for many molecules.[1-4] Almost all of these molecules, however, belong to the statistical limit case, where the fluorescence is characterized by a single exponential decay. Except for 1,3,5-triazine,[14,22] pyrimidine is the first example of the intermediate case molecule in which IVR has been found to occur. It is worthy of note that the IVR in pyrimidine is observed even for levels with small excess vibrational energies ($\approx$1000 cm^{-1}). In a statistical limit case molecule with a size similar to benzene and with no side chain, IVR is observed usually for levels with excess energies of more than $\approx$2000 cm^{-1}.[5,6] For some alkylbenzenes[4,7] the IVR is observed for levels with very small excess energies such as 530 cm^{-1}. However, these molecules have low frequency modes like the torsion or the bending of the alkyl chain, so that the situation in alkylbenzenes is different from that in pyrimidine. Using the vibrational frequencies in the literature,[18] the vibronic state density of pyrimidine at ΔE=1000 cm^{-1} in S_1 was found to be as small as $\approx$0.06 cm from the Haarhoff formula.[23] It should be reasonable, therefore, to consider that the rotational levels will cause the effective state density to increase and thereby will be involved in the IVR occurring in S_1 pyrimidine.

^{129}I Mössbauer Spectroscopic Studies of Tetrathiafulvalene-Iodine Charge-Transfer Salts

Hiroshi SAKAI,* Manabu MIZOTA,† and Yutaka MAEDA
Research Reactor Institute, Kyoto University,

(Received May 19, 1986)

The Mössbauer effect of ^{129}I has been applied to investigate tetrathiafulvalene-iodine (TTF-I_n) charge-transfer salts at 16 K. The electrically conductive TTF-$I_{0.71}$ salt shows a broad single-line with the isomer shift of -0.36 mm s^{-1}, suggesting that the iodine atoms on the average are not completely ionic ($I^{-1.0}$) but are negatively charged by about 0.9 ($I^{-0.9}$) in the low temperature phase. This is due to the weak interactions of the iodine atoms with the sulfur atoms of the TTF molecules. This fact is consistent with the crystallographic data and the electron spin resonance spectra of the salt. This salt is recognized as a partially oxidized mixed-valence compound. The spectrum of the TTF-I_3 salt consists of two sets of quadrupole octets, corresponding to the central and terminal iodine atoms of the slightly distorted I_3^- ion. The charge density localized on each iodine atom of the I_3^- ion is close to that of the isolated I_3^- ion. That is, the salt is regarded as a simple ionic compound, for which a high electrical conductivity can not be expected. It is confirmed that a small amount of the TTF-I_2 salt coexists in the TTF-$I_{0.71}$ phase obtained from the solution of excess TTF and iodine. In the salt the iodine atoms exist as polyiodides consisting predominantly of I_3^- units.

Tetrathiafulvalene (TTF) is a good π-electron donor which forms highly conductive charge-transfer complexes (or salts) with various electron acceptors. The high electrical conductivity arises from the segregated donor and/or acceptor stacks and the incomplete charge-transfer from the donor to the acceptor. In the TTF-iodine system three phases have been confirmed by X-ray diffraction: TTF-$I_{0.71}$ (monoclinic),[1,2] TTF-I_2 (orthorhombic),[3] and TTF-I_3 (monoclinic).[4] However, the crystal structure of the TTF-I_2 phase is not yet established in detail. In the monoclinic TTF-$I_{0.71}$ salt, the dc conductivity at room temperaure is observed to be $\approx$400 S cm^{-1} along the needle c-axis, which is comparable to that of TTF-TCNQ (TCNQ, tetracyano-*p*-quinodimethane).[3,5] The salt exhibits a phase transition near 210 K between the metallic (high temperature) phase and the semiconductive (low temperature) phase. The crystallographic data of the salt in the metallic phase suggest that the TTF molecules form segregated stacks along the c-axis with an intermolecular separation of about 3.56 Å and the iodine atoms, probably iodide ions I^-, occupy the channels between the TTF stacks.[1,2] Preliminary X-ray results of the salt at low temperature reveal no major change in crystal structure.[3] According to Ref. 3, the room-temperature conductivity for the orthorhombic TTF-I_2 salt is found to be $\approx 10^{-3}$ S cm^{-1} along the TTF stacking axis. The iodine atoms seem to exist as small polyiodide species, probably predominately triiodide ion I_3^-. In the monoclinic TTF-I_3 salt,[4] the TTF molecules do not form segregated stacks but exist as completely oxidized $(TTF)^+$ dimers interspersed between pairs of triiodide ions. The electrical conductivity of the salt is observed to be $\approx 10^{-9}$ S cm^{-1} at room temperature, as one would expect from the crystal structure.

It is important to estimate the degree of charge-transfer and interactions between the TTF molecules and the iodine atoms in order to understand the electrical properties of these TTF-iodine salts. The ^{129}I Mössbauer spectroscopy is a powerful method for this purpose. The Mössbauer parameters such as the quadrupole coupling constant (e^2Qq), the asymmetry parameter (η), and the isomer shift (δ), are directly related to the charge distribution and the charge density of the iodine atom. Previously ^{129}I Mössbauer spectroscopy has been successfully applied to iodine complexes or salts exhibiting high electrical conductivity: perylene-iodine,[6,7] metal glyoximate-iodine,[8,9] metal phthalocyanine-iodine,[8,10] and oligoaniline-iodine.[11] The Mössbauer spectrum of the TTF-$I_{0.71}$ salt has been measured, but the detailed analysis and discussion are not given.[8] In this paper we report the results of the ^{129}I Mössbauer spectroscopic study of the TTF-$I_{0.71}$ and TTF-I_3 salts. The Mössbauer data of the TTF-I_2 salt coexisting in the TTF-$I_{0.71}$ phase are also presented.

Experimental

Materials. The commercially available TTF (Aldrich Chemical Co.) was recrystallized from cyclohexane. The radioisotope ^{129}I, in the standard from of Na ^{129}I in a Na_2SO_3 solution (New England Nuclear Co.), was oxidized with 3 mol dm^{-3} H_2SO_4 and 10% H_2O_2, and the resulting molecular iodine ($^{129}I_2$) was extracted with benzene. The iodine solution was thoroughly washed with water and passed through a Teflon filter to eliminate any slight amount of water. The ^{129}I-labeled TTF-iodine salts were prepared on a small scale by mixing together benzene

† Present address: Mitsubishi Fusion Center, Mitsubishi Denki Bldg, 2-3, Marunouchi 2-Chome, Chiyoda-ku, Tokyo 100.

solutions of TTF and iodine ($^{129}I_2$) with the prescribed mole ratios. A precipitate obtained from the solution with a composition of TTF:I=1:0.71 contains the TTF-$I_{0.71}$ salt and small amounts of another salt, probably TTF-I_2. Therefore, the precipitate was recrystallized from acetonitrile. The iodine contents of the TTF-iodine salts were checked on nonradioactive (natural iodine) preparation samples by elemental analysis: Found; C, 24.52; H, 1.28; I, 30.38%. Calcd for TTF-$I_{0.71}$:C, 24.48; H, 1.37; I, 30.60%. Found: C, 11.79; H, 0.67; I, 66.31%. Calcd for TTF-I_3:C, 12.32; H, 0.69; I, 65.07%. No pure TTF-I_2 salt could be isolated by recrystallization from acetonitrile.

Measurements. A single-line $^{66}Zn^{129}Te$ Mössbauer source was prepared by irradiating 140 mg $^{66}Zn^{128}Te$ at a thermal neutron fluence rate of 2×10^{13} n $cm^{-2}s^{-1}$ for 1 h in the Kyoto University Reactor (KUR). The source was checked by the spectrum against a single-line Cu ^{129}I absorber (10 mg ^{129}I cm^{-2}). The line width at half maximum was found to be 1.12 mm s^{-1} for the single absorption peak. The isomer shift of Cu ^{129}I was −0.42 mm s^{-1} for the source, which is in good agreement with the literature.[12] Measurements were carried out in a transmission geometry by cooling the source and the absorber to 16 K in the same way as reported previously.[11]

Results and Discussion

^{129}I Mössbauer spectra of the recrystallized TTF-$I_{0.71}$ (absorber thickness; 12 mg ^{129}I cm^{-2}) and TTF-I_3 (13 mg ^{129}I cm^{-2}) salts at 16 K are shown in Fig. 1(a) and (c), respectively. The former shows only a single absorption peak (no quadrupole hyperfine splitting), while the latter consists of two kinds of quadrupole octets. Figure 1(b) shows the spectrum of a precipitate (29 mg ^{129}I cm^{-2}) obtained from the benzene solution with a composition of TTF:I=1:0.71. The spectrum evidently consists of one singlet and two different quadrupole octets. These spectra were analyzed by the least-squares method. The solid curves in the figure represent the best-fitted Lorentzian spectra and the dashed curves indicate their components. Table 1 gives the Mössbauer parameters obtained such as the quadrupole coupling constant (e^2Qq) and its sign, the asymmetry parameter (η), the isomer shift (δ), and the line width (2Γ). Included inTable 1 for comparison are results of the isolated I_3^- ions in the [Ru(η-$C_5H_5)_2$I]I_3[13] and β-carotene-I_3[14] complexes and of I_3^- chains in the *N,N'*-diphenyl-*p*-phenylenediamine-iodine (DPPD-I_x) and *N,N'*-diphenylbenzidine-iodine (DPB-I_x) complexes.[11]

TTF-$I_{0.71}$ Salt. The single-line spectrum of TTF-$I_{0.71}$ with the small δ value suggests that the iodine atom exists almost as an ionic I^- ion. This result is in good agreement with that of Marks.[8] However, the δ value (=−0.36±0.05 mm s^{-1}) for this salt is slightly larger than that for the typical I^- ion in the KI crystal (δ =−0.51±0.025 mm s^{-1}).[15] This implies that a slight amount of covalency is present between the I^- ion and the TTF molecules. According to the detailed crystallographic data of the salt,[2] each iodine atom has four sulfur neighbors and there are two characteristic coordination geometries; a distorted tetrahedron and a distorted square planar. The I···S bond distances for both coordination geometries are in the range of 3.56 to 3.79 Å, less than the sum of the respective van der Waals radii (4.0 Å). Furthermore, the presence of the interaction between the iodine and the sulfur atoms has been suggested from the *g* value and the line width of the ESR spectra of the salt.[16]

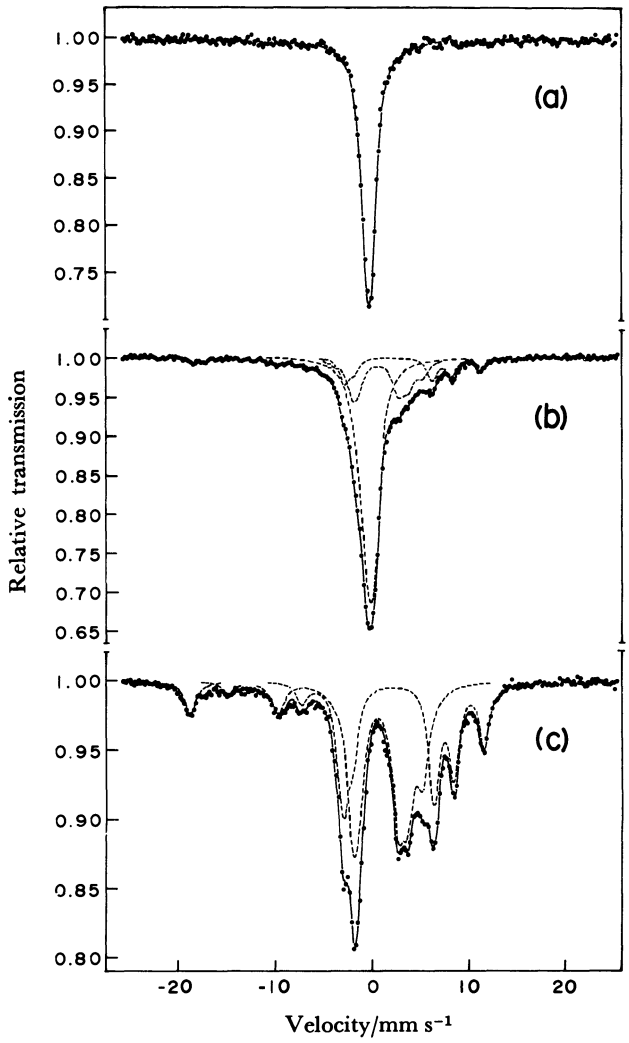

Fig. 1. ^{129}I Mössbauer spectra at 16 K of (a) the TTF-$I_{0.71}$ salt recrystallized from acetonitrile, (b) the precipitate obtained from the benzene solution with composition of TTF: I=1 : 0.71 (shows the presence of the TTF-$I_{0.71}$ and TTF-I_2 salts), and (c) the TTF-I_3 salt.

The charge density on the iodine atom can be evaluated from the semiempirical relation as follows;[12]

$$\delta(\text{mm s}^{-1}) = -9.2\,h_s + 1.5\,h_p - 0.54 \quad \text{(for ZnTe source)}, \qquad (1)$$

where h_s and h_p are the numbers of 5s- and 5p-electron holes, respectively, in the $5s^25p^6$ configuration. Therefore, the h_p is expressed as

a) The e^2Qq values are converted to the ^{127}I nucleus. b) The δ values are relative to the ZnTe source.
c) The ratios are normalized with respect to the I_c atom. d) $U_p=-e^2Qq_{obsd}/e^2Qq_{atom}$, $e^2Qq_{atom}=2292.7$ MHz.
e) $\delta=1.5\,h_p-0.54$ (mm s^{-1}). f) The e^2Qq value is obtained by analysis with a fixed line width (1.12 mm s^{-1}).
* The errors quoted in this work include estimated systematic errors.

$$h_p = 6 - (N_x+N_y+N_z), \quad (2)$$

where N_x, N_y, and N_z are the populations of the 5p-electrons in the x, y, and z orbitals, respectively. If only 5p-electrons take part in bond formation, the h_p value is calculated to be 0.12 from the δ value. This implies that the iodine atom on the average is negatively charged by 0.88 in the TTF-$I_{0.71}$ salt. The average covalency per I···S bond is, therefore, found to be 3%. The e^2Qq value is affected only a little by the slight covalency. In the tetrahedral coordination geometry the e^2Qq value would be zero, regardless of the extent of covalency. In the case of the square planar geometry, the contribution of the covalency to e^2Qq may be calculated on the basis of the Townes and Dailey approximation as follows;[12]

$$U_p = -e^2Qq_{obsd}/e^2Qq_{atom} = -N_z + (N_x+N_y)/2, \quad (3)$$

where U_p is the number of unbalanced p-electrons and e^2Qq_{atom}, the atomic iodine quadrupole coupling constant. The latter is equal to 2292.7 MHz for the ^{127}I nucleus. Since the z principal axis (V_{zz}) of the electric field gradient (EFG) tensors lies along the four-fold axis in the square planar coordination, the 5pz orbital has two nonbonded electrons, i.e., N_z=2.00. Substituting the values of h_p and N_z into Eq.2, one obtains N_x=N_y=1.94. If all iodine atoms are surrounded in a square planar configuration by four sulfur atoms, the covalency of 3% for each I···S bond leads to +138 MHz for e^2Qq from Eq. 3. However, the crystallographic results of the salt suggest that about 40% of the iodine atoms have a distorted square planar coordination and the residual 60% have a distorted tetrahedral coordination.[2] Therefore, the spectrum of the salt should have two components corresponding to two kinds of iodine atoms, one in a distorted square planar arrangement and the other in a distorted tetrahedron. Unfortunately, since the resolution of the Mössbauer spectrum of ^{129}I is not very high, it may be difficult to distinguish between them.

The line width of the spectrum is apparently broad compared with that of Cu ^{129}I with nearly the same absorber thickness. The broadening is mainly due to the slight covalency of the I···S bonds described above. When the spectrum was analyzed with the fixed line width (1.12 mm s^{-1}) determined from the single-line spectrum of Zn^{129}Te vs. Cu^{129}I and with the theoretical intensity ratios obtained from the square of the Clebsch-Gordan coefficient $|CG|^2$, the e^2Qq value was found to be 130 MHz. If a larger line width, due to the saturation effect, is used for the analysis, this value would further decrease. The e^2Qq value obtained from the broadening of the line-width is in good agreement with that predicted from the δ value within experimental error. It is concluded that on the average the iodine atom in the TTF-$I_{0.71}$ salt is not completely ionic ($I^{-1.0}$), but is negatively charged by about 0.9 ($I^{-0.9}$) in the low temperature (semiconductive) phase (16 K). The average covalency per I···S bond is estimated to be 3%, which is likely from the I···S bond distances. The ^{129}I Mössbauer spectrum in the high temperature (metallic) phase of the salt is important and interesting in order to understand the phase transition near 210 K. Unfortunately, because of a significant decrease in the Mössbauer resonance absorption, the measurement of the spectrum could not be performed above 210 K.

TTF-I_3 Salt. The Mössbauer spectrum of the TTF-I_3 salt is similar to those of the linear triiodide anions observed in the β-carotene-I_3,[14] DPPD -I_x, and

DPB-I_x complexes.[11] The crystallographic data of the salt have revealed that the iodine atoms exist as a slightly distorted triiodide anion.[4] The bond distances between the iodine atoms in the asymmetric triiodide anion are 2.907 and 2.953 Å, respectively, while the bond angle ∠I-I-I of 175.40° deviates slightly from linearity. The distances between two terminal iodine atoms and sulfur atoms of the TTF molecules are in the range of 3.636 to 3.989 Å, suggesting weak intermolecular interactions. By analogy with the Mössbauer spectra of the other I_3^- ions, it is appropriate to assign the iodine with the larger quadrupole splitting to the central iodine atom (I_c), and the other splitting to the two terminal iodine atoms (I_t). A slight broadening of the line width has been observed for I_t compared with that for I_c, suggesting that the charge densities on the two I_t atoms are slightly different from each other, i.e., the I_3^- ion is slightly asymmetric. This is consistent with the result of the crystal structure. Therefore, the values of e^2Qq, η, and δ given in Table 1 are the means of those for two I_t atoms. The absorption area ratio of I_t and I_c was found to be 1.6:1, which is close to the values obtained for the other I_3^- ions in the $[Ru(\eta\text{-}C_5H_5)_2I]I_3$ and β-carotene-I_3 complexes, as shown in Table 1. The deviation from the composition ratio of 2:1 in the I_3^- ion is due to the differences in the recoilless fraction and in the saturation effect, as discussed in our previous paper.[11] The small η value for the I_c atom is in accord with the fact that the I_3^- ion is almost linear. The bond angle of 175.40° leads to only 0.01 for η, assuming that two I_t atoms are equivalent. In this case e^2Qq for I_c is negative in sign and the z principal axis (V_{zz}) of the EFG tensors lies along the direction of the bonding axis. The small η value for the I_t atoms implies that the interaction is little present between the I_t atoms and the sulfur atoms of the TTF molecules.

The charge density of 5p-electrons localized on each iodine atom can be estimated from the values of δ and e^2Qq using Eqs. 1—3. The U_p value is close to the h_p value on the average for two I_t atoms of the asymmetric I_3^- ion. This suggests that the bonding of I_t is mainly due to $5p_\sigma$-electrons. If $5p_\pi$-electrons take part in an intra- or intermolecular bond formation, the relationship $U_p < h_p$ is generally observed. Therefore, the I_t atoms are unlikely to be interacting with sulfur atoms of the TTF molecules, consistent with the small η value. The I_t atom of the salt is negatively charged by about 0.50 e^- on the average due to the values of U_p and h_p. This charge density on the terminal iodine atom is in good agreement with that of the usual isolated I_3^- ion. For the I_c atom the h_p value is larger than the U_p value, which is always found in the I_c atoms of the other I_3^- ions, as shown in Table 1. This phenomenon has been successfully explained on the basis of the contribution of the core $4d_\sigma$-electrons, on the I_c atom, to the linear I_3^- bond formation, in addition to the delocalized three-center four-electron bonding scheme.[11,17] Consequently the charge density localized on the I_c atom of the I_3^- ion is computed to be +0.01 e^- from the values of δ and e^2Qq using Eqs. 4 and 5 of Ref. 17. The charge density is close to that on the I_c atom of the successive I_3^- chain in the DPPD-$I_{2.4}$ complex rather than to that on the isolated I_3^- ion. This seems to be attributed to the fact that the I_3^- ion in the TTF-I_3 salt is slightly asymmetric and bent. It is concluded that the iodine atoms of the TTF-I_3 salt exist as an almost isolated I_3^- ion and the interaction of the I_3^- ion with sulfur atoms of the TTF molecules is extremely weak. Since the TTF-I_3 salt is regarded as a simple ionic compound, a high electrical conductivity is not expected for the salt, consistent with the observed conductivity ($\approx 10^{-9}$ S cm^{-1}).[4]

TTF-I_2 Salt. A precipitate obtained from the solution with a composition of TTF:I=1:0.71 showed a complicated spectrum consisting of one broad singlet and small amounts of two different quadrupole octets, as shown in Fig. 1(b). If the broad single-line spectrum corresponds to the iodine of the TTF-$I_{0.71}$ salt, the δ value actually agrees well with that of TTF-$I_{0.71}$, the residual two quadrupole octets must arise from iodine species of another TTF-I_n salt. The Mössbauer parameters of the iodine species are evidently different from those of the TTF-I_3 salt, though of lower precision because of the weak intensities and the broad line widths of the iodine species. Warmack et al.[3,18] have reported that two different types of charge-transfer crystals are formed by slow diffusion of TTF and iodine in acetonitrile: monoclinic TTF-$I_{0.71}$ (needles) and orthorhombic TTF-I_2 (flat platelets). In the latter TTF-I_2 form the iodine columns seem to contain small polyiodide species, probably predominantly I_3^-. It is reasonable to assume that the unknown iodine species corresponds to the I_3^- unit of the TTF-I_2 salt. That is, the iodine with the larger quadrupole splitting can be assigned to the central iodine atom (I_c) of the I_3^- unit, whereas the other to the two terminal iodine atoms (I_t), in analogy with the I_3^- ion of the TTF-I_3 salt. However, the values of e^2Qq and δ for the I_3^- unit of TTF-I_2 are considerably different from those for the isolated I_3^- ion of TTF-I_3, as shown in Table 1. Further, the line widths are very broad for the I_3^- unit. The optical data for the salt have suggested the presence of monomers (I^-) and dimers (I_2) in the iodine columns, in addition to the trimers (I_3^-).[18] Accordingly, the I_3^- units in the polyiodides containing the I_3^-, I_2, and I^- species are presumably distorted significantly compared with the *symmetric* isolated I_3^- ion. Furthermore, the spectrum of the dimer (for free iodine molecule, $e^2Qq = -2250 \pm 30$ MHz, $\delta = +0.94 \pm 0.05$ mm s^{-1} [19]) present in the poly-

iodide may be superimposed on that of the I_c atom in the I_3^- unit. The spectrum of the monomer, of course, can not be distinguished from that of the coexisting TTF-$I_{0.71}$ salt. These effects may complicate the spectrum of the I_3^- unit present in the TTF-I_2 salt, and then the spectrum may not permit a quantitative discussion of the charge density of the iodine species. It is concluded that the TTF-I_2 salt is formed from the benzene solution of excess TTF and iodine, in addition to the TTF-$I_{0.71}$ salt. The iodine atoms in the iodine columns of TTF-I_2 exist as polyiodides consisting predominantly of I_3^- units. These results are consistent with the crystallographic data and the optical data of the TTF-I_2 salt.

We are very grateful to Prof. Takenobu Higashimura (Research Reactor Institute, Kyoto University) for his useful discussion and encouragement. This work was supported by the grant in aids of special research project on properties of molecular assemblies (No. 59212018, No. 60104002) from the Ministry of Education, Science and Culture.

Electrochemical Study on the Initial Stages of the Electropolymerization of 1-Pyrenamine in Acetonitrile

Takeo Ohsaka, Kazuhiko Hirabayashi, and Noboru Oyama*
Department of Applied Chemistry for Resources, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184
(Received May 20, 1986)

The kinetic study of the mechanism for the reaction of the initial stages of the electropolymerization of 1-pyrenamine (PA) in an acetonitrile solution was carried out by cyclic voltammetry (CV) and double potential-step chronoamperometry (DPSCA). The experiments were conducted at various time windows (i.e., at various scan rates of CV and various potential-step widths of DPSCA) and under the conditions of the presence or absence of the basic or acidic additives (pyridine, 2,6-lutidine, trifluoroacetic acid). As a result, it was found that the mechanism of the reaction of the initial stages of the electropolymerization of PA is an "ECE" mechanism, and that the chemical reaction interposed between successive electron transfers is considered as the radical-radical coupling reaction rather than the radical-parent monomer coupling reaction. The second-order rate constant for the radical-radical coupling reaction was estimated to be $(1.0\pm 0.8)\times 10^5\ M^{-1}\ s^{-1}$ (1 M=1 mol dm^{-3}). The cyclic voltammetric responses for the oxidation of PA were varied by the presence or absence of the basic or acidic additives. This can be explained considering the basicity of the additives and their influences in the deprotonation reactions following the heterogeneous electron-transfer step.

One of the most active areas in a recent electrochemical research deals with "electropolymerization."[1-60] The attractiveness of electropolymerization stems not only from its potentiality in the synthesis[27-44] of new organic conducting, semiconducting or nonconducting polymers, but also from the point of the modification of electrode surfaces.[1-26] A number of recent papers[1-60] on electropolymerization are concerned with the preparation of polymeric compounds, the characterization of their electrochemical, electrical, physicochemical, spectroscopic and other kinds of properties, and the applications of "composite electrode materials" produced by the modification of electrode surfaces by electropolymerization. In contrast, there have been only a few papers[38,45,46,55,61-63] concerning the studies of the mechanism of electropolymerization.

It seems to be quite difficult (or impossible) to elucidate quantitatively the whole mechanism of the electropolymerization of a given monomer, since in general many reaction steps are involved in the chemical polymerization reaction, as being apparent from the fact that it can be regarded as "chain reactions." However, the electropolymerization occurs at and/or in the vicinity of electrode surface and at least the first step of the polymerization (i.e., dimerization) can be considered as "follow-up chemical reaction" from a viewpoint of the mechanism of electrode reaction.[65] In other words, in the initial step of electropolymerization the initiators for polymerization (they are usually radical ions) are first produced at electrode surface by the heterogeneous electron-transfer reaction of parent monomers and then dimerization and any higher polymerization proceed at and/or in the vicinity of electrode surface. Many electrochemical methods which are suitable for the study of such chemical reactions coupled to the heterogeneous electron-transfer have been ever developed.[66]

In this paper, we report the kinetic study of the mechanism of the reaction of the initial stages in the electropolymerization of 1-pyrenamine (PA, Fig. 1) in an acetonitrile solution by means of cyclic voltammetry (CV) and double potential-step chronoamperometry (DPSCA) which have proved to be useful for the study of the chemical reactions which are associated with heterogeneous electron-transfer reaction proper.[66-69] Recently, we[36] have reported the preparation of poly(1-pyrenamine) (PPA) film by the electropolymerization of PA, the characterization of its electrochemical, physicochemical and electrical properties,and the spectroscopic identification of the structure of the PPA film. The electrochemical responses obtained for the initial step of the electropolymerization of PA seem to be simple compared with other monomers (e.g., aniline and pyrrole). This is the first reason why we chose PA as the first candidate for the examination of the mechanism of electropolymerization. The second reason is that the first dimerization reaction, regarded as a follow-up chemical reaction, is not so fast and thus DPSCA can be applied to the determination of the rate constant of the dimerization reaction. In addition, the third reason is that no study has been reported on the mechanism of the initial-step

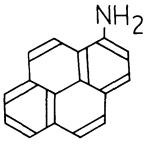

Fig. 1. Structure of 1-pyrenamine.

reactions in the electropolymerization of PA. It will be shown that the mechanism of the reaction of the initial stages in the electropolymerization of PA is an "ECE" mechanism, and that the chemical reaction interposed between successive electron transfers is considered as the radical-radical coupling reaction rather than the radical-parent monomer coupling reaction.

Experimental

Materials. 1-Pyrenamine (PA) (Aldrich Chemical Co.) was purified by the procedure described previously.[36] Acetonitrile (Wako Pure Chemical Industries, LTD) was distilled by ordinary technique after dehydration on molecular sieves (5A 1/16, Wako). Pyridine (Wako) of reagent grade was twice distilled under reduced pressure. Tetrabutylammonium tetrafluoroborate ($(n\text{-}C_4H_9)_4NBF_4$, $TBABF_4$) (Tokyo Kasei Co.) was of reagent grade. The basal-plane pyrolytic graphites (BPG) (Union Carbide Co.) were used as electrodes.[36] All other chemicals were of reagent grade and were used as received without further purification.

Apparatus and Procedures. A standard three-electrode electrochemical cell was used for all electrochemical experiments. The electrode assembly consists of a BPG disk electrode (area; 0.20 cm^2) as working electrode, a sodium chloride saturated calomel electrode (SSCE) as reference electrode and a spiral platinum wire as counter electrode. The compositions of the electrolytic solutions were 0.2 M $TBABF_4$+1—10 mM PA+0—25 mM pyridine (or CF_3COOH or 2,6-lutidine) in acetonitrile.

For cyclic voltammetry and double potential-step chronoamperometry (DPSCA), a home-made instrument was employed. The experiments of DPSCA were conducted according to the previously described procedure.[69] The width (τ) of the applied potential pulse was varied from 0.5 to 100 ms. An IR compensation was employed. The current-time responses of DPSCA were monitored and stored on a Nicolet 3091 oscilloscope and then the enlarged current-time curves were displayed on an X-Y recorder (Graphtec Co. WX 4403). The analysis of DPSCA's data was carried out according to the procedure originally suggested by Schwarz and Shain[70].

All experiments were run under nitrogen atmosphere at laboratory temperature (25±1°C). Potentials were measured and are quoted with respect to SSCE.

Results

Cyclic Voltammetry. The typical cyclic voltammograms obtained at a BPG disk electrode in an acetonitrile solution containing 0.2 M $TBABF_4$+5 mM PA are shown in Fig. 2, where to prepare a fresh electrode surface the BPG electrode was cut parallel to the eletrode surface with a scalpel each measurement. In the first forward potential scan at 10 V s^{-1} the anodic peak can be observed at ca. 0.65 V vs. SSCE. This peak is considered to correspond to the oxidation of PA to the corresponding cation radical (PA^+).[84] When the electrode potential was scanned to more positive potentials than 0.65 V vs. SSCE, additional anodic peaks were obtained.[36] From the viewpoint of polymer formation, the potential application of about 0.8 V vs. SSCE to the working electrode is enough to lead to the electropolymerization of PA at electrode surface. When the electrode potential was turned to negative, the cathodic peak corresponding to the anodic peak at 0.65 V vs. SSCE was observed at 0.55 V vs. SSCE, though the peak current is much smaller than the anodic one due to the consumption of the electrogenerated PA^+ by the follow-up chemical reaction. Furthermore, the cathodic peak at ca. 0.3 V corresponds to the reduction of the oxidized forms of the dimeric, oligomeric, and/or polymeric products which can be considered to be formed from the electrogenerated PA^+'s and/or PA's during the period (ca. several tens ms) of the potential scan from ca. 0.5 V to 0.8 V and then to ca. 0.5 V at 10 V s^{-1}. During the second forward scan, the new anodic peak is observed at ca. 0.4 V and corresponds to the cathodic peak at 0.3 V. In the further potential cycling between −0.5 and 0.8 V, two anodic peaks and two cathodic ones are obtained as shown in Fig. 2A. The peak currents at 0.55 and 0.65 V tend to decrease with the potential cycling, while the peak currents at 0.3 and 0.4 V tend to increase with the cycling of electrode potential. This suggests that the electroactive products deposite onto the electrode surface and at the same time the diffusion of PA monomers to the electrode surface through the deposited product layer becomes more difficult.[36]

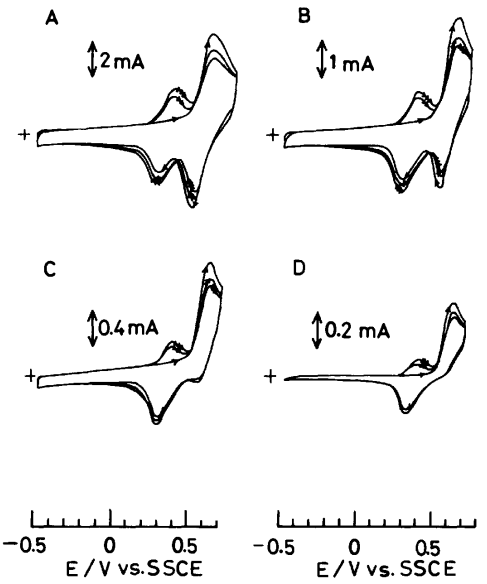

Fig. 2. Scan rate dependence of cyclic voltammograms obtained at a BPG disk electrode in an acetonitrile solution containing 0.2 M $TBABF_4$ and 5.0 mM PA. Scan rate: (A): 10, (B): 5.0, (C): 1.0, and (D): 0.2 Vs^{-1}. Electrode area: 0.20 cm^2.

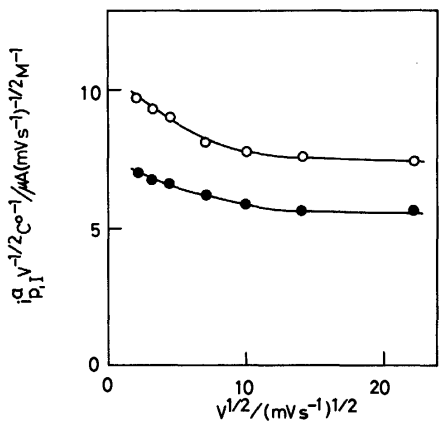

Fig. 3. Dependence of $i^a_{p,I}/v^{1/2}C^o$ on potential scan rate ($v^{1/2}$) at different concentrations of PA. Concentration of PA (C^o): (○): 1.0 mM, (●): 5.0 mM. Other experimental conditions are the same as in Fig. 2.

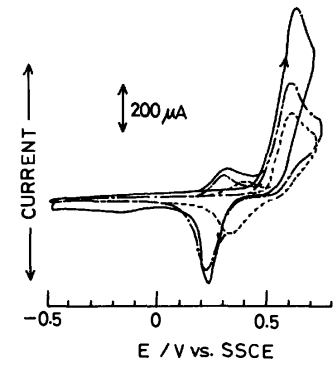

Fig. 4. Cyclic voltammograms of PA and PA-pyridine mixtures. Concentration of PA: 5.0 mM. Concentration of pyridine: (——): 25.0, (— — —): 2.5, and (----): 0 mM. Scan rate: 100 mV s^{-1}. Other experimental conditions are the same as in Fig. 2.

Furthermore, it is apparent from Fig. 2 that the peak current ratio of the cathodic peak current ($i^c_{p,I}$) corresponding to the reduction of PA^+ to the anodic peak current ($i^a_{p,I}$) corresponding to the oxidation of PA decreased with decreasing the potential scan rate (v) and at v=0.2 V s^{-1} the $i^c_{p,I}$ was not substantially observed. Also, the values of $i^a_{p,I}/C^o v^{1/2}$ (C^o: concentration of PA) decreased with $v^{1/2}$ in a way which is dependent on C^o (Fig. 3). This behavior is taken as an indication that the chemical complication that follows the electron transfer may have a higher than first-order kinetics. These results suggest that the follow-up chemical reactions which consume the electrogenerated PA^+'s occur at and/or in the vicinity of the electrode surface on the time scale of this experiment.

Figure 4 shows the effect of the addition of various amounts of pyridine into the electrolytic solution upon the cyclic voltammetric response of PA. An increase of pyridine concentration produces an increase in $i^a_{p,I}$ towards a value corresponding to a two-electron electrode reaction. A similar result was obtained when 2,6-lutidine was used instead of pyridine. The effect of an acidic medium was also studied by addition of anhydrous CF_3COOH to the electrolytic solutions. The results are shown in Fig. 5. Increasing amounts of CF_3COOH produced a decrease in $i^a_{p,I}$, while the peak potential ($E^a_{p,I}$) shifted to more positive values. This was expected, since in an acidic medium the free amine forms a protonated species which is electrochemically inactive.

Double Potential-Step Chronoamperometry (DPSCA). Figure 6 shows the typical current-time curve obtained in the DPSCA's experiment of the PA system. In this case, the electrode potential (E_1) was first set at the potential region where no oxidation of PA occurs substantially and then the potential was stepped to the potential (E_2) at which the oxidation of PA is

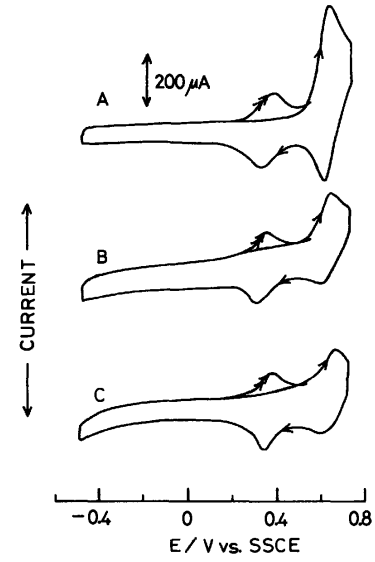

Fig. 5. Cyclic voltammograms of PA in the presence and absence of CF_3COOH. Concentration of PA: 1.0 mM. Concentration of CF_3COOH: (A): 0, (B): 1.0, and (C): 10.0 mM. Scan rate: 1 V s^{-1}. Other experimental conditions are the same as in Fig. 2.

diffusion-controlled and for a given period (τ) the electrode potential was held at this potential, and after that the electrode potential was re-stepped to the potential (E_3) at which the reduction of the electrogenerated PA^+ is diffusion-controlled. Typically, E_1=−0.2 V, E_2=0.7 V, and E_3=0.4 V vs. SSCE. However, it is not easy to choose appropriately the potentials E_2 and E_3, as can be seen from the cyclic voltammograms shown in Fig. 2. The reasons are as follows: (i) the potential regions corresponding to E_2 and E_3 are narrow due to the occurrence of the succeeding oxidation or reduction process and (ii) the peak potentials ($E^c_{p,I}$ and $E^a_{p,I}$) corresponding to $i^c_{p,I}$ and $i^a_{p,I}$ shift to more cathodic and anodic potentials, respectively, with shortening the time window of the

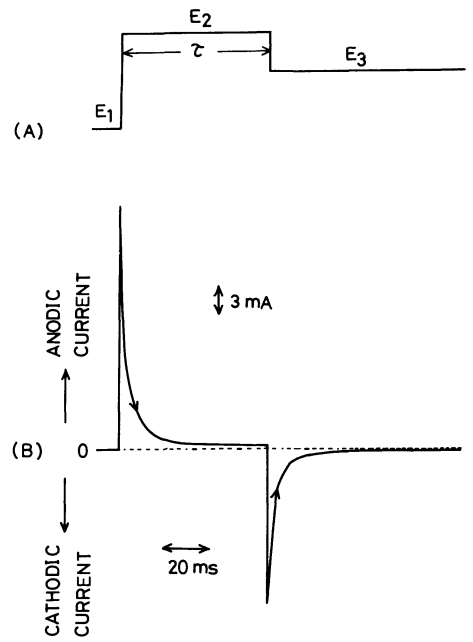

Fig. 6. (A) Typical potential-step mode used in the DPSCA measurement of the PA system. $E_1=-0.2$, $E_2=0.7$, and $E_3=0.4$ V vs. SSCE. Potential-step width (τ): 60 ms. (B) The current-time curve obtained for the potential-step application shown in A. Solution composition: 0.2 M $TBABF_4$+1.0 mM PA in acetonitrile. Electrode area: 0.20 cm^2.

measurement (i.e., τ). The latter phenomenon is apparent from Fig. 2 and is due to the fact that the electrode reaction of the PA/PA^+ redox couple is not completely reversible on the time scale of the measurement. To overcome these problems, the cyclic voltammogram of PA was observed at the scan rate which corresponds to the time scale of each DPSCA's experiment and then on the basis of the obtained cyclic voltammogram the most reasonable E_2 and E_3 potentials were chosen. Furthermore, by changing slightly the E_2 and E_3 potentials, the DPSCA's measurement was repeated. The current-time response obtained for the forward potential step, during which the oxidation of PA to PA^+ occurs, was found to nearly obey the chronoamperometric Cottrell equation, that is, a plot of i vs. $t^{-1/2}$ was almost linear and passed the origin.[66]

From the cyclic voltammetric behavior shown in Fig. 2, we assumed that the mechanism of the reaction of the initial stages of the electropolymerization of PA is apparently the "ECE" mechanism, that is, the oxidation reaction of PA to PA^+ (E), the follow-up chemical reaction consuming PA^+ (C) and the reduction (and oxidation) of the product (i.e., dimer) produced by the follow-up chemical reaction (E) occur continuously. We can assume various mechanisms for such chemical reactions interposed between successive electron transfers.[66,67] In this study, the mechanisms of the most popular two types were suggested for the follow-up chemical reaction; "radical-radical coupling" reaction and "radical-parent monomer coupling" reaction. Thus, the following two ECE mechanisms were assumed for the initial stages of the electropolymerization of PA.

Mechanism I:

$$A \overset{E_1^{0\prime}}{\rightleftharpoons} B \quad (1)$$

$$2B \xrightarrow{k} C \quad (2)$$

$$C \overset{E_2^{0\prime}}{\rightleftharpoons} D \quad (3)$$

Mechanism II:

$$A \overset{E_1^{0\prime}}{\rightleftharpoons} B \quad (1)$$

$$A + B \xrightarrow{k} C \quad (2')$$

$$C \overset{E_2^{0\prime}}{\rightleftharpoons} D \quad (3)$$

where Eqs. 1 and 3 show the heterogeneous electron-transfer reactions of the A/B couple and the C/D couple, respectively, the formal oxidation-reduction potentials of which are $E_1^{0\prime}$ and $E_2^{0\prime}$, respectively and $E_2^{0\prime}<E_1^{0\prime}$, and Eqs. 2 and 2′ indicate the chemical reactions which proceed at and/or in the vicinity of electrode surface. In the present case, A, B, C, and D correspond to PA, PA^+, $(PA)_2$ and $(PA)_2^+$, respectively, where $(PA)_2$ and $(PA)_2^+$ are the dimer of PA and its cation radical, respectively.

The distinction between Mechanism I and Mechanism II is possible by analyzing the dependence of the current ratio $i^c(t=2\tau)/i^a(t=\tau)$ on $\log(kC^\circ\tau)$,[67] where $i^c(t=2\tau)$ and $i^a(t=\tau)$ show the cathodic current (at $t=2\tau$) for the reduction of PA^+ to PA and the anodic current (at $t=\tau$) for the oxidation of PA to PA^+, respectively, in the DPSCA's current-time curves, τ is the potential-step width, and k is the apparent rate constant of the reactions expressed by Eqs. 2 and 2′. The theoretical curves[67] representing the relations between $i^c(t=2\tau)/i^a(t=\tau)$ and $\log(kC^\circ\tau)$ for Mechanisms I and II are shown in Fig. 7 together with the experimental plots. As can be expected from these theoretical curves,[67] the examination of the dependences of $i^c(t=2\tau)/i^a(t=\tau)$ on $\log(kC^\circ\tau)$ at larger values of $\log(kC^\circ\tau)$ allowed us to determine which of the two mechanisms more suitably applies to the initial stages of the follow-up chemical reaction. The experimentally available quantity $i^c(t=2\tau)/i^a(t=\tau)$ is plotted vs. $\log(C^\circ\tau)$. By overlaying the experimental and theoretical plots and by appropriately shifting the experimental plot along the abscissa and ordinate of the theoretical plot, the two can be superimposed. The relative location of the experimental and theoretical axes permits the evaluation of the rate constant, k.

The resulting plots of $i^c(t=2\tau)/i^a(t=\tau)$ vs. $\log(C^\circ\tau)$ seem to fall on a continuous curve which represents

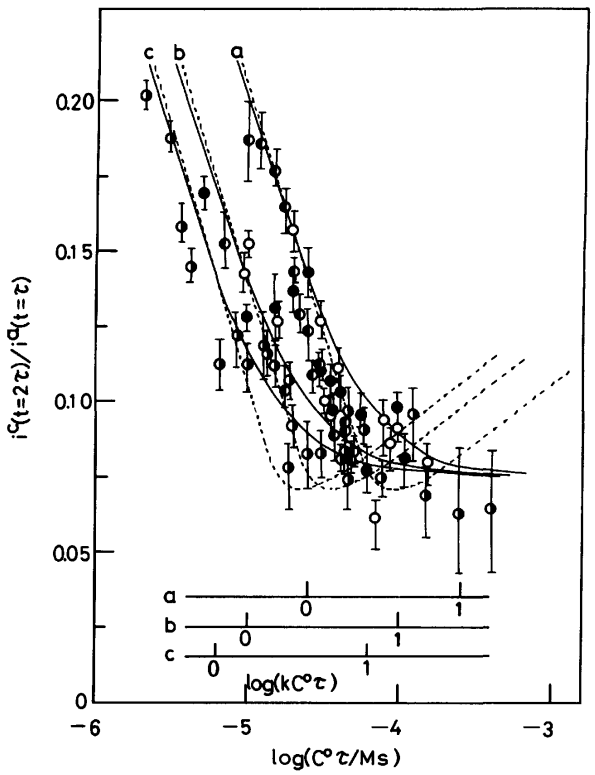

Fig. 7. Polts of $i^c(t=2\tau)/i^a(t=\tau)$ vs. $\log(C^\circ\tau)$. Solid and dashed curves indicate the theoretical $i^c(t=2\tau)/i^a(t=\tau)-\log(kC^\circ\tau)$ curves for Mechanism I and Mechanism II, respectively. The curves a, b, and c correspond to $k=0.4\times10^5$, 1.0×10^5, and 1.6×10^5 $M^{-1}s^{-1}$, respectively. Closed circles indicate the experimental data. Supporting electrolyte: 0.2 M $TBABF_4$. Concentration of PA: (●): 0.5, (○): 1.0, (◑): 5.0, and (◐): 10.0 mM. Widths of error bars indicate uncertainties in the measurements of $i^c(t=2\tau)/i^a(t=\tau)$.

the $i^c(t=2\tau)/i^a(t=\tau)-\log(kC^\circ\tau)$ relation for Mechanism I rather than that for Mechanism II, irrespective of the used values of C° and τ. In this case, the C°'s used were 0.50, 1.0, 5.0, and 10.0 mM, and the τ's were arbitrarily changed in the range of ca. 0.5 to 100 ms. Using the overlay matching technique just described the experimental points were matched with the theoretical curve. From the comparison of these experimental and theoretical curves, the value of k was estimated to be $(1.0\pm0.8)\times10^5$ $M^{-1}s^{-1}$.

Discussion

From the data obtained above, one can see that the initial-stage process of the electropolymerization of PA is symbolized as an ECE type of mechanism, and that the chemical reaction interposed betweeen successive electron transfers is the radical-radical coupling (PA^+-PA^+ coupling) reaction rather than the radical-parent monomer coupling (PA^+-PA coupling) reaction. Further, from the previous paper,[36] the coupling of PA^+'s is considered to occur at the 1- and 6- positions and/or the 1- and 8- positions. The mechanistic scheme for an electropolymerization via such a radical-radical coupling seems to be familiar in the electropolymerization of many aromatic compounds.[41,45,46,55,61,64,72,73] In the case of these electropolymerization, when the electrode oxidation reaction occurs, the radical cation concentration at the anode surface is high, whereas the concentration of parent monomer is low, rendering reactions between radical cations more probable than their reactions with parent monomers. This may be due to the fact that the radical-radical coupling reaction is likely to be faster than the diffusion of the parent monomer into the vicinity of the electrode. Therefore, the situation under consideration is very different from typical polymerization reactions occurring in the bulk of a solution, where the concentration of parent monomer is always much higher than those of the reactive intermediates (such as radical ions).

Two types of electrochemical polymerizations have seemed to be recently accepted;[55,74-77] one is the electrochemically initiated polymerization[75-77] and the other is the stoichiometric electrochemical polymerization.[55,74] In the former case, the initiators of polymerization are formed by the heterogeneous electron-transfer reaction of parent monomers and then the propagation reaction, chain-transfer reaction, termination reaction, etc. are thought to occur as in usual chemical polymerization reactions. In the latter case, on the other hand, the reactive intermediates are formed by the heterogeneous electron-transfer reactions of parent monomers as well as the products (the aromatic dimer, the higher molecular weight oligomers, etc.) and the electropolymerization via the reactions between them proceeds. The stoichiometric electrochemical polymerization was first described with polypyrrole by the IBM research group[55,74] and since then, it has been reported that it is applicable to the heterocyclic compounds such as pyrrole, thiophene, indole and benzo[*b*]thiophene,[38,55,72-74] the nonbenzenoid aromatic hydrocarbons such as azulene,[55,78] and the polycyclic aromatic hydrocabons such as pyrene and fluorene.[37-39,55] The electrochemical polymerization of PA is also regarded as a stoichiometric electrochemical polymerization. In general, such a stoichiometric electrochemical polymerization is symbolized as $E(CE)_n$ on the basis of an extension of customary electrochemical abbreviation.[55,65] In the present study, the initial stages of the electropolymerization of PA were elucidated as an ECE mechanism. Of course, note that further reactions proceed actually as can be seen from the fact that the degree of the polymerization of PA is ca. 8.[36]

Further, it is remarkable that the cyclic voltammetric responses for the oxidation of PA were varied by the presence or absence of the basic or acidic additives. An increase of pyridine (or 2,6-lutidine)

concentration produces an increase in $i^a_{p,I}$ towards about twice the $i^a_{p,I}$ value in the absence of pyridine (or 2,6-lutidine). These additives are stronger bases than PA in acetonitrile and would replace it as proton acceptor. Then, the overall reaction corresponding to the first anodic peak may be considered as a two-electron process, as being previously suggested for the anodic oxidation of 1-naphthylamine in acetonitrile[80,81] and would thus be represented by the following equation:

$$2PA + B \rightleftarrows D^{2+} + 2BH^+ + 4e^- \quad (4)$$

where B is the basic additives, BH^+ is the protonated form of B and D^{2+} is the dicationic dimer of PA. In contrary, the addition of the acidic additives such as CF_3COOH to the electrolytic solution of PA caused a decrease in $i^a_{p,I}$ and a shift of $E^a_{p,I}$ to more anodic values. This may be understood considering that if PA is protonated in an acidic medium, it becomes electroinactive. The similar behaviors have been reported for the anodic oxidation of the other aromatic compounds (e.g., 2-fluorenamine,[79] 1-naphthylamine,[80,81] *o*- and *p*-phenylenediamine,[64,82] and aniline[83]) in nonaqueous solutions. From a viewpoint of the preparation of the poly(1-pyrenamine) film on electrode surfaces, it is preferable to electrolyze PA in the presence of basic additives, as reported previously.[36]

Finally, we demonstrate that the DPSCA technique used in this study would be successfully applicable to the kinetic study (e.g., the determination of mechanistic pathways and associated chemical rate) of the initial stages of the electropolymerization of many aromatic compounds other than PA.

High-Temperature Reaction of NH_3-N_2O System in Shock Waves

Nobuyuki FUJII, Syuji UCHIDA, Hisaaki SATO, Shiro FUJIMOTO† and Hajime MIYAMA*
Department of Materials Science and Technology, The Technological University of Nagaoka, Kamitomioka, Nagaoka 940-21
(Received May 21, 1986)

The high-temperature reaction of NH_3 with N_2O in shock waves was investigated by measuring ultaviolet absoption of NH_3 and OH, and infrared emission of N_2O, in the temperature range of 1700—2300 K on the mixture of NH_3-N_2O diluted with large amount of argon. A comparison of the observed decays of NH_3 and N_2O and the formation of OH with those obtained by computer simulation behind the incident shock wave was carried out. From the comparison, the rate constants of the following elementary reactions were determined: $NH_3+O\rightarrow NH_2+OH[k_4=10^{12.5}\exp(-25.5\,kJ/RT)\,cm^3\,mol^{-1}\,s^{-1}]$; $NH_3+OH\rightarrow NH_2+H_2O[k_5=10^{12.5}\exp(-8.4\,kJ/RT)\,cm^3\,mol^{-1}\,s^{-1}]$.

The high-temperature oxidation of NH_3 has been studied by many researchers,[1-4] and it was reported that NH_2 radicals play important roles.[1] Among the formation reaction of NH_2, the most important reactions in the initial stage of the reaction, $NH_3+O\rightarrow NH_2+OH$ and $NH_3+OH\rightarrow NH_2+H_2O$ have been investingted by several reserchers and their rate constants have been recommended.[5,6] However, larger values of the rate constants have also been reported.[4,7-9]

The objective of the present work is to examine the above two rate constants precisely by measuring spectroscopically the concentrations of NH_3, N_2O, and OH in the high-temperature reaction of NH_3-N_2O system in shock waves. Since the high temperature dissociation of N_2O is the initiation reaction of above reaction system and its rate constants have been determined exactly,[8,10,11] the decomposition of N_2O was studied in the incident shock waves at first. Simulatin of the reaction was carried out and the results were compared with the experiments. After confirming the accuracy of this experimental technique by the comparison, reaction of NH_3-N_2O was studied in the incident shock waves.

Experimental

The shock tube used in this study is made of stainless steel tubing of 46 mm internal diameter, consisting of a test section of 3.6 m long, a high-pressure section of 2 m long and a dump tank located at the end of the test section. The shock tube had a leak rate less than 5×10^{-4} Torr min^{-1} (1 Torr=133.322 Pa) and was evacuated to less than 2×10^{-4} Torr before each experiment. Polyester diaphragms were pressure burst using H_2 driver gas. The incident shock wave velocity was measured by four piezo-electric gauges located at intervals of 200 mm and a time counter, and the shock parameters were calculated from the shock velocity. An observation section is installed at 3.1 m down stream from the diaphragm. The time history of NH_3 was monitored by measuring the ultraviolet absorption of NH_3 at 200 nm by using an optical system consisting of a D_2 lamp, a monochromator, and a photomultiplier. N_2O time history was monitored by the infrared emission of N_2O at 4.52 μm with an InSb detector through an interference filter (half width: 0.18 μm). Also at the same location, the pressure profile was measured by a piezoelectric gauge. On the other hand, simultaneously with measurement of NH_3, the formation of OH radical was observed by resonant absorption at 306 nm by using OH lamp powered by a microwave discharge in a flow of H_2O vapor. Calibration of OH absorption was carried out by the exeriment of shock heated H_2-O_2-Ar mixtures. These signals were displayed on a digital storage oscilloscope. Experiments were carried out on mixtures of N_2O (1%) and argon (99%) and of NH_3 (1—2%), N_2O (0.3—1%) and argon (97.6—98.7%). The experimental conditions were; 1700—2300 K and 0.9—2.1 atm as summarized in Table 1.

Results and Discussion

Dissociation of N_2O. High-temperature decom-

Table 1. Experimental Conditions

Mixture	N_2O %	NH_3 %	Ar %	T_{20} K	p_{20} atm

1 atm=101325 Pa.

† Present address: Department of Chemistry, National Defense Academy, Hashirimizu, Yokosuka 239.

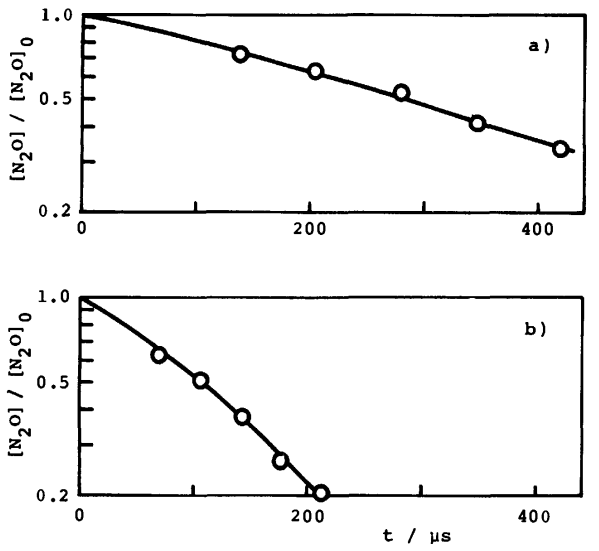

Fig. 1. Examples of the comparison of the experimentally measured N_2O first order decays in mixture I (symbols) with simulated ones (lines). a): $T_0=1855$ K, $p_0=2.01$ atm, b): $T_0=2010$ K, $p_0=1.93$ atm.

position of N_2O has been studied by many researchers[8,10,11] and its reaction scheme is well-established. That is, the following elementary reactions (1)—(3) are important at the inital stage of the reaction;

(1) $N_2O + M \longrightarrow O + N_2 + M$,
(2) $N_2O + O \longrightarrow NO + NO$,
(3) $N_2O + O \longrightarrow N_2 + O_2$.

When the O atoms are in the steady state, the decomposition rate of N_2O is given by the following equation;[8,10]

$$d[N_2O]/dt = -2k_1[N_2O][M], \quad (1)$$

where [M] is the concentration of the third body. Accordingly, the rate constant of the dissociation of N_2O is obtained as follows by integrating Eq. 1;

$$k_1 = (2[M]t)^{-1}\ln([N_2O]_0/[N_2O]), \quad (2)$$

where subscript 0 shows the initial condition.

In the present experiment, the decay profile of N_2O infrared emission intensity measured behind the incident shock wave deviated from the first-order rate law as the reaction proceeded. Examples of the decay of N_2O are shown in Fig. 1. From the initial slope of the emission, the rate constants for the dissociation of N_2O were obtained according to Eq. 2. They are listed with the experimental conditions in Table 2. The Arrhenius plot of k_1 is shown in Fig. 2, together with the values recommended by Baulch et al.,[10] by Just,[11] and by Hanson et al.[8] Agreement between the values obtained in the present experiment and the recommended values are very good. From the plot of Fig. 2, the following Arrhenius expression was obtained;

Table 2. Experimental Results for Mixture I

Run	T_{20} / K	p_{20} / atm	$[M]_{20}$ / mol cm^{-3}	k_1 / cm^3 mol^{-1} s^{-1}
1	1550	2.05	1.61×10^{-5}	3.64×10^{6}
2	1580	1.89	1.44	4.43×10^{6}
3	1680	1.92	1.39	1.38×10^{7}
4	1690	1.93	1.40	1.87×10^{7}
5	1800	2.02	1.38	5.02×10^{7}
6	1855	2.01	1.33	9.58×10^{7}
7	1929	1.89	1.20	1.74×10^{8}
8	2010	1.93	1.18	2.94×10^{8}

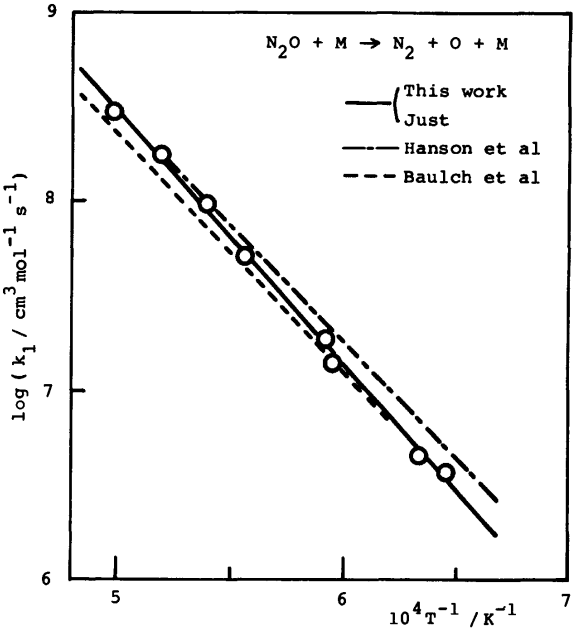

Fig. 2. Arrhenius plots of k_1.

$$k_1 = 10^{15.21}\exp(-257.7\ \text{kJ}/RT)\ \text{cm}^3\ \text{mol}^{-1}\ \text{s}^{-1}.$$

Then, the decay of N_2O was calculated by computer simulation by using elementary reactions (1)—(3) and their reverse reactions. In this calculation, the rate constant of Reaction (1) obtained in this experiment was used and values recently recommended by Hanson et al.[8] for Reactions (2) and (3) were adopted. In this simulation the heat of reaction and the correction for the nonideality of shocked flow caused by the boundary layer behind the incident shock front[12,13] were taken into account. The calculated decay profiles of N_2O agreed with the experiments as shown in Fig. 1. From the results, it was confirmed that the shock tube technique coupled with the above mentioned computer simulation had a good accuracy in the present experiment.

Reaction of NH_3 with N_2O. Reaction mechanism: The reaction of NH_3 with N_2O at high temperatures is initiated by the decomposition of N_2O and the main

Table 3. Reaction Schemes and Rate Parameters[a)]

Reaction	Mechanism A[6)]			Mechanism B[7)]		
	log A	B	E/kJ	log A	B	E/kJ
1. $N_2O + M \rightarrow N_2 + O + M$	15.21		257.7	23.84	−2.5	272.0
2. $N_2O + O \rightarrow NO + NO$	13.84		111.7			
3. $N_2O + O \rightarrow N_2 + O_2$	14.00		117.2			
4. $NH_3 + O \rightarrow NH_2 + OH$	12.49		25.5	13.34		37.2
5. $NH_3 + OH \rightarrow NH_2 + H_2O$	12.50		8.4	13.91		35.2
6. $NH_3 + NH_2 \rightarrow N_2H_3 + H_2$	11.90	0.5	90.4			
7. $N_2H_3 + M \rightarrow NH_2 + NH + M$	12.80		41.8

9. $NH_2 + O \rightarrow HNO + H$				14.82	−0.5	0
10. $NH_2 + OH \rightarrow NH + H_2O$				11.70	0.5	8.3
11. $HNO + M \rightarrow H + NO + M$				16.25		203.7
12. $H + N_2O \rightarrow N_2 + OH$				13.88		63.2
13. $H + NH_3 \rightarrow NH_2 + H_2$				14.30		97.4

a) $k = AT^B\exp(-E/RT)$ in units of $cm^3\ mol^{-1}\ s^{-1}$.

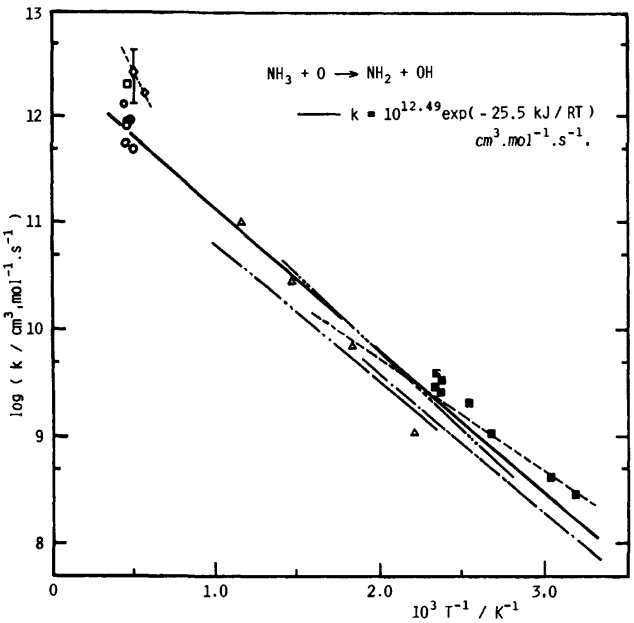

Fig. 3. Arrhenius plots of k_4. Solid line: this work, other lines : from Baulch et al.,[10)] ○: Fujii et al.,[6)] ◇: Salimian et al.,[7)] □: Saito et al.,[14)] ■: Kirchner et al.,[15)] △: Perry.[16)]

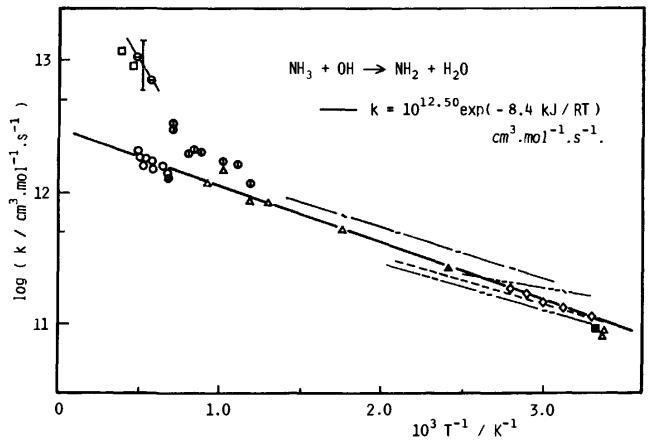

Fig. 4. Arrhenius plots of k_5. Solid line: this work, other lines, ●, △, ▲, ■: from Fujii et al.,[5)] ○: Fujii et al.,[5)] ⊖: Salimian et al.,[7)] □: Zabielski et al.,[9)] ◇: Stephens,[17)] ⓘ: Jeffries et al.[18)]

subsequent reactions are;

(4) $NH_3 + O \longrightarrow NH_2 + OH$, $\Delta H = 28.5\ kJ\ mol^{-1}$,

(5) $NH_3 + OH \longrightarrow NH_2 + H_2O$, $\Delta H = -42.6\ kJ\ mol^{-1}$.

The reaction scheme in the initial stage of this system, presented by Fujii et al. (Mechanism A)[6)] is shown in Table 3. Here, Reactions (1)—(3) are those of the decomposition of N_2O, Reactions (4)—(6) are main reactions for the consumption of NH_3 and Reactions (7) and (8) are the subsequent reactions. Also the scheme reported by Salimian et al. (Mechanism B)[7)] is shown in the table. In this scheme, Reaction (9) is included as the reaction of NH_2 with O, then H atom plays an imporant role for the formation of OH. Also, Salimian el al.[4)] reported the kinetic model including 60 reactions of the N-O, N-H, N-H-O, and O-H system (Mechanism B′). However, the rate constants of many of these reactions were not accurately known and their values were estimated for the simulation.

As for the rate constants k_4 and k_5, Fujii et al.[5)] obtained k_4 by measuring ultraviolet absorption of NH_3 in NH_3-H_2-O_2-Ar mixtures. Also, Fujii et al.[6)] obtained k_5 by measuring ultraviolet absorption of NH_3 and infrared emission of N_2O in NH_3-N_2O-Ar mixtures. On the other hand, Salimian et al.[7)] measured ultraviolet absorption of OH and infrared emission of NH_3 in NH_3-N_2O-Ar mixtures and obtained k_4 and k_5 simultaneously. Zabielski et al.[9)] mea-

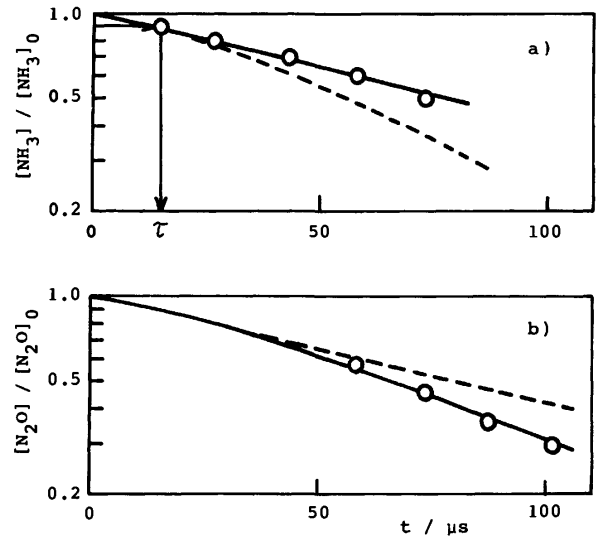

Fig. 5. Examples of the comparison of the experimentally obtained first order decays of NH_3 and N_2O in mixture III (symbols) with simulated ones (lines) T_0=2110 K, p_0=2.13 atm, a): NH_3, b): N_2O.

sured concentration profiles of NH_3, OH, and O in a low-pressure CH_4-O_2-Ar flat flame containing small amounts of NH_3 and obtained k_5 using k_4 given by Salimian et al.[7] The values of k_4 and k_5 by Salimian et al.[7] and k_5 by Zabielski et al.[9] were about 5 times as large as those recommended by Fujii et al.[5,6] Jefferies and Smith[18] measured k_5 over the range 840—1425 K by using an infrared laser pyrolysis technique (10.6 μm) with laser-induced fluolescence detection of OH. The values of k_5 at 1425 K were about 2 times larger than those by Fujii et al.[5] The Arrhenius plots of these rate constants are shown in Figs. 3 and 4, together with the values reported by other researchers. For the experimental data at high and low temperatures, nonlinear-Arrhenius expressions were adopted for k_4 by Salimian et al.[7] and for k_5 by Salimian et al.,[7] Zabielski et al.[9] and Jefferies et al.[18] In order to justify the experimental curved-Arrhenius expression, they calculated the rate constants by the transition state theory using some assumptions. The rate constants of other Reactions (6)—(8) have not yet been measured accurately.

Consumption of NH_3 and N_2O: The concentration of NH_3 decayed almost according to the first order rate law in NH_3-N_2O system. The concentration of N_2O decayed also according to the first-order rate law and the rate of the decay in the equimolar mixture of NH_3 and N_2O was almost similar to that of the decomposition of N_2O. Examples of the first order decays of NH_3 and N_2O are shown in Fig. 5.

In order to examine the contribution of each elementary reaction to the decay rate of NH_3, the sensitivity checks described previously[1] were applied as follows. The decay of NH_3 was computed using

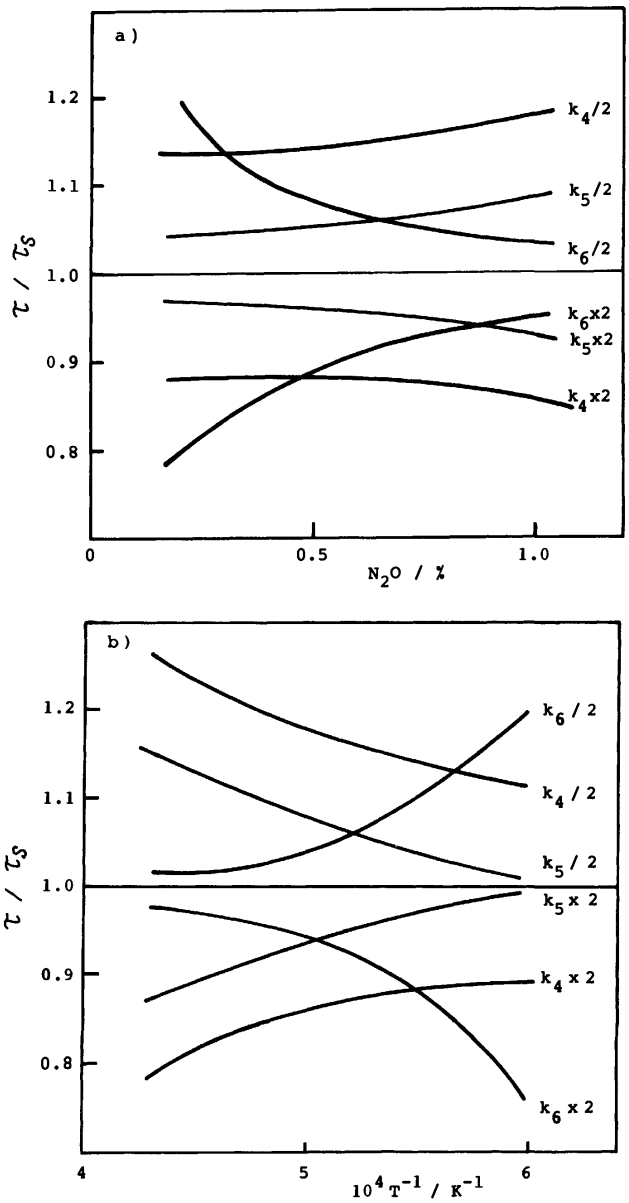

Fig. 6. Sensitivity check of the elementary reactions of (4), (5), and (6) for NH_3 consumption in NH_3-N_2O-Ar mixture. τ_s: Calculated reaction time obtained using the standard rate constants cited in Table 3. τ: Calculated reaction time obtained using the doubled ($k\times2$) or halved ($k/2$) value of the standard rate constant of Reaction (4), (5), or (6), and the standard values for other reactions. a) N_2O concentration dependence of τ/τ_s, NH_3=1%, T=2000 K, p=2 atm. b) Temperature dependence of τ/τ_s, NH_3: N_2O: Ar=1 : 1 : 98, p=2 atm.

Mechanism A, by either halving or doubling the standard rate constant of each elementary reaction shown in Table 3, and keeping other rate constants unchanged. The computed reaction time required for 10% consumption of NH_3, τ in Fig. 5, was found to be very sensitive to the change in the rate constants of Reactions (1) and (4)—(6), but not sensitive to those of

other elementary reactions. Examples of these results of the sensitivity checks comparing the effects by Reactions (4)—(6) are shown in Figs. 6 a) and b). From the figures, it is shown that the calculated reaction time τ is not sensitive to the rate constant of Reaction (6), when the N_2O concentration is higher than 1% (when NH_3 is 1%) and the temperature is higher than 2000 K. Therefore, mixtures I and II were omitted for the simulation to determine the value of k_4 without using reaction (6). Also, when the N_2O concentration is higher than that of NH_3, it is considered that the subsequent Reaction (12) becomes important. Therefore, N_2O rich mixtures was not examined in the present simulation to determine k_4 without using reaction (12). Based on the discussion, the mixture III was used for the simulation at first, in which only three Reactions (1), (4), and (5) were used.

The rate constant of Reaction (4) was determined by fitting the simulated τ value of NH_3 decay to the experimental one, where the rate constant k_1 determined in this experiment and k_5 of Fujii et al.[5] were

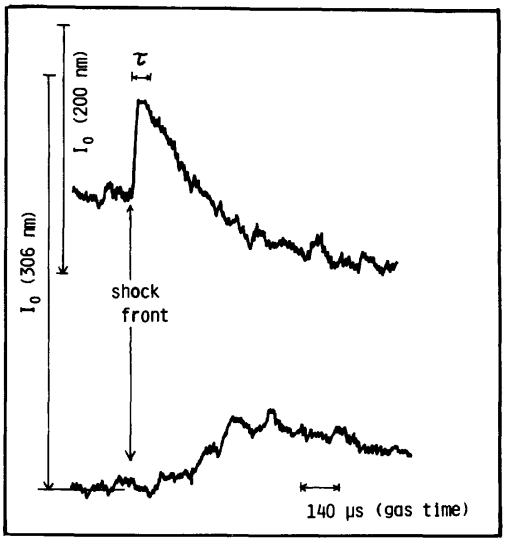

Fig. 8. Typical experimental records of NH_3 decay (upper trace) and OH formation (lower trace), NH_3: N_2O : Ar=1 : 1 : 98, T_0=1853 K, p_0=2.26 atm.

used. The rate constants of Reaction (4) obtained are shown in Table 4 and Fig. 4.

The decays of NH_3 and N_2O calculated by using reactions (1), (4), and (5) are shown by the dotted lines in Fig. 5. They agreed with the experimental values in the initial stage of the reaction. The deviation of the calculated curves from the experimental ones after the reaction time τ were improved by adding the subsequent Reactions (2), (3), and (6)—(8) to the reaction scheme, as shown by the solid lines in Fig. 5.

Computer simulatons using reactions (1)—(8) shown in Table 3 were also carried out for the mixtures II and IV, which were omitted for the simulation using reactions (1), (4), and (5) as described above. The time histories of NH_3 concentration obtained by the simulation almost agreed with the experimental ones, as well as in the case of III shown in Fig. 5. The overall rate constant for the first order decay of NH_3 was obtained according to the following equation;

$$-d[NH_3]/dt = k_{overall}[NH_3] \quad (3)$$

The comparison of the overall first order rate constant obtained by the simulation using Mechanism A with those obtained by the experiments are shown in Fig. 7.

From the results of the present study, it was found that the high temperature reaction of NH_3 with N_2O can be explained by the Reactions (1)—(8) shown in Table 3.

Formation of OH: The formation of OH were measured simultaneously with the decay of NH_3 in shock heated NH_3-N_2O equimolar mixtures. Typical experimental records of NH_3 and OH are shown in Fig. 8. Since the detection limit of OH absorption was about 5×10^{-10} mol cm^{-3}, high noise level prevented to

examine the OH formation in the very initial stage of the reaction. In order to evaluate the rate of OH formation, concentration of OH at $t=100$ μs, $[OH]_{t=100}$, were taken from the experimental record of OH. The value is shown in Table 5, together with τ value of NH_3 consumption.

In order to examine the rate constants of Reactions (4) and (5), calculations were performed using the above described two mechanisms A and B. A comparison of the experimental concentrations of OH at $t=100$ μs with calculated values are shown in Fig. 9. In this figure, the values calculated by Mechanism A agree well with the experiments, but those by Mechanism B are much lower than the experiments. Also, the changes of the computed concentrations of NH_3 and OH were compared with the experiments in the period of about 50% NH_3 consumption. Figures. 10 (I) and (II) show examples of comparison of the

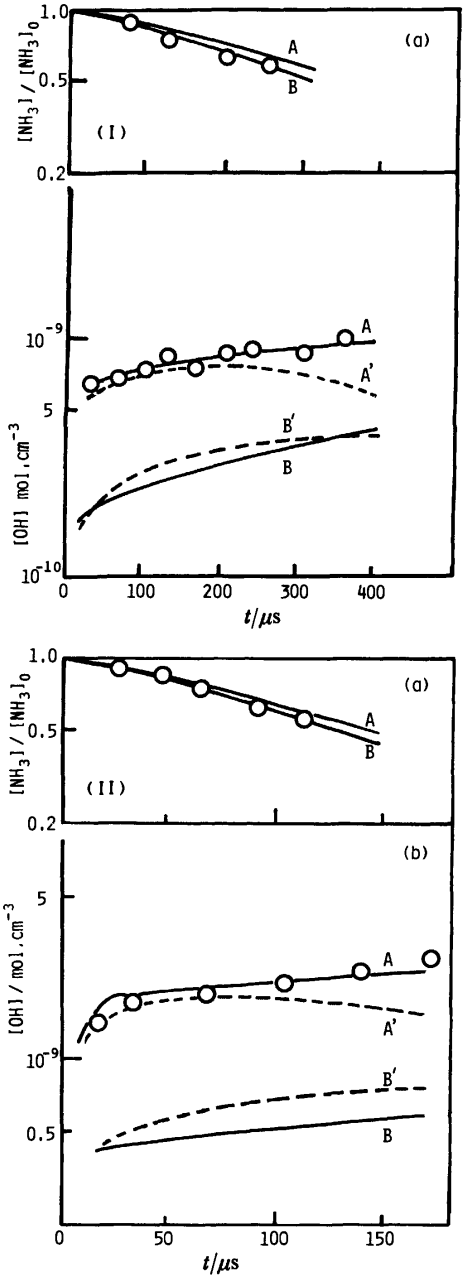

Fig. 10. Comparison of the experimental profiles (symbols) of (a) NH_3 (b) OH with those obtained by calculations (lines). Solid lines A and B are those calculated by Mechanisms A and B respectively. Broken lines A′ and B′ are those calculated by Mechanisms A′ and B′, respectively.
(I) NH_3 : N_2O : Ar=1 : 1 : 98, $T_0=1854$ K; $p_0=2.25$ atm, (II) $T_0=1990$ K; $p_0=2.08$ atm.

experimental profiles of NH_3 and OH with calculated ones. As shown in the figures, consumption of NH_3 calculated by Mechanism B are faster than those by Mechanism A, however both values are not very different from the experimental values. For those of OH formation, the profiles calculated by Mechanism A are much closer to the experimental profiles than those by Mechanism B as shown in the figures.

In addition, a calculation based on Mechanism A using the k_4 and k_5 values reported by Salimian et al.[7] and a calculation based on Mechanism B using the k_4 and k_5 values reported by Fujii et al.[5,6] were carried out. The former results were not very different from the results of the calculation based on Mechanism B listed in Table 3, while the latter results were similar to those of Mechnism A listed in Table 3, in the initial stage of the reaction.

The effects of the subsequent reactions on NH_3 consumption and OH formation were also calculated. As the subsequent reactions of Mechanism A, 54 reactions from the report by Salimian et al. (Mechanism B')[4] were adopted. The results of the calculation using 62 reactions and their reverse reactions (Mechanism A') were compared with the experiments. Examples of the calculated profiles of NH_3 consumption and OH formation by Mechanisms A' and B' are shown by broken lines A' and B' in Figs. 10 (I) and (II). They do not deviate appreciably from the original profiles A and B, respectively, in the initial stage of the reaction, inspite of including many reactions of which rate constants are not known accurately.

From the comparisons described above, it was found that the calculated OH profiles by Mechanism A are much closer to the experiments than those by Mechanism B, and the effects of the subsequent reactions on OH formation can be ignored in the initial stage of the reaction. Thus, the rate constans k_4 and k_5 determined from Mechanism A in the initial stage of the reaction are reasonable and those obtained by Salimian et al.[7] seem to have been overestimated.

It was reported that the amount of adsorbed NH_3 on the wall of stainless steel was several times the value calculated by assuming monomolecular layer adsorption.[19] In the experiments by Salimian et al., the concentration of NH_3 introduced into the shock tube was about 4×10^{-9} mol cm^{-3} at 300 K. In such a low concentration, the adsorption of NH_3 cannot be ignored. Since in the experiments of Jefferies et al.[18] the mixture was irradiated by a TEA CO_2 laser at 10.6 μm, there is a possibility that NH_3 molecules themselves decomposed by the laser irradiation and the decomposed products accelerate the consumption of OH. This might give higher k_5 value. Also, the curved Arrhenius plots calculated by the transition state theory were based upon the arbitrary selection of parameters.[7,9,18] From those reasons, linear expressions were preferred to the curved ones for Arrhenius plots of k_4 and k_5.

In conclusion, the linear Arrhenius expressions for the rate constants of Reactions (4) and (5) combining the values at low temperatures[5,6,16,17] are proposed as follows:

(4) $NH_3 + O \longrightarrow NH_2 + OH$

$$k_4 = 10^{12.5\pm0.4}\exp(-25.5\pm2.3\ \mathrm{kJ}/RT)\ \mathrm{cm^3\ mol^{-1}\ s^{-1}}$$

(5) $NH_3 + OH \longrightarrow NH_2 + H_2O$

$$k_5 = 10^{12.5\pm0.1}\exp(-8.4\pm0.1\ \mathrm{kJ}/RT)\ \mathrm{cm^3\ mol^{-1}\ s^{-1}}$$

Reflection Spectra of $(DBTTF)_4 \cdot (BF_4)_2 \cdot EtOH$ Complex

Masashi TANAKA
Department of Chemistry, College of General Education, Nagoya University, Chikusa-ku, Nagoya 464
(Received May 26, 1986)

The polarized reflection spectra of the crystal of $(DBTTF)_4 \cdot (BF_4)_2 \cdot EtOH$ complex were measured and the optical parameters were determined by the simulation of the observed reflection spectra. The theoretical analysis of the observed spectra shows that the electronic structure of DBTTF cation molecules is typical of the island type configuration. The 4000 and 11500 cm^{-1} bands polarized parallel to the stacking axis were assigned to the CT_2 and CT_1 bands, and the parameters U and t of the Hubbard Hamiltonian were estimated to be U=8950 cm^{-1} and t=1250 cm^{-1}.

There has been considerable interest recently in organic conductors which have highly abnisotropic electrical, optical and magnetic properties. Tetrathiafulvalene-tetracyanoquinodimethane (TTF-TCNQ) is one of them which received the most detailed attention. After the discovery of the TTF-TCNQ complex, many compounds with fulvalene rings were synthesized to obtain the radical salts with highly electrical conductivity. Dibenzotetrathiafulvalene (DBTTF) is one of those compounds[1] and the direct oxidation of DBTTF by halogens and metal halides were reported to yield radical salts such as $(DBTTF)_2I_3$,[2] $(DBTTF)_8(SnCl_6)_3$,[3] and $(DBTTF)_3(SnBr_6)$,[3] $(DBTTF)_2(Cu_2Cl_6)$,[4] and $(DBTTF)_2(Cu_2Br_6)$.[5] The employment of tetrafluoroborate as an oxidant was reported to yield the ion-radical salt $(DBTTF)(BF_4)_{0.8}$ showing a high conductivity up to 180 K.[6] We repored the crystal structure of another complex $(DBTTF)_4(BF_4)_2$ EtOH.[7] In the present paper, the reflection spectra of the crystal of $(DBTTF)_4 \cdot (BF_4)_2 \cdot EtOH$ complex are reported and the results of the theoretical analysis are presented by using the Hubbard approximation.

Experimental

The crystal of $(DBTTF)_4 \cdot (BF_4)_2 \cdot EtOH$ complex was prepared in an ethanol solution. The reflection spectra of the single crystal at the normal incidence were measured over the range of 5000—25000 cm^{-1} by means of a reflection spectrophotometer made in our laboratory. All calculations for the analysis of the experimental data were made on a FACOM M382 computer of Nagoya University.

Theoretical

For the island type system[8] of $[(DBTTF)_3]^{2+}$ cations the Hamiltonian H may be given by the Hubbard Hamiltonian as follows,

$$H = -t \sum_i \sum_{\sigma=\alpha,\beta} (a^+_{i,\sigma} a_{i+1,\sigma} + a^+_{i+1,\sigma} a_{i,\sigma}) + U \sum_i n_{i,\alpha} n_{i,\beta} \quad (1)$$

where $a^+_{i,\sigma}$ and $a_{i,\sigma}$ are the creation and anihilation operators of the π-electron occupying HOMO of the DBTTF molecule at the i-th site, σ represents the spin of π-electron, $n_{i,\sigma}=a^+_{i,\sigma}a_{i,\sigma}$ is the number of π-electron on the i-th site, t is the electron transfer integral and U the intramolecular Coulomb integral. Then, the ground and lower excited configuration functions for the singlet state are taken into account for the calculation of the electronic states of the island type system.[8]

$$\Phi^{1,2} = \frac{1}{\sqrt{2}}(a_{1,\beta}a_{2,\alpha} - a_{1,\alpha}a_{2,\beta})\Phi_{HF} \quad (2)$$

$$\Phi^{2,3} = \frac{1}{\sqrt{2}}(a_{2,\beta}a_{3,\alpha} - a_{2,\alpha}a_{3,\beta})\Phi_{HF} \quad (3)$$

$$\Phi^{1,3} = \frac{1}{\sqrt{2}}(a_{1,\beta}a_{3,\alpha} - a_{1,\alpha}a_{3,\beta})\Phi_{HF} \quad (4)$$

$$\Phi^{CT}_1 = a_{3,\alpha}a_{3,\beta}\Phi_{HF} \quad (5)$$

$$\Phi^{CT}_2 = a_{1,\alpha}a_{1,\beta}\Phi_{HF} \quad (6)$$

$$\Phi^{CT}_3 = a_{2,\alpha}a_{2,\beta}\Phi_{HF} \quad (7)$$

Here, Φ_{HF} means the Hartree-Fock wave function of the neutral trimer of DBTTF. The energy of the island type system is calculated by diagonalizing the secular determinant for the symmetrical and the antisymmetrical states as is shown in the next equations,

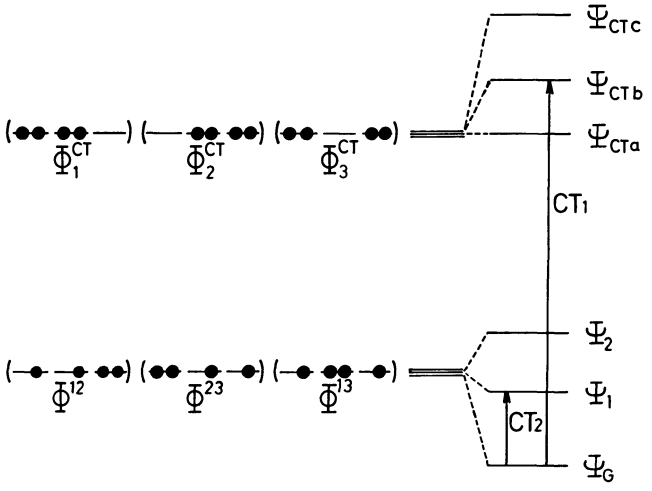

Fig. 1. Energy diagram of the island trimer type configuration.

$$\begin{array}{l|ccc} \Phi^{1,3} & 0 & \sqrt{2}t & 0 \\ \frac{1}{\sqrt{2}}(\Phi^{1,2}+\Phi^{2,3}) & \sqrt{2}t & 0 & -\sqrt{6}t \\ \frac{1}{\sqrt{2}}(\Phi_1^{CT}+\Phi_2^{CT}+2\Phi_3^{CT}) & 0 & -\sqrt{6}t & U \end{array}, \tag{8}$$

and

$$\begin{array}{l|ccc} \frac{1}{\sqrt{2}}(\Phi^{1,2}-\Phi^{2,3}) & 0 & \sqrt{2} & 0 \\ \frac{1}{\sqrt{2}}(\Phi_1^{CT}-\Phi_2^{CT}) & \sqrt{2}t & U & 0 \\ \frac{1}{\sqrt{3}}(\Phi_1^{CT}+\Phi_2^{CT}-\Phi_3^{CT}) & 0 & 0 & U \end{array}. \tag{9}$$

Then, the eigenvalues and eigenfunctions are obtained as follows and the energy diagram of the cation trimer system is depicted in Fig. 1.

$$\Psi_G = c_0\left\{\frac{1}{2}(\Phi^{1,2}+\Phi^{2,3}-\sqrt{2}\Phi^{1,3}) + \frac{\sqrt{3}t}{U-\sqrt{2}t}\frac{1}{\sqrt{6}}(\Phi_1^{CT}+\Phi_2^{CT}+2\Phi_3^{CT})\right\},$$
$$E_G = -\sqrt{2}t - \frac{3t^2}{U+\sqrt{2}t}, \tag{10}$$

$$\Psi_1 = \frac{b_1}{\sqrt{2}}(\Phi^{1,2}-\Phi^{2,3}) + \frac{b_2}{\sqrt{2}}(\Phi_1^{CT}-\Phi_2^{CT}),$$
$$E_1 = \frac{U-\sqrt{U^2+8t^2}}{2}, \tag{11}$$

$$\Psi_2 = c_1\left\{\frac{1}{2}(\Phi^{1,2}+\Phi^{2,3}+\sqrt{2}\Phi^{1,3}) + \frac{\sqrt{3}t}{U-\sqrt{2}t}\frac{1}{\sqrt{6}}(\Phi_1^{CT}+\Phi_2^{CT}+2\Phi_3^{CT})\right\},$$
$$E_2 = \sqrt{2}t - \frac{3t^2}{U-\sqrt{2}t}, \tag{12}$$

$$\Psi_{CT,a} = \frac{1}{\sqrt{3}}(\Phi_1^{CT}+\Phi_2^{CT}+\Phi_3^{CT}),$$
$$E_{CT,a} = U, \tag{13}$$

$$\Psi_{CT,b} = -\frac{b_2}{\sqrt{2}}(\Phi^{1,2}-\Phi^{2,3}) + \frac{b_1}{\sqrt{2}}(\Phi_1^{CT}-\Phi_2^{CT}),$$
$$E_{CT,b} = \frac{U+\sqrt{U^2+8t^2}}{2}, \tag{14}$$

$$\Psi_{CT,c} = c_2\left\{\frac{1}{\sqrt{6}}(\Phi_1^{CT}+\Phi_2^{CT}+2\Phi_3^{CT}) - \frac{\sqrt{3}t}{U+\sqrt{2}t}\frac{1}{2}(\Phi^{1,2}+\Phi^{2,3}-\sqrt{2}\Phi^{1,3}) - \frac{\sqrt{3}t}{U-\sqrt{2}t}\frac{1}{2}(\Phi^{1,2}+\Phi^{2,3}+\sqrt{2}\Phi^{1,3})\right\},$$
$$E_{CT,c} = U + \frac{3t^2}{U+\sqrt{2}t} + \frac{3t^2}{U-\sqrt{2}t}. \tag{15}$$

Here, c_0, c_1, c_2, b_1, and b_2 are given by the following equations,

$$c_0 = \left\{1+\frac{3t^2}{(U+\sqrt{2}t)^2}\right\}^{-1/2},$$
$$c_1 = \left\{1+\frac{3t^2}{(U-\sqrt{2}t)^2}\right\}^{-1/2},$$
$$c_2 = \left\{1+\frac{3t^2}{(U+\sqrt{2}t)^2}+\frac{3t^2}{(U-\sqrt{2}t)^2}\right\}^{-1/2},$$
$$b_1 = \left\{\frac{1}{2}\left(1+\frac{U}{\sqrt{U^2+8t^2}}\right)\right\}^{-1/2},$$

and

$$b_2 = -\left\{\frac{1}{2}\left(1-\frac{U}{\sqrt{U^2+8t^2}}\right)\right\}^{-1/2}. \tag{16}$$

The optically allowed transitions are the CT_2 transition from Φ_G to Φ_1 and the CT_1 transition from Φ_G to $\Phi_{CT,b}$, and their transition energies are given by

$$\Delta E_{CT_2} = E_1 - E_G = \frac{U-\sqrt{U^2+8t^2}}{2} + \sqrt{2}t + \frac{3t^2}{U+\sqrt{2}t}, \tag{17}$$

and

$$\Delta E_{CT_1} = E_{CT,b} - E_G = \frac{U+\sqrt{U^2+8t^2}}{2} + \sqrt{2}t + \frac{3t^2}{U+\sqrt{2}t}. \tag{18}$$

The transition moments of these two bands may be expressed as follows,

$$\langle\Psi_G|M|\Psi_1\rangle = c_0\left\{\frac{b_1}{\sqrt{2}} - \frac{2tb_2}{U+\sqrt{2}t}\right\}\boldsymbol{R}, \tag{19}$$

and

$$\langle\Psi_G|M|\Psi_{CT,b}\rangle = c_0\left\{-\frac{b_2}{\sqrt{2}} - \frac{2tb_1}{U+\sqrt{2}t}\right\}\boldsymbol{R}, \tag{20}$$

were $\boldsymbol{R}$ is the vector between the nearest neighboring DBTTF molecules. Then, the oscillator strengths of the CT_2 and CT_1 bands are given by the next equations,

$$f_{CT_2} = 3 \times 1.09 \times 10^{11} \times \Delta E_{CT_2} \times |\langle\Psi_G|M|\Psi_1\rangle|^2, \tag{21}$$

and

$$f_{CT_1} = 3 \times 1.09 \times 10^{11} \times \Delta E_{CT_1} \times |\langle\Psi_G|M|\Psi_{CT,b}\rangle|^2. \tag{22}$$

Here U and t are in cm^{-1} and $\boldsymbol{R}$ is in cm.

