of catalyst/g	Recovery of N/%				
		600 °C	700 °C	800 °C	900 °C	1000 °C
Pyridine	0	— a)	— a)	— a)	— a)	— a)
	1	— a)	81.3	90.2	90.4	82.0
	2	54.7	94.7	99.3	101.3	88.6
	3	48.7	90.3	99.3	100.6	82.8

	3	70.5	70.5	69.5	38.2	27.7

a) End point not clear due to the presence of unreacted pyridine.

The nitrogen in pyridine was recovered quantitatively by 4%-Fe/Al_2O_3 except for No. 5 whose pore size is the largest among the Al_2O_3 we used. The reason for the low recovery of pyridine by No. 5 has not been clarified. We assume the removal of some pyridine from the catalyst during the drying process due to larger pore size (low adsorptivity for pyridine), since 8-quinolinole (oxine), having lower vapor pressure than pyridine, was recovered quantitatively.

The activity and acidity of Al_2O_3 did not remarkably affect the recovery of the nitrogen compounds. On the other hand, both *p*-dinitrobenzene and azobenzene could not be recovered quantitatively under the conditions in Table 1.

In urea (Type I), which is the same as pyridine except for the fact that it contains only one carbon atom in a molecule, the recovery increased as $FeCl_3$ concentration decreased except for No. 5. Iron(III) chloride supported on Al_2O_3 is assumed to undergo oxidation to Fe_xO_y during the course of pyrolysis, urea or its intermediates being considered to be partly oxidized due to the excessive presence of Fe_xO_y causing the low recovery of ammonia. Low concentration of $FeCl_3$ is recommended. The results obtained for No. 1 Al_2O_3 which supported no $FeCl_3$ showed a 95.0% recovery, which is a little low.

Effect of the Amount of Catalyst and Heating Temperature. The effect of the amount of the additional catalyst, covering the sample supported on the catalyst (1.5 g) in the boat, and that of heating temperature in the hot zone on the recovery of pyridine, *p*-dinitrobenzene, azobenzene, urea, and ammonium sulfate were studied. The results are given in Table 2. The concentration of the catalyst was 4%-Fe/Al_2O_3.

Pyridine was recovered quantitatively by the catalyst of 2 and 3 g at 800 and 900 °C, respectively. Below 700 °C the pyrolysis of pyridine could not be completed. Presumably oxidation took place to reduce the recovery at temperatures above 1000 °C.

Although nitro and N–N bonded compounds such as *p*-dinitrobenzene and azobenzene have not been determined quantitatively, 800 °C and 2—3 g of catalyst are suitable.

Ammonium sulfate required no additional covering catalyst for conversion into ammonia, low temperatures (700 °C) being suitable. Oxidation by Fe_xO_y produced on Al_2O_3 during pyrolysis supposedly causes NH_4^+ being partly converted into NO_x or N_2. A certain amount of $FeCl_3$ is necessary to release ammonia from the ammonium sulfate, since the recovery of ammonia was very low (55.1%) with use of only Al_2O_3, supporting no $FeCl_3$, as a catalyst at 800 °C.

Urea, containing one carbon atom in the molecule, requires higher temperatures for its conversion into ammonia as compared with ammonium sulfate, decreasing tendency in the recovery with an increase in the amount of catalyst being smaller than that of ammonium sulfate.

Effect of the Period of Time from Sample Insertion to Steam Supply. The method is not automatic, and sudden pyrolysis before the connection of the steam generator might cause a loss of some of the pyrolyzed products escaping out of the open end of the pyrolysis tube. A portion of the sample might burn, forming N_2 and NO_x instead of NH_3 as a result of the exposure to the air before steam is supplied.

The period of time from sample insertion to steam supply was varied using pyridine as a sample, and the effect on the recovery of nitrogen was investigated in order to estimate how long the period is allowed to determine nitrogen compounds quantitatively (Fig. 3). The concentration of $FeCl_3$ in the catalyst was 4%-Fe/Al_2O_3.

Although the boiling temperature of pyridine is

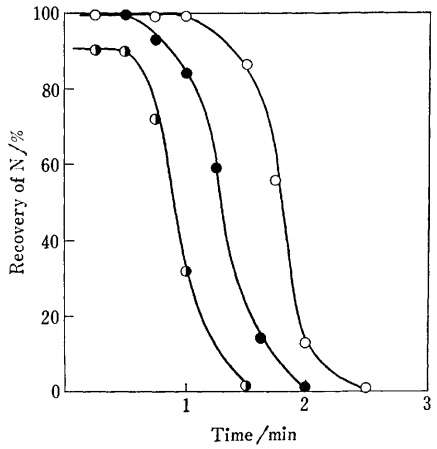

Fig. 3. Effect of the period of time from sample insertion to steam supply on the recovery of nitrogen. Reaction temperaure; ○: 800, ●: 900, ◑: 1000 °C, sample: pyridine (1 mg N), steam flow rate: 2.5 g/min.

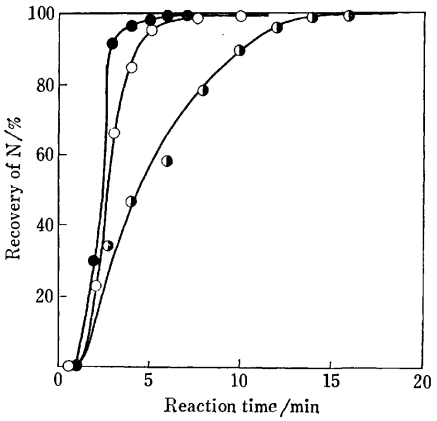

Fig. 4. Time required for pyrolysis reaction. Steam flow rate; ◑: 2.0, ○: 2.5, ●: 4.0 g/min, sample: pyridine (1 mg N), reaction temperature: 800 °C.

not high (115.5 °C), it was adsorbed on the catalyst in the hot zone of the pyrolysis tube at least for 1 min at 800 °C and 30 s at 900 °C presumably because of its adsorption to the catalyst and also the heat capacity of the sample boat and the catalyst, which prevent rapid rise in temperature.

Nitrogen in pyridine was not recovered quantitatively at 1000 °C, even when the steam was supplied immediately (5 s after insertion of the sample boat).

Similar results were obtained in the case of aniline and indole. Thus, it is not necessary to connect the steam generator quickly.

Time Required for Pyrolysis. The effect of the steam flow rate on the pyrolysis of pyridine is shown in Fig. 4. The ammonia produced by the reaction at 800 °C was recovered quantitatively within 10 min at a flow rate higher than 2.5 g/min. As compared with other methods such as the conventional Kjeldahl and Dumas method, our method is simple and rapid, even though more time is requied for the steam distillation of ammonia as in the Kjeldahl method.

Other Materials as Catalysts for Pyrolysis. Iron(III) chloride supported on porous Al_2O_3 was found to be effective for the nitrogen determination of compounds of Type I. Iron(II) sulfate and $Fe(NO_3)_3$ were examined for the effect of anion on pyrolysis.

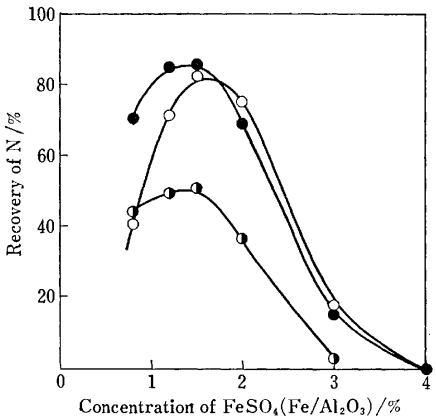

Fig. 5. Effect of $FeSO_4$ as a catalyst for pyrolysis. ○: Pyridine, ◑: *p*-dinitrobenzene, ●: azobenzene, reaction temperature: 800 °C, steam flow rate: 2.5 g/min.

Table 3. Application to various nitrogen compounds

Compound	Sample taken mg N	Found mg N
Pyridine	0.97	0.97
Quinoline	0.94	0.91
Acridine	1.01	0.98
Pyrrole	0.93	0.90
Indole	0.97	0.93
Carbazole	1.03	1.00
Aniline	1.00	0.97
Urea[a)]	1.00	0.98
Ammonium sulfate[a)]	1.00	1.00
N,N'-Diphenylthiourea	1.00	1.03
Phenazine	0.97	0.95
Imidazole	1.01	0.97
Acetanilide	0.98	0.95
p-Methoxybenzonitrile	0.97	0.95
p-Dinitrobenzene	1.00	0.76
5-Nitrosalicylic acid	0.99	0.89
Azobenzene	1.00	0.85
Benzotriazole	1.00	0.28

Reaction conditions; catalyst: 4%-Fe/Al_2O_3, reaction temp: 800 °C, steam: 2.5 g/min, reaction time: 10 min.
a) Covering catalyst: 0 g, reaction temp: 700 °C.

Plots of the concentration of $FeSO_4$ supported on Al_2O_3 (Fe/Al_2O_3) *vs.* the recovery of pyridine, *p*-dinitrobenzene, and azobenzene are given in Fig. 5. The recovery is not quantitative. As compared with chloride ion, highly concentrated sulfate ion adversely affects the pyrolysis of organic compounds.

The nitrate ion affected the reaction much more adversely, producing almost no ammonia but NO_x or N_2 releasing NO_2 due to the thermal decomposition of the nitrate ion.

Cobalt and nickel might also be useful for the reac-

tion. However, $CoCl_2$ and $NiCl_2$ supported on Al_2O_3 gave no satisfactory results.

Application to Various Nitrogen Compounds. The results of various nitrogen compounds analyzed are given in Table 3. Compounds of Type I such as pyridine and aniline were determined satisfactorily, but not those of Types II and III, nitro and N–N bonded compounds.

Reproducibility of the Method. The reproducibility of the method was examined, the average recovery of pyridine (n=8) being 98.1% with a standard deviation of 0.77%.

(Received February 29, 1980)

The crystal and molecular structure of the title complex has been determined by X-ray diffraction using 1882 reflections. The crystal was orthorhombic, with the space group $Pbn2_1$; $a=10.98(2)$, $b=18.496(4)$, $c=7.341(9)$, $Z=4$, $D_x=1.99$, $D_m=1.98(2)$ g cm^{-3}, μ(Mo $K\alpha$)$=19.3$ cm^{-1}, and the final R value was 0.036. A distorted ψ-pentagonal bipyramid is formed around the central antimony(III) atom by two nitrogen and two oxygen atoms, together with a lone electron pair at the equatorial positions and two oxygen atoms at the axial positions. One of the Sb–O distances, 2.78 Å, is longer than the others (2.20(2) Å on the average), and it is determined that the carbonyl oxygen is essentially of the free-acid type and that its carbonyl oxygen is weakly coordinated. The splitting of the ν_{as}(COO) band of its infrared and Raman spectra shows the existence of both free and coordinated carboxyl groups. The ^{1}H- and ^{13}C-NMR results show that the antimony(III)–edta complex does not exchange with the free ligand in an aqueous solution at pH 1.5—3.5.

There has been a growing interest in the study of antimony(III) complexes in recent years. Privalova and Ryabenhikov isolated and analyzed 1:1 edta (H_4(edta)=ethylenediaminetetraacetic acid) and other amine-*N*-polycarboxylato complexes of antimony(III).[1] Bhat and Iyer determined the formation constants of the antimony(III)–edta complex,[2] as well as those of the antimony(III)–*N*-(2-hydroxyethyl)ethylenediamine-*N,N,N'*-triacetato complex,[3] in an aqueous solution using spectrophotometric and potentiometric methods; the results were reinvestigated by Özer and Bogucki using the potentiometric titration technique.[4] The infrared spectral study was reported by Iyer and Shankar,[5] while the chelatometric titration of antimony(III) using edta was reported by Takamoto[6] and by Yurist.[7]

From these results, it seems that the antimony(III)-edta complex, Sb(Hedta)$\cdot n\,H_2O$ (n=1,2), should be a very stable compound. Accoding to Bhat,[2] the apparent formation constant of the complex ion [Sb(edta)]$^-$ in an aqueous solution shown by the following equation is about 10^{25}:

$$SbO^+ + 2H^+ + (edta)^{4-} = [Sb(edta)]^- + H_2O$$

In fact, the antimony(III)–edta complex does not decompose even in an acid medium with a pH of 2. However, the antimony in the edta chelate can easily and almost immediately be replaced by zinc, copper, or other metals in an aqueous solution over pH=4, and the back titration with a metal salt solution is possible only under limited conditions.[6,7]

To study this interesting complex, the present authors have determined the crystal and molecular structure of the acid chelate, Sb(Hedta)$\cdot 2\,H_2O$, by the X-ray diffraction method: its infrared and Raman spectra were also examined. Moreover, the state of the complex in an aqueous solution was investigated by means of the NMR technique.

Experimental

Syntheses of Chelates. (Hydrogen Ethylenediaminetetraacetato)antimony(III) Dihydrate; $Sb(C_{10}H_{13}N_2O_8)\cdot 2H_2O$: This compound was prepared by a slight modification of the method of Bhat;[2] the drop-by-drop addition of antimony(III) chloride in 1 M hydrochloric acid into 0.1 M Na_2H_2(edta) precipitates the complex (1 M=1 mol dm^{-3}). The drop-by-drop addition is essential; if the two solutions are mixed all at once, only H_4(edta) and the hydroxide of antimony(III) are obtained. The complex was partly hydrolized when it was recrystallized from water. The mixed solvent of acetonitrile and water (3:1 v/v) was good for the purpose. The analytical results support the chemical composition: $SbC_{10}H_{17}N_2O_{10}$. Found: Sb, 26.8; C, 27.01; H, 3.78; N, 6.20%. Calcd for $SbC_{10}H_{17}N_2O_{10}$: Sb, 27.23; C, 26.87; H, 3.83; N, 6.27%. Formula weight per 1 mol of edta, Found 453; Calcd, 447.

Sodium Ethylenediaminetetraacetatoantimony(III) Trihydrate: $Na[Sb(C_{10}H_{12}N_2O_8)]\cdot 3H_2O$: This salt was obtained by neutralizing the acid-form complex with a calculated quantity of sodium hydroxide, followed by the evaporation of the water. A more convenient procedure was to mix calculated quantities of Na_4(edta) in an acetic acid–sodium acetate (1:1) buffer, and of antimony(III) chloride. The salt was purified by reprecipitation from water–methanol. Found: Sb, 24.7; C, 24.58; H, 3.76; N, 5.75%. Calcd for $NaSbC_{10}H_{18}N_2O_{11}$: Sb, 25.00; C, 24.66; H, 3.73, N, 5.75%. Formula weight per one mol of edta; Found: 482; Calcd: 487.

X-Ray Measurements. The single crystals of Sb(Hedta)$\cdot$ 2 H_2O were obtained as colorless thin plates, which were stable in open air. As they were too brittle, a crystal 0.3$\times$ 0.1$\times$0.3 mm in size was used for the X-ray measurements without any more reshaping.

Formerly, this crystal was thought to be monoclinic.[8] However, we found that when new axes, a,b, and c, were chosen as follows, the new α,β, and γ were all 90°.

$$\begin{pmatrix} a \\ b \\ c \end{pmatrix} = \begin{pmatrix} 1 & 0 & 1 \\ 0 & -1 & 0 \\ 1 & 0 & 0 \end{pmatrix} \begin{pmatrix} a' \\ b' \\ c' \end{pmatrix}$$

(Where a', b', and c' are former axes of the monoclinic unit cell.[8])

The new space group was confirmed by the results of the reinvestigation of the Weissenberg photographs, as well as the systematic absence of the reflections. Consequently, the results of the present analysis are essentially identical with those of the previous paper,[8] although they are more refined. The crystallographic data are as follows: $SbC_{10}H_{17}N_2O_{10}$, F.W.=447.01, orthorhombic, space group $Pbn2_1$, $Z=4$, $a=10.98(2)$, $b=18.496(4)$, $c=7.341(9)$ Å, $D_x=1.99$, $D_m=1.98(2)$ g cm^{-3}, μ(Mo $K\alpha$)$=19.35$ cm^{-1}.

The reflections within the range of $2\theta<60°$ were collected

by Rigaku automated four-circle diffractometer, applying the ω-2θ scan technique. Independent 1882 reflections with $|F_o|>3\sigma(|F_o|)$ were used for the structure refinement. The intensities were corrected for Lorentz and polarization factors, but no correction was made for the absorption and extinction. All the calculations were carried out on a HITAC 8700/8800 computer at the Computer Center of The University of Tokyo, using the local version of UNICS.[9] The atomic scattering factors, and the corrections for the anomalous scattering of the antimony atom were taken from authentic tables.[10]

Structure Determination. The structure was solved by the heavy-atom method and refined by the block-diagonal least-squares method. The position of the antimony atom was obtained from the three-dimensional Patterson function, while the positions of all the other non-hydrogen atoms were successively located by Fourier syntheses. The positions of the hydrogen atoms were calculated and fixed. Their isotropic temperature factors were all assumed to be 5.0, which was twice the value of the average isotropic temperature factor of the bonded carbon atoms.

In the last cycle of the refinement with anisotropic temperature factors for all non-hydrogen atoms, all the parameter shifts were less than one-third of the corresponding standard deviations. The final R-value was 0.036.[11]

It was difficult to determine the chirality of the crystal from the discrepancy indices. The reversal of the sign of all the z coordinates gave the final R-value of 0.037 after the refinement. Although a slight difference between the final R-values is found between them, it is likely to be within the range of error. Therefore, the former polarity of the crystal was adopted.

The Other Measurements. The infrared spectra of the samples were obtained by means of a JASCO infrared spectrophotometer, type 403G, using Nujol and hexachloro-1,3-butadiene mull.

The Raman spectra of Sb(Hedta)·2 H_2O (crystalline powder packed in a glass capillary tube (ϕ=0.5 mm) were measured by means of a JEOL LASER Raman spectrophotometer, type JRS-409D, using the JLG-A4 argon-ion LASER.

The proton NMR spectra were obtained by means of a JEOL-JNM-MH-100 (100 MHz) NMR spectrometer, using about a 0.2 mol dm^{-3} D_2O solution of samples at 26 °C with DSS (Sodium 3-(trimethylsilyl)-1-propanesulfonate, δ= 0 ppm) and t-butyl alcohol (δ=1.27 ppm downward from DSS) as the internal standards. The carbon-13 NMR were obtained by means of a JEOL C-60-HL spectrometer (15 MHz for ^{13}C-NMR), using a ϕ=8 mm sample tube and using acetic acid and cyclohexane as the external standards. The results were obtained from 32- to 128-times accumulation of the measurements.

The pH of the solution was the direct reading of the pH-meter (HM-5A type Toa Denpa Kogyo); the pD values were not corrected, as the composition of the sample solution was not always simple.

Results and Discussion

The final atomic parameters, except those for hydrogen atoms, are listed in Table 1,[12] the interatomic distances, in Table 2, and the bond angles, in Table 3. The perspective drawing of the complex and the numbering scheme of atoms are shown in Fig. 1, and a projection of the structure along the c-axis, in Fig. 2.

The Sb, N(1), N(2), O(4), and O(6) atoms are almost on a plane; the deviations of these atoms from the calculated best plane are shown in Table 4. The bond angles, N(1)–Sb–N(2), N(1)–Sb–O(4), and N(2)–Sb–O(6), were in the range of 64—77°; however, that of O(4)–Sb–O(6) was 149.6°, almost twice the former ones. This is due to the existence of a lone electron pair in this direction. The small angles of N–Sb–N and N–Sb–O cannot be explained only by the elongated metal–O and metal–N bond lengths compared with those of the first transition-metal edta complexes.

Therefore, the central metal in this chelate is in a

(=: Hydrogen bonding)

ϕ-pentagonal bipyramidal environment. The hepta-coordinated pentagonal bipyramidal structure is found in several edta chelates such as $Rb[Fe^{III}(edta)(H_2O)]\cdot H_2O$,[13] $Sn[Sn^{II}(edta)(H_2O)]\cdot H_2O$,[14] and $[Mg(H_2O)_6][Mg(edta)(H_2O)]\cdot 2H_2O$.[15]

Moreover, such hexa-coordinated metal chelates, *i.e.*, ϕ-hepta-coordinated ones including a lone pair, are also found in the complexes of bivalent group IVB metals or of tervalent group VB metals.[14,17,18] In the cases of tris(oxalato)antimonate(III),[15] and of tris(diphenylthiophosphinato)antimony(III),[16] the lone pair is in the axial direction, which is more desirable from the point of view of VSEPR consideration[19] than the structure of this antimony(III)–edta complex. As the coordinating atoms of an edta cannot occupy all of the five positions of a planar pentagon because of its steric hindrance, the lone-pair electrons seem to occupy the equatorial direction. The O(2)–Sb–O(8) axis bends in the direction opposite to the lone pair, because the repulsion from the lone-pair electrons is stronger than the other bonding-pair ones. The Sb–

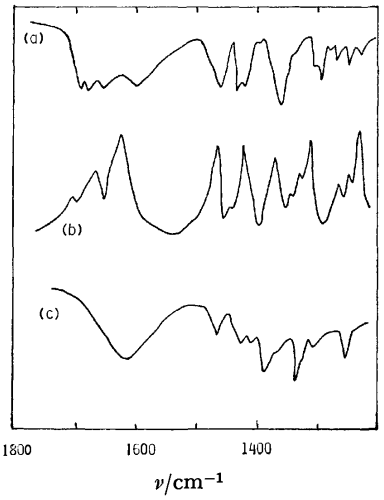

Fig. 3. Infrared (a), and Raman (b) spectra of (hydrogen ethylenediamine-*N*,*N*,*N*′,*N*′-tetraacetato)antimony(III) dihydrate, and infrared spectra of its sodium salt (c).

O(2) and Sb–O(8) bonds make angles of 65.7, and 74.4° respectively with respect to the average Sb–N(1)–N(2)–O(4)–O(6) plane.

Antimony(III), generally, does not make a strong bond with a nitrogen atom of amines. As antimony(III) has a strong affinity to a hydroxo group, when some amine is added, it reacts with the hydroxo group produced by the hydrolysis of an amine, except under a strictly dry medium. The Sb–N distances of this complex are shorter than that of the $SbCl_3$–aniline adduct (2.525 Å),[20] and the Sb–N bond of this edta complex is stronger than that of the common antimony(III)–amine complexes.

With respect to the bond lengths of Sb–O and of C–O, there are two types of carboxyl groups in the chelate: Type 1: the bond lengths of Sb–O(2), Sb–O(6), and Sb–O(8) are in the range of 2.18 and 2.24 and are normal.[17,21–26] The difference between the two C–O bond lengths of each carboxyl group of this type is in the range of 0.02 and 0.04 Å, like the usual ionized carboxyl group.[27a] Type 2: Sb–O(4) distance, 2.79 Å, is out of the ordinary. The C(6)–O(3) is longer than C(6)–O(4) by 0.10 Å, which is comparable with the value of a free carboxylic acid. Therefore, this type of carboxyl group is likely to be in a free-acid form, coordinating to an antimony atom with its carbonyl oxygen atom. This type of coordination seems to cause the especially strong acidity of Sb(Hedta) ($pK_a=1.02$).[4] Of all the carboxyl groups, the Type 2 group has the largest deviations from the best plane, as is shown in Table 4. This phenomenon is also found at the coordinated-acid-form carboxyl group in $[Cu(H_2edta)(H_2O)]$.[28]

One of the crystalline water oxygen atoms, O(W1), forms a hydrogen bond with O(3) of the Type 2 carboxyl group. This O(3)–H···O(W1) distance is 2.55 Å, and it agrees with that of a hydrogen bond between a water and an acid.[27b] The other hydrogen bonds of the crystalline-water oxygens are those between O(W1)···O(5)^{I}, O(W1)···O(1)^{II}, O(W1)···O(W2)^{III}, and O(W2)···O(7), as is shown in Table 2 and Fig. 2, where O(1), O(5), and O(7) are all Type 1 carboxyl-group oxygen atoms.

The infrared and Raman spectra of the complex have essentially the same absorption bands; almost all peaks of the infrared spectra were recognized also in its Raman spectra between 200 and 4000 cm^{-1}. The spectra between 1200 and 1800 cm^{-1} are shown in Fig. 3. In the case of $Sb(Hedta)\cdot 2H_2O$, the ν_{as}(COO) peak in the infrared spectra splits into 4 peaks, and that in the Raman spectra, into 3 peaks.

The band at 1693 cm^{-1} of the infrared spectra (1702 cm^{-1} in Raman spectra) shows the existence of a free carboxyl group, while the 1677 and 1651 cm^{-1} bands of the infrared spectra (1667 cm^{-1} band of the Raman spectra) are those of the coordinated carboxyl groups; both of them are ν_{as}(COO) bands. Although some additional splitting is recognized in the spectra of this region, it is probably due to the difference in the effects on each carboxyl group of its coordination bond, its position in the ψ-pentagonal bipyramidal configuration, and the hydrogen bonds of crystalline waters around it.

According to Nakamoto[29b,c] and Sawyer,[30–32] the ν_{as}(COO) band of metal-edta chelates appears at about 1650 cm^{-1}, when the coordinate bond is a rather covalent-dominant one. As has been shown above, the wave numbers of the band of the Sb–edta complex are higher than those of typical covalent-dominant edta complexes, such as Cr(III) (1640 cm^{-1}), Co(III) (1645 cm^{-1}), and Th(IV) (1630 cm^{-1}).[32]

The sodium salt of the antimony(III)–edta complex has a broad ν_{as}(COO) band at about 1630 cm^{-1}, lower than that of the free-acid-type complex. This effect is due to the more ionic character of the Type 2 carboxyl group in this salt.

Like the edta complexes of other metals,[29c,30–32] four bands in the 1302—1470 cm^{-1} region, which are likely ν_s(COO) or its mixing bands, were observed in the infrared as well as in the Raman spectra.

In the far-infrared region, the band near 240 cm^{-1} is tentatively assigned as the ν(Sb–O) band, and those in the 370—390 cm^{-1} region, as the ν(Sb–N) modes, by analogy to the amino-acid complexes of several metals.[29a]

This antimony(III)–edta complex can also exist even in an aqueous solution of a limited pH region, in spite of the tendency of the common antimony(III) salt to be easily hydrolyzed, a fact which is proved by the NMR spectral data to be shown below.

In the cases of covalent-dominant edta complexes, such as Co(III)–,[33] Zr(IV)–,[34] and Hf(IV)–edta,[34] the AB pattern was observed in their ^{1}H-NMR spectra due to the fixation of the ligand. In the case of the Bi(III)–edta complex, as well as of the Sb(III)-*trans*-1,2-cyclohexanediamine-*N*,*N*,*N*′,*N*′-tetraacetic acid complex, both of them can be expected to have a structure very near to that of the antimony(III)–edta complex, and the acetato-proton peak splits into an AB-pattern quartet due to the spin-spin coupling of geminal protons, as the nitrogen atoms of the ligand in these complexes bond tightly with the central metal. The typical ^{1}H-NMR spectra of $Sb(Hedta)\cdot 2H_2O$ in an aqueous solution containing a sodium acetate–

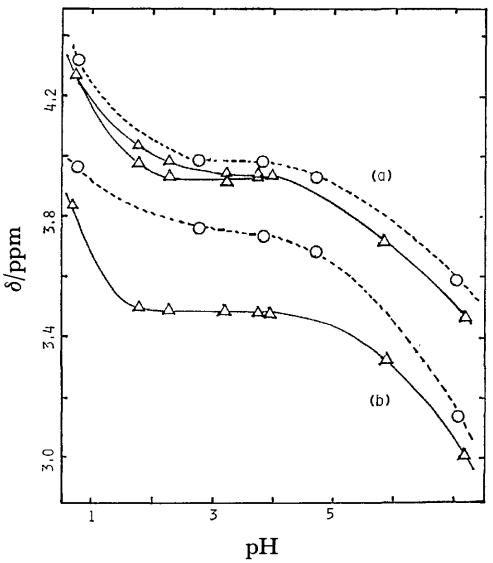

Fig. 4. Chemical shifts of acetato (a), and ethylene (b) protons of Sb(Hedta) complex (—○--) compared with those of sodium salt of edta (—△—) in D_2O solution. (δ: DSS=0, downwarp +) (pH shown is the reading of a pH meter; correction for D_2O was not applied).

acetic acid buffer show two peaks; one for the acetato-protons, and the other for ethylene-protons of the ligand. The acetato-proton peak clearly splits into two or more peaks in the pH region of 1.5—3.5, with a splitting of 3 Hz. The ethylene-proton peak also seems to have some fine structure when the pH of the solution is in the same region. However, the splitting is too small to be identified clearly.

The relations between the pH of the solution and the chemical shifts of acetato- and ethylene-protons of the ligand in the antimony(III)–edta complex are shown in Fig. 4. As is shown in the figure, when the pH of the solution was between 1.5—3.5, the chemical shifts of both peaks, especially those of the ethylene-protons, are different from those of the sodium salt of edta. This fact seems to show that the edta ligand in the antimony(III)–edta complex bonds with the metal atom only in the 1.5—3.5 pH region. This fact coincides with the result of a potentiometric titration study by Özer.[4]

When disodium salt of edta is added to the solution of the antimony(III)–edta complex in the pH region of 1.5—3.5, a new peak due to the ethylene-proton of the $[H_2(edta)]^{2-}$ ion appears, in addition to the original two peaks of the antimony complex (The acetato-proton peak of the excess salt could not be recognized; it is probably due to the accidental overlapping of the peaks of the antimony complex with that of the disodium salt.) From this fact, it can be said that the edta ligand in the antimony complex does not exchange with the free ligand ion in the aqueous solution of this pH region; this is a proof of the strong covalent character bond between the ligand and the central metal atom of the complex.

Although the ^{13}C-NMR of the acid-type complex Sb(Hedta) could not be measured by our spectrometer because of its low solubility, its sodium salt was examined by the technique. The peak for its carboxyl carbons, 176.6; for ethylene carbons, 62.0: for acetato-methylene carbons, 57.0 (δ ppm, downward from TMS). No splitting of the carboxyl carbon peak was found. The ethylene and acetato methylene carbon peaks of the antimony complex shift to a lower magnetic field than the tetra- and disodium salts of the free ligand. (Na_4(edta): 181.0, 60.4, and 53.5; Na_2H_2(edta): 171.5, 58.9, and 52.5 ppm, respectively, for carboxyl, ethylene, and acetato-methylene carbons.) As the chemical shifts of both types of ligand carbons are very different from those of the free ligand, it is likely that the edta ligand in this complex does not dissociate from the central antimony(III) atom, not even in the aqueous solution. The chemical shifts of the carboxyl carbons in some metal-edta complexes were shown by Hagen and others.[35] Compared with their data, the resonances of the carbon atoms of the antimony(III)–edta chelate appear in a relatively higher magnetic field than the corresponding peaks of common edta complexes.

The authors greatly appreciate the help of Dr. Akiko Kobayashi for the X-ray diffractometer measurements, performed under the guidance of Professor Yukiyoshi Sasaki, The University of Tokyo. A part of this work was supported by a Grant-in-Aid for Scientific Research of the Ministry of Education, Science and Culture.

The Determination of Kojic Acid Using the Stopped-flow Method†

Hiroshi TANIGAKI, Hitoshi OBATA,* and Tai TOKUYAMA
Department of Chemistry, Faculty of Engineering, Kansai University, Suita, Osaka 564
(Received March 12, 1980)

A kinetic method of the determination of kojic acid with 2,6-dichlorophenolindophenol(DCIP) is described. The oxidized form of DCIP, reacting with kojic acid, changes to the colorless reduced form of DCIP. By spectrophotometrically measuring the rate of discoloration, the apparent first-order rate constant, k_{app}, and the second-order rate constant, k, were obtained. The determination of kojic acid in the fermentation medium is possible by using k the constant, even in the presence of various organic substances.

Recently, kojic acid has attracted considerable attention in the food industry because it can be used as a starting material for synthesizing maltol and ethylmaltol, which are flavor enhancers of foods. It is often necessary to determine exactly the kojic acid which is produced in a fermentation medium. The colorimetric analysis of kojic acid with ammonium iron(III) sulfate has been widely used as a standard method[1–6] for the determination of kojic acid in a fermentation medium because of its simplicity and convenience, however, it involves some drawbacks in that it is susceptible to interference by the turbidity or color of the samples. Recently, the reaction of reductones with 2,6-dichlorophenolindophenol(DCIP) has been studied by Hiromi *et al.*,[7] Tonomura *et al.*,[8] and our laboratory[9–13] using the stopped-flow method, and its application to the determination of L-ascorbic acid and triose reductone has been suggested, since kojic acid is a pseudo-reductone whose redox behavior is quite similar to that of L-ascorbic acid.

Experimental

Materials. The DCIP is obtained from the Merck Chemical Co. Kojic acid was produced by the fermentation method using *Aspergillus oryzae* M-128.[14] It was purified by sublimation *in vacuo* at 130 °C. The other reagents used were of an analytical grade purchased from Wako Pure Chemical Industries, Ltd.

Measurement of the Rate Constant. The apparatuses used in this study were a Hitachi spectrophotometer Model 101 with a mixing injector and a Towa Model EPR-10A recorder. The reduction of DCIP was followed by measuring the absorbance at 525 nm,[13] the light path of the cell being 10 mm. The reactions were performed at 25 °C in a 0.2 mol dm^{-3} acetate buffer or a 0.2 mol dm^{-3} sodium phosphate buffer containing both 0.2 mol dm^{-3} sodium chloride and 5% 1-butanol, the DCIP was dissolved in distilled water containing 0.2 mol dm^{-3} sodium chloride and 5% 1-butanol. The concentration of the DCIP was kept at less than 5% of the concentration of kojic acid. The DCIP solution was prepared a fresh daily. All the kinetic results presented are the average of three measurements.

Results and Discussion

If we consider that the reaction of kojic acid with DCIP proceeds in a way similar to that of L-ascorbic acid, the reaction can be expected to obey the following second-order kinetics:

$$-d[\text{DCIP}]/dt = k[\text{kojic acid}][\text{DCIP}] = k_{app}[\text{DCIP}]$$

where [kojic acid] and [DCIP] represent the concentrations of kojic acid and DCIP respectively. When [kojic acid] is greatly in excess of [DCIP], k_{app} is the apparent first-order rate constant and k_{app} equals k times the initial concentration of kojic acid.

Reaction Curve of the Reaction of Kojic Acid with DCIP. Figure 1 shows the reaction curve of the reaction of kojic acid with DCIP. The reduction of DCIP was followed by the disappearance of the color at 525 nm for DCIP. In the initial stage of the reaction, a dead time due to the apparatus was observed. The apparent first-order rate constant(k_{app}) can be calculated from the absorbance changes by means of the following equation:[15]

$$\ln (A_0 - A_\infty / A_X - A_\infty) = k_{app}t$$

where A_0, A_X, and A_∞ represent the absorbances at $t=0$, X, and ∞ (the termination of the reaction) respectively. The first-order plot is linear, as is shown in Fig. 2. The apparent first-order rate constant, k_{app}, was obtained from the slope of the plot.

k-pH *Profile.* Figure 3 shows the pH dependence of the second-order rate constant, k. The second-order rate constants were obtained by dividing the k_{app} by the concentration of kojic acid. A maximum was observed in the acidic region (pH 6.0—6.5) for fast reactions. A bluff was observed at pH 7.0 for slow reactions. The k at pH 6.3 was about 5 times as large as that at pH 8.0. The half-time of the reaction, $t_{1/2}$, was 47.9 s for the kojic-acid concentration of 12.5 mmol dm^{-3} at pH 6.3. The plot of log k

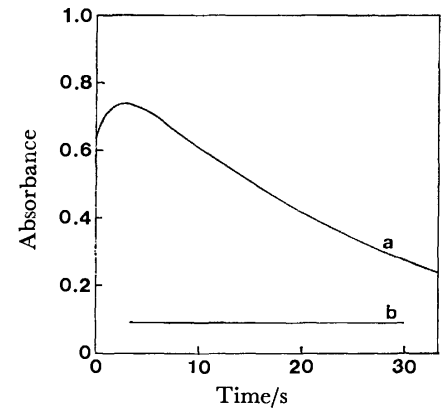

Fig. 1. Reaction curve of the reaction of kojic acid with DCIP at 25 °C.
pH 6.0, 10 mm cell, 525 nm, [kojic acid]=100 mmol dm^{-3}, [DCIP]=200 μmol dm^{-3}. a: Reaction signals, b: signals of the termination of reaction.

† This work was presented at the ACS/CSJ Chemical Congress, Honolulu, April 1979.

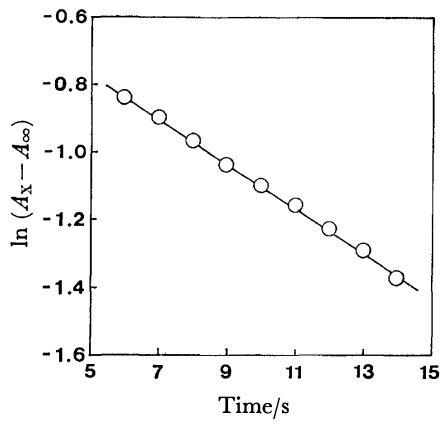

Fig. 2. First-order plot of the reaction of kojic acid with DCIP at 25 °C.
The experimental conditions were the same as in Fig. 1. A_X and A_∞ indicate the values of absorbances at time=X and ∞ (the termination of reaction). It was obtained from the slope of the plot that k_{app} was 6.81×10^{-2} s^{-1}.

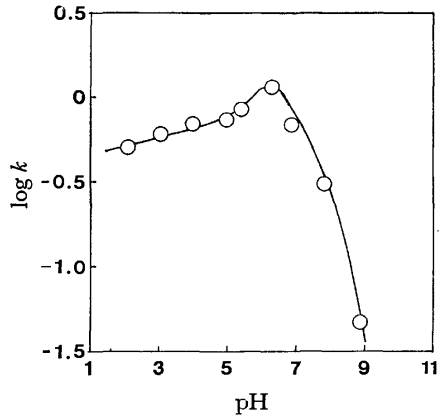

Fig. 3. The pH dependence of the second-order rate constants of the reaction of kojic acid with DCIP at 25 °C.
[Kojic acid]=12.5 mmol dm^{-3}, [DCIP]=200 μmol dm^{-3}, the ionic strength of the buffer solution was 0.10.

TABLE 1. EFFECTS OF VARIOUS ADDED SUBSTANCES ON THE k OF THE REACTION OF KOJIC ACID WITH DCIP AT 25 °C

Added substance	k / mol dm^{-3} s^{-1}	Relative rate constant
None	1.18	1.00
Glycine	1.13	0.96
L-Phenylalanine	1.18	1.00
L-Tryptophan	1.20	1.02
Malic acid	1.19	1.01
Succinic acid	1.19	1.01
Fructose	1.21	1.03
Glucose	1.13	0.96
Sucrose	1.19	1.01
$FeCl_3 \cdot 6H_2O$	38.6	32.7
$MgCl_2 \cdot 6H_2O$	1.21	1.03
$ZnCl_2$	1.18	1.00

pH 6.3, [kojic acid]=12.5 mmol dm^{-3}, [DCIP]=200 μmol dm^{-3}, [Added substance]=12.5 mmol dm^{-3}.

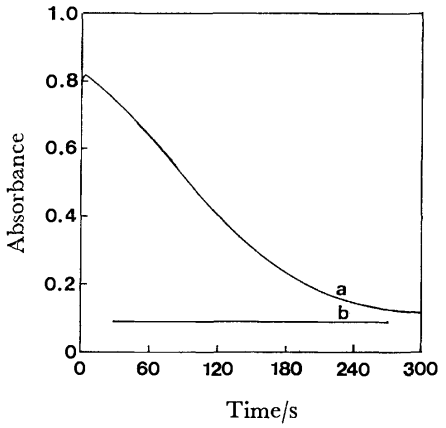

Fig. 5. Reaction curve of the reaction of DCIP with kojic acid in the fermentation medium at 25 °C. pH 6.0, [DCIP]=200 μmol dm^{-3}. a: Reaction signals, b: signals of the termination of reaction. The growth medium were glucose (10.0 g), $MgSO_4 \cdot 7H_2O$ (0.05 g), KH_2PO_4 (0.1 g), and bonito extract (0.25 g). The culture was shaken on a rotary shaker for 72 h at 25 °C.

against the pH is different from that obtained for the reaction of L-ascorbic acid with DCIP. These results suggest that the reaction mechanism of kojic acid with DCIP is considerably different from that of L-ascorbic acid over a wide pH range.

Calibration Curve of Kojic-acid Determination. Figure 4 shows the proportionality between k_{app} and the kojic-acid concentration at pH 4.0 and 6.0. It gives a straight line, suggesting the possibility of applying the reaction to the determination of kojic acid. The determination of kojic acid using the stopped-flow method was possible, even in the pH 2—7 region and in concentrations from 1 to 100 mmol dm^{-3}.

Effects of Various Substances. Table 1 shows the effects of various substances often encountered in kojic-acid determination; amino acids, organic acids, sugars, and metal ions were tested. The results show that

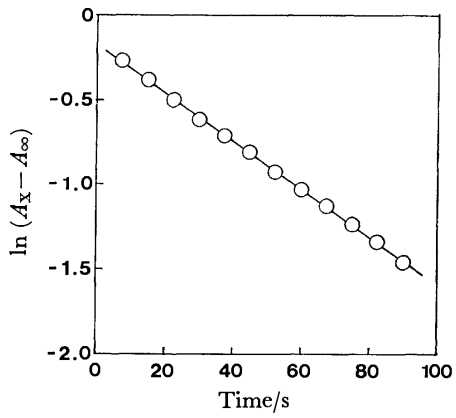

Fig. 6. First-order plot of the reaction of DCIP with kojic acid in the fermentation medium at 25 °C. The experimental conditions were the same as in Fig. 5. It was obtained from the slope of the plot that k_{app} was 1.41×10^{-2} s^{-1}.

most additives, except for iron(III) chloride, do not interfere with the determination of kojic acid. The iron(III) chloride, however, reacted with kojic acid.[1)]

Analysis of Kojic Acid in the Fermentation Medium. The growth medium of the mold strain of *Aspergillus* was prepared with glucose (10.0 g), $MgSO_4 \cdot 7H_2O$ (0.05 g), KH_2PO_4 (0.1 g), and bonito extract (0.25 g). The culture was shaken on a rotary shaker for 72 h at 25 °C. Figure 5 shows the results of the analysis of the kojic-acid fermentation medium containing various substances. The apparent first-order rate constant (k_{app}) was obtained from the slope of the apparent first-order plot of Fig. 6. In this method, the kojic-acid concentration in broth was determined to be 18.0 mg cm^{-3}. By the colorimetric method, the amount of kojic acid was determined to be 18.3 mg cm^{-3}. The analytical data obtained by the stopped-flow method is in fair agreement with the colorimetric data. The determination of kojic acid using the stopped-flow method may be recommended for use with colored and turbid samples such as the fermentation medium of molasses.

We wish to thank Professor Keitaro Hiromi, Department of Food Science and Technology, Faculty of Agriculture, Kyoto University, and Professor Masanosuke Takagi, College of Agriculture, University of Osaka Prefecture, for their valuable advice on the stopped-flow measurement of the reaction rate of kojic acid.

Hypochlorite Oxidation of Ammonia. Effective Removal of Ammonia from Waste Water by UV-irradiation[1)]

Makoto KIMURA, Teiichi SUZUKI, and Yoshiro OGATA*

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received March 14, 1980)

The hypochlorite oxidation of ammonia giving rise to nitrogen evolution was carried out in the dark or under irradiation in order to study the reaction mechanism and application to waste water treatment. UV-irradiation accelerates remarkably the rate of decomposition of unfavorable chloramines. The acceleration covers the pH region 2—12, where corresponding dark reactions are slow. The irradiation also affects the formation of by-products such as NO_2^- and NO_3^-, the effect being a slight increase in NO_2^- formation in the pH range 2—12. These results suggest an effective industrial application to avoid eutrophication in seas and lakes. The irradiation effect is discussed in relation to reaction mechanism, in which the irradiation possibly facilitates the N–N bond formation after chloramine formation.

Hypochlorite salt, especially sodium hypochlorite, oxidizes ammonia or ammonium ion in water. Though the oxidation is useful for hydrazine synthesis, it usually leads to rapid and quantitative evolution of nitrogen in the presence of excessive oxidant.

$$2NH_3 + 3NaOCl \longrightarrow N_2 + 3H_2O + 3NaCl \quad (1)$$

Another industrial application has recently been worked out for waste water treatment.[2–4)] Ammonia together with related nitrogen compounds brings about serious eutrophication in seas and lakes, so that an effective industrial plan is required. This hypochlorite oxidation of ammonia is called break-point chlorination.[2–4)] Generally, the oxidation rate is not high enough at low NH_3 concentration as observed in ordinary waste water, so that unfavorable chlorinated products such as NH_2Cl, $NHCl_2$, and NCl_3 remain, depending on the pH as well as relative dosage of the oxidant to NH_3.[2)] As regards the elimination of chloramines, the active carbon is proposed because of its industrial availability.[4)]

On the other hand, hypochlorites are susceptible to light, decomposing to oxygen and chlorate along with chloride ion.[5)] Studies in this laboratory have shown that irradiation with hypochlorite enables complete oxidation of several organic substances which otherwise cannot be attained.[6–8)] This article describes the effect of irradiation in the hypochlorite oxidation of ammonia, and the influencing factors such as pH and the molar ratio of hypochlorite to ammonia. A probable mechanism is discussed.

Experimental

Materials. Sodium hypochlorite was prepared by taking into account the dissociation constant for HOCl.[9)] Into ice-cooled 0.20 M (1 M=1 mol dm^{-3}) aqueous NaOH (1 l) was absorbed commercial chlorine gas until the solution showed 0.10 M by iodometry and pH 10 with a glass-electrode. After its pH was adjusted to 12 by addition of NaOH, the solution was stored in a refrigerator (stable at least for several months). An ammonia solution was prepared by dissolving a weighed amount of ammonium sulfate in distilled water. Buffer solutions except for preliminary experiments were prepared by mixing each 0.02 M phosphoric, boric and acetic acids with an appropriate amount of 0.10 M NaOH (Britton-Robinsons' buffer solution). Analytical reagents were used.

Instruments. UV and visible absorption measurements were carried out on a Hitachi 124 spectrophotometer in 1 cm cells. UV-irradiation reactions were conducted in a vessel equipped with a Halos 100 W high-pressure mercury lamp. Gas chromatograms were taken on a Yanaco 550 using a column of Molecular Sieves 5A.

Analysis. Iodometric titration was carried out according to the usual procedures to determine residual concentrations of oxidants such as $OCl^-/HOCl$, Cl_2, NH_2Cl, $NHCl_2$, NCl_3, and NO_2^-/HNO_2, but not NO_3^-/HNO_3 nor $ClO_3^-/HClO_3$. Rapid titration was carried out for the sake of clear end point, since slow air oxidation causes regeneration of HNO_2.

Ammonia was determined by Nessler's method according to JIS K 0101-1976. In order to attain distinct coloration, the resulting solution should be adjusted to pH 12. The calibration curve was based on the absorbance at 450 nm, its apparent molar coefficient being 1.6×10^3 in the range 0.10—0.50 mM ammonia.

Concentrations of NO_2^-/HNO_2 and NO_3^-/HNO_3 were determined by Gries' method involving diazotization of acidified aniline and the subsequent azo-dye development with 1-naphthylamine. The determination involves the reduction of HNO_3 to HNO_2 after elimination of HNO_2. Both procedures were carried out according to JIS K 010-1976.

Dark Reaction. Examination of breakpoint was carried out in buffered 2.0 mM ammonia solutions of pH 9.5, 7.9, 7.3, 6.9, 5.1, 2.6, and 1.6 by adding an appropriate amount of aqueous NaClO. After 15 min, concentrations of residual active chlorine were determined iodometrically.

The influence of pH on reaction rate was examined as follows. To a solution of 20 mM NH_3 (10 ml) mixed with a buffer solution (80 ml) was added 25, 30, or 35 mM aqueous NaClO (10 ml) with stirring. The reaction solution was kept standing in the dark for 1 h, and an aliquot (10 ml) was titrated iodometrically. The results are given in Table 1.

Identification of chloramines formed initially is based on the following UV spectra; absorption max. (ε) OCl^-, 292 nm(392); HOCl, 235 (105); Cl_2, 315 (34); NH_2Cl, 245 (416); $NHCl_2$, 297 (265); NCl_3, 340 (255).[10)] The acidity constant of HOCl and hydrolysis constant of Cl_2[9)] were taken into consideration for assigning the species in the reaction solutions.

Irradiation Reaction. Irradiation was carried out at room temperature in the air. For the product analysis of evolved gas, it was performed under helium with the system connected to a gas burette. For detection of ClO_3^-, zinc powder reducing ClO_3^- to Cl^- was added to the ir-

radiated solutions adjusted at pH 5, and the concentration of resulting Cl^- was determined by colorimetry of iron(III) thiocyanate after addition of ammonium iron(III) sulfate and mercury(II) thiocyanate. The color development was checked with ClO_3^- solutions, and calibrated with standard Cl^- solutions.

Comparative experiments between dark and irradiation reactions were carried out as follows. A buffer solution (320 ml) was mixed with a 20 mM NH_3 solution (40 ml) and 25 or 30 mM aqueous NaClO (40 ml) was added with stirring. Half of the resulting solution was irradiated for 5—20 min until the iodometric titer became constant. Aliquots were diluted to an appropriate concentration and adjusted to neutral to make test solutions for analysis of NH_3, NO_2^-, and NO_3^-. Their standard calibration curves were checked from time to time. The other half of the solution was kept standing in the dark for 5—10 d in a stoppered flask, then worked up by a similar analytical procedure. The results are given in Table 2.

UV absorptions of species: NO_2^-, 354 nm (ε 23); HNO_2, 371 (44); NO_3^-, 357 (12); HNO_3, 371 (19). Supplementary irradiation of 5.0 mM NH_3 was conducted in the presence of $NaNO_2$ (5.0 mM) or $NaNO_3$ (5.0 mM) at various pH for 1 h, no significant decrease being observed in the concentration of NH_3, NO_2^-, nor NO_3^-.

Results

Dark Reaction. At 2 mM concentration of ammonia, the dark reaction of ammonia with hypochlorite proceeds rapidly to a considerable extent at room temperature. The change is readily followed by iodometric titration, on addition of an appropriate amount of aqueous sodium hypochlorite to buffered ammonia solutions. Studies on breakpoint chlorination show that a plot of residual active chlorine *vs.* the amount of the oxidant added gradually reaches a maximum and then drops sharply to a minimum (breakpoint), increasing again.[2-4] The breakpoint lies at the molar ratio 3/2, hypochlorite (Ox) to ammonia (Ox/NH_3), or slightly above, which corresponds to Eq. 1. The reaction was examined over a wide range of pH at a reaction time of 15 min. Such a breakpoint was observed in the pH range 4—8. However, a solution at pH>8 and pH<4 gave no breakpoint. A curve for pH 9.5 is located at a little lower than the expected line for no ammonia oxidation. At pH 2.6, a slightly distinct minimum was observed at about 2.0 of Ox/NH_3.

In order to examine the influence of H on residual

a) Reaction time; dark 5-10 d, irradiation 20 min (a 100 W high-pressure mercury lamp).

active chlorine, a series of runs were conducted in buffer solutions with three values of the ratio Ox/NH_3 adjusted around the stoichiometric ratio of 3/2 (Table 1).

When a sufficient amount of hypochlorite ($Ox/NH_3 > 3/2$) is used in the pH region 4—10, oxidation is completed within at least 1 h. When Ox/NH_3 is lower than 3/2, oxidation takes place sluggishly. Thus, a deviation from the neutral solution causes insufficient oxidation, even with excess oxidant.

The progress of reaction was followed by UV spectroscopy. Immediate measurements on addition of aqueous hypochlorite to buffered ammonia showed new absorptions corresponding to NH_2Cl, $NHCl_2$, and NCl_3[10] instead of OCl^-, HOCl, and Cl_2, apart from contamination of OCl^-, HOCl, and Cl_2 formed readily from sodium hypochlorite (see Experimental). The type of chloramines formed depends not only on pH,[2,10] but also on Ox/NH_3. UV measurements on various ratios of Ox/NH_3 (0.5—3.0) were carried out at several pH. At pH 12.0, the absorption of NH_2Cl alone took place up to *ca.* 1.0 of Ox/NH_3, while two absorptions of NH_2Cl and OCl^- appeared over 1.0 of Ox/NH_3. Solutions of pH 9.5 gave an absorption indicating overlap of NH_2Cl and HOCl up to 1.3 of Ox/NH_3, the absorption at 290 nm becoming distinct with an increase in Ox/NH_3. Since aqueous sodium hypochlorite at pH 9.5 exists as a form of HOCl, the absorption at 290 nm may be assigned to $NHCl_2$ rather than OCl^-. At pH 5.1, the result was similar to that at pH 9.5. At pH 2.6, the third absorption appeared at 340 nm, and was assigned to NCl_3 and/or Cl_2. These chloramines undergo rapid interconversion as well as nitrogen evolution, determination of their equilibrium constants being unsuccessful.

Effect of Irradiation. The iodometric titer decreased very rapidly when solutions containing NH_2Cl, $NHCl_2$, NCl_3 or their equilibrated species (*vide infra*) were irradiated with UV light of wavelength > 290 nm. Consumption of the oxidant was completed after 5—20 min by internal irradiation with a 100 W high-pressure mercury lamp. UV study of the resulting solutions showed transparency at 210—370 nm, indicating photo-decomposion of chloramines. The gas evolved was confirmed to be nitrogen by gas chromatography. The volumetric determination of evolved nitrogen gave an over 80% yield on the basis of NaClO assuming that the irradiation is also expressed as in Eq. 1. In order to estimate ClO_3^- which is formed in *ca.* 40% yield on irradiation of aqueous NaClO alone,[5] several attempts on Cl^- determination were made after treatment with zinc powder which reduced ClO_3^- to Cl^-. But no significant increase in Cl^- concentration was observed with this reduction treatment.

Several breakpoint chlorination studies reveal that NO_2^- and NO_3^- are accompanied as by-products in the reaction in alkaline media.[2] Such a side reaction was also observed in the irradiation reaction. Comparative experiments between dark and irradiation reactions (Table 2) were conducted by changing the ratio Ox/NH_3 as well as pH. For completion of the reaction, 5—10 d were required in the dark, while only 20 min was sufficient under irradiation. The concentrations of residual NH_3, NO_2^-, and NO_3^- were determined.

Discussion

We see from residual active chlorine in dark reactions (Table 1) that the rate of reaction depends on the relative ratio of Ox/NH_3 as well as pH of the solution. UV spectra show transient existence of chloramines such as NH_2Cl, $NHCl_2$, and NCl_3. The type of chloramine formed depends on pH,[2,10] *viz.*, alkaline or neutral solution gives NH_2Cl, while NCl_3 is favored at pH below 4, the relatively unstable $NHCl_2$ being formed in the pH range 4.5—5.0. This was confirmed by our observation. Since nitrogen evolution requires 3/2 mol of hypochlorite for 1 mol of NH_3 (Eq. 1), the chloramine formation should also depend on Ox/NH_3. One mol of NH_2Cl, $NHCl_2$, and NCl_3 requires 1, 2, and 3 mol of hypochlorite, respectively. NH_2Cl, $NHCl_2$, and NCl_3 are then in equilibrium with each other and even with OCl^-, HOCl, and Cl_2. Possible equilibria in the system of ammonia and sodium hypochlorite are as follows.

$$NH_3 + H_2O \rightleftharpoons NH_4OH \rightleftharpoons NH_4^+ + OH^- \quad (2)$$

$$Cl_2 + H_2O \rightleftharpoons HOCl + H^+ + Cl^- \quad (3a)$$

$$HOCl \rightleftharpoons H^+ + OCl^- \quad (3b)$$

$$NH_3 + HOCl \rightleftharpoons NH_2Cl + H_2O \quad (4a)$$

$$NH_2Cl + HOCl \rightleftharpoons NHCl_2 + H_2O \quad (4b)$$

$$NHCl_2 + HOCl \rightleftharpoons NCl_3 + H_2O \quad (4c)$$

By taking advantage of the low reactivity of NH_2Cl (slow nitrogen evolution) in a high alkaline solution, the equilibrium constant for $NH_2Cl + OH^- \rightleftharpoons NH_3 + OCl^-$ was estimated to be 1.6×10^{-3} at 15 °C,[12] showing the preference of NH_2Cl to free NH_3. According to our preparative attempts, generation of NCl_3 requires a highly acidic solution to suppress the nitrogen evolution and to enable ultimate chlorination of NH_3. Though $NHCl_2$ requires the ratio Ox/NH_3 of 2, a maximum amount of $NHCl_2$ is generated under the conditions where Ox/NH_3 is slightly lower than 3/2 at pH 4.0—4.5. In any event, the formation of chloramines such as NH_2Cl, $NHCl_2$, and NCl_3 is a rapid process, influencing the whole oxidation mechanism at the initial stage.

The reaction time in the dark is shortened by a factor of over 100 for the present systems, where the ratio Ox/NH_3 is less than that of stoichiometry (Table 2). The acceleration effect due to UV-irradiation would provide an effective industrial design in waste water treatment, where thermal acceleration cannot be applied. The UV-irradiation may also have an advantage over active carbon[4] because of the applicability at various pH.

The dark and irradiation reactions give essentially the same products, though the amount of by-product NO_2^- in the irradiation is larger than that in the dark. The similarity in products is of interest, since species OCl^-, HOCl and Cl_2 equilibrated with NH_2Cl, $NHCl_2$, and NCl_3 (Eq. 2) might decompose into oxygen or chlorate ion on irradiation.[5] Our results suggest that NH_3 can be oxidized in accordance with Eq. 1. The

reason is not clear why the dark and irradiation reactions differ in the by-product formation of NO_2^-. Solutions of NO_2^-, HNO_2, NO_3^-, and HNO_3 possess very weak absorptions at wavelength<400 nm (see Experimental). However, the irradiation of these species in the presence of NH_3 or NH_4^+ gave rise to neither significant evolution of nitrogen nor change in concentration of NO_2^- and NO_3^-. Thus, irrespective of by-product formation, the irradiation reaction should proceed via a path analogous to the dark reaction.

The mechanism of nitrogen evolution, in particular the process after the rapid formation of chloramines, has not been clarified. Schmitz *et al.*[13] reported in their study on the side-reaction of $NHCl_2$ that the following condensation takes place between two mol of $NHCl_2$, leading to nitrogen, as an explanation for chlorinated products of ethers.

$$NHCl_2 + OH^- \longrightarrow Cl_2N^- + H_2O \quad (5a)$$

$$Cl_2N^- + NHCl_2 \longrightarrow Cl_2N\text{-}NHCl + Cl^- \quad (5b)$$

$$Cl_2N\text{-}NHCl \xrightarrow[-HCl]{} Cl\text{-}N{=}N\text{-}Cl \longrightarrow N_2 + 2Cl \quad (5c)$$

The postulate involves deprotonation with base (Eq. 5a). On the basis of UV spectra, stepwise chlorination occurs to a greater extent with lowering in pH to give $NHCl_2$ and NCl_3. As a result, the postulate might be in line with the fact that the dark reaction is more rapid in neutral solution than in solutions of higher or lower pH (Table 1). However, species undergoing N–N bond formation do not seem to be restricted to $NHCl_2$, since irradiation enables nitrogen evolution from NH_2Cl in an alkaline solution or from NCl_3 in an acidic solution. Thus the following kinds of condensation are possible:

$$Cl_2N^- + NH_2Cl \longrightarrow Cl_2N\text{-}NH_2 + Cl^- \quad (6a)$$

$$Cl_2N^- + NCl_3 \longrightarrow C_2N\text{-}NCl_2 + Cl^- \quad (6b)$$

Even the intervention of hydrazine may be possible, since the reaction of aqueous NaOCl with NH_3 gives hydrazine which is readily oxidized to nitrogen.

As regards acceleration by irradiation, in the case of *N*-chlorinated organic compounds irradiation causes their homolytic N–Cl bond cleavage because of its low bond energy.[15] It might affect the step of decomposition of chlorinated hydrazine (Eqs. 5c and 6), assuming that it is rate-determining. The rate-determining step for nitrogen evolution might be N–N bond formation (Eq. 5a, 5b, or 6) rather than decomposition (Eq. 5c), since chloramines are detected instead of unstable chlorinated hydrazines. Irradiation can change the acid dissociation constants of phenols or amines.[16] The change of basicity of chloramines by irradiation is probable in this case. Photoexcitation energy might be changed to molecular thermal energy, *e.g.*, vibrational energy, facilitating N–N bond formation (Eqs. 5a, 5b and 6).

The authors would like to thank Dr. K. Takagi for his valuable discussions. Acknowledgement is made to Toa Gohsei Co. for the supply of chlorine gas.

Preparation of Polynuclear (Diamine)telluratocobalt(III) Complexes

Yutaka Hosokawa* and Yoichi Shimura

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received April 11, 1980)

Penta- and hexa-nuclear condensates of mono(diamine)cobalt(III) complexes and tellurates have been prepared and some of the optically active isomers separated. They are $[\{Co(TeO_6H_4)(diamine)\}(Te_2O_{10})\{Co(TeO_6H_4)(diamine)\}]^{6-}$ (brown complexes) and $[\{Co(TeO_6H_4)(diamine)\}(TeO_6)\{Co(TeO_6H_4)(diamine)\}]^{4-}$ (blue complexes), where diamine=ethylenediamine, (*R*)-(−)-propylenediamine, and (*R*,*R*)-(−)-1,2-cyclohexanediamine. The structures have been determined from the visible and ultraviolet absorption and circular dichroism spectra; the electrostatic repulsion between cobalt(III) and tellurium(VI) atoms is considered in detail.

Continued efforts have been made to synthesize polynuclear complexes of a hybrid type between a metal chelate and a heteropoly condensed complex. Several cobalt(III) compounds such as $[Co_2(Te_2O_{10}H_4)(en)_4]Cl_2$,[1] $H_3[Co_4I_3O_{18}(en)_3]$,[2] and $Na_5[Co(Nb_6O_{19})(dien)]$[3] were reported in previous papers. The former tetranuclear complex $[Co_2(Te_2O_{10}H_4)(diamine)_4]^{2+}$ prepared by dehydration condensation of a binuclear complex $[Co(TeO_6H_4)(diamine)_2]^+$ has a chain structure consisting of two bis(diamine)cobalt(III) and two tellurate(VI) octahedra. The present report is concerned with the preparation of similar polynuclear condensates of mono(diamine)cobalt(III) complexes and tellurates. Some pentanuclear $[Co_2Te_3O_{18}H_8(diamine)_2]^{4-}$ and hexanuclear $[Co_2Te_4O_{22}H_8(diamine)_2]^{6-}$ complexes have been obtained which also have chain structures consisting of five or six octahedra sharing edges. Ordinary compact structures, which have been found in iso- and hetero-poly oxoanions such as $Nb_6O_{19}^{8-}$ and $[CoMo_6O_{24}H_6]^{3-}$, are unfavorable for the present complexes. Reasonable chain structures have been inferred by considering the need to avoid electrostatic repulsion between cobalt(III) and tellurium(VI) atoms. The bidentate diamine ligands used are ethylenediamine (en), (*R*)-(−)-propylenediamine (*l*-pn), and (*R*,*R*)-(−)-1,2-cyclohexanediamine (*l*-chxn).

Experimental

Preparation, Separation, and Optical Resolution of Complexes. (1) $Li_4[\{Co(TeO_6H_4)(en)\}(TeO_6)\{Co(TeO_6H_4)(en)\}]\cdot 6H_2O$ (Blue en Complex): A solution of 2.3 g (10 mmol) of $Te(OH)_6$ in 20 cm³ of water was added to a solution of 1.3 g (5 mmol) of *trans*(NH_3)-$[CoCl_2(NH_3)_2(en)]Cl\cdot H_2O$[4] in 15 cm³ of water. To the mixture was added a solution of 0.8 g (20 mmol) of sodium hydroxide in 10 cm³ of water. The resulting solution was stirred mechanically at about 65 °C until the evolution of ammonia ceased. After being cooled in an ice-bath, the solution was poured into a column (3 cm × 70 cm) of anion exchanger (QAE Sephadex A-25, Cl^- form). The adsorbed band was eluted with 0.2 mol dm^{-3} lithium chloride solution (pH 10 by 1 mol dm^{-3} lithium hydroxide); during that time the column was cooled by flushing it with ice-water. Several red and blue bands eluted rapidly. To the combined eluates was added a large amount of acetone. The precipitate was then separated by a centrifuge, washed a few times with acetone, and dried in a stream of air. This solid was dissolved in a small amount of water and the solution was poured into a column of the type mentioned above, and the adsorbed band was eluted with the same eluting reagent. Three colored bands, purple, blue, and brown, were eluted in this order. The first purple eluate was discarded in this work. The last brown eluate was preserved for the treatment in (2) to obtain another complex. The blue middle eluate was concentrated at 15 °C in a rotary evaporator, and a large amount of methanol–acetone (1:10) mixture was added to the concentrated solution. After the mixture had been kept in a refrigerator overnight, the blue precipitate was collected by a centrifuge, recrystallized at 0 °C from lithium hydroxide solution (pH 10) by adding methanol–acetone mixture, and washed repeatedly with methanol and acetone. Found: C, 4.56; H, 3.45; N, 5.32; Co, 11.2; Te, 36.4%. Calcd for $Li_4[\{Co(TeO_6H_4)(en)\}(TeO_6)\{Co(TeO_6H_4)(en)\}]\cdot 6H_2O$: C, 4.78; H, 3.39; N, 5.23; Co, 10.5; Te, 36.3%. Cobalt was weighed as Co_3O_4 and tellurium as the metal.

(2) $Li_6[\{Co(TeO_6H_4)(en)\}(Te_2O_{10})\{Co(TeO_6H_4)(en)\}]\cdot 7H_2O$ (Brown en Complex): The brown eluate from the chromatography in (1) was concentrated at about 20 °C in a rotary evaporator, and a large volume of methanol–acetone mixture was added to the concentrated solution. The brown product was isolated by a similar method to that used in (1). Found: C, 3.74; H, 2.74; N, 4.19; Co, 8.8; Te, 38.3%. Calcd for $Li_6[\{Co(TeO_6H_4)(en)\}(Te_2O_{10})\{Co(TeO_6H_4)(en)\}]\cdot 7H_2O$: C, 3.76; H, 3.00; N, 4.39; Co, 9.2; Te, 40.0%.

(3) $K_4H_2[\{Co(TeO_6H_4)(en)\}(Te_2O_{10})\{Co(TeO_6H_4)(en)\}]\cdot 4H_2O$: The brown en complex obtained in (2) was dissolved in 0.001 mol dm^{-3} potassium hydroxide solution, and to this was added an appropriate amount of potassium chloride. After the resulting solution had been kept in a refrigerator overnight, the product was separated by filtration, washed a few times with cold water, methanol, and acetone, and dried in a desiccator over calcium chloride. Found: C, 3.59; H, 2.64; N, 4.20%. Calcd for $K_4H_2[\{Co(TeO_6H_4)(en)\}(Te_2O_{10})\{Co(TeO_6H_4)(en)\}]\cdot 4H_2O$: C, 3.39; H, 2.56; N, 4.19%.

(4) $Li_4[\{Co(TeO_6H_4)(l\text{-}pn)\}(TeO_6)\{Co(TeO_6H_4)(l\text{-}pn)\}]\cdot 5.5H_2O$ (Blue l-pn Complex) and $Li_6[\{Co(TeO_6H_4)(l\text{-}pn)\}(Te_2O_{10})\{Co(TeO_6H_4)(l\text{-}pn)\}]\cdot 9H_2O$ (Brown l-pn Complex): These were obtained by almost the same procedure as for the corresponding en complexes. A solution of 2.3 g (10 mmol) of $Te(OH)_6$ in 15 cm³ of water was added to a solution of 1.37 g (5 mmol) of *trans*(NH_3)-$[CoCl_2(NH_3)_2(l\text{-pn})]Cl\cdot 4H_2O$[4] in 25 cm³ of water, and to the mixture was added a solution of 0.8 g (20 mmol) of sodium hydroxide in 15 cm³ of water. The solution was concentrated to about 15 cm³ at 70 °C with mechanical stirring, and poured into a column similar to that used in (1). The column chromatography showed two colored bands, blue and brown, in this order. The blue and brown complexes were isolated as described in (1). Found: C, 6.68; H, 3.67; N, 5.23%. Calcd for $Li_4[\{Co(TeO_6H_4)(l\text{-pn})\}(TeO_6)\{Co(TeO_6H_4)(l\text{-pn})\}]\cdot 5.5H_2O$: C, 6.72; H, 3.67; N, 5.23%. Found: C, 5.41; H, 3.23; N, 4.16%. Calcd for $Li_6[\{Co(TeO_6H_4)(l\text{-pn})\}(Te_2O_{10})\{Co(TeO_6H_4)(l\text{-pn})\}]\cdot 9H_2O$: C, 5.38; H,

3.47; N, 4.18%.

The latter complex was dissolved in a small amount of water, and the solution was treated by column chromatography as described above. The adsorbed band separated gradually into two brown bands, 1 and 2 in this order, when eluted with 0.15 mol dm^{-3} lithium chloride solution (pH 10.5 by 1 mol dm^{-3} lithium hydroxide). Both eluates showed a similar absorption spectrum to that of the unseparated brown *l*-pn complex. The brown *l*-pn 1 and 2 complexes have $\Delta\varepsilon = +0.44$ and $+1.72$, respectively, at the Na D line.

(5) $Li_6[\{Co(TeO_6H_4)(l\text{-chxn})\}(Te_2O_{10})\{Co(TeO_6H_4)(l\text{-chxn})\}]\cdot 12H_2O$ (Brown l-chxn Complex): A solution in 15 cm^3 of water was made of 1.57 g (5 mmol) of *trans*(Cl)-$[CoCl_2(NH_3)_2(l\text{-chxn})]Cl$, which was obtained according to the method[4] for the corresponding en complex using *l*-chxn instead of en. To this solution was added first a solution of 2.3 g (10 mmol) of $Te(OH)_6$ in 20 cm^3 of water and then a solution of 0.8 g (20 mmol) of sodium hydroxide in 15 cm^3 of water. The resulting solution was stirred mechanically at 60 °C for 3 h, and was then poured into a column similar to that in (*1*). The column chromatography showed one brown band predominantly. Found: C, 9.53; H, 3.84; N, 3.73; Te, 33.4%. Calcd for $Li_6[\{Co(TeO_6H_4)(l\text{-chxn})\}(Te_2O_{10})\{Co(TeO_6H_4)(l\text{-chxn})\}]\cdot 12H_2O$: C, 9.79; H, 4.11; N, 3.73; Te, 34.6%.

(6) Optical Resolution of the Blue and Brown en Complexes: A solution of 0.012 g of Λ-$(+)_{589}$-$[Co(en)_3]Br_3\cdot H_2O$ in 10 cm^3 of water was added gradually to a solution of 0.15 g of the blue en complex in 20 cm^3 of lithium hydroxide solution of pH 11 at about 5 °C. After the resulting solution had been kept in a refrigerator overnight, the yellow green diastereomer was separated by filtration, and washed with cold water a few times. It was difficult to replace the $(+)_{589}$-$[Co(en)_3]^{3+}$ cation of the less soluble diastereomer by an ordinary cation such as K^+ or Na^+. Then, to the filtrate containing the more soluble diastereomer was added an appropriate amount of cation exchanger (SP Sephadex C-25, Na^+ or K^+ form) to remove $(+)_{589}$-$[Co(en)_3]^{3+}$. The cation exchanger was filtered and CD of the filtrate was measured. The blue en complex in this solution has $\Delta\varepsilon = -0.31$ at the Na D line.

The optical resolution of the brown en complex was made by the same procedure as that used for the blue en complex, using 0.13 g of the brown en complex and 0.024 g of Λ-$(+)_{589}$-$[Co(en)_3]Br_3\cdot H_2O$; the CD of the filtrate was measured after removing $(+)_{589}$-$[Co(en)_3]^{3+}$. The brown en complex has $\Delta\varepsilon = -0.52$ at the Na D line.

(7) $[\{Co(dien)(H_2O)\}(Te_2O_{10}H_4)\{Co(dien)(H_2O)\}]Cl_2\cdot 5H_2O$ (Tetranuclear dien Complex): A solution of 1.15 g (5 mmol) of $Te(OH)_6$ in 10 cm^3 of water was added, with mechanical stirring, to a solution of 1.35 g (5 mmol) of *mer*-$[CoCl_3(dien)]$ in 20 cm^3 of water at 60—70 °C (dien= diethylenetriamine). A solution of 1.12 g (20 mmol) of potassium hydroxide in 10 cm^3 of water was added to the solution by portions. After being stirred mechanically at 65 °C for *ca.* 3 h, the mixture was kept in a refrigerator overnight. The light red precipitate was filtered, and to the filtrate was added an appropriate amount of acetone. After the solution had been kept in a refrigerator overnight again, the red oily precipitate was separated by decanting the supernatant liquid. The product was recrystallized from a small amount of cold water by adding acetone, and washed with a methanol–water (5:1) mixture, methanol, and ethanol. Found: C, 10.52; H, 4.38; N, 9.22; Te, 28.0%. Calcd for $[\{Co(dien)(H_2O)\}(Te_2O_{10}H_4)\{Co(dien)(H_2O)\}]Cl_2\cdot 5H_2O$: C, 10.62; H, 4.47; N, 9.29; Te, 27.8%.

Measurements. The visible and ultraviolet absorption spectra were taken on a Shimadzu UV-200 spectrophotometer. The CD spectra were recorded on a JASCO MOE-1 spectropolarimeter. The absorption and CD measurements of the present complexes (lithium salts) were made in aqueous lithium hydroxide solutions (pH 10) over the concentration range 10^{-3} to 10^{-5} mol dm^{-3} at *ca.* 10 °C. The ^{13}C nuclear magnetic resonance spectra were measured in deuterium oxide with a Varian XL-100-15 NMR spectrometer.

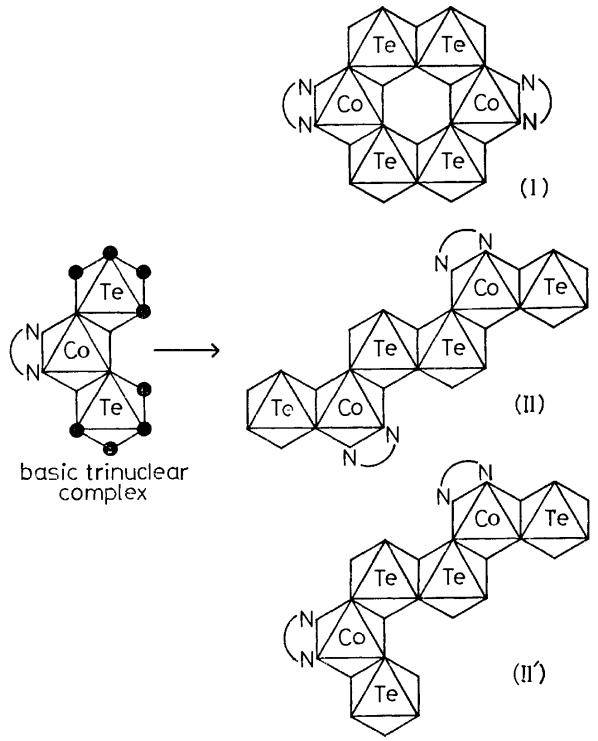

Fig. 1. Some condensation products of a basic trinuclear complex $[Co(TeO_6H_4)_2(diamine)]^-$. Hydroxo lignads of the basic complex are marked by circles.

Results and Discussion

The brown and blue complexes were separated by column chromatography from the reaction mixture of *trans*(NH_3)- or *trans*(Cl)-$[CoCl_2(NH_3)_2(diamine)]^+$, $Te(OH)_6$, and alkali in a proper molar ratio at 60—70 °C. Because all the complexes, particularly blue ones, were unstable in solution at room temperature, the solutions were carefully treated below 15 °C. The yields of blue complexes were much less than those of the brown ones.

The Brown Complexes. The composition $M_6[Co_2Te_4O_{22}H_8(diamine)_2]$ was confirmed by the preparative method and elemental analysis. A previous paper[1] reported that two binuclear complexes $[Co(TeO_6H_4)(diamine)_2]^+$ were prepared from the reaction mixture of *cis*-$[CoCl_2(diamine)_2]Cl$, $Te(OH)_6$, and alkali, the corresponding tetranuclear complexes $[Co_2(Te_2O_{10}H_4)(diamine)_2]^{2+}$ being obtained by dehydration condensation of the coordinated orthotellurate moieties of the binuclear complexes. Since the starting cobalt(III) complex used in the present study has only one diamine ligand, trinuclear complexes $[Co(TeO_6H_4)_2(diamine)]^-$ and hexanuclear condensates $[Co_2Te_4O_{22}H_8(diamine)_2]^{6-}$ may be formed in the

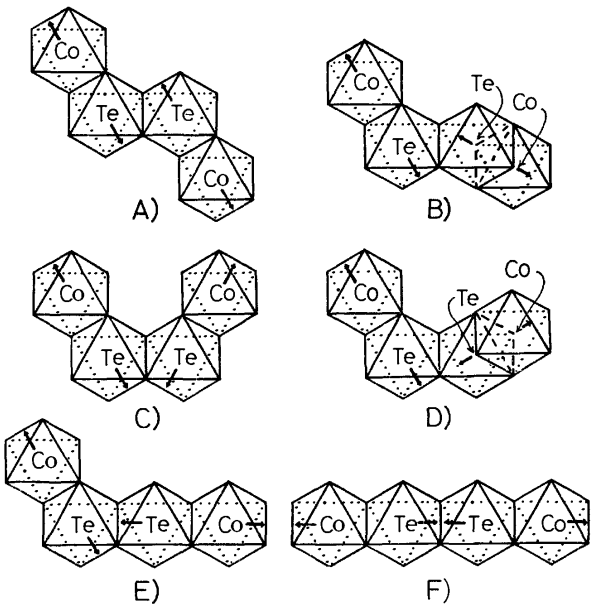

Fig. 2. Isomerism of the Co–Te–Te–Co tetra-octahedra.

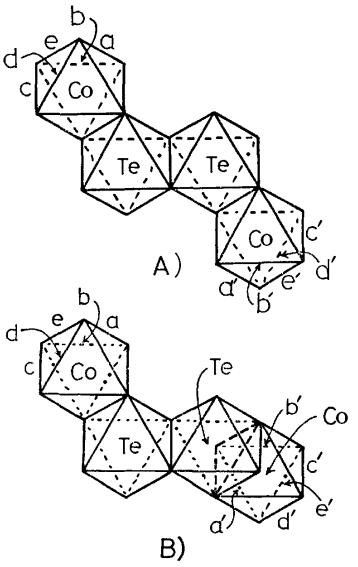

Fig. 3. Numbering for the edges of structures A) and B).

reaction mixture. As is seen in Fig. 1, when the condensation occurs by edge-sharing in two tellurate ligands of each trinuclear complex simultaneously, only a ring structure (I) is possible. This structure has a C_{2h} symmetry unsuitable for the brown complexes optically resolved. When it occurs in one tellurate ligand of each trinuclear complex, many kinds of hexanuclear chain structures, such as (II) and (II'), are possible. The isomerism of this type of chain structure (Te–Co–Te–Te–Co–Te hexa-octahedra) can be formally treated as follows by starting from a tetranuclear Co–Te–Te–Co tetra-octahedra structure. For the tetra-octahedra, the six structures shown in Fig. 2 are possible. The adjacent tellurium(VI) and cobalt(III) atoms repulse each other electrostatically in the directions of the marked arrows, and hence the

tellurium(VI)-tellurium(VI) repulsion increases in the order A)<B)<D)<C)<E)<F). Furthermore, because the two cobalt(III) octahedra are more separated for A) and B) than for C) and D), the former two have a smaller repulsion between the cobalt(III) octahedra than the latter two. Since this kind of electostatic repulsion should have the primary influence upon the structure of polynuclear complexes,[5] the structures A) and B) are probable for the tetra-octahedra of present complexes. Thus far only the structure A) has been found in $[Co(diamine)_2(Te_2O_{10}H_4)Co(diamine)_2]^{2+}$ (diamine=en and *l*-chxn)[1] and $[(en)_2Cr(OH)_2Cr(en)(OH)_2Cr(en)(OH)_2Cr(en)_2]^{6+}$.[6] As shown in Fig. 3, the edges of two cobalt(III) octahedra in the structure A) (C_i symmetry) and B) (C_2 symmetry) are named a,b,c,d,e,a′,b′,c′,d′, and e′. In the cases of both structures, A) and B), fifteen hexa-octahedra structures can be formed by adding two more TeO_6 octahedra, as shown in Table 1. Among the thirty structures, A)-(cc′), -(dd′), -(dc′), B)-(cc′), -(dd′), and -(dc′) are expected to have less electrostatic

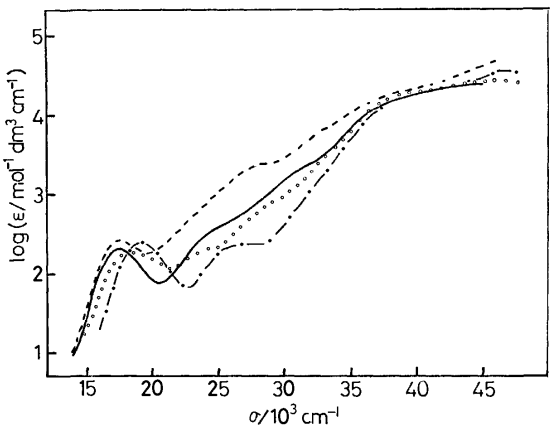

Fig. 5. Absorption spectrum of blue en complex $[\{Co(TeO_6H_4)(en)\}(TeO_6)\{Co(TeO_6H_4)(en)\}]^{4-}$ (·——), brown en complex $[\{Co(TeO_6H_4)(en)\}(Te_2O_{10})\{Co(TeO_6H_4)(en)\}]^{6-}$ (----), $[\{Co(dien)(H_2O)\}(Te_2O_{10}H_4)\{Co(dien)(H_2O)\}]^{2+}$ (○○○○), and $[Co(en)_2(Te_2O_{10}H_4)Co(en)_2]^{2+}$ (—·—).

repulsion between cobalt(III) and tellurium(VI) atoms in the local Te–Co–Te–Te tetra-octahedra units, since two such local tetra-octahedra units of these six structures have the structure A) or B). Because the brown en complex was optically resolved, the structures A)-(cc') and -(dd'), which have a center of symmetry, are excluded from consideration. The ^{13}C-NMR spectrum of the brown en complex showed only a band at *ca.* 42 ppm with respect to TMS. Thus, the structures A)-(dc') and B)-(dc'), which have no element of symmetry, are omitted. In this way it is concluded that the most probable structure is B)-(cc') or -(dd') of C_2 symmetry (Fig. 4-a). As is seen in Figs. 4-b and -c, a $\Delta(\Lambda\text{-}\Lambda)\Delta$-B)-(cc') isomer is formed by condensing the apexes 1 and 1 as well as 2 and 2 of two Δ-$[Co(TeO_6)_2(diamine)]$ groups, and the enantiomer $\Lambda(\Delta\text{-}\Delta)\Lambda$-B)-(cc') from two Λ-$[Co(TeO_6)_2(diamine)]$ groups. A $\Lambda(\Lambda\text{-}\Lambda)\Lambda$-B)-(dd') isomer is formed by condensing the apexes 1 and 1 as well as 3 and 3 of two Λ-$[Co(TeO_6)_2(diamine)]$ groups, and the enantiomer $\Delta(\Delta\text{-}\Delta)\Delta$-B)-(dd') from two Δ-$[Co(TeO_6)_2(diamine)]$ groups.

The absorption spectrum of brown en complex is characteristic of a *cis*-CoN_2O_4 type complex and similar to that of $[Co(CO_3)_2(en)]^-$ (σ_{max}=17500 and 25600 cm^{-1})[7] in the d-d absorption band region (Fig. 5). The first absorption band (at 17600 cm^{-1}) is located at a lower energy than those of $[Co(en)_2(Te_2O_{10}H_4)Co(en)_2]^{2+}$ (at 19200 cm^{-1}) of the *cis*-CoN_4O_2 type and $[\{Co(dien)(H_2O)\}(Te_2O_{10}H_4)\{Co(dien)(H_2O)\}]^{2+}$ (at 18500 cm^{-1}) of the *mer*-CoN_3O_3 type. The second absorption band is obscured by overlapping with a strong absorption band at about 28000 cm^{-1} (long ε=3.4). The latter band is not observed for the ditellurate $[Te_2O_{10}H_{8-n}]^{n-}$ and orthotellurate $[TeO_6H_{6-n}]^{n-}$ ions, and also does not appear for $[Co(ox)_x(en)_{3-x}]^{n\pm}$ (x=1[8] and 2[9]) or $[Co(CO_3)_x(en)_{3-x}]^{n\pm}$ (x=1[8] and 2[7]). The strong band shifts to higher energy in the order of complex types: *cis*-CoN_2O_4 (at 28000 cm^{-1})→*mer*-CoN_3O_3 (at *ca.* 29000 cm^{-1})→*cis*-CoN_4O_2 (at *ca.* 33000 cm^{-1}). These bands are assigned to charge-transfer (CT) transitions from the coordinated orthotellurate or ditellurate oxygen ions to cobalt(III). Table 2 shows that the same absorption behavior is observed for all the complexes of the brown type.

The CD spectra of brown en and *l*-pn complexes are shown in Figs. 6 and 7. The CD curve of $(-)^{CD}_{589}$ brown en complex, which was obtained from the more soluble diastereomer with Λ-$(+)_{589}$-$[Co(en)_3]^{3+}$, consists of a main CD band with negative sign and a weak one with positive sign (at lower energy side) in the first absorption band region (Fig. 7 and Table 3). Since the Λ-$[Co(CO_3)_2(en)]^-$ and Λ-$[Co(ox)_2(en)]^-$ complexes show a main CD band with positive sign in this region,[7,10] the $(-)^{CD}_{589}$ brown en complex will have Δ-configuration in regard to skew pairs of the orthotellurate and ethylenediamine chelate rings about local cobalt(III) atoms (see Fig. 4), provided that the CD of this complex in the first absorption band region comes mainly from chiral configurations about local cobalt(III) atoms. Thus, the configuration of $(-)^{CD}_{589}$ brown en complex is tentatively assigned to be $\Delta(\Lambda\text{-}\Lambda)\Delta$-B)-(cc') or $\Delta(\Delta\text{-}\Delta)\Delta$-B)-(dd').

Two diastereomeric isomers, 1 and 2, of $[\{Co(TeO_6H_4)(l\text{-pn})\}(Te_2O_{10})\{Co(TeO_6H_4)(l\text{-pn})\}]^{6-}$ were separated by column chromatography. The configurational and vicinal CD contributions are separable for many kinds of cobalt(III) complexes by utilizing an additivity rule for CD curves of a pair of diastereomeric isomers.[11] The calculated Δ-configurational CD curve agrees well with the observed CD curve of Δ-enantiomer of brown en complex (Fig. 7). The configurational CD ($\Delta\varepsilon_{ext}$=+0.64 at 17000 cm^{-1}) is weaker than the vicinal CD ($\Delta\varepsilon_{ext}$=+1.08 at 17000 cm^{-1}). From the sign patterns of isolated config-

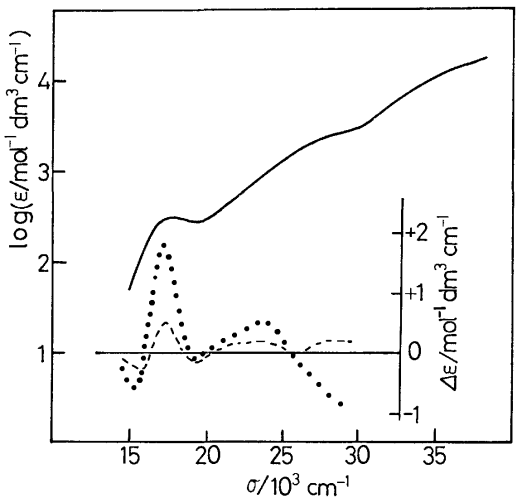

Fig. 6. Absorption spectrum of unresolved [{Co(TeO_6H_4)(*l*-pn)}(Te_2O_{10}){Co(TeO_6H_4)(*l*-pn)}]$^{6-}$ (——) and CD spectra of the resolved brown *l*-pn 1 (----) and and 2 (••••) diastereomeric isomers.

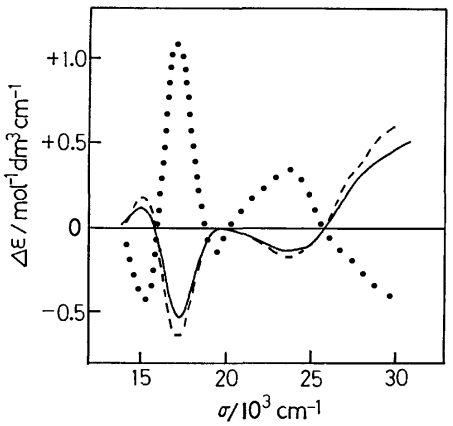

Fig. 7. Calculated configurational (----) and vicinal (••••) CD curves of [{Co(TeO_6H_4)(*l*-pn)}(Te_2O_{10})-{Co(TeO_6H_4)(*l*-pn)}]$^{6-}$, and observed CD curve (——) of $(-)_{589}^{CD}$-[{Co(TeO_6H_4)(en)}(Te_2O_{10}){Co(TeO_6H_4)(en)}]$^{6-}$.

urational CD curves it is likely that the isomer 1 has $\Delta(\Lambda\text{-}\Lambda)\Lambda$-B)-(cc') or $\Lambda(\Delta\text{-}\Delta)\Delta$-B)-(dd') configuration and the isomer 2 $\Lambda(\Lambda\text{-}\Delta)\Lambda$-B)-(cc') or $\Lambda(\Lambda\text{-}\Lambda)\Lambda$-B)-(dd').

The Blue Complexes. These were obtained as a by-product in the preparation of the brown complexes. They have the chemical composition $M_4[Co_2Te_3O_{18}H_8(diamine)_2]$ as confirmed by the preparative procedure and elemental analysis. It is supposed that the complexes have a Te–Co–Te–Co–Te penta-octahedra structure. The isomerism of the penta-octahedra can be formally treated by edge-sharing of a TeO_6 octahedron with each outer cobalt(III) octahedron of a Co–Te–Co tri-octahedra structure. Then, from the same consideration as used for the brown en complex, the most probable structure is (I) or (II) of C_2 symmetry (Fig. 8). Because these structures have no axis of rotatory reflection, a pair of enantiomers are possible. In fact, the blue en complex was optically resolved. Two diastereomeric isomers are possible for the blue *l*-pn complex, but the chromatographic separation was unsuccessful. The absorption spectrum of blue en complex is similar to that of the brown en complex in the d-d absorption band region (Fig. 5 and Table 2.) The second absorption band appears as a shoulder because of overlapping with the CT absorption band at about 30000 cm^{-1} ($\log\varepsilon=3.2$). The CT band is at higher energy than that for the brown complex. As is shown in Fig. 9 and Table 3, the CD pattern of $(-)_{589}^{CD}$ blue en complex is similar to that of $(-)_{589}^{CD}$ brown en complex (Fig. 7), though the former shows three CD

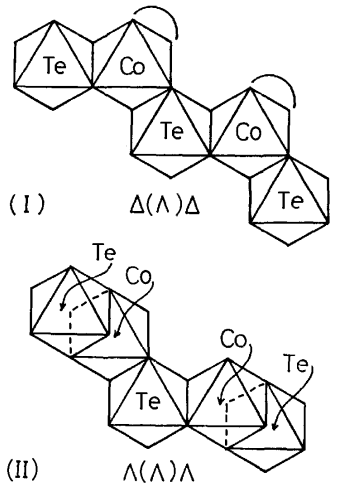

Fig. 8. Proposed structures of $[\{Co(TeO_6H_4)(diamine)\}(TeO_6)\{Co(TeO_6H_4)(diamine)\}]^{4-}$.

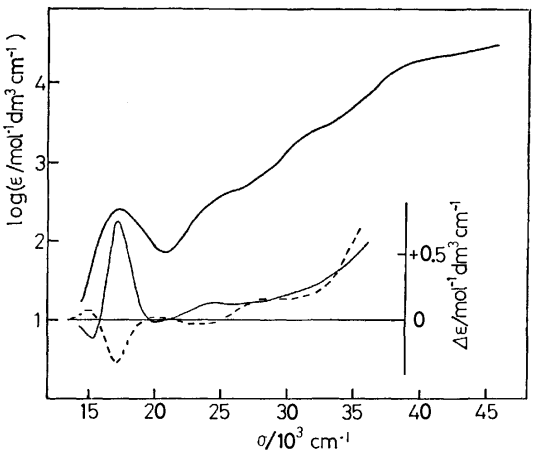

Fig. 9. Absorption and CD spectra (——) of unresolved $[\{Co(TeO_6H_4)(l\text{-pn})\}(TeO_6)\{Co(TeO_6H_4)(l\text{-pn})\}]^{4-}$ and CD spectrum (----) of $(-)^{CD}_{589}$-$[\{Co(TeO_6H_4)(en)\}(TeO_6)\{Co(TeO_6H_4)(en)\}]^{4-}$.

bands with positive, negative, and positive signs from the lower energy side in the first absorption band region. As the sign of the main CD band is negative, the configurations of local cobalt(III) octahedra will be Δ. Thus, $(-)^{CD}_{589}$ blue en complex is tentatively assigned to be $\Delta(\Delta)\Delta$-(I) or $\Delta(\Delta)\Delta$-(II) (see Fig. 8).

Tetranuclear dien Complex. This complex was isolated from the reaction mixture of *mer*-$[CoCl_3(dien)]$, $Te(OH)_6$, and alkali in a proper molar ratio at 60—70 °C. In this case, only the tetranuclear complex was obtained, which corresponds to a condensate of the binuclear complex $[Co(TeO_6H_4)(dien)(H_2O)]^+$. The second d-d absorption band is obscured by overlapping with a strong CT absorption band at 29000 cm^{-1} ($\log \varepsilon = 2.9$). The CT band is located at lower energy than that for the blue diamine complexes (Fig. 5). This reflects the existence of Te_2O_{10} unit in the structure. As the first d-d absorption band is broad, the terdentate dien ligand may be coordinated meridionally.

Metal Complexes of Peptides. I. The Cobalt(III) Complexes Containing Dipeptidate and *N*-Methyliminodiacetate as Mixed Ligands

Hiroshi KAWAGUCHI,* Makoto KANEKIYO, Tomoharu AMA, and Takaji YASUI

Department of Chemistry, Faculty of Science, Kochi University, Akebono-cho, Kochi 780

(Received May 6, 1980)

The mixed-ligand complexes, $Ba[Co(mida)(dipept)]_2$ (where mida is *N*-methyliminodiacetate and dipept denotes dianions of glycyl-L-alanine, L-alanylglycine, glycyl-L-leucine, L-leucylglycine, glycyl-β-alanine, β-alanylglycine, L-alanyl-β-alanine, and β-alanyl-L-alanine) have been prepared. The structure and properties of these complexes have been characterized by their electronic absorption, CD, and NMR spectral data.

Most studies on the metal complexes with peptides have attempted to understand the behavior of metal ions in living systems.[1] However, there are not enough data on the structures and properties of the cobalt(III) complexes with peptides.

The crystal structure of the cobalt(III) complex with glycylglycinate has been determined by the X-ray method.[2] In this complex the dipeptide binds to cobalt in terdentate fashion (meridional form) through the nitrogens of amino and amide groups and the oxygen of carboxyl group. The preparation and properties of the bis(dipeptidato) complex, $[Co(\alpha_1\text{-}\alpha_2)_2]^-$ ($\alpha_1\text{-}\alpha_2$ represents the dianion of the dipeptide $H_2\alpha_1\text{-}\alpha_2$, where α_1 is the *N*-terminal residue) have been studied in detail by Boas *et al.*[3] On the other hand, little work has been done on the mixed-ligand complexes containing dipeptide and one other ligand, though the complexes $[Co(NH_3)_3(\alpha_1\text{-}\alpha_2)]^+$ and $[Co(dien)(\alpha_1\text{-}\alpha_2)]^+$ have been prepared and characterized by Browning *et al.*[4]

Recently we found that the complexes of $[Co(ida)(\alpha_1\text{-}\alpha_2)]^-$ exhibit novel spectral behavior in the region of the d-d transition band,[5] compared with that for the typical cobalt(III) chromophore of the type $[Co(N)_3(O)_3]$.[6] In the present paper we report the preparation of mono(dipeptidato) complexes of the type $[Co(mida)(\alpha_1\text{-}\alpha_2)]^-$, where mida represents the dianion of *N*-methyliminodiacetic acid, H_2mida. These complexes have been characterized by elemental analysis, ^1H-NMR, absorption, and CD spectroscopy. In order to study the influence of the chelate-ring size of dipeptide on the properties of the $[Co(mida)(\alpha_1\text{-}\alpha_2)]^-$ complexes, especially on the absorption and CD spectra, the complexes of the dipeptides containing β-alanine have been studied in detail. The effects of the pH on the absorption and CD spectra have been also examined.

Experimental

Ligands. *N*-Methyliminodiacetic acid (H_2mida) was prepared according to the literature.[7]

Glycyl-β-alanine was prepared by a combination of conventional techniques, using *N*-(benzyloxycarbonyl)glycine (z-gly) and β-alanine ethyl ester (β-ala-OEt) as the starting materials.[8] Dicyclohexylcarbodiimine coupling was used to form the dipeptide derivative from these precursors. The peptide hydrobromide (H_2gly-β-ala·HBr) was formed by the reaction of z-gly-β-ala-OEt with aqueous NaOH solution and then with HBr-acetic acid. The HBr salts of β-alanylglycine (H_2β-ala-gly), L-alanyl-β-alanine (H_2L-ala-β-ala), and β-alanyl-L-alanine (H_2β-ala-L-ala) were also prepared by the same method as that of H_2gly-β-ala·HBr. These dipeptides were used for the syntheses of the complexes without removing HBr. The other dipeptides, glycylglycine (H_2gly-gly), L-alanylglycine (H_2L-ala-gly), glycyl-L-alanine (H_2gly-L-ala), L-leucylglycine (H_2L-leu-gly), and glycyl-L-leucine (H_2gly-L-leu), were obtained commercially from Sigma Chemical Company and Protein Research Foundation. These dipeptides were used without further purification.

Preparation of Complexes. *Ba[Co(mida)(gly-L-ala)]$_2$·5H_2O*: An aqueous solution (10 cm^3) of cobalt(II) chloride hexahydrate (2.37 g, 0.01 mol) was added slowly to an aqueous solution (10 cm^3) containing glycyl-L-alanine (1.46 g, 0.01 mol) and *N*-methyliminodiacetic acid (1.47 g, 0.01 mol), adjusting the pH of the mixed solution at *ca.* 9.5 with sodium hydroxide. The resulting solution was oxidized with lead dioxide (5 g) at 40 °C for about 1 h with stirring, and then it was cooled to room temperature. After removal of insoluble material by filtration, the filtrate, which contained $[Co(gly\text{-}L\text{-}ala)_2]^-$, $[Co(mida)_2]^-$, $[Co(mida)(gly\text{-}L\text{-}ala)]^-$, and some minor products, was chromatographed on a column (4.5 cm × 90 cm) of QAE-Sephadex A-25 using 0.05 M† KCl as an eluant. After the elution of bis(dipeptidato)cobaltate(III) complex, the objective dark-gray band ($[Co(mida)(gly\text{-}L\text{-}ala)]^-$) was separated completely from the overlapped brown-violet band (*fac*-$[Co(mida)_2]^-$) by further development of another column (4.5 cm × 90 cm) connected to the original column with a teflon tube (ϕ 1 mm). The eluted solution from the dark-gray band was concentrated to a small volume (20—30 cm^3) using a rotary evaporator at *ca.* 35 °C. To the concentrated solution was added a large amount of methanol, and then potassium chloride which deposited was filtered off. The filtrate was concentrated again to a few milliliters, and the residual KCl in the solution was removed by using a Sephadex G-10 column (3 cm × 90 cm). The deliquescent potassium salt of the complex was converted to barium salt by chromatography on SP-Sephadex C-25 to give a crystalline product. The barium salt was recrystallized from an aqueous solution by addition of ethanol and acetone.

The preparations of the type $Ba[Co(mida)(\alpha_1\text{-}\alpha_2)]_2$ containing other dipeptide ligands were carried out by the same method as described above. Analytical data of the new complexes are listed in Table 1.

[Co(NH_3)$_3$(gly-β-ala)]Cl·H_2O: Preparation of this compound was performed in the same way as that for the corresponding glycylglycinato complex.[4] Concentrated aqueous ammonia (15 cm^3) was added to the solution containing glycyl-β-alanine hydrobromide (4.54 g, 0.02 mol) and cobalt(II) chloride hexahydrate (4.74 g, 0.02 mol) in water (10 cm^3). Hydrogen peroxide (30%, 2 cm^3) was added slowly to the above ammoniac solution with constant stirring and then the solution was gently warmed for 10 min. The complex, $[Co(NH_3)_3(gly\text{-}\beta\text{-}ala)]^+$, in the reactant solution

† 1 M = 1 mol dm^{-3}.

$[Co(NH_3)_3(gly\text{-}\beta\text{-}ala)]Cl\cdot H_2O$	19.68	(19.52)	6.30	(6.23)	23.11	(22.77)

was separated from by-products on a SP-Sephadex C-25 column (4.5 cm × 50 cm) by elution with 0.05 M KCl solution. Potassium chloride was removed by the same method as that described above. The complex obtained was recrystallized from an aqueous solution by addition of ethanol.

$K[Co(\beta\text{-}ala\text{-}gly)_2]\cdot H_2O$: β-Alanylglycine hydrobromide (2.27 g, 0.01 mol) was dissolved in water (10 cm^3). The solution was adjusted to pH *ca.* 9.5 with sodium hydroxide. An aqueous solution containing $Co(NO_3)_2\cdot 6H_2O$ (1.46 g, 5 mmol) in water (10 cm^3) was added drop-by-drop to the above solution, adjusting the pH of the solution at *ca.* 9.5 with NaOH. After an addition of activated charcoal (0.5 g) the mixed solution was oxidized by an air stream for 12 h. The reactant solution was chromatographed on a QAE-Sephadex A-25 column (4.5 cm × 90 cm). The objective complex was eluted with 0.05 M KCl, and KCl was removed by the same method as that for the $Ba[Co(mida)(gly\text{-}L\text{-}ala)]_2$ complex. The complex was recrystallized from water by addition of ethanol and acetone.

Measurements. The absorption spectra were measured by a Hitachi 557-type spectrophotometer and the CD spectra by a JASCO J-22 spectropolarimeter. The proton NMR spectra were recorded on a JEOL MH-100 spectromcter with DSS as an internal reference.

Results and Discussion

The mixed ligand complexes, $[Co(mida)(\alpha_1\text{-}\alpha_2)]^-$, were conveniently prepared by the oxidation of the aqueous solutions containing cobalt(II) chloride, dipeptide, and H_2mida with lead dioxide, but this preparative method gave also substantial quantities of by-products: $[Co(mida)_2]^-$, $[Co(\alpha_1\text{-}\alpha_2)_2]^-$, and others. The yields of the mixed ligand complexes depend very much on the pH of the reaction solutions; at low pH (*ca.* 7) a large amount of $[Co(mida)_2]^-$ and minor products were formed, and at high pH (*ca.* 11) the initially formed precipitate (presumably cobalt(II) hydroxide) prevented the formation of the mixed type complexes. The pH range of 9 to 10 was most suitable for the preparation of the mixed type complexes; the racemization of active peptides may also be ignored in this pH range.[3] With the dipeptides containing β-alanine, however, the reactions were carried out in the pH range of 8 to 9 to prevent the formation of precipitate.

The $[Co(mida)(\alpha_1\text{-}\alpha_2)]^-$ anion was separated from other uninegative complexes, $[Co(mida)_2]^-$ and $[Co(\alpha_1\text{-}\alpha_2)_2]^-$, on a QAE-Sephadex A-25 column by elution with 0.05 M KCl. The order of the elutions was: $[Co(\alpha_1\text{-}\alpha_2)_2]^-$, $[Co(mida)_2]^-$, and $[Co(mida)(\alpha_1\text{-}\alpha_2)]^-$. In the cases of the β-alanylglycine and β-alanyl-L-alanine, however, the $[Co(mida)(\beta\text{-}ala\text{-}\alpha_2)]^-$ was eluted faster than the $[Co(mida)_2]^-$ anion. For all the peptides used here, it was difficult to separate completely $[Co(mida)(\alpha_1\text{-}\alpha_2)]^-$ from $[Co(mida)_2]^-$ on a QAE-Sephadex column, but these complexes could be separated by the different solubility of their potassium salts in a mixed solvent of methanol–water. Partial separation of these complexes also occurs on a Sephadex G-10 column. The potassium salts of the $[Co(mida)(\alpha_1\text{-}\alpha_2)]^-$ could not be often obtained in crystal state, because they are very hygroscopic. Accordingly, the salts were converted to the barium salts to give crystalline products.

Proton NMR Spectra. The dipeptide containing only α-amino acids coordinates to cobalt(III) in meridional configuration, and the chelate rings of the dipeptide ligand take the coplanar form. This has been established for the bis(glycylglycinato) complex by two independent X-ray crystallographic studies.[2,9] The ^{1}H-NMR spectrum of $[Co(mida)(gly\text{-}gly)]^-$ in slightly basic D_2O shows only one AB pattern (δ_A=4.42, δ_B=4.02 ppm, J_{gem}=16.5 Hz) for the two CH_2 groups of mida, indicating that both gly-gly and mida adopt the *mer* disposition.[5] An additional support for the *mer* structure of $[Co(mida)(gly\text{-}gly)]^-$ is provided by ^{13}C-NMR data; the peaks at 66.1 and 183.1 ppm can be assigned to two methylene and two carboxyl carbons, respectively, indicating an equivalence of the two acetate groups in mida ligand. The ^{1}H-NMR data of other $[Co(mida)(\alpha_1\text{-}\alpha_2)]^-$ in slightly basic D_2O are listed in Table 2. With the dipeptides containing only α-amino acids, the structure of these complexes can be also concluded to be *mer* on the basis of the ^{1}H-NMR data of the mida ligand. In the spectra of $[Co(mida)(gly\text{-}L\text{-}ala)]^-$ and $[Co(mida)(gly\text{-}L\text{-}leu)]^-$, the signal of the C-terminal methine proton can not be assigned clearly because of the overlap of the methylene signals of mida. The same situation is also realized in $[Co(mida)(L\text{-}leu\text{-}gly)]^-$; the resonances due

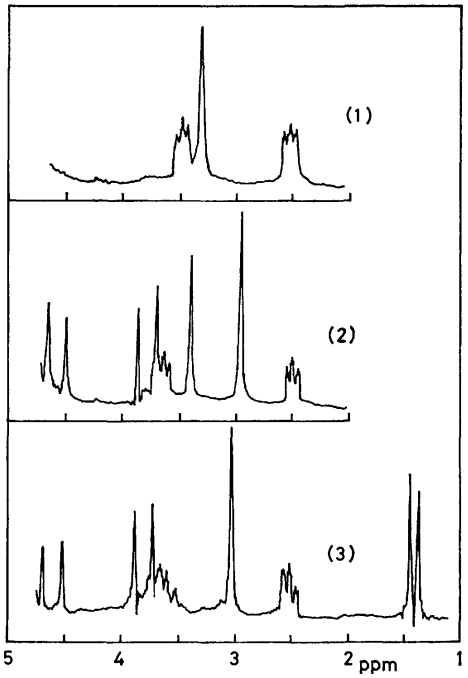

Fig. 1. The ^{1}H-NMR spectra of [Co(NH_3)$_3$(gly-β-ala)]$^+$ (1), [Co(mida)(gly-β-ala)]$^-$ (2), and [Co(mida)(L-ala-β-ala)]$^-$ (3) in alkaline D_2O.

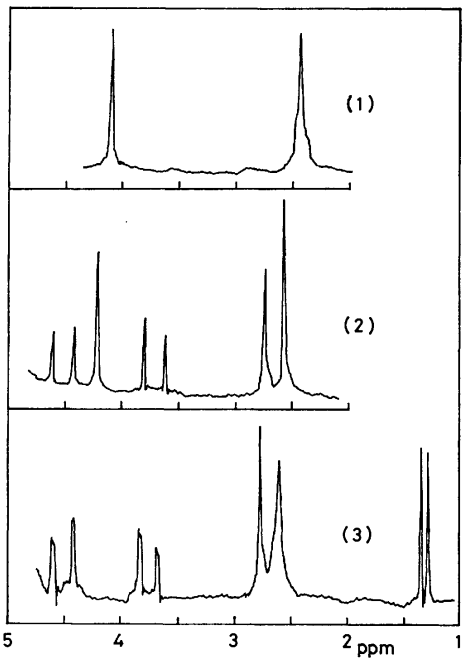

Fig. 2. The ^{1}H-NMR spectra of [Co(β-ala-gly)$_2$]$^-$ (1), [Co(mida)(β-ala-gly)]$^-$ (2), and [Co(mida)(β-ala-L-ala)]$^-$ (3) in alkaline D_2O.

to the C-terminal CH_2 which are only slightly inequivalent (4.35 and 4.38 ppm) are overlapped by one component of the resonances due to the CH_2 of mida. In the present study, the [Co(mida)(L-leu-gly)]$^-$ is the only example in which the C-terminal CH_2 protons are inequivalent at 100 MHz.

Examination of molecular models indicates that the dipeptides containing β-alanine can coordinate to cobalt(III) in both *mer* and *fac* configurations. On the other hand, the mida ligand adopts preferably the *fac* disposition, although the *mer*-K[Co(mida)$_2$] has been stably isolated.[10] Figure 1 shows the comparison among the ^{1}H-NMR spectra of [Co(NH_3)$_3$-(gly-β-ala)]$^+$, [Co(mida)(gly-β-ala)]$^-$, and [Co(mida)-(L-ala-β-ala)]$^-$ ions in slightly basic D_2O. The spectrum of [Co(NH_3)$_3$(gly-β-ala)]$^+$ exhibits three resonance peaks: a singlet signal due to the N-terminal CH_2 at 3.28 and two broad triplet-like peaks due to the C-terminal -CH_2-CH_2- at 2.50 and 3.45 ppm. In the [Co(mida)(gly-β-ala)]$^-$ complex, the resonances of the gly-β-ala ligand are analogous to those of [Co-(NH_3)$_3$(gly-β-ala)]$^+$, and an AB pattern in the range of 3.66 to 4.62 ppm can be assigned to the two CH_2 groups of mida, giving a hint of the equivalence of the two methylenes. This spectrum supports the assertion that the [Co(mida)(gly-β-ala)]$^-$ complex has the *mer* configuration. The same situation is realized in the [Co(mida)(L-ala-β-ala)]$^-$ complex, in which only one AB pattern resonance due to the two CH_2 of mida indicates that the *mer* configuration is taken.

TABLE 3. ABSORPTION AND CD SPECTRA OF THE TYPE [Co(mida)(α_1-α_2)]$^-$ COMPLEXES IN THE d-d TRANSITION REGION MEASURED IN WATER

sh: Shoulder.

The complex, [Co(β-ala-gly)$_2$]$^-$, shows a simple NMR spectrum (Fig. 2). The two peaks with the relative intensity of 2:1 at 2.43 and 4.12 ppm can be assigned to the N-terminal $-CH_2-CH_2-$ and C-terminal CH_2 protons, respectively. In the spectrum of [Co(mida)(β-ala-gly)]$^-$, the two singlets at 2.58 and 4.20 ppm can be assigned to the N-terminal $-CH_2-CH_2-$ and C-terminal CH_2 protons, respectively, and the AB pattern (δ_A=4.50, δ_B=3.70 ppm, J_{gem}=17.0 Hz) to the two CH_2 groups of mida. It is also suggested that the configuration of [Co(mida)(β-ala-gly)]$^-$ is *mer*. A singlet resonance which arises from the $-CH_2-CH_2-$ group of the β-ala-gly in these complexes is in accordance with the data observed for the *cis*(N)*trans*-(O_g,N)-[Co(β-ala)(gly)(ox)]$^-$ complex.[11]

In the case of the dipeptide complexes containing β-alanine, the chelate rings of the coordinated dipeptide are not coplanar. Consequently, the conformational isomerism due to the puckered β-alanine ring can be expected for the [Co(mida)(α_1-β-ala)]$^-$ or the [Co(mida)(β-ala-α_2)]$^-$. However, the interconversion between the ring conformations is presumed to be easy. The simple ^{1}H-NMR spectra of β-alanyl groups in their complexes may be attributed to the rapid interconversion. The [Co(mida)(α_1-α_2)]$^-$ complex provides another problem of the conformational isomerism arising from the choice of the conformation of mida ligands: which is the methyl group of mida directed to, the C- or the N-terminal residue of dipeptide ligand? In all the [Co(mida)(α_1-α_2)]$^-$ complexes isolated in this work, the signal assigned to the methyl protons of mida exhibited a sharp singlet, suggesting an existence of only one isomer. Our present data are not sufficient to decide the conformation of the mida ligand. The possibility of the rapid interconversion between the two conformational isomers due to the methyl moiety may be ignored, because such interconversion requires the rupture of the coordinate bond.

Absorption Spectra. Figure 3 shows the absorption spectra of the [Co(mida)(gly-L-ala)]$^-$ and [Co(mida)(L-ala-gly)]$^-$ complexes together with their CD spectra. The absorption spectra of both complexes are quite similar to each other and also to that of [Co(mida)(gly-gly)]$^-$ (the spectra are little affected by the α-substituents in the N- and C-terminal residues of dipeptides). Such similarities were also observed in the spectra of [Co(mida)(gly-L-leu)]$^-$ and [Co(mida)(L-leu-gly)]$^-$ complexes. The spectral data are summarized in Table 3. The typical cobalt(III) chromophore of the type *mer*-[Co(N)$_3$(O)$_3$] shows two d-d transition bands (the lower-energy one is slightly split) with nearly equal intensity in the visible region.[6] However, the [Co(mida)(α_1-α_2)]$^-$ complexes show three bands in the visible region; two components in the lower-energy band region have enhanced intensities and are markedly separated from each other.

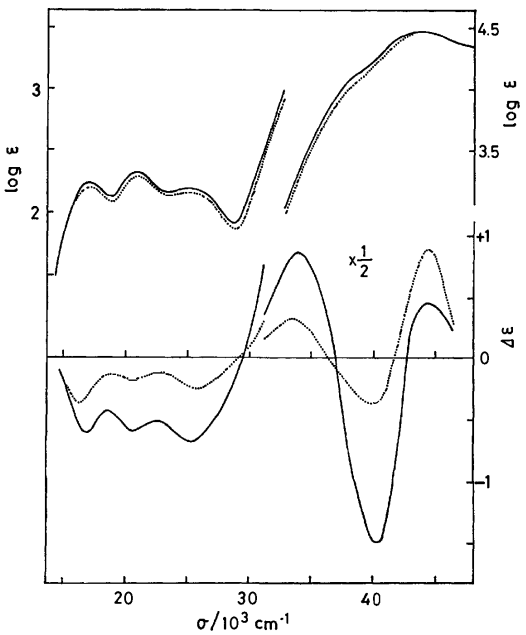

Fig. 3. The absorption and CD spectra of [Co(mida)(gly-L-ala)]$^-$ (——) and [Co(mida)(L-ala-gly)]$^-$ (·····) in water.

As shown in Fig. 4, the absorption spectrum of the [Co(mida)(L-ala-β-ala)]$^-$ complex is similar to that of the type [Co(mida)(α_1-α_2)]$^-$ complex in which both α_1 and α_2 are α-amino acid residues, though they differ from one another in the relative intensities of the two band components in the lower-energy band region. On the other hand, the [Co(mida)(β-ala-L-ala)]$^-$ (Fig. 4) shows the remarkably different absorption behavior in the d-d transition region, com-

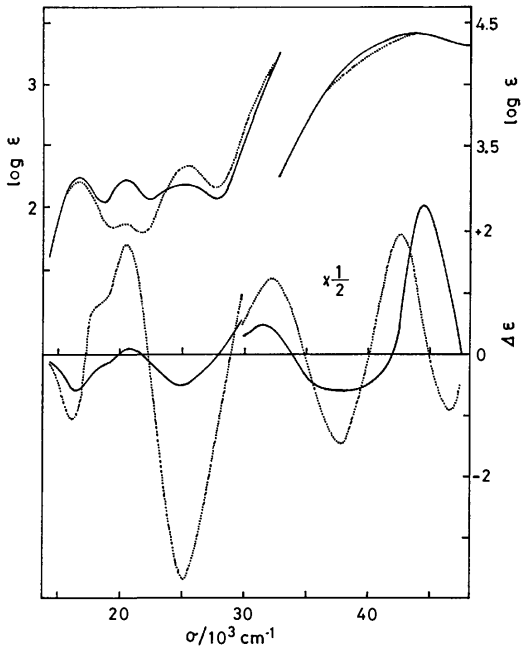

Fig. 4. The absorption and CD spectra of [Co(mida)(L-ala-β-ala)]⁻ (——) and [Co(mida)(β-ala-L-ala)]⁻ (·····) in water.

pared with those of the other [Co(mida)(α_1-α_2)]⁻ complexes; one of the split lower-energy bands has low intensity, but the higher-energy band has enhanced intensity. The spectrum of the [Co(mida)(β-ala-gly)]⁻ complex indicates quite similar behavior to that of the corresponding complex with β-ala-L-ala. Molecular models provide no obvious reasons for the difference between the spectral behaviors of the [Co(mida)(α_1-β-ala)]⁻ and [Co(mida)(β-ala-α_2)]⁻ complexes.

CD Spectra. Unlike the bis(dipeptidato)cobalt(III) complexes, the chelate rings forming the environment of the central cobalt are symmetrical in the [Co(mida)(α_1-α_2)]⁻ complex, ruling out any configurational contribution to the optical activity. Also, in the case of the dipeptide, α_1-α_2, where both α_1 and α_2 are α-amino acids, no conformational contribution to the optical activity can be invoked, because of the planarity of the entire dipeptide ligand. Therefore the sole source of optical activity in the d-d transition region is ascribed to the vicinal effect of the asymmetric carbon.[12]

Both the [Co(mida)(L-ala-gly)]⁻ and [Co(mida)(gly-L-ala)]⁻ complexes show three negative CD bands associated with three absorption bands in the visible region (Fig. 3 and Table 3). Similar CD spectra were obtained for the [Co(mida)(L-leu-gly)]⁻ and [Co(mida)(gly-L-leu)]⁻ complexes. It is remarkable that these complexes have a comparatively intense CD associated with the higher-energy d-d band. The asymmetry factor $g(=\Delta\varepsilon/\varepsilon)$ for the higher-energy d-d band is comparable to that for the lower-energy one, whereas in most optically active cobalt(III) complexes, the g value for the higher-energy band is much lower than that for the lower-energy band.[13] There is a large difference in the magnitude of $\Delta\varepsilon_{ext}$ between [Co(mida)(gly-L-ala)]⁻ and [Co(mida)(L-ala-gly)]⁻,

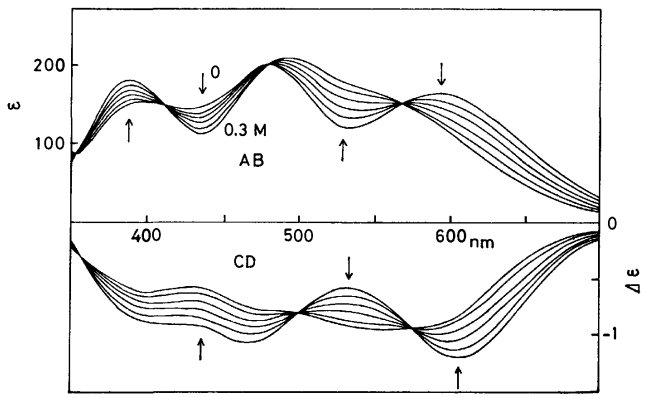

Fig. 5. The absorption (AB) and CD spectral changes of [Co(mida)(gly-L-leu)]⁻ in $HClO_4$ (0, 0.02, 0.05, 0.1, 0.2, 0.3 M).

which is not easy to explain, as the bis(dipeptidato)-complexes with these peptides have similar values of $\Delta\varepsilon_{ext}$. Also, this difference can not be attributed to the racemization of ligand during the synthesis of the complex, because in the weak alkaline solution only the C-terminal methylene or methine protons undergo the exchange reaction.[3]

As shown in Fig. 4, both the [Co(mida)(β-ala-L-ala)]⁻ and [Co(mida)(L-ala-β-ala)]⁻ complexes show the negative and positive CD bands associated with the lower-energy d-d transition and a strong negative CD band associated with higher-energy d-d transition. The CD data for these complexes also show that the magnitude of $\Delta\varepsilon_{ext}$ from the C-terminal active center is larger than that of $\Delta\varepsilon_{ext}$ from the N-terminal one. The [Co(mida)(β-ala-L-ala)]⁻ complex has extremely intense CD bands in the d-d transition region, especially in the higher-energy side. Though the puckering in the β-alanine-chelate ring of the β-ala-α_2 (or α_1-β-ala) ligand gives rise to some conformational contribution to the total CD, it is unlikely on the examination of molecular models that one conformation would be favored.

Protonation on [Co(mida)(α_1-α_2)]⁻. An example is described in detail of the protonation on the [Co(mida)(α_1-α_2)]⁻ species with glycyl-L-leucinate in acid solution. As shown in Fig. 5, on increasing the acid concentration, two components of the lower-energy d-d band approach each other and the higher-energy d-d band shifts to the higher-energy side with increasing of the intensity. The CD bands in the lower-energy d-d transition change in the same pattern as the absorption bands do, whereas the CD band in the higher-energy band region decreases in intensity. The changes of the absorption and CD spectra show isosbestic points and also are reversible, indicating that the changes are due to the protonation on the amide oxygen of the coordinated peptide,[14] and ruling out the successive protonation on the coordinated carboxyl group which has been proposed for the $[Co(NH_3)_3(\alpha_1\text{-}\alpha_2)]^+$ complexes.[4] The conjugate system of the amide group should be strikingly affected by the protonation following the spectral change. These acidic solutions were stable on standing at room temperature for several hours. The same situation was realized for

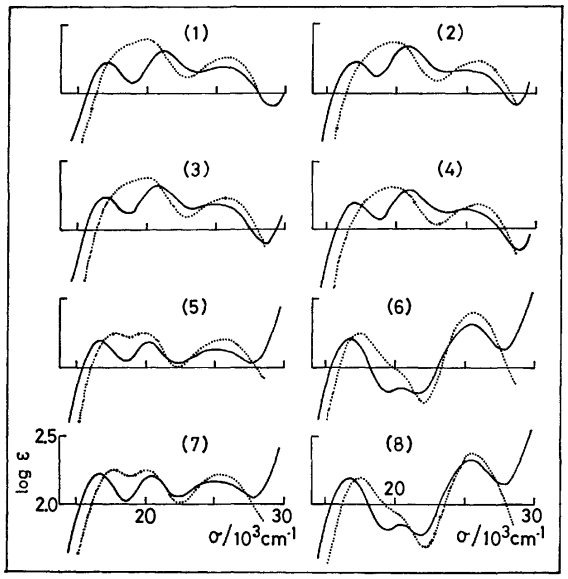

Fig. 6. The absorption spectra of the type [Co(mida)-$(\alpha_1\text{-}\alpha_2)$]$^-$ in water (——) and 60% $HClO_4$ (·····). $\alpha_1\text{-}\alpha_2$: (1) gly-L-leu, (2) L-leu-gly, (3) gly-L-ala, (4) L-ala-gly, (5) gly-β-ala, (6) β-ala-gly, (7) L-ala-β-ala, (8) β-ala-L-ala.

the other [Co(mida)$(\alpha_1\text{-}\alpha_2)$]$^-$ complexes examined. Figure 6 shows the comparison between the absorption spectra in water and in 60% $HClO_4$, *i.e.*, the spectra of the deprotonated and protonated type complexes. The spectral change caused by protonation is larger for the [Co(mida)$(\alpha_1\text{-}\alpha_2)$]$^-$ complex than for the [Co-$(\alpha_1\text{-}\alpha_2)_2$]$^-$ complex.

The protonation on the amide group intimately depends on the kind of dipeptide ligand; for the dipeptides containing β-alanine, especially N-terminal β-alanine, the protonation occurred in the weakly acidic solution, whereas for the dipeptides with N-terminal substituent, the protonation took place in the strongly acidic solution. However, it was impossible to calculate precisely the pK_a for the protonation on the amide group from the variation of ε or $\Delta\varepsilon$ with pH, because of the difficulty of the measurement of meaningful pH in strongly acidic solutions. The pK_a values estimated semi-quantitatively decreased in the following order:

[Co(mida)(β-ala-L-ala)]$^-$ ≃ [Co(mida)(β-ala-gly)]$^-$ > [Co(mida)(gly-β-ala)]$^-$ > [Co(mida)(L-ala-β-ala)]$^-$ > [Co(mida)(gly-L-leu)]$^-$ ≃ [Co(mida)(gly-L-ala)]$^-$ > [Co(mida)(gly-gly)]$^-$ > [Co(mida)(L-leu-gly)]$^-$ ≃ [Co(mida)(L-ala-gly)]$^-$.

Synthesis and Characterization of Cobalt(II), Nickel(II), and Copper(II) Complexes with 2-Furancarbaldehyde Oxime

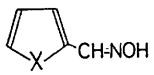
Hiro KUMA, Kyoji MOTOBE, Wasuke MORI, and Shoichiro YAMADA*

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received May 15, 1980)

Cobalt(II), nickel(II), and copper(II) complexes with 2-furancarbaldehyde oxime have been prepared and characterized mainly on the basis of electronic spectra and magnetic data. The cobalt(II) and nickel(II) complexes of the formula $MX_2(oxime)_4$ (X=Cl, Br) have been isolated. They are all six-coordinated, the oxime being coordinated as a unidentate through the nitrogen atom. Copper(II) forms complexes of the formula $CuX_2(oxime)_2$ (X=Cl, Br). Possible structures for these complexes are discussed.

It has recently been concluded that 2-thiophenecarbaldehyde oxime (Ia, abbreviated as tox in the present paper) forms metal complexes of the type $MCl_2(tox)_4$ and $MBr_2(tox)_4$, M being Co(II), Ni(II), and Zn(II). The ligand tox in these complexes is coordinated as a unidentate through the nitrogen atom,[1] contrary to the previous claim[2] that only complexes of the type $MCl_2(tox)_2$ could be isolated, *tox* in these complexes functioning as a bidentate through its nitrogen and sulfur atoms.



I

a: X=S, b: X=O

It was also claimed previously that 2-furancarbaldehyde oxime (Ib, abbreviated as *fox*) formed metal complexes of the type $MCl_2(fox)_2$, in which the ligand fox was coordinated as a bidentate through two oxygen atoms.[3,4] In view of our isolation of $MX_2(tox)_4$ instead of $MX_2(tox)_2$, reexamination of the metal complexes with fox is thought to be rewarding and significant. It is also interesting to examine whether or not the furan oxygen atom of fox may be coordinated with the metal ion.

Experimental

Materials. *syn*(α)- and *anti*(β)-2-Furancarbaldehyde oxime were prepared as reported previously.[5]

With *anti*-2-furancarbaldehyde oxime, all the metal complexes described below were synthesized successfully, their analytical data being given in Table1 . With *syn*-2-furancarbaldehyde oxime, however, the cobalt(II) and copper(II) complexes were synthesized in a similar manner, while attempts to isolate the nickel(II) complexes have so far been unsuccessful.

Dihalogenotetrakis(2-furancarbaldehyde oxime)cobalt(II), $CoX_2(fox)_4$ (X=Cl, Br). Cobalt(II) halide hexahydrate (10 mmol) was added to a solution of 2-furancarbaldehyde oxime (40 mmol) in ethanol (100 cm^3) at 50 °C. The reaction was continued for 2 h. A brown precipitate was recrystallized from methanol to give orange (X=Cl) and red-orange (X=Br) crystals.

$Co(NCS)_2$(fox)$_2$. A method similar to the dihalogeno complexes yielded only $Co(NCS)_2(fox)_2$ instead of $Co(NCS)_2(fox)_4$. The precipitate was recrystallized from methanol to give red-brown crystals. Attempts to isolate $Co(NCS)_2(fox)_4$ have so far been unsuccessful.

Dihalogenotetrakis(2-furancarbaldehyde oxime)nickel(II), NiX_2(fox)$_4$ (X=Cl, Br). These complexes were prepared as yellow-green crystals in a manner analogous to the corresponding cobalt(II) complexes. Recrystallization was carried out from methanol.

Ni(NCS)$_2$(fox)$_4$. A solution of nickel(II) thiocyanate (10 mmol) and fox (40 mmol) in ethanol (100 cm^3) was heated at 60 °C with stirring under reflux for 3 h. The solution was filtered and evaporated to about half the volume. A pale green precipitate was recrystallized from methanol-chloroform (3:7) to give green crystals.

The nickel(II) and cobalt(II) complexes described above are soluble in methanol, ethanol, and chloroform, but insoluble in benzene.

CuX_2(fox)$_2$ (X=Cl, Br). A suspension of anhydrous copper(II) halide (10 mmol) and fox (20 mmol) in ethanol (100 cm^3) was heated at 50 °C for 1 h. A brown precipitate was recrystallized from ethanol to yield red-brown (X=Cl) and dark brown (X=Br) needle-like crystals.

These copper(II) complexes are soluble in hot methanol and ethanol, but insoluble in chloroform.

Measurements. Electronic absorption spectra of the complexes were measured on a Shimadzu MPS-50L spectrophotometer. Infrared spectra were recorded as Nujol mulls using a Hitachi EPI-S2 infrared spectrophotometer and a Hitachi 215 infrared spectrophotometer.

Magnetic susceptibilities of the cobalt(II) and nickel(II) complexes were measured by the Gouy method at room temperature. Magnetic measurements with the copper(II) complexes were carried out in the temperature range of 4.2—300 K by the Faraday method using a Cahn balance.

Powder X-ray diffraction patterns were obtained with a Rigakudenki 4001-A2 diffractometer using Co $K\alpha$ radiation and an iron filter.

Results and Discussion

Nickel(II) Complexes. Previously a compound of composition $NiCl_2(fox)_2$ was reported and was claimed to contain the molecules of fox functioning as bidentate ligands.[3,4] In the present work, however, this complex could not be isolated, but compounds of the formula $NiX_2(fox)_4$ only were obtained, X being Cl, Br, and NCS.

The nickel(II) complexes prepared are paramagnetic and of a high spin type (Table 1). Their magnetic moments are in the range expected for the six-coordinate nickel(II) complexes.

The electronic absorption spectra of $NiCl_2(fox)_4$ and $NiBr_2(fox)_4$ are very similar to those of *trans*-$NiX_2(tox)_4$ (Fig. 1). Hence, it is presumed that $NiX_2(fox)_4$ (X=Cl, Br) have a six-coordinate *trans*-dihalogeno structure, in which the oxime molecules are bound through their nitrogen atoms as unidentate ligands with the nickel-

Table 1. Analytical data of nickel(II), cobalt(II), and copper(II) complexes with 2-furancarbaldehyde oxime

$CoBr_2(fox)_4$	36.22	3.28	8.54	36.24	3.04	8.45	5.11
$Co(NCS)_2(fox)_2$	36.03	2.81	13.90	36.27	2.54	14.10	4.90
$CuCl_2(fox)_2$	33.40	3.14	7.82	33.67	2.83	7.86	1.86
$CuBr_2(fox)_2$	27.17	2.58	6.48	26.95	2.23	6.29	1.88

a) μ: BM at room temperature.

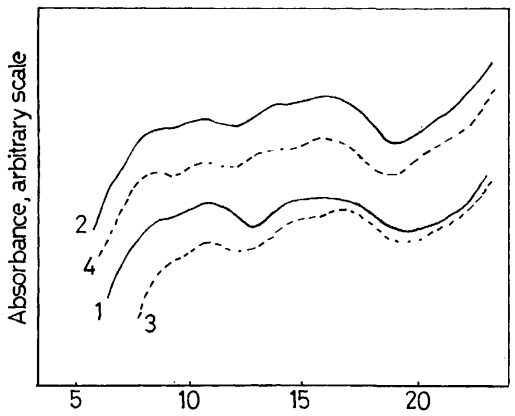

Fig. 1. Electronic absorption spectra of *trans*-$NiX_2(fox)_4$ (——) and *trans*-$NiX_2(tox)_4$ (----) in Nujol. 1: X=Cl, 2: X=Br, 3: X=Cl, 4: X=Br.

(II) ion. The powder X-ray diffraction pattern of $NiCl_2(fox)_4$ is similar to that of $NiBr_2(fox)_4$. The Ni–O (furan) vibration around 400—500 cm^{-1} previously reported for $NiCl_2(fox)_2$[4] was not observed for $NiCl_2(fox)_4$ prepared in the present work.

The approximate symmetry of *trans*-$NiX_2(fox)_4$ is D_{4h}. Six-coordinate nickel(II) complexes of O_h symmetry show three spin-allowed d-d bands, each of which is split into two components as the symmetry of the complexes changes from O_h to D_{4h}. The observed flat absorption curves are regarded as due to overlapping of split components of the d-d bands.

The complex $Ni(NCS)_2(fox)_4$ is paramagnetic with a moment of 3.2 BM, and its electronic absorption spectrum is typical of the six-coordinate nickel(II) complex (Table 2). Infrared O–N stretching, C–S stretching, and NCS bending vibrations occur at 2108, 830, and 470 cm^{-1}, respectively, indicating that the NCS^- ions are bound through the nitrogen atoms with the nickel(II) ion. Each of these bands appears as a single symmetrical peak, in agreement with the *trans*-diisothiocyanato structure.[6]

The d-d band splitting for *trans*-$Ni(NCS)_2(fox)_4$ may be small, since fox lies close to NCS^- in the spectrochemical series, both the ligands being coordinated through the nitrogen atom. The electronic spectrum

$Co(NCS)_2(fox)_2$	3430	1655
$CuCl_2(fox)_2$	3250	1660
$CuBr_2(fox)_2$	3260	1660
fox(anti-form)	3155	1645

of this complex is similar, in the shape of the whole curve as well as in the band maxima, to that of *trans*-$Ni(NCS)_2(NH_3)_4$, which also shows very slight splitting of the d-d bands.[7]

Just like the nickel(II) complexes with such a nitrogen-coordinating unidentate as tox,[1] the nickel(II) complexes with fox show hydrogen-bonded OH stretching vibrations at about 3200—3300 cm^{-1} (Table 3).

Cobalt(II) Complexes. Previously reported $CoCl_2(fox)_2$[3,4] has not been isolated, but $CoX_2(fox)_4$, X being Cl and Br, have been obtained in the present

TABLE 4. MAXIMA OF MAIN d-d BANDS OF COPPER(II) COMPLEXES WITH 2-FURANCARBALDEHYDE OXIME AND RELATED LIGANDS

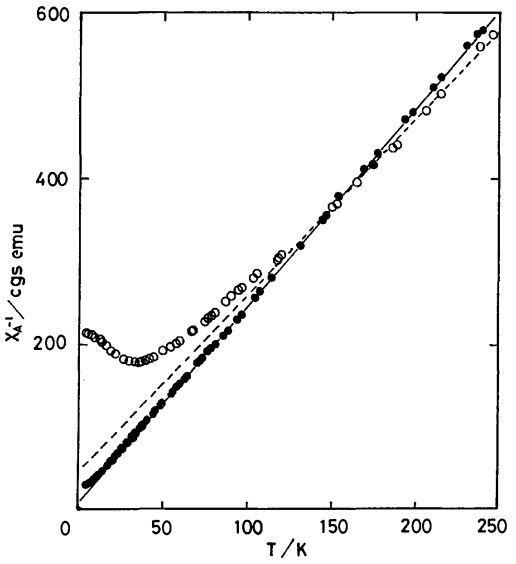

Fig. 2. Plots of reciprocal magnetic susceptibilities (corrected for the temperature-independent paramagnetism) of $CuX_2(fox)_2$ against absolute temperature. ●: Experimental for X=Cl, ○: experimental for X=Br. The solid line (X=Cl) and dashed line (X=Br) were derived theoretically from the Curie-Weiss law, θ and g being 4 K and 2.12 for X=Cl and 20 K and 2.25 for X=Br. The value for $N\alpha$ was assumed to be 60×10^{-6} cgs emu.

work. On the other hand, the complex $Co(NCS)_2(fox)_2$ has been isolated instead of $Co(NCS)_2(fox)_4$.

The complexes $CoX_2(fox)_4$ are paramagnetic with magnetic moments of 5.0—5.1 BM, which are in the range expected for the six-coordinate cobalt(II) complexes (Table 1), the d-d band maxima being nearly equal to those of *trans*-$CoX_2(tox)_4$ (Table 2). The powder X-ray pattern of $CoCl_2(fox)_4$ is very similar to that of $NiCl_2(fox)_4$, which has been presumed to have a *trans*-dihalogeno structure. It is very likely, therefore, that the complexes $CoX_2(fox)_4$ have a six-coordinate *trans*-dihalogeno structure, in which the ligands *fox* are coordinated as unidentate ligands to the cobalt(II) ion through the nitrogen atom, the oxygen atom in *fox* not being bound to the metal ion.

The complex $Co(NCS)_2(fox)_2$ is paramagnetic with a magnetic moment of 4.9 BM, which lies in the range expected for the six-coordinate cobalt(II) complex, Its electronic spectrum (Table 2) is also in agreement with this stereochemistry. Its infrared C–N stretching, C–S stretching, and NCS bending vibrations appear at 2100, 780, and 484 and 475 cm^{-1}. These values indicate the presence of the bridging NCS group on the basis of the previously proposed criteria.[8]

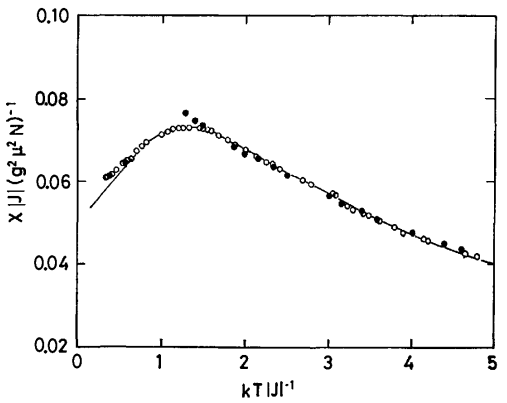

Fig. 3. Magnetic susceptibilities (corrected for the temperature-independent paramagnetism) of $CuX_2(fox)_2$. ●: Experimental for X=Cl, ○: experimental for X=Br. The solid curve was obtained by the method of Bonner and Fisher assuming the antiferromagnetic linear chain and on the basis of the Heisenberg model for the interaction between spins with $S=1/2$. For $CuCl_2(fox)_2$ $J/k=-3.5$ K, $g=2.06$, $N\alpha=60\times10^{-6}$ cgs emu and for $CuBr_2(fox)_2$ $J/k=-25$ K, $g=2.27$, $N\alpha=60\times10^{-6}$ cgs emu.

Exactly like the corresponding nickel(II) complexes,[1] $CoX_2(fox)_4$ exhibit hydrogen-bonded OH stretching vibrations at about 3200—3300 cm^{-1}, while $Co(NCS)_2(fox)_2$ shows a sharp OH band at a much higher frequency, indicative of the presence of the non-hydrogen-bonded NOH group (Table 3). When *fox* is bound with the metal ion, ν(C=N) and ν(N–O) frequencies of *fox* are found to shift toward higher frequencies. These findings are similar to those of the corresponding complexes with *acox* and *tox*, *acox* being acetaldehyde oxime. The Co–O(furan) vibration at about 400—500 cm^{-1}, which was reported previously for $CoCl_2(fox)_2$,[4] has not been observed with $CoX_2(fox)_4$ prepared in the present work.

Copper(II) Complexes. Two copper(II) complexes $CuX_2(fox)_2$, X being Cl and Br, have been obtained in the present work. In view of the results on the corresponding cobalt(II) and nickel(II) complexes and also on the metal complexes with related oximes,[1,9] it may be reasonable to assume that *fox* is coordinated as a unidentate ligand through its nitrogen atom in $CuX_2(fox)_2$.

Billing and Underhill examined correlation between electronic absorption spectra and stereochemistry of complexes of the type CuX_2L_2, L being pyridine and its derivatives.[10] On the basis of their conclusions, the stereochemistry of $CuX_2(tox)_2$ and $CuX_2(acox)_2$ was discussed with reasonable success in previous papers.[1,9] The d-d band maxima of $CuX_2(fox)_2$ are close to those of the multinuclear complexes $CuX_2(tox)_2$ and $CuX_2(py)_2$ (Table 4).[1] According to the criteria reported previously,[1,10] and in view of the present finding that *fox* lies very close to *tox*, *acox*, and *py* in the spectrochemical series, the electronic spectra

seem to indicate that $CuX_2(fox)_2$ most probably have a multinuclear structure similar to that of $CuX_2(tox)_2$, $CuX_2(acox)_2$, and $CuX_2(py)_2$, in which the copper(II) ions are six-coordinated with halide ions as bridges. The two complexes $CuCl_2(fox)_2$ and $CuBr_2(fox)_2$ have a similar structure, since they show similar powder X-ray diffraction patterns.

The copper(II) complexes with such a structure as assumed above are expected to exhibit the antiferromagnetism characteristic of the chain structure with bridges, –Cu–X–Cu–X–Cu–. Room temperature moments of $CuX_2(fox)_2$, which are 1.86 (X=Cl) and 1.88 BM (X=Br), differ very little from the normal moments. As shown in Fig. 2, the susceptibilities obey the Curie-Weiss law in the higher temperature range, the Curie-Weiss constants θ being 4 K for $CuCl_2(fox)_2$ and 20 K for $CuBr_2(fox)_2$. The temperature dependence of magnetic susceptibilities below 5 K is shown in Fig. 3. Except for deviation below 1.5 K for the chloro complex, the data are in good coincidence with the theoretical curves derived by the method of Bonner and Fisher,[11] which is based upon the assumption of an infinite one-dimensional Heisenberg spin lattice with $S=1/2$.

These findings combined may be regarded as supporting the assumption of the antiferromagnetic interaction through halide ions between copper ions in the proposed structure.

The present authors are grateful to Professor Masayoshi Obashi for powder X-ray diffraction patterns.

Synthesis and Characterization of Metal Complexes with Schiff Bases Obtained from *N,N'*-Bis(3-aminopropyl)piperazine and Salicylaldehyde Derivatives

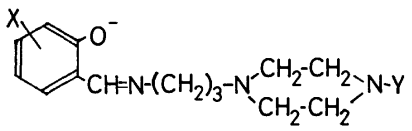
Hiro KUMA and Shoichiro YAMADA*

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received June 10, 1980)

Cobalt(II), nickel(II), cobalt(III), manganese(III), and iron(III) complexes have been synthesized with Schiff bases (abbreviated as X-sal-prpi) derived from *N,N'*-bis(3-aminopropyl)piperazine and salicylaldehyde derivatives. On the basis of electronic spectra, infrared spectra, and magnetic data, the structures of the metal complexes are discussed. Complexes of the type Co^{II}(X-sal-prpi) are five-coordinated, and M^{III}(X-sal-prpi)ClO_4 consist of six-coordinated $[M(X\text{-sal-prpi})]^+$ and free ClO_4^- ions, the ligands X-sal-prpi being quinquidentate in the former and sexadentate in the latter.

It was previously reported that the ligands X-salen-pip (Ia) with four donor atoms form cobalt(II) and nickel(II) complexes of the type M(X-salen-pip)$_2$, in which X-salen-pip serve as terdentate ligands, one of the four donor atoms not being bound to the metal ions.[1] It is now interesting to examine metal complexes with the similar ligands X-sal-prpi (Ib) having six donor atoms and compare the results with those of X-salen-pip.† The present paper describes synthesis and characterization of some 3d metal complexes with these new ligands, *i.e.*, Schiff bases obtained from *N,N'*-bis(3-aminopropyl)piperazine and salicylaldehyde derivatives.



I

a: Y = H

b: Y = $-(CH_2)_3$-N=CH-

Experimental

Materials. The Schiff bases H(X-sal-prpi) (X=H, 5-Cl, 5-Br) were synthesized in the following way. *N,N'*-Bis(3-aminopropyl)piperazine (0.5 mol) was added gradually to a solution of X-salicylaldehyde (1 mol) in ethanol (300 ml), the reaction vessel being placed in an ice bath. The solution was stirred for 30 min. A yellow crystalline precipitate was collected by filtration and recrystallized from ethanol to give yellow crystals. Elemental analysis agreed with the empirical formulae of the compounds. Mp 76 (X=H), 106 (X=5-Cl), 113 °C (X=5-Br).

Ni(X-sal-prpi) (X=H, 5-Cl, 5-Br). To a solution of nickel(II) acetate tetrahydrate (10 mmol) in ethanol (100 ml) was added a Schiff base H(X-sal-prpi) (11 mmol) and the mixture was heated with stirring on a water bath at about 70 °C for 10 min, followed by addition of sodium acetate trihydrate (12.5 mmol); a green precipitate appeared in 30 min. The reaction was continued for 3 h and a green crystalline precipitate was collected by filtration and washed with hot methanol. Attempts to recrystallize the products from such solvents as chloroform and benzene have not been successful.

Co(X-sal-prpi) (X=5-Cl, 5-Br). These cobalt(II) complexes were prepared as red crystals in a manner similar to the corresponding nickel(II) complexes. Recrystallization was carried out from methanol.

[Co(X-sal-prpi)]ClO_4 (X=H, 5-Cl, 5-Br). Cobalt(II) acetate tetrahydrate (10 mmol) was added to a solution of H(X-sal-prpi) (11 mmol) in ethanol (100 ml), and the brown solution was heated on a water bath at about 65 °C for 10 min. Sodium acetate trihydrate (12.5 mmol) and sodium perchlorate (10 mmol) were added to the solution, and the reaction was continued for 3 h. A brown precipitate was recrystallized from methanol to give brown crystals. Molar conductivities (Λ/Ω^{-1} cm^2 mol^{-1}): 98.5 (X=H); 88.1 (X=5-Cl); 84.0 (X=5-Br).

[Mn(X-sal-prpi)]ClO_4 and [Fe(X-sal-prpi)]ClO_4 (X=H, 5-Cl, 5-Br). These complexes were prepared in a manner similar to the corresponding cobalt(III) complexes. The manganese(III) complexes were obtained as dark green crystals by recrystallization of the crude products from methanol or chloroform. The iron(III) complexes were isolated as dark brown crystals, recrystallization being carried out from ethanol. Λ/Ω^{-1} cm^2 mol^{-1}: 98.7 (X=H, Mn^{3+}); 102.2 (X=5-Cl, Mn^{3+}); 98.8 (X=5-Br, Mn^{3+}); 95.0 (X=H, Fe^{3+}); 89.4 (X=5-Br, Fe^{3+}).

