It has been established that a protic solvent often shifts the CT absorption band to the blue side.[5] However, the direction of the TFAA solvent shift, defined by Eq. 2, is obviously the opposite of that expected on going from DCM to a protic solvent. The primary effect of TFAA on the intramolecular CT bands is totally different from that of familiar protic solvents. On the other hand, the strong hydrogen-bonding ability of TFAA has been proved by C-13 NMR investigations of various ketones.[22] The chemical shifts show that TFAA molecules attach selectively to carbonyl oxygens in a hydrogen-bonding manner. Sep *et al.* also observed such an effect on acid anhydrides by means of C-13 NMR spectrometry.[21] In this sense, TFAA is in marked contrast to ethanol, which may act as a proton acceptor rather than as a proton donor.[23] The same situation must be true in the present case. The $\Delta h\nu_{ICT}$ quantity can, hence, be interpreted as due to hydrogen bonding between the solute and the solvent molecules.

Here, we should note that, when hydrogen bonding effectively occurs between solvent molecules and a molecule of the type shown in Table 1, the acceptor ability related to the LUMO of the solute is improved because of the increased core charge on each carbonyl oxygen.[21] The donor ability related to the HOMO can, nevertheless, be expected to remain almost unchanged because of the geometrical HOMO-LUMO separation. Therefore, the energy shift of the intramolecular CT band in TFAA can be ascribed mostly to a change in the electron affinity of the acceptor part.

By analogy with Eq. 1, the following expression may hold for intramolecular CT compounds with common donor parts:

$$h\nu_{ICT} = -a_2E_a + b_2, \quad (3)$$

where E_a is the electron affinity of the acceptor part and where a_2 and b_2 are constants characteristic of the common donor part. In the CT-excited state, the charge on the donor part decreases to the same extent as the charge on the acceptor part increases. As both a_1 in Eq. 1 and a_2 in Eq. 3 are determined principally by the degree of charge transfer,[18,19] we can assume that a_2 is close to a_1 for the same group of intramolecular CT compounds. Thus, the change in the acceptor electron affinity on going from DMC to TFAA can be evaluated as:

$$\Delta E_a = -\Delta h\nu_{ICT}/a_1. \quad (4)$$

By the use of experimental values for $\Delta h\nu_{ICT}$, an increase in the electron affinity of the methyleneindandione part, on the average, is calculated to be 0.41 eV in TFAA. A larger amount of change in electron affinity is conceivable for 2-(1-naphthyl)-*p*-benzoquinone in TFAA.

It has been inferred from analogous bathochromic shifts of the intermolecular CT bands that the electron

affinities of typical acceptor molecules in association with anthracene might also be enhanced in the same solvent.[21] However, in the case of binary CT complexes, the position and the orientation of an acceptor, relative to those of a donor, are not firmly fixed in the solution phase because the binding energy between the two components is very small.[1] Both components must be fluctuating rather independently as a result of thermal agitation. Strong hydrogen bonding may further deform the shape of the complex when it is dissolved in TFAA. For binary CT complexes, a linear portion in the band-peak versus solvent-composition curve has an appreciable slope, although the same pair of solvents (*i.e.*, TFAA and DCM) are employed[21]. This may reflect the nonrigidity of binary CT complexes in solution. On the other hand, the present results on intramolecular CT compounds are mostly free from ambiguities arising from these factors. The distance between the donor and the acceptor is kept unchanged because of the existence of a direct bond between them. Therefore, we might safely say that the shift of an intramolecular CT absorption band is indeed due to the increased electron affinity of the acceptor part, but a similar conclusion with regard to binary CT complexes[21] appears a bit less decisive.

Remarks

In addition to 2-(arylmethylene)-1,3-indandiones and 2-(1-naphtyl)-*p*-benzoquinone, we have examined the solvatochromism of many other compounds of the intramolecular CT type. However, when one or more hetero atoms were present in the π-electron framework of the donor part, it was not easy to analyze the resulting solvation effect in detail. For example, solvent effects on **A5** are not simple because specific interactions occur between solvent molecules and hetero atoms in both the donor and acceptor parts. When more than a small amount of the solvent effect on the acceptor side is cancelled by that on the donor side, it is quite difficult to separate the overall solvent shift between the two sides of the molecule. The absorption spectrum of **A5** in TFAA is totally different from that in DCM. For this reason, the present study had to be limited strictly to intramolecular CT compounds in which there are no hetero atoms in the donor part. The donor parts of these compounds are supposedly inert to the hydrogen-bonding effect of TFAA. Such compounds, each with a single kind of substituent on the acceptor side, were, hence, most suitable for analyzing a specific solvation effect induced by TFAA.

According to the simple CT theory,[1] a vibrational structure of a CT absorption band might be characteristic of the acceptor component because a CT transition may naively be viewed as an electron jump to the LUMO localized in the acceptor.[24] In the present case, the band shape scarcely changes even when a strong hydrogen bonding occurs between solute and solvent molecules. This may imply that the vibrational modes which determine the contour of the intramolecular CT absorption band are little affected by the hydrogen-bond formation. In line with this, there is no drastic change in the absorption intensity, either.

In this context, Kuboyama *et al.* assigned the first absorption band of 4-pyrone to the intramolecular CT transition from the ethereal oxygen to the carbonyl group.[25] The solvent shift induced on going from heptane to 1,1,1,3,3,3-hexafluoro-2-propanol (HFP) is quite large (*ca.* 1200 cm^{-1}). HFP is also a strong hydrogen-bonding solvent.[21] However, the shape of the intramolecular CT band is somewhat deformed in this solvent. This is probably due to a considerable reorganization of the π-electron framework of 4-pyrone, since its whole conjugated system is very compact. The existence of a second, but very weak, absorption band was predicted near the intramolecular CT band;[25] it may also be responsible for the deformation of the CT band.

One of us (J.A.) is grateful to the Ministry of Education, Science, and Culture, Japan, for a Scientific Research Grant-in-Aid (No. 164116).

Polymer Effects under Pressure. IV. The Hydrolysis of Phenyl Esters Catalyzed by α-Chymotrypsin up to 2000 bar[1)]

Yoshihiro TANIGUCHI* and Keizo SUZUKI

Department of Chemistry, Faculty of Science and Engineering, Ritsumeikan University, Kita-ku, Kyoto 603

(Received October 16, 1979)

The rates of the hydrolysis of 2-valeryloxy(C_5)- and 2-heptanoyloxy(C_7)-benzoic acids catalyzed by α-chymotrypsin (α-CHT) were measured at pressures up to 2000 bar at 30 °C and pH 7.8 in a 0.05 M Tris buffer solution. The apparent Michaelis constant, K_m^{app}, was estimated to vary from 5.9 to 9.9 mM, and k_{cat} from 11×10^{-3} to 52×10^{-3} s^{-1}, for the C_5 ester, and K_m^{app}, from 4.7 to 10 mM, and k_{cat} from 37×10^{-3} to 200×10^{-3} s^{-1}, for the C_7 ester, between 1 and 2000 bar. From the pressure dependences of K_m^{app} and k_{cat}, the volume changes accompanying the dissociation of the enzyme–substrate complex and the activation volume for the process of the product formation were calculated to be -6.3 ± 2 and -20 ± 2 cm^3/mol for the C_5 ester and -9.5 ± 2 and -21 ± 2 cm^3/mol for the C_7 ester. The effects of the pressure on the hydrolysis of *p*-nitrophenyl acetate (PNPA) catalyzed by α-CHT have also been measured up to 3000 bar at pH 7.8 in a 0.05 M Tris buffer solution and at 25 °C and 35 °C. The activation volumes were -3 cm^3/mol at 25 °C and -4 cm^3/mol at 30 °C and 25 °C. These results were discussed on the basis of the X-ray study of the enzyme–substrate complex.

Werbin and McLaren[2)] have studied the effect of the pressure on the rate of the α-chymotrypsin-catalyzed hydrolysis of casein and of the L-tyrosine ethyl ester over a limited range of substrate concentrations. The activation volume of the former was -13.8 cm^3/mol for the apparent first-order rate constant, while that of the latter was -13.5 cm^3/mol for the zeroth-order rate constant. Recently Lockyer *et al.*[3)] have studied the pseudo-first-order rate of the hydrolysis of *p*-nitrophenyl esters. The activation volumes for the deacylation of the corresponding acyl-enzymes, were -6, -3, and -2 cm^3/mol for the *p*-nitrophenyl esters of acetic, isobutyric, and pivalic acid respectively. The relationship between these negative volume changes and the mechanism of the enzyme reaction was not clarified in detail. While there was no loss of activity of α-CHT in the pH 7.8 Tris buffer solution after pressure treatment for 1 h at 2000 bar and at 22 °C (this result was also supported by Miyagawa and Suzuki[4)]), it is not clear whether or not α-CHT undergoes reversible inactivation.

In the present study, the enzyme activity was first measured in the hydrolysis of PNPA catalyzed by α-CHT up to 3000 bar at three temperatures. The hydrolysis rate of 2-valeryloxy(C_5)- and 2-heptanoyloxy-(C_7)-benzoic acids catalyzed by α-CHT was measured up to 2000 bar at 30 °C. The results were compared with those of PNPA in order to discuss the reaction mechanism of the α-CHT-catalyzed hydrolysis.

Experimental

Materials. The 2-valeryloxy(C_5)- and 2-heptanolyoxy-(C_7)-benzoic acids were obtained by the method of Hofstee.[5)] The products, recrystallized five times from ethanol, were freed from unchanged 2-hydroxybenzoic acid, as checked by the absorption at 300 nm of 2-hydroxybenzoic acid. C_5 ester: mp 84—85 °C (lit,[5)] mp 86 °C); MS (75 eV); Found: *m/e* 222.0888. Calcd for $C_{12}H_{14}O_4$: M, 222.1082. C_7 ester: mp 72.5—73.0 °C (lit,[5)] 70 °C); MS (75 eV); Found: *m/e* 250.1200. Calcd for $C_{14}H_{18}O_4$: M, 250.1398. The PNPA (Aldrich Chemical Co., Inc.) was recrystallized twice from hexane; mp 79—80 °C (lit,[6)] mp 79.5—80 °C). The α-CHT was obtained from the Nutritional Biochemicals Co. (3× crystallized, Lot #6373). The methanol and acetonitrile were distilled before use.

Apparatus and Procedure. The high-pressure apparatus and procedure have been reported in detail in a previous paper.[1a)] The hydrolysis was performed at pH 7.8 in a 0.05 M Tris-HCl buffer up to 3000 bar for PNPA and up to 2000 bar at 30 ± 0.1 °C for 2-acyloxybenzoic acids. The hydrolysis was monitored by observing the change in the optical density at 400 nm due to the *p*-nitrophenolate ion and at 300 nm due to 2-hydroxybenzoic acid by means of a Hitachi-Perkin Elmer EP 139-type spectrophotometer directly under pressure. The sample cell for the measurement of the UV region was made up of a quartz window, and the pressure-transmitting fluid was silicone oil (Shinetsu Chemicals Co.), which was found to be free from absorbance near 300 nm. The enzyme stock solutions were assayed using PNPA before each experiment. The data used from all the enzyme hydrolyses were taken during the first 30 min of each run.

Results

Hydrolysis of C_5 and C_7 Esters. These esters are hydrolyzed spontaneously in the absence of the enzyme. The rate of the spontaneous hydrolysis was proportional to the ester concentration. Therefore, the rate of hydrolysis in the presence of the enzyme, V_{app}, is separated into two terms, the uncatalyzed rate, V_w, and the enzyme-catalyzed rate, V_{cat}:

$$V_{app} = V_{cat} + V_w. \quad (1)$$

At each pressure, the hydrolysis rates, V_{cat}, for the enzyme reaction obtained by means of Eq. 1 increase with the substrate concentration, then level off at higher concentrations, thus following the Michaelis-Menten kinetics as is shown in Eq 2:

$$E + S \underset{K_m^{app}}{\rightleftharpoons} ES \xrightarrow{k_{cat}} E + P, \quad (2)$$

where E is the enzyme; S, the substrate; ES, the Michaelis complex, and P, the product. When $[E]\ll[S]$, the rate of the product formation is expressed as:

$$V_{cat} = \frac{k_{cat}\cdot[E]\cdot[S]}{K_m^{app}+[S]}, \quad (3)$$

where [E] and [S] denote the enzyme and substrate

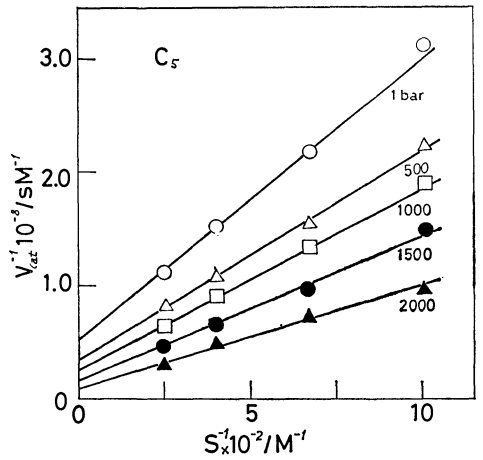

Fig. 1. Lineweaver-Burk plots of the enzyme hydrolysis of C_5 ester at pH 7.8 (0.05 M Tris–HCl) in 9% methanol–water at 30 °C. The enzyme concentration is 2×10^{-6} M.

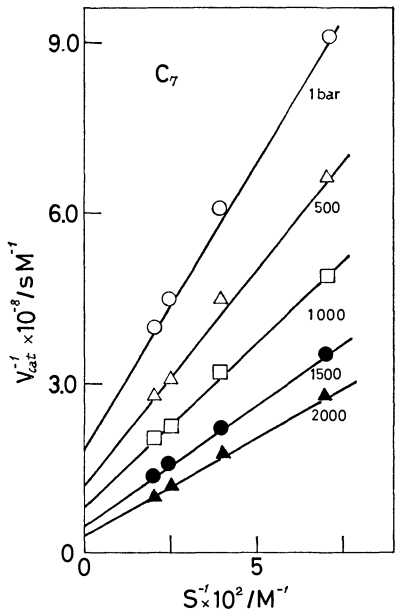

Fig. 2. Lineweaver-Burk plots of the enzyme hydrolysis of C_7 ester at pH 7.8 (0.05 M Tris–HCl) in 9% methanol–water at 30 °C. The enzyme concentration is 2×10^{-6} M.

concentrations. K_m^{app} and k_{cat} were determined by the least-squares method from the Lineweaver-Burk plots between $1/V_{cat}$ and $1/[S]$ in Eq. 4, as is shown in Figs. 1 (C_5) and 2 (C_7):

$$\frac{1}{V_{cat}} = \frac{K_m^{app}}{k_{cat}[E]}\cdot\frac{1}{[S]} + \frac{1}{k_{cat}[E]} \quad . \qquad (4)$$

These values are shown in Table 1. From the linear relationship of the logarithms of K_m^{app} and of k_{cat} *vs.* the pressure established in Figs. 3 and 4, the volume change ΔV accompanying the dissociation of the Michaelis complex and the activation volume, ΔV^*, accompanying the process of the product formation were determined to be -6.3 ± 2 and -20 ± 2 cm³/mol for

the C_5 ester -9.5 ± 2 and -21 ± 2 cm³/mol for the C_7 ester respectively.

Hydrolysis of PNPA. PNPA is also hydrolyzed spontaneously in the absence of the enzyme. The rate of the spontaneous hydrolysis is proportional to the PNPA concentration. Therefore, the enzyme rate, V_{cat}, was obtained by means of Eq. 1. When $[E]\ll[S]$ at PNPA concentrations higher than $[S]=1.6\times10^{-5}$ M,[6] the reaction rate can be considered to be substrate-independent and to be proportional to the enzyme concentration. At each pressure, the rate constants, k_{cat}, were obtained by means of Eq. 5:

$$k_{cat} = V_{cat}/[E]. \qquad (5)$$

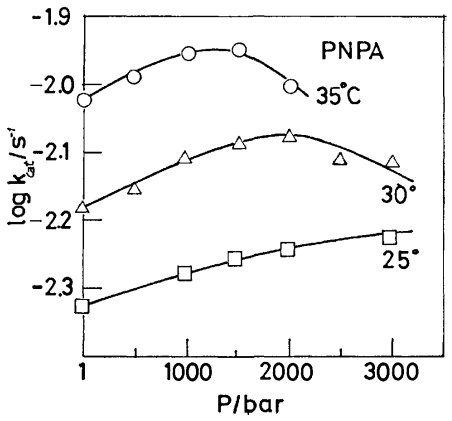

Fig. 5. Pressure effects of log k_{cat} for enzyme hydrolysis of PNPA at pH 7.8 (0.05 M Tris-HCl) in 1.6% acetonitrile–water at 25 °C, 30 °C, and 35 °C, respectively. The enzyme concentration is 2×10^{-6} M, and PNPA concetration is 9.56×10^{-5} M.

The relationship between the logarithm of k_{cat} and the pressure at 30 °C and 35 °C in Fig. 5 shows the maxima at a certain pressure, while at 25 °C it simply increases up to 3000 bar. Lockyer *et al.*[3] reported that the value of log k_{cat} for PNPA increases linearly up to 2000 bar at 20 °C and that the activation volume is −6 cm³/mol. Therefore, phenomena in which the k_{cat} values decrease above a certain pressure (2000 bar at 30 °C and 1500 bar at 35 °C) indicate the loss of the activity of α-CHT under pressure. This interpretation is also directly supported by a recent study of the pressure denaturation based on the measurement of the fluorescence of α-CHT up to 5000 bar.[7] The activation volumes at 1 bar are −3 cm³/mol at 25 °C and −4 cm³/mol at 30 °C and 35 °C respectively.

Discussion

In the hydrolysis catalyzed by α-CHT, the pathway containing acylation and deacylation is shown by Eq. 6:

$$\begin{array}{l} E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ES \xrightarrow{k_{acyl}} Acyl\text{-}E + P_1 \\ \qquad\qquad\qquad\qquad\qquad\quad \Big\downarrow k_{deacyl} \\ \qquad\qquad\qquad\qquad\qquad\quad E + P_2. \end{array} \tag{6}$$

The kinetic parameters can, then, be expressed by:

$$K_m^{app} = K_m \cdot k_{deacyl}/(k_{acyl}+k_{deacyl}), \tag{7}$$

$$k_{cat} = k_{acyl} \cdot k_{deacyl}/(k_{acyl}+k_{deacyl}), \tag{8}$$

where:

$$K_m = (k_{-1}+k_{acyl})/k_1. \tag{9}$$

Then,

$$K_m^{app} = K_m \cdot k_{cat}/k_{acyl}. \tag{10}$$

From the pressure dependences of K_m^{app} and k_{cat}, ΔV and ΔV^* are given by the following equations:

$$\Delta V = \Delta V_m + \Delta V^* - \Delta V^*_{acyl}, \tag{11}$$

$$\Delta V^* = \Delta V^*_{acyl} + \Delta V^*_{deacyl} + RT\partial \ln (k_{acyl}+k_{deacyl})/\partial P. \tag{12}$$

From the study of the pH effect on the hydrolysis of 2-acyloxybenzoic acids catalyzed by α-CHT, Hofstee[8] suggested that the rate-determining step for the overall reaction of the rate constant, k_{cat}, is the acylation. The k_{acyl} value is nearly equal to the k_{deacyl} for 2-acyloxybenzoic acids catalyzed by α-CHT because the k_{cat} values for C_5 and C_7 esters, as shown in Table 1, are approximately half of the k_{deacyl} values: 16.8×10^{-3} s^{-1} for the C_5 ester and 69×10^{-3} s^{-1} for the C_7 ester,[9] respectively. The ΔV^* values of −20 cm³/mol for the C_5 ester and −21 cm³/mol for the C_7 ester at 30 °C agree with those of −20 cm³/mol, accompanied by the hydrolysis of 3-nitro-4-butyryloxybenzoic acid (NBBA) and 3-nitro-4-valeryloxybenzoic acid (NPeBA) catalyzed by the copolymer of 1-vinyl-2-methylimidazole with 1-vinylpyrrolidone (MI-VP),[1a] in which the deacylation process is not the rate-determining step, at least. In the hydrolysis of the PNPA ester, in which the deacylation process is the rate-determinig step,[6] the ΔV^* values are −3 cm³/mol at 25 °C and −4 cm³/mol at 30 °C and 35 °C. The difference in the sizes of the activation volume between the two process, acylation and deacylation, is of interest.

The detailed mechanism of the charge-relay system accompanying the acylation and the deacylation of α-CHT was proposed by Blow *et al.*[10] Following the model of the acylation step in Fig. 6, the formation of one hydrogen bond between the NH group of the imidazole ring of His-57 and the carbonyl oxygen atom of the substrate, and one covalent bond between the alkoide anion of Ser-195 and the carbonyl carbon atom of the substrate is expected to be established on the transition state, accompanied by the formation of the tetrahedral intermediate between the substrate and α-CHT. The volume changes accompanying the formation of such bonds are established to be about from −10 to −15 cm³/mol for one covalent bond[11,12] and from −5 to −7 cm³/mol for one hydrogen bond.[13,14] Therefore, the value of −20 cm³/mol accompanying the acylation process, which is independent of the length of the alkyl chain of the substrate, is reasonable.

In the deacylation step shown in Fig. 7, at first there occur the formation of one covalent bond between the oxygen atom of the H_2O molecule and the carbon atom of the carbonyl group, and the rupture of one covalent bond, accompanied by the release of the acyl group from acyl-α-CHT. Secondly, there occur a breaking of the weak interaction (ionic bonds, hydrogen bonds, and hydrophobic interactions) between the acyl group and the side-chain groups of amino acids around the active center of α-CHT. As the volume change, accompanied by the appearance and the disappearance of covalent bonds, can be expected to cancel each other out, the observed activation volumes for each substrate, −13 cm³/mol for L-tyrosyl-,[2] −7 cm³/mol for 3-(3-indolyl)-acryloyl-,[15] −6 to −4 cm³/mol for acetyl[3] −3 cm³/mol for isobutyryl,[3] and −2 cm³/mol for pivaloyl-α-CHT,[3] would come from the latter term. The differences in these volume changes can be discussed from the point of view of the detailed structure of the active center of acyl-α-CHT, as determined in the X-ray studies.

From the structure of 3-(3-indolyl)acryloyl-α-CHT

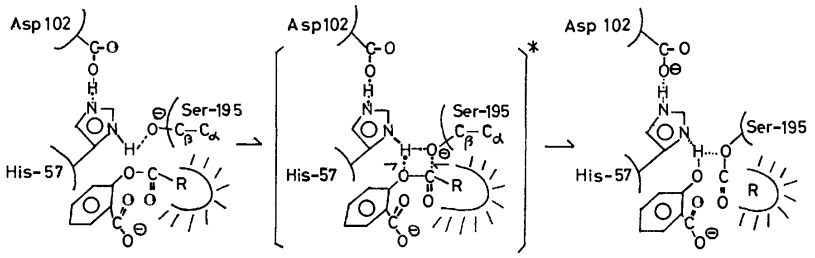

Fig. 6. Modified mechanism for the acylation step of α-CHT proposed by Blow *et al.*, (1969). R is the alkyl chain.

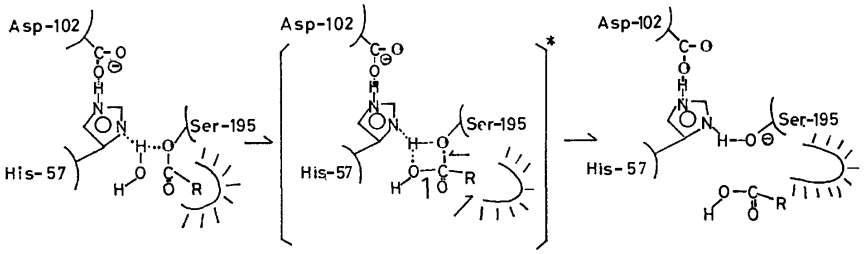

Fig. 7. Modified mechanism for the deacylation step of acyl-α-CHT proposed by Blow *et al.*, (1969). R is the alkyl chain.

determined by Henderson,[16] it is clear that one H_2O molecule acts as a hydrogen bond bridge between the acyl oxygen atom and the NH group of the imidazole ring of His-57 and that the indole ring exists in the hydrophobic cavity. Simultaneously with rupture of the hydrophobic interactions in the deacylation process, the NH group of the indole ring is freed from hydrophobic interaction and can form a hydrogen bond with a H_2O molecule. If a hydrogen bond connected to the carbonyl oxygen atom does not change, the value of -7 cm^3/mol for the 3-(3-indolyl)acryloyl group corresponds to the formation of a hydrogen bond between the NH group of indole and a H_2O molecule, because the rupture of such hydrophobic interaction does not contribute to the volume change; *i.e.*, the volume change accompanied by the formation of hydrophobic interaction containing the benzene ring is nearly zero.[17]

In the deacylation of L-tyrosinyl-α-CHT, the OH group of tyrosine ($pK_a=10$) ionizes when the tyrosine residue is transferred from the hydrophobic cavity of α-CHT to the pH 7.8 buffer solution. The volume change accompanied by the ionization of the tyrosine residue was estimated to be -11.3 cm^3/mol from the study of the pressure effect on the ionization of *p*-nitrophenol.[18] Therefore, the value of -13 cm^3/mol can be explained as being due to the ionization of the tyrosine residue.

The volume changes accompanying the deacylation of acyl (acetyl, isobutyryl, pivaloyl, valeryl, heptanoyl)-α-CHT come mainly from the rupture of the hydrophobic interaction between the alkyl chain of acyl-α-CHT and the hydrophobic cavity of α-CHT. This view is supported by the two facts of a negative volume change accompanied by the rupture of the hydrophobic interaction[19] and of the observed negative values of the experimental activation volume for the deacylation of acyl-α-CHT. Moreover, the observed binding constants of the esters and α-CHT increase with an increase in the length of the alkyl chain of the acyl group up to the size of C_7, which is the optimum hydrocarbon chain.[8] Therefore, it is to be expected that the longer the hydrocarbon chain, the more negative the value of the volume change will be on the rupture of hydrophobic interaction. The expected volume change is -6.3 cm^3/mol for the C_5 ester and -9.5 cm^3/mol for the C_7 ester, judging from a study of the pressure effect on K_m^{app} to be described later. As the value of -20—-21 cm^3/mol accompanying the process of the product formation is too small to explain the rupture of the hydrophobic interaction between the acyl groups of the esters and the hydrophobic pocket of α-CHT, the rate-determining step in this experimental system seems not to be the deacylation step. On the other hand, the amount of the volume change expected from the rupture of hydrophobic interaction between the acetyl, isobutyryl, or pivaloyl group and the hydrophobic pocket of α-CHT is opposite to the experimental results (-6 to -4 cm^3/mol for acetyl, -3 cm^3/mol for isobutyryl, and -2 cm^3/mol for pivaloyl)[3]; *i.e.*, the larger the hydrophobicity of acyl groups, the less negative the value of the activation volume. This fact can be explained in terms of the relationship between the molecule size of acyl groups and the size of the hydrophobic pocket of α-CHT. The X-ray study of Steitz *et al.*[20] determined the size of the pocket to be approximately 1.0—1.2 nm × 0.55—0.65 nm × 0.33—0.45 nm. The van der Waal's radius of the acetyl group is 0.40 nm, while those of isobutyryl and pivaloyl are over 0.5 nm. Therefore, the acetyl group can fit into the pocket, but the bulky groups of isobutyryl and pivaloyl are too large to do so. The ΔV^* values, which are -4 to -6 cm^3/mol for acetyl, -3 cm^3/mol for isobutyryl, and -2

cm^3/mol for pivaloyl groups, are explained by the ratio of the hydrophobic contact of the acyl groups of the esters to the hydrophobic pocket of α-CHT.

When the acylation step is the rate-determining one, the value of K_m^{app} is found by Eq. 7 to be equal to the value of K_m. If k_{-1} were larger than k_{acyl} is Eq. 9, the value of K_m would be the true dissociation constant of the Michaelis complex. The values of -6.3 cm^3/mol for the C_5 ester and -9.5 cm^3/mol for the C_7 ester correspond to the volume change accompanying the dissociation of the Michaelis complex. The amino acids surrounding the hydrophobic pocket in contact with the acyl group through the hydrophobic interaction are Met-195, Val-213, and Try-215. As the contribution of such aromatic compounds as Try-215 to the volume change accompanied by the formation of the hydrophobic interaction is negrigibly small (nearly zero),[17] the average number of the alkyl chain of the side chains of Met-195 and Val-213 is three. Therefore, the estimated volume change for the interaction between the hydrocarbon part of C_3 and the valeryl or heptanoyl groups are in the range of -5 to -10 cm^3/mol, as established by the study of the model compounds.[19] Thus, the driving force of the association of the substrate to the enzyme, α-CHT is shown to be primarily the hydrophobic interaction, as has already been described.

It is concluded that the negative volume change accompanying the dissociation of the Michaelis complex is due primarily to the hydrophobic interaction between the substrates and α-CHT. The value of ΔV^*_{acyl} is explained by the formation of the tetrahedral intermediate in the transition state of the acylation process. These values of ΔV^*_{deacyl} are derived by breaking weak interactions between the acyl groups and side-chain groups of amino acids around the active center of α-CHT, as deduced from the X-ray study of the enzyme-substrate complex.

One of the present authors (Y. T.) is grateful for financial support from the Matsunaga Memorial Science Foundation. We are both also grateful to Dr. R. K. Williams, University of Guelph, Canada, for his advice and continuous encouragement; to Dr. S. Kunugi, Kyoto University, for his advice, and to Miss K. Saeki, Kobe Women's College of Pharmacy, Japan, for the measurement of the molecular weight of the C_5 and C_7 esters using the mass spectrometer.

Chiral Mesophases of 12-Hydroxyoctadecanoic Acid in Jelly and in the Solid State. I. A New Type of Lyotropic Mesophase in Jelly with Organic Solvents

Taro TACHIBANA,* Tomoko MORI, and Kayako HORI*
Department of Chemistry, Ochanomizu University, Otsuka, Bunkyo-ku, Tokyo 112
(Received October 26, 1979)

Thermally reversible jellies of optically active 12-hydroxyoctadecanoic acid (12HOA) with CCl_4 or aromatic solvents form a lyotropic mesophase, which shows enantiomeric circular dichroism (CD) and induced CD due to achiral molecules added to the jellies, indicating that the jellies have a supramolecular helicoidal structure. The X-ray examination revealed that the jellies are composed of a number of small, ordered domains with such a lamellar structure as is observed in the crystalline solid. The supramolecular helicoidal structure was associated with the lamellar structure; as a result, it was suggested that the lyotropic mesophase has a chiral smectic structure and, furthermore, that the mesophase is present in thin, fibrous aggregates of 12HOA molecules within which the jellies are enmeshed.

Optically active 12-hydroxyoctadecanoic acids (12HOA) form thermally reversible jellies with aromatic solvents or carbon tetrachloride, while the racemic 12HOA separates out as crystals from the saturated solution in these solvents. We have recently found that the jellies present images very similar to that of the liquid crystalline phase under a polarizing microscope, and that they exhibit an enantiomeric circular dichroism (CD) in a region of wavelengths where the molecules have no absorption.[1] These hitherto undescribed observations led us to infer that the jellies form a lyotropic mesophase with a supramolecular chiral structure. The best-known example of such mesophases is a cholesteric (chiral nematic) mesophase formed by such synthetic polypeptides as poly(γ-benzyl glutamate) (PBG) in organic solvents.[2] Lyotropic mesophases with a cholesteric structure composed of a low-molecular-weight compound were recently reported for swelling gels of *N*-acylamino acids in aromatic solvents.[3] We found that the jellies of 12HOA were composed of a chiral smectic mesophase structure which exists locally as small domains with randomly-oriented helical axes. This paper will describe a new chiral mesophase, which is different from the cholesteric mesophase of PBG or *N*-acylamino acids.

Experimental

Materials. The crystalline samples of (*R*)-12HOA were purified from commercial products, as has been described previously.[4] The (*S*)-12HOA was prepared by a method described previously from the methyl ester of (*R*)-12HOA.[4] The purities, as estimated from the results of gas chromatography, the melting point, and the specific rotatory power ($[\alpha]_D^{25}$/deg dm^{-1} cm^3 g^{-1} (in pyridine)), of these samples were as follows: (*R*), 99.1%, 353.4 K (lit,[4] 353.6 K), −0.46 (lit,[5] −0.41); (*S*), 97.2%, 352.3 K, +0.44 (lit,[5] +0.3±0.1). The solvents for jelly formation were of a reagent grade and were further purified by the standard method.

Methods. The mesomorphic textures were observed by using an Olympus POM polarizing microscope. The CD spectra were recorded on a JASCO J-20A spectropolarimeter using 1—10 mm thick cells, depending on the concentration (25—120 mmol l^{-1}). The CD were expressed by the molar ellipticity $[\theta]$/deg dm^2 dmol^{-1}. The absorption spectra were measured on a Shimadzu UV-200S spectrophotometer. The X-ray diffraction patterns of jellies were obtained using a Rigaku Rotaflex 2078 diffractometer with Cu $K\alpha$ radiation, with 50 kV and 200 mA. Jellies about 1 mm thick were formed in the opening of an aluminum sample holder and were sandwiched by two poly(ethylene terephthalate) films 7 μm thick. X-Ray diffraction patterns for jellies with benzene were successfully obtained by a transmission method, which was carried out for samples fixed vertically to an incident beam. By this method, the obtained patterns were almost uninfluenced by poly(ethylene terephthalate) films in the range of $2\theta = 1°$—$30°$. However, the transmission method was unsuccessful for jellies with CCl_4 because of the large scattering power of the Cl atoms. In this case, a conventional reflection method was available, but the peaks at low diffraction angles were very much smaller than those for jellies with benzene measured by means of a transmission method, because of the absorption of X-rays due to their long path in a poly(ethylene terephthalate) film cover at a low-angle incidence.

Results and Discussion

Jelly Formation. Chiral 12HOA dissolves readily in aromatic solvents and chlorinated solvents, such as carbon tetrachloride, chloroform, or dichloromethane, at high temperatures. These solutions set to jellies, on cooling, in a reversible way. Jellies with benzene or carbon tetrachloride are almost transparent; therefore, these are used as samples for optical studies. Solutions above 25 mmol l^{-1} in carbon tetrachloride and above 33 mmol l^{-1} in benzene set to jellies at 25 °C. The transition between solution and jelly occurred over a narrow temperature range and showed hysteresis because of the slow rate of the transition. The jellies were thixotropic, indicating that the jelly structure is held by weak bondings.

According to our previous infrared spectroscopic study,[6] the jellies are held by molecular association involving intermolecular hydrogen bonding in which almost all the hydroxyl groups take part; isotropic solutions of chiral 12HOA in carbon tetrachloride exhibited the absorption bands due to the free hydroxyl groups in addition to the absorption bands due to the hydrogen-bonded hydroxyl groups, while the jellies gave only the absorption bands due to the hydrogen-bonded

hydroxyl groups. Furthermore, the infrared spectral results led us to conclude that the hydroxyl groups link the chiral molecules by multiple hydrogen bonding, forming long sequences of hydrogen bonds. Such hydrogen bonding was also found for both the crystalline solids and the built-up multilayers, and it was assumed to exist also in the monolayers at the air-water interface.

When hot solutions of 12HOA were rapidly cooled in an ice-bath, the jellies thus formed were found to scatter a bluish light, which disappeared at room temperature after a short period. This indicates a heterogeneous structure of the jellies; the scattering centers grow to such various sizes that the centers scatter light over a wide range of wavelengths. A bluish scattering light was also observed for the crystalline powder of 12HOA immersed in benzene or carbon tetrachloride. This indicates that the dissolution of crystals of 12HOA into the solvents occurs through the jelly formation.

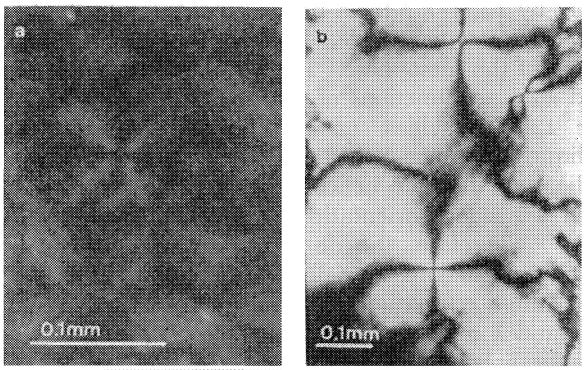

Fig. 1. Microscopic textures of jellies of (*R*)-12HOA–CCl_4 between crossed polarizers.
(a): Spherulitic texture (43 mmol l^{-1}); (b): Schlieren texture (318 mmol l^{-1}).

Microscopic Examination. Hot solutions of (*R*)-12HOA in carbon tetrachloride were placed between two glass plates and cooled to room temperature. The resultant thin films of the jellies were examined by means of a polarizing microscope. The jellies were birefringent; however, the sign of birefringence was not determined because of the difficulty of preparing the oriented single domain samples. The jellies displayed a spherulitic or Schlieren texture between crossed polarizers. The microscopic textures are shown in Fig. 1. The surface treatment of supporting plates had no effect on these textures. There was a general tendency for the spherulitic texture to occur in the jellies prepared by the slow cooling of the solutions of a lower concentration and for the Schlieren texture to occur in the jellies prepared by the rapid cooling of the solutions of a higher concentration. These textures are similar to the patterns observed previously in thermotropic[7] or lyotropic liquid crystals.[8] Thus, the microscopic observation indicates that the jellies have local orders with a mesomorphic structure. Generally, it is difficult to determine from the microscopic texture whether the type of lyotropic mesophase is nematic, smectic, or cholesteric.

The spherulitic domains showed an extinction cross, which was unchanged on the rotation of the stage of the polarizing microscope. The optical sign of the spherulitic domains, as determined by using a sensitive color plate, was negative. A similar spherulite-like phase with optically negative sign has also been observed for the *N*-octadecanoyl-L-glutamic acid–dimethyl phthalate system, which was regarded as a liquid crystalline phase of the cholesteric type.[3]

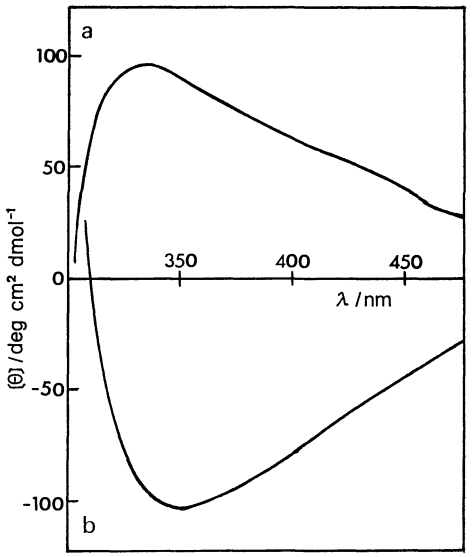

Fig. 2. Enantiomeric CD bands of jellies of 12HOA–CCl_4 at room temp.
(a): (*S*)-12HOA, 25.7 mmol l^{-1}; (b): (*R*)-12HOA, 35.7 mmol l^{-1}.
The location of the CD maximum was insensitive to change of temperature (see Fig. 6).

Circular Dichroic Studies. The jellies exhibited a weak, but definite CD band with a peak around 370 nm, a range of wavelengths in which they absorbed no light. The sign was negative for the *R*-enantiomer and positive for the *S*-enantiomer, irrespective of the solvents used. Figure 2 shows a typical example of the enantiomeric CD bands for jellies of (*R*)- and (*S*)-12HOA with carbon tetrachloride. This enantiomeric relationship was observed quite reproducibly, though the intensities, $[\theta]$, and the locations of the CD maximum, λ_{max}, were rather scattered. This indicates that the CD bands originate from the chirality of the 12HOA molecule. A similar CD spectrum was also observed for jellies with other solvents, such as benzene (λ_{max}: around 480 nm) and toluene (λ_{max}: around 470 nm). Linear dichroism, which is attributable to any strain introduced on jelly formation, was little observed when examination was done by means of the procedure of Tunis-Schneider and Maestre.[9] The observed CD spectrum is thus ascribed to the selective reflection of circularly polarized light in one sence by the chiral jellies. The same optical phenomenon has been observed for cholesteric liquid crystals and explained by assuming a supramolecular helicoidal structure with a twist determined by the chirality of the constituent molecules.[7]

An enantiomeric induced circular dichroism (ICD) could also be observed for some achiral molecules when

they were dissolved in jellies of chiral 12HOA. Figure 3 shows the ICD bands (superimposed on the CD curve of the jelly) and the electronic spectra between 330 and 395 nm for anthracene dissolved in a jelly of (*R*)-12HOA. The ICD bands show a single sign (negative for (*R*)-12HOA and positive for (*S*)-12HOA) and follow the electronic spectral bands closely. Such ICD characteristics have also been observed for lyotropic cholesteric mesophases of PBG[10] and other polypeptides, and more recently for those of *N*-acylamino acids.[3] Figure 4 shows similar ICD results obtained for a cyanine dye, pynacyanole chloride, which was not soluble in carbon tetrachloride, but was solubilizable in solutions or jellies of 12HOA with the same solvent. These ICD results support the assumption that 12HOA jellies are composed of a type of lyotropic chiral mesophase with a supramolecular helicoidal structure.

The dimensions of the structure may be estimated assuming the model of the helicoidal structure proposed by de Vries.[11] The model postulates only a helical stacking of birefringent layers, regardless of whether or not the helicoidal structure is a cholesteric type. The CD band is due to the selectively reflected light with circular polarization in one sense. In this case, λ_{max} is simply related to the pitch, p, of the supramolecular helix by $\lambda_{max}=\bar{n}.p$ for a normal incidence to the layers in a homeotropic sample, where $\bar{n}$ is an average refractive index of the mesophase. For an oblique incidence, $[\theta]$ and λ_{max} are functions of the angle of incidence. For the 12HOA jellies, no angular dependence for an oblique incidence could be found in $[\theta]$ and λ_{max}, indicating that the helicoidal structures are dispersed, with a random orientation of the helical axes in the jelly. Therefore, the de Vries equation can not be strictly applied to the jellies of 12HOA. However, a very rough estimation of p from the observed values of λ_{max} and $\bar{n}$ may be possible. For example, p was 250 nm for a jelly with carbon tetrachloride with $\lambda_{max}=$ 370 nm and $\bar{n}=1.46$, while p was 320 nm for a jelly with benzene with $\lambda_{max}=480$ nm and $\bar{n}=1.50$. Though λ_{max} appeared in a visible wavelength region, the band ranged within a wide region of wavelengths, so that such an iridescent color as was observed for cholesteric liquid crystals was not exhibited. The CD maximum for a jelly sample containing any additive was found to be shifted to a longer wavelength than that for the original jelly. Since little differences in $\bar{n}$ were found between additive-free and additive-containing jellies with carbon tetrachloride (for example, n_D^{22} is 1.4600 for the former and 1.4603 for a jelly containing 8.8 mmol l^{-1} of anthracene), the shift of λ_{max} is ascribed to an increase in the pitch of the helicoid with the incorporation of additive molecules into the helicoidal structures.

The chirality of the chiral mesophase can be found by determining the handedness of the reflected or transmitted light with circular polarization from the CD band (the pitch band). In the case of jellies of (*R*)-12HOA, the sign of the CD is negative, as is shown in Fig. 2, indicating that right-hand circularly polarized light is selectively reflected by the jelly. Therefore, the screw sense of the molecular helical arrangement is right-handed.[12] That is, the sense of the supramolecular helix is right-handed (P-helicity) for (*R*)-12HOA and left-handed (M-helicity) for (*S*)-12HOA.

The above-mentioned results indicate that there is a striking similarity between jellies of 12HOA and typical cholesteric mesophases. However, there are several differences in CD characteristics between two systems.

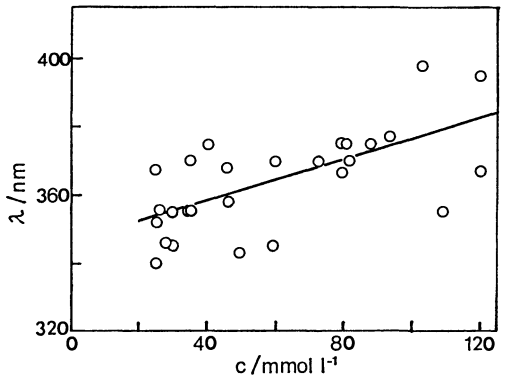

Fig. 5. Concentration dependence of λ_{max} of jellies of (*R*)-12HOA–CCl_4.

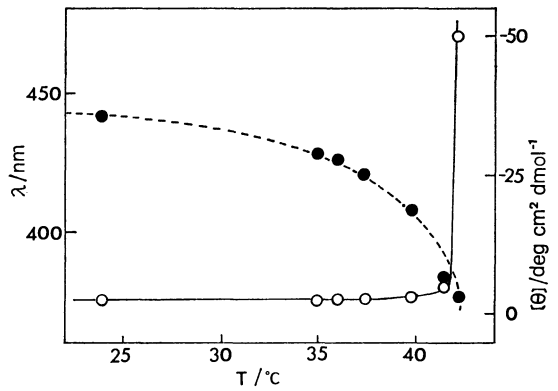

Fig. 6. Temperature dependence of λ_{max} (○) and $[\theta]$ (●) of a jelly of (*R*)-12HOA–CCl_4 jelly (81.7 mmol l^{-1}).
The jelly melted into isotropic soln. at 42 °C.

First, the magnitude of ICD for anthracene is about 2000 deg cm^2 $dmol^{-1}$, which is small compared to the values for thermotropic cholesteric liquid crystals ($\approx 10^6$)[13] and to those for lyotropic cholesteric liquid crystals such as PBG ($\approx 10^4$).[10] Second, the value of λ_{max}, which is related to p, increased slightly with an increase in the concentration of 12HOA, as is shown in Fig. 5. This is quite different from the result observed for the lyotropic cholesteric mesophase of PBG, since Robinson reported[14] that p was proportional to $1/C^2$, where C is the volume fraction of the polymer in the lyotropic cholesteric mesophase. Thirdly, the location of λ_{max} was independent of the temperature in the range from 22 to 41 °C, just below the melting point of the jelly, as is shown in Fig. 6. The temperature independence of λ_{max} is remarkably in contrast with the observations for thermotropic or lyotropic cholesteric mesophases. These facts suggest that the chiral mesophase of 12HOA is different from the chiral nematic phase. Figure 6 shows also that $[\theta]$ decreases rapidly to zero, only when the temperature approaches the melting point of the jelly.

X-Ray Diffraction Studies. Figure 7 shows the X-ray diffraction patterns for jellies with benzene and for a specimen of the crystalline powder of (*R*)-12HOA. The jelly patterns exhibited comparably sharp reflections corresponding to a long spacing of 4.67 nm, together with a wide, diffuse reflection corresponding to a short spacing of 0.46 nm. Similar patterns have often been obtained for lyotropic liquid crystals composed of amphiphilic compounds,[15] in which the values of the long spacing becomes larger with a decrease in the concentration of the solute. However, it was found that, in contrast with such lyotropic liquid crystals, the long spacing obtained for the jellies was almost in accord with that obtained for the crystalline powder, independent of the concentration of 12HOA. Therefore, the jelly pattern obtained is essentially the same as the powder pattern, although the former is, as a whole, broader. This indicates that the jellies are composed of a number of small domains with a lamellar structure similar to that in the crystalline solids, though the diffuse reflection with spacing corresponding to 0.46 nm indicates that the organization of the hydrocarbon chains in the lamellar structure of the small domains in the jellies is less ordered than that in the crystalline solids. The gel patterns are generally known to be similar to the powder patterns, as has been shown, for example, in the case of the aluminum dilaurate–cyclohexane gels.[16]

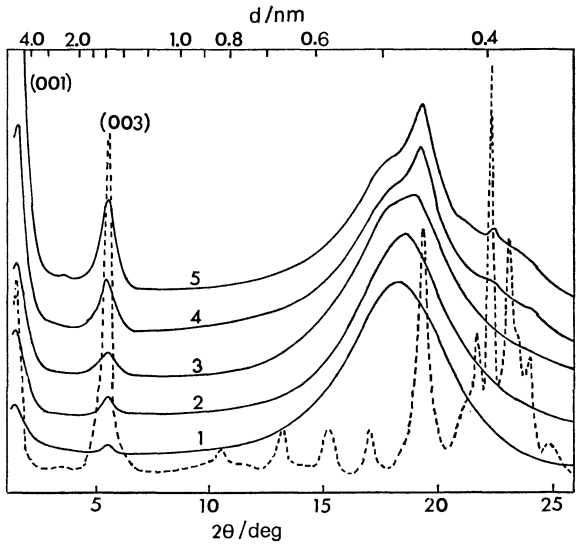

Fig. 7. X-Ray diffraction patterns for jellies of (*R*)-12HOA–benzene (——) and for a specimen of crystalline powder of (*R*)-12HOA (------).
(1) 24.3 mmol l^{-1}, (2) 57.6 mmol l^{-1}, (3) 64.1 mmol l^{-1}, (4) 160 mmol l^{-1}, (5) 257 mmol l^{-1}.

The long spacing, 4.67 nm, is interpreted as the distance between double plane layers of oriented amphiphilic molecules. The extended length of the bimolecule of 12HOA can be inferred from that of octadecanoic acid, which is an analogue of 12HOA. The latter is estimated from the length of the crystallographic c axis, it having been reported to be 4.938 nm for the B-form[17] and 5.07 nm for the C-form.[18] A comparison of these values with 4.67 nm leads us to conclude that, both in small domains in jellies and in crystalline solids, the bimolecules of 12HOA are packed in layers, with the long axis of the molecule tilting at about 21° from normal to the layer plane.

The crystal structure of 12HOA has not been analyzed, because it was not obtained as single crystals of a suitable size. However, a tentative interpretation has been given[6] on the basis of the powder patterns, in combination with the infrared spectral results and the concept of the subcell introduced by Vand.[19] The molecular chains of 12HOA can be closely packed, with a simultaneous formation of hydrogen-bond sequences extending along the b_s axis, in the triclinic subcell, whose dimensions, a_s, b_s, and γ_s, are 0.45 nm, 0.54 nm, and 120°. Assuming the remaining subcell dimensions, c_s, α_s, and β_s, to be 0.26 nm, 70°, and 108°, which are typical values previously reported for triclinic subcells,[20] the short spacings between a_sc_s planes and between b_sc_s planes are calculated to be 0.46 nm and 0.39 nm respectively. These values are consistent with those corresponding to strong reflections observed for the crystalline powder sample, as is shown in Fig. 7.

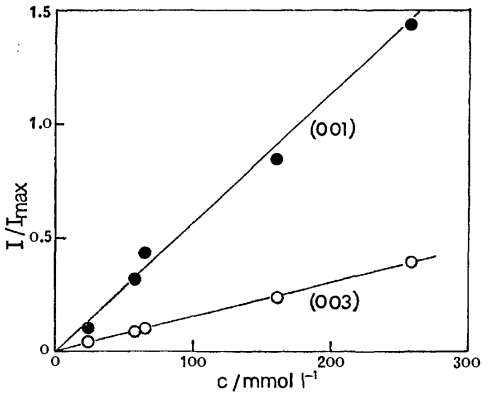

Fig. 8. Concentration dependence of the ratio of the peak height (I) of the (001) or (003) reflection relative to the maximal height (I_{max}) of the reflection corresponding to the short spacings.

The reflection peaks corresponding to the long spacing were found to become greater with an increase in the concentration. For convenience, the ratio of the peak height of the (001) or (003) reflection relative to the maximal height of the wide, diffuse reflection corresponding to a series of short spacings was plotted against the concentration. Figure 8 shows that the ratio is linearly proportional to the concentration, indicating that the lamellar structure becomes more ordered as the concentration is increased. It can also be seen from Fig. 7 that the peak corresponding to a spacing of 0.46 or 0.39 nm, which represents the spacing between a_sc_s planes or between b_sc_s planes respectively, comes to appear on the broad reflection curve with an increase in the concentration. This suggests that a crystalline order develops as the concentration is increased. Similar X-ray results were also obtained for the jellies with carbon tetrachloride by using a reflection method described in the Experimental section.

X-Ray studies were done also for the jellies containing anthracene or pynacyanole chloride, which gave the ICD. On adding the additives, it was found that the reflection peaks corresponding to the long spacing decreased remarkably in intensity without any alternation in the position of the peak, and that the peak of the broad reflection tended to shift slightly to a lower diffraction angle. This fact indicates that the lamellar structure in the jellies becomes less ordered when the additives are included. On the other hand, the CD maximum for the jellies containing any additive shifted to a longer wavelength than that for the additive-free jellies. This shift implies an increase in the helical pitch in supramolecular helicoidal structures, that is, a decrease in the helicoidal order in the jellies. The X-ray studies and the CD results strongly suggest that the supramolecular helicoidal structure exists in the lamellar structure constituting the small domains locally dispersed in the jellies. As has been described previously, the bimolecules of 12HOA in the domains are packed in layers with the long axis of the molecule tilting from normal to the layer. Therefore, one can consider the possibility that tilted chiral amphiphilic molecules of 12HOA in adjacent parallel layers are slightly skewed rather than parallel, so that a helicoidal structure is formed with a helical axis normal to the molecular layers. Such a structure has recently been found[21] in some thermotropic smectic liquid crystals; it is called the twisted smectic C mesophase or the chiral smectic C mesophase. It is thus possible to consider that 12HOA in jellies forms a lyotropic mesophase with a chiral smectic structure, a new kind of mesophase. Further studies are required to establish the details of such a mesophase and to locate the additive molecules which give rise to the ICD by becoming involved into the helicoidal lamellar structure.

Chiral Structure in Jellies. Jellies are composed of a continuous network of molecular aggregates or polymer chains in which the solvent is trapped.[22] The presence of helically twisted fibers in the jellies of 12HOA has been demonstrated by the use of an electron microscope after the removal of the solvent by evaporation.[4] It was then found that fibers were of a uniform thickness of about 10—100 nm and that the pitch of the helical twisting was about 80—1000 nm. There is no doubt that such fibers provide the crystalline domains responsible for the X-ray diffraction, although the fibers enmeshing the jellies may be thinner than the fibers seen by an electron microscope.

A very interesting and relevant question is the relation between the supramolecular helicoidal structure in the chiral mesophase and the macro-helical structure of twisted fibers observed under an electron microscope. With regard to the one enantiomer, the two helices are reversed; in the case of the *R*-enantiomer, the screw sense is right-handed for the chiral mesophase and left-handed for the macro-helix of the fibers. Therefore, the twisting of the fibers itself is not the origin of the CD in the jellies.

When the jellies on the supporting plates are dried, solid films were formed. As will be described in detail in Part 2, the solid films exhibited a CD band and X-ray diffraction patterns similar to those observed in the jellies. Therefore, the molecular arrangement in the solid films is considered to be essentially the same as

that in fibers within the jellies. It may thus be concluded that a chiral smectic structure giving rise to the CD exists in the structure of molecular layers constituting the solid films or the fibers. Such a chiral structure of 12HOA is formed only through the jelly state. It was impossible to obtain the chiral mesophase by heating the crystals or by cooling the isotropic melt.

The optical properties of the chiral smectic mesophase are known to be identical with those of cholesteric mesophases for the normal incidence of light.[23] The same optical properties would be expected to be displayed by the chiral mesophase of 12HOA. However, the fibers of 12HOA are randomly dispersed in the jellies, so that the chiral mesophase in the jellies is present locally as small domains which are dispersed with randomly-oriented helical axes within the jellies. This would explain the broadening and the weak intensity of the observed CD band compared with the effect in planar cholesteric mesophases.

Electron microscopy in our laboratory has shown that large ribbon-like fibers tend to be split into many thinner and helically twisted fibers.[24] This indicates that the double molecular layers of 12HOA are stacked approximately parallel to the direction of the width of the fibers. The helical axis of the chiral smectic structure in the molecular layers is directed to the width of the fibers.

It is also interesting to note that the chiral amphiphilic molecules such as 12HOA form helically organised systems in such different stages as a helical mesophase and helically twisted fibers. A similar relationship has also been seen in the case of synthetic polypeptides; the polymer molecules of the α-helix form a lyotropic cholesteric liquid crystal[2] and helically twisted fibers.[25]

The jellies of chiral 12HOA are a two-phase system, composed of the solvent and the fibers comprising the chiral smectic mesophase. In this point, the jellies of 12HOA are a unique chiral system of matter. This interesting chiral mesophase may provide an asymmetric medium in which any asymmetric reactions can occur.

A Conductance Study of the Complexation Reaction of Dibenzo-24-crown-8 with Alkali Metal Ions in Propylene Carbonate and Methanol

Yasuyuki TAKEDA* and Hisao YANO

Department of Chemistry, Faculty of Science, Chiba University, Yayoi-chō, Chiba 260

(Received November 16, 1979)

The formation constants (K_{ML^+}) for 1:1 complexes of dibenzo-24-crown-8 (DB24C8) with alkali metal ions (Na^+, K^+, Rb^+, and Cs^+) in propylene carbonate (PC) and methanol have been determined conductometrically at different temperatures in order to obtain the values of the enthalpy (ΔH) and entropy changes (ΔS). The complexation reactions between DB24C8 and the alkali metal ions in PC and methanol are all exothermic, and the ΔS values of these systems are all negative. In the case of the PC system, there is no considerable difference in ΔS among the alkali metal ions (Na^+, K^+, Rb^+, and Cs^+); thus, the K_{ML^+} sequences depend entirely on the $-\Delta H$ sequences. Since, in methanol, the $-\Delta H$ and $-\Delta S$ values for K^+ are nearly equal to those for Cs^+, and since the largest $-\Delta H$ value for Rb^+ is balanced by the largest $-\Delta S$ value, DB24C8 shows no selectivity for the alkali metal ions (K^+, Rb^+, and Cs^+) in methanol.

The complexation reaction between dibenzo-24-crown-8 (DB24C8) and metal ions has been investigated by different methods, *e.g.*, calorimetry,[1] conductometry,[2] and solvent extraction.[3] Moreover, solvent extraction with DB24C8 has been used in the separation of barium(II) from strontium(II).[4]

DB24C8 forms stoichiometrically stable complexes with metal ions. They are mostly 1:1 complexes in solution. Since DB24C8, whose configuration is termed cylindrically symmetrical,[5] is a flexible crown ether and has a large cavity size (4.5—5.0 Å[6]), great conformational changes are required to fold around the metal ion on complexation. In the DB24C8 complex, the metal ion held in the cavity is partially wrapped around by DB24C8.[7] The stability of the complexes depends largely on the solvent medium[2] and the flexibility of the DB24C8 ring.[1]

The present study was undertaken in order to understand in detail the thermodynamics of the complexations of DB24C8 with alkali metal ions in nonaqueous solvents. In this paper, the formation constants for 1:1 complexes of DB24C8 with alkali metal ions in propylene carbonate (PC) and methanol have been determined conductometrically at different temperatures in order to obtain the values of the enthalpy and entropy changes.

Experimental

Materials. The method of the purification of DB24C8 (Nisso Co., Ltd.) was as has previously been described.[4] Lithium, sodium, and potassium perchlorates were obtained commercially. Rubidium and caesium perchlorates were prepared by adding an equimolar perchloric acid solution to an aqueous solution of rubidium bromide and caesium chloride respectively. All these perchlorates were recrystallized from water five times and, before use, dried at 150 °C in a vacuum oven. PC was distilled twice under nitrogen at about 12 mmHg. Methanol was allowed to stand in contact with molecular sieves for several days and then distilled twice. In each case of PC and methanol the middle 70% of the distillate was used. The water contents of the finally purified PC and methanol determined by the Karl Fischer titration were less than 0.01 and 0.03% respectively. The conductivities of the final products of PC and methanol were less than 5×10^{-8} and 1×10^{-7} ohm^{-1} cm^{-1} respectively.

Apparatus and Procedure. The conductance measurements were made on a Yanagimoto conductivity outfit, model MY-7, in a thermostated water bath at 10, 15, 20, 25, 30, and 35 ± 0.02 °C. Two cells were used with cell constants of 0.09317 and 0.2046 cm^{-1}.

The experimental procedure to obtain formation constants of DB24C8 complexes with alkali metal ions is as follows; a solution of the alkali metal perchlorate (5×10^{-4} M; 1 M= 1 mol dm^{-3}) 200 cm^3 was placed in the cell (volume 300 cm^3) and the resistance of the solution was measured. Then a step-by-step increase in the DB24C8 concentration was effected by a quick transfer with a pipet from the solution of DB24C8 (PC: 1×10^{-2} M, methanol: 5×10^{-3} M) to the cell, until the total concentration of DB24C8 was about two-and-a-half (methanol) or four times (PC) as large as that of the alkali metal perchlorate. The resistance of the solution in the cell was remeasured after each transfer.

Results

The molar conductivity, Λ, *vs.* $[L]_t/[M]_t$ plots for caesium perchlorate at 10, 15, 20, 25, 30, and 35 °C in PC and in methanol are given in Figs. 1 and 2 respectively, where $[L]_t$ and $[M]_t$ are the total concen-

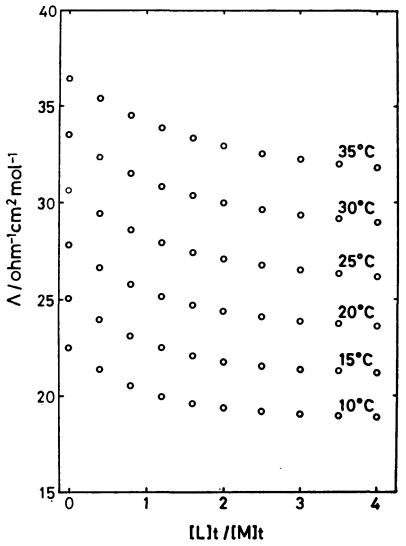

Fig. 1. Λ *vs.* $[L]_t/[M]_t$ plots for caesium perchlorate in PC at different temperatures.
$[M]_t=5\times10^{-4}$ M.

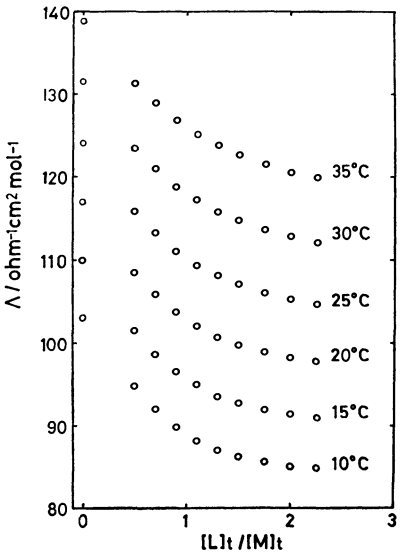

Fig. 2. Λ *vs.* $[L]_t/[M]_t$ plots for caesium perchlorate in methanol at different temperatures.
$[M]_t = 5 \times 10^{-4}$ M.

trations of DB24C8 and the alkali metal ion respectively. The Λ *vs.* $[L]_t/[M]_t$ plots show a decrease in Λ with an increase in the DB24C8 concentration. The experimental plots of the other alkali metal perchlorates in PC and methanol are similar, and so have been omitted. In the cases of the Li^+–PC and methanol and the Na^+–methanol systems, since hardly any change in Λ is found in spite of an increase in the DB24C8 concentration, the conductometric determination of the complex formation constant is impossible. It is assumed that the association between the cation and the perchlorate ion in PC and methanol is negligible under these highly dilute experimental conditions and that, in this work, DB24C8 forms the 1 : 1 complexes with the alkali metal ions in PC and methanol.

The equilibrium equation is given by:

$$\begin{array}{ccccc} M^+ & + & L & \rightleftarrows & ML^+ \\ \alpha[M]_t & & [L]_t-(1-\alpha)[M]_t & & (1-\alpha)[M]_t, \end{array} \quad (1)$$

where M^+, L, and α are the alkali metal ion, DB24C8, and the fraction of free alkali metal ions. Accordingly, the complex formation constant, K_{ML^+}, is defined by:

$$K_{ML^+} = [ML^+]/[M^+][L] = (1-\alpha)/\alpha[L]. \quad (2)$$

The observed conductivity, κ, is written as:

$$\kappa = \kappa_{MClO_4} + \kappa_{MLClO_4}, \quad (3)$$

where κ_{MClO_4} and κ_{MLClO_4} are the conductivities of alkali metal perchlorate and alkali metal DB24C8 perchlorate respectively. The molar conductivities are given by:

$$\Lambda_{MClO_4} = \kappa_{MClO_4}/[M^+] = \kappa_{MClO_4}/\alpha[M]_t, \quad (4)$$

$$\Lambda_{MLClO_4} = \kappa_{MLClO_4}/[ML^+] = \kappa_{MLClO_4}/(1-\alpha)[M]_t, \quad (5)$$

where Λ_{MClO_4} and Λ_{MLClO_4} are the molar conductivities of alkali metal perchlorate and alkali metal DB24C8 perchlorate respectively. As a consequence of Eqs. 4 and 5, Eq. 3 can be transformed into:

$$\Lambda = \kappa/[M]_t = \alpha\Lambda_{MClO_4} + (1-\alpha)\Lambda_{MLClO_4}. \quad (6)$$

Since the DB24C8 concentration was kept low ($<2.5 \times 10^{-3}$ M) during these experiments, corrections for viscosity changes were neglected. As a consequence of Eq. 6, Eq. 2 can be transformed into:

$$K_{ML^+} = (\Lambda_{MClO_4}-\Lambda)/(\Lambda-\Lambda_{MLClO_4})[L], \quad (7)$$

where $[L] = [L]_t - [M]_t(\Lambda_{MClO_4}-\Lambda)/(\Lambda_{MClO_4}-\Lambda_{MLClO_4})$.

The procedure for obtaining the K_{ML^+} value is as follows. The Λ_{MLClO_4} value is estimated from the Λ values at the points of large $[L]_t$ to $[M]_t$ ratios. Using this Λ_{MLClO_4} value, the K_{ML^+} value in Eq. 7 is calculated. The actual K_{ML^+} and Λ_{MLClO_4} values are calculated by a nonlinear least-squares analysis.[8] In each system the K_{ML^+} values increase monotonously with a decrease in temperature. The $\log K_{ML^+}$ *vs.* T^{-1} plot shows a linear relationship for each system. By way of example, the $\log K_{ML^+}$ *vs.* T^{-1} plots for the caesium–PC and methanol systems are given in Fig. 3. The values of the enthalpy change, ΔH, and the entropy

Table 1. $\log(K_{ML^+}/\text{mol}^{-1}\,\text{dm}^3)$, ΔH, and ΔS values for the complexation of alkali metal ions with DB24C8 in various solvents

Crown ether	Cation	Solvent	$\log K_{ML^+}$ (at 25 °C)	$-\Delta H$ / kJ mol^{-1}	$-\Delta S$ / JK^{-1} mol^{-1}
DB24C8	Na^+	PC	4.1_6	$37._7$	$46._0$
		70 wt% CH_3OH in H_2O[1]	1.54	32.4	79.1
	K^+	PC	3.7_3	$34._5$	$44._4$
		CH_3OH	3.5_7	$35._3$	$49._4$
		70 wt% CH_3OH in H_2O[1]	2.42	35.7	73.6
	Rb^+	PC	3.5_5	$32._9$	$42._3$
		CH_3OH	3.8_6	$39._4$	$57._7$
		70 wt% CH_3OH in H_2O[1]	2.55	36.5	73.6
	Cs^+	PC	3.4_6	$32._3$	$42._3$
		CH_3OH	3.8_4	$36._8$	$49._0$
		70 wt% CH_3OH in H_2O[1]	2.48	37.4	77.8
DB30C10[9]	Cs^+	CH_3OH		53.22	95.48

change, ΔS, calculated from these data are summarized in Table 1, together with the $\log K_{ML}^+$ values at 25 °C and the literature values.

Discussion

The complexation reactions between DB24C8 and the alkali metal ions in PC and methanol are all exothermic, and the ΔS values of these systems are all negative (Table 1). DB24C8 is a large crown ether and has a great ligand-ring flexibility. The uncomplexed DB24C8 may be more flexible than the complexed DB24C8. It thus appears that the negative ΔS values are largely attributable to the great conformational changes when a complexation reaction occurs. It may be seen from Table 1 that, in methanol, the ΔS value of Cs^+ for DB24C8, which is smaller than dibenzo-30-crown-10 (DB30C10), is much larger than that for DB30C10. The $-\Delta H$ sequences of the alkali metal ions with DB24C8 in PC are $Na^+ > K^+ > Rb^+ \geq Cs^+$, while those in 70 wt% CH_3OH are completely the reverse. In the case of the DB24C8–PC system, there is no considerable difference in ΔS among the alkali metal ions; thus, the $\log K_{ML}^+$ sequences entirely depend on the $-\Delta H$ sequences (Table 1). Since, in methanol, the $-\Delta H$ and $-\Delta S$ values of DB24C8 for K^+ are nearly equal to those for Cs^+, and since the largest $-\Delta H$ value for Rb^+ is balanced by the largest $-\Delta S$ value, DB24C8 shows no selectivity for the alkali metal ions in methanol. In methanol, the ΔH value of Cs^+ for DB24C8, which has smaller donor oxygen atoms than DB30C10, is much larger than that for DB30C10.

Among the solvents, the $-\Delta S$-value series for the Na^+–, the K^+– and Cs^+–, and the Rb^+–DB24C8 systems are given in the order PC$\ll$70 wt% CH_3OH, PC$<$methanol$\ll$70 wt% CH_3OH, and PC$<$methanol$<$70 wt% CH_3OH, respectively (Table 1). It may be attributed chiefly to the solvent structural influences of methanol and water that, in the case of each alkali metal ion-DB24C8 system, the $-\Delta S$ value increases on moving from PC to 70 wt% CH_3OH. Moreover, in the cases of the K^+, Rb^+, and Cs^+–DB24C8 systems, the large increase in $-\Delta S$ on going from methanol to 70 wt% CH_3OH may be largely due to the stronger water structural influences compared to methanol. For the Na^+–DB24C8 system, the larger $-\Delta H$ and the much smaller $-\Delta S$ values of PC result in the much greater $\log K_{ML}^+$ value compared to 70 wt% CH_3OH. Although, in the cases of the K^+, Rb^+, and Cs^+–DB24C8 systems, there is no considerable difference in ΔH, the K_{ML}^+ values in PC and methanol are as large as one order of magnitude larger than that in 70 wt% CH_3OH. This is largely attributed to the much smaller $-\Delta S$ values in PC and methanol compared to 70 wt% CH_3OH (Table 1). Since, in each case of the K^+ and Cs^+–DB24C8 systems, there are no significant differences in ΔH and ΔS between PC and methanol, the $\log K_{ML}^+$ values in PC and methanol are nearly equal. For the Rb^+–DB24C8 system, the larger $-\Delta H$ value in methanol is canceled by the larger $-\Delta S$ value compared to PC; thus, there is no considerable difference in $\log K_{ML}^+$ in PC and methanol.

TABLE 2. ($\Lambda_{MLClO_4}/\Omega^{-1}$ cm^2 mol^{-1}) VALUES IN METHANOL AT DIFFERENT TEMPERATURES

Temp/°C	Λ_{MLClO_4}		
	K^+	Rb^+	Cs^+
	$[M]_t =$ 5.054×10^{-4} M	$[M]_t =$ 5.044×10^{-4} M	$[M]_t =$ 5.041×10^{-4} M
10	82.41	81.53	82.11
15	88.76	87.39	87.52
20	93.90	93.27	93.68
25	100.2	99.15	98.97
30	106.5	104.8	105.4
35	112.9	111.8	112.3

The Λ_{MLClO_4} values of K^+, Rb^+, and Cs^+ in methanol at different temperatures are given in Table 2. As can be seen from Table 2, the $[M]_t$ values of K^+, Rb^+, and Cs^+ are nearly equal to one another, and there is scarcely any difference in Λ_{MLClO_4} among K^+, Rb^+, and Cs^+ at the same temperature, suggesting that the charge of the alkali metal ion held in the DB24C8 cavity is effectively shielded by the DB24C8 and that the DB24C8 complexes with the alkali metal ions in methanol are approximately equal to each other in size.

The Thermal Stability of Metal Cation-TCNQ Anion Radical Salts

Yoshio KISHIMOTO* and Wataru SHIMOTSUMA

Materials Research Laboratory, Matsushita Electric Industrial Co., Ltd., Moriguchi, Osaka 570

(Received September 17, 1979)

To study the thermal stability of several metal cation–TCNQ salts (mainly alkali metal salts), the variation in the electrical resistivity and the characteristics of the chemical degradations by heating were measured. Most metal–TNCQ salts do not melt and are not sublimated, but have decomposition points at about 320 °C. Na(TCNQ) has a stable resistivity, even after heating for 500 hours at 200 °C, and is the most stable among the metal–TCNQ salts tested. Metal–TCNQ salts are gradually damaged from the surfaces of the crystalline powders by heating, and the TCNQ molecule is oxidized, thus losing CN groups. The crystallization process of the TCNQ salts has a great influence upon their thermal stabilities. In the complex salt $Cs_2(TCNQ)_3$, the application of d.c. voltage gives rise to the polarization current at a temperature near 200 °C, and the TCNQ molecules tend to migrate in the electric field.

Charge-transfer complexes based on 7,7,8,8-tetracyanoquinodimethane (TCNQ) have been extensively studied as organic metals or one-dimensional conductors in recent years; they have also received considerable interest in connection with their possible use as electronic materials.[1,2] Considering the life as electronic material or the compounding process with polymeric materials in practical use, the thermal stability of a TCNQ complex is highly important. Many TCNQ complexes with organic electron-donors are susceptible to thermal decomposition; metal–TCNQ salts are thermally more stable because of the low ionization potentials of metals. However, the thermal stability of the metal–TCNQ salts has been studied only by DTA and TGA.[3,4]

In this paper, in order to ascertain the upper limit of the thermal stability of TCNQ complexes, the thermal stabilities of several metal cation–TCNQ anion radical salts (mainly alkali metal salts) have been studied from both sides of their electrical resistivities and chemical degradations. The thermal stabilities have mainly been studied at the comparatively high temperatures of 200—250 °C in air; after the heating at 200—250 °C, the resistivity and chemical degradation of the TCNQ salts were measured at room temperature (RT). To study the variation in the resistivity, the dependence of the RT resistivity on the heating time, the temperature dependence of the resistivity, the d.c. polarization currents at temperatures ranging from RT to 200 °C, and the differences in the variation in the resistivity with several crystallization methods were measured. Moreover, the chemical degradations were analyzed by means of DTA, TGA, IR spectra, elemental analysis, or X-ray powder diffraction patterns.

Experimental

Synthesis of Metal–TCNQ Salts. Polycrystalline samples of Li(TCNQ), Na(TCNQ), K(TCNQ), $Cs_2(TCNQ)_3$, Ba(TCNQ)$_2$, and Cu(TCNQ) were prepared by refluxing for 4 h mixed acetonitrile solutions of TCNQ and metal iodides.[3] CsI and $BaI_2 \cdot 2H_2O$, which are insoluble in acetonitrile, were dissolved in a small amount of methanol, after which the solutions were added to TCNQ solutions. The hot mixed solutions were cooled to 0 °C, and the polycrystalline powders of the TCNQ salts thus deposited were filtered off and washed with acetonitrile.

Electrical Measurements. About constant weights of the polycrystalline powder samples were introduced into glass capillaries 1.5 mm in inner diameter and were packed to a saturated thickness of about 1 mm by pressing them repeatedly (about thirty times) under a weight of 230 g. Under a pressure of 13 kg/cm^2 and using electrodes composed of stainless steel sticks, the resistances for d. c. voltage were measured. In order to check the correctness of electrical measurements, the following measurements were carried out. The resistance was influenced by the pressure and electrode materials, but was over the wide range of 0.3—300 V/cm and showed a linear dependence on the thicknesses of the samples in the capillaries. When graphite powders were used as elctrodes instead of stainless steel, the samples showed lower resistivities, but the temperature dependence of their resistivities had the same temperature coefficients. Further, both these samples showed constant currents for 1 h under a voltage of 10 V at 30, 45, 60, 80, and 100 °C.

Analysis of Degradated Products. The IR spectra were measured by means of a JASCO Model DS-403G infrared spectrophotometer using the KBr-wafer technique. The DTA and TGA were performed by using an electric microbalance(Rigaku Electric Co., Ltd.), and each sample was measured under the following two conditions: by increasing the temperature at the rate of 10 °C/min from RT to 1000 °C, or by holding the temperature at 250 °C for 1 h after increasing temperature at the rate of 2.5 °C/min from 200 °C to 250 °C. The X-ray diffraction patterns were measured by means of a Philips PW-1009 X-ray diffractometer, using Cu $K\alpha$ radiation as the X-ray source(35 kV, 10 mA).

Results and Discussion

Thermal Stability of Resistivity. The temperature dependences of the resistivity of metal–TCNQ salts are shown in Fig. 1. All these curves except that of K-(TCNQ) are in accord with Arrhenius' equation at temperatures below 120 °C, but crystals of K(TCNQ) show unstable non-linear characteristics. The time dependence of the resistivity at 200 °C under a d.c. voltage of 10 V (about 100 V/cm) is shown in Fig. 2; $Cs_2(TCNQ)_3$ shows a remarkable variation in the current based on the polarization of the carriers. The variation in the resistivities with the time at 200 °C is faster, probably because of the existence of the electric field, than that (Fig. 3(1)) of the salts loaded only with heat at 200 °C. The resistivities of metal–TCNQ salts cooled from 200 °C to RT become higher than those shown in Fig. 1 as well as in Ref. 5, but the

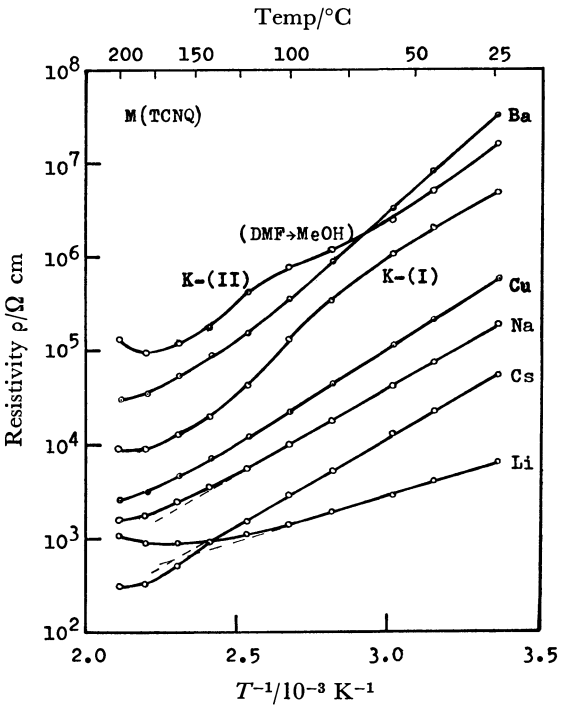

Fig. 1. Temperature dependence of resistivity of metal–TCNQ salts.

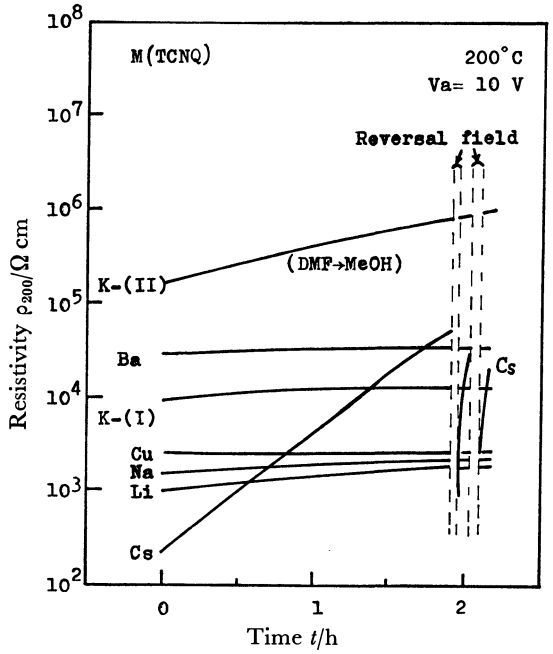

Fig. 2. Dependence of resistivity on time at 200 °C under d.c. voltage of 10 V (about 100 V/cm).

variations in the resistivities of Na(TCNQ), Cu(TCNQ), and $Ba(TCNQ)_2$ were only small.

After the six kinds of metal–TCNQ salts were heated at 200, 220, and 250 °C, their resistivities were measured at the RT of 24 °C. The results are shown in Fig. 3 and Table 1. Here, Li(TCNQ)-A and Na(TCNQ)-A are new samples synthesized at the same time as the other metal salts, while Li(TCNQ)-B and Na(TCNQ)-B are old samples synthesized about 9 years ago and kept

in air for that long period. These results are characterized by the retention of comparatively constant resistivities, followed by rapid increases in the resistivities, with a resemblance to the induction period of thermal degradation in the stabilizer-filled polymer.[6] Here, the threshold times at the variation points in these figures are evaluated from the intersecting points of the dashed lines and are here termed the "electrical life," t_{th}. The values of t_{th} are tabulated in Table 1. Na(TCNQ) has the longest life among the metal–TCNQ salts tested. These values of t_{th} belong to a very stable class of organic materials, and so the tested metal–TCNQ salts have been shown to have a satisfactory stability in practical use as electronic materials.

The t_{th}-1/T plots of K(TCNQ) shows straight lines, but the life at RT estimated from the linear characteristics of K(TCNQ) is too long. The t_{th}-1/T values of other metal–TCNQ salts, plotted from the data shown in Table 1, do not show straight lines, but the slopes of the plots are almost all the same. In order to estimate the life at RT, the t_{th}-1/T characteristics need to be measured over a range of temperatures wider than 200—250 °C. In Fig. 3, except for the case of $Cs_2(TCNQ)_3$, the value of ρ_{24} of each sample, which was heated at the temperatures of 200, 220, and 250 °C, varies even though the material is the same, but the results seem to be based on the change in the crystal state by heating at a different temperature or on the stresses of the crystal at the time of the drop in the temperature.

Thermal Degradation of Complex Salt – $Cs_2(TCNQ)_3$. $Cs_2(TCNQ)_3$ shows a remarkable variation in the current at temperatures near 200 °C, as is shown in Fig. 2, although the results of the elemental analysis of a sample heated for only 7.2 h at 200 °C show the same composition as virgin $Cs_2(TCNQ)_3$. Also after the reversal of the electric field, a remarkable variation in the current, the so-called absorption current, also occurs. Such characteristics are examples of ionic behavior based on the polarization of the carrier by an electric field, different from the constant current under a d.c. electric field in the case of electronic conduction, and show that TCNQ molecules in crystal of $Cs_2(TCNQ)_3$ easily migrate at temperatures close to 200 °C in response to the electric field. These factors coincide with the behavior shown in Ref. 7. Besides, needle crystals of $Cs_2(TCNQ)_3$ are gradually pulverized to microcrystals with the sublimation of a liberated molecule such as $TCNQ^0$ during the heating of 200—250 °C. The X-ray diffraction peaks of the heated $Cs_2(TCNQ)_3$ are also gradually lowered, while keeping the same peak pattern. Therefore, the thermal degradation of the salt is surmised to occur gradually from the surface of the crystal powders. After a longer heating, the composition of the degradated product seems to come close to the value of Cs(TCNQ) judging from the composition of elements shown in Table 2.

Thermal Degradation of Simple Salts. As is shown in Table 3, the DTA data indicate that the decomposition points are above 285 °C and that heating for 1 h at 250 °C does not cause any peak in the DTA curve. The weight losses also occur to only a small extent in that condition. However, upon heating for several hours at that temperature (250 °C), a rapid increment of resistivity occurs except in the case of Na(TCNQ), as is shown in Fig. 3 and Table 1. Na(TCNQ), whose electrical life, t_{th}, is 600 h at 200 °C has a very excellent stability. The high stability of Na(TCNQ) is considered to be related to the finding that the beginning temperature, T_{h2}, of the second peak in the DTA data is higher than that of the other salts by about 100 degrees. This high stability is probably due to the pertinence of the ionic radius of sodium, which has a low ionization potential in the crystal.

Many of these alkali or alkali earth metal–TCNQ salts whose metals have low ionization potentials are

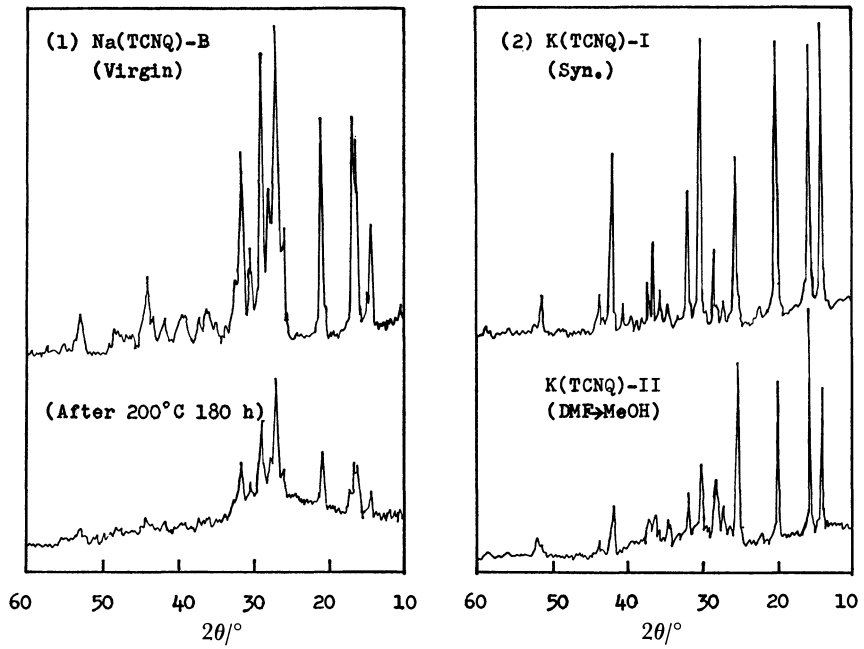

Fig. 4. Variation of X-ray diffraction patterns of Na(TCNQ) and K(TCNQ).

degradated to become black without any evaporation or sublimation, but K(TCNQ) changes its color variously with the degree of degradation, as will be shown below. Cu(TCNQ) sublimes near 355 °C, and its thermally decomposed product upon long heating at 200 °C seems to include metallic copper. This is probably due to the weak ionization tendency of copper. The results of elemental analysis are shown in Table 2. The metal–TCNQ salts are degradated to lose CN groups. In numerous cases of color changes of salts occurring with degradation, the degradation is characterized by a variation in the resistivity immediately after the color change. It is clear that the color change reflects the variation in the composition of TCNQ salt.

The X-ray diffraction peaks of Na(TCNQ) are lowered with its degradation, showing the same patterns as are shown in Fig. 4(1). Therefore, the thermal degradation is considered to occur gradually from the surface of the crystalline powders. Besides, the data of IR spectrophotometry on the degradated products of Na(TCNQ) and K(TCNQ) show peaks at the wave numbers of 750, 1380, 1670, 1740, and 3400 cm^{-1}. These peaks are deduced to show a hydrogen bond, carbonyl group, or carboxyl group formed by the oxidation of the TCNQ molecule, but the correct molecular structures of the degradated products of TCNQ salts are still not clear. The solubilities of the tested metal–TCNQ salts and their degradated products in water and in acetonitrile are tabulated in Table 2, along with the colors of the solutions. K(TCNQ) and $Cs_2(TCNQ)_3$ change to very water-soluble substances upon heating.

Thermal Stabilities of Various K(TCNQ) Crystals. K(TCNQ)-I was synthesized in acetonitrile by using the above-described method. By means of the recrystallization or reprecipitation of the K(TCNQ)-I, the following four kinds of K(TCNQ) were prepared:

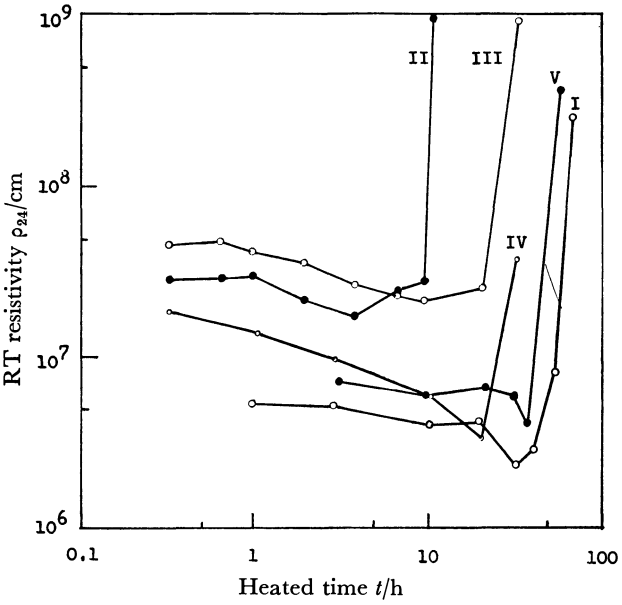

Fig. 5. Stability of RT resistivity of various K(TCNQ) crystals heated at 200 °C.
ρ_0: Initial resistivity and RT: 24 °C.

T_h and T_w are the beginning temperatures of the exothermic peak and the weight loss respectively. a) 10 °C/min from RT to 1000 °C. b) 2.5 °C/min from 200 °C to 250 °C and hold at 250 °C for 1 h.

resistivites are about one order of magnitude higher than the values measured immediately after compacting the crystalline powders into a capillary. The variation in the RT resistivities of these K(TCNQ) crystals upon heating at 200 °C is also shown in Fig. 5. K(TCNQ)-II shows the most unstable result among the samples (I—V) in the figure; the results have a tendency similar to that of the DTA data shown in Table 3. Since the K(TCNQ)-II does not show any weight loss at temperatures below 250 °C, but does show low peaks in the X-ray powder pattern, as is shown in Fig. 4(2), this instability may be deduced to be based on the difference is crystal states rather than a residual DMF solvent.

Figure 5 shows that the crystallization processes exert great influences upon their thermal stabilities; it is interesting that K(TCNQ)-I, prepared in synthesis, shows a fairly stable result. In the heating process, K(TCNQ) crystals show various color changes different from those of many metal–TCNQ salts, as is shown in Table 2; the color changes of K(TCNQ)-(I—V) correspond to the variation in resistivities shown in Fig. 5.

In conclusion, the thermal stabilities of metal–TCNQ salts may be summarized as follows:

(1) Na(TCNQ) has a stable resistivity, even after heating for 500 h at 200 °C, and is the most stable among the metal–TCNQ salts tested.

(2) Most of the metal–TCNQ salts do not melt and are not sublimated, but have a decomposition point at about 320 °C.

(3) Metal–TCNQ salts are considered to be gradually damaged from the surface of crystalline powders by heating, and the TCNQ molecule is oxidized, losing CN groups.

(4) The crystallization process and the crystal state of the salts have a great influence upon the thermal stabilities.

(5) In the $Cs_2(TCNQ)_3$ complex salt, the application of the voltage gives rise to a polarization current at a temperature near 200 °C, and the TCNQ molecules tend to migrate in the electric field and to be slightly sublimated at that temperature.

(6) When the voltage is applied to metal–TCNQ salts at temperatures above 150 °C, the salts often suffer irreversible variations in their resistivities.

Temperature Dependence of Structural Propensity of 1-Butanol in Water

Neriyanuri Manohara Murthy and Saraswatula Venkata Subrahmanyam*

Department of Physics, SVU Autonomous Post-Graduate Centre, Anantapur 515003, India

(Received July 9, 1979)

The temperature dependence of structural propensity of 1-butanol has been studied by investigating its effect on the temperature of sound velocity maximum (TVM) in aqueous mixtures of glycerol and pyridine. The structural contribution to the shift in TVM of binary solution, $[\Delta T_{str}]_{exp}$ was found to be positive at low concentrations of 1-butanol for aqueous pyridine solutions whose TVM are 37.6 °C and 23.7 °C. For aqueous glycerol solutions whose TVM is 43.3 °C, $[\Delta T_{str}]_{exp}$ values, in the entire concentration range of 1-butanol studied, are found to be negative. The results indicate that below 40 °C 1-butanol behaves as a structure promoter while above 40 °C it behaves as a structure breaker.

The effect of solutes (electrolytes or nonelectrolytes) in promoting the hydrogen bonded structure of water is a function of temperature. Structure makers at low temperatures are known to behave as structure breakers at high temperatures.[1-4] Our earlier studies[5,6] on the effect of 1-butanol on the temperature of adiabatic compressibility minimum and sound velocity maximum of water indicate structure breaking property at high temperatures (around 60 and 75 °C) where as the density maximum studies by Wada and Umeda[7] (around 4 °C) indicate structure making propensity for this solute.

To understand the temperature dependence of structural propensity of 1-butanol, we have taken up a study of the effect of 1-butanol on the temperature corresponding to the sound velocity maximum of aqueous mixtures of glycerol (TVM=43.3 °C) and pyridine (TVM 37.6 and 23.7 °C) and the results are presented in this paper. Glycerol and pyridine which are known to be effective structure breakers[8] were chosen simply to lower TVM of water to any desired value at which the effect of 1-butanol could be studied to delineate its temperature dependence of structural propensity.

Experimental

Triple distilled degassed water was used to prepare stock solutions of aqueous glycerol and pyridine. These solutions were used to prepare ternary solutions of 1-butanol of desired concentration. The concentration of 1-butanol in the ternary solution was calculated by considering the aqueous binary stock solution as a solvent of effective molecular weight M_{12} given by $X_wM_w+X_sM_s$ where M_w, M_s and X_w, X_s represent the molecular weights and mole fractions respectively of water and glycerol and or pyridine. Ultrasonic velocity in binary solutions of aqueous glycerol and pyridine and in the ternary solutions with 1-butanol as the third component was determined using a single crystal variable path interferometer working at 3 MHz with an accuracy of ±0.003%. The details of the experimental technique and the method of measurement of velocity and temperature of the experimental liquid were discussed elsewhere.[5] The velocity measurements were confined to a temperature range of ≃5 °C on either side of TVM at intervals of ≃2 °C. AR grade glycerol, pyridine, and 1-butanol were used in the present study after necessary purification following the procedure given by Weissberger.[9]

Results

Diffraction corrected ultrasonic velocity as a function of temperature at different concentrations of 1-butanol in aqueous glycerol (M_{12}=24.7455, X_s=0.0909) and in aqueous pyridine solutions (M_{12}=20.5599, X_s=0.0416 and M_{12}=21.7209, X_s=0.0606) are presented graphically in Figs. 1 to 3. In all the solutions since the shape of the velocity temperature curves are similar to that of pure water, the template of the velocity-temperature curve for pure water was used to fix TVM and the accuracy in fixing TVM is ±0.2 °C.

Discussion

The shift in the temperature corresponding to the sound velocity maximum in the binary solutions of aqueous glycerol or pyridine due to the addition of 1-butanol may be given by

$$\Delta T = (T_{exp})_{ternary\ sol} - (T_{exp})_{binary\ sol.} \quad (1)$$

ΔT may be thought of as arising due to two effects namely dilution effect and structural effect. The dilution effect is always to lower TVM but the structural effect may be positive or negative depending on whether the nonelectrolyte promotes or disrupts the binary solution structure. These two effects may be separated by considering the expressions representing the temperature dependence of velocity in aqueous glycerol

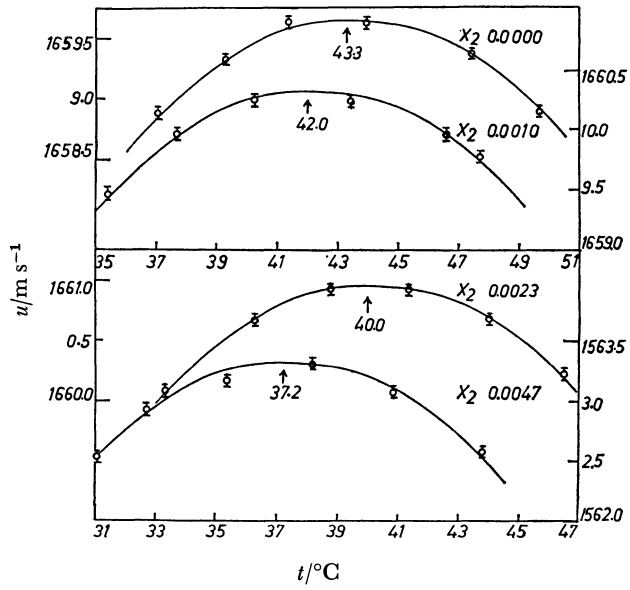

Fig. 1. Ultrasonic velocity *versus* temperature in aqueous solutions of glycerol at different molefractions of 1-butanol.

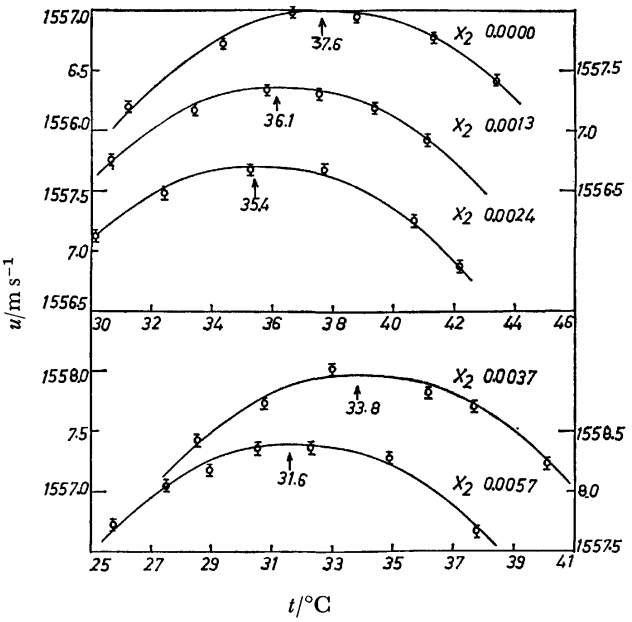

Fig. 2. Ultrasonic velocity *versus* temperature in aqueous solutions of pyridine at different molefractions of 1-butanol.

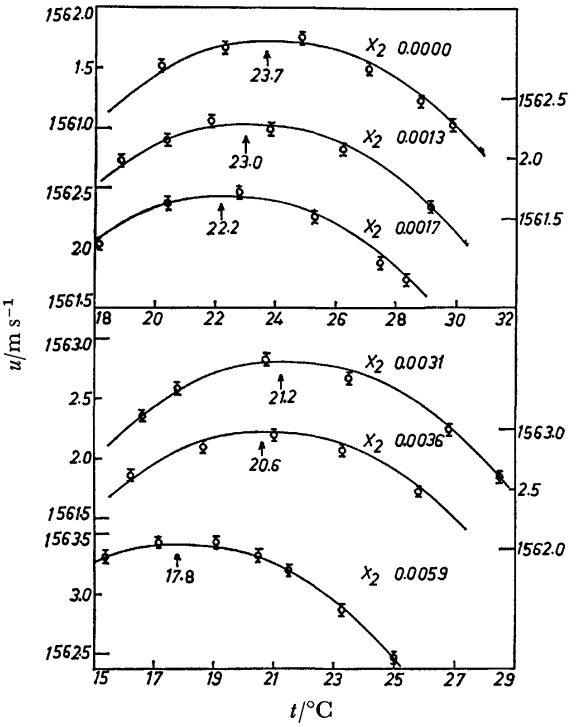

Fig. 3. Ultrasonic velocity *versus* temperature in aqueous solutions of pyridine at different molefractions of 1-butanol.

or pyridine and the nonelectrolyte.

The structural contribution to the shift in the temperature of sound velocity maximum in the ternary solution can be calculated using the following expressions that may be obtained on the same lines as that for pure water.[6]

$$[\Delta T_{str}]_{exp} = T_{exp} - T_{id}, \quad (2)$$

where

$$T_{id} = T_{\text{binary sol}} - \left(\frac{\phi_2}{\phi_{12}}\right)^2\left(\frac{W_{12}}{W_2}\right)\frac{\alpha}{(2\beta)}\left(\frac{u_{12}}{u_2}\right)^3, \quad (3)$$

where ϕ_{12}, ϕ_2 and W_{12}, W_2 represent the volume fractions and weight fractions of binary aqueous solution and 1-butanol respectively in the ternary solution. α represents the temperature coefficient of sound velocity in 1-butanol and u_{12} and u_2 the velocities in the aqueous binary solution and solute respectively. For 1-butanol u_2 is given by

$$u_2 = u_2^\circ - \alpha t, \quad (4)$$

where u_2° and α are 1323.58 m s^{-1} and 3.3644 m s^{-1} °C^{-1} respectively and t represents the temperature in °C. u_{12} may be written as

$$u_{12} = u_{12}^\circ - \beta(T-t)^2. \quad (5)$$

The values of u_{12}°, β, and T for stock solutions of aqueous glycerol and pyridine are given in Table 1.

Table 1. Values of u_{12}°, β, and T for aqueous binary solutions

Solvent	X_s	u_{12}° / m s^{-1}	β / m s^{-1} °C^{-2}	T / °C
Aqueous glycerol	0.0909	1559.67	0.0204	43.3
Aqueous pyridine	0.0416	1556.99	0.0204	37.6
	0.0606	1561.72	0.0184	23.7

In all cases T_{id} was calculated using the method of successive approximations. Table 2 gives the values of T_{exp}, T_{id}, ΔT, and $[\Delta T_{str}]_{exp}$ at different concentrations of 1-butanol. The variation of $[\Delta T_{str}]_{exp}$ *versus* molefraction X_2 of 1-butanol in different aqueous binary solutions are shown graphically in Fig. 4 along with the $[\Delta T_{str}]_{exp}$ *versus* X_2 of 1-butanol in pure water taken from literature.[6] From the figure it is clear that below 40 °C 1-butanol behaves as a structure maker since $[\Delta T_{str}]_{exp}$ values are positive for solutions in which the TVM are 37.6 and 23.7 °C. $[\Delta T_{str}]_{exp}$

X_B: Molefraction of 1-butanol when aqueous glycerol or aqueous pyridine is treated as cosolvents of effective molecular weights $M_{G,W}$ or $M_{P,W}$. X_G/X_P: Molefraction of glycerol/pyridine when aqueous 1-butanol is treated as cosolvent of effective molecular weight $M_{B,W}$.

values are negative for solutions in which the values of TVM are 43.3 and 74 °C indicating that above 40 °C 1-butanol behaves as a structure breaker. The behaviour of 1-butanol above 40 °C as a structure breaker was also confirmed from the studies on volumetric behaviour of aqueous isomeric butyl alcohols.[10] Hence the results of the present study indicate that as temperature increases the structure making efficiency of 1-butanol decreases and at temperatures above 40 °C it behaves as a structure breaker.

It is necessary to note that the assignment of structure making or breaking nature to 1-butanol as a function of temperature is valid only when 1-butanol has little interaction with glycerol or pyridine in the ternary system and interacts only with the water. Our results are based on the assumption that the aqeuous glycerol or pyridine as seen by 1-butanol is aqueous and the interactions between 1-butanol and glycerol or pyridine in the presence of water are negligible when compared with the interaction of 1-butanol with the aqueous nature of the solution structure. To know whether this is the actual situation prevailing in the ternary system, we have calculated the shift in TVM of water due to the addition of the two organic solutes (independently) namely glycerol or pyridine and 1-butanol to water, ΔT_{calcd}, and a comparison is made with the observed shift, ΔT_{obsd}, (74 °C− T_{exp} in the ternary solution) to see whether the shift ΔT is additive with respect to them. Our earlier data[6,8] on TVM of aqueous glycerol, pyridine, and 1-butanol are taken for the evaluation of the shifts corresponding to the concentrations of these solutes in the ternary systems. The shifts in the TVM of water corresponding to the concentrations of the present study are obtained

by least square fitting of the data.[6,8] As per the data presented in Table 3, the agreement between the calculated and observed shifts is quite good in the case of the ternary system water+glycerol+1-butanol. In the case of the ternary system water+pyridine+1-butanol, except when the concentrations of 1-butanol and pyridine are 0.0057 and 0.0414 and 0.0059 and 0.0602, the agreement between the calculated and experimental shifts is quite good. These observations indicate that ΔT is additive with respect to each solute and the effect of 1-butanol, glycerol, and pyridine on TVM of pure water is respectively independent of each other coexisting solute. However, the difference between the calculated and observed shifts for the ternary systems in which $X_B=0.0057$, $X_P=0.0414$ and $X_B=0.0059$, $X_P=0.0602$; which is about 2%, in our view, is due to the effect of temperature on the structure making or breaking power of the solutes being different in aqueous solution and in the ternary system and may not be considered as due to the influence of pyridine on 1-butanol or *vise versa* in their efficiency to shift the TVM of the solution. We would like to mention at this juncture that this point needs extensive study of ternary systems containing the two organic solutes which are both either structure breakers or structure makers. Further experimentation in this direction is in progress.

Macroscopic Viscosity and Dielectric Relaxation Process of Ethyl and Butyl Acetates

Sudhir Kumar Saxena, Jagdish Prasad Shukla, and Mahesh Chandra Saxena*
Department of Physics, Lucknow University, Lucknow, India
(Received October 13, 1979)

Dielectric constants and losses have been measured at 9.8 GHz microwave frequency for ethyl and butyl acetates in benzene and benzene-paraffin oil mixtures at 18 °C. The data obtained has been analysed in terms of the two relaxation times $\tau_{(1)}$ and $\tau_{(2)}$ using Higasi, Koga, and Nakamura method and their dependence on the viscosity has been examined. Since the observed values of $\tau_{(1)}$ and $\tau_{(2)}$ are significantly different, the systems studied represent two Debye type dispersions. It has been found that the relaxation behaviour giving rise to $\tau_{(1)}$ in both the ester molecules is not effected to any appreciable extent by the increased macroscopic viscosity. The dielectric relaxation time $\tau_{(2)}$ associated with the molecular process lengthens with the increasing macroscopic viscosity of the medium.

Dielectric relaxation process in aliphatic esters (acetates) have been studied by a number of workers[1-5] both in pure liquids and in solutions. The absorption process in these systems have been attributed to the molecular as well as the group rotations. Dependence of the dielectric relaxation time on the viscosity of the medium has been extensively examined by several workers[6-10] and various empirical relations have been proposed. Grubb and Smyth[11] studied some substituted naphthalene, anisole, primary and secondary amines and diamines in paraffin oil and have estimated the relaxation times τ_1 and τ_2 associated with the molecular and group processes. The enthalpies were evaluated for methyl iodide, chlorobenzene, cyanocyclopropane *etc.* by Balogun and Cumper[12] using benzene+liquid paraffin oil as solvents. In study, Crossley and Srivastava[13] reported the value of 'x' ($=\Delta H_\gamma/\Delta H_\varepsilon$) for acetophenone, anisoles, bromobenzene, and *p*-dimethoxybenzene in the mixture of solvents, paraffin oil and heptane, and paraffin oil and hexadecane. Recently in another study[14] using solvent of high viscosity they have resolved the dielectric data of 1-butanol and 1-decanol into two relaxation process (τ_1) and (τ_2). It has been observed that molecular relaxation time changes rapidly with the changing viscosity of the solvent–solute mixture. However, the relaxation time (τ_2) practically remains constant. The effect of the macroscopic viscosity of the solvent on the process which probably arises from the group rotation have been examined only for a few cases with varying high viscosity.

Aliphatic esters have been examined for their dielectric behaviour using various methods.[1-5] The investigations were however confined only to the studies relating to the relaxation mechanism and their structure. It was, therefore, considered worthwhile to examine ethyl acetate and butyl acetate in the solvent mixtures of paraffin oil and benzene which provide a high viscous medium for the dipolar rotations. The dielectric data was resolved into two absorption processes, $\tau_{(1)}$ being an implicit function of τ_1 and τ_2 and weight factor C_1 and $\tau_{(2)}$ associated with the molecular process and the effect of macroscopic viscosity on $\tau_{(1)}$ has been examined. This has been found to be in agreement with the earlier studies of Crossley *et al.*[14] on 1-butanol and 1-decanol.

Experimental

The dielectric constant ε' and dielectric loss ε'' have been measured at x-band at frequency 9.8 GHz by the technique of Robert and von-Hippel[15] as modified by Dakin and Works.[16] The refractive indices of different dilute solutions at infinite frequency was measured by Abbe's refractometer. The dielectric constant at infinite frequency was obtained by squaring the refractive indices of different dilute solutions respectively. The possibility of Poley absorption is ruled out as the microwave frequency used for the measurement is comparatively much low. The static dielectric constant have been measured by the calibrated dipolemeter based on the principle of heterodyne beat method. The measurement of ε' and ε'' are accurate upto $\pm 2\%$ and $\pm 5\%$ respectively.

Average viscosity of the solvent solute mixture was obtained by taking the mean of six values for a group of solutions of various solvents obtained by measuring the fall time of liquid in the capillary of the Ostwald's viscometer.

Chemicals. The chemicals used were of purest quality available, both the ethyl acetate and butyl acetate were obtained from the British Drug House (Ltd.) England. The physical properties of both the esters were checked against the literature values. The solvent benzene were distilled twice before use. The benzene (A. R. grade) was obtained from B. D. H. (England) and medicinal liquid paraffin oil was obtained from Liberty Pharmaceutical (Ltd.) Bombay (India). The mixture of benzene and paraffin oil in the following percentage were used as solvent for the measurements.

1: 100% paraffin oil
2: 10% benzene+90% paraffin oil
3: 20% benzene+80% paraffin oil
4: 30% benzene+70% paraffin oil.

Theory: The slopes a_0, a', a'', and a_∞ have been obtained by plotting the weight fraction *versus* ε_0, ε', ε'', and ε_∞ for both the compounds. The values have been reported in Table 1. The slopes are defined by the set of Eq. 1.

$$\begin{aligned} \varepsilon_0 &= \varepsilon_{10} + a_0 W_2 \\ \varepsilon' &= \varepsilon_1' + a' W_2 \\ \varepsilon'' &= a'' W_2 \\ \varepsilon_\infty &= \varepsilon_{1\infty} + a_\infty W_2. \end{aligned} \quad (1)$$

The subscripts 1 and 2 refer to pure solvent and solute respectively. Similarly ε_∞ refers to the dielectric constant at infinite frequency. ε_0 is the dielectric constant at static field and W_2 is weight fraction of the solute.

The most probable relaxation time τ_{OH} and the distribution

Table 1. The slopes a_0, a', a'', and a_∞ for ethyl and butyl acetate in benzene and paraffin oil (p.o.) mixture at 18 °C

Compound	Concentration	a_0	a'	a''	a_∞
(A) Ethyl acetate	100% p.o.	3.33	2.66	1.05	−0.28
	90% p.o.+10% benzene	2.86	2.35	0.95	−0.26
	80% p.o.+20% benzene	2.50	2.12	0.80	−0.256
	70% p.o.+30% benzene	2.20	1.90	0.70	−0.25
(B) Butyl acetate	100% p.o.	2.96	2.10	1.00	−0.265
	90% p.o.+10% benzene	2.58	1.80	0.83	−0.25
	80% p.o.+20% benzene	2.12	1.50	0.70	−0.21
	70% p.o.+30% benzene	1.74	1.30	0.55	−0.19

Table 2. Distribution parameter 'α', most probable relaxation time τ_{OH} by Higasi method, $\tau_{(1)}$, $\tau_{(2)}$, and $\tau_{(0)}$ obtained by Higasi, Koga, and Nakamura method and dipole moment at 18 °C

Compound	Concentration	α	η poise	τ_{OH} ps	$\tau_{(1)}$ ps	$\tau_{(2)}$ ps	$\tau_{(0)}$ ps	$\mu_{(D)}$ expt Debye	$\mu_{(D)}$ Lit.
(A) Ethyl acetate	100% p.o.	0.14	0.233	5.7	5.8	10.5	7.8	1.81	1.86
	90% p.o.+10% benzene	0.12	0.070	5.4	5.7	9.3	7.2	1.76	
	80% p.o.+20% benzene	0.07	0.038	5.3	5.5	7.8	6.6	1.66	
	70% p.o.+30% benzene	0.06	0·024	5.1	5.3	7.0	6.1	1.56	
(B) Butyl acetate	100% p.o.	0.25	0.240	7.1	6.9	16.3	10.6	1.98	1.84
	90% p.o.+10% benzene	0.24	0.090	6.8	6.6	15.5	10.1	1.80	
	80% p.o.+20% benzene	0.22	0.059	6.6	6.5	14.6	9.7	1.65	
	70% p.o.+30% benzene	0.20	0.025	6.1	6.1	13.1	8.9	1.45	

parameter 'α' have been calculated from the Eq. 2, given by Higasi *et al.*[17]

$$\tau_{OH} = \frac{1}{W}\left[\frac{A^2+B^2}{C^2}\right]^{1/2(1-\alpha)}$$
$$1-\alpha = \frac{2}{\pi}\tan^{-1}\frac{A}{B}, \quad (2)$$

where

$$A = a''(a_0-a_\infty)$$
$$B = (a_0-a')(a'-a_\infty) - a''^2 \quad (3)$$
$$C = (a'-a_\infty)^2 + a''^2.$$

Having obtained the appreciable value of distribution parameter 'α', the dielectric relaxation mechanism has been further resolved by Higasi, Koga, and Nakamura method[18] in terms of the two relaxation times $\tau_{(1)}$ and $\tau_{(2)}$ defined by the Eqs. 4 and 5:

$$\tau_{(1)} = \frac{1}{W}\frac{a''}{(a'-a_\infty)}, \quad (4)$$

$$\tau_{(2)} = \frac{1}{W}\frac{(a_0-a')}{a''}. \quad (5)$$

The slopes a_0, a', a'', and a_∞ are defined by the set of Eq. 1. The average probable relaxation time $\tau_{(0)}$ is obtained by the geometrical mean of $\tau_{(1)}$ and $\tau_{(2)}[\tau_{(0)}=\sqrt{\tau_{(1)}\tau_{(2)}}]$.

The apparent dipole moment was calculated by Higasi's method[19] employing Eq. 6.

$$\mu^2 = \frac{27kT}{4\pi N}\frac{M_2}{d_1}\frac{a_0-a_\infty}{(\varepsilon_1'+2)^2}$$
$$= B^2(a_0-a_\infty), \quad (6)$$

where

$$B = \left\{\frac{27kTM_2}{4\pi Nd_1}\right\}^{1/2}\frac{1}{(\varepsilon_1'+2)}$$

M_2 is the molecular weight of the substance and d_1 is the density of the solvent, and other symbols have their usual meaning.

Discussion

(A) Ethyl Acetate. An examination of Table 2 shows that the distribution parameter 'α' for ethyl acetate has a variation (0.14—0.06) when the concentration of paraffin oil varies from 100% to 70% in benzene. The highest value of distribution parameter 'α' is 0.14 in 100% p.o. and the lowest value, 0.06 has been observed in 70% p.o. in benzene. These observations are in agreement with the earlier investigations of Smyth *et al.*[1] The appreciable value of the distribution parameter 'α', indicates the existence of more than one relaxation process occurring in the system. The most probable relaxation time τ_{OH} evaluated using Higasi method[17] has been found to vary from 5.1—5.7 ps in the range of concentration changing from 70% p.o. in benzene to 100% p.o. The dielectric

dispersion has been further resolved by Higasi, Koga, and Nakamura method,[18] into two separate processes which gave rise to two relaxation time $\tau_{(1)}$ and $\tau_{(2)}$. $\tau_{(1)}$, which is related to the group process has been found to vary from 5.3—5.8 ps when the concentration varies from 70% p.o. in benzene to 100% p.o. $\tau_{(2)}$, which represent the molecular process has been found to vary from 7.0—10.5 ps in the same concentration range. The average relaxation time $\tau_{(0)}=\sqrt{\tau_{(1)}\tau_{(2)}}$ for the overall process was found to vary from (6.1—7.8 ps). An examination of Table 2 reveals that the relaxation time $\tau_{(1)}$ associated with the group process for all the concentrations remains almost constant, whereas, the other relaxation time $\tau_{(2)}$ related to the molecular process varies appreciably with the concentration of the solvent. These results are in agreement with the previous studies of Srivastava and Crossley[14] on alcohols and of Grubb and Smyth[11] on substituted anisoles, naphthalene, and substituted amines. It has also been observed that $\tau_{(0)}$ the average relaxation time is slightly greater than the most probable relaxation time τ_{OH}. They are consistent with the previous observation of Higasi *et al.*[5] on alkyl acetates.

The dipolemoment of the compound has been calculated in various solvents. It has been observed that the dipolemoment varies from 1.56—1.81 D for the concentration of p.o. varying from 70% p.o. to 100% p.o. These values are not much different from the literature value[20] of dipolemoment (=1.86 D) for ethyl acetate in solution. The value is highest in 100% p.o. and is decreasing with the dilution of paraffin oil with benzene. This is in agreement with the reports on similar data by Srivastava and Crossley[14] for 1-butanol and 1-decanol in paraffin oil and heptane mixture.

(B) Butyl Acetate. The distribution parameter 'α' for butyl actate shows variation (0.20—0.25) in the concentration range of 70% p.o. in benzene to 100% p.o. The 'α' values are found to decrease with the dilution of paraffin oil with benzene, which is in agreement with the previous study by Smyth *et al.*[1] The most probable relaxation time τ_{OH} has been found to vary from 6.1—7.1 ps, while the concentration of paraffin oil and benzene mixture changes from 70% p.o.+30% benzene to 100% p.o. The most probable relaxation time τ_{OH} for butyl acetate is found to be longer than ethyl acetate. This is as expected due to the bigger size of this molecule. On further resolving the absorption by Higasi, Koga, and Nakamura method[18] the two relaxation times obtained were $\tau_{(1)}$ (=6.1—6.9 ps) and $\tau_{(2)}$ (=13.1—16.3 ps) in the concentration range used. The two distinct values for $\tau_{(1)}$ and $\tau_{(2)}$ indicate the existence of two distinct relaxation processes in the system. It has been observed that $\tau_{(1)}$ for butyl acetate is longer than $\tau_{(1)}$ for ethyl acetate for the same concentration range. This is as expected since $\tau_{(1)}$ arises perhaps from the rotation of the heavier group-C_4H_9 around the carbon–carbon bond. Similar results were reported by Grubb and Smyth[11] on α- and β-methoxy- and ethoxy-naphthalenes in the solution of decalin and Nujol. Further it is observed that the relaxation time $\tau_{(1)}$ is practically constant with the varying macroscopic viscosity of the solvent, which is in agreement with the earlier investigations of Srivastava and Crossley[14] on alcohols and Grubb and Smyth[11] on amines, naphthalene, and anisole.

$\tau_{(2)}$ and $\tau_{(0)}$ both are found to be larger for butyl acetate than the values obtained for ethyl acetate in the same concentration range. This follows the usual dependence on the shape and size of molecules in process.

The dipolemoment in the various solvents have been calculated by Higasi method.[19] It is found to vary from (1.45—1.98 D) when the concentration varies from 70% p.o. in benzene to 100% p.o. The value resembles well within the experimental error from the literature value[20] 1.84 D for the butyl acetate in the solution. The highest value for dipolemoment was observed in 100% p.o. which is decreasing with the dilution of paraffin oil with benzene.

A graph has drawn between log $\tau_{(1)}$ and log η_s and log $\tau_{(2)}$ and log η_s (Figs. 1 and 2). It has been observed that the relaxation time $\tau_{(1)}$ is practically constant with the macroscopic viscosity of solvent and solute. A line of greater slope has been observed for $\tau_{(2)}$ showing that molecular relaxation time is varying appreciably with the viscosity for both the ester molecules. It is in agreement with the earlier observations by several workers.[11,14,21]

Conclusion

The microwave absorption studies on ethyl and butyl acetates in high viscous solvents exhibit a flexible behaviour. The two relaxation time $\tau_{(1)}$ and $\tau_{(2)}$ for both the systems have been found to be appreciably distinct. The effect of average macroscopic

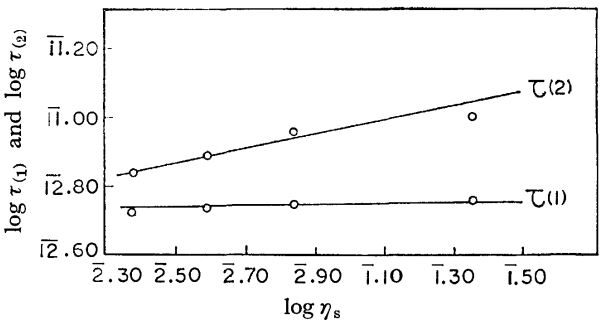

Fig. 1. Plot of log $\tau_{(1)}$ and log $\tau_{(2)}$ *vs.* log η_s (ethyl acetate).

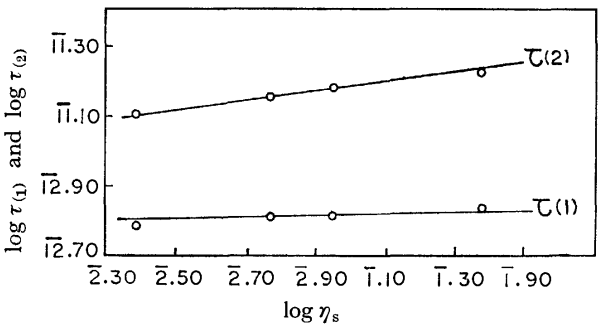

Fig. 2. Plot of log $\tau_{(1)}$ and log $\tau_{(2)}$ *vs.* log $\eta_{(s)}$ (butyl acetate).

viscosity of the medium has been observed for both the molecules. $\tau_{(1)}$ for ethyl acetate varies from (5.3—5.8 ps) while the viscosity changes from (0.024—0.233 poise). $\tau_{(2)}$ for the same system changes from (7.0—10.5 ps). Similarly for butyl acetate, $\tau_{(1)}$ has been found to be slightly longer, in the range 6.1 to 6.9 ps for the viscosity variations from 0.025 to 0.243 poise whereas $\tau_{(2)}$ varies from 13.1 ps to 16.3 ps. This clearly indicates that $\tau_{(1)}$ for both the systems practically remains constant with the macroscopic viscosity of the medium whereas $\tau_{(2)}$ varies in different media according to the size and shape of the molecules. The two straight lines, drawn for the variation of $\tau_{(1)}$ and $\tau_{(2)}$ with viscosity show the similar effect. It can, therefore, be concluded that the viscosity of the medium has hardly any effect so far as the process giving rise to the relaxation time $\tau_{(1)}$ is concerned. This perhaps can be associated with the internal rotation of the group attached to the two species. This is in agreement with the earlier studies on a few other molecular species.[11,14,21]

One of us (S. K. Saxena) is grateful to University Grant Commission, New Delhi (India) for the award of financial assistance and the Teacher fellowship under "faculty improvement programme" to complete this work.

Hydroxyamidine as a Highly Selective Extractant for Spectrophotometric Determination of Molybdenum with Thiocyanate

Raghunandan Singh KHARSAN and Rajendra K. MISHRA*
Department of Chemistry, Ravishankar University, Raipur-492010, India

(Received April 16, 1979)

A highly selective method for the extractive-spectrophotometric determination of molybdenum is described. Molybdenum is reduced with ascorbic acid in strongly acidic media (2.0—4.5 mol dm^{-3} HCl), and complexed with N^1-hydroxy-N^1-*p*-tolyl-N^2-(3,4-dimethylphenyl)benzamidine in the presence of thiocyanate. The stoichiometry of mixed complex is found to be 1:2:2 (metal:reagent:thiocyanate). The red-orange molybdenum complex shows a sharp maximum at 470 nm having molar absorptivity 3800 dm^3 mol^{-1} cm^{-1}. All the metal ions associated with a matrix of molybdenum such as Ni(II), Co(II), Cu(II), Mn(II), Ti(IV), Zr(IV), V(V), Nb(V), Ta(V), and W(VI) do not interfere. The applicability of the method has been tested with an ore and various alloys.

A number of reagents such as thiocyanate–tin(II) chloride,[1] thiocyanate–copper(I) chloride,[1] toluene-3,4-dithiol,[1] phenylhydrazine,[1] chloranilic acid,[1] mercaptoacetic acid,[1,2] dithiooxamide,[3] 4-methyl-2-pentanol,[4] 2-mercapto-4*H*-1-benzothiopyran-4-one,[5] potassium ethylxanthate,[6] monooctyl α-anilinobenzylphosphonate thiocyanate,[7] and salicylhydroxamic acid[8] have been reported for extraction photometric determination of molybdenum. N^1-hydroxy-N^1,N^2-diarylbenzamidines, monobasic and bidentate chelating agents have been used for gravimetric determination[9-11] of nickel, copper, and molybdenum and colorimetric determination[12-14] of manganese, iron, and vanadium. N^1-Hydroxy-N^1-*p*-tolyl-N^2-(3,4-dimethylphenyl)benzamidine (abbreviated as Hhtdb), a newly synthesized monobasic and bidentate chelating agent is found to be a selective chromogenic reagent for extractive-photometric determination of molybdenum(V)–thiocyanate complex into benzene (using ascorbic acid as a reducing agent).

The present method is compared with the other methods mentioned above. All the methods except for those using thiocyanate–tin(II) chloride and thiocyanate–copper(I) chloride suffer either from interference of one or more elements such as iron, copper, nickel, cobalt, tin, titanium, zirconium, niobium, chromium, and tungsten, or absorbance due to reagent at wavelength of maximum absorption. The thiocyanate–tin(II) chloride is commonly used for extractive-photometric determination of molybdenum. However, a serious drawback of this method is that the colour intensity produced by a constant quantity of molybdenum depends upon a number of factors such as volume of the aqueous phase, coefficient of expansion of isopentyl alcohol, concentration of iron, and tin(II). The thiocyanate–copper(I) chloride method also has a number of drawbacks from a practical standpoint. The original volume of the sample solution should not exceed a few millilitres and iron should not be present in more than minute amounts. The disadvantages are overcome successfully in the present *N*-hydroxyamidine thiocyanate method. The *N*-hydroxyamidine thiocyanate method is simple, rapid and highly selective. Moreover, it is free from volume ratio of aqeuous phase, concentration of reagents, order of addition of reagents, temperature, standing time and correlation of colour intensity with iron concentration.

The present paper reports the solvent extraction and photometric determination of molybdenum(V)–thiocyanate complex with htdb, various optimization constants and nature of complex separation from various diverse ions and its application to the analysis of ore and alloys.

Experimental

Apparatus. Absorbance measurements were made with an ECIL UV-VIS spectrophotometer model-865 matched with 1-cm silica and quartz cuvettes. All pH measurements were made with a Systronic pH meter type-322.

Standard Molybdenum Solution. A 1000-ppm molybdenum solution was prepared by dissolving 1.8401 g of A. R. ammonium molybdate tetrahydrate in glass distilled water and diluting to 1 dm^3. The metal content of the solution was determined with use of 8-quinolinol.[15] The stock solution was diluted to desired concentration.

Preparation of Reagent. The reagent was prepared by condensation of equimolar ratio of *N*-(3,4-dimethylphenyl)-benzimidoyl chloride and *N*-*p*-tolylhydroxylamine in ether medium.[13,16] The resulting hydrochloride was treated with dilute ammonia to liberate the corresponding free base. The free base was crystallized from benzene:petroleum ether (2:1). Mp 154 °C; yield 68%. Found: C, 79.64; H, 6.42; N, 8.22%. Calcd for $C_{22}H_{22}N_2O$: C, 80.00; H, 6.66; N, 8.48%.

A 0.1% w/v solution of reagent in benzene was used. A 10 and 5% w/v aqueous solution of ascorbic acid and potassium thiocyanate respectively, were used throughout the experiment.

Procedure. Place an aliquot of solution containing 200 μg of molybdenum on a 100-cm^3 separatory funnel. To this add 5 cm^3 of ascorbic acid followed by 5 cm^3 of potassium thiocyanate in final dilution of 25 cm^3 aqueous volume with subsequent adjustment of the acidity to 3.5 mol dm^{-3} HCl. Add 25 cm^3 benzene solution of reagent and equilibrate for 3 min. Allow the phases to separate and transfer the benzene layer to a 50-cm^3 beaker containing 2 g of anhydrous sodium sulfate. Measure the absorbance at 470 nm against a reagent blank.

Results and Discussion

Absorption Spectra. The absorption spectra of reagent and mixed complex are shown in Fig. 1. The reagent shows a negligible absorption in the region 450—700 nm. In the presence of thiocyanate a stable orange-red Mo(V)–htdb–SCN mixed complex is formed into benzene, showing a molar absorptivity of 3800 dm^3 mol^{-1} cm^{-1} at 470 nm.

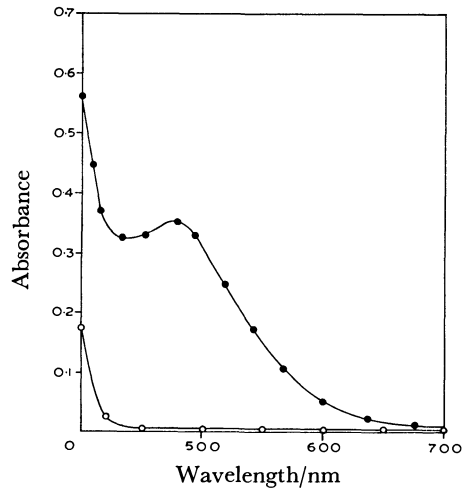

Fig. 1. Absorption spectra.
●: Mo(V)–htdb–SCN (8.33 10^{-5} M C_{Mo}), ○: 0.1% (w/v) Hhtdb in benzene.

Effect of Experimental Variables. Various water immiscible organic solvents such as benzene, toluene, carbon tetrachloride, and chloroform were examined for extracting the molybdenum mixed complex. Benzene was found to be the best solvent because of high extractability of mixed complex of molybdenum into it.

The acidity of aqueous phase was maintained with hydrochloric acid. Other mineral acids are unsuitable for extraction. If the concentration of hydrochloric acid in aqueous phase lies between 0.5—8.0 mol dm^{-3} the position of the absorption band of benzene extract remains intact but the absorbance value is affected. The optimum acidity range was found to be 2.0—4.5 mol dm^{-3} HCl.

A 30 and 300 fold molar excess of Hhtdb and thiocyanate were necessary for quantitative extraction of molybdenum. Addition of more reagents (100 and 2000 fold molar excess of Hhtdb and thiocyanate, respectively) has no adverse effect on the absorption and maximum wavelength of the coloured complex.

The period of equilibration was varied from 3 to 30 min. Extraction being quantitative after 3 min, it is recommended that the mixture be shaken for at least 3 min.

Variation in volume of aqueous phase in the range 10—60 cm^3 and temperature range 20—35 °C caused no measurable change in the absorbance of the molybdenum mixed complex. The benzene extract was stable for at least 20 h at 27±2 °C.

Beer's Law, Optimum Concentration Range and Precision. The molybdenum concentration range which follows Beer's law was found to be 3—20 ppm of metal. The optimum concentration range evaluated on the basis of the Ringbom plot[17] was 5—18 ppm of molybdenum. The precision of the system was checked by measuring the absorbance values of 10 samples, each containing 200 μg molybdenum/25 cm^{-3}. The relative standard deviation of the method was found to be 0.98%.

Composition. In molybdenum–thiocyanate–htdb mixed complex the ratio of molybdenum to reagent and thiocyanate was determined by the curve fitting method[18] (log absorbance *vs.* log [M] of reagent/thiocyanate). The results showed the formation of a 1:2:2 (metal:reagent:thiocyanate) mixed complex in benzene (Figs. 2 and 3).

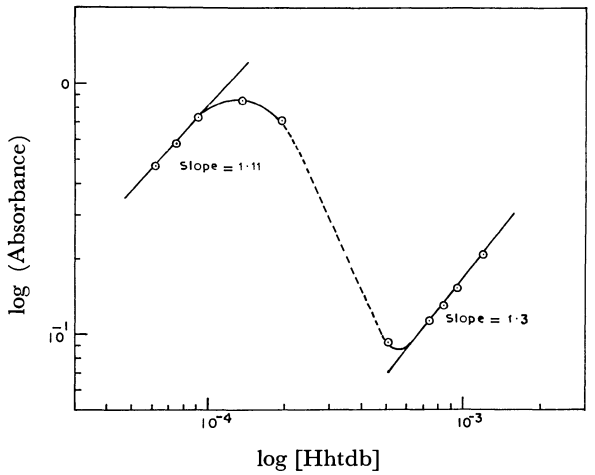

Fig. 2. Curve fitting method to determine the ratio of Mo(V) to $HOC_{22}H_{21}N_2$ in Mo(V)–$OC_{22}H_{21}N_2$–SCN complex.
0.1 mol dm^{-3} SCN, 3.0 mol dm^{-3} HCl.

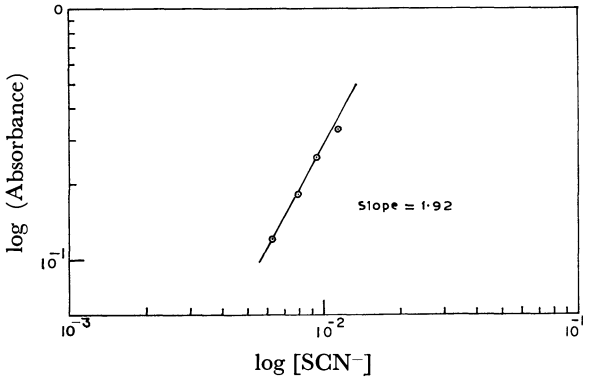

Fig. 3. Curve fitting to determine the ratio of Mo(V) to SCN^- in Mo(V)–$OC_{22}H_{21}N_2$–SCN complex.
0.003 mol dm^{-3} $HOC_{22}H_{21}N_2$, 3.0 mol dm^{-3} HCl.

The absorbance of Mo(V)–htdb–SCN mixed complex varies with the amount of reagent. Absorbance increases up to 2 fold molar excess of reagent, then a sudden decrease in absorbance is observed in 3—6 fold molar excess and beyond 6 fold molar excess the absorbance gradually increases. The results indicate that 1:1:2 and 1:2:2 (metal:htdb:SCN) stable complexes are formed (Fig. 2). However, if the reagent is added in excess only a 1:2:2 mixed complex is formed.

The overall extraction equilibrium may be expressed as follows:[19]

$$MoO^{3+} + 2SCN^- + 2Hhtdb_o \rightleftharpoons MoO(SCN)_2OC_{22}H_{21}N_2(HOC_{22}H_{21}N_2)_o + H^+,$$

where $HOC_{22}H_{21}N_2$ denotes hydroxyamidine and subscript o, the organic phase.

Effect of Foreign Ions. In order to study the effect of diverse ions on the determination, an aliquot of molybdenum solution containing 200 μg of the metal was transferred to a 100-cm^3 separatory funnel and to this was added a solution containing a known

amount of diverse ions. The acidity was adjusted to 3.5 mol dm^{-3} with hydrochloric acid and the total volume to about 25 cm^3, molybdenum being extracted with the reagent as described above. Chloride, bromide, nitrate, sulfate, urea, thiourea, tin(II), triethanolamine, borate, phthalate, selenate, alkali, and alkaline earth elements and lanthanoid elements have no interfering effect up to 3000 ppm. The tolerance limits for other ions are given in Table 1.

Application of the Method. In order to test the validity of method, two alloy steels obtained from Bureau of Analysed Sample Ltd., Newham Hall, Middlesbrough, Yorks, and an ore from Indian Bureau of mines, Nagpur, India, have been employed. The results are given in Table 2.

Table 1. Tolerance limit for diverse ions

Ions added	Tolerated amount[a] / ppm	Ions added	Tolerated amount[a] / ppm
Fe(III)	1500	Ce(IV)	500
Ti(IV)	120	V(V)	120
Zr(IV)	700	Nb(V)	200

Table 2. Determination of molybdenum in ore and alloy steels

Sample	Certified value / %	Found,[a] %	Standard deviation
Ore[b]	2.9	2.89	±0.0328
Steel, BCS[c] No. 64a	4.11	4.08	±0.0469
Steel, BCS[c] No. 241/1	0.52	0.495	±0.0636

a) An average of 6 determinations. b) Obtained from Indian Bureau of Mines, Nagpur. c) British Chemical Standard.

Dissolve an appropriate weight of the sample (1 g for 0.5% of molybdenum, 0.1—0.3 g for 5% of molybdenum) in 50 cm^3 sulfuric acid, and oxidize with concentrated nitric acid. The solution is evaporated almost to dryness 3—4 times and diluted with water. Undissolved silica and inorganic matter are filtered off and the solution is diluted to a definite volume in a calibrated flask. Take an aliquot of this solution, add 5 cm^3 of ascorbic acid solution and determine the molybdenum content by the procedure given above.

Stereochemistry of Base-catalysed Addition of Methyl Mercaptoacetate to Acetylenic Ketones and Esters. Effects of Activating Groups and Solvents

Mohamed Nabih BASYOUNI,* Mohamed Tawfik OMAR, and Edwar Amin GHALI
Chemistry Department, Faculty of Science, Ain Shams University, Abbassia, Cairo, Egypt
(Received May 1, 1979)

Piperidine-catalysed addition of methyl mercaptoacetate to benzoyl- and *p*-chlorobenzoyl-phenylacetylenes in ethanol gave the corresponding (*Z*)-1-aryl-3-(methoxycarbonylmethylthio)-3-phenyl-2-propen-1-one. However, *p*-anisoylphenylacetylene gave a mixture of (*Z*)- and (*E*)-3-(methoxycarbonylmethylthio)-1-(*p*-methoxyphenyl)-3-phenyl-2-propen-1-ones in the ratio of 4: 1. This ratio was completely inverted when the latter addition was carried out in dry benzene. Rationalisation of these results is presented which depends on the effect of activating groups and solvents on the stereochemistry of addition. Piperidine-catalysed addition of methyl mercaptoacetate to methyl phenylpropiolate in ethanol gave methyl (*Z*)-3-(methoxycarbonylmethylthio)cinnamate. Hydrazine hydrate converted some of the above mono-adducts into some pyrazole derivatives.

As the continuation of our work[1,2] on the stereochemistry of the base-catalysed addition of thiols to non-terminal acetylenes, we now report the results obtained from such addition of methyl mercaptoacetate to aroylphenylacetylenes, which has not been investigated previously. Furthermore, the addition to methyl phenylpropiolate was also investigated. The work was undertaken primarily to obtain more precise information on the effect of activating groups and solvents on the stereochemistry of the addition.

Thus, when methyl mercaptoacetate was added to benzoyl- and *p*-chlorobenzoyl-phenylacetylenes Ia and Ib in the presence of a catalytic amount of piperidine in ethanol at room temperature, the solid products obtained were proved to be (*Z*)-3-(methoxycarbonylmethylthio)-1,3-diphenyl-2-propen-1-one IIa and (*Z*)-3-(methoxycarbonylmethylthio)-1-(*p*-chlorophenyl)-3-phenyl-2-propen-1-one IIb, respectively. However, *p*-anisoylphenylacetylene Ic reacted with methyl mercaptoacetate under the same experimental conditions, giving two mono-adducts, that is, (*Z*)-3-(methoxycarbonylmethylthio)-1-(*p*-methoxyphenyl)-3-phenyl-2-propen-1-one IIc and its (*E*)-isomer III in the ratio of about 4: 1.

(*E*)-III

The structures of the mono-adducts IIa—c and III were determined from the following evidence: i) analytical data, ii) the infrared spectra, which show,

TABLE 1. SPECTRAL DATA FOR COMPOUNDS II AND III

				3.9	(3H, s, OCH_3)

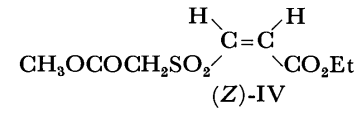
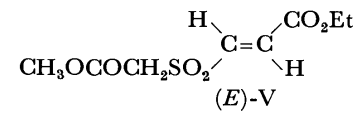
a) Lit,[5] $\nu_{C=O}$ at 1730 cm^{-1} and λ_{max} (ε) 275(10500), 211(10580).

inter alia, the bands at 1640—1660 cm^{-1} and 1725—1780 cm^{-1}. The low frequency band may be correlated with $\nu_{C=O}$ of α,β-unsaturated ketones[3] and the higher frequency one with $\nu_{C=O}$ of saturated esters,[3] iii) the electronic spectral data exhibit absorption maxima at 323—332 nm characteristic of chalcones[4] and iv) the NMR spectra of the mono-adducts IIb, IIc, and III agree quite well with the structures assigned to them (*cf.* Table 1).

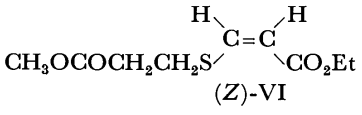
Tentative assignment of configuration to the mono-adducts IIc and III, obtained from methyl mercaptoacetate and *p*-anisoylphenylacetylene, as (*Z*) and (*E*), respectively, was based on the following: it has been reported by Bohlmann and Bresinsky[5] that in (*Z*)- and (*E*)-sulfones IV and V, respectively, the signal for SCH_2 protons in the former appears at higher field than that for the corresponding protons of the latter. Also, Halphen and Owen[6] have found that the signals for SCH_2 and $C\underline{H}_2CO_2CH_3$ in ethyl *cis*-3-[2-(methoxycarbonyl)ethylthio]acrylate VI appear at higher field when compared with those of the corresponding *trans* isomer. Since in the present investigation the signal for the SCH_2 protons in the major isomer appears at relatively higher field than that for the minor isomer, the former may be similarly assigned the (*Z*)-configuration and the latter the (*E*)-configuration. It is worth noting that the signal for the ester methyl protons of the (*Z*)-isomer appears at higher field than that of the corresponding protons of the (*E*)-isomer whereas the signals for the methoxyl groups of both isomers appear at the same position (with same strength) (*cf.* Table 1).



(*Z*)-IV



(*E*)-V

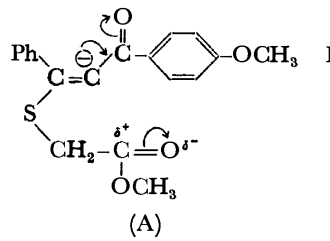


(*Z*)-VI

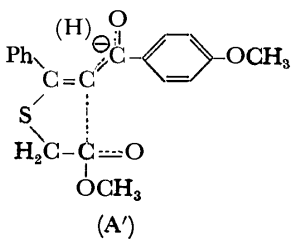
However, this tentative assignment was further confirmed from the following evidence: a) the electronic spectral data of the two isomers IIc and III. Thus, it is evident from Table 1 that the absorption maxima of IIc are shifted slightly to longer wave lengths with increasing strength, compared with those of III. This indicates that III has the (*E*)-configuration whereas IIc must have the (*Z*)-configuration which is consistent with the cis-trans relationship[7] on the one hand and with the configurations of *cis*- and *trans*- chalcones[4] on the other, and b) the infrared spectra of the two isomers which show $\nu_{C=O}$ of α,β-unsaturated ketone system at 1640 and 1660 cm^{-1} (Table 1). The higher value must be of the (*E*)-isomer III and the lower of the (*Z*)-isomer IIc. This is consistent with those of transoid and cisoid enones,[8] respectively.

Similarly, the mono-adducts IIa and IIb were assigned the (*Z*)-configuration on the basis of the results that their electronic spectra are similar to that of (*Z*)-IIc and also from the value of $\nu_{C=O}$ of the α,β-unsaturated ketone system (*cf.* Table 1). Moreover, the signals for SCH_2 and CO_2CH_3 protons in IIb are the same as those of (*Z*)-IIc in position and strength.

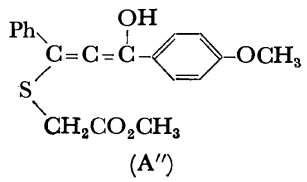
Formation of only the (*Z*)-isomers IIa and IIb in the case of addition of methyl mercaptoacetate to acetylenic ketones Ia and Ib, respectively, and (*Z*)-IIc as a major product in the case of Ic is in accord with the rule of *trans* nucleophilic addition.[9] However, formation of some (*E*)-isomer III from the addition of methyl mercaptoacetate to *p*-anisoylphenylacetylene Ic merits explanation, since it has been reported[2] that the piperidine-catalysed addition of arenethiols to Ic under the same experimental conditions, gives only the (*Z*)-mono-adducts, namely (*Z*)-3-arylthio-1-(*p*-methoxyphenyl)-3-phenyl-2-propen-1-ones, *via* a concerted mechanism. It seems, therefore, that the mercaptoalkanoate moiety had played a role that facilitates formation of the (*E*)-isomer III and that a different mechanism, most probably a stepwise one might be operating in such addition. According to this mechanism, the mercaptoalkanoate anion adds first to Ic to give the anion (A) in which an interaction between the positively polarized carbon atom of the ester carbonyl group and the negatively charged α-acetylenic carbon atom is possible (*cf.* transition state A′). As a result of this interaction, proton abstraction from the protic solvent is no longer localized on the α-acetylenic carbon atom but can occur at the ketonic carbonyl oxygen atom as well, since the basicity of the latter is enhanced owing to the activating effect of the *p*-methoxyl group. Thus, addition of the proton can occur either to the α-acetylenic carbon atom or to the oxygen atom of the ketonic group. It is evident that in the former case addition of the proton will lead to formation of only the (*Z*)-isomer IIc, whereas in the latter case an enolate A″ is formed. Tautomerisation of A″ to the carbonyl compound can then lead to a mixture of the (*Z*)-IIc and its (*E*)-isomer III.



(A)



(A′)



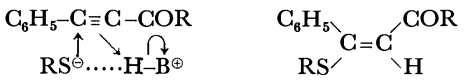
(A″)

Formation of only the (*Z*)-isomers IIa and IIb on treating Ia and Ib, respectively, with methyl mercaptoacetate under the same experimental conditions can be explained on the basis that in the transition state, the proton will add preferentially to the α-acetylenic carbon atom, since in these cases the basicity of the oxygen atom of the ketonic group is not enhanced as a result of the absence of activating *p*-substituent groups.

It is worth noting that the degree of *trans* stereoselectivity for nucleophilic additions of arenethiols to terminal acetylenes of the type H–C≡C–Y in methanol has been reported,[10] depending on the nature of the activating group Y and decreasing in the case that Y is a carbonyl-containing group, *i.e.* CO_2CH_3 or $COCH_3$. An enolate intermediate has also been proposed in these cases.[10]

Since (*Z*)-IIc is configurationally stable under the same experimental conditions (see Experimental), formation of its (*E*)-isomer III could not arise from it by post-isomerisation.

If concerted addition of a proton from a protic solvent is indeed a major factor in *trans* addition, a change of solvent might produce a change in product stereochemistry. An aprotic solvent would be incapable of making such an involvement and, if in such a solvent a thiol and a basic catalyst were to behave as thiolate-protobase ion pair, protonation might, perforce, take place on the same side as thiolate coordination, so that a *trans* product might be formed by *cis* addition. This postulate has been tested previously by Halphen and Owen[6] who studied the addition of mercaptoalkanoic acid to ethyl propiolate in different solvents and concluded that the base-catalysed addition of thiols to terminal acetylenes, *i.e.* propiolates, in dilute solution of aprotic solvents will, in general, favour the formation of *trans* enesulfides (by *cis* addition). The results obtained from the present investigation may be taken as an added proof for the validity of this mechanism in the case of addition of thiolates to non-terminal acetylenes in an aprotic solvent. Thus, when methyl

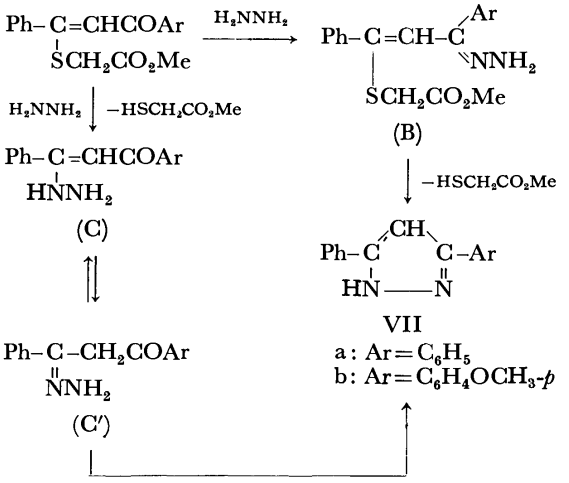


mercaptoacetate was allowed to add at room temperature to *p*-anisoylphenylacetylene Ic in dry benzene and in the presence of piperidine as a catalyst, two mono-adducts were separated (see Experimental), the major product (45%) being identical (mp, mixed mp, and IR spectroscopy) with (*E*)-3-(methoxycarbonylmethylthio)-1-(*p*-methoxyphenyl)-3-phenyl-2-propen-1-one III and the minor product (10%) being identical with (*Z*)-3-(methoxycarbonylmethylthio)-1-(*p*-methoxyphenyl)-3-phenyl-2-propen-1-one IIc. It is worth noting that the ratio of the (*Z*)-isomer IIc to its (*E*)-isomer III when the addition was carried out in ethanol at room temperature was found to be 4: 1.

It may, therefore, be concluded that the presence of the activating groups, namely COAr, in conjugation with the triple bond of non-terminal acetylenes can affect the stereochemistry of the base-catalysed addition of methyl mercaptoacetate in such a manner as to permit some *cis* addition, and that the change of solvent from a protic to an aprotic solvent can produce a dramatic change in product stereochemistry, *i.e.* gives predominantly *trans* or (*E*)-mono-adducts resulting from *cis* addition. Furthermore, a total stereoselectivity was observed during the addition of the same nucleophile to the non-terminal acetylenic ester, namely methyl phenylpropiolate.

Thus, piperidine-catalysed addition of methyl mercaptoacetate to methyl phenylpropiolate Id in ethanol gave methyl 3-(methoxycarbonylmethylthio)cinnamate IId which was analytically pure and showed the infrared-spectral bands for $\nu_{C=O}$ at 1760 (sh), 1730, and 1720 cm^{-1}, which may be correlated with $\nu_{C=O}$ of saturated esters[3] and α,β-unsaturated esters.[3] It is worth noting that Bohlmann and Bresinsky[5] have studied the addition of methyl mercaptoacetate to ethyl phenylpropiolate in dimethyl sulfoxide containing potassium *t*-butoxide as a catalyst and obtained a mono-adduct whose spectral data (see Table 1) are in good agreement with those of the product obtained from the present investigation, namely IId. They[5] did not assign any configuration to the mono-adduct. However, the compound in our hands may be tentatively assigned the (*Z*)-configuration on the basis of the results that similar addition of thiolates to ethyl phenylpropiolate proceeded exclusively by *trans* addition.[11]

The mono-adducts IIa and IIc reacted with hydrazine hydrate to give 3,5-diphenylpyrazole VIIa and 1*H*- or 2*H*-3-(*p*-methoxyphenyl)-5-phenylpyrazole VIIb, respectively. The reaction may be represented as involving an *in situ* formation of the hydrazone (B) whose NH_2 group then attacked the β-carbon atom to give the cyclised product with elimination of methyl mercaptoacetate or alternatively the hydrazine may attack the β-carbon atom first with expulsion of methyl mercaptoacetate to give (C), not isolated, which is tautomeric with (C'). Condensation of the NH_2 group with the carbonyl group can then lead to the pyrazole derivative.



Experimental

All melting points are not corrected. Infrared and electronic spectra were measured on a Unicam SP 1200 spectrophotometer (KBr discs) and Beckmann DK 2 spectrophotometer (in ethanol), respectively. NMR spectra (in $CDCl_3$) were determined on a Varian T 60 instrument using TMS as an internal reference.

(Z)-IIa—c and (E)-III 1-Aryl-3-(methoxycarbonylmethylthio)-3-phenyl-2-propen-1-ones. To a solution of the ketone Ia, b, or c (0.005 mol) in ethanol (10 ml) was added a solution of methyl mercaptoacetate (0.005 mol) in ethanol (10 ml) followed by one drop of piperidine. The reaction mixture was then allowed to stand at room temperature for *ca.* 20 h. The precipitated solids were filtered off and recrystallized from an

Table 2. (*Z*)-1-Aryl-3-(methoxycarbonylmethylthio)-3-phenyl-2-propen-1-ones IIa—c and (*E*)-3-(methoxycarbonylmethylthio)-1-(*p*-methoxyphenyl)-3-phenyl-2-propen-1-one III

Compound	Melting point °C	Yield %	Formula	Found (%) C	H	S	Calcd (%) C	H	S

a) From light petroleum (bp 80—100 °C). b) From light petroleum (bp 60—80 °C). c) From light petroleum (bp 60—80 °C), mixed mp with III 60—65 °C. d) From benzene–light petroleum (bp 60—80 °C).

appropriate solvent to give the *(Z)-title compounds*. Evaporation of the mother-liquor at room temperature after separation of the (*Z*)-IIc gave a solid residue which was fractionally recrystallized from light petroleum (bp 60—80 °C) to which had been added few drops of benzene to give (*E*)-III. The combined mother-liquors after isolation of (*E*)-III were evaporated at room temperature to give a small amount of (*Z*)-IIc. The results are given in Table 2.

When dry benzene was used as a solvent in the case of addition of methyl mercaptoacetate to *p*-anisoylphenylacetylene Ic, the precipitated solid was fractionally crystallized from benzene–light petroleum (bp 60—80 °C) to give the (*E*)-3-(methoxycarbonylmethylthio)-1-(*p*-methoxyphenyl)-3-phenyl-2-propen-1-one III in 45% yield, mp and mixed mp with the sample obtained from the addition in ethanol 112—113 °C. The mother-liquors gave a precipitated solid which was recrystallized from light petroleum (bp 60—80 °C) to give the (*Z*)-3-(methoxycarbonylmethylthio)-1-(*p*-methoxyphenyl)-3-phenyl-2-propen-1-one IIc in 10% yield, mp 88—89 °C, not depressed upon admixture with the (*Z*)-IIc obtained from the reaction using ethanol as a solvent.

Attempted Isomerisation of (Z)-3-(Methoxycarbonylmethylthio)-1-(p-methoxyphenyl)-3-phenyl-2-propen-1-one, IIc. Piperidine (0.1 ml) was added to a solution of the *title compound* (0.001 mol) in ethanol or benzene (5 ml) and the solution kept at room temperature for 20 h. The solid obtained after allowing the solvent to evaporate at room temperature was crystallized from light petroleum (bp 60—80 °C) to give unchanged starting material (mp, mixed mp, and IR spectroscopy) in *ca.* 95% recovery.

Methyl (Z)-3-(Methoxycarbonylmethylthio)cinnamate, IId. To a solution of methyl phenylpropiolate Id (0.01 mol) in ethanol (20 ml) was added methyl mercaptoacetate (0.01 mol) followed by one drop of piperidine and the solution was allowed to stand at room temperature until crystallization occurred. Recrystallization of the filtered solid product from benzene–light petroleum (bp 60—80 °C) gave the title compound as colourless crystals in 55% yield, mp 97—98 °C. Found: C, 58.5; H, 5.3; S, 12.4%. Calcd for $C_{13}H_{14}SO_4$: C, 58.6; H, 5.3; S, 12.0%. Evaporation of the mother-liquors left an oil which contained unchanged starting materials since infrared spectroscopy shows, *inter alia*, $\nu_{C\equiv C}$ at 2200 cm^{-1}.

3,5-Diphenylpyrazole, VIIa, and 1H- or 2H-3-(p-Methoxyphenyl)-5-phenylpyrazole, VIIb. To a solution of the monoadducts IIa or IIc (0.003 mol) in ethanol (20 ml) was added excess hydrazine hydrate and the reaction mixture was refluxed for 2.5 h. After 24 h the solid product was collected by filtration and recrystallized from ethanol. 3,5-Diphenylpyrazole VIIa was obtained as colorless crystals in 86% yield, mp 199—200 °C, undepressed upon admixture with an authentic specimen.[12] 1*H*- or 2*H*-3-(*p*-methoxyphenyl)-5-phenylpyrazole VIIb was obtained in 82% yield, mp 155—156 °C, undepressed upon admixture with an authentic specimen.[12]

NMR Studies of Zerovalent Metal π-Complexes of Dibenzylideneacetone. III. Conformation and Bonding of the Mononuclear Palladium and Platinum Complexes

Hisao TANAKA and Hiroshi KAWAZURA*

Faculty of Pharmaceutical Sciences, Josai University, Sakado, Saitama 350-02

(Received July 20, 1979)

Synopsis. ^{1}H-NMR spectorscopy of the M[$(C_6H_5$-CH=CH)$_2$CO]$_3$ (M=Pd,Pt) complexes revealed that the coordinated olefinic moieties are fixed in the *s-trans* form, while the uncoordinated ones are fluxional around the *s-cis* form. The fluxional behavior of the uncoordinated olefins was explained in terms of the π-back donation in the complexes.

The dibenzylideneacetone (dba) ligand provides a unique series[1,2] of zerovalent Pd and Pt complexes in which only the olefinic double bond participates in the bonding to the metal. As has been reported in the preceding papers,[3,4] the binuclear complexes, M(dba)$_3$ (M=Pd, Pt), retain a rigid structure, even in solution, where the two olefinic double bonds of dba are separately joined to the two metal atoms. However, the mononuclear complexes, M(dba)$_3$ (M=Pd, Pt), are expected to be in a more flexible form because of the existence[5] of olefinic portions free from coordination. We wish to report here on the fluxional behavior of the free olefinic portions, seen by ^{1}H-NMR spectroscopy, and on its correlation with the π-back bonding nature in the complexes.

Results and Discussion

Figure 1 shows the ^{1}H-NMR spectra of the compounds, M[$(C_6D_5$CH=CH)$_2$CO]$_3$ (M=Pd, Pt). Two kinds of AB quartet patterns are found in both spectra, where the high-field one and the low-field one originate from the protons of the coordinated olefin and from those of the free olefin in a given dba ligand respectively. The NMR parameters are gathered in Table 1, where δ_A and δ_B are the chemical shift of the proton on the carbonyl side (H_A) and that on the phenyl side (H_B) respectively.

As has previously been discussed,[3,4,6] the conformation of the olefinic moiety of the dba ligand can be discriminated from the magnitude of the internal shift $\delta_{AB}(=\delta_B-\delta_A)$; $\delta_{AB}\leqslant 0.4$ for the *s-cis* form and $\delta_{AB}\geqslant 1.0$ ppm for the *s-trans* form. Therefore, the coordinated olefins with δ_{AB} of 1.22 for the Pd complex and that of 1.08 ppm for the Pt complex are found to be in the *s-trans* form. On the other hand, the uncoordinated olefins have δ_{AB}'s of 0.50 and 0.82 ppm for the respective complex, comparable to that of 0.63 ppm for free dba.

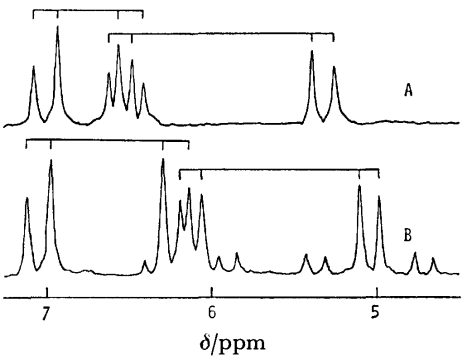

Fig. 1. ^{1}H-NMR spectra of Pd[$(C_6D_5$CH=CH)$_2$CO]$_3$ (A) and Pt[$(C_6D_5$CH=CH)$_2$CO]$_3$ (B), measured in $CDCl_3$ at −60 °C.

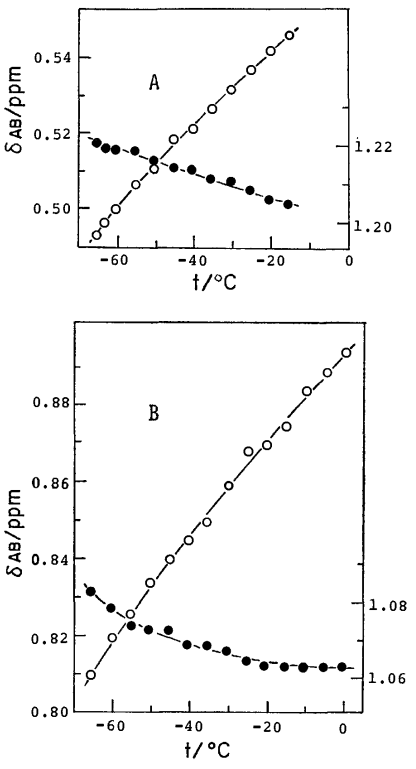

Fig. 2. Temperature dependence of the δ_{AB} for the coordinated (●; right ordinate) and uncoordinated olefins (○; left ordinate): A; Pd(dba)$_3$ and B; Pt(dba)$_3$ in $CDCl_3$.

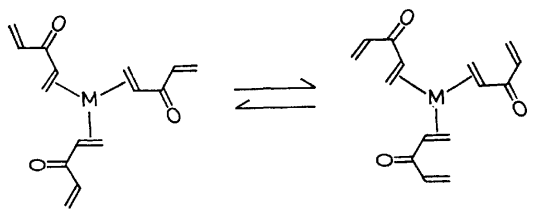
In order to ascertain the detail of the ligand conformation, we have examined the temperature dependence of δ_{AB} (Fig. 2). With an increase in the temperature, the δ_{AB}'s for the coordinated olefins decrease slightly, indicating a characteristic aspect of the behavior[4] of the fixed *s-trans* form,[7] while the δ_{AB}'s for the uncoordinated olefins increase markedly, as in free dba, in which the olefins are in an equilibrium[6] between the major *s-cis* and minor *s-trans* forms. Thus, the temperature dependence of δ_{AB} for the uncoordinated olefins was analyzed assuming the following equilibrium and thermodynamic relation:



$$\ln \frac{\delta_{AB}^{obsd}-\delta_{AB}^{t}}{\delta_{AB}^{c}-\delta_{AB}^{obsd}} = -\frac{\Delta H}{RT} + \frac{\Delta S}{R},$$

$$\delta_{AB}^{obsd} = c^{c}\delta_{AB}^{c} + c^{t}\delta_{AB}^{t} \quad (c^{c}+c^{t}=1).$$

Here, δ_{AB}^{c} and δ_{AB}^{t} are the intrinsic values of δ_{AB} for the *s-cis* and *s-trans* forms. When the optimal values[8] of ΔH and ΔS are adopted, δ_{AB}^{c} and δ_{AB}^{t} are 0.44 and 1.48 ppm for the Pd complex and 0.50 and 1.47 ppm for the Pt complex; the values are close to the corresponding values[6] of 0.44 and 1.59 ppm for free dba. The conformer populations of the *s-cis* form (c^{c}) are 0.90(−15°) and 0.94(−60°) in the Pd complex and 0.62(−15°) and 0.67(−60°C) in the Pt complex.

Thus, the dba ligands of the Pd complex might exist almost entirely in the *s-cis*, *s-trans* form, as in the crystalline state,[5] while those of the Pt complex could contain an appreciable amount of the *s-trans*, *s-trans* form. The conformational difference between the two complexes can be understood in terms of the metal-olefin π-back donation. As has already been clarified by an INDO calculation of the dba molecule,[6] the *s-trans*, *s-trans* form has a highly repulsive interaction arising mainly from the proximity of the two H_B protons, and so becomes destabilized in the free state. The coordination to the metal, however, causes a little change in the geometry of the dba molecule, such as an out-of-plane bending[9] of the olefinic hydrogens, which diminishes the core repulsion within the ligand and makes feasible the existence of the *s-trans*, *s-trans* form. Such a stabilization effect of *s-trans*, *s-trans* form would be more effective in the Pt complex than in the Pd complex, since the π-back donation is stronger in the Pt complex, as is confirmed[4] by the values of the *trans*-olefinic coupling, J_{AB}, and the mean shift, $\bar{\delta}_{H}[=(\delta_{A}+\delta_{B})/2]$. We conclude that the π-back donation not only plays a major role in determining the bonding strength of the coordinated olefin in the zerovalent metal complex, but also determines the conformational attitude of the uncoordinated counterpart.

Experimental

The complexes, $M[(C_6D_5CH{=}CH)_2CO]_3$ (M=Pd,Pt), were prepared by the method of Moseley and Maitles,[10] using the dba-d_{10}.[6] To assign δ_A and δ_B, the $M[(C_6D_5CD{=}CH)_2CO]_3$ and $M[(C_6D_5CH{=}CD)_2CO]_3$ compounds were synthesized by a similar method. The samples were prepared at *ca.* −60 °C and were measured on a JEOL PFT/EC 100 spectrometer. Least-squares calculations for the analysis of δ_{AB} were performed on an IBM 1130 machine at Josai University.

A Re-investigation of the Conformational Interconversion in the 1,2,3,6,7,8-Hexahydropyrene Anion Radical by ENDOR

Masamoto Iwaizumi,* Shouichi Kita, Masahiro Kohno,† and Taro Isobe
Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira, Sendai 980
†*Analytical Instrument Division, JEOL, Ltd., Akishima, Tokyo 196*

(Received August 14, 1979)

Synopsis. The ENDOR spectra of the 1,2,3,6,7,8-hexahydropyrene anion radical were measured at −94—−60 °C. Based on the computer simulation of the temperature-dependent ENDOR spectra, the thermodynamic constants of the conformational interconversion of the anion radical were determined and compared with those previously obtained by ESR spectroscopy.

Magnetic resonance spectroscopy has been used as one of the most effective techniques for the investigation of chemical-dynamic processes. Many papers have been reported on the ESR investigation of the conformational intercoversion of radical molecules. Iwaizumi *et al.*[1] and de Boer *et al.*[2] have reported on the line-width-alternation effect on the ESR spectra of the anion radical of 1,2,3,6,7,8-hexahydropyrene (HP) (Fig. 1);

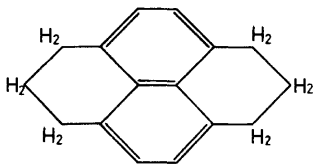

Fig. 1. 1,2,3,6,7,8-Hexahydropyrene, HP.

they attributed the effect to the conformational interconversion of the $HP^{\cdot}$ molecule between a chair form and a boat form. Claridge *et al.*[3] and Pijpers *et al.*[4] made more detailed kinetic studies and obtained the thermodynamic constants of the conformational interconversion through a computer simulation of the ESR spectra, depending on the temperature. However, appreciably different thermodynamic parameters were reported by the two groups (see Table 1). Both groups measured the ESR spectra of $HP^{\cdot}$ in the same solvent, but they used different counter ions in their experiments; *i.e.*, Claridge *et al.* treated $HP^{\cdot}$ in 1,2-dimethoxyethane (DME) with the sodium ion, while Pijpers *et al.* treated $HP^{\cdot}$ in DME with the potassium ion. In our experiment, however, no differences in the ESR spectra could be found between those two solvent and counter-ion systems to give such different thermodynamic constants. In the present work, we attempted a reexamination of the conformational interconversion of $HP^{\cdot}$ by means of ENDOR spectroscopy. Shain has also examined $HP^{\cdot}$ by the use of ENDOR, but he could not observe the ENDOR spectra at various temperatures.[5]

The magnitude of ENDOR enhancement depends on all the possible transition rates in the spin system; it changes with the temperature and with the viscosity of the solvents, and in some cases the observation of the ENDOR spectra is limited to a narrow temperature region. In Shain's experiment, where DME was used as the solvent, the observation of the ENDOR spectra was possible only in the vicinity of the freezing point of the solution (up to about 10 °C above the freezing point). In the present work, we used bis(2-methoxyethyl) ether (diglyme), with a higher viscosity than DME, and DME as the solvents. The latter was used for the measurements at temperatures below the freezing point of the former.

Results and Discussion

The ENDOR spectra were recorded with a JEOL ES-EDX-1 ENDOR spectrometer. By the use of diglyme, the ENDOR spectra could be observed up to about −60 °C. Over the temperature range used (−60 — −94 °C), the line widths, positions, and shapes of the ENDOR signals due to the β and γ protons change with the temperature; the signals due to the β protons broaden, and the separation between the two lines attributable to the axial and equatorial ones becomes smaller with an increase in the temperature, representing that the dynamic process of the β protons is in the slow-rate region, $\Delta\omega_{\beta}\tau \ll 1$, while the two ENDOR lines attributable to the axial and equatorial γ protons observed at the low temperatures collapse into a single line with an increase in the temperature, representing that the dynamic process of the γ protons ranges from the slow- to the fast-rate region, $\Delta\omega_{\gamma}\tau \gg 1$—$\Delta\omega_{\gamma}\tau \ll 1$. Here, τ is the mean lifetime of each conformation, and $\Delta\omega_{\beta}$ and $\Delta\omega_{\gamma}$ are $2\pi|(a_{\beta ax}-a_{\beta eq})/2|$ and $2\pi|(a_{\gamma ax}-a_{\gamma eq})/2|$ respectively, the hyperfine coupling constants for the axial and equatorial β and γ protons, $a_{\beta ax}$, $a_{\beta eq}$, $a_{\gamma ax}$, and $a_{\gamma eq}$, being measured in Hz. We obtained τ values as a function of the temperature, based on the computer simulation of the line shape, for the β- and γ-proton ENDOR lines. It is known that the line-shape for ordinary ENDOR lines of radicals should be a saturated Lorentzian.[6] In the present case, however, we ignored such an effect and simply assumed that the line-shape for the ENDOR signals under the dynamic process are expressed by the

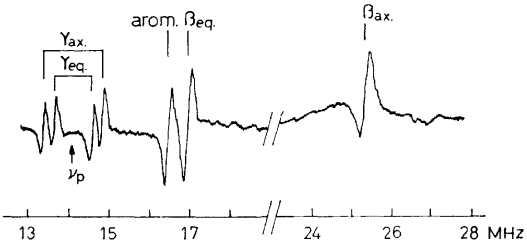

Fig. 2. ENDOR spectrum of $HP^{\cdot}$ in DME with K^+ at −94 °C. ν_p is free proton frequency and β_{ax}, β_{eq}, γ_{ax}, γ_{eq}, and arom. indicate the signals due to the axial and equatorial β and γ protons and aromatic protons, respectively.

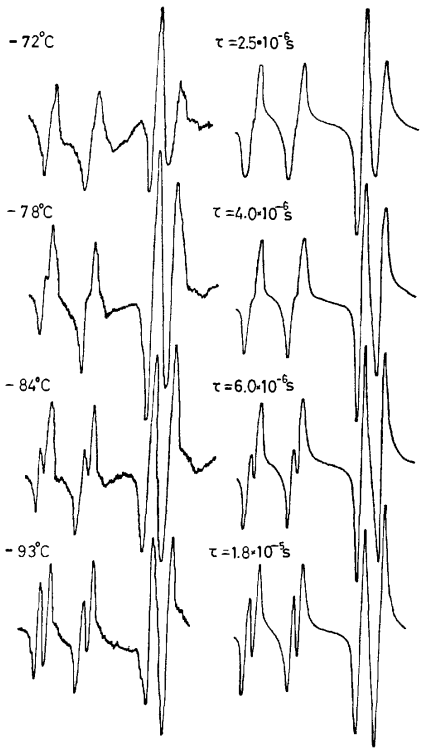

Fig. 3. Temperature dependence of the ENDOR spectra and the computer simulations. The spectrum at −93 °C was observed from $HP^{\bullet}$ in DME with K^+ and the others from $HP^{\bullet}$ in diglyme with K^+.

modified Bloch equation.[7] The line shapes were calculated by using the four-jump model[8] and using the $a_{\beta ax}$, $a_{\beta eq}$, $a_{\gamma ax}$, and $a_{\gamma eq}$ values obtained from the spectrum at the lowest temperature in the experiment. For the evaluation of τ, we also applied the following equations for the β-proton ENDOR signals:

$$1/T_2'(\text{ENDOR}) = k'$$

$$\Delta\omega = (\Delta\omega_{\beta}^2 - 8k'^2)^{1/2}$$

where $1/T_2'$ (ENDOR) is an additional line-broadening in the ENDOR signals, $\Delta\omega$ is the observed separation between the ENDOR lines due to the axial and equatorial β protons, and $k'=1/2\tau$.[9] Figure 3 shows the temperature dependence of the ENDOR signals in the

14—17 MHz region, and the computer simulations of the spectra, the ENDOR signals due to the aromatic protons being expressed as having the same intensity over the present temperature range. The Arrehnius plot is shown in Fig. 4. The thermodynamic constants thus obtained are listed in Table 1. It may be seen that the obtained thermodynamic constants are in rather good agreement with Claridge *et al.*'s values, and that the activation energy, E_{act}, obtained in the present work for $HP^{\bullet}$ is smaller than the value reported by Pijpers *et al.* Pijpers *et al.* have indicated that the E_{act} for $HP^{\bullet}$ is larger than that for HP^{+}; *i.e.*, the E_{act} for $HP^{\bullet}$ is 41.8 kJ mol^{-1}, while the E_{act} for HP^{+} is 14.6 kJ mol^{-1}.[4] However, such a large difference in the E_{act} between the anion and the cation radicals seemed quite surprising, though in our ESR studies of the conformational interconversion of 4,5,9,10-tetrahydropyrene ion radicals, too, a larger activation energy has been observed for the anion radical.[10] The E_{act} value obtained in the present work indicates that the difference between the E_{act} for the anion and the corresponding cation radical may be rather smaller than that reported by Pijpers *et al.* It may also be noted that the E_{act} for $HP^{\bullet}$ is smaller than that for the intercoversion between a chair and a boat form of the neutral cyclohexane molecule, 42.3 kJ mol^{-1}.[11]

The ENDOR Spectrum of 1,7,7-Trimethylbicyclo[2.2.1]heptane-2,3-dione Semiquinone in Solution

Reiko Tosa,*† Yashige Kotake, Masaharu Okazaki, Hideo Shikata,†† and Keiji Kuwata

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received September 3, 1979)

Synopsis. The ENDOR spectra of 1,7,7-trimethylbicyclo[2.2.1]heptane-2,3-dione semiquinone (camphorsemiquinone anion) showed a sharp temperature variation in the intensity of each ENDOR line. The relationship between the optimum temperature for the ENDOR enhancement and the relaxation mechanisms was discussed on the basis of the experimental results.

Sharp variations with the temperature in the relative intensities of ENDOR signals have been a problem of much interest in connection with the discussion of the relaxation mechanism[1–4] and finding the optimum conditions for ENDOR experiments[3] in solution. Generally, the nuclear relaxation due to the electron-nuclear dipolar (END) interaction[2] and the flip-flop transition due to the modulation of isotropic hyperfine interaction[4] are known to be effective for ENDOR enhancement in solution. The camphorquinone anion has a rigid structure, as is shown in Fig. 1; therefore, the hyperfine interaction can hardly be expected to be modulated by the internal motions of the molecule.[4] Moreover, an unpaired electron delocalizes in the O–C–C–O moiety, and the END interaction is estimated to be small because β, γ, and δ-protons are distant from the unpaired electron. Thus, it seemed it would be interesting to observe the ENDOR of this anion and discuss the mechanisms of ENDOR.

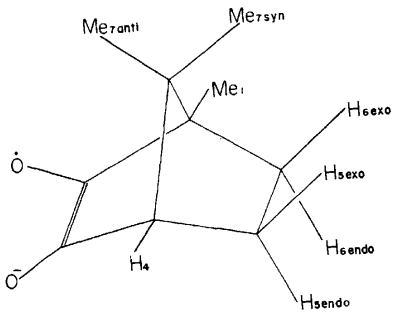

Fig. 1. The molecular structure of camphorquinone.

1,7,7-Trimethylbicyclo[2.2.1]heptane-2,3-dione (camphorquinone) was reduced with sodium (or potassium)-isopropoxide in isopropyl alcohol, which had been dehydrated by refluxing with calcium hydride, and then transferred to a sample tube by vacuum distillation. Samples were diluted until the effect of the Heisenberg spin exchange or intermolecular dipolar interaction on the ESR spectrum became negligible. For ENDOR observation, the magnetic field was fixed at an intense

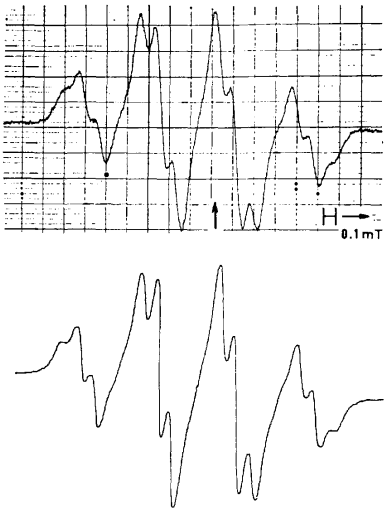

Fig. 2. ESR spectrum of camphorquinone anion in isopropyl alcohol. Upper, experimental spectrum; lower, spectrum simulation using A_{iso}'s given in Table 1.

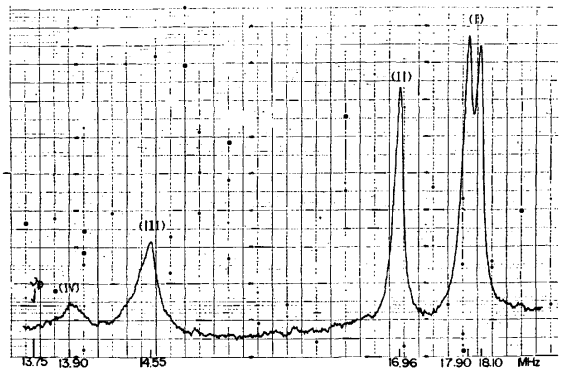

Fig. 3. ENDOR spectrum of camphorquinone anion in isopropyl alcohol at −40 °C.

peak of the high-field side, as is indicated in Fig. 2.

The ENDOR spectrum at frequencies higher than that of the free proton frequency (ν_p=13.75 MHz) is shown in Fig. 3, where the ENDOR lines are numbered from I through IV from the high-frequency side. The doublet at 18 MHz showed a tendency to enlarge the incision as the microwave power decreased. This doublet may result from two hyperfine interactions of a similar, but slightly different magnitude; it is not caused by the coherence effect because of the absence of any change in the splitting on a decrease in the rf power.

For a series of compounds with a molecular frame similar to camphorquinone, by the varying substituents, the ESR spectra were analysed in detail by Russell.[5] In the ENDOR spectrum of camphorquinone, a slight

a) The largest value among the anisotropic hyperfine coupling constants.

difference in the hyperfine splittings for two *exo*-protons, which had been assumed by Russell to be equivalent, came to light (see Table 1). This difference may be due to the slight asymmetry of the structure of this ion. The broadening of the ENDOR lines, (III) and (IV), seems to show an overlap of ENDOR lines for the protons with slightly different hyperfine splitting constants from each other, but no further resolution could be obtained.

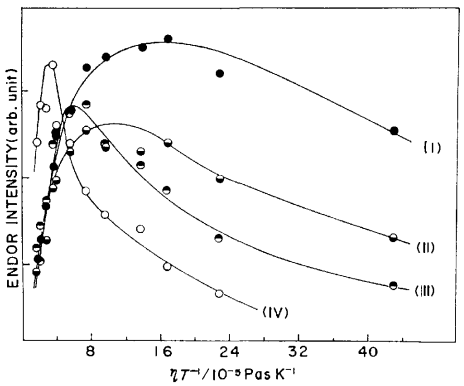

Fig. 4. Dependence of ENDOR intensity on η/T in isopropyl alcohol.
(I) *exo*-protons, (II) proton at 4 position, (III) *syn*-protonin the methyl group at 7 position, (IV) *endo*-protons (also *anti*-proton in the methyl group at 7 position).

For each peak of the ENDOR spectrum, the dependency of the intensity on η/T, where η is the viscosity coefficient of the solvent, was examined, and the optimum temperature where ENDOR enhancement reaches its maximum was obtained (Fig. 4). According to the assignment with the values of A_{iso}, which give adequate ESR simulation, it was presumed that the (I)—(IV) ENDOR lines correspond to H_{exo}, H_4, $Me_{7\,syn}$, and H_{endo} (also $Me_{7\,anti}$) protons respectively.

The END term and isotropic term for each proton are given in Table 1. The isotropic term was determined from the ESR spectrum simulation and then confirmed more minutely by ENDOR. The END term was estimated by the theory of McConnell and Strathdee,[6] using the unpaired electron density calculated by the HMO method.

When the END mechanism dominates for α protons on the aromatic ring, it has been found that the proton with the larger END term shows a maximum ENDOR intensity at a lower value of η/T than the proton with the smaller END term.[3] In the present system, the same relationship was found on H_{exo}'s and H_4 protons, but not on H_{endo} and H_4 protons. As the reason for this discrepancy, it was postulated that the $Me_{7\,anti}$ proton has an A_{iso} value very close to those for $H_{5\,endo}$ and $H_{6\,endo}$; thus, the multiplicity of the electron-spin state increases and the optimum temperatures of the H_{endo}'s shift to higher values.[7]

The anisotropic interaction of the $Me_{7\,anti}$ protons with an unpaired electron may be supposed to be fairly large when these methyl protons move to the vicinity of the π-conjugate system in the semiquinone anion in the course of the internal rotation of the methyl group. Then, the relaxation of the nuclear spins of the methyl protons may be greatly accelerated by the modulation of the anisotropic interaction due to the molecular motion or internal motions of the methyl group. This possibility, however, is not supported at the present stage of experiments, for no clear difference in the relaxation behavior has been found between the $Me_{7\,anti}$ protons and the $Me_{7\,syn}$ protons, which have a much smaller anisotropic interaction. This is probably due to the shorter correlation times of the motions induced by the Brownian motion of the solvent molecules.

In the $H_{5\,exo}$, $H_{6\,exo}$, and H_4 protons, a smaller difference was found between the optimum temperatures for the H_{exo}'s and H_4 than would be expected from the difference between their END terms; this may be due to the shift of the optimum temperature for H_{exo}'s to a higher value because of the higher multiplicity for H_{exo} protons.

The Configuration of the Adsorbed Polymer at the Solid-Liquid Interface as Depicted by ESR and IR Studies

Harutoshi SAKAI* and Yoshio IMAMURA

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received October 16, 1979)

Synopsis. Bound segment fractions of adsorbed poly(methyl methacrylate) on silica in CCl_4 were determined by both the spin-labeling technique and infrared spectroscopy. The ESR method yielded considerably larger values than the IR, indicating a highly flattened structure of the adsorbed polymer. However, the greater reliability of the ESR method was pointed out.

Problems of the configurational properties of chain polymer molecules adsorbed at the solid-liquid interface have been receiving much attention in both theoretical and practical fields. In many of the theoretical treatments, it has been predicted that the fraction of the bound segments, p, becomes close to unity in the case of a strong attractive force between the segment and the surface.[1] The experimental estimation of p was first reported by Fontana and Thomas using IR spectroscopy.[2] They obtained values of p from 0.3 to 0.4 for the adsorbed poly(alkyl methacrylate) on silica in organic solvents. Later experiments showed a similar tendency.[3,4] Recently, an ESR technique, the spin-label method, has been employed by Robb *et al.*[5] for studies of the adsorption of poly(vinylpyrrolidone) onto silica, mainly from aqueous solutions. The ESR values of p from 0.6 to 0.9 were appreciably higher than the results from the IR method. A comparison of the ESR and IR techniques was attempted by Robb and Smith, mainly from the standpoint of utility.[6] However, it could not be decided whether the large difference in the estimated values of p comes from the differences in the adsorption systems (polymer, solvent, and solid) or from those in the evaluating methods, since they had merely compared their ESR observations with the published data obtained by the IR method. In the present work, we will deal with an experimental comparison of ESR and IR methods using the case of adsorbed poly(methyl methacrylate) on silica from a CCl_4 dilute solution.

Experimental

Spin-labeled PMMA was prepared by the anionic copolymerization of methyl methacrylate and 4-methacryloyloxy-2,2,6,6-tetramethyl-1-piperidyloxyl (molar ratio 450: 1) with a phenylmagnesium bromide catalyst in toluene at 0 °C.[7] One fraction of the narrow molecular-weight distribution, obtained by repeated fractional precipitation, was used throughout the adsorption experiments. The number-average mol wt of the fraction used was determined to be 1.22×10^5 by membrane osmometry. The spin-label concentration in the polymer was about one label per 400 monomer residues. Cabosil M-5 supplied by Cabot, Far East, Inc., was used as the adsorbent; it had a specified surface area of 220 m^2/g for nitrogen adsorption. The polymer was adsorbed onto the silica from a CCl_4 dilute solution at 25 °C. Measurements of the ESR spectra were performed on a JEOL JES FE-3X spectrometer, while the corresponding IR spectra were recorded on a JASCO, DS 403G spectrometer.

Results and Discussion

In Fig. 1, (a) shows a typical IR absorption of the adsorbed PMMA, while (b) shows the normal spectrum of the free polymer in the CCl_4 solution. The spectrum (c), which was attributed to the H-bonded carbonyl, was obtained by graphical subtraction of (b) from (a), after conversion into a suitable intensity scale. In this case, the H-bonding seems to bring about a frequency shift from 1736 to 1712 cm^{-1} and a line broadening. The fraction of the H-bonded carbonyl groups in the adsorbed polymer was determined by a modification of the method of Kalnin'sh *et al.*[3] The integrated absorption intensity was used for the calculation instead of the extinction coefficient.

A typical ESR spectrum of the adsorbed PMMA is shown in Fig. 2(e). The line shape indicates that the spectrum is composed of several portions which are easily distinguishable in their molecular motion. These arise from differences in the configurational states of the segments in the adsorbed polymer chain. From the analysis of the line shape, we concluded that the spectrum of the adsorbed polymer could be separated into three component spectra. On the other hand, we obtained three different spectra of PMMA which have different degrees of motional freedom. These are shown in Fig. 2(a), (b), and (c);

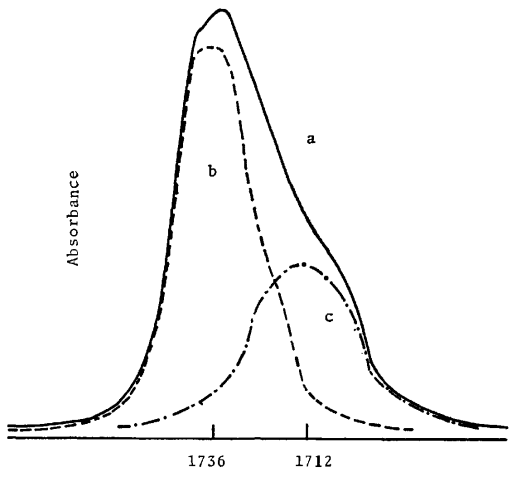

Fig. 1. IR absorption spectra of PMMA at the C=O stretching frequency.
a: Adsorbed on silica in CCl_4, b: in free CCl_4 solution, c: produced by graphycal subtraction of (b) from (a).

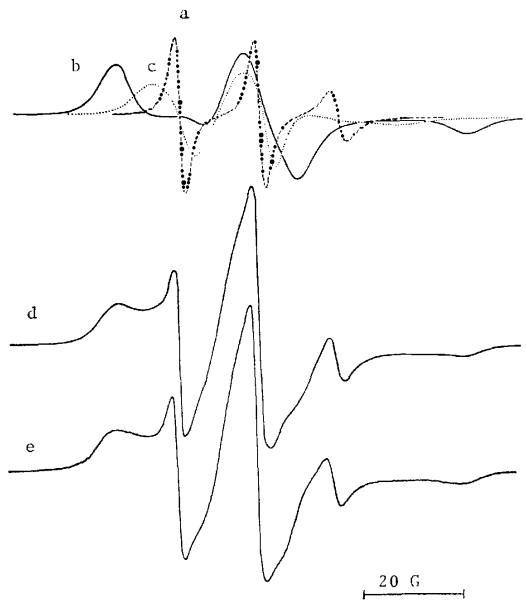

Fig. 2. ESR spectra of spin-labeled PMMA.
Top: a; in CCl_4 solution at 10 °C, b; in the frozen solution at −120 °C, c; of the molten state at 146 °C. Center: d; reproduced by superposition of above three model spectra. Bottom: e; adsorbed on silica in CCl_4 at 25 °C.

(a): a free polymer solution of a low viscosity at 10 °C (2 mg/ml), (b): a solution cooled to the frozen state at −120 °C, (c): a highly viscous polymer in the molten state at 146 °C. Apparently, the chain mobility decreased in the order of (a), (c), and (b). From the observation of the apparent line shape, the three spectra were found to correspond roughly to the three components of the adsorbed polymer. These three reference spectra were superimposed upon one another with suitable intensity ratios to reproduce the observed spectrum (e). The reproduced spectrum (d) closely fits in the observed line shape. In the polymer chain lying on the solid surface, the sequences of the segments directly bound to the surface should have restricted motion, while the detached segments should be much more mobile. Therefore, the component in a very strongly immobilized state was assigned to the train segments directly bound to the surface. The other two components, in relatively mobile states, were assigned to the free segments which are forming a short loop or a long loop. Our experimental evidence that the spin labels do not have a stronger affinity for the silica surface than the original MMA monomer demonstrates that specific adsorption through the nitroxide labels does not proceed during the polymer-adsorption process.

The values of p obtained by the ESR analysis are plotted against θ in Fig. 3. Here, θ is the amount of adsorption relative to the saturated adsorption, By our preliminary experiments, the saturated amount of adsorption was almost independent of the molecular weight of the polymer, while p decreased moderately with an increase in the mol wt. The fractions of the H-bonded carbonyl groups obtained by the IR analysis are also plotted in Fig. 3. The results from ESR exhibit a much higher level than the IR results. Both ESR and

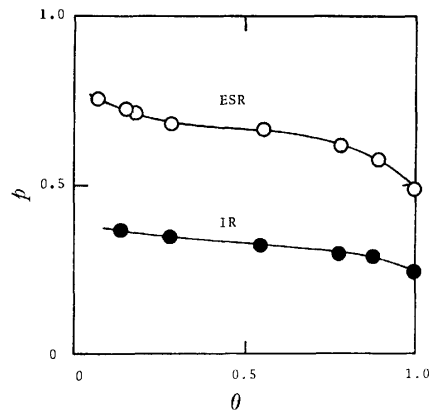

Fig. 3. Fraction of bound segments (p) *vs.* relative amount of adsorption (θ).

IR values of p were moderately decreased with an increase in θ. At the initial stage of a small amount of adsorption, θ=0.27, the ESR value of p was 0.67, which showed an appreciably flattened structure of the adsorbed polymer.

Cabosil silica has, as is well known, a partially hydrolized surface and a relatively small density of silanol groups on its surface. Most of those silanol groups are "isolated hydroxide" groups which are distant from one another beyond 4 Å. The density of the surface silanol available for the H-bonding with the polymer carbonyl was estimated to be about 3 OH per 100 Å^2 or less from the results obtained for the saturation adsorption (1.77 mg/m^2), where 24% of the carbonyls of the adsorbed PMMA were H-bonded. If a sequence of the segments is anchored only by the H-bonding with such dilute silanols, the absorbed sequence should be highly elongated along the surface.

One possible explanation for the large differences in our results from ESR and IR methods is as follows; some of the segments in a train interact with the silanol groups, while the remaining train segments interact with "non-hydroxylic sites"[8] on the silica surface. The IR method evaluates only the segments adsorbed through the H-bonding between the carbonyl and the silanol, whereas the ESR method evaluates the segments adsorbed in any mechanism. Therefore, the conventional IR method tends to estimate p values smaller than the actual values. On the other hand, we consider that the ESR method is more advantageous, as it visualizes the actual structure of the adsorbed polymer.

Simple Topological Theory of Aromaticity for Annulenes and Radialenes

Jun-ichi AIHARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received January 5, 1980)

Synopsis. Simple theory of aromaticity for annulenes and radialenes is developed by means of generalized total π-electron energy indexes, and is used to rationalize thermochemical stability and diamagnetic susceptibility exaltation of these compounds.

Total π-electron energy, E_π, is one of the fundamental quantities in chemistry of conjugated compounds. It is essential to the estimation of their thermochemical stability and reactivity. Molecular orbital (MO) theory has so far provided much information concerning total π-electron energies of conjugated hydrocarbons.[1] In parallel with this, a considerable amount of effort has been devoted to correlating the total π-electron energy E_π with particular structural features of a conjugated system.[2] Coefficients of the Hückel MO characteristic polynomial P(X) also reflect E_π in a like manner.[2-5] They can easily be evaluated by inspection of a molecular geometry.[5-7] Hosoya *et al.* previously proposed a modified topological index for E_π as a function of most coefficients of $P(X)$.[3] We later generalized it so as to include contributions from all the coefficients.[4] Our generalized total π-electron energy index Z^* is formally defined as

$$Z^* = |P(\mathrm{i})|, \tag{1}$$

where $\mathrm{i}=\sqrt{-1}$. In the case of alternant hydrocarbons, Z^* exactly agrees with Hosoya's modified topological index.[3,4] The total π-electron energy can nicely be approximated as[4]

$$E_\pi \approx E_\pi^* = 6.0846 \log Z^*, \tag{2}$$

in units of β. In this note I would like to show that Eqs. 1 and 2 are very useful for elucidating aromatic character of annulenes and radialenes.

∞	∞	2.5432	2.5465

First, the Z^* value of [N]annulene is given in a general form as

$$Z^* = \frac{1}{\sqrt{5}}\left(\frac{1+\sqrt{5}}{2}\right)^{N+1} - \frac{1}{\sqrt{5}}\left(\frac{1-\sqrt{5}}{2}\right)^{N+1} - 2(-1)^{N/2}. \tag{3}$$

Derivation of this expression is based on the recursion formula for obtaining topological indexes of annulenes.[8] Individual Z^* values are presented in Table 1. Since E_π^* represents estimated total π-electron energy of [N]-annulene, the π-electron energy per annulene unit structure is given as $2E_\pi^*/N$. This quantity corresponds to a sum of π-electron energies of the C=C bond and its adjacent C–C bond in the canonical structure.[9,10] As easily seen from Table 1, the $2E_\pi^*/N$ value oscillates about the limiting value of 2.5432β. This limiting value is an estimated π-electron energy per unit structure for an infinitely large annulene, which is evidently free from aromaticity.

Accordingly, annulenes with $2E_\pi^*/N < 2.5432\beta$ are predicted to be aromatic, and those with $2E_\pi^*/N > 2.5432\beta$ to be antiaromatic. Although these predictions seem very rough, they are in good accord with Hückel's $(4n+2)$ rule of aromaticity.[11] All annulenes predicted to be aromatic possess $(4n+2)$ π-electrons, and those predicted to be antiaromatic possess $4n$ π-electrons. Such a way of aromaticity consideration is exactly the same as those presented by Aihara,[10] Cocordano,[12] and Haddon.[13] The Hückel MO π-electron energies per unit structure are favorably compared with the $2E_\pi^*/N$ values in Table 1. Another important point is that the π-electron energy per unit structure becomes nearly constant for annulenes with $N \geq 20$. This aspect of our total π-electron energy index Z^* is quite consistent with the finding of Dewar *et al.*[14] and Hess and Schaad[9] that bond energies are additive for nonaromatic species.

Next, the Z^* value of [N]radialene is expressed as

$$Z^* = \begin{cases} (1+\sqrt{2})^{N+1} + (1-\sqrt{2})^{N+1} - 2(-1)^{N/2} & \text{for } N = 2n \\ \{[(1+\sqrt{2})^{N+1} + (1-\sqrt{2})^{N+1}]^2 + 4\}^{1/2} & \text{for } N = 2n+1, \end{cases} \tag{4}$$

where n is an integer. Derivation of this expression is also based on the recursion formula for obtaining topological indexes of radialenes.[8] Individual Z^* values are listed in Table 2. A radialene unit structure is a combination of the CH_2=C bond and its adjacent C–C bond in the canonical structure.[9,10] Unlike annulenes, radialenes appear substantially olefinic in nature except for slightly antiaromatic [4]radialene. All the π-electron energies per unit structure (E_π^*/N) are very close to the limiting value of 2.3290β. Comparison with MO π-electron energies per unit structure[9,10,14] supports nonaromatic character of radialenes thus predicted. These results are of course

Table 2. π-Electron energies per unit structure of radialenes (E_π/N) in units of β

11	16238.00	2.3290	2.4320
12	39200.00	2.3290	2.4320
13	94642.00	2.3290	2.4320
14	228488.00	2.3290	2.4320
15	551614.00	2.3290	2.4320
∞	∞	2.3290	2.4320

consistent with our graph theory of aromaticity.[15]

An NMR criterion of aromaticity has also been used according to which diamagnetic ring currents indicate aromaticity while paramagnetic ring currents indicate antiaromaticity.[16] We can show that such a magnetic criterion of aromaticity is identical with the above energetic criterion. When an external magnetic field, H, is applied perpendicularly to the molecular plane, our total π-electron energy index of [N]annulene becomes[17]

$$Z^* = \frac{1}{\sqrt{5}}\left(\frac{1+\sqrt{5}}{2}\right)^{N+1} - \frac{1}{\sqrt{5}}\left(\frac{1-\sqrt{5}}{2}\right)^{N+1} - 2(-1)^{N/2}\cos\Theta_N H, \quad (5)$$

where $\Theta_N = 2\pi e S_N/hc$. Here, S_N is the area enclosed by the [N]annulene ring, and e, h, and c are the standard constants with these symbols. When $N=4n+2$, the applied magnetic field decreases Z^*, so it decreases E_π^*. Conversely, when $N=4n$, the applied magnetic field increases both Z^* and E_π^*. Thus the effect of the magnetic field H on [$4n+2$]annulenes is exactly opposite to that on [$4n$]annulenes. This gives the reason why [$4n+2$]annulenes are diamagnetic while [$4n$]annulenes are paramagnetic.[16] Note that the second derivative of the total π-electron energy with respect to H gives the magnetic susceptibility of a conjugated system.[17] It should be noted that the sign of the susceptibility obtained from Eq. 5 agrees with experiment, so does the sign of the ring current.[16]

On the other hand, for [N]radialene in the magnetic field,

$$Z^* = \begin{cases} (1+\sqrt{2})^{N+1} + (1-\sqrt{2})^{N+1} - 2(-1)^{N/2}\cos\Theta_N H & \text{for } N = 2n \\ \{[(1+\sqrt{2})^{N+1} + (1-\sqrt{2})^{N+1}]^2 + 4\cos^2\Theta_N H\}^{1/2} & \text{for } N = 2n+1. \end{cases} \quad (6)$$

When N is even, the field effect on [N]radialene is in principle analogous to that on [N]annulene, but the former is much smaller than the latter. When N is odd, the field effect is essentially negligible. These suggest that marked diamagnetic susceptibility exaltation cannot be anticipated for radialenes. This is in harmony with their olefinic character.[9,10,14,15] We have thus been able to elucidate two major features of aromaticity, *i.e.*, specific stability and enhanced diamagnetism, in terms of our generalized total π-electron energy index Z^*.

Since 1971, Hosoya and coworkers have been interpreting various molecular properties in terms of topological indexes.[3,6,8,18] The present theory of aromaticity can hence be regarded as a practical extension of their topological chemistry. Simplicity and elegance are characteristics common to all these works.

The Back-extraction Behavior of Chelate Compounds. III.† The Extraction and the Back-extraction of the Metal (II) Diethyldithiocarbamates

Takaharu HONJO* and Hisanori IMURA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received October 2, 1979)

Synopsis. The behavior of trace amounts of cadmium(II), cobalt(II), copper(II), iron(II), mercury(II), manganese(II), nickel(II), lead(II), and zinc(II) in backextraction has been examined in order to establish the basic conditions for the separation of metals as their diethyldithiocarbamates by back-extraction.

A number of papers and reviews concerning the solvent extraction of metal diethyldithiocarbamates have been presented, but scarcely no back-extraction techniques have been examined and applied to the separation of metals.[1] In the present work, the behavior of trace amounts of cadmium(II), cobalt(II), copper(II), iron(II), mercury(II), manganese(II), nickel(II), lead(II), and zinc(II) in back-extraction has been examined in order to establish the basic conditions for the separation of metals as their diethyldithiocarbamates by back-extraction.

Experimental

Extraction. Extraction was carried out with a buffered solution containing a radioactive tracer; the pH was adjusted to the desired value by mixing an appropriate amount of 10^{-2} M (1M=1 mol dm^{-3}) of hydrochloric acid, acetic acid, sodium acetate, and sodium hydroxide. A solution of 5×10^{-3} M of DDDC (diethylammonium diethyldithiocarbamate) in carbon tetrachloride (10 cm^3) was shaken by means of a mechanical shaker (340 strokes/min) with an equal volume of an aqueous solution containing 10^{-4} M of each metal for 5 min at room temperature (20—25 °C). After centrifugation, a 3-cm^3 portion of each phase was pipetted out into a test tube, after which the radioactivity was counted with a NaI(Tl) scintillation counter. The distributions of Cu(II) and Ni(II) were spectrophotometrically determined by measuring the absorbance of $Cu(DDC)_2$ at 436 nm and that of $Ni(DDC)_2$ at 440 nm respectively. The concentration of uncomplexed DDDC in the organic phase was spectrophotometrically determined as a copper chelate in carbon tetrachloride. The pH of the aqueous phase was measured again after extraction by means of the pH meter.

Back-extraction. Since an organic phase which had been prepared by the standard extraction procedure contained an uncomplexed DDDC in a different quantity because of its decomposition, the organic phase was shaken with a buffered solution of pH 8—9 in order to remove the uncomplexed DDDC just before the back-extraction procedure. Then a 5-cm^3 aliquot of the organic phase was shaken with a 5-cm^3 portion of an aqueous solution adjusted to the desired pH or acidity for 5 min at room temperature. The distribution was determined as in the case of the extraction.

Percent Extraction. The percentage of extraction, %E, and the percentage of back-extraction, $\%E_{back}$ can be calculated by means of these equations: $\%E=D(1+D)\times100$ and $\%E_{back}=D^*(1+D^*)\times100$, where D and D^* are the net distribution ratios of a metal in the extraction and the back-extraction respectively.

Results and Discussion

The shaking time of 5 min was preferred in the extraction process, because the decomposition of DDDC and its metal chelates seems quite small within this time, as is shown in Fig. 1. The Mn–DDC chelate extracted was the most unstable among all the metal–DDC chelates in carbon tetrachloride, and decomposed gradually just after the extraction. The extraction of 10^{-4} M of 9 divalent metals was carried out with 5×10^{-3} M of DDDC in carbon tetrachloride for each, while the back-extraction of the metal diethyldithiocarbamates extracted was done with various acidic and basic aqueous solutions. The results are shown in Fig. 2 as a function of the pH or HCl(M) of the aqueous phase. The symbols in the two figures, A→O and O→A,

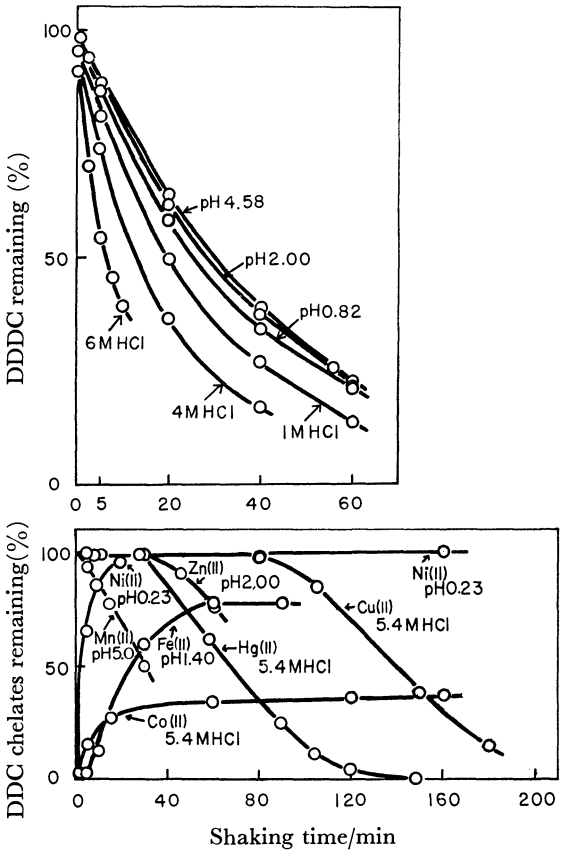

Fig. 1. Percentage of remaining of 10^{-3} —10^{-2} M of DDDC and its metal chelates in carbon tetrachloride on continuous shaking with an aqueous solution of various pH or various concentration of hydrochloric acid.

denote the extraction and the back-extraction of the chemical species respectively. The data on the $pH_{1/2}$ values (the pH of the half-extraction) and the $HCl_{1/2}$ (the concentration of hydrochloric acid of the half-extraction of metal diethyldithiocarbamates) obtained in the present extraction system are summarized in Table 1. The disagreement of the $pH_{1/2}$ and the $HCl_{1/2}$ values appearing in the liquid-liquid extraction of Cu(II), Hg(II), Pb(II), Cd(II), and Zn(II) with DDDC may be due to the fact that the concentration of DDDC is equivalent to those of metals in carbon tetrachloride in the back-extraction. The curves of Mn(II), Fe(II), Co(II), and Ni(II) in the extraction and the back-extraction give asymmetrical forms, suggesting an irreversible extraction process, *i.e.*, the oxidation of the metals or a slow rate of chelate formation during extraction. However, the curves of Zn(II) and Hg(II) in the extraction and the back-extraction became exactly symmetrical when the back-extraction was carried out with 5.0×10^{-3} M of DDDC in carbon tetrachloride. The solvent effect on the extractions of Zn(II) and Mn(II) with DDDC has also been investigated. As is shown in Fig. 3, Zn(II) and Mn(II) are readily extracted with non-polar solvents, such as benzene and carbon tetrachloride. The extractability of Zn(II) and Mn(II) with DDDC in nitrobenzene was found to be enhanced. The unstable $Mn(DDC)_3$ in carbon tetrachloride after extraction was not decomposed for at least 15 min with 12% nitrobenzene and not for 1 h with 80% nitrobenzene. This fact may result from the solvation effect of nitrobenzene, which has polarity; this polarity decreases the decomposition of DDDC and its metal chelates.

Table 1. $pH_{1/2}$ and $HCl_{1/2}$ values determined by the extraction and the back-extraction of metals with 5×10^{-3} M of DDDC in carbon tetrachloride

Metal	$pH_{1/2}$ or $HCl_{1/2}$	
	Extraction	Back-extraction[a]
Cd(II)	0.1	0.4

The Crystal Structures of Monoclinic and Triclinic Forms of Bis[(*R*)-1,2-propanediame]platinum(II) Chloride Dihydrate

Choji MAEDA, Keiji MATSUMOTO, and Shun'ichiro OOI*

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received October 8, 1979)

Synopsis. The crystal structures of monoclinic and triclinic forms of $[Pt(R\text{-pn})_2]Cl_2\cdot 2H_2O$ have been determined from diffractometer data. Despite the difference in crystal systems, the complex cations in the two kinds of crystals have essentially the same structure. The disposition of the CH_3 groups is *trans*. One of the chelate rings is of the λ conformation, with an equatorial CH_3 group, while the other has the δ conformation, with an axial CH_3 group.

The bis[(*R*)-1,2-propanediamine]platinum(II) ion ($[Pt(R\text{-pn})_2]^{2+}$) may exist in *trans* and *cis* isomers. The 100 MHz PMR spectrum of $[Pt(R\text{-pn})_2]Cl_2$ shows one methyl doublet at 1.35 ppm, indicating either that the compound comprises only one isomer or that methyl signals due to the *trans* and *cis* isomers are virtually superimposed in the 100 MHz spectrum.[1] The X-ray structure analysis of the title compound has disclosed that the compound contains only the *trans* isomer.

Experimental

$[Pt(R\text{-pn})_2Cl_2\cdot 2H_2O$ was prepared in two different ways. i) $[Pt(Cl)_2(R\text{-pn})]$ was treated with an excess of *R*-pn; subsequent recrystallization from water yielded predominantly monoclinic crystals, with a small amount of triclinic crystals. ii) The reaction of $PtCl_2$ with an excess of *R*-pn in water gave a compound with the same formula as that obtained in i), but in this case the quantity of triclinic crystals was larger than that of monoclinic ones. Both the monoclinic and triclinic crystals gave satisfactory analyses.

Crystal Data: 1) Monoclinic form (**1**), $a=5.181(2)$, $b=21.142(11)$, $c=6.776(2)$ Å, $\beta=96.50(3)°$, $D_m=2.02$, $D_c=2.03$ g cm^{-3}, $Z=2$, space group $P2_1$, μ(Mo $K\alpha$)$=103.6$ cm^{-1}: 2) Triclinic form (**2**), $a=10.688(9)$, $b=6.786(4)$, $c=5.174(3)$Å, $\alpha=96.27(6)°$, $\beta=96.54(6)°$, $\gamma=86.19(4)°$, $D_m=2.02$, $D_c=2.02$ g cm^{-3}, $Z=1$, space group P1, μ(Mo $K\alpha$)$=103.1$ cm^{-1}.

The intensities were measured on an automated diffractometer by means of the ω-2θ scan method, with graphite-monochromated Mo $K\alpha$ radiation. Crystal size: $0.20\times 0.20\times 0.25$ mm for **1**, $r=0.07$ mm for **2** (ground spherically); scan speed: 0.017° s^{-1} for **1** and **2**; scan range: $(0.8+0.2\tan\theta)°$ for **1**, $(1.0+0.2\tan\theta)°$ for **2**; background measurement at each end of the scan range: 20 s for **1** and **2**; maximum 2θ value: 55° for **1**, 50° for **2**; number of reflections with $F_0^2>3\sigma(F^2_0)$: 1576 for **1**, 1691 for **2**.

The refinement of the structures were performed by means of the block-diagonal least-squares method. The function minimized was $\sum w(F_0-|F_c|)^2$. The convergence was attained with $R=0.033$ ($R_w=0.042$) for **1** and $R=0.039$ ($R_w=0.048$) for **2**. w for **1**: $w=0.7$ for $F_0<13.0$, $w=1.0$ for $13.0\leq F_0\leq 32.0$, $w=(32.0/F_0)^2$ for $F_0>32.0$. w for **2**: $w=0.7$ for $F_0<17.0$, $w=1.0$ for $17.0\leq F_0\leq 40.0$, $w=(40.0/F_0)^2$ for $F_0>40.0$. No attempt was made to locate the H atoms. The atomic scatterings factors, with corrections for anomalous scattering of Pt^0 and Cl^-, were taken from Ref. 2. The F_0-F_c tables are deposited as Document No. 8015 at the Chemical Society of Japan. The atomic coordinates are listed in Table 1. All the computations were performed by using programs in UNICS[3] on a FACOM 230-60 computer at this University.

Results and Discussion

The crystal structures of **1** and **2** are shown in Fig. 1. Both the monoclinic and triclinic crystals comprise only the *trans* isomer with substantially identical

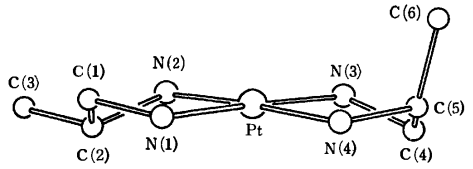

Fig. 2. The structure of $[Pt(R\text{-pn})_2]^{2+}$ ion.

structures. Moreover, the environments of the complex ions in the two structures have a close resemblance to one another. Furthermore, the two-dimensional crystal structure parallel to (010) in **1** is similar to that parallel to (100) in **2**, though the three-dimensional structures are different from each other in the stacking modes along the axes perpendicular to the respective planes. Such hircumstances are reflected in the interrelation between cte unit-cell dimensions of the two kinds of crystals; the a, b, c, and β in **1** are very close in magnitude to c, $2a$, b, and α in **2**. All the amino H atoms are involved in N–H···Cl hydrogen bonds, which are rather weak in view of the N···Cl distances.

One chelate ring has a λ conformation, with an equatorial CH_3 group, while in the other the conformation is δ, with an axial CH_3 group (Fig. 2). There have been two conflicting views regarding the behavior of the 5-membered chelate ring composed of Pd(II) or Pt(II) with the pn ligand. The observed coupling constants among the CH_2 and CH protons have been shown to be consistent with theoretical ones obtained from the conformationally fixed ring model with an equatorial CH_3 group.[1] On the other hand, the ^1H–^1H[4] and ^{195}Pt–^{13}C coupling constants,[5] as well as the circular dichroism intensity,[6] have been utilized to estimate the abandance ratio of the λ conformer to the δ conformer in the Pt(or Pd)-pn ring on the assumption that a rapid $\lambda \leftrightarrow \delta$ inversion takes place in the chelate ring. The λ: δ ratios were estimated to be 50: 50 and 70: 30 from the analyses of the ^1H–^1H and ^{195}Pt–^{13}C coupling constants respectively, and 3: 1, from that of the CD data, indicating the presence of a considerable amount of the axial CH_3 conformer in solution. Although the structure in a solid is not always held in solution, the axial CH_3 ring found in this work is indicative of the flexibility of the Pt-pn ring. From the point of view of the inverting ring model, the $\lambda\delta$ conformer is favorable in entropy term by $RT\ln 2$ over the $\lambda\lambda$ or $\delta\delta$ conformer. Provided that there exists no significant difference between the strain energies of the λ and δ rings, and that the two rings in the bis chelate are inverted independently from each other, the $\lambda\delta$ conformer is the most abundant species in solution. The finding that both kinds of crystals contain only the $\lambda\delta$ conformer implies that the assumption is not far from the real situation, although the conformation is largely dependent on the crystal packing.

This research was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Reaction of Bis[1-(2-pyridylazo)-2-naphtholato]cobalt(III) Chloride, $[Co^{III}(pan)_2]Cl$, with Hyperoxide in Dimethyl Sulfoxide†

Katsura MOCHIZUKI, Taira IMAMURA, and Masatoshi FUJIMOTO*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received October 18, 1979)

Synopsis. The complex $[Co^{III}(pan)_2]^+$ was found to react in DMSO with hyperoxide, O_2^-, to give a bivalent cobalt complex $[Co^{II}(pan)_2]^0$. The oxidation of $[Co^{II}(pan)_2]^0$ to $[Co^{III}(pan)_2]^+$ by oxygen did not proceed in DMSO in the absence of water and/or H^+. The standardization of O_2^- in DMSO were also described.

In aqueous solution the cobalt(II) complex $[Co^{II}(pan)_2]^0$ formed by the reaction of Co^{2+} and 1-(2-pyridylazo)-2-naphthol, PAN, was found to be successively oxidized to the cobalt(III) complex by dissolved oxygen.[1,2] In the present report the reaction of $[Co^{III}(pan)_2]^+$ and O_2^- in DMSO was investigated, where hyperoxide acts as a reducing agent.

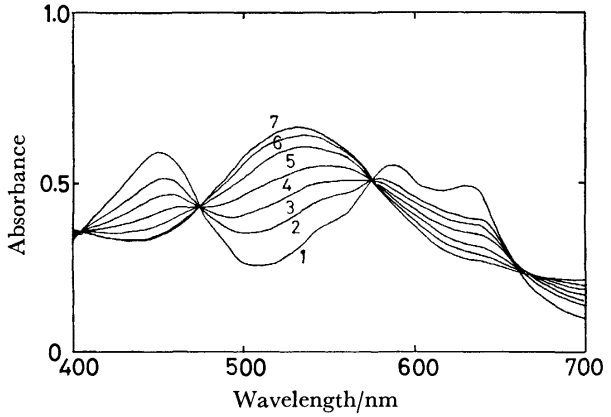

Fig. 1. The spectral change in the reaction of $[Co^{III}(pan)_2]Cl$ with O_2^- in DMSO. Initial concentrations of the complex and O_2^- are 2.18×10^{-5} and 2.99×10^{-4} mol dm^{-3}, respectively. The solution contains 1.42×10^{-3} mol dm^{-3} dicyclohexyl-18-crown-6 as a solubilizing agent. The spectrum was recorded at 0 (1), 0.5 (2), 4 (3), 11 (4), 30 (5), 60 (6), and 125 min (7).

Reaction of $[Co^{III}(pan)_2]Cl$ with O_2^-. Figure 1 shows a typical example of the spectral change for the reaction of $[Co^{III}(pan)_2]^+$ and O_2^- in DMSO. Each spectrum was recorded at appropriate time intervals. The spectra changed with isosbestic points at 475, 575, and *ca.* 650 nm.[3] The absorptions around 450 and 600 nm due to $[Co^{III}(pan)_2]^+$ decreased with the increase of a new absorption around 530 nm. The spectrum due to the free ligand PAN was not observed in the course of the reaction. The final spectrum of the reaction was essentially the same as the spectrum of (1) $[Co^{II}(pan)_2]^0$ observed as an intermediate in the course of the reaction between Co^{2+} and PAN,[2] (2) $[Co^{II}(pan)_2]^0$ observed in the deoxygenated system,[2] and (3) the final product obtained by the electrolytic reduction of $[Co^{III}(pan)_2]Cl$.[4] These results suggest the formation of $[Co^{II}(pan)_2]^0$ ($\lambda_{max}=530$ nm, $\varepsilon=28000$ mol^{-1} dm^{-3} cm^{-1} in DMSO) by the reaction of $[Co^{III}(pan)]^+$ with O_2^-.

The changes in the absorbance *vs.* time for the reaction of $[Co^{III}(pan)_2]^+$ with O_2^- in deoxygenated media and in undegassed solution were compared with each other. For the deoxygenated system the solutions of the two reactants were separately degassed beforehand by freezing several times. No difference in the rates of the reduction was observed between these two systems. This result suggests that the oxygen dissolved in the solution does not affect the rate of the reduction of $[Co^{III}(pan)_2]^+$ by O_2^-.

Kinetic measurements were carried out using a stopped-flow method under the conditions of O_2^- in large excess over the ligand. The pseudo-first-order rate constant, k_{obsd}, showed a first-order dependence on the total concentrations of $[O_2^-]_0$ (1.3×10^{-4}—6.3×10^{-4} mol dm^{-3}). From the slope and the intercept of the linear plots of k_{obsd} against $[O_2^-]$ the forward and the backward rate constants, k_f and k_d, were evaluated to be 5.2×10^2 mol^{-1} dm^3 s^{-1} and $<10^{-2}$ s^{-1}, respectively.

Stability of $[Co^{II}(pan)_2]^0$ in DMSO. When dry oxygen was passed for 1—2 h through a dry DMSO solution of $[Co^{II}(pan)_2]^0$ obtained by electrolytic reduction, no oxidation was observed, the spectrum remaining unchanged at least for 1 h. However the addition of a small amount of water (0.5 cm^3 H_2O to 3.5 cm^3 DMSO) changed the spectrum gradually to that of $[Co^{III}(pan)_2]^+$. Marked acceleration of the oxidation to $[Co^{III}(pan)_2]^+$ was observed by the addition of a slight excess of perchloric acid over $[Co^{II}(pan)_2]^0$; a large excess of perchloric acid dissociated the ligand PAN from cobalt(II) complex. These results suggest that the oxidation of $[Co^{II}(pan)_2]^0$ by oxygen does proceed in the presence of H_2O and/or H^+. The considerable stability of $[Co^{II}(pan)_2]^0$ in dry non-protonic solvent as DMSO and also the small value of k_d in dry DMSO support the following mechanism:

$$Co^{2+} + 2PAN \overset{H^+}{\rightleftharpoons} [Co^{II}(pan)_2]^0$$
$$\underset{O_2^- \text{ in DMSO}}{\overset{O_2,\ H_2O \text{ and/or } H^+}{\rightleftharpoons}} [Co^{III}(pan)_2]^+,\ k_d,\ k_f.$$

This mechanism is the same as that postulated for the reaction of copper phenanthroline complex with oxygen and hyperoxide.[5]

Experimental

Materials. The complex $[Co^{III}(pan)_2]Cl$ was pre-

† Presented in part at the 1979 Winter Meeting in Hokkaido of the Chemical Society of Japan and the Japan Society for Analytical Chemistry, Sapporo, February 2, 1979, Abstract, p. 25.

pared from cobalt(II) chloride and PAN (Dojindo, Kumamoto). Stoichiometric amount of cobalt(II) chloride in water and PAN in dioxane were slowly mixed with stirring. The solution was diluted with a large amount of water. Precipitates formed were filtered, washed successively with dioxane–water (1:20) and water, and dried *in vacuo*. Found: C, 58.66; H, 3.70; N, 13.57; Cl, 5.92%. Calcd for $C_{30}H_{20}N_6O_2CoCl \cdot H_2O$: C, 59.17; H, 3.64; N, 13.80; Cl, 5.82%.

Dicyclohexyl-18-crown-6 (perhydrodibenzo-18-crown-6) (Nippon Soda) and KO_2 (ICN Pharmaceuticals) were used without further purification. Dimethyl sulfoxide was dried with calcium hydride, distilled under reduced pressure, and stored under argon atmosphere. The solution of O_2^- was prepared by dissolving KO_2 in DMSO by adding dicyclohexyl-18-crown-6 in DMSO.[5]

Standardization of O_2^- in DMSO with Iodine. The concentration of O_2^- in DMSO solution was determined titrimetrically. To three cubic centimeters of a *ca.* 1×10^{-3} mol dm^{-3} solution of O_2^- in a capped optical cell a freshly-prepared standard DMSO solution of iodine (2.0×10^{-2} mol dm^{-3}) was added using a microsyringe, and the absorbance at 400 nm was measured after 15 min. The final absorbance was plotted against the amounts of I_2 solution added, showing the gradual decrease until it began to increase at the end point **A** in proportion to the concentration of an excess of iodine (see the inset of Fig. 2). The concentration of O_2^- was determined from the amount of iodine consumed at **A** based on the following reaction.

$$2O_2^- + I_2 \longrightarrow 2O_2 + 2I^-$$

Stability of O_2^- in DMSO. Figure 2 shows the change in the concentration of O_2^- in DMSO with the lapse of time stored at room temperature in a tightly-sealed flask in the dark as described in the literature.[5] Seventy percent of O_2^- based on the weighed amount of KO_2 was found to remain unchanged even a day after preparation. After 2 weeks the concentration of O_2^- decreased to 60%.

Measurements. Absorption spectra were measured at 25±0.2 °C with a Hitachi recording spectrophotometer Model EPS-3T. Platinum electrodes were used for the electrolytic reduction of the complex. Kinetic measurements were carried out with a Union Giken stopped-flow spectrophotometer Model 1300.

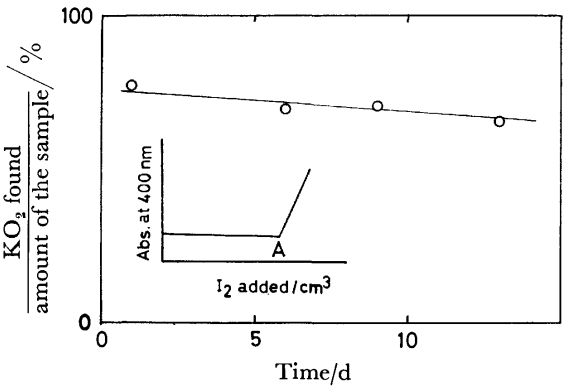

Fig. 2. The change in the concentration of O_2^- in DMSO solution with the lapse of time. The initial concentration of O_2^- was *ca.* 1×10^{-3} mol dm^{-3}. The inset shows a typical pattern for the change in absorbance at 400 nm against the volume of standard I_2 added (see the text).

Studies on the Solvent Extraction of Metal Perchlorates. I. Partition of Sodium(I) between Aqueous Perchlorate, Thiocyanate, and Iodide Solution and Hexane Containing Trioctylphosphine Oxide

Satoshi KUSAKABE and Tatsuya SEKINE*

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received November 26, 1979)

Synopsis. Extraction equilibria of sodium (I) in aqueous 1 mol dm^{-3} sodium salt–hexane containing trioctylphosphine oxide systems were measured at 25 °C. The extracted species was always trisolvate, the extraction being improved in the order $NaClO_4$>NaSCN>NaI>$NaNO_3$. This is explained in terms of the hydrofobic and hydrophilic tendencies of the anions.

The solvent extraction behavior of metal perchlorates with solvating type extractants differs somewhat from that of other salts in which the interactions between the metal ion and the anions are to some extent coordinative. We have measured the distribution ratio of sodium(I) between aqueous perchlorate solutions and hexane containing trioctylphosphine oxide (TOPO). In the present paper, the results are compared with those in other systems containing other kinds of anion.

Experimental

All the reagents were of reagent grade. A weighed amount of TOPO, supplied by Dojindo Laboratories, Kumamoto, was dissolved in hexane and washed with 0.1 mol dm^{-3} sodium hydroxide, the supernatant portion of organic phase being washed with water. Sodium perchlorate was recrystallized three times from water. The sodium salts were dissolved in water and the concentration was measured by gravimetry.

The distribution measurements were carried out in a room thermostated at 25±0.3 °C. A 5—7 cm^3 portion of a 1 mol dm^{-3} sodium salt solution and the same volume of a TOPO–hexane solution were placed in stoppered glass tube, agitated mechanically and centrifuged. A portion of the organic phase was transferred into another tube and the sodium (I) was back-extracted into 0.01 or 1 mol dm^{-3} nitric acid. The sodium content was measured by flame photometry.

Results and Discussion

The extraction of sodium(I) as ion-pairs with an anion, X^-, with TOPO can be expressed by

$$Na^+ + X^- + n\text{TOPO(org)} \rightleftarrows Na(TOPO)_n{}^+X^-\text{(org)}, \quad (1)$$

where "org" denotes chemical species in the organic phase. When the organic phase is an essentially nonpolar solvent, the dissociation of the extracted ion-pairs can be neglected. Since the solvation number was always three, we obtain the equation

$$D = [Na(I)]_{org}/[Na(I)] = [Na(TOPO)_3{}^+X^-]_{org}/[Na^+] = K_{ex3}[X^-][TOPO]^3_{org}, \quad (2)$$

where K_{ex3} is the extraction constant defined by

$$K_{ex3} = [Na(TOPO)_3{}^+X^-]_{org}/[Na^+][X^-][TOPO]^3_{org}. \quad (3)$$

Since perchloric acid[1] as well as thiocyanic and hydroiodic acid[2] are well extracted with TOPO, we get

$$[TOPO]_{total} = [TOPO]_{org} + m[HX(TOPO)_m]_{org} + 3[Na(TOPO)_3{}^+X^-]_{org} \quad (4)$$

$$= [TOPO]_{org} + mK_h[H^+][X^-][TOPO]^m_{org} + 3K_{ex3}[Na^+][X^-][TOPO]^3_{org} \quad (5)$$

where K_h is given by

$$K_h = [HX(TOPO)_m]_{org}/[H^+][X^-][TOPO]^m_{org}. \quad (6)$$

When the extraction of the acid is negligible, we have

$$[TOPO]_{org} = [TOPO]_{total} - 3K_{ex3}[Na^+][X^-][TOPO]^3_{org}. \quad (7)$$

Equation 5 indicates that the "free" TOPO concentration decreases with an increase in acidity and consequently a decrease in metal extraction. This was experimentally confirmed. For example, when the total TOPO concentration was 0.1 mol dm^{-3} and the aqueous phase was a perchlorate medium, the log D was −2.3 if the aqueous phase was neutral. However, it turned out to be −2.6 and −3.4 when the acid concentration in the initial aqueous phase was 0.01 and 0.03 mol dm^{-3}, respectively.

The free TOPO concentration and extraction constants were calculated by a successive approximation procedure by means of Eqs. 2 and 7 using a least squares computer program. A good fit of the calculated values and experimental data was obtained only when an extraction of trisolvates, $Na(TOPO)_3{}^+X^-$, was assumed. The constants obtained are:

$NaClO_4$: $\log K_{ex3} = 1.01 \pm 0.14$

NaSCN: $\log K_{ex3} = 0.38 \pm 0.11$

NaI: $\log K_{ex3} = -0.46 \pm 0.14$

where the limit of the error is 3σ. Figure 1 shows the dependence of the distribution ratio on the calculated free TOPO concentration. The solid lines were calculated by introducing these values into Eq. 2.

Attempts were made to analyze the acid dependence of the perchlorate extraction by means of Eqs. 2 and 5 using the K_h value of perchloric acid,[1] $10^{3.15}$. However, the results were lower than the calculated ones when the TOPO and/or acid concentration was high. This may be due to changes in the activity coefficients of the chemical species in the organic phase. When both the acid and TOPO concentrations were high (*e.g.* initial TOPO and acid concentrations 0.1 mol dm^{-3}), a second organic phase appeared.