The optical reflectivity R can be expressed by the following equation

$$R = \frac{1+|\varepsilon|-\sqrt{2(|\varepsilon|+\varepsilon_1)}}{1+|\varepsilon|+\sqrt{2(|\varepsilon|+\varepsilon_1)}}. \tag{23}$$

and the dielectric function $\varepsilon(\omega)$ are approximated by the semiclassical Lorentz model,

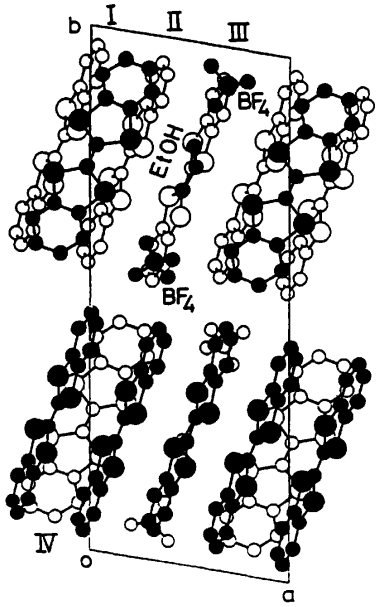

Fig. 2. The projection of the structure of $(DBTTF)_4\cdot(BF_4)_2\cdot EtOH$ along the c axis.

$$\varepsilon(\omega) = \varepsilon_{core} + \sum_j \frac{\Omega_j^2}{\omega_j^2-\omega^2-i\omega\gamma_j} = \varepsilon_1(\omega) + i\varepsilon_2(\omega), \quad (24)$$

where $\varepsilon_1(\omega)$ and $\varepsilon_2(\omega)$ are the real and imaginary parts of the dielectric function of the DBTTF cation trimers, and $|\varepsilon|=\sqrt{\varepsilon_1^2(\omega)+\varepsilon_2^2(\omega)}$. The oscillator strength f is determined by using the equation,

$$f = \frac{m_e}{4\pi Ne^2}\Omega_j^2. \quad (25)$$

Here, m_e is the electron mass and N is the number density of DBTTF molecule. By fitting the above-mentioned equations of the reflectivity R to the observed values, the optical parameters of the complexes $(DBTTF)_4\cdot(BF_4)_2\cdot EtOH$ may be obtained and their energy structure can be determined.

Results and Discussion

$(DBTTF)_4\cdot(BF_4)_2\cdot EtOH$ crystallizes in the form of the dark blue needle and the space group is monoclinic $C2/m$.[7] The projection of the structure along the c axis is shown in Fig. 2. The structure consists of two crystallographically independent stacks. The DBTTF molecules (I, II, and III) are stacked parallel to each other in columns along the a axis. The angles between the mean planes of these DBTTF molecules and the a axis are almost equal and the mean interplanar spacing is 3.6A. The fourth DBTTF (IV) and ethanol and two BF_4^- anions form another sheet along the same direction. The molecular plane of DBTTF (IV) is almost perpendicular to the column of the other three DBTTF (I, II, and III) molecules.

Table 1. Dielectric Parameters of the Lorentz Fits of Reflectivity Data for $(DBTTF)_4\cdot(BF_4)_2\cdot EtOH$

	$//a$ spectrum		$\perp a$ spectrum
ε_{core}	2.1		2.5
Ω_j/cm^{-1}	7500	5000	5000
ω_j/cm^{-1}	3800	11500	16500
γ_j/cm^{-1}	2500	3000	4000
f	0.32	0.14	0.14

Table 2. Hubbard Parameters (t and U) Determined by the Analysis of the Reflection Spectra of Various DBTTF Crystals[11,12]

Type	Compound	t/cm^{-1}	U/cm^{-1}
Alternant	$(DBTTF)_3(SnBr_6)$	2000	
Dimer	$(DBTTF)_2(Cu_2Cl_6)$	2200	6500
	$(DBTTF)_2(Cu_2Br_6)$	2300	7700
Island	$(DBTTF)_4(BF_4)_2EtOH$	1250	8950

On the other hand, Raman spectra of the complex shows that the DBTTF ν_5 band (totally symmetric streching vibrational mode of the central C=C bond) are observed at three Raman frequencies of 1540, 1442, and 1400 cm^{-1}.[9] The ν_5 band at 1540 cm^{-1} corresponds to that of the neutral DBTTF molecule and another one at 1400 cm^{-1} to the fully ionized cation radical $DBTTF^+$. The third band (ν_5=1442 cm^{-1}) is located intermediately between those of the neutral and cation molecules.

The above consideration suggests that the molecule (IV) is neutral and the other three molecules (I, II, and III) are ionized. Then, the island type model may be used to the analysis of the reflection spectra. The reflection spectra were observed for the polarizations

parallel and perpendicular to the a axis on the ac plane as is shown in Fig. 3. The 4000 cm^{-1} band in the a axis spectrum can be assigned to the CT_2 band and the 11000 cm^{-1} band to the CT_1 band. The 16000 cm^{-1} in the $\perp a$ axis spectrum are assigned to the short axis component of the LE band of $DBTTF^+$ cation radical.[10]

The best fit of Eq. 23 to the observed reflectivity is obtained and the calculated reflection spectra are depicted in Fig. 3 in order to compare with the observed ones. The obtained parameters Ω_j, ω_j, γ_j, and ε_{core} are shown in Table 1 together with the oscillator strength determined by Eq. 25. Then, the experimental data (ΔE_{CT_1}=11500 cm^{-1}, f_{CT_1}=0.14, ΔE_{CT_2}=3800 cm^{-1}, f_{CT_2}=0.32, and R=3.6 A) give U=8950 cm^{-1} and t=1250 cm^{-1} which correspond to the calculated values (ΔE_{CT_1}=11500 cm^{-1}, f_{CT_1}=0.04, ΔE_{CT_2}=1900 cm^{-1} and f_{CT_2}=0.41). The obtained parameters (t and U) are shown in Table 2 together with those estimated by the analysis of other crystals ($(DBTTF)_3(SnBr_6)$,[11] $(DBTTF)_2(Cu_2Cl_6)$,[12] and $(DBTTF)_2(Cu_2Br_6)$[12]). In these crystals, the interplanar distances between DBTTF's are almost same (3.6 A) but the stacking behaviors are different. Therefore, the smaller t and the larger U values for $(DBTTF)_4 \cdot (BF_4)_2 \cdot EtOH$ may be explained by the comparison of the overlap integrals between the HOMO's of DBTTF in the crystals.

The Precipitation of Monodispersed α-Iron(III) Oxide Particles from Iron(III) Chloride-Glycine System in Aqueous and 2-Propanol/Water Media

Shuichi HAMADA,* Shin NIIZEKI, and Yoshiyuki KUDO
Department of Applied Chemistry, Faculty of Science, and Institute of Colloid and Interface Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received May 31, 1986)

Monodispersed α-iron(III) oxide (hematite) particles were prepared by aging iron(III) chloride solutions in the presence of glycine at elevated temperatures, 98—100 °C. An aqueous solution of glycinatoiron (III) complex directly gave monodispersed double spheres of hematite, ≈4 μm in size, under the specified conditions, for example, 2.0×10^{-2} mol dm^{-3} $FeCl_3$, 0.60 mol dm^{-3} glycine, and 0.46 mol dm^{-3} HCl for 96 h. The hematite particles grew up through the polynuclear layers mechanism. By the forced hydrolysis in 2-propanol/water mixed solution of 30% by volume, monodispersed cuboidal hematite particles, 0.06—0.43 μm in size, were also obtained through the conversion of β-iron(III) hydroxide oxide previously deposited. The nucleation rate was markedly affected by acidity at the latter case. The formation processes of these monodispersed hematite particles are discussed.

The preparation of monodispersed (hydrous) metal oxide particles has been studied extensively.[1-10] Monodispersed α-iron(III) oxide (hematite) particles have also been produced by the forced hydrolysis of iron(III) salt solutions under a limited set of conditions.[2,4-6,8,9] In this process, iron(III) hydroxide oxide is usually produced first and then transforms into hematite. However, monodispersed double spheres of hematite have been directly prepared from an iron(III) chloride-glycine aqueous system[6] without precipitation of β-iron(III) hydroxide oxide, while glycinatoiron(III) complex acts as a reservoir of hydroxo complexes. In the present work, the preparation process of the monodispersed hematite particles was studied in both the aqueous and 2-propanol/water mixed solutions containing glycine.

Experimental

Materials. All of reagents used in this work were of a guaranteed grade and employed without further purification. A stock solution of iron(III) chloride was previously passed through a membrane filter, of 0.2 μm pore size, before use. The solution thus obtained (≈3 mol dm^{-3}) did not show any visual change over one month. An aliquot of the stock solution was diluted to the fixed concentration of 2.0×10^{-2} mol dm^{-3} together with desired amounts of glycine and hydrochloric acid with doubly distilled water or 2-propanol/water mixed solvent of 30% by volume.

Procedures. A freshly prepared mixed solution was tightly sealed in a screw-capped glass tube and then aged for 24—96 h at 100±1 °C in a thermostated air oven. After the reaction, the particles were centrifuged at 1700 g and then washed repeatedly with doubly distilled water. The morphology and size of the particles were observed with scanning and transmission electron microscopes.

To reveal the formation process of the monodispersed hematite particles, the iron(III) chloride-glycine aqueous solution was aged in a flask equipped with a condensor at 98±0.5 °C in an oil bath. The concentration of iron species remaining in a supernatant solution was followed colorimetrically using 1,10-phenanthroline at regular time intervals, after the solids had been centrifuged at 45000 g. The supernatant solution thus obtained did not show any Tyndall cone. The concentration of iron(II) species was determined in the presence of iron(III) species using absorbances at different wavelengths. The amount of iron(III) species was estimated from the difference between those of iron(II) and the total iron species: the latter value was determined after the iron(III) species had been completely reduced to the iron(II) state.

When the hematite particles were produced through the conversion of β-iron(III) hydroxide oxide in the 2-propanol/water system, changes in their amounts were also followed spectrophotometrically, after they had been separated by repeated centrifugation at 500, 1300, and 45000 g, followed by solution in hydrochloric acid.

The amounts of monomeric and polymeric iron(III) complexes were determined spectrophotometrically on the basis of reactivity to 8-quinolinol.[11] The total iron(III) concentration was determined after the polymeric species had been depolymerized in 0.1 mol dm^{-3} hydrochloric acid at 80 °C for 10 min. The 8-quinolinatoiron(II) complex was previously confirmed not to exhibit absorbance over the wavelength between 380 and 600 nm.

Results

Concentration Changes of Soluble Iron(III) and (II) Species during Deposition of Monodispersed Hematite Particles in Aqueous Solution. The monodispersed doubly spherical hematite particles have been prepared under a limited set of conditions by the forced hydrolysis of the aqueous iron(III) chloride solution including glycine.[6] Figure 1 displays an example of monodispersed hematite particles prepared by aging a solution of 2.0×10^{-2} mol dm^{-3} $FeCl_3$, 0.60 mol dm^{-3} glycine, and 0.46 mol dm^{-3} HCl at 100 °C for 96 h. An average size of the particles was estimated as 4.1 μm with relative standard deviation of 0.08. The particles were attributable to aggregates of well-crystallized fine hematite particles, according to their X-ray powder diffraction pattern[12] and morphology.

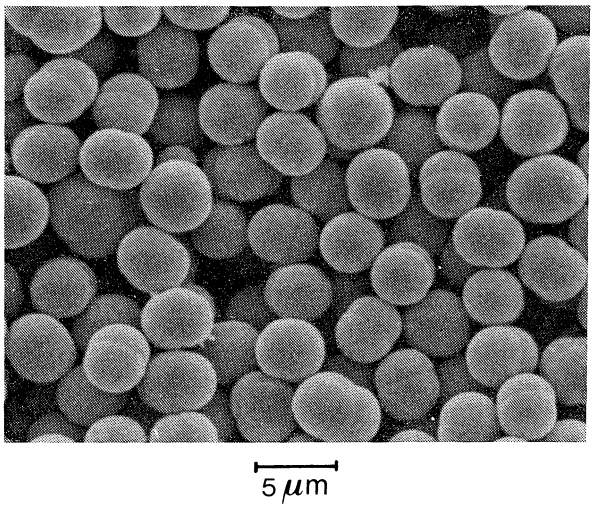

Fig. 1. Doubly spherical hematite particles obtained by hydrolysis at 100 °C for 96 h. Aging conditions: $[FeCl_3]=2.0\times10^{-2}$, [HCl]=0.46, and [Gly]=0.60 mol dm^{-3}.

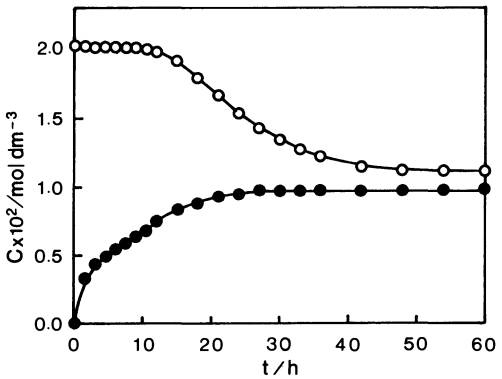

Fig. 2. Concentration changes in total and Fe(II) species in supernatnat solution during hydrolysis at 98 °C. Symbols: ○: total iron, ●: Fe(II).

The forced hydrolysis gave excellent monodispersed hematite particles only over a narrow composition range of the solution between 0.40 and 0.60 mol dm^{-3} for glycine and from 0.39 to 0.50 mol dm^{-3} for HCl under the fixed iron(III) chloride concentration of 2.0×10^{-2} mol dm^{-3}.[6] The pH of the solutions initially ranged between 1.5 and 1.8 and scarcely changed after the reaction because of the buffer action of the glycine.

Iron(III) nitrate and sulfate solutions containing glycine and the corresponding acid gave only irregularly shaped hematite or α-iron(III) hydroxide oxide particles.

In order to reveal the formation process of monodispersed hematite particles, the concentrations of iron species in the supernatant solution were followed at 98±0.5 °C up to 60 h. A starting solution was prepared similar to that shown in Fig. 1. The

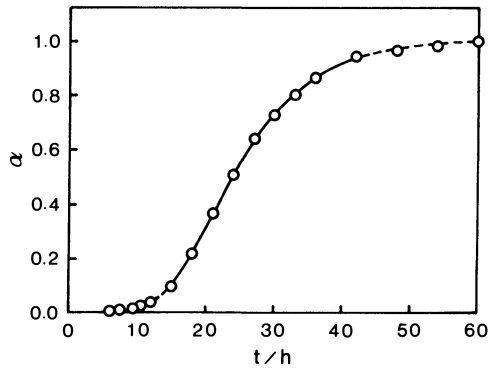

Fig. 3. Change in reaction degree during hydrolysis at 98 °C. ○: Observed, —: Calculated.

particles appeared after an induction period of around 10 h and then developed, while the iron(III) species were partially reduced into iron(II) state by glycine present, as shown in Fig. 2. Finally, the total iron concentration reached 1.1×10^{-2} mol dm^{-3} after 50 h. The concentration of iron(II) species became almost constant as 1.0×10^{-2} mol dm^{-3} after 30 h. Thus, effective concentrations of iron(III) for producing the hematite equal those between the upper and lower curves. The difference in the concentrations, C_s, between the total iron and iron(II) species at the final state corresponds to the solubility of hematite under the given conditions.

Growth Process of Double Spheres of Hematite. The reaction degree, α, is defined as:

$$\alpha = (C_0-C)/(C_0-C_s-C_{Fe(II)}) \quad (1)$$

where C_0 is the initial concentration of iron(III), C the total concentration of iron species at reaction time t, and $C_{Fe(II)}$ that of iron(II), respectively. Based on the results in Fig. 2, the reaction degree, α, was estimated as shown in Fig. 3.

According to Nielsen,[13] the radial growth rate is expressed as Eq. 2 when the particles developed through a polynuclear layers mechanism.

$$dr/dt = 0.60\, dJ'^{1/3}R'^{2/3} \quad (2)$$

where J' and R' are the nucleation and growth rates of two-dimensional surface nuclei. Both terms are given as:

$$J' = k_m C_r^m \quad [C_r=C-C_s-C_{Fe(II)}] \quad (3)$$

$$R' = d^2DC_r \quad (4)$$

where d is the height of the surface nuclei, k_m the apparent rate constant of surface nucleation, and D the diffusion coefficient, respectively. On the other hand, the radius of the monodispersed particles at t can be given as:

$$r = r_f\alpha^{1/3} \quad (5)$$

where r_f is the final radius of the particle. On the basis

of differentiation of Eq. 5, the following equation is obtained as:

$$dr/dt = 0.33\, r_f \alpha^{-2/3} d\alpha/dt \quad (6)$$

Finally, Eq. 7 can be derived by combining Eq. 6 with Eq. 1 as:

$$d\alpha/dt = KC_r^{(m+2)/3}\alpha^{2/3} \quad (7)$$

where

$$K = 1.8\, k_m^{1/3} d^{7/3} D^{2/3} r_f^{-1} \quad (8)$$

However, Eq. 7 was not integrable because the concentration of iron(II) changed continuously in this system; accordingly a numerical method was employed. At first, the parameters, m and K, were estimated as 1.22 and 22.6[14] by the least squares method using the logarithmic values of $d\alpha/dt$, C_r, and α. Equation 7 was integrated by the Runge–Kutta method using these values. The solid curve shown in Fig. 3 displays the reaction degree thus calculated, which agreed well with the experimental values over a wide range of the reaction degree from around 0.1 to 0.9. Similar studies were also made on the diffusional and mononuclear layer mechanisms,[13] but neither of them fitted the experimental values. These results indicated that the double spheres of hematite developed through the polynuclear layers mechanism including condensation and polymerization of hydroxoiron(III) complexes on the surface of particles, as suggested by Flynn.[15]

Hydroxoiron(III) Complexes in Iron(III) Chloride-Glycine Aqueous System. To reveal a role of the monomeric and polymeric hydroxoiron(III) complexes on the formation of hematite particles, the fractions of these species in the solution were examined spectrophotometrically during the forced hydrolysis. Murphy et al.[16] have mentioned that only unpolymerized iron(III) species were reactive to 8-quinolinol. Furthermore, Iwase et al.[11] have specified that monomeric and dimeric species, Fe^{3+}, $[FeOH]^{2+}$, and $[Fe_2(OH)_2]^{4+}$, were extractable in chloroform as 8-quinolinate by shaking for 10 s, in addition to monomeric sulfatoiron(III) complex.

According to the above facts, the polymerization of iron(III) ions was examined first as follows: The pH values of 1.0×10^{-2} and 2.5×10^{-3} mol dm^{-3} iron(III) perchlorate solutions were adjusted in the range from 1.70 to 2.20 and from 1.98 to 2.43 respectively. After standing the solutions at 25±0.5° C for 24 h, 8-quinolinatoiron(III) complex was extracted in 10 cm^3 chloroform by vigorous shaking for 10 s. Figure 4 displays the fractions of extractable iron(III) species as a function of pH. These results clearly indicate that the hydroxoiron(III) complexes were drastically polymerized at pH 2.2 and 2.4, respectively, in spite of no precipitation, depending upon the total concentration of iron(III) species.

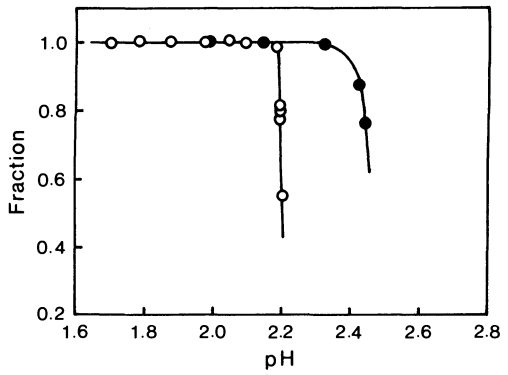

Fig. 4. Fractions of extractable Fe(III) species at 25 °C and I=0.5. Conditions: $[Fe(ClO_4)_3]=1.0\times10^{-2}$ (○) and 2.5×10^{-3} (●) mol dm^{-3}.

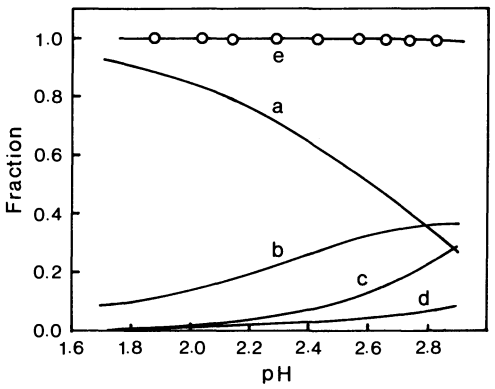

Fig. 5. Fractions of extractable Fe(III) species and respective species at 25 °C and I=0.5. Conditions: $[Fe(ClO_4)_3]=5.0\times10^{-4}$ mol dm^{-3}, a: Fe^{3+}, b: $[FeOH]^{2+}$, c: $[Fe(OH)_2]^{+}$, d: $[Fe_2(OH)_2]^{4+}$, and e: total.

On the other hand, a much diluted solution (5.0×10^{-4} mol dm^{-3}) scarcely showed any polymerization in the pH range between 1.87 and 2.82, as shown in Fig. 5. The circles in Fig. 5 stand for the fractions of extractable iron(III) species. Furthermore, the solid curves a—d indicate the fractions of Fe^{3+}, $[FeOH]^{2+}$, $[Fe(OH)_2]^{+}$, and $[Fe_2(OH)_2]^{4+}$ which were calculated by the Newton–Raphson method using the formation constants for the respective hydroxo complexes at 25 °C and ionic strength of 0.5.[17–20] The curve e displays the sum of above fractions, which agrees well with the experimental values. The fraction of $[Fe_3(OH)_4]^{5+}$ was confirmed to be negligible in this diluted solution. Thus, the results suggest that $[Fe(OH)_2]^{+}$ is also extractable as the 8-quinolinatoiron(III) complex.

On the basis of above results, the behavior of the polymeric iron(III) species in the iron(III) chloride–glycine aqueous solution was examined in the following way. A solution with the same composition shown in Fig. 1 was aged for desired periods at 98±0.5 °C. After the reaction, the solids formed were

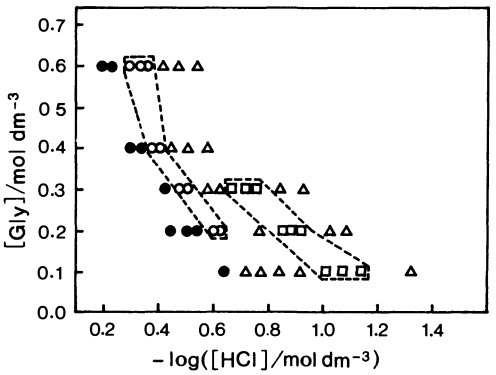

Fig. 6. Concentration domain of glycine and HCl for making hematite particles by hydrolysis at 100 °C for 48 h in 2-propanol/water mixture. Coditions: $[FeCl_3]=2.0\times10^{-2}$ mol dm^{-3}, 2-propanol; 30% by volume, Symbols: ○: double sphere, □: cube, △: irregular, and ●: no precipitation.

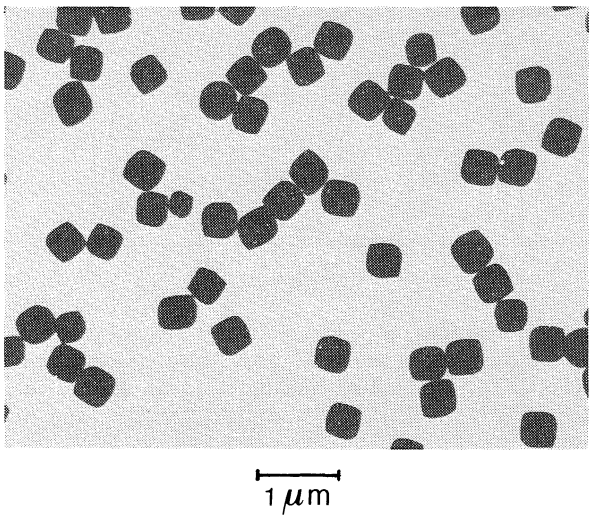

Fig. 7. Cuboidal hematite particles obtained by forced hydrolysis at 100 °C for 56 h in 2-propanol/water mixed solution. Conditions: $[FeCl_3]=2.0\times10^{-2}$, [HCl]=0.16, and [Gly]=0.20 mol dm^{-3}, 2-prpanol: 30% by volume.

completely removed by centrifugation at 45000 g. As mentioned above, iron(III) ions were partially reduced into the iron(II) state, so that the actual total iron(III) concentration was separately determined after depolymerizing the polymeric species. The presence of chloride ions and glycine in the solution did not have any influence on the determination with 8-quinolinol. However, the total fraction of the monomeric and dimeric iron(III) species remained constant as $1.00\pm0.00_6$ during the course of aging up to 48 h at intervals of 6 h. In addition, no polymeric iron(III) species was observed in the solution before aging.

Formation of Monodispersed Hematite Particles in 2-Propanol/Water System. Figure 6 shows the

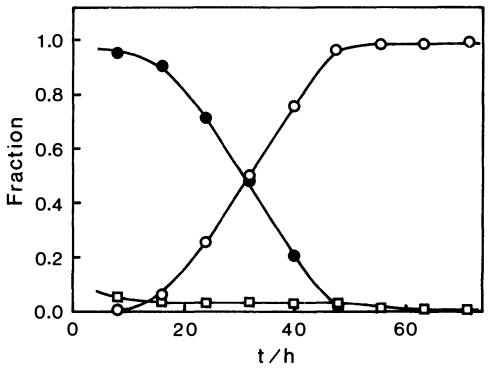

Fig. 8. Conversion of β-FeOOH during hydrolysis at 100 °C in 2-propanol/water mixed solution. Conditions: $[FeCl_3]=2.0\times10^{-2}$, [HCl]=0.14, and [Gly] =0.20 mol dm^{-3}, Symbols: ●: β-FeOOH, ○: hematite, □: Fe(III) species in supernatant solution.

domain of hydrochloric acid and glycine concentrations for making hematite particles by the forced hydrolysis at 100 °C for 48 h under the fixed concentration of 2.0×10^{-2} mol dm^{-3} iron(III) chloride in 2-propanol/water mixed solutions of 30% by volume. The solutions with the composition indicated by the symbol ○ directly gave the monodispersed double spheres of hematite as in the aqueous solutions.

In addition, monodispersed cuboidal hematite particles were obtained in the region shown by the symbol □, in contrast to the former case. In this process, β-iron(III) hydroxide oxide[21] appeared first and then transformed into cubes of hematite. Iron(III) ions are much more hydrolyzable in alcohol/water mixtures than in aqueous solutions.[22,23] Therefore, the β-iron(III) hydroxide oxide would result from much higher supersaturation of hydroxoiron(III) complexes at an initial stage of the forced hydrolysis in rather dilute acid. Thus, a mixture of hematite and fine hydroxide oxide particles was obtained by the forced hydrolysis. It was, however, easy to separate them by repeated slow and high speed centrifugation. Figure 7 shows the cuboidal particles thus separated. The symbols ● indicate the region in which no precipitation occurred even after 100 h.

Conversion of β-Iron(III) Hydroxide Oxide to Hematite in 2-Propanol/Water System. In order to examine the conversion process, the respective amounts of β-iron(III) hydroxide oxide and hematite were followed at regular time intervals during the forced hydrolysis, in addition to that of the soluble iron species in the supernatant solution. A solution was prepared as $[FeCl_3]=2.0\times10^{-2}$, [HCl]=0.14, and [Gly]=0.20 mol dm^{-3} in the 2-propanol/water mixture of 30% by volume. The solution was aged at 100±0.5 °C in an oil bath. After the reaction, the precipitates were first separated by centrifugation at 45000 g and then the extremely fine β-iron(III)

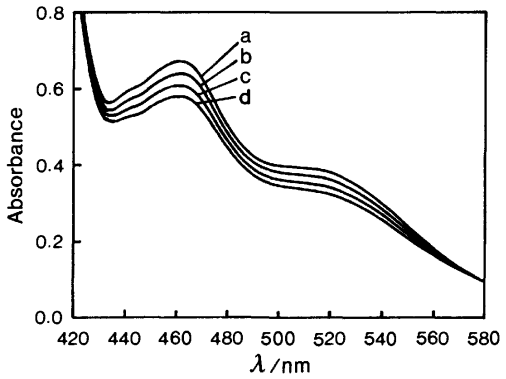

Fig. 10. Spectra of $Fe(ClO_4)_3$-glycine aqueous solution at $I=0.5$. Conditions: $[Fe(ClO_4)_3]=1.9\times10^{-2}$, $[HClO_4]=0.45$, and [Gly]=0.80 mol dm^{-3}, temperature: a: 15, b: 20, c: 25, and d: 30 °C, cell length: 1 cm.

hydroxide oxide particles were isolated from the solid phase by repeated slow and fast centrifugation. The amounts of iron(III) in the each phase were determined spectrophotometrically using 1,10-phenanthroline.

Figure 8 displays the fractions of the β-iron(III) hydroxide oxide, hematite, and soluble iron(III) species as a function of the reaction time. The rate of appearance of the hematite was the same as that of the disappearance of the β-iron(III) hydroxide oxide and the conversion continued until all the β-iron(III) hydroxide oxide had disappeared. This fact clearly indicated that the cuboidal hematite particles developed through the conversion of β-iron(III) hydroxide oxide. The total concentration of hydroxo, chloro, and glycinato complexes of iron(III) in the supernatant solution remained constant (6.0×10^{-4} mol dm^{-3}) throughout the conversion. The soluble iron (III) species were scarcely reduced to the iron(II) state by glycine in this process, in contrast to the aqueous system.

The results in Fig. 8 indicate that the soluble iron(III) species were continuously supplied by the dissolution of β-iron(III) hydroxide oxide and the supersaturation of hydroxoiron(III) complexes was appropriately maintained during the growth of the monodispersed hematite particles.

Growth of Cuboidal Hematite Particles. Figure 9 shows the growth of the cubes at 100±0.5 °C as a function of aging time. A starting solution was prepared similar to that shown in Fig. 8 except for the acid concentration. The relative standard deviation of the particle size remained almost constant in the range 0.11—0.13 in 0.15 mol dm^{-3} hydrochloric acid during the growth from 12 to 40 h. The size of the cuboidal particles reached a plateau at which the β-iron(III) hydroxide oxide was completely consumed.

Though the growth rate of the particles was almost identical ($\approx6.7\times10^{-3}$ μm h^{-1} in the linear part), the final particle size significantly increased with the acid concentration even in a narrow range from 0.12 to 0.16 mol dm^{-3} (pH 2.0—1.6). According to the final size and the consumption time of the β-iron(III) hydroxide oxide, the nucleation rate of the hematite was greatly enhanced with increasing pH even at the same concentrations of iron(III) and glycine.

Excellent monodispersed cuboidal hematite particles have also been obtained through a similar conversion process in alcohol/water mixed solutions without glycine.[4,5] In this case, the particles developed to around 4 μm through slow nucleation even at the same concentration of iron(III) chloride.

Discussion

The hematite particles have been recognized to form through the transformation of β-iron(III) hydroxide oxide in acidified iron(III) chloride solutions at elevated temperatures.[4,5,21,24] Highly-polymerized cationic hydroxoiron(III) complexes have been confirmed to form at an initial stage of hydrolysis of iron(III) chloride solution, followed by their precipitation as β-iron(III) hydroxide oxide.[25,26] However, Atkinson et al.[24] have observed that rather low-molecular-weight hydroxoiron(III) complexes would act as the precursor of hematite. Actually, the aqueous solutions of iron(III) chloride-glycine system did not show the presence of any polymeric iron(III) species before and after aging, from which the monodispersed hematite particles directly originated.

Figure 10 displays the spectra of an iron(III) perchlorate-glycine aqueous solution at different temperatures. The absorption bands ranged between around 435 and 580 nm were charasteristic of the glycinatoiron(III) complex.[27] A decrease in the

absorbance was clearly shown as the temperature increased, which indicated that the glycinatoiron(III) complex was dissociated at higher temperatures in spite of the negative enthalpy change of protonation of glycine anions (-45.0 ± 0.2 kJ mol^{-1}).[28,29] Thus, the enthalpy change of the formation of glycinatoiron(III) complex would be negative: this consideration can be reasonable because the formation of glycinatometal complexes is mostly exothermic except for indium and lanthanoids.[30]

By the use of the formation constants for hydroxo,[17-20] chloro,[31,32] and glycinato[27] complexes of iron(III) and the dissociation constants of glycine,[33] the sum of the fractions of chloro and glycinato complexes was numerically estimated as 0.84 at 25 °C under the conditions given in Fig. 1. According to the enthalpy changes of the formation of the respective species (36 kJ mol^{-1} for $Fe^{3+}+H_2O=[FeOH]^{2+}+H^+$,[17] -33 kJ mol^{-1} for $2[FeOH]^{2+}=[Fe_2(OH)_2]^{4+}$,[19] 72 kJ mol^{-1} for $Fe^{3+}+2H_2O=[Fe(OH)_2]^{+}+2H^+$,[17] 21 kJ mol^{-1} for $Fe^{3+}+Cl^-=[FeCl]^{2+}$,[31] and 5.0 kJ mol^{-1} for $[FeCl]^{2+}+Cl^-=[FeCl_2]^+$,[34] the amounts of $[FeOH]^{2+}$ and $[Fe(OH)_2]^+$ would increase much more than those of chloro complexes at higher temperatures by the degradation of glycinato complex. Although it is uncertain which hydroxoiron(III) complex is the actual precursor of hematite paricles, the glycinatoiron(III) complex was obviously indicated to participate as the soluble reservoir of hydroxo complex for originating the monodispersed hematite particles.

The monodispersed double spheres of hematite obtained in the 2-propanol/water mixed solution would be produced through a process similar to that in the aqueous solution.

When β-iron(III) hydroxide oxide, which was separately prepared and washed, was treated at 100 °C in the same solution given in Fig. 8 but without iron(III) chloride, the dissolution of hydroxide oxide quickly reached an equilibrium state in around 15 min. On the basis of the mass balance during the dissolution of hydroxide oxide and the deposition of hematite, it was concluded that the total concentration of the iron(III) species was not controlled by the dissolution rate of the β-iron(III) hydroxide oxide but by the solubility of the hydroxide oxide. Thus, the suspension of β-iron(III) hydroxide oxide would give an appropriate supersaturation of hydroxoiron(III) complexes to form the monodispersed hematite particles under the conditions suitably adjusted.

In addition, the formation mechanism of monodispersed cuboidal hematite particles in the presence of glycine would be basically the same as that in the alcohol/water mixtures without glycine.[5] However, the final size of the particles was greatly reduced by the presence of glycine even under the same concentrations of total iron(III) chloride, depending on the acid concentration. As the size distribution was kept

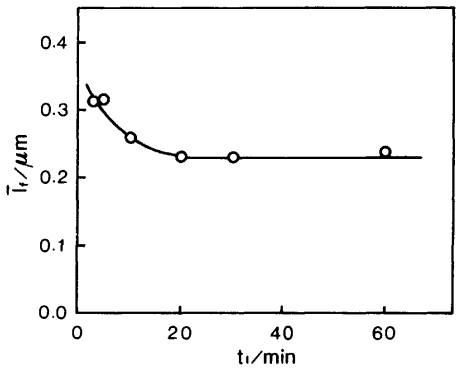

Fig. 11. Influence of acid concentration changed at t_1 on final size of cuboidal hematite particles at 100 °C. Conditions: $[HCl]_i=0.13$ and $[HCl]_f=0.15$ mol dm^{-3}.

almost constant (the relative standard deviation of 0.11—0.13 for 40 h) throughout the forced hydrolysis, the nucleation of the hematite particles would be completed at an early stage of the conversion. The dependence of acid concentration on the final size of hematite particles was also examined by a different way as follows: A solution contained 0.13 mol dm^{-3} hydrochloric acid and the same concentrations of iron(III) chloride and glycine as shown in Fig. 8 was aged at 100±0.5 °C for specified periods, t_1, from 3 to 60 min. The solution was then quenched to room temperature and its acidity was immediately changed to 0.15 mol dm^{-3} by adding hydrochloric acid, followed by repeated heating for 48—60 h.

Figure 11 displays the final size of the hematite particles as a function of t_1. The particles grew larger when the acidity was increased only at very early stages of aging. As shown in Fig. 9, the solution gave the final sizes of 0.22 and 0.35 μm at 0.13 and 0.15 mol dm^{-3} of hydrochloric acid respectively. Thus, these facts indicated that the final size was scarcely affected by the acidity applied after completion of the nucleation.

On the other hand, the cuboidal hematite particles can be also obtained when β-iron(III) hydroxide oxide particles were separately prepared and then aged in a solution without iron(III) ions under suitable conditions. In order to examine the dependence of the nature of β-iron(III) hydroxide oxide on the final size of hematite particles, three kinds of the hydroxide oxide were prepared under the conditions shown in Table 1. These were centrifuged and washed ten times with distilled water. These particles, as the iron(III) concentration of 2.0×10^{-2} mol dm^{-3}, were aged under the conditions shown in Table 2. The final sizes of the hematite particles thus prepared are also given in Table 2. The samples B and C gave hematite particles with final sizes of 0.22—0.37 μm which depended merely on the initial pH for preparing β-iron(III) hydroxide oxide, regardless of the original size of the

Table 1. Preparing Conditions for β-FeOOH at 100 °C[a)]

a) $[Fe(III)]=2.0\times 10^{-2}$ mol dm^{-3} as β-FeOOH, 2-propanol: 30% by volume. b) Observed at 25 °C before aging. c) The reaction did not complete even for 120 h.

hydroxide oxide, the presence of glycine, and the pH at aging. Contrary to the above results, the sample A, obtained from the solution without glycine, yielded much larger hematite particles in spite of the almost identical size of the original β-iron(III) hydroxide oxide and the aging conditions.

These facts imply that the nature of the hematite nuclei would depend definitively on the initial conditions in producing β-iron(III) hydroxide oxide. The nuclei would originate on the surfaces of the hydroxide oxide, probably by epitaxial nucleation, at the beginning of the reaction and tightly bind to the original hydroxide oxide. In the pH range applied in this work, the fraction of glycine anions is of the order of 10^{-9}, so that the adsorption of the anions would be negligible. If glycine anions adsorbed on the surfaces and reduced an interfacial energy of hematite particles, the growth rate should be also strongly affected by the acidity even in the narrow range of pH similar to the nucleation rate. Actually, little adsorption was observed even at pH 4.

However, glycine anions would combine strongly with embryos of hematite prior to the formation of stable nuclei even at low pH, because of a large excess surface energy of the embryos. In such a situation, the interfacial energy of the embryos would be significantly reduced, depending on the amount of adsorbed glycine anions, i.e., the acidity, which enhances the nucleation rate. Actually, the aging of the solutions without glycine gave much slower nucleation rates.[4,5)]

Exciplexes in Perfluorohydrocarbon. Charge-Transfer Interaction between Exciplexes and Perfluorohexane

Koji KANO,* Masaru YANAGIMOTO, and Shizunobu HASHIMOTO
Department of Applied Chemistry, Faculty of Engineering, Doshisha University, Kamikyo-ku, Kyoto 602
(Received June 3, 1986)

The rate constants for photochemical processes of pyrene in perfluorohexane (PFH) and hexane containing *N,N*-dimethylaniline (DMA) have been determined by analyzing the rise and decay curves of the pyrene-DMA exciplex to study the interaction between electronically polar exciplex and an extremely nonpolar solvent, PFH. In PFH, the dissociation of the exciplex to the original pyrene in the excited singlet state and DMA was decelerated and the radiationless deactivation of the exciplex to the ground states was accelerated. In the case of the naphthalene-triethylamine exciplex system, the radiationless deactivation of the exciplex was also much faster in PFH than in hexane. These results suggest charge-transfer interactions between the polar exciplexes and PFH. The negative charges of the exciplexes may transfer to the strongly electronegative fluorine atom(s) of PFH. The deceleration of the back reaction and the acceleration of the radiationless deactivation seem to lead the efficient fluorescence quenching of pyrene and naphthalene by amines in PFH.

Solvation plays an essentially important role to dominate physical properties and chemical reactivities of molecules in solutions. Several studies have demonstrated very weak solute-solvent interactions in perfluorohydrocarbons. The absorption and fluorescence emission spectra of benzene in perfluorinated alkanes are very similar to those in vapor phase.[1-3] The vibronic bands of the electronic spectra of 9*H*-xanthene-9-thione and its related thiones in perfluorohexane (PFH) are well-resolved compared with those in 3-methylpentane glass at 77 K.[4,5] These spectral data clearly indicate a very weak perturbation of the electronic states of solute molecules by perfluorohydrocarbon solvents. The fluorescence intensities of the vibronic bands of the pyrene monomer are known to be sensitive toward solvent polarity. This probe molecule also indicates extremely weak dipole-dipole interaction between pyrene and perfluorohydrocarbons.[6,7] A Kamlet-Taft's π^* value is one of the measures of the ability of a solvent to interact with solute through dipole-dipole interaction.[8,9] Table 1 shows the π^* values of various perfluorohydrocarbons together with the dielectric constants (ε) and the refractive indexes (n_D). The Kamlet-Taft's π^* values of perfluorohydrocarbons are large and negative, indicating very weak solute-solvent interactions in these solvents. Fluorine atom is so electronegative that perfluorohydrocarbon solvents show extremely low polarizabilities leading to weak van der Waals interactions.

Table 1. Dielectric Constants (ε), Refractive Indexes (n_D), and Kamlet-Taft's π^* Values for Perfluorohydrocarbons

	ε	n_D	π^*
Perfluoro(dimethyldecalin)	1.94[a]	1.312[a]	−0.33[a]
Tris(perfluorobutyl)amine	1.90[a]	1.291[a]	−0.36[a]
Perfluorooctane	1.85[a]	1.271[a]	−0.41[a]
Perfluoroheptane	1.765[a]	1.258[a]	−0.39[a]
Perfluorohexane	1.679[b]	1.251[c]	−0.40[d]

a) Ref. 9(b). b) This work. c) N. Ishikawa, *Petrotech*, **6**, 761 (1983). d) Ref. 8 e).

In spite of these physical aspects, we scarecely know chemical reactivities in perfluorohydrocarbons. Since perfluorinated alkanes are less active toward triplet carbonyl compounds than corresponding hydrocarbons, they are suitable solvents for phosphorescence measurements at room temperature.[10] Metal pentacarbonyls ($M(CO)_5$, M=Cr, Mo, and W) generated by the photolysis of the metal hexacarbonyls are very reactive toward carbon monoxide, cyclohexane, and nitrogen in perfluoro(methylcyclohexane) (PFMCH) because $M(CO)_5$ is free from solvation in PFMCH.[11] In some cases, perfluorohydrocarbons act as electron acceptors. The fluorescence emissions of triethylamine[12] and hydrocarbons such as cyclohexane, decalin, and 2,3-dimethylbutane[13] are quenched by perfluorohydrocarbons through charge-transfer interactions.

The present study deals with the solvent effects of perfluorohexane (PFH) on exciplex formation and dissociation. PFH shows the smallest ε and π^* values among the perfluorohydrocarbons listed in Table 1. The exciplex states have been well-known to be very sensitive toward solvent polarity because of their polar structures.[14] The exciplex, therefore, may be useful as a probe to study the interaction of polar solutes with extremely nonpolar solvents, perfluorohydrocarbons.

Experimental

Materials. Naphthalene was purified by sublimation. Pyrene was chromatographed on silica gel with cyclohexane and recrystallized from cyclohexane. Anthracene (Nakarai, 99.9%), triethylamine (TEA, Nakarai, reagent grade), and PFH (PCR Research Chemicals) were used without further

purification. Reagent grade of *N,N*-dimethylaniline (DMA, Nakarai) was purified by distillation prior to use. Spectral grades of hexane and cyclohexane (Nakarai) were used.

Measurements. Fluorescence emission and excitation spectra were taken on a Hitachi 650—60 spectrofluorometer (emission and excitation bandwidths=2 nm). Fluorescence quantum yields of naphthalene and pyrene (Φ_X) were determined by measuring the corrected fluorescence spectra of very dilute sample solutions. The optical densities of the samples were arranged to be less than 0.05 at excitation wavelengths. We used the reported fluorescence quantum yields (Φ_{ST}) of naphthalene (0.21)[15] and pyrene (0.60)[6] in cyclohexane as standards. Both sample and standard solutions were excited at the same wavelength. Φ_X, therefore, can be represented as

$$\Phi_X = \Phi_{ST}(FA_X/FA_{ST})(A_{ST}/A_X)(n_X^2/n_{ST}^2), \quad (1)$$

where FA is the spectral area, A is the optical density at the excitation wavelength, and n is the refractive index. The fluorescence decay curves were taken using an Ortec-PRA single photon counting apparatus and analyzed by a Simplex method using an NEC 9801 microcomputer. All samples were degassed by five freeze-pump-thaw cycles.

Dielectric constant (ε) of PFH was kindly measured at 25 °C by Professor Shimizu and Mr. Tsuchihashi of this university by using a Shibayama dielectric constant measurement apparatus SS207-B.

Results

Figure 1 shows the fluorescence spectra of pyrene in PFH containing various amounts of DMA. Upon addition of DMA, the fluorescence intensities of the pyrene and anthracene monomers decreased and new broad fluorescence bands due to the exciplexes appeared at longer wavelengths in nonpolar solvents. The exciplex emission was also observed for the naphthalene–TEA system. The fluorescence maxima (λ_{max}) of these exciplexes are listed in Table 2. The peak of the fluorescence band of the anthracene–DMA exciplex was obscure in hexane and cyclohexane due to overlap with the monomer fluorescence band. In each system, the fluorescence maximum of the exciplex in PFH was observed at the shortest wavelength. A good linear relationship between the energy of the pyrene–DMA exciplex emission band (ν_E) and the solvent polarity parameter ($f(\varepsilon,n)$) was observed for the pyrene–DMA system:[16]

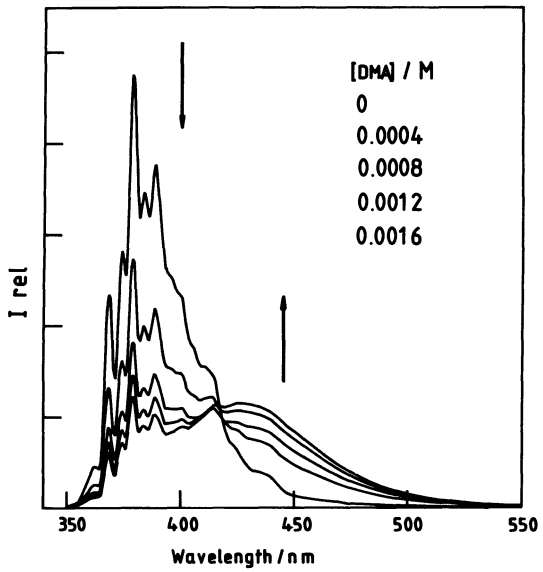

Fig. 1. Fluorescence spectra of pyrene (1×10^{-6} M) in degassed PFH in the absence and the presence of DMA at 25 °C. Pyrene was excited at 328 nm.

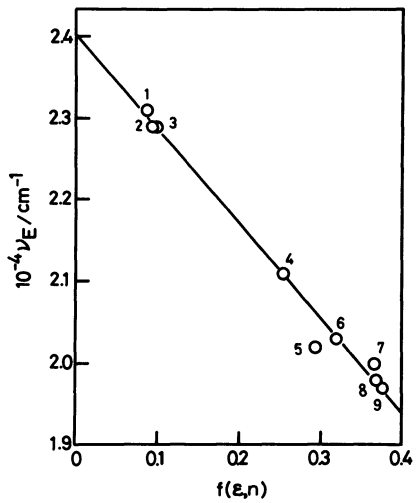

Fig. 2. Plot of the energy of the fluorescence maximum of the pyrene–DMA exciplex (ν_E) vs. the solvent polarity parameter $f(\varepsilon, n)$: 1: PFH, 2: hexane, 3: cyclohexane, 4: diethyl ether, 5: ethyl acetate, 6: dichloromethane, 7: isopropyl alcohol, 8: propyl alcohol, 9: ethanol.

a) The K_{SV} and k_q values in the parentheses were determined from the Stern-Volmer plots for fluorescence lifetime of anthracene.

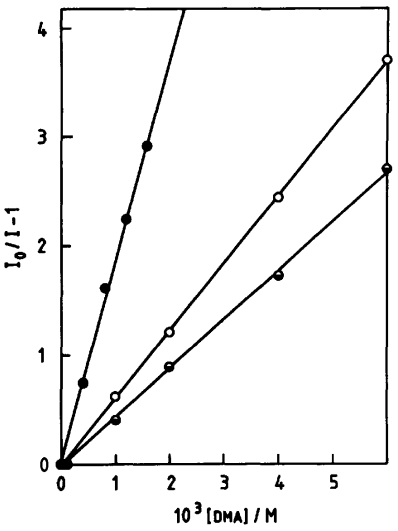

Fig. 3. Stern-Volmer plots for the fluorescence quenching of pyrene (1×10^{-6} M) by DMA in degassed PFH (●), hexane (◒), and cyclohexane (○) at 25 °C. Pyrene was excited at 328 nm in PFH, 334 nm in hexane, and 335 nm in cyclohexane. The fluorescence intensities (I) were followed at 378 nm in PFH and 382 nm in hexane and cyclohexane.

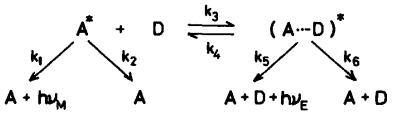
$$f(\varepsilon, n) = 2(\varepsilon-1)/(2\varepsilon+1) - (n^2-1)/(2n^2+1). \quad (2)$$

The plot of ν_E vs. $f(\varepsilon,n)$ is shown in Fig. 2. A plot for PFH does not deviate from the straight line. The same linear relationship between ν_E and $f(\varepsilon,n)$ has been observed for the naphthalene-TEA system.[17]

A simple Stern-Volmer relationship could be applied for the fluorescence quenching of pyrene, anthracene, and naphthalene by amines (Fig. 3) and the results are summarized in Table 3. The fluorescence quenching parameters, the Stern-Volmer constants (K_{SV}) and the rate constants of fluorescence quenching (k_q), determined for the pyrene-DMA system in hexane and for the anthracene-DMA system in cyclohexane are in good agreement with those reported by Ware and his coworkers.[18,19] In each system, both K_{SV} and k_q values obtained for the fluorescence quenching in PFH were significantly larger than those in hexane and cyclohexane. In order to understand the reasons for very efficient fluorescence quenching in PFH, we determined the all rate constants of photochemical processes shown in the following scheme:



The fluorescence decays of monomer and exciplex can be written as Eqs. 2 and 3, respectively:[20,21]

$$I_M(t) = a_1\exp(-\lambda_1 t) + a_2\exp(-\lambda_2 t), \quad (3)$$

$$I_E(t) = a_3[\exp(-\lambda_1 t) - \exp(-\lambda_2 t)], \quad (4)$$

where

$$\lambda_{1,2} = 1/2[k_1 + k_2 + k_3[Q] + k_4 + k_5 + k_6 \mp \{(k_1+k_2+k_3[Q]-k_4-k_5-k_6)^2+4k_3k_4[Q]\}^{1/2}]. \quad (5)$$

From Eq. 3, linear correlations between $(\lambda_1+\lambda_2)$ and $\lambda_1\lambda_2$ and [Q] can be expected:

$$\lambda_1 + \lambda_2 = k_1 + k_2 + k_3[Q] + k_4 + k_5 + k_6 \quad (6)$$

$$\lambda_1\lambda_2 = (k_1+k_2)(k_4+k_5+k_6) + (k_5+k_6)k_3[Q] \quad (7)$$

The k_3 and (k_5+k_6) values are determined from the slopes of the plots of $(\lambda_1+\lambda_2)$ vs. [Q] and of $\lambda_1\lambda_2$ vs. [Q], respectively. Since (k_1+k_2) can be obtained from the fluorescence decay of a fluorophore in the absence of quencher, k_4 is determined from the intercept of the plot of $(\lambda_1+\lambda_2)$ vs. [Q]. The k_1 and k_2 values are presented from the fluorescence lifetime (τ_0) and quantum yield (Φ_{M0}) of a fluorophore in the absence of quencher:

$$\tau_0 = (k_1+k_2)^{-1} \quad (8)$$

$$\Phi_{M0} = k_1/(k_1+k_2) \quad (9)$$

In the presence of quencher, the ratio of the fluorescence quantum yield of exciplex to that of monomer (Φ_E/Φ_M) is represented as

$$\Phi_E/\Phi_M = (k_5/k_1)\{k_3[Q]/(k_4+k_5+k_6)\}. \quad (10)$$

From the slope of the plot of Φ_E/Φ_M vs. [Q], one can get k_5. We obtained Φ_E/Φ_M value at each quencher concentration by measuring spectral areas of monomer and exciplex emissions:

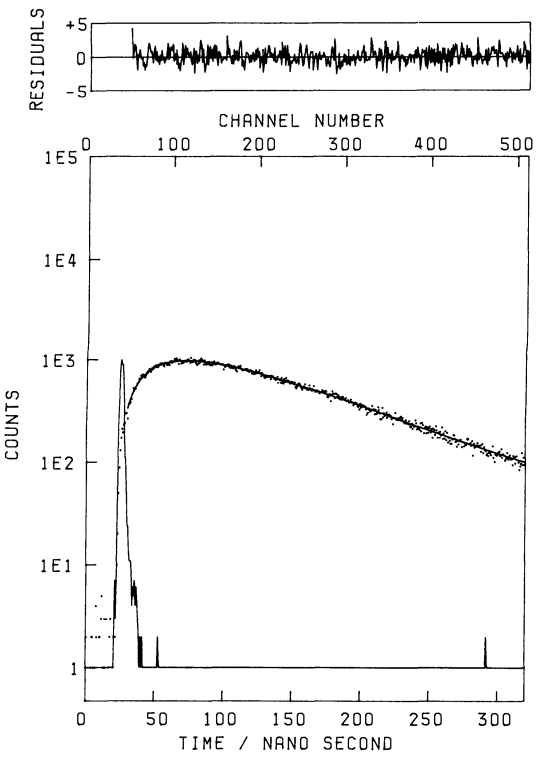


Fig. 4. Fluorescence decay curve of the pyrene–DMA exciplex in degassed PFH at 7 °C. The concentrations of pyrene and DMA were 1×10^{-6} and 1.5×10^{-3} M, respectively. Pyrene was excited at 328 nm and the exciplex emission was passed through a Toshiba glass filter VY-45 to eliminate the monomer emission. The best fit provided the rise and decay times of 29.5 and 91.8 ns, respectively ($\chi_\nu^2=1.09$).

$$\frac{\Phi_E}{\Phi_M} = \frac{\int I_E(\nu)d\nu}{\int I_M(\nu)d\nu} \quad (11)$$

The λ_1 and λ_2 values were determined from the fluorescence rise and decay curve of the exciplex. A typical example of the rise and decay curve of the pyrene–DMA exciplex in PFH is shown in Fig. 4. The plots of $(\lambda_1+\lambda_2)$ and of $\lambda_1\lambda_2$ vs. [DMA] are given in Figs. 5 and 6, respectively. The results shown in Figs. 5 and 6 were treated statistically by using a microcomputer to determine k_3 and (k_5+k_6). We had large experimental errors for determining λ_1 and λ_2 from the monomer fluorescence decay curve. The fluorescence quantum yields of naphthalene and pyrene in PFH

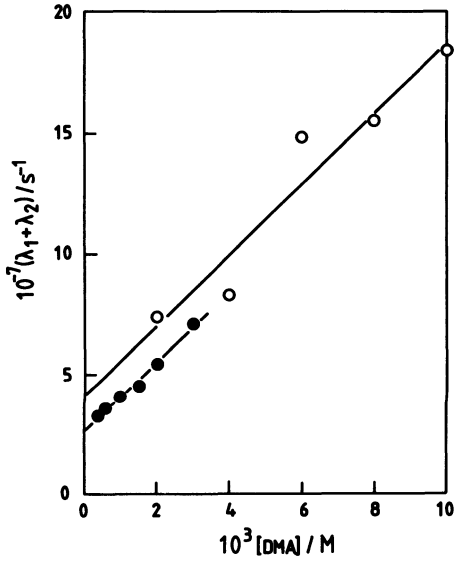

Fig. 5. Dependence of $(\lambda_1+\lambda_2)$ on the DMA concentration for the pyrene–DMA system in PFH (●) and hexane (○) at 7 °C.

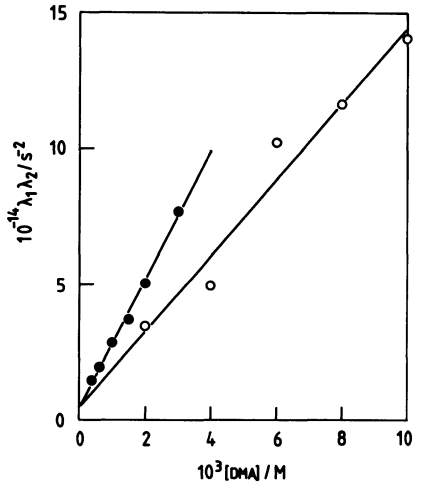

Fig. 6. Dependence of $\lambda_1\lambda_2$ on the DMA concentration for the pyrene–DMA system in PFH (●) and hexane (○) at 7 °C.

Table 4. Fluorescence Quantum Yields (Φ_{M0}) of Naphthalene and Pyrene in Degassed PFH and Hexane in Absence of Quencher

Fluorophore	Solvent	T/°C	Φ_{M0}
Naphthalene	Perfluorohexane	25	0.20
Naphthalene	Hexane	25	0.21
Pyrene	Perfluorohexane	25	0.33
Pyrene	Hexane	25	0.49
Pyrene	Perfluorohexane	7	0.35
Pyrene	Hexane	7	0.51

Table 5. Rate Constants for Photochemical Processes of Pyrene-DMA System in Degassed PFH and Hexane at 7 °C

	PFH	Hexane
$10^{-6}k_1$ s^{-1}	0.88±0.05	1.1±0.1
$10^{-6}k_2$ s^{-1}	1.6±0.1	1.1±0.1
$10^{-10}k_3$ M^{-1} s^{-1}	1.5±0.1	1.5±0.1
$10^{-7}k_4$ s^{-1}	0.69±0.17	3.0±1.6
$10^{-6}k_5$ s^{-1}	2.3±0.2	2.5±1.1
$10^{-6}k_6$ s^{-1}	13.0±1.0	7.0±2.0

and hexane are listed in Table 4. From the results listed in Tables 3 and 4, the k_1 and k_2 values were evaluated. The determined rate constants for the photochemical processes of the pyrene-DMA system are summarized in Table 5.

In the case of the naphthalene-TEA system, the rise time of the exciplex emission at 25 °C was so short that the λ_1 and λ_2 values could not be determined accurately. Although large errors might be included, we evaluated the $(k_4+k_5+k_6)$ values by extrapolating λ_2 to the zero TEA concentration. The λ_2 values were determined by fitting the experimentally obtained decay curves with trial single-exponential decay functions at larger t. Figure 7 shows the plots of λ_2 vs. [TEA] in PFH and hexane. The slope of the plot of Φ_E/Φ_M vs. [TEA] gives $(k_3k_5/k_1)/(k_4+k_5+k_6)$ (see Eq. 10). Since the k_1 value can be known from the fluorescence lifetime and quantum yield of naphthalene in the absence of quencher, the k_3k_5 value can be evaluated. The rate constant for fluorescence quenching is represented as

$$k_q = k_3(k_5+k_6)/(k_4+k_5+k_6). \quad (12)$$

From Eq. 12, we could get the k_3k_6 value. Table 6 summarizes the results.

Table 6. Rate Constants for Photochemical Processes of Naphthalene-TEA System in PFH and Hexane at 25 °C

	PFH	Hexane
$10^{-6}k_1$ s^{-1}	2.1	1.8
$10^{-6}k_2$ s^{-1}	8.5	6.6
$10^{-15}k_3k_5$ s^{-2} M^{-1}	2.5	1.6
$10^{-16}k_3k_6$ s^{-2} M^{-1}	7.2	0.94
k_6/k_5	29	6

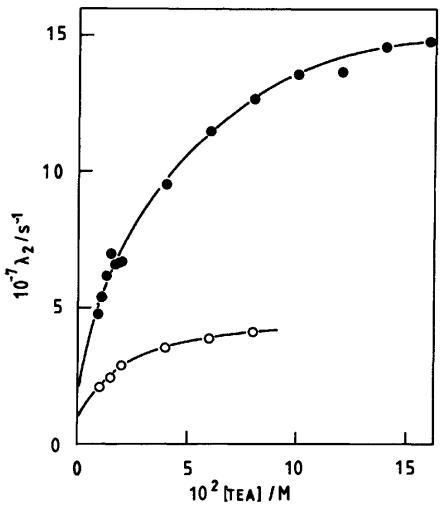

Fig. 7. Plots of λ_2 vs. [TEA] for the pyrene-DMA exciplex in PFH (●) and hexane (○) at 7 °C.

Discussion

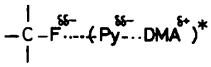
The photochemical processes of the fluorophores such as pyrene, anthracene, and naphthalene in the presence of aromatic or aliphatic amines have been well known to be dependent on solvent polarity.[14] In nonpolar solvents, these fluorophores in the excited singlet states form the exciplexes in collision with amines while direct electron transfers from amines to photoexcited fluorophores occur without exciplex formation in strongly polar solvents. If an exciplex is fluorescent, the emission maximum of the exciplex shifts to longer wavelength with increasing solvent polarity because the exciplex having an electronically polar structure is solvated to a large extent by polar solvent. These characteristics of exciplex seem to be suitable for investigating the interaction between photoexcited solute and perfluorocarbon solvent. Especially, exciplexes may be very interesting probes for studing interaction of electronically polar solute with perfluorinated solvent, which has not been examined.

Fluorescence Quenching. The fluorescence quenching of pyrene and anthracene by DMA and of naphthalene by TEA was carried out in PFH, hexane, and cyclohexane. As indicated in Fig. 3 and Table 3, the fluorescence quenching in PFH proceeds much faster than that in hexane and cyclohexane. In the case of pyrene, the k_q values obtained at 7 °C are considerably larger than those at 25 °C. This should be due to the back reaction of the pyrene-DMA

exciplex to the original precursors, pyrene in the excited singlet state and DMA in the ground state. The back reaction is accelerated at higher temperature.[18] Very efficient fluorescence quenching occurred in the anthracene-DMA system in PFH, the k_q values being $3.44\times10^{10}\,M^{-1}\,s^{-1}$ (1 M=1 mol dm^{-3}) at 7 °C and $2.23\times10^{10}\,M^{-1}\,s^{-1}$ at 25 °C. Since the viscosity (η) of PFH at 20 °C is 0.7 cP (1 P=0.1 Pas), the diffusion-controlled rate constant (k_{diff}) is calculated to be $1.4\times10^{10}\,M^{-1}\,s^{-1}$ using Stokes-Einstein-Smoluckowski's equation, $k_{diff}=8RT/(2000\eta)$. The k_q values are much larger than the calculated k_{diff} value. Then we measured the fluorescence lifetime of the anthracene monomer at each DMA concentration to obtain k_q for dynamic quenching. The Stern-Volmer plots for the fluorescence lifetimes provided the k_q values of $1.59\times10^{10}\,M^{-1}\,s^{-1}$ at 7 °C and $1.79\times10^{10}\,M^{-1}\,s^{-1}$ at 25 °C, which are very close to the calculated k_{diff} value. These results indicate the occurrence of a static quenching in this system. Although the mechanism of the static quenching is not clear, one possibility is the formation of ground-state aggregates of anthracene and DMA due to low solubilities of these solute molecules in PFH. In the case of the pyrene-DMA system, however, the fluorescence decay curve (see Fig. 4) indicates that the exciplex forms dynamically. The efficient fluorescence quenching of pyrene by DMA in PFH, therefore, cannot be interpreted in terms of the ground-state aggregates.

Pyrene-DMA System. We determined the rate constants for the photochemical processes of the pyrene-DMA system according to the procedures described in detail by Cheung and Ware.[18] The results are summarized in Table 5. Since the fluorescence rise time of the pyrene-DMA exciplex was so short in PFH at 25 °C that the measurements were undertaken at 7 °C. The exciplex formation for the pyrene-DMA system has been verified to be diffusion-controlled process.[18,22] The k_3 values in cyclohexane at 20 °C and in hexane at 7.6 °C have been reported to be 9.8×10^9 and $1.37\times10^{10}\,M^{-1}\,s^{-1}$, respectively.[18,22] The k_3 value ($1.5\times10^{10}\,M^{-1}\,s^{-1}$) in hexane at 7 °C obtained in the present study is in good agreement with the reported value. The k_3 value in PFH is the same as that in hexane. As mentioned above, the Stokes-Einstein-Smolukowski's equation predicts that k_{diff} in PFH is $1.4\times10^{10}\,M^{-1}\,s^{-1}$ at 20 °C which is very close to k_3 obtained in this study.

The large difference between PFH and hexane was found in the k_4 and k_6 values. The fluorescence quenching rate constant, k_q, is represented as Eq. 12. The large k_q value in PFH, therefore, is ascribed to the smaller k_4 and larger k_6 values compared with the case in hexane. If the solute-solvent interaction in PFH is very weak as predicted from ε and π^* values (Table 1), the back reaction of the exciplex (k_4) in PFH should be faster than that in hexane because of the smaller stabilization of the pyrene-DMA exciplex in PFH. The experimental result, however, is opposite from the assumption. Therefore, we have to consider the interaction between the exciplex and surrounding PFH molecules. Alford et al. have found that the fluorescence of TEA is efficiently quenched by perfluorohydrocarbons such as PFMCH, octafluorocyclobutane, and perfluoro-2-butene in both vapor and liquid phases.[12] In cyclohexane, k_q for the fluorescence quenching of TEA by PFMCH is $1.3\times10^{10}\,M^{-1}\,s^{-1}$. Alford et al. assumed a charge-transfer (CT) interaction as the fluorescence quenching mechanism. Similarly, the fluorescence of hydrocarbons such as cyclohexane, decalin, and 2,3-dimethylbutane is also quenched by perfluorohydrocarbons such as PFMCH and perfluorodecalin.[13] Choi and Lipsky proposed a quenching mechanism involving charge transfer from photoexcited hydrocarbons to perfluorohydrocarbons.[13] In the case of pyrene, the fluorescence quantum yield (Φ_{M0}) and lifetime (τ_0) of the pyrene monomer in PFH without quencher are somewhat smaller than those in hexane (see Tables 3 and 4). Although CT interaction between photoexcited pyrene and PFH may be accounted for the smaller Φ_{M0} in PFH, the quenching by PFH was not so remarkable. Meanwhile, since the pyrenyl moiety of the exciplex is negatively charged and is expected to have a lower ionization potential compared with photoexcited pyrene, it can be expected to transfer the negative charge of the pyrenyl moiety to the strongly electronegative fluorine atom(s) of PFH:



The CT interaction between the exciplex and PFH may decelerate the back reaction of the exciplex and accelerate the radiationless deactivation of the exciplex leading to smaller k_4 and larger k_6. If the CT interaction stabilizes the exciplex, the fluorescence maximum of the exciplex may shifts to longer wavelength in PFH. No novel behavior of PFH, however, was observed in the plot of ν_E vs. $f(\varepsilon,n)$ as shown in Fig. 2. In the present stage, we do not have any experimental data to explain the fluorescence maximum of the pyrene-DMA exciplex in PFH. Presumably, the Franck-Condon ground state of the exciplex should be considered to answer this problem. The Franck-Condon ground state may still interact with PFH because PFH interacting with the exciplex can be regarded microscopically as a sort of a polar solvent. Another plausible mechanism for the smaller k_4 value in PFH is the self association of the exciplex. It can be assumed that the activation energy due to weak association of the exciplex causes the deceleration of the back reaction of the exciplex. However, this mechanism should be excluded by the fact that the

fluorescence quenching of pyrene in PFH obeys a simple Stern-Volmer linear relationship (see Fig. 3).

Naphthalene-TEA System. In this system, we could not determined all rate constants for the photochemical processes because of a very fast rise of the exciplex emission intensity. However, we could evaluate the k_6/k_5 values as mentioned in the Results Section. As Table 6 shows, the k_6/k_5 value in PFH is much larger than that in hexane. Judging from the results obtained for the pyrene-DMA system, it may be reasonable to assume that the k_5 value for PFH does not differ largely from that for hexane. The radiationless deactivation of the exciplex in PFH, therefore, should be much faster than that in hexane as the case of the pyrene-DMA system. The CT interaction between the polar naphthalene-TEA exciplex and PFH may accelerate the radiationless deactivation.

Isotachophoretic Analysis of Quaternary Ammonium Ions by Using α-Cyclodextrin as Complex-Forming Agent

Masato TAZAKI,† Takashi HAYASHITA,†† Yasumitsu FUJINO, and Makoto TAKAGI*
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Higashi-ku, Fukuoka 812
(Received January 23, 1986)

The isotachophoretic behavior of aromatic nucleus-containing quaternary ammonium ions was studied in the presence of a neutral ligand, α-cyclodextrin. Due to the interaction of cyclodextrin with the hydrophobic aromatic nucleus, isomeric ammonium ions containing, e.g., an *o*-, *m*-, or *p*-disubstituted benzene ring, were satisfactorily separated. In the absence of cyclodextrin, the separation of the isomers was poor. A theoretical approach was also used in order to evaluate the binding equilibrium constant (K) between the analyte ion and α-cyclodextrin through an isotachophoretic measurement. The binding constants (log K) with (*o*-, *m*-, and *p*-methylbenzyl)trimethylammonium ions were found to be 0.8, 1.1, and 1.6, respectively.

During the past twenty years, substantial progress has been made concerning isotachophoresis, both in regard to theory and instrumentation, making it an important physicochemical tool for the analysis of ionic species in solution. In this technique, ion separation is based on a difference in the ionic mobilities under an electrical potential gradient. Therefore, the most important task in isotachophoresis is to control or modify the effective mobility of analyte ions in order to expand its analytical applications.

Several approaches have been made to modify the mobility of ionic species: (i) a pH adjustment of the leading solution, (ii) a change in the solvent polarity, and (iii) the use of complex-forming equilibria with counter ions.[1-10] As a new approach, we have recently proposed a system in which an electrically-neutral ligand is used to bind ionic species and to alter their effective ionic mobility.[11] For example, by adding an appropriate amount of crown ethers to the leading solution, some alkali and alkaline earth metal ions (which otherwise did not form electrophoretically resolved zones) could be mutually separated.

On the other hand, cyclodextrins are known to have specific interactions with various aromatic compounds in aqueous solution.[12] This type interaction has recently been successfully used for improving the chromatographic separation of aromatic compounds and amino acids.[13-16] Further, the separation of optical isomers has been attained by taking advantage of the chiral nature of cyclodextrins.[17,18] Such interactions of cyclodextrins with aromatic compounds should be directly applicable to an isotachophoretic system; in fact, we have found that the separation of bulky (lipophilic) inorganic anions can be improved by adding α-cyclodextrin (α-CD).[11]

During the present study, we looked at the effect of α-CD on the isotachophoretic separation of quaternary ammonium ions. These ions, especially those in isomeric forms, are difficult to separate under conventional isotachophoretic conditions. The addition of α-CD greatly improved the separation. The study was also extended to an evaluation of the binding constant between the analyte ammonium ion and α-CD.

Experimental

Apparatus A Shimadzu IP-2A isotachophoretic analyzer was combined and used with a potential gradient detector (model PGD-1). The ion-migration current and the temperature were set at 50 μA and 25 °C, respectively. The length of the analyzing capillary tube (PTFE; i. d. 0.5 mm) was 15 cm.

Reagents. Ten mM (1 M=1 mol dm^{-3}) of hydrochloric acid or 10 mM of an acetic acid-potassium acetate (1:1) buffer solution was used as the leading solution. The solution also contained 0.01 wt% poly (vinyl alcohol) (PVA) and an appropriate amount of α-CD. A terminating solution was prepared by dissolving 5 mM of (*p*-methylbenzyl)trimethylammonium bromide or 5 mM of 1-naphthylamine hydrochloride in water. The quaternary ammonium salts used as analyte ions were synthesized by a conventional reaction between tertiary amines and substituted benzyl halides in methanol or in ethanol. After recrystalization from ethanol-ether, the structure and purity of the product was confirmed by ^{1}H NMR, melting points and an elemental analysis.

Results and Discussion

Mobility of Analyte Ions. In isotachophoresis, each electrophoretic zone migrates at a constant velocity

$$v = \bar{m}_L E_L = \bar{m}_A E_A = \bar{m}_T E_T, \quad (1)$$

where $\bar{m}$ and E are the effective mobility and the (electric) potential gradient, respectively. The suffixes denote the quantities related to leading (L), analyte (A) and terminating (T) zones or ions. In our

†† Present address: Department of Applied Chemistry, Faculty of Engineering, Kanagawa University, Kanagawa-ku, Yokohama 221.

measurements, the potential gradient at each zone was obtained from an isotachopherogram. The mobility of the ion corresponding to each zone was then calculated by using Eq. 1 once the isotachopherogram was calibrated against ions of a known ionic mobility. In doing this, we had to be careful that the potential gradient read on isotachopherogram as a step height (cm) was not an absolute, but rather a relative value. Also, the observed step height could possibly contain a detector-drift term. Therefore, in order to determine the correct mobility of analyte ions from an isotachopherogram, several internal standard ions (calibration ions) of known mobility were required. They were subjected to the same isotachophoresis along with the analyte ions.

In the present study, K^+, Na^+, Li^+, and tetraethylammonium (TEA^+) were used as calibration ions. Figure 1 shows the potential gradient (step height) observed for these calibration ions as well as an analyte ion, (*p*-methylbenzyl)trimethylammonium ion (which is used in this case as a terminating ion). The calibration ions were such that no interaction was reported or could be expected to take place with the α-CD. The observed potential gradient of these ions, however, steadily increased as the α-CD concentration in the leading solution was increased.

In order to analyze the effect of α-CD on the calibration ions, the observed potential gradient (step height) for those ions was plotted against the reciprocals of the mobility of the ions (Fig. 2). Since this depends on their ionic atmosphere or the salt concentration in the solution, an appropriate correction was made to the absolute ionic mobility (the value at infinite dilution) by using the Debye-Hückel-Onsager equation.[19] The ionic concentration in each electrophoretic zone was calculated according to the regulating function derived from isotachophoretic equilibrium.[1]

As shown in Fig. 2, the plots resulted in good straight lines. This could be expected from Eq. 1, except that the observed potential-gradient values contained a drift term as indicated by the intersection of the lines with the ordinate. This is consistent with the experimental observation that when isotachopherogram was recorded from the start of sample-ion electrophoresis, the potential gradient of the leading zone began to drift upward at around the middle of the leading zone and then again became constant (flat) just before the analyte zones appeared. This detector-drift was quite reproducible, but could not be eliminated in spite of the extensive effort made during this study.

Figure 2 further shows that the slopes of the lines increased as the concentration of the α-CD in the leading solution was increased. This α-CD effect is associated with a decrease in the mobility of calibration ions in the presence of α-CD. The complexation of these calibration ions by α-CD might decrease their effective mobilities, but the well-defined straight lines shown in Fig. 2 can hardly be explained by such a bimolecular complexation. On the other hand, since α-CD is a rather large molecule, a change in the physical property of a bulk solution can be expected, even at a relatively low molar α-CD concentration.

According to Stokes' law, the ionic mobility is reciprocally proportional to the viscosity of the medium. This and Eq. 1 predict that if the viscosity of a solution increases with the addition of α-CD, the slopes of the lines in Fig. 2 increase with the increase in the α-CD concentration while retaining their straightness. Therefore, the mobility-lowering effect by α-CD must be entirely due to the change in the viscosity. This conclusion is also in line with the results shown in Fig. 1. Thus, the calibration ions unanimously show only a slight and an almost linear

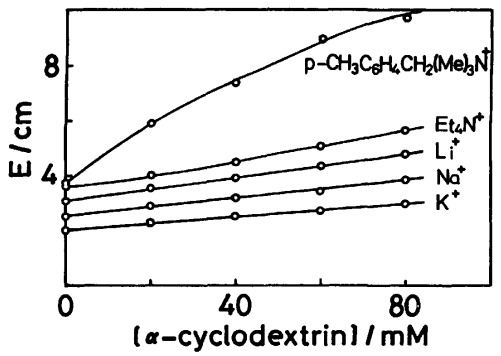

Fig. 1. Isotachophoresis of calibration ion in the presence of α-CD. Relation between potential gradient and α-CD concentration in leading solution. E: potential gradient as measured by step height (cm) in isotachopherogram. Leading solution, 10 mM HCl containing α-CD and 0.01 wt% PVA; terminating solution, 5 mM (*p*-methylbenzyl)trimethylammonium bromide; analyzing capillary tube (PTFE; i.d., 0.5 mm), 15 cm; ion migration current, 50 μA; 25 °C.

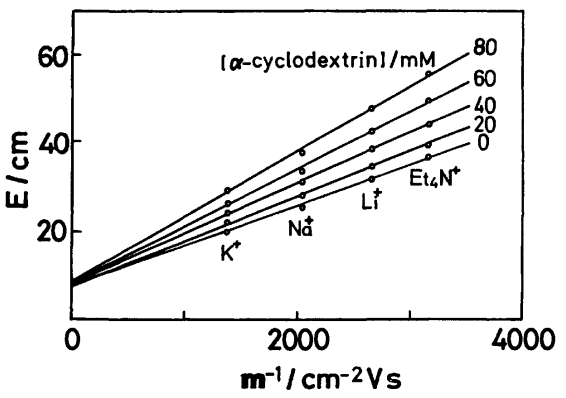

Fig. 2. Relation between potential gradient (E) and reciprocal ionic mobility (m^{-1}) of calibration ions at various α-CD concentrations. Calibration lines. For ionic mobility, see Eq. 2. For E and migrating conditions, see Fig. 1.

increase in potential gradient upon increasing the α-CD concentration. On the other hand, the (*p*-methylbenzyl)trimethylammonium ion, which is expected to make a specific (bimolecular) interaction with α-CD, shows a marked potential-gradient increase. The general behavior, therefore, is quite different.

In order to quantitatively extract the (purely) complexing effect of α-CD from the observed potential-gradient data, it was necessary to either cancel out or to make calibrations for both the detector signal-drift and the viscosity effect of α-CD. For this purpose, a calibration line (the same as that shown in Fig.2) was prepared for each α-CD concentration and was used to correlate the observed potential gradient and the mobility (reciprocal mobility) of the analyte ions. With the aid of such a calibration line, we could obtain the mobility of any analyte ion at any α-CD concentration by simply measuring the corresponding step height on the isotachopherogram.

Another way of looking at this is that the mobility of the analyte ion obtained from such a calibration method is not a real but, rather, an ideal or abstracted one since the contribution from the viscosity effect is artificially eliminated. According to Stokes' law, the above-mentioned mobility m_i and the actual mobility m_i are related by

$$m_i = \frac{\eta_{[CD]>0}}{\eta_{[CD]=0}} \times m_i, \tag{2}$$

where η is the viscocity of the medium.

Isotachophoresis of Quaternary Ammonium Ions and Complexation with α-CD. Figure 3 illustrates an isotachophoretic separation of analyte cations (A^+ and B^+) in the presence of an electrically-neutral ligand (N). L^+ and T^+ indicate the leading and terminating cations, respectively. Q^- represents the counter anion.

The binding constants or association constants of ligand N with A^+ and B^+ are defined by Eqs. 3 and 4. Then, the effective mobilities of A^+ and B^+ ($\bar{m}_A$ and $\bar{m}_B$: mobilities which are observed experimentally) in their sample zones in the presence of ligand N can be expressed by Eqs. 5 and 6. The latter equations indicate that cations A^+ and B^+ can be separated from each other even when they have the same ionic mobilities ($m_A=m_B$) if the binding constants with N are appreciably different ($K_{AN} \neq K_{BN}$):

$$K_{AN} = \frac{[AN^+]_A}{[A^+]_A[N]_A} \tag{3}$$

$$K_{BN} = \frac{[BN^+]_B}{[B^+]_B[N]_B} \tag{4}$$

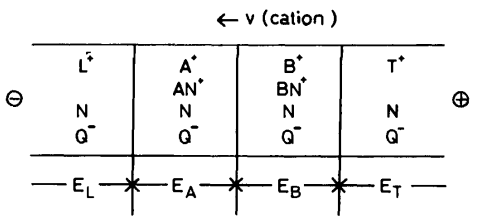

Fig. 3. Isotachophoretic separation of cations in the presence of neutral ligand. E_i: potential gradient in the *i*-th zone, *v*: migration velocity of cation, L^+: leading ion, A^+: B^+: analyte ions, T^+: terminating ion, N: neutral ligand, Q^-: counter ion.

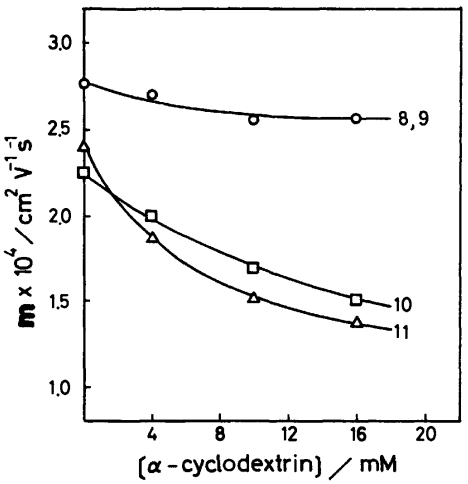

Fig. 7. Complexing effect of α-CD on the mobility of some quaternary pyridinium ions. For ***m***, see Eq. 2. Migration conditions are the same as those in Fig. 5.

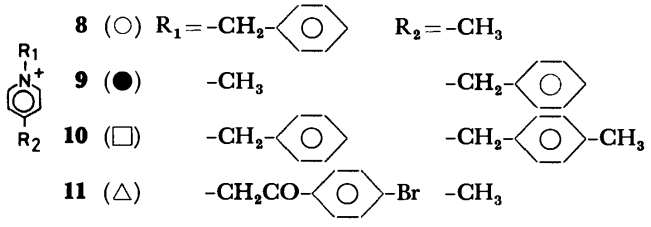

$$\bar{m}_A = \frac{m_A[A^+]_A + m_{AN}[AN^+]_A}{[A^+]_A + [AN^+]_A} = \frac{m_A + m_{AN}K_{AN}[N]_A}{1 + K_{AN}[N]_A} \quad (5)$$

$$\bar{m}_B = \frac{m_B[B^+]_B + m_{BN}[BN^+]_B}{[B^+]_B + [BN^+]_B} = \frac{m_B + m_{BN}K_{BN}[N]_B}{1 + K_{BN}[N]_B}. \quad (6)$$

Figures 4 and 5 summarize the effect of α-CD on the mobilities of (substituted benzyl) trimethylammonium ions. Figure 6 shows one of the typical isotachopherograms obtained in these studies. It can be seen that the isomeric ammonium ions showed no indication of a mutual separation in the absence of α-CD. These (quaternary) ammonium ions are not acids nor bases in ordinary pH range (i.e., their electrophoretic behavior is not dependent on pH); therefore, the pH change in the medium can not help their separation. A change of medium from aqueous to organic does not show much promise either. The addition of α-CD brought about a clear separation (indicated in Figs. 4—6). Obviously, the separation was caused by complexation with α-CD (implicated by Eqs. 5 and 6). In fact, it is conceivable that this is the only way to achieve a separation of this type of organic ions by isotachophoresis, since the means are quite scarce for assuring a specific interaction with such isomeric quaternary ammonium ions.

One can see in Figs. 4 and 5 that the complexation characteristics of α-CD is clearly reflected in the mobility change of isomeric ammonium ions. α-CD is a cylinder-like molecule with an internal hydrophobic cavity which fits the size and the polarity of aromatic (benzene) derivatives. When inclusion complexes are formed with disubstituted benzenes, it is generally accepted that o- and m-isomers suffer steric hindrance from the wall of the cavity while p-isomers do not. Among *o*-(**1**), *m*- (**2**), and *p*-(**3**) methyl-substituted benzyl isomers, the p-isomer (**3**) shows the most pronounced mobility decrease upon an addition of α-CD. This indicates that the p-isomer formed the most stable inclusion complex. Because of its high molecular weight, the α-CD complex exhibits a much lower mobility than that of the uncomplexed ammonium ion ($m_A = m_B > m_{AN} = m_{BN}$). If the complex formation (binding) constant of isomer A is larger than that of isomer B ($K_{AN} > K_{BN}$ in Eqs. 3 and 4), the observed (effective) mobility of isomer A becomes smaller than that of isomer B ($\bar{m}_A < \bar{m}_B$ in Eqs. 5 and 6).

A distinct difference in the migration behavior was observed when α-CD was added to isomeric (nitrobenzyl) trimethylammonium ions (**4** and **5**; Fig. 5). The p-substituted isomer indicated a much stronger interaction with α-CD. For trisubstituted aromatic compounds **6** and **7**, however, a simplified consideration can not be made regarding the preference of complexation among the isomers. However, the analytical importance of cyclodextrin complexation is obvious if one looks at the separation achieved by applying only 5 mM α-CD to the leading solution.

Figure 7 shows the effect of α-CD on the mobility of some quaternary pyridinium ions. An inspection of the figure suggests that pyridinium moieties are too hydrophilic to be effectively bound in the hydrophobic cavity of cyclodextrin. It was rather discouraging that the mixture of isomers **8** and **9** could not be resolved. Compounds **10** and **11**, which carry more

lipophilic (larger) substituents on the pyridinium ring, showed a substantial decrease in mobility upon the addition of α-CD.

Estimation of Binding Constant. A theoretical treatment of the present isotachophoretic system is simple since the complexation of analyte ions (cations) only takes place with an electrically neutral ligand (α-CD).

First, a mass balance is taken for counter ions (anion) in the leading (L) and its neighboring analyte (A) zones. This gives

$$-m_Q E_A[Q^-]_A + m_Q E_L[Q^-]_L = v([Q^-]_A - [Q^-]_L), \quad (7)$$

where Q^- stands for a counter anion and the suffixes A, L, and Q denote the quantities related to these ionic species or their zones.

Since the neutral ligand in zone A exists in both free (N) and charged (AN^+) forms, it can move under the potential gradient in the zone. The effective mobility of the ligand in zone A is given by

$$\bar{m}_{N,A} = \frac{m_{AN}[AN^+]_A}{[AN^+]_A + [N]_A}. \quad (8)$$

Then, the mass balance for neutral ligand in the leading and its neighboring analyte zones is given by

$$\bar{m}_{N,A} E_A C_{N,A} = v(C_{N,A} - C_{N,L}), \quad (9)$$

where $C_{N,A}$(=$[AN^+]_A$+$[N]_A$) and $C_{N,L}$ are the concentrations of the neutral ligand in the analyte (A) zone and the leading solution, respectively.

Finally, Eqs. 10 and 11 are obtained from the electrical neutrality of each zone:

$$[A^+]_A + [AN^+]_A = [Q^-]_A \quad (10)$$

and

$$C_L = [Q^-]_L, \quad (11)$$

where C_L is the concentration of leading cation in the leading zone (=concentration of the leading electrolyte).

From these equations, coupled with Eqs. 1 and 3—6, the parameters could be eliminated (except for m_L, m_A, m_{AN}, m_Q, C_L, $C_{N,L}$, $[N]_A$, and K_{AN}). This afforded the following equation, which is a cubic function with respect to $[N]_A$:

$$m^*_{AN}K_{AN}^2[N]_A^3 + (m^*_A + m^*_{AN} - m^*_{AN}K_{AN}C_{N,L})K_{AN}[N]_A^2 + \{m^*_A + (m^*_A - m^*_{AN})m^*_L/m_L K_{AN}C_L - (m^*_A + m^*_{AN})K_{AN}C_{N,L}\} \times [N]_A - m^*_A C_{N,L} = 0 \quad (12)$$

where,

$$m^*_i = m_i + m_Q \ (i=L, A, AN).$$

To solve Eq. 12, the viscosity effect of α-CD must be considered. The mobility of individual ionic species at any α-CD concentration can be expressed as indicated before by Eq. 2, where m_i is the mobility of the ionic species free from the viscosity effect of α-CD and η is the viscosity of a medium containing α-CD at a specific concentration. By using Eq. 2, $\bar{m}_i$ and m_i can be replaced by $\bar{m}_i$ and m_i, respectively, in Eqs. 1 as well as 5-12. The resulting equations, as they appear, indicate only a simple replacement of $\bar{m}_i$ and m_i by $\bar{m}_i$ and m_i, respectively, and a replacement of E_i by $E_i \times (\eta_{[CD]=0}/\eta_{[CD]>0})$. This means that, even if numerical viscosity data is not available, Eq. 12 can be solved for $[N]_A$ by using the mobility data in the presence and the absence of α-CD after calibrating for the viscosity effect of α-CD.

The mobility of uncomplexed analyte ions could be experimentally determined during the present study. On the other hand, the mobility of α-CD-complexed analyte ions (m_{AN} or m_{AN}) could not be experimentally obtained, since complexation never went to completion under our isotachophoresis conditions. Now, a relationship between the relative mobility U (m_{TEA}=1.00) and the molecular weight is known to exist which follows the phenomenological equation:[20]

$$U/Z = 14.7/\sqrt{Mw} - 0.29, \quad (13)$$

where Z is an ionic charge and Mw is a molecular weight. By using this equation we could estimate the absolute mobility of α-CD-bound quaternary ammonium ions (complexed cation) with reasonable accuracy. The value (4.94×10^{-5} $cm^2 V^{-1} s^{-1}$ for (methyl-substituted benzyl)trimethylammonium-α-CD complex; Mw=972.85+164.27=1137.12), thus obtained, was used in Eq. 12. Then, we could numerically calculate the concentration of the free neutral ligand in the analyte zone ($[N]_A$) as a function of the binding constant (K_{AN}), where the concentration of the ligand in the leading zone was set as a parameter. Once $[N]_A$ was known, we could readily obtain $\bar{m}_A$ from Eq. 5; these $\bar{m}_A$ values were compared with the experimentally-obtained $\bar{m}_A$ value in order to check the validity of the value of parametrically-chosen K_{AN} values (see below).

A computer-assisted calculation was performed by using the Newton-Raphson method for solving cubic functions (Eq. 12) and by using an iterative method for approximating the ionic-strength modification to the absolute mobility (m_{0i}) using the Debye-Hückel-Onsager equation. Figure 8 summarizes the result of the theoretical calculation, where the effective mobility of the analyte ion is plotted as a function of the binding constant with α-CD. The effect of the α-CD concentration is also included in the figure.

The profiles in Fig. 8 indicate that as the K_{AN} value decreases or the α-CD concentration becomes lower, the effective mobility of the analyte ion approaches that of the free ion. On the other hand, as the K_{AN} value increases or the α-CD concentration increases, the effective mobility of the analyte ion approaches that of the α-CD-bound (complexed) analyte ion.

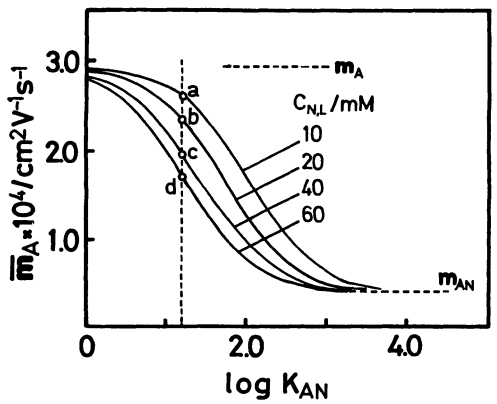

Fig. 8. Mobility change of (methyl-substituted benzyl) trimethylammonium ion (A) as a function of its binding constant (K_{AN}) with α-CD (N). Theoretical calculation. Parameters used are as follows. Absolute mobility m_{0i} ($cm^2\ V^{-1}\ s^{-1}$): $m_{0L}=362.5\times10^{-5}$, $m_{0Q}=79.08\times10^{-5}$, $m_{0A}=31.55\times10^{-5}$, $m_{0AN}=4.94\times10^{-5}$. Concentration (M): $C_L=0.0102$, $C_{N,L}=0.010$, 0.020, 0.040, 0.060.

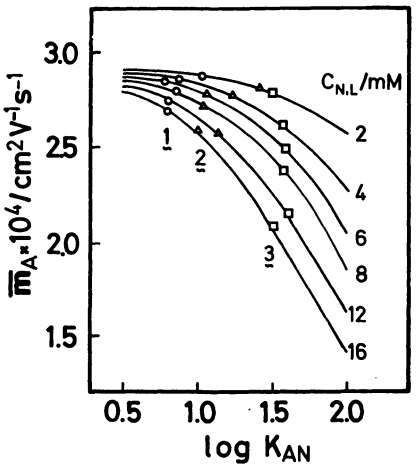

Fig. 9. Comparison of calculated and experimentally-obtained mobility. Determination of binding constant (K_{AN}) of (*o*-, *m*-, and *p*-methylbenzyl)trimethylammonium ions with α-CD. Experimental and calculation conditions are the same as those in Figs. 4 and 8.

Such behavior is in good accordance with our intuitive chemical picture and is quite reasonable.

The series of theoretical lines in Fig. 8 are useful for experimentally evaluating the binding constant between the analyte ions and α-CD. Consider that one carried out isotachophoresis of a certain analyte ion in the presence of 10, 20, 40, and 60 mM α-CD and obtained mobility data at each α-CD concentration. If the assumptions that were made in preparing the theoretical lines in Fig. 8 are correct, the observed mobility data should fall on a single vertical line crossing the four theoretical lines at experimental points a, b, c, and d. The intersect of the vertical line with the abscissa defines the required binding constant K_{AN}.

Figure 9 includes the mobility data obtained for (*o*-, *m*-, and *p*-methylbenzyl)trimethylammonium ions along with some theoretical mobility lines at various α-CD concentrations. Though experimental points are somewhat scattered at low α-CD concentrations, the data define fairly reasonable vertical lines, affording binding constants ($\log K_{AN}$) of 0.8, 1.1, and 1.6 for o-, m-, and p- isomers, respectively. Such low binding constants are usually accessible only by methods which involve multi-stage interactions, such as liquid chromatography. The present method using isotachophoresis is obviously characterized by a similar feature and is considered to be generally useful both for detecting and quantitatively treating weak interactions between an ion and an uncharged ligand.

Synthesis of Copper(II)-Dithiooxamide Complex in Zirconium Phosphate[1)]

Yoshitsugu HASEGAWA,* Midori KAMIKAWAJI, and Kaname SASAKI
Department of Industrial Chemistry, Faculty of Technology, Tokyo University of Agriculture and Technology, Nakamachi, Koganei, Tokyo 184
(Received April 12, 1986)

Copper(II)-dithiooxamide (rubeanic acid) complex was synthesized in the interlayer region of zirconium phosphate. The product, called ZP-CuLra, was chracterized by chemical analysis, thermal analysis, infrared spectroscopy, and X-ray diffractometry. The chemical composition of ZP-CuLra was represented as $ZrCu(H_2NCS)_2(PO_4)_2 \cdot H_2O$ or $ZrCu(HNCS)_2(HPO_4)_2 \cdot H_2O$. The interlayer distance of ZP-CuLra was found to be 9.0 Å. By analogy with Cu(II)-rubeanic acid complex prepared in a solution, a structural model of ZP-CuLra was proposed.

Zirconium phosphates have been studied most extensively as inorganic ionexchangers.[2)] Of these the α-from, $Zr(HPO_4)_2 \cdot H_2O$, is crystalline and its crystal structurc has been determined.[3)] Hence, the interrelation between the ion-exchange reaction and the change in the structure has been investigated for many cations. Also, α-zirconium phosphate behaves as a host when an organic molecule intercalates into the interlayer space.[4)] Recently, the application of α-zirconium phosphate to new materials has been examined.[2)]

Dithiooxamide, $(NH_2CS)_2$, (so-called to rubeanic acid (RA)), has been used in analytical chemistry.[5)] When RA is added to a solution containing Cu(II), a black precipitate (Cu-ra complex) is formed. It has been found that this Cu-ra complex exhibits semiconductivity and antiferromagnetism.[6)] The complex is considered to be a coordination polymer. Since it is amorphous, its physicochemical properties have not been explained theoretically. Abboudi et al. have studied large-angle X-ray scattering of the amorphous compound and proposed a structural model.[7)]

Montmorillonite, a typical clay mineral, has a layered structure similar to α-zirconium phosphate. Many attempts have been made to control tacticity using this clay as a template. Son et al. prepared the Cu-ra complex in an interlayer space of montmorillonite and found that the complex was monomeric and oriented in such a way that the molecular plane of the ligand was parallel to the silicate layer.[8)] They suggested that because the distance between Cu(II) in montmorillonite was too large to bridge with rubeanic acid molucules, only a monomeric compound was formed.[9)] The ion-exchange capacity of the clay used was 0.95 meq g^{-1}. Since α-zirconium phosphate has a larger ion-exchange capacity than montmorillonite, it can be expected that the distance between Cu(II) in the interlayer space will be shorter than that in montmorillonite. Consequently, if Cu(II) can be made to react with rubeanic acid in α-zirconium phosphate layer, a polymeric compound can be formed.