Analytical data of the complexes prepared in the present work are shown in Table 1.

Measurements. Electronic absorption spectra of the complexes were measured on a Shimadzu MPS-50L spectrophotometer. The absorption maxima of the metal complexes in solution are almost coincident with those of the same complexes in the solid state. Infrared spectra were recorded as Nujol mulls using a Hitachi 215 infrared spectrophotometer. Magnetic measurements at room temperature were carried out by the Gouy method using $CoHg(SCN)_4$ as a calibrant. Conductivity measurements with methanolic solutions were carried out using a calibrated Toa-Electronics CG 201 PL conductivity cell and a Toa-Electronics Model CM-1DB conductivity bridge. The concentration of the solutions was 1/2000 mol dm^{-3}. The conductivity measurement with [Fe(5-Cl-sal-prpi)]ClO_4 was not carried out because of its low solubility in appropriate solvents.

Results and Discussion

Bivalent Metal Complexes. With cobalt(II) and nickel(II), complexes of the type M^{II}(X-sal-prpi) were isolated (Table 1). Since the nickel(II) complex is diamagnetic and shows a d-d band at 16.1×10^3 cm^{-1}, it is presumed that the nickel(II) ion in this complex

† For X=H, these ligands are abbreviated as salen-pip and sal-prpi, respectively.

ν: 10^3 cm^{-1}. sh: Shoulder.

is planar four-coordinated. This complex does not show a sharp melting point, and is probably polymeric. From the experimental data so far available, it is difficult to draw a definite conclusion about its precise structure.

Contrary to the nickel(II) complex, the cobalt(II) complexes Co(X-sal-prpi) show sharp melting points. They are paramagnetic (Table 1), and their electronic spectra have d-d bands typical of the five-coordinated cobalt(II) complexes, as shown in Fig. 1 and Table 2. It is thus found that five of the six donor atoms in the ligands are coordinated to cobalt(II) ion.

Infrared C=N frequencies of the cobalt(II) complexes are at lower frequencies than those of the free ligands (Table 3), and appear as a single peak, implying that the two imine nitrogen atoms of the ligands are coordinated to the metal ion. Similarly, infrared bands of the free ligands at about 1560—1570 cm^{-1}, which are usually ascribed to C–O vibrations, appear as a single peak and are shifted toward appreciably lower frequencies as the ligands are bound to the cobalt(II) ion, implying that the two phenolic oxygen atoms of the ligands are bound to the cobalt(II) ion. These facts lead to the presumption that only one of the two tertiary nitrogen atoms of the ligands is bound to the cobalt(II) ion in these complexes.

Tervalent Metal Complexes. With manganese(III), iron(III), and cobalt(III), complexes of the type M^{III}(X-sal-prpi)ClO_4 were isolated. The perchlorate ion in these complexes is not coordinated, since a broad infrared band due to the free perchlorate ion appears at about 1040 to 1110 cm^{-1}.[2] This is borne out by their electric conductivities, which are found to be in the range between 89 and 103 Ω^{-1} cm^2 mol^{-1}, showing that they are 1:1 electrolytes.[3] As shown in Table 3, stretching C=N and C–O frequencies of the complexes lie at lower frequencies than those of the free ligands, and each of them appears as a single peak, implying that the two imine nitrogen atoms and two phenolic oxygen atoms are bound to the metal ion.

The cobalt(III) complexes are diamagnetic. Judging from the general tendency of the cobalt(III) ion, the low spin cobalt(III) complexes obtained in the present work are reasonably assumed to be six-coordinated. Their electronic absorption spectra, which are similar to each other, are also in agreement with this view. Examination of the model shows that in the most favourable structure the four nitrogen atoms occupy the coordination sites at the corners of the square, the two oxygen atoms being *trans* to each other. The d-d band at about 14 to 21×10^3 cm^{-1}, which is assigned to the $^1T_{1g}\leftarrow{}^1A_{1g}$ transition in the O_h symmetry scheme, is found to be composed of two components, as may be seen in Fig. 1 and Table 2. The significant band splitting seems to support the *trans*-configuration.[4]

The manganese(III) and iron(III) complexes are of a high spin type (Table 1). Infrared spectra of M(X-sal-prpi)ClO_4, M being Mn(III) and Fe(III), are similar to those of Co(X-sal-prpi)ClO_4 in the whole region from 650 to 4000 cm^{-1}. All the infrared bands are almost coincident with the corresponding bands of the cobalt(III) complexes. It is thus very likely that the coordination mode of the multidentate ligands X-sal-prpi is similar in the manganese(III), iron(III), and cobalt(III) complexes.

The manganese(III) complexes exhibit a broad d-d band at about 16×10^3 cm^{-1}, which may be assigned, in the octahedral group, to the $^5T_{2g}\leftarrow{}^5E_g$ transition.[5]

In the spectra of the iron(III) complexes some feeble, sharp spin-forbidden d-d bands appear at about 10×10^3 cm^{-1}. However, most of the spin-forbidden bands are hidden under an intense metal-to-ligand charge transfer band, whose maximum occurs at 19.5 (X=H), 19.1 (X=5-Cl), and 19.2×10^3 cm^{-1} (X=5-Br).

All these findings combined show that the manganese(III) and iron(III) complexes most probably have a configuration similar to that of the corresponding cobalt(III) complexes, namely a *trans*-six-coordinated $(N)_4(O)_2$ configuration.

(Received November 8, 1979)

α- and β-Cyclodextrins were tosylated with tosyl chloride in an alkaline solution. The products were confirmed to be monotosylated compounds, and the tosyl group was introduced at the C-3 position of one glucose unit of the cyclodextrin molecule. The 1:1 complex formation of cyclodextrin with tosyl chloride was observed spectrometrically.

Cyclodextrins (CD) have been shown to form inclusion complexes with many kinds of molecules. For this reason, CD has been used to simulate an enzyme action.[1-3] Bender *et al.* showed enzyme-like actions of CD, that is, a large rate enhancement and stereospecificity in ester hydrolysis, and saturation and competitive inhibition phenomena, kinetically.[4,5]

In order to prepare a better enzyme model, several modified cyclodextrins have been synthesized. For example, Cramer and Mackensen synthesized imidazole-containing cyclodextrins by tosylation techniques in organic solvents.[6-8] In these procedures, one or more primary hydroxyl group(s) of cyclodextrins were modified, and so it was difficult to prepare regiospecific monosubstituted cyclodextrins. The introduction of an imidazole group of the primary hydroxyl side of cyclodextrins resulted in only a slight rate enhancement. It was not clearly ascertained if the formation of cyclodextrin acylate in an aqueous solution proceeded through complexation, but the benzoate group was attached on the secondary hydroxyl side.[5,9,10]

Another route to attach functionality on the secondary hydroxyl side of cyclodextrin is carboxymethylation by using the anion of dimethylsulfoxide. Bender's group introduced hydroxamic-acid derivatives on the more open face of the cyclodextrin molecule by using this method.[11,12] Imidazole-containing α-cyclodextrin, the catalytic group of which was introduced on a glucose unit, was prepared *via* monotosylated cyclodextrin in an aqueous solution.[13]

In this paper, we wish to report a simple, useful method for the preparation of regiospecific monotosylated cyclodextrins, the tosyl group of which is introduced on the secondary alcohol side of cyclodextrin accompanying 1:1 complex formation between tolylsulfonyl chloride and cyclodextrin in an aqueous solution. We also wish to suggest the mechanism of this regiospecific tosylation.

Experimental

p-Tolylsulfonyl-β-cyclodextrin. β-Cyclodextrin (1 g) was dissolved in a 0.15 M (1 M=1 mol dm^{-3}) sodium hydroxide solution (40 ml) with a pH of around 13.0. *p*-Tolylsulfonyl chloride (1 g) was dissolved in a minimum quantity of acetonitrile, after which the solution was magnetically stirred, drop by drop, into the alkaline solution. The suspension was then vigorously stirred for 1 h, adding 1 M NaOH occasionally to maintain the pH of the solution at more than 12.5. The reaction was terminated by neutralization with 1 M hydrochloric acid. The reaction mixture was filtered *in vacuo* to remove the unreacted *p*-tolylsulfonyl chloride, and then the filtrate was passed through a column with a cation-anion exchanger (Amberlite MB-3 ϕ 1.5×50 cm) and eluted with water. The desalted eluate was condensed and dried with a water bath *in vacuo*. The HPLC data, obtained using a OSD-SIL column (Tokyo Soda LS-410, ϕ 0.5×30 cm) eluted with 10% acetonitrile in water and detected by UV absorption at 254 nm, indicated there were more than 20 species in this crude product. The purity, calculated on the basis of the UV peak area, showed 70% of the main product. The present crude tosyl-CD (*ca.* 0.9 g) was dissolved in a minimum amount of water, and then the solution poured into a large amount of methanol (150 ml). The methanol solution was filtered and evaporated to dryness. The residue from the methanol (0.6 g) was dissolved again in warm water (9 ml, 60 °C) and filtered. The solution was left in a refrigerator at 5 °C for a few days. The white crystalline product was collected by filtration and dried *in vacuo* (0.4 g). In submitting the sample to elemental analysis, the present product (1 g) was further purified by a combination of various types of column chromatography. The aqueous solution was passed through porous polystyrene gel (ϕ 3×20 cm, DIAION HP-20). The column was washed with water, and the trapped component was eluated by the use of 30% aqueous methanol. The fractions containing tosylated CD were indicated by UV absorption, refractive index, and optical rotation, and were then collected and liophilized. Also, the product was purified by the use of gel chromatography (Sephadex G-15, ϕ 3×100 cm), eluated with water as well as a Lober column (ϕ 2.5×31 cm, Merck) and eluated with 10% acetonitrile in water. The yield was 0.1—0.3 g for each column chromatography. The purity was confirmed by HPLC and ^{1}H-NMR. Mp 168—170 °C (dec). Found: C, 43.66; H, 6.08%. Calcd for $C_{49}H_{76}O_{37}S\cdot 3H_2O$: C, 43.72; H, 6.14%.

p-Tolylsulfonyl-α-cyclodextrin. The tosylation of α-CD was carried out in the manner used for β-CD described above, except for the reaction medium. A carbonate buffer solution of pH 12 was used. For the purified sample: mp 160—162 °C; Found: C, 43.04; H, 6.28%. Calcd for $C_{43}H_{66}O_{32}S\cdot 3H_2O$: C, 43.16: H, 6.31%.

The R_f values of these two tosyl CD products in TLC on silica gel were 0.41 for α-CDOTs and 0.54 for β-CDOTs respectively (solvent: 1-butanol-dimethylformamide-water, 2:1:1; detecting reagent: iodine vapor or diphenylamine spray, followed by UV radiation). λ_{max} nm (logε: 274(2.40), 265 (2.70), and 263(2.78) for α-CDOTs, and 273(2.63), 265(2.71), and 262(2.73) for β-CDOTs, with referrence to 273(2.65), 265(2.75), and 262(2.75) for EtOTs at pH 6.50, 25 °C.

6-(Mono)-O-tolylsulfonyl-α-cyclodextrin. This compound was prepared by the method of Melton and Slessor.[14] The purification of the crude product was carried out by filtration through a Celite pad and by recrystalization from

95% ethanol. The total yield was 30%. Found: C, 43.46; H, 6.40%. Calcd for $C_{43}H_{66}O_{32}\cdot 3H_2O$: C, 43.16; H, 6.31%. Mp 155—157 °C (reported[14] 159—162 °C); the R_f in TLC was 0.55.

NMR Measurement. The ^{13}C-NMR measurement of tosyl CD was carried out at the concentration of 0.1—0.5 g in 1.0 ml of a D_2O or DMSO-d_6 solution, referred to dioxane as an internal standard with 2700—10000 times accumulation. The ^{1}H-NMR was observed in a 10% (g/ml) D_2O solution, using trimethylsilyl tetradeutropropionate as the internal referrence.

Partial Hydrolysis of Monotosylated β-Cyclodextrin. The present monotosylated β-CD, prepared in an aqueous solution, was partially hydrolized in a 1 M HCl solution at 80 °C for 6 h. The reaction mixture was neutralized with 1 M NaOH and then desalted with an ion exchanger, Amberlite MB-3. In the product, two components were observed with HPLC and paper chromatography (in 1-butanol–dimethylformamide–water (2:1:1), with dimethylaniline–phtalic acid as the detecting reagent). The lower spot of the R_f value (0.55) was the same as that of authentic glucose. The hydrolyzate was purified by gel chromatography using Sephadex G-15, giving a product with a higher R_f value (0.72) in the paper chromatography; the product was confirmed as monotosylated glucose by characterization by NMR; 2.22(ppm) due to the CH_3 of the tosyl group, 3.2—4.0 due to nonanomeric C–H, 5.0 due to C_1H, and 6.8—7.3 due to benzene-ring C–H. Both the R_f value (0.72) and the spectrum of ^{1}H-NMR agreed with those of authentic 3-*O*-tosyl glucose, which was prepared according to Freudenberg and Ivers.[23]

Determination of Dissociation Constants. The increase in the absorbance of the aromatic chromophore in the presence of cyclodextrin was determined by the spectrophotometric method. To suppress the disturbance due to the hydrolysis of tosyl chloride and the pH change in the solution, the UV absorbance was observed within several seconds after the mixing of tosyl chloride. With a change in CD concentration from 0—0.955×10^{-2} M, the substrate concentration was held constant at 5.0×10^{-5} M. A linear relationship was observed between the spectral change and the added concentration of CD, employing the Benesi-Hildebrand plot at 246 nm with the equation: $C_{CD}\cdot C_{TsCl}/\Delta A = K_{diss}/\Delta\varepsilon + C_{CD}/\Delta\varepsilon$, where K_{diss} indicates a dissociation constant; C_{CD}, the initial concentration of CD; C_{TsCl}, the initial concentration of TsCl; ΔA, the change in the absorbance, and $\Delta\varepsilon$, the difference between the molar extinction coefficients of the free and the complexed substrate. The slope ($1/\Delta\varepsilon$) and the intercept ($K_{diss}/\Delta\varepsilon$) were obtained by the least-squares method.

Results and Discussion

Tosylation of α-, and β-Cyclodextrins in an Aqueous Medium. The reaction of α-, and β-CD with TsCl in an alkaline solution at room temperature for an hour gave products. The products from both α-CD and β-CD were confirmed to be monotosylated compounds (α-CDOTs and β-CDOTs) by UV estimation referred to ethyl tosylate (EtOTs) as well as by ^{1}H-NMR estimation by the peak area.[15–17] It is noteworthy that only one tosyl residue was introduced to a CD molecule in spite of there being many hydroxyl groups on a CD molecule. The optimum alkaline concentrations were around pH 12 for α-CD and around pH 13 for β-CD. Prolonged (12 h) and short (6 min) reactions gave a low attachment of the tosyl residue on CD. One hour was the optimum reaction time. The optimum reaction temperature was about 20 °C in the range of 0—60 °C.

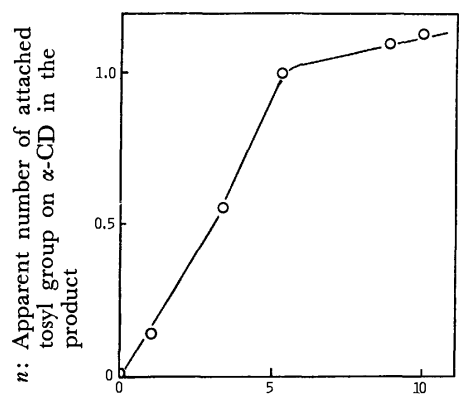

Fig. 1 The number of attached tosyl group on α-CD is plotted as a function of [TsCl]/[α-CD]. Tosylation was occured in 0.15 M NaOH solution at 25 °C for 1 h. The number (n) was calculated from the ^{1}H-NMR measurement.

As is shown in Fig. 1, when the ratio of the initial concentration of TsCl/α-CD was changed from 0 to 10, the plot of the apparent number of the tosyl group introduced on α-CD gave a saturation curve. It seemed that the number, n, increased linearly with the increase in the TsCl/α-CD ratio, which ranged 0 to 5. Hardly more than one tosyl residue to one CD molecule was introduced, even if the TsCl concentrations was 10 times larger than the CD concentration. When CD was tosylated in pyridine, in contrast, CD reacted easily with more than one TsCl and the number (n) would be stoichiometrically controlled. These facts suggest strongly there is 1:1 complex formation during the tosylation reaction in an aqueous solution.

The present product of tosyl-CD was compared with the tosyl-CD through stoichiometrically controlled monotosylation in pyridine, where the tosyl group was attached on a primary hydroxyl group of a glucose unit.[14] The R_f value of TLC was distinctly different between α-CDOTs prepared in pyridine and the α-CDOTs prepared in an aqueous solution. This fact suggested that the present monotosylated α-CD, prepared in an aqueous solution had a tosyl group at a secondary hydroxyl group of a glucose unit of a CD molecule.

The ^{13}C-NMR spectra of these tosyl CD's were observed and assigned according to the literature.[19–22] There was no evidence that each tosyl CD was a mixture of any isomers. The comparison of these spectra showed clearly that each of the tosylated cyclodextrins should have a single and particular structure as a tosyl CD. It had been reported that the amino group of amino-α-CD derived from the present tosylated α-CD was introduced at the C-3 position of a glucose of the CD molecule by means of ^{13}C-NMR spectroscopy.[13] Therefore, the tosyl group of the present tosylated α-CD may be introduced mainly at the C-3 position of the glucose ring of α-CD.

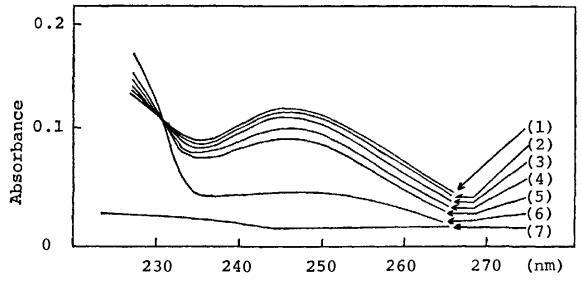

Fig. 2. Spectrum of tosyl chloride at varying α-CD concentrations; pH 6.50, 25 °C, acetonitrile/buffer= 0.5% (v/v). [TsCl] is 5.0×10^{-5} M. [α-CD] is changed at 9.55, 6.63, 3.32, 1.66, 0.332, and 0 ($\times10^{-3}$ M) from the curve 1 to 6 respectively. [TsCl] and [α-CD] are none for the curve 7.

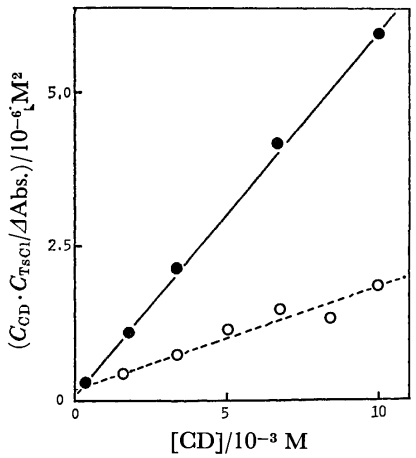

Fig. 3. Benesi-Hildebrandt plot for the mixture of CD and TsCl.
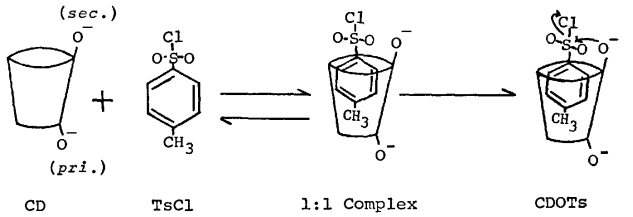
●: α-CD, ○: β-CD.

In order to get direct evidence to determine the substituted position of the tosylated β-CD group, the partial hydrolysis of β-CDOTs was carried out. The resulting hydrolyzate gave two spots in paper chromatography. The lower spot agreed with that of authentic 3-*O*-tosylglucose. The structure of the purified component with the higher R_f value was observed by ^{1}H-NMR to be monotosylglucose. The ^{1}H-NMR spectra and R_f values were coincident with the authentic sample of 3-*O*-tosylglucose. This result strongly suggested that the tosyl group of β-CDOTs was introduced at the C-3 position of glucose unit of β-CD.

Direct Evidence for a Complex Formation. The changes in the UV absorption spectra of TsCl in aqueous solutions with various amounts of the excess α-CD are shown in Fig. 2. A comparison of the UV spectra of EtOTs and TsOH with that of TsCl in an α-CD solution showed a distinct difference. Therefore, the broad absorption at around 245 nm in Fig. 2 must be due to the complex formation of CD with TsCl, and not to TsOH or tosylated CD. Moreover, the complex formation of CD with TsCl may be confirmed by the observation of the isosbestic point (Fig. 2). The Benesi-Hildebrand plots[18] for both α-CD and β-CD with TsCl gave a straight line (Fig. 3). The dissociation constants (K_{diss}) for the



Scheme 1. The mechanism of the regiospecific monotosylation of cyclodextrin with *p*-tolylsulfonyl chloride in alkaline solution.

complexes of CD with TsCl, as calculated from the slopes of these lines, are 0.68×10^{-3} M for α-CD and 1.8×10^{-3} M for β-CD. These dissociation constants showed that the binding of α-CD to TsCl is tighter than in the case of β-CD, which may allow the alkoxide anions of α-CD more chances to attack the sulfur atom of TsCl than β-CD. This suggested that α-CD reacted with TsCl more easily than β-CD and why α-CD reacted with TsCl at a lower pH than did β-CD.

Mechanistic Scheme. The mechanistic scheme of the regiospecific tosylation of cyclodextrin with tosyl chloride in an alkaline solution is shown schematically in Scheme 1. As soon as tosyl chloride was dispersed in water, a cyclodextrin cavity should form a 1:1 complex with a tosyl chloride molecule. In that case, as the methyl group of the tosyl chloride consists of the hydrophobic part of the molecule, the methyl group should be near the primary hydroxyl group down into the cyclodextrin cavity, as is shown in the scheme. The sulfonyl chloride group should be positioned near the secondary hydroxyl group. The scale molecular model (CPK model) indicated that the distance between the sulfur atom of TsCl in the complex and the C-3 oxygen atom of the glucose unit in CD was a little shorter than the distance between the sulfur atom and the C-2 oxygen atom. This proximity effect between the sulfonyl chloride and the secondary hydroxyl group may accelerate the nucleophilic attack of a secondary hydroxyl (3-*O*) anion as the sulfur atom of the tosyl chloride molecule. This would result in a single tosylated CD on a specific secondary hydroxyl of cyclodextrin.

Monochromatic Light-induced Reactions of Benzophenone Hydrazones and the *N*-Acetyl Derivatives in Carbon Tetrachloride in the Presence of Oxygen[1)]

Hiroshi SUGINOME*,** and Tsutomu UCHIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received December 24, 1979)

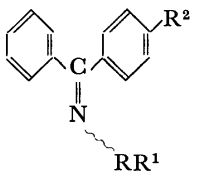
Irradiation of hydrazones of benzophenone, 4-methylbenzophenone and 4-methoxybenzophenone in carbon tetrachloride with monochromatic light in the presence of oxygen afforded the corresponding azine, resulting from N–N bond cleavage, as the major product together with the hydrazone hydrochloride. In contrast to the hydrazones, benzophenone acetylhydrazone in carbon tetrachloride in the presence of oxygen afforded an unstable hydroperoxide as the only product, on photolysis with monochromatic light (288±8 nm); this product was transformed spontaneously into benzophenone on evaporation of the solvent at room temperature. 4-Methylbenzophenone acetylhydrazone and 4-methoxybenzophenone acetylhydrazone reacted in a manner similar to benzophenone acetylhydrazone. Irradiation of benzophenone diacetylhydrazone with 266±8 nm light under conditions analogous to the photo-reactions of hydrazones and acetylhydrazones resulted in loss of an acetyl group, resulting in N–CO bond cleavage to afford acetylhydrazone. The mechanism of the photooxygenation of benzophenone acetylhydrazones is interpreted in terms of chlorine radical-induced autoxidation.

In previous papers,[2)] it was reported that steroidal cyclic ketone acetylhydrazones afforded various yields of lactams on photolysis in the presence of oxygen, while the corresponding hydrazones gave the azines under similar conditions. It was of interest to compare the behavior of alicyclic ketone hydrazone and acetylhydrazone with that of aromatic ketone hydrazone and acetylhydrazone when they were irradiated in the presence of oxygen under similar conditions.

In this paper, we report results of photoinduced oxygenation of some benzophenone acetylhydrazones and diacetylhydrazones in carbon tetrachloride. A comparison is made with the behavior of the parent hydrazones under similar conditions. To avoid secondary photodecompositions[3)] as much as possible, all the photolyses were undertaken with monochromatic light.

Results

Benzophenone hydrazone (**1**),[4)] 4-methoxybenzophenone hydrazone (**3**),[5)] 4-methylbenzophenone hydrazone (**5**),[6)] their *N*-acetyl derivatives (**2**, **4**, and **6**), and *N*-diacetyl derivative (**7**) were prepared by the standard methods.



1 R=R¹=R²=H
2 R=R²=H, R¹=Ac
3 R=R¹=H, R²=OCH_3
4 R=H, R¹=Ac, R²=OCH_3
5 R=R¹=H, R²=CH_3
6 R=H, R¹=Ac, R²=CH_3
7 R=R¹=Ac, R²=H

The 4-substituted hydrazones, **3** and **5**, and their *N*-acetyl derivatives, **4** and **6**, used for the photoreactions were a mixture of *E* and *Z* isomers, as indicated by their NMR spectra (Table 1). All the hydrazones exhibited two strong absorption maxima due to $\pi\rightarrow\pi^*$ transitions in their UV spectra in dioxan, one at 277—278 nm and the other at 223—234 nm. The absorption at the longer wavelength showed a hypsochromic shift and a hyperchromic effect in methanol, as expected for the $\pi\rightarrow\pi^*$ transitions.

The acetylhydrazones also exhibited two absorption maxima, stronger than the hydrazones, attributable to $\pi\rightarrow\pi^*$ configurations.[7)] The absorptions at the longer wavelength in methanol exhibited bathochromic shifts to 285—288 nm in dioxan. As for the hydrazones, the shorter wavelength absorptions (222—231 nm) in dioxan exhibited hypsochromic shifts to 205—208 nm and a hyperchromic effect in methanol.

Photolysis. A solution of benzophenone acetylhydrazone (**2**) (30 mg in 4 ml of carbon tetrachloride containing oxygen) was irradiated with monochromatic light of 288±8 nm generated by a JASCO CRM-FA grating spectro-irradiator. The progress of the reaction was monitored by the NMR and UV spectra. The irradiation caused the gradual disappearance of the absorption maximum at 288 nm in the UV spectrum, and two singlets due to NH and acetyl protons at τ 1.82 and τ 7.74 emerged in the NMR spectrum. Irradiation for 110 h resulted in the disappearance of the UV absorption maximum at 288 nm and the replacement of the signals due to NH and acetyl protons by a 3-H singlet at τ 7.99 and a 1-H singlet at τ 7.79. In fact, examination of the solution by TLC disclosed the absence of the starting material and the formation of a single product much more polar than the starting material. The addition of aqueous potassium iodide to the solution liberated iodine immediately. The NMR spectrum of the photolyzed solution at 75° showed little change in the spectrum, indicating that the product in solution was stable at that temperature. However, the evaporation of the solvent caused a total decomposition of the product. The NMR spectrum of the residue after removal of the

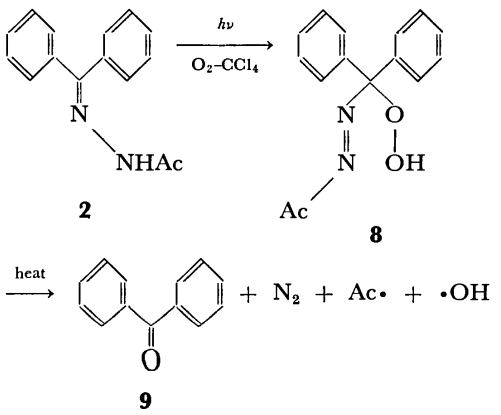
Table 2. The yields of benzophenones in the photolysis of benzophenone acetylhydrazones in carbon tetrachloride with monochromatic light

Compound	Wavelength of the irradiation light (nm)	Time of irradiation (h)	Yield of benzophenones (%)
2	288±8	110	60
2[a]	286±8	168	0
4	289±8	43	73
6	289±8	48	63

a) Solvent: dioxan.

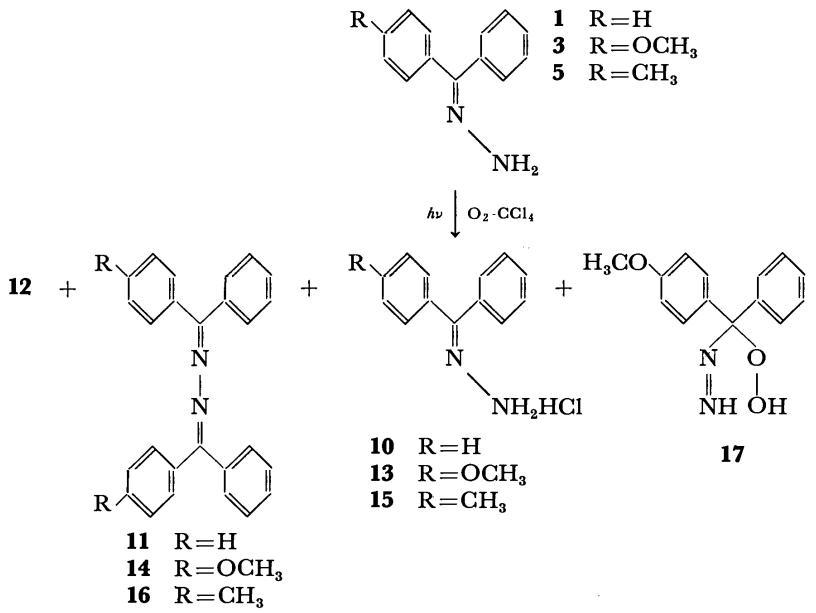


Scheme 1.

solvent disclosed that the signal due to the acetyl group had vanished, and it was actually the spectrum of benzophenone which was isolated in 79% yield by preparative TLC. These observations confirmed that a highly unstable intermediate was formed, which decomposed spontaneously to afford benzophenone upon evaporation of the solvent.

A hydroperoxide structure **8** accommodates all the NMR spectral results, the chemical properties and the result of TLC (Scheme 1). Two singlets at τ 7.99 and 7.79 are ascribable to the acetyl and the hydroperoxide protons. The hydroperoxide proton signals usually resonate at τ −0.3 to −0.75.[8,9] The considerable upfield shift is attributable to shielding by the aromatic ring.

In contrast to the benzophenone acetylhydrazone, irradiation of benzophenone hydrazone (**1**) itself with monochromatic light (270±8 nm) for 72 h under conditions comparable to the case of *N*-acetyl derivative afforded three products: **10**, **11**, and **12** (Scheme 2). Product **10**, which gradually separated as a solid on the wall of the vessel while being irradiated, was identified as benzophenone hydrazone hydrochloride[10] (25% yield). Product **11**, mp 161—163 °C, was iden-



Scheme 2.

Table 3. Products and the yields in the photolysis of benzophenone hydrazones in carbon tetrachloride with monochromatic light

Compound	Wavelength of light (nm)	Time of irradiation (h)	Yields of products (%)		
			The azine	The ketone	The hydrochloride
1	277±8	72	50	0	25
3	279±8	20	7	25	32
5	276±8	11	47	0	31

tified as benzophenone azine by a comparison with a specimen prepared by the reported method.[4] The third product, **12**, mp 230—232 °C, the structure of which has not been deduced, exhibited the molecular ion at *m/e* 418 in the mass spectrum and a single absorption maximum at 307 nm in the UV spectrum.

Irradiation of other two nuclear substituted acetylhydrazones **4** and **6** in carbon tetrachloride with monochromatic light gave results parallel with those for acetylhydrazone **2**. The reaction conditions and the yields of the product ketone are shown in Table 2.

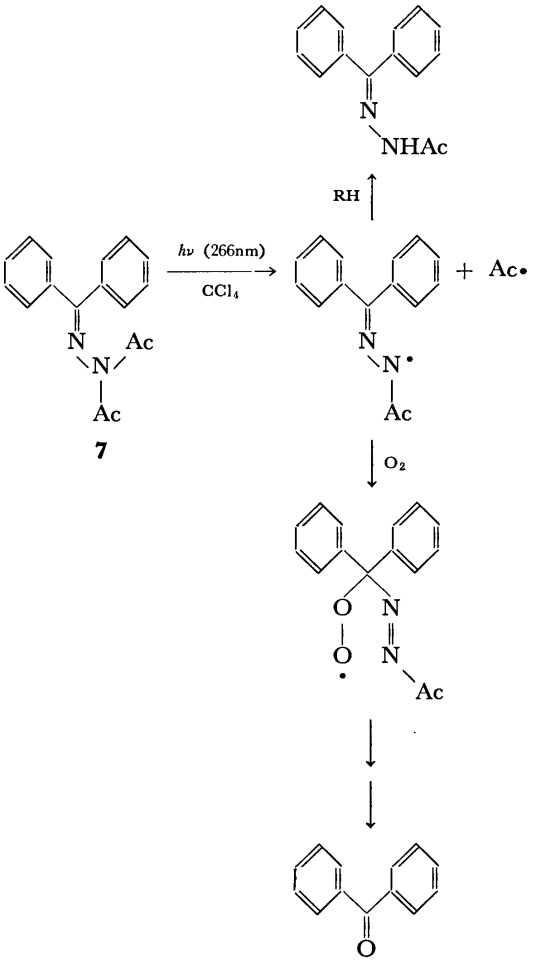
In order to obtain further information with regard to the role of the solvent, photolysis of benzophenone acetylhydrazone (**2**) in dioxan with monochromatic light (286±8 nm) was carried out under conditions similar to those in carbon tetrachloride. However, no trace of hydroperoxide was found after 168 h irradiation and the starting material was recovered.

Irradiation of nuclear substituted hydrazone **5** in carbon tetrachloride with appropriate monochromatic light provided results parallel to the case of the hydrazone **1**. It is notable, however, that while the irradiation of the hydrazones **1** and **5** did not afford any parent ketones, the irradiation of the hydrazone **3** afforded a significant amount of the parent ketone formed *via* a hydroperoxide **17**. The reaction conditions and the yields of products are shown in Table 3.

These results are in a sharp contrast with the results by Binkley,[16] who reported that irradiation of benzophenone hydrazone (**1**) in oxygen-free methanol, with Vycor-filtered light, afforded diphenylmethane (26%) and benzophenone (34%). Repetition of this photolysis in the presence of oxygen with monochromatic light showed the photoreaction in methanol to be slower than that in carbon tetrachloride and confirmed the formations of only diphenylmethane and benzophenone as the products. Photolysis in dioxan with Vycor-filtered light was also carried out. Diphenylmethane was again the major product (28%), accompanied by the azine (3%) and the parent ketone (15%). The formation of diphenylmethane by irradiation in this aprotic solvent in the presence of oxygen seems to suggest that the reaction does not involve radical species and that the methylene proton(s) of diphenylmethane may be provided by an ionic intramolecular proton transfer from the amino group, although no experiments in deuteriodioxan were undertaken.

Finally, photolysis of benzophenone diacetylhydrazone **7** in carbon tetrachloride with monochromatic light (266±8 nm) was carried out in order to define further structural requirement for the formation of the hydroperoxide. It was expected that the photoinduced transformation of **7** may be slower than that of acetylhydrazone **2**, since the former did not have a hydrogen on the nitrogen center. However, the disappearance of **7** was found to complete in a period even shorter than in the case of benzophenone acetyl-

hydrazone (90 h). The NMR spectrum of the solution exhibited four sharp singlets at τ 6.42, 7.62, 7.78, and 8.02 in 1:0.7:0.2 ratio, a broad singlet at τ 1.38, and a multiplet at τ 2.22 to 2.80. Examination of the product by TLC disclosed the formation of virtually two products, the Rf values of which were identical with those of benzophenone and benzophenone acetylhydrazone (**2**). These two compounds were isolated by preparative TLC in 77 and 20% yields. Two singlets at τ 1.38 and 7.78 in the photolyzed solution can be attributable to benzophenone acetylhydrazone (**2**). Other singlets in the solution could be due to volatile products resulting from the reaction of the acetyl radical.



Scheme 3.

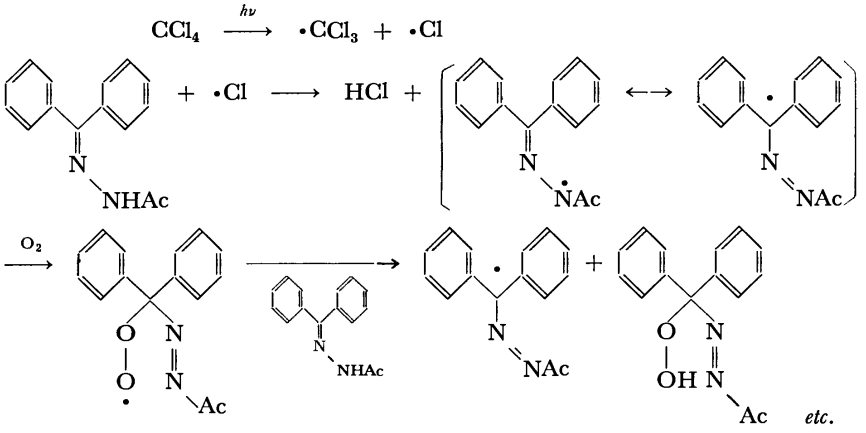
Discussion

There are at least two possible mechanistic pathways for the formation of the hydroperoxides (*e.g.*, **8**) from the acetylhydrazones. One is *via* a radical-induced autoxidation observed for benzaldehyde phenylhydrazones by Busch and Dietz.[9,11] Another is by sensitized oxygenation, as observed for acetone phenylhydrazone by Schenck and Wirth.[12] In this case, singlet oxygen is involved.[13]

Of these two mechanisms, involvement of singlet oxygen, which might be generated *via* sensitization by the acetylhydrazone itself, is ruled out, since no hydroperoxides are formed in the photolysis in dioxan. Thus, oxygenation through the autoxidation remains as a mechanistic possibility. To compare the present reaction with the autoxidation of benzaldehyde phenylhydrazone, benzophenone acetylhydrazone **2** in benzene was subjected to autoxidation under the conditions analogous to the autoxidation of benzaldehyde phenylhydrazone.[11] However, no hydroperoxide **8** was formed under these conditions and irradiation was necessary to obtain hydroperoxide **8** from acetylhydrazone **2**.

One of the probable autoxidation pathways for the hydroperoxide formation is depicted in Scheme 4. In this pathway, a chlorine atom generated from carbon tetrachloride abstracts a hydrogen attached to the amide nitrogen of the acetylhydrazone to form a stabilized amidyl radical and to initiate a chain reaction. Generation of chlorine atoms from carbon tetrachloride under the experimental conditions was confirmed by the formation of the hydrochlorides **10**, **13**, and **15** in the photolysis of the hydrazones. It should be noted that this autoxidation process for the acetylhydrazones predominates over other processes such as N–N bond cleavage, which is almost only reaction in monochromatic photolysis of benzophenone hydrazones, and N–CO bond cleavage.

In contrast to the acetylhydrazone, the parent hydrazones are virtually unreactive toward oxygen under irradiation, with the exception of 4-methoxybenzophenone hydrazone (**3**) in which 25% of the parent



Scheme 4.

ketone was formed together with the azine (Table 3). The major reaction in the hydrazone photolysis is the homolysis of the N–N bond to afford the imino radicals. The homolysis probably takes place from the excited singlet state of the hydrazones since it occurs even in the presence of oxygen.[14] For the hydrazones, generation of a nitrogen-centered radical *via* the abstraction by electrophilic chlorine atom is probably more difficult than for the acetylhydrazones, owing to the lower stabilization of the radicals to be formed.

In this connection, it is notable that only 4-methoxybenzophenone hydrazone (**3**) afforded the hydroperoxide (as indicated by the formation of the parent ketone). We explain this in terms of the polar effects that frequently influence radical reactions.[15] The reactions involving electrophilic chlorine atom have a considerable ionic character.[15] In the present case, the electron-donating methoxyl substituent should stabilize the transition state and facilitate the hydroperoxide formation. The electron-donating effect of a methoxyl group also may play a role in accelerating the attack by the chlorine atom on the hydrogen atom attached to the nitrogen. The difference in the products in the photo-reaction of benzophenone hydrazones in carbon tetrachloride and those in methanol or dioxan is appreciable. Although the exact reason for this difference is not clear, it is likely that a photochemical N–N bond cleavage in the hydrazone is facilitated by the protonation of the amino group with the hydrogen chloride generated by irradiation.

The foregoing experiments showed that a primary photochemical reaction of the diacetylhydrazones is the cleavage of one of the N–CO bonds[17] rather than the N–N bond cleavage. The N–CO bond cleavage is followed by competitive processes: *i.e.*, the combination of the amidyl radical with oxygen or with hydrogen from another substrate or chlorine abstraction of the amidyl radical from the solvent. These processes may lead to the observed products. We noted previously[2] that in the photolysis of acetyl- and diacetylhydrazones of some steroidal alicyclic ketones, no azine resulting from N–N bond cleavage was formed. The present results with regard to acetyl- and diacetylhydrazones of aromatic ketones seem to be parallel to the previous results[2] in that no azine was found in the products.

Experimental

For instruments used and general procedure see part 30.[18] The mass spectra were taken with a Hitachi RMU-6E spectrometer (ion source temperature 200 °C; ionizing voltage 80 eV) with the exception of **5**. The mass spectrum of **5** was taken with a Hitachi JMS-D 300 spectrometer (ion source temperature 175 °C and ionizing voltage 70 eV).

*Benzophenone Hydrazone (**1**).* This hydrazone was prepared by the described procedure,[4,10] mp 97—99 °C (lit,[4] mp 97—98 °C). UV ν_{max} (dioxan) 278 nm (ε: 11500), ν_{max} (CH_3OH) 281 nm (ε: 23000), ν_{max} (CCl_4) 288 nm (ε: 24000); MS, *m/e* (rel. intensity) 196 (M^+, 100%).

*Benzophenone Acetylhydrazone (**2**).* Benzophenone hydrazone (1.8 g) and acetic anhydride (7 ml) in pyridine (10 ml) were stirred for 63.5 h at room temperature. After the addition of methanol, the solvent was removed by the addition of benzene and the residue was dissolved in chloroform. The organic layer was washed with 2 mol dm^{-3}-hydrochloric acid and water successively and dried (Na_2SO_4). After removal of the solvent, the residue was recrystallized from diethyl ether to afford benzophenone acetylhydrazone (1.64 g), mp 106—107.5 °C. Found: C, 74.84; H, 5.57; N, 11.50%. Calcd for $C_{15}H_{14}N_2O$: C, 75.60; H, 5.92; N, 11.76%. UV ν_{max} (dioxan) 286 nm (ε: 18700); ν_{max} (CH_3OH) 281 nm (ε: 23000); ν_{max} (CCl_4) 288 nm (ε: 24000); IR, 3179 (NH), 1688 (NHCO), 1332, 1311, 1290, 1127, 1020, 954, 784, and 770 cm^{-1}; MS, *m/e* (rel. intensity) 238 (M^+, 60%), 196 (100), and 195 (89).

*4-Methoxybenzophenone Hydrazone (**3**).* 4-Methoxybenzophenone (3 g) and hydrazine hydrate (15 ml) in ethanol (30 ml) were refluxed for 22 h. A part of the solvent was removed and the crystals which appeared were collected by filtration, (1.77 g). These were a 2:3 mixture of *E* and *Z* isomers, judged by the NMR spectrum, but recrystallization from ethanol twice afforded a more abundant single isomer, mp 95—96.5 °C, which gave a single peak due to the methoxyl at τ 6.24 (lit,[5] α-form, mp 95—96 °C). Found: C, 74.15; H, 6.29; N, 12.32%. Calcd for $C_{14}H_{14}N_2O$: C, 74.31; H, 6.24; N, 11.38%. UV ν_{max} (dioxan) 278 nm (ε: 15000); ν_{max} (CH_3OH) 278 nm (ε: 17400); ν_{max} (CCl_4) 279 nm (ε: 12600); IR 3422 and 3309 (NH_2), 1609, 1251, 1073, 1028, and 838 cm^{-1}. MS, *m/e* (rel. intensity) 226 (M^+, 100), 195, and 128 (50).

*4-Methoxybenzophenone Acetylhydrazone (**4**).* The hydrazone **3** (1.5 g) and acetic anhydride (5 ml) in pyridine (7.5 ml) were stirred for 18 h at room temperature. After work-up as usual, the residue was recrystallized from acetone to yield the acetylhydrazone (1.47 g), mp 98—99 °C. Found: C, 71.65; H, 6.01; N, 10.51%. Calcd for $C_{16}H_{16}N_2O_2$: C, 71.62; H, 6.01; N, 10.44%. UV ν_{max} (dioxan) 285 nm (ε: 18800); ν_{max} (CH_3OH) 287 nm (ε: 22400); ν_{max} (CCl_4) 289 nm (ε: 17500); IR 3180 (NH), 1665 (CONH), 1605, 1507, 1334, 1303, 1243, 1169, 1128, 1037, 843, 779, and 698 cm^{-1}. MS, *m/e* (rel. intensity) 268 (M^+, 79), 226 (78), and 225 (100).

*4-Methylbenzophenone Hydrazone (**5**).* 4-Methylbenzophenone (3 g) and hydrazine hydrate (15 ml) in ethanol (30 ml) were refluxed for 10 h. A part of the solvent was removed and the crystals which appeared were collected by filtration to yield the hydrazone (2.90 g). This was a 2:1 mixture of *E* and *Z* isomers, judged by the NMR spectrum. Recrystallization from ethanol twice afforded a more abundant single isomer, which showed a single peak due to the methyl (τ 7.57), mp 87.5—88.5 °C (lit,[6] mp 80—81 °C). UV ν_{max} (dioxan) 277 nm (ε: 12000); ν_{max} (CH_3OH) 272 nm (ε: 12000); ν_{max} (CCl_4) 276 (ε: 11800); IR 3360 (NH_2), 1579, 1076, and 832 cm^{-1}. MS, *m/e* (rel. intensity) 210 (M^+, 100), 195 (20), and 194 (20).

*4-Methylbenzophenone Acetylhydrazone (**6**).* The hydrazone **5** (1.5 g) and acetic anhydride (10 ml) in pyridine (15 ml) were stirred for 17 h at room temperature. After the addition of methanol, the solvent was removed by the addition of benzene. The residue was dissolved in diethyl ether. The solution was washed with water and dried (Na_2SO_4). The usual work-up gave a residue which was recrystallized from diethyl ether. (659 mg), mp 95—96 °C. Found: C, 76.37; H, 6.41; N, 11.05%. Calcd for $C_{16}H_{16}N_2O$: C, 76.16; H, 6.39; N, 11.10%. UV ν_{max} (dioxan) 288 nm (ε: 19100); ν_{max} (CH_3OH) 285 nm (ε: 19800); ν_{max} (CCl_4) 289 nm (ε: 18400). IR 3180 (NH), 1674 (NHCO), 1336, 1309, 1297, 1113, 1020, 960, 832, and 778 cm^{-1}. MS, *m/e* (rel. intensity) 252 (M^+, 71%), 210 (98), and 209 (100).

Photolysis of Benzopenone Acetylhydrazone (2) in the Presence of Oxygen with Monochromatic Light (286±8 nm). In Carbon Tetrachloride: Benzophenone acetylhydrazone (**2**) (30 mg) in purified carbon tetrachloride[19] (4 ml) saturated with oxygen in a quartz vessel was placed in the chamber of a CRM-FA grating spectro-irradiator and was irradiated. The progress of the reaction was monitored by UV spectroscopy. The intensity of the absorption maximum at 288 nm gradually diminished during irradiation and after 110 h the absorption maximum nearly vanished. The NMR spectrum also showed that the signals of the starting material were replaced by those of the product (see text). The solvent was evaporated and the residue was purified by preparative TLC with a 1:1 mixture of benzene and diethyl ether to afford benzophenone (18 mg). A small amount of a more polar unidentified compound (3 mg) was obtained.

In Dioxan: Benzophenone acetylhydrazone (100 mg) in dioxan (Dotite Spectrosol, Wako, Japan) (4 ml) was irradiated with 286±8 nm wavelength light for 168 h. The absence of the hydroperoxide in the solution was proved by TLC and the absence of the parent ketone was confirmed by the NMR spectrum of the product after evaporation of the solvent.

Photolysis of 4-Methoxybenzophenone Acetylhydrazone (4) in the Presence of Oxygen with Monochromatic Light (288±8 nm). 4-Methoxybenzophenone acetylhydrazone (**4**) (30 mg) in purified carbon tetrachloride (4 ml) saturated with oxygen in a quartz vessel was irradiated for 43 h as for benzophenone acetylhydrazone. After removal of the solvent, the residue showed two spots in TLC (benzene). This was subjected to preparative TLC to afford two fractions. The more mobile fraction (22 mg) was nearly pure 4-methoxybenzophenone. The less mobile fraction (few mg) was unidentified gum.

Photolysis of 4-Methylbenzophenone Acetylhydrazone (6) in the Presence of Oxygen with Monochromatic Light (294±8 nm). 4-Methylbenzophenone acetylhydrazone (**6**) (30 mg) in purified carbon tetrachloride (4 ml) saturated with oxygen in a quartz vessel was irradiated for 48 h, as done for benzophenone acetylhydrazone. After removal of the solvent, the residue showed two spots on TLC (benzene), but the less mobile spot was very weak. Preparative TLC of the residue afforded two fractions. The more mobile fraction (19 mg) was nearly pure 4-methylbenzophenone. The less mobile fraction (6 mg) was an unidentified gum.

Photolysis of Benzophenone Hydrazone (1) in Dioxan in the Presence of Oxygen with Vycor-filtered Light. Benzophenone hydrazone (**1**) (500 mg) in dioxan (220 ml) was irradiated with a Hanovia 450-W high pressure Hg arc with a Vycor-filter until the starting material disappeared (24 h). After removal of the solvent, the oily residue was subjected to preparative TLC with benzene to afford three fractions. The most mobile fraction (120 mg) was diphenylmethane and the next mobile fraction (28 mg) was benzophenone. The 3rd fraction (194 mg) was still a mixture, which was subjected to preparative TLC with a 3:1 benzene and hexane. Three developments afforded major two fractions. The more mobile fraction (14 mg) was the azine **11** which was recrystallized from ethanol. The less mobile fraction (40 mg) was benzophenone.

Photolysis of Benzophenone Hydrazone (1) in the Presence of Oxygen with Monochromatic Light (270±8 nm). In Carbon Tetrachloride: Benzophenone hydrazone (30 mg) in purified carbon tetrachloride (4 ml) containing oxygen in a quartz vessel was irradiated with monochromatic light for 72 h, as done for *N*-acetylbenzophenone hydrazone (**2**). During the irradiation, a solid appeared in the solution. The solid (9 mg) was collected by filtration and was recrystallized from methanol to yield hydrazone hydrochloride **10**, mp 166—167 °C (lit,[10] mp 183 °C). This was identified by its mass spectrum. Removal of the solvent from the filtrate afforded the residue (17 mg). This was subjected to preparative TLC with a 4:1 benzene–diethyl ether mixture to afford four fractions. The most mobile fraction (15 mg) was identified as benzophenone azine (**11**), which was recrystallized from methanol (5 mg), mp 161—163 °C (lit,[4] mp 162—164 °C). The second and third mobile fractions (4 mg and 3 mg) were unidentified gums. The fourth fraction (5 mg) was recrystallized from methanol to yield crystals (**12**), mp 230—232 °C. UV ν_{max} (CCl_4) 307 and 280 nm (inflexion); ν_{max} ($CHCl_3$) 1707 and 1111 cm^{-1}; MS, *m/e* (rel. intensity) 418 (M^+, 2), 223 (15), and 196 (100).

In Methanol: Benzophenone hydrazone (**1**) (2 mg) in methanol (Dotite Spectrosol, Wako, Japan) (4 ml) was irradiated with monochromatic light (273±8 nm). Irradiation for 5 h completed the photo-decomposition. After evaporation of the solvent, the residue was subjected to preparative TLC with a 4:1 benzene and diethyl ether mixture to afford seven fractions. All the fractions except the most mobile one was very minor. The most mobile fraction was again subjected to preparative TLC with a 1:3 hexane and benzene mixture to afford more mobile diphenylmethane and less mobile benzophenone. Both compounds were identified by comparisons of the UV spectra and the TLC behaviors with those of the authentic materials.

Photolysis of 4-Methoxybenzophenone Hydrazone (3) in the Presence of Oxygen with Monochromatic Light (277±8 nm). The hydrazone (20 mg) in carbon tetrachloride (3 ml) containing oxygen was photolyzed for 20 h. The solid (11 mg) which separated was collected and recrystallized from methanol–diethyl ether to afford hydrochloride **12** (2 mg), mp 127—130 °C. The residue (13 mg) obtained by evaporation of the filtrate was subjected to preparative TLC with 1:5 hexane and benzene to afford three fractions. The most mobile fraction (1.5 mg) was azine **13** which was identified by a comparison with the specimen prepared by a ground state reaction. The second mobile fraction (5 mg) was 4-methoxybenzophenone. The least mobile fraction (7.5 mg) was an unidentified gum.

Photolysis of 4-Methylbenzophenone Hydrazone (5) in the Presence of Oxygen with Monochromatic Light (287±8 nm). The hydrazone (30 mg) in carbon tetrachloride (4 ml) was photolyzed for 11 h. The solid (11 mg) which separated was collected and recrystallized from methanol to afford hydrochloride **15** (5 mg), mp 138—139 °C. The residue (20 mg) obtained by the evaporation of the filtrate of the photolyzed solution was subjected to preparative TLC with a 4:1 benzene and diethyl ether mixture to afford two fractions. The mobile fraction was again purified by preparative TLC with a 5:1 benzene and hexane mixture to afford the azine **16** (14 mg), which was identified by a comparison with the authentic specimen prepared by a ground state reaction.

Preparation of 4-Methoxybenzophenone Azine (13). 4-Methoxybenzophenone (400 mg), hydrazine hydrate (0.3 ml), and potassium hydroxide (1 g) were refluxed in ethanol (3 ml) for 20 h. A part of the solvent was removed and the solution was extracted with chloroform. The chloroform solution was neutralized with 2 mol dm^{-3} hydrochloric acid, washed with water, and dried (Na_2SO_4). Evaporation of the solvent left the residue which was purified by preparative TLC with a 1:5 hexane and benzene mixture to afford an oily azine **15** (450 mg). This azine could not be induced to crystallize. IR (CCl_4) 1614, 1516, 1398, 1458, 1308, 1249, 1176, 1042, 724, and 698 cm^{-1},

*Preparation of 4-Methylbenzophenone Azine (**15**).* 4-Methylbenzophenone (400 mg), hydrazine hydrate (0.3 ml) and potassium hydroxide (1 g) in ethanol (3 ml) were refluxed for 3 h. A part of the solvent was removed by a rotary evaporator and the solution was extracted with dichloromethane. The dichloromethane solution was worked up as done for 4-methoxybenzophenone azine. The product was purified by preparative TLC with a 1:5 hexane and benzene mixture to afford an oily azine **15** (69 mg). This was recrystallized from methanol–diethyl ether (31 mg), mp 137—138 °C. IR 1607, 1588, 1322, 1303, 1177, 823, 767, 718, and 694 cm^{-1}.

*Attempted Autoxidation of Benzophenone Acetylhydrazone (**2**). In the Presence of Hydrogen Peroxide and Oxygen.* Benzophenone acetylhydrazone (60 mg) in benzene (10 ml) and 30% hydrogen peroxide (1 drop) were stirred under air for 288 h at room temperature. TLC showed that no product other than the starting material was present in the solution.

In the Presence of Oxygen: Benzophenone acetylhydrazone (100 mg) in benzene (0.6 ml) was bubbled with oxygen and the solution was stirred for 96 h in an atmosphere of oxygen at room temperature. After removal of the solvent, the residue was recrystallized from diethyl ether to afford the starting material (26 mg). Removal of the solvent left a residue which was subjected to preparative TLC with a 1:3 benzene and dichloromethane to afford two fractions. The more mobile fraction (39 mg) was examined by the NMR spectrum, which showed no aromatic protons. The less mobile fraction (30 mg) was the starting material.

*Benzophenone Diacetylhydrazone (**7**).* Benzophenone hydrazone (2.014 g) and acetic anhydride (10 ml) in pyridine (10 ml) were stirred for 20 h at 70—80 °C. After the addition of methanol, the reaction mixture was worked up as done for the preparation of benzophenone acetylhydrazone. After removal of the solvent, the residue was subjected to column chromatography (Wako gel C-200; 45 g). Elutions with benzene and benzene containing increasing amounts of chloroform afforded two fractions. The less polar fraction (1.845 g) was recrystallized from diethyl ether to afford benzophenone diacetylhydrazone, mp 121—124 °C. Found: C, 72.86; H, 5.66; N, 9.81%. Calcd for $C_{17}H_{16}N_2O_2$: C, 72.84; H, 5.75; N, 9.99%; UV ν_{max} (MeOH) 208 nm (ε: 25000), and 245 nm (ε: 16000); ν_{max} (dioxan) 253 nm (ε: 14000).

*Photolysis of Benzophenone Diacetylhydrazone (**7**) in the Presence of Oxygen with Monochromatic Light (266±8 nm) in Carbon Tetrachloride.* Benzophenone diacetylhydrazone (**7**) (30 mg) in purified carbon tetrachloride (3 ml) in a quartz vessel was placed in the chamber of a CRM-FA grating spectroirradiator and was irradiated. The progress of the reaction was monitored by TLC, which showed the disappearance of the starting material after 90 h. After evaporation of the solvent, the residue was subjected to preparative TLC (Merck, silica gel 60F-254) with a 1:1 mixture of benzene and diethyl ether to afford two fractions. The more mobile fraction (15 mg) was benzophenone and the other (5 mg) was benzophenone acetylhydrazone.

We thank Mrs. T. Okayama for the measurements of NMR spectra.

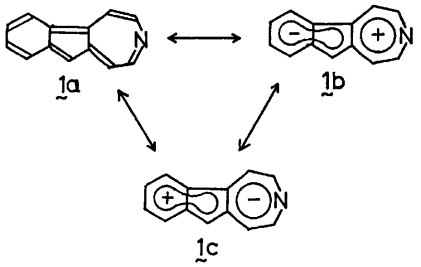
Synthesis of Indeno[1,2-*d*]azepine Derivatives

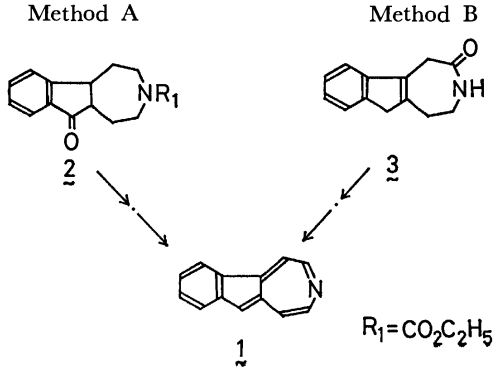
Masaru KIMURA,* Kyosuke SATAKE, Shigeaki YONEMORI, and Shiro MOROSAWA
Department of Chemistry, Okayama University, Tsushimanaka 3-1-1, Okayama 700
(Received January 28, 1980)

4-Ethoxyindeno[1,2-*d*]azepine(**18**) and 10-bromo-4-ethoxyindeno[1,2-*d*]azepine were prepared by *O*-ethylation of indeno[1,2-*d*]azepin-4-ol(**12ab**) and 10-bromoindeno[1,2-*d*]azepin-4-ol(**13ab**) with Et_3OBF_4 in 62 and 69% yields, respectively. **12ab** was obtained by bromination of 1,2,3,4,5,10-hexahydro-4-indeno[1,2-*d*]azepine(**3**) or 1,2,3,4-tetrahydroindeno[1,2-*d*]azepin-4-one with NBS, and subsequent dehydrobromination of the corresponding bromide formed *in situ* on basic alumina in 10% yield. When the bromination time was over 20 h, only **13ab** was isolated in 20% yield. Direct dehydrogenation of **3** with DDQ gave 10-chloroindeno[1,2-*d*]azepin-4-ol in 27% yield. The NMR and electronic spectra of **18** indicated the presence of a fully conjugated 14-pi ring system in it. We also investigated the possibility for dehydrogenation of 3-ethoxycarbonyl-1,2,3,4,5,5a,10,10a-octahydroindeno[1,2-*d*]azepin-10-one.

We have derived a simple synthetic approach for benz[*a*]azulene derivatives containing a nitrogen atom in the seven-membered ring that should lead to new theoretical and practical fields. Benz[*a*]azulene is a typical nonbenzeniod aromatic compound having two $(4n+2)$pi ring systems.[1] When an electron withdrawing >C=N– bond is introduced into part of the seven-membered ring, the stable 14-pi ring system may be destabilized by the contribution of a canonical structure like **1c**. As shown here, unconventional physical and



chemical properties can be anticipated to be associated with such molecules as **labc**. Although there are five basic skeletones for azabenz[*a*]azulene, *i.e.*, indeno[2,1-*b*]-, indeno[2,1-*c*]-, indeno[1,2-*d*]-, indeno[1,2-*c*]-, and indeno[1,2-*b*]azepine, only 3-ethoxycarbonyl indeno[2,1-*b*]azepine(**4**) was prepared and studied by Treibs *et al.*[2] Furthermore, most of the reported azazulenes[3] to date, such as cyclopent[*c*]azepine,[3a] 6,7,8-triphenylcyclopent[*b*]azepine,[3b] and **4** have been prepared by the method using no dehydrogenation process to furnish the ring system. The development of a general synthesis of indenoazepines by dehydrogenation of the corresponding saturated ring system is desiable. We wish to report two independent methods (methods A and B) utilized in the preparation of **1** by the use of **2** and **3**. In method A, we investigated the possibility for dehydrogenation of **2**. In method B, we wish to report the successful synthesis of novel **18** from **3**.



Results and Discussion

Method A. Some Attempts for Dehydrogenation of **2**: This method was characterized by the use of **2**, the structure of which was established.[4] Mono- and dibromination of **2** were effected with 1 equiv of bromine in ether solution. Upon dehydrobromination of the corresponding bromides using lithium chloride in DMF at 120 °C, there was a yellow oil obtained. Preparative column chromatography of the reaction mixture on silica gel permitted purification and isolation of 3-ethoxycarbonyl-1,2,3,4,5,10-hexahydroindeno[1,2-*d*]-azepin-10-one(**5**), and 3-ethoxycarbonyl-1,2,3,10-tetrahydroindeno[1,2-*d*]azepin-10-one(**6**). The structures of **5** and **6** were deduced from the following NMR, IR, electronic spectra, and elemental analyses. An elemental analysis suggested that **5** was formulated as $C_{16}H_{17}NO_3$ and **6** was $C_{16}H_{15}NO_3$. Therefore a new double bond and two double bonds were introduced into **2**, and **5** and **6** were prepared, respectively. The electronic spectrum of the yellow compound **5** showed strong absorption bands at 237 (log ε, 4.54) and 244 nm (4.55). This absorption pattern was similar to that of 8-methyl-1,2,3,4-tetrahydrofluoren-9-one(**7**).[10] In NMR spectrum of **5**, the resonances of methylene groups appear at 2.45—2.49 (4H, m) and 3.45—3.88 ppm (4H, m). These results support the structure of **5**. The electronic spectrum of the red compound **6** showed three absorption bands at 224 (log ε, 4.22), 277 (4.34), and 455 nm (2.93). In NMR spectrum of **6**, the resonances of methylene groups appear at 2.88 (2H, t, J=4.5 Hz), and the resonances at 5.75 (1H, d, J=9.1 Hz) and 7.02 ppm (1H, d, J=9.1 Hz)

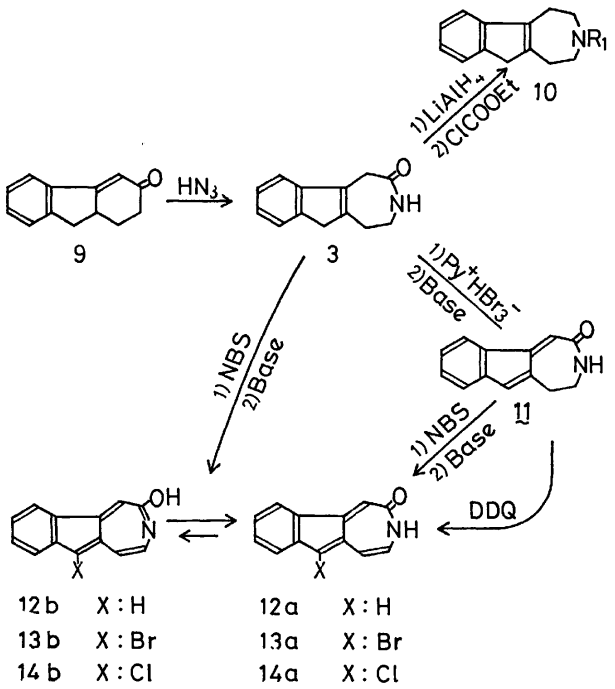
8

are corresponding to γ and δ protons of $\alpha,\beta,\gamma,\delta$-unsaturated ketone system in **6**. These results support the structure of **6**. The results of bromination and subsequent dehydrobromination of **2** are summarised in Table 1. Allylic bromination of both **5** and **6** were achieved with 1 equiv of NBS in the presence of a catalytic amount of bezoyl peroxid. The dehydrobrominations of the corresponding bromides with LiCl in DMF produced a complex and tarry mixture. Similarly, the dehydrogenation of **5** and **6** with DDQ produced a complex and tarry mixture. In the case of dehydrogenation of **5** with triphenylmethyl tetrafluoroborate, **6** was isolated by preparative TLC. Dehydrogenation of **6** with triphenylmethyl tetrafluoroborate gave no evidence for the formation of **8**. It thus became necessary to develop another method for preparing **1** by the use of more stable intermediates.

Method B. *Synthesis of **18** and **19** from **3***: Considering the difficulty of the preparation of a fully conjugated azepine system from hydroazepine(**2**), we chose **3** as an intermediate into which introduction of >C=N– bond was accomplished with the aid of tautomerism between the lactam form (**12a**) and azepinol form (**12b**). The reaction sequence is outlined in Scheme 1. The ring expansion of 1,2,3,9a-tetrahydrofluoren-3-one (**9**)[5] with sodium azide in PPA at 40 °C, followed by column chromatography on neutral alumina produced **3** in 60% yield. For the confirmation of the structure, **3** was treated successively with $LiAlH_4$ and ethyl chloroformate. The expected 1-ethoxycarbonyl-1,2,3,4,5,10-hexahydroindeno[1,2-*d*]azepine (**10**: R=$CO_2C_2H_5$) was obtained in 80% yield. **10** was identified by comparison with the NMR and IR data of the authentic sample obtained by Kimura and Morosawa.[4a] Bromination of **3** with 1.1 molar equiv of pyridinium hydrogenbromide perbromide in acetic acid at 40 °C for 4 h,



Scheme 1.

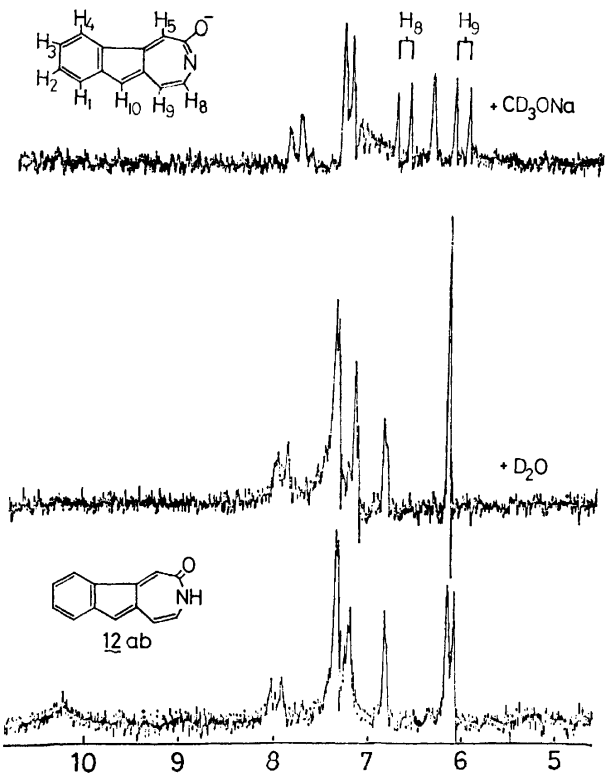


Fig. 1. NMR spectra of **12ab** in DMSO-d_6 (bottom), in the presence of few drops of D_2O (middle), and in the presence of 1 equiv of CD_3ONa (top).

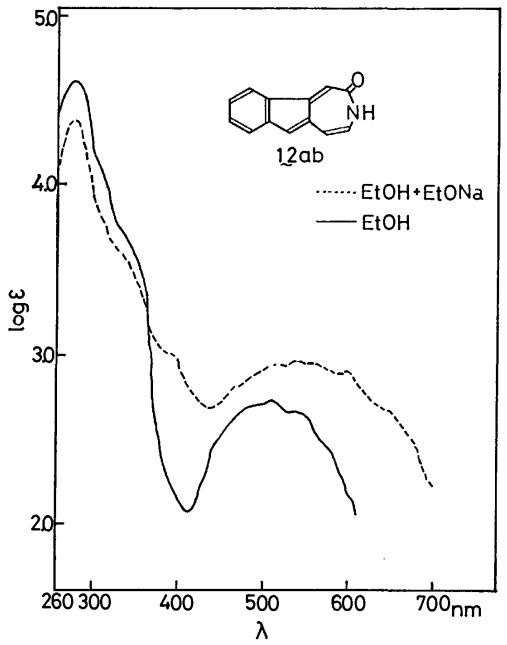

Fig. 2. Electronic spectra of **12ab** in EtOH (——) and in the presence of 1 equiv of EtONa (----).

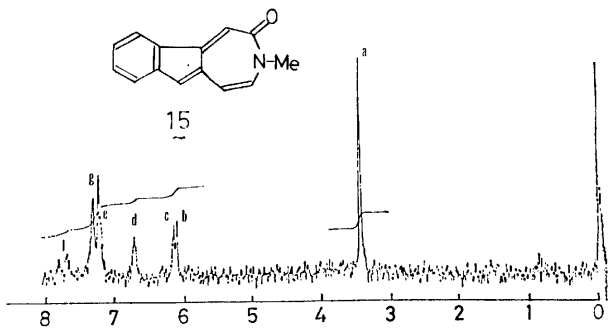

Fig. 3. NMR spectrum of **15** in $CDCl_3$.

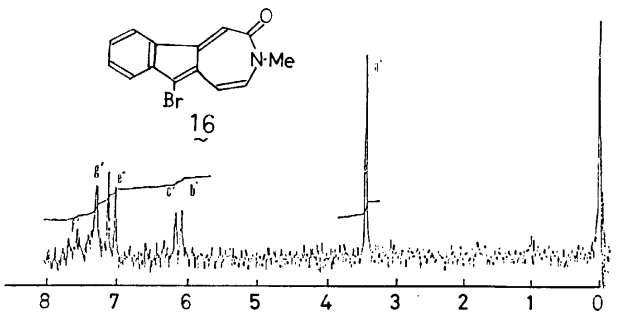

Fig. 4. NMR spectrom of **16** in $CDCl_3$.

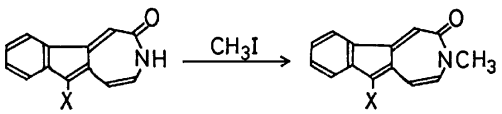
followed by dehydrobromination of the corresponding bromide on basic alumina, produced a yellow-orange solid **11** in 83% yield. Bromination of **11** with 1.1 molar equiv of NBS in refluxing benzene in the presence of a catalytic amount of benzoyl peroxide for 10 h, followed by dehydrobromination of the corresponding bromide formed *in situ* on basic alumina, produced **12ab** in 10% yield. The NMR spectrum of the reddish purple solution of **12ab** in DMSO-d_6 showed resonance peaks at 6.25 (2H), 7.40 (1H), 7.20—7.60 (4H), 7.95 (1H), and 10.25 ppm (1H). When a few drops of D_2O were added to the solution, the resonance peak at 6.25 ppm became pseudo singlet and the resonance peak at 10.25 ppm disappeared. The resonance peak at 6.25 ppm became a pair of doublet peaks at 6.05 (1H, d, J=9 Hz, H_9) and 6.75 ppm (1H, d, J=9 Hz, H_8) with the addition of 1 equiv of CD_3ONa (shown in Fig. 1). On the basis of these findings the resonance peak at 6.25 ppm may be assigned to the adjacent 8- and 9-protons of **12ab**. The IR spectrum of **12ab** showed absorptions at 3200 and 1650 cm^{-1} for >NH and >C=O streching of the amide group, respectively. The electronic spectrum of **12ab** in EtOH showed absorptions at λ_{max} 510 (log ε, 2.9), 345(sh), 283 nm(4.7). When 1 equiv of EtONa was added to the solution, the absorptions shifted to a longer wavelength by ≈50 nm (shown in Fig. 2). The bathochromic shift in basic solution was attributable to the substantial enhancement of the double bond character of the >N(CO)– bond by the removal of the amide proton.[6]

When the refluxing time of the bromination of **3** with NBS was over 20 h, **13ab** was obtained in a 20% yield. On the other hand, the direct dehydrogenation of **3** with DDQ in refluxing benzene for 20 h, followed by chromatography on silica gel eluting with CH_2Cl_2, produced purple solids **14ab** in 20% yield. The reaction mechanisms for the formation of these unexpected products (**13ab** and **14ab**) were now under-investigation. **3** and **11** showed strong infrared absorptions at 1670 and 1650 cm^{-1}, respectively, as streching for each amide's carbonyl in their lactam rings occured. Both **13ab** and **14ab**, however, showed medium infrared absorptions at 1640 cm^{-1} as streching for the amide's carbonyl in their lactam rings occured. The electronic spectra of **13ab** and **14ab** were similar to that of **12ab**. The possition of X in **13ab** and **14ab** (Scheme 1) was determined in the following discussion.

N-Methylation of **12ab**, **13ab**, and **14ab** using an excess of 40% NaOH and CH_3I with a trace of benzyltriethylammonium chloride under phase-transfer conditions[7] at room temperature for 12 h produced high yields of **15**, **16**, and **17**, respectively. The assignment



12ab	X:H	15	X:H
13ab	X:Br	16	X:Br
14ab	X:Cl	17	X:Cl

of the position of entry of the bromine atom was determined by the comparison between NMR spectra **15** and **16** in the presence of a shift reagent ($Eu(fod)_3$). The NMR spectra of **15** and **16** are shown in Figs. 3 and 4. Figures 5 and 6 show plots of the induced shifts *vs.* the shift reagent/substrate mole ratios (E/S) for the substrates **15** and **16**, respectively. In Figs. 3 and 4, the absorption labeled by a and a′ are assigned to methyl groups of **15** and **16** in terms of their integrations and chemical shifts of 3.50 and 3.45 ppm, re-

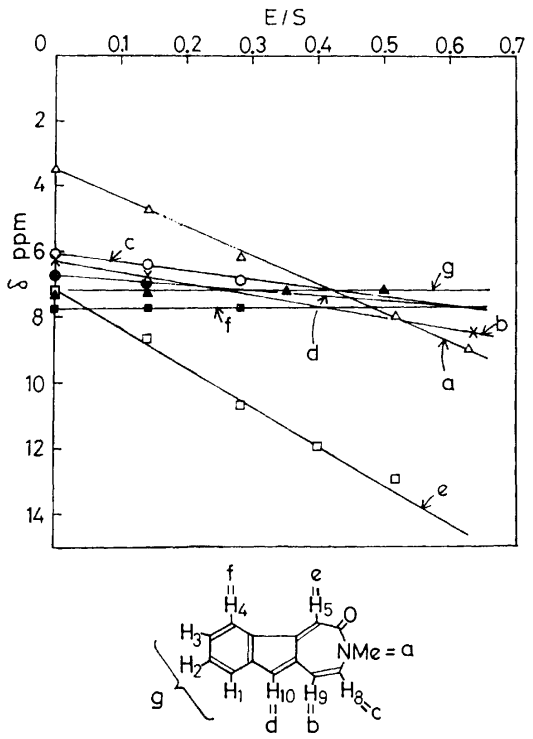


Fig. 5. δ *vs.* E/S for **15** with $Eu(fod)_3$ in $CDCl_3$.

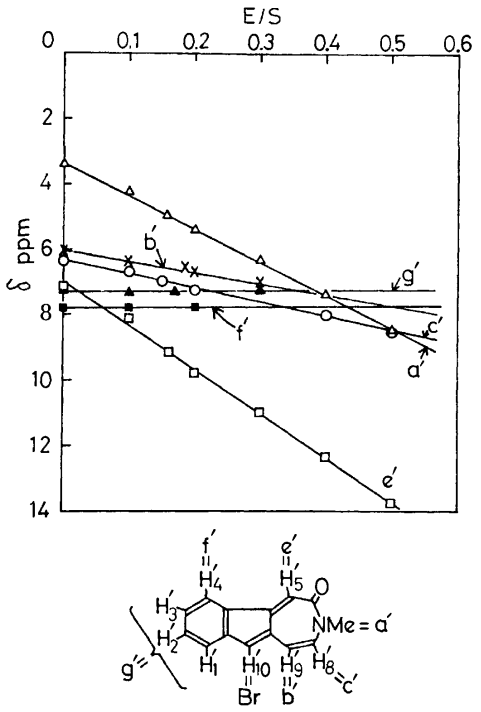

Fig. 6. δ *vs.* E/S for **16** with $Eu(fod)_3$ in $CDCl_3$.

spectively. The sizable shifts observed in their methyl protons nearest to their carbonyl groups indicate association through their carbonyl groups. The shifts of vinyl protons e and e′ were greater than the other vinyl protons in Figs. 5 and 6, respectively. Each of these should be assigned to H_5 and H_5' where the positions are nearest to each carbonyl group. Two couples of their resonances of f and g, and f′ and g′ were assigned to each benzene ring, due to the lack

of shifts up to equimolar ratios of **15** to $Eu(fod)_3$ and of **16** to $Eu(fod)_3$. Two pairs of b and c, and b′ and c′ were assigned to H_8 and H_9, and H_8' and H_9', respectively, with each coupling constant $J=10$ Hz. In Figs. 4 and 6, lack of the resonance corresponding to H_{10}' indicated that the position was substituted by bromine atom. The electronic spectra of **15** and **16** are shown in Figs. 7 and 8, respectively. Com-

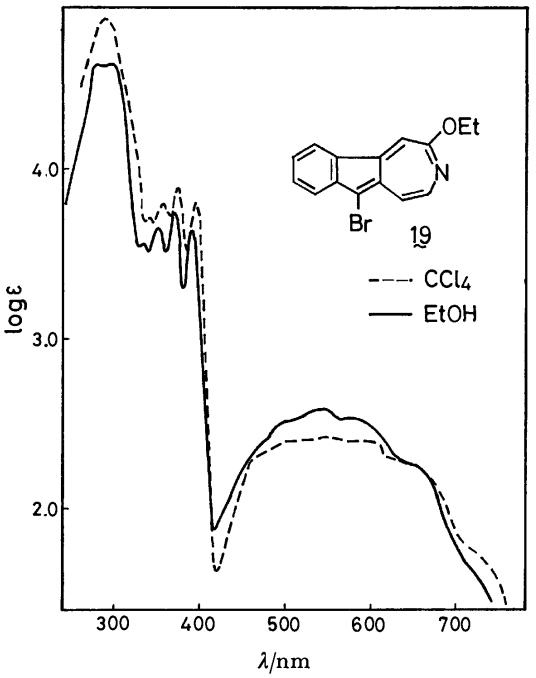

Fig. 13. Electronic spectra of **19** in EtOH (——) and in CCl_4 (----).

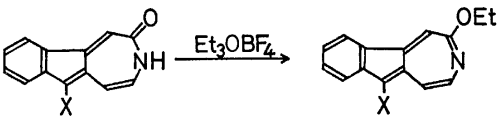
parison of NMR spectrum of **17** with that of **16** revealed that the position of the entry of the chlorine atom to the indeno[1,2-*d*]azepine ring was the same as that of the bromine atom in **16** (see Figs. 4 and 9).

O-Ethylation of **12ab** and **13ab** with triethyloxonium tetrafluoroborate[8] led to the isolation of the novel 4-ethoxyindeno[1,2-*d*]azepine (**18**) and 10-bromo-4-ethoxyindeno[1,2-*d*]azepine(**19**) in 53 and 60% yields,



12ab X:H
13ab X:Br

18 X:H
19 X:Br

respectively. These compounds were found to be labile by treatment with base, and had to be handled with care to avoid decomposition during chromatography on alumina.[9] Their structures followed from their spectral characteristics. IR showed 1640 and 1585 cm^{-1} as representative of the streching of the >C=N– and >C=C< bonds, respectively. In Fig. 10 the resonance of hydrogens H_8 and H_9 appears at lower fields than those of **15** by $\approx$1.00 ppm. This deshielding of the ring protons in **18** indicated the aromatic character of the 14-pi ring system supporting diamagnetic anisotropy. The electronic spectrum of **18** in CCl_4 (Fig. 11) was similar to that of benz[*a*]azulene itself.[1a,4b] The longest absorption band of **18** shifted to a longer wavelength by $\approx$50 nm than that of **15** (see Figs. 7 and 11). These results also indicated the presence of a fully conjugated 14-pi ring system in **18**. **19** showed similar characteristics on NMR and electronic spectra to that of **18** (Figs. 12 and 13).

Experimental

The structures of all the new compounds were cofirmed by NMR, IR, UV, and elemental analyses. All melting points and boiling points are uncorrected. IR(nujol) spectra were determined on a JASCO IR A-1 grating infrared spectrometer. NMR($CDCl_3$/TMS, Hitachi-Perkin Elmer R-20) spectra were obtained at 60 MHz unless otherwise noted. The chemical shifts are represented in terms of δ values. UV(Hitachi UV-200) spectra were obtained in terms of nm. Column chromatography and TLC were performed using Wakogel C-200, and Kieselgel 60F 254 respectively. **2** and **9** were prepared by the method developed by M. Kimura and S. Morosawa,[4a] and E. Bergmann *et al.*[5] respectively. Triphenylmethyl tetrafluoroborate was prepared by the procedure developed by H. J. Dauben, Jr., *et al.*[11]

*3-Ethoxycarbonyl-1,2,3,4,5,10-hexahydroindeno[1,2-d]azepin-10-one(**5**) and 3-Ethoxycarbonyl-1,2,3,10-tetrahydroindeno[1,2-d]azepin-10-one(**6**).* To a stirring solution of 3-ethoxycarbonyl-1,2,3,4,5,5a,10,10a-octahydroindeno[1,2-*d*]azepin-10-one (**2**, 490 mg, 1.7 mmol) in 25 ml of ether was added a solution of bromine (310 mg, 1.9 mmol) in CCl_4 over a period of 20 min at 0 °C. After stirring for additional 10 min at room temperature, the solution was washed with 10% aqueous $NaHSO_3$, and 5% aqueous $NaHCO_3$ and dried over $MgSO_4$. The solvent was removed to give a yellow oil (670 mg). The viscous slightly yellow bromide was employed without further purification. A suspension of LiCl (720 mg, 1.7 mmol) and the crude bromide (600 mg, 1.7 mmol) in 15 ml of dry THF was heated at 120 °C for 7 h under a nitrogen atmosphere. After being cooled to room temperature, the solvent was removed *in vacuo*, and the residue was taken up in benzene. The solution was washed with saturated aqueous NaCl solution, and the solvent was removed to give a brown oil. The oil was chromatographed on silica gel (benzene as eluent) to give 21.3 mg(5.3%) of **7**, 129.3 mg(31%) of **5**. **5**: IR(KBr) 1703, 1694, 1621, 1603, 1595 cm^{-1}; NMR 1.28 (3H, t, J=7.1 Hz), 2.43—2.94 (4H, m), 3.45—3.88 (4H, m), 4.22 (2H, q, J=7.1 Hz), 6.93—7.68 ppm (4H, m); UV λ_{max} (EtOH) 237 (log ε, 4.54), 244 (4.55), 305 (2.95). Found: C, 70.74; H, 6.52; N, 4.97%. Calcd for $C_{16}H_{17}NO_3$: C, 70.83; H, 6.32; N, 5.16%. **6**: IR(KBr) 1700, 1690, 1606, 1590 cm^{-1}: NMR 1.33 (3H, t, J=7.1 Hz), 2.88 (2H, t, J=4.5 Hz), 3.92 (2H, t, J=4.5 Hz), 5.75 (1H, d, J=9.1 Hz), 7.02 (1H, d, J=9.1 Hz), 6.88—7.88 ppm (4H, m); UV λ_{max} (EtOH) 224 (log ε, 4.22), 277 (4.34), 455 (2.93). Found: C, 71.06; H, 5.61; N, 4.97%. Calcd for $C_{16}H_{15}NO_3$: C, 71.36; H, 5.61; N, 5.20%.

*Dehydrogenation of 3-Ethoxycarbonyl-1,2,3,4,5,5a,10,10a-octahydroindeno[1,2-d]azepin-10-one(**2**) with DDQ.* A solution of **2** (50 mg, 0.183 mmol) and DDQ (138 mg, 0.549 mmol) in 1 ml of dry dioxane was refluxed for 53 h under a nitrogen atmosphere. After cooling to room temperature, the solvent was removed to give a brownish residue. The residue was separated with TLC (silica gel, 50% ether in benzene) to give **6** (5.4 mg, 11%, R_f (silica gel, benzene/ether=1:1)= 0.61), **5** (15.6 mg, 31%, R_f=0.47), and **2** (17.3 mg, 35% recovered, R_f=0.38). These products were identified by comparison of their R_f values and UV data with those of each authentic sample.

*Dehydrogenation of **2** with Pd/C.* A suspension of **2** (500 mg, 1.83 mmol) and 8%-Pd/C (500 mg) in 4 ml of dry decalin was refluxed for 53 h under a nitrogen atmosphere. After cooling to room temperature, the Pd/C was filtered off and the filtrate was passed through short column (silica gel, eluting with benzene). Removing the solvent under reduced pressure, 390 mg of red oil was remained. The residue was chromatographed using a silica gel column with 50% ether in benzene as eluent. From first fraction, 8.3 mg of **6** was collected, and 7.3 mg of **5** was collected from second fraction. **5** and **6** were identified by the method shown in preceeding experiment.

*Dehydrogenation of **2** with Triphenylmethyl Tetrafluoroborate.* A mixture of **2** (20 mg, 0.073 mmol) and triphenylmethyl tetrafluoroborate (26.6 mg, 0.081 mmol) in 2 ml of dry acetic acid was refluxed for 8.5 h under an argon atmosphere. Additional 24.2 mg (0.073 mmol) of triphenylmethyl tetrafluoroborate was added and the brown solution was refluxed for additional 4.5 h under the same conditions. After cooling to room temperature, the solvent was removed under reduced pressure, and a brown residue was poured into water and extracted with ether. The ethereal extract was dried over Na_2SO_4. After removing the solvent, brown oil (16.4 mg) was obtained. This oil was chromatographed on silica gel eluting with 5% ether in benzene to give **6** (1.7 mg, 8.6%) and **2** (6.3 mg, 32%). **2** and **6** were identified by the method shown in preceeding experiment.

*Dehydrogenation of **5** with DDQ.* A solution of **5** (20 mg, 0.074 mmol) and DDQ (98%, 18.8 mg, 0.081 mmol) in 2 ml of dry dioxane was refluxed for 9 h under an argon atmosphere. Additional DDQ (17.1 mg, 0.074 mmol) was added to the mixture and the solution was refluxed for another 24.5 h. After usual workup, **5** was recovered.

*Dehydrogenation of **5** with Triphenylmethyl Tetrafluoroborate.* A solution of **5** (20 mg, 0.074 mmol) and triphenylmethyl tetrafluoroborate (51.1 mg, 0.16 mmol) in dry acetic acid was refluxed for 14 h under a nitrogen atmosphere. After usual workup, **6** (3.4 mg, 17%) was obtained and **5** (12.9 mg, 65%) was recovered. **5** and **6** were identified by the method shown in preceeding experiment.

*Dehydrogenation of **6** with DDQ.* A solution of **6** (5.0 mg, 0.019 mmol) and DDQ (13.0 mg, 0.056 mmol) in 3 ml of dry dioxane was refluxed under an argon atmosphere. The reaction was monitored by TLC and the starting material was completely disappered after 17 h. Some uncharacterized polymer was obtained.

*Dehydrogenation of **6** with Triphenylmethyl Tetrafluoroborate.* A solution of **6** (5.0 mg, 0.019 mmol) and triphenylmethyl tetrafluoroborate (12.3 mg, 0.037 mmol) in 2 ml of dry acetic acid was refluxed under an argon atmosphere and the reaction was monitored by TLC. No reaction was observed up to 6.5 h and only **6** was recovered.

*1,2,3,4,5,10-Hexahydroindeno[1,2-d]azepin-4-one (**3**).* To a stirring mixture of **9** (3.58 g, 0.036 mol) and phosphorus pentaoxide (1.7 g, 0.012 mol) in 600 g of polyphosphoric acid (105%) was added in portions sodium azide (3.5 g, 0.054 mol) over 1 h at 40—50 °C and the reaction mixture was stirred for 48 h at same temperature. After cooling to room temperature, the reaction mixture was poured onto ice–water, and extracted with chloroform. The extract was washed with 5% aqueous $NaHCO_3$, then with water, and was dried over $MgSO_4$. The residue obtained on evaporation of the solvent was solidified to give an orange solid (2.7 g, 70%). The solid was subjected to column chromatography on neutral alumina eluting with CH_2Cl_2 to give **3** (2.3 g, 60%): pale yellow prisms from C_2H_5OH, mp 207—209 °C; IR 3250, 1670 cm^{-1}; UV λ_{max} (EtOH) 207 (log ε, 4.28), 260 (4.01); NMR(CCl_4) 2.50—2.90 (2H, m), 3.28 (2H, bs), 3.45—3.75 (4H, m), 7.00—7.60 (5H, m, aromatic H and NH). Found: C, 78.21; H, 6.51; N, 7.10%. Calcd for $C_{13}H_{13}NO$: C, 78.36; H, 5.58; N, 7.03%.

*3-Ethoxycarbonyl-1,2,3,4,5,10-hexahydroindeno[1,2-d]azepine (**10**).* A suspension of $LiAlH_4$ (0.72 g, 19 mmol) in

40 ml of dry THF was stirred and refluxed for 1 h. After cooling on an ice bath, a solution of **3** (1.5 g, 7.5 mmol) in dry THF (100 ml) was added dropwise over a period of 1 h. After addition was complete, the mixture was stirred 24 h at room temperature. A sufficient amount of 3 N aqueous hydrochloric acid (10 ml) was carefully added dropwise to decompose excess $LiAlH_4$. The acidified solution was workup immediately by extraction with ether. To the ether extract was added 3% aqueous potassium carbonate (30 ml), and ethyl chloroformate (3.8 g, 35 mmol). After stirring for 1 h, the ether layer was separated. The ether was removed and the residue was distilled under reduced pressure to give the indene **10** (1.63 g, 80%), bp 214—217 °C/0.2 Torr. **10** was identified by comparison of IR and NMR spectra with those of authentic sample obtained by M. Kimura and S. Morosawa.[4a]

*1,2,3,4-Tetrahydroindeno[1,2-d]azepin-4-one (**11**).* A solution of **3** (100 mg, 0.50 mmol) and pyridinium hydrogenbromide perbromide (192 mg, 0.6 mmol) in 15 ml of dry acetic acid (passed through alumina) was heated at 40 °C for 6 h. The residue obtained on evaporation of the solvent was taken up in chloroform. Column chromatography on alumina eluting with chloroform gave **11** (60 mg, 61%): orange prisms from CH_2Cl_2, mp 201 °C; IR 3180, 1650, 1600(sh) cm^{-1}; UV λ_{max} (EtOH) 260 (log ε, 4.5), 330 (3.9), 380(sh); NMR (DMSO-d_6) 2.60—3.00 (2H, m), 3.10—3.50 (2H, m), 6.69 (2H, bs), 7.20 (3H, m), 7.65 (1H, bs), 8.10 (1H, m). Found: C, 79.10; H, 5.89; N, 6.96%. Calcd for $C_{13}H_{11}NO$: C, 79.16; H, 5.62; N, 7.10%.

*Indeno[1,2-d]azepin-4-ol (**12ab**).* 1) A solution of **3** (5 g, 26 mmol), NBS (5.1 g, 29 mmol), and benzoyl peroxide (100 mg, 0.41 mmol) was refluxed at 45 °C for 24 h. The reaction mixture was chromatographed on alumina eluting with 4% ethanol in CH_2Cl_2 to give **11** (2.0 g, 40%) and **12ab** (502 mg, 10%). **12ab**: black fine prisms from CH_2Cl_2, mp 240 °C (sublimed); IR 3200, 1650 cm^{-1}; UV λ_{max} (EtOH) 283 (log ε, 4.7), 345 (sh), 510(2.9); NMR (DMSO-d_6) 6.25 (2H, m), 6.40 (1H, s), 7.10—7.20 (4H, m), 7.95 (1H, d), 10.25 (1H, m). Found: C, 79.63; H, 4.43; N, 6.76%. Calcd for $C_{13}H_9NO$: C, 79.98; H, 4.65; N, 7.17%. **11** was identified by comparison of IR and NMR spectra with those of authentic sample obtained in preceeding experiment. 2) A solution of **11** (200 mg, 1.0 mmol) and NBS (180 mg, 1.0 mmol) in benzene was refluxed in the presence of a catalytic amount of benzoyl peroxide for 4.5 h. After cooling to room temperature, the reaction mixture was passed through alumina eluting with CH_2Cl_2, removed the solvent to give a black solid. Recrystallization of the solid from THF gave **12ab** (20 mg, 10%). **12ab** was identified by comparison of its IR and NMR spectra with those of authentic sample obtained in preceeding experiment.

*10-Bromoindeno[1,2-d]azepin-4-ol (**13ab**).* A solution of **11** (100 mg, 0.51 mmol) and NBS (100 mg, 0.56 mmol) in CH_2Br_2 was refluxed at 120 °C (bath temperature) in the presence of a catalytic amount of benzoyl peroixide for 24 h. After usual workup, **13ab** (60 mg, 43%) was obtained: black fine hair like needles from THF, mp 320 °C dec; IR 3200, 3130, 1675, 1638, 1615, 1600 cm^{-1}; NMR (DMSO-d_6) 6.00—6.55 (2H, m), 7.22—7.60 (4H, m), 8.00—8.25 (1H, m), 10.30—10.50 ppm (1H, bs); UV λ_{max} (EtOH) 286 (log ε, 4.7), 350(sh), 368(sh), 500(3.0). Found: C, 56.87; H, 2.88; N, 4.82%. Calcd for $C_{13}H_8NOBr$: C, 56.96; H, 2.94; N, 5.11%.

*10-Chloroindeno[1,2-d]azepin-4-ol (**14ab**).* A solution of **11** (1.6 g, 8.1 mmol) and DDQ (5.5 g, 24 mmol) in dry dioxane was refluxed for 24 h under a nitrogen atmosphere. After cooling to room temperature, the reaction mixture was filtered and passed through short alumina column eluting with $CHCl_3$. After removing the solvent, the residue was column chromatographed on alumina eluting with CH_2Cl_2 to give **14ab** (530 mg, 28%): black hair like needles from THF, mp 260 °C dec; IR 3200, 3130, 1675, 1640, 1620, 1598 cm^{-1}; NMR (DMSO-d_6) 6.05—6.50 (2H, m), 7.20—7.70 (4H, m), 8.25—8.95 (1H, m), 10.20—10.60 ppm (1H, m); UV λ_{max} (EtOH) 285 (log ε, 4.7), 350(sh), 368(sh), 515 (2.9). Found: C, 67.69; H, 3.27; N, 5.75%. Calcd for $C_{13}H_8NOCl$: C, 67.99; H, 3.51; N, 6.10%.

*3-Methylindeno[1,2-d]azepin-4-one (**15**).* To a 50% aqueous solution of NaOH (5 ml) was added a solution of **12ab** (30 mg, 0.15 mmol) and benzyltriethylammonium chloride (41 mg, 0.18 mmol). After 15 min stirring at room temperature, 52 mg of MeI (0.36 mmol) was added to the suspension. The reaction mixture was stirred for 40 min at room temperature. Organic layer was separated, washed with water, and dried over $MgSO_4$. The residue obtained by evaporation of the solvent was recrystallized from ethanol to give **15** (30 mg, 95%): brown needles from CH_2Cl_2, mp 149—150 °C; IR 1628, 1620, 1600(sh) cm^{-1}; UV λ_{max} (EtOH) 275 (log ε, 4.2), 330(sh), 505(2.9); NMR 3.50 (3H, s), 6.09 (1H, d, J=9 Hz), 6.29 (1H, d, J=9 Hz), 6.80 (1H, s), 7.29 (1H, s), 7.20—7.55 (3H, m, aromatic H), 7.82 ppm (1H, bs, aromatic H). Found: C, 80.01; H, 5.27; N, 6.71%. Calcd for $C_{14}H_{11}NO$: C, 80.36; H, 5.30; N, 6.69%.

*10-Bromo-3-methylindeno[1,2-d]azepin-4-one (**16**).* The reaction was carried out as described for the preparation of **14ab**. The crude product was purified by recrystallization from CH_2Cl_2: **16**, 95% yield, dark brown needles, mp 154—156 °C; IR 1655, 1640(sh), 1605(sh), 1598 cm^{-1}; UV λ_{max} (EtOH) 280 (log ε, 4.64), 354 (3.76), 372(3.66), 500 (2.98); NMR 3.42 (3H, s), 6.05 (1H, d, J=10 Hz), 6.35 (1H, d, J=10 Hz), 7.05 (1H, s), 7.22—7.62 (3H, m, aromatic H), 7.75 ppm (1H, bd, aromatic H). Found: C, 68.48; H, 3.91; N, 5.47%. Calcd for $C_{14}H_{10}NOCl$: C, 69.00; H, 4.14; N, 5.75%.

*10-Chloro-3-methylindeno[1,2-d]azepin-4-one (**17**).* The crude product, obtained in a similar way used for **14ab**, was crystallized from CH_2Cl_2: **17**, 95% yield, dark brown needles, mp 160—160.5 °C; IR 1652(sh), 1640, 1603(sh), 1596 cm^{-1}; UV λ_{max} (EtOH) 277 (log ε, 4.66), 330 (3.82), 345(3.75), 490(3.08); NMR 3.45 (3H, s), 6.10 (1H, d, J=10 Hz), 6.45 (1H, d, J=10 Hz), 7.20 (1H, s), 7.20—7.60 (3H, m, aromatic H), 7.75 ppm (1H, bs, aromatic H). Found: C, 58.45; H, 3.27; N, 4.85%. Calcd for $C_{14}H_{10}NOBr$: C, 58.36; H, 3.50; N, 4.86%.

*4-Ethoxyindeno[1,2-d]azepine (**18**).* In a dry 20 ml two-necked flask protected from atmospheric moisture was placed a solution of freshly redistilled boron trifluoride etherate (74 μl, 0.58 mmol) in 2 ml of anhydrous ether. Epichlorohydrin (36 μl, 0.45 mmol) was added dropwise at 40 °C. When the epichlorohydrin had been added, the oil which initially formed began to solidify. The mixture was stirred at room temperature for 2 h, and the solvent was decanted. The triethyloxonium tetrafluoroborate was washed well with anhydrous ether and dissolved in 1.5 ml of dry CH_2Cl_2. This solution was stirred at 10—15 °C while a solution of **12ab** (20 mg, 0.10 mmol) in 2 ml of dry CH_2Cl_2 was added dropwise. The resulting solution was stirred at room temperature for 12 h. To the stirred solution was cautiously added 2 g of a 50% aqueous potassium carbonate solution. After separation of CH_2Cl_2 layer, the solution was washed with water, and dried over $MgSO_4$. The solution was passed through silica gel to give crude **18** (14 mg, 62%): purple

fine needles from CH_2Cl_2, mp 115—117 °C; IR 1640, 1585 cm^{-1}; UV λ_{max} (EtOH) 288 (log ε, 4.5), 345(3.6), 361 (3.6), 382(3.5), 544(2.6); NMR(CCl_4) 1.38 (3H, t, J= 7 Hz), 4.29 (2H, q, J=7 Hz), 6.73 (1H, d, J=9 Hz), 6.82 (1H, s), 7.03 (1H, d, J=9 Hz), 7.15—7.60 (3H, m, aromatic H), 7.45 (1H, s), 8.07 (1H, d, aromatic H). Found: C, 80.50; H, 6.64; N, 6.17%. Calcd for $C_{15}H_{13}NO$: C, 80.69; H, 8.87; N, 6.27%.

*10-Bromo-4-ethoxyindeno[1,2-d]azepine (**19**).* The crude product, obtained in a similar way used for **18**, was crystallized from CH_2Cl_2 to give **19**: 69%, black fine prisms from CH_2Cl_2, mp 143—144 °C; IR 1650, 1640, 1600, 1580 cm^{-1}; UV λ_{max} (EtOH) 290 (log ε, 4.60), 352(3.65), 370(3.74), 390 (3.64), 544(2.59); NMR(CCl_4) 1.37 (3H, t, J=7 Hz), 4.30 (2H, q, J=7 Hz), 6.32 (1H, d, J=9 Hz), 7.17 (1H, d, J= 9 Hz), 7.36 (1H, s), 7.40—7.70 (3H, m, aromatic H), 7.99 (1H, d, aromatic H). Found: C, 59.58; H, 3.86; N, 4.54%. Calcd for $C_{15}H_{12}NOBr$: C, 59.60; H, 3.97; N, 4.64%.

(Received February 18, 1980)

The thermal oligomerization of methacrylaldehyde oxime leads preferentially to two 2,4,7-trimethylperhydroisoxazolo[2,3-*a*]pyridine-2,7-dicarbaldehyde dioximes, which are comformationally isomeric with each other. The crystal structure of the α-form has been determined by means of X-ray diffraction. It is monoclinic, with the space group $P2_1/a$. The cell dimensions are $a=7.858(3)$, $b=13.186(6)$, $c=17.259(6)$ Å, $\beta=130.38(3)°$, and $Z=4$. The molecules are linked by OH···O and OH···N intermolecular hydrogen bonds, with the O···O and O···N distances of 2.794(6) and 2.760(5) Å respectively. Since attempts of the crystallization of the β-form have been unsuccessful, the determination of its chemical structure was attempted by means of ^{13}C-NMR spectroscopy and gas chromatography-mass spectrometry. The β-form is, at any rate, different from the α-form.

Methacrylaldehyde oxime undergoes spontaneous polymerization on heating to give, though in a very low yield, oligomers which consist of several products, including isomeric bicyclic trimers. A previous paper has shown that the recrystallization of the oligomers from methanol gives colorless, needle-like crystals, which are identified as 2,4,7-trimethylperhydroisoxazolo[2,3-*a*]pyridine-2,7-dicarbaldehyde dioxime(**1**).[1] The present paper will be concerned with the structure determination of two isomers (α- and β-forms) of **1**. In order to obtain detailed information on the molecular structure of the α-form, the X-ray crystal structure analysis has been carried out. Since the crystallization of the β-form has been unsuccessful, the spectroscopic determination of the chemical structure was attempted.

Experimental

Oligomerization of Methacrylaldehyde Oxime. The thermal oligomerization of methacrylaldehyde oxime was carried out at 60—90 °C for 10 h in an ampoule. The unreacted monomer was removed in a stream of nitrogen under reduced pressure, the residue was placed in a large amount of ether, and then the oligomer was precipitated. Three crystallizations from methanol gave colorless needle crystals of **1** (α-form). After the removal of these crystals, the mother liquor was condensed, and then an isomeric trimer of **1** (β-form) was fractionated by gas chromatography, silicon OV-17 (5%) supported on Gaschrom Q being used as the stationary phase.

Mass and NMR Spectroscopy. The mass spectra were measured on a Shimadzu LKB-9000 mass spectrometer, equipped with a gas-chromatographic inlet system. The ionizing potential was 70 eV, and the ionizing current was 60 μA. The ^{13}C-NMR spectra were obtained with a Hitachi R-42 FT apparatus (22.6 MHz), using DMSO-d_6 as the solvent and the internal standard.

X-Ray Diffraction. An α-form crystal, with approximate dimensions of $0.5\times0.5\times0.8$ mm, was mounted on a Syntex R_3 automated four-circle diffractometer. The unit-cell dimensions were precisely determined by the least-square method, using 11 reflections measured on the diffractometer with graphite-monochromatized Mo K_α radiation (collimator size, 1.5 mm). The crystal data are summarized in Table 1.

The intensity data were collected on the diffractometer with the same radiation, using the ω scan mode ($2\theta\leqq50°$) at a variable scan speed. Reflections with intensities below the minimum intensity (150) were collected at the minimum scan speed (3 ° min^{-1}); those with intensities above the maximum intensity (2500) were collected at the maximum scan speed (30 ° min^{-1}). Medium-range intensities were collected at a scan speed on a linear scale between the minimum and maximum speeds. The intensities of the reference reflections were measured periodically; they showed no significant fluctuation during the course of data collection. Background counts were accumulated in each 1-scan range (in degree) before and after each scan and at the same scan speed. A total of 2409 independent reflections were collected, among which 1699 ($I\geqq1.96\ \sigma\ (I)$) were classed as observed. These intensity data were corrected for Lorentz and polarization effects, but not for absorption [μ(Mo K_α)= 1.0 cm^{-1}].

Structure Determination and Refinement

The structure was solved by the direct method (MULTAN program package[2]). The atomic parameters were then refined by the block-diagonal least-squares method, using anisotropic temperature factors for all the non-hydrogen atoms and isotropic ones for hydrogen atoms. The final value of R was 0.078 for non-zero reflections. In the least-squares procedure, the function minimized was $\Sigma(|F_o|-|F_c|)^2$.

The computer programs used were the Syntex R_3 package.*** The atomic-scattering factors were taken from "International Tables for X-Ray Crystallography," Vol IV.[3] All the calculations were carried out on the NOVA 3 belonging to the diffractometer. The atomic parameters are given in Table 2.****

Results and Discussion

Molecular Structure. Figure 1 shows the molecular structure, while the bond distances and bond angles are given in Tables 3 and 4 respectively. The six-membered ring (piperidine ring) of the α-form has a chair comformation, and the five-membered ring, which is in a half-chair form, is joined to the piperidine ring through two equatorial-type bonds (N(8)–O(1) and C(9)–C(3)). The two rings are approximately coplanar to each other. The methyl groups at the C(4) and C(7) carbons are equatorial, while the oxime group at the C(7) carbon is axial. In addition, the oxime and methyl groups at the C(2) carbon are on the same side of the average coplane of the rings, and on the opposite side, with the methyl group at the C(7) carbon, respectively. The bond distances

*** The MULTAN program is modified for the Syntex R_3 diffractometer.

O, Carbon; ●, Nitrogen; ○, Oxygen

Fig. 2. Orthogonal projection of the crystal structure viewed along the a-axis.
Dashed lines exhibit hydrogen bonds.

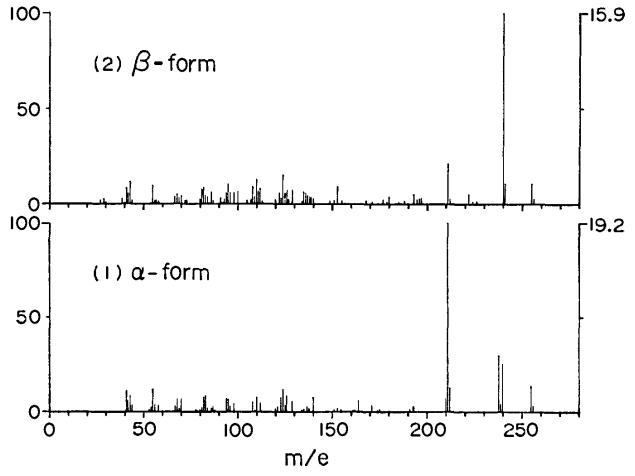

Fig. 3. Mass spectra of (1) α- and (2) β-forms.

between the skeleton atoms are in the range of 1.548 to 1.460 Å; they seem to be reasonable. The deviation of the N(8)–C(3)–C(9) angle from the tetrahedral angle corresponding to the sp^3 hybrid orbital is obviously to be ascribed to the highly-strained ring system caused by the heterobicyclic compound. On the whole, the values of the bond distances and angles shown in the tables are reasonable except that the C(4)–H(4) distance is too long.

Crystal Structure. The crystal structure is shown in Fig. 2. Both oxygen and nitrogen atoms participate in the hydrogen bond. The molecules related by a center of symmetry form a cyclic aggregate by means of O(18)–H···O(14) hydrogen bonds, 2.794(6) Å. The aggregates are linked by O(14)–H···N(8) hydrogen bonds, 2.760(5) Å, to make a three-dimensional network.

Characterization of the β-form. Since the attempts of crystallization of the β-form has been unsuccessful, the determination of the chemical structure was attempted by ^{13}C-NMR and mass spectrometric methods.

Table 5. Assignment of ^{13}C-NMR peaks of **1**

Structure	Peak position/ppm from TMS	
	α-form	β-form
$-CH_3$	18.79 24.42 27.42	10.86 12.59 24.38
$\backslash CH_2 /$	30.16 35.28 44.41	27.15 30.78 41.75
$\backslash CH /$	36.44	30.47
$\backslash CH\text{-}N /$	65.99	59.13
$\backslash C\text{-}N /$	60.75	61.41
$\backslash C\text{-}O /$	77.62	77.16
$-CH{=}N-$	150.40 154.44	154.41 156.48

As is shown in Fig. 3, the mass spectra of both α- and β-forms have a molecular ion peak at *m/e* 255, and they give similar fragmentation patterns except for the base ion peaks, which appear at *m/e* 211 (the lost of the oxime radical) for the former and at *m/e* 240 (the lost of the methyl radical) for the latter.

The NMR peak assignments are shown in Table 5, together with those of the α-form. The peak positions for the α-form were assigned by using the off-resonance technique and on the basis of the molecular structure determined by means of X-ray diffraction. The assignments for the β-form were made by comparison with those for the α-form. Carbon atoms of the β-form, particularly C(4), C(9), C(10), and C(11), resonate at a higher magnetic field compared with those of the α-form; that is due to a steric compression effect. These data reveal that the β-form is a geometrical isomer of the α-form, 2,4,7-trimethylperhydroisoxazolo[2,3-*a*]pyridine-2,7-dicarbaldehyde dioxime. The most plausible structure of the β-form is as follows. In the five-membered ring fused to the piperidine ring, the O(1) atom remains equatorial, but the C(3) atom goes to the axial position, the two rings being neither coplanar nor perpendicular to each other. Further, it can also be concluded that the methyl and oxime groups at the C(7) atom are axial and equatorial respectively, contrary to those of the α-form, because the C(11) and C(12) atoms of the β-form resonate 12 ppm higher and 4 ppm lower respectively than those of the α-form.

Reduction by a Model of NAD(P)H. 28. Reduction of an α-Diketone in the Presence of Zinc Ion

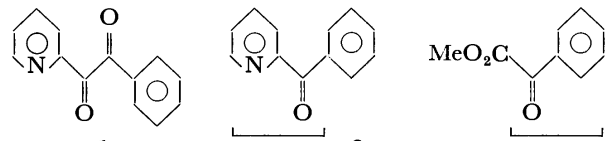
Atsuyoshi Ohno,* Shinro Yasui, and Shinzaburo Oka
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received February 22, 1980)

Reduction of 1-phenyl-2-(2-pyridyl)-1,2-ethanedione with 1-benzyl-1,4-dihydronicotinamide in acetonitrile in the presence of zinc perchlorate has been studied. The α-diketone coordinates onto zinc ion through its pyridine-ring nitrogen and benzene-side carbonyl oxygen, whereas the reduction takes place on pyridine-side carbonyl group. It is concluded that an effective ligand to a metal ion is not necessarily a facile substrate of the reduction.

Approaches to elucidate the role of bivalent metal ion in the reduction with an NAD(P)H-model compound have been tried from many aspects.[1-6] In the preceding paper, it was claimed that an effective ligand to a metal ion is not necessarily a facile substrate of the reduction with an NAD(P)H-model compound.[7]

An α-diketone, 1-phenyl-2-(2-pyridyl)-1,2-ethandione (**1**), has two carbonyl groups and can be regarded either as 2-benzoylpyridine (**2**) analog or as methyl benzoylformate (**3**) analog, both of which have been

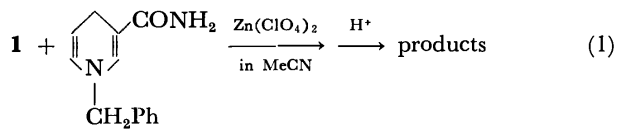


1 **2** **3**

known to be good substrates for metal ion-catalyzed reduction with an NAD(P)H-model compound.[4,5] Therefore, an interest is focused to the point whether **1** acts like **2** or **3** in the metal ion-catalyzed reduction. Note that **2** forms a complex with bivalent metal ion in a considerable amount,[8,9] whereas **3** interacts little with metal ion.[4] In this connection it is interesting to reveal which carbonyl group in **1** is subjected to the reduction and what factor governs the selectivity.

Results and Discussion

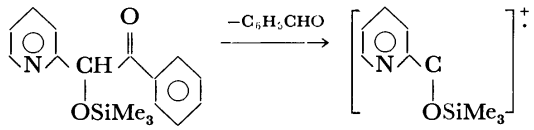
Product Analysis. The reaction of **1** with equimolar amount of 1-benzyl-1,4-dihydronicotinamide (BNAH) in the presence of equimolar amount of zinc perchlorate in acetonitrile at 50 °C for 1 h (Eq. 1) afforded a single product besides 1-benzyl-3-carbamoylpyridinium ion (BNA^+). Unfortunately, however, this



(1)

product was very unstable under the air. During the procedure to isolate the product from the reaction mixture on preparative TLC, the product was converted smoothly into the starting material **1**. Therefore, the structure of the product was elucidated after protecting the hydroxyl group in the product by trimethylsilylation.

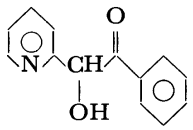
After treatment of the reaction mixture with 1,1,1,3,3,3-hexamethyldisilazane (HMDS), gas-phase chromatography-mass spectroscopy (GC-MS) gave a fragment at $m/e=179$, which could be assigned to the ion **4** suggesting the structure **5** for the trimethylsilylated



5 **4**

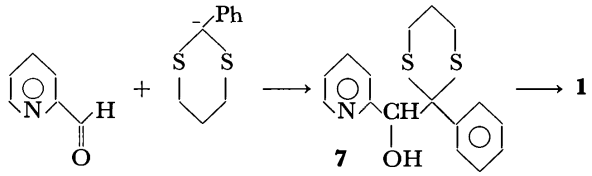
(2)

product. Consequently, the product from the reduction of **1** with BNAH was identified to be 2-hydroxy-1-phenyl-2-(2-pyridyl)ethanone, **6**. NMR spectrum of the product also confirmed the structure.



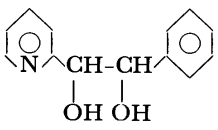
6

An attempt to synthesize the authentic **6** ended in failure. Instead, **7** afforded **1** on hydrolysis. This



(3)

observation supports the fact that **6** is oxidized to **1** quite easily. When **1** was allowed to react for 22 h with three equivalences of BNAH in the presence of zinc ion in acetonitrile at 50 °C, the product obtained in poor yield was a mixture of *threo*- and *erythro*-diastereoisomers of 1-phenyl-2-(2-pyridyl)-1,2-ethanediol, **8**.



8

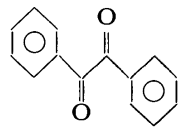
Complexation with Zinc Ion. Complexation of **1** with zinc ion was noted spectrophotometrically. A double reciprocal plot of the stoichiometric concentration of zinc ion present in a solution against the change in absorbance of the solution at 292 nm showed a straight line (correlation coefficient; $r>0.999$), indicating that the complexation obeys Eq. 4;

$$S + M \overset{K_S}{\rightleftharpoons} SM \qquad (4)$$

where S and M denote **1** and zinc ion, respectively. The complexation constant, K_S, at 25 °C in acetonitrile was given to be 65 M^{-1} by dividing the intercept

with the slope of the straight line.[7] Spectrometry was performed with stoichiometric concentrations of **1** and zinc perchlorate to be 2.87×10^{-5} M and (0.26—1.51) $\times 10^{-2}$ M, respectively.

On the other hand, benzil, **9**, showed no change

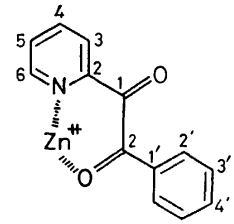


9

in spectrum even upon the addition of large excess of zinc perchlorate, which indicates that there is little interaction, if any, between **9** and zinc ion. This fact may reveal that a ring nitrogen is prerequisite to the complexation, and may rule out the possibility of bidentate complexation through two carbonyl oxygens.

To elucidate the structure of **1**–zinc ion complex, ^{1}H- and ^{13}C-NMR studies were carried out. Table 1 shows metal ion-induced shifts in ^{1}H- and ^{13}C-NMR spectra of **1** on addition of lithium, magnesium, and zinc perchlorates in CD_3CN. The fact that the shifts induced by lithium ion are the smallest among those induced by three different metal ions can be compared with the previously reported result that both chemical and optical yields in lithium ion-catalyzed reduction of **3** with a chiral NAD(P)H-model compound are remarkably lower than those catalyzed by magnesium or zinc ion.[10,11] Since ionic radii of lithium and magnesium ions are approximately the same,[12] the result indicates that the complexation depends largely on the charge density on the metal ion.

In Table 2, a comparison between zinc ion-induced maximum shifts for **1** and **2** is listed. It should be noted that the shifts of both pyridine-ring and benzene-ring carbons in **1** have similar values to those in **2**. This fact suggests that magnetic environments of pyridine and benzene rings in **1**–zinc ion complex resemble to those in **2**–zinc ion complex, inferring that the carbonyl group in **2**–zinc ion complex corresponds to the benzene-side carbonyl group in **1**–zinc ion complex. Recall that **2** coordinates bidentately onto zinc ion through pyridine-ring nitrogen and carbonyl oxygen.[7] Since **1** cannot behave as a tridentate ligand due to its structural requirement, it is reasonable to conclude that **1** coordinates onto zinc ion bidentately through pyridine ring and benzene-side carbonyl oxygen, **10**.



10

Although the sign in shifts of signals from carbonyl carbons are reversed in **1** and **2**, it is important that the shift of signal from benzene-side carbonyl carbon is larger than that from pyridine-side carbonyl carbon.[13]

It is interesting to point out that **1**–zinc ion complex prefer a six-membered ring structure. Although distorted octahedral geometry has been proposed for a certain pyridine derivative–zinc perchlorate complex,[14,15] the structure of 2-cinnamoylpyridine–zinc ion complex has been determined to be tetrahedral.[16,17] The six-membered ring structure presently proposed for **1**–zinc ion complex may be in accordance with tetrahedral structure, because six-membered ring is less strained in tetrahedral structure than in octahedral one.

Table 1. Metal ion-induced shifts ($\Delta\delta$) in ^{13}C- and ^{1}H-NMR spectra of 1-phenyl-2-(2-pyridyl)-1,2-ethanedione (**1**) on the addition of $M(ClO_4)_n$ in CD_3CN[a,b,c]

$\Delta\delta = \delta_{complexed} - \delta_{free}$

order relationship (correlation coefficient; $r>0.999$) for more than at least two half-lives. The results are listed in Table 3. Obviously, the rate constant-zinc ion concentration profile has a maximum similarly to those of **2** and other 2-acylpyridines.[1,7] Computer-assisted simulation of the profile gave a numerical value for a constant $k_1K_B+k_2K_S$ to be 2.65×10^4 M^{-2} s^{-1},[1] where K_B, k_1, and k_2 are defined by Eqs. 5 and 6;

$$B + M \overset{K_B}{\rightleftharpoons} BM \tag{5}$$

$$\left.\begin{aligned} BM + S &\xrightarrow{k_1} \\ SM + B &\xrightarrow{k_2} \end{aligned}\right\} \text{products} \tag{6}$$

and B, S, and M denote BNAH, **1**, and zinc ion, respectively.

Role of Zinc Ion. Both kinetics and reaction site indicate that **1** behaves like **2** rather than like **3**. More striking fact revealed by the present study is that the carbonyl group which coordinates onto zinc ion is different from the one subjected to the reduction. Although reasonable explanation for this fact has not been given yet, stereochemical requirement for the carbonyl groups at the transition state should be taken into account as one of controlling factors.[18] 2-Cinnamoylpyridine is an example of a substrate where the reaction and coordination sites are different each other.[16] However, since these positions are conjugated, the result from 2-cinnamoylpyridine is not surprising.

Conjugation of two carbonyl groups in **1** is not efficient, because a canonical form with a positive charge on an oxygen is unstable. Therefore, **1** may be the first example of a substrate which has different reaction site from the coordination site. In addition, a comparison of calculated rate constants for rate-determining proton (or hydrogen atom)-transfer step shows that non-coordinated carbonyl group in **1** has larger reactivity than coordinated carbonyl group in **2**.

The present result confirms the idea that an effective ligand to a bivalent metal ion is not necessarily a facile substrate of the reduction with an NAD(P)H-model compound.

It seems likely that zinc ion plays a role to enhance the encounter of a model compound and substrate by coordinating onto both reagents. Another role of zinc ion is to catalyze the initial electron-transfer step,[19] but it interferes the following transfer of a proton (or hydrogen atom).

Experimental

1-Phenyl-2-(2-pyridyl)-1,2-ethanedione, **1** (mp; 70.5—71 °C), was prepared according to a literature procedure.[20,21] Other materials were obtained and purified as described in the preceding paper.[7] Procedures for determining rate and complexation constants were also described in the preceding paper.[7]

Product Analysis. A solution of 6.3 mg (0.030 mmol) of **1**, 6.7 mg (0.031 mmol) of BNAH, and 9.0 mg (0.034 mmol) of zinc perchlorate in 0.5 ml of acetonitrile was allowed to react at 50 °C under nitrogen atmosphere in the dark for 1 h. A 10 μl aliquot was mixed with 10 μl of 1,1,1,3,3,3-hexamethyldisilazane (HMDS), then the mixture was analyzed on a Shimadzu LKB-9000S GC-MS Spectrometer equipped with a PACK 300DG-b Computing System. Reproducibility from three times experiments was satisfactory.

The mass spectrum obtained showed a fragment at $m/e=179$ with fragments of small intensities at $m/e=180$ and 181. Such a fragmentation pattern is common to moieties that contain a silicon atom.[22] Therefore, this fragment was assigned to the cation radical **4**. Other fragments appeared at $m/e=135$, 105, and 77.

The production of 1-phenyl-2-(2-pyridyl)-1,2-ethanediol, **8**, from **1** on the reduction with BNAH was confirmed as following: a solution of 52.7 mg (0.250 mmol) of **1**, 159.9 mg (0.747 mmol) of BNAH, and 69.2 mg (0.262 mmol) of zinc perchlorate in 10 ml of acetonitrile was allowed to react at 50 °C under nitrogen atmosphere in the dark. After 22 h, complete consumption of **1** was confirmed on TLC. Then, aqueous sodium carbonate was added to the solution and the mixture was extracted three times with benzene. The organic layer was washed once with water, dried over anhydrous sodium sulfate, and concentrated *in vacuo* remaining 150 mg of solids. The solids were separated into four fractions on preparative TLC with ethyl acetate as an eluent. A NMR spectrum of each product was recorded. The first product (with the largest R_f-value) was identified to be **1** generated during the procedure of isolation (15 mg; 28% yield). The structure of the third product was determined as **8** based on comparison of its NMR spectrum with that of the authentic sample (*ca.* 5 mg; 10% yield). Unfortunately, the second (17 mg) and the fourth (10 mg) products could not be identified.

NMR Spectroscopy. Proton and carbon-13 NMR studies were carried out in CD_3CN. The concentration of **1** employed was 0.4 M for each run.[23]

The signals in ^{13}C-NMR spectrum of **1** were assigned as following: in the proton-decoupled spectrum, four signals at 134.03, 152.23, 196.73, and 197.56 ppm had low intensities. Moreover, these four signals did not split in the off-resonance spectrum, then these are attributed to C-2, C-1′, C=O-1, and C=O-2 carbons. By comparing with the chemical shifts of 2-benzoylpyridine, **2**, the signals at 134.03 and

152.23 ppm could easily be assigned to C-1′ and C-2 carbons, respectively.[8] In the non-decoupled spectrum of **1**, the signal at 197.56 ppm showed more complex coupling pattern than the signal at 196.73 ppm, indicating that the signal at 197.56 ppm was attributable to C=O-2 carbon. Long-range coupling of C=O-1 carbon with four protons on the pyridine ring would be simpler than that of C=O-2 carbon with five protons on the benzene ring. Other signals could be assigned on the basis of comparison with those of **2**,[8] benzophenone,[24] and benzil, **9**.[25]

Correlation of Physical Unit. A unit used for temperature is correlated with the SI-unit by the following equation

$$t/°C = T/K - 273.15.$$

Restricted Rotation Involving the Tetrahedral Carbon. XXXIV. Stable Rotamers of 9-Arylfluorenes Carrying Oxygen-substituents in the Ortho Position of the Aryl Group[1,2]

Mikio NAKAMURA and Michinori ŌKI*,**

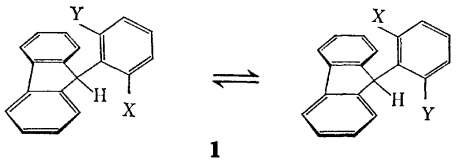
Department of Chemistry, School of Medicine, Toho University, Omorinishi, Ota-ku, Tokyo 143

** *Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113*

(Received May 31, 1980)

9-(2-Hydroxy-1-naphthyl)fluorene, 9-(2-hydroxy-4,6-dimethylphenyl)fluorene, and their methyl ethers have been prepared. They give stable rotamers, *sp* and *ap*, at room temperature. *ap* forms of the hydroxylic compounds are favored over the *sp* and contrary is true for the methyl ethers. These results are attributed to the stabilization of the *ap* form of the hydroxylic compounds due to intramolecular OH···π interaction. Barriers to rotation are *ca.* 105 kJ mol^{-1}.

9-Arylfluorenes (**1**) are unique systems which exhibit high barriers to rotation about the C_9–C_{ar} bond.[3] In some special cases they give stable rotational isomers, *sp* and *ap*, at room temperature.[4] As for the equilibrium between rotamers, the bulkiness of substituents X and Y are known to be primarily important.[5] That is, the predominant conformation is the one in which a bulkier substituent proximates the hydrogen in 9 position. Since the substituent X or Y in each



1

rotamer is quite close to the fluorene ring, electronic interaction may occur, if a substituent has a proper character, to affect the equilibria and barriers to rotation. In fact, we have found that the charge-transfer interaction has taken place between the fluorene ring and the aroyl moiety in aroates of 9-(2-hydroxy-1-naphthyl)fluorene.[6] Thus, 9-arylfluorene is a good model for investigation of the interaction between two groups. We wish to report in this paper the syntheses of the compounds **4**—**7**, which carry oxygen-substituents in an ortho position of the aryl group and thermodynamic and kinetic parameters involving the rotational isomers. The effects of the oxygen-substituents on the thermodynamic and kinetic values will be discussed in terms of molecular interactions.

Experimental

Spectral Measurement. ^{1}H NMR spectra were determined either on a Hitachi R-20B spectrometer operating at 60 MHz or on a Varian EM 390 operating at 90 MHz. The chemical shifts of the characteristic signals of 9-arylfluorenes are given in Table 1. IR spectra were obtained on a Hitachi EPI G-3 spectrometer.

Syntheses. The syntheses of methyl ethers (**4** and **6**) were carried out by the Grignard reaction between 9-fluorenone and an appropriate arylmagnesium bromide followed by reduction with hydriodic acid at room temperarure. The hydroxylic compounds (**5** and **7**) were prepared either by demethylation of the methyl ether or by a series of similar reactions used for the syntheses of the methyl ethers.

9-(2-Methoxy-4,6-dimethylphenyl)-9-fluorenol (2). To a vigorously stirred tetrahydrofuran solution of 2-methoxy-4,6-dimethylphenylmagnesium bromide, prepared from 1.02 g (0.047 mol) of 1-bromo-2-methoxy-4,6-dimethylbenzene[7] and 1.20 g (0.049 mol) of magnesium, was added 5.41 g

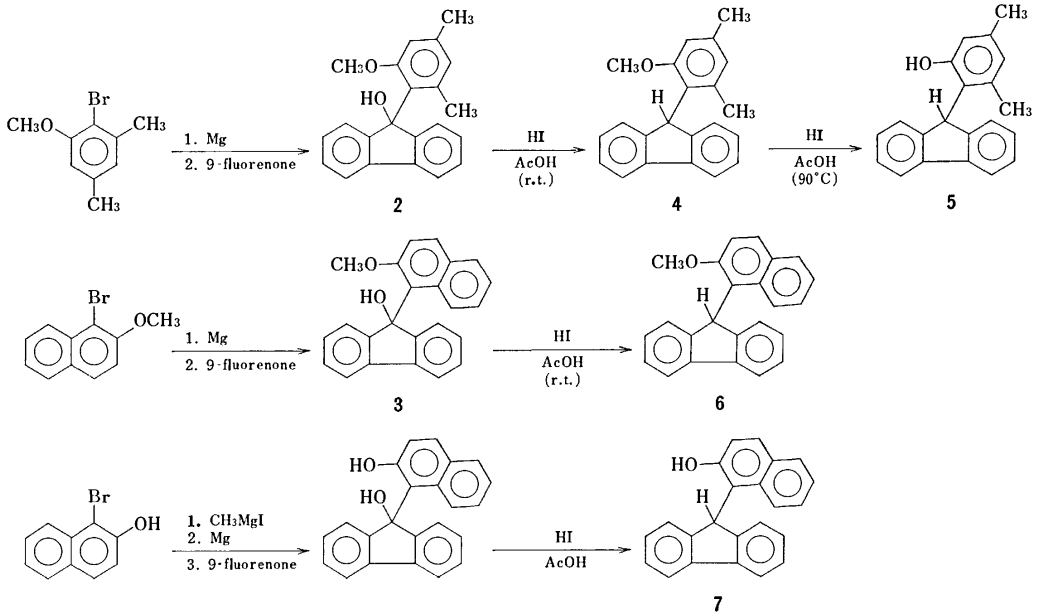


Table 1. ^{1}H NMR data of 9-arylfluorenes ($CDCl_3$, δ)

Compound	Form	2′-OCH_3	2′-OH	4′-CH_3	6′-CH_3	3′-H	5′-H	8′-H	9-H
4	*sp*	3.92	—	2.30	1.10	6.75	6.44	—	6.03

(0.03 mol) of 9-fluorenone at 0 °C. The reaction mixture was stirred for 3 h at room temperature and was then heated with stirring for 1 h. The mixture was cooled and treated with aqueous ammonium chloride. The organic layer was dried over sodium sulfate. After evaporation of the solvent, the product was purified by chromatography on silica gel. Elution with benzene gave a pure product, mp 93.0—94.5 °C, in 78% yield based on 9-fluorenone. Found: C, 83.22; H, 6.37%. Calcd for $C_{22}H_{20}O_2$: C, 83.51; H, 6.37%. ^{1}H NMR ($CDCl_3$, δ): 1.27 (*sp*-6′-CH_3), 2.92 (*ap*-6′-CH_3), 2.27 (*sp*- and *ap*-4′-CH_3), 2.85 (*ap*-OCH_3), 4.05 (*sp*-OCH_3), 6.49 (*sp*-5′-H), 6.80 (*sp*-3′-H). The population ratio (*ap*/*sp*) was 1/9.7 in $CDCl_3$ at 34 °C.

*9-(2-Methoxy-4,6-dimethylphenyl)fluorene (**4**).* To a solution of 1.2 g (3.8 mmol) of **2** in 50 mL of acetic acid was added 10 mL of 57% hydriodic acid. The solution was stirred for 5 h at room temperature, poured into water, and then extracted with ether. The ether layer was washed with aqueous sodium hydrogencarbonate and then with aqueous sodium hydrogensulfite, and dried over sodium sulfate. After evaporation of the solvent, the products were separated by chromatography on alumina. Elution with hexane gave a pure *sp* form, mp 128—129 °C, in 55% yield. Found: C, 88.04; H, 6.59%. Calcd for $C_{22}H_{20}O$: C, 87.96; H, 6.71%. The chloroform solution of the *sp* form was heated for 5 h to make an equilibrium mixture and the *ap* form thus formed was separated by preparative thin layer chromatography on silica gel. The R_f value of the *ap* form was smaller than that of the *sp* form. The mp of the *ap* form was 131—133 °C. The identity of the *ap* form was established by the spectral data and the equilibration experiment: heating the *ap* afforded the same mixture of *sp* and *ap* forms which was obtained by heating the *sp* form.

*9-(2-Hydroxy-4,6-dimethylphenyl)fluorene (**5**).* To a solution of 1.10 g (43.7 mmol) of **4** in 50 mL of acetic acid was added 10 mL of 57% hydriodic acid. The solution was stirred for 5 h at 90 °C and then treated similarly as in the synthesis of **4**. The products were chromatographed on silica gel and eluted with benzene-hexane. The *ap* isomer was obtained as easily eluted fractions. Recrystallization from benzene-hexane gave pure *sp*, mp 144—145 °C, and *ap*, mp 102—104 °C. Found: (*sp*): C. 87.79; H, 6.20%. Calcd for $C_{21}H_{18}O$: C, 88.08; H, 6.34%. The identity of the *ap* form was established as described above.

*9-(2-Methoxy-1-naphthyl)-9-fluorenol (**3**)*, mp 130—131 °C, was prepared by treating 2-methoxy-1-naphthylmagnesium bromide with 9-fluorenone in tetrahydrofuran. The yield was 85% based on the fluorenone. Found: C, 85.37; H, 5.34%. Calcd for $C_{24}H_{18}O_2$: C, 85.18; H, 5.36%. ^{1}H NMR ($CDCl_3$, δ): 2.4 (*ap*-OH), 3.00 (*ap*-OCH_3), 4.19 (*sp*-OCH_3), 9.72 (*ap*-8′-H). The population ratio (*ap*/*sp*) was 1/3.4 in $CDCl_3$ at 34 °C.

*9-(2-Methoxy-1-naphthyl)fluorene (**6**).* To a solution of 2.1 g (6.2 mmol) of **3** in 70 mL of acetic acid was added 15 mL of 57% hydriodic acid. The solution was stirred for 5 h at room temperature and then treated similarly as in the case of **4**. The products were separated by chromatography on silica gel. Elution with hexane gave a pure *sp* form, mp 121—122 °C, in 72% yield. Found: C, 89.26; H, 5.55%. Calcd for $C_{24}H_{18}O$: C, 89.41; H, 5.63%. The chloroform solution of the *sp* form was refluxed for 5 h to make an equilibrium mixture and the *ap* form thus formed was separted by thin layer chromatography on silica gel. The *ap* form was eluted after the *sp* form and was then recrystallized from benzene-hexane, mp 125—126 °C. Found: C, 89.42; H, 5.70%. Calcd for $C_{24}H_{18}O$: C, 89.41; H, 5.63%.

*9-(2-Hydroxy-1-naphthyl)fluorene (**7**).* To a vigorously stirred tetrahydrofuran solution of 4.5 g (20 mmol) of 1-bromo-2-naphthol was added an ether solution of methylmagnesium iodide, prepared from 3.6 g (25 mmol) of methyl iodide and 0.65 g (27 mmol) of magnesium in ether. The reaction mixture was stirred for 10 min. The resulting suspension of the magnesium salt of 1-bromo-2-naphthol was put into a dropping funnel and was added dropwise to 0.48 g (20 mmol) of magnesium in tetrahydrofuran at the refluxing temperature. After the addition was completed, the reaction mixture was heated with refluxing for 2 h, cooled to room temperature, and then 2.16 g (12 mmol) of 9-fluorenone was added in small portions. The solution was refluxed for 1 h, cooled, and treated with aqueous ammonium chloride. The organic layer was dried over sodium sulfate and the solvent was evaporated completely *in vacuo*. The resulting oil was dissolved in 100 mL of acetic acid and 20 mL of 57% hydriodic acid was added. The mixture was stirred for 5 h at room temperature and then treated similarly as in the case of **4**. The products were separated by chromatography on silica gel. Elution with benzene gave 0.3 g (8%) of *ap*, mp 176—177 °C, and then 1.5 g (41%) of *sp*, mp 88—89 °C. Found (*ap*): C, 89.82; H, 5.06%. Calcd for $C_{23}H_{16}O$: C, 89.58; H, 5.23%. The identity of the *sp* form was established by equilibration.

Kinetics. A $CDCl_3$ solution of the *sp* form of **4** was put in an NMR sample tube and was heated at a given temperature. New signals attributable to the *ap* form gradually increased in their intensities. Since the features are the large chemical shift differences between two methoxyl signals ($\Delta\delta$=*ca.* 1.0 ppm), the increase and decrease in intensities of these signals were monitored. The rates of isomerization were obtained at 4 different temperatures by assuming the unimolecular reversible process. Putting these rate constants into Eyring's equation, we could obtain the activation parameters for rotation. The rates for rotation were similarly obtained with **5** and **6** by monitoring the change in intensities of 6′-methyl and 2′-methoxyl signals, respectively. In the case of **7**, the change in intensities of hydroxyl signals were monitored since the proton exchange between these hydroxyl groups was found to be frozen on

Table 2. Kinetic Parameters for the internal rotation and equilibrium constants at 56.3 °C for 9-arylfluorenes

Compound	Process	ΔH^*/kJ mol^{-1}	ΔS^*/J K^{-1} mol^{-1}	ΔG^*_{329}/kJ mol^{-1}	K

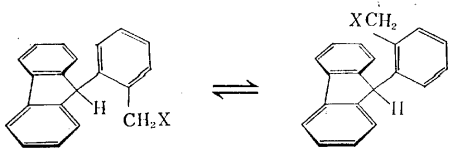
the NMR time scale.

Results and Discussion

Assignment of Stereochemistry. For the two rotamers isolated, stereochemistry was assigned with the use of ^{1}H NMR spectroscopic features as were used previously.[4] The features are a high field signal due to the 2′-substituent (OH or OCH_3) and a low field signal due to the 6′-CH_3 of **4** and **5** or the 8′-H of **6** and **7** for the *ap* form. The contrary is true for the *sp* isomers: a high field signal due to 6′-CH_3 of **4** and **5** or the 8′-H of **6** and **7** and a low field signal due to OH or OCH_3. The protons of the hydroxyl or methoxyl group is a little far from the fluorene ring but the chemical shift differences were large enough for the assignment of the structures. The chemical shifts of the characteristic protons are given in Table 1.

Conformational Equilibria. Equilibrium constants are given in Table 2 together with kinetic parameters for rotation about the C_9–C_{ar} bond. The interesting features of the data are that, in both naphthyl and phenyl series, the *ap* forms of the phenolic compounds (**5** and **7**) are favored over the corresponding *sp* forms by *ca.* 2 kJ mol^{-1} at 56.3 °C. The *ap* forms of the methyl ethers (**4** and **6**), on the contrary, are less stable than the *sp* forms by *ca.* 3 kJ mol^{-1} at the same temperature. This is rather unusual, since a hydroxyl group is considered to be almost equal to a methoxyl group in the effective size.[8] The facts that the equilibrium constants (*ap*/*sp*) of 9-(2-methylphenyl)- (**8a**) and 9-(2-ethylphenyl)fluorene (**8b**) are 1/1.6 and 1/3.3, respectively, supplement the anomaly of the results observed with **4**—**7**.[5] The reason for this anomaly



8 a) X=H b) X=CH_3

is probably the stabilization due to intramolecular OH···π interaction, involving the hydroxyl group and the fluorene ring. Thus the infrared spectra were measured and the results are given in Table 3. Clearly, the OH···phenyl interaction[9] is indicated for the *ap* forms, whereas the *sp* form is present as a free phenol in dilute solutions in carbon tetrachloride. We then measured the IR spectra by imitating the conditions of the NMR measurement: chloroform as a solvent and concentrations of *ca.* 0.3 mol L^{-1}. Although the bands are shifted a little due to the solvent effects, the *ap* forms give the monomer OH···π bonded absorption only. As for the absorption of the *sp* forms, compound **5** gives only the free OH band. Compound **7**, in contrast, shows a shoulder, probably due to the dimer.[10] Although the reason for the absence of the dimer band in *sp*-**5** is unknown at present, the absence of the dimer in the *ap* forms can be ascribed to the steric effect, since sterically crowded phenols are known to exhibit monomer bands only even at a high concentration.[11] The IR study described above clearly shows that the OH···π interaction is the main origin for the stabilization of the *ap* forms of the phenolic compounds.

Table 3. ν_{OH} absorption spectral data

Compound	Solvent	Concentration / mmol L^{-1}	ν_{OH} / cm^{-1}
sp-**5**	CCl_4	9.4	3611
	$CHCl_3$	260	3602
ap-**5**	CCl_4	5.7	3546
	$CHCl_3$	250	3535
sp-**7**	CCl_4	9.6	3610
	$CHCl_3$	250	3600, 3558(sh)
ap-**7**	CCl_4	10	3533
	$CHCl_3$	320	3521

Barriers to Rotation. The OH···π stabilization is also reflected to the barriers to rotation as shown in Table 2: the free energies of activation for rotation of the phenolic compounds are larger by *ca.* 4 kJ mol^{-1} than those of the methyl ethers in the *ap*→*sp* processes. If we assume that the energy level of the *sp* form of the phenolic compound is equal to that of the corresponding methyl ether, then the free energy profile may be written as shown in Fig. 1 for compounds **4** and **5**. The figure indicates that the energy level of the transition state of **4** is higher than that of **5** by 1.2 kJ mol^{-1}, which may be ascribed to the difference in steric effects between methoxyl and hydroxyl groups on the transition states for rotation. We read also from the figure that the difference in free energies of *ap* forms of **4** and **5** is 5.3 kJ mol^{-1}. Since this value contains the difference in energies ascribable to the steric effects of methoxyl and hydroxyl groups in the *ap* form, the net stabilization may be *ca.* 4 kJ mol^{-1}, which conforms with the OH···π interaction energy.[12,13] The same calculation was

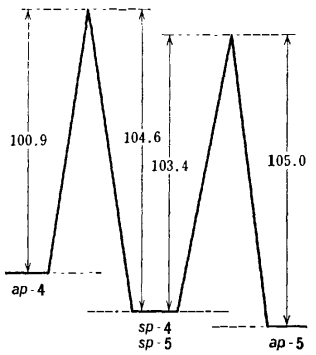


Fig. 1. Free energy profiles of **4** and **5** at 56.3 °C (kJ mol^{-1}).

applied to compounds **6** and **7** and *ca.* 3 kJ mol^{-1} was derived as the net stabilization energy of the *ap* form due to the OH$\cdots\pi$ interaction.

Comparison of the barriers to rotation of the oxygen-compounds studied here with those of the corresponding methyl or substituted methyl compound reveals that the formers exhibit lower barriers: Arrhenius activation energies for rotation of 9-(2-methyl-1-naphthyl)fluorene[14] and 9-(2-bromomethyl-6-methylphenyl)fluorene[4] are known to be 125 kJ mol^{-1} and 113 kJ mol^{-1}, respectively, for the *sp*→*ap* processes. The lowering of the barriers to rotation of compounds **4**—**7** may be attributed to lessening of the van der Waals radii of the substituents in 2′ position by going from a methyl to an oxygen, which directly affects the transition state for rotation. The difference in the barriers between the naphthyl and 2-methylphenyl analogs is smaller in the oxygen-compounds than the hydrocarbons (approximated by the bromomethyl compound). The reason for this phenomenon must further be studied.

(Received February 29, 1980)

3,6-Dideoxy-3-*C*-methyl-2-*O*-methyl-D-galactopyranose(**12**) was prepared in 10 steps from methyl 4,6-*O*-benzylidene-3-deoxy-3-*C*-methyl-α-D-altropyranoside. **12** was converted into 4,5-di-*O*-acetyl-3,6-dideoxy-3-*C*-methyl-2-*O*-methyl-D-galactose, which was then condenced in ether with (methoxymethylene)triphenylphosphorane (generated from the phosphonium salt with the dimethylsulfinylmethanide anion in ether) to produce 5,6-di-*O*-acetyl-2,4,7-trideoxy-4-*C*-methyl-1,3-di-*O*-methyl-D-*galacto*-1-enoheptitol (**16**). The treatment of **16** with NBS in methanol, followed by the debromination of the resulting 2-bromo aldehyde dimethyl acetal with tributylstannane, deacetylation, and mild methanolysis afforded methyl 2,4,7-trideoxy-4-*C*-methyl-3-*O*-methyl-β-D-*galacto*-heptopyranoside(**19**), which then provided the title compound **20** upon Jones oxidation. The potential intermediates, the 1-lithio-1-(methyl 2,4-dideoxy-4-*C*-methyl-3-*O*-methyl-α-L-*arabino*-pentopyranos-5-yl)ethene and (*E*)-2-(methyl 2,4-dideoxy-4-*C*-methyl-3-*O*-methyl-α-L-*arabino*-pentopyranos-5-yl)propenylcopper intermediates, were prepared from **20** *via* the corresponding alkenyl iodide and (methyl 2,4-dideoxy-4-*C*-methyl-3-*O*-methyl-α-L-*arabino*-pentopyranos-5-yl)ethyne and were demonstrated to condense with benzaldehyde and ethylene oxide respectively.

Rifamycins are the first natural compound with an aromatic ring system spanned by a long aliphatic bridge,[2] called the ansa chain. The aliphatic chain compound, **1**, corresponding to the intact ansa chain present in rifamycin B, O, S, and SV has thus far been neither isolated from a natural source nor synthesized. Corey[3] has recently reported the highly stereoselective synthesis of some fragment intermediates for the elaboration of the ansa-chain portion of rifamycins. In the course of our synthetic studies of rifamycins, the new ansa-chain compound, **2**, the deacetylated cyclic methyl acetal derivative of **1**, has been isolated[1] on the novel degradation of 25-deacetylrifampicin. We have been interested[4] in the synthesis of the rifamycin ansa chain in the form of **2**, which is considered to be a useful intermediate in the synthesis of rifamycin. This paper deals with the synthesis of methyl 2,4,6,7-tetradeoxy-4-*C*-methyl-3-*O*-methyl-α-L-*arabino*-heptopyranosid-6-ulose (**20**), a viable synthetic intermediate containing the cyclic methyl acetal moiety of **2**, and with its conversions into the potential intermediates, **23** or **26**, utilizable in the coupling reaction with the second synthetic segments, such as **A** or **B**, with the aldehydic or epoxidic functionality (Scheme 1).