Experiments were carried out with sodium nitrate, bromide, and chloride. The extractions were very poor. After careful purification of TOPO by the procedure

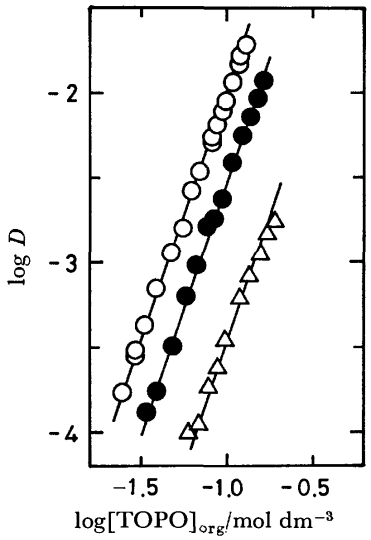

Fig. 1. The distribution of sodium perchlorate (○), thiocyanate (●), and iodide (△) as a function of the calculated free TOPO concentration in hexane. The aqueous phase was 1.0 mol dm^{-3} solution of each salt.

described, the distribution ratio was, in all cases, lower than 10^{-4} with 0.1 mol dm^{-3} TOPO.

The interactions between sodium ion and the anion in the ion-pairs might mainly be electrostatic and thus the effect of the anion on the solvation of the metal ion should be slight. This may be the reason why only the solvation number of 3 was found among the three sodium salts in the present study, differing from the findings previously reported: the solvation number of perchlorates of cobalt(II),[3] nickel(II),[4] and zinc(II)[5] with TOPO is larger than that of their thiocyanates. It is also different from the TOPO extraction of mineral acids into hexane. The solvation number of TOPO of thiocyanic and nitric acid was unity while that of perchloric and hydrohalogenic acid was two. This can be explained on the assumption that the interactions between the proton and the anion of the acid is not purely electrostatic in this nonpolar solvent.

The distribution ratio of sodium(I) under identical conditions is higher in the order, perchlorate>thiocyanate>iodide>nitrate. In all cases, the nature of the cations in the ion-pairs, $Na(TOPO)_3^+X^-$, should be similar and the extraction is mainly affected by the extractability of the anion. The large size and small tendency of hydration of perchlorate ion are favorable for its extraction. Thiocyanate ion is also large, and not as hydrophilic as to interfere with its extraction. The two anions differ from nitrate ion: although nitrate ion is large, its hydrophilic nature should make its extraction much poorer. The order observed among the halides may also be explained from this standpoint.

It should be noted that the extraction of sodium perchlorate from 1 mol dm^{-3} sodium perchlorate solution is not very poor when the TOPO concentration is high. Even at high pH where the extraction of perchloric acid is negligible, the sodium perchlorate extraction somewhat decreases the TOPO concentration. For example, when the initial TOPO concentration in hexane is 0.1 and 0.2 mol dm^{-3}, the extraction of sodium perchlorate from its 1 mol dm^{-3} solution decreases the free TOPO concentration to 0.083 and 0.13 mol dm^{-3}, *viz.*, the free TOPO concentration decreases to 83 and 65% under these conditions. However, when the TOPO concentration is lower than 0.018 mol dm^{-3}, the decrease is calculated to be less than 1%. The same is true in the thiocyanate and iodide extraction systems though the effect is smaller than in the perchlorate system.

Several reports have appeared on the solvent extraction of sodium(I).[6] However, only a few deal with that of sodium salts;[7-9] no quantitative analysis seems to have been made on their extraction equilibria. However, since sodium perchlorate solutions are often employed as the ionic media of solvent extraction of metal ions with solvating type extractants in nonpolar solvents, this type measurement is indispensable for a precise analysis of metal extraction equilibria in such systems.

The authors are grateful to Messrs. Yuichi Ishida and Kenji Ohira for their assistance in the experiments.

The Glucosylation of Several Alcohols with Tetra-*O*-benzyl-α-D-glucopyranose and a Mixture of *p*-Nitrobenzenesulfonyl Chloride, Silver Trifluoromethanesulfonate, and Triethylamine

Shinkiti KOTO,* Tadaaki SATO, Naohiko MORISHIMA, and Shonosuke ZEN
School of Pharmaceutical Sciences, Kitasato University, Shirokane, Minato-ku, Tokyo 108
(Received September 20, 1978)

Synopsis. A novel glucosylation of several alcohols using 2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranose and a ternary mixture of *p*-nitrobenzenesulfonyl chloride, silver trifluoromethanesulfonate, and triethylamine is presented.

The development of methods for the glycosylation is important in carbohydrate chemistry.[1] Recently, several syntheses of glucosides using 2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranose (**1**) have been reported.[2] We ourselves have briefly communicated a two-stage glucosylation using a novel procedure for generating the reactive sulfonate[3] from **1** and a ternary mixture of *p*-nitrobenzenesulfonyl chloride (NsCl), silver trifluoromethanesulfonate (AgOTf), and triethylamine (Et_3N).[4] This report will present a further finding that the one-stage treatment of an equimolar mixture of **1** and an alcohol with the ternary mixture in dichloromethane afforded the corresponding glucosides containing the β-anomer predominantly, as is shown in Table 1. This

Table 1. Glucosylation of alcohols with tetra-*O*-benzyl-α-D-glucopyranose (**1**) and a mixture of *p*-nitrobenzenesulfonyl chloride, silver trifluoromethanesulfonate, and triethylamine

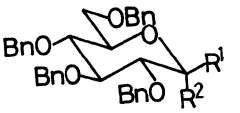
7	Ct	/1/	56 (16/40)	(72)	17	22[e]
8	Dh	/1/	76 (13/60)	(93)	0	18[f]

a) Yields are based on the weight of products separated chromatographically, referring to that of **1** charged. b) Ch=cyclohexyl, Cm=cyclohexylmethyl, Ct=5α-cholestan-3β-yl, Dh=6-(2,4-dinitroanilino)hexyl, Me=methyl. c) /1/=one-stage treatment, /2/=two-stage treatment. d) Yields based on the **1** used. e) The recovery of the alcohol was 37%. f) The recovery of the alcohol was 23%.

constitutes a convenient method for the preparation of β-glucoside from **1**. The self-condensation of **1**, yielding octa-*O*-benzyl-α,α- and α,β-trehalose (**7a** and **7b**),[5] was prevented in the one-stage glucosylation of alcohols with a primary hydroxyl group. Silver chloride and *p*-nitrobenzenesulfonic acid were deposited in the course of the reaction. Thus, the overall reaction is written by Eq. 1, where G denotes the tetra-*O*-benzyl-D-glucopyranosyl moiety:

	R^1	R^2
1	H	OH
2a	H	OMe
2b	OMe	H
3a	H	OCm
3b	OCm	H
4a	H	OCh
4b	OCh	H
5a	H	OCt
5b	OCt	H
6a	H	ODh
6b	ODh	H
7a	H	OαG
7b	OαG	H



Bn=benzyl
Ch=cyclohexyl
Cm=cyclohexylmethyl
Ct=5α-cholestan-3β-yl
Dh=6-(2,4-dinitroanilino)hexyl
Me=methyl
αG=2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl

$$\alpha\text{GOH} + \text{ROH} + \text{NsCl} + \text{AgOTf} + \text{Et}_3\text{N} \longrightarrow \alpha,\beta\text{GOR} + \text{AgCl} + \text{NsOH} + \text{Et}_3\text{N}\cdot\text{TfOH}. \quad (1)$$

It should be noted that the self-condensations of **1** were unavoidable in the one-stage glucosylation of alcohols with a secondary hydroxyl group. The ternary mixture cannot be stored even at 0 °C, since an appreciable amount of bis(*p*-nitrophenyl) sulfoxide is formed.[6]

Experimental

General. The instruments used are identical with those mentioned in the foregoing papers,[5,7] except for the JEOL JDX-7F X-ray powder diffractometer (Cu *K*α ray, λ=153.2 pm, Ni filter). The dichloromethane (Wako), cyclohexylmethanol (Tokyo Kasei), cyclohexanol (Koso), and triethylamine (Wako) were distilled and stored over molecular sieves (Linde 3A) before use. Compound **1**,[7] *p*-nitrobenzenesulfonyl chloride (Tokyo Kasei), 5α-cholestan-3α-ol (Tokyo Kasei), and 6-(2,4-dinitroanilino)-1-hexanol (mp 76—77 °C, Found: C, 50.55, H, 6.05, N, 15.03%. Calcd for $C_{12}H_{17}N_3O_5$: C, 50.88, H, 6.05; N, 14.83%), prepared by the treatment of 6-amino-hexanol (Aldrich) with 2,4-dinitrofluorobenzene (Wako) and $NaHCO_3$ in aq ethanol, as well as silver trifluoromethanesulfonate, made by the neutralization of Ag_2CO_3 (Wako) with aq trifluoromethanesulfonic acid (Kanto Denka Kogyo), were stored *in vacuo* over P_2O_5.

General Procedure for One-stage Glucosylation. To a mixture of **1** (180 mg, 0.33 mmol), alcohol (0.33 mmol), *p*-nitrobenzenesulfonyl chloride (74 mg, 0.33 mmol), and silver trifluoromethanesulfonate (86 mg, 0.33 mmol) in dichloromethane (1.8 ml), we added triethylamine (47 μl, 0.33 mmol) at −40 °C (bath temperature) and the resulting mixture was stirred well. The bath temperature gradually rose at the rate of 1.0 °C/min to 0 °C, at which temperature the mixture was then stirred for 3 h. After the addition of powdered $NaHCO_3$ (*ca.* 0.1 g) and stirring at room temperature, the mixture was filtered, evaporated, and chromatographed on silica gel (Kanto Kagaku), using three kinds of solvent systems: benzene and butanone (Solvent A), hexane and ethyl acetate (Solvent B), and chloroform and ethyl acetate (Solvent C),

respectively; these solvents were also used for TLC on silica gel (Merck, 7731).

General Procedure for Two-stage Glucosylation.[4,8] To an equimolar mixture of **1** (180 mg, 0.33 mmol), *p*-nitrobenzenesulfonyl chloride (74 mg), and silver trifluoromethanesulfonate (86 mg) in dichloromethane (1.8 ml), we added triethylamine (47 μl, 0.33 mmol) at −40 °C. After the bath temperature was risen to −10 °C, the mixture was stirred for 30 min. An alcohol (0.33 mmol) was then added, and agitation was continued at 0 °C for 3 h. Work-up was done as has been described above.

*Self-condensation of **1** with the Ternary Mixture.* To a mixture of **1** (90 mg, 0.17 mmol), *p*-nitrobenzenesulfonyl chloride (37 mg), and silver trifluoromethanesulfonate (43 mg) in dichloromethane (0.9 ml), we added triethylamine (24 μl) at −40 °C. The bath temperature rose to room temperature at the rate of 1.0 °C/min. The processed reaction mixture was chromatographed using Solvent A (gradient, 100: 1—20: 1) to give **7a** (17.5 mg, 20%) and then **7b** (36.6 mg, 42%). Compounds **7a** and **7b** were identified with those prepared before.[7]

*Alternative Synthesis of **5a**.* Ethyl 2.3,4,6-tetra-*O*-benzyl-1-thio-α-D-glucopyranoside[9] (40 mg, 0.83 mmol) in dichloromethane (0.5 ml) was treated with Br_2 in dichloromethane (0.62 g/ml, 22 μl) at room temperature for 10 min. After evaporation to dryness, the syrup thus obtained was reacted with 5α-cholestan-3β-ol (32 mg, 0.083 mmol), tetrabutylammonium bromide[10] (27 mg, 0.083 mmol), and 2,6-lutidine (10 μl, 0.083 mmol) in dichloromethane (0.5 ml) overnight. Chromatography using Solvent A (40: 1), followed by recrystallization from hexane, afforded **5a** (59 mg, 78%) (Found: C, 79.39; H, 8.83%).

*Alternative Synthesis of **5b**.* A mixture of 3β-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyloxy)-5α-cholestan[11] (0.14 g, 0.2 mmol), KOH (0.35 g), and benzyl chloride (1.4 ml) was heated at 100 °C for 16 h. After processing, chromatography sing Solvent A (40: 1) and recrystallization from hexane gave **5b** (0.08 g, 73%) (Found: C, 79.44; H, 8.70%).

Isolation of p-*Nitrobenzenesulfonic Acid and Silver Chloride.* The reaction mixture of glucosylation carried out on a 0.33-mmol scale using cyclohexylmethanol was filtered to give a solid. Subsequent washings of solid with methanol on evaporation afforded hydroscopic crystals of *p*-nitrobenzenesulfonic acid (42 mg, 62%), identified with the authentic sample by determining their IR (KBr) spectra. A washed solid (≈40 mg, >80%) on the filter was identified with AgCl by determining its X-ray powder diffraction.

Examination of the Stability of the Ternary Mixture. To a mixture of *p*-nitrobenzenesulfonyl chloride (73.8 mg, 0.33 mmol) and silver trifluoromethanesulfonate (85.7 mg, 0.33 mmol) in dichloromethane (1.8 ml), we added triethylamine (47 μl, 0.33 mmol) at −40 °C; the bath temperature was programmed as it was in the one-stage treatment. The mixture was then directly poured onto a column of silica gel, which was subsequently chromatographed with benzene. Bis(*p*-nitrophenyl)sulfoxide (8.2 mg, 17%) (mp 181.5 °C, UV_{max} (95% C_2H_5OH) 268 nm (ε 1.8×10^4) [lit,[12] mp 178—180 °C, UV_{max} (95% (C_2H_5OH) 268 nm (ε 1.82×10^4)], Found: C, 49.33, H, 2.66; N, 9.71. M^+ − 16. 276,[13] Calcd for $C_{12}H_8N_2O_5S$: C, 49.32; H, 2.76; N, 9.58%, MW 292. 27) and the slower-moving *p*-nitrobenzenesulfonyl chloride (55.7 mg, 75%), identified with an authentic sample by determining the mp, IR (KBr), and MS (M^+ 221, M^++2. 223), were thus obtained.

We wish to thank the Kanto Denka Kogyo Co. for their gift of trifluoromethanesulfonic acid and Mr. Yoshio Hamada for his technical assistance.

The Formation of Two Kinds of Thiophene Derivatives by the Reaction of the 4*H*-Pyran-4-thione Derivative with Dimethyloxosulfonium Methylide in a One-pot Process

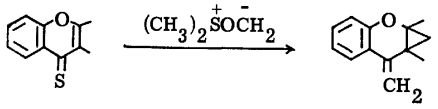
Hiroshi YAMAOKA,* Ikuhiro MISHIMA, and Terukiyo HANAFUSA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-senda-machi, Naka-ku, Hiroshima 730

(Received July 21, 1979)

Synopsis. The reaction of 2,6-dimethyl-3,5-diphenyl-4*H*-pyran-4-thione with dimethyloxosulfonium methylide occurred facilely to give two kinds of 2-thienylacetones, accompanied by a five-membered α,β-unsaturated thione, a naphtho-[2,1-*b*]thiophene derivative, and a hemithioacetal.

In our previous report, the reaction of the 4*H*-1-benzopyran-4-thione (chromothione) derivatives with dimethyloxosulfonium methylide (DOSM) was reported to give 3,4-benzo-5-methylene-2-oxabicyclo[4.1.0]hept-3-enes (vinylcyclopropanes), with the increment of two methylene groups, accompanied by the removal of the sulfur in a one-pot procedure, although there have been few reports on the addition of DOSM to thioketones.[1] There is, thus, interest in the study of the behavior of DOSM toward the parent 4*H*-pyran-4-thione derivative, **1**, in comparison with the benzo-condensed chromothione system.



Experimental

The mps are uncorrected. The IR and the UV spectra were measured with Hitachi 215 and 124 model apparatuses respectively. The ^{1}H-NMR spectra were measured on a Varian T-60 spectrometer in $CDCl_3$, using tetramethylsilane as the internal standard. We are indebted to Drs. Shizuko Eguchi and Yasuhito Uchio, Hiroshima Univ., for obtaining the mass and the ^{13}C-NMR spectra respectively.

Preparation of Thione **1**. The treatment of 2,6-dimethyl-3,5-diphenyl-4*H*-pyran-4-one[2] with P_2S_5 in 1,2-dichloroethane under reflux for 2 h afforded pinkish prisms. Mp 224—226 °C (80% yield, from 2-propanol) (see Table 1).

Reaction of 4H-Pyran-4-thione **1** *with DOSM*. To DOSM in dimethyl sulfoxide (15 ml), prepared from NaH (66% in oil, 130 mg, 3.57 mmol) and trimethyloxosulfonium iodide (850 mg, 3.86 mmol), dry ether (5 ml) and **1** (500 mg, 1.71 mmol) were added, after which the mixture was stirred at room temperature for several minutes under a nitrogen atmosphere. After the usual work-up process, the crude product was purified by the use of a silica-gel column, followed by preparative TLC using ether-light petroleum as the eluent, to give five products (see Table 1): **2**, violet oil (15 mg, 3%, λ_{max} 355 nm (log ε 3.42), unstable; a facile isomerization occurred to give **3** quantitatively); **3**, colorless oil (80 mg, 15%; monooxime, mp 180—182 °C from methanol–water); **4**, mp 40—42 °C (38 mg, 7%, from light petroleum); **5**, mp 117—119 °C (trace, from light petroleum, λ_{max} 243 (4.58), 285 (3.92), 315 (3.28), 329 nm (3.41)); **6**, mp 110—112 °C (110 mg, 19%, from light petroleum, λ_{max} 297 nm (3.47); monoacetate, *m/e* 380 (M^+), 338, 205 (base), calcd for $C_{23}H_{24}O_3S$ (Mw 380); δ 7.58—7.13 (10H, m), 3.80 (2H, s, methylene), 2.10 (3H, s), 2.02 (3H, s), 1.98 (3H, s), 1.92 (3H, s)).

Results and Discussion

The treatment of **1** with DOSM in dimethyl sulfoxide (DMSO) afforded five products, **2**, **3**, **4**, **5**, and **6**, whose structures were assigned to a five-membered α,β-unsaturated thione, two kinds of thienylacetones, a naphthothiophene, and a hemithioacetal, respectively, on the basis of their microanalyses and spectral data, as shown in the table (see also Experimental section). The production of two kinds of 2-thienylacetone derivatives, **a**, was expected by comparing the spectral characteristics of **3** and **4** with those of the related 2-furylacetones.[3] The UV spectrum of **5** agreed well with the parent naphtho[2,1-*b*]thiophene reported in the literature.[4] Therefore, it is noteworthy that all these compounds in our present work contain sulfur, while vinylcyclopropanes have been obtained by the reaction of chromothione with DOSM.[1]

Now let us discuss the structural problem of two kinds of thiophene derivatives, **3** and **4**. As it has been reported that the acid-catalyzed deuterium exchange of α-hydrogen on the thiophene ring took place 10^3 times as fast as that of β-hydrogen,[5] **3** and **4** were subjected to deuterium exchange in acetic acid-d_4 at 140 °C for 1.5 h; it was found that a vinyl signal (δ=6.87 in **3**) completely disappeared, while, on the contrary, another signal (δ=6.65 in **4**) appeared sufficiently in the ^{1}H-NMR spectra. Accordingly, **3** possesses α-hydrogen on the thiophene ring, while there is no such hydrogen in **4**.

Compound **2** rearranged facilely into **3** quantitatively under neat conditions. Ketone, **7**,[3] was treated with P_2S_5 in carbon tetrachloride at room temperature for 6 h to give **4**, but **3** could not be detected. It may, therefore, be expected that there are two kinds of formation routes, where **3** and **4** are derived from a five-membered thione, **2** (Path A), and a six-membered one, **b** (Path B), *via* the Michael adduct, **c**, at the first stage; nonetheless, there is a high reactivity of the thiocarbonyl group at the C-4 position of **1**. One of the plausible pathways for understanding the production of these materials is presented in the Scheme 1.

It is interesting that **2** was isolated as the sole product (30%) from **1** and DOSM, concomitant with the recovery of **1**, when DMSO was diluted with tetrahydrofuran (THF) (1:2 v/v) at 0 °C for 30 min; this is probably because of the stabilization of the intermediate desirable for five-membered α,β-unsaturated thione formation.

Table 1. The IR, NMR, mass, and elemental analyses data

Compound	IR ν_{max} (cm^{-1})	^{1}H-NMR δ (ppm) in $CDCl_3$	Mass (*m/e*)	Found (Calcd) % C	H	S	Formula

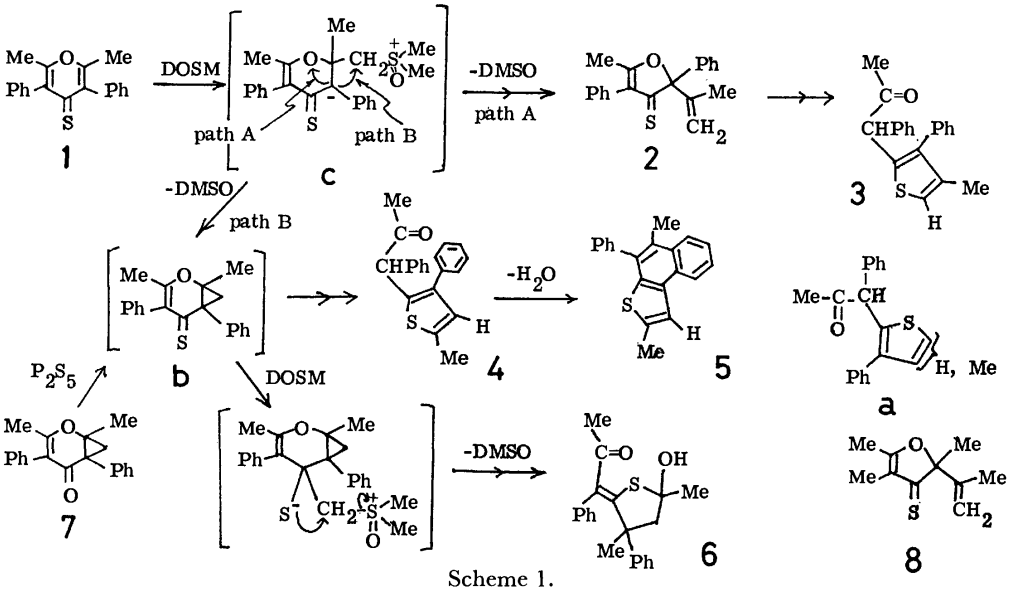
* ^{13}C-NMR ($CDCl_3$) δ: **3**, 205.1 (s), 141.3, 138.2, 137.1, 136.7, 130.6, 129.8, 129.4, 128.8, 128.5, 128.1, 127.9, 127.5, 120.3 (d), 58.9 (d), 29.2 (q), 15.4 (q). **4**, 205.1 (s), 140.6, 138.8, 138.5, 136.8, 133.1, 128.7, 128.5, 127.9, 127.4, 127.2, 58.3 (d), 29.0 (q), 15.0 (q). **6**, 211.8 (s), 149.0 (s), 137.2 (s), 136.7 (s), 130.4, 128.6, 128.5, 128.3, 127.3, 81.9 (s), 78.7 (s), 51.7 (t), 30.0 (q), 26.4 (q), 18.4 (q). a) It was separated to δ 5.42 and 5.17 in C_6D_6. b) Too unstable to obtain an analytically pure sample. c) Base peak. d) Monooxime. e) Nitrogen. f) J=16 Hz. g) Downfield shifts (δ, ppm) caused by the addition of Eu(fod)$_3$ (1 equiv.) are shown in brackets.



Scheme 1.

The reaction of DOSM to 2,3,5,6-tetramethyl-4*H*-pyran-4-thione in DMSO did not afford any vinylcyclopropanes, but only complicated mixtures difficult to identify, when THF–DMSO was used as the solvent, a five-membered unsaturated thione, **8**, could be isolated in a 5% yield: λ_{max} 345 nm; $\delta(CCl_4)$ 4.98 (1H, s), 4.83 (1H, s), 2.20 (3H, s), 1.82 (3H, s), 1.55 (6H, s); *m/e* 182 (M^+), 167, 139.[6]

In summary, the reactivity of 4*H*-pyran-4-thiones to DOSM is found to be quite different from that of the corresponding benzo-condensed reactants.

We are indebted to the Ministry of Education for two Scientific Research Grants in Aid (374168 and 447022).

(Received October 30, 1979)

Synopsis. Copper(I) iodide dissolves into warm hexamethylphosphoric triamide to give a black solution, in which polymethylated iodobenzenes undergo nucleophilic attack by azide and selenocyanate ions, giving the corresponding aryl azides and selenocyanates in low to good yields. In the absence of copper(I) salt, however, the reaction does not take place. Cyanide, cyanate, thiocyanate, and fluoride ions bring about a decoloration of the reaction mixture and no displacement reactions ensue, while the tellurocyanate ion affords the corresponding aryl cyanides while liberating elemental tellurium.

The traditional methods for converting organic halides to the corresponding pseudohalides involve displacement reactions with alkali metal pseudohalides; these methods are unsatisfactory or even fail with most aryl halides. The most commonly employed procedures of preparing aryl pseudohalides are thus based on the reaction of diazotized aromatic amine with pseudohalide ions, preferably in the presence of an appropriate catalyst.[2] However, these methods are often limited by the availability of the starting amines, especially in the case of polysubstituted systems.

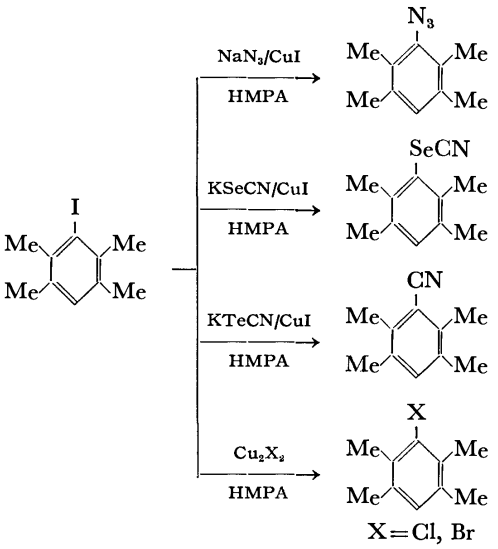
During the course of preparing some polyalkylbenzene derivatives, we have found that copper(I) iodide dissolved in hexamethylphosphoric triamide (HMPA) can induce the reaction of nonactivated aryl iodides with some pseudohalide ions, such as azide and selenocyanate ions. This reaction has not previously been reported in the literature, but it seems to have some potential as an alternative route to aryl azides and selenocyanates.[3,4]

Copper(I) iodide dissolves into warm HMPA to give a black solution, in which polymethylated iodobenzenes are activated to such an extent as to undergo nucleophilic attack by azide and selenocyanate ions, giving the corresponding aryl azides or aryl selenocyanates in low to good yields. Curiously, the reaction does not proceed to completion even in the presence of a large excess of a nucleophilic reagent. Without copper(I) salt, no displacement reaction takes place. Moreover, when other dipolar aprotic solvent systems, including *N*,*N*-dimethylformamide, *N*,*N*-dimethylacetamide, and *N*-methylpyrrolidone, are used, the reaction fails to occur.

The replacement of copper(I) iodide by copper(I) chloride or bromide, as expected,[5] leads to a facile halogen exchange, and the corresponding aryl chloride or bromide are obtained in nearly quantitative yields. Several attempts to accomplish similar reactions between aryl chloride and pseudohalide ions in the presence of copper(I) chloride have, however, been unsuccessful. With this combination, the characteristic coloration of the reaction mixture is not observed.

Of considerable interest is the finding that the addition of other pseudohalide ions, *i.e.*, cyanide, cyanate, or thiocyanate ions, to a black solution of aryl iodide and copper(I) iodide in HMPA results in a decoloration of the reaction mixture, and no displacement reactions ensue. These results are in contrast to those obtained from the reactions of aryl iodides with copper(I) cyanide and thiocyanate in warm HMPA, in which aryl cyanides[6] and diaryl disulfides[7] respectively are obtained in high yields. Alkali fluorides also produce decoloration.

In one procedure, potassium tellurocyanate[8] is allowed to react with aryl iodides in a mixture of HMPA and dimethyl sulfoxide (DMSO). In the presence of copper(I) iodide, tellurocyanate undergoes immediate decomposition, with the deposition of a dark grey tellurium powder, and aryl cyanide is the sole identifiable product obtained. Since potassium cyanide does not react with aryl iodide, not even in the presence of copper(I) iodide, the copper(I) cyanide resulting from the decomposition of the initially formed copper(I) tellurocyanate seems to be responsible for the formation of aryl cyanide.[6] The mechanism of the activation of polyalkylated aryl iodides by copper(I) iodide is not clear at present, although one may expect a possible role of the *in situ*-formed copper(I) azide or selenocyanate.



Scheme 1.

Experimental

The melting points were determined on a hot-stage apparatus and are uncorrected. The infrared spectra were run as Nujol mulls on a Hitachi 215 spectrophotometer; only

prominent peaks were recorded. The ^{1}H-NMR spectra were measured in deuteriochloroform with a Varian T-60 spectrometer, using TMS as the internal standard, unless otherwise stated. The mass spectra were obtained on a Hitachi RMS-4 mass spectrometer with an ionizing potential of 70 eV, and selenium-containing peaks are reported for ^{80}Se.

The iodoarenes were prepared by the direct iodination of the corresponding arenes with iodine/periodic acid.[9] Hexamethylphosphoric triamide was dried over phosphorus pentaoxide and distilled prior to use. The alkali azide, cyanide, cyanate, thiocyanate, and selenocyanate were used as received. The potassium tellurocyanate was obtained by gently heating tellurium powder and potassium cyanide in dry DMSO and was used in solution.[8]

The mode of reaction is illustrated below by the representative preparations of pentamethylphenyl selenocyanate and 2,3,5,6-tetramethylphenyl azide. No effort was made to optimize the reaction.

Pentamethylphenyl Selenocyanate. A mixture of iodopentamethylbenzene (1.37 g; 5 mmol), copper(I) iodide (0.48 g; 2.5 mmol), and HMPA (7 ml) was heated with stirring at 100—110 °C until a black solution resulted, to which potassium selenocyanate (1.44 g; 10 mmol) was then added in one portion. The mixture was stirred for 7—12 h at this temperature and then poured into water. The milky solution gradually separated a precipitate, which was filtered off and extracted with hexane using a Soxhlet extractor. From the concentrated extract, the selenocyanate separated as pale yellow plates. Yield, 0.59—0.91 g (47—72%). Mp 123—124 °C. ^{1}H-NMR: δ 2.27 (s, 3Me) and 2.62 ppm (s, 2Me); IR: ν_{max} 2145, 1055, 1005, and 910 cm^{-1}. Found: C, 57.02; H, 6.00; N, 5.42%; M$^+$, 253. Calcd for $C_{12}H_{15}NSe$: C, 57.15; H, 5.99; N, 5.55%; M$^+$, 252.2.

In a similar fashion, 2,3,5,6-tetramethylphenyl selenocyanate was obtained from iododurene in 45—61% yields. Pale yellow plates; mp 88—89 °C. ^{1}H-NMR: δ 2.25 (s, 2Me), 2.52 (s, 2Me), and 7.02 ppm (s, 1H$_{arom}$); IR: ν_{max} 2150, 995, 875, and 790 cm^{-1}. Found: C, 55.39; H, 5.64; N, 5.66%; M$^+$, 239. Calcd for $C_{11}H_{13}NSe$: C, 55.47; H, 5.50; N, 5.88%; M$^+$, 238.2.

2,3,5,6-Tetramethylphenyl Azide. To a black homogenious solution of iododurene (0.68 g; 2.6 mmol) and copper(I) iodide (0.48 g; 2.5 mmol) in HMPA (5 ml), sodium azide (1.3 g; 20 mmol) was added in one portion. The deep red mixture was heated at 70—90 °C for 24 h and then quenched by the addition of water. Heating at higher temperatures led to the extensive decomposition of the azide formed. The product was extracted with ether, washed with water, and dried over sodium sulfate. The subsequent removal of the solvent gave a white crystalline mass, which showed a sharp IR band due to the azide group at 2100 cm^{-1}. Since the pure azide could not be obtained by fractional crystallization and chromatography over alumina, the product mixture was treated with an excess of lithium aluminum hydride in tetrahydrofuran; the resulting 2,3,5,6-tetramethylaniline was isolated and identified as an *N*-acetyl derivative. Mp 205—207 °C (lit,[10] 207 °C). The displacement reaction by the azide ion proceeded slowly, and the conversion, as calculated from the integration area of the ^{1}H-NMR peaks of the methyl groups, never exceeded 15% under the above conditions.

By a similar treatment, iodopentamethylbenzene was converted into the corresponding azide (10—15% conversion calculated from the ^{1}H-NMR peak area), which was reduced to pentamethylaniline and identified as an *N*-acetyl derivative. Mp 212—214 °C (lit,[11] 213 °C).

Reaction with Potassium Tellurocyanate. To a solution of iododurene (1.30 g; 5 mmol) and copper(I) iodide (0.48 g; 2.5 mmol) in HMPA (10 ml), a fresh solution of potassium tellurocyanate (1.92 g; 10 mmol) in DMSO (10 ml)[8] was added all at once. The mixture, which had turned dark brown with the liberated tellurium powder, was heated with stirring at 100—110 °C for 12 h and then poured into water. A dark grey precipitate was filtered off and extracted with hexane using a Soxhlet extractor. The extract was evaporated under reduced pressure, and the residue was recrystallized from ethanol to give white needles (0.08 g; 10%); it was identified as 2,3,5,6-tetramethylbenzonitrile by direct comparison with an authentic specimen. Mp 74—75 °C (lit,[12] 76—77 °C). ^{1}H-NMR: δ 2.22 (s, 2Me), 2.41 (s, 2Me), and 7.08 ppm (s, 1H$_{arom}$); IR (KBr): ν_{max} 2200, 1470, 1375, and 1000 cm^{-1}.

Reaction with Copper(I) Chloride. A mixture of iododurene (0.78 g; 3 mmol), copper(I) chloride (0.40 g; 4 mmol), and HMPA (6 ml) was kept at 90—100 °C for 4 h and then diluted with water. A grey precipitate was filtered off and extracted with hexane using a Soxhlet extractor. The extract was evaporated to give chlorodurene as a white mass (0.50 g; 99%) which, on recrystallization from aqueous ethanol, melted at 45—47 °C (lit,[13] 47.5—48 °C).

The Reductive Coupling of Organic Halide Using Hydrazine and a Palladium Amalgam Catalyst. I. The Preparation of Biaryls

Riichiro NAKAJIMA,* Yuji SHINTANI, and Tadashi HARA

Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Karasuma Imadegawa Kamikyo-ku, Kyoto 602

(Received November 6, 1979)

Synopsis: Iodoarenes could be converted to the corresponding biaryls in high yields by the use of a catalytic amount of a palladium amalgam in place of a palladium–calcium carbonate catalyst in Busch's reaction. The 2,3′-isomer content in the bitolyls obtained by the homo-coupling of *o*-iodotoluene was 15% when palladium was used, while it was 1% when a palladium amalgam was used, and the latter was re-usable. The present method is further applicable to some iodoalkanes.

The preparation of symmetrical biaryls with haloarenes is ordinarily accomplished by either one-step or two-step procedures in which the former uses a metal, as in the Ullmann reaction,[1] or a zerovalent metal complex, as in the reaction discovered by Semmelhack *et al.*;[2] while the latter uses the Grignared reagent. The Ullmann reaction is applicable to ortho-halo-substituted arenes, but it is greatly inhibited or prevented by the presence of such substituents as amino, hydroxyl, and free carboxyl groups.[1] Moreover, the reaction does not usually proceed under mild conditions. In Semmelhack's reaction, the zerovalent complex is very sensitive to air and heat, and the presence of ortho substituents in the haloarenes slows down the reaction velocity.[2] The method reported by Taylor *et al.*,[3] involving the reaction *via* the Grignard reagent, is a good one for the preparation of biaryls in respect to the yield, but it can not be used for ortho-halo-substituted arenes.

In the methods described above, a stoichiometric amount or an excess amount of metal are required, and a reaction which proceeds with a catalytic amount of the metal is desirable for the preparation of biaryls. Busch's reaction[4] has not been used for the preparation of biaryls since the reaction proceeds in accordance with a radical reaction mechanism and the yield of biaryls is low except for biquinolyls,[5–7] which have not been prepared by other methods. On the other hand, Jullia[8] and Norman[9] have recently reported the coupling of haloarenes in the presence of palladium supported on activated charcoal[8] and of palladium metal prepared *in situ* from palladium acetate.[9] However, these reaction conditions are not suitable for the preparation of the biaryls, because the hydrogenation and the dimerization of the haloarenes take place at the same time. This investigation has, therefore, been carried out in order to find suitable conditions for preparing the biaryl.

The reductive homo-coupling of iodoarenes with hydrazine was found to proceed in a high yield under mild conditions by the use of a palladium amalgam catalyst and to be further applicable to ortho-substituted iodoarenes. The present method is simple and easy to operate in comparison with the ordinary method; also, it is a useful method for preparing biaryls.

Results and Discussion

Carriers other than the calcium carbonate in Busch's reaction have been examined for the preparation of biaryls, but no better results were obtained. Although Busch's reaction had not been examined without using a carrier,[4–7] the coupling of iodo-*p*-xylene (**1**) with hydrazine gave 2,2′,5,5′-tetramethylbiphenyl (**2**) in an 18.9% yield and *p*-xylene by the use of the palladium prepared *in situ* from palladium chloride (**3**). The coupling of **1** with a palladium–calcium carbonate catalyst in place of the palladium metal gave **2** in an 11.8% yield. Therefore, the reductive coupling with hydrazine did not always require a carrier. Nickel, copper, and mercury, which had been prepared *in situ* from the corresponding metal chloride, were not observed to catalyze the coupling of iodobenzene under the same conditions. The use of the palladium amalgam prepared *in situ* from mercury(II) chloride (**4**) (0.43 mmol) and **3** (0.50 mmol) as the catalyst enhanced the yield of **2** to 70.6%, about four times as large as that in the absence of mercury. In this case, the hydrogena-

Table 1. Coupling of haloarenes with hydrazine by the use of a palladium amalgam or palladium metal

tion was depressed. Some representative results of haloarenes are shown in Table 1. The use of the palladium amalgam in place of palladium increased the yield of biaryl in the coupling of all the iodoarenes listed in Table 1, but decreased that of bromobenzene. It was further found in the coupling of *o*-iodotoluene that the use of the amalgam catalyst hindered the migration of the bonding position which occurred on the intermediate complex [Ph–Pd–X] in the absence of mercury and decreased the contents of 2,3′-dimethylbiphenyl from 15% to 1.3%. The present method was applicable to the synthesis of 2,2′-disubstituted biaryls much like the Ullmann reaction, but iodomesitylene, which had substituents at both ortho positions, did not give the biaryl, in contrast with the Ullmann reaction.

Since **3** as well as **4** was reduced with hydrazine in the initial reaction stage to give the metal, and since the produced amalgam was present throughout the reaction, the reuse of the recovered amalgam as the catalyst was examined for the preparation of **2**. As is shown in Table 1, **1** gave **2** in a 74% yield with **3** and **4**. **2** was obtained in yields of 45% and 53% with the first recovered palladium amalgam (97.5% of the theoretical amount) and with the second recovered one (79.6% of the theoretical amount) respectively. The recoveries of **1** in these reactions were 0.4%, 12.2%, and 1.8% respectively. The use of palladium and mercury in place of these chlorides gave **2** in a 47% yield. Therefore, the following conclusions may be drawn: (1) Both the salts and the metals (amalgam) can be used as catalysts. (2) The activity of the catalyst does not decrease very much even after the reaction, and so the catalyst is re-usable. Since the present method is operationally simple, highly selective, and widely applicable, it offers advantages over the previous methods for the preparation of symmetrical biaryls.

As is shown in Table 2, the present method is also applicable to the reductive coupling of iodoalkanes, but the yield is still unsatisfactory. Further experiments are now in progress.

Experimental

Materials. The reagents and solvent employed were of a commercially available grade except those noted below. Iodo-*p*-xylene,[10] 3-iodo-*o*-xylene,[11] 4-iodo-*o*-xylene,[11] iodomesitylene,[10] *p*-iodoethylbenzene,[10] 4-iodo-1,2-dimethoxybenzene,[12] and 1-iododecane[13] were prepared by the methods given in the literature. The purity of all the halo compounds was determined by GLPC to be over 98%.

Table 2. Coupling of iodoalkanes with hydrazine by the use of a palladium amalgam catalyst (Method B)

Iodoalkane	Coupling product	Yield/%
1-Iodohexane	dodecane	0.2
Iodocyclohexane	bicyclohexyl	6.7
1-Iododecane	eicosane	2.5

Reductive Coupling of **2** *with Palladium (Method A).* A mixture of **1** (21.7 mmol), **3** (0.51 mmol), 85% hydrazine hydrate (**5**) (9.8 mmol), and sodium hydroxide (**6**) (101 mmol) in methanol (12 ml) was refluxed for 6.5 h with stirring. The resulting mixture was filtered, and the residual metal was washed with benzene and water. **2** was obtained by the steam distillation of the filtrate. The amount of **2** was determined by GLPC, using biphenyl as the internal standard. The palladium–calcium carbonate catalyst, prepared by a usual method from calcium carbonate (1.0 g) and **3** (0.51 mmol), was also used in place of **3**.

Reductive Coupling of Organic Halide with a Palladium Amalgam Catalyst (Method B). A mixture of organic halide (25 mmol), **3** (0.50 mmol), **4** (0.50 mmol), and **6** (125 mmol) in 16 ml of methanol containing **5** (15 mmol) was stirred for 6 h under refluxing. The resulting mixture was filtered, and the inorganic residues were washed with benzene and water. After the organic layer had separated from the aqueous layer of the filtrate, the dimer was obtained by either the evaporation of the solvent or distillation *in vacuo*, followed by weighing. After 6 hs' reaction, almost no organic halide was recovered from the reaction mixture. The purity of the reaction products was determined by GLPC to be over 98% except in the case of 4,4′-diaminobiphenyl (97%). The reaction products were identified by their retention time, GC-MS (EI and CI), and NMR spectra in comparison with those of authentic samples.

Reductive Coupling of Haloarenes with a Palladium Catalyst (Method C). The experiment was carried out in the same manner as in Method B except that only **3** (2.5 mmol) was used in place of **3** and **4**.

Synopsis. The reactions of 7-methoxy-2-phenyl-2*H*-1-benzopyran and 7-methoxy-2-phenyl-4*H*-1-benzopyran with lead(IV) acetate gave 2-benzoyl-6-methoxybenzofuran and 6-acetoxy-3-methoxy-6-(3-oxo-3-phenyl-1-propenyl)-2,4-cyclohexadien-1-one. The reactions of 7-methoxy-2-(*p*-methoxyphenyl)-2*H*-1-benzopyran and 7-methoxy-2-(*p*-methoxyphenyl)-4*H*-1-benzopyran with lead(IV) acetate also gave the corresponding benzofuran and cyclohexadienone. The reaction pathway is discussed.

As a continuation of the previous reports[1,2] on the oxidations of 2-phenyl-2*H*-1-benzopyrans and 2-phenyl-4*H*-1-benzopyrans with potassium permanganate, which gave flavones in excellent yields, we have now investigated the reactions of these benzopyrans and related compounds with lead(IV) acetate in various organic solvents and with different molar ratios of the oxidant to the substrate.

When 7-methoxy-2-(*p*-methoxyphenyl)-2*H*-1-benzopyran (**1b**) was oxidized with lead(IV) acetate in boiling benzene, two compounds (**5b** and **6b**) were isolated. The NMR spectrum of **5b**, $C_{17}H_{14}O_4$ (mp 149 °C), indicated that the structure is 6-methoxy-2-(*p*-methoxybenzoyl)benzofuran (Fig. 1), which was confirmed by independent synthesis: the reaction of 2-hydroxy-4-methoxybenzaldehyde with 2-bromo-*p*-methoxyacetophenone gave **5b**. The structure of **6b** was confirmed by means of a study of its NMR spectrum to be 6-acetoxy-3-methoxy-6-[3-(*p*-methoxyphenyl)-3-oxo-1-propenyl]-2,4-cyclohexadien-1-one (Fig. 1), in which the configuration of the C=C double bond in the side chain is *trans* (J=16.0 Hz). TLC showed that there were many other products, which, however, could not be purified. Similarly, the reaction of 7-methoxy-2-phenyl-2*H*-1-benzopyran (**1a**) gave the corresponding 2-benzoyl-6-methoxybenzofuran (**5a**) (mp 105—106 °C) and 6-acetoxy-3-methoxy-6-(3-oxo-3-phenyl-1-propenyl)-2,4-cyclohexadien-1-one (**6a**). The reaction of such other 2-phenyl-2*H*-1-benzopyrans as 2-(*p*-methoxyphenyl)-2*H*-1-benzopyran, which has no methoxyl group at the 7-position, resulted in a complex mixture of products and failed to give the corresponding benzofuran and cyclohexadienone. Therefore, it seems that the presence of a methoxyl group at the 7-position of 2-phenyl-2*H*-1-benzopyran is necessary to give the above products. We were particularly interested in the fact that the ring contraction took place to form a benzofuran ring, and so we subsequently studied its reaction pathway.

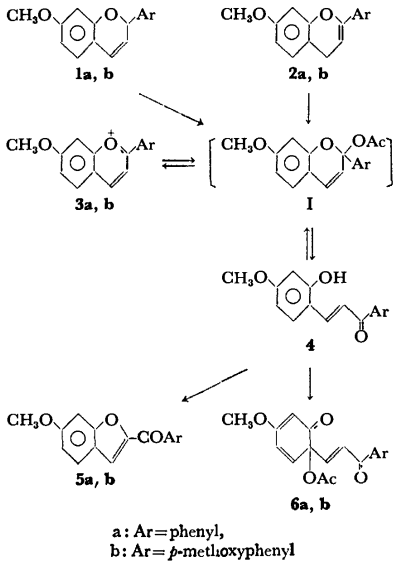

Fig. 1.

It was found that the reactions of 2-phenyl-4*H*-1-benzopyrans (**2a** and **2b**) with lead(IV) acetate in benzene also gave the benzofurans (**5a** and **5b**) and the cyclohexadienones (**6a** and **6b**) in yields similar to those in the reactions of **1a** and **1b** (Entries 3, 4, 9, and 10). When the reaction of **2b** was conducted in chloroform, the yields were practically the same as those in benzene (Entry 11). In acetic acid, however, the yield of **5b** decreased, whereas the yield of **6b** increased, and a characteristic fluorescence of flavylium ion was observed. This may suggest that either the flavylium ion (**3**) or 2-acetoxy-2-phenyl-2*H*-1-benzopyran (I) could be a reaction intermediate. Thus, the oxidation of **3b** was carried out under various reaction conditions. As has been mentioned above, the yield of **5b** in the reaction of **2b** in acetic acid was lower than in any other solvent, but the reactions of **3a** and **3b** in acetic acid containing two equivalents of potassium acetate gave **5a** and **5b** in improved yields (Entries 6 and 14—16). This indicates that I is a more adequate reaction intermediate. It is well known that the hydrolysis of the flavylium ion (**3**) gives an equilibrium mixture of 2-hydroxy-2-phenyl-2*H*-1-benzopyran and (*Z*)- and (*E*)-2-hydroxychalcone;[3] in fact, the treatment of **3b** with acetic acid containing potassium acetate did give (*E*)-2-hydroxy-4,4′-dimethoxychalcone (**4**). The reaction of **4** with lead(IV) acetate gave **5b** and **6b**. It has been reported that the reaction of *o*-substituted phenols with lead(IV) acetate gave 6-acetoxy-2,4-cyclohexadienones[4] and that the reaction of phenols with a double bond in the side chain with this reagent gave a cyclized compound, as has been shown in the cases of 2′-hydroxychalcones,[5] 2-hydroxystilbene,[6] 3-(*o*-hydroxyphenyl)-coumarin,[7] and 2′-hydroxyisoflavone.[8] Thus, it may be concluded that the reaction pathway of this interesting ring-contraction is as is shown in Fig. 1. **1** and **2** are oxidized by lead(IV) acetate to give I. Isomerization between **1** and **2** is not likely to occur under the present reaction conditions, as both **1b** and **2b** were recovered unchanged on heating in benzene.

Table 1. Reactions of 2-phenyl-2*H*-1-benzopyrans (**1**), 2-phenyl-4*H*-1-benzopyrans (**2**), flavylium perchlorates (**3**), and 2-hydroxy-4,4′-dimethoxychalcone (**4**) with lead (IV) acetate

a) A: acetic acid, B: benzene, C: chloroform, and K: potassium acetate (2 mmol). b) Heating was continued for 30 min. c) Isolated yield, based on the amount of the substrate used.

I can also be formed by the addition of the acetate ion to **3**. I then becomes a mixture of (*Z*)- and (*E*)-chalcones, the latter being oxidized to give **5** and **6**.

Experimental

All the ^{1}H-NMR spectra were recorded for the deuteriochloroform solution with a Hitachi R-24 NMR spectrometer, with TMS as the internal standard. The IR spectra were recorded for the chloroform solution with a JASCO IRA-1 spectrometer, while the UV spectra were recorded for the methanol solution on a Hitachi EPS-3T UV spectrophotometer. The melting points were determined on a Yanagimoto hot-stage and are uncorrected.

Materials. 7-Methoxy-2-phenyl-2*H*-1-benzopyran (**1a**),[1] 7-methoxy-2-(*p*-methoxyphenyl)-2*H*-1-benzopyran (**1b**),[9] 7-methoxy-2-phenyl-4*H*-1-benzopyran (**2a**),[2] 7-methoxy-2-(*p*-methoxyphenyl)-4*H*-1-benzopyran (**2b**),[10] 7-methoxyflavylium perchlorate (**3a**),[11] 4′,7-dimethoxyflavylium perchlorate (**3b**),[12] and (*E*)-2-hydroxy-4,4′-dimethoxychalcone (**4**)[13] were prepared by the literature methods.

*Oxidations of 2-Phenyl-2*H*-1-benzopyrans (**1a** and **1b**), 2-Phenyl-4*H*-1-benzopyrans (**2a** and **2b**), Flavylium Perchlorates (**3a** and **3b**), and (E)-2-Hydroxy-4,4′-dimethoxychalcone (**4**).* To a mixture of a substrate (1 mmol) and a solvent (20 ml), lead(IV) acetate[14] (1.5—3 mmol) was added, after which the mixture was heated for 30 min. The reaction mixture was filtered (in the case of a reaction using acetic acid as the solvent, the acetic acid was removed *in vacuo* and the residue was extracted with chloroform), and the filtarte was concentrated and chromatographed on TLC, with chloroform as the developing solvent. **5a** and **5b** were further purified by recrystallization.

*2-Benzoyl-6-methoxybenzofuran (**5a**)*: Mp 105—106 °C (MeOH); IR 1640 cm^{-1} (C=O); UV λ_{max} (log ε) 236^{sh} (3.99), 259 (4.00), and 345 nm (4.34); NMR δ=3.87 (3H, s, OCH_3), 6.8—7.1 (2H, m, $H_{(5)}$ and $H_{(7)}$), 7.4—7.7 (5H, m), and 7.9—8.1 (2H, m, $H_{(2')}$ and $H_{(6')}$). Found: C, 75.96; H, 4.81%. Calcd for $C_{16}H_{12}O_3$; C, 76.18; H, 4.80%.

*6-Methoxy-2-(p-methoxybenzoyl)benzofuran (**5b**)*: Mp 149 °C (MeOH); IR 1645 cm^{-1} (C=O); UV λ_{max} (log ε) 228^{sh} (4.23), 259^{sh} (3.81), 307^{sh} (4.07), and 347 nm (4.33); NMR δ=3.89 (6H, s, 2×OCH_3), 6.8—7.2 (4H, m, $H_{(3')}$, $H_{(5)}$, $H_{(5')}$, and $H_{(7)}$), 7.45 (1H, s, $H_{(3)}$), 7.57 (1H, d, J=8.5 Hz, $H_{(4)}$), and 8.08 (2H, m, $H_{(2')}$ and $H_{(6')}$). Found: C, 72.33; H, 5.01%. Calcd for $C_{17}H_{14}O_4$; C, 72.33; H, 5.00%.

*6-Acetoxy-3-methoxy-6-(3-oxo-3-phenyl-1-propenyl)-2,4-cyclohexadien-1-one (**6a**)*: Mp 116—117 °C; IR 1680 and 1758 cm^{-1} (OAc); UV λ_{max} (log ε) 260 (3.93) and 308^{sh} nm (3.72); NMR δ=2.21 (3H, s, OAc), 3.82 (3H, s, OCH_3), 5.59 (1H, t, J=1.5 Hz, $H_{(2)}$), 6.26 (2H, d, J=1.5 Hz, $H_{(4)}$ and $H_{(5)}$), 6.67 (1H, d, J=17.6 Hz, $H_{(1')}$), 7.37 (1H, d, J=17.6 Hz, $H_{(2')}$), 7.3—7.7 (3H, m) and 7.8—8.0 (2H, m); MS *m/e* 312.0941 (calcd for $C_{18}H_{16}O_5$; 312.0998), 284, 270, 202, 165, 160, 152, 111, and 105.

*6-Acetoxy-3-methoxy-6-[3-(p-methoxyphenyl)-3-oxo-1-propenyl]-2,4-cyclohexadien-1-one (**6b**)*: Liquid; IR 1680 (C=O) and 1760 cm^{-1} (OAc); UV λ_{max} (log ε) 225 (4.26) and 295 nm (4.19); NMR δ=2.21 (3H, s, OAc), 3.81 (3H, s, OCH_3), 3.87 (3H, s, OCH_3), 5.61 (1H, t, J=1.5 Hz, $H_{(2)}$), 6.27 (2H, d, J=1.5 Hz, $H_{(4)}$ and $H_{(5)}$), 6.65 (1H, d, J=16.0 Hz, $H_{(2')}$), 7.01 (2H, m, $H_{(3'')}$ and $H_{(5'')}$), 7.37 (1H, d, J=16.0 Hz, $H_{(1')}$), and 8.04 (2H, m, $H_{(2'')}$ and $H_{(6'')}$); MS *m/e* 342.1088 (calcd for $C_{19}H_{18}O_6$; 342.1103), 314, 300, 282, 190, 165, 161, 111, 135, and 92.

*Preparation of 6-Methoxy-2-(p-methoxybenzoyl)benzofuran (**5b**).* To a hot, ethanolic solution (20 ml) of 2-hydroxy-4-methoxybenzaldehyde (456 mg) and potassium hydroxide (168 mg), we added 2-bromo-*p*-methoxyacetophenone (689 mg), after which the reaction mixture was heated under reflux for 2 h. The reaction mixture was then acidified with dilute hydrochloric acid, and the precipitates were collected. The subsequent recrystallization of the crude product from ethanol gave colorless needles (375 mg, 44%); mp 149 °C.

*Treatment of 4′,7-Dimethoxyflavylium Perchlorate (**3b**) with Potassium Acetate in Acetic Acid.* **3b** (367 mg) was heated in acetic acid (10 ml) containing potassium acetate (200 mg) for 5 min. The reaction mixture was then diluted with water (60 ml), and the precipitates were collected by filtration to give **4** (240 mg, 85%), found to be identical with an authentic sample in all respects.

The authors wish to thank Dr. Shinzaburo Hishida at Hitachi, Ltd., Katsuda, for his measurements of the mass spectra.

Reactions of Thionitrites or Thionitrates with Carbanions

Koichi SHINHAMA, Yong Hae KIM, and Shigeru OAE*

Department of Chemistry, The University of Tsukuba, Niiharigun, Ibaraki 305

(Received November 10, 1980)

Synopsis. Reaction of several thionitrites (RSNO) or thionitrates ($RSNO_2$) with carbanions such as Grignard reagents, alkyllithium, or the carbanion of diethyl malonate gave *C*-alkylthio derivatives such as sulfides or diethyl (alkylthio)malonates.

In the course of our studies on the synthetic applications of thionitrites (RSNO)[1] and thionitrates ($RSNO_2$),[2] the two initial key intermediates in the oxidation of thiols with dinitrogen tetraoxide (N_2O_4), we found that both thionitrites and thionitrates reacted rapidly with carbanionic species such as Grignard reagents, alkyllithium, and the carbanion of diethyl malonate below room temperature. This paper deals with these reactions.

When thionitrites (**1**) or *t*-butyl thionitrate (**2a**) were treated with phenylmagnesium bromide (**3a**) or methylmagnesium iodide (**3b**) in diethyl ether, the corresponding sulfides (**4**) were obtained as the main products, besides small amounts of disulfides (**5**) and thiols (**6**).

4b: R=*p*-Tol, R′=CH_3 **5b**: R=*t*-Bu **6b**: R=*t*-Bu
4c: R=*t*-Bu, R′=Ph

When thionitrite **1a** was treated with methyllithium (**7a**) or benzyllithium (**7b**)[3] in diethyl ether, nearly the same results were obtained as in the reaction with the Grignard reagents. Sulfide **4b** and benzyl *p*-tolyl sulfide (**4d**) were the major products, as summarized in Table 1.

These reactions were considered to proceed *via* the nucleophilic attack of the carbanionic species on the sulfur atoms of **1** or **2a**. The carbanions do not seem

to attack the nitrogen atom, in view of the lack of formation of the *C*-nitroso or *C*-nitro compound. **1** and **2a** were found to decompose during the reaction to give small amounts of the corresponding disulfides **5**. The thiols **6** are considered to be formed by the reaction of disulfides **5** with carbanions.

When **2a** was treated with diethyl malonate (**8**) in the presence of potassium hydroxide, diethyl (*t*-butylthio)malonate (**9**) was obtained in a good yield. This reaction did not proceed without potassium hydroxide. The reaction of **1b** with diethyl malonate (**8**) in the presence of potassium hydroxide did not give **9** but uncharacterized products.

Meanwhile, treatment of 1.4 equiv. of *p*-chlorophenyl thionitrate (**2b**) with diethyl malonate (**8**) in the presence of potassium hydroxide gave diethyl bis(*p*-chlorophenylthio)malonate (**10**) as the major product. However, when this reaction was carried out in the presence of a large amount of potassium hydroxide, ethyl (*p*-chlorophenylthio)acetate (**12**), which might be formed by partial hydrolysis of diethyl (*p*-chloro-

TABLE 1. REACTIONS OF THIONITRITES **1a—b**, OR THIONITRATE **2a** WITH CARBANIONS **3a—b** OR **7a—b**

Substrate	Carbanion	[Carbanion]/[Substrate]	Temp/°C	Time/min	Product[a]	Isolated yield/%
1a	**3a**	3	−70	3	**4a**[b,d]	57
1a	**3b**	3	−70	3	**4b**[b,e]	43
1a	**7a**	1	−70	3	**4b**[b,e]	57
1b	**3a**	1	0—5	5	**4c**[c,f]	72
2a	**3a**	1.1	0—5	5	**4c**[c,f]	79
1a	**7b**	1	−70	3	**4d**[b,g]	32

a) IR and NMR spectra of all these sulfides were identical with those of authentic samples. b) Small amounts of disulfide **5a** and thiol **6a** were also obtained. c) A small amount of disulfide **5a** was confirmed by GC-MS spectrum. d) Bp (bath temp) 135—140 °C/3 mmHg (lit,[4] 163—163.5 °C). e) Bp (bath temp) 90 °C/3 mmHg (lit,[5] 104—104.5 °C/20 mmHg). f) Bp (bath temp) 85—90 °C/3 mmHg (lit,[6] 73 °C/5 mmHg). g) Bp (bath temp) 100—110 °C/2 mmHg, mp 44 °C (lit,[7] 46 °C).

Table 2. Reactions of thionitrates **2a—b** with diethyl malonate **8** in the presence of potassium hydroxide

Thionitrate	Thionitrate: KOH: **8**	Temp °C	Time min	Product	Isolated yield/%
2a	5 : 8 : 6	25	3	**9**	79[a]
2a	10 : 16 : 5	0—5	3	**9**	74[b]
2b	7 : 8 : 5	0—5	3	**10**[d]	29[b,c]
2b	5 : 16 : 5	0—5	3	**12**[e]	72[b]

a) Based on thionitrate **2a**. b) Based on diethyl malonate **8**. c) After recrystallization from EtOH solution. d) Small amounts of compounds **11** and **12** were also formed. e) Small amounts of compounds **10** and **11** were also formed.

phenylthio)malonate (**11**) followed by decarboxylation, was obtained as the major product. These results are listed in Table 2.

Experimental

All the melting points and boiling points were uncorrected. Elemental analyses were carried out by the Chemical Analysis Center at our University. Analytical determinations by GLC were performed on a Hitachi 163 gas chromatograph fitted with the following column (3 mm o.d. × 3 m): 10% SE-30 on Chromosorb W. ^{1}H-NMR spectra were taken at 60 MHz on a Hitachi R-24 A or R-24 apparatus. IR spectra were recorded with a Hitachi 215 spectrometer. Mass spectra were recorded with a Hitachi RMU-6M spectrometer.

*Thionitrites (**1a—b**).* These compounds were prepared from the corresponding thiols with dinitrogen tetraoxide following the procedure reported by us.[1,2b] Pure thionitrite **1a** was quite unstable at room temperature, and hence this compound was used as a solution in diethyl ether immediately after preparation. Pure thionitrite **1b** was rather stable at room temperature.

*Thionitrates (**2a—b**).* Thionitrates **2a—b** were prepared from the corresponding thiols with excess dinitrogen tetraoxide.[2] Thionitrate **2a** was stable and remaining almost in pure form at room temperature for several weeks. Thionitrate **2b** was unstable at room temperature and hence was used immediately (within 30 min) after recrystallization from diethyl ether.

*Reactions of Thionitrites (**1a—b**) or Thionitrates (**2a—b**) with Grignard Reagents (**3a—b**) or Alkyllithium (**7a—b**).* The following is a typical procedure. The Grignard reagent **3a** (7 mmol) in diethyl ether (5.4 ml) was added to a stirred solution of thionitrite **1b** in dry diethyl ether (5 ml) for a few minutes at 0—5 °C. The solution was stirred further for *ca.* 3 min. The red solution of thionitrite **1b** turned to a white suspension. A cold HCl aq solution was added to the solution and then the mixture was extracted with diethyl ether. The ethereal extract was dried ($MgSO_4$), concentrated, purified by TLC (silica gel, hexane), and distilled giving 835 mg (72%) of the sulfide **4c**: bp (bath temp) 85—90 °C/3 mmHg (1 mmHg = 133.322 Pa) (lit,[6] 73 °C/5 mmHg).

*Diethyl (t-Butylthio)malonate (**9**).* A mixture of thionitrite **2a** (675 mg, 5 mmol) and diethyl malonate **8** (961 mg, 6 mmol) was added for a few minutes to a stirred solution of potassium hydroxide (450 mg, 8 mmol) in ethanol (3 ml) at room temperature. The solution was stirred further for *ca.* 3 min, and then cold HCl aq solution was added and the mixture was extracted with diethyl ether. The ethereal extract was dried ($MgSO_4$), concentrated, purified by TLC (silica gel, hexane: ether = 10: 1), and distilled, giving 980 mg (79%) of the compound **9**: bp (bath temp) 100—110 °C/3 mmHg. IR (neat): 1725, 1365, 1242, 1150, 1075, and 1030 cm^{-1}. NMR (CCl_4): δ 1.28 (t, 6H, CH_3-), 1.35 (s, 9H, *t*-Bu), 4.00 (s, 1H, -C<u>H</u>), and 4.13 (q, 4H, -C<u>H</u>$_2$-). MS (70 eV), *m/e* (rel. intensity), 245 (5, M$^+$), 191 (41, $^+$SCH-$(CO_2Et)_2$), 159 (16, $^+CH(CO_2Et)_2$), 118 (23, $^+SCHCO_2Et$), and 57 (100, *t*-Bu$^+$). Found: C, 52.82; H, 8.18%. Calcd for $C_{11}H_{20}O_4S$: C, 53.20; H, 8.11%.

*Diethyl Bis(p-chlorophenylthio)malonate (**10**).* A mixture of thionitrate **2b** (1.41 g, 7 mmol) and diethyl malonate **8** (0.80 g, 5 mmol) was added for a few minutes to a stirred solution of potassium hydroxide 0.45 g, 8 mmol) in ethanol (3 ml) at 0—5 °C. The solution was stirred further for *ca.* 3 min, and then cold HCl aq solution was added and the mixture was extracted with diethyl ether. The crude product was purified by TLC (silica gel, hexane: ether = 10: 1) and recrystallization (from ethanol) to give 643 mg (29% from diethyl malonate **8**) of compound **10**: mp 89—90 °C. IR (KBr): 1725, 1260, 1090, 1038, 1009, and 815 cm^{-1}. NMR (CCl_4): δ 1.14 (t, 6H, CH_3-), 4.01 (q, 4H, -C<u>H</u>$_2$-), 7.25 (d, J=8 Hz, 4H, ring protons), and 7.55 (d, J=8 Hz, 4H, ring protons). MS (70 eV), *m/e* (rel. intensity), 443 (16, M$^+$), 370 (4, $(p\text{-Cl-}C_6H_4S\text{-})_2C(CO_2Et)^+$), and 300 (100, *p*-Cl-$C_6H_4SC(CO_2Et)_2^+$). Found: C, 51.58; H, 4.04%. Calcd for $C_{19}H_{18}Cl_2O_4S_2$: C, 51.24; H, 4.07%.

*Ethyl (p-Chlorophenylthio)acetate (**12**).* A mixture of thionitrate **2b** (5 mmol), and diethyl malonate **8** (5 mmol) was added for a few minutes to a stirred solution of potassium hydroxide (16 mmol) in ethanol (8 ml) at 0—5 °C. The solution was stirred further for *ca.* 3 min, then cold HCl aq solution was added and the mixture was extracted with diethyl ether. Then the product was distilled giving 825 mg (72%) of compound **13**: bp 140—143 °C/2 mmHg (lit,[8] 126—130 °C/1 mmHg). IR (neat): 1720, 1260, 1140, 1085, 1020, and 820 cm^{-1}. NMR (CCl_4): δ 1.25 (t, 6H, CH_3-), 4.18 (q, 4H, -C<u>H</u>$_2$-), 4.35 (s, 1H, -C<u>H</u>), and 7.13—7.70 (m, 4H, ring protons). MS (70 eV), *m/e* (rel. intensity), 230 (55, M$^+$) and 157 (100, $p\text{-Cl-}C_6H_4SCH_2^+$). Found: C, 51.86; H, 4.99%. Calcd for $C_{10}H_{11}ClO_2S$: C, 52.06; H, 4.80%. Small amounts of compound **10** and **11** were also confirmed by GC-MS spectra. Compound **11**: MS (70 eV), *m/e* (rel. intensity), 302 (53, M$^+$), 229 (35, $p\text{-Cl-}C_6H_4SCHCO_2Et^+$), and 156 (100, $p\text{-Cl-}C_6H_4SCH^+$).

Studies on Heterocyclic Analogs of Azulene. VII.[1] Regioselective Cycloadditions of Cycloheptimidazole to Electron-deficient Olefins

Noritaka ABE* and Tarozaemon NISHIWAKI

Department of Chemistry, Faculty of Sciences, Yamaguchi University, Yamaguchi 753

(Received November 19, 1979)

Synopsis. Cycloheptimidazole reacted with electron-deficient olefins (*e.g.*, ethyl acrylate or acrylonitrile) to give the regioselective [6+2] cycloadducts, which were readily dehydrogenated to give 2a,3-dihydro-1,2a-diazacyclopent[*cd*]-azulenes.

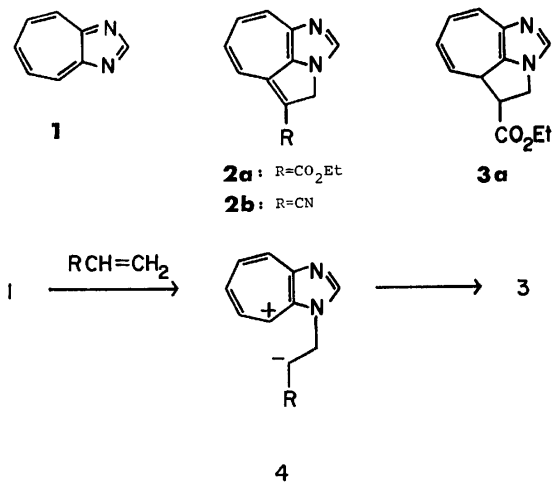
We have recently reported[2] that the reaction of aza analogs of azulene with dimethyl acetylenedicarboxylate affords cycloadducts, the formation of which is accounted for in terms of an intramolecular cyclization of an extended dipolar species.[3] This paper is concerned with the regioselective cycloadditions of cycloheptimidazole with electron-deficient olefins.

When a mixture of cycloheptimidazole (**1**) and ethyl acrylate was heated under reflux for 20 h, two products, ethyl 2a,3-dihydro-1,2a-diazacyclopent[*cd*]azulene-4-carboxylate (**2a**) (24%) and ethyl 2a,3,4,4a-tetrahydro-1,2a-diazacyclopent[*cd*]azulene-4-carboxylate (**3a**) (48%), were isolated as red needles and an unstable pale yellow oil, respectively. The ^{1}H-NMR spectrum of the former (**2a**) shows two 1H doublets at δ 6.89 (H-8) and 7.23 (H-5) (J=11 Hz) and two 1H double doublets at δ 6.12 (H-7) and 6.51 (H-6) (J=11 and 9 Hz) assignable to seven-membered ring protons, and a 2H doublet at δ 5.07 (J=1.5 Hz, H-3) which shows a long-range coupling with the H-2 proton resonating at δ 7.62 (t, J=1.5 Hz), in addition to signals for an ethyl group. An absorption at 1675 cm^{-1} in its IR spectrum indicates the presence of a conjugated ester carbonyl. These observations allow the ester group to be assigned at C-4. The latter compound was found to be rather unstable and changed into **2a** on storage in air or by dehydrogenation with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone supporting the structure of **3a**. IR spectrum of picrate of **3a** shows an absorption of unconjugated ester carbonyl at 1720 cm^{-1}, and ^{1}H-NMR spectrum of the picrate accords with the structure in spite of its quite complex feature.

Since the presence of a dehydrogenation catalyst such as palladium–charcoal may stimulate[4] the formation of **2a**, the reaction was repeated in the presence of palladium–charcoal. As expected, **2a** was obtained in higher yield and **3a** was not isolated at all.

Acrylonitrile similarly reacts with **1** in the absence of palladium–charcoal to yield **2b** as red prisms (15%), according to the manner of the regioselective [6+2] cycloaddition reaction. This reaction was sluggish than that of ethyl acrylate, *i.e.*, 73% of the starting material **1** was recovered even after reflux for 48 h.

In these reaction, the electrophilic olefin attacks the ring nitrogen to give a dipolar species (**4**) followed by the intramolecular cyclization reaction. These results further lend support the mechanism we advanced previously for the reaction of **1** with dimethyl acetylenedicarboxylate.[2]



4

Experimental

Melting points were uncorrected. IR spectra were recorded for Nujol mulls. ^{1}H-NMR spectra were recorded with JEOL FX-100 (100 MHz) or Hitachi R-24B (60 MHz) spectrometers. UV spectra were measured for ethanol solutions. Kiesel gel 60 was used for chromatography unless otherwise stated. Yields are based on consumed starting material.

*Reaction of **1** with Ethyl Acrylate.* (*a*): A mixture of **1** (1.00 g) and ethyl acrylate (4.00 g) was heated under reflux for 20 h. Reaction mixture was evaporated under reduced pressure, and the residue was chromatographed. Elution with chloroform gave **2a** (0.176 g, 24%), red needles (from petroleum ether), mp 80—82 °C, UV_{max} 223 nm (log ε 4.36), 253^{sh} (4.18), 359 (4.13), 375 (4.08), 424 (3.57), 448 (3.61), 477 (3.55), 513 (3.35), 555^{sh} (2.95). IR 1675 cm^{-1} (ester C=O). ^{1}H-NMR ($CDCl_3$) δ=1.32 (3H, t, J=7 Hz, CH_3), 4.22 (2H, q, J=7 Hz, OCH_2), 5.07 (2H, d, J=1.5 Hz, H-3), 6.12 (1H, dd, J=11 and 9 Hz, H-6), 6.51 (1H, dd, J=11 and 9 Hz, H-7), 6.89 (1H, d, J=11 Hz, H-8), 7.23 (1H, d, J=11 Hz, H-5), 7.62 (1H, t, J=1.5 Hz, H-2). Found: C, 68.39; H, 5.58; N, 12.08%. Calcd for $C_{13}H_{12}N_2O_2$: C, 68.41; H, 5.30; N, 12.27%. Picrate of **2a**, red needles (from ethanol), mp 195—197 °C (dec.). IR 1680 cm^{-1} (ester C=O). Found: C, 49.85; H, 3.40; N, 15.04%. Calcd for $C_{19}H_{15}N_5O_9$: C, 49.89; H, 3.31; N, 15.31%. Elution with ethyl acetate gave **3a** as a pale yellow oil (0.349 g, 48%). Picrate of **3a**, orange needles (from ethanol), mp 166—167 °C. IR 1720 cm^{-1} (ester C=O). ^{1}H-NMR (DMSO-d_6) δ=1.27 (3H, t, J=7 Hz, CH_3), 4.18 (2H, q, J=7 Hz, OCH_2), 4.2—4.7 (4H, m, H-3, 4, and 4a), 5.5—6.8 (5H, m, H-2, 5, 6, 7, and 8), and 9.00 (1H, s, OH), and phenyl proton of picric acid appeared at δ 8.55 (2H, s). Found: C, 49.75; H, 3.97; N, 15.00%. Calcd for $C_{19}H_{17}N_5O_9$: C, 49.67; H, 3.73; N, 15.25%. Further elution gave the starting material **1** (0.579 g). (*b*): A mixture of **1** (0.30 g), ethyl acrylate (4.00 g), and 5% palladium–charcoal (0.10 g) was heated under reflux for 20 h. The mixture was cooled and filtered. The filtrate was evaporated under reduced pressure and the residue was similarly chro-

matographed as above to afford **2a** (0.129 g, 41%) and the starting material **1** (0.120 g).

*Reaction of **1** with Acrylonitrile.* A mixture of **1** (0.60 g) and acrylonitrile (4.00 g) was heated under reflux for 48 h. The mixture was evaporated under reduced pressure, and the residue was chromatographed. Elution with chloroform gave **2b** (0.034 g, 15%), red prisms (from cyclohexane), mp 149—150 °C, UV_{max} 223 nm (log ε 4.16), 256^{sh} (4.04), 354 (3.93), 370^{sh} (3.85), 424 (3.34), 452 (3.33), 483 (3.25), 520 (3.06), 560^{sh} (2.74). IR 2200 cm^{-1} (C≡N). ^{1}H-NMR ($CDCl_3$) δ=5.07 (2H, d, J=1 Hz, H-3), 6.12 (1H, dd, J=11 and 8 Hz, H-6), 6.44 (1H, dd, J=11 and 8 Hz, H-7), 6.66 (1H, d, J=11 Hz, H-5), 6.90 (1H, d, J=11 Hz, H-8), 7.64 (1H, t, J=1 Hz, H-2). Found: C, 73.05; H, 3.85; N, 23.02%. Calcd for $C_{11}H_7N_3$: C, 72.91; H, 3.89; N, 23.19%. Elution of ethyl acetate gave the starting material **1** (0.438 g).

*Oxidation of **3a**.* A mixture of **3a** (0.050 g) and 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (0.055 g) in benzene (20 ml) was heated under reflux for 24 h, then chromatographed on alumina. **2a** (0.035 g, 71%) was eluted with chloroform.

We thank Dr. Masafumi Yasunami, Tohoku University, for NMR spectral determination.

Synthesis Using Allylidenedihydropyridines. VIII.[1] Facile Preparation of 2-Alkylthio-3-vinylpyrazolo[1,5-*a*]pyridines

Akikazu KAKEHI,* Suketaka ITO, and Kozo WATANABE

Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano 380

(Received December 12, 1979)

Synopsis. Reactions of 1-[bis(alkylthio)methyleneamino]-2-methylpyridinium iodides with activated ethoxymethylene compounds in the presence of alkali gave the corresponding 1-[bis(alkylthio)methyleneamino]-2-allylidene-1,2-dihydropyridines in considerable yields, and their thermolyses in benzene afforded 2-alkylthio-3-vinylpyrazolo[1,5-*a*]-pyridine derivatives.

In a previous paper a report was given on a simple preparation method of 2-alkylthio-1-vinylindolizine derivatives from the corresponding pyridinium 1-[(alkylthio)thiocarbonyl]methylides.[2] The extension of this route for synthesizing its azaanalogue, 2-alkylthio-3-vinylpyrazolo[1,5-*a*]pyridine, should be possible if an appropriate starting material such as pyridinium 1-[(alkylthio)thiocarbonyl]aminide is available.[3] In contrast with pyridinium 1-[(alkylthio)thiocarbonyl]-methylide,[4] however, such type of pyridinium 1-aminide has not been reported. In this paper we wish to report the syntheses of pyridinium 1-[(alkylthio)thiocarbonyl]-aminides and of the title compounds using them.

Since the smooth formation of *S*-involving pyridinium betaines from the reactions of various pyridinium 1-methylides with carbon disulfide are well known,[4] the preparation of pyridinium 1-[(alkylthio)thiocarbonyl]aminide by a similar procedure was attempted and accomplished well when the reaction of pyridinium 1-aminide with carbon disulfide was carried out in the presence of a certain alkylating agent: When a mixture of 1-amino-2-methylpyridinium iodide (**1**), carbon disulfide, and dimethyl or diethyl sulfate was treated with potassium hydroxide in ethanol, the expected 2-methylpyridinium 1-[(methylthio)- (**2**) or 1-[(ethylthio)-thiocarbonyl]aminide (**3**) was obtained in 59 or 65% yield. The respective reactions of **2** and **3** with methyl and ethyl iodide gave the *S*-alkylated products, 1-[bis(methylthio)- (**4**) and 1-[bis(ethylthio)-methyleneamino]-2-methylpyridinium iodide (**5**), in quantitative yields. The reactions of the pyridinium salts (**4** and **5**) with ethyl (ethoxymethylene)cyanoacetate (**6**) and 3-(ethoxymethylene)pentane-2,4-dione (**7**) in the presence of potassium carbonate afforded the corresponding 1-[bis(alkylthio)methyleneamino]-2-allylidene-1,2-dihydropyridine derivatives (**8**—**11**) in 47—56% yields. These compounds (**8**—**11**) were then thermolysed smoothly in refluxing benzene to give 2-alkylthio-3-vinylpyrazolo[1,5-*a*]pyridines (**12**—**15**) with the elimination of methanethiol or ethanethiol. Interestingly, pyrazolopyridines (**12**—**15**) were very stable and unchanged even in dilute hydrochloric acid or aqueous sodium hydroxide. However, **13** and **15** were decomposed by the treatments of conc. hydrochloric acid to yield products (**16** and **17**), and **12** and **14** under similar conditions gave only intractable tarry substances. These results are summarized in the following Scheme.

The structures of these compounds (**2** and **3**, **4** and **5**, **8**—**11**, and **12**—**15**) were determined by their physical and spectral analyses and by comparisons with spectral data of known pyridinium 1-aminides, pyridinium salts, 2-allylidene-1,2-dihydropyridines, and 3-vinylpyrazolo-[1,5-*a*]pyridines, respectively.[3] On the other hand, those of **16** and **17** were concluded to be the monodeacetylated compounds of starting pyrazolopyridines (**13** and **15**), because their NMR spectra exhibited a characteristic AB quartet signal coupled with 16.0 Hz at δ 7.89, 7.62, 6.78, and 6.50 (**16**) or at δ 7.90, 7.82, 6.79, and 6.51 (**17**) and only one acetyl singlet at δ 2.35

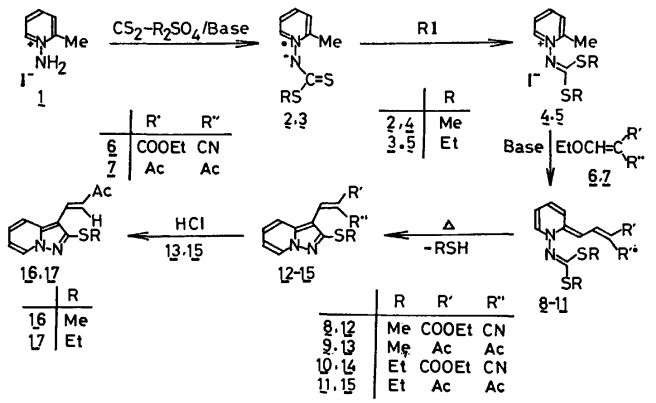
a) Neat.



(**16**) or 2.37 (**17**) due to the protons of the 3-vinyl moiety.[5] Furthermore, the configuration of the 3-vinyl group was determined to be *trans* by the large coupling constant (16.0 Hz) between the olefinic protons.

Experimental

Melting points were measured with a Yanagimoto micro-melting point apparatus and are uncorrected. Microanalyses and IR spectra were measured with a Perkin-Elmer 240 Elemental Analyzer and a Hitachi 260-10 Infrared Spectrophotometer, respectively, and are listed in the Table. The NMR spectra were determined with a Varian EM360A Spectrometer in deuteriochloroform with tetramethylsilane as an internal standard. The chemical shifts are expressed in δ values.[6]

Preparations of 2-Methylpyridinium 1-[(Alkylthio)thiocarbonyl]-aminides (2 and 3). To an ethanolic solution (50 ml) of 1-amino-2-methylpyridinium iodide (**1**, 4 mmol), carbon disulfide (6 mmol), and dimethyl or diethyl sulfate (6 mmol) aqueous potassium hydroxide (9 mmol in 5 ml of water) was added dropwise under stirring at room temperature. After the addition the mixture was stirred for additional 1 h, and then poured into ice–water (200 ml). The resulting solution was extracted two times with chloroform (100 ml) and the combined extract was washed with water, dried over anhydrous sodium sulfate, and concentrated at reduced pressure. Column separation (alumina) of the residue and recrystallization from chloroform–hexane gave **2**, 59%, mp 128—129 °C, δ 2.57 (3H, s, SMe), and 2.64 (3H, s, C_2–Me), and **3**, 65%, mp 113—115 °C, δ 1.37 (3H, t, J=7.0 Hz, $SCH_2\underline{CH_3}$), 2.62 (3H, s, C_2–Me), and 3.13 (2H, q, J=7.0 Hz, $S\underline{CH_2}CH_3$), as colorless crystals.

Preparations of 2-Alkylthio-3-vinylpyrazolo[1,5-a]pyridine Derivatives (12—15). To a chloroform solution (30 ml) of **2** or **3** (2 mmol) methyl or ethyl iodide (2 ml) was added at room temperature and the solution was allowed to stand for 20 min. The reaction mixture was then concentrated and the residue was recrystallized from chloroform–ether to give **4**, mp 134—136 °C, and **5**, mp 131—132 °C, as slightly brown crystals in almostly quantitative yields. The mixture of salt (**4** or **5**, 2 mmol) and ethoxymethylene compound (**6** or **7**, 2 mmol) was treated with potassium carbonate (5 g) in chloroform (50 ml) at room temperature for 3 d and, then, the reaction solution was filtered to remove insoluble substances. The filtrate was concentrated at reduced pressure and the residue was separated by column chromatography (alumina) using ether and then chloroform as eluents. Recrystallizations from chloroform–hexane of the crude products gave **8**, 50%, mp 116—117 °C, δ 1.30 (3H, t, J=7.0 Hz, $OCH_2\underline{CH_3}$), 2.57 and 2.73 (each 3H, s, SMe), 4.22 (2H, q, J=7.0 Hz, $O\underline{CH_2}CH_3$), 5.57 (1H, d, J=14.0 Hz, vinyl-H), and 8.19 (1H, d, J=14.0 Hz, vinyl-H), **9**, 47%, mp 93—95 °C, δ 2.40 (6H, s, 2×COMe), 2.56 and 2.80 (each 3H, s, SMe), 6.85 (1H, d, J=14.0 Hz, vinyl-H), and 7.98 (1H, d, J=14.0 Hz, vinyl-H), **10**, 51%, mp 108—109 °C, δ 1.28, 1.32, and 1.49 (each 3H, t, J=7.0 Hz, $OCH_2\underline{CH_3}$ and 2×$SCH_2\underline{CH_3}$), 3.10 and 3.33 (each 2H, q, J=7.0 Hz, $S\underline{CH_2}CH_3$), 4.51 (2H, q, J=7.0 Hz, $OCH_2\underline{CH_3}$), 5.53 (1H, d, J=14.0 Hz, vinyl-H), and 8.18 (1H, d, J=14.0 Hz, vinyl-H), and **11**, 56%, mp 101—102 °C, δ 1.30 and 1.49 (each 3H, t, J=7.0 Hz, $SCH_2\underline{CH_3}$), 2.33 (6H, s, 2×COMe), 3.10 and 3.39 (each 2H, q, J=7.0 Hz, $S\underline{CH_2}CH_3$), 6.73 (1H, d, J=14.0 Hz, vinyl-H), and 8.01 (1H, d, J=14.0 Hz, vinyl-H). A benzene solution (30 ml) of 2-allylidene-1,2-dihydropyridine (1 mmol) was heated under reflux until the TLC spot of the material disappeared (about 3—6 h). The reaction mixture was then concentrated and separated by column chromatography (alumina) using ether. Recrystallizations from ether-hexane afforded 2-alkylthio-3-vinylpyrazolopyridines (**12**—**15**) as yellow needles: **12**, 57%, mp 169—170 °C, δ 1.39 (3H, t, J=7.0 Hz, $OCH_2\underline{CH_3}$), 2.70 (3H, s, SMe), 4.37 (2H, q, J=7.0 Hz, $O\underline{CH_2}CH_3$), and 8.34 (1H, s, vinyl-H), **13**, 43%, mp 104—105 °C, δ 2.29 and 2.42 (each 3H, s, COMe), 2.68 (3H, s, SMe), and 7.73 (1H, s, vinyl-H), **14**, 55%, mp 143—144 °C, δ 1.40 and 1.43 (each 3H, t, J=7.0 Hz, $OCH_2\underline{CH_3}$ and $SCH_2\underline{CH_3}$), 3.27 (2H, q, J=7.0 Hz, $SCH_2\underline{CH_3}$), 4.38 (2H, q, J=7.0 Hz, $O\underline{CH_2}CH_3$), and 8.39 (1H, s, vinyl-H), **15**, 53%, oil, δ 1.44 (3H, t, J=7.0 Hz, $SCH_2\underline{CH_3}$), 2.31 and 2.47 (each 3H, s, COMe), 3.29 (2H, q, J=7.0 Hz, $S\underline{CH_2}CH_3$), and 7.88 (1H, s, vinyl-H).

Acid Hydrolyses of 13 and 15. Pyrazolopyridines (**13** or **15**, 100 mg) was dissolved in 10 ml of concd hydrochloric acid and kept for 3 h at room temperature. The solution was concentrated to dryness at reduced pressure and the residual oil was separated by column chromatography (alumina) using ether and then chloroform as eluents. Recrystallizations of the crude products from chloroform–hexane gave 2-methylthio-(**16**), 65%, mp 142—144 °C, and 2-ethylthio-3-(3-oxo-1-butenyl)pyrazolo[1,5-*a*]pyridine (**17**), 79%, mp 107—109 °C, as pale yellow needles. On the other hand, similar treatments of **12** and **14** gave only tarry substances and the separation of any significant products from them was unsuccessful.

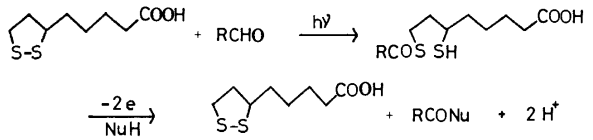
(Received December 17, 1979)

Synopsis. Irradiation of phenazine in acetaldehyde or propionaldehyde solution gave an *N*-acylated 5,10-dihydrophenazine. Acridine similarly gave 9-acyl-9,10-dihydroacridine, and 10-methylacridinium salt gave 9-acyl-10-methyl-9,10-dihydroacridine. In methanol *N*-acylated dihydrophenazines reacted with *N*-bromosuccinimide to give phenazine and methyl carboxylates in quantitative yield.

p-Benzoquinones are known to undergo reductive acylation with aldehydes under photo-irradiation.[2)] When the resultant hydroquinone monocarboxylates are oxidized in the presence of appropriate nucleophiles, oxidative acyl activation takes place, and the acyl group is transferred to the nucleophile with a concurrent reproduction of *p*-benzoquinones.[3)] The entire process, the reductive acylation followed by the oxidative acyl transfer, constitutes a cycle which converts aldehydes into activated acyl compounds by means of a quinone-hydroquinone redox pair as an acyl carrier. A similar process has been disclosed recently by us for a 1,2-dithiolane-1,3-dithiol redox pair, and a formal resemblance of the process to the reaction of coenzyme lipoic acid in pyruvate dehydrogenase has been pointed out (Eq. 1).[4–7)] In living organisms there are several redox coenzymes which contain nitrogen heterocycles, *e.g.*, flavin and nicotinamide, and it would be interesting to study nigrogen heterocycles for the reaction similar to quinones and 1,2-dithiolanes.



(1)

Results and Discussion

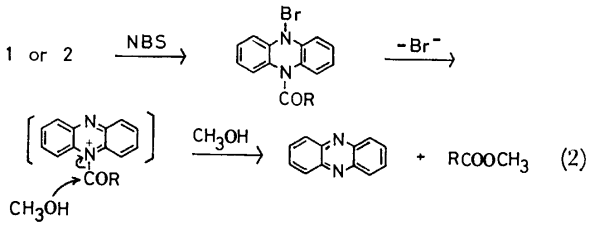
The results of photo-reactions are summarized in Table 1. Besides the heterocycles in Table 1, 1,10-phenanthroline, quinoxaline, quinoline, and benzothiazole were subjected to photo-irradiation in propionaldehyde solution, but the starting heterocycles were recovered unreacted. *N*-alkylated quinolinium and 1-benzyl-3-carbamoylpyridinium chlorides gave intractable complex mixtures. The reactions in Table 1 generally gave complicated mixtures, and the isolation of the products was attained by recrystallization and column chromatography.

The mechanism of the present photochemical reductive acylation is yet to be studied. In contrast to the reaction of 1,2-dithiolanes which was effected under both photochemical and thermal (in the presence of AIBN as radical initiator) conditions,[7)] the reaction of phenazine proceeded only under photo-irradiation. The photo-reduction of acridine[8)] and phenazine[9)] has been reported. The reductive photo-alkylation of acridine by aliphatic carboxylic acid has also been described.[10)] The present reaction may be related to these reactions in mechanism. The acylation reaction will find a synthetic use for the preparation of acylphenazines, since the synthesis of acetyl- and propionylphenazine has not been described in the literature reflecting the difficulty of the direct acylation of the phenazine nucleus.

Table 1. Photo-reaction of nitrogen heterocycles with aldehydes

Heterocycle	Aldehyde	Irradiation time/h	Product (yield/%)
	CH_3CHO	6	 **1** (35)
	C_2H_5CHO	5	 **2** (20)
			 **3** (19)
	CH_3CHO	2	 **4** (36)
	C_2H_5CHO	3	 **5** (52)

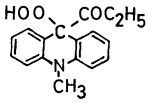
The 5-acyl-5,10-dihydrophenazines **1** and **2** in methanol were allowed to react with *N*-bromosuccinimide (NBS) at room temperature. The oxidation proceeded in a few minutes to give a quantitative yield of methyl carboxylates and phenazine. The plausible mechanism is formulated in Eq. 2. Thus, it is concluded that phenazine undergoes the same type of reductive acylation and oxidative acyl transfer reactions as those



(2)

of quinones and 1,2-dithiolanes.

The oxidation of **4** or **5** did not bring about such an acyl activation. The compound **5** was found to be gradually oxidized in the air, even in the isolated crystalline state, to give 10-methyl-9(10*H*)-acridinone. The reaction most probably involved the formation of a 9-hydroperoxy derivative **6** by air oxidation and its subsequent decomposition to propionic acid and 10-methyl-9(10*H*)-acridinone.



6

Experimental

Photo-reaction of Phenazine with Acetaldehyde. Phenazine (0.40 g) was dissolved in acetaldehyde (200 ml), and the mixture was irradiated under nitrogen at $\leq$10 °C by a 100W immersion type high pressure mercry lamp.[4,6] The light shorter than 330 nm in wavelength was eliminated by a liquid filter (NaBr–Pb $(NO_3)_2$–H_2O).[6] After 6 h irradiation, the red reaction mixture was evaporated, the residue was digested in 5 ml of benzene, and the insoluble red solid was collected. Recrystallization from ethanol gave reddish crystals, 0.22 g (**1**, 35%). For further purification, the product dissolved in chloroform was passed through a short column of silica gel. Another recrystallization from ethanol gave white grannular crystals. mp 258—260 °C (254—255 °C[11]); IR (Nujol) 3280 (NH) and 1650 cm^{-1} (CO); NMR (CF_3CO_2H) δ=2.58 (3H, s, CH_3), 7.0—7.6 (8H, m, aromatic H). Found: C, 74.90; H, 5.46; N, 12.48%. Calcd for $C_{14}H_{12}N_2O$: C, 74.98; H, 5.39; N, 12.49%.

Photo-reaction of Phenazine with Propionaldehyde. The reaction was carried out in a similar manner to the above procedure using 0.55 g of phenazine in 150 ml of propionaldehyde. After 5 h photo-irradiation, the mixture was concentrated. The solid product was filtered and recrystallized from ethanol. Yellow needles (**3**). Yield, 0.14 g, 19%; mp 123—123.5 °C; IR (Nujol) 1685 cm^{-1} (CO); NMR (CCl_4) δ=1.29 (3H, t, J=7.0 Hz, CH_3), 3.43 (2H, q, CH_2), 7.6—8.4 (7H, m, aromatic H); MS (*m/e*) 236 (M^+), 179 ($M^+-C_2H_5CO$). Found: C, 75.88; H, 5.14; N, 11.82%. Calcd for $C_{15}H_{12}N_2O$: C, 76.25; H, 5.12; N, 11.85%. The filtrate from the concentrated reaction mixture was further evaporated to dryness, and the residue was dissolved in a small amount of ethanol. The addition of hexane produced precipitates, which were recrystallized from ethanol to give reddish crystals. **2**. Yield, 0.15 g, 20%. Another recrystallization from ethanol after passing through a short column of silica gel in chloroform gave white grannular crystals. mp 193—194 °C; IR (Nujol) 3250 (NH) and 1650 cm^{-1} (CO); NMR ($CDCl_3$) δ=1.10 (3H, t, J=7.0 Hz, CH_3), 2.52 (2H, q, CH_2), 6.12 (1H, s, NH, D-exchange), 6.6—7.5 (8H, m, aromatic H); MS (*m/e*) 238 (M^+), 181 ($M^+-C_2H_5CO$). Found: C, 75.49; H, 5.97; N, 11.72%. Calcd for $C_{15}H_{14}N_2O$: C, 75.61; H, 5.92; N, 11.75%.

Photo-reaction of Acridine with Acetaldehyde. Acridine (2.01 g) dissolved in acetaldehyde (200 ml) was irradiated for 2 h. The white precipitates formed (9,9′,10,10′-tetrahydro-9,9′-biacridine,[12] 0.12 g, 12%) were filtered off, and the filtrate was concentrated to dryness. The residue was subjected to column chromatography (silica gel, benzene) to yield **4** as colorless crystals. Yield, 0.45 g, 36%; mp 92—93 °C (benzene); IR (KBr) 3350 (NH) and 1687 cm^{-1} (CO); NMR ($CDCl_3$) δ=1.98 (3H, s, CH_3), 4.90 (1H, s, HC←), 6.27 (1H, s, NH) 7.5—8.4 (8H, m, aromatic H). Found: C, 80.93; H, 5.86; N, 6.45%. Calcd for $C_{15}H_{13}NO$: C, 80.69; H, 5.87; N, 6.27%.

Photo-reaction of 10-Methylacridinium Chloride with Propionaldehyde. 10-Methylacridinium chloride (1.02 g) in propionaldehyde (100 ml) was irradiated for 3 h. A part of the salt remained undissolved. The reaction mixture was filtered and concentrated to dryness. The residue was taken in chloroform and sujected to column chromatography (silica gel, chloroform) to give pale yellow crystals of **5**. Yield, 0.36 g, 52%; mp 60—63 °C; IR (Nujol) 1710 cm^{-1} (CO); NMR ($CDCl_3$) δ=0.83 (3H, t, J=7.0 Hz, $CH_2\underline{CH_3}$), 2.35 (2H, q, CH_2), 3.37 (3H, s, NCH_3), 4.85 (1H, s, HC←), 6.7—7.4 (8H, m, aromatic H). Found: C, 81.10; H, 6.87; N, 5.58%. Calcd for $C_{17}H_{17}NO$: C, 81.24; H, 6.82; N, 5.57%. The sample stored in the dark in a desiccator turned to high-melting yellow crystals in a year. A recrystallization from ethanol gave yellow needles, mp 202—204 °C, which proved to be 10-methyl-9(10*H*)-acridinone (mp 199 °C[13]) by comparing with an authentic sample.[13]

Oxidation of 1 by NBS. **1** was dissolved in 5—10 mmol/dm^3 concentration in 10 ml methanol. The methanol contained hexane as internal standard for the subsequent GLC analysis. NBS was added in twice molar excess of **1**, and the mixture was stirred at room temperature (—20 °C). UV spectra showed the formation of phenazine to be complete in 5 min according to Eq. 2. The GLC analysis on 10% tetraethyleneglycol on Celite at room temperature indicated 80—100% formation of methyl acetate. Both hexane and methyl acetate peaks appeared before the solvent (methanol) peak under these GLC conditions. The oxidation of **2** similarly confirmed the reaction in Eq. 2.

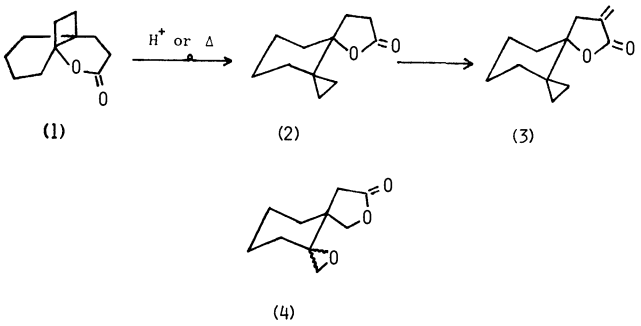
Synthesis of 1,6-Dioxadispiro[2.0.4.4]dodecan-7-one

Kiyomi KAKIUCHI,* Yasuhiro HIRAMATSU, Yoshito TOBE, and Yoshinobu ODAIRA
Department of Petroleum Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received December 20, 1979)

Synopsis. 1,6-Dioxadispiro[2.0.4.4]dodecan-7-one, a useful intermediate of dispiro-α-methylene-γ-butyrolactones, was synthesized in a good overall yield by the cycloaddition of dichloroketene to 1,2-dimethylenecyclohexane, and the zinc dust reduction of the chlorine atoms, followed by the Baeyer-Villiger oxidation with *m*-chloroperbenzoic acid.

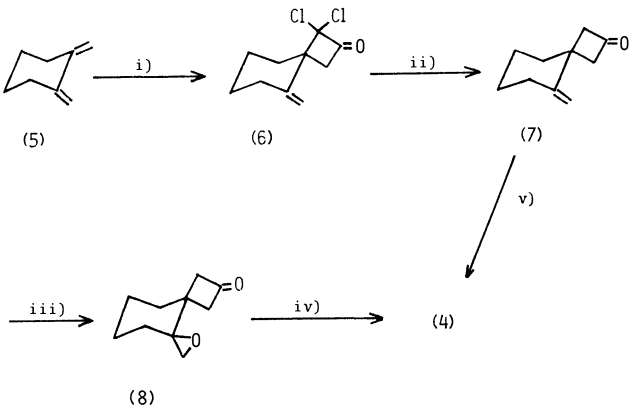
Recently, much attention has been paid on the chemistry of α-methylene-γ-butyrolactones, especially, concerning the structure-biochemical activity relationship, because a number of naturally occurring sesquiterpene lactones display antitumor and/or cytotoxic activity attributed to this moiety.[1] From the above point of view, we previously reported on the synthesis of the dispiro-γ-butyrolactone (**2**), being a useful intermediate of the dispiro-α-methylene-γ-butyrolactone (**3**) having a spiro cyclopropane ring,[2] by the acid catalyzed or thermally induced cyclobutyl-cyclopropylcarbinyl type rearrangement of the propellalactone (**1**).[5] As part of the study on the synthesis of various types of dispiro-γ-butyrolactones, we wish to report here a convenient synthesis of 1,6-dioxadispiro[2.0.4.4]-dodecan-7-one (**4**) having a spiro epoxide linkage which is expected to enhance the reactivity of the conjugated lactone toward biological nucleophiles.[1a]



The epoxy-γ-lactone **4** was prepared as outlined in Scheme 1; i) the cycloaddition of dichloroketene to 1,2-dimethylenecyclohexane employing the high-dilution method,[6] ii) the reductive removal of the chlorine atoms with zinc dust–acetic acid,[7] iii) the epoxidation with *m*-chloroperbenzoic acid (MCPBA), and iv) the Baeyer-Villiger oxidation.

A solution of equal amounts of trichloroacetyl chloride and phosphoryl chloride in ether was added dropwise over a period of 5 h to an ethereal solution of 1,2-dimethylenecyclohexane (**5**), which was readily available from *cis*-1,2-cyclohexanedicarboxylic anhydride, and excess of activated zinc, and the mixture was refluxed for 30 h. The 1: 1 cycloadduct, that is the spiro dichlorocyclobutanone (**6**), was obtained in a 61% yield.[8] The reductive removal of the chlorine atoms from **6** with excess of zinc dust and acetic acid in ether at room temperature gave the spiro cyclobutanone (**7**) in a 71% yield. The epoxidation of **7** with 1.2 equivalent of MCPBA in chloroform at room temperature for 3 h afforded the epoxy cyclobutanone (**8**) in a 71% yield.[9] Finally, the Baeyer-Villiger oxidation of **8** with 1.2 equivalent of MCPBA in chloroform at room temperature for 6 d gave a 1: 1 mixture of two epoxy-γ-lactones **4**[10] in a 70% yield. The γ-lactone **4** was also obtained directly from the cyclobutanone **7** by the oxidation with 3-fold excess of MCPBA for 6 d (77%).

In this way, 1,6-dioxadispiro[2.0.4.4]dodecan-7-one **4**, a key compound for the synthesis of dispiro-α-methylene-γ-butyrolactones having an epoxide linkage, was synthesized in a good yield by means of the efficient dichloroketene addition.



Scheme 1.

i) Cl_3CCOCl, Zn(Cu), $POCl_3$, Et_2O, 30 h; ii) Zn, AcOH, Et_2O, 30 h; iii) MCPBA (1.2 eq.), $CHCl_3$, 3 h; iv) MCPBA (1.2 eq.), $CHCl_3$, 6 d; v) MCPBA (3 eq.), $CHCl_3$, 6 d.

Experimental

IR spectra were recorded using a JASCO IR-G spectrometer. ^1H NMR spectra were obtained on a JEOL JNM-PS-100 spectrometer, using Me_4Si as an internal standard and CCl_4 as a solvent. MS spectra were measured with a Hitachi RMU-6E spectrometer.

1,2-Dimethylenecyclohexane (**5**)[11] was prepared in a similar method to that of Davalian *et al.*,[12] and purified by distillation using a spinning-band distillation column.

1,1-Dichloro-5-methylenespiro[3.5]nonan-2-one (6). A solution of 8.1 ml (0.078 mol) of freshly distilled trichloroacetyl chloride and 6.8 ml (0.078 mol) of phosphoryl chloride (distilled from K_2CO_3) in 440 ml of dry ether was added dropwise over 5 h to a mixture of 8.4 g (0.078 mol) of **5** and 7.6 g (0.114 mol) of activated zinc in 600 ml of dry ether under a nitrogen atmosphere. The reaction mixture was stirred at reflux for additional 30 h. The excess zinc was filtered and washed with ether. The filtrate was concentrated *in vacuo* to *ca.* 25% of its original volume, an equal volume of pentane added, and

the solution stirred for 1 h to precipitate zinc salts. The solution was decanted from the residue, washed successively with water, a cold saturated $NaHCO_3$ solution and brine, and dried (Na_2SO_4). The solvent was removed *in vacuo* and the residue was distilled under reduced pressure. After recovery of 2.6 g of **5** (bp 60 °C/90 Torr), 7.1 g of **6** was obtained as pale yellow oil (61%): bp 86—88 °C/0.8 Torr; IR 1800, 1635 cm^{-1}; NMR δ 1.16—2.50 (m, 8H), 2.66 (d, J= 17 Hz, 1H), 3.62 (d, J=17 Hz, 1H), 4.80 (s, 1H), 5.08 (s. 1H); MS *m/e* 222 (M^++4), 220 (M^++2), 218 (M^+). Found: C, 54.91; H, 5.56%. Calcd for $C_{10}H_{12}OCl_2$: C, 54.82; H, 5.52%.

5-Methylenespiro[3.5]nonan-2-one (7). A mixture of 7.0 g (0.032 mol) of **6**, 10 g of zinc, and 10 ml of acetic acid in 150 ml of dry ether was stirred at room temperature for 30 h.[13] The reaction mixture was filtered and the filtrate was washed with saturated $NaHCO_3$ solution, brine, and dried (Na_2SO_4). The solvent was removed *in vacuo* and the residue was distilled under reduced pressure to give 3.4 g of the cyclobutanone **7** (71%): bp 68—69 °C/3 Torr; IR 1775, 1635 cm^{-1}; NMR δ 1.45—1.82 (m, 6H), 2.02—2.28 (m, 2H), 2.45—2.80 (m, 2H), 2.88—3.24 (m, 2H), 4.68 (s, 1H), 4.78 (s, 1H); MS *m/e* 150 (M^+). Found: C, 79.84; H, 9.54%. Calcd for $C_{10}H_{14}O$: C, 79.95; H, 9.39%.

1-Oxadispiro[2.0.3.4]undecan-6-one (8). A solution of 250 mg (1.7 mmol) of **7** and 440 mg (2.0 mmol) of 80% MCPBA in 10 ml of chloroform was stirred at room temperature for 3 h. The solution was washed with saturated Na_2SO_3 solution, saturated $NaHCO_3$ solution, water, and dried (Na_2SO_4). The solvent was evaporated *in vacuo* to give 197 mg of **8** as colorless oil (71%). Analytical sample was obtained by preparative GLC: IR 1775 cm^{-1}; NMR δ 1.20—2.08 (m, 8H), 2.24—3.12 (m, 6H); MS *m/e* 166 (M^+). Found: C, 72.05; H, 8.70%. Calcd for $C_{10}H_{14}O_2$: C, 72.26; H, 8.49%.

1,6-Dioxadispiro[2.0.4.4]dodecan-7-one (5). A solution of 100 mg (0.65 mmol) of **8** and 170 mg (0.78 mmol) of 80% MCPBA in 10 ml of chloroform was stirred at room temperature and the progress of the reaction was monitored by GLC. After 6 d, the solution was treated as described above. Chromatography on silica gel (20% ether–petroleum ether) gave 87 mg of **4** as colorless oil (74%).[10] 471 mg of **4** was also obtained in 77% yield from the reaction of 500 mg (3.3 mmol) of **7** and 2.2 g (9.9 mmol) of 80% MCPBA in 27 ml of chloroform for 6 d: IR 1765 cm^{-1}; NMR δ 1.20—2.00 (m, 8H), 2.04—2.72 (m, 4H), 3.60—4.20 (m, 2H); MS *m/e* 182 (M^+). Found: C, 65.72; H, 7.75%. Calcd for $C_{10}H_{14}O_3$: C, 65.91; H, 7.74%.

Diazoalkane Complexes of Molybdenum†

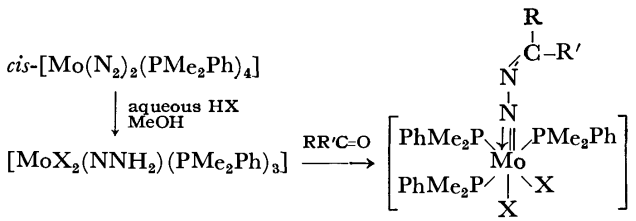
Yasushi MIZOBE, Yasuzo UCHIDA, and Masanobu HIDAI*
Department of Industrial Chemistry, The University of Tokyo, Hongo, Tokyo 113
(Received January 14, 1980)

Synopsis. The hydrazido(2-) complexes $[MoX_2(NNH_2)(PMe_2Ph)_3]$ (X=Cl or Br) derived from bis(dinitrogen) complex and HX react with aldehydes or ketones to give a series of diazoalkane complexes $[MoX_2(\rightleftharpoons N{-}N{=}CRR')(PMe_2Ph)_3]$.

Extensive studies on the reactions of coordinated dinitrogen in well defined complexes to form C–N bonds have been undertaken in order to open a new chemistry of dinitrogen. Aroyl, acyl, and alkyl halides have been shown to react with the dinitrogen complexes of molybdenum and tungsten, *trans*-$[M(N_2)_2(dpe)_2]$ (M=Mo or W; dpe=$Ph_2PCH_2CH_2PPh_2$), to afford the complexes containing organo-nitrogen ligands.[1] The same reactions with the dinitrogen complexes of mono(tertiary) phosphines $[M(N_2)_2(L)_4]$ (M=Mo or W; L=PMe_2Ph or $PMePh_2$), however, released the coordinated dinitrogen as dinitrogen gas.[2] We have recently found a more versatile route to the formation of C–N bonds from coordinated dinitrogen, which involved the condensation of the hydrazido (2-) complexes $[MF(NNH_2)(dpe)_2][BF_4]$ derived from *trans*-$[M(N_2)_2(dpe)_2]$ (M=Mo or W) and HBF_4 with a variety of aldehydes or ketones (RR′ C=O) to yield the diazoalkane complexes $[MF(\rightleftharpoons N{-}N{=}CRR')(dpe)_2][BF_4]$.[3] We report here preparation of diazoalkane complexes of molybdenum containing PMe_2Ph by the similar condensation reactions.

Results and Discussion

The hydrazido(2-) complexes $[MoX_2(NNH_2)(PMe_2Ph)_3]$ (X=Cl or Br) which are readily obtained from *cis*-$[Mo(N_2)_2(PMe_2Ph)_4]$ and aqueous HX in methanol[4] condense with aldehydes or ketones to give



diazoalkane complexes. The condensation reactions are markedly accelerated by catalytic amount of acids, though the reaction of aldehydes occurs smoothly even in the absence of acids. Spectroscopic data of the diazoalkane complexes are given in Table 1. These complexes give rise to strong ν(C=N) bands in the 1520—1570 cm^{-1} region of the infrared spectra. The ^1H-NMR spectra show two triplets and one doublet with intensity 6H each which are characteristic of virtually coupled *meridional* phosphine methyls in a complex lacking a plane of symmetry containing the phosphines. As observed in the diazoalkane complexes reported previously,[3,5] the substituents R and R′ are in inequivalent positions. Thus, the complex $[MoCl_2(N_2CMe_2)(PMe_2Ph)_3]$ exhibits two singlets at 1.5 (intensity 3H) and 1.7 ppm (intensity 3H) assignable to the methyls on the nitrogen-bearing carbon.

Acetophenone readily condenses with the complexes $[MoX_2(NNH_2)(PMe_2Ph)_3]$, though it does not react with the hydrazido(2-) complexes $[MF(NNH_2)(dpe)][BF_4]$ (M=Mo or W) probably because of a steric effect.[3] In the case of acetylacetone, one of the two carbonyl groups condenses with the $MoNNH_2$ group and other remains free (ν(C=N), 1570; ν(C=O), 1720 cm^{-1}). The complex dissolved in CD_2Cl_2 shows a complicated NMR spectrum, which is interpreted in

Table 1. New diazoalkane complexes of molybdenum $[MoX_2(N_2CRR')(PMe_2Ph)_3]$

X	R	R′	Yield (%)	Analytical data[a] C	H	N	ν(C=N) (cm^{-1})	NMR (alkyl region) (ppm)

† Preparation and Properties of Molybdenum and Tungsten Dinitrogen Complexes. 12.

terms of an equilibrium between keto and enol forms ($C\underline{H}_3CO$–, $C\underline{H}_3C(OH)$=, $C\underline{H}_3CN$–, 1.9—2.2; –$C\underline{H}$=C(OH)–, 4.8; –$C\underline{H}_2COCH_3$, 3.3 ppm). Chatt and Hidai *et al.*[5] have recently shown that diazoalkane complexes of tungsten containing PMe_2Ph are prepared by the similar condensation reactions and treatment of the complex $[WBr_2(N_2CMe_2)(PMe_2Ph)_3]$ with HBr gas in CH_2Cl_2 yields hydrazine and acetone azine in moderate yields. On the other hand, when the diazoalkane complex of molybdenum $[MoCl_2(N_2CMe_2)(PMe_2Ph)_3]$ are treated with an excess of HCl gas in CH_2Cl_2, 0.22 mol of ammonia and 0.32 mol of hydrazine per metal atom are formed, together with a trace of acetone azine.[6]

Experimental

All reactions were carried out under dry dinitrogen using standard Schlenk-tube techniques. The complexes *cis*-$[Mo(N_2)_2(PMe_2Ph)_4]$ and $[MoX_2(NNH_2)(PMe_2Ph)_3]$ (X= Cl or Br) were prepared by published methods.[4] Analytical data of the diazoalkane complexes of molybdenum are shown in Table 1.

Preparation of $[MoCl_2(N_2CHPh)(PMe_2Ph)_3]$. To a suspension of $[MoCl_2(NNH_2)(PMe_2Ph)_3]$ (183 mg, 0.300 mmol) in CH_2Cl_2 (3 ml) was added benzaldehyde (121 μl, 1.20 mmol) at room temperature. After stirring for several minutes, a greenish-brown homogeneous solution was produced. After a further 6 h, hexane (3 ml) was added to the solution to give greenish-brown crystals, which were filtered off, washed with ether, and then dried *in vacuo* (86 mg, yield 41%).

Preparation of $[MoCl_2\{N_2C(CH_2)_5\}(PMe_2Ph)_3]$. To a suspension of $[MoCl_2(NNH_2)(PMe_2Ph)_3]$ (212 mg, 0.347 mmol) in CH_2Cl_2 (3 ml) was added cyclohexanone (0.29 ml, 2.8 mmol) and one drop of concentrated (*ca.* 35%) hydrochloric acid. A red homogeneous solution was immediately obtained. After stirring for 15 min, the volume was reduced *in vacuo* to *ca.* 1 ml and hexane (4 ml) was added. Red needles precipitated from the solution, which were filtered off, washed with ether, and dried *in vacuo* (215 mg, yield 90%).

In similar fashion were prepared $[MoBr_2\{N_2C(CH_2)_5\}(PMe_2Ph)_3]$, $[MoCl_2(N_2CMePh)(PMe_2Ph)_3]$, $[MoBr_2(N_2CMePh)(PMe_2Ph)_3]$, $[MoCl_2(N_2CMe_2)(PMe_2Ph)_3]$, and $[MoCl_2\{N_2CMe(CH_2COMe)\}(PMe_2Ph)_3]$.

Synthesis of Dihydrosphingosine

Yutaka SAITOH, Yoshihiko MORIYAMA,** Hiroshi HIROTA, and Takeyoshi TAKAHASHI*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

***Institute of Chemistry, Kyoto Prefectural University of Medicine, Taishogun, Kita-ku, Kyoto 603*

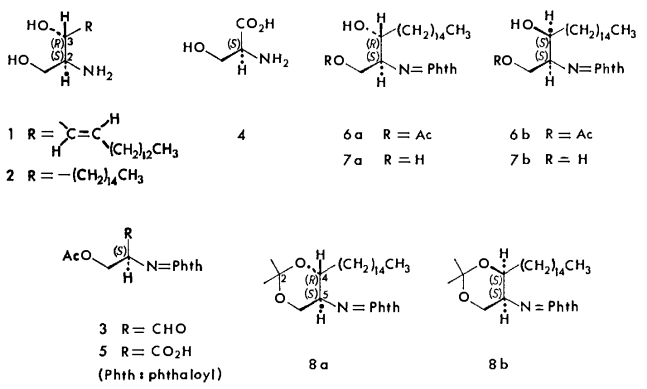
(Received January 18, 1980)

Synopsis. A conversion of (*S*)-3-acetoxy-2-phthalimidopropanal into dihydrosphingosine is described.

A number of syntheses of sphingosine (**1**), dihydrosphingosine (**2**), and related compounds have been reported.[1-3] This paper deals with a convenient synthesis of dihydrosphingosine [**2**; (2*S*,3*R*)-*erythro*-2-aminooctadecane-1,3-diol] from (*S*)-3-acetoxy-2-phthalimidopropanal (**3**).

The chiral aldehyde (**3**) was prepared from L-serine (**4**) *via* (*S*)-3-acetoxy-2-phthalimidopropanoic acid (**5**) by the known procedure.[2] The Grignard reaction of **3** with pentadecylmagnesium bromide in ether at a temperature between −88 and −45 °C gave a mixture of diol monoacetates (**6a** and **6b**). This mixture was subjected to acid hydrolysis and the product mixture was separated by column and thin-layer chromatography to afford (2*S*,3*R*)-*erythro*-2-phthalimidooctadecane-1,3-diol (**7a**) and (2*S*,3*S*)-*threo*-2-phthalimidooctadecane-1,3-diol (**7b**) in 13% and 1% yields from **3**, respectively.

The *erythro* and *threo* configurations were shown for **7a** and **7b**, respectively, on the basis of the following evidence. Treatment of **7a** with 2,2-dimethoxypropane in the presence of *p*-toluenesulfonic acid gave an acetonide (**8a**) in an almost quantitative yield. Acetalization of **7b** gave the corresponding acetonide (**8b**) in 55% yield. The coupling constant between a C-4 proton and a C-5 proton was determined to be 10 Hz and 5 Hz for **8a** and **8b**, respectively; the two protons should be in a *trans* relationship for **8a** and in *cis* one for **8b**. Acid hydrolysis of these acetonides (**8a** and **8b**) gave the diols (**7a** and **7b**), respectively.



These results suggest that a stereoselective attack[2] of the Grignard reagent to the aldehyde (**3**) was effected preferentially from the less hindered side of **3** to give predominantly the desired *erythro* derivative (**6a**).

Finally, hydrazinolysis of **7a** afforded dihydrosphingosine (**2**) in 81% yield.

Experimental

IR spectra were measured with a Hitachi EPI-G2 spectrometer, ^{1}H-NMR spectra with a JEOL PS-100 (100 MHz), a Varian EM-390 (90 MHz), or a Hitachi R-20B (60 MHz) spectrometer in deuteriochloroform solution containing tetramethylsilane as an internal standard, high resolution and chemical ionization (CI-MS) mass spectra with a JEOL JMS-D300 mass spectrometer. Measurements of optical rotation were carried out with a JASCO polarimeter DIP-SL, and high performance liquid chromatography (HPLC) analyses with a Waters liquid chromatograph model ALC-GPS 202-401. For column chromatography Wakogel C-200 (Wako Pure Chemical Industries) was used. Thin-layer chromatography (TLC) was carried out on Kieselgel GF_{254} (E. Merck, Darmstadt) in 0.25 mm thickness.

Grignard Reaction of (S)-3-Acetoxy-2-phthalimidopropanal (3) with Pentadecylmagnesium Bromide. A solution of pentadecylmagnesium bromide (3.6 mmol) in ether (60 ml) was added dropwise to a solution of the aldehyde (**3**; 0.94 g, 3.6 mmol) in ether (3.6 ml) with stirring under an argon atmosphere at a temperature between −88 and −80 °C. After the mixture had been stirred at −78 °C for 2 h and then at −45 °C for 30 min, a saturated aqueous solution (10 ml) of ammonium chloride was added at −45 °C. The reaction mixture was treated in the usual way to give a residue (1.90 g) which was chromatographed on a column of silica gel (60 g). Elution with hexane–ethyl acetate (17: 3) gave a mixture (410 mg) of crude diol monoacetates (**6a** and **6b**). This mixture was purified by preparative TLC to give a sample for spectral measurements; this sample showing one spot on TLC gave two peaks at R_t=28.4 min (major product; **6a**) and R_t=27.7 min (minor product; **6b**) on HPLC examination [column: μ-PORASIL, 1/4(inch) × 1(foot); solvent system: 30% ether–hexane; flow rate: 1 ml/min]. However, separation of each of two diastereomers (**6a** and **6b**) was unsuccessful due to proximity of their retention times. Mixture of **6a** and **6b**: mp 60 °C (crystallized from acetone): IR (KBr) 3400, 2920, 2850, 1780, 1750, 1710, 1560, 1380, 1370, 1250, 1240, and 720 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 0.90 (3H, t-like; $-CH_2C\underline{H}_3$), 1.97 (3H, s; CH_3-CO–), 3.77 (1H, br. s; disappeared on addition of D_2O; –OH), 4.10 (1H, br. s; –C<u>H</u>–OH), 4.35 (1H, m; –C<u>H</u>–N–), 4.60 (2H, m; $-C\underline{H}_2OAc$), and 7.85 (4H, m; aromatic H's).

In the column chromatography described above, successive elution with hexane–ethyl acetate (4: 1) gave a residue (*ca.* 450 mg) showing ^{1}H-NMR signals at δ 6.58 (2H, s; $-\underline{C}=CH_2$), 7.75 (4H, m; aromatic H's), and 9.63 (1H, s; –CHO). This suggested that the unchanged starting material (**3**) suffered elimination of acetic acid to give 2-phthalimido-2-propenal. Further purification of the residue was not carried out.

Treatment of **3** with the Grignard reagent at room temperature resulted in a formation of a complex mixture probably due to an attack of the reagent to the phthaloyl grouping. Further examination of the mixture was not effected. In the reaction at a temperature between −88 and −45 °C, this kind of product mixture was not formed,

*Acid Hydrolysis of the Mixture of Diol Monoacetates (**6a** and **6b**).* The mixture of crude diol monoacetates (**6a** and **6b**; 410 mg) was added to a solution (30 ml) prepared from 1 M hydrochloric acid and methanol (1:9 v/v), and the whole mixture was refluxed for 3 h. The reaction mixture was neutralized with aqueous sodium hydrogencarbonate solution and extracted thrice with chloroform. The combined chloroform solution (total 30 ml) was treated in the usual way to give a solid (380 mg), which was chromatographed on a column of silica gel (12 g). Elution with hexane–ethyl acetate (7:3) gave a mixture of **7a** and **7b**, and then pure **7a** (125 mg). This mixture was subjected to separation by TLC to afford **7a** (71 mg) and **7b** (16.4 mg; 1% yield from **3**). The *erythro*-diol (**7a**; total 196 mg) was obtained in 13% yield from **3**. (2*S*,3*R*)-*erythro*-2-Phthalimidooctadecane-1,3-diol (**7a**), mp 69—70 °C (crystallized from hexane–ethyl acetate), $[\alpha]_D^{24}$ −6° (*c* 0.18; EtOH); IR (Nujol) 3400, 1780, and 1705 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 0.89 (3H, t-like; $-CH_2C\underline{H}_3$), 3.1—3.6 (2H, broad signal; 2×OH), 4.18 [4H, m; HO–C<u>H</u>–C<u>H</u>($C\underline{H}_2$OH)–N–], and 7.81 (4H, m; aromatic H's); CI-MS (using methane as reactant gas) *m/e* 432 $(M+1)^+$. Found: *m/e* 431.3033. Calcd for $C_{26}H_{41}NO_4$: M, 431.3034. (2*S*,3*S*)-*threo*-2-Phthalimidooctadecane-1,3-diol (**7b**), mp 46—48 °C (crystallized from hexane–ethyl acetate), $[\alpha]_D^{23}$ +3° (*c* 0.24; $CHCl_3$); IR (KBr) 3450, 2920, 2850, 1780, 1710, 1470, 1400, 1380, and 720 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 0.89 (3H, t-like; $-CH_2C\underline{H}_3$), 3.3—3.6 (2H, broad signal; 2×OH), 4.05 (3H, m; $-C\underline{H}_2$OH and –C<u>H</u>OH), 4.35 (1H, m; –C<u>H</u>–N–), and 7.81 (4H, m; aromatic H's); CI-MS *m/e* 432 $(M+1)^+$. Found: *m/e* 431.3034. Calcd for $C_{26}H_{41}NO_4$: M, 431.3034.

Acetalization of the erythro-*Diol (**7a**).* A solution of the *erythro*-diol (**7a**; 50 mg) in 2,2-dimethoxypropane (1.5 ml) containing a trace of *p*-toluenesulfonic acid was stirred at room temperature for 10 h. The reaction mixture was treated in the usual way to give a residue, which was subjected to purification by preparative TLC giving an acetonide (**8a**; 53.9 mg) in an almost quantitative yield. (4*R*,5*S*)-2,2-Dimethyl-4-pentadecyl-5-phthalimido-1,3-dioxane (**8a**), mp 65—65.5 °C (crystallized from ethanol), $[\alpha]_D^{30}$ +18° (*c* 0.21; EtOH); IR (Nujol) 1780, 1720, 1260, 1200, 1160, 1120, 1105, 1090, 1075, and 800 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 0.89 (3H, t-like; $-CH_2C\underline{H}_3$), 1.48 and 1.67 (each 3H, s; *t*-CH_3), 3.73 [1H, dd, J=10 and J=5 Hz, $C_{(6a)}$–H], 4.28 [1H, td, J=10 and J=5 Hz; $C_{(5a)}$–H], 4.53 [1H, t, J=10 Hz; $C_{(6\beta)}$–H], 4.65 [1H, m; $C_{(4\beta)}$–H], and 7.86 (4H, m; aromatic H's); CI-MS *m/e* 472 $(M+1)^+$; MS *m/e* 456.3114 $(M-15)^+$. Found: C, 74.12; H, 9.64; N, 3.17%. Calcd for $C_{29}H_{45}NO_4$: C, 73.84; H, 9.62; N, 2.97%.

Acetalization of the threo-*Diol (**7b**).* The *threo*-diol (**7b**; 28 mg) was dissolved in 2,2-dimethoxypyropane (1.5 ml) containing a trace of *p*-toluenesulfonic acid, and the solution was stirred at room temperature for 12 d. The reaction mixture was treated in the usual way to give a residue. This was subjected to separation by preparative TLC to afford the corresponding acetonide (**8b**; 16.7 mg) in 55% yield, besides unchanged **7b** (11.1 mg). When the reaction was carried out for 12 h, almost all the starting material (**7b**) was found to be unchanged. (4*S*,5*S*)-2,2-Dimethyl-4-pentadecyl-5-phthalimido-1,3-dioxane (**8b**), mp 59—60 °C (crystallized from ethanol), $[\alpha]_D^{25}$ −20° (*c* 0.15; $CHCl_3$); IR (Nujol) 1780, 1710, 1230, 1170, 1140, 1120, and 880 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 0.90 (3H, t-like; $-CH_2C\underline{H}_3$), 1.45 and 1.61 (each 3H, s; *t*-CH_3), 3.96 [1H, dd, J=11 and J=7 Hz; $C_{(6)}$–H], 4.16 [1H, m; $C_{(4a)}$–H], 4.41 [1H, dd, J=11 and J=7 Hz; $C_{(6)}$–H], 4.70 [1H, td, J=7 and J=5 Hz; $C_{(5a)}$–H], and 7.90 (4H, m; aromatic H's); CI-MS *m/e* 472 $(M+1)^+$; MS *m/e* 456.3106 $(M-15)^+$.

*Acid Hydrolysis of the Acetonides (**8a** and **8b**).* The (4*R*,5*S*)-acetonide (**8a**; 38 mg) was added to a solution (5 ml) prepared from 1 M hydrochloric acid and methanol (1:9 v/v), and the mixture was refluxed for 2 h. The reaction mixture was neutralized with aqueous sodium hydrogencarbonate solution and extracted with chloroform. The chloroform solution was treated in the usual way to give the *erythro*-diol (**7a**; 20.9 mg). The *threo*-diol (**7b**) was obtained from the (4*S*,5*S*)-acetonide (**8b**) by the same acid hydrolysis.

Hydrazinolysis of the erythro-*Diol Phthalimide (**7a**).* Hydrazine hydrate (80%; 0.2 ml) was added to a solution of the *erythro*-diol phthalimide (**7a**; 70.5 mg) in ethanol (1.3 ml), and the mixture was refluxed for 1.5 h. The reaction mixture was extracted with dichloromethane (5 ml) after addition of water (1 ml) and potassium hydroxide (0.2 g). The organic layer was treated in the usual way to give a residue, which crystallized from chloroform to afford an *erythro*-amine (**2**; 39.8 mg) in 81% yield. (2*S*,3*R*)-*erythro*-2-Aminooctadecane-1,3-diol (**2**; dihydrosphingosine), mp 76.5—77.5 °C (lit,[4] 78.5—79 °C), $[\alpha]_D^{21}$ +5° [*c* 0.40; $CHCl_3$–EtOH (9:1)] (lit[4] +6°); IR (Nujol) 3350, 3300, 1620, 1580, 1070, and 1040 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 0.88 (3H, t-like; $-CH_2C\underline{H}_3$), 2.87 [5H, broad signal; H<u>O</u>–CH_2–C<u>H</u>($N\underline{H}_2$)–C<u>H</u>(O<u>H</u>)–], and 3.70 (3H, broad signal; $-C\underline{H}_2$OH and –C<u>H</u>OH). Found: *m/e* 301.2964. Calcd for $C_{18}H_{39}NO_2$: M, 301.2979.

Determination of Stoichiometry and Formation Constant of Molecular Complexes by Differential Refractometry

Ram SAHAI* and Vinod SINGH
Department of Chemistry, V. S. S. D. College, Kanpur 208002, India
(Received September 8, 1979)

Synopsis. A more adequate method has been proposed to determine the stoichiometry and equilibrium constant of molecular complexes by Job method using differential refractometry in modification of Yoshida and Ōsawa method. This method has been verified on phenol–naphthalene system in cyclohexane at 35 °C. The equilibrium constant (K_1=4.9±0.20 dm^3 mol^{-1}), obtained by this method is in good agreement with the literature value.

In our previous investigations to determine the formation constants of molecular complexes, nuclear magnetic resonance,[1] spectrophotometric,[2] refractometric,[3,4] and differential refractometric[5] methods have been used. Yoshida and Ōsawa[6] have also used the refractometric method to determine the equilibrium constant of 1:1 molecular complexes by Job method. In their approach they have plotted n^2 *versus* molar ratio of the solutes [donor(D) and acceptor(A)] and observed the maximum deviation from the additive line (k). As they have pointed out that due to limited accuracy of the instrument, they could not get the reliable value of the equilibrium constant (K_1) because of increased solute concentration (10^{-1} mol dm^{-3}). In this communication an alternate method has been suggested to get the reliable value of K_1 under the conditions of Yoshida and Ōsawa, using the differential refractometry in Job method.

Reagent grade (BDH) phenol, naphthalene were used after further purification. A. R. grade cyclohexane was purified by standard procedures.[7] Stock solutions of phenol (0.10 mol dm^{-3}) and naphthalene (0.10 mol dm^{-3}) were prepared by weighing on an analytical balance and then diluted to the required volume in volumetric flask by cyclohexane.

The refractive indices have been measured by Bausch and Lomb refractometer with an accuracy of ±0.0002. All the measurements were carried out at 35±0.1 °C. The experiment has been carried out for two sets. Firstly, the refractive indices of phenol and naphthalene (0.0 mol dm^{-3}—0.6 mol dm^{-3}) were observed separately and then the refractive indices of mixed solution (phenol+naphthalene), keeping the total concentration constant (0.6 mol dm^{-3}). Secondly, the refractive indices of phenol and naphthalene (0.0 mol dm^{-3}—1.0 mol dm^{-3}) were measured separately and then the refractive indices of mixed solution (phenol+naphthalene), keeping the total concentration constant (1.0 mol dm^{-3}). The refraction per cm^3 due to charge-transfer ($\Delta\Omega C_{DA}$) has been calculated for each set by using Eq. 1 as suggested by Sahai and Singh.[5]

$$10^3(\phi-\phi_D) - \Omega_A C_A^\circ = 6000(n-n_D)n_D/(n_D^2+2)^2 - \Omega_A C_A^\circ = \Delta\Omega C_{DA}. \quad (1)$$

In Eq. 1 $\Omega_A C_A^\circ$ may be calculated by Eq. 2.

$$\Omega_A C_A^\circ = 10^3(\phi_A-\phi_0) = 6000(n_A-n_0)n_0/(n_0^2+2)^2 \quad (2)$$

The quantity Ω_j for the jth solute is defined as

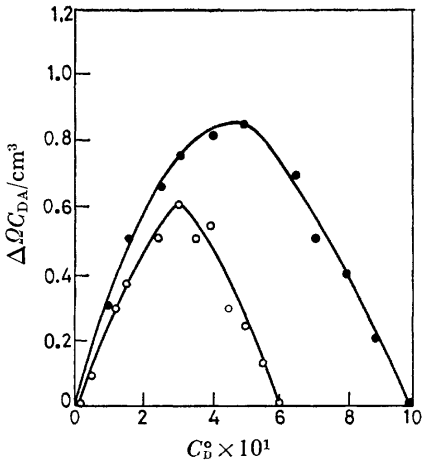

Fig. 1. A Plot of the refraction per cm^3 due to charge-transfer, $\Delta\Omega C_{DA}$/cm^3 *versus* molar ratio of solutes indicating 1:1 stoichiometry of phenol–naphthalene complex.

$\Omega_j=R_j-V_j\phi_0$; where R_j is the apparent molar refraction and V_j the apparent molar volume of the jth solute.[5] The refraction per cm^3 of solvent (ϕ_0), acceptor (ϕ_A), donor (ϕ_D), and solution (ϕ) may be calculated by the relations: $\phi_0=(n_0^2-1)/(n_0^2+2)$; $\phi_A=(n_A^2-1)/(n_A^2+2)$; $\phi_D=(n_D^2-1)/(n_D^2+2)$; $\phi=(n^2-1)/(n^2+2)$, where n_0, n_A, n_D, and n are the refractive indices of solvent, acceptor, donor and solution (donor+acceptor) respectively.[3] A plot of $\Delta\Omega C_{DA}$ *versus* molar ratio of solutes for phenol naphthalene complex has been shown in Fig. 1 which suggests 1:1 stoichiometry of this complex. After getting a more reliable value of k from this plot, the equilibrium constant (K_1) has been calculated by Yoshida & Ōsawa's[6] equation (Eq. 3).

$$K_1 = 2\sqrt{k}\{\sqrt{k}(C+C')-(C+kC')\}/(C-kC')^2, \quad (3)$$

where k is the maximum deviation from the base line for two different concentrations of solutes (C and C').

The refractive index of phenol as well as that of naphthalene increases in cyclohexane with concentration. When phenol solution is mixed with naphthalene, a neutral complex is formed. The plot of Δn, the difference in refractive indices of calculated and observed values, against (complex) is linear indicating that there is no interaction between the complex and individual species.

A change in electron cloud density in the neutral atom or molecule will lead to a change in the polarizability. Since the complex is generally more polar than the components, the electronic polarizability or refractive index increases and the deviation depends upon the extent of interaction between the donor and acceptor. Therefore stronger the complex, the larger the deviation in the refractive index value.

The small deviation in refractive index of the mixed system of phenol and naphthalene in cyclohexane shows that the interaction between phenol and naphthalene is weak. In the present case the deviation is positive and the maximum is observed at 1:1 molar ratio. The K value obtained thus is 5.8 ± 0.20 dm^3 mol^{-1} at 35 °C which is slightly higher compared to the value calculated from the available data.[8] But the K value obtained from the plot of $\Delta\Omega C_{DA}$ *versus* molar ratio of solutes is 4.9 ± 0.20 dm^3 mol^{-1} at 35 °C which is almost comparable with that of the calculated value. As the refractive index for visible light varies with the wavelength, the electron polarization is somewhat uncertain. So the K value obtained by the plot of n^2 *versus* molar ratio of solutes must be accepted with care.

Due to the limited accuracy of the instrument, the solute concentration was raised (0.10 mol dm^{-3}) in order to get k value sufficient to fit in Eq. 3. At this higher concentration, the solute aggregation occurs which prevents to get the reliable value of K_1. But this problem has been resolved in the present scheme in which instead of the plot of n^2 *versus* molar ratio, the refraction per cm^3 due to charge-transfer, ($\Delta\Omega C_{DA}$), has been calculated and plotted against molar ratio. The equilibrium constant obtained by the plot of $\Delta\Omega C_{DA}$ *versus* molar ratio of solutes ($K_1=4.9\pm0.20$ dm^3 mol^{-1}) is more reliable than that of K_1 obtained by the plot of n^2 *versus* molar ratio of the solutes ($K_1=5.8\pm0.20$ dm^3 mol^{-1}) which is in agreement with that of literature value.[9] In the present scheme, the refraction per cm^3 due to solvent, acceptor and donor has been considered whereas in the earlier methods[6,10,11] the square of refractive indices (n^2) of solution was taken into account only. Thus the data obtained by the present scheme are more reliable than that of earlier one. It, therefore, appears that the present method may prove better to calculate the equilibrium constant (K_1) of the weak complexes within the limited accuracy of the instrument for which the concentration of the solutes is ought to be high. Though the present scheme involves a lot of complexity in the experimental procedure but the data obtained are more reliable compared to the earlier method.[6]

One of us (V.S.) is thankful to Kanpur University, Kanpur for the award of U.G.C. Fellowship. The authors are grateful to Professor P.C. Nigam (I. I. T., Kanpur) for providing some experimental facilities to carry out this work.

Studies on Complexes of Metal(II) Carboxylates with Donor Molecules. IV.[1] Complexes of Nickel(II) Chloroacetates with Pyridine *N*-Oxides and Triphenylphosphine Oxide

Narsingh KUMAR,* Piyara Lal KACHROO, and Rama KANT
Department of Chemistry, University of Jammu, Jammu 180001, India
(Received June 16, 1979)

Synopsis. Twelve green crystalline complexes with the general formula $[Ni(O_2CR)_2 \cdot L]_2$ were prepared by the reaction of stoichiometric amounts of pyridine *N*-oxide, 2-methylpyridine *N*-oxide, 3-methylpyridine *N*-oxide, and triphenylphosphine oxide with nickel(II) mono-, di-, and trichloroacetates in methanol. The complexes were characterized by elemental analyses, conductance, magnetic moments, IR and electronic spectra as neutral, binuclear, carboxylato bridged species identical to those of copper(II) acetate monohydrate. The complexes involve varying degrees of magnetic interaction which diminishes with increasing chlorine substitution in the chloroacetate moiety.

Studies on binuclear metal(II) carboxylate complexes of the type $[M(O_2CR)_2 \cdot L]_2$ (especially, when M=Cu) reveal that the extent of magnetic interaction in these systems is largely determined by the nature of the carboxylate anion and the addend ligand.[2-4] However, in complexes of nickel(II) propionate and butyrate with aromatic amine oxides, we found that the magnetic moments of these complexes are independent of the nature of the alkanoate anion.[5] Since chloroacetic acids widely differ in acid strength, their nickel(II) complexes have been examined in order to assess the effect of varying basicity of the carboxylate anions on magnetic and other properties of the resulting complexes. The results of these studies are presented in this paper.

Experimental

Materials. Trinickel(II) carbonate tetrahydroxide tetrahydrate was repeatedly washed with hot water and then dried in the air. The chloroacetic acids and the amine oxide ligands were purified by vacuum distillation. Triphenylphosphine oxide hemihydrate was heated at 105 °C in a vacuum for 3 h and subsequently recrystallized from dry acetone to give the anhydrous compound (mp 154—155 °C). Nickel(II) chloroacetates were prepared as hydrates by the method of Lever and Ogden[6] and its modifications. The anhydrous samples obtained after drying in a vacuum over phosphorus pentaoxide gave satisfactory results in elemental analyses.

Complexes. The complexes were prepared by the direct interaction of the appropriate nickel(II) chloroacetate and the ligand in methanol, using the same general technique as given in the following example.

Bis(chloroacetato)(pyridine N-oxide)nickel(II). To a solution containing 1.48 g (6 mmol) nickel(II) chloroacetate in methanol (125 cm^3) was added, with stirring, a solution of 0.93 g (6.5 mmol) of freshly purified pyridine *N*-oxide in methanol (10 cm^3). The resulting green solution was concentrated to *ca.* 30 cm^3 and filtered while hot. Anhydrous diethyl ether (30 cm^3) was added to the cold filtrate and the green solid which separated out on allowing the filtrate to stand overnight was recrystallized from a 2:1 ethyl acetate–benzene mixture (60 cm^3) containing a small amount of pyridine *N*-oxide (0.15 g). The crystalline product was collected, washed with a 2:1 ethyl acetate–benzene mixture and then dried in a vacuum over phosphorus pentaoxide to yield 1.38 g (68% based on nickel(II) chloroacetate) of the required product.

The remaining nickel(II) chloroacetate complexes were prepared similarly in 50—80% yields. Reactions were also carried out using ligands in higher molar ratio of 1:2, 1:3, and a large excess but the products obtained were invariably of 1:1 stoichiometry, identical to those obtained with reactants in equimolar ratio.

Analyses. Nickel was determined gravimetrically as bis(dimethylglyoximato)nickel(II). Carbon and hydrogen analyses were carried out in the departmental microanalytical laboratory. For chlorine analysis, a sample containing 20—25 mg of chlorine was fused with a mixture of anhydrous sodium carbonate (0.5 g), sodium hydroxide (0.25 g) and sodium (0.1 g) at 700—900 °C for *ca.* 30 min in a platinum crucible. The resulting mass was extracted with distilled water, and the chloride contents of the alkaline extract were determined gravimetrically as silver chloride.

Measurements. Magnetic measurements were carried out at room temperature by the Gouy method using Hg-$[Co(NCS)_4]$ as a calibrant. The electronic spectra were recorded in acetone over 8000—28500 cm^{-1} on a Beckman DK-2A spectrophotometer, while the infrared spectra were scanned on Perkin-Elmer 337 and 621 instruments as Nujol mulls in sodium chloride and polyethylene plates.

Results and Discussion

The results of elemental analyses indicate that the complexes are of 1:1 stoichiometry and can be formulated as $[Ni(O_2CR)_2 \cdot L]$. The complexes are light green to green in color. They are moderately soluble in polar solvents, but are generally insoluble in nonpolar solvents. Molar conductance values of the millimolar solutions of the complexes in methanol are of the order 20–40 S cm^2 mol^{-1} suggesting that the complexes are nonelectrolytic in nature. Molecular weights could not be determined by the cryoscopic method because of insufficient solubility of the complexes in benzene and nitrobenzene.

Electronic Spectra. The electronic spectra of the complexes show the usual three bands (I, III, and IV) around 9000, 15000, and 25000 cm^{-1} as observed in octahedral complexes of nickel(II); these bands are assigned to $^3T_{2g} \leftarrow {}^3A_{2g}$, $^3T_{1g}(F) \leftarrow {}^3A_{2g}$, and $^3T_{1g}(P) \leftarrow {}^3A_{2g}$ transitions.[7] An important feature of the electronic spectra of these complexes is that an additional band (II) is observed at ≈ 14000 cm^{-1}. The band is usually of lower intensity assigned to the spin forbidden, singlet transition $^1E_g(D) \leftarrow {}^3A_{2g}$, gaining intensity through configurational interaction or spin-orbit coupling.[7] The molar extinction coefficient values of the bands fall in the range 2.3—17 dm^3 cm^{-1} mol^{-1} similar to those reported for trans octahedral nickel(II) complexes.[6,7]

a) At room temperature, 290 K. b) Shoulder.

Magnetic Properties. The magnetic moments of the complexes (Table 1) fall in the range 2.60—3.21 BM which are, in general, less than the magnetic moments of 3.15—3.30 BM observed for magnetically normal, octahedral nickel(II) carboxylate complexes.[8] This suggests that the complexes involve some metal–metal interaction and may have a binuclear (or polynuclear), carboxylato bridged structure similar to some nickel(II) trihaloacetate complexes.[9]

The magnetic moment values of the present complexes are significantly higher than the values of 2.35—2.63 BM observed for nickel(II) alkanoate complexes,[7] showing a regular increase from mono-, to di- and trichloroacetate complexes. This indicates that the magnetic interaction in these complexes decreases sharply as the basicity of the chloroacetate anion decreases with increasing chlorine substitution in the acetate moiety.

Infrared Spectra. The N–O stretching frequency which occurs at 1250, 1244, and 1278 cm^{-1} in pyridine *N*-oxide, 2-methylpyridine *N*-oxide, and 3-methylpyridine *N*-oxide is shifted to lower frequencies by 20—60 cm^{-1} in the nickel(II) chloroacetate complexes. This indicates monodentate coordination of pyridine *N*-oxide ligands.[10] δ_{N-O} and γ_{C-H} also show some positive or negative shifts confirming the coordination of *N*-oxide ligands through their oxygen atoms. The P=O stretching vibration shows a negative shift of 19—21 cm^{-1}, while $\delta_{P=O}$ and γ_{C-H} also undergo small shifts indicating that triphenylphosphine oxide is coordinated through its P=O oxygen atom in its complexes.[11]

The asymmetric carboxyl stretching frequency in nickel(II) mono-, di-, and trichloroacetate complexes occurs as a very strong peak at 1638—1622, 1651—1645, and 1695—1690 cm^{-1}, while the symmetric carboxyl stretching frequency is observed at 1376—1372, 1360—1350, and 1346—1340 cm^{-1}, respectively. The upwards shift of $\nu_{COO}(as)$ and downward shift of $\nu_{COO}(sy)$ noted in these complexes is ascribed to the increasing chlorine substitution in the chloroacetate anion.[12] The position and nature of the carboxyl stretching frequencies, as well as their separation, are comparable to the frequencies reported by Lever and Ogden for nickel(II) complexes containing bidentate bridging chloroacetato groups.[6] All this corroborates the view that the complexes under investigation are binuclear, carboxylato bridged species identical to copper(II) acetate monohydrate.[13]

The authors wish to thank Professor O. P. Vig, Head of the Chemistry Department, Panjab University, Chandigarh, for laboratory facilities. One of the authors (R. K.) was granted a Junior Research Fellowship from the University Grants Commission, India.

(Received September 20, 1979)

The structure factors $S_m(Q)$ for aqueous solutions of NaCl and KCl at room temperature have been determined by means of the LINAC-TOF-neutron diffraction method. A revised subtraction method was applied to diffraction data of the solutions. Results obtained for the structure of the nearest hydration shell around ions are as follows. (a) The coordination numbers are 8 for Na^+ and 6 for Cl^- in the NaCl solution and 8 for K^+ and 6 for Cl^- in the KCl solution; (b) the average ion-oxygen distances are 2.50 ± 0.10 Å for Na^+, 2.70 ± 0.10 Å for K^+, and 3.10 ± 0.05 Å for Cl^-; (c) around chloride ions water molecules take the configuration to orient the vector which bisects the D–O–D angle on a straight line joining an oxygen atom and the anion. Analysis was performed on the data of LiCl and CsCl solutions.

Neutron diffraction studies have recently been carried out on aqueous ionic solutions.[1–3] It was found that the method is useful for the determination of the structures of ionic solutions, in particular the structure parameters of the hydration shell around ions such as coordination numbers, ion-oxygen distances, and orientational arrangements of water molecules within the first hydration shell.

The recent development of the TOF-neutron diffraction method, associated with the proposition of improved correction procedures for inelastic scattering, has made it possible to provide more accurate data.[1,4–6] On neutron diffraction data of aqueous ionic solutions, there is no general method of analysis. Three procedures have been proposed so far: the near-neighbor model method by Narten *et al.*,[2] the first-order-difference spectroscopy by Soper *et al.*,[3] and the subtraction method by the authors.[1] However, the method of Narten *et al.* has been questioned especially concerning the nature of the near-neighbor model itself,[4,7,8] while the method of Soper *et al.* using isotopes of nuclear species in the sample is clearly restricted in applicability.

In our study of aqueous solutions of LiCl and CsCl by the subtraction method (Paper I)[1] we obtained information on the structure of the first hydration shell around ions. In order to elucidate the structure of the shell about univalent ions, we have carried out a neutron diffraction study on aqueous solutions of NaCl and KCl, a revised subtraction method being used to confirm the accuracy of the results.

Experimental

The experiment was performed by means of the TOF-neutron diffraction method by LINAC. Details of the apparatus and procedures were reported.[1,4,9]

Two 1.0 M alkali halide solutions (1 M = 1 mol dm^{-3}) were prepared by the addition of extra pure anhydrous sodium chloride and potassium chloride to heavy water. Samples composed of naturally occurring elements were used, the values of coherent scattering amplitudes of the elements being 0.36×10^{-12} cm for Na, 0.37×10^{-12} cm for K, and 0.96×10^{-12} cm for Cl.[10]

Measurements were carried out at room temperature (20.5 °C) at the scattering angle, $2\theta=45°$. We obtained the $S_m(Q)$ data for a range of low Q, 0.9—10.0 $Å^{-1}$ ($Q=4\pi/\lambda\sin\theta$). $S_m(Q)$ curves of NaCl and KCl solutions including that of D_2O are given in Fig. 1. The change in the bump at *ca.* 4 $Å^{-1}$ as well as that in the main peak accompanied by a shoulder at 2.8 $Å^{-1}$ indicate the main effects of ions on the structure of the first hydration shell.

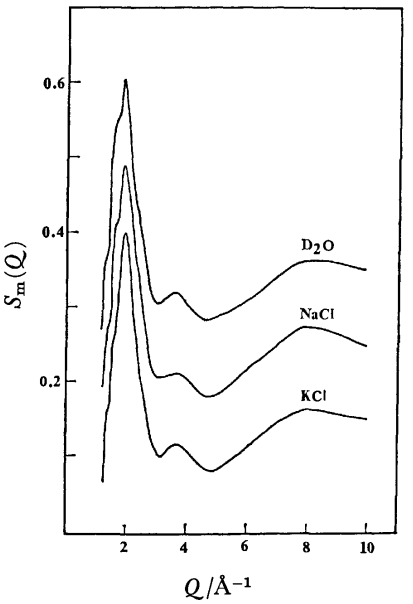

Fig. 1. Observed structure factors for NaCl and KCl solutions at 1 M, compared with the factor for D_2O.

The statistical errors are the same as those reported:[1] 0.5—0.6% in the Q range 2—5 $Å^{-1}$ and 0.9% at *ca.* 8 $Å^{-1}$.

Analysis of Aqueous Solutions of Alkali Chlorides

Subtraction Method of Analysis. In order to analyze the data of comparatively dilute aqueous solutions for determination of the structure of the first hydration shell, we have used a subtraction method in which the structure factor $S_m(Q)_{D_2O}$ of D_2O multiplied by an appropriate fraction is subtracted from the total structure factor $S_m(Q)_{total}$ of solutions.[1] The remaining factor $\Delta S_m(Q)$ thus obtained has been compared with the $\Delta S_m(Q)_{calcd}$ calculated for a structure model of the hydration shell, the structure model which gives the best fit curve being determined. In applying the subtraction method we modify Eq. 2, Paper I,

in an attempt to make the method more available. By introducing a term multiplied by a coefficient a which indicates a contribution of the interactions between water molecules within the first hydration shell and environmental molecules outside of the shell in addition to Eq. 2, Paper I, the remaining factor $\Delta S_m(Q)$ for the first hydration shell becomes

$$\Delta S_m(Q) = S_m(Q)_{total} - \left(\frac{N_w'}{N_w} - x\right) S_m(Q)_{D_2O} - axS_m(Q)_{D_2O}, \quad (1)$$

$$x = \frac{c(n_+ + n_-)}{55.3}, \quad (2)$$

where N_w and N_w' are the mole numbers of water in 1 dm^3 of pure water and those of water in 1 dm^3 of the solutions, respectively, x is the mole fraction of D_2O molecules coordinated in the first hydration shell around ions, n_+ and n_- are the coordination numbers around the cation and the anion, respectively, and c is concentration in M. The second term in Eq. 1 shows the contribution from bulk water outside of the hydration shells, and the third one that from the pairs between molecules within hydration shells and bulk water molecules. In aqueous solutions as dilute as 1 M, we can assume $N_w'/N_w \simeq 1$,[11] and we get

$$\Delta S_m(Q) = S_m(Q)_{total} - (1-x)S_m(Q)_{D_2O} - axS_m(Q)_{D_2O}. \quad (3)$$

In order to study the contribution of the interactions between water molecules in the first hydration shell ($c(n_+ + n_-)$mol) and those outside, the magnitude of a is estimated as follows. The contribution of the interactions to $S_m(Q)$ is supposed to be equal to that of $c(n_+ + n_-)/2$ mol of bulk water molecules on the average, since $c(n_+ + n_-)$ mol of the water molecules in the nearest hydration shell are in contact with ions on the one side, the contribution to the total water-water interactions then becoming approximately half as much as that of the same mol of bulk water. Thus, the magnitude of a is 1/2 in this case. In the analysis used in Paper I, the contribution was neglected, and Eq. 2 in the paper is identical with the case of $a=0$ in Eq. 3 above. We will now compare the two cases, $a=1/2$ and $a=0$.

Calculation of $\Delta S_m(Q)$. In order to determine the structure of the nearest hydration shell in the NaCl and KCl solutions, the observed values of $\Delta S_m(Q)$ are compared with those calculated for various structure models assumed.

The structure of the hydration shell is characterized by several parameters, coordination numbers, ion-oxygen distances, and orientational arrangements of water molecules around ions. The coordination numbers and ion-oxygen distances reported so far are located given in Tables 1 and 2 together with the tables in Paper I. As regards the configuration of water molecules around ions, two forms, linear and bifurcated, are assumed for cations where lone-pair electrons are located in the vicinity of the ions (Paper I, Figs. 5 (a) and (b)) and also for anions where deuterium atoms are located in the vicinity of the ions (Paper I, Figs. 5(c) and (d)).

The calculated remaining factor, $\Delta S_m(Q)_{calcd}$, we have

$$\Delta S_m(Q)_{calcd} = \sum_{\alpha=\pm} [x'_\alpha (\sum_{n=1}^{m_\alpha} b_n)^{-2} \sum_{i=1}^{m_\alpha} \sum_{j=1}^{m_\alpha} b_i b_j \times \exp(-\gamma_{\alpha ij} Q^2) j_0(Q r_{\alpha ij})], \quad (4)$$

where

$$j_0(Qr) = \frac{\sin(Qr)}{Qr}, \quad (5)$$

with summation for α over two contributions from the hydrated structure of cation (+) and anion (−). m_α is the number of atoms within the hydrated structure labelled by α, x'_α the mole fraction of D_2O molecules coordinated in the shell around cation and anion, and b_i the coherent scattering length of nucleus i. $r_{\alpha ij}$ is the distance between nuclei i and j within the hydrated structure labelled by α and their mean-square variations $2\gamma_{\alpha ij}$.

Table 3. Range of parameters for structure models

Ion	Coordination number	Ion-oxygen distance/Å	Type of configurations around ions	(ϕ/degree)
Na^+	4, 6, 8	2.20—2.70	linear	(44.75—64.75)
			bifurcated	(0.0 —20.0)
K^+	4, 6, 8	2.70—3.40	linear	(44.75—64.75)
			bifurcated	(0.0 —20.0)
Cl^-	4, 6, 8	3.00—3.20	linear	(0.0 —20.0)
			bifurcated	(0.0 —20.0)

The contribution from the hydrated structure for each kind of ion is calculated by a similar procedure to that for the water structure previously described,[4] constructed for the corresponding structure models. The model consists of several parameters varying in a range of magnitude (Table 3). For example, in the case of $n_\pm=4$, 6, and 8, tetrahedral, octahedral, and cubic coordination is assumed, respectively, with the variation of ion-oxygen, ion-deuterium, oxygen-oxygen, and oxygen-deuterium distances and the orientational angles.

We calculated $\Delta S_m(Q)$ for a number of structure models with various magnitudes of parameters (Table 3). For both solutions, 36 different structure models with respect to the coordination number and type of orientational configuration were assumed; for each structure model, ion-oxygen distances and the angle ϕ were varied successively at intervals of 0.05 Å and 10°, respectively. In all, we calculated the $\Delta S_m(Q)$ curves for 1,680 different structure models of the first hydration shell in the NaCl solution and for 1,824 different models in the KCl solution, the best structure model being then determined by a comparison of the $\Delta S_m(Q)_{calcd}$ curves with those observed for both solutions.

Table 4. Coordination numbers, ion-oxygen distances and configurations around ions determined in the present study

Ion	Coordination number	Ion-oxygen distance/Å	Configuration around ions (ϕ/degree)
Na^+	8	2.50±0.10	undetermined
K^+	8	2.70±0.10	undetermined
Cl^-	6	3·10±0.05	bifurcated (0.0)

Results of Analysis. The $\Delta S_m(Q)_{calcd}$ curves for different sets of coordination numbers for NaCl and KCl solutions are shown in Figs. 2 and 3, respectively, two sets of observed values of $\Delta S_m(Q)$ being plotted for $a=1/2$ and $a=0$ and the interval between those being hatched. The best fit curves with observed $\Delta S_m(Q)$ are obtained in the case of $n_{Na^+}=8$ and $n_{Cl^-}=6$ for the NaCl solution (Fig. 2 (f)) and in the case of $n_{K^+}=8$ and $n_{Cl^-}=6$ for the KCl solution (Fig. 3 (f)). The curves other than the best fit ones deviate appreciably from both observed $\Delta S_m(Q)$ ($a=1/2$ and $a=0$) (Figs. 2 and 3).

The $\Delta S_m(Q)$ curves with various magnitudes of parameters are shown in Figs. 4 (a)—(d) for $n_{Na^+}=8$ and $n_{Cl^-}=6$ for the NaCl solution, and in Figs. 4 (a')—(d') for $n_{K^+}=8$ and $n_{Cl^-}=6$ for the KCl solution.

The calculated $\Delta S_m(Q)$ curves of the best models thus determined for both solutions are given in Figs. 2 (f) and 3 (f) for NaCl and KCl solutions, respectively. The magnitudes of parameters and orientational configurations for the best models of the first hydration shell are given in Table 4. Concerning the configurations of water molecules within the first hydration shell around Cl^-, we have confirmed that the bifurcated type is predominant for both solutions (Figs. 4 (d) and (d')).[12] However, with respect to the configurations around cations, we could not determined which

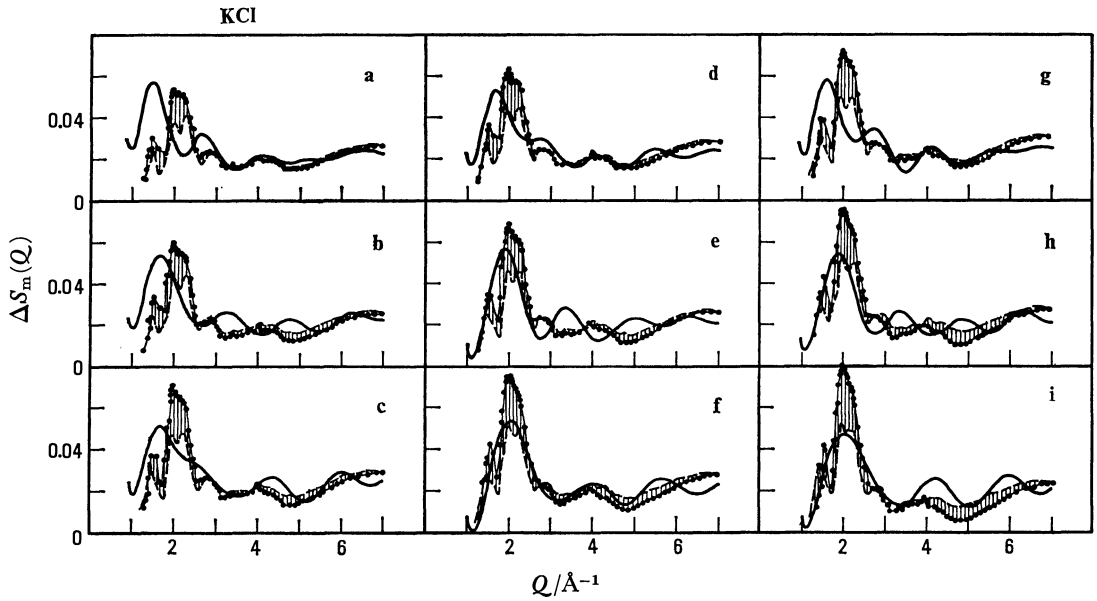

Fig. 3. Changes in the calculated $\Delta S_m(Q)$ with variation of the coordination number for KCl solution, •: observed $\Delta S_m(Q)$ ($a=0$), ----: observed $\Delta S_m(Q)$ ($a=1/2$),

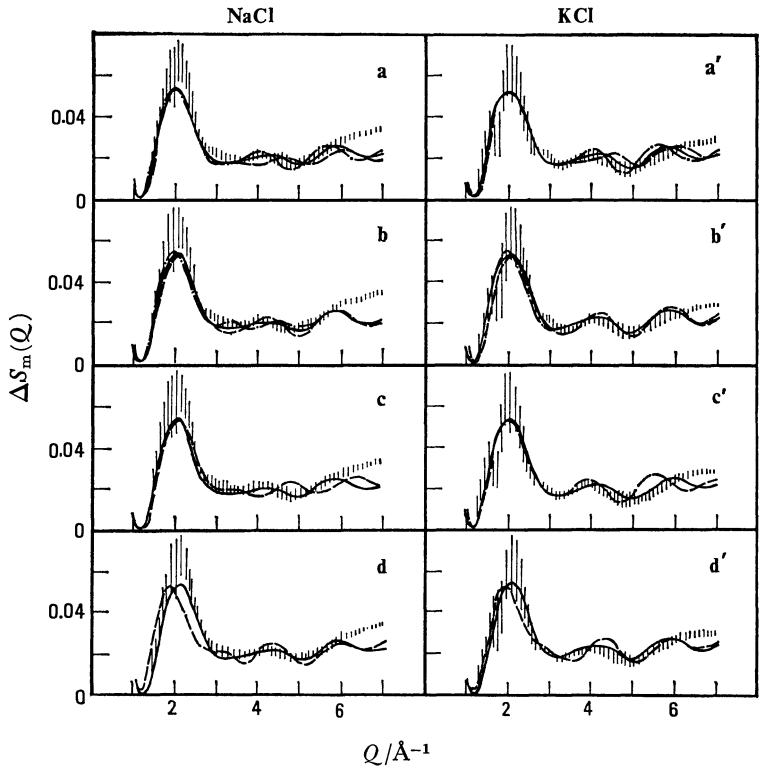

Fig. 4. Changes in the calculated $\Delta S_m(Q)$ with variation of physical parameters for NaCl (a—d) and KCl (a′—d′) solutions. The vertical lines indicate the intervals between two sets of observed values of $\Delta S_m(Q)$ ($a=0$ and $a=1/2$).
(a) $r_{Na^+\text{-}O}$ (all other parameters are identical with those given in Table 4), ----: 2.40 Å, ——: 2.50 Å, —·—: 2.60 Å, (b) $r_{Cl^-\text{-}O}$ (all other parameters are identical with those given in Table 4), ----: 3.00 Å, ——: 3.10 Å, —·—: 3.20 Å, (c) configurations around Na^+ (all other parameters are identical with those given in Table 4), ——: bifurcated, ----: linear, (d) configurations around Cl^- (all other parameters are identical with those given in Table 4), ——: bifurcated, ----: linear, (a′) $r_{K^+\text{-}O}$ (all other parameters are identical with those given in Table 4), ----: 2.60 Å, ——: 2.70 Å, —·—: 2.80 Å, (b′) $r_{Cl^-\text{-}O}$ (all other parameters are identical with those given in Table 4), ----: 3.00 Å, ——: 3.10 Å, —·—: 3.20 Å, (c′) configurations around K^+ (all other parameters are identical with those given in Table 4), ——: linear, ----: bifurcated, (d′) configurations around Cl^- (all other parameters are identical with those given in Table 4), ——: bifurcated, ----: linear.

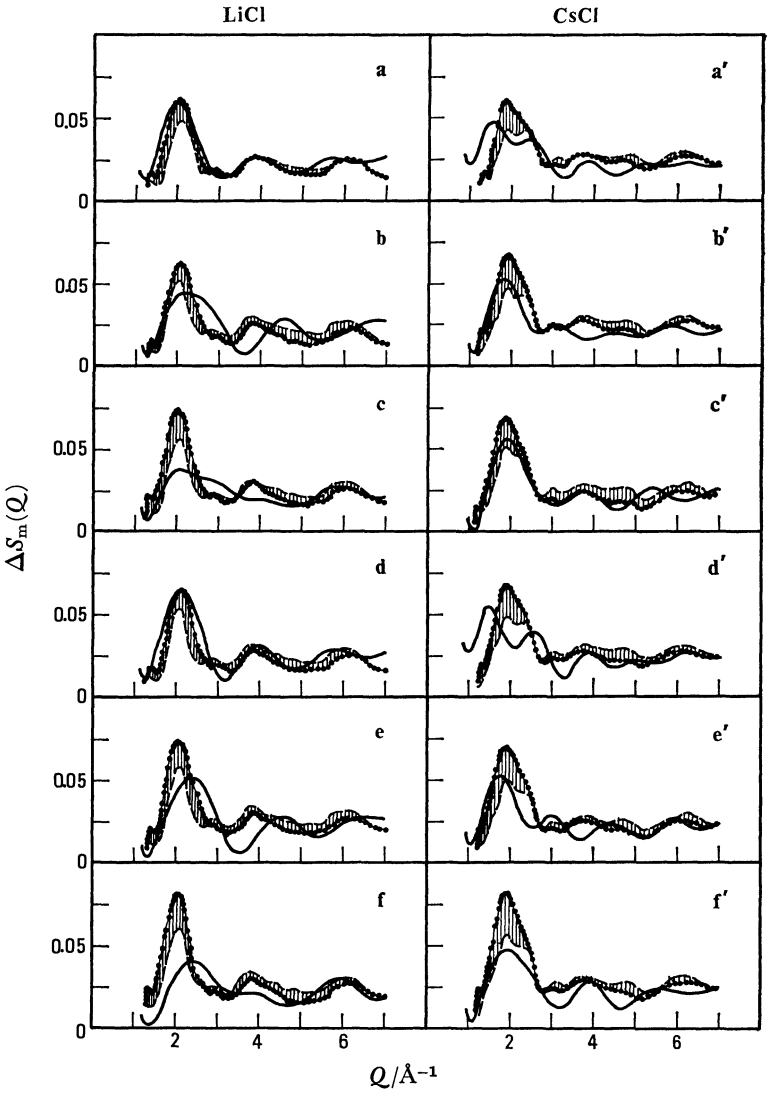

Fig. 5. Changes in the calculated $\Delta S_m(Q)$ with variation of the coordination number for LiCl (a—f) and CsCl (a'—f') solutions.
•: Observed $\Delta S_m(Q)$ ($a=0$), ----: observed $\Delta S_m(Q)$ ($a=1/2$),
(a), (a') $n_+=4$, $n_-=6$, (b), (b') $n_+=6$, $n_-=6$, (c), (c') $n_+=8$, $n_-=6$, (d), (d') $n_+=4$, $n_-=8$, (e), (e') $n_+=6$, $n_-=8$, (f), (f') $n_+=8$, $n_-=8$.

type, linear or bifurcated, is predominant (Figs. 4 (c) and (c')).

From the structure analysis where the parameters have been varied systematically (Table 3), we conclude that structure models shown in Table 4 give the best fit curves with those observed for the NaCl and KCl solutions at 1 M.

The same analysis was performed for the LiCl and CsCl solutions according to the present procedure in order to re-examine the results given in Paper I. The $\Delta S_m(Q)$ curves calculated for different sets of coordination numbers are shown in Fig. 5 and the best fit curves with observed $\Delta S_m(Q)$ are obtained in the case of $n_{Li^+}=4$ and $n_{Cl^-}=6$ for the LiCl solution (Fig. 5 (a)) and in the case of $n_{Cs^+}=8$ and $n_{Cl^-}=6$ for the CsCl solution (Fig. 5 (c')). For the LiCl solution, in the case of a set of coordination numbers which gives the best fit curve ($n_{Li^+}=4$ and $n_{Cl^-}=6$), the $\Delta S_m(Q)$ curves with various magnitudes of parameters are shown in Fig. 6. The adequacy shown in Figs. 5 (a) and (c') is the same as that given in Table 4, Paper I.

We have calculated the difference $\Delta S_m(Q)_{obsd}-\Delta S_m(Q)_{calcd}$ for two cases: $a=1/2$ and $a=0$, where $\Delta S_m(Q)_{obsd}$ is the observed value of the remaining factor (Eq. 3), $\Delta S_m(Q)_{calcd}$ being the calculated value for various models. It was found that the difference is practically independent of over Q all the range. The magnitude of $\Delta S_m(Q)_{obsd}-\Delta S_m(Q)_{calcd}$ is primarily determined by the factor (n_++n_-). $\Delta S_m(Q)_{obsd}-\Delta S_m(Q)_{calcd}$ becomes nearly identical for both cases: ($n_+=4$, $n_-=8$) and ($n_+=6$, $n_-=6$), for example. In Fig. 7, the differences are plotted against (n_++n_-) which is an important factor characterizing various models. For the assignment of $a=1/2$, the differences are essentially zero (Fig. 7). This supports adequacy of the assignment superior to the case of $a=0$.

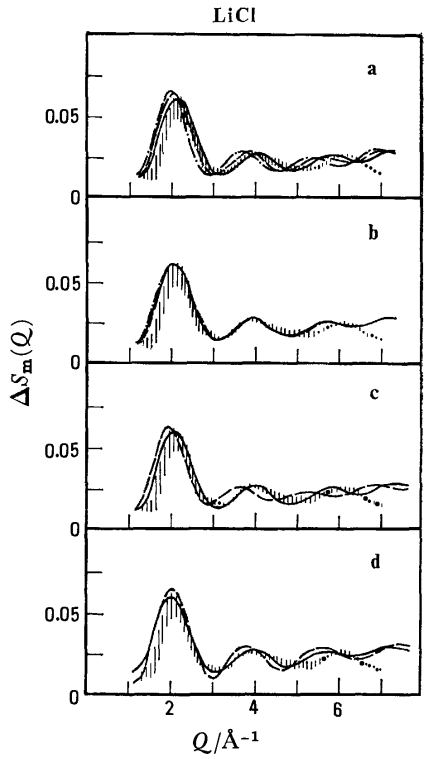

Fig. 6. Changes in the calcualted $\Delta S_m(Q)$ with variation of physical parameters for the LiCl solution. The vertical lines indicate the intervals between two sets of observed values of $\Delta S_m(Q)$ ($a=0$ and $a=1/2$). (a) r_{Li^+-O} (all other parameters are identical with those given in Table 4), ——: 1.90 Å, ----: 2.00 Å, —·—: 2.10 Å, (b) r_{Cl^--O} (all other parameters are identical with those given in Table 4), ----: 3.05 Å, ——: 3.10 Å, —·—: 3.15 Å, (c) configurations around Li^+ (all other parameters are identical with those in Table 4), ——: linear, ----: bifurcated. (d) configurations around Cl^- (all other parameters are identical with those in Table 4), ——: linear, ----: bifurcated.

Discussions and Concluding Remarks

Concerning the structure within the first hydration shell in aqueous solutions of alkali halides, we have determined coordination numbers and average ion-oxygen distances as well as orientational arrangements of water molecules around ions by analyzing the neutron diffraction data. A summary is given herewith on the results of this study and those given in Paper I.

Coordination Number and Ion-oxygen Distances. For Cl^- the coordination numbers are six in all solutions at 1 M, while the number is four for Li^+ and eight for other cations (Na^+, K^+, and Cs^+). The value for Li^+ determined is in line with those reported so far.[1] The values for Na^+, K^+, and Cs^+ reported so far are found to be very diversified. However, according to recent results obtained by molecular dynamics studies for these cations,[13–15] the coordination numbers around the univalent cations are 7—8 except that around Li^+, which is essentially in agreement with ours. From the results of our two studies, the unique behavior of Li^+ in water as compared with that of other alkaline cations has been clarified.

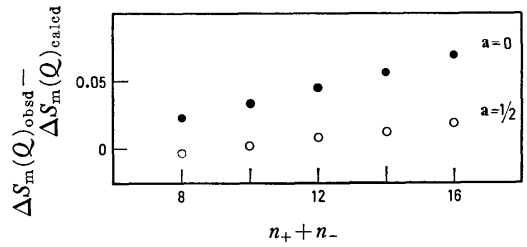

Fig. 7. $\Delta S_m(Q)_{obsd} - \Delta S_m(Q)_{calcd}$ plotted against $(n_+ + n_-)$.

The average ion-oxygen distances for Li^+, Na^+, K^+, Cs^+, and Cl^- within the first hydration shell have been found to be 1.90±0.05 Å, 2.50±0.10 Å, 2.70±0.10 Å, 2.95±0.10 Å, and 3.10±0.05 Å, respectively.

Orientational Configurations around Ions. As regards the orientational configuration of water molecules around ions, it is widely believed that the molecules take either of the two forms, linear or bifurcated, on the average within the hydration shell. we have little experimental knowledge concerning the question.

Our results show that water molecules within the nearest hydration shell take a linear configuration for Li^+ and Cs^+ in LiCl and CsCl solutions and a bifurcated one for Cl^- in NaCl and KCl solutions. Complete determination of the orientational configuration around all ions in solutions has not been achieved.

Correlation Functions Calculated by Using Reference Interaction Site Model Equations for Diatomic Molecular Fluids

Kazumitsu KOJIMA and Kiyoshi ARAKAWA*

Research Institute of Applied Electricity, Hokkaido University, Sapporo 060

(Received September 25, 1979)

The reference interaction site model (RISM) theory was applied to diatomic molecular fluids, by using three different forms of approximation for site-site direct correlation function. Applicability of the three forms of RISM equation, RISM-1, RISM-2, and RISM-3, was examined, site-site pair correlation functions being calculated from them and a comparison of the results with those of computer simulations being made. Structure factor for liquid nitrogen, oxygen, and bromine were obtained from the solution of the RISM-2 equation and compared with experimental results.

In the preceding paper[1] the authors solved the RISM equation coupled with the Percus-Yevick (PY) and the hypernetted chain (HNC) approximations [referred to as the RISM-1 equation] and applied the result to fluids composed of homonuclear diatomic molecules. Johnson and Hazoumé[2] have also applied the RISM-1 equation coupled with the PY approximation to liquid nitrogen and benzene, and obtained identical results. The original RISM-1 equation was given first intuitively by Chandler and Andersen[3] for molecular fluids composed of fused hard spheres. Chandler[4] derived another form of the equation by means of a systematic functional Taylor expansion [referred to as RISM-2 equation].

The original RISM-1 equation was first solved numerically by Lowden and Chandler[5] for homonuclear diatomic fluids with hard sphere potentials, and used in several numerical works since then. The results were found to be of use for interpreting the behavior of polyatomic fluids.[1,6-9] The result given in the preceding paper[1] shows that the RISM-1 equation can be applied to molecular fluids with an arbitrary site-site pair potential. A graph theoretical interpretation of the RISM-1 equation was given by Chandler.[10]

So far no application of the RISM-2 equation to fluid systems seems to have been carried out. We have undertaken to solve it in combination with a PY and a HNC approximation for fluids composed of homonuclear diatomic molecules in order to compare the results with those obtained from the RISM-1 equation.

The model and three forms of the RISM equation are presented, where a new version of the RISM equation (RISM-3) is proposed in Sec. I, and computational procedures in Sec. II. The results are discussed and compared with those of computer simulations,[11,12] as well as with those of other calculations[13] and experimental studies[14,15] in Sec. III. The HNC approximation for RISM-2 equation are given in Appendix by means of the functional Taylor expansion.

Theory

Model and Definition of Statistical Mechanical Functions.[1] Let us consider the same system as that treated previously.[1] The molecular shape is shown in Fig. 1. An intermolecular potential, $w(i,j)$, is expressed as the sum of site-site pair interaction potentials $u_{\alpha\gamma}(|\boldsymbol{r}_i^\alpha-\boldsymbol{r}_j^\gamma|)$.

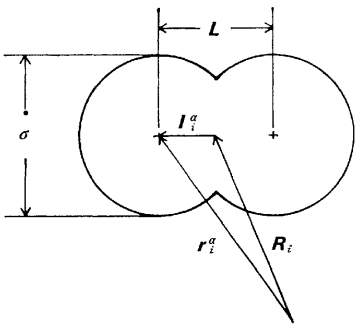

Fig. 1. Shape of RISM molecule.

Two types of site-site pair potentials were chosen: the Lennard-Jones potential[1] and the hard sphere potential,

$$\left.\begin{aligned} u_{\alpha\gamma}(r) &= \infty, \quad r<\sigma, \\ &= 0, \quad r>\sigma, \end{aligned}\right\} \tag{1}$$

where σ is the diameter of the hard sphere.

The site-site total correlation function, $h_{\alpha\gamma}(r)=g_{\alpha\gamma}(r)-1$, is considered, the site-site pair correlation function, $g_{\alpha\gamma}(r)$, being defined as reported.[1] The site-site direct correlation function, $c_{\alpha\gamma}(r)$, is defined by an Ornstein-Zernike type equation[4,10] as

$$\boldsymbol{h}(\boldsymbol{r}) = \boldsymbol{\omega}*\boldsymbol{c}*\boldsymbol{\omega}(\boldsymbol{r}) + \rho\boldsymbol{\omega}*\boldsymbol{c}*\boldsymbol{h}(\boldsymbol{r}) \tag{2}$$

where the * denotes a convolution, ρ the number density and the matrices $\boldsymbol{h}(\boldsymbol{r})$, $\boldsymbol{\omega}(\boldsymbol{r})$, and $\boldsymbol{c}(\boldsymbol{r})$ have element $h_{\alpha\gamma}(r)$, $\omega_{\alpha\gamma}(r)$, and $c_{\alpha\gamma}(r)$, respectively. The first term of $h_{\alpha\gamma}(r)$ in Eq. 2 is expressed as

$$\sum_{\eta,\nu}\int d\boldsymbol{r}'\int d\boldsymbol{r}''\omega_{\alpha\eta}(\boldsymbol{r}'')c_{\eta\nu}(|\boldsymbol{r}''-\boldsymbol{r}'|)\omega_{\nu\gamma}(|\boldsymbol{r}'-\boldsymbol{r}|). \tag{3}$$

The function, $\omega_{\alpha\gamma}(r)$, for the rigid diatomic molecule is expressed as

$$\omega_{\alpha\gamma}(r) = \delta_{\alpha\gamma}\delta(r) + (1-\delta_{\alpha\gamma})(4\pi L_{\alpha\gamma}^2)^{-1}\delta(r-L_{\alpha\gamma}),^{18)} \tag{4}$$

where, $\delta(r)$ and $\delta_{\alpha\gamma}$ are the Dirac delta function and the Kronecker delta, respectively. The Fourier transform representation of Eq. 2 is

$$\hat{\boldsymbol{h}}(\boldsymbol{k}) = \hat{\boldsymbol{\omega}}(\boldsymbol{k})\hat{\boldsymbol{c}}(\boldsymbol{k})\hat{\boldsymbol{\omega}}(\boldsymbol{k})[\boldsymbol{I}-\rho\hat{\boldsymbol{c}}(\boldsymbol{k})\hat{\boldsymbol{\omega}}(\boldsymbol{k})]^{-1}, \tag{5}$$

where $\boldsymbol{A}^{-1}$ denotes the matrix inverse of a matrix $\boldsymbol{A}$ and $\boldsymbol{I}$ the identity matrix.

PY and HNC Approximations. The PY and HNC approximations for the RISM-1 equations[1] are expressed as

$$c_{\alpha\gamma}(r) = y'_{\alpha\gamma}(r)f_{\alpha\gamma}(r) \tag{6}$$

and

$$c_{\alpha\gamma}(r) = y'_{\alpha\gamma}(r)[f_{\alpha\gamma}(r)+1] - \ln y'_{\alpha\gamma}(r) - 1, \quad (7)$$

respectively. Here the $f_{\alpha\gamma}(r)$ and the $y'_{\alpha\gamma}(r)$ are defined by

$$f_{\alpha\gamma}(r) = \exp[-\beta u_{\alpha\gamma}(r)] - 1, \quad (8)$$

and

$$y'_{\alpha\gamma}(r) = g_{\alpha\gamma}(r)[f_{\alpha\gamma}(r)+1]^{-1}, \quad (9)$$

respectively, where the β^{-1} is equal to the Boltzmann constant multiplied by temperature.

Chandler[4] derived the PY approximation for the RISM-2 equation by means of a systematic functional Taylor expansion. The functional form of the PY approximation for the RISM-2 equation is

$$[\boldsymbol{\omega}*\boldsymbol{c}*\boldsymbol{\omega}(\boldsymbol{r})]_{\alpha\gamma} = y_{\alpha\gamma}(r)\bar{f}_{\alpha\gamma}(r), \quad (10)$$

where the $y_{\alpha\gamma}(r)$ and the $\bar{f}_{\alpha\gamma}(r)$ are defined by

$$y_{\alpha\gamma}(r) = g_{\alpha\gamma}(r)[\bar{f}_{\alpha\gamma}(r)+1]^{-1}, \quad (11)$$

and

$$\bar{f}_{\alpha\gamma}(r) = \int d\boldsymbol{1}d\boldsymbol{2}\delta(\boldsymbol{r}^{\alpha})\delta(\boldsymbol{r}^{\gamma}-\boldsymbol{r})\{\prod_{\eta,\nu}[f_{\eta\nu}(r)+1]-1\}, \quad (12)$$

respectively. The $\bar{f}_{\alpha\gamma}(r)$ is the averaged Mayer function when site α on molecule 1 and site γ on molecule 2 are held fixed at a distance r from each other. Let us propose the HNC approximation for the RISM-2 equation expressed as

$$[\boldsymbol{\omega}*\boldsymbol{c}*\boldsymbol{\omega}(\boldsymbol{r})]_{\alpha\gamma} = y_{\alpha\gamma}(r)[\bar{f}_{\alpha\gamma}(r)+1] - \ln y_{\alpha\gamma}(r) - 1. \quad (13)$$

The equation is derived by means of the functional Taylor expansion (see Appendix).

Further, let us propose new approximations (RISM-3) in analogy with Eqs. 6, 10 (PY), and Eqs. 7, 13 (HNC) as follows:

$$[\boldsymbol{\omega}*\boldsymbol{c}*\boldsymbol{\omega}(\boldsymbol{r})]_{\alpha\gamma} = y'_{\alpha\gamma}(r)f_{\alpha\gamma}(r), \quad (14)$$

and

$$[\boldsymbol{\omega}*\boldsymbol{c}*\boldsymbol{\omega}(\boldsymbol{r})]_{\alpha\gamma} = y'_{\alpha\gamma}(r)[f_{\alpha\gamma}(r)+1] - \ln y'_{\alpha\gamma}(r) - 1, \quad (15)$$

respectively. Equations 14 and 15 are similar to the PY and HNC approximations in their functional form, respectively.

Three Forms of the RISM Equation. Various forms of integral equations are given by combining Eq. 5 (Ornstein-Zernike type equation) with one of several types of the PY and HNC approximations. We call Eq. 5 coupled with Eq. 14 or Eq. 15 the RISM-3 equation. The RISM-1 equation[1] is expressed as Eq.5 coupled with Eq. 6 or Eq. 7. The RISM-2 equation[4] is expressed as Eq. 5 coupled with Eq. 10 or Eq. 13. The RISM-1 equation was solved[1] in the case of fluids composed of homonuclear diatomic molecules (Fig. 1), interacting through the Lennard-Jones site-site pair potential. Solutions of the RISM-2 and 3 equation have been obtained for the first time in the case of homonuclear diatomic fluids.

Computational Procedure

Computational Methods. The procedure to solve the RISM-1 equation was reported.[1] The RISM-2 equation was solved by means of an iteration procedure. The functions $h_{\alpha\gamma}(r)$ and $[\boldsymbol{\omega}*\boldsymbol{c}*\boldsymbol{\omega}(\boldsymbol{r})]_{\alpha\gamma}$ have a discontinuity at $r=\sigma_{\alpha\gamma}$. Thus, we define a new function $\gamma_{\alpha\gamma}(r)$,

$$\gamma_{\alpha\gamma}(r) \equiv h_{\alpha\gamma}(r) - C_{\alpha\gamma}(r), \quad (16)$$

where

$$C_{\alpha\gamma}(r) \equiv [\boldsymbol{\omega}*\boldsymbol{c}*\boldsymbol{\omega}(\boldsymbol{r})]_{\alpha\gamma}. \quad (17)$$

$\gamma_{\alpha\gamma}(r)$ is a continuous function of r. By use of it, the RISM-2 equation can be written as

$$\hat{\boldsymbol{\gamma}}(\boldsymbol{k}) = \hat{\boldsymbol{C}}(\boldsymbol{k})\hat{\boldsymbol{\omega}}^{-1}(\boldsymbol{k})\hat{\boldsymbol{C}}(\boldsymbol{k})[\boldsymbol{I}-\rho\hat{\boldsymbol{\omega}}^{-1}(\boldsymbol{k})\hat{\boldsymbol{C}}(\boldsymbol{k})]^{-1}, \quad (18)$$

and

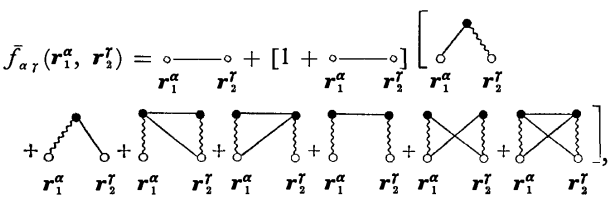
$$\gamma_{\alpha\gamma}(r) = y_{\alpha\gamma}(r) - 1 \quad \text{(PY)},$$
$$= \ln y_{\alpha\gamma}(r) \quad \text{(HNC)}. \quad (19)$$

The initial choise for $y_{\alpha\gamma}(r)$ is $y_{\alpha\gamma}(r)=1$, because the $h_{\alpha\gamma}(r)$ is equal to $\bar{f}_{\alpha\gamma}(r)$ at the low density limit. The iteration has been continued until the self-consistency of

$$\left|\frac{y^{\text{out}}_{\alpha\gamma}(r)-y^{\text{in}}_{\alpha\gamma}(r)}{y^{\text{in}}_{\alpha\gamma}(r)}\right| < 10^{-7} \quad (20)$$

is satisfied.

Calculation of the Function $\bar{f}_{\alpha\gamma}(r)$. For the diatomic molecule, the $\bar{f}_{\alpha\gamma}(\boldsymbol{r}_1^{\alpha}, \boldsymbol{r}_2^{\gamma})$ is represented by Ladanyi and Chandler[16] as follows.



(21)

where ○——○ and ○~~~○ represent $f_{\alpha\gamma}(\boldsymbol{r}_1^{\alpha}, \boldsymbol{r}_2^{\gamma})$ and $s_{\alpha\gamma}(\boldsymbol{r}_1^{\alpha}, \boldsymbol{r}_2^{\gamma})$, respectively. White circles are labeled since they represent particular interaction site at specific locations. Black circles are circles which have been integrated over space and summed over interaction site, *i.e.*

$$\bullet = \sum_{\alpha=1}^{m}\int d\boldsymbol{r}_1^{\alpha}[\mathrm{O}_1].$$

For example, the diagram represents the integral $\sum_{\eta=1}^{m}\int d\boldsymbol{r}^{\eta} f_{\alpha\eta}(\boldsymbol{r}_1^{\alpha}, \boldsymbol{r}^{\eta})s_{\eta\gamma}(\boldsymbol{r}^{\eta}, \boldsymbol{r}_2^{\gamma})$. The last two diagrams of Eq. 21 are omitted because the contribution of these two terms is negligible in the case of hard sphere site-site pair potential.[16]

Calculation of Structure Factors. Neutron scattering experiments can determine the structure factor, $S(k)$, which is expressed in terms of site-site pair correlation functions:

$$S(k) = (\sum_{\alpha=1}^{m} b_{\alpha})^{-2}\sum_{\alpha,\gamma}^{m} b_{\alpha}b_{\gamma}[\hat{\omega}_{\alpha\gamma}(k) + \rho\hat{h}_{\alpha\gamma}(k)], \quad (22)$$

where the b_{α} denotes the coherent neutron scattering amplitude for a nucleus of type α. We carried out the calculations of the structure factors for liquid nitrogen, oxygen and bromine. In order to compare the results with those obtained from experimental studies,[14,15] it is neccesary to determine two molecular

Table 1.

	σ/nm	L/nm	L/σ
N_2	0.33	0.11	0.3
O_2	0.295	0.12	0.407
Br_2	0.33	0.228	0.691

parameters, σ and L, of these diatomic molecules. Hsu *et al.*[9] used the best parameters of the molecules by a comparison of the structure factors calculated with those obtained by experiments.[14,15] The molecular parameters in the present calculations are given in Table 1.

Results and Discussion

Correlation Functions. Figure 2 shows the function, $g_{11}(r)$, calculated by means of the RISM-1, 2, and 3 equations by the use of the PY approximation for diatomic fluids with the hard sphere site-site pair potentials. The $g_{11}(r)$ calculated from the RISM-3 equation is similar in shape to a $g(r)$ of simple hard-sphere fluids. The $g_{11}(r)$ calculated from the RISM-2 equation is in good agreement with that calculated by means of the RISM-1 equation except in the vicinity of first peak. It seems that the difference in the vicinity of the two first peaks results from the use of the two different forms of PY approximations, Eqs. 6 and 10. Figure 3 shows the function $g_{11}(r)$ calculated by the RISM-1, 2, and 3 equations for fluids with the Lennard-Jones site-site pair potentials by the use of the PY approximations as well as the curve obtained by molecular dynamics study.[11] The function $g_{11}(r)$ calculated from the RISM-1 equation is in best agreement with the result of molecular dynamics. It is evident from Fig. 2 that two $g_{11}(r)$ curves calculated by the use of the RISM-1 and 2 equations for hard-sphere fluids are nearly identical with each other over the region $r \geqq \sigma + L$, in sharp contrast to the cases of the Lennard-Jones fluids (Fig. 3).

Figure 4 shows $g_{11}(r)$ calculated by the RISM-2 equation with use of the PY approximation for the fluid with the hard sphere site-site pair potential at two densities. $g_{11}(r)$ at $\rho\sigma^3=0.4$ has a sharp cusp at $r=\sigma+L$, while at a higher density, $\rho\sigma^3=0.65$, a weak square shoulder appears at the same position. At a higher density, the shape of the first peak of the RISM-2 equation differs to some extent from that of the RISM-1 equation as seen by a comparison of Figs. 2 and 4. Figure 5 shows $g_{11}(r)$ calculated by the RISM-2 equation with use of the PY approximation for fluids with the Lennard-Jones site-site pair potentials at two densities, $\rho\sigma^3=0.4$ and 0.65, and at the same temperature, $kT/\varepsilon=4.03$.

Johnson[13] derived a new equation analogous to the RISM-1 equation from the Ornstein-Zernike equation using Fourier-Wigner series, and calculated $g_{11}(r)$ for fluids with hard-sphere site-site potentials. Figure 6 shows a comparison of $g_{11}(r)$ we obtained with Johnson's. Our $g_{11}(r)$ has a shoulder at $r=\sigma+L$ in contrast to the results obtained by Johnson.

Figure 7 shows $g_{11}(r)$ calculated by the RISM-2

equation with use of the PY approximation as well as that obtained by the Monte Carlo (MC) method.[12] $g_{11}(r)$ calculated with use of the PY approximation is in better agreement with the result of MC calculation as compared with that calculated with use of the HNC approximation. Figure 8 shows a comparison of the site-site direct correlation function, $c_{11}(r)$, with results calculated with use of the PY and HNC approximations, including those of MC calculation. $c_{11}(r)$ calculated with use of the PY approximation is in agreement with that obtained by the MC calculation within the range from the origin to $r=\sigma-L$.

Structure Factors. Structure factors calculated with use of the RISM-2 equation are compared with those determined by neutron scattering experiments (Figs. 9—11). Calculations were carried out with use of the RISM-2 equation with the PY approximation

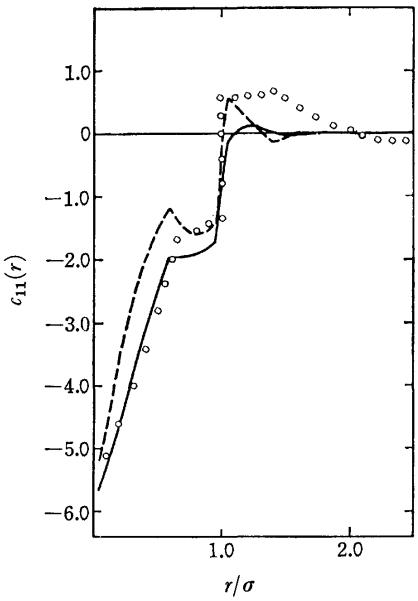

Fig. 8. Site-site direct correlation functions, $c_{11}(r)$, calculated from the RISM-2 equation for diatomic molecular fluids with the hard-sphere potential: $L/\sigma=0.3$ and $\rho\sigma^3=0.4875$.

for diatomic molecular fluids with hard sphere site-site pair potentials. The experimental results are those for liquid nitrogen,[14] oxygen,[14] and bromine[15] under the conditions given in Table 2. The molecular parameters for these liquids[12] are given in Table 1.

The agreement between calculated and experimental results is satisfactory in the cases of liquid nitrogen and liquid oxygen. In liquid bromine, the calculated values deviate from the experimental ones in the vicinity of the first and second peaks. Experimental studies[15] show that the behavior of $S(k)$ of liquid bromine is in sharp contrast to that of liquid nitrogen and liquid oxygen.

The $S(k)$ curves calculated by the RISM-1 and the RISM-2 equations are in good agreement with those obtained from experiment,[1,6,9] for liquid nitrogen and liquid oxygen. The discrepancy between calculated and experimental results for liquid bromine seems to be ascribed to some characteristic of the liquid.[17]

Comparison of the Three Forms of the RISM Equation. Summarizing the results in the present and preceding paper,[1] we can say that the RISM-1 equation gives the best results, *viz.*, the presence of a cusp or a shoulder at $r=\sigma+L$ in $g_{\alpha\gamma}(r)$ curves and agreement of the curves with those given by MD calculations. The numerical results of $g_{\alpha\gamma}(r)$ show that the RISM-1 equation is the best of the three equations, the RISM-2 coming next. Concerning the structure factor curves, the RISM-2 equation seems to give as good results as the RISM-1 equation (Fig. 9 and 10, and Ref. 1).

Table 2.

	ρ/nm^{-3}	T/K
N_2	17.29	77.4
O_2	21.98	84
Br_2	11.76	293

Of the three equations the RISM-1 equation behaves the best on the whole, but it contains some "unallowed diagrams" as stated by Chandler from the viewpoint of topological reduction scheme.[10] In a strict sence the RISM-1 equation contains inconsistensy in its theoretical scheme Thus the RISM-2 equation derived by systematic functional Taylor expansion[4] might be superior to the RISM-1 equation, though the latter is fairly easy to treat in calculation as compared with the other two equations.

Appendix

The HNC approximation for the RISM-2 equation is derived as follows by means of the method of a generalized functional Taylor expansion proposed by Chandler.[4]

Consider the quantity

$$Q_{\alpha\gamma}(\boldsymbol{r},\phi)=\langle\rho_\gamma(\boldsymbol{r})\rangle_\phi\Big[\int d\boldsymbol{I}d\boldsymbol{2}\delta(\boldsymbol{r}_1^\alpha)\delta(\boldsymbol{r}_2^\gamma-\boldsymbol{r})\times\exp\{-\beta\sum_{\eta,\nu}\phi_{\eta\nu}(\boldsymbol{r}_2^\nu-\boldsymbol{r}_1^\eta)\}\Big]^{-1},\tag{A-1}$$

where the function $\phi_{\eta\nu}(\boldsymbol{r}_2-\boldsymbol{r}_1)$ denotes an arbitrary site-site potential function.

At the end points

$$\int d\boldsymbol{I}\delta(\boldsymbol{r}_1^\alpha)Q_{\alpha\gamma}(\boldsymbol{r},\phi=0)=\rho\tag{A-2}$$

and

$$\int d\boldsymbol{I}\delta(\boldsymbol{r}_1^\alpha)Q_{\alpha\gamma}(\boldsymbol{r},\phi=u)=\rho g_{\alpha\gamma}(r)[\bar{f}_{\alpha\gamma}(r)+1]^{-1}.\tag{A-3}$$

We define a new quantity, $Q'_{\alpha\gamma}(\boldsymbol{r},\phi)$, by

$$Q'_{\alpha\gamma}(\boldsymbol{r},\phi)\equiv\ln\Big[\int d\boldsymbol{I}\delta(\boldsymbol{r}_1^\alpha)Q_{\alpha\gamma}(\boldsymbol{r},\phi)\Big].\tag{A-4}$$

If we expand $Q'_{\alpha\gamma}(\boldsymbol{r},\phi)$ in powers of the response $\langle\rho_\eta(\boldsymbol{r}')\rangle_u-\rho$:

$$Q'_{\alpha\gamma}(\boldsymbol{r},u)=Q'_{\alpha\gamma}(\boldsymbol{r},0)+\sum_\eta\int d\boldsymbol{r}'\frac{\delta Q'_{\alpha\gamma}(\boldsymbol{r},\phi)}{\delta\langle\rho_\eta(\boldsymbol{r}')\rangle_\phi}\Big|_{\phi=0}[\langle\rho_\eta(\boldsymbol{r}')\rangle_u-\rho]+\cdots\tag{A-5}$$

Truncating the right hand side of Eq. (A-5) at linear term, we can calculate the term by the use of the relations Eqs. (3.4) and (3.5) in Ref. 4, and obtain

$$\sum_\eta\int d\boldsymbol{r}'\frac{\delta Q'_{\alpha\gamma}(\boldsymbol{r},\phi)}{\delta\langle\rho_\eta(\boldsymbol{r}')\rangle_\phi}\Big|_{\phi=0}[\langle\rho_\eta(\boldsymbol{r}')\rangle_u-\rho]=h_{\alpha\gamma}(r)-[\boldsymbol{\omega}*\boldsymbol{c}*\boldsymbol{\omega}(\boldsymbol{r})]_{\alpha\gamma}.$$

Substituing Eqs. A-2, A-3, and A-6 into Eq. A-5, we get

$$[\boldsymbol{\omega}*\boldsymbol{c}*\boldsymbol{\omega}(\boldsymbol{r})]_{\alpha\gamma}=h_{\alpha\gamma}(r)-\ln g_{\alpha\gamma}(r)[\bar{f}_{\alpha\gamma}(r)+1]^{-1}.$$

The relation is the HNC approximation for RISM-2 equation.

ESR Study of the Phosphorescent State of Benzo[*f*]quinoline

Hiroshi Sekiya, Yasuhiko Gondo,* and Yoshiya Kanda

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received October 1, 1979)

Electron spin resonance absorption has been observed in a single-crystal solid solution of benzo[*f*]quinoline in biphenyl under irradiation at 120 K with light from a high-pressure mercury lamp. The fine structure of the resonance spectrum observed at 9.25 GHz can be described by the spin Hamiltonian

$$\mathbf{H} = \beta \boldsymbol{H} \cdot \boldsymbol{g} \cdot \boldsymbol{S} + D\left[S_z^2 - \frac{1}{3}S(S+1)\right] + E(S_x^2 - S_y^2)$$

in which $S=1$, $D=\pm 0.09926(18)$ cm^{-1}, $E=\mp 0.04781(6)$ cm^{-1}, $g_{xx}=2.0024(6)$, $g_{yy}=2.0018(4)$, and $g_{zz}=2.0018(4)$; the z axis is normal to the molecular plane, the x and y axes being the in-plane fine-structure principal axes. The principal x axis deviates by $\pm 4°$ from the biphenyl long axis and the principal z axis by 7° from the biphenyl out-of-plane axis. The phosphorescence spectra and lifetimes have been measured both at 77 K and at 4.2 K. Marked doublet splittings were observed in the phosphorescence bands at 4.2 K, suggesting a large guest-host interaction.

This work deals with the determination of the principal axes of the zero-field splitting (ZFS) tensor for benzo[*f*]quinoline (BFQ) in its lowest excited triplet state. In order to investigate the nature of the triplet-state wave function, it is important to determine the directions of the principal axes, not to speak of the principal values. However, the number of compounds for which the ZFS principal axes were determined are limited.[1-4] Vincent and Maki[1] showed that the ZFS parameters of quinoxaline, quinoline, and isoquinoline in durene closely resemble those of naphthalene in durene, whereas the principal axes of quinoline and isoquinoline are no longer coincident with the durene axes. Such deviation of the ZFS principal axes has also been found in 1,5-naphthyridine in durene,[2] and 1,6-diazanaphthalene in durene.[3] As for tetramethylpyrazine in durene, de Groot *et al.*[4] showed that the principal axes deviate largely from the durene axes, suggesting that the molecular symmetry does not necessarily specify the principal axes.

The electronic states of BFQ and benzo[*h*]quinoline have been studied extensively in our laboratory, in particular the delayed fluorescence of BFQ in biphenyl host,[5] the concentration depolarization of phosphorescence in ethanol glass,[6] the dipole moments and pK_a values in the ground and first excited singlet states,[7] and the temperature and solvent dependence of the phosphorescence lifetime.[8] The most relevant finding is the fact that no sign of the spin alignment could be detected in these benzoquinolines in their lowest excited triplet states in hexane at 1.3 K, and in biphenyl even at 1.18 K[5,8] According to Antheunis,[9] phenanthrene in its lowest excited triplet state in both biphneyl and fluorene provides intriguing examples; even at 1.2 K the spin-lattice relaxation times are about 1 ms, approximately one thousand times faster than the decay of the lowest excited triplet state to the ground state. The results may justify the claim that the phenanthrene-type compounds are important in the study of the spin-alignment mechanism in the triplet state.

Thus, it seems significant to obtain fundamental information on the lowest excited triplet state of BFQ, in particular, on the ZFS parameters, ZFS principal axes, and ***g***-tensor, from the electron spin resonance (ESR) spectra observed for the single-crystal solid solutions of BFQ in biphenyl. For identification of the triplet state, we have also studied the phosphorescence spectra of BFQ in biphenyl and biphenyl-d_{10} at 77 K and 4.2 K.

Experimental

Materials. BFQ (Tokyo Kasei Kogyo Co., Ltd.) was treated with sulfuric acid and sodium hydroxide as described previously,[10] and then zone-refined extensively. Biphenyl (Wako Pure Chem. Ind., Ltd.) was recrystallized from ethanol or sublimed and then zone-refined. Biphenyl-d_{10} (Merck, Sharp and Dohme Canada, Ltd.) was zone-refined. The sample crystals were grown in Pyrex tubes from the melts in a Bridgman furnace. The initial concentration of BFQ in biphenyl was *ca.* 1.2 mol%, the final concentration in the grown crystals not being known. Samples, sealed in a vacuum into Pyrex tubes, were lowered in the furnace at a rate of 30 mm a day.

Measurements. The ESR spectrometer (Echo Electronics Co., Ltd.) essentially consists of a microwave unit (EWG-10), a 100-kHz phase sensitive detector (E-100D), and a klystron power supply (EKS-1PS). Measurements were carried out using a microwave frequency of 9.25 GHz and a magnetic field modulation of 100 kHz. The microwave frequency was determined with a calibrated cavity wavemeter, the external magnetic fields being determined with a proton NMR gaussmeter. Irradiation of the sample crystals was made with a 250-W high-pressure mercury lamp (USH-250D, Ushio Electric Inc.).

Values of direction cosines of the biphenyl molecular axes in the crystal required for mounting the sample crystals properly in the cavity, were obtained from the molecular planes least-squares fitted to the X-ray diffraction data given by Trotter[11a] (Table 1). The unit cell of the biphenyl crystal is shown in Fig. 1. Main features of the biphenyl

Table 1. Biphenyl direction cosines[a]

	L′	M′	N′
a	−0.30311	−0.51754	0.80017
b	0.00662	0.83747	0.54645
c′	−0.95293	0.17550	−0.24723

a) Ref. 11a. Axis c′ is normal to the ab plane. See Fig. 1.

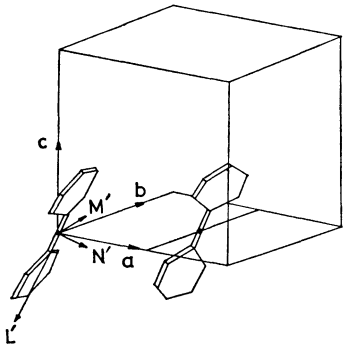

Fig. 1. Biphenyl crystal structure and axis systems.

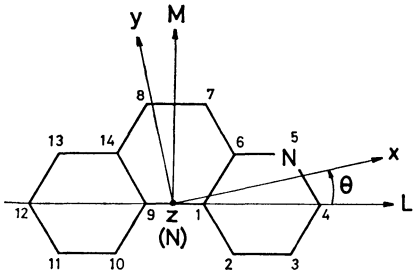

Fig. 2. Molecular axes, L, M, N, ZFS principal axes, x, y, z, and numbering scheme for the benzo[*f*]quinoline molecule.

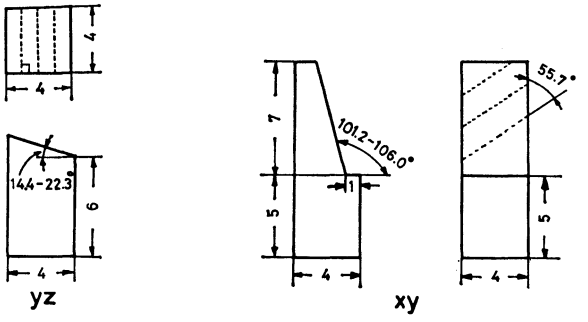

Fig. 3. Quartz wedges used to mount the sample crystals.
The ab plane was attached to the surfaces with the dotted lines which specify the b-axis direction. Lengths are given in mm. With the wedges (a) and (b), the external magnetic field lies in the yz and xy planes, respectively.

crystal are as follows: (1) It is a monoclinic crystal of the space group $P2_1/a$ with two molecules in a unit cell. (2) The crystal cleaves in the ab plane. (3) The long axes of the two molecules in a unit cell are parallel to each other within 3°.[11b,12] Figure 2 shows the molecular axes adopted and designation of the ZFS principal axes, x, y, and z.

Several quartz wedges were devised in order to rotate the static external magnetic field in the fine-structure xy and yz planes of one of the two molecules in a unit cell. Typical wedges, whose geometries are based on the direction cosines given in Table 1, are shown in Fig. 3. A biphenyl crystal doped with BFQ was mounted with its cleavage plane, *viz.*, ab plane, against the surface of a wedge by use of a varnish (GE-7031, General Electric Co.), the wedge being attached to a quartz rod directly connected to a conventional crystal-rotating device. The sample crystals were cooled by a flow of cold nitrogen gas. The sample temperature was estimated to be 120±10 K by putting a thermocouple in place of the sample crystals in the cavity. The ESR signal decays were observed at 77 K with crystals directly immersed in the liquid nitrogen in a Dewar vessel with a finger.

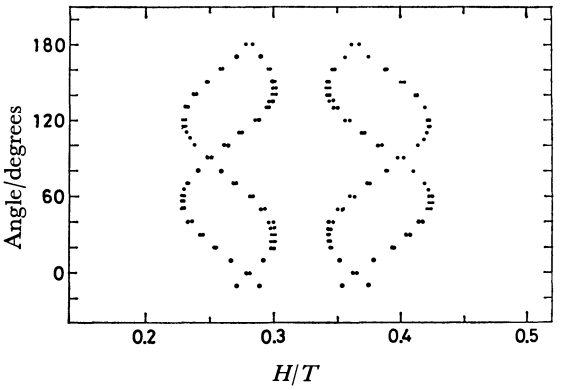

Fig. 4. Angular dependence of the resonance field strength. The magnetic field ***H*** is rotated in the ab plane.

For optical measurements, a 500-W xenon lamp was used for irradiation of the sample crystals directly immersed in the coolant. A saturated aqueous solution of nickel sulfate of 30-mm path length was used to cut the infrared radiation. Emissions from the samples were dispersed with a 750-mm Czerny-Turner-type spectrometer (RM-L21, Nalumi Co., Ltd.). The input signal to a picoammeter (TR-8651, Takeda Riken Industry Co., Ltd.) was obtained with a photomultiplier (R375, Hamamatsu TV Co., Ltd.). The spectra were recorded on a strip chart recorder (model 056, Hitachi, Ltd.), the phosphorescence decay curves being displayed on an oscilloscope (DS-5016, Iwatsu Electric Co., Ltd.) and photographed.

Results and Discussion

ESR Spectra in the ab Plane. Measurements with the external magnetic field ***H*** in the ab plane were carried out in order to confirm the mounting of the sample crystals, without using any particular wedge; the sample crystals were mounted with their cleavage surfaces directly attached to the bottom of the quartz rod. The results are shown in Fig. 4, where the zero degree on the ordinate axis approximately corresponds to the b axis. They closely resemble the corresponding results reported on phenanthrene in biphenyl,[12] except for the fact that eight resonances were found for BFQ, in general, instead of four for phenanthrene. As reported on quinoline, isoquinoline, 1,6-diazanaphthalene, *etc.*,[1-4] the doubling of the number of the resonances can be taken as an evidence for the deviation of fine-structure principal axes from the host molecular axes. It indicates that two magnetically inequivalent orientations are possible for the BFQ molecule at each of the two biphenyl lattice sites. For the sake of convenience, the two sites in a unit cell are designated as site A and site B, respectively, the quartz wedges in Fig. 3 being assumed to fit site A. Arabian numerals, 1 and 2, stand for the two inequivalent

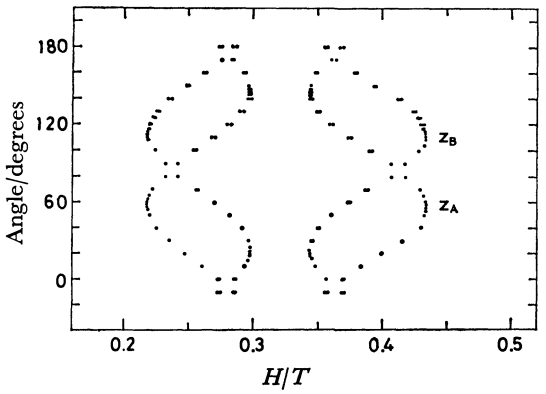

Fig. 5. Angular dependence of the resonance field strength. The magnetic field $\boldsymbol{H}$ is rotated nearly in the yz plane. The inclination of the wedge is 17.6°.

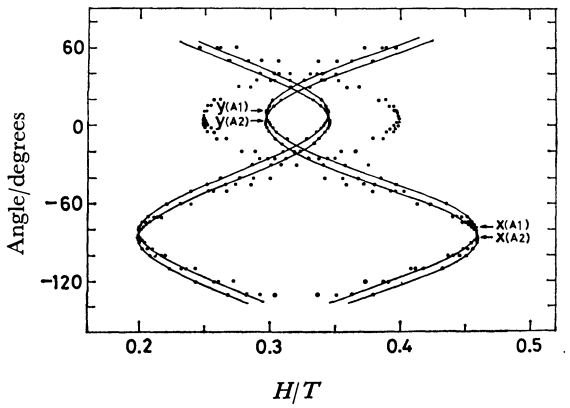

Fig. 6. Angular dependence of the resonance field strength. The mangetic field $\boldsymbol{H}$ is rotated nearly in the xy plane. The dihedral angle of the wedge is 104.8°. Points are experimentally obtained, while solid curves are drawn using the experimental D, E, and g values.

orientations at each site, respectively. Thus, magnetically the orientations of the BFQ molecules are distinguished from each other by the notations, A1, A2, B1, and B2. One of the two patterns (Fig. 4) corresponds to the lattice site for A1 and A2, and the other to that for B1 and B2. The two patterns are essentially the same except for the phase difference, as expected from the crystal structure of biphenyl. This shows that the ab plane has been identified properly in the mounting of sample crystals.

ESR Spectra in the yz Plane. On the basis of results from X-ray diffraction of the biphenyl crystal,[11a] the inclination of the surface of an appropriate wedge should be 17.7° (Fig. 3(a)), for rotation of the external magnetic field $\boldsymbol{H}$ in the M'N' plane of any one of the two biphenyl molecules in a unit cell. Four wedges of inclination in the range 14.4°—22.3° were used. The resonance fields obtained by rotating $\boldsymbol{H}$ nearly in the yz plane are shown in Fig. 5. The apparent principal value of the fine-structure tensor reaches a maximum for the inclination of 17.6° of the wedge surface, *viz.*, the largest separations correspond to the resonances with $\boldsymbol{H}$ on the z axes, the smallest those nearly on the y axes. The low-field transitions with $\boldsymbol{H}$ nearly parallel to the z axes shift to the higher fields for wedge inclinations differing from 17.6°. The spectra corresponding to orientations 1 and 2 are seen to draw closer togerher, coalescing into one spectrum as the directions of $\boldsymbol{H}$ rotates to coincide with the z axis, showing that the molecular planes of the two inequivalent guests at each of the two lattice sites, A and B, are parallel to each other within experimantal errors. Consequently, the angle between the two fine-structure z axes may lead to the dihedral angle between the planes of the A-site and B-site BFQ molecules. From the phase difference in the two distinct patterns (Fig. 5), the dihedral angle can immediately be estimated to be 55.0°, in contrast to 69.3° found for the corresponding dihedral angle between the two biphenyl molecules in a unit cell.[11] Thus, the molecular plane of BFQ is not parallel to that of biphenyl. In particular, the difference of 14.3° in the two angles indicates a decrease of 7° in the relative tilt of the guest plane as compared with the host. Similar observations have been reported by Vincent and Maki[1] for isoquinoline in durene, and by Brandon *et al.*[12] for phenanthrene in biphenyl. Hutchison and McCann studied in detail the system of phenanthrene-d_{10} in biphenyl with the aid of ENDOR at 2 K, reporting that a site of biphenyl is replaced by four differently oriented phenanthrene molecules, and that a maximum difference of 5° is found in the angles defined for the guest and host molecular planes.[13]

ESR Spectra in the xy Plane. Five wedges were used for measurements with $\boldsymbol{H}$ in the xy plane, *viz.*, LM plane, their dihedral angles being in the range 101.2°—106.0° (Fig. 3(b)); a maximum resonance field was realized with a wedge of the dihedral angle 104.8°, and with the b-axis orientation of 55.7° on the wedge surface. In these initial measurements in the xy plane, no account was taken of the fact that the molecular plane of BFQ deviates from that of biphenyl, the external magnetic field not being rotated exactly in the xy plane. In order to bring the external magnetic field exactly in the xy plane, we assumed that the host and guest molecular planes at each site make an angle in the range 6°—7°, on the basis of the finding on the yz-plane experiments. The angle determines the b-axis orientation on the wedge surface; for the angle 6°, the b-axis orientation should be 61.2° instead of 55.7° shown in Fig. 3(b), and for the angle 7°, it should be 62.2°. Measurements were carried out with the wedge of dihedral angle 104.8° and with the two b-axis orientations of 62.0° and 62.8°. Figure 6 shows the results obtained with the orientation of 62.0°. The separations for the resonance fields with $\boldsymbol{H}$ on the y axes are larger than the minimum separations in the yz-plane experiments (Fig. 5), reflecting the fact that the experiments did not sweep the y axes exactly. The L axes of the two sites A and B are parallel to each other, since the four resonances draw closer together and coalesce into one as $\boldsymbol{H}$ moves to the x axes. The coalescence makes it impossible to determine the angle between the principal x axes of A1 and A2 exactly. As for $\boldsymbol{H}$ parallel to the y

axes, the relative deviation of the principal y axis of A1 from that of A2 was found to be 8° in the xy plane, so that the corresponding deviation of the x axes should also be 8°. In view of the observations on other aromatic nitrogen heterocyclic compounds,[1-4)] we assume that the deviation of the x axis from the L axis in A1 is as large in magnitude as and opposite in sign to that in A2. We thus obtain an in-plane rotation of 4° in the ZFS tensor, due to the introduction of a nitrogen atom in the phenanthrene skeleton.

ZFS Parameters. The ZFS parameters were determined by means of the procedure developed by Hutchison and Mangum.[14)] The canonical resonance fields H_{1x}, H_{2x}, H_{1y}, and H_{2y}, were determined from the measurements in the xy plane, whereas H_{1z} and H_{2z} were determined from those in the yz plane, where subscripts 1 and 2 refer to the low- and high-field resonances, respectively. The principal axes of the $\boldsymbol{g}$-tensor have been assumed to coincide with those of the fine-structure tensor, *viz.*, the ZFS tensor. The parameters fitting the spin Hamiltonian

$$\mathbf{H} = \beta \boldsymbol{H} \cdot \boldsymbol{g} \cdot \boldsymbol{S} + D\left[S_z^2 - \frac{1}{3}S(S+1)\right] + E(S_x^2 - S_y^2)$$

are given in Table 2.

The ZFS parameters of BFQ resemble those of phenanthrene in biphenyl,[12)] which confirms that the lowest excited triplet state of BFQ is of the $\pi\pi^*$ type. A remarkeble feature of the ZFS parameters in the phenanthrene-type compounds is the large E value. The E value of BFQ is slightly larger than that of phenanthrene, and the ratio $|E/D|$ of BFQ increases as compared with that of phenanthrerne by *ca.* 4%, suggesting that the spin distribution in BFQ would be more assymmetric than that in phenanthrene. In the ESR study of BFQ in ethanol glass performed by Gondo and Maki,[15)] the signs of D and E were determined to be plus and minus, respectively, by means of magnetophotoselection. The E value in the crystal is almost identical to that in the ethanol glass, whereas the D value is smaller than that in the ethanol glass by *ca.* 2%. Such variations were reported on quinoxaline[1a)] and on phenoxazine by Löhste *et al.*[16)] who suggested that the variations of the ZFS energies in phenoxazine might be due to the solvent polarities and the hydrogen bonding which may induce some change in the molecular geometry. It is not clear, however, what interaction is operative in the case of BFQ.

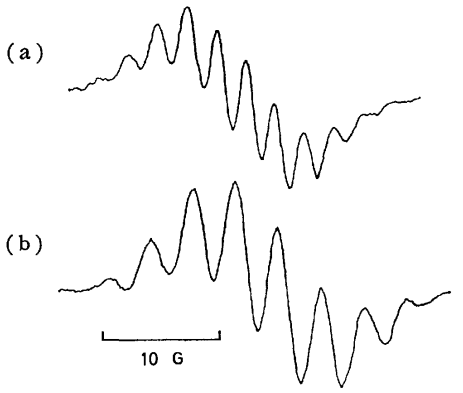

Fig. 7. Observed hyperfine structure of the triplet benzo[*f*]quinoline.
(a): High-field transition with $\boldsymbol{H}$//y, (b): low-field transition with $\boldsymbol{H}$//y.

Gondo and Kanda calculated the principal values and axes of the ZFS tensors for the $\pi\pi^*$ excited triplet states of some aromatic compounds, by employing the Pariser-Parr-type two-center Coulomb repulsion integrals and the core integrals of $\beta_{CC} = -2.39$ eV and $\beta_{CN} = -2.576$ eV.[17)] The results obtained for BFQ are $+0.1105$ cm^{-1}, -0.0582 cm^{-1}, and $+0.6°$, for D, E, and θ, respectively, where θ is the angle defined in Fig. 2(a). The calculated principal values confirm that the observed triplet state is of the $\pi\pi^*$ type. On the other hand, the calculated θ value would not determine the sign of the observed θ of $\pm 4°$, since the value is absolutely small.

Hyperfine Structure. The hyperfine structure of the triplet BFQ was observed for the magnetic field nearly parallel to the fine-structure x axis as well as y axis. The observed spectra are shown in Fig. 7. Although the hyperfine structure is apparently well resolved for the x axis, it is in fact complicated owing to overlapping of the signals due to the different sites. In order to aid the computer simulation of the hyperfine structure, the triplet spin densities given in Table 3 were calculated by an LCAO-SCF-MO-CI approach in which all the singly excited configurations were taken into account, and the Pariser-Parr and Nishimoto-Mataga approximations were adopted for the two-center Coulomb repulsion integrals. It should be noted that these two approximations give essentially the same spin densities for the nitrogen atom, although the Nishimoto-Mataga approximation gives much more

Table 3. Theoretical normalized spin densities ρ based on the Pariser-Parr (PP) and Nishimoto-Mataga (NM) approximations for Coulomb repulsion integrals

uniformly distributed spin densities for the carbon atoms than the Pariser-Parr.[18)]

Simulation of the hyperfine structure was performed by combining the calculated spin densities with the experimentally determined principal values of the hyperfine coupling tensor.[1,19)] The simulated spectra disagree definitely with those observed. The hyperfine structure of BFQ is expected to be complicated owing to its low molecular symmetry; even a small change in the spin distribution tends to provide quite a different hyperfine spectrum. Thus, for further clarification of the hyperfine structure and spin distribution, study on deuterated BFQ's is important.

Table 4. Phosphorescence lifetimes τ of benzo[*f*]-quinoline in biphenyl single crystals

Host	At 4.2 K		At 77 K	
	$\nu_{0,0}$/cm^{-1}	τ/s	$\nu_{0,0}$/cm^{-1}	τ/s
Biphenyl	21573	2.90	21575	2.08 (2.2) [a)]
	21544	2.61		
Biphenyl-d_{10}	21570	2.83	21576	2.29 (2.2) [a)]
	21540	2.57		

a) The values in parentheses were obtained from ESR signal decays.

Phosphorescence Spectra and Lifetimes. Figure 8 shows the phosphorescence spectra of BFQ in biphenyl observed at 77 K and 4.2 K. The obvious difference between the spectra is the multiplet splitting in the spectrum at 4.2 K, each vibronic band apparently consisting of a doublet. Hochstrasser and Noe reported similar multiplet splittings in the fluorescence and phosphorescence spectra of phenanthrene–biphenyl mixed crystals at 1.8 K.[20)] Enlarged features (Fig. 8(b)) are shown around the 0,0-band observed at 4.2 K, the splitting amounting to 29 cm^{-1} in biphenyl and to 30 cm^{-1} in biphenyl-d_{10}. These are considerably larger than the corresponding value of 11 cm^{-1} found for phenanthrene in biphenyl.[20)] The paramagnetic species observed as the triplet BFQ can be identified in part by the phosphorescence lifetimes (Table 4). The phosphorescence lifetime has been found to depend markedly on the solvents as well as temperature.[8)]

Orientation of the Guest Molecule in the Crystal. The angle of rotation of the z axis, *viz.*, N axis, of BFQ in biphenyl is slightly larger than that of phenanthrene in biphenyl.[12)] Such deviation of the principal axes of the guest molecules in the host crystal was studied by Hochstrasser and Small[21)] in connection with the site splittings in the electronic spectra. Their calculations suggest that we should not in general expect exact alignment of the principal axes of a guest and a host molecule. Since the volume occupied by a BFQ molecule is larger than that occupied by a biphenyl molecule, there would naturally be intermolecular interactions which would tilt the z axis of the guest molecule. Incidentally, the z axis of isoquinoline is tilted by 13° in durene,[1)] while that of 1,5-naphthyridine is tilted by 2° also in durene. These results indicate that the z-axis tilting in the aromatic nitrogen heterocyclic compounds would depend on the location of the nitrogen atoms in a complicated manner.

The present work was partially supported by the Ito Science Foundation and by Grants-in-Aid for Scientific Research Nos. 334026 and 347014 from the Ministry of Education, Science and Culture.

Reactions of Pentane and 2-Methylbutane over Solid Super Acids Prepared by Different Conditions

Osamu Takahashi, Takashi Yamauchi,† Toshihiko Sakuhara, Hideshi Hattori,* and Kozo Tanabe

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

† *Nishiki Research Center, Kureha Chem. Ind. Co., Iwaki 974*

(Received October 8, 1979)

The reaction of pentane to 2-methylbutane was carried out at 0 °C over solid super acid catalysts which were prepared by treatment of various metal oxides with SbF_5 under different conditions, and the preparation conditions that affect the catalytic behavior of the catalyst were examined. Among the different base metal oxides, TiO_2–ZrO_2 became the most active catalyst when treated with SbF_5. The maximum conversion to 2-methylbutane which appeared in the reaction of pentane was high when a base metal oxide was treated with SbF_5 at a low temperature, and also when the reaction temperature was low. At the maximum conversion, the selectivity of the catalysts for the skeletal isomerization was almost 100%. As the reaction of pentane proceeded, the catalytic activity for the skeletal isomerization to 2-methylbutane was decreased but that for the formation of 2-methylpropane from 2-methylbutane was increased. The reaction mechanism is briefly discussed.

Recently, many attempts have been made to prepare solid super acids which show catalytic activity for skeletal isomerization of alkanes at low temperature, and most of them are patented. Other than the patents, Magnotta *et al.* reported that a complex of $AlCl_3$ with polystyrene sulfonic acid is active for the cracking and isomerization of hexane at 85 °C.[1,2] Olah *et al.* presented Nafion-H as a solid super acid.[3–5] Ono *et al.* reported that mixtures of aluminum halides with metal sulfates or with metal chloride showed high activities for the isomerization of pentane at room temperature.[6–8]

In our previous paper, we reported the preparation of solid super acids which exhibited catalytic activity for the skeletal isomerizations of butane and 2-methylpropane at room temperature.[9] The solid super acids were prepared by treatment of various types of metal oxides with SbF_5. Over these catalysts, pentane underwent skeletal isomerization to 2-methylbutane.[10] The selectivity to 2-methylbutane was 100% in the initial stage of the reaction, but lowered in the final stage of the reaction, which was caused by successive production of 2-methylpropane. As a result, there appeared a maximum conversion to 2-methylbutane in the course of the reaction. In this paper, several factors which might affect the maximum value of the conversion to 2-methylbutane are examined, and the reasons for appearance of the maximum are discussed. The variable factors examined are the type of base metal oxide, the temperature of treatment of base metal oxide with SbF_5, the number of treatment with SbF_5, the pretreatment temperature of base metal oxide, the reaction phase, and the presence of H_2.

Experimental

Preparation of Catalyst. Solid super acids were prepared by exposure of various metal oxides to SbF_5 vapor followed by evacuation of excess SbF_5. The base metal oxides used in this study were SiO_2, TiO_2, ZrO_2, Al_2O_3, SiO_2–Al_2O_3, and TiO_2–ZrO_2. Silica, TiO_2, and ZrO_2 were prepared by hydrolysis of aqueous solutions of ethyl orthosilicate, titanium tetrachloride, and zirconium dichloride oxide, respectively, with aqueous ammonia, followed by washing with deionized water and calcination at 500 °C in air. Alumina was AE-11 γ-Al_2O_3 purchased from Nishio Ind. Co. Ltd. Silica–alumina was N 631L obtained from Nikki Chemicals Co. Ltd. Titanium dioxide–zirconium dioxide was prepared by hydrolysis of aqueous solution of a mixture of $TiCl_4$ and $ZrOCl_2$ with aqueous ammonia, followed by washing and calcination at 500 °C in air. The composition was 63% TiO_2 and 37% ZrO_2 by mole.

Prior to exposure to the vapor of SbF_5, all base metal oxides were outgassed at 500 °C for 2 h. Procedures of exposure to SbF_5 for 10 min and following evacuation for 10 min were carried out at different temperatures in the range of 0—100 °C, and were repeated different times.