The present study established a preparative method for the Cu-ra complex in α-zirconium phosphate (the product obtained is referred to as ZP-CuLra) and ZP-CuLra was characterized by chemical analysis, infrared spectroscopy, and thermal analysis.

Experimental

Reagents. Rubeanic acid (Tokyo Kasei Co., Ltd.) was recrystallized from ethanol, and then dissolved in acetone. The rubeanic acid was recovered after evaporating the acetone. The other reagents were used without further purification.

Preparation of ZP-CuLra. All ion-exchange reaction was carried out by a batch method. The α-zirconium phosphate was prepared by the direct precipitation method.[10)] It was then converted into the half-exchanged sodium ion form, $ZrNaH(PO_4)_2 \cdot 5H_2O$(ZrNaH).[11)] Copper(II) ion was exchanged by adding ZrNaH to the solution of 0.03 mol dm^{-3} Cu(II) acetate. The mixture was shaken continuously for 48 h at 25 °C in order to prevent the solution from decomposing at elevated temperatures. After the reaction, the solid was centrifuged from the solution, and washed with distilled water. An X-ray diffraction pattern was obtained for the solid, and the sodium ion in the supernatant was determined by atomic absorption spectrometry. The solid was again immersed in Cu(II) acetate solution, and the same procedure repeated. The X-ray diffraction pattern was identical to the copper exchanged form, but the sodium ion was still detected. Since the large amount of the sodium and hydrogen ions in the solid phase was almost exchaned with Cu(II), a solution of 0.03 mol dm^{-3} Cu(II) nitrate was employed and the third ion exchange was carried out. To ensure the exchange, the solid was contacted with 0.01 mol dm^{-3} Cu(II) acetate in the fourth run. The Cu(II) form of the zirconium phosphate (ZP-Cu) was identified by X-ray diffractometry. The ZP-Cu was stored over silica gel in a desiccator.

In order to intercalate the Cu-ra complex in α-zirconium phosphate, the ZP-Cu was immersed in an ethanol solution containing rubeanic acid (0.56 g/120 ml) for 7 days with intermittent shaking. The product was separated by centrifugation, and washed with acetone several times. It was then dried in air at room temperature.

Analytical Procedure. The chemical analysis of ZP-CuLra was carried out as follows. A weighed sample was

heated in a crucible at about 900 °C, and weight loss was determined. A part of the ignited sample was then weighed and decomposed according to the previous method.[12] The precipitate was separated by filtration and dissolved in hydrochloric acid. Zirconium was separated as mandelate and determined according to the literature.[13] Copper was titrated with a standardized EDTA solution, using 1-(2-pyridylazo)-2-naphthol (PAN) as an indicator. Phosphorus was determined gravimetrically as $Mg_2P_2O_7$.[14] Determinations of carbon, hydrogen, nitrogen, and sulfur were carried out by elemental analysis.

X-Ray powder patterns were measured with a Rigaku Geigerflex RAD-2B. The infrared (IR) spectra were measured on an A-302 infrared spectrophotometer (Japan Spectroscopic Co. Ltd.,). The thermogravimetric (TG) and differential thermal analysis (DTA) curves were obtained with a Shimadzu thermal analyzer at a heating rate of 10 °C min^{-1} in static atomosphere.

Results and Discussion

Chemical Composition of ZP-CuLra. Alluli et al. have reported that ZP-Cu can be prepared by the column method.[15] Since the α-zirconium phosphate used was too fine to apply in a column, a batch method was emploed. The X-ray diffraction pattern of ZP-Cu and the loss on ignition agreed well with values reported.[15]

The chemical composition of ZP-CuLra is shown in Table 1. Thermal analysis showed that ZP-CuLra was monohydrate (see later). When Cu(II) salt (for example, nitrate) reacts with rubeanic acid in an ethanol solution, Cu(II) rubeanate is precipitated and an acid (nitric acid) released. Between the interlayer region of zirconium phosphate the counter ion of Cu(II), namely phosphate, is fixed. It is not likely that Cu(II) can form the salt directly in the region. Consequently, the following two formulae must be considered; $ZrCu(NH_2CS)_2(PO_4)_2 \cdot H_2O$(Type I), and $ZrCu(NHCS)_2(HPO_4)_2 \cdot H_2O$(Type II). In Type I a molecule of rubeanic acid coordinates to Cu(II). The rubeanate of Cu(II) is sandwiched between zirconium phosphate layer in Type II. In each case the ZP-CuLra has the same elemental composition. The molar ratio of copper to rubeanic acid or rubeanate and to the water of hydration were in agreement with those obtained for the amorphous compound.[7]

Thermal Analysis. Figure 1 shows TG and DTA curves of ZP-CuLra. Thermal decomposition occurred in three steps. In the first step an endothermic reaction took place in the temperature range of 50—120 °C. Then the second step followed until about 380°C. Though the TG curve indicates that this step consisted of two successive reactions, these reactions can not be separated clearly in the DTA curve. The reactions at this step appears exothermic. It can be considered that the decomposition products are oxidized at the surface of the platinum crucible, and converted to oxides, for example water. At higher temperature (600°C-) the third reaction occurred.

The X-ray diffraction pattern of the solid after heating was identical to that obtained from ZP-Cu. The facts show that the water of hydration and the ligand were removed by heating. The whole process is described as follows:

$$\text{ZP-CuLra} \xrightarrow[\text{step I}]{} \text{anhydrous ZP-CuLra} \xrightarrow[\text{step II}]{} \text{intermediate} \xrightarrow[\text{step III}]{} ZrCu(PO_4)_2.$$

The weight loss at the first step was 4.9% which corresponds to dehydration. The total weight loss of the second and the third step was 23.6%. This is almost equal to the calculated value.

IR Studies. The IR spectra of ZP-CuLra, ZP-Cu, and Cu-ra prepared in a solution are shown in Fig. 2. The spectrum of ZP-CuLra can be considered to be composed of those of ZP-Cu and Cu-ra.

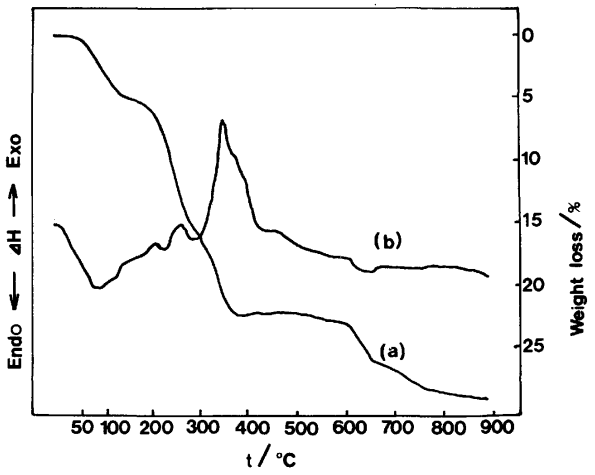

Fig. 1. TG(a) and DTA curve (b) of ZP-CuLra.

Table 1. Chemical Composition of ZP-CuLra/%

	Zr	Cu	PO_4	H	C	N	S
Found	18.11	13.72	37.60	1.27	4.75	5.50	11.14
	(1.00)	(1.08)	(1.99)	(6.35)	(1.99)	(1.98)	(1.75)
Calcd	18.89	13.16	39.33	0.83	4.97	5.80	13.28
	(1.00)	(1.00)	(2.00)	(6.00)	(2.00)	(2.00)	(2.00)

The values in parentheses are the molar ratios of each element to zirconium.

In order to determine Type I or II, it is important to examine the spectra in the region of 3500—3000 cm^{-1}, because the N-H bond gives an absorption band in this region. However, the O-H bond can also be assigned in the same region. According to Horsly et al., the absorption band at 3280 cm^{-1} was assigned to OH in P-OH, and bands at about 3500 and 1620 cm^{-1} to OH in the hydrated water in α-zirconium phosphate.[16] The absorption bands around 3460 and 1620 cm^{-1} disappeared in the IR spectrum after ZP-CuLra was heated in an air-bath at 150 °C. This fact suggests that these bands can be assigned to the hydrated water, and that the water was present in a similar manner as in α-zirconium phosphate.

On the other hand, the absorption bands at 3230 and 1520 cm^{-1} were still present after heating. Taking account of the above observation and the assignment of the spectrum for ZP-CuLra,[17] these bands can be assigned to -NH in $\overset{H}{Cu}\!>\!N-$.

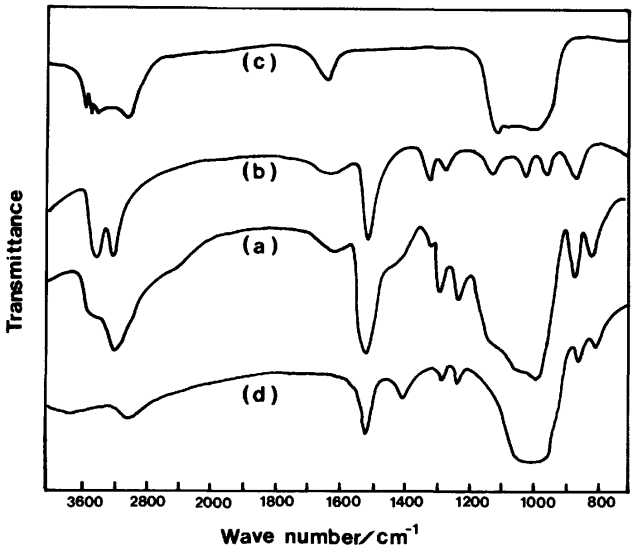

Fig. 2. IR spectrum of (a)ZP-CuLra, (b)Cura, and (c) ZP-Cu. The curve (d) is the spectrum of the sample obtained by heating of ZP-CuLra.

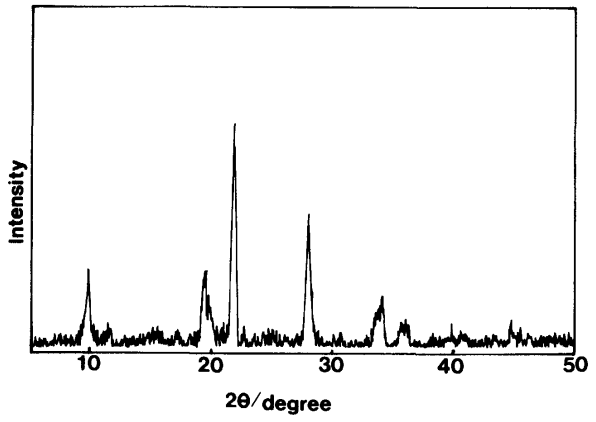

Fig. 3. X-Ray powder pattern of ZP-CuLra.

X-Ray Studies. It is well known that α-zirconium phosphate and its salt forms have a layered structure, and that the interlayer spacing is dependent on the cations present.[2] Hence, the change in an interlayer distance can be estimated from the lowest angle reflection in an X-ray diffractogram.

The X-ray powder pattern of ZP-CuLra is shown in Fig. 3. The interlayer distance of the exchanger phases was changed as follows.

α-$Zr(HPO_4)_2 \cdot H_2O$ 7.6 Å, $ZrNaH(PO_4)_2 \cdot 5H_2O$ 12.1 Å,
$ZrCu(PO_4)_2 \cdot 4H_2O$ 9.7 Å, ZP-CuLra 9.0 Å.

It is noteworthy that the interlayer spacing of ZP-CuLra was smaller than that of ZP-Cu. The molecular structure of rubeanic acid was known to be a planar form and the molecular dimensions were given.[18] The bond angle of HNH and CNH and the bond length of NH were not reported in the literature.[18] The molecular structure of rubeanic acid can be posturated by assuming that these are almost equal to those in thioformamid, $HSCNH_2$, that is, the angle HNH 122°, CNH 118—120°, and the length 1.01 Å.[19] The molecular size of rubeanic acid is estimated as shown in Fig. 4. The width of molecular plane is equal to be 3.60 Å.

.The copper complex can be arranged between the layers of zirconium phosphate in three manners, namely, parallel, perpendicular and inclined to the layers. If the plane of the rubeanic acid is parallel to

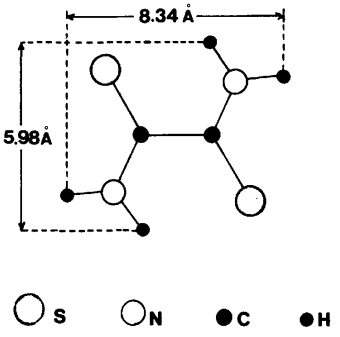

Fig. 4. Molecular size of rubeanic acid.

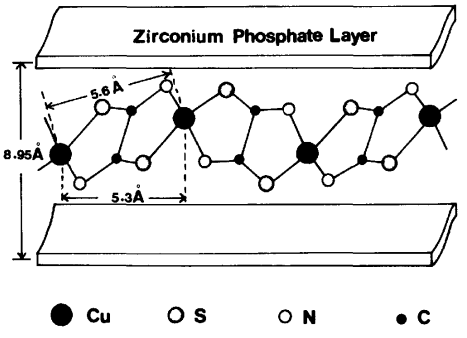

Fig. 5. Proposed model of CuLra complex between the zirconium phosphate layers.

that of the zirconium phosphate, the interlayer distance of ZP-CuLra will be shorter than that observed. When the plane of the acid is perpendicular to that of the exchanger, the distance will be longer. In the third case, the distance is dependent on the slant of the complex plane to the zirconium phosphate layer.

According to Alberti and Costantino,[4] the arrangement of the fixed charge in α-zirconium phosphate is an hexagonal array and the distance between them is equal to be 5.3 Å. It is possible to consider that the projective distance between Cu(II) in the copper form is 5.3 Å. On the other hand, the distance between Cu(II) in Cu-ra prepared in a solution is 5.6 Å according to the structural model proposed by Abboudi et al.[7]

The crystal structure of the salt form of zirconium phosphate has not been analyzed except for the ammonium form. Since the ammonium form has essentially a similar structure to α-zirconium phosphate,[20] it is possible to infer that the crystal structure of ZP-CuLra also is similar to α-zirconium phosphate.

Though the position of the hydrated water molecule was not determined, it is thought that the water molecule is involved in hydrogen bonding with hydrogen atoms over the oxygen atoms in phosphates (see IR Studies).

Assuming that the molecular structure of Cu-ra is persistent in the exchanger phase, the following model is proposed (Fig. 5). The ligand is coordinated to Cu(II) through the nitrogen and sulfur atoms. Between the zirconium phosphate layers the complex forms a polymeric zigzag chain composed of $Cu(NHCS)_2 \cdot H_2O$ as an unit, and the plane of the complex is slightly twisted to the layers of the exchanger.

The authors wish to express their thanks to Prof. Isao Tomita, Tokyo University of Fisheries, for the measurement of thermal analysis.

Interfacial Phenomena in the Extraction Kinetics of Nickel(II) with 2′-Hydroxy-5′-nonylacetophenone Oxime

Hitoshi WATARAI,* Manabu TAKAHASHI, and Kiyoji SHIBATA
Department of Chemistry, Faculty of Education, Akita University, Akita 010
(Received April 24, 1986)

The interfacial adsorption of (*E*)-2′-hydroxy-5′-nonylacetophenone oxime and its role in the extraction kinetics of the nickel(II) ion with the oxime were investigated in heptane/aqueous phase systems by means of a high-speed stirring apparatus. The interfacial oxime concentration was correlated to the organic phase concentration, obeying the Langmuir isotherm. The interfacial activity of the oxime was also measured by means of interfacial tension measurements. The initial extraction rate of nickel(II) ion was linearly proportional to the interfacial concentration of the oxime (rather than to the bulk-phase concentration), to the nickel-ion concentration, and inversely to the hydrogen-ion concentration. These results supported the mechanism that the rate-determining step in the extraction is the 1:1 complex formation at the interface.

Recently, one of the present authors has pointed out the importance of interfacial reaction in the extraction kinetics of zinc(II) and nickel(II) with alkyl-substituted dithizones by means of the high-speed stirring method.[1] The advantages of the new method are (a) that an extraction rate is measured with a high accuracy, even in liquid-liquid dispersions generated by vigorous stirring, and (b) that the amount of extractant adsorbed at the interface in the same dispersed system is determined.[2,3] Therefore, this method is very promising for studies of interfacial phenomena in solvent-extraction kinetics.

In the present study, the role of the interface in the extraction of nickel(II) with (*E*)-2′-hydroxy-5′-nonylacetophenone oxime (HL), the active species of the commercial extractant SME 529, was investigated by means of the high-speed stirring apparatus.

Although the mechanism of the extraction kinetics of nickel(II) with β-hydroxy oxime has recently been discussed,[4,5] the assignment of the location, whether an interface or an aqueous phase, of the rate-determining reaction in a highly agitated extraction system has been remained ambiguous.

Experimental

The oxime was isolated from SME 529 donated by the Shell Chemical Co. and purified by the copper-complex method[6] and silica-gel chromatography. The fraction of the *E*-form in the purified oxime was not less than 0.98. Heptane, Wako G.R., was purified by distillation and used as an organic-phase solvent. The ionic strengths of all the aqueous phases were adjusted to 0.1 by the use of sodium perchlorate, and the pH of the aqueous phase was controlled by employing the acetate buffer (0.002 M, 1 M=1 mol dm^{-3}) and the phosphate buffer (0.002 M).

The high-speed stirring apparatus used in the present study is shown in Fig. 1. Although the principle of this apparatus is the same as that of a previous one,[3] the reproducibility of the stirring conditions, the stability of the spectrophotometric measurement, and the accuracy of the data analysis are much improved by the use of an Ono Sokki HT-431 digital tachometer and a Jasco UVIDEC 430 double-beam spectrophotometer interfaced by means of RS-232C with a NEC PC microcomputer system.

The amount of the oxime adsorbed at the interface in the stirred liquid-liquid system was determined at 25±0.1 °C by employing an equal volume (50 ml) of an organic solution of the oxime and an aqueous solution. When stirring was begun at 4700 rpm, the absorbance of the organic phase observed with a cell with an optical length of 1 cm decreased and reached a constant value. When it was stopped, the absorbance was restored to the initial state. The change in the absorbance was continuously recorded on the chart recorder. Figure 2 shows some typical results of the reversible absorbance decrease caused by stirring. The absorbance decrement, ΔA, defined as the difference between the equilibrium absorbance under no stirring, A, and the one under stirring, A', is considered to be proportional to the interfacial amount of the oxime or to the interfacial concentration, provided that the interfacial area remains constant.[2,6-8] A strong influence of the stirring rate on the magnitude of ΔA was observed in the range of 1000—4000 rpm, suggesting a contribution from the interfacial area, but it was diminished above 4500 rpm.[6] In the present study, 4700 rpm was adopted as the stirring rate.

The extraction rate of nickel(II) was measured at

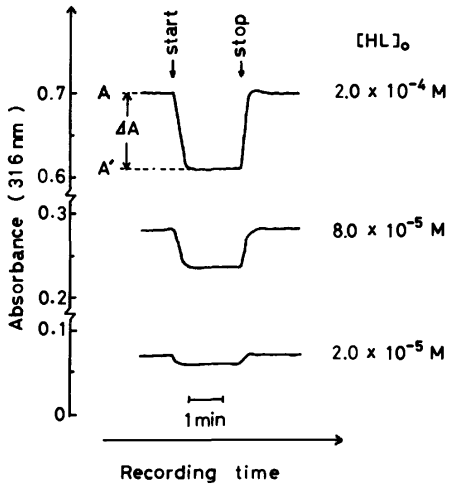

Fig. 2. Reversible change in the organic phase absorbance resulting from stirring at 4700 rpm, pH= 3.01.

25±0.1 °C by means of a microcomputer-assisted system (Fig. 1). Fifty ml of a heptane solution of oxime and 45 ml of an aqueous buffer solution were poured into the three-necked flask, and stirring was begun at 4700 rpm. The organic phase was pumped out through a Teflon phase-separator (Kokuboseiki Co.) and circulated through the flow cell (8 μl; 0.25 cm in optical length) at the flow rate of 16 ml min^{-1}. Extraction was started by injecting 5 ml of a nickel(II) stock solution through a glass syringe into the dispersed mixture. The absorbance of the organic phase was read by the computer at the acquisition rate of 1 data/sec, and it was displayed graphically on CRT as a function of the time. Soon after the termination of the data acquisition, the absorbance data, stored on a floppy disk, were analyzed according to the first-order rate law. The extraction rate constant, k_{obsd}, was calculated by the use of the following equation;

$$\ln \frac{A_f - A_o}{A_f - A_t} = k_{obsd} \cdot t \qquad (1)$$

where A_o, A_t, and A_f correspond to the absorbances of the nickel(II) complex in the organic phase at the start of extraction, at a certain time t, and at the extraction equillibrium. Some typical results of kinetic measurement are shown in Fig. 3. From the observed extraction rate constant, the observed initial extraction rate (in absorbance units), r°_{obsd}, was calculated by the use of this relation;

$$r^{\circ}_{obsd} = (A_f - A_o)k_{obsd}. \qquad (2)$$

In several experiments, the agreement of r°_{obsd} calculated by Eq. 2 and of r°_{obsd} directly obtained from $r^{\circ}_{obsd}=(dA_t/dt)_{t=0}$, which is the definition of r°_{obsd}, was confirmed.

The acid dissociation constant (K_a) of the oxime was estimated as $10^{-9.79\pm0.09}$ from the apparent dissociation constants, $10^{-10.28}$, $10^{-10.45}$, and $10^{-10.76}$, which were obtained in 30, 40, and 50% ethanolic aqueous solution by means of spectrophotometry.

The experiments on the distribution equilibrium of the oxime and the extraction equilibrium of nickel(II) with the

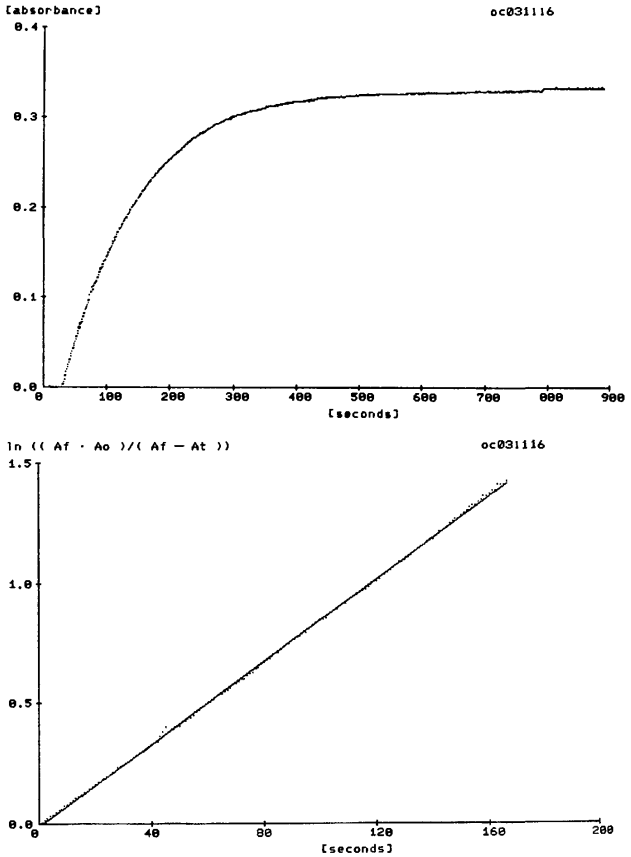

Fig. 3. Typical results of a recorded extraction kinetic run (upper) and a first-order kinetic analysis (lower). $[Ni^{2+}]_{Inlt}=1.0\times10^{-2}$ M, $[HL]_{0,Inlt}=1.0\times10^{-3}$ M, pH=4.52. $k_{obsd}=(8.57\pm0.01)\times10^{-3}$ s^{-1}.

oxime were done by means of the conventional batch method and by means of spectrophotometry at 25±1 °C. The distribution constant (K_D) was calculated as $10^{3.99\pm0.21}$ from the distribution ratio determined in the alkaline region and the acid dissociation constant. The extraction equilibrium of;

$$Ni^{2+} + 2HL_o \rightleftharpoons NiL_{2,o} + 2H^+ \qquad (3)$$

was confirmed and the extraction constant of $10^{-3.99\pm0.41}$ was determined from a slope analysis of the distribution ratio plotted against the pH.

The interfacial tension in heptane/water systems containing the oxime was measured by means of the drop-volume method at 25±0.1 °C, applying the Harkins-Brown correction.[9,10]

Results and Discussion

Interfacial Adsorption of the Oxime. The reversible absorbance decrease caused by stirring was measured while varying the concentration of the oxime. Figure 4 shows the concentration effect as a plot of ΔA against A'. As may be noted in this figure, ΔA approaches a saturated value with the increase in A', which means that the saturation in the interfacial amount of the oxime occurs at a higher-organic-phase

concentration than 10^{-3}M. The effect of the pH on ΔA was not observed under the acidic and neutral conditions (pH=3—6) where the kinetic experiments were conducted.

The interfacial tension in the heptane/water system decreased with an increase in the oxime concentration, as is shown in Fig. 5, demonstrating an interfacial activity of the neutral form of the oxime. Also, Fig. 5 indicates that the heptane/water interface is saturated by oxime when the oxime concentration becomes as concentrated as 10^{-3} M, corresponding to the result observed in the stirring experiment (Fig. 4).

The mechanism of interfacial adsorption in the vigorously stirred systems can be understood in terms of the following discussion. The total amount of oxime in the dispersed system is represented by;

$$[HL]_{init}V_o \simeq [HL]_oV_o + [HL]_iS10^3, \quad (4)$$

where $[HL]_{init}$, $[HL]_o$, and $[HL]_i$ refer to an initial organic-phase concentration before contact with the aqueous phase, an organic-phase concentration under stirring, and an interfacial concentration (mol cm^{-2}) in the dispersed liquid-liquid system, V_o, to the volume (ml) of the organic phase, and S, to the total interfacial area (cm^2) of the dispersed system. If the Langmuir isotherm is assumed to be the adsorption equilibrium of the oxime, $[HL]_i$ is represented by;

$$[HL]_i = \frac{ab[HL]_o}{1+b[HL]_o}, \quad (5)$$

where a corresponds to a saturated interfacial concentration, and ab, to an adsorption equilibrium constant at an infinite dilution, K', itself defined by;

$$ab = K' = \lim_{[HL]_o \to 0} \frac{[HL]_i}{[HL]_o}. \quad (6)$$

From Eqs. 4—6 and the Lambert-Beer equations of;

$$\Delta A = \varepsilon([HL]_{init} - [HL]_o)$$
$$A' = \varepsilon[HL]_o, \quad (7)$$

the following equation can be derived upon the relationship between $1/\Delta A$ and $1/A'$:

$$\frac{1}{\Delta A} = \left(\frac{1}{a} + \frac{\varepsilon}{K'}\frac{1}{A'}\right)\frac{V_o}{\varepsilon S10^3} \quad (8)$$

where ε refers to the molar absorptivity of the oxime in heptane, ε (316 nm)=3.49×10^3 M^{-1} cm^{-1}.

The straight line shown in Fig. 6 confirmed the proposed relationship of Eq. 8, and its slope and intercept gave these two parameters: $K'S$=1.0×10^{-2} l and a S=3.9×10^{-6} mol. Employing a=2.0×10^{-10} mol cm^{-2}, which was determined from Fig. 5 by applying the Gibbs equation,[6] S=2.0×10^4 cm^2 was estimated; by its use, K'=5.1×10^{-7} l cm^{-2} was then calculated. The value of S is consistent with that obtained previously.[8]

Extraction Mechanism of Nickel(II). The dependence of r°_{obsd} on the oxime concentration was examined at a constant pH; the results are shown in Fig. 7. The plot of r°_{obsd} against $[HL]_o$ was curved, and

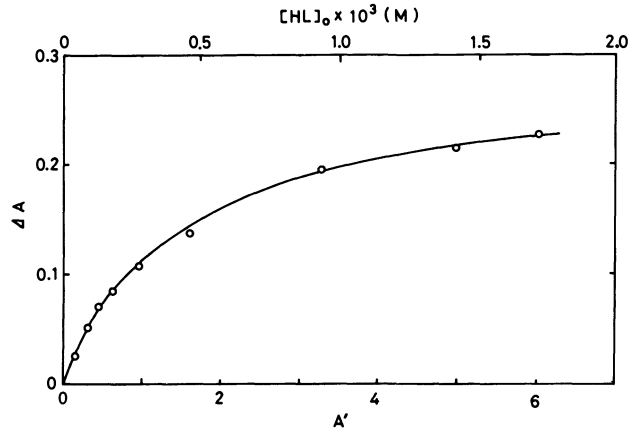

Fig. 4. Dependence of the absorbance decrement, ΔA, on the organic phase absorbance, A,' under stirring. $[HL]_{o,init}$=2.0×10^{-5} M—2.0×10^{-3} M, pH=3.0—6.2, λ=316 nm, 4700 rpm.

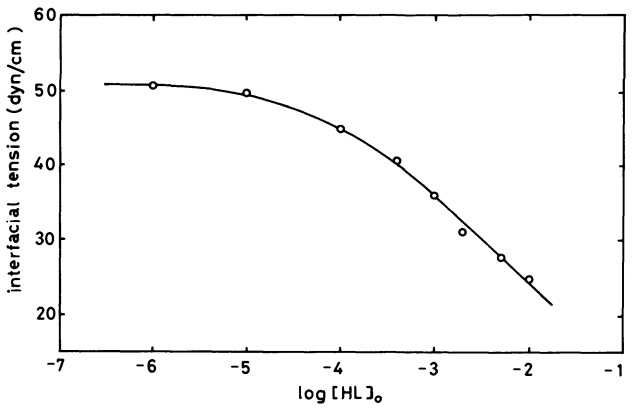

Fig. 5. Lowering of the interfacial tension with increase of the oxime concentration in the heptane/water system.

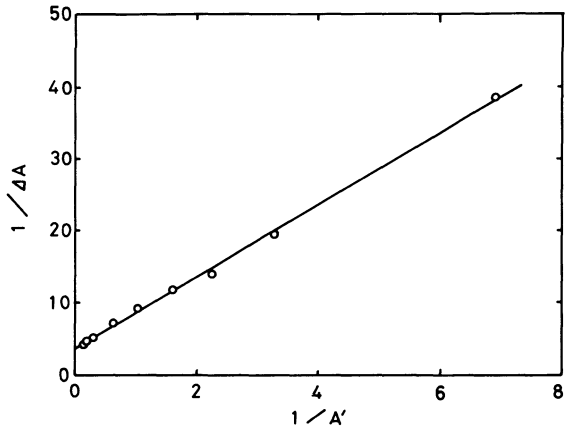

Fig. 6. Linear correlation between $1/\Delta A$ and $1/A'$.

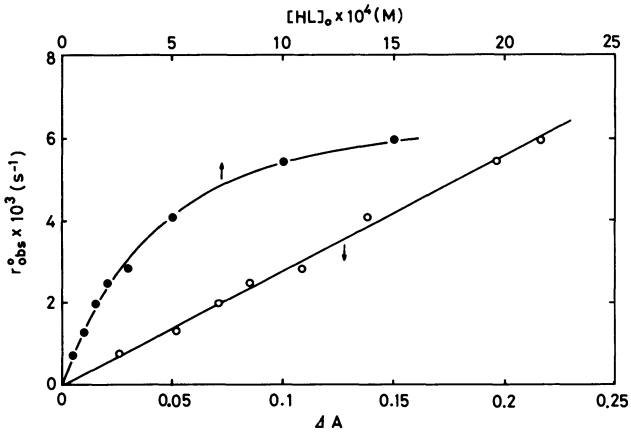

Fig. 7. Linear dependence of the initial extraction rate on ΔA, and nonlinear one on the bulk phase concentration of the oxime. $[HL]_{o,init}=1.0\times10^{-4}$ M—1.5×10^{-3}M, $[Ni^{2+}]_{init}=9.85\times10^{-3}$ M, pH=5.61.

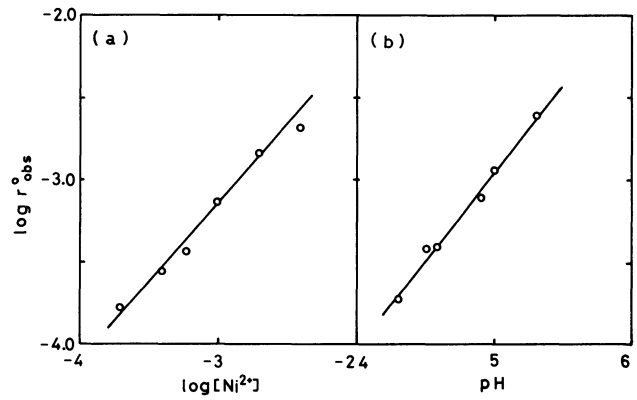

Fig. 8. First-order dependences of the initial extraction rate on nickel concentration (a), and on $[H^+]^{-1}$ (b).

no linear relationship was obtained between them. On the other hand, the plot of r°_{obsd} against ΔA gave a good linearity indicating that r°_{obsd} is proportional to $[HL]_i$, and not to $[HL]_o$. The effects of the nickel-ion concentration and the hydrogen-ion concentration on r°_{obsd} are shown in Figs. 8(a) and 8(b) respectively. In either figure, a linear plot was obtained, and the relation of $r^\circ_{obsd} \propto [Ni^{2+}]/[H^+]$ was experimentally concluded.

If the rate-determining step is 1 : 1 chelate formation in the aqueous phase, as has been reported for other nickel(II)-extraction systems,[11] r°_{obsd} will be represented by;

$$r^\circ_{obsd} = k_1 \frac{K_a}{K_D} \frac{[Ni^{2+}][HL]_o}{[H^+]} \varepsilon_c l, \tag{9}$$

where k_1 refers to the formation-rate constant of NiL^+; ε_c, to the molar absorptivity of NiL_2 in heptane, ε_c (387 nm)=4.53×10^4 M^{-1} cm^{-1}, and l, to the optical length of the flow cell. Although Eq. 9 proposes the relation of $r^\circ_{obsd} \propto [HL]_o$, this is inconsistent with the experimental results (Fig. 7). Furthermore, the magnitude of r°_{obsd} calculated from Eq. 9 under the probable conditions of $k_1=10^5$ M^{-1} s^{-1}, pH=5, $[HL]_o=10^{-3}$ M, and $[Ni^{2+}]=10^{-2}$ M was of an order of 10^{-6} s^{-1} and 10^3 times less than the observed value of r°_{obsd} under the corresponding conditions.

All of the experimental results and the above discussions seems to be favorable for the interfacial reaction mechanism rather than the aqueous-phase reaction mechanism. If the rate-determining step is the formation of a 1 : 1 complex at the interface, the following scheme can be assumed;

$$HL_o \rightleftharpoons HL_i \quad ; \text{ Langmuir isotherm} \tag{10}$$

$$HL_i \rightleftharpoons L_i^- + H^+ \quad ; K_a' \tag{11}$$

$$Ni^{2+} + L_i^- \longrightarrow NiL_i^+ \quad ; k_i \tag{12}$$

where K_a' is the acid dissociation constant at the interface defined by $K_a'=[L^-]_i[H^+]/[HL]_i$ and where k_i is the formation-rate constant of NiL^+ at the interface. The final complex of NiL_2 did not show any significant interfacial adsorption in the stirring experiment. From the scheme, the following equation can be derived for the observed initial extraction rate;

$$r^\circ_{obsd} = k_i[Ni^{2+}][L^-]_i \frac{10^3 S}{V_o} \cdot \varepsilon_c l$$

$$= k_i K_a' \frac{[Ni^{2+}]}{[H^+]} \cdot \frac{\varepsilon_c l}{\varepsilon} \cdot \Delta A. \tag{13}$$

Equation 13 is consistent with the observed relationships between r°_{obsd} and $[Ni^{2+}]$, $[H^+]$ and ΔA, shown in Figs. 7 and 8. Consequently, the proposed mechanism of Eqs. 10—12 is considered to be reasonable. The slope of the line in Fig. 7 and the intercepts of Figs. 8(a) and 8(b) gave the combined parameter of $k_iK_a'=(2.18\pm0.09)\times10^{-5}$ s^{-1} as an averaged value. Although the value of K_a' in the present system has not been determined, if $K_a' \simeq K_a$ is assumed, as has been observed in LIX65N,[8] k_i can be estimated as 1.3×10^5 M^{-1} s^{-1}. The value of k_i is apparently close to the formation-rate constant of the mono(8-quinolinethiol)nickel(II) complex in the aqueous phase.[11]

As has been concluded in the present study, the primary step of an extraction reaction is the adsorption of an extractant at the interface when the extractant has a large distribution constant and, more or less, an interfacial activity. Therefore, the experimental determination of the interfacial concentration of an extractant is very important in evaluating the contribution of an interfacial reaction to the mechanism of extraction kinetics. Also, the utility of the high-speed stirring apparatus for the study of interfacial phenomena was demonstrated. Further studies of the interfacial phenomena in other chelate-extraction systems and ion-association extraction systems are in progress.

The authors wish to thank the Shell Chemical Co., Ltd., for supplying the samples of SME 529 and Dr. Y. Honma of Akita University for his help in making the Teflon stirring bar. This work was financially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Japan (No. 59540353-1984).

Mechanism of Chiral Recognition of Octahedral Metal Complexes Effected by Bis(μ-*d*-tartrato)-diantimonate(III) Anion in Solution. I. Association Models and Their Application to Some $[Co(N)_6]^{3+}$-Type Complexes

Katsuhiko Miyoshi, Shinji Izumoto, and Hayami Yoneda*
Department of Chemistry, Faculty of Science, Hiroshima University,

(Received May 6, 1986)

An association model has been proposed which accounts for how bis(μ-*d*-tartrato)-diantimonate(III) anion, $[Sb_2(d\text{-tart})_2]^{2-}$ ion recognizes the chirality of $[Co(en)_3]^{3+}$ (en=ethylenediamine) and some related cation complexes in solution. In this model, two oxygen atoms of the chiral anion, i.e., the carboxylic oxygen atom (coordinated to the Sb atom) of one *d*-tartrate moiety and the alcoholic oxygen atom (coordinated to the same Sb atom) of the other *d*-tartrate moiety, are hydrogen-bonded to the two amine protons in $[Co(en)_3]^{3+}$ which are directed along either the C_3 or C_2 axis. When these hydrogen bonds are formed along the C_3 axis (C_3 association), $[Sb_2(d\text{-tart})_2]^{2-}$ ion forms a more favorable ion pair with Λ-$[Co(en)_3]^{3+}$, whereas it does with Δ-$[Co(en)_3]^{3+}$ if the two amine protons directed along the C_2 axis are utilized for hydrogen bonding to it (C_2 association). This model is successfully applied to the interpretation of chromatographic behavior of some $[Co(N)_6]^{3+}$-type complexes as well as of their related complexes with amine or phosphine ligands.

It is well-known that bis(μ-*d*-tartrato)-diantimonate(III) anion, $[Sb_2(d\text{-tart})_2]^{2-}$ ion serves as an effective eluent in chromatographic resolution of various octahedral complex cations.[1-3] We have already proposed a so-called L-J model[4] which explains conceptually how the chiral anion recognizes the chirality of a series of $[Co(N)_6]^{3+}$-type complexes. However, this model does not tell us anything about the actual interaction prevailing between $[Sb_2(d\text{-tart})_2]^{2-}$ and $[Co(N)_6]^{3+}$ ions. In addition, several new experimental results have been accumulated which are not easily interpreted within the framework of the L-J model. In the present study, we propose a concrete association model in which $[Sb_2(d\text{-tart})_2]^{2-}$ ion interacts with $[Co(N)_6]^{3+}$-type complexes through intermolecular hydrogen bonding.

Association Models

Experimental Observations. We have at least two experimental results which are quite informative to construct an association model between $[Sb_2(d\text{-tart})_2]^{2-}$ and $[Co(N)_6]^{3+}$ ions. The first is concerned with the effect of added $[Sb_2(d\text{-tart})_2]^{2-}$ ion on the circular dichroism (CD) spectrum of $[Co(en)_3]^{3+}$ in solution; its A_2 component at the first ligand field band is enhanced upon the addition of the chiral anion.[5] Since the A_2 transition is polarized along the C_3 axis, this CD-spectral change implies that the chiral anion approaches the complex predominantly along its C_3 axis to perturb the rotational strength of the A_2 transition.[6] Another observation relevant to the present study is that $[Co(Me_2\text{-en})(en)_2]^{3+}$ (Me_2-en=*N*,*N*′-dimethylethylenediamine) having axial methyl groups almost parallel to the pseudo C_3 axis, i.e., a mixture of its Λ(RR) and Δ(SS) isomers, is eluted considerably slower than $[Co(en)_3]^{3+}$ on the SP-Sephadex column with $[Sb_2(d\text{-tart})_2]^{2-}$ ion employed as an eluent.[7] Furthermore, the degree of optical resolution attained is much lower for $[Co(Me_2\text{-en})(en)_2]^{3+}$. Similar difference in chromatographic behavior has been found between $[Co(sar)(en)_2]^{2+}$ (sar=sarcosinate anion) and its parent complex $[Co(gly)(en)_2]^{2+}$ (gly=glycinate anion).[8] These observations suggest that the axial NH protons directed along the (pseudo) C_3 axis are utilized in the hydrogen-bonding interaction with some oxygen atoms in $[Sb_2(d\text{-tart})_2]^{2-}$ anion.

C_3 Association Model. When the molecular structure of $[Sb_2(d\text{-tart})_2]^{2-}$ ion (shown in Fig. 1) is examined in detail, a pair of oxygen atoms are found whose lone-pair electrons are nicely disposed to interact with two of the three axial NH protons directed along the C_3 axis of $[Co(en)_3]^{3+}$. They are the alcoholic oxygen atom of one *d*-tartrate moiety which is coordinated to the Sb atom and the carboxylic oxygen atom of another *d*-tartrate moiety which is coordinated to the same Sb atom. $[Sb_2(d\text{-tart})_2]^{2-}$ ion

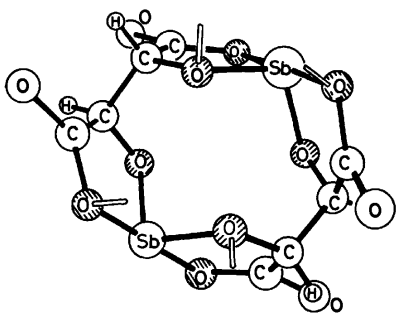

Fig. 1. Molecular structure of $[Sb_2(d\text{-tart})_2]^{2-}$ ion. Two shaded oxygen atoms coordinated to the same Sb atom are used for double hydrogen bonding.

has evidently four such pairs, which may be partly responsible for its high recognition efficiency as compared with *d*-tartrate ion.[9]

In Fig. 2 is depicted the C_3 association model which accomodates the above-mentioned experimental results, taking $[Co(en)_3]^{3+}$ as an example. In this model, the two oxygen atoms of $[Sb_2(d\text{-tart})_2]^{2-}$ ion participates in the double hydrogen bonding to two of the three axial NH protons directed along the C_3 axis, and the remaining part of the chiral anion is disposed opposite to the third NH group free from hydrogen bonding. If a bulky or negatively charged group is present in place of the third NH group, it will impose a steric or electrostatic repulsion on the carboxylic oxygen atom hydrogen-bonded to the complex. Since the double hydrogen bonds are formed along the C_3 axis, this model is called as the C_3 association model.

It is seen in Fig. 2 that the distal carboxylato group of $[Sb_2(d\text{-tart})_2]^{2-}$ ion is situated between the two en chelate rings in the C_3 association with Λ-$[Co(en)_3]^{3+}$ (left model) and a favorable ion pair is thus formed between the two ions, whereas the carboxylato group, particularly its C=O group experiences a steric hindrance from one en chelate ring in the C_3 association with Δ-$[Co(en)_3]^{3+}$ (right model), as indicated by an arrow. In this way, the C_3 association model predicts that $[Sb_2(d\text{-tart})_2]^{2-}$ ion associates more smoothly with the Λ complex than with the Δ complex, in accordance with the experimental result.[5] Since two axial NH protons are utilized in the C_3 association, it follows that six equivalent interaction sites are present in $[Co(en)_3]^{3+}$. Interaction sites are counted similarly for other $[Co(N)_6]^{3+}$-type complexes. Even if a complex is devoid of a true C_3 axis, it may have some C_3 interaction sites; if a set of three NH protons are present on a triangular facet[10] of a complex, they serve as interaction sites equivalent to true C_3 interaction sites. Furthermore, the C_3 interaction is possible even when only two NH protons are present on the triangular facet, provided that the third group is electrically neutral and/or is not bulky (see later).

Another C_3 association is conceivable in which all of the three axial NH protons of $[Co(en)_3]^{3+}$ are simultaneously hydrogen-bonded to three oxygen atoms of $[Sb_2(d\text{-tart})_2]^{2-}$ ion. The three oxygen atoms appropriately disposed in the chiral anion are two oxygen atoms of one carboxylato group in one *d*-tartrate moiety, and the alcoholic oxygen atom on the asymmetric carbon atom to which the other carboxylato group in the same *d*-tartrate moiety as above is directly attached; $[Sb_2(d\text{-tart})_2]^{2-}$ ion has apparently four sets of such three oxygen atoms, each *d*-tartrate moiety providing the two sets. A molecular model consideration reveals that the chiral recognition is similarly effected in this alternative C_3 association model through the steric repulsion imposed stereoselectively by the chelate ring of the Δ complex on the distal carboxylato group. However, this C_3 model is applicable only to those complexes which have three NH protons on the triangular facet. For example, complete chromatographic resolution of $[Co(phen)(en)_2]^{3+}$ and $[Co(acac)(en)_2]^{2+}$ (phen=1,10-phenanthroline and acac=acetylacetonate anion)[3] is not reasonably interpreted by this C_3 model in which triple hydrogen bonds are required. Consequently, we abandon this C_3 model and adopt the aforementioned C_3 model, to interpret the chromatographic behavior of various types of octahedral metal complexes throughout the present study.

C_2 Association Model. Since two NH protons in $[Co(en)_3]^{3+}$ are required for the interaction with $[Sb_2(d\text{-tart})_2]^{2-}$ ion, those NH protons which are directed along the C_2 axis can also be utilized for the double hydrogen bonding. This interaction is called as the C_2 association and its model is depicted in Fig. 3, taking *cis*-$[Co(X)_2(en)_2]^+$ (X=anion ligand) as an example. Here, $[Sb_2(d\text{-tart})_2]^{2-}$ ion approaches the complex along the C_2 axis from the side opposite to X so as to avoid an electrostatic repulsion from X, and

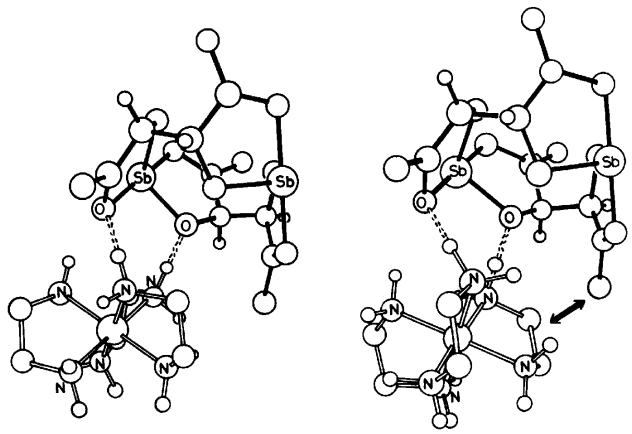

Fig. 2. C_3 Association models for Λ-$[Co(en)_3]^{3+}$-$[Sb_2(d\text{-tart})_2]^{2-}$ (left) and Δ-$[Co(en)_3]^{3+}$-$[Sb_2(d\text{-tart})_2]^{2-}$ (right).

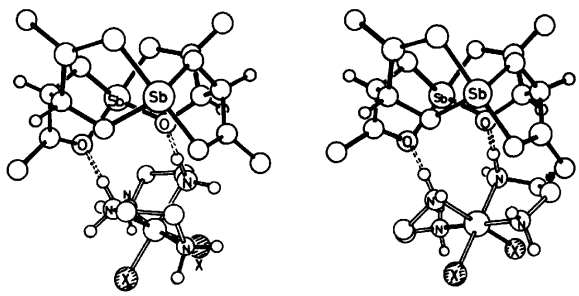

Fig. 3. C_2 Association models for Δ-*cis*-$[Co(X)_2(en)_2]^+$-$[Sb_2(d\text{-tart})_2]^{2-}$ (left) and Λ-*cis*-$[Co(X)_2(en)_2]^+$-$[Sb_2(d\text{-tart})_2]^{2-}$ (right).

the double hydrogen bonds are formed to the two NH protons directed along the C_2 axis. It is evident in Fig. 3 that the distal carboxylato group suffers a steric hindrance from one en chelate ring when the complex has a Λ configuration (right model). On the other hand, a smooth association is possible with *Δ-cis*-$[Co(X)_2(en)_2]^+$ (left model),[11] since the distal carboxylato group is disposed between the two en chelate rings like in the C_3 association with *Δ*-$[Co(en)_3]^{3+}$. Therefore, $[Sb_2(d\text{-tart})_2]^{2-}$ ion forms a more favorable ion pair with the Δ complex in the C_2 association. In fact, $[Sb_2(d\text{-tart})_2]^{2-}$ ion elutes the Δ isomer faster on an ion-exchange column for most of *cis*-$[Co(X)_2(en)_2]^+$-type complexes[12] which adopt the C_2 association predominantly. It should be noted, however, that the C_2 association is possible also for $[Co(N)_6]^{3+}$-type complexes. For example, $[Co(en)_3]^{3+}$ has three C_2 interaction sites in addition to six C_3 interaction sites.

Comparison with Experimental Results

$[Co(N)_6]^{3+}$-Type Complexes. Now, it is possible to count the C_3 and C_2 interaction sites for respective $[Co(N)_6]^{3+}$-type complexes. For simplicity, those sites are neglected here in which the distal carboxylato group suffers a steric hindrance from the chelate ring, viz., no smooth association is possible. For example, *Δ*-$[Co(en)_3]^{3+}$ has six favorable C_3 interaction sites but has no favorable C_2 site. By contrast, *Δ*-$[Co(en)_3]^{3+}$ has no C_3 site but has three favorable C_2 sites. For $[Co(Me_2\text{-}en)(en)_2]^{3+}$ and $[Co(Me\text{-}en)(en)_2]^{3+}$ (Me-en=*N*-methylethylenediamine) having methyl group(s) almost parallel to the pseudo C_3 axis, interaction sites are counted on the assumption that the methyl group does not interfere with the C_3 interaction. Numbers of favorable interaction sites counted in this way agree perfectly with the numbers of L-shaped channels defined in the previous work for $[Co(N)_6]^{3+}$-type complexes.[4] This means that the conceptual L-J model is automatically incorporated into the C_3 association model, but the C_2 association mode has been ignored in the L-J model. Numbers of C_3 and C_2 interaction sites *N* are given for respective $[Co(N)_6]^{3+}$-type complexes in Table 1. It is naturally expected that a complex having a greater difference in *N* between its Λ and Δ enantiomers should be resolved more effectively by ion-exchange chromatography.

In Table 1 are also given the separation factors α, a measure of efficiency of optical resolution attained for respective complexes, when available. It is confirmed in Table 1 that the above expectation is actually fulfilled as far as the C_3 interaction mode is concerned. This suggests that the C_2 interaction mode which has not been taken into account in the L-J model, does not contribute appreciably to chiral recognition of $[Co(N)_6]^{3+}$-type complexes.

Even for the complexes α values of which are not known, the elution order in chromatography is at least in good agreement with the prediction of our association models. The two complexes, *cis* α-$[Co(trien)(NH_3)_2]^{3+}$ (trien=triethylenetetramine) and *fac,fac,mer*-$[Co(tetren)(NH_3)]^{3+}$ (tetren=tetraethylenepentamine) need to examine somewhat in detail. The former complex has eight C_3 sites both for the Λ and Δ isomers; no practical resolution is expected. However, for the Λ isomer, a secondary amine proton is involved

Numbers in parentheses denote numbers of interaction sites at which a secondary amine proton is involved in double hydrogen bonding (see the text). a) Partial resolution. b) Partial resolution for bpy complex.

in the double hydrogen bonding at two of the eight C_3 sites. Since a secondary amine proton is generally more acidic than a primary one, a stronger hydrogen bond is formed with the former proton,[10,13] other conditions being equal. In short, interaction sites associated with a secondary amine proton contribute more to the interaction with $[Sb_2(d\text{-tart})_2]^{2-}$ ion than those with a primary amine proton. Since all of the interaction sites of the Δ isomer are associated with primary amines only, the Λ isomer is expected to interact with $[Sb_2(d\text{-tart})_2]^{2-}$ ion more strongly than the Δ isomer for *cis* α-$[Co(trien)(NH_3)_2]^{3+}$.[14]

For *fac,fac,mer*-$[Co(tetren)(NH_3)]^{3+}$, the Δ isomer has a greater N than the Λ isomer; the Δ isomer may be eluted faster. However, the Λ isomer has three C_3 interaction sites one of which is associated with a secondary amine, while only primary amines are involved in the double hydrogen bonding at all of the four C_3 interaction sites for the Δ isomer. Furthermore, one favorable C_2 site adds to the Λ isomer. In practice, *Λ(S)-fac,fac,mer*-$[Co(tetren)(NH_3)]^{3+}$ has been eluted faster.[15] This implies that a secondary amine proton contributes much more to the total hydrogen-bonding interaction with $[Sb_2(d\text{-tart})_2]^{2-}$ ion than a primary amine proton.[13] Then, the partial resolution of $[Co(Me_2\text{-en})(en)_2]^{3+}$ may be attributed to the fact that the Λ isomer has two usual C_3 sites only, but the Δ isomer has three C_2 sites two of which are associated with a secondary amine.

As is evident from the above discussions, the C_3 association model leads to a general prediction that *Λ*-$[Co(N)_6]^{3+}$-type complexes interact with $[Sb_2(d\text{-tart})_2]^{2-}$ ion more favorably than their antipodes. However, some complexes are known which behave oppositely to the above prediction. For example, Δ isomers are eluted faster in ion-exchange chromatography for a series of $[Co(en)_x(tn)_y(tmd)_z]^{3+}$ complexes when $x=0$[16] (tn=trimethylenediamine and tmd=tetramethylenediamine). In addition, *Λ-cis*-$[Co(tn)_2(NH_3)_2]^{3+}$ is eluted faster, but the elution order is reversed if tn ligands are replaced with tmd ligands.[17,18] These exceptional elution orders are not easily rationalized by our association models, but they may be attributed to conformational lability of these complexes. That is, since axial NH protons are not fixed in these higher-membered chelate complexes, the C_3 mode will not effectively contribute to chiral recognition for these flexible complexes. If the contribution of the C_3 mode is reduced to the extent that the C_2 mode predominates over the C_3 mode, Δ isomers should be eluted faster.

***cis(O)*-$[Co(O)_2(N)_4]^+$-Type Complexes.**[19] When negatively charged donor atom(s) are present in a complex, a care must be taken in counting the C_3 and C_2 interaction sites. For example, $[Co(gly)(en)_2]^{2+}$ has two triangular facets along the pseudo C_3 axis, one composed of three NH protons and the other of two NH protons and one oxygen atom of gly. They are shown schematically in Fig. 4. The former facet provides three normal C_3 sites for the Λ isomer (Fig. 4(a)), but the latter provides only one C_3 site which is expected to suffer an electrostatic repulsion from the negatively charged oxygen atom present nearby (Fig. 4(b)). Since this C_3 site is electrostatically handicapped, it contributes less than the normal C_3 site and is designated as the C_3* site to differentiate it from the normal one. Similar allowance has been made in the ranked L–J model,[19] and should be also made in counting the C_2 sites; *Λ*-$[Co(gly)(en)_2]^{2+}$ has two C_2 sites one of which (C_2*) suffers an electrostatic repulsion from the oxygen atom of gly (Fig. 5). Numbers of interaction sites thus counted for *cis(O)*-$[Co(O)_2(N)_4]^+$-type and related complexes are given in Table 2, where starred numbers in parentheses denote the numbers of such handicapped sites out of all the possible C_3 or C_2 interaction sites.

Three points are mentioned in Table 2. The first is that our association models predict a correct elution order even for *cis(O),trans(N),cis(NH₃)*-$[Co(gly)_2(NH_3)_2]^+$ which is exceptional in that its Δ isomer is eluted faster.[19] The second point is that the elution order is not rationalized for C_2-$[Co(gly)_2(en)]^+$ if the C_3* site is neglected. Thus, the C_3* interaction should be taken into account, particularly when other rival interactions are not possible. Anyway, C_2-$[Co(gly)_2(en)]^+$ should not be resolved effectively.[19] Similarly,

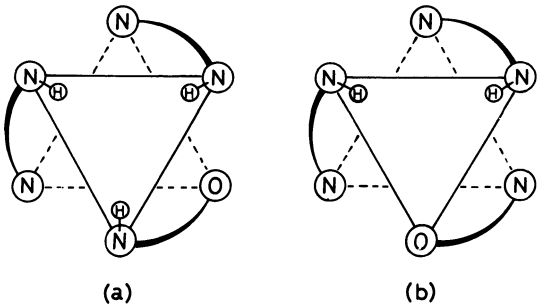

Fig. 4. Triangular facets providing C_3 (a) and C_3* (b) interaction sites in *Λ*-$[Co(gly)(en)_2]^{2+}$.

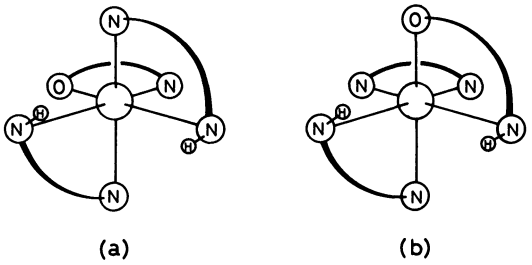

Fig. 5. C_2 (a) and C_2* (b) interaction sites in *Λ*-$[Co(gly)(en)_2]^{2+}$.

no effective resolution is expected for *trans(O)*-[Co(gly)$_2$(en)]$^+$.

Finally, the last two complexes, *fac(NH$_3$)*-[Co(X)(gly)(NH$_3$)$_3$]$^+$ and [Co(X)(gly)(tacn)]$^+$ (X=anion ligand and tacn=1,4,7-triazacyclononane) have been prepared and resolved by ion-exchange chromatography.[20,21] These complexes have a chirality different from those defined by helical rearrangements of chelate rings. Schematic structures of their two enantiomers (a) and (b) are shown in Fig. 6. Shibata et al.[20,21] have found that the (a) enantiomer is eluted faster for the ammine complex, while the (b) enantiomer is for the tacn complex. Our association models predict a correct elution order straightforwardly for the former, while the elution order of the latter complex is not rationalized unless the C_3* mode predominates over the C_2* mode. This will happen since the C_3 mode generally predominates over the C_2 mode.

Complexes with Phosphine Chelates. Recently, Fujita and co-workers have prepared and resolved a number of octahedral Co(III) complexes with phosphine chelates. Since these complexes have invariably some substituents on the phosphorus donor atom(s), they provide us a chance to examine the steric effect of substituents on the C_3 and C_2 interactions.

When the C_3 and C_2 interaction sites are counted for phosphine complexes, an assumption is made that a methyl or phenyl group on the triangular facet prohibits the C_3 interaction involving the two NH protons on the same facet. For example, [Co(en)$_2$(edmp or edpp)]$^{3+}$ (edmp=(2-aminoethyl)dimethylphosphine and edpp=(2-aminoethyl)diphenylphosphine) has two triangular facets, one of which has an axial methyl or phenyl group on the P atom, and thus the C_3 mode is sterically prohibited on this facet. As a result, the Λ isomer has three C_3 sites on the other facet, and the Δ isomer has two C_2 sites. Interaction sites are counted similarly for *fac(N)*-[Co(en)(edmp)$_2$]$^{3+}$ and *fac(N)*-[Co(edmp)$_3$]$^{3+}$. The results given in Table 3 predict correct elution orders for these complexes.[24]

For [Co(en)$_2$(dmpe or dppe)]$^{3+}$ (dmpe=1,2-(dimethylphosphino)ethane and dppe=1,2-(diphenylphosphino)ethane), and *trans(P,P)*-[Co(edmp)$_2$(dmpe)]$^{3+}$, no C_3 interaction is possible. Instead, one C_2 site is present in the Δ isomers, which thus should be eluted faster.[25] On the other hand, [Co(en)(dmpe or dppe)$_2$]$^{3+}$, *trans(P,N)*- and *trans(N,N)*-[Co(edmp)$_2$(dmpe)]$^{3+}$, and [Co(dmpe or dppe)$_3$]$^{3+}$ have no NH protons available for the double hydrogen bonding to the chiral eluent anion, so that practical resolution is not attained for these complexes.[25] In this way, elution orders are correctly predicted for most of the phosphine complexes listed in Table 3 on the assumption that no C_3 interaction is possible on the triangular facet on which an axial methyl or phenyl group is attached to the P atom. In the preceding section, however, interaction sites are counted for *N*-methylated complexes by assuming that an axial methyl group on the N donor atom does not interfere with the C_3 interaction. If the methyl group also prohibits the C_3 interaction, our models fail to predict a correct elution order for [Co(Me$_2$-en)(en)$_2$]$^{3+}$. Thus, a methyl group should be regarded as a steric obstacle to the C_3 interaction only when it is attached to the P

donor atom. Since a P atom is much bigger in size than an N atom, the above claim seems reasonable. A phenyl group is, on the other hand, so bulky that it will always serve as an obstacle whether it is on the P atom or on the N atom, and will exert an additional influence on the C_2 interaction (see later).

Finally, our attention is focused on phosphine complexes with negatively charged ligand(s) such as acetylacetonate (acac) or oxalate (ox) anion. Before they are examined, interaction sites are counted for the two parent complexes, $[Co(acac)(en)_2]^{2+}$ and $[Co(ox)(en)_2]^{+}$. They have two triangular facets composed of two NH protons and one oxygen atom. If an electrostatic repulsion due to the negatively charged oxygen atom of acac or ox is taken into account, they have no C_3 site but have one C_2 site. As a result, the Δ isomer should be eluted faster. In fact, *Δ*-$[Co(ox)(en)_2]^{+}$ is eluted faster as expected, but *Δ*-$[Co(acac)(en)_2]^{2+}$ is eluted *later*.[12] This means, according to our models, that the C_3* interaction is possible for $[Co(acac)(en)_2]^{2+}$. Since the oxygen atom of acac carries a formal charge of −0.5, its electrostatic field is not as strong[26] as that of ox^{2-} or gly^{-} which bears a formal charge of −1.0 on the oxygen atom. In fact, we assumed before that such an electrostatically handicapped C_3* interaction comes into play even for $[Co(gly)_2(en)]^{+}$-type complexes, when other interaction modes do not contribute appreciably. Thus, interaction sites are counted in the following complexes on a fairly valid assumption that the triangular facet composed of two NH protons and one oxygen atom of acac provides one C_3* site, but that of two NH protons and one oxygen atom of ox (or gly) does not. However, the latter facet may contribute if other rival interaction sites are not present or do not contribute appreciably, like in C_2-$[Co(gly)_2(en)]^{+}$, *trans*(*O*)-$[Co(gly)_2(en)]^{+}$, and *trans*(*P,N*)-$[Co(ox)(edmp \text{ or } edpp)_2]^{+}$ (see later). Detailed discussions on the C_3* interaction will be presented elsewhere in connection with the interpretation of chromatographic resolution of *cis*-$[Co(X)_2(en)_2]^{+}$-type complexes.

Now, it is confirmed in Table 3 that our association models afford a satisfactory prediction of the elution order for most of the phosphine complexes with an acac or ox ligand. For example, the Λ isomer should be eluted faster for *fac*(*N*)-$[Co(acac)(en)(edmp \text{ or } edpp)]^{2+}$,[28] since it has one C_3* site besides one C_2 site, whereas the elution order is reversed for the corresponding ox complex, since the C_3* interaction is prohibited but one C_2 site survives in the ox complex. For *trans*(*P,N*)-$[Co(acac)(edmp \text{ or } edpp)_2]^{2+}$ which has one C_3* site, the Λ isomer should be eluted faster. By contrast, no effective resolution is expected for the corresponding ox complex, since it has neither the C_3

(or C_3*) nor the C_2 site.

For *trans*(*P*,*P*)-$[Co(acac)(edpp)_2]^{2+}$ and *trans*(*P*,*P*)-$[Co(ox)(edpp)_2]^{+}$, the Λ isomers are eluted unexpectedly faster, though both of the two *trans*(*P*,*P*) complexes have one C_2 site only. In order to rationalize these anomalous elution orders, the steric influence of a bulky phenyl group must be taken into account. It is true that two phenyl groups are situated in these complexes such that the distal carboxylato group experiences a steric repulsion from either of them in the C_2 interaction with the Δ isomer, while they do not impose any steric hindrance on the antipode. Then, if the steric repulsion due to the phenyl group in the C_2 interaction with the Δ isomer predominates over the usual repulsion due to the P–N chelate ring in the C_2 interaction with the Λ isomer, the Λ isomer should form a relatively stable ion pair with $[Sb_2(d\text{-tart})_2]^{2-}$ ion as compared with the Δ isomer. If the methyl group on the P atom is not bulky enough to serve as a steric obstacle to the C_2 interaction, the Δ isomer should be eluted faster, as our models predict, for the corresponding edmp complexes, *trans*(*P*,*P*)-$[Co(acac)(edmp)_2]^{2+}$ and -$[Co(ox)(edmp)_2]^{+}$. Similarly, the Δ isomer should be eluted faster for *trans*(*P*,*P*)-$[Co(edmp)_2(dmpe\text{ or }dppe)]^{3+}$, whereas the elution order should be reversed for the corresponding edpp complex, *trans*(*P*,*P*)-$[Co(edpp)_2(dmpe\text{ or }dppe)]^{3+}$. Anyway, experimental data are not enough to decide whether the methyl group on the P atom exerts a similar steric effect on the C_2 interaction.

Any of other complexes listed in Table 3 have neither the C_3 (or C_3*) nor the C_2 interaction site, so that no practical resolution is expected for them. However, for *trans*(*P*,*N*)-$[Co(ox)(edmp\text{ or }edpp)_2]^{+}$, one electrostatically handicapped C_3* interaction is conceivable which has been neglected and is shown in Fig. 4(b), and it will come into play because of complete absence of other interactions. Consequently, optical resolution, though it may be partial, is potentially possible with the Λ isomer eluted faster.[29]

The reason is not known why $[Co(en)(dmpe)_2]^{3+}$, $[Co(acac)(en)(dmpe\text{ or }dppe)]^{2+}$, $[Co(acac)_2(dmpe\text{ or }dppe)]^{+}$, and $[Co(acac)_2(edpp)]^{+}$ have been partially resolved by ion-exchange chromatography with $[Sb_2(d\text{-tart})_2]^{2-}$ ion employed as an eluent. Interaction modes other than the C_3 and C_2 hydrogen-bonding interactions must be invoked. Since the SP-Sephadex column is used for the resolution of these complexes, its chirality might be in part responsible.

Hydrophobic Complexes with Aromatic Ligands. It is note worthy that $[Sb_2(d\text{-tart})_2]^{2-}$ ion can recognize the chirality of some hydrophobic complexes with aromatic ligands such as phen or bpy (phen=1,10-phenanthroline and bpy=2,2′-bipyridine). For example, $[Cr(phen\text{ or }bpy)_2(bpdo)]^{3+}$ (bpdo=2,2′-bipyridine *N*,*N*′-dioxide),[31] $[Cr(acac)_2(bpdo)]^{+}$,[32] $[Cr(bpy)(phen)(bpdo\text{ or }mbdo)]^{3+}$ (mbdo=3,3′-dimethyl-2,2′-bipyridine *N*,*N*′-dioxide),[33] $[Co(acac)(en)(bpy)]^{2+}$, *mer*(*N*)-$[Co(acac)(empp\text{ or }edpp)(bpy)]^{2+}$ (empp=(2-aminoethyl)methylphenylphosphine),[28] and $[Ru(bpy)_n(Hpda)_{3-n}]^{2+}$ (Hpda=di-2-pyridylamine)[34] have been resolved by ion-exchange chromatography with $[Sb_2(d\text{-tart})_2]^{2-}$ ion employed as an eluent. Furthermore, complete chromatographic resolution has been attained for some Co(III) complexes with 2,2′-biimidazole[35] and its related ligands,[36] and the Pfeiffer effect has been detected for $[M(phen\text{ or }bpy)_3]^{2+}$ in the presence of $[Sb_2(d\text{-tart})_2]^{2-}$ ion.[37] Since the above complexes have no NH protons available for the double hydrogen bonding to the chiral anion, they associate with it through some interactions other than hydrogen bonding. Though a so-called hydrophobic interaction is one of the plausible interactions, its detailed nature is out of the scope of the present study.

(Received May 14, 1986)

A new type of the mixed ligand complex [Fe(bpy)(phen)(NCS)$_2$] (bpy=2,2′-bipyridine and phen=1,10-phenanthroline) has been prepared by two different methods. The influence of the mixed ligand coordination of bpy and phen to a central iron(II) ion is studied by measurements of the temperature variation of magnetic moments and Mössbauer parameters. It has been demonstrated that the mixed coordination tends to make the $^5T_2$(high-spin) ⇌ $^1A_1$(low-spin) transition more gradual. The spin-crossover transition temperature depends on the electronic property as well as the structure of the ligand coordinated to the central iron(II) ion.

A wide variety of bidentate ligands has been studied in an attempt to prepare iron(II) complexes which exhibit the spin-crossover transition $^5T_2$(high-spin) ⇌ $^1A_1$(low-spin). Almost all spin-crossover iron(II) complexes contain 1,10-phenanthroline (phen), 2,2′-bipyridine (bpy) or their derivatives as bidentate ligands because the ligand field strength of these diamines is intermediate and can afford both high-spin and low-spin states. A few iron(II) complexes of biimidazole and pyridine derivatives are also known to give rise to the spin-crossover transition.[1] A number of topics concerning the spin-crossover transition in iron(II) complexes has already been fully reviewed in recent articles.[2] These articles pointed out that the spin-crossover behavior observed for the electronic configuration $3d^6$ is affected by some factors such as ligand substitution,[3] metal dilution,[4] nature of crystal solvent and anion,[5] and isotopic substitution.[6] In spite of much attention to spin-crossover phenomena there have been relatively few reports on the spin-crossover transition of iron(II) complexes with mixed ligands. Exceptionally Spacu et al.[7] reported the spin-crossover transition of the mixed ligand complex [Fe(py)$_2$(phen)(NCS)$_2$], which stimulated our interest in the preparation of a new mixed-ligand complex for studying the influence of the mixed coordination on spin-crossover behavior.

In the present work we have prepared a new type of the mixed ligand iron(II) complex [Fe(bpy)(phen)(NCS)$_2$] by two different methods. The first method is based on the addition of a methanol solution of iron(II) thiocyanate to a mixed solution of bpy and phen in methanol. The second one is based on stepwise replacing two pyridine ligands of the starting material [Fe(py)$_4$(NCS)$_2$] with a phen, followed by further replacement of the residual two pyridine ligands by a bpy. These two synthetic methods are likely to be very useful in preparing a variety of novel mixed-ligand iron(II) complexes which display the spin-crossover transition $^5T_2$(high-spin) ⇌ $^1A_1$(low-spin). In order to examine the thermally induced spin-crossover transition, we have measured the temperature variation of magnetic susceptibilities and ^{57}Fe Mössbauer spectra of the mixed ligand iron(II) complex [Fe(bpy)(phen)(NCS)$_2$]. Our particular interest is to learn how the mixed coordination of bpy and phen to a central iron(II) ion influences transition temperature, hysteresis effect, and mechanism of spin-transitions.

Experimental

Materials. All reagents were of reagent grade and used without further purification. Tetrakis(pyridine)bis(thiocyanato)iron(II) [Fe(py)$_4$(NCS)$_2$][8] and bis(pyridine)(1,10-phenanthroline)bis(isothiocyanato)iron(II) [Fe(py)$_2$(phen)(NCS)$_2$][7] were prepared according to the literature methods.

Preparation. The mixed ligand complex [Fe(bpy)(phen)(NCS)$_2$] was prepared by the following two methods. Method I: A 50 cm^3 solution of 0.49 g (5.00 mmol) KSCN in methanol was added to a 6 cm^3 solution of 0.70 g (2.50 mmol) $FeSO_4 \cdot 7H_2O$ in water. The resulting precipitate of K_2SO_4 was filtered off with a G4 glass filter. To the filtrate was dropwise added a solution of 0.39 g (2.50 mmol) bpy and 0.45 g (2.50 mmol) phen in 50 cm^3 of methanol with vigorous stirring. After the mixed solution was allowed to stand overnight, red purple crystals obtained were filtered, washed with methanol and dried over silica gel. Found: C, 54.7; H, 3.3; N, 15.4%. Calcd for [Fe(bpy)(phen)(NCS)$_2$]: C, 56.70; H, 3.17; N, 16.53%. Method II: A 20 cm^3 solution of 0.31 g (2.00 mmol) bpy in pyridine was slowly added to a 500 cm^3 solution of 1.02 g (2.00 mmol) [Fe(py)$_2$(phen)(NCS)$_2$] in pyridine. The reaction mixture was stirred at 80 °C for 20 h, then evaporated to 50 cm^3 under reduced pressure. After the solution was cooled to room temperature, red purple crystals obtained were collected by filtration, washed with methanol and dried over silica gel. Found: C, 56.3; H, 3.2; N, 15.5%. Calcd for [Fe(bpy)(phen)(NCS)$_2$]: C, 56.70; H, 3.17; N, 16.53%. All manupulations were performed in a nitrogen-filled glovebox to prevent oxidation of iron(II) compounds.

Physical Measurements. The X-ray diffraction powder patterns were taken at room temperature with a Rigaku-

Denki Geigerflex RAD-IIA X-ray diffractometer using graphite-monochromated Cu $K\alpha$ radiation (λ=0.1542 nm). Infrared spectra were recorded on a Hitachi Perkin-Elmer Model 225 grating infrared spectrophotometer using KBr pellets. The calibration of wavenumbers was carried out using polystyrene film. Magnetic susceptibilities were measured in the temperature range between 77 and 300 K by the Bozorth method with $Hg[Co(SCN)_4]$ as a calibrant.[9] The molar susceptibilities were corrected for diamagnetism using the following corrections: Fe^{2+}, −13; bpy, −105; phen, −128; NCS^-, −35 (in units of 10^{-6} cm^3 mol^{-1}).[10,11] Mössbauer spectra were obtained with a 10 mCi ^{57}Co source in Pd foil (The Radiochemical Centre, Amersham, England) using a Wissel constant-acceleration transducer coupled with a Canberra OMEGA-1 multichannel analyzer. The absorber temperature was varied between 77 and 300 K with a Torisha cryostat. The spectra were fitted to Lorentzian curves with an iterative least-square computer program. The isomer shifts were referred to natural iron foil at 293 K.

Results and Discussion

Preparation of Mixed Ligand Complexes. Thermodynamic data are not available for the prediction whether the mixed ligand complex $[Fe(bpy)(phen)(NCS)_2]$ can be synthesized or not. When the target mixed ligand complex is prepared by Method I, one or more than two unfavorable products such as $[Fe(phen)_2(NCS)_2]$ $[Fe(bpy)_2(NCS)_2]$, $[Fe(phen)_3(NCS)_2]$ or $[Fe(bpy)_3](NCS)_2$ are expected to yield under the present experimental conditions. Of these complexes both $[Fe(phen)_3](NCS)_2$ and $[Fe(bpy)_3](NCS)_2$ are easily distinguishable from $[Fe(phen)_2(NCS)_2]$, $[Fe(bpy)_2(NCS)_2]$, and $[Fe(phen)(bpy)(NCS)_2]$ by elemental analysis or Mössbauer spectroscopy. The formation of $[Fe(bpy)_2(NCS)_2]$ is also ignored because it is synthesized only under more rigorous experimental conditions, e.g. by elimination of bpy from $[Fe(bpy)_3](NCS)_2$.[11] One might still suspect that a mixture of $[Fe(bpy)(phen)(NCS)_2]$ and $[Fe(phen)_2(NCS)_2]$ is formed by Method I. Therefore, we undertook Method II in which the pyridine ligands of $[Fe(py)_4(NCS)_2]$ are stepwise replaced by a bidentate phen or bpy. Since the complete substitution of the two remaining pyridine ligands in $[Fe(py)_2(phen)(NCS)_2]$ was supposed to be the most difficult step of the successive substitution reactions, the reaction mixture was heated for a prolonged period (20 h). In spite of somewhat tedious procedures, the successive substitution method employed in Method II was demonstrated to be an excellent method for preparing a variety of mixed ligand complexes. The preparation of some mixed ligand complexes analogous to $[Fe(bpy)(phen)(NCS)_2]$ is in progress in our laboratory.

Identification of Mixed Ligand Complexes. The identity of the mixed ligand complexes prepared by the above two different methods was confirmed by a comparison of the X-ray diffraction powder patterns as well as the infrared spectra. The X-ray diffraction powder patterns of the mixed ligand complex $[Fe(bpy)(phen)(NCS)_2]$ are shown in Fig. 1. The diffraction powder pattern of $[Fe(phen)_2(NCS)_2]$ is also presented for comparative purposes, although the X-ray diffraction data are already reported on this complex.[12] The diffraction pattern of $[Fe(bpy)(phen)(NCS)_2]$ prepared by Method I agrees with that by Method II, indicating that the mixed ligand complexes prepared by the two different methods are identical. The intensities observed for $[Fe(bpy)(phen)(NCS)_2]$ prepared according to Method I and II are appreciably different from those of $[Fe(phen)_2(NCS)_2]$, while the peak positions are very similar to each other. This means that $[Fe(bpy)(phen)(NCS)_2]$ is isomorphous with $[Fe(phen)_2(NCS)_2]$ and the lattice parameters of the former are also quite similar to those of the latter.

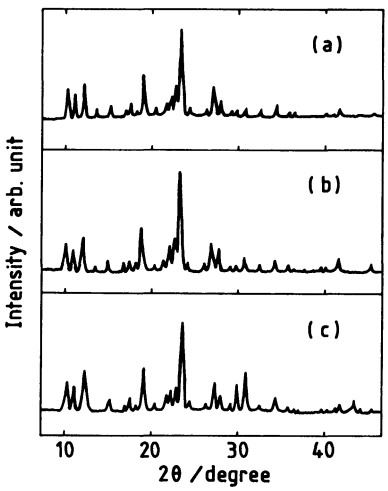

Fig. 1. Comparison of X-ray diffraction powder patterns. (a): $[Fe(bpy)(phen)(NCS)_2]$ prepared by Method I, (b): $[Fe(bpy)(phen)(NCS)_2]$ prepared by Method II, (c) $[Fe(phen)_2(NCS)_2]$.

Table 1. Infrared Absorption Frequencies of Thiocyanato Ligands in $[Fe(bpy)(phen)(NCS)_2]$

Compound	Absorption frequencies/cm^{-1}		
	ν_1(CN str.)	ν_2(SCN bend.)	ν_3(CS str.)
$[Fe(bpy)(phen)(NCS)_2]$[a]	2055	473	800
$[Fe(bpy)(phen)(NCS)_2]$[b]	2055	475	798
$[Fe(phen)_2(NCS)_2]$[c]	2060	(483, 473)	(809)

a) Prepared by Method I. b) Prepared by Method II. c) Taken from 10).

The infrared absorption frequencies observed for [Fe(bpy)(phen)(NCS)$_2$] are listed in Table 1 along with those for [Fe(phen)$_2$(NCS)$_2$]. Three fundamental modes of the thiocyanato ligand are referred to as ν_1(C-N str.), ν_2(N-C-S bend.), and ν_3(C-S str.). The absorption frequencies of these three fundamental modes provide information on whether the central iron(II) ion is coordinated through the nitrogen end or through the sulfur end of the thiocyanato ligand. A comparison of the three frequencies in [Fe(bpy)(phen)-(NCS)$_2$] to those in [Fe(phen)$_2$(NCS)$_2$] which are already reported[10] reveals that the coordination atom of the thiocyanato ligand to the central iron(II) ion is nitrogen in [Fe(bpy)(phen)(NCS)$_2$] prepared by Method I and II. In addition, the range of the absorption frequencies observed for the three fundamental modes clearly indicates that the mixed ligand complexes [Fe(bpy)(phen)(NCS)$_2$] are both in the high-spin state at room temperature. The infrared spectra of mixed ligand complexes are generally very useful in verifying the coordination of different kinds of ligands to a central metal ion. In the present case the absorption positions of bpy are too similar to those of phen to clarify the mixed coordination of both ligands to an iron(II) ion.

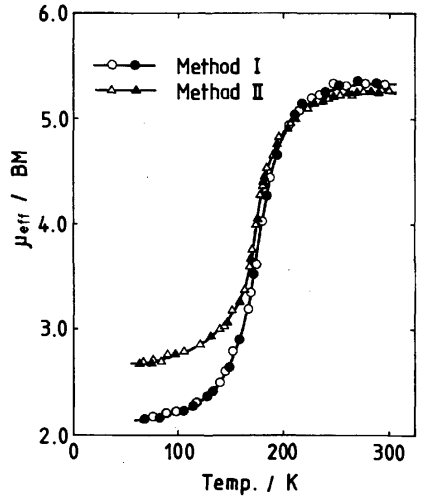

Fig. 2. Temperature dependence of μ_{eff} in [Fe(bpy)-(phen)(NCS)$_2$]. ○: Prepared by Method I, △: prepared by Method II. Open and full symbols represent cooling and heating runs respectively.

Influence of Mixed Coordination on Spin-Crossover Behavior. The variation of the effective magnetic moment μ_{eff} of [Fe(bpy)(phen)(NCS)$_2$] with temperature is shown in Fig. 2. The cooling curve of the temperature dependence of the magnetic moment agrees with the heating one and hence no hysteresis effect is observed for [Fe(bpy)(phen)(NCS)$_2$] within experimental errors. The magnetic moments of [Fe(bpy)(phen)(NCS)$_2$] prepared by Method I and II are deflected suddenly at 179 and 175 K, respectively, each of which is here defined as transition temperature. The marked change in magnetic moments within a narrow temperature range indicates that the present mixed ligand complexes do not belong to the spin-equilibrium type but to the spin-transition one. The rather sharp transition is comparable to a reversible quintet-singlet transition observed for [Fe(phen)$_2$-(NCS)$_2$],[13] in which a cooperative transition mechanism is predominant.

The magnetic moments observed at 77 and 293 K are summarized in Table 2 together with the transition temperature. The magnetic moments of [Fe(bpy)-(phen)(NCS)$_2$] are rather independent of the preparative methods in the high-temperature range 220 to 300 K. In contrast, the complex prepared by Method I gives lower magnetic moments than that by Method II in the low-temperature range below 120 K. The so-called residual paramagnetism depends on the preparative method employed. The disagreement of the residual paramagnetic moments in the low-temperature range is probably due to the difference in topography of crystalline particles, e.g. boundary surface and size of fine crystals.[14] In fact, it is reported that an increase of surface area by grinding and doping fine crystals results in an increase of the residual paramagnetic moments in the low-temperature range.[15] It is to be noted that the residual paramagnetism observed for almost all spin-crossover complexes will be studied because no clearcut explanation has been given to this strange phenomenon. The theoretical interpretation of the temperature dependence of magnetic moments is made more difficult mainly due to the following two reasons: 1)

Table 2. Magnetic Moment and Transition Temperature

Compound	Magnetic moment (BM)		Transition temperature
	High-spin($^5T_2$)	Low-spin($^1A_1$)	
	293 K	77 K	K
[Fe(bpy)(phen)(NCS)$_2$][a]	5.26	2.16	179
[Fe(bpy)(phen)(NCS)$_2$][b]	5.20	2.79	175
[Fe(phen)$_2$(NCS)$_2$][c]	5.17	0.65	174
[Fe(bpy)$_2$(NCS)$_2$][c]	5.20	0.94—1.39	215

a) Prepared by Method I. b) Prepared by Method II. c) Taken from 10) and 11).

The $^5T_2$(high-spin) $\rightleftarrows$ $^1A_1$(low-spin) transition is accompanied by a discontinuous change in metal-ligand distances and 2) the magnetic moments observed in the low-temperature range depend to some extent on the preparative method employed. We believe that the high-spin ($^5T_2$) $\rightleftarrows$ low-spin ($^1A_1$) transition in [Fe(bpy)(phen)(NCS)$_2$] is thermodynamically of first order, although the present complex does not exhibit any hysteresis effect in the experimental time scale of our magnetic measurements.[16] Of course, the conclusive demonstration should be made by heat capacity measurements, particularly because the transition observed in the magnetic moments is almost discontinuous.

Change in Electronic Structure with Spin-Crossover Transition. The Mössbauer spectra obtained at three different temperatures are shown in Fig. 3. Only the spectra of [Fe(bpy)(phen)(NCS)$_2$] prepared by Method II are given as representative ones because the spectral patterns are similar to those by Method I. A quadrupole-splitting doublet characteristic of iron(II) complexes in the high-spin $^5T_2$ state was observed at 298 K. When the absorber temperature was lowered around 190 K, a quadrupole-splitting doublet assignable to the low-spin $^1A_1$ state began to appear in the Mössbauer spectra. As seen from Fig. 3, the absorption intensity, i.e. the area of the quadrupole splitting doublet is much smaller in the high-spin state than in the low-spin state. This indicates that the recoil-free fraction of the iron nucleus in the high-spin state is extremely small as compared with that in the low-spin state. This should be taken into consideration when the high-spin fraction in [Fe(bpy)(phen)(NCS)$_2$] is estimated from the area of the quadrupole splitting doublet.[17] Thus, almost all the high-spin phase seems to be annihilated in the Mössbauer spectra at 77 K, although there are high-spin molecules of [Fe(bpy)(phen)(NCS)$_2$] at least on the surface of microcrystals and/or at the boundary between magnetic domains. Indeed, measurements of temperature variation in magnetic susceptibilities also show that there exist appreciable paramagnetic species even at 77 K.[18]

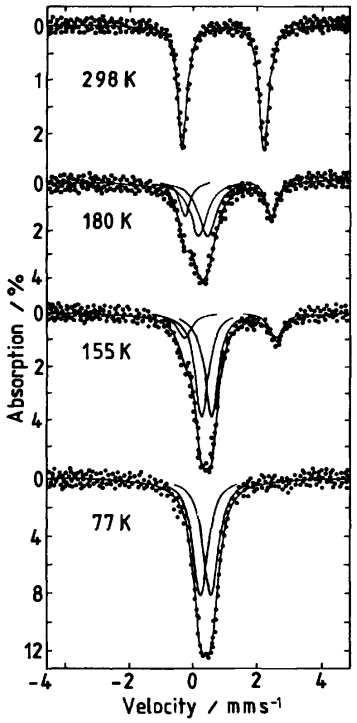

Fig. 3. Mössbauer spectra of [Fe(bpy)(phen)(NCS)$_2$] prepared by Method II.

The Mössbauer parameters obtained at 77 and 293 K are summarized in Table 3, where the parameters of closely related complexes are also listed for comparison. It is noteworthy that the isomer shift as well as the quadrupole splitting decreases on changing from the high-spin to the low-spin state. The thermally induced transition from the high-spin state to the low-spin state is accompanied by an increase in the back donation of 3d electrons to the π^* orbital of the bpy, phen or thiocyanato ligands; the lowering of the 3d electron density around the central iron(II) ion decreases the shielding of the s electron density at the iron nucleus and thereby gives rise to a negative isomer shift. For d^6 iron(II) complexes, the transfer of two electrons from the e_g and t_{2g} orbitals is known to

Table 3. Comparison of Mössbauer Parameters Observed for [Fe(bpy)(phen)(NCS)$_2$] and Related Complexes

Compound	Temp / K	Isomer shift / mms^{-1}	Quadrupole splitting / mms^{-1}
[Fe(bpy)(phen)(NCS)$_2$][a]	293	0.99_3	2.50_9
	77	0.42_3	0.36_9
[Fe(bpy)(phen)(NCS)$_2$][b]	293	0.94_5	2.49_6
	77	0.40_1	0.35_4
[Fe(phen)$_2$(NCS)$_2$][c]	293	1.00	2.67
	77	0.36	0.34

	77	0.36	0.49

a) Prepared by Method I. b) Prepared by Method II. c) Taken from 10) and 11).

cause a considerable reduction in the metal-ligand bond length. Thus, the cell volume generally contracts on going from the high-spin to low-spin state.[19] On transition from the $^5T_2$ state to the $^1A_1$ state, the tendency of phen or bpy to reduce the electron density on the iron is enhanced by the larger overlap of the iron t_{2g} orbitals and the antibonding π^* orbitals of bpy or phen. Consequently, the increased back donation from the central iron(II) ion to the antibonding π^* orbitals of the ligands causes the shortening of Fe-N bond length.

In the high-spin state, the isomer shifts observed for [Fe(bpy)(phen)(NCS)$_2$] are slightly smaller than those for [Fe(bpy)$_2$(NCS)$_2$] and [Fe(phen)$_2$(NCS)$_2$] while the quadrupole splittings lie between both complexes. On the other hand, in the low-spin state the isomer shifts of [Fe(bpy)(phen)(NCS)$_2$] are somewhat larger than those of [Fe(bpy)$_2$(NCS)$_2$] and [Fe(phen)$_2$(NCS)$_2$]. This suggests that the back donation from the t_{2g} orbitals of the iron(II) ion to the antibonding π° orbitals of bpy, phen, and thiocyanato ligands is smaller in [Fe(bpy)(phen)(NCS)$_2$] than in [Fe(bpy)$_2$(NCS)$_2$] or [Fe(phen)$_2$(NCS)$_2$].

The Mössbauer parameters of [Fe(bpy)(phen)-(NCS)$_2$] prepared by Method II are shown as a function of temperature in Fig. 4. In the high-spin temperature range the quadrupole splitting increases with decreasing temperature, while in the low-spin temperature range it is almost independent of temperature. The mixed ligand complex [Fe(bpy)-(phen)(NCS)$_2$] prepared by Method I showed a quite similar tendency in the temperature-dependence of its Mössbauer parameters to that prepared by Method II. The temperature variation of the quadrupole splitting in the high-spin temperature range is ascribed to the Boltzmann distribution of 3d electrons among the sublevels in the distorted octahedral ligand field. On the other hand, the isomer shift increases with decreasing temperature both in the high-spin and in the low-spin temperature ranges. This increasing tendency in the isomer shift is due to the so-called second-order Doppler shift. A dramatic change around 180 K in both the isomer shift and the quadrupole splitting demonstrated that the electronic configuration of the central iron(II) ion abruptly changes around this transition temperature. This discontinuous change in Mössbauer parameters is in good accord with the abrupt $^5T_2$(high-spin) $\rightleftarrows$ $^1A_1$ (low-spin) transition observed for the temperature dependence of magnetic moments.

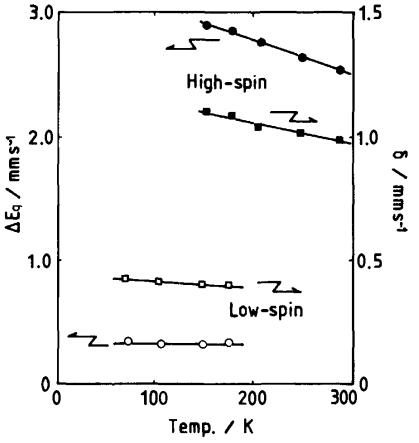

Fig. 4. Temperature dependence of Mössbauer parameters in [Fe(bpy)(phen)(NCS)$_2$] prepared by Method II.

Preparation, Characterization, and Some Reactions of Cationic Hydrido-Carboxylato Complexes of Molybdenum(IV), $[MoH_2(O_2CR)(dppe)_2]^+$

Takashi Ito,* Akihiko Takahashi, and Shigeyoshi Tamura
Department of Materials Chemistry, Faculty of Engineering, Yokohama National University, Tokiwadai, Hodogaya-ku, Yokohama 240
(Received May 20, 1986)

Cationic carboxylatodihydridomolybdenum(IV) complexes, $[MoH_2(O_2CR)(dppe)_2]BPh_4$ (R=CH_3, C_2H_5, CH_2=CH, and CH_2=C(CH_3); dppe=$Ph_2PCH_2CH_2PPh_2$), were prepared by treating $[MoH_4(dppe)_2]$ with RCOOH followed by anion exchange with $NaBPh_4$, and characterized spectroscopically. A possible pathway of the reaction is discussed on the basis of the experiment using CH_3COOD. Light irradiation of the EtOH solution of the cationic acetato complex in the presence and absence of CO afforded the known *cis*-$[Mo(CO)_2(dppe)_2]$ and the neutral hydridoacetato complex, $[MoH(O_2CCH_3)(dppe)_2]$, respectively.

Although molybdenum complexes with the carboxylato ligands bridging singly or multiply bonded two metal centers have been extensively studied,[1] only a few well defined mononuclear carboxylato complexes of molybdenum have been reported.[2-7] Furthermore a very limited number of the carboxylato complexes of molybdenum containing tertiary phosphine ligands have been reported, i.e., $[MoH_2(O_2CCF_3)_2(PMePh_2)_3]$,[3] $[MoH(O_2CR)(PMe_3)_4]$ (R=H, CH_3, and CF_3),[6] $[Mo(O_2CCF_3)_2(dppe)_2]$,[2] and the cationic $[Mo(O_2CCF_3)(dppe)_2]BPh_4$.[2] As an extension of our continuing studies on the preparation of group 6a metal complexes possessing functionally substituted ligands,[7,8] reactions of carboxylic acids, including unsaturated carboxylic acids, with tetrahydridomolybdenum(IV) complex, $[MoH_4(dppe)_2]$ (**1**), are investigated in this study. The analogous Mo(IV) complex with unidentate phosphine ligands, $[MoH_4(PMePh_2)_4]$, has been known to be protonated with some protonic acids such as CF_3COOH and *p*-$CH_3C_6H_4SO_3H$ to give products in which some of the phosphine ligands were dissociated.[3] Recently Caulton et al. have shown that the acidolysis of $[MoH_4(PMe_2Ph)_4]$ with HBF_4 in MeCN yielded dicationic $[MoH_2(PMe_2Ph)_4(MeCN)_2]^{2+}$,[9] whereas the similar reaction in THF (tetrahydrofuran) yielded fluorine-bridged dinuclear cation $[\{(PMePh_2)_3H_2Mo\}_2(\mu\text{-}F)_3]^+$.[10] Here we found that **1** was easily protonated with carboxylic acid RCOOH to give carboxylatodihydridomolybdenum cation of the type $[MoH_2(O_2CR)(dppe)_2]^+$ and H_2.