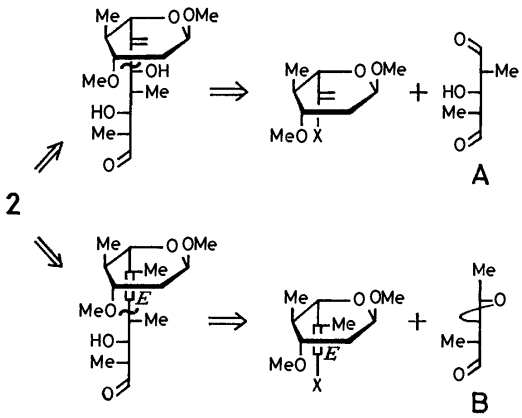
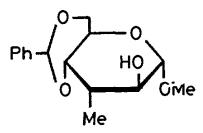


Scheme 1.

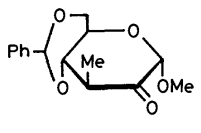
Results and Discussion

The starting material, methyl 4,6-*O*-benzylidene-3-deoxy-3-*C*-methyl-α-D-altropyranoside(**3**),[5-7] could be obtained on a large scale from methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-mannopyranoside[8] and methylmagnesium chloride by the method of Inch and Lewis.[7] The conversion of **3** into methyl 4,6-*O*-benzylidene-3-deoxy-3-*C*-methyl-α-D-glucopyranoside(**5**) was accomplished *via* the inverted keto sugar, **4**, according to

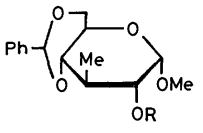
the procedure of Inch *et al.*[9] in a 74% overall yield. The *O*-methylation of **5** with sodium hydride and methyl iodide in DMF gave **6** in a 73% yield. The treatment of **6** with *N*-bromosuccinimide (NBS)



3



4



5 R = H
6 R = Me

in boiling carbon tetrachloride,[10] followed by the lithium aluminium hydride reduction of the bromo derivative, **7**, afforded methyl 3,6-dideoxy-3-*C*-methyl-2-*O*-methyl-α-D-glucopyranoside(**8**) in a 65% yield. The *O*-mesylation of **8** with mesyl chloride in pyridine, followed by the treatment of the resulting 4-mesylate, **9**, with sodium benzoate in DMSO at 120 °C, gave the inverted benzoate **10** in a 61% overall yield from **8**. The acetolysis of **10** with acetic anhydride in the presence of concd sulfuric acid afforded **11** as an anomeric mixture in a 76% yield. The hydrolysis of **11** with sodium hydroxide gave 3,6-dideoxy-3-*C*-methyl-2-*O*-methyl-D-galactose(**12**) in a 92% yield. In preparative runs, compound **12** could be obtained in about a 32% overall yield from **3** without any isolation of the intermediates (**4**—**11**).

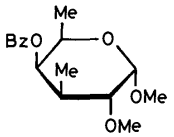
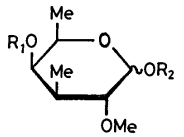
9 R_1 = Me, R_2 = Ms



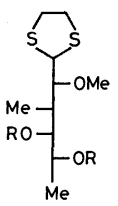
10



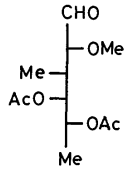
11 R_1 = Bz, R_2 = Ac
12 R_1 = R_2 = H

The conversion of **12** into **19** in a moderate overall yield (23%) was accomplished through the following eight steps. The dithioacetalization of **12** with 1,2-ethanedithiol and concd hydrochloric acid, followed by acetylation with acetic anhydride and 4-dimethylaminopyridine in ethyl acetate, gave **14** in a 70% overall yield. The demercaptalation of **14** with a 2:1 mixture of mercury(II) chloride and red mercury(II) oxide[11] afforded the aldehyde **15** in a 95% yield. The Wittig condensation[12] of **15** in ether with (methoxymethylene)triphenylphosphorane (prepared from the corresponding phosphonium chloride with phenyllithium in ether) yielded the enol ether, **16**, in a low yield (≈10%). When **15** was treated with the ylide in DMSO according to Corey's method,[13] no condensation product was obtained, but when **15** was allowed to react in ether with a two-fold excess of the ylide (prepared by the action of 4 M** methylsulfinylmethanide anion in DMSO[13a]) with the phosphonium chloride in ether), the desired enol ether, **16**, was obtained in a 72% yield as a 7.7:1 mixture of *E* and *Z* isomers. The direct conversion of **16** into the

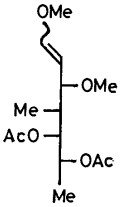
** 1 M=1 mol dm^{-3}.



13 R = H
14 R = Ac

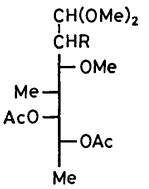


15

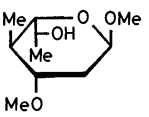


16

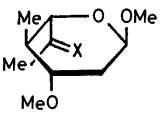
homolog of **15** by acid-catalyzed hydrolysis could not be accomplished because of the predominant formation of the α,β-unsaturated aldehyde by the elimination of the 3-methoxyl group, and so an indirect process was necessary. The treatment of **16** with NBS in methanol containing solid sodium hydrogencarbonate afforded the crystalline bromo dimethyl acetal **17** as an epimeric mixture in a 74% yield. The debromination of **17** with tributylstannane and α,α'-azobisisobutyronitrile gave **18** in a 96% yield. The deacetylation of **18** with sodium hydroxide, followed by mild methanolysis with 0.5% methanolic hydrogen chloride, afforded a 1:5 mixture of methyl 2,4,7-trideoxy-4-*C*-methyl-3-*O*-methyl-α-D-*galacto*-heptopyranoside and its β-anomer, which, after recrystallization, gave the major isomer, **19**, in a 63% overall yield from **18**. The Jones oxidation of **19** afforded the title compound, **20**, in a 93% yield.



17 R = Br
18 R = H



19



20 X = O
21 X = NNH_2

The methyl ketone, **20**, was converted into the alkenyl iodide, **22**, in a 72% yield *via* the hydrazone, **21**, according to the procedure of Barton *et al.*[14] The iodide, **22**, was convertible into the lithium compound, **23**, in ether by treatment with a 1—1.2 equiv of butyllithium[15] in hexane at −78 °C for 1 h. The lithium reagent, **23**, thus obtained was reacted with 1 equiv of benzaldehyde at −50 °C to give the addition product, **24**, in a 54% yield. The potential intermediate, **26**, was derived from **22**. The treatment[16] of **22** with potassium hydroxide in boiling ethanol afforded the alkyne, **25**, in a 74% yield. The alkyne **25** was subjected to an addition reaction[17] with the methylcopper complex which had been prepared from methylmagnesium bromide and a dimethyl sulfide complex of copper(I) bromide[18] in a mixture of ether and dimethyl sulfide according to the procedure reported by Marfat *et al.*[17] The reaction proceeded effectively in the same solvent system at −25 °C for 1 week, resulting in the almost exclusive formation of the alkenylcopper intermediate, **26**, as evidenced by the isolation of the 1-iodo-2-methylalkene, **27**, presumably with an *E*-configuration, in a 52% yield as the sole

addition product after a reaction with iodine.[19] This result indicated that the addition reaction proceeded in a stereospecific syn manner, with copper becoming associated with the terminal carbon, as in the case of simple nonfunctionalized terminal alkyne.[20] Normant *et al.*[21,22] showed that the regioselectivity of the addition of the RCu, MgX_2 reagent to terminal alkynes was affected by the presence of such heteroatom substituents as alkoxyl groups at the propargyric position in the alkyne, and mixtures of products were frequently obtained. The coordination of the hetero atom with a copper moiety has been suggested to explain the formation of products derived from alkenylcopper intermediates with copper at the internal carbon.[23] Under our reaction conditions, the copper reagent forms complexes so strongly with dimethyl sulfide present in the solvent system that the coordination of the copper moiety with the propargyric-ring oxygen atom may be out of the question. The alkenylcopper intermediate, **26**, was converted into the mixed cuprate with 1-lithiopentyne according to the procedure proposed by McGuirk *et al.*[24] and allowed to react with ethylene oxide at −25 °C for 24 h to give the homoallylic alcohol, **28**, in a 46% yield.

Experimental

The melting points were determined on a micro hot-stage Yanaco MP-83 and are uncorrected. The specific rotations were measured with a Carl Zeiss photoelectric precision polarimeter. The ^{1}H NMR (PMR) spectra were determined with Varian A60 and EM-390 spectrometers, using TMS as the internal standard. Unless otherwise stated, the TLC and column chromatography were performed on silica gel Wakogel B-5 and Wakogel C-200 respectively. In general, the concentration was carried out under a reduced pressure of below 30 °C.

*Methyl 4,6-O-Benzylidene-3-deoxy-3-C-methyl-α-D-arabino-hexopyranosid-2-ulose (**4**).* A mixture of dry DMSO (54 ml), dry pyridine (5.5 ml), and trifluoroacetic acid (2.89 ml, 0.037 mol) was added to a solution of **3** (50.0 g, 0.178 mol) in dry benzene (350 ml). A solution of dicyclohexylcarbodiimide (44.2 g, 0.214 mol) in dry benzene (150 ml) was then added, drop by drop, to the mixture under ice-cooling. After the mixture had been stirred at room temperature for 7 h, the precipitates formed were filtered and washed with benzene. The filtrate and washings were combined and washed successively with saturated aqueous $KHSO_4$, $NaHCO_3$, and NaCl solutions, dried, and evaporated to afford a yellow syrup of crude methyl 4,6-*O*-benzylidene-3-deoxy-3-*C*-methyl-α-D-*ribo*-hexopyranosid-2-ulose (51.4 g). This syrup was dissolved in DMF (247 ml) containing triethylamine (23 ml). After being stored at room temperature for 3 d, the mixture was poured into ice water. The precipitates were collected by filtration, washed with water, and dried at 40 °C to afford pale yellow crystals of **4** (43.4 g, 87.5%); mp 127.5—129 °C. Recrystallization from ethyl acetate–hexane gave a pure sample of **4**: mp 130—131 °C; $[\alpha]_D^{27}$ +58° (*c* 1.26, $CHCl_3$); IR (0.122 M, CCl_4) 1750 cm^{-1}; PMR ($CDCl_3$) δ=1.21 (3H, d, 3-Me, J=5.9 Hz), 3.50 (3H, s, OMe), 4.63 (1H, s, H-1), and 5.53 (1H, s, benzylic H). Found: C, 64.87; H, 6.55%. Calcd for $C_{15}H_{18}O_5$: C, 64.73; H, 6.52%.

*Methyl 4,6-O-Benzylidene-3-deoxy-3-C-methyl-α-D-glucopyranoside (**5**).* Powdered $LiAlH_4$ (5.22 g, 0.138 mol) was slowly added to a stirred ice-cooled solution of **4** (38.4 g, 0.138 mol) in dry ether (1.0 l), and then the mixture was stirred at room temperature for 0.5 h. Ethyl acetate (300 ml) and water (0.5 l) were added to the cooled reaction mixture, and it was stirred at room temperature for 1 h. The organic layer thus separated was washed with a saturated aqueous NaCl solution, dried, and evaporated to afford **5** as colorless plates (35.7 g, 92.3%). Recrystallization from methanol–petroleum ether gave a pure sample: mp 150.5—151.5 °C; $[\alpha]_D^{23}$ +94° (*c* 1.04, $CHCl_3$); PMR ($CDCl_3$) δ=1.18 (3H, d, 3-Me, J=6.1 Hz), 1.91 (1H, d, OH, $J_{2,OH}$=11.1 Hz), 3.26 (1H, dd, H-4, $J_{3,4}$=10.7 Hz, $J_{4,5}$=4.7 Hz), 3.48 (3H, s, OMe), 4.71 (1H, d, H-1, $J_{1,2}$=3.6 Hz), and 5.51 (1H, s, benzylic H). Found: C, 64.53; H, 7.27%. Calcd for $C_{15}H_{20}O_5$: C, 64.27; H, 7.19%.

*Methyl 4,6-O-Benzylidene-3-deoxy-3-C-methyl-2-O-methyl-α-D-glucopyranoside (**6**).* Sodium hydride (17.1 g, 55% emulsion in mineral oil) was placed in a flask and washed free from the mineral oil with hexane. The flask was evacuated until the last traces of hexane were removed from the sodium hydride. Dry DMF (75 ml) was then introduced under stirring, and a solution of **5** (10.5 g, 37.5 mmol) in DMF (30 ml) was added dropwise to the stirred ice-cooled contents. After the sirring had been continued at room temperature for 1 h, methyl iodide (34.2 ml, 513.8 mmol) was added dropwise to the stirred ice-cooled mixture over a period of 20 min. After the mixture had been stirred for 1.5 h, the excess of hydride was then destroyed by the careful addition of methanol and the solvents were removed. The residue was taken up with chloroform, washed with water and a saturated aqueous NaCl solution, dried, and evaporated to afford **6** as a yellow crystalline solid (11.5 g). The recrystallization of the crude crystals of **6** from acetone–petroleum ether gave the pure sample (8.00 g, 73%): mp 121—122.5 °C; $[\alpha]_D^{27}$ +84° (*c* 1.10, $CHCl_3$); PMR ($CDCl_3$) δ=1.15 (3H, d, 3-Me J=6.1 Hz), 3.02 (1H, dd, H-2, $J_{1,2}$=3.2 Hz, $J_{2,3}$=10.0 Hz), 3.50 (6H, s, 1- and 2-OMe), 4.86 (1H, d, H-1), and 5.52 (1H, s, benzylic H). Found: C, 65.50; H, 7.49%. Calcd for $C_{16}H_{22}O_5$: C, 65.29; H, 7.53%.

*Methyl 4-O-Benzyl-6-bromo-3,6-dideoxy-3-C-methyl-2-O-methyl-α-D-glucopyranoside (**7**).* A mixture of **6** (8.00 g, 27.2 mmol), NBS (5.08 g, 28.8 mmol), and carbon tetrachloride (120 ml) containing barium carbonate (6.76 g, 34.7 mmol) was refluxed for 2h under stirring (argon atmosphere). The solids were filtered off and washed with carbon tetrachloride. The filtrate and washings were combined and washed with saturated aqueous $Na_2S_2O_3$, $NaHCO_3$, and NaCl solutions successively. The dried solution was evaporated to give **7** (10.0 g, 98.6%) as a colorless syrup which was suitable for the next synthesis. A portion of this product (50 mg) was chromatographyd on silica gel (3 g) with 20:1 benzene–ethyl acetate to afford a pure sample of **7** (39 mg, 78%): $[\alpha]_D^{28}$ +93° (*c* 0.81, $CHCl_3$); PMR ($CDCl_3$) δ=1.04 (3H, d, 3-Me, J=6.4 Hz), 3.12 (1H, dd, H-2, $J_{1,2}$=3.7 Hz, $J_{2,3}$=10.9 Hz), 3.48 and 3.57 (each 3H, each s, 1- and 2-OMe), 4.88 (1H, d, H-4, $J_{3,4}$=9.9 Hz, $J_{4,5}$=10.2 Hz), and 4.94 (1H, d, H-1). Found: C, 51.22; H, 5.46; Br, 21.66%. Calcd for $C_{16}H_{21}O_5Br$: C, 51.49; H, 5.67; Br,

21.41%.

Methyl 3,6-Didoxy-3-C-methyl-2-O-methyl-α-D-glucopyranoside (8). The crude sample of **7** (10.0 g) was dissolved in dry THF (650 ml) and cooled in an ice bath. Powdered $LiAlH_4$ (8.13 g, 215 mmol) was slowly added to the stirred solution. The resulting mixture was refluxed for 1.5 h and then cooled in an ice bath. Ethyl acetate (240 ml) and water (150 ml) were slowly added to the reaction mixture, and the resulting mixture was stirred at room temperature overnight. The mixture was filtered with a super cell, and the filter cake was washed with ethyl acetate. The combined filtrate and washings were washed with a saturated aqueous NaCl solution, dried, and evaporated. The residual syrup (7.30 g) was chromatographed on silica gel (360 g) with 1:1 benzene–ethyl acetate to afford a colorless syrup of **8** (4.0 g, 77%): $[\alpha]_D^{15}$ +159° (*c* 0.56, $CHCl_3$); PMR ($CDCl_3$) δ=1.11 (3H, d, 3-Me, J=6.2 Hz), 1.24 (3H, d, H-6, $J_{5,6}$=6.1 Hz), 2.92 (1H, dd, H-2, $J_{1,2}$=3.1 Hz, $J_{2,3}$=10.7 Hz), 3.43 (6H, s, 1- and 2-OMe), and 4.76 (1H, d, H-1). Found: C, 56.85; H, 9.32%. Calcd for $C_9H_{18}O_4$: C, 56.82; H, 9.54%.

Methyl 3,6-Dideoxy-4-O-mesyl-3-C-methyl-2-O-methyl-α-D-glucopyranoside (9). A mixture of **8** (4.00 g, 21.0 mmol), dry pyridine (40 ml), and mesyl chloride (2.48 ml, 32.0 mmol) was allowed to stand at room temperature for 24 h and then evaporated. The residue was taken up with ethyl acetate, washed with a saturated aqueous NaCl solution, dried, and evaporated to afford pale yellow needles of **9** (5.07 g, 90%). Some of these crystals (71 mg) were chromatographed on silica gel (2 g) with 10:1 benzene–ethyl acetate to give a pure sample (56 mg) as colorless needles: mp 81.5—83.0 °C; $[\alpha]_D^{26}$ +127° (*c* 1.67, $CHCl_3$); PMR ($CDCl_3$) δ=1.17 (3H, d, 3-Me, J=6.3 Hz), 1.32 (3H, d, H-6, $J_{5,6}$=6.0 Hz), 2.99 (1H, dd, H-2, $J_{2,3}$=10.8 Hz), 3.08 (3H, s, OMs), 3.46 (6H, s, 1- and 2-OMe), 4.16 (1H, dd, H-4, $J_{3,4}$=9.7 Hz, $J_{4,5}$=9.7 Hz), and 4.78 (1H, d, H-1, $J_{1,2}$=3.2 Hz). Found: C, 44.44; H, 7.28; S, 11.65%. Calcd for $C_{10}H_{20}O_6S$: C, 44.72; H, 7.53; S, 11.95%.

Methyl 4-O-Benzoyl-3,6-dideoxy-3-C-methyl-2-O-methyl-α-D-galactopyranoside (10). A solution of **9** (105 mg, 0.391 mmol) in DMSO (5.0 ml) was heated with dried sodium benzoate (282 mg, 1.96 mmol) at 120 °C for 6 h. After being cooled to room temperature, the reaction mixture was diluted with ethyl acetate; the solids were filtered off and washed with ethyl acetate. The filtrate and washings were combined and washed with water and a saturated aqueous NaCl solution. The dried solution was evaporated, and the residue (189 mg) was chromatographed on silica gel (5 g) with 5:1 hexane–acetone to afford a syrup of **10** (102 mg, 88.6%): $[\alpha]_D^{29}$ +153° (*c* 0.59, $CHCl_3$); IR (CCl_4) 1720 cm^{-1}; PMR ($CDCl_3$) δ=1.02 (3H, d, 3-Me, J=7.3 Hz), 1.13 (3H, d, H-6, $J_{5,6}$=6.8 Hz), 3.41 (1H, dd, H-2, $J_{1,2}$=3.1 Hz, $J_{2,3}$=10.8 Hz), 3.47 and 3.50 (each 3H, each s, 1- and 2-OMe), 4.12 (1H, dq, H-5, $J_{4,5}$=1.5 Hz), 4.94 (1H, d, H-1), and 5.27 (1H, dd, H-4). Found: C, 65.42; H, 7.45%. Calcd for $C_{16}H_{22}O_5$: C, 65.29; H, 7.53%.

1-O-Acetyl-4-O-benzoyl-3,6-dideoxy-3-C-methyl-2-O-methyl-D-galactopyranose (11). To a solution of **10** (5.30 g, 18.0 mmol) in acetic anhydride (197 ml), concd H_2SO_4 (1.9 ml) was added dropwise under ice-cooling. After being kept at room temperature for 0.5 h, the reaction mixture was poured into cold water (1.8 l), neutralized with solid $NaHCO_3$, and then extracted with chloroform. The extract was washed with a saturated aqueous NaCl solution, dried, and evaporated. The residual yellow-brown syrup (5.8 g) was chromatographed on silica gel (50 g) with 10:1 benzene–ethyl acetate to afford a semi-crystalline solid of **11** (4.41 g, 76.3%) as an anomeric mixture: PMR ($CDCl_3$) δ=1.10 (3H, d, 3-Me, J=6.9 Hz), 1.19 (3H, d, H-6, $J_{5,6}$=6.2 Hz), 2.10 and 2.21 (3H, each s, OAc), 3.38 and 3.54 (3H, each s, OMe), 5.64 and 6.2—6.3 (1H, each d, H-1 of β- and α-anomers, $J_{\beta\text{-}1,2}$=7.9 Hz). Found: C, 63.53; H, 6.88%. Calcd for $C_{17}H_{22}O_6$: C, 63.34; H, 6.88%.

3,6-Didoxy-3-C-methyl-2-O-methyl-D-galactopyranose (12). A 1 M aqueous NaOH solution (3.67 ml) was added to a solution of **11** (490 mg, 1.52 mmol) in dioxane (3.67 ml). After being kept at room temperature for 2 d, the mixture was neutralized with a 0.5 M H_2SO_4 solution and evaporated, and acetone was added to the residue. The insoluble matter was filtered off, and the filtrate was evaporated to afford crude **12** (268 mg, 100%) as a yellow syrup. A sample (60 mg) of the syrup was chromatographed on silica gel (2 g) with 1:1 benzene–ethyl acetate to give a colorless syrup of **12** (55 mg, 92%) as an anomeric mixture; PMR ($CDCl_3$) δ=1.17 (3H, d, 3-Me, J=6.2 Hz), 1.22 (3H, d, H-6, $J_{5,6}$=6.2 Hz), 3.71 (1H, dq, H-5, $J_{4,5}$=2.9 Hz), 4.62 and 5.38 (1H, each d, H-1 of two anomers, $J_{\alpha\text{-}1,2}$=4.4 Hz, $J_{\beta\text{-}1,2}$=7.9 Hz), and 3.80 (2H, s, 1- and 4-OH). Found: C, 54.27; H, 8.98%. Calcd for $C_8H_{16}O_4$: C, 54.53; H, 9.15%.

3,6-Dideoxy-3-C-methyl-2-O-methyl-D-galactose Ethylene Dithioacetal (13). To a stirred solution of the crude **12** (1.08 g) in 1,2-ethylenedithiol (2.57 ml) was added concd HCl (0.63 ml) dropwise under ice-cooling. After being stirred at room temperature for 2 h, the reaction mixture, which showed the presence of a trace amount of **12** on TLC (1:1 benzene–ethyl acetate), was treated with additional concd HCl (1.93 ml) at room temperature for 40 min. The resulting mixture was then poured into ice water and extracted with chloroform. The extract was washed successively with saturated aqueous $NaHCO_3$ and NaCl solutions, dried, and evaporated. The residual yellow syrup (3.18 g) was chromatographed on silica gel (60 g) with 2:1 benzene–ethyl acetate to afford **13** (1.17 g, 76%) as a syrup: $[\alpha]_D^{30}$ +5° (*c* 1.21, $CHCl_3$); PMR ($CDCl_3$) δ=0.98 (3H, d, 3-Me, J=7.0 Hz), 1.28 (3H, d, H-6, $J_{5,6}$=6.4 Hz), 1.7—2.5 (1H, m, H-3), 2.56 (2H, s, 4- and 5-OH), 3.24 (4H, s, S–CH_2–CH_2–S), 3.29 (1H, dd, H-4, $J_{3,4}$=8.2 Hz, $J_{4,5}$=3.0 Hz), 3.63 (1H, dd, H-2, $J_{1,2}$=9.0 Hz, $J_{2,3}$=1.9 Hz), 3.65 (3H, s, OMe), 3.93 (1H, dq, H-5), and 4.68 (1H, d, H-1). Found: C, 47.34; H, 7.76; S, 25.18%. Calcd for $C_{10}H_{20}O_3S_2$: C, 47.59; H, 7.99; S, 25.41%.

4,5-Di-O-acetyl-3,6-dideoxy-3-C-methyl-2-O-methyl-D-galactose Ethylene Dithioacetal (14). To a stirred ice-cooled solution of **13** (2.36 g, 9.35 mmol) in ethyl acetate (24 ml), acetic anhydride (2.12 ml, 22.5 mmol) and 4-dimethylaminopyridine (2.74 g, 22.5 mmol) were added successively; stirring was then continued at room temperature for 0.5 h. The resulting precipitates were filtered off and washed with ethyl acetate. The filtrate and washings were combined and washed successively with water, saturated aqueous $KHSO_4$, $NaHCO_3$, and NaCl solutions, dried, and evaporated. The residual yellow syrup (3.25 g) was chromatographed on silica gel (100 g) with 6:1 benzene–ethyl acetate to afford a practically pure sample of **14** as colorless needles (2.88 g, 91.5%). Recrystallization from ethyl acetate–hexane gave a pure sample: mp 74.5—75.5 °C; $[\alpha]_D^{19}$ +30° (*c* 1.44, $CHCl_3$); PMR ($CDCl_3$) δ=0.90 (3H, d, 3-Me, J=7.0 Hz), 1.21 (3H, d, H-6, $J_{5,6}$=6.2 Hz), 2.10 and 2.18 (each 3H, each s, 4- and 5-OAc), 2.0—2.6 (1H, m, H-3), 3.18 (1H, dd, H-2, $J_{1,2}$=9.3 Hz, $J_{2,3}$=1.7 Hz), 3.23 (4H, s, S–CH_2–CH_2–S), 3.52 (3H, s, OMe), 4.62 (1H, d, H-1), 5.00 (1H, dd, H-4, $J_{3,4}$=8.2 Hz, $J_{4,5}$=3.2 Hz), and 5.18 (1H, dq, H-5). Found: C, 50.21; H, 7.16; S, 18.83%. Calcd for $C_{14}H_{24}O_5S_2$: C, 49.98; H, 7.19; S, 19.06%.

*4,5-Di-O-acetyl-3,6-dideoxy-3-C-methyl-2-O-methyl-D-galactose (**15**).* Red mercury(II) oxide (2.83 g, 13.1 mmol) and mercury(II) chloride (7.10 g, 26.2 mmol) were added successively at room temperature to a solution of **14** (2.00 g, 5.94 mmol) in aqueous 80% acetone (150 ml). The mixture was then stirred efficiently and refluxed under argon for 17 h. The resulting suspension was cooled and filtered through a super cell, and the filter cake was washed thoroughly with acetone. The filtrate and washings were combined and concentrated to remove the acetone. The aqueous residue was extracted with ethyl acetate, and the extract was washed with water and a saturated aqueous NaCl solution, dried, and evaporated. The residual pale yellow syrup was chromatographed on silica gel (78 g) with 3:1 hexane–ethyl acetate to afford **15** as pale yellow plates (1.48 g, 95.4%): PMR ($CDCl_3$) δ=0.89 (3H, d, 3-Me, J=7.1 Hz), 1.20 (3H, d, H-6, $J_{5,6}$=6.1 Hz), 2.10 and 2.18 (each 3H, each s, 4- and 5-OAc), 2.1—2.7 (1H, m, H-3), 3.44 (3H, s, OMe), 3.3—3.6 (1H, m, H-2), 4.9—5.4 (2H, m, H-4 and H-5), and 9.75 (1H, d, H-1).

*5,6-Di-O-acetyl-2,4,7-trideoxy-4-C-methyl-1,3-di-O-methyl-D-galacto-1-enoheptitol (**16**).* A 4 M methylsulfinylmethanide anion in DMSO,[13a] prepared with sodium hydride (6.37 mmol as a 55% dispersion in mineral oil) and DMSO (1.7 ml), was added dropwise to a stirred suspension of (methoxymethyl)triphenylphosphonium chloride (2.31 g, 6.73 mmol) in dry ether (35 ml) under argon at room temperature. The mixture was stirred for 10 min and then, to the resulting red suspension of the ylide, a solution of **15** (0.88 g, 3.37 mmol) in dry ether (18 ml) was added dropwise. After the mixture had been stirred at room temperature for 15 min, the resulting orange suspension was poured into ether (100 ml), and the organic layer was washed with water and a saturated aqueous NaCl solution, dried, and evaporated to a brown syrup (2.56 g). The syrup was chromatographed on silica gel (Mallinckrodt SILICAR CC-7 special, 80 g) with 4:1 hexane–ethyl acetate to afford a practically pure sample of **16** as a pale yellow syrup (0.70 g, 72%). A part of this sample was again chromatographed on the same silica gel with the same solvent system to give an analytically pure sample as a 7.7:1 mixture of the *E*- and *Z*-isomers: PMR ($CDCl_3$) δ=0.88 and 0.91 (3H, each d, 4-Me of *E*- and *Z*-isomers, J_E=7.3 Hz, J_Z=7.0 Hz), 1.19 (3H, d, H-7, $J_{6,7}$=6.7 Hz), 2.08 and 2.17 (each 3H, each s, 5- and 6-OAc), 3.16 and 3.18 (3H, each s, 1-OMe of *E*- and *Z*-isomers), 3.41 (1H, dd, H-3, $J_{2,3}$=9.0 Hz, $J_{3,4}$=3.0 Hz), 3.61 and 3.62 (3H, each s, 3-OMe of *E*- and *Z*-isomers), 6.10 and 6.48 (1H, each d, H-1 of *E*- and *Z*-isomers). Found: C, 58.30; H, 8.24%. Calcd for $C_{14}H_{24}O_6$: C, 58.31; H, 8.39%.

*5,6-Di-O-acetyl-2,4,7-trideoxy-4-C-methyl-3-O-methyl-D-galacto-heptose Dimethyl Acetal (**18**).* To an ice-cooled solution of **16** (1.05 g, 3.63 mmol) in methanol (10 ml) were added solid $NaHCO_3$ (0.37 g, 4.41 mmol) and NBS (0.77 g, 4.41 mmol) successively. After being stirred at 0 °C for 1 h, the mixture was evaporated and the residue was extracted with ethyl acetate. The extract was washed with water and a saturated aqueous NaCl solution, dried, and evaporated to afford a crystalline solid (1.60 g). Chromatography of the solid on silica gel (Mallinckrodt, 80 g) with 3:1 hexane–ethyl acetate gave colorless needles (1.08 g, 74.4%) as an epimeric mixture, **17**, of 5,6-di-*O*-acetyl-2-bromo-2,4,7-trideoxy-4-*C*-methyl-3-*O*-methyl-D-*glycero*-L-*manno*-heptose dimethyl acetal and its D-*glycero*-L-*gluco*-epimer. Tributylstannane (0.33 ml, 1.224 mmol) and α,α'-azobisisobutyronitrile (17 mg) were added to a solution of **17** (409 mg, 1.02 mmol) in dry benzene (6.1 ml). The solution was stirred, under an argon atmosphere, at 60 °C for 1 h and then evaporated. The residual syrup was chromatographed on silica gel (Mallinckrodt, 41 g) with 3:1 hexane-ethyl acetate to give **18** (315 mg, 96% based on **17**) as a syrup: PMR ($CDCl_3$) δ=0.85 (3H, d, 4-Me, J=7.0 Hz), 1.17 (3H, d, H-7, J=6.0 Hz), 2.07 and 2.14 (each 3H, each s, 5- and 6-OAc), 3.26 (3H, s, 3-OMe), 3.34 [6H, s, CH-$(OMe)_2$], 4.42 (1H, dd, H-1, $J_{1,2}$=5.0 Hz, $J_{1,2'}$=6.0 Hz), 4.98 (1H, dd, H-5, $J_{4,5}$=7.5 Hz, $J_{5,6}$=2.5 Hz), and 5.11 (1H, dq, H-6). Found: C, 56.29; H, 8.69%. Calcd for $C_{15}H_{28}O_7$: C, 56.23; H, 8.81%.

*Methyl 2,4,7-Trideoxy-4-C-methyl-3-O-methyl-β-D-galacto-heptopyranoside (**19**).* 1 M aqueous NaOH (9.86 ml) was added to an ice-cooled solution of **18** (1.58 g, 4.93 mmol) in dioxane (9.86 ml), after wihich the mixture was kept at room temperature for 2 h. The reaction mixture was neutralized (pH 7—8) with ion-exchange resin (CG 50 H^+ type), and the filtrate was evaporated to afford a crude syrup (1.21 g) of the deacetylation product. The pure sample of this product was obtained by column chromatography, using silica gel (Mallinckrodt) with 1:2 hexane–ethyl acetate as a colorless syrup, in an 87% yield (Found: C, 55.63; H, 9.84%. Calcd for $C_{11}H_{24}O_5$: C, 55.91; H, 10.24%). A solution of the crude syrup (1.21 g) in 0.5% methanolic hydrogen chloride (59 ml) was allowed to stand at room temperature for 1 h. The reaction mixture was then neutralized with solid $NaHCO_3$ and evaporated. The residue was extracted with ethyl acetate, and the extract was washed with a saturated aqueous NaCl solution, dried, and evaporated to give a pale yellow crystalline solid (1.19 g). The product was chromatographed on silica gel (59 g) with 5:1 chloroform–acetone to afford colorless needles (839 mg, 83% from **18**) melting at 88—98 °C. The PMR analysis (in $CDCl_3$) revealed that these crystals were a 1:5 mixture of α- and β-methyl glycoside, based on the areas of the signals at δ=4.35 (dd, $J_{1,2ax}$=9.8 Hz, $J_{1,2eq}$=2.2 Hz) and δ=4.94 (dd, $J_{1,2ax}$=4.0 Hz, $J_{1,2ex}$=1.5 Hz), which are attributed to the α- and β-anomeric protons respectively. The practically pure major β-anomer, **19**, was obtained on the recrystallization of the mixture from ethyl acetate–hexane as a first crop (366 mg, mp 99.5—101 °C) and a second crop (264 mg, mp 95—100.5 °C), the total yield from **18** being 62.4%. The pure sample of **19** was obtained by the recrystallization of the first crop from the same solvent system: mp 100—101 °C; $[\alpha]_D^{15}$ −102° (*c* 1.00, $CHCl_3$); PMR ($CDCl_3$) δ=0.99 (3H, d, 4-Me, J=6.5 Hz), 1.29 (3H, d, 6-Me, J=6.5 Hz), 1.2—1.7 (1H, m, H-2ax), 1.88 (1H, d, 6-OH), 1.4—2.0 (1H, m, H-4), 2.23 (1H, ddd, H-2eq, $J_{1,2eq}$=1.5 Hz, $J_{2eq,3}$=4.5 Hz, $J_{2eq,2ax}$=12.5 Hz), 3.0—3.6 (2H, m, H-3 and H-5), 3.35 and 3.37 (each 3H, each s, 1- and 3-OMe), 3.6—4.3 (1H, m, H-6), and 4.94 (1H, dd, H-1, $J_{1,2ax}$=4.0 Hz). Found: C, 58.99; H, 9.66%. Calcd for $C_{10}H_{20}O_4$: C, 58.80; H, 9.87%.

*Methyl 2,4,7-Trideoxy-4-C-methyl-3-O-methyl-α-L-arabino-heptopyranosid-6-ulose (**20**)* A solution of **19** (0.24 g, 1.17 mmol) in acetone (4.8 ml) was cooled at −60 °C in a Dry Ice–acetone bath. After the addition of an aliquot (0.872 ml) of the Jones reagent prepared with CrO_3 (1.00 g), concd H_2SO_4 (0.861 ml), and water (2.88 ml), the mixture was allowed to warm to −10 °C and then stirred for 1.5 h; TLC analysis with 2:1 benzene–ethyl acetate then indicated the complete conversion of **19** into a single product, **20**. The reaction mixture was then neutralized with a saturated aqueous $NaHCO_3$ solution and extracted with ether. The extract was washed with a saturated aqueous NaCl solution, dried, and evaporated to a pale yellow oil of crude **20** (0.23 g), which was subsequently chromatographed on silica gel

(8 g) with 5:1 benzene–ethyl acetate to afford a pure sample of **20** (0.22 g, 93%) as a colorless oil: $[\alpha]_D^{17}$ +4° (*c* 1.33, $CHCl_3$); IR (0.168 M, $CHCl_3$) 1720 cm^{-1}; PMR ($CDCl_3$) δ=0.95 (3H, d, 4-Me J=7.0 Hz), 1.53 (1H, ddd, H-2_{ax}, $J_{2ax,3}$=11.0 Hz, $J_{1,2ax}$=3.5 Hz, $J_{2ax,2eq}$=13.0 Hz), 2.22 (3H, s, H-7), 2.26 (1H, ddd, H-2eq, $J_{1,2eq}$=1.5 Hz, $J_{2eq,3}$=4.5 Hz), 3.27 (1H, ddd, H-3, $J_{3,4}$=9.5 Hz), 3.36 and 3.38 (each 3H, each s, 1- and 3-OMe), 3.77 (1H, d, H-5, $J_{4,5}$=10.5 Hz), and 4.96 (1H, dd, H-1). Found: C, 59.41; H, 8.76%. Calcd for $C_{10}H_{18}O_4$: C, 59.38; H, 8.97%.

*Hydrazone **21** of **20**.* A mixture of **20** (0.20 g, 8.35 mmol), ethanol (2 ml), triethylamine (1.17 ml, 8.35 mmol), and 100% hydrazone hydrate (0.191 ml, 3.93 mmol) was refluxed for 1 h. After cooling, the reaction mixture was neutralized with carbon dioxide gas and extracted with chloroform (30 ml). The extract was washed with water, and the aqueous layer was again extracted with chloroform. The combined chloroform layers were washed with a saturated aqueous NaCl solution, dried, and evaporated to afford practically pure colorless needles of **21** (0.21 g, 98%). Recrystallization from chloroform–petroleum ether gave a pure sample: mp 71—72 °C; $[\alpha]_D^{18}$ −72° (*c* 1.11, $CHCl_3$); IR (KBr) 3400 (NH_2) and 1630 cm^{-1} (C=N). Found: C, 55.44; H, 9.20; N, 12.97%. Calcd for $C_{10}H_{20}N_2O_3$: C, 55.53; H, 9.32; N, 12.95%.

*Methyl 2,4,6,7-Tetradeoxy-6-iodo-4-*C*-methyl-3-*O*-methyl-α-*L*-arabino-hept-6-enopyranoside (**22**).* The hydrazone **21** (0.20 g, 0.929 mmol) in THF (9.1 ml) and triethylamine (6.48 ml) was treated with iodine (0.52 g, 2.05 mmol) in THF (1.0 ml) at room temperature with stirring under argon. Initially the iodine color was discharged, triethylamine hydroiodide being precipitated and gas evolved. The orange-colored suspension was stirred at room temperature for 45 min and then diluted with chloroform (75 ml). The mixture was washed with water, 2 M hydrochloric acid, a 5% aqueous $Na_2S_2O_3$ solution (30 ml), and a saturated aqueous NaCl solution, dried, and evaporated. The residual dark brown syrup (0.34 g) was chromatographed on silica gel (13 g) with 15:1 benzene–ethyl acetate to afford colorless needles of **22** (0.21 g, 72%). Recrystallization from ethyl acetate–hexane gave an analytical sample: mp 86—87 °C; $[\alpha]_D^{20}$ −74° (*c* 1.06, $CHCl_3$); IR (0.15 M, $CHCl_3$) 1620 cm^{-1} (C=C); PMR ($CDCl_3$) δ=0.88 (3H, d, 4-Me, J=7.0 Hz), 1.2—1.9 (1H, m, H-4), 1.51 (1H, ddd, H-2ax, $J_{1,2ax}$=3.5 Hz, $J_{2ax,3}$=11.5 Hz, $J_{2ax,2eq}$=13.0 Hz), 2.25 (1H, ddd, H-2eq, $J_{1,2eq}$=1.5 Hz, $J_{2eq,3}$=11.5 Hz), 3.23 (1H, d, with a little long range coupling with H-7′, H-5, $J_{4,5}$=10.0 Hz), 3.1—3.7 (1H, m, H-3), 3.39 (6H, s, 1- and 3-OMe), 4.94 (1H, dd, H-1), 6.01 (1H, d, H-7 or H-7′, $J_{7,7'}$=1.2 Hz), and 6.40 (1H, m, H-7′ or H-7). Found: C, 38.28; H, 5.38; I, 40.32%. Calcd for $C_{10}H_{17}O_3I$: C, 38.48; H, 5.49; I, 40.65%.

*Condensation of **22** with Benzaldehyde* via *the Lithium Compound, **23**.* A solution of **22** (30.4 mg, 0.097 mmol) in dry ether (0.25 ml) was cooled to −78 °C. To the resulting white suspension was added a 1.6 M butyllithium in hexane (0.0729 ml, 0.117 mmol) using a syringe. After the resulting pale yellow solution had been stirred at −78 °C for 2.5 h, benzaldehyde (0.0119 ml, 0.117 mmol) was added slowly *via* the syringe to the solution of the alkenyllithium, **23**, thus formed; stirring was then continued for 1.5 h. The reaction mixture was quenched at 0 °C by the addition of an aqueous saturated NH_4Cl solution, and was then extracted with ether. The organic layers were washed with a saturated aqueous NaCl solution, dried, and evaporated to a pale yellow oil (62.7 mg). The crude product was purified by chromatography on silica gel (3.1 g) with 5:1 hexane–acetone to afford a colorless syrup (15.4 mg, 54%) of the condensation product, **24**, as a 1:1.2 mixture of epimers: PMR ($CDCl_3$) δ=0.78 and 0.84 (3H, each d, 4-Me, J=7.0 Hz), 1.1—1.9 (2H, m, H-2ax H-4), 2.0—2.5 (1H, m, H-2eq), 2.7—2.9 (1H, br, OH), 2.9—3.5 (1H, m, H-3), 3.24, 3.26, 3.35, and 3.39 (6H, each s, 1- and 3-OMe), 3.93 (1H, dd, H-5, $J_{4,5}$=10.5 Hz, $J_{5,=CH}$=2.5 Hz), 4.91 (1H, dd, H-1, $J_{1,2eq}$=1.5 Hz, $J_{1,2ax}$=3.5 Hz), 5.1—5.5 (3H, m, =CH and benzylic H), and 7.42 (5H, s, ArH); M^+ 292 (20 eV).

*Methyl 2,4,6,7-Tetradeoxy-4-*C*-methyl-3-*O*-methyl-α-*D*-arabino-hept-6-enopyranoside (**25**).* The iodide, **22** (0.185 g), was added to a solution of KOH (0.66 g) in ethanol (6.5 ml), after which the mixture was refluxed with stirring for 1.5 h. After cooling, the mixture was neutralized with carbon dioxide gas and extracted with ether (30 ml). The ethereal extract was washed with water and a saturated aqueous NaCl solution, and dried. After the removal of the solvent, the residual brown oil (0.128 g) was chromatographed on silica gel (7 g) with 20:1 benzene–ethyl acetate to afford a colorless oil of **25** (80 mg, 74%): $[\alpha]_D^{19}$ −80° (*c* 0.84, $CHCl_3$; IR (0.211 M, $CHCl_3$) 3300 cm^{-1} (≡CH); PMR ($CDCl_3$) δ=1.10 (3H, d, 4-Me, J=7.0 Hz), 1.49 (1H, ddd, H-2ax, $J_{1,2ax}$=3.5 Hz, $J_{2ax,3}$=11.5 Hz, $J_{2ax,2eq}$=13.0 Hz), 1.3—2.1 (1H, m, H-4), 2.21 (1H, ddd, H-2eq, $J_{1,2ex}$=1.5 Hz, $J_{2eq,3}$=4.5 Hz), 2.45 (1H, d, H-7, $J_{5,7}$=2.5 Hz), 3.22 (1H, ddd, H-3, $J_{3,4}$=9.8 Hz), 3.36 and 3.39 (each 3H, each s, 1- and 3-OMe), 4.14 (1H, dd, H-5, $J_{4,5}$=10.5 Hz), and 4.90 (1H, dd, H-1). Found: C, 65.16; H, 8.57%. Calcd for $C_{10}H_{16}O_3$: C, 65.19; H, 8.75%.

*Methyl 2,4,6,7-Tetradeoxy-7-iodo-4,6-di-*C*-methyl-3-*O*-methyl-α-*L*-arabino-hept-6-enopyranoside (**27**).* A solution of dimethyl sulfide complex[18] of copper(I) bromide (86.6 mg, 0.42 mmol) in ether (0.5 ml) and dimethyl sulfide (0.4 ml) under argon was cooled to −45 °C, at which temperature a white solid was formed; 1.71 M methylmagnesium bromide in ether (0.246 ml, 0.42 mmol) was then added dropwise using a syringe over a period of 2 min. The resulting suspension of a yellow solid was stirred at −45 °C for 2 h, after which a solution of **25** (64.7 mg, 0.351 mmol) in ether (0.15 ml) was added and the mixture was stirred at −25 °C for 1 week. The resulting dark green reaction mixture was cooled to −50 °C, and to this stirred mixture was added iodine (0.107 g, 0.42 mmol). After the mixture had been stirred at −30 °C for 2 h, to the red-brown reaction mixture was added triethyl phosphite (0.024 ml) and 5 M hydrochloric acid (0.524 ml) at the same temperature. The resulting mixture was diluted with ether (20 ml), washed with saturated aqueous $NaHCO_3$ and NaCl solutions, and evaporated after being dried. The residue was chromatographed on silica gel (5.8 g) with 20:1 hexane–acetone to afford **27** (59.6 mg, 52%) as colorless needles and **25** (12.2 mg, 18.9%). A pure sample of **27** was obtained by recrystallization from ethyl acetate and hexane: mp 84—85 °C; $[\alpha]_D^{16}$ −75° (*c* 1.11, $CHCl_3$); IR (KBr) ν_{max}=1620 cm^{-1} (C=C); PMR ($CDCl_3$) δ=0.83 (3H, d, 4-Me, J=7.0 Hz), 1.2—1.8 (1H, m, H-4), 1.49 (1H, ddd, H-2ax, $J_{1,2ax}$=3.5 Hz, $J_{2ax,3}$=11.5 Hz, $J_{2ax,2eq}$=13.0 Hz), 1.86 (3H, d, 6-Me, J=1.2 Hz), 2.26 (1H, ddd, H-2eq, $J_{1,2ex}$=1.5 Hz, $J_{2eq,3}$=4.5 Hz), 2.9—3.5 (1H, m, H-3), 3.36 and 3.39 (each 3H, each s, 1- and 3-OMe), 3.94 (1H, d, H-5, $J_{4,5}$=10.5 Hz), 4.89 (1H, dd, H-1), and 6.34 (1H, m, H-7). Found: C, 40.68; H, 5.93; I, 38.62%. Calcd for $C_{11}H_{19}O_3I$: C, 40.51; H, 5.87; I, 38.91%.

*Reaction of Ethylene Oxide with Complexed Organocopper Reagent **26*** via *Mixed Cuprate.* By the same procedure as was used in the preparation of **27**, a dark green solution of the alkenylcopper intermediate **26** was prepared from **25** (47.4

mg, 0.257 mmol) and cooled to −78 °C. A solution of 1-lithiopentyne prepared from butyllithium (0.308 mmol) and 1-pentyne (0.308 mmol) in ether (0.37 ml), to which HMPA (0.108 ml, 0.616 mmol) had been added, was transferred to the solution of **26** mentioned above. After being stirred for 1 h, ethylene oxide (0.0153 ml, 0.308 mmol) was slowly added with a chilled syringe. The resulting mixture was stirred at −78 °C for 2.5 h, allowed to stand at −25 °C for 24 h, and worked up by the procedure described by McGuirk *et al.*[24] The resulting yellow-green oil (66.4 mg) was chromatographed on silica gel (3.5 g) with 10:1 hexane–acetone to afford a pale yellow syrup (29.2 mg, 46.5%) of the homoallylic alcohol **28**: PMR ($CDCl_3$) δ=0.84 (3H, d, 4-Me, J=7.0 Hz), 1.1—1.9 (2H, m, H-2ax and H-4), 1.69 (3H, d, 6-Me, J=1.0 Hz), 1.79 (1H, br, 9-OH), 2.0—2.6 (3H, m, H-2eq, H-8 and 8′), 3.0—3.5 (1H, m, H-3), 3.35 and 3.39 (each 3H, each s, 1- and 3-OMe), 3.5—3.9 (2H, m, H-9, 9′), 3.75 (1H, d, H-5, $J_{4,5}$=9.5 Hz), 4.88 (1H, dd, H-1, $J_{1,2eq}$=1.5 Hz, $J_{1,2ax}$=3.5 Hz), and 5.46 (1H, m, H-7). Further purification of this sample by repeated chromatography failed to give an analytically pure sample of **28**, but the acetylation of the sample with acetic anhydride in pyridine afforded the pure acetate of **28** showing *m/e* 287 (M^++1) and 286 (M^+) in its mass spectrum: PMR ($CDCl_3$) δ=0.83 (3H, d, 4-Me, J=7.0 Hz), 1.2—1.7 (1H, m, H-4), 1.46 (1H, ddd, H-2ax, $J_{1,2ax}$=3.5 Hz, $J_{2ax,3}$=9.0 Hz, $J_{2ax,2eq}$=13.0 Hz), 1.65 (3H, d, 6-Me, $J_{6\text{-}Me,7}$=1.2 Hz), 2.02 (3H, s, OAc), 2.25 (1H, ddd, H-2eq, $J_{1,2eq}$=1.5 Hz, $J_{2eq,3}$=4.5 Hz), 2.42 (2H, dt, H-8, 8′, $J_{7,8}$=6.8 Hz, $J_{8,9}$=7.2 Hz), 3.0—3.4 (1H, m, H-3), 3.32 and 3.36 (each 3H, each s, 1- and 3-OMe), 3.72 (1H, d, H-5, $J_{4,5}$=10.5 Hz), 4.09 (2H, t, H-9, 9′), 4.88 (1H, dd, H-1), and 5.41 (1H, m, H-7).

We wish to thank Dr. Kuniaki Tatsuta for his helpful discussion and Mr. Saburo Nakada for carrying out the microanalyses. The authors are also grateful to the Institute of Microbial Chemistry for its financial support.

The Total Synthesis of Neomycin C[1]

Sumio UMEZAWA,* Akihiko HARAYAMA, and Yoshio NISHIMURA
Institute of Bioorganic Chemistry, Ida, Nakahara-ku, Kawasaki, Kanagawa 211
(Received March 3, 1980)

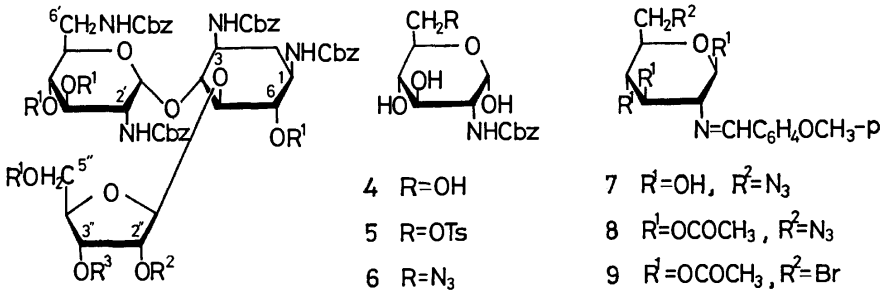
The total synthesis of the pseudo-tetrasaccharides antibiotic neomycin C is described, involving condensation of 6,3′,4′,5″-tetra-*O*-acetyl-1,3,2′,6′-tetra-*N*-(benzyloxycarbonyl)ribostamycin with 3,4-di-*O*-acetyl-2-deoxy-2-(*p*-methoxybenzylideneamino)-6-*O*-tosyl-α-D-glucopyranosyl bromide by a modified Koenigs-Knorr reaction.

Neomycin,[2] a useful antibiotic, was independently discovered by H. Umezawa *et al.*[3] in 1948 and S. A. Waksman *et al.*[2] in 1949. The neomycin complex consists of neomycin A, B, and C, and neomycin C was isolated by Dutcher *et al.*[4] Neomycins are pseudo-tetrasaccharides and show broad-spectrum antibacterial activity. Elucidation of the complete structures of neomycins are achieved by Rinehart *et al.*[5,6] in 1963. We wish now describe in full the total synthesis of neomycin C. This represents the first synthesis of an antibiotic of pseudo-tetrasaccharides.

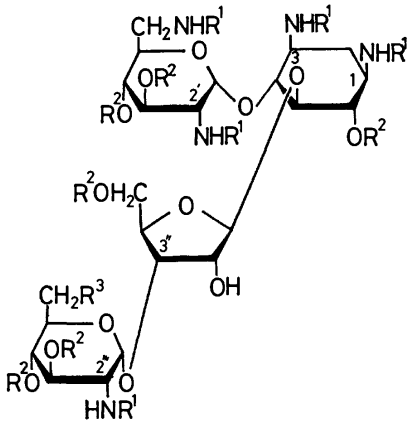
Neomycin C is composed of neosamine C (2,6-diamino-2,6-dideoxy-D-glucopyranose) and ribostamycin which is a pseudo-trisaccharide composed of D-ribose and neamine, a pseudo-disaccharide composed of neosamine C and 2-deoxystreptamine.[7] Neamine was synthesized by S. Umezawa *et al.*,[8] and ribostamycin was subsequently synthesized by Ito *et al.*[9] by ribosylation of neamine. In the present paper, we describe the synthesis of neomycin C by regio- and stereo-selective glycosylation of a pertinently protected ribostamycin (**3**) with a glycosyl halide (**11**) of glucosamine.

Ribostamycin was protected in the following manner. The selective cyclohexylidenation of 1,3,2′,6′-tetra-*N*-(benzyloxycarbonyl)ribostamycin[10] was achieved by treatment with 1,1-dimethoxycyclohexane (2 mol) in *N*,*N*-dimethylformamide (DMF) (20 h at 70 °C) in the presence of *p*-toluenesulfonic acid to give the 2″,3″-*O*-cyclohexylidene derivative (**1**) in 80% yield. Treatment of the acetal with acetic anhydride and pyridine gave the tetraacetyl derivative (**2**) in 98% yield. Decyclohexylidenation of **2** with 50% aqueous acetic acid followed by column chromatography on silica gel provided 6,3′,4′,5″-tetra-*O*-acetyl-1,3,2′,6′-tetra-*N*-(benzyloxycarbonyl)ribostamycin (**3**).

On the other hand, the synthesis of neosamine portion was carried out in the following manner. Our initial approach to the neosamine portion involved treatment of 2-(benzyloxycarbonylamino)-2-deoxy-α-D-glucopyranose[11] (**4**) with tosyl chloride in pyridine to give 2-(benzyloxycarbonylamino)-2-deoxy-6-*O*-tosyl-α-D-glucopyranose (**5**) in 51% yield. Displacement of the tosyl group of **5** with sodium azide in DMF gave 6-azido-2-(benzyloxycarbonylamino)-2,6-dideoxy-α-D-glucopyranose (**6**). Hydrolysis of **6** with 3 M (1 M= 1 mol dm^{-3}) aqueous hydrochloric acid followed by treatment with *p*-anisaldehyde in a mixture of 1 M aqueous sodium hydroxide solution and ethanol afforded 6-azido-2,6-dideoxy-2-(*p*-methoxybenzylideneamino)-β-D-glucopyranose (**7**). Acetylation with acetic anhydride in pyridine then gave 1,3,4-tri-*O*-acetyl-6-azido-2,6-dideoxy-2-(*p*-methoxybenzylideneamino)-β-D-glucopyranose (**8**). However, replacement of the anomeric acetoxyl group of **8** with bromine by treatment with hydrogen bromide in dichloromethane was unsuccessful and resulted in the formation of 1,3,4-tri-*O*-acetyl-6-bromo-2,6-dideoxy-2-(*p*-methoxybenzylideneamino)-β-D-glucopyranose (**9**), the azido group at C-6 being replaced by bromide.[12] A desired glycosyl halide, 3,4-di-*O*-acetyl-2-deoxy-2-(*p*-methoxybenzylideneamino)-6-*O*-tosyl-α-D-glucopyranosyl bromide (**11**), was successfully prepared by conversion of 1,3,4-tri-*O*-acetyl-2-deoxy-2-(*p*-methoxybenzylideneamino)-6-*O*-tosyl-β-D-glucopyranose[13] (**10**) by reaction with hydrogen bromide in dichloromethane (3 h at 0 °C) in 85% yield.



Condensation of the protected glycosyl halide (**11**) with **3** in anhydrous chloroform in the presence of silver carbonate, perchlorate, and Drierite afforded a mixture of condensation products containing the desired pseudo-tetrasaccharide as the main product. Hydrolysis of the Schiff base moiety of the mixture of condensation products at pH 2 in acetone–hydrochloric acid followed by treatment with benzyloxycarbonyl chloride in aqueous acetone in the presence of sodium carbonate and silica-gel chromatography afforde d6,3′,4′,5″,3‴,4‴-hexa-*O*-acetyl-1,3,2′,6′,2‴-penta-*N*-(benzyloxycarbonyl)-6‴-deamino-6‴-tosyl oxyneomycin C (**12**), a colorless solid, in 34% overall yield from **3**. Treatment of **12** with sodium azide in DMF gave the 6‴-azido derivative (**13**) in 85% yield. Finally, de-benzyloxycarbonylation of **13** by catalytic hydrogenolysis with palladium black followed by hydrolysis with 0.5 M barium hydroxide and purification by use of Sephadex C-25 (NH_4^+) completed the synthesis, giving neomycin C (**14**), identical with that obtained from natural source as judged by optical rotations, IR spectra, and ^{1}H-NMR and ^{13}C-NMR spectra. The antibiotic spectra and minimal inhibitory concentrations[1] of the synthetic **14** against test organisms were in agreement with those of natural neomycin C.



12 R^1=Cbz, R^2=Ac, R^3=OTs
13 R^1=Cbz, R^2=Ac, R^3=N_3
14 R^1=R^2=H, R^3=NH_2 (Neomycin C)

Experimental

Thin layer (TLC) and column chromatography were carried out on silica gel of Wakogel B-5 and Wakogel C-200 (Wako Pure Chemicals Co., Ltd., Osaka), and the spots on TLC were visualized with sulfuric acid. ^{1}H-NMR (PMR) spectra were recorded at 60, 90, and 100 MHz with Hitachi R-24, Varian EM-390, and Varian XL-100 spectrometers, respectively.

1,3,2′,6′-Tetra-N-*(benzyloxycarbonyl)-2″,3″*-O-*cyclohexylideneribostamycin (**1**).* To a solution of 1,3,2′,6′-tetra-*N*-(benzyloxycarbonyl)ribostamycin[10] (52 g) in dry DMF (520 ml) were added *p*-toluenesulfonic acid (0.9 g) and 1,1-dimethoxycyclohexane (15.1 g), and the mixture was stirred at 70 °C for 20 h. On TLC of silica gel with benzene–ethyl acetate (1:6), the starting material (R_f 0.01) almost disappeared, and the products of R_f 0.51 (major), R_f 0.89 (minor), and R_f 0.72 (minor) appeared. The solvent was evaporated to half volume, and then the solution was poured into a large amount of water. The resulting precipitate (56 g) was chromatographed on a column of silica gel (2 kg, 76×1040 mm) with benzene–ethyl acetate (1:6) to give a foamy solid, 45.1 g (80%), mp 119—120 °C, $[\alpha]_D^{20}$ +6° (*c* 1.0, chloroform); IR (KBr): 3400, 1700 (broad), and 1520 (broad) cm^{-1}.

Found: C, 61.95; H, 6.13; N, 4.98%. Calcd for $C_{55}H_{66}N_4O_{18}$: C, 61.67; H, 6.21; N, 5.23%.

NMR (in $CDCl_3$): δ 1.0—1.9 (10H m, cyclohexylidene), 5.10 (8H s, 4×COOC$\underline{H}_2C_6H_5$), 7.30 and 7.35 (each s, 20H in all, 4×COOC$H_2C_6\underline{H}_5$).

6,3′,4′,5″-Tetra-O-*acetyl-1,3,2′,6′-tetra*-N-*(benzyloxycarbonyl)-2″,3″*-O-*cyclohexylideneribostamycin (**2**).* To a solution of compound **1** (5 g) in dry pyridine (75 ml) was added acetic anhydride (20 ml), and the solution was allowed to stand at room temperature overnight. On TLC of silica gel with benzene–acetone (7:1), the starting material of R_f 0.01 disappeared, and the product of R_f 0.32 appeared. The mixture was poured into a large amount of water, and the resulting precipitate was filtered and dried to give a colorless solid, 5.7 g (98%), mp 101—102 °C, $[\alpha]_D^{21}$ +16.2° (*c* 1.54, chloroform); IR (KBr): 1740, 1520 cm^{-1}.

Found: C, 60.82; H, 5.92; N, 4.51%. Calcd for $C_{63}H_{74}N_4O_{22}$: C, 61.06; H, 6.02; N, 4.52%.

NMR (in $CDCl_3$): δ 1.0—2.5 (12H m, H_{ax}-2 and H_{eq}-2 and cyclohexylidene), 1.85 and 2.02 (each 6H s, 2×COCH_3) and 7.28 (20H s, 4×C$H_2C_6\underline{H}_5$).

6,3′,4′,5″-Tetra-O-*acetyl-1,3,2′,6′-tetra*-N-*(benzyloxycarbonyl)-ribostamycin (**3**).* Compound **2** (4 g) was dissolved in a hot 50% aqueous acetic acid (320 ml), and the solution was stirred at 80 °C for 12 h. On TLC of silica gel with benzene–acetone (2:1), the mixture showed five spots of R_f 0.82 (starting material, minor), 0.65 (minor), 0.47 (major), 0.32 (minor), and 0.23 (minor). The mixture was poured into a large amount of water, and the resulting precipitate was filtered. The solid was chromatographed on a column of silica gel (160 g, 28×500 mm) with benzene–acetone (2:1) to give a colorless solid, 1.38 g (35%), mp 102—103 °C, $[\alpha]_D^{20}$ +18° (*c* 1.39, chloroform); IR (KBr): 1720, 1620 cm^{-1}.

Found: C, 58.82; H, 5.69; N, 4.84%. Calcd for $C_{57}H_{66}O_{22}N_4$: C, 59.06; H, 5.74; N, 4.83%.

NMR (in $CDCl_3$): δ 1.87, 1.90, 1.94, and 2.00 (each 3H s, COC$\underline{H}_3$) and 7.28 (20H s, $CH_2C_6\underline{H}_5$).

*2-(Benzyloxycarbonylamino)-2-deoxy-6-*O-*tosyl-α-*D-*glucopyranose (**5**).* To a solution of 2-(benzyloxycarbonylamino)-2-deoxy-α-D-glucopyranose[11] (**4**) (4 g) in dry pyridine (80 ml) was added dropwise a solution of *p*-toluenesulfonyl chloride (2.8 g) in dry pyridine (80 ml) at −30 °C for 1.5 h. The solution was stirred at −20 °C for 18 h. On TLC of silica gel with benzene–acetone (2:1), the starting material (R_f 0.03) almost disappeared, and the product (R_f 0.4) appeared. After adding water (20 ml), evaporation of the solvent gave a light brown solid. The solid was chromatographed on a column of silica gel (250 g, 38×450 mm) with benzene–acetone (2:1) to give a colorless solid (3.8 g). Recrystallization from a mixture of benzene–acetone (2:1) afforded colorless crystals, 3.2 g (51%), mp 100—101 °C, $[\alpha]_D^{20}$ +47.6° (*c* 0.36, methanol); IR (KBr): 3400, 1680, 1520, 1170 cm^{-1}.

Found: C, 53.71; H, 5.29; N, 2.90; S, 6.99%. Calcd for $C_{21}H_{25}NO_9S$: C, 53.95; H, 5.39; N, 3.00; S, 6.86%.

NMR (in Py-d_5): δ 2.17 (3H s, $SO_2C_6H_4C\underline{H}_3$), 3.20 (2H s, C$\underline{H}_2C_6H_5$), 5.18 (1H d, *J* 3.5 Hz, H-1), 7.10 and 7.88 (4H ABq, *J* 9 Hz, $SO_2C_6\underline{H}_4CH_3$) and 7.21 (5H s, $CH_2C_6\underline{H}_5$).

*6-Azido-2-(benzyloxycarbonylamino)-2,6-dideoxy-α-D-glucopyranose (**6**).* Sodium azide (7.2 g) was added to a solution of **5** (14.4 g) in DMF (144 ml), and the solution was stirred at 135 °C for 20 min. On TLC of silica gel with benzene–acetone (2:1) the starting material (R_f 0.38) disappeared, and the product of R_f 0.34 (major) and 0.02 (trace) appeared. Evaporation of the solvent gave a solid which was separated into soluble and insoluble parts with dioxane. The soluble part was chromatographed on a column of silica gel (700 g, 80×200 mm) with benzene–acetone (1:1) to give a colorless solid (9.2 g). Recrystallization from a mixture of benzene–acetone (2:1) gave colorless crystals, 8.1 g (78%), mp 175—176 °C, $[\alpha]_D^{20}$ +60.9° (*c* 1.0, water–methanol (1:1)); IR (KBr): 3350 (sho), 2100, 1680, and 1545 cm^{-1}.

Found: C, 50.00; H, 5.41; N, 16.34%. Calcd for $C_{14}H_{18}N_4O_6$: C, 49.70; H, 5.36; N, 16.56%.

NMR (in Py-d_5 containing a small amount of D_2O): δ 5.15 (2H s, $C\underline{H}_2C_6H_5$), 5.7 (1H d, *J* 2 Hz, H-1), and 7.24 (5H s, $CH_2C_6\underline{H}_5$).

*6-Azido-2,6-dideoxy-2-(p-methoxybenzylideneamino)-β-D-glucopyranose (**7**).* Compound **6** (620 mg) was dissolved in 3 M hydrochloric acid (62 ml), and the solution was stirred at 90 °C for 3 h. Evaporation of the solvent and coevaporation with toluene gave a solid (458 mg). The solid was dissolved in 0.5 M aqueous sodium hydroxide (2.3 ml) in ethanol (0.45 ml), and *p*-anisaldehyde (0.3 ml) was added to the solution. The mixture was allowed to stand at room temperature for 30 min and then at 0 °C to give crystalline **7**, 260 mg (44%). Recrystallization from a mixture of acetone–methanol (1:2) gave colorless crystals, 190 mg (32%), mp 168—169 °C, $[\alpha]_D^{20}$ +32.6° (*c* 0.95, methanol); IR (KBr): 2100, 1640, 1610, and 1515 cm^{-1}.

Found: C, 52.54; H, 5.31; N, 17.05%. Calcd for $C_{14}H_{18}N_4O_5$: C, 52.17; H, 5.63; N, 17.38%.

NMR (in Py-d_5 containing a small amount of D_2O): δ 3.77 (3H s, $CHC_6H_4OC\underline{H}_3$), 5.67 (1H d, *J* 7.5 Hz, H-1), 6.95 and 7.95 (4H ABq, *J* 9 Hz, $CHC_6\underline{H}_4OCH_3$), and 8.75 (1H s, $N{=}C\underline{H}C_6H_4OCH_3$).

*1,3,4-Tri-O-acetyl-6-azido-2,6-dideoxy-2-(p-methoxybenzylideneamino)-β-D-glucopyranose (**8**).* To a solution of **7** (430 mg) in dry pyridine (5 ml) was added acetic anhydride (1.5 ml), and the solution was allowed to stand at room temperature overnight. The mixture was poured into 2% aqueous sodium hydrogencarbonate solution (70 ml), and the resulting precipitate was washed with water. Recrystallization from a mixture of ethanol–water (3:1) gave colorless crystals, 400 mg (67%), mp 115—116 °C, $[\alpha]_D^{20}$ +117.6° (*c* 1.43, chloroform); IR (KBr): 2100 and 1755 cm^{-1}.

NMR (in $CDCl_3$): δ 1.88, 2.03, and 2.05 (each 3H s, $COC\underline{H}_3$), 3.43 (1H t, *J* 9 Hz, H-2), 3.0—3.8 (2H m overlapped with OCH_3, $C\underline{H}_2N_3$), 3.86 (3H s, $-OCH_3$), 3.8—4.1 (1H m, H-5), 5.10 (1H t., *J* 9 Hz, H-4), 5.43 (1H t, *J* 9 Hz, H-3), 5.95 (1H d, *J* 9 Hz, H-1), 6.93 and 7.70 (4H ABq, $-N{=}CHC_6\underline{H}_4OCH_3$), and 8.20 (1H s, $-N{=}C\underline{H}C_6H_4OCH_3$).

*1,3,4-Tri-O-acetyl-6-bromo-2,6-dideoxy-2-(p-methoxybenzylideneamino)-β-D-glucopyranose (**9**).* A solution of **8** (100 mg) in dry dichloromethane (5 ml) was saturated with dry hydrogen bromide at −20 °C (about 2 min). Evaporation of the solvent gave a syrup, which was solidified with hexane and washed three times with a mixture of dry ether and dry hexane (4:1). The solid was dissolved in chloroform (20 ml), and the solution was washed several times with phosphate buffer solution (KH_2PO_4–Na_2HPO_4, pH 6.8) and water, and dried (Na_2SO_4). Evaporation of the solvent gave a colorless syrup which was crystallized from a mixture of chloroform, ether and hexane (1:5:20) to give colorless crystals, 50 mg (46%), mp 151—152 °C, $[\alpha]_D^{20}$ +96.8° (*c* 0.67, chloroform); IR (KBr): 1760 cm^{-1}.

Found: C, 49.22; H, 5.07; N, 2.91; Br, 16.45%. Calcd for $C_{20}H_{24}NO_8Br$: C, 49.37; H, 4.98; N, 2.88; Br, 16.44%.

NMR (in $CDCl_3$): δ 1.90, 2.03, and 2.08 (each 3H s, $COC\underline{H}_3$), 3.87 (3H s, $OC\underline{H}_3$), 5.14 (1H t, *J* 9 Hz, H-4), 5.43 (3H t, *J* 9 Hz, H-3), 5.98 (1H d, *J* 9 Hz, H-1), 6.93 and 7.70 (4H ABq, *J* 9 Hz, $N{=}CHC_6\underline{H}_4OCH_3$), and 8.20 (1H s, $N{=}C\underline{H}C_6H_4OCH_3$).

*3,4-Di-O-acetyl-2-deoxy-2-(p-methoxybenzylideneamino)-6-O-tosyl-α-D-glucopyranosyl Bromide (**11**).* A solution of **10** (5 g) in dichloromethane was saturated with anhydrous hydrogen bromide at 0 °C and allowed to stand at 0 °C for 3 h. Evaporation of the solvent gave a syrup, which was solidified with hexane and washed several times with hexane. A chloroform solution of the solid was washed with 1% aqueous sodium hydrogencarbonate solution (pH 7) and several times with phosphate buffer solution (KH_2PO_4–Na_2HPO_4, pH 6.8), dried (Na_2SO_4) and filtered. Evaporation of the filtrate gave a colorless syrup, 4.5 g (85%).

NMR (in $CDCl_3$): δ 1.83, 1.95, and 2.43 (each 3H s, $COC\underline{H}_3$), 3.43 (1H q, *J* 4.5 and 9 Hz, H-2), 3.85 (3H s, OCH_3), 4.17 (2H d, *J* 3.9 Hz, H-6), 5.13 (1H t, *J* 9 Hz, H-4), 5.57 (1H t, *J* 9 Hz, H-3), 6.15 (1H d, *J* 4.5 Hz, H-1), 6.90 and 7.68 (4H ABq, *J* 9 Hz, $N{=}CHC_6\underline{H}_4OCH_3$), 7.35 and 7.82 (4H ABq, *J* 9 Hz, $SO_2C_6\underline{H}_4CH_3$) and 8.27 (1H s, $N{=}C\underline{H}C_6H_4OCH_3$).

*6,3',4',5'',3''',4'''-Hexa-O-acetyl-1,3,2',6',2'''-penta-N-(benzyloxycarbonyl)-6'''-deamino-6'''-tosyloxyneomycin C (**12**).* A mixture of **3** (1.1 g), newly prepared Ag_2CO_3 (4 g) and Drierite (10 g) in dry chloroform was stirred at room temperature for 20 h in the dark. To the mixture was added a solution of **11** (1.8 g) in dry chloroform (20 ml) and then $AgClO_4$ under vigorous stirring. The mixture was stirred at room temperature for 20 h. On TLC of silica gel with benzene–acetone (3:1), the mixture showed four products of R_f 0.45, 0.40, 0.37, and 0.32 and some by-products. The insoluble matter was filtered, and the filtrate was thoroughly washed with chloroform. The filtrate and washings were combined, washed with three portions of 2% aqueous sodium hydrogencarbonate (20 ml), then dried (Na_2SO_4). The solution was evaporated to a syrup (2.8 g). The starting materials and by-products were removed by a short column of silica gel (120 g, 34×250 mm) with benzene–acetone (3:1). The crude product (1.7 g) thus obtained was dissolved in acetone (5 ml), and a small amount of 1 M hydrochloric acid was added to the mixture (pH 2). To the mixture was added a large amount of ether, and the resulting oily precipitate was triturated with five portions of ether (10 ml). The oil (1.5 g) was suspended in a mixture of acetone (20 ml) and water (15 ml). After adjustment of pH of the mixture with Na_2CO_3 to pH 7, Na_2CO_3 (150 mg) was added to the mixture, and then benzyloxycarbonyl chloride (0.25 ml) was added at room temperature under vigorous stirring and stirred at room temperature for 20 h. On TLC of silica gel with benzene–acetone (4:1), the mixture showed four products of R_f 0.23 (major), 0.26 (minor), 0.34 (minor), and 0.36 (minor). The insoluble matter was filtered, and the residue was washed with chloroform. The filtrate and washings were combined, and the solvent was evaporated to syrup, which was dissolved in chloroform (300 ml). The chloroform solution was washed with three portions of water (20 ml), dried (Na_2SO_4) and evaporated. The syrup (1.4 g) was chromatographed on a column of silica gel (120 g, 27×450 mm) with benzene–acetone (5:1) to give **12**, a colorless foamy solid, 555 mg (34%), mp 104—105 °C, $[\alpha]_D^{20}$ +42.2° (*c* 0.97, chloroform); IR (KBr): 3400, 1740, 1530, and 1180

cm^{-1}.

Found: C, 57.94; H, 5.56; N, 3.89; S, 2.03%. Calcd for $C_{82}H_{93}N_5O_{32}S$: C, 58.17; H, 5.54; N, 4.14; S, 1.89%.

NMR (in $CDCl_3$): δ 1.7—2.2 (18H m, $6\times COOCH_3$), 2.47 (3H s, $SO_2C_6H_4C\underline{H}_3$), 7.40 and 7.43 (10H and 15H s, respectively, $5\times CH_2C_6\underline{H}_5$), 7.77 and 7.87 (2H q, J 2 and 8 Hz, two protons of $SO_2C_6\underline{H}_4CH_3$(?)).

*6,3',4',5'',3''',4'''-Hexa-O-acetyl-6'''-azido-1,3,2',6',2'''-penta-N-(benzyloxycarbonyl)-6'''-deamino-neomycin C (**13**).* To a solution of **12** (440 mg) in dry DMF (7 ml) was added sodium azido (NaN_3, 85 mg), and the mixture was stirred at 130 °C for 15 min. On TLC of silica gel with benzene–acetone (2:1), the mixture showed two products of R_f 0.59 (major) and 0.56 (trace). Evaporation of the solvent gave a light brown solid, which was dissolved in chloroform (50 ml). The chloroform solution was washed with two portions of saturated aqueous sodium chloride (10 ml) and two portions of water (10 ml), and dried. The solvent was evaporated to give a syrup, which was chromatographed on a column of silica gel (18 g, 10×540 mm) with benzene–acetone (4:1) to give a colorless foamy solid, 350 mg (85%), $[\alpha]_D^{20}$ +64.4° (c 0.71, acetone); IR (KBr): 3400, 2100, 1740, and 1520 cm^{-1}.

Found: C, 57.46; H, 5.50; N, 7.06%. Calcd for $C_{75}H_{86}N_8O_{29}$: C, 57.61; H, 5.54; N, 7.17%.

NMR (in $CDCl_3$): δ 1.7—2.1 (18H m, $6\times COOCH_3$), 7.40 and 7.42 (15H and 10H s, $5\times COOCH_2C_6\underline{H}_5$).

*Neomycin C (**14**).* The compound **13** was hydrogenated over palladium black in a mixture of dioxane (12 ml), water (4 ml), and acetic acid (0.4 ml) at room temperature under 4 kg/cm^2 pressure of hydrogen for 14 h. After removal of the catalyst, the solution was evaporated to dryness *in vacuo*. The solid was dissolved in a hot 0.5 M aqueous barium hydroxide ($Ba(OH)_2$) (6 ml), and the mixture was stirred at 95 °C for 5 h. To the solution was introduced carbon dioxide, and the resulting precipitates were removed by centrifugation. The supernatant was evaporated to give a colorless solid (150 mg), which was chromatographed on a column of CM Sephadex C-25 (NH_4^+) (30 ml, 10×400 mm). After washing with water (40 ml), the column was eluted with an aqueous ammonia by the linear gradient from 0.0 to 0.3 M to give a colorless solid of neomycin C, 75 mg (61%), hydrochloride: $[\alpha]_D^{20}$ +78° (c 0.86, water); IR (KBr): 3400 (broad), 2950 (broad), 1980 (broad), 1600, 1500, 1030 (sh) cm^{-1}.

NMR (in D_2O): δ 5.52 (1H d, J 3.5 Hz, H-1'''), 5.88 (1H d, J 1 Hz, H-1''), and 5.94 (1H d, J 3 Hz, H-1').

^{13}C NMR (in D_2O): δ 36.4, 42.4, 42.5, 51.1 (2 carbons), 55.9, 56.3, 62.4, 72.2 (2 carbons), 73.98 (4 carbons), 74.5, 75.5, 78.4, 81.7, 82.8, 85.2, 99.7 ($C_{1'}$ and $C_{1'''}$), and 109.45 ($C_{1''}$).

The authors would like to acknowledge stimulating discussions with Professor H. Umezawa, the Institute of Microbial Chemistry. The authors also thank Dr. H. Naganawa for ^{13}C NMR measurements.

Photochemical Ethoxycarbonylation, Formylation, and Ethoxymethylation of Ruthenocene in Ruthenocene–Polychloromethane–Ethanol Systems

Akira Sugimori,* Masaru Matsui, Takeo Akiyama, and Masatsugu Kajitani

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioi-cho 7-1, Chiyoda-ku, Tokyo 102

(Received March 6, 1980)

Similar to ferrocene the UV-irradiation of ruthenocene–polychloromethane–ethanol systems brings about substitution (ethoxycarbonylation for CCl_4, formylation for $CHCl_3$, and ethoxymethylation for CH_2Cl_2) and oxidation. When $CHCl_3$ and CH_2Cl_2 are used, substitution is dominant. In the irradiation of ruthenocene–CCl_4–ethanol system, $[Ru(C_5H_5)_2]^+[RuCl_4]^-$ and cyclopentenes substituted by chlorine and trichloromethyl are obtained. The excitation of the CT-complex between ruthenocene and polychloromethane initiates the reaction.

We have reported the photochemical substitution (ethoxycarbonylation, formylation, ethoxymethylation, and alkylation) in ferrocene–halogenated hydrocarbon–ethanol systems.[1] As to ruthenocene, a ferrocene analog, photochemical oxidation to ruthenocenium ions has been reported.[2,3] However, in these studies the photoreactions of ruthenocene in halogenated hydrocarbon–(alcohol) solutions have been studied mainly on the basis of UV- and visible spectral changes and the product analysis has not been done completely. We report here that the UV-irradiation of ruthenocene–polychloromethane–ethanol systems brings about the substitution similar to that of ferrocene in addition to the oxidation of ruthenocene.

Experimental

Materials. Ruthenocene(**1**) was synthesized from $RuCl_3$ and cyclopentadiene according to Pertici *et al.*[4] mp 198—199 °C.

UV-irradiation. A solution of ruthenocene (4×10^{-2} mol dm^{-3}) in polychloromethane–ethanol (1:1 v/v, 40 cm^3) in a quartz vessel was deaerated by the freeze-thaw method using a vacuum system. The solution was irradiated either with a low pressure or with a high pressure mercury lamp.

Photoproducts. During the irradiation of ruthenocene–CCl_4–ethanol system, a brown precipitate was formed. Other systems gave no precipitate. After the precipitate was filtered, the solvent was distilled off. The residue was extracted with benzene and the products were separated by means of TLC (on silica gel of Merck GF_{254}; developing solvent, benzene).

Ruthenocenium tetrachlororuthenate(III) was identified by the comparison of UV- and IR-spectra with those reported by Traverso *et al.*[2] (Found: C, 25.84; H, 2.64%).

*Ethyl Ruthenocenecarboxylate (**2a**)*[5]: Brownish yellow crystal; mp 77.5—79 °C; IR(KBr disk) 3110, 2960 (C–H), 1690 (C=O), 1130 (ester C–O), 1100 and 995 cm^{-1} (C–H deformation of C_5H_5 ring); NMR (CCl_4) δ=5.01 (2H, t, J=2.0 Hz, ring H at α-position), 4.59 (2H, t, J=2.0 Hz, ring H at β-position), 4.52 (5H, s, H at unsubstituted ring), 4.13 (2H, q, J=7.0 Hz, CH_2), and 1.27 (3H, t, J=7.0 Hz, CH_3); MS (70 eV), *m/e* (rel intensity), 306(56), 304(100), 303(56), 302(42), 301(38) (M^+); 278(38), 276(68), 275(37), 274(28), 273(27) ($(M-C_2H_4)^+$); 234(22), 233(19), 232(40), 231(48), 230(31), 229(29), 228(16) ($(M-COOC_2H_5)^+$ and $(M-COOC_2H_5+H)^+$); 169(18), 167(30), 166(19), 165(15), 164(14) ($(RuC_5H_5)^+$).

A mixture of chlorinated hydrocarbons was obtained. By means of TLC technique it could not be separated completely. However, by the consideration of the results of GC-MS and NMR spectra, two major components were assigned to 3,4,5-tris(trichloromethyl)cyclopentene and 4-chloro-3,5-bis(trichloromethyl)cyclopentene.

3,4,5-Tris(trichloromethyl)cyclopentene. NMR(CCl_4) δ= 6.14 (2H, s, olefinic), 4.03 (2H, d, H=2.0 Hz, H at 3- and 5-position), 3.66 (1H, t, J=2.0 Hz, H at 4-position); MS (20 eV), *m/e* (rel intensity), 350(6), 348(9), 346(9), 344(4) ($(M-2HCl)^+$); 303(31), 301(39), 299(20) ($(M-CCl_3)^+$); 269(20), 267(58), 265(91), 263(54) ($(M-HCl-CCl_3)^+$); 233 (11), 231(31), 229(43), 227(27) ($(M-2HCl-CCl_3)^+$); 185 (6), 183(16), 181(19) ($(M-H-2CCl_3)^+$); 149(6), 147(12), 145(18), 143(16) ($(M-HCl-H-2CCl_3)^+$); 121(15), 119 (48), 117(50) ($(CCl_3)^+$); 113(12), 111(66), 109(100) ($(M-2HCl-H-2CCl_3)^+$).

4-Chloro-3,5-bis(trichloromethyl)cyclopentene. a) LP, Low pressure mercury lamp; HP, High pressure mercury lamp. b) Yield was measured by means of TLC and is based on the quantity of ruthenocene consumed.

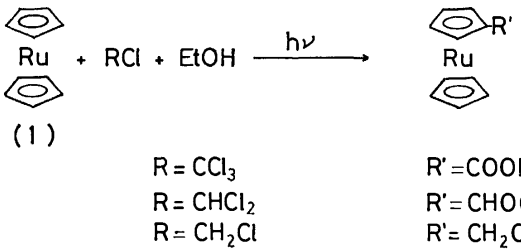
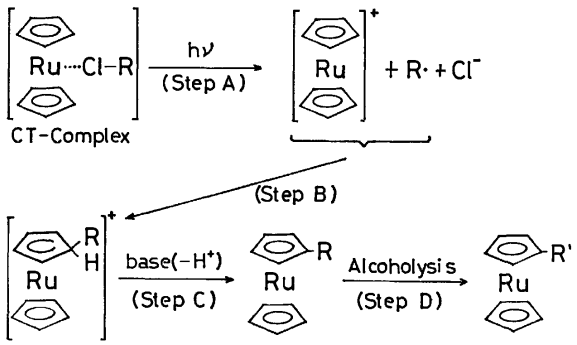
Results and Discussion

Similar to ferrocene (**3**), ruthenocene (**1**) undergoes photochemical substitution, accompanying oxidation.





Scheme 1. Mechanism of photo-substitution.

The type of the photo-substitution in ruthenocene–polychloromethane–ethanol systems is the same as that in ferrocene–polychloromethane–ethanol systems. The yields of the products under various irradiation conditions are shown in Table 1. Formylation in $CHCl_3$–EtOH and ethoxymethylation in CH_2Cl_2–EtOH occur effectively by UV-irradiation. In these reactions the color change that indicates the formation of ruthenocenium tetrachlororuthenate(III) (**4**), an oxidation product, was not observed. On the other hand, the photoreaction of the **1**–CCl_4–EtOH system shows a feature different from that of the **3**–CCl_4–EtOH system: UV-irradiation of ferrocene in a CCl_4–EtOH solution gives effectively the ethoxycarbonylation product, whereas that of ruthenocene gives a small amount of ethyl ruthenocenecarboxylate (**2a**) and considerable amounts of ruthenocenium tetrachlororuthenate(III) and cyclopentenes substituted by chlorine and trichloromethyl group ($C_5H_5Cl(CCl_3)_2$, $C_5H_5(CCl_3)_3$ *etc.*). Under the assumption that the average molecular weight of the cyclopentenes with chlorine and trichloromethyl is 338 (the molecular weight of $C_5H_5Cl(CCl_3)_2$), the yields of the halogenated compounds are estimated to be 40 and 34% for the irradiation with a low pressure mercury lamp and that with a high pressure mercury lamp, respectively.

In the ruthenocene–polychloromethane–ethanol systems the irradiation with a low pressure mercury lamp (with shorter wavelength light) gives higher yields of the substitution products than that with a high pressure mercury lamp (with longer wavelength light) except for the **1**–CCl_4–EtOH system. The light of wavelength longer than 300 nm (pyrex-filtered light) was almost ineffective for the photo-substitution.

Similar to ferrocene, ruthenocene forms charge transfer complexes with halogenated hydrocarbons.[2,3] This fact and the similarity of the photoreactions of ruthenocene to those of ferrocene suggest the mechanism shown in Scheme 1.

The factors which determine the effectiveness of the photo-substitution are: 1) the efficiency of photo-induced electron transfer in the CT-complex between metallocene and polychloromethane (Step A), 2) the reactivity of metallocenium ions with polychloromethyl radicals (Step B), 3) the elimination of H^+ (Step C), and 4) the effectiveness of alcoholysis of chlorine on the side chain (Step D).

The fact that the CT-absorption bands are situated around 280 nm (CTTS-band for ruthenocene–CCl_4, 285 nm)[2,3] can explain the wavelength dependence of the photoreactions.

A remarkable difference between the photoreactions of the **1**–CCl_4–EtOH system and those of the **3**–CCl_4–EtOH system is the low yield of the photo-ethoxycar-

bonylated product for ruthenocene. This difference might be ascribed to the difference in the efficiencies of Step A: the CT-complex between **1** and CCl_4 is expected to be less stable than that between **3** and CCl_4 because of the higher ionization potential of **1** (I_p for ruthenocene, 7.45 eV; I_p for ferrocene, 6.88 eV[7]). However, the association constant for the CT-complex between **1** and CCl_4 was estimated to be similar to that for the complex between **3** and CCl_4 (association constant; for **1**–CCl_4, 0.012 $dm^3\,mol^{-1}$; for **3**–CCl_4, 0.015 $dm^3\,mol^{-1}$).[3] Moreover, the less stable CT-complexes of **1**–$CHCl_3$ and **1**–CH_2Cl_2 give the substitution products in good yields. These facts indicate that the low efficiency of the photo-ethoxycarbonylation in the **1**–CCl_4–EtOH system can not be ascribed to the efficiency of Step A.

Step D is not the controlling step. It has been reported that the solvolysis rate at the carbon atom attached to ruthenocenyl group is greater than that at the carbon atom attached to ferrocenyl group.[8]

The low yield of the ester in the photoreaction of the **1**–CCl_4–EtOH system accompanies the formation of ruthenocenium tetrachlororuthenate(III) and cyclopentenes substituted by chlorine and trichloromethyl. The cyclopentene derivatives are composed mainly of $C_5H_5Cl(CCl_3)_2$ and $C_5H_5(CCl_3)_3$. This result suggests that the decomposition competes with Step C. If the decomposition occurs after the elimination of H^+, the decomposition products of the type $C_5H_4Cl_n(CCl_3)_{4-n}$ should be obtained.

The cationic intermediate formed by the addition of trichloromethyl to metallocenium ions would be destabilized owing to the electron attraction of the trichloromethyl group and would undergo the decomposition. The destabilization would be greater for the more electronegative ruthenium compound than for the iron compound.

The authors are very grateful to the Shimadzu Corporation and Professor Shigeo Nishimura of Tokyo University of Agriculture and Technology for the GC-MS measurements and to Mr. Susumu Kumon of Shin-nihon Jitsugyo Co. for the MS measurements.

Catalysis of the Hydrolysis of *p*-Nitrophenyl 1-Adamantaneacetate by Cyclodextrins

Makoto KOMIYAMA* and Shohei INOUE

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received March 6, 1980)

The cleavage of *p*-nitrophenyl 1-adamantaneacetate was accelerated by β- and γ-cyclodextrins, which was in contrast with their deceleration of the cleavage of a sterically analogous substrate, *p*-nitrophenyl 1-adamantanecarboxylate. The presence and absence of a methylene group in these substrates absolutely governed the directions of the rate effects of the cyclodextrins. The specificity, explicitly showing that cyclodextrins are quite good models of enzymes, was attributed to the difference of the structures of the inclusion complexes of cyclodextrins with these substrates.

Recently cyclodextrins (CDs) have been often used as an enzyme model. One of the important reasons for the increasing attention to CDs is the complex formation of these oligosaccharides with the substrates prior to their catalytic functions. Thus, the stereochemistry in the complex formation can result in the specificities in the subsequent reactions, which is similar to enzymatic reactions.[1]

This paper describes a strict specificity in the catalyses by CDs. It will be shown that the cleavage of *p*-nitrophenyl 1-adamantaneacetate (**1**) is accelerated by β- and γ-cyclodextrins (β- and γ-CDs), in spite of the retardation of the cleavage of sterically a quite analogous substrate, *p*-nitrophenyl 1-adamantanecarboxylate (**2**) by CDs.[2] The mechanism of the CD-catalyzed hydrolysis of **1** is kinetically examined. Furthermore, the difference in the effects of CDs on these two analogous substrates will be discussed in terms of the structures of the CD-substrate complexes by use of the results of absorption spectrometry.

Experimental

Materials. **1** was synthesized from 1-adamantaneacetic acid and *p*-nitrophenol by use of dicyclohexylcarbodiimide as the dehydration reagent and was purified by the recrystallization from ethanol; mp 114.0—114.5 °C; Found; C, 68.35; H, 6.75; N, 4.43%. Calcd for $C_{18}H_{21}NO_4$; C, 68.54; H, 6.72; N, 4.44%. Synthesis of **2** and its characterization were described in the previous paper.[2] α-Cyclodextrin (α-CD) and β-CD were purified by the recrystallization from water. γ-CD was purchased from Nakarai Chemical Co. and was used without further purification. The 0.1 mol dm^{-3} NaOH and NaOD solutions had the factors of 1.00± 0.01 as shown by the titration with 0.1 mol dm^{-3} HCl standard solution.

Kinetics. Hydrolysis of **1** was carried out at 16 °C mostly in the 66:34 (v/v) mixture of 0.1 mol dm^{-3} NaOH aqueous solution and acetonitrile. The reaction was initiated by the addition of 30 μl stock solution of **1** in acetonitrile to the mixture of 2 ml 0.1 mol dm^{-3} NaOH aqueous solution and 1 ml acetonitrile. The initial concentration of **1** was approximately 2×10^{-5} mol dm^{-3}, and the cleavage was followed at 410 nm by the appearance of *p*-nitrophenol.

The cleavage of **1** was also examined in the 99:1 (v/v) mixture of 0.1 mol dm^{-3} NaOH aqueous solution and acetonitrile, which was prepared by the addition of 30 μl stock solution in acetonitrile to 3 ml 0.1 mol dm^{-3} NaOH aqueous solution. In this case, the initial concentration of **1** was kept as low as 5×10^{-6} mol dm^{-3}, because of the poor solubility of **1** in aqueous solution.

Absorption Spectrometry. Absorption spectra were measured at 16 °C in the 66:34 (v/v) mixture prepared similarly as described in the Kinetics section. The initial concentrations of **1** and **2** were 10^{-4} mol dm^{-3}, and that of β-CD was 3×10^{-2} mol dm^{-3}. The absorbance at a specific wavelength was determined by the extrapolation of the absorbance-time dependence to the time of the mixing (the addition of the stock solution).

Product Analyses. The reactions were initiated by the addition of 23 mg of **1** (or 22 mg of **2**) in 2 ml acetonitrile to 4 ml of 0.1 mol dm^{-3} NaOH aqueous solution containing 51 mg of β-CD. The values of $[\beta\text{-CD}]_0$, $[\mathbf{1}]_0$, and $[\mathbf{2}]_0$ were 7.5×10^{-3}, 1.2×10^{-2}, and 1.2×10^{-2} mol dm^{-3}. Considering the K_d's of the β-CD–**1** and β-CD–**2** complexes in the 66:34 mixture shown in Table 1, about 77 and 61% of β-CD in the reaction solutions should form complexes with **1** and **2**, respectively. After 16 s for **1** and 500 s for **2** (the one half-life calculated from k_c's), the reactions were stopped by the addition of a small amount of 1 mol dm^{-3} HCl solution, followed by the extraction with 6 ml ether. The aqueous layer was dried *in vacuo* and the resulting white powder was analyzed by infrared spectrometry.

Results

Figure 1 shows the dependence of the rate constant of the cleavage of **1** (k_{obsd}) on the initial concentrations of CDs ($[CD]_0$). Obviously, both β- and γ-CDs showed acceleration effects of the cleavage of **1**. The data in Fig. 1 were analyzed according to Eq. 1, which is based on the scheme involving the complex formation of CDs with **1** prior to the chemical transformation:

$$(k_{obsd}-k_{un}) = -K_d(k_{obsd}-k_{un})/[CD]_0 + (k_c-k_{un}). \quad (1)$$

Here, k_{un} and k_c are the rate constant of the cleavage of **1** in the absence of CDs and that of **1** incorporated in the CD–**1** complex, respectively, and K_d is the equilibrium constant of the dissociation of the CD–**1** complex.[1]

As shown in Fig. 2, the plots of $(k_{obsd}-k_{un})$ *vs.* $(k_{obsd}-$

k_{un})/[CD]$_0$ exhibited straight lines, from the slopes and the intercepts of which k_c and K_d were determined.

Table 1 lists the values of k_c and K_d for the CD-catalyzed cleavage of **1**. For the purpose of comparison, the values for the cleavage of an analogous substrate, **2**, determined in the previous paper,[2] are also shown.

β- and γ-CDs showed 3.0 and 2.1 fold *acceleration* of the cleavage of **1** in the 66:34 mixture of 0.1 mol dm^{-3} NaOH aqueous solution and acetonitrile, which is in contrast with the 3.3 and 1.4 fold *deceleration* of the cleavage of **2** by β- and γ-CDs. Still larger difference in the rate effects by CDs was found in the cleavages of **1** and **2** in the 99:1 mixture. Thus, the cleavage of **1** was *accelerated* by 1.8 and 1.7 fold by β- and γ-CDs, whereas the cleavage of **2** was *decelerated* by 28 and 13 fold by β- and γ-CDs. However, the effect of α-CD on the cleavages of **1** and **2** was much smaller.

Table 2 shows the D_2O solvent isotope effects on k_c and k_{un} in the 66:34 mixture. k_c's for **1** and **2** in the 66:34 D_2O–acetonitrile mixture were found to be 1.1—1.2 times those in the H_2O–acetonitrile mixture. These results indicated that the cleavages of **1** and **2** incorporated in the CD complexes proceed *via* nucleophilic catalysis by hydroxide ion, since the nucleophilicity of OD^- is 20—40% larger than that of OH^-.[3] Larger nucleophilicity of OD^- than OH^- in the present reactions is definitely shown by the 1.1 fold larger values of k_{un}'s in the D_2O–acetonitrile mixture than those in the H_2O–acetonitrile mixture.

Nucleophilic attack by hydroxide ion indicated above for the CD-accelerated cleavage of **1** and the CD-decelerated cleavage of **2** was supported by the product analyses. After the reactions of β-CD with excess amounts of **1** and **2** (see Experimental), essentially

a) In a 66:34 mixture of 0.1 mol dm^{-3} NaOH H_2O solution (or 0.1 mol dm^{-3} NaOD D_2O solution) and acetonitrile. b) The k_{obsd}'s in the presence of 3×10^{-2} mol dm^{-3} CDs were taken as k_c's here. See the footnote d of Table 1.

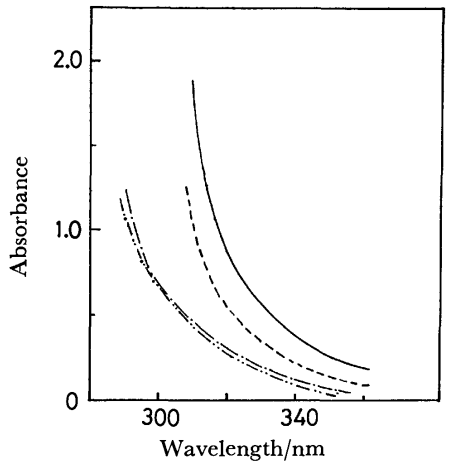

Fig. 3. Absorption spectra of **1** and **2** in the presence and absence of β-CD; —·—, **1**+β-CD; —··—, **1** only; ——, **2**+β-CD; ----, **2** only; [β-CD]=3×10^{-2} and [**1**]=[**2**]=10^{-4} mol dm^{-3} in the 66:34 mixture of 0.1 mol dm^{-3} NaOH aqueous solution and acetonitrile.

all of β-CD was recovered in its intact form as characterized by infrared spectrometry. No carbonyl stretching band due to the β-CD ester of 1-adamantanecarboxylic acid or 1-adamantaneacetic acid, the possible intermediate of nucleophilic catalysis by β-CD, was detected at all. At least some of these intermediates should be trapped by the present procedure (after one half-life of the substrates), if the reaction were involving the nucleophilic attack by β-CD, since the rates of the hydrolyses of the intermediates, which have rather poor leaving groups of pK_a 12 (β-CD),[1] should be smaller than those of **1** and **2**, which have good leaving groups of pK_a 7.1 (*p*-nitrophenol).[4] These arguments are supported by the fact that the rate constant of the alkaline hydrolysis of *p*-nitrophenyl acetate is five fold larger than that of trifluoroethyl acetate, the pK_a of the leaving group of which (12.4) is similar to that of β-CD,[4] and the rate constant of the alkaline hydrolysis of α-CD ester of *p*-nitrobenzoic acid ester is about two fold larger than that of its trifluoroethyl ester.[5]

Figure 3 shows the change in the absorption spectra of **1** and **2** due to the addition of 3×10^{-2} mol dm^{-3} β-CD. Almost all of **1** and **2** should form complexes with β-CD under the present conditions considering the K_d values shown in Table 1. Considerable change was found in the 300—360 nm region in the case of **2**, whereas much smaller change, if any, was observed in the case of **1**. These results indicated that the *p*-nitrophenyl portion of **2** is included in the cavity of β-CD to a greater extent than that of **1** is, since the change of absorption spectrum of *p*-nitrophenol on the complex formation with CDs was well known.[1] The change in the molar absorption coefficient observed for the complex formation between **2** and β-CD is a little bit smaller than the value reported for the complex formation between *p*-nitrophenol and α-CD (2.9×10^3 at 354 nm).[6]

Discussion

This paper shows that catalyses by CDs are quite specific, which is characteristic of enzymatic catalyses. β-CD and γ-CD showed deceleration of the cleavage of **2**, whereas they showed acceleration of the cleavage of **1**. Thus, the presence or absence of a methylene group in the substrate predominantly governs the catalyses by CDs. There have been few reports showing the different directions of the rate effects of CDs on the reactions of analogous substrates,[7] although the magnitudes of the rate effects of CDs (in the same directions) were in some cases strongly dependent on the structures of the substrates.[8] The specificity observed here may be associated with the specific catalysis by β-CD for the selective preparation of vitamin K analogs.[9]

In the previous paper,[2] the deceleration of the alkaline hydrolysis of **2** by β- and γ-CDs was attributed to the steric hindrance by the wall of CDs as well as the electrostatic repulsion between the negative charges of the secondary alkoxide anions of CDs and that of hydroxide ion. The steric hindrance was so important in the hydrolysis of **2** because the adamantyl portion and the carbonyl group are located in a close proximity. Therefore, both of them should be included in the cavity. In the hydrolysis of **1**, however, the methylene group between the adamantyl group and the carbonyl group makes it possible for the carbonyl group to be kept outside the cavity, when the apolar adamantyl group is included in the cavity. Thus, the steric and electrostatic hindrance by CDs is not operative so much in the hydrolysis of **1**.

Absorption spectrometry shown in Fig. 3 is consistent with the above arguments. The *p*-nitrophenyl group of **2**, which is adjacent to the adamantyl group, is partly located inside the cavity (the considerable change in the absorption spectrum), whereas that of **1**, which is located at a larger distance from the adamantyl group, is hardly included in the cavity (the negligible change in the absorption spectrum).

The acceleration of the cleavage of **1** by β- and γ-CDs, which proceeds *via* nucleophilic catalysis by hydroxide ion, is probably attributed to the functions of the primary hydroxyl group(s) of CDs. It is difficult to figure out any mechanism where the secondary hydroxyl groups, which are present in their anionic forms under the present conditions, accelerate the alkaline reactions. Rather, the electrostatic repulsion between the secondary alkoxide anion and hydroxide ion should retard the reactions. The primary hydroxyl group(s) of CDs can alter the microscopic surroundings of the ester group, resulting in the acceleration of the attack by hydroxide ion. Alternatively, the hydrogen bonding of the primary hydroxyl group(s) with the substrate in the transition state can facilitate the alkaline reaction.[10–13] In the hydrolysis of **2**, however, the attack of the hydroxide ion at the carbonyl carbon atom as well as the assistance of the primary hydroxyl groups described above should be unfavorable, since the carbonyl carbon atom is deeply included in the cavity of CDs.

The magnitude of the acceleration of the cleavage of **1** by β- and γ-CDs in the 66:34 mixture of 0.1 mol dm^{-3} NaOH aqueous solution and acetonitrile was larger than that in the 99:1 mixture. This result

is probably associated with the shallower inclusion of the carbonyl carbon atom of **1** in the cavity in the 66:34 mixture than in the 99:1 mixture, resulting in the more efficient nucleophilic attack by hydroxide ion assisted by the primary hydroxyl groups of CDs. This interpretation is supported by the fact that the magnitude of the effect of the deceleration of the cleavage of **2** by CDs was much larger in the 99:1 mixture than in the 66:34 mixture. Here, the shallower inclusion of the carbonyl carbon atom of **2** should enhance the alkaline reaction.

In conclusion, cyclodextrins showed marked specificity in the hydrolyses of analogous substrates, *p*-nitrophenyl 1-adamantaneacetate (acceleration) and *p*-nitrophenyl 1-adamantanecarboxylate (deceleration). This specificity is similar to that of the enzymatic reactions. Present finding confirmed that CDs are quite good models of enzymes.

Substituent Effects in Heterogeneous Catalysis. VII. Temperature Independence of the Relative Rates in Metal-catalyzed Hydrogenation of Cyclohexanone and Its 2-Alkyl Derivatives

Teiji CHIHARA and Kazunori TANAKA*

The Institute of Physical and Chemical Research, Wako, Saitama 351

(Received March 8, 1980)

The rates of hydrogenation of cyclohexanone and its 2-alkyl derivatives have been measured using decalin as the solvent in a temperature range of −5 to 68 °C over Ru/Al_2O_3, Rh/Al_2O_3, and Pt/Al_2O_3 catalysts. As predicted previously, 2-methyl-, 2-ethyl-, and 2-propylcyclohexanone have exhibited nearly identical temperature dependencies in adsorption and hydrogenation, while cyclohexanone and 2-isopropylcyclohexanone had quite different dependencies.

This is a continuation of our series of studies concerning the effects of alkyl substitution in cyclohexanone (**1**) hydrogenation catalyzed by platinum metals. Three recent papers[1-3] have dealt with **1** and its 2-alkyl derivatives, *i.e.*, 2-methyl-, 2-ethyl-, 2-propyl-, 2-isopropyl-, and 2-*t*-butylcyclohexanone (abbreviated to **2m**, **2e**, **2p**, **2ip**, **2tb**, respectively). The activity sequence for hydrogenation of each of the individual ketones is

$$\mathbf{1} > \mathbf{2m} = \mathbf{2e} = \mathbf{2p} > \mathbf{2ip} > \mathbf{2tb}, \quad (1)$$

while the activity sequence for competitive hydrogenation of a mixture of different ketones is

$$\mathbf{1} \gg \mathbf{2m} > \mathbf{2e} > \mathbf{2p} \gg \mathbf{2ip} \gg \mathbf{2tb}. \quad (2)$$

As pointed out previously,[3] sequence (1) seems to be inversely related to the steric hindrance of the alkyl substituents. With respect to the identity **2m**=**2e**=**2p** for the triad ketones having a straight side chain, it should be noted that **2e** and **2p** are viewed as being brought from **2m** by alkyl substitution of a hydrogen atom β to the carbonyl group. Thus, it is unlikely that the triad ketones are significantly different from one another in charge density of the functional group. Another important fact is that the side alkyl chains of **2e** and **2p** are flexible. Owing to this flexibility, upon adsorption of **2e** and **2p** the side chains could point away from the catalyst surface and also from the carbonyl group. In different terms, the steric hindrance of the side chain to adsorption and the subsequent surface reaction remain unchanged on going from **2m** to **2e** or **2p**. Thus, it is expected that the adsorption strength as well as the reactivity of the carbonyl group should be the same for the adsorbed triad ketones, thus, giving rise to the observed identity **2m**=**2e**=**2p** in sequence (1).

The adsorbed triad ketones, however, might be different in entropy factor. It is very likely that upon adsorption a ketone loses its translational and rotational freedom.[4] If so, the greater the substituent, the greater would be the entropy loss. As previoulsy demonstrated, the relative magnitudes of the entropy losses for different ketones can be calculated in terms of the molecular weight (m) and product of the three principal moments of inertia (I). Such calculations account quantitatively for the reactivity differences in sequence (2) between **2m**, **2e**, and **2p**.

The purpose of the present work has been to substantiate the above interpretation of the alkyl substituent effects. One of the basic assumptions involved here is that the adsorption and hydrogenation of the triad ketones (**2m**, **2e**, **2p**) are different only in entropy factor. If this assumption is valid, the heat of adsorption as well as the activation energy must be identical for the triad ketones; that is to say, the relative rates of hydrogenation of the triad ketones must be temperature independent. The present work tests this prediction. For a comparison, **1** and **2ip** are also examined; these are expected to behave quite differently from the triad.

Experimental

Materials. Commercial decalin (Wako Pure Chemical Ind., "First Grade," a mixture of cis and trans isomers) was purified by refluxing with calcium hydride (*ca.* 1 g per liter decalin) for 24 h, followed by distillation. The middle was collected and redistilled with benzoic acid (*ca.* 25 mg per liter decalin).

The catalysts used were the same as those employed previously,[2,3] *i.e.*, Ru/Al_2O_3, Rh/Al_2O_3, and Pt/Al_2O_3, each in the form of pellets (Engelhard Ind., 1/8 inch in diameter containing 0.5 wt% metal).

Kinetic Procedure. The relative rates of hydrogenation of five ketones (**1**, **2m**, **2e**, **2p**, **2ip**) were measured either separately with one of the individual ketones or competitively with an equimolar mixture of **1** and **2** (**2** represents any one of **2m**, **2e**, **2p**, and **2ip**). Hydrogenation runs were conducted by the procedures described previously,[2] with an exception that decalin was used as the solvent in place of cyclohexane. The reaction temperature ranged from −5 °C to 68 °C, and the hydrogen pressure was atmospheric. Decalin was chosen because its liquid-state temperature range is wider than that of cyclohexane and its vapor pressure is lower (9.7 mmHg at 66.1 °C for the isomeric mixture[5]).

Results and Discussion

The linearity of Arrhenius plots was satisfactory over the whole temperature range (−5 °C—68 °C) as shown in Fig. 1. The rate data obtained at both ends of this range are listed in Table 1. Before discussing these data, let us consider the physical meaning of the relative rates involved.

According to a common practice in heterogeneous catalysis, the relative rate R_2/R_1 in competitive reactions may be expressed as

$$R_2/R_1 = k_2K_2/k_1K_1, \quad (3)$$

where k is the rate constant referred to the unit fraction of the surface covered and K is the adsorption equili-

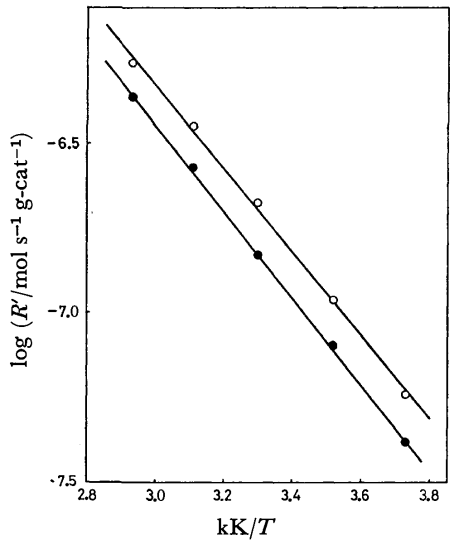

Fig. 1. Typical Arrhenius plots.
Hydrogenation of **1** and **2m** on Ru/Al_2O_3.
○: **1**, ●: **2m**.

brium constant. On the other hand, for the relative rate R_2'/R_1' in individual reactions we have

$$R_2'/R_1' = k_2/k_1, \tag{4}$$

provided that the concentrations of **1** and **2** are sufficiently high that R_2' and R_1' are concentration independent. The establishment of this prerequisite under our reaction conditions has been confirmed by preliminary experiments.[6]

Entropy Factors. Based on Eqs. 3 and 4 we obtain

$$\frac{K_{2e}}{K_{2m}} = \frac{K_{2e}}{K_1}\frac{K_1}{K_{2m}} = \frac{(R_{2e}/R_1)}{(R_{2e}'/R_1')}\frac{(R_1/R_{2m})}{(R_1'/R_{2m}')}. \tag{5}$$

Since sequence (1) indicates $R_{2e}'=R_{2m}'$, Eq. 5 is reduced to

$$\log(K_{2e}/K_{2m}) = \log(R_{2e}/R_1) - \log(R_{2m}/R_1). \tag{6}$$

Since the numerical values for the two terms of the right side are given in Table 1, we can estimate the experimental $\log(K_{2e}/K_{2m})$ values using Eq. 6. On the other hand, a theoretical $\log(K_{2e}/K_{2m})$ value has previosuly[2] been worked out based on the equation

$$\log\left(\frac{K_{2e}}{K_{2m}}\right) = \frac{3}{2}\log\left(\frac{m_{2m}}{m_{2e}}\right) + \frac{1}{2}\log\left(\frac{I_{2m}}{I_{2e}}\right) - \frac{\omega_{2e}-\omega_{2m}}{2.303\,kT}, \tag{7}$$

where ω is the heat of adsorption (negative values for exothermic). In the calculation of the theoretical $\log(K_{2e}/K_{2m})$ value, it was assumed that $\omega_{2e}=\omega_{2m}$. Both experimental and theoretical $\log(K_{2e}/K_{2m})$ values are listed in Table 2. Also for a pair **2e**+**2p**, we can write down two equations which are analogous to Eqs. 6 and 7. The experimental and theoretical $\log(K_{2p}/K_{2e})$ values obtained are also included in Table 2. It is seen that, except for a value of −0.39 for Pt, the agreement between theory and experiment is satisfactory. Since the last term in Eq. 7 has been taken as zero in the theoretical calculations, this agreement provides indirect evidence for the assumed identity in heats of adsorption between the triad ketones, *i.e.*, $\omega_{2m}=\omega_{2e}=\omega_{2p}$.

Energy Factors. The relation between the rate constant k_i referred to adsorbed **1** or **2** and the activation energy is

$$R\frac{\mathrm{d}\ln k_i}{\mathrm{d}(1/T)} = -(\varepsilon_i-\omega_i). \tag{8}$$

Herein R with no subscript is the gas constant and ε_i is the energy required for bringing the substrate i in the bulk solution up to the activated state on the catalyst surface (apparent activation energy). The quantity $\varepsilon_i-\omega_i$, therefore, represents the energy required for bringing the adsorbed i to the activated state (true activation energy), as shown in Fig. 2. The following relation is also available:

$$R\frac{\mathrm{d}\ln K_i}{\mathrm{d}(1/T)} = -\omega_i. \tag{9}$$

From Eqs. 3, 4, 8, and 9 we obtain

$$R\frac{\mathrm{d}\ln(R_2/R_1)}{\mathrm{d}(1/T)} = -(\varepsilon_2-\varepsilon_1) \equiv -\Delta\varepsilon_{2,1} \tag{10}$$

and

$$R\frac{\mathrm{d}\ln(R_2/R_1)}{\mathrm{d}(1/T)} - \left\{R\frac{\mathrm{d}\ln R_2'}{\mathrm{d}(1/T)} - R\frac{\mathrm{d}\ln R_1'}{\mathrm{d}(1/T)}\right\} = -(\omega_2-\omega_1) \equiv -\Delta\omega_{2,1}. \tag{11}$$

TABLE 3. THE VALUES FOR ENERGETIC QUANTITIES

Catalyst	Ketone pair	$\Delta\varepsilon_{2,1}$[a] / kcal mol^{-1}	$\Delta\omega_{2,1}$ / kcal mol^{-1}	Ketone	$\varepsilon_1-\omega_1$ / kcal mol^{-1}
Ru/Al_2O_3				**1**	5.6

	2ip/1	2.2	1.8	**2ip**	6.3

a) 1 kcal=4.184×10^3 J.

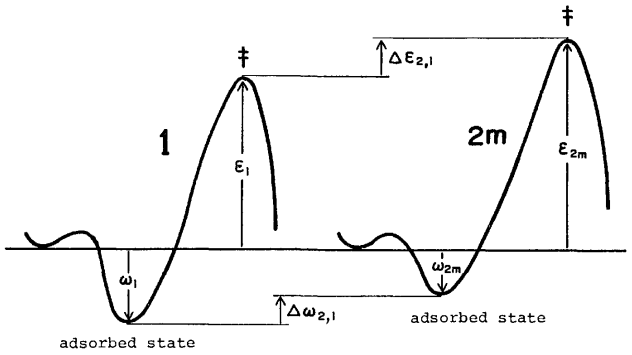

Fig. 2. Comparison of reaction coordinates between **1** and **2m**.

The values for $\Delta\varepsilon_{2,1}$ and $\Delta\omega_{2,1}$ can be estimated from Table 1 using Eqs. 10 and 11, respectively, if $\ln(R_2/R_1)$, $\ln R_2'$, and $\ln R_1'$ are linearly correlated with $1/T$. This sort of linearity has been confirmed with several representative reaction systems which are different in ketone or ketone pair. Table 3 summarizes the values for $\Delta\varepsilon_{2,1}$, $\Delta\omega_{2,1}$ and derived quantities.

Except for the **2m/1** system on Pt, the $\Delta\varepsilon_{2,1}$ values are nearly identical for **2m/1**, **2e/1**, and **2p/1** on each catalysts. This indicates that there is no significant difference in ε between **2m**, **2e**, and **2p**, as predicted in Introduction. In contrast to this near identity, a small but significant jump in ε is seen on going from **1** to **2m** and also for Pt on going from **2p** to **2ip**. Thus, the ε sequence for ketones is

$$\mathbf{1} < \mathbf{2m} \approx \mathbf{2e} \approx \mathbf{2p} < \mathbf{2ip}, \qquad (12)$$

which is the inverse of sequence (1). With respect to $\Delta\omega_{2,1}$ also, sequence (12) holds both for Ru and Pt although the value for **2m** on Pt is again exceptional. At present we cannot explain the unexpected result with **2m** on Pt.

Interestingly, little difference is seen in the true activation energy ($\varepsilon_1-\omega_1$) for **1** and **2**'s; there is no gap when going from **1** to **2m** or from **2p** to **2ip**. This indicates that there is a compensation relation between $|\varepsilon_1|$ and $|\omega_1|$, *i.e.*, the greater the $|\varepsilon_1|$ value, the lower the $|\omega_1|$ value. Although this compensation must reflect certain characteristic features of the surface reaction, they are not clear at present.

In summary, the predicted near identity in the heat of adsorption and in the activation energy for the triad ketones **2m**, **2e**, and **2p** has been confirmed. This near equivalence is understood in terms of the particular conformation of the side chains in the adsorbed state (*cf.* Introduction). Comparing **1** with the triad, the latter is more weakly adsorbed and has a higher activation barrier, as shown in Fig. 2. The same is true for a comparison of the triad with **2ip**.

The present work was partially supported by Grant-in-Aid for Scientific Research No. 454134 from the Ministry of Education, Science and Culture.

One-step Synthesis of 3-(Dialkylamino)indolizines by the Palladium-catalyzed Reaction of α-Bromopyridine, Propargyl Alcohol, and Secondary Amine[1]

Akio Ohsawa, Yoshihito Abe, and Hiroshi Igeta*
School of Pharmaceutical Sciences, Showa University, Shinagawa-ku, Tokyo 142

(Received March 10, 1980)

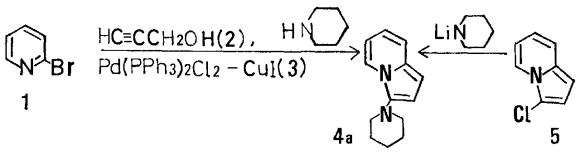
3-(Dialkylamino)indolizines were synthesized in one step by the reaction of 2-bromopyridine, propargyl alcohol, and secondary amines in the presence of $Pd(PPh_3)_2Cl_2$–CuI as a catalyst. 3-(2-Pyridyl)-2-propyn-1-ol and 3-(2-pyridyl)acrylaldehyde were suggested to be intermediates of the reaction. 3-Dialkylamino derivatives of pyrrolo[1,2-*a*]quinoline, pyrrolo[2,1-*a*]isoquinoline, and pyrrolo[1,2-*b*]pyridazine were obtained from the corresponding α-haloazaaromatics in a similar way.

Since the first preparation[2] of indolizine from α-picoline and acetic anhydride, various types of its derivatives have been synthesized by a number of methods undertaken from chemical,[3] pharmaceutical,[4] and physical[5] points of view.

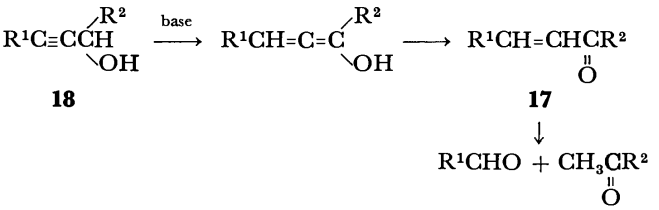
As for aminoindolizines, Hurst *et al.* prepared some of them in several steps in order to evaluate them biologically.[6] Nevertheless, a general synthetic method for aminoindolizine derivatives has not been established. During an examination of the alkynylation of α-haloazaaromatics with propargyl alcohol according to Sonogashira's method,[7] it was found that indolizine derivatives are unexpectedly formed instead of alkynylated products. In this paper, we describe a one-step synthesis of 3-(dialkylamino)indolizines by the reaction of α-haloazaaromatics, propargyl alcohol, and secondary amines, using $Pd(PPh_3)_2Cl_2$–CuI as a catalyst.

Results and Discussion

When 2-bromopyridine (**1**) and propargyl alcohol (**2**) were heated in piperidine with $Pd(PPh_3)_2Cl_2$–CuI (**3**), a somewhat air-sensitive yellow compound (**4a**) was obtained. Its NMR spectrum indicated the presence of a piperidino group and showed signals which were assigned to the protons on the indolizine-ring carbons. The maximum of its UV spectrum appeared at 241 nm ($\varepsilon=2.4\times10^4$), similarly to that of indolizine.[8] On the basis of the elemental analysis and the above data, its structure was assumed to be piperidinoindolizine. Moreover, the position of the piperidino group in **4a** was synthetically confirmed. The product obtained from the reaction of 3-chloroindolizine(**5**)[9] with lithium piperidide was identical with **4a**, and the structure of **4a** was determined to be 3-piperidinoindolizine.



Additionally, the application and limitation of this reaction were examined. The treatment of **1**, **2**, and piperidine in the absence of the catalyst(**3**) did not afford **4a**. The reaction of **1** and **2** in the presence of **3** with other secondary amines, such as morpholine and diethylamine, afforded 3-morpholinoindolizine(**4b**) and 3-(diethylamino)indolizine(**4c**) respectively. However, the use of primary amines (*e.g.*, butylamine) did not afford the corresponding indolizines. The similar treatment of other α-haloazaaromatics, such as 2-chloroquinoline(**6**) and 1-chloroisoquinoline(**7**), in diethylamine afforded 3-(diethylamino)pyrrolo[1,2-*a*]-quinoline(**8**) and 3-(diethylamino)pyrrolo[2,1-*a*]isoquinoline(**9**) respectively. Similarly, the reaction of 3-chloropyridazines (**10**—**12**), which have substituents at the 6-positions, in secondary amines afforded 2-substituted 7-(dialkylamino)pyrrolo[1,2-*b*]pyridazines (**13a**—**c**, **14**, and **15**). These results are shown in Table 1.



The mechanism of the formation of **4c** was investigated. It has been known that the halogen atoms of some haloazaaromatics are substituted with alkynyl groups by means of reactions with monosubstituted acetylenes, in the presence of amines and $Pd(PPh_3)_2Cl_2$–CuI (**3**) as catalysts.[7,10,11] Actually, the reaction of **1** with **2**, Et_2NH, and **3** under mild conditions (30 °C, for 16 h) afforded the 2-alkynylated pyridine, *i.e.*, 3-(2-pyridyl)-2-propyn-1-ol (**16**), in an 89% yield, although it was not obtained in the absence of **3**. When **16** was heated (80 °C, 16 h) in Et_2NH with **3**, the expected indolizine (**4c**) was obtained in a 15% yield, although heating **16** in Et_2NH in the absence of the catalyst did not give **4c** and the starting material was recovered.

a) The compound could not be distilled at 200 °C under 0.01 mm. b) Because elemental analyses of this compound did not give satisfactory data, it was derived into **13a**. See Experimental.

Lappin[12] has assumed that the conjugated ketones (**17**) were the intermediates in the degradation of β-acetylenic alcohols (**18**) with alkali to give aldehydes and methylketones.

Therefore, 3-(2-pyridyl)acrylaldehyde (**19**) was postulated as the intermediate of the reaction from **16** to **4c**; in fact, the alternatively available **19** gave **4c** (56%) on treatment with Et_2NH at room temperature.

On the basis of these observations, we propose that

the reaction proceeds as is shown in Scheme 1.

The cross-coupling between **1** and propargyl alcohol in the presence of an amine and $Pd(PPh_3)_2Cl_2$–CuI might occur to give **16**, which is then transformed into **19** through the 1,3-migration of a hydrogen atom, followed by the ketonization of the allenic alcohol (**20**). The condensation of **19** and Et_2NH then affords the iminium ion (**21**), and an intramolecular cyclization of **21** gives **4c**.

Thus, we have established a one-step synthesis of novel types of indolizines, which are difficult to obtain, using easily available starting materials.

Experimental

The properties of the products are listed in Table 2. All the melting points are uncorrected. All the boiling points are represented by the bath temperature. The NMR spectra were recorded on Hitachi R-20 and R-22 instruments.

General Procedure of One-step Synthesis. A mixture of α-haloazaaromatic (5 mmol), propargyl alcohol (0.6 g, 11 mmol), $Pd(PPh_3)_2Cl_2$ (73 mg, 0.1 mmol), CuI (5 mg), and secondary amine (3 ml) was heated at 60—70 °C for 3—16 h with stirring under a nitrogen atmosphere. The solution was then evaporated to remove the excess amine. The residue was chromatographed over basic Al_2O_3 to give a yellow oil or crystals, and the material was purified by distillation or recrystallization (from pentane or MeOH) to give 3-(dialkylamino)indolizine.

*3-Piperidinoindolizine (**4a**)*: 2-Bromopyridine (0.8 g, 5 mmol), propargyl alcohol (0.6 g, 11 mmol), $Pd(PPh_3)_2Cl_2$ (73 mg, 0.1 mmol), and CuI (5 mg) were heated in piperidine (3 ml) at 80 °C for 16 h with stirring under a nitrogen atmosphere. The solution was then evaporated, and the residue was chromatographed over basic Al_2O_3 with hexane–ether (50:1) to give yellow crystals (**4a**); yield, 0.36 g (36%); mp 58 °C (pentane).

*2-Chloro-7-(diethylamino)pyrrolo[1,2-b]pyridazine (**15**)*: 3,6-Dichloropyridazine (0.75 g, 5 mmol), propargyl alcohol (0.6 g, 11 mmol), $Pd(PPh_3)_2Cl_2$ (73 mg, 0.1 mmol), and CuI (5 mg) were heated in Et_2NH (3 ml) at 70 °C for 16 h. A work-up similar to that used before afforded 2-chloro-7-(diethylamino)pyrrolo[1,2-*b*]pyridazine (**15**) as a yellow oil [bp 150 °C (2 mmHg)] in a yield of 0.16 g (14%).

*Synthesis of 2-Methyl-7-(diethylamino)pyrrolo[1,2-b]pyridazine (**13a**) from **15***: Ni(dppp)Cl_2 (3 mg) was added to a solution of MeMgI prepared from Mg (28 mg) and MeI (150 mg) in ether (3 ml). A solution of **15** (112 mg) was stirred, drop by drop, into the reaction mixture under a nitrogen atmosphere. The oil obtained by the usual work-up[13] was found to be identical with 2-methyl-7-(diethylamino)pyrrolo-[1,2-*b*]pyridazine (**13a**) by TLC, IR, and NMR.

*Reaction of 3-Chloroindolizine (**5**) and Lithium Piperidide.* Ten ml of a solution containing BuLi (15% in hexane) was added dropwise into a solution of piperidine (0.85 g in 10 ml of THF) under a nitrogen atmosphere, with cooling in a Dry Ice–acetone bath. The mixture was allowed to stand at room temperature for 30 min and then cooled again in a Dry Ice–acetone bath. A solution of 3-chloroindolizine (**5**, 0.75 g in 10 ml of THF) was then stirred in, drop by drop. Then the mixture was allowed to stand at room temperature for 16 h, and H_2O (0.5 ml) was added dropwise to the mixture. After filtration and evaporation, the residue was purified by basic Al_2O_3 column chromatography with hexane–ether (20:1), followed by silica-gel chromatography (hexane), to give a compound which was found to be identical with **4a** by means of its NMR and IR spectra and melting point.

Reaction of 3-Chloro-6-methylpyridazine with $BuNH_2$. A mixture of 3-chloro-6-methylpyridazine (0.65 g), propargyl alcohol (0.6 g), $Pd(PPh_3)_2Cl_2$ (73 mg), CuI (5 mg), and $BuNH_2$ (3 ml) was heated at 70 °C for 16 h with stirring under nitrogen. The solution was then evaporated to give a tar. Attempts to isolate products failed.

Reaction of 2-Bromopyridine and Propargyl Alcohol in Et_2NH at 30 °C. A mixture of 2-bromopyridine (1.6 g), propargyl alcohol (1.2 g), $Pd(PPh_3)_2Cl_2$ (146 mg), CuI (10 mg), and Et_2NH (30 ml) was stirred at 30 °C for 16 h under nitrogen. After the filtration of crystals (diethylamine hydrobromide), the filtrate was evaporated and the residue was chromatographed on silica gel with CH_2Cl_2 to give crystals. Recrystallization from ether gave 3-(2-pyridyl)-2-propyn-1-ol; mp 82—83 °C (lit,[14] 82—82.5 °C); yield, 1.2 g (89%). When either $Pd(PPh_3)_2Cl_2$ or CuI was absent, the reaction did not proceed.

Reaction of 3-(2-Pyridyl)-2-propyn-1-ol and Et_2NH. A mixture of 3-(2-pyridyl)-2-propyn-1-ol (0.65 g), Et_2NH (3 ml), $Pd(PPh_3)_2Cl_2$ (73 mg), and CuI (5 mg) was heated at 80 °C for 4 h with stirring under nitrogen. The solution was evaporated, and the residue was chromatographed over basic Al_2O_3 with hexane–ether (50:1) to give 3-(diethylamino)indolizine (**4c**); yield, 0.14 g (15%). A similar operation in the absence of $Pd(PPh_3)_2Cl_2$ and CuI did not give **4c**; rather the starting material was recovered.

Reaction of 3-(2-Pyridyl)acrylaldehyde and Et_2NH. A solution of 3-(2-pyridyl)acrylaldehyde (230 mg) in Et_2NH was allowed to stand at room temperature (26 °C) for 30 min under nitrogen. The solution was then evaporated below 35 °C, and the residue was chromatographed over basic Al_2O_3 with hexane to give 170 mg (56%) of **4c**.

The Synthesis of 2-Styrylazulene and Its Derivatives by the Condensation of 2-Methylazulene Derivatives with Benzaldehydes

Motoyasu SAITO, Tadayoshi MORITA, and Kahei TAKASE*

Department of Chemistry, Faculty of Science, Tohoku University, Aramaki-aza-Aoba, Sendai 980

(Received March 10, 1980)

The reaction of 2-methylazulene derivatives, such as dimethyl 2-methylazulene-1,3-dicarboxylate, methyl 3-cyano-2-methylazulene-1-carboxylate, and 1-cyano- and 1-carbamoyl-2-methylazulenes, with benzaldehyde in the presence of alkoxide resulted in condensation to give 2-styrylazulene derivatives. 2-Styrylazulene, a parent hydrocarbon, and its *p*-nitro and *p*-dimethylamino derivatives were also synthesized.

Styrylazulenes are important azulenic compounds analogous to stilbene and interesting for their chemical and physical properties. Of the five possible position isomers, 1-,[1] 5-,[2] and 6-styrylazulenes,[2] and some derivatives of 4-,[3] and 5-styrylazulenes[4] have been synthesized.

On the other hand, we have found that 2-methylazulene derivatives with electron-withdrawing substituents, such as an alkoxycarbonyl or cyano group, at the 1 (and/or 3)-position easily condensed with benzaldehyde in the presence of alkoxide to give 2-styrylazulene derivatives; an outline of a part of these results has been reported in a preliminary communication.[5] This paper will describe the details of the synthesis of 2-styrylazulene (**1**) and its derivatives by the condensation of 2-methylazulene derivatives with benzaldehydes.

Results and Discussion

2-Methylazulene (**2**) and its derivatives, such as dimethyl 2-methylazulene-1,3-dicarboxylate (**3**), methyl 3-cyano-2-methylazulene-1-carboxylate (**4**), and 1-cyano- (**5**) and 1-carbamoyl-2-methylazulenes (**6**), were prepared, and the condensation reactions of these azulenes with benzaldehyde were examined, in order to synthesize 2-styrylazulenes. The treatment of **2** with benzaldehyde in the presence of sodium ethoxide gave no condensation product. In contrast with this, the treatment of **3** and **4** with benzaldehyde in the presence of sodium methoxide or ethoxide at room temperature resulted in condensation to give 3-methoxycarbonyl- (**7**) and 3-cyano-2-styrylazulene-1-carboxylic acids (**8**) in excellent yields respectively. In a similar manner, **5** gave 1-cyano-2-styrylazulene (**9**) in a good yield. The condensation of **6** with benzaldehyde was not easy, so it proceeded under reflux to give 1-carbamoyl-2-styrylazulene (**10**) in only a low yield of 14%. The structures of **7**, **8**, **9**, and **10** were determined on the basis of the chemical evidence described below, as well as the spectral data. Compounds **7** and **8** are acidic enough to be soluble in an aq sodium hydrogen carbonate solution and gave methyl esters (**11** and **12**) on methylation with diazomethane. The treatment of **7** and **8** with phosphoric acid[6] resulted in decarboxylation to give methyl 2-styrylazulene-1-carboxylate (**13**) and **9** respectively. Further, on treatment with concd sulfuric acid at 100 °C,[6] **9** gave **10**, together with a lactam, judging from the IR spectrum, which exhibits the $\nu_{C=O}$ of amide at 1639 cm^{-1}, compatible with that at 1642 cm^{-1} in 1-carbamoyl-2-methylazulene.[6] The NMR spectral data are also consistent with the assigned structure. The configuration of the ethylenic linkage in the 2-styrylazulenes obtained here is established to be *trans* on the basis of the IR and NMR spectral data.[5] The formation of the hydrolized carboxylic acids, **7** and **8**, even though the reaction was carried out under anhydrous media, is presumed to be *via* lactone-type intermediates.[5]

The fact that **3**, **4**, and **5** easily reacted with benzaldehyde in the presence of alkoxide to give the condensation products indicates that the methyl group at the 2-position in these compounds is acidic enough to yield the carbanion, which can react with benzaldehyde, by means of alkoxide. For this reason, it seems that the electronic effects, that is, the mesomeric and inductive effects of the electron-withdrawing methoxycarbonyl or cyano substituent at the 1 (and/or 3)position of the azulene ring, contribute to the activation of the methyl proton. Such condensation also took place when other aromatic aldehydes were used. Thus, the treatment of **5** with *p*-nitro- and *p*-dimethylaminobenzaldehydes in the presence of sodium ethoxide gave 1-cyano-2-(*p*-nitrostyryl)- (**15**) and 1-cyano-2-(*p*-dimethylaminostyryl)azulenes (**16**) respectively, although in the latter case, the reaction was not easy, but did proceed by heating under reflux.

A parent hydrocarbon, **1**, could be obtained from

Fig. 1.

7 in an 88% yield on hydrolysis with aq ethanolic alkali and the subsequent decarboxylation of the resulting dicarboxylic acid by heating with phosphoric acid. Further, **1** was also obtained from **10** by decarbamoylation[6] on treatment with phosphoric acid. 2-(*p*-Nitrostyryl)- (**17**) and 2-(*p*-dimethylaminostyryl)azulene (**18**) could also be synthesized as follows: the treatment of **15** and **16** with concd sulfuric acid afforded carbamoyl derivatives (**19** and **20**), accompanied by the formation of small amounts of **17** and **18** respectively. Further, the treatment of **19** and **20** with phosphoric acid resulted in decarbamoylation to give **17** and **18** respectively in good yields.

Experimental

All the melting points are uncorrected. The IR spectra were taken on a Shimadzu IR-27 infracord spectrophotometer, and the electronic spectra, on a Hitachi EPS-3 spectrophotometer. The NMR spectra were recorded with a Varian A-60D spectrometer. Compounds **4**, **5**, and **6** were prepared according to a method previously reported.[6]

*Dimethyl 2-Methylazulene-1,3-dicarboxylate (**3**).* This compound was prepared by a procedure similar to that used for the preparation of ethyl methyl 2-methylazulene-1,3-dicarboxylate.[6] A mixture of 940 mg (5 mmol) of 3-acetyl-2*H*-cyclohepta[*b*]furan-2-one[6] and 1.32 g (10 mmol) of dimethyl malonate in a sodium methoxide solution, prepared from 460 mg of sodium and 50 ml of anhydrous methanol, was treated in a manner similar to that previously described.[6] The part insoluble in an aq potassium carbonate solution gave 160 mg (13%) of methyl 3-acetyl-2-hydroxyazulene-1-carboxylate as yellow needles; mp 201—202 °C (from benzene). IR (KBr): 3440, 1670, 1127, and 1053 cm^{-1}. Found: C, 68.62; H, 5.02%. Calcd for $C_{14}H_{12}O_4$: C, 68.84; H, 4.95%.

The part soluble in an aq potassium carbonate solution gave 640 mg (52%) of 3-methoxycarbonyl-2-methylazulene-1-carboxylic acid as pale red crystals; mp 209 °C (dec). The treatment of this acid with diazomethane in a manner similar to that previously described[6] gave 595 mg of **3** as red needles; mp 112—115 °C (from methanol). λ_{max}^{MeOH} 237 nm (log ε 4.50), 270 (4.38), 295 (4.57), 305 (4.66), 343 (3.90), 371 (3.93), and 490 (2.95); IR (KBr): 1690, 1233, and 1080 cm^{-1}. Found: C, 70.01; H, 5.51%. Calcd for $C_{15}H_{14}O_4$: C, 69.75; H, 5.46%.

*3-Methoxycarbonyl-2-styrylazulene-1-carboxylic Acid (**7**).* To a sodium methoxide solution, prepared from 300 mg of sodium and 15 ml of anhydrous methanol, 1.29 g (5 mmol) of **3** and 900 mg (8.5 mmol) of benzaldehyde were added; the mixture was stirred for 5 h and then allowed to stand overnight at room temp. The reaction mixture was diluted with 100 ml of water and shaken with ether. The ether layer was washed with water and concentrated to recover 340 mg of **3**. The combined aq solution was acidified with with 6 M (1M = 1 mol dm^{-3}) hydrochloric acid, and the crystals thus separated out were collected to give 1.10 g (90%) of **7** as red prisms; mp 177—178 °C (from methanol). λ_{max}^{MeOH} 233 nm (log ε 4.50), 295 (4.50), 338 (4.71), 404 (4.20), and 540 (2.75). Found: C, 76.19; H, 4.97%. Calcd for $C_{21}H_{16}O_4$: C, 75.89; H, 4.85%.

*3-Cyano-2-styrylazulene-1-carboxylic Acid (**8**).* A mixture of 900 mg (4 mmol) of **4** and 720 mg (6.8 mmol) of benzaldehyde in a sodium ethoxide solution, prepared from 280 mg of sodium and 20 ml of anhydrous ethanol, was treated in a manner similar to that described above to give 1.17 g (98%) of **8** as reddish brown prisms: mp 238—239 °C (from ethanol). λ_{max}^{MeOH} 230 nm (log ε 4.46), 340 (4.76), 409 (4.23), and 560 (2.72). Found: C, 79.88; H, 4.48; N, 4.69%. Calcd for $C_{20}H_{13}O_2N$: C, 80.25; H, 4.38; N, 4.68%.

*1-Cyano-2-styrylazulene (**9**). a)*: A mixture of 165 mg (1 mmol) of **5** and 180 mg (1.7 mmol) of benzaldehyde in a sodium ethoxide solution, prepared from 70 mg of sodium and 5 ml of ethanol, was stirred for 5 h and then allowed to stand overinght at room temp. The reaction mixture was subsequently diluted with 50 ml of water and extracted with chloroform. After the evaporation of the solvent from the extract, the residue was chromatographed (alumina, benzene) to give 170 mg (67%) of **9** as green needles; mp 119—120 °C (from benzene–cyclohexane). λ_{max}^{MeOH} 231 nm (log ε 4.27), 323 (4.75), 335 (4.83), 388 (4.15), 408 (4,43), 433 (4.42), 558 (2.72), 589 (2.75), and 653 (2.42). Found: C, 90.01; H, 5.15; N, 5.38%. Calcd for $C_{19}H_{13}N$: C, 89.38; H, 5.13; N, 5.49%.

b): A mixture of 220 mg o **8** and 3 ml of 85% phosphoric acid was heated at 100 °C for 30 min; then it was poured into ice water and extracted with chloroform. The extract was worked up as has been described above to give 160 mg (85%) of **9** as green needles; mp 119—120 °C.

*1-Carbamoyl-2-styrylazulene (**10**).* A mixture of 50 mg (0.27 mmol) of **6** and 80 mg (0.76 mmol) of benzaldehyde in a sodium ethoxide solution, prepared from 70 mg of sodium and 3 ml of ethanol, was heated under reflux for 5.5 h. The reaction mixture was then diluted with 20 ml of water and extracted with chloroform. After the evaporation of the solvent from the extract, the residue was chromatographed (silica gel, benzene) to give 10 mg (14%) of **10** as green needles; mp 207—208 °C (from benzene). λ_{max}^{MeOH} 318 nm (log ε 4.64), 327 (4.72), 405 (4.38), and 426 (4.26). Found: C, 83.46; H, 5.82; N, 4.85%. Calcd for $C_{19}H_{15}ON$: C, 83.49; H, 5.53; N, 5.13%.

*Dimethyl 2-Styrylazulene-1,3-dicarboxylate (**11**).* To a suspension of 300 mg of **7** in 20 ml of ether, 5 ml of an ethereal solution of diazomethane was added, after which the mixture was stirred for 3 h and allowed to stand overnight in a refrigerator. After the evaporation of the solvent, the residue was chromatographed (alumina, benzene) to give 300 mg (96%) of **11** as red scales; mp 136—137 °C (from methanol). λ_{max}^{MeOH} 233 nm (log ε 4.59), 294 (4.58), 338 (4.80), 404 (4.31), and 540 (2.81). Found: C, 76.21; H, 5.50%. Calcd for $C_{22}H_{18}O_4$: C, 76.28; H, 5.24%.

*Methyl 3-Cyano-2-styrylazulene-1-carboxylate (**12**).* The treatment of 200 mg of **8** with diazomethane in a manner similar to that described above gave 190 mg (91%) of **12** as red needles; mp 149—150 °C (from cyclohexane). λ_{max}^{MeOH} 232 nm (log ε 4.06), 291 (4.31), 342 (4.77), and 410 (4.35). Found: C, 80.54; H, 4.97; N, 4.47%. Calcd for $C_{21}H_{15}O_2N$: C, 80.49; H, 4.83; N, 4.47%.

*Methyl 2-Styrylazulene-1-carboxylate (**13**).* A mixture of 50 mg of **7** and 1 ml of 100% phosphoric acid was heated at 100 °C for 3 min; then it was poured into 10 ml of ice water and extracted with chloroform. After the evaporation of the solvent, the residue was chromatographed (alumina, benzene) to 35 mg (81%) of **13** as green needles; mp 88—89 °C (from methanol). λ_{max}^{MeOH} 335 nm (log ε 4.50), 402 (4.05), 424 (3.90), and 574 (2.86). Found: C, 83.02; H, 5.52%. Calcd for $C_{20}H_{16}O_2$: C, 83.31; H, 5.59%.

*Treatment of **9** with Sulfuric Acid.* A mixture of 510 mg of **9** and 4 ml of 80% sulfuric acid was heated at 100 °C for 1 h; then it was poured into 80 ml of ice water and extracted with chloroform. After the evaporation of the solvent from the extract, the residue was chromatographed

(alumina, benzene, and chloroform). The first fraction, eluted with benzene, recovered 32 mg of **9**. The second fraction, eluted with benzene, gave 95 mg (19%) of **14** as reddish violet prisms; mp 204—205 °C (from benzene). λ_{max}^{MeOH} 299 nm (log ε 4.65), 358 (3.91), and 376 (3.95). NMR ($CDCl_3$) δ 3.34 (d, J=8.0 Hz, $CHC\underline{H}_2$), 4.94 (t, J=8.0 Hz, $C\underline{H}CH_2$), 5.80 (br s, N$\underline{H}$), 7.05 (s, H-3), 7.4—7.8 (m H-5, -7), 7.38 (br s, C_6H_5), 8.33 (br d, J=9 Hz, H-4), 9.70 (br d, J=9 Hz, H-8). Found: C, 83.46; H, 5.54; N, 5.05%. Calcd for $C_{19}H_{15}ON$: C, 83.49; H, 5.53; N, 5.13%. The third fraction, eluted with chloroform, gave 210 mg (41%) of **10** as green needles; mp 207—208 °C.

*2-Styrylazulene (**1**).* *a)*: A solution of 1.00 g of **7** dissolved in a mixture of 10 ml of a 10% aq potassium hydroxide solution and 100 ml of ethanol, was heated under reflux for 40 min. The subsequent acidification of the solution with 1 M hydrochloric acid separated out 920 mg of 2-styrylazulene-1,3-dicarboxylic acid. A mixture of the acid and 5 ml of 85% phosphoric acid was heated at 100 °C for 15 min and then poured into 100 ml of ice water and extracted with chloroform. After the evaporation of the solvent from the extract, the residue was chromatographed (alumina, benzene) to give 610 mg (88%) of **1** as green scales; mp 207—208 °C (from cyclohexane). Found: C, 93.95; H, 6.11%. Calcd for $C_{18}H_{14}$: C, 93.87; H, 6.13%.

b): A mixture of 80 mg of **10** and 1 ml of 85% phosphoric acid was heated at 100 °C for 1 h; then it was diluted with 20 ml of water and extracted with chloroform. After the evaporation of the solvent, the residue was chromatographed (alumina, benzene) to give 40 mg (59%) of **1** as green scales; mp 207—208 °C.

*1-Cyano-2-(p-nitrostyryl)azulene (**15**).* A mixture of 166 mg (1 mmol) of **5** and 226 mg (1.5 mmol) of *p*-nitrobenzaldehyde in a sodium ethoxide solution, prepared from 53 mg of sodium and 3 ml of ethanol, was stirred for 20 h at 0—10 °C; then it was diluted with 20 ml of water and extracted with chloroform. The extract was washed with water and concentrated, and the residue was chromatographed (alumina, benzene) to give 75 mg (25%) of **15** as bluish green needles; mp 227—228 °C (from benzene). λ_{max}^{MeOH} 233 nm (log ε 4.27), 286 (4.20), 333 (4.72), 404 (4.59), and 424 (4.48). Found: C, 75.51; H, 4.07; N, 9.16%. Calcd for $C_{19}H_{12}O_2N_2$: C, 75.99; H, 4.03; N, 9.33%.

*1-Cyano-2-(p-dimethylaminostyryl)azulene (**16**).* A mixture of 167 mg (1 mmol) of **5** and 255 mg (1.7 mmol) of *p*-dimethylaminobenzaldehyde in a sodium ethoxide solution, prepared from 56 mg of sodium and 3 ml of ethanol, was heated under reflux for 7 h. The reaction mixture was then worked up in a manner similar to that described above, except for the use of chloroform in place of benzene as the solvent for chromatography, to give 113 mg (38%) of **16** as reddish brown needles; mp 196—197 °C (benzene). λ_{max}^{MeOH} 260 nm (log ε 4.17), 307 (4.63), 357 (4.45), and 490 (4.57). Found: C, 84.26; H, 5.91; N, 9.55%. Calcd for $C_{21}H_{18}N_2$: C, 84.53; H, 6.08; N, 9.39%.