Specific surface area was determined by applying the adsorption isotherm of N_2 at the boiling point to BET equation. The amount of SbF_5 remained in the resulting catalyst was determined by measuring the weight change of the sample on exposure to SbF_5.

The reaction was carried out primarily at 0 °C in a closed recirculation reactor having a volume of *ca.* 325 ml. The initial pressure of a reactant was about 50 Torr (1 Torr= 133 Pa), and the amount of catalyst was 0.1 g before exposure to SbF_5. The reaction was also carried out in liquid phase under the atmospheric pressure of N_2 or the 13.5 kg/cm^2 of H_2. The reaction products were analyzed by gas chromatography. A 6-m column packed with VZ-7 was operated at room temperature.

Results

As shown in Table 1, the amount of SbF_5 remained in the catalysts after treatmetn with SbF_5 at different temperatures decreased with increase in the pretreatment temperature. Generally, the amount of SbF_5 was smaller for single component metal oxides than for binary ones. The specific surface areas of the catalysts decreased to a considerable extent on treatment with SbF_5. The areas became smaller as the treatment temperature was lower. For example, the area (445 m^2/g) of SiO_2–Al_2O_3 became 205 when SbF_5 was adsorbed at 30 °C and evacuated at 50 °C and 86 when SbF_5 was adsorbed at 0 °C and evacuated at 0 °C.

The product distributions in the reaction of pentane in 60 min (or 70 min) over the different types of base metal oxides treated with SbF_5 are summarized in

Table 1. Amount of SbF_5 remained in catalyst, wt %

Catalyst[a]	SbF_5 ads. temp/°C	Evacuation temp 0 °C	30 °C	50 °C	100 °C
SbF_5-SiO_2-Al_2O_3	0	49.7	37.6	27.7	
	10	53.2	40.9	34.5	30.7
	30		34.1	32.2	
	100				17.2

	10		33.5	27.2	
	30			29.8	
	100				30.9
SbF_5-SiO_2	0	33.1	18.8	12.8	
	10			18.2	
	30			17.2	
SbF_5-Al_2O_3	0	37.1			
SbF_5-TiO_2	0	23.1			
SbF_5-ZrO_2	0	24.8			

a) Adsorption-desorption cycle in SbF_5 treatment was repeated four times.

Table 2. Treatment with SbF_5 was done at 0 °C both for adsorption and for desorption, and repeated four times. Among the catalysts examined, the SbF_5–TiO_2–ZrO_2 catalyst showed the highest activity. The SbF_5–SiO_2–Al_2O_3 catalyst and the SbF_5–SiO_2 also exhibited high activity.

The time courses of the reactions of pentane and 2-methylbutane over the SbF_5–SiO_2–Al_2O_3 catalyst which was prepared by exposure of SiO_2–Al_2O_3 to SbF_5 at 10 °C followed by evacuation at 30 °C and repeating four times (hereafter represented by SbF_5–SiO_2–Al_2O_3 (10-30) IV) are shown in Figs. 1 and 2. Pressure changes during the reactions were negligible. In the reaction of pentane, only 2-methylbutane was produced in the initial stage of the reaction. In 30 min, 2-methylpropane began to be produced and became a predominant product in 90 min. The maximum conversion to 2-methylbutane was observed in about 60 min. The formation of hexanes was very small compared with that of 2-methylpropane. In the reaction of 2-methylbutane, pentane was produced in the initial period of the reaction in a small amount, and 2-methylpropane began to be formed in 30 min and became the main product.

The features of the time courses in these reactions were commonly observed for all catalysts prepared from different base metal oxides. However, the maximum conversion to 2-methylbutane from pentane

varied with the treatment temperature with SbF_5. The maximum conversions to 2-methylbutane are given in Table 3, and the reaction times to give the maximum conversion are also included in Table 3 in parentheses. As the treatment temperature, especially the evacuation temperature, became higher, the value of the maximum conversion was decreased, and

the reaction time to give the maximum was shortened. Among three different types of catalysts, the SbF_5–SiO_2–Al_2O_3 catalyst exhibited a high maximum conversion over a wide range of the pretreatment temperature, while the SbF_5–TiO_2–ZrO_2 was most easily affected by the treatment temperature, the maximum conversion being lowered from 87% to *ca.* 15% by raising the temperature of evacuation from 0 °C to 50 °C.

The number of repetition of adsorption-desorption cycle in treatment of base metal oxide with SbF_5 also affected the reaction time to reach the maximum conversion to 2-methylbutane. The time courses of the formation of 2-methylbutane from pentane over the SbF_5–SiO_2–Al_2O_3 catalysts which were prepared with different number of repetition of adsorption-desorption cycle at 0 °C are shown in Fig. 3. Although the maximum conversions to 2-methylbutane were almost the same, the initial conversion rates decreased and the reaction times to reach the manixmum conversion was prolonged as the number of repetition increased. The SbF_5–SiO_2–Al_2O_3(0-0) I catalyst and the SbF_5–SiO_2–Al_2O_3(0-0) IV catalyst had the surface areas of 120 and 86 m^2/g, respectively, and contained 49.3 and 49.7 wt % of SbF_5, respectively.

In Fig. 4, the time courses of the reaction of pentane over the SbF_5–SiO_2–Al_2O_3(30-50) IV catalyst at 0 °C and at −20 °C are shown. The maximum conversion to 2-methylbutane was higher when the reaction was carried out at lower temperature, though the initial conversion rate was lower.

When the reaction mixture was briefly evacuated at a certain reaction time and the fresh reactant was introduced, both the conversion rate of pentane and that of 2-methylbutane in the subsequent runs were quite dependent on the reaction time in the previous runs. The time courses of the previous reaction of pentane and the subsequent reaction are shown in Figs. 5 and 6 in which the subsequent reactant was pentane and 2-methylbutane, respectively. When the previous reaction was stopped before the conversion to 2-methylbutane reached the maximum, the isomerization of pentane to 2-methylbutane was faster than the formation of 2-methylpropane from 2-methylbutane in the subsequent runs. On the contrary, when the previous reaction was run to such an extent that the conversion to 2-methylbutane had passed the maximum and the formation of 2-methylpropane had

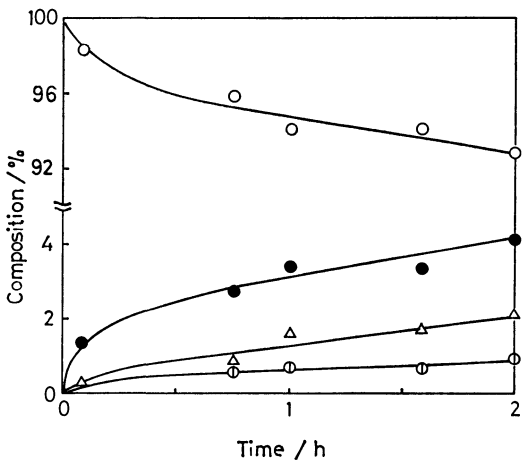

Fig. 7. Liquid phase reaction of pentane over SbF_5–TiO_2–ZrO_2(30-50) IV catalyst at 0 °C under atmolspheric pressure of N_2. Amount of catalyst: 0.269 g, amount of pentane: 10 ml.
○: Pentane, ●: 2-methylbutane, ⓘ: hexanes, △: butane.

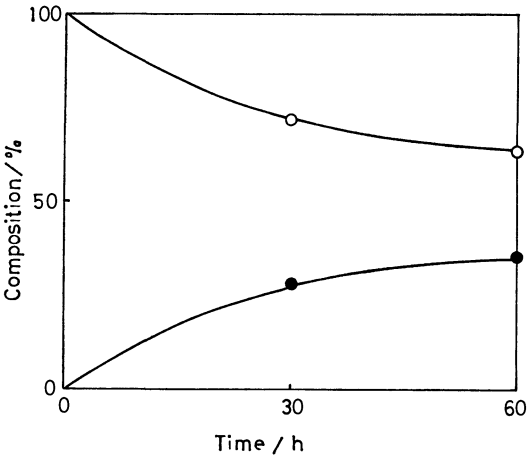

Fig. 8. Liquid phase reaction of pentane over SbF_5–TiO_2–ZrO_2(0-0) IV catalyst at 15 °C under 13.5 kg/cm² of H_2. Amount of catalyst: 0.200 g, amount of pentane: 2 ml.
○: Pentane, ●: 2-methylbutane.

been considerable, the formation of 2-methylpropane from 2-methylbutane became much faster than the isomerization of pentane to 2-methylbutane in the subsequent runs. If the nature of active sites were unchanged throughout the reaction, the reaction features in the subsequent runs would be independent of the reaction time in the previous runs. Therefore, the nature of active sites should gradually change as the reaction proceeds.

The pretreatment temperature of the base metal oxide also affected the catalytic activity. The SbF_5–SiO_2–Al_2O_3(0-0) IV catalyst whose SiO_2–Al_2O_3 had been outgassed at 100 °C prior to treatment with SbF_5 exhibited twice as high conversion rate of pentane as the standard catalyst. The catalytic activity of the SbF_5–SiO_2–Al_2O_3(0-0) IV catalyst whose SiO_2–Al_2O_3 had been outgassed at 1000 °C was negligibly small.

The liquid phase reaction of pentane was carried out over the SbF_5–TiO_2–ZrO_2(30-50) IV catalyst under the atmosphere of N_2. The main product was 2-methylbutane as shown in Fig. 7. 2-Methylpropane was produced from the initial period of the reaction, but not increased to be a main product even in 120 min. Presence of H_2 (13.5 kg/cm²) greatly enhanced the catalytic activity of the SbF_5–TiO_2–ZrO_2(0-0) IV catalyst and the products consisted primarily of 2-methylbutane as shown in Fig. 8. In Fig. 9, the time course of the reaction of 2-methylbutane over the SbF_5–SiO_2–Al_2O_3(30-50) IV catalyst is shown. The conversion rate of 2-methylbutane remained constant until the conversion level of 50%. The main products were hexanes; mostly 2,3-dimethylbutane and 2-methylpentane. To check the elusion of Sb into liquid phase, the liquid products after the reaction

○: Pentane, ●: 2-methylbutane, △: 2-methylpropane, ◐: 2,3-dimethylbutane+2-methylpentane, ◑: 2,2-dimethylbutane+3-methylpentane.

were subjected to atomic absorption spectroscopic analysis. No Sb could be detected.

In order to check whether SbF_3 which may be formed by reduction of SbF_5 is active or not, the reaction of pentane over SbF_3–SiO_2–Al_2O_3 was carried out at 0 °C in a gas phase. The catalyst was found to be completely inactive.

Discussion

The skeletal isomerization of pentane to 2-methylbutane is important, since 2-methylbutane is known to be a harmless sbustance which raises the octane value of gasoline. In the present work, the maximum conversion of pentane to 2-methylbutane was found to be affected by various factors which appeared in preparation of the SbF_5–oxide catalysts. Out of the factors examined in this study, the temperature at which the base metal oxide was treated with SbF_5 exhibited the greatest effect. To obtain a high maximum conversion to 2-methylbutane, the treatment temperature is desirable to be low. Comparison of Table 3 with Table 1 reveals that the maximum conversion increases with the increase of the amount of SbF_5 remained in the catalysts, though the surface areas of the catalysts decreases with the increase of the amount of SbF_5.

The decrease in the conversion to 2-methylbutane as the reaction proceeds is caused by the formation of 2-methylpropane from 2-methylbutane.

Since the catalyst that had been used for the reaction to a considerable extent became not so active for the skeletal isomerization of pentane but active for the formation of 2-methylpropane from 2-methylbutane, the nature of active sites on the catalyst should gradually change as the reaction proceeds.

On the freshly prepared catalyst, only the active sites for the skeletal isomerization of pentane, I-sites, may exist, and I-sites are gradually transformed to the sites which are active for the formation of 2-methylpropane from 2-methylbutane, C-sites, during the skeletal isomerization. An alternative explanation could be this. Both I-sites and C-sites exist on the fresh catalyst, and only I-sites are gradually poisoned as the reaction proceeds. The I-sites are considered to act as Lewis acid sites which abstract hydride ions from pentane to form the carbenium ions, since the existence of Lewis acid sites on SbF_5–SiO_2–Al_2O_3 has been evidenced by infrared spectra of adsorbed pyridine.[11]

According to the deuterium tracer study,[12] 2-methylpropane is not produced by a simple cracking of 2-methylbutane. Two different mechanisms can be proposed for the formation of 2-methylpropane from 2-methylbutane. One of them is the recombination of four methyl and/or methylene groups on the catalyst surface (Eq. 1),[12] and the other is the disproportionation of 2-methylbutane, that is, the dimerization-decomposition mechanism (Eq. 2).[13,14]

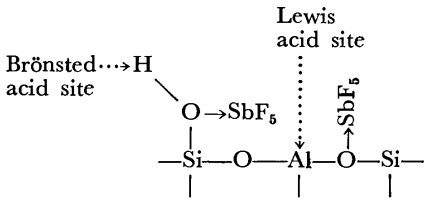
$$\text{2-methylbutane} \xrightarrow{\text{cracking}} \text{methyl and/or methylene groups} \xrightarrow{\text{recombination}} \text{2-methylpropane} \quad (1)$$

$$\text{2-methylbutane} \xrightarrow{\text{dimerization}} C_{10}\ \text{species} \xrightarrow{\text{decomp.}} \text{2-methylpropane} + \text{a hexane} \quad (2)$$

In the Eq. 1, 2-methylbutane was formed from pentane over the I-sites at first and it cracked to the methyl and/or methylene groups over the C-sites. The methyl and/or methylene groups accumulate on the surface as the reaction proceeds. When the accumulation becomes saturated, four methyl and/or methylene groups recombine to produce 2-methylpropane and it desorbs into the gas phase. Since the formation of hexanes are very small compared with that of 2-methylpropane in the gas phase reactions, 2-methylpropane may be produced mainly by the Eq. 1.

In the liquid phase reactions, however, not so large difference exists between the formation of 2-methylpropane and that of hexanes. Therefore, in the liquid phase reactions, the contribution of the Eq. 2 may be much larger than that of the Eq. 1 to the formation of 2-methylpropane. The effect of hydrogen is considered to prevent the carbonization of hydrocarbons or to retard the reduction of SbF_5.

Since the catalytic activity became smaller when the base metal oxide had been previously outgassed at higher temperature, the presence of OH groups on the base metal oxide seems to be necessary to form the active sites by treatment with SbF_5. In the catalyst, SbF_5 may not be simply adsorbed on the surface but may be reacted with surface, propably with surface OH groups. The existence of Brönsted acid sites, besides Lewis acid sites, is also evidenced by infrared study on adsorbed pyridine.[11] The speculative structure of acid sites on SbF_5–SiO_2–Al_2O_3 may be drawn as follows.



SbF_5 adsorbs on oxygen atoms of Al–O–Si and O–H to attract the electron pairs of the oxygen atoms and by the inductive effects, both Lewis and Brönsted acid sites are considered to increase their acid strengths. A small amount of SbF_5 may be reduced to SbF_3 which is inactive for the reaction of pentane.

The Energy Dependence of Selective Hydrogen Atom Abstraction by H(D) Atoms in the Photolysis of Neopentane–Ethane Mixtures at 77 K

Tetsuo MIYAZAKI,* Selma Matheus Loureiro GUEDES, and Kenji FUEKI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received October 9, 1979)

Selective hydrogen-atom-abstraction reaction by an H or D atom has been studied in a *neo*-C_5H_{12}–C_2H_6 (less than 1 mol%) mixture at 77 K by ESR spectroscopy. The H (or D) atom produced by the photolysis of HI (or DI) reacts with *neo*-C_5H_{12} and C_2H_6 to form *neo*-C_5H_{11} and C_2H_5 radicals. In order to obtain H atoms with different kinetic energies, the photolysis was performed with different lights of 313, 254, and 229 nm. The selective formation of the C_2H_5 radical by the reaction of the H (or D) atom with C_2H_6 becomes more effective with the decrease in the energy of the H (or D) atom. The formation of the *neo*-C_5H_{11} radical by the reaction of the H (or D) atom with *neo*-C_5H_{12} becomes more effective with the increase in the energy of the H (or D) atom.

The reaction of the H atom is quite important in chemical kinetics as well as in the radiation chemistry of organic compounds. Though extensive results on the reaction of hot H atom have been reported in the gas phase,[1] information on the solid phase at low temperatures is quite scanty at present.

Recently Miyazaki *et al.* found interesting phenomena concerning hydrogen-atom abstraction reactions by the H atom in the solid neopentane-alkane mixtures at 77 K.[2] When the H atom is produced at 77 K by the radiolysis of neopentane or by the UV-photolysis of hydrogen halide, the H atom reacts selectively with the solute, resulting in the formation of the solute radical. The H atom produced by the radiolysis or the photolysis has excess kinetic energy. When the wavelength of light is changed in the photolysis of HI, an H atom with a different kinetic energy is produced.

In order to obtain information on the reactivity of an H atom with a differential initial kinetic energy in the solid alkane, the reactions of the H atoms produced by the photolysis of HI in neopentane–ethane mixture are studied here.

Experimental

The D content of deuterium iodide, supplied by Merk Sharp and Dohm, Canada, Ltd., is more than 98%. The other reagents used in this study are the same as those used before.[2c]

UV illumination was provided by a medium-pressure mercury lamp with a UV-29 filter, a low-pressure mercury lamp with a UV-25 filter, and a home-made cadmium lamp. The cadmium lamp was made of quartz and kept in an electric furnace at 533 K.[3] The emission spectra of the light from the lamps used in the experiment were measured with an emission spectrometer. The emission spectra are shown in Fig. 1. In order to determine the light absorbed by HI, the extinction coefficient (ε) of HI was measured. Since neopentane is polycrystalline at 77 K, the extinction coefficient of HI was measured in 3-methylpentane glass at 77 K. ε at 254 nm, for example, is 95 $mol^{-1}\,dm^3\,cm^{-1}$, nearly equal to the reported values of 95 $mol^{-1}\,dm^3\,cm^{-1}$ in the gas phase[4] and 127 $mol^{-1}\,dm^3\,cm^{-1}$ in the liquid solvent.[5] The absorption spectrum of 0.5 mol% HI is shown in Fig. 1 by the unit of absorbance percentage, where the pass length of light is 0.3 cm.

The free radical formed in the photolysis was measured at 77 K with a JES-3BX ESR spectrometer. The microwave power levels used did not result in the saturation of the signal of the alkyl radicals.

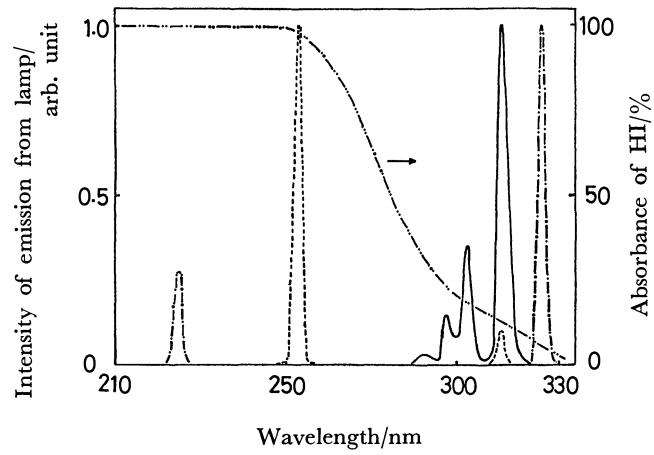

Fig. 1. Emission spectra from lamp and absorbance of HI. Maximum intensity of light from each lamp is normalized to 1.
——: Medium-pressure mercury lamp with UV-29 filter; ----: low pressure mercury lamp with UV-25 filter; —·—: cadmium lamp; —··—: absorbance of HI(0.5 mol %) in 3-methylpentane glass at 77 K, where a pass length of light is 0.3 cm.

Results

The emission intensity multiplied by the absorbance of HI in Fig. 1 corresponds to the light absorbed by HI in the photolysis. The most effective lights for the photolysis of HI are 313 nm from the medium-pressure mercury lamp with a UV-29 filter, 254 nm from the low-pressure mercury lamp with a UV-25 filter, and 229 nm from the cadmium lamp. In fact, the photolysis of HI does not occur upon the irradiation with the cadmium lamp with a UV-29 filter, which cuts off the light of 229 nm and transmits only 326 nm.

Figure 2 shows the yield of the C_2H_5 radical in the photolysis of *neo*-C_5H_{12}–HI(0.5 mol %)–C_2H_6 mixtures at 77 K. The relative yield of the C_2H_5 radical was estimated from the peak height of the C_2H_5 radical in the ESR spectrum. In the present work, the peaks which do not overlap with those of other radicals were used for the measurement of the relative yield of the C_2H_5 radical. The yield of the C_2H_5 radical

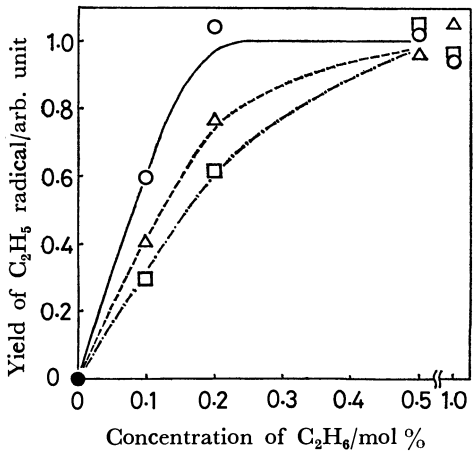

Fig. 2. Yield of C_2H_5 radical against concentration of C_2H_6 in the photolysis of *neo*-C_5H_{12}–HI(0.5 mol %)–C_2H_6 at 77 K. The plateau yield at high concentration of C_2H_6 is normalized to 1.
○: Photolysis at 313 nm; △: photolysis at 254 nm; □: photolysis at 229 nm.

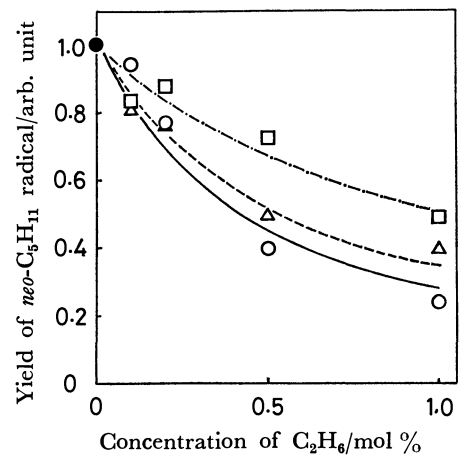

Fig. 3. Yield of *neo*-C_5H_{11} radical against concentration of C_2H_6 in the photolysis of *neo*-C_5H_{12}–HI(0.5 mol %)–C_2H_6 at 77 K. The yield in the absence of C_2H_6 is normalized to 1.
○: Photolysis at 313 nm; △: photolysis at 254 nm; □: photolysis at 229 nm.

increases with the increase in the C_2H_6 concentration and reaches a plateau at a high concentration of C_2H_6. The plateau yield is taken as 1.0.

Figure 3 shows the yield of the *neo*-C_5H_{11} radical in the photolysis of *neo*-C_5H_{12}–HI(0.5 mol %)–C_2H_6 mixtures at 77 K. The relative yield of the *neo*-C_5H_{11} radical was estimated also from the peak height of the *neo*-C_5H_{11} radical in the ESR spectrum. The peak which does not overlap with those of the other radicals was used for the measurement of the yield of the *neo*-C_5H_{11} radical. The yield in the absence of C_2H_6 is taken as 1.0.

Figures 4 and 5 show the yields of the C_2H_5 and *neo*-C_5H_{11} radicals respectively in the photolysis of *neo*-C_5H_{12}–DI(0.5 mol %)–C_2H_6 mixtures at 77 K.

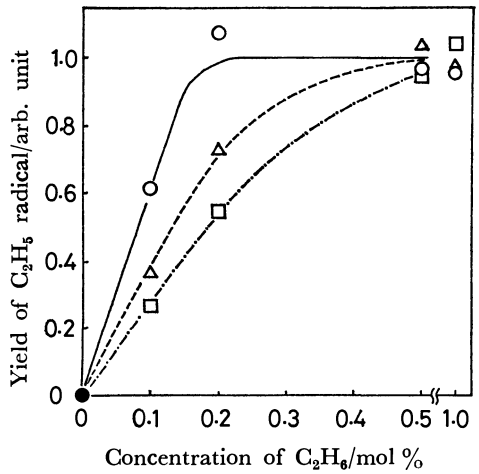

Fig. 4. Yield of C_2H_5 radical against concentration of C_2H_6 in the photolysis of *neo*-C_5H_{12}–DI(0.5 mol %)–C_2H_6 at 77 K. The plateau yield at high concentration is normalized to 1.

Discussion

Formation of the C_2H_5 Radical. When *neo*-C_5H_{12}–HI–alkane mixtures are UV-irradiated or *neo*-C_5H_{12}–alkane mixtures are γ-irradiated at 77 K, the alkyl radical from the solute, such as *i*-C_4H_{10}, C_3H_8, *c*-C_6H_{12}, and C_2H_6, is produced in a much higher yield than would be expected from the concentration of the solute. The reaction mechanism for the selective formation of the alkyl radical has been reported in detail in previous papers,[2a-d,2h] The formation of the alkyl radical by the radical site migration (Reaction 1) can be neglected for the following reasons:

$$\textit{neo}\text{-}C_5H_{11} + RH \longrightarrow \textit{neo}\text{-}C_5H_{12} + R \quad (1)$$

where RH represents the solute, such as *i*-C_4H_{10} and C_2H_6. First, when the *neo*-C_5H_{12}–*i*-C_4H_{10} mixture is

γ-irradiated at 4 K, only the *neo*-C_5H_{11} radical is produced. The selective formation of the C_4H_9 radical is not observed when the irradiated sample is warmed from 4 K to 77 K, though the C_4H_9 radical is formed in the γ-irradiation at 77 K.[2e] Second, when the *neo*-C_5H_{12}–*i*-C_4H_9D-2-d_1–HI mixture is irradiated with UV light at 77 K, the selective formation of the HD molecule and the *t*-C_4H_9 radical is observed, though the H_2 molecule and the *t*-C_4H_9 radical should be formed by the mechanism of the radical-site migration. Thus, the formation of the *t*-C_4H_9 radical is not due to the radical-site migration, but to the selective hydrogen-atom abstraction by the H atom. The other experimental evidence for the selective reaction of the H atoms has been presented in the previous papers.[2b,d] When *neo*-C_5H_{12}–C_2H_6–*i*-C_4H_{10}–HI mixtures are UV-irradiated at 77 K, the yield of the C_2H_5 radical decreases upon the addition of *i*-C_4H_{10}, resulting in the complementary formation of the *t*-C_4H_9 radical.[2h] Therefore, the C_2H_5 radical is also formed by the selective reaction of the H atom.

Figure 2 shows that the yield of the C_2H_5 radical in the photolysis of *neo*-C_5H_{12}–HI(0.5 mol %)–C_2H_6 mixtures increases with the increase in C_2H_6 and reaches a plateau at high concentrations. Since the plateau value is normalized to 1 in Fig. 2, the amounts of the reactive H atoms produced by the photolysis of HI with three different lights are normalized to the same value. The reaction mechanism for the formation of the C_2H_5 radical can be represented as follows:

$$HI + h\nu \xrightarrow{I_2} H + I \quad (2)$$

$$H + C_2H_6 \xrightarrow{k_3} H_2 + C_2H_5 \quad (3)$$

$$H + P \xrightarrow{k_4} \text{product}, \quad (4)$$

where I_2 is the rate of the production of the reactive H atom which reacts with C_2H_6 at high concentrations of C_2H_6. k is a rate constant. Reaction 4 represents some reaction which competes with Reaction 3. P may be *neo*-C_5H_{12} and HI. Since I_2 is normalized to 1,

$$k_3/\{k_4[P]\} = [C_2H_5]/\{[C_2H_6](1-[C_2H_5])\}. \quad (5)$$

Since [P] is constant in the present experiment, $k_3/\{k_4[P]\}$ represents the relative reactivity of Reaction 3 and is summarized in the third column in Table 1. When hydrogen iodide absorbs ultraviolet light, the H atom produced by the photolysis obtains excess kinetic energy. The energetics of the dissociation process is a little complicated by the possibility that iodine atoms can be formed in two electronic states, the ground or the first-excited state.[6] It is assumed here, however, that most of the iodine atoms are in the ground state and that the average initial energy of the hydrogen atom is the difference between the energy of light and the bond energy of HI. The average excess energy is shown in the second column in Table 1. The relative reactivity of the selective hydrogen-atom abstraction reaction increases with the decrease in the kinetic energy of the H atom. If the reactive H atom is a thermal H atom, $k_3/\{k_4[P]\}$ should be independent of the light sources in the evolution of H from HI.

Table 1. Rate constant for hydrogen-atom abstraction reaction by the H(D) atom at 77 K

Wave length of photolysis / nm	Excess energy of the hydrogen atom / kcal/mol	$k_3/\{k_4[P]\}$ [a]	k_8/k_7
neo-C_5H_{12}–HI(0.5 mol%)–C_2H_6			
313	20	1500	250
254	41	1100	190
229	54	600	100
neo-C_5H_{12}–DI(0.5 mol%)–C_2H_6			
313	20	1600	250
254	41	900	130
229	54	500	80

a) The unit of concentration is the mole fraction. See text.

The yield of the C_2H_5 radical in the photolysis of *neo*-C_5H_{12}–DI(0.5 mol %)–C_2H_6 mixtures is shown in Fig. 4. The amount of the C_2H_5 radical increases with the increase in the C_2H_6 concentration and reaches a plateau at a high concentration. The same mechanism as in Reactions 2, 3, and 4 can be applied to the formation of the C_2H_5 radical in the photolysis of DI. The $k_3/\{k_4[P]\}$ value for the D atom, as estimated from Eq. 5, is shown in Table 1. The relative reactivity of the selective hydrogen-atom abstraction by the D atom increases with the decrease in the kinetic energy of the D atom. It is noted that the $k_3/\{k_4[P]\}$ value and its energy dependence for the D atom are similar to those for the H atom.

Formation of the neo-C_5H_{11} *Radical.* Figure 3 shows that the yield of the *neo*-C_5H_{11} radical in the photolysis of *neo*-C_5H_{12}–HI(0.5 mol %)–C_2H_6 mixtures decreases upon the addition of C_2H_6, while that of the C_2H_5 radical increases (Fig. 2). Since the *neo*-C_5H_{11} radical does not react with C_2H_6 in the solid phase at 77 K,[2e] the dependence of the *neo*-C_5H_{11}-radical yield upon C_2H_6 may be due to a competitive reaction between *neo*-C_5H_{12} and C_2H_6 for the H atom.

$$HI + h\nu \xrightarrow{I_6} H' + I \quad (6)$$

$$H' + \textit{neo}\text{-}C_5H_{12} \xrightarrow{k_7} H_2 + \textit{neo}\text{-}C_5H_{11} \quad (7)$$

$$H' + C_2H_6 \xrightarrow{k_8} H_2 + C_2H_5, \quad (8)$$

where I_6 is the rate of the production of the reactive H atom, which produces the *neo*-C_5H_{11} radical in the absence of C_2H_6. The two reactive hydrogen atoms in Reactions 2 and 6 will be compared below. Since I_6 is normalized to 1 in Fig. 3, the following equation is obtained:

$$\frac{1}{[\textit{neo}\text{-}C_5H_{11}]} = 1 + \frac{k_8[C_2H_6]}{k_7[\textit{neo}\text{-}C_5H_{12}]} \quad (9)$$

The average values of k_8/k_7, obtained from the kinetic plots of $1/[\textit{neo}\text{-}C_5H_{11}]$ and $[C_2H_6]/[\textit{neo}\text{-}C_5H_{12}]$, are shown in the last column in Table 1. k_8/k_7 decreases with the increase in the energy of the H atom. Thus, the formation of the *neo*-C_5H_{11} radical becomes more favorable with the increase in the energy of the H atom.

Figure 5 shows the dependence of the *neo*-C_5H_{11} radical yield upon C_2H_6 in the photolysis of *neo*-C_5H_{12}–DI(0.5 mol %)–C_2H_6 mixtures. The yield decreases upon the addition of C_2H_6, while that of the C_2H_5 radical increases (Fig. 4). The same kinetics as in Reactions 6—8 and Eq. 9 can be applied to the formation of the *neo*-C_5H_{11} radical by the D atom. The k_8/k_7 ratio for the D atom is shown in Table 1. k_8/k_7 decreases with the increase in the energy of the D atom.

Now, Reactions 8 and 7 will be compared with Reactions 3 and 4. Since the concentration of P in $k_3/\{k_4[P]\}$ is represented by a mole fraction, $[P]=1$ if P corresponds only to *neo*-C_5H_{12}. In this case, however, the experimental values of k_3/k_4 for the H and D atoms are not equal to k_8/k_7, but about 6 times as large as k_8/k_7 (Table 1). Thus, Reaction 4 must contain some reaction other than Reaction 7.

The ratio of the decrement in the *neo*-C_5H_{11}-radical yield ($-\Delta C_5H_{11}$) to the increment in the C_2H_5-radical yield (ΔC_2H_5) is shown in Fig. 6 as a function of the C_2H_6 concentration. Since the reliability of the $-\Delta C_5H_{11}$ value at 0.1 mol % is low, the value at 0.1 mol % is omitted in the figure. If Reaction 4 represents only a reaction between H (or D) and *neo*-C_5H_{12}, the $-\Delta C_5H_{11}/\Delta C_2H_5$ ratio should be constant at all concentrations of C_2H_6. Figure 6 shows, however, that the ratio is not constant. In fact, this ratio changes more remarkably with the decrease in the energy of the H (or D) atom. Some of the reactive H (or D) atoms which react with C_2H_6 do not react with *neo*-C_5H_{12}, and the role of these H (or D) atoms increases with the decrease in the energy of the H (or D) atom. Therefore, the H atoms in Reaction 2 represent all the hydrogen atoms which react with C_2H_6, while the H′ atoms in Reaction 6 represent only the hydrogen atoms which can react with *neo*-C_5H_{12}.

It is concluded from the energy dependence of the formation of the C_2H_5 radical that H (or D) atoms with different excess energies play an important role in the selective hydrogen-atom abstraction reaction and that the selective reaction occurs more easily with the decrease in the excess energy of the H (or D) atom. The hydrogen atoms with small excess energies migrate through the neopentane matrix at 77 K. The atoms neither react with neopentane nor are deactivated during their migration. These results seem to contradict a kinetic theory of a hot-atom reaction in the gas phase. The reactions in the solid phase, however, may be different from those in the gas phase. Further studies of the reaction and the deactivation process of the hot H atom in the solid phase are now under way.

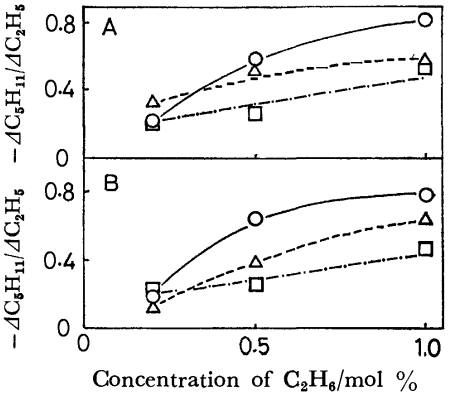

Fig. 6. The ratio of decrement of *neo*-C_5H_{11} radical yield ($-\Delta C_5H_{11}$) to increment of C_2H_5 radical yield (ΔC_2H_5) against concentration of C_2H_6. Figures A and B are *neo*-C_5H_{12}–HI(0.5 mol %)–C_2H_6 system and *neo*-C_5H_{12}–DI(0.5 mol %)–C_2H_6 system respectively.

The Absorption Spectra of Monolayers of Fat-soluble Vitamins and the Orientations of Their Chromophores

Kazunori MATSUKI,* Yukio NAGAHIRA,† and Hideo FUKUTOME
Department of Physics, Faculty of Science, Kyoto University, Kyoto 606
(Received October 11, 1979)

The UV absorption spectra at normal incidence and the polarized spectra at 45° incidence of monolayers of vitamin K_1, α-tocopherylquinone, vitamin E, ergosterol, and vitamin D_2 were measured. The absorption peaks of the monolayers of vitamin K_1, α-tocopherylquinone, and vitamin D_2 shifted to wavelengths longer than those in a hexane solution, while vitamin E and ergosterol showed little shift. The orientations of their chromophores in the monolayers were investigated by means of the dichroic ratios obtained from their polarized spectra. The molecular axes of vitamin K_1, α-tocopherylquinone, and vitamin E were found to be oriented in the range from 0° to about 30° against the normals of their monolayer planes. The molecular axis of ergosterol was found to tilt about 24° against the normal of the monolayer plane. For vitamin D_2, no reliable conclusion could be obtained as to its orientation.

Fat-soluble vitamins and their related compounds used in this study, vitamin K_1, α-tocopherylquinone(α-TQ), vitamin E, ergosterol, and vitamin D_2, have a quinone or a linear polyene moiety as their chromophores and form stable monolayers at air-water interfaces. These compounds exist in biological membranes and are involved in some biochemical processes. Vitamin K_1, α-TQ, and vitamin E are contained in chloroplasts and are thought to play a part in the electron-transfer system. Vitamin D_2 and ergosterol, which are steroid hormones, are known to have strong affinities for biological membranes. Their chromophores are thought to be important in their biological functions.

The states and the interactions of chromophores of these molecules and other fat-soluble vitamins in monolayers are interesting from both biological and physical points of view, but they have not been well studied except for the vitamin A group,[1] although the surface pressure-area curves, surface potentials, and other properties of their monolayers have been investigated by several workers.[2-7] The main difficulty in such a study is that the intensities of the absorption spectra of chromophores in monolayers are generally very small. Several methods of measuring the absorption spectra of monolayers were devised by Jacob *et al.*,[8] Trurnit and Colmano,[9] and Tweet.[10] These methods, however, are all more or less troublesome. More recently, Kuhn *et al.*[11] designed a high-sensitivity spectrophotometer for thin layers and investigated the absorption spectra of monolayers of ionic cyanine dyes substituted with long hydrocarbon chaines. We constructed in our laboratory a spectrophotometer similar to theirs because the absorption spectra of monolayers can be measured more easily with it than with any other methods. We have then measured the polarized absorption spectra of monolayers of vitamin K_1, α-TQ, vitamin E, vitamin D_2, and ergosterol in order to get information about the interactions and the orientations of their chromophores in monolayers.

Experimental

Materials. Guaranteed-reagent-grade vitamin K_1, vitamin D_2, ergosterol, and β-cholestanol were purchased from Nakarai Chemicals, Ltd. The vitamin E (Wako first grade) and phytol were obtained from Wako Pure Chemical Industries, Ltd., and the α-TQ, from the Nutritional Biochemicals Corporation. The absorption spectra of the fat-soluble vitamins in organic solutions were identical with the reported values in peak positions and extinction coefficients as follows: Vitamin K_1 (in hexane): within 1 nm and 4% compared with the values reported for petroleum ether[12] and isooctane(2,2,4-trimethylpentane)[13] solutions; α-TQ (in ethanol): within 1 nm and 5% compared with the values reported for an ethanol solution;[14] vitamin E (in hexane): within 1 nm and 3% compared with the values reported for a cyclohexane solution;[15] vitamin D_2 (in hexane): within 0.5 nm and 2% compared with the values reported for a hexane solution;[16] ergosterol (in ethanol): within 0.5 nm and 3% compared with the values reported for an ethanol solution.[17] All the above chemicals were stored in the dark at about −20 °C in a reduced-pressure desiccator in which air had been replaced with nitrogen. Guaranteed-reagent-grade Na_2HPO_4, KH_2PO_4, and spectroscopic-grade hexane were purchased from Nakarai Chemicals, Ltd. All the chemicals were used without further purification. Twice-distilled water (pH=5.6—5.9) was used in all the experiments. Optically flat quartz slides ($50\times24\times0.8$ mm^3) were obtained from the Takahashi Giken Co.

Methods. The UV-absorption spectra of the above compounds in a hexane solution were recorded on an MPS-5000 spectrophotometer (Shimadzu Co.). The absorption spectra of monolayers were measured with a high-sensitivity spectrophotometer using the single-beam and sample in-sample out technique developed by Kuhn *et al.*[11] The apparatus constructed in our laboratory was the same as theirs in fundamental design. It consists of an automatic scanning monochromator, a self-exciting oscillator system, a light-detecting system (a photomultiplier and a preamplifier), a high-tension control system which feeds a highly negative voltage to the photomultiplier, a lock-in amplifier, and an X-Y recorder. The self-exciting oscillator system consists of a mechanical oscillator made of a long, thin iron plate ($95\times16\times1$ mm^3) which is fixed vertically on a rigid frame made of iron and attached at its top with a holder to mount a quartz slide vertically against the iron plate, two electro-magnets to drive the oscillation of the oscillator, a coil to detect the frequency and the amplitude of the oscillation, and a negative-feedback electric circuit fed with the signal from the coil to provide the magnets with the a.c. current with the resonance frequency of the oscillator and a constant amplitude. The oscillator, with a quartz slide

† Present address: Osaka University of Economics and Law, Gakuonji, Yao City, Osaka 581.

mounted in it, was oscillated at a resonance frequency of about 40 Hz and with a constant amplitude (measured at the center of the quartz slide) of about 10 mm. In measurements of the absorption spectra of monolayers, one half of the quartz slide was covered with a monolayer. Then the sample area of the slide (covered with the monolayer) and the reference area (not covered with it) passed the light beam alternately. The transmitted and modulated light was directed to the photomultiplier. The a.c. signal from the pre-amplifier was amplified by the lock-in amplifier, and the absorbance was recorded. The reference signal for the lock-in amplifier was taken from the self-exciting oscillator system. The following minor modifications were made in our apparatus: The light from the exit slit of the monochromator was focused on the quartz slide not with lenses, but with two mirrors, in order to eliminate the chromatic aberration. The integrated signal from the pre-amplifier was used to regulate the high tension fed into the photomultiplier, because the absorptions of the monolayers are very small.

The a.c. signal from the pre-amplifier was assumed to be a rectangular wave. This assumption is plausible because the boundary between the sample area and the reference area most quickly passes the light beam. The peak-to-peak value of the rectangular wave is proportional to the absorbance because the absorptions of monolayers are very small. The conversion factor from absorption(%) to absorbance is $\log_{10}(e/100)$. The high tension fed into the photomultiplier was adjusted to make the output from the pre-amplifier 50 mV for the case of a 5% absorption. In the lock-in amplifier, the first term of the Fourier series of the rectangular wave is synchronously rectified in the full wave and the rms value of the rectified wave is obtained. The conversion factor from the rms value of the rectified wave to the peak-to-peak value of the rectangular wave is $\pi/\sqrt{2}$. Therefore, the absorbance is obtained by multiplying the output of the lock-in amplifier (volt) by $(\pi/\sqrt{2})\log_{10}e(=0.9647)$. The absorbance measured with our apparatus agreed with that measured with usual spectrophotometers within a 4% error in the range of optical density (OD) of $(3—4)\times10^{-2}$.

The sensitivity of our apparatus was limited by noises which could not be synchronized by the lock-in amplifier. The noise level was 1×10^{-4} OD/layer. The systematic noises caused by the magnetic field and the mechanical vibration from the oscillator system could, however, be suppressed to a level which did not exceed the above random noise level by making a magnetic shielding of the photomultiplier and a mechanical insulation of the oscillator to prevent dissipation of the vibration energy to other parts of the apparatus. Therefore, measurements were possible up to the range of the 2.5×10^{-3} OD/layer on a full scale with a noise level below 4%.

In the measurements of the polarized absorption spectra at 45° incidence, a polarizer (a Glan-Thomson prism made of calcite) was set just before the slide. The polarizer was set in such a manner as to make the plane of polarization parallel to the plane of incidence (p-spectrum) or perpendicular to it (s-spectrum).

The Blodgett method[18] was used for preparing spectroscopic samples of monolayers. A monolayer was spread on twice-distilled water or a 10^{-3} mol/dm^3 phosphate buffer (pH=7.8—8.0) at 20±1 °C by dropping a fresh solution in hexane (5—10 mg/10 cm^3). A clean quartz slide held vertically was moved slowly into the water until the lower half of it sank below the air-water interface. At this time the monolayer was not transferred because the slide was hydrophilic. Then surface pressure was applied to the monolayer by using oleic acid (30 mN/m) or a mixture of ethyl myristate and liquid paraffin (6.3- or 16.3-mN/m)[19] as the piston oil, and the slide was raised slowly from the water. One monolayer was thereby transferred on each side of the lower half of the slide. The absorption spectra were recorded on the high-sensitivity spectrophotometer described above as soon as the slide became dry. All the operations handling monolayers were performed under dim red lights to avoid photochemical decomposition.

The quartz slide was cleaned by immersing it in a hot chromic acid mixture for about one hour. The slide was then washed with a great quantity of city water and immersed in a NaOH solution (pH=*ca.* 12) for about one hour. It was then taken out and washed first with much city water and then with distilled water. Finally, it was rinsed sufficiently with twice-distilled water and dried in an electric dryer. Its cleanliness was checked by light scattering in the dark.

Results and Discussion

In the spectrophotometer with the single-beam and sample in-sample out technique, a transparent plate, half of which is covered with a monolayer, is oscillated at a constant frequency so that the sample area (covered with the monolayer) and the reference area (not covered with it) pass the light beam alternately. The transmitted and modulated light is directed into a photomultiplier. The a.c. signal from it is amplified by a lock-in amplifier, and the absorbance of the monolayer is recorded. Therefore, the measured absorption includes the apparent absorption due to the difference in reflectivity between the monolayer and the plate when their reflectivities do not coincide. The difference between the two reflectivities can be expected to become larger at shorter wavelengths in the UV region because the dispersions of their refractive indices become larger there. Because of the high sensitivity of the apparatus, a very small difference in the reflectivities and even an inhomogeneousness in the quartz slide which can not be detected by usual optical techniques may produce detectable apparent absorptions.

The apparent absorption of a phytol monolayer was subtracted from the apparent absorptions of the monolayers of vitamin K_1, α-TQ, and vitamin E, which have a phytol chain or a phytol-like chain, and the apparent absorption of a β-cholestanol monolayer was subtracted from the apparent absorptions of the monolayers of vitamin D_2 and ergosterol, which have skeletons similar to it, as a correction to cancel out the apparent absorption due to the differences in reflectivity between the monolayers and the quartz slide and to the inhomogeneousness in the slide. Most peculiarities observed in the apparent absorptions of monolayers were eliminated by this correction. For instance, the difference between the apparent p- and s-spectra in the order of the 4×10^{-4} OD/layer, which almost all the monolayers showed in the region of wavelengths longer than 400 nm, were eliminated by this correction. The negative absorption in the order of the 1×10^{-3} OD/layer, which the spectra of the α-TQ and ergosterol monolayers showed in the wavelength region of 220—240 nm, also became positive in ergosterol after this

correction. However, the α-TQ monolayer still showed a small negative absorption at wavelengths shorter than 235 nm (Fig. 2) even after this correction. This seems to be due to the smaller refractive index of the α-TQ monolayer than that of the phytol monolayer in this wavelength region because the long chain of α-TQ does not have the double bond which phytol has. The error due to the difference in the refractive index, which is attributed to the difference in the structure of the long-chain moiety or the skeleton from phytol or β-cholestanol, may become significant in the wavelength region shorter than 250 nm, but its effect does not seem serious in the longer-wavelength region, where the absorption peaks of the chromophores exist.

The polarized absorption spectra at normal and 45° incidences were measured in order to investigate the anisotropy of the monolayers. In the case of the normal incidence, the spectra of monolayers were examined with the plane of polarization set at the angles 0°, ±45°, and 90° against the direction of the withdrawal of the slide from the monolayer on the air-water interface. All the monolayers examined showed no significant difference in the polarized spectra at normal incidence, indicating that no anisotropy in the layer plane existed. In the case of the 45° incidence, however, remarkable differences between the p- and s-spectra were observed, indicating that the molecules in all the monolayers were oriented uniaxially. The apparent dichroic ratio, $R_{app}=A_s/A_p$, was obtained from A_s and A_p, the absorbances of the s- and p-spectra, which were corrected for the apparent absorption as has been described above. We calculated the true dichroic ratio corrected for the interference effect as follows.

The refractive indices of the long-chain moieties of the monolayers, which are almost identical with those of phytol or β-cholestanol, can be assumed to be equal to that of quartz at wavelengths longer than 250 nm, because the apparent absorptions of the phytol and β-cholestanol monolayers due to the differences in their reflectivities from that of the quartz slide were below 4×10^{-4} OD/layer and about one order smaller than the absorption of the chromophores, which amounted to $(1.5—5.0)\times10^{-3}$ OD/layer. Therefore, we can use the equations of correction for the interference at the substrate-air interface proposed by Kuhn *et al.*[11] In the case of a monolayer with a thickness much smaller than the wavelength of the measuring light, the true absorbances are given by:

$$\bar{A}_s = \frac{A_s}{1+r_s} \tag{1}$$

$$\bar{A}_p = \frac{A_p}{1+r_p}, \tag{2}$$

where r_s and r_p are the reflection coefficients for the s- and p-polarized lights respectively at a 45° incidence. We will assume hereafter that the refractive indices of the monolayers are isotropic and coincide with that of quartz. According to Fresnel's equations, r_s and r_p are given by:

$$r_s = \frac{n\cdot\cos\beta-\cos\alpha}{n\cdot\cos\beta+\cos\alpha} \tag{3}$$

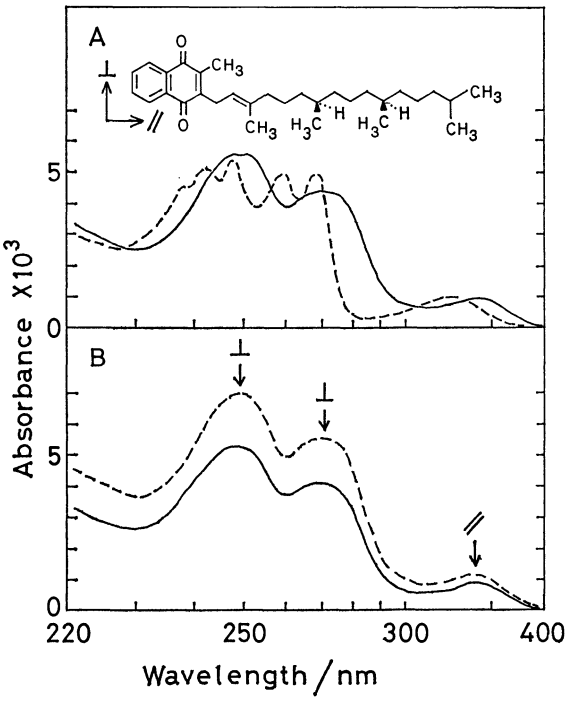

Fig. 1. Absorption spectra of vitamin K_1 monolayer spread on 10^{-3} mol/dm³ phosphate buffer pH 7.8—8.0 and transferred to quartz slide under the surface pressure of 6.3 mN/m.
(A) ——: Absorption of the monolayer at normal incidence (n-spectrum), ----: absorption of the hexane solution in an arbitrarily chosen scale. (B) Polarized spectra of the monolayer at 45° incidence. ——: The plane of polarization is parallel to the plane of incidence (p-spectrum), ----: the plane of polarization is perpendicular to it (s-spectrum). The symbols ⊥ and // indicate the directions of the transition moments.

$$r_p = \frac{n\cdot\cos\alpha-\cos\beta}{n\cdot\cos\alpha+\cos\beta}, \tag{4}$$

where n is the refractive index of quartz; $\alpha(=45°)$, the angle of incidence, and β, the angle of refraction. The refractive index of air is assumed to be unity. Finally, the true dichroic ratio is obtained by:

$$R = \frac{\bar{A}_s}{\bar{A}_p} = \frac{R_{app}(1+r_p)}{1+r_s}. \tag{5}$$

The values of n at the absorption peaks of the monolayers are obtained from the data of Jerrard and Turpin[20] and Malitson[21] for the dispersion of the refractive index of quartz. For instance, n is 1.507 at 250 nm and 1.478 at 340 nm.

We show in Figs. 1 to 5 the observed absorption spectra of the monolayers which are corrected for the apparent absorption. We summarize in Table 1 the positions of the absorption peaks in the hexane solution and in the monolayers and the shifts of the peaks between monolayer and solution.

The spectra of vitamin K_1 and α-TQ monolayers were red-shifted compared with those of their solutions, and the vibronic structures seen in solution disappeared (Figs. 1 and 2). The spectra of the vitamin E mono-

layers (Fig. 3) showed little shift, but the vibronic structure disappeared. The spectra of the ergosterol monolayers (Fig. 4) also showed little shift, but the relative intensities of the vibronic peaks changed greatly compared with those in solution. The spectra of the vitamin D_2 monolayers were slightly red-shifted (Fig. 5).

Concerning the polarized spectra at a 45° incidence, the strengths of the s-spectra were larger than those of the p-spectra in the vitamin K_1, α-TQ, vitamin E, and vitamin D_2 monolayers. On the other hand, the strength of the p-spectrum is about three times as large as that of the s-spectrum in the ergosterol monolayers. The strength of the non-polarized spectrum at a normal incidence (n-spectrum) is smaller than that of the s-spectrum. This indicates that the transition moment of ergosterol tilts only a little against the normal of the layer plane.

The apparent dichroic ratios, R_{app}'s, and the true ones, R's, at the absorption peaks of the monolayers are listed in Table 1. The listed values are the averages of the results for two samples prepared independently.

We calculated the orientation angles of the molecules by assuming a model (Fig. 6A) the same as that of Akutsu *et al.*,[22] because the transition moments in the monolayers were found to be oriented uniaxially. In Fig. 6A, the x-y plane is the layer plane and the y-z plane is the plane of light incidence. Now we assume that the molecules are rigid and have principal axes fixed to them (the 2nd rotation axes). As to the orientation of the whole molecule, it is assumed

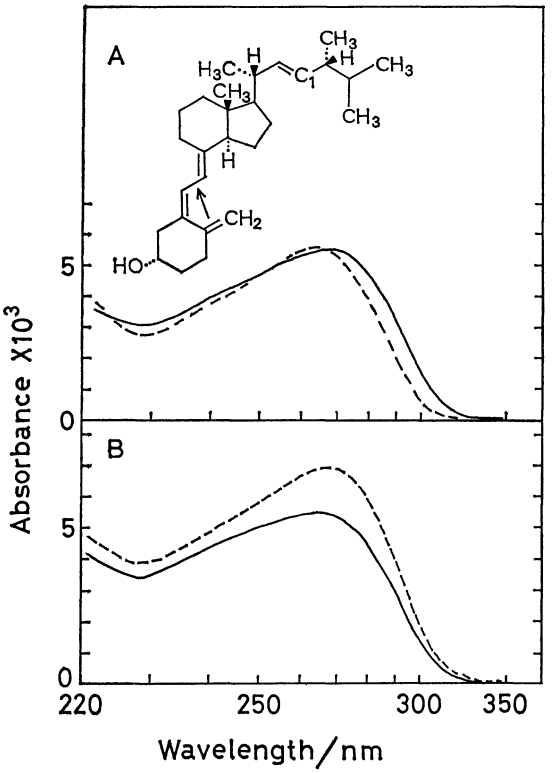

Fig. 5. Absorption spectra of vitamin D_2 monolayer spread on twice distilled water and transferred to quartz slide under the surface pressure of 30 mN/m. Fig. 6. (A) The model of uniaxial orientation of transition moments in a monolayer. The x-y plane is the monolayer plane and the y-z plane is the plane of light incidence. (B) The true dichroic ratio R as functions of the orientation angle γ at different θ's, where n is 1.50 and α is 45°.
Curve a: $\theta=0°$, b: 30°, c: 45°, d: $\arcsin\sqrt{2/3}(=54.7°)$, e: 60°, f: 90°. The angle γ_0 is $\arcsin\sqrt{2/3}$.

that the 2nd rotation axis tilts against the normal of the layer plane (the 1st rotation axis) by a fixed angle, γ, and is distributed uniformly around it. The transition moment in the chromophore is assumed to tilt against the 2nd rotation axis by a fixed angle,

θ, and to be distributed uniformly around it. Then the dichroic ratio is given by:

$$R=\frac{B}{(1-3\sin^2\beta)B+4\sin^2\beta}, \quad (6)$$

where:

$$B = 2\sin^2\theta + 2\sin^2\gamma - 3\sin^2\theta\sin^2\gamma. \quad (7)$$

We show in Fig. 6B how the dichroic ratio, R, depends on γ at different θ's when α is 45° and n is 1.50. As can be seen in Fig. 6B, the relation between R and γ is sensitively dependent on θ. We may note that there is a special value of θ, 54.7°, independently of n, where R equals unity independently of γ. Therefore, if θ is near 54.7°, it is impossible to make a reliable determination of γ from the observation of R. When θ has a definite value not close to 54.7°, we can determine γ from the observed value of R. However, if there is any uncertainty in the value of θ, a unique determination of γ is not possible and we can determine it only in a certain range. There is an ambiguity in the definition of the θ angle in vitamin K_1, α-TQ, and vitamin E because their chromophores may make an internal rotation against the long chain moiety and θ may depend on the conformation of the molecules. On the other hand, in ergosterol and vitamin D_2, the chromophores are fixed to rigid molecular skeletons, and so we can determine θ by quantum mechanical calculations for the directions of the transition moments.

The directions of the transition moments in the chromophore of vitamin K_1 were assumed to be parallel to the O–O direction for the bands at 250- and 270-nm and to be perpendicular to it for the band at 340 nm, as is shown in Fig. 1, according to Kuboyama's calculation of 1,4-naphthoquinone by the simple MO method.[23] The dichroic ratios obtained by us were nearly equal for these two groups of transition (Table 1), where the directions of the transition moments are perpendicular to each other. The γ angle must have the same value for all the transitions. Therefore, the θ's for these transition moments must be nearly equal in order for their R's to be nearly equal. This shows that the 2nd rotation axis must lie on the plane which is perpendicular to the naphthoquinone plane and which bisects the orthogonal angle formed with the two groups of the transition moments. Then, the θ angle may have a value within the range from 45° to 90°. The δ angle between the 2nd rotation axis and the naphthoquinone plane is then given by:

$$\cos\delta = \sqrt{2}\cdot\cos\theta. \quad (8)$$

By curves a and a' in Fig. 7 we show the relations between the θ and γ angles which give the observed values of 1.12 and 1.13 of the R's for the transitions at 250- and 270-nm respectively. Because of the slight difference in n for these transitions, the two curves are not identical, but the difference between them is small. The curve corresponding to the transition at 340 nm is almost identical with the a' curve, and so it is not shown in Fig. 7. The dependence of δ on θ is also shown in Fig. 7. We can see in Fig. 7 that the θ and γ angles consistent with the observed value of R range from 64° to 90° and from 0° to 38° respectively. The tilt angle of the naphthoquinone plane

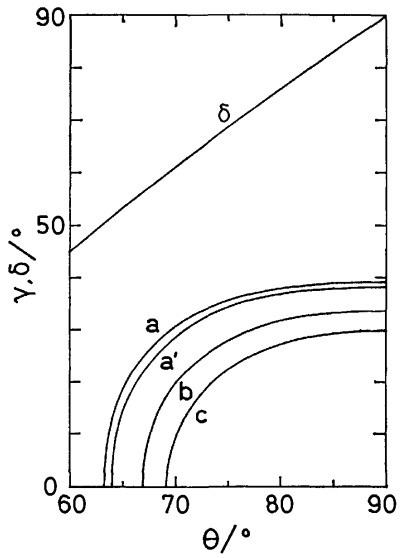

Fig. 7. The trajectories of the angles γ and θ to give the observed values of the dichroic ratio R.
Curve a: R=1.12 and n=1.507 for the 250 nm band of vitamin K_1, a': R=1.13 and n=1.498 for the 270 nm band of vitamin K_1, b: R=1.16 and n=1.498 for the 270 nm band of α-TQ, c: R=1.19 and n=1.491 for the 292 nm band of vitamin E. The θ dependence of the tilt angle δ of naphthoquinone plane against the 2nd rotation axis in vitamin K_1 monolayer is also shown in the upper side.

against the normal of the layer plane (the 1st rotation axis) is distributed in the range from $\delta-\gamma$ to $\delta+\gamma$. If γ has a value not near 0°, then the tilt angle of the naphthoquinone moiety is distributed over a wide range, for instance, from 32° to 92° for γ=30° and from 52° to 128° for γ=38°. As a result, the hydrophilic naphthoquinone moieties in a vitamin K_1 monolayer have to make contacts with the water surface with contact angles distributed over a wide range. Considering the structure of naphthoquinone, it seems to be unnatural that naphthoquinone moieties can make contacts with the water surface with widely distributed contact angles without any meaningful effect on the interaction energy of the monolayer with water. Therefore, it seems likely that γ has a value near the lower boundary, 0°, of its admissible range. When γ is near 0°, θ and δ nearly equal 64° and 51° respectively, and the naphthoquinone plane contacts with the water surface at an almost constant angle of about 51°. As can be seen from Fig. 7, θ is limited in a narrow range from 64° to 71°, even if γ varies from 0° to 30°. Hence, it seems reasonable to guess that γ is smaller than 30° and that θ is close to 64°.

The spectral shifts in vitamin K_1 monolayers can be explained qualitatively by the molecular exciton theory by assuming $\gamma\approx0°$. McRae and Kasha[24] showed that a linear-stacked array of chromophores has a spectrum with a blue shift compared with its monomer spectrum when $\eta<\arcsin\sqrt{1/3}=35.3°$ (η is the complementary angle between the transition moment and the direction of the linear arrangement) and one with a red shift when $\eta>\arcsin\sqrt{1/3}$. The red shift in the spectrum of the vitamin K_1 monolayers can be

explained by this theory, because the η angle is near 64° if the naphthoquinone moieties make stacked linear arrays with their orientation angle, γ, near 0°. Thus, the naphthoquinone moieties in a vitamin K_1 monolayer appear to be stacked at least in a short range.

In α-TQ, the direction of the transition moment was assumed to be parallel to the O–O direction, as is shown in Fig. 2, according to Kuboyama's calculation of benzoquinone.[23] The θ and γ values, which give the observed R value of 1.16, are in the following two ranges: $\theta=0$—34° and $\gamma=67$—90°, and $\theta=67$—90° and $\gamma=0$—34°. Because of the symmetry of Eq. 6 for θ and γ, there are always two sets of solutions in which θ and γ are exchanged when only an R for a transition is available for the determination of γ. Since the 2nd rotation axis should agree roughly with the axis of the long-chain moiety, the former set of solutions is inadequate because it implies that the long chains of some molecules are almost parallel to the water surface. Therefore, we adopt the latter set. The shape of the admissible θ-γ curve for this case is shown by Curve b in Fig. 7. The orientation angle of the plane of the hydrophilic group of α-TQ can not be determined because at least two observable transitions with different directions of the transition moments are necessary for its determination. However, if γ is not near 0°, then the O–O direction of the α-TQ chromophore should make contact angles with the water surface over a wide range from $\theta-\gamma$ to $\theta+\gamma$, for instance, from 56° to 124° for $\gamma=34°$. This also seems to be unnatural, and so we may guess that the value of γ is perhaps on the side near 0° in its admissible range. The red shift in the spectrum of the α-TQ monolayers can be explained in the same manner as in vitamin K_1 if γ is near 0° and if the chromophores of α-TQ are stacked at least in a short range. The η angle then becomes about 67°, which yields a red shift in the spectrum.

The direction of the transition moment in the chromophore of vitamin E was assumed to be perpendicular to the O–OH direction for the band at 292 nm, as is shown in Fig. 3, according to Nishimoto and Fujishiro's calculation of hydroquinone by the ASMO method.[25] The θ and γ angles which give the observed R value of 1.19 are in the following two ranges: $\theta=0$—30° and $\gamma=69$—90°, and $\theta=69$—90° and $\gamma=0$—30°. The former set seems to be inadequate for the same reason as in the case of α-TQ. Similarly, we may guess that γ has a value near 0° in its admissible range, shown by Curve c in Fig. 7. The spectrum of the vitamin E monolayers showed little shift in contrast with those of vitamin K_1 and α-TQ. The spectrum must show a red shift if γ is near 0° and if the chromophores are stacked in a short range, for η becomes about 69° when $\gamma\approx0°$. This suggests that the chromophores in a monolayer of vitamin E are not stacked even in a short range.

In ergosterol, the chromophore for the band from 262 nm to 294 nm is an *s-cis*-butadiene structure. The direction of its transition moment, calculated by the HMO method, roughly agrees with the direction of the molecular axis, as is shown in Fig. 4. We assume for this molecule that $\theta=0°$. From the observed values of R for the vibronic peaks at 262-, 270-, 282-, and 294-nm (Table 1), their γ's are determined to be 22°, 23°, 25°, and 27° respectively. The obtained values of γ agree nicely within an error of 5°. These values are also in good agreement with the tilt angle, 25°, suggested by Langmuir *et al.*[26] from a comparison of the thickness of the built-up film of ergosterol with the X-ray data of its crystal. This provides evidence in support of our method for the determination of the orientation angles. In ergosterol with $\theta=0°$, the η angle is equal to γ. The fact that the spectrum of the ergosterol monolayers showed little shift may be explained by the closeness of the orientation angle, $\gamma\approx24°$, to the critical angle, $\eta=35.3°$, where the molecular exciton theory predicts no-shift. The observed change in the relative absorption intensities at the three vibronic peaks suggests that the coupling between electrons and nuclear vibrations in the excited state suffers a change upon the formation of a monolayer.

The chromophore of vitamin D_2 for the band at 267 nm has a hexatriene structure. We calculated the direction of the transition moment by the HMO method. The chromophore moiety was regarded as plane, and the angles between the adjacent carbon atoms were assumed to be 120°. The result is shown by the arrow in Fig. 5. If the straight line joining the oxygen atom with the carbon atom, C_1, in Fig. 5 is regarded as the 2nd rotation axis, θ is about 56°. This θ value is very close to the angle, 54.7°, at which R equals unity independently of γ, and it is difficult to determine γ from R unless R is measured with a very high accuracy. If we put $\theta=56°$, we can not find the γ angle, which gives the observed value, 1.07 of R. This seems to be due to the insufficient accuracy of the measurement of R. Therefore, we can not get any information about the orientation of the vitamin D_2 molecule from the dichroic ratio. Vitamin D_2 in a monolayer, however, might have an orientation angle, γ, roughly as large as that of ergosterol, because its monolayer area is only slightly larger than that of ergosterol, according to the data of Langmuir *et al.*[26]

We summarize in Table 1 the orientation angles, γ and θ, or their admissible ranges, as determined from the dichroic ratio. The orientation angle, γ, of the principal axis of the ergosterol molecule was determined precisely as 24° (the average of the four values) within an error of 5°. This value is in good agreement with the value, 25°, suggested by Langmuir *et al.* For vitamin K_1, α-TQ, and vitamin E, only the admissible ranges for the orientation angles, γ and θ, were determined. The determined ranges for γ are similar for these three molecules. This suggests that they have a similar arrangement of the molecular axis in their monolayers, perhaps because of the similarity of their molecular structures. However, the shifts in their monolayer spectra suggest that the chromophores of vitamin K_1 and α-TQ are stacked at least in a short range, while those of vitamin E are not even in a short range. In vitamin D_2, no con-

clusion about the orientation of the molecules in its monolayer could be obtained because the value of θ is close to the angle, 54.7°, where the dichroic ratio, R, is independent of γ.

We would like to thank Professor Hans Kuhn for kindly sending us information about the electric circuit of the high-sensitivity spectrophotometer made in his laboratory.

Raman Study of Aqueous Solutions of Tetraalkylammonium and Bis(tetraalkylammonio) Electrolytes

Hiroyasu NOMURA,* Yoshiaki TSUKAMOTO, Ronald Ernest VERRALL,† and Yutaka MIYAHARA

Department of Chemical Engineering, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

† *Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan, S7N, OWO, Canada*

(Received October 11, 1979)

The Raman and infrared spectra of 1,4-bis(triethylammonio)butane dibromide (J4), 1,10-bis(triethylammonio)decane dibromide (J10), and tetraethylammonium bromide (TEABr) were measured in the solid and dissolved states. The Raman spectra of these salts in the solid and solution states were roughly similar to those of normal paraffins having the same number of skeletal atoms, but some minor differences were found. It was confirmed that molecular conformations of these ions in the solid and solution states are somewhat similar and take the all-trans form, but in main chain of J4 and J10, the gauche form is also observed. In addition, the effects of hydrophobic interaction of these salts in aqueous solution are discussed by comparison of the Raman spectra of OH stretching vibration region of water.

A number of nonspectroscopic studies of aqueous solutions of bolaform type electrolytes[1-4] have been reported with the object of investigating their effect on water structure and the ability of the bolaform cation to act as a model for cation-cation pairing in R_4NX systems. Unlike thermodynamic properties, spectroscopic investigations of aqueous solutions of these salts can provide additional information on the conformation of the hydrocarbon chains of these cations in solution.

In a previous paper,[5] it was confirmed by means of Raman spectroscopy that the molecular structure of the tetraalkylammonium ion in aqueous solution is an extended one, *i.e.*, the $-CH_2-$ groups assume an all-trans conformation, much the same as the lower members of the normal paraffin series of molecules.

In this study the Raman and infrared spectra of several bis(tetraalkylammonio) electrolytes and tetraethylammonium bromide were measured in the solid and dissolved states. In this paper emphasis is placed on obtaining information about molecular conformations of the hydrocarbon chains in aqueous solutions from a comparison of the analysis of the Raman spectra in both the solid and solution states. In addition, the effects of hydrophobic interaction of these salts in aqueous solution are discussed by comparison of the Raman spectra of the OH stretching vibration region of water with that for the pure solvent.

Experimental

Materials. Tetraethylammonium bromide, hereafter abbreviated as TEABr was of extra-pure reagent grade supplied by Nakarai Chemical Co., Ltd. The Bis(tetraalkylammonio)salts, 1,4-bis(triethylammonio)butane dibromide and 1,10-bis(triethylammonio)decane dibromide, abbreviated J4 and J10, respectively, were prepared and purified as described elsewhere.[4] Water used was deionized by ion-exchange-regin and distilled by means of usual laboratory techniques.

Apparatus. The apparatus used for Raman spectroscopy measurements consisted of an argon ion laser source manufactured by Coherent Radiation Co., Ltd. and the scattered light was analyzed with a JRS-Ul Laser Raman spectrometer from Japan Electron Optics Laboratory Co., Ltd. An A-2 IR spectrometer manufactured by Japan Spectroscopic Co., Ltd. was used to obtaine IR spectra.

Procedures. Solutions used for Raman measurements were prepared so as to contain 2 M** of bromide ion and $^+NEt_4$ unit, ($^+NEt_3-(CH_2)_2$ for the case of the bolaform cation). All measurements were carried out at room temperature.

The experiments were done using 90° scattering. The horizontal ($I_\parallel$) and vertical ($I_\perp$) components of the scattered light were measured with a polaroid analyzer.

The Raman spectra of water in the OH stretching region were obtained in aqueous solutions of TEABr, J4, and J10. The intensities were corrected for photomultiplier sensitivity. In the case of J10 it was impossible to correct the spectra owing to the existence of luminescence and consequently this salt was excluded from the analysis of salt effect on the OH vibrational spectra. The observed spectra were divided into their isotropic (I_{isot}) and anisotropic (I_{anis}) components.

$$I_{isot} = I_\parallel - 4/3\, I_\perp$$

$$I_{anis} = 4/3\, I_\perp$$

In the case of the infrared measurements, the solid sample was mixed with Nujol and measured at room temperature.

Results and Band Assignments

The Raman and infrared bands observed in the solid state and aqueous solutions are summarized in Table 1. The vibrational assignment of these bands was carried out on the basis of previous assignments made for normal paraffins,[6-9] and tetramethylammonium halides,[10-12] in the solid state.

At low frequencies (below 300 cm^{-1}), lattice modes, which are not observed in aqueous solutions, are found in the solid state for all compounds investigated. Commonly, the $C-N^+$ symmetric and asymmetric stretching bands are observed at about 700 cm^{-1} and 800 cm^{-1}, respectively. These bands are assigned on the basis of the following criteria: (1) The $C-N^+$ symmetric and asymmetric bands must be observed below 752 cm^{-1} and 955 cm^{-1}, respectively, since the corresponding bands for $(CH_3)_4N^+$ are centered at 752 cm^{-1} and 955 cm^{-1}, respectively and, for all compounds investigated in this work the mass of the substitutional groups on the N atom is heavier than that of $(CH_3)_4N^+$.

ρ: Depolarization ratio

(2) The C–N$^+$ symmetric stretching mode gives rise to the strong, polarized, Raman bands usually observed. (3) The asymmetric stretching mode gives rise to the depolarized Raman line and strong infrared band commonly observed. Above 900 cm^{-1}, the Raman and infrared spectra of all compounds investigated are roughly similar to those of normal paraffins having the same number of skeletal atoms.

The band assignments were made from consideration of those criteria and are summarized in the last column of Table 1. A careful comparison of the Raman spectra of solid state and aqueous solution shows that some minor differences exist for the compounds investigated. Therefore it appears that the molecular conformations in the solid and solution states are somewhat similar.

Discussion

Low Frequency Regions (below 500 cm^{-1}). The Raman spectra for each compound in the frequency range below 500 cm^{-1} are shown in Fig. 1. In the solid state, several lattice modes are observed, but in aqueous solutions, these lattice modes disappear. Also, some longitudinal accoustic vibrational modes (LA mode) are observed in both the solid phase and aqueous solution, X-ray crystallographic studies have shown[13,14] that the chain conformation of $-CH_2-$ groups in normal paraffins and in tetraalkylammonium ions are in all-trans form. By analogy with these results, the chain conformations in the Bis(tetraalkylammonio) salts in the solid state can be considered to be in all-trans form.

The LA mode is regarded as a symmetric accordion-type longitudinal vibration of a string of beads with antinodes at the chain ends. Therefore, this band is ascribed to the molecules taking an all-trans form. In the previous paper,[5] studies were reported on the LA band of tetraalkylammonium ions. From the existence of the LA band, it was confirmed that the tetraalkylammonium ions in the solid and aqueous solution are in an extended form, such as the all-trans form of the $-CH_2-$ chain.

For TEA ion, the LA bands were observed at 424 cm^{-1} in the solid and 420 cm^{-1} in aqueous solution.[5] A strong peak is observed at about 420 cm^{-1} in the Raman spectra of J4 and J10 in both states. This band corresponds to the LA band of TEA ion and is ascribed to the LA band in the Et–N–Et structure of the bolaform ion. Therefore, the Et–N–Et structure is mostly in the all-trans form in both states.

In solid J4 and J10, the LA bands of the main chain were also observed, although they were weak. These were identified by the criterion that the frequency of the band decreases as the length of the carbon chain (involving nitrogen atom) increases. The relationship between the frequency of the LA band and the reciprocal carbon number shown in Fig. 2 along with the corresponding relationship for tetraalkylammonium ions.[5] The existence of this band indicates the molecules take an all-trans form in main chain in the solid state. This band is observed weakly in aqueous solution of J4, but not in aqueous solution of J10. Therefore, it appears that in aqueous solution the J4 ions assume an all-trans conformation to some extent but less in those of the J10 ion. This result may be rationalized on the basis that random conformation in the main chain increases as the distance between the two charged nitrogen atoms increases and hence the repulsive force decreases.

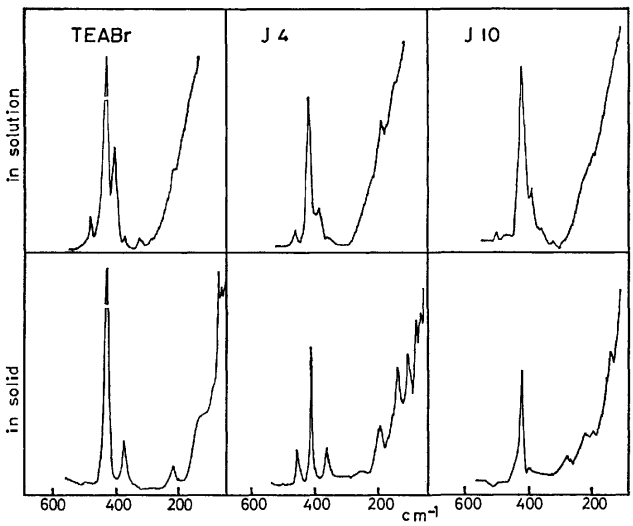

Fig. 1. Raman spectra for TEABr, J4, and J10 in the frequency range below 500 cm^{-1} in the solid and solution states.

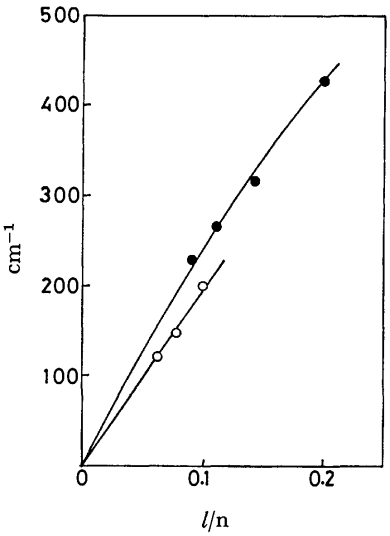

Fig. 2. Relationship between the frequencies of the LA mode and the reciprocal carbon number (involving nitrogen atom); (○) bolaform ions, (●) tetraalkylammonium ions.

Intermediate Frequency Regions (500 cm^{-1}—1400 cm^{-1}). The solution and solid state Raman spectra of TEABr, J4, and J10 are shown in Figs. 3, 4, and 5, respectively. Some minor differences are observed between the two phases. In the case of TEABr, Raman lines observed in aqueous solution at 467 cm^{-1} and 559 cm^{-1} are not seen in the solid state. These lines are ascribed to the rotational conformations around the $-CH_2-CH_2-$ bonds.

In the Raman spectra of J4, the two bands at 466

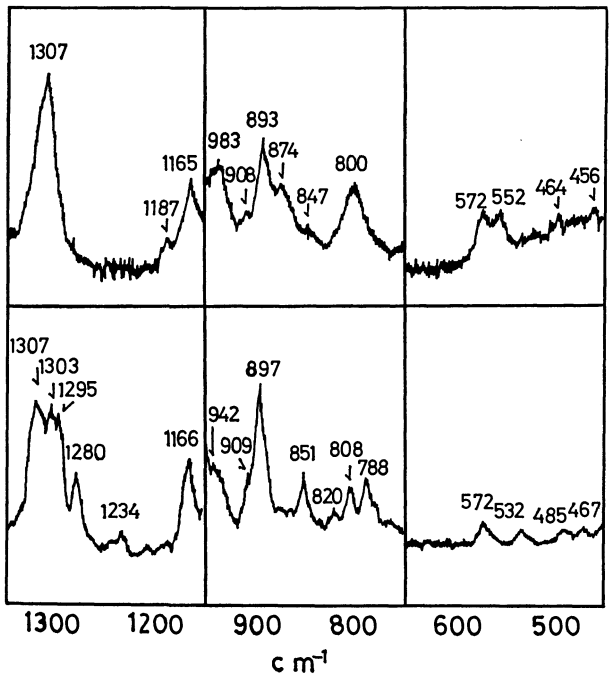

Fig. 3. Raman spectra of TEABr in the solid and solution states in the frequency range from 500 cm^{-1} to 1400 cm^{-1}.

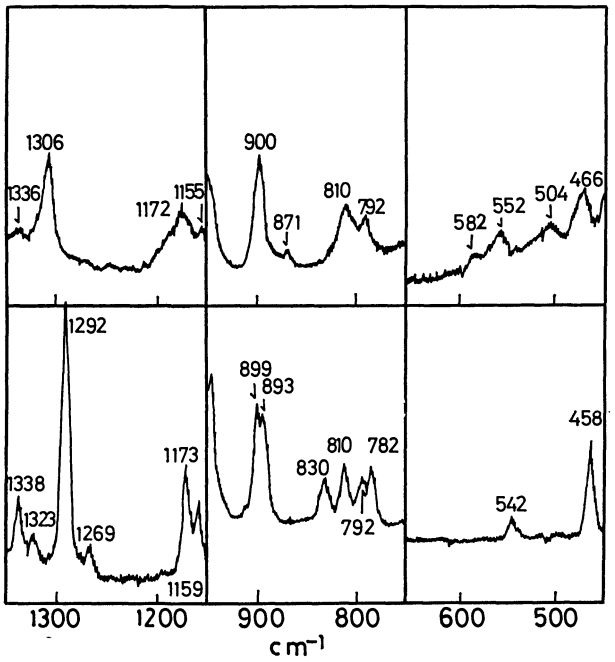

Fig. 4. Raman spectra of J4 in the solid and solution states in the frequency range from 500 cm^{-1} to 1400 cm^{-1}.

cm^{-1} and 552 cm^{-1} in aqueous solution are also observed in the solid state. These lines correspond closely to the Raman bands of TEABr at 467 cm^{-1} and 559 cm^{-1} in aqueous solution, which have been attributed to the *gauche* conformation around the $-CH_2-CH_2-$ bonds. Accordingly, the molecular structures taking a *gauche* conformation in the Et–N structure of J4 exist both in aqueous solution and in the solid state. Further, since the two Raman lines at 504 cm^{-1} and

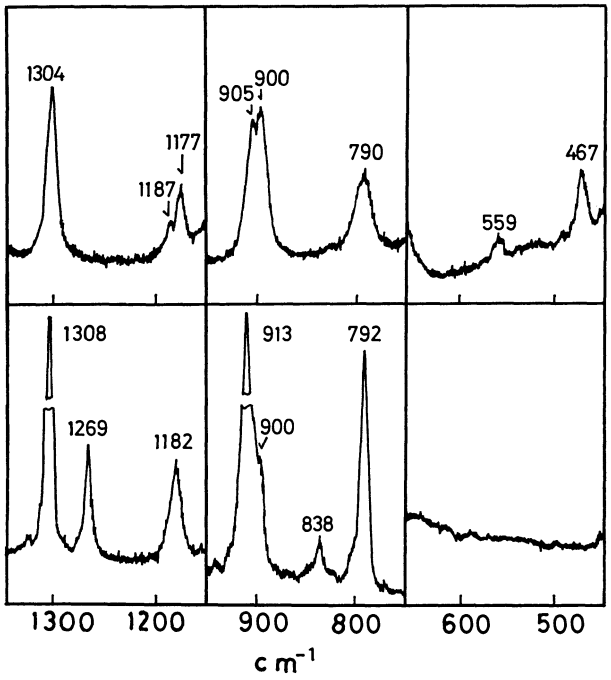

Fig. 5. Raman spectra of J10 in the solid and solution states in the frequency range from 500 cm^{-1} to 1400 cm^{-1}.

582 cm^{-1} in aqueous solution are not observed in the solid state, these may indicate that they are the *gauche* isomers that relate to the main chain of the J4 ions.

For the J10 salt, the two Raman lines observed in solution at 456 cm^{-1} and 552 cm^{-1} are also observed in the solid state. They correspond to those of TEABr at 467 cm^{-1} and 559 cm^{-1} in aqueous solution and have been ascribed to gauche conformation. Therefore, the molecular units taking a gauche conformation in the Et–N chain of J10 exist in both aqueous solution and solid phases. The two Raman lines at 494 cm^{-1} and 572 cm^{-1} in aqueous solution are also found in the solid state. These lines correspond to those of J4 at 504 cm^{-1} and 582 cm^{-1} in aqueous solution, which have been ascribed to the gauche isomers in the main chain. Accordingly, the molecules taking *gauche* form in main chain exist in both states.

The bands located at 1269 cm^{-1} for J4 and 1234 cm^{-1}, 1230 cm^{-1}, 1295 cm^{-1}, and 1303 cm^{-1} for J10 are observed only in the solid state. These bands can be assigned to the twisting-rocking mode of $-CH_2-CH_2-$ groups in the molecular chains. The fact that these bands are not observed in solution indicates that the motion of the $-CH_2-CH_2-$ groups in the main chains of the ions are less constrained. The bands located at 838 cm^{-1} for TEABr, 830 cm^{-1} for J4, and 820 cm^{-1} for J10 are observed in the solid state, but not in solution. Also, the bands located at 782 cm^{-1} for J4 and 788 cm^{-1} for J10 are not observed in solution. Although at this stage we can not assign these bands to the internal motions of these molecules, one may speculate that these bands are related to the terminal $-CH_2-CH_3$ rocking-twisting vibrational modes.

C–H Stretching Vibration Regions (2850 cm^{-1}*—3000*

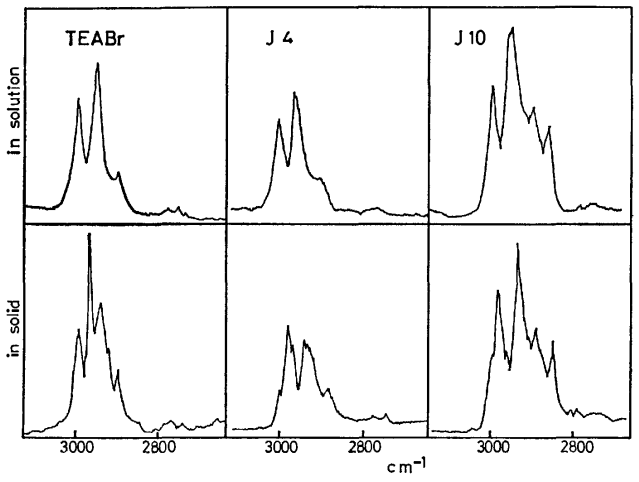

Fig. 6. Raman spectra for TEABr, J4, and J10 in the frequency range from 2850 cm^{-1} to 3000 cm^{-1} in the solid and solution states.

cm^{-1}). The vibrational C–H stretching modes can be classified into two groups; one from the methyl end group and the other arising from the methylene group vibrations. The symmetric and asymmetric methyl C–H stretching vibrations located at 2884 cm^{-1} and 2967 cm^{-1} are independent of the chain length in normal paraffins.[7] On the other hand, the methylene symmetric and asymmetric vibrations located at 2849 cm^{-1}—2861 cm^{-1} and 2912 cm^{-1}—2929 cm^{-1} are slightly dependent on the chain length.[7]

The Raman spectra for each compound in this frequency range are shown in Fig. 6. As can be seen, there are many bands which can be assigned to the methylene group vibration in the solid state. On the other hand in solution, only three bands are observed in each compound, located at about 2900 cm^{-1}, 2951 cm^{-1}, and 2997 cm^{-1} and these frequencies are almost independent of the chain length. In the case of the J10 ion in solution, one additional band at 2861 cm^{-1} is observed. This band can be assigned to the methylene symmetric stretching band. As J10 has 16 $-CH_2-$ units in an ion, this weak band is likely to be observed in the case of J10.[11] The reason that only three bands are observed in the solution state may be due to the fact that, since in the solution state the C–C bond of the main chain and branched chains are rotating or tumbling, then the C–H stretching vibration mode of the methylene groups will be strongly coupled to each other and leads to a reduction in the number of observed bands.

Raman Spectra of Water, OH Stretching Region. The isotropic (I_{isot}) and anisotropic (I_{anis}) Raman spectra of water and aqueous solutions of TEABr and J4 are shown in Fig. 7. The main effect of the salts on the water spectra is to change the spectral line shape. The opposing results are clearly evident for the I_{isot} and I_{anis} spectra; intensities in the lower frequency region (3000 cm^{-1}—3350 cm^{-1}) decrease while intensities in the higher frequency region (3350 cm^{-1}—3550 cm^{-1}) increase, in comparison with the spectrum of water. The effect of salt addition to water is similar to the effects produced by increasing

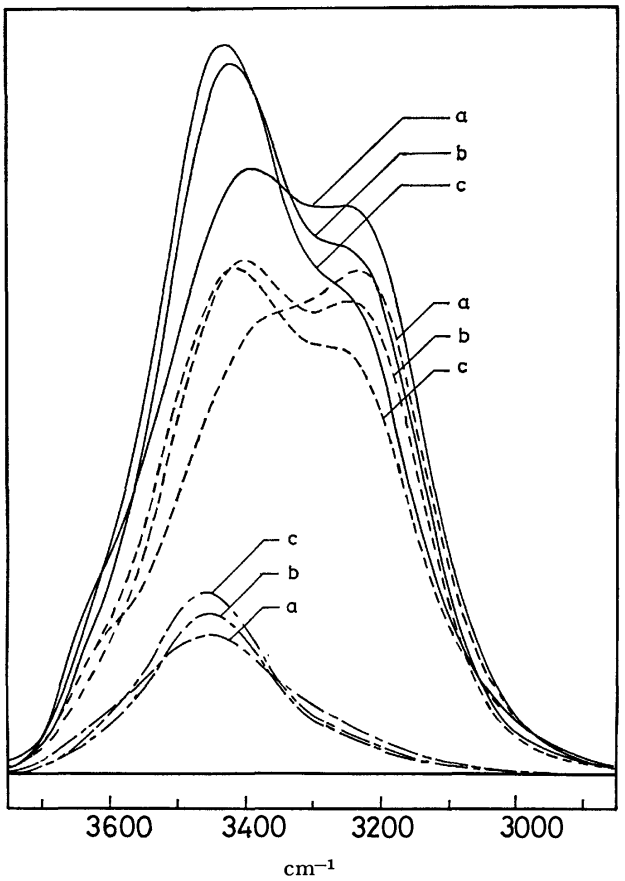

Fig. 7. Effects of added salts on the OH stretching vibration regions; —— observed, —-- isotropic parts, and —•— anisotropic ones.
(a) Water, (b) aqueous solution of TEABr, and (c) aqueous solution of J4.

temperature.[15–17] Therefore these salts, at least superficially seem to have a structure breaking effect on water at these high concentration and this is contrary to their structure-enforcing effect at dilute concentration. The influence of the TEA ion on the OH stretching region is greater than that of the J4 ion. The main effects of these salts on the water structure are of an electrostatic and hydrophobic nature.

Since the molecular conformations of the TEA and J4 ions are both observed to be of the extended form in aqueous solutions and the salt concentrations have been prepared so as to normalize the hydrophobic effect (approximately same hydrocarbon concentration for each ion in solution), it would appear that the difference in line shape for the OH stretching vibration in aqueous solutions of these salts is caused by the electrostatic atmosphere of the ion. The presence of two charged sites in a single ion and the incompatibility of several "type" of water around the solute to "interface" readily indicate the J4 ions are more complex in their influence on solvent interactions.

The Adsorption of Dodecyldimethylammonium Chloride on Aqueous Surfaces of Concentrated NaCl Solutions

Sumio Ozeki and Shoichi Ikeda*

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received October 18, 1979)

Surface tension of aqueous NaCl solutions of dodecyldimethylammonium chloride has been measured at high NaCl concentrations. Surface excesses of surfactant cation, Na^+ and Cl^- are derived by means of the Gibbs adsorption isotherm from the derivatives of surface tension with respect to surfactant concentration and NaCl concentration. The rational mean activity coefficients of surfactant and NaCl are both approximated by a common expression satisfying the Brönsted principle for mixed electrolytes but including the ionic strength as a variable. Saturated value of surface excess of surfactant cation remains constant at low NaCl concentrations up to 0.10 M, while it increases as the NaCl concentration exceeds 0.50 M. The adsorption of Na^+ is negative at low NaCl concentrations, but it increases rapidly and is positive above 0.50 M NaCl. Surfactant and NaCl are subject to the strong salting-out effect when the NaCl concentration is higher than 0.50 M. The Corrin-Harkins plot of the critical micelle concentration at high NaCl concentrations deviates from the straight line.

Recently[1,2] we have developed a general method for applying the Gibbs adsorption isotherm to aqueous solutions of electrolytes and elucidated implication of the Gibbs convention for the dividing surface and distinction of chemical species from components in the multicomponent system. The method enables us to derive the surface excesses of surfactant ion, coion and counterion from surface tension data, when it is applied to aqueous solutions containing an ionic surfactant and a simple salt, having a common counterion, but without forming any micelle yet.

In a previous paper[3] we have published some results of surface tension measurements on aqueous NaCl solutions of dodecyldimethylammonium chloride and derived the surface excesses of surfactant cation (D^+), Na^+, and Cl^- by means of the Gibbs adsorption isotherm. The previous work was restricted to the region of NaCl concentrations less than 0.50 M, and the mean activity coefficients of surfactant and NaCl were both approximated by the limiting expression of the Debye-Hückel equation. Then we obtained a strongly positive adsorption of surfactant cation at the saturation. However, we also found a small positive adsorption for Na^+ or coion, which would not necessarily be reasonable in the presence of dilute NaCl, because coions should be repelled from the surface dominantly occupied by surfactant cations.

In the present work we will extend the surface tension measurements on the same solutions up to the region of higher NaCl concentrations and examine how the surface excesses of ions are influenced by the salting-out effect. In this paper we will present the experimental results obtained in the present work and also include the previous data together. We will develop a treatment based on more exact expressions for the mean activity coefficients of electrolytes and apply it to obtain surface excesses of surfactant cation, Na^+ and Cl^-.

Experimental

Dodecyldimethylammonium chloride was prepared from *N,N*-dimethyldodecylamine by passing dry HCl gas, as previously described.[3] Commercial dimethyldodecylamine was purchased from Tokyo Kasei Kogyo Co., Inc., and purified by fractional distillation.

Surface tension of aqueous solutions was determined at 25±0.01 °C by means of the drop weight method, in the same way as previously performed.[3]

Results

Figure 1 shows the relation of surface tension, γ, with logarithm of molar concentration of surfactant, log C, at different NaCl concentrations, C_s. Surface tension decreases with increasing surfactant concentration and also with increasing NaCl concentration. At concentrations higher than the critical micelle concentration, C_0, surface tension always remains constant. The lowering of surface tension is formally represented by

$$-\mathrm{d}\gamma = RT\{\Gamma_2'\mathrm{d}\ln C + \Gamma_3'\mathrm{d}\ln C_s\} \quad (1)$$

where R is the gas constant and T is the temperature. The apparent surface excesses are defined by

$$\Gamma_2' = -\frac{1}{RT}\left(\frac{\partial\gamma}{\partial\ln C}\right)_{C_s} \quad (2)$$

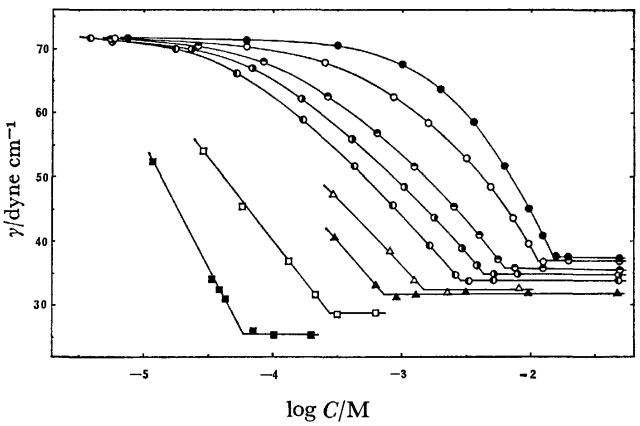

Fig. 1. Variation of surface tension with logarithm of surfactant concentration at different NaCl concentrations.
C_s (M): ●; 0, ○; 0.01, ◓; 0.05, ◑; 0.10, ◐; 0.20, △; 0.50, ▲; 0.94, □; 2.00, ■; 4.00.

† 1 M=1 mol dm^{-3}, 1 dyne cm^{-1}=1 mN m^{-1}.

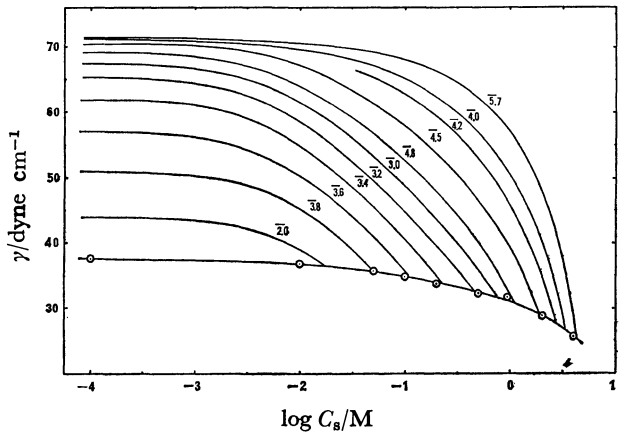

Fig. 2. Variation of surface tension with logarithm of NaCl concentration at different surfactant concentrations. Values of log C are given for the curves obtained by interpolation. ○, Constant surface tension at a given NaCl concentration, obtained at surfactant concentrations higher than the critical micelle concentration.

Table 1. Critical micelle concentration, apparent surface excess and surface tension associated with aqueous NaCl solutions of dodecyldimethylammonium chloride

C_s (M)	C_0 (10^{-3} M)	Γ_2' at C_0 (10^{-10} mol cm^{-2})	γ at C_0 (dyne cm^{-1})
0	14.7	7.66	37.6
10^{-4}	14.6	6.90	37.6
0.01	11.4	6.34	36.9
0.05	6.27	4.64	35.8
0.10	4.29	4.39	34.8
0.20	2.84	4.13	33.9
0.50	1.48	4.02	32.4
0.94	0.725	4.03	31.8
2.00	0.276	4.52	28.8
4.00	0.059	6.74	25.6

$$\Gamma_2' = -\frac{1}{RT}\left(\frac{\partial \gamma}{\partial \ln C_s}\right)_C. \tag{3}$$

As can be seen in Fig. 1, it is clear that $\Gamma_2'=0$ for $C>C_0$.

In Fig. 2 surface tension is plotted against log C_s at different surfactant concentrations. The lowest curve gives dependence of the constant surface tension on NaCl concentration, the constancy being observed at concentrations higher than the critical micelle concentration.

Table 1 summarizes related numerical data derived from Figs. 1 and 2, together with those previously obtained. With increasing NaCl concentration, the value of Γ_2' decreases in the range of NaCl concentrations up to 0.50 M, and then it increases rapidly at higher NaCl concentrations. In addition, the constant value of surface tension observed above C_0 is lowered with increasing NaCl concentration. The critical micelle concentration decreases with increasing NaCl concentration.

Discussion

The Gibbs Adsorption Isotherm. We will be mainly concerned with the adsorption of ions in the region of concentrations lower than the critical micelle concentration. It was shown[1] that the Gibbs adsorption isotherm for aqueous solutions containing DCl (dodecyldimethylammonium chloride) and NaCl can be expressed by either

$$-d\gamma = \Gamma_{D^+}d\mu_{D^+} + \Gamma_{Na^+}d\mu_{Na^+} + \Gamma_{Cl^-}d\mu_{Cl^-} \tag{4}$$

or

$$-d\gamma = \Gamma_{D^+}d\mu_{DCl} + \Gamma_{Na^+}d\mu_{NaCl} \tag{5}$$

provided that no micelle is formed yet. Here Γ_i is the surface excess of species or component, i, and μ_i is its chemical potential. Equation 4 is subject to an electroneutrality condition

$$\Gamma_{D^+} + \Gamma_{Na^+} = \Gamma_{Cl^-} \tag{6}$$

while Eq. 5 is free from such a subsidiary condition.

The chemical potentials of DCl and NaCl are given by

$$\mu_{DCl} = \mu^\circ_{DCl} + RT \ln y_\pm^2 C_{D^+}C_{Cl^-} \tag{7}$$

$$\mu_{NaCl} = \mu^\circ_{NaCl} + RT \ln y_{s\pm}^2 C_{Na^+}C_{Cl^-} \tag{8}$$

where the superfix ° means the standard states assigned to 1 M DCl and 1 M NaCl, respectively, in the ideal state, and $y_\pm$ and $y_{s\pm}$ are the mean activity coefficients of DCl and NaCl. The molar concentrations of ions are expressed by

$$C_{D^+} = C,\ C_{Na^+} = C_s, \text{ and } C_{Cl^-} = C + C_s. \tag{9}$$

The molar mean activity coefficients of DCl and NaCl, $y_\pm$ and $y_{s\pm}$, can be related to their rational mean activity coefficients, $f_\pm$ and $f_{s\pm}$, by[5a]

$$\frac{y_\pm}{f_\pm} = \frac{y_{s\pm}}{f_{s\pm}} = \frac{\rho_w}{\rho - \dfrac{M-2M_w}{1000}C - \dfrac{M_s-2M_w}{1000}C_s} \tag{10}$$

where M_w, M, and M_s are the molecular weights of water, DCl, and NaCl, respectively, and ρ_w and ρ are the densities of water and the solution respectively.

It will be demonstrated below that the rational mean activity coefficients of DCl and NaCl can be approximately represented by an identical expression as a function of ionic strength, $C+C_s$. Then we have identities and introduce abbreviations as follows:

$$\eta = \left(\frac{\partial \ln y_\pm^2}{\partial C}\right)_{C_s} = \left(\frac{\partial \ln y_{s\pm}^2}{\partial C}\right)_{C_s} \tag{11}$$

$$\eta_s = \left(\frac{\partial \ln y_\pm^2}{\partial C_s}\right)_{C} = \left(\frac{\partial \ln y_{s\pm}^2}{\partial C_s}\right)_{C} \tag{12}$$

Introducing these approximations we arrive at the expression of Gibbs adsorption isotherm in the form of Eq. 1, in which the apparent surface excesses are given by

$$\Gamma_2' = \left(1+\frac{C}{C+C_s}+\eta C\right)\Gamma_{D^+} + \left(\frac{C}{C+C_s}+\eta C\right)\Gamma_{Na^+} \tag{13}$$

$$\Gamma_3' = \left(\frac{C_s}{C+C_s}+\eta_s C_s\right)\Gamma_{D^+} + \left(1+\frac{C_s}{C+C_s}+\eta_s C_s\right)\Gamma_{Na^+}. \tag{14}$$

By solving Eqs. 13 and 14 we obtain the surface excesses of D^+ and Na^+, and also, together with Eq. 6 we have the surface excess of Cl^-.

$$\Gamma_{D^+} = \frac{1}{2+\eta C+\eta_s C_s}\left\{\left(1+\frac{C_s}{C+C_s}+\eta_s C_s\right)\Gamma_2' - \left(\frac{C}{C+C_s}+\eta C\right)\Gamma_3'\right\} \quad (15)$$

$$\Gamma_{Na^+} = \frac{1}{2+\eta C+\eta_s C_s}\left\{-\left(\frac{C_s}{C+C_s}+\eta_s C_s\right)\Gamma_2' + \left(1+\frac{C}{C+C_s}+\eta C\right)\Gamma_3'\right\}, \quad (16)$$

and

$$\Gamma_{Cl^-} = \frac{1}{2+\eta C+\eta_s C_s}(\Gamma_2'+\Gamma_3'). \quad (17)$$

It can be readily seen from Eq. 15 that

$$\Gamma_{D^+} = \Gamma_2' \quad (18)$$

provided that C_s is very high or much higher than C. That is, the value of Γ_{D^+} is independent of the choice of activity coefficients of DCl and NaCl, if the NaCl concentration is sufficiently high.

The Mean Activity Coefficients and Their Derivatives. The molar mean activity coefficients of DCl and NaCl are related to their rational mean activity coefficients by means of Eq. 10. We will derive the approximate forms of rational mean activity coefficients of DCl and NaCl in their mixed solutions as follows.

According to Brönsted's principle of specific interaction of ions,[4,5d] the rational mean activity coefficients can be written

$$\log f_\pm = -\frac{P\sqrt{C+C_s}}{1+Qa\sqrt{C+C_s}} + BC + B_{Cl\text{-}C_s} \quad (19)$$

$$\log f_{s\pm} = -\frac{P\sqrt{C+C_s}}{1+Qa\sqrt{C+C_s}} + B_s C_s + B_{Cl\text{-}C} \quad (20)$$

where the constants, P and Q, of the Debye-Hückel electrostatic term are determined by temperature and dielectric constant, and the ionic radius, a, serves as an adjustable parameter.[5b] The salting-out constants, B and B_s, are characteristic of DCl and NaCl, respectively, and the specific ion interaction constant, B_{Cl^-}, represents the averaged specific interaction of Cl^- with D^+ and Na^+. Our experimental range covers 0—10^{-2} M for C and 0—4.00 M for C_s.

In a recent work Cutler, Meares, and Hall[6] measured the activity coefficients of sodium dodecyl sulfate in NaCl solutions and found that the mean activity coefficient obeys the Debye-Hückel equation of Guggenheim type, that is, P=0.5115 and Qa=1.000 in Eq. 19, when the NaCl concentration is in the range of 0—0.2 M and the surfactant concentration is lower than the critical micelle concentration. This means that an ionic surfactant behaves like a simple salt such as NaCl unless micelles are formed. Then we may anticipate that the activity coefficient of dilute surfactant obeys Eq. 19, in which the salting-out term is negligibly small.

Robinson and Stokes[5c] published following values of parameters in Eq. 20 which fit well the observed values of $\log f_{s\pm}$ for NaCl solutions up to 2.00 M at 25 °C.

$$P = 0.5115, \quad Qa = 1.316, \quad B_s = 0.055 \quad (21)$$

In Eq. 19 we will also be able to use the identical value of Qa, because of thermodynamic requirement and of small contribution of the ionic-size term. In addition, since the value of C is small, it will not introduce serious errors even if we put $B=B_s$.

We have scarce information about the value of B_{Cl^-}. The result of Cutler *et al.*[6] suggests that the last term of Eq. 19 is negligibly small when C_s is lower than 0.2 M. We may expect that the value of B_{Cl^-} is not very large. Then the last term of Eq. 20 would have a small magnitude as compared to the other two terms: if C_s is as low as 0.01 M, the term will be negligible in comparison with the former, and if C_s is higher, the term will be much smaller than the salting-out term. Considering such a small contribution of this term and also the principle of ionic strength, we may include it in a single term without serious errors by putting $B_{Cl^-}=B$.

In this approximation we have a common expression for the molar mean activity coefficients of DCl and NaCl:

$$\log f_\pm = \log f_{s\pm} = -\frac{P\sqrt{C+C_s}}{1+Qa\sqrt{C+C_s}} + B_s(C+C_s) \quad (22)$$

together with Eqs. 21. Then we obtain

$$\eta = \eta_0 + \frac{2\left[\left(\frac{\partial\rho}{\partial C}\right)_{C_s} - \frac{M-2M_w}{1000}\right]}{\rho - \frac{M-2M_w}{1000}C - \frac{M_s-2M_w}{1000}C_s} \quad (23)$$

$$\eta_s = \eta_0 + \frac{2\left[\left(\frac{\partial\rho}{\partial C_s}\right)_{C} - \frac{M_s-2M_w}{1000}\right]}{\rho - \frac{M-2M_w}{1000}C - \frac{M_s-2M_w}{1000}C_s} \quad (24)$$

where

$$\eta_0 = -\frac{2.303P}{(1+Qa\sqrt{C+C_s})^2\sqrt{C+C_s}} + 4.606B_s. \quad (25)$$

For actual calculations of ρ and $(\partial\rho/\partial C_s)_C$ we may use the literature values of density of NaCl solutions.[7] The density of aqueous electrolyte solutions can be represented by a quadratic form of molal concentration, m_s, up to 4.00 M, which is equivalent to write

$$\frac{C_s}{m_s} = \rho_w - \alpha m_s \quad (26)$$

where α is a constant. For NaCl solutions at 25 °C, ρ_w=0.9970 g cm^{-3} and α=0.0183. It is found alternatively that

$$\rho = \rho_w + 0.00387\sqrt{C_s} + 0.0362C_s. \quad (27)$$

For the calculation of $(\partial\rho/\partial C)_{C_s}$, which is given by

$$\left(\frac{\partial\rho}{\partial C}\right)_{C_s} = \frac{M(1-\bar{v}\rho_0)}{1000} \quad (28)$$

at low C values, we have used the value of partial specific volume of DCl, $\bar{v}$, in water, 1.06,[8] where ρ_0 is the density of water or NaCl solutions.

Surface Excesses of Ions. Figure 3 shows the surface excesses of D^+, Na^+, and Cl^- as functions of surfactant concentration. It is seen in Fig. 3 (a)

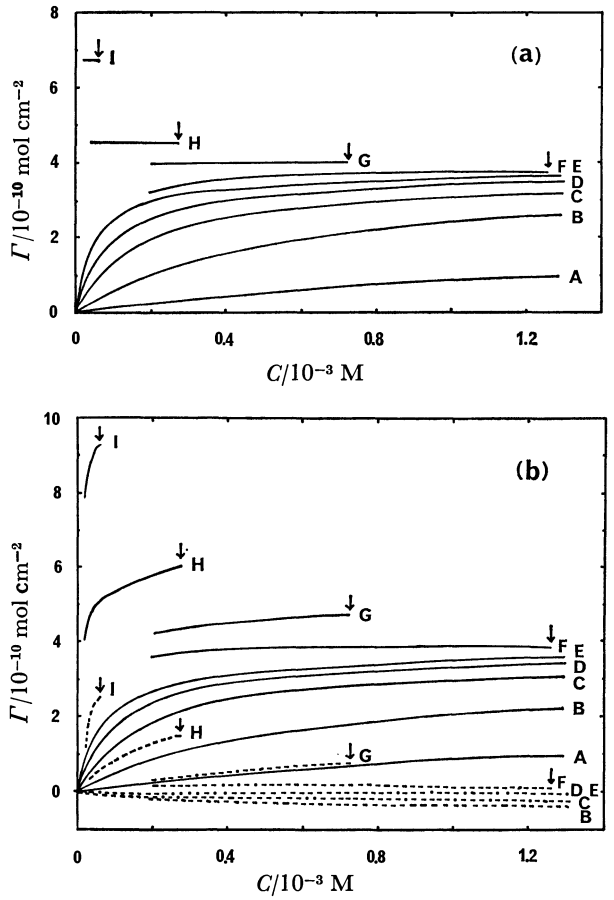

Fig. 3. Adsorption isotherms of ions on aqueous surfaces of different NaCl concentrations. (a) Γ_{D^+} *vs.* C; (b) Γ_{Na^+} (----) and Γ_{Cl^-} (——) *vs.* *C*. Arrows indicate the location of critical micelle concentrations. C_s (M): A; 0, B; 0.01, C; 0.05, D; 0.10, E; 0.20, F; 0.50, G; 0.94, H; 2.00, I; 4.00.

that the value of Γ_{D^+} increases more rapidly and reaches the saturated value at a lower concentration, as the NaCl concentration is higher. This is caused by the electrostatic shielding effect of added NaCl on the charged layer of adsorbed surfactant. When the NaCl concentration exceeds 0.20 M, the value of Γ_{D^+} has already reached the saturated value and is constant at the concentration range in concern. Table 2 gives the saturated values of Γ_{D^+} at different NaCl concentrations, which are obtained as the values of Γ_{D^+} at the critical micelle concentration. Figure 4 shows the saturated value of Γ_{D^+} as a function of NaCl concentration. With increasing NaCl concentration, the saturated adsorption of surfactant cation is at first almost constant and then slightly decreases. When the NaCl concentration exceeds 0.50 M, the adsorption increases at higher NaCl concentrations. This increase in adsorption must be ascribed to the salting-out effect of NaCl. The observed behavior of saturated adsorption of dodecyldimethylammonium ion is different from that of dodecyl sulfate ion, since it was reported for aqueous solutions of sodium dodecyl sulfate[9–11] that the adsorption of dodecyl sulfate ion is strongly promoted by the addition of NaCl up to 0.1 M. The difference in adsorption behavior between

C_s (M)	Γ_{D^+} at C_0 (10^{-10} mol cm^{-2})	Γ_{Na^+} at C_0 (10^{-10} mol cm^{-2})	Γ_{Cl^-} at C_0 (10^{-10} mol cm^{-2})
0	4.13[a)]	—	4.13[a)]
0.01	4.27	−0.36	3.91
0.05	4.26	−0.23	4.03
0.10	4.25	−0.16	4.09
0.20	4.08	−0.01	4.07
0.50	4.01	0.09	4.10
0.94	4.03	0.67	4.70
2.00	4.52	1.49	6.01
4.00	6.74	2.51	9.25

a) These values were calculated by using the limiting expression of Debye-Hückel equation for the mean activity coefficient of surfactant.

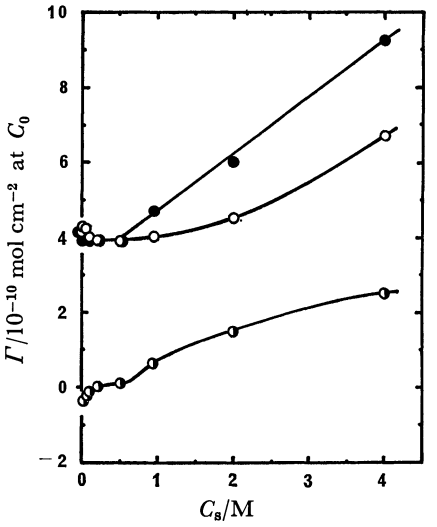

Fig. 4. Surface excesses of ions at the critical micelle concentration plotted against NaCl concentration. ○; Γ_{D^+}, ◑; Γ_{Na^+}, ●; Γ_{Cl^-}.

these surfactants must be elucidated in future work.

It is seen in Fig. 3 (b) that the adsorption of Na^+ and Cl^- is still increasing without reaching their saturation even at the critical micelle concentration, if the NaCl concentration is higher than 0.50 M. Values of Γ_{Na^+} and Γ_{Cl^-} at the critical micelle concentration are also listed in Table 2, and they are plotted as functions of NaCl concentration in Fig. 4. Previously,[3] the value of Γ_{Na^+} was calculated at low NaCl concentrations, by assuming the limiting expression of Debye-Hückel equation for activity coefficients, and it was found to be positive. In the present treatment assuming a more exact equation for the activity coefficients, the value of Γ_{Na^+} at the critical micelle concentration is negative at low NaCl concentrations, and then it turns to be positive at NaCl concentrations higher than 0.10 M. The negative adsorption of coion, Na^+, at low NaCl concentrations seems to be more reasonable. The initial negative adsorption of Na^+ decreases with increasing NaCl concentration, which numerically comes from the contribution of the effect

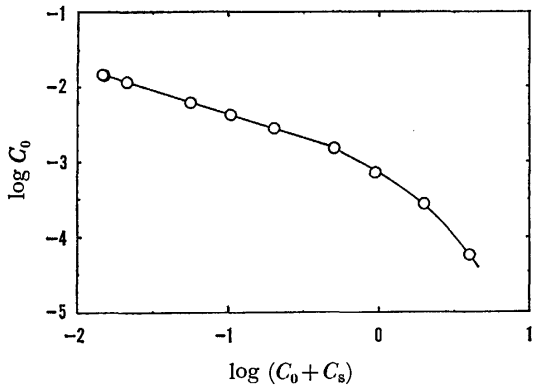

Fig. 5. The Corrin-Harkins plot. Relation of logarithm of critical micelle concentration with logarithm of chloride ion concentration.

of ionic size represented by the term, Qa, in Eq. 22. In the Gouy theory of diffuse double layer an increase in negative adsorption of coion should occur when the NaCl concentration increases. The marked increase in positive adsorption of Na^+ observed at NaCl concentrations higher than 0.50 M is caused by the salting-out term, B_s, of Eq. 22.

In the above treatment we have made some simplification to express the two rational activity coefficients in the common form, Eq. 22. In Eq. 19 we could also set $B=B_{Cl^-}=0$, as was found by Cutler *et al.*,[6] but this would not be applicable for the region of higher NaCl concentrations. If we assume $B=B_{Cl^-}=0$, however, Eq. 16 leads to much larger values of Γ_{Na^+} at higher NaCl concentrations. We may then conclude that the approximate form of activity coefficients, Eq. 22, is effective in the Gibbs adsorption isotherm for mixed solutions of an ionic surfactant and a simple salt, as far as the surfactant does not form micelles.

The Corrin-Harkins Relation. Previously[3] we have demonstrated that the Corrin-Harkins plot of the critical micelle concentration is linear up to 0.20 M NaCl. As can be seen in Fig. 5, however, such a linear relation no longer holds between logarithm of critical micelle concentration and logarithm of ionic strength, when the plot is extended to higher NaCl concentrations. It seems likely that the linear Corrin-Harkins relation is closely connected with the electrostatic shielding effect of simple salt but is disrupted by the other effects such as counterion binding and salting-out.

In a current paper[12] we are reporting the same results on the critical micelle concentration determined by light scattering. According to the results of light-scattering measurement, the Corrin-Harkins plot is linear as far as the spherical micelles are formed, but it deviates from the straight line when the rod-like micelles become more stable. It is inferred that the sphere-rod transition of ionic micelles would be caused by the difference in electrostatic effect of added salt, or, more directly, in the degree of counterion binding.

The Gibbs Adsorption Equation for Aqueous Solutions Containing a Weak Base

Shoichi IKEDA* and Sumio OZEKI

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received October 18, 1979)

The Gibbs adsorption isotherm for quaternary systems of water, weak base, HCl or NaOH, and NaCl including a vapor-solution interface is expressed in terms of variations of chemical potentials of neutral components added to make up the solution. Four systems are treated, and the Gibbs convention is introduced in such a way that the surface excess of added water is zero and the surface excesses of solute components are defined. Assuming that the activity coefficients of solute components are unity, the lowering of surface tension is given in terms of variations of total molar concentrations of weak base or its hydrochloride, HCl or NaOH, and NaCl, or of pH of the solution.

Recently[1,2] we have established a general method for applying the Gibbs adsorption isotherm to aqueous solutions containing two or three electrolytic solutes, either strong or weak. So far there has been no clear cognizance for an electrolyte solution containing two kinds of electrolytic solutes to be a multicomponent system, and, when the Gibbs adsorption isotherm has been applied to an aqueous solution of an ionic surfactant and a simple salt, the lowering of surface tension of the solution has been exclusively connected with the variation of surfactant concentration alone.[3–6] We have pointed out[1,2] that such an aqueous solution must be treated as a ternary system and the lowering of surface tension should be represented as a function of variations of concentration of simple salt as well as of surfactant concentration. The application of this method to aqueous solutions of a cationic surfactant has been exemplified previously[7,8] to derive the surface excesses of various ions on the solution.

When we are concerned with aqueous solution of a weak electrolyte such as an ionic-nonionic surfactant, in the presence of a strong acid or base and a simple salt, we have to treat the solution as a quaternary system, and the lowering of its surface tension should be related to the variations of concentrations of surfactant, acid or base, and simple salt. In a previous paper[9] we have applied the method to aqueous solution of a cationic-nonionic surfactant in the presence of HCl and NaCl, in which the lowering of surface tension is expressed as a function of variations of concentrations of surfactant and NaCl, as well as of degree of neutralization instead of concentration of HCl.

In the present paper we will give a general treatment of the Gibbs adsorption isotherm applied to aqueous solution containing a weak base, HCl or NaOH, and NaCl. Following four systems of added components are considered: (I) H_2O+D+HCl+NaCl, (II) H_2O+D+NaOH+NaCl, (III) H_2O+DHCl+HCl+NaCl, and (IV) H_2O+DHCl+NaOH+NaCl, where D is a weak base capable of combining with H^+ to form a cation DH^+. Final results will be given in the form as a function of variations of molar concentrations of added components, D or DHCl, HCl or NaOH, and NaCl, or alternatively, of molar concentrations of two components, D or DHCl, and NaCl, and pH of the solution. These equations enable us to derive the surface excesses of total base (D+DH^+), added HCl or NaOH, and NaCl from the derivatives of surface tension with respect to concentrations of added base (D) or its hydrochloride (DHCl), and of NaCl, as well as to concentration of added HCl or NaOH, or, alternatively, to pH of the solution.

Expressions in Terms of Chemical Potentials

A plane surface of aqueous solution formed by dissolving a weak base D or its hydrochloride DHCl, strong acid HCl or alkali NaOH, and NaCl into water will be treated with reference to its surface tension at constant temperature. The plane surface forms a vapor-solution interface. Since the weak base D combines with H^+ to form a cation DH^+ in water, or DH^+ dissociates into D and H^+ in water, and water itself consists of H_2O, H^+, and OH^-, the Gibbs adsorption isotherm for the vapor-solution interface can be written in terms of chemical potentials of species

$$-d\gamma = \Gamma_{H_2O}d\mu_{H_2O} + \Gamma_D d\mu_D + \Gamma_{H^+}d\mu_{H^+} + \Gamma_{DH^+}d\mu_{DH^+} + \Gamma_{Na^+}d\mu_{Na^+} + \Gamma_{OH^-}d\mu_{OH^-} + \Gamma_{Cl^-}d\mu_{Cl^-}, \quad (1)$$

where γ is the surface tension of solution, Γ_i and μ_i are the surface excess and chemical potential of species, i. Equation 1 is subject to several conditions of equilibrium and stoichiometry. Among them, water and the weak base are in ionization equilibrium, respectively, respresented by

$$\mu_{H_2O} = \mu_{H^+} + \mu_{OH^-}, \quad (2)$$

$$\mu_{DH^+} = \mu_D + \mu_{H^+}. \quad (3)$$

Furthermore, stoichiometric relations hold for strong electrolytes:

$$\mu_{DHCl} = \mu_{DH^+} + \mu_{Cl^-}, \quad (4)$$

$$\mu_{HCl} = \mu_{H^+} + \mu_{Cl^-}, \quad (5a)$$

$$\mu_{NaOH} = \mu_{Na^+} + \mu_{OH^-}, \quad (5b)$$

$$\mu_{NaCl} = \mu_{Na^+} + \mu_{Cl^-}. \quad (6)$$

Equations 2 and 3, together with the electroneutrality condition among surface excesses of ionic species

$$\Gamma_{H^+} + \Gamma_{DH^+} + \Gamma_{Na^+} = \Gamma_{OH^-} + \Gamma_{Cl^-}, \quad (7)$$

reduce the number of variables in Eq. 1 from 7 to 4. Individual cases will be demonstrated below, and Eq. 1 may be represented in terms of variations of chemical potentials of four added components, *i.e.*, H_2O, D or DHCl, HCl or NaOH, and NaCl.

Since the number of variances should be 3 for the

quaternary system including an interface or two phases at constant temperature, the Gibbs convention must be introduced, so that the surface excess of solvent, *i.e.*, water, may vanish. The expression of the Gibbs convention for the individual cases is not necessarily given in a comprehensive form, but it proves to represent that the total surface excess of added water counted as moles of H_2O is zero.[10]

Thus, Eq. 1 can be completely converted into a form consisting of independent variables alone, and the lowering of surface tension is given by variations of chemical potentials of added solute components.

Expressions in Terms of Solute Concentrations

When we express the chemical potentials of added components in terms of their molar concentrations, we can obtain the Gibbs adsorption isotherm in the form given by the variations of molar concentrations of added solutes. To do this in a tractable form, we make an assumption that the solution is ideal and the activity coefficients of added solute components are unity. Let the molar concentration of added D or DHCl be C, that of added HCl or NaOH be C_A or C_B, and that of NaCl be C_S, respectively. Then the chemical potentials are given by

$$\mu_D = \mu_D^\circ + RT \ln C_D \tag{8a}$$

$$\mu_{DHCl} = \mu_{DHCl}^\circ + RT \ln C_{DH^+} C_{Cl^-} \tag{8b}$$

$$\mu_{HCl} = \mu_{HCl}^\circ + RT \ln C_{H^+} C_{Cl^-} \tag{9a}$$

$$\mu_{NaOH} = \mu_{NaOH}^\circ + RT \ln C_{Na^+} C_{OH^-} \tag{9b}$$

$$\mu_{NaCl} = \mu_{NaCl}^\circ + RT \ln C_{Na^+} C_{Cl^-}, \tag{10}$$

where the superfix $\circ$ refers to the standard states.

There are several restrictions among the molar concentrations of species present in the solution, C_D, C_{DH^+}, C_{H^+}, C_{Na^+}, C_{OH^-}, and C_{Cl^-}. Concentrations of counter ion, C_{Cl^-} and coion, C_{Na^+}, for the surfactant ion are given by C_A or C_B and C_S. If the ionic product of water is defined by K_w, the molar concentrations of H^+ and OH^- are mutually dependent by means of Eq. 2, *i.e.*,

$$C_{H^+} C_{OH^-} = K_W. \tag{11}$$

If the degree of ionization or protonation is α, the molar concentrations of base, in unionized and ionized forms, are given by

$$C_D = (1-\alpha)C \text{ and } C_{DH^+} = \alpha C, \tag{12}$$

and the ionization equilibrium, Eq. 3, is defined by the ionization constant

$$\frac{1-\alpha}{\alpha} C_{H^+} = K. \tag{13}$$

There is the condition of electroneutrality in bulk

$$C_{H^+} + C_{DH^+} + C_{Na^+} = C_{OH^-} + C_{Cl^-}. \tag{14}$$

Then we can obtain C_{H^+} or α as a function of C and C_A or C_B for individual cases. For this purpose, however, we have to solve a cubic equation with respect to C_{H^+} or α, which is derived by substituting Eqs. 11, 12, and 13 into Eq. 14. For the derivation of the Gibbs adsorption equation it is not necessary to have C_{H^+} or α itself but to evaluate dC_{H^+} or $d\alpha$, and, consequently, we differentiate the cubic equation with respect to C and C_A or C_B and obtain dC_{H^+} or $d\alpha$ as a function of dC and dC_A or dC_B. The function includes α explicitly, and for numerical evaluation we have to calculate it from C, C_A, or C_B, and K and K_w by solving the cubic equation.

The final form of the Gibbs adsorption isotherm is written

$$-d\gamma = RT\{\Gamma_2 d \ln C + \Gamma_X d \ln C_X + \Gamma_3 d \ln C_S\}, \tag{15}$$

where X is A for HCl and B for NaOH. It should be noted, however, that values of Γ_A and Γ_B do not imply the surface excesses of HCl and NaOH, respectively. Values of Γ_2, Γ_X, and Γ_3 can be evaluated from the derivatives of surface tension with respect to molar concentrations of added components.

Alternatively, we are often interested in assigning pH of a solution rather than giving molar concentration of HCl or NaOH added. In such cases we must express α in terms of C_{H^+} from Eq. 13 and then C_A or C_B in terms of C_{H^+} and C from the cubic equation of C_{H^+} as mentioned above.

The lowering of surface tension is then given by

$$-d\gamma = RT\{\Gamma_c d \ln C + \Gamma_h d \ln C_{H^+} + \Gamma_3 d \ln C_S\}, \tag{16}$$

where Γ_c can be obtained from the derivative of surface tension at constant pH with respect to molar concentration of the weak base or its hydrochloride, and Γ_h can be evaluated from the variation of surface tension with pH. Γ_3 is identical with that in Eq. 15.

(I) $H_2O+D+HCl+NaCl$. This system was treated previously,[9] and a modification of the derived equations was applied to surface tension of aqueous solutions of a nonionic-cationic surfactant at different degrees of neutralization. The Gibbs convention has the form

$$\Gamma_{H_2O} + \Gamma_{OH^-} = 0, \tag{17}$$

and the Gibbs adsorption isotherm can be written as

$$-d\gamma = (\Gamma_D + \Gamma_{DH^+}) d\mu_D + (\Gamma_{Cl^-} - \Gamma_{Na^+}) d\mu_{HCl} + \Gamma_{Na^+} d\mu_{NaCl}. \tag{18}$$

Concentrations of counterion and coion are given by

$$C_{Cl^-} = C_A + C_S \text{ and } C_{Na^+} = C_S. \tag{19}$$

For Eq. 15 we have

$$\Gamma_2 = \left(1 + \frac{\alpha^2 C}{Q_A}\right)(\Gamma_D + \Gamma_{DH^+}) - \frac{\alpha C}{Q_A}(\Gamma_{Cl^-} - \Gamma_{Na^+}), \tag{20a}$$

$$\Gamma_A = -\frac{\alpha C_A}{Q_A}(\Gamma_D + \Gamma_{DH^+}) + \left(\frac{C_A}{Q_A} + \frac{C_A}{C_A + C_S}\right)\Gamma_{Cl^-} - \frac{C_A}{Q_A}\Gamma_{Na^+}, \tag{20b}$$

$$\Gamma_3 = \frac{C_S}{C_A + C_S}\Gamma_{Cl^-} + \Gamma_{Na^+}, \tag{20c}$$

where

$$Q_A = \alpha(2-\alpha)C - C_A + 2C_{H^+} \tag{20d}$$

$$= -\alpha^2 C + C_A + 2C_{OH^-}. \tag{20e}$$

Solving Eqs. 20a,b,c we have

$$\Gamma_D + \Gamma_{DH^+} = \frac{1}{H_A}\left\{(H_A - \alpha^2 C)\Gamma_2 + \frac{\alpha C}{C_A}(C_A + 2C_S)\Gamma_A - \alpha C \Gamma_3\right\}, \tag{21a}$$

$$\Gamma_{Cl^-} = \frac{C_A+C_S}{H_A}\left\{\alpha\Gamma_2 + \frac{1}{C_A}(H_A-C_A-2C_S)\Gamma_A + \Gamma_3\right\}, \quad (21b)$$

$$\Gamma_{Na^+} = \frac{1}{H_A}\left\{-\alpha C_S\Gamma_2 - \frac{C_S}{C_A}(H_A-C_A-2C_S)\Gamma_A + (H_A-C_S)\Gamma_3\right\}, \quad (21c)$$

where

$$H_A = 2\alpha C + 2C_S + 2C_{H^+} \quad (21d)$$

$$= 2C_A + 2C_S + 2C_{OH^-}. \quad (21e)$$

Similarly, for Eq. 16 we have

$$\Gamma_c = \Gamma_D + \Gamma_{DH^+} + \frac{\alpha C}{C_A+C_S}\Gamma_{Cl^-} \quad (22a)$$

$$\Gamma_h = -\alpha(\Gamma_D+\Gamma_{DH^+}) + \left(1+\frac{Q_A}{C_A+C_S}\right)\Gamma_{Cl^-} - \Gamma_{Na^+} \quad (22b)$$

and, solving Eqs. 22 and 20c, we have

$$\Gamma_D + \Gamma_{DH^+} = \frac{1}{H_A}\left\{(H_A-\alpha^2C)\Gamma_c - \alpha C(\Gamma_h+\Gamma_3)\right\} \quad (23a)$$

$$\Gamma_{Cl^-} = \frac{C_A+C_S}{H_A}\{\alpha\Gamma_c+\Gamma_h+\Gamma_3\}, \quad (23b)$$

$$\Gamma_{Na^+} = \frac{1}{H_A}\{-\alpha C_S\Gamma_c - C_S\Gamma_h + (H_A-C_S)\Gamma_3\}. \quad (23c)$$

(II) $H_2O+D+NaOH+NaCl$. In order to suppress possible ionization of weak base dissolved in water, NaOH is added to the solution. In this case the Gibbs convention for the dividing surface is expressed by

$$\Gamma_{H_2O} + \Gamma_{H^+} + \Gamma_{DH^+} = 0, \quad (24)$$

and the Gibbs adsorption isotherm has the form

$$-d\gamma = (\Gamma_D+\Gamma_{DH^+})d\mu_D + (\Gamma_{Na^+}-\Gamma_{Cl^-})d\mu_{NaOH} + \Gamma_{Cl^-}d\mu_{NaCl}. \quad (25)$$

Concentrations of counterion and coion are given by

$$C_{Cl^-} = C_S \text{ and } C_{Na^+} = C_B + C_S. \quad (26)$$

For Eq. 15 we have

$$\Gamma_2 = \left(1+\frac{\alpha^2C}{Q_B}\right)(\Gamma_D+\Gamma_{DH^+}) - \frac{\alpha C}{Q_B}(\Gamma_{Cl^-}-\Gamma_{Na^+}), \quad (27a)$$

$$\Gamma_B = \frac{\alpha C_B}{Q_B}(\Gamma_D+\Gamma_{DH^+}) - \frac{C_B}{Q_B}\Gamma_{Cl^-} + \left(\frac{C_B}{Q_B}+\frac{C_B}{C_B+C_S}\right)\Gamma_{Na^+}, \quad (27b)$$

$$\Gamma_3 = \Gamma_{Cl^-} + \frac{C_S}{C_B+C_S}\Gamma_{Na^+}, \quad (27c)$$

where

$$Q_B = \alpha(2-\alpha)C + C_B + 2C_{H^+}, \quad (27d)$$

$$= -\alpha^2C - C_B + 2C_{OH^-}. \quad (27e)$$

Solving Eqs. 27a,b,c we have

$$\Gamma_D + \Gamma_{DH^+} = \frac{1}{H_B}\left\{(H_B-\alpha^2C)\Gamma_2 - \frac{\alpha C}{C_B}(C_B+2C_S)\Gamma_B + \alpha C\Gamma_3\right\}, \quad (28a)$$

$$\Gamma_{Cl^-} = \frac{1}{H_B}\left\{\alpha C_S\Gamma_2 - \frac{C_S}{C_B}(H_B-\alpha^2C-C_B)\Gamma_B + (H_B-C_S)\Gamma_3\right\}, \quad (28b)$$

$$\Gamma_{Na^+} = \frac{C_B+C_S}{H_B}\left\{-\alpha\Gamma_2+\frac{1}{C_B}(H_B-\alpha^2C-C_B)\Gamma_B+\Gamma_3\right\}, \quad (28c)$$

where

$$H_B = 2\alpha C + 2C_B + 2C_S + 2C_{H^+} \quad (28d)$$

$$= 2C_S + 2C_{OH^-}. \quad (28e)$$

Similarly, for Eq. 16 we have

$$\Gamma_c = \Gamma_D + \Gamma_{DH^+} - \frac{\alpha C}{C_B+C_S}\Gamma_{Na^+}, \quad (29a)$$

$$\Gamma_h = -\alpha(\Gamma_D+\Gamma_{DH^+}) + \Gamma_{Cl^-} - \left(1+\frac{Q_B}{C_B+C_S}\right)\Gamma_{Na^+}, \quad (29b)$$

and, solving Eqs. 29 and 27c, we have

$$\Gamma_D + \Gamma_{DH^+} = \frac{1}{H_B}\{(H_B-\alpha^2C)\Gamma_c - \alpha C(\Gamma_h+\Gamma_3)\}, \quad (30a)$$

$$\Gamma_{Cl^-} = \frac{1}{H_B}\{\alpha C_S\Gamma_c + C_S\Gamma_h + (H_B-C_S)\Gamma_3\}, \quad (30b)$$

$$\Gamma_{Na^+} = \frac{C_B+C_S}{H_B}\{-\alpha\Gamma_c-\Gamma_h+\Gamma_3\}. \quad (30c)$$

(III) $H_2O+DHCl+HCl+NaCl$. In order to suppress possible hydrolysis of hydrochloride of weak base, HCl is added to the solution. In this case the Gibbs convention is written as

$$\Gamma_{H_2O} + \Gamma_{OH^-} = 0, \quad (31)$$

and the Gibbs adsorption isotherm is given by

$$-d\gamma = (\Gamma_D+\Gamma_{DH^+})d\mu_{DHCl} + (\Gamma_{Cl^-}-\Gamma_D-\Gamma_{DH^+} - \Gamma_{Na^+})d\mu_{HCl} + \Gamma_{Na^+}d\mu_{NaCl}. \quad (32)$$

Concentrations of counterion and coion are

$$C_{Cl^-} = C + C_A + C_S \text{ and } C_{Na^+} = C_S. \quad (33)$$

For Eq. 15 we have

$$\Gamma_2 = \left(1-\frac{\alpha(1-\alpha)C}{P_A}\right)(\Gamma_D+\Gamma_{DH^+}) + \left(\frac{(1-\alpha)C}{P_A}+\frac{C}{C+C_A+C_S}\right)\Gamma_{Cl^-} - \frac{(1-\alpha)C}{P_A}\Gamma_{Na^+}, \quad (34a)$$

$$\Gamma_A = -\frac{\alpha C_A}{P_A}(\Gamma_D+\Gamma_{DH^+}) + \left(\frac{C_A}{P_A}+\frac{C_A}{C+C_A+C_S}\right)\Gamma_{Cl^-} - \frac{C_A}{P_A}\Gamma_{Na^+}, \quad (34b)$$

$$\Gamma_3 = \frac{C_S}{C+C_A+C_S}\Gamma_{Cl^-} + \Gamma_{Na^+}, \quad (34c)$$

where

$$P_A = -(1-\alpha)^2C - C_A + 2C_{H^+}, \quad (34d)$$

$$= (1-\alpha^2)C + C_A + 2C_{OH^-}. \quad (34e)$$

Solving Eqs. 34a,b,c, we have

$$\Gamma_D + \Gamma_{DH^+} = \frac{1}{Z_A}\left\{(Z_A-\alpha^2C)\Gamma_2 - \frac{C}{C_A}[Z_A-(1+\alpha)(\alpha C+C_S)-\alpha C_A]\Gamma_A - \alpha C\Gamma_3\right\}, \quad (35a)$$

$$\Gamma_{Cl^-} = \frac{C+C_A+C_S}{Z_A}\left\{\alpha\Gamma_2 + \frac{1}{C_A} \times [Z_A-(1+\alpha)C-C_A-2C_S]\Gamma_A + \Gamma_3\right\}, \quad (35b)$$

$$\Gamma_{Na^+} = \frac{1}{Z_A}\left\{-\alpha C_S\Gamma_2 - \frac{C_S}{C_A}[Z_A-(1+\alpha)C-C_A -2C_S]\Gamma_A+(Z_A-C_S)\Gamma_3\right\}, \quad (35c)$$

where

$$Z_A = 2\alpha C + 2C_S + 2C_{H^+} \quad (35d)$$

$$= 2C + 2C_A + 2C_S + 2C_{OH^-}. \quad (35e)$$

Similarly, for Eq. 16 we have

$$\Gamma_e = \Gamma_D + \Gamma_{DH^+} + \frac{\alpha C}{C+C_A+C_S}\Gamma_{Cl^-}, \quad (36a)$$

$$\Gamma_h = -\alpha(\Gamma_D+\Gamma_{DH^+}) + \left(1+\frac{P_A}{C+C_A+C_S}\right)\Gamma_{Cl^-} - \Gamma_{Na^+}, \quad (36b)$$

and, solving Eqs. 36 and 35c, we have

$$\Gamma_D + \Gamma_{DH^+} = \frac{1}{Z_A}\{(Z_A-\alpha^2C)\Gamma_e - \alpha C(\Gamma_h+\Gamma_3)\}, \quad (37a)$$

$$\Gamma_{Cl^-} = \frac{C+C_A+C_S}{Z_A}(\alpha\Gamma_e+\Gamma_h+\Gamma_3), \quad (37b)$$

$$\Gamma_{Na^+} = \frac{1}{Z_A}\{-\alpha C_S\Gamma_e - C_S\Gamma_h + (Z_A-C_S)\Gamma_3\}. \quad (37c)$$

(IV) $H_2O+DHCl+NaOH+NaCl$. The Gibbs dividing surface is set in such a way that

$$\Gamma_{H_2O} + \Gamma_{H^+} - \Gamma_D = 0, \quad (38)$$

and the Gibbs adsorption isotherm is written as

$$-d\gamma = (\Gamma_D+\Gamma_{DH^+})d\mu_{DHCl} + (\Gamma_D+\Gamma_{DH^+}+\Gamma_{Na^+} -\Gamma_{Cl^-})d\mu_{NaOH} + (\Gamma_{Cl^-}-\Gamma_D-\Gamma_{DH^+})d\mu_{NaCl}. \quad (39)$$

Concentrations of counterion and coion are given by

$$C_{Cl^-} = C + C_S \text{ and } C_{Na^+} = C_B + C_S. \quad (40)$$

For Eq. 15 we have

$$\Gamma_2 = \left(1-\frac{\alpha(1-\alpha)C}{P_B}\right)(\Gamma_D+\Gamma_{DH^+}) + \left(\frac{(1-\alpha)C}{P_B}+\frac{C}{C+C_S}\right)\Gamma_{Cl^-} - \frac{(1-\alpha)C}{P_B}\Gamma_{Na^+}, \quad (41a)$$

$$\Gamma_B = \frac{\alpha C_B}{P_B}(\Gamma_D+\Gamma_{DH^+}) - \frac{C_B}{P_B}\Gamma_{Cl^-} + \left(\frac{C_B}{P_B}+\frac{C_B}{C_B+C_S}\right)\Gamma_{Na^+}, \quad (41b)$$

$$\Gamma_3 = \frac{C_S}{C+C_S}\Gamma_{Cl^-} + \frac{C_S}{C_B+C_S}\Gamma_{Na^+}, \quad (41c)$$

where

$$P_B = -(1-\alpha)^2C + C_B + 2C_{H^+} \quad (41d)$$

$$= (1-\alpha^2)C - C_B + 2C_{OH^-}. \quad (41e)$$

Solving Eqs. 41a,b,c we have

$$\Gamma_D + \Gamma_{DH^+} = \frac{1}{Z_B}\left\{(Z_B-\alpha^2C)\Gamma_2 + \frac{C}{C_B}[Z_B-(1+\alpha^2)C-\alpha C_B-(1+\alpha)C_S]\Gamma_B - \frac{C}{C_S}[Z_B-\alpha(1+\alpha)C-\alpha C_S]\Gamma_3\right\}, \quad (42a)$$

$$\Gamma_{Cl^-} = \frac{C+C_S}{Z_B}\left\{\alpha\Gamma_2 - \frac{1}{C_B}[Z_B-(1+\alpha)C-C_B-2C_S]\Gamma_B + \frac{1}{C_S}[Z_B-(1+\alpha)C+C_S]\Gamma_3\right\}, \quad (42b)$$

$$\Gamma_{Na^+} = \frac{C_B+C_S}{Z_B}\left\{-\alpha\Gamma_2 + \frac{1}{C_B}[Z_B-(1+\alpha)C-C_B-2C_S]\Gamma_B + \frac{1}{C_S}[(1+\alpha)C+C_S]\Gamma_3\right\}, \quad (42c)$$

where

$$Z_B = 2\alpha C + 2C_B + 2C_S + 2C_{H^+}, \quad (42d)$$

$$= 2C + 2C_S + 2C_{OH^-}. \quad (42e)$$

Similarly, for Eq. 16 we have

$$\Gamma_e = \Gamma_D + \Gamma_{DH^+} + \frac{C}{C+C_S}\Gamma_{Cl^-} + \frac{(1-\alpha)C}{C_B+C_S}\Gamma_{Na^+}, \quad (43a)$$

$$\Gamma_h = -\alpha(\Gamma_D+\Gamma_{DH^+}) + \Gamma_{Cl^-} - \left(1+\frac{P_B}{C_B+C_S}\right)\Gamma_{Na^+} \quad (43b)$$

and, solving Eqs. 43 and 41c, we have

$$\Gamma_D + \Gamma_{DH^+} = \frac{1}{Z_B}\left\{(Z_B-\alpha^2C)\Gamma_e - \alpha C\Gamma_h - \frac{C}{C_S}[Z_B-\alpha(1+\alpha)C-\alpha C_S]\Gamma_3\right\}, \quad (44a)$$

$$\Gamma_{Cl^-} = \frac{C+C_S}{Z_B}\left\{\alpha\Gamma_e + \Gamma_h + \frac{1}{C_S}[Z_B-(1+\alpha)C-C_B]\Gamma_3\right\}, \quad (44b)$$

$$\Gamma_{Na^+} = \frac{C_B+C_S}{Z_B}\left\{-\alpha\Gamma_e - \Gamma_h + \frac{1}{C_S}[(1+\alpha)C+C_S]\Gamma_3\right\}. \quad (44c)$$

Discussion

As was pointed out previously,[1,2] it has been shown that the Gibbs adsorption isotherm can be expressed in either of two forms, *i.e.*, in terms of variations of chemical potentials of constituents of two types, for an electrolyte solution. One is based on the ionic and nonionic species present in the solution, as given by Eq. 1, and the other is based on the neutral components added to make up the solution. The former expression is subject to various restrictions such as the ionic equilibria, Eqs. 2 and 3, and the stoichiometry, Eqs. 4—7, among different species, while the latter is free from such restrictions, except for setting the position of dividing surface. It was demonstrated that both expressions are equivalent and the dividing surface should be carefully drawn only after the latter expression has been obtained. The Gibbs convention is then expressed by Eq. 17, 24, 31, or 38, as is also illustrated in the expression for the Gibbs-Duhem equation.[10] As a result, the Gibbs adsorption isotherm is expressed in the form of Eqs. 18, 25, 32, or 39 by

the variations of chemical potentials of all the solute components added and their surface excesses can be defined uniquely.

There has been a prevailing superstition that the Gibbs adsorption isotherm should be written down in terms of chemical potentials of ionic and nonionic species present in the solution, since Guggenheim[11] gave it exclusively in this expression. Furthermore, this expression has often lead to an erroneous expression for the Gibbs convention in the cases containing weak electrolytes or attending hydrolysis of salts, because the ionization of water itself has been overlooked.[3,11,12]

After introducing the correct Gibbs convention, we can proceed to convert the chemical potentials of solute components into their (molar) concentrations, by relying on some approximations. In the present work we have made an approximation that the activity coefficients of all the solute components are unity. Even in this approximation, the calculation is intricate. After a straightforward calculation, the lowering of surface tension is expressed in terms of variations of concentrations of added components, or of pH of solution, as given by Eq. 15 or 16. Then we can readily derive the surface excesses of three species, *i.e.*, $D+DH^+$, Cl^-, and Na^+, as functions of three experimentally measurable quantities, Γ_2, Γ_X, and Γ_3, or Γ_e, Γ_h, and Γ_3. For the actual calculation we may usually neglect C_{H^+} or C_{OH^-} in the final equations.

It is not possible to separate the surface excess of DH^+ from that of D, nor to derive the surface excesses of H^+ and OH^-, as far as only measurements of surface tension are performed.

As special cases we will now derive expressions for ternary systems without added HCl or NaOH. Two systems, (I) and (II), reduce to $H_2O+D+NaCl$, and we put $C_X=0$ and $\Gamma_{Cl^-}=\Gamma_{Na^+}$. Then we have

$$\Gamma_D + \Gamma_{DH^+} = \left(1-\frac{\alpha^2 C}{2C_{OH^-}}\right)\Gamma_2, \tag{45a}$$

$$\Gamma_{Cl^-} = \Gamma_{Na^+} = \frac{1}{2}\Gamma_3. \tag{45b}$$

Similarly, two other systems, (III) and (IV), reduce to $H_2O+DHCl+NaCl$, and we put $C_X=0$. Since the surface excess of total added hydrochloride should be equal to that of Cl^- not originating from added NaCl, we have $\Gamma_D+\Gamma_{DH^+}=\Gamma_{Cl^-}-\Gamma_{Na^+}$. Then we obtain

$$\Gamma_D + \Gamma_{DH^+} = \frac{P}{Y}\{(C+2C_S)\Gamma_2 - C\Gamma_3\} \tag{46a}$$

$$\Gamma_{Cl^-} = \frac{C+C_S}{Y}\{P\Gamma_2 + 2C_{H^+}\Gamma_3\} \tag{46b}$$

$$\Gamma_{Na^+} = \frac{1}{Y}\{C_S P\Gamma_2 + 2(C+C_S)C_{H^+}\Gamma_3\}, \tag{46c}$$

where

$$P = -(1-\alpha)^2 C + 2C_{H^+} = (1-\alpha^2)C + 2C_{OH^-} \tag{46d}$$

$$Y = -(1-\alpha)^2 C^2 + 4(C+C_S)C_{H^+}$$
$$= 2(1-\alpha^2)C(C+2C_S) + 4(C+C_S)C_{OH^-}. \tag{46e}$$

Finally we will suggest that formal conversion is possible from the quaternary systems containing a weak base treated in this paper to those of a weak acid treated in a previous paper,[1] when $\Gamma_{HD}+\Gamma_{D^-}$ is substituted for $\Gamma_D+\Gamma_{DH^+}$, and Γ_{Cl^-} and Γ_{Na^+} are exchanged, in the equations cited below.

Equations, 20a,b,c, 21a,b,c, 22, and 23 hold for (I') $H_2O+HD+NaOH+NaCl$, if C_A and C_{H^+} in Eqs. 20d and 21d are replaced by C_B and C_{OH^-}, respectively. Similarly, Eqs. 27a,b,c, 28a, b, c, 29, and 30 are valid for (II') $H_2O+HD+HCl+NaCl$, if C_B and C_{H^+} in Eqs. 27d and 28d are replaced by C_A and C_{OH^-}, respectively.

Equations 34a,b,c, 35a,b,c 36, and 37 hold for (III') $H_2O+NaD+NaOH+NaCl$, if C_A and C_{OH^-} in Eqs. 34e and 35e are replaced by C_B and C_{H^+}, respectively. Similarly, Eqs. 41a,b,c, 42a,b,c, 43, and 44 are valid for (IV') $H_2O+NaD+HCl+NaCl$, if C_B and C_{OH^-} in Eqs. 41e and 42e are replaced by C_A and C_{H^+}, respectively.

Catalysis by Alkaline Earth Metal Oxides. I. The Mechanism of Ethylene Hydrogenation on Calcium Oxide

Kaname Kasama, Yasunobu Inoue,* and Iwao Yasumori

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received October 26, 1979)

The mechanism of ethylene hydrogenation on a thermally activated CaO was studied in the overall temperature range of 197—623 K. The maximum in the reaction rate was observed around 320 K, while the activation energy was found to vary with the range of reaction temperatures, *i.e.*, 12.6 kJ/mol (197—273 K) and −16.7 kJ/mol (373—623 K). The partial pressure dependence of the rate was also different in these ranges; the reaction orders with respect to the hydrogen and ethylene pressures were 0.7 and nearly zero at 273 K respectively, whereas the orders shifted to 1.0 and 0.9 at 523 K in the pressure range from 6 to 40 Torr (1 Torr= 133.3 Pa). The reaction with deuterium at 523 K produced ethane containing widely distributed deuterium and was accompanied by the formation of highly-exchanged ethylene, HD, and H_2 molecules in the gas phase. On the contrary, the reaction at 273 K formed ethane [D_2] (>60%) selectively, and the hydrogen-deuterium exchange occurred to a lesser extent in both ethylene and deuterium. By the proposed associative mechanism, the variation in the kinetic behavior with the temperature was explained in terms of the change in the slow step from the reaction between the adsorbed hydrogen and surface ethylene to the hydrogenation of the ethyl radical. The poisoning of the hydrogenation by preadsorbed CO indicated that only 0.5% of the total surface atoms contributed actively to the reaction. On the basis of these results, the structures of active sites are briefly discussed.

Alkaline earth metal oxides have been known to become catalytically active in the H_2–D_2 equilibration reaction after irradiation with γ-rays.[1] Recently, however, Boudart *et al.* found that the thermal treatment *in vacuo* at temperatures as high as 873 K can activate MgO to catalyze the same reaction.[2] This finding has turned attention to the possibility of alkaline earth metal oxides as effective catalysts for other reactions. Tanabe and his co-workers found that the hydrogenation[3a,3b] as well as the isomerization[4] of olefins was catalyzed by BaO, MgO, CaO, and SrO when these oxides were evacuated at definite ranges of high temperatures. The mechanisms of such a generation of high activity and of the hydrogenation are of particular interest, but no precise information about them has so far been obtained.

In our series of work, we first studied the catalytic activity of calcium oxide in ethylene hydrogenation, since the reaction on CaO had not been investigated in detail, though extensive data on reactions over transition metals[5] and their oxides[6] had been accumulated. For a better understanding of the reaction mechanism, the kinetic study was carried out over a wide range of reaction temperatures and was supplemented by an analysis of deuterium distributions in the reaction of ethylene with deuterium. It is known that catalyses by transition metals and their oxides contrast remarkably with each other in terms of the deuterium distributions in the produced ethane;[6] metal surfaces provide a wide distribution of ethane from [D_0] to [D_6], whereas such oxides as Cr_2O_3[7] or ZnO[8] are characterized by the selective formation of ethane [D_2]. These features are apparently attributable to the nature of the active sites on the catalysts; in this regard, an examination of the deuterium distributions in the reaction on CaO is interesting.

It is necessary to determine the portion of the surface which participates in the catalytic reaction. The poisoning by preadsorbed CO was, therefore, examined, and the quantitative relationship between the increased amount of surface CO and the extent of activity fall was obtained. On the basis of these results, we can provide a brief description of the structure of the active sites, the details of which will appear in a following paper.

Experimental

The calcium oxide used as a catalyst was prepared by decomposing calcium hydroxide of an extra pure grade, purchased from the Junsei Kagaku Co., Ltd., *in vacuo*. The oxide thus obtained was evacuated ($<1\times10^{-6}$ Torr) for 2 h at temperatures between 873 and 1273 K. Emission spectral analysis showed that CaO contained Mg (<3 ppm), Si (<80), Fe (<0.1), Cu (<0.5), and Mn (<10). Ethylene hydrogenation was studied at temperatures between 197 and 623 K over a pressure range from 6 to 40 Torr by using a closed circulating system with a volume of 610 ml which was directly connected to a gas chromatograph for the analysis of C_2-hydrocarbons. About 0.2 g of CaO was used for the kinetic runs. Since ethane was the only product under the present experimental conditions, the initial rate of ethane formation was employed as the measure of catalytic activity throughout the study. In the reaction of ethylene with deuterium, the product and reactants were separated gas chromatographically and analyzed on a Hitachi RMU-7M mass spectrometer at an ionization voltage of 70 V. Hydrogen, hydrogen deuteride, and deuterium were analysed by means of a gas chromatograph.[9] The adsorption of CO on CaO activated at various temperatures was measured at room temperature and under pressures up to 40 Torr.

The hydrogen (99.99% pure), deuterium (containing less than 0.5% HD), carbon monoxide (99.5%), and ethylene (99.8%) were obtained from the Takachiho Chemical Co., Ltd., and were used without further purification.

Results

Figure 1 shows the variation in the surface area and the catalytic activity, V_e, represented by the ethane molecules produced per min and per m^2 of CaO as a function of the evacuation temperature. With an increase in the temperature, the surface area decreased monotonously, whereas V_e exhibited a max-

imum at 1073 K, which is larger by approximately one order of magnitude than the activity of the catalysts treated at 873 or 1273 K. This variation in the activity is similar to that previously reported by Hattori *et al.*,[3a] although their results involved no correction for the change in the surface area. Figure 1 also shows V_e for the oxides which were prepared by calcining $Ca(OH)_2$ in air at 873, 973, or 1073 K for 2 h, followed by evacuation at 1073 K for 2 h. In this case the V_e's were smaller by 40 to 60% than those for the catalysts prepared by the decomposition *in vacuo*.

Since the CaO surface activated at 1073 K exhibited not only the maximum activity, but also the typical

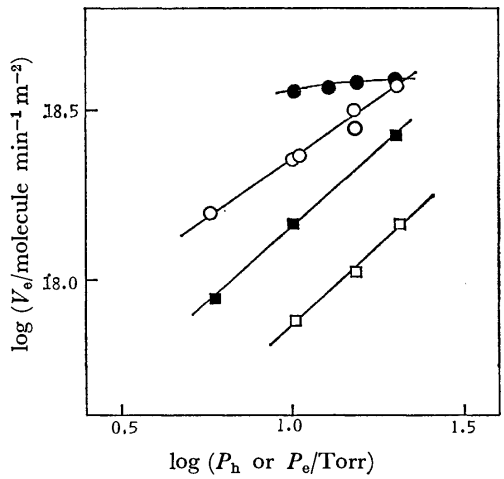

Fig. 3. Partial pressure dependence at 273 and 523 K. ○; $5.8<P_h<20$ Torr, P_e=10 Torr at 273 K, ●; $10<P_e<20$ Torr, P_h=20 Torr at 273 K, □; $10<P_h<20$ Torr, P_e=10 Torr at 523 K, ■; $6<P_e<20$ Torr, P_h=20 Torr at 523 K.

features of the catalysis, the kinetic study was carried out on the surface, unless otherwise stated. A gradual decay in the activity occurred during the course of the reaction at 533 K; the original activity was attenuated to almost 40% in the second run and to 10% in the third run. The activity thus reduced was, however, restored almost completely to the initial level after evacuation at 1073 K; hence, prior to each kinetic run, the catalyst was evacuated at that temperature for 30 min.

Figure 2 illustrates the Arrhenius plots of the hydrogenation in the temperature range between 197 and 623 K. The maximum in the rate appeared at around 340 K; the values of the apparent activation energy were determined to be 12.6 kJ mol^{-1} below 340 K and −16.7 kJ mol^{-1} above it. Such a complicated behavior suggests that the kinetics of the reaction is different in these regions. Thus, the reactions at 273 and 523 K were investigated as typical of the two regions. Figure 3 shows the partial pressure dependence of the rate. For the hydrogenation at 273 K, the reaction orders with respect to the hydrogen pressure, P_h, and the ethylene pressure, P_e, were, respectively, 0.7 and nearly zero, whereas at 523 K these orders shifted to 1.0 and 0.9. The deuterium distributions in ethylene and ethane at conversions of from 10 to 80% are summarized in Tables 1 and 2, together with the isotopic compositions of hydrogen in the gas phase. It should be noted that the differences in the distributions as well as the reaction orders between the reactions at these temperatures are striking. No isotopic exchange between D_2 and C_2H_6 occurred on CaO at reaction temperatures up to 523 K.

The adsorption of CO on CaO was examined at room temperature and in the pressure range up to 40 Torr. The amount CO adsorbed increased with the CO pressure and attained an almost saturation at the highest pressure employed. After the first run of adsorption the CO-covered surface was evacuated

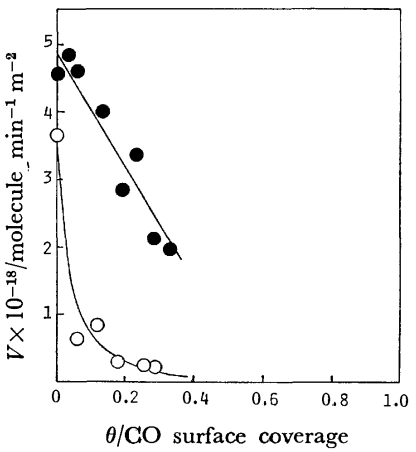

Fig. 4. Effect of preadsorbed CO on ethylene hydrogenation.
○; 273 K, ●; 373 K, P_h=20 Torr, P_e=10 Torr. CaO evacuated at 1073 K. The number of CO molecule at θ=1.0 is 1.48×10^{17} molecule m^{-2}.

at room temperature for 30 min and then exposed again to CO. In the second run, no significant adsorption occurred, indicating that the sites for the adsorption are saturated almost completely with the irreversibly bound CO. The amount at saturation was evaluated to be 1.6, 14.8, and 3.7×10^{16} molecules m^{-2} for CaO outgassed at 873, 1073, and 1273 K respectively. The evacuation temperature, after the first run of adsorption, was raised to 373 K, but the subsequent exposure to CO at room temperature gave rise to no detectable adsorption. Such a strong adsorption of CO accords with the preliminary results on thermal desorption; no gases were evolved from the surface with CO adsorbed on heating up to 423 K.

The effect of the irreversibly adsorbed CO upon the catalytic activity was examined at different reaction temperatures. Figure 4 indicates that the catalytic activity at 373 K decreased almost linearly with the increase in the coverage of CO, whereas the reaction at 273 K was characteristic in showing a drastic fall in the activity at the initial coverage of CO adsorption. The extrapolation of the plot showed that the activity is completely destroyed at the surface density of CO, 8×10^{16} molecules m^{-2}, which corresponds to about 0.5% of the total surface atoms.

Discussion

Reaction Pathway and Mechanism. The variation in the kinetic behavior of the reaction with the reaction temperature has been reported on the hydrogenation of ethylene[10] and 1-butene[11] over Ni metal catalysts. It is of interest that a similar phenomenon was observed in the present study of the reaction catalyzed by the calcium oxide surface. Such a similarity in the kinetic behavior is striking in the high-temperature region.

During the course of the reaction with deuterium in the high-temperature region, an equilibrium among the partial pressures of H_2, HD and D_2 in the gas phase was readily reached, and highly-exchanged ethylenes with deuterium were produced, even in a conversion as low as 11%. Thus, the following pathway of the reaction including the associative adsorption of ethylene can be proposed:

$$H_2(g) \rightleftharpoons 2H(a) \quad (1)$$

$$C_2H_4(g) \rightleftharpoons C_2H_4(a) \quad (2)$$

$$H(a) + C_2H_4(a) \rightleftharpoons C_2H_5(a) \quad (3)$$

$$H(a) + C_2H_5(a) \longrightarrow C_2H_6(g) \quad (4)$$

where (g) and (a) denotes, respectively, species in the gas phase and the adsorbed state. The observed deuterium distributions clearly indicate that Steps (1) and (2) are in a pseudo-equilibrium. The wide distributions of deuterium in the produced ethane further suggest that the forward and reverse processes of Step (3) are fast. Accordingly, the surface reaction (4)

is assumed to be the rate-determining step in the reaction at high temperatures, and we can obtain the following rate equation for ethane formation:

$$V_e^h = k_4\theta_h\theta_{el} = \frac{k_4K_hK_eK_3P_hP_e}{(1+\sqrt{K_hP_h}+K_eP_e+K_3K_eP_e\sqrt{K_hP_h})^2} \quad (5)$$

where θ_h and θ_{el} denote, respectively, the fractions of the hydrogen atom and the ethyl radical, which occupy the surface sites. The k_4, K_h, and K_e constants are the rate constant and the adsorption constants of hydrogen and ethylene respectively. K_3 is an equilibrium constant in Step (3). When $1 \gg \sqrt{K_hP_h}+K_eP_e+K_3K_eP_e\sqrt{K_hP_h}$, Eq. 5 is reduced to

$$V_e^h = k_4K_hK_eK_3P_hP_e = kP_hP_e \quad (6)$$

which agrees with the experimental pressure dependence. Equation 6 leads to the energy relationship, $E_a=E_t-Q_h-Q_e-Q_3$, where E_t is the activation energy of Reaction Step (4); Q_h is the heat of hydrogen adsorption; Q_e, the heat of ethylene adsorption, and Q_3, the heat of Reaction 3. The amounts of hydrogen and ethylene adsorbed on the CaO surface are so small that no reliable numerical data on the heat of adsorption are available at present, but the negative value of the apparent activation energy, $E_a=-16.7$ kJ mol^{-1}, is explicable if $E_t<Q_h+Q_e+Q_3$, as is seen in the case of Ni catalysts.

In the low-temperature range below 340 K, the characteristic features are the hydrogen order of 0.7, which was smaller than that, 1.0, for Ni and other transition metal catalysts, and also the selective formation of ethane[D_2] in the reaction with deuterium. Unlike Ni metal, no drastic rise in ethane[D_0] in the initial stage of the reaction was observed. The exchanged ethylene as well as hydrogen deuteride was produced in the gas phase, but their fractions were much smaller than those in the high-temperature range. These results predict that Step (3) is relatively slow compared to the other steps. In order to explain the kinetic order of 0.7 with respect to hydrogen, however, we have to introduce the assumption that a pair of dissociated hydrogen atoms on an isolated site is allowed to react with the adsorbed ethylene, because the contribution of hydrogen atoms in a randomly-mixed state to the reaction leads to a rate equation which cannot provide a kinetic order higher than 0.5. The assumption of an isolated site is supported by the results of CO posioning, which revealed that the fraction of the active site is less than 0.5% of the total surface. The selective formation of ethane-[D_2] is also well accounted for by the nearly irreversible addition of the paired deuterium atoms on the site. Thus, the rate of ethane formation, V_e^1, is given by the following equation:

$$V_e^1 = k_3^1\theta'_h\theta_e = \frac{k_3^1K_hK_eP_hP_e}{(1+K_hP_h+K_eP_e)^2} \quad (7)$$

where θ'_h and θ_e are the fractions of coverage for the adsorbed hydrogen atom pair and for the adsorbed ethylene respectively. k_3^1 is a rate constant. Equation 7 was then transformed into

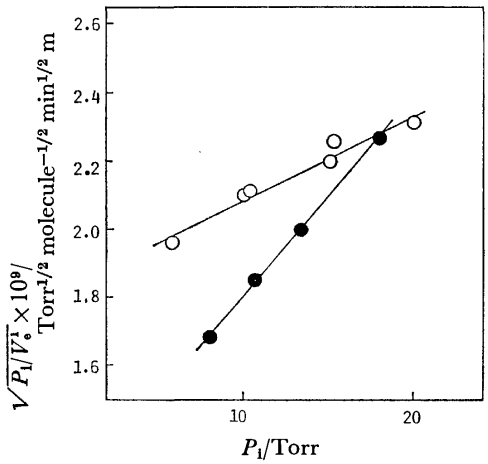

Fig. 5. Plots of $\sqrt{P_l/V_e^1}$ *vs.* P_l.
○; $P_l=P_h$ ($P_e=10$ Torr), ●; $P_l=P_e$ ($P_h=20$ Torr).

$$\sqrt{\frac{P_h}{V_e^1}} = \sqrt{\frac{1}{k_3^1K_hK_eP_e}}(1+K_eP_e+K_hP_h) \quad (8)$$

or

$$\sqrt{\frac{P_e}{V_e^1}} = \sqrt{\frac{1}{k_3^1K_hK_eP_h}}(1+K_eP_e+K_hP_h). \quad (9)$$

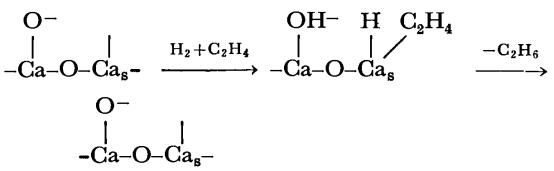
Figure 5 shows the plots of the $\sqrt{P_e/V_e^1}$ term against P_e (P_h=constant) and of the $\sqrt{P_h/V_e^1}$ term against P_h (P_e=constant). The linear relationships observed in the experimental results indicate the validity of the derived equation and, hence, the mechanism proposed.

It is of interest to compare the present data with those of others. The activation energy of 12.6 kJ mol^{-1} in the low-temperature range was smaller than those for such transition metal catalysts as Ni, Fe, and Pd,[5] 30—40 kJ mol^{-1}. This is due to the fact that the slow step of the hydrogenation on CaO is the addition of the dissociated hydrogen atom pair to the adsorbed ethylene, whereas that on the metals is the dissociative adsorption of hydrogen. Another difference was observed in the deuterium distributions in ethane; the selectivity of ethane[D_2] formation in the present case was considerably higher than the earlier-reported values, 20% for Ni[10] (363 K and 20% in conversion), 22% for Fe[12] (173 K and 100%), and 17% for Pd[13] (257 K and 5%). The selectivity, however, was much less than those, almost 100% for such oxides as Cr_2O_3[7] (273 K), ZrO[8] (298 K), and Co_3O_4[14] (296 K). The CaO surface is also different from these metals in the infeasibility of the isotopic exchange between D_2 and ethane. Since the catalytic properties are different from those of the transition metals or their oxides, one can rule out the possibility that the catalytic activity of CaO might be ascribable to a trace of such components exposed at the surface.

As for the density of the active sites, the amount of CO which caused zero activity enables us to determine the fraction of the active part at be about 0.5%, which corresponds to 8×10^{12} surface ions cm^{-2}, provided that a CO molecule adsorbs on a surface ion. This result also shows that only specific sites are able to contribute to the catalytic reaction. By the use of this value, the turn-over frequency, N_t, was determined to be 0.75 s^{-1} at 273 K (P_h=20 and P_e=10

Torr). For a comparison of N_t, the data of others were corrected to the conditions of our work. N_t is given as 0.7—1.3 s^{-1} for the silica-supported Pt[15] after calculation using the rate equation of $V_e=k'P_H^{1.0}P_e^{0.0}$. The value of N_t for the reaction on ZnO is evaluated to be 3×10^{-4}—6×10^{-4} s^{-1} by using the pressure dependence of a half-order with respect to the hydrogen pressure and by assuming that a reactive ethylene occupies an active site.[8,16] These comparisons clearly show that the activated CaO is able to catalyze the hydrogenation of ethylene effectively.

Structure of Active Sites. A detailed study of the active sites will be published in a subsequent paper;[17] thus, we will present here only a brief description of the plausible models of the structure of the sites and the pathway of the hydrogenation on them. The decomposition of $Ca(OH)_2$ caused the rearrangement of the structure from trigonal hydroxide to cubic oxide. A recent mass-spectrometric analysis of gases evolved during the thermal decomposition of $Mg(OH)_2$ to MgO showed that hydrogen is released together with H_2O by evacuation at high temperatures.[18] This suggests that the desorption of hydrogen leaves oxygen atoms which are coordinatively unsaturated and negatively charged. The same processes presumably take place on CaO, since the oxide tends to form the peroxide more readily than does MgO. Thus, the electron-donating species, $-O-\overset{O^{\delta-}}{\underset{|}{Ca}}-O-$, are likely to participate in the catalytic cycle of the hydrogenation. The importance of this species, O_s^-, adjacent to an isolated OH^- group has also been pointed out in the case of the H_2–D_2 equilibration reaction on MgO.[2] It is plausible that the active sites on CaO for the equilibration are analogous to those on MgO. It should be noted, however, that there existed a clear difference in the activation temperature of CaO for these reactions; CaO evacuated at 1273 K still possessed a high capability of catalyzing the equilibration reaction,[2] but lost its activity for the hydrogenation of ethylene. These facts indicate that the active sites for the reactions are not identical and predict that the hydrogenation requires a contribution from the exposed Ca cations. This view is supported by the preliminary results on the structural rearrangement of CaO upon heat treatment.[17] The fact that the active sites correspond to a small surface fraction, 0.5%, of the total surface atoms shows only a part of the surface in a specific conformation to be effective; thus, we tentatively propose a structure which is composed of the exposed Ca ion and the nearby O_s^- species. The hydrogenation of ethylene presumably proceeds as follows:



where Ca_s denotes the exposed Ca ion.

The poisoning effect of CO on the hydrogenation of ethylene varied with the reaction temperature. The catalytic activity for the reaction at a high temperature decreased almost proportionaly to the CO coverage as a consequence of the homogeneous occupation of the active sites. This homogeneous character in the distribution of the active sites is probably achieved by the migration of hydrogen atoms from site to site at high temperatures. The presence of the hydrogen atom is consistent with the proposed mechanism that the rate-determining step is the surface reaction of a hydrogen atom with an ethyl radical. On the contrary, the poisoning effect at low temperatures was characterized by a marked fall in the activity in the initial coverage of CO. The presence of hydrogen-pair atoms together with ethylene in the low-temperature reaction puts more restrictions on the conformation of the active sites available for their adsorption than those for the reaction at high temperatures.

The adsorbed state of CO on CaO is not clear at present, but information from an infrared spectroscopic study of CO adsorbed on MgO[19] is available; the exposure of MgO evacuated at 1273 K to CO at room temperature gave rise to two absorption peaks at 2100 cm^{-1}, in addition to complex bands in the region of 1450 cm^{-1}. The former absorption is characteristic of the stretching vibration of the CO molecule linked through the carbon atom to a single atom of the surface, whereas the latter might be associated with the CO molecule undergoing interaction with O^- and/or O^{2-} in the vicinity.[20] A CO adsorption of a similar type is plausible in the case of CaO, and it appears likely that CO exists as a linear form on the exposed $-Ca_s-$.

A study is now in progress by the aid of X-ray Photoelectron Spectroscopy and ESR to clarify further the details of the structure and nature of the active sites.

Solvent Effect on the Partition Equilibrium of Normal Aliphatic β-Diketones between Heptane and Water–Dimethyl Sulfoxide Mixed Solvents. The Extended McDevit-Long Approach

Hitoshi WATARAI and Nobuo SUZUKI*

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

(Received October 30, 1979)

The partition equilibria of 7 normal aliphatic (C_5-C_9) β-diketones were investigated in the two-phase systems of heptane/water–dimethyl sulfoxide (DMSO) mixed solvents at 25 °C. The partition coefficients, P, of the keto and enol forms of the β-diketones were determined, and the linear correlations between log P and the number of carbon atoms in the *n*-alkyl groups were observed. In general, an increase in the mole fraction of DMSO, X_S, in the mixed-solvent phase caused a lowering of the partition coefficient, while with smaller β-diketones, distinct maxima were observed at $X_S \simeq 0.2$. The solvent effect of the mixed-solvent phase was interpreted on the basis of the extended McDevit-Long theory previously proposed by the present authors.

The importance of the solvent effect of the aqueous phase on the liquid-liquid partition equilibrium is well recognized by workers engaged in extraction chemistry. For example, an increase in the electrolyte concentration in the aqueous phase improves the extraction of nickel(II) with acetylacetone[1] and the partition of 8-quinolinol[2] and β-diketones.[3] Recently, it has been reported that the introduction of a water-missible organic solvent, *e.g.*, acetone,[4] 2-propanol,[5] or DMSO,[6] into the aqueous phase also improves the extraction of inorganic substances, *e.g.*, uranium,[4] protactinium,[5] or hafnium.[6] However, no systematic investigation of the role of the aqueous phase has yet been reported.

Previously, we pointed out that the partition coefficient of acetylacetone in the heptane/water–DMSO system shows a distinct maximum at a mole fraction of DMSO of about 0.2.[7] Recently, we observed that the addition of an organic solvent to the aqueous phase produces an interesting effect like a salting-out on the partition of the nonpolar solute and that the variation in the partition coefficient at a different solvent composition can be interpreted semi-quantitatively by making use of the extended McDevit-Long theory.[8]

In the present study, the partition coefficients of a series of normal aliphatic β-diketones in the two-phase system of heptane/water–DMSO are determined, and the substituent effect and the solvent effect are discussed.

Experimental

Chemicals. The acetylacetone (Nakarai, G. R.) was purified by fractional distillation. The methods of synthesis and purification of the normal aliphatic β-diketones were described previously.[9] The β-diketones are listed in Table 1. The solvents used in this study were purified by a method described previously.[7] The mixed aqueous solvents were prepared by weight at desired mole fractions within ±0.0005.

Partition Experiment. Five ml of a heptane solution of β-diketone ($<10^{-2}$ M) and an equal volume of the mixed solvent were stirred by means of a magnetic stirrer in a water-jacketted partition vessel thermostated at 25±0.1 °C for 12 h. After standing for 2 h, the mixed-solvent phase was pipetted out into a quartz cell and the concentration of β-diketone in the solution was determined photometrically. The partition coefficient was calculated from the initial concentration and the concentration in the mixed-solvent phase. For larger β-diketones, a relatively concentrated solution (0.1 M) in heptane has to be used because of its large partition coefficient, but no concentration effect on the partition coefficient was observed up to 0.54 M. Partition measurements were repeated twice or more, and the relative standard deviation was within 3%.

Estimation of Enol Fraction. β-Diketones are present as enol and keto forms in both phases of the partition system. The NMR method is now considered to be the most reliable one for the determination of the enol fraction of β-diketone in solution.[10] In the present study, however, the NMR method is difficult to apply because of the low solubility of the β-diketones and the large solvent signals of water–DMSO mixed solvent, which make an accurate determination of the enol fraction impossible. Previously, we found, for acetylacetone, a linear relationship between the apparent molar absorptivity at the absorption maximum and the enol fraction as determined by the NMR method.[7,11] Therefore, the enol fractions of normal aliphatic β-diketones in the mixed solvents were estimated by making use of the empirical relationship, assuming that the substituent effect of the alkyl group on the molar absorptivity could be neglected. The error in the estimated enol fraction is less than 0.05. The enol fractions in heptane were determined by the NMR method. The enol fraction was calculated from the integrated signal intensities of the keto-methylene protons and the enol-methine proton, or from those of the methyl protons in both tautomers.

Results

The observed partition coefficients and the enol fractions in heptane and in mixed solvents are listed in Table 1. The partition coefficients for the keto and enol forms are calculated from the following equations:

$$P_K = \frac{1-f_o}{1-f}P \qquad P_E = \frac{f_o}{f}P. \tag{1}$$

In Fig. 1, log P_K and log P_E are shown as functions of the mole fraction of DMSO. The results show that the variation in the partition coefficient with X_S is more remarkable for the enol tautomer than for the keto tautomer and that a distinct maximum in the partition coefficient appeares at $X_S \simeq 0.2$ for smaller β-diketones.

Discussion

Correlation between log P *and the Carbon Number.*

The plots of log P_K and log P_E against the number of carbon atoms in the *n*-alkyl substituent show a linear relationship in every partition system (Fig. 2); *i.e.*,

$$\log P = An + B, \tag{2}$$

where A corresponds to the logarithm of the partition coefficient of the methylene group, log P(–CH_2–), and B, to that of the enol or diketone skeleton, log P(–COCHCOH–) or log P(–$COCH_2CO$–). The values of A and B, obtained from the slope and intercept in Fig. 2, respectively, are illustrated in Fig. 3. This decreasing order of the partition coefficients: P(–CH_2–) > P(–COCHCOH–) > P(–$COCH_2CO$–) was observed in every partition system; it corresponds to the expected order of increase in the dipole moment of the groups. Log P(–CH_2–) decreases monotonously with the increases in X_s and gives an equal value for the two tautomers. Both log P(–COCHCOH–) and log P(–$COCH_2CO$–) show maxima in the water-rich region. From the results shown in Fig. 3, the maxima in log P_K and log P_E, which become remarkable in smaller β-diketones, as has been noted in Fig. 1, can be ascribed to those in log P(–$COCH_2CO$–) and log P(–COCHCOH–).

Composition Dependence of Partition Coefficient.

In a previous paper, the McDevit-Long theory has been extended to the estimation of the activity coefficient in a water–organic solvent mixture.[8] In this extended treatment, the activity coefficient of a nonelectrolyte infinitely diluted in an aqueous mixed solvent can be expressed by the following equation;

$$\ln f_n = -\frac{v_n^\infty}{RT}\frac{P_i}{\alpha T}\frac{v^E}{v}, \tag{3}$$

where f_n and v_n^∞ refer to the activity coefficient and the partial molar volume of the nonelectrolyte respectively; v and v^E to the mean molar volume of the ideal mixed solvent and the excess molar volume of the real mixed solvent, and P_i and α, to the internal pressure and the coefficient of the thermal expansion of the mixed solvent respectively. The activity coefficient given by Eq. 3 reflects the difference in the cavity-formation energy or the solvophobic interaction energy of the solute in different solvent systems, the ideal mixed solvent, and the real mixed solvent, because a direct interaction between the solute and the solvent molecules is left out of account in this treatment. When Eq. 3 is applied to an interpretation of the solvent effect, the contribution of the solvation should be eliminated by a reasonable treatment. For this purpose, we adopted the volume-fraction treatment, which is recommended for the calculation of the excess value when the molar volumes of the solute and the solvent differ considerably,:[12]

$$\Delta \ln P_x = \ln P_x - (1-\phi_s)\ln P_{x,0} - \phi_s \ln P_{x,1}, \tag{4}$$

where P_x refers to the partition coefficient in the mole-

fraction scale, ϕ_s to the volume fraction of DMSO, and the subscripts 0 and 1 to the heptane/water and heptane/DMSO systems. $\Delta \ln P_x$ in Eq. 4 corresponds to $\ln f_n$ in Eq. 3. From Eqs. 3 and 4, a linear correlation between $\Delta \ln P_x$ and the pressure factor, $-(P_1/\alpha T)(v^E/v)$, can be expected. In practice, for acetylacetone and other β-diketones the plots of $\Delta \ln P_x$ against $-(P_1/\alpha T)(v^E/v)$ show linear correlations both for the keto form and the enol form (Figs. 4 and 5). The slopes in these figures are expected to increase with increases in the molar volume or length of the alkyl chain (*cf.* Eq. 3). The slopes for keto forms were plotted against the molar volumes, v_n, calculated assuming that the molar volume of the acetylacetone-keto form is 110.99 cm^3 mol^{-1} [13] and the volume of methylene group is 22.2 cm^3 mol^{-1}.[14] Figure 6 shows clearly a proportionality between $\Delta \ln P_x$ and the molar volume. From these results, it may be concluded that the maximum observed in the partition coefficient is correlated to the increase in the pressure factor $-(P_1/\alpha T)(v^E/v)$, which reflects an increase in the solvent-solvent interaction. This situation is quite similar to a salting-out phenomenon induced by a structure-making electrolytes. The composition dependences of the group partition coefficient, P(–CH_2–), P(–$COCH_2CO$–) and P(–COCH-COH–), shown in Fig. 3, can also be understood from the present consideration.

A further discussion will be given to compare the slopes in Figs. 4 and 5 with the one expected from Eq. 3, but the observed slope is one half to one-third of the expected one. This is noted also by McDevit and Long in their original treatment of the salt effect;[15] they ascribed the discrepancy in their results to a disregard of the closest distance between electrolyte and nonelectrolyte and suggested the introduction of the correction term of $a/(a+b)$, where a and b correspond to the distances of the closest approach to the average "solvated" ion and to the nonelectrolyte molecule, respectively. Recently, Cross and McTigue

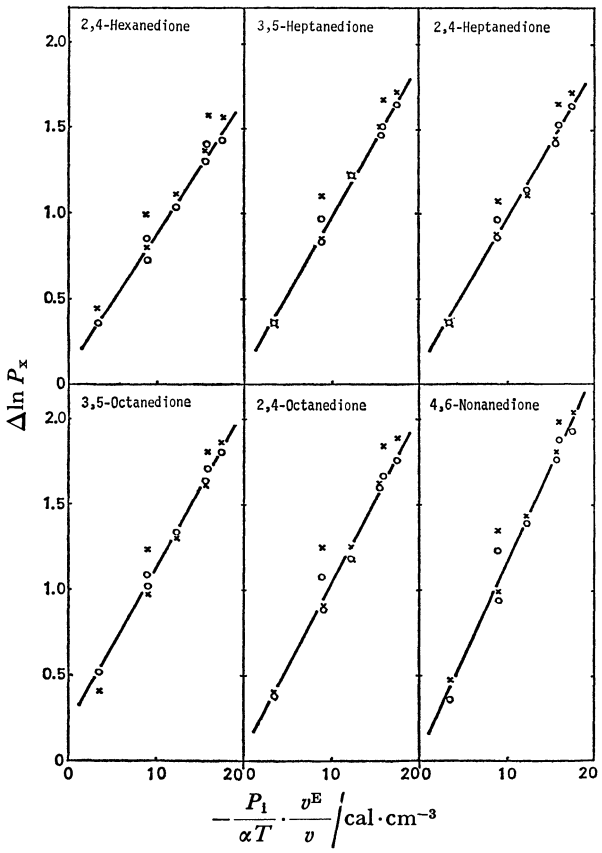

Fig. 5. Correlation between $\Delta \ln P_x$ and the pressure factor for normal aliphatic β-diketones.

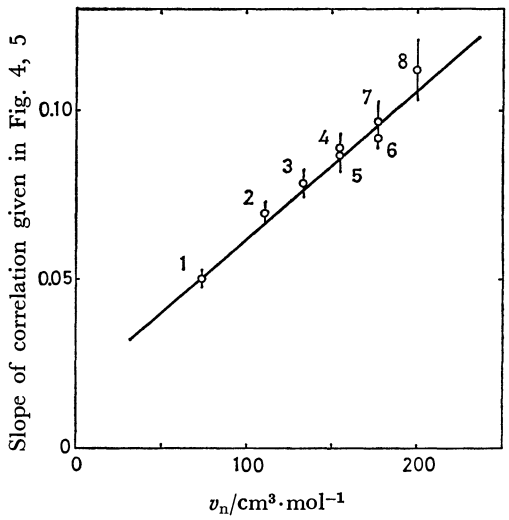

Fig. 6. Correlation between the slopes shown in Figs. 4 and 5 and the estimated molar volumes of the solutes. 1: Acetone (Ref. 8), 2: acetylacetone, 3: 2,4-hexanedione, 4: 3,5-heptanedione, 5: 2,4-heptanedione, 6: 3,5-octanedione, 7: 2,4-octanedione, 8: 4,6-nonanedione.

have reported a successful interpretation of the salting effect in a concentrated electrolyte solution by taking into account the correction term.[16] In the present study also, we introduce the term of $a'/(a'+b')$, where a' and b' correspond to the van der Waals radius of the mixed solvent and radius of the nonelectrolyte.

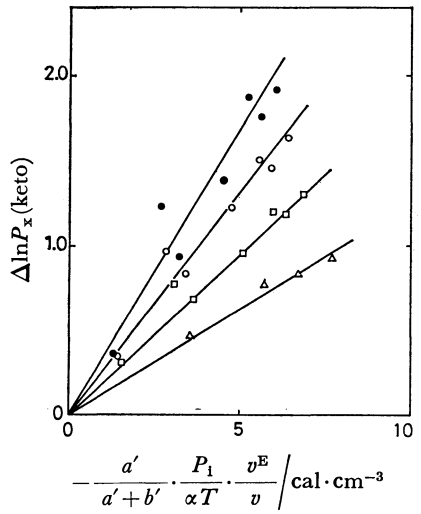

Fig. 7. Correlation between $\Delta \ln P_x$ of keto forms and $-\{a'/(a'+b')\}(P_1/\alpha T)(v^E/v)$.
The slopes of the solid lines are the expected one of v_n/RT; △: Acetone (Ref. 8), □: acetylacetone, ○: 3,5-heptanedione, ●: 4,6-nonanedione.

The values of a' and b' were calculated by

$$a' = \left(\frac{v - 593/P_1}{4.189}\right)^{1/3} \quad (5)$$

$$b' = \left(\frac{v_n}{4.189}\right)^{1/3}. \quad (6)$$

Equation 5 is based on the same idea as that proposed by Bagley et al. in which the occupied volume in a liquid is estimated from the internal pressure.[17] The slopes obtained from the plot of $\Delta \ln P_x$ against $-a'/(a'+b')\ (P_1/\alpha T)\ (v^E/v)$ were very close to the expected one of v_n/RT, as is shown in Fig. 7.

In conclusion, it is noteworthy that the solvent effect of a highly associated mixed solvent such as water–DMSO, could be interpreted by means of a new solvent parameter, *i.e.*, the pressure factor, which can be calculated from the available solvent parameters. The usefulness of the pressure factor as a measure of the solvent effect due to the solvent-solvent interaction was demonstrated. We believe that the solvophobic contribution to the solvent effect should be investigated in detail for a quantitative elucidation of the role of an aqueous solvent in solvent extraction and in reversed-phase chromatography.

The authors wish to express their gratitude to the Takeda Science Foundation for the financial support granted to this research.

An ENDOR Study of the Hindered Internal Rotation of the Cyclopropyl Group in the 2,6-Di-*t*-butyl-4-cyclopropylphenoxyl Radical

Fumio SHIMODA*

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisendamachi, Naka-ku, Hiroshima 730

(Received November 1, 1979)

The ESR and ENDOR spectra were observed for the 2,6-di-*t*-butyl-4-cyclopropylphenoxyl radical. The assignments of the proton hyperfine coupling constants were confirmed with reference to those of the 2,6-di-*t*-butyl-4-methyl- and 4-(1-deuteriocyclopropyl)phenoxyl radicals. The β-proton hyperfine coupling constant for the cyclopropyl group and its temperature dependence were precisely determined. Of particular interest is the fact that the observed cyclopropyl β-proton splitting is smaller than the γ-proton splittings (A_4^{β}: 0.72, $A_4^{\gamma^1}$: 0.83, $A_4^{\gamma^2}$: 1.44 G at -70 °C). Based on the modified $\cos^2\theta$ rule, $A_4^{\beta}=(1.85\langle\cos^2\theta\rangle-0.10)\times A_4^{Me}$, where the conjugative interaction between the π-system and the cyclopropyl pseudo π-orbital was incorporated, as proposed by Hudson and Bauld, the β-proton splitting was evaluated. The magnitude of the β-proton splitting and its temperature dependence were interpreted in terms of the restricted rotation of the cyclopropyl group in a two-fold potential; the stable conformation was the bisected one. The rotational barrier height, which corresponds to the difference in energy between the bisected and perpendicular conformations, was estimated to be 2.6 kcal/mol. The rotational barrier was attributed to the stabilization of the bisected conformation arising from the conjugative interaction of the aromatic and cyclopropyl moieties.

It has been well-known for a long time that a cyclopropyl group has a stronger π-conjugative ability than the other alkyl groups,[1] and so the behaviour of a cyclopropyl group in chemical reactions has been of interest. For example, accelerations by a cyclopropyl group have been observed in the reactions which proceed *via* a cationic intermediate.[2] The results have been explained in terms of the conjugative stabilization effect of a cyclopropyl group for the intermediate. This effect is greatly affected by the conformation of the cyclopropyl group.[3] On the other hand, the double-bond character of a cyclopropane ring and its electronic structure have been investigated in detail. Several models of the bond system in cyclopropane have been proposed by several authors.[4] The Walsh model of the chemical bonds in cyclopropane, which is a typical model, suggests that the conjugative interaction between the pseudo π-orbital of the cyclopropyl ring and the phenyl π-system is at its maximum when the molecule adopts the bisected conformation in which C_1–H_β bond of the cyclopropyl ring lies on the aromatic plane (Fig. 1). Indeed, the conformational investigations of the cyclopropylbenzene by using NMR spectroscopy support the above expectation.[5]

* Present address: Department of Applied Physics and Chemistry, Faculty of Engineering, Hiroshima University, Sendamachi, Naka-ku, Hiroshima 730.

It has been established that the internal rotation of an alkyl group can be studied for the various free radicals on the basis of the ESR and ENDOR techniques. For a number of aromatic radicals, the rotational barrier of an alkyl group has been estimated by the Heller-McConnell relationship[6] with the aid of some statistic procedures treating the observed β-proton splitting and its temperature dependence. Particularly, the hindered internal rotations of alkyl groups in the 4,4′-dialkylbiphenyl anion radicals[7] and the 2,6-di-*t*-butyl-4-alkylphenoxyl radicals[8] have been reported in previous papers.

In the present paper, from an analysis of the temperature dependence of the β-proton splitting on the basis of the modified $\cos^2\theta$ rule,[9] the hindered internal rotation of the cyclopropyl group in the 2,6-di-*t*-butyl-4-cyclopropylphenoxyl radical has been studied. The comparison of the results thus obtained with those for the other 2,6-di-*t*-butyl-4-alkylphenoxyl radicals[8] has been made with the purpose of examining the effect of the cyclopropyl group on the aromatic neutral radical. In this radical series, the spin density on the carbon atom of the phenoxyl moiety to which an alkyl group is attached is expected to be generally high. If this is so, the cyclopropyl β-proton splitting as well as its temperature dependence may be precisely determined. Therefore, this phenoxyl radical may be adequate for this study.

Results

ESR Spectra. The ESR spectra of the 2,6-di-*t*-butyl-4-cyclopropylphenoxyl radical (Radical-H) and the 2,6-di-*t*-butyl-4-(1-deuteriocyclopropyl)phenoxyl radical (Radical-D), generated by the lead-dioxide oxidation of the corresponding phenols,[10] in toluene were observed in the temperature range from -80 °C to 20 °C. As is shown in Fig. 2, the pattern of the ESR spectrum observed for the Radical-H varied with the change in the temperature, while that for the Radical-D remained unchanged. These results imply that the magnitude of the cyclopropyl β-proton hy-

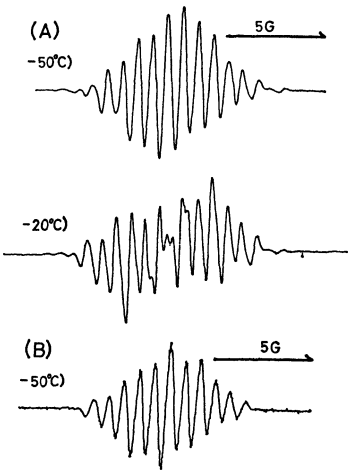

Fig. 2. ESR spectra of the Radical-H and Radical-D. (A) Radical-H, (B) Radical-D.

perfine coupling constant is strongly dependent on the temperature. The hyperfine coupling constants, however, could not be determined precisely because of the poorly resolved ESR spectrum.

ENDOR Spectra. The ENDOR spectrum of the Radical-H at −70 °C, shown in Fig. 3 (A), was composed of five signals in the upper half of the spectrum. With reference to the hyperfine splittings for the 2,6-di-*t*-butyl-4-alkylphenoxyl radicals,[8] the signals at 13.91 and 16.21 MHz could be assigned to the splittings due to the *t*-butyl protons and two protons at the 3-positions of the phenoxyl moiety respectively. The signal corresponding to the cyclopropyl β-proton splitting, at 14.84 MHz, was easily assigned with reference to the ENDOR spectrum of the Radical-D, as is shown in Fig. 3 (B). The other signals, at 15.01 and 15.81 MHz, were then assigned to those due to the non-equivalent pair of cyclopropyl γ-proton splittings. The analyzed hyperfine coupling constants of the Radical-H, Radical-D, and related phenoxyl radicals are summarized in Table 1. As may be seen in Fig. 3 (A), the β-proton splitting for the Radical-H showed a large positive temperature dependence. The temperature dependence of these hyperfine coupling constants for the Radical-H is depicted in Fig. 4.

In comparing the coupling constants for the Radical-H with those for the 2,6-di-*t*-butyl-4-alkylphenoxyl radicals,[8] the following interesting facts may be pointed out:

(1) The magnitude of the β-proton coupling constant for the cyclopropyl group was much smaller than those for the other alkyl groups, but its temperature dependence was considerably large.

(2) The magnitudes of the non-equivalent γ-proton coupling constants were several times as large as that for the 2,6-di-*t*-butyl-4-isopropylphenoxyl (isopropylphenoxyl) radical.

Discussion

Magnitude of the β-Proton Splitting. In the previous works on the 4,4′-dialkylbiphenyl radical anions and the 2,6-di-*t*-butyl-4-alkylphenoxyl (alkylphenoxyl) radicals, the magnitude of the β-proton splitting was interpreted in connection with the steric interaction between the aromatic ring protons and the rotating alkyl group.[7,8] From this point of view, the β-proton splitting for the Radical-H may resemble to that for the isopropylphenoxyl radical, because both the skeletal composition and the size of a cyclopropyl group seem to be similar to those of an isopropyl group. In fact, the β-proton splitting for the 4,4′-dicyclopropylbiphenyl anion was 3.31 G[11,12] (1 G=10^{-4} T) and that for the 4,4′-diisopropylbiphenyl anion was 2.78 G[7] at −90

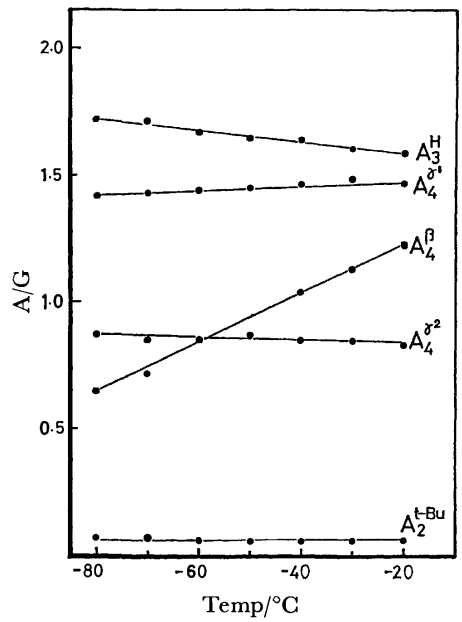

Fig. 4. Temperature dependence of the hyperfine coupling constants for the Radical-H.

°C. The results were in line with the above expectation. However, the observed β-proton splitting for the Radical-H deviated greatly from the expectation, as has been described in the previous section (see Table 1). This discrepancy could not be explained solely in terms of the steric interaction model.

The small value of the β-proton splitting, which is remarkably distinct from that for the 4,4'-dicyclopropylbiphenyl anion, suggests that the cyclopropyl group in the Radical-H strongly prefers the bisected conformation (Fig. 1-A). That may be attributed to the conjugative interaction between the aromatic and cyclopropyl moieties.

Similar observations have been reported in earlier works. In the semidiones, the β-proton splitting of the cyclopropyl group was one-tenth as large as that of the methyl group.[13] For the cyclopropylmethyl radicals, the β-proton splitting was much smaller than that for the methyl substituent.[14] In aromatic radicals, the β-proton splitting for the 4,4',4"-tricyclopropyltriphenylmethyl radical was one-sixth that of methyl-substituted analogue.[11] These observations were interpreted in terms of the propensity of the bisected conformation for the cyclopropyl group.

Temperature Dependence of the β-Proton Splitting. The magnitude of a β-proton splitting is often calculated using the following equations:

$$A^{\beta} = \langle Q(\theta) \rangle \rho^{\pi}, \quad (1)$$

and:

$$Q(\theta) = B_0 + B_2 \cos^2 \theta, \quad (2)$$

where B_0 and B_2 are empirical parameters, ρ^{π} is the spin density on the aromatic-ring carbon attached to an alkyl group, and θ is the angle between the axis of the $2p_z$ orbital and the C–H_{β} bond of the alkyl group, both projected on the plane perpendicular to the bond between the methine carbon of the alkyl group and the aromatic carbon. The term of $\langle \cos^2 \theta \rangle$ is the quantum mechanical average of $\cos^2 \theta$ over the appropriate rotational wave functions.

The Data at −60 °C.
a) The ENDOR signal disappeared.

For the cases of the alkylphenoxyl radicals (alkyl; Et, *i*-Pr, and *c*-He), Eq. 1 was successfully approximated to Eq. 3 on the basis of the following assumptions:[8] (1) The values of $A_2^{t\text{-Bu}}$ (*t*-butyl proton splitting) and A_3^H (phenoxyl-ring proton splitting) for the above phenoxyl radicals were nearly the same as that for the 2,6-di-*t*-butyl-4-methylphenoxyl (methylphenoxyl) radical; hence, each spin density on the 4-carbon of the phenoxyl ring among these alkylphenoxyl radicals was much like that for the methylphenoxyl. (2) If the methyl group in the methylphenoxyl radical is assumed to rotate freely, the value of the $\langle \cos^2 \theta \rangle$ is one-half it, since the methyl-proton splitting for this radical remains almost unchanged from −45 °C to 15 °C. Therefore, $B_2\rho_4^{\pi}$ was assumed to be $2 \times A_4^{Me}$. A_4^{Me} is the methyl-proton splitting for the methylphenoxyl radical. (3) The B_0 term being smaller than the $B_2\langle \cos^2 \theta \rangle$ term, the B_0 term was neglected in Eq. 2:

$$A_4^{\beta} = 2 \times A_4^{Me} \langle \cos^2 \theta \rangle. \quad (3)$$

Although the first assumption may be appropriate for the Radical-H, the latter two assumptions may be no longer valid for any cyclopropyl-substituted radicals. There are two difficulties with the above simple model:

(1) Because of the conjugative interaction between the aromatic π-system and the cyclopropyl pseudo π-orbital, the mechanism which induces spin density on the β-hydrogen atom may be different. Therefore, the B_0 and B_2 terms for the cyclopropyl-substituted radical systems may not be identical to those for the cases of the normal alkyl-substituted radicals.

(2) The propensity of the cyclopropyl group to take the bisected conformation makes the $\langle \cos^2 \theta \rangle$ value small in Eq. 2. When the $\langle \cos^2 \theta \rangle$ value is small, the contribution of the B_0 term is no longer negligible.[15] To avoid the above difficulties, Hudson and Bauld added a third term, one which resulted from the conjugative interaction between the cyclopropyl group and the π-system, to the conventional Heller-McConnell relationship.[6] They divided the third term into conformational-dependent and -independent parts, which they then added to the B_0 and B_2 terms respectively of the normal $\cos^2 \theta$ rule. From the comparative study of the 4-(2-cyclopropyl-1-ethynyl)nitrobenzene and the 4-(1-propynyl)nitrobenzene anion radicals, they sug-

gested that the conjugative effect produced a negative spin density at the β-hydrogen atom and proposed Eq. 4 for the conformational analysis of a cyclopropyl group in a radical system:[9]

$$A_4^{\beta} = [1.85\langle\cos^2\theta\rangle - 0.10] \times A_4^{Me}. \quad (4)$$

The β-proton splitting of the methylphenoxyl radical, A_4^{Me}, was 11.20 G.[8] With the aid of the Boltzmann statistics, the β-proton splitting of the Radical-H as a function of the temperature was calculated based on Eqs. 4 and 6.

$$\theta = \alpha + \theta_0 \quad (5)$$

$$\langle\cos^2\theta\rangle = \frac{\sum_{i=0} \langle\psi_i(\alpha)\,|\cos^2(\alpha+\theta_0)|\,\psi_i(\alpha)\rangle e^{-E_i/kT}}{\sum_{i=0} e^{-E_i/kT}} \quad (6)$$

Here, the wave functions, $\psi_i(\alpha)$, and the eigen values, E_i, are obtained by solving the following equation:

$$-\frac{\hbar^2}{2I}\left(\frac{d^2\psi_i}{d\alpha^2}\right) + [V_{(\alpha)} - E_i]\psi_i = 0. \quad (7)$$

In Eq. 7, the moment of inertia, I, of the molecular fragment aryl-cyclopropyl may be calculated to be 7.8×10^{-39} g cm^2 for the Radical-H, assuming that the preferred rotation of the residual group occurs about the long axis of this radical. In Eq. 7, $V_{(\alpha)}$ is the potential function to the internal rotation of the cyclopropyl group in this radical. In order to solve Eq. 7, the precise potential function must be assumed. Sorriso *et al.* and Collet *et al.*[16] theoretically calculated the angular dependence of the rotational barrier in the cyclopropylbenzene by means of the molecular orbital theory. By reference to these results, the potential function was approximated as follows:

$$V_{(\alpha)} = \frac{V_0}{2}(1-\cos 2\alpha). \quad (8)$$

In Eq. 8, V_0 is the difference in energy between the lowest energy state, the bisected conformation, and the highest one, the perpendicular. The α value is the dihedral angle between the β-proton and the aromatic plane, so it is equal to zero in the bisected conformation and $\pi/2$ in the perpendicular. The θ_0 value in Eq. 5 becomes equal to $\pi/2$. The Hamiltonian matrix, $\langle i|H|j\rangle$, was diagonalized by expanding the wave function in a Fourier series:

$$\psi_i(\alpha) = \sum_{j=0} (A_{ij}\cos j\alpha + B_{ij}\sin j\alpha). \quad (9)$$

The temperature dependences of $\langle\cos^2\theta\rangle$ as a function of V_0 for the Radical-H have also been calculated. The results calculated in the temperature range from −80 °C to 0 °C for the various values of V_0 are shown in Fig. 5. The best agreement between the calculated and the experimental temperature dependence, evaluated by means of Eq. 4, was obtained with V_0=2.6 kcal/mol (1 kcal=4.184 kJ). On the other hand, the magnitudes $\langle\cos^2\theta\rangle$ evaluated from Eq. 3 were very small. In this case, the potential barrier calculated was 5.0—7.5 kcal/mol, although the observed temperature dependence of the β-proton splitting could not be adequately explained. The latter value of the potential barrier, which corresponds to

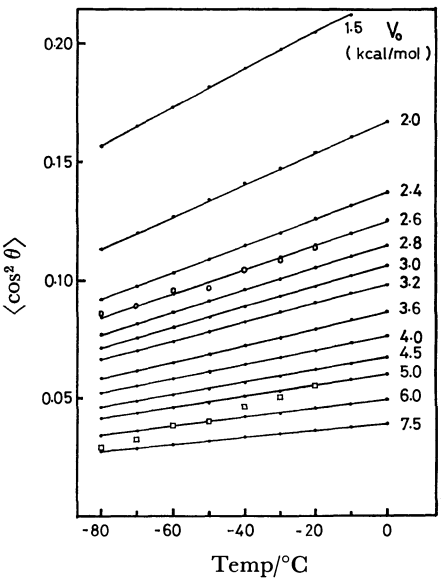

Fig. 5. The theoretically calculated and experimental temperature dependence of $\langle\cos^2\theta\rangle$ for the Radical-H. The numerical calculations were carried out with various values of V_0, which was the energy difference between the bisected and perpendicular conformation. —●—; Theoretically calculated values of $\langle\cos^2\theta\rangle$, ○; $\langle\cos^2\theta\rangle$ vaules evaluated from Eq. 4, □; $\langle\cos^2\theta\rangle$ values evaluated from Eq. 3.

the energy difference between the bisected and perpendicular conformation (Fig. 1), may be comparable to the conjugative energy between two phenyl rings for the biphenyl molecule when the molecule is coplanar (about 6 kcal/mol).[17] Then, the potential barrier of 5.0—7.5 kcal/mol may not be adequate for the internal rotation of the cyclopropyl group in the Radical-H. However, the former value, 2.6 kcal/mol, is more appropriate for this radical. This result is compatible with the results of other investigations of the cyclopropylbenzene made using several techniques. Parr and Schaefer have reported on the basis of their NMR measurements, that the rotational barrier of the cyclopropyl group in the cyclopropylbenzene (assuming a two-fold potential) was 2.0±0.3 kcal/mol.[5] Based on the molecular orbital calculations for the cyclopropylbenzene,[16] the energy difference between the bisected and perpendicular conformations was reported to be 11.7 kJ (2.8 kcal/mol; CNDO/2) or 3.67×10^{-2} au. (2.3 kcal/mol; INDO). The compatibility with the other results implies the validity of the adoption of Eq. 4 to estimate the $\langle\cos^2\theta\rangle$ for the Radical-H.

In previous papers, the potential barriers to the internal rotation of the alkyl group in the alkyl-substituted biphenyl anion and phenoxyl radicals have been reported. As is shown in Table 2, in the 4,4′-dialkylbiphenyl radical anion series[7] the rotational barriers were 1.0, 1.2, and 1.2 kcal/mol for the 4,4′-diethyl-, 4,4′-diisopropyl-, and 4,4′-dicyclohexylbiphenyl anions respectively. In the phenoxyl series,[8] those for the 2,6-di-*t*-butyl-4-ethyl-, -4-isopropyl-, and -4-cyclohexylphenoxyl radicals were 1.1, 1.6, and 1.6 kcal/mol respectively. In both cases, the rotational

	c-Pr	0.37 (at −80 °C)[a]	0.46		9

The V_0 values show the highest values for the two-fold potential (Et, *c*-Pr) or the double-well potential (*i*-Pr, *c*-He). The V_m values show the medium value for the double-well potential (*i*-Pr, *c*-He). For particulars, see Refs. 7 and 8. a) The $\langle\cos^2\theta\rangle$ values were estimated based on Eq. 4.

barriers obtained were very similar to each other for the same alkyl groups, and in both they were interpreted in terms of the steric repulsion between the rotating alkyl group and the aromatic protons. However, the rotational barrier of the cyclopropyl group in the Radical-H deviated remarkably from the above alkylphenoxyl radical series. Based on the magnitudes of $\langle\cos^2\theta\rangle$ at −90 °C as evaluated with Eq. 4, Hudson and Bauld estimated the rotational barrier of the cyclopropyl group in the 4,4′-dicyclopropylbiphenyl radical anion to be 0.46 kcal/mol, assuming a two-fold potential in which the bisected conformation was more stable than the perpendicular one.[9] The present conclusion that the rotational barrier of the cyclopropyl group in the Radical-H is 2.6 kcal/mol is not compatible with their result. Because the steric factors are nearly comparable with the two cases, the difference in the rotational barriers for these radicals may be mainly correlated to the proportion of the contribution of the conjugative interaction between the cyclopropyl and aromatic moieties. The difference may not be expected from the solvent effects or the difference in the moment of inertia.[15] Therefore, the conjugative interaction in the Radical-H may be anticipated to be considerably important.

The Conjugative Interaction. The conclusion obtained in the previous section indicates that the contribution of the π-type conjugation between the cyclopropyl group and the π-system is more significant in the Radical-H than in the 4,4′-dicyclopropylbiphenyl anion radical. This difference may be well understood in terms of the perturbational molecular orbital theory.[18]

On the basis of the perturbational molecular orbital theory, Hoffmann *et al.* have discussed the stabilization of the cyclopropyl carbinyl cation arising from the interaction of the cyclopropyl group and the vacant carbonium $2p_z$ orbital.[19] The stabilization energy, E_s, of a molecule arising from the conjugative interaction between the cyclopropyl pseudo-π-orbital and the aromatic π-system may be approximately comprehended in terms of the following equations and the energetic

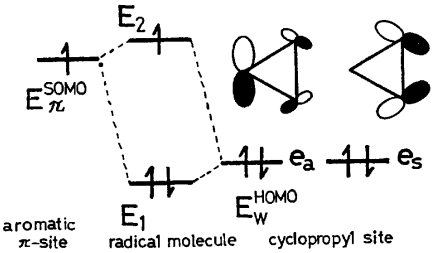

Fig. 6. Energy diagram: left-handed and right-handed are schemes of the cyclopropyl site and aromatic π-site respectively, before a perturbational interaction. The central one is the energy diagram after the interaction. E_π^{SOMO}; the energy level of the SOMO for the aromatic π-system, which contains unpaired electron, E_w^{HOMO}; the energy levels of the HOMO for the cyclopropyl system. E_1 and E_2; the energy levels of the radical molecule after the perturbational interaction between the aromatic and the cyclopropyl system. The right-handed pictures are the outline for the HOMO of the Walsh-type molecular orbitals for the cyclopropyl system, the symmetry labels refer to the C_s point group.

picture shown in Fig. 6:

$$E_s = \frac{|H_{ij}|^2}{\Delta E}, \qquad \Delta E = E_\pi^{SOMO} - E_W^{HOMO}, \tag{10}$$

$$|H_{ij}|^2 = (C_i^\pi)^2(C_j^W)^2\beta^2, \tag{11}$$

where H_{ij} is the matrix element of the perturbational interaction and where ΔE is the energy difference between the SOMO (Singly Occupied Molecular Orbital) of the π-system, E_π^{SOMO}, and the HOMO (Highest Occupied Molecular Orbital) of the cyclopropyl Walsh orbital, E_w^{HOMO} (see Fig. 6). The $|H_{ij}|^2$ term contains the square of the coefficients of the corresponding AO's (Atomic Orbitals) at the carbon atoms, attached to each other, for the HOMO of the cyclopropyl and the SOMO of the aromatic moieties; β is the resonance integral between the aromatic π-system and the cyclopropyl group. Only one orbital in the HOMO's of the cyclopropane which interacts with the π-system is denoted as e_a, because the Walsh-type orbital denoted e_s has a node on the plane of the three-membered ring at the cyclopropyl-1-carbon atom (Fig. 6). The resonance integral, β, should be dependent on the conformation of the cyclopropyl group, because the Walsh-type orbital denoted as e_a spreads on the plane of the three-membered ring. The terms of $(C_j^W)^2\beta^2$ in Eq. 11 for the Radical-H and the 4,4′-dicyclopropylbiphenyl anion being assumed to be equal, the stablization energy arising from the conjugative interaction, E_s, may be proportional to the square of the coefficient of the SOMO-AO on the aromatic carbon attached to the cyclopropyl group. On the other hand, the stabilization energy, E_s, is inversely proportional to the energetic separation between the SOMO of the π-system and the HOMO of the cyclopropyl group.

The results of the HMO calculation, summarised in Table 3, suggest that the contribution of the conjugative interaction in the Radical-H is larger than that of the 4,4′-dicyclopropylbiphenyl radical anion. When the molecule adopts the bisected conformation,

TABLE 3. THE CALCULATED SOMO ENERGIES AND COEFFICIENTS AT THE AROMATIC 4-POSITIONS[20]

	Biphenyl anion[a]	Phenoxyl[b]
Aromatic SOMO energy	$\alpha-0.705\beta$	$\alpha+0.894\beta$
Aromatic SOMO coefficient	0.398	0.545

a) Data from Ref. 20a. b) The values of the parameters, α_o as the Coulomb integral and β_{c-o} as the resonance integral, for the 2,6-di-*t*-butylphenoxyl radical were $\alpha+2\beta$ and 0.6β respectively.[20b] The HMO calculation was carried out by neglecting the contributions from the two *t*-butyl groups.

the overlapping between the π-orbital of the phenoxyl and the cyclopropyl pseudo-π-orbital is at its maximum, therefore, the stabilization effect is the most. On the contrary, the overlapping is at its minimum, and the effect is least in the perpendicular conformation. The large potential barrier estimated for the Radical-H can be understood from this point of view.

Experimental

General. All the melting points are uncorrected. The IR spectra were obtained on a Hitachi 215 spectrometer; the Mass spectra, on a Hitachi RMS-4 and RMU-6L spectrometer; the NMR spectra, on a Varian T-60 spectrometer, and the UV spectrum, on a Hitachi 124 spectrophotometer. The chemical shifts of the NMR spectra are given in ppm (δ), with tetramethylsilane as the internal standard.

The ESR spectra were measured on a JEOL-ME-3X spectrometer operating with a 100 kHz magnetic-field modulation. The ENDOR spectra were measured in the temperature range from -80 °C to -20 °C using a JEOL-EDX-1 spectrometer operating with a 80 Hz magnetic-field modulation. About 150 W of continuous radiowaves (frequency modulated at 6.5 kHz) were present in the cavity for NMR excitation.

Materials. *2,6-Di-t-butyl-4-acetylphenyl Acetate*: Into a cold mixture of anhydrous aluminum chloride (67 g, 0.5 mol) and acetyl chloride (31 ml, 0.4 mol) in carbon disulfide (150 ml), was added a solution of the commercial 2,6-di-*t*-butylphenol (31 g, 0.15 mol) in the same solvent (70 ml) below 5 °C[21] over a 2-h period. After being stirred for an hour at room temperature, the mixture was heated under reflux for 2 h. Then, the mixture was poured into an ice-cold 1 mol dm^{-3} HCl solution, the organic layer was separated, and the aqueous layer was extracted with a solvent. The combined organic layer was washed with water, an aqueous sodium hydrogencarbonate solution, and water, successively. The subsequent evaporation of the solvent, after being dried with anhydrous calcium chloride, gave a solid residue, which was then recrystallized from hexane to give colorless prisms (35 g) in an 80% yield.

Mp 100.5—101.2 °C. NMR (CCl_4) 7.83 (s, 2H), 2.50 (s, 3H), 2.29 (s, 3H), 1.37 (s, 18H). IR (nujol) 1765 cm^{-1} and 1680 cm^{-1}. Found: C, 74.60; H, 9.15%; M$^+$, 290. Calcd for $C_{18}H_{26}O_3$: C, 74.45; H, 9.02%; M, 290.

2,6-Di-t-butyl-4-(1-hydroxyethyl)phenyl Acetate: A solution of the above acetate (20 g, 0.07 mol) dissolved in 2-propanol (120 ml) was gradually stirred into a suspension of sodium borohydride (1.3 g, 0.03 mol) in 2-propanol (50 ml) at room temperature. After being stirred for 2 d at room temperature, the solvent was removed *in vacuo*. The residue was slowly poured into a cold 1 mol dm^{-3} HCl solution; then the aqueous layer was extracted with ether three times. The organic layer was washed with a saturated solution of sodium hydrogencarbonate and water. After the solution had been dried over anhydrous sodium sulfate, the concentration of the solution *in vacuo* gave a solid residue, which was subsequently recrystallized from cyclohexane to afford colorless plates (15 g, 74%).

Mp 103.4—104.0 °C, NMR (CCl_4) 7.25 (d, 1H, J= 2 Hz), 7.18 (d, 1H, J=2 Hz), 4.68 (q, 1H, J=6 Hz), 2.24 (s, 3H), 2.13 (s, 1H, OH), 1.40, 1.33 (d, J=6 Hz, s, 21H), IR (nujol) 3550 and 1740 cm^{-1}. Found: C, 74.12; H, 9.75%; M$^+$, 292. Calcd for $C_{18}H_{28}O_3$: C, 73.93; H, 9.65%; M, 292.

2,6-Di-t-butyl-4-ethenylphenyl Acetate: Into concd phosphoric acid (6 g) was added a solution of the above hydroxy ester (8.8 g, 0.03 mol) dissolved in benzene (60 ml). The mixture was heated under a gentle reflux of benzene for 3 h, until no more water was taken off as an azeotropic mixture. The organic layer was then washed with water and an aqueous sodium hydrogencarbonate solution. The evaporation of the solvent *in vacuo* left a colorless oil (7 g), which was employed as the reactant of the following experiment without any further purification. The NMR and IR data were as follows: NMR (CCl_4) 7.33 (s, 2H), 6.68 (dd, 1H, J= 11 Hz, 17 Hz), 5.64 (d, 1H, J=17 Hz), 5.16 (d, 1H, J= 11 Hz), 2.22 (s, 3H), 1.37 (s, *t*-Bu), and IR (nujol) 1775 cm^{-1}.

2,6-Di-t-butyl-4-cyclopropylphenyl Acetate: Into a mixture of palladium acetate (10 mg) and a solution of the above crude oil (7 g) dissolved in ether (30 ml) was added an ethereal solution of diazomethane,[22] prepared from 45 g of *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide according to a previously reported method[23] in an ice–salt bath over a 3-h period. Since the yellow color which is indicative of the presence of diazomethane remained unchanged, additional palladium acetate (10 mg) was added. The mixture was stirred overnight at room temperature and then washed with cold 1 mol dm^{-3} HCl and water. After the mixture has been dried, the removal of the solvent *in vacuo* gave a pale yellow oil. If the olefinic absorptions (6.8—5.0 ppm) were found upon NMR observation, the above procedure was done over again. The product was purified by alumina-column chromatography, using cyclohexane and benzene as eluents. The product (5.9 g) was eluted in the fraction of the mixed solvent (5—10% benzene and 90—95% cyclohexane). The NMR and IR data were as follows: NMR (CCl_4) 6.93 (d, 2H), 2.24 (s, 3H), 1.35 (*t*-Bu), 0.55—0.98 (m, 4H), and IR (neat) 1770 cm^{-1}.

2,6-Di-t-butyl-4-cyclopropylphenol: To an ethereal suspension of lithium aluminum hydride (0.6 g, 0.02 mol), was added a solution of the above acetate (5.9 g, 0.02 mol) in ether (10 ml) below 10 °C over period of an hour. After the mixture had been stirred at room temperature for an hour, it was heated under reflux for 2 h. Then, cold water was added to the mixture and it was poured into an ice-cooled 1 mol dm^{-3} HCl solution, the organic layer was separated, and the aqueous layer was extracted with ether. The combined organic layer was washed with water, an aqueous sodium hydrogencarbonate solution, and water. After the organic layer had been dried, the solvent was removed off *in vacuo* to leave a yellow, crystalline substance. It was chromatographed on silica gel, using light petroleum ether as the eluent. The first fraction gave white crystals. Recrystallization from pentane gave 2.4 g of white plate crystals. The total yield of the product from the 2,6-di-*t*-butyl-4-(1-

hydroxyethyl)phenyl acetate was 32%.

Mp 63.5—65.0 °C, NMR (CCl_4) 6.80 (s, 2H), 4.82 (s, 1H), 1.52—1.80 (m, 1H), 1.43 (s, 18H), 0.46—0.88 (m, 4H). IR (nujol) 3660 cm^{-1}. Found: C, 82.72; H, 10.75%; M^+, 246. Calcd for $C_{17}H_{26}O$: C, 82.87; H, 10.64%; M, 246. UV_{max} (hexane) 224 nm (log ε: 3.6).

The desired deuterio compound was prepared from the 2,6-di-*t*-butyl-4-acetylphenyl acetate in a manner similar to that used in the preparation of the 2,6-di-*t*-butyl-4-cyclopropylphenol. Deuterium was introduced by means of sodium borodeuteride reduction.

2,6-Di-t-butyl-4-(1-deuterio-1-hydroxyethyl)phenyl Acetate: To a suspension of sodium borodeuteride (0.4 g, 0.01 mol) in 2-propanol (20 ml), a saturated solution of the 2,6-di-*t*-butyl-4-acetylphenyl acetate (5.6 g, 0.02 mol) in the same solvent was added. Thereafter, the procedure described above was employed. The spectral data of the product; mp 102.6—103.3 °C (4.5 g, 81% yield) are as follows: NMR (CCl_4) 7.23 (d, 1H, J=2 Hz), 7.18 (d, 1H, J=2 Hz), 2.23 (s, 3H), 2.17 (s, 1H, OH), 1.37, 1.33 (s, s, 21H); IR (nujol) 3530 and 1740 cm^{-1}; M^+ 293.

2,6-Di-t-butyl-4-(1-deuterioethenyl)phenyl Acetate: A solution of the above acetate (4 g, 0.01 mol) dissolved in benzene (30 ml) was added to a suspension of concd phosphoric acid (4 g) in benzene (20 ml). The further procedure, described above, gave an oily product. The NMR data were as follows: NMR (CCl_4) 7.25 (s), 5.59 (m), 5.15 (s), 2.26 (s), 1.36 (*t*-Bu).

2,6-Di-t-butyl-4-(1-deuteriocyclopropyl)phenyl Acetate: Into a mixture of palladium acetate (10 mg) and a solution of the above crude oil dissolved in ether (20 ml) was added an excess of an ethereal solution of diazomethane in an ice–salt bath over a 3-h period. The further procedure was as has been described above; it gave 3.5 g of an oily product. The NMR data were as follows: NMR (CCl_4) 6.96 (s), 2.23 (s), 1.32 (*t*-Bu), 0.56—0.93 (m).

2,6-Di-t-butyl-4-(1-deuteriocyclopropyl)phenol: Into a suspension of lithium aluminum hydride (0.5 g, 0.01 mol) in ether (10 ml), a solution of the above acetate (3.5 g) in the same solvent (10 ml) was added below 10 °C for 1 h. Subsequent treatment as above gave white crystalline plates (1.0 g, 0.004 mol).

The total yield of the product from the 2,6-di-*t*-butyl-4-(1-deuterio-1-hydroxyethyl)phenyl acetate was 28%. Mp 60.5—63.0 °C, NMR (CCl_4) 6.78 (s, 2H), 4.80 (s, 1H), 1.45 (s, 18H), 0.49—0.86 (m, 4H); IR (nujol) 3650 cm^{-1}; M^+, 247.

Preparation of the Radicals. *In vacuo*, both phenoxyl radicals were prepared by the oxidation of the corresponding phenols with lead dioxide (PbO_2) in toluene.[10] Both solutions of the radicals were slightly blue.[24]

Computations. The numerical computations were carried out on the HITAC 8700 system in the Hiroshima University Computing Center.

The author wishes to thank Professor Terukiyo Hanafusa for his valuable discussions and encouragement throughout the course of this work. The author is also grateful to Dr. Fujito Nemoto for his support in the ESR and ENDOR measurements, his gift of the computing programs, and his useful discussions. The author is also indebted to Professor Kazuhiko Ishizu and Dr. Kazuo Mukai for their helpful suggestions. The ESR and ENDOR observations were performed at the Chemistry Department of Ehime University.

Boron Isotope Separation by Ion Exchange Chromatography Using Weakly Basic Anion Exchange Resin

Yoichi SAKUMA,* Masao AIDA, Makoto OKAMOTO, and Hidetake KAKIHANA

Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received November 2, 1979)

Isotopic plateau displacement chromatography, a useful method for isotope separation is presented. The boric acid band formed in a column of weakly basic anion exchange resin Diaion WA21 can be eluted with pure water. In order to obtain good accumulation of the isotope effect, a series of experiments with different migration length were carried out. The boron-10 enriched part of the boric acid absorbed band was always preceded by the isotopic plateau part, in which the atomic fraction of boron-10 was maintained at its original value. The atomic fraction of boron-10 at the end of the chromatogram increased with migration length, and in the case of 256-m migration, boron-10 was enriched from its original atomic fraction of 19.84 to 91.00%, the separation factor S being constant irrespective of migration length: $S=1.0100\pm0.0005$.

The following conditions have been found to be favorable for effective isotope separation in chromatographic systems.[1,2] (1) The single stage separation factor should be large. (2) The rates of the ion exchange and isotope exchange reactions should be as high as possible. (3) When the separation factor is not so large as in the case of hydrogen-deuterium isotope separation, sharp band boundary such as characteristic of displacement chromatogram should be maintained at the front or at the rear, if possible at both ends of the chromatographic band. (4) Chromatography should be carried out in such a way that an "isotopic plateau zone" in which the atomic fraction of isotopes remains at its original value, always exists somewhere within the chromatogram. (5) Column operation should be as simple as possible.

Kotaka *et al.* reported that a boric acid band formed in a column packed with weakly basic anion exchange resin (Diaion WA21) can be eluted with pure water, resulting in good isotope fractionation.[3] The result seems to satisfy the five conditions mentioned above. (1) The separation factor is comparatively large (about 1.01). (2) The rates of ion exchange and isotope exchange reaction are not very low. (3) Under suitable conditions, a sharp boundary can be formed at the rear of the boric acid band, where boron-10 would be enriched. (4) An isotopic plateau zone can be maintained if the boric acid band is sufficiently long. (5) The operation is easy. The boric acid band can be eluted with pure water, and the eluted column can be used again with no special regeneration process.

These prospects were realized and the optimum experimental conditions to maintain the isotopic plateau displacement chromatography were found.[2] In the present paper we will report the results obtained with various migration lengths under the optimum conditions.

Experimental

A boric acid saturated band formed in a column of weakly basic anion exchange resin Diaion WA21 can be eluted with pure water, keeping the isotopic plateau displacement chromatogram at the rear part under certain conditions.[2] The optimum conditions are: concentration of boric acid solution, 0.1 mol dm^{-3}; temperature, 40 °C; rate, 20 $cm^3\ h^{-1}\ cm^{-2}$. Experiments were carried out with migration lengths of boric acid band 1—256 m.

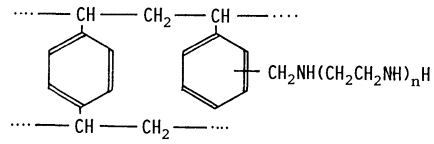

Fig. 1. Structure of Diaion WA21 resin.

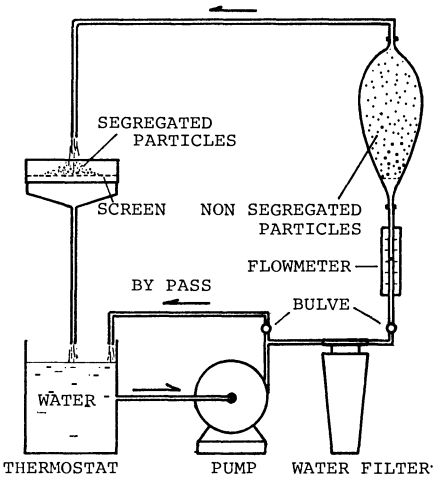

Fig. 2. An apparatus for segregating resin particle size.

Anion Exchange Resin. The structure of the weakly basic anion exchange resin Diaion WA21 is shown in Fig. 1. At first, the resin particles in chloride form were segregated by size (Fig. 2), and the particles between 80 and 100 mesh were packed into the column in chloride form.

Apparatus. The apparatus (Fig. 3) and method were the same as reported.[2] The height of the resin bed was 1 m and its diameter 21 mm. In order to detect the conductivity of the resin phase, a pair of platinum electrodes were inserted at the bottom of the resin bed. Since the conductivity of the boron band is much higher than that of the resin of free base form, the movement of boron band through column is effectively followed by the conductivity between the platinum electrodes.