Results and Discussion

Preparation of the Complexes. On stirring the mixture of yellow crystals of $[MoH_4(dppe)_2]$ (**1**) and acetic acid in vacuo at room temperature for several hours, a purple homogeneous solution resulted with accompanying release of two molar equivalents of H_2. Evaporating the solvent off from the solution left deep purple oil, which was solidified into red powder (**2a**) by triturating it in hexane. The product **2a** turned purple powder on treatment it with $NaBPh_4$ in ethanol and vermilion needles (**3a**) were obtained by recrystallization of the purple powder from acetone. The products **2a** and **3a** were characterized as $[MoH_2(O_2CCH_3)(dppe)_2]CH_3CO_2$ and its anion-exchanged compound, $[MoH_2(O_2CCH_3)(dppe)_2]BPh_4 \cdot 0.5(CH_3)_2CO$, respectively, on the basis of analytical (for **3a**) and spectral evidence (vide infra). The analogous carboxylatodihydridomolybdenum cations, $[MoH_2(O_2CR)(dppe)_2]A$ [A=RCO_2 (**2**) and BPh_4 (**3**)], were obtained similarly for propionic, acrylic, and methacrylic acids (Table 1).

$$\underset{(\mathbf{1})}{[MoH_4(dppe)_2]} + 2RCOOH \longrightarrow \underset{(\mathbf{2})}{[MoH_2(O_2CR)(dppe)_2]RCO_2} + 2H_2 \quad (1)$$

$$\mathbf{2} + NaBPh_4 \xrightarrow{EtOH} [MoH_2(O_2CR)(dppe)_2]BPh_4\ (\mathbf{3}) + RCOONa \quad (2)$$

R = CH_3(**a**), CH_2CH_3(**b**), CH_2=CH(**c**), CH_2=C(CH_3)(**d**)

Since purification of the carboxylate derivatives **2** is usually more difficult as compared with that of **3** due to their poor tendencies to be crystallized, their characterizations were achieved mainly spectroscopically, although the latter have been fully analyzed as shown in Table 2. Considerable low values of the observed molecular weight in acetone as compared with the calculated values and the conductivity measurements of their acetone solution (Λ, these values are compared with the observed value of 92.5 S cm^2 mol^{-1} for $NaBPh_4$ under similar conditions) as shown in Table 2 strongly support their proposed ionic formulation.

In order to obtain some mechanistic information of the reaction (1), the similar reaction of **1** with acetic acid-*d* was examined and the formation of dideuteride analogue of **2a** with the accompanying evolution of H_2 and D_2 (molar ratio of 1.0/4.2, total amount 2.1 mol/mol of **1**) was observed. The mechanistic aspect will be discussed in the later section.

$$[MoH_4(dppe)_2]\ (\mathbf{1}) + 2CH_3COOD \longrightarrow [MoD_2(O_2CCH_3)(dppe)_2]CH_3CO_2\ (\mathbf{2a}\text{-}d_2) + 0.4H_2 + 1.7D_2 \quad (3)$$

Identification of the dideuteride **2a**-d_2 was achieved by confirming the disappearance of the Mo–H signals in the ^{1}H NMR spectrum of the isolated tetraphenylborate derivative, $[MoD_2(O_2CCH_3)(dppe)_2]BPh_4$ (**3a**-d_2), in $CDCl_3$. Furthermore, the absence of an H–D exchange process between the cationic acetatodihydrido complex **2a** and acetic acid-*d* was suggested by confirming that there was no difference in the ^{1}H NMR spectra taken in $CDCl_3$ before and after treatment of **2a** with excess CH_3COOD at room temperature for 3 days.

IR Spectra of the Complexes. Carboxylatodihydridomolybdenum cations **2** showed weak Mo–H stretching absorption bands at around 1880 cm^{-1}. In addition, moderately strong absorptions at around 1460 cm^{-1} and fairly weak ones at around 1380 cm^{-1} were observed, which were assigned to asymmetric and symmetric CO_2 stretchings, respectively, of the coordinated carboxylato ligand.[11] The relatively low

a) Measured as KBr disk; values in cm^{-1}. b) 90 MHz in $CDCl_3$. Given as chemical shift δ in ppm, downfield positive from tetramethylsilane as an internal reference. Signals due to dppe ligand, BPh_4 anion and solvated acetone are omitted for brevity. Multiplicity abbreviations are: pq = pseudo quintet, t = triplet, m = multiplet. c) In parentheses are multiplicity, ^2J(P-H) in Hz, and **relative intensity**. d) In parentheses are multiplicity, J(H-H), [J(P-H)] in Hz, **relative intensity**, and assignment where necessary.

values of the separation between these two ν(OCO) bands (60—100 cm^{-1}) suggest that the carboxylato ligands in these complexes coordinate to the metal bidentately.[11,12]

NMR Spectra of the Complexes. As shown in Table 3 and Fig. 1, ^1H NMR spectra of carboxylato complexes **3** showed a characteristic pseudo quintet signal [apparent J(PH)=ca. 40 Hz] assignable to hydride protons at around δ −4, which is not so much different from the parent neutral tetrahydride **1** [δ(Mo–H)=−3.64 in chlorobenzene].[13] The pseudo quintet pattern of the signal may be analyzed as $A_2M_2X_2$ spin system where A_2 are hydride protons, and M_2 and X_2 are pairs of two equivalent phosphorus atoms. The deviation of the signal pattern from the typical 1:4:6:4:1 quintet suggests that the values of J(AX) and J(AM) differ slightly each other. Methyl protons of the acetato ligand in **3a** resonated at δ 0.03 as a triplet which was higher than the corresponding free acetic acid by δ 2.1.[14] The similar trends were observed for the protons attached to α-carbon of the propionato ligand of the complex **3b** in accordance with the reported results for hydridocarboxylato complexes of ruthenium.[15] Measurement of the phosphorus-decoupled ^1H NMR for complexes **3a** and **3b** revealed that both the pseudo quintet signals of Mo–H and the triplet signals of the protons attached to the α-carbon changed to singlets (Fig. 1), indicating that these splittings originated from the coordinated phosphines.

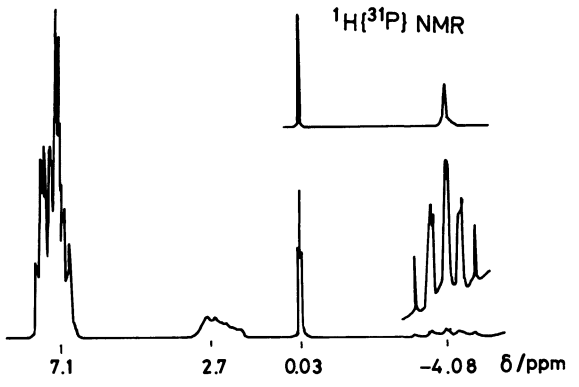

Fig. 1. ^1H NMR spectra of $[MoH_2(O_2CCH_3)(dppe)_2]BPh_4$ (**3a**), (100 MHz in $CDCl_3$ at room temperature).

In the ^{13}C NMR spectra of complexes **3**, carbonyl carbon of the carboxylato ligand resonated at δ 181—191 (Table 4). The signals due to carboxylato ligands were observed at the reasonable positions as judged from their corresponding ^1H NMR signals.

$^{31}P\{^1H\}$ NMR spectra of the complexes **3a—d** (Table 4) consisted of double triplets appearing at about δ 81 and 61, respectively, downfield from the external PPh_3 reference, which suggests that there are two pairs of magnetically unequivalent phosphorus nuclei, each consisting of two equivalent phosphori. The ^{31}P NMR spectra did not show any change at the temperature range from 20 to 70 °C.

Structure of the Complexes. On the basis of the spectral evidences described above, the bicapped octahedral structure, either I or II, seems to be most conceivable for the present octacoordinate cationic complexes **3**, although a square antiprism and a dodecahedron arrangements have been known to occur most commonly in the octacoordinate complexes.[16] The $A_2M_2X_2$ pattern of the hydride signal of the ^1H NMR spectra is elucidated by assigning A to the hydrides, M to the equatorial phosphori P_2 and P_3, and X to the axial P_1 and P_4, respectively. Of the two triplets of ^{31}P NMR signals, the signals at 61 ppm may be assigned to the mutual trans axial phosphorus atoms P_1 and P_4, and those at 81 ppm to equatorial P_2 and P_3.[15b] Of the two possible structures, structure I in which two hydride caps are directed toward the side occupied with phosphine ligands seems to be more preferable to II in view of the steric congestion around the hydrogen atoms. The pentagonal bipyramidal structure has been determined recently for the related

Table 4. $^{13}C\{^1H\}$ and $^{31}P\{^1H\}$ NMR Data for $[MoH_2(O_2CR)(dppe)_2]BPh_4$ (**3**)

Complex	^{13}C NMR[a]			^{31}P NMR[b]

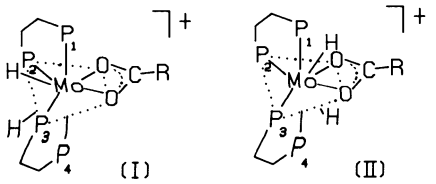
a) 22.5 MHz in $CDCl_3$. Given as chemical shift δ in ppm, downfield positive from tetramethylsilane as an internal reference. Signals due to dppe ligand, BPh_4 anion and solvated acetone which appeared at the ordinary region are omitted for brevity. All signals listed appeared as a singlet unless stated otherwise. b) 36.2 MHz in $CDCl_3$. Given as chemical shift δ in ppm, downfield positive from triphenylphosphine in CH_2Cl_2/C_6D_6 as an external reference. All signals are observed as triplet. c) For those there are two figures each of which corresponds to P_E and P_A respectively, and these differences may be originated from the second order couplings between various phosphori. d) Obscured due to overlapping with dppe and BPh_4 signals.



(I) (II)

neutral, seven-coordinate, hydridocarboxylatomolybdenum complex in which the hydride ligand resides in a pentagonal plane flanked with two equatorial phosphorus nuclei.[6]

Properties and Some Reactions of the Complexes. Carboxylatodihydridomolybdenum(IV) complexes **2** and **3** are moderately stable to air in the solid state and even in the solution in the dark. Furthermore, they are thermally stable: The solid acetato complex **3a** was found to be stable in vacuo up to 150 °C. The complexes bearing carboxylate anions **2** were soluble in chloroform, dichloromethane, ethanol, and acetone and slightly soluble in benzene and toluene, whereas those with BPh_4 anions **3** were soluble only in acetone and the halogenated solvents. When the solution of **3a** in $CHCl_3$ was heated at 60 °C for 2 h in the dark, 14% of CH_2Cl_2 on the basis of **3a** was formed. Subsequently, by allowing the resulting solution to leave under the exposure of the sunlight for 10 days, the formation of CH_2Cl_2 in 85% yield was observed. These results suggest that the cation which is thermally stable is easily activated by the light irradiation.

$$\mathbf{3a} + CHCl_3 \xrightarrow{h\nu} CH_2Cl_2 + \text{yellow complex} \quad (4)$$

Although complexes **2a** and **3a** were found to be inert to CO, alkenes (e.g. 1-heptene), alcohols (e.g. 2-propanol), and phenol even heating at 60 °C, complex **2a** released one mole of acetic acid on irradiation in ethanol with high pressure mercury lamp for 5 h to yield the neutral monohydrido acetato complex **4a** (21%).[17]

$$\mathbf{2a} \xrightarrow{h\nu,\,EtOH} [MoH(O_2CCH_3)(dppe)_2] + CH_3COOH \quad (5)$$
$$(\mathbf{4a})$$

The reaction was accompanied by the side reaction to form H_2 in 70% yield and acetaldehyde (32%) together with the orange complex which was tentatively assigned to $[Mo(O_2CCH_3)_2(dppe)_2]$ (12%) on the basis of its IR spectrum (see Experimental).

$$\mathbf{2a} + CH_3CH_2OH \xrightarrow{h\nu} [Mo(O_2CCH_3)_2(dppe)_2] + CH_3CHO + 2H_2 \quad (6)$$

The mechanism of the oxidation of ethanol to aldehyde with **2a** is not clear at the present stage.

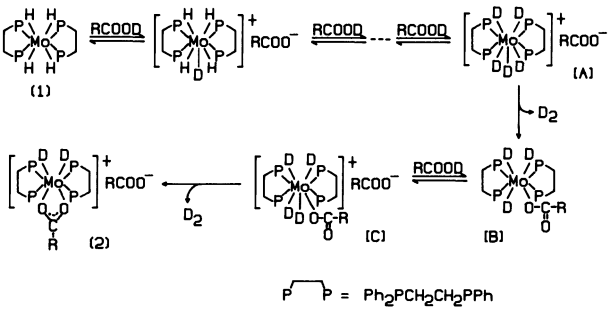
Under the Hg-lamp irradiation, **2a** reacted with 1 atm of CO in EtOH to yield, after 37 h, a small amount of the known dicarbonylmolybdenum complex together with the uncharacterized carbonyl complexes.

$$\mathbf{2a} + CO \xrightarrow{h\nu,\,EtOH} cis\text{-}[Mo(CO)_2(dppe)_2] + \text{Mo-carbonyls} \quad (7)$$

Finally, the carboxylato ligands of the cationic carboxylatodihydrido complexes **3** were found to be thermally labile in the presence of carboxylic acid to exhibit ligand exchange. Thus, by heating the acetato complex **3a** in acetone in the presence of excess methacrylic acid at 60 °C for 7 h, the methacrylato complex **3d** was obtained in a quantitative yield as is judged from the ^1H NMR spectrum of the isolated compound. The formation of equimolar amount of acetic acid in this reaction was confirmed by the GLC measurement. Conversely, complex **3d** was converted into acetato complex **3a** by stirring **2d** in acetone at 60 °C for 17 h in the presence of acetic acid.

$$[MoH_2(O_2CCH_3)(dppe)_2]^+ + CH_2{=}C(Me)COOH \rightleftharpoons [MoH_2(O_2CC(Me){=}CH_2)(dppe)_2]^+ + CH_3COOH \quad (8)$$
$$(\mathbf{3a}) \qquad\qquad (\mathbf{3d})$$

Discussion as to the Formation of the Cation $[MoH_2(O_2CR)(dppe)_2]^+$ (2). The first stage of the reaction between tetrahydrido complex **1** and carboxylic acid RCOOH to form carboxylatodihydrido cation **2** may be the protonation of **1** to give intermediate pentahydrido cation (**A**) (Scheme). Although this intermediate species was not able to be observed in the present system, the corresponding tungsten pentahydride has been prepared by the reaction between $[WH_4(PMePh_2)_4]$ and trifluoroacetic acid.[3] The selective evolution of D_2 gas when **1** was allowed to react with CH_3COOD [equation (3)] suggests that the equilibrium between **1** and the protonated molybdenum cation (**A**) as shown in the Scheme may be attained rapidly followed by a fairly slow reductive elimination of D_2. This process may be accompanied by the transfer of the acetate anion from the outer sphere to the inner sphere to yield the neutral 18-electron intermediate species (**B**).



P⌒P = $Ph_2PCH_2CH_2PPh$

Scheme

The trideuterido intermediate possessing the unidentately coordinated acetato ligand (**B**) may be protonated by another mole of acetic acid to give the cationic intermediate (**C**), which releases D_2 with the concomitant transfer of the acetato ligand from the unidentate to the bidentate fashion to attain 18-electrons of the metal center in the final product **2a**. The alternative path from (**B**) to **2a** which involves intermediary formation of monohydride **4a** by reductive elimination of H_2 from (**B**) was ruled out since **4a** was found to be inert to RCOOH.[17] The evolution of a small amount of H_2 in the reaction of **1** with CH_3COOD suggests that there exists, in addition to that shown in the Scheme, a minor process where H_2 is released prior to the deuteriation of **1** leading to (**A**). The dihydridomolybdenum(II) intermediate thus formed may be rapidly converted into (**B**) by reversible protonation with RCOOD as is judged from the absence of an HD component in the evolved gas.

Experimental

Most manipulations were carried out either under dry, oxygen-free nitrogen or argon or in vacuo with Schlenk-type flasks. Solvents were dried, purified in the usual manner, and stored under an atmosphere of argon. Commercial carboxylic acids were degassed and introduced into the reaction flask by a trap to trap method in order to avoid contamination with oxygen and moisture.

Infrared spectra were recorded on a JASCO A-202 spectrometer using KBr disks prepared under an inert atmosphere. Nuclear magnetic resonance spectra were measured on JEOL JNM-PMX-60 (^1H, 60 MHz) and JNM-FX-90Q (^1H, 90 MHz; ^{13}C, 22.5 MHz; ^{31}P, 36.2 MHz) spectrometers. $^1H\{^{31}P\}$ NMR spectra were recorded on a JEOL JNM-FX-100 (100 MHz) spectrometer. The molecular weight was measured in acetone at 25 °C using Mechrolab Vapor Pressure Osmometer Model 302. The electric conductivity of the complex solution was measured in acetone at 18 °C with TOA CM-5B conductivity meter. The organic products formed in the reactions were quantitatively analyzed by GLC using internal standard. GLC was recorded on a Shimadzu GC-7APTF or GC-3BT gas chromatography using PEG-20M, SDC-410, and/or SDC-550 columns and helium as carrier gas. Non-condensable gas evolved through the reaction was measured by a Toepler pump and analyzed by a mass spectrometer (Hitachi Model M-80) and GLC using Molecular Sieve 5A column. $[MoH_4(dppe)_2]$ (**1**) was prepared as previously reported.[18] Acetic acid-*d* was prepared from acetic anhydride and D_2O.

Preparation of Acetatodihydridobis[1,2-bis(diphenylphosphino)ethane]molybdenum(IV) Tetraphenylborate (3a). To $[MoH_4(dppe)_2]$ (**1**) (1.45 g, 1.62 mmol) was added 20 ml of acetic acid by means of a trap-to-trap method. The mixture was stirred in vacuo at room temperature for 3 h to give a purple solution. Evolution of H_2 (3.06 mmol) by the reaction was observed in the flask. Unreacted acetic acid was evaporated off from the solution in vacuo to leave a deep purple sticky solid which was dissolved in 75 ml of EtOH, and the solution was filtered. To the red filtrate was added 1.24 g (3.63 mmol) of $NaBPh_4$ to give purple precipitate, which was filtered and washed with EtOH. Recrystallization of the purple product from acetone afforded vermilion needles of $[MoH_2(O_2CCH_3)(dppe)_2]BPh_4\cdot\frac{1}{2}(CH_3)_2CO$ (**3a**) (1.41 g, 72%). Analytical results for **3a** are listed in Table 2. Inclusion of half mole of acetone as crystallization solvent in **3a** was also confirmed by the intensity measurement of its ^1H NMR spectrum.

In a separate experiment which aimed at the isolation of acetatodihydridobis[1,2-bis(diphenylphosphino)ethane]molybdenum(IV) acetate (**2a**), 1.13 g (1.26 mmol) of $[MoH_4(dppe)_2]$ (**1**) was allowed to react with 16 ml of acetic acid at room temperature under argon for 1 h to give a purple solution. After excess acetic acid being evaporated off from the solution, the resulting sticky solid was triturated in hexane at −50 °C or in Et_2O at room temperature to give red precipitate, which was filtered off, washed well with Et_2O and dried in vacuo to give red powder of $[MoH_2(O_2CCH_3)(dppe)_2]CH_3CO_2$ (**2a**) [ν(MoH)=1890 w, br; ν(OCO) of $CH_3CO_2^-$=1710 s; $\nu(OCO)_{asym}$=1465 m; $\nu(OCO)_{sym}$=1407 w cm^{-1}] (1.09 g, 85%).

The other carboxylato complexes **2** and **3** were obtained similarly. Reaction conditions of each synthesis are listed in Table 1. Complexes **3** were found to contain half (**3c** and **3d**) or one equivalent (**3b**) of acetone as crystallization solvent as is judged from their elemental analyses and ^1H NMR spectra (see Table 2).

Photodegradation of 2a. $[MoH_2(O_2CCH_3)(dppe)_2]CH_3CO_2$ (**2a**) (0.500 g, 0.494 mmol) in 120 ml of EtOH was irradiated with 100 W high pressure mercury lamp at room temperature under N_2 for 5 h to cause the color change of the solution from purple to brown. Evolution of 0.3 mmol (70%) of H_2 in the vapor phase was detected by the GLC analysis. A volatile component, in which acetic acid (0.31 mmol, 63%) and acetaldehyde (0.16 mmol, 32%) were observed to present by its GLC analysis, was removed in vacuo to leave brown powder, which was fractionally crystallized from Et_2O to give orange crystals of $[MoH(O_2CCH_3)(dppe)_2]$[17] (**4a**) (0.101 g, yield 21.4%) and yellow powder. The latter was tentatively assigned to $[Mo(O_2CCH_3)_2(dppe)_2]$ [$\nu(CO_2)$=1618 s, 1580 w, 1360 m, and 1297 vs cm^{-1}] (0.061 g, 12%).

Authors are indebted to Drs. F. Ozawa and Y. Nakamura of Tokyo Institute of Technology for the measurement of mass and $^1H\{^{31}P\}$ NMR spectroscopy, respectively, and to Mr. T. Saito of the same Institute for elemental analyses. They also acknowledge to Dr. H. Suezawa of Yokohama National University for the NMR measurement with an FX-90Q instrument.

(Received May 28, 1986)

The title complex was synthesized and its crystal and molecular structures were determined by the single-crystal X-ray diffraction technique. The crystal is orthorhombic with a space group $P2_1nb$, a=14.953(4), b=15.955(4), c=7.6838(9) Å. The structure was solved by means of the heavy-atom method and the final R value was 0.059. The mercury atom is in the tetrahedral geometry, coordinated with four sulfur atoms of the thiocyanate (SCN) ions, and the cobalt atom is in the octahedral geometry, coordinated with four nitrogen atoms of SCN ion and two oxygen atoms of *N*-methylformamide which occupy the *cis* positions. Each pair of different kinds of metal atoms is bridged by an SCN ion and are in a three-dimensional network. Twenty-four membered rings of $Co_3Hg_3(SCN)_6$, where the metal atoms are arranged hexagonally in a chair-form, are condensed two-dimensionally approximately parallel to the (1 0 0) plane. All mercury atoms on one plane are bridged by SCN ions to the cobalt atoms of the polymeric plane next to the [1 0 0] direction, while the cobalt atoms are linked by SCN ions to the mercury atoms on the next plane of the opposite side. The mfa ligands take their positions in the vacancy of the network.

The cobalt(II) mercury(II) thiocyanate (**1**) was found to have a diamond-like three-dimensional polymeric structure,[1] where both kinds of the metal atoms are in the tetrahedral geometry, and each pair of the different kind of metal atoms are bridged by one thiocyanate (SCN) ion. In **1**, a twenty-four membered ring containing three mercury and three cobalt atoms and six thiocyanate ions is formed as the unit where the six metal atoms are in a chair-form hexagonal arrangement. The units are condensed and linked three-dimensionally in a crystal comprising a diamond-like structure.

The pyridine (py) and *N*,*N*-dimethylformamide (dmf) adducts of **1**, $CoHg(SCN)_4py_2$ (**2**),[2] and $CoHg(SCN)_4dmf_2$ (**3**),[3] were obtained and their structures were elucidated; they are in the respective characteristic three-dimensional polymeric structures. Since the types of the networks of **1**, **2**, and **3** are different from each other, it is expected that if another kind of the Lewis-base adduct of **1** is obtained, it may have a different type of the three-dimensional network structure. Previously, the present authors studied and determined the crystal structures of some adducts of **1**.[4-6] Among them, relatively bulky amide molecules, such as *N*,*N*-dimethylacetamide (dma)[5] and *N*-methyl-2-pyrrolidone (mpd),[6] were shown to form a kind of inclusion compound of the type $CoHg(SCN)_4(H_2O)_2\cdot 2L$ (where L=dma or mpd).

Along this line of research, the title complex has been synthesized, where the added Lewis base, *N*-methylformamide (mfa) is smaller in size than dma or mpd (and even py or dmf). Its crystal and molecular structure has been determined by the X-ray diffraction method using its single-crystal.

Experimental

Synthesis of Bis(*N*-methylformamide)tetrakis(thiocyanato)-cobalt(II)mercury(II) (4). A crystalline powder of **1** (1.0 g, 2.0 mmol) was dissolved into mfa (20 cm^3), and 3 cm^3 of water was added to the solution. It was left standing for several days and crystals of **4** were deposited. The red-violet crystals were filtered off and dried over silica-gel. Yield: 0.65 g, 54%. Found: Co, 9.63; C, 15.45; H, 1.57; N, 14.00%. Calcd for $CoHgC_8N_6O_2S_4$: Co, 9.66; C, 15.75; H, 1.65; N, 13.78%.

Intensity-Data Collection. A crystal shaped into a sphere[a] (ϕ=0.21 mm) was used for the intensity data measurement. Crystallographic data are: $CoHgC_8H_{10}N_6O_2S_4$ F.W.=609.99, orthorhombic, with the space group of $P2_1nb$, a=14.953(4), b=15.955(4), c=7.6838(9) Å, U=1833.2(7) Å^3, Z=4, D_m=2.21(3) Mg m^{-3}, D_x=2.21 Mg m^{-3}, μ(Mo $K\alpha$)=9.94 mm^{-1}. Reflections within a range of $3°<2\theta<60°$ were collected on a Rigaku AFC-6A automated four-circle X-ray diffractometer with graphite-monochromated Mo $K\alpha$ radiation. The ω—2θ scan technique was employed (scan speed, 4° min^{-1} in 2θ; scan width, 1.12+0.5tanθ°(θ)). Of the 3072 independent reflections measured, 1707 $|F_o|>3\sigma(|F_o|)$ reflections were used for the structure determinaion. The intensities were corrected for Lorentz and polarization factors as well as for absorption. The latter correction was made using a numerical Gaussian integration.[7]

Structure Determination. The structure was solved by the heavy atom method. The positions of the mercury and cobalt atoms were deduced from a three-dimensional Patterson map, while the other non-hydrogen atoms were located by means of succesive Fourier syntheses. Their positional and thermal parameters (first isotropic and finally anisotropic) were refined by a block-diagonal least-squares method.

a) The crystal was shaped by rolling it on the fine particle sand-paper while pressing very weakly.

During the final refinement step, the shift of the all the parameters was less than $\sigma/3$'s. At the step, two spots remained at positions about 2.1 Å from the mercury atom on the differential synthesis map. A calculation of the structure analysis was repeated using new intensity data obtained from another crystal, but the spot remained, although the intensity of the both spots were about 3 electrons Å^{-3}. As these spots were about 2.1 Å from the thiocyanate nitrogen atoms, their positions were too near to be thought of as those of the coordinated water oxygen atoms. Actually, the infrared spectra of the complex, as well as the element analysis did not show the existence of water in the crystal. The adopted space group was also found to be the correct one from Weissenberg and oscillation photographs. Therefore, the spots are now thought to be due to a termination effect owing to the large mercury atom; such a phenomenon was sometimes found around a heavy atom. The final R value obtained by applying anisotropic temperature parameters was 0.059.[8] As the R value for structure with an inversed chirality was 0.064, the structure was not adopted.

All calculations were carried out on a HITAC M-280H computer apparatus at the Computer Center of the University of Tokyo using a local version of the UNICS program system.[9] The atomic scattering factors were taken from Ref. 10.

Other Measurement. The magnetic moment of the solid sample was measured at 20 °C using a Gouy balance.

scheme of the atoms. A crystal-packing diagram of the unit cell is shown in Fig. 3.

Each mercury atom is coordinated with four thiocyanate sulfur atoms and has a tetrahedral geometry. The average Hg-S length is 2.545 Å (maximum Hg-S(3), 2.588(7) and minimum Hg-S(1), 2.518(6) Å) which is about the same as the sum of the Pauling's radii, 2.52 Å (r_{Hg}=1.48, r_S=1.04 Å).[12] The average angles of S-Hg-S and Hg-S-C are 109.5 and 95.5°, respectively. These bond lengths and angles about the mercury atoms of these complexes are normal compared with several mercury thiocyanates whose structures are crystallographycally known.[1,13-15]

The cobalt atom is hexa-coordinated and is in an octahedral geometry, where two amide oxygen atoms are ligated in a *cis*-orientation, and four thiocyanate nitrogen atoms are bonded to the rest positions. The average Co-N and Co-O bond-lengths are 2.104, and 2.108 Å, respectively. Although they are a little longer than the respective sums of the Pauling radii, 2.02 and 1.98 Å (where r_{Co}=1.32, r_N=0.70, r_O=0.66 Å), such Co-O[16-18] and Co-N[19-21] lengths are found in many octahedral cobalt(II) complexes. The bond angles N-Co-N′ are; N(2)-Co-N(3^{ii})=177.5(8)°, and the other five angles are 90.15° on the average. Including the bond angles around the cobalt atoms, such as O-Co-N and O-Co-O, it was thought that the octahedral geometry of the cobalt core is not much deformed from the ideal one. The bond angle Co-N-C is 172° on the average (maximum Co-N(4^{iii}),

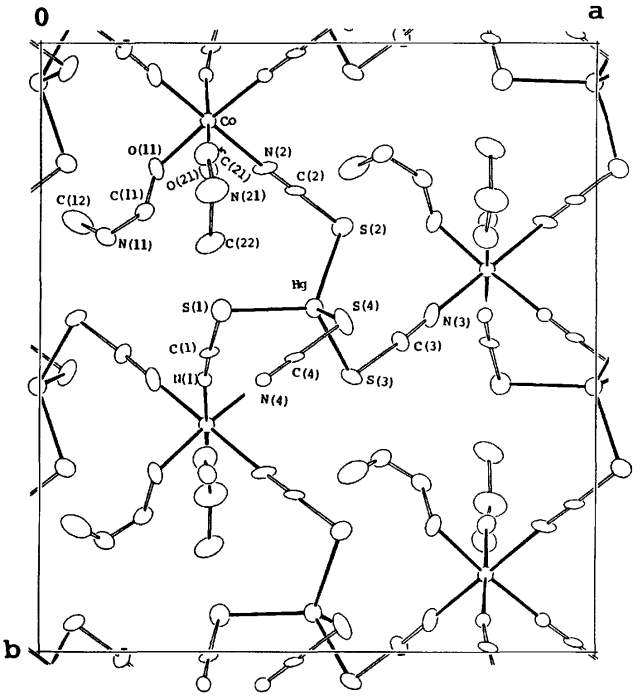

Fig. 3. The projection of the unit cell of the complex to the (0 0 1) plane.

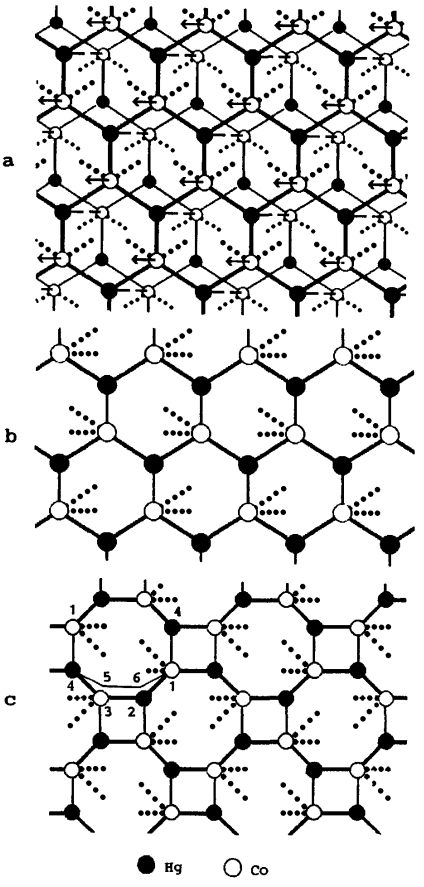

Fig. 4. The schematic presentation of the projection of the metal atomic arrangements of the complexes.
a: $CoHg(SCN)_4(mfa)_2$ projected to (1 0 0) plane,
b: $CoHg(SCN)_4(mfa)_2$ projected to (0 0 1) plane,
c: $CoHg(SCN)_4(dmf)_2$ projected to an appropriate plane.
Each solid line indicates the thiocyanato bridge. The broader lines show respective polymeric planes parallel(a) or perpendicular(b and c) to the projected plane. The dotted lines indicate the Lewis base molecules.

174(2); minimum Co-N(1^{i})-C(1^{i}), 168(2)°), being deformed only slightly from 180°.

Each pair of mercury and cobalt atoms are bridged by a thiocyanate ion (where the sulfur atom is ligated to the mercury and the nitrogen atom to the cobalt atom).

The projection of the metal atoms of **4** onto the (1 0 0) plane is shown schematically in Fig 4-a, where each bridging thiocyanate ion between the metal atoms is abbreviated as a straight line, in place of the real one which is broken at the sulfur atom position in about right angle. As shown in the figure, there are two kinds of two-dimensional networks (shown by broad and narrow lines) piled up alternatively. Both of them consist of condensed twenty-four membered rings where each three mercury and cobalt atoms are arrayed hexagonally in a chair form, and their average plane is parallel to (1 0 0). The dotted lines indicate mfa molecules. Each mercury atom in the plane is bridged by a thiocyanate ion to the cobalt atoms on the parallel next polymer plane on one side, (shown by the broken line), while each cobalt atom is linked to the mercury atom on the plane of the other side (shown by the arrow), respectively. All such interlayer bridging SCN ions are the S(3)-C(3)-N(3) types.

As shown in Fig. 4-b, which is a schematic presentation of the projection of the network to the (0 0 1) plane, there are other kinds of twenty-four membered rings represented by the hexagons of their metal atomic positions. However, projections of the hexagons are not very deformed. They are very different from the exact chair forms since the up and down deviations of the respective metal atomic positions from the average plane are irregular. Thus the three-dimensional network of complex 4 is regarded as consisting of a unit cage surrounded by two chair forms (up and down face parallel to (1 0 0) plane), and three deformed (side ones) twenty-four membered rings. The cages are arranged three-dimensionally and mfa ligands take positions in them.

A type of cage consisting of twenty-four membered rings was also found in **1**,[1] but all the hexagons of the metal-atom positions of all the rings were in the chair form. The metal atoms were arrayed like the carbon atoms in a diamond crystal.

According to Udupa's data of **3**,[3] two dmf oxygen atoms are ligated to a cobalt atom in a cis orientation, but its bridging structure is much different from that of **4** (written as follows). As schematically shown in Fig. 4-c, which is the projection to an appropriate plane, there are the same types of the twenty-four membered ring units; the hexagons indicating the metal-atom positions are condensed and linked to form a planar-type polymer which are spread perpendicular to the paper plane (one such hexagon is shown schematically as 1—6 in the figure). All the hexagons are in a boat form; the concave and convex types are arrayed alternatively. Their planar networks are shown by the broad lines in the figure. The metal atoms at the head and tail (1 and 4) positions of one hexagon unit are also bridged to the respective different kind of metal atoms at the 4 or 1 positions of another ring on a parallel next plane by the thiocyanate ions, while the other four metal atoms (2,3,5, and 6 position ones) are linked to the respective other kind of metal atoms on the next parallel plane of the opposite side. Thus, in **3** there are two kinds of cages (large and small ones) and as shown in the figure the side wall of the large one consists of two thirty-two membered rings (including, each, four mercury and cobalt atoms as well as eitht thiocyanate ions). Thus, the crystal of **3** has the vacant small cages other than the large cages to accomodate large dmf ligands in them; it is expected to have a less compact structure than that of **4**; the density of **3** and **4** are 2.01[3] and 2.21, respectively.

According to Beauchamp,[2] in **2**, two py nitrogen atoms are axially ligated to a cobalt atom, and four thiocyanate nitrogen atoms equatorially; its unit cage comprises two thirty-two membered rings ($Co_4Hg_4(SCN)_8$) and four sixteen-membered rings ($Co_2Hg_2(SCN)_4$) and the shape of the unit cage is much different from that of **1** or **4**.

From these comparisons of the framework, in **4** the mfa ligand can be included into the network of **1** with a relatively minor modification of the network, although the diamond-like structure of **1** is lost.

On the other hand, as py and dmf consist of six and five non-hydrogen atoms, respectively, they are relatively large in size compared with mfa which has only four non-hydrogen atoms. Therefore, the frameworks of **2** and **3** are too much different from those of **1** and **4** to take in these additional ligands.

The magnetic moment of 4 is about 5.02 BM (1 BM=$9.274078(36)\times10^{-24}$ JT^{-1}) at 20 °C. The value is almost the same as that of the related adducts, such as **2** or **3**, and which is the typical value for cobalt(II) complexes in an octahedral geometry.

The authors are greatly obliged to Dr. Mamoru Shimoi, Assistant Professor of Tohoku University, for his helpful discussions during this study.

Selective Modification of the Two Type I Copper Sites in Human and Bovine Ceruloplasmin with the Action of Azide and L-Cysteine

Takeshi SAKURAI* and Akitsugu NAKAHARA
Institute of Chemistry, College of General Education, Osaka University,
Toyonaka, Osaka 560
(Received May 31, 1986)

The two type I copper sites of human and bovine ceruloplasmin (CP) were indirectly modified through the binding of N_3^- to types II and III copper ions. Based on the fact that the activities of CP's modified with N_3^- were 85 and 47% for human and bovine CP, respectively, it was disclosed that the electronic and steric states of the "fast" type I Cu or "CuA" which is coupled with the types II and III copper ions was changed reversibly, whilst the "slow" type I Cu or "CuB" which is not coupled with the types II and III copper ions was changed to a type II copper ion and/or irreversibly reduced. On the other hand, the reaction of a limited amount of L-cysteine with CP gave the absorption and electron paramagnetic resonance spectra of CP whose CuB was selectively reduced. The treatment of this CP with 4,7-diphenyl-2,9-dimethyl-1,10-phenanthroline-4′,4″-disulfonate did not result in the selective removal of CuB.

Ceruloplasmin (CP) is one of the serum globulins possessing oxidase activity towards Fe(II) and some aromatic amines and phenols.[1] Like the other multicopper oxidases, laccase,[2] and ascorbate oxidase,[3] CP contains three kinds of copper(II) ions besides one or more copper(I) ions, i.e. two type I coppers characterized by the intense absorption at 610 nm and very small hyperfine coupling constants in the electron paramagnetic resonance (EPR) spectrum, one type II copper with EPR hyperfine parameter similar to that found in usual tetragonal copper(II) complexes and a pair of type III copper ions which are antiferromagnetically coupled and exhibit relatively strong absorption at around 330 nm.[1] It has been revealed that the two type I coppers of human and bovine CP's are oxidized at different rates:[4,5] The "fast" one or "CuA" has been elucidated to be coupled with the types II and III copper ions, constituting the active site, whilst the "slow" one or "CuB" is isolated from the active site.[5] Many studies on the effect of anions like N_3^-, SCN^-, OCN^-, F^- on human CP(HCP) have reached the conclusion that only one of the two type I coppers is indirectly affected by the anions in the light of the absorption change at 610 nm.[6,7] However, in the previous work on bovine CP(BCP) we disclosed both the type I coppers are affected by these anions: The steric and electronic structure of one of the two type I coppers is reversibly changed, whereas the other is irreversibly reduced and/or changed to a type II copper.[8] In the present paper, we report the discrimination of the two type I coppers both of which are indirectly perturbed by N_3^-. Further, we furnish the absorption and EPR spectra of CP whose CuB is selectively reduced.

Experimental

HCP was purchased from Green Cross Corp. and BCP was prepared from bovine serum as described previously.[5,8] The absorption ratio of A_{610}/A_{280} was 0.041 and 0.044 for HCP and BCP, respectively. All reagents used were of analytical grade. Absorption spectra were obtained on a Union Giken SM-401 high sensitivity spectrophotometer and circular dichroic (CD) spectra on a JASCO J-500A spectropolarimeter. EPR spectra were recorded on a JEOL FE-1X spectrometer at 77 K. The amount of EPR detectable Cu^{2+} was estimated based on an EPR signal intensity of ethylenediaminetetraacetatocopper(II) as a standard. Total copper content of CP was determined using a Jarrell-Ash AA-1 atomic absorption spectrometer.

Results and Discussion

The absorbance at 610 nm of HCP treated with 1720

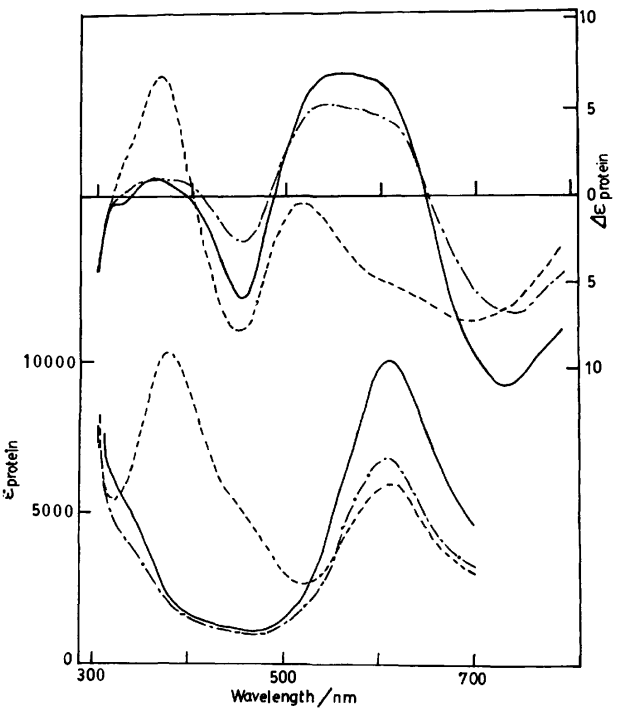

Fig. 1. Absorption and CD spectra of native (——), N_3^--treated (×1720, incubated for 2 d) (----), and dialyzed (——) human ceruloplasmin (protein concentration 2.9×10^{-5} mol dm^{-3}, pH 6.5, 0.1 mol dm^{-3} Na-phosphate buffer).

fold excess of N_3^- for 2 days decreased to 60% of the original intensity. Concomitantly, new band appeared at 381 and at 450 nm (Fig. 1). In the CD spectra, the sign of the band at about 660 nm arising from the charge transfer, S^-(cysteine)→Cu inverted from positive to negative because of the change of the steric and electronic states of one type I copper: The steric structure has been supposed to change from tetrahedrally distorted tetragon to trigonal pyramid.[9] The ellipticity of the negative CD band at 448 nm coming from the charge transfer, N(histidine)→Cu became greater, being accompanied by a development of a positive band at 370 nm due to the charge transfer, N_3^-→Cu (types II and III coppers). Simultaneously, the band at about 330 nm arising from the type III coppers almost lost its intensity. However, the CD spectral pattern returned to the original one after N_3^- was removed by dialysis against buffer solution. Each band showed a smaller intensity (Fig. 1) in accordance with the absorbance decrease of the band centered at 610 nm, although 9% recovery of the absorption intensity was observed. In the EPR spectra, the type II copper signal changed significantly: $g_{//}$=2.26, $A_{//}$=0.019 cm^{-1} for native HCP and $g_{//}$=2.26, $A_{//}$=0.015 cm^{-1} for N_3^--treated HCP (Fig. 2). The spin Hamiltonian parameters of one type I copper also changed slightly: $g_{//}$=2.21, $A_{//}$=0.0072 cm^{-1} for native HCP and $g_{//}$=2.18, $A_{//}$=0.0076 cm^{-1} for N_3^--treated HCP. Another possibility is that the type I copper which has the former parameter was reduced and/or changed to a type II copper. However, in the simulation study the following parameters were given for the two type I coppers of HCP: $g_{//}$=2.21, $A_{//}$=0.0074 cm^{-1} and $g_{//}$=2.22 and $A_{//}$=0.0095 cm^{-1}.[10] The former set of values are similar to those observed in our study. But the signal containing the latter parameters have not been observed in the present study. The whole feature of EPR spectrum returned to that similar to the native HCP after dialysis, while the increase of the type II copper signal(s) was noticeable. The amount of EPR detectable Cu^{2+} was estimated to be 3.0, 2.7, and 2.9 for native, N_3^--treated, and N_3^--treated and succeedingly dialyzed HCP. This result indicates that one type I copper was changed mostly to a type II copper through the binding of N_3^- to the type II and III copper ions even taking into consideration that the estimation error of EPR detectable Cu^{2+} is 10% or even more.

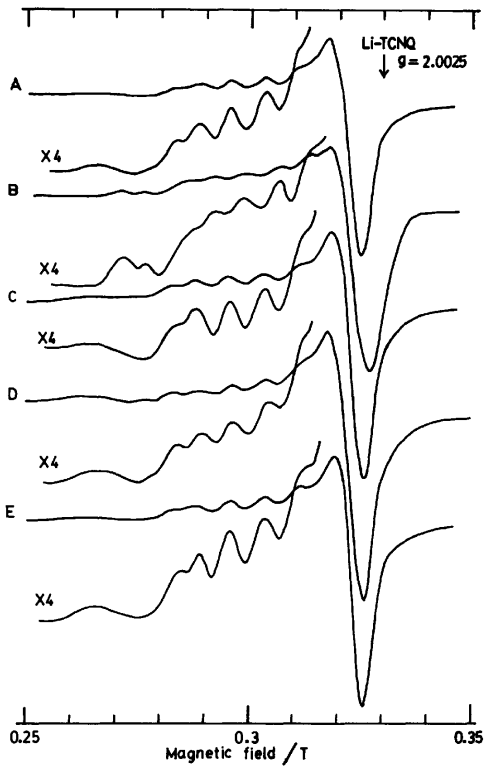

Fig. 2. X-band EPR spectra of native(A), N_3^-(×1720)-treated(B), dialyzed as (B)(C), DDP-treated after cysteine-treatment(D), and dialyzed as (D)(E) human ceruloplasmin; microwave frequency 9.21 GHz, microwave power 5 mW, modulation 0.8 mT at 100 kHz, amplitude 630 or 1000.

The activity[11] of the dialyzed HCP after N_3^--treatment for oxidizing 1,4-benzenediamine was 85%

Table 1. Characterization of Modified HCP and BCP

State of CP	Total Cu	EPR detectable Cu^{2+}	Relative oxidase activity/%	Relative absorbance at 610 nm/%
Native HCP	6.8	3.0	100	100
N_3^--treated HCP	—	2.7	—	60
Dialyzed HCP after N_3^--treatment	6.8	2.9	85	69
Cysteine-treated HCP	—	2.2	88	66
Dialyzed HCP after cysteine-treatment	6.9	2.7	87	77
Native BCP	6.7	3.0	100	100
N_3^--treated BCP	—	3.1	—	59
Dialyzed BCP after N_3^--treatment	6.7	3.7	47	45
Cysteine-treated BCP	—	2.0	98	54
Dialyzed BCP after cysteine-treatment	6.3	2.6	74	—

of that of the native HCP in spite of the 31% decrease of the absorbance at 610 nm (Table 1). The two type I coppers have been differentiated from the different rate of reoxidation, i.e. the "fast" one or "CuA" and the "slow" one or "CuB".[5] The former has been believed to be coupled with the types II and III coppers to constitute the active site, while the latter is not.[6,7] In addition, CuA has been supposed to be affected irreversibly by several anions such as N_3^-, since this anion binds with types II and III coppers to exert the fatal perturbation on protein structure. However, the fact that the dialyzed HCP after N_3^--treatment still reserved the activity indicated that CuA is the type I copper which is reversibly modified by the treatment with N_3^-. On the other hand, CuB is supposed to be changed mainly to a type II copper irreversibly owing to its reduction by the S^- group of the cysteine residue, the succeeding disruption of the Cu-S (cysteine) bond and the final automatic reoxidation.

A similar behavior was also observed for BCP (spectra are not shown). Although BCP is especially unstable, the dialyzed BCP after N_3^--treatment showed 45% activity as compared with that of the native enzyme (Table 1). The conservation of the oxidase activity indicates again that CuA was reversibly modified by N_3^- as was observed in the case of HCP. The amount of EPR detectable Cu^{2+} increased from 3 to 3.7 probably because the destruction of the active site including the type III site had occurred during the treatment of this enzyme with N_3^-.

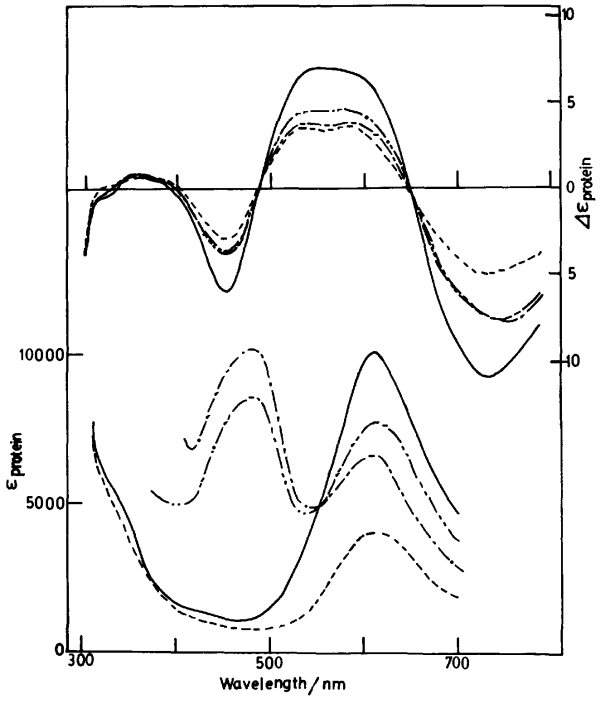

Fig. 3. Absorption and CD spectra of native (——), cysteine-treated (----), DDP-treated after cysteine-treatment (——), and dialyzed (——) human ceruloplasmin.

Native HCP was treated in three steps with two moles of L-cysteine. The resulting HCP gave absorption and CD spectra whose all bands were reduced to almost half of the native enzyme. Since CuA is coupled with the types II and III coppers, electrons afforded to this copper site were intramolecularly transferred to the type II copper and finally to the type III coppers where O_2 received them to give $2H_2O$. This intramolecular electron-transfer process is so rapid that electrons received by CuA are consumed in a few minutes.[12] However, the electron received by CuB is not transferred to other coppers because this type I copper is isolated from the active site. Accordingly CuB is autooxidized rather slowly, although the rate is not so slow as the autooxidation rate of the type I copper of simple blue copper proteins like plastocyanin, azurin, stellacyanin, plantacyanin, nitrite reductase, and amicyanin.[13] Thus the resulting absorption, CD and EPR spectra of the cysteine-treated HCP was not affected by CuB. This means that those spectra correspond to those of laccase which has the intrinsic one type I, one type II, and a pair of type III copper ions. It is not unexpected that the whole feature of the EPR spectrum was rather similar to that of the native enzyme (Fig. 2), even if the amount of EPR detectable Cu^{2+} was really decreased from 3.0 to 2.0. A rigorous EPR simulation study for the native enzyme should be performed again very carefully, since the former simulation study[10] suggested that the two type I coppers gave apparently different EPR parameters (vide supra).

In order to remove CuB selectively, 4,7-diphenyl-2,9-dimethyl-1,10-phenanthroline-4′,4″-disulfonate (DDP) was acted on a cysteine treated-HCP. A strong new band, which does not contribute to the CD spectrum, appeared at 485 nm. The absorption did not become pale appreciably after dialysis against buffer solution, since the Cu(I)-complex was firmly bound on the protein surface. The EPR detectable amount of Cu^{2+} increased from 2.3 for the cysteine-treated state to 2.7 for the dialyzed state. The corresponding absorptions at 610 nm were 66 and 77% of that of the native HCP, respectively, indicating that CuB was mainly changed to a type II copper irreversibly and was partly reduced and succeedingly autooxidized during dialysis. The net decrease of 0.3 Cu^{2+} may arise from the exclusion of CuB by the chelating reagent. Alternatively, since the experimental error in estimating the EPR detectable amount of Cu^{2+} is usually 10% or more, CuB may not be removed at all and the copper source of the 485 nm band might be copper(I) ions bound on protein surface. The activity of cysteine treated HCP did not change appreciably (Table 1),[14] indicating that CuB does not contribute to the appearance of the oxidase activity of

HCP. A similar result was also obtained in the case of BCP (Table 1)(spectra are not shown).

As a conclusion, it was confirmed that the type I CuA is assembled together with the types II and III copper ions to form the active site, but the type I CuB is isolated from the active site. Both the type I coppers are affected indirectly by the action of N_3^- on CP. Then, unexpectedly, CuB is mainly altered to a type II copper irreversibly, whereas CuA is reversibly modified in its steric and electronic states.

The present work was partly supported by a Grant-in-Aid for Scientific Research No. 61740348 from the Ministry of Education, Science and Culture.

Inversion at Selenium in the Bis(β-diketonato)[2-(methylseleno)-ethylamine]cobalt(III) Ion

Kiyohiko NAKAJIMA, Masaaki KOJIMA, and Junnosuke FUJITA*
Department of Chemistry, Faculty of Science, Nagoya University,
Chikusa-ku, Nagoya 464
(Received June 10, 1986)

The selenide (selenoether) complexes, $[Co(\beta\text{-dik})_2(CH_3SeCH_2CH_2NH_2)]^+$ (β-dik: acac=2,4-pentanedionate, Clacac=3-chloro-2,4-pentanedionate, Meacac=3-methyl-2,4-pentanedionate, and dbme=1,3-diphenyl-1,3-propanedionate) were prepared and separated into two racemic pairs of the diastereomers (Δ(*R*)Λ(*S*) and Δ(*S*)Λ(*R*) isomers). The complexes in solution epimerize by inversion at the selenium atom, and the rates were followed by high-performance liquid chromatography in the temperature range of 30.3—55.0 °C in 0.05 mol dm^{-3} Na_2SO_4 (acac, Clacac, and Meacac complexes) or in methanol (dbme complex). The $\Delta G^{\ddagger}_{25\,°C}$ values for inversion of $[Co(\beta\text{-dik})_2(CH_3SeCH_2CH_2NH_2)]^+$ decrease in the order β-dik=Clacac(108)>acac(106)>dbme(104)>Meacac(100 kJ mol^{-1}), and the decrease in $\Delta G^{\ddagger}_{25\,°C}$ comes mainly from a decrease in $\Delta H^{\ddagger}$. The effect of substituents is electronic and the Hammett relationship was found to hold for the inversion rates of the acac, Clacac, and Meacac complexes.

The selenium atom of a selenide (RSeR′) ligand becomes chiral on coordination to a metal ion. It has been reported that inversion at a coordinated selenide site is too rapid for the resolution in such complexes as Pt^{II}, Pt^{IV}, and Pd^{II}.[1] In a previous paper, however, we reported that inversion at selenium in $[M^{III}(RSeCH_2CH_2NH_2)(tren)]^{3+}$ (M^{III}=Co, Rh; R=CH_3, CH_3CH_2, $C_6H_5CH_2$; tren=tris(2-aminoethyl)amine=$N(CH_2CH_2NH_2)_3$) is so slow that they can be resolved by conventional methods, and that the inversion rates are dependent on the steric crowding around the Se-R group of the complexes.[2]

In order to investigate the electronic effect on the inversion rate, we have prepared a series of $[Co(\beta\text{-dik})_2(CH_3SeCH_2CH_2NH_2)]^+$ (β-dik: Clacac=3-chloro-2,4-pentanedionate, Meacac=3-methyl-2,4-pentanedionate, and dbme=1,3-diphenyl-1,3-propanedionate) and studied the inversion kinetics.

A part of this study has been reported briefly.[3,4]

Experimental

$[Co(acac)_2(CH_3SeCH_2CH_2NH_2)]ClO_4$. This complex was prepared from $[Co(acac)_2(H_2O)_2]$ and $CH_3SeCH_2CH_2NH_2$ by the same method as that for $[Co(acac)_2(CH_3SeCH_2CH_2NH_2)]PF_6$[3] except that $LiClO_4$ was used instead of NH_4PF_6. Yield: 42%. Found: C,31.71; H, 4.83; N, 2.27%. Calcd for $C_{13}H_{23}NClCoO_8Se$: C, 31.56; H, 4.69; N, 2.83%.

$[Co(Clacac)_2(CH_3SeCH_2CH_2NH_2)]ClO_4$. This complex was prepared by chlorination of $[Co(acac)_2(CH_3SeCH_2CH_2NH_2)]ClO_4$ with *N*-chlorosuccinimide by a method similar to that for $[Co(Clacac)(en)_2](ClO_4)_2$.[5] To a methanol solution (15 cm^3) of *N*-chlorosuccinimide (0.041 g, 3.07×10^{-4} mol) was added $[Co(acac)_2(CH_3SeCH_2CH_2NH_2)]ClO_4$ (0.050 g, 1.01×10^{-4} mol), and the solution was stirred for ca. 4 h at room temperature. The reaction mixture was diluted with water (20 cm^3) and applied on a column (φ 1.1 cm×6 cm) of SE-Toyopearl HW-40 (fine).[6] The adsorbed product was washed with water and eluted with 0.05 mol dm^{-3} Na_2SO_4. The column showed two green bands. The faster-moving band (minor product) seemed to contain $[Co(Clacac)(acac)(CH_3SeCH_2CH_2NH_2)]^+$ on the basis of the absorption spectrum, but this complex was not isolated. The eluate containing the slower-moving band (major product) was collected and mixed with $LiClO_4$ (ca. 5 g), and the complex was extracted with chloroform (50 cm^3×3). The chloroform layer was dried with anhydrous $MgSO_4$ and evaporated under reduced pressure to dryness. The deep green residue was dissolved in acetone (0.4 cm^3)–water (1.6 cm^3), and the solution was evaporated slowly in a desiccator over P_2O_5 to yield deep green crystals, which were collected by filtration, washed with cold water, and air dried. Yield: 0.03 g (53%). Found: C, 27.71; H, 3.76; N, 2.49%. Calcd for $C_{13}H_{21}NCl_3CoO_8Se$: C, 27.96; H, 3.53; N, 2.20%.

$[Co(Meacac)_2(CH_3SeCH_2CH_2NH_2)]ClO_4$. To a cold aqueous solution (7 cm^3) of NaOH (0.70 g, 1.75×10^{-2} mol) was slowly added 3-methyl-2,4-pentanedione[7] (2.0 g, 1.75×10^{-2} mol). The solution was then added dropwise to an aqueous solution (10 cm^3) of $CoCl_2\cdot 6H_2O$ (2.1 g, 8.83×10^{-3} mol). A yellow powder precipitated was collected quickly by filtration. This product was believed to be crude $[Co(Meacac)_2(H_2O)_2]$ and was used without purification. It is not stable even in the solid state; the color changes from yellow to green. To a hot (ca. 50 °C) ethanol solution (20 cm^3) containing $CH_3SeCH_2CH_2NH_2\cdot HCl$ (0.10 g, 5.73×10^{-4} mol) and LiOH (0.014 g, 5.8×10^{-4} mol) was added freshly prepared $[Co(Meacac)_2(H_2O)_2]$ (0.20 g, 6.2×10^{-4} mol). The color of the solution turned deep green immediately. The mixture was heated at 50 °C with stirring for 30 min. After cooling to room temperature, the solution was mixed with 3 mol dm^{-3} $LiClO_4$ (10 cm^3), and the complex was extracted with chloroform (200 cm^3×2). The chloroform layer was evaporated to dryness under reduced pressure, the deep green residue was dissolved in water, and then the solution was applied on a column (φ 2.2 cm×8 cm) of SP-Sephadex C-25. After washing the column with water the adsorbed product was eluted with 0.05 mol dm^{-3} Na_2SO_4. The column showed a green and a brown band. From the eluate containing the faster-moving green band the complex was isolated as the perchlorate by the same method as that for the Clacac complex, and recrystallized from water. Yield: 0.063 g (21%). Found: C, 34.80; H, 5.47; N, 2.89%. Calcd for $C_{15}H_{27}NClCoO_8Se$: C, 34.47; H, 5.21; N, 2.68%.

$[Co(dbme)_2(CH_3SeCH_2CH_2NH_2)]ClO_4\cdot H_2O$. To an eth-

anol solution (10 cm^3) of LiOH (0.12 g, 5.0×10^{-3} mol) was added slowly 1,3-diphenyl-1,3-propanedione (1.125 g, 5.0×10^{-3} mol). The resulting yellow suspension was added dropwise to an ethanol solution (6 cm^3) of $CoCl_2\cdot6H_2O$ (0.595 g, 2.5×10^{-3} mol). The mixture containing a yellow-orange precipitate was mixed with water (10 cm^3), stirred for 30 min at room temperature, and then the precipitate was collected by filtration. It was dissolved in hot ethanol (65 cm^3)–chloroform (35 cm^3), and the solution was evaporated to a volume of ca. 30 cm^3 and cooled to give fine orange crystals, which were collected by filtration and air dried. Yield: 1.30 g. This product was believed to be $[Co(dbme)_2(H_2O)_2]$ and was used to prepare $[Co(dbme)_2(CH_3SeCH_2CH_2NH_2)]^+$ without analysis. To an *N*,*N*-dimethylformamide (DMF) solution (40 cm^3) of $[Co(dbme)_2(H_2O)_2]$ (1.00 g, 1.85×10^{-3} mol) was added a DMF solution (10 cm^3) containing $CH_3SeCH_2CH_2NH_2\cdot HCl$ (0.322 g, 1.85×10^{-3} mol) and triethylamine (0.187 g, 1.85×10^{-3} mol). Acetic acid (2 cm^3) and PbO_2 (0.221 g, 9.25×10^{-4} mol) were added to the solution, the mixture was stirred for about 30 min at 30—40 °C, and then filtered. The filtrate was mixed with 0.5 mol dm^{-3} $NaClO_4$ (200 cm^3) with vigorous stirring to yield a green precipitate, which was recrystallized from chloroform by adding hexane. Yield: 1.04 g (74%). Found: C, 52.19; H, 3.97; N, 2.00%. Calcd for $C_{33}H_{33}NClCoO_9Se$: C, 52.09; H, 4.37; N, 1.84%.

$[Co(Bracac)_2(CH_3SeCH_2CH_2NH_2)]ClO_4$. This complex was obtained from the acac complex by a method similar to that for the corresponding Clacac complex using *N*-bromosuccinimide instead of *N*-chlorosuccinimide. Yield: 30%. Found: C, 23.91; H, 3.13; N, 2.25%. Calcd for $C_{13}H_{21}NBr_2ClCoO_8Se$; C, 23.93; H, 3.24; N, 2.15%. This complex is stable in the solid state but decomposes gradually in aqueous solution (ca. 5% in a day at room temperature).

$[Co(NO_2acac)_2(CH_3SeCH_2CH_2NH_2)]ClO_4$. This complex was prepared by nitration of $[Co(acac)_2(CH_3SeCH_2CH_2NH_2)]ClO_4$ in a manner similar to that for $[Co(NO_2acac)_3]$.[8] Yield: 42%. The complex is not stable even in the solid state and was not analyzed; the color of the complex changed from purple to brown on storage in a vial. The complex in water was estimated to decompose by ca. 10% in a day on the basis of the absorption spectrum.

Separation of the Diastereomers. The complexes $[Co(Clacac)_2(CH_3SeCH_2CH_2NH_2)]^+$ and $[Co(Meacac)_2(CH_3SeCH_2CH_2NH_2)]^+$ were separated into two racemic pairs of the diastereomers ($\Delta(R)\Lambda(S)$ and $\Delta(S)\Lambda(R)$) by column chromatography on SE-Toyopearl (eluent: 0.05 mol dm^{-3} Na_2SO_4) in the same manner as that for $[Co(acac)_2(CH_3SeCH_2CH_2NH_2)]^+$.[3] The column showed two green bands, but the diastereomers were not isolated because they are likely to epimerize. Each eluate was kept in a freezer at ca. −20 °C for kinetic studies. The diastereomers do not interconvert detectably over a period of at least 1 month under the given conditions.

$[Co(dbme)_2(CH_3SeCH_2CH_2NH_2)]^+$ was separated into the diastereomers by fractional crystallization of the perchlorate salt. $[Co(dbme)_2(CH_3SeCH_2CH_2NH_2)]ClO_4\cdot H_2O$ (0.14 g, 1.84×10^{-4} mol) was dissolved in chloroform (3 cm^3), and hexane (4 cm^3) was added dropwise. After cooling the solution in an ice bath, the crystals which deposited were collected. Almost pure (purity>95%) $\Delta(S)\Lambda(R)$ isomer (0.05 g) was obtained by repeated (4 times) recrystallization from chloroform–hexane by the same method as above. The purity was checked by a high-performance liquid chromatographic method (vide infra). The $\Delta(S)\Lambda(R)$ isomer (purity>95%) was also obtained by slow evaporation of a methanol solution of the perchlorate salt at room temperature.

Partial Resolution of $[Co(dbme)_2(CH_3SeCH_2CH_2NH_2)]^+$. Partial resolution of $[Co(dbme)_2(CH_3SeCH_2CH_2NH_2)]^+$ was achieved by column chromatography. About 5 mg of $[Co(dbme)_2(CH_3SeCH_2CH_2NH_2)]ClO_4\cdot H_2O$ dissolved in a small amount of methanol was applied on a column of D-TA(ES)-Toyopearl[6] (ϕ1.7 cm×30 cm; eluent: 0.02 mol dm^{-3} sodium (*R*,*R*)-tartrate in 70% methanol-30% water). A recycling chromatographic technique was employed. After three times of recycling, the first and the last fractions of the band showed CD spectra almost mirror image of each other in the region of 340—600 nm, indicating partial resolution of the complex.

Kinetic Studies. Kinetics of epimerization of $[Co(dbme)_2(CH_3SeCH_2CH_2NH_2)]^+$ was studied by a method similar to those for $[Co(acac, Clacac, or Meacac)_2(CH_3SeCH_2CH_2NH_2)]^+$.[3,4] Since the complex is insoluble in water, methanol was used as the solvent. Portions of the reaction mixture were withdrawn at intervals, and chromatographed with a column (ϕ 0.46 cm×15 cm) of JASCO Finepack SIL $C_{18}S$ and 0.1 mol dm^{-3} sodium dodecyl sulfate in 72.5% CH_3CN–27.5% H_2O as the eluent. The chromatography was carried out with a JASCO TRI ROTAR V system at a flow rate of 1.0 cm^3 min^{-1}, the $\Delta(R)\Lambda(S)$ isomer being eluted faster. The two isomers ($\Delta(R)\Lambda(S)$ and $\Delta(S)\Lambda(R)$) were detected at 315 nm where they give the same molar absorption coefficient and no detectable change in absorbance was observed during the epimerization reaction.

Measurements. Absorption and circular dichroism (CD) spectra were recorded on a Hitachi 323 spectrophotometer and a JASCO J-40CS spectropolarimeter, respectively. ^1H NMR spectra in $CDCl_3$ solutions were measured with a JEOL PMX-60 spectrometer using TMS as an internal reference.

Results and Discussion

Preparation and Characterization of the Complexes. Metal-acac complexes are known to be susceptible to electrophilic substitutions such as halogenation, nitration, or acetylation at the central methine of the acac chelate.[9] The $[Co(acac)_2(CH_3SeCH_2CH_2NH_2)]^+$ complex was halogenated (chlorinated, brominated) and nitrated, respectively, by *N*-halosuccinimide and a mixture of copper(II) nitrate and acetic anhydride. The ^1H NMR spectra verified the substitutions at the methine of the acac ligand. The resonances due to the methine protons in the spectrum of the parent complex disappeared completely on halogenation or nitration. The Bracac and NO_2acac complexes were unstable in solution, and the kinetics of epimerization reactions could not be studied. $[Co(Meacac or dbme)_2(CH_3SeCH_2CH_2NH_2)]^+$ was prepared by oxidizing a mixture of $[Co(Meacac or dbme)_2(H_2O)_2]$ and $CH_3SeCH_2CH_2NH_2$. The Meacac complex was easily

oxidized on exposure to the air, while the dbme complex was not formed under similar conditions and PbO_2 was used as an oxidizing agent.

Four stereoisomers, $\Delta(R)$, $\Delta(S)$, $\Lambda(R)$, and $\Lambda(S)$ are possible for the present complexes (Fig. 1). The complexes were separated into two isomers (racemic pairs of the diastereomers), $\Delta(R)\Lambda(S)$ and $\Delta(S)\Lambda(R)$, by column chromatography on SE-Toyopearl or by fractional crystallization. The structures of the isomers were assigned on the basis of the ^1H NMR spectra. Table 1 lists the ^1H NMR spectral data. In the $\Delta(R)\Lambda(S)$ isomer, the Se-methyl group is placed over one of the two acac chelate rings and the methyl protons will be shielded by the acac ring. Thus, the isomer whose Se-methyl signal is observed at a higher magnetic field is assigned to the $\Delta(R)\Lambda(S)$ isomer.

The absorption spectral data for [Co(acac, Clacac, Meacac, or dbme)$_2$($CH_3SeCH_2CH_2NH_2$)]$^+$ are given in Table 2, and the spectra are shown in Fig. 2. The spectral difference between the isomers is very small in each complex.

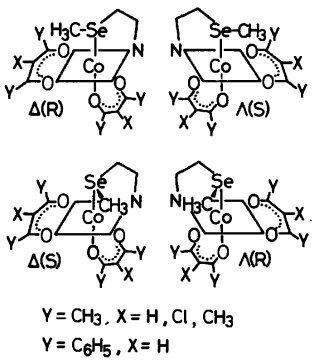

Fig. 1. The four stereoisomers of [Co(β-dik)$_2$($CH_3SeCH_2CH_2NH_2$)]$^+$.

Table 1. ^1H NMR Data for [Co(β-dik)$_2$($CH_3SeCH_2CH_2NH_2$)]$^+$ in $CDCl_3$

β-dik	Assignment	Chemical shift (Se-methyl, δ)
acac	$\Delta(R)\Lambda(S)$	1.63
	$\Delta(S)\Lambda(R)$	1.94
Clacac	$\Delta(R)\Lambda(S)$	1.60
	$\Delta(S)\Lambda(R)$	1.96
Bracac	$\Delta(R)\Lambda(S)$	1.61
	$\Delta(S)\Lambda(R)$	1.98
Meacac	$\Delta(R)\Lambda(S)$	1.53
	$\Delta(S)\Lambda(R)$	1.90—2.00[a]
dbme	$\Delta(R)\Lambda(S)$	1.49
	$\Delta(S)\Lambda(R)$	1.93

	$\Delta(S)\Lambda(R)$	2.08

a) Overlapping with the *C*-methyl signals.

The absorption spectra of the acac, Clacac, and Meacac complexes are similar to that of [Co(acac)$_2$(en)]$^+$[10,11] (en=ethylenediamine) except a strong band at 32000—33000 cm^{-1} assignable to an Se-to-Co^{III} charge transfer transition.[2,12,13] The present complexes show the first absorption band, $^1A_{1g}\rightarrow{}^1T_{1g}$ (O_h) around 17000 cm^{-1}, and a shoulder in the region of 23000—24000 cm^{-1}. [Co(acac)$_2$(en)]$^+$ also shows a shoulder at ca. 24000 cm^{-1} and it has been assigned to the second d-d absorption band, $^1A_{1g}\rightarrow{}^1T_{2g}$ (O_h).[10,11] The first d-d absorption band of [Co(β-dik)$_2$($CH_3SeCH_2CH_2NH_2$)]$^+$ shifts to lower energies as β-dik is changed from acac (17100 cm^{-1}) through Clacac (16800 cm^{-1}) to Meacac (16600 cm^{-1}). It has been reported that the intensities of the first absorption band of cobalt(III)-acac complexes increase on halogenation.[5] [Co(acac)$_2$($CH_3SeCH_2CH_2NH_2$)]$^+$ is the case.

The bands observed at energies higher than 32000 cm^{-1} in the spectra of the acac, Clacac, and

Solvent, a): H_2O, b): CH_3OH.

Meacac complexes can be assigned to the π-π^* transitions of the β-diketonate ligand[14,15] and an N-to-Co^{III} charge transfer transition. $[Co(dbme)_2(CH_3SeCH_2CH_2NH_2)]^+$ shows the first d-d absorption band at nearly the same position as that for the Clacac complex. The absorption bands observed at energies higher than 22000 cm^{-1} for the dbme complex are more intense than those for the other complexes probably because of overlapping of the intense phenyl group transitions.

Inversion at the Coordinated Selenium Atom. In a previous paper,[3] we have shown that the epimerization of $[Co(acac)_2(CH_3SeCH_2CH_2NH_2)]^+$ is caused by the inversion at the selenium atom. The related complexes, Clacac and Meacac complexes, are expected to epimerize by the same way, and the dbme complex is also suggested to epimerize in a similar way on the basis of the CD spectrum. The dbme complex was partially resolved into the enantiomers by column chromatography. The CD spectra changed only slightly during epimerization. In general, the optical activity of a metal complex is explained by the superposition of the configurational (chiral arrangement of ligands around the metal ion) and the vicinal (chiral ligand) effects, the former being larger.[16,17] These observations suggest that the small CD change is caused by inversion at the selenium atom and that the configuration around the cobalt(III) ion remains unchanged. Thus, all the complexes studied here are believed to epimerize by selenium inversion.

The epimerization of $[Co(\beta\text{-dik})_2(CH_3SeCH_2CH_2NH_2)]^+$ was studied in the temperature range of 30.3—55.0 °C. $\Delta(S)\Lambda(R)$-$[Co(acac, Clacac, or Meacac)_2(CH_3SeCH_2CH_2NH_2)]^+$ was epimerized in 0.05 mol dm^{-3} Na_2SO_4, and $\Delta(S)\Lambda(R)$-$[Co(dbme)_2(CH_3SeCH_2CH_2NH_2)]^+$ was done in methanol since the complex is insoluble in water. The rates were followed by high-performance liquid chromatography. This method has the great advantages of a short elution time and micro quantities of samples. Figure 3 shows a typical set of elution curves obtained at intervals after $\Delta(S)\Lambda(R)$-$[Co(dbme)_2(CH_3SeCH_2CH_2NH_2)]ClO_4$·$H_2O$ had been dissolved in methanol at 40.0 °C. The area of band I ($\Delta(R)\Lambda(S)$ isomer) increases whereas that of band II ($\Delta(S)\Lambda(R)$ isomer) decreases with time as the result of epimerization:

$$\Delta(R)\Lambda(S) \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \Delta(S)\Lambda(R)$$

where k_1 and k_{-1} denote the forward and reverse rate constants, respectively. In each kinetic run, the plot of $\ln[S_t^{II}/(S_t^I+S_t^{II})-S_\infty^{II}/(S_\infty^I+S_\infty^{II})]$ vs. time gave a straight line for at least three half-lives (S_t^I, S_t^{II}, S_∞^I, and S_∞^{II}

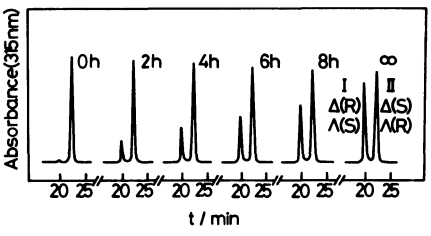

Fig. 3. Change in the elution curve during the epimerization of $\Delta(S)\Lambda(R)$-$[Co(dbme)_2(CH_3SeCH_2CH_2NH_2)]ClO_4$·$H_2O$ in methanol at 40.0 °C. Chromatographic conditions: column, JASCO Finepack SIL $C_{18}S$, ϕ0.46 cm × 15 cm; eluent, 0.1 mol dm^{-3} sodium dodecyl sulfate in 72.5% CH_3CN–27.5% H_2O; flow rate, 1.0 cm^3 min^{-1}; UV detection, 315 nm.

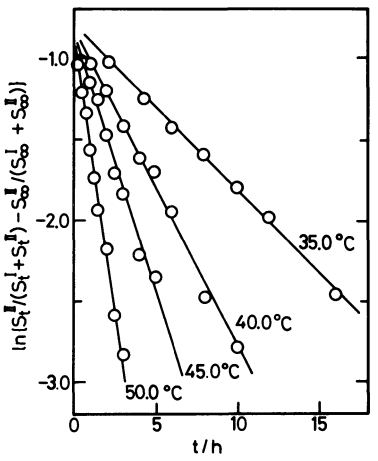

Fig. 4. The plots of $\ln[S_t^{II}/(S_t^I+S_t^{II})-S_\infty^{II}/(S_\infty^I+S_\infty^{II})]$ against time for the epimerization of $\Delta(R)\Lambda(S)$-$[Co(dbme)_2(CH_3SeCH_2CH_2NH_2)]^+$ at 35.0, 40.0, 45.0, and 50.0 °C (S_t^I, S_t^{II}, S_∞^I, and S_∞^{II} denote the areas of bands I and II at time t and at infinite time).

Solvent, a): 0.05 mol dm^{-3} Na_2SO_4, b): CH_3OH.

denote the areas of bands I and II at time t and at infinite time). The slope gave the first-order rate constant, k_{obsd} (Fig. 4). The rate constants for the epimerization were calculated from the equilibrium constant, K_{eq}, and the observed rate constant:

$$K_{eq} = k_1/k_{-1} = S_\infty^{II}/S_\infty^{I}$$
$$k_{obsd} = k_1 + k_{-1}.$$

The K_{eq} value was constant for each complex in the temperature range of 30.3—55.0 °C. The values of k_1 and k_{-1} are given in Table 3.

The racemization of $[Co(CH_3SeCH_2CH_2NH_2)(tren)]^{3+}$ and related complexes has been suggested to take place intramolecularly by pyramidal inversion at the selenium atom which proceeds via a trigonal intermediate.[2] The epimerization of $[Co(\beta\text{-dik})_2(CH_3SeCH_2CH_2NH_2)]^+$ also seems to proceed intramolecularly, since the rates are independent of pH.

Eyring treatments of $\ln(k_1/T)$ and $\ln(k_{-1}/T)$ vs. T^{-1} (Fig. 5) yielded activation parameters given in Table 4. The $\Delta G^{\ddagger}_{25\,°C}$ values for inversion of $[Co(\beta\text{-dik})_2(CH_3SeCH_2CH_2NH_2)]^+$ decrease in the order β-dik=Clacac>acac>dbme>Meacac. This order coincides with the decreasing order of $\Delta H^{\ddagger}$ values. The decrease in $\Delta G^{\ddagger}_{25\,°C}$ values comes mainly from a decrease in $\Delta H^{\ddagger}$, the $\Delta S^{\ddagger}$ values making relatively small contributions. Examination of molecular models indicates that the substituents (Cl, Me, Ph) on a β-diketonate chelate ring do not induce a large steric effect on the inversion at the selenium atom. Thus the enthalpy change associated with the inversion seems to arise from the electronic influence of the substituents on β-diketonate chelate rings. This view is supported by the Hammett correlation shown in Fig. 6, where logarithms of the observed rate constants at 40 °C for the Clacac and Meacac complexes relative to that for the acac complex are plotted against the Hammett σ_p values. The aromatic character of the coordinated acac is known.[18] The data follow a straight line with a slope equal to −2.9. The result shows that the Cl (or Me) substituent of the Clacac (or Meacac) complex, which is at the para position to the central metal, withdraws (or releases) the electron on the selenium atom via the central metal to decrease (or increase) the rate. For the inversion rates at sulfur of organic sulfonium ions, it is well-known that substituents more electronegative than carbon slow the rate.[19] The Hammett relationship was also reported to hold for the proton-exchange rate of ethylenediamine of $[Co(acac, Bracac, or NO_2acac)_2(en)]^+$.[20]

If we take the pK_a value of a substituted Hacac in the enol form (Hacac: 8.23, HMeacac: 9.2, Hdbme: 9.1)[21] as a measure of the electronic effect of the substituent, then the order of $\Delta G^{\ddagger}_{25\,°C}$ and $\Delta H^{\ddagger}$ values should be related to that of the pK_a values. The $\Delta G^{\ddagger}_{25\,°C}$ and $\Delta H^{\ddagger}$ values of $[Co(\beta\text{-dik})_2(CH_3SeCH_2CH_2NH_2)]^+$ decrease in the order β-dik=acac>dbme>Meacac. The order is in accord with that of electron-

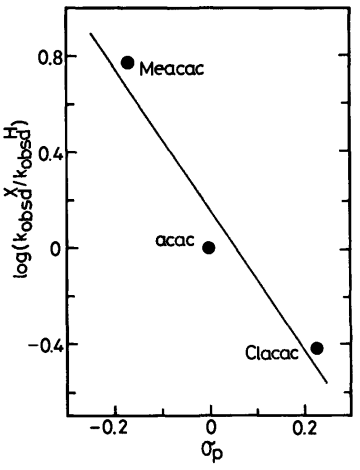

Fig. 6. Hammett's relationship for the inversion rate of $[Co(acac, Clacac, or Meacac)_2(CH_3SeCH_2CH_2NH_2)]^+$.

withdrawing tendency of the substituents predicted from the pK_a values. That the dbme and Meacac ligands increase electron density on the selenium atom via the central metal is also suggested by ^1H NMR spectra; for example, the CH_3Se- signal of the dbme complex is observed at a higher field than that of the acac complex (Table 1). Thus, the difference in inversion rate among the present complexes is explained by the difference in electron density on the selenium atom which is induced by the substituent on the β-diketonate skeleton. The inversion rate of $[Co(NO_2acac)_2(CH_3SeCH_2CH_2NH_2)]^+$, which has highly electron-withdrawing NO_2- groups (σ_p=0.78), is expected to be very slow. Unfortunately, the complex was so unstable that we could not determine the rate.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 58470032 from the Ministry of Education, Science, and Culture.

The Crystal and Molecular Structure of 6-Bromo[2.2]paracyclo-(4,8)[2. 2]metaparacyclophane

Yosuke Koizumi, Hisanori Horita, Tetsuo Otsubo, Nobutami Kasai,*,† and Soichi Misumi*

The Institute of Scientific and Industrial Research, Osaka University, Ibaraki, Osaka 567

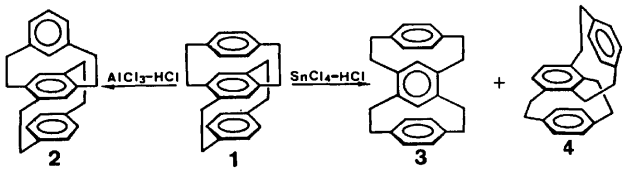
†Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

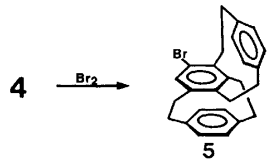
(Received February 20, 1986)

The molecular structure of the title compound has been determined by means of X-ray diffraction. $C_{26}H_{25}Br$, M 417.4, orthorhombic, space group $P2_12_12_1$, a=12.713(1), b=14.998(1), c=10.156(1) Å, V=1936.3(1) Å^3, D_m=1.43 g cm^{-3}, D_c=1.432 g cm^{-3} for Z=4.

Novel skeletal rearrangement of triple-layered [2.2]paracyclophane (**1**) to triple-layered [2.2]metaparacyclophanes (**2**—**4**) with several Friedel-Crafts acids has been reported by Misumi and coworkers.[1]

Structures of [2.2]metacyclo(4,7)[2.2]paracyclophane (**2**) and [2.2]paracyclo(4,6)[2.2]metaparacyclophane (**3**) were determined by PMR and alternative syntheses,[2]





and molecular structures of **2** and **3** have been reported recently.[3] This paper deals with the molecular structure of **5** which was derived from the third rearranged isomer, [2.2]paracyclo(4,8)[2.2]metaparacyclophane (**4**) in quantitative yield. A preliminary result of the structure has been reported.[1]

Experimental.

Colorless bipyramidal crystal, recrystallized from benzene-ethyl acetate, with approximate dimensions of 0.5× 0.5×0.5 mm was mounted on a Rigaku automated, four-circle diffractometer. Unit cell dimensions and integrated intensities were measured on the diffractometer with Zr-filtered Mo $K\alpha$ radiation (λ=0.71069 Å). Intensity data were collected by the θ—2θ scan technique: The 2θ scan rate was 2° min^{-1}, and the scan width was from $\{2\theta(\alpha_1)-0.9\}$ to $\{2\theta(\alpha_2)+0.9\}$°. Backgrounds were measured for 10 s at both ends of a scan. Five standard reflections were measured after every 50 reflections, which showed no intensity decrease during the experiment. In total, 2833 reflections out of 3416 were observed. Usual Lorentz and polarization corrections were applied but an absorption correction was ignored [μ(Mo $K\alpha$)=23.7 cm^{-1}].

Structure Solution and Refinement

The structure was solved by the heavy atom method, and refined anisotropically by the block-diagonal least-squares procedure (*HBLS* V).[4] The function minimized was $\sum w(\Delta F)^2$. Hydrogen atoms were located on the calculated positions, which were confirmed on the difference Fourier map. They were refined isotropically. The R value converged to 0.080 for non-zero (0.117 for all) reflections. The weighting schemes used were $w=(F_{max}/|F_o|)^2$ for $|F_o| \geqq F_{max}$, w=1 for $|F_o| < F_{max}$, and w=0.1 for $|F_o|$=0. Atomic parameters are listed in Table 1.††

†† Tables of anisotropic temperature factors, coordinates of hydrogen atoms, and observed and calculated structure factors are kept at the Chemical Society of Japan, Document No. 8646.

Atomic scattering factors used were taken from International Tables for X-Ray Crystallography.[6] Calculations were done mainly on a NEAC 2200—500 computer at the Computation Center, Osaka University, and at the final stage an ACOS 850 computer was used at the Crystallographic Research Center, Institute for Protein Research, Osaka University.

Results and Discussion

Molecular Structure. Structure of the molecule[7] is shown in Fig. 1. Bond distances and bond angles are given in Fig. 2. Both the upper and lower layer benzene rings are in boat form. The deformation angles[3] p_1 and q_1 at the C(3) atom (Fig. 3) are 11.6 and 16.4°, p_2 and q_2 at the C(6) 12.7 and 14.9°, p_3 and q_3 at the C(19) 11.7 and 16.0°, and p_4 and q_4 at the C(22) 13.6 and 13.7°. These benzene rings have normal bond distances [av. 1.387 and 1.390 Å]. Among the bond angles in these rings, the inner angles at the bow and stern of the boat form show a tendency to have the smaller angles than 120°, though it is not fully significant: C(4)-C(3)-C(8)=117.3(8), C(5)-C(6)-C(7)=118.7(8), C(20)-C(19)-C(24)=116.7(8), and C(21)-C(22)-C(23)=118.1(8)°.

Regio- and Stereochemistry of Bromochlorinations of Alkynes with Molecular Bromine Chloride and Dichlorobromate(1−) Ion

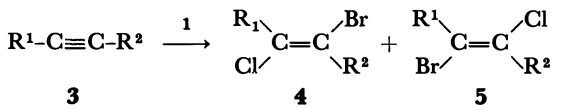
Takeshi NEGORO* and Yoshitsugu IKEDA
Department of Chemistry, Faculty of Education, Wakayama University,
Sakaedani, Wakayama 640
(Received April 15, 1986)

The bromochlorination of phenyl- and alkyl-substituted acetylenes with tetrabutylammonium dichlorobromate(1−) (**1**) in dichloromethane was found to be *anti*-stereospecific and nonregiospecific (regiospecific in the case of phenylacetylene). Whereas the addition of molecular bromine chloride (**2**) to phenyl-substituted acetylenes was found to give nonstereospecific and regiospecific adducts, the reaction of alkyl-substituted acetylenes gave *anti*-stereospecific and nonregiospecific adducts. These results suggest that the addition of **1** involves an attack of chloride ion to a three-centered π-complex in the product-forming stage, and that the addition of **2** to phenyl-substituted acetylenes involves a vinyl cation intermediate (but a bridged bromonium ion intermediate in the case of alkyl-substituted acetylenes).

The stereochemistry of bromine addition to alkynes has been known to markedly depend both on reaction conditions and on the structure of alkynes.[1,2] *Anti*-stereospecific addition was observed for the bromination of alkynes in the presence of bromide ion.[1,2] However, only a few scattered data have been made available on the bromochlorination of alkynes. The reaction of diphenylacetylene,[3] ethyl 3-butynoate,[4] or 1-hexyne[5] with molecular bromine chloride (**2**) has been reported to give the corresponding bromo chloro adducts in an *anti*-stereospecific manner. We have reported that tetrabutylammonium dichlorobromate-(1−) (**1**) reacted with phenyl- or alkyl-substituted ethylenes to give bromo chloro adducts in nearly quantitative yields, and that the addition took place in an *anti*-stereospecific manner,[6,7] while that the regio- and stereochemistries of the bromochlorination of alkenes[6,7] or dienes[8] with **1** are strikingly different from those with **2**. As a continuation of our studies, we have studied on the regio- and stereochemistries of the reaction of **1** and **2** with various alkynes.

Results and Discussion

The reaction of 1-phenylpropyne (**3a**), 1-hexyne (**3c**), or 2-hexyne (**3d**) with tetrabutylammonium dichlorobromate(1−) (**1**) in CH_2Cl_2 gave a mixture of (*E*)-Markownikoff and (*E*)-*anti*-Markownikoff adducts (**4a**, **c**, and **d** and **5a**, **c**, and **d**, respectively) in nearly quantitative yields (Scheme 1 and Table 1).



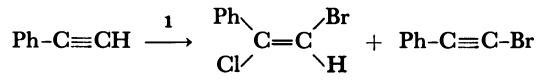
3 **4** **5**

a: R^1=Ph, R^2=Me **c**: R^1=*n*-Bu, R^2=H
d: R^1=*n*-Pr, R^2=Me

Scheme 1.

Similarly, treatments of symmetrical alkynes such as diphenylacetylene (**3e**: R^1=R^2=Ph) and 3-hexyne (**3f**: R^1=R^2=Et) with **1** also gave the corresponding bromo chloro adducts (**4e** and **4f**, respectively) in an *anti*-stereospecific manner (Table 1).

On the other hand, the reaction of phenylacetylene (**3b**: R^1=Ph, R^2=H) with **1** gave a mixture of (*E*)-2-bromo-1-chloro-1-phenylethene (**4b**) and 1-bromo-2-phenylethyne (**6b**) (Scheme 2 and Table 1).



3b **4b** **6b**

Scheme 2.

The formation of **6b** cannot be ascribed to the subsequent secondary reaction of **4b**, since prolonged reaction time did not cause any change in the ratio of the products. Further, the bromo chloro adduct **4b** was stable under the reaction conditions. Formation

a) Reactions were carried out with 20 mmol of **1**, 20 mmol of **3**, and 50 ml of CH_2Cl_2 at 20 °C. b) Percentages are normalized to 100%. Determined by ^{1}H NMR analysis. c) Isolated yield. Yields in parentheses were determined by ^{1}H NMR using 1,2-dibromo-1-phenylethane as the internal standard. d) M=Markownikoff adduct (**4**). *a*M=*anti*-Markownikoff adduct (**5**). e) The other product was 1-bromo-2-phenylethyne (**6b**, 58%). Determined by GLC analysis.

of 1-bromo-2-phenylethyne (**6b**) has already been reported for the reaction of **3b** with bromine.[2]

Although attempts to separate two regioisomers (**4** and **5**) were unsuccessful, the orientation of halogen atoms was elucidated mainly on the basis of the chemical shifts of the protons in the ^{1}H NMR spectra of the adducts. The structures of **4** and **5** have been determined by a comparison of their ^{1}H NMR or ^{13}C NMR spectra with those of the corresponding dibromo and dichloro adducts. It has been known that the proton β to a bromine atom is deshielded relative to the one β to a chlorine atom, and that the proton α to a chlorine atom is deshielded relative to the one α to a bromine atom.[5,9] Thus, the methyl protons of **4a** give δ=2.56 but those of **5a** δ=2.45, in agreement with the observation that the methyl protons (δ=2.60) of (*E*)-1,2-dibromo-1-phenylpropene are deshielded relative to those (δ=2.41) of (*E*)-1,2-dichloro-1-phenylpropene. Similarly, the methyl protons (=C-CH_3) of **4d** give δ=2.38 but those of **5d** δ=2.27 (Experimental). Control experiments revealed that all the bromo chloro adducts are stable under the reaction conditions.

Treatments of alkynes (**3a** and **3b**) with molecular bromine chloride (**2**) in CH_2Cl_2 gave the corresponding (*E*)- and (*Z*)-Markownikoff adducts (**4** and **4'**) in a regiospecific and nonstereospecific manner (Scheme 3 and Table 2).

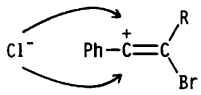
a) Reactions were carried out with 10 mmol of **2**, 20 mmol of **3**, and 50 ml of CH_2Cl_2 at 20 °C. b) Percentages are normalized to 100%. Determined by ^{1}H NMR analysis. Yields in parentheses were determined by GLC analysis. c) Determined by GLC analysis. d) M=Markownikoff adduct. *a*M=*anti*-Markownikoff adduct. e) Determined by ^{13}C NMR analysis. f) Ref. 3. Isolated yield.

As with the reaction with **1**, the reaction of alkyl-substituted acetylenes (**3c** and **3d**) with **2** gave a mixture of (*E*)-Markownikoff and (*E*)-*anti*-Markownikoff adducts (**4** and **5**) in a nonregiospecific and *anti*-stereospecific manner, and the reaction of 3-hexyne (**3f**) gave the *anti*-stereospecific adduct (**4f**) (Table 2). The yields of the bromo chloro adducts were lower than those in the reaction of **1** because dibromo- and dichloroalkenes were formed as by-products in every case.

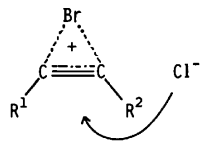
An inspection of the data in Tables 1 and 2 clearly reveals that the regio- and stereochemistries of the bromochlorinations of alkynes depend greatly both on the structure of alkynes and on the bromochlorinating agents employed. Therefore, the electronic structure of the intermediate in the product-forming step must depend both on the substituent on the acetylene linkage and on the bromochlorinating agents.

Regio- and Stereochemistries of the Reaction of 3 with 2. As shown in Table 2, the addition of molecular bromine chloride (**2**) to phenyl-substituted alkynes such as **3a** and **3b** is nonstereospecific and regiospecific. This result can be explained by assuming a mechanism involving the attack of chloride ion on an open vinyl cation intermediate **7**, in which the cationic character of the phenyl-substituted carbon atom is stabilized by overlap of *p*-orbitals of the phenyl group; a similar reaction intermediate has been suggested for the bromination of these alkynes with molecular bromine.[1,2]



(7)

On the other hand, the addition of **2** to alkyl-substituted acetylenes **3c**, **3d**, and **3f** gave only *trans*-bromo chloro adducts (Table 2). Such an *anti*-stereospecific addition of **2** to these alkynes are fully in accordance with the mechanism involving a bridged bromonium ion intermediate **8**.[2]

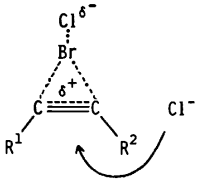


(8)

Meanwhile, the addition of **2** to monoalkyl-substituted acetylene **3c** gave the Markownikoff adduct **4c** as the major product. This implies that the attack of chloride ion on the intermediate **8** occurs at the alkyl-substituted carbon atom. Thus, the orientation of the addition of **2** would be due to the electronic effect of the alkyl substituent which stabilizes the developed cationic character on the alkyl-substituted carbon atom in the intermediate **8**.[5]

Regio- and Stereochemistries of the Reaction of 3 with 1. In contrast to the addition of **2** to alkynes, the

addition of **1** is in an *anti*-stereospecific manner irrespective of substituents on the acetylene linkage (Table 1). Thus, the addition of **1** to phenyl-substituted alkynes **3a** and **3b** gave only the *anti*-stereospecific adducts. This result cannot be explained on the basis of the mechanism involving an open vinyl cation intermediate **7** for the addition of **2** to **3a—b** as described above. We would like to suggest another possible mechanism which involves the attack of chloride ion on a three-centered π-complex intermediate **9** in a product-forming step with a very little charge development on the unsaturated carbon; a similar intermediate has been suggested for the addition of **1** to alkenes and dienes.[6-8]



(9)

Meanwhile, the addition of **1** to phenylacetylene (**3b**) gave only the regiospecific Markownikoff adduct **4b**. The addition to 1-phenylpropyne (**3a**) was in a regioselective Markownikoff manner. These results imply that the attack of chloride ion on the intermediate **9** occurs on the phenyl-substituted carbon atom. Thus, the orientation of the bromochlorination with **2** would depend on the electronic effect of phenyl substituent which stabilizes the developed cationic character on the phenyl-substituted carbon atom in the intermediate **9**. The addition of **1** to 1-hexyne (**3c**) gave the regioselective Markownikoff adduct **4c**. Thus, the orientation of addition with **1** can be influenced also by the electronic effect of the alkyl substituent.