*2-(p-Nitrostyryl)- (**17**) and 1-Carbamoyl-2-(p-nitrostyryl)-azulene (**19**).* *a)*: A mixture of 340 mg of **15** and 4 ml of concd sulfuric acid was heated at 100 °C for 3 h and then diluted with 50 ml of water. The crystals thus separated out were collected and chromatographed (alumina, benzene and chloroform). The first fraction, eluted with benzene, gave 10 mg (3%) of **17** as green prisms; mp 254—256 °C (from chloroform). λ_{max}^{MeOH} 231 nm (log ε 4.07), 282 (4.50), 323 (4.51), 406 (4.60), 425 (4.51), 584 (2.67), and 627 (2.64). Found: C, 78.42; H, 4.61; N, 4.89%. Calcd for $C_{18}H_{13}O_2N$: C, 78.53; H, 4.76; N, 5.09%. The second fraction, eluted with chloroform, gave 230 mg (64%) of **19** as green needles; mp 238—239 °C (from chloroform). λ_{max}^{MeOH} 230 nm (log ε 4.97), 284 (4.50), 327 (4.59), and 404 (4.55). Found: C, 71.64; H, 4.43; N, 8.60%. Calcd for $C_{19}H_{14}O_3N_2$: C, 71.69; H, 4.43; N, 8.80%.

b): A mixture of 260 mg of **19** and 3 ml of 100% phosphoric acid was heated at 100 °C for 3 h and then worked up in a manner similar to that described above to give 69 mg (31%) of **17** as green prisms; mp 254—256 °C.

*2-(p-Dimethylaminostyryl)- (**18**) and 1-Carbamoyl-2-(p-dimethylaminostyryl)azulene (**20**).* *a)*: A mixture of 310 mg of **16** and 3 ml of 80% sulfuric acid was treated in a manner similar to that described above. The first fraction from chromatography, eluted with benzene, gave 30 mg (11%) of **18** as reddish brown scales; mp 237—238 °C (from benzene). λ_{max}^{MeOH} 262 nm (log ε 4.30), 294 (4.68), 340 (4.56). Found: C, 87.76; H, 7.10; N, 5.00%. Calcd for $C_{20}H_{19}N$: C, 87.87; H, 7.01; N, 5.12%. The second fraction, eluted with benzene, gave 130 mg (40%) of **20** as brownish green prisms; mp 249—250 °C (from chloroform–ethyl acetate). λ_{max}^{MeOH} 302 nm (log ε 4.50), 352 (4.36), 468 (4.44). Found: 79.38; H, 6.05; N, 8.88%. Calcd for $C_{21}H_{20}ON_2$: C, 79.71; H, 6.37; N, 8.85%.

b): A mixture of 100 mg of **20** and 1 ml of 85% phosphoric acid was heated at 100 °C for 2 h; then it was worked up in a manner similar to that described above to give 48 mg (56%) of **18** as reddish brown scales; mp 237—238 °C.

Acid-catalyzed Rearrangement of the *exo*-1,2-Dioxetane Derivative from 1-Isopropylidene-4,4-diphenyl-2,5-cyclohexadiene[1)]

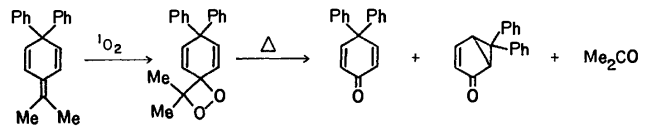
Akira KAWAMOTO, Hisashi UDA,* and Nobuyuki HARADA

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, 2-1-1 Katahira, Sendai 980

(Received March 13, 1980)

It is shown that acid-catalyzed decomposition of the 1,2-dioxetane derivative, 3,3-dimethyl-7,7-diphenyl-1,2-dioxaspiro[3.5]nona-5,8-diene, obtained from 1-isopropylidene-4,4-diphenyl-2,5-cyclohexadiene, gives 1-methyl-1-(*o*-terphenyl-4′-yl)ethyl hydroperoxide, bis[1-methyl-1-(*o*-terphenyl-4′-yl)ethyl] peroxide, 1-(1-hydroperoxy-1-methylethyl)-4,4-diphenylcyclohexa-2,5-dien-1-ol, and *o*-terphenyl-4′-ol, along with the usual dioxetane-scission product, 4,4-diphenyl-2,5-cyclohexadienone. The distribution and yield of these products depend on acidic agents and/or conditions employed.

Recent work by Zimmerman and coworkers[2)] concerning the thermal decomposition of the 1,2-dioxetane **2** derived from 1-isopropylidene-4,4-diphenyl-2,5-cyclohexadiene (**1**) prompts us to report results concerning the acid-catalyzed decomposition of **2** obtained simultaneously and independently in our laboratory.[1)] Zimmerman and coworkers reported[2)] that the thermal decomposition of **2** produced the rearranging excited state of 4,4-diphenyl-2,5-cyclohexadienone (**3**), which gave 6,6-diphenylbicyclo[3.1.0]hex-3-en-2-one (**4**),



1 2 3 4

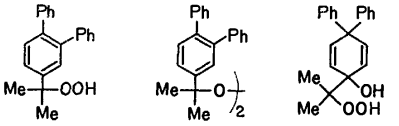
along with **3** and acetone.[3)] In our hands, the acid-catalyzed decomposition of **2** gave the *o*-terphenyl derivatives through a novel rearrangement pathway involving the scission of a carbon-oxygen bond, the migration of a phenyl group, and aromatization, which demonstrates that in the case of a special derivative the new type of cleavage of a dioxetane ring, competing with the usual dioxetane scission, may also occur.[4)]

Results and Discussion

The starting isopropylidenediphenylcyclohexadiene **1** was prepared by the Wittig reaction of the dienone **3** with isopropylidenetriphenylphosphorane.

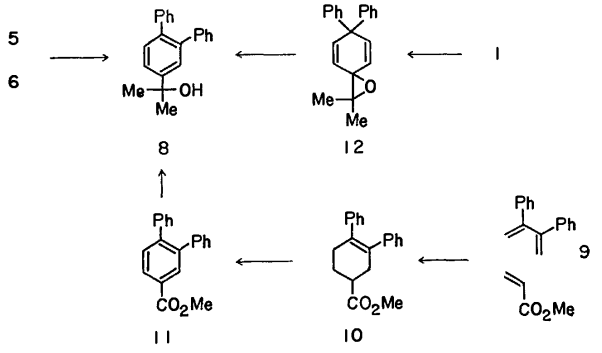
Photooxidation. Photooxidation of **1** in anhydrous methanol at −78 °C using Rose Bengal as a sensitizer gave, after immediate separation by preparative thin-layer chromatography (TLC) on silica gel below −12 °C, a 60—90% yield of the crystalline dioxetane **2**, mp 57—61 °C (dec). The 1,2-dioxetane structure of **2** was verified by the spectral and chemical properties. A wide range of the yield of **2** depends on the reaction and/or isolation conditions: concentration, irradiation time, temperature, the nature of TLC plate, and so on. In fact, on further purification, **2** appreciably decomposed on a preparative silica gel plate to produce more polar substances (see below).

Decomposition of the 1,2-Dioxetane 2 on Silica Gel. From the observation that the dioxetane **2** is extremely sensitive to the photooxidation and isolation conditions, we have examined the reactivity of **2** to acidic agents. Re-chromatography (preparative TLC on silica gel) of **2** at 0 °C afforded, in addition to the dienone **3** (usually the major product), three crystalline products, the *o*-terphenyl hydroperoxide **5**, mp 125.5—128 °C, the dimeric *o*-terphenyl peroxide **6**, mp 148—150 °C, and the hydroxy hydroperoxide **7**, mp 124—126 °C, respectively. From a number of experiments, it was found that the decomposition of **2** on silica gel was greatly affected not only by temperature for charging and developing but also by the nature of silica gel plates used (probably due to activity, water-content, *etc*). Thus, the yields of these products were not always constant, varying appreciably from run to run; particularly, often compound **7** was not isolated due to its instability (see below).

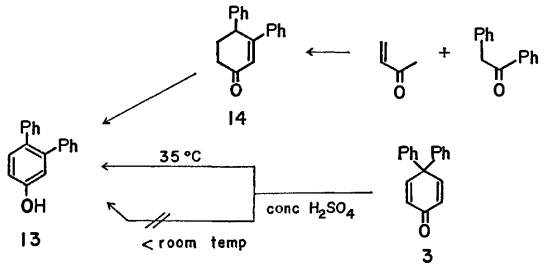


5 6 7

The structure of compound **5** was elucidated on the basis of the following spectral and chemical evidence. Compound **5** revealed the 1,3,4-trisubstituted benzene proton signals in the ^1H NMR and the absorption maxima characteristic of an *o*-terphenyl chromophor in the UV spectrum. Compound **5** showed positive potassium iodide-starch test, and treatment of **5** with various reducing reagents gave quantitatively the hydroxy compound **8**. The authentic sample of **8** was prepared by two alternative ways as shown in Scheme 1. The Diels-Alder reaction of 2,3-diphenyl-1,3-butadiene (**9**) with methyl acrylate provided the adduct **10**. Bromination of **10**, followed by dehydrobromination or direct dehydrogenation of **10** with DDQ afforded methyl *o*-terphenyl-4′-carboxylate (**11**),



Scheme 1.



Scheme 2.

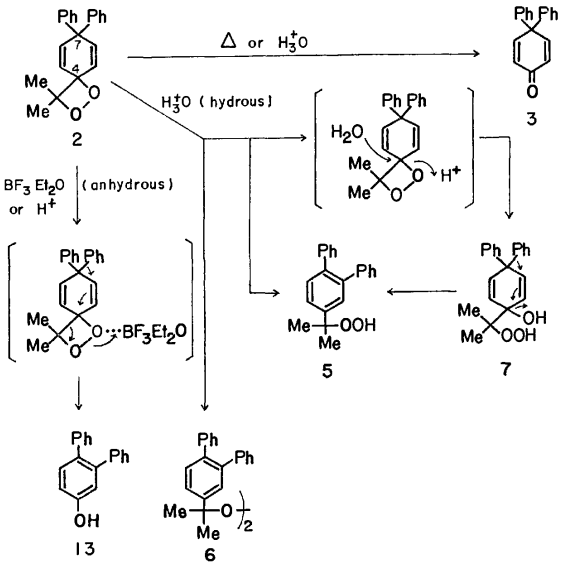
which was then transformed into **8** by the action of excess methylmagnesium iodide. Treatment of **1** with *m*-chloroperbenzoic acid gave the unstable exocyclic epoxide **12**, which was easily converted into **8** by chromatography on silica gel. The sample of **8** thus obtained was identical with that derived from **5**. The latter reaction sequence clearly indicates that the 4,4-diphenyl-2,5-cyclohexadienyl system easily undergoes a phenyl migration and aromatization.

Similarly, the product **6** also gave quantitatively the alcohol **8** on lithium aluminum hydride reduction or catalytic hydrogenation; thus, combining with the close resemblance of the spectral (^{1}H NMR and UV) properties to those of **5** or **8** and with the analytical result, the structure of **6** was assigned to be the dimeric *o*-terphenyl peroxide.

The third component **7** is the most polar compound and shows the simple ^{1}H NMR spectrum including the AB-type signal due to olefinic protons (total 4H) and the broad signal due to two protons exchangeable with deuterium oxide. These data suggests that this compound possesses a symmetrical structure having two hydroxylic functions. Furthermore, **7** is fairly unstable in solutions. The ^{1}H NMR spectrum of **7** in carbon tetrachloride or deuteriochloroform changed gradually on standing, and the final spectrum, after a few hours at 30 °C, was wholly in accord with that of the hydroperoxide **5**. From these facts, the vicinal hydroxy hydroperoxide structure **7** was assigned to this compound, and **7** meets the requirement of an intermediate in the rearrangement of **2** to **5**. The easy transformation of **7** into **5** in chlorinated solvents may be catalyzed by a trace of hydrogen (or deuterium) chloride contaminated.

Decomposition of the 1,2-Dioxetane 2 by Hydrochloric Acid. The same decomposition of **2** was also induced by hydrochloric acid, and temperature dependence on product distribution was observed. Thus, treatment of an ethereal solution of **2** with 2—6 M (1 M=1 mol dm^{-3}) hydrochloric acid at room temperature gave **3** (*ca.* 29%), **5** (*ca.* 15%), and **6** (*ca.* 34%), respectively. While below 0 °C **6** was obtained quantitatively. On treating a chloroform solution of **2** with concd hydrochloric acid below −10 °C, **6** also arose as the single product. Further, we found that these compounds **5** and **6** were not interconverted under the conditions examined, and therefore, they would be formed from **2** through different pathways subtly depending upon the environmental conditions.

Decomposition of the 1,2-Dioxetane 2 under Anhydrous Conditions. A noteworthy feature of the decomposition of **2** under the anhydrous conditions is the



Scheme 3.

formation of a new product. Treatment of an ethereal solution of **2** with boron trifluoride etherate below −12 °C or with concd sulfuric acid below −10 °C afforded quantitatively *o*-terphenyl-4′-ol (**13**). Compound **13** was identical with a sample, which was prepared through 3,4-diphenyl-2-cyclohexenone (**14**) as shown in Scheme 2, as determined by comparison of the spectra. Since **13** corresponds to the dienone-phenol rearrangement product of the dienone **3**, **3** seems to be the most probable precursor of **13**. It was found, however, that **3** was stable even at room temperature to both of boron trifluoride etherate and concd sulfuric acid in ether. The rearrangement of **3** to **13** ultimately occurred upon prolonged refluxing. Thus, **3** would not be the precursor of **13** from **2** under the decomposition conditions examined. Acid-catalyzed decomposition of the hydroperoxide **5** to **13** corresponds to the synthetic process of phenol from cumene through cumene hydroperoxide, and therefore, the process of **2**→**5**→**13** would be an alternative pathway for the formation of **13**. However, from the fact that compound **5**, as well as compound **6**, was also inert under the decomposition conditions of **2**, this process also appears unlikely. Consequently, **13** would be formed directly from **2** through a novel fragmentation.

When wet ether was used in the decomposition of **2** by boron trifluoride etherate below −20 °C, the peroxide **6** became the sole isolable product (24%).

It is to be noted that the ionic decomposition of **2** was also observed on heating at 60—70 °C in carbon tetrachloride. The reaction was carried out in an NMR tube in the ordinary manner and followed by the ^{1}H NMR spectrum. The temporary production of the hydroxy hydroperoxide **7** could be detected, and the final product was shown to be a 1:2—5:1 mixture of **3** and **5**; there was no indication of the presence of the rearranged bicyclic ketone **4**. Traces of hydrogen chloride and water in carbon tetrachloride may cause the ionic fragmentation. Turning to the photooxidation experiment of **1**, the use of chloroform as a solvent at room temperature led to the formations

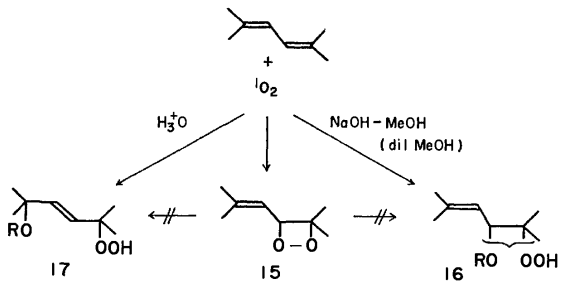
of **3**, **5**, and **6**.

As is clear from the results discussed above the reactivity of the dioxetane **2** is extremely sensitive to acidic agents and environmental conditions, and the product distribution and yield are very diverse. Although the detailed mechanisms for the formation of the products still remained unclarified, because of the low availabilities and/or the high sensitivities of both **2** and products, the results are summarized in Scheme 3.

It is conceivable that the dienone **3** arises partly from the usual thermal fission and partly from the acid (or impurities)-catalyzed one of the dioxetane ring.

The most important mode of the reaction of **2** under the hydrous conditions is the competitive cleavage of the ring carbon (C4)–oxygen bond of the dioxetane moiety. Such a cleavage of 1,2-dioxetane ring has been observed in the rearrangement of tetramethyl-1,2-dioxetane by boron trifluoride in aprotic solvents, resulted from one-oxygen coordination with boron trifluoride.[4b] In our case, easy and selective cleavage of the C4–O bond in **2** might be due to the allylic nature of C4. The ring opening and the attack of water at C4 gives the hydroxy hydroperoxide **7**. The hydroperoxide **5** is certainly formed by dehydration of **7** as discussed earlier. However, the direct pathway from **2** involving ring opening, migration of a double bond and subsequently of a phenyl group, and deprotonation can not be ruled out. The mechanism for formation of the dimeric peroxide **6** is still obscure. Anyhow, a high migratory aptitude of phenyl group and stabilization by aromatization, in addition to the allylic nature of a dioxetane carbon, should promote the formations of **5** and **6**. Among these factors, a phenyl substituent at C7 plays the most important role in the rearrangement, because the 4,4-dimethyl analogue of **1**, on sensitized photooxidation, underwent exclusively the usual 1,2-dioxetane fission to produce 4,4-dimethyl-2,5-cyclohexadienone in quantitative yield.

In view of the recent findings by Hasty and Kearns,[4a] the vicinal hydroxy hydroperoxide **7** is a unique compound as a product derived from 1,2-dioxetane derivatives. They demonstrated that the mono (epidioxide) **15** derived from 2,5-dimethyl-2,4-hexadiene can not be the intermediate in the formation of the vicinal hydroxy (or methoxy) hydroperoxide **16** which was produced by photooxidation of the above diene in basic nucleophilic solvents, as well as in the formation of the 1,4-hydroxy (or methoxy) hydroperoxide **17** in acidic media.



As described above, the phenol **13** would arise directly from **2**, not through **3** or **5**. An explanation for the process leading to **13** is that the coordination of acidic agents to the dioxetane oxygen atom attached to C4 might initiate the ionic fragmentation, and the simultaneous isomerization and aromatization as in the case of **5** or **6** would produce **13** as shown.

Experimental

Melting points are uncorrected. IR spectra were obtained with a Hitachi EPI-S2 or G2 and UV spectra with a Hitachi EPS-3T spectrophotometer. ^1H NMR spectra were recorded with a JEOL C-60HL (60 MHz), PMX-60 (60 MHz), or PS-100 (100 MHz) instrument with TMS as an internal standard; coupling constants are given in Hz. Mass spectra were taken with a Shimadzu LKB-9000 instrument. Silica gel (Merck GF-254) was used for analytical and preparative thin-layer chromatography (TLC); solvent systems are indicated in parentheses. Almost all of new compounds described in this paper did not give the satisfactory analytical data; the variable percentages (always low) of carbon were observed. This may be due to the thermal instabilities and/or the high contents of aromatic carbon atoms of these compounds.

*1-Isopropylidene-4,4-diphenyl-2,5-cyclohexadiene (**1**).* To a stirred suspension of isopropyltriphenylphosphonium iodide[5] (520 mg, 1.20 mmol) in anhydrous ether (15 ml) was added a solution of butyllithium in hexane (20%, 0.6 ml, 1.30 mmol) dropwise at room temperature under nitrogen. After stirring at room temperature for 15 min, a solution of 4,4-diphenyl-2,5-cyclohexadienone (**3**)[6] (250 mg, 1.00 mmol) in anhydrous ether (6 ml) and DMSO (2.5 ml) was added dropwise, and the reaction mixture was heated under reflux for 2 h. After the removal of insoluble material by filtration, the filtrate was washed with aqueous DMSO (50%, 50 ml). The water layer was extracted with a 2:1 mixture of petroleum ether and ether. The combined organic layers were washed with water and saturated brine, dried, and concentrated. The residual oil (380 mg) was chromatographed on silica gel using petroleum ether as an eluant to afford crystals. Recrystallization from petroleum ether yielded the triene **1** (180 mg, 78%): mp 90 °C (lit,[2] mp 89—91 °C); IR ($CHCl_3$) 1595, 1480, 1440, and 1375 cm^{-1}; ^1H NMR ($CDCl_3$) δ 1.89 (6H, s), 5.98 (2H, br. d, J=10.5), 6.67 (2H, d, J=10.5), and 7.42 (10H, s). Found: C, 92.33; H, 7.65%. Calcd for $C_{21}H_{20}$: C, 92.60; H, 7.40%.

*Photooxidation of **1**.* *(a) In Methanol at Low Temperature [Isolation of 3,3-Dimethyl-7,7-diphenyl-1,2-dioxaspiro[3.5]nona-5,8-diene (**2**)]*: A solution of **1** (300 mg) and Rose Bengal (5 mg) in anhydrous methanol (40 ml) and petroleum ether (5 ml) was irradiated with three 200 W tungsten lamps at −78 °C for 2.5 h. Finely dispersed stream of dry oxygen was passed through the solution continually during irradiation. The solvent was removed by vacuum distillation at −40 °C. The residue was chromatographed on two thin-layer silica gel plates (20×20 cm, 1:3 ether–petroleum ether) below −12 °C to give 300 mg (90%, the best result) of a pale yellow oil, which crystallized on standing at −12 °C. Recrystallization from petroleum ether at −12 °C gave **2**: mp 57—61 °C (lit,[2] mp 72—74 °C); IR (CCl_4) 1660, 1595, 1485, 1460, 1370, 1210, 1195, 1075, and 695 cm^{-1}; ^1H NMR (CCl_4, 100 MHz) δ 1.43 (6H, s), 6.35 (2H, d, J=10.5), 6.57 (2H, d, J=10.5), and 7.18 (10H, small split s). The dioxetane **2** could be stored as the dilute solutions in anhydrous THF, ether, benzene, and cyclohexane below −20 °C for several months.

(b) In Methanol at Room Temperature: A solution of **1** (130 mg) and Rose Bengal (5 mg) in anhydrous methanol (30 ml) was photooxidized at room temperature. After irradiation for 1.5 h, work-up in the same manner at room

temperature gave 55 mg (47%) of **2** and 50 mg (43%) of **3**, respectively.

(c) In Chloroform at Room Temperature: A solution of **1** (150 mg) and Methylene Blue (5 mg) in $CHCl_3$ (30 ml) was photooxidized at room temperature for 2.5 h and worked up in the same manner to give 40 mg (30%) of **3**, 25 mg (16%) of **5**, and 26 mg (17%) of **6**.

*Decomposition of **2** on Silica Gel and the Properties of the Products **5**, **6**, and **7***. The dioxetane **2** was re-chromatographed on thin-layer silica gel (1:3 or 1:4 ether–petroleum ether) at 0 °C to produce four UV detectable bands. Collection of these bands, followed by elution with ether and evaporation of the solvent without applying heat gave, in the order of moving, **6**, **3**, **5**, and **7** (variable yields from run to run), respectively.

1-Methyl-1-(*o*-terphenyl-4′-yl)ethyl hydroperoxide (**5**): mp 125.5—128 °C from methanol; positive KI-starch test; IR (CCl_4) 3600, 3500—3100, 1600, 1480, 1440, and 700 cm^{-1}; UV (EtOH) λ_{max} 235 (ε 31000) and 255 nm (ε 20000);[7] ^1H NMR ($CDCl_3$) δ 1.72 (6H, s), 7.24 (10H, s), around 7.30 (1H, br. s, OOH), 7.43 (1H, dd, J=8.8 and 1.9), 7.58 (1H, d, J=8.8), and 7.58 (1H, d, J=1.9); mass *m/e* 288 (parent peak, M^+-16).

Bis[1-methyl-1-(*o*-terphenyl-4′-yl)ethyl] peroxide (**6**): mp 148—150 °C (not recrystallized); IR (CCl_4) 1600, 1480, 1440, and 700 cm^{-1}; UV (EtOH) λ_{max} 235.5 (ε 60800) and 255 nm (ε 27100); ^1H NMR ($CDCl_3$) δ 1.69 (12H, s), 7.18 (20H, s), 7.41 (2H, d, J=8.5), 7.49 (2H, d, J=2.0), and 7.53 (2H, dd, J=8.5 and 2.0). Found: C, 87.20; H, 6.81%. Calcd for $C_{42}H_{38}O_2$: C, 87.77; H, 6.66%. The molecular weight could not be determined by a mass spectral or vapor pressure osmometric method, being presumably due to easy cleavage of the peroxide linkage.

1-(1-Hydroperoxy-1-methylethyl)-4,4-diphenylcyclohexa-2,5-dien-1-ol (**7**): mp 124—126 °C (not recrystallized); IR (CCl_4) 3600, 3650—3100, 1595, 1490, 1175, 865, and 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ 1.18 (6H, s), 2.24 (2H, br. s, OH and OOH), 6.07 (2H, d, J=10.5), 6.32 (2H, d, J=10.5), and 7.28 (10H, s).

*Decomposition of **2** by Hydrochloric Acid. (a)*: A stock solution of **2** in ether (*ca.* 41 mg, 2.1 ml) was diluted with anhydrous ether (2 ml) at −20 °C, and then 2 M HCl (1 drop) was added to this solution. The resulting mixture was vigorously stirred at room temperature for 15 min. The mixture was washed with dilute $NaHCO_3$ solution, water, and saturated brine, dried, and evaporated. The residue was chromatographed on preparative TLC (1:3 ether–petroleum ether) to afford **3** (*ca.* 29%), **5** (*ca.* 15%), and **6** (*ca.* 34%).

(b): The reaction mixture (the same amount as above) was stirred at −18——8 °C. After the reaction was completed (4 d), the mixture was worked up in the same manner, except the use of 1:6 ethyl acetate–petroleum ether as a developing solvent in this case, to give **6** (*ca.* 90%).

(c): A stock solution of **2** in THF (*ca.* 30 mg, 3 ml) was diluted with anhydrous ether (2 ml) at −20 °C, and then 6 M HCl (0.4 ml) was added. The reaction mixture was vigorously stirred at 0 °C for 50 min. Work-up in the same manner yielded **6** (*ca.* 100%).

(d): A stock solution of **2** in cyclohexane (*ca.* 65 mg, 6.5 ml) was diluted with $CHCl_3$ (5 ml) at −10 °C, and then concd HCl (a catalytic amount) was added. The reaction mixture was vigorously stirred below 10 °C for 10 min and worked up in the same manner to give **6** (*ca.* 97%).

*Decomposition of **2** under the Anhydrous Conditions and the Product **13***. *(a)*: *By Boron Trifluoride Etherate*. A stock solution of **2** in THF (*ca.* 50 mg, 3 ml) was diluted with anhydrous ether (10 ml) at −70 °C under nitrogen, and then boron trifluoride etherate (1 drop) was added. The reaction mixture was stirred at −18——12 °C for 2.5 h. Then, the mixture was passed through a short column of silica gel with the aid of ether and evaporated. The residue was chromatographed on preparative TLC (1:7 ethyl acetate–petroleum ether) to give 40 mg (*ca.* 100%) of very viscous oily *o*-terphenyl-4′-ol (**13**): yellow ferric chloride test; IR ($CHCl_3$) 3570, 3550—3100, 3040, 3010, 1600, 1470, 1300, 1210, 890, and 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ 5.60 (1H, br.s, OH), 6.73 (1H, dd, J=9.1 and 2.8), 6.77 (1H, d, J=2.8), 7.05 (10H, m), and 7.15 (1H, d, J=9.1). This compound was identical with the synthetic sample (IR, ^1H NMR, see below).

When ether saturated with water was used for dilution and the reaction was conducted below −20 °C for 15 h, only **6** (*ca.* 24%) was obtained.

(b) By Concd H_2SO_4: A stock solution of **2** in ether (*ca.* 40 mg, 2 ml) was diluted with anhydrous ether (2 ml) at −70 °C, and then concd H_2SO_4 (1 drop) was added. The reaction mixture was stirred below −10 °C for 1 h under nitrogen. Work-up in the usual manner (washing, evaporation, and chromatography) gave 30 mg (*ca.* 100%) of **13**.

*1-Methyl-1-(o-terphenyl-4′-yl)ethanol (**8**). (a) From **5***: To a solution of **5** (26 mg) in anhydrous THF (5 ml) was added lithium aluminum hydride (12 mg), and the reaction mixture was heated at 50 °C for 1 h. The cooled mixture was poured into ice–water and thoroughly extracted with ether. The combined extracts were washed with water and saturated brine, and dried. Removal of the solvent under reduced pressure gave 23 mg (94%) of **8**: mp 144.5—145.5 °C from methanol–petroleum ether; IR (CCl_4) 3500, 3400 (br.), 1600, 1480, 1395, 1360, and 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ 1.70 (6H, s), 7.24 (10H, s), 7.43 (1H, dd, J=8.8 and 1.9), 7.58 (1H, d, J=8.8), and 7.58 (1H, d, J=1.9); mass *m/e* 288 (M^+). This compound was identical with the synthetic sample (see below) as determined by the mixed melting point determination and by comparison of the spectra.

Reduction of **5** with other reagents (triethyl phosphite–toluene, KI–isopropyl alcohol, dimethyl sulfide–benzene) also gave **8** in good yield.

*(b) From **6***: To a solution of **6** (25 mg) in anhydrous ether (8 ml) was added lithium aluminum hydride (5 mg) with ice-cooling under nitrogen. After being stirred for 30 min, the mixture was poured into ice–water, and the water layer was extracted with ether three times. The combined extracts were washed with water and saturated brine. Evaporation of the solvent under reduced pressure left 26 mg (100%) of **8**.

Catalytic hydrogenation of **6** over Pd–C in ethanol also gave quantitatively **8**.

*(c) From **1***: To the well-stirred mixture of a solution of **1** (250 mg, 0.92 mmol) in CH_2Cl_2 (20 ml) and 0.5 M $NaHCO_3$ solution (6 ml) was added portionwise *m*-chloroperbenzoic acid (85%, 224 mg, 1.10 mmol) at 0 °C,[8] and the reaction mixture was stirred at 0 °C for 2 h. The organic layer was separated, washed with dilute NaOH solution and saturated brine, dried, and evaporated. The ^1H NMR spectrum indicated that the crude product was a 2:1 mixture of the epoxide **12** and **8**. Preparative TLC (1:2 ether–petroleum ether) of the crude mixture showed a single UV detectable band. Collection of this band, followed by elution with ether and evaporation provided 260 mg (98%) of **8**.

(d) Synthesis: 2,3-Diphenyl-1,3-butadiene (**9**), bp 150—170 °C (bath)/10 Torr (1 Torr=133.322 Pa), mp 46—47 °C, was prepared by dehydration of 2,3-diphenylbutane-

2,3-diol with $KHSO_4$.[9]

A mixture of **9** (1.4 g, 6.5 mmol), methyl acrylate (3.3 g, 38 mmol), and hydroquinone (20 mg) was heated in a sealed tube at 140 °C (bath temperature) for 15 h. The excess acrylate was removed by distillation under reduced pressure. The residual yellow solid was dissolved in 1:6 ether–petroleum ether and passed through a short column of silica gel to afford 1.74 g (88%) of methyl 3,4-diphenyl-3-cyclohexenecarboxylate (**10**), which gradually crystallized on standing: mp 181 °C; IR (neat, before crystallized) 1735, 1595, 1485, 1430, 1170, and 700 cm^{-1}; ^1H NMR (CCl_4) δ 1.70—2.20 (2H, m), 2.20—2.80 (5H, m), 3.59 (3H, s), and 6.92 (10H, s).

A solution of **10** (584 mg, 2.0 mmol) and DDQ (1.36 g, 6.0 mmol) in toluene (10 ml) was heated under reflux for 26 h under nitrogen. The solvent was removed by distillation under reduced pressure. The brown residue was chromatographed on silica gel (30 g) using 1:1 ether–petroleum ether as an eluant to give 535 mg (92%) of methyl *o*-terphenyl-4′-carboxylate (**11**): IR ($CHCl_3$) 1715, 1600, 1435, 1120, and 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ 3.93 (3H, s), 7.20 (10H, s), 7.53 (1H, d, J=9.0), and 8.00—8.21 (2H, m).

A solution of **10** (292 mg, 1.0 mmol), NBS (373 mg, 2.1 mmol), and dibenzoyl peroxide (8 mg) in CCl_4 (4 ml) was heated under reflux for 80 min under nitrogen. After removal of the insoluble precipitate by filtration, the solvent was expelled by distillation under reduced pressure. The residue was dissolved in pyridine (5 ml), and the resulting solution was heated under reflux for 1 h. The reaction mixture was poured into water and extracted with ether three times. The combined extracts were washed with water, dilute $CuSO_4$ solution, water, and saturated brine, and dried. Evaporation of the solvent left 280 mg (97%) of **11**.

To a solution of methylmagnesium iodide, prepared from magnesium (1.34 g) and methyl iodide (9.9 g) in anhydrous ether (25 ml), was added dropwise a solution of **11** (5.29 g, 18.3 mmol) in anhydrous ether–benzene (2:1, 50 ml) over a period of 15 min at room temperature under nitrogen, and the reaction mixture was stirred for 100 min. Saturated NH_4Cl solution was added, and the water layer was extracted with each 40 ml portions of ether three times. The combined extracts were washed with 2 M HCl, water, and saturated brine. Evaporation of the solvent left a dark brown oil (5.5 g). Chromatography of this oil on silica gel (160 g) using 1:1 ether–petroleum ether as an eluant afforded 5.17 g (98%) of **8**.

*o-Terphenyl-4′-ol (**13**).* *(a) From **3***: To a solution of **3** (50 mg) in anhydrous ether (3 ml) was added concd H_2SO_4 (1 drop), and the reaction mixture was heated under reflux for 48 h. When the mixture was stirred at room temperature, no reaction was observed after 12 h. The cooled mixture was diluted with more ether and washed with dilute $NaHCO_3$ solution and saturated brine, and the solvent was removed by distillation. The residue was chromatographed on preparative TLC (1:5 ethyl acetate–petroleum ether) to yield 35 mg (70%) of **13**.

The reaction of **3** (50 mg) by boron trifluoride etherate (2 drops) in boiling anhydrous ether (4 ml) proceeded extremely slowly. Even after 3.5 d, almost starting material remained unchanged.

(b) Synthesis: To a solution of deoxybenzoin (19.7 g, 0.1 mol) in anhydrous ether (300 ml) was added methyl vinyl ketone (freshly distilled, 7.1 g, 0.1 mol) at 0 °C. Then, to this solution was added dropwise a solution of KOH (1.7 g) in ethanol (15 ml) over a period of 30 min at 0 °C under nitrogen, and the resulting mixture was stirred at 0 °C for 70 min; white precipitate gradually separated. This slurry was poured into a mixture of ice (200 g) and 1 M HCl (35 ml), and the precipitate was collected by filtration, washed with water, and dried *in vacuo* over concd H_2SO_4. The organic layer of the filtrate was separated, washed with water and saturated brine, and evaporated to dryness to yield a solid material. The precipitate and the solid residue were combined and suspended in ethanol (95%, 300 ml). To this slurry was added concd HCl (20 ml), and the resulting mixture was heated under reflux. After 20 min, the mixture became a homogeneous solution, and the refluxing was continued for 2 h. The reaction mixture was poured into cold water (500 ml) and extracted with ether three times. The combined extracts were washed with water and saturated brine, and dried. Evaporation of the solvent and recrystallization of the solid residue from aqueous methanol gave 17 g (69% overall) of 3,4-diphenyl-2-cyclohexenone (**14**): mp 96—97.5 °C; IR (CCl_4) 1670, 1600, 1490, 1442, 1328, 1250, 1170, 885, and 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ 2.00—2.80 (4H, m), 4.35 (1H, m), 6.75 (1H, s), and 7.30 (10H, split s). Found: C, 86.75; H, 6.54%. Calcd for $C_{18}H_{16}O$: C, 87.06; H, 6.50%.

A solution of **14** (124 mg, 0.5 mmol), DDQ (139 mg, 0.6 mmol), and fused *p*-toluenesulfonic acid (19 mg) in anhydrous benzene (12 ml) was heated under reflux for 4 h under nitrogen. The reaction mixture was poured into ice–water and extracted with ether. The combined extracts were washed with water and saturated brine, and evaporated. The residue was chromatographed on preparative TLC (1:4 ethyl acetate–petroleum ether) and distilled at 90—140 °C (bath)/0.3—0.5 Torr to afford 108 mg (88%) of viscous oily **13**, which gradually crystallized on standing: mp 48—51 °C (still adhesive, being unable to recrystallize). Found: C, 87.48; H, 5.96%. Calcd for $C_{18}H_{14}O$: C, 87.77; H, 5.73%.

Polar Effects in the Reactions of a Series of Substituted Diphenyldiazomethanes with Chloranil

Takumi OSHIMA and Toshikazu NAGAI*

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received March 28, 1980)

The kinetics and products of the reactions of fifteen meta- and para-substituted diphenyldiazomethanes with chloranil were investigated in tetrahydrofuran. The second-order rate constants, k, increased with the electron-donating ability of the substituents, and the values could be correlated with the Yukawa-Tsuno equation: $\log k/k_0 = -1.67(\sigma^0 + 0.66\,\Delta\bar{\sigma}_R^+) + 0.009$, ($r = 0.996$). The ρ value, -1.67, indicates the large development of a positive charge at the diazo carbon in the transition state, while the R value, 0.66, confirms the considerable stabilization of the positive charge by the π-electronic contribution of the para substituents. The products of these reactions were the corresponding 2,3,5,6-tetrachlorohydroquinone poly(benzhydryl)ethers, but these polyethers were easily hydrolyzed into the corresponding benzophenones and tetrachlorohydroquinone(HQ). On the other hand, the initial presence of water or methanol as an additive changed the reaction features to give benzophenone or α,α-dimethoxydiphenylmethane, together with HQ. Reaction mechanisms which account for the results are discussed.

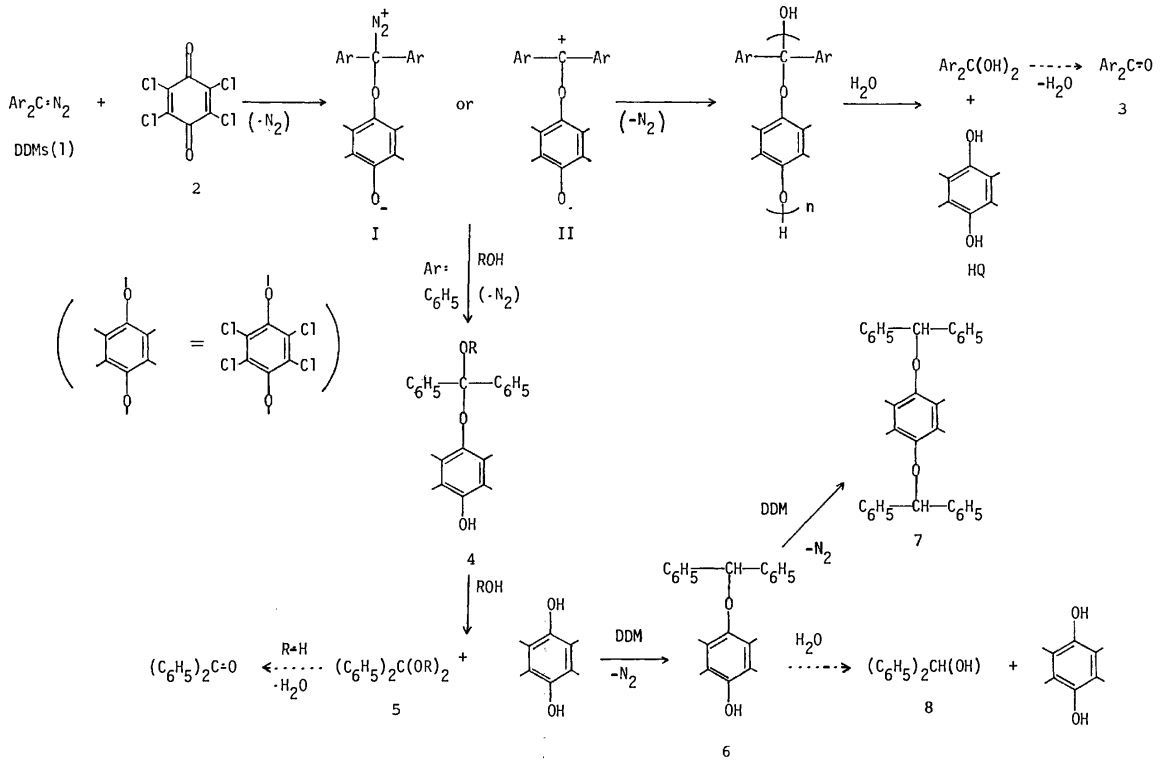
Continuing interest is being paid to the reactions of diazoalkanes with quinones from the synthetic and mechanistic points of view.[1] This is because diazoalkanes are typical 1,3-dipoles[1a,2] with a high electron density on the diazo carbon,[3] while quinones behave as dipolarophiles[1b,4] or electron acceptors[5] with reactive conjugated C=O and C=C bonds. For example, epoxides were obtained when diazomethane was allowed to react with tetrahalo-substituted quinones such as chloranil, because the C=O bonds are more reactive than the C=C bonds in these quinones.[6] We reported in a previous paper[7] that the reactions of several phenyldiazomethanes with chloranil gave stilbenes and spirooxetanes instead of epoxide. We will now extend the diazoalkanes–chloranil systems to a series of diaryldiazomethanes and will describe the kinetics and the mechanism.

Results and Discussion

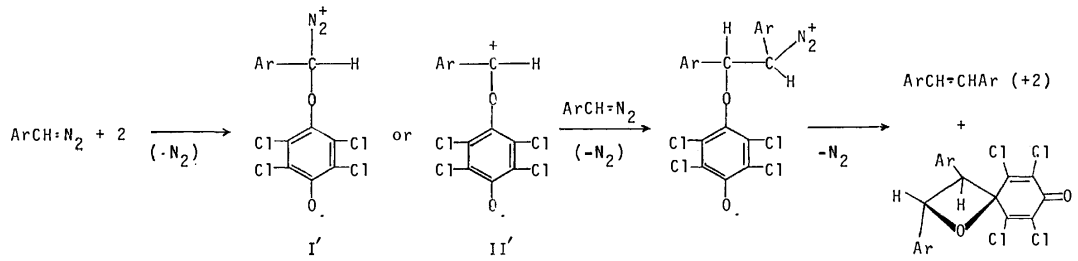
Product Studies. The reactions of diphenyldiazomethane (DDM) and its fourteen meta- and para-substituted analogues (DDMs) (**1**) with an equimolar amount of chloranil (**2**) were conducted in tetrahydrofuran at 30 °C. The decomposition rates were found to be much more accelerated with the increase in the electron-donating abilities of the substituents. For example, the presence of *p,p'*-dimethoxy substituents instantaneously brought about the deposition of a white precipitate, accompanied by a vigorous evolution of N_2, while *p*-nitro-substituted DDM needed one week for the complete disappearance of the diazo color. All these reactions gave some precipitates or suspensions which were easily degradated into the corresponding substituted benzophenones (**3**) and tetrachlorohydroquinone (HQ) on standing in atmospheric moisture or by the addition of aqueous THF. Moreover, the crude reaction mixtures were also completely changed into almost equimolar amounts of the corresponding **3** and HQ on treatment with aqueous THF. These hydrolyses show the stoichiometry to be 1 mol of DDMs to 1 mol of **2**, while the total yields of **3** or HQ are, in most cases, greater than 93%. An elemental analysis of the precipitate obtained in the case of DDM exhibited a composition (C; 54.35, H; 2.46%) very close to the combined molecular formula, $C_{19}H_{10}Cl_4O_2$, of diphenylmethylene and **2**. The IR spectrum (KBr) of this precipitate showed a weak absorption in the OH region, but no appreciable C=O absorption was observed, indicating that the quinonoid structure of **2** has already been lost.

From this chemical and spectroscopic information, it is natural to consider that the structure of these hydrolyzable products is made up by the polyether linkage depicted in Scheme 1. These polyethers consist of an alternate combination of diarylmethylenes and a chloranil moiety with a benzenoid functionality. Accordingly, it can be suggested that intermediary diazonium betaines(I) or carbonium betaines(II) play an important role in the present polymerization process. The propagation of the polyether linkage may be terminated by the action of residual water present in the solvent, the end groups thus becoming hemiketalic OH and phenolic OH. Therefore, the polymerization degree (n) will lie at a lower value with an increase in the water content; we could not estimate the value of n because the precipitates were not soluble in common aprotic solvents and were easily hydrolyzable. The degradation of these polyethers under the influence of water is caused by the successive hydrolytic cleavage of the ether linkage; the dihydroxydiarylmethanes thus formed are easily converted into **3** with a loss of water.

On the other hand, the initial presence of a large amount of water is expected to give, exclusively, the unstable ether (**4**), capable of undergoing subsequent hydrolysis. Indeed, the presence of a five-fold excess of water (ROH, R=H) in the DDM–**2** system brought about the formation of benzophenone and HQ, in addition to small amounts of benzhydrol (**8**) and tetrachlorohydroquinone dibenzhydryl ether (**7**) (Scheme 1). These two by-products seem to be derived from the acid-induced decomposition of DDM with the resulting HQ; the formation of **8** can be ascribed to the hydrolysis of tetrachlorohydroquinone benzhydryl ether (**6**) on work-up. A similar reaction was found in the presence of methanol ($R=CH_3$), where α,α-dimethoxydiphenylmethane (**5**, $R=CH_3$) was



Scheme 1.



Scheme 2.

afforded instead of benzophenone.[8] These solvolysis reactions evidently confirm the occurrence of an intermediate I or II.

Interestingly, the present reactions gave neither olefins nor spirooxetanes; this is in dramatic contrast to the case of phenyldiazomethanes.[7] These products were well explained as arising from the subsequent nucleophilic attack of the diazoalkanes on the diazonium(I′) or carbonium betaine(II′) intermediate, as provided in the present system (Scheme 2). The reason why I or II reject such a nucleophilic attack is probably to be attributed to two factors. One is the steric hindrance due to the presence of two aromatic rings, which screen the central carbon atom from the nucleophilic attack of DDMs. The other is the lesser nucleophilic reactivity of the carbon atom of DDMs compared to that of phenyldiazomethanes. Consequently, the only possible behavior of I and II is to polymerize each other in the absence of strong nucleophiles.

Kinetic Studies. As was noticed in the product studies, the disappearance of the color of the DDMs was much accelerated by introducing the electron-donating substituents in the meta and the para positions of the aromatic rings of DDMs. In order to estimate these polar effects in more detail, the decompositions of fifteen meta- and para-substituted DDMs were followed spectrophotometrically in the presence of high dilute DDMs with respect to **2**; moderate reaction rates were thereby attained, thus avoiding the precipitate formation. The rates determined by monitoring the decrease in the diazo color were found to obey a simple pseudo-first order kinetic law. The rate constants (k_{obsd}) of the decomposition of DDM with various concentrations of **2** are shown in Table 1; the linear dependence of k_{obsd} on the concentration of **2** is held within the limits of experimental error: $10^5 k_{obsd}/s^{-1} = 535[\text{Chloranil}] - 0.31$. Therefore, the second-order rate constants, k, were obtained simply by dividing the k_{obsd} by the concentration of **2**. The values of k thus determined for the meta- and the para-substituted DDMs at various temperatures are given in Table 2, together with the activation parameters. It can be noted that the *p,p′*-dimethoxy substituents caused a 2500-fold increase in the rate compared with the *p*-nitro substituent at 30 °C. In the case of DDM, the rate of the decomposition was also determined by monitoring the evolved N_2, and

the second-order rate constant was nearly equal to that determined by the spectroscopic method. This means that there is no accumulation of any type of intermediate with the N_2 group in the course of the reaction.

The dependence of log k/k_0 on the Hammett σ constants[9] and the Brown σ^+ constants[10] is shown in Fig. 1. For disubstituted DDMs, the σ and the σ^+ values used are the sums of the values for the two substituents. Four meta-substituted DDMs gave an excellent linear dependence ($\rho=-1.52$), $r=0.996$ (correlation coefficient) when the simple Hammett equation and normal σ values were used. When correlating the series of fifteen meta- and para-substituted DDMs and using the normal σ values, though, we obtained substantially worse results ($r=0.933$, $\rho=-2.10$). The correlation line appears to curve upward from the meta line. The replacement of σ by σ^+ caused a considerable improvement in the correlation ($r=0.980$, $\rho=-1.37$), though a downward deviation from the meta line is still found for the methoxy-substituted DDMs. Neither the σ nor σ^+ values apparently fit the correlation of the para-substituted DDMs well.

Table 1. Observed first-order rate constants, k_{obsd}, for the decomposition of DDM(1.70×10^{-3} mol dm^{-3}) with a large excess of chloranil (**2**) in tetrahydrofuran at 40 °C

10^2[Chloranil] / mol dm^{-3}	$10^4 k_{obsd}$ / s^{-1}
8.33	4.41
6.66	3.59
5.83	3.01
5.00	2.68
4.16	2.17
3.33	1.76

Therefore, we used the two-parameter Yukawa-Tsuno equation,[11] log $k/k_0=\rho(\sigma^0+R\Delta\bar{\sigma}_R^+)$, where σ^0, R, and $\Delta\bar{\sigma}_R^+$ are the normal substituent constant, the resonance reaction constant, and the resonance substituent constant respectively. The results of regression anal-

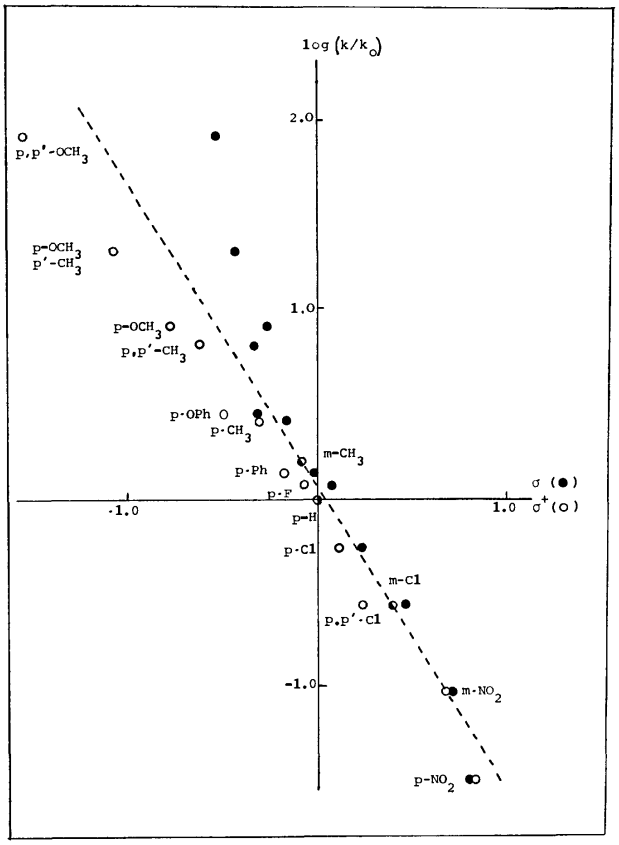


Fig. 1. The plot of log k/k_0 against the Hammett σ(●) and Brown σ^+(○) constants.

Table 2. Second-order rate constants, k, and activation parameters for the decompositions of the substituted DDMs (**1a**—**o**) with chloranil (**2**) in tetrahydrofuran

DDMs	Substituents	$10^3 k$/l mol^{-1} s^{-1} 30 °C	40 °C	50 °C	ΔH^* / kJ/mol	ΔS^* / J/mol K

a) The value in parentheses was determined at 30.5 °C by the volumetric method employing a 2-molar excess of **2** with respect to DDM.

Table 3. Solvent dependence of the rate constants, k, and the activation parameters for the decomposition of DDM with chloranil (**2**)

Solvent	$DN(-\Delta H_{SbCl5})$	E_T	$10^3\,k/1\,mol^{-1}\,s^{-1}$			ΔH^*	ΔS^*
			30 °C	40 °C	50 °C	kJ/mol	J/mol K
1,2-Dichloroethane	0	41.9	30.5	62.5	111	50.1	−109
Acetonitrile	14.1	46.0	23.4	49.3	85.8	50.2	−110
Ethyl acetate	17.1	38.1	5.34	10.4	20.1	51.2	−119
Benzene	0.1	34.5	2.66	6.09	12.3	59.7	−92.2
Tetrahydrofuran	20.0	37.4	2.43	5.35	10.9	58.5	−102

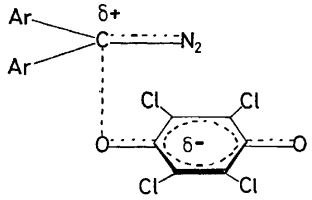
ysis indicate that the use of a two-parameter equation improves the correlation significantly (Eq. 1):

$$\log k/k_0 = -1.67(\sigma^0+0.66\Delta\bar{\sigma}_R^+) + 0.009, \quad (r=0.996,\ s=0.08,\ n=15) \qquad (1)$$

The negative sign and the magnitude of ρ (−1.67) are consistent with the large development of a positive charge at the diazo carbon in the activation process. The value of R=0.66 also confirms that a considerable resonance stabilization of the transition state is required in the present system.

The dependence of the rate on the solvents shows an acceleration or a retardation unexpected from the solvent parameters, *e.g.*, the E_T values (Table 3).[12] A similar unexpected tendency has been observed in the reaction of DDM with tetracyanoethylene (TCNE).[13] These phenomena seem to be ascribable to the stabilization of the initial state caused by the formation of donor–acceptor complexes between these electron acceptors and the solvents. In fact, TCNE is well known to form a strong complex with THF,[14] where the most retarded rate was observed. When the rates were examined as a function of the solvent donor number (DN),[15] the measure of the solvent donability, a decrease in the rate with the increase of DN was always found except in the case of benzene. This exception may be responsible for the lowest E_T value among these solvents, because the charge-separated transition state is not sufficiently solvated in such a nonpolar medium. In this manner, the stabilization of the initial state is so pronounced in the solvent with a high donor number that the rate is no longer directly correlated with the solvent polarities.

Mechanistically, the formation of polyether and the occurrence of the solvolysis reaction in the present system can be well explained by assuming the participation of the diazonium betaine(I) or the carbonium betaine(II) intermediate, as just as in the case of the reactions of phenyldiazomethanes with **2**.[7] The kinetic data presented in this paper provide some information concerning the transition state. The large negative entropies of activation are indicative of the highly ordered transition state usually encountered in 1,3-dipolar cycloaddition.[16] However, the magnitude of the charge separation, as revealed by the Hammett correlation as well as by the solvent effects, appears unmatched in the isopolar transition states of 1,3-dipolar additions. Therefore, the present system is postulated to proceed through the polar transition state depicted below, though the polar transition state of 1,3-dipolar addition[17] can not be ruled out.



Experimental

The IR and NMR spectra were recorded on Hitachi 215 and Varian EM-360 spectrometers respectively. The UV spectra were observed with Hitachi 323 and JASCO UVIDEC 505 instruments.

Materials. The chloranil was of commercial origin and was recrystallized twice from benzene; mp 290 °C. All the diaryldiazomethanes were made by the oxidation of the corresponding hydrazones with yellow mercury(II) oxide as has been previously described.[18] The physical properties of these diazoalkanes were all listed in a previous paper[13] except for *p,p'*-dimethoxy-(mp 100—101 °C (ether) (lit,[9] mp 99—100 °C), UV: λ_{max}=540 nm (ε=85, THF)), *m*-nitro-(mp 53—54 °C(petroleum ether–ether)(lit,[20] an oil), UV: 500 nm (ε=138, THF)), and *p*-nitrodiphenyldiazomethane (mp 80—82 °C (petroleum ether–ether) (lit,[20] mp 80—83 °C), UV: 500 nm (ε=326, THF)). The THF and benzene were refluxed over lithium aluminum hydride and then fractionated. The acetonitrile and 1,2-dichloroethane were refluxed over phosphorus pentaoxide and then fractionated. The ethyl acetate was dried over anhydrous calcium carbonate and then fractionated.

Kinetic Measurements. In order to satisfy the requirements of pseudo first-order treatment, the kinetic reactions were usually carried out in the presence of a 20- to 50-fold molar excess of **2** with respect to DDMs. The change in optical density at the wavelength of the absorption maxima (524—525 nm) of DDMs (**1a—m**) was conveniently monitored because **2** in THF is transparent in this region. The procedure was similar to that described in a previous paper.[13] In the case of the nitro-substituted DDMs (**1n,o**), however, the temperature of the reaction solutions was kept at 30±0.1 °C by the use of a Haake circulator, and the absorption at 500 nm was followed over a 70-percent decomposition at certain time intervals. The pseudo first-order rate constants (k_{obsd}) were determined graphically from plots of $-\ln x$ against the time, where x is the concentration of the remaining DDMs. In all cases, excellent straight lines were obtained. Then, the second-order rate constants (k) obtained by dividing k_{obsd} with the initial concentration of **2** were reproducible to within ±3% (usually two determinations).

Reactions of Diaryldiazomethanes (DDMs) with 2 in THF. The reaction of diphenyldiazomethane (DDM) will be described below as a typical example; the reactions of the

other DDMs were carried out similarly until the characteristic color of the diazo compounds had faded. To a THF solution (40 ml) of **2** (1.0 g, 4.07 mmol) we added, all at once, a THF solution (20 ml) containing DDM (0.79 g, 4.07 mmol) at 30 °C. The purple color of DDM slowly disappeared with a slight evolution of N_2. After 6 h standing, the precipitate (0.8 g) which appeared was filtered, dried *in vacuo*, and submitted to IR measurement and elemental analysis. This white precipitate was completely hydrolyzed to benzophenone and HQ on 3 d exposure to atmosphere or by the addition of aqueous THF. The removal of the solvent, followed by the column chromatography (silica gel) of the hydrolyzed mixtures gave almost equimolar amounts of benzophenone (0.34 g, 46.0%) and HQ (0.47 g, 46.5%), with benzene and ether as the eluents. The filtrate from the white precipitate was dried *in vacuo*, and the residue was treated with a small portion of aqueous THF for 1 h. The column chromatography of the hydrolyzed mixtures also gave equimolar amounts of benzophenone (0.37 g, 50.0%) and HQ (0.52 g, 51.5%). The benzophenones (**3a**—**o**) were identified by a comparison of their IR and NMR spectra with those of authentic samples produced by the Friedel-Crafts reaction. The HQ was identified by a comparison of its IR spectrum with that of an authentic sample.[21]

Reaction of Diphenyldiazomethane (DDM) with 2 in H_2O–THF. To a THF solution (40 ml) of **2** (1.0 g, 4.07 mmol) we added, all at once, a THF solution (20 ml) containing DDM (0.79 g, 4.07 mmol) and H_2O (0.36 g, 20 mmol) at 30 °C. After 6 h standing, the removal of the solvent, followed by column chromatography, gave tetrachlorohydroquinone dibenzhydryl ether (**7**) (40 mg, 3.4% based on DDM used), recovered **2** (0.10 g, 10%), and benzophenone (0.64 g, 86%) with a petroleum ether–benzene mixture, and then HQ (0.85 g, 84%) and benzhydrol (**8**) (50 mg, 6.7%) with a benzene–ether mixture. The product, **7**, was recrystallized from benzene; mp 190—192 °C; IR (KBr): 1407, 949, and 689 cm^{-1}; NMR (δ, $CDCl_3$) 6.43 (2H, s) and 7.28 (20H, s); Found: C, 66.05; H, 3.89%. Calcd for $C_{32}H_{22}Cl_4O_2$: C, 66.23; H, 3.82%. Compound **7** was identified by a comparison of its IR and NMR spectra with those of an authentic sample given by the reaction of DDM with HQ.

Reaction of DDM with 2 in CH_3OH–THF. The reaction was carried out under conditions similar to those described in the H_2O–THF system. After 6 h standing, the removal of the solvent gave a pasty reaction mixture, the NMR spectrum of which showed the presence of large amounts of α,α-dimethoxydiphenylmethane (**5**). However, the **5** slowly hydrolyzed into benzophenone in the reaction mixture, so that the product analyses were made according to two different procedures. First, one-half of the reaction mixture was washed with 3×20 ml pentane to extract the **5**. The pentane solution was shaken with a small portion of aqueous $NaHCO_3$ (5%), washed with water, and dried over sodium sulfate. The concentration of the filtrated solution yielded crystalline **5** (0.39 g, 85%), mp 106—107 °C; IR (KBr): 1209, 1085, 1053, 987, and 689 cm^{-1}; NMR (δ, $CDCl_3$) 3.10 (6H, s, OCH_3) and 7.13—7.57 (10H, m, aromatic H); Found: C, 78.98; H, 7.01%. Calcd for $C_{15}H_{16}O_2$: C, 78.92; H, 7.06%. Second, the other half of the reaction mixture was chromatographed (silica gel). Elution with a petroleum ether–benzene mixture successively afforded **7** (25 mg, 4%), the recovered **2** (0.11 g, 11%), and benzophenone (0.31 g, 84%), while elution with a benzene–ether mixture gave HQ (0.42 g, 83%) and **8** (30 mg, 8%). Thus, **5** was completely hydrolyzed to give benzophenone during the isolation process by the chromatography.

Cyclization of Isothiosemicarbazones. III.[1] Formation of Thiazolines and Thiazoles through Potential Sulfonium Salts from *N,S*-Disubstituted Isothiosemicarbazones

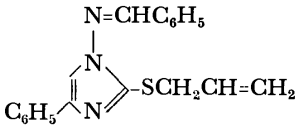
Chiji YAMAZAKI

Department of Chemistry, School of Hygienic Sciences, Kitasato University, Kitasato, Sagamihara 228

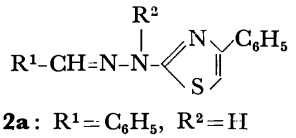
(Received March 31, 1980)

The reaction of 3,4-disubstituted isothiosemicarbazones with α-bromo ketones led to the formation of 4-thiazoline derivatives, the substituents on the sulfur atom being cleaved as bromides. They are identical with the compounds obtained by the condensation of the corresponding thiosemicarbazones, having significantly lower *E*/*Z* ratios in certain products than in those from thiosemicarbazones. The yields of 4-thiazolines widely vary with the substituents on the N-4 and the sulfur atom in the isothiosemicarbazones and also with halo ketones. A mechanism has been suggested which deals with a sulfonium-formation and dissociation process at the apparently less nucleophilic sulfur atom of isothiosemicarbazone. The mechanism might explain the effect of changes in the substituents on the sulfur atom upon the yield of 4-thiazolines, the higher contents of (*Z*)-4-thiazoline from (*E*,*E*)-2,6-dichlorobenzaldehyde 3-allyl-4-methylisothiosemicarbazone, and the inertness or less reactivity of anisaldehyde 2,3-dimethylisothiosemicarbazone and salicylaldehyde 3-allyl-4-phenylisothiosemicarbazone. Differentiation between isomeric thiazole and 4-thiazoline compounds was also described.

Cyclocondensation of a number of isothiosemicarbazones with α-halo carbonyl compounds leads to the formation of 2-mercapto-1*H*-imidazole derivatives and other nitrogen-containing heterocycles.[1,2] In an attempt to improve the yield of imidazoles, an equimolar mixture of benzaldehyde *S*-allylisothiosemicarbazone (**3r**) and phenacyl bromide (**4b**) was heated in toluene at a bath temperature of 130 °C. An appreciable amount of compound was detected with a characteristic resonance at δ 6.80 ppm in chloroform-*d* together with the major product of 1-benzylideneamino-2-allylthio-4-phenyl-1*H*-imidazole (**1**). On the basis of spectral



1



2a: $R^1=C_6H_5$, $R^2=H$
2b: $R^1=p$-$CH_3OC_6H_4$, $R^2=CH_3$

data and elemental analysis, the compound has been identified as benzaldehyde 4-phenyl-2-thiazolylhydrazone (**2a**). The formation of **2a** is of particular interest because it apparently involves an allyl-phenacyl exchange reaction on the much less nucleophilic sulfur atom of the isothiosemi-carbazone than that of alkyl sulfides,[3] probably through a sulfonium formation and dissociation process.[4] In the present work, some isothiosemicarbazones in which the N-2 or N-4 was blocked by certain substituents to prevent the imidazole formation were reacted with α-bromo ketones and the effects of substituent on the formation of sulfur-containing five-membered ring were examined in order to elucidate the reaction pathway.

Results and Discussion

An equimolar mixture of **3n** and **4b** was heated in toluene at a bath temperature of 130 °C for 90 min. A product with a characteristic resonance at δ 6.10 ppm in chloroform-*d*, having a molecular formula $C_{23}H_{19}N_3OS$ (M^+, 385) and showing no NH stretching band in the IR spectrum, was obtained by column-chromatographic separation on silica gel. It was found to be identical with a compound prepared by the condensation of anisaldehyde 4-phenylthiosemicarbazone with **4b** according to methods[5] for the preparation of 2-[alkylidene(or arylmethylene)hydrazono]-4-thiazolines and consequently assigned a structure of 2-(*p*-methoxyphenylmethylenehydrazono)-3,4-diphenyl-4-thiazoline (**5k**).

The NMR spectrum of a low-boiling portion distilled from the reaction mixture of **3o** and **4b** in toluene was found to be indentical with that of 3-bromopropene in this solvent, providing evidence for the formation of **6c** in the reaction. Similarly, a volatile compound formed by the reaction between **3b** and **4b** was identified as 1-bromopropane (**6b**). The expected high-boiling **6d** was detected by direct NMR measurement at intervals of the reaction mixture of **3p** and **4b** in toluene-d_8. No bromomethane (**6a**), which would be formed from the reaction of **3n**, was collected. The equation of the present reactions between 3,4-disubstituted isothiosemicarbazones (**3**) and α-bromo ketones (**4**) can thus be written as in Scheme 1.

The conditions for obtaining **5k** in the preliminary work can successfully be applied to the reactions of other isothiosemicarbazones, representing a general procedure[6] for carrying out the present reactions. The formation of **5** from 3,4-disubstituted isothiosemicarbazones showed considerable solvent-dependence (Table 1). Little or no formation of **5** was noted in acetic acid, 1-butanol, and dimethyl sulfoxide (DMSO),[8] a complex mixture being produced from which no identifiable materials were isolated. A polar solvent might promote the sulfonium formation, since the transition state for the reaction is more polar than the starting materials.[9] On the other hand, the starting isothiosemicarbazones and bromo ketones are not very stable in polar solvents, particularly in those having solvolytic action on the bromo ketone to generate hydrogen bromide which might destroy the starting materials or facilitate side reactions at elevated temperatures. Less polar solvents such as toluene and chlorobenzene seem to be more suitable for the 4-

a) From the corresponding *S*-allylisothiosemicarbazones, **3j** and **3o**, at a bath temperature of 130 °C for 20 min.

thiazoline or thiazole formation rather than highly polar ones.

When **3n** was allowed to react with **4b** in acetonitrile or ethanol at the reflux temperature, 3-(*p*-methoxyphenyl)-4-phenyl-5-methylthio-4*H*-1,2,4-triazole was the only product which could be isolated and identified,[10] its yield amounting to 30% in the latter solvent. The triazole may be formed through electrocyclic reaction[11] of the starting isothiosemicarbazone followed by autoxidation of the intermedially formed 3-methylthio-4-phenyl-5-(*p*-methoxyphenyl)-1,5-dihydro-1,2,4-triazole by analogy with oxidative cyclization of thiosemicarbazones.[12]

Since the ring closure of 3,4-disubstituted isothiosemicarbazone with loss of **6** involves displacement of R^3 by a phenacyl group, the reaction might depend primarily upon the nature of substituent on the sulfur atom. An equimolar mixture of **3i**, **3j**, **3k**, and **4b** in toluene was heated at a bath temperature of 130 °C for 15 min. **4b** disappeared and the approximate molar ratio of the remaining isothiosemicarbazones, estimated on the basis of the NMR spectrum, was found to be 1:18:30 for allyl, benzyl, and methyl compounds, respectively. Although the ratio may represent the relative reactivity of the three isothiosemicarbazones, the yield of **5h** in this reaction was only as little as 42% based on the consumed isothiosemicarbazones due to undetermined side reactions. The above order of reactivities of isothiosemicarbazones, however, is reflected in the actual yields of **5** obtained by the reaction of anisaldehyde 4-methyl- and 4-phenylisothiosemicarbazones bearing allyl, benzyl, or methyl group on the sulfur atom with **4b** in toluene (Table 2). This is in line with the order of stability of the carbocations corresponding to these substituents, the order not being affected by the nature of R^4. The higher yields of **5** from 3-allyl- and 3-benzylisothiosemicarbazones can be rationalized as a result of easy ionization of these groups by S_N1 type pathway from the positively charged

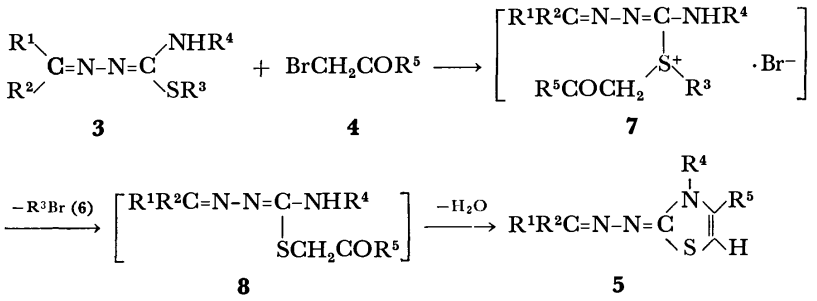
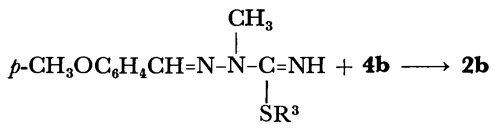


Scheme 2. Mechanism of 4-thiazoline formation.

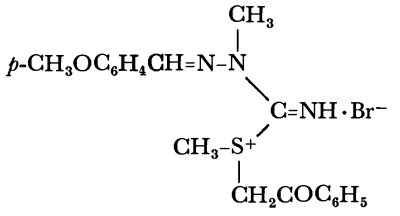
sulfur atom of potential sulfonium salt (**7**). On the other hand, the reaction of **3b** with **4b** gave **5b** (10% yield) and **6b**, but no 2-bromopropane which would be formed if the 3-propyl group is dissociated as a free carbocation from the sulfur atom. Thus 3-propyl- and probably also 3-methylisothiosemicarbazones should react with **4b** to yield the corresponding **5** through S_N2 type dissociation of the sulfonium salt (**7**) into **6b** or **6a** and *S*-phenacylisothiosemicarbazone ($R^5=C_6H_5$) (**8**). In either case, **8** may rapidly cyclize to **5** and can be considered a common intermediate through which the same 4-thiazoline was produced from the corresponding thiosemicarbazone. A tentative mechanism for the 4-thiazoline formation is shown in Scheme 2. The reaction should involve, as the first step, nucleophilic attack of the α-carbon of the halo ketone by sulfur atom as in the simple alkylation reaction of alkyl sulfides.[4] However, the nucleophilicity of the sulfur atom of isothiosemicarbazones seems to be much lower than that of alkyl sulfides, since one of the α-carbons becomes attached to electron-withdrawing groups and the lone electron pairs on the sulfur conjugate to the 2,3-diaza-1,3-butadiene system which may further extend to R^1. Thus the thiazoline formation from isothiosemicarbazones can occur with acetonyl and phenacyl bromides (**4a** and **4b**), but not with the corresponding less reactive chlorides even under drastic conditions.

Under general reaction conditions, **9a** was unreactive and gave no expected thiazole (**2b**) upon heating with **4b** in toluene. In contrast to the inertness of 2,3-dimethyl compound (**9a**), 2-methyl-3-allylisothiosemicarbazone (**9b**) and 2-methylthiosemicarbazone (**9c**) gave **2b** in 64 and 81% yields, respectively. The



9a: $R^3=CH_3$
9b: $R^3=CH_2CH=CH_2$
9c: $R^3=H$

methyl group at the 2-position is by no means obstructive to the ring closure of the probable *S*-phenacylisothiosemicarbazone. The extremely diminished reactivity of **9a** may be explained in terms of the restraint of S_N2-type attack of the bromide ion on the methyl carbon in the sulfonium salt (**10**), presumably due to the free rotation about the N^2–C bond, which gives **10** a less rigid, fluttering structure, the methyl moiety



10

responsible for this reaction thus being a more elusive target for bromide ion. On the other hand, **9b** can produce *S*-phenacylisothiosemicarbazone and **6c** through S_N1 pathway from the sulfonium salt, leading to the formation of the corresponding thiazole. *o*-Hydroxybenzylidene compound (**3g**) required much longer reaction periods (5 h or more) than did the *o*-methoxy analog (**3h**) to give **5e** in comparable yields, although salicylaldehyde 4-phenylthiosemicarbazone gave **5e** in almost quantitative yield upon brief heating with **4b**. Since **3h** gave **5f** in 55% yield within 20 min, the strong intramolecular hydrogen bonding associated with the phenolic hydrogen and the N-1 atom (νOH 3060 cm^{-1} at 2×10^{-3} mol dm^{-3} in carbon tetrachloride) should account for the lower reactivity of **3g** by withdrawing electrons through 2,3-diaza-1,3-butadiene system from the sulfur atom. The unexpectedly high yield of **5d** from **3e** may be interpreted as a result of the exclusion of possible side reactions involving the azomethine double bond by virtue of the two bulky phenyl groups attached.

With bromoacetone (**4a**), major portions of the starting isothiosemicarbazones (**3j** and **3o**) remained unreacted under the general reaction conditions, **5g** and **5i** being obtained in 17 and 5% yields, respectively. Prolonged periods of time caused darkening of the reaction mixture, giving no improvement in the yield of **5**. 2-Arylmethylenehydrazono-3,4-disubstituted 4-thiazolines obtained are given in Table 3.

Compound **5m** formed through the allyl-phenacyl exchange reaction from (*E*,*E*)-**3q**[13] consists of two isomers, *E* and *Z* forms, and has higher content of *Z* (38%) than that produced by the reaction between (*E*)-2,6-dichlorobenzaldehyde 4-methylthiosemicarbazone (**11**) and **4b**, the latter route giving a mixture of *E* (91%) and *Z* (9%) forms. The higher content of *Z* compound was not the result of simple thermal isomerization of initially formed *E* isomer to *Z* form, since the pure (*E*)-**5m** isomerized to only 8% to *Z* upon heating in toluene at 130 °C for the same period of time as that for the reaction of **3q** with **4b**. a) δ ppm from internal TMS in $CDCl_3$.

minished bond order of the CH=N^1 bond in the intermediate species bearing positive charge on the sulfur atom might be responsible for the promoted isomerization. These isomers could be differentiated on the basis of the NMR spectrum in which the azomethine proton (CH=N^1) of *E* form resonated at δ 8.61 and that of *Z* form at δ 7.65 ppm in chloroform-*d*. In view of the greater difference (0.96 ppm) between the chemical shifts of the azomethine protons of these two isomers and a smaller difference (0.26 ppm) between the resonances of N-methyl protons and the substantially equivalent value for the H-5 proton on the thiazoline ring (Table 3), the isomerism should be about the C=N^1 bond rather than N^2=C bond.[14] The proximity of aldehydic proton to the electron pair of nitrogen in *Z* aldoxime caused upfield shift of that proton relative to the corresponding *E* aldoxime.[15] Thus the predominant isomer exhibiting downfield resonance should be of *E*-configuration. A trace of *Z* compound was also detected in the reaction of **3d** with **4b**, being easily removed by means of column chromatography. Recently, assignment of isomeric hydrazones of 2,6-dichlorobenzaldehyde on the basis of NOE observation[16] has been proposed and the conclusions may similarly apply to the present compounds.

A predominant tautomer has been determined by means of UV spectroscopy[17] in the 2-hydrazino-4-phenylthiazole and 2-hydrazono-4-phenyl-4-thiazoline system. An isomeric pair of thiazole (**2b**) and 4-thiazoline (**5h**) showed certain spectral differences sufficient to distinguish them from each other. In the mass spectrometry, the primary fragmentation of **5h** occurred at the N^2=C bond to produce a fragment ion, *m/e* 176, representing the base peak, whereas that of **2b** took place at the N–N bond giving an ion, *m/e* 134 (100%) (*p*-$CH_3OC_6H_4$–$C{\equiv}\overset{+}{N}H$). The former ion may be produced by hydrogen transfer from the azomethine carbon to the sulfur of thiazoline ring, probably through a six-membered transition state. This was confirmed by the spectrum of 2-(α-deuteriobenzylidenehydrazono)-3,4-diphenyl-4-thiazoline which showed a fragment ion, *m/e* 239, as compared with the value *m/e* 238 for that of the corresponding protium compound (**5b**). Further differentiation could be made on the basis of NMR spectra of **2b** and **5h** (Table 4). The resonance of H-5 proton on the heterocyclic ring seems to be of particular diagnostic value for this purpose.

Experimental

General. Melting points were determined in an open glass capillary and are uncorrected. ^1H NMR spectra, obtained with a Hitachi R-24 spectrometer (60 MHz) in chloroform-*d*, are given in δ ppm downfield from internal tetramethylsilane unless otherwise stated. IR spectra were obtained on a Hitachi EPI-G2 or 260-30 grating spectrophotometer and mass spectra (75 eV) on a Japan Electron Optics JMS-D100 mass spectrometer. Wakogel C-300 was used for column chromatography. Commercial phenacyl bromide (**4b**) was recrystallized from ethanol to give colorless prisms, mp 50 °C (lit,[18] mp 50 °C).

Thiosemicarbazones. All the thiosemicarbazones, R^1R^2C=NNHCSNHR^4, were prepared by the conventional method.[19] New ones are (R^1, R^2, R^4, % yield, mp °C, and elemental analyses given): C_6H_5, CH_3, CH_3, 78, 134.5—136. Found: C, 57.83; H, 6.39; N, 20.57%. Calcd for $C_{10}H_{13}$-

N_3S: C, 57.96; H, 6.32; N, 20.28%. *o*-$CH_3OC_6H_4$, H, C_6H_5, 87, 150—151. Found: C, 63.07; H, 5.28: N, 14.82%. Calcd for $C_{15}H_{15}N_3OS$: C, 63.15; H, 5.30; N, 14.73%. *p*-$CH_3OC_6H_4$, H, $CH(CH_3)_2$, 81, 192—193.5. Found: C, 57.26; H, 6.91; N, 16.69%. Calcd for $C_{12}H_{17}N_3OS$: C, 57.35; H, 6.82; N, 16.72%. 2,6-$Cl_2C_6H_3$, H, CH_3, 89, 190—191. Found: C, 41.11; H, 3.39; N, 16.27%. Calcd for $C_9H_9Cl_2N_3S$: C, 41.23; H, 3.46; N, 16.03%.

Isothiosemicarbazones. The compounds **3a**—**3r** were prepared according to the procedure reported previously[20] with some appropriate modifications. New ones are: **3a** (HBr salt): yellow prisms (from EtOH), mp 163—164 °C, yield 89%. Found: C, 45.99; H, 5.09; N, 13.63%. Calcd for $C_{12}H_{16}BrN_3S$: C, 45.86; H, 5.13; N, 13.37%. **3b**: colorless prisms (from hexane), mp 58—59 °C, yield 31%. Found: C, 68.55; H, 6.45; N, 13.90%. Calcd for $C_{17}H_{19}N_3S$: C, 68.66; H, 6.44; N, 14.13%. **3c** (HBr salt): pale yellow prisms (from EtOH), mp 161—162.5 °C, yield 93%. Found: C, 54.24; H, 4.80; N, 11.32%. Calcd for $C_{17}H_{18}BrN_3S$: C, 54.26; H, 4.82; N, 11.17%. **3d** (HBr salt): colorless needles (from EtOH), mp 156—157 °C, yield 87%. Found: C, 47.44; H, 5.53; N, 12.80%. Calcd for $C_{13}H_{18}BrN_3S$: C, 47.56; H, 5.53; N, 12.80%. **3e** (HCl salt): faintly yellowish needles (from aqueous *i*-PrOH), mp 128—129 °C, yield 61%. Found: C, 70.07; H, 6.15; N, 13.63%. Calcd for $C_{18}H_{19}N_3S$ (free base): C, 69.88; H, 6.19; N, 13.58%. **3f**: yellow prisms (from benzene–*i*-PrOH, 1:1 by volume), mp 137—138 °C, yield 89%. Found: C, 63.10; H, 5.29; N, 14.83%. Calcd for $C_{15}H_{15}N_3OS$: C, 63.15; H, 5.30; N, 14.73%. **3g**: pale yellow needles (from *i*-PrOH), 78—78.5 °C, yield 77%. Found: C, 65.50; H, 5.44; N, 13.56%. Calcd for $C_{17}H_{17}N_3OS$: C, 65.58; H, 5.50; N, 13.50%. **3h** (HBr salt): pale yellow fine needles (from EtOH), mp 157—158 °C, yield 88%. Found: C, 52.99; H, 4.93; N, 10.30%. Calcd for $C_{18}H_{20}BrN_3OS$: C, 53.21; H, 4.96; N, 10.34%. **3j** (HBr salt hemihydrate): yellow needles (from MeOH), mp 116.5—117 °C, yield 83%. Found: C, 44.06; H, 5.45; N, 11.72%. Calcd for $C_{13}H_{18}BrN_3OS \cdot 1/2H_2O$: C, 44.20; H, 5.42; N, 11.89%. **3k**: pale yellow fine needles (from i-Pr_2O), mp 55—56 °C, yield 96%. Found: C, 64.88; H, 6.00; N, 13.42%. Calcd for $C_{17}H_{19}N_3OS$: C, 65.16; H, 6.11; N, 13.41%. **3m** (HBr salt hemihydrate): pale yellow prisms (from EtOH), mp 98—99 °C, yield 92%. Found: C, 47.28; H, 6.13; N, 10.99%. Calcd for $C_{15}H_{22}BrN_3OS \cdot 1/2H_2O$: C, 47.25; H, 6.08; N, 11.02%. **3n**: pale yellow needles (from EtOH), mp 112 °C, yield 89%. Found: C, 64.15; H, 5.78; N, 14.13%. Calcd for $C_{16}H_{17}N_3OS$: C, 64.20; H, 5.72; N, 14.04%. **3o** (HBr salt): pale yellow needles (from EtOH), mp 157—158 °C, yield 89%. Found: C, 53.01; H, 4.91; N, 10.41%. Calcd for $C_{18}H_{20}BrN_3OS$: C, 53.21; H, 4.96; N, 10.34%. **3p**: faintly yellowish needles (from benzene–*i*-PrOH, 1:3 by volume), mp 138—138.5 °C, yield 87%. Found: C, 70.61; H, 5.52; N, 11.05%. Calcd for $C_{22}H_{21}N_3OS$: C, 70.38; H, 5.64; N. 11.19%. **3q** (HBr salt): pale yellow prisms (from EtOH), mp 167.5—168.5 °C, yield 62%. Found: C, 37.62; H, 3.65; N, 11.18%. Calcd for $C_{12}H_{14}BrCl_2N_3S$: C, 37.62; H, 3.68; N, 10.97%. **3r**: colorless needles (from hexane), mp 41—41.5 °C, yield 80%. Found: C, 60.52; H, 5.86; N, 19.28%. Calcd for $C_{11}H_{13}N_3S$: C, 60.26; H, 5.98; N, 19.15%. **9b** (HBr salt): pale yellow needles (from MeOH), 175—175.5 °C, yield 54%. Found: C, 45.46; H, 5.22; N, 12.30%. Calcd for $C_{13}H_{18}BrN_3OS$: C, 45.35; H, 5.27; N, 12.21%.

*The Reaction of Benzaldehyde 3-Allylisothiosemicarbazone (**3r**) with Phenacyl Bromide (**4b**).* A solution of **3r** (0.22 g, 1 mmol) and **4b** (0.20 g, 1 mmol) in toluene (1 ml) was heated under reflux in an oil bath at 130 °C for 20 min and then the solvent was evaporated under reduced pressure. The residue was partitioned between chloroform and a 10% aqueous sodium carbonate solution. The organic layer was washed with water, dried over anhydrous sodium sulfate and evaporated. The remaining viscous liquid (0.31 g) was subjected to column-chromatographic separation on silica gel (20 g) using a benzene–ethanol mixture (98:2 by volume). Two fractions, imidazole (0.11 g) and thiazole (0.02 g), each consisting a substantially pure compound, were obtained. Recrystallization of the former twice from ethanol gave **1** as pale yellow needles (0.02 g), mp 101—102 °C. IR (KBr): 3140 cm^{-1} (νC–H of imidazole ring[2]); NMR: 3.95 (2H, dt, $J=7$ Hz and *ca.* 1 Hz, SCH_2), 5.03—6.43 (3H, m, CH_2=CH), 7.36 (6H, m, $H^{m,p}$ of two phenyls), 7.69 (1H, s, H-5 of imidazole ring), 7.78 (4H, m, H^o of two phenyls), 8.25 (1H, s, CH=N); MS (75 eV), *m/e* (rel intensity), 319(100) (M^+), 277(29), 220(97), 215(93), 173(34), 117(51), 104(31), 103(69), 77(45), 41(22). Found: C, 71.26; H, 5.33; N, 13.05%. Calcd for $C_{19}H_{17}N_3S$: C, 71.45; H, 5.37; N, 13.16%; M, 319. This was identical with a compound obtained by the standard method.[2] The thiazole **2a** exhibited IR and NMR spectra identical with those of an authentic sample (mp 191—192 °C; Found: C, 69.03; H, 4.63; N, 14.82%; M^+, 279. Calcd for $C_{16}H_{13}N_3S$: C, 68.80; H, 4.69; N, 15.05%; M, 279) which was prepared by heating an equimolar mixture of benzaldehyde thiosemicarbazone and **4b** in 80% aqueous ethanol and neutralizing the hydrobromide formed with aqueous sodium carbonate. The hydrobromide conventionally prepared from the thiazole fraction showed no depression in melting point on mixing with the authentic sample (223 °C).

*The Reaction of Benzaldehyde 3-Allyl-4-phenylisothiosemicarbazone (**3c**) with **4b** (a Typical Example).* A mixture of **3c** (0.3 g, 1 mmol), **4b** (0.2 g, 1 mmol), and toluene (2 ml) was heated in an oil bath at 130 °C for 20 min with occasional agitating and then the solvent was removed under reduced pressure. The residue was partitioned between chloroform and a 10% aqueous sodium carbonate solution. The organic layer was washed with water, dried over anhydrous sodium sulfate and evaporated. The remaining crystalline solid (0.38 g) was subjected to column chromatography on silica gel (30 g) eluting with benzene containing 1% by volume of ethanol. A homogeneous fraction (140 ml) gave **5b** as yellow crystals (0.21 g, 59%), mp 189—190 °C. Recrystallization from an acetone–benzene mixture (1:1 by volume) gave yellow prisms, mp 189.5—190.5 °C. NMR: 6.15 (1H, s, H-5 of 4-thiazoline ring), 7.15 (5H, s, phenyl), 7.27 (5H, s, phenyl), 7.32 (3H, m, $H^{m,p}$ of benzylidene group), 7.73 (2H, m, H^o of benzylidene group), 8.22 (1H, s, CH=N); MS, *m/e* (rel intensity), 355(100) (M^+), 326(25), 238(86), 133(22), 91(15), 77(48). Under similar conditions except for a heating period of 2.5 h, **3b** gave **5b** in 10% yield. The same compound was also obtained by refluxing benzaldehyde 4-phenylthiosemicarbazone (mp 189—191 °C, lit,[19a] mp 189 °C) with **4b** in 95% ethanol for 1 h and by recrystallization of the product, after being converted into the free base by an aqueous sodium carbonate solution, from an acetone–benzene mixture, mp 190—191.5 °C. Mixed melting point with **5b** showed no depression. Similarly benzaldehyde-α-*d* 4-phenylthiosemicarbazone (C_6H_5CD=N–NHCSNHC$_6H_5$) afforded the corresponding monodeuteriothiazoline, mp 190.5—191.5 °C; IR (KBr): νC–D 2200 cm^{-1}; MS, *m/e* (rel intensity) 356(100) (M^+), 327(25), 239(70), 133(16), 91(18), 77(32).

*The Reaction of 2,6-Dichlorobenzaldehyde 3-Allyl-4-methylisothiosemicarbazone (**3q**) with **4b**.* A mixture of **3q** (0.3

g, 1 mmol), **4b** (0.2 g, 1 mmol), and toluene (1 ml) was heated under reflux for 2.5 h and then evaporated under reduced pressure. Work-up of the residue in the same way as described in the reaction of **3c** with **4b** gave a thiazoline fraction (0.21 g, 58%) consisting of 62% *E* and 38% *Z* forms. This fraction was further subjected to column chromatography on silica gel (20 g) with benzene as an eluent giving a *Z* fraction (0.045 g) which preceded an *E* fraction (0.07 g). The *Z* compound, (*Z*)-**5m**, crystallized from ethanol as yellow plates (0.04 g), mp 149.5—150 °C. NMR: 3.12 (3H, s, NCH_3), 5.98 (1H, s, H-5 of 4-thiazoline ring), 7.27 (3H, s, 2,6-dichlorophenyl), 7.38 (5H, s, phenyl), 7.65 (1H, s, CH=N); MS, *m/e* (rel intensity), 363(30), 361(41) (M^+), 326(100), 176(29), 134(7), 123(17), 102(45), 91(13), 77(10). The *E* compound, (*E*)-**5m**, was obtained as a yellow oil which gradually solidified upon standing. Recrystallization of the solid from ethanol gave fine yellow needles, mp 96—97.5 °C. NMR: 3.38 (3H, s, NCH_3), 5.97 (1H, s, H-5 of 4-thiazoline ring), 7.20 (3H, m, 2,6-dichlorophenyl), 7.35 (5H, s, phenyl), 8.61 (1H, s, CH=N); MS, *m/e* (rel intensity), 363(25), 361(35) (M^+), 326(100), 176(36), 134(32), 123(27), 102(72), 91(17), 77(18). When **5m** containing *Z* isomer was converted into the hydrobromide and the salt recrystallized from ethanol, pure (*E*)-**5m** hydrobromide was obtained as pale yellow prisms solvated with one molecule of ethanol, mp 213.5—214 °C not depressed by the authentic sample prepared by the reaction of 2,6-dichlorobenzaldehyde 4-methylthiosemicarbazone with **4b**. NMR: 1.20 (3H, t, J=7 Hz, CCH_3), 3.72 (2H, q, J=7 Hz, CCH_2), 4.01 (3H, s, NCH_3), 6.81 (1H, s, H-5 of 4-thiazoline ring), 7.35 (3H, s, 2,6-dichlorophenyl), 7.51 (5H, m, phenyl), 9.70 (1H, s, CH=N), broadly dispersed signal centered at about 14.1 ($\overset{+}{N}H$ and OH). Found: C, 46.72; H, 3.95; N, 8.70%. Calcd for $C_{19}H_{20}BrCl_2N_3OS$: C, 46,64; H, 4.12; N, 8.59%.

*The Reaction of Anisaldehyde 2-Methyl-3-allylisothiosemicarbazone (**9b**) with **4b**.* A mixture of **9b** (0.09 g, 0.34 mmol), **4b** (0.07 g, 0.35 mmol), and toluene (0.5 ml) was refluxed for 2 h and evaporated under reduced pressure. The residue was worked up by the same procedure as described for the reaction of **3c** with **4b** to give anisaldehyde 1-methyl-1-(4-phenyl-2-thiazolyl)hydrazone (**2b**) (0.07 g, 64%) as yellow plates, mp 178—180 °C. Recrystallization from an *i*-Pr_2O–AcMe mixture (1:1 by volume) raised the melting point to 186.5—187 °C. NMR: 3.69 (3H, s, NCH_3), 3.81 (3H, s, OCH_3), 6.88 (1H, s, H-5 of thiazole ring), 6.92 (2H, d, J=9.0 Hz, *p*-methoxyphenyl), 7.32 (3H, m, $H^{m,p}$ of phenyl), 7.56 (1H, s, CH=N), 7.63 (2H, d, J=9.0 Hz, *p*-methoxyphenyl), 7.89 (2H, m, H^o of phenyl). Found: C, 66.79; H, 5.29; N, 12.86%; M^+, 323. Calcd for $C_{18}H_{17}N_3OS$: C, 66.86; H, 5.30; N, 13.00%; M, 323. The same compound was obtained by refluxing anisaldehyde 2-methylthiosemicarbazone (0.22 g, 1 mmol; mp 191 °C, lit,[21] mp 192 °C) and **4b** (0.20 g, 1 mmol) in ethanol (5 ml) for 1 h and neutralizing the hydrobromide with aqueous sodium carbonate as pale yellow plates (0.26 g, 81%), mp 185—187 °C, not depressed by admixture with the compound prepared as above.

The author wishes to thank Miss Kuniko Saito and Miss Tomoko Watanabe for their helpful technical assistance in the preparation of compounds.

Substitution and Elimination Reactions *via* One Electron Transfer Process. A New Olefin Synthesis from β-Nitro Sulfones[1]

(Received April 15, 1980)

gem-Bromonitro compounds or *gem*-dinitro compounds couple with carbanions derived from α-cyano sulfones or α-carbonyl sulfones to give β-nitro sulfones. The nitro and sulfonyl groups are eliminated from the coupling products on treatment with reductive one electron transfer reagents to give α,β-unsaturated carbonyl compounds or nitriles.

Reductive elimination of nitro groups from the vicinal dinitro compounds is a useful procedure for olefin synthesis, where olefins are obtained in good yields by the action of mild reducing agents such as sodium sulfide,[3] tin(II) chloride,[4] or calcium amalgam.[5] If one of the nitro groups can be replaced by a sulfonyl group in this type of elimination, synthetic utility must increase to give a wide variety of olefins from β-nitro sulfones.

In this paper we wish to report the preparation of β-nitro sulfones by the reaction of *gem*-bromonitro compounds(**1**) or *gem*-dinitro compounds(**2**) with α-sulfonyl carbanions followed by the conversion of β-nitro sulfones to olefins.

Results and Discussion

Preparation of β-Nitro Sulfones. The reaction of *gem*-bromonitro compounds(**1**) or *gem*-dinitro compounds(**2**) with α-sulfonyl carbanions was carried out in *N*,*N*-dimethylformamide (DMF) or dimethyl sulfoxide(DMSO) as shown in Eq. 1. Carbanions sta-

$$\underset{\substack{|\\ NO_2}}{R^1R^2C}\text{–X} + ArSO_2\text{–}\bar{C}(Y)R^3M^+ \longrightarrow \underset{\substack{|\\ NO_2}}{R^1R^2C}\text{—}\underset{\substack{|\\ SO_2Ar}}{C(Y)R^3} \quad (1)$$

1 X=Br; **2** X=NO_2; Y=CN, -C(=O)-; Ar=*p*-Tolyl or phenyl; M=Na, K; **4**

bilized by the sulfonyl and cyano groups or by the sulfonyl and carbonyl groups react with **1** or **2** to give the cross coupling products(**4**), but carbanions stabilized by one sulfonyl group or by the sulfonyl and nitro groups do not react with **1** or **2** at all. Results are summarized in Table 1.

Compounds **1** or **2** undergo a variety of reactions with carbanions. The following three types of reactions have been reported; 1) cross coupling reaction *via* a radical chain process, 2) cross coupling reaction *via* a radical non-chain process, 3) oxidative dimerization of carbanions.[6] Carbanions which undergo type 1 reaction are those derived from nitroalkanes, malonate esters, malonitriles, β-keto nitriles, cyanoacetates, β-keto esters, and β-diketones.[7]

It is clear that the coupling reaction of Eq. 1 proceeds *via* a radical chain process, since it is completely inhibited by the presence of 10 mol% of di-*t*-butylnitroxide. Thus, carbanions derived from α-cyano sulfones and α-carbonyl sulfones undergo type 1 reaction. A chain sequence of this type of reaction can be expressed as follows.

$$R\text{–}X + C^- \longrightarrow R\text{–}X^{\cdot-} + C\cdot$$
$$R\text{–}X^{\cdot-} \longrightarrow R\cdot + X^- \qquad X=\text{leaving groups}$$
$$R\cdot + C^- \longrightarrow R\text{–}C^{\cdot-} \qquad C^-=\text{carbanions}$$
$$R\text{–}C^{\cdot-} + R\text{–}X \longrightarrow R\text{–}C + R\text{–}X^{\cdot-}$$

It should be emphasized that the coupling reaction using α-sulfonyl carbanions involves anion radical intermediates from which a sulfonyl group can be eliminated.[8] Actually, α,β-unsaturated nitriles are formed in about 10% yield during the preparation of **4c**, **4d**, **4f**, or **4g**. This lowers the yield of the coupling products, however, this finding has an important bearing in a sense of organic synthesis.

Potassium is used as a counter cation of carbanions to prepare **4j**, **4l**, and **4m**. The reactions using sodium as a counter cation proceed very slowly. For example, it takes about 30 h to complete the reaction to prepare **4l** when sodium is a counter cation. Not much attention has been paid to counter cations of carbanions in nucleophilic substitution reaction *via* a radical chain process. Although sodium salts of carbanions have often been used, potassium salts seem to be much more reactive than sodium salts and are generally the reagent of choice.[9]

All attempts to bring about a coupling reaction of a carbanion stabilized by one sulfonyl group with **1** or **2** have failed. Starting materials were recovered unchanged (see Table 1). Simple β-nitro sulfones, the requisite starting materials to get non-functionalized olefins, have not been available by this S_{RN} route. Carbanions stabilized by one nitro group react with **1** or **2** very rapidly to afford the coupling products in good yields,[3] but highly stabilized carbanions such as those stabilized by the nitro and sulfonyl or by the nitro and carbonyl groups do not react with **1** or **2**. A possible explanation is that these highly stabilized anion is not a good electron donor to the S_{RN} acceptor.[10] Thus elimination from the vicinal dinitro compounds cannot be applied to the preparation of olefins substituted by electron-withdrawing groups at the sp^2 center.

Conversion of β-Nitro Sulfones to Olefins It is expected that the nitro and sulfonyl groups are eliminated from β-nitro sulfones on treatment with reductive one electron transfer reagents. In fact, **4a** is converted to olefin(**5a**) on treatment with various one electron transfer reagents as shown in Table 2 (Eq. 2). Inter-

a) Pure isolated products. b) Besides **5l**, α,β-unsaturated sulfone (**6**) was obtained in 15% yield.

benzenethiolate or the lithium salt of 2-nitropropane can induce the elimination of Eq. 2, when the reaction mixture is irradiated by a 150 W tungsten lamp. Among various reducing agents, sodium sulfide is the best one to prepare olefins in its availability, effectiveness and in the mildness of the reaction conditions. β-Nitro sulfones(**4**) listed in Table 1 are converted to olefins (**5**) on treatment with sodium sulfide in DMF at room temperature (Eq. 3). Results are summarized

$$\mathbf{4} + Na_2S \longrightarrow \underset{(\mathbf{5})}{R^1R^2C{=}C(Y)R^3} + NaNO_2 + S + ArSO_2Na \quad (3)$$

$Y = CN, -\overset{\overset{O}{\|}}{C}-$

in Table 3. The reaction proceeds very rapidly as shown in Fig. 1. The yield in the table refers to pure and isolated products. The reaction proceeds smoothly to give **5** in good yields, for example, the yield of **5a** or **5f** determined by GLPC using an internal standard is 92 and 97%, respectively. On treatment with sodium sulfide, elimination from **4h**, **4i**, or **4j** proceeds faster than hydrolysis of an ester function of these compounds. Thus, α,β-unsaturated carboxylates are obtained in good yields on treatment with **4h**, **4i**, or **4j** with sodium sulfide.

But the reaction of **4l** with sodium sulfide gives the mixture of **5l** and α,β-unsaturated sulfone(**6**) (Eq. 4).

$$\mathbf{4l} + Na_2S \longrightarrow \mathbf{5l} + \underset{(\mathbf{6})}{Me_2C{=}C(SO_2Ar)Me} \quad (4)$$

Compound **6** is formed by elimination of the nitro and acetyl groups from **4l**. This may proceed *via* one electron transfer process.[11]

It is recommended to carry out the coupling reaction

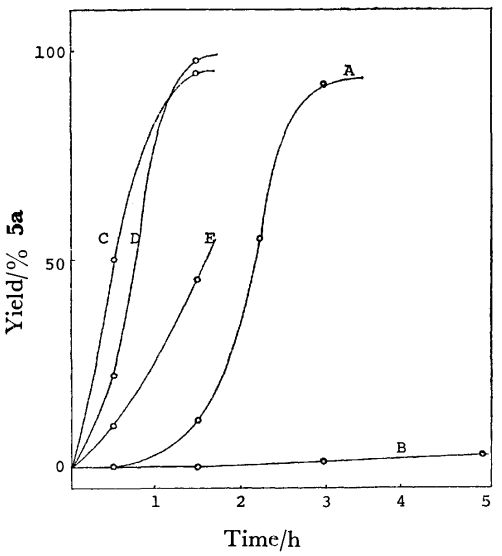

Fig. 1. Effects of di-*t*-butylnitroxide and nitro aromatics on the reaction of Eq 3. A: None, B: di-*t*-butylnitroxide (5 mol%), C: *m*-DNB (10 mol%), D: *p*-DNB (10 mol%), E: nitrobenzene (10 mol%).

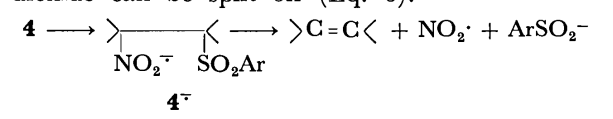
of carbanions with **1** or **2** and the subsequent elimination by one-pot procedure to prepare α,β-unsaturated nitriles, for some amounts of olefins are already formed while the coupling reaction proceeds. Thus, α,β-unsaturated nitriles are obtained in good yields by the one-pot procedure shown in Eq. 5. Results are summarized in Table 4.

$$\mathbf{1}\text{ or }\mathbf{2} + \underset{CN}{R^3\bar{C}}\text{-}SO_2Ar\ Na^+ \xrightarrow[3\,h]{-20\text{ or }0^\circ C} \xrightarrow[3\,h]{rt} \underset{Na_2S}{R^1R^2C{=}C(CN)R^3} \quad (5)$$

The elimination of the nitro and sulfonyl groups from β-nitro sulfones is not a simple ionic process. This is clear from the data in Fig. 1, where the effect of di-*t*-butylnitroxide or nitro aromatics on the reaction of Eq. 3 is summarized. Five mol% of di-*t*-butylnitroxide inhibits this reaction completely, this fact suggests that the present elimination reaction proceeds by a free radical chain mechanism. As shown in Fig. 1, the reaction is strongly affected by nitrobenzene, *m*-dinitrobenzene (*m*-DNB), and *p*-dinitrobenzene(*p*-DNB). These nitro aromatic compounds generally retard the substitution reaction *via* one electron transfer

processes, but the present reaction is accelerated by these π-acids. These facts, and observations of other aliphatic nitro system,[3,7] suggest that the elimination reaction is initiated by the formation of anion radical of β-nitro sulfone, from which sulfinate ion and nitrogen dioxide can be split off (Eq. 6).[12]



(6)

The unique olefin synthesis reported herein provides a potentially useful alternative to the classical methods using carbonyl compounds and carbanions. An important feature of the present procedure is that both the coupling and the elimination steps proceed *via* radical chain mechanism involving one electron transfer process to give highly hindered olefins under mild conditions.

Experimental

Solvents were purified by distillation. The IR spectra were recorded with a Hitachi 215 spectrophotometer. The ^{1}H-NMR spectra were recorded using a JEOL PE-100 spectrometer with TMS as an internal standard. GLPC analyses were performed with a Varian Aerograph 920 using a column containing Silicone DC-550 (20%, 1 m). The following compounds were prepared by the standard procedure; *gem*-bromonitro compounds,[13] *gem*-dinitro compounds,[14] α-cyanoalkyl sulfones.[15] Other sulfones were prepared by the reaction of the corresponding bromides with sodium *p*-toluenesulfinate or sodium benzenesulfinate in DMF. All reactions for the preparation of β-nitro sulfones (**4**) and olefins (**5**) were performed under a nitrogen atmosphere.

Preparation of β-Nitro Sulfones (4). Preparation of 4a as a Typical Procedure: Sodium hydride (44 mmol, 50% mineral oil dispersion) was placed in a 300 ml flask which was fitted with a rubber septum through which reagents can be introduced by a syringe. After sodium hydride was washed with hexane to remove mineral oil, the flask was placed under nitrogen and 50 ml of DMF was introduced *via* a syringe. A solution of 2-tosylpropionitrile (8.4 g, 40 mmol) in 50 ml of DMF was added dropwise to sodium hydride and the mixture was stirred until the evolution of hydrogen ceased. Then the DMF solution of the carbanion was cooled to 0 °C and to this solution was added 2-bromo-2-nitropropane (8.1 g, 40 mmol) in 30 ml of DMF. The resulting solution was stirred at 0 °C for 1.5 h. Working up by dilution with water, benzene extraction, followed by aqueous washing of the benzene layer, drying over anhydrous magnesium sulfate, and concentration gave a solid material. The crude material was recrystallized from ethanol to give **4a** (8.6 g, 73% yield). Other β-nitro sulfones were prepared by the similar procedure, but **4g** and **4i** were purified by column chromatography on silica gel using benzene as an eluent. Compound **4b** consisted of two diastereomers (A and B). They were separated by column chromatography on silica gel using benzene as an eluent. The ratio of A to B was unity. For the preparation of **4j**, **4k**, and **4m**, t-C_4H_9OK was used as a base instead of NaH. Reaction conditions are summarized in Table 1 and physical data of **4** are summarized in Table 5.

Inhibition Study. The reaction of the sodium salt of 2-tosylpropionitrile with 2-bromo-2-nitropropane was carried out at 0 °C. Each experiment consists of the sodium salt of the nitrile (6 mmol) and the nitro compound (7 mmol) in 15 ml of DMF and a reaction time of 1 h. Working up was carried out in the usual way. In the absence of di-*t*-butylnitroxide the crude product was subjected to column chromatography on silica gel using benzene as an eluent to give **4a** (1.0 g, 68% yield). In the presence of di-*t*-butylnitroxide (0.086 g, 0.6 mmol) **4a** was not detected on TLC. The crude product was subjected to column chromatography to give 2-tosylpropionitrile (0.85 g, 70% recovery).

Conversion of 4a to 5a under Various Conditions. Compound **4a** (1 mmol) was treated with various reducing reagents (3 mmol) under conditions listed in Table 2. After the period listed in the table, diethyl malonate (1 mmol) which is an internal standard was added. Then the reaction mixture was worked up in the usual manner and the organic materials were analyzed by GLPC. Yield of **5a** was determined from calibration curve which was made from pure **5a** and diethyl malonate. Results are summarized in Table 2.

Conversion of β-Nitro Sulfones (4) to Olefins (5) by Sodium Sulfide. General Procedure: A mixture of **4** (15 mmol) and $Na_2S \cdot 9H_2O$ (5.0 g, 18 mmol) in 30 ml of DMF was stirred at room temperature for 3 h, then 150 ml of water was added and the mixture was extracted with diethyl ether three times. The extract was washed with water, dried over magnesium sulfate, and concentrated. Distillation gave **5**. The following olefins were prepared by this procedure.

Physical Properties: **5a**: Bp 60 °C/35 Torr. (1 Torr=133.32 Pa, lit,[16] 155—157 °C). ^{1}H-NMR (CCl_4); δ 2.04 (3H, s), 1.82 (6H, s). IR (neat); 2215 cm^{-1} (CN), 1640 cm^{-1} (C=C). MS (20 eV), *m/e* (rel intensity), 95 (M^+, 100), 80(41), 68 (50).

5b: Bp 82 °C/40 Torr (lit,[17] 64 °C/17 Torr). ^{1}H-NMR (CCl_4); δ 2.44 (1H, q, J=7.5 Hz), 2.23 (1H, q, J=7.5 Hz), 2.07 (1.5H, s), 1.88 (3H, s), 1.84 (1.5H, s), 1.12 (1.5H, t, J=7.5 Hz), 1.06 (1.5H, t, J=7.5 Hz). IR (neat); 2215 cm^{-1} (CN), 1640 cm^{-1} (C=C). MS (20 eV), *m/e* (rel intensity), 109 (M^+, 14), 94(16), 67(14), 43(100).

5c: Bp 112.5 °C/32 Torr (lit,[18] 131/63 Torr). ^{1}H-NMR (CCl_4); δ 2.72—2.42 (2H, m), 2.42—2.16 (2H, m), 1.80 (3H, s), 2.0—1.6 (4H, m). IR (neat); 2215 cm^{-1} (CN), 1640 cm^{-1} (C=C). MS (20 eV), *m/e* (rel intensity), 121 (M^+, 34), 106(13), 67(80), 43(100).

5d: Bp 110 °C/15 Torr (lit,[19] 103 °C/13 Torr). ^{1}H-NMR (CCl_4); δ 2.6—2.4 (2H, m), 2.4—2.2 (2H, m), 1.87 (3H, s), 1.8—1.4 (6H, m). IR (neat); 2205 cm^{-1}(CN), 1627 cm^{-1}(C=C). MS (20 eV), *m/e* (rel intensity), 135 (M^+, 46), 120(20), 81(74), 68(100).

5e: Bp 92 °C/25 Torr. ^{1}H-NMR (CCl_4); δ 2.24 (2H, q, J=7.1 Hz), 2.07 (3H, s), 1.86 (3H, s), 1.13 (3H, t, J=7.1 Hz). IR (neat); 2210 cm^{-1}(CN), 1635 cm^{-1}(C=C). MS (20 eV), *m/e* (rel intensity), 109 (M^+, 12), 94(20), 67(12), 43(100).

5f: Bp 95 °C/25 Torr. ^{1}H-NMR (CCl_4); δ 2.19 (2H, m), 2.08 (3H, s), 1.85 (3H, s), 1.6—1.2 (4H, m), 0.97 (3H, t, J=7.1 Hz). IR (neat); 2210 cm^{-1} (CN), 1635 cm^{-1}(C=C). MS (20 eV), *m/e* (rel intensity), 137 (M^+, 25), 122(17), 96(18), 69(100).

5g: Bp 93.5 °C/0.6 Torr. ^{1}H-NMR (CCl_4); δ 2.17 (2H, m), 2.06 (3H, s), 1.84 (3H, s), 1.1—1.6 (12H, m), 0.89 (3H, t, J=7.5 Hz). IR (neat); 2210 cm^{-1}(CN), 1635 cm^{-1}(C=C). MS (20 eV), *m/e* (rel intensity), 193 (M^+, 51), 178(62), 164(80), 136(100).

5h: Bp 106 °C/100 Torr (lit,[20] 99 °C/81.5 Torr). ^{1}H-NMR (CCl_4); δ 4.10 (2H, q, J=7.0 Hz), 2.00 (3H, s), 1.77 (6H, s), 1.28 (3H, t, J=7.0 Hz). IR (neat); 1700 cm^{-1} (C=O), 1620 cm^{-1}(C=C). MS (20 eV), *m/e* 135 (M^+).

5i: Bp 95 °C/38 Torr (lit,[21] 67—72 °C/14 Torr). ^{1}H-

NMR (CCl_4); δ 4.14 (2H, q, J=7.0 Hz), 2.29 (2H, q, J=7.0 Hz), 1.94 (3H, s), 1.80 (3H, s), 1.28 (3H, t, J=7.0 Hz), 0.97 (3H, t, J=7.0 Hz). IR (neat); 1700 cm^{-1} (C=O), 1620 cm^{-1} (C=C). MS (20 eV), *m/e* 156 (M^+).

5j: Bp 54 °C/9 Torr (lit,[22] 67 °C/13 Torr). ^{1}H-NMR (CCl_4); δ 4.07 (2H, q, J=7.2 Hz), 2.25 (2H, q, J=7.2 Hz), 1.92 (3H, s), 1.78 (3H, s), 1.26 (3H, t, J=7.2 Hz), 0.95 (3H, t, J=7.2 Hz). IR (neat); 1700 cm^{-1} (C=O), 1630 cm^{-1} (C=C).

5k: Bp 109 °C/12 Torr (lit,[23] 71—73 °C/0.9 Torr). ^{1}H-

NMR (CCl_4); δ 4.20 (2H, t, J=7.5 Hz), 3.0—2.7 (2H, m), 2.21 (3H, t, J=1.5 Hz), 1.88 (3H, s). IR (neat); 1740 cm^{-1} (C=O), 1665 cm^{-1} (C=C).

5l: Bp 57 °C/49 Torr (lit,[24] 145—148 °C). ^{1}H-NMR (CCl_4); δ 2.10 (3H, s), 1.81 (6H, s), 1.73 (3H, s). IR (neat); 1690 cm^{-1} (C=O), 1610 cm^{-1} (C=C).

5m; Bp 80—82 °C/11 Torr (lit,[25] 78—79 °C/10 Torr). ^{1}H-NMR (CCl_4); δ 2.50 (2H, m), 1.9—2.1 (4H, m), 2.15 (3H, t, J=1.5 Hz), 1.80 (3H, s). IR (neat); 1700 cm^{-1} (C=O), 1610 cm^{-1} (C=C). MS (20 eV), *m/e* (rel intensity), 124 (M^+, 100), 108 (48), 96 (19), 82 (21).

Preparation of Olefins (5) by One-pot Procedure. Preparation of **5o** is described here as a typical procedure. To the 20 ml of the DMF solution of the sodium salt of 2-tosyldecanenitrile (20 mmol) which had been prepared as mentioned in the preparation of **4** was added 2,2-dinitroheptane (1.1 g, 6 mmol) in 5 ml of DMF at −20 °C, and the resulting solution was stirred at −20 °C for 3 h. Then $Na_2S \cdot 9H_2O$ (2.4 g, 9 mmol) was added to this solution. The reaction mixture was stirred at room temperature for additional 3 h. After the usual work up, the crude product was distilled to give **5o** (0.93 g, 62% yield). Bp 144.5 °C/1 Torr. ^{1}H-NMR (CCl_4); δ 2.35 (2H, t, J=7.5 Hz), 2.14 (2H, t, J=7.5 Hz), 2.02 (1.5H, s), 1.79 (1.5H, s), 1.30 (18H, m), 0.90 (6H, m). The NMR spectra show that **5o** consists of the equal amount of *E* and *Z* isomer. IR (neat); 2210 cm^{-1} (CN), 1630 cm^{-1} (C=C). MS (20 eV), *m/e* (rel intensity), 249 (M^+, 53), 234 (33), 220 (53), 206 (100), 192 (60). Found: C, 81.81; H, 12.82; N, 5.42%. Calcd for $C_{17}H_{31}N$: C, 81.86; H, 12.53; N, 5.62%. Similarly, **5n** was prepared in 68% yield. Bp 108 °C/21 Torr. ^{1}H-NMR (CCl_4); δ 2.36 (1.3H, t, J=7.5 Hz), 2.14 (0.7H, t, J=7.5 Hz), 2.02 (1H, s), 1.86 (3H, s), 1.80 (3H, s), 1.34 (6H, m), 0.92 (3H, t, J=7.5 Hz). IR (neat); 2210 cm^{-1} (CN), 1630 cm^{-1}(C=C). MS (20 eV), *m/e* (rel intensity), 151 (M^+, 38), 136 (15), 95 (85), 82 (100).

Elimination from 4l by Sodium Sulfide. The reaction of **4l** with sodium sulfide was carried out in the same way as described in a general procedure. A volatile product (**5l**) was distilled and the residue was subjected to a column chromatography to give **6** in 15% yield. Mp 60.5—61.5 °C. ^{1}H-NMR ($CDCl_3$); 7.72 (2H, d, J=7.5 Hz), 7.28 (2H, d, J=7.5 Hz), 2.42 (3H, s), 2.22 (3H, m), 1.89 (3H, m), 1.88 (3H, s). IR (Nujol); 1610 cm^{-1} (C=C). Found: C, 64.44; H, 7.12%. Calcd for $C_{12}H_{16}SO_2$: C, 64.25; H, 7.19%.

Reaction of 4a with Sodium Sulfide in the Presence of Di-t-butylnitroxide or Aromatic Nitro Compounds. The reaction of **4a** (0.888 g, 3 mmol) with sidium sulfide (2.16 g, 9 mmol) in 30 ml of DMF was carried out at room temperature in the presence of various additives, *i.e.*, A: none, B: di-*t*-butylnitroxide (0.022 g, 0.15 mmol), C: *m*-DNB (0.05 g, 0.3 mmol), D: *p*-DNB (0.05 g, 0.3 mmol), E: nitrobenzene (0.037 g, 0.3 mmol). The yield of **5a** was determined by GLPC, and the results are summarized in Fig. 1.

The present work was partially supported by a Grant-in-Aid for Scientific Research (No 447020) from the Ministry of Education, Science and Culture.

8) The sulfone group is eliminated as a sulfinate ion from anion radicals of α-nitro sulfones: N. Kornblum, S. D. Boyd, and N. Ono, *J. Am. Chem. Soc.*, **96**, 2580 (1974). So the behaviour of anion radicals of β-nitro sulfones is of interest.

9) We have found that the potassium salts of β-diketones or β-keto esters are also more reactive to **1** or **2** than the corresponding sodium salts. This finding has enabled one to prepare new coupling products of carbanions with **1** or **2** which are difficult to prepare using the sodium salts.

10) Reactivity of carbanions to **1** or **2** is an interesting problem, but complexities of chain sequence preclude a detailed discussion about this. The reaction of free radicals with carbanions to form anion radicals consists of the following equilibrium. $R\cdot + C^- \rightleftharpoons R^- + C\cdot \rightleftharpoons R\text{-}C^{\cdot}$ It is noteworthy that the chain reaction proceeds when the stability of R^- and C^- is close.

A New and Highly Effective Aldol Synthesis[1)]

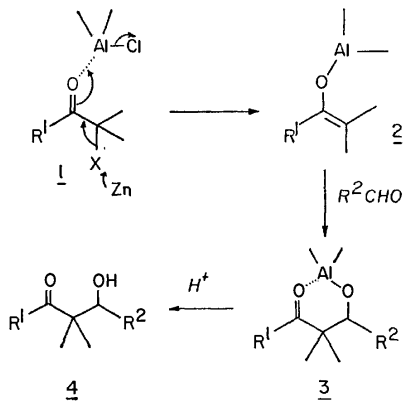
Keiji MARUOKA,† Shinsuke HASHIMOTO, Yoshizo KITAGAWA,
Hisashi YAMAMOTO,† and Hitosi NOZAKI*
Department of Industrial Chemistry, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606
(Received April 26, 1980)

A new approach has been demonstrated for the regiospecific aldol synthesis by the simultaneous addition of α-halo carbonyl derivatives and aldehydes or ketones to a suspension of diethylaluminum chloride and zinc in tetrahydrofuran at low temperature. This technique is also employable under mild conditions for the Reformatsky reaction to give β-hydroxy esters in excellent yield. One of the unique synthetic applications of this process is illustrated by the intramolecular cyclization of α-bromo esters of ω-hydroxy aldehyde, which produces macrolides, an important class of compounds in the antibiotic field.

Carbon-carbon σ-bond formation, one of the most fundamental operations in organic chemistry, is often accomplished by the aldol synthesis.[2)] During the past decade numerous directed intermolecular aldol condensations have been explored with generation of the regiospecific metal enolates and interception of the initially formed aldol products as stable metal chelates.[3)] Certain regiospecifically generated, kinetic lithium enolates can retain their integrity in the aldol reaction at low temperature. The use of magnesium and zinc enolates prevents the unfavorable dissociation of the metal chelate, and boron enolates have recently been employed in stereoselective aldol syntheses.[4)]

Compared to the metals described above, aluminum shows an exceptionally high affinity for oxygen atom (138 kcal/mol for Al–O bond),[5)] and, therefore, its enolate would be one of the most attractive candidates to enhance the stability of the metal chelates in the aldol condensation. In principle, organoaluminum compounds have a vast potential as an agent of aldol reaction. However, this concept has not been generally accepted for synthesis owing to the lack of an effective procedure for converting a carbonyl compound into a reactive aluminum enolate.[6)]

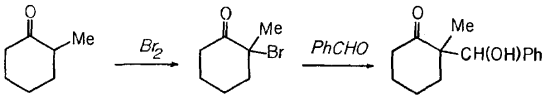
Herein, we describe a new process for regioselective generation of aluminum enolate by the coupled attack of dialkylaluminum chloride and zinc on the α-halo ketone.[7)] The enolate **2**, thus obtained, is sufficiently reactive to carbonyl compound activated by trivalent aluminum producing the stable tetradentate chelate of the ketolate **3**. Aqueous work-up yields the aldol **4** in excellent yield.



† Present address: Department of Chemistry, University of Hawaii, 2545 The Mall, Honolulu, Hawaii 96822.

Although a comparable path can be followed by two molecules of an α-halo ketone condensing each other, this would be subject to experimental control using the simultaneous addition of α-halo ketones and carbonyl compounds at low temperature provided that the reduction is sufficiently faster under acceptable conditions.[8)] This new approach has now been realized: Gradual addition (40 min) of a mixture of carbonyl compound and α-halo ketone in dry tetrahydrofuran (THF) to a suspension of zinc dust and diethylaluminum chloride (Et_2AlCl) in THF–hexane in the presence of a catalytic amount of copper(I) bromide with stirring at −20 °C under argon resulted in clean generation of the ketolate. Addition of pyridine, removal of cooling bath, and aqueous work-up afforded the desired β-hydroxy ketone in high yield (Table 1).

The regioselectivity of this reaction was demonstrated by the treatment of 2-bromo-2-methylcyclohexanone (**5**) and benzaldehyde with Et_2AlCl–Zn in THF at −20 °C to furnish the expected β-hydroxy ketone **6** in quantitative yield, without any contamination of the regioisomer (Entry 3). Since the starting bromide **5** may be prepared with high regioselectivity,[9)] the present method must be the simplest route to the β-hydroxy ketone **6**.



5 6

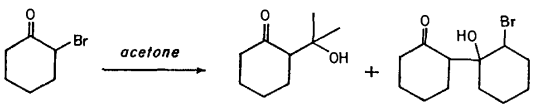
Additional examples are also summarized in Table 1. It should be noted that the use of diethylaluminum chloride and the choice of solvents and temperatures are crucial to the success of these reactions. In the absence of diethylaluminum chloride, only unchanged carbonyl compounds were recovered under these mild conditions. The relative effect of solvents and temperatures was indicated by the reaction of 2-bromocyclohexanone with isobutyraldehyde. In diethyl ether at −40 °C, only a trace amount of the desired 2-(1-hydroxy-2-methylpropyl)cyclohexanone (**7**) was produced, whereas at high temperature (25 °C) many side products were detected by TLC. The use of THF as solvent with reaction temperatures of −78 and −40 °C afforded **7** in yields of 0 and 85%, respectively. At 0 °C, the reaction proceeds as expected (86%), but with some contamination of undesired dehydrated and retro-aldol products of **7**.

Table 1. Synthesis of β-hydroxy carbonyl compounds[a)]

Entry	Bromo ketone or bromo ester	Aldehyde or ketone	Temp °C	Additive[b)]	Products	Isolated yield(%) (*erythro*/*threo*)
1	α-Bromoacetophenone	Isobutyraldehyde	−20	CuBr	$PhCOCH_2CH(OH)CH(CH_3)_2$	92
		Cinnamaldehyde	−20	CuBr	$PhCOCH_2CH(OH)CH{=}CHPh$	92
		Cyclohexanone	−20	CuBr	$PhCOCH_2C(OH)(CH_2)_5$	83
2	2-Bromocyclohexanone	Benzaldehyde	−20	CuBr	2-(α-Hydroxybenzyl)-cyclohexanone	97(1/1)[f)]
		Isobutyraldehyde	−20	CuBr	2-(1-Hydroxy-2-methylpropyl)-cyclohexanone	93[g)]
		Acetone[c)]	−20	d)	2-(1-Hydroxy-1-methylethyl)-cyclohexanone	75
3	2-Bromo-2-methyl-cyclohexanone	Benzaldehyde	−20	CuBr	2-(α-Hydroxybenzyl)-2-methylcyclohexanone	100(4/3)[f)]
4	2-Bromocamphor	Acetone	r.t.	d)	3-(1-Hydroxy-1-methylethyl)-camphor	79
5	Ethyl bromoacetate	Benzaldehyde	0	CuBr	$PhCH(OH)CH_2COOEt$	94
		Cyclohexanone	r.t.	CuBr	$(CH_2)_5C(OH)CH_2COOEt$	93
6	Methyl γ-bromo-crotonate	Benzaldehyde	−20	CuBr	$PhCH(OH)CH(CH{=}CH_2)COOMe$[e)]	100(50/44)[h)]

a) Unless specified, the reactions were carried out according to the general procedure in the experimental section. b) A catalytic amount of copper(I) bromide (0.05 equiv) was added. c) Excess acetone (5 equiv) was used for this reaction. d) Zn–Ag couple was employed without any additive. e) None of the γ-alkylation product ("normal Reformatsky ester") was detected in the reaction mixture. See Ref. 7. f) The ratio of the stereoisomers (*threo* and *erythro*) was determined by an absorption due to the benzylic proton ($CDCl_3$) as shown in the experimental section. See also Refs. 3-a and 3-b. g) *Erythro*/*threo* ratio could not be determined by NMR and TLC analyses. h) Determined by the isolated yield: See the experimental section for this compound.

Treatment of 2-bromocyclohexanone (1 equiv) and acetone (1.1 equiv) with Et_2AlCl–Zn gave the cross aldol product **8** (42%) along with the self-condensation product. Thus, with less reactive carbonyl compounds, the relative amount of self-condensation product increases. Such difficulty might be circumvented by using excess carbonyl compounds with more reactive zinc. Accordingly, the zinc–silver couple[10] was chosen with excess acetone (5 equiv) to furnish **8** in 79% yield (Entry 2).



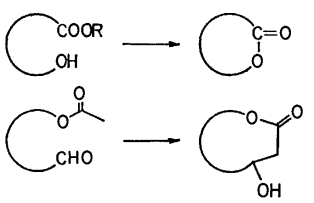
8

This new technique for the regiospecific aldol synthesis can be employed equally well under mild conditions for the Reformatsky reaction.[11] In a similar manner described above, Reformatsky products were produced from the corresponding α-halo esters and carbonyl compounds in excellent yield as were indicated in Table 1 (Entry 5, 6). In contrast with the normal Reformatsky reaction,[12] the reaction of methyl γ-bromocrotonate with benzaldehyde in the presence of Et_2AlCl–Zn afforded only the α-adduct in quantitative yield. This result suggests that the addition of aluminum enolate to the carbonyl component (initially activated by trivalent aluminum) proceeds *via* a six-membered transition state to furnish the stable aluminum chelate **3**.

Although simplicity and convenience of this aldol synthesis are appealing, the fact that the reaction proceeds in high yield with simultaneous addition of a halo ketone and an aldehyde is even more important. The highly successful application of the new method is the synthesis of macrocyclic lactones which forms the next subject of this paper.

Although the macrolide has been the attractive synthetic target in a number of laboratories, most synthetic methodologies for the macrolide are based on the internal esterification in the cyclization step (Eq. 1) and there exist a few basically different approaches.[13]

Indeed at the outset of this work there were no known synthetic methods capable of generating efficiently 3-hydroxy lactones from acyclic structures (Eq. 2). Gradual addition of the bromoacetate of

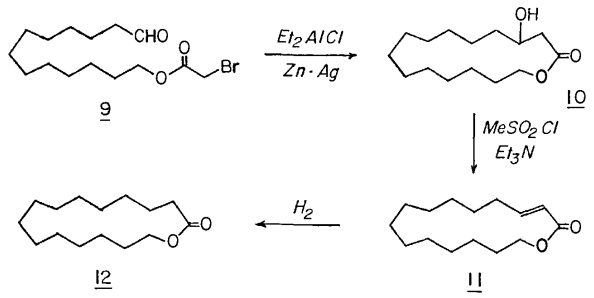


(1)

(2)

13-hydroxytridecanal **9**[14] in THF from a mechanically driven syringe over 4 h to a stirred suspension of zinc–silver couple and diethylaluminum chloride in THF at 35 °C under argon effected cyclization to 3-hydroxypentadecanolide (**10**) as the major product. Termination of the reaction with pyridine, followed by acidic

work-up gave the crude product, which was purified by column chromatography on silica gel (ether–hexane, 1:1) to afford pure lactone **10** in 48% yield. Dehydration of **10** in CH_2Cl_2 with methanesulfonyl chloride and excess triethylamine at room temperature for 11 h gave 2-pentadecenolide (**11**). Hydrogenation of **11** in ethanol–ethyl acetate over palladium on charcoal produced exaltolide (**12**).



9 10 11 12

Similarly, several 3-hydroxymacrolides **13**—**16** were prepared starting from α-bromo esters of ω-hydroxy aldehyde, $BrCHRCOO(CH_2)_nCHO$ with $n=9$ or 11, and R=H or CH_3. The following list of macrolides shows the effectiveness of the new method with good yields as indicated in the parenthesis. Of crucial importance to this macrolide synthesis was the observation that the more substituted aluminum enolates derived from $BrCHRCOO(CH_2)_nCHO$ with $R=CH_3$ are substantially more reactive toward the carbonyl component to give **14** or **16** in higher yield relative to that of the unsubstituted homologs. Since the α-methyl-β-hydroxy unit in macrolides **14** or **16** is a common functionality in a variety of macrolide antibiotics including erythromycin and methymycin,[16] this method may provide a useful entry to the antibiotic field, starting with simple α,ω-diols.[17]

Experimental

Instrumentation. The infrared spectra were taken with a Shimadzu IR-27-G spectrometer; the mass spectra with a Hitachi RMU-6L mass machine; the GLPC analyses with a Yanagimoto GCG-550F; and NMR spectra with a JNM-PMX 60 or Varian EM-360 spectrometer. The chemical shifts are expressed in parts per million downfield from internal tetramethylsilane ($\delta=0$). Splitting patterns are indicated as s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet. The microanalyses were performed at the Elemental Analyses Center of Kyoto University. All experiments were carried out under an atmosphere of dry argon. The products were purified by preparative thin layer chromatography on silica gel PF-254 plates (Merck), or by preparative column chromatography on silica gel E. Merck Art. 7734.

Purification or Preparation of Solvents, Metals, and Reagents. The following solvents were used: tetrahydrofuran—freshly distilled from sodium benzophenone ketyl; dichloromethane—dried over 4 Å molecular sieves. Zinc dust was washed with 5% hydrochloric acid.[17] Zinc-silver couple was obtained from zinc dust and silver acetate by a literature procedure.[10] A 1 M solution of diethylaluminum chloride was prepared by the dilution of neat diethylaluminum chloride (Ethyl Co.) with hexane under argon. Commercially available α-bromoacetophenone, 3-bromocamphor, ethyl bromoacetate, and methyl γ-bromocrotonate were used without purification. 2-Bromocyclohexanone was prepared according to the procedure in the literature.[18] 2-Bromo-2-methylcyclohexanone was obtained by the bromination of 2-methylcyclohexanone with bromine in ether at −40——50 °C.[9] 1,10-Decanediol and 1,12-dodecanediol were the commercial products of the highest purity. 1,13-Tridecanediol was prepared as follows: Reaction of cyclododecanone with diethyl carbonate and metallic sodium under reflux gave diethyl tridecanedionate, which was reduced with lithium aluminum hydride in THF to afford 1,13-tridecanediol.[19]

Preparation of β-Hydroxy Ketones. The β-hydroxy ketones were prepared by reaction of α-bromo ketones with either ketones or aldehydes according to the following general procedure: A solution of diethylaluminum chloride (1.1 mmol) in hexane was added to a slurry of zinc dust (1.5 mmol) and a catalytic amount of copper(I) bromide (0.05 mmol) in anhydrous THF (3 ml) with stirring under argon at 20 °C. The resulting mixture was cooled to −20 °C, and a solution of an α-bromo ketone (1 mmol) and an aldehyde (or a ketone) (1.1 mmol) in anhydrous THF (5 ml) was added slowly over 40 min at −20 °C. After 15 min at −20 °C, the cooling bath was removed. The reaction mixture was quenched by the addition of pyridine (0.3 ml)[20] and then poured into 2 mol dm^{-3} hydrochloric acid (10 ml). The ether extracts were washed with brine, dried over magnesium sulfate, and concentrated *in vacuo* to afford a β-hydroxy ketone after purification by preparative TLC (ether–benzene, 1:5).

3-Hydroxy-4-methyl-1-phenyl-1-pentanone. Reaction of α-bromoacetophenone with isobutyraldehyde gave the title compound as a colorless oil:[21] IR (neat) 3450 cm^{-1} (OH), 1673 cm^{-1} (C=O); NMR ($CDCl_3$) δ 7.10—8.13 (5H, m, aryl CH), 3.79—4.20 (1H, m, CH–O), 3.69 (1H, s, OH), 3.00 (2H, m, CH_2C=O), 1.78 (1H, m, CH), 0.99 (6H, d, $J=6.6$ Hz, CH_3); mass *m/e*(%) 105 (100), 174 (4, M^+-18); mp 50.5—52.0 °C (recrystallized from pentane as white crystals).

1,5-Diphenyl-3-hydroxy-4-penten-1-one. The title compound was prepared by the reaction of α-bromoacetophenone with cinnamaldehyde as a yellow oil: IR (neat) 3470 cm^{-1} (OH), 1675 cm^{-1} (C=O); NMR ($CDCl_3$) δ 6.94—8.31 (10H, m, aryl CH), 6.70 (1H, d, $J=16$ Hz, PhCH=C), 6.24 (1H, dd, $J=16$, 5.6 Hz, PhC=CH), 4.91 (1H, q, $J=5.6$ Hz, CH–O), 3.22 (2H, d, $J=6$ Hz, CH_2C=O), 2.84—3.61 (1H, s, OH); exact mass spectrum *m/e* 252.301 (Calcd for $C_{17}H_{16}O_2$ 252.313); mp 51—53 °C (recrystallized from pentane-ether as white crystals).

α-(1-Hydroxycyclohexyl)acetophenone. Reaction of α-bromoacetophenone with cyclohexanone afforded the title compound as a colorless oil;[22] IR (neat) 3513 cm^{-1} (OH), 1672 cm^{-1} (C=O); NMR ($CDCl_3$) δ 7.05—8.18 (10H, m, aryl CH), 3.88—4.01 (1H, s, OH), 3.10 (2H, s, CH_2C=O), 1.05—2.17 (10H, broad s, aliphatic CH); mass *m/e*(%) 105 (100),

200 (3, M^+-18); mp 79—80 °C (recrystallized from pentane as white crystals).

*2-(α-Hydroxybenzyl)-2-methylcyclohexanone (**6**).* Reaction of 2-bromo-2-methylcyclohexanone (191 mg, 1 mmol) with benzaldehyde (117 mg, 1.1 mmol) afforded *erythro* and *threo* mixtures of **6** (218 mg) as a pale yellow oil[21] in quantitative yield after purification by preparative TLC (ether–hexane, 1:1): NMR ($CDCl_3$) δ 7.23 (5H, s, aryl CH), 4.92, 5.00 (1H, s, CH–O), 3.53 (1H, s, OH), 2.26—266. (2H, m, $CH_2C{=}O$), 1.35—2.09 (6H, broad s, aliphatic CH), 1.00, 1.09 (3H, s, CH_3). The ratio of the *erythro* and *threo* isomers was determined by the relative intensities of the benzylic proton absorptions (NMR ($CDCl_3$) δ 4.92 (*erythro*) and 5.00 (*threo*)) to be nearly 4:3. Column chromatography of the pure **6** on silica gel (ether–hexane, 3:1) gave the fraction of pure *threo* isomer and a mixture of *erythro* and *threo* isomers (34 mg). The pure *threo* isomer has the following physical properties: IR (neat) 3503 cm^{-1}, (OH), 1690 cm^{-1} (C=O): NMR ($CDCl_3$) δ 7.15 (5H, s, aryl CH), 4.97 (1H, s, CH–O), 2.87 (1H, s, OH), 2.27—2.59 (2H, m, $CH_2C{=}O$), 1.35—2.05 (6H, broad s, aliphatic CH), 1.01 (3H, s, CH_3); mass *m/e*(%) 77 (100) 200 (0.1, M^+-18).

2-(α-Hydroxybenzyl)cyclohexanone. Condensation of 2-bromocyclohexanone with benzaldehyde yielded *erythro* and *threo* mixtures of the title compound (198 mg, 97% yield) as white solids after purification by preparative TLC (ether–hexane, 1:1). The NMR spectrum ($CDCl_3$) of the product showed the ratio of the *threo* and *erythro* isomers to be 1:1. This analysis was determined by an absorption due to the benzylic proton peak at δ 4.73 and 5.30. Column chromatography of the product on silica gel (benzene–ether, 10:1) separated two isomers. The first fraction was the *erythro* isomer: IR (neat) 3496 cm^{-1} (OH), 1697 cm^{-1} (C=O); NMR ($CDCl_3$) δ 7.27 (5H, s, aryl CH), 5.35 (1H, d, J= 2.3 Hz, CH–O), 2.90 (1H, s, OH), 1.08—2.73 (9H, broad s, aliphatic CH and CHC=O); mass *m/e*(%) 77 (100), 186 (2.5, M^+-18); mp 103—105 °C (recrystallized from hexane–ethyl acetate; lit,[21] mp 103.5—104.5 °C). From the second fraction the *threo* isomer was obtained: IR (neat) 3483 cm^{-1} (OH), 1698 cm^{-1} (C=O); NMR ($CDCl_3$) δ 7.30 (5H, s, aryl CH), 4.77 (1H, d, J=9 Hz, CH–O), 3.72 (1H, s, OH), 1.03—2.86 (9H, broad s, aliphatic CH and CHC–O); mass *m/e*(%) 77 (100), 186 (3.5, M^+-18); mp 75.5—77.5 °C (recrystallized from hexane; lit,[21] mp 75 °C).

*2-(1-Hydroxy-2-methylpropyl)cyclohexanone (**7**).* Reaction of 2-bromocyclohexanone with isobutyraldehyde produced **7** as a pale yellow oil[21]: bp 74—78 °C (bath temp, 1 mmHg); IR (neat) 3510 cm^{-1} (OH), 1688 cm^{-1} (C=O); NMR ($CDCl_3$) δ 3.47 (1H, m, CH–O), 3.03 (1H, s, OH), 1.32—2.74 (9H, broad s, aliphatic CH and CHC=O), 0.89 (6H, m, CH_3); mass *m/e*(%) 55 (100), 152 (15, M^+-18). The *erythro*/*threo* ratio of **7** could not be determined by TLC and NMR analyses.

2-(1-Hydroxy-1-methylethyl)cyclohexanone. The title compound was obtained from 2-bromocyclohexanone (1 equiv) and excess acetone (5 equiv) in the presence of diethylaluminum chloride and zinc-silver couple at −20 °C: bp 68—71 °C (bath temp, 1 mmHg (lit,[23] bp 78—80 °C/4 mmHg)); IR (neat) 3488 cm^{-1} (OH), 1690 cm^{-1} (C=O); NMR ($CDCl_3$) δ 3.95 (1H, s, CH–O), 1.42—2.62 (10H, aliphatic CH, CHC= O, and OH), 1.22 (6H, m, CH_3): mass *m/e*(%) 43 (100), 141 (5, M^+-15).

3-(1-Hydroxy-1-methylethyl)camphor. Reaction of 3-bromocamphor with acetone was performed at 20 °C using zinc-silver couple. Stirring was further continued for 1 h at 20 °C. The mixture was then quenched in a usual manner and purified by preparative TLC (ether–hexane, 1:1) to give the title compound as white crystals: mp 80—90.5 °C (recrystallized from hexane); IR (Nujol) 3473 cm^{-1} (OH), 1728 cm^{-1} (C=O); NMR ($CDCl_3$) δ 1.27, 1.46 (6H, two s, CH_3C–O); exact mass spectrum *m/e* 210.330 (Calcd for $C_{13}H_{22}O_2$ 210.317).

Preparation of β-Hydroxy Esters. The β-hydroxy esters were prepared in the same way as the β-hydroxy ketones.

Ethyl 3-Hydroxy-3-phenylpropionate. The title compound was produced from ethyl bromoacetate and benzaldehyde as a colorless oil: bp 120—123 °C (bath temp, 1 mmHg (lit,[24] bp 154 °C/12 mmHg)); IR (neat) 3435 cm^{-1} (OH), 1728 cm^{-1} (C=O); NMR ($CDCl_3$) δ 7.28 (5H, s, aryl CH), 5.06 (1H, t, J=7 Hz, CH–O), 4.08 (2H, q, J=7 Hz, CH_2–O), 3.40 (1H, s, OH), 2.65 (2H, d, J=7 Hz, $CH_2C{=}O$), 1.18 (3H, t, J=7 Hz, CH_3); mass *m/e*(%) 107 (100), 165 (5, M^+-29), 176 (4, M^+-18), 194 (22, M^+).

Ethyl 1-Hydroxycyclohexylacetate. Reaction of ethyl bromoacetate with cyclohexanone at 20 °C yielded the title compound as a colorless oil: bp 85—88 °C/2 mmHg (lit,[25] bp 89—93 °C/4 mmHg); IR (neat) 3499 cm^{-1} (OH), 1710 cm^{-1} (C=O); NMR ($CDCl_3$) δ 4.32 (2H, q, J=7 Hz, CH_2–O), 3.37 (1H, s, OH), 2.43 (2H, s, $CH_2C{=}O$), 1.52 (10H, broad s, aliphatic CH), 1.26 (3H, t, J=7 Hz, CH_3); mass *m/e* (%) 55 (100), 168 (6.8, M^+-18), 186 (6.5, M^+).

Methyl 2-(α-Hydroxybenzyl)-3-butenoate. Reaction of methyl γ-bromocrotonate (179 mg, 1 mmol) with benzaldehyde (117 mg, 1.1 mmol) at −20 °C gave the *erythro* and *threo* isomers of the title compound in quantitative yield as a colorless oil[12] after purification by preparative TLC (ether–hexane, 1:1). None of the γ-alkylation product was detected in the crude product. Column chromatography of the product on the silica gel (ether–hexane, 1:3) separated the pure *erythro* isomer (92 mg), a mixture of two isomers (16 mg), and the pure *threo* isomer (80 mg). These isomers have the following physical properties. *Erythro* isomer: IR (neat) 3549 cm^{-1} (OH), 1726 cm^{-1} (C=O); NMR ($CDCl_3$) δ 7.24 (5H, s, aryl CH), 5.96 (1H, ddd, J=8.0, 11.4, 18.8 Hz, =CH–C), 5.36—4.98 (3H, m, CH_2=C and CH–O), 3.63 (3H, s, CH_3), 3.39 (1H, dd, J=6.4, 8.0 Hz, C=C–CH), 2.92 (1H, s, OH); mass *m/e*(%) 77 (100), 188 (18.8, M^+-18): *Threo* isomer: IR (neat) 3437 cm^{-1} (OH), 1707 cm^{-1} (C=O); NMR ($CDCl_3$) δ 7.31 (5H, s, aryl CH), 5.72 (1H, ddd, J=7.8, 10.8, 17.2 Hz, =CH–C), 4.79—5.40 (3H, m, CH_2=C and CH–O), 3.77 (3H, s, CH_3), 3.50 (1H, dd, J= 8.8, 17.2 Hz, C=C–CH), 2.84 (1H, s, OH).

Preparation of Macrolides. Five hydroxy macrolides were prepared by the intramolecular aldol condensation of α-bromo esters of ω-hydroxy aldehydes. The synthesis of 3-hydroxypentadecanolide (**10**), starting from 1,13-tridecanediol is representative.

*13-Hydroxytridecyl Bromoacetate (**17**).* A solution of bromoacetyl bromide (5.18 g, 24 mmol) in anhydrous THF (20 ml) was added dropwise to a solution of 1,13-tridecanediol (4.32 g, 20 mmol) in THF (100 ml) containing *N,N*-dimethylaniline (2.79 ml, 22 mmol) under argon at 20 °C. Stirring was continued for 15 min at 20 °C. Then the solution was diluted with ether, washed with 2 mol dm^{-3} hydrochloric acid. The ether extracts were washed with brine, dried over sodium sulfate, and concentrated *in vacuo* to afford **17** (3.57 g, 53%) as white crystals after purification by column chromatography on silica gel (ethyl acetate–hexane, 2:5): IR (Nujol) 3375 cm^{-1} (OH), 1731 cm^{-1} (C=O); NMR ($CDCl_3$) δ 4.10 (2H, t, J=6 Hz, $CH_2OC{=}C$), 3.76 (2H, s, CH_2Br), 3.57 (2H, t, J=6 Hz, CH_2–O), 1.00—1.98 (23H, broad s, aliphatic CH and OH).

Found: C, 53.32; H, 8.98%. Calcd for $C_{15}H_{28}BrO_3$: C, 53.41; H, 8.67%.

TABLE 2. Continued

Products	Boiling point (°C)[a] (Melting point)	IR (cm^{-1})[b]	NMR (δ)	Found, % (Calcd)
			J=1.6, 6.8, CH_2C=O), 1.78 (3H, d, J=7, CH_3), 1.28 (18H, s, aliphatic CH_2)	
16	180/2 mm Hg	3425 (OH) 1725 (C=O)	3.40—4.53 (3H, m, CH_2O, CH-O), 2.80 (1H, s, OH), 2.52 (1H, q, J=6.8, CHC=O), 1.33 (23H, br s, aliphatic CH, CH_3)	C, 70.31 (70.27) H, 11.21 (11.01)

a) Bath temperature. b) Liquid film. c) Nujol mull.

Bromoacetate of 13-Hydroxytridecanal (9). Collins oxidation of **17** was slightly modified as follows: Chromium trioxide (5 g, 50 mmol) was added portionwise to a solution of pyridine (8.09 ml, 100 mmol) in dry dichloromethane (125 ml) at 0 °C, and the resulting brown suspension was stirred for 5 min at 0 °C followed by 1 h at 20 °C. Celite-545 (dried *in vacuo* for 1 h at 150 °C before use) and then **17** (1.685 g, 5 mmol) dissolved in dry dichloromethane (25 ml) were added at 0 °C. After further stirring for 10 min, the suspension was treated with powdered $NaHSO_4 \cdot H_2O$ (6.25 g). The complete removal of pyridine was checked by TLC. The suspension was diluted with hexane (200 ml), filtered through Celite-545, and washed with hexane. The filtrate was concentrated *in vacuo* to afford **9** (1.495 g, 89% yield) as a colorless oil after purification by column chromatography on silica gel (ether–hexane, 1:2): IR (neat) 2723 cm^{-1} (CHO), 1721, 1731 cm^{-1} (C=O); NMR ($CDCl_3$) δ 9.65 (1H, m, CHO), 4.06 (2H, t, J=6 Hz, CH_2O), 3.67 (2H, s, CH_2Br), 2.33 (2H, t, J=6 Hz, CCH_2C=O), 1.28 (20H, broad s, aliphatic CH).

Found: C, 53.51; H, 8.33%. Calcd for $C_{15}H_{27}BrO_3$: C, 53.74; H, 8.12%.