Operation. A column packed with the Diaion WA21 resin in chloride form was converted into free base form by passing NaOH solution (Fig. 4-i), and was washed with pure water (Fig. 4-ii). To the column was fed excess (*ca.* 1.2 dm^3) 0.1 mol dm^{-3} H_3BO_3 solution to form a band saturated with boric acid and boron-10 depleted effluent from the column was discarded (Figs. 4-iii,iv); a few columns

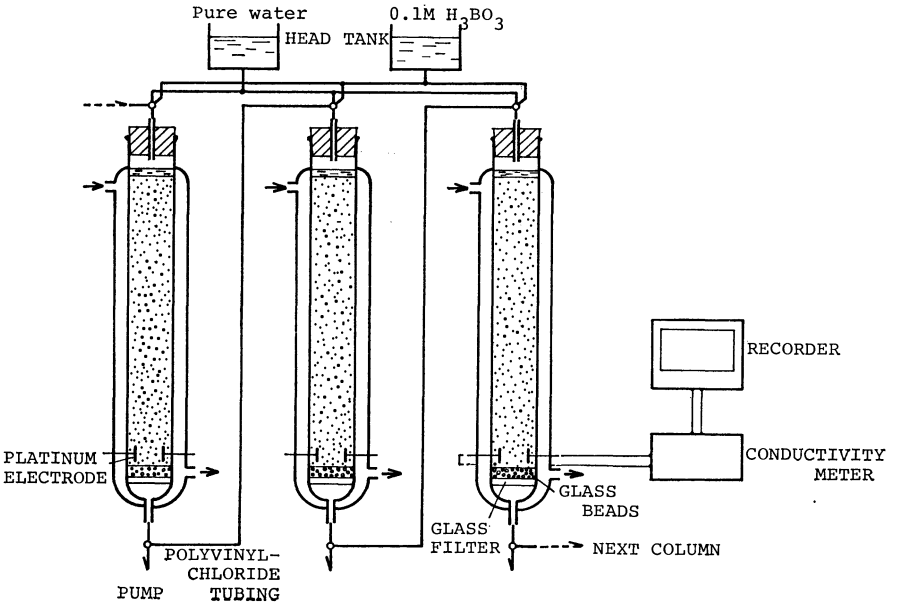

Fig. 3. Experimental apparatus.

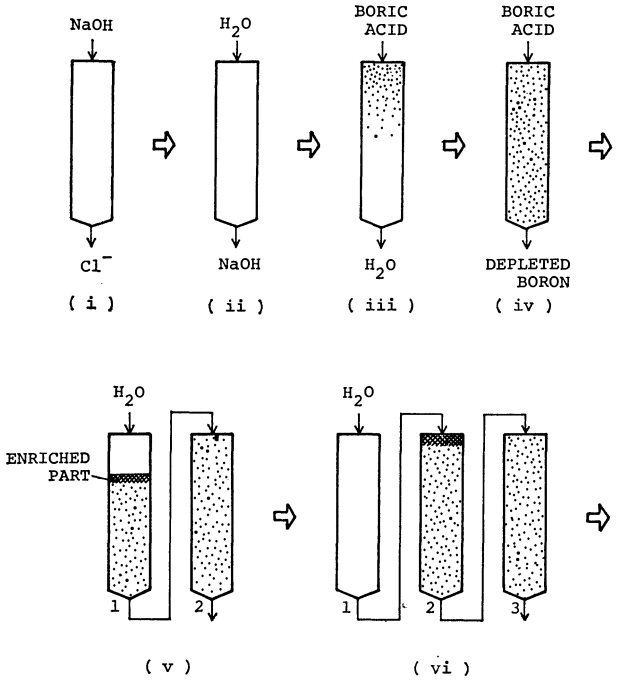

Fig. 4. Column operation.

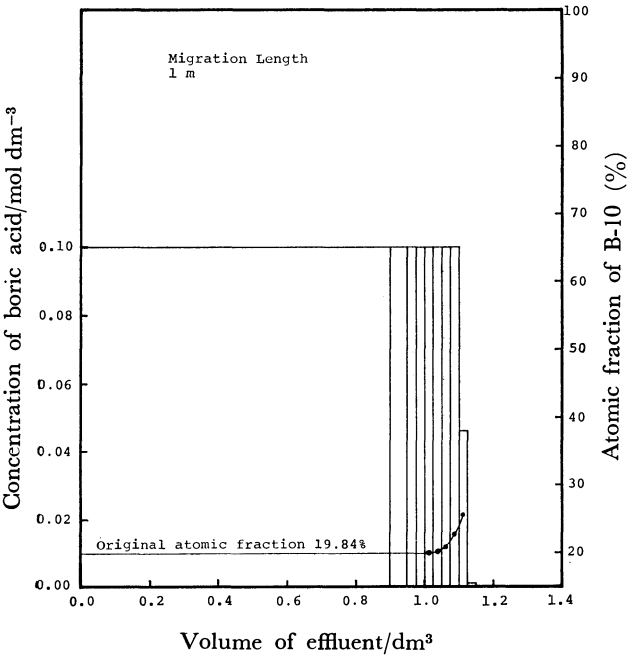

Fig. 5. Elution curve and isotope distribution curve of 1 m migration.

were treated in a similar way. The columns were equilibrated with boric acid aqueous solution having natural abundance ratio of boron isotopes (boron-10 content 19.84%); the columns were slightly enriched with boron-10. Two columns were connected in series by a thin polyvinyl chloride tubing.

Pure water was fed to the first column in order to elute the boric acid band, boron-10 being enriched at the rear boundary (Fig. 4-v). The effluent from the second column (the column holding isotopic plateau) was discarded. The third column was connected to the second column in series when the boric acid band of the first column had been completely transferred to the second column (Fig. 4-vi). The first column was again saturated with 0.1 mol dm^{-3} H_3BO_3 aqueous solution having natural abundance ratio of boron isotopes and used for another plateau holding column (the fourth column, Figs. 4-iii,iv). In the case of a longer migration length about 50 m, it was necessary to use three columns in series to hold the isotopic plateau region. In this way the chromatogram was migrated to the required length; 1, 2, 4, 8, 16, 32, 64, 128, and 256 m. The effluent of each experiment was collected in fraction.

Measurements. The samples were analyzed in a similar way to that reported.[1,2] The concentration of boric acid was determined by neutralization titration using mannitol and the atomic fraction of boron-10 by the surface ionization method using a Variant MAT CH-5 mass spectrometer.[4]

Reabents. All the chemicals used were of reagent grade.

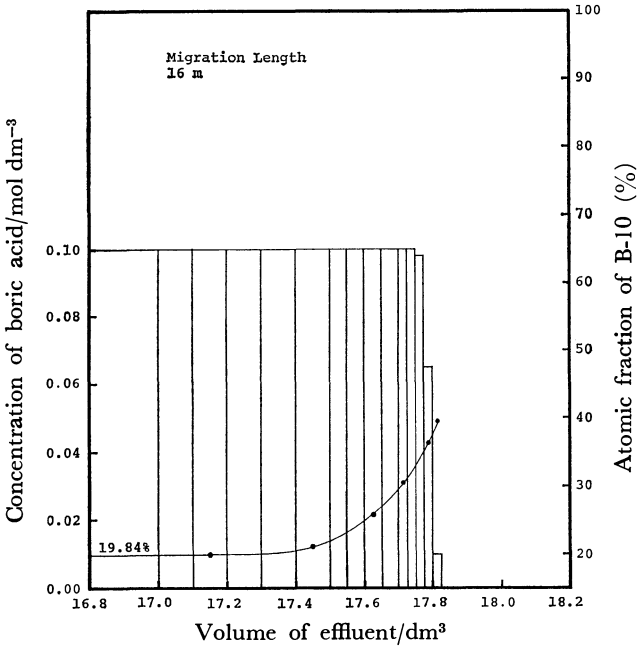

Fig. 6. Elution curve and isotope distribution curve of 32 m migration.

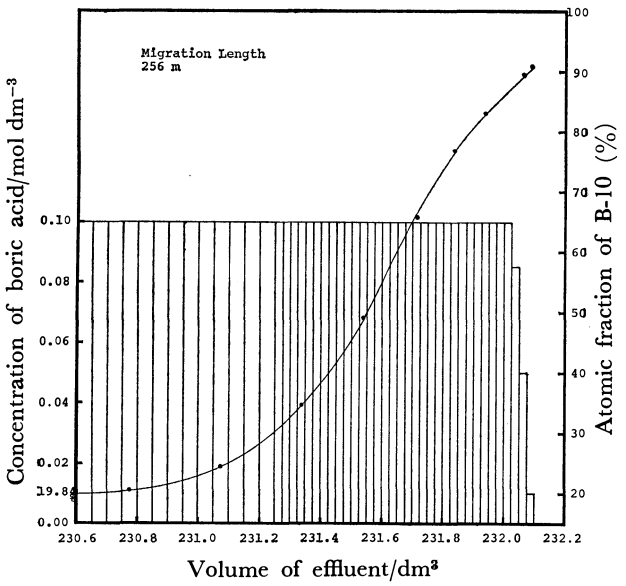

Fig. 7. Elution curve and isotope distribution curve of 256 m migration.

Results and Discussion

Three examples of the elution curve and isotope distribution curve of each run are shown in Figs. 5—7. The profiles of enriched zone of boron-10 are surveyed with regard to migration length in Fig. 8.

Migration Length and Extent of Boron-10 Enrichment. The most enriched boron-10 was always obtained at the most rear part of the chromatogram. The atomic fractions of boron-10 at the end of each chromatogram increased steadily with increase of migration length (Table 1). This indicates that an ideal chromatogram is accomplished in each run.

In the case of 256-m migration, boron-10 was enriched to 91.00% from its original atomic fraction of 19.84.

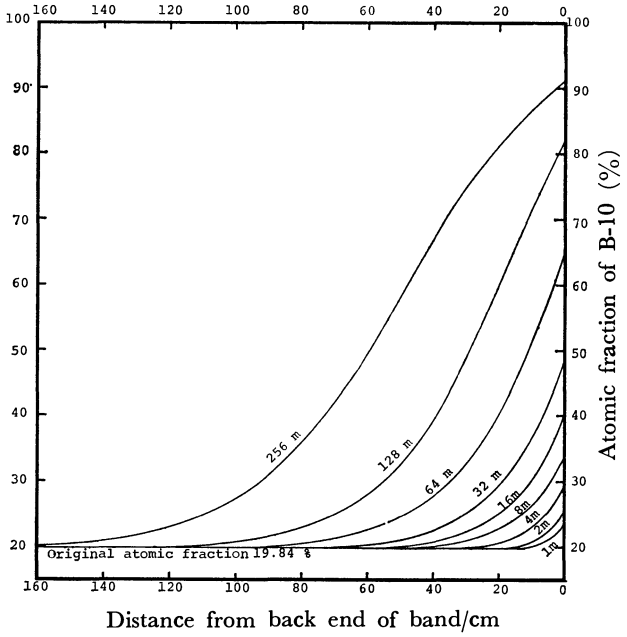

Fig. 8. Dependence of atomic fraction of boron-10 on migration length.

Table 1. Migration length *vs.* separation factor S and maximum atomic fraction of boron-10

L[a] / m	S[b]	R_m[c] / %
1	1.0096	25.62

a) Migration length of each run. b) Separation factor. c) Maximum atomic fraction of boron-10 obtained. d) Average value of S.

Migration Length and Separation Factor. The single stage separation factor S is defined by

$$S = \frac{[\overline{^{10}B}][^{11}B]}{[^{10}B][\overline{^{11}B}]} \quad (1)$$

where [ ] denotes the concentration of isotopes in the aqueous phase and [¯] the concentration of the isotopes in the resin phase. The value of separation factor S can be obtained from the data by means of

$$S = \frac{\Sigma f_i(R_i - R_0)}{QR_0(1-R_0)} + 1 \quad (2)$$

where f_i is the total amount of boron in the i-th fraction, R_0 the original atomic fraction of boron-10, R_i the atomic fraction of boron-10 in the i-th fraction and Q the total capacity of ion exchange column. The

calculated values are given in Table 1. The separation factor S is constant irrespective of migration length. This is quite different from the results obtained by Hagiwara *et al.* on lithium isotope separation[5] and by Aida *et al.* on boron isotope separation,[1] in which the separation factor decreases with increase of migration length. The experiments were carried out without holding the isotopic plateau part in the chromatogram, the depleted part being mixed with an enriched part during the course of migration, making it impossible to obtain a reliable value of separation factor. In the present study, an isotopic plateau region in which the atomic fraction of isotopes remains unchanged always existed, no mixing taking place. The value obtained by means of Eq. 2 gives a satisfactory separation factor.

Conclusion

(1) Boron-10 was enriched from its original atomic fraction of 19.84 to 91.00% by the simple process of eluting a boric acid band with pure water through columns of weakly basic anion exchange resin Diaion WA21.

(2) The steady increase in atomic fraction of boron-10 with migration length indicates the merit of isotopic plateau displacement chromatography.

(3) At 40 °C a constant value 1.010 was obtained for the separation factor irrespective of migration length 1—256 m.

Studies of the Interaction of Poly(ethylene oxide) with Sodium Dodecyl Sulfate by Gel Filtration

Tsunetaka SASAKI,* Kaoru KUSHIMA, Kazunori MATSUDA, and Hitoshi SUZUKI

Department of Chemistry, Faculty of Science, Tokai University, Hiratsuka 259-12

(Received November 8, 1979)

The interaction between poly(ethylene oxide) (PEO), with a molecular weight of 6000, and sodium dodecyl sulfate (SDS) was studied by the gel-filtration method. The elution curve of the PEO–SDS system showed a tail of the elution volume smaller than that of SDS micelles at a concentration larger than about 4 mmol dm^{-3}. This suggests that the PEO–SDS (PS) complex is formed in the system. The dissolution-state diagram in the presence of PEO was then constructed in which the fractions of SDS single ions, SDS micelles, and the PS complex were shown against the SDS concentration. For a constant concentration of PEO, the molecular weight of the PS complex increased with the increase in the concentration of SDS up to the CMC of the PEO–SDS system, beyond which it became constant. The molecular weight of the PS complex was estimated to decrease from 21000 at 0.025 wt% PEO to 15000 at 0.2 wt% PEO.

The interaction of poly(ethylene oxide) (PEO) with sodium dodecyl sulfate (SDS) has been studied by the measurements of: (1) the equilibrium dialysis,[1] (2) the electrical conductance,[2,3] (3) the surface tension,[2,3] (4) the viscosity,[2] and (5) the solubilization.[3] (1) is a direct method of detecting the change in molecular size; however, it requires a long time to attain an equilibrium and also needs a supporting electrolyte of a concentration sufficient to suppress the Donnan effect, while from (2) to (5) are indirect methods. The band-gel-filtration method adopted in the present study offers a simple and direct method of measuring PEO–SDS interaction free from any supporting electrolyte. Using this method, two of the present authors have previously reported the interaction between poly(vinyl acetate) and SDS.[4] The present paper reports the studies of the interaction between PEO and SDS.

Experimental

Materials. Commercial pure-grade SDS previously recrystallized from ethanol was refluxed with charcoal in ethanol, filtered, and recrystallized. The purified sample showed no minimum in the surface tension *vs.* concentration curve. The PEO used was a commercial pure-grade substance with the mean molecular weight of 6000; it was dissolved in methanol, precipitated by the addition of diethyl ether, filtered, and dried. The gel used for packing the column was Sephadex G 100 produced by Farmacia.

Apparatus and Measurement. Gel-filtration apparatus used is shown in Fig. 1. Gel column used was 30 cm in length and 1.2 cm in inner diameter. For the measurement, sample solution of 30 cm^3 was introduced in the gel column, eluted with water and the elution curve was obtained by the conductometry. The flow rate was about 0.5 cm^3 min^{-1}. The measurement was made in an air thermostat at 30±0.5 °C.

Results and Discussion

Figure 2 is the elution curve showing the conductance *vs.* elution volume for the SDS solution. In this figure, Curve 1 is the elution curve of the SDS solution below the CMC. The curve shows a single tail, S, and a conductance plateau, κ_s. The elution volume of the tail and the height of plateau, corresponds to the size and the concentration respectively, of SDS single ions. Curve 2 in Fig. 2 is the elution curve of the SDS solution above the CMC. Here, the elution tail consists of two steps, S′ and M, which correspond to the sizes of single ions and micelles, while the heights of the two plateaux, κ_{cmc} and κ_m, correspond to the concentrations of single ions at the CMC and micelles respectively.

Figure 3 shows the elution curve of the PEO–SDS system for constant PEO and various SDS concentrations. Here, Curve 1 indicates the elution curve of the solution containing SDS below 4 mmol dm^{-3}. The curve shows a tail of a single step, S, and a corresponding single conductance plateau κ_s. Above 4 mmol dm^{-3} up to a certain concentration which is later identified as the CMC of the PEO–SDS system, the type of elution curve as represented by Curve 2 with tail of two steps, S′ and C, and two conductance plateaux,

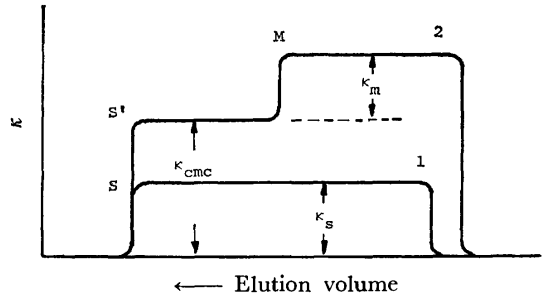

Fig. 2. Elution curve of SDS system.

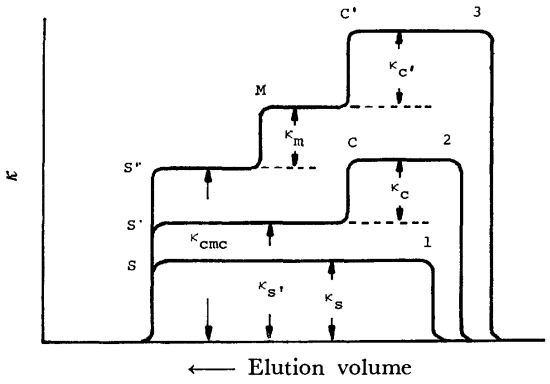

Fig. 3. Elution curve of PEO–SDS system.

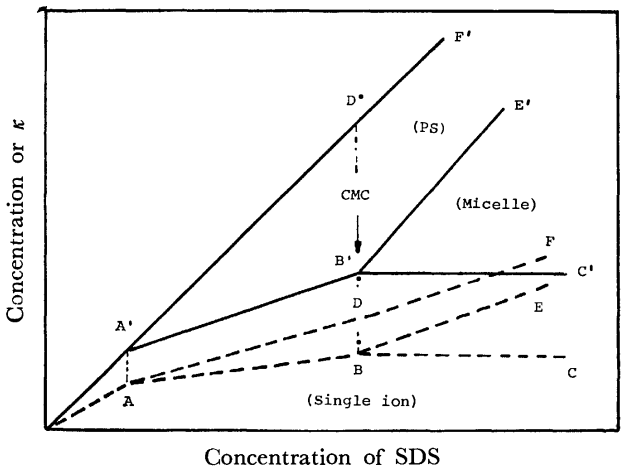

Fig. 4. Phase diagram of PEO–SDS system.
——; Concentration, ----; κ.

κ_s, and κ_c, was observed. At a higher concentration of SDS beyond the CMC, Elution Curve 3 was obtained. Here, the elution tail showed three steps, S", M, and C', and three conductance plateaux, κ_{cmc}, κ_m, and $\kappa_{c'}$.

Now, when we compare these three curves, 1, 2, and 3, with Fig. 2, it can be confirmed, that S, S', and S" correspond to the tails of SDS single ions, M to the tail of the SDS micelles, and C and C', to the tails of particles containing SDS and being larger than the SDS micelles. These particles can be regarded as forming the PEO–SDS complex (the PS complex). By plotting the conductances κ_s, κ_m, κ_c, *etc.*, against the total concentration of SDS, the lines in Fig. 4 were obtained. By transforming the conductances into the concentration, the solid lines in Fig. 4 were obtained.

The conductance *vs.* concentration relations for SDS single ions and SDS micelles, as obtained from Fig. 2, were used to convert the conductance values to the concentrations of the single ionic and micellar SDS. The concentration of the PS complex was obtained as the difference between the total concentration of SDS and the sum of the concentration of the SDS single ions and micelles.

The solid lines in Fig. 4 show the range of the regions of the SDS single ions the SDS micelles, and the PS complex; that is, the area below the OA'B'C' line

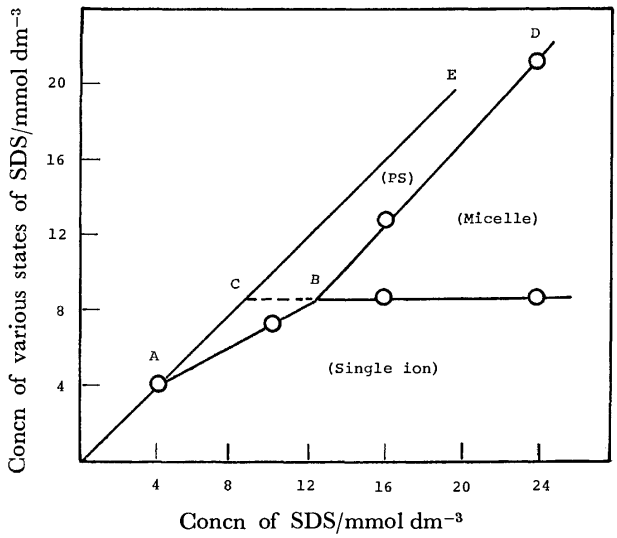

Fig. 5. Phase diagram of PEO–SDS system (0.05wt% PEO).

is the region of single SDS ions, the E'B'A'F' area the region of the PS complex, and the E'B'C', the region of the SDS micelles. Below the point A', the SDS is exclusively in the state of single ions not combined with PEO. Between A' and B', free SDS single ions and the SDS complex are in a mutual equilibrium. In the region above the point B', SDS micelles appear in the solution in addition to the PS complex and free SDS single ions. The concentration of SDS single ions was constant in this region and was equal to the CMC of the pure SDS solution. This suggests that the point B' is the CMC of the PEO–SDS system.

In such a manner, we can construct a diagram of the dissolution state of the SDS. Four such diagrams were obtained for SDS solutions containing 0.025, 0.05, 0.1, and 0.2 wt% of PEO. Figure 5 shows the results obtained for the SDS solution containing 0.05 wt% PEO. The concentration of SDS at point A is 4 mmol dm^{-3}. This concentration was almost independent of the concentration of PEO, except for the lowest concentration of 0.025 wt% PEO, where the point A shifted to 6 mmol dm^{-3}. This tendency is in accord with the results obtained by Jones.[2] The amount of SDS bound to PEO, which was estimated as the ordinate between lines AB and AC, increased from point A to B, which may suggest an increase in the size of the PS complex. This is in accord with the decrease in the elution volume from 23.0 cm^3 to 18 cm^3, for instance, for the 0.1 wt% PEO system. Beyond point B, the size of the PS complex became nearly constant, as judged from the constancies of the elution volume and the ordinate between BD and CE in this region in Fig. 5, although, according to Jones,[2] it is uncertain whether or not the size of the complex beyond point B continues to increase by the further binding of SDS.

The maximum amount of SDS bound to PEO can be calculated from the difference in the concentration of SDS between points B and C and the concentration of PEO. The calculated binding ratio de-

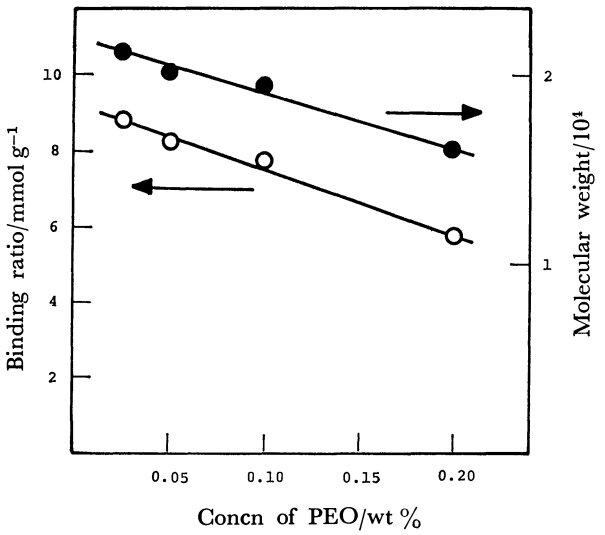

Fig. 6. Binding ratio and molecular weight of PEO–SDS complex.

creased with an increase in the PEO concentration, as is shown by the open circles in Fig. 6. The decrease in the SDS binding ratio agrees with the increase in the elution volume of the PS complex with the PEO concentration.

In Fig. 6, the maximum binding ratio at 0.1 wt% PEO is 7.7 mmol SDS/g PEO. This is comparable with the value of about 9 mmol SDS/g PEO in the presence of 1 mol dm^{-3} sodium chloride, as estimated from the equilibrium dialysis results obtained by Shirahama.[1)]

In the present study, the absolute size of the PS complex was not estimated by comparing the elution volume to that of the standard-molecular-weight substances. However, from the known weight ratio of SDS to PEO shown in Fig. 6 and the mean molecular weight 6000 of PEO, the molecular weight of the PS complex at CMC was calculated to be as shown by the solid circles. The molecular weight decreased from about 21000 at 0.025 wt% PEO to 15000 at 0.2 wt% PEO, as may be seen in the figure.

Adsorption of Dyes, Chromate, and Metallic Ions by Poly(ethyleneimine)

Tsunetaka Sasaki,* Osamu Asakawa, Kazuyo Kurosawa,
Minoru Mizushima, and Teruhiro Nakazono
Department of Chemistry, Faculty of Science, Tokai University, Hiratsuka 259-12

(Received January 21, 1980)

Ion exchange and chelate properties of poly(ethyleneimine) resin (PEI) were studied. Adsorption of neucoccin anions (NC^-) (maximum 1.7×10^{-4} mol/g) was greater than that of Crystal Violet cations (CV^+) (maximum 0.17×10^{-4} mol/g), indicating that PEI is an anion exchanger. CV^+ adsorption increased with the addition of sodium polyacrylate due to its bridging action between CV^+ ions and PEI. Adsorption of CrO_4^{2-} was confirmed to be much greater than that of NC^- ions amounting to 4×10^{-3} mol/g at a sufficiently concentrated solution of CrO_4^{2-}. The acid exchange capacity of PEI was found to be about the same as the maximum amount of adsorption of CrO_4^{2-}. Kinetics of adsorption of CrO_4^{2-} by PEI was studied at various temperatures. Adsorption followed a bimolecular reaction. Activation energy of 28.03×10^3 J/mol obtained is a right order of magnitude as an ion exchange adsorption. Chelating adsorption of Fe^{3+} and Cu^{2+} ions by PEI studied, the maximum amounts of adsorption being 3.1×10^{-3} mol/g and 3.3×10^{-3} mol/g, respectively. The values are greater than those for other synthetic polyethylene polyamine. PEI can be used as an anion and metallic cation adsorbent.

Poly(ethyleneimine) resin (PEI) is obtained in a large amount as a water insoluble by-product during the synthesis of polyethylene polyamine oligomers, causing trouble as an industrial waste. However, it is an effective anion exchanger as regards its chemical structure, and it would be worthwhile to study its behavior as both an anion exchanger and a cation chelating resin, like many synthetic polyamine reported.[1,2] It is noted that cheap anion exchangers can scarcely be found, while there exist abundant available cation exchangers such as clay minerals including bentonite and kaolinite.[3]

In the present experiment, adsorption of chromate, iron(III) and copper(II) ions as inorganic ions, and Crystal Violet and neucoccin as organic ions by PEI has been studied.

Experimental

Materials. PEI (Shunan Petroleum Co.) is a brown, fluffy, water insoluble powder. The sample for the measurement was prepared by removing impurities, washing with water and repeated decantation until the supernatant layer became clear after 10 min. The sample was then dried at 100 °C and kept in a desiccator.

Organic ions used were Crystal Violet cation (CV^+) and neucoccin anions (NC^-), inorganic ions being chromate anions (CrO_4^{2-}), iron(III) (Fe^{3+}), and copper(II) (Cu^{2+}) cations. For purification, Crystal Violet was precipitated from its ethanol solution by addition of diethyl ether. The precipitate was filtered and dried under reduced pressure. Neucoccin was recrystallized from its aqueous solution by addition of anhydrous sodium carbonate. Crystals deposited were filtered, washed with ethanol and dried under reduced pressure. Potassium chromate, iron(III) chloride, and copper(II) sulfate of guaranteed grade were used without further purification. Commercial sodium polyacrylate (NaPA) was used without further purification, the degree of polymerization being 22000—66000.

Measurement. The amounts of adsorption of CV^+ and NC^- were calculated from the difference in concentration of the solute before and after the adsorption by PEI. The concentration was determined with a spectronic colorimeter (Shimazu Spectronic 20) at wavelengths 480 nm and 580 nm for CV^+ and NC^-, respectively. The amounts of adsorption of CrO_4^{2-}, Fe^{3+}, and Cu^{2+} were calculated as in the cases of CV^+ and NC^-. The concentration was determined with a Hitachi atomic absorption spectrometer at wave lengths of 357.9, 248.5, and 324.7 nm, respectively. The experiments were carried out at room temperature, *ca.* 25 °C unless otherwise stated.

Results and Discussion

Adsorption of CV^+ and NC^-. Adsorption Isotherm: 0.1 g of PEI was put in a test tube containing 20 cm^3 solution of varying CV^+ and NC^- concentrations. The solutions were shaken frequently for 1 h and the amounts of adsorption determined. The results are shown in Fig. 1. We see that maximum adsorption of NC^- of 1.7×10^{-4} mol/g PEI is greater than that

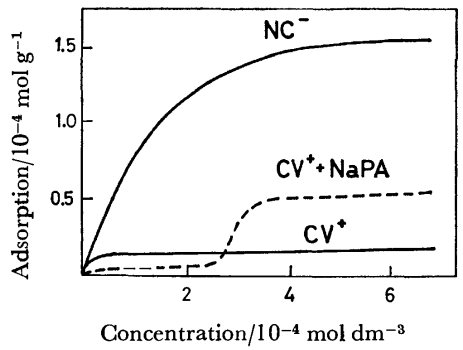

Fig. 1. Adsorption of dyes by PEI.

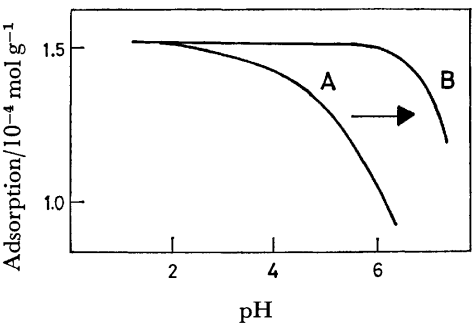

Fig. 2. Effect of pH on NC^- adsorption by PEI.

of CV^+ of 0.17×10^{-4} mol/g PEI. This confirms that PEI behaves as an anion exchanger as a whole. The slight adsorption exhibited by CV^+ might be due to the nonexchange adsorption.

Effect of pH *on* NC^- *Adsorption.* 0.1 g of PEI was added to a test tube containing 21 cm^3 of 7.88×10^{-4} mol/dm^3 NC^- solution of varying pH adjusted by the addition of HCl and NaOH, the solutions being shaken frequently for 1 h. The amount of adsorption calculated is plotted against pH before and after the adsorption in Fig. 2. The amount of adsorption increases with the decrease in pH, while pH increases with adsorption. These reactions can be explained by

$$RNH + NC^- + H^+ \longrightarrow RNH_2^+NC^-$$

where RNH denotes PEI. The equation indicates that PEI is an anion exchanger or an acid adsorbent.

Bridging Action of NaPA for the Adsorption of CV^+ *by PEI.* Because of the anion exchange property of PEI, adsorption of CV^+ was found to be small (Fig. 1). However, the adsorption of CV^+ might increase with the addition of a polymer anion such as NaPA. In the present experiment, 60 ppm of NaPA was added to the solution of CV^+ and the adsorption was measured under the same conditions as in the preceding experiments (broken line, Fig. 1). A marked increase took place in the amount of adsorption by the addition of NaPA in a higher concentration region of CV^+ as expected, but a slight decrease is seen in the lower concentration region. The increase of CV^+ adsorption by the addition of NaPA is explained by the bridging action of polyacrylate anions between PEI molecules and CV^+ cations. A similar bridging action has been reported in the case of EDTA.[4] The decrease of CV^+ adsorption at lower concentration is probably due to polyacrylate anions, not acting as a bridge but covering the sites on PEI available for the adsorption of CV^+ ions.

Adsorption of CrO_4^{2-}. *Adsorption Isotherm*: 0.2 g of PEI was added to 50 cm^3 of CrO_4^{2-} ion solutions of varying concentration in an Erlenmeyer flask, and the amount of adsorption was measured after stirring for 2 h. The result is shown in Fig. 3. The adsorption of CrO_4^{2-} ions is 4×10^{-3} mol/g PEI at 3×10^{-3} mol/dm^3 CrO_4^{2-} concentration. The amount is greater than that of NC^- ion which might be due to the smaller size of anions which can penetrate the inner surface of PEI.

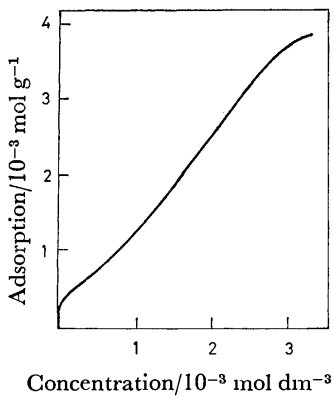

Fig. 3. Adsorption of CrO_4^{2-} by PEI.

Effect of pH *on* CrO_4^{2-} *Adsorption.* The effect of pH on CrO_4^{2-} adsorption was studied as in the case of NC^- adsorption. 0.2 g of PEI was added to 200 cm^3 of 0.84×10^{-3} mol/dm^3 CrO_4^{2-} solution, the pH of the solution being adjusted by addition of HCl. The amount of adsorption was measured after stirring at 25 °C for 1 h. The result is plotted against pH at equilibrium in Fig. 4. Adsorption of CrO_4^{2-} exhibits a maximum at pH 3, the behavior differing from the effect of pH on NC^- (Fig. 2). The increase of adsorption with the decrease of pH down to 3 can be explained by

$$2RNH + CrO_4^{2-} + 2H^+ \longrightarrow (RNH_2^+)_2CrO_4^{2-}$$

as in the case of NC^-. However, the decrease of adsorption of CrO_4^{2-} below pH 3 may be due to the following reaction:

$$(RNH_2^+)_2CrO_4^{2-} + 2HCl \longrightarrow 2RNH_2^+Cl^- + H_2CrO_4$$

The ion exchange of CrO_4^{2-} ions with Cl^- ions as well as the formation of weak acid H_2CrO_4 seem to favor the desorption of CrO_4^{2-} ions.

Rate of CrO_4^{2-} *Adsorption.* To 500 cm^3 of 0.85×10^{-3} mol/dm^3 K_2CrO_4 solution was added 0.5 g of PEI and the concentration of CrO_4^{2-} ions was measured at various intervals with stirring at constant temperatures in the range 9.5 °C—40.2 °C. Figure 5 shows plot of concentration C in 10^{-3} mol/dm^3 *vs.* time t in min at 19.8 °C. In most cases a rapid decrease in CrO_4^{2-} ion concentration took place during the first 10 or 20 min, equilibrium being attained after *ca.* 1 h.

A linear plot was obtained between $1/(C-C_\infty)$ and t (Fig. 6), which can be expressed as

$$1/(C-C_\infty) = Kt + L \qquad (1)$$

where C_∞, K, and L are constants, C_∞ being the equilibrium concentration after a sufficiently long time. Differentiating Eq. 1, we get

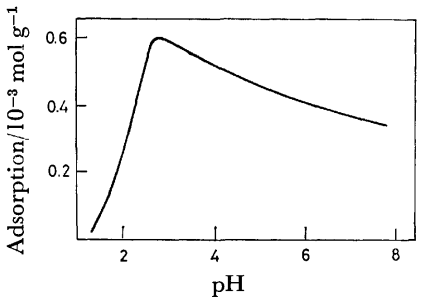

Fig. 4. Effect of pH on CrO_4^{2-} adsorption by PEI.

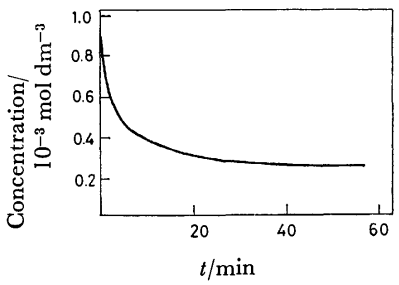

Fig. 5. Rate of CrO_4^{2-} adsorption by PEI.

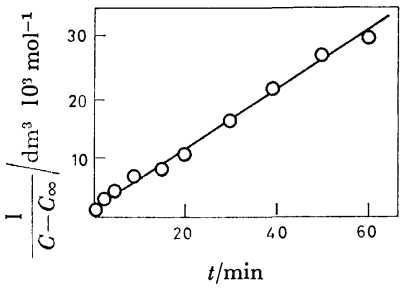

Fig. 6. $\frac{1}{C-C_\infty}$ *vs.* t plots.

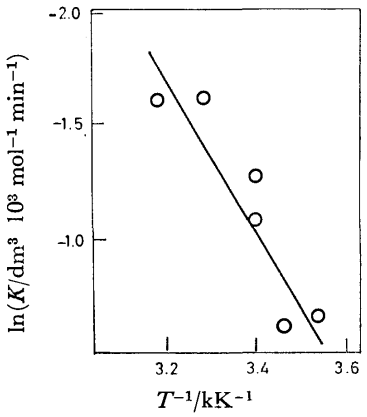

Fig. 7. Arrhenius plots.

$$-dC/dt = K(C-C_\infty)^2 \quad (2)$$

The precise physical meaning of Eq. 2 expressing a bimolecular reaction is not clear. Arrhenius plot was made between ln K and the reciprocal of the absolute temperature T (Fig. 7). From the straight line we get the activation energy 28.03×10^3 J/mol. This is considered to be reasonable as a value for the ion exchange reaction in an aqueous solution.[5]

Anion Exchange Capacity of PEI. Anion exchange capacity was measured for PEI by the method of Kunin and Myers.[6] A given amount of the chloride form of PEI prepared by treatment with HCl solution and washing with ethanol was first treated with ammonia and then with aqueous Na_2SO_4 solution. The chloride contents in ammonia and aqueous Na_2SO_4 solution were then determined by titration with aqueous $AgNO_3$ solution. Weak base, strong base and total exchange capacities were calculated from the chloride contents, and found to be 1.51, 8.23, and 9.73 meq/g PEI, respectively. The strong base exchange capacity can be compared with the saturation amount, *ca.* 8 meq/g PEI, of CrO_4^{2-} adsorption, as estimated from Fig. 3. It was also confirmed that the exchange capacity obtained for PEI is larger as compared with that for the polyethylene polyamine synthesized as an ion exchanger.[2]

Adsorption of Fe^{3+} and Cu^{2+}. Although the adsorption of dye cation, CV^+, by PEI is comparatively small, the adsorption of metallic cations such as Fe^{3+} and Cu^{2+} might be large due to the amine complex formation of these ions with PEI.[1]

Rate of Fe^{3+} and Cu^{2+} Adsorption. 0.1 g of PEI was added to 200 cm^3 of 1×10^{-4} mol/dm^3 (pH=8) and Cu^{2+} (pH=7) ion solutions and the resulting solutions were stirred. 5 cm^3 each was taken at different times from these solutions and the concentration decrease due to the adsorption measured, the result being plotted against time of adsorption (Fig. 8). Adsorption is rapid and is completed within 10 min.

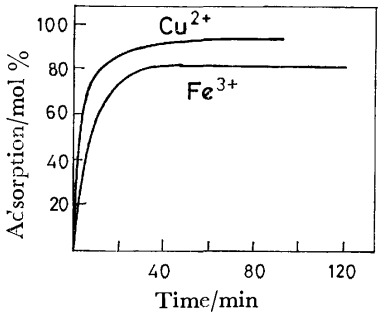

Fig. 8. Rate of adsorption of Fe^{3+} and Cu^{2+} by PEI.

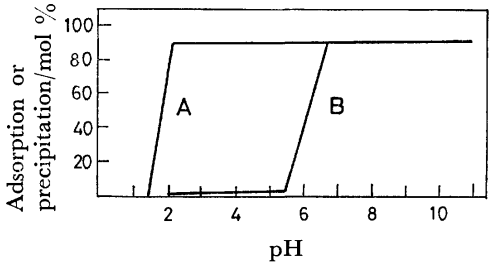

Fig. 9. Effect of pH of Fe^{3+} adsorption by PEI. A; Amount of adsorption, B; amount of precipitation.

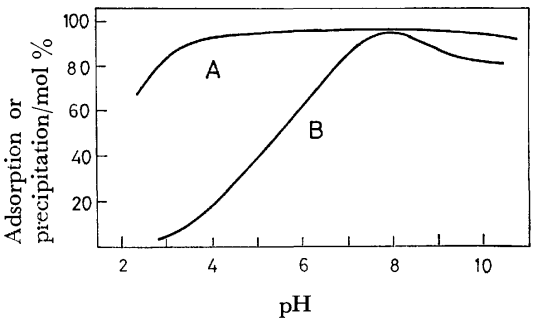

Fig. 10. Effect of pH on Cu^{2+} adsorption by PEI. A; Amount of adsorption, B; amount of precipitation.

Effect of pH on Fe^{3+} and Cu^{2+} Adsorption. The pH of 1×10^{-4} mol/dm^3 Fe^{3+} and Cu^{2+} ion solutions was adjusted by the addition of HCl and NaOH. To 50 cm^3 of these solutions was added 0.1 g of PEI and the amount of adsorption was calculated from the concentration decrease of the solution due to adsorption after stirring for 1 h. The amount of adsorption expressed in terms of the percentage of the initial amount of solute is plotted against the pH in Figs. 9 and 10; the amount of removed Fe^{3+} and Cu^{2+} ions due to precipitation by the addition of NaOH without PEI was measured and the results are also plotted against pH for comparison. We see a distinct adsorption effect of Fe^{3+} and Cu^{2+} by PEI below pH 7. However, the amount of adsorption and precipitation became equal for the systems with and without PEI above pH 7. Thus, from this graph alone we cannot

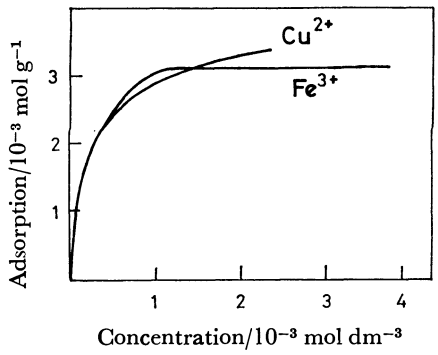

Fig. 11. Adsorption isotherm of Fe^{3+} and Cu^{2+} by PEI.

confirm whether adsorption or precipitation takes place above pH 7. However, we believe that the adsorption of Fe^{3+} and Cu^{2+} on PEI takes place even in this pH region, since these ions can be floated with PEI by shaking the suspension with the addition of polyacrylamide and cationic surfactant, while iron and copper hydroxides without PEI cannot be floated from its suspension by a similar treatment.

Adsorption Isotherms of Fe^{3+} and Cu^{2+}. To 50 cm^3 of Fe^{3+} and Cu^{2+} ion solutions of varying concentration was added 0.1 g of PEI at pH 5 and the solutions were continuously stirred. After 1 h the amount of adsorption was measured; the result is plotted against equilibrium concentration in Fig. 11. The maximum amounts of adsorption were found to be about 3.1×10^{-3} mol/g and 3.3×10^{-3} mol/g PEI for Fe^{3+} and Cu^{2+}, respectively. The maximum amount of adsorption for Cu^{2+} is larger in the order of magnitude than the amount of adsorption reported for synthetic polyethylene polyamine,[5] but smaller than the simple ion exchange adsorption of CrO_4^{2-} ions by PEI.

Conclusion. From the results obtained, PEI is considered as a good anion exchange adsorbent as well as a chelating agent for metallic cations. Such properties are conveniently and effectively utilized further in the operation of ion flotation.

X-Ray Photoelectron Spectroscopic Study of Tetrathiafulvalene-Tetracyanoquinodimethane (TTF·TCNQ) and Related High Conductive Organic Complexes

Isao Ikemoto, Masamichi Yamada, Tadashi Sugano, and Haruo Kuroda
Research Centre for Spectrochemistry and Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113
(Received November 9, 1979)

Tetrathiafulvalene–tetracyanoquinodimethane (TTF·TCNQ) and related high conductive organic complexes were studied by X-ray photoelectron spectroscopy (XPS). The N 1s peak shape of TTF·TCNQ evaporated film was found to change by X-ray irradiation; the high-binding energy shoulder of the N 1s peak increased its intensity with X-ray irradiation time and finally showed a new peak separated by about 1.5 eV from the main peak. TTF·TCNQ was found to be 1:1 both in the surface and in the bulk. The amounts of charge transfer in TTF·TCNQ and other TTF complexes as well as those in 5,6:11,12-bis(dithio)naphthacene(tetrathiotetracene, TTT) complexes were determined from the analysis of the S 2p peak shape. The amount of charge transfer is 0.56 ± 0.05 in TTF·TCNQ and 0.55 ± 0.05 in TTF·TNAP (tetracyanonaphthoquinodimethane). The molecular ratio of $(donor)^+$ in donor molecules is 0.71 ± 0.05 in $TTF\cdot Br_{0.7}$, 0.52 ± 0.05 in $TTF\cdot I_{0.7}$, 0.65 ± 0.05 in $(TTF)_3(BF_4)_2$, 0.49 ± 0.05 in $(TTT)_2I_3$, and 0.93 ± 0.05 in $(TTT)(TCNQ)_2$, which correspond respectively to 100, 73, 100, 100, and 100% charge transfer between donors and acceptors. The N 1s peak shape of TTF·TCNQ is also discussed.

The charge-transfer salt, tetrathiafulvalene–tetracyanoquinodimethane (TTF·TCNQ), is a typical example of the organic solid that exhibits the behaviors as a quasi-one-dimensional conductor. The crystal of TTF·TCNQ was initially considered to be composed of TTF^+ and $TCNQ^-$ as a result of a complete charge transfer from TTF to TCNQ. However, several experimental evidences were accumulated later to indicate that the charge transfer between TTF and TCNQ is not complete.[1-10]

There are a variety of highly-conductive charge-tranfer salts which involve TTF or its analogs as the electron donor and/or TCNQ or its analogs as the electron acceptor. In almost all cases of these metal-like conductors, donor stacks and/or acceptor stacks are in a mixed-valence state as in TTF·TCNQ. It is now believed that this mixed-valence character has an important bearing on the metallic behaviors of these organic solids.

X-Ray photoelectron spectroscopy (XPS) could provide informations concerning the electronic state of a mixed-valence molecular stack. If holes in a donor stack (or electrons in an acceptor stack) are highly localized, each core electron peak in the XPS spectrum will be composed of the components corresponding to the neutral molecule and the ion, respectively. On the other hand, if holes in a donor stack (or electrons in an acceptor stack) are completely delocalized, the core electron peaks will be of single component corresponding to the partially ionized state of the molecule.[11]

Some years ago, we first reported the results of the XPS studies on a series of TCNQ salts.[12,13] As compared with the N ls peaks of TCNQ simple salts, the N ls peaks were found to be significantly broader in the XPS spectra of TCNQ complex salts, as if it is composed of the peaks due to the neutral molecule and ion of TCNQ. However, the observed peak shapes could not be satisfactorily reproduced by the simple superposition of the N ls peak of $TCNQ^0$ and that of $TCNQ^-$.[13] In the XPS spectra of TCNQ salts, the N ls peaks are always accompanied by a strong shake-up satellite, which seems to vary depending on the intermolecular charge-transfer interaction within a TCNQ stack. This introduces a considerable complexity into the analysis of the observed peak profile. In contrast, the S 2p peak of TTF is not accompanied by a strong satellite. Thus it seems worthwhile to see if the S 2p peak profiles in the XPS spectra of TTF salts can be well interpreted by the superposition of the components associated with TTF^0 and TTF^+.

There is another aspect which should be examined in order to establish the interpretation of the XPS spectra of TTF·TCNQ and related materials. The chemical composition in the surface region could be different from the bulk. In effect, it was pointed out by Ritsko *et al.*,[14] from the XPS studies of an evaporated film of TTF·TCNQ, that the surface of a TTF·TCNQ film prepared at room temperature was more nitrogen rich than the bulk. Thus we tried to know if there is actually any significant difference between the bulk and surface by means of the observation of the angular dependence of the XPS spectrum.

In the present paper, we will report the results of these XPS studies made on a series of TTF salts and related materials.

Experimental

Materials. The chemical formulae of the organic donors and acceptors used in the present study are given in Fig. 1.

TTF, TTT, and TNAP were synthesized according to the literatures.[15-19] Other compounds were commercially obtained.

The crystalline powders of the charge-transfer salts were prepared by the procedures described in the literatures.[18,20-22] In the cases of the bromide and iodide of TTF, the mole ratio of donor and acceptor is known to vary depending on the condition of preparation.[20,21] We obtained $TTF\cdot Br_{0.7}$ and $TTF\cdot I_{0.7}$ by the methods given in our previous paper.[15]

XPS Measurements. X-Ray photoelectron spectra were

measured with a McPherson ESCA 36 electron spectrometer using Mg $K\alpha$ (1253.6 eV) as the stimulating radiation. In all cases except K·TCNQ, TTF·TNAP and TTT salts, samples were deposited onto aluminum plates by the sublimation within the sample chamber of the spectrometer. XPS measurements were also done on powder samples pressed onto aluminum plates. The spectra thus obtained were almost the same as those obtained with evaporated films. To measure the spectrum of TTF solid, the sample was deposited onto an aluminum substrate cooled with a dry ice–ethanol mixture in order to reduce the evaporation of TTF.

The binding energies of photoelectron peaks were calibrated by using the Au $4f_{7/2}$ peak (83.8 eV) of a thin gold film deposited on the sample surface.

To vary the photoelectron take-off angle, an angle-variable sample holder was specially designed so as to be incorporated into our XPS spectrometer. The details of this sample holder will be reported elsewhere.[23]

Results and Discussion

Angular Dependence of XPS Spectrum of TTF·TCNQ and the Effects of X-Ray Irradiation. We measured the XPS spectrum of an evaporated film of TTF·TCNQ setting the photoelectron take-off angle θ, measured from the sample plane, at 10° and at 80°. We noted that the shape of N ls peak changed with time as we repeated XPS measurements on the same sample. Figure 2 shows the variation of the N ls peak shape with X-ray irradiation time, observed under the conditions that $\theta=80°$. The intensity at the high-binding energy shoulder of the N ls peak increased with irradiation time, and finally showed a new peak separated by about 1.5 eV from the main peak. The irradiation effect did not appear so clearly in the spectra measured at $\theta=10°$. In this case, the

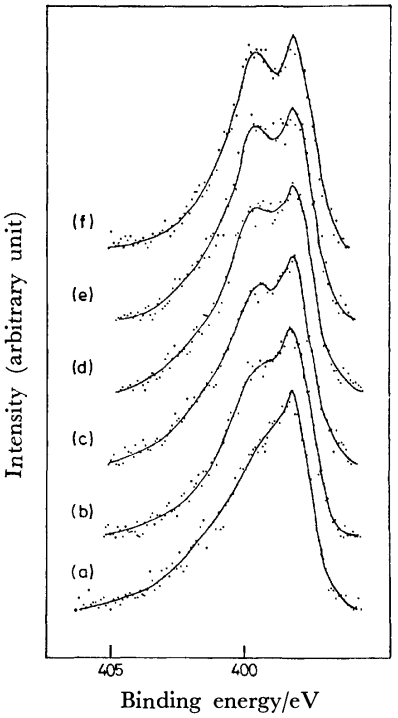

Fig. 2. The variation of the N ls peak shape of TTF·TCNQ evaporated film with X-ray irradiation time. (The photoelectron take-off angle is 80°.)
X-Ray irradiation time: (a) 0 min, (b) 200 min, (c) 465 min, (d) 630 min, (e) 795 min, and (f) 960 min.

change of the N ls peak shape was almost negligible after 400 min irradiation while a significant change was observable with the same film when $\theta=80°$.

It is well established that, when the angular distribution of XPS spectrum is measured on a very flat surface of a solid sample, the contribution of the surface relative to that of the bulk increases with the decrease of the photoelectron take-off angle. It was discussed by Fadley *et al.* that the same tendency can be also expected when the sample is an evaporated film with considerable surface roughness.[24] However, an opposite interpretation was taken by Ritsko *et al.*, in the case of the TTF·TCNQ evaporated film.[14] They observed by a scanning electron microscope that needle crystals of TTF·TCNQ are standing up on the substrate. From this structure of the film, they considered that the XPS spectrum obtained at a high take-off angle must reflect the surface state more strongly than the spectrum obtained at a low take-off angle. This interpretation seems to be consistent with our results concerned with the X-ray irradiation effect, since, in our experiments, the change of the N ls peak shape was markedly observed in the spectra measured at $\theta=80°$, not at $\theta=10°$, while the change by X-ray irradiation is naturally expected to take place rather in the surface region than in the bulk.

We found no appreciable change by X-ray irradiation in the S 2p peak shape, even if a marked change had already taken place in the N ls peak of the same sample.

We estimated the N/S atomic ratio from the in-

Table 1. Angular dependent XPS results of TTF·TCNQ evaporated films

	Run	Measured peaks	X-Ray irradiation time / min	Take-off angle/°	N/S atomic ratio

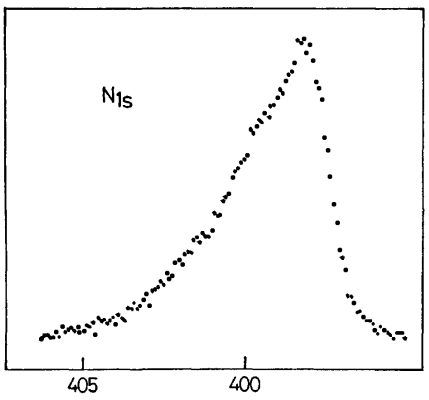

Fig. 3. The intrinsic N 1s peak of TTF·TCNQ. (Refer the text.)

tegrated intensities of the N 1s and S 2p peaks.[25] The results are given in Table 1. In each experiment, an evaporated film of TTF·TCNQ was freshly prepared, and the N 1s and S 2p peaks were repeatedly recorded by setting the take-off angle at either 10° or 80°. The results show that the N/S atomic ratio does not vary on X-ray irradiation in spite of the change of the N 1s peak shape. It should be noted also that the atomic ratio is the same within the experimental error between the cases $\theta=10°$ and 80°, the average value being 0.94 ± 0.03 for $\theta=10°$ and 0.96 ± 0.04 for $\theta=80°$. This fact may indicate that the mole ratio of TTF and TCNQ is not significantly different between the surface and the bulk, and does not vary with X-ray irradiation.

The mechanism that causes the change of the N 1s peak shape of TTF·TCNQ is not clear at present. The new peak which appeared at the high-binding energy side of the main peak after a long X-ray irradiation could correspond to the N 1s peak due to $TCNQ^0$.[9] If this is the case, we should consider that the ratio of TCNQ neutral molecule to $TCNQ^-$ ion increased in the surface region by X-ray irradiation. One could suspect that this change of the $TCNQ^0/TCNQ^-$ ratio is associated with a partial loss of TTF molecules from the surface region. But this is not likely to be the case since the N/S atomic ratio did not change with X-ray irradiation. If the new peak is attributable to $TCNQ^0$, a possible interpretation for the appearance of this peak could be that the electron transfer from $TCNQ^-$ to some adsorbed chemical species is enhanced by some way with X-ray irradiation. But we cannot exclude the possibility that the new peak is associated not with $TCNQ^0$, but with some product of an X-ray induced chemical reaction.

In any case, it is of vital importance to record the N 1s peak with a fresh film minimizing X-ray irradiation time in order to get the true peak shape. We summed up the data obtained within a short measuring time on several freshly-deposited TTF·TCNQ films, and obtained the N 1s peak shape which is shown in Fig. 3. This can be taken as the true N 1s peak shape without the deformation due to X-ray irradiation. It is very asymmetric with a long tail in the higher binding energy side. This is considerably different from the N 1s peak shapes which were reported by other authors.[6,14] The peak shapes hitherto reported seem to correspond to the state which has been already affected by X-ray irradiation.

Peak Shape and Degree of Charge Transfer. The S 2p spectra of TTF, $(TTF)^+\cdot(DDQ)^-$, TTT, and $(TTT)^+\cdot(ClO_4)^-$ are shown in Fig. 4. In each case, the observed spectrum shows a peak corresponding to S $2p_3/_2$ and a shoulder corresponding to S $2p_1/_2$. The overall fwhm (full width at half-maximum height) is 2.1 eV in the cases of TTF and TTT, and 2.5 eV in the cases of $(TTF)^+\cdot(DDQ)^-$ and $(TTT)^+\cdot$

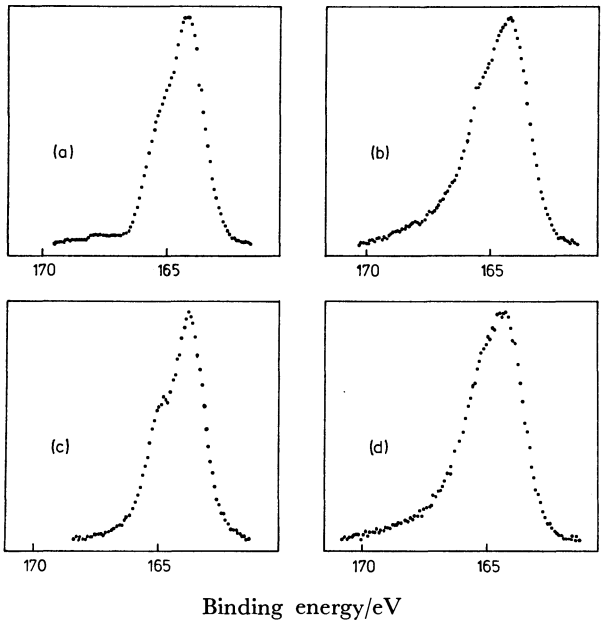

Fig. 4. S 2p peaks in the XPS spectra of (a) TTF, (b) TTF·DDQ, (c) TTT, and (d) TTT·(ClO_4).

$(ClO_4)^-$.[26] Any strong shake-up satellite does not appear in these S 2p spectra.

The S 2p spectra of TTF·$Br_{0.7}$, TTF·$I_{0.7}$, $(TTF)_3(BF_4)_2$, TTF·TCNQ, and TTF·TNAP are shown in Fig. 5. The peak profiles observed in these cases are significantly different from those shown in Fig. 4, showing a larger peak width; the fwhm is 2.7—3.1 eV in these cases. Obviously, TTF stacks in TTF·$Br_{0.7}$ and TTF·$I_{0.7}$ are in a mixed-valence state. From the chemical composition of TTF·$Br_{0.7}$, one can expect that about 70 percent of TTF molecules are in the state of TTF^+ and the remaining 30 percent are in the state of TTF^0, provided that all bromine atoms are in the state of Br^-. As shown in Fig. 5, the S 2p spectrum of TTF·TCNQ is similar to those of TTF·$Br_{0.7}$ and TTF·$I_{0.7}$, and distinctly different from those of $(TTF)^+\cdot(DDQ)^-$ and $(TTF)^+\cdot(ClO_4)^-$. This fact suggests that an incomplete charge transfer is taking place in TTF·TCNQ.

Assuming that the observed S 2p peak profile of $(TTF)^+\cdot(DDQ)^-$ is the one characteristic of TTF^+ and that of TTF is the one characteristic of TTF^0, we tried to reproduce the observed peak profiles of mixed-valence TTF salts by superimposing these two standard peak profiles, treating their separation and relative intensities as adjustable parameters. We defined the following error function:

$$R = \sum_i |I_{obsd}(E_i) - I_{calcd}(E_i)|/I_{obsd}(E_i)$$

where $I_{obsd}(E_i)$ is the observed intensity at the binding energy E_i and $I_{calcd}(E_i)$ is the calculated intensity of the superimposed peak profile at the same binding energy. We calculated the R value for each assumed parameter set and looked for the minimum point of the R map, which was taken to give the parameter set for the best fit between the observed and calculated peak profiles. All of these calculations were performed by use of a computer HITAC 8700/8800 at the Computer Center, University of Tokyo. The final results of the simulations for the mixed-valence TTF salts are shown in Fig. 5 with solid lines. The TTF^0 and TTF^+ components are shown in the same figure with broken lines. The results shown in Fig. 5 indicate that the S 2p peak profiles observed of the mixed-

The errors were estimated from the *R*-maps obtained from the peak profile analysis.

valence TTF salts can be very satisfactorily reproduced by superimposing the S 2p peaks of TTF^+ and TTF^0.

From the intensity ratio of the component peaks which gives the best fit between the observed and calculated peak profiles ,we can estimate the relative amounts of TTF^+ and TTF^0 in each mixed-valence TTF salt. The results are listed in Table 2. In the case of TTF·$Br_{0.7}$, the relative amount of TTF^+ is determined to be 71 percent, which agrees well with the value that is expected from the chemical composition. The shape of the Br 3d peak of this salt coincides well with that of the Br 3d peak of KBr. Thus all XPS data consistently indicate that bromine atoms in TTF·$Br_{0.7}$ are completely in the state of Br^-. This is also consistent with the ESR data.[15] In the case of $(TTF)_3(BF_4)_2$, 67 percent of TTF molecules must be in the state of TTF^+ since each BF_4 group receives one electron from TTF. The relative amount of TTF^+ derived from the peak profile analysis is in good agreement with the above value. These examples do indicate the validity of our procedure of peak profile analysis. It is interesting to see that, in the case of TTF·$I_{0.7}$, the peak profile analysis gave the relative amount of TTF^+ significantly smaller than the value that is expected from the chemical composition. We noted also that the profile of the I $3d_{3/2}$ peak is appreciably different from that of KI, indicating that there are some iodine species which are different from I^-. Using the peak profile of I $3d_{3/2}$ of KI, we decomposed the I $3d_{3/2}$ peak observed of TTF·$I_{0.7}$ into the component corresponding to I^- and the one corresponding to the other iodine species which has less negative charge, possibly being in the state of I^0. The analysis of I $3d_{3/2}$ peak profile mentioned above gave the conclusion that about 79 percent of iodine atoms are in the state of I^-. If we assume that the remaining iodine atoms are in the neutral state, the relative amount of TTF^+ is expected to be 56 percent. This is in good agreement with the value obtained from the analysis of the S 2p peak profile. Seemingly an incomplete charge transfer is taking place in TTF·$I_{0.7}$. This conclusion is consistent also with the ESR data, which indicate that some unpaired spins are on iodine atoms.[15]

In the case of TTF·TCNQ, the analysis of the S 2p peak profile gave the relative amount of TTF^+ as 56 percent. From the analysis of the X-ray diffuse scattering, Comès *et al.*[5] and Kagoshima *et al.*[3] concluded that the degree of charge transfer from TTF to TCNQ is to be 59 percent. The relative amount of TTF^+ determined by the analysis of the S 2p peak profile is in good agreement with the above conclusion. The analysis of the S 2p peak profile gives almost same degree of charge transfer for TTF·TNAP.

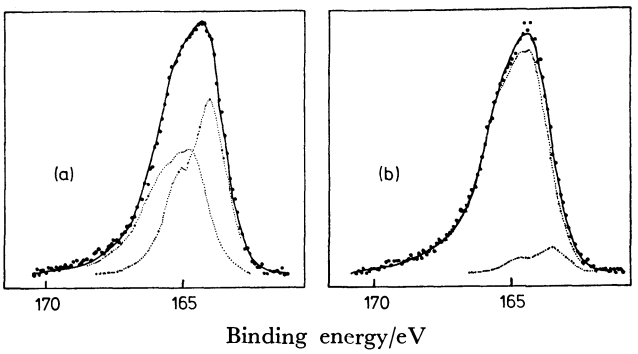

Fig. 6. S 2p peaks in the XPS spectra of (a) $(TTT)_2I_3$ and (b) (TTT)$(TCNQ)_2$.
Observed peak (•••), simulated peak (——), and component peaks of simulation (···).

The same procedure was taken for the analysis of S 2p peak profiles of TTT salts, using the S 2p peak profile of TTT and that of $(TTT)^+\cdot(ClO_4)^-$ as the standard peak profiles for TTT^0 and TTT^+ respectively. Results are shown in Fig. 6 and Table 2. In $(TTT)_2I_3$, iodine is known to exist as I_3^-.[27,28] Thus one should expect that a half of TTT molecules are in the ionized state. The result obtained by the analysis of the S 2p peak profile agrees with the above expectation. According to the analysis of the S 2p peak profile, almost all TTT molecules are in the ionized state in (TTT)$(TCNQ)_2$. If this is the case, a half of TCNQ molecules are in the state of $TCNQ^-$ and the remaining half are in the state of $TCNQ^0$. The shape of the N ls peak of this material is the same as those of the TCNQ complex salts where 50 percent of TCNQ molecules are in the ionized state, hence it is consistent with the conclusion obtained from the S 2p peak.

As we have mentioned, we treated the separation of the two component peaks as an adjustable parameter. This is because the shifts of the peaks associated with neutral molecules and ions are not necessarily the same for all TTF salts (or TTT salts), so that their separation could vary more or less from salt to salt. The relative separation of the component peaks obtained from the peak profile analysis was 0.9 eV for TTF·$Br_{0.7}$ and $(TTF)_3(BF_4)_2$, 1.0 eV for TTF·$I_{0.7}$, 1.2 eV for TTF·TCNQ, 1.4 eV for TTF·TNAP and 0.7 eV for the two TTT salts studied here. These values seem to be quite reasonable for the separation between the peaks due to TTF^0 and TTF^+ (or between those due to TTT^0 and TTT^+), but it is not possible to carry out at the present stage a quantitative discussion on the difference of the peak separation obtained for different salts.

The results described above show that observed S 2p peak profiles of TTF and TTT salts can be well reproduced by superimposing the standard peak profile characteristic of the neutral molecule and that of the

ion with an appropriate intensity ratio, and by this peak profile simulation, we can determine the ratio of neutral molecules and ions (or the degree of charge transfer).

As we have already mentioned, the situations are rather complicated in the case of the N ls peaks of TTF·TCNQ and TCNQ complex salts. The N ls peak profile of TTF·TCNQ, shown in Fig. 3, cannot be reproduced by superimposing the N ls peak profile observed of TCNQ and that of K·TCNQ with the intensity ratio that is expected from the degree of charge transfer. Almost same N ls peak profile is observed for $[(C_6H_5)_3PCH_3]^+(TCNQ)_2^-$ and other TCNQ complex salts which formally contain $TCNQ^-$ and $TCNQ^0$ with 1:1 mole ratio. In this respect, $Cu^+(TCNQ)_2^-$ is an exception. In this case, the observed N ls peak can be almost exactly reproduced by superimposing the N ls peak profile of $TCNQ^0$ and that of $TCNQ^-$ with the intensity ratio corresponding to the 1:1 mole ratio.[29] Unfortunately, the crystal structure of $Cu(TCNQ)_2$ is not known so far, but the arrangement of $TCNQ^0$ and $TCNQ^-$ in this salt is likely to be quite different from those in other TCNQ complex salts since $Cu(TCNQ)_2$ does not exhibit the absorption band which is characteristic of the charge transfer between $TCNQ^-$ and $TCNQ^0$.

TTF·TCNQ is a metal-like conductor, and conduction electrons (or holes) might be delocalized along the TTF stack as well as along the TCNQ stack. In spite of this delocalization of conduction electrons, the S 2p spectrum of TTF·TCNQ can be well explained as the superposition of the peak due to TTF neutral molecules and that due to TTF^+ ions. This fact may suggest that each TTF molecule in TTF·TCNQ can be regarded to be either in the state of TTF^+ or in the state of TTF^0 within the characteristic time scale of photoionization by X-ray. On the other hand, the N ls peak profile cannot be reproduced by the superposition of the peaks due to $TCNQ^0$ and $TCNQ^-$. The delocalization of conduction electrons along the TCNQ stack is not likely to be the origin of this phenomenon, since almost the same peak profile is observed also in many TCNQ complex salts which are not metal-like conductors, but are semiconductors of relatively low conductivity. Ritsko *et al.* suggested that the N ls peak profile of TTF·TCNQ could be understood in terms of the Hush's model[30] for the mixed-valence two-site system, by considering the local delocalization of valence electrons among neighboring TCNQ ions and molecules.[14] But, if this is the case, it is not easy to understand why the same mechanism does not work in the case of the S 2p spectra of TTF salts while a strong charge-transfer interaction is also taking place between TTF^0 and TTF^+.

As we have mentioned, in the N ls spectra of TCNQ salts, the relative intensity of the satellite band varies depending on the charge-transfer interaction between $TCNQ^-$ ions or between $TCNQ^0$ and $TCNQ^-$. Thus, one cannot expect anyway that the observed N ls peak profile of a TCNQ complex salt will be exactly reproduced by simply superimposing the N ls peaks of TCNQ and $K^+\cdot(TCNQ)^-$. Therefore, it is possible that each TCNQ molecule in a mixed-valence TCNQ stack can be regarded to be either in the state of $TCNQ^-$ or in that of $TCNQ^0$ as in the case of TTF molecules in a mixed-valence TTF stack, disregarding the delocalization of valence electrons, within the characteristic time scale of photoionization by X-ray, and the failure of the analysis of N ls peak profile is entirely due to the disturbing effect of the strong shake-up satellite.

The Light-driven Electron Transfer Reaction of Chlorophyll a–Lumiflavin in Micelle

Akio Yoshimura* and Shunji Kato

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received November 9, 1979)

The light-driven electron transfer reaction for the system of chlorophyll a–lumiflavin in micelles was studied by means of flash photolysis. In the sodium dodecyl sulfate micellar solution, the chlorophyll a cation radical appeared on the flash excitation and then decayed by means of a second-order process under aerated conditions as well as under deaerated conditions (the radical was not observed in dioxane). The decay parameter in the aerated solution was smaller than that in the deaerated solution by a factor of twenty. The difference in the decay parameter was explained in terms of the function of the surface charge of micelles. In the deaerated solution, the chlorophyll a cation radical decays by means of a reaction with lumiflavin semiquinone of no charge; in the aerated solution, however, it decays by means of a reaction with the O_2^- produced by the electron transfer from lumiflavin semiquinone to oxygen. The latter decay reaction is retarded by the charge on the micelles.

In the photosynthesis, it is established that the electron is transferred from the excited chlorophyll a (Chl a) in P700 (the primary reaction center of the photosystem I of chloroplasts) to $NADP^+$-reductase, which has flavin adenine dinucleotide (FAD) as the prosthetic group, through ferredoxin (iron–sulfer protein). Wang *et al.* studied the complexes of Chl a derivatives, with flavins as model complexes for P700, and observed the light-induced electron-transfer reactions from the chlorophyll to the flavin.[1] The electron-transfer reactions from Chl a to *p*-benzoquinone[2] or to Chl a[3,4] were also examined under suitable homogeneous conditions, and it was concluded that the electron transfer proceeded from the singlet excited state of Chl a[3] or from the triplet state.[2,4]

In the chloroplast membrane, the specific environmetal effect must play an important role. Micellar systems have been examined[5] as models for membrane, especially in order to clarify the interfacial effects. In this work, kinetical studies have been made of Chl a–lumiflavin in aqueous micellar systems. Photolyses under different concentrations of dissolved oxygen were performed. Lumiflavin was used instead of riboflavin as an electron acceptor to avoid the interference of the reactive side chain, as in our previous studies of the sensitized photooxygenation.[6] Photolysis in dioxane was also examined in order to make a comparison with that in an ordinary solution.

Experimental

Materials. The chlorophyll a was extracted from spinach, purified chromatographically by the procedure of Strain and Svec,[7] and stored at −20 °C. The lumiflavin was synthesized as has been described by Hemmerich *et al.*[8] The sodium dodecyl sulfate (SDS) was recrystallized from ethanol, and the hexadecyltrimethylammonium bromide (CTAB) was recrystallized from ethanol–ether. The dioxane was freshly distilled after several days of refluxing over sodium.

Procedure. All the sample solutions were prepared just before their use. The Chl a–SDS solutions were prepared by the following procedure. The Chl a was first dissolved in ethanol, mixed with a concentrated SDS solution containing a buffer, and finally diluted with the buffer solution. The final solutions contained 2% ethanol by volume. In anionic micellar solutions such as SDS solutions, the local pH value around the micelles is lower than the bulk according to the electrostatic potential of the micellar surface. Therefore, the SDS solutions were required to be rather basic (pH 9.0) to avoid the elimination of Mg from Chl a. As the buffer, *N*-tris(hydroxymethyl)methyl-3-aminopropanesulfonic acid (TAPS, 0.05 M†) was used. The concentration of Chl a was adjusted to be not less than 7 μM, because it is less stable at lower concentrations. Chlorophyll a dissolved in this manner was stable for two hours, judging from the absorption spectrum.

The Chl a–CTAB solutions were prepared just as the Chl a–SDS solutions, but the solutions were adjusted to pH 7.2 with a sodium phosphate buffer. Unlike anionic micellar solutions, the local concentration of the hydroxide ion around the CTAB micelles is relatively high, and it tends to cause the allomerization (oxidative degradation) of Chl a.

The critical micelle concentration (CMC) values of the surfactants were determined by the use of a stalagmometer. The amounts of dissolved oxygen in aerated solutions were measured by means of Winkler's method.[9] The solutions with reduced concentrations of oxygen were prepared by purging with mixtures of nitrogen and oxygen of known compositions.

Flash photolysis was carried out in a 1-cm rectangular quartz cell or in a 10-cm cylindrical quartz cell, with exciting light from xenon flash lamps (9 μs half-maximum duration) through red glass filters (cut off at 580 nm) to avoid the excitation of lumiflavin. The fluorescence was measured with a Hitachi MPF-2A fluorescence spectrophotometer.

Partition of Reactants between SDS Micellar and Water Phases. In the SDS micellar solution, Chl a is exclusively present in the micellar phase, because Chl a is insoluble in water. On the other hand, lumiflavin is present in both micellar and water phases. The partition of lumiflavin into them was determined from the measurements of the change in the fluorescence intensity of lumiflavin with different concentrations of SDS. The fluorescence intensity ratio of micellar solutions to the solution without micelles was independent of the lumiflavin concentration in the range from 30 μM to 100 μM (the solubility limit in the bulk). Therefore, the distribution of lumiflavin can be treated as the partition equilibrium.

Putting the fluorescence yields in aqueous and micellar phases as ϕ_a and ϕ_m respectively ($\phi_m > \phi_a$ in this case), the intensity ratio of the fluorescence of the micellar solution to the aqueous solution for the same dye concentration is

† In this paper 1 M = 1 mol dm^{-3}.

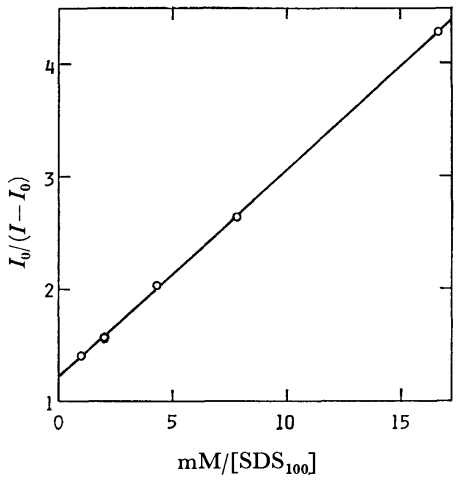

Fig. 1. The plots of $I_0/(I-I_0)$ *vs.* the inverse of the concentration of SDS micelle.
Lumiflavin, 30 μM; 0.05 M TAPS at pH 9.0 (27 °C); excitation at 440 nm; emission at 520 nm.

written as;

$$\frac{I}{I_0} = \frac{\phi_a[LF_a] + \phi_m[LF_m]}{\phi_a[LF_t]}, \quad (1)$$

where $[LF_m]$ is the partial apparent concentration of lumiflavin in the micellar phase relative to the total volume of the micellar solution, $[LF_a]$ is the concentration in the aqueous phase, and $[LF_t]=[LF_m]+[LF_a]$. On the other hand, the partition coefficient (K), which is the ratio of the local concentration of lumiflavin in the micellar phase to $[LF_a]$ (the volume of the micellar phase is negligibly small compared with the total volume), is written as;

$$K = \frac{[LF_m]/[N_a v_m[M])}{[LF_a]}, \quad (2)$$

where [M] is the molar concentration of micelle particles, v_m is the volume of a micelle, and N_a is the Avogadro constant. By combining Eqs. 1 and 2, Eq. 3 is obtained:

$$\frac{I_0}{I-I_0} = \left(\frac{\phi_a}{\phi_m-\phi_a}\right)\left(\frac{1}{KN_a v_m[M]}+1\right). \quad (3)$$

The micelle concentration [M] was estimated from the aggregation number (100)[10] and the CMC value (2.0 mM) under these conditions, assuming a constant concentration of the monomer surfactant above the CMC. Figure 1 shows that Eq. 3 holds, from which the partial concentration of lumiflavin present in the micellar phase is obtained for a given micelle concentration ($KN_a v_m = 7.0\times10^3$ M^{-1}, at 20 °C).

The highest concentration of lumiflavin examined was 270 μM under the SDS concentration of 27 mM (micelle concentration: 250 μM); then, the concentration of lumiflavin in the micelles was calculated to be 170 μM, and the concentration of lumiflavin in the bulk, to be 100 μM (nearly saturation).

Assuming the Poisson distribution of the lumiflavin molecules among the micelle particles, the fraction of micelles which contain no lumiflavin molecules is $e^{-\lambda}$, where λ is the ratio of the number of lumiflavin molecules in micelles to the number of micelle particles. Under the present conditions, where the concentration of micelles and the partial concentration of lumiflavin in the micellar phase are 250 μM and 170 μM respectively, the fraction of micelles with lumiflavin is calculated to be 0.53.

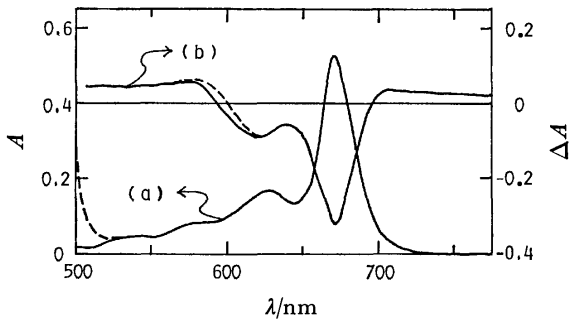

Fig. 2. The absorption spectra (a) and the transient difference spectra immediately after the flash excitation (b) of Chl a in the deaerated SDS micellar solutions with and without lumiflavin.
Chl a, 10 μM; lumiflavin, 0 mM (——) and 270 μM (- - -); SDS, 27 mM; 0.05 M TAPS at pH 9.0 by 200 J flash.

The local concentration of lumiflavin in the micelle particles is evaluated as 30 mM, assuming a spherical micelle with a radius of 1.8 nm, which is 300 times larger than the solubility in water and about 10 times larger than that in chloroform.

The oxygen concentration in the aerated solution with 27 mM SDS (250 μM in micelle concentration) and 50 mM TAPS at 30 °C was 233 μM, while that in the solution without SDS was 226 μM. The increase in the 7 μM oxygen content is attributable to the solubilization of oxygen in micelles. This means that only one-thirtieth of the micelles contain oxygen, on the average, although the local concentration of oxygen in micelles is calculated to be as high as 2 mM, which agrees with the solubility of oxygen in typical organic solvents.

Results and Discussion

Photolysis in Deaerated SDS Micellar Solutions. When a deaerated SDS micellar solution of Chl a without lumiflavin was irradiated by flashing light, only the triplet state of Chl a was observed as the transient species; it showed a broad absorption spectrum (Fig. 2) and decayed exponentially at the rate parameter of 1380 s^{-1}. The second-order component due to the T–T annihilation was not observed.

The addition of 270 μM lumiflavin had little effect on either the transient absorption spectrum or the initial absorbance change on the flash excitation (Fig. 2) and effected no permanent change at all. However, the kinetical behavior of the transient species was quite different; that is, the decay followed a second-order rate, as is shown in Fig. 3a. The value of $k_1/(\Delta\varepsilon d)$ is determined from the slope to be 1.0×10^4 s^{-1} at 670 nm for a 1-cm cell, where k_1 (M^{-1}S^{-1}) is the rate parameter of the second-order process, $\Delta\varepsilon$(M^{-1} cm^{-1}) is the difference in the molar absorption coefficients between the transient and final species at 670 nm, and d is the cell length in cm.

The transient absorbance change induced by the flash irradiation is considered to be due to the electron-transfer reaction from Chl a to lumiflavin in the initial stage, followed by the backward electron-transfer reaction between the Chl a cation radical and lumiflavin

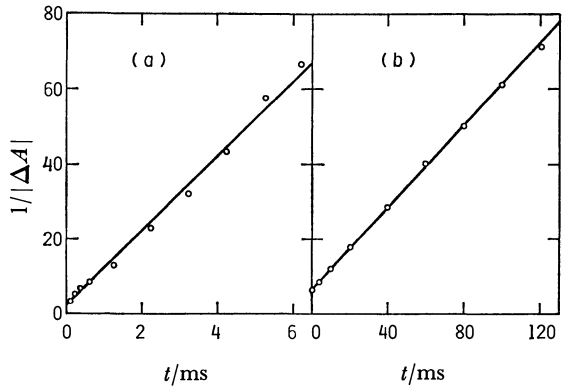

Fig. 3. Second order decay of the flash induced absorbance change of Chl a with lumiflavin in the deaerated (a) and aerated (b) SDS micellar solutions.
Chl a, 10 μM, lumiflavin, 270 μM; 0.05 M TAPS at pH 9.0 by 200 J flash, observed at 670 nm with 1-cm cell.

semiquinone, which are the products of the initial reaction. If both radicals remained in the same micelle after the initial stage, the back reaction should be first-order, contradicting the observation. Accordingly, the lumiflavin semiquinone anion radical must be immediately expelled to the bulk by the effect of the negative charge of the micelle. This second-order decay was also observed in the solution of Chl a with a lower concentration of lumiflavin (15 μM), where 97% of the Chl a molecules are in micelle particles free from lumiflavin. Therefore, the triplet state of Chl a in micelles (Chl a^T_m) can also react, within its lifetime, with the lumiflavin present in the bulk (LF_a):

$$\text{Chl } a^T_m + LF_a \longrightarrow \text{Chl } a^{+\cdot}_m + LF^{-\cdot}. \quad (4)$$

When the flash energy was increased, the initial absorbance change asymptotically reached 0.46 for 10 μM Chl a in the micellar solution with lumiflavin (270 μM). Under these limiting conditions, Chl a is completely converted to the cation radical. Therefore, $\Delta\varepsilon$ is calculated to be 4.6×10^4 M^{-1} cm^{-1}, and the rate parameter, (k_1) to be 4.6×10^8 M^{-1} s^{-1}.

The decay reaction was examined for different ionic strengths in the presence of 0-, 0.07-, and 0.13-M NaCl, and it was found that the decay was not altered. This shows that the species reacting with Chl a cation radicals in micelles is the protonated form (LFH·) of the lumiflavin semiquinone anion radical, with no charge:

$$\text{Chl } a^{+\cdot}_m + \text{LFH}\cdot \xrightarrow{k_1} \text{Chl } a_m + LF + H^+, \quad (5)$$

where k_1 is the rate parameter evaluated above. Under the present conditions (pH 9.0), it is natural that most of the lumiflavin semiquinone radicals exist in the acidic form, with no charge, in the close vicinity of micelle particles, because the pK_a value of LFH· has been reported to be 8.36[11] and the pH in the vicinity of SDS micelles is lower by 2 units than the value in the bulk.[12]

Photolysis in Aerated SDS Micellar Solutions. In an aerated SDS micellar solution, Chl a showed no absorbance change upon flash irradiation, but upon the addition of 270 μM lumiflavin, the following absorbance change was observed upon the flash excitation. The transient-difference spectrum was similar to those observed in the deaerated solutions, but the decay was much slower. The decay kinetics was also second-order as is shown in Fig. 3b, from which the slope is obtained as 540 s^{-1} at 670 nm with a 1-cm cell. The initial absorbance change for an infinite light intensity was obtained to be 0.23 at 670 nm with 10 μM Chl a and 270 μM lumiflavin, this is half of the value for the deaerated solution.

Table 1. Effect of NaCl on the decay parameter (k) of the Chl a cation radical in the aerated SDS micellar solutions

[NaCl] / M	k / 10^7 M^{-1} s^{-1}	k/k_0
0	2.5	(1)
0.055	3.5	1.41
0.104	4.7	1.88
0.179	5.4	2.16

Chl a, 10 μM; lumiflavin, 270 μM; SDS, 27 mM; 0.05 M TAPS pH 9.0.

Combining this with the finding that 53% of Chl a is present with lumiflavin in the same micelle, one may safely propose the following mechanism. The triplet Chl a in a micelle is rapidly quenched by oxygen in the aqueous phase without reacting with lumiflavin if lumiflavin is absent in the same micelle:

$$\text{Chl } a^T_m + O_2 \longrightarrow \text{Chl } a_m + O_2. \quad (6)$$

However, if present, Chl a is immediately oxidized to the cation radical and the lumiflavin semiquinone anion radical is expelled from the micelle. This anion radical will be rapidly oxidized back to lumiflavin as:

$$LF^{-\cdot} + O_2 \longrightarrow LF + O_2^{-\cdot}. \quad (7)$$

Since the pK_a value of $HO_2\cdot/O_2^{-\cdot}$ is 4.88,[13] the reduced oxygen exists exclusively as $O_2^{-\cdot}$, even in the vicinity of a micelle when the bulk pH value is 9:

$$\text{Chl } a^{+\cdot}_m + O_2^{-\cdot} \xrightarrow{k_2} \text{Chl } a_m + O_2. \quad (8)$$

Using the same $\Delta\varepsilon$ value as in the case of the deaerated solution, the rate parameter (k_2) is calculated to be 2.5×10^7 M^{-1} s^{-1}, about one-twentieth of the value for the deaerated solution. This slow back reaction of the Chl a cation radical can be explained by the repulsive action of the anionic micelle against $O_2^{-\cdot}$. This is supported by the fact that the decay parameter is increased with the concentration of sodium chloride, as is shown in Table 1.

When the dissolved oxygen concentration is reduced to below 30 μM, a fast process appears at the initial stage of the decay profile, and the initial absorbance change becomes larger (Fig. 4). The fraction of the slower component is obtained from the later stage of the decay curve; its change with the oxygen concentration is also shown in Fig. 4. In these low oxygen concentrations, the reactions in Eqs. 4 and 6 compete with each other, as do the reactions in Eqs. 5 and 7.

Photolysis in Dioxane. On the flash excitation

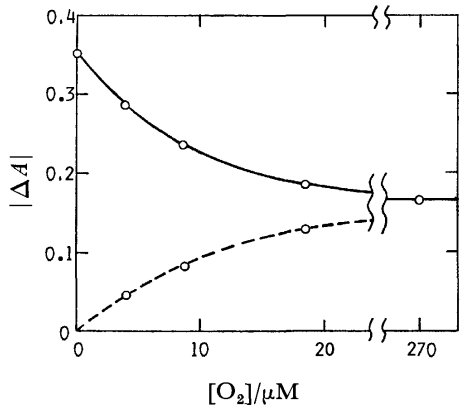

Fig. 4. Variation of the initial absorbance change of 10 μM Chl a in the presence of 270 μM lumiflavin by 200 J flash at 670 nm, with the concentration of oxygen.
Total (——); the component with the longer life time (----).

of Chl a in deaerated dioxane, the triplet state of Chl a was observed. It decayed at 700 s^{-1} at a low concentration of the triplet state, and the second-order component due to the T–T annihilation was overlapped at the early stage of the decay. (In the micellar solutions, the T–T reaction is blocked, because each Chl a is present statistically in a different micelle under the conditions examined.) On the flash photolysis of Chl a in the deaerated dioxane with 90 μM lumiflavin, the signal height and the decay were almost the same as those without lumiflavin. That is to say, neither the light-driven electron transfer reaction nor the quenching occurs in such a nonpolar solvent. In aerated solutions with and without lumiflavin, no absorbance change was observed after the flash excitation.

Photolysis in CTAB Micellar Solutions. When Chl a was irradiated by flashing light in a deaerated CTAB micellar solution, the triplet state of Chl a appeared as in the SDS solution and showed a first-order decay with 1600 s^{-1}. However, in the presence of 160 μM lumiflavin, the results were quite different from those in the SDS solutions; that is, the transient absorbance change in the deaerated solution was markedly small compared with the change in the SDS solution, and it was barely observed at all in the aerated solution. Under these conditions, lumiflavin acts mainly as quencher for the triplet state of Chl a. These results can be explained by saying that the escape of the lumiflavin semiquinone from the micelle is blocked by the positive charge of the cationic micelle.

The function of the surface charge of micelles is a dominant factor in both the formation and decay processes of the Chl a cation radical.

(Received November 17, 1979)

Infrared absorption spectra, ultraviolet absorption spectra, phosphorescence spectra, phosphorescence lifetimes, and phosphorescence excitation spectra have been examined of 1-propyl-2-thiouracil in various solvents, including CCl_4, CH_3OH, CCl_4+CH_3OH, and CCl_4+9-ethyladenine. For 1-cyclohexyluracil, and for 2-*S*-propyl-2-thiouracil, similar infrared spectroscopic examinations were also made. The results obtained are as follows: (1) In CCl_4, the 2-thiouracil residue forms a hydrogen-bond complex with the adenine residue, in which the C^4=O is involved in the hydrogen-bond. (2) The binding of 2-thiouracil and adenine is much stronger than that of 2-thiouracil and CH_3OH; the 2-thiouracil·methanol binding is stronger than the uracil·methanol binding. (3) The hydrogen-bonding of the 2-thiouracil residue (with CH_3OH or with adenine) causes an elevation of the lowest singlet excited state S_1, which is probably an $^1(n\pi^*)$, from 2.5×10^4 cm^{-1} to 2.6×10^4 cm^{-1}, and the lowest triplet excited state T_1, which is probably an $^3(n\pi^*)$, from 2.4×10^4 cm^{-1} to 2.6×10^4 cm^{-1}. (4) The hydrogen bonding of the 2-thiouracil residue causes a great enhancement of the phosphorescence intensity. On the basis of these observations, a discussion is given on the nature of the inter-base hydrogen-bonds involving 2-thiouracil residue.

2-Thiouracil is a modified base, closely related with a number of naturally occurring nucleic acid constituents. Yeast $tRNA_3^{Glu}$, for example, has 2-thiouridine-5-acetic acid methyl ester as the first letter of its anti-condon triplet.[1] The thymidine residue in the TψC sequence is partly replaced by 2-thiothymidine residue in the tRNAs of *Thermus thermophilus*, an extremely thermophilic bacterium.[2] In an attempt to characterize the hydrogen-bondings involving the 2-thiouracil residue, we have made a detailed spectroscopic examination of 1-propyl-2-thiouracil, which is soluble both in polar and nonpolar solvents.

Experimental

Materials and Methods. 1-Propyl-2-thiouracil was prepared by a direct alkylation of 2-thiouracil (from Tokyo-Kasei Co.) with propyl bromide, following the method previously given for N-1 alkylation of uracil.[3,4] 1 Mol of 2-thiouracil and 2/3 mol (or less) of propyl bromide were mixed together in a small amount of dry dimethyl sulfoxide with 1 mol of potassium carbonate, and the slurry was kept at room temperature for 48 h under vigorous stirring. After removing K_2CO_3 by filtration, the clear solution was concentrated *in vacuo*, and an excess of ethanol was added. The precipitates, unreacted 2-thiouracil, was discarded after filtration. This process was repeated three times or more until the 2-thiouracil is adequately removed from the solution. The final filtrate was subjected to a silica gel chromatography with CCl_4/*t*-BuOH(10:1) as the eluent. Two fractions corresponding to 1-propyl-2-thiouracil and to 2-*S*-propyl-2-thiouracil were obtained. The yields of the above products were about 3% and 20%, respectively. Both were purified by recrystallization from ethanol. No 3-propyl derivative was produced. The 1-propyl-2-thiouracil sample, thus obtained, gave a single spot in a thin layer chromatography: R_f 0.82 with $CHCl_3/C_2H_5OH$=9/1. Melting point, 187 °C.

The ultraviolet absorption spectrum of 1-propyl-2-thiouracil was found to be identical to 1-ethyl-2-thiouracil in neutral and pH 12 solutions. The 1-ethyl-2-thiouracil sample was provided by Professor D. Shugar of Department of Biophysics, Institute of Experimental Physics, University of Warsaw, Poland, to whom we are indebted. The product was also identified by its mass spectrum (M^+(*m/e*): Found 170, Calcd, 170) and elementary analysis. Found: C, 49.34; H, 6.09; N, 16.52; O, 9.37; S, 18.78%. Calcd for $C_7H_{10}N_2OS$: C, 49.39; H, 6.21; N, 16.46; O, 9.40; S, 18.83%.

2-*S*-Propyl-2-thiouracil obtained as described above was identified by infrared absorption spectrum,[5] ultraviolet absorption spectrum,[5] melting point (117 °C), and elementary analysis. Found: C, 49.24; H, 5.97; N, 16.50; O, 9.16; S, 18.59%. Calcd for $C_7H_{10}N_2OS$: C, 49.39; H, 6.21; N, 16.46; O, 9.40; S, 18.83%.

1-Cyclohexyluracil was prepared by Dr. T. Katsura, Research Institute for Polymer and Textiles, Tsukuba, and was kindly given us by him. Its infrared and ultraviolet absorption spectra were found to be identical with what are known.[6,7]

9-Ethyladenine is a gift of Professor T. Miyazawa, Department of Biochemistry and Biophysics, Faculty of Science, University of Tokyo. Its identification was made by the infrared and ultraviolet absorption spectra.[6,7]

All the solvents used were carefully purified by distillation and then mostly by an activated alumina column. Bases were dissolved in these solvents by the use of a sonicator and by heating at 40 °C with hot air. For phosphorescence measurements, the solutions were carefully degassed in a vacuum line.

Infrared absorption spectra were observed by the use of a Digilab FTS-14 Fourier transform spectrophotometer. The disturbance due to the atmospheric water vapour was removed by filling the inside of the instrument with dry air. Each of the absorption curves in Figs. 1, 2, and 4 was recorded with resolution=4 cm^{-1} and number of scans=240. Each of the sample solutions was placed in one of the following three sealed cells: one with KBr windows and with 1 mm path, another with CaF_2 windows and 1 mm path, and that with CaF_2 windows and 50 μm path. The actual optical path lengths of these cells were determined by examining interference patterns. Ultraviolet absorption spectra were examined by the use of a Hitachi 124 spectrophotometer. Phosphorescence was observed with a Hitachi MPF-4 fluorometer with a phosphoroscope. Spectral slit width was set at 10 nm. Phosphorescence decay curves were obtained by the use of a nitrogen laser of 20 kW in the peak power

and 8 ns in duration time. This was combined with a monochromator, photomultiplier (HTV R106 UH) and Tektronix 465 (100 MHz) oscilloscope. Decay curves were also observed with another apparatus with two electromagnetic shutters placed before and after the light beam (313 nm from a Hg lamp) goes into the sample,[8] through the courtesy of Professor Minoru Kinoshita, Dr. Noriko Iwasaki and Dr. Nobuyuki Nishi, Institute for Solid State Physics, University of Tokyo.

Infrared Absorption Spectra

Carbonyl Bands of Free Base. As is shown in Fig. 1 (top), 1-propyl-2-thiouracil shows two absorption bands at 1723 and 1712 cm^{-1} in the carbonyl stretching region, in its dilute CCl_4 solution (concentration 1.3×10^{-3} M). In dilute CS_2 solution it shows two bands at 1720 and 1710 cm^{-1}. 1-Cyclohexyluracil, which has two carbonyl groups at 2- and 4- positions, shows also two bands in the 1700 cm^{-1} region, at 1719 and 1698 cm^{-1}.

The appearance of two (instead of one) carbonyl bands for 1-propyl-2-thiouracil, free from any hydrogen bonds, may be ascribed to a Fermi resonance, although there is no strong evidence established for supporting this idea.

Self-association. When the concentration of 1-propyl-2-thiouracil in CCl_4 is increased from 2.8×10^{-4} M to 1.9×10^{-3} M, a lowering of the absorption intensities of the 1723 and 1712 cm^{-1} bands takes place while their intensity ratio remains unchanged. In addition, a new band appears at 1691 cm^{-1} (see Fig. 2). These are considered to be caused by a formation of a hydrogen-bond dimer of two 2-thiouracil residues, such as Fig. 3 (d). The 1691 cm^{-1} band is assigned to such a dimer. On the basis of an intensity measurement of the 1723 and 1691 cm^{-1} bands, and by postulating only one form of dimer, the equilibrium constant of the dimerization has been estimated to be about 40 M^{-1} in CCl_4 at 34 °C.

2-*S*-Propyl-2-thiouracil shows three bands (at 1700, 1713, and 1675 cm^{-1}) in its dilute (1.9×10^{-4} M) CCl_4 solution (see Fig. 2, lower). The former two are assignable to the carbonyl bands of free base, while the last one is assignable to a dimer band. The equilibrium constant of dimerization of 2-*S*-propyl-2-thiouracil has been found to be about 100 times as great as that of 1-propyl-2-thiouracil (see Fig. 3 (f)).

Hydrogen-bond Complex with Methanol. When methanol is added to a dilute CCl_4 solution of 1-propyl-2-thiouracil, the 1723 and 1712 cm^{-1} bands become weaker and two new bands appear at 1708 and 1693 cm^{-1}, which become stronger with the methanol concentration (see Fig. 4, top). Both of the 1708 and 1693 cm^{-1} bands are attributed to a binary complex of 1-propyl-2-thiouracil and methanol bound through

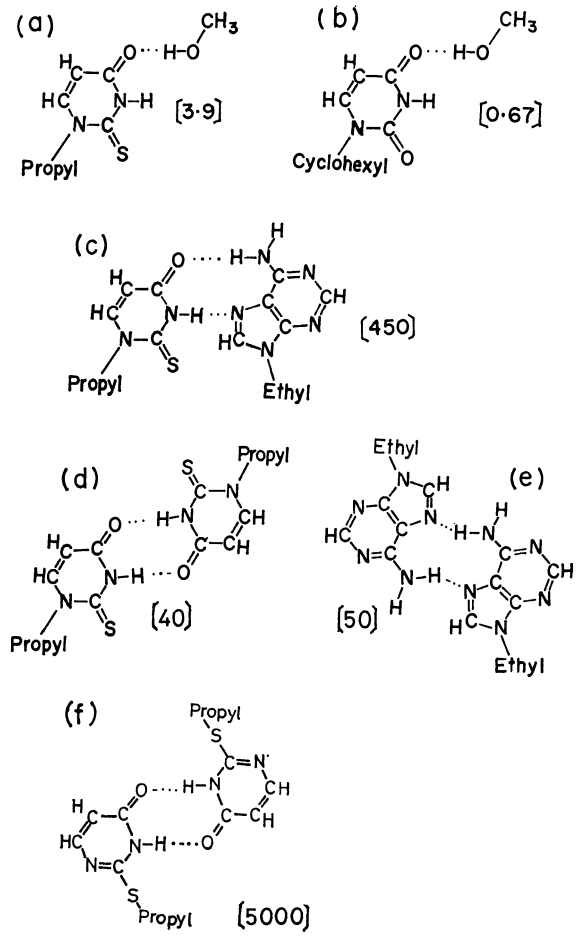

Fig. 3. Possible structures of hydrogen-bonded complexes involving uracil, 2-thiouracil, and/or adenine residues. The figure in bracket indicates the equilibrium constant in M^{-1} of the association reaction of each complex in CCl_4 at 34 °C. The equilibrium constants have been calculated by the method of Refs. 6 and 14.

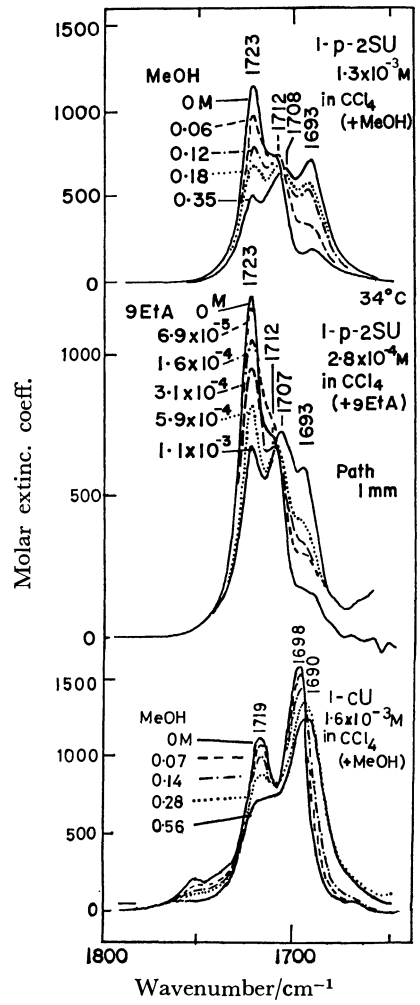

Fig. 4. Infrared absorption spectra of 1-propyl-2-thiouracil in the solutions of CCl_4+CH_3OH and in the solutions of CCl_4+9-ethyladenine and of 1-cyclohexyluracil in the solutions of CCl_4+CH_3OH.

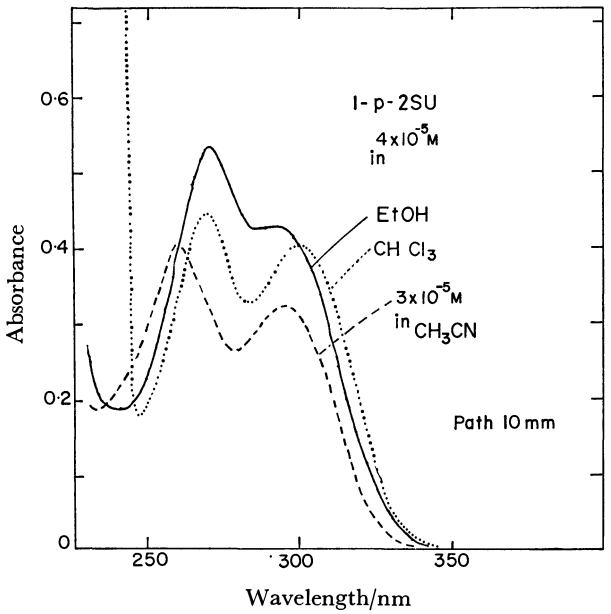

Fig. 6. Ultraviolet absorption spectra of 1-propyl-2-thiouracil in various solvents.

the O–H···O hydrogen bond between the methanol OH and position-4 carbonyl of the 2-thiouracil residue (see Fig. 3 (a)). By assuming that only one form of complex is involved in the methanol-2-thiouracil interaction, the equilibrium constant for that complex formation has been estimated from the intensity measurements of the carbonyl bands. This is found to be 3.9 M^{-1} in CCl_4 at 34 °C. This value is to be compared with the equilibrium constant, 0.67 M^{-1}, for the complex formation (Fig. 3 (b) and Fig. 4, bottom) between methanol and 1-cyclohexyluracil, which was determined in a similar way in dilute CCl_4 solution at 34 °C.

Association with Adenine. If 9-ethyladenine, instead of methanol, is added to the dilute CCl_4 solution of 1-propyl-2-thiouracil, the complex formation is caused more easily. As may be seen in Figs. 4 (middle) and 5, the lowering of the 1723 cm^{-1} band (free C=O) and the elevation of the 1693 cm^{-1} band (hydrogen-bonded C=O) take place for 9-ethyladenine at a concentration 100 times as low as that for methanol. This fact may be taken as indicating that a binding (such as Fig. 3 (c)) of 2-thiouracil and adenine residues is much greater than that of 2-thiouracil and methanol. The association constant of the former pair has been determined to be 450 M^{-1} in CCl_4 at 34 °C.

Ultraviolet Absorption Spectra

Solvent Effect. 1-Propyl-2-thiouracil shows two strong absorption peaks at 268 and 300 nm in $CHCl_3$, while in ethanol these two come closer, at 272 and 295 nm (Fig. 6).

Complex with Methanol. On adding methanol to a dilute (7×10^{-4} M) CCl_4 solution of 1-propyl-2-thiouracil, two absorption peaks (see Fig. 7 upper) at 269 and 301 nm (molar extinction coefficient are 12800 and 10400 respectively) are replaced by other

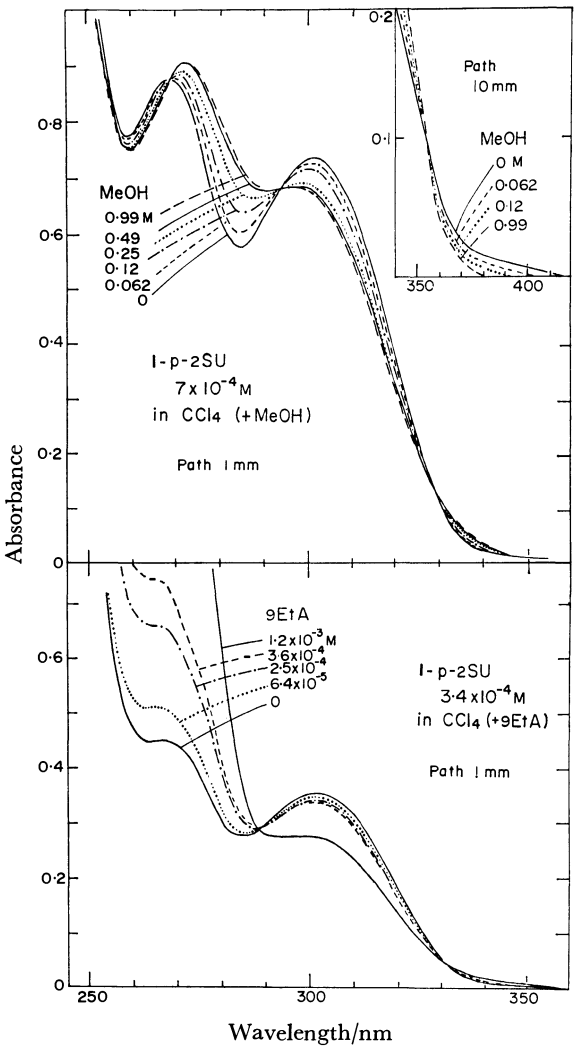

Fig. 7. Ultraviolet absorption spectra of 1-propyl-2-thiouracil in the solutions of CCl_4+CH_3OH (upper) and in the solutions of CCl_4+9-ethyladenine (lower).

two strong peaks at 272 and 298 nm. There appear isosbestic points not only at 268 and 294 nm, but also at 329 and 352 nm. Thus, there must be a very weak absorption band at about 400 nm in dilute CCl_4 solution, and this is shifted to a shorter wavelength on forming a complex with methanol. This weak band (molar extinction coefficient $\fallingdotseq 10^2$) is assignable to an n-π^* transition, and the two strong bands to π-π^* transitions.

The lowering of the 301 nm peak (or the elevation of the 269 nm peak) takes place on adding methanol in parallel with the lowering of the 1723 cm^{-1} band (see Figs. 4 and 5). Therefore, these ultraviolet spectral changes are attributed to the change from free 2-thiouracil base to the hydrogen-bonded complex which is the same as what was observed in our infrared spectroscopic examination. On the basis of a series of absorption intensity measurements, the association constant is calculated here to be 5.5 M^{-1} (which is comparable to 3.9 M^{-1}, obtained in the infrared absorption measurements).

By a similar experiment on a dilute methylcyclohexane solution of 1-propyl-2-thiouracil with ethanol,

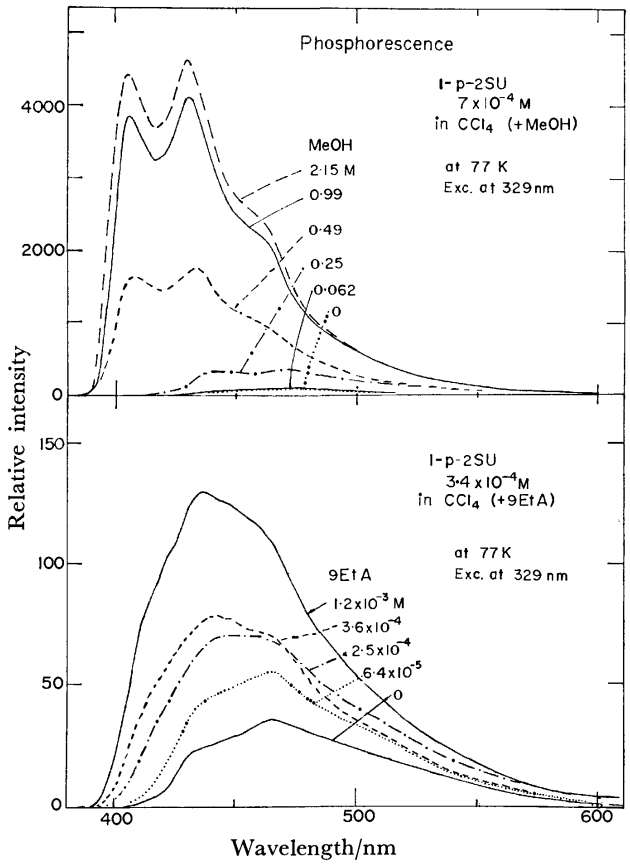

Fig. 8. Phosphorescence spectra of 1-propyl-2-thiouracil dissolved in the solutions of CCl_4+CH_3OH (upper) or dissolved in the solutions of CCl_4+9-ethyladenine (lower) and then cooled by liquid nitrogen. Sector: fast (about 10000 rpm).

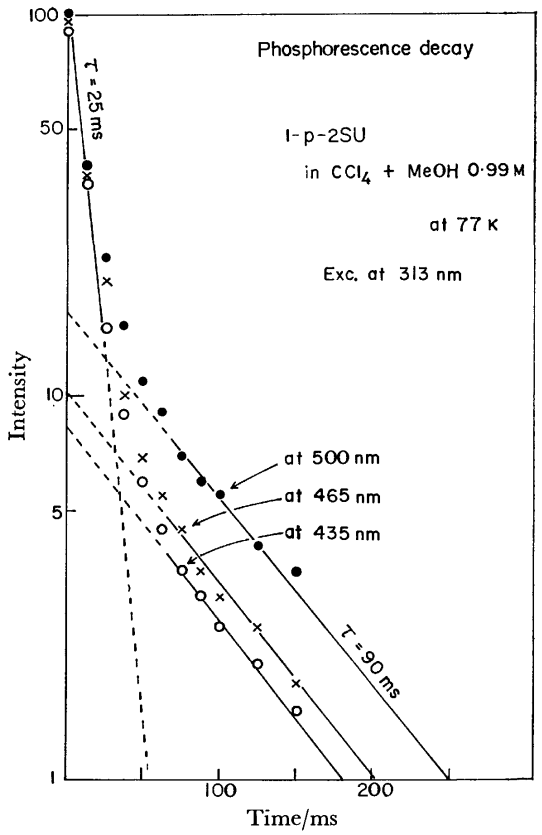

Fig. 9. Phosphorescence decay curves of 1-propyl-2-thiouracil dissolved in the solutions of CCl_4+CH_3OH and then cooled to the liquid nitrogen temperature. τ is the life time, which is the time required for bringing the intensity from 1 to 1/e.

the association constant of 1-propyl-2-thiouracil and ethanol is estimated to be 4.7 M^{-1}. When 2,2,2-trifluoroethanol, which is considered to be a stronger proton donor than ethanol (or methanol), is added to the dilute CCl_4 solution of 1-propyl-2-thiouracil, the complex bands appear at 270 and 291 nm. Here, the equilibrium constant for the complex formation is found to be 7.4 M^{-1}.

Complex with 9-Ethyladenine. Next 9-ethyladenine was added to the dilute CCl_4 solution of 1-propyl-2-thiouracil to observe ultraviolet absorption spectrum of the thiouracil–adenine complex examined in the infrared spectroscopy. Here a spectral change similar to that observed when CH_3OH was added instead of 9-ethyladenine was observed (see Fig. 7, lower). The isosbestic points appear at 289 and 331 nm. The decrease in the absorption intensity at 300 nm, which is considered to correspond to the decrease in the amount of free 2-thiouracil residue, goes in parallel with the lowering of the 1723 cm^{-1} band (see Figs. 4 and 5).

Phosphorescence

At liquid nitrogen temperature, 1-propyl-2-thiouracil shows only a weak phosphorescence (excited at 329 nm) with peaks at 445 and 465 nm in CCl_4. The phosphorescence is also very weak in 2-methylpentane and in methylcyclohexane. In all of these nonpolar solvents, the quantum yield ϕ_P was estimated to be 10^{-3}, on the basis of a comparison with the known phosphorescence of naphthalene.[9] While, in acetonitrile $\phi_P=0.02$, and in methanol and in ethanol $\phi_P=0.1$. In all of these three polar solvents, the phosphorescence maxima are found at 408 and 432 nm. When methanol is added stepwise into a dilute CCl_4 solution of 1-propyl-2-thiouracil, a stepwise increase in phosphorescence intensity is observed at 408 and 432 nm (Fig. 8, upper). When 9-ethyladenine is added, a similar increase in phosphorescence intensity at 408 nm (shoulder) and 432 nm (peak) is observed, except that it is observed at much lower concentration of 9-ethyladenine than that of methanol (Fig. 8, lower).

Phosphorescence lifetime of 1-propyl-2-thiouracil in pure CCl_4 was found to be 90 ms. Figure 9 shows phosphorescence decay curves at various wavelengths for 1-propyl-2-thiouracil in a mixed solvent CCl_4+0.99 M CH_3OH. On the basis of our infrared spectroscopic study, roughly 80% of the 1-propyl-2-thiouracil molecules in the solution are supposed to be involved in a hydrogen-bond complex (with CH_3OH) and remaining 20% are free. While, the phosphorescence decay curves indicate that the emission from this consists of two components: one with lifetime=25 ms at liquid N_2 temperature) which predominates at 435 nm and the other with lifetime=90 ms whose

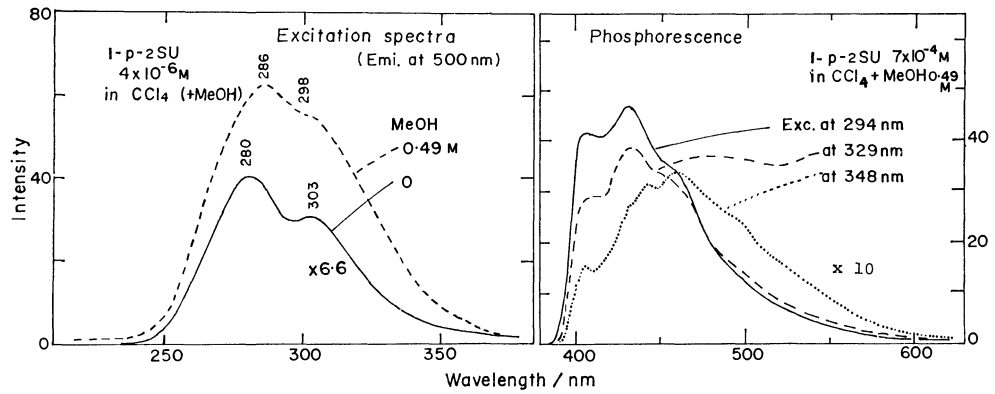

Fig. 10. (Left) Uncorrected excitation spectra of phosphorescence of 1-propyl-2-thiouracil dissolved in CCl_4 with and without CH_3OH. Sector: fast (about 10000 rpm). (Right) Phosphorescence spectra of 1-propyl-2-thiouracil in CCl_4+CH_3OH, where half of the thiouracil molecules are involved in a hydrogen-bond complex and the other half are free, with various excitation wavelengths. Sector: slow (about 1000 rpm).

contribution is only 17% (at zero time) at 500 nm and 8% at 435 nm.

The phosphorescence excitation spectrum of the free 1-propyl-2-thiouracil molecule has its maxima at 280 and 303 nm (Fig. 10, left). On going from a pure nonpolar solvent (CCl_4) to a mixed solvent ($CCl_4+0.49$ M CH_3OH) the excitation spectrum shows a change which is similar to the corresponding change in the ultraviolet absorption spectrum; *i.e.*, a blue shift of the longest wavelength peak and a red shift of the second longest wavelength peak. In the mixed solvent of $CCl_4+0.49$ M CH_3OH, about 50% of the 1-propyl-2-thiouracil molecules are involved in a hydrogen-bond complex (with CH_3OH) and 50% is free, on the basis of our infrared spectroscopic study. Figure 10 (right) shows phosphorescence spectra of 1-propyl-2-thiouracil in such a solvent with various excitation wavelengths (294, 329, and 348 nm). This figure indicates that the phosphorescence component with longer lifetime is located in the longer wavelength region ($\approx$500 nm), and that the longer wavelength excitation (348 nm) causes the longer lifetime component.

Discussion

It has been shown in our present study that, in an interaction of the 2-thiouracil residue with a residue having a proton-donating power, the position-4 carbonyl can act as a strong proton-acceptor.

Secondly, it has been found that the proton accepting power of the position-4 carbonyl of 2-thiouracil residue is greater than that of uracil residue. This is supported by an infrared spectroscopic study in the NH stretching region (3000 cm^{-1}) made by one of us, Higuchi.[10] This finding may be associated with some biological significance. Thus, it is in consistence with the fact[11] that a trinucleotide diphosphate codon $s^2U_pU_pU$ or $U_ps^2U_pU$ causes an *in-vitro* ribosome binding of *Escherichia coli* $tRNA^{Phe}$ (whose anticodon is G_pA_pA) more efficiently than a codon U_pU_pU. The finding may also be associated with the fact that a thermal stability of *Thermus thermophilus* HB8 tRNA is acquired by replacing the ribothymidine in its TψC loop by 2-thiothymidine.[2] It is true that an X-ray structure analysis for yeast $tRNA^{Phe}$ showed that the ribothymidine in TψC sequence binds to 1-methyladenosine with the position-2 carbonyl in the hydrogen bonding.[12] We suspect, however, that the position-4 carbonyl (instead of the position-2 carbonyl) is involved in the corresponding hydrogen bonding in the HB8 tRNA. We like to point out that, such a hydrogen bonding is quite possible if the 1-methyladenosine takes a *syn* conformer instead of *anti* (like in yeast $tRNA^{Phe}$), and that such a small variation in the bonding scheme is not improbable among different tRNA molecules.

It has been shown that the binding between 2-thiouracil residue and adenine residue is much stronger than the binding between 2-thiouracil residue and methanol. This fact indicates that there must be a second hydrogen bond between the 2-thiouracil and adenine residues in addition to the hydrogen bond between the position-4 carbonyl of the 2-thiouracil and the position-6 amino group of adenine. The second hydrogen bond may be formed between the position-3 imide of 2-thiouracil and position-7 nitrogen of adenine but it may also be formed between the position-3 imide of 2-thiouracil and position-1 nitrogen of adenine.

We have shown in the present work that hydrogen bonding of 2-thiouracil residue with alcohol or with adenine causes a marked enhancement of the phosphorescence. This fact suggests that phosphorescence may be a useful probe of the intramolecular environment of the 2-thiouracil residue in a biological system. In pursuing this line, however, it is desirable to discuss on the nature of the excited singlet and triplet states of this residue (especially these states with hydrogen bonding) slightly more in detail.

The ultraviolet absorption spectrum suggests (see Fig. 7) that 2-thiouracil residue in nonpolar solvent has an $n\rightarrow\pi^*$ level (S_1) at 2.5×10^4 cm^{-1} (its 0—0 transition is probably around 400 nm) and two $\pi\rightarrow\pi^*$ levels (S_2 and S_3) around 2.9×10^4 cm^{-1} (340 nm). When its position-4 carbonyl is brought into an intermolecular hydrogen bonding, S_1 is elevated by about 1300 cm^{-1}, S_2 is elevated by about 400 cm^{-1}, while

Table 1. A classification of phosphorescence of 2-thiouracil residue

	Transition frequency cm^{-1} (nm)	Intensity	Lifetime ms	Proposed assignment of the triplet state
I	24000 (410)	Weak	90	$^3(n\pi^*)$, free
II	26000 (385)	Strong	25	$^3(n\pi^*)$ with H-bonds

S_3 is lowered by about 300 cm^{-1}. On the basis of Strickler-Berg relation, [13] the radiative lifetime of S_1 is estimated to be 10^{-6} s (from the $S_1 \leftarrow S_0$ absorption intensity) and of S_2 10^{-8} s at room temperature. The fluorescence quantum yield ϕ_F is very low; it is less than 10^{-4}. Therefore, from the relation $\phi_F = k_F/(k_F + k_{nr}^F + k_{isc})$, k_{nr}^F and/or k_{isc} must be as high as 10^{10}, where k_F ($\fallingdotseq 10^6$) is the $S_1 \rightarrow S_0$ fluorescence rate constant, k_{nr}^F is the $S_1 \rightarrow S_0$ internal conversion rate constant, and k_{isc} is the $S_1 \rightarrow T_1$ intersystem crossing rate constant. Because phosphorescence is appreciable at liquid nitrogen temperature, k_{isc} is supposed to be high here.

In interpreting the observed phosphorescence spectra, we propose to classify them into two, as shown in Table I. The weak phosphorescence of 1-propyl-2-thiouracil residue in pure CCl_4 (see Fig. 8, upper) with lifetime 90 ms ($k_p \fallingdotseq 11$ s^{-1}) is spectrum I. When methanol is added to the CCl_4 solution, a stronger phosphorescence appears first at the slightly shorter wavelength with nearly the same lifetime. Its intensity becomes stronger with the methanol concentration. A further addition of methanol to the solution results in the appearance of a new phosphorescence, at about 1600 cm^{-1} higher frequency than spectrum I. This is spectrum II. The phosphorescence lifetime of spectrum II is shorter *i.e.*, 25 ms ($k_p = 40$ s^{-1}) at 77 K. There would be no problem to attribute spectrum I to the free 2-thiouracil residue. We speculate here that the intensity of spectrum I, which is due to the free molecule, becomes higher by a change of the environment, *i.e.*, from matrix without methanol to that with some amount of methanol. On the other hand, the fact that the spectrum II become stronger with methanol concentration is attributable to the increase of the amount of 2-thiouracil hydrogen-bonded to methanol. In other words, we postulated here a dynamic equilibrium among free triplet-state 2-thiouracil residue $^3(2SU)^*$, a hydrogen-bonded complex $^3(2SU)^* \cdot CH_3OH$ and the free CH_3OH molecules.

We wish to express our thanks to Dr. Junko Nakamura, the Institute of Physical and Chemical Research, and Professor Michiya Itoh, the Faculty of Pharmaceutical Sciences, Kanazawa University, for their kind help and valuable discussions. This work was partly supported by a grant from Ministry of Education.

(Received November 17, 1979)

Sound velocity and density measurements for H_2O and D_2O solutions of hexamethylphosphoric triamide (HMPT), $[(CH_3)_2N]_3PO$ at 25 °C have been carried out. The concentration dependence of the molar volumes and adiabatic compressibilities calculated therefrom are interpreted in terms of the water structure. The differences found between the H_2O and D_2O solutions are similarly explained.

Aqueous HMPT solutions are of interest in the study of hydrophobic interactions and structural variations of water. Recently, the large retarding action of HMPT on the rotational mobility of water molecules[1] has been observed. HMPT is miscible in all proportions with water, forming strong hydrogen bonds.[2] Having several nonpolar groups, HMPT can be regarded as a simplified model element of biopolymers that exhibit complex interactions with water. With this in mind, we have conducted a study of sound velocity, density and compressibility of HMPT solutions in H_2O and D_2O to elucidate the characteristics of the hydration of this molecule.

Experimental

The sound velocity, U, in aqueous HMPT solutions over the concentration range used was determined by two methods. For both H_2O and D_2O solutions, a sing-around ultrasonic velocimeter UVM-2 (Cho-onpa Kogyo) at 5 MHz was used. Deionized, distilled and deaerated water was used as a calibration liquid. The standard U values of water were taken from the work of Greenspan and Tschiegg.[4] The measurements were performed with an accuracy of ± 4 cm s^{-1} for each sample. A conventional ultrasonic interferometer method[4] at a frequency of 3 MHz was also used for H_2O solutions for comparison purposes. The accuracy of the measurements was within $\pm 0.2\%$.

The density of the aqueous HMPT solutions was determined at 25.00 °C with a digital precision densimeter, DMA 02C (Anton Paar). The instrument was placed in an air thermostat controlled at 25 ± 0.1 °C and the temperature of the sample solution was regulated by circulating water at a rate, *ca.* 6 dm^3 min^{-1} from an external thermostat with a stability of ± 0.001 °C. Reproducibility of the frequency for water was within $\pm 5 \times 10^{-7}$. The calibration was made with distilled mercury (Merck, Suprapur 13.5336 g cm^{-3}),[5] water (0.997045 g cm^{-3})[6] and distilled toluene (Eastman Kodak, Spectrograde), the density of which was determined as 0.862247 g cm^{-3}.[7,8] Calibration was repeated every day using water and the toluene.

HMPT (Aldrich, $n_D^{20\,°C} = 1.4579$, $d^{20\,°C} = 1.03$ g cm^{-3}, bp= 230 to 232 °C at 740 mmHg) was used as received. For the interferometric method, HMPT purified by the method given in Ref. 9 was used. D_2O had 99.75% deuterium content.

Results

The sound velocity (U) and the density (d) for HMPT solutions in H_2O and D_2O, and also for 0.5

a) Determined by ultrasonic interferometer.

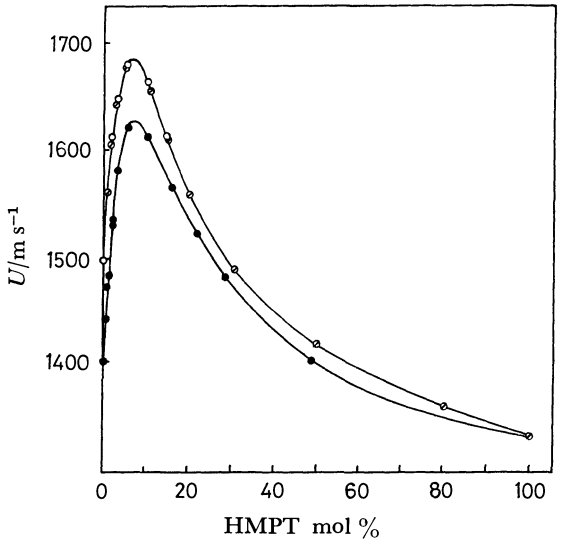

Fig. 1. Ultrasonic velocity in aqueous solutions of HMPT at 25 °C: in H_2O (⊘, ultrasonic interferometer method; ○, sing-around method) and in D_2O (●, sing-around method).

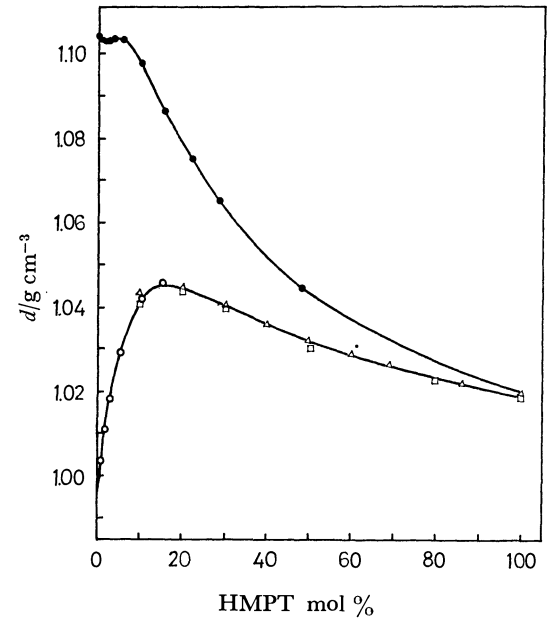

Fig. 2. Densities of aqueous solutions of HMPT in H_2O (○) and D_2O (●) at 25 °C. Data represented by △[12] and □[2] are taken from literatures.

mol dm^{-3} NaCl solution in D_2O at 25 °C are shown in Table 1. The value of the sound velocity for pure D_2O is consistent with reported values.[10,11] Figures 1 and 2 show the variations of U and d with HMPT concentration in H_2O and D_2O. In Fig. 2, the reported values[2,12] of the densities of HMPT solutions are also plotted. The sound velocity shows maxima at *ca.* 7 mol % HMPT in both H_2O and D_2O solutions.

The density of HMPT solutions in H_2O passes through a maximum at 15—20 mol % HMPT. On the other hand, the density of the solutions in D_2O shows a rather complicated variation with a minimum at 1.5% HMPT. The minimum in the D_2O solution disappears on addition of small amounts of NaCl.

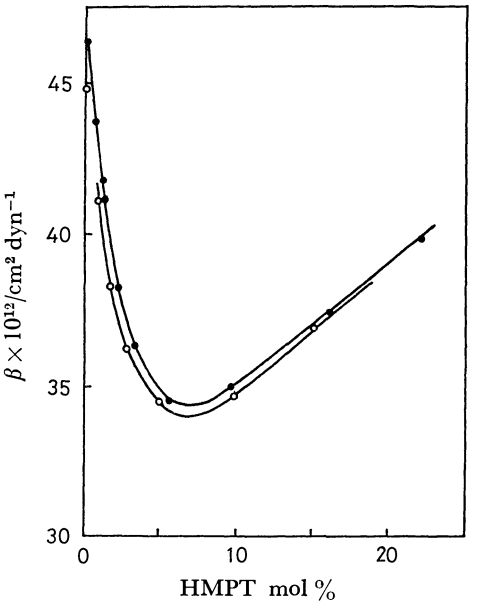

Fig. 3. Adiabatic compressibility of aqueous solutions of HMPT in H_2O (○) and D_2O (●) at 25 °C.

From the data of the sound velocity and the density for aqueous HMPT solutions, the adiabatic compressibility, β, was calculated. Figure 3 shows that β values for the H_2O and D_2O solutions pass minima at *ca.* 7 mol % HMPT. The variation of β is more pronounced in D_2O solutions than in H_2O solutions.

Discussion

The apparent molar volumes of HMPT calculated from the density data are presented in Fig. 4. A similar concentration dependence of apparent molar volumes is found for a number of hydrophobic molecules, *e.g.*, *t*-butanol, in aqueous solution.[13–15] The molecular mechanism of hydrophobic hydration can be described as a stabilization of water structure under action of nonpolar groups or molecules.[19–22] In the present case, the stabilization of water structure is ascribed to the filling of the cavities of the water structure with the nonpolar groups or molecules. As a consequence, the fraction of water molecules in the framework increases.[16,18] The concept of the inclusion of HMPT molecules in the cavities of water structure has been employed to explain some physicochemical properties of its aqueous solutions.[1,2,22] In terms of the structural model of nonelectrolytes in aqueous solution,[17,23,24] the volumetric changes on the introduction of HMPT molecules into water can be interpreted based on two effects; 1) the exclusion of free water molecules from the cavities caused by the occupation by HMPT molecules and the partial displacement of water molecules in the framework, and 2) the increase in the fraction of water molecules in the water tetrahedral structure outside the first coordination sphere of HMPT.

Given the similarity in the structures of light and heavy water[25,26] and the types of interaction between nonpolar groups of HMPT and H_2O and D_2O molecules in the cavities, there is a strong possibility that

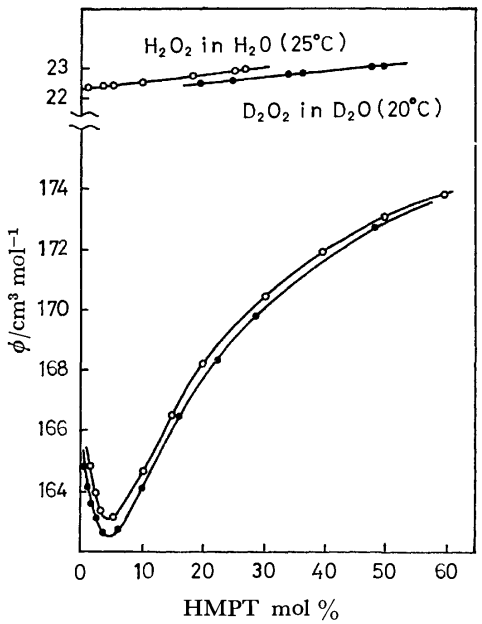

Fig. 4. Apparent molar volumes of HMPT at 25 °C and H_2O_2[27] in H_2O (○) and D_2O (●).

HMPT has a similar effect on the structures of light and heavy water. However, as the fraction of the cavities filled with free water molecules in the D_2O structure is smaller than in the H_2O structure, the fraction of free water molecules excluded by HMPT molecules from the cavities, mainly into the framework, must be greater for H_2O solutions. Accordingly, the apparent molar volume of HMPT (ϕ_{HMPT}) in H_2O is expected to be greater than in D_2O, which is actually found in Fig. 4.

We can explain the concentration dependence of ϕ_{HMPT} in H_2O and D_2O solutions along the same lines. The first of the above mentioned volumetric effects, associated with the introduction of nonelectrolyte molecules into water in the concentration range where the solution structure is based on the tetrahedral water structure, is the same for solutions of polar or nonpolar molecules. This effect does not undergo any serious change in solutions where cavities are available. The second effect is not found for a nonelectrolyte that undergo hydrophilic hydration.[23,24] The concentration dependence of the apparent molar volume of H_2O_2 in aqueous solution,[28] which is typical of a hydrophilic hydration, is shown in Fig. 4. The effect of increasing water structure outside the first hydration sphere around a hydrophobic molecule is such that, as the cavities become free of water molecules, each subsequent fraction of the molecule can eject from the cavities a smaller number of water molecules than the preceding one.

This process corresponds to a decrease in the apparent molar volume of HMPT with increasing concentration. It is expected to be observed up to the solution concentration corresponding to the complete or maximum possible filling of the water cavities with HMPT molecules. At higher concentrations, the durability of the water tetrahedral structure is exhausted and one can anticipate the initiation of transition to a different type of the spatial ordering of the system with the appearance of the contacts, HMPT–HMPT and HMPT–H_2O–HMPT. At these concentrations, the filling of the cavity volume by HMPT molecules becomes less and less important. This is connected with the significant increase in the values of ϕ_{HMPT} beyond the concentration range corresponding to a water-like ordering. The same type of structural ordering found in light and heavy water warrants the same number of cavities in their structures and hence the occurance of ϕ_{HMPT} minima at similar concentrations as actually observed in the experiments. The use of geometrical models to describe the introduction of HMPT molecules into the water structure with simultaneous substitution of the sites and cavity filling, enables one to estimate the concentration range where practically all water molecules bound to each other by a tetrahedral arrangement enter into the first surrounding sphere of HMPT molecules. At higher concentrations, the appearance of HMPT–HMPT contacts is observed by the X-ray method.[27]

The difference in the variations of the adiabatic compressibilities in H_2O and D_2O solutions (Fig. 3) can be explained using the same model for the solution structure. The sharper compressibility drop observed for D_2O solutions when changing from pure water to a solution is explained by a greater packing of D_2O structure when HMPT is added. This is due to the fact that the fraction of the cavities filled with water molecules is less for D_2O than for H_2O, and hence for D_2O, a smaller fraction of water molecules is excluded from the cavities into the sites on addition of HMPT. That the minimum values of β and of ϕ_{HMPT} in H_2O and D_2O solutions occur at approximately the same concentration follows from the similarity of the networks in H_2O and D_2O when all the molecules are located in the sites. The slight differences in the concentrations corresponding to the minimum ϕ_{HMPT} and β are likely to be related to the different structural states of the system at these concentrations. In the model under discussion, the first minimum corresponds to the maximum possible cavity filling when all the water molecules are distributed over the hydrate spheres, but a certain number of intermediate cavities may still exist. The minimum value of β can be related to a more complete cavity filling with simultaneous appearance of the contacts, HMPT–HMPT and HMPT–H_2O–HMPT.

Electrochemical Study of Spectral Sensitization Using AgCl Sheet Crystal as a Window. Ag^+ Ion Effect

Seiichi SUMI,* Tadashi WATANABE, Akira FUJISHIMA, and Kenichi HONDA
Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received November 20, 1979)

With use of AgCl sheet crystal as a window, sensitized photocurrent was measured in an electrochemical cell with a lock-in amplifier. With five sensitizing dyes having different lowest vacant levels, it was found that the higher the level of the dye, the larger the sensitized photocurrent, the sensitized photocurrent increasing with decreasing pAg of the dye-bearing solution. The Ag^+ ion effect can be explained by a band edge shift of the AgCl electrode, which also explains the blue desensitization recovery by Ag^+ ions.

Recent studies on spectral sensitization have made it clear that the electron transfer mechanism is dominant.[1-3] On the basis of electron transfer, three processes of donation or acceptance between the dye and silver halide (AgX) can be considered (Fig. 1): (1) spectral sensitization, *i.e.*, electron transfer from excited dye to the conduction band of the AgX (Fig. 1a), (2) desensitization, *i.e.*, the transfer generated in AgX by intrinsic light absorption to the dye (Fig. 1b), (3) hole injection, *i.e.*, the transfer from the AgX valence band to oxidized dye (Fig. 1c). Ag^+ ion is known to influence these processes.

As regards (1), Gilman *et al.*[1,4] found that spectral sensitivity increases with decreasing pAg (pAg=$-\log[Ag^+]$) of photographic emulsions and explained this by a subconduction band event, a process in which Ag^+ ions at the AgX surface accept electrons from excited dyes to form silver atoms, with the result that the surface sensitivity of the photographic emulsion increases. Silver atoms are unstable, decomposing by thermal energy to Ag^+ ions and electrons, and the electrons go up the conduction band of the AgX. Iwasaki *et al.*[5] have utilized electrochemical techniques using AgCl sheet crystal as a membrane. They found that sensitized photocurrent (SPC) increases with decrease in the pAg of the solution containing dye, and explained the phenomenon by a band edge shift of AgCl.

As regards (2), Collier and Gilman[6] found the recovery of blue desensitization by Ag^+ ions in emulsion systems, and explained this by a subconduction band event.

As regards (3), Berriman and Gilman[7] reported a restraining action by Ag^+ ions in photographic emulsion systems, and explained it by change in the oxidation potential of silver by Ag^+ ions.

In connection with AgX/dye electron donation/acceptance, it is of great interest that Ag^+ ions can influence these three processes. In our experiment on the Ag^+ ion effect using electrochemical techniques, five sensitizing dyes were used, each having different lowest vacant levels. Constitutional formulas of the dyes and their energy levels[1] are shown in Figs. 2 and 3, respectively. Using these dyes, we measured SPC based on electron transfer from excited dyes to the AgCl conduction band[5,8] by an electrochemical method with use of a lock-in amplifier, AgCl sheet crystal being used as an electrochemical cell window.

Experimental

Preparation of AgCl Sheet Crystal. 2 M (1 M=1 mol dm^{-3}) $AgNO_3$ (Kojima Chemical Co., Ltd., reagent grade) and 5 M HCl (Sankyo Chemical Co., Ltd., reagent grade) were mixed, and the resulting precipitate was washed with distilled water and ground to powder in a mortar. The powder was packed into a quartz tube, and melted at 465 °C in a vacuum. When all the AgCl powder was melted, zone melting was carried out at a velocity of 1 cm/h. The upper (less pure) half of the transparent crystal produced was used in dye-adsorption experiments. The lower half was used to measure SPC. Cutting was done by a slicer (Maruto Co., Ltd.) to make crystals 0.5 mm thick, and the crystal surface was treated with 1 M KCN and polished with silk cloth to make it 80% transparent. All the crystals showed nearly the same behavior toward blank photocurrent which is due to intrinsic light absorption, as well as dark current which is based on interstitial silver ion.

Apparatus for Measurement. The apparatus is shown in Fig. 4. The exciting light from a 500 W Xe lamp (Ushio Electric Co.) illuminated the AgCl-dye interface through a light chopper, an interference filter (10 nm half-width), and transparent AgCl. AgCl electrode potential was adjusted to 0.4 V *vs.* a saturated calomel electrode (SCE) with dry cells. SPC was measured with a lock-in amplifier having a frequency of 125 Hz. During measurement, contact to the voltmeter was broken to exclude noise.

Measurement of Sensitized Photocurrent. The AgCl sheet crystal was held in contact with an electrochemical cell with epoxy resin. After *ca.* 10 h the crystal face not in contact with the electrolyte solution was attached to a lead wire with silver paste, while the opposite face was etched with 1 M KCN for 15 min and washed with distilled water. Dye solutions A, B, C, D, and E were prepared, methanol content being 5 vol % for A and B, 15% for C, 35% for D, and 25% for E. A dye solution with 0.04 M KNO_3 was put into the cell. SPC measurement was started 30 min after the addition of dye solution, and repeated every 10 min to check changes due to dye adsorption. If no change was observed, $AgNO_3$ solution was added to control pAg, SPC being measured after 5 min. After SPC measurement at pAg 1, dark currents were again measured to confirm that no large change have occurred in comparison with solutions without dye.

All experiments were carried out at room temperature in a dark room, the solution used not being deoxidized. The photon distribution of the light source was measured with a thermocouple.

Adsorption Experiments. The AgCl sheet crystal was immersed for 30 min in dye solutions of the same composition as those used in the SPC measurement (in this case dye adsorbed to both faces of AgCl crystal), and washed with hexane. The absorbance of this dyed crystal was measured as a reference of AgCl without dye using Shimadzu Model MPS-5000 recording spectrometer, after which the crystal was again immersed for 10 min in the same solution to check changes due to dye adsorption. The duration of immersion increased when such a change was found. The pAg of the dye solution was controlled by addition of $AgNO_3$ solution. The crystal was immersed in the solution for 5 min and washed with hexane, and its absorbance was measured. All the experiments were carried out at room temperature in a dark room.

Results

The characteristics of dye A are shown in Fig. 5. The insets in Fig. 5 a) and b) show the dependence of values of solid curve peaks on pAg. The adsorption of dye A decreases with the addition of Ag^+ ions, the absorption peak of the dye solution remaining unchanged. The dye solutions are diluted slightly by the addition of $AgNO_3$ solution. It was found that the 500 nm peak in the SPC action spectra is based on a dye monomer, and the 465 nm peak on a dimer. In the adsorption of dye A, the absorption peaks shifted to longer wavelength by an approximately 20 nm than that for the solution itself by stabilization, its SPC action spectra coinciding with its absorption spectrum when dye was adsorbed. The SPC increased, despite the decrease in adsorption of dye A with lowering pAg. The pAg ∞ shows the case without addition of $AgNO_3$.

The characteristics of dye B are shown in Fig. 6 a) and b). Adsorption was not influenced by Ag^+ ions, while SPC increased with lowering in pAg. The peak at 585 nm arose from a dye monomer, and the SPC of dimer could not be detected clearly.

Figure 7 shows the characteristics of dye C. Adsorption was not influenced by Ag^+ ions. No SPC could be detected at pAg 4 and above, but at 3 and below, SPC increased with fall in pAg. A 600 nm absorption peak arose from a dye monomer and 560 nm peak from a dimer. We could detect only the monomer peak in SPC. It is very interesting that SPC could be detected only at pAg 3 and below for dye C.

Figure 8 shows the characteristics of dye D. Adsorption was not influenced by Ag^+ ions, SPC increasing with decreasing pAg. An SPC peak was detected at 585 nm based on a monomer, but there was no clear peak on a dimer.

For dye E, no SPC could be detected down to pAg 1.

Though the methanol content of the various dye solutions was changed from 5% to 35%, the change in reference electrode (SCE) potential was less than 20 mV,[9] negligibly small. The redox potential of halide ions, which can act as electron donors,[15] shifted due to the change in methanol content. However, the amount contained as a counter ion to the cation dyes was very small, so that this effect can also be neglected. The NO_3^- ions contained in the 0.04 M electrolyte solution did not behave as electron donors.[15] The changes in methanol content influenced dye ad-

sorption only.

Levy[10] found that if AgX is brought into contact with silver, a print-out effect occurs, producing small silver specks absorbing light of *ca.* 585 nm wavelength. In our experiments, blank photocurrents were measured for 3 h, but almost no effect was detected at wavelengths of 500—700 nm. Thus it is concluded that the print-out effect due to silver paste does not influence SPC. The actual duration of SPC measurement including all processes was *ca.* 2 h.

Discussion

As shown in Figs. 5—8, the absorption spectra of dyes adsorbed to AgCl coincide with the SPC action spectra detected by the lock-in amplifier, showing that SPC indicates electron transfer from excited dyes to the conduction band of AgCl.[5,8] No dark currents based on interstitial Ag^+ ions could be detected with the lock-in amplifier at a light chopper frequency of 125 Hz.

However, in electrochemical studies using other semi-

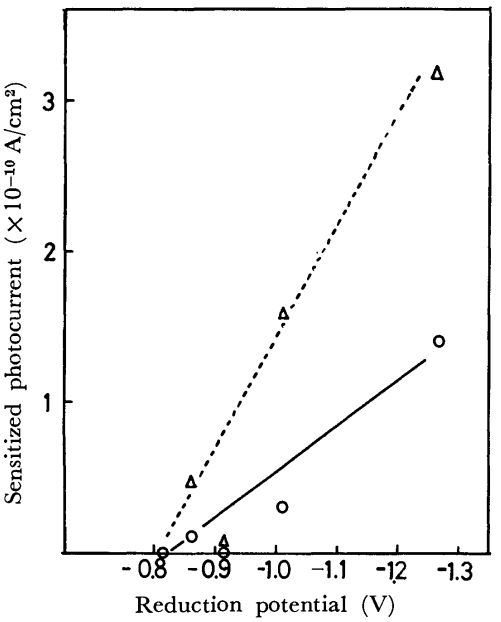

Fig. 9. Relation between SPC and reduction potential of sensitizing dyes.
----: at pAg 1, ——: at pAg ∞.

conductors such as ZnO,[2] and TiO_2,[3] SPC values exceeded 10^3 times of our values. This indicates that difficulty of movement of electrons from the excited dyes is due to resistance and electron traps in the AgCl. It is evident that this trait makes AgX most sensitive to light.

Since dye adsorption was restrained or not influenced by Ag^+ ions (Figs. 5—8) and the absorption peaks of adsorbed dyes did not change with lower pAg, the interaction between the dyes and Ag^+ ions can be neglected.[5] Ag^+ ions and NO_3^- ions can not donate electrons to oxidized dyes because of their redox potentials.[15] Therefore, the increase in SPC with lower pAg indicates a higher probability of electron transfer from excited dyes to the AgCl conduction band. Our results coincide qualitatively with those of the experiments of Gilman[1] on emulsion systems.

Increase in the spectral sensitivity of dye A was reported to be only slightly dependent on Ag^+ ions.[1] However, in our experiments, the SPC of dye A was greatly influenced by Ag^+ ions. Since the adsorption of dye A was reduced by Ag^+ ions even 5 min (Fig. 5b), it seems that the adsorption is reduced more in emulsion than in the electrochemical system so that the spectral sensitivity of the emulsion did not change.

Figure 9 shows the relationship between SPC and the reduction potential of sensitizing dyes;[1] the higher the reduction potential, the larger the SPC. This finding indicates that the electron transfer mechanism is dominant in this system. Adsorption experiments, however, showed that there is not much difference among dyes in terms of absorbance; we suppose that the quantum efficiency in spectral sensitization is proportional to the SPC.

We measured the current due to electrons going through the conduction band of the AgCl. If Ag^+ ions at the surface of AgCl trap the electrons, and the

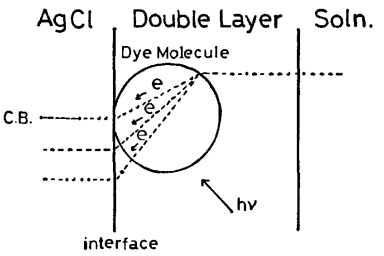

Fig. 10. Mechanism of Ag^+ ion effect.

electrons are excited to the conduction band by thermal energy, SPC should increase as pAg falls. At room temperature, however, thermal excitation energy is 20—30 mV, so we can neglect this thermal process. Since high-level electrons such as those in dye A can transfer smoothly to the conduction band, even temporary traps by Ag^+ ions bring about a decrease in SPC. Explanation of the Ag^+ ion effect by means of a subconduction band event does not seem feasible.

Yaenicke,[11] Leubner,[12] and Berriman and Gilman[7] considered that the Ag^+ ion effect arises from the potential shift of AgX. From the relationship between a potential shift of AgCl and SPC, Iwasaki *et al.*[5] postulated that the Ag^+ ion effect is due to a band edge shift of AgCl. Usually a potential shift of a semiconductor is measured by the flatband potential using the Mott-Schottky relationship, but if the present experiment is conducted using an AgCl electrode, Ag^+ ions in electrolyte solution are deposited as silver at the AgCl surface, making quantitative measurement impossible. However, this effect can also be measured by adding Cl^- ions.[14]

The flatband potential of AgCl was found to shift cathodically with an increase in Cl^- ions in the electrolyte solution. If Ag^+ ions were added, the flatband potential would shift anodically in contrast to Cl^- ions. Since potential distribution through the dye molecules becomes steeper with lower pAg, the rate of electron transfer from the excited dye increase, the probability of the transfer becoming higher (Fig. 10).

This provides a particularly satisfactory explanation in the case of dye C (Fig. 7a). There is no overlap between the excited level of this dye and the AgCl conduction band at pAg 4 and above. At pAg 3 and below, overlap begins to occur due to the anodic potential shift, SPC becoming detectable.

Studies on the SPC change in TiO_2–pH[3] and ZnO–pH[2] systems by a potential shift of a semiconductor show that SPC increases by several powers of ten with lower pH. In our experiments, however, the increase was only a few times. This can be attributed to the small shift of potential of AgCl. In a CdS–S^{2-}, Cd^{2+} system,[13] flatband potential shift differs according to the face index. However, since we have used no AgCl single crystal, it was impossible to determine its face index.

The recovery of blue desensitization[6] by Ag^+ ions can also be explained by the potential shift. It was deduced that the electron transfer from the conduction band of the AgX to the dyes occurs with lower prob-

ability as a result of band edge shift.

Conclusion

1. The use of AgCl sheet crystal as a window of an electrochemical cell is very effective in the study of spectral sensitization. 2. The Ag^+ ion effect arises from the potential shift of AgX. 3. The electron transfer is the dominant mechanism in AgX spectral sensitization.

We would like to thank Dr. Paul B. Gilman, Jr., the Kodak Research Laboratory, for valuable dyes, and Dr. Tamotsu Iwasaki and Dr. Kiminori Itoh of our laboratory for their useful suggestions.

Pressure and Solvent Shifts of Absorption Spectra. II. Intramolecular Charge Transfer Bands[1)]

Seiji SAWAMURA, Yoshihiro TANIGUCHI, and Keizo SUZUKI*

Department of Chemistry, Faculty of Science and Engineering, Ritsumeikan University, Kita-ku, Kyoto 603

(Received December 7, 1979)

Absorption spectra of intramolecular CT bands of nitrobenzene, *p*-nitrophenol, *p*-nitroaniline, acetophenone, *p*-hydroxyacetophenone, and *p*-aminoacetophenone are observed in several nonpolar solvents at 1 bar, and in heptane up to 4400 bar. The fact that all solvent shifts are linearly red for the function of refractive index (n) of solvents, $(n^2-1)/(2n^2+1)$, consists with the solvent shift theory. On the other hand, the pressure shifts are not straight but convex upward for $(n^2-1)/(2n^2+1)$ and the red shifts by pressure exceeds the solvent shifts. The similar convex pressure shifts are found in ^1L_b bands of several aromatic compounds by plotting the high pressure data of Robertson *et al.* in spite of the straight solvent shifts in these ^1L_b bands measured by us. Therefore the convex pressure shift may be regarded as a general tendency of the electronic spectrum, being ascribed to decrease in the distance between a solute and the surrounding solvents by compression. From comparison with the pressure shift of the intramolecular CT band, it is suggested that, in the pressure shift of the intermolecular CT band of the I_2 complexes shifted to red previously, the effect of decrease in the bond distance between a donor and an acceptor proposed by Offen and Nakashima contributes to not a red shift but a blue shift.

The pressure shifts of the intermolecular charge transfer (CT) bands have been observed to be red,[1-7)] blue,[1,8)] and red to blue.[1,3,4,6)] Offen and Nakashima ascribed these shifts to a sum of two effects of the increase in the dielectric constant (or refractive index) of solvent contributing to a red shift and the decrease in the bond distance between a donor and an acceptor contributing to a red or blue shift,[8)] and their interpretation was supported by us.[1)] Whether the decrease in the bond distance contributes to a red or blue shift in the observed pressure shift may be clarified by eliminating the effect of increase in the dielectric constant of solvent from the pressure shift.

As the binding energy of the covalent bond between a donor and an acceptor in the chromophore of intramolecular CT band is much larger than that of CT interaction of the chromophore of intermolecular CT band (*i.e.*, CT complex), the bond distance between a donor and an acceptor in the chromophore of intramolecular CT band is thought to be far less compressible than that of the CT complex. Therefore, from comparison of the pressure shift between intermolecular and intramolecular CT band, the effect of decrease in the bond distance of CT complex by compression may become clear. In the present study, the pressure and solvent shifts of the intramolecular CT bands were interpreted in comparison with those of π-π^* (^1L_b) band of aromatic compounds, and then compared with those of intermolecular CT bands. Used chromophores of the intramolecular CT band are nitrobenzene, *p*-nitrophenol, *p*-nitroaniline, acetophenone, *p*-hydroxyacetophenone, and *p*-aminoacetophenone. These have well-defined CT bands in the ultraviolet region. In these chromophores, $-NO_2$ and $-\overset{O}{\overset{\|}{C}}CH_3$ (-Ac) correspond to acceptors, and  -, HO- -, and H_2N- - correspond to donors.

Experimental

Nitrobenzene and acetophenone were distilled under reduced pressure. *p*-Nitrophenol, *p*-nitroaniline, *p*-hydroxyacetophenone, and *p*-aminoacetophenone were recrystallized from aqueous ethanol. Benzene, toluene, chlorobenzene, phenol, and solvents (pentane, hexane, heptane, cyclohexane, and decalin) were purified by usual method.[9)] The method of measuring the absorption spectra under high pressure was reported.[10)] Refractive indices (n) of the solvents at high pressure were estimated from the dielectric constant (ε) of Refs. 11, 12, and 13 using the relation, $n^2=\varepsilon$.

Results and Discussion

Solvent Shift. Comparison between the solvent and pressure shifts of CT band is important in order to investigate the contribution of the refractive index of solvents to the pressure shifts. Ooshika[14)] and McRae[15)] theoretically proposed Eq. 1 for the estimation of solvent shift of electronic spectrum in nonpolar solvents.

$$\Delta\tilde{\nu} \equiv \tilde{\nu}_s - \tilde{\nu}_o = C_{solv}\frac{n^2-1}{2n^2+1}, \quad (1)$$

where $\tilde{\nu}_o$ and $\tilde{\nu}_s$ are wavenumber at absorption maxima in the vapor and the solvent whose refractive index is n, respectively. C_{solv} is a constant and consists of a sum of two terms: one is the dispersive interaction between a chromophore and the surrounding solvents, and the other is the electrostatic interaction between the chromophore permanent dipole and the solvent dipole thereby induced. The values of $\tilde{\nu}_s$ in nonpolar solvents are expected to depend linearly on $(n^2-1)/(2n^2+1)$ of the solvents. Solvent shifts of several intermolecular CT bands in nonpolar solvents have been linear for $(n^2-1)/(2n^2+1)$ of the solvents.[1,16)] In Fig. 1 absorption maxima of intramolecular CT bands are plotted against $(n^2-1)/(2n^2+1)$ of nonpolar solvents. All CT bands shift to red linearly with increase in $(n^2-1)/(2n^2+1)$. Values of the slopes (C_{solv}) in Fig. 1 are shown in Table 1, and are comparable with those of intermolecular CT bands ($C_{solv} \approx 10^4$ cm^{-1}).[1,16)]

Pressure Shift. Figure 2 shows absorption spectra of intramolecular CT band of *p*-nitroaniline in heptane at several pressures. The absorption maximum shifts to red with increasing pressure. Other

Solvents are pentane ($(n^2-1)/(2n^2+1)=0.179$), hexane (0.185), heptane (0.190), cyclohexane (0.203), and decalin (0.220).

Table 1. Slopes of solvent (C_{solv}) and pressure (C_{press}) shifts of several intramolecular CT bands

	C_{solv} / 10^3 cm^{-1}	C_{press}[a] / 10^3 cm^{-1}
(A) Nitro compounds		
	−13±2	−16±3
	−14±2	−22±3
	−15±2	−25±3
(B) Acetyl compounds		
	−9±2	−10±3
	−11±2	−16±3
	−15±2	−19±3

a) Estimated from the straight line through the two points at 1 and 1100 bar in Figs. 3 and 4.

intramolecular CT bands behave similarly. The observed shifts are plotted in Figs. 3 and 4 as a function of $\Delta[(n^2-1)/(2n^2+1)]$ of heptane. All of shifts are not straight for $\Delta[(n^2-1)/(2n^2+1)]$ but convex upward. Values of the initial slopes in Figs. 3 and 4 are shown in Table 1 as C_{press}. The red shift by pressure (C_{press}) exceeds the solvent shift (C_{solv}) in each chromophores.

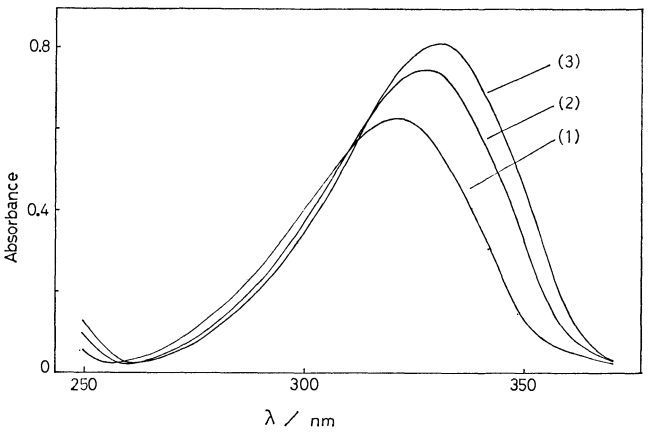

Fig. 2. Absorption spectra of intramolecular CT band of H_2N-  -NO_2 in heptane (2.7×10^{-5} mol dm^{-1}). (1) 1 bar, (2) 2.2 kbar, (3) 4.4 kbar. The absorptions are not corrected for compression.

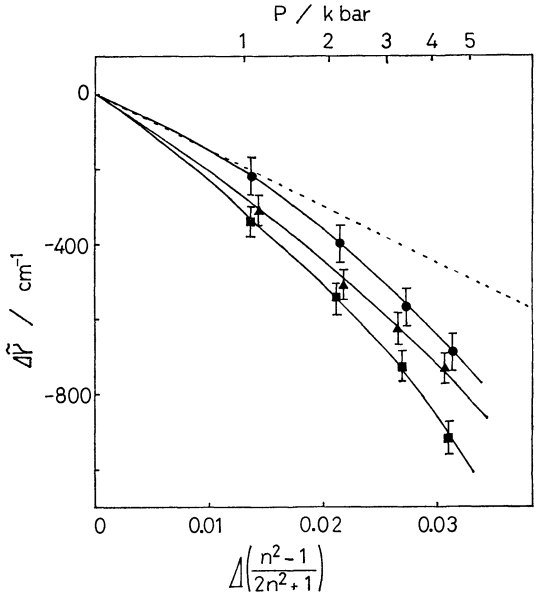

Fig. 3. Pressure shifts of intramolecular CT bands of nitro compounds in heptane.
The marks are the same as in Fig. 1. $\Delta\tilde{\nu}=\tilde{\nu}_P-\tilde{\nu}_1$, where $\tilde{\nu}_P$ and $\tilde{\nu}_1$ are wavenumber of absorption maxima at P and 1 bar. $\Delta[(n^2-1)/(2n^2+1)]=(n_P^2-1)/(2n_P^2+1)-(n_1^2-1)/(2n_1^2+1)$, where n_P and n_1 are refractive indices of solvent at 1 and P bar. Dotted line shows the solvent shift of H_2N-  -NO_2 ($C_{solv}=-15\times10^3$ cm^{-1}).

In the serieses of (A) and (B) of Table 1, the chromophores of larger C_{solv} values have larger C_{press} values. This fact shows that there is a contribution from the refractive index of solvent for the pressure shift of intramolecular CT band. The similar relation between C_{press} and C_{solv} was observed in the intermolecular CT bands of the series of I_2 complexes and tetracyanoethylene (TCNE) complexes (CT complexes with I_2 and TCNE as acceptors, respectively).[1)]

Pressure shifts of the electronic absorption spectra of molecules, such as π-π^* band or intramolecular

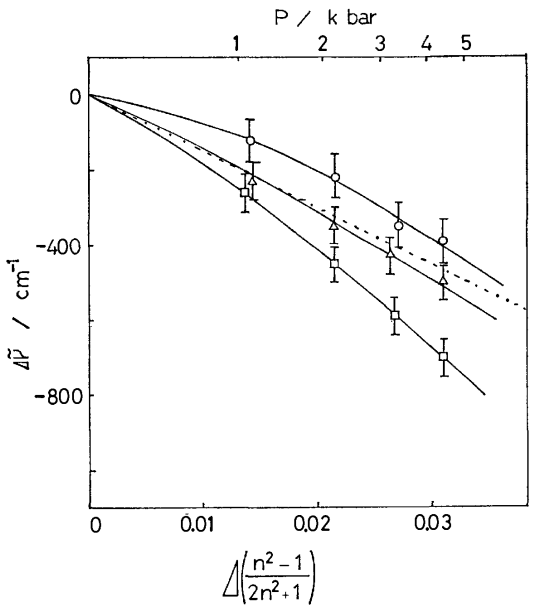

Fig. 4. Pressure shift of intramolecular CT band of acetyl compounds in heptane.
The marks are the same as in Fig. 1. $\Delta\tilde{\nu}$ and $\Delta[(n^2-1)/(2n^2+1)]$ are defined in Fig. 3. Dotted line shows the solvent shift of H_2N-⟨○⟩-Ac ($C_{solv}=-15\times10^3$ cm^{-1}).

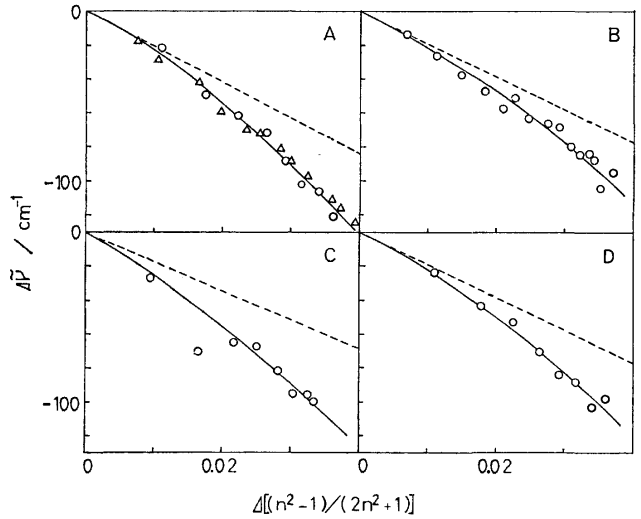

Fig. 5. Comparison between pressure and solvent shifts of ^1L_b band of several aromatic compounds.
A: Benzene at 261 nm, $C_{solv}=-2100$ cm^{-1}. B: Toluene at 271 nm, $C_{solv}=-1900$ cm^{-1}. C: Chlorobenzene at 271 nm, $C_{solv}=-1700$ cm^{-1}. D: Phenol at 277 nm, $C_{solv}=-1900$ cm^{-1}. Data of pressure shifts (—) in pentane (△) and hexane (○) were cited from Ref. 17 and solvent shifts (----) were estimated in present work as well as in Fig. 1.

CT band, have been studied without an attention whether the shift is convex or not for $(n^2-1)/(2n^2+1)$ of solvent. Then the previous data of pressure shifts should be reexamined. As such data, only the table of absorption maxima (λ_{max}) in π-π^* (^1L_b) bands of several aromatic compounds by Robertson *et al.*[17]

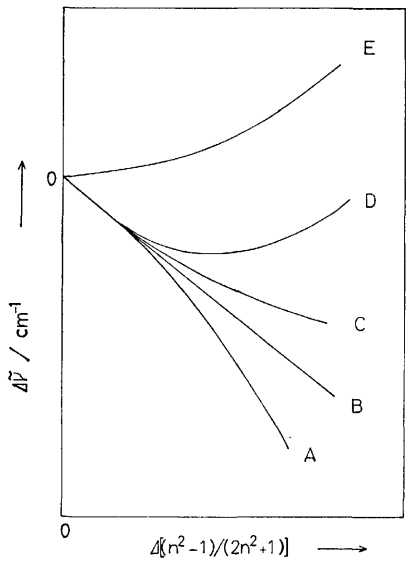

Fig. 6. Several patterns of pressure shift.
A: Convex red shift which should be normal for the pressure shift. Intramolecular CT bands in Figs. 3 and 4 and ^1L_b bands in Fig. 5. B: Straight red shift which is redder than the solvent shift. Benzene– and toluene–I_2 complexes. C: Concave red shift. Mesitylene– and Et_2O–I_2 complexes. D: Inversion shift from red to blue. Hexamethylbenzene–, Et_2S–, and Et_2Se–I_2 complexes. E: Blue shift. Et_3N–, *n*-Pr_3N–, and *n*-Bu_3N–I_2 complexes.

can be evaluated. The data is plotted in Fig. 5 as a function of $\Delta[(n^2-1)/(2n^2+1)]$ of solvent. All pressure shifts are not straight for $\Delta[(n^2-1)/(2n^2+1)]$ but convex upward as well as those of intramolecular CT bands in Figs. 3 and 4, though the solvent shifts (dotted lines in Fig. 5) measured by us as well as in Fig. 1 are straight for $(n^2-1)/(2n^2+1)$ of solvents. The deviation of pressure shift from the solvent shift is observed.

The solvent shift theory of Ooshika and McRae expressed by Eq. 1 considers the dispersive interaction and the electrostatic interaction between a chromophore and the surrounding solvents. Such interactions are a function of the distance between a chromophore and the solvents, and enhanced with decrease in the distance. Therefore, if the distance decreases by compression, pressure shift should deviate from the shift estimated by Eq. 1 and its deviation should become large with increasing $(n^2-1)/(2n^2+1)$ of solvent (or increasing pressure). The pressure shifts in Figs. 3, 4, and 5 deviated from the solvent shifts may be ascribed to such an effect.

Pressure shifts of intermolecular CT bands of I_2 complexes observed in the preceding paper[1] are not convex upward but concave or straight as shown in shifts B, C, D, and E of Fig. 6, where absolute values of the shifts are out of consideration and only the patterns of shifts (*i.e.*, straight, convex, or concave shift) are considered. In comparison with the convex shift (shift A) of the intramolecular CT band, there seems to be a blue shift contribution for the shifts of intermolecular CT bands, not only shifts D and E

but also shifts B and C. As such difference in the pressure shifts between the intermolecular and intramolecular CT bands seems to correspond to whether the bond distance between a donor and an acceptor is reducible or not by compression, the contribution to the pressure shift of the I_2 complexes from the decrease in the bond distance is thought to be a blue.

We wish to thank Mr. Mitsuharu Matsumoto and Mr. Kenji Matsuda for their assistance in the experiments.

Photooxidation of 2-Hydroxy Acids by Copper(II) Species in Aqueous Solution

Ryoka MATSUSHIMA,* Yoshinori ICHIKAWA, and Katsuyuki KUWABARA
Department of Industrial Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu 432
(Received December 8, 1979)

Ultraviolet irradiation of aqueous lactic, glycolic, or 2-hydroxybutanoic acid in the presence of copper(II) leads to photoredox reaction to give corresponding α-keto acid, aldehyde with evolution of carbon dioxide, and the precipitate of copper(I). The mole ratio of the carbonyl products to the consumption of copper(II) is close to 0.5. Oxidative decarboxylation dominates at pH>1 while the formation of α-keto acids favors at lower pH. The formation of α-keto acids is selectively suppressed by the addition of free radical scavengers. Free radical oxidations of the acids with bromine atom or benzoyl radicals give exclusively α-keto acids. The reaction mechanism has been discussed.

Despite many publications and potential utility of the photoredox reactions of Cu(II)–organic substrate systems,[1] their mechanisms seem to have been less clarified, except for a few cases, *e.g.*, the Cu(II) complexes of malonate,[2] 2,9-dimethyl-1,10-phenanthroline,[3] and 2,2′-biquinoline derivatives.[4]

On the other hand, catalytic photoreactions of organic substrates with Cu(I)[5,6] and Cu(II)[7,8] species have received much attention in synthetic as well as in mechanistic photochemistry.

In several cases the apparent photocatalyses of Cu(II) species seem to be relevant to the reversible cycles leading to no final (apparent) reduction of Cu(II).

In this paper we deal with the photooxidation of 2-hydroxy acids by Cu(II) species whose results are comparable with those for the uranyl–lactic acid system.[9]

Experimental

Guaranteed grade reagents were used without further purification while water was used after deionization and distillation.

The acidity of solution was adjusted with dilute sodium hydroxide or perchloric acid solution using a pH meter (Toa Denpa). Each sample solution was deoxygenated by bubbling with oxygen-free nitrogen current for 30 min, after the upper surface of the solution had been covered with liquid paraffin to keep airtight in one of identical Pyrex test tubes. It was then irradiated with light from a 400 W high pressure mercury lamp by means of a merry-go-round irradiation apparatus thermostated at 20 °C.

The consumption of Cu(II) species during photolysis was followed either by measuring its 810 nm absorption, or by colorimetric determination of the Cu(I) precipitate formed. The carbonyl products (aldehydes and α-keto acids) were converted into the precipitate of 2,4-dinitrophenylhydrazone derivatives (2,4-DNP).

The 2,4-DNP derivatives were then separated from each other on PLC (silica gel–benzene) and were identified by comparing their IR and NMR spectra with those of authentic samples. The amounts of the aldehydes and the α-keto acids were determined by colorimetric measurements at 360 nm in chloroform and at 380 nm in aqueous 0.25 mol/dm^3 sodium carbonate solution respectively, after the mixture of the 2,4-DNP precipitates had been separated by extraction with chloroform/aqueous 0.25 mol/dm^3 sodium carbonate solution.[9] The formation of carbon dioxide was implied by white precipitate which was formed when the evolved gases from the photoreaction mixture were passed through an aqueous barium(II) solution. UV absorption was measured by means of a Hitachi 124-Type recording spectrophotometer.

Results

Photooxidation of Lactic Acid by Cu(II) Species. Aqueous acid solution containing 0.2—0.4 M† lactic acid and 0.1 M Cu(II) sulfate gave acetaldehyde with evolution of carbon dioxide, pyruvic acid, and Cu(I) precipitate, on irradiation with light of 313—366 nm at 20 °C. No carbonyl products were detected either by thermal reaction at 70—80 °C for 5 h or by photolysis in the absence of Cu(II) species. Aqueous pyruvic acid in the presence of Cu(II) species underwent no significant decomposition under the photolytic conditions.

Table 1 lists the mole of Cu(II) species consumed, ΔCu(II), and the sum of the carbonyl products, A+P, formed during photolysis in various pH regions. In the pH region of 1.5—3.5 the mole ratio (A+P)/ΔCu(II) is close to 0.5 in consistent with the redox

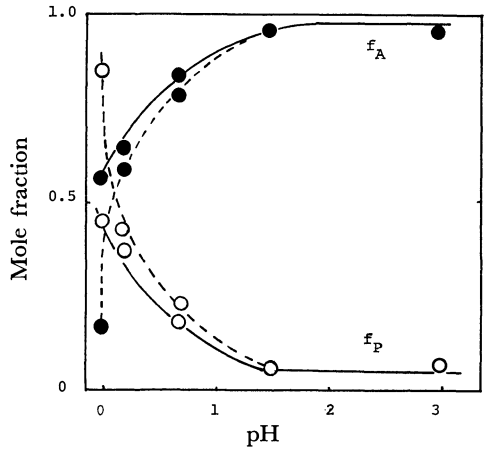

Fig. 1. Mole fractions of acetaldehyde (A) and pyruvic acid (P) formed in the photolysis of aqueous lactic acid–Cu(II) solution in Pyrex test tubes. (——): Deoxygenated, (----): not deoxygenated, before irradiation. Cu(II) sulfate: 0.1 M, lactic acid: 0.4 M, irradiation time: 5 h, f_A: A/(A+P), f_P: P/(A+P).

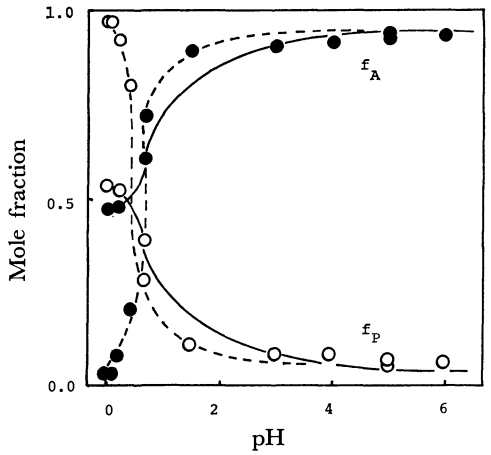

Fig. 2. Mole fractions of acetaldehyde (A) and pyruvic acid (P) formed in the photolysis of aqueous lactic acid–Cu(II) solution in glass ampuls. (——): Deoxygenated, (----): not deoxygenated, before irradiation. Other conditions and notations are the same as those in Fig. 1.

stoichiometry, both in the absence and presence of the dissolved oxygen. However, photolysis at pH≦1 in the presence of oxygen gives no final Cu(II)-reduction, implying reversible redox reaction of Cu(I) and Cu(II) species.

Figure 1 illustrates the pH-dependence of the mole fractions of acetaldehyde f_A and pyruvic acid f_P; f_A decreases and f_P increases with the decrease in pH. The broken lines in Fig. 1 show the effects of the dissolved oxygen which are significant in a lower pH region. Figure 2 illustrates the results obtained by irradiation in glass ampoules in the absence (solid lines) and presence (broken lines) of the dissolved oxygen, somewhat differing from those by irradiation in Pyrex test tubes. The present experiments have been carried out by the latter method because of its better reproducibility and simplicity, without further clarification of the discrepancy between the two methods.

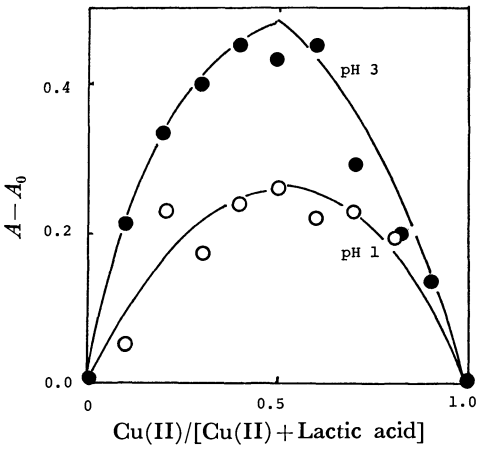

Fig. 3. Application of the continuous variation method to aqueous Cu(II)–lactic acid solution, as measured at 320 nm (pH 3) and at 290 nm (pH 1). Lactic acid+Cu(II)=0.20 M.

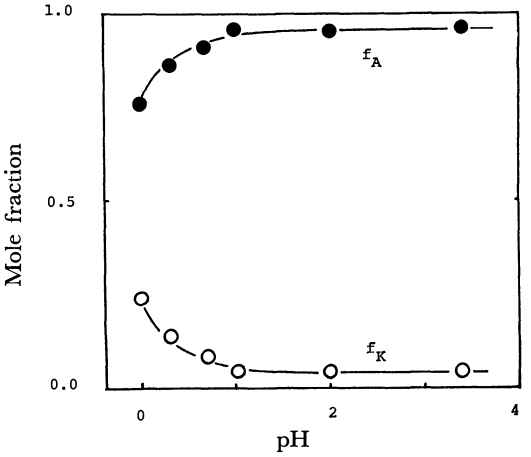

Fig. 4. Mole fractions of propanal (A) and 2-oxobutanoic acid (K) formed in the photolysis of deoxygenated aqueous 2-hydroxybutanoic acid–Cu(II) solution. Cu(II) sulfate: 0.1 M, 2-hydroxybutanoic acid: 0.2 M, f_P: A/(A+K), f_K: K/(A+K). Similar results were obtained for glycolic acid–Cu(II) solution.

The composition of aqueous Cu(II)–lactic acid solution in the ground state equilibrium was investigated, in relation to the pH-dependence of the photoproducts. Application of continuous variation method revealed the formation of a 1:1 Cu(II)–lactate complex in a higher pH region, while no such complex formation was observed at pH near zero (Fig. 3).

Photooxidation of Glycolic and 2-Hydroxybutanoic Acids by Cu(II) Species. On irradiation under conditions similar to those for the Cu(II)–lactic acid system, deoxygenated aqueous solution containing 0.2 M glycolic acid and 0.1 M Cu(II) sulfate gave glyoxylic acid, formaldehyde with evolution of carbon dioxide, and a small amount of unidentified carbonyl product, besides Cu(I) precipitate. Similar irradiation of 2-hydroxybutanoic acid–Cu(II) solution gave 2-oxobutanoic acid, propanal with evolution of carbon dioxide, and a small amount of unidentified carbonyl product, besides the Cu(I) precipitate. The pH-de-

pendences of the mole fractions of the carbonyl products are shown in Fig. 4, which is comparable with those in Fig. 1.

Effects of Additives. In order to test the possible involvement of free radical intermediates, the effects of some free radical scavengers have been investigated for the photoredox reaction of the Cu(II)–lactic acid system. Table 2 lists the results with bromide ion, showing selective suppression toward the formation of pyruvic acid. Tables 3 and 4 are the effects of acrylonitrile in different pH regions and in different acrylonitrile concentrations at pH 0 respectively, which again reveal selective suppression toward the formation of pyruvic acid. For example, the yield of pyruvic acid is decreased to 1/25 (from 1.43 to 0.056 mM) while that of acetaldehyde to 1/2 (from 1.60 to 0.83 mM), by the addition of 4 mM acrylonitrile. Figure 5 is a plot of f_A and f_P as a function of pH in the presence and absence of acrylonitrile. The addition of *t*-butyl alcohol (20 v/v%) as a scavenger of hydroxyl radical[10] suppressed the formation of pyruvic acid almost completely without affecting the yield of acetaldehyde, in the photooxidation of lactic acid with Cu(II) chloride at pH 0, 1, and 1.5.

Figure 6 illustrates the effects of maleic acid, showing selective suppression toward acetaldehyde formation. Though maleic acid suppresses the formation of both acetaldehyde and pyruvic acid considerablly, the effect is much more pronounced toward the former.

Neither acetaldehyde nor pyruvic acid formation was suppressed by the addition of 1 mM sodium azide, an effective scavenger of singlet molecular oxygen, in the photolysis of the Cu(II)–lactic acid system at pH 0, 1, and 1.5.

Free Radical Oxidations of 2-Hydroxy Acids. Since the formation of α-keto acids has been assumed

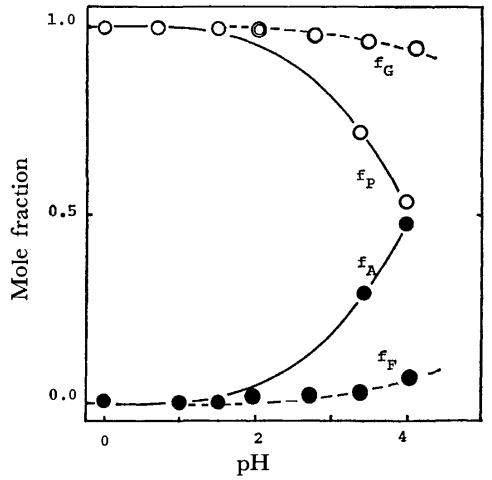

Fig. 7. Mole fractions of aldehydes (●) and α-keto acids (○) formed in the photolyses of aqueous lactic acid (——) and glycolic acid (——), in the presence of 0.5 M bromine. The results with 2-hydroxybutanoic acid were similar to those with lactic acid.

to involve free radical processes, it appeared of interest to investigate free radical oxidations for comparison with the Cu(II)-photooxidation. Reaction of 2-hydroxybutanoic acid with benzoyl peroxide at 80—90 °C in benzene for 20 min led, indeed, to the formation of 2-oxobutanoic acid without propanal formation. Photooxidation of lactic, glycolic, and 2-hydroxybutanoic acids by bromine water (without deoxygenation) gave corresponding α-keto acids with minor amounts of aldehydes. The pH-depencences of the two sets of the carbonyl products are shown in Fig. 7. The pH-dependences appear to be in sharp contrast to those of the Cu(II)-photooxidation.

These results seem to provide some evidence for the intermediacy of free radical processes in the formation of α-keto acids as will be discussed in the following section.

Reaction of lactic acid with Fenton's reagent, which generates hydroxyl and hydroperoxyl radicals,[11] gave no carbonyl products. Nor was formed 2-oxobutanoic acid by reaction of 2-hydroxybutanoic acid with singlet molecular oxygen generated by reaction of sodium hypochlorite with hydrogen peroxide.[12]

Discussion

The pH-dependences of the photooxidation of 2-hydroxy acids by Cu(II) species are apparently similar to those of the photolysis of the uranyl–lactic acid system under similar conditions.[9]

Because of the similarity it seems reasonable to refer to the outline of the latter photoreactions. It has been shown that pyruvic acid is formed at pH≦1 *via* electron or α-hydrogen atom abstraction by excited state uranyl ion on bimolecular collisions with lactic acid while the formation of acetaldehyde and carbon dioxide dominates in a higher pH region *via* unimolecular photodecomposition of uranyl–lactate complex, for the photolysis of aqueous uranyl–lactic acid solution. Later, ESR detection of free radical intermediates, such as $R\dot{C}(OH)R'$,[13] and kinetic isotope effects[14] have strongly supported the assumed mechanisms for the photooxidation of alcohols and acids by uranyl ion.

Similar mechanism seems to be applicable to the photooxidation of 2-hydroxy acids by Cu(II) species with a minor modification.

Equation 1 represents the ground state equilibrium between Cu(II), 2-hydroxy acid (HA), and a 1:1 chelate complex (CuX). Here, Cu(II) represents aquo complex ion which may be present far apart from or in the close proximity of HA without formation of chelate complex. Equations 2 and 3 represent the processes for the formation of α-keto acids and aldehydes, respectively.

The pH-dependence of the two carbonyl products may be interpreted as a reflection of the ground state equilibrium. Equations 1—3 may explain the fact that the formation of α-keto acids is favored by the decrease in pH while oxidative decarboxylation is favored by the increase in pH. UV excitation of CuA would lead to unimolecular redox, *i.e.*, electron transfer from the carboxyl group to the metal center (*d*), followed by oxidative decarboxylation to give aldehyde (*e*). On the other hand, Cu(II) is excited to its LMCT excited state, Cu(II)*, which then undergoes redox reaction with HA on bimolecular collision to produce radical intermediate, $R\dot{C}(OH)COOH$. This radical would be rapidly oxidized by Cu(II)[15] to give α-keto acid.

If the free radical $P\dot{C}(OH)COOH$ is actually the precursor of α-keto acids in the photooxidation by Cu(II) species, as suggested in Eq. 2, then α-hydrogen atom abstraction by other oxidants should also give α-keto acids. In fact, oxidation by free radicals generated in thermolysis of benzoyl peroxide or in photo-

Scheme 2.

lysis with bromine water (where bromine atoms are formed as active species)[16] gave α-keto acids as the main carbonyl products, in consistent with our assumption.

The selective suppression toward the formation of α-keto acid by free radical scavengers (Tables 2—4) may be interpreted as follows. Because of its bareness the intermediate $\mathrm{R\dot{C}(OH)COOH}$ would be sensitive to the radical scavengers and be effectively scavenged, whereas the intermediate precursor for aldehyde is assumed to be less sensitive to the additives due to complexation or less bareness (Eq. 3). Studies on the flash photolysis of Cu(II)–malonate complex have demonstrated that the oxidized ligand remains bound to the reduced metal center until it undergoes further redox reaction.[2] The suppression of both acetaldehyde and pyruvic acid formation by maleic acid may be ascribable to the dual effects of maleic acid acting as both a masking agent toward complex formation and a radical scavenger.

No satisfactory explanation is available as yet for the effects of the dissolved oxygen. Singlet molecular oxygen is ruled out since its reaction with 2-hydroxybutanoic acid did not give 2-oxobutanoic acid and since sodium azide did not affect the yields of the carbonyl products in the Cu(II)-photooxidation of lactic acid. Nor is the role of the hydroperoxyl radical relevant since pyruvic acid was not produced by reaction of lactic acid with Fenton's reagent. Reoxidation of the Cu(I) species by the dissolved oxygen to Cu(II) species is considered to be relevant to the oxygen effects, at least partly. In aerated solution at pH near 0 no practical (final) reduction is observed, while in a higher pH region the ratio $(A+P)/\Delta Cu(II)$ is close to the value expected from Scheme 1. This in turn implies that cyclic (or catalytic) photooxidation by Cu(II) species can only be effective in a highly acidic ($pH \leqq 0$) solution in the presence of the dissolved oxygen.

As to the primary interactions of Cu(II)* with HA to give $\mathrm{R\dot{C}(OH)COOH}$, following processes may be considered; 1) direct H-atom abstraction, 2) oxidation of water by LMCT interaction to give $\dot{O}H$ radical, followed by H-atom abstraction by $\dot{O}H$ from HA, 3) electron transfer from HA to Cu(II)* giving radical cation, followed by deprotonation and radical rearrangement to the more stable radical (Scheme 2).

The $\dot{O}H$ radical mechanism (Eq. 5) might be supported by the selective suppression by *t*-butyl alcohol toward pyruvic acid formation. In fact, photoredox reaction of the labile Cu(II) complex of 2,9-dimethyl-1,10-phenanthroline has been shown to involve the $\dot{O}H$ radical process.[3] However, the failure to observe pyruvic acid formation by reaction of lactic acid with Fenton's reagent excludes this possibility. The direct H-atom abstraction (Eq. 4) is a likely process, and many thermal and photochemical oxidations of organic substrates by transition metal ions seem to involve this process. However, it seems more likely that electron transfer (Eq. 6) occurs as the primary act than the direct H-atom abstraction, because of the LMCT character of Cu(II)* and larger affinity of Cu(II) for the hydroxyl group than for the α-hydrogen atom of HA.

The primary bimolecular interactions between Cu(II)* and HA would only be effective in a short range. This is because Cu(II)* is assumed to be too short-lived to permit a long range bimolecular reaction, whereas the long lifetime of the excited state uranyl ion, 10^{-5}—10^{-4} s,[17] may permit it.

It may be notable that the pH-dependences of the carbonyl products in the Cu(II)-photooxidation appear to be contrast to those in thermal permanganate oxidation: permanganate oxidation of 2-hydroxy acids gives α-keto acids in basic solution but undergoes oxidative decarboxylation to give aldehydes in acidic solution.[18] Permanganate oxidation of 2-hydroxy acids may be assumed to occur by a similar process to that proposed for the permanganate oxidation of alcohols, *i.e.*, α-hydrogen abstraction as hydrogen atom or hydride ion.[19] The decarboxylation in the acid permanganate oxidation may be ascribable to the vigorousness of the oxidation conditions, whereas in the case of the Cu(II)-photooxidation the decarboxylation is relevant to the unimolecular LMCT interactions of the CuA complex.

Molecular Structures of Complexes of Trimethylamine with Boron Trichloride and Boron Tribromide as Determined by Gas Electron Diffraction

Kinya Iijima and Shuzo Shibata*

Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka 422

(Received December 8, 1979)

The molecular structures of trimethylamine-boron trichloride $(CH_3)_3N \cdot BCl_3$ and trimethylamine-boron tribromide $(CH_3)_3N \cdot BBr_3$ were determined from gas electron diffraction and vibrational-spectroscopic data. The molecular parameters and their uncertainties for $(CH_3)_3N \cdot BCl_3$ were r_g(B–Cl) = 1.836±0.002 Å, r_g(N–B) = 1.652±0.009 Å, r_g(C–N) = 1.497±0.003 Å, r_g(C–H) = 1.107±0.005 Å, ∠ClBCl = 110.9±0.2°, ∠CNC = 108.1±0.3°, while those for $(CH_3)_3N \cdot BBr_3$ were r_g(B–Br) = 2.001±0.003 Å, r_g(N–B) = 1.663±0.013 Å, r_g(C–N) = 1.500±0.005 Å, r_g(C–H) = 1.095±0.007 Å, ∠BrBBr = 110.3±0.3°, ∠CNC = 107.8±0.5°. The potential barriers around the N–B bonds in $(CH_3)_3N \cdot BCl_3$ and $(CH_3)_3N \cdot BBr_3$ were also estimated to be higher than 18 kcal mol^{-1} and about 12 kcal mol^{-1} respectively.

The molecular structures of several N–B and P–B donor-acceptor complexes have been determined recently in the gas phase[1–4] and in the solid phase;[5–8] it was found that the N–B bond length in trimethylamine-boron trifluoride is appreciably longer in the gas phase[3] than that in the solid phases,[5] while the P–B bond length in trimethylphosphine-boron trichloride is similar in the two phases.[4,8] It was also noted that, on the formation of the complex, the structural changes in trimethylamine are quite different from those in trimethylphosphine; that is, in both complexes the CNC angle decreases and the CN distance increases,[3] but the CPC angle increases and the CP distance decreases[4] in comparison with the molecular parameters of free molecules. In order to understand the complicated properties of these molecular complexes, it is necessary to determine the molecular structures of trimethylamine and trimethylphosphine complexes with various boron compounds, BX_3. The present study will report the molecular structures of trimethylamine-boron trichloride $(CH_3)_3N \cdot BCl_3$ and trimethylamine-boron tribromide $(CH_3)_3N \cdot BBr_3$, as determined by means of gas electron diffraction.

The molecular structures of gaseous trimethylamine-boron trifluoride $(CH_3)_3N \cdot BF_3$ and trimethylamine-boron trichloride $(CH_3)_3N \cdot BCl_3$ have been reported by several workers.[1–3] The molecular parameters of $(CH_3)_3N \cdot BF_3$ previously obtained by the present authors[3] were consistent with the microwave spectroscopic data,[1] but these parameters were systematically different from those obtained by Hargittai and Hargittai.[2] Thus, we tried to determine the molecular structure of $(CH_3)_3N \cdot BCl_3$ as well as that of $(CH_3)_3N \cdot BBr_3$ in order to compare its molecular parameters with those reported by them. The rotational barriers about the N–B bonds in $(CH_3)_3N \cdot BCl_3$ and $(CH_3)_3N \cdot BBr_3$ were also estimated from the electron-diffraction and vibrational-spectroscopic data in the present study.

Experimental

The trimethylamine was prepared by the method described in Ref. 9; it was allowed to react in dry benzene with boron trichloride and boron tribromide, which were commercially available from Wako Pure Chemical Industries, Ltd. The complexes were recrystallized from ethanol and then sublimed under a vacuum. Their infrared spectra revealed no impurities.[10]

The electron-diffraction photographs were recorded on Kodak Electron-Image plates using an r^3-sector. The accelerating voltage was 40 kV. Samples of $(CH_3)_3N \cdot BCl_3$ and $(CH_3)_3N \cdot BBr_3$ were vaporized at 192 °C and 212 °C respectively. The beam current was about 0.8 μA; the exposure time at a long camera distance of 294 mm was 20 s, and that at a short camera distance of 144 mm was 40 s. The pressure in the diffraction chamber was below 1×10^{-5} Torr during the experiment. The electron wavelength was measured from the diffraction patterns of thallium chloride.[11] The optical densities of the plates were measured at 0.4 mm intervals by means of a digital microphotometer. The electron-diffraction unit and the digital microphotometer have been described elsewhere.[12]

Analysis and Results

Molecular Intensity and Radial Distribution. The scattering intensities for both complexes were obtained in the ranges of s = 2.5—14.8 and 7.5—34.2 Å^{-1} from the photographic plates taken at the long and short camera distances respectively. They were leveled by theoretical backgrounds, and then the leveled intensities of several plates for each camera distance were averaged. The elastic and inelastic scattering factors were taken from the tables prepared by Schäfer *et al.*[13] and by Cromer and Mann[14] respectively. The inelastic scattering factor for the hydrogen atom was taken from the table prepared by Tavard *et al.*[15]

The experimental background curves were drawn smoothly; the experimental molecular intensities shown in Figs. 2 and 3 were thus obtained.[16] The radial distribution curves for $(CH_3)_3N \cdot BCl_3$ and $(CH_3)_3N \cdot$

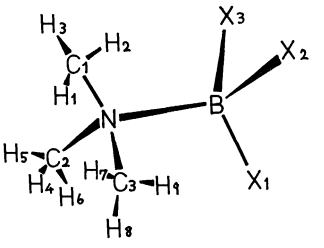

Fig. 1. Numbering of atoms in trimethylamine-boron trihalide (symmetry C_{3v}).

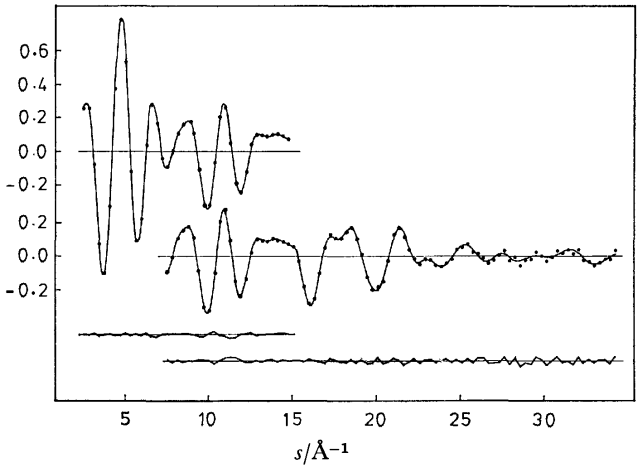

Fig. 2. Molecular intensities for trimethylamine-boron trichloride. The two upper curves are long and short camera-distance data, respectively. Dots represent observed ones, solid curves calculated ones, and the two lower curves the residuals.

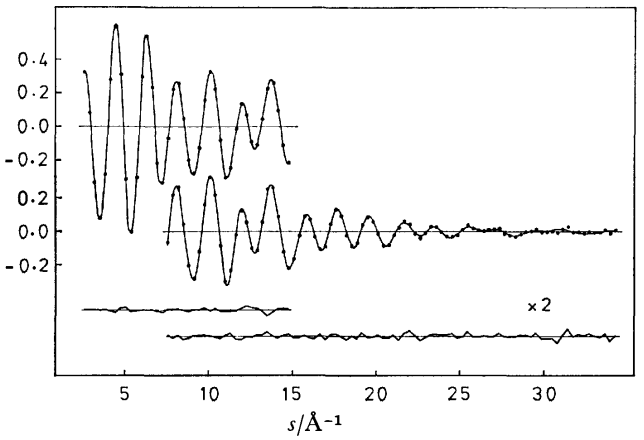

Fig. 3. Molecular intensities for trimethylamine-boron tribromide. The two upper curves are long and short camera-distance data, respectively. Dots represent observed ones, solid curves calculated ones, and the two lower curves two times the residuals.

BBr_3, shown in Figs. 4 and 5 respectively, were calculated by using the molecular intensities in s=2.5—14.8 Å^{-1} from the long camera-distance data and those in s=15.1—34.2 Å^{-1} from the short camera-distance data.

Root-Mean-Square Amplitude of Vibration and Shrinkage Effect. The vibrational spectra for $(CH_3)_3N \cdot BCl_3$ and $(CH_3)_3N \cdot BBr_3$ were observed by Laswick and Taylor in the solid phase.[10] In the present study, the Urey-Bradley force field was adopted, and the vibrational wave numbers were calculated by using the values listed in Table 1. The σ's ($\sigma = [\sum(\tilde{\nu}_{obsd} - \tilde{\nu}_{calcd})^2 / \sum \nu_{obsd}^2]^{1/2}$) were 0.017 and 0.021 for $(CH_3)_3N \cdot BCl_3$ and $(CH_3)_3N \cdot BBr_3$ respectively. The root-mean-square amplitudes of the vibration and shrinkage effects,[17] $r_a - r_\alpha$, based on this force field were also calculated; they are listed in Table 2.

Torsional Vibration and Height of the Potential Barrier. The torsional vibration around the N–B bond cannot be observed directly in the vibrational spectra of these complexes. However, the potential barrier around the N–B bond, V_0, can be estimated from a comparison of the observed mean amplitude for the *gauche* halogen-carbon atomic pair, l(*gauche* X···C), with that calculated from the force field,[3] since this vibration contributes greatly to the l(*gauche* X···C) value.[18]

The l(*gauche* Br···C) value of $(CH_3)_3N \cdot BBr_3$ was found to be 0.164±0.018 Å from the least-squares analysis of the electron-diffraction data. This value corresponds to the V_0 value of 12 kcal mol^{-1}. The lower and upper limits of the V_0 values were estimated to be about 6 kcal mol^{-1} and about 40 kcal mol^{-1} respectively from the error in the observed mean amplitude. The V_0 value in $(CH_3)_3N \cdot BCl_3$ was also estimated to be higher than 18 kcal mol^{-1} from the observed l(*gauche* Cl···C) value of 0.140±0.008 Å.

The force constant of the torsional vibration around the C–N bonds was 0.14×10^{-18} N m in both of the

present complexes. This value corresponds to the V_0 value of 4.4 kcal mol^{-1}, in good agreement with that in the trimethylamine molecule, 4.41 kcal mol^{-1}.[19]

Analysis of the Electron-diffraction Intensities. The molecular parameters of $(CH_3)_3N\cdot BCl_3$ and $(CH_3)_3N\cdot BBr_3$ were determined from the least-squares analysis of the molecular intensities. It was assumed that these molecules have a staggered form with C_{3v} symmetry in the gas phase and that the methyl groups also have C_{3v} symmetry in a staggered form with respect to the C–N bonds. The shrinkage effects for the bonds in the complexes were fixed to the values listed in Table 2. The asymmetry parameters, κ, for the C–H, C–N, N–B, and B–Cl bonds in $(CH_3)_3N\cdot BCl_3$ were estimated to be 12, 2.5, 6.6, and 8.3×10^{-6} Å^3 respectively by means of a diatomic approximation.[20] The κ parameters for the C–H, C–N, N–B, and B–Br bonds in $(CH_3)_3N\cdot BBr_3$ were estimated to be 12, 2.6, 7.1, and 12×10^{-6} Å^3 respectively, while those for the other bonds were assumed to be zero in both the present complexes.

The geometrical parameters, r_α, refined by the least-squares analysis were as follows: r(B–X), r(X···X), r(N–B), r(C–N), r(C···C), r(C–H), and ∠NCH. The r_g parameters were calculated from the r_α parameters obtained in the least-squares calculations;[17] they are

listed in Table 3, together with their limits of error. The errors were estimated from random errors in the least-squares calculations and systematic errors originating from the measurements of the camera distance and the electron wavelength. The mean amplitudes obtained by the least-squares analysis are listed in Table 4. The other mean amplitudes were fixed to the values listed in Table 2 throughout the analysis. The best-fit theoretical intensity curves are shown in Figs. 2 and 3, while the correlation matrices are listed in Tables 5 and 6. The calculations of the mean amplitudes and the shrinkage effects and the least-squares analysis were carried out on a HITAC 8800/8700 computer in the Computer Center of the University of Tokyo.

The observed l(N–B) and l(Br···Br) values in $(CH_3)_3N \cdot BBr_3$ are found to be larger than their calculated values. This disagreement may be due to the fact that the calculation was based on the force field estimated in the solid phase. A large l(N–B) value has also been observed in the analysis of gaseous $(CH_3)_3N \cdot BF_3$;[3] therefore, it may be suggested that the N–B bond is strengthened in the solid phase in comparison with that in the gas phase.

The bond distances of $(CH_3)_3N \cdot BCl_3$ obtained in the present study are shorter by about 0.3% than those obtained by Hargittai and Hargittai.[2] This value is greater than the systematic error in the present study (0.1%), but if random errors are taken into account, the molecular parameters obtained in these independent studies are in essential agreement with each other.

Discussion

The molecular parameters for gaseous trimethylamine-boron trihalide complexes are listed in Table 7 in comparison with those for the complexes in the solid phase and those for the free molecules. When a trimethylamine molecule and a boron trihalide molecule form a complex, the distances of the B–X and C–N bonds increase, while the XBX and CNC angles decrease. The experimental results show that such structural changes are greater in the acceptor molecule than in the donor molecule, and that the magnitude of the changes on the complex formation

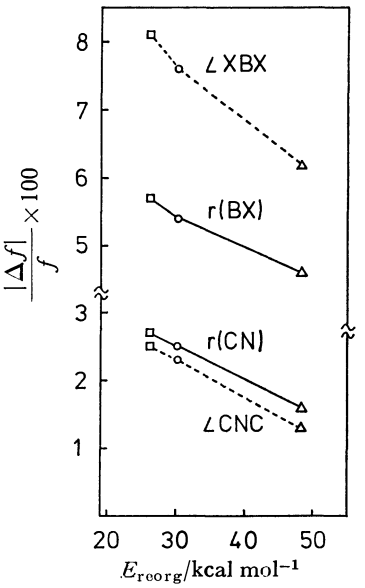

Fig. 6. Parameter changes on complex formation *versus* reorganization energies for acceptor molecules.
Solid curves represent positive Δf and dashed curves negative Δf.
△: $(CH_3)_3N \cdot BF_3$, ○: $(CH_3)_3N \cdot BCl_3$, □: $(CH_3)_3N \cdot BBr_3$. The reorganization energies for BF_3, BCl_3, and BBr_3 are 48.4, 30.3, and 26.2 kcal mol^{-1}, respectively.[25]

is in the order of $(CH_3)_3N \cdot BBr_3 > (CH_3)_3N \cdot BCl_3 > (CH_3)_3N \cdot BF_3$. The fractional difference, $\Delta f/f$, between the parameter in the complex and that in the corresponding free molecule[21–24] is plotted in Fig. 6 against the reorganization energies calculated by Cotton and Leto[25] for boron trihalides. The figure shows a correlation of the structural changes in the donor and acceptor molecules with the reorganization energy of the acceptor molecule. However, no systematic relation can be observed with respect to the N–B bond distance.

In the solid phase,[5–7] the B–X and C–N distances are larger and the XBX angles are smaller than the corresponding values in the gas phase. Furthermore, the N–B dative bonds are much shorter in the solid phase than in the gas phase. These facts indicate that, in the solid phase, the charge transfer occurs to a larger extent, thereby enhancing the dative bonding. This trend is also in accord with our foregoing remarks with regard to its mean amplitude.

The rotational barrier around the N–B bond, V_0, is considerably larger in $(CH_3)_3N \cdot BCl_3$ and $(CH_3)_3N \cdot BBr_3$ than in $(CH_3)_3N \cdot BF_3$, 4.3 ± 0.3 kcal mol^{-1}.[3] As has been described above, the potential barrier for $(CH_3)_3N \cdot BCl_3$ seems to be larger than that for $(CH_3)_3N \cdot BBr_3$, though these barriers could not be determined very accurately in the present study. Thus, the magnitudes of the potential barriers about the N–B bonds are in the order of $(CH_3)_3N \cdot BCl_3 \geq (CH_3)_3N \cdot BBr_3 > (CH_3)_3N \cdot BF_3$, in agreement with that obtained from an NMR study.[26] This order seems to be consistent with the inverse order of the observed N–B bond lengths in the gas phase.

Effect of the Phase Transition in Liposomes on the Fluorescence of Amphiphilic Cyanine Dyes

Kaoru Onuki, Kazue Kurihara, Yoshinori Toyoshima,† and Mitsunori Sukigara*
Institute of Industrial Science, The University of Tokyo, 7—22—1, Roppongi, Minato-ku, Tokyo 106
(Received December 20, 1979)

The dependence of fluorescence intensity of amphiphilic cyanine dyes on the thermotropic fluid-solid phase transition of lipid bilayer membranes has been investigated. *N,N'*-dioctadecyl oxacarbocyanine iodide or *N,N'*-dioctadecyl thiacarbocyanine bromide was incorporated into single lamellar liposomes, and the fluorescence intensity of each dye was observed to be modified considerably by the phase transition of the lipid bilayers. An amphiphilic cyanine dye with single long alkyl chain, *N*-octadecyl-*N'*-methyl thiacarbocyanine bromide was also incorporated in the lipid bilayers, but in this case, the phase transition showed little effect on the fluorescence intensity. These results were interpreted in terms of the effect of the bilayer membrane fluidity and rigidity on the rotational motion of the incorporated cyanine dyes. The phase transition parameters were obtained by applying those amphiphilic dyes as the fluorescence probe of the phase transition of the liposomes.

The fluidity of the hydrocarbon chain in a lipid bilayer membrane has been known to play an important role in the functions of the biological membrane[1,2]. The fluid-solid phase transitions observed in many kinds of lipid membranes are associated with an abrupt change in the membrane characteristics, such as NMR relaxation time[3,4] and permeability,[5] and many methods have been applied for detecting the phase transition, *e.g.* the calorimetry which directly measures the enthalpy change of transition,[6—8] ESR spin label method by which the solubility or the mobility change of the probes in a membrane is detected,[9,10] and light scattering method.[11] Fluorescence probes were also used widely.[12] Fluorescence probes so far used are mainly lyophobic fluorescent materials such as 1,6-diphenyl-1,3,5-hexatriene (DPH) which are localized in the hydrocarbon chain region of the membrane, and its fluorescence anisotropy reflects the microviscosity of that region.[13] Also, the 5-(dimethylamino)-1-naphthylsulfonyl group or 9-anthracenecarbonyl group which covalently binds to the alkyl chain of lipid was used for detecting the microviscosity of the chains[14,15].

A cyanine dye, composed of two long *N*-alkyl chains and a chromophore, has an amphiphilic molecular structure and can be incorporated into a bilayer membrane as a constituent.[16] We reported previously the effect of the phase transition on the aggregation of the dye in the vesicle.[17] Calzaferry *et al.*[18] reported that twisting around the conjugated hydrocarbon bond plays an important role in the nonradiative relaxation of excitation energy. So it is expected that a change in the fluorescence intensity of a cyanine dye incorporated into a lipid bilayer will reflect the difference of the microviscosity of the bilayer. We examined the temperature dependence of the fluorescence intensity of cyanine dyes, such as *N,N'*-dioctadecyl oxacarbocyanine iodide (DSOCC), *N,N'*-dioctadecyl thiacarbocyanine bromide (DSSCC), and *N*-octadecyl-*N'*-methyl thiacarbocyanine bromide (MSSCC) incorporated into a single bilayer vesicle composed of dimyristoyl phosphatidylcholine (DMPC) or dipalmitoyl phosphatidylcholine (DPPC).

† Permanent address: Faculty of Integrated Arts and Sciences, Hiroshima University, Higashisendamachi, Hiroshima 730.

Experimental

DMPC and DPPC were purchased from Sigma Chem. Co. and the cyanine dyes were purchased from the Japanese Research Institute for Photosensitizing Dyes Co. Ltd. and used without further purification. The purity of the reagents was checked by thin layer chromatography. KCl and tris-(hydroxymethyl)aminomethane (tris) of analytical grade were used.

Phosphatidylcholine colyophilized under vacuum with a dye of a desired composition from a benzene solution was suspended in 10 ml of buffered 0.1 M KCl aqueous solution (0.1 M KCl in 0.01 M tris–HCl at pH 7.5). The electrolyte concentrations in the dispersion were kept constant throughout the experiments. The suspension was ultrasonically irradiated (Otake Seisakusho OT-5202 Sonicator) for 20 min at 20 kHz under an argon atmosphere. The sonication temperature was kept about 5 °C above the phase transition temperature of the lipid. After sonication the sample was centrifuged at 13000 r.p.m. for 10 min to remove undispersed reagents.

The phosphatidylcholine concentration in the vesicle dispersion was checked by the Fiske-Subbarow method.[19] The lipid concentration was 1—3 mg/dm^3 throughout the experiments. Concentration of DSOCC, DSSCC, and MSSCC in the vesicle dispersion were estimated from the absorbances at 492 nm, 560 nm, and 560 nm respectively attributed to the monomer bands, using the molecular extinction coefficients determined in methanol. The dye concentration in the dispersion was below 7×10^{-7} mol/dm^3 throughout the experiments. Thus the molar ratio of lipid to dye was 4600—7000, or the local concentration of the dye was less than 1 molecule/vesicle throughout the experiments.

Absorption measurements were carried out using a spectrophotometer, Beckman 25. Fluorescence measurements were performed on a spectrofluorophotometer, Hitachi MPF-2A under argon atmosphere. The temperature was monitored with a thermocouple dipped in the sample cell. The decrease of excitation light intensity caused by the light scattering by the vesicles had little effect on the fluorescence measurement.

Results and Discussion

The fluorescence spectra of the dyes, DSOCC, DSSCC, and MSSCC, in vesicles were respectively quite similar to those in methanol solutions. The fluorescence intensity of DSOCC and that of DSSCC

in the vesicles were two to six times as large as those of the dyes in methanol at 20 °C while the fluorescence intensity of MSSCC was twice the intensity of the same dye in methanol. These facts are interpreted qualitatively in terms of the difference of effective viscosity of the media affecting the freedom of motion of the dyes. The fluorescence of DSOCC and that of DSSCC in vesicles were enhanced as the temperature was lowered, and there are two points, T_1 and T_2 ($T_1 > T_2$), where the increment of the fluorescence intensity changes. Those temperatures are in good agreement with the upper and the lower limits of the phase transition temperature range of each vesicle, suggesting that the temperature dependence of the fluorescence intensity reflects the phase transition of the vesicles. On the other hand, the same measurement of MSSCC did not show any inflection point in the experimental temperature range. If we know the equation which gives the temperature dependence of fluorescence intensity in each phase, we may estimate the fraction of phase transition at any temperature in the region of phase separation.

The fluorescence quantum yield, Φ, is given in the following form.

$$\Phi = \frac{k_f}{k_f + k_1 + k_2 \exp(-E/kT)} \tag{1}$$

where k_f is the rate constant of the fluorescent process, $[k_1 + k_2 \exp(-E/kT)]$reflects the rate constants of the nonradiative processes, and E is the activation energy of a temperature dependent nonradiative porcess. Eq. 1 is rewritten into the following form.

$$\ln\left[\frac{1}{\Phi} - \left(1 + \frac{k_1}{k_f}\right)\right] = \ln\frac{k_2}{k_f} - \frac{E}{kT} \tag{2}$$

We cannot directly apply this equation to our experimental results, because we cannot determine the quantity k_1/k_f at present. The fluorescence quantum yields of oxacarbocyanine and thiacarbocyanine in methanol were respectively reported to be 0.053 and 0.048 at room temperature,[20] and we assume the following temperature dependence of the fluorescence intensity, I_f,

$$\ln I_f = A + \frac{B}{T} \tag{3}$$

where A and B are constants. The above approximation means that the temperature dependent nonradiative process is the dominant path for dissipation of excitation energy. We tested the applicability of Eq. 3 by plotting the temperature dependence of fluorescence intensity of SOCC in methanol in the range, 10—50 °C, showing a good linear relationship between $\ln I_f$ and $1/T$. The plots according to Eq. 3 for DSOCC and DSSCC are shown in Figs. 1 and 2, respectively. These plots clearly show that each $\ln I_f$ *vs.* $1/T$ curve is divided into three parts, *i.e.*, low temperature part, high temperature part, and middle part. The low temperature part and the high temperature part correspond to the monophase regions, and the Arrhenius relation holds as expected. The temperature dependence of the fluorescence intensity of MSSCC incorporated into the DPPC vesicle is shown in Fig. 3. In this case, the fluorescence intensity of MSSCC does not reflect the phase transition. This result suggests that the temperature dependent nonradiative process is the twisting motion of the

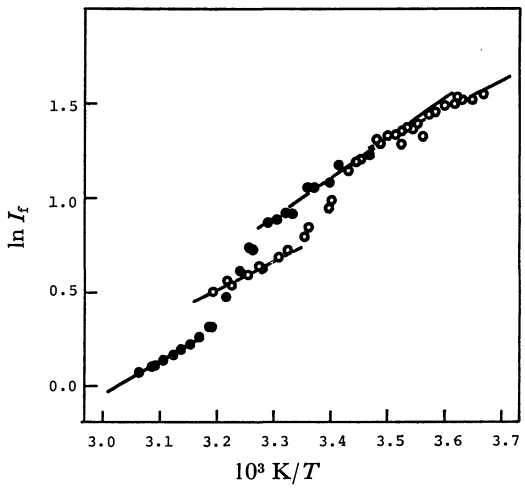

Fig. 1. Logarithm of the fluorescence intensity of DSOCC *vs.* reciprocal of temperature. (○); DMPC vesicles, (●); DPPC vesicles.

chromophore around the bridging bond in the excited singlet state and the suppression of this motion by the membrane lipid moiety will increase the fluorescence intensity of dioctadecyl carbocyanines incorporated into the membrane. Thus, the fluorescence intensity of dioctadecyl cyanines will reflect the phase transition of the lipid bilayers. The observed fluorescence intensity, I_f, in the region of a phase transition may be given in the following form,

$$I_f(T) = I_s(T)\cdot\theta + I_{fl}(T)\cdot(1-\theta) \quad (4)$$

where $I_{fl}(T)$ and $I_s(T)$ are the fluorescence intensity of the dye in the fluid phase region and the solid phase region, respectively, at temperature T, and θ is the fraction of the solid phase region at T. From Eq. 4 we get the following expression for θ.

$$\theta = \frac{I_f(T)-I_{fl}(T)}{I_s(T)-I_{fl}(T)} \quad (5)$$

Temperature dependence of θ is shown in Figs. 4 and 5.

It is possible to calculate the cluster size of cooperative transition from the data in Figs. 4 and 5, if we assume that the solubility of the amphiphilic cyanine dye in the lipid bilayer is not affected by the physical state of the bilayer. The phase transition phenomenon can be regarded as a quasi-first-order reaction with the equilibrium constant, K.

$$K = \frac{\theta}{1-\theta} \quad (6)$$

Combining Eq. 6 with van't Hoff equation, the following equation is obtained.[21]

$$\left(\frac{d\theta}{dT}\right)_{T_m} = \frac{\Delta H_{v.H.}}{4RT_m}, \quad (7)$$

where T_m is the temperature at the center of the transition and $\Delta H_{v.H.}$ is the so-called van't Hoff enthalpy of the transition. Thus, we can calculate the van't Hoff enthalpy from the slope of the curve in Figs. 4 and 5 at $\theta=0.5$. The values of the van't Hoff enthalpy obtained with DSOCC fluorescence were 66.8 kcal/mol and 90.7 kcal/mol for DMPC and DPPC vesicles, respectively. The calorimetrically obtained enthalpy of transition has not been reported for single bilayer vesicles, though the values for multilamellar liposomes have been reported as listed in Table 1. Assuming that those values are also applicable to the phase transition of single bilayer vesicles, the cluster size of the cooperative transition was estimated. The phase transition parameters obtained in the present study are listed in Table 2 together with those obtained by other methods, *e.g.* ESR, fluorescence depolarization, and the differential scanning calorimetry (DSC). The centers of the transition temperatures obtained in the present study are in good agreement with those of the other methods, although values of the cooperativity obtained in this work are smaller than those reported previously. Although the reason for such differences is not clear at the present stage, we may conclude that the fluorescence intensity of the amphiphilic cyanine dyes with two long alkyl chains which are incorporated in bilayer liposomes is significantly modified by the phase transition of the bilayers through the suppression of twisting motion of the chromophores around the bridging chain in the excited singlet state.

Interaction of Water with the Surface of Calcite

Tetsuo MORIMOTO,* Jiro KISHI,† Osamu OKADA, and Toshie KADOTA

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700

† *Research Center for Industry in Okayama Prefecture, Ifuku-cho, Okayama 700*

(Received December 26, 1979)

The interaction of water with the surface of ground calcite was investigated by measuring the water adsorption isotherm and the amount of thermally desorbed molecules *in vacuo*. The results showed that the surface of ground calcite has chemisorbed water at room temperature which can be completely desorbed by evacuation up to 600 °C, and on which water can be physisorbed in a H_2O:OH ratio between 1:2 and 1:1, depending on the conditions of the pretreatment. The isosteric heat of the physisorption of water on the hydroxyls showed that the activity of the adsorption sites for water is reduced by treating the sample at higher temperatures or by washing with water. Moreover, it was found that the surface of the calcite sample starts to release CO_2 molecules by heat treatment at relatively low temperatures below 300 °C *in vacuo*, and that the amount of CO_2 increases exponentially with an increase in the temperature.

It has previously been shown that metal oxide, when preserved in the atmosphere, chemisorbs water to form surface hydroxyls, on which water is further physisorbed, resulting in the alteration of the surface properties.[1-4] The studies of surface properties, especially those of the interaction with water, of inorganic materials provide important information concerning their technical use. We ourselves have reported that $BaSO_4$ only physisorbs, but does not chemisorb, water.[5] Calcite is one of the most important natural resources used as pulverized filler materials. Gammage and Gregg[6] have reported the effect of grinding Iceland Spar on its adsorbability for water. Recently, Goujon and Mutaftschiev[7] have investigated the dependence of the surface properties of ground calcite upon the calcination temperature by means of pH-measurements, heat of immersion, and mass spectrometry, and have concluded that about 30% of the surface carbonate ions are decomposed by calcination up to 450 °C. Hackerman and Hall[8] measured the water adsorption isotherm on calcite, but did not evaluate the effect of the calcination temperature on the adsorbability of water. The purpose of the present work is to study the interaction of water with the calcite surface in various stages of heat treatment, especially the existence and behavior of surface hydroxyls, by measuring the adsorption isotherms of water and the amounts of thermally desorbed water and CO_2.

Experimental

Natural calcite, from the Niimi district in Okayama Prefecture, was ground by using an impact pulverizer; a portion of the finest grade was then collected. The main impurities involved in the original material were SiO_2 0.06, Fe_2O_3 0.07, Al_2O_3 0.04, MgO 0.016, and P 0.01%. Part of the powdered sample was washed with water until the electric conductivity of the supernatant liquid became constant. X-Ray analysis showed the sample to be of the calcite type and not to contain aragonite. Electron-microscopic observation, using a scanning electron microscope (Hitachi S310), of the washed and unwashed samples did not show any characteristic difference between them and any evidence of sharp cleavage along the rhombohedral faces.

A sample of the 12—15 m^2 surface area was first pretreated at 150, 300, or 500 °C for 4 h in a vacuum of 1×10^{-3} Pa, followed by measurement of the water-adsorption isotherm in a volumetric adsorption apparatus equipped with an oil manometer. After measuring the first adsorption isotherm at 25 °C, the sample was exposed to saturated water vapor for 12 h at 25 °C to ensure surface hydration, evacuated at 1×10^{-3} Pa for 4 h at the same temperature to remove physisorbed water, and subjected to the measurement of the second adsorption isotherm of water at the same temperature as before. For the determination of the isosteric heat of adsorption, the second adsorption isotherms were also measured at 15 and 20 °C. The adsorption equilibrium of water was established within a short time, *i.e.*, within 10—20 min, for the whole measurement. The surface area was obtained by means of the BET N_2-adsorption.

The surface water content was determined by the successive ignition-loss method.[9] As it was found from mass analysis that the gas evolved during the course of this measurement is composed of H_2O and/or CO_2, the mixed gas was analysed by separating it into individual components in the following way. The sample treated at room temperature *in vacuo* was heated at 100 °C for 4 h, and the gas expelled was once trapped in a vessel cooled at −196 °C; its amount was determined volumetrically after evaporation at room temperature. Next, the gas was condensed at the temperature of a solid CO_2–ethanol mixture and outgassed to remove the CO_2 thoroughly; then the remaining condensed gas was determined volumetrically after reevaporation as before. The same procedure was repeated after every treatment of the same sample at increasingly elevated temperatures.

Results and Discussion

Figure 1 shows the surface water content and the amount of CO_2 on $CaCO_3$, which were obtained by the successive ignition-loss method. Assuming a water molecule to come from two hydroxyls through the condensation dehydration at higher temperatures, the water content is expressed by the number of OH groups per nm^2 remaining on the surface after the treatment at the temperature indicated, while the amount of CO_2 is the number of total CO_2 molecules evolved when the sample is heated up to the temperature. As is shown in Fig. 1, the surface water content decreases exponentially with a rise in the temperature of the treatment, and vanishes at 600 °C; the absolute values at relatively lower temperatures are comparable to those of metal oxides, but decrease more rapidly

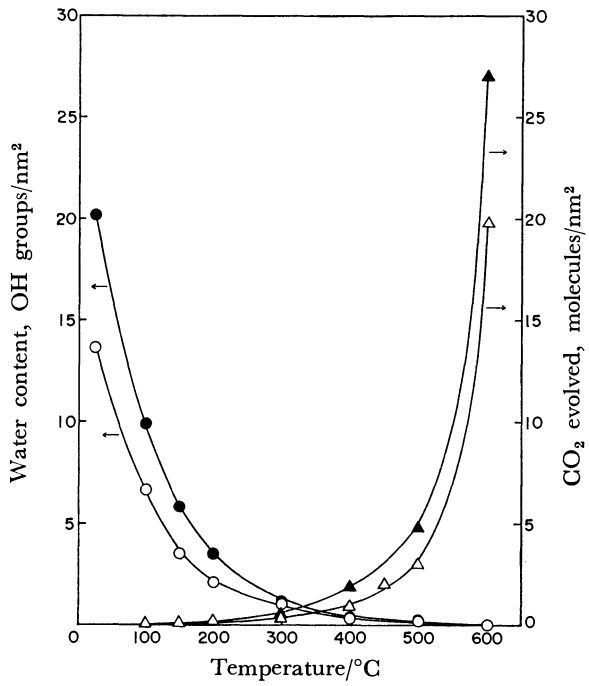

Fig. 1. Surface water content and the amount of evolved CO_2 on calcite as a function of evacuation temperature.
○△, Washed sample; ●▲, unwashed sample.

with a rise in the temperature compared to the cases of metal oxides.[1-4] It should be noticed that the evolution of CO_2 *in vacuo* starts at a very low temperature and increases exponentially with a rise in the temperature up to 600 °C; this result is entirely different from that found by Goujon and Mutaftschiev,[7] *i.e.*, that a constant amount of about 30% of CO_3^{2-} ions on the ground calcite surface was decomposed by outgassing the sample up to 420 °C.

The cleavage of the calcite crystal is known to be perfect on the $(10\bar{1}1)$ plane.[10] Assuming the actual surface of powdered calcite to be composed of this plane, the surface density of each of the Ca^{2+} and CO_3^{2-} ions can be computed to be 4.97 ions/nm². The surface water content of the washed calcite sample, after outgassing at room temperature, was found to be larger than the surface density of the Ca^{2+} ions. However, part of the surface water content survives even after the evacuation at 300 or 400 °C, which leads us to the conclusion that there is a great possibility of the chemisorption of water on the calcite surface.

In the present procedure for measuring water content, a part of the surface CO_3^{2-} ions are dissociated to evolve CO_2 molecules, as is shown in Fig. 1; the amount of CO_2 evolved when the sample is heated at 500 °C *in vacuo* is nearly equal to the number of CO_3^{2-} ions on the crystal surface, as calculated above. Admittedly, the chemisorbed water should have CO_3^{2-} ions beneath it, as is evident from the fact that it is

Table 1. Relation between the amounts of physisorbed and chemisorbed water on the $CaCO_3$ surface (25 °C)

Sample	Pretreatment temperature (°C)	Specific surface area (m^2/g)	V_m (ml/m^2)	V_p ($H_2O's/nm^2$)	V_c ($OH's/nm^2$)	V_h ($OH's/nm^2$)	V_c+V_h ($OH's/nm^2$)	$V_p/(V_c+V_h)$
Washed	150	6.91	0.219	3.98	3.82	3.43	7.25	0.549
	300	6.80	0.236	3.93	4.83	1.17	6.00	0.655
	500	5.70	0.238	3.66	5.48	0.19	5.67	0.646
Unwashed	150	7.72	0.257	5.46	2.90	5.95	8.85	0.617
	300	7.67	0.242	4.65	3.72	1.33	5.05	0.921
	500	5.96	0.247	4.12	5.01	0.14	5.15	0.800

depleted at 500 °C, at which temperature the monolayer of CO_3^{2-} is decomposed completely. This circumstance may be one of the reasons why the desorbability of chemisorbed water from calcite is greater than that from metal oxides.

It is interesting to note that the calcite surface which has never experienced washing with water has a larger amount of chemisorbed water than the sample which was washed. This makes it possible to infer that water can be chemisorbed on the active sites like surface defects as soon as they are formed by grinding the sample in air and that they can be removed by washing the sample with water.

Figure 2 illustrates the adsorption isotherms of water on calcite powders pretreated *in vacuo* at 150, 300, and 500 °C. The adsorption isotherms obtained are all Type II isotherms, according to Brunauer's classification. In addition, the amount of adsorbed water for the first adsorption, measured just after the pretreatment at a higher temperature, is larger than that for the second adsorption obtained after evacuating the sample at room temperature after the first adsorption measurement has been completed; the two isotherms are parallel to each other. The water adsorption isotherm measured by Gammage and Gregg on a precipitated calcite sample is similar to the first adsorption isotherm in the present samples.[6] The parallelism between the first and second adsorption isotherms in the present study is quite similar to the cases of water adsorption on metal oxides.[1,2,11] On the basis of previous discussions concerning the parallelism of the first and second isotherms for most metal oxides,[1,2] we can conclude that the chemisorpion of water occurs on the surface of calcite, the difference between the two isotherms being the amount of chemisorbed water.

Table 1 gives the numerical data analysed from both water adsorption isotherms and water contents on calcite samples. The specific surface area of the samples was measured before the first and second water adsorption measurements, and the two values thus obtained were found to be equal to each other within an experimental error of ±1.5%. V_m and V_p are the monolayer capacities obtained by applying the BET equation to the first and second adsorption isotherms respectively, the latter involving only the amount of physisorbed water and being expressed by the number of water molecules per nm^2. V_m contains both physisorbed and chemisorbed water, expressed as the gaseous volume adsorbed on a unit of the surface area. The amount of chemisorbed water V_c, can, therfore, be obtained by subtracting V_p from V_m after changing the unit of V_m to the number of molecules of H_2O per nm^2; the difference (V_m-V_p) is then expressed as the number of OH groups per nm^2 by assuming a water molecule to be chemisorbed dissociatively on calcite to form two hydroxyls, as in the case of metal oxides. Another quantity of chemisorbed water is the water content, V_h, remaining on the surface after pretreatment at indicated temperatures, as obtained from Fig. 1.

It may be seen from Table 1 that the total amount of chemisorbed water falls within the range of 5 to 9 $OH's/nm^2$, regardless of whether the sample was washed with water or not. This indicates that the surface state of calcite is almost the same after the water adsorption measurement. These values are likely if we consider that a considerable portion of the surface CO_3^{2-} ions have been converted to OH^- ions.

From the above considerations, we may conclude that the real surface of calcite contains chemisorbed water molecules, irrespective of whether the sample was washed with water or not. Here, we may reasonably expect that the surface of calcite has been hydrolysed when washed with water,[7] which results in the formation of a hydroxylated surface according to this reaction:

$$CaCO_3 + 2H_2O \rightleftharpoons Ca(OH)_2 + H_2CO_3 \quad (1)$$

If the outermost monolayer of the calcite surface is altered to a hydroxide layer by this reaction during the course of washing, the resulting sample should release a maximum amount of water molecules or 4.97 H_2O/nm^2 upon heating *in vacuo*; reversely, the dehydrated surface can chemisorb the same number of water molecules. The experimental values, *i.e.*, 5—9 $OH's/nm^2$, of the total amount of chemisorbed water, V_c+V_h, are within this limit.

The evolution of CO_2 from the calcite surface takes place (Fig. 1) through the following reaction upon heat treatment *in vacuo*:

$$CaCO_3 \longrightarrow CaO + CO_2 \quad (2)$$

The CaO layer thus formed will chemisorb water molecules during the adsorption process according to this reaction:

$$CaO + H_2O \rightleftharpoons Ca(OH)_2 \quad (3)$$

Here also, surface hydroxyls are produced and will behave similarly to those formed by the hydrolysis of the calcite surface, as has been described above.