Experimental

All the melting points and boiling points are uncorrected. NMR spectra were recorded on a JEOL JNM FX-60Q and a JEOL C-60HL spectrometer, with TMS as the internal standard. Mass spectra were recorded on a JMS-D-300 mass spectrometer. GLC analyses were performed on a Yanako G-180 gas chromatograph with a Silicone SE-30(10%)-Chromosorb WAW DMCS (2 m) column, with helium as the carrier gas. All the organic starting materials, including the solvents, were distilled just before use.

Tetrabutylammonium dichlorobromate(1−) (**1**) was prepared by the known procedure.[10] Bromine chloride (**2**) was prepared by adding an equimolar amount of bromine to a chlorine-carbon tetrachloride solution.

Reaction of Alkynes with 1. General Procedure: To a solution of **3** (20 mmol) in dichloromethane (50 ml) was added **1** (7.87 g, 20 mmol) at 20 °C over 20 min with stirring. After the yellow color disappeared, the reaction mixture was washed with water and dried over Na_2SO_4. After the solvent was removed by evaporation, the products were purified by distillation. The results are shown in Table 1. Although attempts to separate **4** and **5** were unsuccessful, these structures were determined by a comparison of their ^1H NMR spectra (^{13}C NMR spectra in some cases) with those of the corresponding dibromo and dichloro analogs.

A Mixture of (*E*)-2-Bromo-1-chloro- and (*E*)-1-Bromo-2-chloro-1-phenylpropenes (4a and 5a) from 1-Phenylpropyne (3a): Bp 78—79 °C/2 mmHg (1 mmHg=133.322 Pa); MS *m/z* (rel intensity) 230 (M^+; 100), 232 (135), and 234 (32). Found: *m/z* 229.9488. Calcd for C_9H_8BrCl: M, 229.9498. ^1H NMR ($CDCl_3$) (an asterisk indicates **5a**) δ=2.45,* 2.56 (3H, s, CH_3), and 7.30—7.40 (5H, m, C_6H_5). These assignments were supported for the dibromo and dichloro analogs as follows: (*E*)-1,2-dibromo-1-phenylpropene, ^1H NMR ($CDCl_3$) δ=2.60 (3H, s, CH_3) and 7.20—7.40 (5H, m, C_6H_5); (*E*)-1,2-dichloro-1-phenylpropene, ^1H NMR ($CDCl_3$) δ=2.41 (3H, s, CH_3) and 7.20—7.50 (5H, m, C_6H_5).

(*E*)-2-Bromo-1-chloro-1-phenylethene (4b) and 1-Bromo-2-phenylethyne (6b) from Phenylacetylene (3b): **4b**: bp 85—90 °C/6 mmHg; MS *m/z* (rel intensity) 216 (M^+; 100), 218 (128), and 220 (32). Found: *m/z* 215.9310. Calcd for C_8H_6BrCl: M, 215.9342. ^1H NMR ($CDCl_3$) δ=6.56 (1H, s, CH) and 7.30—7.67 (5H, m, C_6H_5). **6b**: bp 76—78 °C/6 mmHg (lit,[11] bp 40—41 °C/0.1 mmHg); MS *m/z* (rel intensity) 180 (M^+; 100) and 182 (100). Found: *m/z* 179.9550. Calcd for C_8H_5Br: M, 179.9575. ^1H NMR ($CDCl_3$) δ=7.28—7.53 (m, C_6H_5). The ^1H NMR spectrum of **4b** corresponds well with that reported in the literature.[12]

A Mixture of (*E*)-1-Bromo-2-chloro- and (*E*)-2-Bromo-1-chloro-1-hexenes (4c and 5c): Bp 55—56 °C/25 mmHg; MS *m/z* (rel intensity) 196 (M^+; 100), 198 (132), and 200 (32). Found: *m/z* 195.9648. Calcd for $C_6H_{10}BrCl$: M, 195.9655. ^1H NMR ($CDCl_3$) (an asterisk indicates **5c**) δ=0.75—1.10 (3H, br. t), 1.15—1.90 (4H, m), 2.40—2.80 (2H, m), 6.20, and 6.27* (1H, 2s); ^{13}C NMR ($CDCl_3$) (an asterisk indicates **5c**) δ=13.8, 21.6, 21.7,* 28.5,* 29.2, 34.5, 34.9,* 101.1,* 114.8, 127.0, and 136.9.* The ^1H and ^{13}C NMR of a mixture (**4c** and **5c**) correspond well with those reported in the literature.[5]

A Mixture of (*E*)-2-Bromo-3-chloro- and (*E*)-3-Bromo-2-chloro-2-hexenes (4d and 5d) from 2-Hexyne (3d): Bp 35—36 °C/5 mmHg; MS *m/z* (rel intensity) 196 (M^+; 100), 198 (133), and 200 (32). Found: *m/z* 195.9650. Calcd for $C_6H_{10}BrCl$: M, 195.9655. ^1H NMR ($CDCl_3$) (an asterisk indicates **5d**) δ=0.93 (3H, t, *J*=7.3 Hz), 1.18—1.79 (2H, m), 2.27,* 2.38 (3H, 2s), and 2.43—2.74 (2H, m); ^{13}C NMR ($CDCl_3$) (an asterisk indicates **5d**) δ=13.0,* 13.1, 20.3, 20.9,* 25.8,* 25.9, 39.6,* 40.1, 115.9, 121.7,* 125.4,* and 130.5. These assignments were supported for the dibromo and dichloro analogs as follows: (*E*)-2,3-dibromo-2-hexene: ^1H NMR ($CDCl_3$) δ=0.94 (3H, t, *J*=6.7 Hz), 1.28—1.85 (2H, m), 2.41 (3H, s), and 2.65 (2H, t, *J*=7.2 Hz); ^{13}C NMR ($CDCl_3$) δ=13.0, 20.8, 28.8, 42.4, 115.2, and 121.8. (*E*)-2,3-dichloro-2-hexene: ^1H NMR ($CDCl_3$) δ=0.93 (3H, t, *J*=6.7 Hz), 1.26—1.88 (2H, m), 2.00 (3H, s), and 2.52 (2H, t, *J*=7.2 Hz); ^{13}C NMR ($CDCl_3$) δ=13.1, 20.2, 23.2, 37.5, 124.9, and 129.9.

(*E*)-1-Bromo-2-chloro-1,2-diphenylethene (4e) from Diphenylacetylene (3e): Mp 170—172 °C (lit,[3] 173—175 °C); ^1H NMR ($CDCl_3$) δ=7.30—7.66 (m, $2C_6H_5$); ^{13}C NMR ($CDCl_3$) δ=117.7, 128.2, 128.8, 129.0, and 129.1.

(*E*)-3-Bromo-4-chloro-3-hexene (4f) from 3-Hexyne (3f): Bp 55—57 °C/25 mmHg; MS *m/z* (rel intensity) 196 (M^+;

100), 198 (130), and 200 (33). Found: *m/z* 195.9649. Calcd for $C_6H_{10}BrCl$: M, 195.9655. ^1H NMR ($CDCl_3$) δ=1.10 (6H, t, J=7.3 Hz) and 2.41—2.83 (4H, m); ^{13}C NMR ($CDCl_3$) δ=11.4, 12.2, 31.7, 32.2, 122.1, and 130.8.

Reaction of Alkynes (3) with Bromine Chloride (2). To a solution of **3** (20 mmol) in CH_2Cl_2 (50 ml) was added 5.5 ml of BrCl (**2**) solution in CCl_4 (1.8 mol dm^{-3}) at 20 °C over 5 min with stirring. After the reaction completed, the solvent and unreacted alkyne were removed under reduced pressure and the residues were analyzed by GLC and ^1H NMR or ^{13}C NMR. The results are given in Table 2. In all cases, GLC analyses showed the presence of 11—15% of the dichloro adduct and 12—17% of the dibromo adduct as by-products.

The reaction of 1-phenylpropyne (**3a**) with **2** gave a mixture of (*E*)-2-bromo-1-chloro- and (*Z*)-2-bromo-1-chloro-1-phenylpropenes (**4a** and **4a'**, 69%) (**4a**:**4a'**=78:22) with dichloro and dibromo adducts (31%) by GLC analysis. After the bromo chloro adducts were separated by distillation, a column chromatography (silica gel, with hexane as the eluent) of the mixture of **4a** and **4a'** gave almost pure **4a** and **4a'**. **4a**: MS *m/z* (rel intensity) 230 (M^+; 100), 232 (132), and 234 (32). Found: *m/z* 229.9487. Calcd for C_9H_8BrCl: M, 229.9498. ^1H NMR ($CDCl_3$) δ=2.56 (3H, s, CH_3) and 7.30—7.40 (5H, m, C_6H_5). **4a'**: MS *m/z* (rel intensity) 230 (M^+; 100), 232 (133), and 234 (30). Found: *m/z* 229.9485. Calcd for C_9H_8BrCl: M, 229.9498. ^1H NMR ($CDCl_3$) δ=2.32 (3H, s, CH_3) and 7.30—7.40 (5H, m, C_6H_5).

The reaction of phenylacetylene (**3b**) with **2** gave a mixture of (*E*)-2-bromo-1-chloro- and (*Z*)-2-bromo-1-chloro-1-phenylethenes (**4b** and **4b'**, 70%) (**4b**:**4b'**=63:37 by ^1H NMR analysis) with dichloro and dibromo adducts (26%) and a small amount of 1-bromo-2-phenylethyne (**6b**, 4%) by GLC analysis. Although the isolation of **4b** and **4b'** was not carried out, the retention time of GLC and the ^1H NMR (δ=6.56, vinyl proton of **4b** and δ=6.82, vinyl proton of **4b'**) agreed with those of a sample prepared by the reaction of **3b** with copper(II) chloride and bromine.[12]

The authors sincerely wish to thank Professor Shigeru Oae of Okayama University of Science for his kind guidance.

Bromochlorination of Alkenes with Dichlorobromate(1−) Ion. V. Regio- and Stereochemistry for the Bromochlorination of Styrene Derivatives with Dichlorobromate(1−) Ion in Protic Solvents

Takeshi NEGORO* and Yoshitsugu IKEDA
Department of Chemistry, Faculty of Education, Wakayama University, Sakaedani, Wakayama 640
(Received April 24, 1986)

The bromochlorination of styrene derivatives with tetrabutylammonium dichlorobromate(1−) (**1**) in such protic solvents as acetic acid and methanol gives the corresponding bromo chloro adducts along with substantial amounts of solvent-incorporated products in a regiospecific manner (regioselective in the case of 3-nitro- or 2-chlorostyrenes). The reaction of 1-phenylpropenes with **1** gives nonstereospecific but regiospecific adducts. These results suggest that the addition of **1** to styrene derivatives in protic solvents involves an attack of chloride ion or solvent molecule to a bromonium ion intermediate.

In this series of studies, we have reported that the regiochemistry of the bromochlorination of alkenes with tetrabutylammonium dichlorobromate(1−) (**1**) is very sensitive to the structure of alkenes.[1-4] Meanwhile, the regio- and stereochemistries of the reaction of phenyl-substituted alkenes with **1** have been reported to be independent of the solvent polarity when the reaction is carried out in aprotic solvents.[1,2] However, only a few studies have been carried out on the addition of **1** to these alkenes in protic solvents.[1] As a continuation of our studies, the present work was initiated to examine the effect of protic solvents on the regio- and stereochemistries of the addition of **1** to styrene derivatives.

Results and Discussion

The reaction of $(n\text{-}C_4H_9)_4NBrCl_2$ (**1**) with styrene derivatives **2a—f** in acetic acid gave the corresponding bromo chloro compounds **3a—f** along with substantial amounts of solvent-incorporated products **4a—f** in good yields (Scheme 1 and Table 1).

$$\underset{\mathbf{2}}{XC_6H_4CH{=}CH_2} + \mathbf{1} \longrightarrow \underset{\mathbf{3}}{XC_6H_4CHClCH_2Br} + \underset{\mathbf{4}}{XC_6H_4CH(OCOCH_3)CH_2Br}$$

e: X=3-Cl **f**: X=4-Br

Scheme 1.

Table 1. Bromochlorination of **2** with **1** in Acetic Acid[a]

Alkene	Product composition/%[b]		
2	**3**	**3′**	**4**
2a	66.7(65.4)	0	33.3(34.6)
2b	72.2(70.0)	0	27.8(30.0)
2c	72.4(71.4)	0	27.6(28.6)
2d	69.8(70.0)	0	30.2(30.0)
2e	72.7(71.2)	0	27.3(28.8)
2f	72.9(71.6)	0	27.1(28.4)
2g	66.3	2.0	31.7
2h	71.8	6.8	21.4
2i	64.8[c]	0	35.2
2j	66.7[d]	0	33.3

a) Reactions were carried out with 10 mmol of **1**, 10 mmol of **2**, and 20 ml of acetic acid at 20 °C. b) Determined by ^1H NMR analysis. Figures in parentheses represent the product compositions determined by GLC analysis. Percentages are normalized to 100%. Total yields were found to be more than 80% in all runs. c) A mixture of **3i** (89.5%) and **3j** (10.5%). d) A mixture of **3i** (11.5%) and **3j** (88.5%).

On the other hand, the reaction of 2-chloro- and 3-nitrostyrenes (**2g** and **2h**) with **1** gave a mixture of two regioisomers, **3g** and **3h** and **3g′** and **3h′**, and **4g** and **4h**, respectively (Scheme 2 and Table 1).

$$\underset{\mathbf{2}}{XC_6H_4CH{=}CH_2} + \mathbf{1} \longrightarrow \underset{\mathbf{3}}{XC_6H_4CHClCH_2Br} + \underset{\mathbf{3'}}{XC_6H_4CHBrCH_2Cl} + \underset{\mathbf{4}}{XC_6H_4CH(OCOCH_3)CH_2Br}$$

g: X=2-Cl **h**: X=3-NO_2

Scheme 2.

The solvent-incorporated products **4** were found to be formed in a completely regiospecific Markownikoff manner from all the styrene derivatives.

The reaction of *trans*-1-phenylpropene (**2i**) with **1** in acetic acid gave a mixture of *erythro*- and *threo*-2-bromo-1-chloro-1-phenylpropanes (**3i** and **3j**) along with a substantial amount of *erythro*-1-acetoxy-2-bromo-1-phenylpropane (**4i**). When *cis*-1-phenylpropene (**2j**) was allowed to react with **1**, a mixture of **3i**, **3j**, and *threo*-1-acetoxy-2-bromo-1-phenylpropane (**4j**) was obtained (Scheme 3 and Table 1).

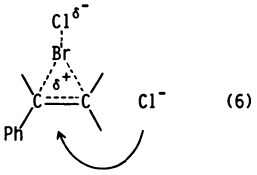
$$PhCH{=}CHCH_3 + \mathbf{1} \longrightarrow PhCHClCHBrCH_3 + PhCH(OCOCH_3)CHBrCH_3$$

2i	**3i**, 58.0%	**4i**, 35.2%
	3j, 6.8%	
2j	**3i**, 7.7%	**4j**, 33.3%
	3j, 59.0%	

Scheme 3.

The formation of the solvent-incorporated products **4** cannot be ascribed to the subsequent secondary reaction of the bromo chloro compounds **3** with acetic acid, since prolonged reaction did not cause any change in the isomer ratio of the products.

We have previously reported that the reaction of **2d—h** with **1** in chloroform occurred in a nonregiospecific manner, although the Markownikoff adducts were formed mainly.[4] The reactions of *trans*- and *cis*-1-phenylpropenes (**2i** and **2j**) with **1** have been found to proceed in an *anti*-stereospecific and nonregiospecific manner in aprotic solvents.[2] Therefore, we have suggested that the addition of **1** to alkenes in aprotic solvents involves a rate- and product-determining attack of chloride ion on a three-center bound π-complex **6**.



(6)

As shown in Table 1, the regio- and stereochemistries of the reaction of **2** with **1** in acetic acid are very different from those of the previous reaction in aprotic solvents.[2,4] Obviously, a different product-determining step is involved in the reaction in acetic acid.

Furthermore, in order to determine the effect of solvent on the regiochemistry of the addition, the reactions of **2e** or **2h** with **1** have been investigated in various solvents. Table 2 presents the data on the effect of solvents on the regiochemistry of bromo chloro adducts obtained from the reactions of **2e** or **2h** with **1**. No change in the regiochemistry has been observed with the reactions in the aprotic solvents. Similar regiochemical results have been observed previously for the reactions of **2i** and **2j**.[2]

On the other hand, the reaction of 3-chlorostyrene (**2e**) in methanol gave a solvent-incorporated product, 2-bromo-1-(3-chlorophenyl)-1-methoxyethane (**5e**, 78%) as the major product. In analogy with the reaction in acetic acid, the resulting bromo chloro adduct **3e** (22%) was found to be formed in a regiospecific Markownikoff manner. Similarly, the reaction of 3-nitrostyrene (**2h**) in methanol also gave 2-bromo-1-methoxy-1-(3-nitrophenyl)ethane (**5h**, 73%) along with a mixture of **3h** and **3h'** (**3h**:**3h'**=93:7) (Table 2).

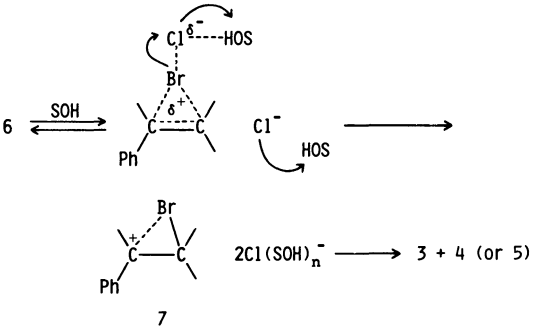
As shown in Table 2, the reaction in protic solvents proceeded in a more regioselective (or regiospecific) manner than the reaction in aprotic solvents. The effect of protic solvents on the regiochemistry cannot be related to the dielectric constant of the medium, since in both acetic acid and ethyl acetate having similar dielectric constants, the regiochemistry was different, whereas chloroform and acetic anhydride have different dielectric constants but gave similar regiochemical results.

Table 2. Regiochemistry of Bromo Chloro Adducts Obtained from the Reactions of **2e** or **2h** with **1** in Various Solvents[a]

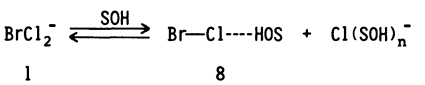
Solvent	Dielectric constant[c]	Product composition/%[b] from **2e**		from **2h**	
		3e	**3e'**	**3h**	**3h'**
$CHCl_3$	4.81	87.6	12.4	71.3	28.7
$CH_3COOC_2H_5$	6.02	87.2	12.8	69.1	30.9
CH_2Cl_2	9.08	87.0	13.0	71.7	28.3
$(CH_3CO)_2O$	20.7	87.7	12.3	70.0	30.0
CH_3COOH[d]	6.19	100	0	91.3	8.7
CH_3OH[e]	32.6	100	0	93.1	6.9

a) At 0 °C. b) Determined by ^1H NMR analysis. Percentages are normalized to 100%. c) J. A. Riddick and E. E. Toops, "Technique of Organic Chemistry," ed by A. Weissberger, Interscience, New York (1955), Vol. VII. d) At 20 °C. From the data of Table 1. e) The yield of **3e** was 22%. The yield of a mixture of **3h** and **3h'** was 27%.

Two different mechanisms can account for the role of such protic solvents as acetic acid and methanol. They are indicated in Schemes 4 and 5.



Scheme 4.



Scheme 5.

According to Scheme 4, the major role of protic solvent is assumed to be the solvation of the external chloride ion (Cl^-) in a three-center bound π-complex **6**, and promoting the ionization of **6** by stabilizing the negatively polarized chlorine atom ($Br^{\delta+}\cdots Cl^{\delta-}$) via hydrogen bonding. The solvent molecule may then assist catalytically the bromine-chlorine bond cleavage, followed by the formation of the cationic intermediate **7**. Evidence for such a specific role of the solvent has been observed by Dubois et al.[5] for the bromination of 1-pentene in methanol.

In Scheme 5, we assume the initial formation of solvated BrCl **8** and chloride ion by the solvation of $BrCl_2^-$ (**1**) in protic solvent. The solvated BrCl **8** thus formed is assumed to react with alkene (**2**) to give the cationic intermediate **7**, which is in turn attacked by chloride ion or solvent molecule to form a mixture of **3** and **4** (or **5**). Although we cannot decide by which mechanism the reactions proceed, the present results clearly show that the addition of **1** to alkenes in protic solvent proceeds via a cationic intermediate **7** prior to the product-determining step.

The regiochemical results in protic solvents (Tables 1 and 2) show that all the styrene derivatives (except **2g** and **2h**) were attacked by chloride ion exclusively on the phenyl-substituted carbon atom of the double bond. Furthermore, the addition of 1-phenylpropenes (**2i** and **2j**) was nonstereospecific, although the trans-addition product was formed mainly (Scheme 3). These results would be taken as evidence supporting that such a cationic intermediate resembles a weakly bridged benzylic carbonium ion intermediate **7**.[6] In the case of the reaction of **2h**, the formation of *anti*-Markownikoff adduct **3h′** would suggest that the intermediate resembles a fully bridged bromonium ion. A similar intermediate has been suggested for the bromination of 3-nitro- and 4-nitrostyrenes in acetic acid.[7] In the case of 2-chlorostyrene (**2g**), a small amount of *anti*-Markownikoff adduct **3g′** was also isolated in the reaction in acetic acid (Table 1). Probably, the formation of this product is due to the combination of polar and steric effects.

Experimental

NMR spectra were recorded on a JEOL JNM FX-60Q and a JEOL C-60HL spectrometer, using TMS as the internal standard. GLC analyses were performed on a Yanako G-180 gas chromatograph with a Silicone SE-30(2.5%)-Chromosorb WAW DMCS (2 m) column, with helium as the carrier gas. All the organic starting materials, including the solvents, were distilled before use. Tetrabutylammonium dichlorobromate(1−) (**1**) was prepared by the known procedure.[8]

Reaction of 2a—j with 1 in Acetic Acid. General Procedure: To a solution of **2** (10 mmol) in acetic acid (20 ml) was added **1** (3.93 g, 10 mmol) at 20 °C over 5 min with stirring. After the yellow color disappeared, the product was isolated by pouring the reaction mixture into a cold saturated aq NaCl solution, followed by extraction with ether (200 ml) and washing with aq $NaHCO_3$ and then with water. The ethereal extract was dried over $MgSO_4$ and concentrated. The crude products were subjected to GLC and NMR. All the results are given in Table 1. Furthermore, the crude products were separated by column chromatography (silica gel) with hexane-ether as the eluent. The structures of the bromo chloro adducts **3** and **3′** were determined by a comparison of their GLC and NMR spectra with those of the authentic samples prepared by the reaction of **1** with styrene derivatives **2** in chloroform.[4] The spectral data of each bromo chloro adduct have been reported in the previous papers.[2,4] The structures of the acetoxy bromide (**4**) were determined by a comparison of their GLC and NMR spectra with those of the authentic samples prepared by the reaction of **2** with bromine in acetic acid.[9] The spectral data are as follows.

1-Acetoxy-2-bromo-1-phenylethane (4a): ^1H NMR ($CDCl_3$) δ=2.12 (3H, s, $OCOCH_3$), 3.61, 3.62 (2H, 2d, J=5.9 and 7.0 Hz, CH_2Br), 5.97 (1H, approx. t, CH), and 7.34 (5H, s, C_6H_5); ^{13}C NMR ($CDCl_3$) δ=20.9, 34.2, 74.7, 126.4, 128.5, 128.6, 137.5, and 169.6.

1-Acetoxy-2-bromo-1-(4-methylphenyl)ethane (4b): ^1H NMR ($CDCl_3$) δ=2.11 (3H, s, $OCOCH_3$), 2.33 (3H, s, CH_3), 3.59, 3.60 (2H, 2d, J=5.9 and 7.3 Hz, CH_2Br), 5.95 (1H, approx. t, CH), and 7.26 (4H, s, C_6H_4); ^{13}C NMR ($CDCl_3$) δ=21.0, 21.2, 34.2, 74.8, 126.5, 129.3, 134.7, 138.6, and 169.7.

1-Acetoxy-2-bromo-1-(4-fluorophenyl)ethane (4c): ^1H NMR ($CDCl_3$) δ=2.12 (3H, s, $OCOCH_3$), 3.58, 3.59 (2H, 2d, J=6.1 and 7.2 Hz, CH_2Br), 5.94 (1H, approx. t, CH), and 6.9—7.6 (4H, m, C_6H_4); ^{13}C NMR ($CDCl_3$) δ=20.9, 34.1, 74.1, 114.9, 116.4, 128.1, 128.7, 133.4, 133.6, 154.5, 169.6, and 170.9.

1-Acetoxy-2-bromo-1-(4-chlorophenyl)ethane (4d): ^1H NMR ($CDCl_3$) δ=2.12 (3H, s, $OCOCH_3$), 3.57, 3.58 (2H, 2d, J=5.9 and 6.7 Hz, CH_2Br), 5.93 (1H, approx. t, CH), and 7.31 (4H, s, C_6H_4); ^{13}C NMR ($CDCl_3$) δ=20.8, 33.8, 74.0, 127.9, 128.8, 134.6, 136.1, and 169.6.

1-Acetoxy-2-bromo-1-(3-chlorophenyl)ethane (4e): ^1H NMR ($CDCl_3$) δ=2.14 (3H, s, $OCOCH_3$), 3.58 (2H, d, J=6.3 Hz, CH_2Br), 5.93 (1H, t, J=6.3 Hz, CH), and 7.28 (4H, br. s, C_6H_4); ^{13}C NMR ($CDCl_3$) δ=20.9, 33.8, 74.0, 124.8, 126.6, 128.9, 129.9, 134.5, 139.6, and 169.5.

1-Acetoxy-2-bromo-1-(4-bromophenyl)ethane (4f): ^1H NMR ($CDCl_3$) δ=2.12 (3H, s, $OCOCH_3$), 3.58 (2H, d, J=6.3 Hz, CH_2Br), 5.91 (1H, t, J=6.3 Hz, CH), and 7.13—7.68 (4H, m, C_6H_4); ^{13}C NMR ($CDCl_3$) δ=20.8, 33.7, 74.0, 122.7, 128.2, 131.8, 136.6, and 169.4.

1-Acetoxy-2-bromo-1-(2-chlorophenyl)ethane (4g): ^1H NMR ($CDCl_3$) δ=2.17 (3H, s, $OCOCH_3$), 3.63, 3.68 (2H, 2d, J=6.9 and 4.4 Hz, CH_2Br), 6.36 (1H, q, 6.9 and 4.4 Hz, CH), and 7.20—7.70 (4H, m, C_6H_4); ^{13}C NMR ($CDCl_3$) δ=20.8, 33.1, 71.4, 127.0, 127.4, 129.7, 132.2, 135.3, and 169.3.

1-Acetoxy-2-bromo-1-(3-nitrophenyl)ethane (4h): ^1H NMR ($CDCl_3$) δ=2.18 (3H, s, $OCOCH_3$), 3.65 (2H, d, J=6.2 Hz, CH_2Br), 6.04 (1H, t, J=6.2 Hz, CH), and 7.70—8.30 (4H, m, C_6H_4); ^{13}C NMR ($CDCl_3$) δ=20.9, 33.5, 73.4, 121.5, 123.6, 129.6, 132.8, 139.6, 148.3, and 169.4.

***erythro*-1-Acetoxy-2-bromo-1-phenylpropane (4i):** ^1H NMR ($CDCl_3$) δ=1.64 (3H, d, J=6.7 Hz, CH_3), 2.15 (3H, s, $OCOCH_3$), 4.15—4.57 (1H, m, CHBr), 5.95 (1H, d, J=5.3 Hz, CH), and 7.34 (5H, s, C_6H_5); ^{13}C NMR ($CDCl_3$) δ=20.8, 20.9, 50.0, 78.2, 127.0, 128.3, 128.4, 137.1, and 169.5.

threo-1-Acetoxy-2-bromo-1-phenylpropane (4j): ^{1}H NMR ($CDCl_3$) δ=1.53 (3H, d, J=6.7 Hz, CH_3), 2.11 (3H, s, $OCOCH_3$), 4.08—4.56 (1H, m, CHBr), 5.82 (1H, d, J=7.8 Hz, CH), and 7.34 (5H, s, C_6H_5); ^{13}C NMR ($CDCl_3$) δ=21.0, 22.4, 50.5, 79.2, 127.1, 128.5, 128.6, 137.1, and 169.5.

Reaction of 2e and 2h with 1 in Aprotic Solvents. To a solution of the alkene (10 mmol) in the solvent (20 ml) was added 10 mmol of **1** at 0 °C over 5 min with stirring. After the yellow color disappeared, the mixture was washed with water and dried over Na_2SO_4. The product of the reaction in acetic anhydride was isolated by pouring the reaction mixture into water, followed by extraction with ether (200 ml) and washing with aq $NaHCO_3$ and then with water. After the solvent was evaporated, the residues were analyzed by ^{1}H NMR. The relative amounts of products were determined from the ratio of the peak areas of the methylene protons of the bromo chloro adducts **3** and **3'**.[4] The results are given in Table 2.

Reaction of 2e and 2h with 1 in Methanol. To a solution of the alkene (10 mmol) in methanol (20 ml) was added **1** (10 mmol) at 0 °C over 5 min with stirring. The solvent was removed by evaporation and ether (200 ml) was added to the residue. The ether solution was washed with aq $NaHCO_3$ and then with water. The ethereal extract was dried over Na_2SO_4 and concentrated. In the case of **2e**, the ^{1}H NMR spectrum of the residue showed a 78:22 mixture of **5e** and **3e** (by integration of the methine protons). In the case of **2h**, the ^{1}H NMR spectrum of the residue showed a 73:27 mixture of **5h** and **3h** with a trace amount of **3h'**.

A column chromatography of the residue (2.12 g) from the reaction of **2e** on silica gel with hexane–ether as the eluent gave 1.50 g of **5e** and 0.4 g of **3e**. The spectral data for 2-bromo-1-(3-chlorophenyl)-1-methoxyethane (**5e**) are as follows: ^{1}H NMR ($CDCl_3$) δ=3.32 (3H, s, OCH_3), 3.46, 3.47 (2H, 2d, J=5.9 and 6.7 Hz, CH_2Br), 4.36 (1H, approx. t, CH), and 7.26—7.35 (4H, m, C_6H_4); ^{13}C NMR ($CDCl_3$) δ=35.7, 57.4, 82.7. 125.0, 126.8, 128.6, 129.9, 134.6, and 141.1. The ^{1}H and ^{13}C NMR spectra of **5e** correspond well with those of the authentic sample prepared by the reaction of **2e** with N-bromosuccinimide (NBS) in methanol.[10] The data for 2-bromo-1-chloro-1-(3-chlorophenyl)ethane (**3e**) have been reported in the previous paper.[4]

Similarly, a column chromatography of the residue (2.13 g) from the reaction of **2h** gave 1.30 g of **5h** and 0.45 g of a mixture of **3h** and **3h'**. The spectral data for 2-bromo-1-methoxy-1-(3-nitrophenyl)ethane (**5h**) are as follows: ^{1}H NMR ($CDCl_3$) δ=3.36 (3H, s, OCH_3), 3.53 (2H, d, J=5.9 Hz, CH_2Br), 4.51 (1H, t. J=5.9 Hz, CH), and 7.67—8.22 (4H, m, C_6H_4); ^{13}C NMR ($CDCl_3$) δ=35.3, 57.6, 82.1, 121.8, 123.4, 129.6, 132.8, 141.4, and 148.4. The ^{1}H and ^{13}C NMR spectra of **5h** correspond well with those of the authentic sample prepared by the reaction of **2h** with NBS in methanol.[10] The ^{1}H NMR spectrum of the isolated bromo chloro adducts showed a 93:7 mixture of **3h** and **3h'**. The data for 2-bromo-1-chloro- and 1-bromo-2-chloro-1-(3-nitrophenyl)ethanes (**3h** and **3h'**) have been reported in the previous paper.[4]

The authors sincerely wish to thank Professor Shigeru Oae of Okayama University of Science for his kind guidance.

Synthetic Approach toward Antibiotic Ezomycins. II. Synthesis of 5-Amino-3,7-anhydro-5-deoxy-octofuranose-(1,4) Derivatives

Osamu Sakanaka, Takashi Ohmori, Shuji Kozaki, and Tetsuo Suami*
Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Yokohama 223
(Received May 1, 1986)

A conversion of 5-acetamido-5-deoxy-1,2:7,8-di-*o*-isopropylidene-3-*o*-methylthiomethyl-β-L-*erythro*-D-allo-octofuranose-(1,4) and -L-talooctofuranose-(1,4) to 5-amino-3,7-anhydro-5-deoxyoctofuranose-(1,4) derivatives has been investigated as a preliminary study for a synthesis of the octose moiety of ezomycins.

Nucleoside antibiotic ezomycins were discovered in a fermentation broth of a strain which was similar to Streptomyces Kitazawaensis.[1] They exhibit antimicrobial activity against limited species of phytopathogenic fungi, such as Sclerotinia and Botritis. Ezomycins A, B, and C comprise a unique bicyclic trans-fused octose derivative,[2-4] which is a target of our present studies. Although several studies related to synthesis of 3,7-anhydrooctofuranose-(1,4) derivatives have been described,[5-7] any derivatives with all functional groups have not yet been synthesized.

In the preceding paper,[8] a synthesis of 5-acetamido-5-deoxyoctofuranose-(1,4) derivatives has been described. A KF-catalyzed Henry reaction between 5-nitro-D-ribose derivative (**1**) and L-glyceraldehyde derivative (**2**) and successive hydrogenation followed by *N*-acetylation afforded three diastereomeric isomers (**3a**, **3b**, and **3c**). Also their absolute configurations of the newly introduced chiral centers on C-5 and C-6 have been established. The configurations of the major product **3a** were found to be identical with those of the octose part of ezomycins.

In the present article, we wish to report a synthesis of 5-amino-3,7-anhydro-5-deoxyoctofuranose-(1,4) derivatives from **3a** and **3b**.

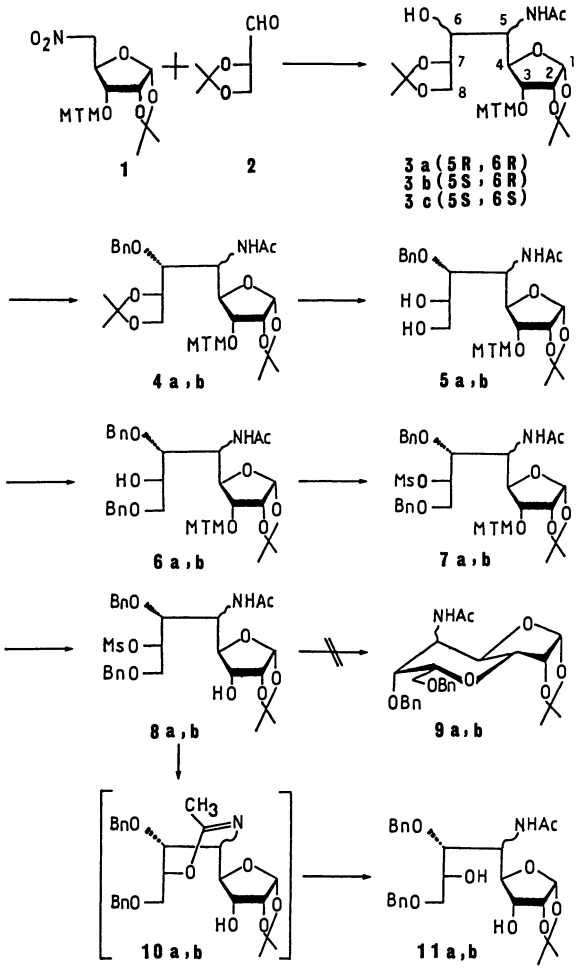
Scheme 1.

Results and Discussion

O-Benzylation of an intact mixture (67% from 1) of **3a** and **3b**, which could not be separated chromatographically, with benzyl bromide and sodium hydride in *N*,*N*-dimethylformamide (DMF) gave the corresponding benzyl ethers (**4a** and **4b**), which could be isolated readily in 49 and 30% yield respectively.



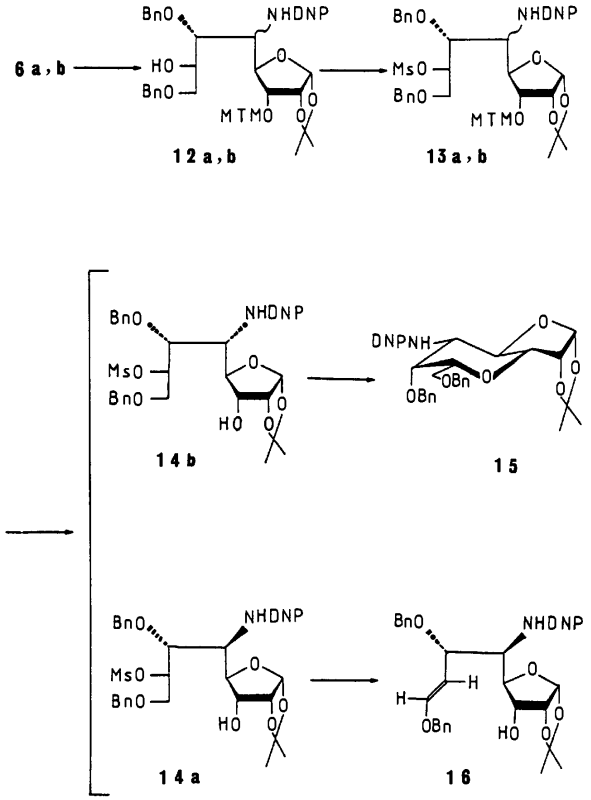
Bn benzyl
Ms methylsulfonyl
MTM methylthiomethyl

Scheme 2.

Selective removal of 7,8-*O*-isopropylidene group in **4a** with aqueous acetic acid afforded a diol (**5a**). Preferential 8-*O*-benzylation of **5a** with benzyl bromide and sodium hydride in tetrahydrofuran (THF) gave 6,8-di-*O*-benzyl compound (**6a**) in 49% yield. *O*-Mesylation of **6a** with methanesulfonyl chloride in pyridine afforded a mesylate (**7a**) in 78% yield. Treatment of **7a** with iodomethane in the presence of sodium hydrogencarbonate in aqueous acetone[9] gave 3-*O*-deprotected compound (**8a**) in 53% yield. Another benzyl ether (**5b**) was also converted to the corresponding compound (**8b**) by the analogous procedure. Cyclization of **8a** to a 3,7-anhydride with a base (NaH or *t*-BuOK) in various solvent systems have been attempted, but in vain. The product was treated with acetic anhydride in pyridine to give a diacetate, which was not an acetylated derivative of **5a**. Therefore, it was thought that an epimerization was caused by a participation of 5-acetamido group. The product derived from **8b** was also an epimerized diol (**9b**). Although a benzyloxycarbonyl or a phthaloyl group was used as protective group of the 5-amino group, a satisfactory result was not obtained.

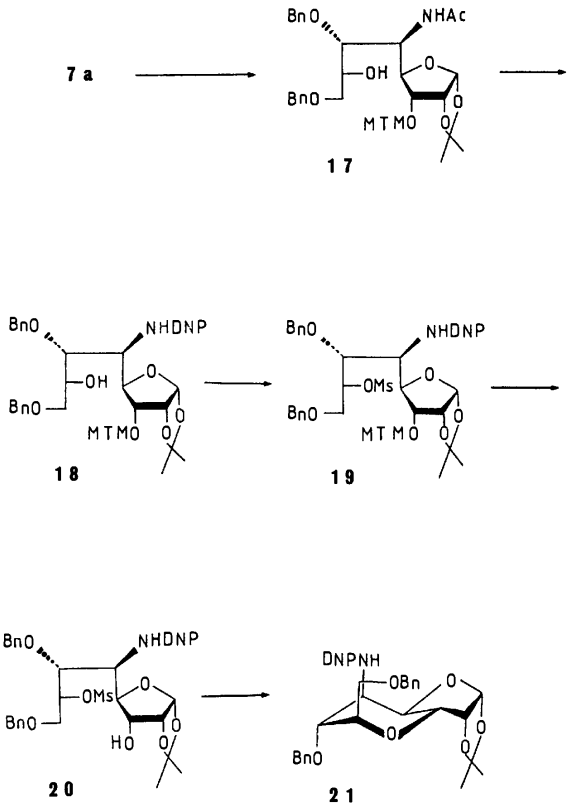
Then, a 2,4-dinitrophenyl group was used as protective group. Hydrolysis of **6a** with sodium hydroxide in aqueous 2-methoxyethanol and successive treatment of the resultant amine with 2,4-dinitrofluorobenzene and triethylamine in THF afforded dinitrophenylamino compound (**12a**) in 75% yield. *O*-Mesylation of **12a** with methanesulfonyl chloride in pyridine yielded a mesylate (**13a**) quantitatively. Treatment of **13a** with iodomethane and sodium hydrogencarbonate in aqueous acetone gave 3-*O*-deprotected compound (**14a**) in 72% yield. Compound **6b** was also converted to the corresponding compound (**14b**) by the analogous procedure. Treatment of **14b** with NaH in DMF afforded the desired 3,7-anhydride (**15**) in 59% yield. However, attemps to cyclize **14a** with a base (NaH or *t*-BuOK) in various solvent systems were unsuccessful. The ^{1}H NMR spectrum of the main product showed a characteristic doublet at δ 6.64 (J=14 Hz), possibly a trans-olefin signal, and a doublet at δ 3.08 (J=6 Hz) assignable to 3-OH. Accordingly, the product is thought to have a structure **16**. The structure is also reasonable for all other signals. The other products were unable to isolate. The conformation of 7-mesyloxy group in **14a** might be unfavorable to a nucleophilic attack of a 3-oxido anion.

Therefore, the epimer of **14a** at C-7 was prepared as follows. Treatment of **7a** with NaH in DMF resulted in an attack of 5-acetamido group to C-7 as above-mentioned and successive acidic workup with silica gel afforded an epimeric product (**17**) in 92% yield. Compound **17** was converted to a mesylate (**20**) by the analogous procedure as described already. Treatment



DNP 2,4-dinitrnphenyl

Scheme 3.



Scheme 4.

of **20** with NaH in dimethyl sulfoxide (DMSO) afforded a bicyclic 3,7-anhydride (**21**) in 66% yield as expected. Since an attack of a 3-oxido anion to C-7 is an S_N2 type reaction, the stereochemistry is non-natural. However, if **21** can be oxidized to an uronic acid, it is expected that the configuration of C-7 can be reversed because of α-position of carboxyl function.

Experimental

Melting points were determined on a Büchi 510 capillary melting point apparatus and are uncorrected. Optical rotations were measured with a Jasco DIP-4 polarimeter. IR spectra were recorded on a Hitachi 225 spectrometer. ^{1}H NMR spectra were recorded on a Varian EM-390 (90 MHz), a JEOL FX-200 (200 MHz), or a JEOL GX-400 (400 MHz) spectrometer with a reference to tetramethylsilane as an internal standard. Mass spectra were recorded on a Hitachi M-80B spectrometer. Solutions were dried over anhydrous sodium sulfate and concentrated below 35 °C. TLC was carried out on glass plates coated with Kieselgel 60 F_{254} (Merck Art. 5715), and compounds were detected by spraying with an H_2SO_4 followed by heating. Chromatography was performed on a silica gel (Merck Kieselgel 60 Art. 7734) column.

5-Acetamido-6-*O*-benzyl-5-deoxy-1,2-*O*-isopropylidene-3-*O*-methylthiomethyl-β-L-*erythro*-L-talooctofuranose-(1,4) (5b). Compound **4b** (104 mg) was dissolved in 70% aqueous acetic acid (2 ml) and the solution was allowed to stand for 14 h at room temperature. Coevaporation with toluene gave a pale yellow syrupy residue, which was chromatographed (chloroform–methanol (v/v) 30:1) to afford **5b** in an almost quantitative yield (95 mg) as crystals: R_f=0.35 on TLC (chloroform–methanol (v/v) 15:1); mp 136—138 °C; $[\alpha]_D^{21}$ +17.2° (*c* 1.06, $CHCl_3$); IR (KBr) 1650 cm^{-1} (NHCO); ^{1}H NMR (90 MHz, $CDCl_3$) δ=1.32, 1.45 (3H×2, s×2, CMe_2), 1.97 (3H, s, NHAc), 2.14 (3H, s, SMe), 3.15 (1H, bs, OH), 5.77 (1H, d, *J*=4 Hz, H-1), 6.26 (1H, d, *J*=10 Hz, NH), 7.30 (5H, m, Ph).

Found: C, 55.78; H, 6.97; N, 3.13; S, 6.59%. Calcd for $C_{22}H_{33}NO_8S$: C, 56.04; H, 7.05; N, 2.97; S, 6.80%.

5-Acetamido-6,8-*O*-di-*O*-benzyl-5-deoxy-1,2-*O*-isopropylidene-3-*O*-methylthiomethyl-β-L-*erythro*-L-talooctofuranose-(1,4) (6b). To a chilled solution (−15 °C) of **5b** (163 mg) in anhydrous THF (4 ml) were added sodium hydride (60% dispersion in mineral oil, 16 mg) and benzyl bromide (45 μl), and the mixture was stirred for 2 h under ice cooling. The mixture was chilled to −15 °C again, and sodium hydride (7 mg) and benzyl bromide (12 μl) were added. The mixture was stirred for 12 h at 5 °C. Coevaporation with ethanol gave a pale yellow syrup, which was chromatographed (chloroform–methanol (v/v) 30:1) to afford 109 mg (56%) of **6b** as a colorless syrup: R_f=0.44 on TLC (ethyl acetate); ^{1}H NMR (90 MHz, $CDCl_3$) δ=1.32, 1.46 (3H×2, s×2, CMe_2), 1.91 (3H, s, NHAc), 2.13 (3H, s, SMe), 2.85 (1H, d, *J*=4 Hz, OH), 5.76 (1H, d, *J*=4 Hz, H-1), 5.84 (1H, d, *J*=10 Hz, NH), 7.15—7.54 (10H, m, Ph×2). Although contaminated with 6,7-di-*O*-benzyl compound (<1/10, judged from NMR spectrum), the product was used in the next step without further purification. Both isomers had a similar mobility in a column chromatography.

6,8-Di-*O*-benzyl-5-deoxy-5-(2,4-dinitrophenylamino)-1,2-*O*-isopropylidene-3-*O*-methylthiomethyl-β-L-*erythro*-L-talooctofuranose-(1,4) (12b). A mixture of **6b** (146 mg), sodium hydroxide (270 mg) and 95% aqueous 2-methoxyethanol (3 ml) was heated for 75 min under reflux. The mixture was partitioned between water and ethyl acetate. The organic layer was washed twice with water, dried and concentrated to dryness. The pale brown syrupy residue was dissolved in THF (3 ml), and to the solution were added triethylamine (68 μl) and 2,4-dinitrofluorobenzene (98 mg). The mixture was stirred for 18 h at room temperature, and partitioned between water and ethyl acetate. The organic layer was washed twice with water, dried and concentrated to dryness. The syrupy residue was chromatographed (toluene–ethyl acetate (v/v) 6:1) to give 141 mg (79%) of **12b** as yellow amorphous solids: R_f=0.47 on TLC (toluene–ethyl acetate (v/v) 2:1); $[\alpha]_D^{22}$ +33.7° (*c* 1.21, $CHCl_3$); IR (KBr) 1520 cm^{-1} (NO_2); ^{1}H NMR (90 MHz, $CDCl_3$) δ=1.33, 1.52 (3H×2, s×2, CMe_2), 1.99 (3H, s, SMe), 2.76 (1H, d, *J*=4 Hz, OH), 5.88 (1H, d, *J*=4 Hz, H-1), 7.06 (1H, d, *J*=10 Hz, H-6′), 7.19—7.42 (10H, m, Ph×2), 7.99 (1H, dd, *J*=10, 3 Hz, H-5′), 9.03 (1H, d, *J*=3 Hz, H-3′).

6,8-Di-*O*-benzyl-5-deoxy-5-(2,4-dinitrophenylamino)-1,2-*O*-isopropylidene-7-*O*-methylsulfonyl-3-*O*-methylthiomethyl-β-L-*erythro*-L-talooctofuranose-(1,4) (13b). To a solution of **12b** (150 mg) in dry pyridine (3 ml) was added methanesulfonyl chloride (70 μl) under ice cooling, and the mixture was stirred for 2 h. After 1 h at room temperature additionally, the mixture was partitioned between 3% aqueous sodium hydrogencarbonate and ethyl acetate. The organic layer was washed with water, dried and concentrated to dryness. The syrupy residue was chromatographed (toluene–ethyl acetate (v/v) 8:1) to give 146 mg (88%) of **13b** as yellow amorphous solids: R_f=0.62 on TLC (toluene–ethyl acetate (v/v) 2:1); $[\alpha]_D^{22}$ +11.6° (*c* 1.35, $CHCl_3$); IR (KBr) 3320 (NH), 1525, 1515 (NO_2) cm^{-1}; ^{1}H NMR (90 MHz, $CDCl_3$) δ=1.33, 1.52 (3H×2, s×2, CMe_2), 1.92 (3H, s, SMe), 2.96 (3H, s, SO_2Me), 5.85 (1H, d, *J*=4 Hz, H-1), 6.89 (1H, d, *J*=10 Hz, H-6′), 7.24—7.43 (10H, m, Ph×2), 7.86 (1H, dd, *J*=3, 10 Hz, H-5′), 8.72 (1H, d, *J*=10 Hz, NH), 8.99 (1H, d, *J*=3 Hz, H-3′).

6,8-Di-*O*-benzyl-5-deoxy-5-(2,4-dinitrophenylamino)-1,2-*O*-isopropylidene-7-*O*-methylsulfonyl-3-*O*-methylthiomethyl-β-L-*erythro*-D-allooctofuranose-(1,4) (13a). To a solution of **12a** (128 mg) in dry pyridine (3 ml) was added methanesulfonyl chloride (43 μl) under ice cooling, and the mixture was allowed to stand overnight in a refrigerator. The reaction mixture was partitioned between saturated aqueous sodium hydrogencarbonate and ethyl acetate. The organic layer was washed with water repeatedly, dried and concentrated to dryness. The residue was chromatographed (toluene-ethyl acetate (v/v) 10:1) to afford 132 mg (93%) of **13a** as yellow amorphous solids: R_f=0.44 on TLC (toluene-ethyl acetate (v/v) 4:1); $[\alpha]_D^{26}$ −47.1° (*c* 1.05, $CHCl_3$); IR (KBr) 3330 (NH), 1525, 1515 (NO_2) cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=1.33, 1.48 (3H×2, s×2, CMe_2), 1.95 (3H, s, SMe), 2.89 (3H, s, SO_2Me), 5.78 (1H, d, *J*=4 Hz, H-1), 7.08 (1H, d, *J*=8 Hz, H-6′), 7.32, 7.37 (5H×2, s×2, Ph×2), 8.18 (1H, dd, *J*=3, 8 Hz, H-5′), 9.12 (1H, d, *J*=3 Hz, H-3′).

6,8-Di-*O*-benzyl-5-deoxy-5-(2,4-dinitrophenylamino)-1,2-*O*-isopropylidene-7-*O*-methylsulfonyl-β-L-*erythro*-D-allooctofuranose-(1,4) (14a). To a mixture of **13a** (107 mg), sodium hydrogencarbonate (59 mg) and 90% aqueous acetone (2 ml) was added iodomethane (0.18 ml) three times at intervals of 1 h under reflux, and furthermore the mixture refluxed for 2 h. The reaction mixture was diluted with ethyl acetate, dried and concentrated to dryness. The syrupy residue was chromatographed (toluene-ethyl acetate (v/v) 3:1) to give 52 mg (53%) of **14a** as yellow amorphous solids: R_f=0.15 on TLC (toluene-ethyl acetate (v/v) 4:1); $[\alpha]_D^{26}$ −43.2° (*c* 1.08, $CHCl_3$); IR (KBr) 3460 (OH), 3330 (NH), 1525, 1515 (NO_2); ^1H NMR (90 MHz, $CDCl_3$) δ=1.34, 1.47 (3H×2, s×2, CMe_2), 2.34 (1H, bs, OH), 2.91 (3H, s, SO_2Me), 5.78 (1H, d, *J*=4 Hz, H-1), 7.09 (1H, d, *J*=10 Hz, H-6′), 7.34, 7.38 (5H×2, s×2, Ph×2), 8.16 (1H, dd, *J*=3, 10 Hz, H-5′), 9.11 (1H, d, *J*=3 Hz).

A Reaction of 14a with NaH. To a solution of **14a** (23.8 mg) in anhydrous DMF (0.5 ml) was added sodium hydride (5.7 mg) under ice cooling, and the mixture was stirred for 3.5 h at room temperature. The mixture was partitioned between water and ethyl acetate. The organic layer was washed twice with water, dried and concentrated to dryness. The residue was chromatographed (toluene-ethyl acetate (v/v) 8:1) to afford 5.2 mg (25%) of an olefinic compound **16** as yellow amorphous solids: R_f=0.37 on TLC (toluene-ethyl acetate (v/v) 4:1); $[\alpha]_D^{26}$ +20.0° (*c* 0.52, $CHCl_3$); IR (KBr) 3480 (OH), 3350 (NH), 1515, 1505 (NO_2) cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=1.30, 1.52 (3H×2, s×2, CMe_2), 3.08 (1H, d, *J*=6 Hz, OH), 5.57 (1H, d, *J*=5 Hz, H-1), 6.64 (1H, d, *J*=14 Hz, H-8), 7.00 (1H, d *J*=10 Hz, H-6′), 7.25, 7.28 (5H×2, s×2, Ph×2), 8.09 (1H, dd, *J*=3, 10 Hz, H-5′), 8.95 (1H, d, *J*=7 Hz, NH), 9.03 (1H, d, *J*=3 Hz, H-3′).

Found: M, 607. Calcd for $C_{31}H_{33}N_3O_{10}$: *m/z*, 607.

5-Acetamido-6,8-di-*O*-benzyl-5-deoxy-1,2-*O*-isopropylidene-7-*O*-methylsulfonyl-3-*O*-methylthiomethyl-β-L-*erythro*-D-allooctofuranose-(1,4) (7a). To a solution of **6a** (1.14 g) in dry pyridine (11 ml) was added methanesulfonyl chloride (0.47 ml) under ice cooling, and the mixture was stirred for 2 h at room temperature. The reaction mixture was coevaporated with toluene, and the residue was partitioned between water and ethyl acetate. The organic layer was

washed with water repeatedly, dried and concentrated to dryness. The residue was chromatographed (toluene–ethyl acetate (v/v) 3:1) to give 1.01 g of **7a** as a colorless syrup: R_f=0.50 on TLC (toluene–ethyl acetate (v/v) 1:1); $[\alpha]_D^{19}$ +11.7° (*c* 1.23, $CHCl_3$); IR ($CHCl_3$) 3390 (NH), 1670 (NHCO), 1350, 1170 (SO_2Me) cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=1.33, 1.54 (3H×2, s×2, CMe_2), 1.91 (3H, s, NHAc), 2.19 (3H, s, SMe), 3.01 (3H, s, SO_2Me), 5.73 (1H, d, *J*=4 Hz, H-1), 7.30, 7.33 (5H×2, s×2, Ph×2).

5-Acetamido-6,8-di-*O*-benzyl-5-deoxy-1,2-*O*-isopropylidene-3-*O*-methylthiomethyl-α-D-*threo*-D-allooctofuranose-(1,4) (17). To a solution of **7a** (905 mg) in anhydrous DMF (9 ml) was added sodium hydride (227 mg) under ice cooling, and the mixture was stirred for 40 min at room temperature. The reaction mixture was partitioned between water and ethyl acetate. The organic layer was washed with water repeatedly, dried and concentrated to dryness. The syrupy residue was dissolved in a small amount of toluene, and a silica-gel column was charged with the solution. After 3 h elution (toluene–ethyl acetate (v/v) 1:2) afforded 733 mg (92.3%) of **17** as a colorless syrup: R_f=0.66 on TLC (ethyl acetate); $[\alpha]_D^{21.5}$ +24.2 (*c* 1.01, $CHCl_3$); IR ($CHCl_3$) 1670 cm^{-1} (NHCO); ^1H NMR (90 MHz, $CDCl_3$) δ=1.33, 1.53 (3H×2, s×2, CMe_2), 1.92 (3H, s, NHAc), 2.19 (3H, s, SMe), 2.52 (1H, d, *J*=3 Hz, OH), 5.75 (1H, d, *J*=4 Hz, H-1), 7.35 (10H, s, Ph×2).

Found: C, 62.06; H, 6.97; N, 2.47; S, 5.87%. Calcd for $C_{29}H_{39}NO_8S$: C, 62.01; H, 7.00; N, 2.49; S, 5.71%.

6,8-Di-*O*-benzyl-5-deoxy-5-(2,4-dinitrophenylamino)-1,2-*O*-isopropylidene-3-*O*-methylthiomethyl-α-D-*threo*-D-allooctofuranose-(1,4) (18). A mixture of **17** (565 mg), sodium hydroxide (452 mg) and 95% aqueous 2-methoxyethanol (5.7 ml) was heated for 1.5 h under reflux. The reaction mixture was partitioned between water and chloroform. The organic layer was washed twice with water, dried and concentrated to dryness. The pale brown syrup was dissolved in THF (5.6 ml) and to the solution were added triethylamine (0.21 ml) and 2,4-dinitrofluorobenzene (225 mg). After 12 h at room temperature the reaction mixture was partitioned between water and ethyl acetate. The organic layer was washed twice with water, dried and concentrated to dryness. The deep yellow syrupy residue was chromatographed (toluene–ethyl acetate (v/v) 3:1) to give 548 mg (79.3%) of **18** as a yellow syrup: R_f=0.18 on TLC (toluene–ethyl acetate (v/v) 5:1); $[\alpha]_D^{20}$ +18.6° (*c* 1.07, $CHCl_3$); IR ($CHCl_3$) 1520, 1330 cm^{-1} (NO_2); ^1H NMR (90 Hz, $CDCl_3$) δ=1.32, 1.50 (3H×2, s×2, CMe_2), 2.00 (3H, s, SMe), 2.48 (1H, d, *J*=3 Hz, OH), 5.72 (1H, d, *J*=4 Hz, H-1), 6.91 (1H, d, *J*=10 Hz, H-6′), 7.32 (10H, s, Ph×2), 8.02 (1H, dd, *J*=3, 10 Hz, H-5′), 9.05 (1H, d, *J*=3 Hz, H-3′).

Infrared C-D Stretching and ^{2}H NMR Spectra of Isopropyl-2-*d* 1-(*p*-Substituted Phenyl)ethyl Ketones. Evidence for the Hydrogen Bond-Like Interaction between C-D Group and Aromatic π-Electrons

(Received May 9, 1986)

Isopropyl-2-*d* 1-(*p*-X-phenyl)ethyl ketones (where, X=H, NO_2, Br, Cl, C_2H_5, CH_3, and NH_2) were shown to have two absorption bands in the C-D stretching region. The absorption band at the higher frequency (ca. 2177 cm^{-1}) is assigned to the C-D···π approached conformer, and the high frequency shift is ascribed to the effect of steric compression. Weak C-D···π hydrogen bond was shown to occur by the measurement of the substituent effect on the formation constant and the relative enthalpy of the C-D···π approached conformer.

Through the recent investigations of ours[1-5] and several other authors,[6,7] it has been clarified that an alkyl group often prefers to take a position close to an aromatic ring in certain molecules. Thus, 2-alkyl-1-arylethanes Ar-CHR-CHXR′ generally take preferably a conformation in which the aryl (Ar) and the alkyl (R′) groups are gauche to each other.[2,3,8] In addition, 1-arylethyl *t*-butyl sulfides and sulfoxides have similar preferred conformations. To account for the preferred conformations of these compounds, weak attractive force is assumed to operate between the aryl and the alkyl groups and named sometimes CH···π interaction, while the nature of the weak interaction remains to be explored. At first, the authors[9,10] tentatively explained this as being originated from weak hydrogen bonding between CH group and aromatic π-electrons similar to the intermolecular interaction between chloroform and benzene.[11,12] However, this interpretation is hypothetical and nothing renders a confident support on it. Alternatively, the observed conformational preferences were reproduced nearly quantitatively by molecular force field calculations.[8,13] The preference for alkyl/aryl approached (gauche) conformations in the series of $ArCH_2CHXR'$ cannot be rationalized without taking into account an attractive interaction between aryl and alkyl groups. Dispersion force is the only general attractive force included in the calculation. Therefore, the CH···π interaction should be ascribed to dispersive force to a large extent.

In spite of this conclusion, presence of weak CH···π hydrogen bonding cannot be excluded completely. On the contrary, the minor contribution of CH···π hydrogen bonding to the stabilization of the alkyl/aryl gauche conformers of 1-aryl-2-alkylethanes is suggested from LIS measurements on this series of compounds.[2-4] Ab initio (4—31G) calculation on 1-phenyl-2-propanol gives small but definitely positive bond population between methyl hydrogen atom and aromatic carbon atoms.[14] However, the absolute values of the bond populations are about one tenth of those for OH···π interaction ((O)-H···C bond populations). If the hydrogen bond-like CH···π interaction does exist, the interaction is expected to become strong when the C-H group is linked to an electronegative atom. Thus, the possibility of such an interaction was examined in the series of 1-phenylalkyl ketones. In order to observe the behavior of the particular hydrogen atom participating in CH···π hydrogen bonding separately, isopropyl-2-*d* 1-(substituted phenyl)ethyl ketones in which the hydrogen atom is replaced by deuterium were prepared, and their infrared and ^{2}H NMR spectra were measured and discussed.

Experimental

Preparation of 1-Aryl Isopropyl-2-*d* Ketones. Appropriately substituted 2-phenylpropionaldehyde was prepared by the method reported by Nerdel and Frohlich[15,16] and reacted with (isopropyl-2-*d*)magnesium bromide in ether. The alcohol obtained as the product was then oxidized by sodium dichromate-sulfuric acid mixture to give the ketone **2**. Other ketones (**3—9**) were also prepared by a similar method. Nitro ketone **2b** was prepared by nitrating ketone **2a**. Reduction of **2b** gives amino ketone **2g**.

All ketones and intermediate alcohols were identified by comparing their boiling points with the reported boiling points of unlabeled ketones[16] and also by their NMR, infrared, and mass spectra.

Measurement of Spectra. ^{2}H NMR spectra were recorded on a JEOL FX 90Q spectrometer in acetone or dimethyl sulfoxide solutions. Infrared spectra were recorded on a Hitachi 225 spectrophotometer using an NaCl cell of 2 cm optical path length in carbon tetrachloride or chloroform solutions. Temperature studies were performed with the carbon tetrachloride solutions.

Results and Discussion

Infrared C-D Stretching Absorptions and Their Assignment. The C-H stretching absorption of methine (isolated C-H) group is known to be very weak in comparison with those of CH_2 and CH_3

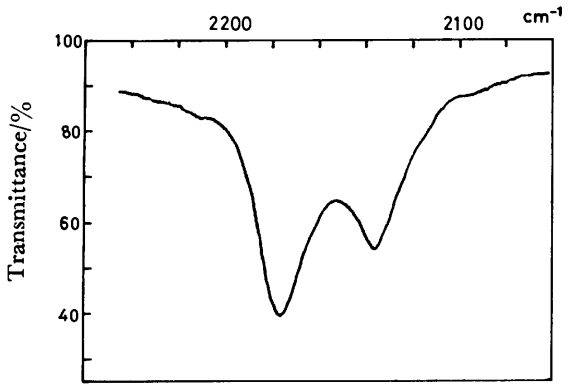

Fig. 1. Infrared C-D stretching absorption of isopropyl-2-*d* 1-phenylethyl ketone in CCl_4 solution.

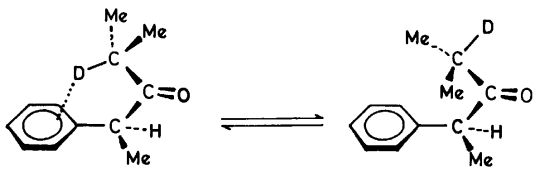
groups,[17] which would make the recognition of the C-H band of isopropyl group extremely difficult. In fact, the C-H band of isopropyl group could not be identified in the spectrum of isopropyl 1-phenylethyl ketone (**1**) probably because of the interference caused by stronger overlapping bands. Thus, the deuterium-labeled analogs, isopropyl-2-*d* 1-(substituted phenyl)-ethyl ketones **2a**—g, were prepared and their infrared spectra in the C-D stretching frequency region (2300—2000 cm^{-1}) were measured.

As shown in Fig. 1, ketone **2a** has two absorption maxima at 2177 and 2136 cm^{-1} in this frequency region. The absorption bands can be characterized in spite of their very low intensity, since both the ketone and the solvent (carbon tetrachloride or chloroform) do not absorb the light of this frequency region.

Since the ketone **2a** has only a C-D bond, two absorption bands should be assigned to two different isomers, most probably rotamers in this case. Fermi resonance and related vibrational couplings might not operate in these circumstances, though they cannot be excluded completely. Temperature dependence measurement decribed later will support the conclusion, showing the presence of two energetically unequal isomers rapidly converting to each other. The sterical structures of the two conformers were estimated by molecular mechanics (MM2) calculations,[8] and the two conformers were tentatively assigned to the most and the next stable conformations (I and II, respectively) from the calculations.



(I) (II)

Table 1. C-D Stretching Absorptions of Isopropyl-2-*d* Ketones R-C-CD(CH_3)$_2$

No.	R	ν/cm^{-1}	No.	R	ν/cm^{-1}
3	Ph	2191	**6**	CMe_3	2195
		2156			2182
2a	PhCHMe	2177	**7**	$CDMe_2$	2182
		2136			2154
4	$PhCH_2$	2153	**8**	CH_2CH_3	2168
					2130
5	$PhCH_2CH_2$	2157	**9**	CH_3	2167
		2130			2130

The absorption frequencies of the two bands are rather higher than estimated from the reported methine C-H frequency 2890±10 cm^{-1}.[18] This frequency can be converted to 2121 cm^{-1} in the C-D stretching region if we assume the band to arise from a pure C-H (or C-D) stretching mode of molecular vibration. As revealed by examining the molecular models and more confidently by the C-H···C(Ar) distance in the most stable conformation(I) estimated from MM2 calculations on ketone **1**, some compression of the C-H bond length is expected to occur with the isopropyl methine group of ketone **1** due to the steric congestion around the bond.[18,19] Therefore, the high frequency shift of the C-D bands of ketones **2a**—g are ascribable to the shortening of the C-D bonds due to the steric compression.

In order to prove the effect of steric compression experimentally, the C-D stretching absorptions of several isopropyl-2-*d* ketones $RCOCDMe_2$ (**3**—**9**) were measured and given in Table 1. In cases of methyl and ethyl ketones (**8** and **9**), as well as 2-phenylethyl ketone (**5**), no steric congestion was expected around the C-D bond in problem. The C-D absorption frequencies of the two series of ketones in Table 1 clearly shows that the high frequency shift is caused by the steric crowdedness, the most crowded *t*-butyl and phenyl ketones (**3** and **6**, respectively) absorbing at the highest frequency in both series. In line with the prediction from MM2 calculations, the C-D bond in one conformer (which absorbs at 2177 cm^{-1} of **2a** is suspected from its high absorption frequency to suffer a considerable compression sterically.[20,21] MM2 calculations further revealed that the C-D bond is located very close and nearly perpendicular to the plane of the aromatic ring of 1-phenylethyl group in this conformer(I), and the nonbonded H(D)·····C_{Ar} distance was calculated to be as close as 2.65 A. The distance is too close to have an optimum van der Waals contact with each other and results in a weak repulsive nonbond interaction between H(D) and C_{Ar}. In accord with the above reasonings, the band at the higher frequency (2177 cm^{-1}) was tentatively assigned to the C-D···π approached conformation(I) and the one at the lower frequency to the conformation(II)

Table 2. C-D Stretching Absorptions of the Ketones *p*-XC$_6$H$_4$CHMeCOCDMe$_2$ (**2**) in CCl_4. (2 cm NaCl Cell; Concentration, ca. 0.05 mol dm^{-3})

No.	X	ν_I/cm^{-1}	ε_I/l mol^{-1} cm^{-1}	ν_{II}/cm^{-1}	ε_{II}/l mol^{-1} cm^{-1}	$\varepsilon_I/\varepsilon_{II}$
2b	NO_2	2174	4.94	2135	4.99	1.10
2c	Br	2174	5.26	2135	4.07	1.29
2d	Cl	2175	6.48	2136	4.59	1.41
2a	H	2177	6.54	2136	4.12	1.59
2e	C_2H_5	2176	5.07	2136	3.30	1.54
2f	CH_3	2176	6.34	2136	3.98	1.59
2g	NH_2	2175	5.65	2135	3.44	1.64

which is estimated to be the next stable from the MM2 calculations.

Possibility of Intramolecular C-D···π Hydrogen Bonding. In turn, C-D···π hydrogen bonding is expected to be favorably formed in the C-D···π approached conformation(I). Ab initio calculations on a more simplified model compound $PhCH_2CH$-(OH)Me also gave a small but definitely positive bond populations between the methyl H and aromatic C atoms opposing in close distances (CH_3 and C_1 or C_2 of phenyl group in a conformer).[14]

Both the unusually short distance from MM2 and the positive bond populations from ab initio MO suggest the occurrence of an intramolecular hydrogen bond-like interaction between the CH and the aromatic π system. If such an interaction is assumed to be present, the formation constant of the intramolecular hydrogen bond could be estimated from the ratio of the absorption intensities (ε_I and ε_{II}) of the two C-D bands assigned to the conformations I and II by Eq. 1.

$$K = a\frac{\varepsilon_I}{\varepsilon_{II}} \text{ or } a\frac{\varepsilon_{int}}{\varepsilon_{free}} \quad (1)$$

As the intrinsic molar extinction coefficients of the C-D···π interacted and the free (non-interacted) conformers (ε_I^0 and ε_{II}^0, respectively) are not necessarily equal, proportionality constant a which is equal to their ratio was introduced. Here, ε_I and ε_{II} are appearent extinction coefficients and related to the intrinsic extinction coefficients by $\varepsilon_I = X_I\varepsilon_I^0$ and $\varepsilon_{II} = X_{II}\varepsilon_{II}^0$, where X_I and X_{II} are molar fractions of conformers I and II.

Since the more electron-rich π system acts as a stronger hydrogen acceptor in forming hydrogen bond, negative slope is expected with the logarithm of the formation constant vs. σ plot for a series of isopropyl-2-*d* 1-(substituted phenyl)ethyl ketones (**2a**—**2g**). Thus the $\log(\varepsilon_I/\varepsilon_{II})$ vs. σ plot was drawn by employing the intensities in Table 2. As expected, the slope of the plot (in Fig. 2) becomes negative, and the above assignment was supported experimentally.

In general, intramolecular hydrogen bonds are cleaved when a stronger hydrogen-donating solvent coexists. Therefore, the spectra of these ketones were measured in chloroform-*d* which is known as a typical C-H hydrogen donor in C-H···π hydrogen bonding.[11,12,22]

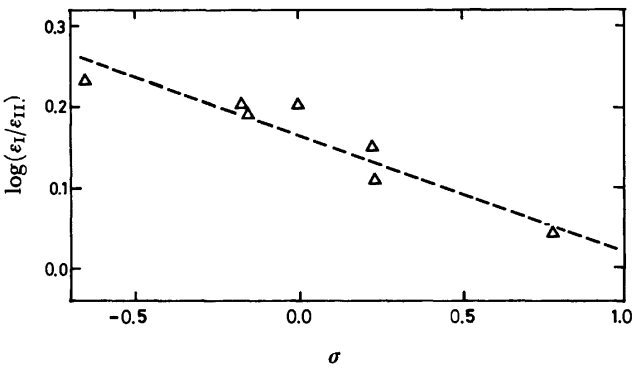


Fig. 2. Substituent effect on the ratios of absorption intensities of the two C-D bands. The $\varepsilon_I/\varepsilon_{II}$ vs. σ plot.

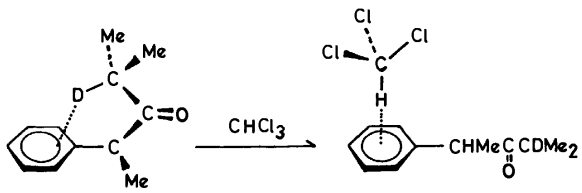

(I) (III)

The results are shown in Table 3. The observed $\varepsilon_I/\varepsilon_{II}$ ratios in Table 3 are significantly smaller than those in carbon tetrachloride. This reveals the fact that conformer I has been converted to the associated species III due to the solvation by forming intermolecular C-H···π hydrogen bond in chloroform. At present, we have no experimental evidence on whether the associated species III takes a conformation similar to the conformer II or not. However, the C-D bond of the associated species must not be very congested judging from its absorption frequency. Thus, the solvent effect on $\varepsilon_I/\varepsilon_{II}$ ratio again supports the above assignment of the C-D stretching bands and the presence of intramolecular hydrogen bonds.

a) A small amount of LiBr for internal lock signal and $CDCl_3$ for reference were added.

Another evidence comes from ^2H NMR spectra of the ketones **2a**—g. The deuterium atom is located just above and very close to the plane of aromatic ring in conformer I and expected to resonate at a higher frequency than the one in conformer II due to the anisotropy effect of strongly diamagnetic aromatic ring. This implies that the electron-donating substituent on the aromatic ring favors the conformation I and, hence, causes a high field shift of the ^2H chemical shift. ^2H NMR of ketones **2** are given in Table 4. Due to the limitations from the solubility of LiBr for internal locking (since LiBr is sparingly soluble in CCl_4), the measurements were carried out in acetone containing a small amount of chloroform-d as an internal reference. As anticipated, the ^2H chemical shifts tend to move towards high fields in the order of decreasing electron-withdrawing ability and increasing electron-donating ability of the substituent, i.e., in the order of decreasing σ value.[23,24)]

In conclusion, the C-D bond is sterically enforced to oppose the aromatic ring to have a considerable overlap of its antibonding orbital with the aromatic π-MO and is favorable in forming a C-D···π hydrogen bond. Judging from the substituent electronic effect and the solvent effect discussed above, the existence of the intramolecular hydrogen bonding between the isopropyl methine group and π-electrons on the aromatic ring becomes confident.

Substituent Effect on the Enthalpy of the C-D···π Interacted Conformer. As is remarked briefly in relation to the assignment of the C-D stretching bands, the intensities of the two C-D absorption bands

are temperature dependent. This provides us with a clue to elucidate the nature of the intramolecular interaction, since we can estimate the relative enthalpies of the C-D···π interacted conformers by measuring the formation constant K (given by Eq. 1) as a function of temperature. The measurements were carried out with carbon tetrachloride solutions of ketones **2a**—g, and the results are given in Table 5. The differences in enthalpy between the two conformers (ΔH) were calculated by Eq. 2 from the slope of $\log K$ vs. T^{-1} plots obtained by least squares calculation.[25]

$$\log K = -(\Delta H/R)T^{-1} + \Delta S/R \quad (2)$$

Here, K could be substituted by $\varepsilon_I/\varepsilon_{II}$ since a (in Eq. 1) affects only the entropy term in Eq. 2.

The relative enthalpies ΔH ($=H_I-H_{II}$) in Table 5 showed that the C-D···π interacted conformer(I) is not the most stable. This conclusion on the conformational preference does not agree with the prediction from MM2. However, the difference in enthalpy is less than 2 kJ mol^{-1} (or 0.5 kcal† mol^{-1}) which is known to be the maximal deviation from the experiment in MM2 calculations on hydrocarbons.[26]

If we assume that the substituent on the aromatic ring does not affect the stability of the free conformer(II), the relative enthalpy (ΔH) should give the relative stability of the C-D···π interacted conformer(I). The assumption seems entirely reasonable since the C-D bond is separated by a saturated carbon and a carbonyl carbon atoms from the aromatic ring, and the electronic effect is not likely to be transmitted through them. After all, the ΔH value can be a measure of the enthalpy of the C-D···π hydrogen-bond formation.

The C-D···π hydrogen bond is expected to be strengthened in the increasing order of π-electron density on the aromatic carbon atoms. Hence, electron-donating substituent on the aromatic ring should favor the hydrogen bond and stabilize the C-D···π interacted conformer. This leads to the conclusion that the ΔH should be lower when the substituent is more electron-donating. As easily seen from the ΔH vs. σ plot in Fig. 3, the relative enthalpies in Table 5 are in line with the theoretical consequences on the substituent effect, giving a straight line with a positive ρ value (ρ=+0.605 kJ mol^{-1}). In other words, the C-D···π interacted conformer becomes more stabilized with ketone 2 carrying an electron-donating substituent and less stabilized with ketone 2 carrying an electron-withdrawing substituent. Without an exception, hydrogen-bonded system previously investigated were shown to behave similarly towards the effect of polar substituents.[27] Thus, the substituent effect on the ΔH's renders another support on the C-D···π hydrogen bonding in isopropyl-2-*d* 1-arylethyl ketones (**2**).

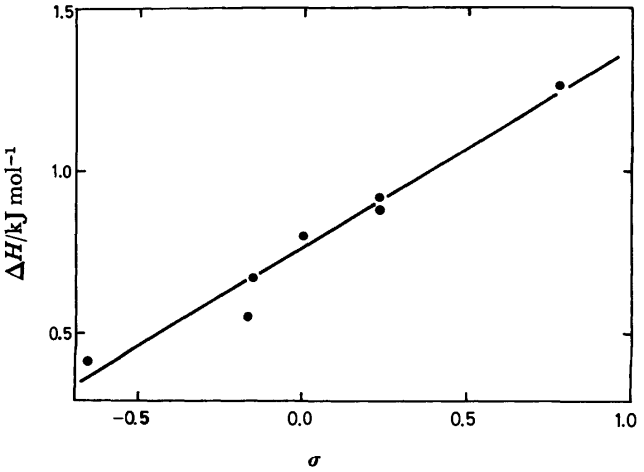

Fig. 3. Substituent effect on the relative enthalpies of the C-D···π interacted conformers. The ΔH vs. σ plot.

This research was partly supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture to which the authors are grateful.

(Received May 12, 1986)

Eight terminal acetylenic fatty acids from 5-hexynoic to 12-tridecynoic acids and their methyl, ethyl, and isopropyl esters were synthesized via *o*-nitrophenyl selenides. These acids and esters all showed inhibitory effect on lettuce seed germination and seedling growth. The effect was dependent on the number of carbon atoms in acetylenic chain. 8-Nonynoic acid showed potent activity, and its methyl ester was the most effective among the test compounds. In addition, the acids showed antifungal activity which increased as the number of carbon atoms increased.

There have been some attempts to relate the chemical structure of fatty acids to inhibition of seed and pollen germination. In a series of straight-chain saturated monocarboxylic acids, Raynolds showed that the inhibitory activity on lettuce seed germination increased with the number of carbon atoms of the acids and that the main structure-activity correlation was lipophilic in nature.[1,2] Orito et al. studied the effects of a variety of monocarboxylic acids with and without hydroxy substituent at the 2- or 3-positions on pollen germination in *Camellia sinensis*.[3] They showed that the intensity of inhibition was related not only to the carbon number of the acid but also to the degree of unsubstitution of the carbon chain. We recently reported the isolation of 8-nonynoic (**1d**) and 9-decynoic (**1e**) acids and their methyl esters (**2d**) and (**2e**) from the stem bark of *Hibiscus rosa-sinensis*.[4] These metabolites were found to be inhibitors of the germination of lettuce seeds. The acid (**1d**) showed higher activity than **1e**, and the esters (**2d**) and (**2e**) were more active than the corresponding free acids. Thereupon, considerable attention was devoted to the correlation of inhibitory activity with number of carbon atoms in terminal acetylenic fatty acids and esters.

In this research, eight acids from 5-hexynoic (**1a**) to 12-tridecynoic (**1h**) acids and their methyl (**2a**—h), ethyl (**3a**—h) and isopropyl (**4a**—**h**) esters were prepared via ω-(*o*-nitrophenylseleno) esters and their effects on lettuce seed germination and seedling growth were studied. Further, the antimicrobial properties of the acids (**1a**—**h**) were examined, since acetylenic fatty acids 7-octynoic (**1c**), 8-nonynoic (**1d**), 10-undecynoic (**1f**), and 11-dodecynoic (**1g**) acids have been described to inhibit the growth of some fungi.[5-8]

Results and Discussion

Synthesis. Seven acids from 5-hexynoic (**1a**) to 12-tridecynoic (**1h**) acids were prepared from the corresponding terminal diols via the *o*-nitrophenyl selenides (Scheme 1), except that **1f** was prepared from commercially available 10-undecenoic acid. Primary alkyl phenyl selenides obtained from bromides or alcohols were shown to produce terminal olefins in good yield,[9,10] which were easily converted into acetylenes by a typical method. From the terminal diols (n=3—10), 1,6-hexanediol to 1,13-tridecanediol, except 1,11-undecanediol, the corresponding bromo esters (**5**) were prepared in three steps in ca. 35% yield by monobromination with hydrobromic acid followed by oxidation and methylation. Treatment of the esters (**5**) with *o*-nitrophenyl selenocyanate in the presence of sodium borohydride under nitrogen in ethanol at room temperature[9] gave *o*-nitrophenyl selenides (**7**) in 75—80% yields. The structures of **7** were comfirmed by elemental analysis, ^{1}H NMR and mass spectra (Table 1). In their ^{1}H NMR spectra, the methylene protons attached to selenium atom appeared at about δ 2.9. The EI-MS of each selenide displayed a $(M+1)^+$ ion and a characteristic M−201 peak which was apparently due to the fission of -CH_2-Se- bond. It also contained to more prominent peaks indicating further successive loss of methanol and carbon monoxide. On the other hand, the alcohols (**4d**) and (**4e**), obtained by hydrolysis of the bromo esters (**5d**) and (**5e**), were also converted into the selenides (**7d**)

and (**7e**) in 73 and 78% yields, respectively, by using *o*-nitrophenyl selenocyanate with tributylphosphine in tetrahydrofuran at room temperature.[10] Decomposition of these selenides (**7**) by 30% hydrogen peroxide produced the corresponding olefins (**8**) in ca. 85% yields.

The synthesis was completed by converting **8** into the corresponding acetylenes (**1**), by bromination with bromine and subsequent dehydrobromination with ethanolic potassium hydroxide under reflux, in ca. 80% yields. In this simple method, the formation of allene compounds was minimal. The purification of these (**1a**—**h**) acids was done by column chromatography after methylation into **2a**—**h**. The ethyl (**3a**—**h**) and isopropyl (**4a**—**h**) esters were obtained from **1** by treatment with concentrated sulfuric acid under reflux in absolute ethanol and 2-propanol, respectively.

Activity on Seed Germination. To assess the effect of the variation in number of carbon atoms and ester substituents on the acetylenic fatty acids and their derivatives, the inhibitory activity of eight synthetic acids (**1a**—**h**) and their methyl (**2a**—**h**), ethyl (**3a**—**h**), and isopropyl (**4a**—**h**) esters on lettuce seed germina-

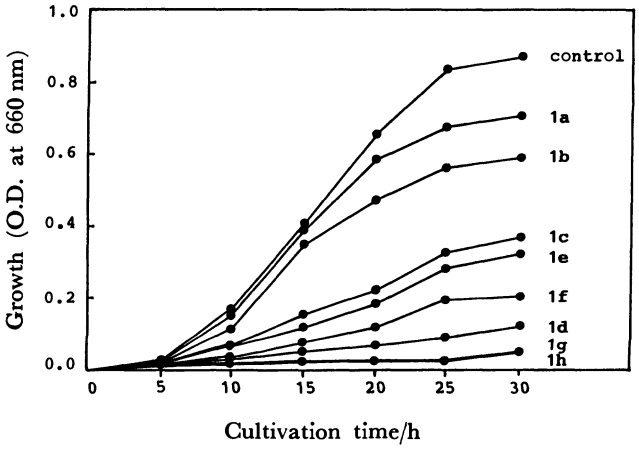

Fig. 2. Inhibitory effect of the acid (**1a**—**h**) on growth of *Hansenula anomala*.

tion were compared. Figure 1 presents the relationship between the concentration of the acids and the percentage of germination. The millimolar concentration producing 50% inhibition of germination is obtained from each curve. The inhibitory activity of all test compounds at a given concentration is shown in Table 2.

Among the acids tested, 8-nonynoic acid (**1d**) was the most potent and showed 50% inhibition at 0.13 mM (1 M=1 mol dm^{-3}). The activity of **1d** was much greater than that of nonanoic and 8-nonenoic acids so far reported.[1,4] Thus, it is apparent that the introduction of a terminal acetylenic group in the fatty acids increase inhibitory activity. As with the case of the acids, the activity of each set of methyl, ethyl and isopropyl esters was dependent on the number of carbon atoms in acetylenic chain with maximum activity at carbon number 9. The ester moiety also affected activity, a bulky one causing a decrease in activity. These results suggest that the lipophilicity-hydrophilicity balance of the compound is a fundamental requirement for the expression of marked inhibitory activity. In general, free acids showed greater activity than the corresponding esters. However, naturally occurring methyl 8-nonynoate (**2d**) and methyl 9-decynoate (**2e**) showed greater activity than the free acids (**1d**) and (**1e**). Their activities are comparable to those of well-known inhibitors, 3-indoleacetic acid[2] and abscisic acid.[11]

Activity on Seedling Growth. Four acids and three esters were selected among the synthetic compounds based on the above results of germination test and their activity tested on the hypocotyl growth in lettuce seedlings. As shown in Table 3, the acids showed similar inhibitory activity to the germination test, In which 8-nonynoic acid (**1d**) exhibited greater activity than the other acids. Its methyl ester (**2d**) was the most effective. It is interesting to note that these terminal acetylene compounds are also observed to inhibit a photosynthetic path.[12]

Antimicrobial Activity. The acids (**1g**) and (**1h**) showed weak and broad antifungal activity. The minimum inhibitory concentrations against almost all yeasts and filamentous fungi tested were 20—200 μg ml^{-1} (data not shown). Bacteria were insensitive to both **1g** and **1h**. The other acids (**1a**—**f**) were little antifungal. However, they inhibited in some degree, the growth of *Hansenula anomala* as shown in Fig. 2. In general, the inhibitory activity increased as the number of carbon atoms in the acids increased. Interestingly, **1d** was exceptionally active.

The structural significance of 8-nonynoic acid and its ester derivatives on the biological activity in microorganisms and plants remains to be elucidated.

Experimental

Mps are uncorrected. UV spectra were measured in methanol (MeOH) with a Shimadzu UV-210A spectrometer and IR spectra recorded on a Shimadzu IR-408 spectrometer. ^{1}H NMR spectra in chloroform-*d* with TMS as internal standard (δ=0) were measured at 60 (JEOL MH-60), 100 (JEOL MH-100), and 360 MHz (by Dr. Iwashita at Suntory Institute for Bioorganic Research). EI-Mass spectra were measured with a JEOL JMS-D300 apparatus and FD-mass spectra by Dr. Naoki at Suntory Institute for Bioorganic Research.

Bromo Esters from Terminal Diols. Commercially available terminal diols of 1,6-hexanediol to 1,10-decanediol and 1,12-dodecanediol, and 1,13-tridecanediol obtained from 1,13-tridecanedioic acid by methylation with diazomethane (CH_2N_2) and lithium aluminium hydride (LAH) reduction, were converted to the corresponding bromo esters by the following general procedure. A terminal diol (0.03 mol) was treated in a soln of 48% hydrobromic acid (HBr) (8.7 g) and concd sulfuric acid (H_2SO_4) (1.5 ml) for 3 h under reflux. A crude product extracted with ether was oxidized with potassium permanganate ($KMnO_4$) (2.5 g) in 20% H_2SO_4 (28 ml) at 15—20 °C. After methylation with CH_2N_2, the crude product was chromatographed over silica gel to give the bromo ester (**5**).

Bromo Ester 5. **5a** (oil): Yield 33%; IR (neat) 1740 cm^{-1}; ^{1}H NMR δ=2.36 (2H, t, J=7 Hz), 3.42 (2H, t, J=6.5 Hz), 3.70 (3H, s). **5b** (oil): Yield 33%. **5c** (oil): Yield 35%. **5d** (oil): Yield 36%. **5e** (oil): Yield 37%. **5g** (oil): Yield 37%. **5h** (oil): Yield 39%.

Methyl 9-Hydroxynonanoate (6d) and Methyl 10-Hydroxydecanoate (6e). The bromo esters (**5d**) and (**5e**) were hydrolyzed with 20% aq sodium hydroxide (NaOH) at 50 °C and the products were methylated with CH_2N_2 to give **6d** and **6e** in 93 and 91% yields, respectively. **6d**, mp 56.5—57.5 °C: IR (neat) 3400, 1740 cm^{-1}; ^{1}H NMR δ=2.27 (2H, t, J=7 Hz), 3.33 (2H, t, J=6 Hz), 3.69 (3H, s). **6e**, mp 59.5—60.5 °C: IR (neat) 3350, 1740 cm^{-1}; ^{1}H NMR δ=2.31 (2H, t, J=7 Hz), 3.32 (2H, t, J=6 Hz), 3.67 (3H, s).

Preparation of Selenides 7. 1) **From Bromide.** To a cooled (0 °C) suspension of *o*-nitrophenyl selenocyanate (1.43 g, 6.3 mmol) in abs ethanol (EtOH) (20 ml) under nitrogen (N_2), sodium borohydride ($NaBH_4$) (0.28 g, 7.4 mmol) was added with stirring. A bromo ester (**5**) (5.7 mmol) was added and the soln stirred at room temp for 13 h. After removal of EtOH, the crude product was chromatographed over silica gel to give **7**, a yellow crystalline compound. ii) **From Alcohol.** A soln of **6** (2.4 mmol) in tetrahydrofuran (THF) (8 ml) containing *o*-nitrophenyl selenocyanate (2.9 mmol) under N_2 was treated dropwise with tributylphosphine (2.9 mmol) at room temp. After being stirred for 30 min, the solvent was removed in vacuo. The crude product was purified by chromatography.

***o*-Nitrophenyl Selenides 7.** **7a**, mp 25.0—26.0 °C: IR (Nujol) 1730, 1590, 1560 cm^{-1}; ^{1}H NMR δ=2.35 (2H, t, J=7 Hz), 2.95 (2H, t, J=7.5 Hz), 3.70 (3H, s), 7.37—7.73 (3H, m), 8.47 (1H, d, J=8 Hz). Table 1.

Olefins 8 from Selenides 7. Into a cooled (0 °C) soln of a selenide **7** (3 mmol) in THF (30 ml), 30% aq hydrogen peroxide (H_2O_2) (8 ml) was added dropwise. The ice bath was removed and the soln was stirred for additional 24 h. The reaction mixture was diluted with water (H_2O) and extracted with hexane to give **8**, a very smelly oil.

Terminal Olefins 8. **8a**: Yield 68%; EIMS m/z 128 (M$^+$); IR (neat) 3070, 1740, 1640 cm^{-1}; ^{1}H NMR δ=2.35 (2H, t, J=7 Hz), 3.66 (3H, s), 4.78 (1H, br d, J=8 Hz), 4.88 (1H, br d, J=15 Hz), 5.41—6.11 (1H, m). **8b**: Yield 72%; EIMS m/z 142 (M$^+$). **8c**: Yield 80%; EIMS m/z 156 (M$^+$). **8d**: Yield 85%: EIMS m/z 170 (M$^+$). **8e**: Yield 84%; EIMS m/z 184 (M$^+$). **8g**: Yield 82%; EIMS m/z 198 (M$^+$). **8h**: Yield 80%; EIMS m/z 212 (M$^+$).

Acetylenic Esters 2 from Olefins 8. To a soln of olefin **8** (2 mmol) in chloroform ($CHCl_3$) (10 ml), excess bromine (Br_2) was added and the soln was stirred for 1 h at room temp. After being treated in the usual way, the product was made to react with potassium hydroxide (KOH) (1.7 g) in abs EtOH under reflux for 3 h. After being acidified, the product was extracted with hexane and methylated with CH_2N_2 to give **2**, a smelly oil, which was purified by chromatography over silica gel.

Acetylenic Esters 2. **2a**: Yield 68%; EIMS m/z 126 (M$^+$), 94, 81, 74, 68; IR (neat) 3300, 2100, 1730 cm^{-1}; UV 206 nm (ε 150); ^{1}H NMR δ=1.98 (1H, t, J=2.8 Hz, HC≡C-), 2.17 (2H, dt, J=2.8 and 7.0 Hz, ≡C-CH$_2$-), 2.28 (2H, t, J=7.0 Hz, -CH$_2$CO-), 3.73 (3H, s, -CO$_2$CH$_3$). **2b**: Yield 65%; EIMS m/z 140 (M$^+$), 108, 81, 74, 68. **2c**: Yield 70%; EIMS m/z 156 (M$^+$), 94, 81, 74, 68. **2d**: Yield 75%; EIMS m/z 168 (M$^+$), 137, 94, 81, 74, 68, 54. **2e**: Yield 78%; EIMS m/z 182 (M$^+$), 151, 108, 87, 74, 68, 54. **2f**: Yield 75%; EIMS m/z 196 (M$^+$), 165, 108, 87, 81, 74, 68. **2g**: Yield 73%; EIMS m/z 210 (M$^+$), 179, 108, 87, 81, 74, 68. **2h**: Yield 74%; EIMS m/z 224 (M$^+$), 193, 108, 87, 81, 74, 68.

Acetylenic Acids 1. Methyl ester **2** was gently refluxed in a small amount of 30% aq KOH for 30 min and the soln acidified with dil hydrochloric acid (HCl) to give **1**. **1a** (oil)[13]: UV 206 nm (ε 430); IR (neat) 3300, 3200—2500, 2100, 1705 cm^{-1}. **1b** (oil)[13]: UV 206 nm (ε 450). **1c** (oil): UV 206 nm (ε 450). **1d**, mp 22—23 °C: UV 206 nm (ε 490). **1e**,[14] mp 24.5—25.5 °C: UV 206 nm (ε 510). **1f**,[15] mp 29.5—30.0 °C: UV 206 nm (ε 540). **1g**, mp 33—34 °C: UV 206 nm (ε 780). **1h**, mp 40—41 °C: UV 206 nm (ε 860).

Ethyl and Isopropyl Esters 3 and 4. Ethyl and isopropyl esters **3** and **4** were obtained from the acids (**1**) by treatment with concd H_2SO_4 in abs EtOH and *i*-PrOH under reflux, respectively.