3-Hydroxypentadecanolide (10). A solution of diethylaluminum chloride (1.5 mmol, 1.5 ml of a 1 M solution) in hexane was added to a slurry of zinc-silver couple (3.27 g, 50 mmol) in anhydrous THF (50 ml) under argon at 20 °C. After 10 min, the suspension was warmed to 35 °C and a solution of **9** (335 mg, 1 mmol) in THF (10 ml) was added slowly over a period of 4 h. Stirring was continued for an additional 20 min, and the reaction was terminated by the addition of pyridine (0.9 ml). Then the suspension was diluted with ether, washed with iced 2 mol dm^{-3} hydrochloric acid, and brine. The organic layer and ether extracts of the aqueous washings were dried and concentrated to afford **10** (175 mg, 48% yield) as a colorless oil after purification by column chromatography on silica gel (ether–hexane, 1:1): IR (neat) 3427 cm^{-1} (OH), 1729 cm^{-1} (C=O); NMR ($CDCl_3$) δ 3.58—4.25 (1H, m, CH-O), 4.13 (2H, t, J=5 Hz, CH_2O), 2.82 (1H, s, OH), 2.53 (2H, d, J=5.5 Hz, CH_2C=O), 1.35 (22H, broad s, aliphatic CH); mass m/e(%) 238 (M^+-H_2O).

Found: C, 70.30; H, 10.88%. Calcd for $C_{15}H_{28}O_3$: C, 70.27; H, 11.01%.

2-Pentadecenolide (11). A solution of **10** (85 mg, 0.33 mmol) in dichloromethane (1.5 ml) was treated with methanesulfonyl chloride (51 μl, 0.66 mmol) in the presence of triethylamine (0.37 ml, 2.66 mmol) at −20 °C. The resulting white suspension was allowed to warm to room temperature. Further stirring was continued for one day at room temperature. The mixture was poured onto iced water and extracted with ether. Purification of the crude product by column chromatography on silica gel (ether–hexane, 1:15) gave **11** in 79% yield as a colorless oil: IR (neat) 1716 cm^{-1} (C=O), 983, 1460 cm^{-1} (C=C); NMR (CCl_4) δ 6.75 (1H, dt, J=7.2, 15.4 Hz, CH=C-C=O), 5.63 (1H, d, J=15.4 Hz, CH-C=O), 4.10 (2H, t, J=5.2 Hz, CH_2O), 2.19 (2H, m, CH_2C=C), 1.31 (20H, broad s, aliphatic CH); mass m/e(%) 238 (M^+).

Found: C, 75.31; H, 10.92%. Calcd for $C_{15}H_{26}O_2$: C, 75.58; H, 10.99%.

Synthesis of Exaltolide (12). 2-Pentadecenolide (**11**) (65 mg) was hydrogenated in ethanol–ethyl acetate over 10% palladium on charcoal at room temperature for two days to give **12** (48 mg) as colorless semi-solids: IR (neat) 1730 cm^{-1} (C=O); NMR (CCl_4) δ 4.02 (2H, t, J=5.2 Hz, CH_2O), 2.22 (2H, t, J=6.2 Hz, CH_2C=O), 1.32 (24H, broad s, aliphatic CH); mass m/e(%) 240 (M^+).

The syntheses of other hydroxy macrolides such as 3-hydroxydodecanolide (**13**), 3-hydroxy-2-methyldodecanolide (**14**), 3-hydroxytetradecanolide (**15**), and 3-hydroxy-2-methyltetradecanolide (**16**), starting from the corresponding α,ω-diols, $HO(CH_2)_nOH$ with n=10, 12 were carried out exactly as described above. The physical properties and analytical data of these four macrolides and their precursors are shown in Table 2.

The authors wish to thank the Ministry of Education, Science and Culture, Japan, for Grant-in-Aid (No. 110309, 203014).

Studies on Heteropentalenes. II.[1] Cycloaddition of Imidazo[2,1-*b*]thiazoles, Thiazolo[3,2-*a*]benzimidazole, and Imidazo[2,1-*b*]benzothiazole with a Reactive Acetylenic Ester

Noritaka Abe,* Tarozaemon Nishiwaki, and Noriko Komoto
Department of Chemistry, Faculty of Sciences, Yamaguchi University, Yamaguchi 753
(Received April 28, 1980)

Cycloaddition of imidazo[2,1-*b*]thiazoles with dialkyl acetylenedicarboxylate follows dual courses depending on the polarity of the solvent, affording pyrrolo[2,1-*b*]thiazoles in an aprotic nonpolar solvent, or imidazo[1,2-*a*]-pyridines and imidazo[3,4-*a*]pyridines, together with thiophenes, in an aprotic polar solvent. Thiazolo[3,2-*a*]-benzimidazole and imidazo[2,1-*b*]benzothiazole were also found to react with the acetylenedicarboxylate to give pyrido[1,2-*a*]benzimidazole and pyrrolo[2,1-*a*]benzothiazole, respectively. The reactions would be accounted for in light of the Diels-Alder reaction in an aprotic nonpolar solvent and the 1,4-dipolar cycloaddition in an aprotic polar solvent.

Cycloaddition of nitrogen-heterocycles with acetylenic esters has received attention.[2] Our success in the cycloaddition of azaazulenes with dimethyl acetylenedicarboxylate (DMAD)[3] prompted us to extend the study to aromatic azapentalenes.[4] A number of papers have appeared on the cycloaddition of mesoionic azapentalenes.[5] Attempts to obtain a cycloadduct by reactions of neutral azapentalenes with reactive olefins and/or acetylenes do not seem successful, the reactions of pyrrolo[2,1-*b*]thiazoles with DMAD[6] and those of imidazo[2,1-*b*]thiazoles with maleic anhydride or diethyl azodicarboxylate[7] affording only the Michael adducts. We wish to report on the cycloaddition of imidazo[2,1-*b*]thiazoles and other related 10π-electron bicyclic systems (*e.g.* thiazolo[3,2-*a*]benzimidazole and imidazo[2,1-*b*]benzothiazole) with reactive acetylenic esters.

The reaction of ethyl 3-methyl-6-phenylimidazo[2,1-*b*]thiazole-2-carboxylate (**1a**) with DMAD was carried out under various conditions (Table 1). When the reaction was carried out in boiling acetonitrile, three products, 2-ethyl 6,7-dimethyl 3-methylpyrrolo[2,1-*b*]-thiazole-2,6,7-tricarboxylate (**2a**), tetramethyl 3-phenylimidazo[1,2-*a*]pyridine-5,6,7,8-tetracarboxylate (**3a**), and 5-ethyl 2,3-dimethyl 4-methylthiophene-2,3,5-tricarboxylate (**4**), were isolated in 25, 42, and 41% yields, respectively. The reaction in *N*,*N*-dimethylformamide (DMF) at bp proceeded similarly, but the yield of **2a** in the reaction at room temperature decreased remarkably. When the solvent was replaced by hot xylene, compound **2a** was obtained as the sole product in a better yield than in hot acetonitrile or DMF, benzonitrile being detected in the reaction mixture.

The structures of **2a**, **3a**, and **4** were assigned by means of their spectroscopic data as well as their elemental analyses. The ^{1}H NMR spectrum of **2a** reveals two methyl-singlets at δ 2.75 (3H) and 3.90 (6H), ethyl-signals at δ 1.34 and 4.37, and a singlet at δ 7.58 (1H) assignable to a proton at C-5. The ^{13}C NMR spectrum displays fourteen signals in agreement with the assigned structure. The ^{1}H NMR spectrum of **3a** has a 1H-singlet at δ 7.85 (H-2) together with four methyl-singlets at δ 3.20, 3.90, 3.93, and 4.10, and a phenyl multiplet at δ 7.3—7.5. Of four methyl-singlets, the one resonating at the highest field is assigned to a CO_2Me group at C-5, which should be shielded by a phenyl group at C-3. The ^{1}H NMR spectrum of **4** shows a methyl-singlet at δ 2.49 in addition to signals for ester groups at δ 3.87 (3H, s), 3.93 (3H, s), 1.38 (3H, t, J=7 Hz), and 4.35 (2H, q, J=7 Hz).

As shown in Table 1, the reaction of **1b** with DMAD in hot xylene proceeded in a similar way to give **2b**, whereas that in hot acetonitrile or DMF afforded tetramethyl 1-phenyl-3-(1-propynylthio)imidazo[3,4-*a*]-pyridine-5,6,7,8-tetracarboxylate (**5**) in addition to **3a**. The structure of **5** was assigned on the basis of the results of elemental analysis as well as its ^{1}H NMR spectrum which has four methyl ester-singlets at δ 3.16, 3.84, 3.91, and 4.07, a methyl-singlet at δ 1.90, and a phenyl multiplet at δ 7.3—7.7. Like **3a**, the singlet at δ 3.16 is assigned to a CO_2Me group at C-8, which should be shielded by a phenyl group at C-1. Resemblance of the UV spectrum of **5** with

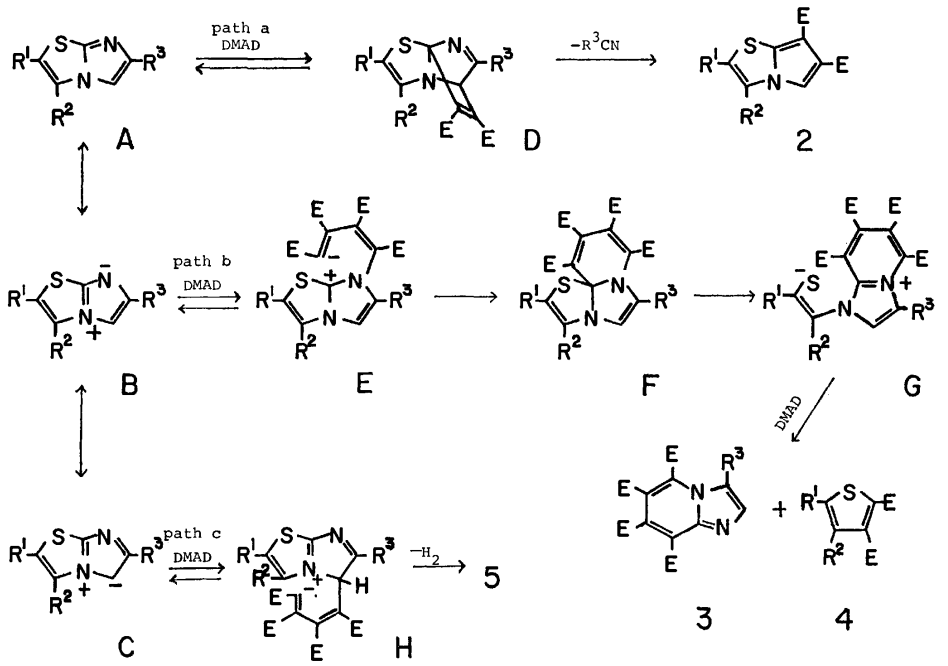
a) Yields are based on consumed starting materials.



Scheme 1.

that of **3a** further supports the assigned structure.

Likewise, **1a** and **1b** react with diethyl acetylenedicarboxylate (DEAD) in hot xylene giving **2f** and **2g**, respectively, in good yields.

It appears that elimination of nitrogen- or sulfur-containing moiety from **1** highly depends on the polarity of the solvent. For the sake of clarification, 3-methylthiazolo[3,2-*a*]benzimidazole (**6**) and 2-methylimidazo[2,1-*b*]benzothiazole (**7**), respectively, were allowed to react with DMAD. The reaction of **6** in acetonitrile yielded tetramethylpyrido[1,2-*a*]benzimidazole-1,2,3,4-tetracarboxylate (**8**) with loss of the sulfur-containing moiety, whereas that of **7** in xylene gave dimethyl pyrrolo[2,1-*b*]benzothiazole-2,3-dicarboxylate (**9**) with elimination of acetonitrile and two unidentified 1:4-adducts **11** and **12**.

Plausible mechanisms for the reactions of imidazo[2,1-*b*]thiazole **1** with the reactive acetylenic ester are given in Scheme 1. In an aprotic nonpolar solvent, the reaction proceeds *via* a Diels-Alder addition of the neutral species **A** with the acetylenedicarboxylate followed by the retrogression of the adduct **D** to give **2** (path a). In an aprotic polar solvent, the ionic species **B** undergoes a 1,4-dipolar cycloaddition with DMAD to give intermediates **E**, **F**, and **G** successively. At the final stage of the reaction, **G** reacts with DMAD to give imidazo[1,2-*a*]pyridine (**3**) together with the thiophene (**4**) (path b). Potts *et al.* also postulated a zwitter ion like **G** for the reaction of thiazolium-*N*-ylides with DMAD to give 1*H*-pyrido[2,1-*c*][1,4]thiazines.[8] However, if R^1 in **1** is hydrogen, the ionic species **C** reacts with DMAD to form an intermediate **H**, from which thioether **5** is produced by loss of H_2 (path c).

In order to confirm the postulate that a bulky substituent at C-6 in the imidazo[2,1-*b*]thiazoles facilitates the isolation of intermediates **D** and **F** (Scheme 1), we examined the reactions of **1c** and **1d** with DMAD in xylene or acetonitrile. However, the products were found to be those formed by the loss of the sulfur- or nitrogen-containing moiety from the intermediates.

The reaction of **1a** with the acetylene is sluggish; over 80% yield of the starting **1a** was recovered even after being allowed to react with DMAD in xylene at room temperature for 27 d. The reaction of 6-methylimidazo[2,1-*b*]thiazole (**1e**) with DMAD in either xylene or acetonitrile was rapid and the solution boiled when DMAD was added to a solution of **1e** to give **3e** and an unidentified 1:4-adduct **10**. The results suggest that an electron-attracting substituent would decrease the electron density of the imidazole ring of **1** and hence its nucleophilic reactivity towards the acetylenedicarboxylate, whereas an electron-donating substituent would enhence its reactivity.

No such Michael-type adducts[6,7] were isolated.

Experimental

Melting points were uncorrected. ^1H and ^{13}C NMR spectra were taken with Hitachi R-24B (60 MHz) and Varian FT-80A spectrometers, respectively, for solutions in $CDCl_3$ with TMS as an internal standard. UV spectra were measured for solutions in ethanol and IR spectra for Nujol mulls. Kieselgel 60 was used for chromatography. Yields are based on the consumed starting materials. Imidazo[2,1-*b*]thiazoles (**1b** and **1e**),[9,10] thiazolo[3,2-*a*]benzimidazole (**6**),[9] and imidazo[2,1-*b*]benzothiazole (**7**)[9] were prepared as reported.

*Synthesis of Ethyl 3-Methyl-6-phenylimidazo[2,1-b]thiazole-2-carboxylate (**1a**).* A stirred mixture of ethyl 2-amino-4-methylthiazole-5-carboxylate[11] (10 g) and α-bromoacetophenone (10.6 g) in 1-butanol (40 ml) was heated under reflux for 3 h and cooled in an ice bath. Ethyl 3-methyl-6-phenylimidazo[2,1-*b*]thiazole-2-carboxylate hydrobromide (8.3 g, 40%) precipitated was recrystallized from ethanol as colorless prisms, mp 199—200 °C. A mixture of the salt (5 g) in water (150 ml) was heated under reflux for 3 h, free base precipitated on cooling, being filtered off and dried (2.3 g, 62%). Recrystallization from ethanol gave **1a** [colorless needles, mp 143—144 °C, UV_{max} 257^{sh} (log ε 4.37), 265 (4.38), 280 (4.38), 287 (4.38), 294^{sh} (4.36); IR 1690 cm^{-1} (ester C=O); ^1H NMR δ=1.38 (3H, t, *J*=7 Hz, CH_3), 2.72 (3H, s, CH_3), 4.33 (2H, q, *J*=7 Hz, OCH_2), 7.3—7.5 (3H, m, phenyl), 7.55 (1H, s, H-5), 7.7—7.9 (2H, m, phenyl). Found: C, 62.89; H, 4.97; N, 9.81; S, 11.08%. Calcd for $C_{15}H_{14}N_2O_2S$: C, 62.97; H, 4.93; N, 9.78; S, 11.20%].

*Synthesis of Ethyl 6-t-Butyl-3-methylimidazo[2,1-b]thiazole-2-carboxylate (**1c**).* Ethyl 6-*t*-butyl-3-methylimidazo[2,1-*b*]-thiazole hydrobromide was prepared in 78% yield in the same way as for **1a** from ethyl 2-amino-4-methylthiazole-5-carboxylate (17.5 g), 1-bromo-3,3-dimethyl-2-butanone[12] (16.1 g), and 1-butanol (70 ml) and recrystallized from ethanol as colorless prisms, mp 202—203.5 °C. This salt (3.2 g) was added to a sodium ethoxide solution prepared from Na (0.4 g) and abs ethanol (30 ml). The mixture was heated under reflux for 3 h and evaporated to dryness under reduced pressure, the residue being dissolved in water. Extraction with ether and evaporation of the dried (Na_2SO_4) extracts gave **1c** [1.78 g, 73%, colorless prisms (from ligroine), mp 92—93 °C. UV_{max} 274 nm (log ε 4.18); IR 1680 cm^{-1} (ester C=O); ^1H NMR δ=1.36 (9H, s, *t*-butyl), 1.38 (3H, t, *J*=7 Hz, CH_3), 2.73 (3H, s, CH_3), 4.33 (2H, q, *J*=7 Hz, OCH_2), 7.10 (1H, s, H-5). Found: C, 58.87; H, 6.76; N, 10.42; S, 12.29%. Calcd for $C_{13}H_{18}N_2O_2S$: C, 58.62; H, 6.81; N, 10.52; S, 12.04%].

*Synthesis of 6-t-Butyl-3-methylimidazo[2,1-b]thiazole (**1d**).* 6-*t*-Butyl-3-methylimidazo[2,1-*b*]thiazole hydrobromide was prepared in 83% yield in the same way as for **1a** from 2-amino-4-methylthiazole (15.8 g), 1-bromo-3,3-dimethyl-2-butanone (24.7 g) and 1-butanol (70 ml), and recrystallized from ethanol as colorless prisms, mp 242—243 °C. A mixture of this salt (5 g), NaOH (1 g), and ethanol (30 ml) was heated under reflux for 1 h and evaporated to dryness under reduced pressure. The residue was dissolved in water and extracted with ether. Evaporation of the dried (Na_2SO_4) extracts left **1d** [2.8 g, 79%, colorless prisms (from petroleum ether), mp 83—85 °C, UV_{max} 245 nm (log ε 3.80); ^1H NMR δ=1.34 (9H, s, *t*-butyl), 2.32 (3H, d, *J*=1 Hz, CH_3), 6.28 (1H, q, *J*=1 Hz, H-2), 7.04 (1H, s, H-5). Found: C, 62.02; H, 7.28; N, 14.38; S, 16.49%. Calcd for $C_{10}H_{14}N_2S$: C, 61.82; H, 7.26; N, 14.42; S, 16.50%].

*Reaction of **1a** with DMAD.* A mixture of **1a** (1.00 g), DMAD (2.48 g), and the solvent (50 ml) was allowed to react and then evaporated to dryness under reduced pressure. Chromatography of the residue with benzene and benzene–chloroform (1:1) eluted benzonitrile [IR (neat) 2200 (CN) and 700 cm^{-1} (phenyl)], compounds **4**, **1a**, **2a**, and **3a**, successively. The conditions and yields for reactions of **1a**—**e**, **6**, and **7** with acetylenic esters are given in Table 1.

2a: Colorless needles (from ethanol), mp 166.5—167 °C, UV_{max} 226 nm (log ε 4.34), 257^{sh} (4.43), 265 (4.48), 292 (3.82), 316^{sh} (3.58); IR 1730, 1705, and 1655 cm^{-1} (ester (C=O); ^1H NMR δ=1.34 (3H, t, *J*=7 Hz, CH_3), 2.75 (3H, s, CH_3), 3.90 (6H, s, 2×OCH_3), 4.37 (2H, q, *J*=7 Hz, OCH_2), 7.58 (1H, s, H-5). ^{13}C NMR δ=12.1 (q, CH_3), 14.2 (q, CH_3), 51.6 (q, OCH_3), 52.0 (q, OCH_3), 61.9 (t, OCH_2), 104.5 (s, C-7), 116.3 (d, C-5), 118.4 (s, C-6), 122.1 (s, C-2), 137.3 (s, C-3), 139.2 (s, C-7a), 161.7 (s, C=O), 162.7 (s, C=O), 163.4 (s, C=O). Found: C, 51.56; H, 4.73; N, 4.17; S, 10.09%. Calcd for $C_{14}H_{15}NO_6S$: C, 51.68; H, 4.65; N, 4.31; S, 9.85%.

3a: Yellow needles (from ethanol), mp 152—153 °C, UV_{max} 261 nm (log ε 4.41), 300^{sh} (3.69), 357 (3.53); IR 1740, 1730, and 1715 cm^{-1} (ester C=O); ^1H NMR δ=3.20 (3H, s, OCH_3), 3.90 (3H, s, OCH_3), 3.93 (3H, s, OCH_3), 4.10 (3H, s, OCH_3), 7.3—7.5 (5H, m, phenyl), 7.85 (1H, s, H-2). Found: C, 58.98; H, 4.56; N, 6.78%. Calcd for $C_{21}H_{18}N_2O_8$: C, 59.15;

H, 4.26; N, 6.57%.

4: Colorless needles (from ethanol), mp 67—68 °C, UV_{max} 275 nm (log ε 4.27); IR 1740, 1720, and 1705 cm^{-1} (ester C=O); ^1H NMR δ=1.38 (3H, t, J=7 Hz, CH_3), 2.49 (3H, s, CH_3), 3.87 (3H, s, OCH_3), 4.35 (2H, q, J=7 Hz, OCH_2). Found: C, 50.53; H, 4.99; S, 11.03%. Calcd for $C_{12}H_{14}O_6S$: C, 50.34; H, 4.93; S, 11.20%.

*Reaction of **1a** with DEAD.* A mixture of **1a** (0.70 g) and DEAD (1.66 g) in xylene (30 ml) was heated under reflux for 27 h, and worked up as above to give **2f**.

2f: Colorless needles (from ligroine), mp 109—110 °C, UV_{max} 226 nm (log ε 4.19), 257^{sh} (4.42), 265 (4.49), 292^{sh} (3.92), 316 (3.67); IR 1725, 1710, and 1650 cm^{-1} (ester C=O); ^1H NMR δ=1.40 (9H, t, J=7 Hz, 3×CH_3), 2.75 (3H, s, CH_3), 4.37 (6H, q, J=7 Hz, 3×OCH_2), 7.58 (1H, s, H-5). Found: C, 54.54; H, 5.68; N, 4.08; S, 9.27%. Calcd for $C_{16}H_{19}NO_6S$: C, 54.38; H, 5.42; N, 3.96; S, 9.07%.

*Reaction of **1b** with DMAD.* A mixture of **1b** (1.00 g), DMAD (3.32 g), and the solvent (30 ml) was allowed to react and then worked up as for **1a**. Compound **1b**, **5**, and **2b** were eluted successively.

2b: Colorless needles (from ligroine–benzene), mp 148—149 °C, UV_{max} 225 nm (log ε 4.28), 242 (4.29), 290 (4.08); IR 1725 and 1705 cm^{-1} (ester C=O); ^1H NMR δ=2.43 (3H, d, J=0.5 Hz, CH_3), 3.93 (6H, s, 2×OCH_3), 6.62 (1H, q, J=0.5 Hz, H-2), 7.62 (1H, s, H-5). Found: C, 51.99; H, 4.37; N, 5.50; S, 12.48%. Calcd for $C_{11}H_{11}NO_4S$: C, 52.16; H, 4.38; N, 5.53; S, 12.66%.

5: Yellow needles (from ethanol), mp 186—187 °C, UV_{max} 255 nm (log ε 4.14), 297^{sh} (3.74), 373 (3.59); IR 1735 and 1710 cm^{-1} (ester C=O); ^1H NMR δ=1.90 (3H, s, CH_3), 3.16 (3H, s, OCH_3), 3.84 (3H, s, OCH_3), 3.91 (3H, s, OCH_3), 4.07 (3H, s, OCH_3), 7.3—7.7 (5H, m, phenyl). Found: C, 58.14; H, 4.16; N, 5.35; S, 6.14%. Calcd for $C_{24}H_{20}N_2O_8S$: C, 58.06; H, 4.06; N, 5.46; S, 6.46%.

*Reaction of **1b** with DEAD.* A mixture of **1b** (1.00 g) and DEAD (3.18 g) in xylene (30 ml) was heated under reflux for 14 h, and then worked up as for **1a** to give **2g**.

2g: Colorless prisms (from ethanol), mp 114—115 °C, UV_{max} 225 nm (log ε 4.18), 235 (4.18), 243 (4.18), 291 (3.96); IR 1720 and 1695 cm^{-1} (ester C=O); ^1H NMR δ=1.39 (6H, t, J=7 Hz, 2×CH_3), 2.40 (3H, d, J=1 Hz, CH_3), 4.34 (4H, q, J=7 Hz, 2×OCH_2), 6.52 (1H, q, J=1 Hz, H-2), 7.52 (1H, s, H-5). Found: C, 55.53; H, 5.33; N, 4.85; S, 11.34%. Calcd for $C_{13}H_{15}NO_4S$: 55.50; H, 5.37; N, 4.98; S, 11.40%.

*Reaction of **1c** with DMAD.* A mixture of **1c** (0.90 g), DMAD (2.40 g), and the solvent (50 ml) was allowed to react and then worked up as for **1a** to give compounds **4**, **1c**, **2a**, and **3c** successively.

3c: Yellow needles (from ethanol), mp 119—120 °C, UV_{max} 261 nm (log ε 4.34), 302 (3.52), 358 (3.60); IR 1735 and 1710 cm^{-1} (ester C=O); ^1H NMR δ=1.47 (9H, s, *t*-butyl), 3.90 (6H, s, 2×OCH_3), 3.93 (3H, s, OCH_3), 4.05 (3H, s, OCH_3), 7.82 (1H, s, H-2). Found: C, 56.24; H, 5.47; N, 6.71%. Calcd for $C_{19}H_{22}N_2O_8$: C, 56.15; H, 5.46; N, 6.89%.

*Reaction of **1d** with DMAD.* A mixture of **1d** (1.00 g), DMAD (3.60 g), and the solvent (30 ml) was allowed to react and then worked up as for **1a** to give compounds **2b** and **3c** successively.

*Reaction of **1e** with DMAD.* A mixture of **1e** (1.00 g), DMAD (4.12 g), and the solvent (30 ml) was allowed to react and then worked up to give **3e** as a yellow oil, identified as a picrate, and an unidentified 1:4-adduct **10**.

3e: Picrate of **3e**, yellow prisms (from ethanol), mp 153—154 °C, UV_{max} 255 nm (log ε 4.56), 315^{sh} (4.03), 354 (4.31); IR 3350 (OH) and 1740 cm^{-1} (ester C=O); ^1H NMR (DMSO-d_6) δ=1.07 (3H, t, J=7 Hz, CH_3), 2.42 (3H, d, J=0.5 Hz, CH_3), 3.45 (2H, q, OCH_2), 3.87 (6H, s, 2×OCH_3), 3.95 (3H, s, OCH_3), 4.03 (3H, s, OCH_3), 7.13 (1H, bs, OH), 7.45 (1H, q, J=0.5 Hz, H-2), 7.95 (1H, bs, OH), 8.53 (2H, s, phenyl). Found: C, 45.44; H, 3.84; N, 10.85%. Calcd for $C_{22}H_{20}N_5O_{15}\cdot C_2H_5OH$: C, 45.08; H, 3.94; N, 10.95%.

10: Yellow prisms (from ethanol), mp 235—236 °C, UV_{max} 298 nm (log ε 4.20), 420 (4.06); IR 1730, 1705, and 1685 cm^{-1} (ester C=O); ^1H NMR δ=1.57 (3H, s), 3.62 (3H, s), 3.67 (3H, s), 3.75 (6H, s), 3.76 (3H, s), 3.83 (3H, s), 3.85 (3H, s), 3.88 (3H, s), 5.26 (1H, d, J=8 Hz), 6.43 (1H, s), 6.45 (1H, d, J=8 Hz). Found: C, 50.89; H, 4.40; N, 3.86; S, 4.50%. Calcd for $C_{30}H_{30}N_2O_{16}S$: C, 50.99; H, 4.28; N, 3.96; S, 4.54%.

*Reaction of **6** with DMAD.* A mixture of **6** (1.00 g) and DMAD (3.87 g) in acetonitrile (30 ml) was left to stand at room temperature for 3 h, and worked up as described for **1a** to give **8** (0.51 g).

8: Yellow needles (from ligroine–benzene), mp 146—147 °C, UV_{max} 277 nm (log ε 4.60), 285^{sh} (4.56), 326 (3.68), 375 (3.45); IR 1740 and 1730 cm^{-1} (ester C=O); ^1H NMR δ=3.90 (3H, s, OCH_3), 3.92 (3H, s, OCH_3), 4.08 (3H, s, OCH_3), 4.20 (3H, s, OCH_3), 7.3—7.8 (3H, m, H-7,8,9), 8.07 (1H, dm, J=8 Hz, H-6). Found: C, 57.12; H, 3.97; N, 6.92%. Calcd for $C_{19}H_{16}N_2O_8$: C, 57.00; H, 4.03; N, 7.00%.

*Reaction of **7** with DMAD.* A mixture of **7** (0.94 g) and DMAD (2.13 g) in xylene (30 ml) was heated under reflux for 5 h, and worked up as described for **1a** to give **9** (0.213 g) and two unidentified 1:4-adducts **11** (0.138 g) and **12** (0.47 g).

9: Colorless needles (from ethanol), mp 147—149 °C, UV_{max} 241 nm (log ε 4.62), 268^{sh} (4.13), 288 (4.13); IR 1740 and 1710 cm^{-1} (ester C=O); ^1H NMR δ=3.95 (6H, s, 2×OCH_3), 7.2—7.8 (4H, m, H-5,6,7,8), 7.98 (1H, s, H-1). Found: C, 58.07; H, 3.98; N, 4.98; S, 11.38%. Calcd for $C_{14}H_{11}NO_4S$: C, 58.12; H, 3.83; N, 4.84; S, 11.08%.

11: Yellow prisms (from ethanol), mp 234—235 °C, UV_{max} 291 nm (log ε 4.37), 414 (4.28); IR 1750, 1735, and 1700 cm^{-1} (ester C=O); ^1H NMR δ=1.72 (3H, s), 2.92 (3H, s), 3.48 (3H, s), 3.67 (3H, s), 3.68 (3H, s), 3.72 (3H, s), 3.78 (3H, s), 3.83 (3H, s), 3.86 (3H, s), 5.05 (1H, s), 7.2—7.6 (4H, m). Found: C, 53.98; H, 4.45; N, 3.50; S, 4.51%. Calcd for $C_{34}H_{32}N_2O_{16}S$: C, 53.96; H, 4.27; N, 3.70; S, 4.24%.

12: Orange needles (from ethanol), mp 163—165 °C, UV_{max} 265 nm (log ε 4.15), 435 (3.80); IR 1735, 1725, and 1670 cm^{-1} (ester C=O); ^1H NMR δ=1.67 (3H, s), 3.37 (3H, s), 3.50 (6H, s), 3.61 (3H, s), 3.71 (3H, s), 3.80 (3H, s), 3.84 (3H, s), 3.88 (3H, s), 5.95 (1H, s), 7.05—8.0 (4H, m). Found: C, 54.02; H, 4.41; N, 3.33; S, 4.35%. Calcd for $C_{34}H_{32}N_2O_{16}S$: C, 53.96; H, 4.27; N, 3.70; S, 4.24%.

We thank Dr. Masafumi Yasunami, Tohoku University, for NMR spectral determination.

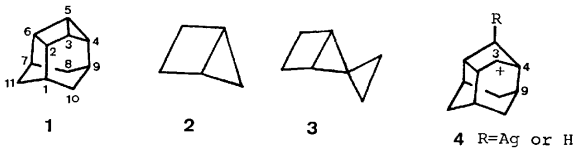
(Received April 30, 1980)

Treatment of 3,5-dehydronoriceane (**1**) with a catalytic amount of silver tetrafluoroborate results in a novel skeletal rearrangement to afford tetracyclo[5.3.1.$0^{2,6}$.$0^{3,9}$]undec-4-ene (2,4-ethenonoradamantane) (**5**) in 85% yield. Empirical force-filed calculations suggest that there is no substantial difference in strain energies between **1** and bicyclo[2.1.0]pentane which is inert toward silver(I) ion. Acetolysis of *endo*-3-noricyl (*endo*-tetracyclo[5.3.1.$0^{2,6}$.$0^{4,9}$]undec-3-yl) tosylate (**7**) gives *exo*-3-acetoxynoriceane (*exo*-3-acetoxytetracyclo[5.3.1.$0^{2,6}$.$0^{4,9}$]undecane) (**11**), *exo*-4-acetoxytetracyclo[5.3.1.$0^{2,6}$.$0^{3,9}$]undecane (**12**), and **5** in a ratio of 36:42:22. Similar acetolysis of the *exo*-isomer of **7** gives the same products but in a different ratio (**11**:**12**:**5**=9:47:44). A stepwise carbocation mechanism is proposed for the above mentioned silver(I) ion-catalyzed rearrangement.

Transition metal-catalyzed rearrangement of strained organic molecules has become one of the most exciting and intriguing fields of chemistry in a past decade and a number of unexpected and interesting isomerizations have been reported.[2] Among them, silver(I) ion-catalyzed rearrangements of strained σ-bonds have demonstrated remarkable and unique carbon-carbon σ-bond reorganization reactions.[2-4] Meanwhile, in spite of their high strain energies, bicyclo[2.1.0]pentane (**2**) and the even more strained spiro compound (**3**) have been found to be inert toward silver(I) ion.[5-7] We have recently reported the synthesis of 3,5-dehydronoriceane (**1**),[8] which possesses the partial bicyclo[2.1.0]pentane structure constrained within a rigid cage molecule. Although **1** has shown

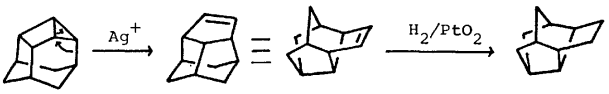


Scheme 1.

similar reactivities in hydrogenation[8] and other reactions[9] to bicyclo[2.1.0]pentane (**2**) itself,[10] we have found that **1**, unlike **2**, does react with silver(I) ion to follow a skeletal rearrangement.[11] Since nonconcerted mechanism involving carbocation intermediate has been strongly suggested to account for the hitherto known silver(I) ion-catalyzed rearrangements,[2-4] behavior of the supposed carbocation intermediate such as **4** may deserve to be investigated. In this paper, we would like to describe a new silver(I) ion-catalyzed rearrangement of bicyclo[2.1.0]pentane system together with empirical force-field calculations of strain energies of **1** and **2**, and acetolyses of *exo*- and *endo*-3-noricyl tosylates (**7** and **8**).

Results and Discussion

When **1** was treated with 3.6 mol% of silver tetrafluoroborate in chloroform at room temperature for 18 h, a novel skeletal rearrangement similar to those of cubyl systems[2,3] took place to give tetracyclo[5.3.1.$0^{2,6}$.$0^{3,9}$]undec-4-ene (2,4-ethenonoradamantane) (**5**) in 85% yield. Catalytic hydrogenation of **5** gave known tetracyclo[5.3.1.$0^{2,6}$.$0^{3,9}$]undecane (**6**),[12] confirming the structure of **5**.



Scheme 2.

Primarily we anticipated that the strain around the central bond of **1** would be higher than that of the corresponding bond of **2** in order to explain the observed different reactivity toward silver(I) ion between **1** and **2**. Despite the acknowledged inadequacy of the presently available force-field models for cyclopropane derivatives,[13] we hoped that errors due to the force-field would cancel each other when closely related molecules were compared in molecular mechanics calculations (Table 1). The force-field[13] reproduces the geometry of **2** well, though it overestimates the strain in **2** by *ca.* 30 kcal/mol. Attention should be directed to the small difference in energy terms between **1** and **2**.[14] For **1** and **2** there appears to be no substantial difference in strain around the central bonds as well as in the whole molecule. In addition, the bow-and-stern C···C as well as flagpole H···H nonbonded interactions in the boat cyclohexane ring of **1** amount to only *ca.* 2 kcal/mol. Thus, any rationalization of the observed reactivity of **1** toward silver(I) ion compared with **2** must be based on something besides strain.

Although two mechanisms, concerted [$_{\sigma}2_{a}+_{\sigma}2_{a}$][15] and step-wise carbocation rearrangements, have been considered for silver(I) ion-catalyzed rearrangements, many experiments strongly favor the latter.[2-4] If so, 3-noricyl cation such as **4** (R=Ag) should be a supposed intermediate in the present reaction. There are two possibilities for 1,2-alkyl shift. Migration of the C_1–C_2 bond to C_3 gives again the noriceane skeleton, while shift of the C_4–C_9 bond leads to the more stable tetracyclo[5.3.1.$0^{2,6}$.$0^{3,9}$]undecane system.[12] However, our calculation has shown that there is

TABLE 1. MOLECULAR MECHANICS CALCULATIONS ON **1** AND **2** USING THE ENGLER FORCE-FIELD

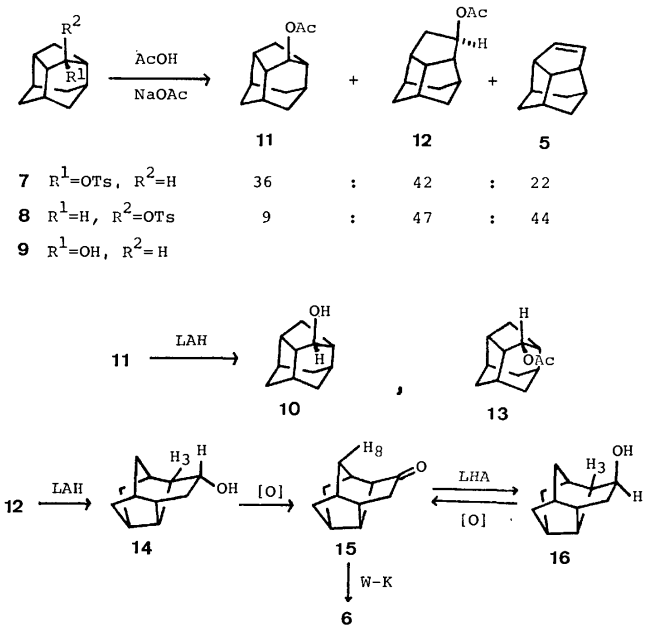


Scheme 3.

a large dihedral angle (45°) between sp^2-vacant orbital at C_3 of **4** (R=H) and the migrating C_4–C_9 bond, suggesting that such a rearrangement would be unfavorable. We, therefore, have studied the behavior of 3-noricyl cation (**4**, R=H) generated under solvolytic conditions in order to know whether the rearrangement is feasible or not.

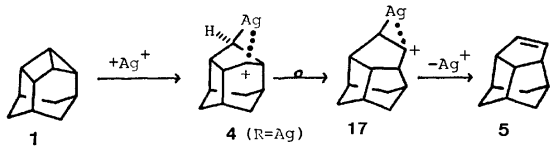
Two isomeric *endo*- and *exo*-3-noricyl tosylates (**7** and **8**), prepared from the corresponding alcohols (**9** and **10**) by the usual way, were solvolyzed in acetic acid containing sodium acetate as a buffer. Acetolysis of the *endo*-tosylate (**7**) gave *exo*-3-acetoxynoriceane (**11**), *exo*-4-acetoxytetracyclo[5.3.1.$0^{2,6}$.$0^{3,9}$]undecane (**12**), and **5** in 95% yield in a ratio of 36:42:22. A similar acetolysis of the *exo*-isomer (**8**) gave the same products but in a different ratio (**11**:**12**:**5**=9:47:44). Lithium aluminum hydride reduction of **11** gave *exo*-3-noriceanol (**9**), which was shown to be identical with the one obtained in the reduction of 3-noriceanone with lithium in liquid ammonia.[16] Reduction of **12** with lithium aluminum hydride gave the alcohol, *exo*-tetracyclo[5.3.1.$0^{2,6}$.$0^{3,9}$]undecan-4-ol (**14**), which was oxidized with CrO_3–pyridine complex to afford tetracyclo[5.3.1.$0^{2,6}$.$0^{3,9}$]undecan-4-one (**15**).[12,17] Wolff-Kishner (W-K) reduction of **15** gave **6** confirming the parent skeleton. Lithium aluminum hydride reduction of **15** gave exclusively the isomeric *endo*-tetracyclo[5.3.1.$0^{2,6}$.$0^{3,9}$]undecan-4-ol (**16**), which reproduced **15** upon treatment with CrO_3–pyridine complex. The ^{1}H-NMR (PMR) spectra of **14** and **16** showed a doublet of doublet (J=6.9 and 2.7 Hz) at 4.33 ppm and the quintet (J=10.5, 6.3, and 4.8 Hz) at 4.58 ppm due to C_4-protons, respectively. Model investigations (Dreiding model) tell us that the *endo*-proton should not couple with the adjacent bridg-head proton (H_3) because of the large dihedral angle (*ca.* 90°). Accordingly, **14** and **15** were assigned to be *exo*- and *endo*-tetracyclo[5.3.1.$0^{2,6}$.$0^{3,9}$]undecan-4-ols, respectively. This elucidation does not contradict the exclusive formation of **16** due to the steric hindrance of H_8 in the reduction of **15** with lithium aluminum hydride.

No formation of *endo*-3-acetoxynoriceane (**13**)[16] in either acetolysis of *endo*- or *exo*-3-tosylate (**7** or **8**) may be due to large steric hindrance of the "bowsprit" hydrogen (*viz.* *endo*-H_{10}) in the boat conformation. The same steric hindrance is shown in the hydride reduction of 3-noriceanone giving exclusively *endo*-3-noriceanol (**9**).[16] The steric effect can be also responsible for the exclusive formation of **12**, as is seen in the hydride reduction of **15** (*vide supra*). More interesting is the difference in the ratio of the rearranged products (*viz.* **12** and **5**) to the unrearranged one (*viz.* **11**) between the two tosylates (**7** and **8**). The ratio is 1.8 for the *endo*-tosylate (**7**), while that is 9.1 for the *exo*-one (**8**). The stereoelectronic control can give rise to the large difference; the leaving group (*viz.* tosyloxyl group) in **8** is arranged in an almost perfect antiperiplanar position with reference to the migrating C_4–C_9 bond, where the rearrangement can

take place most easily. Furthermore, it should be also noted that almost twice as much the rearranged products as the unrearranged one are formed even in the acetolysis of the *endo*-tosylate (**7**), in which the orientation of the leaving group is not favorable for the rearrangement. Thus, 3-noricyl cation (**4**, R=H) is decisively a mutable entity into tetracyclo[5.3.1.$0^{2,6}$.$0^{3,9}$]undecane system; this implies that a stepwise carbocation mechanism is quite possible in the present silver(I) ion-catalyzed rearrangement of **1**.

An attempt was also made to trap the supposed carbocation intermediate (**4**, R=Ag) by a nucleophilic solvent. Treatment of **1** with silver(I) ion in methanol caused no rearrangement and **1** was recovered almost quantitatively.[18] Furthermore, in order to make it clear whether proton can induce the same rearrangement, **1** was treated with a catalytic amount of *p*-toluensulfonic acid in refluxing benzene. However, no substantial change was observed; this indicates that proton is far from effective for the rearrangement.

The following scheme can be delineated for a stepwise carbocation mechanism. The strain energy difference between **1** and **5** is estimated to be *ca.* 40 kcal/mol[19] sufficient for the rearrangement.[2,3] In addition, the recently proposed stabilizing interaction between silver and a carbocation center[4] appears to be more efficient in the rearranged carbocation (**17**) than in the unrearranged one (**4**, R=Ag). Judging from the fact that halonium ion and certain metal ions approach the central bond of the bicyclo[2.1.0]pentane system of **1** from the front side,[9] it is highly probable that silver(I) ion also behaves in a similar manner and, consequently, the silver takes the suitable orientation for the interaction with the carbocation center, as is shown in the scheme.



Scheme 4.

In conclusion, the present results have clearly demonstrated that both of ring strain and suitable geometry are equally important in silver(I) ion-catalyzed rearrangements of strained polycylic molecules.[3,4]

Experimental

All the temperatures were uncorrected. The melting points were measured in sealed capillaries. The IR spectra were obtained on a Shimadzu IR-27 spectrometer. The conventional mass spectra were taken by using a Hitachi RMS-4 mass spectrometer and the exact mass spectrum was obtained on a Hitachi RMU-8GN mass spectrometer. The PMR and ^{13}C-NMR (CMR) spectra were obtained on Varian EM-390 and CFT-20 spectrometers, TMS being chosen as the internal standard. The microanalyses were performed by Kyoto University Elemental Analysis Center. All the reactions were carried out under nitrogen unless otherwise noted.

*Silver(I) Ion-catalyzed Rearrangement of Pentacyclo[5.3.1.$0^{2,6}$.$0^{3,5}$.$0^{4,9}$]undecane (**1**) to Tetracyclo[5.3.1.$0^{2,6}$.$0^{3,9}$]undec-4-ene (**5**).* A solution of **1** (1.00 g; 6.88 mmol) in $CHCl_3$ (7 ml) was stirred in the presence of $AgBF_4$ (48 mg; 0.25 mmol) at room temperature for 18 h in the dark. After evaporation of the solvent, the residue was dissolved in hexane and insoluble materials were removed by filtration. The solvent was evaporated and the residue was chromatographed on silica gel. Elution by hexane gave **5** (0.86 g, 85%): mp 150—153 °C. MS *m/e* (rel intensity): 146 (M^+, 43), 92 (53), 80 (100), 79 (56), 68 (70). IR (CCl_4): 2930, 1470, 1450, 1340, 1305, 1080, 1025, 710 cm^{-1}. PMR δ (CCl_4): 5.68 (2H, t, J=1.5 Hz), 3.10 (1H, q, J=6.3 Hz), 2.60 (2H, br. s), 2.23 (1H, br. s), 2.00—1.20 (8H, complex m). CMR δ ($CDCl_3$): 128.0 (CH), 59.2 (CH), 55.8 (CH), 44.9 (CH_2), 35.9 (CH), 35.1 (CH), 31.2 (CH_2). Found: *m/e* 146.1095. Calcd for $C_{11}H_{14}$: M, 146.1095.

*Reduction of **5** to Tetracyclo[5.3.1.$0^{2,6}$.$0^{3,9}$]undecane (**6**).* A solution of **5** (148 mg; 1.01 mmol) and a small amount of PtO_2 in ethyl acetate (7 ml) was vigorously stirred under hydrogen. After one equivalent of hydrogen was absorbed, the catalyst was removed by filtration and the solvent was evaporated. The residue was chromatographed on silica gel. Elution by hexane gave **6** (118 mg, 79%), which was identical with the authentic specimen.[12]

endo-*Tetracyclo[5.3.1.$0^{2,6}$.$0^{4,9}$]undec-3-yl* p-*Toluenesulfonate (**7**).* To a solution of *endo*-tetracyclo[5.3.1.$0^{2,6}$.$0^{4,9}$]-undecan-3-ol (**10**)[16] (429 mg; 2.62 mmol) in pyridine (10 ml) was added *p*-toluenesulfonyl chloride (1003 mg; 5.26 mmol) at 0 °C. The mixture was allowed to stand overnight at room temperature and then poured onto ice–water. The organic materials were extracted with ether and washed with cold 5% HCl aq and brine, and dried (Na_2SO_4). After filtration, the solvent was evaporated to give a solid (816 mg). Recrystallization from hexane afforded **7** (745 mg, 89%): mp 89—92 °C. IR (KBr): 2930, 1350, 1180, 1165, 1095, 1020, 1015, 975, 960, 895, 850, 840, 820, 670 cm^{-1}. PMR δ (CCl_4): 8.73 (2H, d, J=8.4 Hz), 7.27 (2H, d, J=8.4 Hz), 4.32 (1H, s), 2.43 (3H, s), 2.53—0.77 (14H, br. complex m). CMR δ ($CDCl_3$): 144.5 (C), 134.5 (C), 129.8 (CH), 127.7 (CH), 85.0 (CH), 42.9 (CH), 41.3 (CH), 41.0 (CH_2), 38.3 (CH), 36.7 (CH), 31.2 (CH_2), 30.3 (CH), 23.2 (CH), 21.6 (CH_3). Found: C, 67.61; H, 7.11%. Calcd for $C_{18}H_{22}O_3S$: C, 67.89; H, 6.96%.

exo-*Tetracyclo[5.3.1.$0^{2,6}$.$0^{4,9}$]undec-3-yl* p-*Toluenesulfonate (**8**).* The reaction of *exo*-tetracyclo[5.3.1.$0^{2,6}$.$0^{4,9}$]undecan-3-ol (**9**) (62 mg; 0.38 mmol) with *p*-toluenesulfonyl chloride (145 mg; 0.76 mmol) in a similar manner to the above gave **8** (88 mg, 74%) after recrystallization from hexane. **8**: mp 62—64 °C. IR (KBr): 2930, 1600, 1355, 1180, 950, 925, 860, 845, 820, 670 cm^{-1}. PMR δ(CCl_4): 7.71 (2H, d, J=8.4 Hz), 7.28 (2H, d, J=8.4 Hz), 4.90 (1H, s), 2.47 (3H, s), 2.60—0.80 (13H, br. complex m). CMR δ($CDCl_3$): 144.6 (C), 135.1 (C), 130.0 (CH), 127.6 (CH), 85.7 (CH), 48.5 (CH), 41.3 (CH+CH_2), 38.8 (CH), 38.7 (CH), 37.6 (CH), 31.7 (CH), 30.9 (CH_2), 29.7 (CH_2), 21.6 (CH_3). Found: C, 67.63; H, 6.59%. Calcd for $C_{18}H_{22}O_3S$: C, 67.89; H, 6.96%.

*Acetolysis of **7**.* A solution of **7** (842 mg; 2.64 mmol) and sodium acetate (328 mg; 4.00 mmol) in glacial acetic acid (26 ml) was refluxed for 4 h. The reaction mixture was poured onto water and extracted with CH_2Cl_2. The organic layer was washed with brine, aqueous $NaHCO_3$ and brine, and dried (Na_2SO_4). After filtration, the solvent was evaporated to give a colorless oil (519 mg) which was chromatographed on silica gel. Elution by hexane gave **5** (82 mg, 21%) and the subsequent elution by hexane and CH_2Cl_2 (4:1) afforded a mixture of **11** and **12** (401 mg, 74%) in a ratio of 23:27 [GLC (PEG 20 M, 180 °C)]. The calculated ratio of **11**:**12**:**5** was 36:42:22. Each of the

acetates was isolated by preparative GLC. *exo*-3-Acetoxytetracyclo[5.3.1.$0^{2,6}$.$0^{4,9}$]undecane (**11**): bp 85—90 °C (bath temp)/2000 Pa. MS *m/e* (rel intensity): 206 (M^+, 4), 164 (11), 146 (100). IR (neat): 2930, 1735, 1370, 1245, 1055, 1025 cm^{-1}. PMR $\delta(CCl_4)$: 5.07 (1H, s, $W_{1/2}$=3.0 Hz), 1.95 (3H, s), 2.60—0.90 (14H, br. complex m). CMR $\delta(CDCl_3)$: 170.7 (C), 76.8 (CH), 47.9 (CH), 41.5 (CH_2) 41.3 (CH), 38.4 (CH), 37.9 (CH), 37.7 (CH), 31.5 (CH), 31.0 (CH_2), 30.1 (CH_2), 23.2 (CH_2), 21.4 (CH_3). Found: C, 75.50; H, 8.72%. Calcd for $C_{13}H_{18}O_2$: C, 75.69; H, 8.80%. *exo*-4-Acetoxytetracyclo[5.3.1.$0^{2,6}$.$0^{3,9}$]undecane (**12**): bp 90—97 °C (bath temp)/3066 Pa. IR (neat): 2930, 1740, 1360, 1250, 1020 cm^{-1}. PMR $\delta(CCl_4)$: 5.05 (1H, dd, J=7.5 and 3.0 Hz), 1.93 (3H, s), 2.87—1.37 (14H, br. complex m). Calcd for $C_{13}H_{18}O_2$: H, 75.69; H, 8.80%.

Acetolysis of ***8***. A solution of **8** (71 mg; 0.22 mmol) and sodium acetate (28 mg: 0.34 mmol) in glacial acetic acid (2.5 ml) was refluxed for 4 h. Similar work-up and subsequent column chromatography to the above gave **5** (8 mg, 24%) and a mixture of **11** and **12** (14 mg, 30%) in a ratio of 3:17 [GLC (PEG 20 M, 180 °C)]. The calculated ratio of **11**:**12**:**5** was 9:47:44.

exo-*Tetracyclo*[*5.3.1.*$0^{2,6}$*0.*^{4,9}]*undecan-3-ol* (***10***). To a suspension of $LiAlH_4$ (59 mg; 1.55 mmol) in dry ether (5 ml) was added dropwise a solution of **11** (110 mg; 0.53 mmol) in dry ether (2 ml). The mixture was stirred under reflux for 1 h and quenched with saturated aqueous Na_2SO_4. The organic layer was washed with brine and dried (Na_2SO_4). After filtration, the solvent was evaporated and the residue was chromatographed on silica gel. Elution by a mixture of hexane and CH_2Cl_2 (4:1) gave **10** (78 mg, 89%): mp 243—244 °C. MS *m/e* (rel intensity): 164 (M^+, 80), 146 (49), 135 (57), 92 (45), 91 (46), 79 (89), 68 (100). IR (KBr): 3260, 2925, 1075 cm^{-1}. PMR $\delta(CDCl_3)$: 4.30 (1H, s, $W_{1/2}$=3.0 Hz), 2.70—0.80 (15H, br. complex m). CMR $\delta(CDCl_3)$: 72.6 (CH), 50.5 (CH), 41.7 (CH_2), 41.0 (CH), 40.0 (CH), 38.2 (CH), 37.6 (CH), 31.5 (CH), 31.3 (CH_2), 30.0 (CH_2), 22.5 (CH_2). Found: C, 80.30; H, 10.09%. Calcd for $C_{11}H_{16}O$: C, 80.44; H, 9.83%.

exo-*Tetracyclo*[*5.3.1.*$0^{2,6}$.$0^{3,9}$]*undecan-4-ol* (***14***). The reduction of **12** (34 mg; 0.17 mmol) with $LiAlH_4$ (41 mg; 1.08 mmol) in a similar manner to the above gave **14** (24 mg, 99%): mp 128—132 °C. MS *m/e* (rel intensity): 164 (M^+, 65), 146 (57), 80 (95), 79 (100), 68 (91). IR (KBr): 3300, 2925, 1025 cm^{-1}. PMR $\delta(CDCl_3)$: 4.33 (1H, dd, J=6.9 and 2.7 Hz), 2.78 (1H, q, J=6.0 Hz), 2.63—1.30 (14H, br. complex m). CMR $\delta(CDCl_3)$: 75.2 (CH), 60.4 (CH), 51.5 (CH), 48.4 (CH), 43.1 (CH_2), 42.9 (CH_2), 40.0 (CH), 39.7 (CH_2), 38.5 (CH), 30.6 (CH_2). Found: C, 80.31; H, 10.05%. Calcd for $C_{11}H_{16}O$: C, 80.44; H, 9.83%.

Tetracyclo[*5.3.1.*$0^{2,6}$.$0^{3,9}$]*undecan-4-one* (***15***). To a solution of pyridine (0.7 ml) in CH_2Cl_2 (3.5 ml) was added portionwise CrO_3 (169 mg; 1.69 mmol) under stirring. After 10 min, a solution of **14** (27 mg; 0.16 mmol) in CH_2Cl_2 (2 ml) was added to the above mixture and stirred for 1.5 h. The reaction mixture was washed with 5% aqueous NaOH, 5% aqueous HCl and brine, and dried (Na_2SO_4). After filtration, the solvent was evaporated and the residue was chromatographed on silica gel. Elution by a mixture of hexane and CH_2Cl_2 (9:1) gave **15** (24 mg, 90%): mp 180—182 °C. MS *m/e* (rel intensity): 162 (M^+, 100), 120 (33), 92 (30), 79 (62). IR (KBr): 2925, 1750, 1180 cm^{-1}. PMR $\delta(CDCl_3)$: 3.00—1.10 (14H, br. complex m). CMR δ ($CDCl_3$): 221.0 (C), 60.4 (CH), 49.2 (CH), 46.5 (CH), 44.0 (CH_2), 43.1 (CH_2), 42.2 (CH_2), 41.5 (CH), 39.8 (CH), 30.1 (CH_2). Found: C, 81.39; H, 8.83%. Calcd for $C_{11}H_{14}O$: C, 81.44; H, 8.70%.

Wolff-Kishner Reduction of ***15***. A solution of **15** (12 mg; 0.07 mmol), KOH (68 mg), and 100% $NH_2NH_2 \cdot H_2O$ (0.07 ml) in diethylene glycol (0.5 ml) was stirred at 110 °C for 30 min and subsequently at 180 °C for 3 h. The materials on the condenser was dissolved in pentane and washed with brine, and dried (Na_2SO_4). After filtration, the solvent was evaporated to give **6** (5 mg, 44%), which was shown to be identical with the authentic specimen.[12]

endo-*Tetracyclo*[*5.3.1.*$0^{2,6}$.$0^{3,9}$]*undecan-4-ol* (***16***). The reduction of **15** (23 mg; 0.14 mmol) with $LiAlH_4$ (26 mg; 0.68 mmol) in a similar manner to the above gave **16** (22 mg, 94%): mp 178—180 °C. MS *m/e* (rel intensity): 164 (M^+, 5), 146 (57), 80 (90), 79 (67), 68 (100). IR (KBr): 3300, 2925, 1100, 1050, 1015 cm^{-1}. PMR $\delta(CDCl_3)$: 4.58 (1H, quintet, J=10.5, 6.3, and 4.8 Hz), 2.75—1.20 (br. complex m). CMR $\delta(CDCl_3)$: 76.0 (CH), 55.9 (CH), 50.1 (CH), 49.0 (CH), 43.6 (CH_2), 41.1 (CH), 38.8 (CH), 37.3 (CH), 36.6 (CH_2), 30.8 (CH_2). Found: C, 80.61; H, 10.08%. Calcd for $C_{11}H_{16}O$: C, 80.44; H, 9.83%. The oxidation of **16** (13 mg; 0.08 mmol) with CrO_3 (77 mg; 0.77 mmol)–pyridine (0.38 ml)–CH_2Cl_2 (2 ml) in a similar manner to the above reproduced **15** (12 mg, 93%).

We thank Professor P. von R. Schleyer for a copy of the program Strain and Dr. R. Konaka of Shionogi Phamaceutical Co. Ltd. for obtaining the exact mass spectrum of **5**. Calculations were performed at Hokkaido University Computing Center. This work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Japan (No. 434025).

(Received April 30, 1980)

Oxymercuration of 3,5-dehydronoriceane (**1**) followed by sodium borohydride reduction gives exclusively *endo*-3-noriceanol in 80% yield. The *trans*-1,3-addition organomercury intermediate is isolated as *endo*-3-acetoxy-*exo*-5-(chloromercurio)noriceane. Oxidation of **1** with thallium(III) acetate gives three diacetates, *exo,exo*- and *endo,exo*-3,5-diacetoxynoriceanes [(**9**) and (**10**)] and *endo,exo*-4,5-diacetoxytetracyclo[5.3.1.$0^{2,6}$.$0^{3,9}$]undecane (**11**) in a ratio of 6:61:27 in 68% combined yield. The analogous oxidation of **1** with lead(IV) acetate gives **9**, **10**, and **11** in a ratio of 50:25:25 in 80% combined yield. On the basis of the stereochemistry of the products as well as the products distribution, we propose that 1,3-bridged metal ion intervenes and plays an important role in the oxymetallation reaction of bicyclo[2.1.0]pentane system.

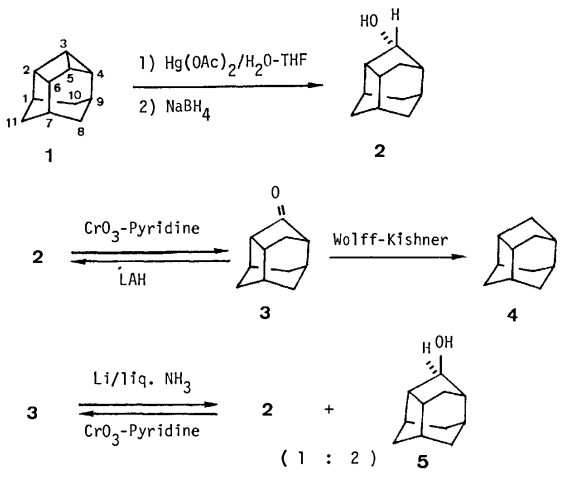
Electrophilic or radical-type cleavage of cyclopropane ring in a cage molecule has proved to become one of the powerful methods of functionalizing a cage compound.[2] Oxidative cleavages of cyclopropane rings by mercury(II), thallium(III), and lead(IV) salts give mono- and difunctionalized compounds *via* oxymetallations. We have recently reported the synthesis of 3,5-dehydronoriceane (**1**),[3] which incorporates bicyclo-[2.1.0]pentane moiety in its cage structure. Since oxidations of highly strained bicyclo[2.1.0]pentane with the metal salts have been reported to rupture the central bond exclusively,[4] we anticipate that **1** can give hitherto unknown 3-mono- and 3,5-difunctionalized noriceanes when allowed to react with the metal salts. In addition to this synthetic possibility, the bicyclo-[2.1.0]pentane system fixed in the cage structure is expected to provide some mechanistic insight which is concerned with the stereochemistry of the initial attack of the metal ion and remains to be explored.[5]

Results

*Oxidation of **1** with Mercury(II) Acetate.* When **1** was treated with mercuric acetate in aqueous THF and subsequently reduced with sodium borohydride, *endo*-3-noriceanol (**2**) was obtained as a sole product in 80% yield. The structure of **2** was determined as follows. Oxidation of **2** with CrO_3–pyridine complex gave a keto compound, 3-noriceanone (**3**), which was reduced to afford noriceane (**4**)[3] by Wolff-Kishner (W-K) method, confirming a parent skeleton of **2**. Whereas reduction of **3** with lithium aluminum hydride reproduced **2**, a treatment of **3** with lithium in liquid ammonia gave **2** and its stereoisomer, *exo*-3-noriceanol (**5**) in 85% combined yield (**2**:**5**=1:2 by ^{1}H-NMR (PMR) analysis). Although the separation of **5** from **2** was unsuccessful, the regeneration of **3** in the oxidation of the mixture indicated that **5** and **2** were stereoisomeric with each other in reference to the 3-position.[6] An inspection of molecular model (Dreiding) suggests us that *exo*-H on the 3-position should couple more with the adjacent protons in PMR spectroscopy than the *endo*-one does. Since the PMR spectra of **2** and **5** show a broad singlet with half-width of 8.0 Hz at 3.90 ppm and a singlet with half-width of 3.4 Hz at 4.30 ppm, respectively, we conclude that **2** is *endo*-3-noriceanol and that **5** is the *exo*-isomer.

In addition to the above elucidation, we inspected the PMR spectra of **2** and 3-noriceanol-5-*d* (**6**), which was prepared by the oxymercuration of **1** followed by the reduction with sodium borodeuteride, by using NMR shift reagent [Eu(dpm)$_3$]. As is shown in Fig. 1, the results of PMR shift experiment for **2** are compatible with the assigned structure of **2**. Figure 2 shows partial PMR spectra of **2** and **6** in the presence of Eu(dpm)$_3$. The signal shown as a doublet of doublet (J=5.5 and 12.0 Hz) at *ca.* 6.6 ppm (*viz.* H_{5X}) in Fig. 2a disappears in Fig. 2b and the signal shown as a doublet (J=12.0 Hz) at *ca.* 5.9 ppm (*viz.* H_{5N}) in Fig. 2a appears as a singlet in Fig. 2b. Since Fig. 1 indicates that the slope for H_{5X} is slightly steeper than that for H_{5N}, H_{5X}, and H_{5N} must be *exo*- and *endo*-protons, respectively. These results imply that deuterium is exclusively located on the *exo*-5-position and, therefore, **6** is determined to be *endo*-3-hydroxy-*exo*-5-deuteronoriceane.

In order to gain further insight about the stereochemistry of the oxymercuration of the bicyclo[2.1.0]-



Scheme 1.

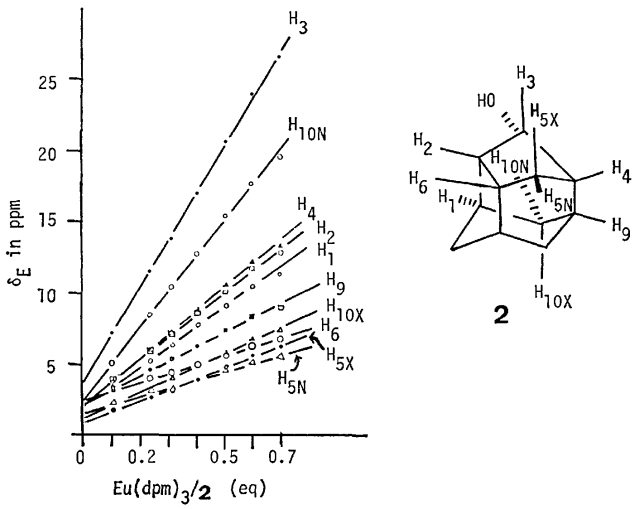


Fig. 1. Variation of chemical shift, δ_E, with molar ratio $Eu(dpm)_3$/**2**.

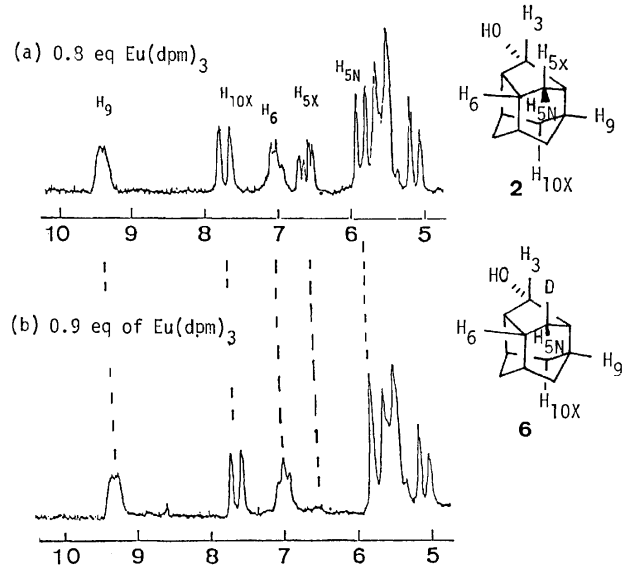

Fig. 2. Partial PMR spectra of **2** and **6** in the presence of $Eu(dpm)_3$; a for **2**, b for **6**.

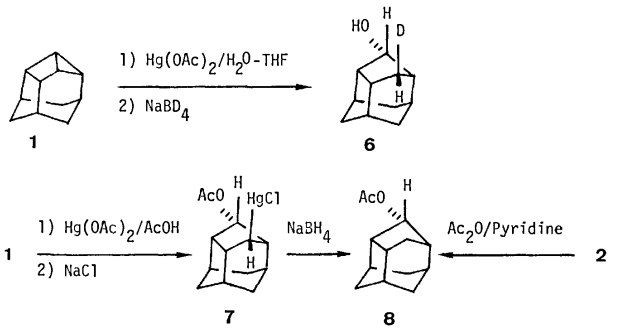
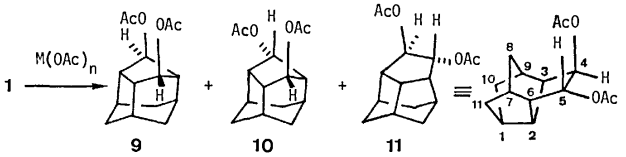
pentane system, a organomercury intermediate was intentionally isolated and examined. A reaction of **1** with mercury(II) acetate in glacial acetic acid followed by an addition of sodium chloride gave an organomercury compound (**7**) in 95% yield. The compound, **7**, was reduced with sodium borohydride to give *endo*-3-acetoxynoriceane (**8**), which was also obtained by acetylation of the alcohol, **2**. A similar PMR shift experiments with **7** and **8** to the above led to the conclusion that **7** is *endo*-3-acetoxy-*exo*-5-(chloromercurio)noriceane (Scheme 2); this implies that the oxymercuration must proceed in a *trans*-fashion.

Oxidations of **1** *with Thallium(III) and Lead(IV) Acetates.* When **1** was oxidized with thallium(III) acetate in glacial acetic acid at room temperature for 4 h, three diacetates, *exo,exo*-3,5- and *endo,exo*-3,5-diacetoxynoriceanes (**9** and **10**) and *endo,exo*-4,5-diacetoxytetracyclo-[5.3.1.$0^{2,6}$.$0^{4,9}$]undecane (**11**), were obtained along with a small amount of an unidentified product (**12**) (**9**:**10**:



Scheme 2.



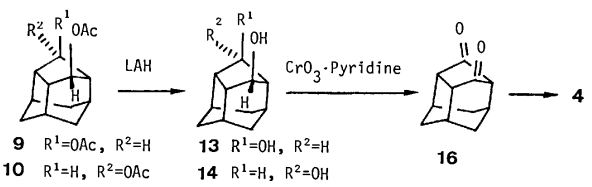
$Tl(OAc)_3$;	6	:	61	: 27
$Pb(OAc)_4$;	50	:	25	: 25

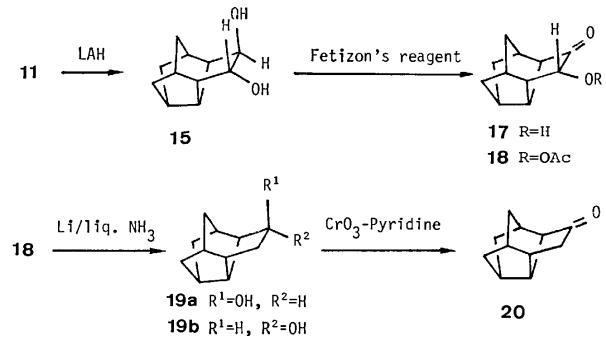
Scheme 3.

11:**12**=6:61:27:6, estimated from the area ratio in GLC analysis) in 68% combined yield. A similar oxidation of **1** with lead(IV) acetate at room temperature for 24 h gave the same three products, **9**, **10**, and **11** (**9**:**10**:**11**=50:25:25 by GLC analysis) in 80% combined yield.

The structures of **9** and **10** were determined as follows. The diacetates, **9** and **10**, were separated by preparative GLC and reduced to the corresponding diols (**13** and **14**) with lithium aluminum hydride, respectively. Oxidations of **13** and **14** with CrO_3–pyridine complex gave one kind of diketone, 3,5-noriceanedione (**16**), which afforded noriceane (**4**) on base-catalyzed reduction of the semicarbazone of **16**. Accordingly, it is evident that **9** and **10** are stereoisomeric 3,5-diacetoxynoriceanes. Out of three possible isomers, *endo,endo*-3,5- and *exo,exo*-3,5-isomers have a plane of symmetry, whereas *endo,exo*-one does not. Since ^{13}C-NMR (CMR) and PMR spectra of **10** showed a lack of the symmetry, **10** was determined to be *endo, exo*-3,5-diacetoxynoriceane. On the other hand, CMR spectrum of **9** indicated the presence of symmetry and its PMR spectrum showed a singlet with a half-width of 2.7 Hz at 5.17 ppm, indicating the *exo*-configuration of the substituents at 3- and 5-positions (*vide supra*). Thus, **9** was determined to be *exo,exo*-3,5-diacetoxynoriceane.

The structure of **11** was determined by the following chemical transformations. Reduction of **11** followed by oxidation with Fetizon's reagent[7] gave *exo*-5-hydroxytetracyclo[5.3.1.$0^{2,6}$.$0^{3,9}$]undecan-4-one (**17**).[8] Acetylation of **17** with acetic anhydride in pyridine gave *exo*-5-acetoxytetracyclo[5.3.1.$0^{2,6}$.$0^{3,9}$]undecan-4-one (**18**). Reductive cleavage of **18** with lithium in liquid ammonia gave a mixture of stereoisomeric tetracyclo[5.3.1.$0^{2,6}$.$0^{3,9}$]undecan-4-ols (**19a** and **19b**).[6] Subsequent oxidation of the mixture gave tetracyclo-[5.3.1.$0^{2,6}$.$0^{3,9}$]undecan-4-one (**20**).[6] As the PMR and





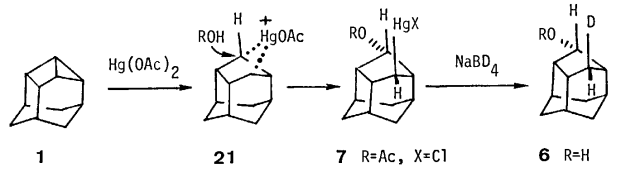
Scheme 4.

CMR spectra of **11** showed a lack of a plane of symmetry, **11** was determined to be *endo,exo*-4,5-diacetoxytetracyclo[5.3.1.$0^{2,6}$.$0^{3,9}$]undecane.

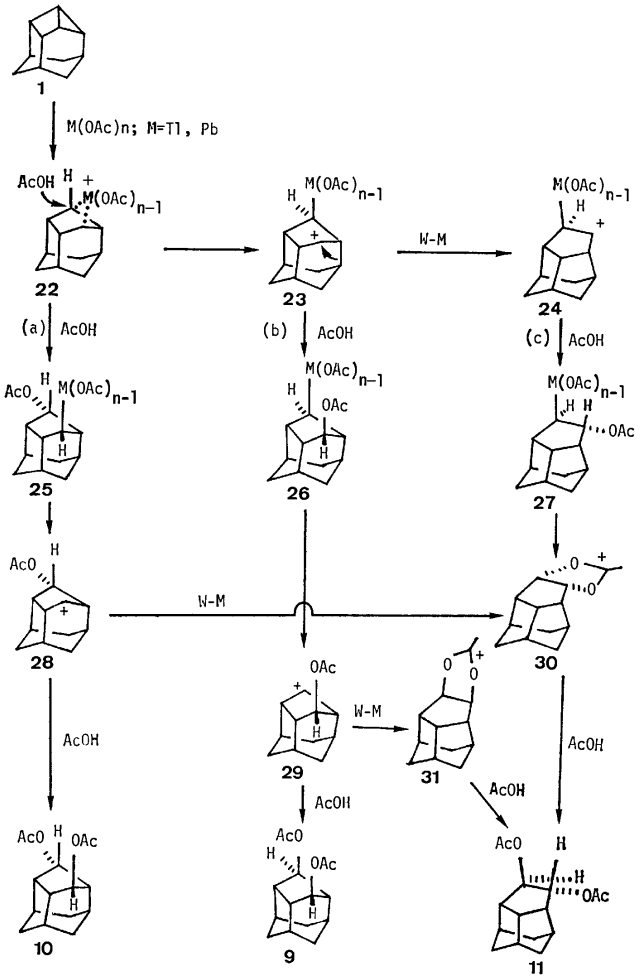
Discussion

The structures of **6** as well as **7** allow us to delineate the following scheme as a possible reaction pathway (Scheme 5). An initial electrophilic attack on the bicyclo[2.1.0]pentane system by mercury(II) ion must take place from the front side of the central bond with retention of configuration to produce the 1,3-bridged acetoxymercurium ion (**21**).[9] This is subsequently captured by nucleophilic solvent with complete inversion of configuration. By taking account of the fact that solvolyses of 3-noricyl tosylates give nothing but *exo*-3-noricyl acetate and a considerable amount of the rearranged products,[6] we can safely conclude that the 1,3-bridged ion (**21**) intervenes significantly in the oxymercuration reaction of bicyclo-[2.1.0]pentane system. Although Levina *et al.* reported that the oxymercuration of bicyclo[2.1.0]pentane itself gave 3-hydroxycyclopentylmercury(II) acetate,[4b] the stereochemistry of the product was not studied. We believe that the present result is the first example which clarifies a stereochemical course and provides a strong evidence for an intervention of an 1,3-bridged mercurium ion in oxymercuration reaction of bicyclo-[2.1.0]pentane system. In addition, it is noteworthy that reduction of the organomercury compound with sodium borohydride proceeds with retention of configuration.

In the cases of oxidations with thallium(III) and lead(IV) acetates, the reaction pathways are more speculative than the above because an isolation of the corresponding organometallic intermediates has been impossible and, accordingly, their decomposition modes are unknown. Judging from the fact that the reactions lack the stereoselectivity and that some amount of the rearranged product, **11**, is obtained, it is highly



Scheme 5.



Scheme 6.

probable that a free carbocation character is involved in the reactions. The following rather simple scheme (Scheme 6) may reasonably explain the results. The initial attack on the bicyclo[2.1.0]pentane system by the metal ion would take place from the front-side to produce the 1,3-bridged metal ion (**22**) analogous to **21** in the case of the oxymercuration. Nucleophilic capture of **22** with the solvent gives an *endo*-acetoxyorganometallic intermediate (**25**), which, on decomposition, could produce a "free" carbocation intermediate (**28**). The *endo,exo*-diacetates (**10**) is the expected product in nucleophilic capture of **28** with the solvent, because, as described before, 3-noricyl cation formed in the solvolysis is attacked by nucleophile exclusively from the *exo*-side[6] (path a in Scheme 6).

When the 1,3-bridged metal ion (**22**) is so unstable as to convert into a "free" carbocation (**23**), an *exo*-acetoxyorganometallic intermediate (**26**) may be formed by the same reason as described above. Subsequent

decomposition and nucleophilic capture could afford the *exo,exo*-diacetate (**9**) (path b in Scheme 6). The "free" carbocation (**23**) is also possibly subjected to Wagner-Meerwein rearrangement into tetracyclo[5.3.1.$0^{2,6}$.$0^{3,9}$]undecane system (**24**), which could give the *trans*-diacetate (**11**) *via* 1,2-acetoxyl-participation (path c). The diacetate (**11**) could be also formed from **28** as well as **29** through the pathways shown in the Scheme.

Thus, it can be safely said that the amount of the *endo,exo*-diacetate (**10**) depends on the stability of the 1,3-bridged metal ion (**22**). The fact that the yield of **10** is higher with thallium(III) acetate than with lead(IV) acetate implies that **22** (M=Tl) is more stable than **22** (M=Pb). In addition, it is evident that **22** (M=Hg, namely **21**) is much more stable than the both (**22**, M=Tl and Pb). This order of stability of the 1,3-bridged metal ions (Hg>Tl>Pb) is consistent with the order of the stability of C–M bonds (Hg>Tl>Pb).[10]

In conclusion, it has been found that oxymetallations of 3,5-dehydronoriceane (**1**) with mercury(II), thallium(III), and lead(IV) acetates give 3-mono- and 3,5-difunctionalized noriceanes in good yields along with a small amount of *trans*-4,5-difunctionalized tetracyclo[5.3.1.$0^{2,6}$.$0^{3,9}$]undecane. The present results also provide the first evidence for an intervention of an 1,3-bridged metal ion in oxymetallation reaction of bicyclo[2.1.0]pentane system.

Experimental

All the temperatures were uncorrected. The melting points were measured in sealed capillaries. The IR spectra were obtained on a Shimadzu IR-27 spectrometer. The mass spectra were taken by using a Hitachi RMS-4 mass spectrometer. The PMR and CMR spectra were obtained on Varian EM-390 and CFT-20 spectrometers, TMS being chosen as the internal standard. The microanalyses were performed by Kyoto University Elemental Analysis Center.

endo-*Tetracyclo*[*5.3.1.*$0^{2,6}$.$0^{4,9}$]*undecan-3-ol* (*2*). To a solution of $Hg(OAc)_2$ (478 mg; 1.5 mmol) in THF (3 ml) and water (3 ml) was added pentacyclo[5.3.1.$0^{2,6}$.$0^{3,5}$.$0^{4,9}$]-undecane (**1**) (219 mg; 1.5 mmol) and the mixture was stirred for 1 h at room temperature. Then, 3 M aqueous NaOH (3 ml) and subsequently 3 ml of a solution of 0.5 M $NaBH_4$ in 3 M aqueous NaOH were added and the mixture was stirred for additional 1 h. After the precipitated mercury was removed by filtration, organic materials were extracted with CH_2Cl_2, washed with brine, and dried (Na_2SO_4). After filtration, the solvent was evaporated and the residue was chromatographed on silica gel. Elution by hexane and ether (1:1) gave **2** (198 mg, 80%): mp 270 °C. MS *m/e* (rel intensity): 164 (M^+, 70), 146 (45), 135 (51), 92 (50), 91 (46), 80 (99), 79 (95), 68 (100). IR (KBr): 3200, 2930, 1465, 1300, 1290, 1160, 1090, 1055 cm^{-1}. PMR δ ($CDCl_3$): 3.90 (1H, br. s, $W_{1/2}$=8.0 Hz), 2.67—0.80 (15H, br, complex m). CMR δ ($CDCl_3$): 76.9 (CH), 44.8 (CH), 42.1 (CH), 41.4 (CH_2), 38.5 (CH), 38.4 (CH), 36.7 (CH), 31.9 (CH_2), 31.4 (CH_2), 30.7 (CH), 24.4 (CH_2). Found: C, 80.51; H, 9.89%. Calcd for $C_{11}H_{16}O$: C, 80.44; H, 9.83%.

Tetracyclo[*5.3.1.*$0^{2,6}$.$0^{4,9}$]*undecan-3-one* (*3*). To a solution of pyridine (5 ml) in CH_2Cl_2 (25 ml) was added gradually CrO_3 (730 mg; 7.3 mmol) and then a solution of **2** (195 mg; 1.2 mmol) in CH_2Cl_2 (20 ml). The reaction mixture was stirred for 1 h at room temperature and washed with 5% aqueous NaOH, 5% aqueous HCl, and brine, and dried (Na_2SO_4). After filtration, the solvent was evaporated and the residue was chromatographed on silica gel. Elution by hexane and ether (3:1) afforded **3** (183 mg, 95%): mp 259—261 °C. MS *m/e* (rel intensity): 162 (M^+, 98), 134 (92), 92 (99), 79 (100). IR (Nujol): 2925, 1750, 1460, 1370 cm^{-1}. PMR δ ($CDCl_3$): 2.95—1.10 (14H, br. complex m). CMR δ ($CDCl_3$): 221.7 (C=O), 51.5 (CH), 45.7 (CH), 43.5 (CH), 41.8 (CH_2), 41.4 (CH), 38.6 (CH), 34.0 (CH), 32.3 (CH_2), 30.2 (CH_2), 21.6 (CH_2). Found: C, 81.31; H, 8.69%. Calcd for $C_{11}H_{14}O$: C, 81.44; H, 8.70%.

Wolff-Kishner Reduction of ***3*** *to Tetracyclo*[*5.3.1.*$0^{2,6}$.$0^{4,9}$]-*undecane* (*4*). A solution of **3** (120 mg; 0.74 mmol), KOH (600 mg; 10.7 mmol), 100% $NH_2NH_2 \cdot H_2O$ (470 mg; 9.4 mmol) in diethylene glycol (3 ml) was stirred at 110 °C for 30 min and then at 180 °C for 3 h. Sublimate on the condenser was dissolved in hexane and washed with brine, and dried (Na_2SO_4). After filtration, the solvent was evaporated to give almost pure **4** (96 mg, 88%), which was identical with the authentic specimen[3] in all respects (GLC retention time, mass, PMR, and CMR spectra).

Reduction of ***3***. (*a*): To a suspension of $LiAlH_4$ (146 mg; 3.8 mmol) in dry ether (5 ml) was added dropwise a solution of **3** (125 mg; 0.77 mmol) in dry ether (5 ml). The reaction mixture was stirred at room temperature for 30 min and then quenched with sat aqueous Na_2SO_4. The organic layer was separated, washed with brine, and dried (Na_2SO_4). After filtration, the solvent was evaporated to give **2** (118 mg, 97%) as a sole product (PMR analysis). (*b*): A solution of **3** (230 mg; 1.4 mmol) in dry ether (10 ml) was added to dry liq ammonia (50 ml) at −78 °C. To this mixture were added NH_4Cl (6.15 g; 115 mmol) and then Li (559 mg; 80 mmol) in small pieces over 30 min. The reaction mixture was refluxed until the blue color disappeared. The ammonia was evaporated and water (50 ml) was added. The aqueous solution was acidified with 5% aqueous HCl and extracted with ether. The ethereal solution was washed with sat aqueous $NaHCO_3$ and brine, and dried (Na_2SO_4). After filtration, the solvent was evaporated and the residue was chromatographed on silica gel. Elution by hexane and ether (1:1) gave a mixture of **2** and *exo*-tetracyclo[5.3.1.$0^{2,6}$.$0^{4,9}$]undecan-3-ol (**5**) (197 mg, 85%). Although **5** could not be separated from **2** by either column chromatography or GLC, a comparison of the PMR spectrum of the mixture with that of pure **5**[6] indicated that a ratio of **2** to **5** was 1:2. Furthermore, the mixture (39 mg; 0.24 mmol) was oxidized with CrO_3 (204 mg; 2.0 mmol) and pyridine (0.8 ml) in CH_2Cl_2 (5 ml) reproduced **3** (32 mg, 83%).

endo-*3-Hydroxy*-exo-*5-deuterotetracyclo*[*5.3.1.*$0^{2,6}$.$0^{4,9}$]*undecane* (*6*). A similar oxymercuration reaction of **1** (292 mg; 2.0 mmol) to the above followed by reduction with $NaBD_4$ gave **6** (200 mg, 61%). The extent of monodeuteration was shown to be 90% by mass spectroscopic analysis. ***6***: Mp >270 °C. MS *m/e* (rel intensity): 165 (M^+, 76), 147 (32), 136 (40), 93 (44), 92 (50), 80 (100), 79 (82), 69 (82). IR (KBr): 3320, 2940, 1485, 1385, 1295, 1160, 1095, 1055 cm^{-1}. PMR δ ($CDCl_3$): 3.88 (1H, br. s, $W_{1/2}$=7.8 Hz), 2.70—1.20 (12H, br. complex m), 1.03 (2H, d, J=12.0 Hz). CMR δ ($CDCl_3$): 76.9 (CH), 44.7 (CH), 42.0 (CH), 41.4 (CH_2), 38.4 (2CH), 36.7 (CH), 31.9 (CH_2), 31.4 (CH_2), 30.6 (CH), 25.0, 24.0, 23.0 (CHD). Found: C, 79.93; H(D), 10.53%. Calcd for $C_{11}H_{15}DC$: C, 79.95; H(D), 10.37%.

endo-*3-Acetoxy*-exo-*5-(chloromercurio)tetracyclo*[*5.3.1.*$0^{2,6}$.$0^{4,9}$]-*undecane* (*7*). A solution of $Hg(OAc)_2$ (118 mg; 0.37

mmol) and **1** (50 mg; 0.34 mmol) in glacial AcOH (1 ml) was stirred at room temperature for 1 h. To the mixture was added a solution of NaCl (242 mg; 4.1 mmol) in ice-water (10 ml). After 20 min, white precipitates were collected by filtration and washed with water, and dried over P_2O_5 at reduced pressure to give **7** (144 mg, 95%): mp 183—186 °C. IR (KBr): 2925, 1735, 1370, 1455, 1065 cm^{-1}. PMR δ ($CDCl_3$): 4.58 (1H, dd, J=5.5 and 2.5 Hz), 2.08 (3H, s), 3.00—0.85 (13H, br. complex m). Found: C, 35.65; H, 4.15%. Calcd for $C_{13}H_{17}ClHgO_2$: C, 35.38; H, 3.88%.

endo-*3-Acetoxytetracyclo*[*5.3.1.0*^{2,6}*.0*^{4,9}]*undecane* (***8***).

(a): A solution of **2** (51 mg; 0.31 mmol) in pyridine (0.5 ml) and acetic anhydride (0.25 ml) was kept at room temperature overnight. The mixture was poured onto 5% aqueous HCl and extracted with CH_2Cl_2. The organic layer was washed with aqueous Na_2CO_3 and brine, and dried (Na_2SO_4). After filtration, the solvent was evaporated and the residue was chromatographed on silica gel. Elution by hexane and CH_2Cl_2 (4:1) afforded **8** (59 mg, 91%): bp 90 °C (bath temp)/1995 Pa. MS *m/e* (rel intensity): 206 (M^+, 7), 146 (100). IR (neat): 2930, 1745, 1365, 1245, 1070, 1055 cm^{-1}. PMR δ (CCl_4): 4.55 (1H, br. s), 2.00 (3H, s), 2.70—0.85 (14H, br. complex m). CMR δ ($CDCl_3$): 170.9 (C=O), 78.2 (CH), 42.7 (CH), 41.7 (CH), 41.3 (CH_2), 38.4 (CH), 36.8 (CH), 36.3(CH), 31.6 (CH_2), 31.5 (CH_2), 30.6 (CH), 23.9 (CH_2), 21.5 (CH_3). Found: C, 75.74; H, 8.86%. Calcd for $C_{13}H_{18}O_2$: C, 75.69; H, 8.80%.

(b): To a solution of **7** (42 mg; 0.10 mmol) in THF (2 ml) was added a solution of $NaBH_4$ (23 mg; 0.61 mmol) in 3 mol dm^{-3} aqueous NaOH (1 ml) and the mixture was stirred at room temperature. After 1 h, CH_2Cl_2 was added to the mixture and the mercury was removed by filtration. The organic solution was washed with brine and dried (Na_2SO_4). After filtration, the solvent was evaporated and the residue was chromatographed on silica gel. Elution by hexane and CH_2Cl_2 (4:1) gave **8** (10 mg, 50%) which was identical with that prepared above.

Oxidation of ***1*** *with Thallium(III) Acetate.* A solution of **1** (147 mg; 1.0 mmol) and $Tl(OAc)_3$ (572 mg, 1.5 mmol) in glacial AcOH (10 ml) was stirred at room temperature for 4 h under argon. Then, CH_2Cl_2 and water was added to the mixture. After filtration, the organic layer was washed with brine and aqueous $NaHCO_3$, and dried (Na_2SO_4). After filtration, the solvent was evaporated and the residue was chromatographed on silica gel. Elution by hexane and CH_2Cl_2 (7:3) gave a mixture of the three diacetates (**9**, **10**, and **11**) along with a small amount of an unidentified product (**12**) (181 mg, 68%). A ratio of **9**, **10**, **11**, and **12** was estimated to be 6:61:27:6 (GLC analysis, AP 180 °C). Each of **9**, **10**, and **11** was isolated by preparative GLC. *exo,exo*-3,5-Diacetoxytetracyclo[5.3.1.0^{2,6}.0^{4,9}]undecane (**9**): mp 77—79 °C. Calcd for $C_{11}H_{16}O_2$: C, 73.30; H, 8.95%.

Tetracyclo[*5.3.1.0*^{2,6}*.0*^{4,9}]*undecane-3,5-dione* (***16***). Oxida-

tion of **13** (134 mg; 0.74 mmol) with CrO_3 (1350 mg; 13.5 mmol)-pyridine complex in a similar manner to the above gave **16** (80 mg, 61%): mp 184—187 °C. MS *m/e* (rel intensity): 176 (M^+, 93), 166 (66), 79 (50), 66 (100). IR (KBr): 2935, 1770, 1735, 1215, 1145, 1080 cm^{-1}. PMR δ (CCl_4): 3.30—2.50 (6H, br. complex m), 2.20—1.50 (6H, br. complex m). CMR δ ($CDCl_3$): 210.3 (C=O), 63.5 (CH), 59.9 (CH), 46.9 (CH), 44.7 (CH), 42.6 (CH_2), 33.0 (CH_2). Found: C, 74.71; H, 7.12%. Calcd for $C_{11}H_{12}O_2$: C, 74.97; H, 6.86%. A similar oxidation of **14** (52 mg; 0.29 mmol) with CrO_3 (515 mg; 5.2 mmol)-pyridine complex also afforded **16** (43 mg, 85%).

*Reduction of **16** to **4**.* Semicarbazide hydrochloride (300 mg; 2.7 mmol) and KOAc (300 mg; 3.1 mmol) were dissolved in a mixture of water (1 ml) and methanol (3 ml), and undissolved materials were removed by filtration. The diketone (**16**) (52.8 mg; 0.30 mmol) was dissolved in the above solution (1 ml) and kept at room temperature for one week. The precipitates (61 mg) were collected by filtration and dissolved in diethylene glycol (2 ml) containing KOH (153 mg; 2.7 mmol). The mixture was heated at 110 °C for 1 h and subsequently at 180 °C for 20 h. Sublimate on the condenser was dissolved in pentane and washed with brine, and dried (Na_2SO_4). After filtration, the solvent was evaporated and the residue was chrmatographed on silica gel. Elution by pentane gave **4** (4 mg, 9%) as a sole product, which was identical with authentic specimen.[3]

exo-*5-Hydroxytetracyclo[5.3.1.0^{2,6}.0^{3,9}]undecan-4-one (**17**).* A suspension of **15** (37 mg; 0.21 mmol) and Fetizon's reagent (1.2 g)[7] in dry benzene (50 ml) was stirred under reflux for 1 d. After filtration, the solvent was evaporated to give **17** (31 mg, 85%): mp 141—143 °C. MS *m/e* (rel intensity): 178 (M^+, 100), 150 (32), 79 (42). IR (KBr): 3375, 2930, 2880,1735, 1175, 1035 cm^{-1}. PMR δ ($CDCl_3$): 4.03 (1H, s), 3.30—1.15 (13H, br. complex m). CMR δ ($CDCl_3$): 221.5 (C=O), 75.5 (CH), 60.3 (CH), 53.6 (CH), 47.2 (CH), 44.2 (CH_2), 43.0 (CH_2), 42.2 (CH), 39.7 (CH), 39.3 (CH), 31.0 (CH_2). Found: C, 74.28; H, 8.08%. Calcd for $C_{11}H_{14}O_2$: C, 74.13; H, 7.92%.

exo-*5-Acetoxytetracyclo[5.3.1.0^{2,6}.0^{3,9}]undecan-4-one (**18**).* A solution of **17** (31 mg; 0.17 mmol) and acetic anhydride (0.2 ml) in pyridine (0.4 ml) was kept at room temperature overnight and poured onto 5% aqueous HCl. The mixture was extracted with CH_2Cl_2 and washed with aqueous Na_2CO_3 and brine, and dried (Na_2SO_4). After filtration, the solvent was evaporated to give **18** (33 mg, 73%): bp 90—100 °C (bath temp)/133 Pa. MS *m/e* (rel intensity): 220 (M^+, 13), 178 (100), 160 (20), 91 (14). IR (neat): 2930, 2880, 1745, 1370, 1225, 1175, 1035 cm^{-1}. PMR δ (CCl_4): 4.48 (1H, s), 2.07 (3H, s), 3.20—1.15 (12H, br. complexm). CMR δ ($CDCl_3$): 216.5 (C=O), 169.9 (C=O), 76.5 (CH), 60.9 (CH), 52.2 (CH), 47.3 (CH), 44.1 (CH_2), 42.8 (CH_2), 42.1 (CH), 39.7 (CH), 39.5 (CH), 30.8 (CH_2), 20.8 (CH_3). Found: C, 71.04; H, 7.28%. Calcd for $C_{13}H_{16}O_2$: C, 70.89; H, 7.32%.

*Chemical Transformation of **18** to Tetracyclo[5.3.1.0^{2,6}.0^{3,9}]undecan-4-one (**20**).* To liquid ammonia (10 ml) was added at −78 °C a solution of **18** (33 mg; 0.15 mmol) in dry ethyl ether (3 ml) and subsequently small pieces of lithium (112 mg; 16 mmol). The mixture was refluxed for 5 h and ammonia was evaporated. After an addition of water, the mixture was extracted with ether, washed with brine, and dried (Na_2SO_4). After filtration, the solvent was evaporated to give a mixture of tetracyclo[5.3.1.0^{2,6}.0^{3,9}]-undecan-4-ols (**19a** and **19b**, *ca.* 1:1 by PMR analysis, 20 mg, 81%),[6] which, on oxidation with CrO_3–pyridine complex, afforded **20** as a sole product (13 mg, 63%). The ketone (**20**) was identical with that prepared by the different route.[6]

This work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Japan (No. 434025).

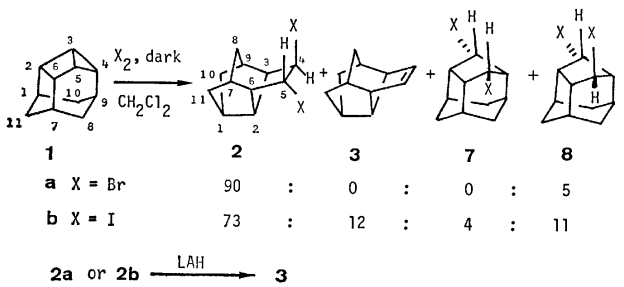
(Received April 30, 1980)

Halogenations of 3,5-dehydronoriceane (**1**) in dichloromethane in the dark exclusively or predominantly give *endo,exo*-4,5-dihalotetracyclo[5.3.1.$0^{2,6}$.$0^{3,9}$]undecanes; these results provide a decisive evidence for the front side attack on the bicyclo[2.1.0]pentane system by halonium ion. On the other hand, the corner side attack on the bicyclo[2.1.0]pentane system by halogen radicals takes place in photohalogenations of **1**, which give *endo,endo*- and *endo,exo*-3,5-dihalonoriceanes. In addition, the halogenation of **1** in the dark is found to be sensitive to the solvent polarity and the ionic nature of the halogen used. Bromination of **1** in nonpolar solvents in the dark likely proceeds through intervention of the 1,3-bridged bromonium ion.

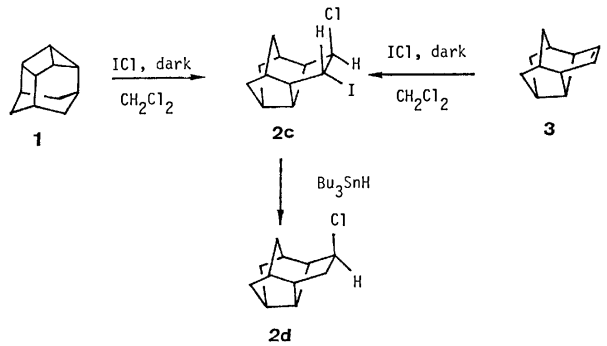
In 1965 LaLond[3] reported that halogenation of bicyclo[2.1.0]pentane gave predominantly *trans*-1,2-dihalocyclopentane. On the basis of the results, he postulated the mechanism that consisted of conversion of an initially formed 1,3-bridged halonium ion into 1,2-bridged one *via* 1,2-hydride migration. To our knowledge, there has been no further report on the mechanism of halogenation of bicyclo[2.1.0]pentane system. Either the validity of the above mechanism or mechanistic details including the stereochemical fate of the halogen (*i.e.*, whether front side attack with retention of configuration or corner side attack with inversion of configuration) remains unexplored.[4] We have recently reported the synthesis of 3,5-dehydronoriceane (**1**)[5] and expect that **1** is a likely model compound for solving the above problems to some extent, because **1** has the partial bicyclo[2.1.0]pentane structure constrained within a rigid cage structure. We now wish to desribe here our results on the stereochemical aspects of the halogenation reaction of bicylo-[2.1.0]pentane system as well as the susceptibility of the reaction to the solvent and the halogen used.[6]

Results and Discussion

*Halogenation of **1** in the Dark.* When **1** was treated with bromine in dichloromethane at −78 °C in the dark, *endo,exo*-4,5-dibromotetracylo[5.3.1.$0^{2,6}$.$0^{3,9}$]undecane (**2a**) was obtained predominantly along with a small amount of *endo,exo*-3,5-dibromonoriceane (**8a**) (*vide infra*) and an unidentified compound (**2a**:**8a**=90:5).[7,8] The structure of **2a** was determined by elemental analysis, spectroscopic data ^{1}H-NMR (PMR) and ^{13}C-NMR (CMR) which showed a lack of a plane of symmetry, and the debromination to tetracyclo-[5.3.1.$0^{2,6}$.$0^{3,9}$]undec-4-ene (**3**)[9] with lithium aluminium hydride. A similar treatment of **1** with iodine gave predominantly *endo,exo*-4,5-diiodotetracyclo[5.3.1.$0^{2,6}$.-$0^{3,9}$]undecane(**2b**), along with **3** and *endo,endo*- and *endo,exo*-3,5-diiodonoriceanes (**7b** and **8b**, *vide infra*) (**2b**:**3**:**7b**:**8b**=73:12:4:11). Although **2b** has never been isolated in a pure form because of its rapid decomposition to the olefin (**3**), the structure of **2b** has been elucidated by a resemblance between the PMR spectra of **2a** and **2b** as well as the chemical trans-formation to **3**.



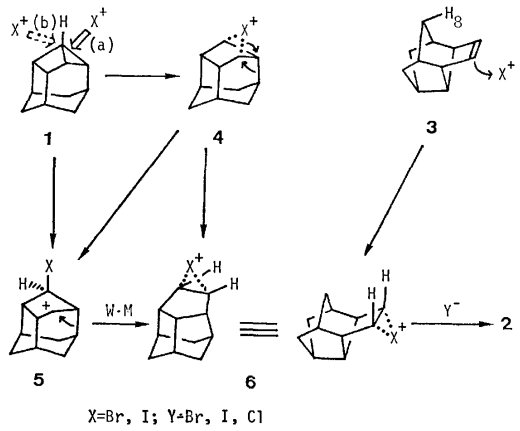
Scheme 1.



Scheme 2.

In order to investigate the stereochemistry of these halogenations, the reaction of **1** was effected with iodine chloride, the attacking species of which was the iodonium ion, under a similar conditions to the above. This gave exclusively *endo*-4-chloro-*exo*-5-iodotetracyclo-[5.3.1.$0^{2,6}$.$0^{3,9}$]undecane (**2c**) in 78% yield. The configurations of halogens in **2c** were determined as follows. (i) As the coupling patterns of H_4 and H_5 in the PMR spectrum resemble those of **2a** and **2b**, the stereochemistry of the halogens should be trans. (ii) The selective reduction **2c** with Bu_3SnH gave 4-chlorotetracyclo[5.3.1.$0^{2,6}$.$0^{3,9}$]undecane (**2d**), the PMR spectrum of which showed a quintet at 4.55 ppm due to H_4. Since PMR spectra of *exo*- and *endo*-4-tetracyclo-[5.3.1.$0^{2,6}$.$0^{3,9}$]undecanols have shown a doublet of doublet at 4.33 ppm and a quintet at 4.58 ppm, respectively, due to H_4,[10] the configuration of the chlorine substituent in **2d** is determined to be *endo*. (iii) Furthermore, the reaction of **3** with iodine chloride afforded the same chloro iodo compound (**2c**).

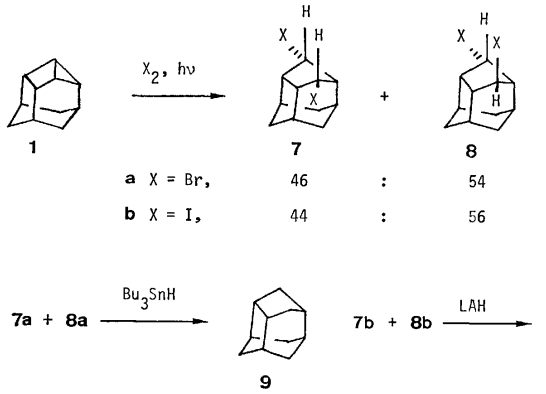
Scheme 3 can best explain the above results. The



Scheme 3.

initial attack on the bicyclo[2.1.0]pentane group by halonium ion (X^+) must take place from the front side (a) with retention of configuration, but not from the corner side (b) with inversion of configuration. The resulting carbocation intermediate (**5**) may undergo Wagner-Meerwein (W-M) rearrangement to give an 1,2-bridged halonium ion (**6**). It would be also possible that **6** is produced through an 1,3-bridged halonium ion (**4**), as is shown in Scheme 3. A nucleophile (Y^-) captures **6** to afford the *trans*-dihalides (**2**). The same 1,2-bridged halonium ion (**6**, X=I) is also generated from the olefin (**3**) because of the steric hindrance due to H_8. Thus, it has been established that halonium ions may participate with the central bond of the bicyclo[2.1.0]pentane system in an edge fashion and we believe that this is the first decisive experimental evidence for front side attack on the bicyclo[2.1.0]pentane system by halonium ions.

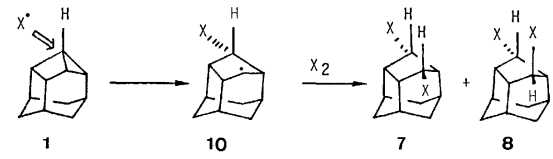
Photohalogenation of ***1***. While halogenations of **1** in dichloromethane in the dark give predominantly or exclusively the rearranged products (**2**), a small amount of unrearranged 1,3-addition products (**7** and **8**) is also produced, especially in the iodination. We, therefore, have investigated photohalogenations of **1**, because it has been known that photohalogenations of cyclopropanes take place in a radical fashion to give 1,3-dihalides.[11] When **1** was allowed to react with bromine in carbon tetrachloride under the irradiation through soft glass filter by means of 300 W medium-pressure mercury arc, *endo,endo*- and *endo,exo*-3,5-dibromonoriceanes (**7a** and **8a**) were obtained in 72% combined yield (**7a**:**8a**=46:54). Similarly, a photoiodination of **1** under the daylight[12] gave *endo,endo*- and *endo,exo*-3,5-diiodonoriceans (**7b** and **8b**) in 96% combined yield (**7b**:**8b**=44:56).



Scheme 4.

The structures of **7** and **8** were determined as follows. Reduction of the mixture of **7a** and **8a** with Bu_3SnH gave noriceane (**9**)[5] and deiodination of **7b** and **8b** with lithium aluminium hydride reproduced **1**. Since **8a** and **8b** have been shown to have to symmetry by NMR analyses, these must be *endo,exo*-3,5-dihalonoriceanes. The PMR spectra of **7a** and **7b** showed only one kind of a broad singlet with half-width of 8.5 Hz due to H_3 and H_5. In noriceane system, the *exo*-H_3 (or H_5) appears as a broad singlet with half-width of *ca.* 8.5 Hz and *endo*-one does as a sharp singlet with half-width of *ca.* 3 Hz.[13] Consequently, **7a** and **7b** were determined to be *endo,endo*-3,5-dihalonoriceanes.

Thus, it has been found that photohalogenations of **1** give *endo,endo*- and *endo,exo*-3,5-dihalonoriceanes in a ratio of *ca.* 1:1. No *exo,exo*-isomer has been detected. These results are compatible with the mechanism which has been suggested for photohalogenations of cyclopropanes.[11] According to the mechanism, the initial attack on the bicyclo[2.1.0]pentane system by halogen radical takes place from the corner side with inversion of configuration to give *endo*-3-halonoricyl radical (**10**). The subsequent non-stereoselective abstraction of a halogen atom from a halogen molecule can give a mixture of an almost equal amount of **7** and **8** (Scheme 5).



Scheme 5.

Solvent Effects on the Halogenation of ***1***. In addition to the new insight mentioned above on the halogenation of **1**, we have found that considerable amount of the unrearranged dihalides (**7** and **8**) are produced even in the dark when the solvent is changed from dichloromethane to carbon tetrachloride (Table 1). As shown in Table 1, the iodination did not give the rearranged product (**2b**) but the unrearranged ones (**7b** and **8b**). In the case of the bromination, both of the rearranged and unrearranged dibromides were formed. Furthermore, it is interest-

Table 1. Halogenation of **1** in CCl_4 in the dark

	Halogens	Yield/%	Products ratio/%[a] 2 : 7 : 8
a	X=Y=Br	77	52 : 1 : 33[b]
b	X=Y=I	59	0 : 42 : 58
c	X=I, Y=Cl	95	100 : 0 : 0

a) Determined by GLC and/or PMR analyses.
b) An identified product was also obtained.

TABLE 2. BROMINATION OF **1** IN VARIOUS SOLVENTS IN THE DARK

Run	Solvent	E_T-value[a]	Temp/°C	Products ratio/%[b,c]			
				2a :	**7a** :	**8a**	**7a/8a**
1	CH_2Cl_2	41.1	−78	91	0	5	0
2			15[d]	90	0	5	0
3	$CHCl_3$	39.1	−78	89	0	6	0
4			15[d]	80	0	12	0
5			61[e]	74	0	22	0
6	Et_2O	34.6	−78	19	30	37	0.81[f]

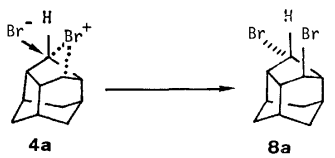
9			15[d]	52	1	33	0.03
10	Cyclohexane	31.2	6[g]	39	14	41	0.34
11			15[d]	51	11	32	0.34

a) Taken from Ref. 14. b) Determined by GLC analysis. c) In all cases except for ether, a small amount of an unidentified product was formed.[8] d) Room temperature. e) Reflux temperature. f) Two unidentified products were formed. g) Freezing point of the solvents.

ing that the iodochlorination gave only the rearranged product (**2c**). These results strongly suggest that the iodination of **1** in carbon tetrachloride proceeds in a radical fashion even in the dark and that the iodochlorination takes place in an ionic fashion regardless of the polarity of the solvent. In addition, attention should be paid to the predominant formation of the *endo,exo*-isomer (**8a**) over the *endo,endo*-one (**7a**) in the bromination; this indicates the possibility of another non-radical reaction pathway. We, therefore, have investigated the solvent effects on bromination of **1** in more detail.

Table 2 summarizes the results. Two major distinctive features should be mentioned as follows. (i) As the polarity (E_T-value)[14] of the solvent decreases, the formation of the unrearranged products (**7a** and **8a**) increases. (ii) More *endo,exo*-isomer (**8a**) is always formed than the *endo,endo*-one (**7a**). Especially in runs of 1—5, 8, and 9, **8a** is exclusively produced over **7a**. This is in a marked contrast to the bromination of bicyclo[3.1.0]hexane in chloroform in the dark which gives *cis*- and *trans*-1,3-dibromocyclohexane in an almost 1:1 ratio.[4] The predominant or exclusive formation of the *endo,exo*-isomer (**8a**) can be best rationalized by assuming that a 1,3-bridged bromonium ion such as **4** (X=Br) mentioned before is captured by bromide ion (Scheme 6). It is highly probable that a lifetime of **4a** is longer in nonpolar solvents than in polar ones becasue the latters can stabilize a carbocation character by solvation in greater extent than the formers. In other words, the 1,3-bridging can be stronger in nonpolar solvents than polar ones. As a result, more rearranged product (**2a**) is formed in polar solvents; this is compatible with the fact that, in general, rearrangements during halogenations of alkenes are enhanced by utilizing polar solvents.[15] Although we do not think that the limited data available here can permit to discuss a further precise mechanism, the present results give a strong support for the intermediacy of the 1,3-bridged halonium ion such as **4** in halogenations of bicyclo[2.1.0]pentane system and reveal that halogenations of bicyclo[2.1.0]pentane system are sensitive to the solvent polarity as well as nature of the halogen used.[16]



Scheme 6.

Experimental

All the temperatures were uncorrected. The melting points were measured in sealed capillaries. The IR spectra were obtained on a Shimadzu IR-27 spectrometer. The mass spectra were taken by using a Hitachi RMS-4 mass spectrometer. The PMR and CMR spectra were obtained on Varian EM-390 and CFT-20 spectrometers, TMS being chosen as the internal standard. The microanalyses were performed by Kyoto University Elemental Analysis Center. All the reactions were carried out under nitrogen unless otherwise noted.

*Bromination of Pentacyclo[5.3.1.0^{2,6}.0^{3,5}.0^{4,9}]undecane (**1**) in CH_2Cl_2.* To a solution of **1** (292 mg; 2.0 mmol) in CH_2Cl_2 (15 ml) was added a solution of Br_2 (320 mg; 2.0 mmol) in CH_2Cl_2 (10 ml) at −78 °C in the dark. The reaction mixture was stirred for 1 h and washed with aqueous $Na_2S_2O_3$ and brine, and dried ($CaCl_2$). After filtration, the solvent was evaporated and the residue was chromatographed on silica gel. Elution by hexane gave a mixture of *endo,exo*-4,5-dibromotetracyclo[5.3.1.0^{2,6}.0^{3,9}]undecane (**2a**), **8a** (*vide infra*), and an unidentified compound in a ratio of 91:5:4 (estimated from GLC analysis, AP 170 °C) (525 mg, 86%). Pure **2a** was obtained by preparative GLC. **2a**: mp 58—61 °C. MS *m/e* (rel intensity): 227, 225 (M^+−Br, 94, 100), 145, (63). IR (KBr): 2925, 1465, 1305, 1265, 1200, 1155, 785, 770, 725 cm^{-1}. PMR δ (CCl_4): 4.70 (1H, dd, J=6.5 and 4.5 Hz), 4.47 (1H, d, J=4.5 Hz), 2.97 (1H, q, J=6.0 Hz), 2.82—2.42 (3H, complex m), 2.37—1.20 (8H, br. complex m). CMR δ ($CDCl_3$): 61.5 (CH), 58.0 (CH), 67.8 (CH), 47.8 (CH), 42.2 (CH_2), 41.0 (CH), 39.4 (CH), 39.4 (CH), 30.1 (CH_2). Found: C, 42.87; H, 4.88%. Calcd for $C_{11}H_{14}Br_2$: C, 43.17; H, 4.61%.

*Debromination of **2a** with $LiAlH_4$.* To a suspension of $LiAlH_4$ (54 mg; 1.42 mmol) in ether (5 ml) was added a solution of **2a** (84 mg; 0.27 mmol) in ether at room temperature. The reaction mixture was stirred for 1.5 h and quenched with sat aqueous Na_2SO_4. The organic layer was separated by decantation and dried (Na_2SO_4). After filtration, the solvent was evaporated and the residue was chromatographed on silica gel. Elution by hexane gave tetracyclo[5.3.1.$0^{2,6}$.$0^{3,9}$]undec-4-ene (**3**) (22 mg, 55%) which was identical with the authentic specimen.[9]

*Iodination of **1** in CH_2Cl_2.* To a solution of **1** (73 mg; 0.50 mmol) in CH_2Cl_2 (5 ml) was added a solution of iodine (127 mg; 0.50 mmol) in CH_2Cl_2 (5 ml) at room temperature in the dark. The reaction mixture was stirred for 1 h and washed with aqueous $Na_2S_2O_3$ and brine, and dried ($CaCl_2$). After filtration, the solvent was evaporated to give a mixture of *endo,exo*-4,5-diiodotetracyclo[5.3.1.$0^{2,6}$.$0^{3,9}$]undecane (**2b**), **3**, **7b** and **8b** (*vide infra*) in a ratio of 73:12:4:11 (PMR analysis) (187 mg). The diiodide (**2b**) has never been isolated in a pure form because of its rapid decomposition to **3** and iodine. The following data for **2b** were deduced from the measurement of the mixture. **2b**: PMR δ (CCl_4): 4.72 (1H, dd, J=6.3 and 5.4 Hz), 4.45 (1H, d, J=5.4 Hz), 3.18—1.18 (12H, br. complex m). CMR δ ($CDCl_3$): 64.2 (CH), 58.4 (CH), 47.0 (CH), 41.8 (CH_2), 41.7 (CH), 41.4 (CH_2), 41.2 (CH), 39.8 (CH), 39.5 (CH), 34.7 (CH), 29.6 (CH_2). To a suspension of $LiAlH_4$ (61 mg) in ether (5 ml) was added a solution of the above products mixture (127 mg) in ether (3 ml) at room temperature and the mixture was stirred for 1 h. Usual work-up followed by column chromatography on silica gel gave a mixture (39 mg) of **3** and **1** in a ratio of 3:1.

*Iodochlorination of **1** in CH_2Cl_2.* To a solution of **1** (219 mg; 1.50 mmol) in CH_2Cl_2 (10 ml) was added a solution of iodine chloride (244 mg; 1.50 mmol) in CH_2Cl_2 (10 ml) at room temperature in the dark. The reaction mixture was stirred for 45 min, washed with aqueous $Na_2S_2O_3$ and brine, and dried (Na_2SO_4). After filtration, the solvent was evaporated and the residue (400 mg) was distilled to give *endo*-4-chloro-*exo*-5-iodotetracyclo[5.3.1.$0^{2,6}$.$0^{3,9}$]undecane (**2c**) (361 mg, 78%): bp 90 °C (bath temp)/67 Pa. MS *m/e* (rel intensity): 183, 181 (M^+—I, 33, 100), 145 (30). IR (neat): 2950, 2875, 1310, 770, 750 cm^{-1}. PMR δ (CCl_4): 4.80 (1H, dd, J=6.5 and 4.5 Hz), 4.40 (1H, d, J=4.5 Hz), 3.03 (1H, q, J=6.0 Hz), 2.87—1.20 (11H, br. complex m). CMR δ ($CDCl_3$): 73.8 (CH), 63.3 (CH), 57.3 (CH), 48.1 (CH), 42.5 (CH_2), 42.3 (CH_2), 41.5 (CH), 38.9 (CH), 38.3 (CH), 32.5 (CH), 29.7 (CH). Found: C, 43.04; H, 4.78%. Calcd for $C_{11}H_{14}ClI$: C, 42.9; H, 4.57%.

endo-*4-Chlorotetracyclo[5.3.1.$0^{2,6}$.$0^{3,9}$]undecane (**2d**).* A solution of **2c** (97 mg; 0.26 mmol) and Bu_3SnH (84 mg; 0.29 mmol) in dry benzene (3 ml) was refluxed for 1 h washed with brine, and dried (Na_2SO_4). After filtration, the solvent was evaporated and the residue was sublimed (62 °C/1729 Pa) to give **2d** (29 mg, 62%): mp 79—82 °C. MS *m/e* (rel intensity): 184, 182 (M^+, 20, 61), 146 (77), 80 (88), 79 (83), 68 (100). PMR δ (CCl_4): 4.45 (1H, dt, J=10.8 and 5.7 Hz), 2.72—1.25 (14H, br. complex m). CMR δ ($CDCl_3$): 61.8 (CH), 56.6 (CH), 50.2 (CH), 49.7 (CH), 43.1 (CH_2), 43.0 (CH_2), 41.1 (CH), 39.5 (CH), 38.9 (CH), 37.8 (CH_2), 30.3 (CH_2). Found: C, 72.56; H, 8.51%. Calcd for $C_{11}H_{15}Cl$: C, 72.32; H, 8.28%.

*Iodochlorination of **3**.* To a solution of **3** (77 mg; 0.53 mmol) in CH_2Cl_2 (5 ml) was added a solution of iodine chloride (120 mg; 0.74 mmol) in CH_2Cl_2 (5 ml) at room temperature in the dark. The reaction mixture was stirred for 2 h, washed with aqueous $Na_2S_2O_3$ and brine, and dried (Na_2SO_4). After filtration, the solvent was evaporated and the residue was distilled to give **2c** (53 mg, 33%) which was identical with that described above.

*Photobromination of **1**.* To a solution of **1** (59 mg; 0.47 mmol) in CCl_4 (10 ml) was added dropwise a solution of bromine (124 mg, 0.04 ml; 0.78 mmol) in CCl_4 (4 ml) at 0 °C under irradiation through soft glass filter by 300 W medium-pressure mercury arc over 2 min and the mixture was washed with aqueous $Na_2S_2O_3$ and brine, and dried (Na_2SO_4). After filtration, the solvent was evaporated and the residue was chromatographed on silica gel. Elution by hexane gave a mixture of *endo,endo*-3,5-dibromotetracyclo[5.3.1.$0^{2,6}$.$0^{4,9}$]undecane (**7a**) and *endo,exo*-3,5-dibromotetracyclo[5.3.1.$0^{2,6}$.$0^{4,9}$]undecane (**8a**) in a ratio of 46:54 (PMR analysis) (89 mg, 72%). Each of the products was isolated by preparative GLC (AP, 180 °C). **7a**: mp 98—101 °C. MS *m/e* (rel intensity): 308, 306, 304 (M^+, 2, 5, 2), 227 (97), 225 (100), 145 (66). IR (KBr): 2925, 1480, 1295, 1210, 865, 815, 670 cm^{-1}. PMR δ (CCl_4): 4.00 (2H, s, $W_{1/2}$=8.5 Hz), 3.00 (2H, d, J=13.5 Hz), 2.85—2.30 (6H, br. complex m), 1.65 (2H, s), 1.00 (2H, d, J=13.5 Hz). CMR δ ($CDCl_3$): 48.5 (CH), 47.6 (CH), 44.3 (CH), 40.9 (CH_2), 37.9 (CH), 30.8 (CH), 30.1 (CH_2). Found: C, 43.18; H, 4.59%. Calcd for $C_{11}H_{14}Br_2$: C, 43.16; H, 4.61%. **8a**: mp 74—77 °C. MS *m/e* (rel intansity): 308, 306, 304 (M^+, 5, 10, 5), 227 (97), 225 (100), 145 (73). IR (KBr): 2930, 790, 680 cm^{-1}. PMR δ (CCl_4): 5.00 (1H, s, $W_{1/2}$=8.5 Hz), 4.63 (1H, s, $W_{1/2}$=3.0 Hz), 3.08 (1H, d, J=13.5 Hz), 2.28—1.40 (9H, br. complex m), 1.12 (1H, d, J=13.5 Hz). CMR δ ($CDCl_3$): 53.6 (CH), 53.5 (CH), 49.4 (CH), 46.6 (CH), 45.1 (CH), 41.5 (CH), 40.8 (CH_2), 36.8 (CH), 33.7 (CH), 30.6 (CH_2), 30.0 (CH_2). Found: C, 43.17; H, 4.69%. Calcd for $C_{11}H_{14}Br_2$: C, 43.16; H, 4.61%.

*Reduction of a Mixture of **7a** and **8a** with Bu_3SnH.* A mixture of **7a** and **8a** (166 mg; 0.54 mmol), Bu_3SnH (189 mg; 0.65 mmol), and $NaBH_4$ (20 mg; 0.53 mmol) in THF (10 ml) was refluxed overnight and quenched with 5% aqueous HCl. The mixture was poured onto water and extracted with hexane. The organic layer was washed with brine and dried (Na_2SO_4). After filtration, the solvent was evaporated to give **9** as a sole hydrocarbon product. The product, **9** (30 mg), was isolated by preparative GLC and shown to be identical with the authentic specimen[5] by GLC and PMR analyses.

*Photoiodination of **1**.* To a solution of **1** (73 mg; 0.50 mmol) in CH_2Cl_2 (5 ml) was added a solution of iodine (127 mg; 0.50 mmol) in CH_2Cl_2 under daylight at room temperature. The mixture was stirred for 1.5 h, washed with aqueous $Na_2S_2O_3$ and brine, and dried (Na_2SO_4). After filtration, the solvent was evaporated to give a mixture of *endo,endo*-3,5- and *endo,exo*-3,5-diiodotetracyclo[5.3.1.$0^{2,6}$.$0^{4,9}$]undecanes (**7b** and **8b**) (191 mg, 96%) in a ratio of 45:56 (GLC and PMR analyses). Each of the products was isolated by preparative GLC (HVSG, 165 °C). **7b**: mp 123—125 °C. MS *m/e* (rel intensity): 400 (M^+, 4), 273 (100), 146 (88). IR (KBr): 2925, 1480, 1200, 860, 620 cm^{-1}. PMR δ (CCl_4): 3.98 (2H, s, $W_{1/2}$=8.5 Hz), 3.20 (2H, d, J=13.5 Hz), 2.90—2.25 (6H, complex m), 1.65 (2H, s), 0.95 (2H, d, J=13.5 Hz). CMR δ ($CDCl_3$): 48.3 (CH), 44.0 (CH), 40.8 (CH_2), 38.4 (CH), 30.3 (CH), 29.5 (CH_2), 18.9 (CH). Found: C, 33.01; H, 3.54%. Calcd for $C_{11}H_{14}I_2$: C, 33.02; H, 3.53%. **8b**: 115—118 °C, MS *m/e* (rel intensity): 400 (M^+, 8), 273 (100), 146 (89). IR (KBr): 2925, 1475, 1200, 765, 690, 650 cm^{-1}. PMR δ (CCl_4): 4.97 (1H, s, $W_{1/2}$=8.5 Hz), 4.63 (1H, s, $W_{1/2}$=3.0 Hz), 3.27 (1H, d, 13.5 Hz), 2.90—2.25 (6H, complex m),

2.05–1.35 (complex m), 1.08 (1H, d, J=13.5 Hz), 1.04 (1H, d, J=13.5 Hz). CMR δ ($CDCl_3$): 54.3 (CH), 47.4 (CH), 45.8 (CH), 42.6 (CH), 40.1 (CH_2), 37.5 (CH), 33.2 (CH), 32.0 (CH), 30.2 (CH_2), 29.6 (CH_2), 24.7 (CH). Found: C, 32.98; H, 3.51%. Calcd for $C_{11}H_{14}I_2$: C, 33.02; H, 3.53%.

Deiodination of a Mixture of ***7b*** *and* ***8b*** *with* $LiAlH_4$. To a suspension of $LiAlH_4$ (91 mg; 2.4 mmol) in dry ether (5 ml) was added dropwise a solution of a mixture of **7b** and **8b** (190 mg; 0.48 mmol) in dry ether (5 ml) at room temperature. The mixture was stirred overngiht and quenched with sat aqueous Na_2SO_4. Usual work-up gave **1** (60 mg, 87%).

Bromination of ***1*** *in Various Solvents in the Dark.* To a solution of **1** (10—29 mg; 0.07—0.20 mmol) in each of the solvents (2 ml) described in Table 2 was added bromine (17—50 mg; 0.11—0.31 mmol) in the solvent (1 ml) in the dark. The mixture was stirred for 1 h and analyzed by GLC (AP, 170 °C) before and/or after usual work-up. The results were summarized in Table 2.

Iodination of ***1*** *in* CCl_4 *in the Dark.* To a solution of **1** (69 mg; 0.47 mmol) in CCl_4 was added a solution of iodine (138 mg; 0.54 mmol) in CCl_4 (10 ml) in the dark at room temperature. The reaction mixture was stirred for 25 h, washed with aqueous $Na_2S_2O_3$ and brine, and dried (Na_2SO_4). After filtration, the solvent was evaporated to give a mixture of products (111 mg, 59%) which was shown to consist of **7b** and **8b** in a ratio of 42:58 by GLC and PMR analyses.

Iodochlorination of ***1*** *in* CCl_4 *in the Dark.* To a solution of **1** (128 mg; 0.88 mmol) in CCl_4 (5 ml) was added a solution of ICl (171 mg; 1.05 mmol) in CCl_4 (2 ml) in the dark at room temperature. The mixture was stirred for 1 h, washed with aqueous $Na_2S_2O_3$ and brine, and dried (Na_2SO_4). After filtration, the solvent was evaporated and the residue was chromatographed on silica gel. Elution by hexane gave **2c** (256 mg, 95%).

This work was partially supported by a Grant-in-Aid for Scientific Research from the Minsitry of Education, Japan (No. 434025).

Reaction of Dialkyl-substituted Alkynes with Carbon Dioxide Catalyzed by Nickel(0) Complexes. Incorporation of Carbon Dioxide in Alkyne Dimers and Novel Cyclotrimerization of the Alkynes

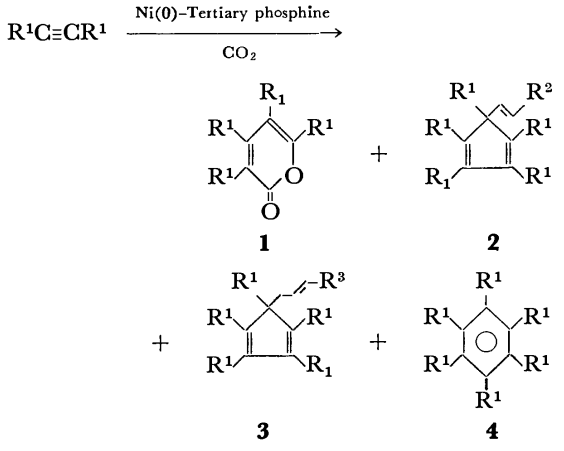
Yoshio INOUE,* Yoshio ITOH, Haruo KAZAMA, and Harukichi HASHIMOTO

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aoba, Aramaki, Sendai 980

(Received May 16, 1980)

$Ni(cod)_2$–$Ph_2P(CH_2)_4PPh_2$ system (cod=1,5-cyclooctadiene) catalyzed the reaction of 3-hexyne, for example, with CO_2 to give a CO_2 incorporated product, *i.e.*, tetraethyl-2-pyrone, in a fairly good yield together with novel two cyclotrimers of the alkyne having cyclopentadiene structures, *i.e.*, pentaethyl-5-(1-propenyl)-1,3-cyclopentadiene and pentaethyl-5-allyl-1,3-cyclopentadiene. The novel two cyclotrimers were formed selectively on $Ni(cod)_2$–PPh_3 system under CO_2, whereas under N_2 the main trimer was hexaethylbenzene. A nickelacyclopentadiene intermediate has been proposed for the pyrone formation. The novel two cyclotrimers were also formed on the oligomerization catalyzed by a cationic nickel hydride complex, $[HNi(Ph_2PCH_2CH_2PPh_2)_2]OCOCF_3$, together with a novel dimer having a methylenecyclobutene structure, *i.e.*, 1,2,4-triethyl-3-ethylidenecyclobutene. The effect of phosphine added and that of active-hydrogen compounds on the novel oligomerization are mentioned.

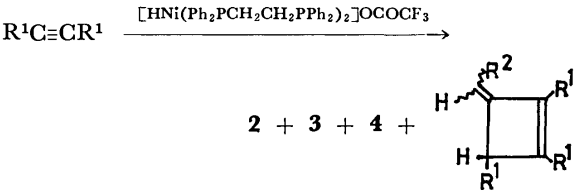
We are currently studying the CO_2 chemistry for the purpose of using it as a raw material for organic syntheses. There are many reports on the reaction of metal compounds with CO_2 in recent years but only a few examples of the catalytic fixation of CO_2 in organic compounds by transition metals have been known. Earlier papers in this series have dealt with novel reactions of CO_2 with dialkyl-substituted alkynes like 3-hexyne and 4-octyne to form pyrone derivatives (**1**) catalyzed by $Ni(cod)_2$–tertiary phosphine system.[1] This reaction is interesting because CO_2 can be catalytically linked in an alkyne dimer. In addition to the pyrone (**1**) we got two novel cyclotrimers having cyclopentadiene structures, **2** and **3**, which were accompanied by hydrogen migration together with a usual cyclotrimer, hexaalkylbenzene (**4**). Small amounts of several other products including two tetramers of the alkynes were also formed.



a; R^1=Et, R^2=Me, R^3=H
b; R^1=Pr^n, R^2=Et, R^3=Me

The course of the reaction between CO_2 and alkynes was quite sensitive to the phosphine added, resulting in significantly altered products distributions.

It has also been found that a cationic nickel hydride complex$[HNi(Ph_2PCH_2CH_2PPh_2)_2]OCOCF_3$ catalyzed the novel cyclotrimerization of alkynes to afford **2** and **3**. In this system a novel dimer (**5**) having a methylenecyclobutene structure was also formed.[2]



a; R^1=Et, R^2=Me
b; R^1=Pr^n, R^2=Et

5

Although cyclotrimerization of internal alkynes to benzene derivatives has been catalyzed by various kinds of nickel complexes, cyclotrimerization accompanied by hydrogen migration seems rather rare.[3]

In this paper we wish to describe the effect of phosphine added on the CO_2-alkyne reaction and that of active-hydrogen compounds on the novel oligomerization of the alkyne.

Results and Discussion

The results of the reaction between CO_2 and 3-hexyne and 4-octyne employing a variety of tertiary phosphines are summarized in Tables 1 and 2, respectively. Almost the same effects of the phosphine

TABLE 1. REACTION OF 3-HEXYNE CATALYZED BY $Ni(cod)_2$–PHOSPHINE SYSTEM UNDER CO_2 PRESSURE[a]

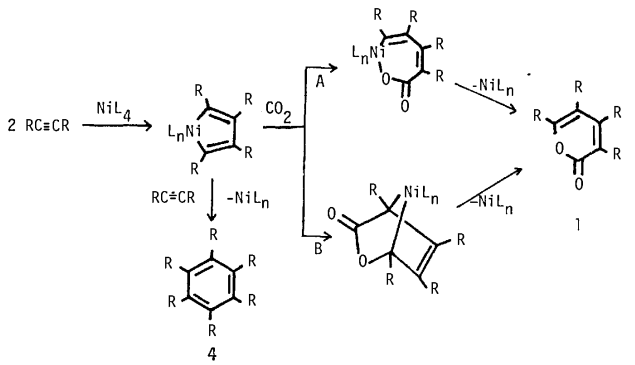
a) 4-Octyne; 6.8 mmol, and the other conditions were the same as those in Table 1. b) Based on 4-octyne charged (by GLC). c) 0.4 mmol of water was added. d) Not analyzed. e) 6.5 mmol of water was added.

were observed in 3-hexyne and 4-octyne reactions. The ditertiary phosphine, $Ph_2P(CH_2)_4PPh_2$, was found to be the most effective for the formation of the pyrone (**1**), whereas the novel cyclotrimer (**2**) was obtained as the main product in the $Ph_2PCH_2CH_2PPh_2$ and PPh_3 systems. In case of $Ph_2P(CH_2)_3PPh_2$, 3-hexyne reacted only scarcely. In the $Me_2PCH_2CH_2PMe_2$ system, higher oligomers of 3-hexyne were the main products with a low conversion of 3-hexyne.

A possible mechanism for the pyrone formation involves a nickelacyclopentadiene as an intermediate (Scheme 1).[4)] The formation of the nickelacyclopentadiene complex from two moles of alkyne and a nickel complex is followed by CO_2 insertion into a nickel-carbon bond to give a carboxylated complex, which then eliminates the pyrone with intramolecular C–O coupling (Route A). Another route involving [4+2]cycloadditions of the cyclopentadiene complex with CO_2 in the sense of Diels-Alder reaction (Route B) cannot be eliminated but is less probable because CO_2 does not undergo [4+2]cycloaddition with dienes.[5)] Attack of another alkyne molecule to the nickelacyclopentadiene complex will result in the formation of a benzene derivative.



Scheme 1.

The diphosphines of the type $Ph_2P(CH_2)_nPPh_2$ have high coordinating ability by chelation. ^{31}P NMR studies[6)] show that the bonding ability to Ni(0) is in the order

$$Ph_2P(CH_2)_3PPh_2 \approx Ph_2P(CH_2)_2PPh_2 > Ph_2P(CH_2)_4PPh_2.$$

In case of $Ph_2P(CH_2)_3PPh_2$, the reaction took place with great difficulty. This diphosphine has such a high coordinating ability that blocks active sites of nickel to stop the reaction almost completely.

In the proposed scheme above, CO_2 is acting as an electrophile. So a nickel complex bearing more basic ligands is expected to react profitably with CO_2. But the experimental result showed that the diphosphine $Me_2PCH_2CH_2PMe_2$, which is more basic than the corresponding phenyl derivative $Ph_2PCH_2CH_2PPh_2$, was scarcely effective for the formation of the pyrone. This may be ascribed to the steric bulkiness of the phenyl groups in the latter phosphine: CO_2 is competing with an alkyne molecule in reacting with the nickelacyclopentadiene intermediate. Smaller molecule (CO_2) can preferencially react with the intermediate in the $Ph_2P(CH_2)_nPPh_2$ system.

The marked effect of the diphosphine $Ph_2P(CH_2)_4PPh_2$ on the pyrone formation can be ascribed to its adequate coordinating ability and the steric bulkiness.

The reactivity of the other internal alkynes toward CO_2 was also examined. 2-Hexyne gave possible four isomers of 2-pyrone with ill selectivity and also gave many isomers of cyclopentadiene derivatives on $Ni(cod)_2$–$Ph_2P(CH_2)_4PPh_2$ system. 2-Butyne did not react with CO_2 at 120 °C on 20 h reaction by the same (or $-PPh_3$) system in benzene only giving a higher oligomer in very small amount. A reaction mixture of 2-butyne after 40 h reaction at 120 °C by $Ni(cod)_2$–PPh_3 system, however, showed a carbonyl stretching vibration at 1705 cm^{-1} in its IR chart indicating that 2-butyne reacted with CO_2. But the amount of the product was too small to decide the structure. Diphenylacetylene did not react at all under these reaction conditions.

Various kinds of organometallic compounds are known to oligomerize acetylenic compounds into cyclic trimers. The product is hexasubstituted benzene in case of a disubstituted alkyne. The other type of catalytic cyclotrimerization has not been observed for disubstituted alkynes.

In the present reaction of disubstituted alkynes under CO_2, novel cyclotrimerization accompanied by hydrogen migration occurred: $Ni(cod)_2$–$Ph_2PCH_2CH_2PPh_2$ system afforded a novel trimer (**2b**) in 72% yield on the reaction of 4-octyne under CO_2 pressure as shown in Table 2. So the further investigation on the oligomerization of disubstituted alkynes was made. Results of the oligomerization of 3-hexyne and 4-octyne by nickel complexes are summarized in Table 3. The effect of CO_2 was remarkable because $Ni(Ph_2PCH_2CH_2PPh_2)_2$ complex or $Ni(cod)_2$–$Ph_2PCH_2CH_2PPh_2$ (1:1) system scarcely catalyzed the oligomerization of 3-hexyne. $Ni(Ph_2PCH_2CH_2PPh_2)_2$–AcOH (or –PhOH) system afforded a small amount of the cyclopentadiene derivatives. When PPh_3 was used **2a** was formed selectively under CO_2 as shown in Table 1. Under N_2, however, the main product was **4a**. Such effect of CO_2 to alter the catalyst properties has been also observed in the dimerization of butadiene catalyzed by transition metal complexes. For example, $Pt(PPh_3)_3$ converts butadiene to a cyclic dimer, 4-vinylcyclohexene, under N_2 or Ar atmosphere. However a linear dimer, 1,3,7-octatriene, becomes the

Table 3. Oligomerization of 3-hexyne and 4-octyne by nickel catalysts[a)]

predominant product when CO_2 is introduced.[7)] In this case a direct effect of CO_2 on the catalyst has been suggested.

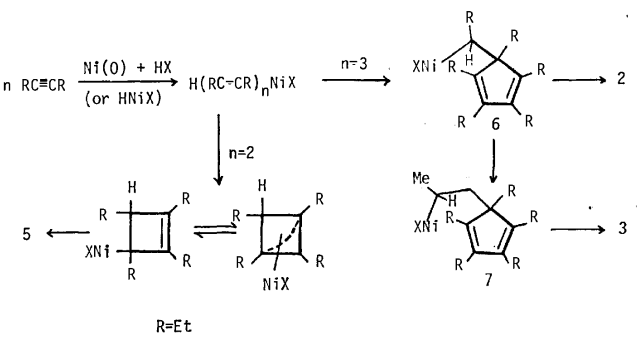
It is necessary to make a complex in a coordinately unsaturated state for the occurrence of the reaction. It has been said that a protic acid such as PhOH has an effect to liberate the ligand around the metal atom to place the complex in such a state.[8)] Even if a protic acid or CO_2 has such a function, the product will be as benzene derivative.

The intermediacy of transition metal hydride complexes in the catalytic oligomerization of olefins and diolefins accompanied by hydrogen migration has been recognized. Various nickel hydride complexes have been obtained from the reaction of zerovalent nickel with acids such as H_2SO_4, HCl, CF_3COOH, $HClO_4$, C_6H_5OH, and CH_3COOH by protonation or oxidative addition. Although the starting nickel complex is not a hydride one, carbonic acid from a catalytic amount of water and CO_2 may be a candidate for producing a nickel hydride species in the present system. Water was added to examine the effect on the product distribution in alkyne oligomerization catalyzed by $Ni(cod)_2$–$Ph_2PCH_2CH_2PPh_2$ system under CO_2. 0.15 Equivalent of water to nickel had a slight effect for the formation of **2a** and **3a** under CO_2 as shown in Table 1. The possibility that **2a** was derived from **3a** by isomerization might be excluded because with a short reaction time of 0.5 h rather than the usual 20 h, the distribution of the products did not significantly change. One or excess molar equivalent of water brought about the lowering of the catalytic activity, decreasing the selectivity for **1b** and **2b**, and increased the selectivity for **3b** as shown in Table 2. The preferencial formation of **3** over **2** resembled the results in the nickel hydride complex system (*vide infra*).

In order to clarify the role of hydride species on the alkyne oligomerization, the catalytic action of a cationic hydride complex, $[HNi(Ph_2PCH_2CH_2PPh_2)_2]$-$OCOCF_3$, which was prepared from $Ni(Ph_2PCH_2CH_2PPh_2)_2$ and CF_3COOH,[9)] was examined. Actually this complex oligomerized 3-hexyne (and 4-octyne) into **2**, **3**, and **4**, and in this case a novel dimer, 1,2,4-triethyl-3-ethylidenecyclobutene (**5a**), which was not yielded in the CO_2-concerned system, was also obtained as the main product. This is a rare example of the catalytic dimerization of internal alkynes involving the migration of hydrogen. There is a possibility that the oligomerization of 3-hexyne was catalyzed by traces of acid.[10)] But it could be excluded by a control experiment. The products of these types were formed in reactions catalyzed by metallic species.

It is not certain at the present time whether CO_2 has a direct effect on the catalyst or has a tendency to produce a hydride species. But at least a certain nickel hydride complex can catalyze the novel cyclotrimerization.

Although we could not get positive data by NMR study (see the experimental part), we tentatively propose the following scheme for the novel cyclotrimerization and dimerization of 3-hexyne as a possible one by analogy with the one proposed by Maitlis on the palladium induced cyclotrimerization of alkynes.[3)] The σ-butadienyl (n=2) and the σ-hexatrienyl (n=3) complex can ring close to the cyclobutenyl and the cyclopentadiene complex which is then converted into **5** and **2**, respectively. If **6** isomerizes into another cyclopentadiene complex (**7**) with 1,2-hydride shift,[3)] **3** is formed.



Scheme 2.

Certainly other mechanisms are possible but one other possibility for the formation of the dimer **5** is mentioned here: That is the isomerization of a cyclobutadiene compound to the dimer (**5**).[11,12)]

Experimental

IR, ^{1}H NMR (coupled with spin decoupling method), ^{13}C NMR (coupled with off-resonance technique), mass, and UV spectra were recorded on following apparatus, respectively; Shimadzu IR-430, Hitachi R-24A (60 MHz), JNM MH-100, JMS 06H, and Shimadzu UV 200. Quantitative analyses were performed by GLC on a Shimadzu GC-3AH instrument equipped with a FFAP column with helium as a carrier gas. Preparative GLC was performed on a Shimadzu GC-2H instrument equipped with a FFAP column with hydrogen as a carrier gas.

Materials. 2-Butyne, 2- and 3-hexyne, and 4-octyne were commercially obtained. Diphenylacetylene was prepared according to the published method.[14] The diphosphines $Ph_2P(CH_2)_nPPh_2$ (n=2,3,4)[15] and $Me_2P(CH_2)_2PMe_2$[16] were synthesized according to the methods reported previously. The synthesis of the cationic nickel hydride complex $[HNi(Ph_2PCH_2CH_2PPh_2)_2]OCOCF_3$ was reported previously.[1]

Reaction of 3-Hexyne with CO_2 Catalyzed by Nickel Complexes. To a 100 ml stainless steel autoclave equipped with a magnetic agitator, benzene (5 ml), 3-hexyne (1 ml, 8.8 mmol), $Ni(cod)_2$ (110 mg, 0.4 mmol), and $Ph_2P(CH_2)_4PPh_2$ (341 mg, 0.8 mmol) were added under N_2 atmosphere. Then CO_2 was introduced to the pressure of 50 kg·cm^{-2}. The autoclave was heated to 120 °C and agitated for 20 h. The reaction mixture was analyzed by GLC. The other alkynes were reacted with CO_2 similarly.

Oligomerization of 3-Hexyne Catalyzed by the Cationic Nickel Hydride Complex. To a 20 ml glass ampoule, benzene (5 ml), 3-hexyne (1 ml, 8.8 mmol), and $[HNi(Ph_2PCH_2CH_2PPh_2)_2]OCOCF_3$ (0.387 g, 0.4 mmol) were added under N_2 atmosphere. After the ampoule was cooled in liquid N_2, it was evacuated, sealed, and then agitated for 5 h at 120 °C. The reaction products were analyzed by GLC. Oligomerization of alkynes in other systems was performed similarly.

Identification of Products. Volatile products were flash distilled from the reaction mixtures (oil bath temperature of ≈200 °C) at 1 mmHg,* and were purified by preparative GLC.

*Tetraethyl-2-pyrone (**1a**)*: IR (neat): 1700 (C=O), 1630 (C=C), and 1550 cm^{-1} (C=C). ^{1}H NMR (C_6D_6): δ 0.5—1.3 (12H, m, CH_3), 1.6—2.2 (6H, m, CH_2), and 2.4 (2H, q, J=5.4 Hz, CH_2). MS: *m/e* (rel intensity), 208 (M^+, 16), 180 (27), 165 (100), and 57 (18). UV_{max} (EtOH): 304 nm.

*Tetrapropyl-2-pyrone (**1b**)*: IR (neat): 1705 (C=O), 1635 (C=C), and 1550 cm^{-1} (C=C). ^{1}H NMR (C_6D_6): δ 0.5—2.7 (m, CH_3 and CH_2). Found: C, 77.83; H, 11.62%. Calcd for $C_{17}H_{28}O_2$: C, 77.22; H, 10.67%.

*Pentaethyl-5-(1-propenyl)-1,3-cyclopentadiene (**2a**)*: IR (neat): 972 cm^{-1} (*trans* C=C). ^{1}H NMR (C_6D_6): δ 0.44 (3H, t, J=7.0 Hz, $C_{(5)}$-$CH_2\underline{CH_3}$), 0.96 (12H, m, CH_3), 1.50 (3H, d, J=6.0 Hz, $\underline{CH_3}CH$=), 1.60 (2H, q, J=7.0 Hz, $C_{(5)}$-$\underline{CH_2}CH_3$), 1.85—2.34 (8H, m, CH_2), 4.81 (1H, d, J=15.6 Hz, $\underline{HC}$=CHCH$_3$), and 5.33 (1H, m, HC=C$\underline{H}$CH$_3$). ^{13}C NMR (CD_3COCD_3): δ 144.9 (s), 143.0 (s), 136.2 (d),122.1 (d) 64.2 (s), 22.9, 19.5, 19.2, 18.4, 15.6, 15.2, and 7.8. MS: *m/e* (rel intensity), 246 (M^+, 60), 217 (100), 189 (24), and 161 (22). UV_{max} (EtOH): 206, 239, and 265 nm. Both the large spin coupling constant J=15.6 Hz in the ^{1}H NMR spectrum and the strong absorption at 972 cm^{-1} in the IR spectrum indicate that the double bond in the propenyl group has the *trans* configuration.