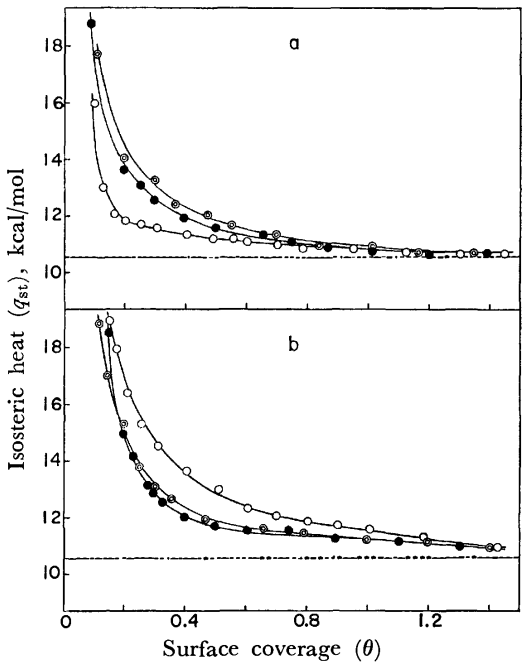

Fig. 3. Isosteric heat of adsorption of water on (a) washed and (b) unwashed calcite.
○, 150 °C; ●, 300 °C; ◎, 500 °C. Broken line represents the heat of liquefaction of water.

Indeed, it is interesting to realize that the total number of chemisorbed water molecules is 5—9 OH's/nm^2, despite the fact that at least two layers of CaO should be formed on the 500 °C-treated samples due to the decarbonation of $CaCO_3$ and the dehydration of $Ca(OH)_2$. In other words, only the outermost layer of the two CaO layers is considered to be partially hydroxylated during the water-adsorption process.

As may be seen from Table 1, the ratio, $V_p/(V_c+V_h)$, of the number of physisorbed water molecules in the first monolayer to that of the underlying hydroxyls is between 1:2 and 1:1. This indicates that a water molecule is physisorbed on one hydroxyl group or on two hydroxyls.

The isosteric heat of the physical adsorption of water, q_{st}, on the fully hydroxylated surface of calcite can be obtained by applying the Clausius-Clapeyron equation to the water-adsorption data in Fig. 2; it is illustrated in Fig. 3. The q_{st} value reveals a decreasing curve with an increase in the coverage of water, θ, and approaches the heat of the liquefaction of water at $\theta=1$, which indicates a characteristic surface heterogeneity in the samples used. Hackerman and Hall reported the q_{st}-curve of water on the 100 °C-treated powdered calcite, which is similar to that obtained on the washed and 150 °C-treated sample in the present study; it is not clear, however, whether their measurement was carried out on a fully hydroxylated surface.[8] With the washed sample in the present study, treatment at 300 or 500 °C gives higher q_{st} values than that at 150 °C, whereas with the unwashed sample the 150 °C-treatment provides the highest value among the three treatments; the q_{st} curves of the 300 °C- and 500 °C-treated samples are similar to each other regardless of whether the sample is washed or unwashed. If the sample is unwashed, the surface will involve a variety of active sites, such as corners, edges, and other kinds of surface defects, and washing will remove some of these stronger adsorption sites; a partial removal of active sites will more or less also take place when the sample is subjected to heat treatment at higher temperatures. Thus, both the washing and the heating of the original sample may produce a similar surface activity. Finally, the washed and 150 °C-treated sample seems to give too small activity for water adsorption. This may be due to the fact that the fully washed surface of calcite could have lost active sites through dissolution and hydrolysis, resulting in the establishment of a less active surface; however, the succeeding treatment at higher temperatures (300 or 500 °C) produces more active surfaces.

The authors are indebted to Dr. Shigeharu Kittaka in Okayama College of Science and Dr. Mahiko Nagao in Okayama University for their helpful discussions.

Quantitative Study of Metachromasy. The Analysis of the Dye–Polyphosphate Multiequilibrium System by the Principal Component Analysis Method

Mineo TAKATSUKI

Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received December 26, 1979)

The absorption spectra of three dyes, 9-aminoacridine (AA), Crystal Violet (CV), and Trypaflavine (TF), were measured in the presence of sodium polyphosphate (NaPP). The optical titrations were performed at phosphate residue-to-dye ratios between 26.6 and 2130 for AA, between 42.6 and 788 for CV, and between 53.9 and 1120 for TF. Using a model in which the condensation of dyes to a polyelectrolyte and the bound monomer⇌bound aggregate equilibrium in the vicinity of the polymer are assumed, the extended principal component analysis was applied to the observed spectra of each dye–NaPP system. The equilibrium constants and the pure spectra of bound dye species were determined. Both the bound monomer and the bound dimer were present in the AA–NaPP system, while the bound monomer, bound dimer, and bound tetramer were present in both CV– and TF–NaPP systems. In all the cases, the absorption spectrum of the bound monomer showed a slight bathochromic shift. The absorption spectrum of the bound dimer of AA showed a considerable bathochromic shift without any new band, while the spectrum of the bound dimer and bound tetramer of CV and TF showed metachromasy bands in wavelength ranges both shorter and longer than the peak wavelength of free CV and TF.

An aqueous solution of several dyes in the presence of a polyelectrolyte shows a color change, namely metachromasy, which is affected in various ways by the combination of dyes and polymers.[1–22] Many papers have been published on the interaction between metachromatic dyes and biological polymers including DNA,[4,6,14–22] because most metachromatic dyes show mutagenic effects. In order to investigate the interactions between the dyes and polymers, the measurement of the absorption spectra is a useful method. However, the absorption spectra of a dye-polyelectrolyte solution are generally composed of some absorbing species, whose fractions vary with the change in the molar ratio of the polymer residue to the dye (P/D). Therefore, in order to study the nature of metachromasy quantitatively, the number of absorbing species and the 'pure' spectrum of the species in an equilibrium system of dye and polymer have to be determined.

The method of principal component analysis (the PCA method) was extended to determine not only the number of absorbing species in an equilibrium system, but also the equilibrium scheme among the species and their pure absorption spectra.[23] The PCA method was successfully applied to the equilibrium systems of cationic dyes and various polyanions in the low-P/D region between 0 and 1.[4,5] The presence of two dye species, namely a free and a bound dye, in the low-P/D region was ascertained for those systems. Furthermore, it was predicted that two or more bound dye species are present in the high-P/D region.[5]

The main purpose of this work is to determine the number of bound dye species over a wide P/D region and to determine the equilibrium scheme of the dye–polymer system and the absorption spectrum of the bound-dye species by using the PCA method. It is also interesting to study the effect of the structure of the dye on the metachromasy. Therefore, three different dyes 9-aminoacridine (AA, monoaminoacridine dye), Crystal Violet (CV, triphenylmethane dye), and Trypaflavine (TF, diaminoacridine dye), all of which interact with DNA and show metachromasy,[4,20,21] were chosen as sample dyes. Sodium polyphosphate (NaPP), which can be thought of as a model of the DNA backbone, was chosen as the polymer, because the pure spectrum of the dye species bound to NaPP will give information about distinguishing the interaction between the dye and the ionized group of DNA from that between the dye and the base pair of DNA.

The application of the PCA method to the spectra observed over a wide P/D region revealed that only two bound-dye species are present in the AA–NaPP system and that only three are present in the CV– and TF–NaPP systems. Such results do not agree with the cooperative binding model, which has been used for metachromasy, because that model implies that a large number of bound-dye species are present over a wide P/D region.[9,10,24,25] Hence, a new model was proposed for the metachromasy. In the present model, it was assumed that the dyes are condensed near the polyelectrolyte and aggregate in its vicinity. Then, the equilibrium constants among the bound-dye species and their pure spectra were determined by the extended PCA method.

Experimental

Materials. The preparation of AA was reported elsewhere.[26] The dyes of CV and TF are the same samples as were reported previously.[4] The NaPP samples (with number-average degrees of polymerization, $\bar{n}$, of 154 and 158) used in this work are the same refractionated preparations as have been described elsewhere.[2] The difference in the degree of polymerization of the two NaPP's did not affect the metachromasy for CV and TF.[2,3]

Procedure. A series of absorption spectra of a dye solution were measured by titrating it with an NaPP solution delivered through a micrometer buret (Gilmont). The volume change in the titrate was made smaller than 10% so as not to shift the binding equilibrium. The concentration of the dye solution was optically determined immediately before the addition of the NaPP solution from the molar absorption coefficient: 1.03×10^4 at 401 nm for AA, 9.20×10^4 at 592 nm for CV, and 4.67×10^4 at 452 nm for TF. The initial concentrations of AA, CV, and TF were 44.3 μM (1 μM = 1×10^{-6} mol dm^{-3}), 8.37 μM, and 9.58 μM re-

spectively. The residue concentrations of the titrant NaPP were 0.847 M ($\bar{n}=158$) for AA and 0.301 M ($\bar{n}=154$) for CV and TF. The absorbances of NaPP in the UV range were subtracted from the observed absorbance of the AA–NaPP system.

Measurements. A Hitachi EPS-3T recording spectrophotometer was used together with matched pair of 1-, 2-, and 5-cm long quartz cells. The temperature of the solution was kept at 25 °C. Other precautions for measurements were described in Ref. 4.

The Extended Principal Component Analysis Method

The PCA method, which is applicable to the family of spectrophotometric data including absorption, CD, and ORD spectra for the determination of the number of components involved in a chemical equilibrium system, was extended to determine the equilibrium scheme, equilibrium constant, and the pure spectrum of components in an equilibrium system.[23,27] A specific application to the multiequilibrium system will be described here, because the description of the general method has been given previously.[4,23,27]

Assume that m observed absorption spectra are measured at n selected wavelengths, λ_j, $j=1\cdots n$. The observed data can be represented as an $m\times n$ matrix, $\boldsymbol{D}$:

$$\boldsymbol{D}=\begin{pmatrix} D_1(\lambda_1)\cdots D_1(\lambda_n) \\ \cdots\cdots\cdots\cdots \\ D_m(\lambda_1)\cdots D_m(\lambda_n) \end{pmatrix}. \tag{1}$$

The number of absorbing species, which are assumed to vary independently, can be determined by the variation in the eigenvalue of the second-moment matrix, $\boldsymbol{A}$, which is constructed by the product of the data matrix, $\boldsymbol{D}$, and its transposed matrix, ${}^t\boldsymbol{D}$: $\boldsymbol{A}={}^t\boldsymbol{D}\boldsymbol{D}$. The eigenvalues and eigenvectors can be calculated by the diagonalization of the $\boldsymbol{A}$ matrix. The magnitude of the eigenvalue represents the contribution of the corresponding eigenvector to the $\boldsymbol{D}$ matrix. In view of the reading error of the observed spectra, if the ratio of a given eigenvalue to the maximum eigenvalue is greater than 10^{-5}, the corresponding eigenvector is thought to be significant. If p eigenvalues satisfy such a condition, one can conclude that the data matrix is composed of p independent principal components. The data matrix can be reconstructed by a linear combination of the p eigenvectors as follows:

$$\boldsymbol{D}=\boldsymbol{f}\boldsymbol{e}=\begin{pmatrix} f_{11}\cdots f_{1p} \\ \cdots\cdots \\ f_{m1}\cdots f_{mp} \end{pmatrix}\begin{pmatrix} e_{11}\cdots e_{1n} \\ \cdots\cdots \\ e_{p1}\cdots e_{pn} \end{pmatrix}, \tag{2}$$

where $\boldsymbol{f}$ is the linear combination coefficient matrix and $\boldsymbol{e}$ is the eigenvector matrix. Furthermore, the molar absorption coefficient matrix, $\boldsymbol{\varepsilon}$, which represents the pure spectrum of the p absorbing species, can also be transformed from the p eigenvectors by means of the transformation matrix, $\boldsymbol{t}$: $\boldsymbol{\varepsilon}=\boldsymbol{t}\,\boldsymbol{e}$.[23] The evaluation of the ε's is reduced to the problem of evaluating the $\boldsymbol{t}$ matrix.

According to Beer's law, a $\boldsymbol{D}$ matrix can also be represented by the product of a concentration matrix, $\boldsymbol{C}$, and an $\boldsymbol{\varepsilon}$ matrix: $\boldsymbol{D}=\boldsymbol{C}\,\boldsymbol{\varepsilon}$. Thus, the $\boldsymbol{C}$ matrix is given by the product of an $\boldsymbol{f}$ matrix and an inverse matrix of $\boldsymbol{t}$: $\boldsymbol{C}=\boldsymbol{f}\,\boldsymbol{t}^{-1}$.[23] The $\boldsymbol{f}$ matrix can be calculated from Eq. 2 by the least-squares method. Thus, the $\boldsymbol{C}$ matrix can also be evaluated if the $\boldsymbol{t}$ matrix is given.

The PCA method was extended to evaluate the most probable $\boldsymbol{t}$ matrix by successive examinations of the probable equilibrium equation for an unknown equilibrium system. A general expression for the equilibrium constant among the p absorbing species is:

$$K=\prod_{i=1}^{p}[X_i]^{\nu_i}, \tag{3}$$

where X_i is the ith absorbing component and ν_i is the stoichiometric coefficient of X_i, whose equilibrium concentration is denoted by the brackets. The substitution of the elements of the $\boldsymbol{C}$ matrix into the right-hand side of Eq. 3 yields m different values for K unless the elements of the $\boldsymbol{t}$ matrix and the assumed equilibrium expression are correct. In order to discriminate the most probable $\boldsymbol{t}$ matrix and the equilibrium expression from the remainder, the coefficient of the variation, S, of K is defined by Eq. 4 and used as a criterion:

$$S=\left(\frac{1}{m}\sum_{j=1}^{m}(K_j-\bar{K})^2\right)^{1/2}\Big/\bar{K}, \tag{4}$$

where $\bar{K}$ denotes the mean value of K_j. The elements of the $\boldsymbol{t}$ matrix and the equilibrium expression which yields the minimum S value can be determined by iterative calculations.

In the multiequilibrium system, the values of S are calculated for individual equilibrium constants, and then the mean value of the S's for the equilibrium constants is used as a criterion. In the iterative calculations, the $\boldsymbol{t}$ matrix sometimes gave as the S values some minima where the calculated concentrations and/or ε of absorbing species were negative. Therefore, the most probable $\boldsymbol{t}$ matrix was selected to yield the positive value for the concentrations and to minimize the value of S. In this work, an acceptable upper limit of 0.10 was preset for the minimized value of S in view of the experimental errors.[23] All the calculations were carried out with a HITAC-8700 computer in FORTRAN language.

Results

Absorption Spectra of AA–, CV–, and TF–NaPP Systems. The absorption spectra of dye–NaPP systems over a wide P/D region were measured in order to obtain significant information on the metachromasy by the use of the extended PCA method. The absorption spectra of AA were measured in both visible and UV wavelength ranges, because the ^1L_a and ^1L_b bands of free AA are located in visible and UV ranges separately.[21,28] As is shown in Fig. 1(a), the ε's of the four bands of AA in the visible range increase and their positions shift toward shorter wavelengths with the increase in P/D. A few UV absorption spectra of AA are shown in Fig. 1(b). The intensities of the two bands in the UV range also increase, and

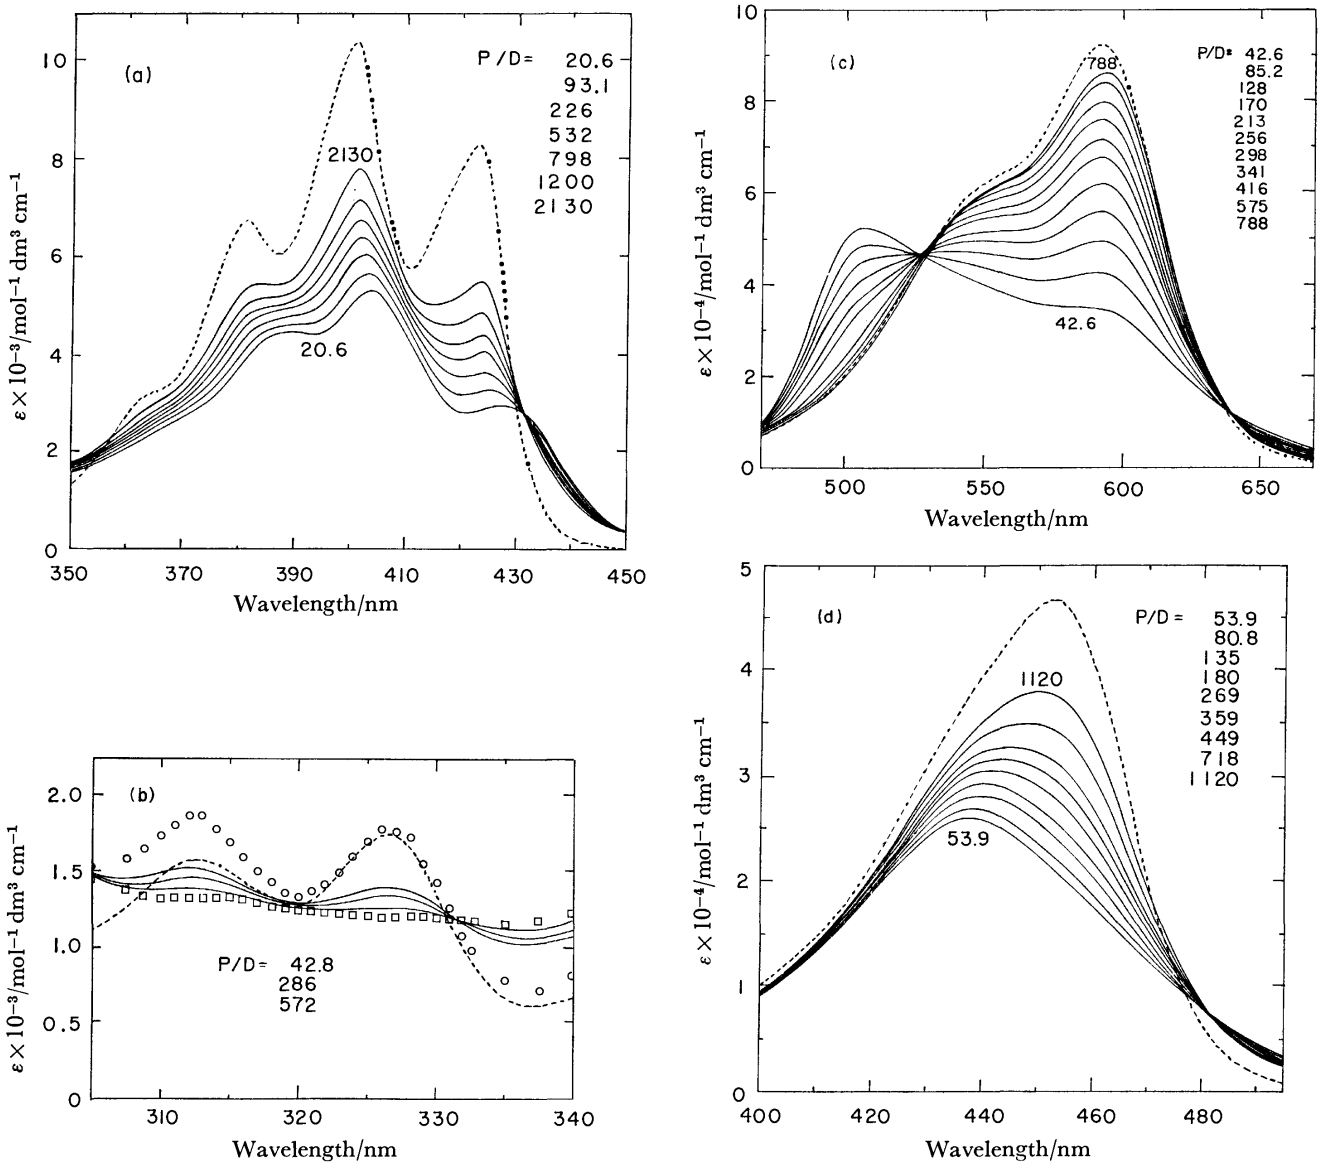

Fig. 1. Visible (a) and UV (b) absorption spectra of AA and visible absorption spectra of CV (c) and TF (d) in the high P/D region.
The concentrations of dyes are: (a) 44.3 μM, (b) 44.3 μM, (c) 8.37 μM, and (d) 9.58 μM. The concentrations of NaPP are listed in each figure in terms of P/D, the order of which corresponds to the order of the increase in the maximum absorbance. Spectrum of free dye is shown by dashed curve in each figure for comparison. Pure spectra of bound monomer (○) and dimer (□) are shown in (b).

TABLE 1. THE POSITIONS OF ISOSBESTIC POINTS

Dye	P/D	Wavelength/nm			
AA	0—1[a]	306	331	352	428
	26.6—2130	—	—	350	431
CV	0—1[b]	460	529	639

their positions shift toward shorter wavelengths with the increase in P/D. Figure 1(c) shows that a remarkable metachromasy band of CV observed at 510 nm gradually disappears and that the ε at the peak position of the free dye spectrum increases with the increase in P/D. In the TF–NaPP system, as is shown in Fig. 1(d), the ε at the absorption peak increases and its position shifts toward longer wavelengths with the increase in P/D.

The positions of the observed isosbestic points and P/D regions, in which the isosbestic points were observed, are listed in Table 1 for each system. In the CV- and TF–NaPP systems, the isosbestic points were observed within a high-P/D region, while those in the AA–NaPP system were observed over a wide P/D region. It is noteworthy that the isosbestic points observed in the high-P/D region differ from those in the low-P/D region in all the cases shown in Table 1. This means that more than two absorbing components are present throughout the P/D region.

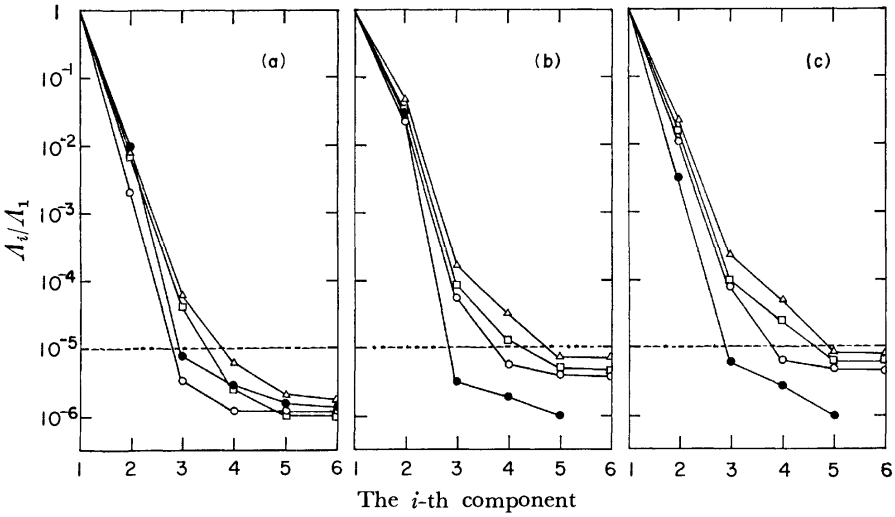

Fig. 2. Variation in eigenvalue Λ_i with the i-th absorbing component for various combinations of observed spectra in the systems of NaPP and AA (a), CV (b), and TF (c). P/D regions of spectra applied the PCA method are; ○: high P/D region ((a) P/D=26.6—2130, (b) 42.6—788, and (c) 53.9—1120), ●: low P/D region ((a) P/D=0—1.02, (b) 0—1.21, and (c) 0—1.25), □: high P/D region and free dye, △: high P/D region and low P/D region. The dashed line indicates the lower limit of the magnitude of eigenvalue for principal component. Selected wavelengths are (a) 48 points from 356 to 450 nm, (b) 50 points from 470 to 666 nm, and (c) 48 points from 400 to 494 nm.

CV	2[b)]	3	4	4
TF	2[b)]	3	4	4

a) Ref. 29. b) Ref. 4.

The Number of Absorption Species in AA–, CV–, and TF–NaPP Systems. In order to determine the number of absorbing species in each system, the PCA method was applied to the observed spectra. In each system, four data matrices were analyzed: 1) a set of spectra observed in the high-P/D region, 2) a set of spectra observed in the low-P/D region,[4,29)] 3) a set of spectra observed in both the low- and high-P/D region, and 4) a set of spectra observed in the high-P/D region and the spectrum of a free dye. The variations in the eigenvalues, Λ_i, with the ith component are shown in Figs. 2(a)—(c). The number of absorbing species in each set was determined by the use of the criterion mentioned in the previous section. The results listed in Table 2 show that three absorbing species of AA and four of CV and TF are present in the entire P/D region. In all the systems, the sum of the number of species in the low-P/D region and the number of species in the high-P/D region is greater by one than the number of species in the entire P/D region. That is, there is a common species in the low- and high-P/D regions. Furthermore, the results show that the absorbing species present in the high-P/D region differ from the free dye, because the number of species is increased by the addition of the spectrum of the free dye to the spectra observed in the high-P/D region. Thus, it can be said that two bound-dye species of AA and three of CV and TF are present in the high-P/D region. It can also be said that the amount of free dye in the high-P/D region is negligibly small. Therefore, the presence of the free dye can be neglected in the analysis of the observed data in the high-P/D region.

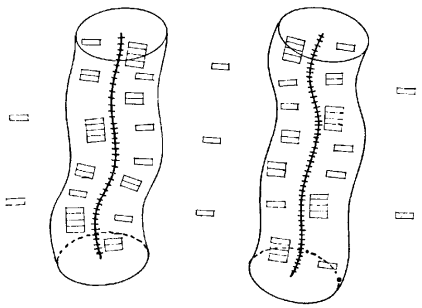

Fig. 3. Schematic model of dye–polyelectrolyte solution.

Equilibrium Scheme among the Bound-dye Species and Their Absorption Spectra. The number of bound-dye species determined in the preceding section is contrary to the number of those expected by the cooperative binding model, which has previously been used for Metachromasy,[9,10,24,25)] as will be discussed later. In this work, a model is used for the distribution of dyes in a polyelectrolyte solution on the basis of the theory for the condensation of the counter ion of a polymer.[30)] As is shown in Fig. 3, dyes in a polyelectrolyte solution are classified into two categories: dyes freely moving outside the region occupied by macroions, and those condensed as bound but mobile ions in the vicinity of the polymer. Assume that the equilibrium of aggregation among the bound

TABLE 3. VALUES OF S FOR EQUILIBRIUM SCHEMES EXAMINED

AA		CV				TF		
n	S	Scheme	S	Concn	Spectrum	S	Concn	Spectrum
2	0.075	I	—	posi.	neg.	—	posi.	neg.
3	0.22	II	0.21	posi.	neg.	0.22	posi.	neg.
4	0.52	III	0.09	posi.	posi.	0.09	posi.	posi.
		IV	—	posi.	posi.	—	posi.	neg.

—: $S>1$.

dyes is established inside the region occupied by macroions. Generally, the equilibrium equation for the aggregation can be expressed as follows:

$$n\mathrm{D}_1^b \rightleftharpoons \mathrm{D}_n^b, \tag{5}$$

where D_1^b is the bound monomer dye and D_n^b is the bound n-mer dye. In the vicinity of the polymer, the concentration of the respective bound-dye species may be proportional to the ratio of the amount of dyes to that of the polymer residues. Therefore, the equilibrium constant in the vicinity of the polymer can be represented as:

$$K = \frac{[\mathrm{D}_n^b]/C_p}{([\mathrm{D}_1^b]/C_p)^n} \tag{6}$$

where C_p denotes the total concentration of the polymer residues. In the application of the extended PCA method to the multiequilibrium system, such an expression for the equilibrium constant of the individual equilibrium is convenient for finding the most probable combination of equilibrium equations.

The presence of two bound-dye species in the high-P/D region of the AA–NaPP system was confirmed. Hence, the equations for the aggregation numbers, n, of 2, 3, and 4 were examined on the assumption that a bound-dye species is the bound monomer dye. The values of S, minimized for each n, are listed in Table 3. The minimized value of S for $n=2$ is smaller than the preset upper limit of S and is the smallest in the three cases of $n=2$, 3, and 4. The minimized values of S for $n=3$ and 4 exceed the preset upper limit; therefore, the aggregation number in the AA–NaPP system is two.

In both CV– and TF–NaPP systems, there are three bound-dye species, one of which may be the bound monomer. The following four equilibrium scheme were considered for those systems. As Scheme I, the simplest growth process of aggregation was adopted. The equilibrium equations and equilibrium constants can be expressed as follows:

$$2\mathrm{D}_1^b \rightleftharpoons \mathrm{D}_2^b, \quad K_1 = \frac{[\mathrm{D}_2^b]/C_p}{([\mathrm{D}_1^b]/C_p)^2}, \tag{7}$$

$$\mathrm{D}_1^b + \mathrm{D}_2^b \rightleftharpoons \mathrm{D}_3^b, \quad K_2 = \frac{[\mathrm{D}_3^b]/C_p}{([\mathrm{D}_1^b]/C_p)([\mathrm{D}_2^b]/C_p)}. \tag{8}$$

In Scheme II, the formation of the bound tetramer from two bound dimers was assumed to be as follows:

$$2\mathrm{D}_1^b \rightleftharpoons \mathrm{D}_2^b, \quad K_1 = \frac{[\mathrm{D}_2^b]/C_p}{([\mathrm{D}_1^b]/C_p)^2}, \tag{9}$$

$$2\mathrm{D}_2^b \rightleftharpoons \mathrm{D}_4^b, \quad K_2 = \frac{[\mathrm{D}_4^b]/C_p}{([\mathrm{D}_2^b]/C_p)^2}. \tag{10}$$

TABLE 4. EQUILIBRIUM CONSTANTS OF AGGREGATION AMONG THE BOND-DYE SPECIES AT 25 °C

Dye	K	K_1	K_2
AA	2.2×10^3		
CV		6.6×10^1	2.8×10^6
TF		2.8×10^2	2.8×10^7

The formation of a bound dimer from two bound monomers and the direct formation of a bound tetramer from four bound monomers were assumed to proceed as in Scheme III:

$$2\mathrm{D}_1^b \rightleftharpoons \mathrm{D}_2^b, \quad K_1 = \frac{[\mathrm{D}_2^b]/C_p}{([\mathrm{D}_1^b]/C_p)^2} \tag{11}$$

$$4\mathrm{D}_1^b \rightleftharpoons \mathrm{D}_4^b, \quad K_2 = \frac{[\mathrm{D}_4^b]/C_p}{([\mathrm{D}_1^b]/C_p)^4} \tag{12}$$

As Scheme IV, the formation of a bound trimer from three bound monomers and the formation of a bound hexamer from two trimers were assumed to proceed as follows:

$$3\mathrm{D}_1^b \rightleftharpoons \mathrm{D}_3^b, \quad K_1 = \frac{[\mathrm{D}_3^b]/C_p}{([\mathrm{D}_1^b]/C_p)^3} \tag{13}$$

$$2\mathrm{D}_3^b \rightleftharpoons \mathrm{D}_6^b, \quad K_2 = \frac{[\mathrm{D}_6^b]/C_p}{([\mathrm{D}_3^b]/C_p)^2} \tag{14}$$

The minimized S value for each scheme is listed in Table 3. In both CV– and TF–NaPP systems, the S value for Scheme III is the smallest among the four schemes and smaller than the preset upper limit of S, and all the corresponding concentrations and ε values are positive. The values of S for the formation of the trimer and the hexamer were extremely large whenever the $\boldsymbol{t}$ matrix gave positive values to the elements of the concentration matrix, $\boldsymbol{C}$.

The fractions of the bound monomer, f_1^b, and the bound dimer, f_2^b, of AA and the fractions of the bound monomer, the bound dimer, and the bound tetramer, f_4^b, of CV and TF obtained from $\boldsymbol{C}$ matrix are plotted as functions of P/D in Figs. 4(a)—(c). The equilibrium constants are listed in Table 4. In Fig. 4, the solid curves show the value of the fractions which were obtained by the Newton method with the values of K for AA or K_1 and K_2 for CV and TF by solving Eq. 6 ($n=2$ for AA) and Eqs. 11 and 12 (for CV and TF) at a given P/D ratio for the concentrations. In the AA–NaPP system, the fraction of the bound monomer increases and that of the bound dimer decreases with the increase in the P/D value. In both the CV– and TF–NaPP systems, the fraction of the bound monomer increases with the increase in P/D and that

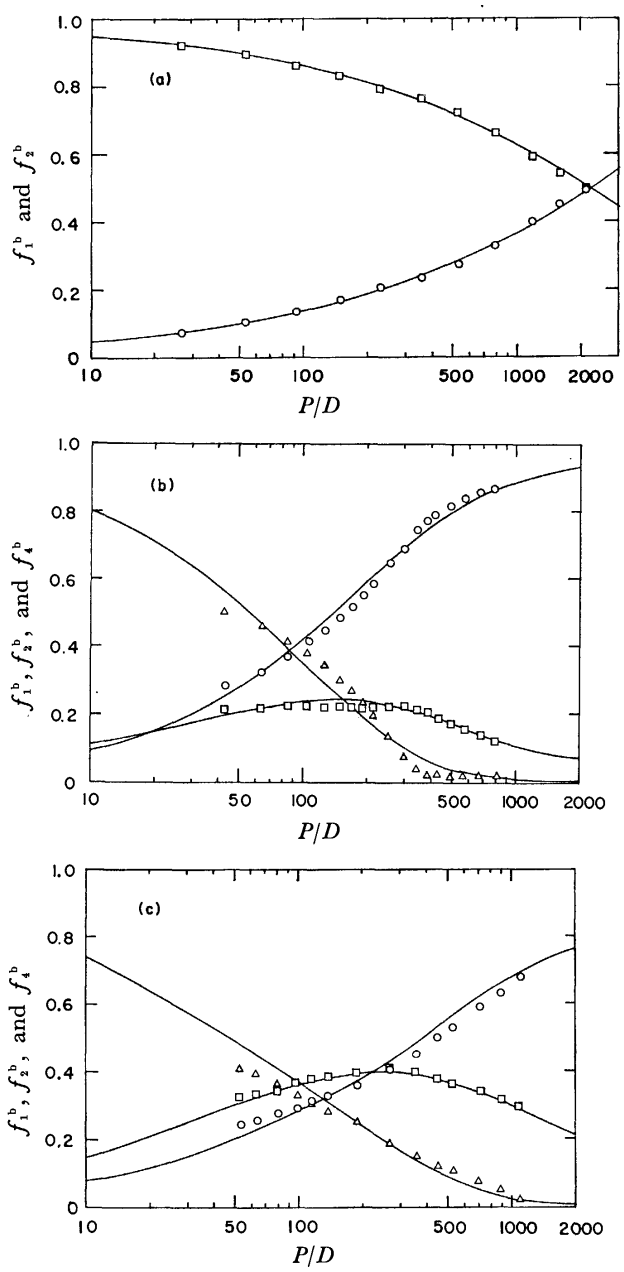

Fig. 4. Variation in the fraction of bound dye species with P/D for (a) AA–, (b) CV–, and (c) TF–NaPP systems.
○: Bound monomer, □: bound dimer, and △: bound tetramer.

of the bound dimer shows a maximum at a P/D value of *ca.* 200. The fraction of the bound tetramer tends to increase with the decrease in P/D.

The pure absorption spectra of bound-dye species of AA, CV, and TF thus obtained are shown in Figs. 5(a)—(c). In all the systems, a slight bathochromic shift is observed in the spectrum of the bound monomer. The absorption spectrum of the bound dimer of AA shows hypochromism and a bathochromic shift, while that of the bound dimer and tetramer of CV and TF has absorption bands at both shorter and longer wavelengths than the position of the main band of the free dye. It is noteworthy that the absorption spectrum of the bound dimer of AA and the bound tetramers of CV and TF excellently fits that of the bound-dye species obtained in the low-P/D region.[4,29]

The UV absorption spectrum of the bound monomer and dimer of AA shown in Fig. 1(b) was calculated from three observed spectra, while the fractions of the bound monomer and dimer were obtained from Fig. 4(a) by the least-squares method using the following equation:

$$\varepsilon_\lambda = f_1^b \varepsilon_\lambda^1 + f_2^b \varepsilon_\lambda^2, \tag{15}$$

where ε_λ^1 and ε_λ^2 denote the molar absorption coefficients of the monomer and the dimer respectively and where ε_λ denotes the apparent molar absorption coefficient of the observed spectrum at the λ wavelength. In the UV range, the absorption spectrum of the bound monomer shows a slight bathochromic shift, while that of the bound dimer shows hypochromism and a bathochromic shift, as is observed in the visible-wavelength range.

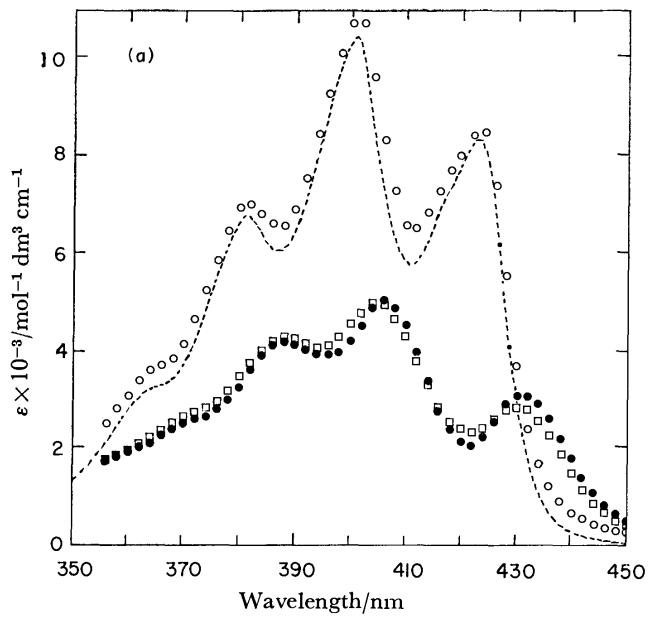
Discussion

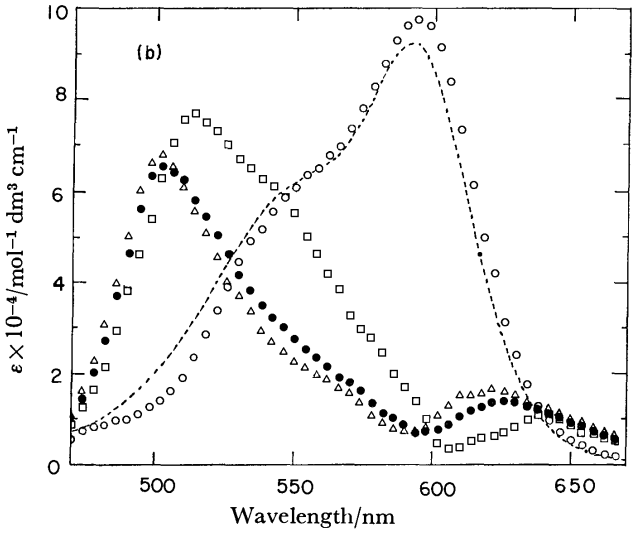
The Number of Bound-dye Species over a Wide P/D *Region.* In order to interpret the metachromasy, a model in which the dyes are bound cooperatively to polyelectrolyte has been used. According to the model, the spectral changes of the dye-polymer solution are attributed to the change in the distribution of dyes on the polymer. Several quantitative expressions[10,24,25] have been used for the distribution of dyes on the polymer chain, assuming that the aggregated dyes interact with the nearest neighbor bound dye. The cooperative binding model implies that the mean aggregation number depends on the P/D (*cf.* Eq. 22 in Ref. 10 and Eq. 22 in Ref. 25), so that a large number of bound-dye species are expected in the wide P/D region. Hence, in order to examine whether or not the cooperative-binding model expresses the metachromatic phenomena correctly, the number of bound-dye species has to be ascertained over a wide P/D region.

The application of the PCA method to the absorption spectra observed over a wide P/D region clearly revealed that there are only two bound-dye species for AA and only three for CV and TF. These results contradict the results expected from the cooperative-binding model.

Equilibrium Scheme of the Binding of Dye to NaPP. In this study, the bound dyes were assumed to be condensed near the polyelectrolyte. Therefore, the equilibrium scheme of the bound monomer⇌bound aggregate in the vicinity of the polymer molecule was examined by the extended PCA method. As is shown in Fig. 4, the agreement between the experimental and calculated data for the fraction of the respective bound-dye species is reasonably good. This means that the simple equilibrium equation expressed by Eq. 5 can be adopted to represent the metachromatic phenomena observed in the high-P/D region.

In a previous report,[4] the equilibrium constant for the binding of a dye to a polyelectrolyte in the low-P/D region less than unity was expressed as follows:





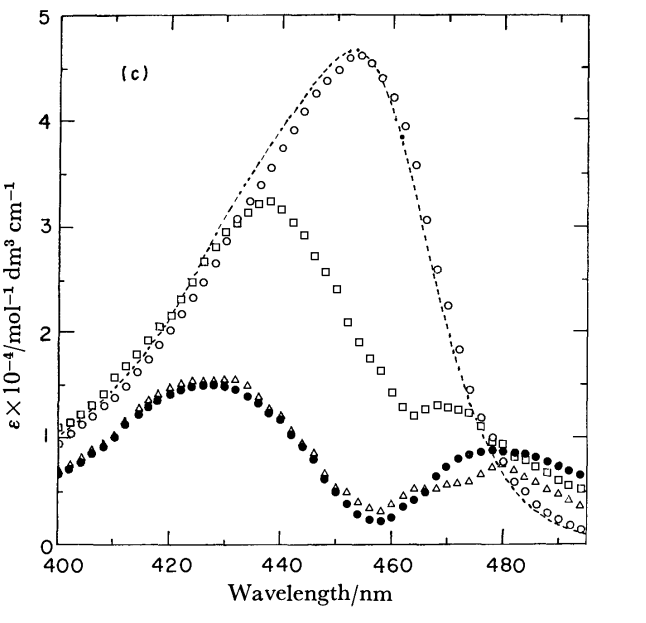


Fig. 5. Pure absorption spectra of bound dyes of AA (a), CV (b), and TF (c).
○: Bound monomer, □: bound dimer, and △: bound tetramer. The absorption spectrum of free dye and bound dye spectrum obtained in the low P/D region are shown by dashed curve and closed circles respectively.

$$K = \frac{[\text{complex}]}{[\text{free dye}][\text{unoccupied binding site}]^{\alpha}}, \tag{16}$$

where α is an empirical parameter. This equation may represent the distribution of the free dye and the total condensed dye in a solution; then the equilibrium constant for the formation of an aggregate in the vicinity of the polymer may be expressed by Eq. 6. Therefore, the amount of dye molecules represented as a complex in Eq. 16 is equal to the sum of the dye molecules of the respective bound-dye species. The fraction of the bound dimer of AA and that of the bound tetramers of CV and TF tends to increase up to unity in the low-P/D region, as is shown in Fig. 4. Hence, the amount of the dye molecules of the complex in Eq. 16 is nearly equal to that of the bound dimer for AA and that of the bound tetramers for CV and TF in the low-P/D region. This is consistent with the fact that the spectrum of the bound dimer of AA and that of the bound tetramers of CV and TF fits into the spectrum of the bound-dye species obtained in the low-P/D region. That is, the bound dimer of AA and the bound tetramers of CV and TF may be primarily present in the low-P/D region. Pal and Mandel[31] also suggested, for the pynacyanol–poly(L-glutamic acid) system, that dyes bound to a long polymer chain may form several small stacks, primarily tetra- and pentamer.

Equation 6 can be express another equilibrium scheme when the equation is rewritten with attention to the counter ion of the polyelectrolyte. In the polyelectrolyte solution without any added salt, the concentration of counter ions, for example, that of Na of NaPP, is equal to that of the polymer residues, so that Eq. 6 can be rewritten as follows:

$$K = \frac{[\mathrm{D}_n^b][\mathrm{Na}]^n}{[\mathrm{D}_1^b]^n[\mathrm{Na}]} = \frac{[\mathrm{D}_n^b][\mathrm{Na}]^{n-1}}{[\mathrm{D}_1^b]^n}. \tag{17}$$

In a previous report,[5] it was clarified that the fraction of bound CV and TF at a P/D, for example, $P/D=1$, increases with an increase in the chain length of NaPP. It was also reported that the amount of bound Na increases with an increase in the chain length of NaPP.[32] These facts suggest that the polyelectrolyte condenses not only the dyes, but also the counter ions, near it and that complexes are formed with the polymer residues, the dyes and the counter ions. Therefore, if it can be assumed that the dyes are bound to the polymer by the Na, Eq. 17 can be rewritten as follows:

$$K = \frac{[\mathrm{NaD}_n^b][\mathrm{Na}]^{n-1}}{[\mathrm{NaD}_1^b]^n}. \tag{18}$$

That is, this equation represents the following scheme:

$$n\mathrm{NaD}_1^b \rightleftharpoons \mathrm{NaD}_n^b + (n-1)\mathrm{Na} \tag{19}$$

where n bound monomers, which are bound to the

polymer by an Na, form the n-mer bound to the polymer by an Na. The participation of sodium in the formation of the dye–polyelectrolyte complex might be represented by the empirical parameter, α, introduced into Eq. 16, as has previously been mentioned.[4,5] The participation of sodium in the metachromasy could not be examined by the PCA method; however, it may be examined by means of electrochemical measurements, such as electrophoretic, potentiometric, and conductometric measurements.[2,3,33]

The Pure Spectrum and Structure of Bound-dye Species. The pure spectra of bound-dye species could be obtained for AA, CV, and TF by the application of the extended PCA method to a set of absorption spectra observed over a wide P/D region. It was revealed that the absorption spectra of the bound monomers of AA, CV, and TF show a slight bathochromic shift. The visible and UV absorption bands of AA, CV, and TF are attributable to the π-π^* transition.[34,35] The bathochromic shift of the π-π^* transition is generally induced by interaction with the polar solvent or the formation of a hydrogen bond.[36] Therefore, the bathochromic shift observed for the bound monomer may be due to the interaction between the dye and the ionized group of NaPP. The observed bathochromic shift is very small, so that it may be thought that the dye in monomeric form is loosely bound to NaPP and moves in its vicinity. Yamaoka and Noji[37] reported a sharp triplet line in the ESR spectrum of the spin-labeled proflavine–NaPP system at $P/D=200$; this also suggests that a bound-dye species rotates or moves rapidly.

The absorption spectrum of the bound dimer of AA shows a bathochromic shift, while those of the bound dimer and tetramer of CV and TF have absorption bands at wavelengths both shorter and longer than the position of the main band of the free dye. According to the exciton theory for metachromasy,[38] the relations between the position of the metachromasy bands and the orientation of the transition moments in a dye oligomer have been classified into three categories: (i) a parallel side-by-side orientation of the particular transition moments gives rise to the band on the shorter-wavelength side of the transition characterizing the monomer, (ii) an asymmetric oblique orientation gives rise to two bands, on both shorter- and longer-wavelength side, and (iii) a head-to-tail orientation gives rise to a band on the longer-wavelength side. Both the visible and UV absorption spectra of the bound dimer of AA show a bathochromic shift. The visible and UV transition moments of the monomer-free AA are at right angles.[21,28] If a pair of transition moments of AA is oriented head-to-tail in a dimer so as to have a band on the longer-wavelength side, the other pair of transition moments must be oriented side-by-side so as to have a band on the shorter-wavelength side. That is, the relation between the position of the metachromasy bands and the orientation of the transition moment in the dimer of AA is not classified into any category.

The position and number of metachromasy bands may be related to the symmetry of the dye structure, because the absorption spectrum of spin-labeled proflavine, in which the two-fold symmetry of proflavine is distorted by the spin-labeling to an amino group, has two bands, at wavelengths both shorter and longer than the position of the main band of proflavine,[29] while that of doubly spin-labeled proflavine, which is labeled at two aminogroups and which has a two-fold symmetry, has a band on the shorter-wavelength side.[39] Therefore, the absorption spectrum of a dye may have bands at wavelengths both shorter and longer than the position of the original band when the symmetry of the dye is sufficiently distorted. On the other hand, when the symmetry characterizing the monomer dye is not distorted sufficiently by the interaction between the dye and another substance, the absorption spectrum may show only a shift, without any new band. Therefore, the model of the bound dimer shown in Fig. 6 was considered for AA, CV, and TF. In the model, it was assumed that two dye molecules are combined not only by hydrophobic interaction, but also by the interaction between positively charged nitrogen and amino or dimethylamino nitrogen. Then, each of the two dyes has a two-fold symmetry in AA, while the symmetry of the monomer dye is distorted in the dimers of CV and TF.

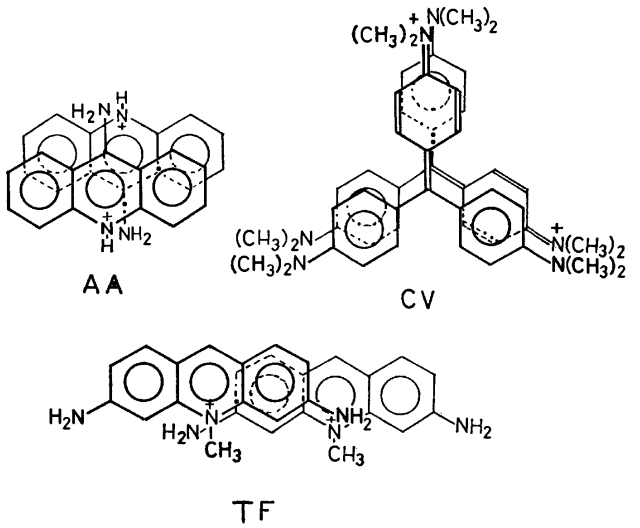

Fig. 6. Schematic model of bound dimer.

The symmetry in the bound tetramer may be more heavily distorted than that in the dimer, because the absorption band located on the shorter-wavelength side shows a larger hypsochromic shift in the bound tetramer than in the bound dimer, as is shown in Figs. 5(b) and (c). The bound tetramers of CV and TF may be more attracted than the monomer by the NaPP because of the four postively charged nitrogen atoms. Therefore, the conformation of the bound aggregate may depend on the backbone structure of the polymer, such as the mean distance between the functional groups of the polymer. Hence, the position and intensity of the absorption bands of the bound-dye species may depend on the polymers, as has previously been mentioned.[4]

For a quantitative discussion of the position of metachromasy bands, however, information is necessary on the electronic states and transition moments of the

aggregated dyes. The LCAO calculation may provide such information. Since the extended PCA method is powerful in a multicomponent system, its application to a series of absorption spectra of dye–polyelectrolyte systems at various temperatures or ionic strenghts should yield information leading to a fuller understanding of metachromasy.

Conclusion

The number of bound-dye species was determined to be two for the AA–NaPP system and three for the CV– and TF–NaPP systems. Using a simple model, in which the condensation of dyes near the polymer is assumed, the equilibrium constant, aggregation number, and pure absorption spectra of the bound-dye species were determined by the extended PCA method. The spectrum of the bound monomer shows a slight bathochromic shift in all cases. The absorption spectrum of the bound dimer of AA shows a considerable bathochromic shift. On the other hand, the absorption spectra of the bound dimer and tetramer of CV and TF have absorption bands at wavelengths both shorter and longer than the position of the main bands of free CV and TF.

The author wishes to express his hearty gratitude to Assistant Professor Kiwamu Yamaoka of Hiroshima University for his helpful discussions and continuous encouragement in the course of this study.

Shapes of the ν_1 Band of Liquid Chloroform and Intermolecular Interaction

Tetsuo SUZUKI, Yumiko K. TSUTSUI, and Tsunetake FUJIYAMA*,†

(Received January 5, 1980)

The infrared absorption spectrum for the ν_1 fundamental of chloroform or chloroform-*d* shows strong asymmetry, with a remarkable tailing on the high-frequency side. The observed band-width of the ν_1 fundamental of chloroform-*d* is significantly narrower than that of chloroform. These asymmetric band profiles of the ν_1 bands of chloroform and chloroform-*d* can be interpreted in terms of the existence of two different types of chloroform molecules. One is a molecule which interacts with another molecule, and the other is a non-interacting molecule. The isotope effect on the band-width can be explained in terms of the difference in the reduced mass for chloroform and chloroform-*d*.

It has been well established, that the absorption maximum of the infrared absorption spectrum for the ν_1 band of chloroform decreases from 3033 to 3018 cm^{-1}, and that the intensity increases from 11 to 198 $cm^2\ mol^{-1}$, on passing from the gas to the liquid phase.[1,2] These spectral changes have been interpreted in terms of the formation of hydrogen bonding in the liquid phase.[3] However, Rothschild *et al.* have studied the band shapes of the Raman scattering spectra and the infrared absorption spectra for the ν_1 band of chloroform and have concluded that the vibrational relaxation processes for the ν_1 band of chloroform do not support the presence of hydrogen bonding in the pure liquid.[4] Thereafter, several studies of the line-shape of the ν_1 band of chloroform and chloroform-*d* in the liquid phase have been reported.[5—9] All these reports have concluded that the shape of the ν_1 band may not be affected by the existence of hydrogen bonding. In other words, the observed width of the ν_1 band has been regarded as a homogeneous width. However, as will be shown in the present report, the observed infrared absorption spectrum for the ν_1 fundamental of chloroform or chloroform-*d* shows strong asymmetry, with a remarkable tailing on the high-frequency side. Therefore, the observed band-width can not be analyzed on the basis of the homogeneous width.

It has also been established that the band-width of the ν_1 fundamental of chloroform-*d* is significantly narrower than that of chloroform. Moradi-Araghi *et al.* have considered that the increased vibrational relaxation rate in chloroform, in comparison with that in chloroform-*d*, is ascribable to the stronger coupling between the ν_1 vibration and the molecular motions in the liquid, which itself arises from the anharmonic terms in the vibrational Hamiltonian.[8]

We will show in the present report that the observed asymmetric band profiles of the infrared-absorption spectra for the ν_1 bands of chloroform and chloroform-*d* can be interpreted in terms of the existence of a hydrogen-bonding-like interaction in the liquid phase. It will also be shown that the isotope effect on the band-width can be explained in terms of the difference in the reduced mass for chloroform and chloroform-*d* instead of the anharmonicity in the vibrational Hamiltonian.

Experimental

All the chemicals used in this work were commercially available reagents. The chloroform was passed through a chromatographic column packed with alumina to remove the ethanol used as a stabilizer. The eluent was fractionally distilled. The elimination of water and ethanol from the sample solution was confirmed by observing the infrared-absorption spectra. The chloroform-*d* was purchased from E. Merck Co., Ltd., and was dried over zeorite A-3. The carbon tetrachloride was purified by fractional distillation. The solutions were prepared gravimetrically.

The absorption spectra were recorded with a Perkin-Elmer 180 infrared spectrometer at the temperature of 22± 1 °C. A sample cell with NaCl windows was used, and the thickness of a sample was determined by the interference-fringe method. The absorption spectra of the ν_1 bands of chloroform and chloroform-*d* were measured under resolutions of 0.7 cm^{-1} and 0.5 cm^{-1} respectively and at the scanning speed of 4 $cm^{-1}\ min^{-1}$.

The observed spectra were then reduced to:

$$\frac{1}{lv}\ln\left(\frac{I_0}{I}\right)$$

where v is the wave number in cm^{-1}; l, the thickness of the sample; I_0 the intensity of the incident light, and I, the intensity of the transmitted light. The relative intensities, I^c, were defined as:

$$I^c = \frac{f_d}{l}\int_{band}\frac{1}{v}\ln\left(\frac{I_0}{I}\right)dv \qquad (1)$$

where f_d is the correction factor for the dielectric-field effect. Since the intensities of the observed bands were weak, Polo-Wilson's scheme[10] was applied to the dielectric-field correction; that is, the correction factor, f_d, was expressed as:

$$f_d = \frac{9n_D}{(n_D^2+2)^2} \qquad (2)$$

where n_D is the refractive index of the solution.

Results and Discussion

Observed Spectra. The observed spectra of the ν_1 band of pure liquid chloroform are shown in Fig. 1 (see the circles). The peak frequency and the full width at the half maximum are found to be 3018 cm^{-1} and 12.8 cm^{-1} respectively. It is apparent from the figure that the part of the half-intensity band-width which falls on the high-frequency side of the

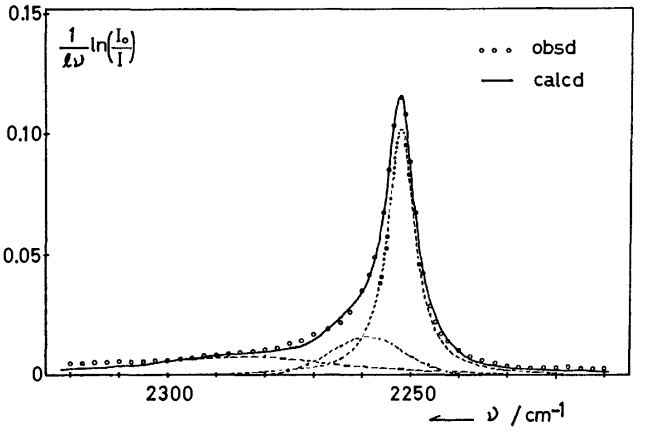

Fig. 2. Observed (circles) and calculated (real line) spectra for the ν_1 band of $CDCl_3$.

band maximum is broader than the corresponding part on the low-frequency side. The observed spectrum of the ν_1 band of pure liquid chloroform-*d* is shown in Fig. 2 (see the circles). The peak frequency and the full width at half the maximum are found to be 2252 cm^{-1} and 8.0 cm^{-1} respectively. The observed band profile of chloroform-*d* is similar to that of chloroform. However, there appears a remarkable isotope effect on the vibrational band-width.

Separation of the Observed Band into Symmetry Band Profiles. First, our attention was focused on the asymmetry of the band profile observed for the ν_1 band of chloroform. It can easily be ascertained that the asymmetry does not originate from any hot bands or any bands originating from isotopic species. Also, the asymmetry cannot be ascribed to any overlapping of summation bands, because the asymmetric band profiles are closely analogous both for pure liquid chloroform and chloroform-*d*.

An attempt was made, therefore, to resolve the observed asymmetric band profile into some symmetric intensity distribution functions in order to understand the origin of the asymmetry. First, we used two Lorentzian functions which correspond to the peaks at 3060 and 3018 cm^{-1} for pure chloroform (see Fig. 1). The agreement between the calculated and observed profiles was poor until we added another band between the 3060 and 3018 cm^{-1} bands. The best fit between the observed and calculated profiles has been obtained by considering two Lorentzian functions near 3060 and 3018 cm^{-1} and one Gaussian function near 3030 cm^{-1}. The explicit expression of the linear combination is given by:

$$F(\nu) = \frac{h_1\gamma_1^2}{(\nu-\nu_1)^2+\gamma_1^2} + h_2\exp\left\{-\frac{\ln 2}{\gamma_2^2}(\nu-\nu_2)^2\right\} + \frac{h_3\gamma_3^2}{(\nu-\nu_3)^2+\gamma_3^2}. \quad (3)$$

The observed and calculated spectra of the ν_1 band of chloroform are shown in Fig. 1. The best-fit parameter values of these functions are summarized in Table 1. Hereafter, we will call the broader Lorentzian at the highest frequency "the band 3," the narrower Lorentzian at the lowest frequency "the band 1," and the Gaussian "the band 2."

Table 1. Best-fit parameters of the ν_1 bands of $CHCl_3$ and $CDCl_3$

		Band 1	Band 2	Band 3
$CHCl_3$	γ/cm^{-1}	5.1	12	28
	h	0.1220	0.0204	0.0106
	ν/cm^{-1}	3017.5	3028	3062
	I^c/cm^{-1}	1.522	0.406	
$CDCl_3$	γ/cm^{-1}	3.4	9	22
	h	0.1025	0.0160	0.00799
	ν/cm^{-1}	2252	2259	2284
	I^c/cm^{-1}	0.853	0.239	

For chloroform-*d*, the observed intensity distribution was also expressed by a linear combination of two Lorentzian functions and one Gaussian function, as is shown in Fig. 2. The best-fit parameter values of the functions for chloroform-*d* are also listed in Table 1.

Assignment of the Resolved Bands. In order to assign the resolved bands, the spectra of the ν_1 band observed in the liquid phase are compared with those observed in the gas and solid phases in Table 2. The ν_1 band is observed at 3033 and 3007 cm^{-1} in the gas and solid phases respectively. The intensity of the ν_1 band, on the other hand, increases from 11 to 400 cm^2 mol^{-1} on passing from the gas to the solid phase. As is seen in Table 2, the frequency and intensity observed in the liquid phase take values intermediate between those of the gas and solid phases. These spectral changes have been interpreted in terms of the hydrogen-bond formation between chloroform molecules.[3] Therefore, it is reasonable to expect the existence of the two kinds of chloroform molecules in the liquid phase. One is a molecule which forms a hydrogen bonding with another chloroform molecule; the other is a molecule which behaves rather like a free molecule. We call these two kind of chloroform molecules a "strongly interacting molecule" and a "weakly interacting molecule" respectively.

Based upon these ideas, we assign the band 1 at the lowest frequency to the ν_1 vibration of the strongly

Table 2. Observed intensities and frequencies for the ν_1 bands of $CHCl_3$ and $CDCl_3$ in the gas, liquid, and solid phases

	Frequency, ν_0/cm^{-1}			Intensity, Γ/cm^2 mol^{-1}		
	Gas	Liquid	Solid[d]	Gas[a]	Liquid[c]	Solid[d]
$CHCl_3(\nu_1)$	3032.9[b]	3018	3007	11	198	400
$CDCl_3(\nu_1)$	2265[a]	2252	2250	3	127	133

Table 3. Concentration dependence of band parameters and intensities

	mol % ($CHCl_3$)	100	80	50	40	20
Band 1	ν_0/cm^{-1}	3017.5	3017.5	3017.5	3017.5	3017.5
	$\Delta\nu_{1/2}$/cm^{-1}	10.2	10.2	10.2	10.2	10.2
	I^c/cm^{-1}	1.552	1.078	0.758	0.495	0.216
	I^*/cm^{-1}	1.552	1.347	1.264	1.238	1.081
Band 2	ν_0/cm^{-1}	3028	3027	3027	3027	3026
	$\Delta\nu_{1/2}$/cm^{-1}	24	24	24	24	24
	I^c/cm^{-1}	0.406	0.336	0.270	0.186	0.0972
	I^*/cm^{-1}	0.406	0.421	0.450	0.466	0.486

interacting molecule. The band 2, on the other hand, is assigned to the ν_1 vibration related to the weakly interacting molecule.

The assignment of the band 3 has not yet been established. Its band maximum is observed 40 cm^{-1} higher than that of the band 1 and its half-width is much broader than that of the band 1. Therefore, we can safely conclude that the band 3 is not related to any fundamental vibrations. As no absorption band is observed in this wavenumber region for the gas sample,[2] it may arise from the combination tone of the ν_1 fundamental and the pseudo-lattice vibrations.[11]

If the assignments of the bands 1 and 2 are correct, the relative intensities, I_2/I_1, of the bands 1 and 2 should be equal for liquid chloroform and chloroform-*d*. It may be seen from Table 1 that the relative intensity, I_2^c/I_1^c, was observed to be 0.27 in chloroform and 0.28 in chloroform-*d*. These results partially support the validity of the present assignment of the bands 1 and 2.

Concentration Dependence of the Relative Intensities of the Band 1 and the Band 2. In order to confirm the validity of the assignment of the band 1 and the band 2, the concentration dependence of the intensities of the band 1 and the band 2 were observed in the binary solutions of chloroform–carbon tetrachloride. Since excess enthalpy is positive in a chloroform–carbon tetrachloride mixture,[12] the existence of a hydrogen-bonding-like interaction can be expected between chloroform molecules. This interaction is assumed to be broken down in the carbon tetrachloride solution. With the increase in the carbon tetrachloride concentration, therefore, it is expected that the number of the strongly interacting molecules will decrease while the number of the weakly interacting molecules will increase. In other words, the intensity of the band 1 is expected to decrease, while that of the band 2 is expected to increase.

The intensity change due to dilution is listed in Table 3. The quantities, I_1^* and I_2^*, of the table are defined as:

$$I_1^* \equiv \frac{c_0 f_d}{cl}\int_{\text{band 1}} \frac{1}{\nu}\ln\left(\frac{I_0}{I}\right)d\nu \simeq \frac{c_0 f_d}{cl}\int \frac{h_1\gamma_1^2}{(\nu-\nu_1)^2+\gamma_1^2}d\nu \quad (4)$$

$$I_2^* \equiv \frac{c_0 f_d}{cl}\int_{\text{band 2}} \frac{1}{\nu}\ln\left(\frac{I_0}{I}\right)d\nu \simeq \frac{c_0 f_d}{cl}\int h_2 \exp\left\{-\frac{\ln 2}{\gamma_2^2}(\nu-\nu_2)^2\right\}d\nu, \quad (5)$$

in cm^{-1}, where c_0 is the molar concentration of chloroform in pure liquid and c, the molar concentration of chloroform in solution. Table 3 shows that, as the concentration of carbon tetrachloride increases, I_1^* decreases, while I_2^* increases. These results support the validity of the assignments for the band 1 and the band 2.

Based upon these results, an attempt was made to obtain the absolute intensities of the band 1 and the band 2. The absolute intensities, Γ_1 and Γ_2, are given by:

$$I_1^* = c_0\frac{c_1}{c}\Gamma_1 \quad (6)$$

$$I_2^* = c_0\frac{c_2}{c}\Gamma_2 \quad (7)$$

where c_1 and c_2 are the molar concentrations of the chloroform molecules corresponding to the band 1 and the band 2 respectively. The $c=c_1+c_2$ relation and Eqs. 6 and 7 give the relation:

$$\frac{I_1^*}{\Gamma_1}+\frac{I_2^*}{\Gamma_2} = c_0$$

or:

$$I_1^* = -(\Gamma_1/\Gamma_2)I_2^* + \Gamma_1 c_0. \quad (8)$$

By plotting I_1^* against I_2^* at a series of concentrations, a straight line with a slope of $-(\Gamma_1/\Gamma_2)$ is generated so long as the absolute intensities, Γ_1 and Γ_2, are independent of the concentration. The values of Γ_1 and Γ_2 are obtained from the extrapolated I_1^* value at $I_2^*=0$ and the (Γ_1/Γ_2) value.[13]

TABLE 4. INTENSITIES AND FREQUENCIES OF THE BAND 1 AND BAND 2, AND THE ν_1 BANDS IN THE GAS AND SOLID PHASES

	Gas	Liquid		Solid[c]
		Band 1	Band 2	
Γ/cm^2 mol^{-1}	11[b]	250—300	45—60	400
ν_0/cm^{-1}	3032.9[a]	3017.5	3028	3007

a) See Ref. 2. b) See Ref. 1. c) See Ref. 16.

The values of the peak frequencies and the absolute intensities for the band 1 and the band 2 are listed in Table 4, together with those values for pure chloroform in the gas and solid phases. It may be seen from the table that the peak frequency and the absolute intensity of the band 1 are rather close to those values for the solid chloroform. On the other hand, the peak frequency and the absolute intensity of the band 2 are closer to those values for the gas chloroform. These results are consistent with the idea that there exist two kinds for chloroform molecules in the liquid phase. One is a strongly interacting molecule which causes the band 1 to appear, while the other is a rather weakly interacting molecule which causes the band 2 to appear.

Incidentally, the relative population of the strongly interacting molecules to the weakly interacting molecules in liquid chloroform was estimated to be 44% using the values of Γ_1 and Γ_2 and also Eqs. 6 and 7.

Isotope Effect on the Band-width. It is of much interest to consider the isotope effect on the band-width of the ν_1 fundamental. The band-widths of the ν_1 fundamentals are observed to be quite different for liquid chloroform and chloroform-*d* (see Table 1). This result is rather strange because of the following reason.

If the coupling between the vibrational and rotational motions of a molecule is negligible, the observed band-width, $\Delta\nu_{1/2}$, of an infrared spectrum may be expressed as:

$$\Delta\nu_{1/2} = \delta_v + \delta_r \tag{9}$$

where δ_v is the width originating from the vibrational relaxation and δ_r, the width originating from the reorientational relaxation. Since the moments of inertia and viscosity are almost equal for chloroform and chloroform-*d*, the values of δ_r for chloroform and chloroform-*d* should be almost equal also. It is ascertained that the effect of the vibrational relaxation of the resonace type is negligibly small for the ν_1 band because of the weak absorption intensity.[14] Therefore, we tried to explain the isotope effect on the band-width by considering the random modulation of vibration frequencies due to the surrounding molecules.

In order to elucidate the isotope effect on the vibrational relaxation due to the random-frequency modulation, we consider a harmonic oscillator whose vibrational frequency is modulated by a stochastic potential, $V(t)$, arising from the neighbouring molecules. In the present case, it can reasonably be assumed that the dissipation process of the vibrational energy is negligible, because the correlation time of $V(t)$ is much longer than the inverse of the harmonic frequency of the unperturbed oscillator. The vibrational relaxation function is, then, characterized by two parameters: the mean-square magnitude of the frequency shift, Δ, and the correlation time of the stochastic potential, τ_c, which are defined as:

$$\Delta^2 \equiv \langle(\Delta\omega)^2\rangle \tag{10}$$

$$\tau_c \equiv \frac{1}{\Delta^2}\int_0^\infty \langle\Delta\omega(0)\Delta\omega(t')\rangle dt' \tag{11}$$

where $\Delta\omega$ is the vibrational frequency shift due to the stochastic potential and where $<\ >$ indicates an average over the ensemble.[15]

If the condition

$$\Delta\cdot\tau_c \gg 1 \tag{12}$$

is fulfilled, the frequency modulation is very slow. Therefore, a line shape is a direct reflection of the random distribution of $\Delta\omega$. If the random distribution of $\Delta\omega$ is Gaussian, the vibrational relaxation function, $\psi_v(t)$, is also Gaussian, as is expressed by:

$$\psi_v(t) = \exp(i\omega_0 t)\exp\left(-\frac{\Delta^2}{2}t^2\right) \tag{13}$$

where ω_0 is the harmonic frequency of the unperturbed oscillator. Therefore, the corresponding line shape function, $I(\omega)$, is:

$$I(\omega) = \frac{1}{\sqrt{2\pi}\Delta}\exp\left\{-\frac{(\omega-\omega_0)^2}{2\Delta^2}\right\} \tag{14}$$

and the half-width due to the vibrational relaxation, δ_v, becomes:

$$\delta_v = 2\sqrt{2\ln 2}\,\Delta. \tag{15}$$

On the other hand, if the condition

$$\Delta\cdot\tau_c \ll 1 \tag{16}$$

is fulfilled, the frequency modulation is fast and the spectrum shows the phenomenon of motional narrowing. The vibrational relaxation function, $\psi_v(t)$, is expressed as:

$$\psi_v(t) = \exp(i\omega_0 t)\exp(-\Delta^2\tau_c|t|). \tag{17}$$

The line-shape function, $I(\omega)$, is expressed as:

$$I(\omega) = \frac{1}{\pi}\frac{\Delta^2\tau_c}{(\omega-\omega_0)^2+(\Delta^2\tau_c)^2}. \tag{18}$$

Therefore, the half-band width is:

$$\delta_v = 2\Delta^2\tau_c. \tag{19}$$

Since the correlation time, τ_c, of $V(t)$ is rather similar for the two isotope species, the isotope effect on the band-width may be ascribed to the mean-square magnitude, Δ, of the frequency shift. For the fundamental band, the frequency shift, $\Delta\omega$, originating from the intermolecular potential, V, is given by:

$$\Delta\omega = \frac{1}{2\omega_0}\left(\frac{\partial^2 V}{\partial Q^2}\right)_0 \tag{20}$$

where Q is the normal coordinate corresponding to the harmonic vibration. As Q is expressed as:

$$Q = \sqrt{\mu}\,\Delta r \tag{21}$$

where μ is the reduced mass of the oscillator, and Δr, the displacement from equilibrium, $(\partial^2 V/\partial Q^2)_0$ is given by:

Table 5. Calculated values of δ_r and δ_v

Modulation		Band 1		Band 2	
		δ_v/cm^{-1}	δ_r/cm^{-1}	δ_v/cm^{-1}	δ_r/cm^{-1}
Slow	$CHCl_3$	13.4	−3.2	23.6	0.4
	$CDCl_3$	10.0	−3.2	17.6	0.4
Fast	$CHCl_3$	7.7	2.5	13.5	10.5
	$CDCl_3$	4.3	2.5	7.5	10.5

$$\left(\frac{\partial^2 V}{\partial Q^2}\right)_0 = \frac{1}{\mu}\left(\frac{\partial^2 V}{\partial(\Delta r)^2}\right)_0. \quad (22)$$

A straightforward calculation using Eqs. 10, 20, and 22 leads to:

$$\Delta = \frac{1}{2\omega_0\mu}\sqrt{\left\langle\left(\frac{\partial^2 V}{\partial(\Delta r)^2}\right)_0^2\right\rangle}. \quad (23)$$

Since $\langle(\partial^2 V/\partial(\Delta r)^2)_0^2\rangle$ seems to be unchangeable on isotope substitution, Δ_H/Δ_D may be expressed by:

$$\Delta_H/\Delta_D = (\omega_{0D}\mu_D)/(\omega_{0H}\mu_H). \quad (24)$$

In Eq. 24, all the symbols suffixed by H and D correspond to chloroform and chloroform-*d* respectively. The force constant also seems to be unchageable on isotope substitution.

Therefore, the ratio of μ_H and μ_D is:

$$\mu_D/\mu_H = (\omega_{0H}/\omega_{0D})^2. \quad (25)$$

Equations 24 and 25 give this relation:

$$\Delta_H/\Delta_D = \omega_{0H}/\omega_{0D}. \quad (26)$$

Consequently, in the case of a slow modulation, the ratio of the half-widths for chloroform and chloroform-*d* is:

$$\delta_{vH}/\delta_{vD} = \omega_{0H}/\omega_{0D}. \quad (27)$$

In the case of a fast modulation, on the other hand, δ_{vH}/δ_{vD} is given by:

$$\delta_{vH}/\delta_{vD} = (\omega_{0H}/\omega_{0D})^2. \quad (28)$$

Since the δ_r value is considered to be almost equal for the two isotope species, the δ_r and δ_v values can be calculated from Eqs. 9, 27, and 28; the results are summarized in Table 5.

It may be concluded from the results shown in Table 5, first of all, that the present experimental results do not correspond to the case of a slow modulation, because the δ_r is calculated to be negative for the band 1 if we apply the slow-modulation limit to the present system.

In the fast-modulation limit, however, the δ_r values are calculated to be positive for both the band 1 and the band 2. Moreover, the δ_r of the band 2 is much larger than that of the band 1. This seems quite reasonable if we consider that the rotational motion of the molecule corresponding to the band 1 is hindered by the interaction from the surrounding molecules much more strongly than that of the molecule corresponding to the band 2. It is interesting to add that the δ_r for chloroform is calculated to be about 22.4 cm^{-1} if we apply the free-rotation model. This δ_r value of 22.4 cm^{-1} is closer to the δ_r value of the band 2 than to that of the band 1. These results support the idea that the fast-modulation limit is a more appropriate model to explain the observed isotope effect on the band-width than is the slow modulation limit. It has also been concluded that the isotope effect on the band-width of the ν_1 fundamental of chloroform arises mainly from the difference in the vibrational relaxation width. These conclusions are quite consistent with the assignment of the bands 1 and 2 to the two different types of chemical species existing in the liquid phase of chloroform, *i.e.*, the existence of the strongly and the weakly interacting molecules.

Concluding Discussion. The main results of the present work may be summarized as follows:

(1) There exist two different types of chloroform molecules in pure liquid chloroform. One is a molecule which interacts with another molecule, and the other is a non-interacting molecule.

(2) Although the infrared absorption spectrum for the ν_1 band of chloroform shows a single peak, the observed spectrum consists of two bands, which correspond to the two different types of chloroform molecules in the pure liquid. Both the peak frequency and the absorption intensity are different for these two bands in liquid chloroform; the observed band profile for the ν_1 vibration is asymmetric.

(3) The isotope effect on the width of the ν_1 band can be explained in terms of the difference in the reduced mass.

(4) Incidentally, the present results reveal the real difficulty of the intensity study of condensed phases. The intensities of the vibration spectra observed for the condensed systems have been used mainly for the study of intermolecular interactions. This can be done by comparing the intensities observed for the gas and condensed phases. It has been shown in the present work that a vibration spectrum of a condensed phase is, in principle, composed of many different bands with different band maxima and intensities. These different bands should correspond to different chemical species or different types of intermolecular interactions. In order to override this difficulty, the detailed study of the band shapes of the vibration spectra should be strongly pushed forward, together with the intensity measurements of condensed systems.

Excess Volumes of Ternary Mixtures

Masanao KATO

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

(Received January 11, 1980)

An expression for excess volumes of multi-component mixtures was derived, and its applicability to the experimental values of ternary mixtures was demonstrated. It was found, in 1,2-dichloroethane+benzene+cyclohexane, ethanol+benzene+cyclohexane and ethanol+acetone+cyclohexane mixtures, that the agreements between the calculated and the experimental values were satisfactory.

Many expressions and models for the thermodynamic properties of a liquid mixture have been proposed by many workers in the past two decades. Of these theories, some semi-empirical equations, such as the Wilson equation[1,2] and the UNIFAC equation,[3] have successfully interpreted the experimental values in many liquid mixtures. These theories can be extended to the calculation of the thermodynamic quantities observed in the multi-component mixtures,[1-4] despite some ambiguity in the physical meaning of the parameters involved. However, these theories are useless for the expression of the excess volume of the mixtures.

From this point of view, the present author recently proposed a new semi-empirical expression for the excess volume of binary mixtures based on the local composition in the mixture, and demonstrated that the results calculated by means of the equation are in good agreement with the experimental values.[5] This expression contains only two semi-empirical parameters for molecular arrangement in a binary mixture and can be expected to be extended to ternary mixtures in a simple manner. In this study, the expression for multi-component mixtures was derived, after which we examined its applicability to the experimental values obtained in three different ternary mixtures, 1,2-dichloroethane+benzene+cyclohexane, ethanol+benzene+cyclohexane, and ethanol+acetone+cyclohexane mixtures, selected as typical mixtures.

Theoretical

In multi-component mixtures consisting of n species, consider the n kinds of cells, each of them including an i-th ($1 \leqq i \leqq n$) component at the center. In this situation, if molecular association can be neglected, the volume occupied by one mol of the central molecule i, v_i, is expressed as follows:[5]

$$v_i = v_{1i}x_{1i} + v_{2i}x_{2i} + \cdots + v_{ii}x_{ii} + \cdots + v_{ni}x_{ni}, \quad (1)$$

where v_{ji} is the volume of the i-th component surrounded by the j-th component, and where x_{ji} denotes a local mole fraction of the j-th component in the vicinity of the i-th component. From Eq. 1, the volume of the mixture, v_{mix}, is represented as follows:

$$v_{mix} = \sum_{i=1}^{n} x_i \left(\sum_{j=1}^{n} v_{ji}x_{ji} \right). \quad (2)$$

Since the volume of an ideal mixture, v_{ideal}, is:

$$v_{ideal} = \sum_{i=1}^{n} x_i v_i^* = \sum_{i=1}^{n} x_i v_{ii}, \quad (3)$$

where v_i^* denotes the molar volume of the pure i-th component, the excess volume, v^E, is represented as follows:

$$v^E = \sum_{i=1}^{n} x_i \left(\sum_{j=1}^{n} (v_{ji} - v_{ii})x_{ji} \right). \quad (4)$$

In Eq. 4, the $\sum_{j=1}^{n} x_{ji} = 1$ relation was used. If the non-randomness factor, Λ_{ji}, is defined as:[5]

$$\frac{x_{ji}}{x_{ii}} = \Lambda_{ji}\frac{x_j}{x_i}, \quad (5)$$

the local mole fraction, x_{ji}, is represented as follows:

$$x_{ji} = \frac{\Lambda_{ji}x_j}{\sum_{k=1}^{n} \Lambda_{ki}x_k}. \quad (6)$$

From Eqs. 4 and 6, the expression for the excess volume of a multi-component mixture is obtained as follows:

$$v^E = \sum_{i=1}^{n} x_i \left(\frac{\sum_{j=1}^{n} (v_{ji} - v_{ii})\Lambda_{ji}x_j}{\sum_{k=1}^{n} \Lambda_{ki}x_k} \right). \quad (7)$$

The parameters $(v_{ji} - v_{ii})$ and Λ_{ji} can be obtained from the data of binary mixtures by a method previously described.[5]

Experimental

1,2-Dichloroethane, benzene, cyclohexane, acetone (Wako Pure Chemical Industries, Ltd.; G.R. grade) and ethanol (Kanto Chemical Co., Ltd.; G.R. grade) were used. Each of them was purified by means of fractional distillation on an apparatus with a 1.5-meter condenser under a reflux ratio of 3:1; a middle portion was collected at a constant condensation temperature. The purified reagents showed no signal due to any impurity on G.L.C. The densities and vapor pressures at 298.15 K agree well with the literature values.[6]

The excess volumes were obtained from density measurements made by using pycnometers with contents of 1.9 cm^3, 6 cm^3, and 9 cm^3 and immersed in a thermostat controlled at (298.15±0.001) K.

Results and Discussion

In this study, the excess volumes of binary and ternary mixtures were measured since only a few literature data on the excess volume of a ternary mixture are available.[7,8] The applicability of Eq. 7 was examined in the following sequence.

Binary Mixtures. The observed excess volumes of seven binary mixtures, *i.e.*, 1,2-dichloroethane+benzene, benzene+cyclohexane, 1,2-dichloroethane+cyclohexane, acetone+cyclohexane, ethanol+acetone,

ethanol+benzene, and ethanol+cyclohexane mixtures, are listed in Table 1. These mixtures were selected because they are strongly non-ideal mixtures and because they possess a sufficient magnitude of excess volumes to be measured from density with sufficient accuracy. The data obtained were smoothed by the method of least squares to the following polynomial equation:

$$v^E = x(1-x)\sum_{i=0}^{4} A_i\,(1-2x)^i. \qquad (8)$$

TABLE 2. THE VALUES OF COEFFICIENTS FOR THE POLYNOMIAL EQUATION (Eq. 8) AT 298.15K

Ethanol(1)+cyclohexane(2)	2.2039	−0.1407	0.8225	0.2304	0.4036	0.0120

The obtained parameters, A_i, and standard deviation, σ, are summarized in Table 2. The partial molar volumes at an infinite dilution, v_i^∞ (as $v_i^\infty - v_i^*$), non-randomness factors, Λ_{ji}, and volume parameters, $v_{ji}-v_{ii}$ are also listed in Table 3. The volume parameters were calculated from $v_i^\infty - v_i^*$ by the use of the following equation:

$$v_{ji} - v_{ii} = \frac{(v_i^\infty - v_i^*) - \Lambda_{ij}(v_j^\infty - v_j^*)}{1 - \Lambda_{ij}\Lambda_{ji}}. \quad (9)$$

From Eq. 9, the volume change in the central molecule, i, surrounded by an unlike molecule, j, can be estimated. In the mixtures which show a positive deviation, the $v_{21}-v_{11}$ and $v_{12}-v_{22}$ values are smaller than the values of the corresponding $v_1^\infty - v_1^*$ and $v_2^\infty - v_2^*$ respectively. The $v_i^\infty - v_i^*$ values contain the volume changes of both the central and the surrounding molecules. On the other hand, the $v_{ij}-v_{jj}$ values consist of only the volume change of the central molecule. In the ethanol+acetone mixture, which shows a negative excess volume, the small $v_{12}-v_{22}$ value of acetone shows little volume change upon interaction with ethanol molecules, while the negative value of $v_{21}-v_{11}$ for ethanol shows a decrease in the volume upon interaction with acetone. In the ethanol+benzene mixture, the negative value of the volume change of benzene indicates the OH-π interaction and the positive value of ethanol molecule results from the destruction of the hydrogen-bonding interaction of the ethanol molecules.

The excess volumes calculated from Eq. 7 are in good agreement with the experimental values, shown by solid lines in Fig. 1. The solid lines were drawn on the basis of Eq. 7.

Ternary Mixtures. The excess volumes of three ternary mixtures, the 1,2-dichloroethane+benzene+cyclohexane, ethanol+benzene+cyclohexane, and ethanol+acetone+cyclohexane mixtures, were measured and compared with the values calculated from Eq. 7. In the 1,2-dichloroethane+benzene+cyclohexane mixture, all binary mixtures composed of the three components show positive excess volumes. In the ethanol+benzene+cyclohexane mixture, the ethanol+benzene binary mixture shows an S-shaped excess-volume curve. The ethanol+acetone mixture in the ethanol+acetone+cyclohexane mixture shows a negative excess volume. These three ternary mixtures are typical systems which show representative excess-volume curves. When two binary mixtures composed of the components of the ternary mixtures show negative excess volumes, the calculated and observed excess volumes are considered to have a tendency similar to that when two binary mixtures show positive excess volumes, if the signs of the values of the excess volume and the volume parameters are changed.

ternary mixtures are summarized in Table 4. As is shown in this table, the calculated excess volumes of all the ternary mixtures are in good agreement with the experimental values. The maximum difference between the calculated and the observed values is about 0.09 cm^3 mol^{-1}, most of the differences are within 0.05 cm^3 mol^{-1}.

As has been described above, the present expression for the excess volumes of multi-component mixtures is considered to be successful in reproducing the experimental values. As Eq. 7 shows, the excess volume can be determined in terms of the molecular arrangement in a mixture, the intermolecular interaction assessed by non-randomness factors, and the molecular size as measured from the $v_{ij}-v_{jj}$ values.

From these results and this discussion, it should be noticed that the excess volumes of ternary mixtures can be represented without ternary terms of molecular-size parameters and three-body interaction in a given mixture, as was shown in the derivation of Eq. 7. The effect of three-body interaction is considered to be small, and the degree of correction required for the three-body terms can be assumed to be of the same magnitude as the difference between the observed and the calculated values in Table 4, *i.e.*, about 0.05 cm^3 mol^{-1}.

Theory of A.c. Polarization and A.c. Polarography and Voltammetry of Two-step Surface Redox Reactions

Tadaaki KAKUTANI* and Mitsugi SENDA

Department of Agricultural Chemistry, Faculty of Agriculture, Kyoto University, Kyoto 606

(Received January 14, 1980)

Theoretical expressions are presented of the a.c. polarization and of the a.c. polarography and voltammetry for a two-step surface redox reaction ($O_{ad}+n_1e\rightleftharpoons S_{ad}$, $S_{ad}+n_2e\rightleftharpoons R_{ad}$) in which the charge transfer reactions take place exclusively between the adsorbed reactants O_{ad}, S_{ad}, and R_{ad}, and all the reactants are adsorbed so strongly that the amount of O, S, or R brought to or removed from the electrode surface can be neglected. The interaction between the adsorbed reactants is assumed to be expressed by Frumkin's a-parameters. The effect of the double layer impedance is taken into account. Several simplified cases are discussed in detail.

There have been recently increasing studies on redox modified electrodes, which are prepared by attaching irreversibly redox species to the surface of an electrode material (*via* irreversible adsorption, coating, or chemical binding *etc.*), in prospect of their applications to electroanalysis and electrocatalysis (for reviews, see Refs. 1 and 2). Information on the electrochemical characteristics of surface redox reactions is very important in the applications of the redox modified electrodes. For this purpose cyclic voltammetry has been widely used. In a previous paper[3] we have presented a theory of the faradaic impedance and of a.c. polarography and voltammetry for surface redox reaction ($O_{ad}+ne\rightleftharpoons R_{ad}$) in which the interaction between the adsorbed reactants and the correction for the double layer impedance are taken into account. This theory has been applied to the electrode processes of ferredoxins irreversibly adsorbed on the mercury electrode surface.[4,5] The results indicated that a.c. polarography and voltammetry are powerful techniques, in particular, for elucidating the kinetic aspect of the electrode processes.

Two-step charge transfer mechanism is an important mechanistic category in biochemical as well as chemical redox reactions. Numerous studies have been devoted to this type of electrode reaction (EE mechanism) and theoretical treatments of the EE mechanism have been presented for d.c.[6-13] and a.c.[14-18] polarography and other electrochemical techniques.[19-25] To our knowledge, however, no theoretical treatment of a.c. polarization has been presented for the two-step surface redox reaction (*surface EE mechanism*).

In this study we present a theory of the faradaic impedance and of a.c. polarography and voltammetry for the two-step surface redox reaction. In this theory the interaction between the adsorbed reactants is taken into account. Also the effect of the double layer impedance is considered.

Derivation of the General Expressions

Let us consider a two-step surface redox reaction,

$$\text{1st Step: } O_{ad} + n_1e \rightleftharpoons S_{ad} \tag{1a}$$

$$\text{2nd Step: } S_{ad} + n_2e \rightleftharpoons R_{ad}. \tag{1b}$$

In the following we shall make the same assumptions as made in the previous work:[3] (a) the charge transfer reactions take place exclusively between the adsorbed reactants, (b) all the electroactive species (O, S, and R) are adsorbed so strongly (irreversibly) that the amount of O, S, or R brought to or removed from the electrode surface by mass transfer can be neglected in comparison with the amount which remains adsorbed, and (c) the interaction between the adsorbed reactants can be expressed by Frumkin's a-parameters.[26]

Since the surface redox reaction proceeds exclusively between the adsorbed reactants (assumption (a)), the faradaic current-density, I_F, is a function of the electrode potential, E, and the surface concentration of the reactants, Γ_O, Γ_S, and Γ_R;

$$I_F = I_F(1) + I_F(2) \tag{2a}$$

$$I_F(1) = g_1(E, \Gamma_O, \Gamma_S) \tag{2b}$$

$$I_F(2) = g_2(E, \Gamma_S, \Gamma_R), \tag{2c}$$

where Γ_i (i=O, S, or R) is the amount of the adsorbed reactant i per unit electrode surface area, $I_F(1)$ and $I_F(2)$ are the faradaic current-densities of the first and second step, respectively.

For a small variation of the potential, δE, superimposed on the "d.c." potential, E_{dc}, ($E=E_{dc}+\delta E$), the surface concentration Γ_i will change around the mean ("d.c.") value, $\overline{\Gamma}_i$, with a small variation, $\delta\Gamma_i$, ($\Gamma_i=\overline{\Gamma}_i+\delta\Gamma_i$) and the faradaic current-density will be given by

$$I_F = I_{dc} + \delta I_F. \tag{3}$$

Thus we have for the first harmonic of faradaic current,[27] $\delta_1 I_F$,

$$\delta_1 I_F = \delta_1 I_F(1) + \delta_1 I_F(2), \tag{4a}$$

$$\delta_1 I_F(1) = (\partial I(1)/\delta E)\delta_1 E + (\partial I(1)/\partial\Gamma_O)\delta_1\Gamma_O + (\partial I(1)/\partial\Gamma_S)\delta_1\Gamma_S, \tag{4b}$$

$$\delta_1 I_F(2) = (\partial I(2)/\partial E)\delta_1 E + (\partial I(2)/\partial\Gamma_S)\delta_1\Gamma_S + (\partial I(2)/\partial\Gamma_R)\delta_1\Gamma_R, \tag{4c}$$

where $\delta_1 E$ and $\delta_1\Gamma_i$'s are the first harmonic variations of E and Γ_i's, respectively. From assumption (b) we further have

$$d(\delta_1\Gamma_O)/dt = j\omega\delta_1\Gamma_O = \delta_1 I_F(1)/n_1F, \tag{5a}$$

$$d(\delta_1\Gamma_S)/dt = j\omega\delta_1\Gamma_S = -(\delta_1 I_F(1)/n_1F) + (\delta_1 I_F(2)/n_2F), \tag{5b}$$

$$d(\delta_1\Gamma_R)/dt = j\omega\delta_1\Gamma_R = -\delta_1 I_F(2)/n_2F, \tag{5c}$$

where j is the operator $(-1)^{1/2}$, and ω the angular frequency of sinusoidal variations.

By combining Eqs. 4a to 5c we obtain the *I-E* characteristic for sinusoidal variation of small amplitude,

$$\delta_1 I_F = \delta_1 I_F^{real} + j\delta_1 I_F^{imag} = \frac{(r_1+r_2)-j[y_1+y_2+(n_1/n_2)x_1-(n_2/n_1)x_2]}{(r_1r_2-y_1y_2-x_1x_2)-j(r_2y_1+r_1y_2)}\delta_1 E, \tag{6a}$$

$$\delta_1 I_F^{real} = \frac{(r_1+r_2)(r_1r_2-y_1y_2-x_1x_2)+(r_1y_2+r_2y_1)[y_1+y_2+(n_1/n_2)x_1-(n_2/n_1)x_2]}{(r_1r_2-y_1y_2-x_1x_2)^2+(r_1y_2+r_2y_1)^2}\delta_1 E, \tag{6b}$$

$$\delta_1 I_F^{imag} = \frac{(r_1+r_2)(r_1y_2+r_2y_1)-(r_1r_2-y_1y_2-x_1x_2)[y_1+y_2+(n_1/n_2)x_1-(n_2/n_1)x_2]}{(r_1r_2-y_1y_2-x_1x_2)^2+(r_1y_2+r_2y_1)^2}\delta_1 E, \tag{6c}$$

where $\delta_1 I_F^{real}$ and $\delta_1 I_F^{imag}$ are the real and imaginary component of the faradaic a.c. current-density, respectively, and r_1, r_2, y_1, y_2, x_1, and x_2 are given by

$$r_1 = 1/(\partial I(1)/\partial E), \tag{7a}$$

$$r_2 = 1/(\partial I(2)/\partial E), \tag{7b}$$

$$y_1 = (1/\omega n_1 F)[-(\partial I(1)/\partial \Gamma_O) + (\partial I(1)/\partial \Gamma_S)]/(\partial I(1)/\partial E), \tag{7c}$$

$$y_2 = (1/\omega n_2 F)[-(\partial I(2)/\partial \Gamma_S) + (\partial I(2)/\partial \Gamma_R)]/(\partial I(2)/\partial E), \tag{7d}$$

$$x_1 = (1/\omega n_1 F)(\partial I(1)/\partial \Gamma_S)/(\partial I(1)/\partial E), \tag{7e}$$

$$x_2 = (1/\omega n_2 F)(\partial I(2)/\partial \Gamma_S)/(\partial I(2)/\partial E). \tag{7f}$$

Because of the specific adsorption of the reactants, the non-faradaic impedance may differ from that observed in the absence of the electroactive species. In this case we can assume that the surface charge density on the electrode, q, is a function of E, Γ_O, Γ_S, and Γ_R only. Thus for sinusoidal variation of the nonfaradaic current-density we have for the first harmonic,[27]

$$\begin{aligned}\delta_1 I_{NF} &= (dq/dt)_{ac} \\ &= j\omega[(\partial q/\partial E)\delta_1 E + (\partial q/\partial \Gamma_O)\delta_1 \Gamma_O + (\partial q/\partial \Gamma_S)\delta_1 \Gamma_S \\ &\quad + (\partial q/\partial \Gamma_R)\delta_1 \Gamma_R].\end{aligned} \tag{8}$$

From Eqs. 5a, 5b, 5c, and 8 we obtain for the non-faradaic a.c. current-density,

$$\begin{aligned}\delta_1 I_{NF} &= [(m_1-n_1)/n_1]\delta_1 I_F(1) + [(m_2-n_2)/n_2]\delta_1 I_F(2) \\ &\quad + j\omega(\partial q/\partial E)\delta_1 E\end{aligned} \tag{9}$$

where $(m_1-n_1)/n_1$ and $(m_2-n_2)/n_2$ are given by

$$(m_1-n_1)/n_1 = (1/n_1F)[(\partial q/\partial \Gamma_O)-(\partial q/\partial \Gamma_S)], \tag{10a}$$

$$(m_2-n_2)/n_2 = (1/n_2F)[(\partial q/\partial \Gamma_S)-(\partial q/\partial \Gamma_R)], \tag{10b}$$

Thus for the total (faradaic and non-faradaic) a.c. current-density we obtain

$$\begin{aligned}\delta_1 I_t &= \delta_1 I_F + \delta_1 I_{NF} \\ &= (m_1/n_1)\delta_1 I_F(1) + (m_2/n_2)\delta_1 I_F(2) + j\omega(\partial q/\partial E)\delta_1 E,\end{aligned} \tag{11}$$

and the real and imaginary component of the total a.c. current are

$$\delta_1 I_t^{real} = (m_1/n_1)\delta_1 I_F^{real}(1) + (m_2/n_2)\delta_1 I_F^{real}(2), \tag{12a}$$

$$\begin{aligned}\delta_1 I_t^{imag} &= (m_1/n_1)\delta_1 I_t^{imag}(1) + (m_2/n_2)\delta_1 I_F^{imag}(2) \\ &\quad + \omega(\partial q/\partial E)\delta_1 E,\end{aligned} \tag{12b}$$

where $\delta_1 I_F^{real}(i)$ and $\delta_1 I_F^{imag}(i)$ are the real and imaginary component of $\delta_1 I_F(i)$, respectively, and are given by

$$\delta_1 I_F^{real}(1) = \frac{r_2(r_1r_2-y_1y_2-x_1x_2)+(r_1y_2+r_2y_1)[y_2+(n_1/n_2)x_1]}{(r_1r_2-y_1y_2-x_1x_2)^2+(r_1y_2+r_2y_1)^2}\times \delta_1 E, \tag{13a}$$

$$\delta_1 I_F^{real}(2) = \frac{r_1(r_1r_2-y_1y_2-x_1x_2)+(r_1y_2+r_2y_1)[y_1-(n_2/n_1)x_2]}{(r_1r_2-y_1y_2-x_1x_2)^2+(r_1y_2+r_2y_1)^2}\times \delta_1 E, \tag{13b}$$

$$\delta_1 I_F^{imag}(1) = \frac{r_2(r_1y_2+r_2y_1)-(r_1r_2-y_1y_2-x_1x_2)[y_2+(n_1/n_2)x_1]}{(r_1r_2-y_1y_2-x_1x_2)^2+(r_1y_2+r_2y_1)^2}\times \delta_1 E, \tag{13c}$$

$$\delta_1 I_F^{imag}(2) = \frac{r_1(r_1y_2+r_2y_1)-(r_1r_2-y_1y_2-x_1x_2)[y_1-(n_2/n_1)x_2]}{(r_1r_2-y_1y_2-x_1x_2)^2+(r_1y_2+r_2y_1)^2}\times \delta_1 E. \tag{13d}$$

As pointed out previously,[3] the term $\omega(\partial q/\partial E)\delta_1 E$ on the right-hand side of Eq. 12b can be estimated from double-layer capacity measurements employing very high frequencies and for practical purpose can be eliminated approximately by the conventional method of correction for a.c. base current as usually used in a.c. polarographic technique:

$$\begin{aligned}\delta_1 I_{corr}^{imag} &= \delta_1 I_t^{imag} - \omega(\partial q/\partial E)\delta_1 E \\ &= (m_1/n_1)\delta_1 I_F^{imag}(1) + (m_2/n_2)\delta_1 I_F^{imag}(2).\end{aligned} \tag{12c}$$

On the other hand it is very difficult to estimate the terms (m_1/n_1) and (m_2/n_2) experimentally. However, since the potential range in which the faradaic current of each step appears does not exceed a few tenths of a volt, it would be reasonable to assume that these terms are practically constant within the range studied.

In a similar manner as has been done in the previous work,[3] we assume that the current-potential-concentration characteristic can be expressed as

$$I_F = I_F(1) + I_F(2) \tag{14a}$$

$$I_F(1) = n_1F(\overleftarrow{V}(1)-\vec{V}(1)) \tag{14b}$$

$$I_F(2) = n_2F(\overleftarrow{V}(2)-\vec{V}(2)) \tag{14c}$$

$$\overleftarrow{V}(1) = k_s'(1)f_2\theta_t B_S(1)^{-1}\exp[\beta_1(n_1F/RT)(E-E_{o1})] \times \exp[-a_{SS}f_2\theta_t - a_{SO}f_1\theta_t - a_{SR}(1-f_1-f_2)\theta_t] \tag{14d}$$

$$\vec{V}(1) = k_s'(1)f_1\theta_t B_O(1)^{-1}\exp[-\alpha_1(n_1F/RT)(E-E_{o1})] \times \exp[-a_{OO}f_1\theta_t - a_{OS}f_2\theta_t - a_{OR}(1-f_1-f_2)\theta_t] \tag{14e}$$

$$\overleftarrow{V}(2) = k_s'(2)(1-f_1-f_2)\theta_t B_R(2)^{-1}\exp[\beta_2(n_2F/RT)(E-E_{o2})] \times \exp[-a_{RR}(1-f_1-f_2)\theta_t - a_{RO}f_1\theta_t - a_{RS}f_2\theta_t] \tag{14f}$$

$$\vec{V}(2) = k_s'(2)f_2\theta_t B_S(2)^{-1}\exp[-\alpha_2(n_2F/RT)(E-E_{o2})] \times \exp[-a_{SS}f_2\theta_t - a_{SO}f_1\theta_t - a_{SR}(1-f_1-f_2)\theta_t]. \tag{14g}$$

In these equations $B_i(1)$ and $B_i(2)$ are constants related to the molar adsorption energies of species i on the electrode surface at $E=E_{o1}$ and $E=E_{o2}$, respectively; a_{ij} is the Frumkin's a-parameter of interaction between

the adsorbed molecules i and j (a_{ij} is positive for attraction and negative for repulsion); θ_t is the total coverage defined by $\theta_t=\Gamma_t/\Gamma_m=\theta_O+\theta_S+\theta_R$ with $\theta_O=\Gamma_O/\Gamma_m$, $\theta_S=\Gamma_S/\Gamma_m$, $\theta_R=\Gamma_R/\Gamma_m$, and $\Gamma_t=\Gamma_O+\Gamma_S+\Gamma_R=\overline{\Gamma}_O+\overline{\Gamma}_S+\overline{\Gamma}_R$, Γ_m being the maximum value of the total surface concentration; $f_1=\theta_O/\theta_t$, $f_2=\theta_S/\theta_t$; $k'_s(1)=k_s(1)\Gamma_m$; $k'_s(2)=k_s(2)\Gamma_m$; $k_s(1)$ and $k_s(2)$ are respectively the rate constants of the first and second charge transfer step at the formal standard potentials of the surface redox reactions, E'_{o1} and E'_{o2}, which are defined by

$$E'_{o1}=E_{o1}+[RT/(\alpha_1+\beta_1)n_1F][\ln(B_S(1)/B_O(1))-(1/3)(a_{OO}-a_{SS}+a_{OS}-a_{SO}+a_{OR}-a_{RS})\theta_t] \quad (15a)$$

$$E'_{o2}=E_{o2}+[RT/(\alpha_2+\beta_2)n_1F][\ln(B_R(2)/(B_S(2))-(1/3)(a_{SS}-a_{RR}+a_{SR}-a_{RS}+a_{SO}-a_{RO})\theta_t] \quad (15b)$$

α_i and β_i (i=1 and 2) are the transfer coefficients for cathodic and anodic charge transfer of the i-th redox step, respectively. E_{o1} and E_{o2} correspond to the standard potentials of the redox couples O/S and S/R in the bulk of solution, respectively. Here we shall make the following two assumptions: (1) α_i's and β_i's are independent of the potential, and (2) the a_{ij}-parameters are independent of the potential. These assumptions will be reasonable as the first approximation, because the potential range in which the faradaic a.c. current appears does not exceed a few tenths of a volt.

From Eqs. 7a to 7f and 14a to 14g we obtain

$$r_1=(1/n_1F)[\beta_1(n_1F/RT)\overleftarrow{V}_{dc}(1)+\alpha_1(n_1F/RT)\vec{V}_{dc}(1)]^{-1} \quad (16a)$$

$$r_2=(1/n_2F)[\beta_2(n_2F/RT)\overleftarrow{V}_{dc}(2)+\alpha_2(n_2F/RT)\vec{V}_{dc}(2)]^{-1} \quad (16b)$$

$$y_1=(r_1/\omega)\{\vec{V}_{dc}(1)[(1/\overline{\Gamma}_O)-(a_{OO}-a_{OS})(\theta_t/\Gamma_t)]+\overleftarrow{V}_{dc}(1)[(1/\overline{\Gamma}_S)-(a_{SS}-a_{SO})(\theta_t/\Gamma_t)]\} \quad (16c)$$

$$y_2=(r_2/\omega)\{\vec{V}_{dc}(2)[(1/\overline{\Gamma}_S)-(a_{SS}-a_{SR})(\theta_t/\Gamma_t)]+\overleftarrow{V}_{dc}(2)[(1/\overline{\Gamma}_R)-(a_{RR}-a_{RS})(\theta_t/\Gamma_t)]\} \quad (16d)$$

$$x_1=(r_1/\omega)[\overleftarrow{V}_{dc}(1)(1/\overline{\Gamma}_S)-(\overleftarrow{V}_{dc}(1)a_{SS}-\vec{V}_{dc}(1)a_{OS})(\theta_t/\Gamma_t)] \quad (16e)$$

$$x_2=-(r_2/\omega)[\vec{V}_{dc}(2)(1/\overline{\Gamma}_S)-(\vec{V}_{dc}(2)a_{SS}-\overleftarrow{V}_{dc}(2)a_{RS})(\theta_t/\Gamma_t)]. \quad (16f)$$

Here $\overleftarrow{V}_{dc}(1)=\overleftarrow{V}(1)[E=E_{dc}, f_1=\overline{f_1}, f_2=\overline{f_2}]$, $\vec{V}_{dc}(1)=\vec{V}(1)[E=E_{dc}, f_1=\overline{f_1}, f_2=\overline{f_2}]$, $\overleftarrow{V}_{dc}(2)=\overleftarrow{V}(2)[E=E_{dc}, f_1=\overline{f_1}, f_2=\overline{f_2}]$, and $\vec{V}_{dc}(2)=\vec{V}(2)[E=E_{dc}, f_1=\overline{f_1}, f_2=\overline{f_2}]$ with $\overline{f_1}=\overline{\Gamma}_O/\Gamma_t$ and $\overline{f_2}=\overline{\Gamma}_S/\Gamma_t$, and these are related to the faradaic d.c. current-densities by

$$(I_F(1))_{dc}/n_1F=\overleftarrow{V}_{dc}(1)-\vec{V}_{dc}(1), \quad (17a)$$

$$(I_F(2))_{dc}/n_2F=\overleftarrow{V}_{dc}(2)-\vec{V}_{dc}(2). \quad (17b)$$

(i) A.c. Polarization with Negligible Rectification[27] *at D.c. Equiliblium Potential*: In this case

$$(\overleftarrow{V}_{dc}(1)-\vec{V}_{dc}(1))_{equilibrium}=0 \quad (18a)$$

$$(\overleftarrow{V}_{dc}(2)-\vec{V}_{dc}(2))_{equilibrium}=0 \quad (18b)$$

and the mean surface-coverage fractions $\overline{f_1}=\overline{\Gamma}_O/\Gamma_t$ and $\overline{f_2}=\overline{\Gamma}_S/\Gamma_t$ are given by

$$E_{dc}=E_{o1}+[RT/(\alpha_1+\beta_1)n_1F][\ln(B_S(1)/B_O(1))-(1/3)(a_{OO}-a_{SS}+a_{OS}-a_{SO}+a_{OR}-a_{SR})\theta_t+\ln(\bar{f}_1/\bar{f}_2)+(1/3)(1-3\bar{f}_1)G_1\theta_t+(1/3)(1-3\bar{f}_2)H_1\theta_t] \quad (19a)$$

$$E_{dc}=E_{o2}+[RT/(\alpha_2+\beta_2)n_2F][\ln(B_R(2)/B_S(2))-(1/3)(a_{SS}-a_{RR}+a_{SR}-a_{RS}+a_{SO}-a_{RO})\theta_t+\ln(\bar{f}_2/(1-\bar{f}_1-\bar{f}_2))+(1/3)(1-3\bar{f}_1)G_2\theta_t+(1/3)(1-3\bar{f}_2)H_2\theta_t] \quad (19b)$$

with

$$G_1=a_{OO}-a_{OR}-a_{SO}+a_{SR} \quad (20a)$$

$$H_1=a_{OS}-a_{OR}-a_{SS}+a_{SR} \quad (20b)$$

$$G_2=a_{SO}-a_{SR}-a_{RO}+a_{RR} \quad (20c)$$

$$H_2=a_{SS}-a_{SR}-a_{RS}+a_{RR} \quad (20d)$$

In this case r_1, r_2, y_1, y_2, x_1, and x_2 are given by

$$r_1=[(\alpha_1+\beta_1)(n_1F/RT)I_o(1)]^{-1} \quad (21a)$$

$$r_2=[(\alpha_2+\beta_2)(n_2F/RT)I_o(2)]^{-1} \quad (21b)$$

$$y_1=[(\alpha_1+\beta_1)(n_1^2F^2/RT)\omega\Gamma_t]^{-1}\times[(1/\bar{f}_1)+(1/\bar{f}_2)-(G_1-H_1)\theta_t] \quad (21c)$$

$$y_2=[(\alpha_2+\beta_2)(n_2^2F^2/RT)\omega\Gamma_t]^{-1}\times[(1/\bar{f}_2)+(1/(1-\bar{f}_1-\bar{f}_2))-H_2\theta_t] \quad (21d)$$

$$x_1=[(\alpha_1+\beta_1)(n_1^2F^2/RT)\omega\Gamma_t]^{-1}[(1/\bar{f}_2)-(a_{SS}-a_{OS})\theta_t] \quad (21e)$$

$$x_2=-[(\alpha_2+\beta_2)(n_2^2F^2/RT)\omega\Gamma_t]^{-1}[(1/\bar{f}_2)-(a_{SS}-a_{RS})\theta_t] \quad (21f)$$

where $I_o(1)$ and $I_o(2)$ are respectively the exchange current densities of the first and second step at $E=E_{eq}$, and are given by

$$I_o(1)=n_1F\Gamma_tk_s(1)(\bar{f}_1B_O(1)^{-1}\gamma_O)^{\beta_1/(\alpha_1+\beta_1)}\times(\bar{f}_2B_S(1)^{-1}\gamma_S)^{\alpha_1/(\alpha_1+\beta_1)} \quad (22a)$$

$$I_o(2)=n_2F\Gamma_tk_s(2)(\bar{f}_2B_S(2)^{-1}\gamma_S)^{\beta_2/(\alpha_2+\beta_2)}\times((1-\bar{f}_1-\bar{f}_2)B_R(2)^{-1}\gamma_R)^{\alpha_2/(\alpha_2+\beta_2)} \quad (22b)$$

with

$$\gamma_O=\exp\{-[a_{OO}\bar{f}_1+a_{OS}\bar{f}_2+a_{OR}(1-\bar{f}_1-\bar{f}_2)]\theta_t\} \quad (23a)$$

$$\gamma_S=\exp\{-[a_{SS}\bar{f}_2+a_{SO}\bar{f}_1+a_{SR}(1-\bar{f}_1-\bar{f}_2)]\theta_t\} \quad (23b)$$

$$\gamma_R=\exp\{-[a_{RR}(1-\bar{f}_1-\bar{f}_2)+a_{RO}\bar{f}_1+a_{RS}\bar{f}_2]\theta_t\} \quad (23c)$$

The phase angle, ψ, is given by

$$\cot\psi=(\delta_1I_F^{real}/\delta_1I_F^{imag})=\frac{(r_1r_2-y_1y_2-x_1x_2)(r_1+r_2)+(r_1y_2+r_2y_1)[y_1+y_2+(n_1/n_2)x_1-(n_2/n_1)x_2]}{(r_1y_2+r_2y_1)(r_1+r_2)-(r_1r_2-y_1y_2-x_1x_2)[y_1+y_2+(n_1/n_2)x_1-(n_2/n_1)x_2]} \quad (24)$$

(ii) A.c. Polarography and Voltammetry for D.c. Reversible Steps: Equations 19a, 19b, 21a to 21f, and 24 are applicable without alteration to a.c. polarography and a.c. cyclic voltammetry of the two-step surface redox reaction, when both the steps (1a) and (1b) are d.c. reversible (d.c. Nernstian), that is, when $k_s(1)\tau\gg1$ and $k_s(2)\tau\gg1$ in a.c. polarography with a d.m.e. whose drop time is τ or when $4RTk_s(1)/n_1Fv\gg1$ and

$4RTk_s(2)/n_2Fv \gg 1$ in a.c. voltammetry with the potential sweep rate of v;

$$(\overleftarrow{V}_{dc}(1)-\overrightarrow{V}_{dc}(1))_{dc\ reversible} \approx 0 \tag{25a}$$

and

$$(\overleftarrow{V}_{dc}(2)-\overrightarrow{V}_{dc}(2))_{dc\ reversible} \approx 0. \tag{25b}$$

Simplified Cases

In the following we shall consider several simplified cases, in which both the redox steps (1a) and (1b) are d.c. reversible, and $n_1=n_2=n$, $\alpha_1=\alpha_2=\alpha$, and $\beta_1=\beta_2=\beta$.

Case (I): $a=a_{OO}=a_{OS}=a_{OR}=a_{SS}=a_{SO}=a_{SR}=a_{RR}=a_{RO}=a_{RS}$. When all the interaction parameters a_{ij}'s are of the same value, a, the effect of the interaction between the adsorbed reactants on a.c. waves is characterized implicitly by the parameter a in Eqs. 27a and 27b; that is, the terms r_1, r_2, y_1, y_2, x_1, and x_2 are reduced to

$$r_1 = \left[(\alpha+\beta)nF(nF/RT)k_{sap}(1)\Gamma_t\frac{(\sqrt{K})^{\alpha/(\alpha+\beta)}\rho^{\beta/(\alpha+\beta)}\rho}{(1+\sqrt{K}\rho+\rho^2)}\right]^{-1} \tag{26a}$$

$$r_2 = \left[(\alpha+\beta)nF(nF/RT)k_{sap}(2)\Gamma_t\frac{(\sqrt{K})^{\beta/(\alpha+\beta)}\rho^{\beta/(\alpha+\beta)}}{(1+\sqrt{K}\rho+\rho^2)}\right]^{-1} \tag{26b}$$

$$y_1 = \left[(\alpha+\beta)nF(nF/RT)\omega\Gamma_t\frac{\sqrt{K}\rho^2}{(1+\sqrt{K}\rho+\rho^2)(\sqrt{K}+\rho)}\right]^{-1} \tag{26c}$$

$$y_2 = \left[(\alpha+\beta)nF(nF/RT)\omega\Gamma_t\frac{\sqrt{K}\rho}{(1+\sqrt{K}\rho+\rho^2)(\sqrt{K}\rho+1)}\right]^{-1} \tag{26d}$$

$$x_1 = -x_2 = \left[(\alpha+\beta)nF(nF/RT)\omega\Gamma_t\frac{\sqrt{K}\rho}{(1+\sqrt{K}\rho+\rho^2)}\right]^{-1} \tag{26e}$$

where

$$k_{sap}(1) = k_s(1)B_O(1)^{-\beta/(\alpha+\beta)}B_S(1)^{-\alpha/(\alpha+\beta)}\exp(-a\theta_t) \tag{27a}$$

$$k_{sap}(2) = k_s(2)B_S(2)^{-\beta/(\alpha+\beta)}B_R(2)^{-\alpha/(\alpha+\beta)}\exp(-a\theta_t) \tag{27b}$$

$$K = \exp[(\alpha+\beta)(nF/RT)(E'_{o1}-E'_{o2})] \tag{28}$$

$$\rho = \exp[(\alpha+\beta)(nF/RT)(E_{dc}-E'_o)] \tag{29}$$

with

$$E'_{o1} = E_{o1} + [RT/(\alpha+\beta)nF]\ln[B_S(1)/B_O(1)] \tag{30}$$

$$E'_{o2} = E_{o2} + [RT/(\alpha+\beta)nF]\ln[B_R(2)/B_S(2)] \tag{31}$$

$$E'_o = (E'_{o1}+E'_{o2})/2. \tag{32}$$

In these equations K corresponds to the formation constant of the adsorbed intermediate S_{ad} defined by

$$K = [S_{ad}]^2/[O_{ad}][R_{ad}] \tag{33}$$

and E'_o to the formal standard potential of the adsorbed redox couple O_{ad}/R_{ad}.

From Eqs. 6b, 6c, and 26a to 26e, $\delta_1 I_F^{real}$ and $\delta_1 I_F^{imag}$ are given by

$$\delta_1 I_F^{real} = (\alpha+\beta)nF(nF/RT)\omega\Gamma_t\frac{\sqrt{K}\rho\rho^{\alpha/(\alpha+\beta)}}{(1+\sqrt{K}\rho+\rho^2)} \times \frac{\{\sqrt{K}[\lambda_1\lambda_2\rho^{2\alpha/(\alpha+\beta)}-(1+\sqrt{K}\rho+\rho^2)][\lambda_1(\sqrt{K})^{\beta/(\alpha+\beta)}+\lambda_2(\sqrt{K})^{\alpha/(\alpha+\beta)}\rho]+(\sqrt{K}+4\rho+\sqrt{K}\rho^2)[\lambda_1(\sqrt{K})^{\beta/(\alpha+\beta)}(1+\sqrt{K}\rho)+\lambda_2(\sqrt{K})^{\alpha/(\alpha+\beta)}(\sqrt{K}+\rho)]\}\delta_1 E}{\{K[\lambda_1\lambda_2\rho^{2\alpha/(\alpha+\beta)}-(1+\sqrt{K}\rho+\rho^2)]^2+[\lambda_1(\sqrt{K})^{\beta/(\alpha+\beta)}(1+\sqrt{K}\rho)+\lambda_2(\sqrt{K})^{\alpha/(\alpha+\beta)}(\sqrt{K}+\rho)]^2\rho^{2\alpha/(\alpha+\beta)}\}} \tag{34a}$$

$$\delta_1 I_F^{imag} = (\alpha+\beta)nF(nF/RT)\omega\Gamma_t\frac{\sqrt{K}\rho}{(1+\sqrt{K}\rho+\rho^2)} \times \frac{\{\rho^{2\alpha/(\alpha+\beta)}[\lambda_1(\sqrt{K})^{\beta/(\alpha+\beta)}+\lambda_2(\sqrt{K})^{\alpha/(\alpha+\beta)}\rho][\lambda_1(\sqrt{K})^{\beta/(\alpha+\beta)}(1+\sqrt{K}\rho)+\lambda_2(\sqrt{K})^{\alpha/(\alpha+\beta)}(\sqrt{K}+\rho)]-\sqrt{K}[\lambda_1\lambda_2\rho^{2\alpha/(\alpha+\beta)}-(1+\sqrt{K}\rho+\rho^2)][\sqrt{K}+4\rho+\sqrt{K}\rho^2]\}\delta_1 E}{\{K[\lambda_1\lambda_2\rho^{2\alpha/(\alpha+\beta)}-(1+\sqrt{K}\rho+\rho^2)]^2+[\lambda_1(\sqrt{K})^{\beta/(\alpha+\beta)}(1+\sqrt{K}\rho)+\lambda_2(\sqrt{K})^{\alpha/(\alpha+\beta)}(\sqrt{K}+\rho)]^2\rho^{2\alpha/(\alpha+\beta)}\}} \tag{34b}$$

with

$$\lambda_1 = \omega/k_{sap}(1) \tag{35a}$$

$$\lambda_2 = \omega/k_{sap}(2). \tag{35b}$$

For the phase angle we obtain

$$\cot\psi = \delta_1 I_F^{real}/\delta_1 I_F^{imag} = \frac{\{\sqrt{K}[\lambda_1\lambda_2\rho^{2\alpha/(\alpha+\beta)}-(1+\sqrt{K}\rho+\rho^2)][\lambda_1(\sqrt{K})^{\beta/(\alpha+\beta)}+\lambda_2(\sqrt{K})^{\alpha/(\alpha+\beta)}\rho]+(\sqrt{K}+4\rho+\sqrt{K}\rho^2)[\lambda_1(\sqrt{K})^{\beta/(\alpha+\beta)}(1+\sqrt{K}\rho)+\lambda_2(\sqrt{K})^{\alpha/(\alpha+\beta)}(\sqrt{K}+\rho)]\}\rho^{\alpha/(\alpha+\beta)}}{\{\rho^{2\alpha/(\alpha+\beta)}[\lambda_1(\sqrt{K})^{\beta/(\alpha+\beta)}+\lambda_2(\sqrt{K})^{\alpha/(\alpha+\beta)}\rho][\lambda_1(\sqrt{K})^{\beta/(\alpha+\beta)}(1+\sqrt{K}\rho)+\lambda_2(\sqrt{K})^{\alpha/(\alpha+\beta)}(\sqrt{K}+\rho)]-\sqrt{K}[\lambda_1\lambda_2\rho^{2\alpha/(\alpha+\beta)}-(1+\sqrt{K}\rho+\rho^2)][\sqrt{K}+4\rho+\sqrt{K}\rho^2]\}}. \tag{36}$$

Case (I)-(i): *A.c. Wave (I).* When $k_{sap}(1)=k_{sap}(2)=k_{sap}$ and $\alpha=\beta$, it can easily be shown from Eqs. 34a, 34b, and 36 that both components of the a.c. wave as well as the $\cot\psi$ *versus* E_{dc} curve are symmetrical with respect to the E'_o-axis and that the value of $\cot\psi$ at $E_{dc}=E'_o$, $[\cot\psi]_{E_{dc}=E'_o}$, is given by

$$[\cot\psi]_{E_{dc}=E'_o} = \lambda/(K)^{1/4} \tag{37}$$

with $\lambda=\omega/k_{sap}$. Thus in this simplified case a plot of $[\cot\psi]_{E_{dc}=E_o}$ against angular frequency yields a straight line passing through the origin with a slope of $k_{sap}^{-1}(K)^{-1/4}$. Since the thermodynamic parameter K can, if n and $(\alpha+\beta)$ are known, be determined from the reversible linear sweep (d.c.) voltammograms as will be described in *Case (I)-(iii)*, we can determine the apparent rate constant, k_{sap}, from this plot.

Case (I)-(ii): *Reversible A.c. Wave(I).* When

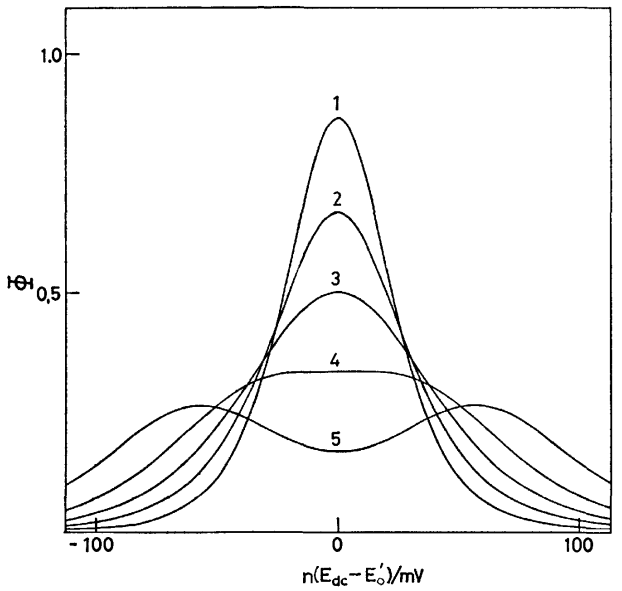

Fig. 1. Normalized reversible a.c. wave(I) calculated by Eq. 38 with $\alpha+\beta=1$.
K: (1); 0.1, (2); 1, (3); 4, (4); 16, (5); 100.

both the rate constants $k_{sap}(1)$ and $k_{sap}(2)$ are so large (*i.e.*, $\omega/k_{sap}(1)\ll 1$ and $\omega/k_{sap}(2)\ll 1$) that the conditions $(r_1/y_1)\ll 1$ and $(r_2/y_2)\ll 1$ are satisfied, Eq. 6 is reduced to

$$(\delta_1 I_F)_{rev} = (\delta_1 I_F^{imag})_{rev} = \frac{y_1+y_2+x_1-x_2}{y_1y_2+x_1x_2}\delta_1 E$$
$$= (\alpha+\beta)nF(nF/RT)\omega\Gamma_t \times \frac{\rho[\rho(\sqrt{K}\rho+2)+(\sqrt{K}+2\rho)]}{(1+\sqrt{K}\rho+\rho^2)^2}\delta_1 E \quad (38)$$

and

$$\cot\psi \to 0.$$

Namely, $\delta_1 I_F^{real}$ becomes vanishingly small and ψ approaches 90°. In Eq. 38 ρ and K are given by Eqs. 29 and 28, respectively. This equation predicts that the reversible a.c. wave (voltammograms with stationary electrode as well as polarograms with d.m.e.) is symmetrical with respect to the potential $E_{dc}=E_o'$. The normalized a.c. waves, $\Phi\equiv(\delta_1 I_F)_{rev}/nF(nF/RT)\omega\Gamma_t\delta_1 E$, are shown in Fig. 1 for different values of K at $(\alpha+\beta)=1$.

When $K\ll 16$, there is only one peak, of which the peak potential E_p^{rev} is equal to E_o'. The peak current, $(\delta_1 I_F^p)_{rev}$, and the half-peak width, $\Delta E_{p/2}^{rev}$, are given by

$$(\delta_1 I_F^p)_{rev} = (\alpha+\beta)nF(nF/RT)\omega\Gamma_t\frac{2}{(2+\sqrt{K})}\delta_1 E \quad (39)$$

$$\Delta E_{p/2}^{rev} = [2RT/(\alpha+\beta)nF]\,|\ln\xi| \quad (40)$$

where ξ is the solution of the equation: $\xi^4-K\xi^3+(K-4\sqrt{K}-6)\xi^2-K\xi+1=0$.

On the other hand, there are two peaks for $K>16$. Their peak potentials E_{p1}^{rev} and E_{p2}^{rev} are given by

$$E_{p1}^{rev} = E_o' + [RT/(\alpha+\beta)nF] \times \ln[(K-8)+\sqrt{(K-4)(K-16)}]/2\sqrt{K} \quad (41a)$$

$$E_{p2}^{rev} = E_o' + [RT/(\alpha+\beta)nF] \times \ln[(K-8)-\sqrt{(K-4)(K-16)}]/2\sqrt{K}. \quad (41b)$$

Thus the thermodynamic parameter K can be determined from the half-peak width, $\Delta E_{p/2}^{rev}$, for $K\leqslant 16$, or from the peak separation, $|E_{p1}^{rev}-E_{p2}^{rev}|$, for $K>16$, if $(\alpha+\beta)$ and n are known.

Case (I)-(iii): *Reversible D.c. Wave.* Furthermore it can be shown that the theoretical expression of the reversible linear sweep (d.c.) voltammogram is the same as that of the reversible a.c. wave if the term $\omega\delta_1 E$ is replaced by the potential sweep rate v. That is, the shape of the reversible linear sweep (d.c.) voltammogram is the same as that of the reversible a.c. wave, and the peak potential of the reversible linear sweep (d.c.) voltammogram, E_p^{dc}, coincides with the peak potential of the reversible a.c. wave, E_p^{rev}; $E_p^{dc}=E_p^{rev}=E_o'$, and the same discussion as described in *Case (I)-(ii)* is applicable to the reversible linear sweep (d.c.) voltammograms.

Application of these simplified equations given in *Case (I)-(i)* through *(I)-(iii)* to the electrode processes of flavins irreversibly adsorbed on mercury electrode surface will be reported in a succeeding paper.

Case (II): $a_{OO}+a_{SO}=a_{OS}+a_{SS}=a_{OR}+a_{SR}=a_{SO}+a_{RO}=a_{SS}+a_{RS}=a_{SR}+a_{RR}$, $a_{ij}=a_{ji}$ *(i,j=O, S, or R) and* $\alpha=\beta$. In this simplified case, the effects of the interaction between the adsorbed reactants on a.c. waves can be characterized explicitly by an interaction parameter $G=2(a_1-a_2)$ (Eq. 44) and implicitly by (a_1+a_2) (Eq. 43). That is, the terms r_1, r_2, y_1, y_2, x_1, and x_2 are reduced to

$$r_1 = [2\alpha nF(nF/RT)k_{sap}(1)\Gamma_t(\bar{f}_1\bar{f}_2)^{1/2}]^{-1} \quad (42a)$$

$$r_2 = [2\alpha nF(nF/RT)k_{sap}(2)\Gamma_t\bar{f}_2^{1/2}(1-\bar{f}_1-\bar{f}_2)^{1/2}]^{-1} \quad (42b)$$

$$y_1 = [2\alpha nF(nF/RT)\omega\Gamma_t]^{-1}[(1/\bar{f}_1)+(1/\bar{f}_2)-G\theta_t] \quad (42c)$$

$$y_2 = [2\alpha nF(nF/RT)\omega\Gamma_t]^{-1}[(1/\bar{f}_2)+(1/(1-\bar{f}_1-\bar{f}_2))-G\theta_t] \quad (42d)$$

$$x_1 = -x_2 = [2\alpha nF(nF/RT)\omega\Gamma_t]^{-1}[(1/\bar{f}_2)-(1/2)G\theta_t] \quad (42e)$$

where

$$k_{sap}(1) = k_s(1)(B_O(1)B_S(1))^{-1/2}\exp[-(1/2)(a_1+a_2)\theta_t] \quad (43a)$$

$$k_{sap}(2) = k_s(2)(B_S(2)B_R(2))^{-1/2}\exp[-(1/2)(a_1+a_2)\theta_t] \quad (43b)$$

and G is given by

$$G = 2(a_1-a_2) \quad (44)$$

with

$$a_1 = a_{OO} = a_{SS} = a_{RR} = a_{OR} = a_{RO} \quad (45a)$$

$$a_2 = a_{OS} = a_{SO} = a_{SR} = a_{RS}. \quad (45b)$$

The mean fractions of the surface coverages $\bar{f}_1$ and $\bar{f}_2$ are related to the d.c. potential E_{dc} by

$$E_{dc} = E_o' + [RT/2\alpha nF][\ln\sqrt{K}+\ln(\bar{f}_1/\bar{f}_2) - (1/2)(1-2\bar{f}_2)G\theta_t] \quad (46a)$$

$$E_{dc} = E_o' + [RT/2\alpha nF][-\ln\sqrt{K}+\ln(\bar{f}_2/(1-\bar{f}_1-f_2)) + (1/2)(1-2\bar{f}_2)G_t] \quad (46b)$$

where E_o' and K are respectively defined as

$$E_o' = (E_{o1}'+E_{o2}')/2 \quad (47)$$

$$K = \exp[(2\alpha nF/RT)(E'_{o1}-E'_{o2})] \quad (48)$$

with $E'_{o1}=E_{o1}+[RT/2\alpha nF]\ln[B_S(1)/B_O(1)]$ and $E'_{o2}=E_{o2}+[RT/2\alpha nF]\ln[B_R(2)/B_S(2)]$.

The a.c. wave is expressed by Eq. 6 with Eqs. 42a to 48, and the phase angle by Eq. 24 with Eqs. 42a to 48, which are, when $G=0$, reduced to the same equations as given in *Case (I)*.

Case (II)-(i): A.c. Wave(II). When it is further assumed that $k_{sap}(1)=k_{sap}(2)=k_{sap}$, it can easily be shown from these equations that both components of the a.c. wave as well as the cot ψ *versus* E_{dc} curve are symmetrical with respect to the E'_o-axis. Furthermore the value of cot ψ at $E_{dc}=E'_o$, $[\cot\psi]_{E_{dc}=E'_o}$, is given by

$$[\cot\psi]_{E_{dc}=E'_o} = (\omega/k_{sap})[2A/(2B-C-G\theta_t)] \quad (49)$$

with

$$A = [2/\eta(1-\eta)]^{1/2} \quad (50a)$$

$$B = (1+\eta)/\eta(1-\eta) \quad (50b)$$

$$C = 2/\eta \quad (50c)$$

$$\eta = \{1+(2/\sqrt{K})\exp[(1/2)(1-2\eta)G\theta_t]\}^{-1}. \quad (50d)$$

That is, $[\cot\psi]_{E_{dc}=E'_o}$ is proportional to angular frequency but in this case the slope of a plot of $[\cot\psi]_{E_{dc}=E'_o}$ *versus* ω depends on the interaction parameter $G\theta_t$ as well as K and k_{sap}. Since K and $G\theta_t$ can, if n and α are given, be determined from the reversible linear sweep (d.c.) voltammograms as will be described in *Case (II)-(iii)*, these three parameters, *i.e.*, k_{sap}, $G\theta_t$, and K, can be determined by combination of the a.c. and d.c. measurements.

Application of these simplified equations to the electrode processes of a ferredoxin irreversibly adsorbed on the surface of the dropping mercury electrode has been reported in another article.[5]

Case (II)-(ii): Reversible A.c. Wave(II). When the rate constant k_{sap} is so large compared to ω that $(r_1/y_1)\ll 1$ and $(r_2/y_2)\ll 1$, then, the a.c. wave(II) is reduced to the reversible a.c. wave(II), $\delta_1 I_F^{rev}$, which is expressed by

$$\delta_1 I_F^{rev} = (\delta_1 I_F^{imag})_{rev} = \frac{y_1+y_2+x_1-x_2}{y_1y_2+x_1x_2}\delta_1 E \quad (51)$$

and the phase angle approaches 90°. In this equation the terms y_1, y_2, and $x_1=-x_2$ are given by Eqs. 42c, 42d, and 42e, respectively. The mean fractions of the surface coverages $\overline{f_1}$ and $\overline{f_2}$ are related to the d.c. potential E_{dc} by Eqs. 46a and 46b.

These equations predict that the a.c. wave is also symmetrical with respect to the E'_o-axis. However, in contrast to *Case (I)-(ii)*, the wave shape will change with changing the total surface coverage θ_t. That is, with increasing $G\theta_t$, the normalized peak current, $\Phi_p\equiv(\delta_1 I_F^{rev})_p/nF(nF/RT)\omega\Gamma_t$, becomes larger and the half-peak width, $\Delta E_{p/2}^{rev}$, smaller, as shown, for example, for the case of $K=1$ in Fig. 2. Thus the two parameters K and G can be determined from the reversible a.c. waves measured at various values of θ_t if n and α are given.

Case (II)-(iii): Reversible D.c. Wave. It can easily be shown that the theoretical equations of the reversible linear sweep (d.c.) voltammogram are the same as those of the reversible a.c. wave if the term $\omega\delta_1 E$ is replaced by the potential sweep rate v. Thus the same discussion as described in *Case (II)-(ii)* is applicable to the reversible linear sweep (d.c.) voltammograms.

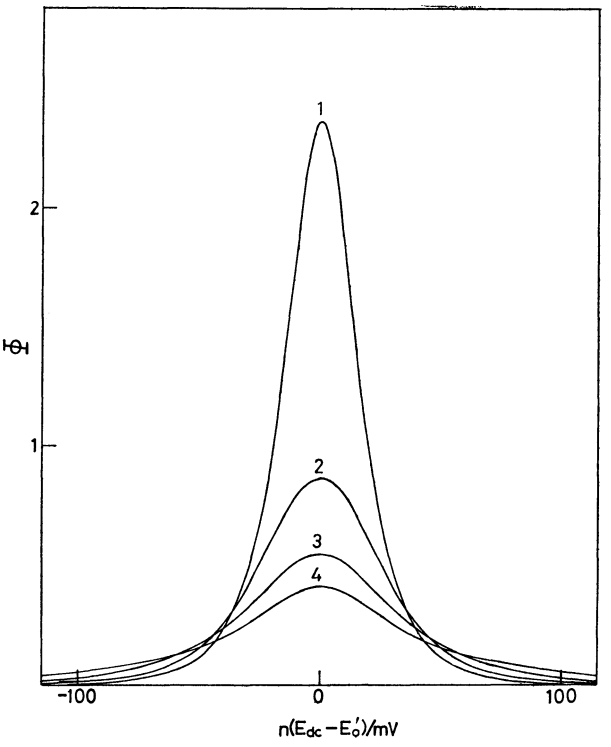

Fig. 2. Normalized reversible a.c. wave(II) calculated by Eqs. 51, 42c, 42d, 42e, 46a, and 46b with $\alpha=\beta=0.5$ and $K=1$.
$G\theta_t$: (1); 3, (2); 1, (3); −1, (4); −3.

A Study of Electronic Structure of 1,2,4,5-Tetracyanobenzene Anion Radical by Resonance Raman Effect

Kenji YOKOYAMA* and Shiro MAEDA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received February 8, 1980)

Resonance Raman spectrum of 1,2,4,5-tetracyanobenzene anion radical ($TCNB^-$) was measured and compared with that of the neutral molecule (TCNB). Particularly, a Raman line assigned to C_1C_2 stretching vibration decreased its frequency remarkably when TCNB was converted to $TCNB^-$. This decrease indicated that the lowest unoccupied molecular orbital (LUMO) of TCNB had a node on C_1C_2 bonding, showing that the LUMO belonged to an a_u species. Furthermore vibrational analyses of TCNB and $TCNB^-$ were carried out and the assignment of their Raman lines was confirmed.

1,2,4,5-Tetracyanobenzene (TCNB, see Fig. 1) is a familiar molecule as an electron acceptor and many spectroscopic studies have been carried out in connection with its charge transfer interaction. However, the symmetry of the lowest unoccupied molecular orbital (LUMO) of TCNB has not been certified clearly. A simple theory such as linear combination of molecular orbital (LCMO) method shows only that both of an a_u and a b_{1u} MO can become the LUMO but does not indicate which MO really is the LUMO. ESR studies do not lead to a clear conclusion, either.[1]

Recently, Takahashi and Maeda reported resonance Raman spectra of some aromatic anion radicals and found the striking resonance enhancement of their skeletal stretching vibrations.[2] They studied the change of frequency of the respective Raman lines when a neutral molecule was converted to an anion radical and showed that the change was closely related to the distribution of nodes of the LUMO which is occupied by an unpaired electron.

Therefore, in the present study, resonance Raman spectrum of TCNB anion radical ($TCNB^-$) was measured and compared with that of TCNB in order to certify the assignment of the LUMO more clearly. Furthermore $TCNB^-$ has a pseudo degeneracy in the ground electronic state, which is an interesting case among the complicated vibronic potentials. Consequently vibrational analyses were carried out taking a vibronic effect into account.

Experimental

Commercially available TCNB (Frinton Laboratories) was used after sublimation, together with one offered by Dr. M. Tahara, our laboratory. TCNB-d_2 was offered by Prof. T. Takenaka, Kyoto University. Tetracyanoethylene (TCNE), tetracyanoquinodimethane (TCNQ) and hexamethylbenzene (HMB) (Tokyo Kasei) were used after sublimation and recrystallization. Tetrahydrofuran (THF), 1,2-dimethoxyethane (DME), and *N,N*-dimethylformamide (DMF) (Wako, Special Grade) were degassed and dehydrated repeatedly *in vacuo* after distillation and used as solvents for anion radicals. Acetonitrile and dichloromethane (Wako, Spectroscopic Grade) were used without further purification.

$TCNB^-$ was prepared by reduction with alkali metals *in vacuo* as usual.[3]

Raman spectra were obtained with a JEOL 400D spectrometer equipped with a HTV 649 photomultiplier, using a CR 52G Ar^+ laser as a continuous exciting source.

All measurements were carried out at room temperature.

Results and Discussion

Resonance Raman Spectra and Their Assignment. $TCNB^-$ showed an intense absorption band at 463 nm, as shown in Fig. 2, which is in good agreement with the result by Ishitani and Nagakura.[3] Figure 3 shows the resonance Raman spectrum of $TCNB^-$ by 457.9 nm excitation in THF solution, together with the Raman spectrum of TCNB in acetonitrile solution. The observed values of Raman shift and depolariza-

b) Raman spectrum of TCNB in acetonitrile solution (2.8 mol·dm^{-3}) by 488.0 nm excitation. s) Lines of solvent, t) Lines of TCNB. A 2237 cm^{-1} line was measured in THF solution.

tion ratio of $TCNB^-$ are shown in Table 1. All of the observed lines are totally symmetric because they were strongly polarized. The spectrum is not affected by varying solvents (THF, DME, and DMF) and cations (Na^+ and K^+).

The assignment of the observed Raman lines of $TCNB^-$ was carried out by referring to the assignment of Raman lines of TCNB. Table 1 shows the assignment for $TCNB^-$ and TCNB. TCNB has three totally symmetric lines, 1260, 1546, and 2237 cm^{-1} in the region of their skeletal stretching vibrations. Takenaka *et al.* assigned these lines to a mixing mode of C_1C_6 stretching and C_1C_7 stretching, a C_1C_2 stretching and a CN stretching vibration, respectively.[4] The three lines of $TCNB^-$, 1279, 1456, and 2198 cm^{-1}, should correspond to the fundamental vibrations of TCNB, 1260, 1546, and 2237 cm^{-1}, respectively. A 725 cm^{-1} line of TCNB may correspond to one of a few weak lines of $TCNB^-$ observed in 600—700 cm^{-1} region. A 402 cm^{-1} line of TCNB corresponds to a 408 cm^{-1} line of $TCNB^-$.

The present correspondence of the three Raman lines assigned to the skeletal stretching vibrations between TCNB and $TCNB^-$, which is essential in the later discussion, was confirmed by the resonance Raman study of CT complex of TCNB. Kaya *et al.*

reported the resonance Raman effect of weak CT complex[5] and obtained an interesting result where the degree of resonance enhancement of Raman lines of an acceptor moiety by the excitation at CT absorption band was closely related to the change in frequency of the acceptor molecule when it was converted to the anion radical. In a weak CT complex, an acceptor moiety in an excited CT state can be regarded as an anion radical. According to the Franck-Condon mechanism of Raman intensity, when a deviation of molecular geometry of an acceptor from neutral molecule to anion radical is large along a vibrational coordinate, the Raman lines of the acceptor moiety which relate to the vibrational coordinate show resonance enhancement by the excitation at CT absorption band.

TCNB forms CT complex with HMB and the complex has an absorption band of CT character at 426 nm. Figure 4 shows the observed resonance Raman spectrum of HMB–TCNB by the excitation with 457.9 nm line. The change of intensity by complex formation was observed for the three skeletal stretching vibrations of TCNB but any frequency changes were not observed. A striking enhancement was observed to take place for 1546 cm^{-1} line and a mild enhancement for 2237 cm^{-1} line, while 1260 cm^{-1} line showed an inappreciable change of intensity, as shown in Fig. 5. On the other hand, when TCNB is converted to TCNB$^-$, the above mentioned three lines of TCNB

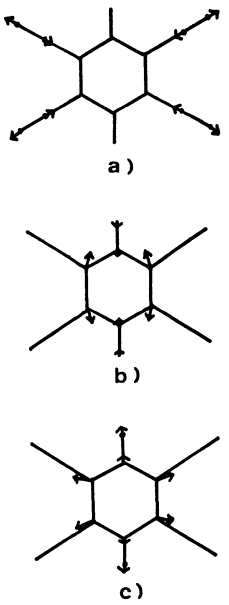

Fig. 6. The Cartesian displacements of normal vibrations of TCNB$^-$.

show the frequency changes, 1546−1456=90, 2237−2198=37, and 1260−1279=−19 cm^{-1}, respectively. These values correspond to the change of force constants, −11.6, −3.3, and +3.0%, respectively. These imply, in turn, the changes of bond order, that is, bond length of the relating CC and CN bondings. Therefore it is reasonably supported that the change of bond length from TCNB to TCNB$^-$ is striking for C_1C_2, mild for CN and C_1C_7 bondings. This inclination is parallel to that of resonance enhancement of the Raman intensity for the CT complex by the excitation at CT absorption band. Consequently, it is confirmed that the present relations of the three Raman lines between TCNB and TCNB$^-$ are reasonable.

Assignment of the LUMO of TCNB. The present analysis of Raman spectra of TCNB$^-$ led to a clearcut assignment of the LUMO of TCNB, as follows. As TCNB has four substituents on 1,2,4, and 5 positions, the two components of e_{2u} MO of benzene (one a_u MO, the other b_{1u} MO) are able to form bonding MO's with orbitals of substituents (see Fig. 1). When TCNB is reduced to TCNB$^-$, an unpaired electron occupies the LUMO of TCNB. If the a_u MO is occupied, C_1C_2 and CN bondings become to have more antibonding character, while C_1C_7 bonding becomes to have more bonding character. Therefore the force constants of the former bondings decrease, but that of the latter bonding increases. Consequently, the Raman lines assigned to C_1C_2 and CN stretching vibrations decrease their frequencies, while the line assigned to C_1C_7 stretching vibration increases its frequency. If the b_{1u} MO is occupied, the Raman lines assigned to C_1C_6 and CN stretching vibrations decrease their frequency, while the lines assigned to C_1C_7 and C_1C_2 stretching vibrations increase their frequency.

The present result shows the large decrease in fre-

quency from 1546 cm^{-1} for TCNB to 1456 cm^{-1} for $TCNB^-$, as shown in Table 1. The line at 1456 cm^{-1} for $TCNB^-$ has the character of C_1C_2 stretching vibration according to our calculation, as shown in Fig. 6. The Cartesian displacement of this mode was almost unchanged for TCNB. Therefore, this result asserts that an additional electron does occupy the a_u MO but not the b_{1u} MO. This is also supported by the moderate decrease of CN stretching vibration fre-

quency and the slight increase in frequency of the mixing mode of C_1C_6 and C_1C_7 stretching vibrations. These Cartesian displacements are also shown in Fig. 6. Thus it is concluded clearly that the LUMO of TCNB is the a_u MO. This conclusion agrees with the result of PPP-SCF-MO calculation of TCNB by Iwata *et al.*[6]

Vibrational Analyses of In-plane Vibrations of TCNB and TCNB$^-$. A normal coordinate calculation based on Urey-Bradley force field with Kekulé potential was carried out for TCNB and TCNB$^-$. In this calculation, the library programs, BGLZ and LSMB, of the computer center, the University of Tokyo, were used.

First, normal vibrations of TCNE and TCNQ were investigated in order to get an initial set of force constants for TCNB. The observed frequencies of TCNE and TCNQ are shown in Tables 2 and 3.[7-9] Their molecular parameters are the same as previously reported.[7,9] A more reasonable and transferable set of force constants was obtained by a trial and error method for TCNE and TCNQ as shown in Fig. 7. The calculated frequencies show good agreements with the observed values as shown in Tables 2 and 3.

An initial set of force constants of TCNB was derived from those of benzene,[10] 1,2,4,5-tetrachlorobenzene,[11] TCNE, and TCNQ. Table 4 shows the observed frequencies of TCNB reported by Takenaka *et al.*[4] The values of molecular parameters reported by Niimura *et al.* were used.[12] The distribution pattern of the Kekulé potential function of TCNB has been estimated from bond-bond polarizability, $\pi_{rs,tu}$, using PPP-SCF-MO of TCNB[6,13] under the approximation that $d\beta/dr$=constant for various bonds, as shown in Fig. 8 (β; resonance integral). Kekulé constant has been taken zero, initially. An adjustment by a trial and error method was carried out for the skeletal stretching force constants and the Kekulé constant. The final set of force constants of TCNB is shown in Fig. 7. Their values were reasonable in view of the bond orders of the corresponding bondings.[6] The calculated frequencies agree with the observed values as shown in Table 4.

For TCNB$^-$, the skeletal stretching force constants were changed according to the following equation, (bond order)$\propto$[(stretching force constant)$-$(Kekulé constant)$\times$(self bond-bond polarizability)].

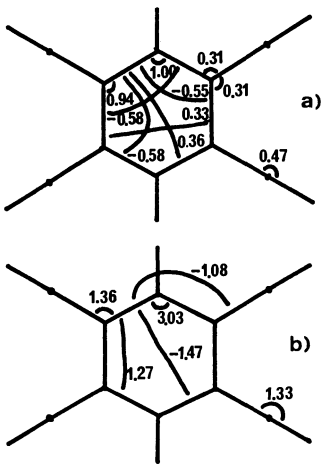

Fig. 8. Distribution patterns of $\pi_{rs,tu}$ of TCNB and TCNB$^-$. a) TCNB, b) TCNB$^-$.
The values are normalized as $\pi_{16,65}$ of TCNB=1.00.

The distribution pattern of Kekulé potential function of TCNB$^-$ is considerably changed from that of TCNB as shown in Fig. 8. As previously mentioned, the vacant b_{1u} MO of TCNB$^-$ must be located close to the a_u MO. Therefore, the denominator $E_{a_u}-E_{b_{1u}}$ in the formula of $\pi_{rs,tu}$ is fairly small, resulting in a large change in the Kekulé potential function. The pattern of the Kekulé potential of TCNB$^-$ (Fig. 8 b)) is similar to the pattern of the symmetry coordinate of C_1C_6 stretching vibration belonging to b_{1g} species, that is to say, there is a strong vibronic interaction between the a_u and the b_{1u} MO through this vibrational mode.

The calculated frequencies of TCNB$^-$ and their assignment based on L_x matrix and potential energy distribution are shown in Table 5. They agree with the observed values. Figure 6 shows the Cartesian displacements of the totally symmetric skeletal stretching vibrations derived from the L_x matrix. A Raman line of TCNB$^-$ at 520 cm^{-1} was assigned to C_1C_7N bending vibration of a_g species on the basis of this calculation. The C_1C_6 stretching vibration belonging to b_{1g} species shows remarkable decrease in frequency from 1605 cm^{-1} for TCNB to 810 cm^{-1} for TCNB$^-$, as shown in Tables 4 and 5. This decrease is due to the vibronic interaction between the a_u and the b_{1u} MO. A Raman line of TCNB$^-$ at 928 cm^{-1} cannot be assigned so far. This totally symmetric line is strong and has a combination line at

$2383 \approx 928 + 1456\ cm^{-1}$. So it may be assigned to a totally symmetric fundamental, but TCNB has not such a line in 750—1200 cm^{-1} region, nor other 1,2,4,5-tetrasubstituted benzene, for example 1,2,4,5-tetrachlorobenzene.[11] The assignment of this line has not been resolved rigorously and will be a further problem whereas it is guessed that this line may originate from the vibronic interaction.

The authots thank Prof. Tohru Takenaka, Kyoto University, and Dr. Masao Tahara, our laboratory, for offering of TCNB-d_2 and TCNB, respectively.

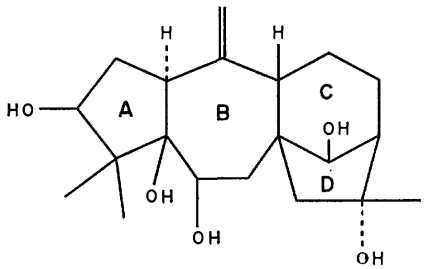
The Crystal and Molecular Structure of Grayanotoxin II

Akio FURUSAKI,* Nobuyuki HAMANAKA, and Takeshi MATSUMOTO
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received October 16, 1979)

The detailed molecular geometry of grayanotoxin II has been examined by means of X-ray crystallographic analysis. The crystals are orthorhombic, with four molecules in a unit cell with dimensions of $a=10.040$, $b=26.517$, and $c=6.672$ Å; the space group is $P2_12_12_1$. 1908 unique intensity data were collected on a four-circle diffractometer with LiF-monochromated Cu $K\alpha$ radiation. The structure was solved by the Monte Carlo direct method, using the 20 strongest reflections as the starting set; the 3rd random phase set led to the correct solution. The R value reached 3.8% by repeated block-diagonal least-squares refinements. The A, B, C, and D rings take envelope, twist-chair, chair, and half-chair conformations respectively. The conformation of the B ring closely resembles the preferred one of cycloheptane itself. The crystal consists of hydrogen-bonded double molecular layers piled parallel to the (010) plane.

A number of grayanane diterpenoids have been isolated from *Leucothoe grayana Max.*, *Pieris japonica* D. Don, *Rhododendron japonicum* Suringer, *etc.*, and their structures have been extensively investigated.[1-3] Since these diterpenoids contain four rings, especially a flexible seven-membered ring, their chemical reactivities are closely related to the ring conformations. Although one of the grayanoids, grayanotoxin (hereafter G) I, was subjected to X-ray crystallographic analysis, details of the molecular geometry have not yet been published.[4] In the present paper, we wish to report on the X-ray structure determination and molecular geometry of another grayanoid, G II (**1**).



1

Experimental

A colorless, single crystal with dimensions of about $0.3\times0.4\times0.6$ mm^3 was used for the X-ray measurement. The crystal data are summarized in Table 1. The cell dimensions and reflection intensities were measured on a Rigaku four-circle diffractometer using Cu $K\alpha$ radiation ($\lambda=1.5418$ Å) monochromatized with an LiF crystal. The intensity measurement was made by the θ-2θ continuous-scan technique at a 2θ scan rate of 2° min^{-1}; the background was measured for 30—60 s at each end of the scan range. Three standard reflections, measured at intervals of every 62 reflections, showed no significant decrease in intensity during the course of data collection. The intensities were corrected for the Lorentz and polarization factors, but not for the absorption or the extinction effect. In the range of 2θ values up to 140°, 1908 unique structure factor magnitudes above the $2\sigma(F)$ level were selected for the structure determination.

Table 1. The crystal data

Mol. formula	$C_{20}H_{32}O_5$
Mol. weight	352.5
Crystal system	Orthorhombic
Space group	$P2_12_12_1$
Cell dimensions	$a=10.040(3)$ Å
	$b=26.517(5)$
	$c=6.672(2)$
V	1776.3 Å^3
Z	4
D_x	1.318 g cm^{-3}
μ(Cu $K\alpha$)	7.14 cm^{-1}

Structure Determination

In the early stage of the structure determination, attempts were made to solve the structure by the symbolic-addition method,[5] but all such attempts were unsuccessful. The structure was finally elucidated by the Monte Carlo direct method.[6] The 20 strongest reflections were chosen as members of the starting set. Tentative phase values for the starting reflections were derived from successively-generated random numbers. In order to extend this tentative phase set, 10 cycles of the tangent procedure were performed using 421 $|E|$ values above 1.30; during the first 5 cycles, the phases of the starting reflections were kept constant. The 3rd phase set, which showed a low R_K value of 24.6% ($R_K=\Sigma||E_o|-k|E_c||/\Sigma|E_o|$), led to the correct solution. An E-map calculated with 407 phases clearly revealed the locations of all 25 non-hydrogen atoms.

The structure thus obtained was refined by the block-diagonal-matrix least-squares method, first with isotropic and then with anisotropic temperature factors. After all the 32 hydrogen atoms had been located in a difference Fourier map, further least-squares refinement was repeated including these hydrogen atoms with isotropic temperature factors. For this refinement, the following weighting scheme was used:

$$W = 1/\{\sigma(F)^2\exp(AX^2+BY^2+CXY+DX+EY)\},$$

where $X=|F_o|$ and $Y=\sin\theta/\lambda$. The coefficients, A, B, C, D, and E, are constants which were determined from the $(\Delta F)^2$ values. The final value of $R=\Sigma||F_o|-k|F_c||/\Sigma|F_o|$ was 3.8%. The atomic parameters thus obtained are listed in Table 2. The tables of the observed and calculated structure factors are kept at the Chemical Society of Japan (Document No. 8025).

TABLE 2. THE FINAL ATOMIC PARAMETERS AND ESTIMATED STANDARD DEVIATIONS

(1) The non-hydrogen atoms.

The temperature factors are defined as $\exp[-(\beta_{11}h^2+\beta_{22}k^2+\beta_{33}l^2+\beta_{12}hk+\beta_{13}hl+\beta_{23}kl)]$.

a) The hydrogen atoms are denoted by the number of the carbon atom to which they are attached, suffixed by a, b, or c where necessary.

All the calculations were performed on a FACOM 230-75 computer at the Hokkaido University Computing Center, using our own programs. Random numbers were generated by calling a function RANDOM which existed in the program library of the Computing Center. The atomic scattering factors were taken from the International Tables.[7)]

Results and Discussion

Molecular Structure. The molecular structure of G II is illustrated in Fig. 1, where each atom is represented as a thermal ellipsoid enclosing a 50%

Table 3. The bond distances (l/Å) and angles (ϕ/°), with their standard deviations

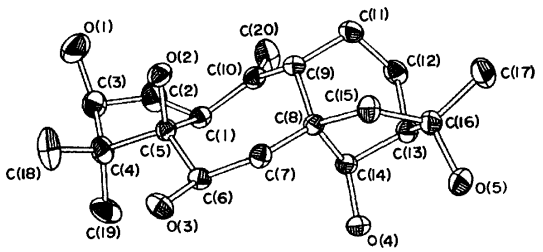

Fig. 1. A perspective view of the G II molecule. For the sake of clarity, hydrogen atoms are omitted.

probability. As can be seen in Fig. 1, the molecular framework obtained corresponds precisely to Structure **1** based on the chemical evidence.[1] The bond distances and angles and the dihedral angles are listed in Tables 3 and 4 respectively.

The five-membered A ring takes a deformed envelope conformation, with the C(4) atom deviating remarkably from the mean plane for the other four atoms in this ring. The O(1)H and O(2)H hydroxyl groups occupy the 1,3-diaxial positions in the A ring and form an intramolecular hydrogen bond, O(2)–H··· O(1), with each other (see Table 5). The equatorial methyl carbon, C(18), is only 3.004(3) Å distant from the O(3) atom. Because of this close contact, the C(5)–C(4)–C(18) and C(5)–C(6)–O(3) angles, 114.4 and 112.1°, may become somewhat greater than the standard tetrahedral angle.

The seven-membered B ring has a somewhat complicated conformation an approximate two-fold rotation axis running through the C(10) atom and the middle point of the C(6)–C(7) bond. This conformation corresponds almost exactly to the most stable twist-chair form of cycloheptane itself.[8] It is an interesting fact that, notwithstanding its incorporation in the complicated ring-system, the B ring keeps such a flexible conformation. All the sp^3-valency angles in the B ring are greater than 109.5°. Especially the C(6)–C(7)–C(8) and C(5)–C(1)–C(10) angles, 124.3 and 119.5°, are quite within the range of the normal sp^2-valency angle. The exocyclic methylene group, $C(20)H_2$, nearly eclipses the $C(11)H_2$ group around the C(9)–C(10) bond. As a result, the distance between the H(20a) and H(11a) atoms is only 1.92(5) Å. The difference of 5° between the C(1)–C(10)–C(20) and C(9)–C(10)–C(20) angles is probably due to this steric repulsion.

Table 5. The hydrogen bonds, X–H···Y

X	Y	X···Y (l/Å)	H···Y (l/Å)	X–H···Y (ϕ/°)
(1) Intramolecular				
O(2)	O(1)	2.818(2)	2.17(4)	144(4)
O(5)	O(4)	2.757(2)	2.07(5)	144(5)
(2) Intermolecular				
O(1)	O(5)[a]	2.871(3)	2.04(4)	169(4)
O(3)	O(4)[b]	3.122(2)	2.41(4)	173(3)
O(4)	O(3)[c]	2.785(2)	2.02(3)	152(3)

Symmetry codes are: a) $-1+x$, y, $1+z$; b) x, y, $1+z$; c) $3/2-x$, $-y$, $-1/2+z$.

The six-membered C ring in G II adopts a chair conformation, although it has recently been found that, in some other grayanoids, the C ring takes a boat conformation.[9] Since the seven-membered ring composed of the C(8), C(9), C(11), C(12), C(13), C(15), and C(16) atoms takes a boat conformation, the axial hydrogen, H(11b), is close to the H(15b) and H(17b) atoms; the distances are 2.12(5) and 2.20(5) Å respectively.

The five-membered D ring has a half-chair conformation, with an approximate two-fold rotation axis running through the C(15) atom. Since this conformation gives the 1,3-diaxial positions to the O(4)H

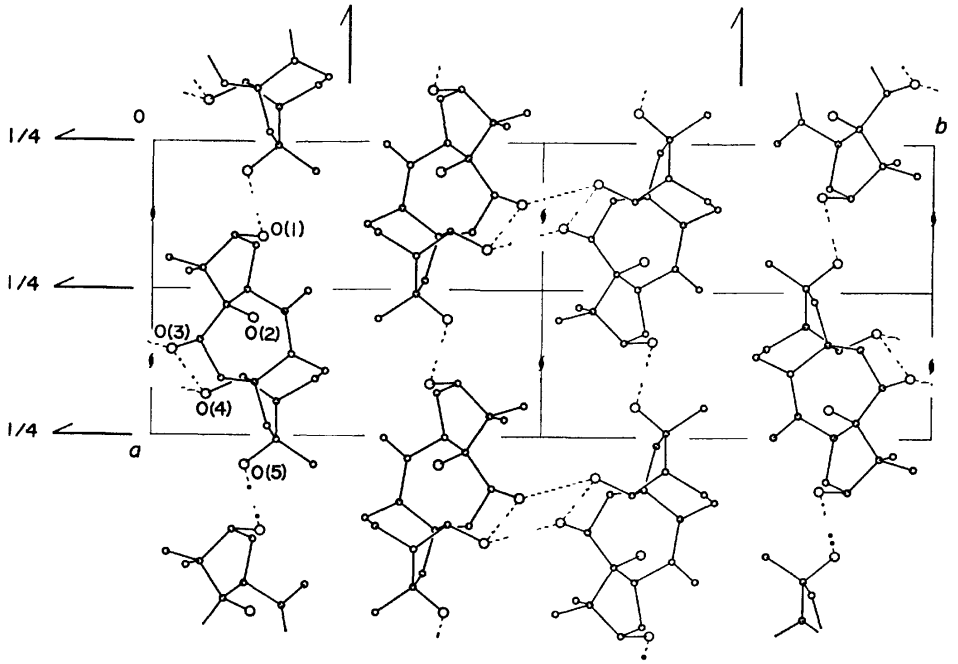

Fig. 2. The crystal structure viewed along the c axis.

and O(5)H hydroxyl groups, a stable intramolecular hydrogen bond, O(5)–H···O(4), is formed. The C(17)H_3 group, like the other two methyl groups, takes a stable staggered conformation.

Crystal Structure. The crystal structure viewed along the c axis is drawn in Fig. 2. The details of hydrogen bonding are given in Table 5. The molecules are connected by three kinds of intermolecular hydrogen bonds, forming a double molecular layer about the two-fold screw axes along the c axis. These molecular layers parallel to the (010) plane are further held together mainly by the van der Waals interactions.

Copper(I) and Copper(II) Complexes of Tripod Ligands, Tris(2-alkylthioethyl)amine

Masatatsu Suzuki,* Hajime Kanatomi, Hiroyuki Koyama, and Ichiro Murase

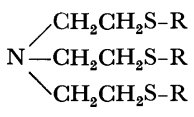
Laboratory of Chemistry, College of General Education, Kyushu University, Ropponmatsu, Chuo-ku, Fukuoka 810

(Received July 26, 1979)

A series of five-coordinate copper(II) complexes with tripod ligands, tris(2-alkylthioethyl)amines (NS_3–R, R=CH_3, C_2H_5, *n*-C_3H_7, *i*-C_3H_7, and *t*-C_4H_9), $[Cu(NS_3–R)L](ClO_4)_n$, where L represents Cl^-, Br^-, I^-, NCS^-, im(imidazole), py(pyridine) and H_2O, $n=1$ or 2 were prepared and characterized. The electronic, infrared and ESR spectral data suggest that $[Cu(NS_3–Me)im](ClO_4)_2$ and $[Cu(NS_3–Me)OH_2](ClO_4)_2$ have a five-coordinate square pyramidal geometry, the other complexes having distorted trigonal bipyramidal or trigonal bipyramidal geometry. The copper(I) complexes with NS_3–Me, $[Cu(NS_3–Me)]ClO_4$ and [Cu(NS_3–Me)NCS] were also prepared and characterized.

The stereochemistry of various cobalt(II) and nickel(II) complexes with tripod ligands, tris(2-alkylthioethyl)amine (NS_3–R), has been extensively studied, the bulkiness of the terminal donor groups being found to exhibit a marked influence on the geometry of the complexes.[1,2] In general, tripod ligands (L) such as tris(2-aminoethyl)amine and tris(2-dimethylaminoethyl)amine form penta-coordinated copper(II) complexes, $[CuLX]^+$ with additional monodentate anionic ligands (X) and the ligands (L) carrying bulky substituents bound to terminal donor atoms tend to form trigonal bipyramidal complexes.[3,4] For similar type ligands (NS_3–R) containing sulfur, however, only a little information is available on the stereochemistry of their copper(II) complexes, only the Cu(II) complex of tris(2-methylthioethyl)amine, [Cu(NS_3–Me)Br]Br being known to take a trigonal bipyramidal geometry.[1]

In the present work, copper(II and I) complexes with tripod ligands, NS_3–R (I) have been studied by varying the terminal alkyl groups R with additional monodentate ligands. The stereochemistry of the complexes is discussed in terms of IR, ESR, and electronic spectra. A study of this kind of copper complex containing sulfur would give useful information on the chemistry of so-called copper proteins which sometimes exhibit unusual behavior as copper complexes.[5-8]



(I)

R=Me, Et, *n*-Pr, *i*-Pr, or *t*-Bu

Experimental

Ligands. Tris(2-alkylthioethyl)amine (NS_3–R), where R refers to methyl, ethyl, *n*-propyl, isopropyl, and *t*-butyl, were prepared according to the procedure of Ciampolini *et al.*[1]

Complexes. $[Cu(NS_3–R)X]ClO_4$ (R=Me, Et, *n*-Pr, *i*-Pr, and *t*-Bu; X=Cl^- and Br^-) A methanol solution of copper(II) halide (1 mmol) was mixed with NS_3–R (1 mmol) in methanol. To this mixture (20 cm^3) was added a methanol solution (20 cm^3) of sodium perchlorate (2 mmol). Green crystals were immediately precipitated. In the case of the bromo complexes of NS_3-*i*-Pr and NS_3-*t*-Bu, ether was added to the reaction mixture to promote crystallization.

[Cu(NS$_3$–R)NCS]ClO$_4$ (R=Me or Et). NH_4NCS (1 mmol) in methanol (10 cm^3) was added to a methanol solution (20 cm^3) of $Cu(ClO_4)_2·6H_2O$ (1 mmol) and NS_3–R (1 mmol). The complex soon precipitated as dark green crystals.

[Cu(NS$_3$–R)OH$_2$](ClO$_4$)$_2$ (R=Me or Et). A methanol solution (20 cm^3) of NS_3–R (1 mmol) was mixed with $Cu(ClO_4)_2·6H_2O$ (1 mmol) in methanol (20 cm^3). Addition of ether gave green crystals.

[Cu(NS$_3$–Me)I]ClO$_4$. A cold methanol solution (20 cm^3) of NaI (1 mmol) was added to an ice-cold solution of $Cu(ClO_4)_2·6H_2O$ (1 mmol) and NS_3–Me (1 mmol) in methanol (20 cm^3) and the mixture was left to stand in a refrigerator overnight. The complex was obtained as a dark green powder.

[Cu(NS$_3$–R)Y](ClO$_4$)$_2$ [R=Me or Et; Y=Pyridine (py) or Imidazole (im)]. A methanol solution (20 cm^3) of NS_3–R (1 mmol) was mixed with $Cu(ClO_4)_2·6H_2O$ (1 mmol) in methanol (20 cm^3). To the mixture was added 1 mmol of pyridine or imidazole in methanol (10 cm^3). Green (Y=py) or dark blue (Y=im) crystals were obtained upon cooling.

[Cu(NS$_3$–Me)]ClO$_4$. $[Cu(CH_3CN)_4]ClO_4$ (1 mmol)[9] was added to a methanol solution (20 cm^3) of NS_3–Me (1 mmol) and the mixture was heated on a water bath for few minutes. A small amount of insoluble material was filtered off and the filtrate was cooled in a refrigerator. The complex was obtained as colorless crystals.

[Cu(NS$_3$–Me)NCS]. $[Cu(NS_3–Me)]ClO_4$ (1 mmol) was dissolved in warm methanol (30 cm^3). NH_4NCS (1 mmol) in methanol (10 cm^3) was added to the solution. Colorless crystals were immediately precipitated.

All complexes were air-dried at room temperature. The results of elemental analyses are given in Table 1.

Measurements. Electronic spectra in solid state and in solution were obtained with a Hitachi EPS-3T recording spectrophotometer, and infrared spectra with a Hitachi 295 infrared spectrophotometer by means of a KBr disk. Electrolytic conductivities were measured with a Yokogawa·Hewlett·Packard 4261A LCR meter in approximately 10^{-3} mol/dm^3 *N,N*-dimethylformamide (DMF) solution at 25 °C. Molecular weights were determined in DMF at 53 °C with a Hitachi Osmometer Type-115, calibrated with benzil. The concentration of each sample was approximately 10^{-2} mol/dm^3, the results being reproducible in ±3%.

Results and Discussion

Pyridine or imidazole reacted with equimolar $[Cu(NS_3–R)OH_2]^{2+}$ to form $[Cu(NS_3–R)py]^{2+}$ or $[Cu(NS_3–R)im]^{2+}$. However, addition of pyridine or imidazole in great excess resulted in displacement of

s: Shoulder. a) No peak observed up to 29,000 cm^{-1}.

the ligand NS_3–R to form $[Cu(py)_4]^{2+}$ or $[Cu(im)_4]^{2+}$. A similar displacement was observed with various bidentate ligands such as ethylenediamine, 2,2′-bipyridine, and glycine. This tendency suggests that the thioether group in the NS_3–R ligands has poor affinity to a copper(II) ion.

The chloro, bromo, and aquo complexes were considerably stable in acidic solution. For example, $[Cu(NS_3\text{–}Me)Cl]ClO_4$ could be recrystallized from hot 6 mol dm^{-3} hydrochloric acid, though NS_3–Me was replaced by chloride anions to give $[CuCl_3]$ $[H(NS_3\text{–}Me)]$ in hot concd hydrochloric acid.

The coloration of NS_3–R complexes in solution gradually fades on standing, this being attributable to the reduction of Cu(II) to Cu(I). When a basic aqueous solution of $[Cu(NS_3\text{–}Me)OH_2](ClO_4)_2$ was heated for a few minutes, a small amount of a monovalent copper complex $[Cu(NS_3\text{–}Me)]ClO_4$ was ob-

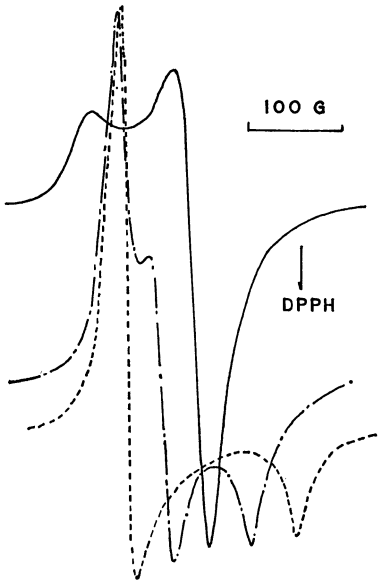

Fig. 1. The powder ESR spectra of $[Cu(NS_3–Me)im](ClO_4)_2$ (—), $[Cu(NS_3–Me)Cl]ClO_4$ (—·—), and $[Cu(NS_3–Et)Cl]ClO_4$ (----).

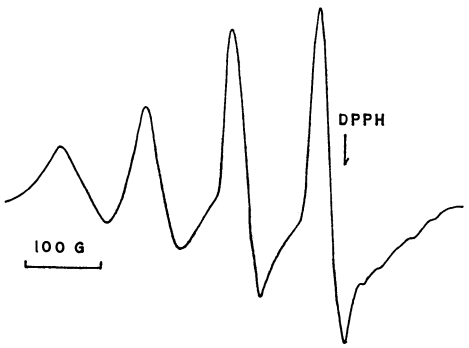

Fig. 2. ESR spectrum of $[Cu(NS_3–Et)Cl]ClO_4$ in DMF at liquid nitrogen temperature.

tained as colorless crystals.

$[Cu(NS_3–R)I]ClO_4$ is extremely unstable, reddish brown $[Cu(NS_3–Me)]I_3$ being isolated from the aqueous solution. This is due to the reduction of the Cu(II) ion by the coordinated iodide ion.

The powder ESR data are summarized in Table 2. The powder technique provides only crystal g-values rather than molecular g-values, the results sometimes causing misinterpretation.[10–12] However, the technique was useful for a rough estimation of the electronic ground state of the copper(II) complexes we studied. The results are supported by the electronic spectra as well as by the frozen solution ESR spectra.

The complexes are classified into four groups (a—d) from their ESR patterns (Table 2). The representative spectra of each group are given in Fig. 1 except for that of (d). The group (a) complex, $[Cu(NS_3–Me)im](ClO_4)_2$ shows an axial spectrum with $g_{\parallel} > g_{\perp}$, suggesting a $d_{x^2-y^2}$ electronic ground state.[12] Thus, a penta-coordinated square pyramid or a hexa-coordinated octahedron can be considered as a possible geometry. For the octahedron, coordination of one perchlorate anion is essential. However, the coordinated perchlorate anion was absent since no splitting of the ν(Cl–O) was observed in the infrared spectrum.[13] It can be assumed that group (a) complexes should have the penta-coordinated square pyramidal geometry. Group (b) complexes show axial spectra with $g_{\parallel} < g_{\perp}$ and group (c) complexes rhombic ones in which one of the g-values is less than 2.04. It is reasonable to suppose that group (b) and (c) complexes have a d_{z^2} or $ad_{z^2}+bd_{x^2-y^2}$ ($a \gg b$) ground state in trigonal bipyramidal or distorted trigonal bipyramidal geometry.[12] Group (d) complexes showed broad ESR spectra and could not be characterized.

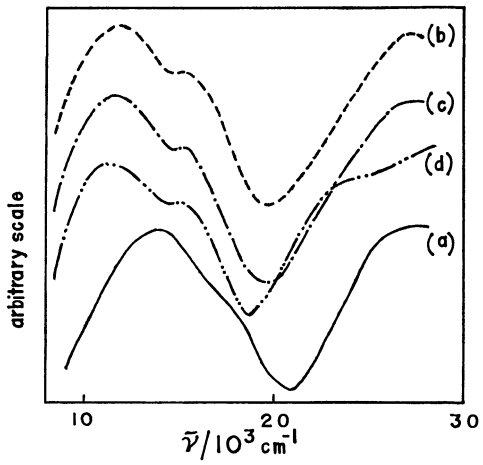

Fig. 3. Reflectance spectra of $[Cu(NS_3–Me)im](ClO_4)_2$ (——), $[Cu(NS_3–Me)Cl]ClO_4$ (—·—), $[Cu(NS_3–Me)Br]ClO_4$ (—··—), and $[Cu(NS_3–Et)Cl]ClO_4$ (----).

The ESR spectra were also measured in DMF and nitromethane at room temperature and at liquid nitrogen temperature. Only three complexes, $[Cu(NS_3–Me)Cl]ClO_4$, $[Cu(NS_3–Et)Cl]ClO_4$, and $[Cu(NS_3–t\text{-}Bu)Cl]ClO_4$ exhibited relatively simple spectra at liquid nitrogen temperature.[14] The spectrum of $[Cu(NS_3–Et)Cl]ClO_4$ (Fig. 2) is a typical one for trigonal bipyramidal copper(II) complexes.[15–17]

Since the frozen solution spectra of these complexes were unresolved in high field region, $g_{\parallel}$-values were calculated using $<g>$ values $[<g>=(g_{\parallel}+2g_{\perp})/3]$ from the room temperature spectra with $g_{\perp}$-values from the frozen solution spectra with the following results: $g_{\parallel}=2.015$, $g_{\perp}=2.122$ for $[Cu(NS_3–Me)Cl]ClO_4$; $g_{\parallel}=2.023$, $g_{\perp}=2.120$ for $[Cu(NS_3–Et)Cl]ClO_4$; $g_{\parallel}=2.023$, $g_{\perp}=2.128$ for $[Cu(NS_3–t\text{-}Bu)Cl]ClO_4$. The $g_{\parallel}$-values suggest that the complexes have a geometry of trigonal bipyramid or distorted trigonal bipyramid in DMF as well as in solid state.

The reflectance spectral data are also given in Table 2. The complexes $[Cu(NS_3–R)X]ClO_4$ ($X=Cl^-$, Br^-, I^-, and NCS^-) belonging to group (b), (c), or (d) show an intense band at lower energy side and a less intense band at higher energy side (Fig. 3). These spectra are closely similar to those of trigonal bipyramidal complexes, $[Cu(NS_3–Me)Br]Br$[1] and $[Cu(Me_6–tren)Br]Br$[18] where Me_6–tren represents tris(2-dimethylaminoethyl)amine. The energy shift of the d-d bands can be correlated with the position of the coordinated anion X in the spectrochemical series. The spectral similarity suggests that $[Cu(NS_3–R)X]$-

ClO_4 in groups (b), (c), and (d) have similar geometry, *i.e.*, trigonal bipyramidal or distorted trigonal bipyramidal. Ciampolini *et al.*[1] assigned two bands at 11400 and 15200 cm^{-1} observed for [Cu(NS_3–Me)Br]Br to the electronic transitions of $d_{x^2-y^2}$, $d_{xy} \rightarrow d_{z^2}$, and d_{xz}, $d_{yz} \rightarrow d_{z^2}$, respectively. Their assignment seems to be valid for the present [Cu(NS_3–R)X]ClO_4 type complexes. It should be noted that these complexes have extremely high intensities (ε=700—1000) of the d-d bands at the lower energy side as compared with that of [Cu(Me_6-tren)Br]Br (ε=450).[18] It is probably due to the lower symmetry of the complexes. The molar extinction coefficients were reported to be 390 at 11400 cm^{-1} in nitromethane for [Cu(NS_3–Me)Br]Br,[1] but *ca.* 900 for freshly prepared solution for [Cu(NS_3–Me)Br]ClO_4. This discrepancy is attributed to the instability of these complexes in solution. They exhibit some bands in the near ultraviolet and ultraviolet region (Table 2), and probably contain electronic transitions of X (σ and π) and S (σ and/or π) to Cu(II), since the free ligands showed no absorption in this region.

It should be noted that [Cu(NS_3–Me)im]$(ClO_4)_2$ of group (a) has a d-d band maximum at 14080 cm^{-1} whereas [Cu(NS_3–Me)py]$(ClO_4)_2$ of group (c) has one at 12580 cm^{-1}. Since imidazole and pyridine have similar ligand field strength, the large difference in the d-d transition energy should be attributed to the difference in their geometry. This is in line with the grouping by powder ESR spectra. The grouping of [Cu(NS_3–Me)OH_2]$(ClO_4)_2$ to (a) and [Cu(NS_3–Et)OH_2]$(ClO_4)_2$ to (b) is also supported by the electronic spectral data.

Although no principle controlling the stereochemistry of the tripod ligand copper(II) complexes could be found in the present investigation, the combination of the bulkiness of the terminal alkyl groups and the ligand field strength of the fifth monodentate ligands may have some influence on the geometry of the complexes.

Copper(I) Complexes. The copper(II) complexes undergo self reduction to the copper(I) complexes in solution. In fact, the copper(I) complexes isolated are very stable towards molecular oxygen even in solution. Although direct evidence for structure determination is lacking, it could be assumed from the steric requirement of the tripod ligands that [Cu(NS_3–Me)]ClO_4 is trigonal pyramidal and [Cu(NS_3–Me)-NCS] trigonal bipyramidal or square pyramidal.

The infrared spectrum of [Cu(NS_3–Me)NCS] showed the CN stretching vibration of NCS^- at 2080 cm^{-1} which indicates the coordination of NCS^- in the solid state.[19] On the other hand, the conductivity measurement in DMF reveals that the complex is an 1:1 electrolyte which could be formulated as [Cu(NS_3–Me)]NCS or [Cu_2(NS_3–Me)$_2$NCS]NCS. The molar conductance based on the former was 43 Ω^{-1} cm^2 mol^{-1}, being typical for an uni-univalent electrolyte.[20] Molecular weight determination[18] revealed that the van't Hoff factor i values are 1.3 for the former and 2.6 for the latter. These values suggest that the complex is monomeric in DMF. The low conductance value based on the monomeric form seems to be attributable to the following equilibrium in DMF:

$$[Cu(NS_3\text{-}Me)NCS] \rightleftharpoons [Cu(NS_3\text{-}Me)]^+ + NCS^-$$

The conductivity of [Cu(NS_3–Me)]ClO_4 in DMF suggests that the complex can be formulated as [Cu_n(NS_3–Me)$_n$]$(ClO_4)_n$ (Λ=79 Ω^{-1} cm^2 mol^{-1} for n=1, Λ=158 Ω^{-1} cm^2 mol^{-1} for n=2 *etc.*). The van't Hoff factor i values were $1.7 \times n$. It is probable that the complex is monomeric with the formula, [Cu(NS_3–Me)]ClO_4 in DMF.

Our thanks are due to Prof. S. Kida, and Prof. H. Okawa, Dr. Y. Nishida and Mr. Y. Nonaka for helpful discussions and valuable comments, and to Mr. Y. Nonaka for the ESR measurement and Prof. A. Matsubara and Mr. K. Nomura for the conductivity measurement.

A Quantum Chemical Study on the Ion Influence on Linear Water Polymer

Bernd M. Rode,† Ryo Fujikura, and Shizuo Fujiwara*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received October 26, 1979)

Quantum chemical model calculations have been performed using an STO-3G basis set for linear water polymers under the influence of electrostatically approximated cations and anions. It is found that the influence of the cations on the ligand chains can be described properly as a purely electrostatic interaction from the third water molecule on. The mutual influencing of cation and anion in ion pairs separated by more than one solvent molecule seems to be also a merely electrostatic one. An estimation of the range of these electrostatic forces is given.

Recently, one of the present authors (S.F.) has shown experimentally that any simple ion or molecule in aqueous solution requires a certain volume of solution for the maintenance of the free motion and named the latter "molecular space."[1] This raised several questions concerning the nature and the extent of the ion-solvent interactions being responsible for this phenomenon.

Due to technical and computational limitations, usual quantum chemical calculations concerning the interactions of ions with solvent molecules can take into account only a few solvent molecules and represent, therefore, a rather poor approximation to the reality of solutions. Several attempts have been made, therefore, to take into account the conditions of the solution by means of perturbation terms or electrostatic approximations.[2-4] Large computations of some examples of solvated ions[5] and a study on the interaction of a cation with an anion through 2—3 water molecules[6] allow a limited comparison of the results obtained by the approximations with those of full *ab initio* calculations.

Recent calculations of hydrated ions by the MESQUAC-MO-method[4,7] allowed to obtain ion-solvent interaction energies up to the third shell and proved to form a good basis for the discussion of the structural influence of the ion on the surrounding water layers and hence for the phenomenon of the "molecular space."

In the work presented here, we have carried out model calculations on the nature of ion/solvent interactions as a function of the distance between the ion and the water molecules. A molecular model consisting of cation and/or anion bonded to a linear water chain was used for this purpose. It was to be expected that this model would indicate something about the relevant contributions to the binding of solvent molecules even at larger distances and hence form a useful basis for the construction of larger theoretical models for hydrated ions.

Experimental

General Remarks. The idea to reduce the computational problem by means of a partial electrostatic treatment is based on general considerations on importance and range of the contributions to the chemical bond. For ions with ns^2np^6 valence electron configuration, the description as electrostatic point charges seems to be reasonable within certain limitations, as it has been shown already in an analogous example.[3] The interaction between two solute entities, either ions or molecules, which are separated over a larger distance, may be interpreted in terms of the typical "quantum effect" of interference,[7] which is proportional to the overlap integral and hence decreasing exponentially with the distance r, whereas the electrostatic terms, decreasing with r^{-1}, will be effective even at a larger distance and hence can be a dominant factor of interaction over such distances. One of the main scopes of this work was to find out at what distance electrostatic effects will dominate the quantum effects. If one attempts to describe a model for the interaction of an ion with a "chain" of water molecules applying an electrostatic approximation for the central ion, the description of the ion interaction with the first water molecule will be somewhat less satisfactory. For the ion-binding to the first water molecule, however, accurate MO-HF-SCF calculations have been performed,[8] and including the consideration of the experimental gas phase interaction energies, the results of our simplified model calculation can be controled easily.

Performance of the Calculations. The cations were taken into account by means of the point charges of +1 and +2 for alkali and alkaline earth metal ions, respectively, sited at the *ab initio* SCF energy optimized distances from the oxygen of the water molecule (C_{2v} symmetry). The procedures taken here are same as that shown in a previous paper[3] for the case of ion-amide interactions. The corresponding values are given in Table 1.

The water molecule(s), linked to a chain of increasing length ($n=1,2,\cdots 8$) were considered by a nonempirical all-electron (*ab initio*) LCAO-MO-SCF treatment using an STO-3G basis set.[9] In order to evaluate the effect of the ion species, the energy of the chain was calculated with and without the "perturbation" by the point charges representing the ions. Subtracting both energy values the ion solvent interaction energy is obtained. Dividing this value by the number of water molecules building up the chain, one obtains the stabilization energy per water molecule,

Table 1. The distance between the point charge of the metal ion and the coordinative center of the water molecule

Bond	Distance/Å	Bond	Distance/Å
Li-O	1.85	Mg-O	1.85
Na-O	2.10	Ca-O	2.10
K-O	2.63	Ba-O	2.46
Cs-O	2.80	I-H	1.87
Be-O	1.46

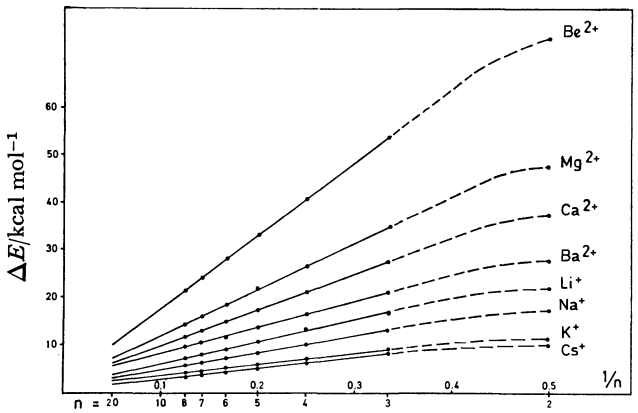

Fig. 1. Stabilization energy per water molecule for varying chain lengths and ions *versus* the inverse number of water molecules in the polymer.

which will be the basis for further discussion.

The geometry of the chain was based on the following values: O–H=0.96 Å, O/H/O=104.5°, O···H–O=2.75 Å. Furthermore, we have performed some calculations on ion pair interactions, *i.e.*, the interaction between the cation and the anion separated from each other by solvent molecules. For this purpose, iodide ion was taken as the counter anion which was linked to the other end of the water chain.

All calculations have been performed using a modified GAUSSIAN 70 program at the FACOM 230-60/75 computer of the Institute of Physical and Chemical Research at Wako City.

Results and Discussion

Applicability of the Method. The use of the electrostatic approximation for the ions is somewhat problematic due to the neglect of some binding effects and the charge transfer. In the case of the main group metal ions, however, these effects could be shown to be of rather minor magnitude.[4,7] The energies calculated within our model approach here prove this once more being in quite satisfactory agreement with the binding energies obtained by either full *ab initio* calculations or gas phase experiments (*cf.* Table 2). We can expect, therefore, that the electrostatic approach for the ions is justified and would not influence the reliability of the results to a serious extent.

Binding of Single Ions to the Water Chain. In Table 2 the binding energies per water molecule in a chain containing 1 to 8 molecules are listed. As can be seen from Fig. 1, they decrease linearly with $1/n$ from the third water molecule on, which actually means a decrease following the law of Coulomb interactions decreasing with $1/r$. We can conclude, therefore, that for a correct description of the ion-solvent interaction concerning the first and second water molecules, we need the formalism of quantum theory allowing to reflect redistribution of electron density within the solvent molecules upon ion influence. For the more far located water molecules (*i.e.* the third and all further molecules), a purely electrostatic interaction of ion and solvent molecules seems to exist. It will be sufficient, therefore, to use an electrostatic approximation for these solvent molecules when discussing their interaction with the ion. This gives a further proof for the applicability of the MESQUAC-MO method to such systems.[4,7] This statement is expected to hold even for ions not having the noble gas electron configuration, as the stronger quantum effects appearing in the ion-solvent binding of such ions should be restricted mainly to the interaction with the first solvation layer. The absolute value for the interaction energy calculated for the iodide ion with water is also in good agreement with the corresponding *ab initio* value and the widely discussed effect of this low binding energy on the phenomenon of "negative" hydration.[11] For Cs^+, however, which also shows negative hydration, this phenomenon cannot be predicted from the present calculation. The reasons for the latter fact are to be seen mainly in the uncertainity of the ion-ligand distance chosen according to the ionic radii only, and in an artificial stabilization for larger cations due to the merely electrostatic description. For iodide ion, this failure could be avoided partially using the distances obtained in previous full *ab initio* calculations.

Solvent Separated Ion Pairs. The stabilization energies per water molecule in chains separating cations and anion are listed in Table 3. As can be shown from Fig. 2, the mutual interaction of the ions through the water chain seems to follow the $1/n$ (*i.e.*, the $1/r$) Coulomb law for any case where more than one solvent

Table 3. Stabilization energies per water molecule for solvent separated ion pairs of alkali iodides, for chain lengths 1—8 (in kcal/mol)

n	Li(water)I	Na(water)I	K(water)I	Cs(water)I
1	101.2	91.1	76.7	73.8
2	48.5	43.3	35.9	34.5
3	32.5	29.0	24.0	23.1
4	22.9	20.3	16.8	16.1
5	18.1	16.1	13.3	12.7
6	14.6	13.0	10.7	10.3
7	12.5	11.1	9.1	8.5
8	10.7	9.5	7.8	7.5

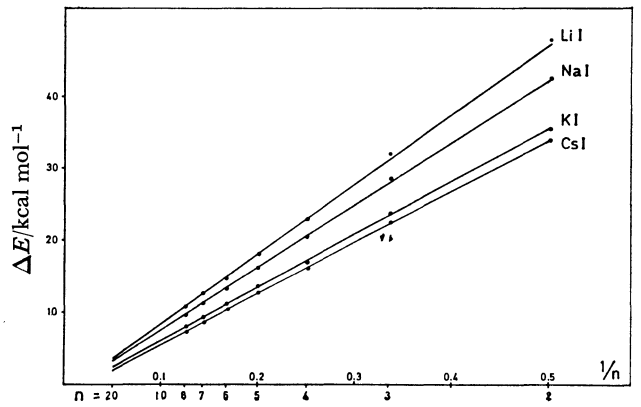

Fig. 2. Stabilization energy per water molecule for varying chain length and ion pairs *versus* the inverse number of water molecules in the polymer.

molecule is present. We can expect therefore also for larger solvent separated ion pairs that an electrostatic description of the cation/anion interaction will be quite satisfactory and sufficient.

The Range of Interactions. The level of 7.1 kcal/mol, being the hydrogen bond energy within the STO-3G *ab initio* framework, actually represents the "critical level" down to which ion-solvent binding energy might have some influence on the solvent structure. The linear chain model, however, is insufficient for the description of the solution reality, since it is an idealized structure, not taking into account effects of 3-dimensional solvates, thermal motions and entropic contributions, which all will lead to a faster decrease of structural influence of the ions. It is, however, useful for a rough estimation of a theoretical upper limit of the range of interaction under "optimal" conditions, *i.e.*, in a well ordered solvent matrix. For such a case, we have to expect, according to the values of Tables 2 and 3, rather far reaching effects of binding. This seems to be in agreement with some recent discussions within the framework of an extended donor-acceptor theory.[12]

Besides representing an estimation of the possible upper limit of interaction ranges, these data might get some practical importance in systems, where a peculiar ordering of the solvent molecules can take place, as for example in quick frozen solutions or in gel matrices.

Summarizing thus the results of our model calculations, we can assume that the application of mixed electrostatic-quantum chemical calculation procedures, taking into account far reaching binding effects by purely electrostatic terms, seem to be justified. The same can be expected for the theoretical investigation of solvent separated ion pairs containing more than one water molecule as a dielectric between the ions. The range of these electrostatic effects will depend very strongly on the degree of ordering of these solvent molecules and hence be influenced strongly by thermal and entropy effects. Finally, a construction of theoretical models describing well ordered solvent matrices will have to consider rather large unities in order to describe all interactions possible in such a system.

Thanks are due to Dr. S. Iwata for his kind support with the computing facilities at the Institute of Physical and Chemical Research at Wako City. Thanks are due also to the Funds zur Förderung der Wissenschaftlichen Forschung (Vienna, Austria, Project Nr. 3725) and the government of Tyrol for financial support.

The Reaction of *cyclo*-Triphosphate with L-Valine

Mitsutomo Tsuhako,* Naoko Fujita, Akiko Nakahama, Tsuneo Matsuo, Masamitsu Kobayashi, and Shigeru Ohashi**

Kobe Women's College of Pharmacy, Kitamachi, Motoyama, Higashinada-ku, Kobe 658

***Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812*

(Received November 8, 1979)

The reaction of *cyclo*-triphosphate(P_{3m}) with L-valine in an aqueous solution was studied by means of anion-exchange chromatography, paper chromatography, chemical analysis for phosphorus and valine, IR spectroscopy, and ninhydrin reaction. 1) P_{3m} reacted with L-valine at pH 10—12 to form an unknown compound, the amount of which reached about 22% at pH 12 and about 9% at pH 10. This compound decomposed into orthophosphate-(P_1) and valine at a lower pH. 2) The unknown compound was proved to be a P_1-derivative of valine,  , which has a P–N bond in its molecule. 3) In the reaction of P_{3m} with L-valine at pH 10, in addition to the unknown compound, small amounts of tetra(P_4) and pentaphosphate(P_5) were produced. 4) The disappearance rate of P_{3m} in this reaction was first-order, and its rate constants were 0.317 and 0.138 d^{-1} at pH 12 and 10 respectively at room temperature. 5) Short-chain phosphates, such as P_1, pyro (P_2), and triphosphate(P_3), did not react with L-valine at all. 6) The mechanism of the reaction of P_{3m} with L-valine was discussed.

It was first reported in 1958 by Quimby and Flautt[1] that P_{3m} easily underwent ring cleavage by ammonia to give amidotriphosphate. After that, the reactions of various alkylamines with P_{3m} and *cyclo*-tetraphosphate(P_{4m}) have been studied by Feldmann.[2–5] Furthermore, the application of condensed phosphates as inhibitors to the formation of *N*-nitrosodimethylamine, which is a well known carcinogenic substance and which is easily formed by the reaction of dimethylamine with nitrous acid or nitrite, has recently been reported.[6] That is, when a condensed phosphate is added to an aqueous solution of dimethylamine, they react with each other and the reaction of dimethylamine with nitrous acid or nitrite is inhibited. On the other hand, Rabinowitz,[7–9] applying various phosphates as condensing agents for the polymerization of glycine or alanine, has obtained the corresponding dimers (glycylglycine and alanylalanine) and trimers (glycylgylcylglycine and alanylalanylalanine).

As has been described above, the reactions of cyclic phosphates with ammonia and its derivatives have attracted notice from various points of view. However, up to the present, little attention has been paid to the phosphorus-containing products in the reaction between cyclic phosphates and amino acids or to the mechanisms of the formation of these products. The present investigation was undertaken to see what products, especially phosphorus-containing products, are formed in the reaction of P_{3m} with L-valine, an α-amino acid. The reaction products were examined by means of anion-exchange chromatography, paper chromatography, chemical analysis for phosphorus and valine, IR spectroscopy, and ninhydrin reaction. For the sake of comparison, the reactions of L-valine with P_1, P_2, and P_3 were also tested. From the data obtained, the mechanism of the reaction of P_{3m} with L-valine was discussed.

Experimental

Chemicals. Sodium *cyclo*-triphosphate hexahydrate,[10] $Na_3P_3O_9 \cdot 6H_2O$, was prepared by heating sodium dihydrogenorthophosphate dihydrate at 530 °C for 5 h, cooling it slowly to room temperature, and then crystallizing from an aqueous solution. The $Na_3P_3O_9 \cdot 6H_2O$ thus obtained was identified by paper chromatography and X-ray diffractometry. Reagent-grade L-valine was used without purification. Unless otherwise stated, guaranteed reagents from Wako Chemical Industries, Ltd., were used without further purification.

Reaction between cyclo-*Triphosphate and* L-*Valine.* Two aqueous solutions, 0.4 mol dm^{-3} sodium *cyclo*-triphosphate hexahydrate and 0.4 mol dm^{-3} L-valine, were mixed in a volume ratio of 1:1. The pH of the mixture was about 5.8. The solution was then adjusted with a 6 mol dm^{-3} sodium hydroxide solution to the prescribed pH (10 and 12) and allowed to stand at room temperature. With the progress of the reaction, the pH of the solution was gradually lowered, and then the sodium hydroxide solution was added to maintain the prescribed pH. It was also observed that, at pH values below 9, the solution became moldly.

Anion-exchange Chromatography.[11,12] A chromatographic column of 64×1.5 cm I. D. packed with an anion-exchange resin, Bio-Rad AG 1-X8 (chloride form) of 100—200 mesh, was used. The gradient-elution technique was employed. Sodium chloride solutions of 0.32 mol dm^{-3} and 0.12 mol dm^{-3} were stored in a reservoir (3000 cm^3) and a mixing bottle (750 cm^3) respectively. 150 and 40 cm^3 of a mixture (2:1) of the 0.1 mol dm^{-3} tetrasodium ethylenediaminetetraacetate (EDTA-4Na) and 0.1 mol dm^{-3} disodium ethylenediaminetetraacetate (EDTA-2Na) solutions were added to the sodium chloride solutions in the reservoir and the mixing bottle. The pH of the eluent was about 10. The sample solution was diluted 20 times, and 1 cm^3 of it was injected into a column. The effluent was collected in 10-g fractions with a fraction collector of the weight type.

Determination of Phosphorus.[11,13] The phosphorus in the effluent was determined by the orthophosphoric heteropoly-blue method. To 10-g of the fractionated effluent, 2 cm^3 of the molybdenum(V)–molybdenum(VI) reagent[14] and about 5 cm^3 of distilled water were added. The mixture was heated in a water bath at 95 °C for 1 h. After cooling, the solution was made up to 25 cm^3 with distilled water. The absorbance was measured at 830 nm by means of a Hitachi Spectrophotometer, 100-20 type.

Determination of Valine. A Hitachi Amino-acid An-

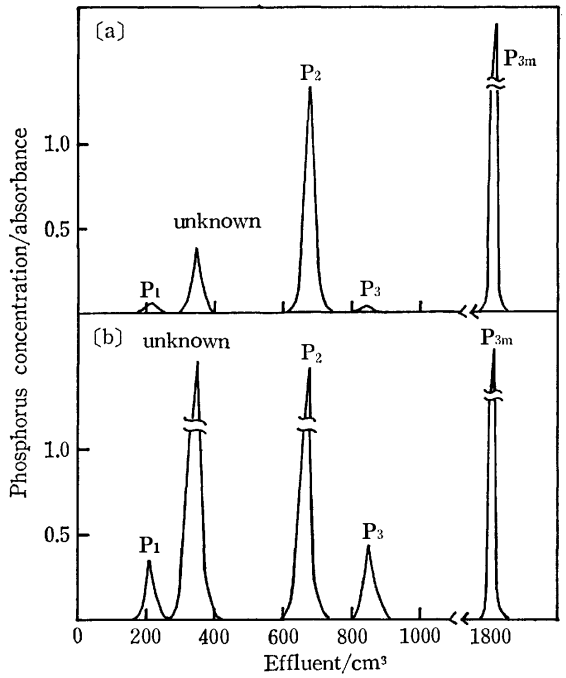

Fig. 1. Elution patterns for the reaction products of P_{3m} with L-valine at pH 12.
(a): After 1 d, (b): after 14 d.

alyzer, KLA-5 type, was used for the determination of valine in the reaction products.

Paper Chromatography. Using Toyo Roshi No. 51A filter paper and acidic and basic solvents,[15-17] the phosphate species in the reaction products were paper-chromatographed by an ascending technique at 5 °C and at room temperature for about 20 h.

Ninhydrin Reaction. To 5 cm³ of the fractionated effluent we added a few drops of a 5% ninhydrin solution, after which the mixture was boiled and then cooled. The reddish purple coloration indicates the presence of valine.

IR Spectroscopy. After the fractionated effluent had been dehydrated under reduced pressure, it was submitted to IR spectroscopy. Since, in the sample, sodium chloride was present in a large amount, a direct measurement was possible without any dilution with potassium bromide. A Hitachi Infrared Spectrophotometer, EPI-S2 type, was used.

Results and Discussion

Reaction of cyclo-*Triphosphate with* L-*Valine.* The aqueous solutions of P_{3m} and L-valine were mixed at a molar ratio of 1:1 and adjusted to pH 10 and 12 with a sodium hydroxide solution. When the mixture was allowed to stand at room temperature, the pH of this solution gradually lowered. This may suggest the formation of chain phosphates and/or their derivatives by the reaction of P_{3m} with water and/or L-valine. During the progress of the reaction, the sodium hydroxide solution was added to maintain the prescribed pH. The reaction products of P_{3m} with L-valine were separated by anion-exchange chromatography. As examples, the elution patterns for the reaction mixture at pH 12 after 1 d and after 14 d are shown in Fig. 1. Between the elution peaks of P_1 and P_2, a peak of an unknown compound appeared. P_2 began

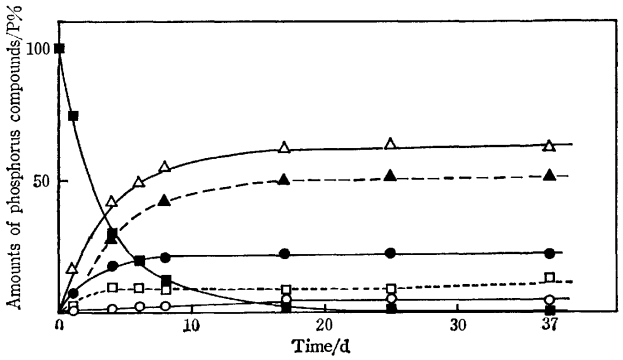

Fig. 2. Change of the amounts of phosphorus compounds in the reaction of P_{3m} with L-valine at pH 12.

to precipitate as crystals of tetrasodium pyrophosphate decahydrate on the 2nd day. Figure 2 shows the changes in the amounts of P_1, P_2, P_3, P_{3m}, and the unknown compound during the progress of the reaction. As can be seen from Fig. 2, the amount of the starting material, P_{3m}, rapidly decreased with time and became nearly zero within four weeks. On the contrary, the amounts of P_2 and the unknown compound gradually increased with time, reached about 62 and 22% respectively after 2 weeks, and after that were almost constant. Although the amounts of P_1 and P_3 were less than those of P_2 and the unknown compound, they gradually increased with time.

The products obtained by the reaction of P_{3m} with L-valine at pH 10 were somewhat different from those obtained at pH 12 and consisted of six kinds of phosphates, *i.e.*, the unknown compound, P_1, P_2, P_3, P_4, and P_5. The changes in the amounts of the unknown compound, P_1, P_2, P_3, and P_{3m} with time are shown in Fig. 3. The data for P_4 and P_5 are omitted, because their amounts are very small. Unlike the results in the case of pH 12, the yield of the unknown compound at pH 10 reached a maximum, about 9%, after 7—8 d, and after that gradually decreased. It was only about 2.6% after 31 d. The amounts of P_4 and P_5 formed at pH 10 were about 0.7 and 0.5% respectively after

31 d. It is an interesting phenomenon that, at pH 10, P_4 and P_5 are produced. The mechanism of their formation has not yet been definitely proved, but will be discussed later.

The above experimental results indicate that the yield of the unknown compound was higher at pH 12 than that at pH 10. In order to confirm this fact, the reaction of P_{3m} and L-valine was tried at a lower pH. A mixture of P_{3m} and L-valine solutions at a molar ratio of 1:1 was allowed to react at pH 12 for a week. After that, this sample solution was divided into two portions, one being set at pH 12 and the other being allowed to stand without any adjustment of the pH. The yields of the products in these two series of experiments are shown in Fig. 4, in which the amount of precipitated P_2 has been omitted. The variations in the pH are indicated below the abscissa. The amounts of P_2, P_3, and P_{3m}, when the pH was not controlled, are also omitted, because they are almost the same as those when the pH was controlled at 12. When the pH was not controlled, the pH of the solution gradually decreased with the progress of the reaction, and the yield of the unknown compound decreased and became nearly zero at pH 9.8. On the contrary, the yield of P_1 was found to increase sharply. The curve of the formation of the unknown compound has a tendency reverse-symmetric to that of P_1. This suggests that the unknown compound, initially formed in a large quantity at pH 12, decomposed into P_1 as the pH of the solution was lowered. This means, in turn, that the unknown compound may be a P_1-derivative of valine.

The disappearance rates of P_{3m} in the reactions with L-valine at pH 12 and 10 at room temperature were found to be first-order. The rate constants were 0.317 and 0.138 d^{-1} at pH 12 and 10 respectively.

The reactions of P_{3m} with L-valine at molar ratios of 0.1:1, 0.5:1, 5:1, and 10:1 were also studied at pH 12, but it was found that the products were completely the same kinds as those at the molar ratio of 1:1. By the reactions of P_{3m} with L-valine in neutral and acidic solutions, no unknown compound was obtained at all.

Molecular Structure of the Unknown Compound. As has been described in the preceding section, it was concluded that the unknown compound may be a P_1-derivative of valine. In order to get more information on the molecular structure of this compound various methods were employed. A solution of the unknown compound, separated by ion-exchange chromatography, was paper-chromatographed with an acidic solvent. The unknown compound gave a spot with a strong coloration at the position corresponding to P_1 and another spot with a weak coloration at a position between those of P_1 and P_2. The latter may be due to the unknown compound. The former may be due to the P_1 produced by the hydrolysis of the unknown compound in the acidic solvent. This fact also supports the idea that the unknown compound is a P_1-derivative of valine.

The amounts of phosphorus and valine in the unknown compound separated by ion-exchange chromatography were determined by chemical analysis. It was found that the ratio of phosphorus to valine in the unknown compound is unity, suggesting that this unknown compound is a P_1-derivative of valine containing P_1 and valine in the molar ratio of 1:1.

Each solution fractionated by ion-exchange chromatography was dehydrated under reduced pressure to obtain the respective components in a solid state and tested by ninhydrin reaction and IR spectroscopy. The results are shown in Fig. 5. In this elution, an eluent containing no EDTA was employed, because EDTA disturbs the ninhydrin reaction. The components in the fractions of 50—100 and 300—400 cm^3 are ninhydrin-reaction positive. The component in the former fractions is attributable to the unreacted valine. The component in the latter fractions is attributable to the unknown compound. These results also support the idea that the unknown compound is a P_1-derivative of valine. Furthermore, from the IR spectra, the components in the fractions of 180—250 and 630—700 cm^3 were proved to be P_1 and P_2 respectively. Figure 6 shows the IR spectrum of the component in the fraction with an elution peak at

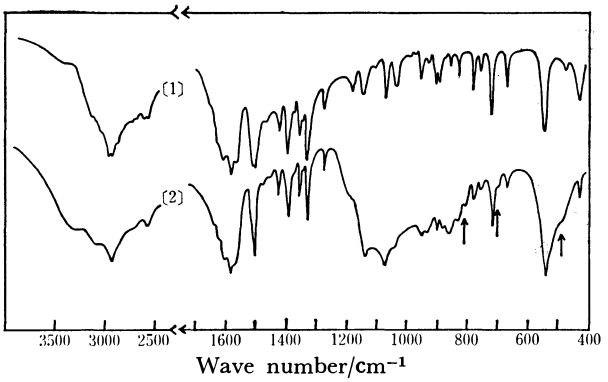

Fig. 6. IR spectra of L-valine and the unknown compound.
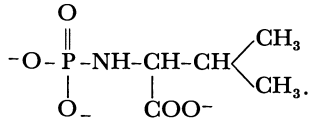
Arrow (↑): absorption due to the P-N bond, (1): L-valine, (2): unknown compound.

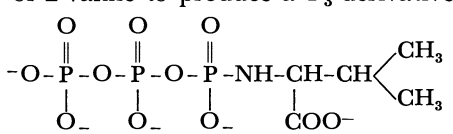
about 350 cm[3] (the unknown compound). The unknown compound indicates absorptions at about 2950, 1610—1560, 1500, 1420, 1390, 1350, 1330, 1270, 780, 720, and 540 cm^{-1} attributed to valine. In addition, at about 1150—1050, 1000—950, and 860 cm^{-1} absorptions attributable to P_1 [18,19] are found. Further, at about 810—800 (ν_{P-N}), 700 (ν_{P-N}), and 490 cm^{-1} (δ_{P-N}) weak absorptions, which may be due to the P–N bond,[20-23] are found. Also, strong absorptions caused by the carboxylato group of valine are observed at about 1610—1550 and 1400 cm^{-1}. Therefore, this unknown compound probably has the P–N bond and the COO^- group in its molecule.

From all the results presented above, it was concluded that the unknown compound is a P_1-derivative of valine, an anion of *N*-(1-carboxy-2-methylpropyl)phosphoramidic acid,



Reaction of Short-chain Phosphates with L-*Valine.*
A solution of trisodium orthophosphate, tetrasodium pyrophosphate, or pentasodium triphosphate was mixed with the L-valine solution in a molar ratio of 1:1, and then the mixed solution was adjusted with a sodium hydroxide solution to pH 12 and allowed to react at room temperature. No reaction products were observed at all in the reactions of L-valine with P_1 and P_2. Only in the reaction of P_3 was a slight amount of P_2, produced by the hydrolysis of P_3, observed. Therefore, it may be concluded that, from short-chain phosphates, such as P_1, P_2, and P_3, no phosphate derivatives of valine can be formed.

Mechanism of the Reaction of cyclo-*Triphosphate with* L-*Valine.* The mechanism of the reaction of P_{3m} with L-valine at pH 10—12 is summarized in Fig. 7. At pH 10—12, P_{3m} is easily attacked by an amino group of L-valine to produce a P_3-derivative of valine;



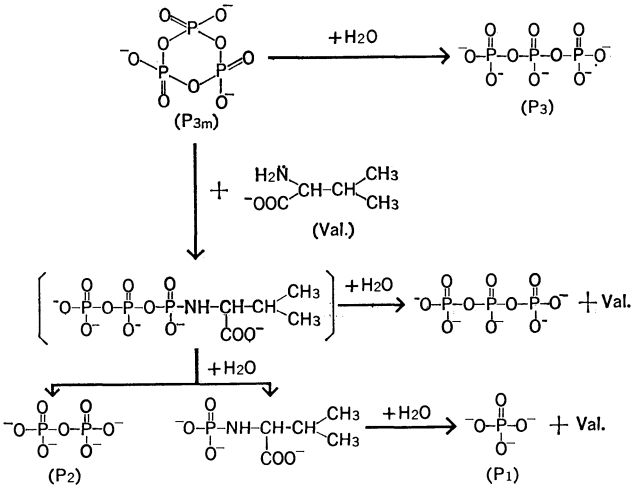


Fig. 7. Mechanism of the reaction of P_{3m} with L-valine.

(P_3-(N)Val). However, since P_3-(N)Val can not be detected at all by means of either ion-exchange chromatography or paper chromatography, this compound may be extremely unstable and immediately hydrolyzed to P_2 and a P_1-derivative of valine, P_1-(N)Val, as well as to P_3 and valine. The latter route of hydrolysis is suggested because the yield of P_3 is much higher than that to be expected from only the hydrolysis of P_{3m}. As has been described before, small amounts of P_4 and P_5 were produced in the reaction of P_{3m} with L-valine at pH 10. This phenomenon may have some connection with Quimby's finding that the amidotriphosphate produced by the reaction of P_{3m} with ammonia in an alkaline solution returns to being P_{3m}, accompanying the abstraction of ammonia, when the solution is acidified. In the present reaction, the following mechanism may be one of the possibilities; P_3-(N)Val reacts with P_1 or P_2 to form P_4 or P_5, accompanying the abstraction of valine. A similar phenomenon has been reported by Feldmann and Thilo,[3] who found that, when a solution of amidotriphosphate is acidified, small amounts of P_4, P_5, and P_6 are produced. On the other hand, in the reaction of P_{3m} with L-valine, divaline and trivaline can not be detected by thin-layer chromatography.

Kinetics of the Formation and Transformation of Alkoxy-derived Strontium Metaborate

Osamu YAMAGUCHI,* Muneaki KAMATA, and Kiyoshi SHIMIZU*

Department of Applied Chemistry, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602

(Received November 26, 1979)

A new metastable SrB_2O_4 was formed by heating amorphous material prepared by the simultaneous hydrolysis of strontium and boron alkoxides. Crystallization isotherms were obtained by means of the Avrami equation $\ln(1-\alpha)=-kt^n$ with $n=2$, the activation energy being determined to be 351 kJ/mol. The kinetics of transformation of metastable into stable SrB_2O_4 is interpreted by the first-order equation $-\ln(1-\alpha)=kt$. Activation energies are 498 kJ/mol and 343 kJ/mol for initial and final stages, respectively.

Crystalline strontium metaborate (SrB_2O_4) has been known only in orthorhombic modification.[1,2] In a previous paper[3] dealing with the heating process of mixed powder prepared by the simultaneous hydrolysis of strontium and boron alkoxides, it was reported that metastable SrB_2O_4, similar in structure to low-temperature form of ZnB_2O_4,[4,5] is formed at 650—690 °C. The present study deals with the kinetics of the formation of metastable SrB_2O_4 and the transformation of metastable into stable SrB_2O_4. The kinetic data were analyzed with use of available solid state models.

Experimental

Materials and Procedure. Boron triethoxide was of guaranteed purity. Strontium methoxide was synthesized by heating strontium metal (purity 99.9%) in an excess amount of dehydrated methanol at 64 °C for 5 h. A mixture of boron and strontium alkoxides in the mole ratio $Sr^{2+}/B^{3+}=1:2$ was poured into aqueous ammonia solution at 25 °C. The temperature was slowly raised up to 60 °C while being stirred. The resulting mixed powder (starting powder, average particle size *ca.* 550 Å) was washed repeatedly with hot water and dried at 60 °C under reduced pressure.

Measurement. Thermal analyses (TG, DTA) were carried out in the air at the heating rate 10 °C/min. Alpha-alumina was used as a standard material in DTA. On the basis of DTA data, the specimens heated at the rate 10 °C/min were examined by means of X-ray diffraction using nickel filtered copper K_α. The scanning speed 1/4°/min of the goniometer was selected to satisfy the accuracy of *d*-spacing. Kinetic studies of the formation of metastable SrB_2O_4 and its transformation into stable SrB_2O_4 have been made by means of X-ray diffraction. The starting powder was pre-heated; the specimens were placed in an electric furnace equipped with a temperature regulator, heated for the desired time, and then cooled repidly to room temperature.

Results and Discussion

Thermal Analysis. TG analysis of the starting powder showed that the weight loss is 16.7% due to the loss of ammonia, absorbed water, hydrated water, and organic residue from the parent alcohol up to 560 °C. On the other hand, two exothermic reactions in DTA were observed at 650—690 °C and 715—780 °C. X-Ray diffraction analysis confirmed that the first exothermic peak (650—690 °C) is due to the crystallization of metastable SrB_2O_4 from an amorphous phase, the second (715—780 °C) to the transformation of metastable phase into stable SrB_2O_4.

X-Ray Analysis. The starting powder was amorphous, no significant change being observed up to 600 °C. The peaks corresponding to metastable SrB_2O_4[3] appeared after heating at 620 °C for 5 min, and the intensity increased rapidly up to 670 °C. Table 1 gives the X-ray powder diffraction data of metastable SrB_2O_4. The observed *d*-values of the compound were similar to those of ZnB_2O_4 of low-temperature form, the structure of which has not been determined. Both compounds disagree in relative intensities of main peaks.[3] The peaks of stable SrB_2O_4 (orthorhombic)[1,2] appear when heated at 710 °C, the specimen heated at 780 °C showing characteristic X-ray diffraction pattern of stable SrB_2O_4.

Kinetics of the Formation of Metastable SrB_2O_4. Figure 1 shows the fraction of the crystallized metastable SrB_2O_4 at 620, 640, and 660 °C. The starting powder was pre-heated at 580 °C. The fractional crystallization of each specimen was determined from

the height of $d=3.36$ Å, the main characteristic peak. A well-crystallized specimen was obtained by heating at 670 °C for 30 min. Magnesium oxide (MgO) was used as an internal standard. Crystallization isotherms were characterized by sigmoidal shape (Fig. 1), the kinetics being best described by the Avrami equation (Fig. 2),[6]

$$\ln(1-\alpha) = -kt^n \qquad (n=1.9-2\fallingdotseq 2) \qquad (1)$$

where α, t, k, and n are the fractional crystallization, time, rate constant, and a constant related to the reaction mechanism, respectively. The metastable SrB_2O_4 powder consists of plate-like particles. From the result and the fact that the Avrami equation with $n=2$

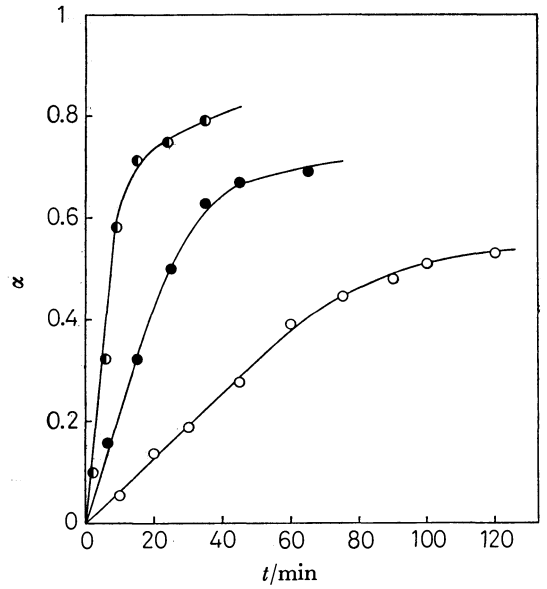

Fig. 3. Phase transformation from metastable into stable SrB_2O_4 as a function of time at different temperatures.

fits crystallization curves over the whole range, two dimensional growth of metastable SrB_2O_4 with site-saturation for nucleation seems to be the rate-determining step. The activation energy calculated from the Arrhenius plot is 351 kJ/mol.

Kinetics of the Transformation. The fractional transformation of metastable into stable SrB_2O_4 was determined as a function of time at different temperatures (Fig. 3). Metastable SrB_2O_4 obtained by heating the starting powder at 670 °C for 30 min was used as a starting material. The fractional transformation was determined from the heights of the main characteristic peaks of metastable ($d=3.36$ Å) and stable SrB_2O_4 ($d=2.69$ Å), using the calibration curve prepared with known compositions. No line broadening was observed during the course of transformation.

Attempts were made to fit the results to kinetic laws. As shown in Fig. 4, transformation isotherms are best described by the first-order equation,[7]

$$-\ln(1-\alpha) = kt \quad (2)$$

where α is the fractional transformation and t time. There are linear portions in each of the plots. The rate constants were determined from the slopes of the straight lines. Activation energies are 498 kJ/mol and 343 kJ/mol for initial and final stages, respectively. They might represent activation energies for nucleation process and propagation process, respectively.[8]

Reactions of Halogeno-bridged Organopalladium(II) Complexes with an Electron-rich Olefin. New Cyclopalladated Carbene Complexes, and (Carbene)chloropalladium(II) Complexes Containing a σ,π-Methallyl Group or a π-Coordinated-chelating Alkyl-Palladium σ-Bond

Katsuma HIRAKI,* Keiichi SUGINO, and Masayoshi ONISHI*

Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Bunkyo-machi, Nagasaki 852

(Received November, 30, 1979)

A chloro-bridged organopalladium(II) complex, di-μ-chloro-bis(3-*t*-butylthio-2-methoxy-2-methylpropyl-1-*C*,*S*)dipalladium(II) reacted with an electron-rich olefin, bis(1,3-diphenyl-2-imidazolidinylidene) (L_2) to yield a new dinuclear carbene complex, di-μ-chloro-bis(1,3-diphenyl-2-imidazolidinylidenato-2-*C*,2′-*C*)dipalladium(II) (**4**). Complex **4** was treated with thallium acetylacetonate, triisopropyl phosphite, 4-picoline, silver acetate, and L_2, affording the corresponding new carbene complexes. On the basis of spectroscopic properties, these complexes were ascribed to new complexes containing cyclopalladated chelate structure in the carbene ligand. Di-μ-chloro-bis(1-3-η^3-methallyl)dipalladium(II) and di-μ-chloro-bis(6-*exo*-methoxy-3a,4,7,7a-tetrahydro-*endo*-4,7-methanoindene-*endo*-5σ, 2π)dipalladium(II) reacted with L_2 to give new mononuclear (carbene)chloropalladium(II) complexes possessing a σ,π-methallyl group and a π-coordinated-chelating alkyl-palladium σ-bond, respectively.

Recently, some aryl(carbene)palladium(II) complexes were prepared from reactions of chloro-bridged cyclopalladated complexes towards an electron-rich olefin, bis(1,3-diphenyl-2-imidazolidinylidene) [=CN(Ph)-CH_2CH_2N(Ph)]$_2$ (L_2).[1] However, few works have been reported as regards isolation and characterization of alkyl- and vinyl(carbene)palladium(II) complexes,[2] while several alkyl-,[3-6] aryl-,[7] and ethynyl(carbene)-platinum[8] complexes have been reported.

It is interesting to compare the reactivities of chloro-bridged alkyl-, π-allyl-, and 1-alkenylpalladium(II) complexes towards L_2 with that of the cyclopalladated complexes. The present paper deals with the reactions of the chloro-bridged alkyl- or π-methallylpalladium(II) complexes towards L_2, and with the resulting new types of (carbene)organopalladium(II) complexes, *i.e.* cyclopalladated carbene complexes, and (carbene)-chloropalladium(II) ones containing a σ,π-methallyl group or a π-coordinated-chelating alkyl-palladium σ-bond. A preliminary communication of this work has been published recently.[9]

Experimental

General Procedures. Melting points, molecular weight, molar conductivity, and IR and ^{1}H-NMR spectra were determined according to the previous paper.[1] ^{13}C-NMR spectra were measured on a JEOL model FT-100 spectrometer, using tetramethylsilane as an internal standard.

The electron-rich olefin L_2,[10] thallium(I) acetylacetonate,[11] and the chloro-bridged organopalladium(II) complexes, di-μ-chloro-bis(3-*t*-butylthio-2-methoxy-2-methylpropyl-1-*C*,*S*)-dipalladium(II) (**1**),[12] di-μ-chloro-bis(1-3-η^3-methallyl)dipalladium(II) (**2**),[13] and di-μ-chloro-bis(6-*exo*-methoxy-3a,4,7,7a-tetrahydro-*endo*-4,7-methanoindene-*endo*-5σ,2π)dipalladium(II) [{Pd(6-MeO-themi)Cl}$_2$] (themi=3a,4,7,7a-tetrahydro-*endo*-4,7-methanoindene-*endo*-5σ,2π) (**3**)[14] were prepared according to the respective literature.

*Reaction of **1** with L_2.* A mixture of **1** (1.42 mmol) and L_2 (1.44 mmol) in 27.5 ml of *m*-xylene was heated under reflux for 40 min. Resulting black precipitates were collected and extracted with boiling acetonitrile for 10 h. The extracted solid was washed with dichloromethane to afford microcrystals, di-μ-chloro-bis(1,3-diphenyl-2-imidazolidinyl-idenato-2-*C*,2′-*C*)dipalladium(II) [{Pd(dpim)Cl}$_2$] (dpim= 1,3-diphenyl-2-imidazolidinylidenato-2-*C*,2′-*C*) (**4**).

*Reaction of **4** with Tl(acac).* A benzene suspension of **4** (0.11 mmol) and Tl(acac) (0.23 mmol) was heated at reflux for 2 h. After benzene was removed, the residue was extracted with dichloromethane. Addition of diethyl ether to the extract yielded a pale yellow white needle, [Pd-(dpim)(acac)] (**5**).

*Reaction of **4** with Triisopropyl Phosphite.* A tetrahydrofuran (THF) suspension of **4** (0.14 mmol) and triisopropyl phosphite (1.74 mmol) was heated at reflux for 30 min to yield a brown solution. The solution was concentrated at reduced pressure and diluted with hexane to afford a pale yellow solid. The solid was recrystallized from dichloromethane-hexane to give a pale yellow needle, [Pd(dpim)Cl-{P(OCHMe$_2$)$_3$}] (**6**).

*Reaction of **4** with 4-Picoline.* A THF suspension (10 ml) of **4** (0.18 mmol) and 4-picoline (pic) (0.37 mmol) was heated under reflux for 2.5 h. After the solvent was evaporated at reduced pressure, the residue was extracted with dichloromethane. Addition of diethyl ether to the extract gave a pale yellow-white needle, [Pd(dpim)Cl(pic)] (**7**).

Halogen metathesis of **7** with lithium bromide took place in acetone at room temperature, followed by the similar procedures to the preparation of **7**, to afford [PdBr(dpim)-(pic)] (**8**).

*Reaction of **4** with Silver Acetate.* An acetone suspension (12.5 ml) containing **4** (0.14 mmol) and silver acetate (0.30 mmol) was heated at reflux for 2 h. The solvent was removed, and the resulting residue was recrystallized from dichloromethane and hexane to yield an acetato-bridged complex, [{Pd(dpim)(O$_2$CMe)}$_2$] (**9**).

A methanol suspension (10 ml) involving **9** (0.10 mmol) and lithium bromide (0.70 mmol) was heated under reflux for 6 h, and then stirred at room temperature for 1 d. The resulting solids were collected and washed with methanol and diethyl ether to give a bromo-bridged complex, [{PdBr-(dpim)}$_2$] (**10**).

*Reactions of **4** and **10** with L_2.* A *m*-xylene suspension (15 ml) containing **4** (0.28 mmol) and L_2 (0.34 mmol) was refluxed for 2 h. After the solvent was removed with a rotary evaporator, the residue was recrystallized from dichloromethane-hexane to afford a dicarbene complex, [Pd-(dpim)ClL]·1/2CH_2Cl_2 (**11**).

An acetone suspension (12.5 ml) involving **11** (0.19 mmol),

a) In cm^{-1}, in KBr disk. b) ν(C(aromatic)–N)}. c) For the pyridine ring.

4-picoline (0.54 mmol), and sodium perchlorate–water(1/1) {Na[ClO$_4$]·H$_2$O} (0.21 mmol) was heated under reflux for 1.5 h. After acetone had been evaporated, the resulting residue was recrystallized from acetonitrile–diethyl ether to give an ionic complex, [Pd(dpim)L(pic)]ClO$_4$ (**12**).

Complex **10** (0.10 mmol) reacted with L_2 (0.10 mmol) in refluxing *m*-xylene (10 ml) for 2 h, followed by the similar treatment to **11**, to yield [PdBr(dpim)L] (**13**).

Reaction of 2 with L_2. The electron-rich olefin L_2 (0.27 mmol) was added to a toluene solution (10 ml) of **2** (0.25 mmol). The mixture was heated under reflux for 10 min. Addition of hexane to the resulting solution afforded cream needles, [Pd(σ,π-CH$_2$CMe=CH$_2$)ClL] (**14**).

Reaction of 3 with L_2. A toluene suspension (12.5 ml) containing **3** (0.16 mmol) and L_2 (0.17 mmol) was heated under reflux for 30 min. Addition of petroleum ether to the resulting solution gave an off-white needle, [Pd(6-MeO-themi)ClL] (**15**).

Reactions of 14 and 15 with L_2. A benzene–*m*-xylene mixture (1:1, 12 ml) involving **14** (0.25 mmol) and L_2 (0.24 mmol) was heated under reflux for 2.7 h. After the solvents were evaporated at a reduced pressure, the resulting solid was recrystallized from dichloromethane and hexane to give **11** in 23.4% yield.

Similarly, **15** (0.19 mmol) reacted with L_2 (0.20 mmol) in *m*-xylene (10 ml) under reflux for 11 h to afford **11** in 25.2% yield.