Ethyl Esters 3. **3a** (oil)[13]: Yield 70%; EIMS m/z 140 (M$^+$), 94, 88, 81, 68. UV 206 nm (ε 170); IR ($CHCl_3$) 3300, 2100, 1735 cm^{-1}; ^{1}H NMR δ=1.26 (3H, t, J=7.5 Hz, -CO$_2$CH$_2$CH$_3$), 1.94 (1H, t, J=3 Hz, HC≡C-), 2.24 (2H, dt, J=3 and 7 Hz, ≡C-CH$_2$-), 2.38 (2H, t, J=7 Hz, -CH$_2$-CO-), 4.20 (2H, q, J=7.5 Hz, -CO$_2$CH$_2$CH$_3$). **3b** (oil)[13]: Yield 70%; EIMS m/z 154 (M$^+$), 108, 88, 81, 68; UV 206 nm (ε 170). **3c** (oil): Yield 75%; EIMS m/z 168 (M$^+$), 108, 94, 88, 68; UV 206 nm (ε 204). **3d** (oil): Yield 74%; EIMS m/z 182 (M$^+$), 167, 108, 81, 68; UV 206 nm (ε 270). **3e** (oil)[14]: Yield 74%; EIMS m/z 196 (M$^+$), 108, 88, 81, 68; UV 206 nm (ε 470). **3f** (oil): Yield 72%; EIMS m/z 210 (M$^+$), 94, 88, 81, 68; UV 206 nm (ε 470). **3g** (oil): Yield 75%; EIMS m/z 224 (M$^+$), 94, 88, 81, 68; UV 206 nm (ε 830). **3h** (oil): Yield 72%; EIMS m/z 238 (M$^+$), 108, 88, 81, 68; UV 206 nm (ε 950).

Isopropyl Esters 4. **4a** (oil): Yield 68%; EIMS m/z 154 (M$^+$), 112, 94, 81, 68; UV 205 nm (ε 150); IR ($CHCl_3$) 3300, 2100, 1735 cm^{-1}; ^{1}H NMR δ=1.21 (6H, d, J=6 Hz, -CO$_2$CH-(CH$_3$)$_2$), 1.97 (1H, t, J=3 Hz, HC≡C-), 2.27 (2H, dt, J=3 and 7 Hz, ≡C-CH$_2$-), 2.39 (2H, t, J=7 Hz, -CH$_2$CO-), 4.09 (1H,

sept, J=6 Hz, $-CO_2C\underline{H}Me_2$). **4b** (oil): Yield 69%; EIMS m/z 168 (M^+), 108, 94, 81, 68; UV 205 nm (ε 170). **4c** (oil): Yield 70%; EIMS m/z 182 (M^+), 94, 81, 80, 68; UV 205 nm (ε 190). **4d** (oil): Yield 70%; EIMS m/z 196 (M^+), 102, 94, 81, 68; UV 205 nm (ε 190). **4e** (oil): Yield 72%; EIMS m/z 210 (M^+), 108, 102, 94, 81; UV 205 nm (ε 830). **4f** (oil): Yield 72%; EIMS m/z 224 (M^+), 122, 102, 81, 68; UV 205 nm (ε 1400). **4g** (oil): Yield 71%; EIMS m/z 238 (M^+), 136, 102, 94, 81; UV 205 nm (ε 1700). **4h** (oil): Yield 70%; EIMS m/z 252 (M^+), 150, 102, 81, 68; UV 205 nm (ε 1700).

Seed Germination Test. Twenty seeds of lettuce (*Lactuca sativa*, L., cv. Grand Rapids) were placed on 2 layers of filter paper in a 9-cm Petri dish containing 4 ml of test solution. The dish was incubated at 23 °C in the dark room. After 3 d, the percentage germination was determined. The test was repeated three times and the mean values calculated.

Seedling Growth Test. Lettuce seeds were germinated on filter paper moistened with distilled water for 2 d. Twenty seedlings were selected for size uniformity and planted on 2 layers of filter paper in a 9-cm Petri dish containing 4 ml of test solution. Seedlings were grown for another 3 d at 23 °C in the dark, and then hypocotyl length was measured.

Antimicrobial Test. Test organisms: fungus; *Mucor mucedo* IFO 0136, *Rh. chinensis* IFO 4745, *Asp. niger* ATCC 6275 and *P. crustosum* Thom: Yiest; *S. cerevisiae* IFO 0203, *C. utilis* ATCC 42402, *Schiz. pombe* IFO 0342 and *H. anomala* IFO 0136: bacteria; *S. aureus* NCTC 8530, *B. subtilis* K-49, *E. coli* IFO 3545 and *Ps. aeruginosa* IAM 1007. Minimum inhibitory concentration of test compound was determined by a two-fold dilution method reported previously.[16] Effect on yeast growth was evaluated turbidimetrically as follows. *Hansenula anomala* IFO 0136 was cultured in 5 ml malt wort containing a test compound at 100 μg/ml in a test tube at 25 °C. The growth was periodically examined as the optical density at 660 nm.

We are grateful to Dr. Hiroyuki Akita (The Institute of Physical and Chemical Research) and Professor Koji Hasegawa (Kagoshima University) for helpful discussion and suggestions. Our thanks are also due to Dr. Hideo Naoki and Dr. Takashi Iwashita (Suntory Institute for Bioorganic Research) for FD-mass and ^1H NMR (360 MHz) and to Dr. Kozo Shibata (Osaka City University) for elemental analysis.

(Received May 15, 1986)

Four new bitter quassinoid glycosides, yadanziosides K, M, N, and O were isolated from *Brucea javanica* (L.) MERR and their structures were determined by spectral measurement and chemical means. The aglycone of yadanzioside O was found to exhibit a significant antitumor activity against the murine P388 lymphocytic leukemia and this aglycone could be prepared from brusatol.

"Ya-dan-zi," seed of *Brucea javanica* (L.) MERR has been used as a Chinese medicine for the treatment of cancer, and the main components with antileukemic activity have been investigated.[2)] We examined the minor components of "Ya-dan-zi," and reported structure elucidation of sixteen new bitter principles.[3)] Further investigation led to the isolation of four new quassinoid glycosides, yadanziosides K, M, N, and O (**1**—**4**). This paper describes structure determination of these bitter principles (**1**—**4**) and a preparation and antileukemic activity of the aglycone of yadanzioside O (**4**).

The methanol extract of defatted seeds of *B. javanica* was partitioned between dichloromethane and water. The organic layer was subjected to separation by a silica-gel column chromatography, followed by a Lobar column Lichroprep RP-8, Toyopearl HW-40S, or silicic acid column chromatography to afford yadanzioside K (**1**; ca. 0.001% yield), yadanzioside M (**2**; ca. 0.0005% yield), yadanzioside N (**3**; ca. 0.0001% yield), and yadanzioside O (**4**; ca. 0.0002% yield).

Yadanzioside K (**1**) crystallized from methanol, mp 214.5—216.5 °C and showed the presence of three tertiary methyl, two vinyl methyl, an acetoxyl, and a methoxycarbonyl groups and an olefinic proton in the ^{1}H NMR spectrum (Table 1), and the presence of an α,β-unsaturated carbonyl group was shown by the UV spectrum. The molecular formula, $C_{36}H_{48}O_{18}$, was inferred from ^{13}C NMR spectrum (Table 2) together with a peak at *m/z* 769 ($[M+H]^+$) in the secondary ion mass spectrometry (SI-MS) and hydrolysis with β-glucosidase to give bruceantinol (**5**)[4)] as the major aglycone. The glycosylation shifts of signals due to C-3 and C-4 were $\Delta\delta$+2.1 and +18.3 ppm, respectively (Table 2), and the signal due to the $C_{(4)}$-CH_3 was observed at δ 2.04 as a singlet in the ^{1}H NMR spectrum of **1**. Thus the structure of yadanzioside K (**1**) was determined to be 3-*O*-(β-D-glucosyl)bruceantinol.

Yadanzioside M (**2**) was obtained as amorphous powder from acetone-hexane, mp 208—213 °C (decomp). The EI-MS showed a peak at *m/z* 542 ($[M-C_6H_{10}O_5]^+$) and the SI-MS afforded a peak at *m/z* 727 ($[M+Na]^+$). Enzymatic hydrolysis of **2** with β-glucosidase afforded bruceantarin (**6**)[5)] as the major aglycone. These observations suggest the molecular formula, $C_{34}H_{40}O_{16}$, for **2**. The ^{1}H NMR spectrum of **2** showed the presence of a doublet signal (J=7 Hz) due to $C_{(4)}$-CH_3 at δ 1.18 and a singlet signal at δ 7.26 assignable to $C_{(1)}$-H. This fact suggests the bruceantarin moiety enolizes into a 2-hydroxy-3-keto-1-ene structure, which forms the β-glucoside linkage through the oxygen atom on C-2 of the aglycone.[3b)] The configuration of the $C_{(4)}$-CH_3 of **2** was inferred to be α-equatorial from the structural similarity to bruceoside A.[2c)] The structure (**2**) is, therefore, proposed for yadanzioside M.

Yadanzioside N (**3**), mp 175—180 °C, showed a doublet signal due to an anomeric proton at δ 5.47 (J=7.0 Hz) in the ^{1}H NMR spectrum, a peak at m/z 733 ($[M+Na]^+$) in SI-MS, and a peak at m/z 548 ($[M-C_6H_{10}O_5]^+$) in EI-MS. These spectral data together with ^{13}C NMR spectrum (Table 2) indicate that **3** is a hexoside with the molecular formula, $C_{34}H_{46}O_{16}$. Yadanzioside N (**3**) was hydrolyzed with 1.5 M (1 M=1 mol dm^{-3}) sulfuric acid in boiling methanol to afford an aglycone (**7**) and D-glucose, the latter of which was identified by GLC after trimethylsilylation. The aglycone (**7**), mp 180—183 °C, was shown to have the molecular formula, $C_{28}H_{36}O_{11}$, by high-resolution mass spectrum (HR-MS), and a peak at m/z 111 in EI-MS suggested the presence of a heptenoyl group ($C_6H_{11}CO$) in the side chain. Since the ^{1}H NMR spectrum revealed the presense of an isopropyl group and a vinyl methyl group (δ 1.06 d (J=6.8 Hz) and 2.14 d (J=1.1 Hz), respectively) in the side chain and the shift values of signals due to these groups are similar to those of bruceantin (**8**)[6] in ^{1}H and ^{13}C NMR spectra, the side chain might be 3,4-dimethyl-2-pentenoyl group. The UV absorption maxima appeared at 220 and 267 nm in ethanol solution, and the latter was shifted to 314 nm on addition of alkali, indicating the presence of a diosphenol moiety.[7]

In the ^{1}H NMR spectrum of **3**, a doublet signal due to $C_{(11)}$–H appeared at δ 6.20, which is lower than that of bruceantin (**8**).[6] On irradiation of a broad triplet signal due to $C_{(4)}$–H at δ 2.24, signals at δ 0.87 due to $C_{(4)}$–CH_3 and at δ 6.10 due to $C_{(3)}$–H became sharp. On the other hand, the aglycone (**7**) showed a doublet signal due to $C_{(4)}$–CH_3 at δ 1.11 and a doublet signal due to an olefinic proton at C-3 at δ 5.74 with a coupling constant, J=2.4 Hz. These spectral features suggest that the configuration of $C_{(4)}$–CH_3 is α-equatorial and that A-ring of the aglycone (**7**) is the same as that of norquassin.[7] From these observations and ^{1}H and ^{13}C NMR spectral comparison with bruceantin (**8**), the aglycone (**7**) was shown to be an isomer with 1-keto-2-ene structure of bruceantin (**8**). Since no bathochromic shift of the UV absorption maxima of **3** was observed on addition of alkali, the glycoside linkage was shown to be formed through an oxygen atom on C-2 of the aglycone (**7**). The structure of yadanzioside N (**3**) was, therefore, determined to be methyl 2-(β-D-glucopyranosyloxy)-13β,20-epoxy-15β-

Table 2. ^{13}C NMR Spectra of Yadanziosides K (**1**), M (**2**), N (**3**), and O (**4**), Bruceantin (**8**), and Some Aglycones

a) 22.5 MHz, C_5D_5N. b) 67.5 MHz, $CDCl_3$. c) 22.5 MHz, $CDCl_3$. d) The assignment of signals may be reversed. e) and j)—n) are the same as d). f) Aromatic carbon atom adjacent to the carbonyl carbon. g) Carbon atom at *o*-position. h) Carbon atom at *m*-position. i) Carbon atom at *p*-position.

[(2*E*)-3,4-dimethyl-2-pentenoyloxy]-11β,12α-dihydroxy-1,16-dioxo-2-picrasen-21-oate, which is a new type bruceoside with a quassin-type A-ring.

Yadanzioside O (**4**), mp 183—188 °C, was found to be a hexose with the same skeleton as yadanzioside G (**9**)[3b] except for an additional triplet signal (δ 22.0) due to a methylene group from the comparison of ^{13}C NMR spectra (see Table 2). The ^1H NMR spectrum of **4** also revealed the presence of an acetoxyl, an ethyl, and two methyl groups assignable to the side chain together with an olefinic proton. Therefore the structure of the side chain could be formulated as 15-*O*-(4-acetoxy-3-ethyl-4-methyl-2-pentenoyl), and geometry of the double bond was assigned to be 2*E* by the following difference NOE measurement of **4** at 400 MHz. Irradiation of the signal due to $C_{(2')}$-H at δ 6.10 resulted in an enhancement of the signals at δ 1.49 and 1.51 due to the geminal methyl group at C-4′.

Yadanzioside O (**4**) was hydrolyzed with β-glucosidase to yield an aglycone (**10**), mp 138—143 °C, which gave no molecular ion but a fragment ion at *m/z* 560 due to a loss of acetic acid in the EI-MS. The ^1H and ^{13}C NMR spectra of **10** were very similar to those of bruceantinol (**5**)[4] except for signals due to the

additional methylene group in the side chain. This fact implies that A-ring of **10** possesses 3-hydroxy-3-en-2-one structure; the signal due to $C_{(4)}$-CH_3 appeared at δ 1.85 as a doublet signal with a small coupling constant (J=2.2 Hz). An anomeric proton was observed at δ 5.28 as a doublet signal (J=8.1 Hz) and a signal due to $C_{(4)}$-CH_3 appeared at δ 1.16 as a doublet signal (J=8.1 Hz) in the ^{1}H NMR spectrum of **4**. Since these spectral features are almost the same as those for yadanzioside G (**9**) and also yadanziosides A,[3b] C,[3b] F,[3a] and J,[3a] the structure of yadanzioside O (**4**) was determined to be methyl 2-(β-D-glucopyranosyloxy)-13β,20-epoxy-15β-[(2*E*)-4-acetoxy-3-ethyl-4-methyl-2-pentenoyloxy]-11β,12α-dihydroxy-3,16-dioxo-1-picrasen-21-oate. Yadanzioside O (**4**) is a bruceoside with the largest carbon number in the 15-*O* side chain so far in nature.

The structure (**10**) proposed for the aglycone of yadanzioside O was confirmly established by the partial synthesis, which was achieved by the reaction of (2*E*)-4-acetoxy-3-ethyl-4-methyl-2-pentenoic acid (**11**) with 3-*O*-(*t*-butyldimethylsilyl)bruceolide (**12**) derived from brusatol (**13**).

Methyl (2*E*)-3-ethyl-4-hydroxy-4-methyl-2-pentenoate (**14**) was prepared by the Wittig-Honer reaction[8] of 2-hydroxy-2-methyl-3-pentanone (**15**)[9] with a Wittig reagent derived from dimethyl (methoxycarbonylmethyl)phosphonate using sodium hydride as a base in dimethoxyethane (DME). The reaction did not occur at room temperature, but took place at boiling temperature to afford the reaction product (**14**) together with a considerable amount of undesirable by-products. Separation of **14** from the reaction mixture was attained by preparative liquid chromatography to afford **14** in 27% yield. Geometry of the double bond of **14** was determined after hydrolysis and acetylation. Although a double bond isomer, the starting material (**15**), and unidentified by-products were obtained from the reaction mixture, neither further purification nor identification for these products was carried out. Hydrolysis of **14** with alkali followed by acetylation yielded 4-acetoxy-3-ethyl-4-methyl-2-pentenoic acid (**11**) in 95% yield from **14**. The synthetic unsaturated acid (**11**) showed a singlet signal due to the olefinic proton at δ 5.85, which was almost the same as the shift value (δ 5.78) observed for yadanzioside O aglycone (**10**). Thus the double bond geometry of **11** was concluded to be 2*E*.

The derivation of the skeletal part and introduction of the side chain into $C_{(15)}$-OH are as follows; brusatol (**13**) was treated with *t*-butyldimethylsilyl chloride in the presence of imidazole in DME to afford 3-*O*-(*t*-butyldimethylsilyl)brusatol in 94% yield, which, on hydrolysis with potassium methoxide in dry methanol, gave 3-*O*-(*t*-butyldimethylsilyl)bruceolide (**12**) in 65% yield.[10] The esterification of the acid (**11**) with **12** was effected in the presence of dicyclohexylcarbodiimide (DCC) in dichloromethane,[11] and the reaction product (**16**) was subjected to deprotection by a treatment with 5% hydrofluoric acid-acetonitrile or with tetrabutylammonium fluoride in tetrahydrofuran (THF) at 0 °C. The synthetic specimen was found to be completely identical with yadanzioside O aglycone (**10**).

Yadanzioside O aglycone (**10**) exhibited a significant antitumor activity against the murine P388 lymphocytic leukemia[12] and the ILS values for the natural specimen were 8.2, 37.1, and 47.2% at 1, 2, and 4 mg/kg/d dose levels, respectively. The ILS values for the synthetic one were 42.3 and 46.4% at 4 and 6 mg/kg/d dose levels, respectively, but a toxicity was observed at 8 mg/kg/d dose level.

Experimental[13]

Extraction and Separation. Pulverized seeds (49.5 kg) of *B. javanica*, "Ya-dan-zi" were defatted with hexane (100 l) twice and then with extracted with methanol (100 l) twice. The methanol extract was concentrated in vacuo to give a syrup, to which the equal volume of water was added. The aqueous solution was completely defatted with hexane (7 l) three times and then extracted with dichloromethane five times. The organic layer was concentrated to give an oily residue (158 g), which was subjected to the following separation.

Column A. The residue (158 g) was dissolved in chloroform and absorbed on silica gel (335 g). After the solvent was removed in vacuo, the silica gel was placed on the top of a column of silica gel (2.5 kg) and elution was performed with the following solvents; benzene (frs 1—3, each 1.5 l), benzene-ethyl acetate (2:1, frs 4—10; 1:1, frs 11—19; 1:2, frs 20—23, each 1.5 l), ethyl acetate (frs 24—30, each 1.5 l), 10% methanol in ethyl acetate (frs 31—35, each 2 l), and 20% methanol in ethyl acetate (frs 36—40, each 2 l).

Column B. The fractions 35—37 of Column A were combined to give a residue (73 g), a part (10.7 g) of which was chromatographed on silica gel (850 g) eluted with lower layer of chloroform-methanol-water in the following ratio; frs 1—6 (25:4:1), frs 7—11 (20:4:1), and frs 11—24 (16:4:1) in 400 ml fraction each.

Column C. A part (55.3 g) of the fractions 35—37 of Column A was separated by column chromatography on silica gel (2.5 kg) eluted with lower layer of chloroform-methanol-water (25:4:1). Thirty fractions (each 500 ml) were collected.

Column D. The fraction 21 of Column C gave a residue (3.8 g), a part (500 mg) of which was separated by reversed phase chromatography using Lobar column Lichroprep RP-8 size B. Elution (each fraction, 10 g) was performed with methanol-water (4:6—5:5). Fractions 55—63 gave yadanzioside O (**4**; 16 mg).

Column E. A part (826 mg) of the fraction 24 (2.2 g) of Column C was subjected to separation using Lobar column eluted with methanol-water (4:6). Eighty-two fraction (each 10 g) were collected. Fractions 62—65 gave yadanzioside M (**2**; 25 mg).

Column. F. Tne fraction 27 (1.2 g) of Column C was separated using Lobar column eluted with methanol-water

(4:6—5:5). Seventy-six fractions (each 10 g) were collected. Fractions 70—76 gave yadanzioside N (**3**; 25 mg).

Column G. The fractions 12 and 13 of Column B were combined and evaporated to afford a residue (5.2 g), a part (1.5 g) of which was separated using Lobar column. Elution (each 10 g) was performed with methanol-water (4:6) and 142 fractions were collected.

Column H. The fractions 64—74 (89 mg) of Column G were combined and separated by gel chromatography using Toyopearl HW-40S. Elution with methanol (each 10 g) gave yadanzioside M (**2**; 22 mg) in fractions 56—62.

Column I. The fractions 127—142 of Column G gave a residue (17 mg), which was separated using Toyopearl HW-40S. Elution (each 10 g) with methanol gave yadanzioside O (**4**; 5 mg).

Column J. The fraction 14 (932 mg) of Column B was purified by partition chromatography on silicic acid (400 g) pretreated with water (270 ml). Elution (each 250 ml) was performed with 0, 3, 6, ···, 24% ethanol in chloroform (each 1 l).

Column K. The fractions 16 and 17 of Column J were combined (524 mg) and chromatographed using a Lobar column. Elution (each 10 g) was performed with methanol-water.

Column L. The fractions 17—24 of Column K were combined and evaporated to afford a residue (291 mg), which was separated using Toyopearl HW-40S. Elution (each 10 g) with methanol gave yadanzioside K (**1**; 24 mg) from fractions 41 and 42.

Yadanzioside K (1). $[\alpha]_D^{23}$ +15° (*c* 1.0, EtOH); $[\alpha]_D^{18}$ −31° (*c* 0.9, C_5H_5N); IR (KBr) 3450, 1740, 1645, and 1065 cm^{-1}; UV (EtOH) 222 nm (ε 17000) and 252 nm (ε 9000); ^1H NMR (Table 1); ^{13}C NMR (Table 2); EI-MS *m/z* (%) 546 ([M−162−60]$^+$: 1.4), 438 (3), 420 (1.4), 402 (1.9), 392 (1.8), 149 (18), 109 (90), 83 (70), 60 (100), and 57 (82); SI-MS *m/z* 769 ([M+H]$^+$); HR-MS (EI) *m/z* 546.2100. Calcd for $C_{28}H_{34}O_{11}$: *m/z* 546.2100.

Enzymatic Hydrolysis of 1. Yadanzioside K (**1**; 67 mg) in water (5 ml) was treated with β-glucosidase (20 mg) at 37 °C for 2 weeks and the usual work-up afforded bruceantinol (**5**; 17 mg) together with the starting material (**1**; 35 mg).

Yadanzioside M (2). $[\alpha]_D^{26}$ +39° (*c* 1.3, EtOH); IR (KBr) 3450, 1740, 1680, 1640, 1075, 1050, and 720 cm^{-1}; UV (EtOH) 231 nm (ε 16000) and 255 nm (ε 9000); ^1H NMR (Table 1); ^{13}C NMR (Table 2); EI-MS *m/z* (%) 542 ([M−162]$^+$; 3.8), 438 (6.6), 420 (3.5), 402 (3.4), 392 (2.4), 374 (2), 369 (2), and 105 (100); SI-MS *m/z* 727 ([M+Na]$^+$); HR-MS (EI) *m/z* 542.1804. Calcd for $C_{28}H_{30}O_{11}$: *m/z* 542.1789.

Enzymatic Hydrolysis of 2. Yadanzioside M (**2**; 60 mg) in water (6 ml) was hydrolyzed with β-glucosidase (28 mg) under the same conditions as before to yield bruceantarin (**6**; 11 mg) and the unchanged material (**2**; 24 mg).

Yadanzioside N (3). $[\alpha]_D^{24}$ +7.6° (*c* 1.8, EtOH); IR (KBr) 3420, 1740, 1680, 1640, 1080, 1045, and 1020 cm^{-1}; UV (EtOH) 222 nm (ε 13400) and 255 nm (ε 5100); ^1H NMR (Table 1); ^{13}C NMR (Table 2); EI-MS *m/z* (%) 548 ([M−$C_6H_{10}O_5$]$^+$; 0.1), 530 (0.8), 438 (0.6), 420 (0.9), 402 (5), 372 (4), 345 (3), 315 (4), and 111 (100); SI-MS *m/z* 733 ([M+Na]$^+$), 549, 531, 439, 421, 185, and 111; HR-MS (EI) *m/z* 548.2264. Calcd for $C_{28}H_{36}O_{11}$: *m/z* 548.2258.

Acid Hydrolysis of 3. A solution of yadanzioside N (**3**; 35 mg) in 1.5 M sulfuric acid-methanol (14 ml) was heated under reflux for 4 h. The reaction product, after removal of the solvent, was extracted with dichloromethane and divided into an organic layer and an aqueous layer. The usual work-up of the organic layer gave a residue, which was purified by column chromatography on silica gel (1 g). Elution with 5% methanol in chloroform yielded an aglycone (**7**; 11 mg), mp 180—183 °C; $[\alpha]_D^{24}$ +30° (*c* 0.7, EtOH); IR (KBr) 3460, 1750, 1685, 1645, 1050, and 1010 cm^{-1}; UV (EtOH) 220 nm (ε 16100) and 267 nm (ε 5500); on addition of potassium hydroxide, the latter maximum shifted to 314 nm (ε 4000); ^1H NMR (Table 1); ^{13}C NMR (Table 2); EI-MS *m/z* (%) 548 (M$^+$; 0.3), 530 (3), 512 (0.2), 420 (1), 402 (10), 372 (6), 345 (4), 315 (4), and 111 (100); HR-MS *m/z* 548.2282. Calcd for $C_{28}H_{36}O_{11}$: M, 548.2257. The aqueous layer, obtained from the acid hydrolysis of **3**, was passed through a short column of anion-exchange resin (Amberlite IRA-400, hydroxide form) and the eluate was evaporated in vacuo to give a residue. The residue was identified as D-glucose by GLC after trimethylsilylation.

Yadanzioside O (4). $[\alpha]_D^{21}$ +20° (*c* 2.0, EtOH); IR (KBr) 3430, 1740, 1680, 1640, 1065, 1050, and 1020 cm^{-1}. UV (EtOH) 224 nm (ε 14900) and 254 nm (ε 8000); ^1H NMR (Table 1); ^{13}C NMR (Table 2); EI-MS *m/z* (%) 560 ([M−$C_6H_{10}O_5$−AcOH]$^+$; 0.7), 438 (3), 420 (0.8), 402 (1), 392 (0.9), 141 (8), 123 (29), and 60 (100); SI-MS *m/z* 805 ([M+Na]$^+$), 561, 439, and 421.

Enzymatic Hydrolysis of 4. Yadanzioside O (**4**; 72 mg) was hydrolyzed with β-glucosidase (20 mg) to afford an aglycone (**10**; 13 mg) together with the starting material (**4**; 33 mg). **10**: Mp 138—143 °C; $[\alpha]_D^{27}$ +23° (*c* 0.6, EtOH); IR (KBr) 3450, 1740, 1640, and 1060 cm^{-1}; UV (EtOH) 222 nm (ε 14800) and 278 nm (ε 7000); ^1H NMR (Table 1); ^{13}C NMR (Table 2); EI-MS *m/z* 560 ([M−AcOH]$^+$; 1.5), 438 (4), 420 (3), 402 (4), 392 (6), 354 (18), 278 (36), 140 (56), 123 (68), 111 (82), and 60 (100); HR-MS *m/z* 560.2258. Calcd for $C_{29}H_{36}O_{11}$: *m/z* 560.2258.

Methyl (2*E*)-3-Ethyl-2-hydroxy-4-methyl-2-pentanoate (14). A Wittig reagent was prepared from dimethyl (methoxycarbonylmethyl)phosphonate (3.4 ml; 4 equiv) and sodium hydride (750 mg; 4 equiv) in DME (60 ml) at room temperature for 1 h under nitrogen atmosphere in a three-necked flask and then the solution was heated under reflux. To the solution 2-hydroxy-2-methyl-3-pentanone (**15**; 500 mg, 4.3 mmol) in DME (10 ml) was added and the heating was continued for 4 h. The usual work-up gave a residue, which was subjected to separation by preparative LC (Liquid Chromatograph LC-08, Japan Analytical Industry, column: JAIGEL-1H and 2H; solvent: chloroform) to afford methyl (2*E*)-3-ethyl-4-hydroxy-4-methyl-2-pentenoate (**14**; 203 mg) as an oil, IR (neat) 3460, 1710, 1640, and 750 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=1.13 (3H, t, *J*=8 Hz), 1.39 (6H, s), 2.57 (2H, q, *J*=8 Hz), 3.68 (3H, s), and 6.03 (1H, s); ^{13}C NMR (22.5 MHz, $CDCl_3$) δ=14.8q, 22.4t, 29.0q, 29.0q, 50.9q, 77.4s, 112.7d, 167.3s, and 170.6s; EI-MS *m/z* (%) 157 ([M−15]$^+$; 33), 154 (94), 139 (28), 129 (100), 122 (57), 111 (20), 97 (91), and 85 (65).

(2*E*)-4-Acetoxy-3-ethyl-4-methyl-2-pentenoic Acid (11). Methyl (2*E*)-3-ethyl-4-hydroxy-4-methyl-2-pentenoate (**14**; 468 mg) was treated with 5% potassium hydroxide solution (15 ml) at 80 °C for 10 h. Acidification by addition of 0.25 M sulfuric acid and the usual work-up afforded (2*E*)-3-ethyl-4-hydroxy-4-methyl-2-pentenoic acid as an oil quantitatively,

IR (film) 3450, 3300—2500, 1700, and 1640 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=1.13 (3H, t, J=8 Hz), 1.43 (6H, s), 2.56 (2H, q, J=8 Hz), and 6.07 (1H, s); EI-MS m/z (%) 143 ($[M-15]^+$; 22), 140 (39), 125 (28), 115 (100), and 97 (38).

The carboxylic acid (430 mg) above obtained was acetylated with acetic anhydride (1 ml) in the presence of triethylamine (5 ml) and 4-dimethylaminopyridine (DMAP, 330 mg) at room temperature for 3 h with stirring. To the cooled solution was added 2 M hydrochloric acid (50 ml) and the reaction product was extracted with ether (30 ml×3). The extracts were combined and washed with 2 M hydrochloric acid (30 ml) and then with water. The usual work-up gave a residue, which was purified by column chromatography on silica gel (25 g). Elution with 0—2% methanol in chloroform yielded (2*E*)-4-acetoxy-3-ethyl-4-methyl-2-pentenoic acid (**11**; 95% yield) as an oil, IR (neat) 3500—2500, 1740, 1700, and 1640 cm^{-1}. ^1H NMR (90 MHz, $CDCl_3$) δ=1.13 (3H, t, J=8 Hz), 1.59 (6H, s), 2.62 (2H, q, J=8 Hz), 2.02 (3H, s), and 5.85 (1H, s); ^{13}C NMR (22.5 MHz, $CDCl_3$) δ=14.4q, 21.9q, 21.9q, 26.6q, 26.6q, 82.9s, 113.9d, 169.1s, 169.6s, and 171.0s; EI-MS m/z (%) 158 ($[M-42]^+$; 5), 140 (100), 125 (81), 122 (33), 112 (38), 97 (85), 60 (23), and 43 (56).

Reaction of 3-*O*-(*t*-Butyldimethylsilyl)bruceolide (12) with 11. 3-*O*-(*t*-Butyldimethylsilyl)bruceolide (**12**; 970 mg),[10] DMAP (21 mg), and DCC (362 mg) were dissolved in dry dichloromethane (15 ml) under nitrogen atmosphere and the acid (**11**; 351 mg) in dichloromethane (15 ml) was added. The mixture was stirred at 25 °C overnight and filtered through a column of Celite. The filtrate was washed with water (50 ml), 5% acetic acid (50 ml), and then water (50 ml). The usual work-up gave a residue, which was purified by column chromatography on silica gel (50 g). Elution with 1% methanol in chloroform afforded a 3-*O*-(*t*-butyldimethylsilyl) derivative (**16**; 469 mg) of the aglycone (**10**) together with the starting material (**12**; 579 mg). **16**: Mp 281.5—283 °C, colorless needles from chloroform-acetone; IR (KBr) 3560, 3380, 1745, 1680, 1650, 1060, and 1020 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=0.13 (3H, s), 0.17 (3H, s), 0.97 (9H, s), 1.13 (3H, t, J=7 Hz), 1.39 (3H, s), 1.56 (6H, s), 1.85 (3H, brs), 2.01 (3H, s), 3.78 (3H, s), 4.22 (2H, br), 4.62 (1H, d, J=8 Hz), 4.80 (1H, brs), 5.78 (1H, s), and 6.20 (1H, d, J=13 Hz); EI-MS m/z (%) 677 ($[M-(CH_3)_3C]^+$; 6), 659 (4), 635 (14), 617 (92), 598 (16), 537 (47), 495 (8), 478 (27), 424 (16), 326 (13), 123 (100), and 60 (58); HR-MS (EI) m/z 677.2656. Calcd for $C_{33}H_{45}O_{13}Si$: m/z 677.2629.

Deprotection of 3-*O*-(*t*-Butyldimethylsilyl) Group of 16. i) A solution of 3-*O*-(*t*-butyldimethylsilyl) derivative (**16**; 50 mg) in acetonitrile-47% hydrofluoric acid (10:1, 3 ml) was stirred at room temperature for 4 h. After addition of dichloromethane and water, the organic layer was separated. The aqueous layer was extracted with dichloromethane twice and the organic layers were combined. The usual work-up gave a residue, which was chromatographed on silica gel (5 g). Elution with 1% methanol in chloroform yielded yadanzioside O aglycone (**10**; 21 mg). ii) To a solution of 3-*O*-(*t*-butyldimethylsilyl) derivative (**16**; 244 mg) in THF (5 ml) was added tetrabutylammonium fluoride (230 mg) in THF (5 ml) at 0 °C under nitrogen atmosphere. The solution was stirred for 30 min at the same temperature and chloroform (100 ml) was added. The organic solution was washed with a saturated sodium hydrogencarbonate solution. The washings were extracted with chloroform (50 ml×2) and the organic solution and the extracts were combined and worked up as usual. Column chromatographic separation on silica gel (15 g, eluted with 3% methanol in chloroform) afforded yadanzioside O aglycone (**10**; 206 mg).

The authors wish to thank Mr. Hideo Naoki of Suntory Institute for Bioorganic Research for measurement of SI-MS.

The Ability of the Proline Residue to Promote Successive-Intramolecular Hydrogen Bonds in Oligopeptides[1)]

Mitsuaki NARITA, Shizuko ISOKAWA, Masamitsu DOI, and Ryuhei WAKITA
Department of Industrial Chemistry, Faculty of Technology, Tokyo University of Agriculture and Technology, Koganei 184
(Received May 15, 1986)

In order to investigate the ability of the Pro residue to promote helical folding in oligopeptides, the IR spectroscopic conformational study of the oligo(Leu)s containing the Pro residue was performed in dichloromethane. Their IR difference spectra suggested the occurrence of successive-intramolecular hydrogen bonds just like incipient α-helical structures formed by one, two, three, and so forth $i \rightarrow i-4$ hydrogen-bonding patterns, alluding to the ability of the Pro residue to promote helical folding in the peptides. However, the intensities of hydrogen-bonded absorption bands in the amide A region of each peptide strongly suggested that conformations of the peptides investigated were also contributed by other intramolecularly hydrogen-bonded folded structures, which had lower absorption coefficients. The initiation mechanism of successive-intramolecular hydrogen bonding in the peptides is apparently attributed to the disturbance of the β-sheet formation by the rotation of the tertiary peptide bond plane (Leu-Pro), that is, the restriction of the values of the backbone dihedral angles ϕ and ψ of the Pro residue due to the low flexibility of the pyrrolidine ring.

In connection with the design of the synthetic route for peptides and proteins based on the solubility prediction method,[2-5)] it is of particular importance to investigate the nucleation site of helical folding in peptide intermediates since the β-sheet→helical conformational transformation gives rise to the great improvement on solubility of peptide intermediates.[6-8)] The investigation of the initiation mechanism of helical folding in proteins is also one of the quite interesting problems for understanding the mechanism of protein folding and also for predicting protein folding from amino acid sequences. However, it has been well recognized that the determination of nucleation sites of helical folding in peptides and proteins is quite difficult.[9)] In our recent papers,[6-8)] we demonstrated the great ability of the Aib residue to promote helical folding in peptides and subsequently proposed that the restriction of the backbone dihedral angles ϕ and ψ of an amino acid residue to the helical region is one of important initiation mechanisms of helical folding in natural proteins. Therefore, it is of particular interest to investigate the ability of the Pro residue to promote helical folding in peptides since the most frequently observed conformations for the Pro residue lie in the region of the backbone dihedral angles $\phi=-60\pm10°$ and $\psi=-30\pm20°$ (helical region), and $\phi=-60\pm10°$, $\psi=120\pm20°$ due to the low flexibility of the pyrrolidine ring in the Pro residue.[10)]

Thus, in this paper, we give attention to the Pro residue, which is hitherto emphasized to be a strong helix and β-sheet breaker.[11-14)] As for conformations of oligo(Leu)s containing the Pro residue,[14)] in the solid state, the insertion of the Pro residue into homooligo(Leu)s caused the disturbance of the β-sheet structure by the rotation of the tertiary peptide bond plane (Leu-Pro). On the other hand, in methanol, the CD patterns of the oligo(Leu)s containing the Pro residue suggested the existence of a detectable amount of the α-helical structure. In this paper, we investigate the ability of the Pro residue to promote helical folding in oligo(Leu)s containing the Pro residue using IR difference spectra in dichloromethane and discuss the role of the Pro residue in remarkable improvement on solubility of peptide intermediates containing the Pro residue.

Experimental

The samples of Boc-Leu$_2$-OBzl **1**, Boc-Leu$_3$-OBzl **2**, Boc-Leu$_4$-OBzl **3**, and Boc-Leu$_5$-OBzl **4** were prepared by the method described in the previous paper.[14)] The other peptides **5**—**10** examined in this study were also prepared by the essentially same method described previously for

Table 1. Elemental Analysis of the Peptides **5**—**10**

Compound	Formula	Found (Calcd)		
		C (%)	H (%)	N (%)
5	$C_{45}H_{83}N_7O_{10}\cdot H_2O$	60.23 (60.04)	9.48 (9.52)	11.03 (10.89)
6	$C_{35}H_{56}N_4O_7$	65.31 (65.19)	8.71 (8.75)	8.93 (8.69)

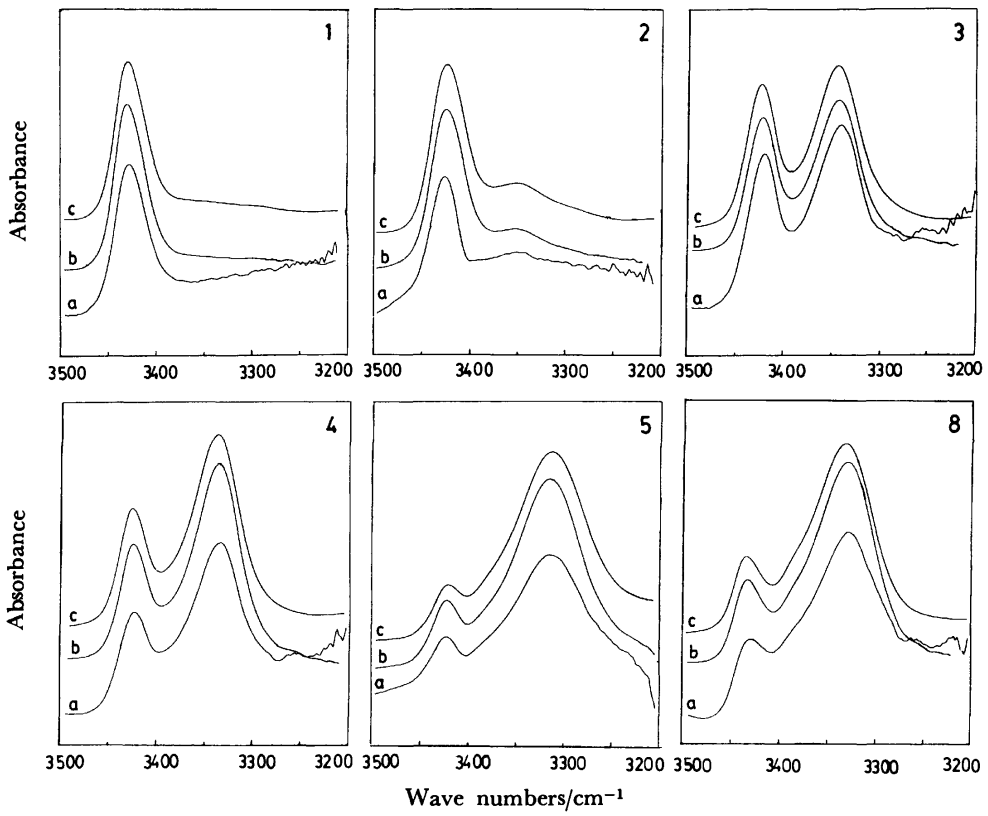

Fig. 4. IR absorption spectra in the amide A region of the peptides **1**—**4** and **8** in dichloromethane over the wide range of concentrations (0.10—10 mM). a: 0.10 mM, b: 1.0 mM, c: 10 mM.

of concentrations by employing 0.5 mm- and 5 mm-path length cells with potassium bromide windows.

Results and Discussion

The peptides **1**—**10** examined in this study are listed in Fig. 1. The IR spectra in the N-H stretching region of the peptides **1**—**5** and **6**—**10** in dichloromethane (1.0 mM (1 M=1 mol dm^{-3})) are shown in Figs. 2 and 3, respectively. The spectra in Figs 2, 3, 5, 7, and 9 are shown with the same scale of absorbance. The spectra in Figs. 2 and 3 show two distinct bands at 3430—3420 and 3350—3320 cm^{-1} although the latter band of the dipeptide **1** is negligible. The bands at 3430—3420 cm^{-1} are clearly due to the free urethane and peptide N-H stretching vibration, and the bands at 3350—3320 cm^{-1} can arise from the hydrogen-bonded N-H groups.[5,15-18] Figure 4, as typical examples, shows the IR spectra of the peptides **1**—**5** and **8** over the wide range of concentrations (0.10—10 mM). Intensity ratios of the hydrogen-bonded N-H absorption to the free N-H absorption (A_H/A_F) for each peptide do not vary much with concentration, indicating that, especially at concentrations lower than 1.0 mM, the hydrogen-bonded N-H absorptions are due almost exclusively to intramolecularly hydrogen-bonded folded species as reported for Boc-Leu_n-OCH_3 (n=3—6).[17]

For the purpose of elucidating intramolecularly hydrogen-bonded folded species, the IR difference spectra between the dipeptide **1** and the peptides **6** through **9** are examined in the amide A region. As shown in Fig. 5, the absorptions of the free urethane and peptide N-H groups in the peptides **6**—**9** are almost clearly compensated with those absorptions in the peptide **1**. When we presume that the absorption coefficients of the free urethane and peptide N-H groups in the unordered structure for the dipeptide **1** are nearly equal to those absorption coefficients in the α-helical structures for the peptides **6**—**9**, the results in Fig. 5 suggest the occurrence of incipient α-helices formed by one, two, three, and four $i \rightarrow i-4$ hydrogen-bonding patterns in the peptides **6**—**9**, respectively, as shown in Fig. 6 schematically. These conformational

behaviors are just the same with those of the oligo(Leu)s containing the Aib residue as reported previously.[6,7] Furthermore, although the tripeptide **2** possesses low amounts of intramolecularly hydrogen-bonded folded species, the IR difference spectra between the tripeptide **2** and the peptides **3**—**5** and **10** are also examined in the amide A region (Fig. 7). When we also presume the α-helical structures for the peptides **3**—**5** and **10** (Fig. 8), the three free N-H groups in the helical structures for each peptide look like to be almost compensated with the three N-H groups of the peptide **2**. Small positive and negative peaks around 3440 and 3420 cm^{-1} in Figs. 5 and 7 are probably caused by the difference in the band positions of the free N-H groups.

In the α-helical structures for the peptides **3**—**10** in Figs.6 and 8, three peptide carbonyl groups and one C-terminal ester carbonyl group are free from hydrogen bonding. Therefore, the IR difference spectra between the tetrapeptide **3** and the peptides **4**, **5**, **9**, and **10** are useful to investigate the absorption bands assigned to hydrogen-bonded peptide carbonyl groups. Figures 9a and 9b show their IR difference spectra in the amide A and amide I regions, respectively. Except for the peptide **9**, the three free N-H groups in the presumed α-helices for the peptides **4**, **5**, and **10** are again almost compensated with the free N-H groups in the presumed α-helix for the peptide **3** (Fig. 9a). On the other hand, the peptide **9** has only two free N-H groups in the α-helical structure, and the IR difference spectrum between the peptides **3** and **9** shows a negative band at 3420 cm^{-1}. Shoulder bands around 3370 cm^{-1} in Fig. 9a are probably explained by the difference in the band positions of the hydrogen-bonded N-H groups or the contribution of other intramolecularly hydrogen-bonded folded-structures. In Fig. 9b, the strong intensity bands at 1666—1655 cm^{-1} in the amide I region also suggest the α-helical structures.[15-18] The bands at 1632—1630 cm^{-1} are probably assigned to the hydrogen-bonded Pro carbonyl groups in the peptides **9** and **10**. The tendency that the hydrogen-bonded absorption bands in the amide A and amide I regions for the peptides **4**, **9**, and **10** shift to lower frequencies with increasing peptide chain length is quite resembled with that for oligo(Leu)s containing the Aib residue[6,7] and the homopeptides Z-Aib_n-OBu^t (n=3—11),[19] which have 3_{10}-helical structures. With respect to the heptapeptide **5** having the Aib residue, the ^1H NMR study also suggests that it has the α-helix in $CDCl_3$.[20]

The conformational analysis of the peptides **3**—**10** mentioned above is based on the assumption that the absorption coefficients in the amide A region of the free urethane and peptide N-H groups in the unordered structures for the peptides **1** and **2** are nearly equal to those absorption coefficients in the α-helical structures for the peptides **3**—**10**. However, the fully developed, stable α-helical structures in Figs. 6 and 8 are not supported by the intensities of

hydrogen-bonded N-H groups (Figs. 5 and 7). In Table 2, the relative intensities for hydrogen-bonded N-H groups of each peptide are summarized when we presume the α-helical structures for the peptides **3**—**10**. With respect to the homopeptides Z-Aib$_n$-OBu^t (n=3—11),[19] it was reported that a fully-developed, stable 3_{10}-helix was formed at about the octamer level. Therefore, we estimated the percentages[21] of α-helical structures for each peptide using the data of the A_H/A_F ratios for Z-Aib$_n$-OBu^t (n=8—11).[19] The results are also summarized in Table 2. The data strongly suggest that each peptide does not exist only in the fully-developed, stable α-helical structure but coexists in intramolecularly hydrogen-bonded folded-structures which have lower absorption coefficients. Since the assumption is probably not suitable that the absorption coefficients in the amide A region of the free urethane and peptide N-H groups in the unordered structures for the peptides **1** and **2** are nearly equal to those absorption coefficients in the α-helical structures for the peptides **3**—**10**, we should assume that conformations of the peptides **3**—**10** are contributed by the α-helical structures, other successively intramolecularly hydrogen-bonded folded-structures, and the unordered structures free from hydrogen bonding. This conclusion may be in compatible with the ^{1}H NMR result of the peptide **5** that its α-helical structure is not so tight around the C-terminal.[20]

High solubility in dichloromethane of the hexapeptide **8** and the higher oligopeptides **5**, **9**, and **10** is in remarkable contrast with the fact that homologous oligo(Leu) counterparts are practically insoluble in dichloromethane due to their β-sheet structures in the solid state.[5,14] The Pro residue in the peptide **10**, for example, clearly disturbs the development of the β-sheet aggregation by the rotation of the tertiary peptide bond plane (Leu-Pro), facilitating solvation of the peptide chain to cause helical folding. Thus, the ability of the Pro residue to promote helical folding in dichloromethane of the octapeptide **10** is attributed to the disturbance of the β-sheet aggregation, that is, the restriction of the values of the backbone dihedral angles ϕ and ψ of the Pro residue due to the low flexibility of the pyrrolidine ring. The fact that the Pro residue promotes helical folding in the peptides **6**—**10** suggests that the Pro residue included in the N-terminal, four amino acid residues of a helical region plays the role of the nucleation site in helical folding in natural proteins. Undoubtedly, the Pro residue can play the role of the nucleation site in helical folding only when the Pro residue is included in the sequence having high potential for helical formation. In fact, it is well recognized that the Pro residue is frequently found in N-terminal portions of helical regions in natural proteins.[11]

Furthermore, in connection with the design of the synthetic route for peptides and proteins based on the solubility prediction method,[2-5] the fact that the Pro residue promotes successive-intramolecular hydrogen bonds in oligopeptides is of particular interest since helical folding in peptide intermediates, which gives rise to the remarkable solubility improvement, is of quite importance for the design of the synthetic route for peptides and proteins. For example, we assume to be able to design successfully the synthetic route for globin proteins which contain several Pro residues in N-terminal portions of helical regions.

Table 2. Relative Intensities and Wave Numbers of Hydrogen-Bonded N-H Absorption Bands and Helical Contents of Each Peptide

Compound	Relative intensities of hydrogen-bonded N-H absorption bands[a]	Helical content/%[a,b]	Wavenumbers of hydrogen-bonded N-H absorption bands/cm^{-1} [c]
3	0.87	64	3344
4	0.84	62	3336
5	1.00	75	3315
6	0.56	42	3332
7	0.73	54	3331
8	0.80	59	3331
9	0.77	57	3325
10	0.85	63	3323

a) Relative intensities of R/n in Figs. 5 and 7, where R is the area of each N-H absorption bands, and n is the number of intramolecular hydrogen bonds of the α-helices formed by each peptide in Figs. 6 and 7. b) Calculated from the equation, helical content/% = R×100/5.5nA, where A is the half area of the free N-H absorption band of the peptide **1** in Fig. 2, and the coefficient, 5.5, is obtained as $2A_H/A_F/n'$ in Fig. 5 of Ref. 19. c) The band positions of each peptide in Figs. 2 and 3.

Conformations in the Solid State and Solubility Properties of Protected Homooligopeptides of Glycine and β-Alanine[1)]

Mitsuaki NARITA,* Masamitsu DOI, Koji KUDO, and Yusuke TERAUCHI
Department of Industrial Chemistry, Faculty of Technology, Tokyo University of Agriculture and Technology, Koganei 184
(Received May 23, 1986)

IR spectroscopic conformational analyses of Boc-Gly$_n$-OBzl (n=3—7) and Boc-(β-Ala)$_n$-OBzl (n=3—8) were performed in the solid state, suggesting the occurrence of the β-sheet structure in the higher oligomers (n=5—8). Solubility data indicate that insolubilities of Boc-Gly$_n$-OBzl and Boc-(β-Ala)$_n$-OBzl in high-polar solvents begin at hexa- and heptapeptide levels, respectively. Insolubility of protected homooligopeptides of Gly and β-Ala was estimated to be caused by β-sheet aggregation. The high potential for the β-sheet formation of Boc-Gly$_n$-OBzl and Boc-(β-Ala)$_n$-OBzl ($n\geqq5$) could clearly be attributed to the great freedom of the peptide backbone dihedral angles of each of the Gly and β-Ala residues in the β-sheet structure. The implications of a replacement of a few Gly residues with β-Ala residues in surface regions of proteins are also discussed.

The solubility prediction method proposed by us is principally based on the hypothesis that the insolubility of protected peptide intermediates is essentially caused by a β-sheet aggregation consisting of peptide chains equal to or larger than an octapeptide sequence level;[2)] it provides the scope of the design of synthetic routes for peptides and proteins.[2-4)] In the solubility prediction method, the coil conformation parameters, P_c, for each amino acid residue are used for estimating the potential for the β-sheet formation. Here, the value of P_c for the Gly residue is 1.50, which is similar to the value of P_c for the Pro residue, 1.59. These P_c values represent the fact that in globular proteins Gly residues appear in coil conformation regions[5)] as frequently as Pro residues, and that Gly-rich peptides are readily soluble in organic solvents. On the other hand, considering the high flexibility of the peptide backbones of the Gly-rich peptides,[6)] peptides larger than a certain peptide size appear to be insoluble in high-polar solvents due to the β-sheet aggregation.

Therefore, in this work, an investigation of the relationship between the conformation and solubility of protected homooligopeptides of Gly and β-Ala was carried out to confirm the generality of the above hypothesis. The second purpose in this study was to demonstrate that protected homooligopeptides of Gly and β-Ala have a high potential for β-sheet formation due to the great freedom of the peptide backbone dihedral angles of each of Gly and β-Ala residues in the β-sheet structure. In relation to the creation of novel proteins with improved properties, which can not be produced by a recombinant DNA method,[7)] we have discussed the effect of the replacement of a few Ala residues with Aib residues; these have the ability to promote helical folding in helical regions of proteins.[8)] The final purpose in this study was to discuss the possibility and implications of the replacement of the Gly residue with the β-Ala residue in proteins through the investigation of the similarity of conformational behaviors between the Gly and β-Ala residues.

Experimental

General. Uncorrected capillary melting points will be reported. Analytical instruments and conditions were described in a previous paper.[8)]

Synthesis of the Peptides 1—6. The tripeptides **1a** and **1b** were prepared by the usual stepwise elongation, starting with H-Gly-OBzl and H-β-Ala-OBzl as amino components, respectively, in the conditions described before for the preparation of oligopeptides.[8)] The higher oligopeptides **2**—**6** were prepared by fragment condensation in dichloromethane or DMF using DCC activation in the presence of HOBt as described before for fragment condensation.[8)] Procedures for the removal of the Boc group from the peptides (n=2—4) and of the Bzl group from the peptides (n=2—4) were essentially the same to those described previously.

IR Measurements. The IR absorption spectra of the solid samples were recorded with a Jasco Model DS-701G spectrometer in a nujol mull.

Results

Synthesis and Solubility Properties of Protected Homooligopeptides of Gly and β-Ala. The synthetic route for Boc-Gly$_n$-OBzl (n=3—7) and Boc-(β-Ala)$_n$-OBzl (n=3—8) is set out in the Scheme. The tripeptides **1a** and **1b** (n=3) were prepared by the usual stepwise elongation, starting with H-Gly-OBzl and H-β-Ala-OBzl as amino components, respectively.

a) Coupling yields in final steps. b) Purified by washing with hot MeOH.

Both amino components were obtained from the corresponding TosOH salts with an equivalent of NMM. The stepwise elongation was performed in dichloromethane using DCC activation.[9] For the preparation of the higher oligopeptides **2**—**6**, the removal of the Boc group[10] from the peptides (n=2—4) was performed in 3 M HCl/AcOEt (1 M=1 mol dm^{-3}), and removal of the Bzl group,[11] in AcOH/MeOH by hydrogenolysis in the presence of Pd/C as catalyst, respectively. The higher oligopeptides **2**—**6** were obtained by fragment condensation in dichloromethane or DMF using DCC activation in the presence of HOBt.[12] The peptides **1**—**6** were purified by repeated recrystallization or by washing with hot MeOH. The synthetic results and elemental analyses of the peptides **1**—**6** are given in Tables 1 and 2. Their solubility properties are also shown in Table 3.

IR Absorption Study in the Solid State of Protected Homooligopeptides of Gly and β-Ala. The IR absorption spectra in the amide A and amide I regions of the peptides **1a—5a** and **1b—6b** in the solid state are presented in Figs. 1 and 2, respectively. The assignments of the various bands of the peptides **1—6** were made on the basis of theoretical and experimental data for oligopeptides.[13-16] The peptides **1** and **2** (n=3 and 4) in Figs. 1 and 2 show strong bands around 3290 cm^{-1} and a few bands in the amide A region, indicating a predominant conformation with hydrogen bonds, most probably of the interchain type, but quite different from the usual antiparallel β-sheet structure, as assumed on Boc-Gly_n-OPEG (n=3 and 4).[15] However, details of the IR absorption frequencies of Boc-Gly_n-OPEG (n=3 and 4) are different from those of Boc-Gly_n-OBzl (n=3 and 4) due to the effect of the bulky and bifunctional PEG. In the case of the peptide **1b**, the absorption band of the ester carbonyl group shifts around 1715 cm^{-1}, indicating its hydrogen bonding with a N-H group. When n=5 the peptides **3a** and **3b** have a strong band around 3290 cm^{-1} in the amide A region and weak and strong bands around 1685 cm^{-1} and 1630 cm^{-1}, respectively, in the amide I region, accompanied by a shoulder around 1655—1645 cm^{-1}. These bands indicate the predominant antiparallel β-sheet and other coexistent conformations.[15] These results are quite different from the ternary helix conformation reported on CH_3CO-Gly_n-NHC_2H_5 (n=1—4) and poly$(Gly)_n$,[16] which have strong characteristic absorption bands at 3285 cm^{-1} in the amide A region, 1646 cm^{-1} in the amide I region, and 1560 cm^{-1} in the amide II region. The peptides **4—6** having n=6—8 assume predominantly the antiparallel β-sheet structure as reported on Boc-Gly_n-OPEG (n=7—9),[15] although the broad bands around 1640—1630 cm^{-1} suggests the coexistence of other conformations. Through an IR conformational analysis in the solid state of the peptides **1—6**, the conformational behaviors of each oligo(β-Ala) are very close to those of the corresponding oligo(Gly).

Discussion

By using the IR absorption spectra in the solid state of the peptides **1—6**, the occurrence of the β-sheet structure was actually established for Boc-Gly_n-OBzl (n=5—7) and Boc-$(\beta\text{-Ala})_n$-OBzl (n=5—8), and insolubilities in high-polar solvents of Boc-Gly_n-OBzl and Boc-$(\beta\text{-Ala})_n$-OBzl begin at hexa- and heptapeptide levels, respectively. As in the case of protected homooligo-L-leucines,[17] protected oligopeptides having various hydrophobic side chains,[8] and protected oligopeptides having various polar side chains,[3] insolubility of the homooligopeptides of Gly and β-Ala was estimated to be mainly caused by β-sheet aggregation. Boc-Gly_n-OBzl (n=6 and 7) and Boc-$(\beta\text{-Ala})_n$-OBzl (n=7 and 8) are practically insoluble even in the high-polar solvents such as DMF, DMA, NMP, DMSO, and HMPA (Table 3). Smaller critical sizes for the insolubility of Boc-Gly_n-OBzl and Boc-$(\beta\text{-Ala})_n$-OBzl than protected other oligopeptides[3,8,17] are probably due to the high symmetry of peptide backbones of homooligopeptides of Gly and β-Ala.

According to the solubility prediction method based on the $\langle P_c \rangle$ values of the average coil conformation

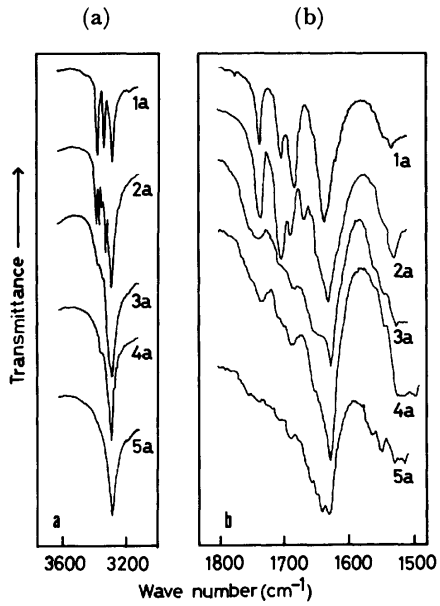

Fig. 1. IR absorption spectra of the peptides **1a—5a**. a: The amide A region; b: the amide I region.

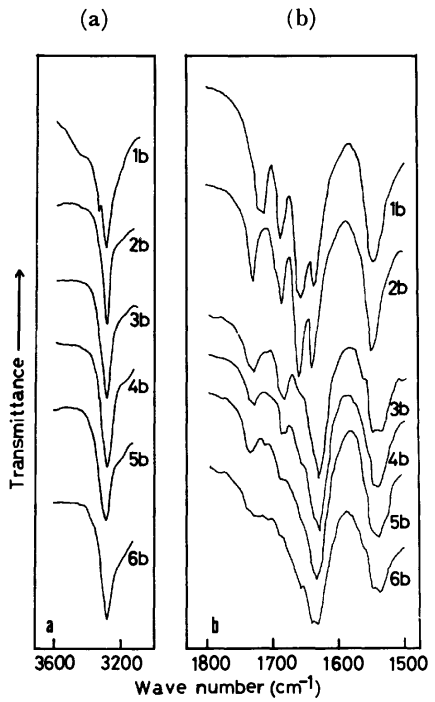

Fig. 2. IR absorption spectra of the peptides **1b—6b**. a: The amide A region; b: the amide I region.

parameters of protected homooligo(Gly)s, they are predicted to be easily soluble due to the great freedom of the backbone dihedral angles ϕ and ψ of the Gly residue.[2] Actually, the Gly residue can explore a large conformational space,[6] thus inducing a high flexibility to the peptide chain. The great freedom of the backbone dihedral angles ϕ and ψ of the Gly residue is essentially attributed to the fact that there is no substituent on the C^{α} atom of the Gly residue. The great freedom is just due to the release in the Gly residue of the steric hindrance between O_{i-1} and C^{β}_{i} (postulated C^{β} atom on C^{α}_{i}), between N_{i+1} and C^{β}_{i}, and between H_{i+1} and C^{β}_{i} as illustrated in Fig. 3a. This fact results in the large value of W_{free}, which leades the peptide chain to various conformations:

$$\Delta S_{\beta\text{-sheet}} = S_{\beta\text{-sheet}} - S_{free} = R \ln W_{\beta\text{-sheet}} - R \ln W_{free}, \quad (1)$$

where $S_{\beta\text{-sheet}}$ is the entropy value in the β-sheet structure and S_{free} that in the free structure.[18] R is the gas constant, $W_{\beta\text{-sheet}}$ the probability of a β-sheet structure and W_{free} that of the free structure. On the other hand, the high potency for a β-sheet formation of Boc-Gly_n-OBzl ($n \geqq 5$) represents the large value of $\Delta S_{\beta\text{-sheet}}$ in Eq. 1, thus inducing the large value of $W_{\beta\text{-sheet}}$ in Eq. 1. The large value of $W_{\beta\text{-sheet}}$ corresponds to the great freedom in the β-sheet structure of the backbone dihedral angles ϕ and ψ of each Gly residue of Boc-Gly_n-OBzl. If the value of $W_{\beta\text{-sheet}}$ in the β-sheet structure of Boc-Gly_n-OBzl is as small as the values of W of various other conformations, Boc-Gly_n-OBzl inevitably has various conformations, resulting in coil conformation structures. The conformational behavior of Boc-(β-Ala)$_n$-OBzl is, essentially, quite similar to that of Boc-Gly_n-OBzl. The freedom of the peptide backbone of Boc-(β-Ala)$_n$-OBzl is much greater than that of Boc-Gly_n-OBzl due to an additional release in the β-Ala residue of the steric hindrance between O_{i-1} and O_i, between O_{i-1} and C^{β}_{i}, between O_{i-1} and N_{i+1}, between H_{i+1} and O_{i-1}, and between H_i and H_{i+1} as illustrated in Fig. 3b. Due to the fact that there is no substituent on the C^{α} and C^{β} atoms of the β-Ala residue, each β-Ala residue in the β-sheet structure can explore the large conformational space, inducing the high flexibility to the peptide chain in the β-sheet structure. Using the CPK models of the antiparallel β-sheet structures of Boc-Gly_7-OBzl and Boc-(β-Ala)$_7$-OBzl, we can actually confirm the great freedom of the methylene groups in the antiparallel β-sheet structures of Boc-Gly_7-OBzl and Boc-(β-Ala)$_7$-OBzl.

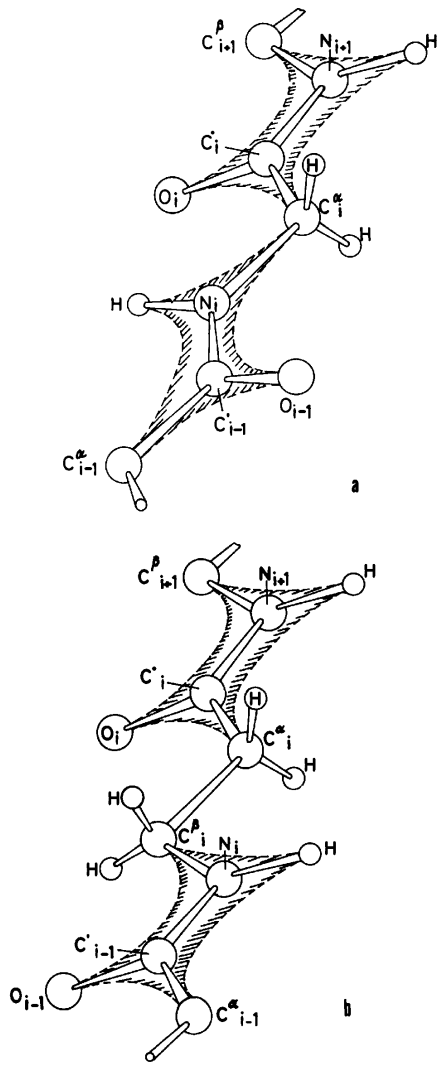

Fig. 3. Release of steric hindrance (a) in the Gly residue and (b) in the β-Ala residue.

The large value of W_{free} of the Gly residue compared with other amino acid residues corresponds to the fact that Gly residues in globular proteins have various values of the backbone dihedral angles ϕ and ψ, as shown by X-ray diffraction studies of globular proteins. Thus, the Gly residue often appears in turn structures,[19] that is, in surface regions of globular proteins. Since the β-Ala residue has a value of W_{free} that is larger than the Gly residue, it is estimated that we can suitably replace the Gly residue with the β-Ala residue in surface regions of globular proteins without changing the protein structures essentially. Moreover, active sites of proteins are usually located on the surface regions of the proteins, especially clefts or crevices, and the packing density in the active sites is usually low.[6] These facts mean that the active sites have a greater freedom than the other regions. Therefore, the replacement of a few Gly residues with β-Ala residues in surface regions of proteins offers the prospect for creating novel proteins which can not be produced by the recombinant DNA method.[7] The replacement techniques also offer the potential for altering protein functions in ways not possible by any other method, just as mentioned in protein engineering pioneered by genetic technology.[20]

A Novel and Highly Efficient Asymmetric Synthesis of Optically Active Anthracyclinones[1)]

Michiyo SUZUKI, Yoshikazu KIMURA, and Shiro TERASHIMA*
Sagami Chemical Research Center, Nishi-Ohnuma, Sagamihara, Kanagawa 229
(Received May 21, 1986)

The bromolactonization of the optically active acetals derived from 2-acetyl-5,8-dimethoxy-3,4-dihydronaphthalene and (*R,R*)-*N,N*:*N'*,*N'*-tetraalkyltartaramide was found to proceed highly diastereoselectively, giving mixtures of the seven-membered bromo lactones and the bromohydrins. The predominantly produced bromo lactones could be effectively converted to (*R*)-2-acetyl-5,8-dimethoxy-1,2,3,4-tetrahydro-2-naphthol, the AB ring synthon of optically active 11-hydroxyanthracyclinones, >95% ee, in one pot reaction. Application of the explored synthetic scheme to 2-acetyl-5,12-dimethoxy- and 2-acetyl-5-methoxy-3,4-dihydro-6,11-naphthacenedione similarly gave (*R*)-2-acetyl-2,5,12-trihydroxy- and (*R*)-2-acetyl-2,5-dihydroxy-1,2,3,4-tetrahydro-6,11-naphthacenedione, the advanced key synthetic intermediates of optically active 4-demethoxy- and 11-deoxy-4-demethoxyanthracyclinones, 94% ee and >99% ee, respectively, by way of mixtures of the seven- and six-membered bromo lactones.

The anthracycline antibiotics, adriamycin (**1a**) and daunorubicin (**1b**), hold leading positions of anticancer agents because of their prominent activity against various types of human cancers.[2)] While various undesirable side effects, the most notable and serious of which is dose-related cardiotoxicity,[2,3)] restrict their wide utilization for cancer chemotherapy, more improved therapeutic indices can be expected for recently discovered natural 11-deoxyanthracyclines (**1e,f**)[4)] and synthetically explored unnatural 4-demethoxy-[5)] and 11-deoxy-4-demethoxyanthracyclines[6)] (**1c,d** and **1g,h**).

Syntheses of optically active natural and unnatural 11-hydroxyanthracyclinones (**2a—d**),[7)] the aglycones of **1a—d**, have been achieved by employing asymmetric syntheses[8-13)] or optical resolutions[5a-c,14-23)] as key processes for producing optically active compounds. However, a synthetic scheme which is generally applicable not only to optically active **2a—d** but also to their 11-deoxy congeners (**2e—h**), seems to be still lacking.[24)]

By selecting (*R*)-2-acetyl-5,8-dimethoxy-1,2,3,4-tetrahydro-2-naphthol ((***R***)-**3**) as a model target compound, an efficient synthetic method being generally applicable to the whole family of optically active anthracyclinones (**2a—h**) was sought. As for (***R***)-**3** which is anticipated to be one of the most versatile AB ring synthons for the chiral synthesis of **2a—d**,[7)] numerous synthetic methods have so far been explored by employing asymmetric synthesis[8-11,13)] or optical resolution.[5a-c,14,22)]

Previously, the authors reported the asymmetric synthesis of (***R***)-**3** in which the bromolactonization of (*S*)-*N*-(α,β-unsaturated acyl)proline derivatives constitutes the key diastereoselective reaction.[8)] We succeeded in obtaining (***R***)-**3** of 97% ee by sequential manipulation of the formed bromo lactone by way of (*R*)-2-hydroxy-5,8-dimethoxy-1,2,3,4-tetrahydro-2-naphthoic acid. However, this asymmetric synthesis was found to be less practical and to lack generality because of long synthetic steps for obtaining the reaction substrates, requirement of a stoichiometric amount of expensive (*S*)-proline as a chiral source, and failure of construction of the α-hydroxy ketone functionality from the optically active α-hydroxy acid moiety involved in the 1,2,3,4-tetrahydro-6,11-naphthacenedione system.[25)]

We have now explored another efficient asymmetric synthesis of (***R***)-**3** by featuring the bromolactonization of the optically active acetal (**8**) prepared from readily available 2-acetyl-5,8-dimethoxy-3,4-dihydronaphthalene (**6**) and (*R,R*)-*N,N*:*N'*,*N'*-tetraalkyltartaramide (**5**).[26)] Moreover, it appears that this asymmetric

synthesis can be similarly employed for producing highly optically active (*R*)-2-acetyl-2,5,12-trihydroxy- and (*R*)-2-acetyl-2,5-dihydroxy-1,2,3,4-tetrahydro-6,11-naphthacenedione ((*R*)-7-deoxy- and (*R*)-7,11-dideoxy-4-demethoxydaunomycinone) ((***R***)-**4d**,**h**) from the tetracyclic 2-acetyl-3,4-dihydro-6,11-naphthacenedione derivatives (**21**). These optically active tetracyclic α-hydroxy ketones (***R***)-**4d**,**h** are usable as the advanced key synthetic intermediates of unnatural 4-demethoxy and 11-deoxy-4-demethoxyanthracyclinones (**2c**,**d** and **2g**,**h**).[6,7,9,15,23]

This report details the exploration of this novel asymmetric synthesis which is considered to be more practical and general than the previously reported methods.[8-13]

Asymmetric Synthesis of Optically Active (*R*)-2-Acetyl-5,8-dimethoxy-1,2,3,4-tetrahydro-2-naphthol ((*R*)-3). The starting material (**6**) of the asymmetric synthesis could be prepared from 5,8-dimethoxy-2-tetralone[27] by addition of ethynylmagnesium bromide and Rupe rearrangement of the formed propargylic alcohol.[9] However, modification of the method reported by Russell et al.[28] was found to be more promising for obtaining a large quantity of **6**. Thus, treatment of 4a,5,8,8a-tetrahydro-1,4-naphthoquinone[29] with acetic anhydride and potassium hydroxide, followed by isomerization of the $C_{6,7}$-double bond of 1,4-diacetoxy-5,8-dihydronaphthalene catalyzed with pentacarbonyliron(0), Friedel-Crafts acetylation of 1,4-diacetoxy-5,6-dihydronaphthalene, alkaline hydrolysis of the diacetates, and methylation of the two phenolic hydroxyl groups, readily produced **6**.

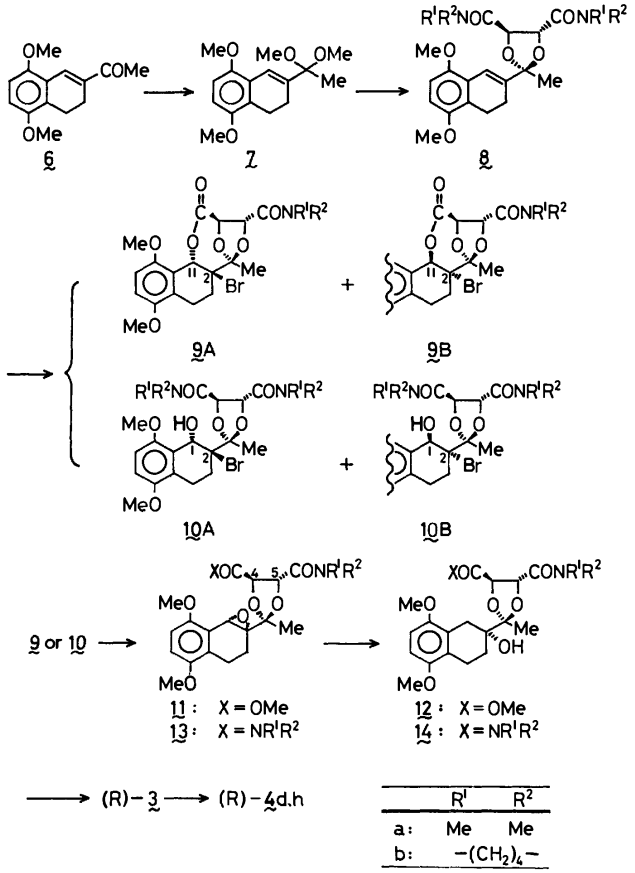

Chart 1.

While the direct acetalization of **6** with **5** was found to be sluggish, preparation of the optically active acetals **8** could be effectively accomplished by successive acetalization and transacetalization as shown in Chart 1. Thus, acetalization of **6** with trimethoxymethane in the presence of *dl*-10-camphorsulfonic acid (CSA) followed by transacetalization of the formed dimethylacetal (**7**) with (*R*,*R*)-*N*,*N*:*N'N'*-tetramethyltartaramide (**5a**)[30] gave **8a** in 92% overall yield.

After numerous unsuccessful attempts,[31,32] it was finally found that when **8a** was treated with *N*-bromoacetamide in a mixture of *N*,*N*-dimethylformamide (DMF) and water (100:1)[33] at 0 °C for 15.5 h, a mixture of the bromo lactone (**9a**) and the bromohydrin (**10a**) could be obtained in 83 and 7% yields, respectively. Separation of **9a** and **10a** was readily accomplished by column chromatography. The bromo lactone obtained as a mixture of the two diastereomers (**9aA** and **9aB**) (vide infra) showed mp 140 °C (decomp) and $[\alpha]_D^{20}$ −110° (chloroform). The formation ratio of **9aA** to **9aB** was estimated to be more than 97.5:2.5 based on the optical purity of (***R***)-**3** derived from this sample. Recrystallization of the mixture of **9aA** and **9aB** from a mixture of dichloromethane and ether gave the predominantly formed bromo lactone **9aA** in a pure form, mp 140—140.5 °C and $[\alpha]_D^{20}$ −114° (chloroform). The structures of **9aA** and **9aB** could be assigned as (2S,11S)- and (2R,11R)-configurations, by assuming that the bromolactonization and epoxide formation (vide infra)

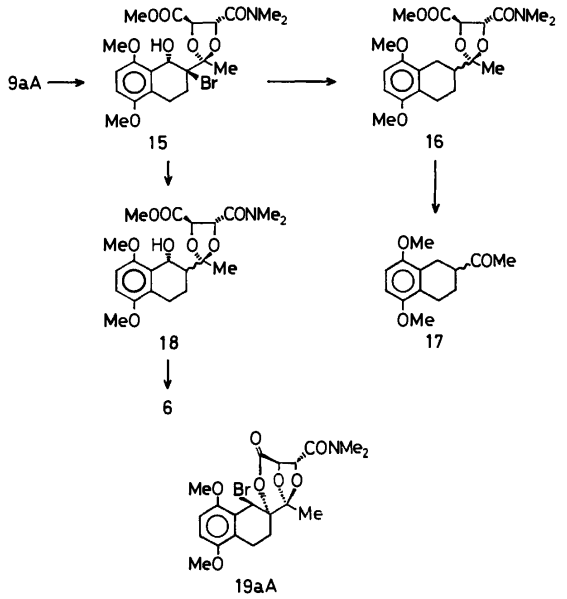

Chart 2.

proceed in a trans fashion and an S_N2 manner, respectively. The bromohydrin (**10a**) isolated as a caramel, also consisted of the two diastereomers (**10aA** and **10aB**). The formation ratio could be similarly estimated to be 85.5:14.5 by converting this mixture to (***R***)-**3**. By assuming that the epoxide formation proceeds in an S_N2 manner, **10aA** and **10aB** were anticipated to belong (1S,2S)- and (1R,2R)-configurations, respectively.

In order to establish rigorously the seven-membered bromo lactone structure of **9a**, some chemical transformations were next examined using predominantly formed **9aA**. As shown in Chart 2, **9aA** was treated with methanol in the presence of triethylamine to give the methyl ester (**15**) as a colorless caramel, $[\alpha]_D^{20}$ +35.8° (chloroform), in a quantitative yield. The C_{11}-proton of **9aA**, which appeared as a doublet at δ 5.87, moved to δ 5.47 in the NMR spectrum of **15**. This spectral feature may strongly support the seven-membered structure of **9aA**. Catalytic reduction of **15** over palladium on carbon under a hydrogen atmosphere produced the acetal (**16**) as a diastereomeric mixture. Without separation of the two diastereomers, hydrolysis of **16** with concd hydrochloric acid gave 2-acetyl-5,8-dimethoxy-1,2,3,4-tetrahydro-naphthalene (**17**)[34] in 94% overall yield from **15**. On the other hand, debromination of **15** with tributyltin hydride followed by acidic removal of the chiral acetal group regenerated **6** with concomitant dehydration of the primarily formed β-hydroxy ketone. Since these chemical transformations should afford (***R***)-**3** if **9aA** has the six-membered bromo lactone structure (**19aA**), the successful preparation of **17** and **6** clearly discloses the seven-membered bromo lactone structure of **9aA**. The similarity of the NMR spectrum of the mixture of **10aA** and **10aB** to that of **15** unambiguously supports the bromohydrin structure of **10a**.

The bromo lactone **9aA** was elaborated to (***R***)-**3** by the following three successive operations. As shown in Chart 1, treatment of **9aA** with anhyd potassium carbonate in methanol gave an 80% yield of the epoxide (**11a**). Catalytic hydrogenation of **11a** over palladium on carbon quantitatively produced the alcohol (**12a**), which on acidic hydrolysis yields (***R***)-**3**, mp 127.5—129 °C and $[\alpha]_D^{20}$ −48.4° (chloroform), 100% ee,[35] in 89% yield. Recrystallization of this sample from ether gave analytically pure (***R***)-**3**, mp 129.5—130.5 °C, $[\alpha]_D^{20}$ −48.7° (chloroform). On the other hand, when the mixture of **9aA** and **9aB** directly obtained from the bromolactonization, was successively treated in methanol under the conditions for epoxide formation, catalytic hydrogenation, and acidic hydrolysis without isolation of the intermediates **11a** and **12a** (one pot reaction), (***R***)-**3**, mp 129.5—130.5 °C and $[\alpha]_D^{20}$ −49.0° (chloroform), >95% ee,[35] could be obtained in 75% overall yield. The same successive treatments of the mixture of **10aA** and **10aB** as described (for above mixture of **9aA** and **9aB**), gave (***R***)-**3**, mp 111—126.5 °C and $[\alpha]_D^{20}$ −32.4° (chloroform), 71% ee,[35] in 38% overall yield by way of the epoxide **13a** and the alcohol **14a**. Based on these results, the formation ratio of **9aA** to **9aB** and that of **10aA** to **10aB** could be firmly established as described above.

Taking into account the chemical yields and formation ratios, separation of **9a** and **10a** seems to be unneccessary for a large scale preparation of (***R***)-**3**. Namely, it is desirable to immediately subject the crude reaction products of the bromolactonization reaction to the three sequential operations in a single flask to yield highly optically active (***R***)-**3**.

In place of **5a**, (*R,R*)-*N,N*:*N'*,*N'*-bis(tetramethylene)tartaramide (**5b**) was similarly usable as a chiral source of the asymmetric synthesis. The enone **6** was converted to **8b** in 85% overall yield by the similar manner to that described for **8a**. The bromolactonization of **8b** under the same conditions as described for **8a** gave **9b** and **10b** in 78 and 8% yields, respectively. The bromo lactone produced as a mixture of **9bA** and **9bB** showed mp 150.5 °C (decomp) and $[\alpha]_D^{20}$ −114° (chloroform). The mixture of the bromohydrins **10bA** and **10bB** was obtained as a caramel. The formation ratio of **9bA** and **9bB** could be estimated as more than 97.5:2.5 by the optical purity of (***R***)-**3** derived from this mixture. However, since the mixture of **10bA** and **10bB** was not subjected to further chemical elaborations, their formation ratio could not be determined. Recrystallization of the mixture of **9bA** and **9bB** readily gave the major bromo lactone **9bA** in a pure state, mp 149.5—150.5 °C (decomp) and $[\alpha]_D^{20}$ −116° (chloroform). Similarly to the case for **9a**, three successive treatments of the mixture **9bA** and **9bB** afforded (***R***)-**3**, mp 129.5—130 °C and $[\alpha]_D^{20}$ −47.6° (chloroform), >95% ee,[35] in 81% overall yield.

The highly diastereoselective bromolactonization may be explained in terms of the kinetically controlled mechanism. As shown in Chart 3, the two diastereomeric bromonium ions (**20A** and **20B**) are anticipated as intermediates for the formation of the

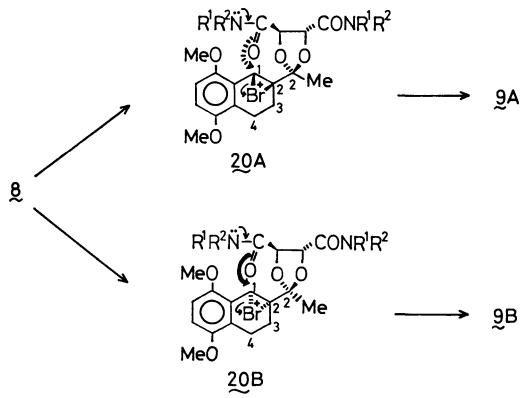

Chart 3.

major and the minor bromo lactones (**9A** and **9B**). Examinations using molecular models disclose that the bond angle between the C_2—C_3 bond and the C_2-CH_3 bond is clearly smaller in **20A** than in **20B**. That is, the C_2-methyl group should be involved in the plane of the 3,4-dihydronaphthalene ring in the conformer of **8** leading to **20A**. On the other hand, the conformer of **8** giving rise to **20B** should have the C_2-methyl group below the plane of the 3,4-dihydronaphthalene ring. Accordingly, less steric interaction between the incoming bromonium ion (Br^+) and the C_2-methyl group may be expected for **20A**, resulting in the formation of **9A** as a kinetically more favored product.

The formation of **10** may be reasonably explained by assuming that the intermediate bromonium ions **20A** and **20B** are opened by the intermolecular nucleophilic attack of water instead of the intramolecular oxygen atom of the amide group. Similar steric interaction between the bromonium ion (Br^+) and the C_2-methyl group may well account for the observed preferential production of **10A** being derived to (***R***)-**3**.

As mentioned above, the highly efficient asymmetric synthesis of (***R***)-**3** was explored by featuring the bromolactonization as a key diastereoselective reaction. While partial racemization is accompanied, Friedel-Crafts reaction of (***R***)-**3** with phthalic anhydride in the presence of aluminium chloride can give rise to the optically active tetracyclic α-hydroxy ketone ((***R***)-**4d**),[9,14] the advanced key intermediate of **2c,d**. Aiming to overcome the inefficient partial racemization and to explore practicality and generality of the developed synthetic scheme, application of the asymmetric synthesis to the preparation of (***R***)-**4d,h** was attemped. This is the subject of the next section.

Asymmetric Synthesis of Optically Active (*R*)-2-Acetyl-2,5,12-trihydroxy- and (*R*)-2-Acetyl-2,5-dihydroxy-1,2,3,4-tetrahydro-6,11-naphthacenedione ((*R*)-7-Deoxy- and (*R*)-7,11-Dideoxy-4-demethoxydaunomycinone) ((*R*)-4d,h). In the field of the asymmetric synthesis of optically active anthracyclinones,[8-13] no general methods which are applicable to both the bicyclic AB and the tetracyclic ABCD ring systems have been explored. Accordingly, application of the developed asymmetric synthesis of (***R***)-**3** to optically active (*R*)-2-acetyl-2,5,12-trihydroxy-1,2,3,4-tetrahydro-6,11-naphthacenedione ((*R*)-7-deoxy-4-demethoxydaunomycinone) ((***R***)-**4d**) was first attempted. Since the methods for stereoselectively introducing the $C_{7\alpha}$-hydroxyl group into (***R***)-**4d** and for converting the C_{14}-position into a hydroxymethyl group have been explored,[15] the ready access to (***R***)-**4d** holds a pivotal position in the synthesis of optically active **2c,d**.

The starting tetracyclic enone (**21i**) required for the asymmetric synthesis of (***R***)-**4d** could be readily produced from ***dl*-4d**.[14,23] Namely, dehydration of ***dl*-4d** with trifluoroacetic anhydride and collidine[36] gave 2-acetyl-5,12-dihydroxy-3,4-dihydro-6,11-naphthacenedione(77%), which on methylation with dimethyl sulfate under phase-transfer conditions afforded **21i** in 82% yield.[37] The dehydrated product of ***dl*-4d** can be also synthesized according to the reported method.[18]

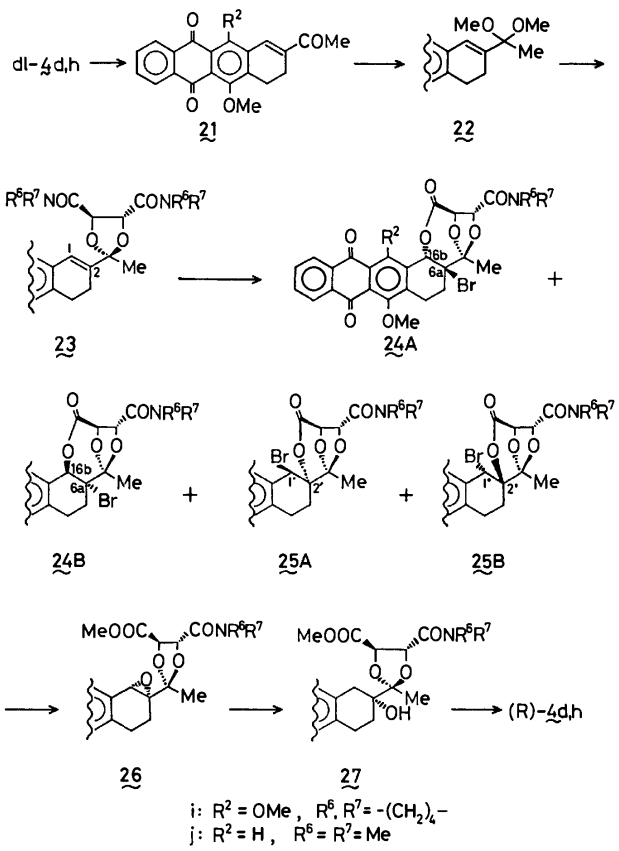

Chart 4.

Acetalization of **21i** with trimethoxymethane followed by transacetalization of the crude dimethyl acetal (**22i**) with **5b** gave the optically active acetal (**23i**) in 89% overall yield. Treatment of **23i** under the same bromolactonization conditions as that employed for **8** produced a mixture of the bromo lactones (**24i** and **25i**) in 78% combined yield. Recrystallization of the mixture with a mixture of chloroform and ether gave the predominantly formed diastereomer of the seven-membered bromo lactone (**24iA**) as a yellow powder, mp 217—219 °C and $[\alpha]_D^{20}$ −263° (chloroform). The minor six-membered bromo lactone (**25iA**) could be also isolated in a pure state as an unstable yellow solid by concentration of the mother liquor of recrystallization in vacuo followed by column chromatography. Structures of **24iA** and **25iA** were tentatively assigned based on their spectral data and successful preparation of highly optically active (***R***)-**4d** from this bromo lactone mixture (vide infra). The NMR spectrum of the bromo lactone mixture (**24i** and **25i**) clearly disclosed that no detectable amounts of the undesired bromo lactones **24iB** and **25iB** were involved in the bromo lactone mixture **24i** and **25i** (<5%). The

formation ratio of **24iA** to **25iA** could be roughly estimated as 6:1 by integral intensity of the C_{16b} and $C_{1'}$-methine signals observed in the NMR spectrum: **24iA**, δ 6.04 (J=2.0 Hz); **25iA**, δ 5.60 (J=2.1 Hz).

Being different from the case for **8**, no bromohydrins corresponding to **10** could not be detected in the crude reaction products. This may be explained by stability of the cationic species at the benzylic position (the C_1-position), which transiently develops during the bromolactonization reaction. The cationic species at the C_1-position produced from **8** can be effectively stabilized by the two methoxyl groups present in the adjacent aromatic ring. Accordingly, the mixture of **9** and **10** can be produced by the intra- and intermolecular nucleophilic attacks at the C_1-position, respectively, in the bromolactonization of **8**. On the other hand, the generation of the cationic species at the benzylic C_1-position should be less favored for **23i** than for **8** by the presence of two carbonyl groups at the $C_{6,11}$-positions. Therefore, the six-membered bromo lactone **25i** resulting from the intramolecular nucleophilic attack at the C_2-tertiary carbon atom, could be obtained in addition to the common seven-membered bromo lactone **24i**. The bromohydrins similar to **10**, which could be produced by the intermolecular trap of the cationic species at the benzylic C_1-position with water, was not detected in the bromolactonization of **23i**.

Smilarly to the preparation of (***R***)-**3** from **9a**, direct treatment of the mixture of **24i** and **25i** with anhyd potassium carbonate in methanol yields the epoxide **25i**, which without isolation was hydrogenated over palladium on carbon to give the alcohol **27i**. Removal of the chiral acetal group with concd hydrochloric acid in ethanol followed by demethylation of the phenolic dimethyl ethers with aluminum chloride in benzene, produced (***R***)-**4d**, mp 215—218.5 °C and $[\alpha]_D^{20}$ −90.4° (chloroform), 94% ee,[35] in 68% overall yield. Recrystallization of this sample readily gave optically pure (***R***)-**4d**, mp 219—220.5 °C and $[\alpha]_D^{20}$ −90.9° (chloroform), $[\alpha]_D^{20}$ −20.0° (chloroform-methanol 1:1).

The same reaction scheme was further applied to the asymmetric synthesis of (*R*)-2-acetyl-2,5-dihydroxy-1,2,3,4-tetrahydro-6,11-naphthacenedione ((*R*)-7,11-dideoxy-4-demethoxydaunomycinone) ((***R***)-**4h**). While 11-deoxy-4-demethoxyanthracyclinones (**1g,h**) have been reported to show notable anticancer activity,[6] no methods have been developed for preparing optically active (***R***)-**4h** which is usable as a versatile synthetic intermediate of their aglycones (**2g,h**).

The substrate **21j** was prepared from ***dl*-4h** synthesized according to the reported method.[38] Sequential methylation of the ***dl*-4h** with dimethyl sulfate in the presence of anhyd potassium carbonate and dehydration of the formed methyl ether ***dl*-4j** with thionyl chloride in pyridine gave **21j**.[39] The yields of the two steps were 87 and 50%, respectively. The enone **21j** was treated by the similar manner to that described for **21i** except for the use of **5a** in place of **5b**, giving **23j** in 77% overall yield. Subjection of **23j** to the bromolactonization conditions gave rise to a mixture of the bromo lactones **24j** and **25j** in 85% combined yield. The predominantly formed diastereomer of the seven-membered bromo lactone **24jA** could be separated in a pure form by recrystallization from a mixture of chloroform and ether, mp 238—239.5 °C and $[\alpha]_D^{20}$ −103° (chloroform). The structures of **24j** and **25j** were assigned by comparing their spectral data with those of **24i** and **25i**, respectively, and by the successful conversion to highly optically acitive (***R***)-**4h** (vide infra). The formation ratio of **24j** to **25j** was similarly estimated as 6:1 based on the NMR spectrum. The undesired bromo lactones **24jB** and **25jB** being diastereomeric to **24jA** and **25jA**, were not detected by means of the NMR of the crude reaction products (<5%).

The same successive treatments of the bromolactone mixture mainly consisting of **24jA** and **25jA**, as those described for the 11-hydroxy series produced (***R***)-**4h**, mp 202.5—204.5 °C and $[\alpha]_D^{20}$ −32.7° (chloroform), >99% ee,[35] by way of **26j** and **27j** in 49% overall yield.

The bromolactonization reactions of **23i,j**, which preferentially produce **24A** and **25A**, can be best explained by the mechanism similar to that proposed for the asymmetric synthesis of (***R***)-**3**.

Following various notable merits are recognizable for the explored asymmetric synthesis: 1) the reaction substrates **6** and **21** are readily available, 2) inexpensive **5**, readily available from natural (*R,R*)-(+)-tartaric acid by way of its diester, can be used as a chiral source, 3) conversion of **6** and **21** to the corresponding optically active α-hydroxy ketones ((***R***)-**3** and (***R***)-**4d,h**) can be accomplished using readily available cheap reagents in one-pot reaction and in good overall yields, 4) (***R***)-**3** and (***R***)-**4d,h** whose optically purity is equal to or more than 95% ee can be regularly produced, 5) all reactions can be performed above 0 °C and strictly anhydrous conditions are not required. Due to these reasons, the asymmetric synthesis developed herein is anticipated to be one of the most practical and general synthetic methods of various structural types of optically active anthracyclinones.

Experimental

General. All melting points were determined with a Yamato MP-21 melting point apparatus and were uncorrected. IR spectral measurements were carried out with a JASCO A-202 diffraction grating infrared spectrometer. NMR spectra were recorded with a Varian EM-390 spectrometer (90 MHz), a Hitachi R-90H spectrometer (90 MHz), and a Bruker AM-400 spectrometer (400 MHz). All signals were expressed as ppm downfield from TMS

used as an internal standard (δ value). Mass spectra were taken with a Hitachi RMU-6MG mass spectrometer. Measurements of optical rotations were performed with a Horiba SEPA-200 automatic digital polarimeter. Wakogel C-200 was used as an adsorbent for column chromatography. All reactions were carried out using anhydrous solvents. Especially, tetrahydrofuran and ether freshly distilled from sodium benzophenone ketyl, and dichloromethane, acetone, pyridine, and *N,N*-dimethylformamide freshly distilled from calcium hydride were used. Following abbreviations are used for solvents and reagents; acetone (Me_2CO), α,α'-azobis(isobutyronitrile) (AIBN), benzene (C_6H_6), *N*-bromoacetamide (NBA), *dl*-10-camphorsulfonic acid (CSA), chloroform ($CHCl_3$), dichloromethane (CH_2Cl_2), *N,N*-dimethylformamide (DMF), dimethyl sulfate (Me_2SO_4), ethanol (EtOH), ether (Et_2O), ethyl acetate (EtOAc), hexane (C_6H_{14}), methanol (MeOH), pyridine (C_5H_5N), tetrahydrofuran (THF), triethylamine (Et_3N), trimethoxymethane ($CH(OMe)_3$).