*Pentapropyl-5-(1-butenyl)-1,3-cyclopentadiene (**2b**)*: IR (neat): 970 cm^{-1} (*trans* C=C). ^{1}H NMR (C_6D_6): δ 0.7—1.1 (18H, m, CH_3), 1.2—1.9 (12H, m, CH_2), 1.9—2.5 (10H, m, CH_2C=), 4.81 (1H, d, J=15.4 Hz, $\underline{HC}$–CHEt), and 5.47 (1H, dt, J=15.4 and 6.5 Hz, HC=C$\underline{H}$Et). The olefinic proton at δ 5.47 ppm appeared as a doublet by irradiation of the methylene proton centered at δ 2.15 ppm. This indicates the existence of the –CH=CHCH$_2$–group. Both the large spin coupling constant J=15.4 Hz and the strong absorption at 970 cm^{-1} in the IR spectrum indicate that the double bond in the 1-butenyl group has the trans configuration.

*Pentaethyl-5-allyl-1,3-cyclopentadiene (**3a**)*: IR (neat): 1640 (C=C), 990 (C=C), and 910 cm^{-1} (C=C). ^{1}H NMR (C_6D_6): δ 0.37 (3H, t, J=7.0 Hz, $C_{(5)}$-$CH_2\underline{CH_3}$), 0.75—1.15 (12H, m, CH_3), 1.38 (2H, q, J=7.0 Hz, $C_{(5)}$-$\underline{CH_2}CH_3$), 1.70—2.35 (10H, m, CH_2), and 4.50—5.50 (3H, m, CH_2=CH). ^{13}C NMR (CD_3COCD_3): δ 143.4 (s), 143.1. (s), 135.9 (d), 114.7 (t), 61.6 (s), 39.9, 27.9, 19.3, 18.7, 15.5, 14.3, and 8.0.

*Pentapropyl-5-(2-butenyl)-1,3-cyclopentadiene (**3b**)*: IR (neat): 965 cm^{-1} (*trans* C=C). ^{1}H NMR (C_6D_6): δ 0.6—1.1 (15H, m, CH_3), 1.2—1.7 (15H, m, CH_2 and CH_3C=), 1.8—2.4 (10H, m, CH_2C=), and 4.9—5.6 (2H, m, CH=CH). The existence of the CH_3CH=C group was confirmed by a spin decoupling experiment; The methyl group which absorbed at δ 1.40 ppm as an indistinct doublet in the array of the methylene proton peaks collapsed to a singlet by irradiation of the olefinic protons. The strong absorption at 965 cm^{-1} in the IR spectrum suggests that the double bond in the 2-butenyl group has the *trans* configuration.

*1,2,4-Triethyl-3-ethylidenecyclobutene (**5a**)*: IR (neat): 800 cm^{-1} (CH=C$\diagup$). ^{1}H NMR (CD_3COCD_3): δ 0.7—1.2 (9H, m, CH_3), 1.2—1.7 (2H, m, CH_2), 1.59 (3H, d, J=7.4 Hz, $\underline{CH_3}CH$=), 1.8—2.4 (4H, m, $CH_3C\underline{H_2}C$=), 2.72 (1H, t, J=5.7 Hz, –$\underline{C}$H–), and 4.58 (1H, q, J=7.4 Hz, $CH_3C\underline{H}$=). ^{13}C NMR (CD_3COCD_3): δ 152.9 (s), 144.0 (s), 143.8 (s), 102.8 (d), 48.5 (d), 24.8, 20.7, 20.4, 14.0, 13.7, 12.6, and 11.9. UV_{max} (n-hexane): 256 nm (ε 6500). We could not determine the geometry of the ethylidene moiety.

*1,2,4-Tripropyl-3-propylidenecyclobutene (**5b**)*: IR (neat): No characteristic peaks were observed other than those due to the propyl groups. ^{1}H NMR (C_6D_6): δ 0.5—2.5 (26H, m, CH_3 and CH_2), 2.90 (1H, t, J=5.3 Hz, –$\underline{C}$H–), and 4.72 (1H, t, J=8.1 Hz, Et$\underline{H}$C=). This compound gave a very similar NMR spectrum to the ethyl counterpart (**5a**). The geometry of the exocyclic double bond could not be determined.

In these experiments it was difficult to assign the multiplicities of the methyl and methylene carbons in **2a**, **3a**, and **5a** by the off-resonance proton-decoupled technique mainly due to the overlap of the bands.

The Study of the Reaction between the Cationic Nickel Complex and 3-Hexyne by ^{1}H NMR. To a solution of 0.484 g (0.5 mmol) of the cationic nickel hydride complex $[HNi(Ph_2PCH_2CH_2PPh_2)_2]OCOCF_3$ in 5 ml of benzene, 113 μl (1 mmol) of 3-hexyne was added with stirring at room temperature. Orange oil was formed immediately at the bottom of the reaction vessel. So this system was unsuitable for NMR study unfortunately. Then the solvent was switched from benzene to CH_2Cl_2. To a solution of 0.1938 g (0.2 mmol) of the nickel complex in 0.5 ml of CH_2Cl_2 was added 45.4 μl (0.4 mmol) of 3-hexyne at room temperature. The homogeneous orange solution was quickly transferred into a NMR tube under N_2, then it was placed in the spectrometer of probe temperature 35 °C. The spectrum showed resonances of 3-hexyne δ 1.0 (CH_3) and 2.0 (CH_2) and

* 1 mmHg=133.322 Pa.

those characteristic of the hydride complex, a broad triplet and a broad singlet due to the ligand at δ 2.4 and 7.1, respectively and a quintet of the hydride at δ −13.0. In 2 h the initial resonances at δ 7.1 and −13.0 disappeared almost completely and those at δ 1.0, 2.0, and 2.4 became broad with appearence of two new resonances at δ 7.5 (broad singlet) and 0.5 (triplet). During the experiment the color of the sample changed into dark red and finally into deep blue. Although GLC analysis showed the formation of **5a** in a low yield, we might not observe the exact course of the reaction because the color change did not seem normal.

α-Cyclodextrin-catalyzed Hydrolysis of 2,2,2-Trifluoroethyl 4-Nitrobenzoate

Makoto KOMIYAMA* and Shohei INOUE

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

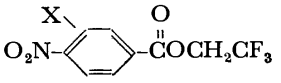
(Received May 21, 1980)

The hydrolysis of 2,2,2-trifluoroethyl 4-nitrobenzoate (**1**) was catalyzed by α-cyclodextrin at pH 8.6, 16 °C. The reaction, involving the complex formation of **1** with α-cyclodextrin, proceeded mostly (80%) *via* the general base catalysis by the secondary alkoxide ion of α-cyclodextrin with 20% contribution of the nucleophilic catalysis. This is the first finding of the general base catalysis of the hydrolyses of esters by cyclodextrins. The rate constants of the cleavage of **1** by the general base catalysis and the nucleophilic catalysis, respectively, of α-cyclodextrin were 5.3×10^{-2} and 1.5×10^{-2} min^{-1}, whereas the value in the absence of α-cyclodextrin was 1.2×10^{-2} min^{-1}. The hydrolysis of an analogous substrate, 2,2,2-trifluoroethyl 3-methyl-4-nitrobenzoate, however, was little affected by α-cyclodextrin, showing that **1** included the cavity of α-cyclodextrin with the nitro group first.

Recently the attention to the catalyses by cyclodextrins (CDs) as enzyme models has been increasing. This is mostly attributable to the fact that the reactions catalyzed by CDs proceed *via* the complex formation of the substrates with the catalysts preceding the catalytic functions, which is consistent with enzymatic reactions.[1]

In spite of so many examples of nucleophilic catalyses by CDs,[1] reports on general base catalyses, which are important in enzymatic reactions, by CDs have been scanty. In the previous paper,[2] however, general base catalysis by CDs was found for the first time in the α-cyclodextrin (α-CD)-catalyzed hydrolysis of 2,2,2-trifluoroethyl 4-nitrobenzoate (**1**), which was accompanied by some contribution of nucleophilic catalysis by α-CD.

In the present study, both the rate constant of the general base catalysis and that of the nucleophilic catalysis for the α-CD-catalyzed hydrolysis of **1** will be determined. Furthermore, the effect of α-CD on the hydrolysis of 2,2,2-trifluoroethyl 3-methyl-4-nitrobenzoate (**2**), which is sterically analogous to **1** but has a methyl substituent in the *ortho* position to the nitro group, will be also shown. The comparison of the results on the reactions of **1** and **2** provides structural information on the binding of **1** with α-CD.



1: X=H
2: X=CH_3

Experimental

Materials. α-CD was purified by the recrystallization from water. The synthesis of **1** and its characterization were described previously.[2] **2** was synthesized by the reaction of 3-methyl-4-nitrobenzoyl chloride, prepared from the corresponding acid and thionyl chloride, with 2,2,2-trifluoroethanol and was purified by the recrystallization from the ethanol-water solution; mp 54.0—54.2 °C.

Kinetics. The hydrolyses of **1** and **2** were carried out at 16 °C in a pH 8.6 borate buffer and in a pH 11.6 carbonate buffer, respectively. The initial concentrations of **1** and **2** were approximately 10^{-4} mol dm^{-3} and the appearance of the corresponding benzoate anions was followed at 296 nm.[3]

The concentration of 4-nitrobenzoyl-α-CD (**4**), the intermediate of the nucleophilic catalysis of the hydrolysis of **1** by α-CD, was determined in the following way. At a predetermined time, sampling of an aliquot of the reaction solution was made, followed by its acidification with small amount of hydrochloric acid. Then, the aliquot was extracted three times with diethyl ether, and the aqueous layer containing **4** as well as α-CD was dried into a white powder *in vacuo*. The amount of **4** in the white powder was determined by measuring the absorbance at 270 nm, after dissolving it in pH 7 buffer.

The rate constant of the hydrolysis of **4** was determined to be 3.1×10^{-3} min^{-1} by the measurement of the change of the absorbance at 260 nm (due to the liberation of 4-nitrobenzoate ion) in the α-CD-accelerated hydrolysis of 3-chlorophenyl 4-nitrobenzoate.[2]

For the D_2O solvent isotope effect experiment, the pD was determined by using the equation: pD=pH meter reading +0.4.[4]

Results

Figure 1 shows the time course of 4-nitrobenzoate ion (**3**) for the hydrolysis of **1** at pH 8.6 in the presence and the absence of 5.0×10^{-2} mol dm^{-3} α-CD. Obviously α-CD showed acceleration of the hydrolysis of **1**.

The appearance of **3** in the absence of α-CD fol-

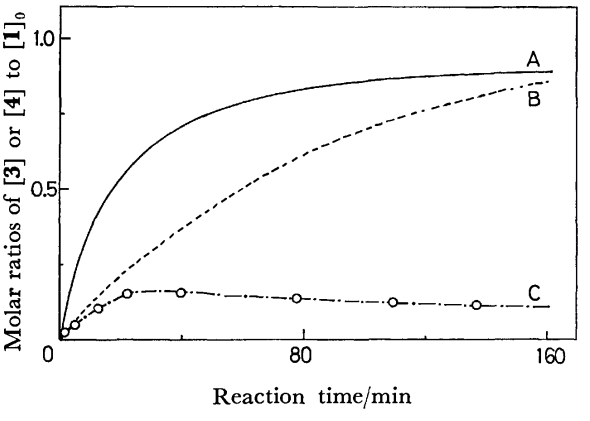


Fig. 1. Time courses of the hydrolysis of 2,2,2-trifluoroethyl 4-nitrobenzoate (**1**) in the presence and the absence of 5×10^{-2} mol dm^{-3} α-CD at pH 8.6, 16 °C; A, ——, 4-nitrobenzoate ion (**3**) in the presence of α-CD; B, ----, **3** in the absence of α-CD; C, —·—, 4-nitrobenzoyl-α-CD (**4**) in the presence of α-CD, where the circles shows the experimental results; the amounts of **3** and **4** are represented by the molar ratios of their concentrations to the initial concentration of **1**.

lowed the first-order kinetics, the rate constant k_{un} being 1.2×10^{-2} min^{-1}. On the other hand, the reaction in the presence of α-CD did not follow the first-order kinetics. This deviation from the first-order kinetics is attributable, as shown later, to the small contribution of nucleophilic catalysis in addition to the major participation of the general base catalysis. Thus, the analysis of the major catalysis was first made by use of the initial slope of the plot of the concentration of **3** *vs.* reaction time, since the initial slope is essentially free from the contribution of the nucleophilic catalysis (see Fig. 4).

As depicted in Fig. 2, the rate constant of the appearance of **3** in the initial stage (k_{obsd}) asymptotically increased with the initial concentration of α-CD ([α-CD]$_0$), indicating the formation of the complex of **1** with α-CD prior to the catalysis. The equilibrium constant of the dissociation of the α-CD-**1** complex (K_d) and the rate constant of the hydrolysis of **1** incorporated in the α-CD–**1** complex (k_c) were determined to be 3.4×10^{-3} mol dm^{-3} and 5.0×10^{-2} min^{-1}, respectively, by plotting the date in Fig. 2 according to Eq. 1;[1]

$$(k_{obsd}-k_{un}) = -K_d(k_{obsd}-k_{un})/[\alpha\text{-CD}]_0+(k_c-k_{un}) \quad (1)$$

The k_c (5.0×10^{-2} min^{-1}) is much larger than the rate constant of the hydrolysis of 4-nitrobenzoyl-α-CD (**4**) (3.1×10^{-3} min^{-1}), the reaction intermediate of the nucleophilic catalysis by the secondary alkoxide ion of α-CD. On the basis of this result, the nucleophilic catalysis by α-CD is definitely ruled out as the major catalysis associated with k_c.

The logarithm of k_{obsd} in the presence of 5×10^{-2} mol dm^{-3} α-CD, where about 94% of **1** form complexes with α-CD, increased linearly with pH (Fig. 3). This fact is consistent with participation of alkoxide ion of α-CD in the catalysis.

The k_{obsd} in the presence of 5×10^{-2} mol dm^{-3} α-CD in D_2O was 1.7 fold smaller than that in H_2O. Here, the difference between the pK_a of the secondary hydroxyl group of α-CD in H_2O and that in D_2O was taken as 0.6.[5] This D_2O solvent isotope effect, considerably different from unity, indicates the general

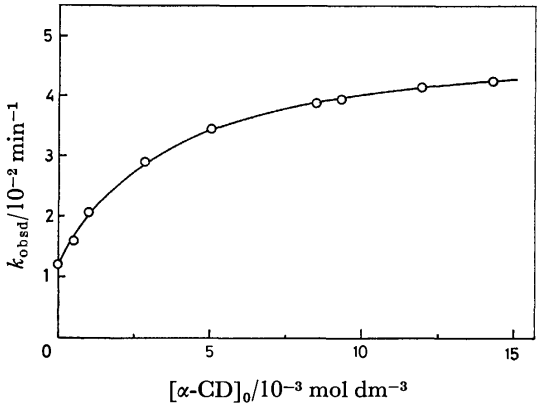

Fig. 2. Dependence of the rate constant of the hydrolysis of **1** (k_{obsd}) on the initial concentration of α-CD at pH 8.6, 16 °C; the k_{obsd}'s were determined from the rate of the appearance of 4-nitrobenzoate ion in the initial stage and are mostly associated with the general base catalysis by α-CD (see the text.).

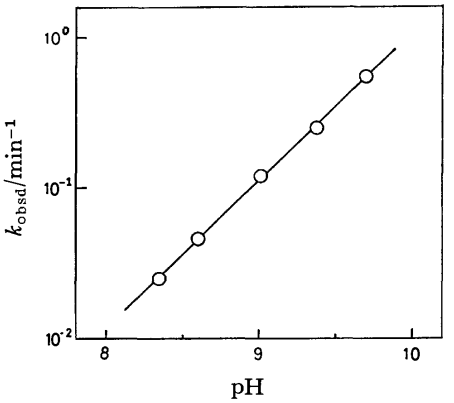

Fig. 3. pH-rate constant profile in the hydrolysis of **1** in the presence of the 5×10^{-2} mol dm^{-3} α-CD at 16 °C.

base catalysis by α-CD. The alkaline hydrolysis assisted by α-CD, which is kinetically indistinguishable from the general base-catalyzed reaction, is unlikely, since the alkaline hydrolysis should show an inverse D_2O solvent isotope effect because of larger nucleophilicity of OD^- than OH^- by 20—40%.[6]

In Fig. 1, the time course of [**4**] in the α-CD-catalyzed hydrolysis of **1**, determined as described in the Experimental Section, is also shown (the C curve). [**4**] first increased with time, showing a maximum around 30 min. The rate constant of the subsequent decrease of the C curve was identical with the independently determined value of the hydrolysis of 4-nitrobenzoyl-α-CD (**4**), 3.1×10^{-3} min^{-1} (see Experimental).

The appearance of **3** due to the nucleophilic catalysis by α-CD was shown by the C curve in Fig. 4, which was estimated by using [**4**] in Fig. 1 and the rate constant of its hydrolysis (3.1×10^{-3} min^{-1}). The amount of **3** due to the nucleophilic catalysis gradually increased with time after being essentially zero for around 30 min.

The B curve in Fig. 4 corresponds to the appearance of **3** due to the general base catalysis by α-CD. This curve is determined by subtracting the appearance of **3** due to the nucleophilic catalysis (the C curve) from the total appearance of **3** measured photometrically (the A curve).

The B curve in Fig. 4 fits well with the first-order kinetics. Table 1 lists the rate constant of the general base-catalyzed hydrolysis of **1** by α-CD as well as that of the nucleophile-catalyzed hydrolysis by α-CD. The second value was determined by using the rate of the appearance of **4** (the C curve in Fig. 1) and the concentration of the residual **1** at a certain time, estimated from the total consumption of **1** (the sum of

Table 1. Rate constants of the cleavage of **1**[a]

Catalysis	Rate constant/10^{-2} min^{-1}
General base catalysis by α-CD	5.3
Nucleophilic catalysis by α-CD	1.5
Uncatalyzed	1.2

a) pH 8.6, 16 °C.

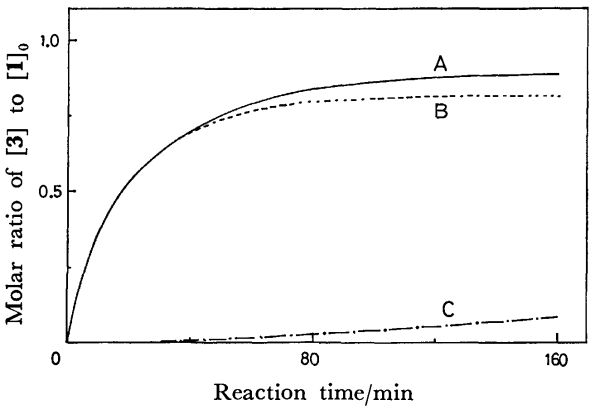

Fig. 4. Time courses of the hydrolysis of **1** in the presence of 5×10^{-2} mol dm^{-3} α-CD at pH 8.6, 16 °C; A, ——, the total amount of **3**; B, ----, **3** due to the general base catalysis by α-CD; C, —·—, **3** due to the nucleophilic catalysis by α-CD; the amount of **3** is represented by the molar ratio of its concentration to the initial concentration of **1**.

the B curve in Fig. 4 and the C curve in Fig. 1). The rate constant of the general base catalysis determined by the first-order plot of the curve B in Fig. 4 (5.3×10^{-2} min^{-1}) is almost identical with the value determined from the initial rate constants (k_{obsd}'s) in Fig. 2 (5.0×10^{-2} min^{-1}).

In contrast with the acceleration of the hydrolysis of **1** by α-CD, α-CD showed little effect on the hydrolysis of an analogous substrate, **2**. The rate constant of the hydrolysis of **2** at pH 11.5 (carbonate buffer), 16 °C in the presence of 5×10^{-2} mol dm^{-3} α-CD (1.4×10^{-2} min^{-1}) was virtually the same as that in its absence (1.3×10^{-2} min^{-1}). No deviation from the first-order kinetics was observed here.

Discussion

The present paper showed that about 80% of the hydrolysis of **1** complexed with α-CD proceeded *via* the general base catalysis by the secondary alkoxide ion of α-CD. This is the first finding of the general base catalysis of the hydrolysis of an ester by CD.

On the complex formation of **1** with α-CD, the nitrophenyl group of **1** included in the cavity with the nitro group first, since no catalysis of α-CD was observed in the hydrolysis of **2** in contrast with the considerable acceleration of the hydrolysis of **1**. The predominant role of the steric hindrance by the adjacent methyl group in the complex formation of **2** with α-CD is consistent with the previous finding that the complex formation of 4-nitrophenol with α-CD is totally inhibited by the methyl substitution of 4-nitrophenol at the 3 position.[7] The structure of the α-CD–**1** complex, where the nitrobenzene group of **1** locates inside the cavity of α-CD, is further supported by the fact that the K_d of this complex (3.4×10^{-3} mol dm^{-3}) is close to that of α-CD–4-nitrophenol complex (5.2×10^{-3} mol dm^{-3}).[7]

The mechanism of the general base catalysis of the hydrolysis of **1** by α-CD is schematically depicted in Fig. 5. A secondary alkoxide ion of α-CD enhances

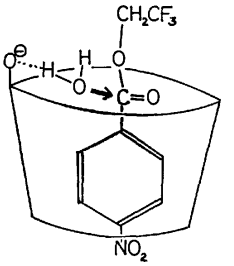

Fig. 5. Mechanism of the general base catalysis of the hydrolysis of **1** by α-CD.

the nucleophilic attack of a water molecule at the carbonyl carbon atom of **1** by partially abstracting a hydrogen atom from the water molecule.

The effectiveness of the general base catalysis by α-CD is attributable to the complex formation of **1** with α-CD, where the secondary alkoxide ion of α-CD functions as an intracomplex catalyst. The rate constant of the intermolecular general base catalysis of the hydrolysis of **1** by the alkoxide ion of α-CD, a base of pK_a 12,[1] was estimated as follows. First the rate constant of the general base-catalyzed hydrolysis of 2,2,2-trifluoroethyl acetate by *N*-methylimidazole (2.3×10^{-4} mol^{-1} dm^3 min^{-1})[8] was converted to the corresponding value of **1** (6.2×10^{-3} mol^{-1} dm^3 min^{-1}) by multiplying the ratio of the rate constant of the alkaline hydrolyses of these two substrates (2.7×10^2).[9] The conversion of the rate constant of the general base-catalyzed hydrolysis of **1** by *N*-methylimidazole (pK 7.0)[10] to that by the secondary alkoxide ion of α-CD (pK_a 12) was made by use of the Brønsted relationship, taking the α for this reaction as 0.5.[11] Consequently, the rate constant of the intermolecular general base-catalyzed hydrolysis of **1** by the secondary alkoxide ion of α-CD was estimated to be 2 mol^{-1} dm^3 min^{-1}. On the other hand, the rate constant of the general base-catalyzed hydrolysis of **1** in the α-CD–**1** complex, referring to the total ionization of α-CD, is calculated to be 1.3×10^2 mol dm^{-3} from the observed value at pH 8.6 (5.3×10^{-2} min^{-1}) and the pK_a of α-CD (12). Thus, the intracomplex general base catalysis of the secondary alkoxide ion of α-CD in the hydrolysis of **1** is equivalent to the catalysis by as large as 65 mol dm^{-3} [12] of the corresponding intermolecular catalyst.

Two reasons are responsible for the small contribution of the nucleophilic catalysis of α-CD in the hydrolysis of **1** in spite of effective nucleophilic catalyses in the hydrolyses of phenyl acetates[13] and *S*-ethyl thiobenzoate.[14] The first reason is that the pK_a of the leaving group, 2,2,2-trifluoroethanol (12.37)[15] is a little bit larger than the pK_a of the secondary hydroxyl group of α-CD (12). Thus, the tetrahedral intermediate, formed by the nucleophilic attack of the secondary alkoxide ion of α-CD at the carbonyl carbon atom of **1**, should return to α-CD and **1** more favorably than produce the products, **3** and **4**. The second reason comes from the structure of the α-CD–**1** complex, in which the nitrobenzene group is located inside the cavity of α-CD. In order for the nucleophilic catalysis to take place, the nitrobenzene group must be taken out of the cavity in the course of the

catalysis, since 4-nitrobenzoyl–α-CD with the nitrobenzene group inside the cavity is too much sterically strained to be formed. This structural change should reduce the rate constant.

In conclusion, the hydrolysis of 2,2,2-trifluoroethyl 4-nitrobenzoate (**1**) catalyzed by α-cyclodextrin (α-CD) proceeds mostly (80%) *via* general base catalysis with 20% contribution of nucleophilic catalysis. The complex formation of **1** with α-CD involves the inclusion of the nitrobenzene group with the nitro group first.

The authors wish to thank Prof. Hidefumi Hirai at The University of Tokyo for his valuable comments.

Coordinative Role of Alkali Cations in Organic Reactions. V. The Perkin Reaction

Narinder S. Poonia,* Swagata Sen, Prafulla K. Porwal, and A. Jayakumar
Department of Chemistry, University of Indore, Indore-1, India

(Received October 1, 1979)

The Perkin condensation of benzaldehyde (PhCHO) and acetic anhydride (Ac_2O) in the presence of an alkali acetate (M^+OAc^-) involves extensive participation of M^+ and takes place best with K^+OAc^-. Employing an excess of meticulously dehydrated K^+OAc^-, a record high yield of cinnamic acid ($\approx$75%) can be obtained in a 60 min reaction. The product of the reaction before hydrolysis is not PhCH=CHCOOCOCH$_3$ as usually believed but potassium cinnamate plus K^+(OAc, HOAc)$^-$. Conductometric solution stability studies on M^+-ligand (M^+=Na^+ and K^+; Ligand=PhCHO, *o*-$NO_2C_6H_4CHO$, *o*-HOC_6H_4CHO) systems in 2-propanol show that stability sequences for PhCHO and *o*-$NO_2C_6H_4CHO$ are NaOAc<KOAc and KOAc<NaOAc, respectively. These are in line with the catalytic efficiency these salts displayed during the condensation reaction. *o*-HOC_6H_4CHO, for which the Perkin condensation is extremely poor, is practically non-complexing with M^+OAc^- in 2-propanol.

It is a rather established belief[1] that in the organic reactions involving caustic alkalis (M^+OH^-) and alkali salts (M^+X^-) the anion of the inorganic reactant is the only or the main participant in the reaction. Because of our experience in the coordination chemistry of these cations,[2] we initiated work on some such reactions and found that M^+ is very important in determining the route[3,4] as well as the efficiency[3-7] of the reaction and discussed such features of alkali and alkaline earth cations as one of the main themes related to their coordination chemistry.[8] In the course of our work we noticed that participation of M^+ was discussed in the nineteen fifties and sixties with respect to reactions such as the aldol condensation of esters with ketones,[9] certain displacement reactions[10] and the benzil-benzilic acid rearrangement[11] but these reports do not appear to have stimulated other workers.

In this article we discuss the role of M^+ during the Perkin reaction, in particular with respect to the synthesis of cinnamic acid. The Perkin reaction is one of the most general organic reactions[12] and has also been reviewed repeatedly.[13-16] Of the various conflicting views about its mechanism the most accepted is that for a system such as PhCHO–Ac_2O–M^+OAc^-, the OAc^- works as a nucleophile and eliminates the α-proton of Ac_2O to produce the carbanion which condenses with PhCHO (Scheme 1).

In the absence of an ionising medium, however, it is difficult to visualize how the chelating OAc^- can be charge-separated from the formally charged M^+ in preference for a feebly charged α-proton of Ac_2O unless M^+ is effectively stabilized through coordinative interactions with PhCHO and Ac_2O. Detailed studies on cinnamic acid synthesis employing K^+OAc^- reveal that K^+ is extensively involved in the reaction and that the product of the reaction before hydrolysis is not A (Scheme 1) but potassium cinnamate plus K^+(OAc, HOAc)$^-$. A record high yield of cinnamic acid ($\approx$75% for a condensation period of 60 min as against 60% and 72% for condensation periods of five[17] and eight[18] hours, respectively) is obtained by using excess potassium acetate. The results of the Perkin reaction with respect to PhCHO, *o*-$NO_2C_6H_4CHO$, and *o*-HOC_6H_4CHO are discussed in the light of their complexing ability toward M^+OAc^- in a medium of low polarity (2-propanol).

Results and Discussion

Synthetic Studies. For the synthesis of cinnamic acid it is known that the yield of the reaction product is drastically decreased when K^+OAc^- in the reaction is replaced by Na^+OAc^-.[19] We confirm this and show further (see Table 1) that the reaction almost fails when Li^+OAc^- is used. This is, obviously, because the M^+OAc^- ion pair is increasingly tight in the order $K^+<Na^+<Li^+$ so that the activity of OAc^-, the complexation of M^+ with PhCHO and Ac_2O, and hence the dissolution of M^+OAc^- in the latter reactants all become increasingly unfavored.

Detailed work with K^+OAc^- revealed that the primary products of the reaction are potassium cinnamate and the acid salt, K^+(OAc, HOAc)$^-$ as evident from the spectra of the reaction products (d to f) in comparison with those of the standard samples (a to c) in Fig. 1. Comparison of the spectra d to f with that of the 1:1 K^+Cin^-–K^+(OAc, HOAc)$^-$ (spectrum c) reveals that the K^+Cin^- contribution dominates when less K^+OAc^- is used in the reaction (spectrum d) and that the K^+(OAc, HOAc)$^-$ contribution dominates

2 : 2 : 1[i]	48

a) All experiments were carried out under nitrogen atmosphere. b) Average of three experimental results, the reaction yield of which varied within ±1%. c) This particular proportion of the reactants has usually been recommended.[17] d) The Perkin condensation is a typically time-dependent and a slow reaction; with this proportion of the reactants the yield is increased to 39% and 72% with Na^+OAc^- and K^+OAc^- respectively, when reaction time was increased to 8 h. e) On addition of the reation product to water, free cinnamic acid is insolubilized in low yield (2—5%) as observed earlier,[1] but this byproduct gradually disappears as K^+OAc^- in the reaction is increased. This may be attributed to partial hydrolysis of potassium cinnamate with the residual amount of AcOH which can persist in reaction mixtures offering insufficient K^+OAc^- for its conversion into $K^+(OAc, HOAc)^-$. f) The yield of cinnamic acid decreases if reaction time is decreased any further but is practically constant if the time is increased even to as long as 8 h. g) The yield of cinnamic acid decreased because of displacement of one reactant from K^+ by the other which is used in excess; the effect is pronounced when the bidentate and hence strongly complexable Ac_2O is used in excess. h) The benzene wash of the reaction product was found to contain potassium cinnamate which was, obviously, carried into this non-polar phase through complexation with Ac_2O. i) The amount of potassium cinnamate in the benzene phase increased further which indicates that PhCHO acts as a co-ligand during complexation (and hence benzene solubilization) of potassium cinnamate with Ac_2O.

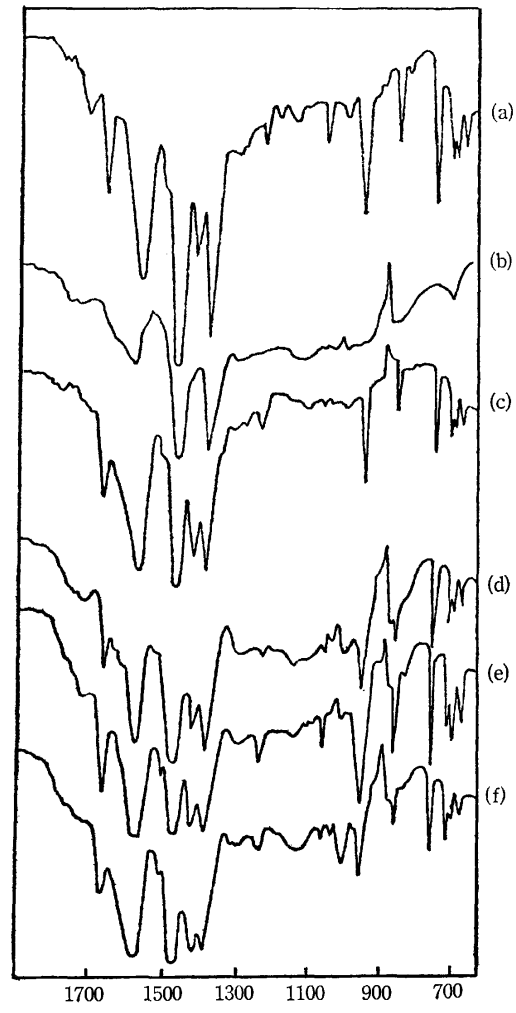

Fig. 1. Showing infrared features (1700—700 cm^{-1}) of some authentic samples [a, potassium cinnamate, b, $K^+(OAc,HOAc)^-$, and c, a 1:1 physical mixture of potassium cinnamate and $K^+(OAc,HOAc)^-$ which was heated at ≈180 °C for 30 min] and products of the Perkin condensation employing different proportions of PhCHO, Ac_2O, and K^+OAc^- [d, 1:1:1; e, 1:1.5:0.6 and f, 1:1.5:2.5].

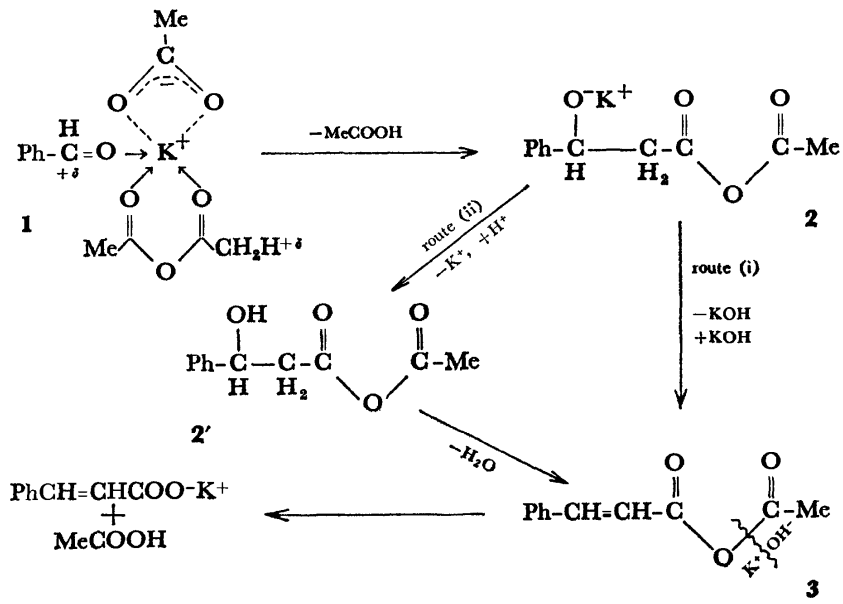
when excess K^+OAc^- is used (spectrum f).

Direct production of potassium cinnamate may be attributed to an interactive organisation[8] of the reactants as shown in Scheme 2. This interactive mode helps (i) PhCHO to develop the required carbonium character, (ii) Ac_2O to have its α-proton cationized, and (iii) K^+OAc^- to become the loose ion pair required to make OAc^- an available nucleophile. Above all, the energy of coordinative interaction of PhCHO and Ac_2O with K^+OAc^- should help the thermodynamically unfavorable processes, *viz.*, charge separation of K^+OAc^- and cleavage of the $C–H_\alpha$ covalent bond. That the alkali cation is required for such an interactive organisation is evidenced by the failure of the condensation when the cation in the reaction is concealed through sandwich encapsulation using benzo-15-crown-5.[20] Simultaneous interaction of PhCHO and Ac_2O with K^+OAc^- is evidenced by the observation that the yield of the reaction is drastically lowered when either PhCHO or Ac_2O is displaced from K^+OAc^- by using the other in excess (see Table 1).

Coordination of K^+OAc^- with PhCHO and Ac_2O



Scheme 2.

is also supported by the observation that the salt can be solubilised just in PhCHO and particularly when Ac_2O is also present. When PhCHO and Ac_2O are used in excess during condensation, even the reaction product, potassium cinnamate, gets complexed and rendered benzene-soluble (see Experimental). Stable solid solvates of alkali and alkaline earth salts involving coordinated PhCHO[21,22] acetone,[21,23] and other ketones[23] have long been characterised.

Accurate kinetic work on this reaction cannot be carried out because it is a high temperature reaction and each organic reactant is unstable with time. Synthesis of a stoichiometric PhCHO–Ac_2O–K^+OAc^- complex is also not possible for it requires a coordinative ligation of a ligand with the cation to be of a particular minimum strength which is apparently not so with PhCHO and Ac_2O.

During the reaction, Ac_2O is susceptible to hydrolysis by moisture which can be incorporated in the system through the hygroscopic K^+OAc^-. AcOH produced by hydrolysis reduces also the effective concentration of K^+OAc^- through the formation of $K^+(OAc, HOAc)^-$. If, on the contrary, an excess of meticulously dehydrated K^+OAc^- is used (see Table 1) a record high yield of cinnamic acid (≈75%) can be obtained by refluxing the reactants just for 60 min. This may in part be because excess K^+OAc^- serves to bind the deleterious byproduct of the reaction, AcOH, and partly because it may help shift the reaction equilibria toward the complexation required for "cationization" of PhCHO and carbanion formation of Ac_2O. In condensation reactions employing M_2CO_3, the favorable role of the alkali has been attributed to its neutralizing action toward HOAc.

Solution Studies. Conductometric studies in the feebly polar 2-propanol reveal (Figs. 2 and 3, Table 2) that K^+OAc^- undergoes a 1:1 interaction with PhCHO ($\log K=2.48$) and Ac_2O ($\log K=3.23$). Na^+OAc^-, which is less favorable for Perkin condensations, interacts relatively weakly with PhCHO ($\log K=2.08$) as well as Ac_2O ($\log K=2.35$). Li^+OAc^-, which does not aid the condensation, behaves insoluble and hence tightly ion-paired in 2-propanol. The most facilitated complexation of K^+ may be attributed to its large size (low charge density) because of which it is comparatively loosely paired with OAc^- (see K_d values in Table 2), and gets effectively polarized by the donor atoms of the neutral ligands. The fact that Ac_2O complexes K^+ more strongly than does PhCHO explains why, in reactions employing a dis-

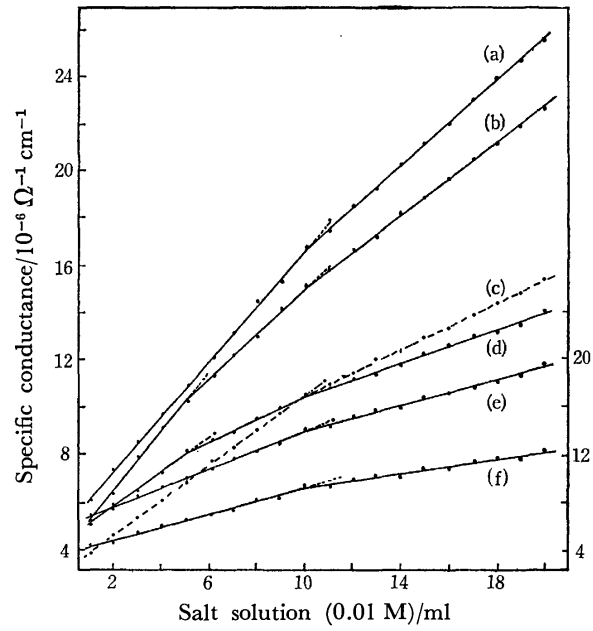


Fig. 2. Specific conductance *versus* salt concentration plots for K^+OAc^- in presence of (a) $NO_2C_6H_4CHO$, (b) Ac_2O, and (c) PhCHO, and for Na^+OAc^- in presence of (d) $NO_2C_6H_4CHO$, (e) Ac_2O and (f) PhCHO. Conductance scale on the right refers to Na^+–OAc^- systems.

Table 2. Dissociation constants (K_d) of M^+OAc^- and log of formation constants (log K) of their complexes with aromatic aldehydes and acetic anhydrides; medium, 2-propanol; temperature 25±1 °C

Salt	K_d mol l^{-1}	System	Stoichiometry	log K
KOAc	2.19×10^{-6}	KOAc-PhCHO	1 : 1	2.48
		KOAc-$NO_2C_6H_4CHO$	1 : 1	2.03
		KOAc-Ac_2O	1 : 1	3.23
			1 : 2	—
NaOAc	5.49×10^{-8}	NaOAc-PhCHO	1 : 1	2.08
		NaOAc-$NO_2C_6H_4CHO$	1 : 1	2.47
			1 : 2	—
		NaOAc-Ac_2O	1 : 1	2.35

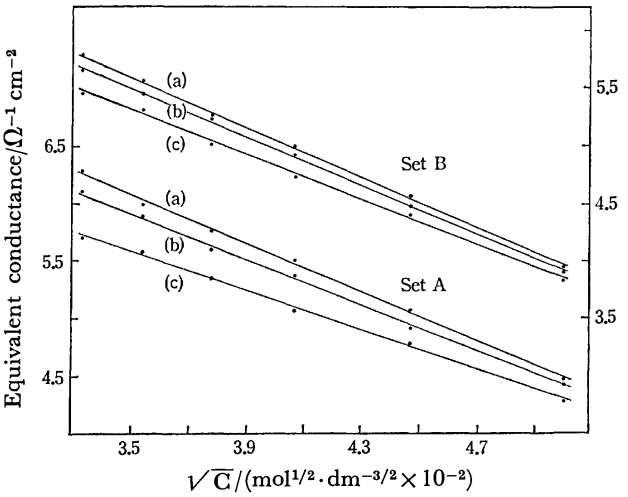

Fig. 3. Equivalent conductance versus salt concentration plots which were used to determine the solution stability values. Set A (K^+OAc^-–PhCHO systems); (a) K^+OAc^-, (b) K^+OAc^-–PhCHO (1:1), and (c) K^+OAc^-–PhCHO (1:10). Set B (K^+OAc^-–Ac_2O systems); (a) K^+OAc^-, (b) K^+OAc^-–Ac_2O (1:1), and (c) K^+OAc^-–Ac_2O (1:10). Conductance scale on the right refers to Ac_2O systems.

proportionately high amount of either of these two, Ac_2O is more effective in reducing the efficiency of the condensation (through displacement of PhCHO from K^+). *o*-HOC_6H_4CHO, which yields only traces of *o*-hydroxycinnamic acid by Perkin reactions,[24] has been found to be practically non-interacting with Na^+-OAc^- or K^+OAc^-.[25]

o-$NO_2C_6H_4CHO$ shows a strong complexation with Na^+OAc^- as well as K^+OAc^- (Table 2) and synthesis of *o*-nitrocinnamic acid is also possible with both.[26] Contrary to what has been noted for PhCHO, however, the stability value is high for Na^+OAc^- and, interestingly, yields of *o*-nitrocinnamic acid in Perkin reaction is also higher for Na^+OAc^-. One of the possible interacting sites of the nitroaldehyde with M^+ is the nitro oxygen which, being linked to the electronegative nitrogen, can be visualized as "reinforced"[8] or "anionic" and hence a more preferable site for the comparatively anionphilic Na^+.[27]

The Condensation Mechanism. Detailed studies on PhCHO–Ac_2O–M^+OAc^- reveal that even before the water treatment the product of the reaction is potassium cinnamate. Obviously, the reaction intermediate (*e.g.*, A in Scheme 1 or **3** in Scheme 2) undergoes molecular degradation right during condensation through some bond cleavage process. Understandably, therefore, **2** loses MOH (*cis*-elimination of M^+ and OH^-) to produce an unsaturated intermediate **3** and MOH molecule then causes bond cleavage of **3** as shown in Scheme 2. That MOH and not M^+OAc^-, is involved in bond cleavage, appears to be supported by the observation that the alkali cinnamate can be produced from a reaction mixture containing less than an equivalent amount of M^+OAc^- such as from PhCHO:Ac_2O:M^+OAc^- (1:1.5:0.6) (see Fig. 1).

There is a likelihood of K^+/H^+ exchange between **2** and MeCOOH so that **2′** is produced (Route (ii)). The water molecule which gets eliminated from the latter, however, has the only recourse of hydrolyzing MOAc and especially Ac_2O. The hydrolysis of the latter appears evidenced by the observation that for obtaining maximum efficiency of the reaction, use of some excess Ac_2O is a requirement (see Table 1).

The suggested mechanism involving simultaneous coordinative organization of the three reactants sorts out earlier conflicts wherein either AcO^-–Ac_2O[28,29] or AcO^-–PhCHO[28,30] interaction has been argued to be a possible triggering step for the condensation. Since alkali cinnamate is the product of the reaction the Perkin's original diacetate mechanism,[31] which has already been disputed[30,32] becomes even less acceptable.

During the *o*-$NO_2C_6H_4CHO$–Ac_2O condensation in the presence of $PhCH_2COONa$, ML, the acid salt $Na^+(PhCH_2COO, PhCH_2COOH)^-$, MLHL, has been detected and considered to be an intermediate of the reaction[33a] because reaction of this acid salt with a mixture of *o*-$NO_2C_6H_4CHO$ and Ac_2O yielded the α,β-unsaturated acid. This view, however, does not present anything new and infact creates confusion because use of this MLHL (wherein L and HL are only hydrogen bonded) at a high reaction temperature amounts to the use of ML plus HL and ML as a participating species. We have failed to synthesize cinnamic acid by the reaction of $K^+(AcO, AcOH)^-$ and PhCHO. Detection of the acid salt as a product (infact byproduct), however, is understandable as we, too, detected in the present work.

The rather "modern view" involving the formation

and participation of alkali salt of enolic acetic anhydride[13] appears unlikely because we failed to synthesize an alkali enolate by the direct reaction of Ac_2O and Na^+OAc^- or K^+OAc^- at 180 °C.[33] Since the condensation temperature (180 °C) is well below the fusion temperature of Na^+OAc^- (324 °C) and K^+OAc^- (299 °C), possible reaction routes involving $^-CH_2COO^-$ (which is believed to exist in fused M^+OAc^-) are also ruled out.

Experimental

Synthesis Procedure. Using 22.5 mmol (2.39 g) as a unit of weight for PhCHO, the PhCHO–Ac_2O–K^+OAc^- mixtures were fused at 180±2 °C in different proportions for different time periods (see Table 1) under a nitrogen atmosphere. The fused solid product was cooled and divided into two equal parts. One part was subjected to the recovery of cinnamic acid to determine its yield following the conventional procedure. The other part was subjected to qualitative examination for which the residue was first scrubbed with benzene or acetone (50 ml) and filtered. The washed residue was subjected to hot stage microscopy and infrared spectroscopy which indicated it to be potassium cinnamate plus $K^+(OAc, HOAc)^-$ (see Fig. 1). The organic filtrate, which contains the polymeric material and the unused PhCHO and Ac_2O plus potassium cinnamate complex involving PhCHO and Ac_2O, was evaporated to dryness in the open to destroy the unused reactant and to decompose the complex. The organic matter from this residue was eliminated by washing with benzene or acetone. The clarified residue was found to be pure potassium cinnamate, the amount of which was found to be in accordance with the amount of PhCHO and Ac_2O used in the reaction.

Condensation in Absence of Alkali Cation. Potassium acetate (1 mmol, 0.098 g) was scrubbed in the absence of moisture with benzo-15-crown-5 (2 mmol, 0.536 g). The solid mixture was treated with PhCHO (1 mmol, 0.106 g) and Ac_2O (1 mmol, 0.102 g). The reaction mixture was subjected to condensation at 180±2 °C for five hours and then processed for the recovery of cinnamic acid following the conventional procedure. A polymeric product instead of cinnamic acid was obtained.

Conductometric Solution State Studies. Stock solutions of the salt (10 mmol) and the ligands (2.5 mmol) were prepared in anhydrous 2-propanol. Complexation and stoichiometry of the resultant complex was followed adopting the conductometric monovariation titration technique[34] while solution stability of each complex was determined following the Matsuura's conductometric dilution technique.[35] For the monovariation technique 40 ml of the ligand solution was titrated with the salt solution (1—25 ml) while applying volume correction.[36] Since for each system which indicated complexation, the initially formed biligand (1:2) complex was converted to a 1:1 complex on the addition of more salt, Matsuura's method was followed to determine the stability of the apparently more stable 1:1 species only. Figure 2 shows the stoichiometry of the selected complexes while Fig. 3 displays the exemplary sets of the phoreograms obtained for the systems K^+OAc^-–PhCHO and K^+OAc^-–Ac_2O.

Configuration Analysis and Electronic State Properties. III. Ten-π-electron Systems

Giuseppe Buemi
Istituto Dipartimentale di Chimica e Chimica Industriale, Università di Catania, Viale A. Doria 8, 95125 Catania, Italy

(Received November 8, 1979)

The electronic state properties of the nonbenzenoid hydrocarbons fulvalene, heptatriafulvalene, dimethylenebenzocyclobutene, [5]radialene, 8-vinylheptafulvene, 1,2-benzofulvene and 2,3-benzofulvene have been studied by means of MIM and PPP-configuration analyses. The resonance integrals evaluated by Kon's equation are satisfactory for the MIM method but not for PPP. On the whole the general spectral trend is fairly predicted by both approximations, the wavefunction composition being in line with the first electronic transitions. The lower energy electronic transitions are found to be a mixture of locally excited and charge transfer states while those computed at higher energy have prevailing charge transfer character.

The electronic state properties of several nonbenzenoid hydrocarbons having four, six and eight π-electrons have been studied[1,2] by means of PPP[3] and MIM methods,[3,4] employing the configuration analysis procedure[5] to interpret the results of PPP calculations directly in terms of the locally excited (Λ) and charge transfer (T_m^k) configurations of the localized orbital model. In this paper the same procedure is extended to the following molecules, having a ten-π-electron system: fulvalene (I), heptatriafulvalene (II), dimethylenebenzocyclobutene (III), [5]radialene (IV), 8-vinylheptafulvene (V), 1,2-benzofulvene (VI) and 2,3-benzofulvene (VII).

Ethylene, *cis*- or *trans*-butadiene and benzene were considered as component systems in MIM model. Their SCF-MOs excited states composition and all the parameters required by the adopted methods are the same as in previous papers.[1,2] The experimental transition energies of ethylene are taken from Ref. 6. Both in MIM and PPP approximations all the monoexcited configurations were considered in the configuration interaction treatment, but in the former method the lowest occupied and highest vacant molecular orbitals of the benzene systems were excluded since they are not necessary for its UV spectrum description.

The topology of the compounds examined is shown in Fig. 1. The ground state charge densities and bond orders obtained are given in Table 1.

Fulvalene (1,1'-Bicyclopentadienylidene) (I). This molecule has been the subject of numerous studies at different level of calculations[7–13] including CNDO/CI;[14] its negative topological resonance energy (TRE) indicates that it is an antiaromatic and very reactive compound.[15] The UV spectrum shows a weak absorption band at 2.9—3.0 eV and an intense band at 3.9—4.0 eV.[7,14] My calculation for which the molecular geometry reported by Brown et Coll.[7] was adopted has been performed by assuming, at MIM level, five ethylene molecules (MIM/A) or two *cis*-butadiene and one ethylene molecules (MIM/B) as component systems. The results obtained are compared with those of PPP-configuration analysis (Table 2). PPP correctly predicts the experimental order of the electronic transitions in contrast to MIM, by which the lowest energy electronic transition was obtained as the most intense one. From the energy order of PPP results, the first electronic transition having prevailing charge transfer character is computed at 3.63 eV (calculated

a) a, b, c, d, and e denote the ethylenic fragments C_1=C_2, C_3=C_4, C_5=C_6, C_7=C_8, and C_9=C_{10}, respectively.

at 3.57—2.91 eV by MIM/A and MIM/B, respectively) and should be assigned to the forbidden $^1B_{1g}\leftarrow{}^1A_{1g}$ transition.

The second electronic transition, polarized along the short molecular axis (x) and computed at 3.81 eV by PPP and at 3.39—3.03 eV (in agreement with experimental result) by MIM/A and MIM/B, is assigned to a $^1B_{3u}\leftarrow{}^1A_{1g}$ transition. It shows noticeable percentage of locally excited states but the largest weights are those due to electronic transfers partially localized inside the two cyclopentadienyl systems and partially directed towards the "external" molecular ethylenic fragment joining the two pentatomic rings. This composition closely resembles that of the lowest energy $^1B_2\leftarrow{}^1A_1$ transition in fulvene, calculated in the range 2.9—3.3 eV.[1]

The most intense third electronic transition, corresponding to the strong absorption band at ≃4.0 eV, is predicted at 4.76 eV by PPP, very close to the value of 4.93 eV obtained by Marschner and Pohle,[10] and at 3.11—2.77 eV by MIM/A and MIM/B. It is a $^1B_{2u}\leftarrow{}^1A_{1g}$ transition polarized along the y molecular axis and results principally from the electronic transfer from the "external" ethylene fragment to the two cyclopentadienyl rings. A similar situation is encountered in the $^1A_1\leftarrow{}^1A_1$ transition of fulvene,[1]

computed by MIM at 3.6—4.0 eV shifting to lower energy in fulvalene by the higher percentage of charge transfer states.

Three electronic transitions, all with predominant charge transfer character and theoretically forbidden, were calculated at 6.44, 6.69 and 6.83 eV by PPP and at 5.31—4.66 eV, 5.86—5.35 eV and 6.11—6.24 eV by MIM/A and MIM/B, respectively. They are assigned to $^1A_{1g}\leftarrow{}^1A_{1g}$, $^1B_{1g}\leftarrow{}^1A_{1g}$, and $^1A_{1g}\leftarrow{}^1A_{1g}$ transitions, in order of sequence.

Two other allowed transitions follow at 7.02 and 7.23 eV calculated by PPP, and at 5.78—5.69 and 6.22—5.92 eV by MIM (the first figure refers to MIM/A, the second to MIM/B). The former, of $^1B_{3u}\leftarrow{}^1A_{1g}$ type, x-polarized, is the predicted charge transfer if MIM/A results are taken into account, a mixture of locally excited (Λ_{1a}, Λ_{1c}) and charge transfer states if the MIM/B results are considered. In both cases, however, its composition resembles that of the $^1B_2\leftarrow{}^1A_1$ transition in fulvene at 6.45 eV[1] with some percentage variation due to the presence of two pentatomic rings in fulvalene. The latter, $^1B_{2u}\leftarrow{}^1A_{1g}$, y-polarized transition, is nearly exclusively due to charge transfers between the ethylene molecules constituting the cyclopentadienyl rings (MIM/A results), and to charge transfers involving the whole π-system with a greater

percentage of locally excited states (MIM/B results). The composition is similar in the corresponding $^1A_1 \leftarrow {}^1A_1$ transition at 6.28 eV in fulvene.[1] It is evident that all the allowed transitions found in fulvalene correspond to the electronic transitions of fulvene as well as in energy and composition.

Heptatriafulvalene (II). The PPP results[16] subjected to configuration analysis are compared with the MIM ones, the energies and oscillator strengths obtained by using Kon's resonance integrals being given (Table 3). Since no experimental spectrum of heptatriafulvalene has been found in the literature a comparison with the theoretical data is not possible, however a discussion about the theoretical transitions is possible with reference to the heptafulvene and triafulvene molecules. The first electronic transition,

having $^1B_2$ symmetry, is calculated by PPP at 2.38 eV[16] or at 3.68 eV (2.09 eV according to CNDO/CI calculations[14]), whilst MIM predicts it at 3.37 eV. Its prevailing charge transfer tendency is evident, but the ethylenic fragment *e* (component of the cyclopropenyl ring) does not appreciably participate to the wavefunction composition. The transition seems to be the same as that at 3.46—3.98 eV (MIM-PPP)[2] and experimentally observed at 2.91 eV[16] in heptafulvene. It would lie at *ca.* 2.8—2.9 eV in the heptatriafulvalene absorption spectrum, probably as a shoulder.

The second electronic transition, computed at 4.15 eV by MIM, at 3.45 eV[16] or 5.05 eV by PPP and at 3.45 eV by CNDO/CI[14] corresponds to the analogous $^1B_2 \leftarrow ^1A_1$ transition found in triafulvene at 4.83—5.48 eV (standard MIM and PPP calculations respectively[1]) and at 4.08 eV in calicene.[2] Even if a consistent percentage of the locally excited state Λ_e is present, the remarkable electronic transfer from ethylene *d* to ethylene *e* determines a spectral shift of about 2 eV with respect to the component molecules.

The third theoretical transition, of $^1A_1 \leftarrow ^1A_1$ type, polarized along the y axis, is the most intense, showing conjugative character. It was calculated at 3.91 eV by CNDO/CI[14] and at 4.27 eV[16] or 5.07 eV by PPP. By MIM it is predicted at 3.22 eV as the lowest energy transition with a strong bathochromic shift with respect to the corresponding transition in heptafulvene (3.94 eV[2]).

The fourth ($^1B_2 \leftarrow ^1A_1$) and fifth ($^1A_1 \leftarrow ^1A_1$) electronic transitions, computed by PPP at 5.91 and 5.96 eV[16] or 6.43 and 6.58 eV (Kon's resonance integrals) and by MIM at 4.94 and 5.36 eV, still have predominating charge transfer character involving the whole π-system shifted at lower energy with respect to the analogous transitions found in heptafulvene.

As in calicene,[2] the triatomic ring is positively charged and the total weight of the PPP-CA states is found to be rather low.

Dimethylenebenzocyclobutene (III). Theoretical and experimental geometrical data concerning the dimethylenebenzocyclobutene molecule are lacking. An improved LCAO method,[17] taking into account both σ and π energy applied to determine the molecular structure and the UV spectrum, shows that the benzene bond lengths are not appreciably different from their standard value of 1.397 Å, the cyclobutene ring being nearly square. The PPP-SCF-MO-LCAO method, modified to take into account the effect of neighbouring atoms[18] gives different results depending on the starting geometry. Since in planar molecules slight differences in bond angles of bond lengths do not appreciably affect the calculated spectra, the benzene ring was chosen as a regular hexagon with all bond lengths equal to 1.4 Å while the values found by electron diffraction studies[19] were taken for the remaining bond lengths and bond angles relative to the dimethylenecyclobutane fragment. At MIM level benzene and two ethylene molecules (MIM/A), or benzene and *cis*-butadiene (MIM/B) were considered as component systems. Similar results obtained in the two cases are compared with the PPP ones (after application of configuration analysis) in Table 4.

The experimental UV absorption spectrum in ethanol[20] exhibits very close maxima in the range 3.7—4.0 eV which would be partially due to bond vibrations. The first weak electronic transition, calculated at 4.34—4.16 eV by MIM and at 4.60 eV by PPP, could be correlated with the absorption in the above region. It closely resembles the bonzenic α band as supported by the large weight relative to the benzenic configuration Λ_{1a} and it is assigned to a $^1A_1 \leftarrow ^1A_1$ transition.

The second, $^1B_2 \leftarrow ^1A_1$, y-polarized transition, calculated at 4.68—4.56 eV by MIM/A and MIM/B, respectively, and at 4.84 eV by PPP, corresponds to the absorption band experimentally observed at 4.52 eV.[20] According to MIM results the predominating weights in its wavefunction composition are those due to locally excited ethylenic (MIM/A) or butadienic (MIM/B) configurations together with electronic transfers between the two ethylenic component systems (MIM/A) or from butadiene to benzene (MIM/B). PPP results, on the contrary, attributes to this transition a benzenic nature. This on the basis that the predominant weight in the relative wavefunction is that of the Λ_{2a} configuration which corresponds to the benzenic p-band.

The third electronic transition is predicted as the most intense transition and is polarized along the x-axis ($^1A_1 \leftarrow ^1A_1$). It is estimated by MIM at 4.93—4.57 eV and by PPP at higher energy (6.08 eV) as a mixture of locally excited and charge transfer states and should be correlated with the intense absorption band observed at 5.4 eV ($\log \varepsilon = 4.8$).

The fourth is a $^1B_2 \leftarrow ^1A_1$, y-polarized, weak transition calculated at 5.36—4.92 eV (MIM/A and MIM/B) and 6.38 eV (PPP). It originates from locally excited and charge transfer configurations involving all the component systems.

The fifth $^1A_1 \leftarrow ^1A_1$ transition is predicted at 5.65—5.22 eV (MIM) and 6.76 eV (PPP) as a forbidden transition, even though an oscillator strength of 0.14 is given by MIM/B. MIM/A points out the charge transfer character of this transition in contrast with MIM/B results predicting an equilibrium between charge transfer and locally excited configurations. The transitions having $^1B_2$ symmetry show different compositions in MIM and PPP approaches. Particularly, while the $^1B_2 \leftarrow ^1A_1$ transitions exhibit a comparable energy calculated by the MIM and PPP methods, the composition of their wavefunctions seem to be interchanged, *i.e.* the composition calculated by the MIM for the transition at 4.56—4.84 eV agrees better with the one calculated by PPP for the transition at $\simeq$6.6 eV, and *vice versa*. In any case however, the agreement is scarcely satisfactory. The second and third electronic transitions of $^1A_1$ symmetry have a composition approximatively comparable with that of the corresponding ones of dimethylenecyclobutene.

The biexcited configurations calculated by configuration analysis (not included in PPP and MIM calculations) have negligible weight (each of them appears with a percentage lower than 1%) so that they should not affect the results. From PPP results,

in which all the monoexcited configurations were included some wavefunctions relative to transitions at energies higher than those given in Table 4, show a noticeable percentage of configurations involving the lowest occupied and the highest vacant benzenic molecular orbitals. A calculation at MIM level in which these configurations were taken into account gave no appreciable variation in energy or composition of the first excited states.

[5]Radialene(Pentamethylenecyclopentane) (IV). The [5]radialene molecule, not known as yet, has been assumed as a regular pentagon with single bond lengths of 1.467 Å and double bonds of 1.366 Å.[21]

The first degenerate electronic transition calculated at 3.57—5.09 eV (MIM-PPP) is a mixture of locally excited and charge transfer configurations (Table 5). Calculations show it is forbidden.

The second ($E_1' \leftarrow A_1'$) transition has a strong intensity and a composition similar to that of the first one. It is predicted at 4.81—5.95 eV (MIM-PPP), *i.e.* very near the theoretical value found for [4]radialene[2] (4.77—6.41 eV (MIM-PPP)) and experimentally observed at 4.59 eV.

The third (forbidden) and fourth (weak) electronic transitions are calculated at 5.32—6.24 eV and 6.04—7.05 eV (MIM-PPP) and originate exclusively from charge transfer configurations. On the whole the results confirm what Heilbronner predicted for this compound.[22]

8-Vinylheptafulvene(7-Methylene-1,3,5-cycloheptatriene) (V). The geometry postulated by Lo and Whitehead was adopted for calculations.[23] The results are given in Table 6.

The UV trend is fairly reproduced by MIM and PPP, even though the latter method gives rather high energy values. The first electronic transition, roughly polarized along the short axis (y), is computed at 3.55—4.17 eV (MIM-PPP) and is to be associated with the weak absorption band experimentally observed at 2.8 eV.[24] PPP predicts it is prevailingly due to charge transfer states while MIM indicates it is a mixture of locally excited and charge transfer configurations. However both methods show that it is localized in the seven-membered ring, corresponding

a) Angle with respect to x-axis.

in energy as well in composition and intensity, to the first electronic transition found in heptafulvene at 3.46—3.98 eV (MIM-PPP) and experimentally observed at 2.9 eV.[2]

The most intense second absorption band occurs at 3.81 eV,[24] the corresponding band in heptafulvene lying at 4.4 eV.[8,24] The bathochromic shift was fairly predicted by calculations. The associated electronic transition, in fact, computed at 3.69—4.97 eV (MIM-PPP) and polarized along the x axis (3.94—5.31 eV in heptafulvene[2]) has prevailing charge transfer character involving the whole π-system with consistent interaction of the vinyl group with the heptafulvene nucleus.

A very similar composition is found for the weak third theoretical electronic transition, computed at 5.28—6.43 eV (where Λ_e is the most consistent among the locally excited states) which appears shifted at lower energy with respect to the corresponding one in heptafulvene (5.62—6.66 eV, MIM-PPP).[2] A lower bathochromic shift is predicted by PPP approach because less interaction is predicted between the vinyl group and the remaining heptafulvene fragment.

Next two transitions, both roughly polarized along the y-axis, are calculated at 5.51—6.51 eV (weak) and 5.76—7.32 eV (intense) by MIM and PPP respectively, being nearly exclusively originated by charge transfers involving principally the heptafulvene π-system.

*1,2-Benzofulvene(1-Methylene-1*H*-indene) (VI).* The bond lengths calculated by the LCAO-MO-SCF-PPP ($\pi+\sigma$) method[23] were adopted for the fulvene ring, benzene being assumed to be a regular hexagon. The most recent UV spectrum[25] shows a great number of absorption bands and shoulders, often very near each other, giving results very difficult to interpret. Three distinct absorption bands were reported by Bloor *et al.*,[13] where reference is made to the spectrum in heptane solution reported by Pullman *et al.*[26] My MIM and PPP-CA results are discordant (Table 7) principally as regards the composition and oscillator strengths of the first and fourth electronic transitions so that the relative assignment is uncertain. Probably this situation is partially due to the molecular asymmetry of this compound. However, the first electronic transition computed at 3.80—3.82 eV by MIM and at 4.35 eV by PPP seems to be associated with the experimental absorption observed at $\simeq$3.6 eV. The second theoretical transition at 4.35—4.10 eV (MIM/A-MIM/B) and 4.47 eV (PPP) corresponds to the absorption band at about 4 eV. The third and fourth calculated transitions might be correlated with the strong absorption at about 4.8 eV. If a comparison is made between the composition of these transitions and the composition of the transitions found in fulvene[1] no resemblance is observed.

*2,3-Benzofulvene(2-Methylene-2*H*-indene) (VII).* As regards 2,3-benzofulvene no spectroscopic data seem to have appeared. Calculations have been performed adopting the molecular geometry of Lo and Whitehead.[23] Three different approaches at MIM level were examined. The molecule was considered to be five interacting ethylene molecules (MIM/A) or two *cis*-butadienes and ethylene (MIM/B) or two *trans*-butadienes and ethylene (MIM/C). The results are given in Tables 8 and 9, together with those of PPP-CA for comparison. In each case a y-polarized $^1B_2 \leftarrow {}^1A_1$

a) a, b, c, d, and e denote fragments C_2=C_3, C_4=C_5, C_6=C_7, C_1=C_8, and C_9=C_{10}, respectively.

transition of weak intensity is predicted as first electronic transition at 2.67, 2.40 and 2.38 eV (MIM/A, MIM/B and MIM/C respectively) and at 3.79 eV (PPP). With respect to the first calculated electronic transition in 1,2-benzofulvene a greater charge transfer character is found, the calculated transition shifting at lower energy. Moreover the composition of the wavefunction relative to this transition is very similar to that of the first transition in fulvene,[1)] where it was computed at 3.3 eV.

The second ($^1A_1 \leftarrow {}^1A_1$) transition is predicted to be very intense and polarized towards the long molecular axis (x). It is calculated by MIM in the range 3.4—3.8 eV and by PPP at 5.32 eV, the result being pre-

valently charge transfer in nature.

Next transition, $^1B_2 \leftarrow {}^1A_1$, found at *ca.* 4.2 eV by MIM and at 5.44 eV by PPP shows charge transfer character if MIM results are taken into account, in contrast with PPP composition where the greatest contribution is given by locally excited states. Since the calculated energy values for the second and the third transition are very close each other it is probable that the third transition (weak) might appear as a shoulder of the second one on higher energy side.

The fourth electronic transition is predicted having $^1B_2$ symmetry with very low intensity and exclusively charge transfers configurations. Both MIM/A and PPP predict that it is lying very near to the fifth $^1A_1 \leftarrow {}^1A_1$ intense electronic transition, probably as a shoulder on lower energy side. On the contrary MIM/C results predict the fourth transition to be forbidden and lying at about 4 eV, in disagreement with the above results.

Conclusion

If [5]radialene and the two benzofulvenes are excluded, the spectra of the molecules studied can be correlated with those of the smaller cyclic compounds which constitute them, by means of the nature, energy and intensity as well as the composition of the corresponding electronic transitions. The principal feature which can be noted by analysing the theoretical electronic transitions energies is the difference between MIM and PPP results. The latter gives values higher than those of MIM and experiment, even if the general

spectral trend is acceptable. The main cause seems to be the resonance integrals. When β_{ij} values are evaluated by the exponential formula

$$\beta_{ij} = -2.38 \exp 1.586 (r_0 - r_{\mu\nu})$$

where r_0 is the C–C bond length in benzene (for details Ref. 16, method I), the energy values calculated by PPP are lower than those obtained with Kon's resonance integrals and nearer to the experimental ones. On the other hand MIM values became too low. For a more reliable comparison of the theoretical results we have chosen Kon's integrals in both methods since calculations on some compounds showed that wavefunction compositions do not appreciably differ in the two cases. The nature of the first electronic transitions, among which those experimentally observed are included, are generally concordant in the two methods while mutual shifts are noted for higher energy wavefunctions. However this behaviour is usual and independent of the molecules. Generally the lowest energy transitions are a mixture of locally excited and charge transfer configurations with nearly exclusively Λ character in compounds including benzene ring, while prevalently charge transfer transitions are found at higher energy values. For all the compounds the calculated ground state bond orders are satisfactory.

New Type of Active Carbon Catalyst for Simultaneous Removal of SO_x and NO_x

Akio NISHIJIMA,* Minoru KURITA, Yoshimichi KIYOZUMI, Rikio KOBAYASHI, Hiroyuki HAGIWARA, Akifumi UENO, Toshio SATO, and Naoyuki TODO

National Chemical Laboratory for Industry, 2-19-19, Mita, Meguro-ku, Tokyo 153 †

(Received April 16, 1979)

Active carbons prepared from nitrogen containing compounds were found to show high activity for SO_2 removal. Enhancement of the activity for NO reduction was realized by supporting vanadium ions on these active carbons. Regeneration of the catalyst was examined with various reducing agents. The activity for SO_2 removal was recovered by removing sulfate ions on the catalyst with NH_3 at 350 °C. The 200 h life test of the present catalyst was carried out for the simultaneous removal of SO_x and NO_x.

Development of the technique for removal of sulfur oxides (SO_x) and nitrogen oxides (NO_x) in a flue gas emitted from a stationary combustion equipment involves complicated problems. Recently, active carbons have been used for the simultaneous removal of SO_x and NO_x in a flue gas.[1,2] SO_x is removed by adsorption on a catalyst as sulfate compounds, NO_x being reduced by NH_3 added in a flue gas as a reducing agent. However, active carbon (AC) developed so far are applied at a low space velocity below 1000 h^{-1} because of lower activities at the temperature range in which AC is of use. Development of active catalysts which can be used at a higher space velocity is desirable. According to studies by Sano and Ogawa[3] on new types of catalysts with higher activity for SO_2 removal, certain impurities such as surface nitrogen species seem to have a good effect on activity. Investigation was carried out in order to improve the activity for simultaneous removal of NO and SO_2. Develpoment of technique for regeneration is also important in connection with the simultaneous reduction. In this paper, the method of regeneration and result of the life test for 200 h are described.

Experimental

Catalyst. As raw materials for active carbons, nitrogen-containing compounds such as polyacrylonitrile or urea resin, a sulfur-containing compound (ashaltene) and a silica-containing compound (chaff) were used. Materials were put into a reactor made of quartz (length 500 mm, diam 60 mm) and were carbonized at *ca.* 250 °C in N_2 flow (1 *l*/h). Activation was carried out in the temperature range 600—1000 °C using water vapor or $ZnCl_2$ as an activating reagent. Some commercial AC were also used as a reference. The nitrogen-containing AC preapred from polyacrylonitrile was found to show superior activity for SO_2 removal and was selected as a carrier for the simultaneous removal of SO_2 and NO. Metal salts were supported by the impregnation method. Impregnation was carried out at 30 °C for 5 h, and the catalysts obtained were dried at 120 °C for 3 h, and then calcined at 250 °C in N_2 stream (1 *l*/h). Catalysts prepared are summarized in Table 1.

Activity Measurement. Activity measurements were carried out at 200 °C at a space velocity of 5000 h^{-1} using a conventional flow reactor made of stainless steel (length 300 mm, diam 25 mm). A gas mixture consisting of SO_2 500 ppm, NH_3 500 ppm, O_2 5 vol%, H_2O 10 vol%, and N_2 was used as standard feed, 300 ppm of NO being added in the case of simultaneous removal. The activities for SO_2 removal and NO reduction were determined by measurements of the concentrations before and after the reaction. Analyses of SO_2 and NO were made with a NDIR type SO_x analyzer and a chemiluminescence type NO_x analyzer, respectively. The analysis of NH_3 was performed by the chemical method (JIS-K-0099).

Measurement of Catalyst Property. Measurement of surface areas and elemental analysis of C and N were carried out by the BET method and CHN corder (Yanaco MT-2), respectively. An X-ray photoelectron spectrometer (Dupont 650B) was used to examine surface properities of the catalysts. An ion microanalyzer (Hitachi IMA-2) and an electron microprobe (Hitachi HU-12) were also used to estimate the line profile of each element and the despersion of supported vanadium ions, respectively.

Results and Discussion

Comparison of AC as Regards Activity for SO_2 Removal. The activities of various AC for SO_2 removal are shown in Fig. 1. AC prepared from nitrogen-containing compounds showed superior activity to other AC, while

those prepared from asphaltene and chaff showed lower activity than commercial ones. Figure 2 shows the effect of space velocity on activity for the removal of SO_2. AC prepared from polyacrylonitrile (PAN) showed high activity at space velocity higher than 10000 h^{-1}, indicating the merit of the AC prepared from nitrogen-containing compounds.

Effect of Preparation Conditions on the Catalytic Activity for SO_2 Removal. Figure 3 shows the effect of activating conditions on activities and capacities of active carbons from PAN for SO_2 removal. When $ZnCl_2$ was used as an activating agent, the catalysts obtained were not active, probably due to the blocking of SO_2 adsorption sites by zinc atom. In fact, the results obtained with the ion micronalyzer showed that the surface concentration of Zn on AC with lower

activity for SO_2 removal is higher than that on AC with higher activity. Though highly active ones were obtained when activated by H_2O, capacity performance of SO_2 removal was found to be deeply dependent on activating conditions. The specific surface area of the AC prepared under various conditions is in the range 300—1000 m^2/g, the activity of these AC being superior to that of commerical ones whose specific surface area is 700—1000 m^2/g. Surface functional groups of carriers play an important role in the catalysis.[4,5] It seems that some kinds of surface species contribute to the performance of SO_2 removal. A few percent of nitrogen atom remained after activation. Nitrogen species seem to exist in the state of C–N or N–N.[6] Thus the nitrogen species existing on the surface of the AC seem to be effective for the SO_2 removal. The amount of SO_2 adsorbed on AC was enhanced when nitrogen species were formed on the usual AC by impregnation with aqueous solutions of

	397.6		

Binding energies were obtained based on C 1s spectra of contaminant carbon (285.0 eV).

nitrogen-containing compounds.[3] The amount of nitrogen in the AC we prepared was in the range 2—12 wt%. The relation between the amount of nitrogen and the performance is shown in Fig. 4. The increase in the amount of nitrogen seems to be correlated with activity. We thus examined the nitrogen species on the surface of AC in order to study the chemical states. Two peaks of N ls spectra were observed on the surface (Table 2), their binding energies being 396.1 and 397.5 eV, respectively. This indicates that two different chemical states of nitrogen atoms exist on the surface of the AC (probably C–N and C–N–N) and that one of them would be more effective for the removal of SO_2.

Effect of Coexisting Gas on Activity for SO_2 Removal. In the removal of SO_2 with NH_3, the following reactions are considered as the mechanism:[1]

$$SO_2 + 1/2O_2 \longrightarrow SO_3 \quad (1)$$

$$SO_3 + H_2O \longrightarrow H_2SO_4 \quad (2)$$

$$H_2SO_4 + NH_3 \longrightarrow NH_4HSO_4 \quad (3)$$

$$NH_4HSO_4 + NH_3 \longrightarrow (NH_4)_2SO_4 \quad (4)$$

Figure 5 shows the effect of coexisting gases on the activity for SO_2 removal. When O_2 or H_2O was removed from the feed gas, the activity decreased rapidly, indicating that the existence of both O_2 and H_2O is indispensable for the removal of SO_2 (Reactions 1 and 2). The activity for SO_2 removal increased to some extent in the absence of NO in the feed gas (Fig. 5). In the case of commercial AC, the activity increased when NO was added to the feed gas. This might be explained by the catalysis of NO for the formation of SO_3. On the other hand, in the AC prepared from polyacrylonitrile, the activity for SO_2 removal was higher in the absence of NO. This is also one of the features of AC from polyacrylonitrile, suggesting that the activity for SO_2 removal depends on C–N–N and/or C–N species on AC. When NH_3 was removed from the feed gas, the activity was found to decrease gradually because of the lack of NH_3 for SO_2 removal (Reactions 3 and 4). The effect of the amount of NH_3 in the feed gas for SO_2 removal is shown in Fig. 6. The capacity SO_2 removal increased with increase in the amount of NH_3 added. Leak of NH_3 was observed at the outlet of the reactor when the concentration of NH_3 in the feed gas exceeded 500 ppm. Thus in the present work, 500 ppm of NH_3 was introduced in the feed gas.

Enhancement of Activity for NO Reduction. Activities of AC for NO reduction do not differ much

AC used in this study was prepared from polyacrylonitrile.

from those of commercial ones. Under the reaction conditions, the activity of AC was so low that only 20% of NO was removed. Enhancement of activity for NO reduction was attempted by supporting various metal salts. Metals such as V or Mn which were found effective for NO reduction when supported on Al_2O_3 or TiO_2[7] were loaded on AC for the enhancement of the activity for NO reduction. Cerium, vanadium and manganese oxides supported catalysts were found to be highly active (Fig. 7). However, the activity of manganese or cerium supported catalyst decreased gradually with formation of the sulfate, regeneration of activity being difficult by the conventional technique. Since vanadium oxide supported catalyst exhibits a high activity for more than 10 h, vanadium ions were supported on the AC to improve the activity. The effect of the content of vanadium ions on both SO_2 removal ability and NO reduction activity was investigated in order to know the optimum content. The activity of the AC for SO_2 removal decreased with increase in the amount of vanadium supported (Fig. 8). On the contrary, the activity for NO reduction increased with increase in the amount of vanadium, apporaching a ceiling value at a certain vanadium content. AC with 2 wt% of vanadium supported showed optimum performance for the simultaneous removal.

Regeneration of Catalyst. The activity of catalyst for SO_2 removal decreases over a certain reaction time (Fig. 1 or 6); that for NO reduction does not decrease over 10 h. Sulfuric acid or ammonium sulfates formed during the course of reaction would diminish the number of active sites for successive adsorption of SO_2. Thus the removal of these compounds from the catalyst is indispensable for the regeneration of the catalyst. Deactivated catalysts were usually regenerated by (a) heating above 400 °C in nitrogen or (b) washing with water. In (a) surface compounds seem to react with AC as follows.

$$2H_2SO_4 + C \longrightarrow 2SO_2 + 2H_2O + CO_2 \quad (5)$$

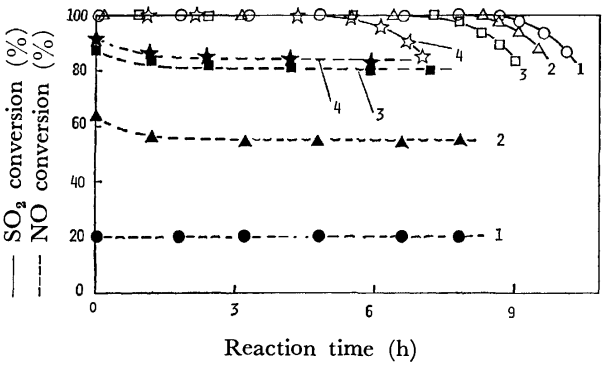

Fig. 8. Effect of amount of vanadium on activity for SO_2 removal and NO reduction.
Amounts of vanadium;
1 ○●: 0 wt%, 2 △▲: 1 wt%, 3 □■: 2 wt%, 4 ☆★: 4 wt%.
Reaction conditions;
Reaction temp: 220 °C, SV: 5000 h^{-1}, SO_2: 500 ppm, NO: 300 ppm, NH_3: 600 ppm, O_2: 5 vol%, H_2O; 10 vol%, N_2: balance.

$$NH_4HSO_4 + C \longrightarrow 2NH_3 + 2H_2O + 2SO_2 + CO_2 \quad (6)$$

Consumption of AC is unavoidable. In (b) elusion of vanadium salt takes place because of its change from oxide to soluble sulfate state in water. A new method free from the loss of active components is desirable.

In an industrial SO_2 removal process using $Cu–Al_2O_3$ catalyst, H_2, CO or low molecular HC is effective.[8] We have found that CO and H_2 are effective and that the consumption of AC caused by the regeneration with H_2 or CO was less than that by heating in nitrogen. When deactivated catalysts are treated with NH_3 gas, however, H_2SO_4 on the deactivated catalyst changes to NH_4HSO_4 or $(NH_4)_2SO_4$ (Reactions 3 and 4), and the consumption of the catalyst (Reactions 5 and 6) decrease as compared with the case in which other reducing agents are used.

Figure 9 shows the variation of photoelectron spectra for S 2p and V $2p_{3/2}$ on the catalyst. The intensity of S 2p peak increased with reaction time, that of V $2p_{3/2}$ peak decreasing gradually. No S 2p peak was observed after regeneration with NH_3. Analysis of sulfate ions (JIS-K-0101) showed no sulfate ions after the regeneration. The results show that sulfur was removed perfectly from the catalyst by regenerating with NH_3 gas. The electronic state of vanadium ions turned electronegative with reaction time (Fig. 9). The change of the electronic state of the active component would affect the activity for NO reduction. The activity of the AC catalyst was found to decrease at the initial state of the reaction (Fig. 8). After regeneration with NH_3 gas, both the electronic state of vanadium ions and the activity for NO reduction were recovered. For practical purposes, repeated regeneration is desirable.

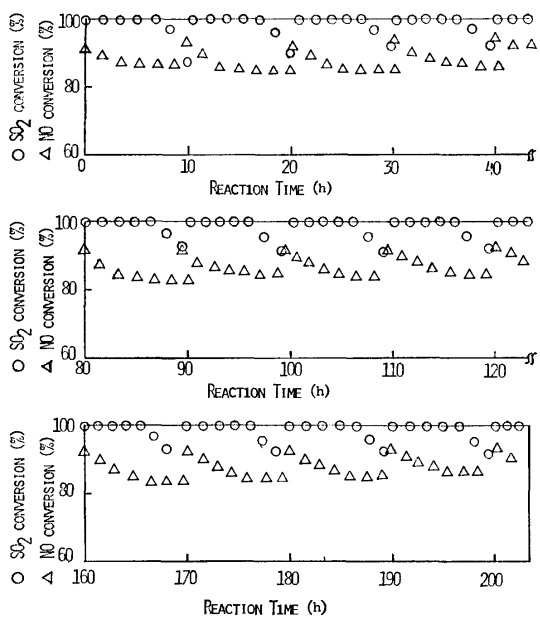

Fig. 10. Life test of simultaneous removal of SO_2 and NO.
Reaction conditions;
Reaction temp: 220 °C, SV: 5000 h^{-1}, SO_2: 500 ppm, NO: 300 ppm, NH_3: 600 ppm, O_2: 10 vol%, H_2O: 10 vol%, N_2: balance.
Regeneration conditions;
Reaction temp: 350 °C, Reaction time: 2 h, SV: 130 h^{-1}, NH_3: 2 vol%, N_2: balance.

Life Test of AC Catalyst for Simultaneous Removal. Figure 10 shows the result of the life test of AC catalyst for the simultaneous removal of SO_2 and NO. After every 10 h, regeneration was performed using NH_3 gas at 350 °C for 2 h. Steady activities over 90% of SO_2 removal and 80% of NO reduction were achieved. The consumption of the catalyst for 200 h of the life test was less than 0.1 ml (20 ml of the catalyst). After the life test, the dispersion of vanadium ions on regenerated catalysts was examined. The particle size of vanadium (smaller than 20 Å) and the highly dispersed state did not change after 20 repetitions of regeneration.

The results indicate that the simultaneous removal of SO_2 and NO with space velocity higher than 5000 h^{-1} is feasible.

(Received September 17, 1979)

Synopsis. Potassium polyaluminate (β_K''-alumina) has been employed as a catalyst for CO shift reaction ($CO+H_2O=CO_2+H_2$). The dependence of catalytic activity on the K^+ content was investigated. The initial reaction rate abruptly increased above 11 wt% K_2O.

Alkali polyaluminates, of which β-alumina has been classified into β, β', and β'',[1] have the characteristic layer structure[2] and are solid electrolytes with high ionic conductivity.[3] Alkali polyaluminates are also effective as catalysts for the steam reforming reaction of hydrocarbons;[4,5] fuel gas of good quality and rich in hydrogen gas can be produced. They are also applicable to atmospheric and vacuum residue oil of inferior quality, and considered to be important materials in view of effective utilization of petroleum energy sources. The catalytic ability of alkali polyaluminates lies mainly in enhancement of water gas shift reaction and gasification of carbon.[4,5] This is characteristic of basic catalysts and is exibited in the steam reforming reaction of inferior hydrocarbons. In the present study, potassium polyaluminate (β_K''-alumina) has been employed as a catalyst for CO shift reaction ($CO+H_2O=CO_2+H_2$) in order to investigate the dependence of catalytic activity on the K^+ content.

Experimental

The powder of β_K''-alumina (Kyushu Taika Renga Co. Ltd.) was pressed into cylindrical pellets, diam 20 mm and thickness 3 mm, under the pressure of 500 kg/cm^2. After the pellets had been calcined at 1300 °C for 1 h in an electric furnace, they were crushed into particles, 1—3 mm in diam Samples with lower K^+ content were obtained by eluting K^+ with purified water, HCl solution, and H_2SO_4 solution. Those with higher K^+ content were prepared by calcining β_K''-alumina pellets containing excess K_2CO_3. The procedure and K_2O content of the samples obtained are given in Table 1. For determination of the K_2O content by flame photometry, the sample was dried at 300 °C for 1 h and dissolved in H_2SO_4–$(NH_4)_2SO_4$ aqueous solution.

The initial rate of the CO shift reaction was measured at 600 °C under differential conditions using a reaction vessel of the normal-pressure flow system. 0.8 g of the catalyst (particle size 14—20 mesh) was diluted with 17.2 g fused alumina (particle size 12—20 mesh) which had been confirmed to be non-active as a catalyst. The volume of the catalyst bed was 10 ml and its height 2 cm. The center of the catalyst bed was placed at the highest temperature region in the reaction tube. The stainless sheath thermocouple (chromel-alumel, JIS 0.75 grade) protected by a high alumina tube was inserted in the center of the catalyst bed, the temperature being controlled by a proportional position temperature regulator (CHINO, NS 141). The temperature fluctuation in the catalyst bed was within ±2.5 °C, the prescribed temperature being controlled within ±5 °C.

Gas sampling was performed after the reaction reached steady state, and the composition of the gas was analyzed by means of a gas chromatograph (Gasukuro Kogyo, KOR-70). Molecular sieves of 5A, 13X, and silica gel were used as separating columns for CO, H_2, and CO_2, respectively. The area under the chromatogram was measured with a digital integrator (Shimadzu, ITG 4A), the gas composition being determined by the absolute calibration method. The error of mass balance of the reaction was within *ca.* ±3%.

Table 1. Specimens

Specimen NO.	Preparation process	Phase[a]	K_2O content[b] wt%
1	$+K_2CO_3$	β''-alumina	14.5
2	$+K_2CO_3$	β''-alumina	14.4
3	$+K_2CO_3$	β''-alumina	12.1
4	No Treatment	β''-alumina	11.4
5	Elution (H_2O)	β''-alumina	11.0
6	Elution (H_2O)	β''-alumina	10.4
7	Elution (H_2O, boiled)	β''-alumina	9.1
8	Elution (HCl, boiled)	β''-alumina	4.1
9	Elution (H_2SO_4, 200 °C)	β''-alumina	1.2

a) Determined by X-ray diffraction method. b) By flame photometry.

Results and Discussion

The initial reaction rate generally depends on the feed gas composition.[6] However, no dependence was observed in a preliminary experiment with use of specimen NO. 4. Thus, the feed gas composition was fixed as $P_{H_2O}/P_{CO}=1$, the total pressure being 1 atm.

The initial rate of the CO shift reaction obtained at 600 °C as a function of K_2O content in β_K''-alumina is shown in Fig. 1. The abrupt variation in the initial rate was found at *ca.* 11 wt% K_2O content. The result indicates that the surface state of β_K''-alumina with over 11 wt% K_2O differs from that with less than 11 wt% K_2O. The samples with less than 11 wt% K_2O also show the X-ray diffraction pattern of β_K''-alumina structure (Table 1), suggesting that H^+ or H_3O^+ ions undergo exchange with K^+ ions in the solid structure. However, the ions might not have been distributed homogeneously in the bulk, the concentration of K^+ ions near the surface being assumed

** Present address: Kyushu Taika Renga Co. Ltd., Urainbe, Bizen, Okayama 705.

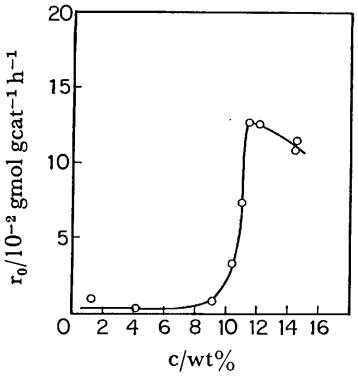

Fig. 1. Initial reaction rate *vs.* K_2O content obtained at 600 °C.

to be lower than expected. If this was the case, the result suggests that K^+ ion on the catalyst surface acts as an active center for the reaction.

The abrupt variation in the initial rate is also understandable if two kinds of K^+ ions exist, one as an active center but easily eluted by water or acid, the other being non-active but stable against elution.

ESR Studies of Temperature Dependent Zero-field Splitting in Yang's Biradical

Kazuo MUKAI,* Kazuhiko ISHIZU, Mizue NAKAHARA, and Yasuo DEGUCHI**
Department of Chemistry, Faculty of Science, Ehime University, Matsuyama 790
***College of Liberal Arts and Science, Kyoto University, Kyoto 606*
(Received March 27, 1980)

Synopsis. The ESR absorptions of Yang's biradical in a few organic solvents have been studied in detail as a function of temperature, and the effect of temperature on the symmetry of the biradical molecule has been discussed on the basis of the temperature dependence of the zero-field splitting parameters.

Yang's biradical is known as a stable π-conjugated phenoxyl biradical, having a structural three-fold symmetrical axis in the molecule.[1] In the previous work, the **D**-tensor values of Yang's biradical have been determined from an analysis of its asymmetric frozen ESR spectrum.[2] The results have provided direct experimental evidence for the asymmetrical molecular distortion in Yang's biradical. On the other hand, in fluid solution the biradical molecule still retains a three-fold symmetry; the results of ESR, NMR, and ENDOR studies[3–5] in solution indicate that the six meta-ring protons are magnetically equivalent, giving a hyperfine splitting attributable to the six meta-ring protons. In the present work, the ESR absorptions of Yang's biradical in a few organic solvents have been studied in detail as a function of temperature, and the effect of temperature on the symmetry of the biradical molecule has been discussed on the basis of the temperature dependence of the zero-field splitting (ZFS) parameters.

Results and Discussion

The toluene rigid matrix ESR spectrum of Yang's biradical shows a characteristic spectrum of a non-axially symmetrical triplet, with $|D|=34.1$ G and $|E|=1.9$ G at 77 K (see Fig. 1(c)).[2] In the low temperature region between −196 and −140 °C, the ESR spectra remain almost unchanged upon variation of the temperature. When the samples were warmed to the higher temperatures, the decrease in the separation between the Z and Z′ lines and the sharpening of both the XY and X′Y′ lines have been observed until the typical triplet spectra become unobservable, as shown in Figs. 1(a) and (b). By recooling the samples to 77 K, it was confirmed that the change in the ESR spectra is reversible. A similar temperature effect on the triplet ESR spectra has also been observed in ethanol and 2-MTHF (2-methyltetrahydrofuran). The ZFS parameters $|D|$ and $|E|$ calculated from the observed spectra[2] are given in Table 1 and Fig. 2. In the low temperature region, the ZFS parameters show no detectable change. At higher temperature, the decrease in D is 10—20% and the decrease in E is 50—60% for the organic solvents used in the present work.

The Yang's biradical is thought to have a fixed structure in the low temperature region, because the ZFS parameters D and E show no detectable change. On warming with a consequent softening of the matrix, the D value decreases, for instance, from 34.1 G at −196 °C to 30.1 G at −110 °C in toluene. We think that one possible reason for the temperature dependence of D may be the rotation of the phenyl rings in Yang's biradical.[6] If one considers the rotation of the three phenyl rings, the average twist angle of each phenyl ring is increased as the temperature is raised. This would result in an increased average separation between the two unpaired electrons and a consequent decrease in the value of D.

At 77 K where Yang's biradical is trapped rigidly in the organic solvent matrices, the molecule has a distorted propeller structure with a non-zero E value,

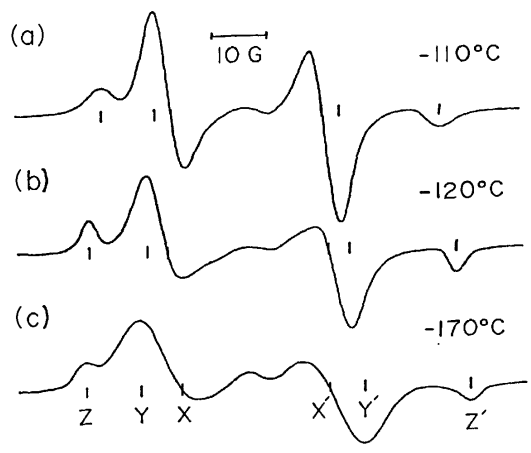

Fig. 1. Temperature dependence of the ESR absorption of Yang's biradical in toluene.

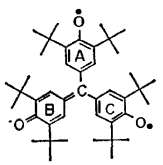
a) The $|D|$ and $|E|$ values were calculated from the $ZZ'=2D$ and $YY'=D+3E$ separations. The E value thus calculated is smaller than the true value, considering the overlaping of the inner two pairs of lines.[2] The experimental errors in the values of $|D|$ and $|E|$ are ± 0.2 and 0.4 G, respectively. $1\,G=10^{-4}\,T$.



Yang's Biradical

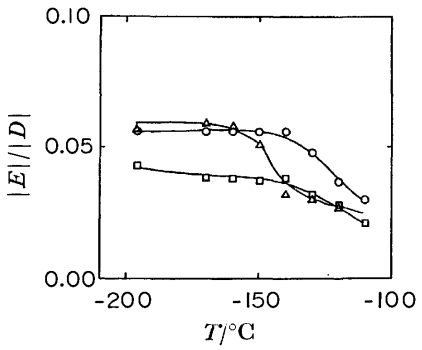


Fig. 3. Temperature dependence of the ratio of $|E|/|D|$ of Yang's biradical in toluene (○), ethanol (□), and 2-MTHF (△).

because of the asymmetric environment due to the frozen-solvent molecules. Although both the D and E values decrease with increasing temperature, the 50—60% decrease in E with increasing temperature is large compared with the 10—20% decrease in D. Among the ZFS parameters, D measures the average distance between electrons. On the other hand, E measures the deviation of the molecule from three-fold or higher symmetry weighted by this distance. Therefore, the ratio E/D provides a measure of the deviation from a structure of high symmetry. In Fig. 3, the ratio E/D is plotted as a function of temperature. The ratio E/D is constant in the low temperature region, but decreases rapidly with increasing temperature at higher temperature region (approaching the melting point of the solvent). This result may be explained by assuming that the degree of molecular asymmetry was decreased with increasing temperature. At the higher temperatures, the decrease in the rigidity of solvent matrix should allow the guest biradical molecule to assume its preferred geometry. This fact corresponds well to the fact that the molecular asymmetry of the Yang's biradical observed at the low temperature is eliminated at room temperature.[3-5]

Yang's biradical is thought to be a derivative of trimethylenemethane (TMM) $(\cdot CH_2)_2C{=}CH_2$, which also has structural three-fold symmetry. Therefore, in TMM biradical, we can expect similar temperature dependent variation in the D and E parameters. However, in the low temperature matrices, TMM shows the characteristic spectrum of an axially symmetrical triplet molecule, with $D=254$ G and $E=0$ G.[7] On the other hand, the decrease in D value of TMM with increasing temperature has been found,[8] and, in addition, the splitting of the XY lines at temperatures above 77 K has been observed,[9] using the deuterium derivative of the TMM, $(\cdot CD_2)_2C{=}CD_2$; the results suggest that the TMM molecule lacks a three-fold symmetry at the high temperature region. Recently, Claesson *et al.*[10] have proposed that the change in D value and the deviation from axial symmetry can be attributed to an anisotropic temperature dependent oscillation about a preferred axis in the TMM plane, from the results of the single crystal study of the triplet TMM molecule. Such a difference in the temperature dependence of the ZFS parameters between the small TMM molecule and the large Yang's biradical molecule is interesting.

Purification of Methylthymol Blue and Methylxylenol Blue by High-Performance Liquid Chromatography†

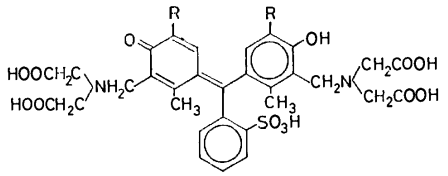
Shoji NAKADA, Mutsuo YAMADA, Tasuku ITO,†† and Masatoshi FUJIMOTO*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received April 17, 1980)

Synopsis. Relatively large amounts of 3,3′-bis[bis(carboxymethyl)aminomethyl]thymolsulfonphthalein (Methylthymol Blue, MTB) and 3,3′-bis[bis(carboxymethyl)aminomethyl]-*p*-xylenolsulfonphthalein (Methylxylenol Blue, MXB) are easily purified by high-performance liquid chromatography (HPLC).

Multidentate ligands of triphenylmethane complexon (TPMC) series, MTB and MXB, are metallochromic indicators for the complexometric titration of a number of metal ions in aqueous solutions.[1] However, only a few quantitative data on the complex formation of these ligands have been reported. These data show serious discrepancies resulting from the use of specimens of low purity.



MTB : R = $CH(CH_3)_2$

MXB : R = CH_3

The purity of synthesized or commercial specimens of these ligands is low. MTB usually contains the starting materials, iminodiacetic acid (IDA) and Thymol Blue (TB), and a by-product, Semi-Methylthymol Blue (SMTB). Similarly, MXB contains IDA, *p*-Xylenol Blue (*p*-XB), and Semi-Methylxylenol Blue (SMXB). Since the monosubstituted products, SMTB and SMXB, and IDA also form stable metal complexes, the use of MTB or MXB free of these impurities is essential for quantitative studies of metal complex formation. However, the separation of IDA, SMTB or SMXB, and TB or *p*-XB from MTB or MXB was not easy; the method of purification reported for MTB[2] is incomplete, and that for MXB has not been established.

In a previous paper we reported the purification of Xylenol Orange (XO) by preparative HPLC.[3] We have applied the method to the purification of MTB and MXB, and succeeded in preparing relatively large amounts of MTB and MXB of high purity.

Ten grams of crude sample of synthesized MTB or MXB was preliminarily purified by cellulose column chromatography (CCC) using a 45 × 1000 mm column packed with 600 g of Whatman CC-31 cellulose powder and 1-butanol saturated with 1% aqueous acetic acid as an eluent. The last fraction of three colored bands clearly separated on the chromatogram was used as a sample for HPLC. In the case of MXB, the yield of the last fraction by CCC was very low as compared with that of MTB. Paper partition chromatography (PPC) of the pre-treated sample gave no spots of SMTB (or SMXB) and TB (or *p*-XB), but a considerable amount of IDA still remained unremoved.

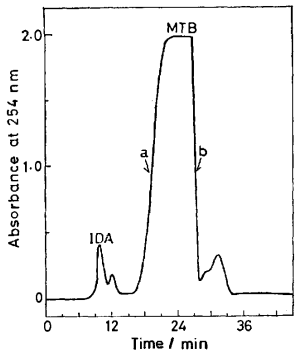


Fig. 1. Elution curve of the pre-purified sample of MTB.

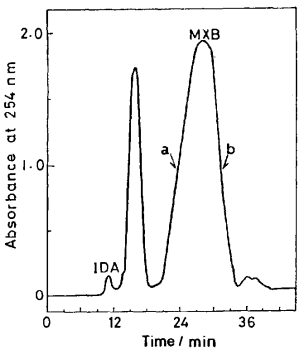

Fig. 2. Elution curve of the pre-purified sample of MXB.

Figure 1 shows a typical elution curve of preparative HPLC for the pre-purified sample of MTB. One gram of the sample pre-purified on CCC was dissolved in 5 cm^3 of water. One cubic centimeter of the sample solution was injected for each run. The separation was accomplished with an eluent, 5% aqueous acetic acid–methanol (60/40, v/v),** at a flow rate 6.0 $cm^3\,min^{-1}$ and at 1500 psi. MTB was clearly separated from the impurities on a preparative scale, a small peak of an unknown substance being observed in the tail portion of the MTB peak. After elution of MTB the column was regenerated by washing with methanol for 20 min. An unknown reddish yellow material probably containing a trace amount of SMTB was flushed out. The column thus regenerated was used repeatedly.

Figure 2 shows an elution curve for the pre-purified sample of MXB under the same conditions as those for MTB except for the use of 5% aqueous acetic acid–methanol (80/20, v/v)** as an eluent. The peak

† Presented in part at the 1980 Winter Meeting of the Chemical Society of Japan and the Japan Society for Analytical Chemistry, Sapporo, Hokkaido, February 1, 1980, Abstract, p. 36.

†† Present address: Institute for Molecular Science, Okazaki 444.

** Preliminary experiments showed that the retention time for the parent triphenylmethane dyes is much longer than that of the corresponding TPMC and IDA as in the case of XO,[3] and that the retention time for TB-series is much longer than that for *o*-CR- and *p*-XB-series. With increase in methanol content in the given eluent, the retention times of *o*-CR, TB, and *p*-XB become shorter. Thus in the case of MTB we applied the eluent of higher methanol content (40%, v/v). The difference in retention time among the three series can be ascribed to the difference in the alkyl substituents in the triphenylmethane skeleton.

Table 1. Elemental analyses and DSC measurements of MTB and MXB

Compound	Formula		Elemental analyses C, %	H, %	N, %	S, %	S/N	Mp/°C
MTB	$C_{37}H_{44}O_{13}N_2S\cdot 3H_2O$	Found	54.80	6.02	3.37	3.93	1.17	201
		Calcd	54.80	6.21	3.46	3.95	1.14	
MXB	$C_{33}H_{36}O_{13}N_2S\cdot 3H_2O$	Found	53.72	5.52	3.59	4.20	1.17	270
		Calcd	52.52	5.61	3.71	4.24	1.14	(dec)

of MXB is much smaller than that of MTB. A colorless component giving a large frontal peak was assigned to an unreactive form of formaldehyde, which was revealed by ultraviolet spectra and chromatographic behavior. As in the case of MTB, a small peak was observed in the tail portion of the MXB peak. This was not assigned to that of the corresponding monosubstituted product, SMXB. The results indicate that the purification of MTB and MXB is not complete by means of a single HPLC even under the best conditions; repeated HPLC is necessary for complete purification.

The effluent between **a** and **b** for each run in Figs. 1 and 2 was collected as the portions of MTB and MXB, respectively. Each effluent was combined, concentrated, and injected again for repeated HPLC. For the effluent after the second HPLC treatment, almost complete purification of MTB or MXB was confirmed by analytical HPLC with a column of Microbondapak C_{18}, 4×300 mm, and a solvent, 5% aqueous acetic acid–methanol (60/40, v/v). The purified MTB or MXB was converted into acid form, concentrated, and dried. For MTB about 300 mg of the acid form of pure specimen was obtained from 1 g of a pre-purified sample. For MXB, however, only 160 mg was obtained from 1 g of a pre-purified sample. The reason for the low yield of MXB can be attributed to structural requirements in MXB.

Experimental

Materials. The solvents used as eluents were purified beforehand. Acetic acid of analytical grade was filtered through a glass filter G4, methanol was distilled, and water was deionized and redistilled. The crude sample of MTB or MXB was synthesized by Mannich condensation from TB or *p*-XB, IDA, and formaldehyde.[4] The sample solutions for HPLC were filtered through a Toyo membrane filter TM-2.

Instruments. A Waters liquid chromatograph Model ALG/GPC 204 equipped with three 7×610 mm columns of Bondapak C_{18}/Porasil B in series and an ultraviolet detector ($\lambda=254$ nm).

Free-Acid Form of Purified MTB and MXB. Aqueous solutions of the sodium salts of purified MTB and MXB were passed through a column of Dowex 50W-X8 in the hydrogen form. The effluents were concentrated at 40 °C in a rotary evaporator and dried in a vacuum desiccator. The purity of the specimens of MTB and MXB was confirmed by elemental analyses and DSC measurements (Table 1). The values of pK_a, λ_{max}, and the molar absorptivity of the aqueous solutions of the pure ligands, MTB and MXB, will be reported.[5]

The authors wish to thank Prof. Yoshio Matsunaga for the kindness in the DSC measurements. The present work was supported by a Grant-in-Aid for Scientific Research from Ministry of Education, Science, and Culture (No. 347031).

The Stereo-differentiating (Asymmetric) Hydrogenation of the C=O Double Bond with a Modified Nickel Catalyst. XXXV. A Facile Method for the Preparation of Optically Pure β-Diols

Kazuhisa Ito, Tadao Harada, and Akira Tai*

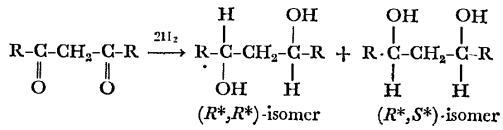
Institute for Protein Research, Osaka University, Yamada-kami, Suita, Osaka 565

(Received April 4, 1980)

Synopsis. The hydrogenation of $RCOCH_2COR$ over a Raney nickel catalyst modified with a mixture of tartaric acid and NaBr gave (*R**, *R**)-$RCH(OH)CH_2CH(OH)R$ selectively with a high optical purity. The substrates with R=CH_3-, CH_3CH_2-, $CH_3CH_2CH_2$-, $CH_3(CH_2)_4CH_2$-, and Ph- were employed in this study. In all cases, the recrystallization of the hydrogenation product gave an optically pure (*R**,*R**)-isomer which was free from the (*R**,*S**)-isomer.

Optically pure β-diols and their derivatives are potentialy useful chiral compounds as chiral solvents, chiral ligands, and chemicals for the preparation of optically active compounds. Althgouh a small amount of (+)-(2*S*,4*S*)-2,4-pentanediol has been prepared by the tedious optical resolution,[1] no practical methods for the large-scale preparation of optically pure compounds have been reported.

In a previous communication, we have briefly reported that the Raney nickel catalyst (RNi) modified with a solution containing tartaric acid (TA) and NaBr (TA–NaBr–MRNi) is an excellent catalyst for the hydrogenation of acetylacetone (Ia) to 2,4-pentanediol (Ib), giving (2*R**,4*R**)-Ib selectively with a high optical purity.[2] The catalyst was also found to be effective for the hydrogenation of other symmetric β-diketones to a mixture of (*R**,*R**)- and (*R**,*S**)-diol.



R=CH_3-, acetylacetone (Ia) 2,4-pentanediol (Ib)
R=CH_3CH_2-, 3,5-heptanedione (IIa) 3,5-heptanediol (IIb)
R=$CH_3CH_2CH_2$-, 4,6-nonanedione (IIIa) 4,6-nonanediol (IIIb)
R=$CH_3(CH_2)_4CH_2$-, 7,9-pentadecanedione (IVa) 7,9-pentadecanediol (IVb)
R=Ph-, dibenzoylmethane (Va) 1,3-diphenyl-1,3-propanediol (Vb)

The results are listed in Table 1. The major product, the (*R**,*R**)-isomer, can be separated from the (*R**,*S**)-isomer by the recrystallization of the reaction product. In all cases, the isolated (*R**,*R**)-isomer was found to be already optically pure. All substrates gave (−)-(*R**,*R**)-isomers in excess when (*R*,*R*)-TA–NaBr–MRNi was used.

As is found in the table, the ratio of the (*R**,*R**)-isomer to the (*R**,*S**)-isomer in the hydrogenation product is slightly decreased with an increase in the chain length of R in the substrate. Consequently, the isolation yield of the (*R**,*R**)-isomer decreases with the increase in the chain length of the substrate. However, the advantage of the present method is that optically pure β-diols are easily obtained by the recrystallization of the hydrogenation products. Furthermore, the preparation of TA–NaBr–MRNi is very simple, and the cost of the catalyst is negligibly low. Therefore, the present method would be easily applicable for the large-scale production of β-diols.

The optical purity of the (*R**,*R**)-isomers listed in Table 1 can be determined by means of the NMR of the diacetate derived from each diol. The chemical shifts for the acetyl group (singlet) of (−)- and (+)-diacetate were separated by 3 to 5 Hz in the presence of 2 molar eqivalents of $Eu(hfmc)_3$ to the acetate. In all cases, the signals of the diacetates derived from (+)-diols appeared at a high field.

The absolute configurations of the diols have not yet been determined except for the case of (−)-(2*R*, 4*R*)-Ib. However, the configurations of the (−)-isomer can be expected to be (*R*,*R*) for the following reasons: 1) the lanthanid-induced shifts of all the (−)-diols in NMR show the same tendency as that of Ib, and 2) the analogues of the substrates thus far examined are hydrogenated to (−)-(*R*)-products over (*R*,*R*)-TA–NaBr–MRNi; *i.e.*, Ia, 4-hydroxy-2-butanone, and methyl acetoacetate are converted to (−)-(2*R*, 4*R*)-Ib, (−)-(*R*)-1,3-butanediol,[3] and (−)-(*R*)-methyl 3-hydroxybutyrate[4] respectively.

Experimental

The ^{1}H-NMR and IR spectra were taken with a JELO FX-100 spectrometer and a Shimadzu IR 27G spectrometer respectively. The optical rotation was measured with a Perkin Elmer 241 polarimeter. The analytical GLC was carried out with a Shimadzu GC 4A-PF gas chromatograph, using a 3 m—5 mm o.d. glass column packed with 15% Ucon 50 HB-2000 on Chromosorb W (Ucon) or 2% Silicone OV-17 on Chromosorb W (OV-17) at the stated temperature. The preparative GLC was carried out with a Shimadzu 3A instrument using a 6 m—6 mm o.d. stainless column packed with OV-17. The preparative TLC was carried out on a Silicagel F plate (Merck Co.) with a solvent of ether/hexane=1/1.

All the chemicals except those listed below were obtained from commercial sources. 3,5-Heptanedione (IIa), 4,6-nonanedione (IIIa), and 7,9-pentadecanedione (IVa) were prepared from an appropriate ester, $RCOOCH_3$, and the 2-alkanones, CH_3COR, by a previously reported method.[5] The physical constants of the products were identical with those previously reported.[5] The GLC analysis indicated that the purity of each compound was more than 97%.

The preparation of TA–NaBr–MRNi and the hydrogenation of each substrate were carried out by a procedure reported before.[2]

Determination of the Ratio of Diastereomers in the Hydrogenation Product. The hydrogenation products of Ia and IIa were directly subjected to the GLC (Ucon) analysis. The GLC data (retention time and column temperature) are as follows: (2*R**,4*R**)-Ib, 170 min/80 °C; (2*R**,4*S**)-Ib, 159 min/80 °C; (3*R**,5*R**)-IIb, 109 min/120 °C; (3*R**,5*S**)-IIb, 99.6 min/120 °C. The GLC analyses of the hydrogenation products of IIIa to Va were carried out after the products had been converted to its trimethylsilyl (TMS) ether. A 0.1-g portion of the sample was treated with 0.2 ml each

Table 1. Hydrogenations of β-diketones over (*R,R*)-TA-NaBr-MRNi[a)]

Substrate	Proportion of diastereomers (%) in the hydrogenation product		Isolation of (*R*, R**)-diol from the hydrogenation product	
	(*R*, R**)-diol	(*R*, S**)-diol	Yield/%	$[\alpha]_D^{20}$ of diol
Ia	87	13	65 (57)	−54.5 (+53.6)
IIa	80	20	30 (25)	−39.1 (+39.0)
IIIa	85	15	11 (13)	−21.4 (+21.2)
IVa	80	20	21 (20)	−10.8 (+11.1)
Va	77	23	20 (23)	−72.7 (+72.3)

a) Figures in parenthese show the results of (*S,S*)-TA-NaBr-MRNi.

of $(CH_3)_3SiCl$ and $(CH_3)_3Si$–NH–$Si(CH_3)_3$ in 20 ml of pyridine at 90 °C for 10 min. After the removal of volatiles under reduced pressure at 90 °C, the residue was mixed with 1 ml of hexane and then centrifuged. The TMS ether in the supernatant was subjected to GLC analysis. The GLC data (retention time, packings of column, and column temperature) are as follows: (4*R**,6*R**)-TMS-IIIb, 58.4 min/Ucon/150 °C; (4*R**,6*S**)-TMS-IIIb, 54.4 min/Ucon/150 °C; (7*R**,9*R**)-TMS-IVb, 89.6 min/Ucon/150 °C; (7*R**,9*S**)-TMS-IVb, 83.6 min/Ucon/150 °C; (1*R**,3*R**)-TMS-Vb, 122 min/OV-17/140 °C; (1*R**,3*S**)-TMS-Vb, 116 min/OV-17/140 °C. The ratio of the diastereomers was evaluated from the ratio of the peak areas of the GLC.

*Isolation of the (*R*,R**)-Isomers from the Hydrogenation Product. (−)-(2*R*,4*R*)-2,4-Pentanediol (Ib)*: A 9-g portion of the hydrogenation product of Ia over (*R,R*)-TA-NaBr-MRNi was dissolved in 10 ml of ether, after which the solution was cooled at −50 °C for 1 h. The crystals precipitated from the solution were taken out and recrystallized from 10 ml of ether at −5 °C to give 5 g of (*2R,4R*)-Ib (bp 111—113 °C/19 mmHg; mp 50.5 °C). The analytical GLC (Ucon, 120 °C) showed a single peak. The crystals were too hygroscopic for the elemental analysis to be performed with a completely dried sample. The results of a partially dried sample were as follows; Found: C, 56.50; H, 11.70%. Calcd for $C_5H_{12}O_2 \cdot (0.1\ H_2O)$: C, 56.70; H, 11.62%. The NMR and IR spectra of the sample were consistent with the structure of Ib. The optical rotation of the sample was as follows; $[\alpha]_D^{20}$ −53.7° (*c* 10, ethanol), $[\alpha]_D^{25}$ −41.2° (*c* 10, $CHCl_3$) (lit,[1)] −41.3° ($CHCl_3$, *c* not stated)). As a large-scale preparation, the hydrogenation of 200 g of Ia over 26 g of (*R,R*)-TA-NaBr-MRNi was carried out in an autoclave with a capacity of 2000 ml. From the hydrogenation products, 131 g of (*2R,4R*)-Ib was obtained.

*(−)-(3*R**,5*R**)-3,5-Heptanediol (IIb)*: A 9 g portion of the hydrogenation product of IIa over (*R,R*)-TA-NaBr-MRNi was dissolved in 20 ml of ether, after which the solution was cooled at −50 °C for 3 h. The crystals thus precipitated were separated from the supernatant solution by decantation at −50 °C. Two successive recrystallizations of the crystals from 20-ml portions of ether at −10 °C gave optically pure (−)-(3*R**,5*R**)-IIb in a yield of 2.7 g (30% based on the crude product) (bp 110 °C/12 mmHg; mp 52—53 °C; Found: C, 62.64; H, 12.21%. Calcd for $C_7H_{16}O_2 \cdot (0.1\ H_2O)$: C, 62.73; H, 12.18%, $[\alpha]_D^{20}$ −39.1° (*c* 10, ethanol)). The analytical GLC (Ucon, 120 °C) showed a single peak. The NMR and IR spectra of the sample were consistent with the structure of IIb.

*(−)-(4*R*,6*R**)-4,6-Nonanediol (IIIb)*: A solution of 9 g of the hydrogenation product of IIIa over (*R,R*)-TA-NaBr-MRNi in 20 ml of ether was kept overnight at −50 °C. The crystals thus precipitated were taken out by filtration in a cold room. Three successive recrystallizations from 20 ml of ether at −10 °C gave 1.4 g of an optically pure (−)-(4*R**,6*R**)-IIIb (16% based on the crude product); mp 58—59 °C; Found: C, 67.05; H, 12.56%. Calcd for $C_9H_{20}O_2 \cdot (0.05\ H_2O)$: C, 67.07; H, 12.57%, $[\alpha]_D^{20}$ −21.4° (*c* 10, ethanol). The NMR and IR spectra of the sample were consistent with the structure of IIIb.

*(−)-(7*R*,9*R**)-7,9-Pentadecanediol (IVb)*: A solution of 9 g of the hydrogenation product of IVa over (*R,R*)-TA-NaBr-MRNi in 20 ml in 20 ml of ethyl acetate was allowed to stand at −50 °C for 1 h. The crystals thus precipitated were taken out at −50 °C and recrystallized three times from 20 ml of ethyl acetate at 5 °C to give 1.9 g of optically pure (−)-(7*R**,9*R**)-IVb (21% based on the crude product); mp 73—74 °C, Found: C, 72.89; H, 13.10%. Calcd for $C_{15}H_{32}O_2$ (0.05 H_2O): C, 73.17; H, 13.18%, $[\alpha]_D^{20}$ −10.8° (*c* 10, ethanol). The NMR and IR of the sample were consistent with the structure of IVb.

*(−)-(1*R*,3*R**)-1,3-Diphenyl-1,3-propanediol (Vb)*: A solution of 9 g of the hydrogenation product of Va over (*R,R*)-TA-NaBr-MRNi in 10 ml of ethyl acetate was allowed to stand at −10 °C overnight. The crystals thus precipitated were separated by filtration and then recrystallized three times from 20 ml of (ether/ethyl acetate)=(8/2) to give 1.8 g of optically pure (−)-(1*R**,3*R**)-Vb (20% based on the crude product); mp 145—147 °C; Found: C, 78.40; H, 7.21%. Calcd for $C_{15}H_{16}O_2 \cdot (0.05\ H_2O)$: C, 78.30; H, 7.45%, $[\alpha]_D^{20}$ −72.7° (*c* 10, ethanol). The NMR and IR spectra of the sample were consistent with the structure of Vb.

Determination of the Optical Purity of the Purified Sample. The optical purities of the purified diols were determined by means of NMR after the diols had been converted to diacetates. Into a solution of 0.5 g of diol in 5 ml of pyridine were added 2 ml of acetic anhydride. The solution was heated at 60 °C for 3 h and then worked up in the usual manner to give the crude diacetate of the diol. The purification of the diacetate was carried out by either preparative GLC (diacetates of Ib and IIb) or preparative TLC (diacetates of IIIb, IVb, and Vb). The NMR spectra were measured with a solution of diacetate (10 mg) and $Eu(hfmc)_3$ (2 molar equvalents to the acetate) in $CDCl_3$ (0.4 ml) at 50 °C. None of the diacetates derived from purified products showed any detectable signal of the antipode.

The autors would like to thank Professor Yoshiharu Izumi for his helpful suggestions and discussions. Thanks are also due to Mrs. Aiko Kobatake for the elemental analyses and Mr. Yuji Hiraki for measuring the NMR spectra.

The Synthesis of 1,3,5-Thiadiazinylium Salts

Isao SHIBUYA

National Chemical Laboratory for Industry, Yatabe, Ibaraki 305

(Received February 4, 1980)

Synopsis. 1,3,5-Thiadiazinylium salts were synthesized in good yields by the reaction of *N*-acyl imidoyl chlorides with thioamides or the treatment of 4*H*-1,3,5-thiadiazines with trityl salts.

Heteroaromatic cation compounds, such as pyrylium, 1,3-oxazinylium salts, and their S-analogs, have been synthesized, and the reactions of these salts with various nucleophiles have been investigated to afford numerous derivatives. In these salts, the S-analog is stabler or less reactive than the corresponding O-analog. The present author has been studying the reaction of the 2,4,6-triphenyl-substituted compounds of these salts with active methylenes in order to ascertain the reactivity of these hetero rings.[1] 2,4,6-Triphenyl-1,3,5-oxadiazinylium salt has been known previously as the adduct of benzonitrile–benzoyl chloride–alminium chloride (2:1:1); since this salt is very hygroscopic, however, it is almost impossible to isolate as a pure salt.[2] On the other hand, the S-analog, 2,4,6-triphenyl-1,3,5-thiadiazinylium salt, has not yet been found, though this salt is supposed to be stabler than the corresponding O-analog. Therefore, it is expected that this salt may be obtained in a good purity if a synthetic route is found. 2-Amino-4,6-diphenyl-1,3,5-thiadiazinylium salts have been synthesized by Liebscher *et al.*[3] but his method is specific and almost impossible to apply to other 1,3,5-thiadiazinylium salts. In order to find the general synthetic method of 1,3,5-thiadiazinylium salts, several probable paths were offered by analogy with those of other known heteroaromatic cations, and their reaction conditions were checked. As a result, it was found that a number of 1,3,5-thiadiazinylium salts (**1**—**11**) were given by the paths, (**A**) and (**B**), shown in Scheme 1.

In Path **A**, *N*-acyl imidoyl chlorides reacted with thioamides in a strong acidic medium to produce cycloization products, **1**—**6**. In Path **B**, the starting

materials, 4*H*-thiadiazines, were obtained by treating a mixture of aldehyde–nitrile–thioamide (1:1:1) with the BF_3–ether complex in chloroform[4] and then treated with trity salt to lead to **7**—**11**.

Satisfactory analytical data were obtained for all the compounds. Their IR spectra have four common characteristic absorptions at 1530–1330 cm^{-1} except for **2**. These salts are not so stable in a dilute solution, and consequently do not show exact UV spectra. The reaction of **1** or **7** with ammonia, hydrazine, or hydroxylamine gave 2,4,6-triphenyl-1,3,5-triazine, 3,5-dipenyl-1,2,4-triazole, or 3,5-diphenyl-1,2,4-oxadiazole respectively in good yields. These results show that the behavior of **1** or **7** toward these nucleophiles is in the same manner as the 2,4,6-triphenyl-1,3,5-oxadiazinylium salt.[5] It is thus confirmed that **1**—**11** are 1,3,5-thiadiazinylium salts.

Experimental

The Reaction of N-*Acyl Imidoyl Chloride with Thioamide.* Into a solution of *N*-acyl imidoyl chloride (0.011 mol) and thioamide (0.010 mol) in 15 ml of acetic anhydride, 1.2 ml of 70% perchloric acid or 2.4 ml of 40% tetrafluoroboric acid was stirred drop by drop, at room temperature for 10 min, the mixture was then allowed to stand at 0—5 °C for 2 d. The resulting precipitate was collected by filtration and then recrystallized from acetonitrile to give **1**—**6**. The data thus obtained are summarized in Table 1.

The Reaction of 4H-*Thiadiazine with Trityl Salt.* Into a stirred solution of 4*H*-thiadiazine (0.010 mol) in 20 ml of acetic anhydride, 0.012 mol of trityl perchlorate or tetrafluoroborate was added at room temperature for 15 min. The mixture was added to dry ether (10 ml), after which the mixture was allowed to stand 3 d at 0—5 °C. The resulting precipitate was collected by filtration and then washed with dry ether to give **7**—**11**. Their data are also given in Table 1.

The Reaction of ***1*** *or* ***7*** *with Ammonia, Hydrazine, or Hydroxylamine.* Into 10 ml of 28% ammonium hydroxide, 30% aqueous hydrazine, or a solution of $NH_2OH \cdot HCl$ (1.5 g) in 10 ml of 5 mol dm^{-3} NaOH, 1 mmol of **1** or **7** was stirred in small portions at 0—5 °C, after which the mixture allowed to stand at room temperature for 2 h. The resulting precipitate was filtered and recrystallized from acetic acid, ethanol, or methanol to give 2,4,6-triphenyl-1,3,5-triazine (87%, mp 233 °C), 3,5-diphenyl-1,2,4-triazole (78%, mp 192 °C), or 3,5-diphenyl-1,2,4-oxadiazole (71%, mp 108 °C) respectively. Their IR spectra were completely superimposed on those of the respective authentic samples.[2,6]

A ^{13}C NMR and CNDO/2 Calculation Study of the Transannular Interaction in [2.2]Metacyclophanes

Kazushi TOKITA, Shoichi KONDO, and Nobuo MORI*

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received February 8, 1980)

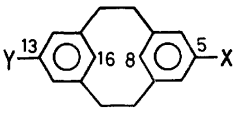
Synopsis. The substituent effects on the chemical shifts and CNDO/2 total electron densities of the facing aryl carbons, C-8 and C-16, in [2.2]metacyclophanes are reported.

In the course of ^{13}C NMR and electron density studies of [2.2]cyclophanes, we found that there is neither detectable transmission of spin information[1] nor detectable charge transfer *via* a transannular route in the ground electronic state.[2] Furthermore, we explained[3] the known paramagnetic proximity effect on aryl carbon resonances in [2.2]cyclophanes[4] by assuming a local decrease in the excitation energy term of the paramagnetic shielding expression by Karplus and Pople.

In the present work, we have studied the relationships between the chemical shifts (δ) and the total electron densities (q^t) of the facing inner aryl carbons, C-8 and C-16, in the nine [2.2]metacyclophanes, **1**—**9**, shown in Table 1. This study has been undertaken mainly in an attempt to explain the recent results by Atobe and Sato[5] that in substituted [2.2]metacyclophanes the resonance of C-8 (or C-16) moves downfield with an increase in the Hammett σ_p constant of a substituent at the 13 (or 5)-position, respectively.

Table 1 gives the excess total electron densities (Δq^t: $4-q^t$) on C-8 and C-16 in **1**—**9** together with the δ values observed in $CDCl_3$. The q^t values were calculated using the CNDO/2-MO method.[6] In these calculations,[7] the geometry of each substituted cyclophane was assumed to be the same as that of the parent hydrocarbon, **1**,[8] but with the hydrogen replaced by a substituent. As for the substituents, X and Y, the standard geometry parameters[9] were used.

TABLE 1. CHEMICAL SHIFTS AND EXCESS TOTAL ELECTRON DENSITIES OF C-8 AND C-16 IN THE CYCLOPHANES



Compound	X	Y	C-8 $\delta(\Delta q^t \times 10^3)$	C-16 $\delta(\Delta q^t \times 10^3)$
1	H	H	136.3[a] (−22)	136.3 (−22)
2	F	H	132.6[b] (−44)	136.2 (−22)
3	NO_2	H	142.1[c] (+1)	136.9 (−25)
4	CH_3O	CH_3	130.0[d] (−53)	133.6 (−32)
5	CH_3	CH_3	133.9[a] (−32)	133.9 (−32)
6	CN	CH_3	140.6[d] (−17)	134.2 (−34)
7	NO_2	CH_3	142.3[d] (+1)	134.4 (−36)
8	CH_3O	CH_3O	129.3[d] (−52)	129.3 (−52)
9	NO_2	CH_3O	141.9[d] (+2)	130.0 (−56)

a) Data taken from Ref. 4. b) From Ref. 3. c) From Ref. 2. d) From Ref. 5.

The δ and the Δq^t values in Table 1 bear a fairly good linear relationship, as Fig. 1 shows. It should be noticed that X (or Y) has small, but significant, effects for both values of C-16 (or C-8), respectively. These effects can be confirmed by inspecting the data for the following groups of compounds, each having either X or Y as a fixed substituent (A) and the other as an unfixed one (B): **1**—**3** (H as A), **4**—**7** (CH_3 as A), **4**, **8**, and **9** (CH_3O as A), and **3**, **7**, and **9** (NO_2 as A).

For example, in the group of **4**—**7** having a methyl as Y (= A), an electron-withdrawing X (= B) causes a decrease in Δq^t (increase in q^t) and an increase in δ (downfield shift of the resonance) for C-16. In the other groups, the same can be found. From this result it is evident that, in spite of the increase in q^t, the resonance of C-16 is shifted downfield. A possible explanation for this downfield shift may be obtained by assuming that the introduction of the electron-withdrawing X causes a decrease in the diamagnetic anisotropy effect of the X-bearing ring, resulting from the decreased electron density, and a local decrease in the electronic excitation energy[10] by a transannular interaction between C-8 and C-16.[3]

The above results give additional support to our previous proposal[3] that the known paramagnetic proximity effect in [2.2]cyclophanes is not due to a decrease in electron density.

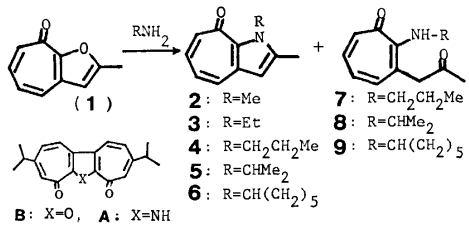
The Preparation of Pyrrolotropones from Furotropones

Hitoshi TAKESHITA,* Atsuko CHISAKA, and Hiroaki MAMETSUKA
Research Institute of Industrial Science, 86, Kyushu University, Hakozaki, Fukuoka 812
(Received March 18, 1980)

Synopsis. Furotropones were transformed into a series of pyrrolotropones by heating with amines. The methine proton of 1-isopropyl-2-methylcyclohepta[1,2-*b*]-pyrrol-8-one was found to appear at an unusually low field.

Recently, we have developed a new method of synthesizing furotropones, 8*H*-cyclohepta[1,2-*b*]furan-8-ones,[1] and difurotropones, 6*H*-cyclohepta[1,2-b:3,4-b']difuran-6-ones.[2] This prompted us to investigate a new method of synthesizing pyrrolotropones,[3,4] 8*H*-cylohepta[1,2-*b*]pyrrol-8-ones, by condensation with amines.[5]

2-Methyl-8*H*-cyclohepta[1,2-*b*]furan-8-one (**1**)[6] was heated with methylamine in a sealed tube to give a single product (**2**). The NMR spectra of **2** clearly showed it to be 1,2-dimethyl-8*H*-cyclohepta[1,2-*b*]pyrrol-8-one. Similarly, products (**3**, **4**, **5**, and **6**) were obtained from reaction with ethylamine, propylamine, isopropylamine, and cyclohexylamine respectively. When bulky amines were used, 2-alkylamino-3-(2-oxopropyl)tropones (**7**, **8**, and **9**) were obtained as by-products. However, **1** did not react with ammonia or *t*-butylamine under comparable conditions.



The structures of these products were deduced from their NMR spectra. The signal arising from the methine proton of the isopropyl group of 1-isopropyl-2-methyl-8*H*-cyclohepta[1,2-*b*]pyrrol-8-one (**5**) was found to appear at an unusually low field (δ[7]: 6.33).

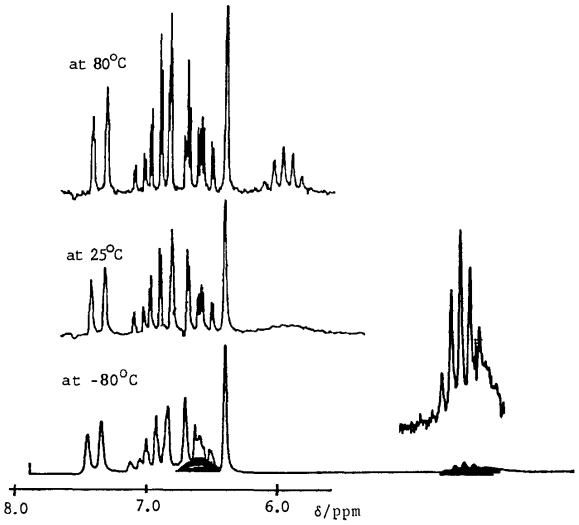


Fig. 1. The temperature dependent NMR spectrum of **5**.

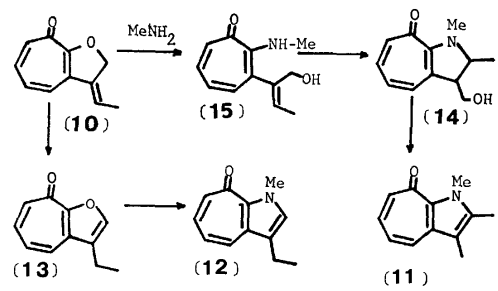
Moreover, although the methine proton appeared as a broad and unsolved signal at room temperature, it became a sharp septet (J=7 Hz) at 80 and 120 °C with almost the same chemical shift (Fig. 1). This extraordinary low-field shift can be explained in terms of the anisotropy of the carbonyl group, which is in the near vicinity of the methine group. This was further confirmed by a low-temperature measurement of the NMR spectrum; although above −40 °C, the NMR features were not very different, at −80 °C, the NMR disclosing the presence of the isomerism by showing pairs of signals, isopropyl methyl doublets, vinyl methyl singlets, and the methine broad multiplets [$\delta^{(CD_3)_2CO}$: 4.7 and 6.6], in a ratio of *ca.* 1:2.[8]

On the other hand, although the methine proton of the 1-cyclohexyl derivative (**6**) could not be identified in the room-temperature NMR spectrum, it was observed as a very broad multiplet at δ *ca.* 5.9 by heating the sample over 80 to 120 °C. Furthermore, a pair of broad, methine-proton signals due to the occurrence of rotational isomerism, as well as other signals, began to appear at $\delta^{(CD_3)_2CO}$: 4.6 and 6.4 (1:2) at −80 °C. The behavior is thus the same as that of **5**.

As we have mentioned, **1** was unreactive with ethanolic ammonia. However, we thought that a dihydrofurotropone, 3-ethylidene-2,3-dihydro-8*H*-cyclohepta[1,2-*b*]furan-8-one (**10**), might be more reactive than the fully conjugated furans such as **1**. Again, no reaction took place when **10** was heated with ethanolic ammonia in a sealed tube, but we found that, with methylamine, **10** yielded, when heating at 100 °C, 1,2,3-trimethylcyclohepta[1,2-*b*]pyrrol-8-one (**11**), 3-ethyl-1-methylcyclohepta[1,2-*b*]pyrrol-8-one (**12**), 3-ethylcyclohepta[1,2-*b*]furan-8-one (**13**), and two other by-products, 3-hydroxymethyl-1,2-dimethyl-2,3-dihydrocyclohepta[1,2-*b*]pyrrol-8-one and 2-methylamino-3(1-hydroxymethylpropen-1-yl)tropone (**14** and **15**). The **11**, product which was also obtained by the thermolysis of **14**, may be formed by the sequence depicted in Scheme 2.



Experimental

Reaction of 1 with Methylamine. A mixture of **1**[6] (80 mg) and methylamine (30% in water, 4 cm³) was heated in a sealed tube at 160 °C for 6 h. The mixture was then chromatographed on a silica-gel column, using hexane–

ethyl acetate as the eluent. The sole product identified was **2**; colorless needles; mp 76—77 °C (from hexane–benzene); 66 mg (76%) [Found: C, 76.29; H, 6.35; N, 8.00%. Calcd for $C_{11}H_{11}ON$: C, 76.27; H, 6.40; N, 8.00%. δ: 2.32 (3H, d, J=1 Hz), 4.14 (3H, s), 6.25 (1H, qm, J=1 Hz), 6.58 (1H, ddd, J=10.5, 5.5, 3.5 Hz), 6.97 (1H, dd, J=3.5, 1 Hz), 6.98 (1H, dd, J=5.5, 1 Hz), and 7.33 (1H, dt, J=10.5, 1 Hz)].

Reaction of ***1*** *with Ethylamine.* Similarly, a mixture of **1** (75 mg) and ethylamine (70% in water, 4 cm³) was heated in a sealed tube at 120 °C for 14 h to give **3** (colorless needles; mp 85—87 °C (from hexane–benzene); 57 mg (65%) [Found: C, 76.95; H, 7.08; N, 7.45%. Calcd for $C_{12}H_{13}ON$: C, 76.97; H, 7.00; N, 7.48%. δ: 1.37 (3H, t, J=7 Hz), 2.41 (3H, s), 4.71 (2H, q, J=7 Hz), 6.33 (1H, s), 6.62 (1H, ddd, J=10.5, 5.5, 4.5 Hz), 7.0 (2H, m), and 7.36 (1H, dt, J=10.5, 1 Hz)]), together with a colorless oil (≈1 mg) which showed spectral features similar to those of uncyclized products, but no further characterization was carried out.

Reaction of ***1*** *with Propylamine.* A mixture of **1** (83 mg) and propylamine (33% in water, 4 cm³) was heated in a sealed tube at 160 °C for 24 h. Subsequently, silica gel chromatography of the mixture gave **7** (a colorless oil; 4.5 mg (4%) [Found: *m/e*, 219(M⁺). δ: 1.05 (3H, t, J=7 Hz), 1.77 (2H, m), 2.28 (3H, s), 3.26 (2H, tm, J=7 Hz), 3.80 (2H, s), 6.54 (1H, dd, J=10, 1 Hz), 6.62 (1H, td, J=9.5, 1 Hz), 7.21 (1H, ddd, J=10, 8.5, 1 Hz), and 7.34 (1H, dd, J=9.5, 1 Hz)]) and **4** (colorless needles; mp 57—58 °C (from hexane–benzene); 89 mg (85%) [Found: C, 77.47; H, 7.53; N, 6.94%. Calcd for $C_{13}H_{15}ON$: C, 77.58; H, 7.51; N, 6.96%. δ: 0.96 (3H, t, J=7 Hz), 1.77 (2H, m), 2.39 (3H, s), 4.59 (2H, t, J=7 Hz), 6.32 (1H, s), 6.61 (1H, ddd, J=10.5, 5.5, 4 Hz), 6.99 (2H, m), and 7.35 (1H, dt, J=10.5, 1 Hz)]).

Reaction of ***1*** *with Isopropylamine.* A mixture of **1** (85 mg) and isopropylamine (33% in water, 4 cm³) was heated in a sealed tube at 160 °C for 23 h to give **8** (a colorless oil; 21 mg (18%) [Found: *m/e*, 219 (M⁺). δ: 1.30 (6H, d, J=7 Hz), 2.27 (3H, s), 3.77 (2H, s), 3.80 (1H, m), 6.52 (1H, dd, J=10.5, 1 Hz), 6.60 (1H, td, J=8, 1 Hz), 7.20 (1H, td, J=10.5, 1 Hz), and 7.33 (1H, dd, J=8, 1 Hz)]) and **5** (colorless needles; mp 78—79 °C (from hexane); 48 mg (45%) [Found: C, 77.17; H, 7.61; N, 6.55%. δ: 1.37 (6H, d, J=7 Hz), 2.51 (3H, d, J=1 Hz), 6.3 (1H, qm, J=1 Hz), 6.1—6.4 (1H, br. m), 6.60 (1H, ddd, J=10.5, 5, 4 Hz), 6.97 (2H, m), and 7.33 (1H, dt, J=10.5, 1 Hz)]).

Reaction of ***1*** *with Cyclohexylamine.* A neat mixture of **1** (96 mg) and cyclohexylamine (200 mg) was heated in a sealed tube at 160 °C for 6 h to give **9** (a colorless oil; 18 mg (12%) [Found: *m/e*, 259(M⁺). δ: 1.1—2.2 (10H, m), 2.28 (3H, s), 3.45 (1H, m), 3.78 (2H, s), 6.57 (1H, dt, J=9, 1 Hz), 6.59 (1H, td, J=9, 1 Hz), 7.18 (1H, td, J=9, 1 Hz), 7.32 (1H, dd, J=9, 1 Hz), and 7.2—7.5 (1H, br., N*H*)]) and **6** (a colorless oil; 20 mg (14%) [Found: M.W., 241.1471. Calcd for $C_{16}H_{19}ON$: 241.1567. δ: 1.1—2.4 (11H, m), 2.53 (3H, d, J=1 Hz), 6.30 (1H, qm, J=1 Hz), 6.60 (1H, ddd, J=10.5, 5, 4.5 Hz), 6.98 (2H, m), and 7.33 (1H, dt, J=10.5, 1 Hz)]).

*Reaction of 3-Ethylidene-8*H*-2,3-dihydrocyclohepta[1,2-*b*]furan-8-one (****10****) with Methylamine.* A mixture of **10** (90 mg) and methylamine (30% in water, 4 cm³) was heated in a sealed tube at 100 °C for 4 h. The mixture was then diluted with water and extracted with ether. Subsequent silica gel column chromatography of the extracts gave **11** (pale yellow prisms; mp 106—107.5 °C (from hexane–methanol); 9.6 mg (9.9%) [Found: C, 76.85; H, 7.22; N, 7.33%. Calcd for $C_{12}H_{13}ON$: C, 76.97; H, 7.00; N, 7.48%. δ: 2.23 (3H, s), 2.34 (3H, s), 4.20 (3H, s), 6.65 (1H, ddd, J=10.7, 6, 3 Hz), 6.9—7.1 (2H, m), and 7.43 (1H, dt, J=10.7, 1 Hz)]), **12** (pale yellow needles; mp 73—74 °C (from hexane–benzene); 5.2 mg (5.4%) [Found: 76.72; H, 6.90; N, 7.59%. δ: 1.26 (3H, t, J=7 Hz), 2.68 (2H, q, J=7 Hz), 4.20 (3H, s), 6.60 (1H, ddd, J=11, 7, 2.5 Hz), 6.85 (1H, s), 7.00 (2H, m), and 7.42 (1H, dt, J=11, 1 Hz)]), **14** (a yellow liquid; 75 mg (70%) [Found: M.W., 205.1103. Calcd for $C_{12}H_{15}O_2N$: 205.1103. δ: 1.28 (3H, d, J=6 Hz), 2.89 (1H, q, J=6 Hz), 3.16 (1H, br. m), 3.51 (3H, s), 3.70 (2H, d, J=6 Hz), 6.44 (1H, ddd, J=10, 8, 2 Hz), and 6.8—7.1 (3H, m)]), and **15** (a yellow liquid; 5.5 mg (5.3%) [Found: *m/e*, 205 (M⁺). δ: 1.92 (3H, d, J=7 Hz), 3.06 (3H, d, J=5.5 Hz), 4.2 (2H, m), 4.5—4.8 (1H, br. s), 5.76 (1H, q, J=7 Hz), 6.57 (1H, d, J=10 Hz), 6.67 (1H, td, J=10, 1 Hz), 7.25 (1H, td, J=10, 1 Hz), 7.39 (1H, dd, J=10, 1 Hz), and 7.2—7.6 (1H, br., N*H*))].

Thermal Dehydration of ***14*** *to* ***11****.* A dimethyl sulfoxide solution (0.3 cm³) of **14** (20 mg) was heated in a sealed tube at 185 °C for 4 h. The NMR analysis indicated the formation of **11** in a 60% yield, together with unchanged **14** (40%).

*Reaction of 3-Ethyl-8*H*-cyclohepta[1,2-*b*]furan-8-one (****13****)*[1] *with Methylamine.* A mixture of **13** (45 mg) and an aqueous solution of methylamine (30%, 4 cm³) was heated in a sealed tube at 120 °C for 7 h. Subsequent silica gel chromatography of the mixture afforded **12** (40 mg; 83%).

The Chemical Shifts of the Bridge Methylene Protons of 1,6-Methano-[11]annulene Systems. Positive Evidence for the Assignments

Tadao UYEHARA* and Akito ICHIDA

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received March 21, 1980)

Synopsis. The assignments of the chemical shifts to the bridge methylene protons of 1,6-methano[11]annulen-9-one (**3**) were established on the basis of their lanthanoid-induced shifting. Those of the protonated cation of **3** were proven from the spectrum of a mixture of 12-d_1 derivatives of **3** in trifluoroacetic acid.

The ^{1}H-NMR chemical shifts of the bridge protons are key indices to know the tropicity of bridged annulenes. Thus, the assignments of the chemical shifts to the bridge protons are quite important, especially those of asymmetrical bridged-annulenes such as 1,6-methano[11]annulene systems.

During the course of our investigations of the condensed pi-electron systems containing the methano-[11]annulene part (**1**) and its protonated species (**2**),[1] we noticed that the chemical shifts of the bridge methylene protons of methano[11]annulenes had been assigned without positive proof. This paper will deal with the evidence for the assignments to the bridge protons of 1,6-methano[11]annulen-9-one (**3**) and its protonated cation (**4**).[2]

Results and Discussion

The chemical shifts of the bridge methylene protons of 1,6-methano[11]annulenes (mainly bicyclo[5.4.1]-dodeca-2,5,7,9,11(1)-pentaen-4-ylidenes), except those of **3**, were previoulsy assigned without any explanation.[3] The assignments to the bridge protons (H_s and H_a, the *syn* and *anti*-protons to the cycloheptatriene system respectively) of **3** by Vogel and his co-workers[2] were based on an assumption of long-range couplings (W-shape couplings) between H_2, (H_5), and H_a (δ= 1.68, (dt), $J_{a,s}$=11.4 Hz, and $J_{a,2}$=$J_{a,5}$=1.5 Hz). The assignment may be reasonable because, in the spectrum most 1,6-methano[11]annulenes,[3] the center of the signals (a doublet) due to the other bridge proton (H_s) appears in the δ=0.2—0.0 range; the chemical shifts of H_s may not be affected greatly by substituents on the C_5-bridge. However, one can point out that the long-range couplings might be replaced by allylic couplings between H_2, (H_5), and H_s, since the allylic angles of H_a (θ=0°, from a molecular model) indicate $J_{allylic}$=0 Hz, while those of H_s (θ=60°) indicate $J_{allylic}$=1.5 Hz. Thus, we can not apply the assignments of the bridge methylene protons of **3** to those of more complicated systems such as **1** without any positive evidence for the W-shape coupling. In order to distinguish the signals for H_a and those for H_3 of **3**, we used lanthanoid-shift reagents ($Eu(fod)_3$ and $Pr(fod)_3$). The lanthanoid-induced shifting (given in Table 1) of the peripheral protons is normal pseudo-contact shifting. Now, the signals appearing as the doublet of triplets at δ=1.68 and as the doublet at δ=0.04 are for H_a and H_s respectively, since the former are shifted more than the latter. *The long-range couplings are exactly due to the W-shape coupling between H_2, (H_5), and H_a.*

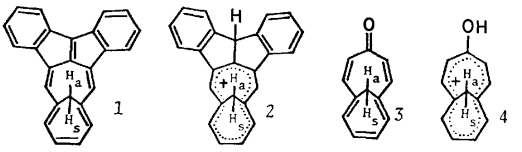
Table 1. Chemical shifts (δ) and lanthanoid-induced shifts ($\Delta\delta$, ppm) of 1,6-methano[11]annulen-9-one (**3**)

Proton	δ[a]	$\Delta\delta$ Concn of $Eu(fod)_3$[b] 0.047	0.063	0.104	$\Delta\delta$ Concn of $Pr(fod)_3$[b] 0.019	0.06
$H_{8,10}$	6.02	c)	−2.01	−2.92	+1.08	+2.78
$H_{7,11}$	7.18	c)	−0.55	−0.78	+0.26	+0.73
$H_{2,5}$	6.90	c)	−0.37	−0.51	+0.12	+0.39
$H_{3,4}$	7.21	c)	−0.37	−0.47	+0.03	+0.14
H_a-(dt)	1.68	−0.68	−0.96	−1.34	+0.57	+1.55
H_s-(d)	0.04	−0.26	−0.36	−0.53	+0.17	+0.59

a) Ref. 2. b) Mole ratios to the substrate. c) Overlapping each other.