Results and Discussion

General Properties. Yields, analytical data, and some physical properties of the new (carbene)palladium(II) complexes are summarized in Table 1. All these complexes are air-stable in the solid state. Mononuclear complexes, **5**—**8** and **12**—**15** are fairly soluble in dichloromethane and chloroform, whereas the halogeno-bridged dinuclear complexes, **4** and **10** are sparingly soluble in usual oragnic solvents. The IR spectra of the twelve complexes showed a strong band near 1280 cm^{-1}, characteristic of ν(C(aromatic)–N} and a medium band at *ca.* 1490 cm^{-1} for ν(C-(carbene)–N} (Table 2).

Cyclopalladated Carbene Complexes, 4—10. The sulfur-chelated alkylpalladium(II) complex, **1** reacted with L_2 in refluxing xylene to afford the cyclopalladated complex, **4**. In the IR spectrum of **4**, two bridging ν(Pd–Cl) bands were observed at 258 and 239 cm^{-1}. The chlorobridged complex, **4** reacted with Tl(acac), triisopropyl phosphite, 4-picoline, and silver acetate,

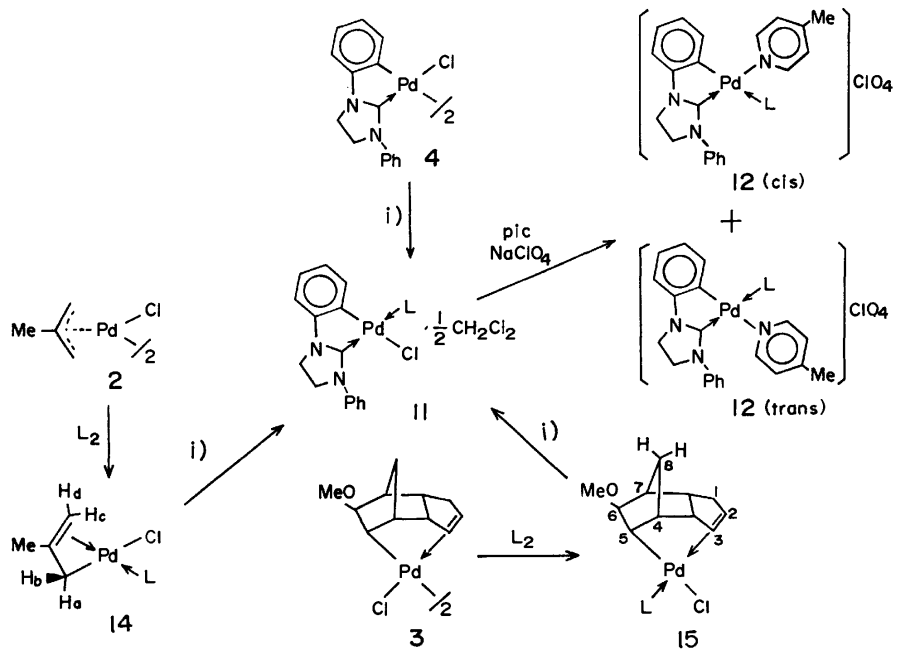
and resulted in the splitting of the chloro-bridged bonds to yield the corresponding complexes, **5**, **6**, **7**, and **9**, respectively (Scheme 1). Bridging acetato ligands of **9** in Nujol mull showed two bands at 1560 and 1420 cm^{-1}. Complexes **7** and **9** were treated with lithium bromide to give the corresponding bromo complexes, **8** and **10**, respectively.

The $^{13}C\{^1H\}$-NMR spectrum of **5** in CD_2Cl_2 exhibited a resonance at δ 192.1 from TMS, characteristic of the carbene carbon (2-C). Three quarternary carbon resonances at δ 149.2, 139.2, and 140.3 are ascribed to a palladium-bonded carbon (2'-C), an *N*-substituted carbon (1'-C) of an *o*-phenylene group, and an *N*-substituted carbon (1''-C) of the uncoordinated phenyl group, respectively,[15] by comparison with the cases of **6** and its related complexes.[1,16] Two oxygen-bonding carbons of acetylacetonato ligand resonated at δ 187.5 and 186.5, and two methyl carbons did



Scheme 2. i) With L_2 in refluxing *m*-xylene or xylene–benzene mixture, followed by recrystallization from dichloromethane–hexane.

at δ 28.0 and 27.3, indicating the non-equivalence of two coordination sites of the acetylacetonato ligand, due to the cyclopalladation of the carbene ligand. In addition, a mass spectrum of **5** exhibited a parent-ion isotope pattern centered at 426 of *m/e* in accord with the proposed structure. Complex **5** showed C=O and C=C stretching bands characteristic of the enolate chelate.

The $^{13}C\{^1H\}$-NMR spectrum of **6** was observed in $CDCl_3$, and gave a doublet at δ 200.6 (^2J=205.1 Hz), attributable to a carbene carbon. This large coupling constant indicates unambiguously that the triisopropyl phosphite ligand is situated *trans* to the carbene carbon.[16] Two doublets at δ 44.6 [^4J(CP)= 3.9 Hz] and 53.8 [^4J(CP)=8.8 Hz] were assigned to two methylene carbons of the 2-imidazolidinylidene ring. Remaining two doublets at δ 121.9 [^4J(CP)= 4.9 Hz] and 138.5 [^3J(CP)=10.7 Hz] were tentatively assignable to 6'-C and 1'-C of the cyclopalladated phenylene group, respectively.[17] These splittings of the carbon resonances were attributable to a long range phosphorus-carbon coupling.[16] Two singlets at δ 140.7 and 150.2 were ascribed to the *N*-substituted aromatic carbon (1"-C) of the unmetallated phenyl group and a palladium-bonded carbon (2'-C), respectively.[17] It is worth noting that a palladium-substituted phenylene carbon in the cyclopalladated complexes resonates in the range of δ 146—151.[1,18]

The ^{1}H-NMR spectra of **5**—**8** showed complicated signals in the range of δ 6.4—8.6, which were attributed to both the cyclopalladated *o*-phenylene group and the unmetallated phenyl one. Moreover, the spectra gave an AA'BB' type multiplet for the ethylene group of the dpim moiety in the region of δ 3.9 to 4.5 (Table 3). Complex **9** exhibited complicated signals in the range of δ 3.0—4.0, which were assignable to the ethylene protons of the dpim moiety.[19]

On the basis of these facts, **4**—**10** were ascribed to new complexes containing cyclopalladated chelate structure within the carbene ligand. It seems likely that the halogeno-bridge splitting reaction of **1** with L_2 afforded an intermediate of a carbene complex retaining the 3-*t*-butylthio-2-methoxy-2-methylpropyl moiety, and that the moiety then abstracted immediately an *ortho*-proton from a phenyl ring attached to the 2-imidazolidinylidene ligand to be eliminated. The presence of such the intermediate is readily inferred from the isolation of (carbene)(π-coorinated chelating alkyl)palladium(II) complex **15**, as stated later. Similar cyclometallated structures have been reported concerning {(alkylamino)(phenylamino)methylenato-1-*C*,2'-*C*}platinum(IV) complexes,[20] {bis(*p*-tolylamino)-methylenato-1-*C*,2'-*C*}platinum(II) ones,[21] and (1,3-di-*p*-tolyl-2-imidazolidinylidenato-2-*C*,2'-*C*)ruthenium-(II) ones.[22]

Di(carbene)palladium(II) Complexes. The halogeno-bridged cyclopalladated complexes, **4** and **10** reacted with L_2 in refluxing xylene to yield the di-carbene complexes, **11** and **13**, respectively. The ^{1}H-NMR spectrum of **11** in DMSO-d_6 showed a singlet at δ 5.7 (1H, 1/2 CH_2Cl_2, as solvent of crystallization) and complicated signals near δ 3.3 (2H) and 3.8 (6H), which were ascribed to the ethylene protons of the cyclopalladated and unmetallated 1,3-diphenyl-2-imidazolidinylidene groups.

Complex **11** reacted with both 4-picoline and Na-[ClO_4]·H_2O in refluxing acetone to afford **12**. Molar conductivity of **12** for 1.0×10^{-3} M acetone solution at 25 °C was 132 Ω^{-1} cm^2/mol, implying a 1:1 electrolyte. Its ^{1}H-NMR spectrum in CD_2Cl_2 exhibited two 4-picoline-methyl singlets at δ 2.16 (*ca.* 0.9H) and 2.34 (*ca.* 2.1H), and three kinds of the 2-imidazolidinylidene-ethylene protons; one at δ 3.3—4.0 (4H, complicated), the second at δ 4.05 (*ca.* 2.8H, singlet),

Table 4. The reactivities of the chloro-bridged dinuclear organopalladium(II) complexes with L_2

Bond type	Complex	Mp/°C	Reaction temp/°C	Main product
Pd-σ-aryl	$[Pd_2\{C_6H_4$-CMe(N=OH)-1-$C,N\}_2Cl_2]$	>210[29]	139	$[Pd\{C_6H_4$-CMe(N=OH)-1-$C,N\}ClL]$[1]

a) See the text.

and the third at δ 4.36 (*ca.* 1.2H, singlet) (Table 3). The data indicate unambiguously that **12** involves two kinds of both the picoline-methyl groups and of the unmetallated 2-imidazolidinylidene moieties in the same ratio of about 7:3. On the basis of these facts, the elemental analyses, and the conductivity data, **12** was ascribed to a mixture of *cis* and *trans* isomeric cationic di(carbene)palladium(II) complexes, each of which contains the cyclopalladated and the unmetallated 1,3-diphenyl-2-imidazolidinylidene moieties. The population ratio of the *cis*: *trans* isomers was about 7:3. The ethylene resonances of the dpim moieties in these isomers overlapped with each other. In consideration of the relative electron-deficient effect of the carbene ligand,[16,23] the lower-field methyl resonance at δ 2.34 and the higher-field ethylene singlet at δ 4.05 were assigned to the major *cis* isomer. The two ethylene singlets of the unmetallated 2-imidazolidinylidene moieties were possibly due to an accidental coincidence, since the signals did not changed actually on cooling to −35 °C.

Carbenepalladium(II) Complexes Containing a σ,π-Methallyl Group or a π-Coordinated-chelating Alkyl-palladium σ-Bond. Complex **2** and **3** reacted with L_2 in refluxing toluene to give **14** and **15**, respectively. The ^{1}H-NMR spectrum of **14** in $CDCl_3$ showed three singlets at δ 1.44 (3H, Me), 1.91 (1H, H_a), and 2.95 (1H, H_c), and two doublets at δ 2.91 [1H, H_b, $^4J(H_bH_d)$=2.5 Hz] and 3.95 (1H, H_d). The doublets of the H_b and H_d were ascribed to a long range coupling through the allylic double bond.[24] This pattern of the methallyl proton resonances indicates that the π-methallyl group in **2** was converted into a σ,π-methallyl one with the displacement of one of the two bridging chlorine atoms by L, similarly to the case of chloro(σ,π-methallyl)(neutral Lewis base)palladium(II).[25] Moreover, **14** exhibited the AA'BB' type resonance for the ethylene protons of L, in the range of δ 4.1 to 4.5.

^{1}H-NMR spectrum of the 6-MeO-themi moiety in **15** showed a methyl resonance at δ 2.64 (3H, singlet), bridge-head methylene ones at δ 0.97 and 1.21 (2H, an AB type quartet), and olefinic one at δ 6.37 (2H, virtually singlet), besides complicated signals in the region of δ 1.6—3.0. In addition, **15** gave AA'BB' type resonances for the ethylene protons of L near δ 4.3 and aromatic resonances in the range of δ 7.2 to 8.4. On the basis of these data, elemental analyses, and IR spectrum, **15** was assigned to a new carbenepalladium(II) complex, which contains the 6-MeO-themi moiety coordinated to the central metal.

It is significantly noteworthy that **14** and **15** involve three kinds of carbon-palladium bond; the carbene-, the alkyl σ-, and the π-olefin-palladium bonds, and that they are regarded as model compounds of the active species in catalytic olefin metathesis reactions.[26] Only four papers have ever been published as concerns isolation of stable complexes which contain both a carbene- and a π-olefin-metal bonds.[27] Complexes **14** and **15** reacted with L_2 in a more severe condition, namely in refluxing xylene, and afforded the dicarbene complex **11** in about 25% yield after recrystallization from dichloromethane–hexane.

Reactivities of the Chloro-bridged Organopalladium(II) Complexes towards L_2. In conclusion, the reactivities of the σ-aryl-, π-methallyl-, σ,π-methallyl-, σ-alkyl-, and σ-1-alkenylpalladium(II) complexes towards L_2 are summarized in Table 4. The cyclopalladated σ-aryl complexes retained the palladium-aryl σ-bond unchanged during the reaction with L_2.[1] The π-methallyl complex, **2** reacted with L_2 in refluxing toluene to give **14**, retaining the palladium-σ,π-methallyl bond, which was furthermore converted into the palladium-aryl σ-bond of the dpim moiety through the reaction with additional L_2 at 97 °C.

The π-coordinated-chelating σ-alkylpalladium(II) complex, **3** and **15** reacted with L_2 in similar manners to the π-methallyl complex, **2** and to the σ,π-methallyl one, **14**, respectively. However, an analogous complex, di-μ-chloro-bis(8-*exo*-methoxycyclooct-4-enyl-*endo*-1σ,4π)dipalladium(II)[14] was treated with L_2 at 45 °C to afford a small amount of a pale yellow powder, which showed two IR bands assignable to the carbene ligand but could not be characterized in details owing to the low yield. Di-μ-chloro-bis(6-*exo*-methoxybicyclo-[2,2,1]hept-2-ene-*endo*-5σ,2π)dipalladium(II), having a relatively low melting point,[30] reacted with L_2 in refluxing benzene for 10 min to yield *ca.* 70%

of palladium black and a small amount of black oil, which was impossible to be characterized. The sulfur-chelated σ-alkylpalladium bond in **1** was converted into the palladium-aryl σ-one of the dpim moiety in the reaction with L_2, not only in refluxing *m*-xylene, but also in refluxing toluene.

A 1-alkenylpalladium(II) complex, di-μ-chloro-bis(2-chloro-3-dimethylamino-3-methyl-1-butenyl-1-*C*,*N*)dipalladium(II)[31] yield only a small amount of a pale olive powder, which exhibited two bands at 1490 and 1275 cm^{-1}, characteristic of the carbene ligand, but could not be full characterized because of the low yield.

It is noteworthy that the carbene ligands studied in the present paper do not insert into the carbon-palladium σ-bond. The innertness of the carbene ligands is probably due to the electron-donating character of two nitrogen atoms attached to the carbene carbon. This shows sharp contrasts with hexafluoro-3-propylidene which inserts into a hydrido-platinum bond,[32] and with alkyl isocyanide which does into an alkyl-palladium σ-bond.[33]

We wish to express our gratitude to Mrs. Hisako Mazume and Miss Yumi Kojima, Nagasaki University, for their technical assistence.

The Reductive Acylation of Organic Disulfides with Aldehydes under Photochemical and Radical Conditions[1)]

Makoto TAKAGI,* Setsuo GOTO, Masato TAZAKI, and Tsutomu MATSUDA*

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received September 6, 1979)

The irradiation of organic disulfides in aldehyde solvents resulted in the reductive fission of the S–S linkage, giving an equimolar mixture of the corresponding thiol and the thiol acylate in a good yield. The cyclic disulfides gave mono *S*-acylated dithiols. The reaction proceeded by means of the photo-initiated radical chain mechanism, and AIBN (azobisisobutyronitrile) effected the same reaction under thermal conditions.

In previous communications, a photochemical reductive acylation of organic disulfides with aldehydes has been described, with particular emphasis on the synthesis and the reaction of the 8-*S*-acylated derivative of coenzyme lipoic acid.[2-4)] The present report includes some of the experimental details. In addition, the reactions under radical conditions are described; these data, combined with those of other photochemical studies, suggest that the photo-reaction of organic disulfides with aldehydes proceeds by means of a photo-initiated radical chain mechanism.

Results

Photo-reactions. Reactions were carried out for $0.5—1\times10^{-2}$ M (1 M=1 mol dm^{-3}) solutions of the disulfide in aldehyde at ≤5 °C under nitrogen or argon, using liquid-filtered ($\lambda<330$ nm removed) radiation from a 100-W immersion-type high-pressure mercury lamp. A radiation through a Pyrex filter ($\lambda<300$ nm removed) may be used with a slight decrease in the yields of the products. The concentration of the disulfides may be increased to 0.2—0.7 M (see the reaction under radical conditions), but the reaction is cleaner when the concentration is lower. The reaction could be followed by TLC or GLC. For 1,2-dithiolane compounds, the color (yellow) disappearance indicated the completion of the reaction. After 1—2 h of irradiation, followed by concentration under reduced pressure, the residue was purified by distillation or column chromatography on silica gel. The experimental procedure has been described in detail elsewhere.[3)] The colorless liquid obtained was identified by elemental and spectral analyses.

TABLE 1. PHOTO-REACTION OF SYMMETRICAL CYCLIC DISULFIDES WITH ALIPHATIC ALDEHYDES

Disulfide	Aldehyde	Irradiation time/min	Product	Yield[a)] %
1	CH_3CHO	90		**5** (71)

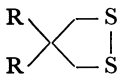
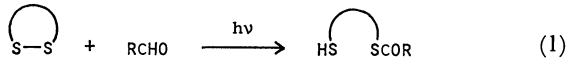
Reaction of Symmetrical Disulfides: The results with cyclic disulfides and aliphatic aldehydes are summarized in Table 1.



1, (R, R) = $(CH_2)_5$
2, R = C_2H_5
3, R = CH_3

4

All the aliphatic aldehydes reacted with similar ease, and the effect on the reactivity of branching on the α-carbon of the aldehyde is unimportant. The effect of the disulfide-ring size, whether five- or six-membered, is also trivial. The reactivities of cyclic disulfides and linear disulfides are similar insofar as the carbons bound to sulfur are not branched (see below). No by-products were detected by either TLC or GLC. Thus, the reaction may be formulated simply by Eq. 1:



(1)

The reactions with aromatic aldehydes were not straightforward. The isolation of the reaction products was not easy, since the benzoins were formed in a considerable amount, along with other unidentifiable, high-boiling by-products. In the reaction of *p*-anisaldehyde with **2**, the formation of the thioester was suggested by the results of spectral analysis, but the isolation was not successful due to the overwhelming side reactions. In view of the complexity of the reaction and the unavailability of the liquid aromatic aldehydes, the photo-reaction with disulfides would not have practical value. Pyruvic acid and formate esters did not react under the conditions of Table 1.

The reaction of symmetrical linear disulfides is shown in Table 2 and Eq. 2.

$$RSSR + R'CHO \xrightarrow{h\nu} RSH + RSCOR' \quad (2)$$

The reaction of dibutyl disulfide with propionaldehyde was monitored by a direct GLC analysis of the reaction mixture, the results are shown in Fig. 1. The reaction of diphenyl disulfide with propionaldehyde is similarly illustrated in Fig. 2. The reaction in Fig. 1 was intentionally chosen from among several similar experiments, since it happened to show an "induction period." The induction period does not appear when the reactants are carefully purified. Aldehydes have to be distilled just before use. For dibutyl disulfide, the reaction approached a theoretical completion (Fig. 1), but for diphenyl disulfide the yields of the products leveled off at 50—60% of the theoretical yield, while the starting disulfide was almost 100% consumed. The fate of the unbalanced sulfur compound is not clear. The decrease in reactivity of aliphatic disulfides as the carbon bound to sulfur becomes branched is obvious in Table 2, suggesting the steric influence on the ease of the reaction.

Reaction of Unsymmetrical Disulfides: Unsymmetrical disulfides were allowed to react with aliphatic aldehyde to clarify the selectivity of *S*-acylation among different thiyl groups. The disulfides used were butyl isopropyl disulfide, *t*-butyl ethyl disulfide, and

Butyl isopropyl disulfide gave *S*-*n*-butyl propionate and *S*-isopropyl propionate in a ratio of more than 7:2 in favor of the former at the completion of the reaction (Fig. 3), indicating that the sulfur bound to primary (butyl) carbon is more than three times as reactive as that bound to secondary (isopropyl) carbon. Even more pronounced is the reaction of *t*-butyl ethyl disulfide (Fig. 4). Only *S*-ethyl acetate was formed, no *S*-*t*-butyl acetate at all being detected. These results are in harmony with those in Table 2, where diisopropyl disulfide is less reactive than dibutyl disulfide, and where di-*t*-butyl disulfide is entirely unreactive. The reactivity difference between aliphatic and aromatic sulfur could not be assessed clearly, because the disproportionation of the unsymmetrical disulfide to symmetrical disulfides took place rapidly (Fig. 5). However, Fig. 5 indicates that the aliphatic sulfur (butylthio group) is more reactive toward the acyl group than the aromatic. The disproportionation did not occur without light, suggesting the introduction of radical species under photo-conditions.

As an unsymmetrical cyclic disulfide, 3-methyl-1,2-dithiane (**15**) was allowed to react with acetaldehyde;

it was found to give the dithiol monoacetate, **16**, in a 96% yield, where the primary thiol was selectively acetylated and the isomeric product could not be detected. The same reactivity has been observed with lipoic acid.[2,3] Thus, the selectivity of acylation among primary and secondary thiyl groups is much more strict in cyclic disulfides than in linear disulfides.

Reactions under Radical Conditions. The disulfides were dissolved in a 0.2—0.7 M concentration in an aldehyde solvent, followed by the addition of AIBN in a 10 mol % concentration of the disulfides. The atmosphere was then replaced with nitrogen, and the mixture was heated to initiate the radical reaction. The products were isolated and identified in a manner similar to that above. The results are summarized in Table 3. Some of the reactions were followed by GLC analysis; the results showed that the progress of the reaction was strikingly similar to those for the photo-reactions, including the appearance of the induction period and the disproportionation of unsymmetrical disulfides.

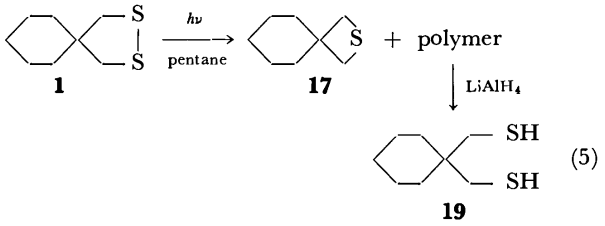
That the reaction proceeds by means of radical chain mechanism is obvious from the facts that it required only a catalytic amount of AIBN and that it did not take place in the absence of AIBN. Peroxides failed to initiate the reaction, and so the RSH–Fe(III) combination failed. Peroxides probably reacted with thiol or thiol acylate and were deactivated. At present, AIBN is the sole radical initiator effective in this reaction.

Discussion

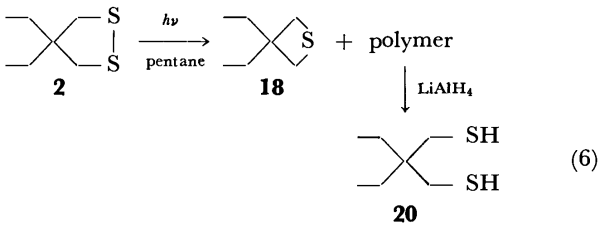
The resemblance between the photo- and the radical reactions suggests that the former is, in fact, a photo-induced radical reaction. The fact that the photo-reaction occurs with non-light-absorbing aliphatic linear disulfides as well indicates that the disulfide is not responsible for the primary photo-act; *i.e.*, it is not the disulfide molecule which is photo-activated and produces radicals. Aliphatic aldehydes have weak absorption maxima in the 290—300 nm region, and since the compounds are used as reaction solvents, the effective absorption extends up over 365 nm, where the major radiation from the high-pressure mercury lamp falls. A radical formation from aldehydes according to Eq. 4 is well documented in the literature.[5]

$$\mathrm{RCHO} \longrightarrow \mathrm{R}\cdot + \cdot\mathrm{CHO} \qquad (4)$$

1,2-Dithiolanes have absorption maxima around 334 nm (ε, 150—200),[6,7] and the possibility could not be excluded that these disulfides accepted the radiation to form radicals, thus initiating the reaction with aldehydes. The formation of the thiyl radical from the cyclic disulfides under photo-irradiation has been shown by Calvin *et al.*[8,9] in their early works on 1,2-dithiolane as well as by other investigators.[10,11] In this context, the photochemical behavior of **1** and **2** was studied. A 1×10^{-3} M solution of **1** or **2** in pentane was irradiated by means of a high-pressure mercury lamp in the usual manner for 100 min. The reaction was followed by GLC and UV spectroscopy (λ_{max}, 334 nm). The subsequent work-up of the mixture gave **17** (19% yield from **1**) and **18** (8% from **2**) along with the recovery of the starting disulfide (50%) and a polymeric material (Eqs. 5 and 6). The polymeric material gave two dithiol compounds, **19** and **20**, upon reduction with lithium aluminium hydride. However, an appreciable amount of the polymer yet remained unconverted to the dithiols, suggesting



1 **17** **19** (5)



2 **18** **20** (6)

that the polymer chain was not composed of mere S–S linkages. Thus, the photo-activated 1,2-dithiolanes seem to perform a complicated series of radical reactions, including a desulfurization to thietanes. The formation of radicals under photo-irradiation was readily indicated by the polymerization of such added vinyl monomers as styrene, butyl vinyl ether, and acrylonitrile. To the authors' knowledge, a photo-desulfurization with ring contraction has not been documented in the literature, and it is quite possible that the unknown photo-products from lipoic acid reported by Brown *et al.*[11] involved a similar structure.

It is also possible that the above-mentioned photo-desulfurization was a result of the particular reaction conditions, where good hydrogen donors to the thiyl radicals were not available. When 2-propanol instead of pentane was used as a solvent, two 1,3-dithiols, **19** and **20** (as determined by iodometry), were formed, and the yield of the thietanes, **17** and **18** was greatly reduced (<1%). It should be stressed, however, that the desulfurized products were formed even in a good hydrogen-donating solvent such as 2-propanol when the disulfide was photo-activated.

As has been noted earlier,[3] the photo-reaction of 1,2-dithiolanes in aldehydes is less clean when the concentration of the disulfide is high. At a concentration below 1×10^{-2} M, the fraction of radiation absorbed by the sulfur compound is unimportant because of the overwhelming absorption by the aldehyde solvent. As the concentration increases, more of the light is absorbed by the sulfur compound, leading to the introduction of side reactions. Thus, the activation of 1,2-dithiolane is not a necessity for the reductive acylation to take place.

The reaction most probably involves the following sequence of events:

(initiation)

$$\text{initiator} \xrightarrow{\Delta} \text{In}\cdot$$

$$(\text{or RCHO} \xrightarrow{h\nu} \text{R}\cdot + \cdot\text{CHO})$$

$$\text{In}\cdot(\text{or R}\cdot) + \text{RCHO} \longrightarrow \text{InH (or RH)} + \text{R}\dot{\text{C}}{=}\text{O} \quad (7)$$

$$\text{In}\cdot(\text{or R}\cdot) + \text{R'SSR'} \longrightarrow \text{In}-\text{SR'} \text{ (or RSR')} + \text{R'S}\cdot \quad (7')$$

(propagation)

$$\text{R}\dot{\text{C}}{=}\text{O} + \text{R'SSR'} \longrightarrow \text{R'S}\cdot + \text{R'SCOR} \quad (8)$$

$$\text{R'S}\cdot + \text{RCHO} \longrightarrow \text{R'SH} + \text{R}\dot{\text{C}}{=}\text{O} \quad (9)$$

A selectivity in acylation appears when the acyl radical attacks the disulfide on a sterically less hindered sulfur. An electronic factor is not responsible for the selectivity, since the electron density on sulfur would not be much different among primary, secondary, and tertiary disulfides in view of the small variation in the acid-dissociation constants of the corresponding thiols.[12] Moreover, an electronegative acyl radical should show a preferred reactivity for the electropositive tertiary thiyl sulfur if the electronic factor were indeed controlling.

Mechanistically related to the present reaction is the photochemical decarbonylation of aliphatic aldehydes at elevated temperatures. The reaction is strongly accelerated by the presence of a catalytic amount of either disulfides or thiols (Eq. 10).[13] An induction period has been reported for the catalysis of disulfides, but not for that of thiols. It is very probable that the reductive acylation of the disulfide first took place to afford the thiol and the thiol acylate, though the formation of the latter had not been studied. After most of the disulfides were consumed, the unimolecular decomposition of the acyl radical became predominant under high-temperature conditions (>140 °C), thus giving carbon monoxide and alkyl radical (decarbonylation, Eq. 11). The alkyl radical then abstracts hydrogen either from thiol or aldehyde to form an alkane molecule (RH) and a chain-propagating radical (either R'S· or R$\dot{\text{C}}$=O). The decarbonylation from the acyl radical is obviously not important at lower temperatures (76 °C, Table 3).

$$\text{RCHO} \xrightarrow[\text{R'SH or (R'S)}_2]{h\nu,\ >140\,^\circ\text{C}} \text{RH} + \text{CO} \quad (10)$$

$$\text{R}\dot{\text{C}}{=}\text{O} \xrightarrow{>140\,^\circ\text{C}} \text{R}\cdot + \text{CO} \quad (11)$$

Experimental

Materials. The cyclic disulfides, **1**,[14] **2**,[14] **3**,[14] **4**,[8] and **15**,[8] were prepared according to the reported procedures. Butyl isopropyl disulfide, butyl phenyl disulfide, and *t*-butyl ethyl disulfide were prepared by oxidizing the corresponding thiol mixtures.[15] Compound **2**, prepared according to the previously reported procedure,[14] showed a small absorption peak at 330 nm in addition to the normal absorption at 334 nm. The former absorption was eliminated by reduction with lithium aluminum hydride, followed by reoxidation with iodine. No differences in reactivity or other spectral characteristics (NMR and IR) were observed between the two methods of preparation. A very minute impurity seems to be responsible for the 330 nm absorption.

Photo-reactions. High-pressure mercury lamps, UVL-100HA (100 W output) and UVL-400HA (400 W) (Riko Kagaku Co.), fitted with Pyrex glass-made double jackets, were used as light sources. The sample solutions, 100—200 ml in volume, were internally irradiated by a liquid-filtered light ($\lambda \leq 330$ nm removed) under nitrogen or argon at ≤ 5 °C. The reaction mixture was analyzed by GLC, using appropriate straight-chain alkanes as internal standards (Figs. 1—5). The reaction product was isolated either by distillation or by column chromatography. The detailed experimental procedure has been described elsewhere.[3]

Radical Reactions. In 10—50 ml of freshly distilled aldehyde we dissolved an appropriate amount of the organic disulfide to give a 0.2—0.7 M solution. AIBN was then added in a 10 mol% concentration of the disulfide, and the mixture was heated under nitrogen or argon to reflex. The reaction was monitored by GLC. The work-up of the reaction mixture was similar to that used in the photo-reactions.

Reaction Products. The simple thiocarboxylates and thiols were identified by comparisons on GLC with authentic samples. The dithiol monocarboxylates were isolated and identified by the spectral method (IR, NMR, and MS) as well as by elemental analysis.

5: Isolated by distillation; 91—92 °C/1 mmHg (1 mmHg=133 Pa); IR (neat) 2580 (SH) and 1695 cm^{-1} (CO); NMR (CCl_4) δ=1.02 (1H, t, J=8.8 Hz, SH), 1.40 (10H, m, cyclic CH_2), 2.28 (3H, s, $COCH_3$), 2.42 (2H, d, CH_2SH), 3.01 (2H, s, CH_2SCO). Found: C, 54.88; H, 8.28%. Calcd for $C_{10}H_{18}OS_2$: C, 55.00; H, 8.30%.

6: Isolated by distillation; 95 °C/2.5 mmHg; IR (neat) 2580 (SH) and 1695 cm^{-1} (CO); NMR (CCl_4) δ=0.78 (6H, t, J=7.1 Hz, CH_3CH_2), 1.07 (1H, t, J=8.8 Hz, SH), 1.36 (4H, q, CH_3CH_2), 2.29 (3H, s, $COCH_3$), 2.37 (2H, d, CH_2SH), 2.92 (2H, s, CH_2SCO). Found: C, 52.36; H, 8.80%. Calcd for $C_9H_{18}OS_2$: C, 52.38; H, 8.79%.

7: Isolated by chromatography (silicagel, benzene); colorless liquid; IR (neat) 2580 (SH) and 1695 cm^{-1} (CO); NMR (CCl_4) δ=0.79 (6H, t, J=7.0 Hz, $CH_3CH_2C\leqslant$), 1.10 (1H, t, J=8.5 Hz, SH), 1.17 (3H, t, J=7.5 Hz, CH_3CH_2CO), 1.36 (4H, q, $CH_3CH_2C\leqslant$), 2.38 (2H, d, CH_2SH), 2.55 (2H, q, CH_3CH_2CO), 2.93 (2H, s, CH_2SCO); MS (*m/e*), 220 (M^+), 163 ($M^+-C_2H_5CO$), 57 (C_2H_5CO). Found: C, 54.78; H, 9.20%. Calcd for $C_{10}H_{20}OS_2$: C, 54.50; H, 9.15%.

8: Isolated by chromatography (silica gel, hexane containing 1% ether); colorless liquid; IR (neat) 2580 (SH) and 1695 cm^{-1} (CO); NMR (CCl_4) δ=0.79 (6H, t, J=7.0 Hz, $CH_3CH_2C\leqslant$), 0.95 (3H, t, J=7.0 Hz, $CH_3CH_2CH_2CO$), 1.07 (1H, t, J=8.6 Hz, SH), 1.36 (4H, q, $CH_3CH_2C\leqslant$), 1.58 (2H, sex, J=7.0, 7.6, $CH_3CH_2CH_2CO$), 2.38 (2H, d, CH_2SH), 2.49 (2H, t, $CH_3CH_2CH_2CO$), 2.92 (2H, s, CH_2SCO). Found: C, 57.03; H, 9.45%. Calcd for $C_{11}H_{22}OS_2$: C, 56.36; H, 9.46%.

9: Isolated by chromatography (silica gel, hexane); colorless liquid; IR (neat) 2580 (SH) and 1695 cm^{-1} CO); NMR (CCl_4) δ=0.78 (6H, t, $CH_3CH_2C\leqslant$), 1.03 (1H, t, J=7.0 Hz, SH), 1.17 (6H, d, J=6.8 Hz, $CH(CH_3)_2$), 1.35 (4H, q, $CH_3CH_2C\leqslant$), 2.37 (2H, d, CH_2SH), 2.72 (1H, sep, $CH(CH_3)_2$), 2.89 (2H, s, CH_2SCO). Found: C, 56.27; H, 9.42%. Calcd for $C_{11}H_{22}OS_2$: C, 56.36; H, 9.46%.

10: Isolated by chromatography (silica gel, hexane containing 5% ether); colorless liquid; IR (neat) 2580 (SH) and 1695 cm^{-1} (CO); NMR (CCl_4) δ=0.79 (6H, t, J=7.0 Hz, $CH_3CH_2C\leqslant$), 1.03 (1H, t, J=8.5 Hz, SH), 1.21

(9H, s, $C(CH_3)_3$), 1.36 (4H, q, $CH_3\underline{CH_2}C\lessgtr$), 2.37 (2H, d, $\underline{CH_2}SH$), 2.87 (2H, s, CH_2SCO). Found: C, 58.22; H, 9.75%. Calcd for $C_{12}H_{24}OS_2$: C, 58.01; H, 9.73%.

13: Isolated by chromatography (silica gel, hexane containing 5% ether); colorless liquid; IR (neat) 3060 (aromatic CH), 2580 (SH), and 1665 cm^{-1} (CO); NMR (CCl_4) δ= 1.09 (1H, t, J=8.5 Hz, SH), 1.46 (10H, m, cyclic CH_2), 2.50 (2H, d, $\underline{CH_2}SH$), 3.22 (2H, s, CH_2SCO), 7.2—7.5 (3H, m, aromatic *m*- and *p*-H), 7.8—8.0 (2H, m, aromatic *o*-H). Found: C, 64.82; H, 7.21%. Calcd for $C_{15}H_{20}OS_2$: C, 64.24; H, 7.18%. a contamination from by-products.

14: Isolated by chromatography (silica gel, hexane containing 2% ether); colorless liquid; IR (neat) 3060 (aromatic CH), 2580 (SH), and 1665 cm^{-1} (CO); NMR (CCl_4) δ= 0.81 (6H, t, J=7.0 Hz, $\underline{CH_3}CH_2$), 1.10 (1H, t, J=8.5 Hz, SH), 1.39 (4H, q, $CH_3\underline{CH_2}$), 2.41 (2H, d, $\underline{CH_2}SH$), 3.10 (2H, s, CH_2SCO), 7.2—7.5 (3H, m, aromatic *m*- and *p*-H), 7.8—8.0 (2H, m, aromatic *o*-H); MS (*m/e*), 268 (M^+), 163 ($M^+-C_6H_5CO$), 105 (C_6H_5CO). Found: C, 63.87; H, 7.34%. Calcd for $C_{14}H_{20}OS_2$: C, 62.64; H, 7.51%. a contamination from by-products.

16: Isolated by distillation, 95 °C/3 mmHg; IR (neat) 2580 (SH) and 1695 cm^{-1} (CO); NMR (CCl_4) δ=1.32 (3H, d, J=6.5 Hz, $\underline{CH_3}CH(SH)CH_2$), 1.37 (1H, d, J= 6.3 Hz, SH), 1.5—1.9 (4H, m, $CH_3CH(SH)\underline{CH_2}\underline{CH_2}CH_2S$), 2.28 (3H, s, CH_3CO), 2.6—3.0 (3H, m, $CH_3\underline{CH}(SH)CH_2$-$CH_2\underline{CH_2}S$). Found: C, 47.24; H, 7.98%. Calcd for $C_7H_{14}OS_2$: C, 47.15; H, 7.91%.

17: Isolated by distillation, 80 °C/1.3 mmHg; IR (neat) 2925, 2850 (CH), and 1452 cm^{-1} (CH); UV (pentane) λ_{max} 266 nm, ε 70; NMR (CCl_4) δ=1.50 (10H, m, 6-membered cyclic CH_2), 2.81 (4H, s, CH_2S). Found: C, 67.73; H, 9.93%. Calcd for $C_8H_{14}S$: C, 67.54; H, 9.92%.

18: Isolated by distillation, 53 °C/10 mmHg; IR (neat) 2925, 2850 (CH), and 1450 cm^{-1} (CH); NMR (CCl_4) δ= 0.83 (6H, t, J=7.5 Hz, CH_3), 1.63 (4H, q, $CH_3\underline{CH_2}$), 2.79 (4H, s, CH_2S). Found: C, 65.45; H, 11.07%. Calcd for $C_7H_{14}S$: C, 64.55; H, 10.83%.

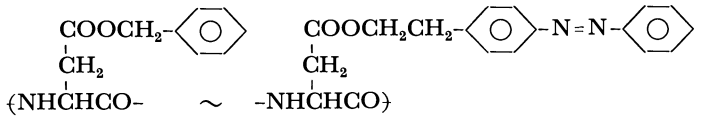
Solvent-induced Conformational Changes of Arylazo-substituted Polyaspartates

Akihiko Ueno,* Keiko Takahashi, Jun-ichi Anzai, and Tetsuo Osa
Pharmaceutical Institute, Tohoku University, Aobayama, Sendai 980
(Received September 20, 1979)

Copolymers of β-benzyl L-aspartate and β-[*p*-(phenylazo)phenethyl] L-aspartate were prepared and their conformations studied by circular dichroism (CD) spectroscopy. The copolymers with less than 40% azo amino acid residues were found to be left-handed (LH) helical, those with more azo amino acid residues right-handed (RH) helical in 1,2-dichloroethane (DCE) solution. The former undergo LH helix→random coil transition on addition of hexafluoro-2-propanol (HFIP) to their DCE solutions, the latter RH helix→LH helix→random coil transition on addition of HFIP. All polymers in DCE exhibit a negative CD band in the side-chain n-π* transition region. The side-chain π-π* CD band was observed only for the copolymers with the highest azo amino acid residues (67%). Its absolute ellipticity decreases with increasing HFIP content, finally disappearing at 10% HFIP. The sign of the n-π* CD band of the copolymer remains negative irrespective of the helix reversion, its absolute ellipticity being unchanged below 10% HFIP and decreasing on further increase in HFIP content. The results suggest solvent-induced changes in orientation or mobility of the side-chain phenylazo moieties.

Circular dichroism (CD) measurements have been extensively used to evaluate the conformation of polypeptides in solution, the evaluation being based on the peptide CD bands. However, it is very difficult to assign the conformation of polypeptides with aromatic side chains since the usually very useful indications are made useless by the presence of additional side-chain CD bands in the same spectral region.[1] In spite of this unfavorable effect, the side-chain CD might provide information of main-chain conformation as well as orientation, mobility and arrangement of side chains themselves. As examples of polypeptides with aromatic side chains, some arylazo polypeptides have been prepared, and their chiroptical properties investigated.[1–10] Goodman *et al.* prepared polypeptides composed of (phenylazo)phenylalanine and its analogues,[2–6] and observed that the peptide CD bands of their α-helices are significantly perturbed by the presence of the aromatic side chains. There is no such complication for the arylazo polyaspartates[7–9] and azo-modified poly(L-glutamic acid).[1,10] The use of these polypeptides would establish a relationship between side-chain CD and main-chain conformation. Various conformations are needed in order to gain insight into the relationship. Arylazo polyaspartates seem to be suitable since polyaspartates often exhibit conformational versatility.[11] Light-induced conformational changes, such as left-handed (LH) helix→right-handed (RH) helix and LH helix→random coil transitions have been observed on some arylazo polyaspartates.[7–9] We have prepared a new series of arylazo polyaspartates composed of β-[*p*-(phenylazo)-phenethyl] L-aspartate and β-benzyl L-aspartate,



and found that their conformations are very sensitive to solvent. Several reports have appeared on solvent-induced conformational changes of polypeptides: helix reversion for polyaspartates[11d,12] and poly[L-β-[3,4-bis(benzyloxycarbonyloxy)phenyl]-α-alanine],[13] transformations between single and double stranded helices for poly(γ-benzyl D-L-glutamate).[14] The present paper deals with the solvent-induced conformational changes of the arylazo copolymers among LH helix, RH helix, and random coil. The behavior of the side-chain CD during the course of conformational change was investigated in order to elucidate the relationship between the side-chain CD and the main-chain conformation.

Results and Discussion

The CD spectra in the region below 260 nm measured for the copolymers dissolved in 1,2-dichloroethane (DCE) are shown in Fig. 1. The spectra of copolymers with less phenylazo residues (azo amino acid residues< 40%) exhibit a positive CD band around 222 nm,

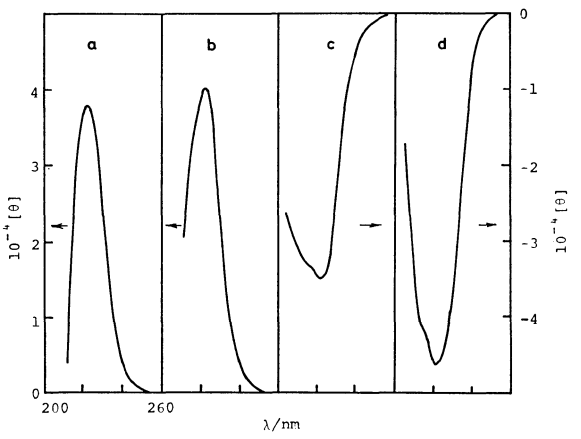


Fig. 1. CD spectra of the copolymers with different contents of phenylazo residues in DCE solution. Phenylazo content: 11% (a); 26% (b); 46% (c); 67% (d).

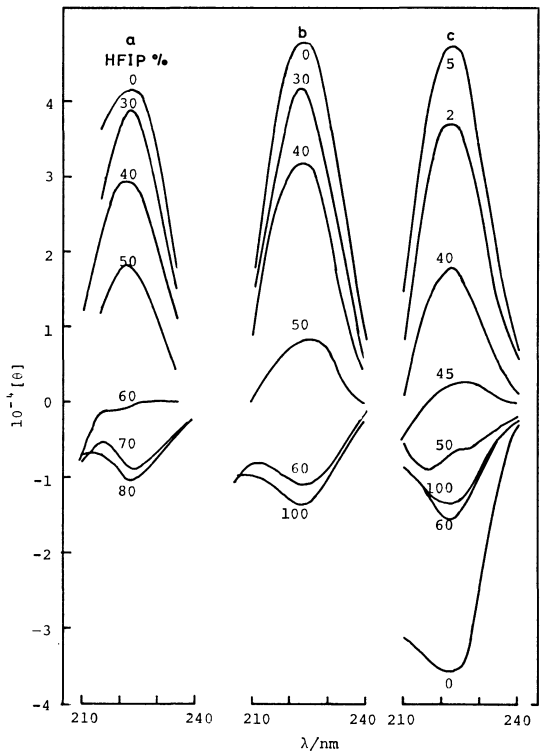

Fig. 2. CD spectra of the copolymers with phenylazo residues of 11% (a), 26% (b), and 46% (c) in mixed solutions of DCE and HFIP.

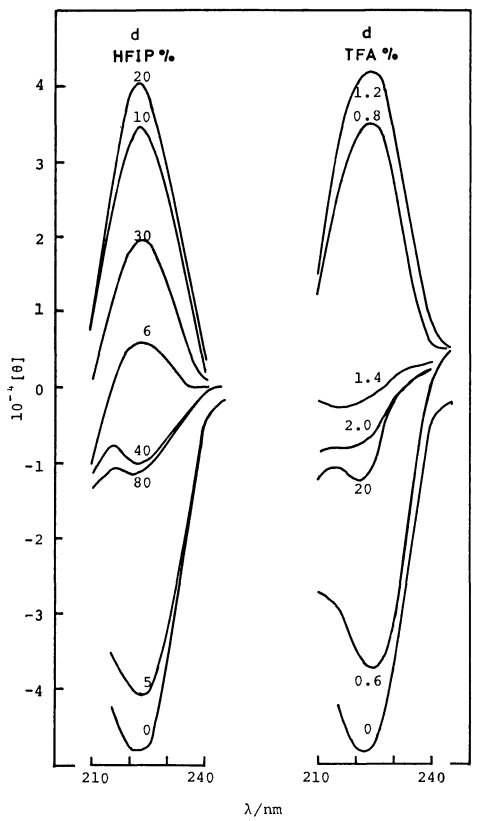

Fig. 3. CD spectra of the copolymer with 67% phenylazo residues in DCE–HFIP and DCE–TFA solvent systems.

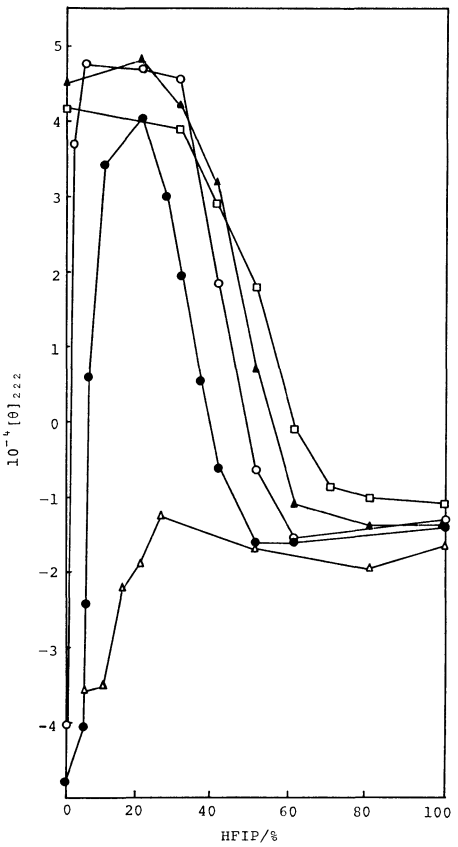

Fig. 4. Dependence of the ellipticity at 222 nm on HFIP content.

characteristic of the LH helix, those with more phenylazo residues (>40%) a negative CD band around 222 nm, characteristic of the RH helix. The homopolymer with 100% azo residues being insoluble in DCE, no spectral measurement was carried out in this solvent.

The CD spectra of the polymers were found to change on addition of hexafluoro-2-propanol (HFIP) to their DCE solutions (Figs. 2, 3, and 4). The molecular ellipticities $[\theta]$ for the copolymers with more than 40% phenylazo residues change from negative to positive on increasing HFIP content (up to 20%), confirming the conformational transition from RH helix to LH helix. Further increase in HFIP content causes another change in the $[\theta]$ values from positive to negative, which may correspond to the conformational transition from LH helix to random coil; increase in HFIP content above 50% causes no significant change. The following transition process is thus established.

$$\text{RH helix} \xrightarrow{\text{HFIP}} \text{LH helix} \xrightarrow{\text{HFIP}} \text{random coil} \quad (1)$$

The anomalous $[\theta]$ values for the random coil suggest that the conformation of these copolymers is not entirely random, possibly due to side chain - side chain steric interactions. Bradbury *et al.* reported a similar phenomenon, the conformational transitions in their case being induced by addition of trifluoroacetic acid

(TFA) or dichloroacetic acid to chloroform solutions of copolymers of β-ethyl L-aspartate and β-benzyl L-aspartate.[12a] RH Helix→LH helix transition for the arylazo polyaspartates we studied was also induced by TFA addition, in agreement with their results (Fig. 5). The helix reversal for arylazo polyaspartates occurs on addition of a very small amount of TFA (<2%). The resulting LH helix readily turns into the random form on further addition of TFA, in line with the behavior of TFA as a random-coil promoting solvent.

In contrast to the copolymers with more than 40% phenylazo residues, the copolymers with less phenylazo residues are LH helical in pure DCE, undergoing only LH helix→random coil transition on addition of HFIP.

$$\text{LH helix} \xrightarrow{\text{HFIP}} \text{random coil} \qquad (2)$$

The homopolymer with 100% phenylazo residues is insoluble in DCE but soluble in HFIP. Its CD spectra at different HFIP contents were therefore measured on solutions prepared by adding DCE to the HFIP solution. The spectrum of the polymer in 100% HFIP exhibits a negative band around 222 nm at-

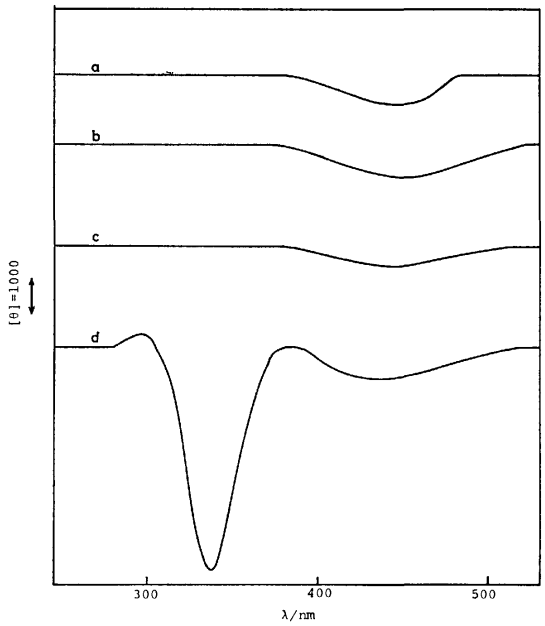

Fig. 6. CD spectra associated with the side-chain n-π* and π-π* transitions in DCE.
Phenylazo content: 11% (a); 26% (b); 46% (c); 67% (d).

tributable to the random-coil form. No positive band appears on increasing the DCE content, the spectrum attributable to a RH helix being finally attained (Fig. 4). Thus, the following process should occur if HFIP is added to the DCE solution.

$$\text{RH helix} \xrightarrow{\text{HFIP}} \text{random coil} \qquad (3)$$

Processes (1), (2), and (3) might arise from an alteration of the energy balance as a consequence of hydrogen bonding of HFIP to the side-chain ester groups, or to the main-chain amide groups.

The CD spectra associated with the side-chain n-π* and π-π* transitions were obtained for the polymers in DCE solution (Fig. 6). Molar ellipticities of the side-chain CD bands were calculated using the molar concentration of phenylazo residues. Among the four copolymers used, only one with 67% phenylazo residues exhibits the π-π* CD band, suggesting that the π-π* CD arises from electronic interactions between the side-chain azobenzene moieties. On the other hand, the n-π* CD band appears for all copolymers, the sign being the same regardless of the conformational differences. The minimum ellipticities around 440 nm are similar irrespective of copolymer composition. The results suggest that side chain-main

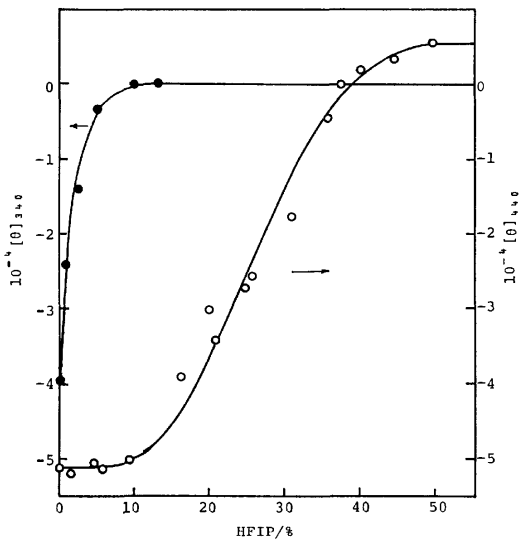

Fig. 7. Dependence of the ellipticities of the side-chain n-π^* and π-π^* CD bands on HFIP content for the copolymer with 67% phenylazo residues.
○: n-π^* CD band around 440 nm, ●: π-π^* CD band around 340 nm.

chain electronic interactions give rise to the band. Addition of HFIP to a DCE solution of the copolymer with 67% phenylazo residues alters both side-chain CD bands. The π-π^* CD band decreases in intensity with increasing HFIP content, finally disappearing at 10% HFIP where the conformation of the polymer is LH helical (Fig. 7). This indicates that the side chain - side chain electronic interactions, which are origin of the π-π^* CD band, become impossible, probably due to the disordered arrangement of the side-chain chromophores in the HFIP-solvated LH helix. The n-π^* CD band of the copolymer with 67% phenylazo residues shows no change up to 10% HFIP in spite of the observed RH helix→LH helix transition in this solvent range, confirming the insensitivity of this band to helix nature. Further increase in the HFIP content causes a decrease in the absolute ellipticity, even in the solvent range where the main-chain conformation remains LH helical. The absolute ellipticity continues to decrease over the HFIP concentration range in which LH helix→random coil transition occurs, the $[\theta]$ value becoming constant with a positive sign for the random-coil form. This behavior of the n-π^* CD band indicates that helical structures are necessary for its appearance. In the helical structures the side chains might be limited in mobility, adopting certain geometric positions in relation to the asymmetric centers of the main-chain backbone.

Experimental

CD spectra were recorded on a JASCO J-20 circular dichrograph apparatus at 25 °C using 0.3—1 g/l solutions. "Dotite Spectrosol" grade DCE and "Merck Urasol" grade HFIP were used without further purification. Due to the absorption of DCE, no spectra could be obtained below 210 nm. Molecular ellipticities for the band around 222 nm were calculated by means of the molar concentration of the amide group. Ellipticities for the side-chain CD bands were calculated by means of the molar concentration of the phenylazo residues. Polymers used for the CD measurements were synthesized as described below.

p-*(Phenylazo)phenethyl Alcohol (1).* The alcohol was prepared from *p*-aminophenethyl alcohol (25 g) and nitrosobenzene (19.5 g) by the method reported previously.[8] Yield, 30.5 g (74%); mp 90—91 °C. Found: C, 74.04; H, 6.22; N, 12.33%. Calcd for $C_{14}H_{14}N_2O$: C, 74.30; H, 6.25; N, 12.38%.

β-[p-*(Phenylazo)phenethyl*] L-*Aspartate (2).* Amino acid **2** was prepared from alcohol **1** (13.3 g) and L-aspartic acid (7.83 g) by the method reported previously.[15] Yield, 15.8 g (79%); mp 199—200 °C. IR (KBr): 1740, 1600, 1240 cm^{-1}. Found: C, 63.09; H, 5.56; N, 12.23%. Calcd for $C_{18}H_{19}N_3O_4$: C, 63.32; H, 5.62; N, 12.31%.

β-[p-*(Phenylazo)phenethyl*] L-*Aspartate* N-*Carboxy Anhydride (3).* *N*-Carboxy anhydride (NCA) was prepared from **2** (4 g) and trichloromethyl chloroformate (2.36 g).[16] The crude product was recrystallized twice from ethyl acetate and hexane. Yield, 0.93 g (22%); mp 160—161 °C. IR (KBr): 1858, 1800, 1766, 1740, 1180 cm^{-1}. Found: C, 62.33; H, 4.80; N, 11.64%. Calcd for $C_{19}H_{17}N_3O_5$: C, 62.11; H, 4.67; N, 11.44%.

Polymers. Polymers with different azo amino acid contents were prepared from **3** and *β*-benzyl L-aspartate NCA by varying the ratio of the two NCAs. Polymerization was carried out in dioxane at room temperature for 5 d using triethylamine as an initiator (monomer/initiator ratio 50:1). The reaction mixture was added to ethanol stirred vigorously. The precipitate was collected by filtration, washed with several portions of ethanol and dried *in vacuo* at 40 °C. Mole percentage of azo amino acid residues in the copolymers was estimated from the nitrogen content obtained by elemental analysis. The reduced specific viscosity, η_{sp}/c, for each polymer was measured for a 0.1% DCE solution at 25 °C. Viscosity measurement for the polymer composed of 100% azo amino acid residues could not be carried out due to its insolubility in DCE. Data for the polymers are sammarized in Table 1.

(Received October 8, 1979)

The electronic structures and molecular conformations of *N*-benzylideneaniline and its several derivatives bearing 2-methyl, 2,6-dimethyl, and/or 4-nitro groups on the anilino benzene ring (ring A) have been investigated by electronic absorption spectroscopy combined with CNDO/S CI calculations. The lower energy bands are assigned and the molecular conformations are estimated. The results show that the 4-nitro derivatives as well as the 2,6-dimethyl derivatives take considerably twisted conformations.

It is well known that the UV absorption spectral pattern of *N*-benzylideneaniline is remarkably different from those of π-isoelectronic *trans*-stilbene and *trans*-azobenzene,[1] and it has been reasonably understood in terms that *N*-benzylideneaniline takes a nonplanar conformation[1b,1c,2] in which the anilino benzene ring (ring A) twists from the rest part of the molecule considerably (see Fig. 1) whereas *trans*-stilbene[1c,3] and *trans*-azobenzene[1c,4] do not take drastically twisted conformations.

The molecular conformations of *N*-benzylideneanilines have been investigated by several methods. A recent gas phase electron diffraction study has indicated that the twist angle θ_N of *N*-benzylideneaniline **1** is about 52°.[5] The PCILO[6] and NDDO[7] calculations also supported the twisted conformation of **1**.

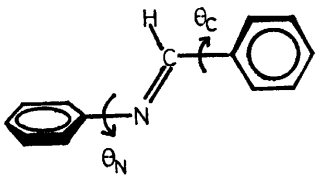

Fig. 1. Twisted conformation of *N*-benzylideneaniline.

In crystalline states, the molecular structures of *N*-benzylideneaniline and some of its derivatives have been determined by X-ray crystallography.[8-14] For example, it was reported that *N*-benzylideneaniline,[8] the 4-carboxy derivative,[8] and the 4-dimethylamino-4′-nitro derivative[9] take nonplanar conformations with the twist angle θ_N of 55.2, 41.1, and 9.1°, respectively. The 4,4′-dichloro derivative crystallizes in two modifications, and in one modification the molecule has the twist angle θ_N of about 25° and in another modification it takes a planar conformation.[10] Similar phenomenon is also found for the 4,4′-dimethyl derivative.[12,13] These facts clearly show that the twist angles θ_N of these compounds in crystals are controlled by the way of molecular packing,[15] and that it is not suitable for estimating the twist angles θ_N of the molecules dissolved in solutions from those determined in crystalline states.

In solution, the electronic absorption spectra of various *N*-bezylideneanilines have already been reported.[1b,1c,2,9,16,17] Historically, Wiegand and Merkel[16] examined for the first time the UV absorption spectrum of *N*-benzylideneaniline and proposed the linear planar model as its structure. Ebara analyzed UV spectra of various substituted *N*-benzylideneanilines including nitro derivatives and postulated that in these compounds the ring A is perpendicular to the rest part of the molecule, the imino nitrogen taking sp hybridization.[2b] This model was taken later by El-Bayoumi and coworkers also in their extensive study of UV absorption spectra of various substituted *N*-benzylideneanilines.[2g] On the other hand, Brocklehurst[1b] and Smith[2c] proposed the model in which the ring A is rather twisted around the C–N bond by the examination of the UV absorption spectra of *N*-benzylideneaniline and related compounds. And nowadays, this model is reasonable, judging from the results for the other phases mentioned above.

Skrabal and his coworkers compared the UV spectra of several substituted *N*-benzylideneanilines with those of their corresponding 5-substituted 2-aryl-3,3-dimethyl-3*H*-indoles, and suggested that substitution of 4-dimethylamino group will reduce the twist angle θ_N, that 4-nitro group would not change the angle, and that the 4-dimethylamino-4′-nitro derivative takes a nearly planar conformation.[2h] Ezumi *et al.* reported that the 4-dimethylamino-4′-nitro derivative takes a nearly planar conformation on the basis of the comparison of its UV spectrum with that of 4-dimethylamino-4′-nitro-*trans*-stilbene together with calculations of the transition energies and intensities of their absorptions, and the planarity of the molecule was attributed to the favourable π-delocalization throughout the molecule by intramolecular charge transfer interaction between the substituents.[9] These results indicate that the substitution on the ring A is quite important in determining the twist angle θ_N.

In order to get deeper insight into the substituent effect on the twist angles θ_N of *N*-benzylideneanilines, an attempt has been made to investigate the effect of 4-nitro group as well as 2-methyl and 2,6-dimethyl groups on the electronic absorption spectra. The electronic absorption spectra of six *N*-benzylideneanilines, that is, *N*-benzylideneaniline **1**, *N*-benzylidene-2-methylaniline **2**, *N*-benzylidene-2,6-dimethylaniline **3**, *N*-benzylidene-4-nitroaniline **4**, *N*-benzylidene-2-methyl-4-nitroaniline **5**, and *N*-benzylidene-2,6-dimethyl-4-nitroaniline **6**, have been measured, and their transition properties have been calculated to interpret the observed spectra.

Method and Results

The electronic absorption spectra of six *N*-benzylideneanilines **1**—**6** are shown in Figs. 2—7, respectively. The observed absorption spectral data are listed in Table 1. The long wavelength regions of the observed spectra were approximately deconvoluted into the first and second main component bands to estimate their transition energies and oscillator strengths which are also included in Table 1. The intensity ratios of the first bands to the second ones are shown in Table 2.

In order to reproduce the observed spectral patterns, the transition energies and the oscillator strengths have been calculated by the CNDO/S[18)] CI calculations including interactions between sixty-four singly-excited configurations for varying degrees of the twist angle θ_N. In the calculations of **1**, **2**, and **3**, the

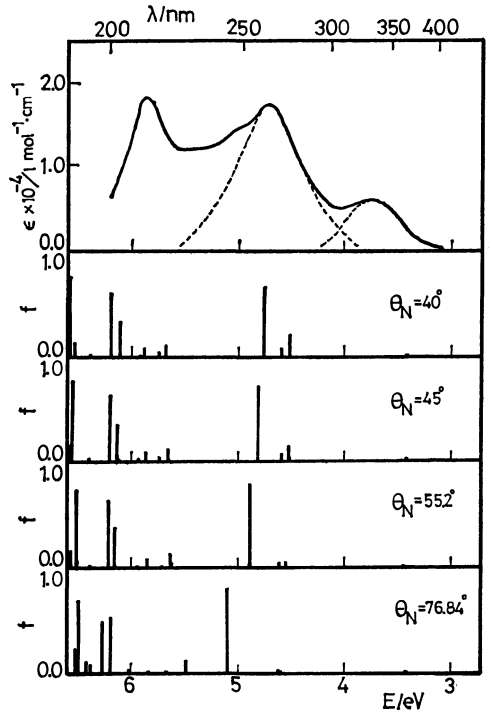

Fig. 3. Observed absorption spectrum and calculated spectral patterns of *N*-benzylidene-2-methylaniline **2**.

twist angles θ_C were kept at the same angle as for crystalline **1**, 10.3°,[8] since, in the preliminary calculations, the spectral pattern was not appreciably changed with its variation from 0° to 10.3°. Likewise, the angles θ_C for **4**, **5**, and **6** were fixed at the same angle as reported for crystalline *N*-(4-methylbenzylidene)-4-nitroaniline, 8.1°.[8]

The calculated results for the spectral patterns at

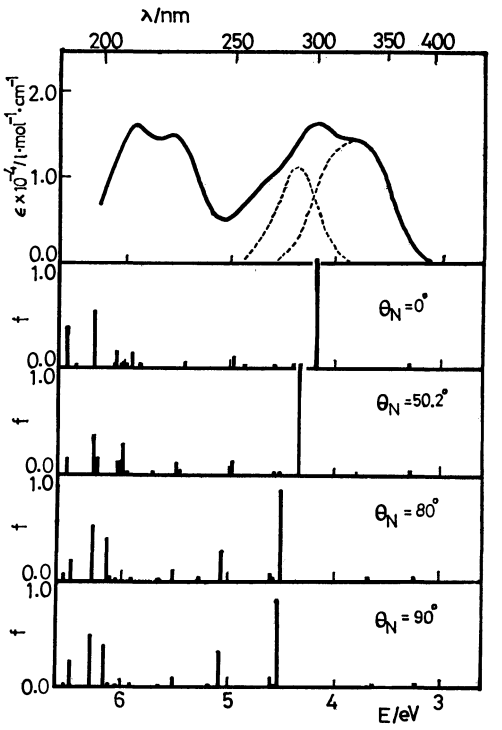

Fig. 5. Observed absorption spectrum and calculated spectral patterns of *N*-benzylidene-4-nitroaniline **4**.

various θ_N are also schematically illustrated in Figs. 2—7, and the ratios of the calculated oscillator strengths of the two strong transitions in the longer wavelength region at the various θ_N are shown in Table 2. Comparison of these calculated ratios with those of the observed ones has enabled us to estimate the twist

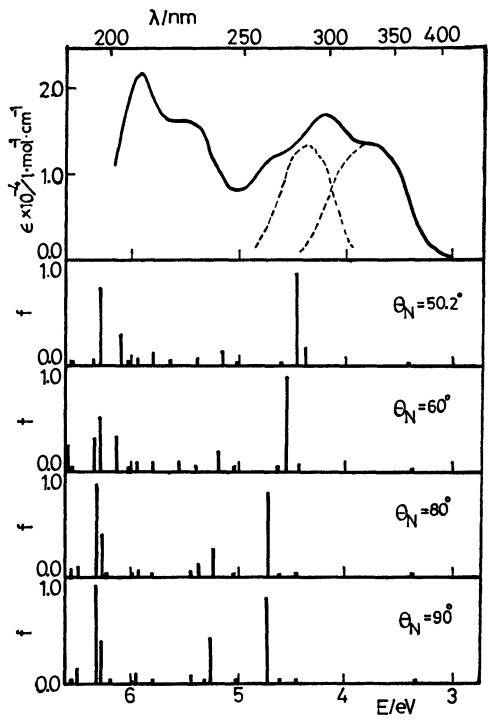

Fig. 6. Observed absorption spectrum and calculated spectral patterns of *N*-benzylidene-2-methyl-4-nitroaniline **5**.

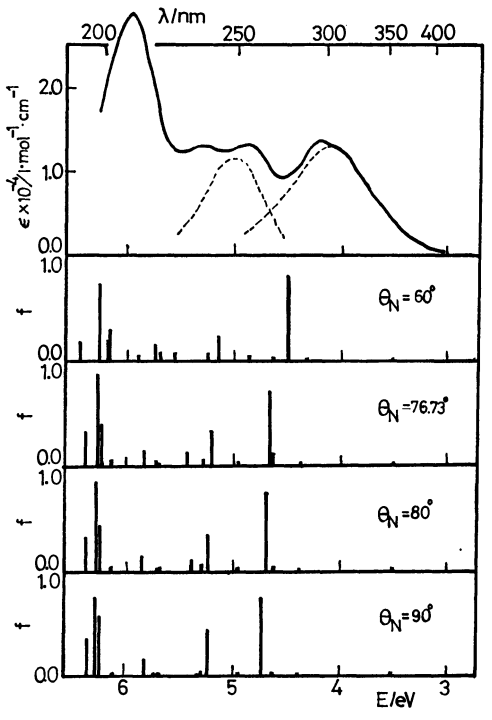

Fig. 7. Observed absorption spectrum and calculated spectral patterns of *N*-benzylidene-2,6-dimethyl-4-nitroaniline **6**.

angle θ_N which can reproduce well the observed results. The twist angles θ_N thus estimated are 30—35, 40—45, 70—80, 90, 90, and 90° for **1**, **2**, **3**, **4**, **5**, and **6**, respectively. Tables 3 and 4 respectively list the calculated transition energies and oscillator strengths for **1** and **4** at the above estimated angles θ_N=35° and 90°, respectively, together with the CI compositions and types of excitations. Figures 8 and 9 show schematic illustrations of the molecular orbitals calculated for **1** and **4** at the above twist angles, respectively.

Discussion

Compound ***1***. As Fig. 2 and Table 1 indicate, **1** shows the first absorption band at 315 nm (3.94 eV) and the intense second band at 264 nm (4.70 eV) in cyclohexane. The calculated transitions at 4.56 and 4.75 eV are regarded to correspond to these observed bands. The observed first band can be assigned mainly to the π-π^* transition with predominant configurations of 34—32, 34—33, and 36—33 (Table 3). Although the calculations predict the existence of an n-π^* transition with low intensity in the long wavelength region, this band was not identified probably owing to its low intensity and overlapping with the strong 315 nm band. The higher energy bands may tentatively be assigned as shown in Table 3.

As Fig. 2 indicates, with the increase in the twist angle θ_N, the first band is expected to decrease in intensity, and on the contrary, the second band is to increase in intensity. As Table 2 and Fig. 2 indicate, the calculation with the twist angle θ_N of 30—35° can well reproduce the observed spectral pattern. This estimated twist angle θ_N is smaller than that observed in the gas phase (θ_N=52±5°[5]); however, the present result may be taken to show that the twist angle θ_N of **1** in a solution is far from 90°, and may be in qualitative agreement with that estimated from photoelectron spectroscopy as described in a subsequent paper.[19]

The method used in this study seems more suitable for estimating approximately the twist angle θ_N than the previous work by Minkin *et al.*[2f] employing the ASMO PPP CI method which was not successful in reproducing the observed intensity ratio of the first to the second band.

Compound ***2***. On introduction of an ortho-methyl group on the ring A (in going from **1** to **2**), the first band undergoes bathochromic shift by 15 nm; however, the second band remains unchanged in position (see Table 1). The intensity of the first band (f=0.13) is moderately reduced compared with **1** (f=0.18), and the intensity ratio of the first to the second band is decreased from 0.50 for **1** to 0.30 for **2**. The results of the calculations (Table 2) show that the twist angle θ_N of **2** may be 40—45° slightly larger than that evaluated for **1**. Accordingly, an ortho-methyl group on the ring A seems to exhibit not so pronounced effect on the twist angle θ_N. The first band is assigned mainly to the π-π^* transition with predominant configurations of 37—33, 37—36, and 38—34. The second band is also assigned mainly to the π-π^* transition with predominant cofiguration of 37—36. Here, molecular orbitals 32—42 of **2** correspond to orbitals 29—39 of **1**, respectively.

Compound ***3***. For compound **3**, its first band, as compared with **2**, shows bathochromic shift by 10 nm and reduces in intensity. The intensity ratio of the first to the second band is much smaller than

a) The transition, indicated *i*-*j*, refers to a one-electron excitation from orbital *i* to virtual orbital *j*. The second column gives the CI coefficient of the configuration *i*-*j*. Orbitals 36 and 37 are the LUMO and HOMO, respectively. b) The apparent band maximum.

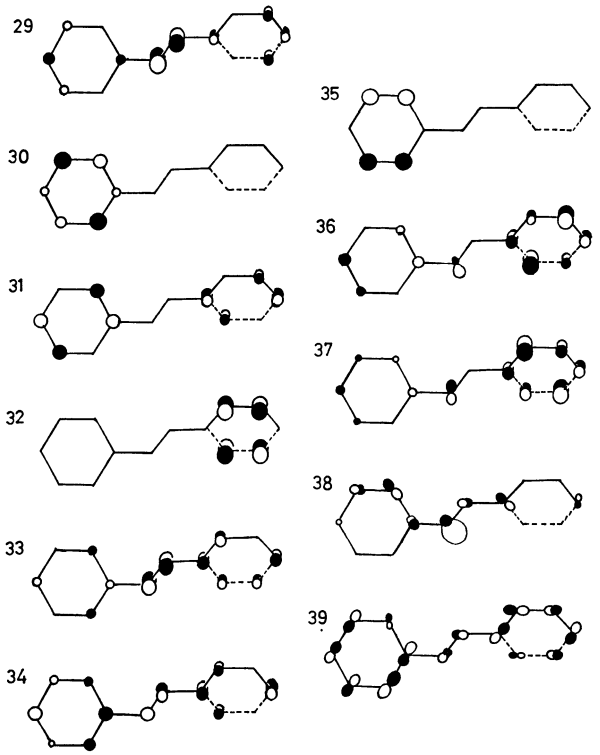

Fig. 8. Molecular orbitals of *N*-benzylideneaniline **1** (θ_N=35° and θ_C=10.3°).

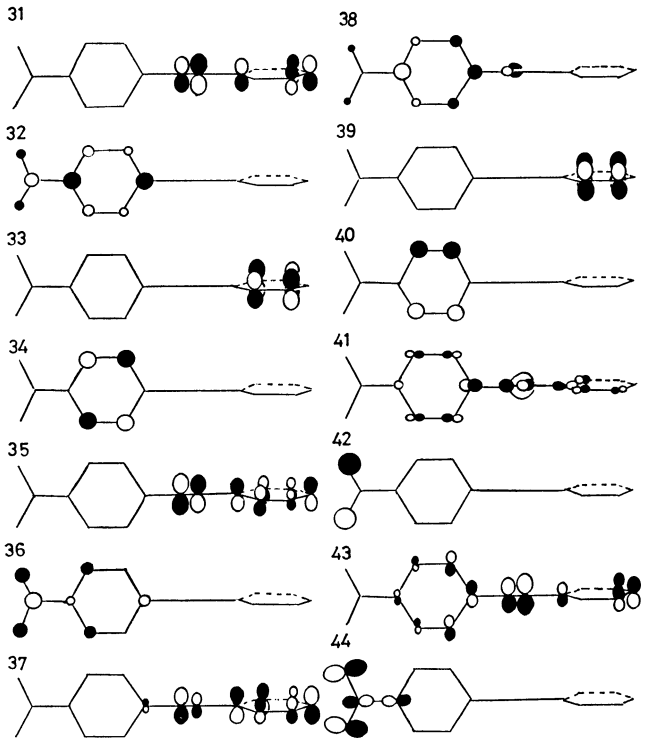

Fig. 9. Molecular orbitals of *N*-benzylidene-4-nitroaniline **4** (θ_N=90° and θ_C=8.1°).

those of **1** and **2**. The present calculations indicate that the first band is assigned mainly to the π-π^* transition with a slight n-π^* character. The π-π^* transition is mainly caused by charge transfer from the ring A to the PhCH=N– group. The second band at 253 nm is also assigned mainly to the π-π^* transition with a slight n-π^* character in which a local excitation in the PhCH=N– group is the main configuration. The most probable twist angle θ_N is estimated to be 70—80° (see Table 2 and Fig. 4). This value corresponds well to that estimated on the basis of the van der Waals radii, $\gtrsim$77°.

It is worth noting that the present calculations provide a quantitative interpretation for the previous UV absorption data by Smith[2c] which show that the consecutive introduction of ortho-methyl groups on the ring A successively lowers the intensity of the first band.

Compound ***4***. Compounds **4**, **5**, and **6** carrying 4-nitro group exhibit characteristic absorption bands in the long wavelength region different from those of **1**, **2**, and **3** which do not carry 4-nitro group. Deconvolution of the observed spectra reveals that, in **4**, **5**, and **6**, the first main bands are stronger in intensity than the second bands in contrast with **1**, **2**, and **3** in which the first bands are weaker in intensity than the second bands (see Figs. 2—7).

For **4**, Fig. 5 and Table 2 indicate that the calculated ratio of the oscillator strengths of the first to the second main transition decreases with the increase in the twist angle θ_N, but the observed ratio is still lower than the calculated one even at the perpendicular conformation (θ_N=90°). This suggests that, within the limitation of the CNDO/S CI calculations employed, **4** assumes a considerably twisted conformation in solution. As Table 4 indicates, the first band can be mainly assigned to the charge transfer excitation from the aniline-like group to the nitro group mixed with the local excitation in the PhCH=N– group.

The present result is in contrast with that by Skrabal and his coworkers who reported, without deconvolution of the spectra, that **4** would have a similar twist angle θ_N to that of **1** on comparsion of the apparent spectral patterns between **4**, **1**, and their corresponding 3*H*-indoles which can be regarded to take planar conformations.[2h] However, as described above, the transition characters of the first and second bands, particularly their intensity ratios, are remarkably different from each other between **1** and **4**. Their postulation, therefore, seems not fully satisfactory.

Compound ***5***. In the case of **5**, similar trend on the twist angle θ_N was observed (Fig. 6 and Table 2). The observed intensity ratio of the first to the second band (f_1/f_2) is 1.48. The twist angle θ_N predicted by the present calculations to reproduce best this intensity ratio is 90°.

The observed first band can be assigned mainly to the π-π^* transition. The main configurations are the so-called charge transfer ones from the toluidine-like group to the nitro group. The second band is also assigned mainly to the π-π^* transition. The main configuration is a local excitation in the PhCH=N– group.

Compound ***6***. Comparison of the observed spectrum of **6** with those calculated at various twist angles θ_N (Table 2 and Fig. 7) leads to conclusion that **6** also takes a considerably twisted conformation like

TABLE 5. ELECTRONIC ABSORPTION SPECTRAL DATA OF *N*-BENZYLIDENEANILINE **1**, *N*-BENZYLIDENE-4-NITROANILINE **4**, AND THE CORRESPONDING 3*H*-INDOLES **7** AND **8**[a]

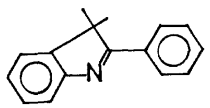
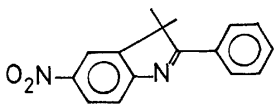
those of **4** and **5**. The first band can be mainly assigned to the π-π^* charge transfer transition from the benzylideneaniline group to the nitro group. The second band is assigned mainly to the π-π^* transition. The main configurations are the excitations to the PhCH=N– group π from the delocalized π-orbitals.

*Consideration on the Electronic Absorption Spectra of 2-Phenyl-3,3-dimethyl-3*H*-indoles.* Finally, it is worth noting that the present CNDO S CI method can well reproduce the reported UV spectral patterns[2h] of 3,3-dimethyl-2-phenyl-3*H*-indole **7** and 3,3-dimethyl-5-nitro-2-phenyl-3*H*-indole **8** regarded as the model compounds for the planar forms of *N*-benzylideneaniline **1** and *N*-benzylidene-4-nitroaniline **4**, respectively. Their spectral data are shown in Table 5. The spectral patterns calculated by the CNDO/S CI method for planar conformations (θ_N=0°) for **1** and **4** are shown in Figs. 2 and 5, respectively. As shown in Table 5, the planarization in each case (from **1** to **7** and from **4** to **8**) is accompanied by increase in the intensity of the first band, and this trend can be well reproduced by the present calculations (see Figs. 2 and 5).



7



8

This finding may suggest that the CNDO/S CI method employed here is suitable for estimating the twist angles θ_N of *N*-benzylideneanilines in solutions.

In summary, it is concluded from the present results that the twist angle θ_N for *N*-benzylideneaniline **1** may be far from 90° and the introduction of 4-nitro group (compound **4**) remarkably increases the twist angle θ_N in the liquid phase.

Experimental

Materials. *N*-Benzylideneanilines **1**—**6** were prepared by refluxing equimolar amounts of appropriate amine and aldehyde in ethanol or benzene in the presence of molecular sieve (Wako synthetic zeolite; 8—12 mesh). For the preparation of **6**, refluxing in xylene for 3 d was required. The new compounds **5**, mp 119—120 °C, and **6**, mp 108—109 °C, gave satisfactory results of elemental analyses and spectroscopic data.

Spectral Measurements. Electronic absorption spectra were recorded with a JASCO UVIDEC-1 double-beam spectrophotometer in cyclohexane at room temperature.

Theoretical Calculations

The CNDO/S[18] CI calculations were carried out with a FACOM 230-75 computer at the Institute of Physical and Chemical Research. All the necessary atomic integrals and parameters were taken from or estimated according to Ref. 18. In the configuration interactions all the singly-excited configurations concerning the eight highest occupied and eight lowest unoccupied molecular orbitals were taken into account. In the evaluation of the oscillator strengths also the ZDO approximation was used. The geometrical structures were properly assumed on the basis of the appropriate data given in Ref. 8.

(Received October 8, 1979)

Electronic structures and molecular conformations have been studied for *N*-benzylideneaniline and its 2-methyl, 2,6-dimethyl, and their 4-nitro derivatives by photoelectron spectroscopy. The lower energy bands are analyzed in detail, and the twist angles θ_N of the anilino benzene rings (ring A) about the carbon-nitrogen bonds are estimated by examining the effect caused by a methyl substitution. It is concluded that *N*-benzylidene-4-nitroaniline takes a more twisted conformation than *N*-benzylideneaniline.

In a preceding paper,[1] the electronic structures and the molecular conformations of *N*-benzylideneaniline and its derivatives bearing 2-methyl, 2,6-dimethyl, and/or 4-nitro groups on the aromatic nuclei on the nitrogen atoms (ring A) (compounds **1**—**6**) have been investigated by electronic absorption spectroscopy.

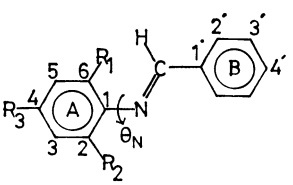
Concerning the photoelectron spectra (PES)[2] of *N*-benzylideneanilines, four reports have been published, but there has been some controversy on the PES band assignment and the molecular conformations estimated by this method.[3-6]

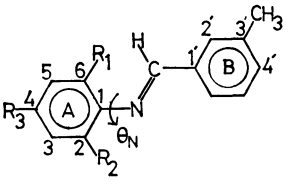
As regards to the twist angle θ_N (see the formula shown below) of *N*-benzylideneanilines, Bally *et al.* have recently estimated the twist angle θ_N to be approximately 36° by PES.[5] Gas phase electron diffraction study has determined the twist angle θ_N to be about 52°.[7] The calculations by the PCILO method with geometry optimization,[8] and by the NDDO method[9] have indicated that *N*-benzylideneaniline is twisted in θ_N by 36° and 65°, respectively. Concerning the PES of substituted *N*-benzylideneanilines, Klasinc *et al.* have investigated *N*-benzylideneaniline and some of its derivatives bearing methoxyl and/or nitro groups *etc.* as ring substituents and tried the HMO calculations.[6] They explained the results on the ground that these compounds take twisted conformations but on the assumption that the twist angle θ_N would be the same among the compounds examined. However, this assumption seems not to be adequate as has been described in the preceding paper.[1]

In order to get deeper insight into these problems, PES of *N*-benzylideneanilines **1**—**6** have been investigated. An attempt has been made to assign the PES bands precisely, and to estimate the molecular conformations of these compounds. The present results support our conclusion in the preceding paper that *N*-benzylidene-4-nitroaniline **4** is more twisted than *N*-benzylideneaniline **1**.

Results and Discussion

Photoelectron spectra have been measured for **1**—**6** and their 3′-methyl derivatives **7**—**12**; the latters are employed to assist the band assignments of the formers. Figures 1 and 2 show the PES of **1**—**6**. Table 1 summarizes the vertical ionization energies, E_{iv}, of **1**—**12**





1: $R_1=R_2=R_3=H$
2: $R_1=H$, $R_2=CH_3$, $R_3=H$
3: $R_1=R_2=CH_3$, $R_3=H$
4: $R_1=R_2=H$, $R_3=NO_2$
5: $R_1=H$, $R_2=CH_3$, $R_3=NO_2$
6: $R_1=R_2=CH_3$, $R_3=NO_2$
7: $R_1=R_2=R_3=H$
8: $R_1=H$, $R_2=CH_3$, $R_3=H$
9: $R_1=R_2=CH_3$, $R_3=H$
10: $R_1=R_2=H$, $R_3=NO_2$
11: $R_1=H$, $R_2=CH_3$, $R_3=NO_2$
12: $R_1=R_2=CH_3$, $R_3=NO_2$

together with those of some related compounds for the sake of comparison.

In the present work, in order to assign the PES bands precisely and to estimate the twist angles, θ_N, the effect of methyl substitution on the ionization energy has been extensively employed, which has been successfully applied to analyze the PES of styrenes,[10] for example.

Band Assignments. As shown in Fig. 1 and Table 1, *N*-benzylideneaniline **1** shows three groups of bands in the range of 8—10.5 eV. In this region, *trans*-stilbene has five π-bands.[11]

The first band of **1** has previously been assigned to the π-orbital corresponding to the highest occupied π-orbital of *trans*-stilbene delocalized over the entire molecular framework.[4] The first bands of the other *N*-benzylideneanilines studied can be reasonably correlated with the first band of **1**.

Compounds **1**, **2**, and **3** exhibit bands at nearly the same ionization energies, E_{iv}, 9.47 (shoulder), 9.49 (shoulder), and 9.47 eV, respectively, irrespective of 2-methyl, and 2,6-dimethyl substitution on the ring A. This fact suggests that these bands do not correspond to the π-orbital localized on the ring A. On the other hand, on 3′-methyl substitution on the benzylidene benzene ring (ring B), these bands are sensitively shifted to the low energy side by 0.34, 0.36, and 0.48 eV, respectively, as shown in Table 1. Accordingly, it is reasonable to correlate these bands with the 9.38 eV π-orbital band of *N*-benzylidenemethylamine.[5] Likewise, the 9.51 eV band of **4** and one of the 9.50 eV

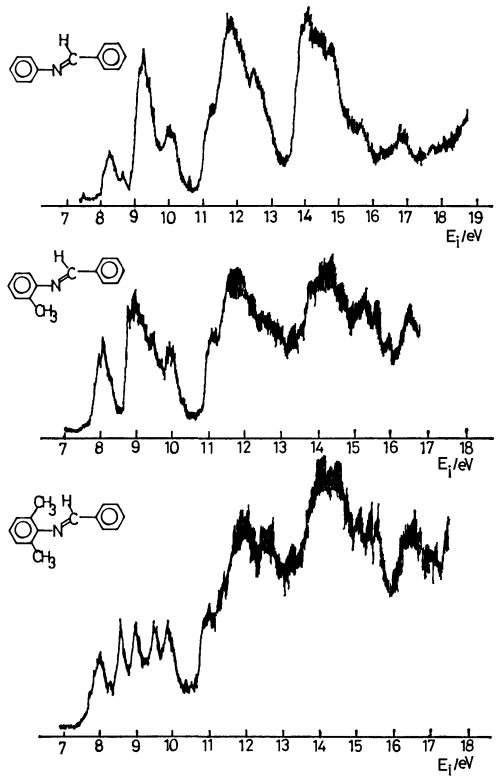

Fig. 1. Photoelectron spectra of **1**—**3**.

bands of **5** can be correlated with the same type of π-orbital since these bands are not sensitive to 2-methyl substitution on the ring A but sensitive to 3'-methyl substitution on the ring B (ΔE_{iv}=0.37 and 0.36 eV in going from **4** to **10** and **5** to **11**, respectively).

In the nitro derivative **4**, one can expect that π-orbitals mainly localized on the ring B should be lower in ionization energy than those on the ring A since the nitro group should increase the ionization energies of orbitals mainly localized on the ring A. This consideration suggests that one of the doubly degenerate 9.73 eV bands of **4** is correlated with the first π-band of nitrobenzene at 9.93 eV.[12,13]

The second band of **3** at 8.54 eV is insensitive to 3'-methyl substitution on the ring B (ΔE_{iv}=0.07 eV in going from **3** to **9**), and is closely located to the 8.71 eV $a_2\pi$ band of *m*-xylene.[12,13] So, it may be reasonably assigned to the π-orbital corresponding to the first $a_2\pi$ band of *m*-xylene. The ionization energy of the first $a_2\pi$ band of *m*-xylene is smaller than that of the $e_{1g}\pi$ band of benzene by 0.52 eV due to the destabilization of the $a_2\pi$ type orbital of the benzene ring by meta-dimethylation. Therefore, the bands corresponding to the 8.54 eV band of **3** are expected to appear around 9.06 eV for **1** and 8.80 eV for **2**. Thus, one of the degenerate 9.17 eV bands of **1** and the 8.80 eV band of **2** may safely be correlated with the 8.54 eV band of **3**. This assignment is supported by the fact that the 8.80 eV band of **2** is not sensitive to 3'-methyl substitution (ΔE_{iv}=0.06 eV in going from

2 to **8**). Similarly, one of the degenerate 9.50 eV bands of **5** and the 9.23 eV band of **6** can be correlated with the 9.73 eV band of **4** corresponding to the first π-band of nitrobenzene.

Assignment of the N-lone pair orbital is now considered by inspecting the well-resolved PES of **3**. As mentioned before, its 8.54 and 9.47 eV bands correspond to the π-orbitals mainly localized on the ring A and the ring B, respectively. The CNDO/S[14] calculations suggest that its 8.94 eV band corresponds to the 8.77 eV π-band of *N*-benzylidenemethylamine and the 9.86 eV band corresponds to the N-lone pair orbital, and, in fact, the 9.86 eV band is not so sensitive to 3'-methyl substitution (ΔE_{1v}=0.06 eV in going from **3** to **9**) as the 8.94 eV band (ΔE_{1v}=0.21 eV in going from **3** to **9**). However, as shown in the preceding paper,[1] *N*-benzylideneanilines examined take, more or less, twisted conformations so that the N-lone pair orbital will interact with π-orbitals to some extent. Therefore, it is not adequate to assign a specific band to the pure N-lone pair orbital, and the 9.86 eV band of **3** has to be considered as "delocalized" N-lone pair orbital. This interpretation seems in keeping with recent postulation by Klasinc *et al.*[6]

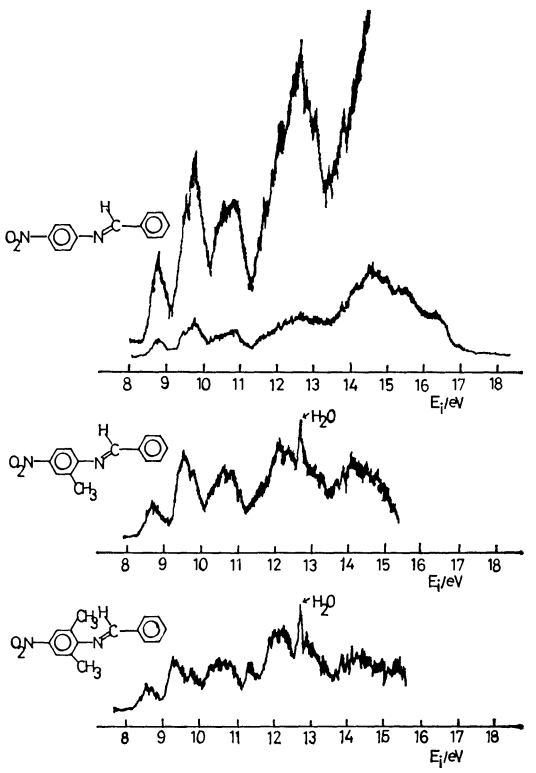

Fig. 2. Photoelectron spectra of **4**—**6**.

The above considerations have enabled us to draw the band correlation diagram as shown in Fig. 3.

Estimation of the Twist Angles, θ_N. We now wish to report an approach to estimate the twist angles θ_N in *N*-benzylideneanilines and present the evidence that the twist angle θ_N is significantly changed by the introduction of 4-nitro group on the ring A.

In the present method, one considers the first band energy difference ΔE_{1v} between **1** and **2** and that between the corresponding 4-nitro derivatives **4** and **5** as the perturbation caused by the substitution of a methyl group for 2-hydrogen on the ring A. Then, the ΔE_{1v} is calculated with changing the twist angle θ_N to find out a value which coincides with the observed ΔE_{1v} value. In the calcualtions, the ΔE_{1v} is estimated by the following equation derived on the basis of the first order perturbation treatment,[15]

$$\Delta E_{1v} = 0.0528 + 1.0110 a_J$$

$$a_J = \sum_{\xi} (3C_{J\xi}^2 + C_{J\tau}^2 + C_{J\tau'}^2)/3,$$

where ξ denotes the position of the methyl substitution and τ and τ' denote the ortho-positions to that

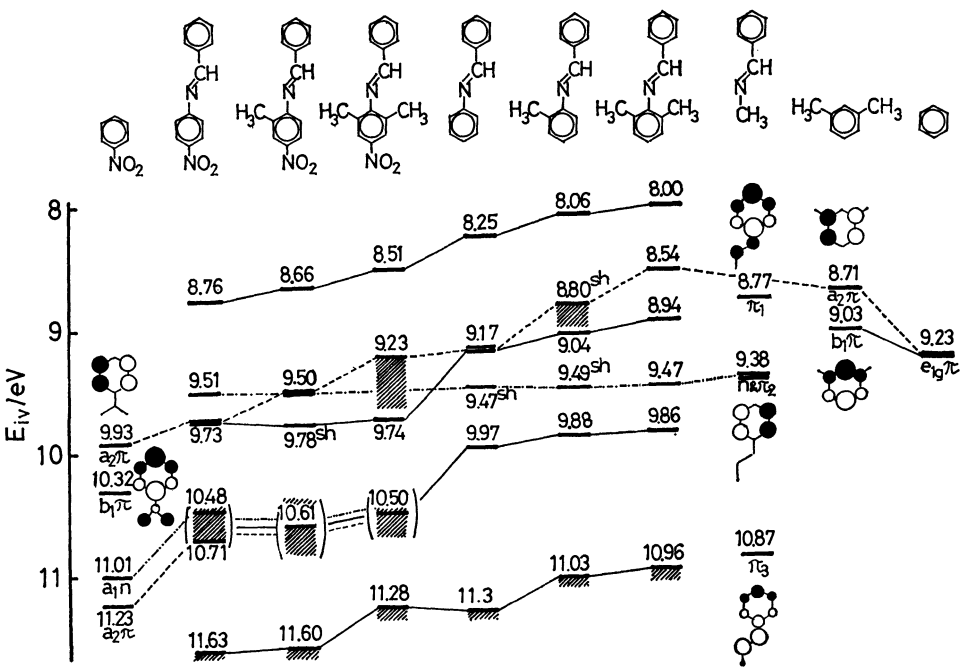

Fig. 3. The observed band correlation diagram for **1**—**6**.

of the methyl substitution. C_{JK} is the coefficient of the K-th AO in the J-th MO. C_{JK}'s were calculated for **1** and **4** by the CNDO/S[14] method at various twist angles θ_N. Then, the corresponding ΔE_{iv} values were calculated by the above equation and plotted in Fig. 4 against θ_N.

As is evident in Fig. 4, the calculated ΔE_{iv}'s become closer to the observed one in the range of smaller twist angle θ_N for **1** and of larger twist angle θ_N for **4**. Estimation of the twist angle θ_N by using the van der Waals radius of a hydrogen atom indicates that the twist angle θ_N for **1** is larger than 48°. Therefore, on taking into account of the probable error (0.02[6] eV **) accompanying the PES measurements and the calculations of ΔE_{iv}, the twist angle θ_N for **1** is estimated to be $48° \lesssim \theta_N \lesssim 55°$. The present result accords with that recently determined by the gas phase electron diffraction (ED) method, 52°.[7]

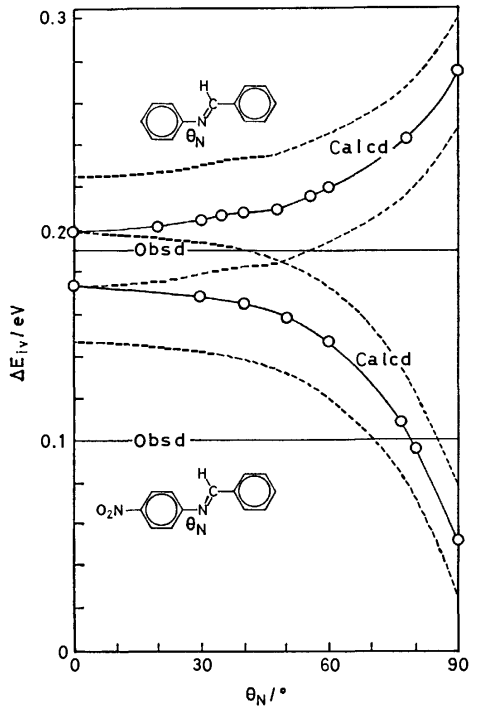

Fig. 4. Variations of the calculated ΔE_{iv} as a function of θ_N.
The broken lines indicate probable error.

Similarly, the twist angle θ_N for **4** can be estimated to be $70° \lesssim \theta_N \lesssim 85°$. These results, to our knowledge, for the first time by PES, indicate that **4** takes a more twisted conformation than **1**. The significant increase in the twist angle θ_N caused by the introduction of 4-nitro group on the ring A can be rationalized in terms of enhancement of conjugation between the N-lone pair and the aromatic π-system due to the strong electron-withdrawing property of the nitro group.

In the case of **1**, the present result on the twist angle θ_N is in qualitative agreement with that given by Bally *et al.*[5] Concerning the first band of **1**, 2-methyl substitution on the ring A shifts the band to lower energy side by 0.19 eV; however, additional 6-methyl substitution (from **2** to **3**) further causes the shift to lower energy side but by only 0.06 eV. Thus, in the series of **1**—**3**, the methyl substituent effect is not additive. The band shape of **1** in the range of 7.8—10.5 eV is very similar to that of **2**. However, it is drastically changed by the introduction of 2,6-dimethyl groups (see Fig. 1). These facts suggest that the twist angle θ_N is significantly increased by the introduction of the two methyl groups because of their steric effect. The twist angle θ_N for **3** can thus be estimated to be $\gtrsim 77°$ by taking into account of the van der Waals repulsion between the imidoyl hydrogen atom and the 2-methyl group of the ring A.

On the other hand, the introduction of 4-nitro group on the ring A increases the ionization energy by 0.51 eV and the successive methyl substitutions (in going from **4** to **5**, and to **6**) decrease the ionization energy by 0.10 and 0.15 eV in each step. In this case, the methyl substituent effect appears to be roughly additive. This fact suggests that the twist angle θ_N is not changed drastically even by the 2,6-dimethyl substitution of **4**. These results are consistent with our results by electronic absorption spectroscopy.[1]

Table 2. Comparison of the twist angle, θ_N

Compound	Method (state)					
	PES (gas)	ED (gas)	UV[a] (solution)	XD (solid)	MO	v.d.W.[b]
N-Bezylideneaniline **1**	(48)[b] −55° 36°[c]	52°[d]	30—35°	55.2°[e]	36°[f] 65°[g]	≳48°
N-Benzylidene-2-methylaniline **2**	(48)[b] −55°		40—45°			≳48°
N-Benzylidene-2,6-dimethyl-aniline **3**	≳(77°)[b]		70—80°			≳77°
N-Benzylidene-4-nitroaniline **4**	70—85°		not far from 90°	50.2°[e,h]		≳48°
N-Benzylidene-2-methyl-4-nitroaniline **5**	70—85°					≳48°
N-Benzylidene-2,6-dimethyl-4-nitroaniline **6**	≳(77°)[b]					≳77°

a) Ref. 1. b) Estimated using the van der Waals radii for a methyl group and a hydrogen atom. c) Ref. 5. d) Ref. 7. e) Ref. 16. f) The PCILO method, Ref. 8. g) The NDDO method, Ref. 9. h) Value observed for *N*-(4-methylbenzylidene)-4-nitroaniline.

** The probable error was calculated by using the data in Table 3 of Ref. 15.

In Table 2 are summarized the twist angles θ_N for **1**—**6** estimated by various methods. It seems to be of interest, that at least in solutions and in the gas phase, the electronic effect of a nitro group as well as the steric effect by bulky 2,6-dimethyl groups may result in considerable twisting of the ring A from the azomethine skeletal plane. It is worth pointing out that in this class of compounds their molecular conformations may be sensitively changed by the electronic effect of a substituent introduced in the aromatic ring on the nitrogen atom.

Experimental

Materials. *N*-benzylideneanilines **1**—**6** were prepared as described in the preceding paper,[1] and other *N*-benzylideneanilines employed were similarly prepared. The new compounds **8**, bp 142—143 °C/7 mmHg, **9**, bp 152—153 °C/2 mmHg, **10**, mp 72—73 °C, **11**, mp 101—102 °C, and **12**, mp 104—105.5 °C, gave the satisfactory results of elemental analyses.

Spectral Measurements. Photoelectron spectra were recorded on the instrument reported previously using the He I resonance line (21.22 eV) as the excitation source, and were calibrated using Xe as an internal standard.[10] The sample inlet and target chamber system was heated up to *ca.* 110—140 °C to obtain sufficient vapor pressure.

Theoretical Calculations

The CNDO/S calculations were carried out with a FACOM 230-75 computer at the Institute of Physical and Chemical Research. The geometrical structures were properly assumed on the basis of appropriate data given in Ref. 16 just as in Ref. 1.

The Preparation of 3-Phenyl[1,2,4]triazolo[4,3-*a*]pyridines and Their Benzologs from *N*-(Phenylsulfonyl)benzohydrazonoyl Chloride and Pyridines[1)]

Suketaka Ito,* Akikazu Kakehi, Toshiyuki Matsuno, and Jun-ichi Yoshida
Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano 380

(Received September 5, 1979)

3-Phenyl[1,2,4]triazolo[4,3-*a*]pyridines were obtained in good yields from *N'*-[α-(1-pyridinio)benzylidene]-benzenesulfonohydrazidates, generated from 2-unsubstituted pyridines and *N*-(phenylsulfonyl)benzohydrazonoyl chloride (**2**), by oxidation with chloranil. The reaction of quinoline and isoquinoline with **2** gave 1-phenyl-3-phenylsulfonyl-3,3a-dihydro[1,2,4]triazolo[4,3-*a*]quinoline and 3-phenyl-1-phenylsulfonyl-1,10b-dihydro[1,2,4]-triazolo[3,4-*a*]isoquinoline respectively, both in good yields; they aromatized to the corresponding triazoles by the 1,2-elimination of benzenesulfinic acid on heating.

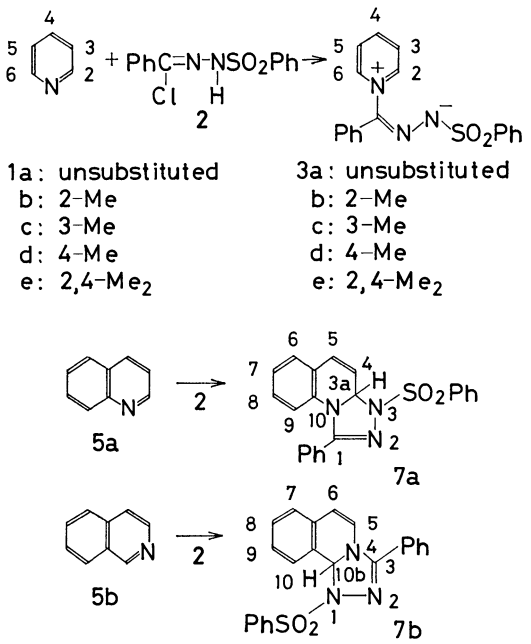
[1,2,4]Triazolo[4,3-*a*]pyridines, -quinolines, and [1,2,4]triazolo[3,4-*a*]isoquinolines[2)] are generally prepared by the ring closure of 2-hydrazinopyridines, -quinolines, or 1-hydrazinoisoquinolines with acidic-type cyclodehydration agents.[3)] A variation of this method involving the oxidative cyclization of 2-pyridylhydrazones and their homologs is also available.[4)]

In the present paper, we wish to describe an alternative route for preparing the title triazolopyridines (**4**) *via* the oxidative cyclization of *N'*-[α-(1-pyridinio)-benzylidene]benzenesulfonohydrazidates (**3**), obtained from *N*-(phenylsulfonyl)benzohydrazonoyl chloride (**2**) and pyridines (**1**), and also a simple method for obtaining [1,2,4]triazoloquinoline (**8a**) and -isoquinoline (**8b**) from quinoline (**5a**) and isoquinoline (**5b**) by the reaction with **2** *via* dihydrotriazoloquinoline (**7a**) and -isoquinoline (**7b**) respectively as the intermediates. A specific feature of **2** lies in the electrophilicity of the imidoyl carbon and the acidity of the amino proton (and hence the stability of the resulting anion), which are enhanced by the phenylsulfonyl group. The sulfonyl group serves not only as the activating group in **2**, but also as the leaving group in a cationic or an anionic mode in the elimination step, leading to the triazoles, **4** and **8**.

Results and Discussion

Reaction of Hydrazonoyl Chloride (2) with Pyridines (1), Quinoline (5a), and Isoquinoline (5b). The reaction of *N*-(2,4-dichlorophenyl)pyruvohydrazonoyl chloride with excess pyridine (**1a**) under refluxing gave *N'*-[α-(1-pyridinio)acetonylidene]-2,4-dichlorophenylhydrazidate.[5)] Analogously, *N*-(phenylsulfonyl)benzohydrazonoyl chloride (**2**) reacted with **1a** and alkyl-substituted pyridines (**1b**—**e**) at room temperature to afford the corresponding, bright-yellow colored pyridinium betaines, *N'*-[α-(1-pyridinio)benzylidene]benzenesulfonohydrazidates (**3**). However, the reaction of **2** with quinoline (**5a**) and isoquinoline (**5b**) yielded 1-phenyl-3-phenylsulfonyl-3,3a-dihydro[1,2,4]triazolo-[4,3-*a*]quinoline (**7a**) and 3-phenyl-1-phenylsulfonyl-1,10b-dihydro[1,2,4]triazolo[3,4-*a*]isoquinoline (**7b**) respectively, both in good yields (Scheme 1, Table 1).

In the reaction of **1** with **2**, the use of a solvent such as dichloromethane and THF resulted in the formation of 3,6-diphenyl-1,4-bis(phenylsulfonyl)-1,4-dihydro-1,2,4,5-tetrazine as a by-product; such a by-product may be formed *via* the mutual nucleophilic process



Scheme 1.

of **3** generated: compounds **3a**—**e** changed into the dihydrotetrazine when dissolved in such solvents.

The IR and NMR spectral data for these compounds are summarized in Table 2. The sulfonyl absorptions near 1275 and near 1135 cm^{-1} in the IR spectra were diagnostic for the characterization of **3a**—**e** and were consistent with those observed at lower frequencies (1270—1285 and 1130—1140 cm^{-1}) with *N*-(1-pyridinio)benzenesulfonamidates.[6,7)] Furthermore, a gross similarity can be seen in the NMR patterns of the pyridine ring between **3a**—**e** and the *N*-(1-pyridinio)-benzenesulfonamidates. The normal sulfonyl-absorption frequencies and the chemical shifts at δ 5.90—6.61 ppm with compounds **7a**, **b** support the cyclized structures.

The mass spectra of **3** (ionizing energy: 75 eV) did not exhibit the M^+ ions: the main fragment ions with the betaine **3a**, for example, are *m/e* 250 (15%), 141 (10%, $PhSO_2^+$), 125 (21%, $PhSO^+$), 105 (23%, $PhC{\equiv}O^+$), 79 (100%, $C_5H_5N^{+\cdot}$), 77 (35%, Ph^+), 52 (60%, $[C_5H_5N\text{–}HCN]^{+\cdot}$), and 51 (34%, $[Ph\text{–}C_2H_2]^+$). The signal at *m/e* 250 is compatible with the $[PhSO_2\text{-}SPh]^{+\cdot}$ ion, probably arising from thermal processes.[8)] The occurrence of the $PhC{\equiv}O^+$ ion can be explained as is illustrated below:

Table 1. Pyridinium betaines, dihydrotriazoloquinoline, and -isoquinoline

Compound	Yield/%[a)]	Mp/°C	Formula	Calcd (%)			Found (%)

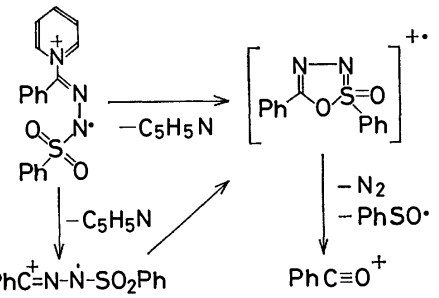
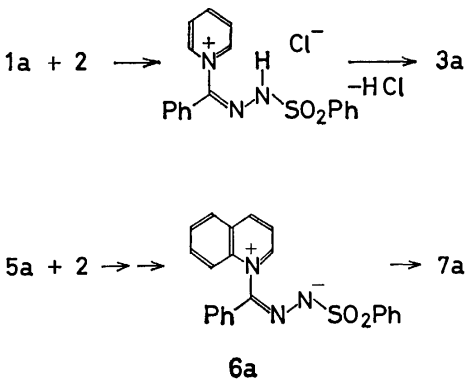
3c	1274 1135	2.33 (s, 3H; 3-Me), 7.03—8.00 (m, 12H; 2 Ph, 4,5-H), 8.43 (br s, 2 H; 2,6-H)
3d	1273 1132	2.35 (s, 3H; 4-Me), 7.02—7.99 (m, 12H; 2 Ph, 3,5-H), 8.47 (dd, 2H; J=5 Hz, J=2 Hz; 2,6-H)
3e	1276 1134	2.26 (s, 3H; 4-Me), 2.45 (s, 3H; 2-Me), 6.80—8.07 (m, 12H; 2 Ph, 3,5-H), 8.33 (d, 1H; J=5 Hz; 6-H)
7a	1364 1176	6.07 (s, 1H; 3a-H), 6.12 (d, 1H; J=8.8 Hz; 4-H), 6.61 (d, 1H; J=8.8 Hz; 5-H), 6.76—8.17 (m, 14 H; 2 Ph, 6,7,8,9-H)
7b	1359 1170	5.90 (d, 1H; J=7.5 Hz; 5-H), 6.29 (d, 1H; J=7.5 Hz; 6-H), 6.42 (s, 1H; 10b-H), 6.93—8.17 (m, 14H; 2 Ph, 7,8,9,10-H)





Scheme 2.

As has previously been reported,[9] **2** does not afford *N*-(phenylsulfonyl)benzonitrilimine, a 1,3-dipole, on treatment with triethylamine, but is subjected to nucleophilic attack on the imidoyl carbon by the hydrazonoyl chloride *N*-anion generated from another molecule of **2** *via* deprotonation, which results in the formation of 3,6-diphenyl-1,4-bis(phenylsulfonyl)-1,4-dihydro-1,2,4,5-tetrazine. Thus, the formation of **3** and **7** probably proceeds *via* the step-by-step mechanism given in Scheme 2. Compound **7a** (and **7b**) should be formed by the 1,5-dipolar cyclization of the betaine intermediate.

The behavior in quinoline and isoquinoline systems different from that in the pyridine series can be explained in terms of the mesomeric effect of the fused benzene ring; that is, the electron deficiency attributable to this effect at the α-carbon (2-C of quinoline, and 1-C of isoquinoline skeleton) in the betaine structure (**6a**, **b**) and that at the amino nitrogen (10-N in **7a** and 4-N in **7b**) may contribute to the ready cyclization of **6a**, **b** and the stabilization of **7a**, **b** respectively. On the other hand, the corresponding pyridine derivatives are lacking in such an effect, and so the aromatic stabilization of the pyridine ring is lost when **3** cyclize to dihydrotriazolopyridines. Consequently, the products from **1** prefer the betaine structure.

*Oxidation of Pyridinium Betaines (**3**) and Dihydrotriazoles (**7**) with Chloranil.* When the betaine **3a** was treated with chloranil (2,3,5,6-tetrachloro-*p*-benzoquinone) in benzene or dioxane at room temperature, 3-phenyl[1,2,4]triazolo[4,3-*a*]pyridine (**4a**) was obtained in a comparable yield, together with a small amount of 3,6-diphenyl-1,4-bis(phenylsulfonyl)-1,4-dihydro-1,2,4,5-tetrazine. 2,3-Dichloro-5,6-dicyano-

a) Oxidizing agent and solvent: chloranil-benzene. The progress of reaction was checked by means of TLC. b) Isolated yield. c) **4c** and **4c**′ were obtained as a mixture; the ratio was determined by means of NMR. d) Recrystallization gave no uncontaminated **4c** or **4c**′, and further purification was not attempted. Mp of the mixture: 156—160 °C (**4c**: lit,[3a] mp 187—188 °C; **4c**′: lit,[3a] mp 115 °C). e) Mp 128—130 °C (lit,[3a] mp 127—128 °C). f) Mp 114—115 °C (lit,[4b] mp 89 °C; lit,[4e] mp 136—137 °C). g) Mp 186—188 °C (lit,[4d] mp 186—187 °C; lit,[4e] 182 °C).

p-benzoquinone (DDQ) or mercury(II) oxide (yellow) also gave **4a** in a diminished yield. The results are summarized in Table 3. 2,3-Dichloro-5,6-dicyano-4-hydroxyphenyl benzenesulfonate generated from DDQ could be isolated. In the case of chloranil, 2,3,5,6-tetrachloro-1,4-phenylene bis(benzenesulfonate) and 2,3,5,6-tetrachlorohydroquinone, disproportionated products of the 2,3,5,6-tetrachloro-4-hydroxyphenyl benzenesulfonate which should be primarily formed, were obtained.

On the same treatment (chloranil–benzene), the betaines **3c**, **d** and the dihydrotriazoles **7a**, **b** afforded the corresponding triazolo compounds, **4c**, **4d**, **8a**, and **8b**, and also **4c**′ which was detected by means of NMR as a minor component in the production of **4c** (Table 4). However, the betaines **4b**, **e** yielded no triazolopyridines; this may be the result of spatial interference between the *C*-phenyl and the α-methyl group of the pyridine ring. UV and NMR spectroscopic studies[10] have revealed the steric interaction between 3-phenyl and 5-methyl group in the 3-phenyl-[1,2,4]triazolo[4,3-*a*]pyridine systems and have led to the conclusion that the 3-phenyl group is coplanar with the bicyclic nucleus in the 5-unsubstituted derivatives, but with a 5-methyl substituent the steric requirement can only be satisfied by the phenyl group adopting a conformation skew to the nucleus. Thus, in the betaines **3b**, **e**, the coplanarity of the *C*-phenyl group with the hydrazidate moiety, if conserved, should prevent the formation of **4b**, **e**.

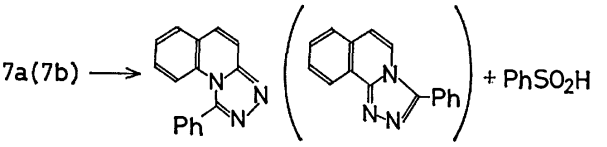
*Aromatization of Dihydrotriazoloquinoline (**7a**) and -isoquinoline (**7b**) by the Thermally Induced Elimination of Benzenesulfinic Acid.* The dihydrotriazolo compounds **7a**, **b** gave aromatized compounds, **8a**, **b** respectively, in good yields, along with *S*-phenyl benzenethiosulfonate (**9**), when refluxed in dioxane or carbon tetrachloride. Compound **9** is probably generated from benzenesulfinic acid[11] (Scheme 4).



8a 8b

Scheme 4.

A direct method in which **2** was treated with **5** in a boiling solvent also gave **8** in a diminished yield. Table 5 summarizes these results. The good leaving ability of the arenesulfinato group has been revealed in aromatization reactions[12] and other reactions, such as a cyclization reaction,[13] and it is probably the driving force for the present reaction.

Experimental

The melting points were determined with a Yanagimoto micromelting point apparatus, Model MP-S3, and are

uncorrected. The microanalysis was performed on a Perkin-Elmer elemental analyzer, Model, 240. The IR, NMR, and mass spectra were recorded with a Hitachi 260, a Varian EM-360A, and a JEOL JMS-013G-2 spectrometer respectively. *N*-(Phenylsulfonyl)benzohydrazonoyl chloride (**2**) was prepared by the method previously reported.[13a]

Preparation of **3**. *General Procedure*: A ground 2.95-g (10 mmol) portion of **2** was dissolved in pyridine (15 ml) at room temperature with stirring. A few minutes after dissolution, the product was separated by adding water, collected by filtration, and then washed with water, followed by small amounts of dilute ethanol. Further purification was achieved by repeated washings with ethanol. The results are summarized in Table 1.

Reaction of **5** *with* **2**. A solution of **5a** (1.42 g, 11 mmol) in dichloromethane (3 ml) was added, drop by drop, to a solution of **2** (1.47 g, 5 mmol) in dichloromethane (5 ml) at room temperature. The reaction mixture was allowed to stand for 10 min. After the subsequent removal of the solvent *in vacuo*, a small portion of water was added to the oily residue. Crystallization was induced by scratching the flask, and the resulting precipitates were filtered. 1-Phenyl-3-phenylsulfonyl-3,3a-dihydro[1,2,4]triazolo[4,3-*a*]-quinoline (**7a**; 1.87 g; 92%) was obtained in a fairly pure state by washing the precipitates with water and then with small amounts of cold ethanol. A further purified specimen could be prepared by repeated washings with ethanol. 3-Phenyl-1-phenylsulfonyl-1,10b-dihydro[1,2,4]triazolo[3,4-*a*]-isoquinoline (**7b**; 1.84 g; 95%) was also obtained from **5b** and **2** in a similar manner. For the preparation of **7**, the procedure for **3** described above can also be used, but the present method may be more convenient. Table 1 shows the results obtained by the former procedure.

Oxdation of **3** *and* **7**. *(A) With Chloranil or DDQ. General Procedure*: A mixture of 2 mmol of **3** (or **7**) and 2 mmol of chloranil (or DDQ) in a 15-ml portion of a solvent (benzene or dioxane) was stirred at room temperature for the period given in Tables 3 and 4. After the removal of the solvent *in vacuo*, the residue was chromatographed on a silica-gel column (100—200 mesh, 2.0×15 cm). Elution with benzene gave traces of 3,6-diphenyl-1,2,4,5-tetrazine and 3,6-diphenyl-1,4-bis(phenylsulfonyl)-1,4-dihydro-1,2,4,5-tetrazine (mp 151—156 °C(dec), 6—30%).[14] Elution with benzene–ether (19:1, and then 9:1, v/v) gave 2,3,5,6-tetrasubstituted 4-hydroxyphenyl benzenesulfonate (from DDQ) or its disproportionated products (from chloranil),[15] 1,4-phenylene bis(benzenesulfonate), and free hydroquinone (total yield in one run: 13—65%).

2,3-Dichloro-5,6-dicyano-4-hydroxyphenyl Benzenesulfonate. Mp 202—204 °C, IR (KBr, cm^{-1}): 1384, 1186 (νSO_2). Found: C, 45.38; H, 1.65; N, 7.17%. Calcd for $C_{14}H_6Cl_2N_2O_4S$: C, 45.55; H, 1.64; N, 7.59%.

2,3,5,6-Tetrachloro-1,4-phenylene Bis(benzenesulfonate). Mp 237—238 °C, IR (KBr, cm^{-1}): 1385, 1191 (νSO_2). Found: C, 40.88; H, 1.73%. Calcd for $C_{18}H_{10}Cl_4O_6S_2$: C, 40.93; H, 1.91%.

2,3,5,6-Tetrachlorohydroquinone. Mp 228—230 °C (lit,[16] mp 230—231 °C). Found: C, 28.96; H, 0.71%.

Elution with benzene–ethanol (19:1, v/v) gave the corresponding triazolo compound, which was then purified by crystallization from benzene or carbon tetrachloride. The results are summarized in Tables 3 and 4. Each triazolo compound gave satisfactory C, H, and N analyses (±0.4%), and all were found to be spectroscopically identical with authentic specimens.

(B) With Mercury(II) Oxide (Yellow). A mixture of **3a** (1.685 g, 5 mmol), HgO (1.62 g, 7.5 mmol), K_2CO_3 (2 g, 15 mmol), $CaSO_4$ (2 g, 15 mmol), and dioxane (50 ml) was stirred for 6 h at room temperature. The reaction mixture was then filtered and washed with dioxane. The filtrate combined with washings was concentrated and then chromatographed to give **4a** (51 mg, 5%). Table 1 shows the results.

Thermolysis of **7**. A 775-mg (2 mmol) portion of **7a** (or **7b**) was refluxed in a 30-ml portion of a solvent (CCl_4 or dioxane) for a period required. After the removal of the solvent, the reaction mixture was chromatographed (silica gel, benzene–ethanol), giving the corresponding triazoloquinoline, **8a** (or -isoquinoline, **8b**), along with *S*-phenyl benzenethiosulfonate, **9** (mp 42—43 °C, lit,[17] mp 45 °C, yield: 20—25%) (Table 5: Method A).

One-flask Preparation of **8** *from* **2** *and* **5**. A mixture of **2** (590 mg, 2 mmol) and **5a** or **5b** (775 mg, 6 mmol) in a solvent (30 ml) was refluxed. The reaction mixture was extracted with chloroform and washed with dilute hydrochloric acid, followed by water. The subsequent chromatographic treatment of the chloroform extract gave **8a** or **8b** (Table 5: Method B).

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education (Grant No. 355369).

The Asymmetric Homogeneous Hydrogenation of Olefins with the Rhodium Complexes of (1*S*,2*S*)-1,2-Bis(diphenylphosphinamino)cyclohexane and (2*S*,3*S*)-2,3-Bis(diphenylphosphinamino)butane

Ken-ichi Onuma,* Tomiyasu Ito, and Asao Nakamura

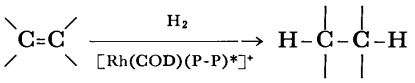
(Received September 22, 1979)

The effect of triethylamine on asymmetric hydrogenation has been studied using the cationic rhodium complex of (1*S*,2*S*)-1,2-bis(diphenylphosphinamino)cyclohexane or (2*S*,3*S*)-2,3-bis(diphenylphosphinamino)butane as a catalyst. By the addition of triethylamine, higher optical yields are achieved in the hydrogenation of (*Z*)-α-acetamidocinnamic acid and itaconic acid and higher conversion rates are obtained in the hydrogenation of (*E*)-2-methylcinnamic acid, mesaconic acid, and citraconic acid. The specific effect of triethylamine on the substrates with a carboxyl group may be explained by the ionization of the carboxyl group, which coordinates the catalytic rhodium complex firmly.

In recent years, the asymmetric hydrogenation of olefins has been successfully carried out with chiral phosphine–rhodium complexes.[1] It has been often observed that the addition of triethylamine improves the reactivity or the stereoselectivity of the asymmetric hydrogenation of olefins,[2] for which several explanations have been attempted. We would like to describe here the effect of triethylamine on the asymmetric hydrogenation of olefins with the rhodium complexes of (1*S*,2*S*)-1,2-bis(diphenylphosphinamino)cyclohexane, [(*S*,*S*)-I][3] and (2*S*,3*S*)-2,3-bis(diphenylphosphinamino)-butane, [(*S*,*S*)-II].[3b] The six olefins listed in Table 1 are adopted as the substrates. As the substrates have different substituents on the olefinic group, the effects of triethylamine on the hydrogenation of these compounds have been interpreted in terms of the structures of the substituents.

Results and Discussion

Either (*S*,*S*)-I or (*S*,*S*)-II was used as a chiral bisphosphine ligand in the catalytic precursor, [Rh(1,5-cyclooctadiene)(bisphosphine)]$^+ClO_4^-$.[4] The six olefins were hydrogenated with each of the rhodium complexes as shown below (Scheme 1). The product



Scheme 1.

was then isolated carefully, and the optical purity was determined. The results are shown in Table 1, together with some results obtained from a neutral *in situ* catalyst. As can be seen there, the cationic catalyst gave better results in both reactivity and stereoselectivity than the neutral catalyst. Therefore, the hydrogenation has been studied with the cationic catalyst.

Effect of Triethylamine. In the absence of triethylamine, (*Z*)-α-acetamidocinnamic acid (III) and itaconic acid (V) were hydrogenated quantitatively. *N*-(1-Phenyl-1-propenyl)acetamide (VIII) was hydrogenated with a conversion of 50%. The other substrates were hydrogenated with lower conversions. Therefore, as for the substituent on the ethylenic bond in the substrate, the acetamido and carboxymethyl groups are considered to play an important role in the hydrogenation. Recent studies[9] on the substrate structures show that an efficient asymmetric hydrogenation depends on the ability of the substrate to form a bidentate complex in the transition state and that the β-carbonyl group in the substituent of an olefin, –C=C–X–C(=O)– (X=NH, CH_2, O), is favorable for the chelate formation. The high conversion rate and optical yield for the hydrogenation of III and V support the importance of the presence of the β-carbonyl group.

The effect of the addition of triethylamine varies, depending on the substrate structures, as follows:

For the substrate with free carboxyl, but no β-carbonyl group of an olefin, *e.g.*, (*E*)-2-methylcinnamic acid (IV), mesaconic acid (VI), and citraconic acid (VII), the conversion rate increases upon the addition of triethylamine, to a particularly remarkable extent in VII. However, the optical yield is low in the presence of triethylamine. The optical yields could not be measured in the absence of triethylamine because of the low conversion rate. Therefore, the effect of triethylamine on the optical yield could not be examined.

For a substrate with both free carboxyl and β-carbonyl groups, *e.g.*, III and V, the hydrogenation proceeds quantitatively irrespective of the presence of triethylamine. As far as the optical yield is concerned, the addition of triethylamine seems to have some favorable effect.

For the substrate with no free carboxyl but with a β-carbonyl group, VIII, the conversion rate rather decreases and the optical yield is not affected.

As has been mentioned above, the addition of triethylamine affects the conversion or the optical yield only in the hydrogenation of a substrate with a free carboxyl group. This implies that triethylamine may interact with the carboxyl group to ionize it and that the substrate may coordinate the catalytic rhodium complex more firmly.

On the addition of triethylamine, the optical yield increases in the hydrogenation of III and V. In the hydrogenation of IV, VI, and VII, however, the optical yield is low even if triethylamine is added. In the former cases, triethylamine is considered to make a chelating substrate–rhodium complex more rigid. In

a) Hydrogenation was carried out with 1 g of a substrate and a cationic rhodium complex in benzene/ethanol (v/v=1/1). b) The triethylamine-to-substrate molar ratio was 1.15. c) Catalytic precursor. (*S*,*S*)-I complex: [Rh(COD)(*S*,*S*)-I]$^+ClO_4^-$. (*S*,*S*)-II complex: [Rh(COD)(*S*,*S*)-II]$^+ClO_4^-$. d) Molar ratio of the substrate to the complex. e) Estimated by NMR analysis. f) Calculated on the basis of the reported value for the optically pure enantiomer as follows: (*S*)-2-methyl-3-phenylpropionic acid; $[\alpha]_D^{20}=+27.02°$ ($c=11.59$, C_6H_6).[5] (*R*)-methylsuccinic acid; $[\alpha]_D^{20}=+16.88°$ ($c=2.16$, EtOH).[6] (*S*)-*N*-(1-phenylpropyl)acetamide; $[\alpha]_D^{20}=-137.8°$ ($c=2.4$, MeOH).[7] *N*-acetyl-(*S*)-phenylalanine; $[\alpha]_D^{20}=+46.0$ ($c=1.0$, EtOH).[8] The predominant configuration of the product is shown in parentheses. g) Hydrogenations were carried out with an *in situ* catalyst. h) The optical rotation was not measured.

the latter cases, the lack of steric control may be caused by the non-rigid conformation of the substrate–rhodium complex because of the absence of the β-carbonyl group. The very low optical yield in VI and VII especially may be caused by the approximately symmetrical structure of the substrates, in which the deviation from the symmetry originates only from the difference in the substituents between the hydrogen and methyl groups.

Catalyst Studies. The (*S*,*S*)-I complex was expected to give a higher optical yield than the (*S*,*S*)-II complex, as the former had a more rigid conformation, restricted by the cyclohexane ring. However, the (*S*,*S*)-I complex gave a conversion rate and/or optical yields similar to those of the (*S*,*S*)-II complex for any of the substrate, as is shown in Table 1. Therefore, it may be concluded that the two complexes have similar reactivities and stereoselectivities.

The stereoselectivity of the catalytic rhodium complexes of (*S*,*S*)-I and (*S*,*S*)-II was compared with that of the other chiral rhodium catalysts, which make a similar seven-membered chelate ring with rhodium, as is shown in Fig. 1. The optical yields and the predominant configurations of the product of the asymmetric hydrogenation of (*Z*)-α-acetamidocinnamic acid

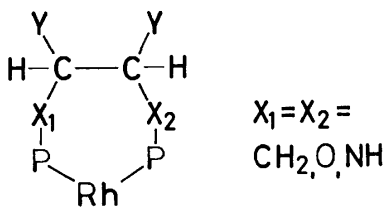

Fig. 1. The seven-membered chelate ring.

are as follows: 72% e.e. (*S*) for (*S*,*S*)-I, 70% e.e. (*R*) for (*R*,*R*)-I,[3b] 62% e.e. (*S*) for (*S*,*S*)-II, 94% e.e. (*S*) for (1*S*,2*S*)-1,2-bis(diphenylphosphinamino)-1,2-diphenylethane,[3a] 82% e.e. (*R*) for (*R*,*R*)-DIOP,[10] 68.5% e.e. (*S*) for (1*S*,2*S*)-1,2-bis(diphenylphosphinoxy)-cyclohexane,[11] 35% e.e. (*S*) for (1*S*,2*S*)-1,2-bis(diphenylphosphinomethyl)cyclohexane,[12] and 36% e.e. (*R*) for (1*R*,2*R*)-1,2-bis(diphenylphosphinomethyl)cyclohexane.[13] Thus the predominant configuration of the product may be supposed to be governed by the configuration arround the asymmetric carbons in the seven-membered ring for any of these eight complexes. That is, the complex with X_1 on the upper side and X_2 on the down side of the plane described in this paper would always give *N*-acetyl-(*S*)-phenylalanine

and the complex with X_1 on the down side and X_2 on the upper side would always give *N*-acetyl-(*R*)-phenylalanine. Therefore, the rhodium complexes with any one of the eight chiral ligands are considered to have essentially the same conformation, even if X is CH_2, NH, or O.

Experimental

General. The melting points were determined with a Yanagimoto melting-point-measuring apparatus, MP-S2. The NMR spectra were recorded on a Varian high-resolution NMR spectrometer, EM-390. The optical rotations were measured with a JASCO J-20 recording spectropolarimeter. The hydrogenations were carried out in a glass autoclave, EM-U-300, of Taiatsu Glass Industry.

Substrates and Solvents. The (*E*)-2-methylcinnamic acid (mp 80—81 °C) was obtained from Nakarai Chemicals. The itaconic acid (mp 162—164 °C dec), mesaconic acid (mp 204—205 °C), and citraconic acid (mp 98—99 °C) were obtained from Tokyo Kasei Industry. The *N*-(1-phenyl-1-propenyl)acetamide was prepared according to the procedure in the literature.[14] The α-acetamidocinnamic acid[15] was prepared by a standard Erlenmeyer procedure. The solvents for hydrogenation were purified as follows: the benzene was distilled, dried over sodium metal, degassed by means of the vacuum technique, and stored under argon; the ethanol was distilled, dried over a molecular sieve, degassed, and stored similarly.

Preparation of (S,S)-*I.* (1*S*,2*S*)-1,2-Cyclohexanediamine was prepared from D-(−)-tartaric acid according to the method of Asperger and Liu:[16] bp 79—81 °C (15 mmHg), $[\alpha]_D^{24}=+40.1°$ ($c=4.9$, C_6H_6). (1*S*,2*S*)-1,2-Cyclohexanediame (6.8 g) was dissolved in dry benzene (180 ml) and dried over NaOH pellets for several days. The benzene solution was transferred into the reaction flask, to which dry triethylamine (16.6 ml) was then added. Chlorodiphenylphosphine (26.4 g) was then added dropwise to the stirred solution at 10 °C. After the addition was complete, the resulting solution was stirred for 30 min at 20 °C. The solution was filtered and concentrated under reduced pressure. (*S*,*S*)-I was separated as crystals, which were recrystallized twice from benzene. 10.0 g. Mp 130—132 °C. $[\alpha]_D^{15}=+4.48°$ ($c=1.0$, C_6H_6). Found: C, 74.60; H, 6.68; N, 5.75; P, 12.50%. Calcd for $C_{30}H_{32}N_2P_2$: C, 74.67; H, 6.68; N, 5.81; P, 12.84%.

Preparation of (S,S)-*II.* (2*S*,3*S*)-2,3-Butanediamine was prepared according to the procedure of Dickey and his co-workers.[17] $[\alpha]_D^{29}=+29.0°$ ($c=3.23$, C_6H_6). (*S*,*S*)-II was prepared by the reaction of chlorodiphenylphosphine and (2*S*,3*S*)-2,3-butanediamine, much like (*S*,*S*)-I. Mp 83—85 °C. $[\alpha]_D^{15}=+2.98°$($c=0.5$, C_6H_6). Found: C, 73.44; H, 6.58; N, 6.09; P, 13.28%. Calcd for $C_{28}H_{30}N_2P_2$: C, 73.67; H, 6.62; N, 6.14; P, 13.57%.

Catalytic Precursors. The cationic rhodium complexes $[Rh(COD)(P\text{-}P)]^+ClO_4^-$ were prepared according to the method of Schrock and Osborn.[4] $[Rh(COD)Cl]_2$ (576 mg) and sodium perchlorate (400 mg) were placed in acetone (4 ml). (*S*,*S*)-I (1.13 g) was then slowly stirred in. Stirring was continued for 5 min, and then dichloromethane (20 ml) was added. The suspension was filtered and washed with dichloromethane. The filtrate was concentrated to *ca.* 5 ml under reduced pressure and then left at room temperature. The wine-red crystals were filtered off, washed with diethyl ether, and air-dried. The yield of the product was 1.46 g. The crystals were solvated with dichloromethane as detected by NMR (δ 5.30 ppm). $[Rh(COD)(S,S)\text{-}I]^+ClO_4^-\cdot 1/2CH_2Cl_2$; mp 142—145 °C (dec); Found: C, 55.38; H, 5.55; N, 3.21%. Calcd for $RhC_{38}H_{44}N_2P_2ClO_4\cdot 1/2CH_2Cl_2$: C, 55.34; H, 5.43; N, 3.35%. The rhodium complex of (*S*,*S*)-II was prepared by the same procedure. The crystals were also solvated with dichloromethane. $[Rh(COD)(S,S)\text{-}II]^+ClO_4^-\cdot 1/2CH_2Cl_2$; mp 143—144 °C (dec); Found: C, 54.02; H, 5.45; N, 3.38%. Calcd for $RhC_{36}H_{42}N_2P_2ClO_4\cdot 1/2CH_2Cl_2$: C, 54.15; H, 5.35; N, 3.46%. These rhodium complexes were stored in an ampoule under argon.

Hydrogenation Procedure. A substrate (1 g), one of the cationic rhodium complexes, ethanol, and benzene were placed in the glass autoclave under argon. The rhodium complex was dissolved completely. In the case of the addition of triethylamine, triethylamine was added at this stage. Hydrogen was then admitted into the autoclave. After the hydrogenation was complete, the solution was filtered and evaporated to dryness. The conversion rate of the substrate was determined by NMR at this stage. For the isolation of the hydrogenation product, either one of the following methods was applied. Method 1: For α-methylsuccinic acid in the absence of triethylamine and *N*-(1-phenylpropyl)acetamide, the product was separated from the insoluble catalyst by extraction with water and by concentration. Method 2: For other cases, the product was dissolved in 0.5 mol dm^{-3} NaOH. The resulting solution was acidified with dilute HCl and repeatedly extracted with a mixed solvent of ether and dichloromethane (v/v= 1/4). The organic layer was dried over anhydrous sodium sulfate and evaporated to dryness.

Asymmetric Hydrogenation with Chiral Aminophosphine–Rhodium Complexes[1] and Chiral Recognition by Bisphosphine–Rhodium Complexes in the Asymmetric Hydrogenation of Olefins through the Chiral Helical Conformation of Phenyl Groups on the Phosphorus Atom

Ken-ichi Onuma,* Tomiyasu Ito, and Asao Nakamura
Central Research Laboratories, Ajinomoto Co., Inc., 1-1 Suzuki-cho, Kawasaki 210
(Received September 22, 1979)

The asymmetric hydrogenation of α-acylaminocinnamic acids with the rhodium complex of (1*R*,2*R*)-1,2-bis(*N*-diphenylphosphino-*N*-methylamino)cyclohexane has been reported to give preferentially (*S*)-amino acids. On the contrary, it has been found that the enantiomeric (*R*)-amino acids are obtained by hydrogenation with the rhodium complex of (1*R*,2*R*)-1,2-bis(diphenylphosphinamino)cyclohexane. The study of the inversion of the stereoselectivity of the rhodium complex of (1*R*,2*R*)-1,2-bis(diphenylphosphinamino)cyclohexane by the *N*-methylation of the ligand in asymmetric hydrogenation has been described. From stereochemical considerations, the chiral helical conformation of the phenyl groups attached on the phosphorus in bisphosphine–rhodium complexes may be responsible for the induced chirality of the product of the hydrogenation. A complex with a left-handed helicity would give (*R*)-amino acid, and a complex with a right-handed helicity would give (*S*)-amino acid. The effects of the solvents and substrate structures on the optical yields are also discussed.

In recent years, the catalytic asymmetric hydrogenation of α-acylaminocinnamic acid has been investigated in order to obtain chiral α-amino acid. Considerable efforts have been devoted not only to developing new chiral ligands,[2] but also to studying the mechanism of asymmetric hydrogenations.[3] Only a few papers have been reported,[2a] however, about the correlation of the ligand structure to the chirality of the products.

The stereochemistry of the produced acylamino acids is reversed by the *N*-methylation of the ligand in the hydrogenation with the rhodium complex of the bis-aminophosphine, which has a 1,2-bis(diphenylphosphinamino)ethane skeleton.[4] For example, (1*R*,2*R*)-1,2-bis(diphenylphosphinamino)cyclohexane, (*R*,*R*)-I, has been found to be an effective ligand for the rhodium-catalyzed asymmetric hydrogenation of α-acylaminocinnamic acids to give preferentially (*R*)-amino acids. On the contrary, its *N*,*N*′-dimethyl derivative, (1*R*,2*R*)-1,2-bis(*N*-diphenylphosphino-*N*-methylamino)cyclohexane, (*R*,*R*)-II, has been reported to give preferentially (*S*)-amino acids under similar reaction conditions. In view of the subtlety of the structural divergence between these two ligands, the origin of this marked difference in stereoselectivity should be further explored. The stereochemical consideration suggests that the chiral inversion may be caused by the difference in the configuration of the nitrogen atom, by which the four phenyl groups are caused to be arranged in a reverse helical orientation in each (*R*,*R*)-I and (*R*,*R*)-II complex.

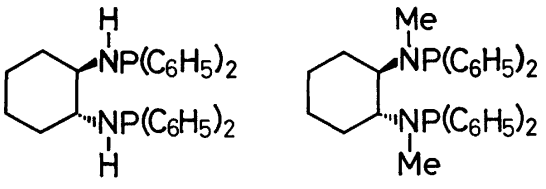

Fig. 1. Chiral aminophosphines, (*R*,*R*)-I (left) and (*R*,*R*)-II (right).

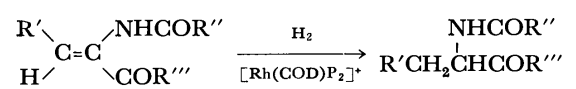
Results and Discussion

The α-acylaminocinnamic acids were hydrogenated with the cationic rhodium complexes of (*R*,*R*)-I, (*S*,*S*)-I, and (2*S*,3*S*)-2,3-bis(diphenylphosphinamino)butane, [(*S*,*S*)-III]. The results are summarized in Table 1.



Scheme 1.

Stereochemical Studies. As can be seen in Table 1, acylamino acids with an *R*-configuration were always obtained preferentially by the hydrogenation using the rhodium complex of (*R*,*R*)-I. On the other hand, the products with an *S*-configuration were preferentially obtained using either (*S*,*S*)-I or (*S*,*S*)-III as the chiral ligand. The most noticeable result is that *N*-acyl-(*S*)-amino acids were always obtained by using the (*R*,*R*)-II complex, contrary to the result obtained with the (*R*,*R*)-I complex. Moreover, it has previously been reported that the chiral inversion of the stereoselectivity by the *N*-methylation of the ligand is also observed in the rhodium complexes of (1*S*,2*S*)-1,2-bis(diphenylphosphinamino)-1,2-diphenylethane[4b] and (*R*)-1,2-bis(diphenylphosphinamino)propane.[4c] Therefore, the inversion may be an essential feature of these aminophosphine–rhodium complexes. The chiral inversion may be deduced as having the same origin, as the complex of (*S*,*S*)-I or (*S*,*S*)-III gives similar results in the hydrogenation, as has been described in the preceding paper.[1] In order to clarify the origin of the chiral inversion, the stereochemistry of these complexes has been considered.

As is shown in Fig. 2, the seven-membered chelate ring, consisting of the rhodium atom and two phosphorus atoms, may be considered to take predominantly a twist-chair conformation,[6] for the repulsion between the phenyl groups and the cyclohexane ring is reduced. By deduction by analogy, with the preferred conforma-

a) Hydrogenation was carried out with 1 g of a substrate and 7 mg of a cationic rhodium complex. b) The ratio of the mixed solvent was 1:1 (v/v). c) Calculated on the basis of the following reported values for optically pure enantiomers: *N*-acetyl-(*S*)-phenylalanine $[\alpha]_D^{26}=+46.0°$ ($c=1.0$, C_2H_5OH),[5] *N*-benzoyl-(*S*)-phenylalanine $[\alpha]_D^{26}=-40.3°$ ($c=1.0$, CH_3OH).[5] The predominant configuration of the product is shown in parentheses. d) Quoted from Refs. 4b, c.

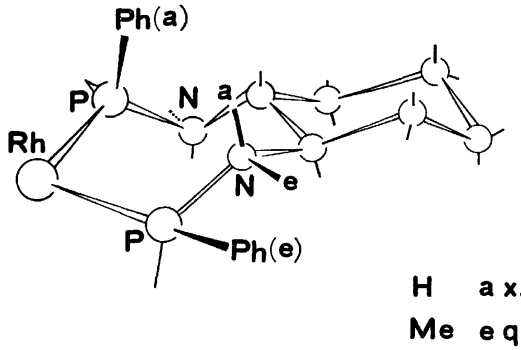

Fig. 2. The conformation of seven-membered chelate ring. The letters of a and ax. mean a *quasi*-axial position. The letters of e and eq. mean a *quasi*-equatorial position.

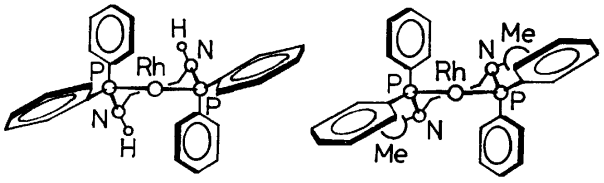

Fig. 3. Chiral skew conformation of four phenyl groups in the rhodium complex of (*R*,*R*)-I and (*R*,*R*)-II. The skeleton of the cycleohexane ring is omitted for simplicity.
Left: (*R*,*R*)-I complex, left-handed helicity; Right: (*R*,*R*)-II complex, right-handed helicity.

tion of piperazine derivatives,[7] the hydrogen atom on the nitrogen atoms in the (*R*,*R*)-I complex may occupy a *quasi*-axial position and so be $(R)_N$, and the methyl group in the (*R*,*R*)-II may occupy a *quasi*-equatorial position and so be $(S)_N$, in the twist-chair conformation. This inversion of the configuration around the nitrogen atoms, despite having the same configuration of $(R)_C$, may exert significant effects on the orientation of the *quasi*-equatorial phenyl groups. Affected by the substituent (H or CH_3) on the nitrogen atoms, the rotation of the *quasi*-equatorial phenyl groups in (*R*,*R*)-I complex and (*R*,*R*)-II complex may be restricted in a reverse direction, and the correlated rotation of the *quasi*-axial phenyl groups may give reverse helical conformations, as is shown in Fig. 3. That is, the four phenyl groups may be twisted in a left-handed orientation in the (*R*,*R*)-I complex and in a right-handed orientation in the (*R*,*R*)-II complex. These preferred conformations can also be satisfactorily understood in terms of the CPK molecular models.

The inversion of stereoselectivity in the asymmetric hydrogenation may be caused mainly by the difference in the helical conformation; the complex with left-handed helicity would give (*R*)-amino acids, while the complex with right-handed helicity would give (*S*)-amino acids. The hypothesis concerning the structural correlation between the helical conformation of phenyl groups and the chirality of the products may also be adopted in treating other results previously reported.[2a,b] The structure of the rhodium complex of (2*S*,3*S*)-2,3-bis(diphenylphosphino)butane has been determined by X-ray analysis.[8] This complex has the left-handed helicity and has been reported surely to give (*R*)-amino acids.[2b] The phenyl groups are skewed in a right-handed orientation in the rhodium complex of (*R*,*R*)-1,2-bis(*P*-phenyl-*o*-methoxyphenylphosphino)ethane,[2a] which has been reported certainly to give (*S*)-amino acids.

Solvent Effect. As is shown in Table 1, the optical yield of the products is dependent on the solvent used in the reaction. For the reaction carried out in an alcohol, such as methanol, ethanol, or 2-propanol, as well as in a mixed solvent of alcohol and benzene, the optical yield generally increases in this order: methanol<ethanol<2-propanol, and is higher in the mixed solvent than in alcohol, with the exception of the hydrogenation in the mixed solvent of 2-propanol and benzene with the (*S*,*S*)-I complex. The solvent may be supposed to play an important role in making a specific conformation of the catalyst more predominant. Thus, a solvent may be considered to contribute to fixing the specific conformation of the transition

state in a degree dependent upon its ability of coordination and its bulkiness.

Substrate Studies. Further studies were carried out on the hydrogenation of α-acylaminocinnamic acid derivatives with the rhodium complexes of (*S,S*)-I and (*S,S*)-III. The results are shown in Table 2.

As can be seen in Table 2, the optical yield depends greatly on the substrate structures. For the effects of substituents of α-acylaminocinnamic acid on the optical yield of the reaction, a tendency to obtain a higher optical yield is generally observed: 1) As for the phenyl group, the unsubstituted one is more advantageous than one with a substituent, such as a hydroxyl, alkoxyl, or acetoxyl group. 2) As for the carboxylic acid moiety, the carbamoyl derivative is more favorable compared with the parent carboxylic acid. Any substituent on the phenyl groups may prevent the substrate from approaching the catalytic rhodium complex. The hydrogenation of α-acetamidocinnamic acid and its amide with the (−)-DIOP–rhodium complex has been reported to give the corresponding product, with 82%e.e. and 71%e.e. respectively.[12] Therefore, the advantage of the carbamoyl group over the carboxyl group may be characteristic of this system.

Experimental

General. The measurements of the melting points, the ^{1}H-NMR, the optical rotations, and the apparatus used for hydrogenation were the same as those described in the preceding paper.[1] The liquid chromatograms were recorded on a Hitachi KLA-5 amino-acid analyzer.

Substrates and Solvents. The α-acetamidocinnamic acid,[13] α-benzamidocinnamic acid,[14] α-acetamido-3,4-dimethoxycinnamic acid,[15] α-acetamido-3,4-methylenedioxycinnamic acid,[13] α-benzamido-3,4-methylenedioxycinnamic acid,[16] α-acetamido-4-hydroxycinnamic acid,[17] α-acetamido-4-acetoxycinnamic acid,[18] and α-acetamido-4-acetoxy-3-methoxycinnamic acid[19] were prepared by standard Erlenmeyer procedures, sometimes with minor modifications of the published directions. The α-benzamidocinnamamide was prepared as follows: 2-phenyl-4-benzylidene-5-oxazolone (15.3 g) was allowed to react with liquid ammonia (20 ml) in a sealed tube at room temperature for one night. The ammonia was then removed by breaking the seal, and the residual crystals were recrystallized from methanol; 10.9 g; mp 165—166 °C, Found: C, 71.99; H, 5.34; N, 10.57%. Calcd for $C_{16}H_{14}N_2O_2$: C, 72.16; H, 5.30; N, 10.52%. The α-acetamidocinnamamide was prepared by a similar procedure; mp 197—198 °C. Found: C, 64.51; H, 5.92; N, 13.59%. Calcd for $C_{11}H_{12}O_2N_2$: C, 64.99; H, 5.92; N, 13.72%.

The solvents for hydrogenation were purified as has been described in the preceding paper.

Preparation of (R,R)-I and Its Rhodium Complex. (1*R*,2*R*)-1,2-Cyclohexanediamine was prepared according to the method of Asperger and Liu;[20] bp 76—78 °C (13 mmHg), $[\alpha]_D^{24}=-41.6°$ ($c=4.9$, C_6H_6). (*R,R*)-I and its cationic rhodium complex were prepared much like (*S,S*)-I, described in the preceding paper; mp 130—132 °C, $[\alpha]_D^{15}=-4.51°$ ($c=1.0$, C_6H_6). Found: C, 74.47; H, 6.65; N, 5.79; P, 12.81%. Calcd for $C_{30}H_{32}N_2P_2$: C, 74,67; H, 6.68; N, 5.81; P, 12.84%. [Rh(COD)(*R,R*)-I]$^+$$ClO_4^-$·1/2$CH_2Cl_2$; mp 142—145 °C (dec), Found: C, 55.87; H, 5.90; N, 3.30%. Calcd for $RhC_{38}H_{44}N_2P_2ClO_4$·1/2$CH_2Cl_2$:

C, 55.34; H, 5.43; N, 3.53%. The rhodium complex was stored in an ampoule under argon.

Hydrogenation Procedure. Hydrogenation was carried out by the method described in the preceding paper. Three methods for the isolation of the hydrogenation product were used, depending on the substrate, as follows: Method 1. For *N*-acetyltyrosine, *O*,*N*-diacetyltyrosine, and *N*-acetyl-*β*-(4-acetoxy-3-methoxylphenyl)alanine, the hydrogenation product was separated from the insoluble catalyst by extraction with water followed by concentration. Method 2. For *N*-acetylphenylalaninamide and *N*-benzoylphenylalaninamide, the product was hydrolyzed with concd hydrochloric acid by refluxing for 1 h. The solution was then filtered, and the filtrate was evaporated to dryness. The optical purity of the phenylalanine thus obtained was determined by means of a liquid chromatogram according to the Manning and Moore method.[21] Method 3. For the other compounds, the product was extracted with 0.5 mol dm^{-3} NaOH. The filtrate was acidified with dilute HCl and then repeatedly extracted with the mixed solvent of ether (5 ml) and dichloromethane (20 ml). The organic layer was dried over sodium sulfate and then evaporated to dryness.

A New Bromophenol from the Red Alga *Polysiphonia urceolata*[1)]

Kazuya KURATA* and Takashi AMIYA†

Department of Industrial Chemistry, Hakodate Technical College, Tokura-cho, Hakodate 042

†*Hokkaido Institute of Pharmaceutical Sciences, Katsuraoka-cho, Otaru 047-02*

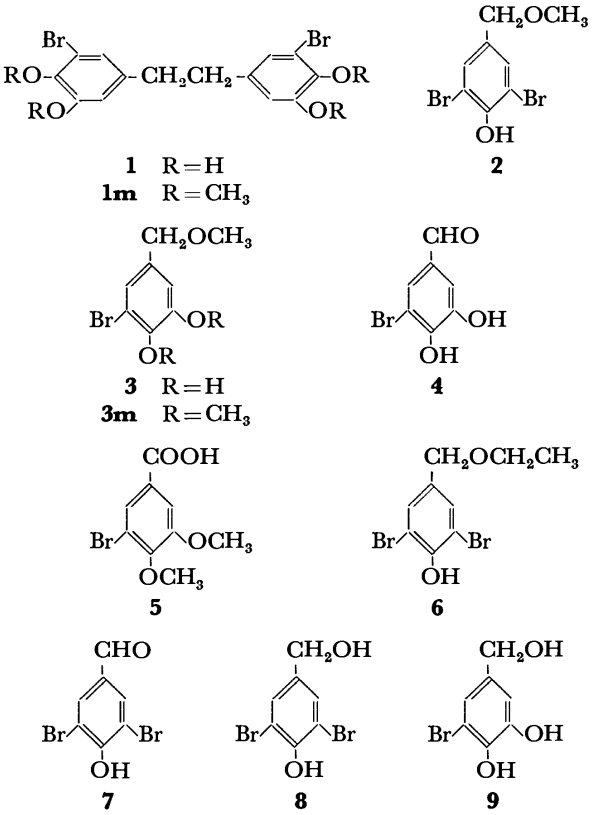
(Received November 2, 1979)

The investigation of the red alga *Polysiphonia urceolata* afforded a new bromophenol, 3,3′-dibromo-4,4′,5,5′-tetrahydroxybibenzyl. The structure was elucidated by a combination of spectroscopic methods and chemical transformations. Besides this compound, seven known bromophenols were isolated.

Many bromophenols have been previously obtained from the red marine algae, Rhodomelaceae,[1-18)] with the *Polysiphonia*, *Rhodomela*, *Odonthalia*, and *Symphyocladia* species being especially rich in bromine-containing compounds. Bromophenols of *Polysiphonia* species have been extensively investigated.[1,3,4,8,9,15,17)] In the course of the investigation of the constituents of the red marine algae, we obtained a new bromophenol, 3,3′-dibromo-4,4′5,5′-tetrahydroxybibenzyl (**1**), together with seven known bromophenols, from *Polysiphonia urceolata*. In this paper the isolation and structural elucidation of these compounds will be described.

An acidic fraction obtained from the dried alga collected at Matsumae Bay by extraction with methanol was chromatographed on silica gel. A benzene eluate gave 3,5-dibromo-4-hydroxybenzyl methyl ether (**2**)[8)] and 3-bromo-4,5-dihydroxybenzyl methyl ether (**3**).[8,9,16)] Their structures were deduced from the chemical and spectral properties, and confirmed by direct comparison with an authentic sample and by conversion to the dimethyl derivative (**3m**) respectively. Compounds **2** and **3** could be artifacts derived by the methylation of the corresponding alcohols or bromophenol precursors during the extraction procedure.[11)] A benzene–ether (19:1) eluate gave 3-bromo-4,5-dihydroxybenzaldehyde (**4**)[3,9)] as the main constituent and 3,3′-dibromo-4,4′,5,5′-tetrahydroxybibenzyl (**1**) as the minor constituent. Compound **1** was a colorless crystalline substance (mp 205—206 °C); elemental analysis established it to be $C_{14}H_{12}O_4Br_2$. It developed an intense green color with iron(III) chloride and precipitated easily on the addition of lead acetate. The mass spectrum showed the presence of 406, 404, and 402 (M^+). The UV spectrum in EtOH exhibited a maximum at 287 nm. The IR spectrum showed bands due to OH groups at 3550, 3470, and 3250 cm^{-1}, and benzene rings at 1595, 1520, and 845 cm^{-1}. The ^{1}H-NMR spectrum showed a signal of methylene protons at δ 2.58 (4H, s), signals of two aromatic protons at δ 6.54 (2H, d, J=2 Hz) and 6.73 (2H, d, J=2 Hz), and signals of phenolic protons at δ 8.72 (2H, bs), and 9.49 (2H, bs). Two finely split doublets at δ 6.54 and 6.73 in the ^{1}H-NMR spectrum indicated a 1,2,3,5-tetrasubstituted benzene ring. The oxidation of tetramethyl ether (**1m**) derived from **1** with potassium permanganate in acetone yielded 3-bromo-4,5-dimethoxybenzoic acid (**5**), which was confirmed by comparison with a synthetic sample of **5**. All of these results helped to elucidate the structure of Compound **1**.

An ethanol extract of the dried alga collected at Hakodate Bay was chromatographed on silica gel.



The TLC separation of a benzene eluate gave 3,5-dibromo-4-hydroxybenzyl ethyl ether (**6**)[8)] and the corresponding benzaldehyde (**7**), which has also been obtained from other marine sources. Compound **4** was also isolated from the benzene–ether (19:1) eluate. Compounds **6** and **7** were identified by comparison with the respective authentic samples. The presence of the benzyl methyl ethers (**2** and **3**) and ethyl ether (**6**) in the methanol and ethanol extracts respectively suggested the existence of a bromophenol precursor similar to lanosol sulfate in *P. lanosa* and *R. larix*. Therefore, we extracted the frozen alga collected at Hakodate Bay with 80% acetone. An acetone-soluble fraction was chromatographed on silica gel. Early-eluted fractions of the benzene–ether (19:1) eluate gave 3,5-dibromo-4-hydroxybenzyl alcohol (**8**),[8,9,15)] which was confirmed by comparison with an authentic sample, whereas later-eluted fractions gave **4** and 3-bromo-4,5-dihydroxybenzyl alcohol (**9**).[8,9,16)] Compound **9** was identified by comparison with a synthetic sample. The dried and frozen alga from Hakodate Bay was lacking in Compound **1**, which is present in the dried alga from Matsumae Bay.

Experimental

All the melting points were determined on a micro hot stage and are uncorrected. The IR spectra were taken on a Hitachi EPI-G2 spectrophotometer, and the UV spectra, on a Hitachi 124 spectrophotometer. The mass spectra were measured on a Hitachi RMO-4E spectrometer, and the ^{1}H-NMR spectra, on a JEOL PMX-60 or Hitachi R-20B spectrometer, using TMS as the internal standard. The column chromatography was carried out over silica gel (Wakogel C-100 or C-200). The TLC was performed on silica gel (Merck silica gel 60 F_{254}) and polyamide (Carl Chleicher & Chüll), with benzene–methanol–acetic acid (45:8:4 v/v) as the eluent.

Extraction and Isolation. *Methanol Extraction*: *P. urceolata* was collected at Matsumae Bay in May, 1974. A methanol extract of the air-dried alga (2.5 kg) gave a syrup, which was then treated with ether. The ether solution was treated with 5% aqueous KOH. The alkaline aqueous solution was acidified with hydrochloric acid and extracted with ether. The acidic fraction (75 g) from the ether extract was chromatographed on a silica-gel column. The column was then eluted, yielding 17 fractions, 4 l each; Fractions 1—13 with benzene and Fractions 14—17 with benzene–ether (19:1). Fractions 1—2 and 7—12 afforded Compounds **2** (650 mg) and **3** (460 mg) respectively. The recrystallization of a solid residue of Fractions 15—17 from benzene–methanol gave Compound **4** (2 g), while Compound **1** (400 mg) was obtained on the recrystallization of the mother liquor.

Ethanol Extraction: The dried alga (2.0 kg) collected at Hakodate Bay in May, 1976, was immersed in ethanol. The subsequent removal of the solvent from the ethanol solution gave an ethanol extract, which was treated with ether. The ether extract (3.2 g) was subjected to chromatography on a silica-gel column. The column was eluted with benzene as has been described above. On separation by TLC (polyamide), the eluate gave Compounds **7** (43 mg; R_f 0.69) and **6** (25 mg; R_f 0.94). The further elution of the column with benzene–ether (19:1) afforded Compound **4** (78 mg).

80% Acetone Extraction: The alga (14 kg) collected at Hakodate Bay in May, 1978, was immersed in 80% acetone. The acetone solution was then evaporated to dryness and treated with dry acetone. The acetone extract (70 g) was chromatographed on a silica-gel column. The column was then eluted with the series of solvents mentioned above. Early-eluted fractions of a benzene–ether (19:1) eluate afforded Compound **8** (1.8 g). Later-eluted fractions contained two components which gave spots with R_f 0.65 and 0.16 on TLC (silica gel). A mixture (3.1 g) of these components was rechromatographed on a silica gel column with benzene–ether (19:1) to give Compounds **4** (670 mg) and **9** (190 mg).

3,3′-Dibromo-4,4′5,5′-tetrahydroxybibenzyl (1). Compound **1** was recrystallized from benzene–methanol to yield colorless needles (120 mg); mp 205—206 °C; λ_{max} (EtOH) 287 nm; IR(KBr) ν 3550, 3470, 3250, 2930, 2860, 1630, 1610, 1595, 1520, 1430, 1340, 1295, 1190, 1000, 905, and 845 cm^{-1}; ^{1}H-NMR (DMSO-d_6) δ 2.58 (4H, s, methylene protons), 6.54 (2H, d, J=2 Hz, aromatic protons), 6.73 (2H, d, J=2 Hz, aromatic protons), 8.72 (2H, bs, phenolic protons), and 9.49 (2H, bs, phenolic protons); MS *m/e* 406, 404, 402 (M^+), 203, 201 ($M^+-C_7H_6O_2Br$), and 185, 183 ($M^+-C_7H_6O_2Br-H_2O$). Compound **1** gave an intense green color with iron(III) chloride and was precipitated easily on the addition of lead acetate.

Found: C, 41.38; H, 2.92%. Calcd for $C_{14}H_{12}O_4Br_2$: C, 41.62; H, 2.99%.

Identification of 1. *a*): The phenol **1** (20 mg), dissolved in ether, was treated with diazomethane, thus yielding a tetramethyl derivative (**1m**) (13 mg) as colorless needles; mp 92—95 °C; IR(KBr) ν 2900, 1600, 1455, 1410, 1365, 1210, 1085, 975, 835, and 770 cm^{-1}.

b): A solution of **1m** (10 mg) in acetone (3 ml) was added to a solution of potassium permanganate (30 mg) in acetone (10 ml). The mixture was refluxed. The resulting precipitates were filtered and extracted with water. The water solution, after acidification with dilute hydrochloric acid, was extracted with ether. The subsequent removal of the solvent from the ether extract gave crystals, which were recrystallized from hexane–ethanol to yield 3-bromo-4,5-dimethoxybenzoic acid (**5**) (2.8 mg); mp 195—198 °C; IR(KBr) ν 2950, 1690, 1595, 1575, 1410, 1290, 1115, 1045, and 990 cm^{-1}. Compound **5** was shown to be identical with a synthetic sample by a comparison of the IR spectrum and TLC.

Synthesis of 5. 3-Bromo-4,5-dimethoxybenzaldehyde was oxidized by the procedure described for the oxidation of **1m**. The recrystallization of the oxidation product from hexane–ethanol furnished **5** as colorless needles; mp 197—198 °C.

Found: C, 41.55; H, 3.28; Br, 30.28%.

3,5-Dibromo-4-hydroxybenzyl Methyl Ether (2). Compound **2** was recrystallized from hexane to yield colorless crystals; mp and mixed mp 70—71 °C; λ_{max} (EtOH) 290 nm (log ε 3.46); IR(KBr) ν 3240, 2990, 2920, 2810, 1590, 1550, 1475, 1280, 1140, 1080, and 860 cm^{-1}; ^{1}H-NMR($CDCl_3$) δ 3.31 (3H, s, $-CH_2O\underline{CH_3}$), 4.28 (2H, s, $-\underline{CH_2}OCH_3$), 5.93 (1H, bs, phenolic proton), and 7.38 (2H, s, aromatic protons); MS *m/e* 298, 296, 294 (M^+), 267, 265, 263 (M^+-OCH_3), 217, 215 (M^+-Br).

3-Bromo-4,5-dihydroxybenzyl Methyl Ether (3). Compound **3** was recrystallized from benzene–methanol to afford colorless needles; mp 98—99 °C; λ_{max} (EtOH) 287 nm; IR(KBr) ν 3450, 3075, 3050, 2950, 2925, 2860, 2830, 1610, 1590, 1525, 1425, 1065, 855, and 840 cm^{-1}; ^{1}H-NMR($CDCl_3$) δ 3.37 (3H, s, $-CH_2O\underline{CH_3}$), 4.33 (2H, s, $-\underline{CH_2}OCH_3$), 5.98 (2H, bs, phenolic protons), 6.79 (1H, d, J=2 Hz, aromatic proton), and 6.98 (1H, d, J=2 Hz, aromatic proton); MS *m/e* 234, 232 (M^+), 203, 201 (M^+-OCH_3), and 153 (M^+-Br).

3-Bromo-4,5-dimethoxybenzyl Methyl Ether (3m). Compound **3** (100 mg), dissolved in ether, was treated with diazomethane, yielding a dimethyl ether (80 mg) as a colorless oil; bp 262 °C; n_D^{20}=1.5474; IR (neat) ν 2930, 2825, 1595, 1570, 1490, 1410, 1100, 1045, 1005, 845, and 815 cm^{-1}; ^{1}H-NMR($CDCl_3$) δ 3.47 (3H, s, $-CH_2O\underline{CH_3}$), 3.95 (6H, s, ϕ-$O\underline{CH_3}$), 4.44 (2H, s, $-\underline{CH_2}OCH_3$), 6.93 (1H, d, J=2 Hz, aromatic proton), and 7.16 (1H, d, J=2 Hz, aromatic proton). This compound was identified with the synthetic **3m** by a comparison of their IR and ^{1}H-NMR spectra.

3-Bromo-4,5-dihydroxybenzaldehyde (4). Compound **4** was recrystallized from benzene–methanol to yield colorless needles; mp and mixed mp 230 °C; λ_{max} (EtOH) 288 nm; IR (KBr) ν 3425, 1650, 1580, 1440, 1310, 1185, 860, and 845 cm^{-1}; ^{1}H-NMR(DMSO-d_6) δ 7.24 (1H, d, J=2 Hz, aromatic proton), 7.53 (1H, d, J=2 Hz, aromatic proton), 9.68 (1H, s, formyl proton), and 10.29 (2H, bs, phenolic protons); MS *m/e* 218, 216 (M^+), 217, 215 (M^+-1), 189, 187 (M^+-CHO), and 137 (M^+-Br).

3,5-Dibromo-4-hydroxybenzyl Ethyl Ether (6). Compound **6** was recrystallized from hexane to yield colorless needles; mp and mixed mp 93—94 °C; λ_{max} (EtOH) 290

nm; IR (KBr) ν 3210, 2970, 2860, 1595, 1555, 1478, 1403, 1305, 1265, 1145, 1075, 1010, 875, and 730 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 1.24 (3H, t, J=7 Hz, $-CH_2\underline{CH_3}$), 3.53 (2H, q, J=7 Hz, $-\underline{CH_2}CH_3$), 5.94 (1H, bs, phenolic proton), and 7.42 (2H, s, aromatic protons).

3,5-Dibromo-4-hydroxybenzaldehyde (7). Compound **7** was recyrstallized from hexane, yielding colorless needles; mp and mixed mp 189—190 °C; λ_{max} (EtOH) 277 and 346 nm; IR(KBr) ν 3180, 2860, 1670, 1580, 1550, 1480, 1415, 1305, 1245, 1205, 1055, 875, 740, and 660 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 7.87 (1H, bs, phenolic proton), 8.10 (2H, s, aromatic protons), and 9.87 (1H, s, formyl proton).

3,5-Dibromo-4-hydroxybenzyl Alcohol (8). Compound **8** was recrystallized from benzene, yielding colorless crystals; mp and mixed mp 119—120 °C; λ_{max} (EtOH) 291 nm; ^{1}H-NMR ($CDCl_3$+DMSO-d_6) δ 4.12 (1H, t, J=4 Hz, $-CH_2O\underline{H}$), 4.60 (2H, d, J=4 Hz, $-\underline{CH_2}OH$), 7.50 (2H, s, aromatic protons), and 7.65 (1H, bs, phenolic proton). The ^{1}H-NMR spectrum of this compound has partially been reported previously.[19]

3-Bromo-4,5-dihydroxybenzyl Alcohol (9). Compound **9** was recrystallized from benzene–acetone yielding colorless needles; mp and mixed mp 104—105 °C; λ_{max} (EtOH) 287 nm; IR (KBr) ν 3410, 2960, 1595, 1425, 1340, 1290, 1185, 1120, 960, 860, and 840 cm^{-1}; ^{1}H-NMR (acetone-d_6) δ 4.48 (2H, s, $-\underline{CH_2}OH$), 4.3—4.7 (1H, bs, $-CH_2O\underline{H}$), 6.85 (1H, d, J=2 Hz, aromatic proton), 6.97 (1H, d, J=2 Hz, aromatic proton), and 8.02 (2H, bs, phenolic protons); MS *m/e* 220, 218 (M^+), 219, 217 (M^+-1), 203, 201 (M^+-H_2O+1), 202, 200 (M^+-H_2O), and 139 (M^+-Br).

We wish to thank Dr. Isao Sekikawa, Hokkaido University, for providing the ^{1}H-NMR and MS and much helpful advice.

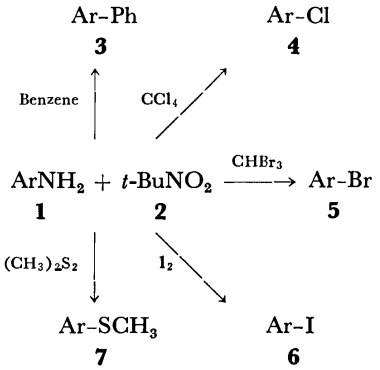
Direct Conversion of Arylamines to the Corresponding Halides, Biphenyls, and Sulfides with *t*-Butyl Thionitrate

Shigeru OAE,* Kōichi SHINHAMA, and Yong Hae KIM
Department of Chemistry, The University of Tsukuba, Niiharigun, Ibaraki 305

(Received November 10, 1979)

t-Butyl thionitrate have been found to be an excellent diazotizing reagent of arylamines in aprotic nonpolar media, affording eventually such products as aryl chlorides, aryl bromides, aryl iodides, biphenyls, and aryl methyl sulfides in the presence of CCl_4, $CHBr_3$, I_2, benzene, and dimethyl disulfide, respectively, *via* extrusion of N_2.

In the course of our studies on the synthetic applications of thionitrites or thionitrates, we now have found that *t*-butyl thionitrate (**2**)[1] was an excellent diazotizing reagent in neutral, aprotic, and homogeneous media to convert various arylamines (**1**) in the presence of carbon tetrachloride, bromoform, iodine in benzene, benzene alone, and dimethyl disulfide to afford the corresponding aryl chloride (**4**), aryl bromide (**5**), aryl iodide (**6**), biphenyls (**3**), and methyl aryl sulfides (**7**), respectively, in good yields.



Although alkyl nitrites have been used for the same purposes,[2] thionitrites and thionitrates are considered to be better reagents for deamination of arylamines **1** due to the relatively weak S–N bonds of thionitrites and thionitrates. Indeed, the thionitrate **2** was found to be a remarkably effective reagent for deamination. Although *t*-butyl thionitrite is also an effective deaminating reagent which can afford aryl halides in the reaction with arylamines in the presence of copper(II) halides in acetonitrile at room temperature,[3] it is not thermally stable as compared to the thionitrate **2** and decomposes readily in boiling benzene or carbon tetrachloride, and hence it was not used for these uncatalyzed reactions.

Reactions of various arylamines (**1a—i**) with **2** in benzene gave the corresponding biphenyls (**3a—i**) in good yields (Table 1). The reaction was found to proceed in a short time when *p*-methoxyaniline (**1c**), which possesses an electron-donating methoxyl group, was treated with thionitrate **2**. However, the yield of 4-methoxybiphenyl (**3c**) was relatively low because of the formation of a large amount of dark uncharacterized substance. On the contrary, *p*-nitroaniline (**1d**) was found to react rather slowly but converted to the corresponding 4-nitrobiphenyl (**3d**) in a good yields in several hours.

1i, 3i: Ar=*o*-CH_3-C_6H_4

Meanwhile, when isopentyl nitrate (**8**) was treated in a similar way with *p*-chloroaniline (**1b**), no reaction took place due undoubtedly to the relatively strong O–N bond of **8**.

$$\mathbf{1b} + \underset{\mathbf{8}}{(CH_3)_2CH(CH_2)_2ONO_2} \xrightarrow{\text{Benzene}} \not\rightarrow \mathbf{3b}$$

When aniline (**1a**) was treated with **2** in toluene, methylbiphenyl (**3j**) was obtained as a mixture of its positional isomers. GLC and ^{1}H-NMR analyses of this reaction mixture showed that the ortho, meta, and para isomers are formed in the ratio of *ca.* 4:2:1.

5c: Ar=*o*-NO_2-C_6H_4

The thionitrate **2** was found to be far better than alkyl nitrite in the syntheses of iodides **6** from the arylamines **1**. Upon treatment of **1** with **2** in the presence of iodine (half mol of amine) in refluxing benzene, the corresponding aryl iodides **6** were obtained in good yields as shown in Table 4. *p*-Toluidine (**1g**) was found to be converted to *p*-iodotoluene with isopentyl nitrite in the presence of iodine after a long reaction time (4 h) in a lower yield (40%).[2d] In

a) Mol ratio. b) Bath temperature.

the reaction of **1** and **2** in benzene, the yields of the corresponding biphenyls **3** were found to be very low due mainly to the superior reactivity of iodine over benzene to result in the rapid formation of **6**.

$$\underset{\mathbf{1}}{ArNH_2} + \underset{\mathbf{2}}{t\text{-}BuSNO_2} + I_2 \xrightarrow{\text{Benzene}} \underset{\mathbf{6}}{Ar\text{-}I}$$

6a: Ar=*p*-Cl-C_6H_4 **6d**: Ar=*o*-NO_2-C_6H_4
6b: Ar=*p*-MeO-C_6H_4 **6e**: Ar=*p*-Br-C_6H_4
6c: Ar=*p*-NO_2-C_6H_4 **6f**: Ar=*p*-CH_3-C_6H_4

Reactions of various arylamines **1** and **2** in dimethyl disulfide gave the corresponding aryl methyl sulfide (**7**) in good yields in a short reaction time and the results are listed in Table 5. Heating the solution prior to the addition of **2** is essential for the reaction. When the reaction was carried out at room temperature, deamination of arylamines **1** was slow and **2** was consumed by the reaction with dimethyl disulfide and the yields of the aryl methyl sulfides were low.

$$\underset{\mathbf{1}}{ArNH_2} + \underset{\mathbf{2}}{t\text{-}BuSNO_2} \xrightarrow{(CH_3)_2S_2} \underset{\mathbf{7}}{ArSCH_3}$$

7a: Ar=*p*-MeO-C_6H_4 **7d**: Ar=*p*-Br-C_6H_4
7b: Ar=*p*-NO_2-C_6H_4 **7e**: Ar=*p*-CH_3-C_6H_4
7c: Ar=*o*-NO_2-C_6H_4

Formation of nitrogen gas was clearly observed by mass spectrum, divulging the reaction to proceed *via* the $ArN_2^+OH^-$ that rapidly decomposes forming an aryl radical (**10**) which then reacts with the solvent or I_2 to afford the corresponding substitution product. Thiosulfonic *S*-ester **9** was also isolated in this reaction.

$$t\text{-}BuSNO_2 \underset{\mathbf{2}}{\rightleftharpoons} t\text{-}BuSONO \xrightarrow{\overset{Ar}{:NH_2\ 1}}$$

$$t\text{-}BuSO^- + ArN^+H_2NO \rightarrow t\text{-}BuSOH + ArN_2^+OH^- \rightarrow$$

$$\underset{\mathbf{10}}{Ar\cdot} + N_2 + H_2O + 1/2\ \underset{\mathbf{9}}{t\text{-}BuSO_2S\text{-}Bu\text{-}t}$$

When octylamine **11** was treated with **2** under similar conditions, no formation of deaminated product was observed, but *N*-(*t*-butylthio)octylamine (**12**) was obtained in a good yield.

$$\underset{\mathbf{11}}{n\text{-}C_8H_{17}NH_2} + \underset{\mathbf{2}}{t\text{-}BuSNO} \xrightarrow[81\%]{} \underset{\mathbf{12}}{n\text{-}C_8H_{17}NHS\text{-}Bu\text{-}t}$$

Experimental

All the melting points and boiling points were uncorrected. Elemental analyses were carried out by the Chemical Analysis Center at our University. Analytical determinations by GLC were performed on a Hitachi 163 gas chromatograph fitted with the following column (3 mm o.d.× 3 m): 10% SE-30 on Chromosorb W. ^{1}H-NMR spectra were taken at 60 MHz on a Hitachi R-24 A apparatus. IR spectra were recorded with a Hitachi 215 spectrometer. Mass spectra were recorded with a Hitachi RMU-6M spectrometer. The starting arylamines are all commercial products. Thionitrate **2** was prepared from the corresponding thiol with dinitrogen tetroxide.[1] Purely isolated deaminated products were used for GLC analyses.

Reactions of Arylamines (1) with Thionitrate (2) in Aromatic Compounds. The following is a typical procedure. *p*-Chloroaniline (**1b**) (637 mg, 5 mmol) and **2** (875 mg, 7 mmol) were refluxed in dry benzene (20 ml) for 6 h. The reaction mixture was concentrated by removing benzene *in vacuo*, and purified by TLC (silica gel, hexane:ether=10:1), affording 569 mg (60%) of 4-chlorobiphenyl (**3b**): mp 75—76 °C (recrystallized from ethanol), (lit,[2b] 76 °C).

Structures of **3a**—**n** were identified by IR, NMR, and mass spectroscopic data. Melting or boiling points of **3a**—**i** were identical with those of literatures as shown in Table 1. Physical and elemental analytical data of **3j**—**n** are listed in Table 6.

Reaction of Arylamines (1) with Thionitrate (2) in CCl_4 or $CHBr_3$. The following is a typical procedure. The thionitrate **2** (845 mg, 7 mmol) was added for a few minutes to a stirred solution of *p*-nitroaniline (**1d**) (690 mg, 5 mmol) in bromoform (10 ml) at 120 °C. After several minutes, vigorous evolution of nitrogen gas was observed. The solution was further stirred for 40 min at 120 °C. The solution was cooled and the solvent was evaporated *in vacuo*. TLC (silica gel, hexane:ether=10:1) gave 752 mg (75%) of pure *p*-bromonitrobenzene (**5b**).

IR spectra of all the halides in Table 3 were identical with those of commercial authentic samples.

Reactions of Arylamines (1) with Thionitrate (2) in the Presence of Iodine. The following is a typical procedure. *p*-Toluidine (**1g**) (535 mg, 5 mmol) and **2** (675 mg, 5 mmol) were added to a stirred solution of iodine (635 mg, 5 mmol) in dry benzene (20 ml). The solution was refluxed for 17 min. After the solution was cooled, diethyl ether was added to the solution and washed with aq sodium thiosulfate solution to remove iodine. The solution was dried ($MgSO_4$), concentrated, and purified by TLC (silica gel, hexane:ether=10:1) to give 812 mg (74%) of pure *p*-iodotoluene (**6f**).

IR spectra of all the iodides in Table 4 were identical with those of commercial authentic samples.

Reactions of Arylamines (1) with Thionitrate (2) in Dimethyl Disulfide. The following is a typical procedure. The solution of *p*-nitroaniline (**1d**) (690 mg, 5 mmol) in dimethyl disulfide (5 ml) was heated (*ca.* 100 °C) in advance. Then, **2** (1.01 g, 7.5 mmol) was added to the stirred solution

Table 6. Physical and analytical data of compounds **3j**—**n**[a]

Synthetic Photochemistry. XVII.[1] The Singlet-oxygen Oxidation of Vinylcyclopropane in the Presence of Diphenyl Sulfide. The Chemical Reduction of a Dioxetane to a *cis*-1,2-Glycol

Toshihide HATSUI and Hitoshi TAKESHITA*

Research Institute of Industrial Science, 86, Kyushu University, Hakozaki, Fukuoka 812

(Received November 14, 1979)

The singlet-oxygen oxidation of a spirocyclic vinylcyclopropane in the presence of diphenyl sulfide, a reducing agent, was shown to form a *cis*-glycol by the O–O cleavage of dioxetane. The determination of the stereochemistry of isomeric glycols obtained by chemical derivation led to a revision of the structure of the azido alcohol formed during the photosensitized oxygenation in a presence of the azide ion to the *trans*-derivative.

Previously, we have reported[2] a *cis*-glycol formation by a photoreductive O–O cleavage of the dioxetane (**A**) in the Rose Bengal (RB)-sensitized photooxidation of **1**, dispiro[cyclopropane-1,3′-tricyclo[5.2.1.$0^{2,6}$]deca-4′,8′-diene-10′,1″-cyclopropane], a spirocyclic vinylcyclopropane, which is a typical dioxetane-forming alicyclic olefin in the singlet-oxygen oxygenation. This new process has been verified by low-temperature experiments monitored by NMR spectroscopy,[13] and its generality has been demonstrated by experiments with indene[2] and thujopsene.[4] From a comparative point of view, it will be worthwhile to examine the chemical reduction of **A**. The results have in fact verified the O–O cleavage to give the *cis*-glycol (**2**) by the thioether-reduction which will be a subject of this paper. In literature, several investigations along the same line of a singlet-oxygen oxidation with a reducing agent are recorded; Kaneko *et al.*[5] used thiourea to reduce the endo-peroxide from cyclopentadiene, and Wassermann and Saito[6] showed the results of the thioether-reduction of a series of photooxygenation products. In this paper we will describe the reaction in a system of diphenyl sulfide (**3**) and Methylene Blue (MB) in chloroform. This selection was made out of consideration of the solubility as well as the moderate reactivity of **3** toward singlet oxygen compared with that of dialkyl sulfides.

When a chloroform solution of **1**, **3**, and MB was irradiated by means of a tungsten lamp under an oxygen atmosphere, a considerable rate retardation was recognized; the reaction was still not completed after 32 h. From the reaction mixture, **2**,[7] **4**, **5**, **6**, and **7** were isolated, along with large amounts of diphenyl sulfoxide and diphenyl sulfone, by silica-gel chromatography. The major product, **4** (41%), and another product, **5** (31%), were identified as the dioxetane-derived dialdehyde and the known vinyloxirane respectively.[8] In addition, a glycol, **2** (19%), was identical with the authentic sample of *cis*-glycol prepared by the RB-sensitized photooxidation of **1**[2] in respect to the NMR spectral analysis and the easy formation of the dioxolane derivative, **8**. **6** (3%) and **7** (3%) were a pair of isomeric ketones, and the NMR and IR spectra of **6** [δ:[9] 0.45 (4H, m), 0.75—1.35 (4H, m), 2.03 (1H, dd, J=19.5, −0.1 Hz*), 2.17 (1H, m), 2.42 (1H, dd, J=19.5, 13.5 Hz*), 2.53 (1H, m), 2.77—3.02 (2H, m), and 6.16 (2H, m). $\nu_{C=O}$: 1730 cm^{-1}] and of **7**[δ: 0.3—0.7 (8H, m), 1.95 (1H, dd, J=19.7, 1.5 Hz), 2.25 (1H, d, J=19.7 Hz),

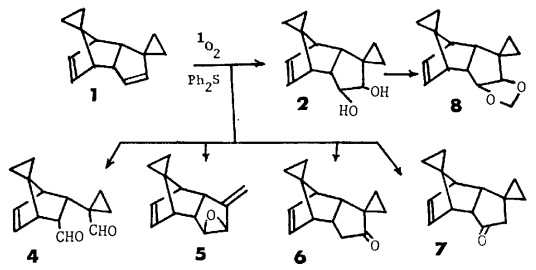

Chart 1.

2.27 (1H, m), 2.58 (1H, m), 2.68 (1H, dd, J=8.5, 4 Hz), 3.25 (1H, ddm, J=8.5, 4.5 Hz), 6.12 (1H, ddd, J=6, 3, 1 Hz), and 6.25 (1H, J=6, 3, 1 Hz . $\nu_{C=O}$: 1740 cm^{-1}] were consistent with the depicted structures (Chart 1), which were themselves supported chemically by the selective derivation of **6** from a monotosylate of **2**.

It is noteworthy that the concomitant formation of **6** and **7** strongly suggests that an epoxide, **9**, is not likely to be their precursor. This can be checked experimentally: The epoxidation of **1** with *m*-chloroperbenzoic acid (MCPA) in dichloromethane yielded no **9**; alternatively, we obtained were isomeric epoxide (**10**), the cyclopropyl ketone (**7**), and two glycol mono-*m*-chlorobenzoates (**11a** and **12**). The **10** was identical with the sample obtained in the sensitized photooxygenation of **1** in the presence of sodium azide[10] or in the RB-sensitized photooxygenation.[1] On the basis of the NMR analysis, **12** was demonstrated to be a *m*-chlorobenzoate of the primary alcohol; it is probably formed by the solvolysis of the cyclopropane. On the other hand, **11a** was convertible to an isomer (**11b**) by prolonged standing at room temperature. The coupling patterns of the NMR spectra of **11a** and **11b** were quite similar and suggested an intact stereochemistry on the oxygen functions. Therefore, **11a** and **11b** must be derivatives of **2**, **11**, and **12** are secondary products of an intermediate epoxide, **9**. **11a** was indeed saponified to **2** in methanol, and **11b** was converted to **2** by an LAH reduction. The spontaneous formation of the *cis*-glycol derivatives during the epoxidation is remarkable, but not surprising; it can be explained in terms of an orbital asistance form the norbornene double bond of **1**.

Meanwhile, the MCPA-oxidation of **1** in a solvent containing methanol yielded predominantly methoxy derivatives, **13**, and its further epoxidized product, **14**, together with **10** and **7**. Again, the ionic cleavage of the cyclopropane ring is characteristic. Therefore,

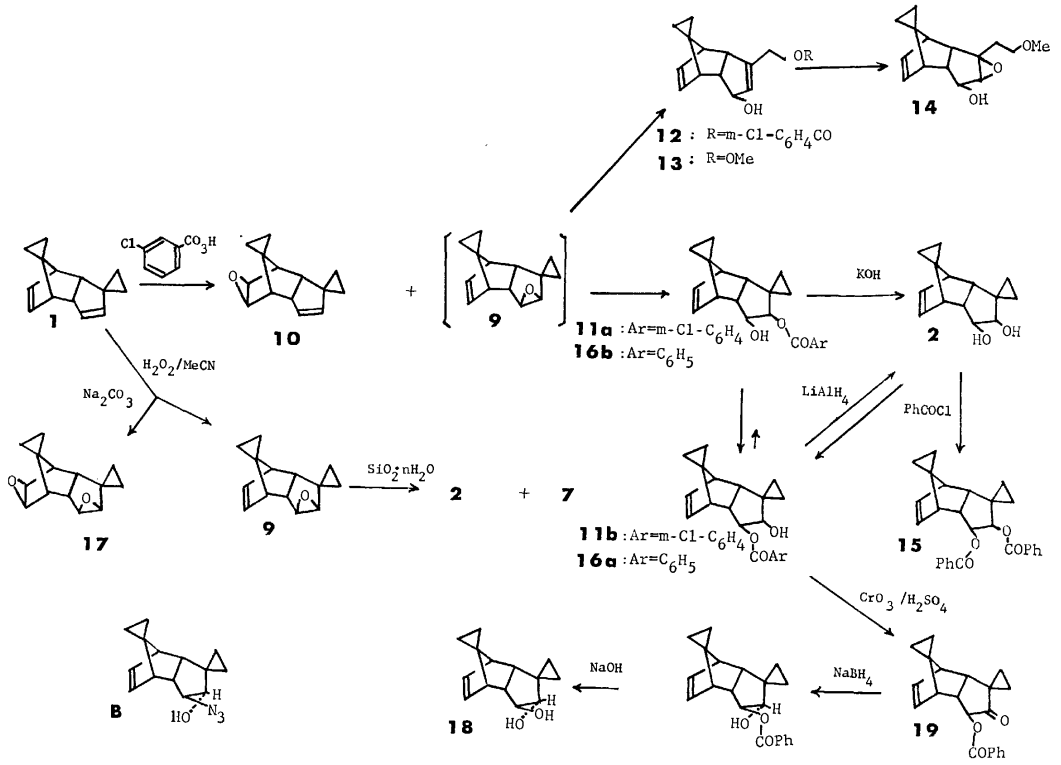

Chart 2.

the absence of the ketone (**6**) in the chemical oxidation is clear evidence of the involvement of independent precursors in chemical and photochemical oxidations.

In this regard, the benzoylation products of **2** were a dibenzoate (**15**) and a monobenzoate (**16**) [δ: 0.40 (7H, m), 0.90 (1H, m), 1.83 (1H, br., OH), 2.04 (1H, m), 2.40 (1H, m), 2.82 (1H, dd, J=9.5, 4 Hz), 3.07 (1H, ddd, J=9.5, 4.5, 3.5 Hz), 3.90 (1H, d, J=4.5 Hz), 5.03 (1H, dd, J=4.5, 3.5 Hz), 6.35 (2H, m), 7.28—7.55 (3H, m), and 7.99 (2H, m) for the **a**-isomer; 4.06 (1H, dd, J=4.5, 4 Hz), and 4.98 (d, J=4 Hz) for the **b**-isomer (**a**:**b**=85:15)]. Again, the monobenzoate showed acyl-migration.

After extensive investigations, we have found a method to obtain this acid-sensitive epoxide, **9**. By the mild oxidation of **1** with the acetonitrile–hydrogen peroxide adduct under weakly basic conditions,[11,12] two epoxides, **9** and **17**, were obtained; they were subsequently purified by fractional recrystallization. **9** (colorless needles, from methanol) was highly reactive, as expected; *i.e.*, a brief treatment with silica gel in chloroform caused a facile conversion into **2** and **7**, but not to **6**. On the other hand, crystalline bisepoxide (**17**), lacking the norbornene C–C bond, was relatively stable.

These findings have established that the precursor of **2** in the photooxygenation must be the dioxetane, **A**. The following points are particularly important: i) There is a difference in the selectivity of the reaction site between the chemical epoxidation and the photooxygenation, ii) there is no incorporation of the solvent nucleophile into the photooxygenation products, iii) there is no cleavage product of the cyclopropane ring in the photooxygenation, and iv) the compositions of the ketones formed in the different reactions differ. Should **2** be derived by the oxidation of **1** by some active species like a complex of diphenyl sulfide and oxygen, the observed reactivity, an overwhelming oxidation at the spiroheptene moiety, must be rather controversial.[10]

At the same time, we wish to make an additional point as to the effect of the reducing agent on the relative yields of **4** and **5** in this sensitized photooxygenation. Upon the addition of **3**, although the yield of **5** was almost unaffected, the yield of **4** decreased considerably, from 85 to 41%. This certainly suggests that the precursor of **5** is not interconvertible with the dioxetane, being parallel to the previous results on the solvent and temperature dependences for the occurrence of **5**.[2,3] Therefore, the precursor of **5**, if any, must be very short-lived to be trapped by a bimolecular process.

Furthermore, since the formation of **6** can not be explained in terms of a simple hydrolysis of **9**, an alternative pathway should be provided. To explain the reaction of the diphenyl-sulfide reduction of dioxetanes, the involvement of dipolar S–O-linked intermediate has been suggested by Wassermann and Saito.[6] In fact, they have identified a *trans*-glycol *via* an epoxide, which is shown to be derived by complicated rearrangements, but have failed to detect a *cis*-glycol. The present study can well be explained also in terms of an S–O-intermediate; otherwise, the direct isolation of **2**, a *cis*-glycol, together with **6** and **7**, isomeric ketones, is difficult to explain. Thus, Chart 3 is provided to interpret all the results.

The coupling patterns in the NMR spectra of the *cis*-glycol derivatives disclosed a discrepancy from those

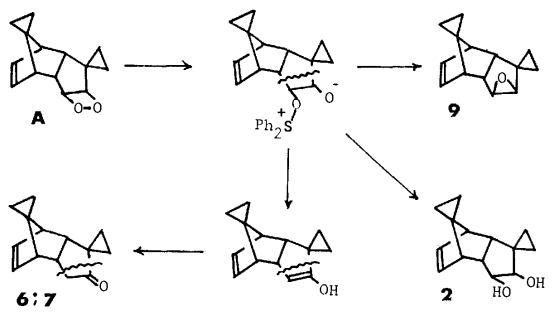

Chart 3.

of the azido alcohol (**B**), which was formed in the sensitized photooxidation of **1** in the presence of sodium azide.[10] The stereochemistry of **17** was identified as *cis* on the basis of the observed $^3J_{CH-OH}$ splittings due to a slow exchange of the hydroxyl proton, and this phenomenon was interpreted in terms of the hydrogen-bonding of the hydroxyl group to the azido group. To solve the problem, we should take the isomeric *trans*-glycol (**18**) for an NMR comparison. Thus, **15** was converted into a keto ester (**19**) by chromium(VI) oxide oxidation; the subsequent reduction of **19** with sodium borohydride yielded another glycol, which must be **18**. Indeed, the spin-spin splitting patterns of the NMR spectrum of **18** were similar to those of **B**. Therefore, the orginal assignment, a *cis*-orientation for the substituents of **B**, must be revised to *trans*.[13] Nevertheless, the conclusion of our previous work, *i.e.*, that the dioxetanes or peroxiranes are not responsible for the formation of azido alcohols, is still valid.

Experimental

*MB-Sensitized Photooxygenation of **1** in the Presence of Diphenyl Sulfide (**3**).* A chloroform solution (15 cm³) of **1** (460 mg), MB (60 mg), and **3** (3.73 g) was irradiated by means of a 500-W tungsten lamp under an oxygen stream at room temperature for 110 h. Subsequent silica gel column chromatography of the mixture gave recovered **1** (170 mg, 37%) and **3** (3.3 g) from the hexane fractions. Subsequently, a vinyloxirane (**5**, 90 mg, 31%), a ketone (**6**, 9 mg, 3%), a colorless oil [Found: M. W., 200.1170. Calcd for $C_{14}H_{16}O$: 200.1201], another ketone (**7**, 8 mg, 3%; colorless prisms; mp 76—77 °C [Found: M. W., 200.1170]), a dialdehyde (**4**, 109 mg, 41%), and a glycol (**2**, 54 mg, 19%; colorless needles, mp 56—57 °C)[7] were eluted from hexane–ether (4:1). From the most polar fractions (hexane–ether=1:1), considerable amounts of diphenyl sulfoxide and diphenyl sulfone were obtained.

*Preparation of a Dioxolane Derivative (**8**).* A benzene solution (1 cm³) of **2** (11.6 mg) and dimethoxymethane (0.5 cm³) containing TsOH (1 mg) was kept at room temperature for 18 h. The mixture was then extracted with benzene, and the extracts were purified on a silica-gel column to give **8** (a colorless oil, 56 mg (45%) [Found: M.W., 230.1334. Calcd for $C_{15}H_{18}O_2$: 230.1307. δ: 0.08—0.75 (7H, m), 0.90 (1H, m), 2.05 (1H, m), 2.36 (1H, m), 2.74 (1H, dd, J=9, 5 Hz), 3.07 (1H, dd, J=9, 5 Hz), 4.08 (2H, s), 4.88 (1H, s), 4.90 (1H, s), 6.22 (1H, ddd, J=6, 3, 1 Hz), and 6.32 (1H, ddd, J=6, 3, 1 Hz). ν: 2950, 1090 cm⁻¹]).

*MCPA-Oxidation of **1** in Dichloromethane: Formation of **7**, **10**, **11**, and **12**.* **1** (900 mg) was dissolved in dichloromethane (15 cm³), after with MCPA (500 mg) was added in portions. After 1 h, an aqueous sodium carbonate was added and then extracted into dichloromethane. Silica gel column chromatography of the extracts gave recovered **1** (440 mg, from hexane–ethyl acetate (98:2)), **10**[2] (130 mg, 26%, from hexane–ethyl acetate (95:5)), **7** (14 mg, 3%, from hexane–ethyl acetate (9:1)), **11** (438 mg, 49%, from hexane–ethyl acetate (8:2 to 7:3) [Found: M.W., 356.1143. Calcd for $C_{21}H_{21}O_3Cl$: 356.1179. δ: 0.28—0.7 (7H, m), 0.88 (1H, m), 2.00 (1H, OH), 2.0 (1H, m), 2.36 (1H, m), 4.04 (1H, t, J=4.5 Hz), 4.95 (1H, d, J=4.5 Hz), 6.33 (2H, m), 7.2—7.6 (2H, m), and 7.7—8.0 (2H, m). ν: 3600, 3480, 1730, 1260 cm⁻¹], a colorless oil), and **12** (174 mg, 20%, from hexane–ethyl acetate (6:4)) [Found: M.W., 356.1184. δ: 0.43 (4H, s), 1.69 (1H, br., OH), 2.25 (1H, m), 2.44 (3H, m), 2.74 (1H, ddd, J=8, 5, 2 Hz), 3.48 (1H, m), 4.12 (1H, br., s), 4.44 (2H, t, J=7 Hz), 5.41 (1H, br., s), 5.99 (2H, m), 7.25—7.55 (2H, m), and 7.8—8.0 (2H, m). ν: 3430, 1735, 1260 cm⁻¹].

*MCPA-Oxidation of **1** in Methanol and Dichloromethane.* **1** (1010 mg) was dissolved in a mixture of methanol (30 cm³) and dichloromethane (8 cm³) and was then oxidized by MCPA (420 mg) at room temperature for 2.5 h. The mixture was treated with $NaHCO_3$ and extracted with dichloromethane. Silica gel chromatography of the extracts afforded, at first, recovered **1** (700 mg), and then **10** (92 mg (28%)), **7** (8 mg (2%)), and a mixture of methoxy derivatives (265 mg (**13**, *ca.* 44%, and **14**, *ca.* 20%)), which were later fractionated by the use of a pre-packed silica gel column (Merck) to give two colorless oils, **13** [Found: M.W., 232.1481. Calcd for $C_{15}H_{20}O_2$: 232.1463. δ: 0.41 (4H, br. s), 1.71 (1H, br., OH), 2.20 (1H, m), 2.24 (2H, t, J=7 Hz), 2.40 (1H, m), 2.69 (1H, ddd, J=7.5, 4.5, 2 Hz), 3.32 (3H, s), 3.4 (1H, m), 3.50 (2H, t, J=7 Hz), 4.08 (1H, m), 5.32 (1H, m), 5.91 (1H, ddd, J=6, 3, 1 Hz), and 6.01 (1H, ddd, J=6, 3, 1 Hz). ν: 3400 cm⁻¹] and **14** [Found: M. W., 248.1381. Calcd for $C_{15}H_{20}O_3$: 248.1413. δ: 0.39 (4H, br. s), 1.75 (1H, dt, J=15, 7 Hz), 2.05 (1H, dt, J=15, 7 Hz), 2.24 (1H, m), 2.32 (1H, br. s, OH), 2.4 (2H, m), 3.12 (1H, m), 3.31 (3H, s), 3.34 (1H, dm, J=2 Hz), 3.43 (2H, tm, J=7 Hz), 3.81 (1H, t, J=2 Hz), and 6.22 (2H, m). ν: 3610, 3500 cm⁻¹].

*Isomerization of **11a** to **11b**.* **11a** (neat liquid, 45 mg) was kept at room temperature for a month. The NMR analysis disclosed the formation of **11b** [δ: 0.42 (4H, m), 0.88 (4H, m), 1.94 (1H, OH), 2.04 (1H, m), 2.38 (1H, m), 2.92 (1H, dd, J=9.5, 4 Hz), 3.08 (1H, dt, J=9.5, 4 Hz), 3.89 (1H, d, J=4.5 Hz), 5.00 (1H, dd, J=4.5, 4 Hz), 6.34 (2H, m), 7.2—7.6 (2H, m), and 7.8—8.0 (2H, m). ν: 3620, 3500, 1728, 1255 cm⁻¹] (**a**:**b**=15:85).

*Saponification of **11a**: Formation of **2**.* **11a** (42 mg) was dissolved in a methanolic KOH solution (0.2 M (1 M= 1 mol dm⁻³), 10 cm³) and then kept at room temperature for 24 h. The mixture was subsequently acidified by dil HCl, and extracted with ether. Silica gel chromatography of the extracts gave a colorless oil, **2** (15 mg, 58%).

*LAH Reduction of **11b** to **2**.* An anhydrous ether solution (3 cm³) of **11b** (77 mg), containing *ca.* 13 mg of **11a**, was treated with LAH (30 mg) for 15 h. The mixture was then chromatographed on a silica gel column to give **2**, 28 mg (51%).

*Benzoylation of **2**: Formation of a Dibenzoate (**15**) and a Monobenzoate (**16**).* A benzene solution (8 cm³) of **2** (290 mg) was treated with benzoyl chloride (262 mg) and pyridine (0.4 cm³) for 48 h. Extractions by dichloromethane and water and subsequent silica gel column chromatography of the extracts gave **15** (colorless prisms, mp 155—156 °C

(from ethanol)) [Found: C, 78.67; H, 6.08%. Calcd for $C_{28}H_{26}O_4$: C, 78.85; H, 6.14%. δ: 0.44 (4H, m), 0.55—0.75 (3H, m), 0.95 (1H, m), 2.06 (1H, m), 2.44 (1H, m), 3.18 (2H, m), 5.20 (2H, m), 6.48 (1H, m), 7.1—7.6 (6H, m), and 7.8—8.0 (2H, m). ν: 1725 cm^{-1}], 42 mg (11%) and **16** (a colorless oil, 236 mg (80%), which consisted of an inseparable mixture (**15a**:**15b**=85:15) [Found: C, 78.07; H, 6.95%. Calcd for $C_{21}H_{22}O_3$: C, 78.23; H, 6.88%]).

*Epoxidation of **1** under Weakly Basic Conditions: Formation of a Bisepoxide (**17**) and a Monoepoxide (**9**).* To an acetonitrile solution (10 cm^3) of **1** (320 mg) and one drop of aqueous 1 M KOH, hydrogen peroxide (30%, 0.7 cm^3) was added under ice-cooling. At once, an evolution of oxygen gas occurred, after which an aqueous 10% sodium carbonate solution was added, drop by drop, until the gas evolution ceased. The mixture was then warmed to 40 °C. After 1 h, the mixture was extracted with dichloromethane and water, and dried on magnesium sulfate. The subsequent evaporation of the solvent *in vacuo* left a crystalline solid (258 mg), which was indicated to be a mixture of **9** and **17** (4:3 according to the NMR spectrometry). Upon fractional recrystallizations from hexane, it gave **17** (colorless prisms, mp 121—122 °C [Found: C, 77.85; H, 7.38%. Calcd for $C_{14}H_{16}O_2$: C, 77.75; H, 7.46%. δ: −0.05—0.25 (2H, m), 0.4—0.75 (4H, m), 0.8—1.05 (2H, m), 1.70 (1H, d, J= 4.5 Hz), 2.08 (1H, d, J=4.6 Hz), 2.40 (1H, dd, J=8.5, 4.5 Hz), 2.94 (1H, dd, J=8.5, 4.6 Hz), 2.99 (1H, d, J= 2.7 Hz), 3.42 (1H, dd, J=3.7, 1 Hz), 3.52 (1H, d, J=2.7 Hz), and 3.59 (1H, dd, J=3.7, 1 Hz)]). Then, recrystallizations of the residue from methanol gave **9** (colorless prisms, mp 80.5—82 °C [Found: M. W., 200.1182. Calcd for $C_{14}H_{16}O$: 200.1201. δ: 0.3—0.8 (8H, m), 2.01 (1H, m), 2.32 (1H, m), 2.50 (1H, dd, J=7.7, 4.2 Hz), 2.79 (1H, d, J=2.4 Hz), 3.17 (1H, dd, J=7.7, 4.3 Hz), 3.28 (1H, d, J=2.4 Hz), and 6.20 (2H, m)]).

*Treatment of **9** with Silica Gel.* A dichloromethane solution (2 cm^3) of **9** was mixed with a silica gel (Merck, Kieselgel 60). The products, as characterized on thin-layer plates, were **7** and **2**.

*Chromium(VI) Oxide Oxidation of **16**: Formation of a Keto Ester (**19**).* An acetone solution (10 cm^3) of **16** (90 mg) was oxidized by chromium(VI) oxide and sulfuric acid for 5 min. A colorless oil, **19** (86 mg, 96%) [Found: C, 78.72; H, 6.29%. Calcd for $C_{21}H_{20}O_3$: C, 78.72; H, 6.29%. δ: 0.45 (4H, m), 0.90—1.55 (4H, m), 2.18 (1H, m), 2.68 (1H, m), 3.05 (2H, m), 4.83 (1H, d, J=3.7 Hz), 6.33 (2H, m), 7.3—7.6 (3H, m), and 8.00 (2H, m). ν: 1740, 1730, 1265 cm^{-1}] was obtained after silica gel chromatography.

*Sodium Borohydride Reduction of **19**: Formation of a* trans*-Glycol (**18**).* A methanol solution (5 cm^3) of **19** (81 mg) was reduced by $NaBH_4$ (52 mg) for 4 h. An aqueous alkaline solution was then added to the mixture, and it was hydrolyzed for 24 h. By silica gel column chromatography of the mixture, the desired glycol (**18**), as a single product, was isolated as colorless crystals (mp 85—86 °C, 42 mg (76%) [Found: M. W., 218.1297. Calcd for $C_{14}H_{18}O_2$: 218.1307. δ: 0.0—0.7 (8H, m), 1.8 (2H, OH), 1.95 (1H, m), 2.32 (1H, m), 2.70 (1H, ddd, J=10, 7, 4 Hz), 2.88 (1H, dd, J=10, 4 Hz), 3.43 (1H, dd, J=8, 7 Hz), 3.86 (1H, d, J=8 Hz), and 6.27 (2H, m). ν: 3320, 1100 cm^{-1}]).

*Conversion of **2** into **6**.* An anhydrous benzene solution (3 cm^3) of **2** (135 mg) was treated with TsCl (150 mg) at room temperature for 15 h and subsequently at 80 °C for 4 h. The mixture was then diluted with dil HCl and extracted with ether, and the extract was purified on a silica-gel column to give a colorless oil, **6** (30 mg, 52%), and some recovered **2** (70 mg, 52%).

(Received November 30, 1979)

Bromination of tricyclo[5.3.1.$0^{4,9}$]undeca-2,5-diene gave *endo*-2,*endo*-6- and *endo*-2,*exo*-6-dibromotetracyclo-[5.3.1.$0^{3,5}$.$0^{4,9}$]undecanes along with *syn*-11,*endo*-2-dibromotricyclo[4.3.1.$1^{3,8}$]undec-4-ene (**10a**) in a ratio of 3:3:1. A thermal treatment of the mixture of these dibromides at 140—150 °C induced a skeletal rearrangement to afford **10a** and *syn*-11,*exo*-2-dibromotricyclo[4.3.1.$1^{3,8}$]undec-4-ene (**10b**) in 87% yield (**10a**:**10b**=2:5). The new "non-bridgehead" 2,11-dehydrohomoadamantane was obtained by the hydrogenation of **10a** and **10b** followed by Wurtz type reductive cyclization. The unsaturated analogue, 2,11-dehydrohomoadamant-4-ene was also synthesized from **10a** and **10b** by the similar cyclization reaction.

The chemistry of strained organic molecules has attracted a considerable attention of many chemists and is still actively being explored.[3] Strained cage compounds which usually contain a cyclopropane and/or cyclobutane ring in their frameworks have demonstrated a number of interesting and unusual chemical properties of carbon-carbon σ-bond.[4] Out of five possible "non-bridgehead" mono-dehydrohomoadamantanes, the strained cage compounds which incorporate a cyclopropane or cyclobutane ring in their cage structures (**1**—**5**), three (**2**, **3**, and **4**) of them have been synthesized and characterized so far.[5-7] As a consequence of our continuing interest in the strained cage compounds,[5b,8] we have investigated a synthetic pathway to 2,11-dehydrohomoadamantane (**1**), a new entry to the "non-bridgehead" dehydrohomoadamantanes. We have recently prepared an interesting diene, tricyclo[5.3.1.$0^{4,9}$]undeca-2,5-diene (**7**),[8c] which is a potential precursor to some substituted homoadamantane (tricyclo[4.3.1.$1^{3,8}$]undecane) derivatives. For example, the homoallylic carbocation (**8**) generated by electrophilic reaction of **7** may produce homoadamantane system *via* homoallyl-cyclopropylcarbinyl-cyclobutyl rearrangement as is shown in Fig. 2.[9] We now wish to report here the synthesis of new "non-bridgehead" dehydrohomoadamantane, 2,11-dehydrohomoadamantane (**1**) as well as 2,11-dehydrohomoadamant-4-ene (**6**) *via* the above mentioned rearrangement.[10]

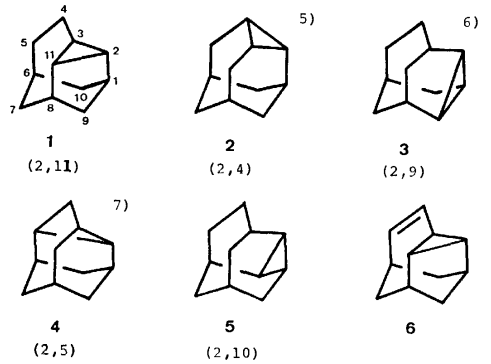

Fig. 1. "Non-bridgehead" dehydrohomoadamantanes.

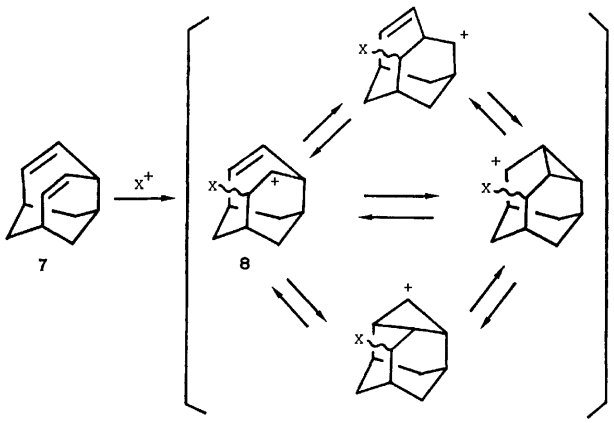

Fig. 2. Homoallyl-cyclopropylcarbinyl-cyclobutyl rearrangement.

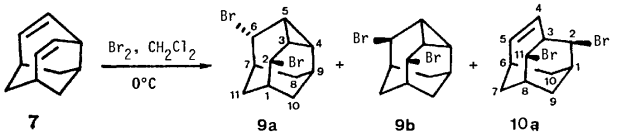
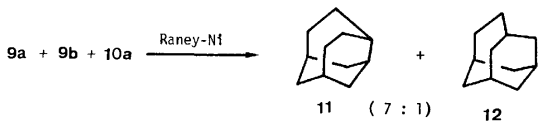
Results and Discussion

When the diene (**7**) was treated with bromine in dichloromethane at 0 °C, three dibromides, *endo*-2,*endo*-6- and *endo*-2,*exo*-6-dibromotetracyclo[5.3.1.-$0^{3,5}$.$0^{4,9}$]undecanes (**9a** and **9b**) and *syn*-11,*endo*-2-dibromotricyclo[4.3.1.$1^{3,8}$]undec-4-ene (**10a**), were obtained in 96% yield (**9a**:**9b**:**10a**=3:3:1 by PMR analysis). Although their complete separation was difficult because of their instabilities toward chromatographic treatment, low temperature recrystallizations made it possible to obtain **9a**, and **9b** in pure forms, respectively. The dibromides, **9a** and **9b**, showed no olefinic proton in their PMR spectra and a absorption band at 3010 cm^{-1} indicative of a cyclopropane ring in their IR spectra. The presence of a plane of symmetry in **9a** was indicated by only one kind of carbinyl protons on the bromine substituted carbons at 4.48 ppm as a singlet shown in its PMR spectrum; this was also confirmed by CMR which demonstrated only seven kinds of carbons. On the other hand, the PMR spectrum of **9b** showed two kinds of carbinyl protons at 4.88 ppm as a triplet (J=6 Hz) and 4.83 ppm as a singlet. It has been already known that the *endo*-carbinyl proton on C_2 (or C_6) of tetracyclo[5.3.1.$0^{3,5}$.$0^{4,9}$]undecane deriva-



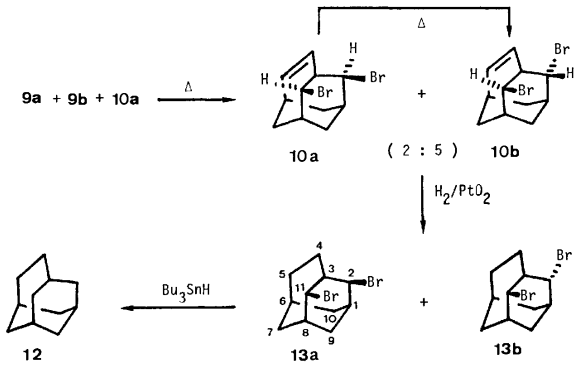
Scheme 1.

tives couples with the adjacent protons as a triplet with coupling constant of *ca.* 6 Hz but the *exo*-one does not in their PMR spectra.[8a,11] Accordingly, the structures of **9a** and **9b** were determined to be *endo*-2,*endo*-6- and *endo*-2,*exo*-6-dibromotetracyclo[5.3.1-$0^{3,5}.0^{4,9}$]undecanes, respectively. The above determination was further supported by the fact that reduction [12,13] of a mixture of the three dibromides by Raney-Ni gave tricyclo[5.3.1.$0^{4,9}$]undecane (**11**)[8] and homoadamantane (**12**) (**11**:**12**=7:1).



Scheme 2.

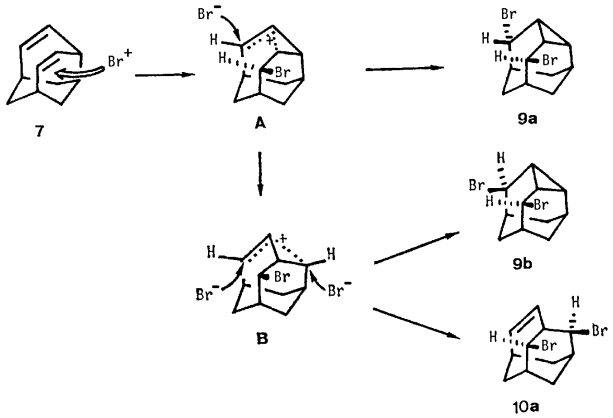
When the mixture of the dibromides (**9a**, **9b**, and **10a**) was heated under the reduced pressure (140—150 °C/533 Pa), an intriguing skeletal rearrangement took place to give **10a** and *syn*-11,*exo*-2-dibromotricyclo[4.3.1.$1^{3,8}$]undec-4-ene (**10b**) in 87% yield (**10a**:**10b**=2:5 by PMR analysis). It was also observed that a prolonged heating converted **10a** into **10b**; this result implies that **10b** is more thermodynamically stable than **10a**. Catalytic hydrogenation of this mixture over PtO_2 gave the saturated dibromides, *syn*-11,*endo*-2- and *syn*-11,*exo*-2-dibromotricyclo[4.3.1.-$1^{3,8}$]undecanes (**13a** and **13b**) in 26 and 53% yields, respectively. Since the saturated dibromides, **13a** and **13b**, were stable toward chromatographic treatment,



Scheme 3.

each of them was easily isolated by column chromatography on silica gel and could be completely characterized. Reduction of **13a** and **13b** with Bu_3SnH gave **12** in high yield, confirming the parent skeleton. The CMR and PMR spectra of **13a** showed only eight kinds of carbons and one kind of carbinyl protons on the bromine substituted carbons at 4.17 ppm as a singlet, respectively. Only *syn*-11,*endo*-2-dibromotricyclo[4.3.1.$1^{3,8}$]undecane can be responsible for the above spectra.[14] Consequently, **13b** was determined to be *syn*-11,*exo*-2-dibromotricyclo[4.3.1.$1^{3,8}$]undecane, because its PMR spectrum demonstrated two kinds of carbinyl protons at 5.10 ppm as a triplet (J=4.2 Hz) and 4.45 ppm as a singlet. Since the structures of **13a** and **13b** were established, those of the unsaturated dibromides, **10a** and **10b**, were deduced to be *syn*-11,*endo*-2- and *syn*-11,*exo*-2-dibromotricyclo-[4.3.1.$1^{3,8}$]undec-4-enes, respectively, on the basis of their CMR and PMR spectra. This deduction was confirmed by further chemical transformations (*vide infra*).

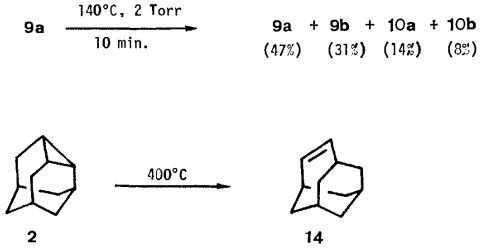
The following mechanistic pathway can well rationalize the formation of **9a**, **9b**, and **10a** in the bromination reaction of the diene **7**. The intervention of the homoallylic cations (A and B) may control the



Scheme 4.

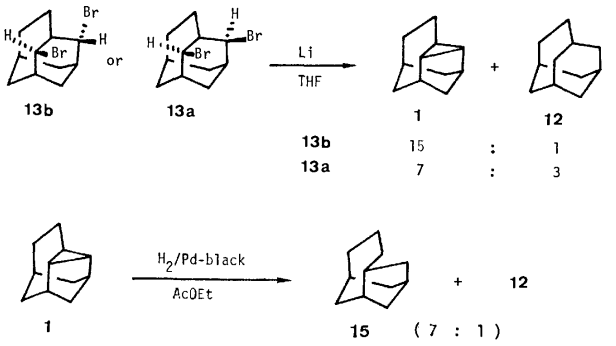
stereochemistry of the bromine addition. The analogous homoallylic cations were quoted in the bromination reactions of bicyclo[2.2.1]heptadiene[15] and bicyclo[2.2.2]octadiene.[13]

Since the thermal rearrangement of **9a** and **9b** seems interesting, the pure **9a** was heated under the same conditions as above in order to obtain further insight about the stereochemical outcome of the bromine substituents. Unfortunately, it was observed by PMR that **9a** was easily isomerized to **9b** under the rection conditions. For example, after 10 min, the mixture consisted of **9a**, **9b**, **10a**, and **10b** in a ratio of 47:31:14:8. Although the stereochemical course of this rearrangement could not be established, this process was much easier than the thermal isomerization of 2,4-dehydrohomoadamantane itself (**2**) to homoadamant-4-ene (tricyclo[4.3.1.$1^{3,8}$]undec-4-ene) (**14**) at 400 °C.[16]



Scheme 5.

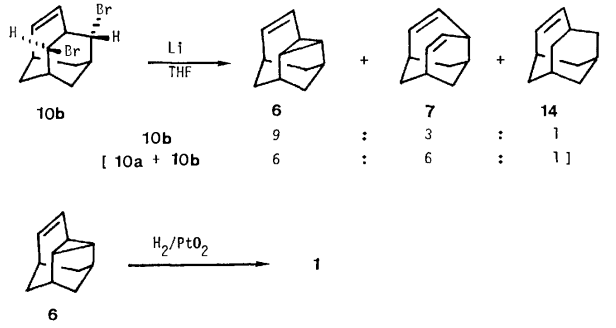
Now that 2,11-dibromotricyclo[4.3.1.$1^{3,8}$]undecanes (**13a** and **13b**) have become in our hands, the next step is reductive cyclization to 2,11-dehydrohomoadamantane (**1**). When **13b** was treated with lithium in dry THF at room temperature for 3.5 h, **1** was obtained in 94% yield along with a slight amount of homoadamantane (**12**) (**1**:**12**=15:1 by GLC analysis).



Scheme 6.

The similar treatment of **13a** with lithium gave the same products in 81% yield (**1**:**12**=7:3). The structure of **1** was confirmed by elemental analysis and spectroscopic data including its CMR spectrum which showed eight kinds of carbons due to its symmetry. Furthermore, hydrogenation of **1** over Pd-black gave 4-homoprotoadamantane (tricyclo[5.3.1.$0^{3,9}$]undecane) (**15**)[17] and **12** in 78% yield (**15**:**12**=7:1 by GLC analysis). This is a marked contrast with the fact that **2** is hydrogenated to give only **12**.[5a]

Whereas **13b** gave predominantly the cyclized product, the similar reaction of the unsaturated dibromide **10b** with lithium afforded a mixture of 2,11-dehydrohomoadamant-4-ene (**6**), the diene **7**, and **14** in 80% yield (**6**:**7**:**14**=9:3:1 by GLC analysis). The same treatment of a mixture of **10a** and **10b** gave **6**, **7**, and **14** in a ratio of 6:6:1 in 89% yield. The structure of **6** was particularly reflected in its CMR spectrum (eight kinds of carbons due to its symmetry) and further acertained by the hydrogenation to **1**.



Scheme 7.

Finally, it should be mentioned that the new "non-bridgehead" dehydrohomoadamantane **1** may be a possible precursor hitherto unknown 2,4-disubstituted 4-homoprotoadamantanes, considering that the C_2–C_3 bond of **1** is easily cleaved upon hydrogenation as is described above.[18] In addition, **6** is an interesting cage molecule because it incorporates a vinylcyclopropane moiety which has long been known as a reactive grouping.[19]

Experimental

All the temperatures were uncorrected. Melting points were measured in sealed capillaries. The IR spectra were recorded on a Shimadzu IR-27 spectrometer. The mass spectra were taken by using a Hitachi RMS-4 mass spectrometer. The exact mass spectrum was obtained on a Hitachi RMU-8GN mass spectrometer. The PMR and CMR spectra were obtained on Varian EM-390 or EM-360 and CFT-20 spectrometers, tetramethylsilane being chosen as the internal standard. Microanalyses were performed in Kyoto University Elemental Analysis Center.

The Reaction of Tricyclo[5.3.1.$0^{4,9}$]undeca-2,5-diene (7) with Bromine. To a solution of **7** (400 mg; 2.70 mmol) in dichloromethane (20 ml) was added dropwise bromine (480 mg; 3.00 mmol) at 0 °C. Then, the reaction mixture was washed with 10% $Na_2S_2O_3$ aq and brine, and dried (Na_2SO_4). After filtration, the solvent was evaporated to give a colorless oil, which contained *endo*-2,*endo*-6-dibromotetracyclo[5.3.1.-$0^{3,5}$.$0^{4,9}$]undecane (**9a**), *endo*-2,*exo*-6-dibromotetracyclo[5.3.1.-$0^{3,5}$.$0^{4,9}$]undecane (**9b**), and *syn*-11,*endo*-2-dibromotricyclo-[4.3.1.$1^{3,8}$]undec-4-ene (**10a**) in a ratio of 3:3:1 (PMR analysis) (808 mg; 96%). When this oil was stored in a refrigerator, colorless crystals appeared. After a small amount of pentane was added, the crystals were collected by filtration and washed with cold pentane to give pure **9a** (197 mg). The filtrate was condensed under reduced pressure and amorphous solids appeared. The solids were collected by filtration, recrystallized from a small amount of pentane at low temperature, and then kept in a refrigerator for a few days to afford pure **9b** (40 mg). **9a**: mp 79—83 °C (dec). MS *m/e* (rel intensity): 308, 306, 304 (M^+, 5, 9, 5), 227 (96), 225 (100), 145 (59). IR (KBr): 3010 (weak), 2925, 1170, 940, 775, 690 cm^{-1}. PMR δ ($CDCl_3$): 4.48 (2H, s), 2.50—0.90 (12H, br. complex m). CMR δ ($CDCl_3$): 55.3 (2CH), 36.1 (2CH), 35.1 (CH_2), 27.2 ($2CH_2$), 23.0 (2CH), 20.9 (CH), 15.3 (CH). Found: C, 43.07; H, 4.90%. Calcd for $C_{11}H_{14}Br_2$: C, 43.16; H, 4.61%. **9b**: mp 57—61 °C (dec). MS *m/e* (rel intensity): 308, 306, 304 (M^+, 6, 12, 6), 227 (96), 225 (100), 145 (63). IR (KBr): 3010 (weak), 2925, 905, 735, 710 cm^{-1}. PMR δ (CCl_4): 4.88 (1H, t, J=6.0 Hz), 4.83 (1H, s), 2.40—1.00 (12H, br. complex m). CMR δ ($CDCl_3$): 61.0 (CH), 53.7 (CH), 36.0 (CH), 35.6 (CH_2), 35.0 (CH), 30.7 (CH_2), 27.3 (CH_2), 24.6 (CH), 22.9 (CH), 21.7 (CH), 20.6 (CH). Found: C, 43.08; H, 4.77%. Calcd for $C_{11}H_{14}Br_2$: C, 43.16; H, 4.61%. The dibromide (**10a**) could not be isolated in a pure form because of its unstability toward thermal and chromatographic treatments. Its spectral data were deduced from the mixture and described below.

*Reduction of **9a**, **9b**, and **10a** with Raney-Ni.* A solution of the dibromides, **9a**, **9b**, and **10a** (139 mg; 0.45 mmol), triethylamine (91 mg; 0.90 mmol), and excess Raney-Ni-W_2 (*ca.* 0.5 g) in cyclohexane was vigorously stirred under hydrogen for 24 h. The reaction mixture was filtered and washed with 5% HCl aq and brine and dried (Na_2SO_4). After being passed through a silica-gel column, the solvent was evaporated to give two hydrocarbons [46 mg; 68%, **11**:**12**=7:1 (GLC analysis, PEG 20 M, 90 °C)]. Each of the products was isolated by preparative GLC and shown to be completely identical with the authentic sample in GLC retention time and PMR.

*Reduction of the Dibromides, **9a**, **9b**, and **10a**.* (1) A mixture of the dibromides (243 mg; 0.79 mmol) and Bu_3SnH (433 mg; 1.49 mmol) in ether (30 ml) was refluxed for 30 h under nitrogen. After the solvent was evaporated, the residue was chromatographed on silica gel. Elution by hexane gave **7** (87 mg; 71%). (2) To a suspension of $LiAlH_4$ (75 mg; 1.97 mmol) in ether (10 ml) was added dropwise a solution of the dibromides (93 mg; 0.30 mmol) in ether (10 ml) and the mixture was stirred at room temperature for 24 h. After a small amount of saturated Na_2SO_4

aq was added to the mixture, the ether layer was separated by decantation and washed with brine, and dried (Na_2SO_4). Filtration followed by evaporation of the solvent gave **7** as a sole product (38 mg; 86%). (3) To a mixture of the dibromides (141 mg; 0.48 mmol), magnesium (35 mg; 1.46 mmol) in dry THF (5 ml) was added a few drops of methyl iodide. The reaction mixture was refluxed overnight under nitrogen, poured onto water, and extracted with ether. The extract was shown to contain only **7** by GLC analysis.