2-Acetyl-5,8-dimethoxy-3,4-dihydronaphthalene (6). a) Preparation from 5,8-Dimethoxy-2-tetralone: Similarly to the reported methods,[9] successive addition of ethynylmagnesium bromide to 5,8-dimethoxy-2-tetralone[27] and Rupe rearrangement of formed *dl*-2-ethynyl-5,8-dimethoxy-1,2,3,4-tetrahydro-2-naphthol gave **6** after purification on column chromatography (CH_2Cl_2 then CH_2Cl_2–Et_2O 9:1). NMR spectrum of this sample were identical with that previous reported.[9]

b) Preparation from 4a,5,8,8a-Tetrahydro-1,4-naphthoquinone: According to the reported method,[28] potassium hydroxide (35 g, 0.62 mol) and acetic anhydride (70 mL, 0.74 mol) were successively added to an acetone solution (300 mL) of crude unstable 4a,5,8,8a-tetrahydro-1,4-naphthoquinone[29] (30 g, 0.18 mol) cooled in an ice bath. The mixture was stirred in an ice bath for 3 h, then at room temperature for 1.5 h. After filtration, the filtrate was concentrated in vacuo to give a residue, which was purified by column chromatography (C_6H_6–EtOAc 10:1) to afford 1,4-diacetoxy-5,8-dihydronaphthalene as a solid. Recrystallization from MeOH gave a pure sample as colorless crystals (20.9 g, 46%), mp 131.5—133.5 °C. IR (KBr) 2900, 1760, 1475, 1370, 1235, 1220, 1195, 1185, 1040, 895, 680, 615, 600 cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.29 (6H, s, $CH_3CO\times2$), 3.19 (4H, br s, C_5–H_2 and C_8–H_2), 5.83 (2H, m, C_6–H and C_7–H), 6.92 (2H, s, aromatic protons). Found: C, 67.91; H, 5.67%. Calcd for $C_{14}H_{14}O_4$: C, 68.28; H, 5.73%.

A mixture of 1,4-diacetoxy-5,8-dihydronaphthalene (20.9 g, 85 mmol) and pentacarbonyliron(0) (0.5 mL, 3.8 mmol, 0.04 equiv) was heated in a sealed tube at 135—140 °C for 6.75 h. After further amount of pentacarbonyliron(0) (1.0 mL, 7.6 mmol, total 1.5 mL, 11.4 mmol, 0.13 equiv) was added, the heating in a sealed tube was continued at the same temperature for 12 h. After cooling, the mixture was directly subjected to column chromatography (CH_2Cl_2 then EtOAc) to give 1,4-diacetoxy-5,6-dihydronaphthalene as a pale yellow solid (16.5 g, 79%). Recrystallization from MeOH gave a pure sample as colorless crystals, mp 140—141 °C (lit.,[28] mp 137—138 °C).

Sequential Friedel-Crafts acetylation of 1,4-diacetoxy-5,6-dihydronaphthalene (13.9 g, 56 mmol), hydrolysis of formed 2-acetyl-5,8-diacetoxy-3,4-dihydronaphthalene, and in situ methylation according to the same method as that reported[28] gave **6** (7.6 g, 58%) after purification by column chromatography (C_6H_6–EtOAc 10:1). Recrystallization from Et_2O afforded a pure sample as pale brown crystals, mp 106—106.5 °C (lit.,[9] mp 106—107 °C). NMR spectrum of this sample was identical with that of the authentic sample obtained in a).

c) Preparation from 15: A mixture of **15** (49.1 mg, 0.10 mmol), tributyltin hydride (123 mg, 0.42 mmol), and AIBN (0.2 mg, 0.001 mmol) in C_6H_6 (1.5 mL) was stirred at 65 °C for 3 h under an argon atmosphere. After further amount of AIBN (0.2 mg, 0.001 mmol) was added, the stirring was continued for 3 h. The mixture was concentrated in vacuo, and the residue was purified by column chromatography (C_6H_6–Et_2O then EtOAc) to give **18** as a caramel (23.8 mg, 57%). IR (KBr) 3525, 1755, 1660, 1490, 1260, 1095 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.57 (3H, s, C_2–CH_3), 1.7—3.2 (6H, m, C_2–H, C_3–H_2, C_4–H_2, and OH), 3.00, 3.14 (6H, two s, $N(CH_3)_2$), 3.78, 3.83 (9H, three s, $OCH_3\times3$, integration ratio of the two signals was 2:1), 4.84 (1H, d, J=6.6 Hz, C_4–H), 5.37 (1H, d, J=6.6 Hz, C_5–H), 5.0—5.5 (1H, m, C_1–H), 6.69 (2H, s, aromatic protons). The NMR spectrum clearly shows that this sample solely consists of the (2R)- or (2S)-isomer and not of a mixture of these two isomers. MS *m/z*: 424, 423 (M^+), 216.

A mixture of **18** (23.8 mg, 0.056 mmol) and concd HCl (0.5 mL) in EtOH (2.0 mL) was heated at reflux for 2 h. After cooling, the whole was diluted with EtOAc (50 mL), and the organic mixture was washed successively with H_2O and satd NaCl. After drying over anhyd $MgSO_4$, filtration and concentration in vacuo followed by separation on column chromatography (C_6H_6–EtOAc 10:1), gave **6** as colorless crystals (9.3 mg, 71%), mp 103.5—105 °C. IR and NMR spectra of this sample were identical with those of the authentic sample obtained in a).

(*R,R*)-(+)-*N,N*:*N′,N′*-Tetramethyltartaramide (5a). This was prepared from commercially available (*R,R*)-(+)-diethyl tartrate according to the reported method.[30] A sample recrystallized from a mixture of CH_2Cl_2 and Et_2O showed mp 184.5—188.5 °C and $[\alpha]_D^{20}$ +44.3° (*c* 1.06, EtOH) (lit,[30] mp 189—190 °C and $[\alpha]_D^{20}$ +43° (*c* 3.0, EtOH)).

(*R,R*)-(+)-*N,N*:*N′,N′*-(+)-Bistetramethylenetartaramide (5b). A mixture of commercially available (*R,R*)-(+)-diethyl tartrate (10.0 g, 49 mmol) and pyrrolidine (10.0 g, 0.14 mol) was stirred at room temperature for 18 h. After concentration in vacuo, the residue was purified by filtration through a short column (EtOAc then EtOAc–MeOH 9:1), to give **5b** as a pale yellow solid (11.6 g, 93%). Recrystallization of this solid from CH_2Cl_2–Et_2O gave an analytical sample of **5b** as colorless crystals, mp 132.5—135 °C and $[\alpha]_D^{20}$ +34.2° (*c* 1.02, EtOH). IR (KBr) 3450, 3400, 1645, 1630, 1460, 1385, 1110, 1090 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.6—2.2 (8H, m, $NCH_2C\underline{H}_2C\underline{H}_2CH_2N\times2$), 3.3—3.8 (8H, m, $NC\underline{H}_2CH_2CH_2C\underline{H}_2N\times2$), 4.20 (2H, d, J=7 Hz, $OH\times2$), 4.50 (2H, d, J=7 Hz, $C\underline{H}OH\times2$). Found: C, 56.00; H, 7.88; N, 10.85%. Cacld for $C_{12}H_{20}N_2O_4$: C, 56.24; H, 7.87; N, 10.93%.

(−)-5,8-Dimethoxy-2-[(4*R*,5*R*)-2-methyl-4,5-bis(dimethylcarbamoyl)-1,3-dioxolan-2-yl]-3,4-dihydronaphthalene (8a). A mixture of **6** (698 mg, 3.0 mol), CSA (15.9 mg, 0.07 mmol), and $CH(OMe)_3$ (1.0 mL, 9.1 mmol) in MeOH (15 mL) was stirred at 0 °C for 12 h, then poured onto satd $NaHCO_3$ (40 mL) cooled in an ice bath. The aqueous

mixture was extracted with EtOAc. The combined organic extracts were washed successively with H_2O and satd NaCl, then dried over anhyd $MgSO_4$. Filtration and concentration in vacuo gave crude **7** as an oil, which was immediately subjected to the next transacetalization.

The diamide **5a** (1.23 g, 6.0 mmol) dissolved in C_6H_6 (25 mL) was added to crude **7** prepared above, and the mixture was heated at reflux for 1.25 h using a Dean-Stark apparatus packed with molecular sieves 3A to remove a small amount of H_2O. After cooling, CSA (20 mg, 0.09 mmol) was added to the reaction mixture, the reflux was further continued for 1.25 h. The whole mixture was poured onto satd $NaHCO_3$ (50 mL) after being cooled, and was extracted with EtOAc. The combined extracts were washed successively with satd $NaHCO_3$, H_2O, and satd NaCl, then dried over anhyd $MgSO_4$. Filtration and concentration in vacuo followed by purification on column chromatography (EtOAc then EtOAc-MeOH 19:1) gave pure **8a** as a colorless caramel (1.16 g, 92%), $[\alpha]_D^{20}$ −4.0° (*c* 0.99, $CHCl_3$). IR (KBr) 1650, 1490, 1260, 1105, 1045, 870, 800, 720, 675 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.60 (3H, s, CH_3), 2.1—2.4 (2H, m, C_3-H_2), 2.6—3.0 (2H, m, C_4-H_2), 2.90, 2.97, 3.20, 3.24 (12H, four s, NCH_3×4), 3.77 (6H, two s, OCH_3×2), 5.19, 5.30 (2H, two d, *J*= each 6.6 Hz, C<u>H</u>CON×2), 6.59, 6.69 (2H, two d, *J*= each 9.3 Hz, aromatic protons), 6.90 (1H, m, C_1-H). MS *m/z*: 419, 418 (M^+), 187, 116, 72. Found: C, 62.40; H, 7.22; N, 6.52%. Calcd for $C_{22}H_{30}N_2O_6 \cdot 0.25H_2O$: C, 62.47; H, 7.27; N, 6.62%.

(−)-5,8-Dimethoxy-2-[(4*R*,5*R*)-2-methyl-4,5-bis(1-pyrrolidinylcarbonyl)-1,3-dioxolan-2-yl]-3,4-dihydronaphthalene (8b). The diamide **5b** (1.15 g, 4.5 mmol) in C_6H_6 (30 mL) was added to crude **7** similarly prepared from **6** (518 mg, 2.2 mmol), and the resulting benzene solution was heated at reflux for 1.25 h using a Dean-Stark apparatus packed with molecular sieves 3A to remove a small amount of H_2O. After cooling, CSA (17 mg, 0.07 mmol) was added to the reaction mixture, and the reflux was further continued for 2 h. After being cooled, the reaction mixture was worked up in the same manner as that described for the preparation of **8a**, giving **8b** as a colorless solid (892 mg, 85%) after purification on column chromatography (EtOAc then EtOAc-MeOH 19:1). Recrystallizatoion from EtOAc-Et_2O-C_6H_{14} gave an analytical sample of **8b** as colorless crystals, mp 163.5—164.5 °C and $[\alpha]_D^{20}$ −21.1° (*c* 1.03, $CHCl_3$). IR (KBr) 1665, 1635, 1490, 1440, 1260. 1105, 1045, 800, 705 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.61 (3H, s, CH_3), 1.7—2.1 (8H, m, $NCH_2C\underline{H}_2$-$C\underline{H}_2CH_2N$×2), 2.1—2.4 (2H, m, C_3-H_2), 2.6—2.9 (2H, m, C_4-H_2), 3.3—4.0 (8H, m, $NC\underline{H}_2CH_2CH_2C\underline{H}_2N$×2), 3.76 (6H, two s, OCH_3×2), 5.04, 5.17 (2H, two d, *J*= each 6.9 Hz, C<u>H</u>CON×2), 6.59, 6.70 (2H, two d, *J*= each 9.0 Hz, aromatic protons), 6.92 (1H, m, C_1-H). MS *m/z*: 470 (M^+). Found: C, 66.22; H, 7.46; N, 5.88%. Calcd for $C_{26}H_{34}O_6N_2$: C, 66.36; H, 7.28; N, 5.95%.

(1*R*,2*S*,11*S*,14*R*,15*R*)-(−)-2-Bromo-15-dimethylcarbamoyl-6,9-dimethoxy-1-methyl-12,16,17-trioxatetracyclo[12.2.1.0^{2,11}.0^{5,10}]-heptadeca-5,7,9-trien-13-one (9aA), (1*S*,2*S*)-2-Bromo-5,8-dimethoxy-2-[(4*R*,5*R*)-2-methyl-4,5-bis(dimethylcarbamoyl)-1,3-dioxolan-2-yl]-1,2,3,4-tetrahydro-1-naphthol (10aA), and Their (2*R*,11*R*)- and (1*R*,2*R*)-Isomers (9aB and 10aB). Bromolactonization of 8a: *N*-Bromoacetamide (718 mg, 5.2 mmol) was added to a solution of **8a** (724 mg, 1.7 mmol) in a mixture of DMF-H_2O (100:1) (15 mL), and the mixture was stirred at 0 °C for 15.5 h. After further amount of NBA (239 mg, 1.7 mmol, total 6.9 mmol, 4.0 equiv) was added, the stirring was continued at the same temperature for 6 h. The reaction mixture was diluted with 10% $Na_2S_2O_3$ (30 mL), and extracted with EtOAc (×3) and CH_2Cl_2 (×2). The organic extracts were combined, washed successively with 10% $Na_2S_2O_3$, H_2O, and satd NaCl, then dried over anhyd $MgSO_4$. Filtration and concentration in vacuo gave a residue (876 mg), a part of which (799 mg) was separated by column chromatography (EtOAc) to give a mixture of **9aA** and **9aB** as a colorless solid (615 mg, 83%), mp 140 °C (decomp) and $[\alpha]_D^{20}$ −110° (*c* 1.02, $CHCl_3$), and a mixture of **10aA** and **10aB** as a colorless caramel (55.8 mg, 7%). IR and NMR spectra of the mixture of **9aA** and **9aB** were identical with those of pure **9aA** (vide infra). Recrystallization of the mixture of **9aA** and **9aB** from CH_2Cl_2-Et_2O gave pure **9aA** as colorless crystals, mp 140—140.5 °C and $[\alpha]_D^{20}$ −114° (*c* 1.00. $CHCl_3$). IR (KBr) 1750, 1645, 1495, 1265, 1240, 1220, 1100, 1090, 1080, 960, 800, 650 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.95 (3H, s, C_1-CH_3), 2.0—3.3 (4H, m, C_3-H_2 and C_4-H_2), 3.00, 3.17 (6H, two s, NCH_3×2), 3.78, 3.81 (6H, two s, OCH_3×2), 5.23, 5.38 (2H, two d, *J*= each 2.0 Hz, C_{14}-H and C_{15}-H), 5.87 (1H, d, *J*=1.9 Hz, C_{11}-H), 6.70, 6.80 (2H, two d, *J*= each 9.6 Hz, aromatic protons). MS *m/z*: 473, 471, 470, 469 (M^+), 467. Found: C, 51.01; H, 5.10; N, 2.94; Br, 17.05%. Calcd for $C_{20}H_{24}NO_7Br$: C, 51.08; H, 5.14; N, 2.98; Br, 16.99%. The mixture of **10aA** and **10aB** exhibited the following spectra. IR (KBr): 3450, 1650, 1490, 1260, 1100, 1050 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.87 (3H, s, C_2-CH_3), 2.1—3.3 (5H, m, C_3-H_2, C_4-H_2, and OH), 3.00, 3.02, 3.18, 3.26 (12H, four s, NCH_3×4), 3.80, 3.86 (6H, two s, OCH_3×2), 5.16, 5.24 (1H, two d, *J*=7.2 Hz and 6.6 Hz, C_4-H or C_5-H), 5.52, 5.67 (1H, two d, *J*=7.2 and 6.6 Hz, C_5-H or 4_4-H), 5.53 (1H, br s, C_1-H), 6.76 (2H, s, aromatic protons). The integration ratio of the two doublets at 5.16 and 5.24 ppm, or at 5.52 and 5.67 ppm was found to be 5.4:1. This value appeared to be consistent with the formation ratio of **10aA** to **10aB** determined by the optical purity of (***R***)-**3** derived from this sample (vide infra). MS *m/z*: 516, 514 (M^+), 496, 418, 229, 189, 187. The formation ratio of **9aA** to **9aB** and that of **10aA** to **10aB** could be determined as more than 97.5:2.5 and 85.5:14.5, respectively, based on the optical purity of (***R***)-**3** derived from these samples (vide infra).

(1*R*,2*S*,11*S*,14*R*,15*R*)-(−)-2-Bromo-15-(1-pyrrolidinylcarbonyl)-6,9-dimethoxy-1-methyl-12,16,17-trioxatetracyclo[12.2.1.0^{2,11}.0^{5,10}]-heptadeca-5,7,9-trien-13-one (9bA), (1*S*,2*S*)-2-Bromo-5,8-dimethoxy-2-[(4*R*,5*R*)-2-methyl-4,5-bis(1-pyrrolidinylcarbonyl)-1,3-dioxolan-2-yl]-1,2,3,4-tetrahydro-1-naphthol (10bA), and Their (2*R*,11*R*)- and (1*R*,2*R*)-Isomers (9bB and 10bB). Bromolactonization of 8b: *N*-Bromoacetamide (372 mg, 2.7 mmol, 3.0 equiv) was added to a solution of **8b** (419 mg, 0.89 mmol) in a mixture of DMF-H_2O (100:1) (7.5 mL) cooled at 0 °C, and the mixture was stirred at the same temperature for 18 h. After 10% $Na_2S_2O_3$ (20 mL) was added, the mixture was worked up in the same manner as that for the bromolactonization of **8a**, giving a mixture of **9bA** and **9bB** as colorless crystals (347 mg, 78%), mp 150.5 °C (decomp) and $[\alpha]_D^{20}$ −114° (*c* 1.04, $CHCl_3$), and a mixture of **10bA** and **10bB** as a caramel (41.3 mg, 8%), after separation by column chromatography (EtOAc then EtOAc-MeOH 95:5). IR and NMR spectra of the mixture of **9bA** and **9bB** were identical with those of pure **9bA** (vide infra). Recrystallization of the

mixture of **9bA** and **9bB** from EtOAc–Et_2O gave pure **9bA** as colorless crystals, mp 149.5—150.5 °C (decomp) and $[\alpha]_D^{20}$ −116° (*c* 1.04, $CHCl_3$). IR (KBr) 1750, 1650, 1495, 1450, 1265, 1225, 1105, 1095, 965, 955 cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.00 (3H, s, C_1-CH_3), 1.7—2.1 (4H, m, $NCH_2C\underline{H}_2C\underline{H}_2CH_2N$), 2.1—3.1 (4H, m, C_3-H_2 and C_4-H_2), 3.4—3.8 (4H, m, $NC\underline{H}_2CH_2CH_2C\underline{H}_2N$), 3.80, 3.83 (6H, two s, OCH_3×2), 5.10, 5.29 (2H, two d, *J*= each 2.0 Hz, C_{14}-H and C_{15}-H), 5.88 (1H, d, *J*=1.7 Hz, C_{11}-H), 6.74, 6.77 (2H, two d, *J*= each 8.7 Hz, aromatic protons). Found: C, 53.30; H, 5.21; N, 2.74; Br, 16.18%. Calcd for $C_{22}H_{26}O_7NBr$: C, 53.24; H, 5.28; N, 2.82; Br, 16.10%. The mixture of **10bA** and **10bB** showed the following spectra. IR (KBr): 3450, 1645, 1490, 1450, 1260, 1100 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.83 (3H, s, C_2-CH_3), 1.5—2.2 (8H, m, $NCH_2C\underline{H}_2C\underline{H}_2CH_2N$×2), 2.2—3.1 (5H, C_3-H_2, C_4-H_2, and OH), 3.2—4.0 (8H, m, $NC\underline{H}_2CH_2CH_2C\underline{H}_2N$×2), 3.77, 3.82 (6H, two s, OCH_3×2), 4.96, 5.34 (2H, two d, *J*= each 7.1 Hz, C_4-H and C_5-H), 5.51 (1H, br s, C_1-H), 6.69 (2H, s, aromatic protons). MS *m/z*: 551, 550, 549, 548. The formation ratio of **9bA** to **9bB** could be determined as more than 97.5:2.5 based on the optical rotation of (***R***)-**3** derived from the mixture of **9bA** and **9bB**. However, the formation ratio of **10bA** to **10bB** could not be determined since the mixture of **10bA** and **10bB** was not derived to optically active **3**.

(1*S*,2*S*)-(+)-2-bromo-5,8-dimethoxy-2-[(2*R*,4*R*,5*R*)-4-methoxycarbonyl-2-methyl-5-dimethylcarbamoyl-1,3-dioxolan-2-yl]-1,2,3,4-tetrahydro-1-naphthol (15). A mixture of **9aA** (98.0 mg, 0.21 mmol) and Et_3N (0.05 mL, 0.68 mmol) in MeOH (2.0 mL) was stirred at 0 °C for 0.25 h under an argon atmosphere. Concentration of the mixture in vacuo followed by purification on column chromatography (EtOAc), gave pure **15** as a colorless caramel (106 mg, 100%), $[\alpha]_D^{20}$ +35.8° (*c* 1.02, $CHCl_3$). IR (KBr) 3500, 1745, 1655, 1490, 1260, 1100 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.83 (3H, s, C_2-CH_3), 2.1—3.1 (4H, m, C_3-H_2 and C_4-H_2), 3.01, 3.15 (6H, two s, $N(CH_3)_2$), 3.21 (1H, d, *J*=3.6 Hz, OH), 3.79, 3.81, 3.83 (9H, three, s, OCH_3×3), 4.97, 5.39 (2H, two d, *J*= each 7.3 Hz, C_4-H and C_5-H), 5.47 (1H, d, *J*=3.6 Hz, C_1-H), 6.72 (2H, s, aromatic protons). The doublet at δ 3.21 disappeared on treatment with D_2O. Irradiation of the doublets at δ 3.21 and 4.97 changed the doublets at δ 5.47 and 5.39 into singlets, respectively. Accordingly, the doublet at δ 5.47 was rigorously assigned to the C_1-proton. MS *m/z*: 504, 503, 502, 501 (M^+), 270, 268. Found: C, 50.05; H, 5.62; N, 2.70; Br, 15.61%. Calcd for $C_{21}H_{28}NO_8Br$: C, 50.21; H, 5.62; N, 2.79; Br, 15.91%.

2-Acetyl-5,8-dimethoxy-1,2,3,4-tetrahydronaphthalene (17). A mixture of **15** (49.3 mg, 0.098 mmol) and 5% Pd/C (20 mg) in MeOH (20 mL) was stirred under a hydrogen atmosphere at room temperature for 16.5 h. After further amount of 5% Pd/C (20 mg) was added, the mixture was stirred under the same conditions for 48 h. Insoluble materials were removed by filtration and washed with EtOAc. The combined filtrate and washings were concentrated in vacuo. The residue was purified by column chromatography (C_6H_6–EtOAc 4:1) to give **16** as a colorless oil. IR (neat) 1760, 1740, 1660, 1485, 1255, 1100, 755 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.44 (3H, s, C_2-CH_3), 1.8—3.2 (7H, C_1-H_2, C_2-H, C_3-H_2, and C_4-H_2), 3.00, 3.14 (6H, two s, $N(CH_3)_2$), 3.77 (9H, three s, OCH_3×3), 4.79, 4.83 (1H, two d, *J*= each 6.6 and 6.2 Hz, integration ratio ca. 2:1, C_4-H), 5.33, 5.34 (1H, two d, *J*= each 6.2 and 6.6 Hz, integration ratio ca. 1:2, C_5-H), 6.60 (2H, s, aromatic protons). Based on the NMR spectrum, this sample was found to consist of the two isomers concerning the C_2-position in a ratio of ca. 2:1. MS *m/z*: 409, 408, 407 (M^+). The total amount of **16** was immediately subjected to the next hydrolysis. Concd hydrochloric acid (0.25 mL) was added to a solution of **16** in EtOH (1.0 mL), and the mixture was heated at reflux for 1 h. After dilution with EtOAc, the organic solution was washed successively with H_2O and satd NaCl. After drying over anhyd $MgSO_4$, filtration and concentration in vacuo followed by separation on column chromatography (C_6H_6–EtOAc 30:1), gave **17** as colorless crystals (21.6 mg, 94% overall yield from **15**), mp 79—83.5 °C (lit,[34] mp 81—82 °C for ***dl*-17**) and $[\alpha]_D^{20}$ +5.0° (*c* 0.12, $CHCl_3$).[40] IR and NMR spectra of this sample were identical with those reported for ***dl*-17**).[34]

(1*S*,2*S*)-(−)-1,2-Epoxy-5,8-dimethoxy-2-[(2*R*,4*R*,5*R*)-4-methoxycarbonyl-2-methyl-5-dimethylcarbamoyl-1,3-dioxolan-2-yl]-1,2,3,4-tetrahydronaphthalene (11a). Anhyd potassium carbonate (16 mg, 0.12 mmol) was added to a suspension of **9aA** (50.6 mg, 0.11 mmol) in MeOH (1.5 mL) under an argon atmosphere, and the mixture was stirred in an ice bath for 0.5 h, then at room temperature for 4 h.[41] After cooling in an ice bath, H_2O (10 mL) was added to the mixture, and the aqueous mixture was extracted with EtOAc. The combined extracts were washed successively with H_2O and satd NaCl, then dried over anhyd $MgSO_4$. Filtration and concentration in vacuo followed by purification on column chromatography (EtOAc), gave **11a** as a colorless caramel (36.2 mg, 80%), $[\alpha]_D^{20}$ −132° (*c* 1.02, $CHCl_3$). IR (KBr) 1760, 1735, 1660, 1495, 1260, 1095, 875, 715 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.57 (3H, s, C_2-CH_3), 1.6—3.3 (4H, m, C_3-H_2 and C_4-H_2), 3.00, 3.20 (6H, two s, $N(CH_3)_2$), 3.75, 3.77, 3.79 (9H, three s, OCH_3×3), 4.41 (1H, s, C_1-H), 5.21 (2H, s, C_4-H and C_5-H), 6.70 (2H, m, aromatic protons). MS *m/z*: 422, 421 (M^+), 217, 216. Found: C, 59.62; H, 6.45; N, 3.28%. Calcd for $C_{21}H_{27}NO_8$: C, 59.85; H, 6.46; N, 3.32%.

(2*R*)-(−)-5,8-Dimethoxy-2-[(2*R*,4*R*,5*R*)-4-methoxycarbonyl-2-methyl-5-dimethylcarbamoyl-1,3-dioxolan-2-yl]-1,2,3,4-tetrahydro-2-naphthol (12a). A mixture of **11a** (129 mg, 0.31 mmol) and 5% Pd/C (33 mg) in THF (5.0 mL) was stirred at room temperature for 21.5 h under a hydrogen atmosphere. The mixture was filtered through a pad of Celite and the Celite layer was washed with CH_2Cl_2. The combined filtrates were concentrated in vacuo. The residue was purified by column chromatography (EtOAc) to give **12a** as a colorless caramel (129 mg, 99%) $[\alpha]_D^{20}$ −58.1° (*c* 1.01, $CHCl_3$). IR (KBr) 3500, 1745, 1660, 1655, 1485, 1260, 1100 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.46 (3H, s, C_2-CH_3), 1.5—2.2 (2H, m, C_3-H_2), 2.4—3.2 (5H, m, C_1-H_2, C_4-H_2, and OH), 2.99, 3.14 (6H, two s, $N(CH_3)_2$), 3.73, 3.77 (9H, three s, OCH_3×3), 5.00, 5.35 (2H, two d, *J*= each 6.3 Hz, C_4-H and C_5-H), 6.59 (2H, s, aromatic protons). MS *m/z*: 423 (M^+), 217, 216, 207, 206. Found: C, 59.43; H, 6.83; N, 3.19%. Calcd for $C_{21}H_{29}NO_8$: C, 59.56; H, 6.90; N, 3.31%.

(*R*)-(−)-2-Acetyl-5,8-dimethoxy-1,2,3,4-tetrahydro-2-naphthol ((*R*)-3). a) Preparation from 12a: Concd hydrochloric acid (0.5 mL) was added to a solution of **12a** (94.5 mg, 0.22 mmol) in EtOH (2.0 mL), and the mixture was stirred under reflux for 2 h. After cooling, the mixture was diluted with H_2O (10 mL) and extracted with EtOAc. The combined organic extracts were washed successively

with H_2O and satd NaCl, then dried over anhyd $MgSO_4$. Filtration and concentration in vacuo followed by purification on column chromatography (C_6H_6-EtOAc 4:1), gave (***R***)-**3** as a colorless solid (49.7 mg, 89%), mp 127.5—129 °C and $[\alpha]_D^{20}$ −48.4° (*c* 0.977, $CHCl_3$). This sample showed identical IR and NMR spectra with those of the authentic sample.[8,9] Optical purity of this sample was determined to be 100% ee by measuring the NMR spectrum in the presence of tris[3-(heptafluoropropylhydroxymethylene)-*d*-camphorato]europium[III] (Eu(hfc)$_3$) in a similar manner to that previously reported.[9] Recrystallization of this sample from Et_2O gave pure (***R***)-**3** as colorless needles, mp 129.5—130.5 °C and $[\alpha]_D^{20}$ −48.7° (*c* 0.368, $CHCl_3$) (lit,[8] mp 128—129 °C and $[\alpha]_D^{20}$ −48.2° (*c* 0.982, $CHCl_3$); lit,[9] mp 128—128.5 °C and $[\alpha]_D^{20}$ −47.1° (*c* 1.11, $CHCl_3$); lit,[14] mp 128—128.5 °C and $[\alpha]_D^{20}$ −46.3° (*c* 0.54, $CHCl_3$).

b) Preparation from the Mixture of 9aA and 9aB: Anhyd Potassium carbonate (55 mg, 0.40 mmol) was added to a suspension of the mixture of **9aA** and **9aB** (179 mg, 0.38 mmol) in MeOH (4.0 mL), and the mixture was stirred at room temperature under an argon atmosphere for 10.5 h. After further amount of anhyd K_2CO_3 (10 mg, 0.07 mmol, total 0.47 mmol) was added, the stirring was continued for 13 h to completely produce the epoxide. 5% palladium on carbon (50 mg) was directly added to the reaction mixture, and the whole mixture was stirred at room temperature under a hydrogen atmosphere for 8.5 h to cleave the epoxide. After concd HCl (1.0 mL) was added, the mixture was heated at reflux for 2 h to effect hydrolysis of the chiral acetal. Concd hydrochloric acid (1.0 mL) was added after 2 h reaction, and the reflux was further continued for 2 h. The reaction mixture was cooled, and the insoluble materials were removed by filtration an washed with EtOAc. The combined filtrates and washings were diluted with H_2O (10 mL), and extracted with EtOAc. The organic extracts were combined, washed successively with H_2O and satd NaCl, then dried over anhyd $MgSO_4$. Filtration and concentration in vacuo followed by purification on column chromatography (C_6H_6-EtOAc 4:1), gave (***R***)-**3** as a colorless solid (71.0 mg, 75%), mp 129.5—130.5 °C and $[\alpha]_D^{20}$ −49.0° (*c* 0.988, $CHCl_3$). This sample showed the IR and NMR spectra identical with those of the authentic sample.[8,9] The optical purity of this sample was similarly calculated to be more than 95% ee by measuring the NMR spectrum in the presence of Eu(hfc)$_3$.[9] Accordingly, the formation ratio of **9aA** and **9aB** could be firmly determined as more than 97.5:2.5. Recrystallization from Et_2O gave pure (***R***)-**3** as colorless needles, mp 130—131 °C and $[\alpha]_D^{20}$ −48.6° (*c* 0.987, $CHCl_3$) (for the reported values, see a)).

c) Preparation from the Mixture of 10aA and 10aB: Treatment of the crude mixture of **10aA** and **10aB** (55.8 mg, 0.11 mmol) with anhyd K_2CO_3 (23 mg, 0.17 mmol) in MeOH (2.0 mL), followed by hydrogenation over 5% Pd/C (23 mg) in MeOH (2.0 mL) and hydrolysis with concd HCl (2.0 mL) in EtOH (2.0 mL) in a similar manner to that described for the preparation of (***R***)-**3** from a mixture of **9aA** and **9aB**, gave (***R***)-**3** as a colorless solid (10.4 mg, 38% overall yield), mp 111—126.5 °C and $[\alpha]_D^{20}$ −32.4° (*c* 1.04, $CHCl_3$) (for the reported values, see a)). This was identified by comparing its IR and NMR spectra with those of the authentic sample.[8,9] Measurement of the NMR spectrum in the presence of Eu(hfc)$_3$ clearly disclosed that the optical purity of this sample was 71% ee. Based on this value, the formation ratio of **10aA** to **10aB** could be calculated as 85.5:14.5.

d) Preparation from the Mixture of 9bA and 9bB: The same successive treatments of the mixture of **9bA** and **9bB** (201 mg, 0.40 mmol) as those described for the preparation of (***R***)-**3** from the mixture of **9aA** and **9aB** gave (***R***)-**3** as a colorless solid (82.4 mg, 81%), mp 129.5—130 ° and $[\alpha]_D^{20}$ −47.6° (*c* 1.02, $CHCl_3$) (for the reported value, see a)). IR and NMR spectra of this sample were identical with those of the authentic sample.[8,9] Measurement of the NMR spectrum in the presence of Eu(hfc)$_3$ disclosed that the optical purity of this sample and the formation ratio of **9bA** to **9bB** were more than 95% ee and 97.5:2.5, respectively.[9]

2-Acetyl-5,12-dimethoxy-3,4-dihydro-6,11-naphthacenedione (21i). a) Preparation of 2-Acetyl-5,12-dihydroxy-3,4-dihydro-6,11-naphthacenedione: Trifluoroacetic anhydride (2.0 mL, 14 mmol) was added to a mixture of ***dl*-4d**[14,23] (137 mg, 0.39 mmol) and collidine (4.0 mL) cooled in an ice bath under an argon atmosphere. After being stirred in an ice bath for 0.5 h and at room temperature for 1 h, the reaction mixture was diluted with H_2O (1.0 mL). The reaction mixture was stirred for 5 min, then poured onto ice-water (50 mL). A solid separated was collected by filtration, and washed successively with H_2O, MeOH, and Et_2O. After drying in vacuo, the crude product obtained as a red solid weighed 99.4 mg (77%), mp 225—236.5 °C. Recrystallization from $CHCl_3$-EtOH gave an analytical sample as red crystals, mp 245—246 °C (lit,[18] mp 235—237 °C). IR (KBr) 1665, 1620, 1590, 1400, 1370, 1335, 1290, 1270, 1260, 1220, 1010, 800, 770, 735 cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.52 (3H, s, CH_3), 2.5—2.85 (2H, m, C_3-H_2), 2.85—3.2 (2H, m, C_4-H_2), 7.7—8.0 (2H, m, aromatic protons), 7.89 (1H, s, C_1-H), 8.3—8.5 (2H, m, aromatic protons), 13.23, 13.56 (2H, two s, phenolic OH×2). Found: C, 71.80; H, 4.33%. Calcd for $C_{20}H_{14}O_5$: C, 71.85; H, 4.22%.[37]

b) Preparation of 21i: Tetrahydrofuran (20 mL) was added to a mixture of 2-acetyl-5,12-dihydroxy-3,4-dihydro-6,11-naphthacenedione (102 mg, 0.31 mmol) and sodium hydride (50% oil dispersion) (36 mg, 0.75 mmol) cooled at −78 °C, and the mixture was degassed in vacuo. Then, the mixture was stirred at room temperature for 0.5 h and at 50 °C for 1 h under an argon atmosphere. After tetrabutylammonium bromide (242 mg, 0.75 mmol) was added, the mixture was stirred at 50 °C for 0.25 h. Dimethyl sulfate (0.25 mL, 2.6 mmol) was added to the resulting mixture, and the whole was stirred at 50 °C for 5 h. After cooling, the mixture was diluted with 1.5 M† HCl and extracted with CH_2Cl_2. The combined extracts were washed with H_2O, and dried over anhyd $MgSO_4$. Filtration and concentration in vacuo followed by purification on column chromatography (CH_2Cl_2-EtOAc 20:1), gave **21i** as a yellow solid (90.8 mg, 82%). Recrystallization from $CHCl_3$-MeOH gave an analytical sample of **21i** as yellow crystals, mp 202.5—204 °C. IR (KBr) 1670, 1325, 1275, 1255, 1035 cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.53 (3H, s, CH_3), 2.4—2.7 (2H, m, C_3-H_2), 2.8—3.2 (2H, m, C_4-H_2), 3.92, 3.99 (6H, two s, OCH_3×2), 7.6—7.9 (2H, m, aromatic protons), 7.80 (1H, s, C_1-H), 8.1—8.3 (2H, m, aromatic protons). Found: C, 72.95;

† 1 M=1 mol dm^{-3}.

H, 4.96%. Calcd for $C_{22}H_{18}O_5$: C, 72.92; H, 5.01%.

2-Acetyl-5-methoxy-3,4-dihydro-6,11-naphthacenedione (21j). a) Preparation of *dl*-4j: A mixture of ***dl*-4h**[38] (506 mg, 1.5 mmol), Me_2SO_4 (596 mg, 4.7 mmol), and anhyd K_2CO_3 (624 mg, 4.5 mmol) in Me_2CO (20 mL) was heated at reflux for 8.5 h. After cooling, insoluble materials were separated and washed with CH_2Cl_2. The combined organic layer was washed with satd $NaHCO_3$ and dried over anhyd $MgSO_4$. Filtration and concentration followed by column chromatography (C_6H_6-EtOAc 4:1) gave ***dl*-4j** as a yellow solid (458 mg, 87%). An analytical sample was prepared as yellow crystals by recrystallization from $CHCl_3$-MeOH, mp 209—209.5 °C. IR (KBr) 3500, 1710, 1675, 1585, 1335 1270 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.9—2.1 (2H, m, C_3-H_2), 2.37 (3H, s, $COCH_3$), 2.7—3.5 (4H, m, C_1-H_2 and C_4-H_2), 3.77, 3.93 (6H, two s, OCH_3×2), 7.6—7.9 (2H, m, aromatic protons), 7.83 (1H, C_{12}-H), 8.1—8.4 (2H, m, aromatic protons). Found: C, 71.41; H, 5.23%. Calcd for $C_{21}H_{18}O_5 \cdot 1/6H_2O$: C, 71.38; H, 5.23%.

b) Preparation of 21j: Thionyl chloride (0.15 mL, 2.1 mmol) was added dropwise to a suspension of ***dl*-4j** (481 mg, 1.4 mmol) in C_5H_5N (10 mL) at room temperature under an argon atmosphere, and the mixture was stirred at the same temperature for 0.5 h. After being cooled in an ice bath, the mixture was diluted with H_2O (30 mL), and extracted with CH_2Cl_2. The combined extracts were washed with H_2O, dried over anhyd $MgSO_4$, then concentrated in vacuo. The residue was purified by column chromatography (CH_2Cl_2 then C_6H_6-EtOAc 10:1), giving **21j** as a yellow solid (230 mg, 50%). Recrystallization from $CHCl_3$-MeOH gave an analytical sample of **21j** as yellow crystals, mp 241.5—243 °C. IR (KBr) 1670, 1580, 1330, 1310, 1280 cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.49 (3H, s, $COCH_3$), 2.3—2.8 (2H, m, C_3-H_2), 2.9—3.2 (2H, m, C_4-H_2), 3.93 (3H, s, OCH_3), 7.43 (1H, m, C_1-H), 7.6—7.9 (2H, m, aromatic protons), 8.00 (1H, s, C_{12}-H), 8.1—8.4 (2H, m, aromatic protons). Found: C, 75.43; H, 4.73%. Calcd for $C_{21}H_{16}O_4 \cdot 1/8H_2O$: C, 75.38; H, 4.89%.

(−)-5,12-Dimethoxy-2-[(4*R*,5*R*)-2-methyl-4,5-bis(1-pyrrolidinylcarbonyl)-1,3-dioxolan-2-yl]-3,4-dihydro-6,11-naphthacenedione (23i). A mixture of **21i** (254 mg, 0.70 mmol), $CH(OMe)_3$ (1.0 mL, 9.1 mmol), and CSA (21.5 mg, 0.093 mmol) in MeOH (25 ml) was stirred at room temperature for 5.5 h under an argon atmosphere. After cooling in an ice bath, the mixture was diluted with satd $NaHCO_3$ (15 mL) and extracted with CH_2Cl_2. The organic extracts were combined, washed with dil $NaHCO_3$, then dried over anhyd $MgSO_4$. Filtration and concentration in vacuo gave crude **22i** as a red solid. ^1H NMR ($CDCl_3$) δ=1.43 (3H, s, C_2-CH_3), 2.2—2.5 (2H, m, C_3-H_2), 2.8—3.1 (2H, m, C_4-H_2), 3.26 (6H, two s, $C(OCH_3)_2$), 3.90, 3.93 (6H, two s, OCH_3×2), 7.15 (1H, t, J=1.5 Hz, C_1-H), 7.6—7.8 (2H, m, aromatic protons), 8.1—8.3 (2H, m, aromatic protons). The total amount of **22i** was immediately subjected to the next transacetalization.

A mixture of crude **22i** and **5b** (358 mg, 1.4 mmol) in C_6H_6 (30 mL) was heated at reflux for 0.5 h using a Dean-Stark apparatus packed with molecular sieves 3A to removed a small amount of H_2O. After CSA (22 mg, 0.095 mmol) was added, the reflux was further continued for 1 h. After being cooled, the mixture was poured onto satd $NaHCO_3$ (50 mL) cooled in an ice bath, and extracted with CH_2Cl_2. The organic extracts were combined, washed with dil $NaHCO_3$, then dried over anhyd $MgSO_4$. Filtration and concentration in vacuo followed by purification on column chromatography (EtOAc-MeOH 19:1), gave almost pure **23i** as a yellow caramel (375 mg, 89% overall yield from **21i**). This was recrystallized from $CHCl_3$-Et_2O to give pure **23i** as a yellow powder, mp 148.5—150.5 °C and $[\alpha]_D^{20}$ −20.4° (*c* 1.02, $CHCl_3$).[42] IR (KBr) 1675, 1645, 1450, 1330, 1275, 1255, 1155, 1045, 995 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.67 (3H, s, C_2-CH_3), 1.7—2.2 (8H, m, $NCH_2CH_2CH_2CH_2N$×2), 2.2—2.5 (2H, m, C_3-H_2), 2.8—3.1 (2H, m, C_4-H_2), 3.3—4.0 (8H, m, $NCH_2CH_2CH_2CH_2N$×2), 3.89, 3.90 (6H, two s, OCH_3×2), 5.11, 5.18 (2H, two d, J= each 7.2 Hz, C_4-H and C_5-H), 7.05 (1H, m, C_1-H), 7.6—7.8 (2H, m, aromatic protons), 8.1—8.3 (2H, m, aromatic protons). Found: C, 67.75; H, 6.00; N, 4.60%. Calcd for $C_{34}H_{36}N_2O_8$: C, 67.99; H, 6.04; N, 4.66%.

(−)-5-Methoxy-2-[(4*R*,5*R*)-2-methyl-4,5-bis(dimethylcarbamoyl)-1,3-dioxolan-2-yl]-3,4-dihydro-6,11-naphthacenedione (23j). A mixture of **21j** (244 mg, 0.73 mmol), $CH(OMe)_3$ (1.0 mL, 9.1 mmol), and pyridinium *p*-toluenesulfonate (PPTS) (39 mg, 0.16 mmol) in a mixture of MeOH (5.0 mL) and CH_2Cl_2 (20 mL) was stirred at 45 °C for 17.5 h under an argon atmosphere. Similar treatments of the reaction mixture to that described for the preparation of **22i** gave crude **22j** after concentration of the combined organic extracts (256 mg, 100%). ^1H NMR ($CDCl_3$) δ=1.40 (3H, s, C_2-CH_3), 2.2—2.5 (2H, m, C_3-H_2), 2.8—3.1 (2H, m, C_4-H_2), 3.23 (6H, two s, $C(OCH_3)_2$), 3.85 (3H, s, C_5-OCH_3), 6.77 (1H, m, C_1-H), 7.5—7.8 (2H, m, aromatic protons), 7.73 (1H, s, C_{12}-H), 8.0—8.3 (2H, m, aromatic protons). This was directly used for the next transacetalization.

A mixture of crude **22j** (256 mg, 0.73 mmol) and **5a** (308 mg, 1.5 mmol) in C_6H_6 (20 mL) was heated at reflux for 0.5 h using a Dean-Stark apparatus packed with molecular sieves 3A to remove a small amount of H_2O. After PPTS (16.2 mg, 0.06 mmol) was added, the mixture was further heated at reflux for 0.5 h. Work-up of the reaction mixture in the same manner as that described for the preparation of **23i** gave as a yellow caramel (294 mg, 77%) after purification on column chromatography (Florisil, EtOAc). This was dissolved in Et_2O (10 mL), and the ethereal solution was stirred in an ice bath to afford an analytical sample of **23j** as a yellow powder, mp 132.5—135.5 °C and $[\alpha]_D^{20}$ −14.6° (*c* 1.03, $CHCl_3$). IR (KBr) 1665, 1630, 1580, 1330, 1280 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.64 (3H, s, C_2-CH_3), 2.2—2.5 (2H, m, C_3-H_2), 2.8—3.1 (2H, m, C_4-H_2), 2.97, 3.02, 3.24, 3.27 (12H, four s, $N(CH_3)_2$×2), 3.90 (3H, s, OCH_3), 5.29, 5.31 (2H, two d, J= each 7.0 Hz, C_4-H and C_5-H), 6.68 (1H, m, C_1-H), 7.6—7.9 (2H, m, aromatic protons), 7.79 (1H, s, C_{12}-H), 8.1—8.4 (2H, m, aromatic protons). Found: C, 67.24; H, 5.94; N, 5.35%. Calcd for $C_{29}H_{30}N_2O_7$: C, 67.17; H, 5.83; N, 5.40%.

(3*R*,4*R*,6*R*,6a*S*,16b*S*)-6a-Bromo-3,6-epoxy-9,16-dimethoxy-6-methyl-4-(1-pyrrolidinylcarbonyl)-3,4,6a,7,8,16b-hexahydro-2*H*,6*H*-naphthaceno[1,2-b][1,5]dioxocin-2,10,15-trione (24iA), (1*R*,1′*R*,2*S*,5*R*,6*R*)-1′-Bromo-5′,12′-dimethoxy-1-methyl-6-(1-pyrrolidinylcarbonyl)-3′,4′-dihydro-3,7,8-trioxaspiro[bicyclo-[3.2.1]octane-2,2′(1′*H*)-naphthacene]-4,6′,11′-trione (25iA), and Their (6a*R*,16b*R*)- and (1′*S*,2*R*)-Isomers (24iB and 25iB). Bromolactonization of 23i: *N*-Bromoacetamide (100 mg, 0.73 mmol) was added to a solution of **23i** (213 mg, 0.35 mmol) in a mixture of DMF-H_2O (100:1) (5.0 mL), and the mixture was stirred at room temperature for 8 h under an

argon atmosphere. After further amount of NBA (49 mg, 0.36 mmol, total 1.1 mmol, 3.0 equiv) was added, the stirring was continued for 3 h. The mixture was cooled in an ice bath, diluted with 10% $NaHSO_3$ (10 mL), and extracted with CH_2Cl_2. The organic extracts were combined, washed successively with 10% $NaHSO_3$ and H_2O, then dried over anhyd $MgSO_4$. Filtration and concentration in vacuo followed by purification on column chromatography (EtOAc), afforded a pale yellow solid which mainly consisted of **24iA** and **25iA** (174 mg, 78%). The formation ratio of **24i** to **25i** was roughly estimated as 6:1 based on the NMR spectrum showing the C_{16b} and $C_{1'}$-protons as two sets of doublets at δ 6.04 and 5.60. Recrystallization of the mixture of **24i** and **25i** from $CHCl_3$-Et_2O gave pure **24iA** as a yellow powder, mp 217—219 °C and $[\alpha]_D^{20}$ −263° (*c* 0.104, $CHCl_3$). IR (KBr) 1755, 1675, 1645, 1450, 1340, 1250, 1225, 1045, 955 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.99 (3H, s, C_6-CH_3), 1.7—2.3 (4H, m, $NCH_2C\underline{H}_2C\underline{H}_2CH_2N$), 2.3—2.9 (2H, m, C_7-H_2), 3.0—3.3 (2H, m, C_8-H_2), 3.3—3.9 (4H, m, $NC\underline{H}_2CH_2CH_2C\underline{H}_2N$), 3.96, 4.03 (6H, two s, OCH_3×2), 5.13, 5.44 (2H, two d, *J*= each 2.0 Hz, C_3-H and C_4-H), 6.04 (1H, d, *J*=2.0 Hz, C_{16b}-H), 7.6—7.9 (2H, m, aromatic protons), 8.1—8.4 (2H, m, aromatic protons). MS *m/z*: 628, 627, 626, 625 (M^+). Found: C, 56.87; H, 4.51; N, 2.14%. Calcd for $C_{30}H_{20}NO_9Br \cdot 0.5H_2O$: C, 56.70; H, 4.60; N, 2.20%.

Concentration of the mother liquor from the recrystallization in vacuo gave a solid (27 mg) in which **25iA** was enriched. This was further separated by column chromatography (C_6H_6-EtOAc 2:1) to give pure **25iA** as a pale yellow solid (7.8 mg), mp 143—184.5° (decomp) and $[\alpha]_D^{20}$ +295° (*c* 0.124, $CHCl_3$). IR (KBr) 1770, 1675, 1455, 1340, 1265, 1040 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.95—2.14 (4H, m, $NCH_2C\underline{H}_2C\underline{H}_2CH_2N$), 2.11 (3H, s, C_1-CH_3), 2.40 (1H, dddd, *J*=14.0, 7.6, 2.1, and 1.1 Hz, $C_{3'-eq}$-H), 2.60 (1H, ddd, *J*=14.0, 11.2, and 7.4 Hz, $C_{3'-ax}$-H), 3.06 (1H, ddd, *J*=18.9, 11.2, and 7.6 Hz, $C_{4'-ax}$-H), 3.34 (1H, ddd, *J*=18.9, 7.4, and 1.1 Hz, $C_{4'-eq}$-H), 3.50—3.63 (4H, m, $NC\underline{H}_2CH_2CH_2C\underline{H}_2N$), 3.94, 4.06 (6H, s, OCH_3×2), 4.81, 5.15 (2H, two s, C_5-H and C_6-H), 5.60 (1H, d, *J*=2.1 Hz, $C_{1'}$-H), 7.72—7.80 (2H, m, aromatic protons), 8.17—8.25 (2H, m, aromatic protons). MS *m/z*: 627, 625 (M^+). High resolution MS: Found: 627.0902 and 625.0881. Calcd for $C_{30}H_{28}NO_9Br$: 627.0925 and 625.0946.

Although the pale yellow solid obtained by the bromolactonization was expected to involve small amounts of **24iB** and **25iB**, these undesired isomers could not be detected by the NMR spectrum. Based on the optical purity of (***R***)-**4d** derived from the mixture of **24i** and **25i**, the total amount of **24iB** and **25iB** should be less than 5%. Since **25i** being a sort of benzyl bromide, seemed to be fairly unstable, the mixture of **24i** and **25i** was immediately subjected to the next reaction.

(3*R*,4*R*,6*R*,6a*S*,16b*S*)-6a-Bromo-3,6-epoxy-9-methoxy-6-methyl-4-(dimethylcarbamoly)-3,4,6a,7,8,16b-hexahydro-2*H*,6*H*-naphthaceno[1,2-*b*][1,5]dioxocin-2,10,15-trione (24jA), (1*R*,1′*R*,2*S*,5*R*,6*R*)-1′-Bromo-5′-methoxy-1-methyl-6-(dimethylcarbamoyl)-3′,4′-dihydro-3,7,8-trioxaspiro[bicyclo[3.2.1]-octane-2,2′(1′*H*)-naphthacene]-4,6′,11′-trione (25jA), and Their (6a*R*,16b*R*)- and (1′*S*,2*R*)-Isomers (24jB and 25jB). Bromolactonization of 23j: *N*-Bromoacetamide (205 mg, 1.5 mmol) was added to a solution of **23j** (254 mg, 0.49 mmol) in a mixture of DMF-H_2O (100:1) (7.0 mL), and the mixture was stirred at room temperature under an argon atmosphere for 7 h. After further amount of NBA (67 mg, 0.49 mmol, total 2.0 mmol, 4.0 equiv) was added, the stirring was continued for 3 h. Work-up of the reaction mixture in the same manner as that described for the bromolactonization of **23i** gave a pale yellow solid which mainly consisted of **24jA** and **25jA** (239 mg, 85%). The formation ratio of **24j** to **25j** was estimated as 6:1, based on the NMR spectrum showing the C_6 and C_1-methyl groups as two singlets at δ 1.98 and 2.05. This solid was recrystallized from $CHCl_3$-Et_2O to give **24jA** as a yellow powder, mp 238—239.5 °C (decomp) and $[\alpha]_D^{20}$ −103° (*c* 0.105, $CHCl_3$). IR (KBr) 1750, 1680, 1640, 1590, 1275, 1255, 1245, 1220 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.98 (3H, s, C_6-CH_3), 2.36 (1H, dddd, *J*=14.8, 7.5, 1.8, and 1.4 Hz, C_{7-eq}-H), 2.65 (1H, ddd, *J*=14.8, 10.6, and 6.9 Hz, C_{7-ax}-H), 3.06, 3.23 (6H, two s, $N(CH_3)_2$), 3.08 (1H, ddd, *J*=19.1, 10.6, and 7.5 Hz, C_{8-ax}-H), 3.30 (1H, ddd, *J*=19.1, 6.9, and 1.4 Hz, C_{8-eq}-H), 3.98 (3H, s, OCH_3), 5.32, 5.47 (2H, two d, *J*= each 1.9 Hz, C_3-H and C_4-H), 7.74—7.83 (2H, m, aromatic protons), 8.13 (1H, s, C_{16}-H), 8.23-8.30 (2H, m, aromatic protons). Found: C, 56.70; H, 4.29; N, 2.38; Br, 14.11%. Calcd for $C_{27}H_{24}NO_8Br$: C, 56.86; H, 4.24: N, 2.46; Br, 14.01%.

Concentration of the mother liquor from the recrystallization in vacuo gave a solid in which the amount of **25jA** was increased. The NMR spectrum of this sample showed the followed signals assignable to **25jA** in addition to those of **24j**. ^1H NMR ($CDCl_3$) δ=2.05 (3H, s, C_1-CH_3), 2.42 (1H, dddd, *J*=14.1, 7.6, and 1.9 Hz, another coupling constant could not be determined due to overlapping, $C_{3'-eq}$-H), 2.54 (1H, ddd, *J*=14.1, 11.3, and 7.0 Hz, $C_{3'-ax}$-H), 3.03, 3.20 (6H, two s, $N(CH_3)_2$), 3.98 (3H, s, OCH_3), 4.98 (1H, s, $C_{1'}$-H, C_5-H, or C_6-H), 5.28 (2H, s, two protons of $C_{1'}$-H, C_5-H, and C_6-H), 7.70—7.84 (2H, m, aromatic protons), 8.08 (1H, s, $C_{12'}$-H), 8.23—8.30 (2H, m, aromatic protons).

While the pale yellow solid obtained by the bromolactonization was anticipated to contain small amounts of **24jB** and **25jB**, these undesired isomers could not be detected by the NMR spectrum. Based on the optical purity of (***R***)-**4h** derived from this sample, the total amount of these isomers should be less than 5%. The mixture of **24j** and **25j** was immediately subjected to the next reaction.

(*R*)-(−)-2-Acetyl-2,5,12-trihydroxy-1,2,3,4-tetrahydro-6,11-naphthacenedione ((*R*)-(−)-7-deoxy-4-demethoxydaunomycinone) ((*R*)-4d). A methanolic suspension (7.5 mL) containing the mixture of **24i** and **25i** (**24i**:**25i** 6:1) (177 mg, 0.28 mmol) and anhyd K_2CO_3 (80 mg, 0.58 mmol) was stirred at room temperature under an argon stmosphere for 3.5 h to produce the epoxide. After 5% Pd/C (30 mg) was added to the resulting suspension, the mixture was stirred under a hydrogen atmosphere for 23 h to cleave the epoxide. Insoluble materials were removed by filtration, and the filtrate was concentrated in vacuo. Ethanol (2.0 mL) and concd HCl (1.0 mL) were added to the concentration residue, and the mixture was heated at reflux for 1 h to hydrolyse the chiral acetal group. After concd HCl (1.0 mL) was added, the reflux was further continued for 1 h. The mixture was cooled, diluted with H_2O (20 mL), and extracted with CH_2Cl_2. The organic extracted were combined, washed with H_2O, then dried over anhyd $MgSO_4$. Filtration and concentration in vacuo gave crude (***R***)-**4i** as a yellow solid. A benzene solution (15 mL) of crude (***R***)-**4i** and anhyd $AlCl_3$

(408 mg, 3.1 mmol) was stirred at 50 °C for 2 h under an argon atmosphere to cleave the two phenolic methyl ethers. After cooling, the mixture was diluted with satd oxalic acid solution (40 mL), and extracted with CH_2Cl_2. The organic extracts were combined, washed with H_2O, then dried over anhyd $MgSO_4$. Filtration and concentration in vacuo followed by purification on column chromatography (C_6H_6–EtOAc 10:1), gave (***R***)-**4d** as orange crystals (67.9 mg, 68% overall yield from the mixture of **24i** and **25i**), mp 215—218.5 °C and $[\alpha]_D^{20}$ −90.4° (*c* 0.104, $CHCl_3$), $[\alpha]_D^{20}$ −20.1° (*c* 0.189, $CHCl_3$–MeOH 1:1) (lit,[9] mp 218—219 °C and $[\alpha]_D^{20}$ −87.0° (*c* 0.115, $CHCl_3$); lit,[14] mp 218—219.5 °C and $[\alpha]_D^{20}$ −90.0° (*c* 0.106, $CHCl_3$); lit,[15] mp 217—219 °C and $[\alpha]_D^{20}$ −90.3° (*c* 0.106, $CHCl_3$); lit,[43] $[\alpha]_D^{20}$ −95.2° (*c* 0.13, $CHCl_3$) and $[\alpha]_D^{20}$ −20.0° (*c* 0.18, $CHCl_3$–MeOH 1:1)). IR and NMR spectra of this sample were superimposable on those of the authentic sample.[9] Methylation of this sample with Me_2SO_4 and anhyd K_2CO_3 in Me_2CO according to the reported procedure[9] reproduced (***R***)-**4i** as a yellow solid in 98% yield after purification on column chromatography (C_6H_6–EtOAc 3:1). The optical purity of (***R***)-**4i** was rigorously determined as 94% ee by measuring the NMR spectrum in the presence of Eu(hfc)$_3$ following the same manner as that reported.[9] Accordingly, the optical yield of (***R***)-**4d** produced from the mixture of **24i** and **25i** was estimated as 94% ee.

(*R*)-2-Acetyl-2,5-dihydroxy-1,2,3,4-tetrahydro-6,11-naphthacenedione ((*R*)-7,11-dideoxy-4-demethoxydaunomycinone) ((*R*)-4h). The same four successive treatments of the mixture of **24j** and **25j** (**24j**:**25j** 6:1) (188 mg, 0.33 mmol) as those described for the preparation of (***R***)-**4d** gave (***R***)-**4h** as yellow crystal (53.8 mg, 49% overall yield from the mixture of **24j** and **25j**), after purification on column chromatography (CH_2Cl_2–EtOAc 7:1), mp 202.5—204.5 °C and $[\alpha]_D^{20}$ −32.7° (*c* 0.104, $CHCl_3$), $[\alpha]_D^{20}$ +17.3° (*c* 0.104, $CHCl_3$–MeOH 1:1). A part of (***R***)-**4h** was recrystallized from C_6H_6 to give an analytical sample as yellow crystals, mp 204.5—206.5 °C and $[\alpha]_D^{20}$ −35.3° (*c* 0.102, $CHCl_3$), $[\alpha]_D^{20}$ +16.0° (*c* 0.100, $CHCl_3$–MeOH 1:1). IR (KBr) 3475, 1705, 1670, 1630, 1590, 1360, 1290 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=1.8—2.1 (2H, m, C_3-H_2), 2.37 (3H, s, $COCH_3$), 2.75, 3.30 (2H, two d, *J*= each 18.0 Hz, C_1-H_2), 2.6—3.1 (2H, m, C_4-H_2), 3.70 (1H, s, OH), 7.47 (1H, s, C_{12}-H), 7.7—7.9 (2H, m, aromatic protons), 8.1—8.4 (2H, m, aromatic protons), 12.95 (1H, s, phenolic OH). Found: C, 70.90; H, 4.74%. Calcd for $C_{20}H_{16}O_5 \cdot 1/6H_2O$: C, 70.79; H, 4.85%.

In order to determine the optical purity of (***R***)-**4h**, the sample (20.2 mg, 0.06 mmol) obtained from the column chromatography was methylated according to the same procedure as that described for (***R***)-**4i**. Purification of the crude product by column chromatography (C_6H_6–EtOAc 4:1) gave (***R***)-**4j** as a yellow solid (18.5 mg, 88%), mp 140—141 °C and $[\alpha]_D^{20}$ +64.7° (*c* 0.102, $CHCl_3$), $[\alpha]_D^{20}$ +43.0° (*c* 0.107, $CHCl_3$–MeOH 1:1). This sample showed the identical NMR spectrum with that of ***dl*-4j**. The NMR spectrum of ***dl*-4j** measured in the presence of Eu(hfc)$_3$ exhibited two sets of two singlets at δ 4.01, 4.24 and 9.18, 9.47. The former two singlets could be assigned to the acetyl group and the latter to the C_{12}-proton. Two singlets at δ 4.24 and 9.47 were only observed in the NMR spectrum of (***R***)-**4j** measured under the same conditions as that for the racemic compound. Accordingly, the optical yield of (***R***)-**4h** produced from the mixture of **24j** and **25j** was determined as more than 99% ee.

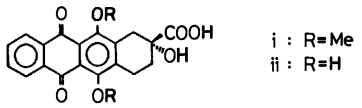
24) Synthesis of 11-deoxyanthracyclinones such as aklavinone and 11-deoxydaunomycinone have been accomplished using an asymmetric cross aldol reaction. See, a) J. M. McNamara and Y. Kishi, *Tetrahedron*, **40**, 4685 (1984); b) H. Sekizaki, M. Jung, J. M. McNamara, and Y. Kishi, *J. Am. Chem. Soc.*, **104**, 7372 (1982).

25) (*R*)-(+)-2-Hydroxy-5,12-dimethoxy-1,2,3,4-tetrahydro-6,11-dioxo-2-naphthacenecarboxylic acid (**i**) produced from 5,12-dimethoxy-3,4-dihydro-6,11-dioxo-2-naphthacenecarboxylic acid by the asymmetric bromolactonization, could not be derived to (***R***)-**4i** by treating with methyllithium.[8] However, we have recently explored that sequential treatments of (*R*)-2,5,12-trihydroxy-1,2,3,4-tetrahydro-6,11-dioxo-2-naphthacenecarboxylic acid (**ii**) with *N,N'*-carbonyldiimidazole, trimethylsilyl trifluoromethanesulfonate, and methylmagnesium bromide efficiently afford (***R***)-**4d**. The acid (**ii**) could be readily obtained from **i** or independently prepared from 5,12-dihydroxy-1,2,3,4-tetrahydro-2,6,11-naphthacenetrione. See ref. 23 and references cited therein.



26) The C_2-symmetric nature of optically active tartaric acid derivatives has been introduced as efficient chiral templates in asymmetric synthesis. For example, P. A. Bartlett, W. S. Johnson, and J. D. Elliott, *J. Am. Chem. Soc.*, **105**, 2088 (1983), and N. Ikeda, I. Arai, and H. Yamamoto, *ibid.*, **108**, 483 (1986). Recently, **5a** has been nicely utilized as a chiral source in the asymmetric nucleophilic addition of organoaluminum reagents to chiral α,β-unsaturated acetals. See, J. Fujiwara, Y. Fukutani, M. Hasegawa, K. Maruoka, and H. Yamamoto, *J. Am. Chem. Soc.*, **106**, 5004 (1984).

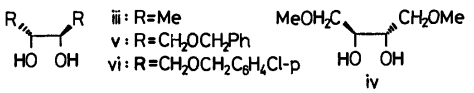
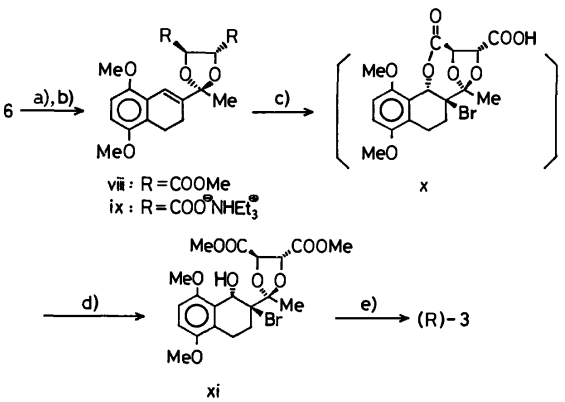
30) D. Seebach, H-O. Kalinowski, W. Langer, G. Grass, and E-M. Wilkam, *Org. Synth.*, **61**, 24 (1983).

31) At the outset of this work, (2*R*,3*R*)-2,3-butanediol (**iii**), (2*S*,3*S*)-1,4-dimethoxy-2,3-butanediol (**iv**), (2*R*,3*R*)-1,4-bis(benzyloxy)-2,3-butanediol (**v**), and (2*R*,3*R*)-1,4-bis(4-chlorobenzyloxy)-2,3-butanediol (**vi**) were employed as chiral sources. When the acetals (**vii**) prepared from **6** and the chiral diols (**iii**—**vi**) were treated with *N*-bromoacetamide and barium hydroxide in a mixture of tetrahydrofuran and water, diastereomeric mixtures of the bromohydrins similar to **10** could be obtained as sole reaction products in almost quantitative yields. These bromohydrins were converted to optically active **3**, 10% ee [(***R***)-**3**, **iii** as a chiral source], 17% ee [(***S***)-**3**, **iy** as a chiral source], 19% ee [(***R***)-**3**, **v** as a chiral source], and 17% ee [(***R***)-**3**, **vi** as a chiral source], by the same sequential treatments as those emplyed for the preparation of (***R***)-**3** from the mixture of **10aA** and **10aB**. On the other hand, the diastereoselective epoxidation of **vii** with *m*-chloroperbenzoic acid, *t*-butyl hydroperoxide-oxobis(acetylacetonato)vanadium(iv), hydrogen peroxide-sodium tangstate, etc., were all found to be fruitless and simply recovered the starting material (**vii**). By accumlating these numerous unsuccessful results, the novel bromolactonization reaction reported herein was finally explored.



32) When (R,R)-(+)-dimethyl tartrate was used in place of **5**, the same successive acetalization and transacetalization gave the chiral acetal (**viii**) in 80% overall yield. Treatment of the bis(triethylamine) salt (**ix**) derived from **viii**, under the conditions for bromolactonization produced the bromo lactone which was presumed to mainly consist of **x**. Since **x** was found to be unstable, it was immediately derived to the bromohydrin (**xi**) in 79% yield from **viii** by methanolysis and esterification. Successive epoxide formation, catalytic hydrogenation, and acidic hydrolysis in the same manner as that described for **9** and **10**, afforded (***R***)-**3**, mp 126.5—127.5 °C and $[\alpha]_D^{20}$ −45.8° (*c* 0.94, $CHCl_3$), 96% ee,[35] in 47% overall yield from **xi** (M. Suzuki, Y. Kimura, and S. Terashima, unpublished results). This asymmetric synthesis of (***R***)-**3** is considered to be less practical than that reported herein because of the complex multi-step operations and the lower overall yield.



a) (i) $CH(OMe)_3$-CSA in MeOH, (ii) (+)-Dimethyl (2*R*,3*R*)-tartrate-CSA-MS3A in C_6H_6. b) Et_4N-H_2O. c) $CH_3CONHBr$(4.0 equiv) in DMF, 0 °C, 45.5 h. d) (i) Et_3N-MeOH, (ii) CH_2N_2. e) (i) K_2CO_3 in MeOH, (ii) H_2-5%Pd/C, (iii) concd HCl.

33) Presence of a small amount of water in the reaction medium was found to be necessary for effecting the successful formation of **9a** and **10a** from **8a**. Considering the fact that the bromolactonization of the bis(triethylamine) salt (**ix**) proceeds in anhyd DMF (see, Ref. 32), the role of

water is considered to promote hydrolysis of the intermediary immonium salt (**xii**) during the bromolactonization.

Dehydrooligopeptides. VII. Convenient Synthesis of Various Dehydrodi- and tripeptide Esters by Using *N*-Carboxy α-Dehydroamino Acid Anhydride[1)]

Chung-gi SHIN,* Yasuchika YONEZAWA, and Masahiro IKEDA
Laboratory of Organic Chemistry, Faculty of Technology, Kanagawa University, Rokkakubashi, Kanagawa-ku, Yokohama 221
(Received May 22, 1986)

The one-pot syntheses of *N*-protected Δ^1- and Δ^2-dehydrodipeptide esters by the coupling of *N*-carboxy α-dehydroamino acid anhydride (ΔNCA) with several kinds of C- or N-protected L-α-amino acids are described. In addition, it was found that a similar coupling of ΔNCA with both C- and N-protected α-amino acids also took place to give Δ^2-dehydrotripeptide derivatives, involving eight kinds of important C-terminal segments of antrimycins and cirratiomycins. The configurational confirmation of the α-dehydroisoleucine residue of the antibiotics is also discussed.

Recently, much attention is being given to the synthesis of dehydrooligopeptides (DHP) from not only pharmacological interests but also regarding its usefulness for asymmetric hydrogenation. Although a number of important results and facts regarding the syntheses and properties of α-dehydroamino acid (DHA) and DHP have been reported by many workers,[2-4)] we also reported a few synthetic methods for DHA and DHP.[5,6)] In particular, the application of *N*-carboxy α-dehydroamino acid anhydride (ΔNCA; **2**), derived from benzyloxycarbonyl (Cbz)-DHA (**1**), to the synthesis of DHP has been briefly reported.[7-10)]

Most recently, some interesting peptide antibiotics, e.g., antrimycins[11-13)] (cirratiomycins)[14)] and lavendomycin,[15,16)] have been discovered and determined structurally. The two kinds of the antibiotics have dehydrohepta- and hexapeptide sequences, containing a dehydrovaline (ΔVal) or a dehydroisoleucine (ΔIle) and a 2-amino-2-butenoic acid (ΔAbu) residue, respectively.

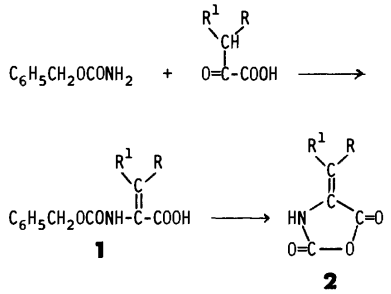
In this paper, we wish to report fully on the synthesis of various kinds of N-protected Δ^1- and Δ^2-dehydrodi- and tripeptide esters,[17)] by a new peptide synthetic method, i.e., the ΔNCA method. Moreover, the synthesis and configuration of all the C-terminal dehydrotripeptide segments of antrimycins are also described.

Results and Discussion

Syntheses of Δ^1- and Δ^2-Dehydrodipeptides. In a preceding paper,[8b)] as is shown in Scheme 1, the synthesis of DHA (**1**) and the corresponding ΔNCA [**2**: **a**; R=R^1=H (ΔAla),[18)] **b**; R=H, R^1=CH$_3$ (ΔAbu), **c**; R=R^1=CH$_3$ (ΔVal), **d**; R=H, R^1=*i*-C$_3$H$_7$ (ΔLeu), **e**; R=H, R^1=C$_6$H$_5$ (ΔPhe)], except for the *N*-carboxy α-dehydroisoleucine anhydride (ΔIle·NCA, **2f**), was reported. Here, according to a previously reported method,[8b,19)] the condensation of 3-methyl-2-oxopentanoic acid with benzyl carbamate was also carried out to give Cbz-α-dehydroisoleucine (**1f**), which was subsequently cyclized to give **2f** in a 90% yield. While the configuration of all the compounds **2** used here except **2f** has a (Z)-geometry, in the case of ΔIle, both the DHA (**1f**) and ΔNCA (**2f**), thus obtained, were found to comprise a mixture of (E)- and (Z)-geometric isomers by ca. a 3:2 ratio. Interestingly, however, it was found that the repeated recrystallization of **2f** from cyclohexane gave only the (E)-isomer.

Generally, by a comparison with the chemical shifts of γ-methylene proton between the (E)- and (Z)-isomers of DHA, the geometry of each isomer could be readily determined. It is well-known that γ-proton of the (E)-isomer of DHA shifts in a lower magnetic field than that of the (Z)-isomer, according to the available criterion reported previously.[20-22)] In the ^{1}H NMR spectrum of **1f** and **2f**, the γ-methylene protons of ethyl groups of (E)-isomer certainly resonate at a lower magnetic field (at δ 2.42 and at δ 2.70) than that of the (Z)-isomer (at δ 2.10 and at δ 2.26): Δδ 0.32 and Δδ 0.44, respectively.

Subsequently, in order to obtain N-protected Δ^1-dehydrodipeptide esters, compounds **2** were subjected to acylation, followed by couplings with L-α-amino acid (AA) esters. After the acylation of **2** with acetyl chloride (Ac-Cl), trifluoroacetic acid anhydride [(Tfa)$_2$O], or di-*t*-butyl carbonate [(Bu^{t}OCO)$_2$O] in the presence of triethylamine or pyridine in tetrahydrofuran (THF) by the usual method, the corresponding *N*-acylated ΔNCA intermediates (**3**, **4**, and **5**), thus



1 **2**

Scheme 1.

formed, were coupled in situ with an appropriate H-L-AA-OMe at room temperature within 1 h to give the desired acyl-Δ^1-(z, L)-dehydrodipeptide-OMe (**6**, **7**, and **8**) in good yields, respectively, as shown in Scheme 2.

On the other hand, to synthesize Δ^2-dehydrodipeptide esters, which seem to be regio-geometric isomers of **6**—**8**, the ΔNCAs (**2**) were similarly acylated with chloride of phthaloyl(Pht)-L-AA-OH and then the resulting Pht-L-AA-ΔNCA intermediates (**9**) yielded were treated in situ with water, methanol, or ethanol to give Pht-Δ^2-dehydrodipeptide-OH (**10**) and their esters (**11**; Me and Et) in ca. 75% yields, respectively. As a result, the acylation of **2** by the acid chloride method was found to be successful. In addition, it was of much interest to explore whether or not the coupling of **2** with N-protected L-AA-OH could proceed using the other peptide synthetic method.

Attempts at conventional coupling of **2** with Boc- or Cbz-L-AA-OH in the presence of dicyclohexylcarbodiimide (DCC) alone have failed. However, fortunately, it was found that a similar reaction readily took place in the presence of pyridine in addition to DCC at pH 5.5—6.0 to form Boc- and Cbz-L-AA-ΔNCA (**9**). The subsequent treatment of the intermediates (**9**) with methanol or ethanol in one-pot gave the expected Boc- and Cbz-Δ^2-(L, z)-dehydrodipeptide-OZ (**12** and **13**; Z=Me and Et) in good yields, respectively, as illustrated in Scheme 3.

The yields, physical constants, the ^{1}H NMR spectral data of all the new dehydrodipeptide derivatives

a) All compounds were analyzed for C, H, and N, and the results were within ±0.3% of theoretical values. b) Colorless needles from chloroform-diisopropyl ether. c) Colorless needles from hexane. d) Measured in DMSO-d_6.

(**6—8** and **10—13**) are summarized in Tables 1—3. In the ^{1}H NMR spectra, no characteristic differences could be observed between the olefin proton signals of the two types of Δ^1- and Δ^2-dehydrodipeptide esters.

From the above results, the possibility of consecutive reactions of **2** with N-protected AA-OH and then H-AA-OZ (Z=Me and Et) instead of alcohols is expected. Furthermore, similar couplings of **2** with appropriate peptides are also anticipated.

Synthesis of Δ^2-Dehydrotripeptides. So far, it has been difficult to synthesize Δ^2-dehydrotripeptide esters, containing a DHA residue in center, by the conventional coupling of Δ^1- or Δ^2-dehydrodipeptide with

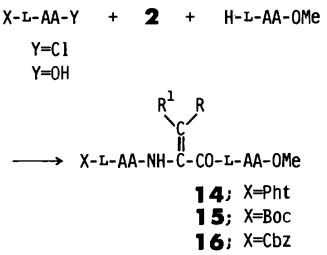
two kinds of C- and N-protected L-α-amino acids, respectively. Accordingly, the ⊿NCA method mentioned above was expected to facilitate the coupling of **2** with the above two kinds of α-amino acids in one-pot. At first the acylation of an equimolar **2** with chloride of Pht-L-AA-OH in the presence of triethylamine in THF at 5—10 °C for 1 h was performed, followed by a treatment with H-L-AA-OMe at room temperature for 1.5 h. As a result, it is interesting to note that the above successive reactions were also completely accomplished in only one-pot to give Pht-⊿²-(L, Z, L)-dehydrotripeptide-OMe (**14**) in good yields.

Furthermore, instead of the acid chloride method, the usual DCC method was also utilized for the synthesis of ⊿²-dehydrotripeptides using **2**. A similar coupling of **2** with Boc- or Cbz-L-AA-OH in the presence of DCC and pyridine in THF or CH_2Cl_2 and then with H-L-AA-OMe gave the expected Boc- and Cbz-⊿²-(L, Z, L)-dehydrotripeptide-OMe (**15** and **16**) via Boc- and Cbz-L-AA-⊿NCA as intermediates in good yields, respectively, as illustrated in Scheme 4. On the other hand, on the contrary, after treating **2** with an amino acid ester in THF, the subsequent treatment of the resulting solution with a N-protected amino acid was found not to be effective. In addition, the simultaneous treatment of **2** with two kinds of C- and N-protected amino acids was also unsuccessful.



Scheme 4.

From the above versatile information, the ⊿NCA method can be firmly believed to be promising for the synthesis of antrimycins as well as the C-terminal ⊿²-dehydrotripeptide moieties. The dehydrotripeptide sequences were composed of L-AA [Ala, Abu, nVal (normal valine), and Leu], DHA (⊿Val and ⊿Ile), and Ser residues in turn, which were variously combined to afford eight kinds of antrimycins. The syntheses of all the partial skeletons have already been briefly reported.[10] However, since the yields were comparatively low, here, the procedures were modified. Consequently, similar reactions of **2c** or **2f** with the four kinds of Boc-L-AA-OH listed above for 12 h (then in situ with H-L-Ser-OMe) were carried out to give the expected Boc-⊿²-dehydrotri-

a) All compounds were analyzed for C, H, and N, and the results were within ±0.3% of theoretical values. b) Colorless needles from chloroform–hexane. c) Measured in methanol.

peptide-OMe (**15**). The yields reached to ca. 65% within 1 h. As a result, in the case of **2f**, even if a pure (E)-isomer was used, it was found that geometric isomerization took place during stepwise couplings to give a 3:2 mixture of the (Z)- and (E)-isomers of **15**.

The yields, physical constants, and the ^{1}H NMR spectral data of **14—16**, involving C-terminal dehydrotripeptides of antrimycins, are summarized in Tables 4—6. From the ^{1}H NMR spectra of the (E)-isomers of **15**, the chemical shifts of CH_3 (δ 1.75s) and $CH_3C\underline{H}_2$ (δ 2.42q) in ΔIle residue and of two CH_3 (δ 1.75s and 2.05s) in ΔVal residue were found to be very similar to those (δ 1.78s, 2.46q, 1.81s, and 2.10s, respectively) of antrimycins.[13] Consequently, the naturally occurring products could be unambiguously determined to have (E)-isomeric structures.

In conclusion, it is worth noting that not only the synthesis of all the C-terminal Δ^2-dehydrotripeptides of antrimycins in one pot but also the configuration of the DHA residues could be readily confirmed.

Experimental

General. Melting points were determined with a Yamato (Model Mp-21) micro melting-point apparatus, and were not corrected. IR spectra were recorded with a Hitachi EPI-G2 grating spectrometer. ^{1}H NMR spectra were measured with a JEOL JMN PS-100 spectrometer in a $CDCl_3$ solution with tetramethylsilane as the internal standard. The specific rotations were measured in a 0.5-dm tube using a JASCO DIP-4 polarimeter (Japan Spectroscopic Co., Ltd.).

Cbz-Dehydroisoleusine (1f). A solution of 3-methyl-2-oxopentanoic acid (0.50 mol) and benzyl carbamate (0.55 mol) in the presence of *p*-toluenesulfonic acid (0.10 mmol) in dry benzene (800 ml) was refluxed for 6 h, removing water by means of water-separator. The reaction solution was extracted three times with a saturated $NaHCO_3$ aqueous solution; then, the combined aqueous extracts were acidified to pH 1—2 with concentrated HCl. The deposited crystals were collected and then recrystallized from benzene to give Cbz-ΔIle-OH (**1f**) as colorless needles. Yield 60% as a mixture of (E)- and (Z)-isomers by 3:2 ratio, mp 141—142 °C. IR (KBr): 3280 (NH), 1700, 1520 (NHCO) cm^{-1}. ^{1}H NMR (DMSO-d_6): δ=1.76 (s, 3H, CH_3-), 2.04 (s, 3H, CH_3-), 2.10 (q, 2H, J=7.0 Hz, $CH_3C\underline{H}_2$-), 2.42 (q, 2H, J=7.0 Hz, $CH_3C\underline{H}_2$-), 8.56 (bs, 1H, -NH-). Found: C, 68.02; H, 6.90; N, 5.61%. Calcd for $C_{14}H_{17}NO_3$: C, 67.99; H, 6.93; N, 5.66%.

***N*-Carboxy-α-dehydroisoleusine Anhydride (2f).** A solution of **1f** (20 mmol) in acetyl chloride (3 ml) and thionyl chloride (9 ml) was stirred at room temperature for 2 h. After removal of the solvent under reduced pressure, dry carbon tetrachloride (30 ml) was added to the crystalline residue and then the resulting solution was concentrated. This procedure was repeated three times. The residual crystals were recrystallized from cyclohexane to give ΔIle·NCA (**2f**) as colorless needles. Yield 90% as a mixture of (E)- and (Z)-isomers by 3:2 ratio, mp 69—101 °C. The mixture was recrystallized repeatedly to give only (E)-isomer, which melting point was 122—123 °C. IR (KBr): 3200 (NH), 1820, 1780 (-O-C=O) cm^{-1}. ^{1}H NMR (DMSO-d_6): (E)-isomer; δ=1.96 (s, 3H, CH_3-), 2.70 (q, 2H, J=7.0 Hz, $CH_3C\underline{H}_2$-). 9.44 (s, 1H, -NH-). (Z)-isomer; δ= 2.24 (s, 3H, CH_3-), 2.26 (q, 2H, J=7.0 Hz, $CH_3C\underline{H}_2$-), 9.44 (s, 1H, -NH-). Found: C, 54.21; H, 5.88; N, 9.07%. Calcd for $C_7H_9NO_3$: C, 54.19; H, 5.85; N, 9.03%.

Ac-Δ^1-Dehydrodipeptide Methyl Esters (6). To a solution of an appropriate **2** (10 mmol) in THF (5 ml) was added acetyl chloride (12 mmol). The resulting solution was approximately neutralized under cooling by adding triethylamine and then stirred at room temperature for 1 h. After concentrating the solution, the residue, thus obtained, was suspended in THF (5 ml) and then with a solution of an appropriate L-α-amino acid ester (12 mmol) in THF (5 ml). with stirring, at room temperature for 1 h. The solvent was removed and the obtained residue was dissolved in chloroform (50 ml); the resulting solution was successively washed twice with 1 M HCl (1 M=1 mol dm^{-1}) and water and then dried over anhydrous Na_2SO_4. After removing the chloroform, the residual crystals or syrup was purified by recrystallization from a mixture of chloroform–diisopropyl ether or hexane and by chromatography on a silica-gel column using a mixture of chloroform and acetone (20:1 v/v) as the eluent. See Table 1.

Tfa-Δ^1-Dehydrodipeptide Methyl Esters (7). To a solution of **2** (10 mmol) in CH_2Cl_2 (5 ml) trifluoroacetic acid anhydride (12 mmol) was added dropwise at 0 °C and the resulting prepared solution was made acidic to pH 5—6 by adding pyridine. After stirring at room temperature for 5 h, an appropriate L-α-amino acid methyl ester (11 mmol) was added to the resultant solution. After stirring continuously for 1 h, CH_2Cl_2 (50 ml) was further added to the reaction solution and then solution, thus prepared, was successively washed twice with 1 M HCl and water and then dried over anhydrous Na_2SO_4. The removal of the solvent gave a residual syrup, which was purified on a silica-gel column using a mixture of benzene and ethyl acetate (20:1 v/v) as the eluent to give **7** as a viscous syrup or as colorless needles from hexane. See Table 1.

Boc-Δ^1-Dehydrodipeptide Methyl Esters (8). To a solution of **2** (10 mmol) in THF (5 ml) was added $(Bu^tOCO)_2O$ (12 mmol) and a few drops of pyridine; the resulting solution was stirred at room temperature for 6 h. A solution of an appropriate L-α-amino acid methyl ester (11 mmol) in THF (5 ml) was added to the solution prepared above, which was then stirred continuously for 1 h. After removing the solvent, the residual syrup was dissolved in ethyl acetate (100 ml) and the resulting solution was successively washed twice with 10% citric acid, a saturated NaCl aqueous solution, and water and then dried over anhydrous $MgSO_4$. The concentration of the solution gave a viscous syrup, which was purified on a silica-gel column using a mixture of benzene and ethyl acetate (5; 1 v/v) as the eluent to give **8** as a colorless viscous syrup or as colorless needles from a mixture of chloroform and diisopropyl ether. See Table 2.

Pht-Δ^2-Dehydrodipeptides (10 and 11). To a solution of **2** (10 mmol) and chloride of phthaloyl-L-α-amino acid (11 mmol) in THF (5 ml) was added dropwise triethylamine until reaching pH 6 under cooling. After stirring at room temperature for 1 h, the resulting solution was treated with methanol or ethanol (10 ml) and then made basic to pH 8—9 by adding triethylamine. After further stirring for 1 h and then removing the solvent under reduced pressure, the residual syrup was dissolved in ethyl acetate (100 ml). The resultant solution was washed twice, successively, with 1 M HCl and water and then dried over anhydrous Na_2SO_4. The concentration of the solution gave a crude syrup which was then purified on a silica-gel column using a mixture of benzene and ethyl acetate (10:1 v/v) as the eluent to give **10** as a colorless viscous syrup or needles.

In a similar manner, a treatment of **2** with Pht-L-AA-Cl in water instead of alcohol was worked up to give **11** as colorless needles. See Table 3.

Cbz- and Boc-Δ^2-Dehydrodipeptide Esters (12 and 13). To a solution of Cbz-L-α-amino acid (11 mmol) and **2** (10 mmol) in THF (5 ml) was added DCC (11 mmol) portionwise at −10 °C. After stirring for 20 min, the resulting solution was made acidic to pH 6 by adding pyridine and then stirred at 0 °C for 1 h. After cooling to stand at room temperature, the stirring was continued for 12 h.

The prepared solution was treated with alcohol (10 ml) and then made basic to pH 9 by adding *N*-methylmorpholine and stirred continuously for 1 h. After removing the solvent under reduced pressure, the residue, thus obtained, was dissolved in ethyl acetate (50 ml) and the resultant solution was allowed to stand under cooling for 1 h. The deposited *N,N'*-dicyclohexylurea was filtered off and the filtrate was further diluted in ethyl acetate (50 ml) and then successively washed twice with 10% citric acid and water and finally dried over anhydrous Na_2SO_4. The evaporation of the solvent gave a syrup or crystalline substance, which was purified on a silica-gel column using a mixture of chloroform and acetone (20:1 v/v) as the eluent to give **12** as a colorless viscous syrup or needles.

In a similar manner, the treatment of **2** with Boc-L-α-amino acid in alcohol was worked up to give **13** as a colorless viscous syrup or needles. See Table 3.

Pht-Δ^2-Dehydrotripeptide Methyl Esters (14). To a solution of **2** (10 mmol) and Pht-L-α-AA-Cl (11 mmol) in THF (5 ml) was added dropwise triethylamine under cooling. When the pH of the solution became to 6, the resulting solution was stirred at room temperature for 1 h and was then treated with an appropriate L-α-amino acid methyl ester (11 mmol) and finally made basic to pH 8—9 by adding triethylamine. After stirring for an additional 1 h and removing the solvent, the residual crystalline substance was dissolved in ethyl acetate (100 ml). The solution, thus obtained, was successively washed twice with 1 M HCl and water and then dried over anhydrous Na_2SO_4. The evaporation of the solvent gave crude crystalline materials, which were purified on a silica-gel column using a mixture of benzene and ethyl acetate (10:1 v/v) as the eluent to give **14** as colorless needles. See Table 4.

Boc- and Cbz-Δ^2-Dehydrotripeptide Methyl Esters (15 and 16). To a solution of Boc-L-α-amino acid (11 mmol) and **2** (10 mmol) in CH_2Cl_2 (5 ml) was added portionwise DCC (11 mmol) at −10 °C. After stirring for 20 min, the resultant solution was made slightly acidic to pH 6 by adding pyridine and then stirring below 0 °C for 1 h. The prepared solution was continuously stirred at room temperature for 12 h and treated with L-α-amino acid methyl ester (11 mmol) and then made basic to pH 9 by adding *N*-methylmorpholine, with stirring for 1 h. After removing the solvent under reduced pressure, the residue, thus obtained, was dissolved in ethyl acetate (50 ml) and the solution was allowed to stand under cooling for 1 h. Deposited *N,N'*-dicyclohexylurea was filtered off and the filtrate was further diluted in ethyl acetate (50 ml) and then successively washed twice with 10% citric acid and water and finally dried over anhydrous Na_2SO_4. The concentration of the solution gave a crystalline product, which was purified on a silica-gel column using a mixture of chloroform and acetone (20:1 v/v) as the eluent to give **15** as a colorless viscous syrup or needles. See Table 5.

In a similar manner, a treatment of **2** with Cbz-Gly-OH and H-L-Ser-OMe was worked up to give **16** as a colorless syrup.

In addition, a similar treatment of **2** with Boc-L-AA-OH and H-L-Ser-OMe gave C-terminal dehydrotripeptide sequences of antrimycins (**15**). See Table 6.

Syntheses of New Optically Active Organosilanes and Their Applications for the Optical-Purity-Determining Agents

Daiyo TERUNUMA,* Masato KATO, Masanao KAMEI, Hidekatsu UCHIDA, Satoshi UENO, and Hiroyuki NOHIRA
Department of Applied Chemistry, Faculty of Engineering, Saitama University, Urawa, Saitama 338
(Received May 23, 1986)

New optically active organosilicon compounds such as (benzylmethylphenylsilyl)acetic acid (**1**) and (ethylmethylphenylsilyl)acetic acid (**2**) were synthesized. Application of these acids as the optical purity determining agents for chiral amines and alcohols were successfully carried out. In addition, it was also revealed that optically active (benzylmethylphenylsilyl)methylamine (**3**) and [benzylmethyl(*o*-tolyl)silyl]methylamine (**4**) are able to be used as the optical purity determining agents for chiral carboxylic acids.

It is well-known that the method of optical purity determination of chiral organic compounds by using NMR spectrometer is one of the most convienient methods. A variety of agents for this purpose have been proposed.[1] One of the most useful agents is α-methoxy-α-trifluoromethylphenylacetic acid, Mosher agent.[2] These agents, however, do not always have a suitable group which shows a par of diastereomeric peaks in its ^{1}H NMR spectrum. In that case, the possibility for determining the optical purity has to depend on the structure of the chiral substrate to be estimated.

On the other hand, in the course of our studies on the syntheses of new optically active carbon-functional organosilanes, it was found that some of them were suitable for the enantiomer-ratio-determining agents.[3]

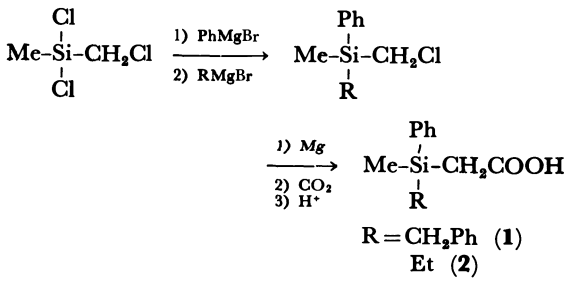
The advantages of these carbon-functional optically active organosilanes as optical-purity-determining agents over the agents which have been developed for this purpose are;

a) One of the most convienient analytical instruments, ^{1}H NMR spectrometer, can be used.

b) The Si-Me signal in the ^{1}H NMR spectra appears in the region of δ 0.1—0.4, where any other signal of ordinary organic compounds rarely appears.

c) The shape of the Si-Me signal is always observed as a sharp singlet.

d) These carbon-functional organosilicon compounds never reacemize during leading them to a pair of diastereomers.



Scheme 1.

Results and Discussion

Synthesis and Resolution. Racemic silylacetic acid derivatives **1** and **2** were obtained by the three steps of Grignard reactions starting from dichloro(chloromethyl)methylsilane in a good yield (Scheme 1).

Resolution of **1** was carried out by the fractional crystallization using 1-phenylethylamine(PEA) as a resolving agent (Fig. 1). Optically pure (+)-**1** was obtained by four times recrystallization of the diastereomer salt of **1** with (+)-PEA from appropriate ratio of benzene-hexane mixed solvent. Then (−)-rich **1** salt was recovered from the filtrates, and the acid was liberated. The acid recovered was treated with (−)-PEA and the diastereomer salt was recrystallized from

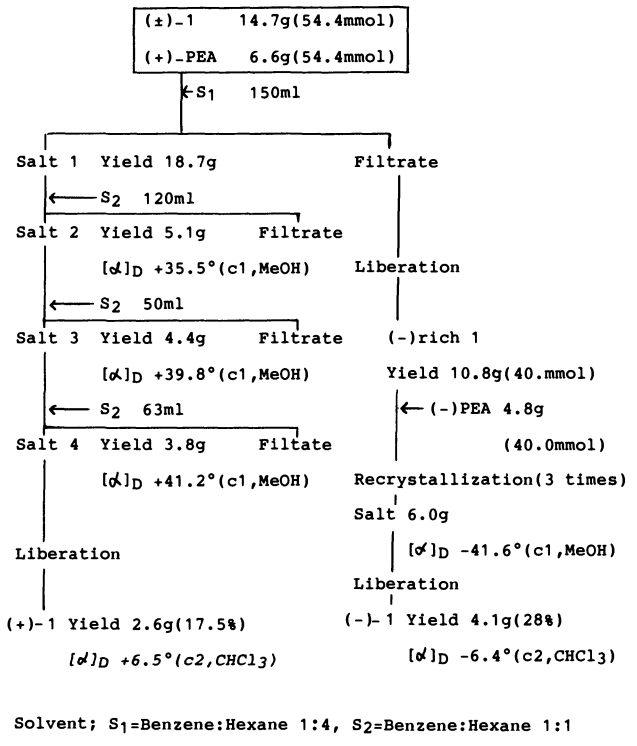


Fig. 1. Optical resolution of **1** using (+)- or (−)-PEA as a resolving agent.