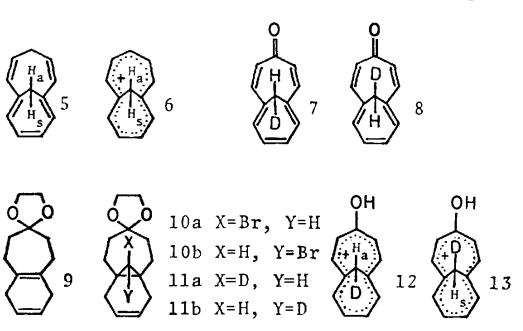
The crucial difference between the multiplicities of H_a and H_s should be generally found in the specta of other 1,6-methano[11]annulenes containing the cycloheptatriene system, such as **1** and the hydrocarbon (**5**).[4]

The spectrum of cation **2** shows a broad-doublet at δ=−0.21 (J=11.4 Hz, $W_{1/2}$=5 Hz) and a doublet at δ=0.45 (J=11.4 Hz, $W_{1/2}$=1 Hz) for the bridge protons.[1] Similarly, the signals for those of **4**[2] and the cation (**6**)[5] are seen as broad-doublets in the higher-field and doublets in the lower-field: **4**: δ=−0.6 (bd) and δ=−0.4 (d); **6**: δ=−1.8 (bd) and δ=−0.3 (d). For those, the high-field- and low-field protons were assigned tentatively



to H_a and H_s respectively.[2,6]

In order to establish the assignments, we chose the 12-monodeuterated derivatives of **4** as the models. A mixture of the ketones (**7** and **8**) was prepared from the acetal (**9**) based on a modification of the method of Vogel.[2] The ^{1}H-NMR spectra of the mixture in CCl_4 and in trifluoroacetic acid (TFA) are shown in Fig. 1. The spectrum in CCl_4 indicates that **7** and **8** are formed in a ratio of 3 to 1. In TFA, the cations (**12** and **13**) should be formed in a 3-to-1 ratio respectively.



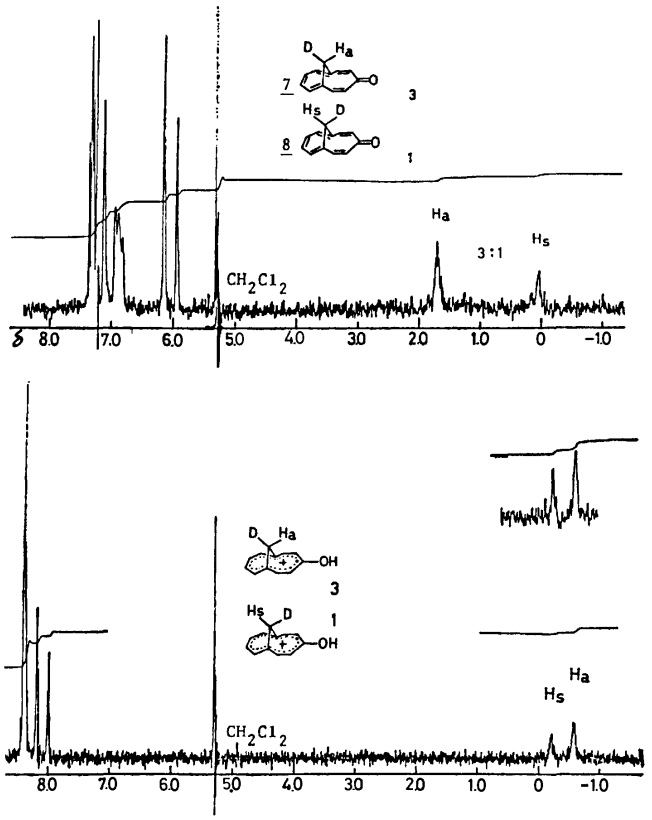


Fig. 1. ^{1}H-NMR spectra of 1,6-methano[11]annulen-9-one-12-d_1 (**7** and **8**) in CCl_4 (upper) and in TFA (lower).

Now, the high-field bridge proton of **4** is H_a, and the other is H_s. Thus, it is true that the line-broadening of the signals for H_a of **4** is due to the W-shape coupling between H_2, (H_5), and H_a. This assignment can aslo be applied to each bridge proton of **2** and **6**.

Experimental

General. Melting points were determined on a Thomas Hoover MP apparatus and are uncorrected. Infrared spectra were recorded on a Hitachi Model 215 spectrometer. NMR spectra were obtained on Varian A-60 or JEOL JNM-PMX 60 spectrometers, using tetramethylsilane and/or dichloromethane as internal standards. Mass spectral studies were conducted using a Hitachi M-52 spectrometer.

*12,12-Dibromotricyclo[5.4.1.0^{1,7}]dodeca-9-en-4-one Ethylene Acetal (**9a**).* To a mixture of the acetal (**9**, 2.0 g) and *t*-BuOK (1.41 g) in dry ether (25 ml) was added a solution of bromoform (1.3 ml) in ether (1.3 ml) at 0 °C under a nitrogen atmosphere over a period of 1 h. After 19 h stirring at 0 °C, the mixture was diluted with water (60 ml) and extracted with CH_2Cl_2 (3×40 ml). The extracts were combined, dried ($MgSO_4$), concentrated, and subjected to chromatography on alumina. The adduct, **9a**, was isolated in a 28.3% yield (1.04 g). **9a**: colorless prisms, mp 95—122 °C; NMR ($CDCl_3$) δ=1.62—1.93 (m, 8H), 2.28 (bd, 4H), 3.88 (s, 4H), and 5.58 (bt, 2H). Found: C, 44.23; H, 4.86%; M$^+$, 380 (1.24%), 378 (2.49%), and 376 (1.58%). Calcd for $C_{14}H_{18}Br_2O_2$: C, 44.47; H, 4.80%.

*12-Bromotricyclo[5.4.1.0^{1,7}]dodeca-9-en-4-one Ethylene Acetal (**10a** and **10b**).* A mixture of **9a** (2.63 g), tributyltin hydride (2.22 g), AIBN (13 mg), and dry cyclohexane (18 ml) was heated at 60 °C for 2.5 h and then at 80 °C for 1.5 h while being stirred under an argon atmosphere. Carbon tetrachloride (5 ml) was then added to the solution, and the mixture was concentrated *in vacuo*. The resulting oil was chromatographed on alumina, and eluted with hexane–benzene. A colorless, amorphous powder (1.61 g) was thus obtained. A mixture of **10a** and **10b**: NMR (CCl_4) δ= 1.53—1.83 (m, 8H), 2.16 and 2.23 (bs each, 4H), 2.88 (s, 0.6H), 3.18 (s, 0.4H), 3.80 and 3.85 (s each, 4H), and 5.48 (bs, 2H). Found: M$^+$, 300 (10.2%) and 298 (11.7%).

*Tricyclo[5.4.1.0^{1,7}]dodeca-9-en-4-one-12-*d$_1$ *Ethylene Acetal (**11a** and **11b**).* To a solution of a mixture of **10a** and **10b** (1.0 g) in THF (dry, oxygen free) was added *n*-BuLi (1.56 M in hexane, 2.9 ml) at −78 °C under argon. After 1.5 h stirring, the solution was allowed to warm to room temperature. After having 0.5 ml of methanol-d_4 syringed in, stirred for 10 min, poured onto brine, and extracted with ether (3×50 ml), the combined organic solutions were dried ($MgSO_4$) and evaporated, yielding a pale yellow oil (728 mg, 98.6%). NMR (CCl_4) δ=0.13 (bs, 0.75H), 0.66 (bs, 0.25H), 1.38—1.78 (m, 8H), 2.20 (bs, 4H), 3.84 (s, 4H), and 5.45 (bs, 2H). The crude **11a** and **11b** thus obtained were used without further purification.

*Bicyclo[5.4.1]dodeca-2,5,7,9,11(1)-pentaen-4-one-12-*d$_1$ *(**7** and **8**).* A solution of bromine (527 mg) in CH_2Cl_2 (7 ml) was added to a mixture of **11a** and **11b** (728 mg) in CH_2Cl_2 (20 ml) at −78 °C over a period of 20 min. The subsequent evaporation of the solvent gave a pale yellow solid, which was then heated under reflux with 15% KOH in methanol (20 ml) for 2 h. After the solvent had then been removed and the mixture had been diluted with water (50 ml) and extracted with ether (3×40 ml), the extracts were combined, dried ($MgSO_4$), and concentrated, yielding a colorless oil (714 mg). To a solution of the crude products in THF (20 ml) were added perchloric acid (60%, 0.4 ml) and water (4 ml), after which the mixture was heated at 50 °C for 5 h. After most of the THF had been removed *in vacuo*, and the mixture had been diluted with water (50 ml), and extracted with ether (3×25 ml), the combined organic solutions were washed with aqueous $NaHCO_3$, water, and brine, dried ($MgSO_4$), and evaporated, thus yielding a pale yellow oil (580 mg). It was chromatographed on silica gel (30 g) and eluted with hexane–benzene, thus yielding bicyclo[5.4.1]-dodeca-7,9,11(1)-trien-4-one-12-d_1 as a pale yellow oil (320 mg, 52%). IR (film) 1716 cm^{-1}; NMR (CCl_4) δ=1.57 (bs, 0.3H), 2.85—3.10 (m, 8.7H), 5.98 (m, 2H), and 6.46 (m, 2H). The dehydrogenation of the ketones (90 mg) with DDQ (418 mg) in benzene (4.5 ml) at 115 °C for 12 h in a sealed tube gave a mixture of **7** and **8** (26 mg, 30%, mp 69.5—71.8 °C) after repeated chromatography on alumina (15 g). IR (CCl_4) 1624 cm^{-1}; MS *m/e* (%) 171(29.7), 170 (4.5), 143 (53.2), and 142 (100).

The Reaction of Thiocumulenes with Fulvene

Takao Saito, Teruhiko Musashi, and Shinichi Motoki*

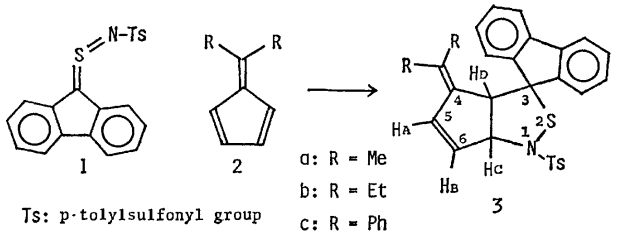
Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

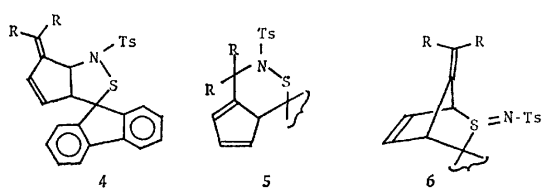
(Received March 25, 1980)

Synopsis. *S*-(9-Fluorenylidene)-*N*-(*p*-tolylsulfonyl)-sulfimide and bis(*p*-tolylsulfonyl)sulfur diimide reacted as 1,3-dipoles with fulvenes to form (2+3)cycloadducts.

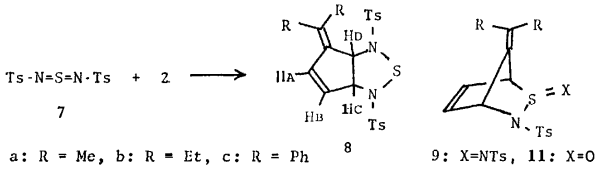
Thiocumulenes add readily to a great variety of multiple bond compounds, giving rise to stable or unstable cycloadducts. *N*-Sulfinylamines (R–N=S=O), sulfur diimides (R–N=S=N–R′), thione *S*-oxides (RR′C=S=O), and sulfimides (RR′C=S=N–R″) react as 2π-components with acyclic dienes to give stable (2+4)-cycloadducts.[1–4] In the reaction with cyclopentadiene, thione *S*-oxides react also as 2π-components,[3] whereas sulfimides react as 1,3-dipoles to give (2+3)cycloadducts.[4] The (2+4)adduct of cyclopentadiene and *N*-sulfinylbenzenesulfonamide can be isolated only at low temperatures, but decomposes into its components at room temperature.[5] Accordingly we took an interest in the reactions of these thiocumulenes with fulvene because fulvene is one of the model compounds which undergo periselective cycloaddition reactions.[6]

The reaction of sulfimide (**1**) with dimethylfulvene (**2a**) under mild conditions produced a single adduct **3a** in nearly quantitative yield. The mass spectra and the elemental analyses suggested that the product was a 1:1-adduct. The IR spectrum showed the presence of νC=C absorption at 1670 cm^{-1} and the absence of any strong νS=N absorption band in the region of 900—1000 cm^{-1}. The ^{1}H NMR spectrum displayed three methyls as singlets at δ 0.57, 1.49 and 2.47 (Ts) and two olefinic and two methine protons (δ 6.59 (H_A, dd), 5.96—5.76 (H_B, H_C, m), 4.04 (H_D, d)). The chemical shifts of H_A-H_D and the coupling constants (J_{AB}=5.3, J_{AC}=1.9, J_{CD}=7.0 Hz) determined by spin-decoupling measurements centered at H_A, H_{B-C}, and H_D are consistent with structure **3** or **4** rather than with **5** or **6**, indicating that H_A and H_B are vicinal olefinic protons and that H_C and H_D are vicinal *cis*-methine protons. In the two methyls of the fulvene moiety, the resonance for the inside methyl group (δ 0.57) appeared at a higher field than that of the outside methyl group (δ 1.49) due to the shielding effect exerted by the diamagnetic anisotropy of the adjacent fluorenylidene ring. This excludes the possibility of the regioisomer **4**. The structure **3** was also supported by the ^{13}C NMR spectroscopy (see Experimental). Treatment of **1** with **2b** and **2c** also gave (2+3)cycloadducts (**3b** and **3c**) in fairly good yields.





When the mixture of bis(*p*-tolylsulfonyl)sulfur diimide (**7**) and **2a** in 1,2-dichloroethane was stirred for a day at room temperature, a minor cycloadduct (**8a**) was obtained together with a major polymeric black tar and *p*-toluenesulfonamide, which might be derived from **7** (the unreacted **7** or **9**) during the column chromatography operation.[7] The IR spectrum of the adduct showed νC=C at 1660 cm^{-1}. In the ^{1}H NMR spectrum, four sets of methyl protons were observed, at δ 1.80, 1.83, 2.42 and 2.44, as singlets. Obviously the two methyls of higher field were those of the substituents at C-6 of the fulvene, and the others arose from the megnetically unequivalent *p*-tolylsulfonyl groups. The four resonances at δ 6.56 (dd, H_A, J_{AB}=5.8, J_{AC}=1.0 Hz), 5.69 (dt, H_D, J_{CD}=6.0, J_{BD}=1.0 Hz), 5.38 (d of m, H_B, J_{AB}=5.8 Hz), and 5.23 (d of m, H_C, J_{CD}=6.0, J_{AC}=1.0 Hz) were assigned to the protons attached to the fulvene frame in **8a** by means of spin-decoupling measurements. These coupling patterns exclude the other peri-isomeric cycloadducts such as the Diels-Alder type (2+4)cycloadduct **9a**. The treatment of **2a** with *N*-sulfinyl-*p*-toluenesulfonamide (**10**) also gave **8a** in a low yield (6%), along with the major decomposed products. Partial conversion of **10** into **7** can account for this anomalous result.[8] As in the reaction between *N*-sulfinylbenzenesulfonamide and cyclopentadiene,[5] it has been considered that **7** and **10** can also interact with **2** to give (2+4)-cycloadducts (**9, 11**), but the adducts would be unstable and decomposed under the reaction conditions.



Reactions of 9-fluorenethione *S*-oxide or 9-xanthenethione *S*-oxide with **2** were unsuccessful, and only decomposed products were formed.[9]

In summary, the thiocumulenes[10] (**1**, **7**) with the preferential 1,3-dipolar nature were found to react with **2** to give the stable (2+3)cycloadducts regio- and siteselectively, whereas the dienophilic thiocumulenes[10] (**10** and thione *S*-oxide) underwent only decomposition reactions, presumably *via* unstable (2+4)cycloadducts.

Experimental

Reaction of Sulfimide (1) with Fulvenes (2). To a partially suspended solution of **1** (914 mg, 2.5 mmol) in

dry 1,2-dichloroethane (30 ml) was added a solution (10 ml) of dimethylfulvene (**2a**) (318 mg, 3 mmol) with stirring at temperature 0—5 °C under a nitrogen atmosphere. The red suspension of **1** gradually disappeared and the solution turned orange-yellow within 1 h. After the reaction mixture was stirred overnight at room temperature, the solvent was evaporated and the residue was recrystallized from benzene–hexane to give spiro[fluorene-9,3′-1′,2′,3′,3′a,4′,6′a-hexahydro-4′-isopropylidene-1′-(*p*-tolylsulfonyl)-2′-thia-1′-azapentalene] (**3a**) as colorless needles (99% yield). None of the other adducts was obtained from the reaction mixture by a chromatography, and the excess of the fulvene was recovered. The adduct **3b** was obtained by a similar treatment and column chromatography (silica gel, benzene and/or dichloromethane). The reaction of **1** with diphenylfulvene (**2c**) was carried out at a temperature of *ca.* 30 °C for 3 h. After the mixture was stirred overnight at room temperature, the solvent was evaporated and the residue was subjected to a column chromatography (silica gel, benzene) to give **3c** as colorless crystals (benzene–hexane, 87%).

3a: 99% yield; mp 210—211 °C; IR (KBr) 1670 cm^{-1} (C=C); ^1H NMR δ 0.57, 1.49 (s, CH_3), 2.47 (s, CH_3(Ts)), 4.04 (d, H_D, J_{CD}=7.0 Hz), 5.76—5.96 (m, H_B, H_C), 6.59 (dd, H_A, J_{AB}=5.3, J_{AC}=1.9 Hz), 7.00—7.92 (m, 12H, arom); ^{13}C NMR δ 20.2 ,21.6 (q, CH_3), 21.7 (q, CH_3(Ts)), 59.2 (d, C-5), 72.3 (s, C-4), 77.0 (d, C-1); MS *m/e* 471 (30, M^+). Found: C, 71.35; H, 5.44; N, 2.97%. Calcd for $C_{28}H_{25}NO_2S_2$: C, 71.32; H, 5.34; N, 2.97%.

3b: 74% yield; mp 166—167 °C; IR (KBr) 1660 cm^{-1} (C=C); ^1H NMR δ 0.26 (t, CH_3 (inside Et)), 0.64 (t, CH_3 (outside Et)), 0.7—1.3 (m, CH_2 (inside Et)), 1.7—2.1 (m, CH_2 (outside Et)), 2.49 (s, CH_3 (Ts)), 4.07 (d, H_D, J_{CD}=7.0 Hz), 5.80—5.96 (m, H_B, H_C), 6.61 (dd, H_A, J_{AB}=5.3, J_{AC}=2.0 Hz), 7.03—7.96 (m, 12H, arom); ^{13}C NMR δ 11.4, 13.1 (q, CH_3), 21.6 (s, CH_3(Ts)), 23.6 25.7 (t, CH_2), 58.7 (d, C-5), 72.4 (s, C-4), 76.8 (d, C-1); MS *m/e* 499 (33, M^+). Found: C, 72.22; H, 5.90; N, 2.76%. Calcd for $C_{30}H_{29}NO_2S_2$: C, 72.13; H, 5.85; N, 2.80%.

3c: 87% yield; mp 215—216 °C; IR (KBr) 1660 cm^{-1} (C=C); ^1H NMR δ 2.45 (s, CH_3(Ts)), 4.66 (d, H_D, J_{CD}=6.8 Hz), 5.89 (ddd, H_C, J_{CD}=6.8, J_{AC}=2.1, J_{BC}=2.1 Hz), 6.07 (dd, H_B, J_{AB}=5.7, J_{BC}=2.1 Hz), 6.14—6.30 (m, 2H, arom), 6.46—6.70 (m, H_A, 3H-arom), 6.77—7.03 (m, 12H, arom); MS *m/e* 595 (39, M^+). Found: C, 76.67; H, 5.03; N, 2.27%. Calcd for $C_{38}H_{29}NO_2S_2$: C, 76.62; H, 4.91; N, 2.35%.

*Reaction of Sulfur Diimide (**7**) with Fulvene (**2**).* The sulfur diimide (**7**) was prepared from *N*-sulfinyl-*p*-toluenesulfonamide (**10**) by the method in the literature.[2,8] A freshly prepared sulfur diimide (**7**) (1.15 g, 3.11 mmol) in a 1,2-dichloroethane solution (15 ml) was dropwise added over a period of 1.5 h to a solution of **2a** in 1,2-dichloroethane (10 ml) with stirring at a temperature of −10—−15 °C. After being stirred overnight at room temperature, the solvent was evaporated and the residue was subjected to column chromatography twice (silica gel, benzene and dichloromethane) to give crude **8a**, which was recrystallized from benzene–ligroin. Consequent elution with methanol gave *p*-toluenesulfonamide (0.69 g, 65%).

8a: Colorless crystals (14% yield); mp 179—180 °C; IR (KBr) 1660 (weak, C=C); ^1H NMR δ 1.80, 1.83 (s, CH_3), 2.42, 2.44 (s, CH_3(Ts)), 5.23 (d of m, H_C, J_{CD}=6.0, J_{AC}=1.0 Hz), 5.38 (d of m, H_B, J_{AB}=5.8 Hz), 5.69 (dt, H_B, J_{CD}=6.0 Hz), 6.56 (dd, H_A, J_{AB}=5.8, J_{AC}=1.0 Hz), 7.20—7.88 (m, 8H, arom); ^{13}C NMR δ 20.9, 22.0 (q, CH_3), 21.6, 21.7 (q, CH_3(Ts)), 70.0, 72.0 (d, C-1, C-5); MS *m/e* 476 (7, M^+). Found: C, 55.59; H, 5.10; N, 5.77; S, 20.06%. Calcd for $C_{22}H_{24}N_2O_4S_3$: C, 55.44; H, 5.08; N, 5.88; S, 20.18%.

8b: Colorless crystals (12% yield); mp 129—131 °C; IR (KBr) 1655 cm^{-1} (weak, C=C); ^1H NMR δ 0.88, 0.96 (t, CH_3), 1.9—2.5 (m, 4H, CH_2), 2.42 ,2.45 (s, CH_3(Ts)), 5.19 (ddd, H_C, J_{CD}=6.0, J_{BC}=2.4, J_{AC}=1.0 Hz), 5.44 (dd, H_B, J_{AB}=6.0, J_{BC}=2.4 Hz), 5.69 (d, H_D, J_{CD}=6.0 Hz), 6.54 (dd, H_A, J_{AB}=6.0, J_{AC}=1.0 Hz), 7.2—7.9 (m, 8H, arom); ^{13}C NMR δ 13.0 ,13.6 (q, CH_3), 21.6, 21.7 (q, CH_3 (Ts)), 24.6, 25.6 (t, CH_2), 70.3, 71.5 (d, C-1, C-5); MS *m/e* 504 (5, M^+). Found: C, 57.13; H, 5.76; N, 5.38; S, 18.92%. Calcd for $C_{24}H_{28}N_2O_4S_3$: C, 57.12; H, 5.59; N, 5.55; S, 19.06%.

8c: Colorless crystals (27% yield); mp 209—210 °C; IR (Nujol) 1670 cm^{-1} (weak, C=C); ^1H NMR δ 2.36 ,2.42 (s, CH_3 (Ts)), 5.29 (ddd, H_C, J_{CD}=6.0, J_{BC}=2.5, J_{AC}=0.8 Hz), 5.65 (dd, H_B, J_{AB}=5.8, J_{BC}=2.5 Hz), 6.31 (d, H_D, J_{CD}=6.0 Hz), 6.49 (dd, H_A, J_{AB}=5.8, J_{AC}=0.8 Hz), 6.9—7.8 (m, 18H, atom); ^{13}C NMR δ 21.6 (q, CH_3 (Ts)), 70.0, 71.7 (d, C-1, C-5); MS *m/e* 600 (2, M^+). Found: C, 64.01; H, 4.69; N, 4.67; S, 15.98%. Calcd for $C_{32}H_{28}N_2O_4S_3$: C, 63.98; H, 4.70; N, 4.66; S, 16.01%.

Reaction of N-*Sulfinyl*-p-*toluenesulfonamide (**10**) with Dimethylfulvene (**2a**).* To a solution of **10** (1.09 g, 5 mmol) in 1,2-dichloroethane (20 ml) was added dropwise a solution of **2a** (0.53 g, 5 mmol) in 1,2-dichloroethane (15 ml) with stirring at 0 °C. The reaction mixture was stirred for 4 h and gradually became darker. After removal of the solvent, the residue was chromatographed (silica gel, benzene, dichloromethane and methanol) to give 72 mg (6%) of **8a**, 20 mg of unidentified material, 0.7 g (82%) of *p*-toluenesulfonamide, and a black tar. The **8a** was identified by comparisons of the IR and NMR spectra with those of the previously mentioned **8a**.

Michael Addition of *p*-Styrenesulfinate to Acrylic Compounds

Hiroyoshi KAMOGAWA,* Hiroyuki KUSAKA, and Masato NANASAWA
Department of Applied Chemistry, Yamanashi University, Takeda 4, Kofu 400

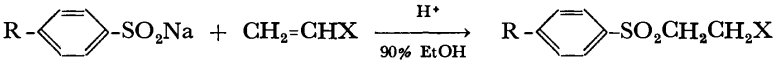
(Received April 11, 1980)

Synopsis. Acrylic compounds CH_2=CHX, where X represents -COOH, $-CONH_2$, -CN, and $-COOCH_2CH_2OH$, were converted into the corresponding 3-(*p*-vinylphenylsulfonyl)- and 3-(*p*-tolylsulfonyl)propionic acids and their derivatives by the Michael addition with *p*-styrene- and *p*-toluenesulfinates, respectively, in the presence of acid as proton source.

In the course of studies on the syntheses of functional vinyl monomers and polymers by the application of the nucleophilic reactions of *p*-styrenesulfinate and its polymer, a number of reactions were reported including simple displacement with halides, reductive addition to quinonoid compounds, and replacement of aromatic nitro group.[1)]

In this note, we wish to report the Michael addition of sodium *p*-styrenesulfinate and its model compound, *p*-toluenesulfinate, to acrylic compounds. A paper describing the Michael addition of arenesulfinates such as *p*-toluenesulfinate to α,β-unsaturated ketones such as methyl vinyl ketone in the presence of acid as proton source[2)] prompted us to undertake this study.

By use of acid either as Michael acceptor itself or as simple proton source we have synthesized a number of novel Michael addition products not obtained under conventional alkaline conditions as follows.



1a: R=CH_2=CH- **1b**: R=CH_3

2a: X=-COOH **2b**: X=$-CONH_2$ **2c**: X=-CN **2d**: X=$-COOCH_2CH_2OH$

3a: R=CH_2=CH-; X=-COONa
3b: R=CH_2=CH-; X=$-CONH_2$
3c: R=CH_2=CH-; X=-CN
3d: R=CH_2=CH-; X=$-COOCH_2CH_2OH$
4a: R=CH_3; X=-COONa
4b: R=CH_3; X=$-CONH_2$
4c: R=CH_3; X=-CN
4d: R=CH_3; X=$-COOCH_2CH_2OH$

It was found that acrylic Michael acceptors employed (**2a—d**) reacted with arenesulfinates (**1a—b**) at room temperature in the presence of an acid. The kind of R considerably affects both yield and mp of product (Table 1). However, weight losses during the course of isolation of products were greater in the case of **3a—d** than in the corresponding **4a—d**; no exact discussion can be made on the yield.

Use of the Michael addition gave rise to easy conversion of the acrylic double bond of a functional monomer to the 2-(*p*-vinylphenylsulfonyl)ethyl group, keeping the functional portion intact. Novel monomers **3a—d** thus synthesized may indicate polymerization behavior differing from that of **2a—d** leading to vinyl polymers with longer side chains, the terminal functional groups of which are more accessible.

Table 1. Yield of Michael-addition products

Compd	Yield/%[a)]	Mp/°C	AcOH
3a	38	179—180	none
3b	20	123—126	added
3c	38	87— 88	added
3d	63	liquid	added
4a	76	300<	none
4b	50	166—168	added
4c	80	93— 96	added
4d	77	liquid	added

a) For products isolated and purified, when required, after 12 h-reaction at room temperature.

Experimental

The infrared, ^{1}H-NMR, and mass spectra were recorded on a Hitachi 215 spectrophotometer, a JNM-PMX 60 spectrometer, and a Hitachi RMU-6 MG spectrometer, respectively, under standard conditions. The elemental analyses were carried out using a Perkin-Elmer 250 instrument.

*Sodium 3-(*p*-Vinylphenylsulfonyl)propionate (**3a**).* A solution of sodium *p*-styrenesulfinate (**1a**; 1.9 g, 10 mmol), synthesized according to the procedure reported,[1)] and acrylic acid (**2a**; 0.72 g, 10 mmol) in 90% ethanol (20 ml) was stirred at room temperature (20 °C) for 12 h to afford a pale pink precipitate, analytically pure without further purification. Found: C, 50.23; H, 4.38%. Calcd for $C_{11}H_{11}O_2SNa$: C, 50.38; H, 4.23%. IR (KBr) 2920, 2850 (CH_2), 1630 (vinyl), 1600 ($-COO^-$, Ar), 1305, 1140 (SO_2), 990, 910 (vinyl) cm^{-1}; NMR (DMSO-d_6+$CDCl_3$) δ 2.5 (t, 2H, CH_2), 3.5 (t, 2H, CH_2), 5.5 (d, 1H, $C\underline{H}_2$=CH–), 6.0 (d, 1H, $C\underline{H}_2$=CH–), 6.8 (q, 1H, CH_2=C$\underline{H}$–), 7.3—8.1 (m, 4H, ArH) ppm.

*Sodium 3-(*p*-Tolylsulfonyl)propionate (**4a**).* The same procedure as that for **2a** was applied to **1b** (4.2 g, 20 mmol) and **2a** (1.5 g, 20 mmol) in 90% ethanol (25 ml) to afford white crystals. Found: C, 48.19; H, 4.22%. Calcd for $C_{10}H_{11}O_2SNa$: C, 47.99; H, 4.43%. IR (KBr) 2960, 2930 (CH_3, CH_2), 1600 ($-COO^-$, Ar), 1280, 1150 (SO_2) cm^{-1}; NMR (D_2O) δ 2.4 (s, 3H, CH_3), 2.7 (t, 2H, CH_2), 3.6 (t, 2H, CH_2), 7.3—7.9 (q, 4H, ArH) ppm.

*3-(*p*-Vinylphenylsulfonyl)propionamide (**3b**).* A solution of **1a** (1.9 g, 10 mmol), **2b** (0.71 g, 10 mmol), and acetic acid (0.6 g, 10 mmol) in 90% ethanol (20 ml) was stirred at room temperature for 12 h. The reaction mixture with a small amount of precipitate was extracted with $CHCl_3$.

The extreact was washed with satd aq $NaHCO_3$, dried over anhyd Na_2SO_4, and evaporated *in vacuo* below 50 °C to leave a solid, which was recrystallized from ethanol to afford light yellow crystals. Found: C, 55.13; H, 5.92; N, 6.13%. Calcd for $C_{11}H_{13}NO_3S$; C, 55.21; H, 5.48; N, 5.85%. IR (KBr) 3420, 3180 (NH_2), 2900 (CH_2), 1690 (C=O), 1600 (Ar), 1300, 1140 (SO_2), 990, 930 (vinyl) cm^{-1}; NMR (DMSO-d_6+$CDCl_3$) δ 2.5 (t, 2H, CH_2), 3.4 (t, 2H, CH_2), 5.5 (d, 1H, $C\underline{H}_2$=CH–), 6.0 (d, 1H, $C\underline{H}_2$=CH–), 6.8 (q, 1H, CH_2=C$\underline{H}$–), 7.3—8.1 (m, 6H, ArH+NH_2) ppm: Mass (*m/e*) 239 (M^+).

*3-(*p-*Tolysulfonyl)propionamide (**4b**).* The same reaction procedure as that for **3b** was applied to **1b** (20 mmol) and **2b** (20 mmol) in the presence of AcOH (30 mmol). The reaction mixture provided a white precipitate upon cooling, which was analytically pure without further purification. Found: C, 52.94; H, 5.94; N, 6.40%. Calcd for $C_{10}H_{13}NO_3S$: C, 52.90; H, 5.70; N, 6.17%. IR (KBr) 3420, 3180, (NH_2), 2950 (CH_2), 1700 (C=O), 1600 (Ar), 1325, 1305 (SO_2) cm^{-1}; NMR (DMSO-d_6+$CDCl_3$) δ 2.5 (s, 3H, CH_3), 2.5 (t, 2H, CH_2), 3.4 (t, 2H, CH_2), 7.1—8.1 (m, 6H, ArH+NH_2) ppm; Mass (*m/e*) 227 (M^+, 1), 91 (100).

*3-(*p-*Vinylphenylsulfonyl)propionitrile (**3c**).* The same procedure as that for **3b** was applied to **1a** (10 mmol) and **2c** (10 mmol) in the presence of AcOH (10 mmol). The clear reaction mixture, when subjected to the same purification procedure except for recrystallization from ethanol–ether, provided pale yellow crystals. Found: C, 59.04; H, 4.96; N, 6.16%. Calcd for $C_{11}H_{11}NO_2S$: C, 59.71; H, 4.56; N, 6.33%. IR (KBr) 2990, 2950 (CH_2), 2250 (CN), 1635 (vinyl), 1600 (Ar), 1305, 1140 (SO_2), 1000, 920 (vinyl) cm^{-1}; NMR (DMSO-d_6+$CDCl_3$) δ 2.8 (t, 2H, CH_2), 3.6 (t, 2H, CH_2), 5.5 (d, 1H, $C\underline{H}_2$=CH–), 6.0 (d, 1H, $C\underline{H}_2$=CH–), 6.8 (q, 1H, CH_2=C$\underline{H}$–), 7.4—8.1 (m, 4H, ArH) ppm; Mass (*m/e*) 221 (M^+, 26), 104 (100).

*3-(*p-*Tolylsulfonyl)propionitrile (**4c**).* The same procedure as that for **3b** was applied to **1b** (20 mmol) and **2c** (20 mmol) in the presence of AcOH (30 mmol). The reaction mixture provided white crystals upon cooling, which were analytically pure without further purification. Found: C. 57.17; H, 5.34; N, 6.69%. Calcd for $C_{10}H_{11}NO_2S$: C, 57.40; H, 5.30; N, 6.69%. IR (KBr) 2990, 2930, 2850 (CH_3, CH_2), 2250 (CN), 1600 (Ar), 1300, 1120, (SO_2) cm^{-1}; NMR (DMSO-d_6+$CDCl_3$) δ 2.5 (s, 3H, CH_3), 2.8 (t, 2H, CH_2), 3.5 (t, 2H, CH_2), 7.3—8.0 (m, 4H, ArH) ppm; Mass (*m/e*) 209 (M^+).

*2-Hydroxyethyl 3-(*p-*Vinylphenylsulfonyl)propionate (**3d**).* The same procedure as that for **3b** was applied to **1a** (10 mmol) and **2d** (10 mmol) in the presence of AcOH (10 mmol) to afford a viscous liquid, which was purified by silica gel column chromatography using ethanol for elution (a viscous pale yellow liquid). Found: C, 54.20; H, 5.80%. Calcd for $C_{13}H_{16}O_5S$: C, 54.92; H, 5.32%. IR ($CHCl_3$) 3500 (OH), 2940, 2900 (CH_2), 1740 (ester), 1640 (vinyl), 1600 (Ar), 1310, 1140 (SO_2), 980, 920 (vinyl) cm^{-1}; NMR ($CDCl_3$) δ 2.6 (s, 1H, OH), 2.8 (t, 2H, CH_2), 3.3—4.0 (m, 4H, $2CH_2$), 4.2 (t, 2H, CH_2), 5.5 (d, 1H, $C\underline{H}_2$=CH–), 5.9 (d, 1H, $C\underline{H}_2$=CH–), 7.8 (q, 1H, CH_2=C$\underline{H}$–), 7.3—8.0 (m, 4H, ArH) ppm; Mass (*m/e*) 284 (M^+, 1), 254 (100).

*2-Hydroxyethyl 3-(*p-*Tolylsulfonyl)propionate (**4d**).* The same procedure as that for **3b** was applied to **1b** (20 mmol) and **2d** (20 mmol) in the presence of AcOH (30 mmol) to afford a viscous yellowish green liquid. Found: C, 52.74; H, 5.89%. Calcd for $C_{12}H_{16}O_5S$: C, 52.93; H, 5.92%. IR ($CHCl_3$) 3450 (OH), 2950, 2900 (CH_3, CH_2), 1740 (ester), 1600 (Ar), 1310, 1145 (SO_2) cm^{-1}; NMR ($CDCl_3$) δ 2.5 (s, 3H, CH_3), 2.5 (s, 1H, OH), 2.7 (t, 2H, CH_2), 3.2—4.0 (m, 4H, 2 CH_2), 4.2 (t, 2H, CH_2), 7.2—8.0 (q, 4H, ArH) ppm; Mass (*m/e*) 254 (M^+-H_2O).

(Received April 18, 1980)

Synopsis. The ^{13}C NMR spectra of ruthenocenophanes, ferrocenophanes and their precursors were measured. The examination of molecular models for metallocenophanes and the spectral data offer some hints about the conformation of the molecules.

We wish to report the carbon chemical shift data of the title compounds and their precursors. The structures of these metallocenophanes are discussed, using the spectral data together with molecular models which were constructed by using the data from X-ray crystallography.[1]

The assignments of the carbon signals were based on standard methods, *i.e.*, the relative intensities, the off-resonance CW decoupling, and a comparison of the signal shift between closely related compounds. In addition, the bridged methylene carbons of [3]- and [4]ruthenocenophanes, and their ferrocenophane homologs were assigned by comparison of their spectra with those of the deuterated compounds which were obtained by the reduction of the corresponding oxo-compounds with $LiAlD_4$ and $AlCl_3$ combination. The chemical shifts are collected in Table 1.

Both proton and carbon signals of ruthenocene (**1**)[2] shifted to lower fields than those of ferrocene (**2**).[2,3] Since a linear correlation between the ^{13}C chemical shift and charge density has been established for a series of monocyclic aromatic systems,[4] such a shift difference suggests that the ruthenium atom pulls the π-electrons from cyclopentadienyl rings more than the iron atom does. This is supported by the fact that electrophilic substitutions *e.g.*, Friedel-Crafts reactions, occur to a lesser extent with **1** than with **2**.[5]

The carbon signals of ruthenocenophanes also appeared at a lower field than those of ferrocenophanes, except for the carbonyl carbon signals. The chemical shifts for carbonyl groups of [4]ruthenocenophan-2-one (**5**) and [4]ferrocenophan-2-one (**6**) show almost equal values. The carbonyl carbon signal of [3]ruthenocenophan-1-one (**3**) shifted to a higher field than that of [3]ferrocenophan-1-one (**4**). The upfield shift of the carbonyl carbon signal is observed by an introduction of the electron-withdrawing substituents at the neighboring position. The simplest interpretation of this trend would attribute the increase in shielding to decreased polarization of the π-bond, because the electron-withdrawing effect of the substituent decreases the contribution of the polarized form.[6] Such a difference in the chemical shifts for the carbonyl carbons may be correlated to the resonance contribution of the carbonyl group; $Cp-\underset{|}{C}=O \leftrightarrow Cp-\overset{+}{\underset{|}{C}}-\bar{O}$. In infrared spectra,[7] however, the absorption band of **3** is at 1656 cm^{-1} and that of **4** at 1681 cm^{-1}. The carbonyl stretching band generally shifts to the shorter wavelength by an introduction of the electron-withdrawing group at the neighboring position.[8] We assume that the chemical shift difference of the carbonyl carbons between **3** and **4** is primarily due to the electron delocalization by the conjugation of this carbonyl group with the cyclopentadienyl ring. Since the cyclopentadienyl rings of **4** are tilted to about 9°,[9] the longer distance between the two rings of **3**[7] results in an appreciable strain on the bridge of the carbon chain connecting these two rings, which are supposed to be tilted to a greater extent. The molecular model for [3]oxophanes indicates that the dihedral angle between the plane of the carbonyl group and the adjacent cyclopentadienyl ring becomes small when the cyclopentadienyl rings are tilted to a greater extent (see Fig. 2; θ_2 is smaller than θ_1). The π-orbital of the carbonyl group can effectively conjugate with the π-system of the cyclopentadienyl ring. As a consequence, the carbonyl carbon signal of **3** shifts to higher field and the carbonyl stretching band shifts to longer wavelengths than those of **4**. Lentzner and Watts reported that in the acylation of [3]-, [4]-, and [5]ferrocenophan-1-ones, the product ratio, (acylated product at the ring opposite side to the carbonyl group)/(acylated product at the ring adjacent to the carbonyl group), was found to be much higher for [5]oxophane than for other homologs. The finding that the ratio for [3]oxophane is approximately twice that for [4]-oxophane was perplexing. They commented that the distortion of the ferrocene nucleus occasioned by a 4-carbon bridge may be greater than that occasioned by a 3-carbon bridge.[5] The molecular model used in the present investigation indicates that the dihedral

a) In $CDCl_3$ unless otherwise indicated. b) Ref. 3. c) A. N. Nesmeyanov, G. B. Shul'pin, and M. I. Rybinskaya, *Dokl. Akad. Nauk. SSSR*, **218**, 1107 (1974). d) Values in parentheses may be interchanged.

angle between the plane of the carbonyl group and the adjacent cyclopentadienyl ring becomes small when the number of carbon of the bridge diminishes from 4 to 3. In consequence, the carbonyl-cyclopentadienyl conjugation would be stronger for the latter ketone. The product ratio which they obtained seems quite reasonable.

The ^{13}C NMR spectra of precursors of phane compounds: formylruthenocene (**11**), ruthenocenylacrylic acid (**13**), ruthenocenylpropionic acid (**15**) and their ferrocene homologs, **12**, **14**, and **16**, were also measured. Similarly to the case of the parent and phane compounds, the carbon signals of cyclopentadienyl rings of ruthenocenes are located at lower fields than those of ferrocenes.

Experimental

NMR Spectra. The ^{13}C FT-NMR spectra were obtained at 25.15 MHz with a JEOL JNM-MH-100 instrument equipped with a JNM-MFT-100 Fourier transform accessory; the instrument was controlled with a JEC-6 spectrum computer. Samples were observed in 5 mm spinning tubes at 15±5% solutions in $CDCl_3$ or DMSO-d_6 at 28 °C. The solvent provided the internal lock signal. The measurement conditions were as follows: pulse width, 27.5 μs (*ca.* 45°); repetition time, 4 s; spectral width, 6.25 kHz; data points, 8192; acquistion time, 0.65 s. Noise modulated proton decoupling was carried out at a nominal power of 20 W and the off-resonance was carried out at a nominal power of 7 W. All chemical shifts are expressed in δ (ppm; downfield from internal Me_4Si). Each observed chemical shift is estimated to be accurate to δ±0.1.

Materials. The compounds employed in this work have been previously prepared: ferrocenophanes and ferrocenes,[10)] ruthenocenophanes, and ruthenocenes.[7)]

Synthetic Studies on Terpenic Compounds. XII.[1] Selective Degradation of the Side Chain in Portulal[2]

Takashi TOKOROYAMA,* Keizo MATSUO,† and Reizo KANAZAWA††
Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558
(Received May 6, 1980)

Synopsis. Stepwise degradation of the side chain in portulal has been investigated in connection with synthetic studies. Selective cleavage of the double bond in the side chain was achieved by ozonolysis after protection of the endo-double bond by iodoetherification of the corresponding alcohol. Further degradation led to the formation of the γ-lactone *via* the δ-lactone.

Portulal (**1**), a diterpene isolated from *Portulaca grandflora* Hook as a plant growth regulator, has a unique perhydroazulenoid skeleton with clerodane substitution.[3] In connection with the total synthesis of **1**,[1,4] we examined the products derived from **1** by degradation of its side chain since they might be utilized for confirming the stereochemistry of synthetic intermediates and also as relay compounds. The results of the investigation are given herewith.

The key problem for selective degradation of the side chain lies in the preferential cleavage of the $\Delta^{13,14}$ double bond, since its reactivity and that in the ring hardly differ. We found a solution to this problem by protecting the ring double bond with internal addition of the angular functional group. After several preliminary experiments the iodoetherification of portulol (**2**), obtained by lithium aluminium hydride reduction of **1**,[5] was found to be feasible. Treatment of **2** under specified conditions (Scheme 1) afforded the iodo ether **3** quantitatively. It was found that the latter can be reverted to the former by the reaction with zinc–silver couple[6] or chromium(II) chloride.[7] Ozonolysis of **3** and subsequent treatment of the product with zinc–silver couple gave an α-ketol **4** which was cleaved by periodic acid to yield the δ-lactone **5**, its IR spectrum showing carbonyl absorption at 1740 cm^{-1}. Further degradation of **5** to **6** was effected by formylation and subsequent treatment with alkaline hydrogen peroxide. The product showed the carbonyl peak at 1770 cm^{-1} in its IR spectrum. A salient feature in the NMR spectrum was the presence of signals due to vinyl methyl and vinylic protons (δ 1.71 and 5.38, respectively), a singlet (δ 2.39) and an AB quartet (δ 4.09 and 4.23) due to the methylene protons of the spiro-γ-lactone and an AB quartet (δ 3.35 and 3.57) due to the hydroxymethyl protons. A counterpart of the latter AB quartet (δ 3.57) split further with coupling constant of 1.5 Hz, this being observable also in the NMR spectrum of the δ-lactone **5**. The extra splitting might be ascribed to the W-letter coupling with 5α proton, indicating that the free rotation of the angular hydroxylmethyl group is sufficiently restricted and stays in the most stable conformation. Oxidation of **6** with Jones' reagent followed by acid treatment afforded the dilactone **7** which has been correlated with the synthetic intermediate of portulal synthesis.[1] Compound **6** was found to be a pertinent relay compound.

Experimental

Melting points are uncorrected. IR spectra were taken on a JASCO IRA-1 spectrometer as films (liquid) or Nujol mulls (solid), ^1H NMR spectra in $CDCl_3$ on a JEOL PS-100 spectrometer and mass spectra on a Hitachi M-52 spectrometer.

Extraction of Portulal (1). Portulal was extracted from *Portulaca grandiflora* Hook by essentially the same procedure as that reported.[5] The cut aerial part of the plant was extracted with methanol and the extract concentrated *in vacuo* to about one-fourth of the original volume. The concentrated solution was washed with petroleum ether and then extracted continuously with ether. The ether layer was washed with saturated aq $NaHCO_3$ and dried with anhydrous Na_2SO_4, the solvent being removed. The neutral extract thus obtained was chromatographed on a silica-gel column. The crystalline material, eluted with benzene-ethyl acetate (1:1) followed by ethyl acetate, was recrystallized from aq methanol giving portulal **1** as needles, mp 119.5—120 °C.

Iodo Ether 3. A solution of $LiAlH_4$ (220 mg, 5.8 mmol) in tetrahydrofuran (20 ml) was added to a solution of **1** (1.359 mg, 4.05 mmol) in anhydrous tetrahydrofuran (30 ml) over a period of 10 min under ice-cooling, After the mixture had been stirred at room temperature for 80

† Present address: Faculty of Pharmaceutical Sciences, Kinki University, Higashiosaka, Osaka 577.

†† Present address: Daiichi Isotope Laboratories, Ltd, Chuo-ku, Tokyo 103.

min, excess reagent was destroyed by the addition of ethyl acetate, water (1.5 ml) and anhydrous $MgSO_4$. Filtration with the aid of Celite and evaporation of the solvent from the filtrate followed by chromatography on a column of silica gel (30 g) afforded portulol (**2**) as a colorless oil (1.388 g), which solidified when cooled. The substance dissolved in a mixture of tetrahydrofuran (30 ml) and water (22 ml) was mixed with aq $NaHCO_3$ (2.298 g, 27.35 mmol) and KI-I_2 solution prepared from KI (3.978 g), I_2 (1.934 g, 7.61 mmol), and water (25 ml). The mixture was stirred at ambient temperature for 4.5 h. Saturated aq $NaHCO_3$ solution was added to reduce excess iodine, the product isolated by ether extraction giving the iodo ether **3** as a pale yellow oil (1.831 g, 98% overall yield): IR 3360 cm^{-1}; ^1H NMR 0.98 (3H, d, J=6 Hz, $-\underset{|}{C}HC\underline{H}_3$), 1.51 (3H, s, $-O\underset{|}{C}CH_3$). 3.61 (2H, s, $-\underset{|}{C}C\underline{H}_2OH$), 3.79, 3.87 (2H, AB q, J=7 Hz, $-CH_2O-$), 4.15 (2H, s, $-\underset{|}{C}=\underset{|}{C}C\underline{H}_2OH$), 4.16 (2H, d, J=7 Hz, $-\underset{|}{C}=C\underline{H}CH_2OH$), 4.38 (1H, br s, $-CH_2C\underline{H}I-$), 5.58 (1H, t, J=7 Hz, $-\underset{|}{C}=C\underline{H}CH_2OH$).

*Reversion of Iodo Ether **3** to Portulol (**2**).* *(a) With Zinc-Silver Couple*: A solution of **3** (54 mg, 0.116 mmol) in dry ether (1.5 ml) was treated with zinc-silver couple prepared[6] from silver acetate (0.2 mg) and zinc dust (25 mg) with addition of ethanol (0.25 ml) and acetic acid (1 drop) under reflux for 1.5 h. After filtration, the filtrate was washed successively with dil. HCl saturated aq $NaHCO_3$ and brine, and dried with anhydrous $MgSO_4$. Evaporation of the solvent and purification of the product by silica gel chromatography gave portulol (**2**) (32 mg, 81% yield).

(b) With $CrCl_2$: A $CrCl_2$ solution (9 ml, *ca.* 3.7 mmol) was added to an ice-cooled solution of **3** (70 mg, 0.151 mmol) in *N,N*-dimethylformamide (8 ml), the mixture being stirred for 1 h. The product was extracted with $CHCl_3$ and the organic layer washed with saturated aq $NaHCO_3$ and brine. Removal of the solvent gave a product which was purified by chromatography (silica gel) to give portulol (**2**) (33 mg, 65% yield).

*δ-Lactone **5**.* The iodo ether **3** (2.47 g, 5.32 mmol) dissolved in methanol (100 ml) was ozonized at −70 °C until blue coloration was observed. After the mixture had been left to stand at −70 °C for 15 min, excess ozone was expelled by bubbling of nitrogen gas. Dimethyl sulfide (390 mg, 6.29 mmol) was then added. The mixture was kept at −70 °C for 30 min, the temperature then being allowed to rise by removal of the cooling bath. Evaporation of the solvent gave a crude product which was dissolved in absolute ether (25 ml) and treated with zinc-silver couple (prepared from silver acetate, 14 mg and zinc dust, 2.4 g), ethanol (3 ml) and acetic acid (2 drops) with stirring at room temperature for 16 h. Work-up afforded the ketol **4** as colorless oil (1.6 g). The product dissolved in a mixture of dioxane (40 ml) and water (20 ml) was treated with $HIO_4 \cdot 2H_2O$ (1.7 g, 7.46 mmol) overnight at room temperature. Chloroform extraction and the washing of the extract solution with saturated aq $NaHCO_3$ followed by evaporation of the solvent gave an oil which was purified by silica-gel chromatography. Elution with chloroform-methanol (25:1) gave δ-lactone **5** as a colorless oil: IR ($CHCl_3$) 3470, 1740 cm^{-1}; ^1H NMR 1.07 (3H, d, J=7 Hz, $-\underset{|}{C}HC\underline{H}_3$), 1.71 (3H, br s, $-CH=\underset{|}{C}C\underline{H}_3$), 2.52 (2H, t, J=7.5 Hz, $-CH_2C\underline{H}_2CO_2-$), 3.33 (1H, d, J=10.5 Hz, $-C\underline{H}_2OH$), 3.56 (1H, dd, J=1.5, 10.5 Hz, $-C\underline{H}_2OH$), 4.25 (2H, s, $-CH_2OCO-$) 5.36 (1H, m, $-\underset{|}{C}=C\underline{H}CH_2-$)

*Conversion of δ-Lactone **5** into γ-Lactone **6**.* NaH (53 mg, 50% oil dispersion) and ethyl formate (0.5 ml) were added to a solution of **5** (50 mg, 0.18 mmol) in dry benzene (3 ml). After addition of a drop of methanol, the mixture was stirred overnight at room temperature. The reaction mixture was diluted with benzene and shaken with water. The aqueous layer was separated and acidified with dil HCl. Isolation of the product with chloroform extraction gave a yellow oil (50 mg). The formyl derivative thus obtained was dissolved in a mixture of methanol (0.7 ml), water (0.5 ml) and 3 M (1 M=1 mol dm^{-3}) NaOH (0.1 ml) and mixed with 3 M NaOH (2 ml) and 30% H_2O_2 (0.8 ml). The mixture was stirred at ambient tempearture, 3 M NaOH (2 ml and 3 ml) and 30% H_2O_2 (0.4 ml and 2.5 ml) being added after 1.5 and 2.5 h, respectively. The reaction was continued overnight and then worked up. Acidification with dil HCl followed by chloroform extraction and chromatographic purification (silica gel) gave the γ-lactone **6** (25 mg, 53% yield) as a colorless oil: IR ($CHCl_3$) 3500, 1770, 1180, 1030 cm^{-1}; ^1H NMR 0.97 (3H, d, J=6.5 Hz, $-\underset{|}{C}HC\underline{H}_3$), 1.71 (1H, br s, $-CH=\underset{|}{C}C\underline{H}_3$), 2.39 (2H, s, $-CH_2CO_2-$), 3.35 (1H, d, J=11 Hz, $-C\underline{H}_2OH$), 3.57 (1H, dd, J=1.5, 11 Hz, $-C\underline{H}_2OH$), 4.09, 4.23 (2H, AB q, J=10 Hz, $-CH_2OCO-$), 5.38 (1H, m, $-\underset{|}{C}=C\underline{H}CH_2-$).

Studies on Biologically Active Pteridines. V.[1] Synthesis of (6*S*)-5,6,7,8-Tetrahydro-1,3,5,6-tetramethyllumazine

Takashi SUGIMOTO* and Sadao MATSUURA

Department of Chemistry, College of General Education, Nagoya University, Chikusa-ku, Nagoya 464

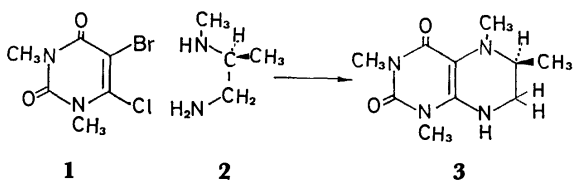
(Received May 12, 1980)

Synopsis. (+)-5,6,7,8-Tetrahydro-1,3,5,6-tetramethyllumazine, a compound derived from enzymically reduced (−)-5,6,7,8-tetrahydro-6-methylpterin, was shown to be of (*S*)-configuration at the C-6 chiral center by a synthesis, which was performed by condensation of 5-bromo-6-chloro-1,3-dimethyluracil and (2*S*)-1-amino-2-(methylamino)propane. The structure of the condensation product was determined unequivocally by an independent synthesis using a regioselective methylation of 5,6,7,8-tetrahydro-1,3,6-trimethyllumazine.

(−)-5,6,7,8-Tetrahydrobiopterin[2] is an essential cofactor for phenylalanine,[3] tyrosine,[4] and tryptophan hydroxylases,[5] all of which play important roles in the biosynthesis of neurotransmitting dopamine or serotonine. Thus, deficiency of tetrahydrobiopterin causes severe neurological disturbance such as atypical phenylketonuria.[6] Tetrahydrobiopterin is produced stereospecifically referring to the C-6 chiral center from 7,8-dihydrobiopterin by dihydrofolate reductase and NADPH; chemical reduction gives a mixture of diastereomers. Since the two diastereomers show different biological properties,[7,8] determination of the C-6 configuration of natural (−)-tetrahydrobiopterin is essential for understanding its properties in biological systems. 5,6,7,8-Tetrahydro-6-methylpterin is also produced stereospecifically from the 7,8-dihydro precursor by the action of the same enzyme, and thus formed (−)-tetrahydro-6-methylpterin and (−)-tetrahydrobiopterin were shown to have same L-configuration at C-6 in a rather indirect manner by comparison with 1,2,3,4-tetrahydro-2-methylquinoxaline.[8]

As an alternative and more direct approach to confirm the C-6 configuration of these pterins, we studied the C-6 configuration of (+)-5,6,7,8-tetrahydro-1,3,5,6-tetramethyllumazine, a compound recently derived from (−)-tetrahydro-6-methylpterin by methylation and deamination without altering the configuration.[9]

We synthesized (6*S*)-5,6,7,8-tetrahydro-1,3,5,6-tetramethyllumazine (**3**) from 5-bromo-6-chloro-1,3-dimethyluracil(**1**) and (2*S*)-1-amino-2-(methylamino)propane (**2**). Heating of **1** and **2** in ethanol gave a tetrahydrolumazine as a main product, which showed a weak basicity (pK_a 5.39) and λ_{max} at 235(sh.) and 286 (pH 8.0) and at 263 (pH 3.0). Its ^{13}C-NMR spectrum showed signals at the following chemical shifts (ppm): 160.3(C-4), 150.7(C-2), 144.1(C-8a), 99.5(C-4a), 50.7 (C-6), 40.0(C-7), 41.4, 28.9, 27.9 (three N–CH_3), and 17.1(C–CH_3). We tentatively assigned the compound as **3**, because it showed resistance toward air oxidation, an important characteristic of N-5 substituted tetrahydropteridines. However, the observed chemical and physical properties could not exclude the possibility that the compound might have the isomeric structure, *i.e.*, 5,6,7,8-tetrahydro-1,3,7,8-tetramethyllumazine. In order to confirm the above assignment, we synthesized racemic **3** by an independent method: 1,3,6-trimethyllumazine[10] was hydrogenated over platinum oxide into 5,6,7,8-tetrahydro derivative, which was subsequently hydrogenated in the presence of formaldehyde over the same catalyst. A methyl group was introduced regioselectively at N-5 to produce (±)-**3**, whose spectral data allowed to confirm the condensation product as (6*S*)-**3**.



1 **2** **3**

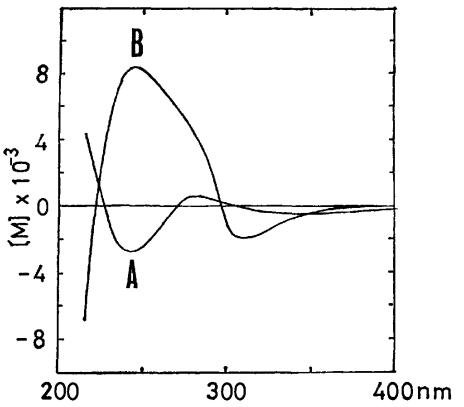


Fig. 1. The ORD curves of (6*S*)-**3**: **A**, at pH 3.0 (cation) and **B**, at pH 8.0 (neutral molecule).

The cation of (6*S*)-**3** showed, as expected, positive Cotton effect in ORD with a peak at 283 nm and trough at 242 nm (Fig. 1), though neutral (6*S*)-**3** gave opposite sign of rotation. The present results confirmed that (+)-**3**, derived from (−)-tetrahydro-6-methylpterin, has (6*S*)-configuration. Consequently, it is concluded that the enzymically reduced (−)-tetrahydro-6-methylpterin has (6*S*)-configuration and the (−)-tetrahydrobiopterin the same (6*R*)-configuration.

Experimental

The elemental analyses were carried out at the Analytical Section, Meijo University. The pK_a values were determined spectroscopically on a Shimadzu UV-300 spectrometer. The ORD curves were measured on a JASCO ORD/UV-5 spectropolarimeter in appropriate pH buffer solutions and the ^{13}C-NMR spectra on a JEOL JNM-PFT-60 NMR spectrometer in $CDCl_3$. The chemical shifts are expressed in terms δ (ppm downfield from the internal TMS).

(2S)-1-Amino-2-methylaminopropane (2). L-Alaninamide[11] (60 g) was formylated by acetic formic anhydride

at 20 °C to give (2*S*)-2-(formamino)propanamide (45 g), mp 112—113 °C (from ethanol) (Found: C, 41.59; 7.11; N, 23.84%. Calcd for $C_4H_8N_2O_2$: C, 41.37; H, 6.94; N, 24.13%). The amide (30 g) and $LiAlH_4$ (45 g) in tetrahydrofuran (1.5 l) was refluxed for 24 h and the excess reagent was decomposed by water. The filtered solution was fractionally distilled twice to give **2** (10 g) boiling at 112—122 °C; ^{13}C-NMR: at δ 58.0 (CH_2), 55.4 (CH), 36.7 (N-CH_3), 24.0 (N-CH_3), and 18.2 (C-CH_3).

*(6S)-5,6,7,8-Tetrahydro-1,3,5,6-tetramethyllumazine (**3**).* A solution of **1**[12] (7.0 g), **2** (2.5 g), and triethylamine (7 g) in ethanol (100 ml) was heated under reflux and nitrogen for 7 h. The solution was evaporated and the residue was dissolved in water (50 ml). The solution was adjusted to pH 1—2 with HCl and extracted continuously with chloroform for 2 h. The aqueous solution was adjusted to pH 7—8 with $NaHCO_3$ and again extracted continuously with chloroform for 1 h. The latter extract was fractionated on a silica gel column (4.5 cm × 40 cm) developed by ethanol and ethyl acetate (1:9). The fraction of the main product was chromatographed once more as above. Evaporation of the eluate gave an oily residue, which was mixed with ethanol (0.5 ml). Dilution with ether (10 ml) and chilling gave colorless prisms (4.85 g) of **3**, mp 164—166 °C (dec), (Found: C, 53.58; H, 7.34; N, 24.90%. Calcd for $C_{10}H_{16}N_4O_2$: C, 53.55; H, 7.19; N, 24.99%); pK_a 5.39±0.01; λ_{max} (log ε) in nm at pH 8.0: 235 (sh., 3.72) and 286 (4.11); at pH 3.0: 263 (4.22).

*Racemic **3**.* 1,3,6-Trimethyllumazine (1.5 g) was hydrogenated over platinum oxide (0.5 g) in methanol (100 ml) at atmospheric pressure and temperature for 1 h. Formalin (37%, 2.5 g) was added to the mixture and hydrogenation was continued over night. The filtered solution was evaporated and chromatographed as above to give colorless prisms (1.24 g) of (±)-**3**, mp 200—202 °C (dec), (from ethanol) (Found: C, 53.63; H, 7.42; N, 24.64%. Calcd for $C_{10}H_{16}N_4O_2$: C, 53.55; H, 7.19; N, 24.99%); pK_a 5.36±0.01; λ_{max} nm (log ε) at pH 8.0: 235 (sh., 3.73) and 286 (4.10); at pH 3.0: 263 (4.22); ^{13}C-NMR at δ 160.3, 150.7, 143.9, 99.6, 50.8, 41.4, 40.1, 28.9, 28.0, and 17.1.

The authors thank Prof. H. Nakata for measuring the NMR spectra, Mrs. N. Nishioka for measuring the pK_a values and UV spectra, and Dr. W. L. F. Armarego, The Australian National University, for sending a pre-publication paper and discussion.

A One Step Transformation of a 7-Oxo Steroid into a 7-Oxa Steroid. A New Photo-oxidation of Cyclic Ketone[1)]

Hiroshi SUGINOME*,** and Chi- Ming SHEA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received May 15, 1980)

Synopsis. Irradiation of 3α,5-cyclo-5α-cholestan-7-one in methanol saturated with oxygen gives a novel cyclo-7-oxa steroid, 3α,5-cyclo-7-oxa-5α-cholestane, together with methyl 3α,5-cyclo-7,8-seco-5α-cholestan-7-oate.

We report here a one-step transformation of 7-oxo-3α,5-cyclo-5α-cholestan-7-one (**1**)[2,3)] into a novel cyclo-7-oxa steroid, 3α,5-cyclo-7-oxa-5α-cholestane (**3**), by irradiation in the presence of oxygen. The ketone **1** in methanol saturated with oxygen was irradiated with a Hanovia 450-W mercury arc through a Pyrex filter for 96 h. Preparative TLC of the reaction mixture gave two major crystalline products, **2** (12%) and **3** (18%), together with several minor products. Product **2** was identified as methyl 3α,5-cyclo-7,8-seco-5α-cholestan-7-oate,[3)] which was an exclusive product when **1** in methanol was photolyzed in the absence of oxygen,[3)] by a direct comparison. The less mobile compound **3** was a new compound; the structure was confirmed to be 3α,5-cyclo-7-oxa-5α-cholestane (**3**) by the analysis of the spectra. The molecular formula $C_{26}H_{44}O$ was determined by high resolution mass spectrometry. The low resolution mass spectrum showed an intense molecular ion peak at *m/e* 372 (14.4%), a M^+-CH_3 peak at *m/e* 357 (5.2%), and the base peak at *m/e* 317. The IR spectrum showed a strong band at 1087 cm^{-1} arising from C–O stretching of a cyclic ether. The NMR spectrum showed a 1H double doublet at τ 9.87 (J=8 and 6 Hz, a cyclopropyl proton) a 1H triplet at τ 9.62 (J=4.5 Hz, a cyclopropyl proton), a 3H singlet at τ 9.26 (18-H) and a 3H singlet at τ 9.01 (19-H). It also showed an AB quartet centred at τ 6.89 and 6.05 (J=12.0 Hz) and a 1H diffused triplet at τ 6.69 (J=7.5 Hz); these are assigned to the C-6 methylene protons and the 8β-H. Assuming the ring B of **3** to be in a chair conformation, the 6α-H should be shielded by the cyclopropane ring, and the doublet at τ 6.89 is thus assigned to the 6α-H.

The photochemical transformation of an oxo steroid into an oxa steroid in the presence of oxygen appears to be a new type of reaction of excited cyclic ketones. The pathway from the excited ketone (A) to cyclic ether **3** is not clear at the present stage. However, the process outlined in Scheme 2 may explain the formation of cyclic ether **3**: here a β-scission of the resulting biradical (B)[4)] could lead to a peroxylactone (C) which photodecarboxylates[5)] to give cyclic ether **3**.

Experimental

For instruments used and general procedures see Ref. 3. Mass spectra were recorded with a Hitachi JMS-D 300 spectrometer (70 eV) by Miss Yuko Chiba of the Faculty of Agriculture.

Photo-oxidation of 3α,5-Cyclocholestan-7-one (1).[2,3)] Ketone **1** (200 mg) in methanol (200 ml) saturated with oxygen was irradiated with a Hanovia 450-W mercury arc through a Pyrex glass filter for 96 h. After the evaporation of the solvent, the product (213 mg) was subjected to preparative TLC (Merck, silica gel 60 F254) with a 1:1 benzene and hexane mixture to give nine fractions: A (35 mg), B (35 mg), C (17 mg), D (4 mg), E (2 mg), F (2 mg), G (2 mg), H (6 mg), and I (77 mg), in the order of decreasing mobility. The fraction (A) was recrystallized from methanol to give seco ester **2**,[3)] mp 72—73 °C. The fraction B was recrystallized from methanol to yield 3α,5-cyclo-7-oxa-5α-cholestane (**3**), mp 144—145 °C. (Found: *m/e* 372.3412. Calcd for $C_{26}H_{44}O$: M^+, 372.3390); for mass, IR, and NMR spectra see text.

Catalysis by Heteropolyacid. III. Acylation and Sulfonylation of Aromatic Compounds Catalyzed by Keggin-structure Heteropolyacids

Kenji NOMIYA, Yoshio SUGAYA, and Makoto MIWA*

Department of Industrial Chemistry, Faculty of Engineering, Seikei University, Musashino-shi, Tokyo 180

(Received June 19, 1980)

Synopsis. Catalytic acylation and sulfonylation reactions of aromatic compounds by Keggin-structure heteropolyacids, $H_4[SiMo_{12}O_{40}]$, $H_3[PMo_{12}O_{40}]$ and $H_4[SiW_{12}O_{40}]$, have been studied. Tungsten is more effective than molybdenum for the reactions.

Brønsted acidity of Keggin-structure heteropolyacid is a key factor in the catalysis for polycondensation of benzyl alcohols[1] and Friedel-Crafts-type reaction.[2] These reactions proceed *via* a carbonium ion mechanism. The constitutional metal of the Keggin-unit is another important factor, molybdenum, rather than tungsten, being effective for the alkylation reaction.[3] We have examined the role of the metal and the hetero atom in the catalytic acylation and sulfonylation for aromatic compounds.

The heteropolyacids, $H_4[SiMo_{12}O_{40}]$, $H_3[PMo_{12}O_{40}]$ and $H_4[SiW_{12}O_{40}]$, were prepared according to the usual method. The mononuclear complex, H_2MO_4 (M=Mo, W), was prepared by heating a hydrochloric aqueous solution of MO_3 at 40—60 °C and cooling. All organic reagents were purified by the usual methods. Acylation was carried out with acetyl chloride and sulfonylation with *p*-tolylsulfonyl chloride (tosyl chloride). Dried toluene, anisole, thiophene and furan were used as aromatic substrates. The reaction mixture was refluxed in the presence of heteropolyacid or mononuclear complex. After refluxing, the cata-

lyst was removed by filtration and acylated products were isolated by distillation under reduced pressure and sulfonylated products by recrystallization from ethanol.[4] They were identified by IR, ^{1}H-NMR and their melting points.

Three heteropolyacids showed effective activity, but the mononuclear complexes showed hardly any. The acylated compounds were obtained from anisole and thiophene, not from toluene and furan, and the sulfonylated compounds from toluene and anisole, not from thiophene and furan. Products were para-substituted for six-membered ring and oriented to 2-position for five-membered ring.

Reaction conditions, yields and turn-over numbers per hour are given in Table 1. The turn-over number per hour, conveniently estimated by a molar ratio of the amount of catalyst used and that of the product obtained per hour, is interpreted not only as a diagnostic parameter of whether the reaction proceeds catalytically or stoichiometrically, but also as a criterion for efficiency of the catalyst. The results are summarized as follows. (1) All the reactions are catalyzed by each heteropolyacid. (2) Acylation proceeds more easily than sulfonylation. (3) The reactions are largely influenced by the kind of metal constituting the Keggin unit, rather than the kind of hetero atom. (4) Of constitutional metals, tungsten, rather than molybdenum, is effective in the reactions; this aspect is contrary to the case of alkylation of toluene with benzyl chloride.[3]

Since the Keggin formula is designated by twelve sexivalent metals, forty bivalent oxygens and one hetero atom, the number of protons as counter ion is determined by the charge of hetero atom, *e.g.*, four for Si, three for P and As. Thus the difference in the number of protons between $H_4[SiMo_{12}O_{40}]$ and $H_3[PMo_{12}O_{40}]$ is not important in the catalysis.

The Acidity and Basicity of Bi_2O_3-based Binary Oxides

Mamoru Ai

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 227

(Received January 26, 1980)

The numbers of both acidic and basic sites in a series of Bi_2O_3–X_nO_m binary oxides, with different kinds and amounts of the second component, X_nO_m, were systematically determined by means of the adsorption of NH_3 and CO_2 from the gas phase, using the static method. Pure Bi_2O_3 has both acidic and basic sites, much like TiO_2, SnO_2, and Fe_2O_3, and it is more basic than these oxides. The generation of an unexpectedly high acidity or basicity was not observed in the combination of Bi_2O_3 with 11 kinds of oxides, and the acid-base properties of the binary oxides can be understood in terms of the nature of the second component. The order of ability for the promotion of the acidity and the diminution of the basicity is: MoO_3, SO_3, $WO_3 > V_2O_5$, $P_2O_5 > Sb_2O_4 > TiO_2$, SnO_2, Fe_2O_3. The addition of K_2O decreases the acidity and increases the basicity. The relationship between the acid-base properties and the catalytic activities for the isomerization of 1-butene, the dehydration and dehydrogenation of 2-propanol, and the oxidative decomposition of formic acid was investigated. It was proposed that the basic sites of the Bi_2O_3-based mixed oxides originate from Bi_2O_3 and that the nature remains approximately the same, regardless of any change in the kind and amount of the second component. However, the acidic sites are generated by the combination with second component; therefore, the nature varies widely depending on the nature of the second component.

Recently, it has been proposed that acid-base-type interaction between the catalyst surface and the organic substance to be oxidized plays the determining role in mild oxidation, and that the combination of metal oxides contributes to a modification of the acid-base properties.[1-3] On this basis, it is of decisive importance to know the acid-base properties of the oxidation catalysts. However, there have been very few reports dealing with the acid-base properties of mixed transition-metal oxides.

The purpose of the present study is to determine systematically the acid-base properties of the Bi_2O_3–X_nO_m (where X_nO_m consists of different kinds and amounts of oxides) binary system and to demonstrate how the incorporation of foreign oxides into Bi_2O_3 modifies the acid-base properties.

Experimental

Catalysts. The catalysts used in this study were a series of Bi_2O_3–X_nO_m with different X/Bi ratios (X/Bi= 0—1.0), where X_nO_m refers to 11 different kinds. They were prepared as follows. The required quantities of bismuth nitrate were dissolved in concentrated nitric acid, and to this was added an aqueous solution or a slurry of the second metallic component; thereafter, 10- to 20-mesh pumice (surface area$<$0.3 m^2/g) originating from volcanic rocks was mixed with the solution, and the mixture was evaporated with vigorous stirring. The amount of pumice was 500 ml in a stream of oxygen at 500 °C for 4 to 5 h. As the starting materials, the following compounds were used: nitrate for Fe; ammonium salts of oxy acids for V, Mo, and W; chlorides (converted to hydroxides by dilute ammonia) for Ti and Sn; hydrate for K; H_2SO_4 for S; H_3PO_4 for P; and Sb powder (converted to oxide by concentrated nitric acid) for Sb. The surface areas were measured by the BET method using nitrogen at −196 °C.

Acidity and Basicity Measurements. Since the Bi_2O_3-based oxides are colored, the determination of the acidity and basicity by an ordinary titration method[4] seems to be difficult; therefore, it was attempted to measure the acidity and basicity by means of the adsorption of the basic and acidic molecules respectively from the gas phase, using the static method.[5-7] NH_3 and CO_2 were chosen as the adsorbates. The amount of adsorption at a pressure of 300 mmHg was measured volumetrically using an ordinary BET apparatus. Subsequently, the catalyst was pumped out for 30 min at the same temperature. Then, similar adsorption procedures were repeated and the amount of readsorption was measured. The amount of irreversible adsorption was obtained as the difference between the amount of readsorption and that of the first adsorption. This was adopted as the measure of the acidity and basicity. The details of the procedures were the same as those described in the previous papers.[5-7]

Catalytic Activity Measurements. The dehydration and dehydrogenation of 2-propanol (IPA), the isomerization of 1-butene, and the oxidative decomposition of formic acid were carried out in an ordinary continuous-flow system. The reactor was a steel tube, 50 cm in length and 1.8 cm in internal diameter. It was immersed in a lead bath, the temperature of which was controlled within ±1 °C. The concentrations of 2-propanol, 1-butene, and formic acid were 1.65, 0.67, and 1.2 mol% in air respectively. The total flow rate was kept constant at 1.5 l/min (at 25 °C), and the amount of catalyst used weighed 1 to 20 g. The details of the experimental procedures were the same as those employed in the previous works.[5-7]

Results

Acidity. The acidity (number of acidic site) per unit of the surface area of the Bi_2O_3–X_nO_m catalysts, as determined by the amount of NH_3 irreversibly adsorbed at 200 °C, is plotted as a function of the X_nO_m content in Figs. 1 and 2.

The acidity of pure Bi_2O_3 is relatively low. The acidity increases markedly upon the incorporation of acidic compounds. The order of this promoting ability is found to be: $SO_3 > MoO_3 > WO_3 > P_2O_5 > V_2O_5 > Sb_2O_4$. The abilities of amphoteric oxides such as SnO_2, TiO_2, Al_2O_3, and Fe_2O_3 are less prominent. The acidic sites are extinguished by the addition of a small amount of K_2O.

Basicity. The basicity (number of basic site) per unit of the surface area of the Bi_2O_3–X_nO_m catalysts, as

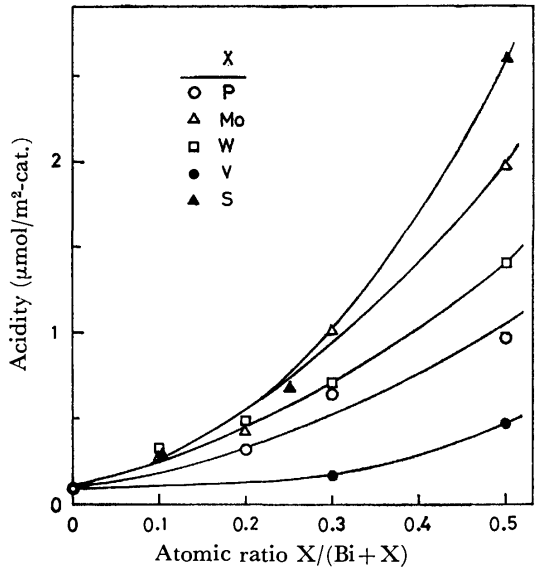

Fig. 1. Acidity of Bi_2O_3–X_nO_m (I).

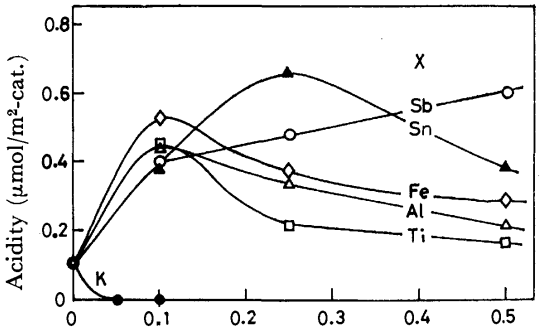

Fig. 2. Acidity of Bi_2O_3–X_nO_m (II).

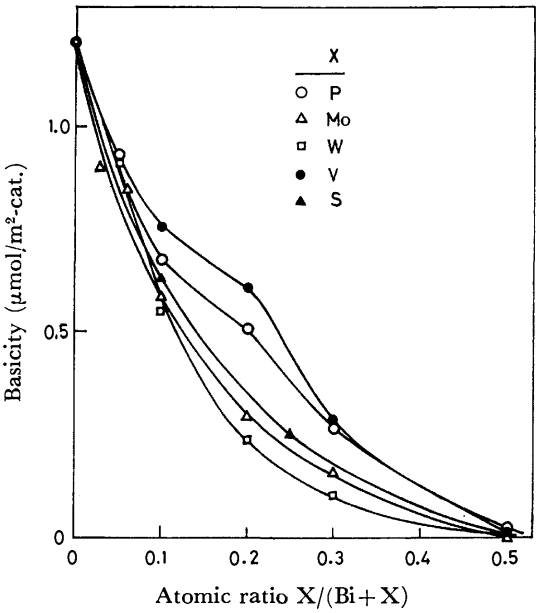

Fig. 3. Basicity of Bi_2O_3–X_nO_m (I).

determined by the amount of CO_2 irreversibly adsorbed at 25 °C, is plotted in Figs. 3 and 4.

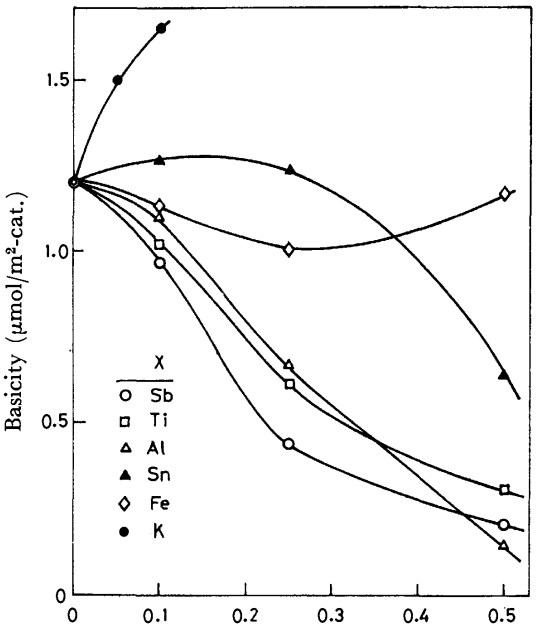

Fig. 4. Basicity of Bi_2O_3–X_nO_m (II).

Bi_2O_3 by itself is fairly basic. The basicity decreases upon the addition of more acidic compounds. The ability to diminish basicity is found to be in this order: $WO_3 > MoO_3 > SO_3 > V_2O_5 = P_2O_5 > Sb_2O_4 > TiO_2 = Al_2O_3 > SnO_2$. The ability of Fe_2O_3 is small, and the addition of K_2O increases the basicity.

Correlation between Acidity and Catalytic Activity. In order to confirm the validity of the acidity data, their correlation with the catalytic activity for certain acid-catalyzed reactions was checked. The dehydration of 2-propanol to propylene and the isomerization of 1-butene to 2-butenes were chosen as the model reactions, since it has been shown with various kinds of mixed metal oxides that the catalytic activity for the two reactions, as measured in a continuous-flow experiment in an atmosphere of air, can be tied with the acidity.[1,5-8]

Dehydration Activity for 2-Propanol: A gaseous mixture of 2-propanol and air was passed through a bed of the catalyst under the above-mentioned conditions. The main products were propylene and acetone, and the amounts of the other products were negligibly small. The rate of dehydration at 242 °C, r_p (mole per hour m^2 of catalyst), was measured for certain binary systems with relatively high acidities. Following the principle of the differential reactor, the conversion was held at a slow level, *i.e.*, usually below 10%.

The results are plotted in Fig. 5 as a function of the acidity of the catalysts. It is found that, so long as the second component, X_nO_m, is the same, the values of r_p vary in the same direction as the acidity.

Isomerization Activity for Butene: The activity for the isomerization of 1-butene to 2-butenes under the circumstances of the oxidation reaction at 473 °C, r_i (mole per hour m^2 of catalyst), was studied for certain binary systems with relatively high acidities.[1,6-8]

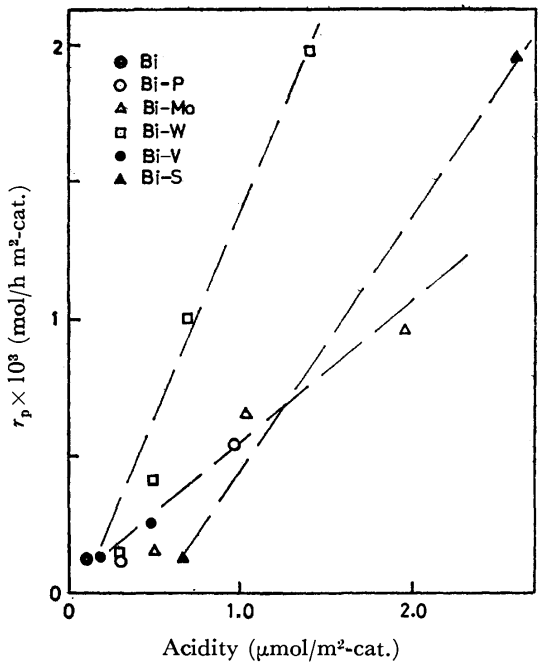

Fig. 5. Relation between the dehydration activity for 2-propanol at 242 °C (r_p) and the acidity of catalyst.

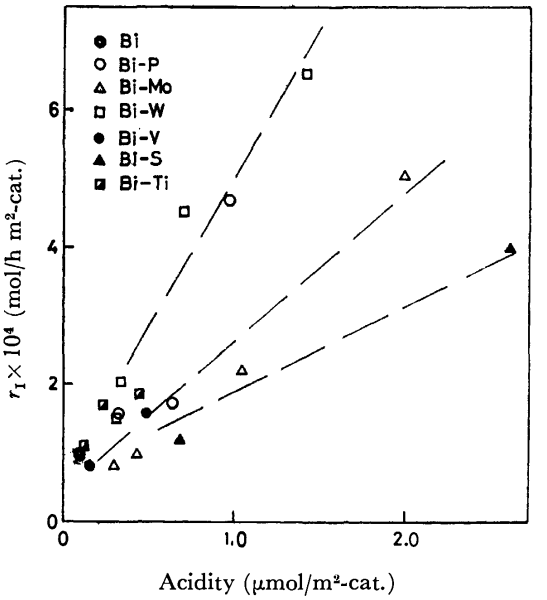

Fig. 6. Relation between the isomerization activity for 1-butene at 473 °C (r_I) and the acidity of catalyst.

It is plotted in Fig. 6 as a function of the acidity of the catalysts. Much as with the dehydration activity for 2-propanol, the isomerization activity changes in the same direction as the acidity, so long as the second component, X_nO_m, is the same.

Correlation between Basicity and Catalytic Activity. Next, the basicity data were confirmed by studying the correlation with the catalytic activity for certain base-catalyzed reactions. It has been shown that the catalytic activity for the oxidative decomposition of formic acid to CO_2[8] and the r_a/r_p ratio, where r_p and r_a are the initial rates of 2-propanol dehydration and dehydrogenation respectively,[1,6,9] are effective as measures of the basicity of the oxidation catalysts.

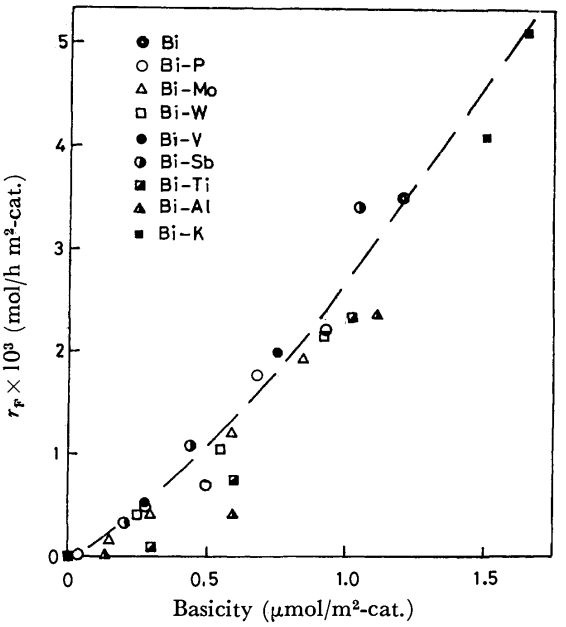

Fig. 7. Relation between the activity for oxidative decomposition of formic acid to CO_2 155 °C (r_F) and the basicity of catalyst.

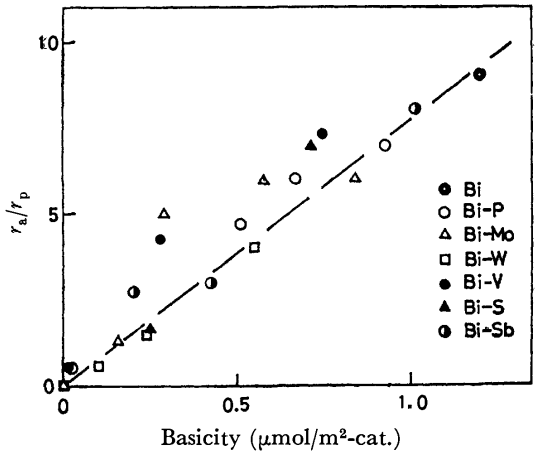

Fig. 8. Relation between the r_a/r_p ration and the basicity of catalyst.

Oxidative Decomposition of Formic Acid: As has been mentioned in a previous paper,[8] the reaction products were CO_2 and H_2O, and the amounts of CO and H_2 were negligibly small. The rate of CO_2 formation at 115 °C, r_F (mole per hour m^2 of catalyst), was measured for each catalyst. It is plotted in Fig. 7 as a function of the basicity of the catalysts. A very good correlation is observed between the activity and the basicity.

(Dehydrogenation Activity)/(Dehydration Activity) Ratio in the Reaction of 2-Propanol: The r_a/r_p ratio is plotted in Fig. 8 as a function of the basicity. A relatively good correlation is obtained between the r_a/r_p ratio and the basicity.

Discussion

It was found that Bi_2O_3 by itself has both acidic and

basic sites, much like TiO_2, SnO_2, and Fe_2O_3, and that Bi_2O_3 is more basic than the latter oxides; this is in conformity with the earlier results.[6,7,9-11] It was also demonstrated in a direct way that the Bi_2O_3-based mixed oxides are, more or less, acid-base bifunctional and that the generation of an unexpectedly high acidity or basicity, which often occurs in combination of metal oxides, was not observed. Therefore, the acid-base properties can be understood relatively easily in terms of the nature of the second components, X_nO_m.[1,2,9] The more acidic the second component, the more acidic and the less basic become the binary oxides. The order of the ability to promote acidity and diminish basicity is found to be: MoO_3, SO_3, $WO_3 > V_2O_5$, $P_2O_5 > Sb_2O_4 > TiO_2$, SnO_2, Fe_2O_3. The effect of the amphoteric oxides, such as TiO_2, SnO_2, Fe_2O_3, and Al_2O_3, is less prominent. Contrary to the acidic compounds, the addition of K_2O decreases the acidity and increases the basicity. In the case of oxidation catalysts, the valence of metal is varied by the combination of oxides, so it seems difficult to predict the acidity generation basing on the hypothesis proposed by Tanabe *et al.*[12]

We would like to propose the following view. When Bi_2O_3 is combined with a more acidic oxide, the basic sites of the mixed oxides originate from Bi_2O_3 and some of the basic sites are extinguished by the combination of the acidic compound, as can be reasonably expected in the case of a liquid acid-base. Accordingly, the natures of the basic sites remain approximately the same, regardless of the changes in kind and amount of the second component, X_nO_m. This may be the main reason why the plots of the activity for base-catalyzed reactions against the basicity give a straight line extraporated through the point of origin.

On the other hand, the acidic sites of the binary oxides do not originate from Bi_2O_3 but are generated by the combination with second components. Consequently, the natures of the acidic sites vary widely depending on the nature of the second components, X_nO_m. This may be the reason why the correlation between the catalytic activity and the acidity is obtained only when the second component is of the same kind.

Structure Determination of the 1,4-Cycloadduct Quenched after the High-pressure Reaction of Tetracyanoethylene with Styrene and Its Derivatives

Masaru NAKAHARA,* Yasuhiro UOSAKI, Muneo SASAKI, and Jiro OSUGI

Department of Chemistry, Faculty of Science, Kyoto University, Oiwake-cho, Kitashirakawa, Sakyo-ku, Kyoto 606

(Received February 4, 1980)

The electronic, ^{13}C NMR, ^{1}H NMR, and IR spectra of the 1,4-cycloadducts of TCNE with styrene, styrene-α-d_1, *p*-chlorostyrene, *p*-methylstyrene, α-methylstyrene, and 1,1-diphenylethylene were taken at low temperatures at 1 bar after the high-pressure reaction; the ^{13}C NMR spectra were of decisive importance in determining the structure; the other kinds of spectra were consistent with the established structure. They have an electronic absorption band around 320 nm, which is assigned to the π-π^* transition of the triene system in the adducts. Neither *cis*- nor *trans*-stilbene, which have a lower ionization potential, provides the 1,4-cycloadduct even at high pressure.

Tetracyanoethylene (TCNE) is one of the strongest electron acceptors to give the EDA (electron-donor-acceptor) complexes with electron donors; it undergoes the 1,2-cycloaddition to electron-rich olefins and the 1,4-cycloaddition to dienes.[1-3] Styrene, which is composed of vinyl and phenyl groups conjugated together, has been considered to yield neither 1,2- nor 1,4-cycloadduct of TCNE under mild conditions,[4] while its derivatives with an electron-donating substituent at *para*-, α-, or β-position are known to afford the 1,2-cycloadducts.[4-7] Actually, a number of papers[8-11] have been published on the formation constant and molar absorption coefficient of the EDA complex between TCNE and styrene without noticing the coexistence of the 1,4-cycloadduct confirmed here.

The present authors found a strong piezochromism in the dichloromethane solution of TCNE and styrene, and showed that a new species having an absorption band around 320 nm was formed reversibly in the solution.[12] The concentration of the new species at atmospheric pressure is too low to provide its IR and NMR spectra, which are required for determining spectroscopically the molecular structure. But the concentration can be increased sufficiently by pressure and decomposition after pressure release can be prevented at a low temperature well below 0 °C. The striking influences of high pressure and low temperature on the unstable species fortunately allows the molecular structure to be clarified unambiguously from the ^{13}C NMR and other spectra.

Experimental

Materials. Styrene and α-methylstyrene were purified by the usual method and distilled immediately before use. Styrene-α-d_1 (98% D atom, Merck Sharp and Dohme Canada Ltd.) and commercial *p*-chlorostyrene (guranteed reagent grade, Nakarai Chemicals Co., Ltd.) were used without further purification. *p*-Methylstyrene and 1,1-diphenylethylene were synthesized according to the methods in the literature[13,14] and purified by repeated distillation at reduced pressure. *trans*-Stilbene was recrystallized twice from ethanol and *cis*-stilbene was distilled at reduced pressure before use. TCNE was sublimed three times or more *in vacuo* at 50—60 °C. Dichloromethane was purified by the usual method and distilled before use. Dichloromethane-d_2 (99.3% D atom) was supplied by CEA (France).

Apparatus and Procedure. Electronic absorption spectra were recorded on a Shimadzu UV-200S spectrophotometer at 1 bar (1 bar = 10^5 Pa) and on a Union RA-405 spectrophotometer at high pressure. IR, ^{1}H NMR, and ^{13}C NMR spectra at 1 bar were measured with JASCO DS-402G, JEOL JNNM-PS-100, and JEOL FX-100 spectrometers, respectively. A high-pressure optical cell[15] with two sapphire windows of 1-cm thickness was used to measure electronic spectra at high pressure. Pressure was measured with a calibrated manganin-coil gage which was put in a flexible teflon capsule filled with silicone oil. The small teflon capsule was fixed on a plug inside the high-pressure optical cell. Thermostatted water was circulated around the cell to keep the temperature at 25±0.1 °C.

Sample solutions of the reaction mixtures of TCNE with styrene and its derivatives were prepared for the spectroscopic investigation in a special way as follows. Styrene or its derivatives were put together with TCNE in a flexible teflon capsule containing (deuterated) dichloromethane (≈1.6 cm^3). The amount of TCNE which was mixed was 2 or 3 times as much as the solubility (<0.1 mol dm^{-3}) in the solvent at room temperature at 1 bar, because pressure markedly enhanced its conversion into the adduct. The capsule was sealed with a teflon plug and a rubber O-ring, and placed in a usual piston-cylinder device having a jacket for thermal control. A pressure of ≈8 kbar was applied to the capsule for several hours at room temperature using silicone oil as a pressure-transmitting fluid, and ice-cold water was circulated through the jacket for an hour. As soon as pressure was released at 0 °C, the cold capsule was taken out from the piston-cylinder device and immersed in liquid N_2 to stock the quenched sample for a long time. Just before a spectroscopic study, the solid solution was melted again at about −95 °C and transferred by a previously chilled syringe to a cell. Cells for electronic and IR spectra were cooled at around 0 °C during the course of the measurements, while NMR glass tubes 10 mm in diameter were kept at −50 °C by circulating cold N_2 vapor around the tubes.

Results and Discussion

Electronic Spectra. On mixing the dichloromethane solutions of styrene and TCNE, a red color appears instantaneously because the EDA-complex formation is a diffusion-controlled reaction. Figure 1 shows the time dependence of the absorption spectrum of the reaction mixture at 1 bar. The absorption peaks at 396 and 480 nm are due to the EDA complex between styrene and TCNE; styrene and TCNE have no absorp-

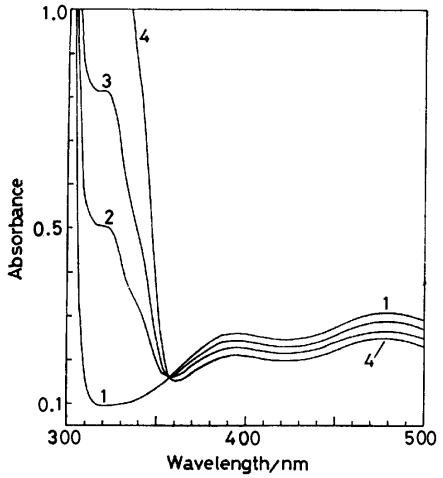

Fig. 1. Time dependence of the electronic spectra of TCNE–styrene mixture in CH_2Cl_2 at room temperature at 1 bar. Concentration (mol dm^{-3}): TCNE, 1.5×10^{-3}; styrene, 0.5. 1, 30 s after mixing; 2, 18.5 min; 3, 47.5 min; 4, 14 h.

tions in the visible region. The absorption of the EDA complex decreases slowly with time, while a new band develops around 320 nm. The absorption spectrum reaches a stationary state after a long time, leaving an isosbestic point at 357 nm. These facts suggest that a new species assigned to the 320-nm band (confirmed later as the 1,4-cycloadduct) is in equilibrium with the EDA complex as

$$D + A \underset{}{\overset{K_1}{\rightleftharpoons}} C \overset{K_2}{\rightleftharpoons} P, \qquad (1)$$

where D, A, C, and P are the donor (styrene), acceptor (TCNE), EDA complex, and new species, respectively, and K_1 and K_2 are equilibrium constants.

Although we could not measure at 1 bar the electronic, IR, and NMR spectra dominated by the new species P, a large pressure effect on the formation equilibrium (K_2) of P was found. The spectra A, B, C, D, and E (except B′) in Fig. 2 were taken at each pressure after they changed no more with time. The decrease with pressure in the absorption of the EDA complex is tremendous, especially at 8 kbar. If only a single equilibrium K_1 were involved in the solution as assumed

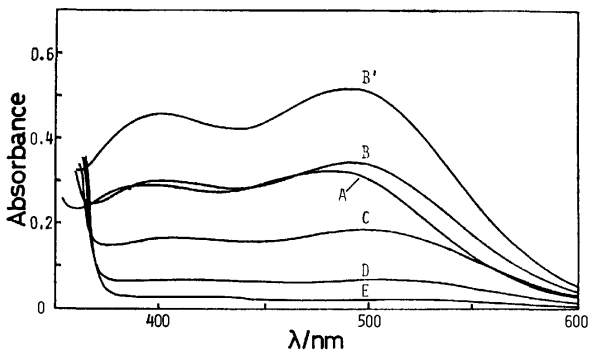

Fig. 2. Effect of pressure on the charge-transfer band of TCNE–styrene mixture in CH_2Cl_2 at 25 °C. Concentration (mol dm^{-3}): TCNE, 6.5×10^{-3}; styrene, 0.26. Path length, 5 mm. A, 1 bar; B and B′ (see the text), 2 kbar; C, 4 kbar; D, 6 kbar; E, 8 kbar.

elsewhere,[8–11] the absorbance would increase with pressure owing to the increase with pressure in the molar absorption coefficient and in the concentration of the EDA complex.[16,17] As a matter of fact, the trend exists transiently in Fig. 2; at 2 kbar, the initial absorbance B′ is larger than the equilibrium one B. The difference indicates that the EDA complex is slowly converted into the new species. The backward reaction from the new species to the complex is also slow, above all at 1 bar, so that the new species can be quenched in the solution.

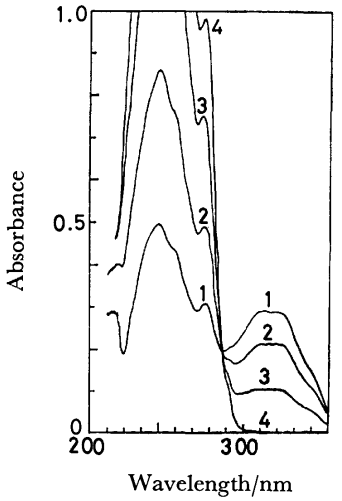

Fig. 3. UV spectra of the decomposing TCNE–styrene adduct in CH_2Cl_2 at room temperature at 1 bar. 1, 10 s after the quenched solution was diluted; 2, 10 min; 3, 30 min; 4, 16 h.

The UV spectra in Fig. 3 are taken at 1 bar after diluting the quenched reaction mixture. The well resolved spectrum of the new species is seen above the isosbestic point at 288 nm; it has a broad maximum between 310 and 325 nm with a shoulder at the longer wavelength. The spectrum below the isosbestic point corresponds to the parent molecules; when we denote the molar absorption coefficient of X at the wavelength λ by $\varepsilon_\lambda(X)$, ε_{250}(styrene) and ε_{250}(TCNE) are, respectively, 1.48×10^4 and 1.10×10^4 cm^{-1} mol^{-1} dm^3 and ε_{278}(TCNE) and ε_{278}(styrene) are, respectively, 1.26×10^4 and 1.2×10^2 cm^{-1} mol^{-1} dm^3. Thus, the variation with time of the absorbances in Fig. 3 discloses that the new species is an adduct between styrene and TCNE. The adduct is composed of an equal number of the parent molecules, because the quantity

$$\frac{A^2_{250}-A^1_{250}}{\varepsilon_{250}(\text{styrene})+\varepsilon_{250}(\text{TCNE})} = 1.36\times10^{-5} \qquad (2)$$

agrees well with

$$\frac{A^2_{278}-A^1_{278}}{\varepsilon_{278}(\text{styrene})+\varepsilon_{278}(\text{TCNE})} = 1.40\times10^{-5}, \qquad (3)$$

where A^1 and A^2 are the absorbances of spectra 1 and 2, respectively. In the dilute solution, the EDA complex is negligible. Hence, if the adduct has the stoichiometry expressed by reaction 1, ε of the adduct at 320 nm is given by the equation:

$$\frac{A^1_{320}-A^i_{320}}{A^i_\lambda-A^1_\lambda}\{\varepsilon_\lambda(\text{styrene})+\varepsilon_\lambda(\text{TCNE})\}=(5.5\pm0.1)\times10^3, \quad (4)$$

where λ=250 and 278 nm and i=2, 3, and 4. Adducts of the same type are found for the substituted styrenes except for the stilbenes, as shown in Table 1. It is unknown at present why neither *cis*- nor *trans*-stilbene provides the adduct under the same condition despite the fact that the ionization potentials are lower than those of the other electron donors.[18]

Table 1. Electronic absorptions of EDA complexes and adducts formed by the reaction of TCNE with styrene and its derivatives in CH_2Cl_2 at 25 °C

Donor	EDA complex λ_{max}/nm	Adduct[a] λ_{max}/nm
Styrene	480±1, 396±1	320±3
p-Chlorostyrene	483±1, 362±1	318±3
p-Methylstyrene	525±1, 401±1	317±3
α-Methylstyrene	495±1, 399±1	325±3
1,1-Diphenylethylene	507±1, ≈400	329±3
trans-Stilbene	597±1, ≈390	—[b]
cis-Stilbene	528±1, 389±1	—[b]

a) Obtained by diluting reaction mixtures quenched after pressurization. b) Adducts are not formed.

^{13}C and ^1H NMR spectra. The ^{13}C NMR spectra of the quenched reaction mixtures of TCNE with styrene, styrene-α-d_1, and *p*-chlorostyrene are of great use in proving that the adduct is really composed of one molecule of styrene and one molecule of TCNE, as in reaction 1, and in deciding how the donor molecule is combined with the acceptor. The ^{13}C NMR spectrum of the 1,4-cycloadduct is anticipated to give fourteen separate signals for the nonequivalent carbons. As a matter of fact, fourteen separate signals are found for the adduct, besides those for the parent molecules (Fig. 4), and the peaks in Fig. 4 are assigned to the carbon atoms numbered in the structural formula for the 1,4-cycloadduct, as summarized in Table 2.[19] The

Table 2. Assignment of the ^{13}C NMR peaks of the 1,4-cycloadducts[a]

Carbon No. (C-X)	Styrene adduct	Styrene-α-d_1 adduct	*p*-Chloro-styrene adduct
X=1	131.47	131.27	133.52

8	32.60	32.40	32.64

a) The 4 peaks between 111 and 108 ppm are due to the cyano carbons. b) The distinction among these is less reliable.

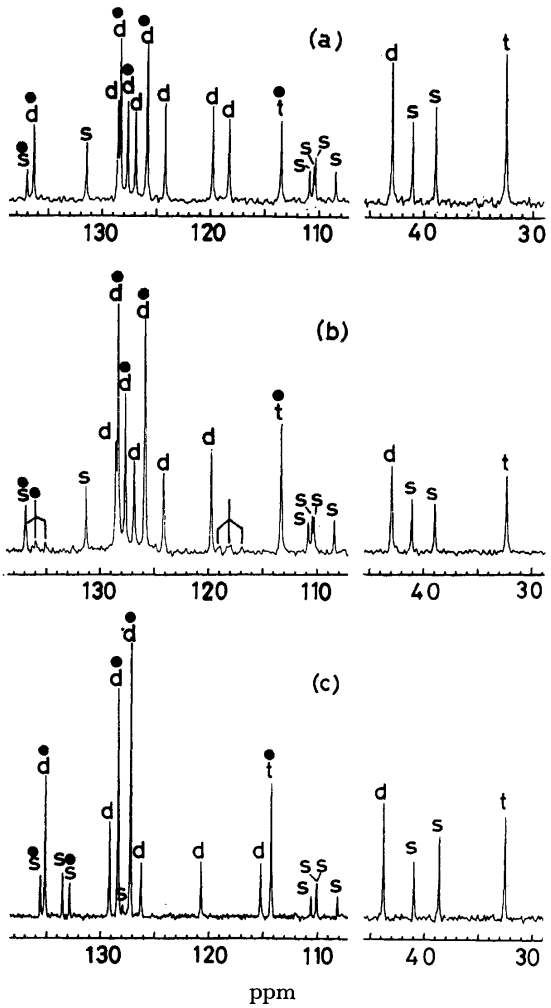

Fig. 4. ^{13}C NMR (complete decoupling) spectrum of the 1,4-cycloadduct in CD_2Cl_2 at −50 °C at 1 bar. (a), TCNE+styrene; (b), TCNE+styrene-α-d_1; (c), TCNE+*p*-chlorostyrene. Symbols s, d, and t denote singlet, doublet, and triplet in off-resonance decoupling, respectively. ●, Due to free styrene or its derivatives. The solubility of TCNE at the low temperature is too low to give signals. Chemical shifts are relative to the TMS reference.

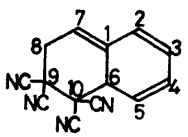

deuteration experiment elegantly reveals that the α-carbon in styrene remains in the sp^2 state in the adduct. This is compatible with the conjugated triene system in the 1,4-cycloadduct. Although it is reported that two acceptor (maleic anhydride) molecules combine with one styrene molecule after the reaction in benzene at 80 °C,[20] such a kind of cycloadduct has not been recognized in the present system. Actually, there is no other possibility than the present one that is consistent with the number, multiplicity, and position of the peaks found in the ^{13}C NMR spectra.

All the information from the ^1H NMR spectra[19] of

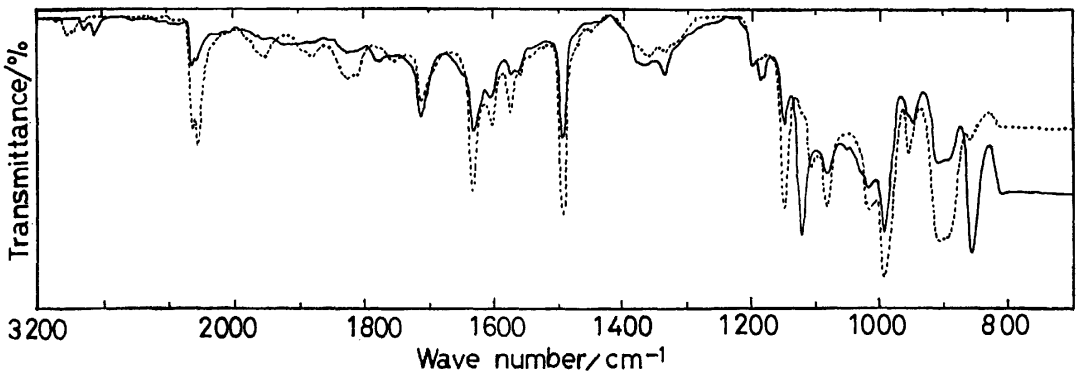

Fig. 5. IR spectra of TCNE–styrene mixture in CH_2Cl_2 around 0 °C at 1 bar.
——, Dominated by the adduct; ----, after the adduct being decomposed.

the quenched reaction mixtures of TCNE with styrene, styrene-α-d_1, and *p*-chlorostyrene is consistent with the conclusion reached above. There are three peaks, at 3.2—3.4, 4.4—4.6, and 5.5—5.7 ppm (internal TMS reference), whose peak ratio is 2 : 1 : 1; they are assigned to H_2C-8, HC-6, and HC-7, respectively. The facts that the styrene-α-d_1 adduct loses the peak at 5.5—5.7 ppm and that the *p*-chlorostyrene adduct does not lose the peaks at 3.2—3.4 and 4.4—4.6 ppm support the 1,4-cycloadduct. The complicated peaks in the range of 5.8 to 6.3 ppm are due to the protons involved in the conjugated triene system. Although a spin-decoupling experiment was attempted to reaffirm the above assignment, the low S/N ratio in the spectra due to the low concentration of the adduct made it difficult to see changes in the signal multiplicity.

IR Spectra. IR spectra tell us more about the molecular structure of the found adduct than do the electronic spectra. Vibrational spectra of the symmetric molecule TCNE have been well studied,[21-24] and the group frequencies related to the complicated molecule of styrene are available.[25,26] Figure 5 shows the IR spectra of the reaction mixture of styrene and TCNE, which is taken by using the quenching technique described in the experimental section. In the adduct, the bands at 2245 and 2220 cm^{-1} characteristic of the C≡N stretches in TCNE decrease in intensity, accompanied by a shift (≈15 cm^{-1}) to the higher frequencies. These changes indicate the loss of the conjugation of the double and triple bonds in TCNE; as a result, the C≡N bonds become stronger in the adduct than in TCNE. The C–C stretching vibrations at 1150 and 955 cm^{-1} in TCNE also decrease in intensity, and the corresponding bands in the adduct appear at the lower frequencies 1123 and 945 cm^{-1}, respectively. Thus, the loss of the conjugation makes also the C–C bonds weaker. The following bands of styrene decrease in intensity as reaction 1 proceeds; the vinylic C–H deformation bands at 990 and 890—910 cm^{-1}, the vinylic C–C stretching band at 1632 cm^{-1}, the aromatic C=C stretching bands at 1600, 1580, and 1500 cm^{-1}, and the combinations and overtones characteristic of the benzene ring[27] at 2000—1700 cm^{-1}. These spectral features of styrene show that both vinyl and phenyl groups are modified by the addition of TCNE; that is to say, the new species found is not the 1,2-cycloadduct. Thus, the IR spectral information supports the structure determination based on the ^{13}C NMR spectra.

Chromophore of the Band around 320 nm. It has been proved that the new species having the band around 320 nm is the 1,4-cycloadduct formed by the reaction of TCNE with styrene and its derivatives. The absorption band is attributed to the conjugated triene system rather than the C≡N group, because the 1,4-cycloadduct is predicted to have a band at 303 nm according to the additivity rule for the conjugated trienes.[28]

There is a short communication[29] which states that styrene derivatives benzylidenecyclopropane and (diphenylmethylene)cyclopropane having the exocyclic or strained double bond, 1,4-cycloadduct thermally to TCNE. In the latter case, the UV absorption at 333 nm with log ε=3.91 is comparable with the present results; moreover, the ^1H NMR signals agree well with those of the 1,4-cycloadduct confirmed here. In the former case, however, two strong peaks at 269 (log ε=4.23) and at 278 nm (log ε=4.21) are reported, although a bathochromic shift is anticipated because of the presence of the electron-donating three-membered ring.[28]

Recent studies on the thermal polymerization of styrene in bulk showed the existence of an absorption band with a maximum at 325 nm. This band is attributed to a Diels-Alder adduct of two styrene molecules, which is considered to be responsible for the initiation of the spontaneous polymerization.[30-32] The present thorough studies on the 1,4-cycloadduct between styrene and TCNE are in favor of the suggestion of the styrene adduct based on the UV spectrum.

Kinetics of the Reactions of Ni(II) with Several Ligands in Water-*t*-Butyl Alcohol Mixtures

Tatsuo TAKAHASHI* and Takefumi KOISO
Department of Chemistry, Fukushima Technical College, Iwaki 970
(Received February 19, 1980)

The kinetics of the complex-formation reactions of Ni(II) with 4-phenylpyridine, isoquinoline, 2,2′-bipyridine, 1,10-phenanthroline, and 2,2′: 6′,2″-terpyridine in water–*t*-butyl alcohol mixtures were investigated by means of stopped-flow measurement. With an increase in the *t*-butyl alcohol content of mixtures for all ligands, the rate constants for the reactions decrease monotonically, while the activation parameters, $\Delta H_f^{\ddagger}$ and $\Delta S_f^{\ddagger}$, pass through distinct minimum values, and the minima occur at the same concentration of *t*-butyl alcohol. The results are briefly discussed in terms of the stability of the outer-sphere complex of Ni(II) with the ligands, and the structural properties of the solvents.

In an aqueous solution, the rate constants and activation parameters for the complex-formation reactions of many metal ions depend only slightly on the nature of ligand and are approximately equal to those quantities for the exchange of the water molecule from the first coordination sphere of metal ions. In such a case, the reaction is best represented by the Eigen dissociative mechanism (I_d), in which the rate-determining step of the reaction is the dissociation of a water molecule from the coordination sphere of the metal ions.[1,2] On the other hand, it was found that the kinetic parameters in certain nonaqueous solutions exhibit a marked ligand dependence, and some solvent properties influencing the kinetic behavior have been discussed.[3-6] Meanwhile, it may be expected that the change from a single-to a two-component solvent increases the number of factors influencing the kinetic behavior. In fact, a few studies[7-9] have revealed that the kinetic behavior of a mixed solvent depends on the composition of the inner-sphere of the metal ions, the steric requirement of the ligands, and the structures of the solvents.

As a part of an investigation aiming at identifying the mixed solvent properties influencing the kinetics, we wish to report here the results of the complex-formation reactions of Ni(II) with pyridine-type ligands in water–*t*-butyl alcohol mixtures.

Experimental

Materials. *t*-Butyl alcohol (Baker analyzed reagent) was purified by distillation from sodium metal (Baker) through a 25 mm ID × 1219 mm-long glass column packed with 6 mm OD × 6 mm-glass tubes. Ni(II) was introduced as the perchlorate. Ni(II) solutions were standardized by EDTA titration, using Murexide as the indicator. Isoquinoline (Eastman) was distilled alone under a vacuum in a Perkin Elmer Model 251 Auto Annular Still with a Teflon spinning band at a reflux ratio of 200 : 1, with a pot temperature of 126 °C and a head temperature of 62 °C. All the other chemicals used were of reagent quality.

Instrumentation and Experimental Procedure. The kinetic measurements were made with a Dionex Corporation (Sunnyvale, Calif.) Model D-110 stopped-flow spectrophotometer equipped with a Kel-F flow system, observing the precautions necessary for adequate temperature control (±0.5 °C). The reactions were monitored at wavelengths where the complexes and free ligands show the largest difference in absorptivity, *viz.*, 272—275 nm, 322—325 nm, 305—310 nm, 270—275 nm, and 334—338 nm for 4-phenylpyridine, isoquinoline, 2,2′-bipyridine, 1,10-phenanthroline, and 2,2′:6′,2″-terpyridine respectively. All the measurements were made under pseudo-first-order conditions with the total ligand concentration (C_L, after mixing) kept constant at 2.5×10^{-5} mol dm^{-3} for 2,2′-bipyridine and 2,2′:6′,2″-terpyridine, and 10^{-4} mol dm^{-3} for 1,10-phenanthroline, while the Ni(II) concentrations (C_{Ni}) were varied in the range from 1×10^{-3} to 5×10^{-3} mol dm^{-3}. In the cases of 4-phenylpyridine and isoquinoline, the complexes are relatively unstable, so that it was necessary to increase C_L to 2.1×10^{-4} mol dm^{-3}, and C_{Ni} to 0.8—2.4×10^{-2} mol dm^{-3} for isoquinoline, and C_L to 2.5×10^{-5} mol dm^{-3}, and C_{Ni} to 0.6—2.0×10^{-2} mol dm^{-3} for 4-phenylpyridine. The absorbancy measurements were made with a Shimadzu Model UV-200 double-beam recording spectrophotometer equipped with temperature control to ±0.5 °C.

Results and Discussion

The observed pseudo-first-order rate constant, k_{obsd}, is given by Eq. 1:[6]

$$k_{obsd} = k_f[Ni^{2+}] + k_d, \quad (1)$$

where k_f and k_d are the overall second-order and first-

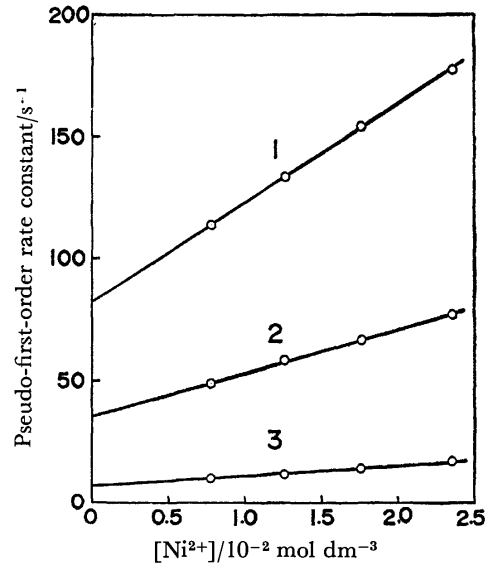

Fig. 1. Pseudo-first-order rate constants for the reaction of Ni(II) with 4-phenylpyridine in water.
Temperature (°C): (1) 35.0, (2) 25.0, (3) 10.0. Concn of 4-phenylpyridine: 2.5×10^{-5} mol dm^{-3}.

order rate constants for a complex-formation reaction and a dissociation reaction respectively. Equation 1 shows that a plot of k_{obsd} *vs.* $[Ni^{2+}]$ should be linear with a slope and an intercept equal to k_f and k_d. A typical result obtained in this study is shown in Fig. 1.

The rate constants at various temperatures for the reactions of Ni(II) with pyridine-type ligands studied in water–*t*-butyl alcohol mixtures are listed in Table 1. In Table 2, the rate constants at 25.0 °C and the activation parameters for the ligands are given for each solvent. The changes in the activation parameters with the solvent composition are shown in Figs. 2 and 3. These are the values of ΔH_f^*, $-T\Delta S_f^*$, and ΔG_f^* relative to pure water. Figures 2 and 3 show that the minima in ΔH_f^* and ΔS_f^* for all ligands occur at the same concentration of *t*-butyl alcohol, and that the rate constants decrease with a substantial compensation of the changes in ΔH_f^* by those in $-T\Delta S_f^*$ over the whole range of solvent compositions studied. Analogous extrema have been found for other properties, such as the partial molal heat of solution of a variety of salts[10] and the limiting cation-transference number[11] in a mixed solvent.

The k_d values can, in principle, be obtained from

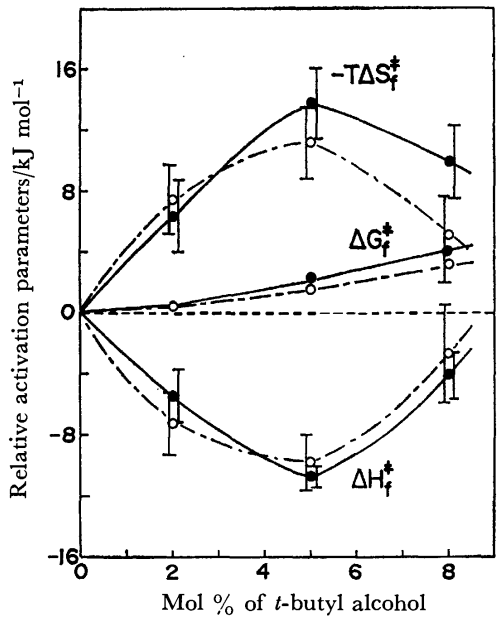

Fig. 3. Activation parameters for the reactions of Ni(II) with 2,2′-bipyridine (-○-○-) and 2,2′:6′,2″-terpyridine (-●-●-) in water–*t*-butyl alcohol mixture, normalized with respect to those in pure water (25.0 °C).

the analysis of the plots of Fig. 1. However, it should be noted that the intercept in Fig. 1 does not always give a correct dissociation-rate constant.[3] At present, it is, therefore, impossible to discuss strictly the solvent dependence on the dissociation reactions of metal complexes using the k_d values obtained by means of Eq. 1. In testing whether or not the complex-formation reaction proceeds through an I_d mechanism, the following equation presented by Chattopadhyay and Coetzee[7] was used:

$$R_1 = (4/3)k_f/K_{ass}k_s, \quad (2)$$

where K_{ass} and k_s are the formation constant of the outer-sphere complex and the rate constant for solvent exchange respectively, and where a dimensionless ratio, R_1, should have a value near unity. The log R_1 values calculated for the reactions in water at 25.0 °C are as follows: 4-phenylpyridine, −0.6; isoquinoline, −0.5; 2,2′-bipyridine, −0.5; 1,10-phenanthroline, −0.1; 2,2′:6′,2″-terpyridine, −0.7. The log k_s value for Ni(II) used was 4.5,[12] and the K_{ass} values were estimated by the Eigen-Fuoss equation.[13,14] Furthermore, the activation parameters, ΔH_s^* and ΔS_s^*, for Ni(II) in water were as follows: $\Delta H_s^* = 58.6$ kJ mol^{-1} and $\Delta S_s^* = +38$ J K^{-1} mol^{-1}.[12] From these results, it may be concluded that the complex-formation reactions of Ni(II) in water proceed through an I_d pathway.

It is probable that the Ni(II) species is solvated by only water molecules in the aqueous mixtures containing a small amount of *t*-butyl alcohol, taking into consideration the results on the form of Ni(II) in methyl alcohol–water mixtures.[15] Moreover, it has been shown that the water structure in mixtures containing a small amount of alcohol is both stiffer and more ordered than in pure water.[3,8,11] As has been assumed by previous workers,[7,8] the sharp decrease in the kinetic parameters shown in Figs. 2 and 3 may, therefore, be interpreted with the framework of an I_d mechanism. That is, the decrease in ΔH_f^* and ΔS_f^* may be caused by the passage of a water molecule from the disordered region near the Ni(II) into a bulk solvent which is more structured than water itself.

The enthalpy of activation should be related to that for solvent exchange as follows:

$$\Delta H_f^* = \Delta H_s^* + \Delta H_{ass}, \quad (3)$$

where ΔH_{ass} is the standard enthalpy for the formation of the outer-sphere complex and will usually be negligible when the ligand is uncharged. In previous papers,[16–18] we ourselves reported that the specific interactions between the inner-sphere and the outer-sphere (*e.g.*, hydrogen-bonding) should be considered in the formation of the outer-sphere complex. The decrease in the dielectric constant of media upon the addition of *t*-butyl alcohol will result in a stronger hydrogen-bonding interaction, and the outer-sphere complex is assumed to be stabilized. The increased stability of the outer-sphere complex may cause the remaining coordinated water molecule to be labilized as a result of the partially ionic character imparted to the water molecule involved in the hydrogen bond. The type of interaction introduced here is similar to the "internal conjugate base" mechanism proposed by Rorabacher.[19] In conclusion, we assume that the decrease in ΔH_f^* and ΔS_f^* upon the addition of *t*-butyl alcohol to water could arise mainly from the combined effects by stiffening the solvent structure and promoting the specific interaction between the inner-sphere and the outer-sphere. The increase in ΔH_f^* and ΔS_f^* upon the further addition of *t*-butyl alcohol to water remains unexplained, but a dramatic change in the solvation shell of Ni(II) and a breakdown of the water structure are expected to be of the greatest importance.

This work has been undertaken at the Department of Chemistry, University of Pittsburgh. We wish to express our deep gratitude to Professor J. F. Coetzee for his kind guidance in the course of this work.

Full-range Bond-order Dependence of Intramolecular Vibrations: Ethylene and Tetracyanoethylene

Jun-ichi AIHARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received March 10, 1980)

For analogous normal vibrations in conjugated systems of a similar type a linear relationship often exists between vibrational frequencies and bond orders. We find that this linearity can, in principle, be extended to include conjugated systems in both excited electronic states and ionic states. This indicates that the linearity covers a full range of bond order conceivable for conjugated systems. Such an aspect of molecular vibrations gives a concise and sometimes decisive clue not only to vibrational assignments but also to structural analyses of conjugated systems in various electronic states. Symmetric C=C stretching vibrations of ethylene and tetracyanoethylene nicely illustrate this situation.

Although most of the constituent atoms contribute to every vibrational mode of a molecule, many of the modes behave as if they were properties of individual functional groups.[1] This effect leads to a characteristic infrared band which appears within a relatively narrow energy range for such functional groups as methyl, hydroxyl, and carbonyl. For conjugated systems vibrational energies have both σ- and π-components. Detailed analysis by Coulson and Longuet-Higgins showed that a force constant for a π bond is a function of π bond order and π bond polarizability.[2] However, the use of bond order alone often suffices to estimate the vibrational frequency.[3] Berthier *et al.* found that a characteristic frequency for a variety of aldehydes and ketones typically gives an excellent linear correlation with a bond order of the carbonyl group.[4]

It is widely known that, when a conjugated compound forms a molecular ion, its infrared and Raman spectra change markedly;[5-9] so do the bond orders. When a conjugated system is electronically excited, such vibrational frequencies as found in the electronic absorption bands often change from those of the ground-state species.[9] However, attempts to correlate these frequencies with the corresponding bond orders have scarcely been made. This kind of study has been restricted to neutral conjugated systems in the ground state, where a change in bond order is rather modest.[3] In this paper, I would like to show that a linear relationship between vibrational frequencies and π bond orders can, in principle, be extended to cases where both quantities change much more widely. Recall that a wide variation in π bond order can usually be realized in the following three ways: exciting a conjugated system of a molecule, removing one or more π electrons from a molecule, and attaching one or more π electrons to a molecule.

Results and Discussion

Ethylene is the simplest conjugated hydrocarbon. A vibrational frequency of the symmetric C=C stretching mode can be detected in the Raman spectrum. It is 1623 cm^{-1} in the ground electronic state.[10] This frequency is reduced to 850 cm^{-1} in the excited electronic state,[10] which is observed as a vibrational component of the first electronic absorption band around 45000 cm^{-1}. Some vibrational frequencies can be seen in a photoelectron spectrum of ethylene.[11] They are ascribed to the molecular cation $C_2H_4^+$. The first photoelectron band corresponds to a removal of a π electron from the single π-valence orbital. This band exhibits a 1230 cm^{-1} vibrational progression, which has been assigned to a symmetric C=C stretching mode of $C_2H_4^+$.

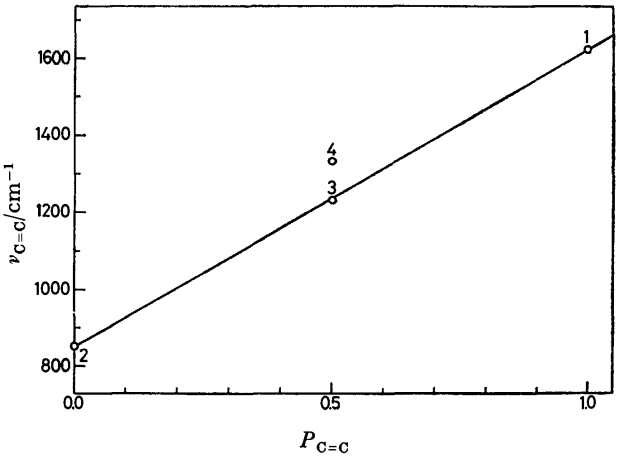

Fig. 1. Plot of $\nu_{C=C}$ *vs.* $P_{C=C}$ for ethylene: 1, C_2H_4; 2, C_2H_4*; 3, $C_2H_4^+$; 4, $C_2H_4^-$.

In order to see if these frequencies ($\nu_{C=C}$) correlate with the corresponding C=C π bond orders ($P_{C=C}$), the former quantities are plotted against the latter ones in Fig. 1. The C=C π bond orders are 1.000 for C_2H_4, 0.000 for C_2H_4*, and 0.500 for $C_2H_4^+$, where C_2H_4 and C_2H_4* denote the ground and excited electronic states of ethylene, respectively. C_2H_4 and C_2H_4* are chosen to draw a reference line in Fig. 1 because the number of π electrons are kept constant. This line is expressed as

$$\nu_{C=C} = 773.0\,P_{C=C} + 850.0. \quad (1)$$

Here, it is surprising to see that this linear relationship can exactly be applied to $C_2H_4^+$. Note that C=C π bonds of C_2H_4, C_2H_4*, and $C_2H_4^+$ cover the full range of π bond order conceivable for conjugated systems.

In 1973 Sanche and Schultz reported an electron transmission spectrum of ethylene in the gas phase.[12] The first band exhibits an average vibrational spacing of 1330 cm^{-1}, which most likely results from a symmetric

C=C stretching vibration of an ethylene anion ($C_2H_4^-$). The C=C π bond order of $C_2H_4^-$ must be the same as that of $C_2H_4^+$. However, this anion is placed about 100 cm^{-1} above the reference line in Fig. 1. This implies that the C=C bond in $C_2H_4^-$ is a bit more stabilized than expected from Eq. 1.

An analogous symmetric C=C stretching mode of tetracyanoethylene (TCNE) gives another good example which supports a wide-range π-bond-order dependence of vibrational frequencies. A Raman spectrum of this compound shows that the vibrational frequency of 1569 cm^{-1} can be assigned to the symmetric C=C stretching mode.[13,14] This frequency is nearly comparable to that of C_2H_4. TCNE exhibits the first electronic absorption band in the energy range 35000—43000 cm^{-1} in the gas phase. Spacings of the vibrational components are irregular, and the 0-1 level seems to be shifted, probably due to an intersection of the two potential surfaces.[15] Its average 1128 cm^{-1} spacing was assigned to the symmetric C=C stretching mode of the excited TCNE molecule (TCNE*).

TCNE is a typical electron acceptor with an electron affinity of 2.89 eV.[16] Therefore, its monoanion ($TCNE^-$) is considerably stabilized,[17] forming many anion radical salts[18] in the form M^+TCNE^-. For these salts it is striking that there appears intense absorption at about 1370 cm^{-1} in a region barren of significant absorption by TCNE.[19] This has been assigned to the totally symmetric C=C stretch which became infrared active by the Ferguson-Matsen mechanism.[20] This interpretation was later justified by a Raman spectroscopic study.[14] The C=C stretch of $TCNE^-$ is influenced by the cation to some extent. Thus C=C stretching frequencies are 1387 cm^{-1} for the lithium, 1390 cm^{-1} for the sodium, 1371 cm^{-1} for the potassium, and 1358 cm^{-1} for the cesium salt.[21] The first absorption band of $TCNE^-$ in solution exhibits numerous vibrational maxima. Unfortunately, the average spacing of 530 cm^{-1} should rather be assigned to the symmetric C–C stretch.[22]

Recently, Khatkale and Devlin prepared $TCNE^{2-}$ and $TCNE^{3-}$ by vacuum condensation methods[23] and measured infrared and Raman spectra of the four molecule series TCNE, $TCNE^-$, $TCNE^{2-}$, and $TCNE^{3-}$. Symmetric C=C stretching frequencies are 1392, 1256, and 1346 cm^{-1} for the sodium salts of $TCNE^-$, $TCNE^{2-}$, and $TCNE^{3-}$, respectively. A photoelectron spectrum of TCNE has been reported by three research groups.[24-26] Stafast and Bock analyzed it[26] and attributed the 1360 cm^{-1} progression of the first band to the symmetric C=C stretch of $TCNE^+$. An uncertainty of $\pm$100 cm^{-1} may be included in this experimental frequency.[24-26]

π Bond orders of the TCNE series were calculated using Coulomb and resonance integrals suggested by Orgel and coworkers.[27] A Coulomb integral for a cyano nitrogen was set equal to $\alpha+\beta$, and a resonance integral for the C≡N bond to 1.2β. The C=C π bond orders thus calculated are 0.700 for TCNE, 0.314 for TCNE*, 0.491 for $TCNE^+$, 0.523 for $TCNE^-$, and 0.347 for $TCNE^{2-}$ and $TCNE^{3-}$. The C=C stretching frequencies are then plotted against the corresponding

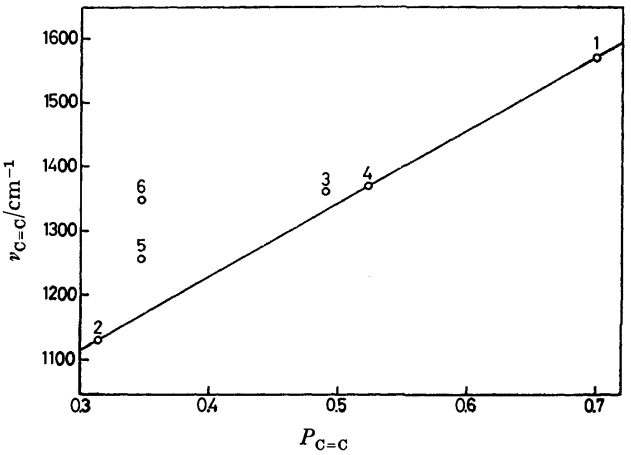

Fig. 2. Plot of $\nu_{C=C}$ *vs.* $P_{C=C}$ for tetracyanoethylene: 1, TCNE; 2, TCNE*; 3, $TCNE^+$; 4, $TCNE^-$; 5, $TCNE^{2-}$; 6, $TCNE^{3-}$.

bond orders in Fig. 2, where a reference line crosses two points representing TCNE and TCNE*. This line is expressed as

$$\nu_{C=C} = 1142.5\,P_{C=C} + 769.6. \quad (2)$$

As seen from Fig. 2, both $TCNE^+$ and $TCNE^-$ are also located near this line. Some other cyanoethylenes appear to behave analogously, although data for the electronically excited species are lacking. The C=C stretching frequencies are 1615 cm^{-1} for acrylonitrile (0.886), 1360 cm^{-1} for its cation (0.515), 1594 cm^{-1} for 1,1-dicyanoethylene (0.806), and 1360 cm^{-1} for its cation (0.523).[26] Here, values in parentheses are the appropriate π bond orders.

We hence feel confident that a linear bond-order dependence of the C=C stretching frequency exists among a variety of electronic states. Note that the C=C π bond order in our case changes within a range of 0.000—1.000, while in the case of aldehyde and ketones[3,4] the C=O π bond order changes modestly, in the range 0.819—0.958. Khatkale and Devlin reported that a plot of the empirical force constant *vs.* bond order is nearly linear for tetracyanoquinodimethane anions ($TCNQ^{n-}$).[28] This fact also supports a universality of such linearity as Eqs. 1 and 2 indicate.

Unfortunately, some exceptional species are found in Fig. 2. As in the case of $C_2H_4^-$, higher anions of TCNE show considerably larger frequencies than expected from Eq. 2. The C=C stretching frequency of $TCNE^{2-}$ deviates upward from the reference line by 90 cm^{-1} and that of $TCNE^{3-}$ by 180 cm^{-1}. It is especially noticeable that the C=C stretching frequency of $TCNE^{3-}$ is somewhat larger than that of $TCNE^{2-}$. The effect of the third π electron added is apparently quite different. This electron is expected to enter an orbital which is nonbonding in the C=C region, so an apparent strengthening of the C=C bond was not anticipated.[23] Accordingly, it is quite natural to consider some possible mechanism which intensifies the C=C bond strength.

We have assumed that skeletal structures of all molecular species are identical with that of a neutral molecule. This may be true for TCNE* and $TCNE^+$ since the 0-0 vibrational component of the first band

is strongest in the electronic absorption spectrum of TCNE[15] and in its photoelectron spectrum.[26] The same situation applies to the ethylene cation.[11] However, there is no reason to believe that the same situation must apply to the other species, especially to higher anions of TCNE.

On the other hand, it is not difficult to imagine that additional π electrons in the TCNE anions are highly delocalized with high polarizability. Perhaps more reasonable is the assumption that the structures of the dianion and the trianion are strongly distorted by asymmetric cation polarization fields, such that the original TCNE D_{2h} symmetry is no longer useful for the purpose of vibrational analyses.[23] According to Jeanmaire *et al.*,[22] the electrogeneration of $TCNE^{2-}$ in acetonitrile containing tetrabutylammonium perchlorate seemed to be electrochemically quasireversible. They speculated that the cause of the quasireversible electron transfer to form the dianion is due to a geometry change and that $TCNE^{2-}$ is a nonplanar species even in solution.[22] Such a tendency toward nonplanarity may be enhanced in $TCNE^{3-}$. For these reasons, we cannot always take the premise that the molecular ion series might constitute such a set of molecular ions that vibrational assignments for the other members would follow smoothly from a firm assignment of the modes of one member of the series. Significant deviation of a vibrational frequency from the reference line should be interpreted as due to a molecular deformation or some other geometry change. However, this does not deny our view that the bond-order dependence of vibrational frequencies holds widely because bond orders are necessarily modified for the deformed species.

A conjugated system of TCNE is fairly large compared with that of ethylene, so $TCNE^-$ appears to retain the geometry of its neutral species. However, it may be impossible for the ethylene monoanion to retain the ground-state geometry of the neutral species because of its compact conjugated system. The deviation of 100 cm^{-1} apparently indicates the degree of extra stabilization of the C=C bond.

I previously observed a vibrational structure in the charge-transfer (CT) absorption band of the naphthalene–TCNE complex in various saturated hydrocarbons.[29] The vibrational frequency was 1300—1400 cm^{-1}. Similar frequencies are found in the solid-state absorption spectra of several aromatic hydrocarbon–TCNE complexes.[30,31] According to Kadhim and Offen,[30] such vibrational frequencies might be characteristic of the acceptor molecule because a CT transition is naively viewed as an electron jump to the lowest unoccupied orbital of the acceptor. The appearance of a 1300—1400 cm^{-1} vibration thus indicates that the TCNE component in the complex is almost completely ionized in the CT excited state since the frequency is close to that of $TCNE^-$ in Fig. 2. On the other hand, the resonance Raman spectrum of TCNE in benzene[32] exhibits a strong line at 1565 cm^{-1}, and that of TCNE in anisole[33] at 1556 cm^{-1}. These frequencies suggest that the ground-state TCNE complexes with benzene and anisole are essentially nonionic, in accord with the prediction by simple CT theory.[34]

Concluding Remarks

As has been examined above, a linear bond-order dependence of vibrational frequencies can, in principle, be extended to a conjugated system in any electronic state. This aspect of intramolecular vibrations can be used to assign not only electronic absorption bands but also photoelectron bands of various conjugated systems. In this connection, Ikemoto *et al.* observed a 1530 cm^{-1} vibrational component in the first photoelectron band of TCNE,[24] and assigned it to the symmetric C=C stretch. However, the frequency of this mode is predicted from Eq. 2 to be close to 1330 cm^{-1}. In this sense the frequency read by Stafast and Bock (1360 cm^{-1})[26] appears more reasonable. If a given vibrational mode deviates to a higher energy side, this should be regarded as a significant indication of a geometry change, and some possible stabilizing mechanism must be considered for the species concerned. Thus the relationship established between π bond orders and vibrational frequencies will give an important and sometimes decisive clue to structural chemistry of conjugated systems, especially when other experimental data are scanty.

The use of the facilities of the Hokkaido University Computing Center is gratefully acknowledged.

Cotton Effect Induced in Optically Inactive Molecules and Molecular Complexes by Optically Active Environment. III. Circular Dichroism Induced by Association of α-Chymotrypsin and Dyes

Yasumasa J. I'HAYA,* Yasunobu OIKAWA, and Tomoyasu NAKAMURA†

Department of Materials Science and Laboratory of Magneto-Electron Physics, The University of Electro-Communications, Chofu, Tokyo 182

(Received April 4, 1980)

Two types of circular dichroism (CD) spectra are found to be induced in the solution systems of α-chymotrypsin (αCT) and dyes. One is a single positive CD band which is due to a 1 : 1 αCT–dye complex (Type I; proflavine, Acridine Yellow G, acriflavine), and the other consists of one positive and one negative CD bands which are mainly due to a complex of the composition, one αCT to two dye molecules (Type II; Pyronin B, Rhodamine 6G). Mechanisms of CD induction tentatively proposed are that in Type I complexes a single dye molecule is bound to an asymmetric environment of the active site of αCT while in Type II complexes two dye molecules are bound at a specific site exerting a dipole-dipole interaction with one another.

There have been published a number of physicochemical and biochemical works on the interaction between biopolymers and dyes, of which the most elegant means may be the measurement of the Cotton effect induced in the corresponding visible absorption region of the dye. This is because once an accurate analysis is accomplished the bound dye molecules play a role as probes in determining the geometrical and electronic structures of the partner, biomacromolecules. Biopolymers that have been hitherto investigated in this way are nucleic acids,[1,2] polypeptides,[3] and polysuccharides,[4] and in all cases the primary cause of circular dichroism (CD) induction is recognized as a complex formation between polymer and dyes, though less quantitative description of such complexes has been found.

We have reported in a previous paper[5] that the Cotton effect is induced in the absorption region of a dye molecule embedded in cellulose diacetate film and proposed a mechanism of CD induction that the dyes are imprisoned in a cage formed by an assembly of the folded chains of cellulose diacetate and the Cotton effect is induced by an electrostatic interaction between electronic transition moments of the dye and of the chromophores involved in the cage. In the present paper, we set our eyes on a system of enzyme and dyes. The concept that an enzyme molecule forms an intermediate complex with a substrate or substrates in an early stage of enzymic action has been well established. It is also well known that each enzymic action has its specificity with respect to a single substrate. In the study of enzyme-dye interactions, whether some sort of specificity appears in a complex formation is an interesting subject. We measured CD spectra induced in a variety of combination systems of enzymes and dyes and tried to find out some interrelation between a way of grouping and whether and what sort of Cotton effects are induced in the visible absorption region of the dyes. We report in what follows the CD spectral features of α-chymotrypsin–dye solutions, the truth being that α-chymotrypsin was found to be the only enzyme to interact overnicely with some specific dyes.

Experimental

Commercial α-chymotrypsin, bovine pancreas (Nutritional Biochemicals, 3X crystallized and lyophilized) was purified by recrystallization three times. Proflavine, Acridine Yellow G, acriflavine, Pyronin B, and Rhodamine 6G were all commercial reagert grade and used without further purification. Stock aqueous solutions of α-chymotrypsin and the dyes were dissolved in 0.1 mol dm^{-3} Tris buffer (pH 8.1—8.5). In order to avoid aggregation of dye molecules, concentrations of the dyes were held in the range of $1—5\times10^{-5}$ mol dm^{-3}. The molar concentration of α-chymotrypsin was calculated from its molecular weight which was assumed to be 25,000.

The absorption spectra were measured with a Hitachi model 124 spectrophotometer, the CD spectra by a JASCO J-40 polarimeter, and the optical rotatory dispersion (ORD) spectra by a JASCO ORD-UV-5 spectrophoto and polarimeter. All the measurements were performed at room temperature.

The ORD measurement (molecular rotation [ϕ]) had such a disadvantage that accurate determination became difficult when the concentration of α-chymotrysin was high, because the ordinanry dispersion of α-chymotrypsin extended over the absorption region of the dyes. For this reason, our primary attention was focused on the CD measurements. The molecular ellipticity [θ] of an induced CD (ICD) band was calculated by using the concentration of a dye involved.

Results

ICD spectra observed for the α-chymotrypsin (αCT)–dye systems may be divided into two classes; Type I consists of a single positive CD band, to which the αCT–proflavine (PF), Acridine Yellow G (AY), and acriflavine (AF) systems belong, and Type II is formed of a longer wavelength negative band and a shorter wavelength positive band, to which the αCT–Pyronin B (PB) and Rhodamine 6G (RG) systems belong. Since the ICD spectra of the same type (Types I and II) are not very much different from one another, we mention in detail only about the representative systems, αCT–PF and αCT–PB.

† Present address: Senshu University, Ikuta, Kawasaki, Kanagawa 214.

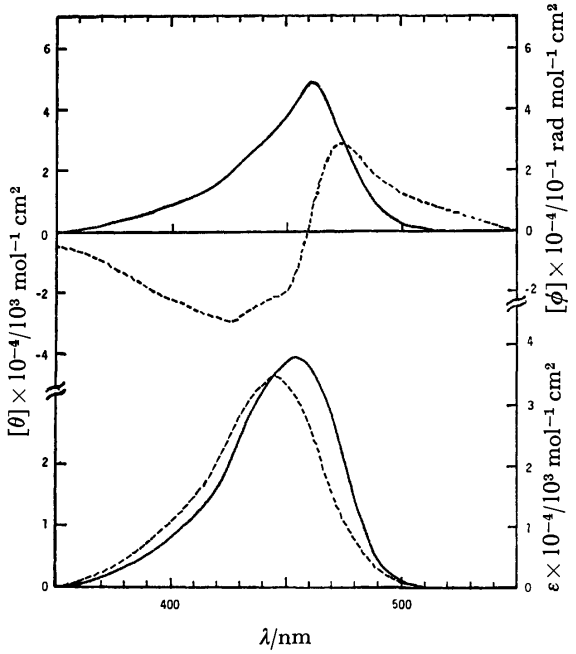

Fig. 1. CD (solid line, upper), ORD (broken line, upper), and visible absorption (solid line, lower) spectra of the α-chymotrypsin–proflavine complex dissolved in Tris buffer. [D]=4.0×10⁻⁵ mol dm⁻³ and [E]/[D]=3.8. The broken line in the lower half is the absorption spectrum of free proflavine of the same concentration.

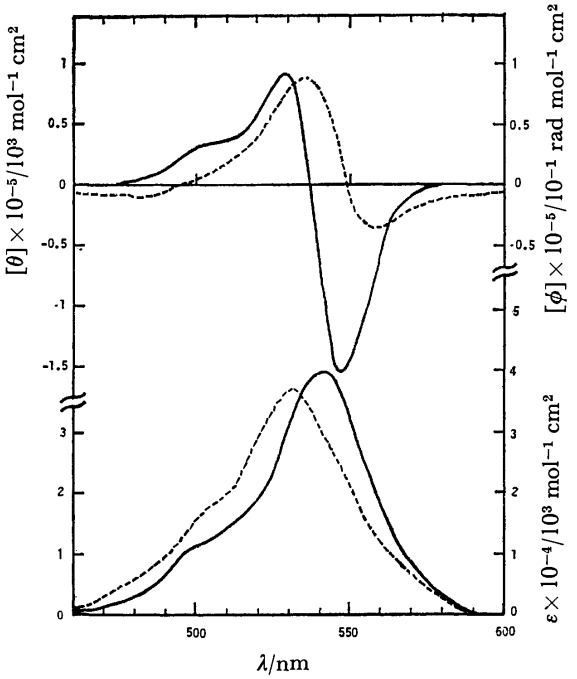

Fig. 3. CD (solid line, upper), ORD (broken line, upper), and visible absorption (solid line, lower) spectra of the α-chymotrypsin–Pyronin B complex dissolved in Tris buffer. [D]=5.0×10⁻⁵ mol dm⁻³ and [E]/[D]=4.0. The broken line in the lower half is the absorption spectrum of free Pyronin B of the same concentration.