*Thermal Rearrangement of **9a**, **9b**, and **10a** to **10a** and **10b**.* Distillation of a mixture of **9a**, **9b**, and **10a** (1041 mg; 3.40 mmol) at 140—150 °C (533 Pa) by means of Kugelrohr gave **10a** and **10b** (903 mg; 87%) in a ratio of 2:5 (PMR analysis). When the mixture (450 mg) was heated at 150 °C for 3 h under atmospheric pressure and then distilled (140—150 °C/267 Pa), only **10b** was obtained (385 mg; 85%). *syn*-11,*exo*-2-Dibromotricyclo[4.3.1.$1^{3,8}$]undec-4-ene (**10b**): mp 123—1255 °C. MS *m/e* (rel intensity): 308, 306, 304 (M^+, 9, 16, 9), 227 (98), 225 (100), 145 (76). IR (KBr): 3025 (weak), 2925, 950, 730, 710, 670 cm^{-1}. PMR δ (CCl_4): 6.20 (1H, t, J=9.0 Hz), 5.70 (1H, t, J=9.0 Hz), 4.90 (1H, t, J=4.5 Hz), 4.67 (1H, s), 3.03 (1H, t, J=7.5 Hz), 2.90—1.40 (9H, br. complex m). CMR δ ($CDCl_3$): 140.5 (CH), 130.2 (CH), 58.6 (CH), 53.0 (CH), 49.6 (CH), 37.9 (CH), 37.5 (CH), 35.5 (CH_2), 32.4 (CH_2), 30.3 (CH), 27.3 (CH_2). Found: C, 43.43; H, 4.90%. Calcd for $C_{11}H_{14}Br_2$: C, 43.16; H, 4.61%. The following spectroscopic data for **10a** were deduced from those of the mixture of **10a** and **10b**. *syn*-11,*endo*-2-Dibromotricyclo[4.3.1.$1^{3,8}$]undec-4-ene (**10a**): PMR δ (CCl_4): 6.05 (2H, m), 4.55 (2H, s), 3.30—1.10 (10H, br. complex m). CMR δ ($CDCl_3$): 140.5 (CH), 132.1 (CH), 53.1 (2CH), 47.6 (CH), 38.1 ($2CH_2$), 35.5 (2CH), 30.3 (CH), 24.7 (CH_2).

syn-11, endo-*2- and* syn-*11*, exo-*2-Dibromotricyclo[4.3.1.$1^{3,8}$]-undecanes (**13a** and **13b**).* A mixture of **10a** and **10b** (915 mg; 2.99 mmol) and PtO_2 (40 mg) in methanol (50 ml) was vigorously stirred under hydrogen. After one equivalent of hydrogen had been absorbed, the catalyst was removed by filtration and the solvent was evaporated to give a crude mixture (886 mg), which was chromatographed on silica gel. Elution by hexane afforded **13b** (599 mg; 53%) and, subsequently, **13a** (240 mg; 26%). **13a**: mp 158—159 °C. MS *m/e* (rel intensity): 229, 227 (M^+—Br, 20, 20), 147 (100), 119 (42), 105 (33), 91 (51). IR (KBr): 2925, 1455, 1215, 1180, 940, 700 cm^{-1}. PMR δ (CCl_4): 4.17 (2H, s), 3.20—1.06 (14H, br. complex m). CMR δ ($CDCl_3$): 56.9 (2CH), 48.5 (CH), 36.8 ($2CH_2$), 35.6 (2CH), 31.9 (CH_2), 30.8 (CH_2), 29.6 (CH), 24.2 (CH_2). Found: C, 42.90; H, 5.18%. Calcd for $C_{11}H_{16}Br_2$: C, 42.88; H, 5.23%. **13b**: mp 162—163 °C. MS *m/e* (rel intensity): 229, 227 (M^+—Br, 29, 30), 147 (100), 119 (29), 91 (44). IR (KBr): 2925, 1455, 665 cm^{-1}. PMR δ (CCl_4): 5.10 (1H, t, J=4.2 Hz), 4.45 (1H, s), 2.93—1.15 (14H, br. complex m). CMR δ ($CDCl_3$): 62.9 (CH), 59.2 (CH), 49.4 (CH), 36.4 (CH), 35.7 (CH_2), 35.0 (CH), 33.8 (CH_2), 32.4 (CH_2), 32.2 (CH_2), 29.9 (CH), 27.8 (CH_2). Found: C, 42.95; H, 5.26%. Calcd for $C_{11}H_{16}Br_2$: C, 42.88; H, 5.23%.

*Reduction of **13a** or **13b** with Bu_3SnH.* A solution of **13b** (140 mg; 0.45 mmol) and Bu_3SnH (610 mg, 2.10 mmol) in benzene (10 ml) was refluxed under nitrogen for 3 h. The reaction mixture was washed with brine and dried (Na_2SO_4). After filtration, the solvent was evaporated to give a crude mixture, which was shown to contain only one hydrocarbon product by GLC analysis (PEG 20 M, 100 °C). The product was collected by preparative GLC and shown to be identical with authentic homoadamantane (tricyclo-[4.3.1.$1^{3,8}$]undecane) (**12**) in GLC retention time and PMR. The similar treatment of **13a** (68 mg; 0.22 mmol) with Bu_3SnH (175 mg; 0.60 mmol) to above also gave **12** as a sole product.

*2,11-Dehydrohomoadamantane (**1**).* A mixture of **13b** (596 mg; 1.94 mmol) and small pieces of lithium (458 mg; 65.00 mmol) in dry THF was stirred at room temperature under nitrogen for 3.5 h and poured onto ice-water. Organic materials were extracted with ether and washed with brine (three times), and dried (Na_2SO_4). After filtration, the solvent was evaporated to give **1** along with a slight amount of **12** (268 mg; 94%, **1**:**12**=15:1 by GLC analysis; PEG 20 M, 100 °C). The analytical sample was obtained by preparative GLC. Similarly, the reaction of **13a** (197 mg; 0.58 mmol) with lithium also afforded **1** and **12** in a ratio of 7:3 (70 mg; 81%). **1**: mp 124—127 °C. MS *m/e* (rel intensity): 148 (M^+, 27), 79 (100). IR (CCl_4): 3030, 2930, 1450 cm^{-1}. PMR δ (CCl_4): 3.00—1.05 (16H, br. complex m). CMR δ ($CDCl_3$): 54.0 (CH_2), 36.7 ($2CH_2$), 36.2 (CH_2), 34.7 (CH), 34.6 (2CH), 28.5 (CH), 28.4 (2CH), 23.6 (CH_2). Found: C, 88.89; H, 10.95%. Calcd for $C_{11}H_{16}$: C, 89.12; H, 10.88%.

*Hydrogenation of **1**.* A suspension of **1** (45 mg; 0.30 mmol) and Pd-black (25 mg) in ethyl acetate (4 ml) was vigorously stirred under hydrogen until **1** disappeared. After removal of the catalyst by filtration, the solvent was evaporated to give a mixture of 4-homoprotoadamantane (**15**) and **12** (36 mg; 78%) in a ratio of 7:1 (GLC analysis; PEG 20 M' 100 °C). Pure **15** was obtained by preparative GLC and shown to be identical with the authentic sample.[17]

*2,11-Dehydrohomoadamant-4-ene (**6**).* A mixture of **10b** (602 mg; 1.97 mmol) and small pieces of lithium (543 mg; 77.6 mmol) in dry THF (30 ml) was stirred for 20 h at room temperature under argon and poured onto ice-water. After filtration, organic materials were extracted with dichloromethane and washed with brine, and dried (Na_2SO_4). After filtration, the solvent was evaporated to give a mixture of three hydrocarbons, **6**, **7**, and **14** (230 mg; 80%), in a ratio of 9:3:1 (GLC analysis; PEG 20 M, 100 °C). Pure **6** (144 mg, 50%) was secured by preparative GLC. **6**: mp 109—110 °C. MS *m/e* (rel intensity): 146 (M^+, 52), 80 (100). IR (KBr): 3020, 2925, 2875, 1670, 1465, 1445, 1350, 1050, 960, 790, 750, 705 cm^{-1}. PMR δ (CCl_4): 5.97 (1H, d.d, J=10.5 and 8.0 Hz), 5.67 (1H, d, J=10.5 Hz), 2.90—1.20 (12H, br. complex m). CMR δ ($CDCl_3$): 139.6 (CH), 126.3 (CH), 54.4 (CH_2), 37.9 (2CH), 33.7 (CH), 30.8 ($2CH_2$), 29.7 (CH), 25.6 (2CH). Found: *m/e* 146.1098. Calcd for $C_{11}H_{14}$: M, 146.1095.

*Hydrogenation of **6** to **1**.* A suspension of **6** (20 mg; 0.13 mmol) and PtO_2 (2 mg) in methanol (2 ml) was vigorously stirred under hydrogen. After one equivalent of hydrogen was absorbed, the mixture was filtered and the solvent was evaporated to give almost pure **1** (13 mg; 64%).

We thank Dr. Ryusei Konaka of Shionogi Phamaceutical Co. Ltd., for obtaining the exact mass spectrum of **6**.

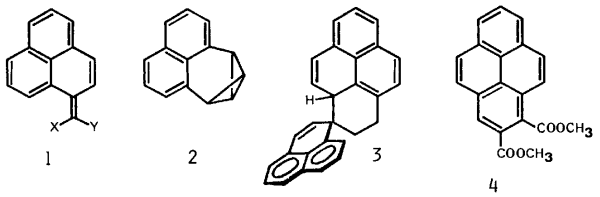
The Chemistry of Phenalenium Systems. XXXI.[1] The Synthesis, Dimerization, and Trapping of 6-Methylenebenzo[*cd*]pyrene

Osamu Hara, Kagetoshi Yamamoto, and Ichiro Murata*
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received December 6, 1979)

The acetolysis of 6-mesyloxymethyl-6*H*-benzo[*cd*]pyrene (**6**) gave 7,7a-dihydrospiro[benzo[*ghi*]perylene-5(6*H*),6′-[6*H*]benzo[*cd*]pyrene] (**13**), whereas, on formolysis, **6** gave spiro[benzo[*ghi*]perylene-5(6*H*),6′-[6*H*]benzo[*cd*]pyrene], 6-hydroxymethyl-6*H*-benzo[*cd*]pyrene, and 6-methyl-6*H*-benzo[*cd*]pyrene as well as **13**. It might reasonably be supposed that the formation of **13** proceeds in a process involving four steps: (i) the formation of the intermediate 6*H*-6-benzo[*cd*]pyren-6-ylmethyl cation (**8**); (ii) the conversion of **8** into the reactive 6-methylenebenzo[*cd*]pyrene (**5**) by the loss of a proton; (iii) the head-to-head self-Diels-Alder dimerization of **5** to the initial dimer, 6,7-dihydrospiro[benzo[*ghi*]perylene-5(4a*H*),6′-[6*H*]benzo[*cd*]pyrene], and (iv) a 1,3-hydrogen shift to form **13**. When 6-methylbenzo[*cd*]pyren-6-yl tetrafluoroborate (**7**) was treated with triethylamine in chloroform, the spiro-dimer, **13**, was also obtained. The reaction of **7** with triethylamine in the presence of dimethyl acetylenedicarboxylate resulted in the formation of dimethyl benzo[*ghi*]perylene-5,6-dicarboxylate. These results strongly suggest the intermediate formation of **5** as a reactive compound.

In connection with our current interest in the chemistry of phenafulvenes (1-methylenephenalene) (**1**)[2,3] we have recently reported the formation of the parent phenafulvene (**1**: X=Y=H) as a reactive intermediate through the transition-metal-promoted isomerization of naphtho[1,8]tricyclo[4.1.0.0^{2,7}]heptene (**2**).[4] The formation of (**1**: X=Y=H) in this reaction has been confirmed by the isolation of its dimer, **3**, and by means of a trapping experiment with dimethyl acetylenedicarboxylate to give dimethyl 1,2-pyrenedicarboxylate (**4**).[4]

In order to learn how the stability of the parent phenafulvene changes with the annelation of benzene rings, we have tried to synthesize 6-methylenebenzo[*cd*]pyrene (**5**) as a higher benzolog of **1**. By analogy with the parent phenafulvene, the compound **5** could not be isolated because of its pronounced reactivity. In the study reported herein, the synthesis of **5** as well as various types of evidence for the intermediate existence of **5** are reported.

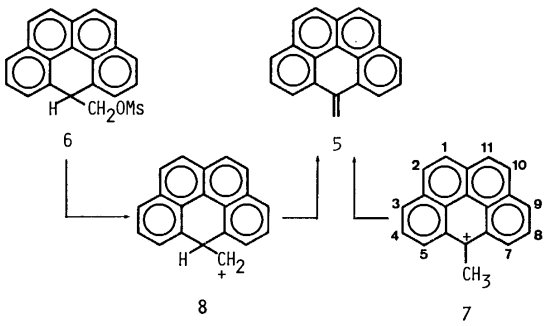


1 2 3 4

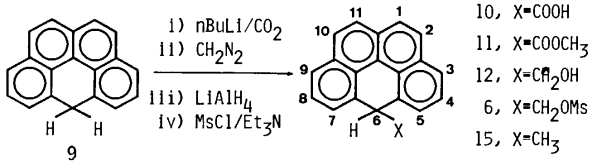
Results and Discussion

As is shown in Scheme 1, either the solvolysis of the mesylate **6**, or the proton abstraction of the 6-methylbenzo[*cd*]pyren-6-yl cation (**7**) appears to be an attractive route leading to **5**.

The synthesis of **6** was accomplished by the sequence of reactions shown in Scheme 2. The treatment of 6*H*-benzo[*cd*]pyrene (**9**) in tetrahydrofuran with butyllithium at −60 °C, followed by carboxylation with carbon dioxide, gave 6*H*-benzo[*cd*]pyrene-6-carboxylic acid (**10**) as the sole product. The exclusive formation of **10** is in good accordance with the highest Hückel charge density[6] at C-6 in the anion derived from **9**. The acid was converted into the methyl ester, **11**, with diazomethane under a nitrogen atmosphere,[7]



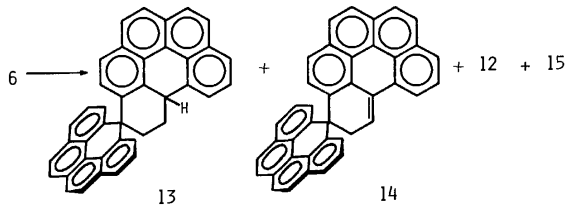
Scheme 1.



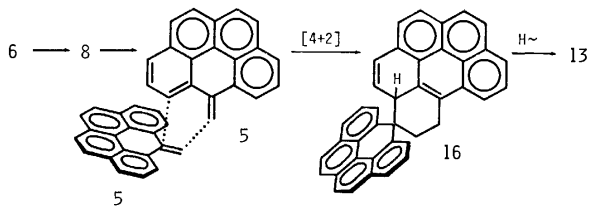
Scheme 2.

The ester, **11**, was reduced with lithium aluminium hydride to the alcohol, **12**, which, on treatment with mesyl chloride in the usual manner, then gave **6**.[8] The strucutres of **11**, **12**, and **6** were unambiguously confirmed by the respective spectroscopic properties given in the Experimental Section.

The acetolysis of **6** in gently refluxing glacial acetic acid led to 7,7a-dihydrospiro[benzo[*ghi*]perylene-5(6*H*),6′-[6*H*]benzo[*cd*]pyrene] (**13**), a dimer of the desired **5**, in a 50% yield, whereas the formolysis of **6** at 50 °C gave **13** in only a 15% yield, along with a trace amount of the corresponding dehydrogenated dimer, spiro[benzo[*ghi*]perylene-5(6*H*),6′-[6*H*]benzo[*cd*]pyrene] (**14**), in addition to **12** (26%) and 6-methyl-6*H*-benzo[*cd*]pyrene (**15**), as is shown in Scheme 3. On the other hand, the formolysis of **6** at 80 °C gave **14** (15%), along with **12** and **15**, in yields similar to those of the above experiment. The elemental analysis and the molecular-weight determination of **13** clearly indicated it to be a dimer of **5**. The final structural proof of **13** was obtained from its ^{1}H-NMR spectrum, which showed one proton triplet at δ 5.01 (H-7a, J= 7.5 Hz), a four-proton multiplet at δ 2.38—2.68, and



Scheme 3.



Scheme 4.

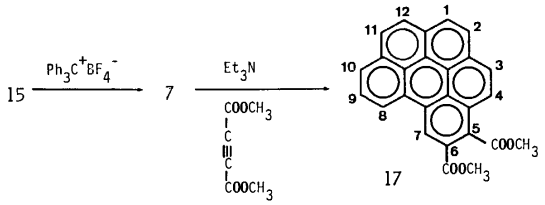
aromatic-proton multiplets at δ 7.00—7.94. The relation between the adjacent protons in the alicyclic moiety was confirmed by the aid of spin-decoupling experiments. Irradiation at about δ 2.6 changed the broad triplet at 5.01 into a broad singlet; conversely, irradiation at 5.01 changed the multiplet at 2.38—2.68 into the pseudo-symmetrical pattern of an AA'-BB'-like system. Furthermore, the electronic spectrum of **13** is very similar to that of **15**, indicating the existence of a benzo[*a*]phenanthrene chromophore in **13**. Although attempts to make an elemental analysis and mass-spectral measurement of **14** were unsuccessful because of its pronounced sensitivity to heat and air, the structure of **14** was established by means of the ^{1}H-NMR and electronic spectra and chemical evidence. The ^{1}H-NMR spectrum of **14** showed signals at δ 3.18 (H-6,6, d, 2H, J=5.0 Hz), 6.47 (H-7, t, 1H, J=5.0 Hz), and 7.03—7.93 (m, 19H). On the irradiation of the signals at δ 6.47, the doublet at δ 3.18 was converted into a clean singlet. A comparison of the electronic spectrum of **14** with that of **13** reflects the bathochromic shift anticipated for the introduction of an exo methylene double bond into the 6*H*-benzo[*cd*]pyrene π-system. An examination of the spectra of several 6-methylenebenzo[*cd*]pyrene derivatives[9] has shown the existence of the same chromophore in **14**. Furthermore, **14** could easily be obtained from **13** by treatment with iodine in benzene. The structure of **15** was established through an independent synthesis (*vide infra*).

The difference in the product distributions between the acetolysis and the formolysis of **6** was explained by the fact that formic acid, as is generally known, gradually decomposes into water and carbon monoxide, even at room temperature.[10] Thus, the intermediate carbonium ion, **8**, partly collapsed into an alcohol, **12**, upon the nucleophilic attack of water. The formation of **15** was closely parallel to the precedent in which triphenylmethanol is reduced to triphenylmethane by formic acid.[11]

A possible explanation for the formation of **13** from **6** might be that the reaction proceeds in a process involving four steps: (i) the initial formation of the intermediate carbonium ion, **8**; (ii) the conversion of **8** into the reactive hydrocarbon, **5**, by the loss of the proton; (iii) the head-to-head self-Diels-Alder dimerization of **5** to the initial dimer, **16**, and (iv) a 1,3-hydrogen shift to form the observed dimer, **13** (Scheme 4). The ease of the hydrogen shift in the final step may be attributed to the difference in π-energy between the 1-vinylpyrene and benzo[*a*]phenanthrene π-moieties in **16** and **13** respectively.[12]

The second synthetic route, which consists of proton abstraction from the 6-methylbenzo[*cd*]pyren-6-yl cation, **7**, would be a more favorable synthetic method for the labile **5**. To this end, 6-methyl-6*H*-benzo[*cd*]pyrene, **15**, readily accessible from **9** through lithiation with butyllithium, followed by methylation with excess methyl iodide, was treated with trityl tetrafluoroborate in chloroform to give a 83% yield of **7**. The structure of **7** was evident from its ^{1}H-NMR spectrum in trifluoroacetic acid, which exhibited signals at δ 3.87 (s, $-CH_3$), 8.33 (d, J=8.6 Hz, H-1,11), 8.57 (d, J=8.6 Hz, H-2,10), 8.41 (dd, J=7.0, 6.5 Hz, H-4,8), 9.12 (d, J=6.5 Hz, H-3,9), and 9.51 (d, J=7.0 Hz, H-5,7).

When the cation, **7**, was treated with triethylamine in chloroform at 0 °C, the spiro dimer, **13**, was obtained in a 42% yield. On the other hand, when the reaction was carried out at −10——15 °C, which is the practical lower limit for the reaction, the only product obtained was **13**, and no hydrocarbon corresponding to **5** could be detected by TLC monitoring. The formation of **13** even at low temperatures, suggested the pronounced reactivity of the initial product, **5**, for the self-Diels-Alder reaction as both 4π and 2π components. In order to confirm the transient existence of **5**, we carried out a trapping experiment. The reaction of **7** with triethylamine in chloroform in the presence of two mole equivalents of dimethyl acetylenedicarboxylate at 0 °C resulted in the formation of the product in a 20% isolated yield; to this product we assigned the structure of dimethyl 5,6-benzo[*ghi*]perylenedicarboxylate (**17**) on the basis of its mass spectrum [*m/e* 392 (M^+, 100%), 361 (M^+-OCH_3, 28%), 274 ($M^+-2COOCH_3$, 28%)], ^{1}H-NMR spectrum [δ 4.10 (s, $-OCH_3$), 4.17 (s, $-OCH_3$), 8.92 (dd, $J_{8,9}$=7.5 Hz, $J_{8,10}$=1.5 Hz, H-8), 9.41 (s, H-7), 7.87—8.28 (m, other aromatic protons)] and its electronic spectrum, which is closely similar to that of the parent benzo[*ghi*]perylene.[13]



Scheme 5.

In conclusion, as in the case of the parent phenafulvene **1**: X=Y=H, all attempts to isolate 6-methylenebenzo[*cd*]pyrene **5** have thus far been unsuccessful, though it can be generated and trapped. Although it is well documented that nonalternant fulvenes, such

as tria-,[14] penta-,[15] and hepta-fulvenes,[16] belong to an extremely reactive group of substances, unsubstituted *exo*-cyclic methylene compounds with odd-alternant polycyclic benzenoid moieties, *e.g.*, **1** and **5**, also not have enough stability to permit isolation.[17]

Experimental

All the melting points were determined on a micro hot stage and are uncorrected. The mass spectra were obtained on a Hitachi RM-50 spectrometer operating at 20 or 70 eV. The electronic spectra were taken on a Hitachi 124 double-beam spectrometer. The NMR spectra were recorded with a Varian XL-100 (100 MHz) spectrometer and are given in δ-values with respect to tetramethylsilane as the internal standard.

6-Methoxycarbonyl-6H-benzo[cd]*pyrene (**11**).* To a stirred solution of 6*H*-benzo[*cd*]pyrene (**9**) (4.2 g, 175 mmol) in 30 ml of dry THF, we added a hexane solution containing 17.5 mmol of butyllithium at −60 °C under nitrogen. The mixture was then stirred for 30 min at this temperature, and dry carbon dioxide gas was bubbled through the solution. The resulting mixture was warmed to 0 °C with a continuous bubbling of carbon dioxide. After having been acidified with dil hydrochloric acid, the reaction mixture was extracted with ether. The ether layer was washed with water and extracted with a saturated aqueous solution of sodium hydrogencarbonate. After having been washed with ether, the aqueous layer was acidified with concd hydrochloric acid to give colorless precipitates which, after filtration and methylation with diazomethane under nitrogen, yielded a crude ester, **11**. The product was chromatographed on alumina, eluted with hexane–benzene (1:1), and recrystallized from hexane–benzene to give pure **11** as pale yellow needles; mp 149—150 °C. MS: *m/e* 298 (M^+, 12%), 239 ($M^+-COOCH_3$, 100%); IR (KBr): 1725 cm^{-1}; NMR ($CDCl_3$): 3.51 (s, 3H, $-CH_3$), 5.81 (bs, 1H, H-6), 7.41—7.81 (m, 10H, other protons).

Found: C, 84.32; H, 4.72%. Calcd for $C_{21}H_{40}O_2$: C, 84.54; H, 4.73%.

6-Hydroxymethyl-6H-benzo[cd]*pyrene (**12**).* A solution of **11** (1.19 g, 4.0 mmol) in 120 ml of dry ether was added, drop by drop, to a suspension of lithium aluminium hydride (152 mg) in 20 ml of dry ether at −20 °C over a 2-h period under nitrogen. After stirring for 3 h at this temperature, the reaction mixture was quenched with ether saturated with water and extracted with benzene. The combined organic layer was washed successively with dil hydrochloric acid, an aqueous solution of sodium hydrogencarbonate, and water, dried (Na_2SO_4), and evaporated under reduced pressure. The residue was recrystallized from hexane–benzene (2:3) under nitrogen to give 870 mg (80%) of **12** as brown prisms; mp 119.5—122 °C. MS: *m/e* 270 (M^+, 3.2%), 239 (M^+-CH_2OH, 100%); NMR ($CDCl_3$): 1.6 (bs, 1H, -OH), 3.60 (d, 2H, J=6.5 Hz, $-CH_2-O$), 4.67 (t, 1H, J=6.5 Hz, H-6), 7.49—7.91 (m, 10H, aromatic protons).

Found: C, 89.15; H, 5.39%. Calcd for $C_{20}H_{14}$: C, 88.86; H, 5.22%.

6-Mesyloxymethyl-6H-benzo[cd]*pyrene (**6**).* To a stirred solution of **12** (270 mg, 1.0 mmol) in 6 ml of dry dichloromethane containing 1.6 mmol of triethylamine, we added, drop by drop, 1.3 mmol of methanesulfonyl chloride in 7 ml of dry dichloromethane at −10 °C over a 30-min period under nitrogen. After stirring for 2 h at this temperature, the solution was poured into ice water and the layers were separated. The organic layer and the combined dichloromethane extracts were washed successively with cold dil hydrochloric acid, an aqueous solution of sodium hydrogencarbonate, and water, and then dried ($MgSO_4$). The solvent was evaporated under reduced pressure, leaving 277 mg (80%) of crude **6**, which was subsequently dissolved in 5 ml of dichloromethane and 5 ml of hexane at the ambient temperature under nitrogen, while the solution was concentrated to a volume of 4 ml. The solution was cooled gradually to −40 °C, giving 172 mg of the analytically pure **6** as pale yellow needles; mp 120—122 °C. MS: *m/e* 348 (M^+, 3%), 252 (M^+-OMs, 33%), 239 (M^+-CH_2OMs, 100%); NMR ($CDCl_3$): 2.39 (s, 3H, $-SO_2CH_3$), 4.28 (d, 2H, J=6.5 Hz, $-CH_2-SO_2-$), 5.04 (bt, 1H, J=6.5 Hz, H-6), 7.57—7.97 (m, 10H, aromatic protons).

Found: C, 72.13; H, 4.61; S, 9.05%. Calcd for $C_{21}H_{16}O_3S$: C, 72.39; H, 4.63; S, 9.20%.

*Acetolysis of **6**.* A solution of **6** (140 mg, 0.4 mmol) in 15 ml of dry acetic acid, containing 96 mg of anhydrous sodium dihydrogenphosphate as a buffer, was refluxed for 1 h under nitrogen. The reaction mixture was then poured into water and extracted with benzene. The extracts were washed with an aqueous solution of sodium hydrogencarbonate and water, and then dried, and the solvent was removed under reduced pressure. The residue was chromatographed on alumina containing 3% of water, eluting with hexane–benzene (9:1), to give 50 mg (50%) of the spiro-dimer, **13**, as pale yellow crystals; mp 158—162 °C (dec). MS: *m/e* 504 (M^+, 25%), 276 (benzo[*ghi*]perylene ion, 100%); UV λ_{max} nm (log ε) (hexane): 219 (4.74), 233 (4.63), 249 (4.19), 256 (4.24), 258 sh (4.22), 262 sh (4.43), 282 (4.67), 293 (4.63), 323 (4.13), 338 (4.00); NMR: see text.

Found: C, 94.98; H, 4.73%. Calcd for $C_{40}H_{20}$: C, 95.21; H, 4.79%.

*Formolysis of **6**.* A solution of **6** (140 mg, 0.4 mmol) in 14 ml of 99% formic acid containing 96 mg of anhydrous sodium dihydrogenphosphate was heated to 40—50 °C over a 4-h period under nitrogen. After workup in the same manner as the acetolysis just described, the crude products were chromatographed on alumina containing 3% of water, eluting gradually with hexane, hexane–benzene (9:1), and benzene. The solvent of each fraction was then evaporated, leaving 4 mg of **15**, 15 mg (15%) of **13**, and 26 mg (26%) of **12**. The structures of **12** and **15** were confirmed from the NMR spectra to be identical with those of the respective authentic compounds.

*Formolysis of **6** at High Temperatures.* A solution of **6** (140 mg, 0.4 mmol) in 14 ml of 99% formic acid containing 96 mg of anhydrous sodium dihydrogenphosphate was heated from room temperature to 80 °C over a 15-min period and then maintained at this temperature for 10 min under nitrogen. The solution was subsequently worked up, and the products were separated by the same procedures as above to give 8 mg of **15**, 15 mg (15%) of the dehydro spiro-dimer, **14**, as yellow crystals, and 23 mg (23%) of **12**. The dimer **14** is gradually decomposed around 80 °C. UV λ_{max} nm (log ε) (hexane): 216 (4.96), 232 (4.82), 265 sh (4.61), 279 (4.66), 320 (4.44), 334 (4.47), 390 (3.91), 413 (3.92); NMR: see text.

*Dehydrogenation of **13**.* A solution of 55 mg (0.11 mmol) of the spiro-dimer, **13**, in 6 ml of benzene was treated with 38 mg (0.3 mmol) of iodine at room temperature for 30 min under nitrogen. The products were chromatographed on alumina containing 2.5% of water, eluting with benzene, and again on the same deactivated alumina with hexane–benzene (9:1), to give 20 mg (45%) of pure **14**, which was identical in every respect with the authentic sample.

6-Methyl-6H-benzo[cd]*pyrene (**15**).* To a stirred solu-

tion of 6*H*-benzo[*cd*]pyrene (**9**) (1.56 g, 6.5 mmol) in 70 ml of dry THF, we added 6.5 mmol of butyllithium in hexane at −60 °C under nitrogen. After having been stirred for 30 min at this temperature, the reaction mixture was quenched by the addition of a large excess of methyl iodide. The mixture was stirred for 1 h at −50 °C, warmed to room temperature, and extracted with benzene. The extracts were washed successively with 2 mol dm^{-3} hydrochloric acid, a saturated aqueous solution of sodium hydrogencarbonate, and water, dried ($MgSO_4$), and evaporated. The residue was chromatographed on alumina with hexane–benzene (1:1). The solvent was evaporated, leaving a yellow solid which was recrystallized from cyclohexane under nitrogen to give pure **15** (1.51 g, 92%) as yellow crystals; mp 122—124 °C. MS: *m/e* 254 (M^+, 17%), 239 (M^+-CH_3, 100%); UV λ_{max} nm (log ε) (hexane): 268.5 (4.39), 278 (4.64), 289 (4.75), 312 (3.95), 325 (3.97), 338 (3.77); NMR: see text.

Found: C, 94.24; H, 5.55%. Calcd for $C_{20}H_{14}$: C, 94.45; H, 5.55%.

6-Methylbenzo[cd]*pyren-6-yl Tetrafluoroborate (7).* To a stirred solution of **15** (1.5 g, 6.0 mmol) in 40 ml of dry chloroform, we added finely powdered trityl tetrafluoroborate (2.05 g, 6.5 mmol) at room temperature. Black solids precipitated at once, after which the mixture was warmed at 50 °C for 2 h. After cooling, the black solid mass was collected by filtration and washed several times with dry chloroform in a dry box. The product was dried *in vacuo* to give 1.7 g (83%) of **7**; mp >350 °C. NMR: see text.

Dimerization of 6-Methylenebenzo[cd]*pyrene (5).* To a suspension of the cation, **7** (340 mg, 1.0 mmol), in 20 ml of dry chloroform, we added, drop by drop, 150 mg (3.0 mmol) of dry triethylamine in 5 ml of dry chloroform at 0 °C over a 15-min period under nitrogen. After stirring for an additional hour, the reaction mixture was poured into 2 mol dm^{-3} hydrochloric acid and the organic layer was washed successively with an aqueous solution of sodium hydrogencarbonate and water, dried ($MgSO_4$), and evaporated at reduced pressure to give a residue which was subsequently chromatographed on alumina containing 2.5% of water with hexane–benzene (9:1) to give 105 mg (42%) of the pure dimer, **13**, as pale yellow crystals, which were identical in every respect with the product of the acetolysis of **6**.

Trapping of 5 by Dimethyl Acetylenedicarboxylate. To a suspension of **7** (170 mg, 0.5 mmol) in 15 ml of dry chloroform containing dimethyl acetylenedicarboxylate (120 mg, 1.0 mmol), we added, drop by drop, triethylamine (75 mg, 1.50 mmol) in 10 ml of dry chloroform at room temperature under nitrogen. After additional stirring for 3 h, the reaction mixture was poured into water. The organic layer was washed successively with water, 2 mol dm^{-3} hydrochloric acid, an aqueous solution of sodium hydrogencarbonate, and water, dried ($MgSO_4$), and evaporated. The residue was chromatographed on alumina with benzene to give 39 mg (20%) of crude **17**. Pure **17** was obtained by recrystallization from hexane–benzene as reddish brown crystals; mp 239—240 °C. IR (KBr): 1725 cm^{-1}; MS and NMR: see text.

Found: C, 80.10; H, 4.19%. Calcd for $C_{26}H_{16}O_4$: C, 79.58; H, 4.11%.

Electrochemical Generation of Unstable Nitrogen Species. Part 4.[1] Electrochemical and Chemical Oxidation of Cyclic and Open-chain Diamines. The Formation of Cyclic Hydrazine Derivatives

Toshio FUCHIGAMI,* Tomoyasu IWAOKA, Tsutomu NONAKA, and Taro SEKINE

Department of Electronic Chemistry, The Graduate School at Nagatsuta, Tokyo Institute of Technology, Nagatsuta-machi, Midori-ku, Yokohama 227

(Received December 7, 1979)

Intramolecular N,N-coupling by the electrochemical oxidation of cyclic and open-chain diamines such as 3,3,7,7-tetraethylperhydro-1,5-diazocine (**1**) and *N,N*-dimethyl-2,2-diethyl-1,3-diaminopropane (**2**) was investigated with the use of platinum, silver, nickel, and carbon anodes. In the case of **1**, cyclic hydrazine derivatives, 3,3,7,7-tetraethyl-1,5-diazabicyclo[3.3.0]octane and 1-(2-ethyl-2-formylbutyl)-4,4-diethyl-4,5-dihydropyrazole, were formed in high current efficiency. In the case of **2**, the corresponding hydrazines, 1,2-dimethyl-4,4-diethylpyrazolidine and 1-methyl-3,3-diethyl-4,5-dihydropyrazole, were obtained in low current efficiency, because C–N bond cleavage took place before N,N-coupling. A carbon anode was found to be effective for N,N-coupling of such diamines. Chemical oxidative N,N-coupling of **1** and **2** was studied by using sodium peroxodisulfate and lead tetraacetate.

A number of studies have been carried out on the electrochemical oxidation of amines from both electrochemical and organic synthetic viewpoints.[2] However, only a few papers deal with electrooxidative N,N-coupling reaction. N,N-Coupling is known only in the case of aromatic amines,[3–6] *e.g.*, the formation of azobenzenes from aniline derivatives.

The initial electrode process of the oxidation of amines is supposed to be one electron transfer from a lone pair of electrons of a nitrogen atom to form a cation radical. In the case of aromatic amines, the life time of the cation radical intermediate thus produced is so long that it can give rise to various intermolecular coupling products.

In the case of aliphatic amines, the cation radical and radical intermediate is so unstable that N,N-coupling is difficult, C–N bond cleavage and/or nucleophilic substitution on an α-carbon supposedly taking place. In their work dealing with anodic N,N-coupling of aliphatic amines, Blackham *et al.*[7] found that 2,2′-dimethyl-2,2′-azopropane and 2,2′-dimethyl-2,2′-azoxypropane, with a total current efficiency 46%, are formed from *t*-butylamine. Recently, Bauer and Wendt[8] and Fuchigami *et al.*[9] found that secondary amines such as dibutylamine and piperidine give the corresponding hydrazine compounds in current efficiency lower than 50%.

In the case of chemical oxidation, no paper dealing with N,N-coupling of aliphatic amines seems to have appeared except for the formation of 1,1′-bipiperidines from piperidines reported by Nomura *et al.*[10]

We have investigated the intramolecular oxidative N,N-coupling of a cyclic diamine and an open-chain diamine such as **1** and **2**. Intramolecular N,N-coupling seems to occur more easily than intermolecular coupling, since reaction sites in the intramolecular N,N-coupling would be closer to each other. Neither electrochemical nor chemical oxidation of such aliphatic diamines seems to have been carried out so far. The chemical oxidative N,N-coupling of **1** and **2** was studied by using sodium peroxodisulfate and lead tetraacetate as an oxidizing reagent.

Results and Discussion

Electrochemical Oxidation of 1 and 2. Electrolysis of **1** was carried out in acetonitrile at a constant potential using various anode materials. In order to prevent **1** from becoming inert to oxidation due to the formation of salt during the course of electrolysis,

TABLE 1. RESULTS OF THE ELECTROCHEMICAL OXIDATION OF 3,3,7,7-TETRAETHYLPERHYDRO-1,5-DIAZOCINE (**1**)

Entry	Anode material	Anode potential (V *vs.* SCE)	Temp °C	Molar ratio of LiOH/**1**	Amount of electricity ($\times 10^4$ C/mol)	Yields of products[a] **3**	Yields of products[a] **4**	Recovery of **1** %

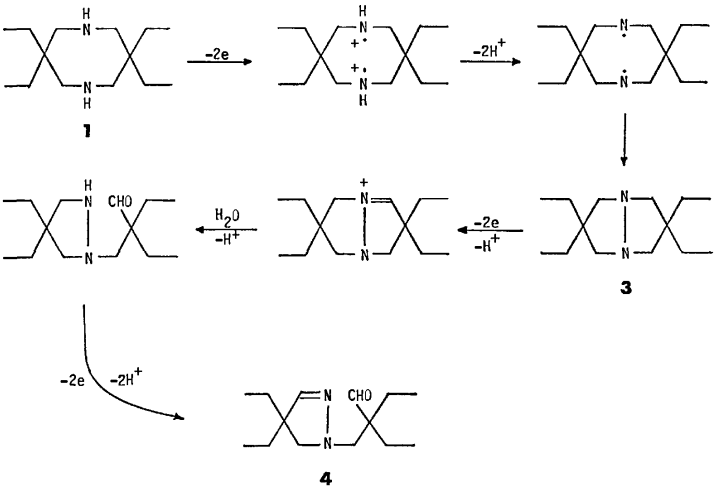
a) Values in parentheses show current efficiency (%). b) Electrolysis of **3**. c) Recovery of **3**.



Scheme 1.

lithium hydroxide powder was suspended in the anolyte. The electrolytic conditions and results are summarized in Table 1.

Two products were detected by gas chromatography. One was identified as 3,3,7,7-tetraethyl-1,5-diazabicyclo[3.3.0]octane (**3**) by comparison of the mass fragmentation† and retention time with those of an authentic sample synthesized separately.[11] The other, isolated by column chromatography on almina with dichloromethane, was identified as 1-(2-ethyl-2-formylbutyl)-4,4-diethyl-4,5-dihydropyrazole (**4**), its structure being confirmed by the following results:

a) The compound shows a positive Tollens test.

b) In the IR spectrum, the characteristic strong absorption of a carbonyl group was observed at 1740 cm^{-1}.

c) In the NMR spectrum measured in CCl_4 with TMS as the internal standard, the characteristic signal of an aldehydic proton was observed at 9.30 ppm, the other signals being explained in terms of the structure of **4**.

d) In the mass spectrum, the molecular ion (*m/e* 238) was observed together with appropriate fragment peaks such as *m/e* 209 (M^+-CHO and/or M^+-Et) and 139 (M^+-Et_2CCHO).

e) The results of elemental analyses of the free base and the 2,4-dinitrophenylhydrazone of **4** agree with the calculated values within normal errors.

The compound thus isolated is neutral colorless oily material; such a 1-substituted dihydropyrazole derivative is unknown so far.

As shown in Table 1, N,N-coupling products were formed as expected, their current efficiency being generally good.

In the case of a platinum anode, both **3** and **4** were formed in approximately equal yields. A change in the anode potential caused no appreciable change in yield. However, the total current efficiency changed with anode potential and electrolytic temperature. N,N-Coupling proceeded efficiently at lower temperature. In the absence of lithium hydroxide, the current decreased more rapidly than in its presence, the yield of **3** being reduced to about one half, while that of **4** increased. The reason for this has not been clarified yet. In the presence of 10 equivalents of lithium hydroxide, *ca.* 193000 C/mol of electricity was consumed and the ratio of **4**/**3** doubled, suggesting that the more the electricity passes, the higher the yield of **4**. Carbon and nickel anodes gave **3** in slightly higher yields than **4**.

The electrochemical oxidation of **1** proceeded at extremely low potentials in the cases of carbon and silver anodes, the latter giving only **4**, though the current efficiency was relatively low. In the case of a silver anode, the initial electrochemical reaction gives an oxide coating on the electrode surface. This seems to effect the oxidation of **1**. The low current efficiency of **4** in the case of the silver anode can be attributed to the formation of silver oxide, since the corrosion of the silver anode surface was observed during the course of electrolysis. Hampson *et al.*[12–14] also found that platinum and silver anodes give different products in the oxidation of aliphatic monoamines in an alkaline solution. A nickel anode[15] behaves like a silver one, but no such tendency was observed in the present work.

Since **3** can be oxidized at a lower potential than **1**†† and **4** is formed by electrochemical oxidation of **3**, **4** seems to be formed by further oxidation of **3** produced in the course of the electrochemical oxidation of **1**.

Formation of **3** and **4** might proceed as shown in Scheme 1.

Intramolecular N,N-coupling of the open-chain diamine (**2**) was investigated. Electrochemical oxidation of **2** was carried out at a constant potential in 1 M NaOH solution instead of acetonitrile in the case of **1**, since the anode was passivated in the acetonitrile solution.

Three basic products were detected in the electrolyte by gas chromatography. 1,2-Dimethyl-4,4-diethyl-

† The mass spectrum of **3** was measured with a gas chromatograph-mass spectrometer.

†† This was shown by current density *vs.* anode potential curves of **1** and **3**. Such bicyclic diamines have extremely low oxidation potentials.[16]

pyrazolidine (**5**) was identified to be the authentic sample synthesized separately by gas chromatography and mass spectrometry. 1-Methyl-3,3-diethyl-4,5-dihydropyrazole (**6**) and 1,3-dimethyl-5,5-diethylperhydropyrimidine (**7**) were isolated by column chromatography and preparative gas chromatography, respectively. Their structures were confirmed by means of elemental analyses and spectral studies.

Table 2. NMR spectral data

	Compound	NMR (δ ppm)[a]
1		0.80 (12H, t, H^a, H^c, H^l, H^n) 1.20 (8H, q, H^b, H^d, H^k, H^m) 1.75 (2H, s, H^g, H^h) 2.53 (s) and 3.36 (s) (8H, H^e, H^f, H^i, H^j)

a) Measured in CCl_4 with TMS as an internal standard. s: Singlet, t: triplet, q: qartet, m: multiplet.

In the NMR spectrum of **6**, the characteristic signal of an imino proton was observed at a low magnetic field such as 6.25 ppm; in that of **7**, the signal of N–H protons disappeared and that of singlet methylene protons appeared newly at 2.62 ppm. The compound was further identified by a mixed-melting-point test with a sample prepared from **2** and formaldehyde in an alkaline solution.

The basic products obtained are new. Their NMR spectral data together with those of the starting diamines, **1** and **2**, are summarized in Table 2.

When a large amount of electricity was passed in the electrolysis, a large amount of acidic substances were formed in addition to the basic products, but their structures could not be established.

The results of electrolysis of **2** are summarized in Table 3.

The N,N-coupling product, **5**, expected in this reaction, was scarcely formed; it was detected in a very small amount only in the case of using a carbon anode. In addition to **5**, a highly oxidized product, **6**, having a N–N bond was formed in a low yield. **6** was formed at the highest current efficiency 16% at a carbon anode, but scarcely formed at all at platinum and silver anodes. **7** was formed in a considerable yield at anodes other than nickel.

2 as well as **1** can be oxidized at a low potential at a carbon anode.

Since the oxidation of **5** was much easier than that of **2** (Fig. 1)††† and **6** was also formed by electrochem-

††† At a carbon anode, a negative shift of current *vs.* potential curve was induced in the presence of diamine, **2** (Fig. 1), no shift being observed at a platinum anode. Such a tendency was also observed in the case of **1**.

ical oxidation of **5** at a lower potential than the oxidation potential of **2**, **6** seems to be formed by further oxidation of **5** produced in the course of the electrochemical oxidation of **2**. Since **7** was formed in a good yield by the reaction of **2** with excess formaldehyde under the same conditions as the electrolysis of **2**, **7** seems to be formed by the reaction of **2** with formaldehyde produced in the course of the electrolysis.

From the results and the formation of 1-methyl-4,4-diethylpyrazolidine (**8**),†††† detected by a gas chromatography-mass spectrometer, electrochemical oxidation of **2** might proceed as in Scheme 2.

Chemical Oxidation of 1 and 2. Nomura *et al.* found that sodium peroxodisulfate is effective for N,N-coupling of piperidines in the presence of silver ions.[10] We investigated chemical oxidation of **1** and **2** with sodium peroxodisulfate and also lead tetraacetate in order to compare the results with those of electrochemical oxidation. The results are summarized in Table 4.

In the oxidation of **1** with sodium peroxodisulfate, the reaction stopped at the initial step of N,N-coupling, **3** being formed as the sole product. On the other hand, oxidation with lead tetraacetate afforded a highly oxidized product, **4**, far exceeding **3** in amount, though one equivalent of the oxidation reagent was employed. **4** was also formed in an excellent yield with use of three equivalents of the reagent.

In the oxidation of **2** with sodium peroxodisulfate, **5**, which could scarcely be obtained by electrolysis, was formed in *ca.* 10% yield. However, the highly oxidized product **6** was formed in a greater amount than **5**, though a large amount of the starting material remained. In the case of an open-chain diamine such as **2**, the oxidation reaction did not stop at the initial step of N,N-coupling, differing entirely from that of a cyclic diamine such as **1**. In the oxidation using lead tetraacetate, the analysis of products was difficult because of the formation of a large amount of polymer. Daniels and Martin[17] found that *N,N'*-

—●—: 1 M NaOH (50 ml), —■—: 1 M NaOH (50 ml)+**2** (1 mmol), —▲—: 1 M NaOH (50 ml)+**5** (1 mmol).

†††† Its structure was tentatively determined by a study of the MS fragmentation: *m/e* 142 (M^+), 127 (M^+—Me), 126 (M^+—Me—H), 113 (M^+—Et).

Table 5. Efficiencies of electrochemical and chemical oxidative N,N-coupling

Anode material or oxidizing reagent	Efficiency of N,N-coupling (Current efficiency or yield %)		
			C	94	16	low
Pt	99	4	low
Ag	67	3	low
Ni	84	0	0
$Na_2S_2O_8/Ag^+$ (1 eq.)	46	25	61[10]
$Pb(OAc)_4$ (1 eq.)	29	—	5

diakyl-1,3-propanediamines affords only unchanged diamines, though the *N,N'*-diaryl derivatives give N,N-coupling products by the oxidation using manganese dioxide.

Comparison of Electrochemical and Chemical Oxidation. Efficiencies of electrochemical and chemical oxidative N,N-coupling of **1** and **2** together with piperidine[10] are summarized in Table 5.

A precise comparison of N,N-coupling efficiencies can not be made because of different reaction conditions. However, points to be noted are as follows. The intramolecular N,N-coupling took place more easily in electrochemical oxidation than in intermolecular oxidation. In the former reaction, N,N-coupling of the cyclic diamine proceeded more readily than that of the open-chain diamine. In the case of the cyclic diamine, current efficiency of the N,N-coupling was good, regardless of anode material. In the case of the open-chain diamine, efficiency changes a great deal with anode material, a carbon anode being most effective for N,N-coupling. A nickel anode was very effective for the oxidation of **1**, but not for **2** and piperidine.

In contrast, the structures of amines did not cause such a large difference in the results in chemical oxidation. Selectivities for the oxidation products differ a great deal in chemical and electrochemical oxidation; *e.g.*, **3** and **4** were formed in higher selectivity by oxidation with sodium peroxodisulfate and lead tetraacetate, respectively, than that in the electrochemical oxidation, selectivity for **7** being higher in the electrochemical oxidation.

Experimental

Materials. 3,3,7,7-Tetraethylperhydro-1,5-diazocine (1) and 3,3,7,7-Tetraethyl-1,5-diazabicyclo[3.3.0]octane (3): **1** and **3** were prepared according to a modification of Kemp's procedure.[11] To a stirred solution of 3,3,7,7-tetraethylperhydro-1,5-diazocine-2,4,6,8-tetrone (0.097 mol) in dry THF was gradually added a solution of diborane hexahydride (0.36 mol) in THF at 0—5 °C. Stirring was carried out at 0—5 °C for 1 h and then at room temperature for 1 h. The mixture was refluxed for 24 h. After cooling, 3 M HCl (1 M=1 mol·dm^{-3}) (200 ml) was added and THF was removed under reduced pressure. The residual solution was refluxed for 1 h. After cooling, the solution was made alkaline and was extracted repeatedly with ether. The extracts were dried over Na_2SO_4 and filtered. Hydrogen chloride gas was passed through the ether solution and the precipitates were collected by filtration. The crystals were treated with methanol at room temperature and insoluble parts were collected by filtration. Recrystallization of the matter from methanol–water (9:1, vol. ratio) gave pure hydrochloride of **1**: mp 231—233 °C (Ref.[11] 219—220 °C). From this salt, the free base of **1** was obtained by treatment with sodium hydroxide and extraction with ether: Yield 36%; mp 31—31.5 °C; *m/e* 226 (M^+). Found: C, 73.78; H, 13.67; N, 12.14%. Calcd for $C_{14}H_{30}N_2$: C, 74.27; H, 13.36; N, 12.37%. The methanolic solution of the filtrate was concentrated to dryness under reduced pressure. The residue was mixed with aqueous sodium hydroxide solution and the solution then extracted with ether. After drying of the ethereal extracts and concentration under reduced pressure, the residual oily substance was distilled under reduced pressure to give a fraction (**3**): Yield 7%, bp 115—116 °C/3 Torr; *m/e* 224 (M^+).

N,N'-Dimethyl-2,2-diethyl-1,3-propanediamine (2): The compound was prepared as a dihydrochloride by reduction of *N,N'*-dimethyl-α,α-diethylmalonamide with diborane by a procedure approximately the same as in the preparation of **1**. Recrystallization from methanol–ethanol (10:1, vol. ratio) gave pure dihydrochloride: Yield 45%; mp 265—267 °C. Found: C, 46.45; H, 10.94; N, 12.18%. Calcd for $C_9H_{24}N_2Cl_2$: C, 46.75; H, 10.46; N, 12.18%. The free base of **2** was obtained as an oil substance from the dihydrochloride: *m/e* 158 (M^+).

1,2-Dimethyl-4,4-diethylpyrazolidine (5): Using approximately the same procedure as above, **5** was prepared from 1,2-dimethyl-4,4-diethylpyrazolidine-3,5-dione.[18] Purification by column chromatography on alumina with hexane–ether (3:1, vol. ratio) gave **5** as an oily substance: *m/e* 156 (M^+), 141 (M^+-Me). Monohydrochloride of **5**: mp 165.5—167.5 °C (from hexane). Found: C, 56.31; H, 11.36; N, 14.54%. Calcd for $C_9H_{21}N_2Cl$: C, 56.08; H, 10.99; N, 14.53%.

1,3-Dimethyl-5,5-diethylperhydropyrimidine (7): The dihydrochloride of **2** (0.5 mmol) was dissolved in 20 ml of 1 M sodium hydroxide, and then 1 ml of 37% aq formaldehyde was added. After stirring for 2 h, the solution was extracted repeatedly with ether. Thorough evaporation of the ethereal extract, dried over anhydrous sodium sulfate under reduced pressure gave **7** as an oily substance: Yield 86%; *m/e* 170 (M^+), 155 (M^+-Me), 126 ($M^+-Me-Et$). Dihydrochloride of **7**: mp 217—218 °C (from isopropyl alcohol).

General Electrolytic Procedures. Electrolysis was carried

out at a constant potential as follows. An H type cell divided with a sintered glass diaphragm was used. Platinum, carbon, nickel, and silver plates (2×4 cm) were used as an anode. A platinum anode was treated with concd nitric acid and the others were carefully polished with an emery paper No. 3000 before electrolysis. 0.1 M Et_4NOTs acetonitrile solution (50 ml) suspending lithium hydroxide powder and 1 M NaOH (50 ml) were used as an anolyte for electrolysis of **1** and **2**, respectively. To the anolyte was added 1 mmol of diamine (**1** and **2**) and then a current was applied.

Analysis of Products. *Electrolysis of 1*: After electrolysis, the anolyte was acidified with hydrochloric acid. Acetonitrile was evaporated under reduced pressure, the residual aqueous solution being made strongly alkaline with sodium hydroxide. The alkaline solution was extracted repeatedly with ether and the ethereal extracts were subjected to gas chromatography (column packing, PEG 20 M, column temperature, 186 °C).

1-(2-Ethyl-2-formylbutyl)-4,4-diethyl-4,5-dihydropyrazole (**4**) was isolated as an oily substance by column chromatography on almina with dichloromethane: *m/e* 209 (M^+). Found: C, 70.44; H, 11.35; N, 11.71%. Calcd for $C_{14}H_{26}N_2O$: C, 70.54; H, 11.00; N, 11.75%.

Electrolysis of 2: After salting-out with sodium chloride, the anolyte was extracted repeatedly with ether and the ethereal extracts were subjected to gas chromatography. Analysis for **5**, **6**, and **7** was carried out on a PEG 20 M column and that for **2** on Chromosorb 103.

In the case of a low material balance between the starting diamine and the products, the above alkaline solution, which was extracted with ether, was acidified with hydrochloric acid. After the acidic solution had been extracted repeatedly with ether, the ethereal extracts were concentrated, the acidic polymer obtained being weighed.

1-Methyl-3,3-diethyl-4,5-dihydropyrazole (**6**) was isolated by column chromatography on almina with dichloromethane: *m/e* 140 (M^+), 111 (M^+-Et). Picrate of **6**: mp 129—130 °C. Found: C, 45.37; H, 5.07; N, 18.91%. Calcd for $C_{14}H_{19}N_5O_7$: C, 45.53; H, 5.18; N, 18.96%. 1,3-Dimethyl-5,5-diethylperhydropyrimidine (**7**) was isolated by preparative gas chromatography: *m/e* 170 (M^+). Dihydrochloride of **7**: mp 217—218 °C. Found: C, 50.05; H, 10.11; N, 11.33%. Calcd for $C_{10}H_{24}N_2Cl_2$: C, 49.39; H, 9.95; N, 11.52%.

Chemical Oxidation. *Oxidation of 1 and 2 with Sodium Peroxodisulfate*: To a stirred mixture of **1** (1 mmol), 0.5 M NaOH–acetone (8—10 ml), and a catalytic amount of silver nitrate (0.02 mmol), was added dropwise a solution of sodium peroxodisulfate (2 mmol) in water (2 ml) at 0 °C. After stirring at 0 °C for 2 h, a small amount of silver oxide was filtered off and the filtrate was extracted repeatedly with ether. The ethereal extracts were subjected to gas chromatography.

Oxidation of **2** with sodium peroxodisulfate was carried out without acetone as a co-solvent in a similar way to that above.

Oxidation of 1 with Lead Tetraacetate: To a stirred solution of **1** (1 mmol) in dry benzene (15 ml) was added lead tetraacetate (1 mmol) in a nitrogen atmosphere. After stirring at room temperature for 1 h, the precipitated lead acetate was filtered off. The filtrate of benzene was washed with 1 M NaOH, dried over Na_2SO_4, and then filtered. The filtrate was subjected to gas chromatography.

Oxidation of Piperidine with Lead Tetraacetate: Piperidine was oxidized in a similar way to that above. Analysis of the product, 1,1′-bipiperidine, was carried out in a similar manner to that described previously.[9]

This work was supported by a grant from the Kawakami Memorial Foundation.

Syntheses of 2*H*-1-Benzothiopyran-2-ones (Thiocoumarins) and Related Compounds from Benzenethiols and Diketene

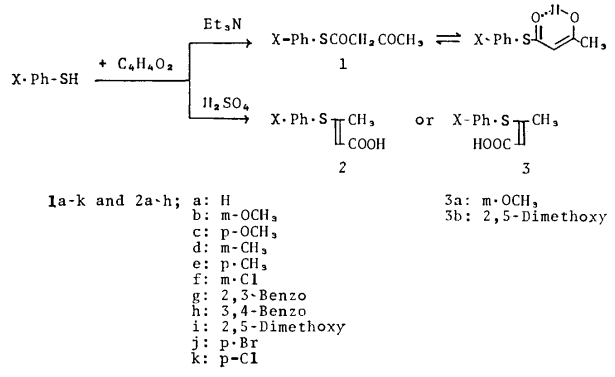
Hiroyuki NAKAZUMI,* Akira ASADA, and Teijiro KITAO
Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka 591

(Received December 14, 1979)

The products formed by the reaction of benzenethiols with diketene in the presence of H_2SO_4 are (*E*)-β-(arylthio)crotonic acids (**2**) and/or isomeric (*Z*)-β-(arylthio)crotonic acids and not, as has been reported, *S*-phenyl 3-oxobutanethioates (**1**). Compounds **1a**—**k**, as the precursor of thiocoumarins, were prepared from benzenethiols and diketene in the presence of triethylamine. The reaction of **1** with various condensing agents has been examined to prepare 2*H*-1-benzothiopyran-2-ones (thiocoumarins). It is found that 4-methyl(thiocoumarins) were conveniently prepared by the reaction of **1** with anhydrous aluminium chloride in yields of 16—48%. When **1** was treated with PPA, isomeric 2-methyl(thiochromones) were preferentially obtained in yields of 5—66%, and compound **2** was isolated as an intermediate. The spectral characteristics of 4-methyl(thiocoumarins) have also been described.

It is well known that 2*H*-1-benzothiopyran-2-ones (thiocoumarins) can not be obtained by the Pechmann reaction of benzenethiols.[1] Thiocoumarins are generally prepared from the unstable 2-mercaptobenzaldehydes which require multistage processes from benzenethiols.[2] Although Konishi *et al.* reported the convenient method to prepare thiocoumarins by the cyclization of *S*-phenyl 3-oxobutanethioates with PPA,[3] the products are mostly not thiocoumarins, but isomeric thiochromones (4*H*-1-benzothiopyran-4-ones).[4] Furthermore, recently we found that the *S*-phenyl 3-oxobutanethioates, described in our previous paper,[4] were really isomeric (*E*)-β-(arylthio)crotonic acids (**2**) and/or (*Z*)-β-(arylthio)crotonic acids (**3**).

We have now prepared a number of *S*-(substituted phenyl) 3-oxobutanethioates (**1**) from benzenethiols and diketene, and studied the cyclization of **1** with various condensing agents to prepare thiocoumarin derivatives. These works were reported in a preliminary form,[5] but in this paper we wish to report further details of these reactions. We also wish to report the spectral characteristics of 4-methyl(thiocoumarins), compared with those of isomeric 2-methyl(thiochromones).



Scheme 1.

Results and Discussion

Preparation of S-*Phenyl 3-Oxobutanethioates.* Recently Yaggi and Douglas reported that the product obtained from the reaction between benzenethiols and diketene in the presence of sulfuric acid was (*E*)-β-(arylthio)crotonic acid **2** (X=H or *p*-Cl).[6] A number of authentic (*E*)-β-(arylthio)crotonic acids (**2**) were prepared from sodium (*E*)-β-chlorocrotonate and sodium benzenethiolates by a similar method to that for **2a**.[7] The IR spectra and mp's of previously reported products, obtained by the reaction of benzenethiols with diketene in the presence of H_2SO_4, were in agreement with those of authentic samples (**2**, except for *m*-methoxy (**3a**) and 2,5-dimethoxy (**3b**) derivatives. No depression in melting point was observed in admixture of any pair of those samples. However, the melting points and IR spectra of *m*-methoxy and 2,5-dimethoxy derivatives are quite different from those of authentic samples. These compounds were assigned to (*Z*)-β-(arylthio)crotonic acid derivatives (**3**), as isomers of **2**, on the basis of NMR spectra of (*Z*)- and (*E*)-β-thio-substituted crotonates.[8] That is, the chemical shifts for the vinylic methyl group and vinylic proton for **3a** and **3b** showed upfield chemical shift of *ca.* 0.5 ppm for vinylic methyl group and downfield chemical shift of *ca.* 0.65 ppm for vinylic proton, compared to the corresponding values for authentic samples. From the results, the products obtained from the reaction of benzenethiols with diketene in the presence of H_2SO_4 are not **1**, described in previous paper, but the isomeric **2** and/

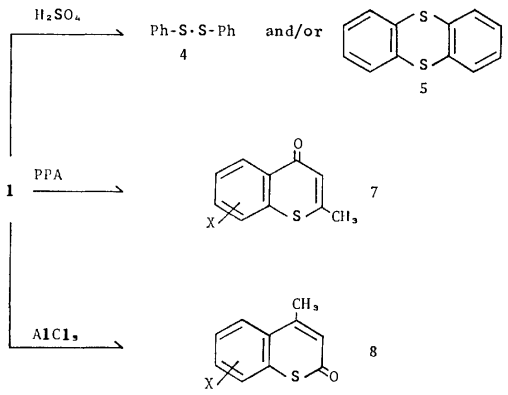
or **3**.

S-Phenyl 3-oxobutanethioates (**1**), precursor of thiocoumarins, were quantitatively prepared by the reaction of benzenethiols with diketene in the presence of triethylamine for 5—20 h at room temperature, and existed in a mixture of the keto-enol tautomeric forms, NMR spectra of which were shown in Table 1.



Scheme 2.

The Reaction of S-*Phenyl 3-Oxobutanethioates (**1**) with Various Condensing Agents.* The reaction of **1a** with sulfuric acid gave diphenyl disulfide (**4**) which was formed by decomposition of **1a**, and/or thianthrene derivatives (**5** and thianthrene 5,10-bis(dioxide) **6**) as oxidized products of **4**.

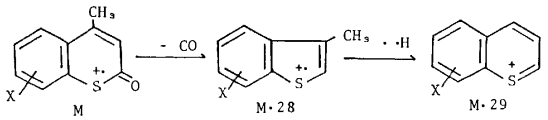
2-Methyl(thiochromone) derivatives (**7**), as the isomeric product of thiocoumarin, were preferentially obtained by treating **1** with polyphosphoric acid (PPA) at 70 °C. In the case of *m*-methoxy derivative (**1b**), only thiocoumarin **8b** was obtained. Compound **8b** also could be obtained from **2b** (X=*m*-OCH_3) and PPA. However, the other *S*-phenyl 3-oxobutanethioates, even with substituents such as methoxyl group(s) (**1c** and **1i**) gave the thiochromone **7** in yields of 10—79%. At lower temperatures of 5—10 °C, the same reaction of **1** afforded (*E*)-*β*-(arylthio)crotonic acid **2** (X=H, *m*-CH_3, or *p*-CH_3) in a low yield (4—10%). It is also known that the reaction of **1a** or **1d** with concd H_2SO_4 (1 equivalent) in Et_2O gave **2** (X=H or *m*-CH_3) in a yield of 21%.[9] It is concluded that compound **2** will be an intermediate to give **7**.

In the case of the use of anhydrous aluminium chloride as a condensing agent, some of 4-methyl(thiocoumarins) (**8**) were conveniently obtained in yields of 10—48% and no 2-methyl(thiochromones) (**7**) were obtained. However, the reaction of all methoxy derivatives of **1** with $AlCl_3$ gave only an oily undetermined material, and none of thiocoumarins was isolated. As the direct reaction of **1** with $AlCl_3$, without solvent, was favorable as regards to yield.[5] some of **8** were prepared by this method. In the cases of reaction of **1a**, **1j**, and **1k** with the suspension

of $AlCl_3$, carbon disulfide or benzene was used as the solvent.

When $ZnCl_2$ was used as a condensing agents for **1a**, **4** was obtained in 11% yield. In the cases of other condensing agents such as PCl_5, P_2O_5, and Ac_2O, oily undetermined materials were obtained.

Spectral Characteristics. The NMR, IR, UV, and mass spectra of **8** are summarized in Table 2. In the mass spectra, the major fragmentation was initial loss of carbon monoxide from the molecular ion, followed by the loss of a hydrogen atom leading to the formation of the ring-expanded thianaphthalenium ion as shown in Scheme 3. There was not the M−40 fragment ion, which was found characteristically in the mass spectra of 2-methyl(thiochromones) (**7**).[4] The base peak of **8** was the M−28 or M−29 fragment ion (Table 2).



Scheme 3.

In the NMR spectra, the benzenoid proton at the 5-position of **8** showed the chemical shift in the range of 7.78—8.00 ppm. The difference between the proton at the 5-position and other aromatic protons was 0.34 —0.53 ppm, whereas that of **7** was *ca.* 1.00 ppm.

In the IR spectra, the carbonyl bands of **8** were found in the range 1635—1650 cm^{-1} and higher by 10—35 cm^{-1} than those of the corresponding thiochromones, except for **8j** and **8k**.

The fluorescent spectra of **8** and **7** were generally very weak, compared to those of the corresponding coumarins.

Experimental

All the melting points are uncorrected. IR spectra were recorded on a Hitachi ESI-S2 spectrophotometer using KBr pellts. ^{1}H-NMR spectra were taken on a Hitachi R-24A spectrometer with tetramethylsilane as an internal standard. Mass spectra were recorded on a Hitachi RMU-6E mass spectrometer operating at 80 eV. The fluorescent spectra were recorded on a Hitachi MPF-2A fluorescent spectrophotometer. Elemental analyses were recorded on a Yanaco CHN recorder MT-2.

(E)-*β*-*(Arylthio)crotonic Acid Derivatives (2).* *Method A*: Concd H_2SO_4 (9.0 g) was added dropwise to Et_2O (50 ml) solution of benzenethiol (5.0 g) at 30 °C. Diketene (5.0 g) was then added to this mixture. After 2 h, ether was removed *in vacuo* at 20 °C, and the residue was poured into an ice–water solution. White solid was separated, collected by filtration and recrystallized from EtOH to give **2a** (5.3 g). Other compounds **2** were prepared by a similar method. **2a**: 60%, mp 174.5—175.5 °C; **2c**: 5%, mp 172—175 °C; **2d**: 65%, mp 165—166 °C; **2e**: 60%, mp 204—205 °C; **2f**: 29%, mp 154—155 °C; **2g**: 10%, mp 198—202 °C; **2h**: 65%, mp 191—195 °C.

The NMR and IR spectra of these compounds corresponded to data of Table 3 described in previous paper.[4]

Method B: NaOH (1.2 g) was added to a solution of (*E*)-*β*-chlorocrotonic acid (2.0 g) in EtOH (10 ml). To the mixture, a solution of sodium *m*-methoxybenzenethiolate (*m*-methoxybenzenethiol (2.0 g)+NaOH (1.6 g)) in EtOH (5 ml) was added dropwise at 50 °C and stirred for 2 h. After cooling, dilute HCl was added to this solution until the pH was 1. The resulting solid was separated, and recrystallized from EtOH to give **2b** (X=*m*-OCH_3), yield 62%, mp 119—121 °C; NMR ($CDCl_3$): δ=2.40 (3H, s), 3.80 (3H, s), 5.28 (1H, s), 6.90—7.30 (4H, m), and 10.2 (1H, b); ν_{CO}: 1680 cm^{-1}. Found: C, 58.76; H, 5.48%. Calcd for $C_{11}H_{12}O_3S$: C, 58.93; H, 5.36%. **2i** (X=2,5-Dimethoxy): yield 50%, mp 126—128 °C; NMR ($CDCl_3$): δ=2.40 (3H, s), 3.80 (3H, s), 3.83 (3H, s), 5.23 (1H, s), 6.95—7.10 (3H, m), and 10.80 (1H, b); ν_{CO}: 1680 cm^{-1}. Found: C, 56.53; H, 5.59%. Calcd for $C_{12}H_{14}O_4S$: C, 56.69; H, 5.51%. Other compounds **2a** and **2c—h** were also prepared by a similar method in yields of 10—51%.

(Z)-*β*-*(Arylthio)crotonic Acid Derivatives (3).* Compound **3b** (X=2,5-dimethoxy) was prepared by the method A for **2a**: yield 22%, mp 169—171 °C; NMR ($CDCl_3$): δ=1.90 (3H, s), 3.78 (3H, s), 3.83 (3H, s), 5.90 (1H, s), and 6.90—7.10 (3H, m); ν_{CO}: 1675 cm^{-1}. Compound **3a** (X=*m*-OCH_3) was prepared by a similar method and isolated from the isomer mixture (**2b** and **3a**) by repeated recrystallization from EtOH. **3a**: mp 170—171 °C; NMR ($CDCl_3$): δ=1.90 (3H, s), 3.80 (3H, s), 5.90 (1H, s), and 7.00—7.30 (4H, m).

S-*Phenyl 3-Oxobutanethioates (1).* Compound **1a** was quantitatively obtained from benzenethiol and diketene in the presence of Et_3N in dichloromethane at room temperature for 20 h.[6] Other compounds **1b—k** were prepared similarly. All of compounds **1a—i** were colorless liquid, and **1j** and **1k** were recrystallized from Et_2O; **1j**: mp 51—53 °C; **1k**: mp 45 °C (lit,[6] 45—46 °C). Liquid **1** was used without purification for the cyclization with condensing agents.

The Reaction of 1 with Concd H_2SO_4. *Method I*: The mixed acid of 30% fuming H_2SO_4 (1.0 g) and concd H_2SO_4 (10 g) was added dropwise to **1a** (5.5 g) under stirring at 0 °C. The mixture was stirred at room temperature for 5 h, and was poured into an ice–water solution. The resulting solid was separated and recrystallized from EtOH to give diphenyl disulfide **4** (1.9 g): yield 61%, mp 58—59 °C.

Method II: Compound **1a** (5.0 g) was added dropwise to concd H_2SO_4 (20 ml) at 15 °C. The mixture was stirred for 5 h at 15 °C and was poured into an ice–water solution. The resulting solid was separated, washed with EtOH and acetone, and purified by acid-pasting to give thianthrene

Table 3. Elemental analyses of 4-methyl-(thiocoumarins) (**8**)

Compound	Formula (MW)	Analysis (%) Calcd (Found) C	H
8f	$C_{10}H_7OSCl$ (210.5)	57.01 (56.76)	3.33 (3.28)
8g	$C_{14}H_{10}OS$ (226)	74.34 (74.96)	4.42 (4.51)
8h	$C_{14}H_{10}OS$ (226)	74.34 (74.30)	4.42 (4.49)
8j	$C_{10}H_7OSBr$ (254.9)	47.08 (47.07)	2.75 (2.69)
8k	$C_{10}H_7OSCl$ (210.5)	57.01 (57.25)	3.33 (3.40)

5,10-bis(dioxide) **6** in 56% yield (mp>320 °C, lit,[10]> 360 °C). Found: C, 51.67; H, 2.97%. From the first filtrate in EtOH, thianthrene **5** was isolated in 4% yield; mp 152—154 °C (lit,[11] 157—159 °C).

The Reaction of 1 with PPA. Compound **1a** (3.0 g) was added to PPA (60 g) at 70 °C and stirred for 1—2 h. After cooling, the mixture was poured into an ice–water solution. The resulting solid was separated and recrystallized from EtOH–water mixture to give **7a** (1.8 g, 66%). Other **7** were similarly prepared. **7c**: X=6-OCH_3, 10%, mp 102—103 °C; **7d**: X=7-CH_3, 23%, mp 98—100 °C; **7e**: X=6-CH_3, 53%, mp 120 °C; **7f**: X=7-Cl, 25%, mp 165—166 °C; **7g**: X=7,8-benzo, 25%, mp 194—195 °C; **7h**: X=5,6-benzo, 15%, mp 126—128 °C; **7i**: X=5,8-dimethoxy, 79%, mp 146—148 °C; **7j**: X=6-Br, 23%, mp 181—182 °C (lit,[12] 176 °C); NMR ($CDCl_3$): δ=2.43 (3H, s), 6.79 (1H, s), 7.23—7.70 (2H, m), and 8.55 (1H, d, J=2 Hz); ν_{co}: 1623 cm^{-1}, Found: C, 46.87; H, 2.81%. λ_{max} (EtOH): 224 (ε 1.8×10^4), 252 (2.5×10^4), 281 (0.3×10^4), 292 (0.3×10^4), and 342b nm (0.8×10^4); **7k**: X=6-Cl, 34%, mp 164—166 °C (lit,[12] 170 °C); NMR ($CDCl_3$): δ=2.46 (3H, s), 6.81 (1H, s), 7.48 (2H, s), and 8.43 (1H, s); ν_{co}: 1628 cm^{-1}. Found: C, 57.13; H, 3.46%. λ_{max} (EtOH): 223 (ε 1.7×10^4), 250 (2.4×10^4), 280 (0.5×10^4), 291 (0.4×10^4), and 342b nm (0.9×10^4).

From the same reaction of **1a**, **1d**, and **1e** at 5—10 °C, **2a** (yield, 4%), **2d** (4%), and **2e** (10%) were isolated, respectively. Under the same conditions at 70 °C, **8b** (X=7-OCH_3) was obtained in 54% yield from **1b**.

The Reaction of 1 with Aluminium Chloride. *Method (i)*: Compound **1a** (3.0 g, 15 mmol) was added to a suspension of $AlCl_3$ (20 g) in CS_2 (20 ml). After reflux for 5 h, the mixture was poured into cold water. The resulting solid was separated and recrystallized from EtOH to give **8a** (1.0 g) in 38% yield, mp 126—127 °C (lit,[2] 124 °C). When benzene was used in the place of CS_2, **8j** and **8k** were obtained; **8j**: 27%, mp 184—185 °C; **8k**: 23%, mp 177—179 °C.

Method (ii): Compound **1a** (3.0 g, 15 mmol) was added to $AlCl_3$ (20 g), and stirred at 80—90 °C for 2 h. After cooling, the mixture was poured into cold water. The resulting solid was separated and recrystallized from EtOH to give **8a** in 48% yield. The others of **8** were similarly obtained by the method (ii); **8d**: 42%, mp 108—109 °C (lit,[2] 110 °C); **8e**: 31%, mp 114—115 °C (lit,[2] 120 °C); **8f**: 22%, mp 157—158 °C; **8g**: 16%, mp 169—171 °C; **8h**: trace, mp 133—134 °C.

The elemental analyses of those compounds were shown in Table 3.

The Fluorescent Spectra. **8b**: F_{max} (EtOH): 402 nm (rel. intensity based on **8b** as a standard); **8g**: F_{max}: 467 nm (1.5); **8h**: F_{max}: 405 (0.74) and 435 nm (0.66); **7b**[4] (X=7-OCH_3): F_{max}: 382 nm (2.0); **7g**: F_{max}: 398 nm (0.73); **7h**: F_{max}: 402 nm (0.6); **7i**; F_{max}: 494 nm (2.9×10); 7-MeO-4-methylcoumarin: F_{max}: 410 nm (2.7×10^2); 7,8-benzo-4-methylcoumarin:[3] F_{max}: 418 nm (9.1×10); 5,6-benzo-4-methylcoumarin:[3] F_{max}: 403 nm (9.6×10^2). The other thiocoumarins and thiochromones which were prepared herein showed no detectable fluorescence.

This work was supported in part by the Grant-in-Aid for Scientific Research from the Ministry of Education (No. 475675).

Carbocyclic Ring Formation by the Intramolecular Reaction between Enol Silyl Ether and Allylic Acetate Moieties

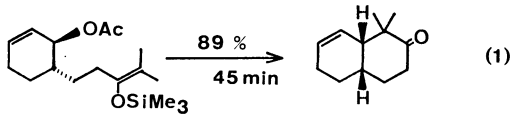
Akira Itoh, Koichiro Oshima,* Hisashi Yamamoto,** and Hitosi Nozaki

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606

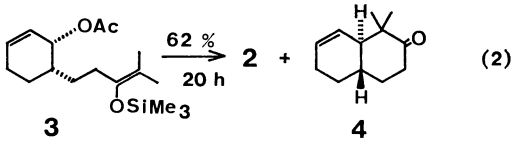
(Received January 12, 1980)

The title reaction of *trans*-3-acetoxy-4-(4-methyl-3-trimethylsiloxy-3-pentenyl)cyclohexene proceeds in the presence of Et_2AlOAr, where Ar=2,6-di-*t*-butyl-4-methylphenyl, affording stereospecifically the *cis* isomer of 2,2-dimethylbicyclo[4.4.0]dec-9-en-3-one. In contrast, the *cis*-disubstituted cyclohexene compound reacts only sluggishly to produce a mixture of the *cis*- and *trans*-fused octalones. Similar stereospecific effect of the allylic double bond configuration on the ease of cyclization has been observed in the synthesis of karahanaenone from 3,7-dimethyl-6-trimethylsiloxy-2,6-octadienyl acetate and related reactions.

We report a remarkable case of stereochemically controlled cyclization reaction proceeding intramolecularly among trimethylsiloxyethenyl group and allylic acetate moiety as shown in Eqs. 1 and 2.

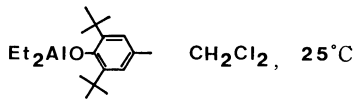


1 2 (1)



3 4 (2)

66 : 34



Obviously, the *trans*-substituted cyclohexenyl acetate (**1**) reacts smoothly in the presence of diethylaluminum 2,6-di-*t*-butyl-4-methylphenoxide as prepared from diethylaluminum chloride and the sterically hindered sodium phenoxide.[1] The resulting product is isomerically homogeneous *cis*-octalone (**2**). In sharp contrast, however, the *cis*-substituted cyclohexene (**3**) is transformed very sluggishly into a mixture of *cis*- and *trans*-octalone (**2** and **4**) only with inferior yields. This observation clearly excludes anticipated, possible intermediacy of the same, "free", allylic carbonium ion from both **1** and **3** which should be further cyclized into the trimethylsiloxy-stabilized cation presumably.

This type of cyclization has originally been described as a means of constructing the skeleton of karahanaenone (**6**) biomimetically (Eq. 3)[2] in the sense that neryl cation "equivalent" cyclizes in the *anti*-Markovnikov manner[3] to form a seven-membered ring. Extention of the same reaction to an isomeric system is shown in Eqs. 4, 5, and 6.

These equations impressively indicate that the (*E*), (*Z*) stereochemistry of the allylic double bond determines the rates of cyclization as well as the yields and distributions of the resulting products. Here again

$MeAl(OCOCF_3)_2$, hexane-CH_2Cl_2, 25°C

the "free" allylic cation does not account for the observed dependence of the reaction on the allylic olefinic bond configuration of the substrates. Under comparable reaction conditions, diethyl geranyl phosphate does react quite analogously as the neryl isomer to afford limonene and terpinolene mixture in the presence of $(Bu^i_2Al)_2O$ in tetrahydrofuran (THF).[5,6] The $(Bu^i_2Al)_2O$–THF combination might increase the life-time of allylic carbonium ion so that (*E*)-allylic carbonium ion can be converted into (*Z*)-isomer which cyclizes with ease.[9]

The aluminum reagent in Eq. 3 through 6, methylaluminum bis(trifluoroacetate) or dimethylaluminum trifluoroacetate, was prepared from trimethylaluminum and calculated amount of trifluoroacetic acid in hexane and was used *in situ*. These proved to give less satisfactory results in the reaction of Eqs. 1 and 2.

Further examples of analogous cyclization are given in Eqs. 7, 8, and 9. For the allylic acetate unequally substituted at α and γ position, the silyl enol ether attacks the less substituted end of the allylic system

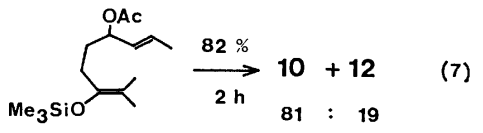
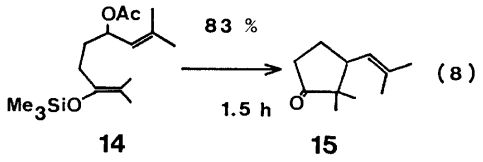
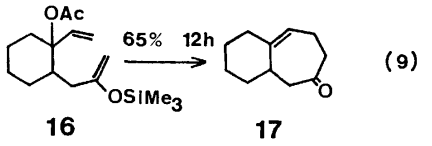
preferentially.

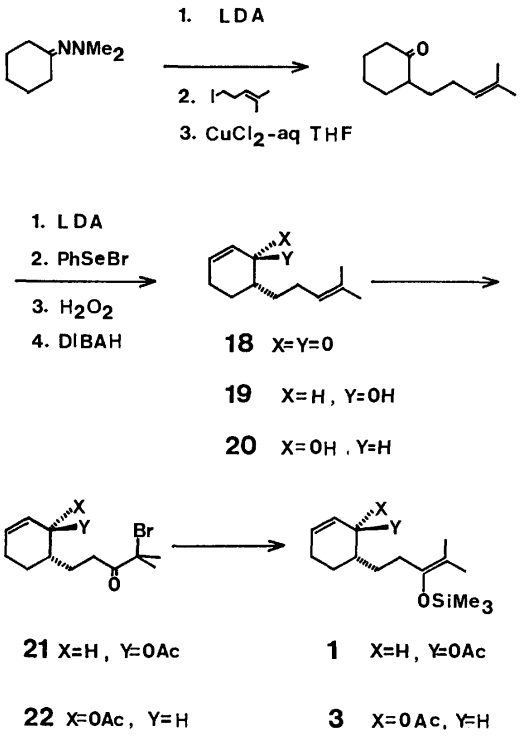
The preparation of cyclization substrates merits brief descriptions. The acetates **1** and **3** are obtained through the sequence in Scheme 1.







Scheme 1.



Experimental

The infrared spectra were determined on a Shimadzu IR-27-G spectrometer; the mass spectra on a Hitachi RMU-6L machine; the GLPC analyses on a Yanagimoto GCG-550F; and the NMR spectra on a JNM-PMX 60 or Varian EM-390H spectrometer. The chemical shifts are given in δ in ppm with TMS as the internal standard. Splitting patterns are designated as s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet. The microanalyses were carried out by the staffs at the Elemental Analyses Center of Kyoto University. All experiments were carried under an atmosphere of dry argon. Tetrahydrofuran was dried by distillation from sodium-benzophenone. Thin layer or thick layer plates were made of E. Merck PF-254, and preparative column chromatography on silica gel E. Merck Art. 7734.

cis-2,2-Dimethylbicyclo[4.4.0]dec-9-en-3-one (2). A mixture of sodium hydride (50%, 50 mg, 1.0 mmol) and 2,6-di-*t*-butyl-4-methylphenol (0.22 g, 1.0 mmol) in hexane (5.0 ml) was stirred for 5 min at 0 °C. After stirring for an additional 15 min at 25 °C, a hexane solution of diethylaluminum chloride (1.0 M, 1.0 ml) was added. After 10 min, the solvent was removed *in vacuo* and the residue was diluted with dichloromethane (7.0 ml). A solution of **1** (157 mg, 0.51 mmol) in dichloromethane (3.0 ml) was added at −23 °C. After 3 h at −23 °C and 45 min at 25 °C, the mixture was poured into 1 mol dm^{-3} HCl and extracted with ethyl acetate (2×20 ml). The combined organic layers were washed with water and saturated aqueous sodium chloride solution and dried over anhydrous sodium sulfate. Removal of solvent *in vacuo* gave an oil which was purified by column chromatography on silica gel (5:1 hexane–ether) to give **2** (80 mg, 89%): IR (neat) 1710, 1382, 1070, 1010, 860, 755, 690 cm^{-1}; NMR (CCl_4) δ 1.06 (s, 3H), 1.24 (s, 3H), 5.63 (bs, 2H); MS *m/e* (%) 179 (9), 178 (M^+, 46), 93 (92), 92 (100), 79 (85). Hydrogenation (PtO_2) of **2** gave *cis*-2,2-dimethylbicyclo[4.4.0]decan-3-one which was spectrometrically identical with an authentic sample.[10]

trans-2,2-Dimethylbicyclo[4.4.0]dec-9-en-3-one (4). A solution of **3** (154 mg, 0.50 mmol) in dichloromethane (3.0 ml) was treated with the aluminum reagent (1.0 mmol) prepared as described above at 25 °C for 20 h. Purification by column chromatography afforded a mixture of **2** and **4** in 62% yield in a ratio of 66:34 as determined by GLPC (10% PEG, 2 m, 122 °C). Careful purification by preparative thick layer chromatography (PLC) on silica gel (5:1 hexane–ether) gave pure sample of **4**: IR (neat) 1708, 1180, 1110 cm^{-1}; NMR (CCl_4) δ 0.97 (s, 3H), 1.09 (s, 3H), 5.62 (m, 2H); MS *m/e* (%) 179 (11), 178 (M^+, 66), 79 (100). The compound **4** was hydrogenated to provide *trans*-2,2-dimethylbicyclo[4.4.0]decan-3-one.[10]

Karahanaenone (6). A solution of trifluoroacetic acid (0.91 g, 8.0 mmol) in hexane (4.0 ml) was added slowly at 0 °C to a solution of trimethylaluminum in hexane (1.0 M, 4.0 ml, 4.0 mmol) to give a white slurry. The mixture was stirred at 25 °C for 15 min and cooled to 0 °C. A solution of **5** (0.28 g, 1.0 mmol) in dichloromethane (8.0 ml) was added and stirring continued at 0 °C for 10 min and 25 °C for 3 h. After the usual workup, PLC (10:1 hexane–ether) gave **6** (130 mg, 85%): bp 160 °C (760 Torr); IR (neat) 1698, 1660, 1398, 1358 cm^{-1}; NMR (CCl_4) δ 1.05 (s, 6H), 1.70 (s, 3H), 2.03—2.30 (m, 4H), 2.55—2.80 (m, 2H), 5.42 (t, 1H, J=5.8 Hz); MS *m/e* (%) 152 (M^+, 100), 109 (66), 95 (94). The compound was identical with the authentic sample.[11] The yield determined by GLPC using 4-*t*-butylcyclohexanone as an internal standard was 95%.

2,2,3-Trimethyl-3-vinylcyclopentanone (8). The above procedure using **7** (142 mg, 0.5 mmol) and dimethylaluminum trifluoroacetate derived from trimethylaluminum (2.0 mmol) and trifluoroacetic acid (2.2 mmol) in dichloromethane (4.0 ml) afforded after usual workup and purification by PLC (10:1 hexane–ether) a mixture of **6** and **8** in 55% (42 mg) yield in a ratio of 82:18 as determined by GLPC (5% PEG 20 M, 1.5 m, 130 °C). Pure sample of **8** was obtained by preparative GLPC and its identity with an authentic sample[12] was established by IR and NMR. **8**: bp 110 °C (bath temp,

50 Torr); IR (neat) 1735, 1640, 1380, 1275, 1000, 915 cm^{-1}; NMR ($CDCl_3$) δ 0.88 (s, 3H), 0.93 (s, 3H), 1.06 (s, 3H), 1.80—2.05 (m, 2H), 2.32 (bd, 2H), 4.87—5.17 (m, 2H), 5.90 (dd, 1H, J=16, 12 Hz); MS *m/e* (%) 152 (M^+, 38), 137 (28), 109 (44), 96 (66), 81 (56), 70 (44), 67 (62), 55 (44), 43 (100), 41 (90).

*2,2,3-Trimethyl-3-cycloheptenone (**10**).* Following the procedure for the preparation of **6**, a solution of **9** (22 mg, 0.08 mmol) was treated with methylaluminum bis(trifluoroacetate) (0.5 mmol) in hexane (0.5 ml) to give **10** (12 mg, 100%): bp 80 °C (bath temp, 20 Torr); IR (neat) 1704, 1655, 1084, 780, 730 cm^{-1}; NMR (CCl_4) δ 1.01 (s, 3H), 1.05 (d, 3H, J=9 Hz), 1.10 (s, 3H), 5.45 (m, 2H); MS *m/e* (%), 153 (11), 152 (M^+, 73), 137 (18), 124 (16), 109 (60), 95 (100), 84 (60); Found: C, 78.97; H, 10.75%. Calcd for $C_{10}H_{16}O$: C, 78.90; H, 10.59%.

*2,2-Dimethyl-3-(1-propenyl)cyclopentanone (**12**)*: IR (neat) 1740, 1090, 1056, 975 cm^{-1}; NMR (CCl_4) δ 0.81 (s, 3H), 0.98 (s, 3H), 1.70 (d, 3H, J=5 Hz), 5.40 (m, 2H); MS *m/e* (%) 153 (12), 152 (M^+, 69), 137 (18), 109 (40), 95 (47), 81 (100); Found: *m/e* 152.1208. Calcd for $C_{10}H_{16}O$: M, 152.1202.

*2,2-Dimethyl-3-(2-methyl-1-propenyl)cyclopentanone (**15**)*: Bp 96 °C (bath temp, 19 Torr); IR (neat) 1745, 1671, 1090, 848, 802 cm^{-1}; NMR (CCl_4) δ 0.82 (s, 3H), 0.94 (s, 3H), 1.60 (s, 3H), 1.70 (s, 3H), 4.87 (bd, 1H, J=9 Hz); MS *m/e* (%) 167 (25), 166 (M^+, 48), 151 (34), 133 (21), 123 (99), 95 (69), 82 (100); Found: C, 79.23; H, 10.62%. Calcd for $C_{11}H_{18}O$: C, 79.47; H, 10.91%.

*Bicyclo[5.4.0]undec-5-en-2-one (**17**)*: IR (neat) 1707, 1225, 1150, 825 cm^{-1}; NMR (CCl_4) δ 2.40 (m, 2H), 2.67 (d, 1H, J=5.3 Hz), 2.70 (d, 1H, J=8.1 Hz), 5.50 (t, 1H, J=4.5 Hz); MS *m/e* (%) 164 (M^+, 61), 108 (52), 107 (52), 93 (71), 79 (100); Found: *m/e* 164.1189. Calcd for $C_{11}H_{16}O$: M, 164.1199.

*6-(4-Methyl-3-pentenyl)-2-cyclohexenone (**18**).* The title compound was prepared from 2-(4-methyl-3-pentenyl)cyclohexanone[13] as described by Reich[14] in 54% yield.

trans- *and* cis-*6-(4-Methyl-3-pentenyl)-2-cyclohexenol (**19** and **20**).* A solution of **18** (2.6 g, 14.6 mmol) and diisobutylaluminum hydride (0.5 M solution in hexane, 35 ml, 17.5 mmol) in benzene (50 ml) was stirred at 0 °C for 1.5 h. The resulting mixture was poured into 1 mol dm^{-3} HCl and extracted with ethyl acetate (2×100 ml). The combined extracts were washed with saturated sodium hydrogencarbonate and water, dried, and concentrated *in vacuo*. Trimethylsilylation (Et_3N, Me_3SiCl) of the crude mixture of **19** and **20** gave separable two bands by PLC (5:1 hexane–benzene). Hydrolysis of the slower moving band (R_f= 0.17) with 1 mol dm^{-3} HCl in tetrahydrofuran afforded **19**: IR (neat) 3330, 1650 cm^{-1}; NMR (CCl_4) δ 0.8—2.2 (m, 10H), 1.60 (s, 3H), 1.67 (s, 3H), 3.71 (m, 1H), 5.06 (t, 1H, J=7.5 Hz), 5.47—5.76 (m, 2H). Faster moving band (R_f= 0.37) gave **20**: IR (neat) 3350, 1650 cm^{-1}; NMR (CCl_4) δ 0.8—2.2 (m, 10H), 1.60 (s, 3H), 1.67 (s, 3H), 3.90 (bs, 1H), 5.07 (t, 1H, J=7.5 Hz), 5.74—5.82 (m, 2H). Hydrogenation of **19** or **20** provided *trans*- or *cis*-2-(4-methylpentyl)cyclohexanol, respectively, whose IR and NMR spectra agree with the published data.[15]

trans-*3-Acetoxy-4-(4-methyl-3-trimethylsiloxy-3-pentenyl)cyclohexene (**1**).* *m*-Chloroperbenzoic acid (70%, 1.47 g, 6.0 mmol) was added portionwise over a period of 30 min at 0 °C to a solution of *trans*-acetate (1.2 g, 5.4 mmol) derived from **19** in dichloromethane (25 ml). After 30 min, the reaction mixture was filtered through a pad of Celite 545 and the filtrate was washed with saturated sodium hydrogencarbonate, dried, and concentrated *in vacuo*. The crude epoxide (1.1 g) was dissolved in toluene (20 ml) and treated with 47% HBr (2.7 ml) at −78 °C. After 2 h, the mixture was poured into water and extracted with ether (2×20 ml). The combined ether layers were washed with brine and dried, and freed of the solvent. Purification of the residual oil by column chromatography on silica gel (10:1 benzene–ethyl acetate) gave *trans*-3-acetoxy-4-(4-bromo-4-methyl-3-hydroxypentyl)cyclohexene (1.1 g) as a pale yellow oil. Oxidation of bromohydrin by the method of Corey and Kim[16] afforded **21** (0.80 g, 74%). A solution of **21** (0.80 g, 2.5 mmol) in THF (5.5 ml) was added to a mixture of zinc–silver couple (0.51 g), chlorotrimethylsilane (0.97 ml, 7.7 mmol), and THF (10 ml) over a period of 30 min at 25 °C.[17] After 30 min, pyridine (2.1 ml, 25 mmol) was added[18] and the reaction mixture was poured into saturated sodium hydrogencarbonate and extracted with ether. After removal of solvent *in vacuo*, the resultant oil was purified by precooled (below 0 °C) silica gel column chromatography (10:1 hexane–ether) to give **1** (0.64 g, 82%): bp 145 °C (bath temp, 3 Torr); IR (neat) 1735, 1680, 1240, 750, 685 cm^{-1}; NMR (CCl_4) δ 0.13 (s, 9H), 1.52 (s, 3H), 1.55 (s, 3H), 1.96 (s, 3H), 4.96 (bs, 1H), 5.65 (m, 2H); MS *m/e* (%) 312 (1), 311 (3), 310 (M^+, 10), 251 (3), 250 (8), 249 (4), 207 (14), 171 (78), 170 (57), 73 (100); Found: C, 66.06; H, 9.97%. Calcd for $C_{17}H_{30}O_3Si$: C, 65.76; H, 9.74%.

cis-*3-Acetoxy-4-(4-methyl-3-trimethylsiloxy-3-pentenyl)cyclohexene (**3**).* In similar fashion, **20** was converted to **3** in 36% overall yield. **3**: bp 145 °C (bath temp, 3 Torr); IR (neat) 1733, 1680, 1248, 750, 682 cm^{-1}; NMR (CCl_4) δ 0.15 (s, 9H), 1.53 (s, 3H), 1.56 (s, 3H), 1.92 (s, 3H), 5.12 (bs, 1H), 5.80 (m, 2H); MS *m/e* (%) 312 (2), 311 (3), 310 (M^+, 11), 251 (4), 250 (10), 249 (4), 207 (16), 171 (54), 170 (88), 73 (100); Found: C, 65.54; H, 9.86%. Calcd for $C_{17}H_{30}O_3Si$: C, 65.76; H, 9.74%.

*6-Trimethylsiloxyneryl Acetate (**5**) and 6-Trimethylsiloxygeranyl Acetate (**7**).* As outlined for the preparation of **1**, the title acetates were obtained from neryl and geranyl acetate, respectively. **5**: bp 130 °C (bath temp, 0.5 Torr); IR (neat) 1740, 1682, 1374, 1250—1225, 1020, 950, 860—840 cm^{-1}; NMR (CCl_4) δ 0.17 (s, 9H), 1.53 (s, 3H), 1.58 (s, 3H), 1.74 (s, 3H), 1.95 (s, 3H), 2.17 (bs, 4H), 4.30 (d, 2H, J=7 Hz); MS *m/e* (%) 284 (3), 220 (6), 206 (4), 180 (17), 157 (35), 116 (23), 90 (69), 75 (72), 73 (100), 43 (59); Found: C, 63.33; H, 10.10%. Calcd for $C_{15}H_{28}O_3Si$: C, 63.33; H, 9.92%. **7**: bp 125 °C (bath temp, 0.5 Torr); IR (neat) 1740, 1677, 1380, 1362, 1240, 1190—1160, 1020, 965, 865, 840, 750 cm^{-1}; NMR ($CDCl_3$) δ 0.16 (s, 9H), 1.53 (s, 3H), 1.59 (s, 3H), 1.72 (s, 3H), 1.97 (s, 3H), 2.16 (bs, 4H), 4.48 (d, 2H, J=7 Hz), 5.31 (t, 1H, J=7 Hz); MS *m/e* (%) 284 (6), 181 (20), 158 (46), 117 (24), 91 (94), 75 (68), 73 (100), 43 (56); Found: C, 63.15; H, 10.06%. Calcd for $C_{15}H_{28}O_3Si$: C, 63.33; H, 9.92%.

*(3Z)-2-Acetoxy-8-methyl-7-trimethylsiloxy-3,7-nonadiene (**9**).* A solution of 6-methyl-5-hepten-2-one (21.4 g, 0.17 mol) in 2,6-lutidine (172 ml, 1.48 mol) was added at 0 °C over 40 min to a suspension of phosphorus pentachloride (89.6 g, 0.42 mol). The precipitate was removed by filtration through a pad of Celite 545 and the filtrate was washed with water, dried, and concentrated *in vacuo*. The crude product and lithium diisopropylamide, prepared from diisopropylamine (42.5 ml, 0.30 mol) and butyllithium (1.6 M hexane solution, 174 ml, 0.28 mol) in THF (300 ml) were reacted at 0 °C for 10 min and acetaldehyde (11.6 ml, 0.21 mol) was added. After usual workup, 8-methyl-7-nonen-3-yn-2-ol (4.7 g, 31 mmol) was obtained in 18% yield based on the heptenone. A mixture of the alcohol (3.1 g, 20.5 mmol), sodium borohydride (0.33 g, 8.5 mmol), and nickel acetate (1.8 g, 7.3

mmol) in ethanol (190 ml) was stirred at 25 °C for 1 h under hydrogen atmosphere. The black precipitate was removed by filtration and the filtrate was concentrated *in vacuo*. Acetylation followed by distillation under reduced pressure (bp 72—73 °C, 0.5 Torr) gave (3*Z*)-2-acetoxy-8-methyl-3,7-nonadiene (2.86 g, 47%). According to the procedure described for the preparation of **1**, the acetate was converted to **9**: IR (neat) 1735, 1678, 1240, 693 cm^{-1}; NMR (CCl_4) δ 0.16 (s, 9H), 1.23 (d, 3H, J=5.8 Hz), 1.56 (s, 3H), 1.58 (s, 3H), 1.96 (s, 3H), 2.16 (m, 4H), 5.2—5.7 (m, 3H); MS *m/e* (%) 286 (5), 285 (3), 284 (M^+, 12), 225 (15), 224 (10), 209 (9), 195 (4), 181 (10), 169 (9), 158 (20), 141 (34), 91 (69), 75 (61), 73 (100); Found: *m/e* 284.1805. Calcd for $C_{15}H_{28}O_3Si$: M, 284.1806.

*(3E)-2-Acetoxy-8-methyl-7-trimethylsiloxy-3,7-nonadiene (**11**).* Reduction of 8-methyl-7-nonen-3-yn-2-ol with lithium aluminum hydride in ether gave (3*E*)-8-methyl-3,7-nonadien-2-ol in 80% yield. As described previously, the alcohol was transformed to **11**: bp 118 °C (bath temp, 2 Torr); IR (neat) 1735, 1677, 1240, 965 cm^{-1}; NMR (CCl_4) δ 0.15 (s, 9H), 1.23 (d, 3H, J=6.3 Hz), 1.52 (s, 3H), 1.56 (s, 3H), 1.92 (s, 3H), 2.13 (m, 4H), 5.1—5.6 (m, 3H); MS *m/e* (%) 286 (2), 285 (5), 284 (M^+, 17), 225 (21), 224 (13), 209 (10), 195 (6), 181 (12), 156 (24), 141 (47), 91 (87), 75 (63), 73 (100); Found: C, 63.18; H, 10.21%. Calcd for $C_{15}H_{28}O_3Si$: C, 63.33; H, 9.92%.

*(2E)-4-Acetoxy-8-methyl-7-trimethylsiloxy-2,7-nonadiene (**13**).* Bp 100 °C (bath temp, 2.5 Torr); IR (neat) 1735, 1678, 1240, 962 cm^{-1}; NMR (CCl_4) δ 0.14 (s, 9H), 1.53 (s, 6H), 1.65 (d, 3H, J=6.3 Hz), 1.7 (m, 2H), 1.90 (s, 3H), 2.0 (m, 2H), 5.07 (m, 1H), 5.27 (dd, 1H, J=15, 7.5 Hz), 5.69 (dq, 1H, J=15, 6.3 Hz); MS *m/e* (%) 286 (2), 285 (2), 284 (M^+, 6), 224 (11), 209 (11), 181 (24), 158 (34), 143 (26), 141 (24), 119 (13), 117 (17), 75 (56), 73 (100); Found: C, 63.46; H, 9.75%. Calcd for $C_{15}H_{28}O_3Si$: C, 63.33; H, 9.92%.

*4-Acetoxy-2,8-dimethyl-7-trimethylsiloxy-2,7-nonadiene (**14**).* A solution of 6-methyl-5-hepten-2-one (6.0 g, 48 mmol) in THF (20 ml) was added at −78 °C over a period of 1 h by means of mechanically driven syringe to a solution of lithium diisopropylamide (53 mmol) generated from diisopropylamine and butyllithium in THF (100 ml). After 20 min, acetone (39 ml, 0.53 mol) was added in one portion and the mixture was stirred for an additional 20 min. The reaction was quenched by addition of acetic acid (3.6 ml, 63 mmol) and the resulting mixture was poured into water and extracted with ethyl acetate. The combined extracts were washed with saturated sodium hydrogencarbonate and brine, dried and concentrated *in vacuo*. The resultant crude oil was purified by column chromatography on silica gel to give 2,8-dimethyl-2-hydroxy-7-nonen-4-one (8.5 g, 97%). A mixture of this β-hydroxy ketone (8.5 g, 46 mmol) triethylamine (32 ml, 0.23 mol), and methanesulfonyl chloride (8.0 ml, 0.10 mol) in dichloromethane (200 ml) was stirred at 25 °C for 15 h. The suspension was diluted with ether and water. After extracting with ether and drying (Na_2SO_4), distillation (bp 49—52 °C, 0.5 Torr) gave 2,8-dimethyl-2,7-nonadien-4-one (7.1 g, 93%). The dienone (5.8 g, 35 mmol) was reduced with sodium borohydride (1.35 g, 35 mmol) in ethanol (35 ml) at 25 °C for 17 h to give an alcohol which was converted to 4-acetoxy-2,8-dimethyl-2,7-nonadiene (bp 75—76 °C, 10.5 Torr, 6.0 g, 82%) by the successive treatment with pyridine (20 ml) and acetic anhydride (20 ml) at 0 °C. Following the procedure for the preparation of **1**, the acetate gave **14** (30% overall yield): bp 139 °C (bath temp, 2 Torr); IR (neat) 1736, 1680, 1252 cm^{-1}; NMR (CCl_4) δ 0.15 (s, 9H), 1.53 (s, 6H), 1.68 (s, 6H), 1.94 (s, 3H), 4.93 (d, 1H, J=8.6 Hz), 5.28 (td, 1H, J=5.8, 8.6 Hz); MS *m/e* (%) 299 (3), 298 (M^+, 9), 239 (11), 238 (32), 223 (26), 195 (27), 158 (26), 141 (33), 91 (29), 75 (52), 73 (100); Found: *m/e* 298.1957. Calcd for $C_{16}H_{30}O_3Si$: M, 298.1963.

*1-Acetoxy-2-(2-trimethylsiloxy-2-propenyl)-1-vinylcyclohexane (**16**).* Vinylmagnesium bromide (0.27 mol) and 2-allylcyclohexanone (14.4 g, 104 mmol) were stirred in THF (200 ml) at 25 °C for 30 min. The reaction mixture was poured into aqueous ammonium chloride and extracted with ether. Distillation under reduced pressure (bp 95—105 °C, 10 Torr) afforded 2-allyl-1-vinylcyclohexanol (14.5 g, 87.7 mmol) in 84% yield. A mixture of this alcohol (6.2 g, 37.5 mmol) and sodium hydride (37.5 mmol) in benzene was refluxed for 1.5 h and diethylene glycol diacetate (6.5 g, 37.5 mmol) was added.[19] The mixture was stirred at 25 °C for 16 h, poured into water, and extracted with ether. Purification by column chromatography on silica gel gave 1-acetoxy-2-allyl-1-vinylcyclohexane (4.0 g, 52%) which was further converted in similar way to silyl enol ether **16** (2.5 g, 65% overall yield): IR (neat) 1736, 1678, 1671, 1010, 908 cm^{-1}; NMR (CCl_4) δ 0.18 (s, 9H), 1.95 (s, 3H), 3.90 (s, 2H), 4.89 (d, 1H, J=17 Hz), 5.03 (d, 1H, J=11 Hz), 5.94 (dd, 1H, J=11, 17 Hz); MS *m/e* (%) 253 (8), 237 (14), 236 (28), 223 (5), 222 (8), 221 (28), 195 (8), 193 (8), 182 (16), 147 (34), 117 (33), 91 (36), 75 (43), 73 (100); Found: *m/e* 296.1810. Calcd for $C_{16}H_{28}O_3Si$: M, 296.1808.

The authors wish to thank the Ministry of Education, Science and Culture, Japan, for the Grant-in-Aid (110309, 203014, 303023, 335042, 403022).

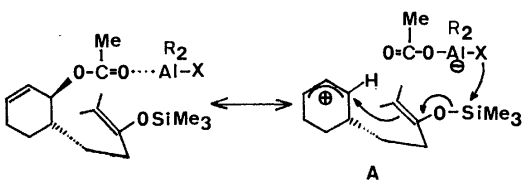
6) The most economical assumption to account for the observations as mentioned here would be as follows. Coordination of the aluminum reagent R_2AlX on the allyl acetate moiety of the substrate **1** in Eq. 1 produces the adduct **A**:



A

The very tight ion-pair lying slightly above the level of such an adduct may experience the attack on silicon atom either by X or by acetoxyl oxygen. This will result in "almost concerted" cyclization proceeding in the stereospecific manner as observed to afford completely homogeneous *cis*-octalone (**2**). Molecular models show such a process can not be expected with the *cis*-substrate (**3**). Similar explanation applies to Eq. 3 through 6. The importance of this kind of combined acid-base attack in the reactions of R_2AlX

reagents has been mentioned, see Refs. 7 and 8.

(Received January 21, 1980)

The relative dissociation constants of meta and para substituted pyridinium ions in H_2O at 25 °C were collected from a number of sources. To understand the actual substituent effects with a combination of inductive(I) and pi-electronic(Pi) effect components, the LSFE equation has been employed statistically for each of the meta and para series.

$$\Delta pK_a = \rho_i\sigma_i + \rho_\pi^+\sigma_\pi^+ + \rho_\pi^-\sigma_\pi^-$$

The results illustrate (1) the I effect from the meta position is 1.2 times more effective than that from the para position, (2) the Pi effects from the para position have clearly different sensitivities for pi-donor($-R$) and pi-acceptor($+R$) classes of substituents; more exalted and more reduced Pi effects than that involved in σ_p° constants for $-R$ and $+R$ groups, respectively. Compared with earlier results from the Taft's DSP and relevant treatments, the soundness of the dual ρ_π approach and, further, the superiority of the LSFE treatment have been demonstrated for the description of substituent effects on basicity changes in pyridines.

Substituent effects on benzene reactivities have been most widely handled with a combination of two components, polar (inductive, I) and resonance (pi-electronic, Pi) effects, each of which is given as a $\rho\sigma$ product.[1,3,4] In an attempt to justify this treatment, the analysis of substituent effects in the extended pi-electron system of naphthalene has been discussed previously.[1,4f] The same treatment should be applicable to reactivities in heteroaromatic pi-electron systems.

Meta and para substituted pyridines are an interesting system for an application of the separation analysis in heteroaromatic reactivities. For basicities of pyridines, certain contradictions have recently appeared in the rationalization of the substituent effects obtained from different equations.[5,6] The validity of an equation may be tested most critically by establishing whether or not the substituent effects on reactivities in pyridines can be treated successfully. In this sense, Taft and coworkers have stressed the power of the DSP treatment[4a] mainly on the basis of the following two facts:[5] (i) the σ_R^+ parameter gives the best-fit DSP correlation, as anticipated from a structural point of view; (ii) the resultant ρ_I is essentially identical with the ρ_I for the corresponding saturated system, the 4-substituted quinuclidines.[7]

$$(\Delta pK_a)_{py}^{p} = 5.15\sigma_I + 2.69\sigma_R^+ \quad (1)$$

$$(\Delta pK_a)_{py}^{p} - (\Delta pK_a)_{qu}^{4} = 2.87\sigma_R^+ \quad (2)$$

The latter point is particularly notable, since it is in line with the relationship between benzoic acid and bicyclo[2.2.2]octane-1-carboxylic acid.[8]

Johnson *et al.* have interpreted the pi-donor para substituent effects using Eq. 3, based on the assumption that substituent effects of para pi-acceptors are exclusively inductive.[6,9]

$$(\Delta pK_a)_{py}^{p} = 5.66\sigma \text{ (for pi-donors) and } 5.66\sigma_I \text{ (for pi-acceptors)};$$

$$(\Delta pK_a)_{py}^{p} - 1.19\ (\Delta pK_a)_{qu}^{4} = 5.66\sigma_R \text{ (for pi-donors)} \quad (3)$$

They argued that the correlation with σ_R parameters (instead of σ_R^+) cast doubt on the validity of the DSP and, generally, of multiple substituent parameter treatments,[6] including our LArSR treatment. Thus, using the same data sets for pyridines and quinuclidines, different authors have reached conflicting conclusions on the significance of the DSP treatment.

We have demonstrated the applicability and the validity of the LSFE Eq. 4 through appropriate separation of substituent effects in various aromatic hydrocarbon systems as well as in the ordinary benzene system.[1]

$$\log k/k_o = \rho_i\sigma_i + \rho_\pi^+\sigma_\pi^+ + \rho_\pi^-\sigma_\pi^- \quad (4)$$

In the present study, we apply Eq. 4 to the analysis of substituent effects on the basicity of pyridines and provide evidence for the significance of the dual ρ_π approach for pi-donor and pi-acceptor substituents characteristic of our LSFE treatment, Eq. 4. The results provide a solution to the above controversial problem on the DSP treatment and characterize the LSFE treatment as a precise and useful equation for the separation analysis of actual substituent effects.

Results and Discussion

A number of reliable ΔpK_a values have been collected from various sources (Table 1). The ΔpK_a values were defined by $pK_H - pK_X$, where both data were determined by the same authors and under the same experimental conditions, unless otherwise noted. From examination of earlier compilations, together with some additional fragmentary data, best values were selected and are listed in the last column of Table 1. The data set consists mostly of Fischer's results, but for alkyl and nitro substituents, Brown's and Bellobono's data were employed, since, for the alkyl substituents, meta and para data were available as a pair, and, for the nitro substituent, Fischer's value was much lower than that reported by the other two authors. A full set of basicity data has been constructed for a total of 52 meta and para substituents.[20]

The present data set for the basicities of pyridines

is comparable in size with that of ΔpK_a for benzoic acids, and shows large substituent effects ($\rho \simeq 6$)[9b] particularly useful for analysis of the substituent effects in detail. Since the solvent is water, it is not necessary to consider solvent modification of substituent constants.[3b]

A least squares calculation gives a linear relation of ΔpK_a with σ_m for meta substituents (n=20) with high precision.[21]

NO_2	0.46	0.000	0.332

a) Data taken from Refs. 22 and 23. b) Not confirmed yet. See Ref. 3b. c) Calcd by 0.415 $\Delta\bar{\sigma}_R^+$. The $\Delta\bar{\sigma}_R^+$ value of *p*-NH_2 was redetermined most recently as −1.10.[24]

$$(\Delta pK_a)_{py}^{m} = 6.240\sigma_m - 0.070 \quad (5)$$

Based on this correlation, apparent $\bar{\sigma}$ values for the pyridine system ($\bar{\sigma}_{py}$) are evaluated as (ΔpK_a+0.07)/6.24 in the same way as in the benzene reactivities (Table 2). In order to shed further light on the substituent effects in the pyridine system, it is appropriate to examine the application of LSFE Eq. 4 to the same data set.

As suggested by Taft, the reliability of any multiparameter correlation depends upon the spread of the values of substituent constants as well as on the non-linearity between the two sets of substituent constants.[4a] The present set covers a sufficiently wide range of substituents whose σ_I and σ_R values, given in Table 3, are scattered widely in an independent manner. In the present analysis, SMe, I, and $NHCOC_6H_5$ substituents were not included, since the substituent constants have not yet been well established. For alkyl groups, only methyl and ethyl groups were included as representative alkyls to prevent too much weight being attached to this class of substituents.

Table 4 summarizes the results of the LSFE analysis,[1,3,22-25] together with those of the relevant Taft DSP[4a,5] and of Johnson's[6] treatments. Examination of the LSFE correlation results reveals the following important facts.

(1) The LSFE Eq. 4 applies both for para and meta series in the present system with excellent precision comparable to that for correlations in the benzene system.

TABLE 4. CORRELATION PARAMETERS BY MEANS OF LSFE AND DSP TREATMENTS

Treatment	Position	Correlation parameters with substituent constants[a)]	Corr. coeff.	SD	Substituents included
LSFE	para	$6.49\sigma_I+9.50\sigma_R^+ +2.20\sigma_R^- -0.03$	0.9972	0.175	Me, Et, Cl, Br, OMe, NH_2, NMe_2, Ph, H, CF_3, COMe, CN, NO_2, COPh, COOMe.
LSFE	meta	$7.67\sigma_I+3.62\sigma_R^+ +2.03\sigma_R^- +0.01$	0.9974	0.123	Me, Et, F, Cl, Br, OMe, NH_2, NMe_2, H, COMe, CN, NO_2, COPh, COOMe.
DSP	para	$5.28\sigma_I+2.71\sigma_R^+ -0.03$	0.9987	0.120	Me, Cl, Br, OMe, NH_2, NMe_2, Ph, H, CF_3, COMe, CN, NO_2, COOMe.
DSP	para	$5.45\sigma_I+4.92\sigma_R(BA)-0.26$	0.9944	0.259	Me, Cl, Br, OMe, NH_2, NMe_2, Ph, H, CF_3, COMe, CN, NO_2, COOMe.
DSP	meta	$6.40\sigma_I+2.69\sigma_R^\circ -0.09$	0.9975	0.124	Me, F, Cl, Br, OMe, NH_2, NMe_2, H, COMe, CN, NO_2, COOMe.
Johnson's[b)]	para	$5.69\sigma_X+0.10$	0.9979	0.172	Me, Cl, Br, OMe, NH_2, NMe_2, Ph, H, CF_3, COMe, CN, NO_2, COOMe.

a) The numerical values for the DSP treatment are taken from Ref. 4a. b) $\sigma_X=\sigma_I+\sigma_R$(BA) for pi-donor substituents and $\sigma_X=\sigma_I$ for pi-acceptors.

(2) In the para correlation, the ρ_R^+ value differs from the ρ_R^-; the ρ_R^+ is higher than, but the ρ_R^- is significantly lower than, the ρ_I value. Note that in our LSFE Eq. 4, $\rho_I=\rho_R^+=\rho_R^-$ or $\rho_R^+/\rho_I=\rho_R^-/\rho_I=1.00$ refers by definition to the benzene σ_p° set.[1,3,22-25)] Neither the ratio ρ_R^+/ρ_I nor ρ_R^-/ρ_I is equal to unity in the present case, but the former (=1.5) is comparable to that of 1.6 for the σ_p constant,[26)] and the latter is much lower than that of 1.0 for the σ_p° constant. The ratio of ρ_R^+/ρ_R^- (=4) is comparable to that for the σ_p^+ constant.[26)]

(3) In the meta series, $\rho_R^+\simeq\rho_R^-$ is approximately satisfied and both ρ_R^+/ρ_I and ρ_R^-/ρ_I give essentially the same value of 0.4, which is comparable to the ratio in the benzene σ_m constant.[26)] It is worthy of note that the ρ_R^- value for the para pi-acceptor series is comparable to either ρ_R^- or ρ_R^+ for the meta series.

(4) The ratio of the inductive components in the meta and para substituent effects, ρ_I^m/ρ_I^p, is found to be 1.18, which is virtually identical with the corresponding ratio 1.17 in the benzene system. Based on $\sigma_I^m=1.17\sigma_I^p$ as in the benzene reactivity, the ρ_m value can be given as 6.5. This lends some support to the basic assumption of Hammett-type treatments; $\rho_m=\rho_p$ is as valid for the pyridine system as for the benzene system.

It is clear from (2) that the effect of pi-donor substituents at the para position is not significantly exalted relative to σ_p° and that the effect of pi-acceptors consists of a minor *Pi* effect. This is further suggested by the LArSR correlation for the present system (corr. coeff., 0.996 and standard deviation, ±0.21):

$$(\Delta pK_a)_{py} = 6.27\ (\sigma^\circ+0.20\Delta\bar{\sigma}_R^+ -0.48\Delta\bar{\sigma}_R^-).$$

The small r^+ and large negative r^- are in good accord with Johnson's conclusion rather than with the conclusion from the best-fit DSP correlation.

As far as the inductive contribution is concerned, all of the characteristic features of the LSFE treatment of the benzene system are found in the pyridine system, (4). In the benzene system, a bi-linear pi-electronic free energy relationship has been shown generally to result from combined meta and para substituent effects based on the inductive contribution factor of 0.85 (=1/1.17):[1,3,22-25)]

$$(\Delta pK_a)^p - 0.85(\Delta pK_a)^m = C_R^+\sigma_R^+ + C_R^-\sigma_R^-.$$

Here, the C_R^+ and C_R^- are coefficients[27)] describing pi-electronic contributions for pi-donor and pi-acceptor substituents, respectively, and are referred to as a simple function of ρ_R^+ or ρ_R^- parameter. As shown in Fig. 1, a good bi-linear relationship intersecting at the unsubstituted point is obtained without the aid of any inductive constants, suggesting the importance of different susceptibilities (duality) to the pi-electronic effect for pi-donor and pi-acceptor substituents in the present pyridine system. The slope for the acceptor groups is close to zero, providing evidence for the small *Pi* contribution from these groups.

The actual substituent effects on the basicities of pyridines are reasonably understood by the LSFE results, characterized by the dual pi-electronic effects. Unit positive charge in the conjugate acid of pyridine probably causes a moderately exalted pi-delocalization with para pi-donor substituents as compared with the *Pi* effect in the σ_p° constant, whereas it also causes the pi-delocalization interaction with para pi-acceptor groups to be lower than that in the σ_p° (repulsive acceptor-acceptor pi-interaction). For electrophilic reactivities in the benzene system, one could observe an exalted pi-delocalization with pi-donors, but scarcely detect such a repulsive saturation in *Pi* effect with pi-acceptor substituents. The present LSFE results for the pyridine system provide further evidence sub-

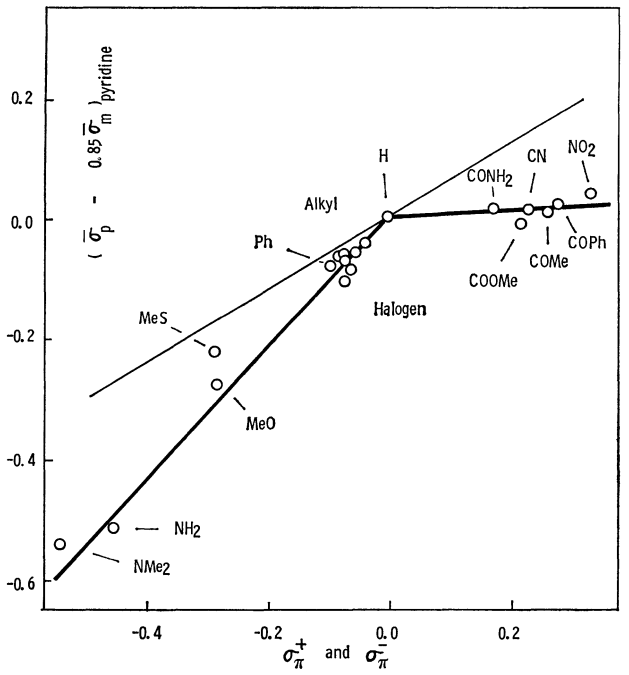

Fig. 1. The quantity of $\bar{\sigma}_p - 0.85\bar{\sigma}_m$ in the pyridine basicity against σ_π^+ and σ_π^-.
A thin line represents the corresponding plot of $\sigma_p^\circ - 0.85\sigma_m$ *vs.* $\sigma_\pi^\pm$.

stantiating the dual *Pi* effects for the analysis of substituent effects on general reactivities.

The DSP treatment,[4,8] using one of the four distinct resonance substituent constants, also results in good correlations of comparable precision for meta and para series by means of σ_R° and σ_R^+ constants, respectively (Table 4). However, significantly different inductive effects were obtained for meta and para derivatives; $\rho_I^m=6.40$, $\rho_I^p=5.28$ (Table 4). From the comparison with ρ_m value, the ρ_I value for the meta correlation appears to be more reasonable. The higher ratio, $\rho_I^m/\rho_I^p=1.2$, may indicate a breakdown of the original Taft assumption,[4a,e] $\rho_I^m=\rho_I^p$. It is interesting to note that the ρ_I in Johnson's correlation is nearly equal to the ρ_I derived from the DSP treatment with σ_R resonance constant (Table 4).

The LSFE treatment essentially stands on the concept that there exists a universal set of pi-electronic effect constants, σ_π^+ and σ_π^-, and that the pi-electronic contributions are expressed as a linear (or bilinear) function of σ_π using dual susceptibilities of ρ_π^+ and ρ_π^- for pi-donor and pi-acceptor substituents, respectively. The relative importance of the pi-electronic contribution from pi-acceptor/pi-donor substituents in any given system is generally accounted for by the ratio of both ρ_π values, whereas in the DSP treatment with a single ρ_R parameter, the relative importance of pi-donor/pi-acceptor resonance must be judged only by the best-fitting $\bar{\sigma}_R$ set. Continuous spectrum of ρ_π^+/ρ_π^- ratio with reaction systems must be characterized by four specific $\bar{\sigma}_R$ classes in the DSP treatment. This duality for the pi-electronic contributions is the most important feature of the LSFE treatment. Johnson's treatment is an extreme case of the dual ρ_π treatment, that is $\rho_\pi^-/\rho_\pi^+\to 0$. The requirement for the σ_R^+ set for the best-fit DSP correlation of the present system is due simply to the high ratio of pi-donor/pi-acceptor resonance contributions; *i.e.*, $\rho_\pi^+/\rho_\pi^-=4$.

Even though the requirement for the σ_R^+ set might imply the enhancement of pi-donor relative to pi-acceptor resonance, the enhancement of resonance relative to inductive effect is found to be quite low; $\rho_R/\rho_I\simeq 0.5$ in the pyridine para series (DSP, Table 4). Accordingly, the actual resonance contribution in this system is not so large as σ_R^+ in the σ_p^+, but is comparable with σ_R in the σ_p constant (since $\sigma_R^+\simeq 1.9\sigma_R$ roughly holds for pi-donors) and the *Pi* contribution of pi-acceptors is as low as that involved in the σ_m constant. Thus, the actual resonance effect evaluated by the best-fit DSP correlation with σ_R^+ is in fact at least qualitatively identical to that evaluated by Johnson's treatment as well as ours. Further, it is worthy of note that the σ_R^+ correlation gives excellent results with precision comparable to ours (Table 4). Johnson argued that the resonance contribution from para pi-acceptors is unreasonable, based on the observed insensitivity to steric twisting of the para nitro derivative. However, the minor resonance contribution of para pi-acceptors, comparable to that from the meta series suggested by DSP analysis, does not appear to be unreasonable, since not all the *Pi* contribution may be eliminated by means of steric twisting of the substituent. Likewise in the LSFE treatment, the *Pi* contribution estimated by the $\rho_\pi\sigma_\pi$ term should not all be referred to as the pi-delocalization effect, but may involve appreciable *I*-π interaction, which is insensitive to the loss of coplanarity.

The point of controversy between Johnson and Taft and coworkers arises from their interpretation of the correlation results. The difference is due essentially to the basic tenet of the DSP approximation.

General reactivities are classified into four distinctly different classes, σ°, σ, σ^+, and σ^-, depending on the mode of resonance interactions. The DSP treatment assumes that each class of substituent effects should be described only by a particularly suited one of four sets of resonance substituent constants, σ_R°, σ_R, σ_R^+, and σ_R^-, characteristic of the corresponding reactivity classes.[4a] In the present case, the requirement of σ_R^+ for the best-fit leads to the conclusion that the system belongs to the σ^+-class reactivity. The Johnson's σ_R-correlation, then, had to be a matter of controversy, since he also adheres to this traditional tenet. The above LSFE analysis provides a key to the solution of the controversy. Brownlee and Topsom put too much importance on the requirement of the σ_R^+ set in their interpretation,[5b] whereas the LSFE results put importance rather more on the resulting $\lambda(=\rho_R/\rho_I)$ value in the DSP treatment, in line with Johnson's criticism. The best-fit $\bar{\sigma}_R$ does not unequivocally indicate the class of resonance demand of the system.

A closely related system, the basicities of pyridine *N*-oxides, is an instructive example in this connection. The substituent effect on the basicities was proposed

to be roughly treated with the σ^+ constants for pi-donor substituents and the σ^- constants for pi-acceptor ones.[28] For this reactivity set, the DSP treatment has been found to give excellent best-fit correlations with either the σ_R or the $\sigma_R^\pm$ set.[29] Thus, the classification based on the best-fit $\bar{\sigma}_R$ set does not have any significance in this system. Further, the Johnson's treatment by no means applies to this system.

Finally, the ΔpK_a data of quinuclidines[7] can be directly incorporated into the regression analysis as an inductive measure instead of using σ_i constants.[30]

$$(\Delta pK_a)^p_{py} = 0.93\ (\Delta pK_a)_{qu} + 9.7\sigma_\pi^+ + 2.4\sigma_\pi^- \quad (6)$$

$$(\Delta pK_a)^m_{py} = 1.12\ (\Delta pK_a)_{qu} + 3.9\sigma_\pi^+ + 2.1\sigma_\pi^- \quad (7)$$

The result again verifies our basic assumption of the duality of *Pi* contributions and the unique position dependency of the *I* contribution, $I_m/I_p=1.17$. The effective scale of the *I* effect relative to that of quinuclidine is found to be 0.93 for the para series. This value differs appreciably from either 1.00 assumed by Taft (Eq. 2) or 1.19 employed by Johnson (Eq. 3). The problem is associated with the scaling of the inductive effects between the aromatic and the equivalent saturated systems, which will be discussed in a separate paper.

(Received January 24, 1980)

Baeyer-Villiger oxidation of 4′-acetylbenzocrown ethers followed by alkaline hydrolysis was proved to be a convenient route to 4′-hydroxybenzo-15-crown-5 and -18-crown-6, which formed air-stable hydrated crystals containing three and one mole of water, respectively, on crystallization from the solvent containing a small amount of water. New bis(benzocrown ether)s, connected by poly(oxyethylene) chain, were obtained in good yields by the reaction of the sodium salts with the ditosylates of di-, tri-, tetra-, and pentaethylene glycol.

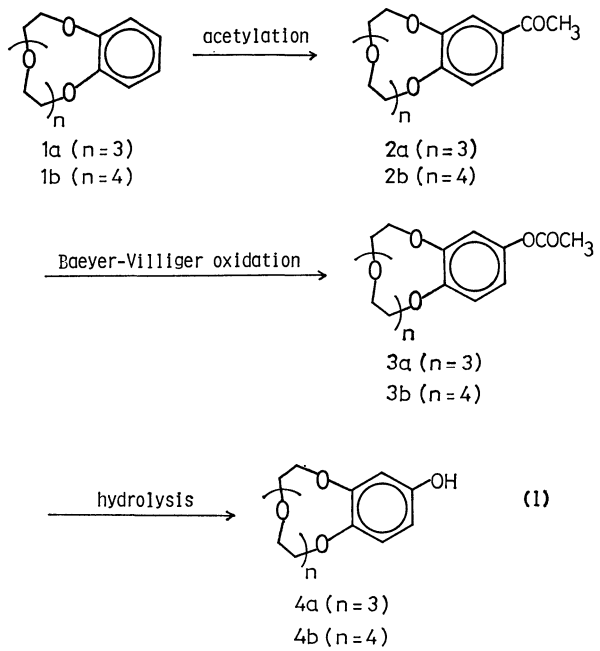
Various substituted benzocrown ethers have been synthesized by either electrophilic substitution to benzocrown ethers or crown ring forming cyclization of substituted catechols. The substituents of the compounds not only serve to modify the nature of complexation with cations, but also have been successfully utilized for preparing other functionalized benzocrown ethers, such as 4′-vinylbenzocrown ethers[2] and several bis(benzocrown ether)s.[3,4] Hydroxybenzocrown ethers are thought to be interesting starting materials for the latter purpose because of the reactive aromatic ring and of the utility of the phenolic hydroxyl group. Thus, various bis(benzocrown ether)s and long-chain substitued benzocrown ethers could be obtained by the reaction of the sodium salts with α,ω-di-, and monotosylates of polymethylene or poly(oxyethylene) chain, respectively. This paper describes the synthesis of 4′-hydroxybenzocrown ethers and the bis(benzocrown ether)s being linked with tri-, tetra-, penta-, and hexa(oxyethylene) chain.

Results and Discussion

4′-Hydroxybenzocrown Ethers. Successful preparation of 4′-hydroxybenzo-15-crown-5 (**4a**) and -18-crown-6 (**4b**) were achieved by the following route (Eq. 1). Hydrolysis of the diazonium salts of 4′-aminobenzocrown ethers in aqueous acid or in the presence of copper catalyst[5] afforded the mixture being too complex to allow isolation, and oxidation of benzocrown ethers with $Tl(OCOCF_3)$[6] led to decomposition of the starting materials.

4′-Acetylbenzocrown ethers (**2**) were prepared by acetylation of the corresponding benzocrown ethers (**1a** and **1b**) with acetic anhydride–polyphosphoric acid in acetic acid at 45 °C for 3 h. Yields of **2a** and **2b** under the optimized reaction conditions were 83% and 80%, respectively.[7] Use of aluminium chloride as the catalyst was proved to be unpractical because of deactivation of the catalyst, and in the reaction of **1a**, **1a**–aluminium chloride (1:1) complex, stable in protic solvent, could be isolated.[7]

Baeyer-Villiger oxidation[8] of **2** with peracetic acid at 30—32 °C for 5 h affords 4′-acetoxybenzocrown ethers (**3**) in high yields. The crude products were purified by either extraction with hot heptane or chromatography on a short alumina-silica gel column (THF or $CHCl_3$) to give white crystals.



Hydrolysis of **3** to 4′-hydroxybenzocrown ethers (**4**) was carried out with aqueous sodium hydroxide at 40—50 °C for 3 h under nitrogen atmosphere. The crude product (**4a**) from **3a** was immediately precipitated as fine needles when the reaction mixture was acidified. In cases where the precipitation did not occur due to inadequate concentration of the product in the acidified solution, the product could be collected by extraction with chloroform. The crude product was further purified by recrystallization from a mixed solvent (THF–$CHCl_3$) containing a small amount of water to give white needles. The crystals were shown to contain three moles of water by measurement of loss of weight under vacuum at 110 °C for 3 h, and also by elemental analysis. Since **4b** did not separate as precipitate under the similar treatment, the product was taken up with chloroform and recrystallized from wet diethyl ether to give flat plates containing one mole of water. The monohydrated crystals showed a single melting point, 52.3—52.6 °C, without any visual transition of the crystal form,

TABLE 1. PREPARATION OF α,ω-BIS(4′-BENZOCROWN ETHER)POLYETHYLENEOXYETHERS

Crown	n	m	Yield/%	Mp/°C	Found C	Found H	Calcd (%) C	Calcd (%) H

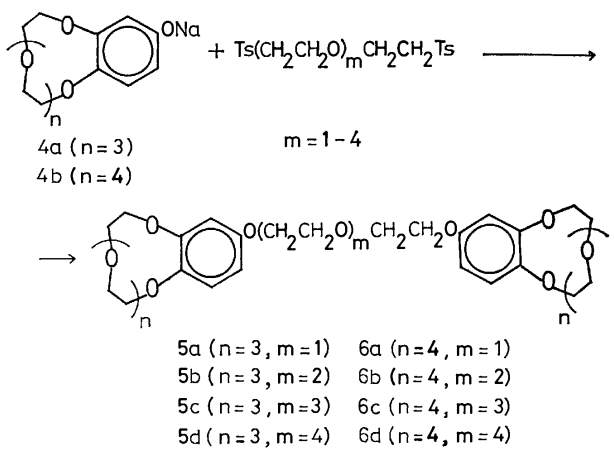
a) 1,8-Dichloro-3,6-dioxaoctane (triethylene glycol dichloride) was used in 1-butanol. The bis(benzocrown ether) was separated by HPLC since the recation product contained butyl ether of 4′-(9-hydroxy-1,4,7-trioxanonyl)-benzo-15-crown-5.

and were easily dehydrated under vacuum at room temperature for a few hours to afford a white solid. On the other hand, the hydrated crystals of **4a** showed two stage of transition of the crystal form at 43—47 °C and 75—78 °C, and completely melted at 100—103.0 °C (mp of the dehydrated crystals). Since, when being dehydrated, both **4a** and **4b** are liable to oxidized by air and readily impart a brown color, it is preferable to store in their hydrated forms and under nitrogen atmosphere. Although Cram and his coworkers[9)] recently described a monohydrated crown ether (a complex), such a trihydrated crown ether has not been reported.

Bis(benzocrown ether)s. Bis(benzocrown ether)s containing crown ether moieties at the two ends of a polymethylene or poly(oxyethylene) chain are known to have increased tendency of loose ion pair formation, and thus are expected to be effective in enhancing the reactivity of anionic species.[3)] Bis(benzocrown ether)s linked by ether linkages with poly(oxyethylene) chain are expected to be more resistant to the action of base (or acid)[4b)] than the known bis(benzocrown ether)s bridged by ester linkages,[3,4a)] and could be favorably utilized to various crown ether assisted reactions. Preparation of the bis(benzocrown ether)s were readily performed by the reaction of *in-situ* prepared sodium salts of **4a** or **4b** (from their dehydrated forms) with two molar equivalents of ditosylates of di-, tri-, tetra-, and pentaethylene glycol in THF (or dioxane–DMSO (10%)) (Eq. 2).



The crude products were chromatographed through an alumina column ($CHCl_3$), and recrystallized from ether–methanol (40:1). The purity and the structures of the products were confirmed by HPLC, IR, NMR, and elemental analysis. The results are summarized in Table 1, but the optimization of the yields has not been carried out.

Features of complex formation with cations and in S_N2 type reactions of these compounds are being investigated.

Experimental

Materials. Benzocrown ethers[10)] (**1a** and **1b**) and the ditosylate[11)] of di-, tri-, tetra-, and pentaethylene glycol were prepared according to the published procedures, respectively. Peracetic acid (9%) in acetic acid was prepared according to the published procedure.[12)]

4′-Acetoxybenzocrown Ethers (3a and 3b). Typical procedure was as follows. To the acetic acid solution of **2** (4.8 mmol), 8.0 g (9.5 mmol) of 9% peracetic acid was added dropwise over a 30 min period at 30—32 °C, and further stirred for 5 h. Longer reaction time caused a decrease of product yield. After aq sodium thiosulfate was added to the reaction mixture to decompose the excess peracetic acid, the solution was neutralized to pH 6 by the addition of Na_2CO_3, and extracted with chloroform. The chloroform layer was dried ($MgSO_4$), and the solvent was removed under vacuum. The residue was purified as mentioned above. 4′-Acetoxybenzo-15-crown-5 (**3a**): 82%; mp 57.0—58.2 °C; M^+: 326; ^{1}H-NMR (δ, $CDCl_3$): 2.25 (CH_3, 3H, singlet), 3.10—4.20 (-OCH_2CH_2O-, 16H, multiplet), 6.30—6.95 (aromatic protons, 3H, multiplet); Found: C, 58.60; H, 6.78%. Calcd for $C_{16}H_{22}O_7$: C, 58.89; H, 6.78%. 4′-Acetoxybenzo-18-crown-6 (**3b**): 65%; mp 48.5—50.0 °C; ^{1}H-NMR (δ, $CDCl_3$): 2.25 (CH_3, 3H, singlet), 3.30—4.30 (-OCH_2CH_2O-, 20H, multiplet); Found: C, 58.16; H 7.08%. Calcd for $C_{18}H_{26}O_8$: C, 58.37; H 7.07%.

4′-Hydroxybenzocrown Ethers (4a and 4b). To a suspension of 4′-acetoxybenzo-15-crown-5 (**3a**) (40 mmol) in water was added aq NaOH at 40—50 °C and the reaction mixture was stirred for 3 h under nitrogen atmosphere. Acidification of the reaction mixture to pH 2 with concd H_2SO_4 gave **4a** (trihydrated form) as fine needles. The precipitate was purified by recrystallization from THF–$CHCl_3$ (1:5) containing a small amount of water. Since **4b** did not formed from the mixture as precipitate under the similar treatment, the product was extracted with chloro-

form and the chloroform layer was dried ($MgSO_4$). After evaporation of solvent, the residual oily product was purified by chromatography (alumina, $CHCl_3$) and following recrystallization from wet diethyl ether. 4′-Hydroxybenzocrown ether (**4a**); 93% mp 100.9—103.0 °C (dehydrated crystal); ^{1}H-NMR (δ, CD_3CN): 2.39 (H_2O, 6H, singlet), 3.55—4.30 (–OCH_2CH_2O–, 16H, multiplet), 6.10—6.82 (aromatic protons, 3H, multiplet), 6.93 (–OH, 1H, broad singlet); Found: C, 49.62; H, 7.62%. Calcd for $C_{14}H_{20}O_6 \cdot 3H_2O$: C, 49.70; H, 7.74%. 4′-Hydroxybenzocrown ether (**4b**): 82%; mp 52.3—52.6 °C; ^{1}H-NMR (δ, CD_3CN): 2.27 (H_2O, 2H, singlet), 3.52—4.34 (–OCH_2CH_2O–, 20H, multiplet), 6.06—7.04 (aromatic protons and –OH, 4H, multiplet and broad singlet were overlapped); Found: C, 55.58; H 7.63%. Calcd for $C_{16}H_{24}O_7 \cdot H_2O$: C, 55.48; H, 7.54%.

*Bis(benzocrown ether)s (**5** and **6**).* General procedure. Triethylene glycol ditosylate or dihalide (1.5 mmol) in THF (or dioxane) was added dropwise to the mixture of 4′-hydroxybenzocrown ether (**3a**) (3 mmol) and sodium hydroxide (5.5 mmol) in THF (or dioxane–DMSO (10%)) under nitrogen atmosphere over a period of 2—3 h and then refluxed for 16—20 h. The reaction mixture was filtered and the filtrate was concentrated under vacuum. The residual oily product was chromatographed through an alumina column ($CHCl_3$) and purified by recrystallization from ether-methanol (40:1). The purity and structures of the product was confirmed by IR, NMR, HPLC, and EA. ^{1}H-NMR (δ, $CDCl_3$); **5a**: 3.46—4.35 (–OCH_2CH_2O–, 40H, multiplet), 6.15—6.94 (aromatic protons, 6H, multiplet). ^{1}H-NMR of other bis(benzocrown ether)s were closely resemble to that of **5a**.

Novel Synthetic Reactions Using Bis(2,2,2-trifluoroethoxy)diorganosulfuranes

Tomoya KITAZUME and Nobuo ISHIKAWA*

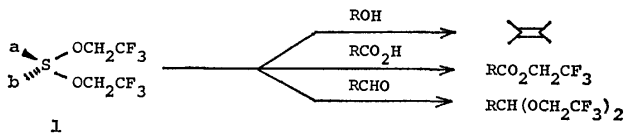
Department of Chemical Technology, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received November 24, 1979)

Alkoxy- or acyloxysulfuranes prepared *in situ* by the ligand exchange of bis(2,2,2-trifluoroethoxy)diorganosulfuranes with alcohols or carboxylic acids were found to behave as a potential alkylating or acylating reagent for the preparation of unsymmetrical sulfides, ketones, and esters.

Many studies have been made on the use of sulfuranes[1-18] but only a very few report on their application to organic synthesis, *viz.*, sulfilimines,[7,8,16] epoxides,[6] and olefins.[6,18]

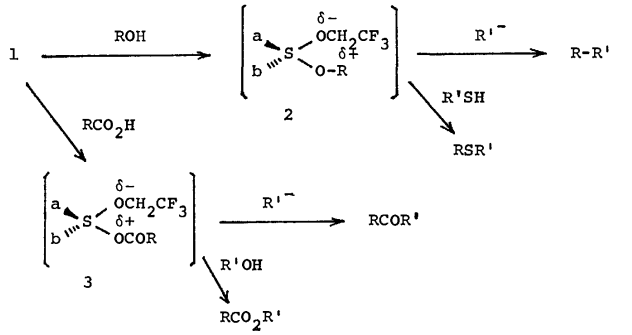
Recently we reported the preparation of bis(2,2,2-trifluoroethoxy)diorganosulfuranes (**1**) in CH_2Cl_2–Et_2O system, and its reactions with alcohols, aldehydes, and carboxylic acids, affording olefins, 2,2,2-trifluoroethylated acetals, respectively.[1]



1

1A (a=b=Ph), 1B (a=Me, b=Ph)

The rapid ligand exchange of one of 2,2,2-trifluoroethoxyl groups of **1** with alcohol or carboxylic acid, giving (2,2,2-trifluoroethoxy)(alkoxy)diorganosulfurane (**2**) or (2,2,2-trifluoroethoxy)(acyloxy)diorganosulfurane (**3**) which affords a positive alkyl or acyl group, has a marked effect on the use of sulfuranes in organic synthesis.



In a continuation of our research on the reactivity of **1**, we report on the formation of unsymmetrical sulfides, ketones, and esters.

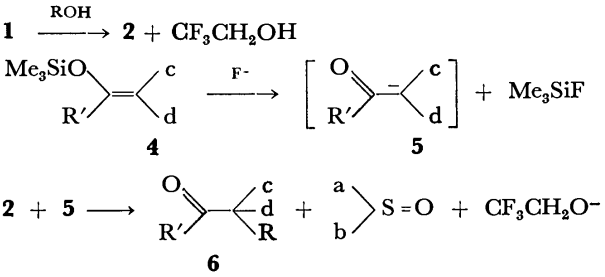
Results and Discussion

Extensive investigations have been carried out on carbon–carbon bond formation, but only a few reports have appeared on *C*-alkylation by alcohols.[19-22]

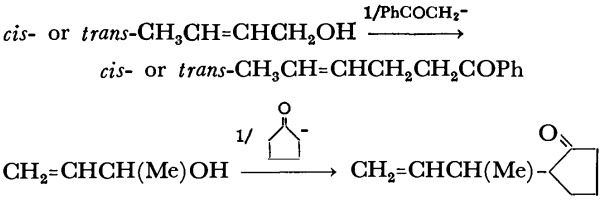
We postulated the presence of (2,2,2-trifluoroethoxy)-(alkoxy)diorganosulfurane (**2**) with a positive alkyl group,[1] and have attempted to establish the carbon chain lengthening using **2**.

The reaction between **2** and Grignard or organolithium reagents was carried out first. However, 2,2,2-trifluoroethyl alcohol released in these systems reacts readily with magnesium or organolithium reagents, and the yields of the expected products were poor.

In contrast, an enolate anion, **5**, generated from trimethylsilyl ether–potassium fluoride system[23-27] readily attacked a positive carbon atom in alkoxysulfurane **2** to form a C–C bond compound (**6**).

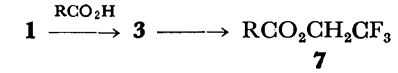


The results showing that no reaction occurs without an alcohol, olefins being obtained from alcohols in the absence of potassium fluoride, support the mechanism in which the ligand exchange of one of 2,2,2-trifluoroethoxyl groups for an alkoxyl group takes place first, the resulting **2** affording a positive alkyl group. A fluoride ion from potassium fluoride would aid formation of the carbanion (**5**) from the silyl enol ether (**3**), and the carbanion would attack the positive carbon atom of **2** to give a product **6**. The procedure seems to be effective for regioselective C–C coupling together with retention of configuration. No allylic rearrangement was observed in the reaction with allyl alcohols (Table 1).



Synthetic application of **1** has been examined as regards the conversion of alcohols into sulfides.[28-30] The high dehydrating ability of the sulfurane made possible the one-pot regioselective synthesis of unsymmetrical alkyl aryl and aryl aryl sulfides (Table 2).

The formation of 2,2,2-trifluoroethyl esters (**7**) by the reaction of sulfurane **1** with carboxylic acids[1] leads to various applications of the intermediate sulfurane **3**.



In fact, the enolated anion **5** and other nucleophiles such as alcohols attacked the positive carbon atom of **3** at −78 °C.

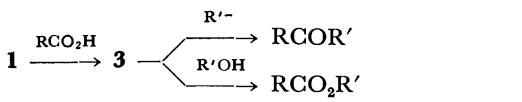
Soc.*, **72**, 59 (1950). d) J. J. Bryan and D. W. Hysert, *Can. J. Chem.*, **49**, 325 (1971). e) T. Kubota, S. Miyashita, T. Kitazume, and N. Ishikawa, *Chem. Lett.*, **1979**, 845.



In each case, inhibition of the pseudorotation to produce 2,2,2-trifluoroethyl esters seems advantageous for producing ketones and esters.

In conclusion, the sulfurane **1** is a useful precursor through **2** or **3** for organic synthesis.

Experimental

General procedures are described.

2-Isopropylcyclohexanone. A mixture of bis(2,2,2-trifluoroethoxy)diphenylsulfurane (12 mmol) prepared from chlorodiphenylsulfonium chloride (14 mmol) and sodium 2,2,2-trifluoroethoxide (28 mmol) *in situ*,[1] and isopropyl alcohol (10 mmol) in freshly dried tetrahydrofuran (10 ml) was stirred at room temperature for 5 min. Into the mixture, were added successively 2-cyclohexenyl trimethylsilyl ether (10 mmol) and calcined potassium fluoride (10 mmol). After being stirred for 24 h, the reaction mixture was poured into water and the resulting oily substance was extracted

with diethyl ether. On removing the solvent, the residue was subjected to distillation *in vacuo*. Final purification was performed by preparative gas chromatography through a column containing 25% Silicone DC 550 on Shimalite. The product, 2-isopropylcyclohexanone, was obtained in a 62% yield, bp 80—82 °C/16 mmHg.**

2-Acetylcyclohexanone. A mixture of bis(2,2,2-trifluoroethoxy)methylphenylsulfurane (12 mmol) prepared from chloromethylphenylsulfonium chloride (14 mmol) and sodium 2,2,2-trifluoroethoxide (28 mmol) *in situ*,[1] acetic acid (10 mmol) and freshly dried tetrahydrofuran (10 ml) was stirred at −78 °C for 10 min. After successive addition of 2-cyclohexenyl trimethylsilyl ether (10 mmol) and calcined potassium fluoride (10 mmol), the mixture was stirred for 10 h. The resulting mixture was then poured into water, and subjected to the usual work-up. Distillation gave 2-acetylcyclohexanone in 71% yield, bp 121—123 °C/21 mmHg.

Ethyl Benzoate. A mixture of bis(2,2,2-trifluoroethoxy)methylphenylsulfurane (12 mmol),[1] benzoic acid (10 mmol) and freshly dried tetrahydrofuran (10 ml) was stirred at −78 °C for 10 min. Ethyl alcohol (10 mmol) was added to the reaction mixture, which was then stirred at −78 °C for 10 h. The mixture was poured into water, and the oily substance extracted with diethyl ether. After removal of the solvent, distillation gave ethyl benzoate in 76% yield, by 84—86 °C/10 mmHg.

Ethyl Phenyl Sulfide. A mixture of bis(2,2,2-trifluoroethoxy)diphenylsulfurane (12 mmol),[1] ethyl alcohol (10 mmol), thiophenol (11 mmol) and freshly dried diethyl ether (10 ml) was stirred at room temperature for 24 h. The reaction mixture was poured into water and the oily layer extracted with diethyl ether. The ethereal extract was washed with 5% aq sodium hydroxide solution and dried over magnesium sulfate. After removal of the solvent, the residual oily material was distilled in a vacuum yielding ethyl phenyl sulfide in 62% yield, bp 72—74 °C/6 mmHg.

** 1 mmHg=133.3 Pa.

Studies of Zone Melting. V. The Solid-Liquid Equilibrium and Zone Melting of the Bibenzyl–Diphenylacetylene System

Hidemoto NOJIMA* and Seigou AKEHI

Department of Industrial Chemistry, Faculty of Engineering, Meiji University, Ikuta, Tama-ku, Kawasaki 214

(Received January 17, 1979)

The phase diagram of the bibenzyl–diphenylacetylene system was determined in detail from DSC by using the following equation:

$$T = \alpha\sqrt{F'} + \beta,$$

where T is the temperature; F', the corrected fraction melted, calculated by the use of the area for the vertex of the peak instead of the total peak area and α and β, the constants. Then, the melting and freezing temperatures were obtained from a plot of T *vs.* $\sqrt{F'}$ by the use of the values of β and $\alpha+\beta$ respectively. The results show the formation of solid solutions with a minimum melting point, at which difficulty in determining the composition often arises from the fact that the slopes of both the solidus and liquidus curves are zero. This could be overcome by multipass zone melting for two samples containing 20 and 30 wt % of diphenylacetylene; after 45 zone passes, the composition of the minimum melting point was found to be 26.4% at the end. Also, by Herington's theory, it has been revealed that zone-melting experiments were attained almost at equilibrium.

The behavior of a solute during the zone melting of binary mixtures can be interpreted to some extent by the phase diagrams of these mixtures. Conversely, it follows that a type of phase diagram may be shown from the results of zone-melting experiments. Herington[1] has theoretically described the relation between the zone-melting behavior and the phase diagrams of binary mixtures. However, few applications of zone melting to the study of the phase diagrams of organic compounds have been reported. By the combined use of zone melting and the differential thermal analysis, Jonchich *et al.*[2] have reconstructed the phase diagram of the phenanthrene–anthracene system, which had previously been reported by Bradley and Marsh,[3] and Kofler.[4]

It has also been reported[5] that the bibenzyl–diphenylacetylene system forms a continuous series of solid solutions with Roozeboom's Type I:[6] the freezing points of all mixtures lie between those of the pure components. The present authors, however, have argued against the above conclusion on the basis of the difference between the crystal structures and the molecular sizes of these two compounds.[7] The present work has been carried out in order to prove our argument against the formation of the phase diagram of Roozeboom's Type I; the solid-liquid equilibrium for this system is investigated in detail by means of both zone melting and DSC (differential scanning calorimetry) in the search for a useful equation for determining the melting and freezing temperatures from the relation between the temperature and the corrected fraction melted in DSC. It has thus been verified that this system does not form a continuous series of solid solutions, as has reported previously,[5] but forms solid solutions with a minimum melting point: Roozeboom's Type III.[6] In this case, the solidus and liquidus curves meet at a minimum temperature, at which the phases existing in equilibrium have the same composition. The slopes of both the solidus and liquidus curves at the minimum melting point are zero, in accordance with the Gibbs-Konovalow rule, and the difference between the melting and freezing temperatures on both sides in the vicinity of the minimum melting point is usually slight. Hence, it is often difficult for the composition at the minimum melting point to be determined precisely by ordinary thermal analysis. In this work, the composition of the minimum melting point was determined precisely by multipass zone-melting experiments for two specimens with initial concentrations at both sides near the composition of the minimum melting ponit, which has roughly been predetermined by DSC.

Moreover, the evaluation of the deviation from equilibrium in the multipass zone-melting experiments is discussed by means of Herington's theory.

No zone-melting experiments have previously been reported for this system.

Theoretical

Determination of the Solidus and Liquidus Curves by DSC. A typical DSC peak for a binary mixture forming a solid solution is shown in Fig. 1, in which the fraction melted, F, at a definite temperature, *e.g.*, T_n, is given in the following way:[11,13]

$$F = \frac{\text{area ACHA}}{\text{area AEFA}}. \tag{1}$$

Strictly speaking, Eq. 1 is valid only when the heats of fusion of the constituents are nearly equal and when the heat of mixing can be neglected in comparison with them. From Fig. 1, Eq. 1 may be rewritten as follows:

$$F = \frac{\text{area BCHB}+\text{area ABJA}}{\text{area BDGB}+\text{area DEFD}+\Delta a}, \tag{2}$$

where Δa denotes the difference between the area ABJA and the area FGIF. Equation 2 may further be rewritten as follows:

$$F = \frac{\text{area BCHB}+\text{area ABJA}}{\text{area BDGB}} \cdot \frac{\text{area BDGB}}{\text{area BDGB}+\text{area DEFD}+\Delta a}. \tag{3}$$

Assuming that the area ABJA is small and can be

neglected in comparison with the area BCHB, the following equation is obtained:

$$F = \frac{\text{area BCHB}}{\text{area BDGB}} \cdot \frac{\text{area BDGB}}{\text{area BDGB}+\text{area DEFD}+\Delta a}. \tag{4}$$

In Eq. 4 it is convenient to put as

$$F' = \frac{\text{area BCHB}}{\text{area BDGB}}, \tag{5}$$

$$K = \frac{\text{area BDGB}}{\text{area BDGB}+\text{area DEFD}+\Delta a}. \tag{6}$$

Hence, the following equation is obtained:

$$F = F'K \tag{7}$$

where F' is the fraction melted as calculated by the use of the areas of the ΔBDG and ΔBCH triangles instead of by the calculation of the total peak area and the area ACHA, as represented by Eq. 1, and where K is the constant, depending upon the samples. It follows that the relation between F and F' is represented by Eq. 7. We will term F' the corrected fraction melted. As will be described below the experimental results are better interpreted experientially by F' than by F.

Furthermore, the conclusion presented below may be made for the corrected fraction melted, F'. From Fig. 1, the following equations are obtained:

$$\text{area ADFA} = \text{area BDFB} + \text{area ABJA}, \tag{8}$$

$$\text{area BDGB} = \text{area BDFB} + \text{area IFGI}. \tag{9}$$

From Eqs. 8 and 9, the following equation is then obtained:

$$\text{area ADFA} = \text{area BDGB} + \text{area ABJA} - \text{area IFGI}. \tag{10}$$

Putting the second and third terms on the right-hand side of Eq. 10 as

$$\Delta b = \text{area ABJA} - \text{area IFGI}, \tag{11}$$

Eq. 10 is rewritten as follows:

$$\text{area ADFA} = \text{area BDGB} + \Delta b. \tag{12}$$

Assuming that Δb is small and can be neglected in comparison with the area BDGB, Eq. 13 is obtained:

$$\text{area ADFA} = \text{area BDGB}. \tag{13}$$

The following relation for F' is obtained, together with the assumption described previously; *i.e.*, the area ABJA can be neglected in comparison with the area BCHB:

$$F' = \frac{\text{area BCHB}}{\text{area BDGB}} = \frac{\text{area ACHA}}{\text{area ADFA}}. \tag{14}$$

In the DSC curve, the abscissa indicates the temperature, while the ordinate indicates the millicalories per second. Moreover, in the DSC chart, the time and the temperature can be read off from the abscissa and the ordinate respectively. Therefore, the assumption presented below and Fig. 1 seems to be true. Since the temperature, T, in the DSC chart is the linear function of time, t, for the line $\overline{BH}$ in Fig. 1, the following equation is obtained:

$$T = kt + l, \tag{15}$$

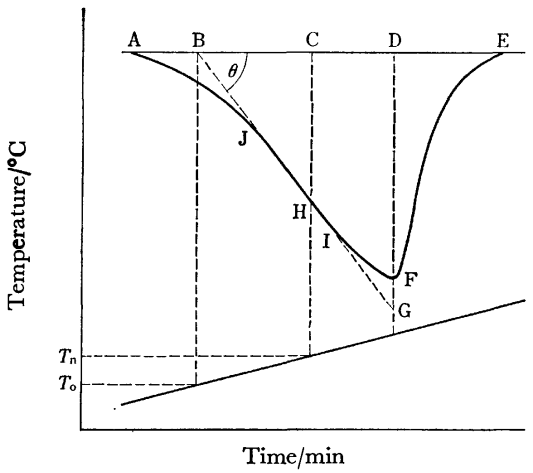

Fig. 1. Schematic diagram for the derivation of Eq. 32.

where k and l are constants. Much as in Eq. 15, for the line $\overline{BC}$ in Fig. 1, Eq. 16 is obtained:

$$T = mt + n, \tag{16}$$

where m and n are constants. Let v denote the chart speed; Eqs. 15 and 16 can then be rearranged as follows:

$$T = \frac{\overline{BH}}{v}k + l, \tag{17}$$

$$T = \frac{\overline{BC}}{v}m + n. \tag{18}$$

Rewrite Eqs. 17 and 18 as follows:

$$\overline{BH} = \frac{v}{k}T - \frac{lv}{k}, \tag{19}$$

$$\overline{BC} = \frac{v}{m}T - \frac{nv}{m}, \tag{20}$$

where it is convenient to put $(v/k)\equiv a$, $(-lv/k)\equiv b$, $(v/m)\equiv c$, and $(-nv/m)\equiv d$. Therefore, Eqs. 21 and 22 are obtained:

$$\overline{BH} = aT + b, \tag{21}$$

$$\overline{BC} = cT + d. \tag{22}$$

As is obvious from Fig. 1, when $\overline{BH}$ is zero; $\overline{BC}$ is also to be zero, and let T_0 be the temperature. Substituting the above conditions into Eqs. 21 and 22 yields Eqs. 23 and 24:

$$T_0 = -\frac{b}{a}, \tag{23}$$

$$T_0 = -\frac{d}{c}. \tag{24}$$

Therefore,

$$ad = bc. \tag{25}$$

The area, S, of the triangle ΔBCH is

$$S = \frac{1}{2} \times \overline{BC} \times \overline{CH} = \frac{1}{2}(aT+b)(cT+d)\sin\theta. \tag{26}$$

Equation 26 is rewritten by Eq. 25 as follows:

$$S = \frac{1}{2}(acT^2+2bcT+bd)\sin\theta. \tag{27}$$

Then, Eq. 28 is obtained:

$$S = \frac{1}{2}ac\left(T+\frac{b}{a}\right)^2 \sin\theta. \quad (28)$$

The area, S_0, of the triangle ΔBDG is represented by

$$S_0 = \frac{1}{2} \times \overline{BD} \times \overline{DG} = \frac{1}{2} \times \overline{BD} \times \overline{BG} \sin\theta. \quad (29)$$

From Eqs. 28 and 29, the corrected fraction melted, F', is obtained by

$$F' = \frac{S}{S_0} = \frac{ac}{\overline{BD} \times \overline{BG}}\left(T+\frac{b}{a}\right)^2, \quad (30)$$

by solving Eq. 30 for T, and from Eq. 23 the following equation is obtained:

$$T = \sqrt{\frac{\overline{BD} \times \overline{BG}}{ac}}\sqrt{F'} + T_0. \quad (31)$$

Since both $\sqrt{(\overline{BD} \times \overline{BG})/ac}$ and T_0 are constants, it is convenient to put these constants as α and β respectively. Then, we obtain Eq. 32:

$$T = \alpha\sqrt{F'} + \beta. \quad (32)$$

The DSC curve is the same in nature as the differential thermal analysis curve,[10] and the vertex of the peak (Point F in Fig. 1) most accurately reflects the melting point,[11] *i.e.*, the conclusion of the melting. Furthermore, in a binary system the melting temperature is signified by the first departure of the base line from the normal (Point A in Fig. 1), while the freezing temperature is signified by the vertex of the peak,[12] at which F'=(area ADFA/area ADFA)=1, as may be seen in Fig. 1.

From the above description, the melting temperature, corresponding to the solidus temperature, may be given by the intercept, β, of Eq. 32 when F' is zero, and the freezing temperature, corresponding to the liquidus temperature, may be obtained from the value of $\alpha+\beta$ when F' is unity, while the melting range is indicated by the slope, α.

Multipass Zone Melting. An equation for the solute distribution resulting from an infinite number of zone passes has been derived by Pfann.[8] This equation is, however, applicable only to a system with constant distribution coefficient. Pfann's equation for the ultimate distribution is as follows:

$$C(Z) = A\exp(BZ) \quad (33)$$

where $C(Z)$ is the solute concentration at the point Z from the top of the sample after the ultimate distribution has been reached and where A and B are constants obtainable from Eqs. 34 and 35:

$$k = \frac{B}{e^B-1}, \quad (34)$$

$$A = \frac{C_0BL}{e^{BL}-1}, \quad (35)$$

where C_0 is the initial concentration of the solute; L, the length of the sample, and k, the constant distribution coefficient. Rewrite Eq. 33 as follows:

$$\ln C(Z) = BZ + \ln A. \quad (36)$$

Moreover, from Eq. 36, the solute distribution at a small distance, dZ, further along the sample is give by

$$\ln C(Z+dZ) = B(Z+dZ) + \ln A. \quad (37)$$

The following equation is derived by subtracting Eq. 36 from 37:

$$\ln\frac{C(Z+dZ)}{C(Z)} = B dZ. \quad (38)$$

Equation 38 is rewritten as follows:

$$C(Z+dZ) = C(Z)\exp(BdZ). \quad (39)$$

Although Eq. 39 is applicable strictly to a system with a constant distribution coefficient, as has already been described, this equation is also approximately applicable to a system with a slight variation in the concentration near the end of the phase diagram. When the distribution coefficient, however, varies appreciably, Eq. 39 fails to be useful.

Herington[1] has extended Pfann's theory to binary systems when the distribution coefficients are dependent on the concentration.

For what follows, it is necessary to summarize his method for calculating the ultimate distribution curve, which should be calculated by the following procedures:

1. Depict a plot of the equilibrium distribution coefficient, k_1, against the concentration, C, of the solute in the solid phase with the aid of the phase diagram.

2. Obtain the values of B_1 from Eq. 40 with the values of k_1 from this plot. The subscript i is used to designate the concentration dependence of these values; the values of B_1 can be obtained essentially from the table of the Einstein function,

$$k_1 = \frac{B_1}{e^{B_1}-1}. \quad (40)$$

Plot the function B_1 against C from the resulting values.

3. Choose, near one end of the phase diagram, an arbitrary value of $C(Z)$. This value must, however, be chosen in the part of the phase diagram applicable to the initial uniform composition of the charge.

4. Read the value of B_1 corresponding to the solid composition $C(Z)$ from the graph obtained in Section 2; let this value be $B_1(Z)$.

5. Calculate, by means of Eq. 41, the value of $C(Z+1/d)$, applicable to the composition at a distance, $1/d$, of a zone length further along the specimen,

$$C\left(Z+\frac{1}{d}\right) = C(Z)\exp\left\{\frac{B_1(Z)}{d}\right\}. \quad (41)$$

6. Using this value for $C(Z+1/d)$, repeat the calculation discussed in Sections 4 and 5 to obtain a new value of B_1, that is, the value of $B_1(Z+1/d)$, and then calculate $C(Z+2/d)$ by means of Eq. 42:

$$C\left(Z+\frac{2}{d}\right) = C\left(Z+\frac{1}{d}\right)\exp\left\{\frac{B_1\left(Z+\frac{1}{d}\right)}{d}\right\}. \quad (42)$$

The calculations should similarly be iterated until the composition asymptotically approaches that of a pure component or the composition of the minimum melting point.

Equations 41 and 42 are rearranged in the following general form:

$$C\left(Z+\frac{n+1}{d}\right) = C\left(Z+\frac{n}{d}\right)\exp\left\{\frac{B_1\left(Z+\frac{n}{d}\right)}{d}\right\}, \quad (43)$$

n=0,1,2,3,……

Experimental

Materials. The bibenzyl and diphenylacetylene used for the determination of the phase diagram were purified by zone refining, followed by recrystallization once from ethanol.

For the multipass zone-melting experiments, a larger quantity of the bibenzyl as the solvent was used than that of the diphenylacetylene used as the solute. However, the zone-refining apparatus** which we employed for refining the chemicals cannot treat a large quantity of chemicals; hence, bibenzyl purified only by recrystallization once from ethanol was used, while the diphenylacetylene was purified by zone refining, followed by recrystallization once from ethanol.

For the determination of the phase diagram, ten specimens of the bibenzyl–diphenylacetylene mixtures (containing 5, 10, 20, 30, 40, 50, 60, 70, 80, and 90 wt % of diphenylacetylene) were prepared by melting in Pyrex ampoules under a dry nitrogen atmosphere and by grinding to powder after the ampoules had been taken out.

For multipass zone-melting experiments, two bibenzyl–diphenylacetylene mixtures containing 20 and 30 wt % of diphenylacetylene were prepared by melting in Pyrex ampoules under a dry nitrogen atmosphere and by grinding to powder after the ampoules had been taken out.

These mixtures were charged in a length of 30 cm in Pyrex tubes with an inner diameter of 0.7 cm and outer diameter of 0.9 cm. Then the tubes were sealed off under a dry nitrogen atmosphere of about 0.9 atm.

Apparatus and Procedures. The melting and freezing temperatures were determied with a Shimadzu differential scanning calorimeter, SC-20, under the following conditions: heating rate, 1 °C/min; chart speed, 40 mm/min; range, ±5 mcal/s.

The multipass zone-melting experiments were carried out with the apparatus described in a previous paper[9] and under the following conditions: zone travel rate, 0.73 cm/h; zone length, 3 cm; zone temperature, 61±1 °C; the number of zone passages, 45.

The samples after zone melting were cut into 3-cm-long divisions. The concentration of diphenylacetylene in each division was determined spectrophotometrically in an ethanol solution by the use of a Hitachi 101 spectrophotometer at a wavelength of 305 nm.

Results and Discussion

The Phase Diagram of the Bibenzyl–Diphenylacetylene System. With the results of DSC, the temperature, T, was plotted against the square root of the corrected fraction melted, $\sqrt{F'}$, as is shown in Fig. 2. From the resulting straight lines, the melting and freezing temperatures were calculated by means of Eq. 32.

As may be seen in Fig. 2, for pure components, that is, bibenzyl or diphenylacetylene, it is in conflict with the phase rule that the relation between T and $\sqrt{F'}$ obeys Eq. 32, like a mixture. Such behavior observed in pure components is probably due to the impossibility of obtaining an absolutely pure substance and a time lag caused mainly by the finite thermal conductivity in the samples during fusion.

Therefore, the value of α in Eq. 32 for a pure component, which may correspond to the apparent melting range caused by the above reasons, should be added to all the observed melting temperatures of the bibenzyl–diphenylacetylene mixtures for the corrections of the temperatures. These corrections were made by using the value, 1 °C, of pure bibenzyl for the specimens with 5 to 20% of diphenylacetylene, and by using the value, 0.8 °C, of pure diphenylacetylene for the specimens with 30 to 90% of diphenylacetylene. The results obtained are presented in Table 1 and Fig. 3; the old data reported by Pascal *et al.*[5] are also shown, represented by the broken lines in Fig. 3.

Indeed, such systems as the azobenzene–stilbene and diphenylacetylene–stilbene form a continuous series of solid solutions because of the close resemblances

of the crystal structures and molecular sizes among these compounds,[7] but bibenzyl is somewhat different in these factors[7] from the above three compounds.

In consequence of these differences in the crystal structure and molecular size, the bibenzyl–diphenylacetylene system may deviate from an ideal solution and may form solid solutions with a minimum melting point, as has previously been predicted.

The Determination of the Composition of the Minimum Melting Point by Multipass Zone-melting Experiments. Figure 4 and Table 2 show the relation between the concentration of diphenylacetylene and the distance in zone lengths along the specimens after 45 zone passes for two specimens containing initially 20 and 30 wt % of diphenylacetylene respectively.

As is obvious from Fig. 3, the distribution coefficient of diphenylacetylene in bibenzyl for 20% of diphenylacetylene is less than unity, whereas, in the case of 30% of diphenylacetylene, the distribution coefficient

Table 2. Distribution of diphenylacetylene in bibenzyl after 45 zone passes

Distance in zone length $\left(\frac{x}{l}\equiv Z\right)$	Concentration of diphenylacetylene (wt %); initial concentration 20 wt % of diphenylacetylene	Concentration of diphenylacetylene (wt %); initial concentration, 30 wt % of diphenylacetylene

is greater than unity. Such a difference in the distribution coefficients is reflected in the two distribution curves of diphenylacetylene shown in Fig. 4.

The two curves are each observed to approach a constant value gradually; this value may correspond to the composition of the minimum melting point. This phenomenon is analogous to that occurring with the fractional distillation of the azeotropic mixtures with a minimum boiling point.

A mixture with the composition of the minimum melting point must be, in principle, obtained at the end of the specimen. However, other impurities tend to concentrate at the end of the specimen; hence, the values at eight fractions from the top of the samples are adopted as the composition of the minimum melting point in both samples. Thus, we obtained the value

of 26.4% at the temperature of 43.2 °C.

The Evaluation of the Extent of Deviation from Equilibrium in the Multipass Zone Melting. Although the composition at the near end of the specimen gradually approaches the composition of the minimum melting point as a result of repeated zone passes, the compositions at the upper regions of the specimens (left part in Fig. 4) seem to become not necessarily equal to the compositions estimated from the phase diagram, depending upon the extent of devaition from equilibrium, which mainly varies with the zone-travel rate.

As is well known, the solute distribution between the solid and liquid phases in a non-equilibrium state is indicated by the effective distribution coefficient. Hence, the extent of the deviation from equilibrium in multipass zone-melting experiments will be discussed by estimating the effective distribution coefficients by means of Herington's method, which will, in the present case, be employed in the reverse of its original purpose so as to calculate the distribution coefficients from the observed distribution curve.

The boundary condition in Eq. 43 must be determined from the viewpoint of the material balance. The values of the Z and $n+1$ in Eq. 43 should be chosen so as to equalize the shaded areas divided into two portions across the lines indicating the initial concentrations for the two curves in Fig. 4. In the present case, the value of d is determined for convenience as unity, for the samples were cut into fractions equal to one zone length. Then, Eq. 43 is rewritten as follows:

$$C\{Z+(n+1)\} = C(Z+n)\exp\{B_1(Z+n)\}. \quad (44)$$

It is obvious from Fig. 4 that the numerical value of Z was defined as 1.5 for both curves. Therefore, $(n+1)$ equals 6 for both the lower and upper curves in Fig. 4. By substituting successively into Eq. 44 the values obtained from the curves in Fig. 4, the respective value of B_1 is calculated. The effective distribution coefficient is calculated by substituting the value obtained above into B_1 in Eq. 40; of course, the k_1 in Eq. 40 should be replaced by the k_e, symbolizing the effective distribution coefficient.

From the resulting effective distribution coefficient, the solute concentration in the liquid phase, C_1, is obtained by the definition of the distribution coefficient, *i.e.*, $k_e=C_s/C_1$, in which C_s is identical with $C(Z+n)$ in Eq. 44.

The results thus obtained are presented in Table 3. The relation between the solid and liquid phases is also shown, together with the results from DSC in Fig. 3, so as to indicate clearly the deviation from equilibrium.

It is revealed that the magnitude of deviation from equilibrium is fairly slight. This is, of course, a fact that does not commonly appear, but it is valid for this experiment. As one reason for such a slight departure from equilibrium, it may be considered that the difference between the melting and freezing temperatures is quite small in this system, as is shown in Fig. 3. Indeed, in the naphthalene–2-naphthol system, the difference between the melting and freezing temperatures is larger than that in the bibenzyl–diphenylacetylene system. Hence, it is shown by Herington's theory that the deviation from equilibrium is fairly great†, in contrast to the result in this work.

Table 3. The effective distribution coefficient and composition of diphenylacetylene in the liquid phase, as obtained by Herington's theory

Distance in zone length $\left(\frac{x}{l}\equiv Z\right)$	Composition of the solid phase (wt %)	Effective distribution coefficient	Composition of the liquid phase (wt %)
Initial concentration, 20 wt % of diphenylacetylene			
1.5	5	0.61	8.2
2.5	12.7	0.81	15.7
3.5	19.5	0.91	21.4
4.5	23.5	0.96	24.5
5.5	25.4	0.99	25.7
Initial concentration, 30 wt % of diphenylacetylene			
Distance in zone length $\left(\frac{x}{l}\equiv Z\right)$	Composition of the solid phase (wt %)	Effective distribution coefficient	Composition of the liquid phase (wt %)
1.5	41.4	1.10	37.6
2.5	33.8	1.07	31.5
3.5	29.7	1.04	28.5
4.5	27.4	1.04	26.3
5.5	26.4	1.01	26.1

Although, in the calculation of the corrected fraction melted, the theoretical ground is still obscure for replacing the total peak area by the area for the vertex of the peak, Eq. 20 has proved of great value as a means of determining precisely the melting and freezing temperatures in DSC, especially in the case of a peak too broad or even a noisy one.

The determination of the composition of the minimum melting point through the multipass zone-melting experiments would be applicable not only to organic systems, but also to inorganic and metallic systems, though an analytical technique must be utilized for determining the components precisely.

Conclusion

The behavior of diphenylacetylene in bibenzyl during zone melting can be well related to the phase diagram with the aid of Herington's theory. This, in other words, suggests the validity of the obtained phase diagram.

The authors wish to thank Professor Masaru Inagaki, of Meiji University, and Professor Sohachiro Hayakawa, of the Tokyo Institute of Technology, for their valuable advice.

Kinetic Studies of Co(II)-Malonate, Malate, and Glycolate Complex-formation Reactions in Aqueous Solutions by the Pressure-shock Method

Shoji HARADA, Masuo KAWASAWA, and Tatsuya YASUNAGA*

Department of Chemistry, Faculty of Science, Hiroshima University, 1-1 Higashisenda-machi, Hiroshima 730

(Received August 14, 1979)

A pressure-shock apparatus applicable for the kinetic studies of rapid reactions in solution was constructed and used to study Co(II)–carboxylate complex-formation reactions. The chelate complex-formation reaction was interpreted in terms of a step-by-step mechanism, and the rate constants were obtained. The chelate-ring closing-and-opening process was revealed to be the rate-determining step.

For the model of the complex formation of bidentate ligands, a step-by-step mechanism has been proposed. When the complex is stable as a chelate complex, the rate-determining step has been assigned to either the first-bond formation-and-dissociation process[1–6] or the chelate-ring closing-and-opening process.[7–9] The purpose of the present work is to examine these assignments for the Co(II)–bidentate carboxylate complex-formation reactions. Although the equilibrium properties of the cobalt(II) carboxylates have been well studied,[10] few kinetic studies have been carried out.[11] The reason may be that the reaction of cobalt(II) ion with ligand is too fast to be studied by conventional techniques.

Another purpose is to test the applicabilities of our newly constructed pressure-shock apparatus. Even though the pressure-jump method[12] is one of the most useful techniques for the kinetic studies of very rapid reactions in solution, applications of this method have been limited to reactions with relaxation times greater than 100 μs. This disadvantageous time constant has been improved by at least one order of magnitude by the pressure-shock method.[13–15]

Experimental

Apparatus. The pressure-shock apparatus constructed was a modification of that described by Platz and Hoffmann.[15] A schematic diagram is shown in Fig. 1. The experimental procedure is as follows. Nitrogen gas of 20 atm is introduced into the low pressure chamber (G). Next, the high-pressure N_2 gas is introduced into chamber (D). The increase of the pressure in chamber (D) bursts or shears out the metal diaphragm (E) at a definite pressure. The pressure-change takes at least 50 μs. While the pressure wave propagates in the low-pressure gas in (G) and in the transmitting liquid (ethanol) (H), the wave front is sharpened and becomes a shock wave.[16] The shock wave is reflected at the bottom of the sample cell (K) and propagates back through the liquid, and an expansion wave is generated at the surface of the liquid; the latter wave cancels the exerted pressure. As a result, the pressure in the sample cell continues to be high until the shock-front returns to the sample cell. The duration of the high-pressure pulse can be varied by changing the liquid level. The relaxation effect was detected conductometrically by a high-frequency bridge of 1.2 MHz. From the pressure-shock trace obtained for a $MnSO_4$ solution, which exhibits a relaxation effect faster than 1 μs (Fig. 2a), the time constant of the present apparatus was determined to be less than 4 μs. The features of the pressure pulses for the $MnSO_4$ solution and the Co(II)–malonate system are shown in Figs. 2b and 2c respectively. The temperature of the cell was controlled at 25.0±0.3 °C by circulating thermostated water through a copper tube spiraled around the shock tube and the cell.

Higher-pressure shock waves can be obtained by increasing the burst pressure by using a thicker metal diaphragm or by the use of lower-molecular-weight gas in the high-pressure chamber and higher-molecular-weight gas in the low-pressure chamber.[16] Following the latter idea, we tried H_2 gas in the high-pressure chamber and obtained a pressure pulse several times larger than that obtained when N_2 gas was used. In the present experiments, however, N_2 gas was used throughout the measurements since H_2 gas is explosive and the advantage was not so remarkable.

Materials. Wako reagent-grade chemicals were used. Stock solutions of cobalt(II) carboxylates were prepared in the same way as those of nickel(II) carboxylates.[4–6] By

considering the hydrolysis of the cobalt(II) ion and the acid dissociation of the ligand, the proper value of the pH was determined; the pH was adjusted by the drop-by-drop addition of dilute nitric acid solution.

Results

The experimental conditions and the reciprocal relaxation times observed are shown in Table 1. The concentration dependence of the relaxation time is best explained by the following equilibria.

$$Co^{2+} + L^{n-} \underset{k_b}{\overset{K\ (k_f)}{\rightleftharpoons}} CoL^{2-n} \quad (1)$$

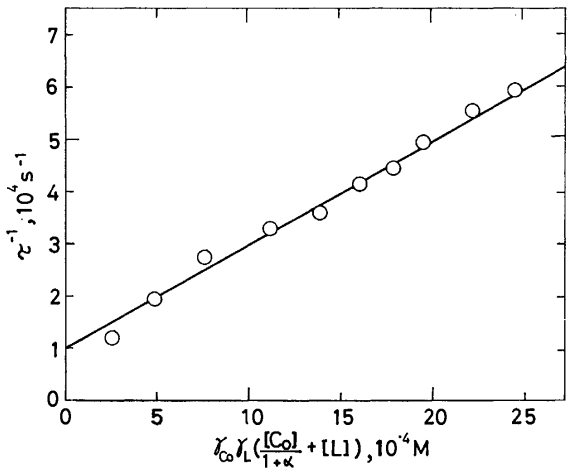

Fig. 3. τ^{-1} *vs.* $\gamma_{Co}\gamma_L\left(\frac{[Co]}{1+\alpha}+[L]\right)$ plot of Co(II)–malate system at 25 °C.

$$HL^{1-n} \rightleftharpoons H^+ + L^{n-} \quad (2)$$

($n=2$ for malonate and malate systems and 1 for glycolate system)

where L^{n-} is a dissociated ligand, HL^{1-n} is a monoprotonated ligand, CoL^{2-n} is a 1:1 complex, k_f and k_b are the rate constants, and $K(=k_f/k_b)$ is the stability constant. In the present pH ranges, the contributions of the complex formation with the monoprotonated ligand (Eq. 3):

$$Co^{2+} + HL^{1-n} \rightleftharpoons CoL^{2-n} + H^+ \quad (3)$$

to the present relaxation phenomenon was neglected. Since the protonation of the carboxyl group (Eq. 2) is much faster than the complex formation reaction (Eq. 1), the relaxation time, τ, of Eq. 1 is expressed by the equation:

$$\tau^{-1} = k_f \cdot \frac{\gamma_{Co}\cdot\gamma_L}{\gamma_{CoL^*}} \cdot \left(\frac{[Co]}{1+\alpha}+[L]\right) + k_b \frac{\gamma_{CoL}}{\gamma_{CoL^*}} \quad (4)$$

with

$$\alpha = \frac{[H]}{K_a+[L]} \quad (5)$$

where γ_i is the activity coefficient of the i-th species, the brackets indicate the concentration, the superscript $\neq$ means the activated complex, K_a is the acid dissociation constant of the (second) carboxyl group, and charges are omitted for the sake of convenience. On the assumptions that the activity coefficient of a noncharged complex is unity, $\gamma_{CoL}=\gamma_{CoL^*}$, and $\gamma_{CoL^*}=\gamma_{L^-}$, Eq. 4 is rewritten in the form:

$$\tau^{-1} = F(C)\cdot k_f + k_b \quad (6)$$

where $F(C)$ is the concentration term including the activity coefficient term. Calculations of the activity cofficients were performed using the Davies equation.[17]

Evaluation of the rate parameters was carried out as follows. First, the concentrations of the species in solution were calucalted from the stability constant, K, which is available in the literature. Then, the τ^{-1} values were plotted against $F(C)$ to give k_f and k_b from the slope and the intercept of the straight line respectively. The ratio of k_f and k_b gives a so-called kinetical-

a) Literature value.

ly determined K which should coincide with the foregoing K value used for the calculation of $F(C)$. If they did not coincide, the kinetically obtained K was used for the calculation of $F(C)$ and the τ^{-1} *vs.* $F(C)$ plot was again drawn. The above procedures were repeated until a self-consistent K value was obtained. The final plot of the Co(II)–malate system is shown in Fig. 3 as an example. The values of k_f, k_b, and K are listed in Table 2, along with the literature value of K.[18,19] The values of K obtained kinetically are in satisfactory agreement with those in the literature.

Discussion

The ligands used in the present experiment are known to make stable chelate complexes with cobalt(II) ion. The chelate complex-formation reaction is represented by the following step-by-step mechanism,

$$\underset{\text{(I)}}{\text{Co} + \text{L}} \underset{k_{-0}}{\overset{K_0}{\rightleftharpoons}} \underset{\text{(II)}}{\text{Co}\,\text{O}^{\text{H}}_{\text{H}}\,\text{L}} \underset{k_{-1}}{\overset{K_1}{\rightleftharpoons}} \underset{\text{(III)}}{\text{Co-L}} \underset{k_{-2}}{\overset{K_2}{\rightleftharpoons}} \underset{\text{(IV)}}{\text{Co=L}} \qquad (7)$$

where (I) represents free ions; (II), an ion-pair; (III), a monodentate complex; and (IV), a chelate complex.

Kinetic studies of the chelate-complex formation of bidentate carboxylates have been widely carried out for the nickel(II) complexes. In these studies, the rate-determining step of the complex formation has been ascribed to either the first-bond formation-and-dissociation process, (II)⇌(III),[1–6] or the chelate-ring closing-and-opening process, (III)⇌(IV).[7–9] In the former concept, the following problems remain unsolved. The values of k_1 obtained from the assumed equation $k_f = k_0 \cdot k_1$, have been regarded as equal to the water-exchange rate constant of the metal ion, k_{H_2O}.[20] However, the consistency has not been necessarily satisfactory, and the k_1's have occasionally been one order of magnitude smaller than k_{H_2O}. Also, even if $k_1 = k_{H_2O}$ could be satisfied, the assumption that $k_2 \gg k_1$ is dubious, because the water-substitution process is also involved in the chelate-ring-closing step, and k_2 cannot exceed k_{H_2O} ($=k_1$). The above reasons led us to adopt the second concept in the present study.

On the assumption that the intermediate species, (II) and (III), are in a steady state, the rate constants in Eq. 7 are related to the overall rate constants, k_f and k_b, by the following equations:

$$k_f = K_0 k_1 \left(\frac{k_2}{k_2 + k_{-1}}\right) \qquad (8)$$

$$k_b = k_{-2}\left(\frac{k_{-1}}{k_2 + k_{-1}}\right). \qquad (9)$$

The equilibrium and kinetic parameters in these equations were evaluated as follows.

K_0 was estimated theoretically by the Fuoss equation:[21]

$$K_0 = \frac{4\pi N a^3}{3000} \cdot e^{-U(a)/kT} \qquad (10)$$

were N is Avogadro's number, a is the distance of the closest approach of two ions, which was assumed to be 8 Å,[22] and $U(a)$ is a Coulomb-energy term. K_0 at $\mu \to 0$ was calculated to be 46 M^{-1} for the malonate and malate systems and 7.7 M^{-1} for the glycolate system.

The value of k_1 was assumed to be equal to that of the k_{H_2O} of the cobalt(II) ion, *i.e.*, $k_{H_2O} = 2.6 \times 10^6$

s^{-1}.[23] This assumption may be made because, in many monodentate complex-formation reactions, the rate-determining step has been revealed to be a water-dissociation process from the coordination site of the metal ion, irrespective of the entering ligand.

The value of k_{-1} was estimated from the pK_a value of the ligand. In the kinetic studies of the complex formation reactions of nickel(II) dicarboxylates, Hoffmann has estimated the k_{-1} value from the following experimental relationship between log k_{-1} and pK_a for each of the ligands:[7-9]

$$\log k_{-1} = -0.22\,pK_a + A \quad (A=\text{constant}). \tag{11}$$

Unfortunately, however, the same relationship has not been established for the cobalt(II) complexes because of the lack of the kinetic data. Thus, in the present case, the k_{-1} of the Co(II)–acetate system was estimated first. Since acetate makes only monodentate complexes, and a reliable stability constant is given in the literature, the k_{-1} can be estimated. First, the stability constant, K, of the acetate complex is related to the equilibrium and rate constants of each step by the equation:

$$K = K_0\,(1+K_1) = K_0\left(1+\frac{k_1}{k_{-1}}\right) \tag{12}$$

where K_0, K_1, k_1, and k_{-1} are the same as in Eq. 7. By employing the values of $K=10^{1.29}\,M^{-1}$,[19] $K_0=7.7\,M^{-1}$, and $k_1=2.6\times10^6\,s^{-1}$, the k_{-1} of the acetate system ($pK_a=4.75$) was calculated to be $1.7\times10^6\,s^{-1}$. Then, applying Eq. 11 to the Co(II)–carboxylate system, the k_{-1} value of each system was estimated from the value of the pK_a of the ligand; *i.e.*, by the use of the values for the acetate system, we obtain:

$$\log (k_{-1}/1.7\times10^6) = -0.22\,(pK_a-4.75). \tag{13}$$

The calculated values of k_{-1} and $K_1(=k_1/k_{-1})$ are listed in Table 3, together with the pK_a values. By the use of the values of K_0, k_1, k_{-1}, k_f, and k_b, the values of k_2 and k_{-2} were calculated by Eqs. 8 and 9; these results are also listed in Table 3.

By comparing the values of the equilibrium and the rate parameters in Tables 2 and 3, we can deduce the following:

(1) The complex is stable as a chelate complex rather than as a monodentate complex or an ion-pair.

(2) The chelate-ring closing and opening reactions are the rate-determining processes of the complex formation and dissociation reactions respectively.

(3) The stability of the malonate complex relative to the others is due to the fact that it has the slowest rate of chelate-ring opening (k_{-2}). The malonate system has once been studied kinetically by the temperature-jump method.[11] Compared with the temperature-jump data, the k_f value of the present work is three times larger, while the k_b value is two times smaller. These inconsistencies may be ascribed to the differences in either the experimental conditions, *e.g.*, the ionic strength, or the stability constants used for the caluclations.

(4) The glycolate complex is one order of magnitude less stable than the others. This is explained by the natures of the ligands, *i.e.*, the electrostatic charge (reflected by K_0), the acidity of the carboxyl group (K_1), and the chelating groups (K_2). From the kinetic standpoint, the fastest chelate-ring-closing rate indicates that a five-membered chelate complex is preferable to the complex formation, while the very rapid chelate-ring-opening rate is due to a weak coordination of a hydroxyl group in comparison with the carboxyl group.

In the malate system, both the equilibrium and the kinetic parameters were close to the corresponding values of the malonate system, even though some differences had been expected from the structural differences of these ligands. Further details of the malate complex formation may be revealed by additional experiments on analogous ligand systems, *e.g.*, β-hydroxypropionate or succinate systems.

Table 3. Equilibrium and rate constants of the step-by-step complex-formation reaction (7) of Co(II) carboxylate at 25 °C and $\mu\to0$

Ligand	Malonate	Malate	Glycolate
pK_a of acid[a]	5.69	5.11	3.83
K_0, M^{-1}	46	46	7.7
K_1	2.4	1.8	1.0

Isotope Effect of the Glass Transition Temperature of Aqueous Solution. LiCl and $ZnCl_2$ Solutions in Water and D_2O

Hitoshi KANNO,* Ichimin SHIROTANI,† and Shigeru MINOMURA†

Department of Chemistry, Meisei University, Hino, Tokyo 191

† *The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minatoku, Tokyo 106*

(Received November 19, 1979)

Synopsis. Glass transition temperatures of the LiCl and $ZnCl_2$ solutions in both water and D_2O were measured as a function of the concentration of the salt. The composition dependence of isotope effect is briefly discussed for these solutions.

In recent years, the glass formation of binary solution systems have been extensively studied.[1–5] It is clear from these studies that glass transition temperature (T_g) is a good parameter such as melting and boiling points to represent the thermodynamic properties of liquid systems, though it is not a fixed point and varies a little with experimental conditions (*e.g.*, cooling and heating rates) and the method by which T_g is determined. To maximize the glass transition temperature as a diagnostic tool for clearifying thermodynamic properties of supercooled liquid systems and their glassy states, it is of importance to investigate the effects of various factors affecting the magnitude of T_g.

In this note, we report the study of the T_g measurements of aqueous LiCl and $ZnCl_2$ solutions in both water and D_2O. Aqueous solutions of LiCl and $ZnCl_2$ were prepared by dissolving anhydrous LiCl and $ZnCl_2$ in either water or D_2O (E. Darmstadt, 99.8% atom D). A conventional, simple DTA system was used for the T_g measurements. The experimental arrangements were essentially the same as used by Angell and Sare[2] in their T_g measurements. Overall cooling rate during quenching a sample solution was about 2×10^3 K/min. The T_g value was obtained at a heating rate of about 5 K/min in the warmup DTA trace from liquid nitrogen temperature with using benzene as a reference material. A Teflon-covered chromel-alumel thermocouple system was used for the differential emf and temperature measurements. The accuracy of the T_g values was estimated to be ±1 °C by determinations of the melting points of ethylether, acetone and other low melting organic compounds. However, the reproducibility of T_g is better than ±0.2 °C.

The results are shown in Figs. 1 and 2. From these figures, we see that ΔT_g ($=T_g$ in D_2O-T_g in H_2O) increases almost linearly with the increase in R (=mol of water/mol of salt) in the concentration region where the T_g measurements were carried out. As there is, to authors' knowledge, no reported T_g value for glassy bulk water and D_2O, it is difficult to estimate how much ΔT_g will be in more diluted concentration region where no glass-forming is observed. However, we expect that homogeneous nucleation temperatures (T_H) of water and D_2O can be a guide for this purpose. The T_H values of water and D_2O are reported to be -38 and -33 °C at normal pressure, respectively.[6] Another possible canditate for estimating ΔT_g between glassy bulk water and D_2O is the glass transition temperatures of glassy crystals $SnCl_2\cdot2H_2O$ and $SnCl_2\cdot2D_2O$ (150 and 155 K, respectively).[7] From these results, the maximum of ΔT_g is estimated to be 5 °C

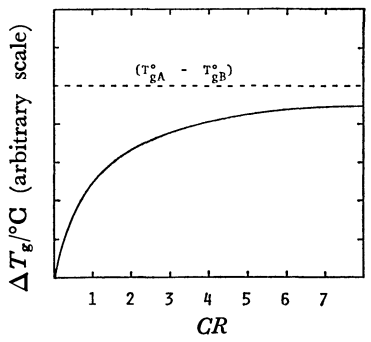

Fig. 3. Variation of ΔT_g as a function of CR.

for these aqueous solutions.

Aqueous solution is a typical non-ideal solution for which no applicable theory exists to interpret isotope effect. However, it is of interest to consider what relation exists between ΔT_g and R in a simple binary solution. An empirical equation which has proven successful in the fitting of experimental T_g data of a binary mixture is[8]

$$T_{gA}(x) = \frac{xT^0_{g1} + C(1-x)T^0_{gA}}{x + C(1-x)} \quad (1)$$

where T^0_{g1} and T^0_{gA} are the glass transition temperatures of pure components 1 and A, respectively, C is the adjustable parameter and x is the mole fraction of the component 1. If component A is replaced by the isotopic species B, we get the following relation under the assumption that C would not change for the isotopic substitution;

$$T_{gB}(x) = \frac{xT^0_{g1} + C(1-x)T^0_{gB}}{x + C(1-x)}. \quad (2)$$

From these two equations, the difference of the glass transition temperatures of the two solutions will be

$$\Delta T_g(x) = T_{gA}(x) - T_{gB}(x) = \frac{(1-x)C(T^0_{gA} - T^0_{gB})}{x + (1-x)C}$$

$$= \frac{CR(T^0_{gA} - T^0_{gB})}{1 + CR}. \quad (3)$$

When $CR \ll 1$, Eq. 3 can be approximated to be

$$\Delta T_g(R) \simeq CR(T^0_{gA} - T^0_{gB}) \quad (4)$$

and when $CR \gg 1$, we get

$$\Delta T_g(R) \simeq (T^0_{gA} - T^0_{gB}). \quad (5)$$

The variation of $\Delta T_g(R)$ is shown in Fig. 3 as a function of the variable CR. It is interesting to apply Eq. 3 to the LiCl and $ZnCl_2$ solutions, though there is some ambiguity about the applicability of Eq. 3 to aqueous solutions. Assuming that $(T^0_{gA} - T^0_{gB})$ is 5 °C, the calculations give $C = 0.4 \pm 0.1$ for the LiCl solution and $C = 0.05 \pm 0.01$ for the $ZnCl_2$ solution. The C value should be 1 in an ideal solution. From these values, it may be said that the non-ideality of the solution is larger for the $ZnCl_2$ solution than for the LiCl solution.

The Fifth Overtone Spectra of Aryl C–H Stretching Vibrations in $C_6H_5CH_{3-n}Cl_n$

Yoshihiro MIZUGAI and Mikio KATAYAMA*

Department of Pure and Applied Sciences, College of General Education, The University of Tokyo, Meguro-ku, Tokyo 153

(Received December 11, 1979)

Synopsis. The fifth overtone frequencies of the aryl C–H vibration of $C_6H_5CH_{3-n}Cl_n$ were observed by means of the thermal-lens technique. The shifts of their vibrational frequencies from that of benzene were found to be proportional to the inductive contribution of the Hammett σ, thus supplying information on the reactivity of the chemical bond.

Since the development of dye lasers, the opto-acoustic and thermal-lens techniques have been powerful methods for studying overtone spectroscopy in polyatomic molecules, where high vibrational levels are excited by means of very weak single photon absorption rather than by multiphoton absorption.[1,2] The experimental study of highly excited vibrational transitions in the ground electronic state offers valuable information on the photodissociation and radiationless transitions of molecules.

In the present article we wish to report our observation of the fifth ($\Delta v_{CH}=6$) overtones of the aryl C–H stretching vibrations of toluene and its chlorinated derivatives, $C_6H_5CH_{3-n}Cl_n$ ($n=0,1,2,3$), in the liquid state. The spectra of the fundamental vibrations, which are mainly attributable to the oscillation of the aryl C–H bond, show relatively complicated structures, and it is difficult to deduce the properties of their C–H bonds from the differences in the fundamental vibrational spectra. However, in their fifth C–H overtone spectra, single broad bands with a bandwidth of about 300 cm^{-1} are observed. The frequencies of their band centers exhibit systematic differences, demonstrating that the change in the electronic properties of $CH_{3-n}Cl_n$ ($n=0,1,2,3$) groups gives rise to the variation in the nature of the aromatic C–H bonds.

The measurements of the C–H overtone spectra were performed by means of the thermal-lens technique. A flashlamp pumped dye laser (Chromatix CMX-4) was used for the exciting light source, and a He–Ne laser with an average power output of 5 mW was operated in the TEM_{00} mode. We can measure the absorption of the exciting laser by observing the decrease in the transmission of the He–Ne laser through the pinhole which is put after the absorption cell. The thermal blooming of the He–Ne laser was observed by means of photodiode.

TABLE 1. THE FIFTH OVERTONE SPECTRA OF ARYL C–H STRETCHING VIBRATIONS IN $C_6H_5CH_{3-n}Cl_n$ ($n=0,1,2,3$) MOLECULES; THE FREQUENCIES, THE SHIFTS FROM THAT OF BENZENE, AND THE LINE WIDTHS

Molecule	Frequency	Shift	Width(fwhm)
$C_6H_5CH_3$	16460 cm^{-1}	−15 cm^{-1}	275 cm^{-1}
C_6H_6	16475	0	235
$C_6H_5CH_2Cl$	16490	+15	270
$C_6H_5CHCl_2$	16520	+45	280
$C_6H_5CCl_3$	16555	+80	310

The observed results for $C_6H_5CH_{3-n}Cl_n$ ($n=0,1,2,3$) and benzene are listed in Table 1. As is shown in this table, the frequencies of the fifth C–H overtone increase with the number of substituted chlorine atoms in the CH_3 group. The aryl C–H overtone of toluene is on the lower side of benzene, while those of the chlorine substituted molecules are at higher frequencies than that of benzene.

It has been found that the frequencies of the overtone spectra are represented quite adequately by this simple two-parameter equation:

$$G_{v,0} = v(A+vB) \quad (1)$$

where A and B are the constants and where v is the vibrational quantum number. At least for high-frequency modes, the experimental results can well be described as corresponding to the excitation of localized modes of vibration rather than a set of symmetry-allowed combination of anharmonic normal modes.[3-5] Thus, it can be understood that the frequencies of the higher overtone of molecular vibrations can give information on the nature of individual isolated chemical bonds.

The overtone spectra of the aryl C–H stretching vibrations of $\Delta v=2$—5 for toluene and α,α,α-trichlorotoluene could be observed by means of a Cary 14 spectrophotometer, but not those of their fifth overtone spectra ($\Delta v=6$). Both the frequencies of the fifth overtone as measured by the thermal-lens technique and the overtone spectra of $\Delta v=2$—5 obtained by the conventional method can be well expressed by the following equations:

$$G_{v,0} = 3094v - 59v^2 \quad \text{for toluene} \quad (2)$$

$$G_{v,0} = 3113v - 58.5v^2 \quad \text{for } \alpha,\alpha,\alpha\text{-trichlorotoluene} \quad (3)$$

where $G_{v,0}$ is expressed in cm^{-1}. On the other hand, the overtone spectra of benzene are represented by:[5]

$$G_{v,0} = 3095v - 58.4v^2. \quad (4)$$

The second terms in these equations, *i.e.*, the B constants in the above three equations, are almost the same. Therefore, it would be reasonable to assume that the B constants in Eq. 1 are the same in benzene and $C_6H_5CH_{3-n}Cl_n$ ($n=0,1,2,3$). Thus, the increase in the number of the substituted Cl atoms in the CH_3 group gives rise to a slight increase in the A constant of Eq. 1, indicating that the strength of the aryl C–H bonds increases with the number of substituted Cl atoms. The experimental results show that the fifth-overtone frequency of $C_6H_5CCl_3$ is the highest and that of $C_6H_5CH_3$ is the lowest, demonstrating that the strength of the local mode of the aryl C–H stretching

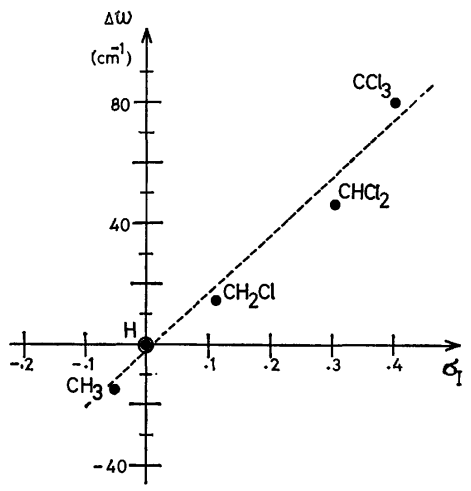

Fig. 1. The relation between the frequencies of the fifth overtone spectra of aryl C–H stretching vibration and the values of σ_I, the inductive contribution in Hammett σ, in $C_6H_5CH_{3-n}Cl_n$(n=0,1,2,3) molecules.

vibration in $C_6H_5CCl_3$ is the strongest among the four molecules of $C_6H_5CH_{3-n}Cl_n$ (n=0,1,2,3) and the benzene molecule. It was also found that the shifts of the fifth-overtone frequencies from that of benzene are proportional to the σ_I values of Hammett, as is shown in Fig. 1.[6] Therefore, the shifts of the frequencies of the higher-overtone spectra provide quantitative measures of the inductive contribution of the Hammett σ, supplying information on the chemical reactivity of a certain bond. This is because the highly excited vibration is well represented by the local mode, *i.e.*, the vibrational mode of an individual isolated bond. Therefore, the nature of its chemical bond is appropriately represented by the frequency of its higher-overtone vibration.

It should be noted that the linewidths of the fifth C–H overtone of $C_6H_5CH_{3-n}Cl_n$ are wider than that of benzene. This is brought about by the fact that the $C_6H_5CH_{3-n}Cl_n$ molecules have non-equivalent aryl C–H local modes with slightly different vibrational frequencies. Although it is desirable to observe the overtone frequencies in the gas phase for the more accurate measurement of their center frequencies, the power output of our laser is not large enough for us to obtain a good signal for the gas phase. Nevertheless, the liquid-state spectra may be expected to provide reliable information on the band center of the overtones.

This work was partly supported by a Grant-in-Aid from the Ministry of Education, Science and Culture. The authors would like to thank Dr. Hiroshi Morita, who allowed us to use the Cary 14 spectrophotometer.

ESR Spectra of Mn(II) Ions in Reversed Micellar Systems

Manabu Senō,* Kiyoshi Sawada, Koji Araki, Hideo Kise, and Kazutoshi Iwamoto

Institute of Industrial Science, The University of Tokyo, 7-22 Roppongi, Minato-ku, Tokyo 106

(Received January 12, 1980)

Synopsis. ESR spectra of hexaaqua complex of Mn(II) in a hexadecyltrimethylammonium bromide (HTAB)/chloroform reversed micellar system are studied. The structure of the Mn(II) complex is distorted at low water concentrations because of the dehydration due to the lack of water molecules available for the complexes. The effect of dehydration of metal ions on their catalysis for ATP hydrolysis is discussed.

In our previous papers,[1,2] we have attempted to characterize the water in reversed micellar systems primarily by near infrared spectra and nuclear magnetic resonance spectra. The water in micelle cores is less polar[1] and more strongly immobilized[2] than the ordinary bulk water. A great deal of investigation has been made on the catalytic effects of reversed micellar systems.[3] For instance, the hydrolysis of adenosine 5′-triphosphate (ATP) is greatly enhanced with metal ions in a dodecylammonium propionate (DAP)–water–hexane system.[1] In this paper, we intend to clarify the relationship between the nature of water in and the catalytic effect of reversed micelles by the ESR measurement of Mn(II) ions.

The ESR line width of Mn(II) ions in aqueous solutions has been studied by several workers. The relaxation of the ESR spectrum has been interpreted in terms of several mechanisms; Garrett and Morgan[4] proposed that the relaxation is principally due to solvent fluctuation around the solvated ions, and that at high temperatures the solvent-ligand exchange effect is not negligible in determining the ESR line width. The relaxation due to the spin-spin interaction is neglected in Mn(II) solutions of concentrations lower than 0.01 mol dm^{-3}.[5] Therefore, if suitable conditions are chosen, the effect of spin-spin interaction and solvent-ligand exchange could be neglected in order to examine exclusively the effect of distortion of the solvent coordinated to metal ions. Thus, the ESR spectra of Mn(II) ions solubilized in the water pools of reversed micelles are expected to give valuable information on the nature of the water.

Experimental

ESR spectra at X band (9.4 GHz) were measured on a JEOL model JES-ME 3X spectrometer at a room temperature (22 °C±1 °C). Analytical grade $MnCl_2 \cdot 4H_2O$ was used without further purification. The purification of hexadecyltrimethylammonium bromide (HTAB), hexadecyltrimethylammonium chloride (HTAC), and chloroform was described previously.[2] Reversed micellar solutions were prepared according to the procedure in the literature.[6]

Results and Discussion

The forth line ($m_I=+1/2$) of the ESR spectrum of Mn(II), which has six hyperfine lines, is the most suitable for line width measurements, since it is least affected by imhomogeneous broadening.[7] Figure 1 shows the line widths of Mn(II) in aqueous solutions and HTAB/chloroform reversed micellar solutions as a function of concentration of $MnCl_2$. As the Mn(II) ions hardly exist in the chloroform phase, the line widths for both systems are reasonably compared to each other at the same ratio of $[Mn(II)]/[H_2O]$. It is estimated in these systems that 0.2 mol dm^{-3} of $MnCl_2$ corresponds to 125 of the ratio of [HTAB]/[Mn(II)] and at most one Mn(II) ion per micelle by considering the aggregation number of HTAB. Therefore, the broadening arising from the spin-spin interaction is almost negligible below this concentration. The observed ESR parametres of hyperfine coupling constant (A) and line width (ΔH) in the reversed micellar system (A=9.2 mT and ΔH=4.0 mT) are similar to those of $[Mn(H_2O)_6]^{2+}$ (A=9.2 mT and ΔH=3.07 mT)[8] and not to those of $[MnCl_4]^{2-}$ (A=7.9 mT and ΔH=0.96 mT) nor $[MnBr_4]^{2-}$ (A=7.5 mT and ΔH=8.0 mT).[8] Moreover, no spectral change was observed in HTAC compared to HTAB system, excluding the possible halogen coordination. Consequently, the ESR line broadening of hexaaquamanganese(II) complex in the reversed micellar system under consideration is thought to be attributable to fluctuations in arrangement of six water molecules in the solvation sphere.

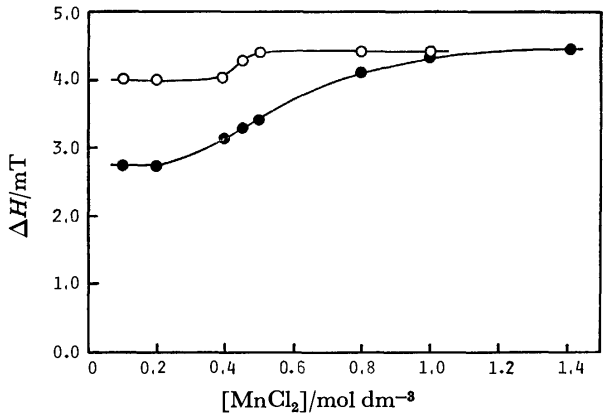

Fig. 1. Line width of Mn(II) as a function of $MnCl_2$ concentration in HTAB/$CHCl_3$ (○) and in aqueous (●) system.
[HTAB]=0.20 mol dm^{-3} and $[H_2O]$=0.444 mol dm^{-3}.

With an increase in water concentration resulting in larger water pools in the micellar cores, the line width of the ESR spectra decreases, gradually approaching to that in aqueous solution (ΔH=2.7 mT in Fig. 2). Figure 3 represents the water concentration dependence of ESR signal intensity, which is proportional to the product of height of the derivative curve and square of its width.[8] It is interesting to

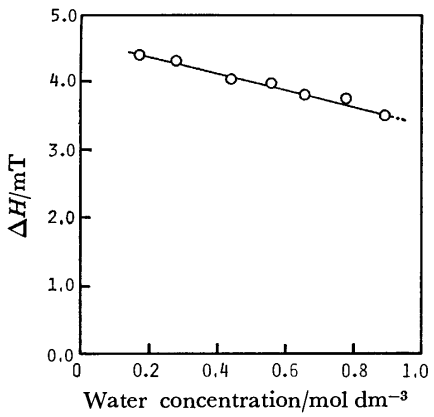

Fig. 2. Effect of water concentration on the line width of Mn(II) at a constant [Mn(II)]/[H_2O] ratio. [Mn(II)]=0.20 mol dm^{-3} of water and [HTAB]=0.20 mol dm^{-3}.

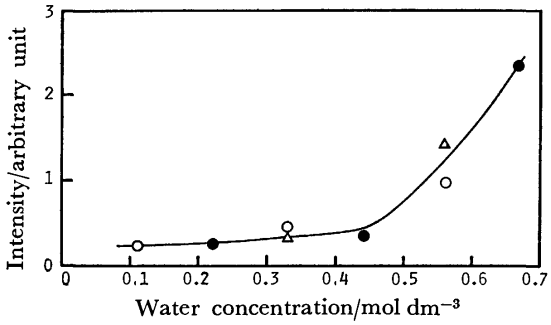

Fig. 3. Effect of water concentration of the ESR intensity of Mn(II).
[HTAB]=0.20 mol dm^{-3}, [Mn(II)]=4.4×10^{-4} mol dm^{-3} (○), 8.8×10^{-4} mol dm^{-3} (●), and 13.2×10^{-4} mol dm^{-3} (△).

note that the intensity remains nearly constant below 0.4 mol dm^{-3} of water concentration irrespectively of the Mn(II) concentration. This indicates that the water of these lower concentrations interacts exclusively with polar head group of HTAB and does not participate in the solvation of Mn(II) ions. As the water concentration increases above 0.4 mol dm^{-3}, the ESR intensity increases even though the ratio of [Mn(II)]/[H_2O] decreases. These results indicate that after completion of the hydration shell of the polar head groups of HTAB molecules, water molecules begin to coordinate to Mn(II) ions. Similar results were obtained by Sunamoto and Hamada[6] and Wells[9] by visible spectra of $CoCl_2$ in the reversed micellar system.

It was reported in the previous paper[1] that the polarity of water estimated from the λ_{max} value of pyridine 1-oxide in the DAP/hexane reversed micellar system decreases with a decrease in [H_2O]/[DAP] ratio, and attains the value between ethanol and chloroform at low water concentrations. The apparent decrease in the polarity is considered to be attributed to the lower degree of hydration of pyridine 1-oxide. This conclusion is supported by the present result that Mn(II) ions are dehydrated in small water pools of reversed micellar cores. The rate enhancement of ATP hydrolysis in the presence of metal ions such as Mg(II) or Mn(II)[10] in the reversed micellar system mentioned above may be accounted as the result of dehydration of metal cations. This could promote the formation of metal–ATP complexes in the reversed micellar system, enhancing the nucleophilic attack of water at condensed phosphate group of ATP.

The Crystal Structure of Tetra-μ-acetato-diruthenium Chloride

Tadashi TOGANO,† Masao MUKAIDA,†† and Terunosuke NOMURA*

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioicho, Chiyoda-ku, Tokyo 102

(Received October 9, 1979)

Synopsis. The crystal structure of $Ru_2(OCOCH_3)_4Cl$ has been determined from visually estimated Cu $K\alpha$ data. The crystal is composed of the dinuclear, carboxylato-bridged species $Ru_2(OCOCH_3)_4^+$ and the bridging chloride anions. The molecular structure is almost identical with that of the analogous butyrato complex, but the chloride-bridged chains run parallel with the c axis only.

Carboxylato ruthenium complexes of the $Ru_2(OCOR)_4Cl$ type (R=Me, Et, *n*-Pr) were first reported by Stephenson and Wilkinson.[1] The structure determination of the analogous butyrato complex was accomplished by Bennett *et al.*, who revealed that the complex contains a dinuclear carboxylato-bridged species, $Ru_2(OCOC_3H_7)_4^+$, with a very short Ru–Ru distance.[2] It has also been indicated that the Ru atoms of the complex exist in the common nonintegral oxidation state of +2.5.

The present authors prepared the complexes of the $Ru_2(OCOR)_4X$ type (R=H, Me, Ph.; X=Cl, Br, I, SCN, NO_3, CH_3COO) independently[3,4] and presumed that these complexes have structures similar to that of the butyrato complex. The present work was undertaken in order to verify this prediction and to obtain more information about the properties of a series of carboxylato complexes.

Experimental

The crystals of $Ru_2(OCOCH_3)_4Cl$ were prepared as has been described previously;[3] they were recrystallized from a 5 mol dm^{-3} acetic-acid solution by means of slow evaporation at room temperature.

The cell constants were determined using Cu $K\alpha$ radiation by the least-squares refinement of the data from 150 reflections of h 0 l and h k 0 Weissenberg photographs, on which copper-powder lines were superimposed for calibration. The density was measured by flotation in a tetrachloromethane–methyl iodide mixture. The crystal data are as follows: $Ru_2(OCOCH_3)_4Cl$, $F.W.$=437.3, monoclinic, space group C2/c, a=14.869(3), b=7.735(1), c=12.868(3) Å, β=109.56(2)°, V=1393 Å^3, D_m=2.25 g cm^{-3}, D_c=2.26 g cm^{-3} (for Z=4), μ=207.5 cm^{-1} (for Cu $K\alpha$ radiation). The intensity data were collected by multiple-film equi-inclination Weissenberg photographs for the layer lines from 0 to 5 on the b axis and for 0 on the c axis. The two crystals were then re-formed into spheres with average diameters of 0.14 and 0.16 mm respectively. The intensities of 1116 independent reflections were corrected for Lorentz-polarization and absorption effects; 87 of them were, however, too weak to be measured and so were assumed to be zero.

Structure Determination

The positions of the ruthenium and chlorine atoms were determined from a three-dimensional Patterson map. Fourier synthesis, phased with the Ru atoms and Cl atoms, revealed all the carbon and oxygen atoms. The structures was refined by the block-diagonal least-squares method. The atomic scattering factors were taken from the International Tables for X-Ray Crystallography.[5] The refinement of the positional and thermal parameters, at first isotropic and subsequently anisotropic for all the Ru, Cl, C, and O atoms, but not the H atoms, reduced the discrepancy factor $R=\Sigma(w||F_o|-|F_c||)/\Sigma w|F_o|$ to 0.09, excluding non-observed reflections (R=0.10 for all 1116 reflections). The final atomic coordinates and thermal parameters are listed in Table 1, and the observed and calculated structure factors in Table 2.†††

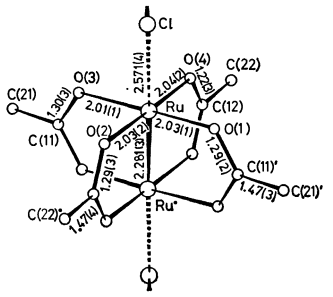

Fig. 1. Molecular structure with the numbering scheme of atoms and bond lengths (/Å) with e.s.d's in parentheses.

The computations were carried out on HITAC 8800/8700 computer at the Tokyo University Computer Center. The computer program used were UNICS by T. Sakurai *et al.* and HBLS IV by T. Ashida. In HBLS IV, the weighting scheme used was $w=(160.0/F_o)^2$ when $F_o>160.0$ and $w=1$ when $F_o\leqq 160.0$.

Results and Discussion

Bennett *et al.* have revealed that the tetra-*n*-butyrato complex contains dinuclear units consisting of two Ru atoms bridged by four *n*-butyrato groups. These dinuclear units, in crystal form, are linked by bridging chlorine atoms into infinite zigzag chains. The molecular structure of the acetato complex is almost identical with that of the butyrato complex. These dinuclear units have virtual D_{4h} symmetry if the alkyl chains are neglected in the case of the butyrato complex.

The geometry of, and bond distances in, the dinuclear cation and chlorine atoms are shown in Fig. 1. The bond angles and planes are given in Tables 3 and 4 respectively. The six nearest neighbors of a ruthenium atom are four oxygen atoms belonging to four different acetato groups, a ruthenium atom, and a chlorine atom. Six such atoms form distorted octahedral configuration about each of the two ruthenium

atoms. The mean values of the four different Ru–O bond lengths, all four O–Ru–O angles, the O–O' distances (2.22 Å) in the carboxylato groups, and the Ru–Cl distance were not significantly different from those of the butyrato complex. The very short Ru–Ru distance (2.281 Å), which was identical with that of the butyrato complex, implies that the interaction between the two metal ions is strong. The oxidation state of the Ru atoms in these complexes is thought to be +2.5, since the two metal atoms of a dinuclear cation are structurally equivalent. The abnormally high magnetic moments (2.90 BM (293 K) for the acetato complex[4)] and 3.37 BM (294 K) for the butyrato complex[1)]) and the electronic spectrum of the $Ru_2(OCOR)_4Cl$ species have been interpreted on the basis of a partial molecular orbital diagram of the M_2X_8 species.[2)]

The only difference between the acetato and butyrato complexes was found in their crystal structures. In both complexes, chloride ions bridged adjacent di-

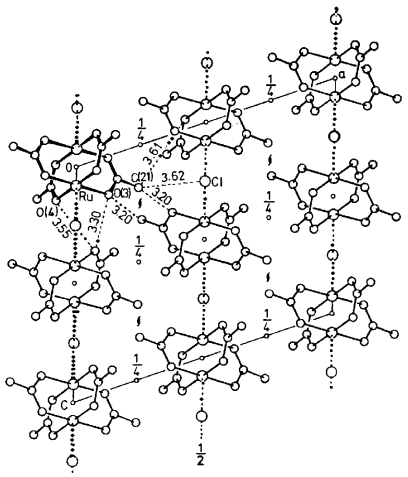

Fig. 2. Projection of the $Ru_2(OCOCH_3)_4Cl$ onto the (0 1 0) plane.

nuclear cations to form infinite zigzag chains. In the butyrato complex (tetragonal, space group I42d), there are alternating chains parallel to the a axis and the b axis. However as is shown in Fig. 2, the chains of the acetato complex (monoclinic, space group C2/c) lie along the c axis only. This finding is thought to reflect a substitution effect of R groups in the complexes.

While this manuscript was being prepared, structural studies of similar dinuclear carboxylato complexes of ruthenium were reported by Bino *et al.*[6)] However, there are some differences between the two acetato complexes, $Ru_2(O_2CCH_3)_4Cl\cdot 2H_2O$, in their article and the $Ru_2(O_2CCH_3)_4Cl$ in our article. In the former complex, the Cl bridges are perfectly linear, but in the latter complex the Cl bridges form zigzag chains, with an angle of 127.6° at the Cl atom.

The authors wish to thank Dr. Teruo Nomura of St. Paul's (Rikkyo) University for his help and advice.

Studies on the Solvent Extraction of Metal Perchlorates. II. Extraction of Alkali Metal Perchlorates with Trioctylphosphine Oxide

Satoshi KUSAKABE and Tatsuya SEKINE*

Departemnt of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received December 12, 1979)

Synopsis. Solvent extraction of alkali metal ions in 1 mol dm^{-3} sodium perchlorate ionic media with trioctylphosphine oxide (TOPO) in hexane was measured. The extraction improved in the order Li(I)>Na(I)>K(I)>Rb(I)>Cs(I). This was explained in terms of the higher ability of solvation with TOPO of the smaller ions. The chemical form of the extracted species was $M(TOPO)_n^+(ClO_4)^-$, where n is three for Li(I), Na(I), and K(I) and three and four for Rb(I) and Cs(I).

Sodium perchlorate in aqueous solution is extractable with trioctylphosphine oxide (TOPO) in hexane but extraction was not effective.[1] In the present investigation, the extraction of other alkali metal perchlorates with TOPO was measured under identical conditions. Factors affecting the extractions are discussed.

Experimental

Hexane solution of TOPO and aqueous sodium perchlorate solution were prepared as reported previously.[1] Lithium hydroxide of reagent grade was dissolved in water and the concentration was measured by titration with a standard acid solution. It was neutralized by perchloric acid, a standard sodium perchlorate solution being added in order to obtain 1.0 mol dm^{-3} (Na, Li)ClO_4. Potassium, rubidium, and caesium chlorides each of reagent grade were dissolved in water and the concentration was measured by titration with a standard silver nitrate solution. One mol dm^{-3} (Na, M)ClO_4 solutions (where M^+ is the alkali metal ion) were prepared from a standard sodium perchlorate solution and the metal chloride solution. The concentration of potassium(I) was 0.025 mol dm^{-3}, that of the other metal ions being 0.01 mol dm^{-3}. The solutions except for that of lithium(I) thus contained a small amount of chloride but its effect on the extraction equilibrium was found to be negligible. The other reagents and procedures were the same as those in the previous work.[1] The distribution experiments were carried out at 25±0.3 °C. An aqueous perchlorate solution and an organic TOPO solution were placed in a glass stoppered tube, agitated vigorously and centrifuged. The metal in the organic phase was back-extracted with 1 mol dm^{-3} nitric acid containing 0.1 mol dm^{-3} of sodium nitrate which was added in order to reduce the error caused by back-extracted sodium perchlorate in flame photometry. The aqueous metal concentration was calculated from the initial aqueous and equilibrium organic concentrations.

Results and Discussion

The distribution ratio of an alkali metal ion is defined by

$$D = [M(I)]_{org}/[M(I)] \quad (1)$$

where the subscript "org" denotes chemical species in the organic phase. Its extraction with TOPO can be written as

$$M^+ + ClO_4^- + n\text{TOPO(org)} \rightleftarrows M(TOPO)_n^+(ClO_4)^-\text{(org)}, \quad (2)$$

$$K_{exn(M)} = [M(TOPO)_n^+(ClO_4)^-]_{org}/[M^+][ClO_4^-][TOPO]_{org}^n. \quad (3)$$

Dissociation of ion-pairs is negligible in solvents essentially nonpolar. The aqueous phase in the present study is neutral and therefore the extraction of perchloric acid should be negligible for statistical treatment. Since the solvation number of sodium perchlorate with TOPO is three,[1] the following equations can be obtained.

$$[TOPO]_{org,total} = [TOPO]_{org} + 3[Na(TOPO)_3^+(ClO_4)^-]_{org} + \sum n[M(TOPO)_n^+(ClO_4)^-]_{org} \quad (4)$$

$$= [TOPO]_{org} + 3K_{ex3(Na)}[Na^+][ClO_4^-][TOPO]_{org}^3 + \sum nK_{exn(M)}[M^+][ClO_4^-][TOPO]_{org}^n. \quad (5)$$

Thus the distribution ratio is given by

$$D = \sum [M(TOPO)_n^+(ClO_4)^-]_{org}/[M^+] = \sum K_{ex(M)}[ClO_4^-][TOPO]_{org}^n. \quad (6)$$

By use of a least squares computer program and the value of extraction constant of sodium(I),[1] $K_{ex3(Na)} = 10^{1.01}$, a successive approximation procedure was carried out by means of Eqs. 3—6, the "free" TOPO concentrations, $[TOPO]_{org}$, and the best-fit extraction constants of metal ion, $K_{exn(M)}$, being obtained. The "best-fit" with the data was obtained when extraction of only trisolvate was assumed for lithium(I) and potassium(I), as well as when extraction of both tri- and tetrasolvate was assumed for rubidium(I) and caesium(I). The extraction constants are given in Table 1. Figure 1 shows the log D *vs.* free TOPO concentration plot (the data of sodium(I) are taken from Ref. 1), the solid curves being calculated by introducing the values of constants in Table 1 into Eq. 6.

It is most probable that the interactions between the TOPO solvated metal ion and the perchlorate ion in the organic phase are electrostatic, *viz.*, the extracted species are ion-pairs. The present results differ from those of extraction into polar solvents in

Org. phase: hexane containing TOPO. Aq phase: Li(I); 0.010 mol dm^{-3} $LiClO_4$+0.99 mol dm^{-3} $NaClO_4$, Na(I); 1.0 mol dm^{-3} $NaClO_4$, K(I); 0.025 mol dm^{-3} KCl+0.975 mol dm^{-3} $NaClO_4$, Rb(I) and Cs(I); 0.01 mol dm^{-3} of chloride+0.99 mol dm^{-3} $NaClO_4$. The solid curves are calculated by means of Eq. 6 and the values in Table 1.

which the solvation of metal ions is weaker than that with TOPO and in which at least a partial dissociation of the extracted ion-pairs is expected. For example, the extraction of sodium(I), potassium(I), rubidium(I), and caesium(I) as ion-pairs with tetraphenylborate ion into nitrobenzene was found to be better in the increasing order of the ionic size of the metal ion.[2] This type of extraction order often found in many other similar ion-pair extraction systems[3] is explained in terms of lower hydration and higher hydrofobic tendencies of large metal ions and in some cases also of their higher tendency to dissociate in the organic phase. The opposit extraction order in the present system can be explained in terms of the order of the formation of TOPO solvates. Although the size of the central metal ions in the TOPO solvates differs, the overall molar size of the solvated cations in the ion-pairs should be similar when the solvation number is the same, the effect of the molar size on the extraction (or the hydrofobic tendencies) should thus be similar. For this reason, best extraction of lithium(I) should be due to its highest tendency to be solvated with TOPO. Even though it is hydrated most strongly among these alkali metal ions in the aqueous phase, its small ionic size is also favorable for solvation with TOPO. The hydration interferes with extraction while TOPO solvation enhances it. However, the fact that the smaller the ionic size, the better the extraction indicates that the stronger solvation with TOPO overcomes the unfavorable stronger hydration. Thus although the metal ions are extracted as ion-pairs, the order of extraction is similar to that with β-diketones reported by Healy.[4] It seems reasonable that the less strongly solvated larger ions, rubidium(I) and caesium(I), have space to accept one more TOPO molecule and are extracted also as tetrasolvates.

No quantitative work seems to have been carried out on the extraction equilibria of these metal perchlorates with solvating type solvents such as TOPO in nonpolar solvents.

The authors are grateful to Messrs. Yuichi Ishida and Kenji Ohira for their assistance in experiments.

Catalysis by 12-Heteropolymolybdic Acid. II. Friedel-Crafts-type Reaction of Aromatic Compounds

Kenji NOMIYA, Yoshio SUGAYA, Sadayoshi SASA, and Makoto MIWA*

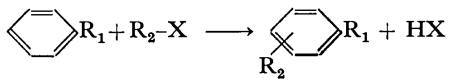
Depertment of Industrial Chemistry, Faculty of Engineering, Seikei University, Musashino-shi, Tokyo 180

(Received November 14, 1979)

Synopsis. 12-Heteropolymolybdic acid, a heteropolyacid of Keggin-structure, behaves as an effective catalyst of the Friedel-Crafts-type reactions for aromatic compounds, such as alkylation by benzyl chloride and *t*-butyl chloride, acylation by acetyl chloride, and sulfonylation by tosyl chloride. The catalyst mainly gives para-substituted products for phenol and anisole. The reactions proceed *via* carbocation-generation mechanism brought about by the strong Brønsted acid.

Except for the catalytic alkylation of benzene with 1-dodecene by silicotungstic acid supported on silica gel,[1] no typical reaction catalyzed by heteropolyacid, recognized as a solid-acid, has been demonstrated in spite of advanced studies on its structure.[2-10]

Nomiya *et al.* have shown the catalytic polycondensation of benzyl alcohol and its derivatives by heteropolyacids of Keggin-structure such as $H_4SiM_{12}O_{40}$ and $H_3PM_{12}O_{40}$ (M=Mo and W).[11] These acids also give the same polybenzyl from benzyl chloride by dehydrohalogenation as that obtained from benzyl alcohol in comparably high yields. We wish to report that these heteropolymolybdic acids are active catalysts in substitution reactions such as alkylation, acylation, and sulfonylation of aromatic systems as well as polymerization reactions. The reaction scheme is as follows.



The reactions were performed by refluxing a mixture of reactants A and B in the presence of the heteropolyacid. The results of typical experiments are given in Table 1. The heteropolyacid homogeneously catalyzes all reactions. The reaction products were identified by IR and ^{1}H-NMR spectra. No poly-branched product was detected. The substituent groups are oriented mainly to the para-position of six-membered aromatic rings of phenol and anisole, and the 2-position of five-membered ring of thiophene. In the former case, only a slight ortho-substitution was detected in the products; no meta-substituted product was observed, indicating that the reaction proceeds by an ionic mechanism. On the benzyl chloride–benzene system the alkylation takes place sparingly, albeit catalytically, whereas on the benzyl alcohol–benzene system, instead of such a reaction, condensation-etherization and polymerization of benzyl alcohol take place. In the acylation of toluene by acetyl chloride, only a trace of the product was obtained.

In all polymerization and alkylation reactions, the catalyst undergoes color change corresponding to the reduced stages of molybdenum ions from original yellow to green and finally to blue.[12] However, the reduction of catalyst would not be essential in the coupling reaction since the initial activity of catalyst and the selectivity and yields of products were not influenced by the recharge of excess amount of reactants to the blue acid obtained. The blue acid appears to be an active catalyst.

In the acylation and sulfonylation reactions the catalyst partly decomposes, producing an unidentified black solid. This might be caused by a specific reaction between the acetyl chloride or the tosyl chloride and the catalyst. No typical color change of yellow-green-blue was observed.

In the reaction of six-membered aromatic substrates, the ease of coupling decreases in the order, alkylation> acylation>sulfonylation. However, in the five-membered substrate such as thiophene, alkylation scarcely takes place by *t*-butyl chloride. Thus, in the case of five-membered substrate, acylation by acetyl chloride takes place more easily than alkylation under the same conditions.

Since the tetrabutylammonium salts of both the unreduced yellow and the reduced blue heteropolyanions show no catalytic activity, the remarkable strong acidity of catalyst would be important.

The catalytic activity of the acid appears to be comparable to that of $Mo(CO)_6$ and Arene–$Mo(CO)_3$ previously reported as "Friedel-Crafts" like catalysts, with respect to the coupling reaction concerned.[13,14] Although typical Friedel-Crafts catalysts, whether homogeneous or heterogeneous, are all Lewis acids and are capable of promoting carbonium ion formation from certain organic molecules, the heteropolyacid and the "Friedel-Crafts" like catalysts would show no Lewis acid property; particularly the former behaves as Brønsted acid. $Mo(CO)_6$ is coordinatively saturated molecules. However, the complex added in the aromatic solvent is easily converted into Arene–$Mo(CO)_3$ prior to the coupling reaction.[13] In the present work, no evidence has been obtained for the direct coordination of arene rings of reactants to the molybdenum ions in the blue heteropolyacid during the course of reaction. The type of reactions studied here appears to be a carbonium-ion generation mechanism brought about by the strong Brønsted acid.

The essential feature of the heteropolymolybdic acid is the stability of catalyst, appearing in particular in the polymerization and alkylation, and the yielding of products with high selectivity in the case of phenol and anisole.

Although the heteropolyacid contains twelve molybdenums, all of them would not play a direct role as active site as in the case of solid-surface catalyst. Thus the turn-over numbers of catalyst have been simply calculated as the molar ratio of catalyst to product. The turn-over number per unit hour (Table 1) shows that (1) all reactions proceed catalytically, not stoichiometrically, and (2) the ease of carbocation forma-

tion may be related to the electronic structure of the halides, decreasing in the order

This tendency corresponds to that in the reactions catalyzed by $AlCl_3$, $Mo(CO)_6$.

The parameters on the corresponding reactions by $Mo(CO)_6$ catalyst and Friedel-Crafts catalyst have been conveniently calculated by the data of Farona and White,[13] and reported data,[15] respectively. The parameters reflect the catalytic efficiency of catalysts, indicating that the former reactions, including the case of the 12-heteropolyacid, are catalytic, and the latter reaction stoichiometric.

Telomerization of Isoprene with Dialkylamine Catalyzed by Palladium Complexes

Masanobu Hidai,* Haruyoshi Mizuta, Kiyomiki Hirai, and Yasuzo Uchida
Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Hongo, Tokyo 113
(Received November 28, 1979)

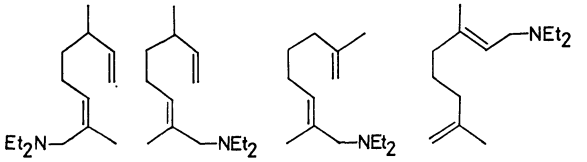
Synopsis. Telomerization of isoprene with diethylamine in the presence of catalytic amounts of palladium chloride and triphenylphosphine under carbon dioxide and/or using methanol as solvent gave three kinds of 2:1 adducts in good yields, one of which was found to be an adduct of new type.

Many transition metal complexes have been shown to catalyze the reaction of 1,3-butadiene with alcohols,[1] carboxylic acids,[2] amines,[3] water,[4] and active methylene and methylidyne compounds[5] yielding mainly 2,7-octadienyl derivatives (2:1 adducts). However, the analogous reactions of isoprene have not been well studied. The reaction of morpholine with isoprene by nickel complexes was reported to give mainly 1:1 adducts along with a small amount of 2:1 adducts.[3] This is in sharp contrast to the ready formation of 2:1 adducts from butadiene and amines with a variety of transition metal complexes. Recently Tanaka *et al.*[6] reported that butyllithium catalyzed telomerization of isoprene which led to formation of (2*Z*)-*N*,*N*-dialkyl-3,7-dimethyl-2,6-octadienylamine in a good yield.

We reported in a previous paper the synthesis of citronellol starting from isoprene through a 2:1 adduct with methanol.[7] We wish here to describe the reaction of isoprene with diethylamine catalyzed by palladium complexes, where carbon dioxide and methanol showed a remarkable effect on the product distribution.

Results and Discussion

Treatment of isoprene with diethylamine in the presence of $PdCl_2$ and triphenylphosphine under carbon dioxide and/or using methanol as solvent gave 2:1 adducts of isoprene and the amine, together with a small amount of 1:1 adducts and isoprene dimers. The 2:1 adducts were found to be a mixture of three octadienyl derivatives **1**, **2**, and **3**. Their structures



1 **2** **3**

have been determined on the basis of the infrared and NMR spectra after their separation by preparative GLC (Table 1). The product **1** gives rise to two quartets at 2.38 and 2.40 ppm in the NMR spectrum assignable to the methylene protons of the diethylamino group, indicating that the product **1** is a mixture of *E*- and *Z*-isomers around the trisubstituted C=C bond. On the other hand, measurement of the nuclear Overhauser effect in the 270 MHz ^1H NMR spectra of the products **2** and **3** clearly showed that they have an *E*-configuration around the trisubstituted C=C bond. Thus, the integrated intensity of the olefinic proton ($-CH_2-C\underline{H}=$) of **2** at 5.35 ppm increased *ca.* 16% by irradiating the methylene protons between the C=C bond and the nitrogen atom, whereas the intensity increased only *ca.* 1.8% by irradiating the methyl protons attached to the C=C bond at 1.71 ppm.

A standard procedure was adopted to study the effect of a number of parameters on the conversion of isoprene and the product ratio (Table 2). The reaction at 100 °C for 24 h under nitrogen without solvent gave only a 14% conversion into a mixture of 1:1 adducts, the adduct **2**, and isoprene dimers. However, the same reaction under carbon dioxide gave a 85% conversion to yield products comprising *ca.* 60% of the 2:1 adducts. The striking feature of this reaction is a large amount of the 2:1 adducts formed under nitrogen when alcohols such as methanol and ethanol were used as solvent. Methanol is especially effective among them and the reaction proceeds smoothly even at room temperature.

Carbon dioxide is effective not only in accelerating the reaction rate, but also in changing the product ratio. When the reaction was run in methanol at 100 °C under nitrogen, the ratio of the adducts **1**, **2**, and **3** was 20:44:28. However, the reaction under carbon dioxide changed the ratio into 40:32:13. The product ratio is also dependent upon the reaction temperature. The high temperature seems to favor the formation of the adducts **2** and **3**, and disfavor the formation of **1** when the reaction was run in methanol.

Among the 2:1 adducts obtained here, the compound **3** is an adduct of new type. The adducts with methanol corresponding to the compounds **1** and **2** are readily produced by using zero-valent palladium complexes as catalyst.[8] Use of a zero-valent palladium complex, $Pd(DBA)_2$ (DBA=dibenzylideneacetone), instead of $PdCl_2$ in the above amination reaction in methanol gave the 2:1 adducts of both diethylamine and methanol in low yields. On the other hand, in the early stage of the reaction in the presence of $PdCl_2$ and triphenylphosphine in methanol at room temperature, the adducts with the amine were only produced, while the adducts with methanol were not obtained at all. These results strongly suggest that a zero-valent complex may not be involved as an active species and that the adducts with the amine are not formed *via* the adducts with methanol, although Hata *et al.*[9] previously reported the exchange reaction of the allylic groups of ethers with a variety of active hydrogen compounds including secondary amines by using palladium complexes. It is of great interest to note that $Pd(DBA)_2$ coupled with diethyl ammonium chloride repressed the formation of the adducts with

a) In all cases, an equimolar amount of triphenylphosphine was added to the palladium complexes. b) The 1 : 1 adducts were mainly composed of *N*,*N*-diethyl-2-methyl-2-butenylamine and *N*,*N*-diethyl-3-methyl-2-butenylamine. c) The isoprene dimers predominantly contained 2,7-dimethyl-1,3,7-octatriene. d) The adducts were 1-methoxy-2,6-dimethyl-2,7-octadiene (9%) and 1-methoxy-2,7-dimethyl-2,7-octadiene (18%). e) The adducts were the same as above d), 4 and 9% respectively.

methanol. This may suggest intervention of proton in the above amination reaction, which may originally come from methanol or diethylcarbamic acid formed from the amine and carbon dioxide, and formation of a positively charged π-allyl intermediate similar to that proposed by Åkermark *et al.*[10]

Experimental

All reactions were performed under oxygen-free conditions. Alcohols and isoprene were dried and distilled over anhydrous $CaSO_4$. Diethylamine was purified by distillation over potassium or sodium hydroxide pellets. Bis(benzylideneacetone)palladium $Pd(DBA)_2$ was prepared according to the procedure reported by Ishii *et al.*[11]

Analysis was carried out with a Hitachi K23 gas chromatograph (He carrier gas through 2 m×3 mm in stainless-steal column, 10% Silicone DC 550) and a Shimadzu GC-5A chromatograph for all preparative GLC (He carrier gas through 2.1 m×10 mm in stainless-steal column, 10% Silicone DC 550). NMR spectra were obtained with a Hitachi Perkin-Elmer 90 MHz instrument using tetramethylsilane (TMS) as internal standard and C_6D_6 as solvent. IR spectra were recorded on a Hitachi 215 instrument.

General Procedure at 28 °C. In a 100 ml two neck flask or a 75 ml Pyrex glass ampule, in which palladium chloride (88.7 mg, 0.5 mmol) and triphenylphosphine (131.1 mg, 0.5 mmol) were placed, isoprene (15 ml, 150 mmol), diethylamine (15 ml, 144 mmol), and methanol (15 ml, 370 mmol) were added in this order. After stirring for 24 h at 28 °C, the reaction gave a 100% conversion into **1** 53%, **2** 33%, **3** 11%, and 1:1 adducts (3%). A mixture of **1**, **2**, and **3** was obtained by distillation (103—105 °C/933 Pa) and separated by preparative GLC at 150 °C. Found: C, 80.52; H, 13.40; N, 6.71% for **1**; C, 80.32; H, 13.16; N, 6.80% for **2**; C, 80.56; H, 13.24; N, 6.51% for **3**. Calcd for $C_{14}H_{27}N$: C, 80.31; H, 13.00; N, 6.69%. IR and NMR spectra are summarized in Table 1.

This general procedure was used for the series of experiments with changes in conditions as summarized in Table 2. The reactions at 100 °C and/or under carbon dioxide were achieved in a 100 ml stainless-steal autoclave for 24 h.

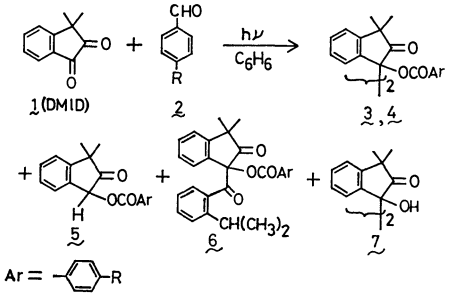
(Received December 3, 1979)

Synopsis. The photochemical reaction of 3,3-dimethyl-1,2-indanedione with aromatic aldehydes in benzene was found to give a mixture of two diastereoisomeric 2:2 adducts, a 1:1 adduct, a 2:1 adduct, and pinacol.

When photolyzed together with aldehydes, cyclic α-diketones in both aliphatic[1] and aromatic systems[2] abstract the formyl hydrogen atom to give in-cage combination products predominantly. In contrast, open chain α-diketones yield out-of-cage products mainly.[3] In the present work, we have investigated the photochemical reaction of 3,3-dimethyl-1,2-indanedione (**1**) (DMID) with several aromatic aldehydes and found a rather unexpected behavior of DMID toward these aldehydes.

After a benzene solution of DMID and *p*-anisaldehyde **2a** had been irradiated in a Pyrex tube for 2 h, the separation of the products by TLC gave two diastereoisomeric 2:2 adducts, **3a** (11%) and **4a** (10%), a 1:1 adduct, **5a** (4%), and a 2:1 adduct, **6a** (7%). In addition, the ^{1}H-NMR spectrum of this reaction mixture showed the presence of pinacol, **7** (15%).[4] The molecular weights of **3a** and **4a**, as determined by the vapor-pressure method, are 598±30 and 620±30 (Calcd, 618.25) respectively. The 2:2 adducts, **3a** and **4a**, show characteristic IR bands due to the unconjugated five-membered cyclic ketone and the aromatic ester at 1777 and 1729 cm^{-1} and at 1768 and 1720 cm^{-1}, respectively. The ^{1}H-NMR spectra show signals at 1.52 (s, 3H), 1.55 (s, 3H), and 3.76 (s, 3H), and at 0.82 (s, 3H), 1.52 (s, 3H), and 3.82 (s, 3H), respectively. The ^{13}C-NMR spectrum of **4a** shows peaks at 213.2 (ketone), 164.1 (ester), 86.1 (s), 55.5 (q, CH_3O–), and 48.9 (s) ppm, besides two methyl carbons and twelve sp^2 carbons. These spectral data and the results of elemental analyses are consistent only with the formulation of **3a** and **4a** as two diastereoisomers of 1,1′-bis(4-methoxybenzoyloxy)-3,3,3′,3′-tetramethyl-1,1′-biindane-2,2′-dione. The molecular weight of **6a**, as determined by the vapor-pressure method, is 430±30 (Calcd, 456.6). The IR spectrum shows characteristic bands at 1757 (unconjugated five-membered cyclic ketone), 1716 (aromatic ester), and 1695 (conjugated ketone). The ^{1}H-NMR and ^{13}C-NMR spectra reveal that the framework of **6a** consists of a half-unit of the 2:2 adduct and the 2-isopropylbenzoyl group. Thus **6a** was identified as 1-(4-methoxybenzoyloxy)-1-(2-isopropylbenzoyl)-3,3-dimethyl-2-indanone. In similar reactions with other aromatic aldehydes, **2b—d**, the products were **3b—d**, **4b—d**, **5b**, **6b—d**, and **7**. The yields and physical properties of the products are summarized in Tables 1 and 2.



Scheme 1.

A plausible mechanism to account for the formation of the photoproducts, **3**, **4**, **5**, **6**, and **7**, is outlined in Scheme 2. The photoexcitation of DMID and the subsequent formyl hydrogen abstraction afford two radicals, **8** and **9**, a large portion of which escape from the solvent cage. The escaped radical, **8**, has earlier been shown to dimerize to yield pinacol **7**.[4] The aroyl radical, **9**, out of the cage attacks the oxygen atom of C-1 carbonyl group of DMID, leading to the formation of the **10** radical; the two radicals then couple with each other to give **3** and **4**. This reaction path is in agreement with the fact that the anisoyl radical, **9a**, generated by the thermal decomposition of di-*t*-butyl diperoxyoxalate,[5] reacted with DMID to give **3a** and **4a**, but neither **5a** nor **6a**. Hydrogen transfer from **8** to **10** will result in the formation of

5. The 2:1 adduct, **6**, is apparently the secondary photoproduct derived from **3** and **4**, since it was not formed upon irradiation with light of wavelength above 400 nm, to which **3** and **4** were transparent. The facile photodecarbonylation of 2-indanone derivatives is a well-known process.[6] Hydrogen transfer to a possible intermediate, the diradical, **11** or *o*-xylylene, **12**, will lead to the formation of **6**. In accord with this, the photochemical conversion of **3** and **4** to **6** occurs in the presence of aromatic aldehydes.

Noteworthy is the finding that the out-of-cage products are formed exclusively in the photochemical reaction of DMID with aldehydes, in spite of the DMID's cyclic structure.

Experimental

The apparatus and equipment used in this study were described in a preceding paper.[4]

A degassed benzene solution of DMID[7] (33 mM) and aldehyde (33 mM) was irradiated for 2 h in a Pyrex tube, using a 300 W high-pressure Hg lamp. After the removal of the solvent, the products were separated by preparative TLC, developing three times with benzene/dichloromethane. The 2:1 adduct, **6**, developed at $R_f \approx 0.7$, the 1:1 adduct, **5**, at ≈ 0.5, and the 2:2 adducts, **3** and **4**, at ≈ 0.2—0.3. The 2:1 adduct, **6**, was purified once more by preparative TLC, developing with benzene, and by recrystallization from dichloromethane/hexane. The 2:2 adducts, **3** and **4**, were recrystallized from chloroform.

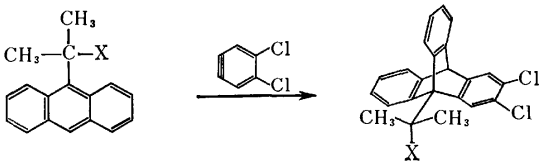
Restricted Rotation Involving the Tetrahedral Carbon. XXXI. Barriers to Rotation in 2,3-Dichloro-9-(1-cyano or 1-methoxycarbonyl-1-methylethyl)triptycenes[1]

Soichi Otsuka, Gaku Yamamoto, Tsutomu Mitsuhashi, and Michinori Ōki*
Department of Chemistry, Faculty of Science, The University of Tokyo, Tokyo 113
(Received December 8, 1979)

Synopsis. The title compounds were prepared to see the effects of substituents in 1-position on the barriers to rotation about the C_9–C_{subst} bond. The barrier was found to be higher for the cyano compound than those for the corresponding compounds carrying a substituent in 1-position, whereas the methoxycarbonyl compound gave almost the same barrier irrespective of the substituent.

In one of the preceding papers, we have shown that the barriers to rotation in 1-substituted 9-(1-cyano-1-methylethyl)triptycenes are always lower than that of 9,10-bis(1-cyano-1-methylethyl)triptycene[2] and have suggested that 9-(1-cyano-1-methylethyl)triptycenes which do not carry a substiuent in 1-position should demonstrate a higher barrier to rotation due to the enhanced stability of the ground state of the rotamers.[3] We wish to report in this paper that 2,3-dichloro-9-(1-cyano-1-methylethyl)triptycene (**1**), which lacks a substituent in 1-position, has shown a higher barrier than those with a substitutent in 1-position. Incidentally, the barrier to rotation of 2,3-dichloro-9-(1-methoxycarbonyl-1-methylethyl)-triptycene (**2**) is almost the same with those carrying a substituent in 1-position.

The syntheses of the compounds in question were carried out as was reported in the previous paper. Usually the ±*sc* form was obtained preferentially and the ±*sc* form (or a ±*sc*-form-rich mixture) was heated to obtain a ±*sc*-*ap* mixture. Chromatography of the ±*sc*-*ap* mixture gave the *ap* form.



1: X=CN
2: X=COOCH$_3$

Experimental

Spectral Measurement. ^{1}H NMR spectra were recorded on a Hitachi R-20B spectrometer operating at 60 MHz. Infrared spectra were obtained with a Hitachi 260-30 infrared spectrometer.

Materials. Syntheses and isomerization were carried out as follows.

2,3-Dichloro-9-(1-cyano-1-methylethyl)triptycene (1). To a refluxing solution of 1.00 g (4.08 mmol) of 9-(1-cyano-1-methylethyl)anthracene and 1.0 ml of isopentyl nitrite in 35 ml of 1,2-dimethoxyethane, was slowly added 1.10 g (5.34 mmol) of 4,5-dichloroanthranilic acid[4] in 15 ml of 1,2-dimethoxyethane under a nitrogen atmosphere. The mixture was heated for further 40 min and filtered. The solution was evaporated and the residue was chromatographed on alumina to give 727 mg of ±*sc*-**1**, mp 283—284 °C. Found: C, 73.65; H, 4.39; N, 3.56; Cl, 18.19%. Calcd for $C_{27}H_{17}Cl_2N$: C, 73.85; H, 4.39; N, 3.59; Cl, 18.17%. ^{1}H NMR ($CDCl_3$, δ): 2.43 (6H, s), 5.26 (1H, s), 7.0—7.2 (4H, m), 7.3—7.6 (3H, m), 7.45 (1H, s), 7.8—8.0 (1H, m), 7.95 (1H, s). IR (KBr): 2235 cm^{-1}.

Refluxing a solution of 337 mg of ±*sc*-**1** in 20 ml of *o*-dichlorobenzene overnight and subsequent chromatography on alumina gave 116 mg of *ap*-**1**, mp 233—235 °C. Found C, 73.56; H, 4.19; N, 3.76; Cl, 17.74%. Calcd for $C_{27}H_{17}Cl_2N$: C, 73.85; H, 4.39; N, 3.59; Cl, 18.17%. ^{1}H NMR ($CDCl_3$, δ): 2.43 (6H, s), 5.26 (1H, s), 7.0—7.2 (4H, m), 7.3—7.5 (2H, m), 7.54 (1H, s), 7.60 (1H, s), 7.8—8.1 (2H, m). IR (KBr): 2240 cm^{-1}.

2,3-Dichloro-9-(1-methoxycarbonyl-1-methylethyl)triptycene (2) was prepared similarly from 9-(1-methoxycarbonyl-1-methylethyl)anthracene and 4,5-dichlorobenzyne. The reaction gave a 6:1 ±*sc* and *ap* mixture in 38% yield after rough chromatography. ±*sc*-**2** was obtained in pure form by chromatography since this form was eluted first: mp 211—213 °C. Found: C, 71.11; H, 4.61; Cl, 16.48%. Calcd for $C_{25}H_{20}Cl_2O_2$: C, 70.93; H, 4.76; Cl, 16.75%. ^{1}H NMR ($CDCl_3$, δ): 2.27 (6H, s), 3.78 (3H, s), 5.20 (1H, s), 6.9—7.5 (7H, m), 7.39 (2H, s), 7.6—7.8 (1H, m). IR (KBr): 1735, 1715 cm^{-1}.

ap-**2**, mp 244—245 °C, was obtained similarly by isomerization of ±*sc*-**2** followed by chromatography. Found: C, 71.19; H, 4.70%. Calcd for $C_{25}H_{20}Cl_2O_2$: C, 70.93; H, 4.76%. ^{1}H NMR ($CDCl_3$, δ): 2.28 (6H, s), 3.77 (3H, s), 5.22 (1H, s), 6.9—7.1 (4H, m), 7.2—7.5 (4H, m), 7.47 (1H, s), 7.72 (1H, s). IR (KBr): 1740 cm^{-1}.

Kinetic Measurement. Solutions of compound **1** or **2** in 1-chloronaphthalene were heated by immersing the samples in appropriate boiling baths. The details were reported elsewhere.[3]

Results and Discussion

Assignment of the ±*sc* structures was not straightforward, since both forms, ±*sc* and *ap*, gave a singlet signal for the methyl groups in ^{1}H NMR spectra. We took advantage of the method of syntheses and an aspect of ^{1}H NMR spectra for the structural assignments. Firstly, the formation of triptycenes from anthracenes and benzynes are known to be stereoselective to a large extent:[4] the incoming benzynes prefer the antiperiplanar position of the largest group. It will be reasonable to assume that the ±*sc*-form is produced preferentially in this case as well as the similar cases reported elsewhere.[3] Secondly, close examination of the NMR spectra in the aromatic region discloses that there are two singlets which are assignable to 1 and 4 protons. It may be reasonable to assume that the protons in 4-position give signals at almost the same chemical shift: a signal at δ 7.45 for the major product of **1** and that at δ 7.54 for the minor are due to 4-protons. Consideration of anisotropy effects of the cyano group[5] leads to the conclusion

Table 1. Rates of isomerization, equilibrium constants and thermodynamic parameters for the processes $\pm sc \rightleftharpoons ap$ of compounds **1** and **2**

	179	1.88×10^{-4}	5.22×10^{-4}	2.78		
	162	3.54×10^{-5}	8.92×10^{-5}	2.52		
	152	1.44×10^{-5}	4.06×10^{-5}	2.82		

Table 2. Kinetic parameters for the internal rotation of compounds **1** and **2**

X	Process	ΔH^* / kJ mol^{-1}	ΔS^* / J K^{-1} mol^{-1}	E_a / kJ mol^{-1}	log A
CN	$\pm sc \rightarrow ap$	164.8	27.2	168.6	14.8
	$ap \rightarrow \pm sc$	172.4	49.8	176.0	16.0
$COOCH_3$	$\pm sc \rightarrow ap$	141.4	−7.5	145.0	13.0
	$ap \rightarrow \pm sc$	142.7	3.8	146.4	13.6

that the 1-proton in $\pm sc$-**1** should give a signal at a lower field than *ap*-**1**. This supports the conclusion that the major product is $\pm sc$-**1**. Similarly, of the two signals due to 1-protons of $\pm sc$-**2** and *ap*-**2**, the signal due to 1-proton of $\pm sc$-**2** should be at a higher field than that of *ap*-**2**. The signals at δ 7.39 for the major product is an overlap of those due to 1- and 4-protons and is at a higher field than the signal at δ 7.72 for the minor product. Thus the major product is again the $\pm sc$ form of **2**.

The equilibrium constants and the rates of isomerization obtained at various temperatures are listed in Table 1. From these values thermodynamic parameters were obtained as also shown in Table 1. Kinetic parameters were obtained by both Eyring plot and Arrhenius plot and are shown in Table 2.

Since the Arrhenius activation energy for rotation of 9-(1-cyano-1-methylethyl)triptycenes which carry a chloro or a methyl group in 1-position is about 150 kJ mol^{-1},[3] those of compound **1** are at least 12 kJ mol^{-1} higher than the former. Thus the barrier to rotation, being the difference in energies between the transition state and the ground state, is high for compound **1** because of the stability of the ground state, although the energy of the transition state for rotation is expected to be lower than that for the corresponding compounds carrying a peri-substituent.

It is interesting to note that the free energy of activation for rotation in compound **2** at 177 °C (143.1 kJ mol^{-1}) is about the same with the corresponding compounds carrying a substituent in 1-position, although in the latter two processes, $\pm sc \rightarrow ap$ and $ap \rightarrow \pm sc$, a fairly large difference has been seen because of the instability of the *ap* form. This phenomenon may to attributed to the raise of the ground state relative to the cyano compound (**1**) because the methoxycarbonyl group is a large group in a plane which causes severe interaction with the triptycyl moiety.

We wish to acknowledge the receipt of a Grant-in-Aid for Scientific Research of the Ministry of Education which supported this work.

Formation of C–S Bond by the Elimination of Perfluorocarboxylic Acid

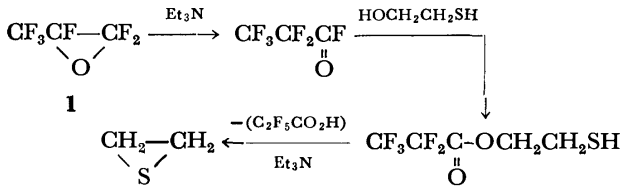
Hajimu KAWA and Nobuo ISHIKAWA*

Department of Chemical Technology, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received December 28, 1979)

Synopsis. Thiirane was readily generated from 2-mercaptoethyl trifluoroacetate or pentafluoropropionate by the intramolecular elimination of the perfluorocarboxylic acid with triethylamine. Alkyl benzyl sulfides were also prepared from benzyl trifluoroacetate or pentafluoropropionate and alkanethiols by the intermolecular elimination of the perfluorocarboxylic acid

In a course of our studies on pentafluoropropionylation of various 1,2-bifunctional ethanes with hexafluoro-1,2-epoxypropane(**1**)–triethylamine system,[1] it was found that a considerable amount of thiirane was formed from 2-mercaptoethanol.

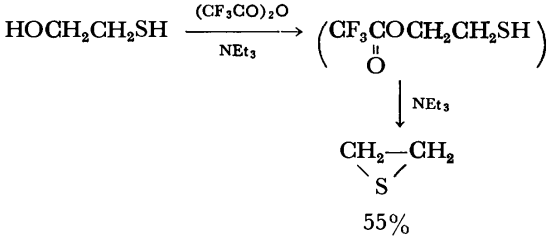


The reaction route shown above was supported by the experimental fact that pentafluoropropionic acid was eliminated very easily from 2-mercaptoethyl pentafluoropropionate (**2**) and thiirane was obtained in a yield of 60%. The formation of thiirane by decarboxylic acid reaction is not of novelty, because Miles and his co-workers have reported that thiirane was formed[2] when they examined the hydrolysis of 2-mercaptoethyl acetate with aqueous sodium hydroxide. However, the yield of thiirane in their reaction is very poor, as a mild base such as triethylamine is not strong enough for the formation of thiirane and this unstable compound easily polymerizes in the presence of aqueous sodium hydroxide.

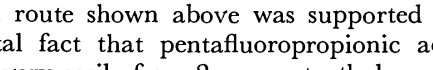
In our process, the reaction in diglyme proceeded smoothly at room temperature, in a short period such as 30 min, and the resulting thiirane was separated by only distillation under a reduced pressure (≈30 mmHg). Thus the perfluorocarboxylate seemed to be a much more convenient intermediate compound for the generation of thiiranes from 2-mercaptoethanols rather than a usual fluorine-free carboxylate.

Further we confirmed that thiirane can also be prepared by treating 2-mercaptoethanol with trifluoroacetic anhydride and two equivalents of triethylamine.

In the extention of the C–S bond formation by



the intramolecular elimination of perfluorocarboxylic acid described above, a similar intermolecular elimination was examined. We chose benzyl alcohol as an active alcohol and reactions of benzyl trifluoroacetate or pentafluoropropionate with several alkanethiols were tried. Several results of the preparation



of benzyl sulfides by this procedure are shown in Table 1. For these intermolecular condensations, it was necessary to apply more polar solvents and higher temperatures.

Table 1. Yields of $PhCH_2SR$ (%)

R	Yield (%) R_f		$PhCH_2SR$	
	CF_3[a]	CF_3CF_2[b]	Bp °C/mmHg [Mp/°C]	(lit)
n-Pr	15	55	88—89/10	(112/14)[c]
n-Bu	20	71	113—114/8	(123/13)[c]
$PhCH_2$	33	76	[48—49]	([49—50])[d]

a) GLC yield. b) Isolated yield. c) I. J. Buchi, M. Prost, H. Eichenberger, and R. Lieberherr, *Helv. Chim. Acta.*, **35**, 1527 (1952). d) "Handbook of Chemistry and Physics," 55th ed, CRC Press, Inc., Cleveland, Ohio (1974—1975), p. C498.

Thus, benzyl perfluorocarboxylate and an alkanethiol were allowed to react in *N*,*N*-dimethylformamide at ≈120 °C in the presence of triethylamine. Pentafluoropropionate gave much higher yields of sulfides than trifluoroacetate did and this should be due to the fact that a pentafluoropropionyloxyl group is a better leaving group compared with a trifluoroacetoxyl group. As the electronegativities of trifluoromethyl and pentafluoroethyl groups are almost similar,[3] the difference should be due to the bulkiness of these leaving groups. Thus in comparison with a trifluoroacetyl group, the bulkier pentafluoropropionyl group should make the ester less stable thermodynamically.

Perfluorocarboxylates of other alcohols, such as cyclohexyl-, allyl-, and *t*-butyl alcohol, were tried for this reaction, but none of good results were obtained.

Experimental

2-Mercaptoethyl Pentafluoropropionate. In a sealed glass vessel, 2-mercaptoethanol (1.56 g, 20 mmol) was treated with hexafluoro-1,2-epoxypropane (bp −27 °C, 3.32 g, 20 mmol) and a catalytic amount of triethylamine (≈0.1 g) in acetonitrile (20 ml) for 30 min at room temperature. The reaction mixture was poured into water and the lower oily layer was separated. It was washed with water, dried ($MgSO_4$) and distilled to give 2-mercaptoethyl pentafluoropropionate (3.23 g, 72%). Bp 67—68 °C/77 mmHg (1 mmHg=133.322 Pa) (lit,[1] 68 °C/77 mmHg).

2-Mercaptoethyl trimethylsilyl ether and diethyl ether

were used instead of 2-mercaptoethanol and acetonitrile in the previous experiment. 2-Mercaptoethyl pentafluoropropionate was obtained in 85% yield.

Thiirane 2-Mercaptoethanol (1.56 g, 20 mmol), triethylamine (2.02 g, 20 mmol), and diglyme (10 ml) were placed in a sealed glass tube, and the mixture was cooled to −70 °C. Liquefied hexafluoro-1,2-epoxypropane (3.32 g, 20 mmol) was introduced into this vessel and the whole was brought to room temperature with stirring. After the reaction was continued for 30 min at this temperature, the pressure was reduced to about 30 mmHg, and the gas evolved was trapped in a Dry Ice–acetone bath. The trapped material was identified to thiirane (0.72 g, 60%). Bp 53—54° C (lit,[4] bp 54.0—54.5 °C).

Triethylamine (2.02 g, 20 mmol) was added to a solution of 2-mercaptoethyl pentafluoropropionate (4.48 g, 20 mmol) in diglyme (10 ml) in an ice bath. The mixture was stirred for 30 min at room temperature. The pressure was then gradually reduced to ≈30 mmHg and evolved thiirane was collected in a Dry Ice–acetone bath (0.84 g, 70%).

To a solution of 2-mercaptoethanol (1.56 g, 20 mmol) and triethylamine (4.04 g, 40 mmol) in diglyme (10 ml), trifluoroacetic anhydride (4.20 g, 20 mmol) was added slowly in an ice bath. After 1 h of stirring at room temperature, thiirane was obtained by a similar treatment (0.60 g, 50%).

Alkyl Benzyl Sulfides. A typical procedure is as follows. The benzyl perfluorocarboxylate (10 mmol) was mixed with a thiol (12 mmol) and triethylamine (15 mmol) in *N,N*-dimethylformamide (5 ml). The mixture was heated at 120 °C for 3 h with stirring and the resulting mixture was subjected to distillation *in vacuo* to give the corresponding sulfide.

Bromophenols from the Red Alga *Rhodomela larix*[1]

Minoru Suzuki, Nobuhiko Kowata, and Etsuro Kurosawa*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received January 14, 1980)

Synopsis. Two new bromophenols, 3-bromo-4-hydroxybenzaldehyde and a brominated dibenzyl ether derivative, were isolated from the red alga *Rhodomela larix*, along with several known bromophenols which have previously been isolated from *R. larix* and other species.

In connection with our interest in the halogenated secondary metabolites of the marine red algae, especially Rhodomelaceae, we have investigated the neutral and acidic constituents of the red alga *Rhodomela larix* (Turner) C. Agardh, which was collected at Oshoro Bay, Hokkaido. Several bromophenols have previously been obtained from this algae, collected in different locations.[2-4] Our specimen displayed no halogenated compound in the neutral constituents, and instead yielded two new bromophenols, 3-bromo-4-hydroxybenzaldehyde (**6a**) and a brominated dibenzyl ether derivative (**8a**), along with known bromophenols, **1a**, **2a**, **3a**, **4a**, **5a**, and **7a**, from the acidic constituents. We wish to report herein the isolation and structures of these brominated phenols.

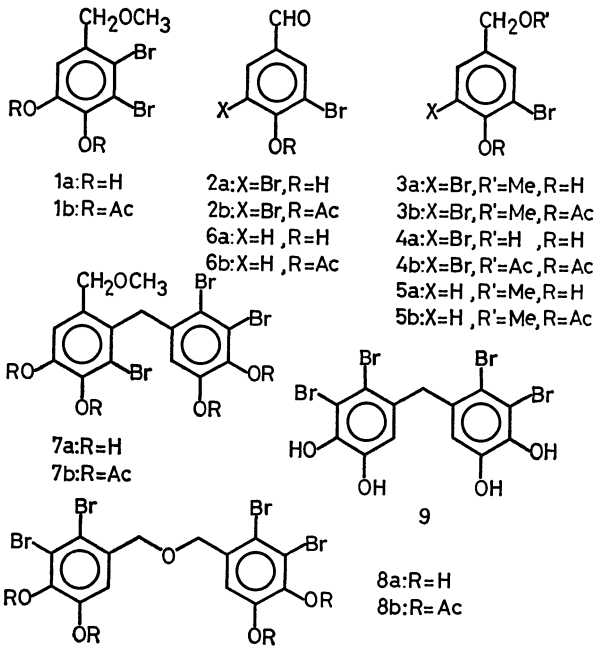
Half-dried algae were extracted with MeOH, and the neutral and acidic fractions were obtained from the MeOH extracts by the usual method. The neutral fraction gave no halogenated compound except for a sterol and a mixture of fatty acid esters. The acidic fraction was subjected to separation by a combination of column and thin-layer chromatography on silica gel to give several bromophenols. The isolation, purification, and identification of these bromophenols were carried out more conveniently *via* their acetates (**1b**—**8b**) (see Experimental section).

The major compound, **1b**, was identified as the acetate of 2,3-dibromo-4,5-dihydroxybenzyl methyl ether (**1a**)[2-4] by comparison of the spectral data with those of an authentic sample.[2] One of the minor compounds, **2b**, was found to be identical with the acetate of 3,5-dibromo-4-hydroxybenzaldehyde (**2a**), which has previously been isolated from the marine annelid *Thelepus setosus*[5] and recently from the red alga *Polysiphonia urceolata*.[6] Compounds **3b** and **4b** were found to be identical with the acetate of 3,5-dibromo-4-hydroxybenzyl methyl ether (**3a**) from *P. urceolata*[7] and *Odonthalia dentata*,[8] and the acetate of 3,5-dibromo-4-hydroxybenzyl alcohol (**4a**) from *O. dentata*,[8-10] *R. confervoides*,[8-10] *P. urceolata*,[6] and other species,[8,10] respectively. Furthermore, **5b** was identified as the acetate of 3-bromo-4-hydroxybenzyl methyl ether (**5a**) from *O. dentata*.[8] The structures of **2b**, **3b**, **4b**, and **5b** were confirmed by syntheses.

Compound **6b**, $C_9H_7O_3Br$, mp 60—62 °C, showed in its NMR spectrum the presence of an aryl acetate group at 2.34 (3H, s), a 1,3,4-trisubstituted aromatic ring at δ 7.26 (1H, d, J=8 Hz), 7.78 (1H, dd, J=8, 2 Hz), and 8.05 (1H, d, J=2 Hz), and an aldehyde group at 9.85 (1H, s). The spectral data of **6b** suggested that **6b** would be the acetate of 3-bromo-4-hydroxybenzaldehyde (**6a**), the structure of which was confirmed by comparison of the physical properties with those of the synthetic sample. To our knowledge, the isolation of 3-bromo-4-hydroxybenzaldehyde (**6a**) is the first example of the natural product.

One of the two other compounds, **7b**, was identified as the acetate of the brominated diphenylmethane derivative (**7a**), which has previously been isolated from *R. larix* together with **9**,[4] by comparison of the spectral data. The other compound, **8b**, $C_{22}H_{18}O_9Br_4$, mp 176—177 °C, revealed in its IR spectrum the absence of hydroxyl and carbonyl groups except for the acetoxyl groups at ν_{max} 1781 cm^{-1}. The NMR spectrum of **8b** showed four signals (each singlet) at δ 2.30 (6H) and 2.36 (6H) due to four acetoxyl groups, 4.70 (4H) due to two Ar–CH_2–(O) moieties, and 7.39 (2H) due to two aromatic protons. Hence, one of nine oxygen atoms in **8b** must form a straight chain ether linkage. The NMR spectrum of **8b** was very similar to that of **1b**, except for the signal of the methoxyl group in **1b**. Therefore, the structure of **8b** would be represented by formula **8b**, which will also be explicable well from the standpoint of biogenesis.

2,3-Dibromo-4,5-dihydroxybenzaldehyde has previously been isolated from *R. larix*.[2-4] However, we could not detect this aldehyde during our examination.[11] The result of our present study seems to be different from those of the previous studies[2-4] on account of the differences of the locations and seasons of the algal collections and/or the extraction procedures.



Experimental

All the mps were uncorrected. The IR spectra were measured on a Nihon-Bunko A-102 spectrometer. The NMR spectra were recorded on a JEOL JNM-PS-100 spectrophotometer, TMS being used as the internal reference. Coupling constants are given in Hz. Silica gel (Merck, Kieselgel 60, 70—230 mesh) was used for the column chromatography, and silica gel (Merck, Kieselgel GF_{254} (Type 60)) was used for the preparative thin-layer chromatography (PTLC).

Isolation. *Rhodomela larix* was collected in September 22, 1978, at Oshoro Bay, Hokkaido. The half-dried algae (1.3 kg) were extracted with MeOH, and the MeOH soln was concentrated under reduced pressure. The residue was percolated with ether, and the ether soln was shaken with 1 M KOH. The ether layer was washed with water, dried over Na_2SO_4, and then evaporated to give a neutral fraction (8 g). The KOH layer was cautiously acidified with dilute HCl and extracted with ether. The ether soln was washed with water, dried over Na_2SO_4, and then evaporated to give an acidic fraction (8 g). Repeated column chromatography of the neutral fraction gave only a sterol (probably cholesterol) and a mixture of fatty acid esters. The acidic fraction was fractionated by column chromatography as follows.

A Benzene-eluted Fraction: This fraction consisted of a mixture of **2a** and **3a**, which was subjected to repeated column chromatography and PTLC to yield **2a** (0.1% of the acidic constituents) and **3a** (0.8%). Acetylation of **2a** and **3a** was carried out with acetic anhydride in pyridine at room temp in the usual manner to yield **2b** and **3b**, respectively.

A Benzene/ether (10:1)-eluted Fraction: This fraction was further chromatographed on PTLC to yield **4a** (0.3%), **5a** (0.6%), **6a** (0.2%), and **1a** (6%). These phenols were acetylated by the usual method to yield **4b**, **5b**, **6b**, and **1b**.

A Benzene/ether (1:1)-eluted Fraction: This fraction consisted of a mixture of **7a** (1%) and **8a** (0.2%), which, following acetylation, was purified by PTLC to yield **7b** and **8b**.

1b: The mp and the spectral data were consistent with those of an authentic specimen.[2]

2b: Mp 110—111 °C (EtOH): IR, ν_{max} ($CHCl_3$): 1790, 1775, 1710, 1565, 1370, 1245, 1190, 1175, 1010, 925, and 890 cm^{-1}; NMR, δ (CCl_4): 2.39 (3H, s), 7.99 (2H, s), and 9.81 (1H, s); MS, *m/e* 324, 322, 320 (M^+). Found: C, 33.50; H, 1.86%. Calcd for $C_9H_6O_3Br_2$: C, 33.57; H, 1.88%.

3b: Colorless oil; IR, ν_{max} (film): 1785, 1775, 1595, 1560, 1405, 1370, 1245, 1205, 1180, 1110, 1010, 890, 805, and 740 cm^{-1}; NMR, δ ($CDCl_3$): 2.40 (3H, s), 3.40 (3H, s), 4.41 (2H, s), and 7.53 (2H, s); MS, *m/e* 340, 338, 336 (M^+).

4b: The mp and the NMR spectrum were consistent with those reported.[9]

5b: Colorless oil; IR, ν_{max} (film): 1770, 1600, 1490, 1370, 1205, 1190, 1105, 1045, 1010, 910, 870, and 825 cm^{-1}; NMR, δ ($CDCl_3$): 2.35 (3H, s), 3.39 (3H, s), 4.43 (2H, s), 7.11 (1H, d, J=8), 7.30 (1H, dd, J=8, 2), and 7.58 (1H, d, J=2); MS, *m/e* 260, 258 (M^+).

6b: Mp 60—62 °C (EtOH–hexane); IR, ν_{max} ($CHCl_3$): 1775, 1705, 1597, 1485, 1375, 1185, 1045, 1010, 915, 890, and 835 cm^{-1}; NMR, δ (CCl_4): 2.34 (3H, s), 7.26 (1H, d, J=8), 7.78 (1H, dd, J=8, 2), 8.05 (1H, d, J=2), and 9.85 (1H, s); MS, *m/e* 244, 242 (M^+). Found: C, 44.44; H, 2.98%. Calcd for $C_9H_7O_3Br$: C, 44.47; H, 2.90%.

7b: Mp 175—177 °C (C_6H_6); IR, ν_{max} ($CHCl_3$): 1777, 1371, 1193, 1141, 1011, 916, and 889 cm^{-1}; NMR, δ ($CDCl_3$): 2.20, 2.30, 2.32, 2.34, 3.31 (each 3H, s), 4.28 (4H, br s), 6.38 (1H, s), and 7.31 (1H, s).

8b: Mp 176—177 °C (chloroform–ether); IR, ν_{max} ($CHCl_3$): 1781, 1372, 1196, 1181, 1141, 1011, 917, and 898 cm^{-1}; NMR, δ ($CDCl_3$): 2.30 (6H, s), 2.36 (6H, s), 4.70 (4H, s), and 7.39 (2H, s); MS, *m/e* 708, 706, 704, 702, 700 ($M^+ - CH_2=C=O$). Found: C, 35.28; H, 2.37%. Calcd for $C_{22}H_{18}O_9Br_4$: C, 35.42; H, 2.43%.

Syntheses of 2b—6b. Bromination of *p*-hydroxybenzaldehyde with Br_2 (1 eq) in AcOH gave a mixture of **2a** and **6a** (1:3), which, following acetylation, was purified by PTLC to give **2b** and **6b**. Treatment of the acetates, **2b** and **6b**, with $NaBH_4$ in EtOH afforded dibromo-*p*-acetoxybenzyl alcohol, and monobromo-*p*-acetoxybenzyl alcohol, respectively. The latter benzyl alcohol was refluxed with MeOH and H_2SO_4 to yield **5a**, which was converted to **5b** by acetylation. The former benzyl alcohol gave **3b** in the same way as has been described above. Moreover, acetylation of the dibromobenzyl alcohol yielded **4b**. These synthetic compounds were identical with the natural bromophenols and their acetates in all respects.

The authors are grateful to Dr. Kazuya Kurata, Department of Industrial Chemistry, Hakodate Technical College, for valuable discussions and for providing the IR and NMR spectra of the acetates of several bromophenols.

Study on V_2O_5–Al_2O_3 Catalyst by Means of XPS for the Reduction of Nitric Oxide with Ammonia

Akio Nishijima,* Yoshimichi Kiyozumi, Akifumi Ueno, Minoru Kurita, Hiroyuki Hagiwara, Toshio Sato, and Naoyuki Todo

National Chemical Laboratory for Industry, Higashi, Yatabe-machi, Tsukuba-gun, Ibaraki 305

(Received June 22, 1979)

Synopsis. The V_2O_5–Al_2O_3 catalyst used for the NO reduction in flue gas from a sintering furnace was studied by means of X-ray photoeloctron spectroscopy and X-ray microanalysis. Effects of dust components accumulated on the catalyst and of electronic states of vanadium ions on catalytic activities were discussed.

Of various methods for the removal of nitrogen monoxide in flue gas emitted from stationary combustion equipments, the catalytic reduction of NO with ammonia seems to be most effective.[1–3] Supported V_2O_5 catalysts have been used for industrial gases. It is desirable to know the influence of dust components (Fe, Si, K, Ca, Na, C, S) in flue gas on the life of the catalysts. A pilot plant test using flue gas from a boiler or a coke oven showed that sulfur oxides (SO_x) reduce the activities of the catalysts.[4,5] However, it was observed that K in the flue gas from a sintering furnace lowers the catalytic activities to a greater extent than SO_x.[6,7] In this study, characterization of the V_2O_5–Al_2O_3 catalyst used in the flue gas from a sintering furnace was made by means of X-ray photoelectron spectrometer and X-ray microanalyzer.

Experimental

The catalyst was prepared by impregnating γ-Al_2O_3 (diam. 6 mm, surface area 210 m^2/g, average pore radius 60 Å) with an aqueous solution of vanadium(IV) oxalate.[6] A life test was carried out with a moving bed type reactor (1000 Nm^3/h) at a space velocity of 10000 h^{-1}. The composition of the dust in the flue gas was Fe 28 wt %, SO_4 25 wt %, K 1.5 wt %, Na 0.6 wt %, that of the flue gas from the sintering furnace being NO 170—280 ppm, SO_2 130—260 ppm, O_2 13—15 vol %, H_2O 10—15 vol %, CO_2 10 vol %, and dust 30—120 mg/Nm^3. 200 ml of catalyst taken from the reactor every 100 h of the reaction time was subjected to examination of the change in catalytic properties. The line profile of each element in the catalyst was obtained with a X-ray microanalyzer (Shimadzu). Dust components on catalyst particles and electronic states of the elements in the catalyst were measured with a X-ray photoelectron spectrometer (Dupont 650 B). The values of the binding energies were referred to C 1s photoelectron spectra of contaminant carbon (285.0).

Results and Discussion

Figure 1 shows line profiles of dust components accumulated on the catalyst. S, Si, and Ca were found in inner parts of the catalyst, K and Fe being restricted to surface layers of catalyst particles (Fig. 1 A). On Fe_2O_3–Al_2O_3 catalysts, K permeated into the catalyst particles to form a complex of $[K_2Fe(SO_4)_2]$. The difference in the behavior of K remains unclarified.

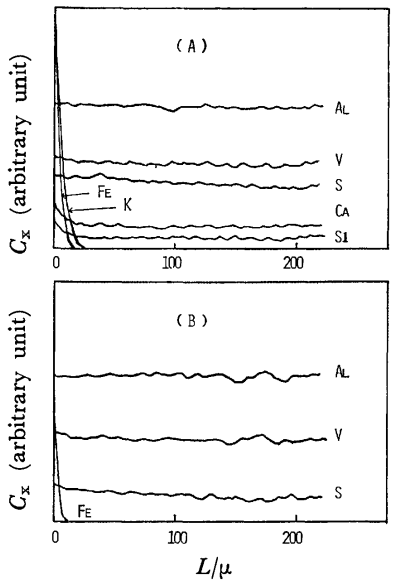

Fig. 1. Distribution analysis of each component in V_2O_5–Al_2O_3 catalyst confirmed by X-ray microanalyzer.
The sample was prepared in a form of hemi-sphere particle to obtain the depth profile. (A): Used for 2000 h, (B): regenerated (heating, washing, and treating with SO_2), L: depth from the surface, C_x: concentration of each component in the catalyst.

The amount of S increased with the reaction time, becoming constant after a certain time. Increase in the concentrations of K, Fe, Ca, and Si continued even after 1000 h.[7] Dust components except S and Fe were removed from the catalyst after regeneration (heating at 550 °C for 2 h and washing at 80 °C for 2 h and subsequent treatment with 500 ppm of SO_2 at 300 °C for 15 h). From the fact that the activity recovered after the regeneration, the effects of S and Fe on the activity are considered to be less than those of the other components.

Figure 2 shows the changes in photoelectron spectra of some dust components on the catalyst. Binding energies of K 2p spectra show that K exists in the form of K_2SO_4. Intensities of these photoelectron spectra, especially those of K and Fe, increased with reaction time. As regards S 2p spectra, the intensity was saturated after 800 h of the reaction. Changes of V $2p_{3/2}$ and Al 2p photoelectron spectra of the catalyst are shown in Fig. 3. The intensity of V $2p_{3/2}$ spectrum decreased more rapidly than that of Al 2p spectrum. This indicates that K sticks predominently on V, the active component, rather than on the carrier, causing a decrease of catalytic activity. The electronic states of vanadium and aluminium ions turned electronegative with reaction time (Fig. 3). The change of elec-

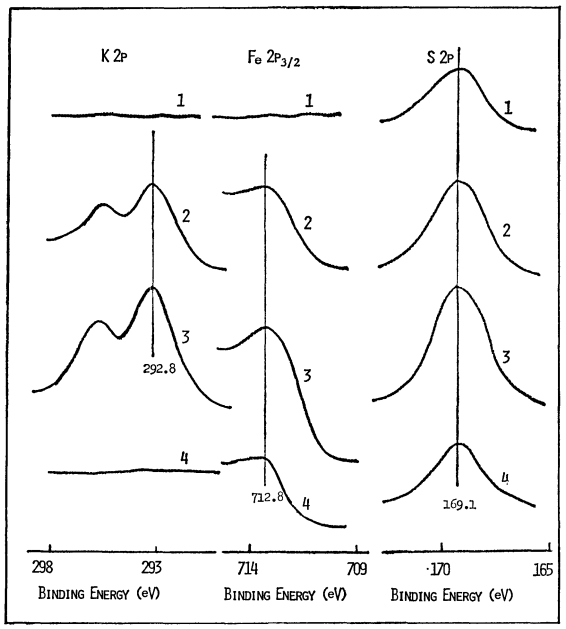

Fig. 2. Change in photoelectron spectra of dust component on V_2O_5–Al_2O_3 catalyst.
1: Fresh (treating with SO_2), 2: used for 600 h, 3: used for 2000 h, 4: regenerated (heating, washing, and treating with SO_2).

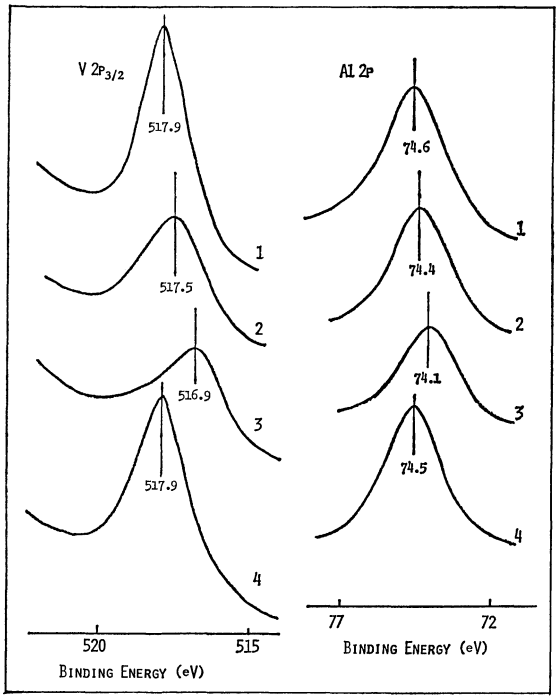

Fig. 3. Change in photoelectron spectra of active component and carrier on V_2O_5–Al_2O_3 catalyst.
1: Fresh (treating with SO_2), 2: used for 600 h, 3: used for 2000 h, 4: regenerated (heating, washing, and treating with SO_2).

tronic state of aluminium ions is due to the formation of $Al_2(SO_4)_3$.[4] The binding energy of vanadium ions of the catalyst subjected to the reaction using the flue gas from the sintering furnace decreased by 1.0 eV, while the value obtained for the catalyst used for a gas without dust components decreased only by 0.5 eV. The difference would be ascribed to the effects of K adhered on V. The optimum electronic state of the cation in the active component shows high activity, the catalytic activity decreasing when the electronic state of the cation deviates from the optimum state to electronegative or electropositive state.[8] Changes in electronic states of vanadium ions would affect the activity of the catalyst for NO reduction. A large decrease in the binding energy would give the result[6] in which the catalytic activity decreases much more rapidly when the catalyst is used in the flue gases containing dust components. The ratio of intensities between V $2p_{3/2}$ and Al 2p spectra and the electronic state of vanadium ions returns to the original one by the regeneration.

Heterogeneous Catalysis in the Liquid-phase Oxidation of Olefins. IV. The Activity of a Supported Vanadium or Chromium Oxide Catalyst in the Decomposition of *t*-Butyl Hydroperoxide

Katsuomi TAKEHIRA,* Takashi HAYAKAWA, and Toshio ISHIKAWA

Catalysis Division, National Chemical Laboratory for Industry, Tsukuba Research Center, Yatabe, Ibaraki 305

(Received March 17, 1979)

The liquid-phase decomposition of *t*-butyl hydroperoxide (*t*-BuOOH) has been carried out in benzene under an N_2 atmosphere using a vanadium or chromium oxide, supported on γ-Al_2O_3 or SiO_2 as the catalyst, for the purpose of clarifying the reaction mechanism of the cyclohexene oxidation. The decomposition of *t*-BuOOH on the supported oxide catalyst was a first-order reaction; the main products were *t*-butyl alcohol, di-*t*-butyl peroxide, and acetone, suggesting that *t*-BuOOH is decomposed homolytically on the catalyst by the Haber-Weiss mechanism. The effect of the vanadium–chromium binary system formation was small, but the interaction between metal oxides and the supports appeared to be important in the *t*-BuOOH decomposition. Tetrahedrally co-ordinated vanadium species were formed on SiO_2 and showed the highest activity, followed by the chromium co-ordinated tetrahedrally on SiO_2 or on γ-Al_2O_3, while an octahedrally co-ordinated vanadium or chromium showed low activity. Such order of the activity was in good agreement with that obtained in the liquid-phase oxidation of cyclohexene. We observed a relatively good correlation between the catalytic activity and the acidity of the supported binary metal oxides. The V_2O_5–SiO_2 system showed an especially large acidity; here *t*-butyl alcohol was dehydrated into di-*t*-butyl ether and 2-methyl propene.

The liquid-phase oxidation of cyclohexene with a heterogeneous catalyst, *i.e.*, vanadium–chromium binary oxides (V–Cr), has been studied in terms of the relationship between its structure and the catalytic activity.[1-3] When the binary system was supported on γ-Al_2O_3 or SiO_2, its activity varied greatly depending on the nature of the carrier.[1] It was suggested that the activity of the supported binary system is mainly due to the interactions between the metal oxides and the carrier; a tetrahedral co-ordination is favored on SiO_2, resulting in the increase in its activity. It was also suspected that the supported binary system catalyzes the autoxidation of cyclohexene by accelerating the decomposition of 1-cyclohexenyl hydroperoxide.[1] To confirm the validity of this mechanism, the decomposition of *t*-butyl hydroperoxide (*t*-BuOOH) on a supported binary oxide catalyst has been studied in the present work. *t*-BuOOH has been frequently used as a model compound in studying the mechanism of the catalytic decomposition of hydroperoxides because complicating reactions, such as hydration and rearrangement, can be minimized with tertially alkyl hydroperoxide.[4-12] Also, a direct comparison can be made with the other investigations where *t*-BuOOH was used.[4-12] A further study of the structure of the supported binary system has concurrently been carried out by measuring the electron-spin resonance and the surface acidity so as to clarify their roles in the oxidation of cyclohexene.

Experimental

Catalysts. The metal acetylacetonates ($Me(acac)_n$) were used as received (Tokyo Chemical Industry Co.). The supported binary system catalysts were prepared by the kneading method reported in a preceding paper.[1] The symbols, concentrations (calculated as $V_2O_5+Cr_2O_3$(wt %)) and compositions (in terms of atomic % of Cr/(V+Cr)) of the supported metal oxides, and the specific surface area (S_s), are shown in Tables 1 and 2 respectively.

Procedure of Reaction. The decomposition of *t*-BuOOH was performed in 10-ml reaction tubes with a joint which fitted into a smoothtapered joint provided with a stopcock. The same amount of catalyst (25 mg of the binary catalyst or 5×10^{-6} mol of $Me(acac)_n$) was added to a series of reaction tubes, in each of which the reaction was allowed to proceed for a different time interval. A reactor tube containing the weighed catalyst was placed in an ethanol-solid carbon dioxide mixture, and a 5-ml portion of a previously prepared benzene solution of *t*-BuOOH (0.1 M) was slowly added to the reactor to avoid the suspension of the catalyst. The reactor was then joined to a vacuum system, and the gas phase was replaced with dry nitrogen. The stopcock was then closed to isolate the system. The reactor was attached to a wrist-action shaker to achieve vigorous agitation and then plunged into an oil bath, the temperature of which could be controlled to within ±0.2 °C. The time was recorded from the moment the tube was immersed in the oil bath. Once the desired reaction-time interval had elapsed, the tube was quickly put back into the

a) Prepared from NH_4VO_3, $Cr(NO_3)_3 \cdot 9H_2O$, and alumina hydrate. b) Prepared from NH_4VO_3, $(NH_4)_2CrO_4$, and alumina hydrate. c) Prepared from NH_4VO_3, $Cr(NO_3)_3 \cdot 9H_2O$, and silica sol. The concentration of metal oxides (calculated as $V_2O_5+Cr_2O_3$) was 20 wt % in each series.

ethanol–solid carbon dioxide mixture to stop any further reaction, and the catalyst was allowed to settle. The clear liquid phase was then removed from the reactor for analysis.

Materials. The *t*-BuOOH was purified by vacuum distillation (40.0 °C/25 mmHg). The di-*t*-butyl peroxide (*t*-Bu_2O_2) obtained from the Nippon Kayaku Co. was shown to be pure by gas chromatography. The di-*t*-butyl ether (*t*-Bu_2O) was prepared by the method of West *et al.*[13] The other materials, *t*-butyl alcohol (*t*-BuOH), acetone, and 2-methyl propene were commercial products and were used without further purification. The benzene used as a solvent was purified by distillation.

Analytical Procedures. The decomposition products, *t*-BuOH, *t*-Bu_2O_2, acetone, 2-methyl propene, and *t*-Bu_2O, were identified by gas chromatography-mass spectrometry, using a Shimadzu LKB 9000 apparatus and using a 2-m column of PEG 6000 at an ionization voltage of 70 eV. The products were determined as follows. Part of the liquid sample was titrated for unconverted *t*-BuOOH by the iodometric method[12] using a mixture of 20 ml of 90:10 isopropyl alcohol–acetic acid and 1 g of NaI. *t*-Bu_2O_2 gave no titer in this method. The rest was treated with sufficient triphenylphosphine for the quantitative conversion of the *t*-BuOOH into *t*-BuOH,[14] and then analyzed for products by gas chromatography using a column of PEG 6000. The benzene used as a solvent was used as the internal standard. Part of the 2-methyl propene formed was detected in the gas phase and was determined by gas chromatography using a column of DMS.

The analytical results of the supported V–Cr catalysts obtained by means of X-ray diffraction, X-ray photoelectron spectroscopy (XPS), and infrared absorption were reported in the preceding paper.[1] The surface area has been determined by the BET method.[1] In the present work, we measured the electron-spin resonance (ESR) and the surface acidity of the catalyst. The ESR spectra of the catalyst evacuated at 400 °C for 2 h were recorded with a JEOL-JES-ME3X spectrometer at 25 °C and at −196 °C. The acid strength and acidity of the catalyst were measured by a butylamine titration method using 4-(phenylazo)-diphenylamine ($pK_a=1.5$) and Methyl Red ($pK_a=4.8$) as Hamett indicators. Silica–alumina, the acidity of which was 0.44 and 0.14 mmol/g in the ranges of $pK_a \leqq 1.5$ and $1.5 < pK_a \leqq 4.8$ respectively, was used as the internal standard because nearly all of the catalysts are strongly coloured.[15]

a) The concentrations of *t*-BuOOH and $Me(acac)_n$ were 10^{-1} and 10^{-5} mol/l respectively in benzene. The reaction temperature was 60 °C. b) First-order rate constants. c) Mol % based on *t*-BuO groups found. d) $Cr(acac)_3$ showed an induction period of about 30 min.

Table 3 shows the results of the decomposition of *t*-BuOOH with various metal acetylacetonate catalysts. In the absence of a catalyst, no reaction was observed. The decrease in the concentration of *t*-BuOOH obeyed good first-order kinetics in all reactions; accordingly, the activity of the metal ion is expressed by the first-order rate constant (k_1). Only $Cr(acac)_3$ showed an induction period (about 30 min), probably because of the stability of its chelate structure. Similar product distributions were observed for nearly all reactions; *i.e.*, the selectivities of the products were as follows: *t*-BuOH, 80%; *t*-Bu_2O_2, 10%, and acetone, 5%. When the reactions gave a sufficiently high conversion, *i.e.*, in the use of the chelates of Co, Mn, or Cr, the gas chromatography indicated the formation of a small amount of formaldehyde (not estimated quantitatively). The results can be interpreted by the following reaction scheme, which was been proposed in the literature:[4-12]

$$2t\text{-BuOOH} \xrightarrow{M^{n+}/M^{(n+1)+}} t\text{-BuOO}\cdot + t\text{-BuO}\cdot + H_2O \quad (1)$$

$$t\text{-BuO}\cdot + t\text{-BuOOH} \longrightarrow t\text{-BuOH} + t\text{-BuOO}\cdot \quad (2)$$

$$2t\text{-BuOO}\cdot \longrightarrow 2t\text{-BuO}\cdot + O_2 \quad (3)$$

$$2t\text{-BuOO}\cdot \longrightarrow t\text{-Bu}_2O_2 + O_2 \quad (4)$$

$$t\text{-BuO}\cdot \longrightarrow CH_3COCH_3 + CH_3\cdot \quad (5)$$

$$CH_3\cdot + O_2 \longrightarrow CH_3OO\cdot \quad (6)$$

$$CH_3OO\cdot + t\text{-BuOO}\cdot \longrightarrow CH_2O + t\text{-BuOH} + O_2 \quad (7)$$

The *t*-BuOOH is decomposed homolytically into peroxy and alkoxy radicals by the Haber-Weiss mechanism (1), followed by the induced decomposition (2) and the competitive reactions of peroxy radicals (3 and 4). Some of *t*-butoxyl radicals are separated into acetones and methyl radicals (5);[5,6,12] the latter products are then converted into formaldehyde (6 and 7).[10-12] Generally speaking, the choice of the metal ion, as long as it can undergo a facile one-electron redox reaction, seems to have little influence on the products. It is worth noting that the chelates of vanadium and chromium showed sufficiently high activities compared with cobalt and manganese chelates.

Effect of the Amount of Metal Oxides Supported. As is shown in the results of the decomposition of *t*-BuOOH with the V–Cr–γ-Al_2O_3 catalyst (Fig. 1), good first-order rate plots were obtained up a conversion of 40% with the heterogeneous catalysts also. The first-order rate constants thus obtained are shown in Table 4, together with the product distribution when the amount of supported metal oxides varied. Both systems, *i.e.*, V–Cr–γ-Al_2O_3 and V–Cr–SiO_2, showed product distributions similar to that obtained with $Me(acac)_n$ catalysts, except that the V–Cr–SiO_2 system gave small amounts of 2-methyl propene and *t*-Bu_2O. Therefore, it may reasonably be considered that the decomposition of *t*-BuOOH on the present heterogeneous catalysts is initiated by the redox reaction 1 and that it then proceeds mainly by means of the radical chain reactions 2—7.

The decomposition proceeds rapidly on the V–Cr–SiO_2 system; this is more clearly observed in Fig. 2, which shows the specific activity of each system. It is noteworthy that the activity increased rapidly when a small amount of metal oxides was supported on SiO_2; on the contrary, no such rapid increase was observed on γ-Al_2O_3. A similar tendency of the activity was also observed when the binary catalysts were used in the oxidation of cyclohexene (see Fig. 4 in the preceding paper[1]).

Effects of Composition and Raw Materials of Metal Oxides. The systems supported on γ-Al_2O_3, *i.e.*, G- and H-series, gave product distributions similar to those obtained with a soluble Co or Mn chelate catalyst, while a different distribution was observed with the I-series, especially those with a high vanadium content, on SiO_2 (Table 5). That is, the I-series gave 2-methyl propene and *t*-Bu_2O, too, and the higher vanadium content increased the selectivity of the two products while decreasing that of *t*-BuOH. Such a tendency was observed more clearly after decomposition for 4 h (Fig. 3); the selectivities of 2-methyl propene and *t*-Bu_2O increased at the expense of that of *t*-BuOH when the I-0, I-2, and I-4 catalysts were used. The selectivity of *t*-Bu_2O_2 or acetone did not change over all the compositions of the I-series catalysts. The I-series

catalysts gave higher decomposition rates than the G- or H-series catalysts. The specific activities are shown in Fig. 4 in terms of k_1/S. When supported on SiO_2, a higher vanadium content resulted in a higher specific activity. Concerning the systems supported on γ-Al_2O_3, the use of $(NH_4)_2CrO_4$ (Cr^{6+}), *i.e.*, the H-series, instead of $Cr(NO_3)_3 \cdot 9H_2O$ (Cr^{3+}), *i.e.*, the G-series, as the raw material caused a markedly high activity at a high chromium content, while both series with low chromium contents showed similar activities. The fact that the H-series contains a higher valence state of chromium ions than the G-series has already been noted.[1] The binary system in the G-series clearly showed an increase in the activity, an increase which may be attributed to the formation of chromium isopolyvanadates, as has already been reported,[3] though the effect of the binary-system formation was not obvious in the I- and H-series.

The order of the activity mentioned above is well correlated with that observed in the oxidation of cyclohexene with the same catalyst systems[1] when the initial rate, R_{max}-A, is adopted as the activity of the I-series (Fig. 5 in the preceding paper[1]). That is, though the O_2 absorption rate shown by I-0 or I-2 in the steady state of cyclohexene oxidation, R_{max}-B, was much lower than would be expected from the *t*-BuOOH decomposition, the initial rate, R_{max}-A, was sufficiently high, in agreement with the decomposition rate. Thus, it may reasonably be considered that the main role of the binary catalyst in the oxidation of cyclohexene is in the acceleration of the homolysis of hydroperoxide.

Dehydration of t-*BuOH on the* V_2O_5–SiO_2 *Catalyst.* Tables 4 and 5 and Fig. 3 reveal that 2-methyl propene and *t*-Bu_2O were formed, together with the radical-reaction products, when the SiO_2-supported catalysts with a higher vanadium content were used. The amounts of 2-methyl propene and *t*-Bu_2O increased at the expense of *t*-BuOH; the amount of 2-methyl propene was, further, about 10 times that of *t*-Bu_2O. In order to clarify the mechanism of the formation of the two products, the variation in their selectivities during the reaction was examined by using the I-0 catalyst (Fig. 5). The decomposition of *t*-BuOOH was finished within about 30 min after the beginning of the reaction. The selectivity of *t*-BuOH reached its maximum value and then decreased gradually during 4 h of reaction; 2-methyl propene and *t*-Bu_2O took the place of *t*-BuOH. In contrast, no change was observed in the selectivities of *t*-Bu_2O_2 and acetone. The I-2 catalyst also showed a similar behavior. Thus, the dehydration of *t*-BuOH is suggested on the I-0 or I-2 catalyst. For the purpose of confirming this possibility, a solution of *t*-BuOH in benzene was treated at 60 °C with the I-2 catalyst in an N_2 atmosphere (Fig. 6). The dehydration of *t*-BuOH into 2-methyl propene was clearly observed, though *t*-Bu_2O was not detected; a similar phenomenon was also observed with

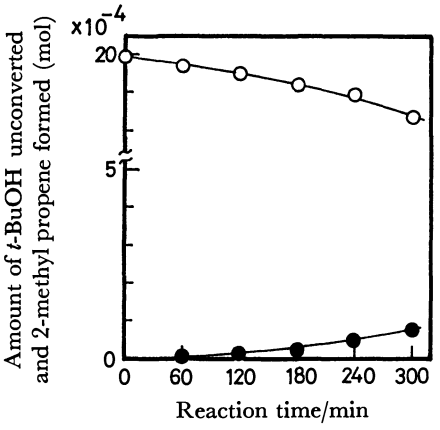

Fig. 6. Dehydration of *t*-BuOH with I-2 catalyst.
The concentration of *t*-BuOOH and the catalyst were 2×10^{-1} mol/l and 5 g/l respectively in benzene. The reaction was carried out under N_2 atmosphere at 60 °C.
○: *t*-BuOH, ●: 2-methyl propene.

the I-0 catalyst. It can, therefore, be concluded that the following dehydrations were catalyzed on the SiO_2-supported system with a high vanadium content:

$$t\text{-BuOH} \longrightarrow CH_3\text{–}C(CH_3)\text{=}CH_2 + H_2O \quad (8)$$

$$2t\text{-BuOH} \longrightarrow t\text{-}Bu_2O + H_2O \quad (9)$$

The probability of the intramolecular dehydration (8) may reasonably be larger than that of the intermolecular one (9), resulting in the higher selectivity of 2-methyl propene (Fig. 5). I-0 showed the X-ray diffraction lines of V_2O_5 crystals; I-2, on the contrary, showed no line,[1] and both the systems catalyzed the dehydration. Therefore, the active species for the dehydration on the catalysts seems to be composed of the vanadium oxide–SiO_2 system.

Co-ordination State of a Metal on a Catalyst. The analytical results of X-ray diffraction, infrared absorption, and XPS have been reported in the preceding paper.[1] The XPS analysis revealed that several valence states of chromium, *i.e.*, Cr^{6+}, Cr^{5+}, and Cr^{3+}, exist on the supported catalysts. On γ-Al_2O_3, the H-series prepared from $(NH_4)_3CrO_4(Cr^{6+})$ includes chromium ions of a higher valence state than the G-series from $Cr(NO_3)_3\cdot 9H_2O$ (Cr^{3+}) at a high chromium content, though the valence state of vanadium was not clearly assigned. Such valence states of metal contributed considerably to the activity for the cyclohexene oxidation[1] and also for the *t*-BuOOH decomposition (Fig. 4); the configuration of metal complexes on the catalyst surface seemed, however, to play a more important role.[1] In order to obtain information about the metal-complex configurations, the ESR spectra were measured.

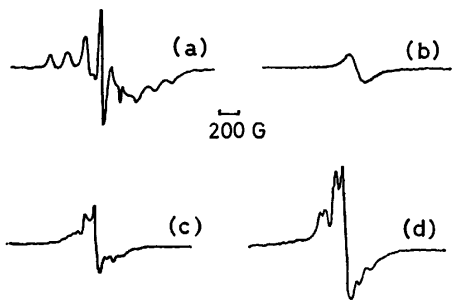

Fig. 7. ESR spectra of the supported vanadia systems.
(a) G-0 at 25 °C, (b) I-0 at 25 °C, (c) I-0 at 25 °C after an exposure to atmosphere at room temperature, (d) I-0 at −196 °C.

The spectra of the supported vanadia systems are shown in Fig. 7. At 25 °C, V_2O_5–γ-Al_2O_3 (G-0) exhibited a characteristic spectrum (a) with hfs due to ^{51}V(IV) in the octahedral (or distorted square pyramidal) co-ordination (VO_5),[16-21] whereas V_2O_5–SiO_2 (I-0) gave a very weak singlet spectrum (b), the line shape of which was nearly Lorentzian. At room temperature, the tetrahedrally co-ordinated V(IV) ions (VO_4) could not be detected by ESR.[16,20,22] Moreover, I-0 showed a clear X-ray diffraction pattern of the V_2O_5 crystal.[1] The (b) spectrum may, therefore, be assigned to V(IV) ions attributable to lattice defects in the V_2O_5 crystal. I-0 showed a spectrum (d) at the temperature of −196 °C; its line shape differed from (a) and (b), probably indicating the (VO_4) formation, as was suggested in the preceding paper.[1] Suzuki *et al.*[20] and Van Reijen *et al.*[16] also detected tetrahedrally co-ordinated V(IV) ions on the V_2O_5–SiO_2 system by ESR at low temperatures. The (b) spectrum became slightly strong and simultaneously anisotropic (c) when the evacuated I-0 was exposed to atmosphere at room temperature. Van Reijen reported that (VO_4) is very sensitive to atmosphere; for example, after the admission of water vapor at room temperature, (VO_4) changes probably to (VO_5), which is sufficiently stable and is detected at room temperature.[16] The (c) spectrum may be of V(IV) ions both in the V_2O_5 lattice defects and in (VO_5). Thus, two types of configurations of vanadium complexes, *i.e.*, (VO_5) on γ-Al_2O_3 and (VO_4) on SiO_2, are recognized.

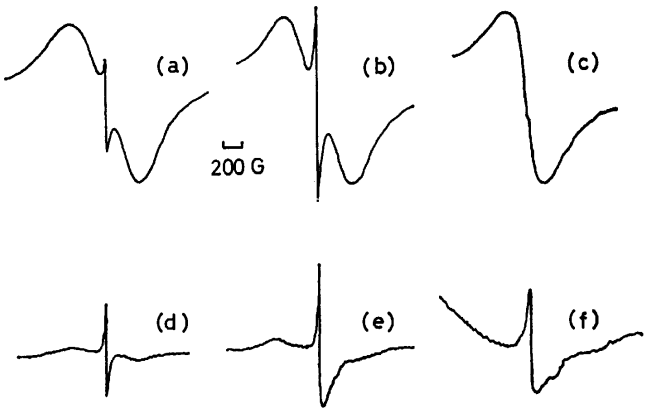

Fig. 8. ESR spectra of the supported chromia systems.
(a): G-10 at 25 °C, (b): H-10 at 25°C, (c): I-10 at 25 °C, (d): G-10 at −196 °C, (e): H-10 at −196 °C, (f): I-10 at −196 °C.

Figure 8 shows the spectra of the supported chromia systems. According to the analytical results obtained by the use of XPS,[1] these systems contained Cr^{5+} and Cr^{3+} ions which can be detected by ESR. X-Ray diffraction measurements showed that the Cr_2O_3 crystal grew on SiO_2, but not on γ-Al_2O_3.[1] Therefore, we can presume that, on γ-Al_2O_3, most of the Cr^{3+} is present in solution in the γ-Al_2O_3 lattice; on SiO_2, though, it is present mainly in a separate chromia phase. At room temperature, the ESR spectra of the Cr_2O_3–γ-Al_2O_3 systems (G-10 and H-10) showed a very broad band and another, relatively sharp peak, characterized by a *g*-factor of 1.97 and a linewidth of approximately 50 G, superimposed on it (a and b). The ratio of the intensities of the two bands varied considerably. The narrow signal may be assigned to the Cr^{5+} ions (the so-called γ-phase), whereas the broad one may be assigned to the Cr^{3+} ions (the β-phase).[24,25] The intensity of the γ-phase was as follows: H-10>G-10; the Cr^{5+} ions are more abundant on the Cr_2O_3–γ-Al_2O_3 system prepared from $(NH_4)_2CrO_4$ than on that prepared from $Cr(NO_3)_3\cdot 9H_2O$. This was in good agreement with the result obtained by the XPS measure-

ment.[1] The Cr_2O_3–SiO_2 (I-10) showed a spectrum similar to those of the Cr_2O_3–γ-Al_2O_3, though the intensity of the narrow band was very weak (c). The broad band may be assigned to the separate phase of the Cr_2O_3 crystals, which was detected by the X-ray analysis.[1] When the sample was cooled to −196 °C. The form of the spectrum changed appreciably; the intensity of the broad band was weakened. Moreover, the narrow signal of I-0 became stronger, accompanied by a marked anisotropy of its *g*-factor (f). The anisotropic signal may be assigned to the Cr^{5+} ions tetrahedrally co-ordinated (CrO_4), which are characterized by a small spin-lattice relaxation time and which are, accordingly, observed only at low temperatures.[16,23] The anisotropy was also observed in the narrow signal of the H-10 catalyst (e). However, G-10 gave a strong, narrow signal of the Cr^{5+} ions co-ordinated octahedrally (d).[23,26] These results can be summarized as follows: the Cr^{5+} ions are mainly co-ordinated tetrahedrally (CrO_4) on SiO_2 and octahedrally (or square-pyramidally) (CrO_5) on γ-Al_2O_3. In the latter case, however, the tetrahedral co-ordination may also occur on the H-series with a high chromium content, because the anisotropy was observed with H-10 at −196 °C, as has been mentioned above. This is supported by the fact that the tetrahedral $(CrO_4)^{3-}$ ions are preferentially found in a highly alkaline solution;[27] an H-series with a high chromium content was prepared from $(NH_4)_2CrO_4$, *i.e.*, in alkaline media. It may also be reasonable to assume that the (CrO_4) tetrahedron is linked to the SiO_2 network by sharing corners or edges with the SiO_4 tetrahedron, because the SiO_2 crystal has a tetrahedral structure.[16,23]

Acidity of Catalyst. The acidities of the supported catalysts obtained by means of the butylamine titration method are shown in Fig. 9; they are classified into two kinds of acid strengths, *i.e.*, $pK_a \leqq 1.5$ and $1.5 < pK_a \leqq 4.8$. γ-Al_2O_3 itself showed a strong acidity, whereas a weak acidity alone was observed on SiO_2. It is noteworthy that, when a small amount of V–Cr binary oxide was added to SiO_2, a remarkable increase in the strong acid sites was observed. On γ-Al_2O_3, the acidity

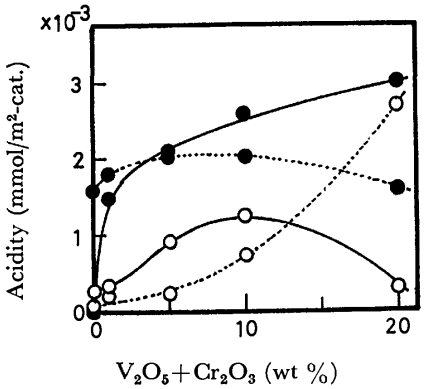

Fig. 9. Acidity on V–Cr–γ-Al_2O_3 or –SiO_2 system catalyst.
●: $pK_a \leqq 1.5$, ○: $1.5 < pK_a \leqq 4.8$.
——: V–Cr–SiO_2, (Cr/(V+Cr)=0.7), -----: V–Cr–γ-Al_2O_3, (Cr/(V+Cr)=0.5).

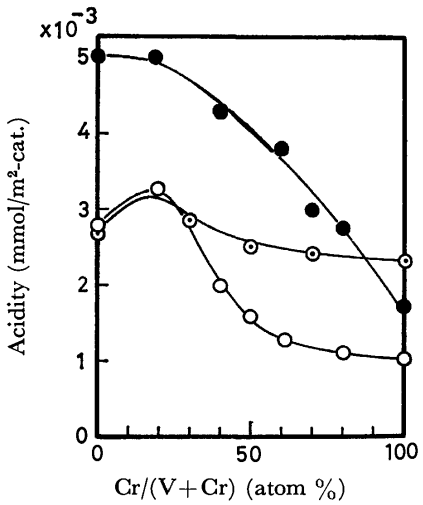

Fig. 10. Acidity of $pK_a \leqq 1.5$ on G-, H-, and I-series catalysts.
○: G-series, ⊙: H-series, ●: I-series.

of $pK_a \leqq 1.5$ did not vary upon the addition of the binary oxide; that of $1.5 < pK_a \leqq 4.8$, however, enhanced by its addition in sufficient amount. The strong acidities ($pK_a \leqq 1.5$) of the three series of catalysts, *i.e.*, the I-, H-, and G-series, are shown in Fig. 10 as the function of the chromium content. The largest acidity was given on SiO_2, whereas, on γ-Al_2O_3, the system prepared from $(NH_4)_2CrO_4$ showed a larger acidity than that prepared from $Cr(NO_3)_3 \cdot 9H_2O$, especially at high chromium contents. When the activities in Figs. 2 and 4 are compared to the acidities in Figs. 9 and 10 respectively, it seems that the activity for the decomposition of *t*-BuOOH is related to the acidity on the supported catalyst. A clear-cut correlation was observed particularly with the V–Cr–SiO_2 series (Fig. 2) and the I-series (Fig. 4), which are both supported on SiO_2. Both the activity and the acidity were at a maximum on the V_2O_5–SiO_2 system (I-0), in which the tetrahedral configuration was detected by ESR. The strength of the acidity of (VO_4) may be sufficiently large to dehydrate *t*-BuOH, as has been described already. The acidity observed on the Cr_2O_3–SiO_2 catalyst may be related to the tetrahedral (CrO_4) configuration, which is formed newly, because SiO_2 showed no acidity ($pK_a \leqq 1.5$) itself.

When supported on γ-Al_2O_3, which itself showed acidity, the correlation was not so clear as on SiO_2, but at a high chromium content the catalyst of the H-series, on which the (CrO_4) configuration was observed, showed both a higher activity and a higher acidity compared to the G-series catalysts. Thus, this higher acidity seems also to be related to the tetrahedral (CrO_4) configuration.

Though the details of the mechanism by which the acidic sites contribute to the autoxidation are not yet clear, it may be suggested that the tetrahedral complexes work both as acidic sites and as active sites for the homolytic decomposition of hydroperoxide, through which process the autoxidation is accelerated. The homolytic decomposition may proceed *via* the co-ordination of hydroperoxide to a vacant site in the

complex; the vacant site is also suspected to behave as an acidic site.

In conclusion, the activity for the cyclohexene oxidation (Fig. 5 in the preceding paper[1]) correlates fairly well with that for the *t*-BuOOH decomposition, supporting the theory of the oxidation mechanism which proceeds *via* the radical decomposition of hydroperoxide. The effects of the V–Cr binary-system formation was not so clear in the *t*-BuOOH decomposition as in the cyclohexene oxidation, but the interaction between the metal oxides and the supports strongly affected the activity for the *t*-BuOOH decomposition. The oxidation activity of the I-series (Fig. 5 in the preceding paper[1]), when compared with those of other series, was considerably lower than would be expected from the *t*-BuOOH decomposition (Fig. 4); such a lowering was most clearly observed at a high vanadium content. This may be due to the instability of the (VO_4) structure: this effect was not clearly observed in the *t*-BuOOH decomposition, which proceeded rapidly, but was recognized in a relatively slow reaction such as the cyclohexene oxidation.

The Crystal Structure of the A′-form of Tridecanoic Acid

Midori Goto* and Eiichi Asada

National Chemical Laboratory for Industry, 1-1, Higashi, Yatabe, Ibaraki 305

(Received July 6, 1979)

The A′-form of tridecanoic acid is triclinic, with the space group $P\bar{1}$ and with $a=4.273(1)$, $b=4.972(1)$, $c=37.69(1)$ Å, $\alpha=90.36(2)$, $\beta=109.44(2)$, and $\gamma=112.43(2)°$. The structure was determined by the Patterson method. Refinement by block-diagonal least-squares methods gave a final R factor of 0.071.

Odd-numbered fatty acids are known to crystallize in three polymorphic forms, named A′, B′, and C′.[1] Their crystal structures have been studied by von Sydow in only one projection (the A′-form[2] and the B′-form[3] of pentadecanoic acid; the C′-form[4] of undecanoic acid). We have now been able to obtain fairly good single crystals of the A′-form of tridecanoic acid; we also investigated its crystal structure.

Experimental

The tridecanoic acid was prepared by the Ajinomoto Co., Ltd. The A′-form crystal was obtained by crystallization in a 2,2,4-trimethylpentane solution. The crystal data and the diffraction intensities were measured on a Rigaku-Denki four-circle diffractometer by using graphite monochromated Cu $K\alpha$ radiation at room temperature (about 20 °C).

Table 1. Crystal data

n-Tridecanoic acid		A′-form	
Molecular formula:		$C_{13}H_{26}O_2$	
Molecular weight:		214	
Transition point:		34 °C	
Triclinic;		$P\bar{1}$	
$z=2$			
a(/Å)	4.273(1)	α(/°)	90.36(2)
b	4.972(1)	β	109.44(2)
c	37.686(8)	γ	112.43(2)

The crystal data are listed in Table 1. The total number of observed reflections was 533 out of 1415 possible reflections within the 2θ angle of 120 °.

Structure Determination

The positions of the carbon atoms were obtained by taking into account the three-dimensional Patterson maps. The positions of the oxygen atoms were obtained by difference synthesis. The positions of the hydrogen atoms, with the exception of the carboxyl hydrogen atom, were calculated by assuming C–H distances of 1.10 Å and a tetrahedral arrangement. The structure was refined by the block-diagonal least-squares method using the HBLS program (ashida).[5]

The R-value was reduced to 0.071. The final atomic parameters obtained are listed in Table 2. The large temperature factors, especially at the end carboxyl groups, may be caused by the proximity of the experimental temperature to the transition point of the acid.

Results and Discussion

The structure of the A′-form of tridecanoic acid reveals a layer characteristic and is not significantly different from that of the A′-form[2] of pentadecanoic acid.

The bond lengths, bond angles, and internal rotation angles are shown in Table 3. Figure 1 is an ORTEP drawing.[7] Table 4 reveals that the molecule may be slightly bowed. The dihedral angle between the plane of the carbon main chain and the plane containing the carboxyl group is calculated to be 15°, nearly the same as that in the A_1-form[8] or the A-super form[9] of lauric acid.

Lauric acid A-super form[8)]	4.33	5.42	2.52	76	109	122	47.1
Lauric acid A_1-form[7)]	4.25	5.41	2.45	75	108	122	47.4
Trilaurin[11)]	4.27	5.40	2.45	75	108	117	47.4

a) The triclinic packing was found in the branched-chain fatty acids. In these compounds, the subcell data vary considerably and show a distorted packing; the structures were studied in only one projection and could not be discussed in detail.

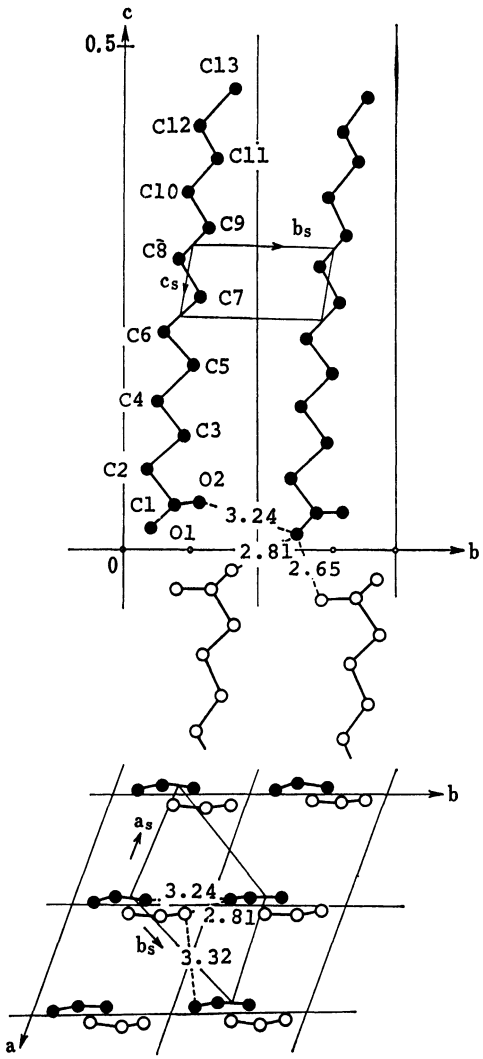

Fig. 2. The crystal structure.
a): Projection along the a*-axis, b): carboxyl groups projected along the c*-axis.

The arrangement of the chain and the end carboxyl group is shown in Fig. 2. The hydrogen bond length is 2.65 Å, and the second closest oxygen contact distance (except for the hydrogen bond) is 2.81 Å. This distance appears to be short compared with that of the other fatty acid,[9,10)] 3.13 Å.

The packing of the zig-zag chains of the carbon atoms is triclinic ($T_{//}$). The dimensions of the subcell are given in Table 5, together with the dimensions in other compounds with triclinic packing.

The structures of the B[10)] and C[11)] forms of the fatty acids reveal a typical layer structure, one in which the carboxyl groups and the methyl groups respectively are situated in alternate layers (parallel to 001). A-forms with the triclinic packing, both A_1[8)]- and A-super[9)] forms of lauric acid, have a structure in which the carboxyl and methyl groups appear mixed in the same layers in the crystal. However, the A'-form of tridecanoic acid has the typical layer structure, just as B-[10)] or C-[11)] forms.

We wish to thank Professor Yoichi Iitaka of the University of Tokyo for his encouragement and helpful discussions; we are also indebted to the Ajinomoto Co., Ltd., for providing the compound.

Solubility of Some Organic Mercury(II) Halides in Water[1]

Kooji TAJIMA,** Fumiaki KAI,* and Tetsuo KAWAHARA

Department of Chemistry, Faculty of Science, Kumamoto University, 2-39-1 Kurokami, Kumamoto 860
***Kumamoto Municipal Institute of Public Health, 1-13-16 Kuhonji, Kumamoto 862*

(Received August 30, 1979)

The solubilities of methylmercury(II) chloride (MMC), methylmercury(II) bromide (MMB), methylmercury(II) iodide (MMI), ethylmercury(II) chloride (EMC), and ethylmercury(II) bromide (EMB) in water have been determined over the temperature range of 10—55 °C (20—40 °C for MMC and EMC). The temperature dependence of the solubilities expressed as mole fractions x_2 was given by the following equations:

$$\log x_{2(\mathrm{MMC})} = -1059/T + 0.176 \quad (20—40\,^\circ\mathrm{C})$$
$$\log x_{2(\mathrm{MMB})} = -1094/T - 0.263 \quad (10—55\,^\circ\mathrm{C})$$
$$\log x_{2(\mathrm{MMI})} = -463/T - 3.246 \quad (10—25\,^\circ\mathrm{C})$$
$$\log x_{2(\mathrm{MMI})} = 5.498 \times 10^6(1/T)^2 - 3.711 \times 10^4(1/T) + 57.814 \quad (25—55\,^\circ\mathrm{C})$$
$$\log x_{2(\mathrm{EMC})} = -1048/T - 0.612 \quad (20—40\,^\circ\mathrm{C})$$
$$\log x_{2(\mathrm{EMB})} = -179/T - 4.293 \quad (10—25\,^\circ\mathrm{C})$$
$$\log x_{2(\mathrm{EMB})} = 5.389 \times 10^6(1/T)^2 - 3.603 \times 10^4(1/T) + 55.322 \quad (25—55\,^\circ\mathrm{C})$$

The thermodynamic parameters for the transfer process from solid to saturated aqueous solution were also determined.

Few papers have been published on the study of the organic mercury(II) compounds from the standpoint of pure chemistry. Waugh *et al.*[2] obtained the solubility product of MMC only at 25 °C from the dissociation constant and solubility in water. Schwarzenbach and Schellenberg[3] reported formation constants and the thermodynamic values of CH_3Hg^+ with several ligands, and Budevsky *et al.*[4] studied an interaction of CH_3Hg^+ with Cl^-. Hepler and Olofsson[5] also reviewed the thermodynamic properties, chemical equilibria, and standard potentials of the organic mercury(II) compounds. However, neither detailed solubility data with water over a wide temperature range nor thermodynamic parameters have been found in the literature.

As pointed out in the preliminary communication,[1] the determination of the solubility of the organic mercury(II) compounds in water is considered to be an urgent need. Accordingly, the present paper describes the solubilities of five organic mercury(II) compounds in water and the partial molal enthalpy and entropy of these compounds for the dissolution process, in which MMC is confirmed as the causal agent of the so-called "Minamata Disease".[6-8] The heat of fusion, one of the very important fundamental properties, was also measured.

Experimental

Materials. MMC, MMB, MMI, EMB, and ethylmercury(II) iodide (EMI)[9] were obtained from Wako Co., Ltd., and EMC from Tokyo Kasei Co., Ltd. They were recrystallized from hot ethanol. Before recrystallization, inorganic mercury(II) as an impurity was detected by spot test of TLC with dithizone. After recrystallization, no color spot due to inorganic mercury(II) was observed. Other impurities were measured quantitatively by a gas chromatograph equipped with an electron capture detector (Yanagimoto, G-80), and then the degree of purity was evaluated. The results are listed in Table 1, together with the melting points. Water was carefully purified twice by distillation with potassium permanganate.

Table 1. Purity and Mp

Substance	Purity / %	Mp[a] / °C
MMC	99.1	168 (ref. values; 167,[10] 168,[10] 174[8])
MMB	99.0	160 (ref. values; 160,[11] 160—161[12])
MMI	93.9	148 (ref. values; 148,[11] 150[10])
EMC	99.3	192 (ref. value; 192[13])
EMB	98.9	192 (ref. value; 192[11])

a) Different melting points have been reported in the literature, and it is our belief that some of these substances may have impurities.

Solubility Measurement. The solubility was determined by density measurements of the saturated aqueous solutions at a given temperature. The saturated aqueous solutions were prepared using two thermostated baths for all experiments. The temperature of the first bath was maintained higher by 3 °C than the desired temperature by continuous stirring, a saturated solution at higher temperature was thus primarily

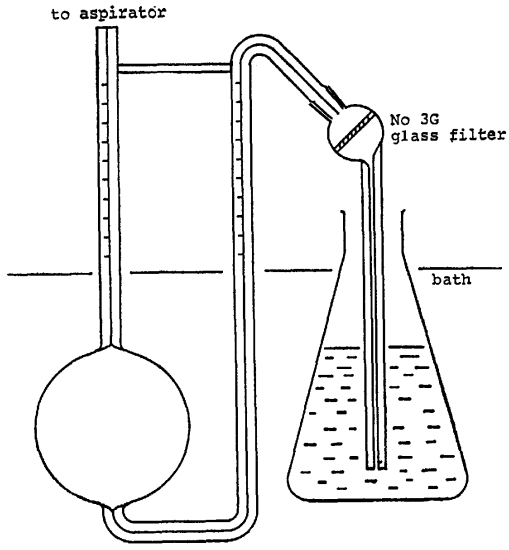

Fig. 1. Handling of solution.

obtained. The constant temperature of this first bath was controlled by a Pt–Hg regulator with ±0.05 °C accuracy. This solution was then immersed in the second bath controlled at the desired temperature with a Pt–toluene–Hg regulator having an accuracy of ±0.01 °C. Great care must be paid to deposition of the solutes with decreasing temperature of the solution and to the handling of such vigorous toxicant. Therefore, the apparatus in Fig. 1 was used to lead the saturated solution directly into the pycnometer (*ca.* 20 ml capacity for MMC and EMC, 45 ml for MMB, MMI, and EMB) without taking out the sample solution from the bath. The pycnometer was joined *via* a glass filter (G-4, 5—10 μ) to the flask containing the thermostated solution and then filled with the solution by aspiration.

Measurement of Heat of Fusion. TG-DTA analysis (Rigakudenki, 8076 E1) was carried out in order to obtain the heat of fusion. For determining the instrumental constant, benzoic acid (mp=122.28 °C, heat of fusion=17.3 kJ mol^{-1}), indium (mp=156.84 °C, heat of fusion=3.3 kJ mol^{-1}), and stannum (mp=231.94 °C, heat of fusion=7.07 kJ mol^{-1}) were used as the standard substances, because the melting points of the organic mercury(II) compounds studied (from 148 °C (MMI) to 192 °C (EMC and EMB) were included in the range of these three standard substances, and these standard substances have no solid-solid phase transition near their melting points. The mean value of the instrumental constant was estimated using $k=M\Delta H/A$ (M: sample weight, ΔH: heat of fusion, A: endothermic peak area) as 2.12.

Results and Discussion

The concentration of a solute is often determined by spectrophotometry. The present solutes, however, have no absorption maxima in the 200—300 nm region. Direct gravimetry could not be applied because of the volatility and high toxicity of the solutes studied. Therefore, the determination of the concentration was performed in this experiment by density measurements of the solutions at a given temperature. The error in density, mainly due to the weighing error of the pycnometer, was ±0.00005 g/cm^3. The relations between the mole fraction x_2 and the density of solution are illustrated in Figs. 2—6. All the figures showed good linearity, with a correlation coefficient of 0.999 at every experimental temperature. Table 2 shows the experimental solubility data expressed as mole fractions at various temperatures. The logarithm of the solubility against the reciprocal temperature is given in Fig. 7, which shows that all the solubilities increased with increasing temperature. From these data, the following solubilities

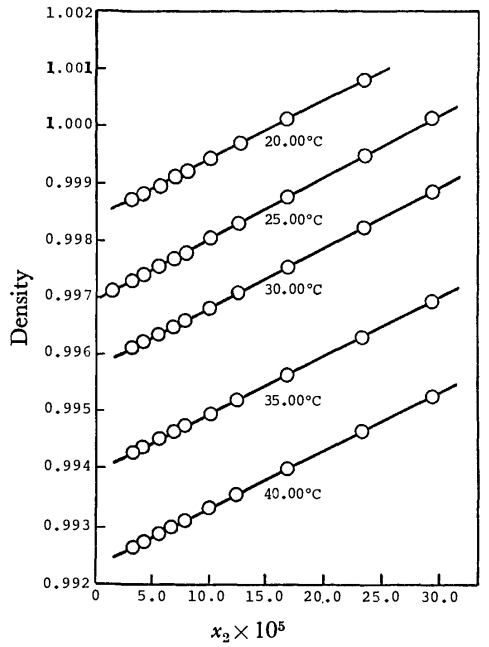

Fig. 2. Relation between mole fraction and density of MMC.

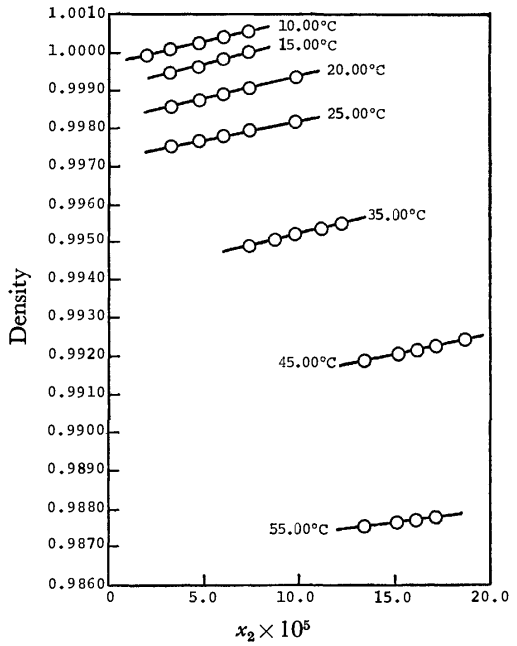

Fig. 3. Relation between mole fraction and density of MMB.

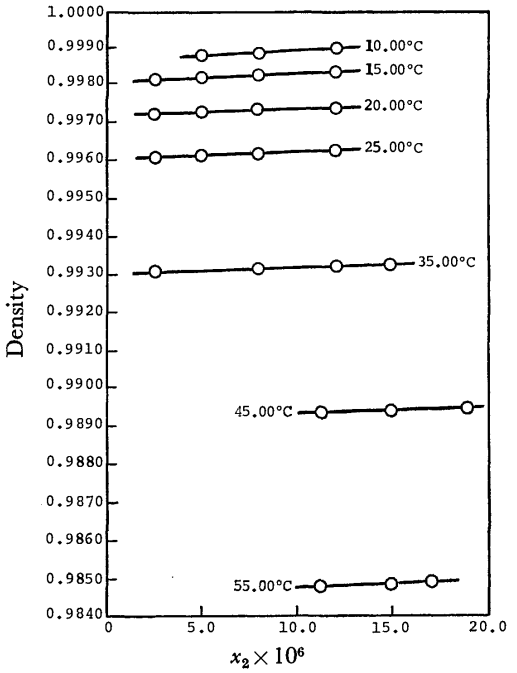

Fig. 4. Relation between mole fraction and density of MMI.

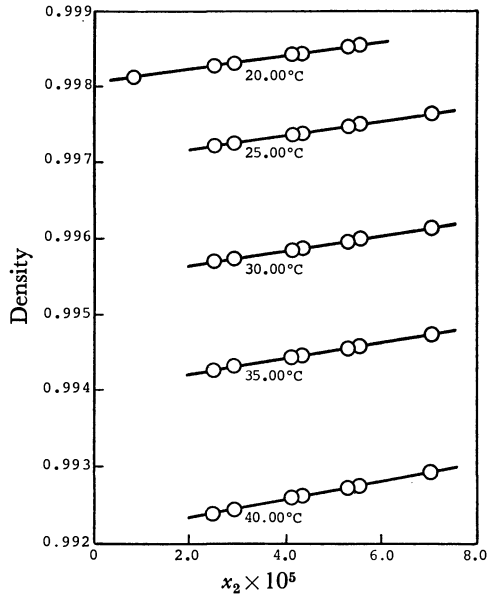

Fig. 5. Relation between mole fraction and density of EMC.

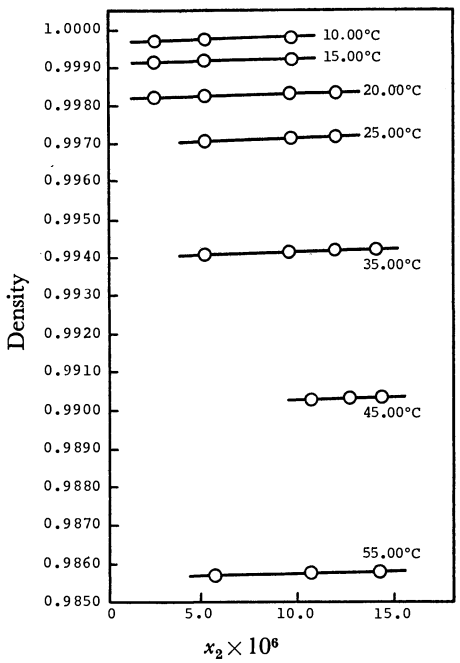

Fig. 6. Relation between mole fraction and density of EMB.

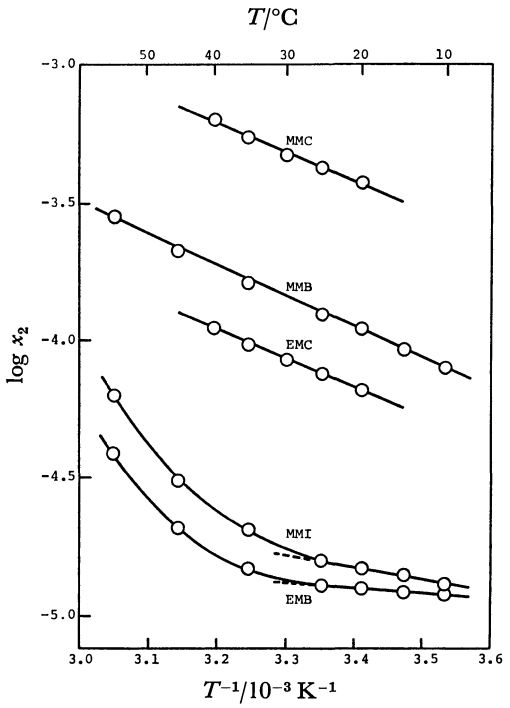

Fig. 7. Temperature dependence of solubility.

were obtained from the least squares fits:

$$\log x_{2(\mathrm{MMC})} = -1059/T + 0.176 \quad (20—40\,°C)$$

$$\log x_{2(\mathrm{MMB})} = -1094/T - 0.263 \quad (10-55\,°C)$$

$$\log x_{2(\mathrm{MMI})} = -463/T - 3.246 \quad (10-25\,°C)$$

$$\log x_{2(\mathrm{MMI})} = 5.498 \times 10^6(1/T)^2 - 3.711 \times 10^4(1/T) + 57.814 \quad (25—55\,°C)$$

$$\log x_{2(\mathrm{EMC})} = -1048/T - 0.612 \quad (20—40\,°C)$$

$$\log x_{2(\mathrm{EMB})} = -179/T - 4.293 \quad (10—25\,°C)$$

$$\log x_{2(\mathrm{EMB})} = 5.389 \times 10^6(1/T)^2 - 3.603 \times 10^4(1/T) + 55.322 \quad (25-55\,°C)$$

As can be seen from Fig. 7, the solubility features of MMI and EMB are different from those of MMC, MMB, and EMC: the former exhibits an abrupt curvature above 25 °C, while the latter shows linearity over the temperature range studied.

For a discussion of the thermodynamic behavior of the dissolution process of the solute, the heat of fusion of the solute was determined. As a typical example, the TG–DTA curve of MMI is shown in Fig. 8. As can be

MMI	3500	8.3
EMC	2500	5.5
EMB	3000	6.5
EMI[9]	3200	6.9

seen from this TG curve, in general, the organic mercury(II) compounds sublime gradually before melting. Accordingly, it was required in this experiment to determine a heat purely due to fusion and not to sublimation. The relation between a sample weight corrected by the TG curve at the melting point (B) and an endothermic peak area (A) was examined repeatedly. The results gave a fine linear relation, as illustrated in Fig. 9. The values of the enthalpy and entropy of fusion, thus obtained, are listed in Table 3, where H_2° and H_2^s (S_2° and S_2^s) denote the enthalpy (entropy) of solution of supercooled liquid and solid, respectively, of the 2nd component.

For the transfer process from solid to saturated solution, the values of partial molal enthalpy and entropy of solution are estimated from the data of the temperature dependence of the solubility by using the following equation,

$$(\bar{H}_2 - H_2^s)/T = \bar{S}_2 - S_2^s \cong R(\partial \ln x_2/\partial \ln T)_{sat}$$

where $\bar{H}_2$ ($\bar{S}_2$) represents the enthalpy (entropy) of a solute in a solution. The thermodynamic parameters calculated from the data of the solubility and fusion are summarized in Table 4. Here the values of $(\bar{H}_2 - H_2^\circ)$ and $(\bar{S}_2 - S_2^\circ)$ mean the enthalpy and entropy changes for mixing of the solute in supercooled liquid and water, and they are related as:

$$(\bar{H}_2 - H_2^\circ) = (\bar{H}_2 - H_2^s) - (H_2^\circ - H_2^s)$$
$$(\bar{S}_2 - S_2^\circ) = (\bar{S}_2 - S_2^s) - (S_2^\circ - S_2^s)$$

The values in Table 4 were calculated by assuming that a molal heat capacity of a supercooled liquid (C_P^l) and that of a solid (C_P^s) are equal at a constant pressure, namely, $\Delta C_P = C_P^l - C_P^s = 0$.

The above discussion was made with the assumption that these solutes are non-electrolytes. Schwarzenbach and Schellenberg,[3] however, reported in detail the interactions of CH_3Hg^+ with Cl^-, Br^-, and I^- in water at 25 °C ($[CH_3Hg^+][Cl^-]/[CH_3HgCl] = 5.62 \times 10^{-6}$ mol dm^{-3}; $[CH_3Hg^+][Br^-]/[CH_3HgBr] = 2.40 \times 10^{-7}$ mol dm^{-3}; $[CH_3Hg^+][I^-]/[CH_3HgI] = 2.51 \times 10^{-9}$ mol dm^{-3}). MMC, MMB, and MMI thus seem to be very weak electrolytes. In order to estimate the effect of these slight dissociations, the thermodynamic values for the dissociation process were calculated by using the above constants. However, no influence was observed on the values of $(\bar{H}_2 - H_2^s)$ and $(\bar{S}_2 - S_2^s)$ in Table 4. Although the values of dissociation of EMC and EMB were not found in the literature, it can be assumed that

Table 4. Thermodynamic parameters

a) x_2 at 25 °C.

dissociations of EMC and EMB are less effective than those of MMC, MMB, and MMI. Further, it should be discussed whether the association of the solute can be neglected or not. However, no presence of, for example, an aggregate has been reported in the literature.

When the solubility behavior of these organic mercury(II) compounds in water is argued, the characteristics of "water" as a solvent should be considered necessarily. Frank and Evans[14] showed that, in spite of the small solubility of hydrocarbons such as higher alcohols in water, the heat of solution was small and the entropy of solution was negative. In order to rationalize this rather unusual situation, they postulated the formation of an "ice" which surrounds dissolved hydrocarbon molecules and they proposed to call this phenomenon an "iceberg" formation. In water, these phenomena are now considered to be usual.[15] This argument will show that, by dissolution of some kind of solute in water, the freedom of the water molecules surrounding the solute is restricted to some extent in the solution, compared with that of pure water.

In this study, the solubility behaviors could be classified into two groups according to the resemblances of the solubility features. In the first, the solubility increased abruptly above 25 °C (MMI and EMB). A behavior similar to this group was reported in the literature for the dissolution of aromatic hydrocarbons[16] such as benzene, toluene, *m*- and *p*-xylene, and ethylbenzene into water. In the cases of the solutes of MMI and EMB, the solubility curve could be divided into two parts: one was that in the 10—25 °C range and the other was that above 25 °C. In the range of 10—25 °C, because of negligibly weak interactions between solvent and solute, water molecules surrounding the solute were ice-like in structure. The tendency toward the formation of this ice-like structure in the 10—25 °C range, however, was considered to be relatively weak, because, as tabulated in Table 4, both the entropy and enthalpy changes for mixing were very small and negative as -1.0——-3.6 cal K^{-1} mol^{-1} and 1—2 kcal mol^{-1} (exothermic) respectively. Upon increasing the temperature above 25 °C, the ice-like structure of the water molecules surrounding the solute was obstructed, and thus the solutes could move more freely in the solution than could those in the 10—25 °C range. This breaking of the ice-like structure, that is, the abrupt increasing of the solubility above 25 °C, can be recognized by the large positive entropy and large endothermic enthalpy changes in Table 4.

In the cases of the solutes of MMC, MMB, and EMC as the second group, the formation of an ice-like structure may have been obstructed owing to the solvent-solute interaction, which was, however, considered to be weak. This interpretation seems to be consistent with the large positive entropy and endothermic enthalpy changes in Table 4. Similar behavios to this second group were reported for iodine,[17] naphthalene and biphenyl.[16] After all, the difference of the solubility features above 25 °C was considered to be mainly due to a delicate variance of the solvent-solute interactions. Although an interpretation for the different solubility features with respect to the kinds of alkyl group and halogen was attempted, it failed because the solubility of a solute having propyl or butyl group could not be measured in our experimental conditions owing to their small solubilities in water.

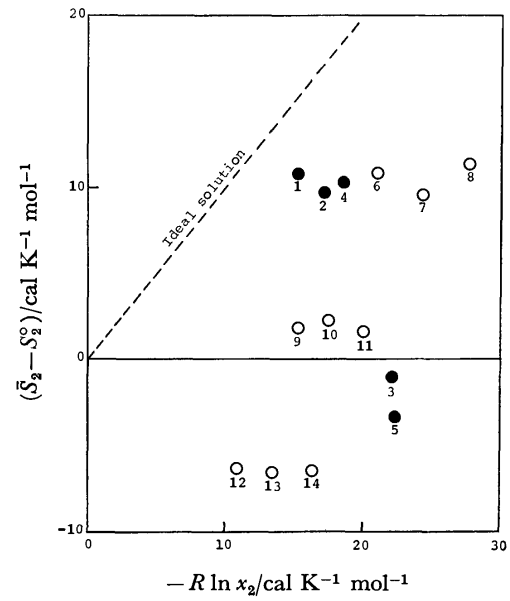

Fig. 10. Plot of $-R \ln x_2$ *vs.* $(\bar{S}_2-S_2^\circ)$.
1: MMC, 2: MMB, 3: MMI, 4: EMC, 5: EMB, 6: iodine,[19] 7: naphthalene,[16] 8: biphenyl,[16] 9: benzene,[16] 10: toluene,[15] 11: ethylbenzene,[16] 12: methane,[15] 13: ethane,[15] 14: propane.[15]

On the basis of the above discussion, so far as a non-polar solute is concerned, an argument of iceberg "making" or "breaking" should not be made as if it were a basic property possessed by a solute itself, but should be done in relation to the temperature studied.

Figure 10 shows the relation of the values of $(\bar{S}_2-S_2^\circ)$ against $-R \ln x_2$. If the solution is an ideal one, both values are identical as dotted line in the figure. For the comparison, besides the organic mercury(II) compounds studied, we plot the thermodynamic values of aromatic hydrocarbons[16] and of alkanes in the liquid state[15] obtained after converting the values in the gaseous state.[18] All the values of $-R \ln x_2$ are adopted as those at 25 °C. The solutes including the reference ones could be roughly classified. That is, the first group contained the solutes having the large positive values of $(\bar{S}_2-S_2^\circ)$, and their temperature dependence of the solubilities was shown to be linear (MMC, MMB, EMC, iodine, naphthalene, and biphenyl). Accordingly, the solutes having almost no ability to form an ice-like structure at the temperature studied were positioned in the vicinity of the ideal line. The second group (MMI, EMB, benzene, toluene, ethylbenzene, methane, ethan, and propane) largely deviated from the ideal line, showing nearly zero or negative $(\bar{S}_2-S_2^\circ)$ values, and the temperature dependence of the solubilities was curved.

The authors wish to thank Drs. M. Nakamizo and S. Sakagami of Goverment Industrial Research Institute, Kyushu, for their help with the TG–DTA measurements. One of the authors (K. T.) wishes to express his thanks

to Mr. S. Kitaoka, Chief of the Institute, for his encouragement throughout the work.

Kinetic and Spectrophotometric Studies of Rhodamine 6G Dimerization in Aqueous Solution

Wataru INAOKA, Shoji HARADA, and Tatsuya YASUNAGA*

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received September 3, 1979)

The dimerization reaction of dye, Rhodamine 6G, in aqueous solution was studied spectrophotometrically and kinetically: the equilibrium constant and the rate constants were found to be $K=1.6\times10^3$ M^{-1}, $k_f=1.1\times10^9$ M^{-1} s^{-1}, and $k_b=7.0\times10^5$ s^{-1}, respectively, at 15 °C. These rate constants, and those of other dyes are discussed. The effect of the ionic strength was also studied.

The aggregation of dye in solution has been of interest as a model system of the self-organization of sub-units into large structures of biological activity. The dimerization reaction of dye has been extensively investigated spectrophotometrically and kinetically. By the spectrophotometric experiments,[1-5] the equilibrium constant was obtained and the effect of additives has been studied. The kinetic experiments,[6-14] showed the rate constants to be very large. The rate constants of these dyes seem to be divided into two groups. Among them, Rhodamine B and 3B have been found to have relatively slow reaction rates, while the reaction of Rhodamine 6G was too fast to be observed by a conventional method.[12,13] Two purposes of the present work are to obtain the kinetic parameters of the dimerization of Rhodamine 6G and to discuss the difference in the rate constants of the two groups.

The increase of the ionic strength is known to promote the dimerization of dye.[3,15] Since the equilibrium constant is the ratio of the association and the dissociation rate constants, the ionic strength effect is also expected to be reflected in the rate constants. Another purpose is to investigate the effect of the ionic strength on this reaction.

Experimental

Rhodamine 6G hydrochloride (Tokyo Kasei) was recrystallized three times from water and dried under vacuum at 110 °C for 12 h. Distilled and deionized water was used throughout the experiment. The ionic strength was adjusted by the addition of NaCl.

The equilibrium constant was determined spectrophotometrically with a Union Giken SM 401 spectrophotometer. The kinetic experiment was performed with a stimulated Raman laser temperature-jump apparatus; the details of the apparatus were described elsewhere.[9] The measurement was carried out at 15 °C.

Results

Rhodamine 6G is known to aggregate in aqueous solution and this monomer-dimer equilibrium is established:

$$2M \underset{k_b}{\overset{k_f}{\rightleftarrows}} D \qquad (1)$$

where M is the monomer, D is the dimer, and k_f and k_b are the association and dissociation rate constants, respectively. The equilibrium constant K is related to the molar extinction coefficient and the concentration of dye as follows:[15]

$$\{(\varepsilon_M-\varepsilon)/C_0\}^{1/2} = (2K/\Delta\varepsilon)^{1/2}\{\Delta\varepsilon-(\varepsilon_M-\varepsilon)\} \qquad (2)$$

where

ε_M: the molar extinction coefficient of the monomer.
ε: the apparent molar extinction coefficient of dye.
$\Delta\varepsilon$: the difference between the molar extinction coefficient of the monomer and that of the dimer *per monomer unit.*
C_0: the initial concentration of dye.

According to Eq. 2, a plot of $\{(\varepsilon_M-\varepsilon)/C_0\}^{1/2}$ *vs.* $(\varepsilon_M-\varepsilon)$ will give a straight line with the intercept $(2K\Delta\varepsilon)^{1/2}$ on the ordinate and $\Delta\varepsilon$ on the abscissa. On this basis, ε_M was evaluated to give the best straight line with the measured values of ε and C_0. The plot is shown in Fig. 1. The equilibrium constant obtained, $K=1.6\times10^3$ M^{-1} at 15 °C, seems to be satisfactory compared with the previously reported values.[4,5,13] Furthermore, the equilibrium constants at various ionic strengths were obtained in the same way; they are listed in Table 1. As shown in the table, with the increase of the ionic strength, the equilibrium constant increases, *i.e.*, the formation of dimer is promoted.

TABLE 1. THE RATE CONSTANTS AND THE EQUILIBRIUM CONSTANT FOR RHODAMINE 6G DIMERIZATION AT VARIOUS IONIC STRENGTHS (15 °C)

Ionic strength (M)	k_f (10^9 M^{-1} s^{-1})	k_b (10^5 s^{-1})	K (10^3 M^{-1})
0.00	1.1	7.0	1.6
0.05	1.2	6.6	1.8
0.10	1.3	5.9	2.2
0.15	1.4	5.4	2.5

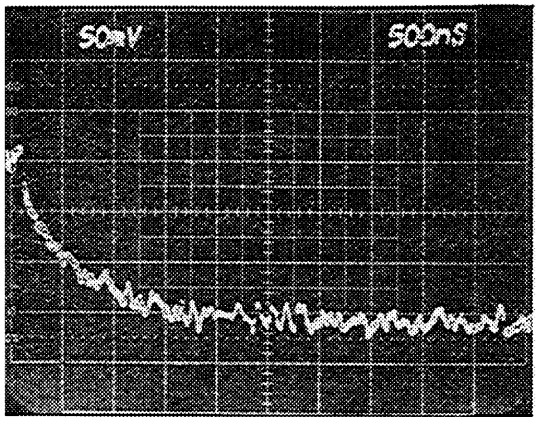

Fig. 2. Typical relaxation curve in 1.0×10^{-3} M Rhodamine 6G at $\mu=0$ M, 15°C, wavelength 525 nm, sweep 500 ns/div.

The kinetic experiment of the dimerization reaction of dye was performed in the concentration range of $(0.5—4.0)\times10^{-3}$ M. The relaxation phenomenon was detected spectrophotometrically at the monomer band (525 nm). A typical relaxation curve is shown in Fig. 2. The relaxation was also observed at the dimer band (500 nm) in the same time range but the change of the relaxation was in the opposite direction; this relaxation curve was not used because of its small relaxation amplitude. Each relaxation curve was characterized by a single relaxation time. Relaxation times were reproducible to $\pm10\%$.

The relaxation time τ is related to the rate constants as follows:

$$\tau^{-1} = 4k_f\bar{C}_M + k_b \qquad (3)$$

where $\bar{C}_M$ is the equilibrium concentration of the monomer, which is calculated from the equilibrium constant and the initial concentration. The plots of τ^{-1} against $\bar{C}_M$ are shown in Fig. 3, where every point of τ^{-1} is the mean value of at least 10 measurements. The good linear relationship indicates that the observed relaxation phenomenon is based on the monomer-dimer equilibrium of dye molecules. The value of k_f was

(The number in parenthesis means the reference number).

obtained from the slope of the straight line. Since the value of k_b was small, it was calculated from k_f and K $(=k_f/k_b)$. The values of k_f and k_b obtained are listed in Table 1.

In order to compare the rate constants of dimerization of Rhodamine 6G with those of other dyes, log k_f and log k_b were plotted against log K in Fig. 4. From the kinetic standpoint of view, dyes in this figure seem to be divided into two groups. In group I, the values of k_f fall in the same order of magnitude and are close to that of the diffusion-controlled rate constant, and the linear relationship between log k_b and log K is recognized. On the other hand, in group II, the values of k_f and k_b are a few orders of magnitude smaller than the corresponding values in group I.

The effect of the ionic strength μ on the rate constants was studied under the conditions of $\mu=0.05$, 0.10, 0.15 M. At $\mu=0.15$ M, the measurement was limited to low concentrations since the dye precipitated at higher concentrations. The plots of τ^{-1} *vs.* $\bar{C}_M$ at different μ are also shown in Fig. 3. The rate constants obtained are listed in Table 1. As shown in the table, the increase of μ induces an increase of K, a small increase of k_f, and a small decrease of k_b.

Discussion

The dimerization reaction 1 may be divided into the following two processes:

$$M + M \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} (M, M) \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} D \qquad (4)$$

where the first process is the diffusion-controlled reaction to form the encounter complex (M,M) and the second process is the intramolecular reaction to form the stable

dimer D. Using the steady-state assumption for the encounter complex, the association and the dissociation rate constants are expressed as follows:

$$k_f = \frac{k_1 k_2}{k_{-1}+k_2} \quad (5)$$

$$k_b = \frac{k_{-1}k_{-2}}{k_{-1}+k_2} \quad (6)$$

The diffusion-controlled rate constants k_1 and k_{-1} can be theoretically estimated to be $k_1 = 1.8\times10^9\ M^{-1}\ s^{-1}$ and $k_{-1} = 3.0\times10^9\ s^{-1}$.[16] These values are in the same order of magnitude as those of other dyes; the difference of dyes is not reflected in the first step of Reaction 4. Inserting the values of k_1, k_{-1}, k_f, and k_b into Eqs. 5 and 6, k_2 and k_{-2} were calculated to be $4.7\times10^9\ s^{-1}$ and $1.8\times10^6\ s^{-1}$, respectively. Since the value of k_2 is very large and is nearly equal to k_1 and k_{-1}, the activation energy should be as small as that of the diffusion-controlled process. In the same way, the rate constants k_1, k_{-1}, and k_2 of other dyes in group I fall in the order of 10^9. Accordingly the difference in the equilibrium constant of the dyes in group I, including Rhodamine 6G, is attributed to that of k_{-2}.

Schelly *et al.*[12,13] have investigated kinetically the dimerization reaction of Rhodamine dyes (B, 3B, and 6G) by the stopped-flow method; the reaction of Rhodamine 6G, however, was too fast to be observed. With use of the reported values of k_f and k_b, the values for k_2 and k_{-2} of both Rhodamine B and 3B were estimated to be of the order of 10^6 and $10^{2.5}$, respectively. These rate constants are much smaller than the corresponding values of Rhodamine 6G, while the equilibrium constants of the dimerization of Rhodamine dyes are of the same order. These results can also be interpreted from the standpoint of free energy: the activation free energy of Rhodamine B and 3B is much higher than that of Rhodamine 6G, though the free energy differences are all of the same order (−4.1——4.7 kcal/mol); the free energy diagram is schematically shown in Fig. 5. Taking into account the structure of these dyes, we see that the existence of two methyl groups in the xanthene plane of Rhodamine 6G does not affect the free energy difference, but does affect the activation free energy between the encounter complex and the stable dimer states. The fact that Rhodamine 6G reacts through a different pathway from Rhodamine B may also be suggested by the μ dependence of the rate constants: the μ dependence of the rate constant of Rhodamine B has been reported to be very large,[12] while that of Rhodamine 6G was found to be small.

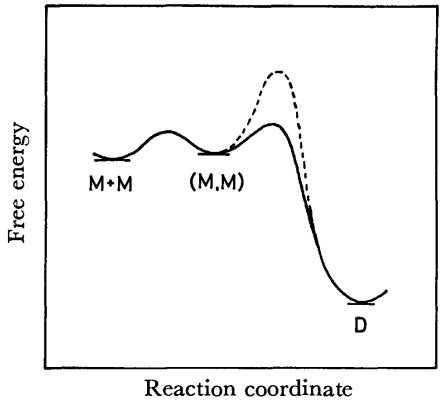

Fig. 5. Schematic diagram of the free energy of Rhodamine dyes.
(------): Rhodamine B and 3B, (——): Rhodamine 6G.

The ionic strength dependency of k_f and k_b given in Table 1 is realized in relation to Reaction 4. Since the dimerization is the reaction between the positive charges, the increase of the counter ion in solution decreases the electrostatic repulsion between dyes and promotes the dimerization, *i.e.*, k_1 increases with the increase of μ, while k_{-1} is unaffected.[18] Since the second step of Reaction 4 is the intramolecular process, the dependence of k_2 on μ may be small. Accordingly, with Eq. 5, the increase of k_f with the increase of μ is interpreted by that of k_1. From the above considerations on the rate constants (k_{-1} and k_2) with Eq. 6, the decrease of k_b with the increase of μ is ascribed to that of k_{-2}. The decrease of k_{-2} with the increase of μ may be understood by the contribution of the counter ion Cl^- to the stabilization of the dimer.

The authors gratefully acknowledge the support of the Toray Science Foundation for the establishment of the stimulated Raman laser temperature-jump apparatus.

Thermal Desorption of Hydrogen Adsorbed on Copper Surface

Isao KOJIMA,* Makoto KIYOMIYA, and Iwao YASUMORI
Department of Chemistry, Tokyo Institute of Technology, Meguro-ku, O-okayama, Tokyo 152
(Received October 6, 1979)

The thermal desorption of hydrogen adsorbed on a clean surface of polycrystalline copper foil was studied under ultra high vacuum conditions. The presence of chemisorbed hydrogen in a dissociated state was verified in a temperature range between 193 and 573 K. During the desorption process, the adsorbed hydrogen atoms recombined into molecules; this follows second order kinetics. The activation energy for desorption was 68.6±8.0 kJ mol^{-1} and remained nearly constant in the range of surface coverage up to 1.6×10^{14} atom cm^{-2}. The isotope effect on the desorption of deuterium was found to be straightforward. These findings showed a good agreement with the results obtained from the analysis of H_2–D_2 equilibration on copper powder catalyst. In addition, the necessary conditions to obtain the exact desorption spectra were inspected with the aid of computer simulation.

Studies on the elementary processes of adsorption and desorption are important in understanding the catalytic reaction on solid surfaces. Although there have been many investigations of the adsorption of hydrogen on copper surfaces,[1–7] the mechanism has not been well established. An activated process for adsorption is the consensus in most of reports,[2,5,6] but they do not give concordant values for the activation energy and the heat of adsorption.

In our previous study,[8] it was shown that H_2–D_2 equilibration on reduced copper powder can be interpreted in terms of the Bonhoeffer-Farkas mechanism, which involves the dissociative adsorption of hydrogen and the surface recombination of adsorbed hydrogen atoms in the reaction pathway. From the analysis of the reaction time course, kinetic parameters of adsorption and desorption were evaluated. In a subsequent work,[9] these results were found to accord well with those of the classical trajectory calculations for the dissociative adsorption on a model (100) copper surface.

Thermal desorption (TD) gives direct information on the adsorbed states, the fraction of coverage, and the kinetics of desorption. A TD measurement, using a conventional high vacuum system, was applied to the hydrogen adsorbed on copper powder and the formation of HD together with H_2 and D_2 was successfully observed by heating the surface covered with hydrogen and deuterium. The estimated value for the activation energy of desorption was, however, about a half of that obtained from the analysis of the reaction kinetics.[10] Accordingly, the present study aimed to solve this contradiction between these experimental results and, further, to make clear the adsorbed state of hydrogen on a copper surface. To attain this purpose, we paid special attention to finding the optimum situation for pursuing the desorption process and designed a desorption system which is operated with high pumping speed in the range of ultra high vacuum (UHV). The desorption spectra obtained by using the system were analyzed in detail. The adsorbed state of hydrogen, the activation energy of desorption, and its dependence on the coverage of adsorbed hydrogen were determined, and the isotope effect on desorption was also inspected. Further, the obtained results were compared with those derived from the study of H_2–D_2 equilibration on copper catalyst.

Experimental

A schematic representation of the apparatus employed is shown in Fig. 1. The experiments were performed in a pyrex glass UHV system. The adsorption–desorption system with a volume of 410 cm^3 consisted of a desorption cell, a pressure gauge, a greaseless glass valve, and an ion getter pump. A 3-stage mercury diffusion pump was connected to the system through a liquid nitrogen cold trap and a bakeable metal valve and used for initial pumpdown to about 10^{-6} Torr (1 Torr= 133.3 Pa). After the bakeout of the system at 530 K for 24 h, a vacuum of about 5×10^{-10} Torr was readily attained by using the ion getter pump.

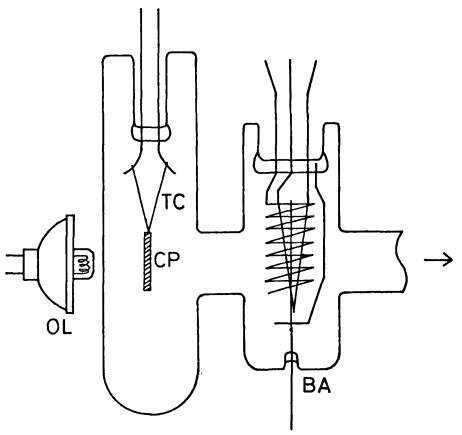

Fig. 1. A schematic representation of desorption system. BA: Bayard-Alpert gauge, CP: copper plate, OL: halogen lamp, TC: Pt–Pt/Rh13% thermocouple.

The desorption spectra were recorded by means of a Bayard-Alpert gauge, through which the desorbed gas was evacuated. This allowed us to measure directly the density of desorbed molecules related to the desorption rate. A polycrystalline plate of copper with a surface area of 4.2 cm^2 was used as the adsorbent. The sample was spot-welded to the junction point of Pt–Pt/Rh13% thermocouple wire, 0.05 mm in diameter, and was hung down in the desorption cell by the wire so as to minimize the temperature fluctuation and the desorption from the thermocouple. The sample after the bakeout was reduced in a flow of hydrogen of pressures between 10^{-3}—10^{-4} Torr at 570—670 K for 48 h and then outgassed at 773 K until no further gas evolution could be detected. The surface cleanliness was judged by the reproducibility of measurements after the reduction-outgas cycle. The surface with a constant

activity could then be obtained by reducing and outgassing several times at 773 K *in vacuo* better than 5×10^{-10} Torr. To avoid the wall effect, the sample was heated directly by infrared irradiation supplied from a halogen reflector lamp, Osram Model 15V 150W. The infrared light beam was dispersed on the copper plate. The heating rate was adjusted in a range 0.2—4 K s^{-1} using a constant-current power supply. Hydrogen pressures measured by the ion gauge were calibrated with nitrogen of equivalent pressures using the published value of the sensitivity ratio, $S_{H_2}/S_{N_2}=0.44$.[11] After the copper surface was exposed to hydrogen of 1×10^{-5}—1×10^{-8} Torr for 45 minutes at room temperature and was evacuated to 5—10×10^{-10} Torr at 193 K, the surface temperature was raised linearly with time up to 570 K.

Results

Since the detailed discussions on the basis for determining kinetic parameters from desorption spectra have already been given,[12,13] only the salient features will be outlined here.

An accurate knowledge of the effective pumping speed is necessary to determine the absolute values of kinetic parameters for desorption. From the following procedure, the pumping speed, S (cm^3 s^{-1}), was determined for hydrogen. The mass balance of gases present in a vacuum system requires the following equation to hold:

$$V\frac{dP}{dt} = Q - S\Delta P \qquad (1)$$

$$\text{and} \quad \Delta P = P - P_0,$$

where P and P_0 are the operating and background pressures in the system, respectively, V is the volume of the system, and Q is the external influx of gases (in Torr cm^{-3} s^{-1}). Accordingly, by introducing hydrogen gas into the closed vacuum system at a constant rate, the influx was evaluated from the increasing rate of pressure:

$$Q = V\frac{dP}{dt}. \qquad (2)$$

Then the system was evacuated and after the pressure attained an equilibrium value, P_{eq}, S was determined by using the relation

$$S = (P_{eq}-P_0)/Q. \qquad (3)$$

From the measurements stated above, S was evaluated to be 2.3×10^3 cm^3 s^{-1} in a pressure range between 10^{-8} and 10^{-6} Torr.

Figure 2 illustrates the typical desorption spectra of hydrogen and deuterium adsorbed at the same fraction of coverage on a surface. Only one peak was observed in each spectrum; the peak of D_2 appeared at the temperature higher than that of H_2 by about 10 K. The temperature at peak maximum shifted to the lower temperature side with increased amount of adsorption under a constant rate of temperature increase and showed the same trend of shift with a decrease of the rate of temperature rise under a constant amount of adsorption. The increase of surface coverage, for example from 1.4×10^{13} to 2.0×10^{14} atom cm^{-2} of hydrogen, shifted the peak maximum from 355 to 327 K at the rate of temperature rise of 1.2 K s^{-1}, and the

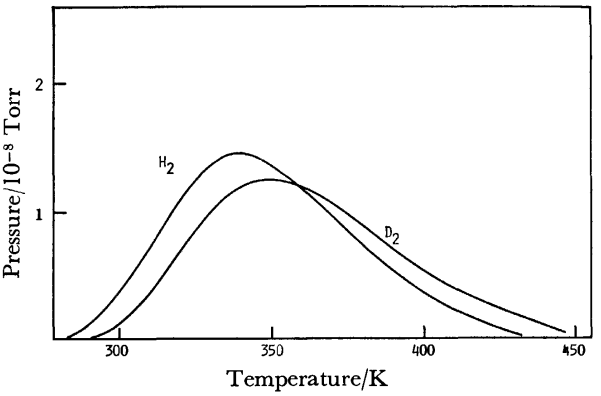

Fig. 2. Thermal desorption spectra of hydrogen and deuterium on copper surface.

increase in the rate from 0.17 to 3.2 K s^{-1} brought about the increase in the peak temperature from 330 to 368 K at the constant coverage of 1.8×10^{13} H-atom cm^{-2}.

Mass balance during the desorption requires that Q in Eq. 1 is replaced by the rate of desorption from the surface:

$$V\frac{dP}{dt} = \frac{A}{C}\frac{dN}{dt} - S\Delta P, \qquad (4)$$

where N is the number of desorbing molecules per unit area, A is the surface area and, C is a conversion factor in a unit of molecule K $Torr^{-1}$ cm^{-3}, which is equal to 3.2×10^{16} at 300 K. In the normal UHV system with large pumping speed, the ratio V/S is negligibly small and therefore the desorption rate becomes approximately proportional to the pressure increase:

$$\frac{dN}{dt} = \frac{C}{A}S\Delta P. \qquad (5)$$

The amount of adsorbed hydrogen, N_0 (molecule cm^{-2}) is given by

$$N_0 = \frac{CS}{A}\int_0^\infty \Delta P\, dt. \qquad (6)$$

The value of the integral in the right hand side of Eq. 6 is proportional to the area of the desorption peak.

The desorption rate per unit surface area is expressed as

$$R_d = \frac{dN}{dt} = \nu \exp(-E_d/RT)n^x, \qquad (7)$$

where ν is the pre-exponential factor, E_d is the activation energy of desorption, n is the number of adsorbed atoms per unit area, and x is the reaction order with respect to the adsorbed species. The desorption was operated in a linear temperature rise with time, *i.e.*, $T=T_0+\beta t$, where β is a coefficient of temperature rise. The differentiation of Eq. 7 with temperature shows that the temperature, T_m, at which the desorption spectrum gives a peak maximum can be correlated with the factors ν, E_d, β, and x by the following equation:

$$E_d/RT_m^2 = (x\, n_m^{x-1}\nu/\beta)\exp(-E_d/RT_m) \qquad (8)$$

where n_m is the number of adsorbed particles remaining at T_m. Then, it is found that

$$\log(T_m^2/\beta) = \frac{E_d}{2.303RT_m} + \log\frac{E_d}{R\nu x n_m^{x-1}}. \qquad (9)$$

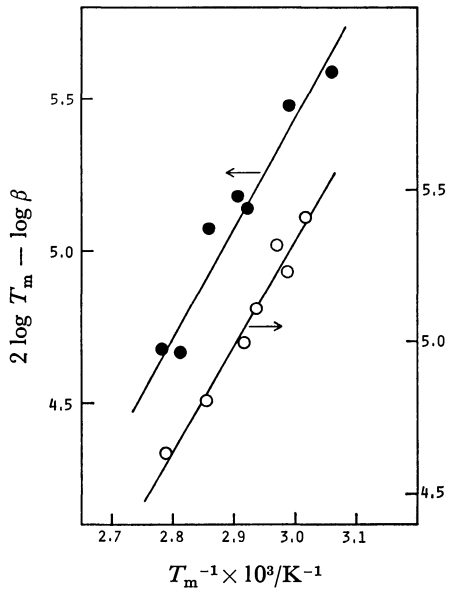

Fig. 3. Plots of (2 log T_m − log β) *vs.* T_m^{-1}.
○: H_2, ●: D_2.

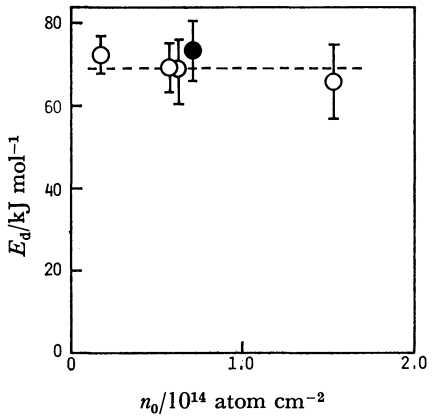

Fig. 4. Invariance of activation energy of desorption with surface concentration.
○: H_2, ●: D_2.

For a constant initial coverage, E_d and n_m would be unchanged even if β is varied. A plot of log (T_m^2/β) *versus* $1/T_m$ gives a straight line with slope of $E_d/2.303\,R$. This relationship is shown in Fig. 3 for adsorbed hydrogen and deuterium at the initial coverages of $6.4\pm0.2\times10^{13}$ H-atom cm^{-2} and $7.2\pm0.3\times10^{13}$ D-atom cm^{-2}, respectively. Figure 4 summarizes the activation energy of desorption as a function of the amount of desorption: Values of E_d for H_2, as shown by open circles, were constant at 68.6 ± 8.0 kJ mol^{-1} up to a surface concentration of 1.6×10^{14} atom cm^{-2}. The filled circle in Fig. 4 shows the activation energy of desorption for D_2. The obtained value of the energy was 73.6 ± 8.0 kJ mol^{-1}, which is slightly greater than that for H_2.

When the thermal desorption is carried out at constant β, the shifts of T_m shown in Fig. 2 lead to the determination of reaction order. Equation 8 can be rearranged to

$$2\log T_m - \frac{E_d}{2.303\,RT_m} = (1-x)\log n_m + \log\frac{\beta E_d}{x\nu R}. \quad (10)$$

Because E_d is constant with coverage, as seen from Fig. 4, a plot of $(2\log T_m - E_d/2.303\,RT_m)$ *versus* log n_m gives a straight line with a slope of $1-x$, where n_m is given by

$$n_m = \frac{CS}{A}\int_{t(T_m)}^{\infty}\Delta P\,dt. \quad (11)$$

The results are shown in Fig. 5. From the slope, the desorption order , x was evaluated to be 2.0 ± 0.2.

The values of E_d and x permitted us to calculate the frequency factor of desorption from the intercept of Fig. 2. This value of ν was found to be $1.0\pm0.5\times10^{-4}$.

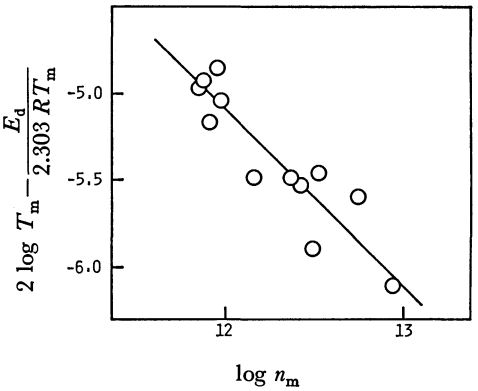

Fig. 5. A plot of $\left(2\log T_m - \frac{E_d}{2.303\,RT_m}\right)$ *vs.* log n_m.

Discussion

The present study proves that the thermal desorption is a useful method for determining the desorption kinetics. However, in typical adsorption systems many complicated situations occur;[14] there may be several different adsorbed states even for a single adsorbed species. In addition, the activation energy of desorption may depend on the concentration of adsorbed species and on the structures of surfaces. Transition metals such as W, Ni, Pt *etc.* have been found to show complicated desorption spectra of hydrogen because of superposed peaks.[14,15] It is, therefore, desirable to use more simple systems in order to perform the precise analysis of the desorption mechanism. In the present study, the desorption spectra on copper showed a single peak which shifted to the higher temperature side with the decreased coverage of surface. The activation energy of desorption was unchanged up to the surface concentration of 1.6×10^{14} atom cm^{-2} or $\theta_H=0.6$ when the saturated amount was estimated at 2.8×10^{14} atom cm^{-2} [8] (Fig. 4) and the desorption order was given by integer number as 2 (Fig. 5). All of these findings lead us to conclude that the chemisorption of hydrogen takes place dissociatively on a copper surface and that the interaction among adsorbed hydrogen atoms is quite weak.

In the previous studies of hydrogen adsorption and H_2–D_2 equilibration, it was found that the isothermal adsorption of hydrogen on a copper surface can be

interpreted in terms of the Langmuir equation for dissociative adsorption.[8,9] This behavior of adsorption was also verified by TD measurements. The activation energy of desorption evaluated by TD agreed well with that obtained from the kinetic measurement, 71 ± 4 kJ mol^{-1}. Further, the desorption rate constant at 287 K was evaluated by using the values of activation energy and the frequency factor as $3.3 \pm 2.0 \times 10^{-17}$ cm^2 molecule^{-1} s^{-1}, which is also consistent with the value $7.9 \pm 6.0 \times 10^{-17}$ obtained in the previous study. In the desorption of deuterium, T_m was higher than that of H_2 for the same fraction of coverage and E_d was also greater than that for H_2, indicating the presence of a normal isotope effect on desorption. The value of E_d for D_2 agreed with the previously obtained value within the experimental error.

In the analysis of the desorption spectrum, the magnitude of the evolution rate, relative to the changing rate of the accumulation in the system, takes an essential role is determining whether Eq. 5 exactly reflects the desorption process or not. When the difference between these two rates is not so large, Eq. 5 is not valid and its use would result in a lower value for the activation energy of desorption than the true one. In order to make the above situation clear, an exact simulation of Eqs. 4 and 7 for the second order desorption was performed by using a computer. As is seen from Figs. 6 and 7, the position of peak maximum shifted to the higher temperature side with the decrease of the pumping speed. The analysis of desorption spectra by using Eq. 9 resulted in the decrease of the apparent activation energy to 40.5 kJ mol^{-1} at 10 cm^3 s^{-1}. Such a depression of the energy seems to be the main reason why an incorrect energy value was obtained by using the usual high vacuum system with low evacuation conductance.[10] The desorption spectrum simulated at the speed of

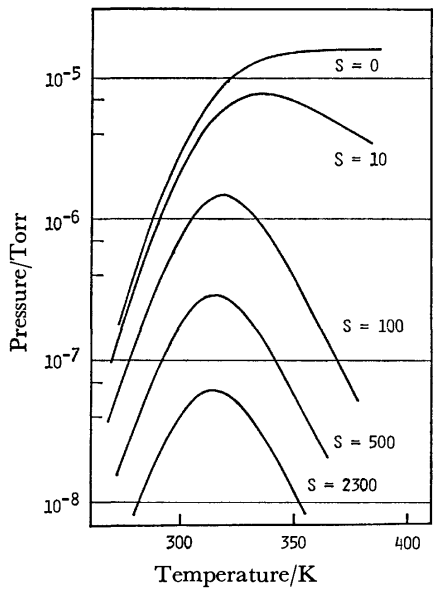

Fig. 6. Effect of pumping speed on desorption spectra. The spectra were simulated for different pumping speed, S (cm^3 s^{-1}) by using Eqs. 4 and 7 in the text. E_d: 68.6 kJ mol^{-1}, ν: 1×10^{-4}, β: 1 K s^{-1}, n_0: 1×10^{14} atom cm^{-2}, A: 4.2 cm^2, V: 410 cm^3.

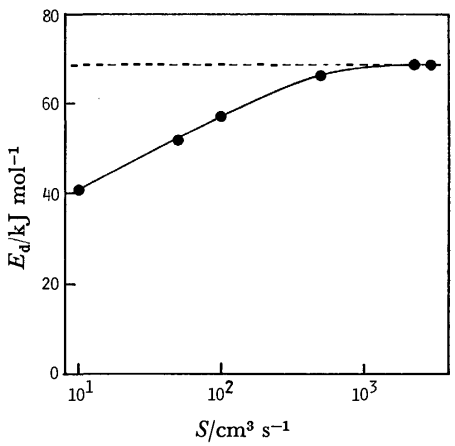

Fig. 7. Calculated activation energy of desorption as a function of pumping speed. Parameters used in the calculation were the same as those of Fig. 6 except that β is changed from 0.2 to 2 K s^{-1}. A dashed line shows the true value of activation energy of desorption.

2300 cm^3 s^{-1} accorded with that calculated from Eq. 5 within 0.1 K. This large difference of the two rates in the present study permitted us to determine exactly the kinetic parameters and mechanism of the desorption. In addition, the pressure gauge was located directly in front of the source of gas evolution; thus the pressure inside the cell and its change on heating was accurately followed and recorded by the gauge. It is to be noted that the same caution should be used for the gas chromatographic TD measurement with respect to the magnitude of the flow rate of the carrier.

Balooch *et al.* found that the activation energy for the adsorption of hydrogen on a copper surface depends on the crystallographic planes, as shown in the sequence $E_a(111) \gtrsim E_a(100) > E_a(113)$.[6] The present study cannot tell whether the desorption rate depends on the lattice planes or not. However, a single adsorbed state was observed on the polycrystalline copper used, and it is likely that the annealed surface exposed preferentially the (100) plane on which hydrogen is mainly adsorbed.

Classical trajectory calculations were applied to the adsorption of hydrogen on copper[9,16] and made possible the microscopic analysis of the process of dissociative adsorption. The desorption of the molecule from the surface is also interesting in view of the energy transfer from the lattice vibration to the vibration of adsorbed atoms and to the motion of molecules released from the surface. The results obtained here will be available for such microscopic descriptions of the behavior of adsorbed atoms. Trajectory calculation studies for the desorption of hydrogen from a copper surface are now in progress and will be published elsewhere.

(Received November 19, 1979)

The structure of the adsorbed layer of water on SnO_2 was investigated by means of thermal desorption, water physisorption, and electron diffraction, using four kinds of SnO_2 samples which differ in method of preparation. Two distinct peaks appear around 513 and 573 K in the thermal-desorption spectra. The peak around 513 K is due to the condensation dehydration of hydroxyls on the (100) plane of SnO_2, on which the two-dimensional condensation of water occurs. The peak around 573 K is associated with that on the (101) plane, on which the physisorption of water is strong and the two-dimensional condensation of water does not occur. The portion of the (100) plane occupied by water molecules is relatively small, and the 1 : 4 ratio (H_2O : OH) holds also on the surfaces on which the two-dimensional condensation of water does not occur. In conclusion, the fully hydroxylated surfaces of SnO_2 are hydrophobic in the sense that they sparsely adsorb water molecules.

In a series of studies[1-4] of the interaction between SnO_2 surfaces and water molecules, we have reported that a two-dimensional condensation of water occurs on the hydrated surface of the SnO_2 obtained from the calcination of stannic acid in air. The electron diffraction of SnO_2 particles and a crystallographic consideration of the hydroxylated surface structure lead to the conclusion that this phenomenon takes place on the surface hydroxyls formed on the (100) plane of SnO_2 with a rutile structure. Furthermore, the ratio of the number of physisorbed water molecules in the monolayer to that of the underlying surface hydroxyls was found to be about 1 : 3—4, indicating a very sparse packing of water molecules in the first physisorbed layer. Since the occurrence of two-dimensional condensation suggests the formation of a close-packed phase of the adsorbate at the monolayer coverage, the fact that water molecules condense two-dimensionally is apparently in conflict with the idea that water molecules are sparsely packed on the same surface.

It may reasonably be expected that there exist crystal planes other than (100), the relative area of which depends on the method of preparation, and that the formation or desorption energy of surface hydroxyls differs on different crystal planes. Therefore, it is interesting to investigate the dependence of the chemisorption or desorption energy of surface hydroxyls upon the nature of the crystal plane. Yamazoe *et al.*[5] reported on the desorbability of chemisorbed water on SnO_2 effected by means of a conventional temperature-programmed desorption technique, as a basis for the development of gas detectors. The aim of the present work is to correlate the peaks in the thermal-desorption spectra of surface hydroxyls to the crystal planes on SnO_2, and also to investigate the above-mentioned contradiction concerning the packing of water molecules on the hydroxylated SnO_2 surfaces.

Experimental

Materials. Tin (IV) oxide of a high purity (99.95%) was obtained from Mitsuwa Pure Chemicals, Ltd. (SnO_2-I). It was prepared by the same method as the sample which we had employed previously,[1-4] *i. e.*, by calcining β-stannic acid formed by oxidizing metallic tin with concd HNO_3. SnO_2-II was obtained by calcining α-stannic acid at 1073 K for 5 h in air, the latter having been prepared by the hydrolysis of $SnCl_4$ with ammonia water.[3] SnO_2-III was prepared by a gas-phase reaction.[6] A mixture of Sn and SnO_2 was heated in a quartz reaction tube at *ca.* 1473 K in a stream of N_2, and the resulting SnO gas was allowed to react with O_2 at the same temperature to give microcrystalline SnO_2 (SnO_2-III). SnO_2-IV was tin (IV) oxide (99.0%) prepared by Wako-Pure Chemicals, Ltd. O_2 and H_2 from a commercial gas cylinder were purified by passing them through a molecular sieve-5A cooled at 195 and 75 K respectively. D_2O (99.75%, Merck) was used without further purification.

Thermal Desorption. As has been described previously,[7] the measurement of the thermal desorption was carried out on a Sartorius vacuum-microbalance. SnO_2 can be readily reduced by evacuation at moderate temperature,[8] and the activity for water adsorption decreased upon reduction.[1,2,4] The surface cleaning of the sample, therefore, was carried out by the following procedure. The sample was evacuated at 773 K for 2 h under a vacuum of 1.3×10^{-2} Pa, heated in O_2 of 13.3 kPa at 773 K for 1 h, cooled room temperature in the O_2 atmosphere, and then evacuated briefly. The reduction of the samples was carried out by exposing the oxygenated sample to H_2 of 6.7 kPa at 433 or 473 K for 2 h. Then, the samples were exposed to saturated water vapor at room temperature for 15 h to ensure a full rehydroxylation of the surface. The thermal-desorption spectra were measured at a heating rate of 5/6 K min^{-1}. The amount of chemisorbed water was determined by the D_2O-exchange method:[9] a fully hydroxylated surface was subjected to three cycles of D_2O vapor exposure (2.0 kPa) at 313 K for 30 min and a subsequent brief evacuation. The number of surface hydroxyls was evaluated from the resulting weight increase in the sample.

Measurement of Water-physisorption Isotherms. The water-physisorption isotherms were measured by using a Sartorius microbalance, except for the case of the measurement of the isosteric heat of physisorption. The sample, rehydrated by the same pretreatment as in the thermal desorption experiments, was evacuated at 313 K for 4 h to remove the physisorbed water, after which the water adsorption was measured at 298 K. The adsorption equilibrium could be usually attained within 10 min, and the resulting isotherm was reversible. The isosteric heat of water physisorption was obtained by applying the Clausius-Clapeyron equation to seven isotherms, which were volumetrically measured in the range from 293 to 308 K. The specific surface area of the samples was determined by applying the BET method to the N_2 adsorption at the temperature of liquid nitrogen.

Residual Gas Analysis during Thermal Desorption. The sample was set into a vacuum line which was essentially

identical with that of the thermal-desorption apparatus, and then the temperature was raised at a constant rate of 10/6 K min^{-1} under evacuation. The change in the residual gas pressures was monitored continuously by means of a mass spectrometer, Hitachi RM-50.

Electron-diffraction Analysis. The electron diffraction was used to identify the exposed crystal surfaces of SnO_2. The measurement was made at an accelerating voltage of 200 kV in an electron microscope, Hitachi HU-200E.

Results and Discussion

Thermal-desorption Spectra of Surface Hydroxyls. The thermal-desorption spectra of surface hydroxyls on SnO_2 are shown in Fig. 1, where the desorption rate ($-dw/dT$) has been obtained by the graphical differentiation of the original thermal-gravimetrical-analysis curve. Oxygenated samples gave two distinct peaks, around 513 (Peak 1) and 573 K (Peak 2), together with the neighboring shallow peaks, which indicate a complex surface heterogeneity, common to all three samples, SnO_2-I, -II, and -III. Peak 1 is the greatest in SnO_2-I and the smallest in SnO_2-III. On the contrary, Peak 2 is very large in SnO_2-III and smaller in SnO_2-I and -II. These two peaks are united in oxygenated SnO_2-IV, indicating that the desorption energy of surface hydroxyls on this sample is heterogeneous. The H_2 treatment of every sample considerably reduced the height of these peaks or caused the disappearance of the peaks in the thermal-desorption spectra. These results indicate that the H_2 treatment of a sample increases the surface heterogeneity, which is consistent with the results[4] obtained from the heat of immersion, and that it suppresses the formation of surface hydroxyls.

Since the overlapping of Peak 2 with the others is smaller for SnO_2-III, a conventional line-shape

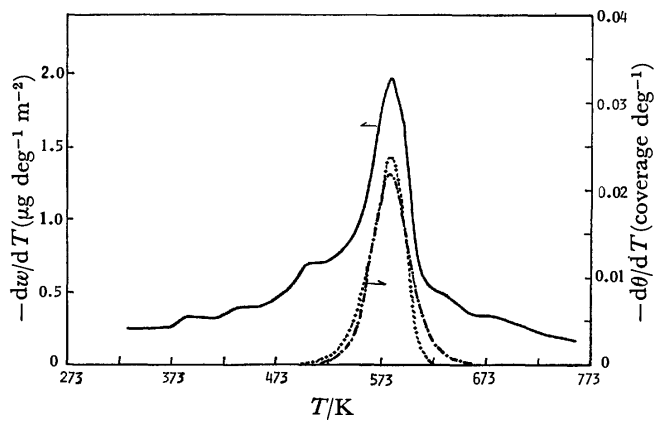

Fig. 2. Line shape analysis of thermal desorption spectrum of chemisorbed water on SnO_2-III.
Full line: experimental, broken line: first order, $E=174$ kJ mol^{-1}, $\nu=3\times10^{12}$ s^{-1}, dotted broken line: second order, $E=238$ kJ mol^{-1}, $\nu=3\times10^{18}$ s^{-1}.

analysis[10] of this peak allows us to estimate the parameters of the desorption kinetics. In the present study, the activation energy (E) and the frequency factor (ν) of the desorption, which give a peak maximum temperature and a peak half-width similar to those of the observed spectrum, were determined using the Polanyi-Wigner desorption-rate equation:[10]

$$-d\theta/dT = (\nu/\beta)\theta^n \exp(-E/RT) \quad (1)$$

where β is the heating rate; θ, the surface coverage of the adsorbed species, and n, the order of the desorption reaction. As is shown in Fig. 2, we could obtain the reasonable values of $E=174$ kJ mol^{-1} and $\nu=3\times10^{12}$ s^{-1} with the assumption of a first order or of $E=238$ kJ mol^{-1} and $\nu=3\times10^{18}$ s^{-1} with the assumption of a second order. In any case, it is evident that the surface hydroxyls which gave rise to Peak 2 are uniform in character, in the sense that an observed desorption peak can be approximated by that calculated with a constant value of the desorption-activation energy, E. The maximum temperature of Peak 1 is independent of the preparation method; from its value, the desorption activation energy was calculated to be 153 kJ mol^{-1} at $\nu=3\times10^{12}$ s^{-1} assuming the first-order kinetics.

In the present work, the gravimetric method was adopted for the measurement of the thermal-desorption spectra of surface hydroxyls. Therefore, it is necessary to check whether or not surface species other than the surface hydroxyls are removed, since SnO_2 is readily reduced when it is heated *in vacuo*. The partial pressure of water in the residual gas during thermal-desorption measurements was found to change similarly to the thermal-desorption spectra shown in Fig. 1. The removal of the surface oxygen of SnO_2 by reduction was monitored by measuring the change in the partial pressures of CO, O_2, and CO_2 in the residual gas. The results revealed that the reduction of the sample took place above *ca.* 473 K, and that its influence on the shape of the peaks in the thermal-desorption spectra was insignificant.

Correlation between the Peaks in Thermal-desorption Spectra and the Jump in the Water-adsorption Isotherm. The

water-physisorption isotherms obtained on the oxygenated and reduced samples are illustrated in Fig. 3. It may be seen from Fig. 3 that the shapes of the isotherm vary drastically with the method of preparation and the pretreatment of the sample. The oxygenated SnO_2-I exhibits a clear jump, which arises from the two-dimensional condensation of water,[1] in the range of relative pressures of 0.02—0.04. This jump can be observed slightly on SnO_2-II, but not on SnO_2-III and -IV. The height of Peak 1 in the thermal-desorption spectra decreases in the same order: SnO_2-I>SnO_2-II> SnO_2-III≃SnO_2-IV, and becomes negligible in SnO_2-III and IV, as has been stated above. Therefore, it is reasonable to consider that the surface hydroxyls of Peak 1 are closely related to the two-dimensional condensation of water. As was demonstrated in the case of SnO_2-III, the surface hydroxyls of Peak 2 are evidently irrelevant to this phenomenon. H_2-treatment caused a marked decrease in the adsorbed amount and, at the same time, a disappearance of the jump in the isotherms for SnO_2-I and -II.

The relation between the amounts of physisorbed and chemisorbed water on SnO_2 are listed in Table 1. V_p is the monolayer capacity obtained by the B-point method from the adsorption isotherms. V_c is the amount of water chemisorbed expressed by OH groups nm^{-2}, which is obtained from the H-D exchange capacity with D_2O vapor. V_r is the reduced amount of SnO_2 samples, expressed by O atoms nm^{-2}, which was calculated from the weight decrease after H_2 reduction. The last column of Table 1 shows the ratio of the number of physisorbed water molecules in the monolayer to that of the underlying surface hydroxyls. The ratio, which is independent of both the method of preparation and the pretreatment conditions, was found to be about 1:4 (H_2O: OH), as has been reported previously.[1,2] Here, it is interesting to note that H_2-treatment reduces the amounts of both the physisorption and chemisorption of water, and that the ratio remains almost unchanged. This suggests that the ratio of about 1:4 (H_2O: OH) holds on the surfaces which are independent of the occurrence of the jump in the adsorption isotherm.

On the same sample as SnO_2-I which had a clear jump in the isotherm in a previous paper,[2] the isosteric heat (q_{st}-θ) curve exhibited a plateau at the same coverage as the jump appeared, indicating a strong lateral interaction between physisorbed water molecules.[1,2] Fig. 4 shows the q_{st}-θ curves of SnO_2-III and -IV, which have no jump in the adsorption isotherm, together with that of the same sample as SnO_2-I which has been reported in the previous paper.[2] The q_{st} curve of SnO_2-III, whose surface was covered with surface hydroxyls with almost the same desorption energy (Peak 2), has a pronounced plateau in the range of coverage of 0.3—0.7. However, this does not reflect a lateral interaction of physisorbed molecules, which leads to the occurrence of the jump, because no jump appeared in the isotherm. It may be a simple indication of surface homogeneity for water physisorption. As the ratio of V_p to V_c on SnO_2-III as well as

Sample was as follows: SnO_2-III (○); SnO_2-IV (⊙); SnO_2-I (●).
A broken line represents the heat of liquefaction of water. Arrows indicate the monolayer coverage of water molecules.

on the other three samples was about 1 : 4, it may be considered that the surface hydroxyls of Peak 2 offer adsorption sites which are homogeneous and separated to such an extent that physisorbed water molecules can not interact with each other. SnO_2-IV, whose surface was covered with surface hydroxyls with a heterogeneous desorption energy, as can be understood from the shallow peak in Fig. 1, gave a q_{st} curve indicating a surface heterogeneity (Fig. 4). The ratio of V_p to V_c on this sample was about 1 : 4, as in the samples with homogeneous surfaces.

The amount of surface hydroxyls giving rise to the two desorption peaks, 1 and 2, in SnO_2-I, which exhibits a clear jump in the physisorption isotherm of water, were estimated roughly from the integrated peak area of the thermal-desorption spectrum. The surface hydroxyls of Peak 1 were only about 7—10% of the total surface hydroxyls, and those of Peak 2, about 13—18%, while the remaining part was occupied by heterogeneous surface hydroxyls. The following conclusion can be drawn from these results: the small ratios of V_p to V_c observed on the SnO_2 sample, where the two-dimensional condensation of water takes place, originated from a simple comparison of the number of the physisorbed water molecules with that of the underlying surface hydroxyls over the whole surface. Thus, it has been found that SnO_2 surfaces, except for the particular ones which are relevant to the two-dimensional condensation of water, are hydrophobic in the sence that they sparsely adsorb water molecules.

Morphological Considerations. Morphological studies[11,12] of the SnO_2 single crystal have shown that the (100), (110), and (101) were well-developed crystal planes, independent of the growing conditions. It was previously inferred[3] from the electron diffraction that SnO_2-I was composed of microcrystals with well-developed (110) and (100) crystal planes. A crystallographic consideration led to the conclusion[2] that the (100) plane of the rutile structure of SnO_2 is responsible for the occurrence of the two-dimensional condensation

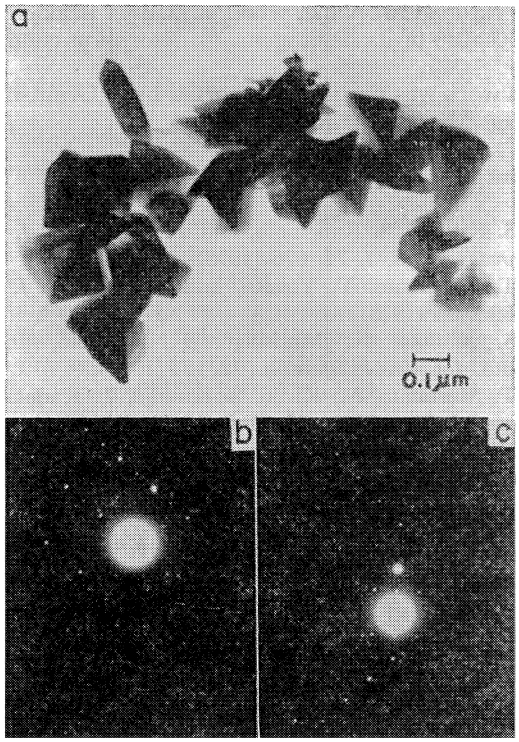

Fig. 5. Electron micrograph (a) and diffraction patterns (b, c) of SnO_2-III. b; N pattern of (101), c; N pattern of (001).

of water. The electron micrograph of Fig. 5 showed that SnO_2-III was composed of particles with a well-defined shape and with an acute angle; their electron diffraction gave two typical types of diffraction patterns, as is depicted in Fig. 5. The crystallographic analysis proved that these are N patterns of the (101) and (001) planes respectively of the rutile structure of SnO_2. The appearance of the former pattern was more frequent, *i.e.*, more than twice as frequent, than that of the latter. Further, the SnO_2-III sample, which has no jump in the water isotherm, did not give the N pattern of the (100) plane of SnO_2. This provides strong support for the idea that the (100) plane of SnO_2 is responsible for the occurrence of the two-dimensional condensation of water, as was proposed earlier.[2,4]

A crystallographic consideration showed that the surface hydroxyls on the (101) plane as well as on the (110) and (111) planes can not form closed hydrogen bonds.[2] Therefore, it may be concluded that the surface hydroxyls on the (101) plane, which give rise to a desorption peak, 2, around 573 K, interact strongly with water molecules through hydrogen bonding, whereas those on the (100) plane, which give rise to a desorption peak, 1, around 513 K, interact with water weakly to cause the two-dimensional condensation on the surfaces. Jones and Hockey[13] suggested that the desorption energy of the surface hydroxyls on the rutile (110) plane changed with the progress of desorption, according to Peri's model,[14] which explains why even uniformly chemisorbed water gives heterogeneous desorption energy on its successive removal. It might be considered that the surface hydroxyls on the (110) plane of SnO_2 desorb *via* a mechanism similar to that

on the rutile (110) plane, where a distinct peak can not arise because of its heterogeneous desorption energy.

This work was partially supported by a Grant-in-Aid from the Ministry of Education.

The Thermal Unimolecular Decomposition of Methyl Chloride behind Shock Waves

Osamu KONDO, Ko SAITO,* and Ichiro MURAKAMI

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730

(Received November 22, 1979)

The thermal decomposition of methyl chloride diluted in Ar has been studied behind shock waves over the temperature range between 1680 and 2430 K and the total density range of 2.0×10^{-6}—3.5×10^{-5} mol cm^{-3}. The decomposition rate was monitored by means of the UV absorption of the CH_3 radical produced. The initiation reaction was found to be the C–Cl bond fission; the process proceeded in the fall-off region under the present experimental conditions. From the fall-off data, low- and high-pressure rate constants (k_0/[Ar] and k_∞) were obtained by the application of a refined RRKM theory involving a weak collision effect. Thus, the Arrhenius expressions were given as:

$$k_0/[\mathrm{Ar}] = 10^{15.56}\exp(-247\ \mathrm{kJ\ mol^{-1}}/RT)\ \mathrm{cm^3\ mol^{-1}\ s^{-1}},$$
$$k_\infty = 10^{13.86}\exp(-383\ \mathrm{kJ\ mol^{-1}}/RT)\ \mathrm{s^{-1}}.$$

The collision efficiency factor, β_c, was obtained as 0.02 at the mean temperature of the experiment by comparing the low-pressure rate constant with the strong collision-rate constant. The high-pressure rate constant was well explained by the maximum free-energy criterion presented by Quack and Troe.

The thermal unimolecular decompositions of halomethanes are very interesting in the following points: 1) They are important test cases for the theories of unimolecular reactions; 2) There are two possible reaction channels as the initiation reaction (*i.e.*, simple bond fission and molecular elimination); 3) The pressure dependence of the unimolecular reaction varies depending on the channel and halogen. The thermal decompositions were previously investigated behind shock waves for CHF_3,[1–4] CH_3F,[5] $CHClF_2$,[4] $CHCl_3$,[4,6] and CH_3I.[7] It was found that the decompositions of these molecules are initiated *via* the molecular elimination except for the case of CH_3I. A common feature of these reactions is that the heats of reaction, ΔH°_r, for the molecular eliminations are always substantially lower than that of the simple bond fissions. In most cases, the unimolecular processes of the molecular elimination were in the high- or falloff-pressure regions under the usual shock-wave conditions.[8] According to the experimental results obtained hitherto, the molecular eliminations which have three-center activated complexes have potential barriers above, but not more than 40 kJ mol^{-1}, the heats of reaction. However, for the case of CH_3I, the value of ΔH°_r for the C–I bond fission is rather lower than that of the HI elimination by about 159 kJ mol^{-1}. Moreover, the unimolecular process of this reaction was found in the low-pressure region. The energy-transfer efficiency in the CH_3I–Ar system was found to be very small.

For the case of CH_3Cl, the heats of reaction of the two channels are very close to each other (the ΔH°_r for the C–Cl bond fission is less than that for the HCl elimination by about 25 kJ mol^{-1}). It can, therefore, be expected that the decomposition occurs mainly *via* the C–Cl bond fission, as has been proposed by Shilov and Sabirova,[9] who investigated the pyrolysis in a flow system. If the experimental data for a unimolecular reaction are obtained in a pressure region, it is, in principle, possible to evaluate the rate constants over the whole pressure region involving low- and high-pressure limits by using currently proposed unimolecular theories. Thus, we can discuss, in the high-pressure region, the intramolecular energy distribution and the form of the activated complex, and, in the low-pressure region, the intermolecular energy transfer.

The present paper will report the thermal decomposition of methyl chloride behind shock waves by monitoring the CH_3 behavior. In this work, we could determine high- and low-pressure rate constants from the fall-off data for the primary unimolecular reaction.

Experimental

The experiments have been performed in a shock tube 5 cm in internal diameter. A detailed description of the procedure was given in a previous paper.[10] The UV-absorption system in this work consisted of a deuterium lamp (HTV, L544) as a light source, a monochromator (Jarrell-Ash, 0.25 M), and a photomultiplier (HTV, R106UH). Output signals from the photomultiplier were fed into a pre-amplifier (Iwatsu DA-2A) and then recorded with a transient recorder (Kawasaki Electronica, TM-1410). The resultant rise time of the signal was about 5 μs, enough for the present purposes. The physical properties of the shock-heated gas were calculated from the incident-shock velocity assuming non-reaction conditions. Although relatively high CH_3Cl mixtures (3—5 mol %) were used occasionally, it was considered that the effect of the enthalpy change during the reaction was negligibly small in the early stage of the reaction, from which the rate data were determined.

Methyl chloride (with a 99.5% stated minimum purity) and Ar (99.998%) were used without further purification. Mixtures (0.2—5.0 mol % CH_3Cl in Ar) were prepared in 10-l glass flasks and were allowed to stand for more than 12 h before use. The experimental conditions behind shock waves were as follows: temperature = 1680—2430 K and total density = 2.0×10^{-6}—3.5×10^{-5} mol cm^{-3}.

The methyl radical has an absorption band due to the $^2A_1\leftarrow{}^2A_2$ electronic transition which has a maximum at 216 nm.[11] Recent high-temperature measurements of the absorption coefficient at two laboratories have shown a good agreement, within the range of experimental error.[12,13] Glänzer *et al.*[12] determined the absorption coefficient of CH_3 produced from shock-heated azomethane at 216 nm (FWHM = 1.6 nm) in the temperature range of 1200—1800 K. Tsuboi[13] also

measured the absorption coefficient at 216 nm (FWHM= 1.4 nm) in a system of ethane–Ar mixtures in the range of 1500—2300 K. Since, in the present study, the absorption measurements were performed at much the same wavelength (FWHM=1.65 nm), it was considered that the absorption coefficient and its temperature dependence reported by the above investigators could be applied to the present analysis of the absorption data without any corrections.

Results

Figure 1 shows a typical absorption record behind reflected shock waves. The absorption intensity begins to increase just behind the reflected shock front and seems to approach a steady value as the reaction proceeds. At the observed wavelength, there is no absorption by the reactant. The products which are considered to have absorptions around 216 nm are C_2H_2, C_2H_3Cl, and HCl, besides the CH_3 radical. The absorption coefficient of C_2H_2 at this wavelength is known to be as small as 1/15 that of CH_3.[13] From the data of the absorption coefficient of C_2H_3Cl at 230 nm ($\varepsilon \simeq 2\times10^5$ cm^2 mol^{-1} at 1600 K),[14] we could estimate that the value at 216 nm is about one-third that of CH_3 at 2000 K. However, since C_2H_3Cl is not the main product, as will be seen later in the computer simulation, its contribution to the absorption profile is negligible. HCl has an absorption band in the vacuum UV region with a maximum at 150—160 nm (ε (160.8 nm)= 1.8×10^6 cm^2 mol^{-1} at 2000 K),[15] while around 200 nm it has a weak absorption which is less than one-tenth the maximum intensity at room temperature.[16] Therefore, the contribution of the HCl absorption to the CH_3 measurement at 216 nm is thought to be negligibly small.

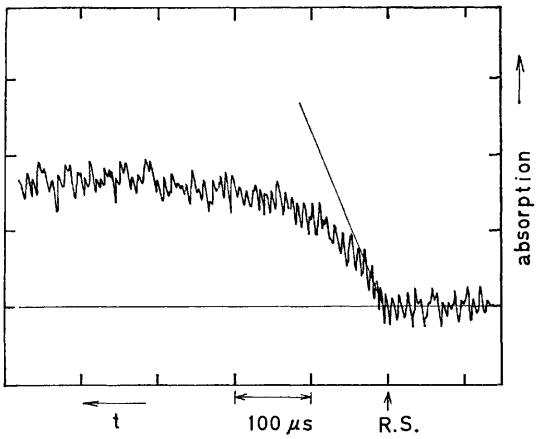

Fig. 1. Typical CH_3 absorption trace at 216 nm during decomposition of CH_3Cl.
T_5=2007 K, $\rho_5=3.52\times10^{-5}$ mol cm^{-3}, 0.5 mol % $CHCl_3$ in Ar. R. S. denotes the reflected shock front.

The initial rate of the CH_3 production was determined by the following relation:

$$\text{Rate} = \{\mathrm{d}[CH_3]/\mathrm{d}t\}_{t=0} = r_0/\varepsilon l$$

$$r_0 = \{\mathrm{d}\ln(I_0/I)/\mathrm{d}t\}_{t=0}$$

where ε is the absorption coefficient; l, the optical path length; I_0, the light intensity of 100% transmission, and

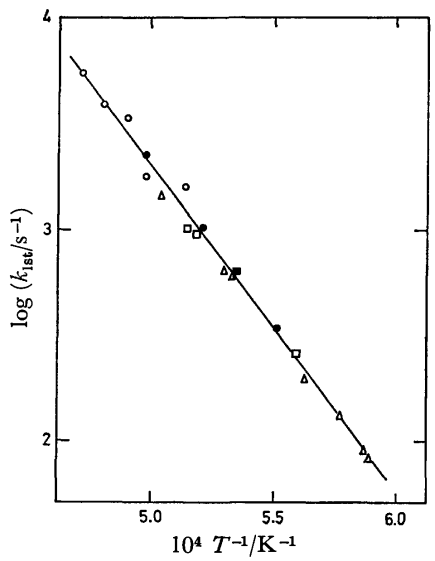

Fig. 2. Arrhenius plot of k_{1st} (initial rate constant of CH_3 production) for different mixtures and at a constant pressure of 5.0 atm (1 atm=101325 Pa).
○: 0.2%, ●: 0.5%, ■: 1.0%, △: 2.0%, □: 2.5%.

I, the intensity of the light that has transmitted the sample gas. In practice, the initial gradient was determined from the initial portion corresponding to the region within about 20% of the steady value. To ascertain the order of the CH_3 production rate with respect to the reactant concentration, the Arrhenius plots of the first-order rate constant, k_{1st}=Rate/$[CH_3Cl]_0$, obtained for various mixtures and at a constant total pressure were made; they are shown in Fig. 2. From this figure it may be seen that k_{1st} does not show any systematic departure from a straight line

Table 1. Arrhenius parameters of k_{1st}

Total density / mol cm^{-3}	T / K	A / s^{-1}	E / kJ mol^{-1}
2.0×10^{-6}	1892—2253	8.1×10^{8}	236 ± 4
3.5×10^{-6}	1790—2428	1.9×10^{9}	247 ± 8
1.4×10^{-5}	1678—2119	1.5×10^{10}	269 ± 10
3.7×10^{-5}	1700—2117	8.5×10^{10}	292 ± 14

as the initial concentration of CH_3Cl changes by 12.5-fold. The same results were obtained under the other total pressures adopted. Figure 3 shows a total density dependence of k_{1st}. Also in Table 1 the values of the Arrhenius parameters of k_{1st} are listed for each total density. From Fig. 3 and Table 1 it appears that the apparent first-order rate constants of the CH_3 production are in the fall-off region under the present experimental conditions. In the fall-off region, both the intermolecular energy transfer process and the intramolecular behavior are important equivalently. Thus, it is necessary to evaluate the limiting rate constants for the discussion based on kinetic theories.

Discussion

Reaction Mechanism of the CH_3Cl Decomposition. In the case of methyl chloride, the following two channels are probable for the initiation reactions:

(1) $CH_3Cl\,(+M) \longrightarrow CH_3 + Cl\,(+M)$
$\Delta H^\circ_{r0} = 347$ kJ mol^{-1}

(1a) $CH_3Cl\,(+M) \longrightarrow CH_2 + HCl\,(+M)$
$\Delta H^\circ_{r0} = 372$ kJ mol^{-1}.

Channel 1 has no barrier above the heat of reaction along the reaction coordinate if the potential barrier due to the centrifugal force is neglected. On the other hand, Channel 1a has an activation energy higher than ΔH°_{r0} because, in this channel, a three-center activated complex may be formed during the course of the reaction. Thus, the difference in the activation energies between the two channels becomes larger than the difference in the heats of reaction. Assuming that the values of the preexponential factor are equal, a rough estimation shows that the rate constant, k_{1a}, is smaller than k_1 by several hundredths at 2000 K. Furthermore, in Channel 1a the CH_2 radical produced is the $^3B_1$ state (a spin-forbidden reaction is known to have a small A factor).

A mechanism of the thermal decomposition of methyl chloride has been proposed by Shilov and Sabirova,[9] who investigated the decomposition at around 1100 K and at pressures of 10—15 Torr (1 Torr=133.322 Pa) in a flow system. From the concentration ratios of the products (HCl, CH_4, and C_2H_2), they proposed the following mechanism:

(1) $CH_3Cl \longrightarrow CH_3 + Cl$
(2) $CH_3Cl + Cl \longrightarrow CH_2Cl + HCl$
(3) $CH_3Cl + CH_3 \longrightarrow CH_2Cl + CH_4$
(4) $CH_3Cl + CH_2Cl \longrightarrow CH_2Cl_2 + CH_3$
(7) $2CH_2Cl \longrightarrow C_2H_4Cl_2$
(8) $C_2H_4Cl_2 \longrightarrow C_2H_3Cl + HCl$
(9) $C_2H_3Cl \longrightarrow C_2H_2 + HCl$

To consider the reaction process in further detail, several reactions including reverse reactions must be added to the above mechanism. Thus, we selected the following as probable reactions:

(1) $CH_3Cl\,(+M) \rightleftharpoons CH_3 + Cl\,(+M)$
(2) $CH_3Cl + Cl \rightleftharpoons CH_2Cl + HCl$
(3) $CH_3Cl + CH_3 \rightleftharpoons CH_2Cl + CH_4$
(4) $CH_3Cl + CH_2Cl \rightleftharpoons CH_3 + CH_2Cl_2$
(5) $C_2H_6\,(+M) \rightleftharpoons 2CH_3\,(+M)$
(6) $Cl_2 + M \rightleftharpoons 2Cl + M$

The values of ΔH°_{f298} and ΔG°_T and the rate constants are listed in Table 2. For the present purposes, we need to know how the CH_3 production rate is affected by the secondary reactions. This is important, particularly because we base the decomposition-rate measurement on the initial slope of the CH_3 absorption records. Since there are no available kinetic data for Reactions 4, 7, and 10, we first assumed that Reaction 4 was negligible and that the values of k_7 and k_{10} were equal to the rate constant for the CH_3 recombination. The k_{1st} value corresponding to the total density considered was used as the rate constant of Reaction 1. At 2007 K, a good agreement is seen between the calculation and the observation over the whole range of reaction times, as is shown in Fig. 4. At 1730 K, however, the CH_3 concentration profiles show that the calculation gives a lower steady value, within a shorter reaction time, compared with the observed profile, as is shown in Fig. 5. It was, therefore, necessary to check the rate constants of the reactions which were connected with the CH_3 production. If the alternative reaction channel of the initiation, *i.e.*, Reaction 1a, is considered, a secondary reaction such as (b) $CH_3Cl + CH_2 \rightarrow CH_3 + CH_2Cl$ is needed for the production of the CH_3 radical. An Arrhenius expression of k_b was assumed by the use of the BEBO method[17] and the transition state theory as:

$$k_b = 10^{11.5}\exp\{-(41.8\text{ kJ mol}^{-1})/RT\}\text{ cm}^3\text{ mol}^{-1}\text{ s}^{-1}.$$

It was ascertained by simulations that the concentration of CH_3 produced by the above reaction was quite low compared with the observed value. Also, it was found that Reaction 5 does not affect the overall reaction profile of CH_3. Thus, it is likely that the computed low values of the steady concentration of CH_3 at lower temperatures are ascribable to the assumption for the k_4, k_7, and k_{10} values. Tentatively, if we use $k_4=10^{11.3}$ cm^3 mol^{-1} s^{-1} and $k_7=k_{10}=10^{11.5}$ cm^3 mol^{-1} s^{-1} at 1730 K, the calculation shows a good agreement with the observed profile (the dotted line in Fig. 5). However, we could not determine a unique set of rate constants which agrees with the profiles obtained over the temperature range and the concentration range employed in this work. Consequently, from the simulation study we found the following facts: (a) At lower temperatures Reaction 4 affects the CH_3 profile seriously, so that it cannot be neglected in considering the reaction mechanism. (b) The recombination reactions 7 and 10 could not be replaced by the recombination rate of CH_3; therefore, they should be evaluated independently. In this respect, it seems unreasonable to use the collision number as the recombination rate constant as in the case of C_2H_5.[18] (c) It was ascertained that the initial slope of the CH_3 production corresponds fairly well to the initiation reaction, *i.e.*, Reaction 1.

Evaluation of Low- and High-pressure Rate Constants.

a. Strong Collision Assumption: In order to evaluate the low- and high-pressure limit rate constants, we first treat the fall-off data on the basis of the strong collision assumption. Figure 6 shows fall-off curves of k_{1st}, with the temperature as a parameter. The solid lines in the figure were calculated by the reduced-form Kassel theory proposed by Troe and Wagner.[19] For the Kassel parameters, S_k and B_k, the definitions as suggested by Troe[20] have been adopted ($S_k=U_{vib}/RT+1=5.4$, 5.5, 5.7, 5.8 and $B_k=B_k(E_0, T, S_k, \nu_i)=15$, 14.5, 14, 13 at 1800, 1900, 2000, and 2100 K respectively, where U_{vib} is the vibrational energy content of CH_3Cl; E_0, the zero temperature activation energy, and ν_i, the vibrational frequencies of CH_3Cl, as taken from Ref. 11. The reduced fall-off curves were obtained using the Kassel integral tables[20] and fitted to the experimental data points in such a way as to meet the following requirements at the same time: (a) The calculated

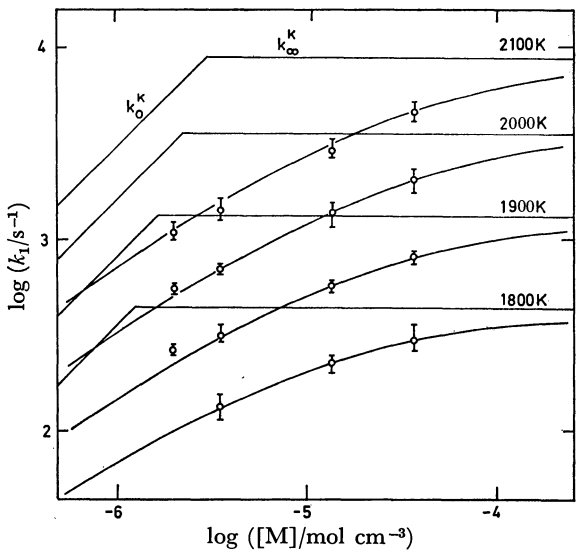

Fig. 6. Pressure dependences of k_{1st} at different temperatures. Full curves are calculated fall-off curves.

curves fit the experimental data points reasonably well, (b) the low- and high-pressure rate constants give temperature-independent activation energies, E_{a0} and $E_{a\infty}$, in the experimental region, and (c) the difference between E_{a0} and $E_{a\infty}$ values obtained is represented approximately by this relation:

$$E_{a\infty} - E_{a0} = (S_{eff}+0.5)R\bar{T},$$

where $S_{eff}=U_{vib}/RT$ and $\bar{T}$ is the mean temperature of the experiments.

The rate constants for the high-pressure limit, k_∞^K, and for the low-pressure limit, k_0^K/[Ar], were then determined at the four temperatures indicated in Fig. 6. Thus, these respective Arrhenius expressions were obtained:

$$k_\infty^K = 10^{11.78}\exp(-315\,\text{kJ mol}^{-1}/RT)\ \text{s}^{-1},$$

$$k_0^K/[\text{Ar}] = 10^{15.08}\exp(-224\,\text{kJ mol}^{-1}/RT)\ \text{cm}^3\ \text{mol}^{-1}\ \text{s}^{-1}.$$

The values of the rate constants evaluated by the above procedure are considered to have an error factor of *ca.* 2.

At first sight, it is likely that the activation energies, $E_{a\infty}$ and E_{a0}, are somewhat lower than those to be expected from the bond-dissociation energy. Also, the preexponential factor of the high-pressure rate constant is considered to be lower than the usual values for the single-bond fission reaction, *i.e.*, $A=10^{13.5\pm1.5}\ \text{s}^{-1}$. In the literature there are experimental results which show somewhat low values for the high-pressure-limit A factor, *e.g.*, $A=10^{11.79}\ \text{s}^{-1}$ for $COF_2\rightarrow COF+F$[21] and $A=10^{12.95}\ \text{s}^{-1}$ for $SF_6\rightarrow SF_5+F$.[22] It is noticable that these experiments were performed in the fall-off region and that the values of the high-pressure rate constant were evaluated by the extrapolation of fall-off curves based on the strong collision assumption. Later Rabinovitch *et al.*[23] corrected the small A factor for the above SF_6 dissociation by considering the weak collision effect to obtain a reasonable value, such as $A=10^{14.11}\ \text{s}^{-1}$. Thus, the above unexpectedly low value of the A factor for $CH_3Cl\rightarrow CH_3+Cl$ may be considered to be the result of the strong collision assumption.

b. Weak Collision Effect on Fall-off Curves: Recently, Luther and Troe[24] published an easy method to obtain a reduced fall-off curve including the weak collision effect. According to this method, the reduced-form rate constant, k/k_∞, is written by the product of three factors as:

$$k/k_\infty = F^{LH}(k_0/k_\infty)F^{SC}(k_0/k_\infty)F^{WC}(k_0/k_\infty) \qquad (I)$$

where $F^{LH}(k_0/k_\infty)$ is a simple Lindemann-Hinshelwood-type fall-off curve, in which the rate constant of the spontaneous reaction, $k(E)$, is independent of the energy,[25a] $F^{SC}(k_0/k_\infty)$ is a factor which includes an energy dependence of $k(E)$,[25b] and $F^{WC}(k_0/k_\infty)$ is a factor pertaining to the weak collision effect.[25c] The parameters used in the calculation of Eq. I are listed in Table 3. Figure 7 shows reduced fall-off curves calculated on the basis of Eq. I. Comparing the two types of fall-off curves in Figs. 6 and 7, it appears that, in the latter, the fall-off region is broad and that the data points fit better than in the former. From the revised fall-off curves in Fig. 7, the high- and low-pressure rate constants are evaluated again, as respectively:

Table 3. Evaluated parameters used for the calculation of k_∞

$\frac{T}{\text{K}}$	S_K	B_K	F^{SC}_{center}	N^{SC}	F^{WC}_{center} a)	N^{WC} a)
1800	5.4	16.1	0.34	1.363	0.63	1.96
1900	5.5	15.6	0.34	1.368	0.62	1.98
2000	5.7	15.5	0.33	1.383	0.62	2.04
2100	5.8	15.1	0.33	1.387	0.62	2.06

a) In the calculations of F^{WC}_{center} and N^{WC}, β_C was taken to be 0.037 at 1800 K (which was the experimental value evaluated from the fall-off curve based on the strong collision assumption) and to have a temperature dependence of $T^{-1.5}$.

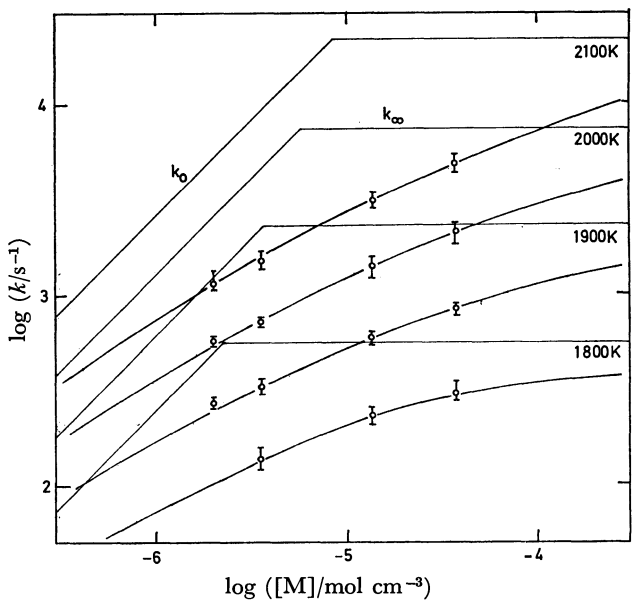

Fig. 7. Fall-off curves computed by considering the weak collision effect.
Data points are the same as in Fig. 6.

$k_\infty = 10^{13.86} \exp(-383 \text{ kJ mol}^{-1}/RT) \text{ s}^{-1}$,

$k_0/[\text{Ar}] = 10^{15.56} \exp(-247 \text{ kJ mol}^{-1}/RT) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$.

The error limits involved in these rate constants are considered to be less than a factor of two. It appears that the values of the activation energies and the preexponential factors appearing in the above results are not unexpected when compared with those of other, similar reactions for the single-bond fission.

Calculation of the Unimolecular Rate Constants. In order to ascertain the validity of the high- and low-pressure limit rate constants determined above, it is nescessary to calculate the rate constants theoretically by using currently useful methods. Thus, we will first perform RRKM calculations for the low-pressure rate constant and discuss the intermolecular energy transfer efficiency at high temperatures. Next, we will calculate high-pressure-limit rate constants by evaluating the maximum free energy in the course of the reaction path for the simple bond-fission process.

a. Low-pressure-limit Rate Constant: The theoretical calculation of the low-pressure rate constant was performed by using the appropriate RRKM strong-collision formulation given by Troe:[26,27]

$$k_0^{\text{SC}} = [\text{M}] Z_{\text{LJ}} \rho_{\text{vib}}(E_0) RT Q_{\text{vib}}^{-1} \exp(-E_0/RT) F_{\text{E}} F_{\text{rot}} F_{\text{anh}} \quad \text{(II)}$$

where Z_{LJ} is the Lennard-Jones collision frequency; $\rho_{\text{vib}}(E_0)$, the vibrational energy level density at E_0; E_0, the threshold energy of the reaction; Q_{vib}, the vibrational partition function; F_{E}, the energy dependence of the density of states; F_{rot}, the centrifugal correction factor, and F_{anh}, the anharmonicity factor.[28] The calculation of Eq. II was performed at four different temperatures. The calculated results are listed in Table 4. The molecular constants used in the calculation are shown in the footnote of Table 4.

Actually, at high temperatures the strong collision assumption is not considered to hold; that is, the average energy, $\langle \Delta E \rangle$, which is transferred during collisions between the reactant and the diluent molecule is much lower than RT, the thermal energy of the system. This effect, the weak collision effect, causes a reduction in the apparent reaction rate at high temperatures. The parameter expressing the weak collision effect is defined as the collision efficiency, β_{c}:

$$\beta_{\text{c}} \equiv k_0^{\text{obsd}}/k_0^{\text{SC}} \quad \text{(III)}$$

and:

$$\beta_{\text{c}}/(1-\sqrt{\beta_{\text{c}}}) \simeq -\langle \Delta E \rangle / F_{\text{E}} kT, \quad \text{(IV)}$$

where k_0^{obsd} is the low-pressure-limit rate constant obtained experimentally. The values of β_{c}, F_{E}, and $-\langle \Delta E \rangle / RT$ are also listed in Table 4. The absolute values of β_{c} range between 0.019 and 0.026 in the temperature range studied; this is considered to be reasonable compared with other, similar reactions in Ar (β_{c}=0.015 for CH_3I at 1400 K[7] and β_{c}=0.02 for CH_4 at 2000 K[29]). The temperature dependence of β_{c}, *i.e.*, $\beta_{\text{c}} \propto T^{-2.0}$, is also reasonable when it is compared with theoretical predictions.[30]

It is interesting to compare the value of $-\langle \Delta E \rangle$ evaluated from the experimental data for different reactions in the same diluent gas. For the CH_3I–Ar system, for instance, $-\langle \Delta E \rangle$ ranges from 0.043 to 0.023 in the temperature range of 1100—1500 K.[7] Although the temperature ranges of these systems do not overlap, it appears that the value of $-\langle \Delta E \rangle$ for the CH_3Cl–Ar system is larger than that for the CH_3I–Ar system by a factor of more than two. For the CH_4–Ar system, a value which is comparable to that of the CH_3I–Ar system can be estimated from the data in Ref. 26 ($-\langle \Delta E \rangle / RT$=0.019 at 2000 K). It may be seen that, in the case of the collinear collision of two rigid spheres, the energy-transfer efficiency per collision is largest when the masses of the two spheres are equal.[31] The relative differences in $-\langle \Delta E \rangle$ for the above three systems (*i.e.*, CH_3Cl–Ar > CH_3I–Ar ≅ CH_4–Ar) may be explained, in part, by the relative differences in mass between the reactant and Ar. In this respect, it is also interesting to observe the $-\langle \Delta E \rangle$ values for a given reaction in various diluent gases.

b. High-pressure-limit Rate Constant: A conventional method of estimating the preexponential factor, A, is by the use of the following relation:

$$A = (e\,kT/h) \exp(\Delta S^*/R)$$

ΔS^*, the entropy change of the activation, was evaluated to be 6.7 G mol^{-1}.[32] Consequently, $A = 10^{15.52}$ s^{-1} at 2000 K.

A theoretical prediction of the rate constant for the high-pressure limit may be given by the transition-state formula:[33]

$$k_\infty = (kT/h)(Q^*/Q)$$

where Q and Q^* are the partition functions of the reactant and the activated complex respectively. It is difficult to predict the form of the activated complex precisely although, in a simple bond fission, it does not take so limited a form as a three- or four-center reaction. In this situation, it is considered to be most suitable to apply the method of the maximum free-energy criterion (MFC method) proposed by Quack and Troe[34] for the calculation of Q^*. This method is based on the statistical adiabatic channel model for the activated complex.[35] Strictly speaking, the rate constant calculated with the

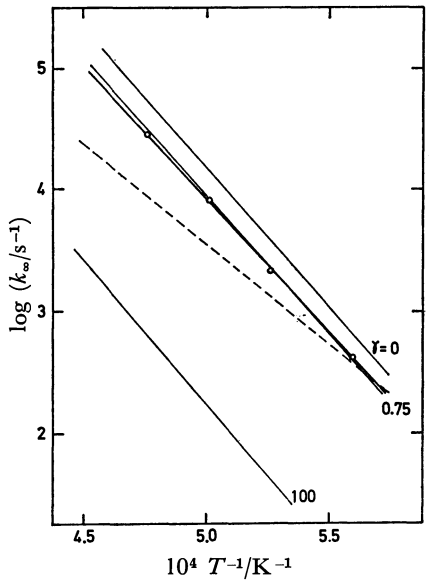

Fig. 8. Comparisons of the high-pressure rate constants. (-○-): k_∞, (------): k_∞^K, (——): k_∞^{MFC}.

MFC method, k_∞^{MFC}, corresponds to the upper limit of the true rate constant.[34] Moreover, the activated complex is defined by the molecular constants of the reactant molecule with only one unknown parameter, γ. Therefore, one could easily calculate the value of Q^* without any large error by using an appropriate γ value. In our calculation, the molecular constants of CH_3Cl and CH_3 were taken from Ref. 11. The C–Cl bond axis was taken as the reaction coordinate. The parameter γ(Å^{-1}) appearing in the equation of the MFC method has the following characteristics: $\gamma=0$ corresponds to the limit of the tight activated complex, and $\gamma=100$, to the limit of the loose activated complex. For many reactions, the calculated values of k_∞^{MFC} are in good agreement with the experimental values when $\gamma=0.75$.[34] In Table 5, the calculated results are listed for $\gamma=0$, 0.75, and 100. In Fig. 8, a comparison is shown between the observed rate constants, k_∞, and k_∞^{MFC}, showing a good agreement when $\gamma=0.75$.

Holbrook[36] analyzed Silov and Sabirova's data and evaluated the rate constants for Reaction 1 as:

$$k_0/[M] = 1.86\times10^4 \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

and:

$$k_\infty = 1.5\times10^{-2} \text{ s}^{-1} \text{ at } 1116.7 \text{ K}.$$

Since the experimental data were near the low-pressure limit, and since he evaluated the limiting values by means of the Hinshelwood plot (*i.e.*, the plot of $1/k$ against $1/P$), the high-pressure value is considered to involve a large error. The extrapolation of the low-pressure rate constant determined in this work leads to $k_0/[Ar]=9.2\times10^3$ cm^3 mol^{-1} s^{-1} at 1116.7 K. Considering that the collision efficiency is large in Shilov and Sabirova's system (M=CH_3Cl), these two experimental values are in good agreement with each other. The value calculated by Forst and St. Laurent[37] is also close to these experimental values.

It was found, in the present study, that the evaluation of the high- and low-pressure-limit rate constants from the fall-off data tends to lead to erroneous results when, especially at high temperatures, the fall-off curve is used without correction for the weak collision effect.

27) J. Troe, *J. Chem. Phys.*, **66**, 4858 (1977).

28) F_{E}, F_{anh}, and F_{rot} were calculated by using the approximated equations, (9.9)—(9.12), appearing in Ref. 27.

29) P. Roth and T. Just, *Ber. Bunsenges. Phys. Chem.*, **79**, 682 (1975).

30) There are two opinions regarding the temperature dependence of β_{c}. Luther and Troe[24] stated that, at the limit of the weak collision, *i.e.*, $-\langle\Delta E\rangle \ll F_{\mathrm{E}}RT$, $\langle\Delta E\rangle$ is constant regardless of the temperature, and that, thus, $\beta_{\mathrm{c}} \propto T^{-1}$. On the other hand Tardy and Rabinovitch (*Chem. Rev.*, **77**, 359 (1977)) proposed $\beta_{\mathrm{c}} \propto T^{-2}$ on the basis of the temperature-independent behavior of $\langle\Delta E\rangle_{\mathrm{down}}$, where $\langle\Delta E\rangle_{\mathrm{down}}$, the average energy transferred per deactivating collision, is related to $\langle\Delta E\rangle$ as:

$$\langle\Delta E\rangle = -\langle\Delta E\rangle^2_{\mathrm{down}}/(\langle\Delta E\rangle_{\mathrm{down}}+F_{\mathrm{E}}RT).$$

If $\langle\Delta E\rangle_{\mathrm{down}}$ is assumed to be independent of the temperature, the above relation leads to a large drop in β_{c} at high temperatures.

31) In a collinear collision of the two rigid spheres A and B, the probability of the energy loss of A, R_{A}, is given by the conservation rules of energy and momentum as:

$$R_{\mathrm{A}} = \frac{4m_{\mathrm{A}}m_{\mathrm{B}}}{(m_{\mathrm{A}}+m_{\mathrm{B}})^2}\left(1-\frac{v_{\mathrm{B}}}{v_{\mathrm{A}}}\right)\left(1+\frac{m_{\mathrm{B}}v_{\mathrm{B}}}{m_{\mathrm{A}}v_{\mathrm{A}}}\right),$$

where m and v are the mass and the velocity along the collinear axis before collision respectively. It appears from this equation that R_{A} reaches its maximum when $m_{\mathrm{A}}=m_{\mathrm{B}}$.

32) ΔS^* for each mode is estimated as: ΔS^*(translation)=0; ΔS^*(rotation)=3.6; ΔS^*(symmetry)=0; ΔS^*(internal vibration)=−3.2 (C–Cl stretch)+6.3 (two H–C–Cl bends).

Requirements for an "Organic Metal"

Gunzi SAITO* and John P. FERRARIS**

Institute for Molecular Science, Okazaki 444

***Chemistry, The University of Texas at Dallas, Richardson, Texas 75080, U.S.A.*

(Received December 3, 1979)

Current theories on the origin of high electrical conductivity in TCNQ-based materials emphasize the need for incomplete charge transfer as well as segregated stacks of donor and acceptor molecules and uniform spacing within the stacks. The requirements for an "organic metal" are discussed in terms of partial charge transfer. An examination of 61 structurally related TTF–TCNQ based complexes suggests that the combinations with the redox potential $-0.02 \leq E_1(\mathrm{D}) - E_1(\mathrm{A}) \leq 0.34$ V have a high possibility of being "organic metals." A method to arrange the complex by the difference between the electrochemical half-wave potentials of the donor and the acceptor molecule is proposed to predict electrical properties of the complex.

Since the discovery of highly electrically conducting charge transfer (CT) complexes[1,2] and anion-radical salts[3,4] of tetracyano-*p*-quinodimethane (TCNQ), several proposals have been forwarded to design new "organic metals." As early as five years after the first report of the electrical properties of TCNQ salts by the Dupont group,[5] LeBlanc proposed the importance of cation polarizability as a criterion for high conductivity.[6] Prior to this, Little[7] suggested a design for a high temperature organic superconductor by incorporation of high polarizability through suitable molecules pendant on a conjugated polymeric backbone. The efforts of organic chemists in the several years following to prepare "organic metals" solely on the basis of polarizability considerations met with little success.[8] Prior to 1973 only three anion radical salts of TCNQ displayed "metallic" behavior over a limited temperature range. The discovery of the TCNQ complex of tetrathiafulvalene (TTF) in 1973 and the demonstration of its metallic properties over a relatively wide temperature range reinstilled interest in the search for organic conductors. To date over 70 "organic metals" have been prepared and subjected to a battery of physical measurements. In general, these "organic metals" may be placed into one of four categories. An estimate of the number of known complexes for each classification is given in brackets.

1. Charge transfer complexes which are ionic at 300 K, with such notables as TTF–TCNQ, TTT (tetrathiatetracene)$_2$–TCNQ, Δ4,4′-bithiopyran–TCNQ and their derivatives and analogs. [>50]

2. Anion radical salts of TCNQ[3,4,9] with formally closed shell cations represented by quinolinium–(TCNQ)$_2$, acridinium–(TCNQ)$_2$ and *N*-methylphenazinium(NMP)–TCNQ. [≈7]

3. Cation radical salts[10] with formally closed shell anions typically halide (or related) salts of TTF, TTT, nickel phthalocyanine or perylene. [≈7]

4. Ternary salts[11] consisting of an amine complexed with TCNQ and iodide or water in varying proportions. [7]

In 1965, McConnel *et al.*[12] classified the alternating CT complexes in the solid state into two distinct categories —those with ionic ground states and those without on the basis of the magnitude of the molecular field energy, $E = \mathrm{N}[(I-A)\rho - M\rho^2/2]$ where I, A, M, and ρ are the ionization potential of the donor, electron affinity of the acceptor, electrostatic energy per DA pair, and the average charge density ($0 \leq \rho \leq 1$) per molecule, respectively, in N DA pairs in the crystal. Matsunaga[13] has pointed out the utility of IR spectra to distinguish the nature of the ground state as applied to a number of CT complexes including aromatic hydrocarbons, aromatic diamines and phenothiazines as donors with *p*-quinones, TCNQ, *etc.* as acceptors. He was able on the basis of IR and electronic spectra to place the alternating CT complexes into groupings similar to McConnell's classifications. In general, ionic complexes were more conducting than nonionic complexes.[14] It was also suggested that the *size* and *shape* of the component molecules were critical factors defining the ionic to nonionic boundary.[14a] It is in the borderline region between these phases that one may expect CT complexes or ion radical salts to display interesting properties like metallic conductivity due to incomplete charge transfer[15] or complex isomerism.[16–18]

Prerequisites to High Conductivity

The search for new materials and an understanding of those already in hand generated numerous criteria for achievement of the metallic state in these systems.[19–22] Some have yet to be fully tested. As a matter of convenience, we choose to divide these criteria into two categories but recognize that they are strongly correlated.

A. *Requirements for Molecular and Crystal Structure.*

1. The component molecule which is responsible for electron transport should be flat in the neutral and ionic state.[3]

2. The donor and/or acceptor should be highly symmetric to avoid strong random potentials which can drive the system insulating (Ref. 1 and references cited therein). The presence of weak electronic or structural disorder need not, in general, destroy the metallic state and may even be the source of stabilization for the uniform chain structure.[17,19,20]

3. The cation (or anion) should be of relatively small size to facilitate polarization effects.[1,2]

4. The geometry of the acceptor should be such that electron withdrawing functional groups are located at diametrically distant points on the molecule to enhance its electron affinity and minimize Coulombic repulsion of electrons in the doubly ionized state.[19]

5. Closely matched physical dimensions for the donor

and acceptor which facilitate packing in the crystal.[22] This militates against bulky substituents.

6. The donor and acceptor moieties must form segregated stacks.[3]

7. The spacing between component molecules in the donor and acceptor stacks must be uniform to delocalize electrons into a single metallic band[19] or into partially filled and partially empty bands which overlap (semimetal).

B. *Requirements for Electronic Structure of Component Molecules and Complexes.*

8. Unpaired electrons on the donor and/or acceptor molecules must be present in the complex.[3,19]

9. Incomplete charge transfer[15] (as will be seen later, this criterion is satisfied by moderately strong donors in combination with moderately strong acceptors such that their redox potential differences are closely matched.).

10. Minimal on site Coulomb repulsive energies to destabilize transitions to a Mott insulator.[19]

11. Enhanced polarizability derived from the introduction of heteroatoms or heavy atoms.[6,22]

12. Formation of a new aromatic sextet upon one electron oxidation or reduction with this aromaticity capable of migrating through the crystal.[21]

13. The dipole moment of the ions should be small.[9b,c]

The achievement of the metallic state in these systems is obviously a complicated interplay of many factors, some of which lend themselves to variability and control. Requirements 1 and 6—8 are fundamental. Unfortunately we are unable to predict *a priori* which systems will necessarily meet criteria 6 and 7. In addition, Torrance[15] has recently demonstrated the necessity of requirement 9. The degree of ionicity (or charge transfer) for several "organic metals" has been estimated by diffuse X-ray scattering measurements, thermopower studies or NMR experiments. Some examples are 0.91—0.94,[23a-c] *ca.* 0.5,[23d] or 0.66,[23e] 0.74,[24] 0.63,[24] and 0.48—0.67[25] for NMP-, HMTSF (hexamethylene-tetraselenafulvalene)-, TSF(tetraselenafulvalene)-, and TTF-TCNQ respectively. Systems with complete charge transfer[12,22a] such as TTF-TCNQF$_4$ and TTT-TCNQF$_4$ are invariably insulators. The lower limit of the degree of ionicity for the appearance of metallic behavior has yet to be determined.

Discussion

In this paper we examine 61 of the complexes based on TTF (or TTT) and TCNQ together with their various derivatives and analogs in an attempt to predict other systems which are likely to yield highly conducting complexes. The choice of this series is two-fold. First, by far the largest number of "organic metals" are related to TTF-TCNQ and the physical properties of many of these have been extensively investigated. Second, the size and shape of the component molecules will affect their mode of packing the magnitude of the polarization energies and Madelung energies in the solid complexes and the repulsive Coulomb energies in the ionized molecules. Therefore, only

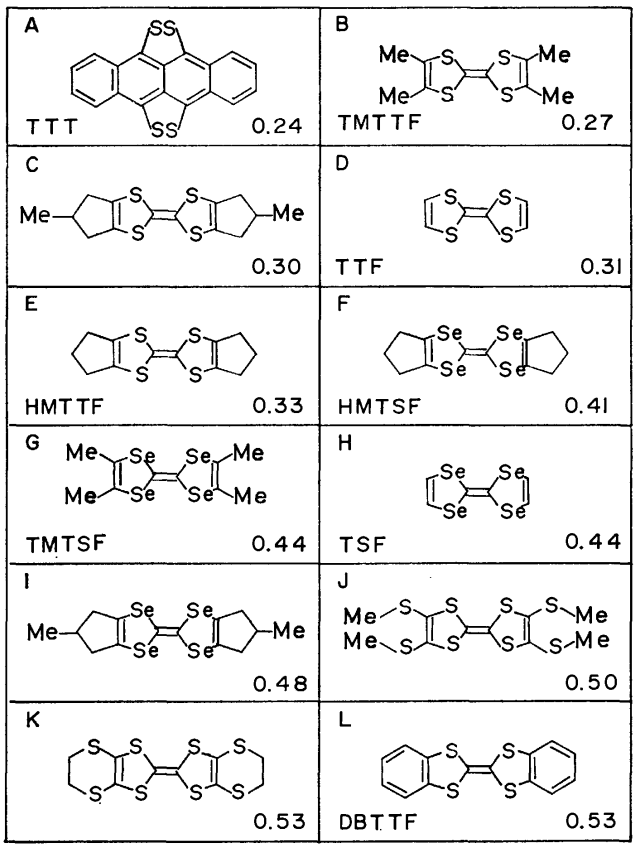

Fig. 1. Electron donors with corresponding electrochemical half-wave potentials.

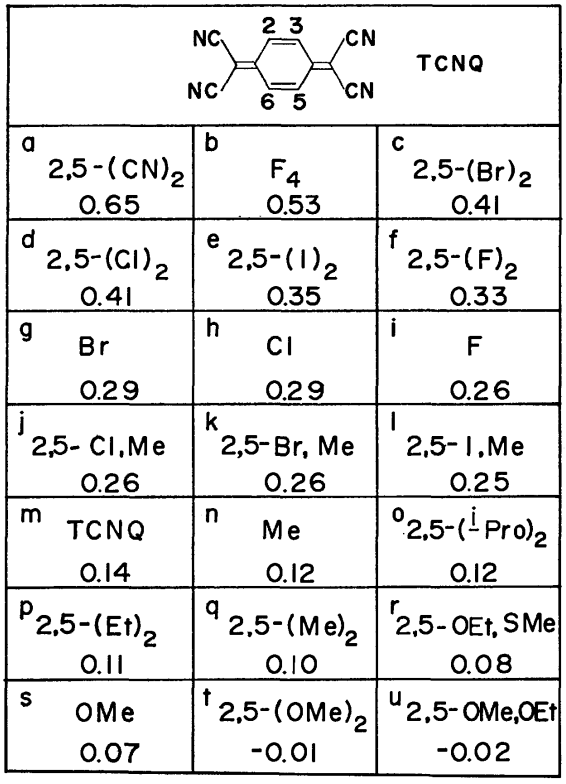

Fig. 2. Electron acceptors with corresponding electrochemical half-wave potentials.

an examination of a series with similar molecular structure can minimize the so called size and shape effect considerably. By this way one may discuss the certain parameter which controls the electric property of the complexes. In this meaning, Torrance's examination which includes a variety of structurally different donors such as Na, NMP, TTF, pyrene, *etc.* may have ambiguity.[15]

In a broad sense these systems should meet all the requirements for high conductivity except number 9, which we may then abstract exclusively. In Figs. 1 and 2 respectively are tabulated the structures of the donor and acceptor molecules considered here along with their first electrochemical half-wave potentials ($D \rightarrow D^+ + e$; $A + e \rightarrow A^-$). We have avoided asymmetric donors intentionally to minimize disorder effects. Since the TTF derivatives form an incomplete set we have also included several TTT complexes in this study. It is apparent that size and shape differences cannot be totally neglected but the differences in on-site Coulomb repulsive energies on the dications should be minimal across the series B-L. We have already shown there is virtually no enhanced on-site Coulomb repulsion present along the series, $TCNQF_n$ (n=0, 1, 2, 4).[26] The lattice energies are expected to be substantially different for the TTT and TTF complexes, but Madelung energies are relatively constant for donors of *similar size* when complexed with TCNQ, *e.g.* −4.6 to −5.3 eV for Na, Rb, NH_4,[27] and −2.3 to −2.4 eV for NMP- and TTF-TCNQ.[28] Therefore as a first approximation we take the Madelung energies as almost constant across the series.

Conductivity results are plotted in Fig. 3.[29] The

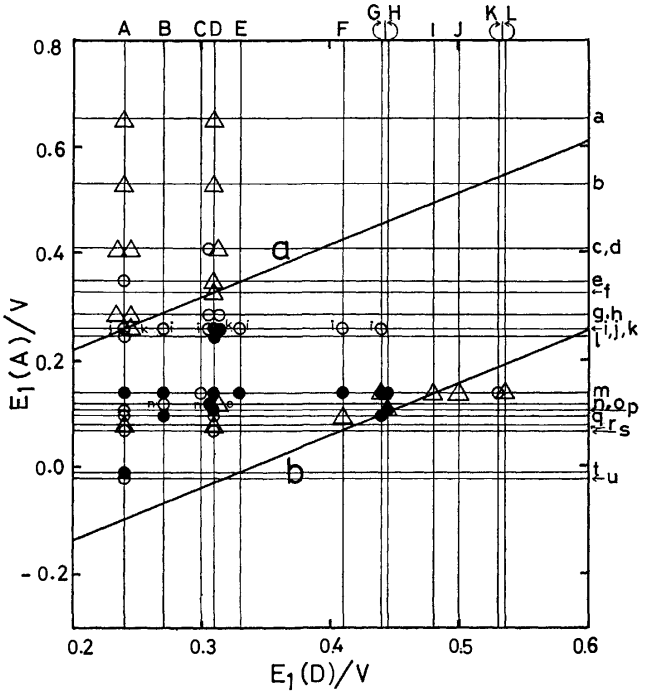

Fig. 3. Conductivity of complexes plotted as E_1 (A) *vs.* E_1 (D).
△=insulators or semiconductors; ○=highly conducting in compaction studies; ●="organic metals."

complexes have been arranged here by placing the ionization potentials of the donors on the abscissa and electron affinities of the acceptors on the ordinate. We have approximated these two quantities by the solution electrochemical half-wave potentials E_1(D) and E_1(A) respectively.[30] Similar treatments have been done by Wheland[22b] and by Torrance,[15] comparing the electric properties of the solid complexes with the solution electrochemical properties of the component molecules. Our treatment is, however, attempts to predict the properties of solid complexes from the solution electrochemical properties of the component molecules solely.

Those complexes in the upper left of the figure have small (I-A) values and favor the completely charge transferred ionic state. Those on the lower right favor the nonionic state. Those complexes which are insulators or semiconductors are represented by triangles whereas open circles designate highly conducting complexes based on compaction studies and closed circles are "organic metals." In general, complexes displaying substantial electrical conductivity fall between the two lines on the graph. The few exceptions are due to several factors. Complexes A–e and D–c are highly conducting due to heavy atom induced enhanced polarizability. Acceptors o and r are too bulky. It is uncertain why complex K–m is conducting. Some combinations yield complexes of variable stoichiometry: A–m (1:2), B–m (1:1), C–m (1:1), and D–l (1:1) are highly conductive but other compositions A–m (1:1),[31] B–m (1.3:2),[32] C–m (2:1)[29g] and D–l (2:1)[33] are semiconductors. There are two modifications of H–p[17] and of G–m,[18] a black "organic metal" and a red insulator. The structure of the latter for H–p has been assigned an alternating structure based on its optical spectrum.[17] The proximity of these complexes to the lower boundary in the absence of heavy-atom effects may place them at the minimum for degree of charge transfer with retention of metallic behavior.

The two boundaries shown are defined by the upper line (a): $E_1(A) = E_1(D) + 0.02$ and the lower line (b): $E_1(A) = E_1(D) - 0.34$ V respectively. Therefore, to the degree our approximation is accurate, *related combinations with the redox potential* $-0.02 \leq E_1(D) - E_1(A) \leq 0.34$ V *have a high probability of being "organic metals," where* $0.24 \leq E_1(D) \leq 0.53$ V *and* $-0.02 \leq E_1(A) \leq 0.65$ V. This result is compared well with those of Wheland[22b] ($|E_1(A) - E_1(D)| \leq 0.25$ V) and of Torrance[15] ($-0.19 \leq E_1(D) - E_1(A) \leq 0.31$ V). Those above line (a) would be completely ionic, those below line (b), nonionic. The idea that CT complexes display a whole spectrum of ionicity is not novel. As early as 1961 Kommandeur classified crystalline organic compounds into five areas based on the magnitude of ($I - A - P_+ - P_- - Q = E^*$) where P_+ and P_- are the polarization energies of the cation and anion and Q the electrostatic Coulomb energy.[34] Recently, Torrance *et al.*[28] have emphasized that in cases where the net electrostatic binding energy $E_B = (I - A) - M/2$ is small (≈ 2 eV), partial charge transfer may be energetically favored. Those complexes falling between lines (a) and (b) satisfy Torrance's criterion with $1.5 \leq (I - A) - M/2 \leq 1.9$ eV (using I=

6.85 eV for TTF,[35] A=2.84 eV for TCNQ[36] and $M/2$= ≈2.3 eV for these complexes.[28] The question still remains what degree of ionicity is necessary for metallic behavior? Investigation of complexes near the boundaries such as D–f, t, u, and D with Me_3TCNQ and Me_4TCNQ should provide the answer.[37] The latter two acceptors are still under construction but their E_1(A) values are estimated to be 0.02—0.03 and −0.01 to 0.00 V respectively. Figure 3 is far from complete and further studies of complexes of B, E—H and L with other known acceptors and weaker TCNQ's are required.

Some of the usages of the diagram are as follows. 1: The electrical property of an unknown TTF–TCNQ based complex can be easily predicted with the aid of the diagram. If the electrochemical potential were obtained for a TTF based donor or a TCNQ based acceptor, the other component molecules can be selected to give metallic complexes baring steric and/or some unforeseen effects. 2: A new TCNQ derivative which gives complexes with metallic behavior can be designed. Metallic complexes with *weak* partial charge transfer, *i.e.* in the proximate region of the lower line, may well be worth synthetic efforts. 3: In the course of the synthesis of TTF derivatives and analogs, the electrical properties of their TCNQ complexes have been compared with that of TTF–TCNQ. Considering the importance of partial charge transfer, this comparison should be made between the complexes belonging to the metallic region in the diagram.

One may extrapolate (with some danger) this treatment to the *p*-quinone acceptors, assuming values for Madelung energies, polarization energies and intermolecular spacings in segregated stacks are similar to their TCNQ counterparts though the *p*-quinones have larger disproportionation energies (*ca.* 0.3 eV)[38] when compared to the TCNQ series with the same E_1(A). Then *p*-chloranil (E_1(A)=0.01 V), *p*-bromanil (0.00 V) and *p*-fluoranil (−0.04 V) complexes with TTF and TMTTF[39] locate just above line(b)while 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (0.51 V) complex with DBTTF[40] locates just below line (a).

We thank the Robert A. Welch Foundation and Research Corporation for support of this work.

Note added in proof: A recent paper by J-M Fabre, M. Vigroux, E. Torreilles, and L. Giral (*Tetrahedron Lett.* **1980**, 607) examined TMTTF–Et_2TCNQ (B-p) and found unusual stoichiometry (3 : 2) and structure. The electrical conductivity is metallic: $\sigma_{300K} \simeq 130\Omega^{-1}$ cm^{-1}.

Film Dichroism. V. Linear Dichroism Study of Acridine Dyes in Films with Emphasis on the Electronic Transitions Involved in the Long-wavelength Band of the Absorption Spectrum

Yukio MATSUOKA and Kiwamu YAMAOKA*

Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received December 10, 1979)

The long-wavelength bands of the absorption spectra of 10-methylacridinium (MeAcr), Acridine Orange (AO), and Acridine Yellow (AY) in the poly(vinyl alcohol) film were investigated by the linear dichroism method. The parallel- and perpendicular-dichroic spectra of each dye were resolved into the long-axis and short-axis polarized absorption components. From these component bands the isotropic spectrum was reconstituted and the reduced dichroism spectrum was simulated by computer with a new technique which utilizes a general expression for the reduced dichroism of planar molecules with the multiple band structure. A weak absorption band (or bands) hidden in a strong one could be revealed by reproducing the observed isotropic and linear-dichroic spectra. The vibrational sub-bands of MeAcr were shown to have the average intervals of *ca.* 1.5×10^3 cm^{-1} for the short-axis polarized ^1L_a band and of *ca.* 0.7×10^3 cm^{-1} for the long-axis polarized ^1L_b band. In the visible region of the isotropic spectrum, the weak ^1L_a band of AO was clearly shown to consist of the fine structure with a regular energy separation, although it is overlapped with the intense ^1L_b band which is also composed of a vibrational structure. The same spectral feature was observed for AY. The dichroic results are discussed under considerations of (1) the overlap of the mutually orthogonal transition moments, whose angles were determined relative to the long axis of the C_{2v}-symmetric dye molecule, (2) the angle between the orientation axis and the long axis of the molecular plane, and (3) the average degree of orientation of dye molecules in the film.

The unambiguous interpretation of the optical rotatory dispersion or the circular-dichroic spectrum of an acridine dye bound to an optically active biopolymer is often hampered because of the overlap of several electronic transitions in the absorption spectrum.[1-6] Acridine may be considered as the mother compound for a large number of the acridine dyes, such as 10-methylacridinium (MeAcr), Acridine Yellow (AY), and Acridine Orange (AO). A thorough understanding of the electronic transitions of acridine should facilitate the precise assignment of the electronic transitions involved in the absorption spectra of those more complicated derivatives of acridine.

The apparent location and the polarization of two electronic transitions of acridine (*i.e.*, the ^1L_a and ^1L_b bands) have been determined from the linear dichroism in the stretched film,[7,8] the polarized fluorescence in solution,[9,10] and the absorption spectrum in polymer matrix.[11] The linearly-polarized absorption spectra of acridine and other related acridine dyes were reported in a previous paper,[8] in which the overlapping ^1L_a and ^1L_b bands were separated with a *reduction procedure*.[12] The fine structure of each electronic band was not analyzed in detail, because a general expression for the linear dichroism of planar molecules was not yet available. The results clearly showed that the 3,6-diamino- or 3,6-bis(dimethylamino)-derivatives of acridine also possess the two electronic transitions in the long-wavelength region of the absorption spectrum.[8] However, the exact wavelength position and the fine structure of the ^1L_a band could not be determined unequivocally because of the weak absorption intensity of the unmasked ^1L_a band, which was overwhelmed by the strong ^1L_b band.[8]

The objective of this paper is to draw a clear conclusion on the controversy over the electronic transitions involved in the long-wavelength region of the absorption spectra of AO and AY on the basis of the detailed spectral data of acridine and MeAcr. For this purpose, the expression for the reduced dichroism of planar molecules[13,14] was extended to cover the absorption spectrum composed of numerous overlapping transitions. With the aid of this general expression, the observed isotropic and reduced dichroic spectra were analyzed by assuming the appropriate Gaussian band shape for the individual absorption bands. Both the ^1L_a and ^1L_b bands of MeAcr, AO, and AY were clearly shown to consist of a series of vibrational sub-bands. The energy separation of the sub-bands was also estimated. The present results have finally clarified the enigmatic character of the absorption spectra of the 3,6-disubstituted acridine dyes.

Experimental

Materials. Acridine dyes used in this work were monocationic 10-methylacridinium (MeAcr), Acridine Orange (AO), and Acridine Yellow (AY),[8] each of which was assumed to be a planar molecule with the negligible out-of-plane transition in the wavelength region between 220 and 550 nm. Poly(vinyl alcohol), (PVA), was used as the film matrix. Preparations of sample and reference films were described before.[8]

Measurements and Analytical Method. Measurements of the dichroic absorption spectra of each dye and the determination of the long- and short-axis polarized absorption spectra were reported previously.[8] For a single absorption band lying in the molecular plane of a given planar molecule, the reduced dichroism ($\Delta A/A$) can be expressed as [13,14]

$$\frac{\Delta A}{A}=\frac{3}{2}\{3(2M_z-1)\cos^2\theta-(3M_z-2)\}\Phi \qquad (1)$$

where Φ is the orientation function and θ is the angle between the transition moment of the absorption band and the molecular z-axis, as defined in Fig. 1. The constant M_z is given by $M_z=\cos^2\phi_z$, where ϕ_z is the angle between the z-axis and the direction of the molecular orientation axis (*cf.* Fig. 1).

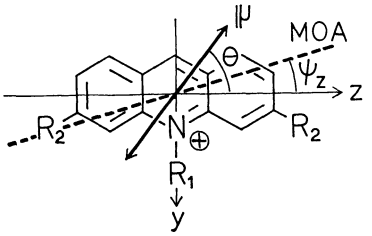

Fig. 1. Molecular coordinate system of acridine nucleus. Transition moment (μ) and molecular orientation axis (MOA) are measured from the molecular z-axis by the angles θ and ϕ_z, respectively.

Equation 1 indicates that the observed quantity $\Delta A/A$ for the single absorption band should be constant over the wavelength region concerned.

If an apparent absorption band is multiple and actually consists of n component bands (i=1, n), the total reduced dichroism should be an appropriate sum from each band and may be rewritten as

$$\frac{\Delta A}{A} = \frac{\sum_{i=1}^{n}\Delta A_i}{\sum_{i=1}^{n} A_i} = \frac{\sum_{i=1}^{n}\frac{3}{2}\{3(2M_z-1)\cos^2\theta_i-(3M_z-2)\}A_i}{\sum_{i=1}^{n} A_i}\,\phi \qquad (2)$$

where A_i is the absorption intensity, expressed with the absorbance, of the ith band. This expression reduces to the one previously derived for the rod-like molecule which may be assumed as the unit vector (Eq. 20 in Ref. 15 where $M_z=1$). Equation 2 indicates that the reduced dichroism can be expressed by the quantities θ_i and A_i, which are dependent on the wavelenth λ, and by M_z and ϕ, which are independent of λ and are characteristic of a particular planar molecule. The value of M_z is independent of the stretch ratio S of the film, while ϕ varies with S and approaches unity as the film is stretched infinitely.[13,14] A computer simulation of an experimental reduced dichroism spectrum by the use of Eq. 2 shows the presence of weak absorption bands overlapped with strong ones.