α-Chymotrypsin–Proflavine. Figure 1 shows the CD, ORD, and visible absorption spectra of the αCT–PF system where the concentration of PF is 4.0×10^{-5} mol dm^{-3} and the molar concentration ratio of αCT to PF, [E]/[D], is 3.8. The single positive ICD band peaked at 462 nm corresponds to the broad absorption band of PF (peak: 456 nm; *cf.* peak of free PF: 445 nm), its molar ellipticity [θ] being 4.9×10^{4}. The corresponding ORD spectrum shows a positive Cotton effect. The peak intensity of the ICD spectrum was found to increase as [E]/[D] increases, while the peak wavelength and the spectral shape remained unchanged. Beyond [E]/[D]=8, the peak intensity itself remained constant, the corresponding [θ] value being 5.5×10^{4}. The relationship between [θ] and [E]/[D] is shown in Fig. 2.

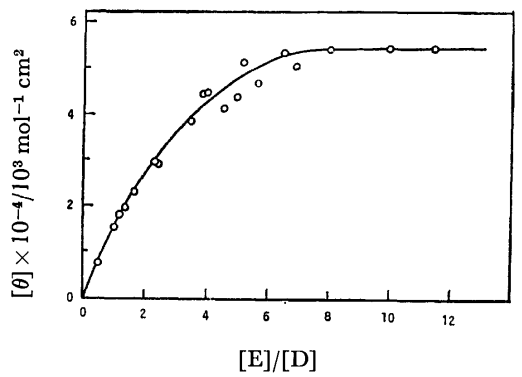

Fig. 2. Concentration dependence of the peak intensity of the induced CD band (462 nm) of the α-chymotrypsin–proflavine complex.

The absorption spectrum of PF shifts to the red and gains its intensity with the addition of αCT. The further shift of the absorption peak is not observed when [E]/[D]≧5, the peak converging to the value 460 nm. Furthermore, we found an isosbestic point at 443 nm.

α-Chymotrypsin–Pyronin B. Figure 3 illustrates the visible absorption and the induced CD and ORD spectra of the αCT–PB system, where the concentration of PB is 5.0×10^{-5} mol dm^{-3} and [E]/[D]=4. Contrary to the αCT–PF system, there appeared both positive and negative CD bands at the absorption region of the dye. The positive maximum lies at 529 nm with $[\theta]=9.1\times10^{4}$ and the negative maximum at 547 nm with $[\theta]=-1.54\times10^{5}$. Furthermore, a shoulder appeared at about 500 nm. As in the case of αCT–PF,

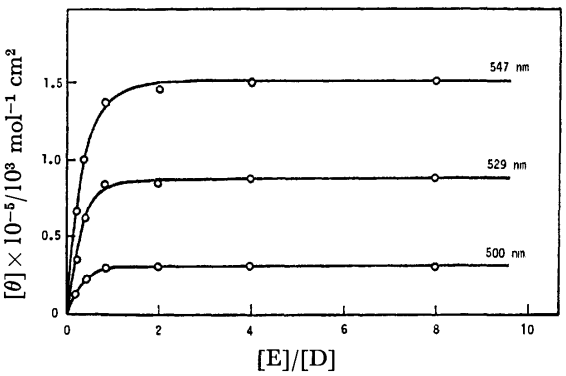

Fig. 4. Concentration dependence of the molecular ellipticities of the positive (529 nm), negative (547 nm), and shoulder (500 nm) CD bands of the α-chymotrypsin–Pyronin B complex.

the peak intensity was concentration dependent but the whole CD spectral feature remained unchanged. In Fig. 4 are plotted the molecular ellipticities of the positive, negative, and shoulder CD peaks against [E]/[D]. It is seen that in excess of [E]/[D]=4 the [θ] values tend to be concentration independent. The converged [θ] value for the positive band is 9.1×10^4, that for the negative band is -1.54×10^5, and that for the positive shoulder is 3.3×10^4.

The absorption spectrum of the αCT–PB system was quite similar to that of the αCT–PF system. The red shift of the absorption peak came to be over at 541 nm when [E]/[D]≧2. Contrary to the αCT–PF system, however, an isosbestic point was not observed explicitly.

The followings are brief descriptions of the results for the other systems.

α-Chymotrypsin–Acridine Yellow G. The positive ICD band was observed as in the case of αCT–PF. The peak of the CD band lies at 461 nm and its concentration dependence closely resembles the αCT–PF system; the [θ] value converges to 8.6×10^3 when [E]/[D]>4. The peak of the visible absortion spectrum of the system shifts from 435 nm (free dye) to 445 nm when [E]/[D] is varied, the latter being the converged value for [E]/[D]>4.

α-Chymotrypsin-Acriflavine. The spectral features of the ICD and visible absorption bands were just a copy of αCT–PF and/or αCT–AY.

α-Chymotrypsin–Rhodamine 6G. Like the αCT–PB system, the positive and negative ICD bands were observed. The whole spectral features of the CD bands are very much like those of αCT–PB, together with the similarity in the appearance of a weak shoulder in the shorter wavelength side. The corresponding ORD curve also resembles the case of αCT–PB. The molecular ellipticities of the negative (548 nm), the positive (529 nm), and the shoulder (505 nm) bands increase with the values of [E]/[D] and tend to converge to the value -5.3×10^5, 3.1×10^5, and 1.2×10^5, respectively, in excess of [E]/[D]=4. The visible absorption spectrum of αCT–RG behaves in the same fashion as that of αCT–PB upon concentration variation.

Finally, we like to add that no ICD spectra were observed with the solution systems of αCT and the following chromophores, though their molecular shapes are more or less analogous to those of the species described above: 9-aminoacridine, Methylene Blue, Toluidine Blue 0, thionine, Pyronin G, Rhodamine B, phenosafranine, Erythrosin B, Eosin B, Eosin Y, and Methyl Orange. Neither spectral shifts were observed in the visible absorption spectra of these solution systems.

Discussion

The observations described above for the αCT-specific dye systems clearly show a complex formation between αCT and the dyes. The appearance and the general features of the induced CD spectra in the aforementioned systems closely resemble those in the systems of nucleic acids, polypeptides, and polysuccharides with a variety of dye molecules.[1–4] Schlessinger and Steinberg[6] reported the appearance of CD absorption induced and circular polarization of fluorescence emitted in αCT–substrate complexes in which the substrates had been proven to bind at specific sites of αCT. However, the appearance of ICD in a system of an enzyme and a molecule which is understood not to receive specific enzymic actions has not been reported before.

As can be seen from the results described before, the ICD spectra and/or the modes of interaction of αCT and the dyes are discriminated into two classes without doubt. The following discussions will be divided into the Type I and Type II complexes.

Type I Complexes. From the shift of the visible absorption spectrum observed in the αCT–PF system, Bernhard *et al.*[7] concluded that a 1 : 1 complex is formed between αCT and PF and the binding site is the enzymic active site of αCT. The latter was deduced from the fact that PF behaves like a competitive inhibitor in enzymic reactions. Bearing in mind that the visible absorption spectrum of the αCT–PF complex resembles the spectrum of PF in various dioxane–water mixtures, a hydrophobic environment of αCT seems to be the primary cause for the formation of the complex. As can be seen in Fig. 2, the [θ] value increases with [E]/[D] until [E]/[D] ≈8 where almost all of the dye molecules are guessed to bind to αCT. The corresponding [θ] value for these saturated states, 5.5×10^4, is considered to be the molecular ellipticity for the αCT–PF complex. Moreover, it is possible that a specific binding site of PF is unique as evidenced from the fact that the shape of ICD spectrum remains unchanged with the increase of [E]/[D].

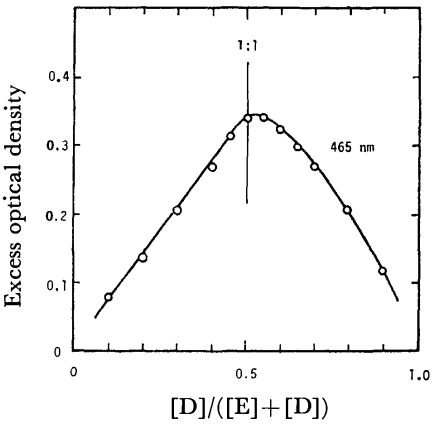

Fig. 5. Demonstration of formation of α-chymotrypsin-proflavine complex by method of continuous variations. [E]+[D]=2.0×10^{-4} mol dm^{-3}.

In order to find out a stoichiometric formula for the complex, we used the method of continuous variations.[8] In Fig. 5 is plotted the difference optical density at 465 nm as a function of [D]/([E]+[D]). From this, it is clear that one PF molecule binds to one αCT molecule in accordance with the conclusion made by Bernhard *et al.*[7]

In previous papers,[2] we proposed two mechanisms of CD induction in the system of DNA- and RNA–dye complexes; one which appears in high P/D (nucleic

acid phosphate to dye ratio) complexes is due to a static asymmetric perturbation caused in a dye monomer (referred to as optical activity I) and the other which appears in low P/D complexes results from an interaction between two dye molecules bound to the nucleic acid helices in the form of a dimer (optical activity II). In other words, the former arises from a one-electron mechanism in a perturbed single dye molecule and/or from an interaction between electric dipole transition moments of a single dye molecule and of neighboring chromophores involved in a macromolecule, and the latter from the exciton-type coupling mechanism between the two dye molecules bound to the biopolymer side by side. The general features of the single positive CD spectrum (Type I) of the αCT–PF complex and optical activity I above are not very much different from one another, so that the mechanism of CD induction in the αCT–PF complex is deduced to be a one-electron origin or the like. That is, αCT and PF form a 1 : 1 complex in which PF is bound near the asymmetric environment of αCT and CD is induced by the interaction of an electrically allowed transition of the dye with magnetically and electrically allowed transitions of the nearby asymmetric perturbers. The very same discussion will apply to the αCT–AY and αCT–AF systems, though we have not shown data of stoichiometric measurements for these complexes.

The questions still remaining are two fold; a definite site of the dyes binding in αCT and a reason why no CD spectra are induced in αCT and analogous dye systems mentioned before. These two problems are related to one another. First of all, it is certain that there is only one dye-binding site per one αCT molecule in the Type I complexes because the absorption spectral shift and the induced CD are like one another. Another basis for this deduction is that many other molecular homologues which have the acridine and phenothiazine rings do not form molecular complexes with αCT, as evidenced from the finding that there is no visible spectral shift in these systems. That is, the acridine and phenothiazine dyes can be classified into two as for the complex formation with αCT; one forms a 1 : 1 complex (Type I) and the other does not, the fashion of complex formation being unique and once a complex is formed CD being induced.

Secondly, it is quite possible that the site of dye binding is the enzyme active site of αCT, since that there exists only one substrate binding site per enzyme molecule has been well established with αCT. Bernhard *et al.*[7] demonstrated that monoacylation of αCT completely displaces the PF molecule from the enzyme active site. It seems therefore that the specific enzyme-dye interaction is restricted to the conformation of the enzyme active site. In fact, we found that no complexes were formed between the same dyes as studied in this paper and pepsin and/or papain.

As will be reported in a forthcoming paper,[9] a dye molecule has to be imprisoned in a certain segment of a partner macromolecule in order to induce optical activity. At the active site of αCT, there is a spatial blank of moderate size surrounded with Histidyl 57, Seryl 195, and Methionyl 192. Whether an enzyme–dye

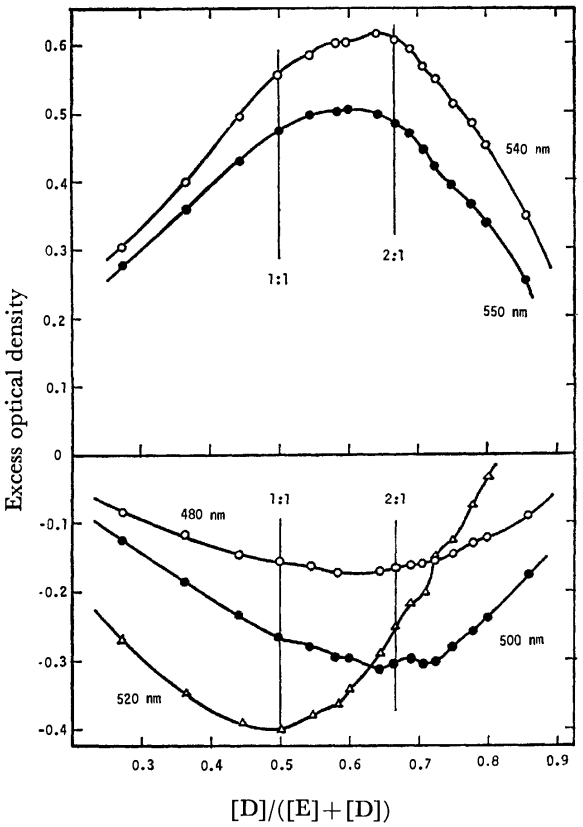

Fig. 6. Demonstration of formation of α-chymotrypsin–Pyronin B complex by method of continuous variations. $[E]+[D]=1.0\times10^{-4}$ mol dm^{-3}.

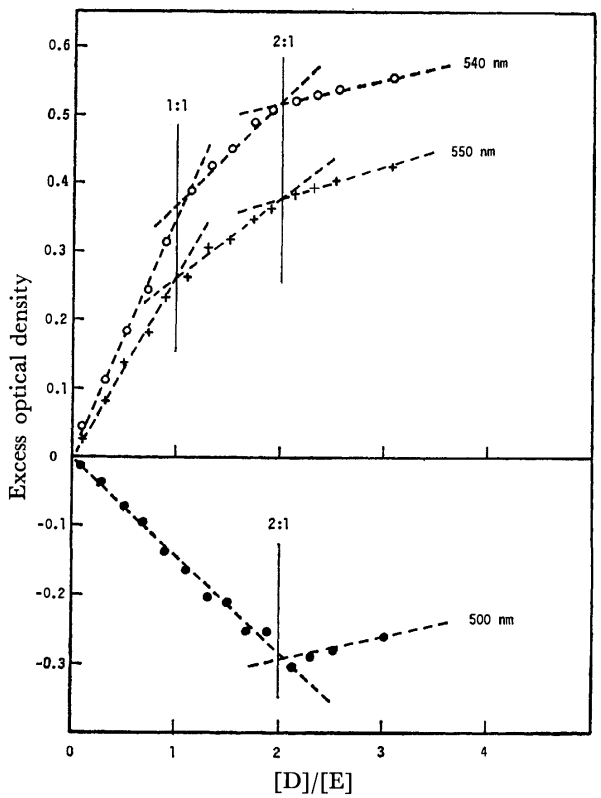

Fig. 7. Demonstration of formation of α-chymotrypsin–Pyronin B complex by molar ratio method. $[E]=3.6\times10^{-5}$ mol dm^{-3}.

complex is formed then depends upon a specific hydrophobic environment of the enzyme active site. This situation looks something like the well-known "lock-and-key" theory in the mechanism of enzyme action.

Type II Complexes. We will discuss the αCT–PB system as a Type II complex in which both positive and negative CD bands are induced. As in the case of the Type I complexes, the visible absorption spectrum of PB shifts to longer wavelength side upon addition of αCT, its general feature resembling closely to that of the absorption spectrum of PB brought about by the decrease of solvent polarity. It is clear therefore that the change in the visible spectral region of the αCT–PB system is due to the binding of PB to αCT which is less polar than water. The reason why a definite isosbestic point is not obtained is probably that there are more than two species of complexes in which stoichiometric compositions of αCT *vs.* PB are different from one another. The experiment of continuous variations revealed that there exists a complex formed by one αCT molecule and two PB molecules in addition to a 1 : 1 complex (Fig. 6). The same result was obtained by using the molar ratio method (Fig. 7).

It is hard to estimate the composition ratio of these two-type complexes. However, one can utilize the following experimental findings in order to guess whether 1 : 1 or 1 : 2 complexes is predominate to induce CD bands: (i) The variation of [E]/[D] with keeping [D] constant does not yield even slight change of the ICD spectral pattern; (ii) the molecular ellipticity becomes constant when [E]/[D] is in excess of 4 (*cf.* Fig. 4); the $[\theta]$ values of the Type II complexes are larger by an order of magnitude than those of the Type I complexes. We may thus conclude that the ICD spectrum shown in Fig. 3 is mainly due to the 1 : 2 complex.

When two dye molecules of the same species are brought together somewhere not far from one another, there occurs a rather strong dipole-dipole coupling. The leading term of the rotatory strength in this case is proportional to $\mathbf{R}\cdot(\boldsymbol{\mu}_1\times\boldsymbol{\mu}_2)$, $\boldsymbol{\mu}_1$ and $\boldsymbol{\mu}_2$ being the electric dipole transition moments of dye 1 and dye 2 respectively and $\mathbf{R}$ being the separation between $\boldsymbol{\mu}_1$ and $\boldsymbol{\mu}_2$.[10] If this is the case in the Type II complexes, the ICD spectrum may be resolved into four components, since in acridine dyes there exist two electric dipole transition moments, one along the molecular long axis and the other along the molecular short axis, both being in the molecular plane. We have carried out a Kronig-Kramers type analysis for the ICD spectrum and the observed optical rotatory dispersion curve of the αCT–PB system (Fig. 3). A resolution of the ICD bands is demonstrated in Fig. 8 which shows that two rotatory strength "couplets" are characteristic forms of dispersion. That is, the observed ICD spectrum is understood as a sum of the two Cotton effects of equal but opposite rotatory strength which are centered at 540 nm and lie less than a band width from one another, and of the other two Cotton effects of similar but smaller type centered at 520 nm. From the coincidence between the recomposed curve and the observed ICD spectrum (the recomposed and observed rotatory dispersion

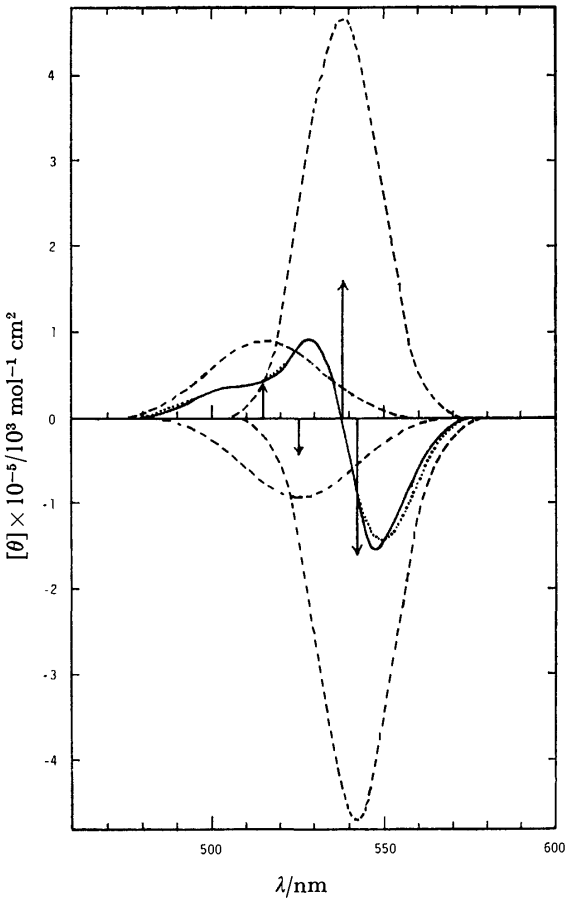

Fig. 8. Resolution of induced CD bands of α-chymotrypsin–Pyronin B complex assuming dipole-dipole coupling. The arrows show the positions and the strengths of electric dipole transition moments, the broken lines the component CD bands, the dotted line resultant CD bands, and the solid line observed CD bands.

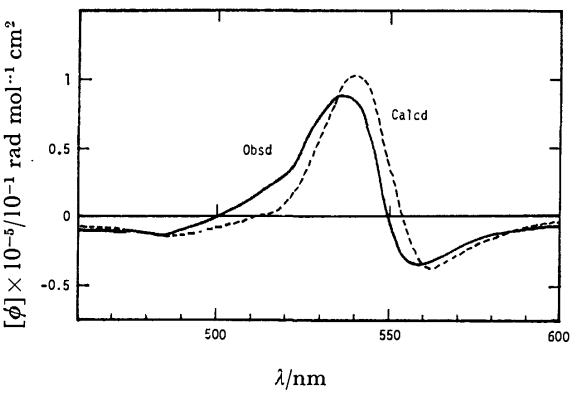

Fig. 9. Recomposed and observed rotatory dispersion curves of α-chymotrypsin–Pyronin B complex.

curves are compared in Fig. 9), a contribution from the 1 : 1 complex is unable to be taken into account. It is possible to speculate that the single dye molecule binds at the active site of αCT and the dye dimer binds at some other specific site, the contribution of the former to CD induction being negligibly small. On the other hand, our feeling at present is that a dye molecule

in the Type II complex is bound at a specific site which is not the active site of αCT and is therefore unable to act as a perturber for CD induction, the second dye molecule getting close to and keeping in a favorable direction side by side with the first dye molecule. If this is the case, the observations described above are well explained and it turns out that by some reason Pyronin G and/or Rhodamine B neither forms a complex with αCT nor associates one another in the neighborhood of the αCT molecule. No answer is possible to a question why there are two species of dyes, one forms a complex with αCT and the other does not.

Conclusion and Remark

The results and interpretation on the induced optical activity of the αCT–dye systems are summarized as follows:

(1) Some dyes form complexes with αCT with the appearance of CD and others do not.

(2) There are two ways of complex formation; whether a dye monomer is bound to αCT (Type I) or a dimer-like dye aggregate (Type II) is.

(3) To the Type I complex, proflavine, Acridine Yellow G, and acriflavine belong, yielding a single positive CD band. Composition of the complex is 1 : 1.

(4) To the Type II complex, Pyronin B and Rhodamine 6G belong, yielding one positive and one negative CD bands. Composition of the complex is mainly two dye molecules to one αCT.

(5) In the Type I complex, the site of dye binding is probably the enzyme active site of αCT which acts as an asymmetric perturber to induce CD in the visible absorption region of the dye.

(6) In the Type II complex, a dye molecule is bound at a specific site which is probably not the active site of αCT, and the second dye molecule combines with the first one in a fashion of forming a dimer. The coupling between the electric dipole transition moments of the two dye molecules is a leading term of the induced rotatory strength.

There are a lot of remaining questions: What is the reason for item (1)? Why any other enzyme does not form complexes with dyes such as those studied in this paper? Is there anything wrong with the reasoning for the site of dye binding? Experiments of the circular polarization of fluorescence and the fluorescence detected circular dichroism in the visible region are in progress, being aimed at the examination of the interaction mechanism in excited states of enzymes and dye chromophores.

The authors thank M. Miyake, K. Ogawa, H. Sakurai, and Y. Tsuboi for their technical assistance.

Thermodynamic Study on Mixed Monolayers of Butyl Eicosanedioate and Tetradecanoic Acid

Yoshiteru HAYAMI, Takeshi YANO, Kinsi MOTOMURA, and Ryohei MATUURA*

Department of Chemistry, Faculty of Science, Kyushu University 33, Hokozaki, Fukuoka 812

(Received April 25, 1980)

In order to clarify the behavior of mixed monolayers of butyl eicosanedioate and tetradecanoic acid, the surface pressure was measured as a function of mean area at various compositions and temperatures. Four types of phase transition were observed. By use of the thermodynamic treatment previously developed, the apparent molar entropy and energy changes associated with the phase transition were evaluated. It was concluded on thermodynamic considerations that the butyl eicosanedioate and tetradecanoic acid monolayers are immiscible in condensed states and their phase diagram has a two-dimensional eutectic point.

It seems valuable to relate the states of monolayers with the molecular structure of film-forming substances by the thermodynamic approach.[1,2] It has been clarified through the study on mixed monolayers that the monolayer systems reveal the ideal,[3,4] eutectic,[5] azeotropic,[6-8] and other behaviors,[9] depending upon their molecular interactions. Now it seems useful to investigate the mixed monolayers of bipolar substances because they are expected to show a two-step transformation. While many works have been reported on the monolayer of dibasic substances since those of Adam *et al.*,[10-12] they are insufficient to make clear the state of the monolayers.

In this paper, the system consisting of tetradecanoic acid and butyl eicosanedioate was employed and the state of monolayers was clarified thermodynamically. Butyl eicosanedioate is a bipolar substance which contains a long carbon chain between two relatively large polar groups.

Experimental

Tetradecanoic acid was purified by vacuum distillation and recrystallization from ether. Butyl eicosanedioate was synthesized by the Fischer method from 1-butanol and eicosanedioic acid (presented by the courtesy of Okamura Seiyu Co.), and its purity was checked by gas-liquid chromatography and elemental analysis. Benzene purified by the standard procedure was used as the spreading solvent. Monolayers were spread on 0.5 mol kg^{-1} sodium chloride solution which was prepared from twice distilled water and sodium chloride (Wako special grade) as done in the previous papers.[6-9]

Surface pressure was measured by a Wilhelmy type electrosurface balance and automatically recorded on the chart paper. Temperature was kept constant within 0.1 K by circulating thermostated water. The surface pressure *vs.* area curve was reproducible within an experimental error.

Results and Discussion

The surface pressure of mixed monolayers consisting of butyl eicosanedioate and tetradecanoic acid was measured at various compositions and temperatures. The surface pressure π *vs.* surface area per monolayer molecule A curves of butyl eicosanedioate obtained at temperatures 290.7, 293.2, 295.7, and 298.2 K are shown in Fig. 1. It is seen that the π *vs.* A curves have two break points which represent phase transitions. The surface pressure of the second transition point

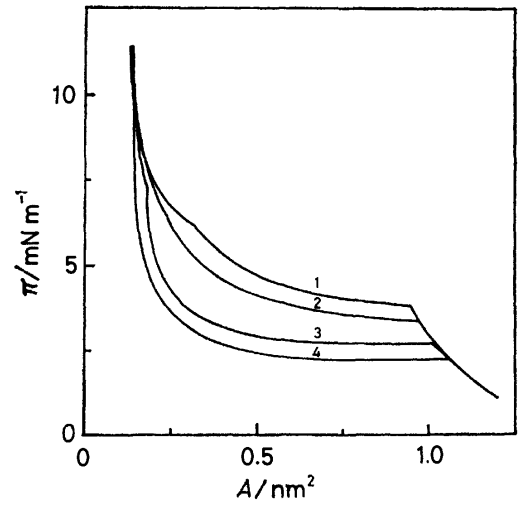

Fig. 1. Surface pressure π *vs.* mean area A curves of butyl eicosanedioate monolayer: (1) 298.2 K, (2) 295.7 K, (3) 293.2 K, (4) 290.7 K.

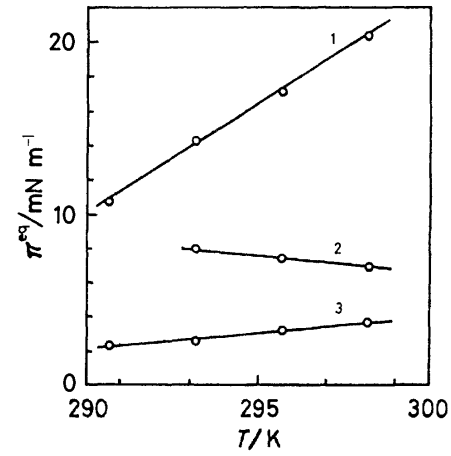

Fig. 2. Transition pressure π^{eq} *vs.* temperature curves: (1) tetradecanoic acid, (2) the second break point, (3) the first break point.

decreases, while that of the first transition point increases, with increasing temperature. This is shown clearly in Fig. 2. Comparing these temperature dependences of the transition pressure π^{eq} with those of tetradecanoic acid, the first break point is found to correspond to the transformation from an expanded to a

condensed film. On the other hand, the π^{eq} *vs.* T curve of the second break point has a negative slope greater than that of substrate with regard to the absolute value. This might suggest that the phase transition is accompanied by a positive entropy change, which leads us to the conclusion that the transformation takes place from the first condensed film (indicated by c(1,I)), in which both polar groups of butyl eicosanedioate molecule are in contact with the substrate, to the second condensed film (indicated by c(1,II)), in which one of them is in contact with the substrate.

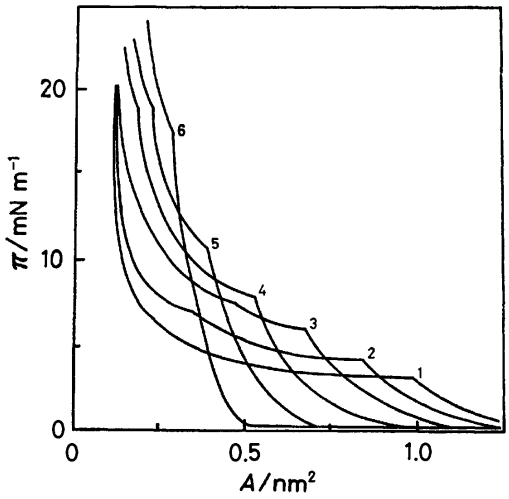

Fig. 3. Surface pressure π *vs.* mean area A curves of butyl eicosanedioate–tetradecanoic acid monolayers at 295.7 K: (1) $x_2^{\pi}=0$, (2) 0.2, (3) 0.4, (4) 0.6, (5) 0.8, (6) 1.

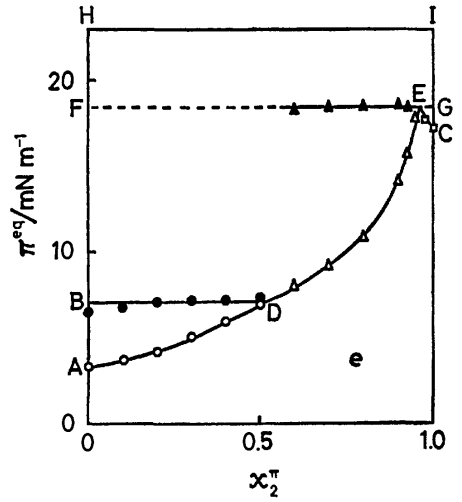

Fig. 4. Phase diagram of butyl eicosanedioate–tetradecanoic acid monolayer at 295.7 K.
Type of transition: ○, (e, c(1, I)); △, (e, c(1, II)); ●, (c(1, I), c(1, II)); □, (e, c(2)); ▲, (e, c(1, II) and c(2)).

The π *vs.* A curves of mixed monolayers obtained at various compositions at 295.7 K are shown in Fig. 3. These curves seem to have several kinds of break point. In Fig. 4, the surface pressure at the break point is plotted against the mole fraction of tetradecanoic acid defined by

$$x_2^{\pi} = n_2/(n_1+n_2), \tag{1}$$

where n_i is the number of moles of film-forming component i. It is seen that the first transition pressure of butyl eicosanedioate increases with addition of tetradecanoic acid (curve AE), whereas the second transition pressure remains approximately constant (curve BD). Similarly, the transition pressure of tetradecanoic acid increases with addition of butyl eicosanedioate (curve CE). These symmetrical π^{eq} *vs.* x_2^{π} curves appear to meet with each other at the point E which lies on the π^{eq} *vs.* x_2^{π} curve (curve FG) of the second break point observed in the concentration range from $x_2^{\pi}=0.50$ to 0.95. It is easily understood that the curves AE and CE express the equilibrium between expanded and condensed films.

Taking into account that the second transition pressure of mixed monolayer at low concentration is approximately equal to that of butyl eicosanedioate monolayer, it may be expected that the line BD in Fig. 4 represents the transformation from the first condensed film c(1,I) to the second condensed film c(1,II). This expectation is realized by consulting the temperature dependence of transition pressure. By measuring the surface pressure of mixed monolayers at 290.7, 293.2, and 298.2 K, the linear π^{eq} *vs.* T plots were obtained. As shown by the curve BD in Fig. 5, their slopes have about the same value. This result supports the above view.

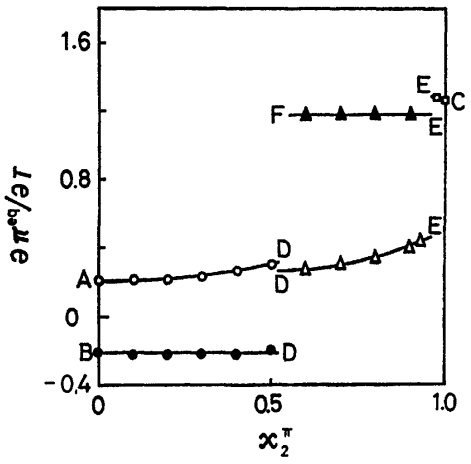

Fig. 5. $\partial\pi^{eq}/\partial T$ *vs.* x_2^{π} curves at 295.7 K.
Type of transition: ○, (e, c(1, I)); △, (e, c(1, II)); ●, (c(1, I), c(1, II)); □, (e, c(2)); ▲, (e, c(1, II) and c(2)).

Inspecting closely Fig. 4, on the other hand, the π^{eq} *vs.* x_2^{π} curve AE of the first break point seems to be divided into two parts at the point D where the curve is intersected by that of the second break point. This is substantiated by the fact that the value of $\partial\pi^{eq}/\partial T$ in Fig. 5 is discontinuous at that point. Thus we are led to the conclusion that the point D is the one where the condensed films c(1,I) and c(1,II) of butyl eicosanedioate and the expanded film, denoted by the

letter e, composed of butyl eicosanedioate and tetradecanoic acid coexist in equilibrium at 295.7 K under atmospheric pressure. Now we may say that the curve AD represents the equilibrium between the films c(1,I) and e and the curve DE the equilibrium between the films c(1,II) and e.

Let us next consider the point E on Fig. 4. Consulting Figs. 4 and 5, we immediately notice that the values of the second transition pressure in the concentration range $x_2^{\pi}=0.50$ to 0.95 are on the straight line FG parallel to the abscissa and their derivatives with respect to temperature are nearly equal. Furthermore, the temperature dependences of the curves DE and CE are found to be significantly different. Taking into consideration that the curve DE refers to the equilibrium of the expanded phase e of mixed monolayer with the condensed phase c(1,II) of butyl eicosanedioate monolayer, therefore, we can assign the curve CE to the equilibrium of the expanded state e with the condensed phase c(2) of tetradecanoic acid monolayer. The above results lead us to the conclusion that the point E represents the state where the films c(1,II), c(2), and e coexist in equilibrium and is called a two-dimensional eutectic point.

Now it is possible to say that the areas ADB, BDEF, CEG, and HFGI in Fig. 4 are the heterogeneous regions composed of the condensed film c(1,I) and expanded film e, the condensed film c(1,II) and expanded film e, the condensed film c(2) and expanded film e, and the condensed films c(1,II) and c(2), respectively. It is needless to say that the area denoted by e is the stable region of expanded film e. Therefore, Fig. 4 can be regarded as a phase diagram of the mixed monolayer of butyl eicosanedioate and tetradecanoic acid at 295.7 K under atmospheric pressure.

Let us now consider to evaluate the apparent molar entropy change $\Delta s^{\gamma}(\alpha,\beta)$ associated with the transition from phase α to phase β. For a pure monolayer, we have the equation[1,13]

$$\Delta s^{\gamma}(\alpha,\beta) = \bar{s}_i^{\gamma,\beta} - \bar{s}_i^{\gamma,\alpha} = N_A(A^{\beta}-A^{\alpha})[(\partial\pi^{eq}/\partial T)_p - (\partial\gamma^{\circ}/\partial T)_p], \quad i = 1, 2, \qquad (2)$$

where s_i^{γ} is the apparent partial molar entropy of component i, γ° the surface tension of substrate, and N_A Avogadro's number. On the other hand, the apparent molar entropy of transition from the expanded phase of mixed monolayer to the condensed phase c(1,I), c(1,II), or c(2) is evaluated with the aid of the relation

$$\Delta s^{\gamma}(e,\beta) = \bar{s}_i^{\gamma,\beta} - \bar{s}_i^{\gamma,e} = N_A[A^{\beta}-A^{e}-(\delta_{i2}-x_2^{\pi,e})(\partial A^{e}/\partial x_2^{\pi,e})_{T,p,\pi}] \times [(\partial\pi^{eq}/\partial T)_{p,x_i^{\gamma,e}} - (\partial\gamma^{\circ}/\partial T)_p], \quad i = 1, 2, \qquad (3)$$

where

$$\delta_{i2} = 0, \quad i = 1; \qquad = 1, \quad i = 2. \qquad (4)$$

The value of $\Delta s^{\gamma}(e,c(2))$ may be calculated by making use of the value of $\partial\pi^{eq}/\partial T$ given in Fig. 5 on the assumption that the area of tetradecanoic acid in the condensed film is replaced by the corresponding one of octadecanoic acid and the value of γ° is approximated by that of pure water. The values obtained are depicted as a function of $x_2^{\pi,e}$ in Fig. 6. In evaluating $\Delta s^{\gamma}(e,c(1,I))$ and $\Delta s^{\gamma}(e,c(1,II))$, however, it is necessary to estimate the values of $A^{c(1,I)}$ and $A^{c(1,II)}$. With the aid of the thermodynamics, we can easily derive the equation which holds at the eutectic point E:

$$(\partial\pi^{eq}/\partial T)_p^{FE} - (\partial\gamma^{\circ}/\partial T)_p = [x_1^{\pi,e}\Delta s^{\gamma}(e, c(1, II)) + x_2^{\pi,e}\Delta s^{\gamma}(e, c(2))]/N_A[(x_1^{\pi,e}A^{c(1,II)} + x_2^{\pi,e}A^{c(2)}) - A^{e}], \qquad (5)$$

where the superscript FE on $(\partial\pi^{eq}/\partial T)_p$ means that its value is the extrapolated one of the curve FE to the point E in Fig. 5. Substituting Eq. 3 and rearranging the resulting equation, Eq. 5 is rewritten in the form

$$A^{c(1,II)} = A^{e} + \{x_2^{\pi,e}(A^{c(2)}-A^{e})[(\partial\pi^{eq}/\partial T)_{p,x_i^{\gamma,e}}^{CE} - (\partial\pi^{eq}/\partial T)_p^{FE}] + x_1^{\pi,e}x_2^{\pi,e}[(\partial A^{e}/\partial x_2^{\pi,e})_{T,p,\pi}^{DE}(\partial\pi^{eq}/\partial T)_{p,x_i^{\gamma,e}}^{DE} - (\partial A^{e}/\partial x_2^{\pi,e})_{T,p,\pi}^{CE}(\partial\pi^{eq}/\partial T)_{p,x_i^{\gamma,e}}^{CE}]\}/x_1^{\pi,e}[(\partial\pi^{eq}/\partial T)_p^{FE} - (\partial\pi^{eq}/\partial T)_{p,x_i^{\gamma,e}}^{DE}]. \qquad (6)$$

The superscripts CE and DE have the same meaning as FE concerning the respective curve. Thus the value of $A^{c(1,II)}$ at the eutectic point can be estimated experimentally; $A^{c(1,II)}=1.68\,A^{c(2)}$ was obtained. By assuming the relation

$$A^{c(1,II)}(\pi')/A^{c(2)}(\pi') = A^{c(1,II)}(\pi)/A^{c(2)}(\pi), \qquad (7)$$

we can now evaluate $\Delta s^{\gamma}(e,c(1,II))$. The value obtained is also shown in Fig. 6.

Further, the following equation is proved to hold at the point D where the three phases e, c(1,I), and c(1,II) coexist in equilibrium:

$$\Delta s^{\gamma}(c(1, I), c(1, II)) = \Delta s^{\gamma}(e, c(1, II)) - \Delta s^{\gamma}(e, c(1, I)). \qquad (8)$$

Substitution of Eqs. 2 and 3 into Eq. 8 and rearrange-

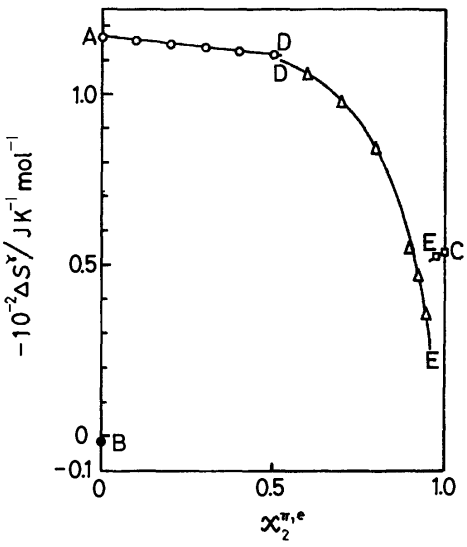

Fig. 6. Apparent molar entropy change Δs^{γ} *vs.* mole fraction of tetradecanoic acid $x_2^{\pi,e}$ curves at 295.7 K. Type of transition: ○, (e, c(1, I)); △, (e, c(1, II)); ●, (c(1, I), c(1, II)); □, (e, c(2)).

ment yield the expression

$$A^{c(1,I)} = A^{e} + \{(A^{c(1,II)} - A^{e})[(\partial\pi^{eq}/\partial T)^{ED}_{p,x_1^{\pi,e}} - (\partial\pi^{eq}/\partial T)^{BD}_{p}] - x_2^{\pi,c}[(\partial A^{e}/\partial x_2^{\pi,e})^{AD}_{T,p,\pi}(\partial\pi^{eq}/\partial T)^{AD}_{p,x_1^{\pi,e}} - (\partial A^{e}/\partial x_2^{\pi,e})^{ED}_{T,p,\pi}(\partial\pi^{eq}/\partial T)^{ED}_{p,x_1^{\pi,e}}]\}/[(\partial\pi^{eq}/\partial T)^{AD}_{p,x_1^{\pi,e}} - (\partial\pi^{eq}/\partial T)^{BD}_{p}]. \quad (9)$$

Thus the value of $A^{c(1,I)}$ was estimated to be $1.86A^{c(2)}$. In a similar manner as above, we can evaluate the values of $\Delta s^{\gamma}(e,c(1,I))$ and $\Delta s^{\gamma}(c(1,I), c(1,II))$ by virtue of Eqs. 2 and 3. The results are also shown in Fig. 6.

It is seen from Fig. 6 that the apparent molar entropy change $\Delta s^{\gamma}(e,c(1,I))$ of butyl eicosanedioate monolayer has an appreciably large negative value as compared with the corresponding one $\Delta s^{\gamma}(e,c(2))$ of tetradecanoic acid monolayer. The value of $\Delta s^{\gamma}(c(1,I), c(1,II))$ is found to be small but definitely positive. These results are compatible with the view that butyl eicosanedioate is a bipolar molecule of which the hydrocarbon chain is long enough to take a bent conformation in the first condensed film. Further, Fig. 6 reveals that the apparent molar entropy change associated with the transformation of component i from expanded to condensed film increases with decreasing $x_1^{\pi,e}$. In cases of the mixed monolayers of tetradecanoic acid with pentadecanoic acid and ethyl heptadecanoate which form homogeneous condensed phases, we have observed that the corresponding apparent partial molar entropy changes of these film-forming substances are approximately constant over the whole range of concentrations.[6] Therefore it is supported by the above results that butyl eicosanedioate and tetradecanoic acid are immiscible in the condensed state.

Now let us evaluate the apparent molar energy changes $\Delta u^{\gamma}(\alpha,\beta)$ and $\Delta u^{\gamma}(e,\beta)$ related, respectively, to $\Delta s^{\gamma}(\alpha,\beta)$ and $\Delta s^{\gamma}(e,\beta)$ (Eqs. 2 and 3) by the expressions[6]

$$\Delta u^{\gamma}(\alpha,\beta) = -(\pi^{eq}-\gamma^{\circ})N_A(A^{\beta}-A^{\alpha}) + T\Delta s^{\gamma}(\alpha,\beta), \quad i = 1, 2 \quad (10)$$

and

$$\Delta u^{\gamma}(e,\beta) = -(\pi^{eq}-\gamma^{\circ})N_A[A^{\beta}-A^{e}-(\delta_{12}-x_2^{\pi,e}) \times (\partial A^{e}/\partial x_2^{\pi,e})_{T,p,\pi}] + T\Delta s^{\gamma}(e,\beta), \quad i = 1, 2 \quad (11)$$

where we have neglected contribution of the apparent molar volume change. Evidently they can be calculated by making use of the experimental results. The numerical values are shown in Fig. 7. It is observed, as expected, that the values of apparent molar energy of transition deviate from the straight line connecting the values of Δu^{γ} for the pure components. Comparing with Fig. 6, we notice that the Δu^{γ} *vs.* $x_2^{\pi,e}$ and Δs^{γ} *vs.* $x_2^{\pi,e}$ curves behave similarly except that the value of $\Delta u^{\gamma}(c(1,I), c(1,II))$ is negative while that of $\Delta s^{\gamma}(c(1,I), c(1,II))$ is positive. It is of importance to note that the value of $\Delta u^{\gamma}(c(1,I), c(1,II))$ is responsible for the difference between $\Delta u^{\gamma}(e,c(1,I))$ and $\Delta u^{\gamma}(e,c(1,II))$ at the discontinuous point D.

Use of Propagators in the Hückel Model

Shigeyuki Aono* and Kiyoshi Nishikawa
Department of Chemistry, Faculty of Science, Kanazawa University, Marunouchi, Kanazawa 920
(Received May 6, 1980)

The electronic structures of molecules composed of identical atoms are investigated in terms of propagators under the Hückel approximation. General rules to get propagators for systems under considerations are presented. Then some physical quantities (the charge densities, the bond orders and the total energies) are obtained by making the analysis of the propagators. Expressions for the mutual polarizabilities are also exactly derived. Some discussions about the approximate natures of current results are made.

Quantum mechanical calculations are usually carried out as follows: First, the Shrödinger equation for a system under consideration is solved under a certain approximation, and then the observed quantities are estimated as the expectation values of the corresponding operators by the use of the wave function. It has been pointed out by Coulson and Longuet-Higgins[1] that even in the quantum chemical calculations the procedure mentioned above is not always necessary. They stressed that once the Hückel determinant is given, any physical quantity is directly calculated without solving the secular equation, by making the analysis of this determinant:

Let

$$\Delta(\omega) \equiv \begin{vmatrix} \alpha_1-\omega & \beta_{12} & \beta_{13} & \cdots & \beta_{1n} \\ \beta_{21} & \alpha_2-\omega & \beta_{23} & \cdots & \beta_{2n} \\ \vdots & \vdots & \vdots & & \vdots \\ \beta_{n1} & \beta_{n2} & \beta_{n3} & \cdots & \alpha_n-\omega \end{vmatrix} \quad (1)$$

where α_i, β_{ik}, and ω are the coulomb integral, resonance integral and energy parameter respectively. Then the bond order q_{rs} (its diagonal term is the charge density) and the total energy E are obtained as

$$q_{rs} = \frac{1}{2\pi i}\int_C dz \frac{\Delta_{rs}(z)}{\Delta(z)}, \quad (2)$$

$$E = \frac{1}{2\pi i}\int_C dz\, z\frac{\partial}{\partial z} \ln \Delta(z). \quad (3)$$

where $\Delta_{rs}(z)$ is the (r,s) cofactor of $\Delta(z)$ and integration with respect to the complex variable z is performed along the so-called Coulson contour shown in Fig. 1. Integration is assumed to include the spin summation.

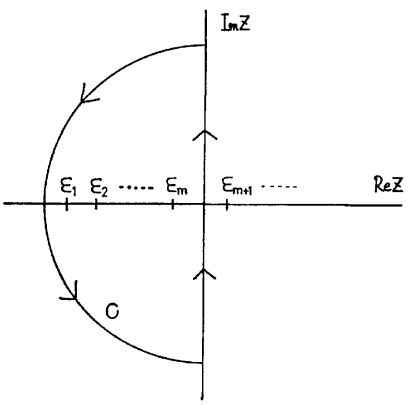

Fig. 1. Coulson contour: ε_1—ε_m are occupied energies and ε_{m+1}.... are unoccupied.

Coulson and Longuet-Higgins have also given similar expressions for mutual polarizabilities. It is needless to say that for these quantities the expressions with LCAO coefficients are commonly used, and that the use of these approximate expressions is only for the convienience of numerical calculations.

In the present work, a theory with propagator is developed in the Hückel model. This is related very closely to the idea of Coulson and Longuet-Higgins. The processes of constructing propagators, however, make clear the physical content of the Hückel model.

Propagator

The Green's function (propagator), corresponding to the linear Hermitian time-independent differential operator $L(r)$ and the complex variable z, is defined as the solution of the equation

$$(z-L(r))G(r,r';z) = \delta(r-r'), \quad (4)$$

subject to certain boundary conditions on the surface of the domain of r and r'. Equation 4 can be considered as the coordinate representation of the operator equation

$$(z-L)G = 1. \quad (5)$$

If $\{|n\rangle\}$ is the complete orthonormal set of the operator L, *i.e.*,

$$L|n\rangle = \lambda_n|n\rangle, \quad (6)$$

$$\langle n|m\rangle = \delta_{nm}, \quad (7)$$

$$\sum_n |n\rangle\langle n| = 1, \quad (8)$$

then one can write

$$G = (z-L)^{-1} = \sum_n \frac{|n\rangle\langle n|}{z-\lambda_n}. \quad (9)$$

$G(r,r';z)$ in Eq. 4 may be regarded as the (r,r') matrix element of the operator G.

Hückel Model. The Hückel Hamiltonian (the tight-binding approximation in the solid state physics) is written as

$$H = \sum_s |s\rangle\varepsilon_s\langle s| + \sum_{st}{}' |s\rangle v_{st}\langle t|, \quad (10)$$

where s and t are site indices. Keeping in mind that we are dealing with molecules which consist of the same kind of atoms, we put $\varepsilon_s=0$, $v_{st}=v$ and the second summation in Eq. 10 is carried out as usual only for the nearest neighbors. Thus the Hamiltonian becomes simply

$$H = v\sum_{st}{}' |s\rangle\langle t|. \quad (11)$$

In order to perform the forthcoming analysis in the present work, we investigate the diatomic molecule a—b in Fig. 2a in terms of propagators. The diagonal term of the Green's function in the zeroth-order approximation, $G_0(a,a;z)$ is simply obtained from Eq. 9 and the first term of Eq. 10 as

$$G_0(a,a;z)=\sum_s \frac{\langle a|s\rangle\langle s|a\rangle}{z-\varepsilon_s}=\frac{1}{z}, \quad (\varepsilon_s=0), \tag{12}$$

where the completeness condition (8) has been used.

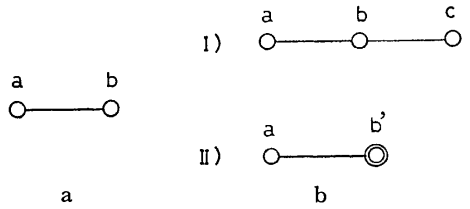

Fig. 2. Schematic diagrams of molecules. a: Diatomic molecule, b: triatomic molecule.

Now we consider the exact propagator $G(a,a;z)$ fully dressed by interactions:

$$\begin{aligned}G(a,a)=&G_0(a,a)+G_0(a,a)vG_0(b,b)vG_0(a,a)\\&+G_0(a,a)vG_0(b,b)vG_0(a,a)vG_0(b,b)vG_0(a,a)+\cdots,\end{aligned} \tag{13}$$

where the first term is the bare propagator, the second includes the interaction twice, the third four times and so on. Equation 13 is rewritten as

$$\begin{aligned}G(a,a)&=G_0(a,a)+G_0(a,a)vG_0(b,b)v[G_0(a,a)\\&\quad+G_0(a,a)vG_0(b,b)vG_0(a,a)+\cdots\\&=G_0(a,a)+G_0(a,a)vG_0(b,b)vG(a,a)\\&=[G_0(a,a)^{-1}-vG_0(b,b)v]^{-1}.\end{aligned} \tag{14}$$

The last expression is the Dyson equation for our simplest case. Substituting Eq. 12 into Eq. 14, we obtain

$$G(a,a;z)=z/(z^2-v^2). \tag{15}$$

It is obvious that the poles of Eq. 15, *i.e.*, the roots of $z^2-v^2=0$, give us the Hückel orbital energies.

The charge density q_a at site a, the bond order q_{ab} and the total energy E are obtained with the propagators as,

$$q_a=\frac{1}{2\pi i}\int_C dz\, G(a,a;z), \tag{16}$$

$$\begin{aligned}q_{ab}&=\frac{1}{2\pi i}\int_C dz\, G(a,b;z)\\&=\frac{1}{2\pi i}\int_C dz\, G(a,a;z)vG_0(b,b;z),\end{aligned} \tag{17}$$

$$E=\frac{1}{2\pi i}\sum_a\int_C dz\, zG(a,a;z), \tag{18}$$

where the integration is made along the Coulson contour and is assumed to include the spin summation. Thus we can easily get the well-known results, $q_a=q_{ab}=1$ and $E=2v$.

General Rules to Get Propagators

We generalize the method in the previous section to the arbitrary finite network. This procedure is called the renormalization perturbation expansion which has been investigated by Anderson[2,3] for the infinite lattice. Generalization will be done step by step in the following.

End Point Propagator. Consider the edge atom a in the triatomic molecule shown in Fig. 2b. If we replace b and c in (I) by b' as in (II), the propagator $G(a,a)$ can be immediately obtained as has been done in the previous section:

$$G(a,a)=[G_0(a,a)^{-1}-vG(b',b')v]^{-1} \tag{19}$$

in which $G(b',b')$ is the propagator dressed only by the interaction between b and c, since the interaction between a and b is already taken into account, that is,

$$G(b',b')=[G_0(b,b)^{-1}-vG_0(c,c)v]^{-1}. \tag{20}$$

In this sense, $G(b',b')$ is rewritten as $G(b,b[a])$ indicating that the effect of site a should be excluded. We rewrite Eq. 19 as

$$G(a,a)=[G_0(a,a)^{-1}-vG(b,b[a])v]^{-1}. \tag{21}$$

This relation is itself a generalized expression for an arbitrary chain molecule, as seen from Fig. 3.

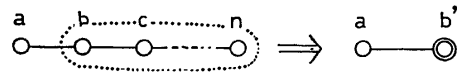

Fig. 3. Renormalization of the propagator of a linear molecule.

The off-diagonal term $G(a,c)$ in Fig. 2b is given by

$$G(a,c)=G(a,a)vG(b,b[a])vG(c,c[a,b]), \tag{22}$$

where it is apparent that $G(c,c[a,b])=G_0(c,c)$. Generalization of Eq. 22 to an arbitrary path is straightforward.

Branching Point Propagator. Consider the propagator $G(b,b)$ at site b in Fig. 2b. Since we have two paths arrived at site b, $G(b,b)$ can be expressed as

$$G(b,b)=[G_0(b,b)^{-1}-vG_0(a,a)v-vG_0(c,c)v]^{-1}. \tag{23}$$

This result is easily generalized to the branching point at which many paths end as shown in Fig. 4:

$$G(b,b)=[G_0(b,b)^{-1}-\sum_i vG(a_i,a_i[b])v]^{-1}. \tag{24}$$

It should be noted that there is no interactions among branches in this case.

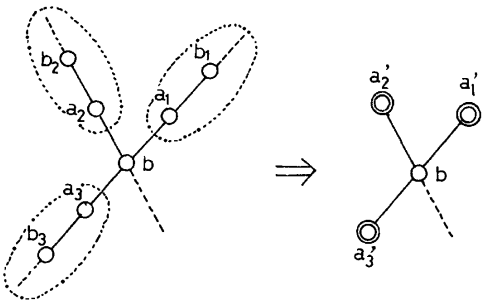

Fig. 4. Schematic diagram of a branched molecule and renormalization of its propagator.

Ring Propagator. We consider a ring of three members as shown in Fig. 5a. In order to obtain $G(a,a)$, we first follow the path $a\rightarrow b\rightarrow c\rightarrow a$. If there were no

interaction between a and c, we would simply have

$$G(a,a) = [G_0(a,a)^{-1} - vG(b,b[a])v]^{-1}. \quad (25)$$

Actually we need a new term $G(b,c[a])$ to enclose the loop, and obtain

$$G(a,a) = [G_0(a,a)^{-1} - vG(b,b[a])v - vG(b,c[a])v]^{-1}. \quad (26)$$

This procedure should be performed also along the path $a \to c \to b \to a$. Thus we obtain

$$G(a,a) = [G_0(a,a)^{-1} - vG(b,b[a])v - vG(b,c[a])v - vG(c,c[a])v - vG(c,b[a])v]^{-1}, \quad (27)$$

where for example

$$G(b,c[a]) = G(b,b[a])vG(c,c[a,b]) \quad (28)$$

is the off-diagonal term of the b—c subsystem.

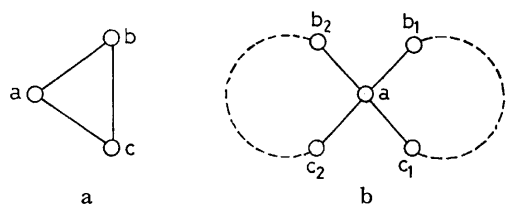

Fig. 5. Schematic diagrams of ring molecules. a: Triatomic ring molecule, b: two rings joinning at site a.

The physical meanings of Eq. 27 are as follows: The propagator $G(a,a)$ is the sum of the quantum mechanical probability amplitude for all the possible ways the electron can propagate in a ring from site a to itself interacting with various sites on the way. The first term is the free propagator given by Eq. 12. The second term represents the process that the electron interacts with site b, propagates many times in the b—c subsystem and finally returns to site a through site b. This process is schematically shown in Fig. 6a. The third term represents a new process due to the ring character. The electron propagates in the b—c subsystem as before, but comes back to site a through site c. This process is also shown in Fig. 6b. The last two terms are the counterparts of the above processes.

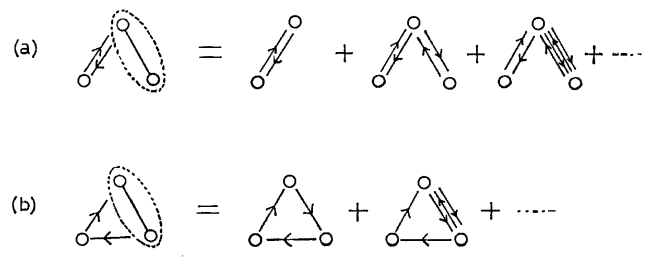

Fig. 6. Renormalization of the interactions between a and b—c subsystem.

The generalization to a more complicated ring shown in Fig. 5b is straightforward. The three types of the processes mentioned above suffice to obtain the propagator for an arbitrary network.

Illustrative Examples

Triatomic Linear Molecule. Substituting Eqs. 12 and 15 into Eqs. 21 and 23, we have

$$G(a,a;z) = G(c,c;z) = \frac{z^2-v^2}{z^3-2zv^2}, \quad (29)$$

$$G(b,b;z) = \frac{z^2}{z^3-2zv^2}, \quad (30)$$

The off-diagonal elements are also easily estimated as

$$G(a,b;z) = \frac{zv}{z^3-2zv^2}, \quad (31)$$

$$G(a,c;z) = \frac{v^2}{z^3-2zv^2}. \quad (32)$$

The Hückel orbital energies are obtained from the poles of these propagators, as $z=\pm\sqrt{2}v$, 0. We can estimate the bond order matrix and the total energy, using Eqs. 17 and 18, respectively, as

$$q = \begin{pmatrix} 1 & 1/\sqrt{2} & 0 \\ 1/\sqrt{2} & 1 & 1/\sqrt{2} \\ 0 & 1/\sqrt{2} & 1 \end{pmatrix}, \quad (33)$$

$$E = 2\sqrt{2}v. \quad (34)$$

It is noted that in this case the Coulson contour has to include the origin.

Triatomic Ring Molecule (Positive Ion). We consider only the case of positive ion for the sake of simplicity. Using Eqs. 12 and 20 in Eq. 27, we get

$$G(a,a;z) = \frac{z^2-v^2}{z^3-3zv^2-2v^2}. \quad (35)$$

The off-diagonal element, $G(a,b)$, can be calculated by taking into account two paths, that is, $a \to b$ and $a \to c \to b$:

$$G(a,b;z) = G(a,a)vG(b,b[a]) + G(a,a)vG(c,c[a])vG(b,b[a,c])$$

$$= \frac{zv+v^2}{z^3-3zv^2-2v^2}. \quad (36)$$

The poles of these propagators determine the Hückel orbital energies as $z=2v$, $-v$(doubly degenerate). If we consider the positive ion case, the contour goes around only the pole, $z=2v$. Then we obtain the bond order and total energy as

$$q_{ij} = 2/3 \text{ for all } i,j, \qquad E = 4v. \quad (37)$$

Chain Molecule; Recurrence Formulae. We have seen in the preceding treatment that any kind of matrix element of the propagator can be constructed from the diagonal elements at the edge of the chain molecule. It is useful at this stage to provide a simple way to obtain them. In this section, G_N denotes the diagonal matrix element at the edge of the chain molecule of N atoms.

It is a simple task to estimate G_N as a continued fraction, *i.e.*,

$$G_N(z)^{-1} = z - \cfrac{1}{z - \cfrac{1}{z - \cfrac{1}{z - \cdots}}}$$

$$\equiv z - \frac{1}{z} + \frac{1}{z} - \frac{1}{z} + \cdots, \quad (38)$$

where we put $v=1$. If there is a more general continued fraction

$$S_N = b_1 + \frac{1}{b_2} + \frac{1}{b_3} + \cdots + \frac{1}{b_N}, \quad (39)$$

this is expressed as

$$S_N = P_N/Q_N, \tag{40}$$

where, for P_N and Q_N, the following recurrence relations hold:

$$\begin{aligned} P_N &= b_N P_{N-1} + P_{N-2}, \\ Q_N &= b_N Q_{N-1} + Q_{N-2}, \end{aligned} \tag{41}$$

with

$$\begin{aligned} P_0 &= 1, \quad P_{-1} = 0, \\ Q_0 &= 0, \quad Q_{-1} = 1. \end{aligned} \tag{42}$$

In the case of Eq. 38, observing that $b_N=(-1)^{N-1}z$, we can easily calculate the first few series for P_N and Q_N. Then we use the mathematical induction to obtain the general formula and get

$$\begin{aligned} P_N &= \varepsilon_N p_N \\ &= \varepsilon_N\left[\sum_k (-1)^k \binom{N-k}{k} z^{N-2k}\right] \end{aligned} \tag{43}$$

where ε_N is the phase factor defined by

$$\varepsilon_N = \begin{cases} (-1)^{(N-1)/2} & \text{for odd } N, \\ (-1)^{N/2} & \text{for even } N. \end{cases} \tag{44}$$

We also obtain

$$Q_N = (-1)^{N-1} P_{N-1}. \tag{45}$$

Combining Eqs. 43 and 45, we have

$$G_N(z)^{-1} = p_N(z)/p_{N-1}(z). \tag{46}$$

It is obvious that p_N is nothing but the Hückel determinant. We list up some p_N in the following:

$$\begin{aligned} p_1 &= z, \\ p_2 &= z^2 - 1, \\ p_3 &= z^3 - 2z, \\ p_4 &= z^4 - 3z^2 + 1, \\ p_5 &= z^5 - 4z^3 + 3z, \\ p_6 &= z^6 - 5z^4 + 6z^2 - 1. \end{aligned} \tag{47}$$

Perturbation Theory

In order to express the various polarizabilities in terms of propagators, we provide an alternative method in the perturbation expansion of the propagator. In the matrix notation,

$$\begin{aligned} \boldsymbol{G}(z) &= \boldsymbol{G}_0(z) + \boldsymbol{G}_0(z)\boldsymbol{v}\boldsymbol{G}_0(z) + \boldsymbol{G}_0(z)\boldsymbol{v}\boldsymbol{G}_0(z)\boldsymbol{v}\boldsymbol{G}_0(z) + \cdots \\ &= \boldsymbol{G}_0(z) + \boldsymbol{G}_0(z)\boldsymbol{T}(z)\boldsymbol{G}_0(z), \end{aligned} \tag{48}$$

where

$$\begin{aligned} \boldsymbol{T}(z) &= \boldsymbol{v} + \boldsymbol{v}\boldsymbol{G}_0(z)\boldsymbol{v} + \boldsymbol{v}\boldsymbol{G}_0(z)\boldsymbol{v}\boldsymbol{G}_0(z)\boldsymbol{v} + \cdots \\ &= \boldsymbol{v}[1-\boldsymbol{G}_0(z)\boldsymbol{v}]^{-1}. \end{aligned} \tag{49}$$

In the above, $\boldsymbol{v}$ is the perturbation whose magnitude is arbitrary in our treatment, so that the full propagators previously obtained are rewritten $\boldsymbol{G}_0$ in this section.

The Perturbation of the Coulomb Potential at Site m. In this case, the perturbation becomes

$$v_{ij} = \begin{cases} \varepsilon_m & \text{for } i=j=m, \\ 0 & \text{for others,} \end{cases} \tag{50}$$

so that $\boldsymbol{T}(z)$ is given by

$$T(i,j;z) = \begin{cases} \varepsilon_m/(1-G_0(m,m;z)\varepsilon_m) & \text{for } i=j=m \\ 0 & \text{for others.} \end{cases} \tag{51}$$

Substituting this into Eq. 48, we get

$$G(a,a) = G_0(a,a) + G_0(a,m)T(m,m)G_0(m,a). \tag{52}$$

Hence, the change in charge density at site a becomes

$$\begin{aligned} \delta q_a &= \frac{1}{2\pi i}\int_C dz(G(a,a;z)-G_0(a,a;z)) \\ &= \varepsilon_m \frac{1}{2\pi i}\int_C dz|G_0(a,m;z)|^2/(1-G_0(m,m;z)\varepsilon_m) \\ &\equiv \varepsilon_m \cdot \Pi_{a;m}, \end{aligned} \tag{53}$$

where the last equation defines the atom-atom polarizability. Remember that we have assumed the integration includes the spin summation. If we neglect $G_0(m,m)\varepsilon_m$ as a small quantity compared to unity, Eq. 53 reproduces the result of the elementary perturbation theory:

$$\Pi^0_{a;m} = \frac{1}{2\pi i}\int_C dz|G_0(a,m;z)|^2. \tag{54}$$

It should be noted that in our exact expression, ε_m is replaced by the effective interaction

$$\begin{aligned} \tilde{\varepsilon}_m &= T(m,m;z) \\ &= \varepsilon_m/(1-G_0(m,m)\varepsilon_m). \end{aligned} \tag{55}$$

Next, evaluating the off-diagonal element of Eq. 48, we get

$$G(a,b) = G_0(a,b) + G_0(a,m)T(m,m)G_0(m,b), \tag{56}$$

from which the change in bond order is derived;

$$\begin{aligned} \delta q_{ab} &= \frac{1}{2\pi i}\int_C dz(G(a,b;z)-G_0(a,b;z)) \\ &= \varepsilon_m \frac{1}{2\pi i}\int_C dz G_0(a,m;z)G_0(m,b;z)/(1-G_0(m,m;z)\varepsilon_m) \\ &\equiv \varepsilon_m \cdot \Pi_{ab;m}, \end{aligned} \tag{57}$$

where the last equation defines the bond-atom polarizability. If we replace $\tilde{\varepsilon}_m$ by ε_m as before, we get

$$\Pi^0_{ab;m} = \frac{1}{2\pi i}\int_C dz\, G_0(a,m;z)G_0(m,b;z). \tag{58}$$

The Perturbation of the Resonance Energy at the Bond (m,n). Here we consider the case that

$$v_{ij} = \begin{cases} v & \text{for } (i,j) = (n,m) \text{ or } (m,n) \\ 0 & \text{otherwise.} \end{cases} \tag{59}$$

In this case, as seen from Eq. 49, non-vanishing part of $\boldsymbol{T}$ becomes a 2×2 matrix and its explicit form may be calculated as follows:

$$\begin{aligned} \boldsymbol{T}(z) &= (\boldsymbol{v}^{-1}-\boldsymbol{G}_0(z))^{-1} \\ &= \begin{pmatrix} -G_0(m,m) & 1/v-G_0(m,n) \\ 1/v-G_0(n,m) & -G_0(n,n) \end{pmatrix}^{-1} \\ &= \frac{\tilde{v}}{1-\tilde{v}^2 G_0(m,m)G_0(n,n)} \begin{pmatrix} \tilde{v}G_0(n,n) & 1 \\ 1 & \tilde{v}G_0(m,m) \end{pmatrix}, \end{aligned} \tag{60}$$

where

$$\tilde{v}(z) = v/(1-G_0(m,n)v). \tag{61}$$

Substituting Eq. 60 into Eq. 48, we obtain

$$\begin{aligned} G(a,a) &= G_0(a,a) + \sum_{k,l}^{m,n} G_0(a,k)\,T(k,l)G_0(l,a) \\ &= G_0(a,a) + \frac{\tilde{v}}{1-\tilde{v}^2 G_0(m,m)G_0(n,n)} \\ &\quad \times [G_0(a,m)\tilde{v}G_0(n,n)G_0(m,a) + G_0(a,m)G_0(n,a) \\ &\quad + G_0(a,n)G_0(m,a) + G_0(a,n)\tilde{v}G_0(m,m)G_0(n,a)]. \end{aligned} \tag{62}$$

Thus, the change in the charge density at site a is

$$\begin{aligned}\delta q_a = v\frac{1}{2\pi i}\int_C dz \frac{1}{(1-vG_0(m,n))(1-\bar{v}^2G_0(m,m)G_0(n,n))} \\ \times[G_0(a,m)\bar{v}G_0(n,n)G_0(m,a)+G_0(a,m)G_0(n,a) \\ +G_0(a,n)G_0(m,a)+G_0(a,n)\bar{v}G_0(m,m)G_0(n,a)] \\ \equiv v\Pi_{a:mn}, \end{aligned} \quad (63)$$

where the final equation defines the atom-bond polarizability.

Comparing Eq. 57 with Eq. 63, we see

$$\Pi_{a:mn} \neq 2\Pi_{mn:a} \quad (64)$$

which is aginst the result of Coulson and Longuet-Higgins.[1] However, if we neglect $vG_0(m,n)$ and $vG_0(n,m)$ as very small quantities compared to unity, the relation $\Pi_{a:mn}=2\Pi_{mn:a}$ approximately holds. (We assume propagators here are real).

Next, by evaluating $G(a,b)$, the similar calculation yields the bond-bond polarizability as

$$\begin{aligned}\Pi_{ab:mn} = \frac{1}{2\pi i}\int_C dz \frac{1}{(1-vG_0(m,n))(1-\bar{v}^2G_0(m,m)G_0(n,n))} \\ \times[G_0(a,m)\bar{v}G_0(n,n)G_0(m,b)+G_0(a,m)G_0(n,b) \\ +G_0(a,n)G_0(m,b)+G_0(a,n)\bar{v}G_0(m,m)G_0(n,b)] \\ \cong \frac{1}{2\pi i}\int_C dz(G_0(a,m)G_0(n,b)+G_0(a,n)G_0(m,b)). \end{aligned} \quad (65)$$

The Poles of T Matrix. It should be noted that the poles of the $\boldsymbol{T}$ matrix exactly give new eigenvalues, since the present theory takes into account the effect of the perturbation to the infinite order. As an illustrative example, we put the perturbation v between a and c in the triatomic linear molecule (see Fig. 7). Then the poles of $\boldsymbol{T}$ matrix in this case are given by the roots of the equation

$$1-\left[\frac{1}{1-vG_0(a,c;z)}\right]^2 G_0(a,a;z)G_0(c,c;z)=0. \quad (66)$$

Using Eqs. 29 and 32, we obtain $z=2v$, $-v$ (degenerate). Thus, we successfully reproduce the eigenvalues of the triatomic ring molecule.

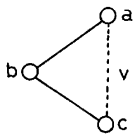

Fig. 7. Interaction v between a and c in the triatomic linear molecule.

Double Perturbations at Site m *and* n. Let us consider a couple of perturbation, ε_m and ε_n at sites m and n. In this case the required interaction is given by

$$\boldsymbol{v} = \begin{pmatrix}\varepsilon_m & 0\\ 0 & \varepsilon_n\end{pmatrix}. \quad (67)$$

For this system we obtain

$$\begin{aligned}\boldsymbol{T}(z) &= \begin{pmatrix}1/\varepsilon_m-G_0(m,m) & -G_0(m,n)\\ -G_0(n,m) & 1/\varepsilon_n-G_0(n,n)\end{pmatrix}^{-1} \\ &= \frac{1}{1-\bar{\varepsilon}_m\bar{\varepsilon}_n|G_0(m,n)|^2}\begin{pmatrix}\bar{\varepsilon}_m & \bar{\varepsilon}_m\bar{\varepsilon}_nG_0(m,n)\\ \bar{\varepsilon}_n\bar{\varepsilon}_mG_0(n,m) & \bar{\varepsilon}_n\end{pmatrix}, \end{aligned} \quad (68)$$

where $\bar{\varepsilon}_m$ is defined in Eq. 55. Thus we can estimate the change of the bond order by evaluating the (a,b) element of Eq. 48, as

$$\begin{aligned}\delta q_{ab} &= \frac{1}{2\pi i}\int_C dz[G(a,b;z)-G_0(a,b;z)] \\ &= \frac{1}{2\pi i}\int_C dz\frac{1}{1-\bar{\varepsilon}_m\bar{\varepsilon}_n|G_0(m,n)|^2}[\bar{\varepsilon}_mG_0(a,m)G_0(m,b) \\ &+\bar{\varepsilon}_nG_0(a,n)G_0(n,b)+\bar{\varepsilon}_m\bar{\varepsilon}_n\{G_0(a,m)G_0(m,n)G_0(n,b) \\ &+G_0(a,n)G_0(n,m)G_0(m,b)\}]. \end{aligned} \quad (69)$$

The first two terms of the square bracket are direct effects separately arisen from two sites, while the remaining terms are indirect ones caused by the perturbation at site $m(n)$ *via* site $n(m)$. If $G_0(m,n)\varepsilon_m$ and $G_0(n,m)\varepsilon_n$ are negligibly small compared to unity, it follows that

$$\delta q_{ab} \cong \frac{1}{2\pi i}\int_C dz[\varepsilon_mG_0(a,m)G(m,b)+\varepsilon_nG_0(a,n)G(n,b)]. \quad (70)$$

This shows the additivity of two perturbing effects in a crude approximation.

Discussion

In the present work, the renormalized perturbation theory had been used to build up propagators for the Hückel model. If we confine ourselves to discuss the obtained results, we have nothing new more than the simple LCAO MO theory does. However, in the course of constructing propagators, we visualize how interactions work in the Hückel model.

Recently, Hosoya[4-8] introduced the topological index as a quantity characterizing the physical properties of hydrocarbons. This is, simply speaking, the sum of absolute values of the Hückel polynomials corresponding to the molecule in question. The value of the topological index increases almost monotonously with the molecular size, and varies as molecular shapes change. Hosoya displayed some parallel trends between topological indices and physical properties. He also found a convenient procedure to calculate the topological indices other than the simple summation mentioned above. His rule which is found in Eq. 7 in reference 5 is almost analogous to the rules indicated by Eqs. 21, 24, and 27. Therefore we are inclined to say that our work has presented some physical basis for Hosoya's intuition, though we have not yet obtained any direct physical interpretation of the topological index.

We turn to discussion of the polarizabilities. The pioneering work of Coulson and Longuet-Higgins has been followed by Fukui *et al.*[9-11] These works including Coulson's are manipulated mainly by the use of properties of the Hückel determinant, but the final expressions of polarizabilities are given in terms of the LCAO coefficients of the zeroth order molecular orbitals. Their results are not beyond the elementary perturbation theory. Here we rewrite the treatment of Coulson and Longuet-Higgins to derive the relationship

$$\Pi_{a:mn} = 2\Pi_{mn:a}. \quad (71)$$

The orbital energy ε_i is given by

$$\varepsilon_i = \sum_a c_{ia}^2\alpha_a + \sum_{mn}c_{im}c_{in}\beta_{mn}, \quad (72)$$

with the optimized LCAO coefficients c_{im} (assumed to

be real). Then it follows that

$$\frac{\partial \varepsilon_i}{\partial \alpha_a} = c_{ia}^2, \quad \frac{\partial \varepsilon_i}{\partial \beta_{mn}} = c_{im}c_{in}. \tag{73}$$

The charge density q_a at site a, and the bond order q_{mn} are given as

$$q_a = 2\sum_i^{\text{occ}} c_{ia}^2 = 2\sum_i^{\text{occ}} \frac{\partial \varepsilon_i}{\partial \alpha_a} = \frac{\partial E}{\partial \alpha_a}, \tag{74}$$

$$q_{mn} = 2\sum_i^{\text{occ}} c_{im}c_{in} = 2\sum_i^{\text{occ}} \frac{\partial \varepsilon_i}{\partial \beta_{mn}} = \frac{\partial E}{\partial \beta_{mn}}, \tag{75}$$

where the factor 2 arises from the spin sum, and E is the total energy. Now we get the polarizabilities

$$\Pi_{a;mn} \equiv \frac{\partial q_a}{\partial \beta_{mn}} + \frac{\partial q_a}{\partial \beta_{nm}} = 2\frac{\partial}{\partial \beta_{mn}}\left(\frac{\partial E}{\partial \alpha_a}\right) \quad (\beta_{mn}=\beta_{nm}), \tag{76}$$

$$\Pi_{mn;a} \equiv \frac{\partial q_{mn}}{\partial \alpha_a} = \frac{\partial}{\partial \alpha_a}\left(\frac{\partial E}{\partial \beta_{mn}}\right). \tag{77}$$

From these expressions, we can conclusively get Eq. 71. The above derivation looks quite general, but is not beyond the elementary perturbation theory, since Eq. 73 is valid only for infinitesimal variations of α or β.

On the other hand, the present theory works even for an arbitrary magnitude of perturbing interaction. The resultant expressions are exact in the Hückel model, so that we can perform any order of perturbation expansion. In order to explain what we mean, we give a simple example shown by Eq. 53. As was mentioned there, the bare interaction ε_m is replaced by the effective interaction $\tilde{\varepsilon}_m$ which is obtained by the infinite repetition of interaction with site m. From the viewpoint of practical use, our theory is not so bad, since propagators in our expressions are easily obtainable from the simple algebra by means of the recurrence formula.

Electrochemical Aspects of a NADH/FAD Model System

Kazuo SASAKI,* Akira KITANI, Atsutaka KUNAI, and Hitoshi MIYAKE
Department of Applied Chemistry, Hiroshima University, Senda-machi, Hiroshima 730
(Received May 6, 1980)

A model system of the NADH/FAD redox couple has been studied by the use of electrochemical techniques. The system studied was composed of 1-benzyl-1,4-dihydronicotinamide (BNAH) and riboflavin (RF), which were used in place of NADH and FAD respectively, dissolved in a DMSO solution. The results obtained were as follows. RF is reduced either by BNAH or sodium borohydride, obeying a second-order rate law, presumably by the mechanism of hydride-ion transfer. The resultant product is inactive to the electrochemical reduction at a mercury-pool electrode. Entirely different products were produced when RF was reduced electrochemically. RF was reduced at a rate of 1 *F*/mol at the initial stage of controlled potential electrolysis to form, probably, a dimeric compound, but the latter product underwent further reduction and the total quantity of electricity necessary for the complete reduction exceeded 10 *F*/mol. Interestingly, the electrolytic reduction gives the same product as that obtained by BNAH when electrolysis is performed in the presence of a sufficient amount of BNAH, indicating that the initial product of electrochemical reduction receives the hydride ion rather than further electrons.

$$2RF + 2e \rightleftharpoons (RF)_2^{2-} \xrightarrow{+H^-,\ +H^+} 2RFH^-$$

The Zn^{2+} added to the BNAH/RF system was found to act as the oxidizing agent of RFH^- and regenerated the neutral RF. This is markedly different from the case of BNAH/organic carbonyl compounds, where the metal ions behave as catalysts to promote the reaction.

In a series of papers,[1-4] we have reported on our electrochemical studies of the reaction of 1-benzyl-1,4-dihydro-nicotinamide (BNAH) with several aromatic compounds. The results may be outlined as follows:

1) Metal cations, which catalyze the redox reactions between BNAH and organic substrates, act as bridging agents in a ternary Michaelis complex composed of BNAH, a substrate, and a metal catalyst.

2) The force sustaining the ternary complex is mainly due to ion-pairing stabilization (Coulomic force between the organic anion and the metal ion).

3) Zinc exhibits the highest catalytic activity.

In the present paper, we should like to report the somewhat different behavior of metal ions observed in the redox reaction between BNAH and riboflavin (Vitamin B_2).

Riboflavin, which will hereafter be abbreviated as RF, is known as a constituent of flavocoenzymes. An excellent review article on the nature and reactions of flavins and flavocoenzymes is available.[5] Electrochemical studies of the same subject were reviewed extensively by Elving.[6]

Studies hitherto reported were done in aqueous media, and only a little is known about nonaqueous systems. By means of cyclic voltammetry, Sawyer[7] studied the qualitative behavior, including the metal-ion interactions, of several flavin compounds in DMF, acetonitrile, and DMSO.

Yoshinaga[8] also studied the electrochemistry of RF in DMF solutions using cyclic voltammetry and a.c. and d.c. polarography. According to these works, RF is reduced exhibiting two one-electron waves the first electron transfer being quasi-reversible, and the second, irreversible.

Experimental

Reagents. The solvent used in this experiment was dimethyl sulfoxide (DMSO). In some preliminary experiments, *N,N*-dimethylformamide (DMF) was also tested. Although the basic behavior of RF was found to be more or less similar in the two solvents, a slight advantage was found with DMSO in the solubility of RF. Commercial DMSO was first treated with Molecular Sieve 3A overnight and then distilled under reduced pressure in a nitrogen atmosphere. The supporting electrolyte was tetraethyl ammonium perchlorate (TEAPC). The RF of Katayama Chemicals was used as purchased. BNAH and its oxidized form BNA^+ were supplied by Dr. Ohnishi of the Sagami Chemical Research Center. The zinc salt was in the form of perchlorate.

Equipment and Procedures. The polarograph used was a Yanagimoto P-8 type, and the basic conditions of measurements were as follows:

Height of mercury column: 63.5 cm

Drop rate: 1.84 mg s^{-1} (at −1.0 V in DMSO)

Drop life: 3.81 s (at −1.0 V in DMSO)

Scan rate: 0.2 V s^{-1}.

The reference electrode was a SCE in a DMSO solution.

The homogeneous reaction of BNAH with RF was studied in a 20-ml polarographic cell in which 10 ml of a test solution had been placed. The test solution, initially composed of 0.1 M (1M=1 mol dm^{-3}) TEAPC and 1 mM RF, was first deoxygenated with bubbling nitrogen, and then BNAH equivalent to 30 mM was dissolved in it. The progress of the reaction was monitored periodically by means of d.c. polarography.

Electrolysis was carried out in a two-compartment cell separated by a glass frit. The working electrode was a mercury pool, and the counter electrode, a platinum foil. In the mercury-pool compartment, a dropping mercury electrode was also inserted to monitor the advance of the electrolysis.

Results

Electrochemical Behavior of RF in DMSO. The electrochemical behavior of RF has been studied by means of a.c. and d.c. polarography as well as by means of cyclic voltammetry.[8] Here, we shall cite only a part of our results.

The d. c. polarogram of 1 mM of RF in DMSO is

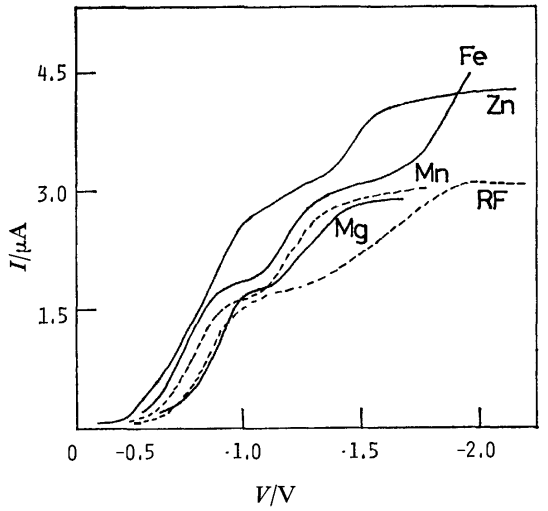

Fig. 1. D. c. polarograms of riboflavin (1 mM) in the presence of equimolar amount of several metal cations.

shown by the dotted curve in Fig. 1. As may be seen, the first one-electron wave appears at $E_{1/2}=-0.90$, and the second, at -1.56 V. Both of the waves are diffusion-limiting, the first one being quasi-reversible, and the second, totally irreversible.

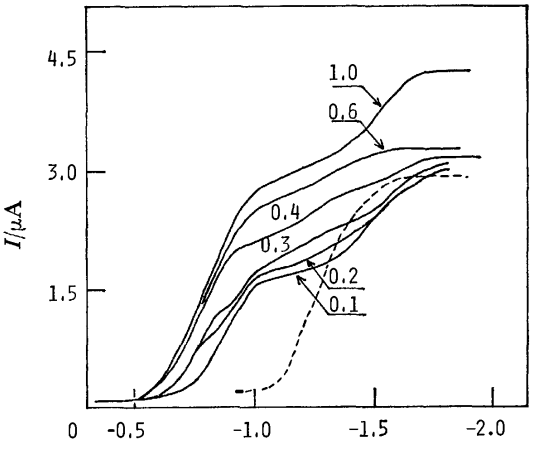

Fig. 2. Effect of zinc ion concentration on the polarogram of riboflavin (1 mM). Numbers indicate Zn^{2+} concentration in mM. Broken curve stands for 1 mM Zn^{2+}.

When equimolar amount of various metal salts are added, the wave shifts in a more positive direction, indicating the existence of ion-pair formation (Fig. 1). Figure 2 shows the effect of the zinc ion at a variety of concentrations. When the concentration of the zinc ion exceeds 0.6 mM, the wave corresponding to Zn^{2+} itself appears and the change in the wave form of RF almost ceases. This may be an indication that, in the ion-pair formed, two molecules of reduced RF are fixed per Zn^{2+} ion, on the average.

Reduction of RF by BNAH in Homogeneous DMSO Solutions. When RF is reacted with a large excess of BNAH in DMSO solutions containing 0.1 M TEAPC, the following reaction proceeds:

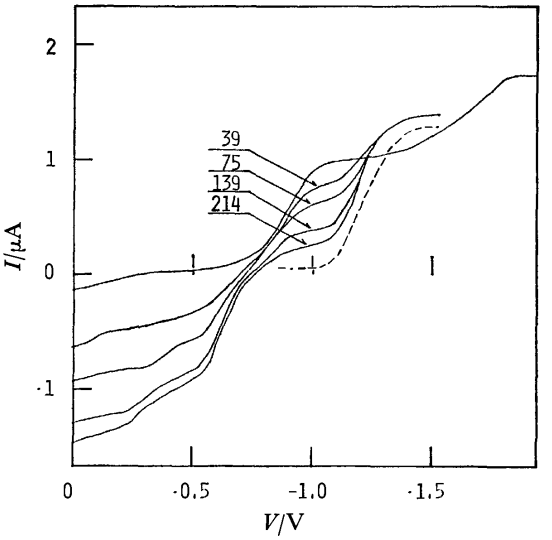

Fig. 3. Change in polarograms with the progress of reaction between BNAH and RF. Numbers indicate reaction time in minutes. The uppermost curve stands for RF before adding BNAH, and broken curve for BNA^+ (1 mM). RF: 1 mM, BNAH: 30 mM.

$$RF + BNAH \xrightarrow{k_{II}} RFH^- + BNA^+. \quad (1)$$

The progress of the reaction was monitored periodically by the aid of polarography with the reacting solution. Figure 3 shows a part of the results, where the initial concentrations of the reactants were 1 mM for RF and 30 mM for BNAH respectively. When the cathodic wave height at -1.1 V, as a measure of the amount of RF remaining unreacted, and the anodic wave height at -0.2 V, for the amount of reduced product, are plotted against each other, Curve A in Fig. 4 is obtained. The slope of the curve is exactly 2, indicating that the reduction occurring is equivalent to a two-electron transfer per molecule of RF. The reaction as a whole can be expressed by Eq. 1. The apparent rate constant was determined to be $(3.7\pm0.2)\times10^{-3}$ M^{-1} s^{-1}.

Westheimer[9] showed that the reaction between NAD^+ and certain organic substrates occurs *via* a hydride-ion mechanism. We are inclined to conclude

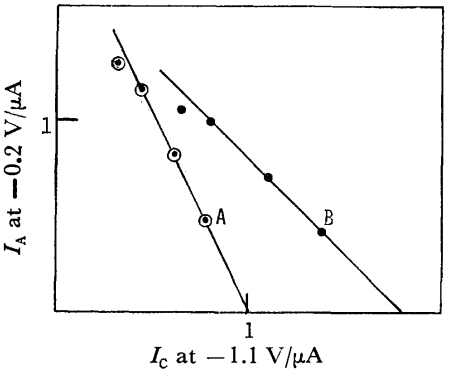

Fig. 4. Equivalency between RF and its reduced product. The abscissa stands for the concentration of RF remained unreacted and the ordinate for reduced RF. A: Without additives, B: with 0.7 mM Zn^{2+}.

that the present reaction, as expressed by Eq. 1, proceeds by the same mechanism, *i.e.*, hydride-ion transfer.[10]

The product, BNA^+, is polarographically reactive and gives a cathodic wave with the half-wave potential at -1.5 V. The curve of the broken line in Fig. 3 stands for the solution of 1 mM BNA^+ observed separately. The curves in Fig. 3 clearly indicate that the wave corresponding to the BNA^+ reduction increases progressively with the reaction time. In this figure, there are two facts worthy of note. The first is that the limiting current at the BNA^+ wave remains constant, regardless of the reaction time, and the second, that the second wave of RF itself disappears completely.

The reason why the second wave disappears can be explained by assuming that the following sequence of reactions is taking place at the dme surface:

$$RF + e \rightleftarrows RF^{\cdot} \quad (2)$$

$$2RF^{\cdot} \longrightarrow (RF)_2^{2-} \quad (3)$$

$$(RF)_2^{2-} + BNAH + H^+ \longrightarrow BNA^+ + 2\,RFH^-. \quad (4)[11]$$

If both the reactions, (3) and (4), are assumed to occur in the closest vicinity of dropping mercury, and if they are assumed to proceed sufficiently rapidly, there may be no $RF^{\cdot}$ which is responsible for the second wave.

The constancy of the wave height at the plateau of the BNA^+ wave also supports the occurrence of Reaction 4. The species responsible for the wave height concerned should be both the RF remaining unreacted and the BNA^+ formed by the homogeneous reaction (1). If the RF remaining unreacted undergoes a series of reactions, (2) to (4), rapidly and quantitatively, the concentration of BNA^+ at the electrode surface will be equal to the sum of those due to the homogeneous reaction (Eq. 1) and produced by the follow-up chemical reaction (Eq. 4). Accordingly, the concentration of BNA^+ should always be equal to the initial concentration of RF itself, 1 mM in this case.

It is worthy of note that RF gives the same product, RFH^-, even when the reaction is initiated by electronation (Eq. 2) as long as a sufficient amount of BNAH is present in the system. In other words, $(RF)_2^{2-}$ reacts more easily with BNAH than it receives further electrons. Very similar behavior was observed when sodium borohydride was used in place of BNAH. This suggests that the role of BNAH is as a hydride-ion source rather than as an electron donor.[10]

Behavior of Zn^{2+} in the Redox Reaction between BNAH and RF. As has been reported previously, BNAH reduces various aromatic carbonyl compounds, and several metal ions have been found to accelerate the rate of the reaction. In contrast to this, the existence of some metal ions apparently retards the reduction of RF with BNAH.

Figure 5 shows the results of a measurement similar to that of Fig. 3. The only difference was that the starting solution contained 0.7 mM Zn^{2+} besides 1 mM of RF and 30 mM of BNAH. Because of the ion-pairing phenomena, the polarogram of RF changed to one two-electron wave. As had been done before the cathodic wave height was plotted against the anodic one to get Curve B in Fig. 4. The slope is exactly unity.

Since the cathodic wave was two-electron, the anodic

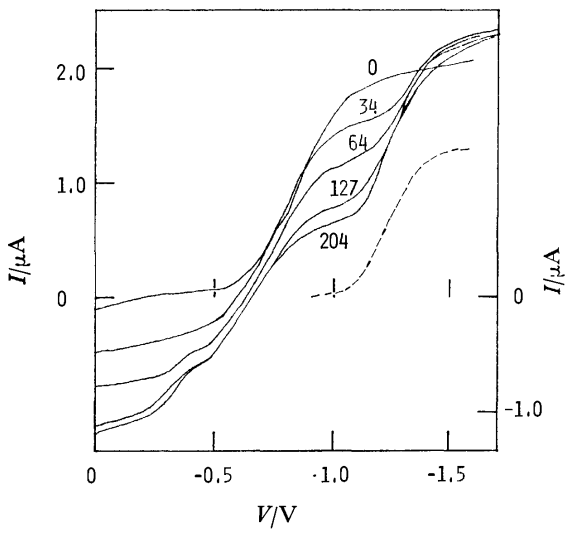

Fig. 5. Change in polarograms with progress of reaction between BNAH and RF in the presence of 0.7 mM Zn^{2+}. RF: 1 mM, BNAH: 30 mM.

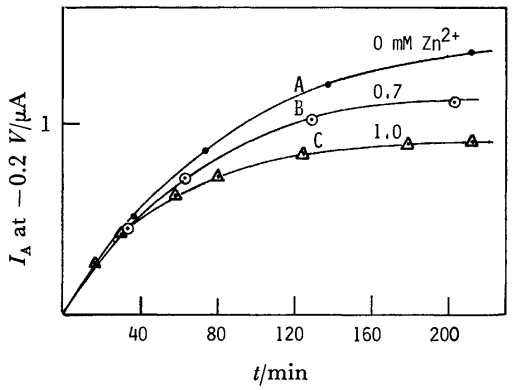

Fig. 6. Accumlation of reduced RF and the effect of Zn^{2+} ion on it.

wave corresponds to a two-electron reaction. The shape of the anodic wave is indistinguishable from that in Fig. 3. Accordingly, one may conclude that the presence of Zn^{2+} does not affect the production of RFH^-.

The anodic wave appearing in the polarograms of Figs. 3 and 5 is due to the reoxidation of the reduction product, RFH^-. Therefore, its wave height can be used as a measure of the concentration of RFH^-. This is examined in Fig. 6, where Curve A stands for the measurement in the absence of Zn^{2+}, and B and C for those in the presence of 0.7 mM and 1.0 mM Zn^{2+} respectively. It is clearly indicated that the accumulation of RFH^- is retarded by the presence of Zn^{2+}.

In Fig. 5, the limiting current at the second plateau, where BNA^+ is reduced, is roughly constant, irrespective to the reaction time. However, the value is much greater than that observed in Fig. 3. This requires an additional explanation. The species responsible for the total wave height of interest are, of course, the BNA^+ produced homogeneously and the RF remaining unreacted, the latter gives a two-electron wave in this case[12] owing to the presence of the Zn^{2+} ion. Accordingly, the difference in the heights of the first and second

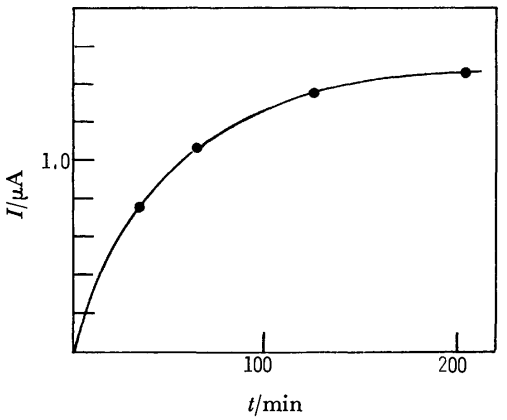

Fig. 7. Increase of BNA^+ concentration with reaction time observed by polarography.
1.5 μA corresponds to 1.2 mM roughly.

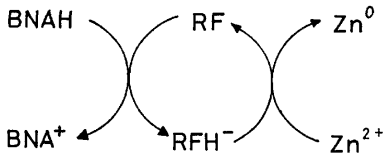
waves must correspond to the concentration of BNA^+ produced by the homogeneous reaction. This is plotted in Fig. 7 against the reaction time. It should be noted that the final value is approximately 1.5 μA, which corresponds to a BNA^+ concentration of 1.2 mM or more. Undoubtedly, this value exceeds the initial concentration of RF. This is a result of the following regeneration reaction:

$$RFH^- + Zn^{2+} \xrightarrow{k_{reg}} RF + H^+ + Zn^\circ. \quad (6)$$

In order to confirm the occurrence of Reaction 6, we carried out the analysis of the zinc ion in the solution phase by means of atomic-absorption spectrometry. If Reaction 6 actually takes place, the Zn^{2+} ion will disappear from the solution. The first measurement was made with 1.0 mM of Zn^{2+} added to a solution of DMSO containing 1 mM of RF and 30 mM of BNAH, and the second with 1.5 mM of Zn^{2+}. The reaction mixture was stirred by means of a magnetic stirrer and kept for several hours at room temperature (*ca.* 22 °C). When the resultant solution was subjected to atomic-absorption spectrometry without any additional treatment, 75 to 80% of the Zn^{2+} was recovered, indicating that the major part of the metallic zinc was still in the solution. Therefore, the solution was brought into contact with mercury and the whole system was vigorously agitated. By this treatment, the metallic zinc can be transferred into the mercury phase.

For the two solutions tested, the initial zinc concentrations of which were 1.0 and 1.5 mM, the values were reduced to 0.05 mM and 0.1 mM respectively. This means, on the average, that, during a period of homogeneous reaction of several hours, each molecule of reduced riboflavin had a chance to return to the oxidized form (RF).

The above findings indicate the following combination of redox cycles:



This is a fact unexpected at the beginning of the present study, some comments will be made below.

Electrochemical Reduction of RF. The controlled potential electrolysis of RF was also studied with a mercury-pool electrode. The change in solution composition was studied also by means of polarography.

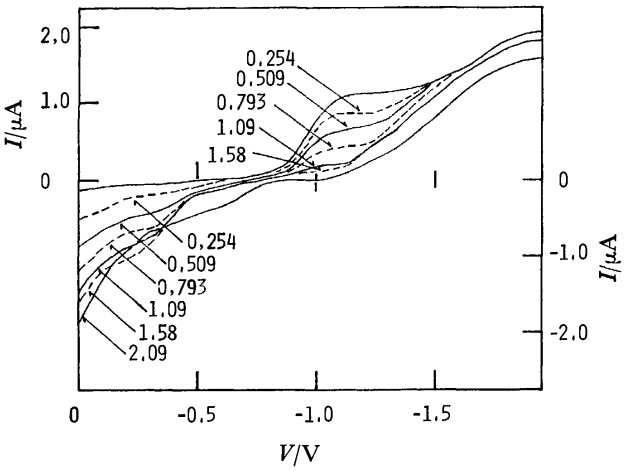


Fig. 8. Progress of controlled potential electrolysis of RF as observed by polarography. Electrolysis was made at −1.90 V. Numerical figures indicate *F*/mol.

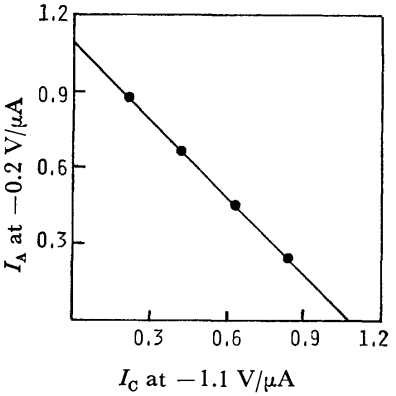

Fig. 9. Coulometric correlation in the electrolytic reduction of RF. The ordinate stands for the amount of reduced product and the abscissa for RF remained.

As is shown in Fig. 8, the first wave of RF reduction decreases with the progress of electrolysis and disappears after passing the electricity of *ca.* 1 *F*/mol. The decreasing cathodic wave and the increasing anodic one are compared in Fig. 9. The slope of this curve is unity, in contrast to Curve A in Fig. 4, where the slope was 2. Since the cathodic wave under consideration is of one-electron, the product which is responsible for the anodic wave seems to be a dimeric compound. The reaction taking place at the cathode electrode may thus be written as:

$$RF + e \rightleftharpoons RF^{\cdot} \quad (7)$$

$$2RF^{\cdot} \longrightarrow (RF)_2^{2-}. \quad (8)$$

Unexpectedly, the wave height at the potential region where RF gives the second wave does not show a marked decrease.

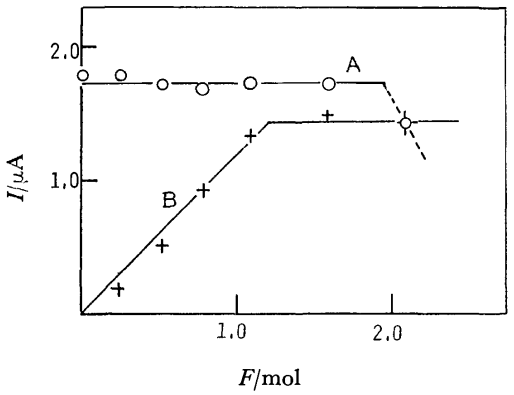

Fig. 10. Analysis of polarograms during the controlled potential electrolysis. Curve A is the wave height at −1.9 V, where not only neutral RF but also several reduced products may contribute to the wave height. Curve B may be considered as the concentration of dimeric product, $(RF)_2^{2-}$.

When the change in wave height measured at −1.9 V is plotted against the quantity of electricity consumed, Curve A of Fig. 10 is obtained. It may be seen that the decrease begins after 2 *F*/mol or so of electricity is consumed. This suggests that the dimer anion $(RF)_2^{2-}$ produced by Eq. 8 is further reduced to contribute to the wave height. The rest of the wave height is, of course, due to the RF remaining. Since the contribution of the latter is simply twice the height of the first wave, the difference will give the concentration of the dimer anion. Curve B in Fig. 10 shows this. The linear increase ceases at a point corresponding to 1 *F*/mol, supporting the foregoing estimation that the initial electrode product is a dimeric compound.[13]

It should be noted that the constant potential coulometry made at −1.9 V indicated that the number of electrons involved exceeds 10. This indicates that, upon electrochemical reduction, RF undergoes a complete reduction for almost all of the reducible groups.

Anodic Oxidation of Reduced Riboflavin (Preliminary Report). From the foregoing descriptions, it is clear that there are at least two types of reduction products. One is the BNAH-product, which is assumed to be the so-called leucoflavin,[14] while the other consists of electrode products. The latter is, in general, a mixture of compounds differing in their stages of reduction. In order to avoid confusion, we will hereafter confine the meaning of "electrode product" to the "dimer compound" which is obtained within the limit of an applied charge of 1 *F*/mol.

The BNAH-product gives a two-stage anodic wave in polarograms, with half-wave potentials at −0.65 (Wave A1) and −0.35 V (A2). The former is much higher than the latter amounting to 85% of the total height. The reoxidation of the electrode product also exhibits a two-stage wave, but the half-wave potentials appear at −0.35 V (A2) and 0 V (A3).

The BNAH-product is sensitive to oxygen, and, if a sufficient amount of oxygen is introduced, the polarogram of the original RF recovers quantitatively. Similarly, RF is regenerated, at least polarographically, when the BNAH-product is subjected to the anodic oxidation at the mercury-pool electrode at −0.5 V.

On the other hand, the electrode product behaves somewhat complicatedly in response to the anodic oxidation. When the electrode product is reoxidized at −0.2 V, Wave A2 disappears after passing a charge of 0.5 *F*/mol, but at this same stage Wave A3 remains unchanged. The disappearance of Wave A2 gives rise to the regeneration of the reduction wave of RF. However, the recovery is, atmost, 60% of the original RF wave.

A tentative explanation for these findings is that the electrode product, which is assumed to be a dimer anion, undergoes one-electron oxidation to give half the original RF:

$$(RF)_2^{2-} + e \xrightarrow{A1} RF + (RF^{\tau})'.$$

One of the products $(RF^{\tau})'$ is solely an assumption in order to explain both the one-electron behavior of the A2 wave and the 50% recovery of the RF wave. When the electrode product is anodically oxidized at +0.2 V, all of the anodic wave disappears, but the reaction is complicated.

The A2 wave appeared in the reoxidation of both the BNAH and electrode products. If the active species responsible for this wave is the same, it should be the dimer anion. As a possibility, the following reaction seems to operate:

$$RFH^- \xrightarrow[A1]{-e} RFH\cdot \xrightarrow[A1]{-e} RF + H^+$$
$$\downarrow \times 2,\ -2H^+$$
$$(RF)_2^{2-} \xrightarrow[A1]{-e} RF + (RF^{\tau})'.$$

9) F. H. Westheimer, H. F. Fisher, E. E. Conn, and B. Vennesland, *J. Am. Chem. Soc.*, **73**, 2403 (1951).
10) The electrochemical behavior of BNAH is totally irreversible. Its anodic oxidation exhibits a two-electron wave at +0.6 V and produces BNA^+, while the reduction of BNA^+ takes place at about −1.0 V. This means that the electron-transfer reaction of BNA^+/BNAH couple is much hindered. Taking into account the result of Westheimer,[9] who indisputablly verified the hydride-ion mechanism for the NAD^+/NADH couple, the homogeneous reaction between BNAH and RF seems to proceed by means of a hydride mechanism. We have found that sodium borohydride, known as a typical hydride-ion source, also reduces RF.

11) There is another way to describe the reaction:

$$2RF^{\cdot} + BNAH + H^{+} \longrightarrow BNA^{+} + 2RFH^{\cdot}. \quad (5)$$

This insists that BNAH attacks the $RF^{\cdot}$ radical anion, but not the dimer anion $(RF)_2^{2-}$. We, however, prefer the mechanism of Eq. 4.

12) The latter species might produce BNA^{+} as a result of a follow-up chemical reaction, as in the manner of Eq. 4. However, this does not affect the total wave height.

13) After passing 1 *F*/mol, the current appears to be constant until *ca.* 2 *F*/mol. This constancy is, however, meaningless for discussion, since the species responsible for this current can not be uniquely specified.

14) Spectrometric identification has not yet been attempted, because the absorption of BNAH masks the flavin spectra.

Absorption and Reflection Spectra of Pure and $ClSO_3H$ Doped Polyacetylene Films

Masashi TANAKA,* Atsushi WATANABE, and Jiro TANAKA
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received May 8, 1980)

Optical absorption and reflection measurements are carried out on pure and $ClSO_3H$ doped polyacetylene films over a wide wavelength region (350—35000 cm^{-1}). In the doped polymer, the transition from the valence band to the impurity level is observed at 870 cm^{-1} and the free carrier absorption band appears over the wide region of 350 to 20000 cm^{-1}, while the interband transition located in the region of 15000 cm^{-1} disappears. This means that doping removes the bond alternation leading to a uniform bond length and all π-electrons contribute to the transport. For the heavily doped films, the d.c. conductivity of polyacetylene films is obtained by the optimum fit of the theoretical curve to the observed absorption and reflection spectra. The obtained values are comparable with the d. c. conductivity ($\sigma \simeq 280$—$250\ \Omega^{-1}\ cm^{-1}$) obtained by the four probe method.

Polyacetylene, $(CH)_x$, is one of the simplest linear conjugated polymers with a single chain structure. The theoretical studies upon the electronic structure of pure $(CH)_x$ polymer showed that the alternant structure was found to have the lowest energy and the energy gap between the π and π^* bands was too high.[1-4] The observation[5,6] of the $\pi \rightarrow \pi^*$ transition band at about 16000 cm^{-1} also showed that the bond alternation is present in the polymer and $(CH)_x$ would be expected to make semiconducting behavior.[7] However, Shirakawa, Heeger, and MacDiarmid and co-workers found that AsF_5 doped $(CH)_x$ films have the high conductivity of about $10^3\ \Omega^{-1}\ cm^{-1}$ [8] and they observed the new absorption bands in the lower frequency region by the absorption and reflection measurements.[9-11] Tanaka *et al.* estimated the optical conductivity by measuring the free carrier absorption band of BF_3 doped film[12] and also showed that $ClSO_3H$ is a good dopant by the d.c. conductivity measurement of $ClSO_3H$, H_2SO_4, and BF_3 doped films.[13]

In the present paper, we report the absorption and reflection spectra in the 350—35000 cm^{-1} region of $(CH)_x$ films doped with $ClSO_3H$ and discuss about the electronic structure of the heavily doped $(CH)_x$ films.

Experimental

The polyacetylene films were prepared from acetylene gas by treatment of the Ziegler catalyst in hexane at −80 °C as described by Shirakawa, Ikeda, and co-workers.[14-16] The films were doped by exposure to the vapor of $ClSO_3H$ *in vacuo*. The dopant level were determined by the measurement of the four probe d.c. conductivity.

After the thin $(CH)_x$ films were polymerized on the KBr plate or the polyethylene film and doped with $ClSO_3H$, the absorption spectra of $(CH)_x$ films were measured with Hitachi IR 260-50 (350—4000 cm^{-1}) and Carl Zeiss M4Q (4000—35000 cm^{-1}) spectrophotometers. For the study of the *cis-trans* isomerization of $(CH)_x$ films, the thin films were polymerized on the inner surface of the 1 cm quartz cell and the absorption spectra of the films kept *in vacuo* were measured with a Carl Zeiss spectrophotometer after heating at 60 °C. The reflection measurement of pure and doped thick films were taken with Hitachi IR 260-50 and a microscopic spectrophotometer (4000—35000 cm^{-1}) made in our laboratory. It consists of an Olympus microscope, a Carl Zeiss Ultrafluar lens (×10), a Nikon crystal mount, a HTV 928 photomultiplier and a PbS tube, and an Intel 8080 microcomputer for data processing.

The Kramers-Kronig (K-K) transformation[17,18] of the reflection spectra of pure $(CH)_x$ films and the best fit of the calculated absorption and reflection spectra of $ClSO_3H$ doped films to the observed spectra were made on a FACOM M-200 computer of Nagoya university.

Results and Discussion

Absorption and Reflection Spectra of Pure $(CH)_x$ Films. The thin $(CH)_x$ film polymerized at −80 °C shows the reddish cupric color and the film becomes blue on heating it *in vacuo*. This color change was explained by the analysis of IR-vibration spectra[14-16] to be due to the *cis-trans* isomerization of $(CH)_x$. In Fig. 1 is shown the visible absorption spectral change of the thin $(CH)_x$ film at 60 °C and *in vacuo*. *cis*-Rich $(CH)_x$ has two vibronic peaks at 17100 and 18300 cm^{-1} and the second peak (18300 cm^{-1}) is the most intense. On heating the *cis*-rich thin film at 60 °C, the broad band in the region of 15000 cm^{-1} becomes more intense and the

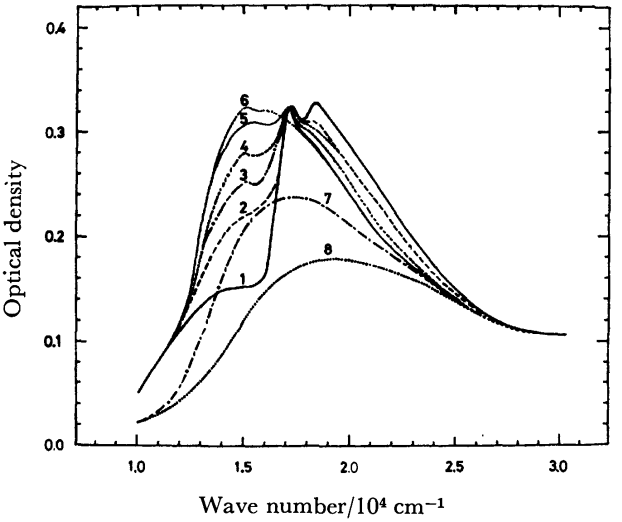

Fig. 1. The visible absorption spectral change due to the *cis-trans* isomerization of the thin $(CH)_x$ film at 60 °C and *in vacuo*. 1) 0.0 h, 2) 3.2 h, 3) 8.2 h, 4) 14.5 h, 5) 2.0 d, 6) 4.9 d 7) 16.3 d, 8) 22.2 d.

18300 cm^{-1} peak of *cis*-$(CH)_x$ becomes weaker. Finally, the 15000 cm^{-1} band of *trans*-$(CH)_x$ has the same absorption intensity as that of the 17000 cm^{-1} band of *cis*-$(CH)_x$ before heating. This means that *cis*-$(CH)_x$ transforms completely to *trans*-$(CH)_x$. After that, the absorption intensity of *trans*-$(CH)_x$ becomes weaker and the maximum peak shifts to the higher frequency region. This fact seems to be due to the formation of the bridge between the $(CH)_x$ chains and the decrease in the C=C conjugated system.

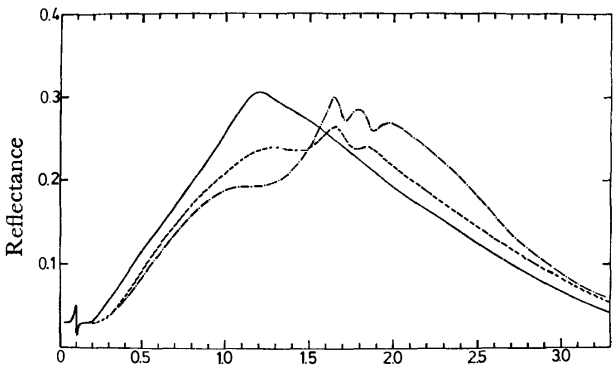

Fig. 2. The reflection spectra of the thick $(CH)_x$ films. ·—·—: 80% *cis*-$(CH)_x$, – – –: 55% *cis*-$(CH)_x$, ——: 85% *trans*-$(CH)_x$.

In Fig. 2 is shown the reflection spectral change of the thick $(CH)_x$ films at about 200 °C. The *cis,trans*-content of $(CH)_x$ films was determined by measuring the optical density of *cis* (740 cm^{-1}) and *trans* (1015 cm^{-1}) C–H out-of-plane vibrations.[16] The reflection spectrum of 80% *cis*-$(CH)_x$ film has the vibronic structures at 16400 and 18000 cm^{-1} as is observed in the absorption spectra of thin $(CH)_x$ films and the 16400 cm^{-1} peak has a reflectivity of 30%. For the 85% *trans*-$(CH)_x$ film, the reflection spectrum has the broad band at 12000 cm^{-1} and the sharp peak at 1015 cm^{-1} corresponding to the C–H out-of-plane mode of *trans*-$(CH)_x$. The main band at 12000 cm^{-1} has a reflectivity of 30.6%. The absorption spectra of $(CH)_x$ film are obtained by the K-K transformation of the reflection spectra as is shown in Fig. 3. The 16400 cm^{-1} band of 80% *cis*-$(CH)_x$ has the maximum absorption coefficient, α, of 2.59×10^5 cm^{-1} and the 12000 cm^{-1} band of 85% *trans*-$(CH)_x$ has $\alpha=2.33\times10^5$ cm^{-1}. On comparison between Figs. 1 and 3, the absorption maxima of thick $(CH)_x$ films are shifted to the lower frequency region than those of the thin films. This may be explained by the difference of the conjugated system length.

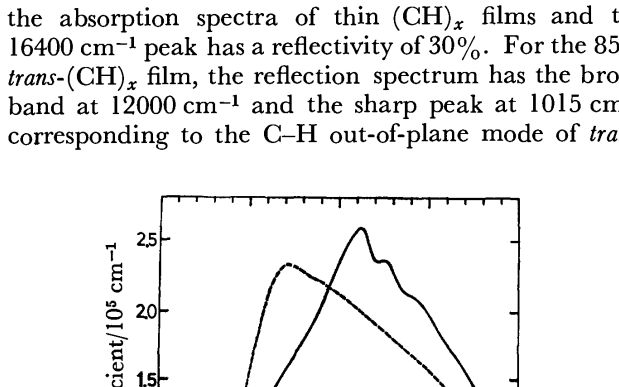

Fig. 3. The absorption spectra obtained from the K-K transformation of the reflection spectra of the thick $(CH)_x$ films. ——: 80% *cis*-$(CH)_x$, – – –: 85% *trans*-$(CH)_x$.

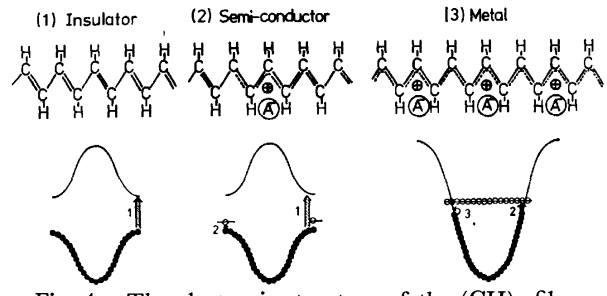

Fig. 4. The electronic structure of the $(CH)_x$ film.

$(CH)_x$ is one of the simplest linear conjugated polymers with a single chain structure and has the configuration of alternating the single and double bonds. Then, the π-electrons on each carbon atom form two separate bands as shown in Fig. 4-1. The one is the bonding π band (valence band) and the other is the antibonding π^* band (conduction band). Accordingly, the complex dielectric constant of $(CH)_x$ is given by the following equation,[19]

$$\varepsilon(\omega)=\varepsilon_{\text{core}}+\sum_{k}\frac{(4\pi Ne^2/m)\hbar^2 f_{\pi k,\pi^* k+q}}{(\varepsilon_{\pi^*}(k+q)-\varepsilon_{\pi}(k))^2-\hbar^2\omega^2-i\hbar^2\omega/\tau_0} \quad (1)$$

where N is the number density of π-electrons, m is the electron mass, and $f_{\pi k,\pi^* k+q}$ is the oscillator strength of the $\pi k\rightarrow\pi^* k+q$ transition. $\varepsilon_{\pi^*}(k+q)$ and $\varepsilon_{\pi}(k)$ are the energy of π and π^* bands. When the momentum of photon, q, is neglected, the imaginary part $\varepsilon_2(\omega)$ of the complex dielectric constant is derived from Eq. 1 as follows,

$$\varepsilon_2(\omega)=\frac{\pi}{2}\frac{4\pi Ne^2}{m}\bar{f}_{\pi,\pi^*}\sum_{k}\frac{\hbar}{\omega}\delta(\varepsilon_{\pi^*}(k)-\varepsilon_{\pi}(k)-\hbar\omega). \quad (2)$$

Here, $\bar{f}_{\pi,\pi^*}$ is the average of the oscillator strength of the $\pi k\rightarrow\pi^* k$ transition. The sum rule of $\varepsilon_2(\omega)$ is defined for a finite range from the absorption edge $E_g=\hbar\omega_g$ to the energy $E_0=\hbar\omega_0$,

$$\int_{\omega_g}^{\omega_0}\omega\varepsilon_2(\omega)d\omega=\frac{\pi}{2}\frac{4\pi Ne^2}{m}\bar{f}_{\pi,\pi^*}\sum_{k}\int_{E_g}^{E_0}\delta(\varepsilon_{\pi^*}(k)-\varepsilon_{\pi}(k)-E)dE$$

$$=\frac{\pi}{2}\frac{4\pi Ne^2}{m}\bar{f}_{\pi,\pi^*}G(E_0) \quad (3)$$

where $G(E_0)$ is the integral of the joint density of state $\rho(E)$ over the energy region of E_g to E_0,

$$G(E_0)=\int_{E_g}^{E_0}\rho(E)dE \quad (4)$$

and

$$\rho(E)=\sum_{k}\delta(\varepsilon_{\pi^*}(k)-\varepsilon_{\pi}(k)-E). \quad (5)$$

In the typical one-dimensional system of the length L,

the band energy $\varepsilon_\pi(k)$ and $\varepsilon_\pi^*(k)$ can be approximated by the parabolic function,

$$\varepsilon_\pi(k) = -\frac{\hbar^2}{2m_\pi}\left(k-\frac{\pi}{2a}\right)^2 \quad (6)$$

and

$$\varepsilon_{\pi^*}(k) = E_g + \frac{\hbar^2}{2m_\pi}\left(k-\frac{\pi}{2a}\right)^2. \quad (7)$$

Then, the joint density of state near the gap edge varies as

$$\rho(E) = \frac{L\sqrt{m_\pi}}{h}(E-E_g)^{-1/2} \quad (8)$$

and the integral of the joint density of state rises toward the square root as follows

$$G(E_0) = \frac{2L\sqrt{m_\pi}}{h}(E_0-E_g)^{1/2}. \quad (9)$$

In this case, $\varepsilon_2(\omega)$ is calculated from the K-K transformation of the reflection spectra (Fig. 2) of $(CH)_x$ films and the sum rule of Eq. 10 is found by integrating $\varepsilon_2(\omega)$,

$$\frac{m}{2\pi^2 Ne^2}\int_{\omega_g}^{\omega_0}\omega\varepsilon_2(\omega)d\omega = f_{\pi,\pi^*}G(E_0), \quad (10)$$

where the number of π-electrons per unit volume of the medium is taken to be $N\approx 2\times 10^{22}$ cm^{-3} from the measured density of $(CH)_x$ (0.4 g/cm^3).[20] The obtained sum rule curves are shown in Fig. 5 together with the

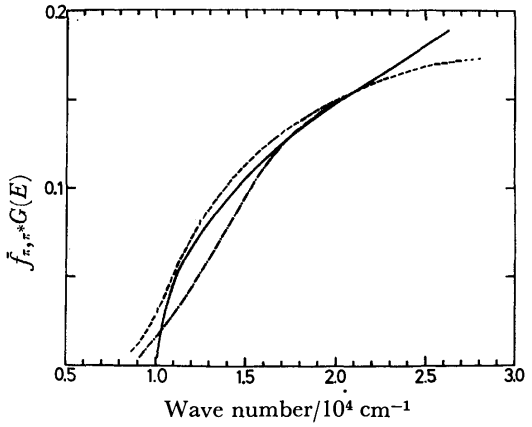

Fig. 5. The sum rule of $\varepsilon_2(\omega)$ obtained from the K-K transformation of the reflection spectra of the thick $(CH)_x$ films. ·—·—·: 80% *cis*-$(CH)_x$, ------: 85% *trans*-$(CH)_x$, ——: $G(E)=A(E-E_g)^{1/2}$.

theoretical curve of $G(E_0)=A(E_0-E_g)^{1/2}$. The good agreement between the observed and theoretical curves indicates that $(CH)_x$ can be treated as the one-dimensional system and that the top of π band and the bottom of π^* band can be approximated as the parabolic function. Accordingly, the absorption band observed in the visible region can be assigned to the direct interband transition (type 1 shown in Fig. 4-1) from the π band to the π^* band.

Absorption Spectra of Thin $(CH)_x$ Films Doped with $ClSO_3H$. In the lightly doped $(CH)_x$ film ($\sigma\simeq 2\times 10^{-2}\ \Omega^{-1}$ cm^{-1}) polymerized on the KBr plate, two infrared peaks of the additional absorption are

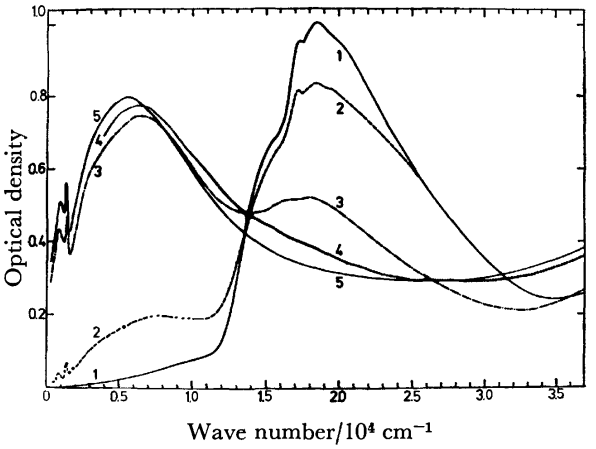

Fig. 6. The absorption spectra of *cis*-rich thin $(CH)_x$ films doped with $ClSO_3H$.
1) Pure $(CH)_x$, 2) $\sigma_0\simeq 2\times 10^{-2}\ \Omega^{-1}$ cm^{-1}, 3) $\sigma_0\simeq 2.6\ \Omega^{-1}$ cm^{-1}, 4) $\sigma_0\simeq 10^2\ \Omega^{-1}$ cm^{-1}, 5) $\sigma_0\simeq 250\ \Omega^{-1}$ cm^{-1}.

observed at 1370 and 870 cm^{-1} as shown in Fig. 6. In doping $(CH)_x$ with $ClSO_3H$, the π-electrons transfer from $(CH)_x$ chain to $ClSO_3H$. The resulting hole (cation) on the polymer chain is bound by the Coulomb potential to the region of the chain near the acceptor ion and the impurity state appears in the energy gap (Fig. 4-2). The band at 870 cm^{-1} can be assigned to the transition (type 2 shown in Fig. 4-2) from the valence band to the impurity 1s level according to Fincher *et al.*[9] and Tanaka *et al.*[12] In this model, the cation on the $(CH)_x$ chain delocalizes near the acceptor ion and a region of the uniform bond lengths occurs. This phenomenon is called "Soliton" and the possibility of the existence of soliton was theoretically recognized.[21,22] The 1370 cm^{-1} mode appears at a frequency approximately intermediate between the single bond (C–C, 950 cm^{-1}) and double bond (C=C, $\simeq$1650 cm^{-1}) stretching mode and may be assigned to the stretching mode of the bond order 1.5 corresponding to the uniform bond lengths, while Harada *et al.*[23] and Rabolt *et al.*[24] concluded that the 870 and 1370 cm^{-1} peaks were the molecular vibration mode.

In addition to the 870 and 1370 cm^{-1} bands, a broad band appears in the region of 8000 cm^{-1} and the absorption intensity of the interband transition at about 17000 cm^{-1} decreases (Fig. 6). The fact that there is an isosbestic point at about 14000 cm^{-1} in the spectra clearly indicates that there is an equilibrium between two absorbing species of the 8000 and 17000 cm^{-1} bands.

In heavily doped $(CH)_x$ films polymerized on the polyethylene films, the 870 and 1370 cm^{-1} bands remain clearly. Furthermore, the absorption band corresponding to the interband transition disappears in the visible region and the broad band observed in the near IR region becomes more intense. The broad band has the maximum peak at about 5500 cm^{-1} and the absorption edge in the region of less than 300 cm^{-1}. This fact suggests that the energy gap between the π and π^* bands becomes zero in the heavily doped $(CH)_x$ and doping removes the bond alternation leading to a

unform bond lengths. Accordingly, the electronic structure of heavily doped $(CH)_x$ consists of one π band and one impurity band. Figure 4-3 shows the observed intraband transition (type 3) and impurity band (type 2), although the transition energy to the impurity level seems to become zero due to the electron screening effect in the metallic state.

In the system, the complex dielectric constant of heavily doped $(CH)_x$ can be easily derived from Eq. 1 by substituting the zero energy gap between the π and π^* bands

$$\varepsilon_{\pi^*}(k+q) - \varepsilon_{\pi}(k) \simeq 0 \tag{11}$$

and the oscillator strength of the intraband transition[19,25]

$$\lim_{q\to 0} \sum_k f_{\pi k, \pi^* k+q} = \lim_{q\to 0} f_{\pi k_F, \pi^* k_F+q} = \frac{m}{\hbar^2}\left(\frac{\partial^2 \varepsilon_\pi(k)}{\partial k^2}\right) = \frac{m}{m^*}. \tag{12}$$

Here, m^* is the effective mass of the free carrier. The obtained dielectric constants are given in the following equations,

$$\varepsilon(\omega) = \varepsilon_{core} - \frac{\omega_p^2}{\omega^2 + i\omega/\tau_0}, \tag{13}$$

$$\varepsilon_1(\omega) = \varepsilon_{core} - \frac{\omega_p^2 \tau_0^2}{1+\omega^2\tau_0^2}, \tag{14}$$

and

$$\varepsilon_2(\omega) = \frac{1}{\omega}\frac{\omega_p^2 \tau_0}{1+\omega^2\tau_0^2}, \tag{15}$$

where the plasma frequency ω_p is defined as follows

$$\omega_p^2 = \frac{4\pi N e^2}{m^*}, \tag{16}$$

and N is the number density of the free carrier. Then, the extinction coefficient $k(\omega)$ and the absorption coefficient $\alpha(\omega)$ are expressed by the next equations,[19]

$$k(\omega) = \{(\sqrt{\varepsilon_1^2+\varepsilon_2^2} - \varepsilon_1)/2\}^{1/2} \tag{17}$$

and

$$\alpha(\omega) = \frac{2\omega}{c}k(\omega) = \frac{\sqrt{2}\,\omega}{c}\{\sqrt{\varepsilon_1^2+\varepsilon_2^2} - \varepsilon_1\}^{1/2}. \tag{18}$$

The maximum absorption coefficient of the interband transition is determined to be 2.58×10^5 cm^{-1} near 17000 cm^{-1} by the K-K transformation of the reflection spectra as is shown in Fig. 3. Accordingly, the absorption coefficient of the intraband transition of the heavily doped film ($\sigma \simeq 250\ \Omega^{-1}$ cm^{-1}) can be estimated as is shown in Fig. 7. Then, the parameters of Eqs. 14 and 15 were determined by the optimum fit of Eq. 18 to the experimental data. The fit was obtained with $\hbar\omega_p = 31000$ cm^{-1}, $\tau_0 = 0.48\times10^{-15}$ s and $\varepsilon_{core} = 6$ (see Table 1). The calculated absorption spectrum based on these values is plotted for comparison with the experimental curves in Fig. 7.

Reflection Spectra of 85% trans-$(CH)_x$ Films Doped with $ClSO_3H$. Reflection spectra of 85% *trans*-$(CH)_x$ films doped with $ClSO_3H$ are shown in Figs. 8 and 9.

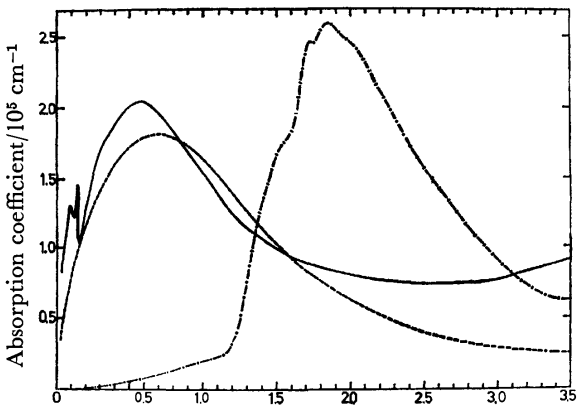

Fig. 7. Comparison between the observed and calculated absorption spectra of the thin $(CH)_x$ film ($\sigma_0 \simeq 250\ \Omega^{-1}$ cm^{-1}) heavily doped with $ClSO_3H$. ——: Observed, ------: theoretical, ·—·—·: pure $(CH)_x$.

Table 1. Optical parameters obtained from the best fit of the absorption and reflection spectra of the heavily doped $(CH)_x$ films

Optical parameter	Absorption spectra	Reflection spectra
ε_{core}	6	1.81
$\hbar\omega_p$/cm^{-1}	31000	28200
τ_0/s	0.48×10^{-15}	0.277×10^{-15}
N/cm^{-3}	1.2×10^{22}—1.8×10^{22}	1.0×10^{22}—1.5×10^{22}
σ_0/Ω^{-1} cm^{-1}	1450	690

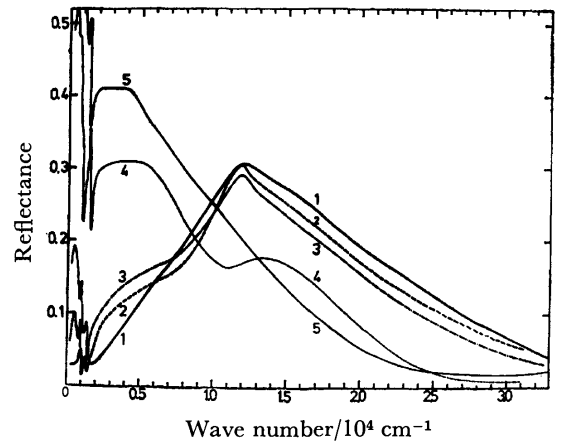

Fig. 8. The reflection spectra of thick 85% *trans*-$(CH)_x$ films doped with $ClSO_3H$. 1) pure $(CH)_x$, 2) $\sigma_0 \simeq 0.1\ \Omega^{-1}$ cm^{-1}, 3) $\sigma_0 \simeq 0.6\ \Omega^{-1}$ cm^{-1}, 4) $\sigma_0 \simeq 20\ \Omega^{-1}$ cm^{-1}, 5) $\sigma_0 \simeq 280\ \Omega^{-1}$ cm^{-1}.

Pure *trans*-$(CH)_x$ has the sharp dispersion peak of C–H out-of-plane mode at 1015 cm^{-1} in addition to the interband transition located in the visible region. Lightly doping of the film with $ClSO_3H$ increases the reflectance below 10000 cm^{-1} and decreases the reflectance over the region of the interband transition. The shoulder at 800 cm^{-1}, the peak at 1400 cm^{-1} and the broad band in the region of 8000 cm^{-1} correspond to those observed in the absorption spectra of thin films

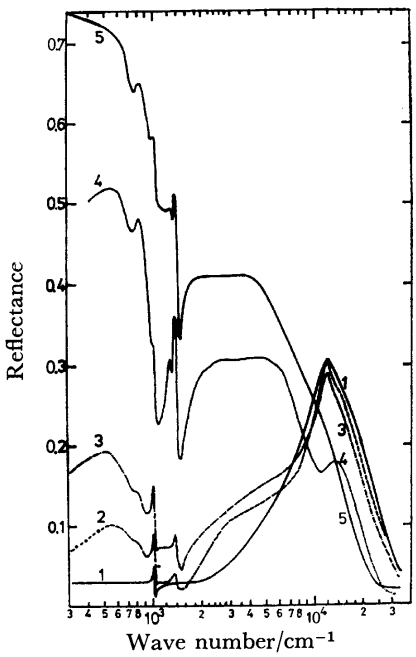

Fig. 9. The plot for the logarithmic wave number of the reflection spectra of thick 85% *trans*-$(CH)_x$ films doped with $ClSO_3H$. 1) Pure $(CH)_x$, 2) $\sigma_0 \simeq 0.1\ \Omega^{-1}\ cm^{-1}$, 3) $\sigma_0 \simeq 0.6\ \Omega^{-1}\ cm^{-1}$, 4) $\sigma_0 \simeq 20\ \Omega^{-1}\ cm^{-1}$, 5) $\sigma_0 \simeq 280\ \Omega^{-1}\ cm^{-1}$.

as shown in Fig. 6. The appearance of the peak below 800 cm^{-1} seems to show that the hole carriers occur in the $(CH)_x$ chain and the $(CH)_x$ film becomes the p-type semiconductor. In heavily doped samples, the reflectance becomes larger and larger below 10000 cm^{-1} and the reflectivity reaches to 70% in the frequency region of lower than 500 cm^{-1} although the interband transition disappears in the visible region. It looks like the metallic reflection spectrum. Furthermore, the 1400 and 800 cm^{-1} bands can be also clearly observed. The increase in the intensity of the 1400 cm^{-1} band means that the region of the uniform bond lengths expands in the $(CH)_x$ chain and the observation of the 800 cm^{-1} implies that the impurity band exists in the metallic π band as shown in Fig. 4-3. The behavior of the reflection spectra of doped thick films is in good agreement with that of the absorption spectra of doped thin films.

The reflectance is given by the following equation[19,26]

$$R = \frac{|\varepsilon|+1-\sqrt{2(|\varepsilon|+\varepsilon_1)}}{|\varepsilon|+1+\sqrt{2(|\varepsilon|+\varepsilon_1)}} \tag{19}$$

and

$$|\varepsilon| = \sqrt{\varepsilon_1^2+\varepsilon_2^2}. \tag{20}$$

Accordingly, the best fit of Eq. 19 to the observed reflection spectrum of the heavily doped film ($\sigma \simeq 280\ \Omega^{-1}\ cm^{-1}$) can be obtained by using the parameters of $\hbar\omega_p = 28200\ cm^{-1}$, $\tau_0 = 0.277 \times 10^{-15}$ s and $\varepsilon_{core} = 1.81$ (see Table 1). The calculated reflection spectrum based on these values is depicted for comparison with the experimental curve in Fig. 10.

Relation of the Obtained Optical Parameters with the Conductivity. The effective mass, m^*, of the free carrier in the $(CH)_x$ chain can be given in the tight

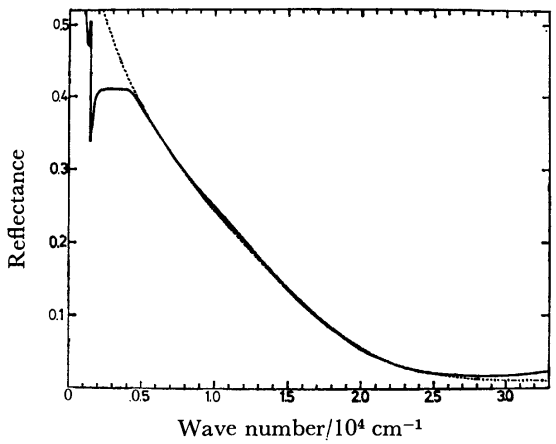

Fig. 10. Comparison between the observed and calculated reflection spectra of the thick $(CH)_x$ film heavily doped with $ClSO_3H$. ——: Observed, ------: theoretical.

binding approximation as follows,[26]

$$\frac{m}{m^*} = \frac{m}{\hbar^2}\left(\frac{\partial^2\varepsilon_x(k)}{\partial k^2}\right) = \frac{4ta^2m}{\pi\hbar^2} \tag{21}$$

and can be estimated to be $0.6 < m/m^* < 0.9$ by using $a = 1.4$ Å and $t = 2.0$—2.5 eV. Then, the number density, N, of the free carrier contributing to the metallic conductivity is given as follows,

$$N = \omega_p^2 m^*/(4\pi e^2). \tag{22}$$

The number density of the free carrier in the metallic $(CH)_x$ film can be extracted by substituting the observed plasma frequency and the effective mass, m^*, into Eq. 22 and is shown in Table 1. The observed number density, N, is comparable with the total π-electron number density ($N \simeq 2 \times 10^{22}\ cm^{-3}$) in the $(CH)_x$ film. This means that all π-electrons contribute to the transport and that heavily doping removes the bond alternation leading to a uniform bond lengths.

Furthermore, the d.c. conductivity, σ_0, is given by Eq. 23,[19]

$$\sigma_0 = \frac{\omega_p^2\tau_0}{4\pi} \tag{23}$$

and is calculated by using the observed plasma frequency, ω_p, and relaxation time, τ_0. The obtained values are comparable with the observed value ($\sigma \simeq 280$—$250\ \Omega^{-1}\ cm^{-1}$) of the d.c. conductivity of the heavily doped films as is shown in Table 1.

The Preparation and ^{13}C-NMR Spectra of Alkoxymethyltriphenylphosphonium Salts

Yoshihisa YAMAMOTO* and Zenjiro KANDA

Faculty of Pharmaceutical Science, Higashi Nippon Gakuen University, Ishikari-Tobetsu, Hokkaido 061-02

(Received May 12, 1980)

Alkoxymethyltriphenylphosphonium salts, $[(C_6H_5)_3PCH_2OR]X$, X: Cl, Br, and I, R: CH_3, C_2H_5, and i-C_3H_7, have been obtained from the reaction of the triphenylphosphine and the corresponding alkyl halomethyl ether. In the ^{13}C-NMR spectra of these salts, the coupling constant (J_{CP}) is 68—71 Hz, which is larger than that (J_{CP}: 48—56 Hz) of $[(C_6H_5)_3PCH_2R]Br$, R: H, CH_3, and i-C_3H_7, Me_3P=S and Me_3P=Se, while it is close to that (66—69 Hz) of Me_3P=O and Et_3P=O. The coupling constant (J_{CP}) of these salts can be caused by the oxygen atom in the salts.

Although the ^{1}H-NMR spectra of methoxymethyltriphenylphosphonium chloride[1] has already been described, the ^{13}C-NMR spectra of alkoxymethyltriphenylphosphonium salts and alkyltriphenylphosphonium salts, except for methyltriphenylphosphonium salt,[2,3] have been the subject of little research.

Previously we have reported on several ylides and Ib-group (Cu,[4] Ag,[4] and Au[5]) or IIb-group[6] (Zn, Cd, and Hg) metal complexes. The present paper will deal with the preparation and ^{13}C-NMR measurements of alkoxymethyltriphenylphosphonium salts, $[(C_6H_5)_3PCH_2OR]X$, X: $[Ag(CN)_2]$, $[Au(CN)_2]$, Cl, Br, and I, R: CH_3, C_2H_5, and i-C_3H_7, and with the ^{13}C-NMR measurements of alkyltriphenylphosphonium salts, $[(C_6H_5)_3PCH_2R]Br$, R: H, CH_3, and i-C_3H_7.

Results and Discussion

Synthesis and Properties. Methoxymethyltriphenylphosphonium salt[1,7] (**1a**, **1b**, and **1c**) and ethoxymethyltriphenylphosphonium salt (**1d**) were prepared by the reaction of triphenylphosphine and the corresponding alkyl halomethyl ether. Isopropoxymethyltriphenylphosphonium bromide (**1e**) was prepared by the reaction of the triphenylphosphine and the bromomethyl isopropyl ether. The alkoxymethyltriphenylphosphonium dicyanoargentate(I) (**2a**—**2c**) and alkoxymethyltriphenylphosphonium dicyanoaurate(I) (**3a**—**3c**) were synthesized by the reaction of **1b**, **1d**, or **1e** and potassium dicyanoargentate(I)[8] or potassium dicyanoaurate-(I)[9] respectively.

$$[(C_6H_5)_3PCH_2OR]Br \xrightarrow{K[M(CN)_2]} [(C_6H_5)_3PCH_2OR][M(CN)_2]$$

R	CH_3	C_2H_5	i-C_3H_7
	1b	**1d**	**1e**

M: Ag, Au

M	R: CH_3	C_2H_5	i-C_3H_7
Ag	**2a**	**2b**	**2c**
Au	**3a**	**3b**	**3c**

$$\xrightarrow{NaNH_2 \text{ or } NaH} (C_6H_5)_3P{=}CHOR$$

4 (in solution)

These salts are soluble in most organic solvents, but are insoluble in ether, ethyl acetate, and benzene.

Attempts at the isolation of the alkoxymethylidenetriphenylphosphorane (**4**) from the reaction mixture of **1a**—**1e** and $NaNH_2$ or NaH in dry THF have been unsuccessful, probably because the electron density of ylide carbanion of **4** is too high, as compared with other unstable alkylidenetriphenylphosphoranes,[4,10] to allow its existence. At present, the ylide **4**[7,11,12] can never be isolated from the solution.

NMR Spectra. The ^{1}H-NMR spectra of **1a**—**1e**, **2a**—**2c**, and **3a**—**3c** were measured in $CDCl_3$ at room temperature. In the ^{1}H-NMR spectrum of **3a**, the signal (3.67 ppm) at the highest field is assigned to the methyl protons of the OCH_3 group. The signal of 5.28 ppm is assigned to the methylene protons of the PCH_2 group. The multiplet signal of 7.8 ppm at the lowest field is assigned to the protons of the phenyl groups. The coupling constants (J_{HCP}: 4 Hz) of the methylene protons of **1a**—**1e**, **2a**—**2c**, and **3a**—**3c** are much smaller than those ($J_{HCP} \approx 13$ Hz) of the alkyltriphenylphosphonium salts, $[(C_6H_5)_3\overset{+}{P}CH_2R]$, R: H (**5a**),[3,13] CH_3 (**5b**),[13] and i-C_3H_7 (**5c**),[13] of tetracovalent phosphorus, as is shown in Table 1. Hendrickson, *et al.*[1] explained the small coupling constant (4 Hz) of **1b** by assuming that the oxygen was partially bound to the positive phosphorus. The coupling constant (J_{HCP}) of $[(C_6H_5)_3PCH_2SeC_6H_5]Br$ (**6**) is 7 Hz,[14] which is also small. The selenium atom in **6** may interact with the positive phosphorus center, but the interaction can be weaker than that of **1a**—**1e**, **2a**, and **3a**, because the coupling constant of **6** is larger than those of these salts.

The ^{13}C-NMR spectra of **1a**—**1e**, **2a**, **3a**, and **5b**—**5c** have also been measured in $CDCl_3$ at room temperature. The doublet signals (10.1—29.2 ppm) at the highest field of **5a**—**5c** are assigned to the carbon of the $PCH_{2(3)}$ group. The chemical shift (10.1 ppm) of the methyl carbon of **5a** is much higher than that (29.2 ppm) of the methylene carbon of **5c**, while the coupling constant (J_{CP}: 56.6 Hz) of the methyl carbon of **5a** is larger than that (47.9 Hz) of the methylene carbon of **5c**. These changes seem to be due to the substituent (R) effect of $[(C_6H_5)_3\overset{+}{P}CH_2R]$; *i.e.*, the isopropyl group of the substituent in **5c** has a greater electron-donating effect than does the hydrogen of **5a**. In the ^{13}C-NMR spectra of **3a**, the doublet signal of 62.9 ppm is assigned to the carbon of the OCH_3 group, and the doublet signal of 66.3 ppm is assigned to the carbon of the PCH_2 group, while the singlet signal of 151.2 ppm is assigned to the cyano carbon of the $[Au(CN)_2]$ ion. The chemical shifts (δ CH_2P: 62—66 ppm) of **1a**—**1e**, **2a**, and **3a** are much lower than those of **5a**—**5c**. The coupling constants (J_{CP}) of these salts are 68—71 Hz, larger than those (48—56 Hz) of **5a**—**5c**, Me_3P=S,[15] and Me_3P=Se,[15] but close to that (66—69 Hz) of

Table 1. ^{1}H-NMR spectra of alkoxymethyltriphenylphosphonium salts

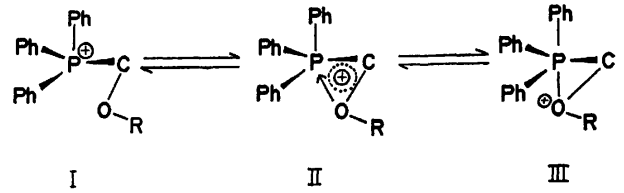
$K[Au(CN)_2]$[a]											154.1s

Solvent and standard: $CDCl_3$ (δ=77.1 ppm). a) D_2O and internal dioxane (δ=67.4 ppm).

$Me_3P{=}O$[16] and $Et_3P{=}O$.[16] The large coupling constants (J_{CP}) of these salts can be caused by the highly electronegative[17] oxygen in salts. As the oxygen atom and the positive phosphorus center in these salts come close to each other and interact, the 2p electrons of the oxygen atom are partially bound to the 3d-orbital of the positive phosphorus. Thus, the positive charge is delocalized over the P——C system, and the phosphorus is considered to be formally pentacovalent (Formulae II and III) with the dsp^3 configuration from the Formulae I—III. The chemical shifts and the coupling constants of **1a—1e**, **2a**, and **3a** receive less influence from the substituent. The anion in these salts has no effect on the chemical shift or the coupling constant. The ^{13}C-NMR data of these salts are collected in Table 2.



I II III

Experimental

Measurements. The NMR spectra were measured with an FX-60 spectrometer (JEOL) for ^{13}C-NMR, and with JNMPMX-60 (JEOL) and R-40 (Hitachi) spectrometers for ^{1}H-NMR.