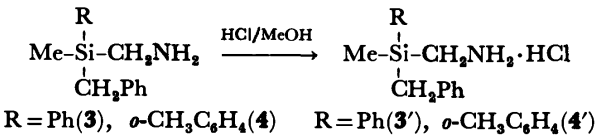
the same solvent descrived above.

Optically active (+)- and (−)-**2** were obtained by using optically active PEA as a resolving agent in a similar manner to that descrived above. It is noted that optically pure **1** can be obtained rather easier than **2**.

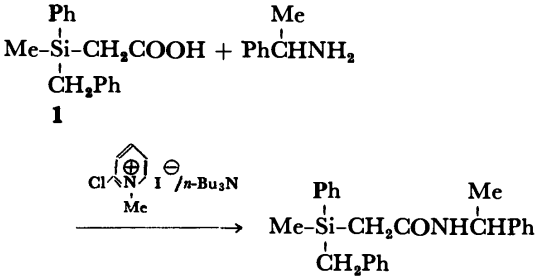
Optically active silylmethylamine derivatives **3** and **4** were obtained by a modified method descrived in the previous paper.[4] Then these optically active amines were converted into salts with hydrochloric acid in order to make them easier to be dealt with (Scheme 2).

The physical properties of optically active **1**, **2**, **3′**, and **4′** are listed in Table 1.

Application of the Enantiomer-Ratio-Determining Agent for a Amine. Optically pure (+)-**1** was treated with (±)- and (−)-PEA in the presence of a condensation agent, 2-chloro-1-methyl-pyridinium iodide,[5] to give the corresponding diastereomeric amides (Scheme 3).



Scheme 2.



Scheme 3.

Proton NMR spectrum of the amide of (+)-**1** with racemic PEA shows two equivalent Si-Me peaks at δ 0.30 and 0.34, but that of with (−)-PEA shows only one peak at δ 0.34 (Fig. 2). These data suggest that optically active **1** is able to be used as an optical-purity-determining agent for the chiral amine. In the diastereomeric amide method, one of the most important points is that the two NMR peaks of an amide derived from racemic amine may not appear in equal intensity, mainly due to the difference in the diastereomeric selectivity of the reaction between the optically active determining agent and the chiral amine. If it happens, the NMR peaks of the diaster-

eomeric amide never reflect the correct enantiomer compositions of the chiral amine. In order to check this point, appropriate grade samples of optically active PEA were prepared, and the values of optical purity measured by a Polarimeter were compared with those calculated from the NMR method (Fig. 3). These results indicate that the correlation between both methods is fairly good. Although the balance of the diastereotopic Si-Me chemical shifts($\Delta\delta$ 0.04) is rater small, it is clear that the estimation of the optical purity of the amine can be done in a significant accuracy based on the unique characters of Si-Me peak: the peak appears in a paticular region and the shape is always sharp singlet, in the NMR spectra.

Then the diastereomeric amides of (+)-**1** with a number of racemic and optically active amines were prepared, and the chemical shifts of Si-Me of the diastereomeric amides were investigated. These results are summarized in Table 2.

In a similar manner, Si-Me chemical shifts of the diastereomeric amides of (+)-**2** with a number of

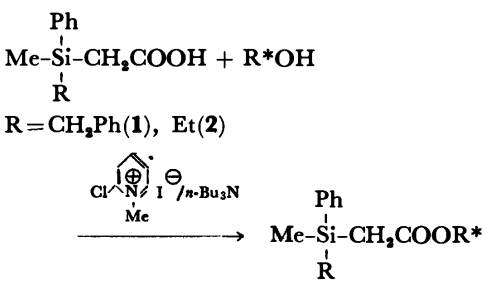
a) The balance of the chemical shifts of the diasteromeric amides of the same and the opposite sign of rotation. b) The data used only racemic amines. c) The separation of the Si-Me peaks was observed after the addition of a little amount of $Eu(fod)_3$. d) The separation of the Si-Me peaks was not observed.

chiral amines were investigated. These results are also summarized in Table 2.

As listed in Table 2, it is clear that most of the pairs of diastereomeric amides of (+)-**1** and (+)-**2** with chiral amines have different chemical shifts. These results suggest that these silylacetic acid derivatives are useful as optical-purity-determining agents for these chiral amines, except for *s*-butylamine.

If the separation of the Si-Me chemical shifts is not observed, addition of a little amount of shift agent, i. e. $Eu(fod)_3$, is often effective, although somewhat broadening of the Si-Me peak result.



Scheme 4.

The values of the separation degree ($\Delta\delta$) were calculated from differences in the chemical shifts of the diastereomeric amides obtained from (+)-**1** and (+)-amines, and those of the amides obtained from (+)-**1** and (−)-amines. It seems that the signs of the separation degree have a definite tendency dependent on the structures of (+)-**1** or (+)-**2** and chiral amines. It is of interest to investigate the correlations between the absolute configurations of the amines and the signs of the separation degrees, although we do not have enough data yet.

The diastereomeric esters of chiral alcohols with (+)-**1** and (+)-**2** were prepared (Scheme 4).

Although the differences in the chemical shifts of the Si-Me of these esters are rather smaller than those of diasteromeric amides, determination of optical purity of these chiral alcohols seems to be possible (Table 3). Actually the optical purity of 2-(2-chlorophenyl)-3-methyl-1-butanol, a new optically active alcohol, was successfully estimated by using (+)-**1**.[6]

Another silylacetic acid derivatives as shown in

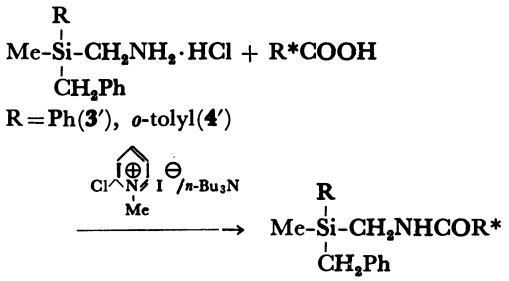
a) The balance of the chemical shifts of the diastereomeric amides.

Table 4, were synthesized. The Si-Me chemical shifts of the diastereomeric amides of these acids with racemic PEA were investigated. The chemical shifts differences of some of these amides reveal rather larger than those of **1** and **2**, but, unfortunately, we have not found out the adequate resolving agent for these acids. The investigation of optical resolution of these acids are in progress.

Application of the Enantiomer-Ratio-Determining Agent for a Carboxylic Acid. The diasteromeric amides of **3'** and **4'** with a number of chiral caboxylic acids were prepared in a similar manner to that described above (Scheme 5).

The chemical shifts of Si-Me of these diastereomeric amides were also measured (Table 5). The most of the Si-Me chemical shifts of the two pairs of diastereomeric amides were separated. It is clear that both **3** and **4** have high potentials enough to estimate the enantiomer ratio of a number of chiral carboxylic acids.



Scheme 5.

Experimental

The melting points and boiling points are uncorrected. The IR spectra were determined with JASCO IR-A 302 spectrometer. The NMR spectra were determined at 60MHz and 90MHz with a JEOL 60Si and FX90Q spectrometer, in $CDCl_3$ using TMS as an internal standard. The optical rotations were measured with a JASCO DIP-360 polarimeter. All the reactions of the Grignard reagents and the preparations of amides and esters were carried out under dry nitrogen atmosphere. All optically active amines and carboxylic acids were prepared by the procedures described in the literatures.[7]

(Benzylmethylphenylsilyl)acetic Acid (1). In a two-necked flask, equipped with a reflux condenser and an additional funnel, magnesium (3.3 g, 0.14 mol) and dry tetrahydrofuran(THF)(90 ml) were placed. A solution of (benzylmethylphenylsilyl)methyl chloride[3] (30.0 g, 0.12 mol) in THF (20 ml) was added to the solution slowly. An exothermic reaction took place. The reaction mixture was refluxed for 3 h after the addition was completed. The reaction mixture was poured into a excess amount of Dry Ice, and then the mixture was allowed to stand at room temperature until the chips of the Dry Ice disappeared. To the mixture, dil. HCl was added and the organic layer was separated from the aqueous solution. The aqueous layer was extracted with ether (30 ml×2). The combined organic and ether layer was washed with water, and then extracted with 10% aq K_2CO_3 (50 ml×3). The alkaline layer was

Table 5. Chemical Shifts of Si-Me of Diastereomeric Amides of (+)-**3** and (+)-**4** with Chiral Carboxylic Acids

b) The separation of the Si-Me peaks was observed after the addition of a little amount of $Eu(fod)_3$.

washed with ether (50 ml), and 3 M†† HCl was added to the solution until the solution changes to acidic. The resulted carboxylic acid was extracted with ether (50 ml×3). The combined extracts was dried over Na_2SO_4, and subsequent evaporation gave **1** in 26.3 g (80%) yield. Mp 36—38 °C. IR (neat) 2900 cm^{-1} (s, COOH), 1680 cm^{-1}. ^1H NMR δ=0.38 (s, 3, Si-CH_3), 2.12 (s, 2, -CH_2C=O), 2.43 (s, 2, -CH_2Ph), 6.7—7.6 (m, 10, Ph), 9.0 (s, 1, COOH). Found: C, 71.33; H, 6.81%. Calcd for $C_{16}H_{18}O_2Si$: C, 71.07; H, 6.71%.

(Ethylmethylphenylsilyl)acetic Acid (2). The phenylmagnesium bromide and the ethylmagnesium bromide were prepared from magnesium (3.3 g, 0.14 mol) and bromobenzene(19.2 g, 0.12 mol) in dry ether (50 ml), and from magnesium (3.3 g, 0.14mol) and bromoethane (13.3 g, 0.12 mol) in dry ether (50 ml), respectively. The phenyl Grinard reagent was added to a solution of (dichloromethylsilyl)methyl chloride[3] (20.0 g, 0.12 mol) in dry ether (30 ml). The mixture was refluxed for 4 h with stirring. Then, the ethyl Grinard reagent was added to the reaction mixture, and it was refluxed for 4 h with stirring. Saturated NH_4Cl was added to the reaction mixture with external cooling. The organic layer was separated and the aqueous layer was extracted with ether (30 ml×2). The combined organic layer was dried (Na_2SO_4). Subsequent evaporation and distillation gave (ethylmethylphenylsilyl)methyl chloride in 17.8 g (73%) yield. Bp 130—135 °C/20 Torr (1 Torr =133.322 Pa). ^1H NMR δ=0.37 (s, 3, Si-CH_3), 1.0—1.2 (m, 5, Et), 2.86 (s, 2, CH_2Cl), 7.1—7.6 (m, 5, Ph).

In a two-necked flask, equipped with a condeser and an additional funnel, magnesium (3.1 g, 0.13 mol) and THF (35 ml) was placed. A solution of (ethylmethylphenylsilyl) methyl chloride (17.0 g, 0.89 mol) in THF (35 ml) was added to the flask. An exothermic reaction took place. After the addition was completed, the reaction mixture was refluxed for 4 h with stirring. The reaction mixture was allowed to stand at room temperature until the chips of Dry Ice disappeared. Workup of the reaction mixture in the similar manner descrived above, and subsequent distillation gave **2** in 12.3 g (69%) yield. Bp 154—157°C/0.9 Torr. IR (neat) 2990 cm^{-1} (s, COOH), 1680 cm^{-1} (s, C=O). ^1H NMR δ=0.41 (s, 3, Si-CH_3), 0.94—1.0 (m, 5, Et), 2.15 (s, 2, CH_2C=O), 7.2—7.5 (m, 5, Ph), 9.6 (broad s, 1, COOH). Found: C, 63.42; H, 7.74%. Calcd for $C_{11}H_{16}O_2Si$: C, 63.30, H, 7.60%.

Another Silylacetic Acid Derivatives. All silylacetic acid derivatives listed in Table 4 were prepared in the similar manner described above. The yield and boiling points of the (alkylarylmethylsilyl)methyl chlorides are as follows; Compound; Yield(%), BP(°C/Torr): MePh(*n*-Pr)$SiCH_2Cl$; 73, 145—150/20: *n*-BuMePhSiCH_2Cl; 82, 130/13: BzEtMeSiCH_2-Cl; 89, 117—119/5: BzMe(*n*-Pr)$SiCH_2Cl$; 87, 95/3: EtMe(*o*-$CH_3C_6H_4$)$SiCH_2Cl$; 72, 108/3: Me(*n*-Pr)(*o*-$CH_3C_6H_4$)$SiCH_2Cl$; 84, 106/2: EtMe(*p*-$CH_3C_6H_4$)$SiCH_2Cl$; 76, 95/3: EtMe(*o*-$CH_3OC_6H_4$)$SiCH_2Cl$; 70, 110/1: AllylMe(*o*-$CH_3C_6H_4$)$SiCH_2Cl$; 76, 120/4: Et(1-Np)MeSiCH_2Cl; 73, 140/3.

The yield and NMR spectra data of the silylacetic acid derivatives are as follows; Compound; Yield(%), Bp(°C/Torr): MePh(*n*-Pr)$SiCH_2COOH$; 51, -, ^1H NMR δ=0.40 (s, 3, Si-CH_3), 0.8—1.3 (m, 7, Pr), 2.15 (s, 2, CH_2), 7.0—7.5 (m, 5, Ph), 12.0 (broad s, 1, COOH): *n*-BuMePhSiCH_2COOH; 18, -, ^1H NMR δ=0.40 (s, 3, Si-CH_3), 0.7—1.5 (m, 9, Bu), 2.10 (s, 2, CH_2), 7.0—7.5 (m, 5, Ph), 11.0 (broad s, 1, COOH): BzEtMeSiCH_2COOH; 75, -, ^1H NMR δ=0.06 (s, 3, Si-CH_3), 0.6—1.4 (m, 5, Et), 1.80 (s, 2, CH_2C=O), 2.16 (s, 2, CH_2Ph), 6.7—7.3 (m, 5, Ph), 12.0 (broad s, 1, COOH): BzMe(*n*-Pr)$SiCH_2COOH$; 65, -, ^1H NMR δ=0.06 (s, 3, Si-CH_3), 0.5—1.7 (m, 7, Pr), 1.80 (s, 2, CH_2C=O), 2.16 (s, 2, CH_2Ph), 6.8—7.3 (m, 5, Ph), 11.5 (broad s, 1, COOH): EtMe(*o*-$CH_3C_6H_4$)-$SiCH_2COOH$; 71, 170/0.6, ^1H NMR δ=0.45 (s, 3, Si-CH_3), 0.99 (s, 5, Et), 2.15 (s, 2, CH_2), 2.45 (s, 3, CH_3), 6.9—7.5 (m, 4, Ar), 12.5 (broad s, 1, COOH); Me(*n*-Pr)(*o*-$CH_3C_6H_4$)-$SiCH_2COOH$; 38, -, ^1H NMR δ=0.45 (s, 3, Si-CH_3), 0.8—1.6 (m, 7, Pr), 2.10 (s, 2, CH_2), 2.45 (s, 3, CH_3), 6.9—7.5 (m, 4, Ar), 11.5 (broad s, 1, COOH): EtMe (*p*-$CH_3C_6H_4$)-$SiCH_2COOH$; 49, 155/0.3, ^1H NMR δ=0.40 (s, 3, Si-CH_3), 0.9—1.1 (m, 5, Et), 2.05 (s, 2, CH_2), 2.35 (s, 3, CH_3), 6.9—7.5 (m, 4, Ar), 11.5 (broad s, 1, COOH): (*o*-$CH_3OC_6H_4$)-EtMe$SiCH_2COOH$; 53, -, ^1H NMR δ=0.36 (s, 3, Si-CH_3), 0.95 (s, 5, Et), 2.10 (s, 2, CH_2), 3.75 (s, 3, O-CH_3), 6.5—7.5 (m, 4, Ar), 11.5 (broad s, 1, COOH): Allyl (*o*-$CH_3OC_6H_4$)-$MeSiCH_2COOH$; 19, -, ^1H NMR δ=0.35 (s, 3, Si-CH_3), 1.90 (d, 2, CH_2), 2.05 (s, 2, CH_2C=O), 3.74 (s, 3, O-CH_3), 4.6—5.0 (m, 2, =CH_2), 5.2—6.2 (m, 1, CH=), 6.5—7.5 (m, 4, Ar), 10.5 (broad s, 1, COOH): EtMe(1-Np)$SiCH_2COOH$; 44, -, ^1H NMR δ=0.59 (s, 3, Si-CH_3), 1.0—1.2 (m, 5, Et), 2.85 (s, 2, CH_2), 7.2—8.0 (m, 7, Ar), 11.5 (broad s, 1, COOH).

Optical Resolution of 1. A solution of (+)-PEA (6.6 g, 54.4 mmol) in a mixed solvent (benzene:hexane 1:4, 50 ml) was added to a solution of (±)-**1**(14.7 g, 54.4 mmol) in the same mixed solvent (100 ml). The solution was allowed to stand over night at room temperature. The salt precipitated was collected by filtration (Salt **1**, yield 18.7 g). The salt **1** was recrystallized from a mixed solvent(benzene-hexane 1:1, 120 ml)(Salt **2**, yield 5.1 g). Further twice recrystallizations were carried out by using the same solvent (Salt **3**, yield 4.4 g) (Salt **4**, yield 3.8 g, $[\alpha]_D$ +41.2° (*c* 1, MeOH)). (+)-**1** was liberated from (+)-PEA and extracted with ether (30 ml×2). The ether solution was dried over Na_2SO_4. Evaporation gave optically pure (+)-**1** in 2.6 g (17.5%) yield. Mp 68—69.5 °C. $[\alpha]_D$ +6.5°(*c* 2, $CHCl_3$).

The first and second filtrates were collected and (−)-rich **1**, was liberated from the solution. (−)-Rich **1** was treated with an equimolar amount of (−)-PEA, and subsequent four times fractional crystallization were carried out. Optically pure salt was obtained in 6.0 g (28%) yield. $[\alpha]_D$ −41.6° (*c* 1, MeOH). Subsequent liberation of the acid, extraction, and evaporation gave optically pure (−)-**1** in 4.1 g (28%) yield. Mp 69—70.5 °C. $[\alpha]_D$ −6.4° (*c* 2, $CHCl_3$).

Optical Resolution of 2. A solution of (+)-PEA in a mixed solvent (benzene-hexane 1:4, 50 ml) was added to a solution of (±)-**2** in the same solvent (100 ml). The solution was allowed to stand over night at room temperature. The precipitated crystalls were collected by filtration. Yield 20.1 g (72%). $[\alpha]_D$ +4.9° (*c* 1, MeOH). The crystalline solid was recrystallized from a mixed solvent (benzene-hexane 1:1). Yield 13.6 g (68%). $[\alpha]_D$ +6.2° (*c* 1, MeOH). It was recrysallized from the same mixed solvent (136 ml). Yield 9.1 g (71%). $[\alpha]_D$ +7.0° (*c* 1, MeOH). It was further recrystallized from the same solvent (180 ml). Yield 7.5 g (55%). $[\alpha]_D$ +7.9° (*c* 1, MeOH). Then, it was recrystallized from benzene (75 ml). Yield 5.8 g (77%). $[\alpha]_D$ +8.0° (*c* 1, MeOH). The salt was recrystallized from benzene (86 ml)

†† 1 M=1 mol dm^{-3}.

again. Yield 4.3 g (75%). $[\alpha]_D$ +8.0° (*c* 1, MeOH). Liberation and subsequent usual work-up gave (+)-**2** in 2.7 g (14%) yield. $[\alpha]_D$ +7.9° (*c* 1, MeOH). Optical purity of this (+)-**2** was estimated as 99% by NMR method using optically pure (+)-PEA.

The enantiomer of **2**, which has oppsite sign of rotation, was recovered from the filtrates. Optically pure (−)-**2** was obtained in a similar manner described above, by several times fractional crystallization of its (−)-PEA salt from appropriate solvents.

Optically Active (Benzylmethylphenylsilyl)methylamine Hydrochloride Salt (3'). To a solution of optically active (+)-**3** (1.0 g, 4.1 mmol), $[\alpha]_D$ +12.6° (*c* 1, Et_2O) in MeOH (5 ml), 3 M HCl (5 ml) was added. The mixture was evaporated and the residue was recrystallized from a mixed solvent (benzene–hexane 2:1, 90 ml). White crystalline salt was obtained in 1.2 g (99%) yield. Mp 166.5—167 °C. $[\alpha]_D$ +45.0° (*c* 1, MeOH). ^{1}H NMR δ=0.50 (s, 3, Si-CH_3), 2.57 (m, 4, $SiCH_2N$, $SiCH_2Ph$), 7.0—7.5 (m, 10, Ph), 9.0 (broad s, 3, NH_3).

Optically Active (Benzylmethyl-*o*-tolylsilyl)methylamine Hydrochloride Salt(4'). To a solution of (+)-**4** (1.0 g, 3.9 mmol), $[\alpha]_D$ +4.3° (*c* 4, Et_2O) in MeOH (5 ml), 3 M HCl (5 ml) was added. The solvent was evaporated and the residue was recrystallized from benzene (50 ml). The salt of (+)-**4** was obtained in 1.0 g (89%) yield. Mp 186.5—187 °C. $[\alpha]_D$ +35.2° (*c*1, MeOH). ^{1}H NMR δ=0.55 (s, 3, Si-CH_3), 2.36 (s, 3, Ph-CH_3), 2.47—2.65 (m, 4, CH_2-N, CH_2ph), 7.0–8.0 (m, 9, Ar), 8.2 (broad s, 3, NH_3).

Preparation of the Diastereomeric Amide of (+)-1 with (±)-PEA. In a flask, equipped with a condenser, a solution of 2-chloro-1-methylpridinium iodide (56 mg, 0.22 mmol) in dry dichloromethane (0.5 ml) was placed. A mixture of (+)-**1** (51 mg, 0.19 mmol), (±)-PEA(22 mg, 0.19 mmol), and tributylamine (82 mg, 0.44 mmol) in dry dichloromethane (0.5 ml) was added to the solution. The reaction mixture was refluxed for 1 h with stirring. Subsequent evaporation and purification by TLC(benzene–ethylacetate 5:1, R_f=0.6) gave the diastereomeric amide in 57 mg (80%) yield. ^{1}H NMR δ=0.34 (two s, 3, Si-CH_3), 1.21, 1.22, 1.28, 1.29 (a pair of d, 3, CH_3), 1.96 (s, 2, CH_2C=O), 2.44 (s, 2, CH_2Ph), 4.6—5.2 (a pair of q, 1, CH), 5.12 (broad s, 1, NH), 7.0—7.5 (m, 15, Ph).

All the amides listed in Tables 2 and 4 were prepared in a similar manner described above. Most of the amides were obtained in the range from 50 to 80% yields.

Preparation of Diastereomeric Ester of (+)-2 with (±)-1-Phenylethanol. In a flask, equipped with a condenser, a solution of 2-chloro-1-methylpyridinium iodide (112 mg, 0.44 mmol) in dry dichloromethane (1 ml) was placed. A mixture of (+)-**2** (83 mg, 0.4 mmol), (±)-1-phenylethanol (49 mg, 0.4 mmol) and tributylamine (160 mg, 0.88 mmol) was added to the flask. The reaction mixture was refluxed for 3 h with stirring. Evaporation and purification by TLC (bnzene, R_f=0.5—0.6) gave the ester in 60 mg (48%) yield. ^{1}H NMR δ=0.32, 0.35 (two s, 3, Si-CH_3), 0.85—1.0 (m, 5, Et), 1.36, 1.37, 1.43, 1.45 (a pair of d, 3, CH_3), 2.15 (s, 2, CH_2), 7.0—7.5 (m, 10, Ph).

All the esters listed in Table 3 were prepared in a similar manner described above. Most of the esters were obtained in the range of 40 to 70% yields.

Preparation of Diastereomeric Amide of (+)-3 with (±)-2-(4-Methylphenyl)-3-methylbutanoic Acid. In a flask, equipped with a condenser, a solution of 2-chloro-1-methylpyridinium iodide (31 mg, 0.12 mmol) in dichloromethane (1 ml) was placed. A mixture of (benzylmethylphenylsilyl) methylamine hydrochloride (28 mg, 0.10 mmol), tributylamine (60 mg, 0.32 mmol), and (±)-2-(4-methylphenyl)-3-methylbutanoic acid (20 mg, 0.10 mmol) was added to the flask. The reaction mixture was refluxed for 1 h with stirring. Evaporation and purification by TLC (dichloromethane, R_f=0.6—0.7) gave the diastereomeric amide in 20.6 mg (50%) yield. ^{1}H NMR δ=0.16, 0.18 (two s, 3, Si-CH_3), 0.60, 0.67, 0.87, 0.94 (a pair of d, 6, CH_3). 2.30 (s, 3, Ar-CH_3), 2.35 (s, 2, Ph-CH_2), 2.1—2.4 (m, 2, CH), 2.9—3.0 (m, 2, CH_2N), 6.9—7.4 (m, 14, Ar).

All diastereomeric amides listed in Table 5 were prepared in a similar manner described above. Most of the amides were obtained in the range of 50—80% yields.

The authors wish to thank the Shin-etsu Chemical Industry Co. for the gift of dichlorodimethylsilane.

Photocatalytic Behavior of Di- and Triferrocenylbenzenes on Reduction of Methyl Viologen and Photochemical Hydrogen Evolution from Methanol under Visible Light

Takeo Akiyama,* Yukihiko Kawaharada, Akira Kondo, Masatsugu Kajitani, Akira Endo, Kunio Shimizu, and Akira Sugimori
Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioi-cho 7-1, Chiyoda-ku, Tokyo 102
(Received May 26, 1986)

1,4- and 1,3-Diferrocenylbenzenes (**1a** and **1b**), 1,2,4- and 1,3,5-triferrocenylbenzenes (**1c** and **1d**) can act as photocatalysts for photochemical hydrogen evolution from methanol in the **1**-methyl viologen MV^{2+}-triethanolamine-colloidal Pt-catalyst system under the irradiation with visible light. The order of the photocatalytic activities of **1** is **1d**>**1c**>**1a**>**1b**. The catalytic activities of **1** can be correlated to the $E_{1/2}$ values. **1** acts as a photocatalyst in the wavelength region of λ>440 nm, whereas it acts as a quencher for the formation of MV^{+} in the wavelength region of λ<440 nm. The highest quantum yield of the formation of MV^{+} catalyzed by **1**(**1d**: $Q_{MV^{+}}$=0.028, at 480 nm) was obtained in the wavelength region where the intensity of the solar light is the largest.

The photochemical evolution of hydrogen from water is of interest[1] because of the need to convert of solar energy into chemical forms. The systems containing a photocatalyst, methyl viologen (MV^{2+}), platinum catalyst, and a sacrificial reductant have been intensively investigated.[1b-f,2] The most popular photocatalysts used in these systems are tris(2,2′-bipyridine)ruthenium(II) chloride[1b-f] and several zinc porphyrin complexes.[2] No ferrocene derivative has been investigated in view of photochemical hydrogen evolution, although ferrocene is known to undergo electron transfer in its excited state when a suitable electron acceptor is present,[3] and the synthetic methods of the ferrocene derivatives have been extensively investigated.[4]

Recently, we reported the photocatalytic behavior of bis(η^5-indenyl)iron(II) on the reduction of MV^{2+} [5] and the photochemical evolution of hydrogen catalyzed by diferrocenylbenzenes in methanol solutions.[6] In this paper we wish to report the full details of the photocatalytic behavior of polyferrocenylbenzenes on the hydrogen evolution under irradiation with visible light and a mechanistic study on the excited state of polyferroenylbenzenes which participate in the reduction of methyl viologen.

Experimental

Materials. 1,4-Diferrocenylbenzene (**1a**) was synthesized from ferrocene (Aldrich Chemical Co., mp 174—176 °C) and 1,4-benzenebis(diazonium tetrafluoroborate) which was prepared by diazotization of *p*-phenylenediamine (Kanto Chemical Co., E.P.) according to the method in the literature:[7] mp 176—179 °C. The ^{1}H NMR spectra of **1a** ($CDCl_3$) δ=7.38 (4H, s, C_6H_4), 4.66 (4H, t, C_5H_4-), 4.32 (4H, t, C_5H_4-), and 4.08 (10H, s, C_5H_5) were identical with those reported.[8]

1,3-Diferrocenylbenzene (**1b**) was prepared similarly from ferrocene and 1,3-benzenebis(diazonium tetrafluoroborate) prepared by diazotization of *m*-phenylenediamine (Kanto Chemical Co., E.P.): mp 188—189 °C (lit,[7] 189—191 °C).

1,2,4-Triferrocenylbenzene (**1c**) was prepared according to the reported method[9] by cyclotrimerization of ethynylferrocene in dioxane in the presence of $Co_2(CO)_8$ as a catalyst: mp 248—250 °C (lit,[9] 246—249 °C); ^{1}H NMR ($CDCl_3$) δ=7.67 (3H, m, C_6H_3), 4.77 (2H, t, C_5H_4-), 4.38 (2H, t, C_5H_4), and 4.12—3.95 (23H, m, C_5H_5×3, 8H from C_5H_4-). These ^{1}H NMR spectral data were identical with those reported by Schlögl and Soukup.[9]

1,3,5-Triferrocenylbenzene (**1d**) was prepared by the acid (HCl)-catalyzed cyclotrimerization of acetylferrocene in the presence of triethyl orthoformate (Wako Junyaku Co., E.P.) according to the method reported by Sasaki and Pittman[10a] and Schlögl and Soukup:[10b] mp 265—265.5 °C (lit,[10] 265—266 °C); ^{1}H NMR ($CDCl_3$) δ= 7.47 (3H, s, C_6H_3), 4.76 (6H, t, C_5H_4-), 4.39 (6H, t, C_5H_4-) and 4.13 (15H, s, C_5H_5). The ^{1}H NMR data were identical with those reported.[10]

Ethynylferrocene was prepared from acetylferrocene (mp 84—86 °C) in the presence of phosphoryl chloride (Wako Junyaku Co., G.R.) and DMF (Wako Junyaku Co., G.R.) and then with sodium hydroxide under the reflux in dioxane according to the method reported by Schlögl and Steyrer[11a]: mp 53.5—55.0 °C (lit,[11] 55—56 °C).

Methyl viologen dichloride hydrate (83%)(Wako Junyaku Co., G.R.) was used as received.

Colloidal platinum catalyst was prepared from dihydrogen hexachloroplatinate(IV) hexahydrate (Wako Junyaku Co., G.R.)(0.20 g) and poly(vinyl alcohol) (Wako Junyaku Co., G.R.)(degree of polymerization=500, 0.160 g) in a methanol-water (50 cm^3, 1/1, v/v) solution according to the method reported by Toshima et al.[12]

Methanol (Wako Junyaku Co., E.P.) was purified by refluxing for 2 h in the presence of calcium hydride and then distilled.

Acetonitrile (Wako Junyaku Co., G.R.) was dried overnight with molecular sieves (Wako Junyaku Co., Molecular Sieves 4A, 1/16). Calcium hydride was added and the mixture was stirred until the gas evolution ceased. This acetonitrile was refluxed for 3—4 h in the presence of anhydrous phosphorus pentaoxide and then distilled under a stream of Ar.

Dioxane (Wako Junyaku Co., Dotite Spectrosol) was used as received.

N,*N*-Dimethylformamide (Wako Junyaku Co., G.R.) was dried over molecular sieves (Wako Junyaku Co., 4A, 1/16) and then distilled under Ar.

Measurements. UV spectra were recorded on a Hitachi 228 UV-Vis spectrophotometer. IR spectra were obtained by use of a Hitachi 260—50 grating spectrophotometer. ^{1}H NMR spectra were taken on a Hitachi R-22 (90 MHz) spectrometer. Gas chromatography for the evolved gas was performed by use of a Shimadzu GC-5A (column: molecular sieves 13X, 30—60 mesh, 2 m; temp: 20 °C; carrier gas: Ar). The gas sample was sucked from the gas buret attached to the cell by using a syringe.

Cyclic voltammetry was carried out for **1a**, **1b**, **1c**, **1d**, ferrocene and tris(2,2′-bipyridine)ruthenium(II) chloride by using a platinum disk electrode (ϕ=2.0 mm)(reference electrode: Ag|0.1 mol dm^{-3} $AgClO_4$ in acetonitrile) in an acetonitrile-tetraethylammonium perchlorate (0.1 mol dm^{-3}) solution.

Irradiation. (a) Hydrogen Evolution. The sample solutions (methanol): 12 cm^3, **1a**: 7.8×10^{-5} mol dm^{-3}, **1b**: 1.4×10^{-4} mol dm^{-3}, **1c**: 2.2×10^{-5} mol dm^{-3}, **1d**: 2.5×10^{-5} mol dm^{-3}, $[Ru(bpy)_3]Cl_2$: 1.40×10^{-5} mol dm^{-3}; MV^{2+}: 4.3×10^{-2} mol dm^{-3}; TEOA: 8.9×10^{-2} mol dm^{-3}; Pt: 1.32×10^{-6} mol) were prepared under a stream of Ar in a quartz vessel (2.5×2.5×6 cm^3) equipped with a gas buret and were irradiated with a 150 W tungsten lamp attached to a slide projector for 2 h. In the cases of ferrocene and phenylferrocene the sample solutions (methanol-dioxane=9:1, v/v, 12 cm^3, ferrocene: 1.1×10^{-4} mol dm^{-3}, phenylferrocene: 9.0×10^{-4} mol dm^{-3}; MV^{2+}: 4.3×10^{-2} mol dm^{-3}; TEOA: 8.9×10^{-2} mol dm^{-3}; Pt: 1.92×10^{-6} mol) were irradiated with a 500 W Xe lamp for 10 min. Comparisons of the catalytic activities of **1** and $[Ru(bpy)_3]Cl_2$ were carried out by comparing the amounts of the evolved gas based on that of the blank system (without metal complex) at 30 min, when the linear correlation between the amount of the evolved hydrogen and the irradiation time was obtained (this relationship was not linear after 30 min). The volume of the evolved hydrogen gas was measured by the gas buret.

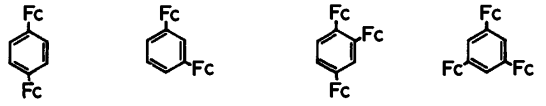
(b) Reduction of Methyl Viologen. The sample solutions containing **1**, MV^{2+}, and TEOA (**1a**: 3.4—6.8×10^{-5} mol dm^{-3}, **1b**: 0.6—1.7×10^{-4} mol dm^{-3}, **1c**: 2.3—4.6×10^{-5} mol dm^{-3}, **1d**: 2.2—5.0×10^{-5} mol dm^{-3}, phenylferrocene: 8.4×10^{-4} mol dm^{-3}; MV^{2+}: 1.29×10^{-2} mol dm^{-3}; TEOA: 6.0×10^{-2} mol dm^{-3}; methanol (for **1a** and **1b**): 5 cm^3; methanol-dioxane (9/1, v/v)(for **1c** and **1d**): 5 cm^3) were prepared under a stream of Ar in a quartz cell (1 cm×1 cm) equipped with a stopcock and were irradiated with monochromatic light (light source: Osram HBO 200 W, monochromator: Shimadzu-Bausch & Lomb grating monochromator, dispersion: 7.4 nm mm^{-1}; slit width: 1.5 mm). The quantitative analysis was carried out by measuring the absorbance at 603 nm (molar absorption coefficient of $MV^{+\cdot}$: 13800 mol^{-1} dm^3 cm^{-1})[13] which is characteristic of $MV^{+\cdot}$.

Actinometry. Actinometry was carried out for 313, 355, 400, 440, 480, 500, 546, and 580 nm light by using potassium trioxalatoferrate(III) according to the method in the literature.[14]

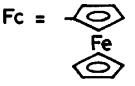
Effect of Additives on the Yield of $MV^{+\cdot}$. (i) To the sample solutions (methanol-dioxane(9:1, v/v) 5 cm^3) containing MV^{2+}(1.29×10^{-2} mol dm^{-3}) and TEOA (6×10^{-2} mol dm^{-3}) was added *trans*-1,3-pentadiene (1.2—5×10^{-4} mol dm^{-3}). The solutions were irradiated with 313 nm light for 3 min and the ratios of the yield of $MV^{+\cdot}$ were calculated. (ii) To the methanol-dioxane(9:1, v/v) solutions containing MV^{2+}(1.29×10^{-2} mol dm^{-3}) and TEOA (6×10^{-2} mol dm^{-3}) was added **1d** (2.5—5×10^{-4} mol dm^{-3}). The solutions were irradiated with 313 nm light for 3 min and $Q_{MV^{+\cdot}}$ values were calculated. (iii) The sample solutions containing **1d**, MV^{2+}, TEOA, and azulene (**1d**: 4.36×10^{-4} mol dm^{-3}, MV^{2+}: 1.29×10^{-2} mol dm^{-3}, TEOA: 6×10^{-2} mol dm^{-3}, azulene: 2.1—8.4×10^{-3} mol dm^{-3}) were irradiated with 480 nm light for 3 min.

Results and Discussion

For the ferrocene derivatives in which several ferrocenyl groups attached to benzene rings can interact with each other through the π-electron system of the benzene ring, the following two important properties of the photocatalyst are expected: (i) a higher light harvesting ability and (ii) a higher electron-donating ability than ferrocene. We thus prepared four ferrocene derivatives of this kind; 1,4-diferrocenylbenzene (**1a**), 1,3-diferrocenylbenzene (**1b**), 1,2,4-triferrocenylbenzene (**1c**), and 1,3,5-triferrocenylbenzene (**1d**), as illustrated below.



(1a) (1b) (1c) (1d)



The electronic absorption spectra of **1a—1d** and those of ferrocene are shown in Fig. 1. These absorption spectra show that **1a—1d** have 10 fold as high light harvesting abilities as that of ferrocene in the wavelength region of 280—500 nm and they have slopes of absorption even at 600 nm. For the utilization of visible or solar light, **1a—1d** are better than ferrocene itself.

Photochemical Hydrogen Evolution Catalyzed by Di- and Triferrocenylbenzenes. The irradiation of the system consisting of **1** (2.2—14×10^{-5} mol dm^{-3}), MV^{2+} (4.30×10^{-2} mol dm^{-3}), triethanolamine (TEOA)(8.9×10^{-2} mol dm^{-3}), colloidal Pt-catalyst (1.32×10^{-6} mol), and methanol (12 cm^3) with a 150 W tungsten lamp for 2 h gave hydrogen gas. The results of the photochemical evolution of hydrogen for **1**-MV^{2+}-TEOA-Pt-MeOH system and for $[Ru(bpy)_3]Cl_2$-MV^{2+}-TEOA-Pt-MeOH system are shown in Fig. 2 and Table 1.

As seen from Fig. 2, **1a**, **1c**, and **1d** show rather high activities for the evolution of hydrogen compared to $[Ru(bpy)_3]Cl_2$, while **1b**, ferrocene, and phenylferrocene show low activity.

The comparisons of the photocatalytic activities of **1** were done by comparing the amount of the evolved hydrogen after the irradiation of 30 min, where a linear correlation between the amount of the evolved

[Ru(bpy)$_3$]Cl$_2$	1.4	9.33(100)	57.1(100)	42.2(100)	555	0.906

a) [MV^{2+}]: 4.3×10^{-2} mol dm^{-3}, [TEOA]: 8.9×10^{-2} mol dm^{-3}, Pt: 1.32×10^{-6} mol, Solvent: methanol, 12 cm^3, Light source: 150 W tungsten lamp, Irradiation time: 30 min. b) The amount of evolved hydrogen gas was based on that of blank experiment. The values in parentheses are percentage of the amount of hydrogen based on that obtained in the case of [Ru(bpy)$_3$]Cl$_2$. c) Fraction of light absorbed by metal complex in 2.5 cm cell ($F=(1-10^{-(2.5)\varepsilon c})\times 100$). The values in parentheses are percentage of the F value based on that obtained in the case of [Ru(bpy)$_3$]Cl$_2$. d) Turnover number$=\dfrac{\text{Amount of evolved hydrogen(mol)}}{\text{Amount of metal complex used(mol)}}$. e) $E_{1/2}=\dfrac{1}{2}(E_p^a+E_p^c)$, where E_p^a and E_p^c are anodic and cathodic peak potentials against Ag|0.1 mol dm^{-3} AgClO$_4$ in acetonitrile. The values in parentheses are the charge numbers of electrode reaction. f) The amount of evolved hydrogen gas was based on that of blank obtained in the same set of experiments which were carried out under the irradiation with a 500 W Xe lamp for 10 min. Fc- represents (C_5H_5)Fe(C_5H_4-).

$[Ru(bpy)_3]Cl_2$ with light absorption of about 50% of $[Ru(bpy)_3]Cl_2$(48% at 440 nm, 58% at 480 nm), (ii) **1c** produces hydrogen 66% of the case of $[Ru(bpy)_3]Cl_2$ with light absorption of 24—28% of that of $[Ru(bpy)_3]Cl_2$, (iii) **1d** produces hydrogen 115% of the case of $[Ru(bpy)_3]Cl_2$ with light absorption of 21—22% of $[Ru(bpy)_3]Cl_2$, (iv) **1b** produces hydrogen 9% of the case of $[Ru(bpy)_3]Cl_2$ with 31% higher light absorption than $[Ru(bpy)_3]Cl_2$, and (v) ferrocene and phenylferrocene do not show any positive effect on the production of hydrogen.

The turnover number (the amount of the evolved hydrogen (mol) per the amount of the metal complex used(mol)) for **1** and $[Ru(bpy)_3]Cl_2$ at 30 min are shown in the fifth column of Table 1. The fact that the turnover numbers of **1a—1d** are all greater than 1 indicates that **1a—1d** act as a catalyst for the photochemical evolution of hydrogen. The order of the catalytic activities of **1** in terms of the amount of the evolved hydrogen is **1d>1c>1a>1b**. It is noteworthy that **1a—1d** show photocatalytic activities, whereas phenylferrocene does not have any catalytic activity. This suggests that more than one ferrocenyl group in a benzene ring is necessary for the appearance of the photocatalytic activity. In the last column in Table 1 are shown redox potentials($E_{1/2}$) of **1** and $[Ru(bpy)_3]Cl_2$ obtained by cyclic voltammetry. **1a—1d** show reversible waves under the experimental conditions. **1a**, **1c**, and **1d** have first oxidation potentials of 0.026, 0.025, and 0.017 V, respectively; these values are all lower than that of **1b** (0.070 V). These electrochemical properties of **1** are roughly parallel to the catalytic activity of **1**; that is, **1** with the lower oxidation potential has the higher photocatalytic activity. That the oxidation potential of **1b** was higher than that of **1a** was ascribed earlier to the inefficiency of the interaction of two ferrocenyl groups through resonance stabilization in the benzene ring.[6] However, the oxidation potential of **1d** is as low as that of **1a**, in spite of having three ferrocenyl groups at positions of benzene ring similar to those for **1b**. The relationship between the electrochemical behavior of **1** and the position of the ferrocenyl groups in the benzene ring still remains unclear and is now under investigation in our laboratory.

Photoreduction of Methyl Viologen Catalyzed by Polyferrocenylbenzenes in Methanol Solutions. In order to obtain evidence that the hydrogen evolution is initiated by the excited state of **1**, followed by an electron transfer from **1** to MV^{2+}, the modified quantum yields (Q_{MV^+}) in terms of the amount of light absorbed by **1** were obtained at various wavelengths.

The modified quantum yield (Q_{MV^+})was calculated based on the amount of the cation radical (MV^+) formed by the contribution of **1** per amount of light absorbed only by 1, as shown in the following equation:

$$Q_{MV^+} = \frac{\text{Amount of } MV^+ \text{ formed by the contribution of } \mathbf{1}}{\text{Amount of light absorbed by } \mathbf{1}(=I\times t)}$$

Two different cases should be considered as to the absorption of the incident light by **1** and MV^{2+}, since the MV^+ is also formed when MV^{2+} only is excited with the light of wavelength shorter than 440 nm. In the case that most of incident light is absorbed by the system (λ<440 nm), Q_{MV^+} can be defined as the following equation:

$$Q_{MV^+} = \frac{[MV^+]_{1+MV^{2+}} - [MV^+]_{MV^{2+}}\times L}{(1-L)} \times \frac{1}{I_0 t}$$

where $[MV^+]_{1+MV^{2+}}$, and $[MV^+]_{MV^{2+}}$, are the amounts of MV^+(mol) in the system consisting of **1** and MV^{2+} and of MV^{2+} only; L is the fraction of light absorbed by MV^{2+} and is defined as:

$$L = \frac{(C_{MV^{2+}})(\varepsilon_{MV^{2+}})}{C_1\varepsilon_1 + (C_{MV^{2+}})(\varepsilon_{MV^{2+}})},$$

where $C_{MV^{2+}}$ and C_1 are the concentrations of MV^{2+} and **1**; $\varepsilon_{MV^{2+}}$ and ε_1 are the molar absorption coefficients of MV^{2+} and **1**; and I_0 is the amount of light quanta(mol) absorbed by the system at wavelength λ per second; t is the irradiation time.

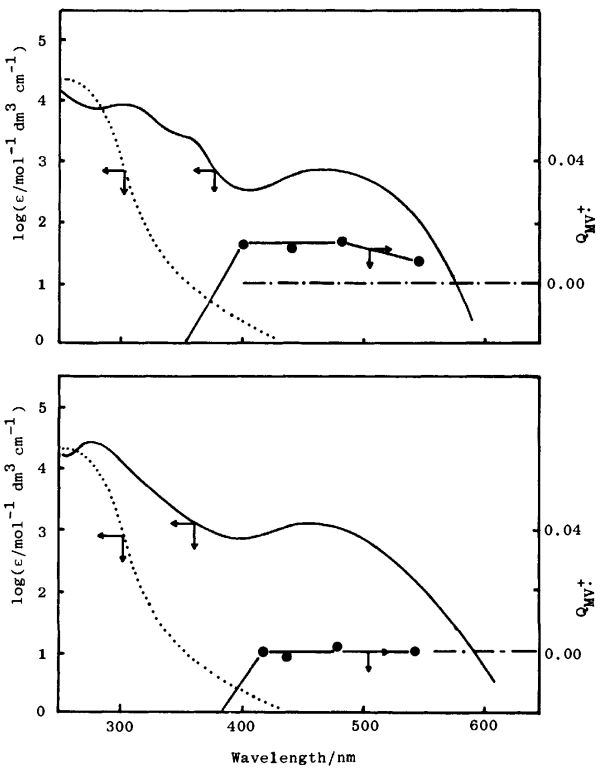

Fig. 3. Wavelength dependences of the quantum yield (Q_{MV^+}) of photoreduction of MV^{2+} catalyzed by 1,4-diferrocenylbenzene(**1a**, above) and 1,3-diferrocenylbenzene(**1b**, below).
(—●—): Q_{MV^+}, (——): Absorption spectra of **1**, (·····): Absorption spectra of methyl viologen.

In the case that most of the incident light is passed through the system and the light is absorbed only by **1** (λ>440 nm), Q_{MV^+} can be defined as the following equation:

$$Q_{MV^+} = \frac{[MV^+]_{1+MV^{2+}} - [MV^+]_{MV^{2+}}}{I \times t},$$

where $[MV^+]_{1+MV^{2+}}$, $[MV^+]_{MV^{2+}}$, and t are the same as defined above; I is the amount of light quanta(mol) absorbed solely by **1** per second. The amount of MV^+ is calculated for the irradiation of 10 min, when the linear relationship between the amount of formed MV^+ and the irradiation time is obtained. However, in the case of the irradiation with 313 nm light, the amount of formed MV^+ at 10 min was obtained by extrapolation of that obtained for 4 min irradiation since the irradiation after 4 min did not follow a linear relationship.

Wavelength dependences of Q_{MV^+} for **1a—d** were obtained as shown in Figs. 3 and 4. These results indicate that: (i) **1a**, **1c**, and **1d** promote the formation of MV^+ in the wavelength region longer than 440 nm where only **1** absorbs light, whereas in the shorter wavelength region, where both MV^{2+} and **1** absorb light competitively, **1** inhibits the formation of MV^+; (ii) the highest Q_{MV^+}(0.028) is obtained in the **1d**-MV^{2+}-TEOA system under the irradiation with 480 nm light, so, **1d** is a suitable photocatalyst for the photochemical hydrogen evolution with solar light, whose intensity is maximum at 480 nm; and (iii) **1b** shows a small promotion effect in the wavelength region longer than 440 nm, but an inhibiting effect similar to that of **1d** was observed in the wavelength region of λ<440 nm.

The inhibiting effect of **1** on the formation of MV^+ in the wavelength region shorter than 440 nm can be accounted for by the quenching of the excited triplet state of MV^{2+}(E_T=299 kJ mol^{-1})[15] by the ground state of **1** (cf. ferrocene: E_T=179 kJ mol^{-1}).[16] In Fig. 5 are shown the Stern-Volmer plots for the effect of a typical triplet quencher, *trans*-1,3-pentadiene(E_T=248 kJ mol^{-1})[17] and **1d**, on the formation of MV^+ under the irradiation with 313 nm light. That the linear correlation in the Stern-Volmer plots was obtained in the cases of both *trans*-1,3-pentadiene and **1d** indicates that the excited triplet state of MV^{2+} is quenched by **1d** by energy transfer process and that this results in the inhibition of the formation of MV^+. Similar results were obtained in the cases of **1a**, **1b**, and **1c**. Recently, Hoffman and Jones II[18] reported that MV^{2+} forms a charge-transfer(CT) complex with TEOA in the ground state and that the excitation of this CT-complex gives MV^+(Φ=0.0018—0.010, at pH 8.7). The results shown in Fig. 5 may thus be explained by the quenching of the excited triplet state of the CT-complex,$^3(MV^{2+}\cdots TEOA)^*_{CT}$ by **1** although the absorption band which originated from the CT-complex was

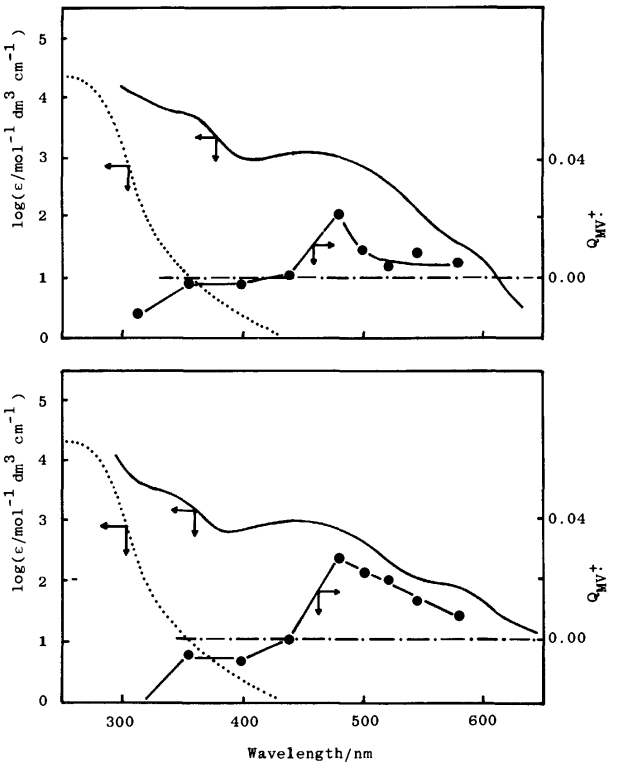

Fig. 4. Wavelength dependences of the quantum yield (Q_{MV^+}) of photoreduction of MV^{2+} catalyzed by 1,2,4-triferrocenylbenzene(**1c**, above) and 1,3,5-triferrocenylbenzene(**1d**, below).

not observed in our case.

The effects of the concentration of **1** (**1c** and **1d**) on Q_{MV^+} under the irradiation with 480, 520, and 580 nm are shown in Figs. 6 and 7. The Q_{MV^+} values are independent of the concentrations of **1**. In Fig. 8 is shown the effect of concentrations of MV^{2+} on Q_{MV^+} values. It is clear that the Q_{MV^+} values are proportional to the concentration of MV^{2+}. The results in Figs. 6—8 show that (i) the photoreduction of MV^{2+} proceeds in first order with respect to the excited state of **1** (Figs. 6 and 7) and (ii) the photoreduction is first order with respect to MV^{2+} under the irradiation with the light of wavelength longer than 440 nm.

Information on the excited state of **1** involved in the photoreduction was gained by another quenching

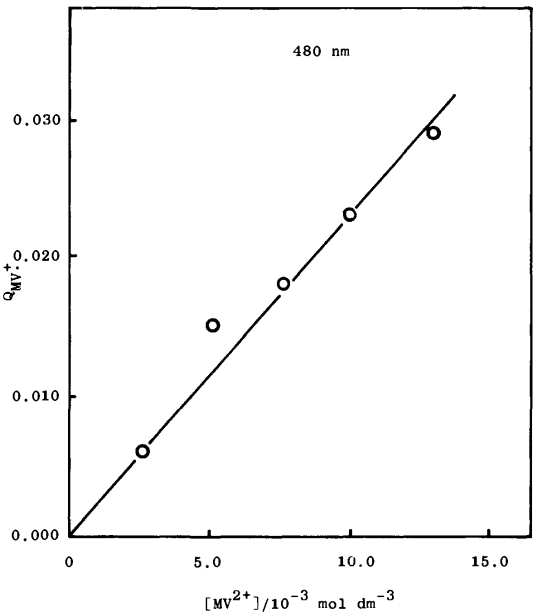

Fig. 8. Dependence of Q_{MV^+} on concentration of methyl viologen (MV^{2+}) under the irradiation with 480 nm light.

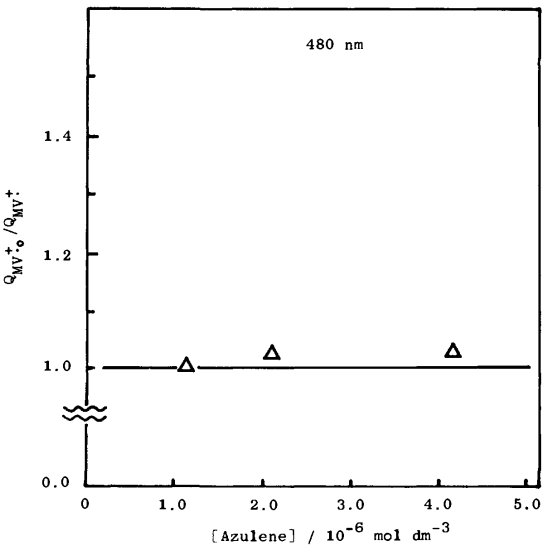

Fig. 9. Stern-Volmer plots for $Q_{MV^+}{}^{\circ}/Q_{MV^+}$ under the irradiation with 480 nm light.

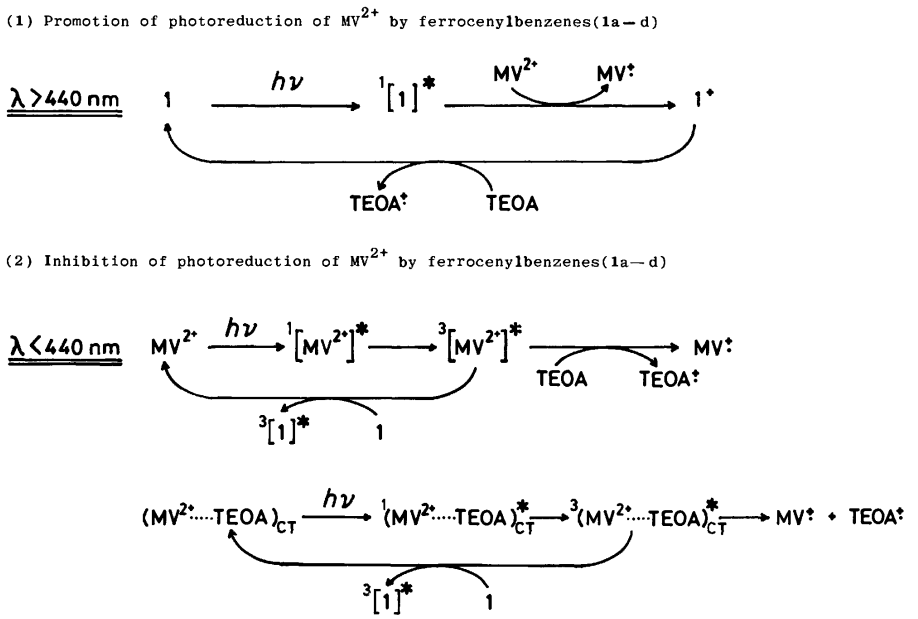
experiment using azulene; its triplet energy level (E_T=163.6 kJ mol^{-1})[19] is lower than ferrocene. The Stern-Volmer plots are shown in Fig. 9. The absence of any effect of added azulene on Q_{MV^+} indicates that the reduction of MV^{2+} is initiated by the excited singlet state of **1**, followed by the electron transfer from ^{1}(**1**)* to MV^{2+} under the irradiation with light of wavelength longer than 440 nm.

The Excited State of 1 Involved in the Photoreduction of Methyl Viologen. The assignments of the absorption bands of di- and triferrocenylbenzenes have not been reported, but those of ferrocene were reported



Scheme 1.

by several workers.[20,21,22] According to Sohn[20] and Gordon,[22] the bands at 440 and 324 nm have d-d character and the bands at 265 nm has LMCT character.[22] In the cases of ferrocene and phenylferrocene the irradiation with the light of wavelength longer than 440 nm gave Q_{MV^+} values of zero. Therefore, the excited state involved in the reduction of MV^{2+} can be considered to have some LMCT character. These red shifts of LMCT-band might be accounted for by the intramolecular interaction of ferrocenyl groups through π-electron systems.

The reaction mechanism for the photoreduction of MV^{2+} catalyzed by **1** is shown in Scheme 1.

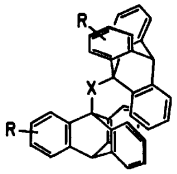
Restricted Rotation Involving the Tetrahedral Carbon. LIX. Stereodynamics of Singly *peri*-Substituted 9-(3,5-Dimethylphenoxy)triptycene Derivatives[1)]

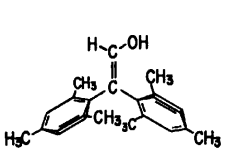
Gaku YAMAMOTO* and Michinori ŌKI
Department of Chemistry, Faculty of Science, The University of Tokyo,
Bunkyo-ku, Tokyo 113
(Received May 26, 1986)

Five singly *peri*-substituted derivatives of 9-(3,5-dimethylphenoxy)triptycene with F, OCH_3, CH_3, Br, and $C(CH_3)_3$ as the *peri*-substituent were synthesized and their dynamic NMR behavior was studied. In any of the compounds, two *m*-methyl groups in the phenoxyl moiety were anisochronous at low temperatures and the signals coalesced into a single peak on raising the temperature. Lineshape analysis afforded the energy barriers to the rate process ranging from 10.1 kcal mol^{-1} (1 cal_{th}=4.184 J) for the F compound to 17.6 kcal mol^{-1} for the $C(CH_3)_3$ one. Molecular mechanics calculations (MM2) were performed on closely related model compounds to obtain the relative steric energies of the ground states and the possible transition states. The results from the dynamic NMR and the molecular mechanics studies suggest the following: When the *peri*-substituent is small (F and OCH_3), the complete gear rotational circuit with the passing of the aryl group over the *peri*-substituent as the rate-determining step is the lowest-barrier process, while when the *peri*-substituent is bulky (CH_3, Br, and $C(CH_3)_3$), the "isolated" rotation of the aryl group at the *ap* site has a lower barrier and is responsible for the observed dynamic NMR behavior. In the 1,3-di-*t*-butyl derivative, restricted rotation of the 1-*t*-butyl group was observed below −75 °C, the free energy of activation being 9.5 kcal mol^{-1}.

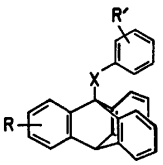
Gear rotation or correlated disrotation of two groups (chemical rotors) attached to a common central atom is a topic of recent interest. Bis(9-triptycyl)-X compounds **1** are chemical bevel gears consisting of a pair of three-toothed wheels.[2)] In these compounds, two wheels are tightly meshed and energy barriers to gear rotation are extremely low, being below the detection limit by dynamic NMR spectroscopy, while those to slippage of the gear are very high when X is oxygen or methylene, giving rise to isolable "phase" isomers.[2a)] Diaryl-X compounds may be regarded as a bevel gear system composed of a pair of two-toothed wheels. Static and dynamic stereochemical behavior of these compounds, however, seems diverse depending on the substituents on the aryl and the X moieties.[3)] Recently, correlated disrotation was clearly proved in 2,2-bis(2,4,6-trimethylphenyl)ethenol (**2**).[3b)]



1



2



3

During the course of our studies on rotational isomerism in 9-substituted triptycene derivatives, we have been interested in the stereodynamics of 9-(arylmethyl)triptycenes (**3**: X=CH_2). These compounds adopt a conformation reminiscent of a bevel gear consisting of a two-toothed wheel and a three-toothed one, an edge of the aryl group being inserted into the notch of the triptycene skeleton.[4a-d)] A rate process which corresponds to either meshed gear rotation or gear slippage can be of low barrier depending on the substitution pattern on both the aryl and the triptycene moieties. We have extended the studies to 9-aryloxytriptycenes (**3**: X=O) by replacing the methylene group by a divalent oxygen and found that 9-(2-alkylphenoxy)-1,4-dimethyltriptycenes behave as dynamic gears, the meshed gear rotation being the lowest-barrier process.[4e,f)] The presence of a substituent at the ortho position of the aryloxyl moiety is an important factor for raising the gear slippage barrier and thus rendering the gear rotation solely detectable.

We describe in this paper the dynamic ^1H NMR and molecular mechanics studies on the stereodynamics of singly *peri*-substituted 9-(3,5-dimethylphenoxy)triptycenes (**4a—e**) which lack an *o*-substituent in the aryloxyl moiety and discuss the results in comparison with those on the carbon counterparts. We also report an almost unprecedented observation of restricted rotation of a *t*-butyl group bonded to a benzene ring found during this investigation.

	X	Y	Z	W
4a	F	F	F	F
4b	OCH_3	H	H	OCH_3
4c	CH_3	H	H	CH_3
4d	Br	Br	Br	Br
4e	$C(CH_3)_3$	H	$C(CH_3)_3$	H

Figure 1 shows six conformers corresponding to energy minima and possible interconversion processes among them. Three rotameric sites, *ap*, $+sc$, and $-sc$, are conceivable about the C_9-O bond, and in each site $CH_3{}^A$ may look outwards (subscript 1) or inwards (subscript 2). Interconversion between ap_1 and $\pm sc_2$ and between ap_2 and $\pm sc_1$ occurs by gear rotation in which the aryl group passes over a *peri*-hydrogen

(GR(H)), while that between $\pm sc_1$ and $\mp sc_2$ occurs by gear rotation of the aryl group over the *peri*-substituent (GR(X)). Another possible process is "isolated" rotation (IR) in which the aryl group rotates by 180° without changing the rotameric site with respect to the C_9–O bond. This process corresponds to slippage of the gear and can occur either at the *ap* site (IR(*ap*)) or at the $\pm sc$ sites (IR(*sc*)).

Results and Discussion

Syntheses. 9-(3,5-Dimethylphenoxy)anthracene (**5**) was prepared in 36% yield by Ullmann reaction of 9-bromoanthracene with 3,5-dimethylphenol.[5] **5** was also obtained by acid-catalyzed condensation of anthrone[6] with 3,5-dimethylphenol but the yield was low (21%). Reactions of **5** with appropriate benzynes gave the triptycenes **4a—e**. 3,5-Di-*t*-butylbenzyne added to **5** to give **4e** and the corresponding 2,4-di-*t*-butyl derivative in ca. 3:1 ratio. Preferential formation of the more crowded regioisomer in the Diels-Alder reaction of benzynes is not unprecedented and has been discussed.[7]

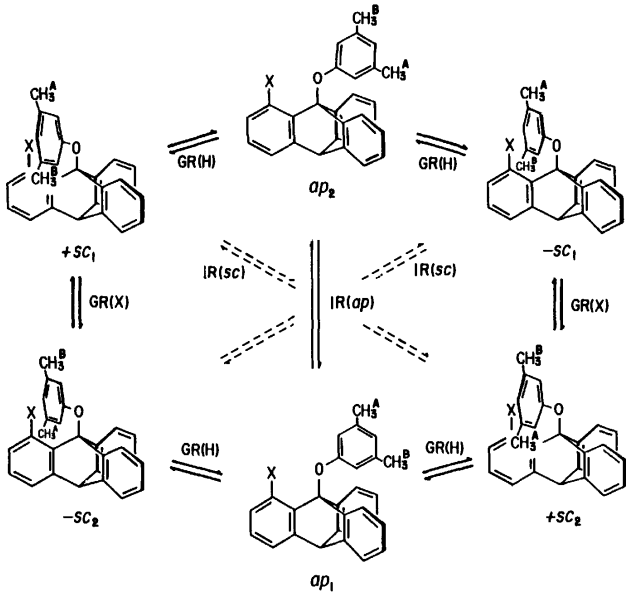


Fig. 1. Conformers of 1-substituted 9-(3,5-dimethylphenoxy)triptycenes and possible interconversion processes among them.

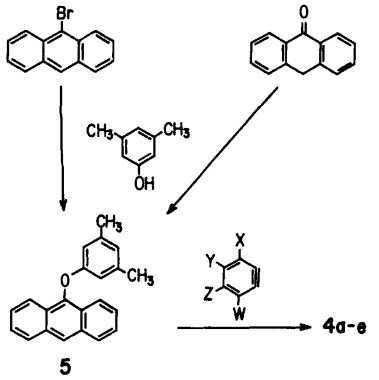

Dynamic NMR Studies. Variable temperature ^{1}H NMR study of the triptycenes **4a—e** revealed a common feature of the temperature dependence of the spectra. In any of the compounds, the signals derived from the *m*-methyl groups in the aryloxyl moiety appear as two equally intense singlets at low temperatures (Table 1) and they broaden and coalesce into a single peak upon raising the temperature. The lineshape change was analyzed as a coalescing AB spin system without mutual coupling using the DNMR3 program.[8] The kinetic parameters obtained are given in Table 2. By the same token, the *o*-protons in the aryloxyl moiety are anisochronous at low temperatures and isochronous at high temperatures. The substituents at 1 and 4 positions in **4b** and **4c** as well as the 3-*t*-butyl group in **4e** give rise to a sharp singlet for each throughout the temperature range

Table 1. Low Temperature ^{1}H chemical Shifts at 400 MHz[a]

Compd	Temp °C	Solvent	3′,5′-CH_3	10-H	1-X	3-Z or 4-W	2′,6′-H	4′-H

a) Aromatic protons in the triptycene moiety are omitted. Chemical shifts are given in δ. All the signals shown in the table are singlets although 2′-, 4′-, and 6′-H are slightly broad. b) See text. c) Overlapped with other aromatic signals.

examined. The 1-*t*-butyl signal in **4e** behaves differently, which will be discussed later in detail. The two *o*-benzeno bridges carrying no substituent are magnetically equivalent in the whole temperature range in any compound.

The spectral feature observed at low temperatures suggests that the molecules exist either solely in *ap* conformation or as a rapidly interconverting mixture of *ap* and $\pm sc$, preserving the diastereotopicity of the *m*-methyl groups in the aryloxyl moiety.

The two *m*-methyl groups should remain diastereotopic so far as the *ap* and $\pm sc$ rotamers rapidly interconvert by to-and-fro gear rotation via GR(H), $+sc_1 \rightleftarrows ap_2 \rightleftarrows -sc_1$ or $+sc_2 \rightleftarrows ap_1 \rightleftarrows -sc_2$. As discussed in the later section, compounds **4a—d** are thought to exist as a mixture of rotamers with respect to the C_9-O bond, while **4e** exists solely as the *ap* rotamer. Observation of only a single pair of methyl signals in **4a—d** in spite of the presence of both *ap* and $\pm sc$ rotamers should mean that GR(H) processes are too fast for the rotamers to be separately observed even at the lowest temperature examined.

Coalescence of the *m*-methyl signals occurs when either the GR(X) or the IR process becomes fast on the NMR time scale. However, which of these processes is the lowest-barrier one responsible for the observed dynamic NMR behavior is neither a priori evident nor is concluded by the NMR analysis.

Molecular Mechanics Calculations. In order to solve the above problem, we planned to resort to molecular mechanics calculations employing the MM2 program.[9] For simplifying the calculations, we adopted compounds **6a—e** as the respective models of **4a—e**; *m*-methyl groups in the aryloxyl moiety and 3- and 4-substituents in **4b**, **4c**, and **4e** were omitted by assuming that the buttressing effects of these groups against the neighboring hydrogen atoms are negligibly small, but halogen atoms at 2, 3, and 4 positions in **4a** and **4d** were included because the possible buttressing effect should be adequately considered.

6a	F	F
6b	OCH_3	H
6c	CH_3	H
6d	Br	Br
6e	$C(CH_3)_3$	H

Calculated steric energies of the ground states, *ap* and $\pm sc$, and of the transition states for the possible dynamic processes, GR(H), GR(X), IR(*ap*), and IR(*sc*), are given in Table 3. We did not make efforts to construct the whole energy surface. In calculating the GR(X) and IR(*ap*) transition states, we assumed geometries of C_s symmetry; the substituted *o*-benzeno bridge coincides with the mirror plane and the phenoxyl benzene ring is perpendicular to it.

The *ap* ground state in any compound is shown to have C_s symmetry; the C_9-O-$C_{1'}$-$C_{6'}$ dihedral angle is 0°, giving rise to a static meshed gear. The $\pm sc$ isomer also resides in a meshed gear conformation, the C_9-O-$C_{1'}$-$C_{6'}$ angle being ca. −5° for the $+sc$ forms of **6a—d** and −19° for $+sc$-**6e**. The $\pm sc$ form is calculated to be less stable than *ap* in any compound, and the detailed discussion on this point is given in the later section.

Table 2. Dynamic NMR Data

Compd	Solvent	Freq / MHz	Temp Range[a] / °C	T_c[b] / °C	ΔH^* / kcal mol^{-1}	ΔS^* / cal mol^{-1} K^{-1}	ΔG^*_{300K} / kcal mol^{-1}

a) The range in which rate constants were obtained. b) Coalescence temperature.

Table 3. Relative Steric Energies by MM2 Calculations[a]

Compd	X	Y	Ground States		Transition States			
			ap	±*sc*	GR(H)	GR(X)[b]	IR(*ap*)[b]	IR(*sc*)
6a	F	F	0	0.61	8.9	11.9	16.4	18.6
6b	OCH_3	H	0	0.52	9.0	14.0	16.5	c)
6c	CH_3	H	0	2.48	10.6	21.4	16.3	c)
6d	Br	Br	0	2.70	11.6	25.4	15.5	23.7
6e	$C(CH_3)_3$	H	0	7.78	14.3	33.1	15.3	c)

a) Values relative to that of *ap* for each compound are shown in kcal mol^{-1}. b) Geometry of C_s symmetry is assumed. c) Not calculated.

Steric energies of the transition states as given relative to that of the most stable ground state are nothing but the energy barriers to the respective processes. Dependence of the calculated barriers on the bulkiness of the *peri*-substituents is compatible with what comes from the intuitive considerations on the molecular models of the compounds: The GR barriers as well as the IR(*sc*) one are highly dependent on the *peri*-substituent but the IR(*ap*) one is rather insensitive to the size of the *peri*-substituent. We must note that, although a bromo group is usually thought to be smaller than a methyl group,[10] the 1-bromo group in **4d** is effectively bulkier than the 1-methyl group in **4c** because of the buttressing effect in **4d**.

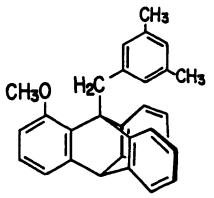
The GR(H) barriers calculated for **6a—d** are small enough to be consistent with the fact that slowing down of this process is not observed in the ^{1}H NMR spectra of **4a—d**.

The IR(*sc*) barrier is inferred to be much higher than the IR(*ap*) one in any compound, although the calculations were made only for **6a** and **6d**, bacause the increased degrees of rotational freedom of the 1-substituent prevented the ready calculation of the IR(*sc*) transition states for **6b**, **6c**, and **6e**. Therefore the IR(*sc*) process may be disregarded as an actually occurring process.

The GR(X) barrier is calculated to be lower than the IR(*ap*) one in **6a** and **6b**, but the situation is reversed in **6c—e**. Although the inaccuracy of the absolute values of the barrier heights should be allowed for, the following deduction would be reasonable. In **4a** and **4b**, the rate process observed by dynamic NMR corresponds to GR(X), while the IR(*ap*) process is responsible for the dynamic NMR behavior in **4c—e**. Therefore, the full gear rotational circuit involving GR(X) as the rate-determining step is the lowest-barrier process when the *peri*-substituent is small (F and OCH_3), but the gear slippage occurs more easily than the full gear rotation when the *peri*-substituent is bulkier (CH_3, Br, and $C(CH_3)_3$). The calculation underestimates the IR(*ap*) barrier in **6e** but the origin is uncertain.

Previously we reported that, in 1-methoxy-9-(3,5-dimethylbenzyl)triptycene (**7**), the free energy barrier to the *ap*→±*sc* conversion at −28 °C is 12.4 kcal mol^{-1} while the one to the exchange of the *m*-methyl groups is roughly estimated to be 12.6 kcal mol^{-1}.[4b] The former process corresponds to GR(H) and the latter to either GR(X) or IR(*ap*). Assuming that the GR(X) barrier should be considerably higher than the GR(H) one, we can assign IR(*ap*) to the process responsible for the *m*-methyl exchange.

A comparison of the data for **4b** with those for **7** reveals the effects of the central group (CH_2 or O) on the barriers to gear rotation and gear slippage. Here the effect of the 4-methoxyl group in **4b** is assumed to be negligible. The GR(H) barrier in **4b** is



7

undetectably low, being calculated as 9.0 kcal mol^{-1} for **6b**, and thus is considerably lower than that in **7**. This may be explained in terms of the large valency effect (tetravalent in C and divalent in O) and the bond length effect partially cancelling the former, as discussed in detail in the previous paper.[4f] The IR(*ap*) barrier is far lower in **7** than in **4b** as calculated for **6b**, suggesting the importance of the bond length effect which causes tighter meshing of the gear in the oxygen compound **4b**. A similar trend in the gear slippage barriers has been observed in bis(9-triptycyl)-X compounds (**1**: X=CH_2 vs. O).[2a]

Rotamer Equilibria. No direct information on the rotamer distributions in **4a—e** is experimentally obtained because the rotamers interconvert rapidly even at the lowest temperature examined. However some information is indirectly obtained by careful examination of the NMR data. The chemical shift difference between the two *m*-methyl signals observed at low temperatures varies from 0.25 ppm for **4a** to 0.51 ppm for **4e** (Table 1), which may reflect the rotamer distribution between *ap* and ±*sc*. As the observed value is the difference between the chemical shift of CH_3^A averaged over the rotamers and that of CH_3^B also averaged over the rotamers and it should be very small if the two rotamers populate comparably and the larger it will be the more the equilibrium shifts to one side. In 9-(3,5-dimethylbenzyl)triptycene derivatives, where the rotamers were separately observed in the NMR spectra, the chemical shift differences between the *m*-methyl groups were 0.45—0.57 ppm.[11b] If the similar values of chemical shift differences are assumed for 9-(3,5-dimethylphenoxy)-triptycene rotamers, it is inferred that the rotamer equilibrium is moderately shifted to one side in **4a—d** and is almost exclusively one-sided in **4e**.

Similar inference can be made from the temperature dependence of the chemical shift difference: It decreases almost linearly with the temperature in **4a—d**, the increment being −0.40, −0.20, −0.33, and −0.27 Hz/deg, respectively, reflecting the increasing population of the minor rotamer at higher temperatures. The chemical shift differences in **4e** is almost independent of the temperature (+0.05 Hz/deg), and thus it is reasonable to conclude that **4e** exists solely as a single rotamer.

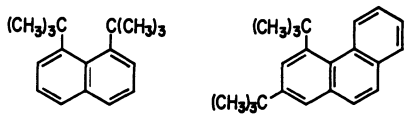
The next question to answer is to which side the equilibrium is shifted. The above reasoning together

with the results of molecular mechanics calculation concludes that **4e** exists solely as the *ap* rotamer. As for **4b** and **4c**, the chemical shifts of the 1-substituent give some information. The 1-methoxyl proton signal in **4b** appears at a considerably high field of δ 3.21 at −56 °C and shifts slightly downfield upon raising the temperature (δ 3.24 at 24 °C). The facts are consistent with the reasoning that the ±*sc* rotamer, in which the 1-methoxyl group is located in the shielding region of the aryl group, is predominant and the population of the less stable *ap* rotamer increases with temperature. In various 1-methoxy-9-(arylmethyl)triptycene derivatives ever examined,[11] the 1-methoxyl group gives its signal at δ 2.89—2.95 in the ±*sc* rotamers and at δ 3.78—3.85 in *ap*. The Winstein-Holnes relation using these values suggests that about two thirds of **4b** exists as ±*sc*. Predominance of the ±*sc* rotamer in **4b** is in line with the behavior observed in the 1-methoxy-9-(arylmethyl)-triptycene derivatives.[11] The population of the *ap* rotamer in 1,4-dimethyl-9-phenoxytriptycene was previously suggested to be about 80% at room temperature from the 1-methyl chemical shift[4f] and the similar value may also be applicable to **4c**.

The population of *ap* of 33 and 80% at room temperature corresponds to the energy difference ($E_{\pm sc}-E_{ap}$) of 0.0 and 1.24 kcal mol^{-1}, respectively, if the statistical factor of 2 for ±*sc* is assumed to be the sole contributor to the entropy term. As the MM2 calculation (Table 3) gives the energy differences of 0.52 and 2.48 kcal mol^{-1} for **6b** and **6c**, respectively, it somewhat overestimates the relative instability of the ±*sc* rotamers. The discrepancies between the NMR and MM2 results may be at least partly ascribed to the insufficiency of the force field used in the calculation as discussed before.[4f]

Restricted Rotation of the 1-*t*-Butyl Group in 4e.[12] In the 400 MHz ^{1}H NMR spectrum of **4e** at ambient temperature, the singlet at δ 1.715 due to the 1-*t*-butyl group appears considerably broader than the one at δ 1.247 assigned to the 3-*t*-butyl group. On lowering the temperature, the low-field signal further broadens and below −75 °C it splits into two peaks. At −96.2 °C, they appear as a three-proton singlet at δ 1.489 and a six-proton singlet at δ 1.815, while the high-field signal remains a sharp nine-proton singlet at δ 1.264. The phenomenon should be ascribed to the restricted internal rotation of the 1-*t*-butyl group. Lineshape analysis of the spectra at −83 to −56 °C using the DNMR3 program[8] gave the following activation parameters: $\Delta H^{\ddagger}=9.2\pm0.6$ kcal mol^{-1}, $\Delta S^{\ddagger}=-1.7\pm2.9$ cal mol^{-1} K^{-1}, $\Delta G^{\ddagger}_{200K}=9.5$ kcal mol^{-1}.

This high energy barrier to rotation of a *t*-butyl group bonded to an sp^2-hydridized carbon atom is unprecedented.[13] Several attempts at observing the restricted rotation of C_{sp^2}–Bu^t bonds by NMR spectroscopy were unsuccessful.[14] The failure might



8 **9**

result from the fact that the presence of a supposedly rotation-hindering group raised not only the transition state energy but also the ground state one. An apparent exception may be 1,8-di-*t*-butylnaphthalene (**8**) derivatives, where an energy barrier of 6.5 kcal mol^{-1} was reported for the internal rotation of the *t*-butyl groups,[15a] although the geometry around the 1- and 8-carbons is far from what is expected for the normal sp^2-hybridization.[15b]

The ORTEP drawing[17] of the lowest-energy conformation of **6e** obtained by the MM2 calculation is shown in Fig. 2. Compound **4e** should reasonably adopt a similar conformation as **6e**. The molecule has a plane of symmetry and two enantiotopic methyl groups (CH_3^A) in the 1-*t*-butyl group face the oxygen atom and the other methyl (CH_3^B) eclipses C-2. The geometrical features that the benzene ring carrying the *t*-butyl group is completely planar, that the C_1–Bu^t bond shows no out-of-plane deformation in spite of the large in-plane distortion, and that the C_9–O bond is also in plane of the benzene ring, are in sharp contrast with those observed in the 1,8-di-*t*-butylnaphthalenes[15b] and 2,4-di-*t*-butylphenanthrene (**9**),[16] where significant distortion from planarity has been noticed. This rigidity of the triptycene skeleton together with the rather small oxygen atom as the obstacle to rotation should cause the high energy barrier to rotation of the 1-*t*-butyl group: The transition state for rotation is effectively raised while the ground state is not raised too much. It will be

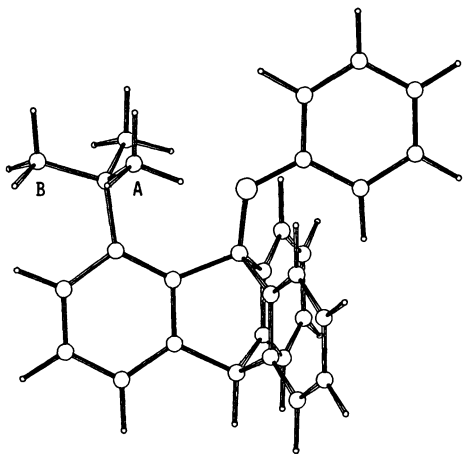


Fig. 2. ORTEP drawing of the most stable conformation of 1-*t*-butyl-9-phenoxytriptycene (**6e**) obtained by the MM2 calculation.

interesting to examine whether 9-substituted 1-*t*-butyltriptycenes generally have high energy barrier to rotation of the 1-*t*-butyl group, and further studies on this point is in progress.

Judging from the relative signal intensities, the CH_3^A protons resonate at a lower field than the CH_3^B protons. The anisotropy and/or the field effect of the oxygen atom as well as the ring current effect of the phenoxyl benzene ring might cause the deshielding of the CH_3^A protons, which should exceed the deshielding effect of the *o*-benzeno ring carrying the *t*-butyl group on the protons of the in-plane CH_3^B group.

Below −90 °C, the CH_3^B signal showed further broadening probably because of the slow-down of the internal rotation of this methyl group, although no discrete splitting of the signal was observed down to −111 °C. The staggered conformation of the methyl group and the presence of the 2-hydrogen atom as the effective obstacle might be responsible for the high rotational barrier of the methyl group.

Experimental

General Methods. ^{1}H NMR spectra at ambient temperature were obtained on a Varian EM-390 spectrometer at 90 MHz in the CW mode and on a JEOL GX-400 spectrometer at 399.65 MHz in the pulse FT mode. Variable temperature ^{1}H NMR spectra were recorded either on a Hitachi R-20B spectrometer at 60 MHz in the CW mode or on GX-400. With R-20B, temperatures were calibrated with a methanol or ethylene glycol sample[18] while they were read as digital outputs and are not corrected with GX-400. ^{19}F NMR spectra were obtained on EM-390 at 84.67 MHz. ^{1}H NMR data given in the Experimental section are those obtained on GX-400 at 21—24 °C, unless otherwise stated.

Preparative gel permeation chromatography was performed on an LC-08 Liquid Chromatograph of Japan Analytical Industry Co., Ltd. using a series of JAIGEL 1H and 2H columns and chloroform as the eluent.

Theoretical spectra for the dynamic NMR simulations were obtained on a HITAC M-280H computer system at the Computer Center of the University of Tokyo (CCUT) using the DNMR3 program.[8]

Molecular mechanics calculations were performed on the M-280H system using the MM2 program in the CCUT Program Library with some modifications of the parameters as described before.[4f,19] In obtaining the transition state energies, the C_{9a}–C_9–O–$C_{1'}$ and C_9–O–$C_{1'}$–$C_{6'}$ bonds were driven near the supposed transition state geometries and the saddle points of energy were sought. In cases of GR(X) and IR(*ap*) transition states, the geometries of C_s symmetry were assumed, although such geometries are not necessarily a prerequisite for the transition states.[20]

9-(3,5-Dimethylphenoxy)anthracene (5). (A) A mixture of 5.14 g (20 mmol) of 9-bromoanthracene, 12.2 g (100 mmol) of 3,5-dimethylphenol, 2.8 g of potassium hydroxide, and 1.0 g of copper powder was heated at 230 °C for 2 h. The cooled mixture was extracted with benzene-water. The benzene layer was washed successively with aqueous sodium hydroxide and water, and dried over magnesium sulfate. After evaporation of the solvent, the residue was chromatographed on alumina with hexane-dichloromethane as the eluent. A fraction containing 1.11 g (6.2 mmol) of anthracene eluted first, followed by a fraction containing **5**. Recrystallization of the eluate from tetrahydrofuran-hexane gave 2.12 g (36%) of **5**, mp 174—175 °C. Found: C, 88.79; H, 6.02%. Calcd for $C_{22}H_{18}O$: C, 88.56; H, 6.08%. ^{1}H NMR ($CDCl_3$, 90 MHz, 35 °C) δ=2.15 (6H, s), 6.45 (2H, s), 6.61 (1H, s), 7.2—7.5 (4H, m), 7.8—8.2 (4H, m), 8.31 (1H, s).

(B) A solution of 5.82 g (30 mmol) of anthrone and 7.33 g (60 mmol) of 3,5-dimethylphenol in 100 mL of toluene containing 1.0 mL of concentrated sulfuric acid was heated with a Dean-Stark water collector for 140 h. The solution was washed successively with aqueous sodium hydroxide and water, dried over magnesium sulfate, and concentrated. Column chromatography of the residue on alumina gave 1.86 g (21%) of **5**.

1,2,3,4-Tetrafluoro-9-(3,5-dimethylphenoxy)triptycene (4a). To a chilled (−78 °C) solution of 0.5 mL (ca. 4.3 mmol) of chloropentafluorobenzene in 30 mL of diethyl ether was added 2.0 mL (ca. 3.1 mmol) of a 10% (w/v) solution of butyllithium in hexane and the solution was stirred for 2 h at −78 °C. To this solution was added 448 mg (1.5 mmol) of **5** and the mixture was allowed to warm up to room temperature with stirring, stirred at room temperature for 2 h and heated under reflux for 2 h. The reaction mixture was washed with water, dried over magnesium sulfate and concentrated. The residue was heated under reflux overnight with 0.5 g (ca. 5 mmol) of maleic anhydride in 10 mL of acetonitrile. After evaporation of the solvent, the residue was chromatographed on alumina with hexane-dichloromethane as the eluent, affording 33 mg (5%) of **4a**, mp 250—252 °C. Found: C, 75.09; H, 4.15%. Calcd for $C_{28}H_{18}F_4O$: C, 75.33; H, 4.06%. ^{1}H NMR ($CDCl_3$) δ=2.241 (6H, s), 5.783 (1H, d, J=1.5 Hz), 6.657 (2H, s), 6.691 (1H, s), 7.00—7.10 (4H, m), 7.40—7.50 (4H, m). ^{19}F NMR ($CDCl_3$, ppm downfield from internal hexafluorobenzene) 3.13 (dd, J=19 and 21 Hz, 2-F), 3.81 (ddd, J=3, 19, and 21 Hz, 3-F), 13.10 (dd, J=15 and 21 Hz, 4-F), 20.39 (br m, 1-F).

1,4-Dimethoxy-9-(3,5-dimethylphenoxy)triptycene (4b). To a boiling solution of 298 mg (1.0 mmol) of **5** in 20 mL of 1,2-dimethoxyethane(DME) was added a solution of 986 mg (5.0 mmol) of 3,6-dimethoxyanthranilic acid[21] in 20 mL of DME and a solution of 1.0 mL (ca. 7.4 mmol) of isopentyl nitrite in 10 mL of DME during the course of 2 h so that excess of isopentyl nitrite always existed in the reaction mixture. The mixture was heated under reflux for 0.5 h and concentrated. The residue was chromatographed on alumina with hexane-dichloromethane as the eluent, affording 70 mg (16%) of **4b**, mp 264—265 °C after recrystallization from tetrahydrofuran-hexane. Found: C, 82.79; H, 5.95%. Calcd for $C_{30}H_{26}O_3$: C, 82.92; H, 6.03%. ^{1}H NMR ($CDCl_3$) δ=2.221 (6H, br s), 3.236 (3H, s), 3.859 (3H, s), 5.898 (1H, s), 6.509 and 6.611 (2H, AB-q, J=8.9 Hz), 6.608 (1H, s), 6.668 (2H, br s), 6.90—7.05 (4H, m), 7.35—7.60 (4H, m).

1,4-Dimethyl-9-(3,5-dimethylphenoxy)triptycene (4c). Similar reaction as above of **5** with 3,6-dimethylanthranilic acid[22] gave **4c**, mp 261—262 °C, in 58% yield. Found: C, 89.33; H, 6.56%. Calcd for $C_{30}H_{26}O$: C, 89.51; H, 6.51%. ^{1}H NMR ($CDCl_3$) δ=2.031 (3H, br s), 2.372 (3H, br s), 2.440 (3H, s), 2.792 (3H, s), 5.622 (1H, s), 6.154 (1H, br s), 6.628

(1H, s), 6.640 and 6.667 (2H, AB-q, J=7.2 Hz), 6.85—7.05 (5H, m), 7.25—7.45 (4H, m).

1,2,3,4-Tetrabromo-9-(3,5-dimethylphenoxy)triptycene (4d). Similar reaction as above of **5** with tetrabromoanthranilic acid[23] gave **4d**, mp 330—332 °C (decomp), in 11% yield. Found: C, 48.62; H, 2.67; Br, 46.80%. Calcd for $C_{28}H_{18}Br_4O$: C, 48.73; H, 2.63; Br 46.32%. ^{1}H NMR ($CDCl_3$) δ=2.054 (3H, br s), 2.344 (3H, br s), ca. 6.1 (1H, br), 6.100 (1H, s), 6.654 (1H, s), 6.95—7.15 (5H, m), 7.30—7.55 (4H, m).

1,3-Di-*t*-butyl-9-(3,5-dimethylphenoxy)triptycene (4e). Similar reaction as above of **5** with 3,5-di-*t*-butylanthranilic acid[7b] gave a ca. 3:1 mixture of **4e** and the isomeric 2,4-di-*t*-butyl-9-(3,5-dimethylphenoxy)triptycene. Separation of the regioisomers was performed by gel permeation chromatography. Even after 20 recycles, complete baseline separation of the isomers was not attained. **4e** was isolated in ca. 18% yield, mp 203—205 °C. Found: C, 88.62; H, 7.58%. Calcd for $C_{36}H_{38}O$: C, 88.84; H, 7.87%. ^{1}H NMR ($CDCl_3$) δ=1.227 (9H, s), 1.722 (9H, s), 1.905 (3H, s), 2.429 (3H, s), 5.322 (1H, s), 5.720 (1H, s), 6.601 (1H, s), 6.8—7.5 (11H, m). The 2,4-di-*t*-butyl compound was isolated in ca. 6% yield, mp 238—239 °C. Found: C, 88.90; H, 7.59%. ^{1}H NMR ($CDCl_3$, 90 MHz, 35 °C): δ=1.14 (9H, s), 1.58 (9H, s), 2.23 (6H, s), 6.14 (1H, s), 6.65 (1H, s), 6.73 (2H, s), 6.8—7.1 (5H, m), 7.3—7.5 (5H, m).

Dynamic NMR as a Nondestructive Method for the Determination of Rates of Dissociation. X. Rates of Dissociation of the C-N Bond in Substituted 1-(1,3-Dithiolan-2-yl)pyridinium Perchlorates[1,2]

Toshiari Morita and Michinori Ōki*
Department of Chemistry, Faculty of Science, The University of Tokyo,
Bunkyo-ku, Tokyo 113
(Received June 6, 1986)

Rates of dissociation of the C-N bond in substituted 1-(1,3-dithiolan-2-yl)pyridinium ions in the perchlorate forms were obtained by the dynamic NMR technique in nitromethane-d_3 and for one case in acetonitrile-d_3. The study of the substituent effects on the rates of dissociation revealed that the rates were linearly correlated with the pK_a values of the substituted pyridines. The mechanism of the dissociation was postulated to be of S_N2 type, the perchlorate ion acting as a nucleophile, from the kinetic data.

Dynamic NMR techniques are unique in that the rates of dissociation of molecular species can be studied in nonpolar aprotic solvents without destruction of the molecule. The so-called topomerization[3] is the key step in this methodology. The method had been originally applied to organometallic compounds[4] and then the method has now been extended to the dissociation of organic halides,[5] ammonium ions derived from tertiary amines and acids,[6] and amine ligands of some coordination compounds.[7] The method is capable of producing the rates of dissociation which exceed the limit obtainable by the classical kinetic method.

Since quaternary ammonium salts can be considered as composed of a tertiary amine and a carbocation, the dissociation of this group of compounds must be on an extrapolation map of the above-mentioned ammonium salts or coordination compounds. From the standpoint of organic chemistry, there are varieties of reactions of quaternary ammonium salts which involve dissociation of the C-N bond in them.[8] Hence it will be interesting to find examples of ammonium salts which give suitable rates of dissociation for the dynamic NMR technique. This will also give information which is useful in understanding the dissociation processes in aprotic solvents.

The crucial point is that we must search a group of compounds which give suitable rate constants of dissociation for the dynamic NMR technique. Our experience showed that the pyridinium salt which was derived from benzyl α-chlorobenzyl sulfide and pyridine exhibited too low rates of dissociation for the dynamic NMR. Thus we explored compounds which could produce more stable carbocation than the α-(benzylthio) benzyl cation. The natural choice was to introduce two sulfur atoms alpha to the cation.

1,3-Dithiolan-2-yl cation was expected to be a good candidate for the system in question. Various attempts to identify the suitable compounds, including the pyridinium compounds derived from 2-chloro-1,3-dithiolane, led to a finding that 1-(1,3-dithiolan-2-yl)pyridinium salts were suitable for the investigation. Perchlorate salts were selected because of their stability and the ease of syntheses.

The compounds were prepared by treating 1,3-dithiolane with triphenylmethyl perchlorate and then with substituted pyridines in acetonitrile. The compounds were rather unstable and were especially moisture-sensitive, if the substituent was electron-withdrawing. In spite of the easy deterioration in the air, they could be purified by recrystallization from acetonitrile-ether, if we handled them carefully, under dry conditions.

The 400 MHz NMR spectra of the compounds were determined as nitromethane-d_3 solutions except for one case, when acetonitrile-d_3 was used. The use of the polar solvent was necessary because their solubilities in nonpolar aprotic solvents were very low. The compounds exhibited either complex AA'BB' patterns or a broad signal for the ring protons of the 1,3-dithiolane, the former giving broadening of the signals at high temperatures and the latter showing AA'BB' signals at low temperatures. The rate process becomes slow as the 4-substituent on the pyridine ring becomes electron-donating. Although we have made various pyridinium salts of this type, which carry electron-withdrawing substituents, their rates of hydrolysis were too large to obtain pure samples. Thus, although the trend in the rate processes mentioned above is apparent, we wish to present the results with the samples only which gave correct elemental analyses in this paper.

The change in the line shapes of the NMR spectra is indicative of the presence of a dynamic process. The site exchange is most reasonably explained by assuming the dissociation of the C-N bond of the pyridinium salts followed by association to the covalent species, when topomerization takes place (Eq. 1). If the basicity of a pyridine compound is high, the C-N bond in question must be stronger than the case of a weak base, because it is the acid-base combination. The above results conform to this expectation, if we assume the dissociation of the C-N bond in the pyridinium ions.

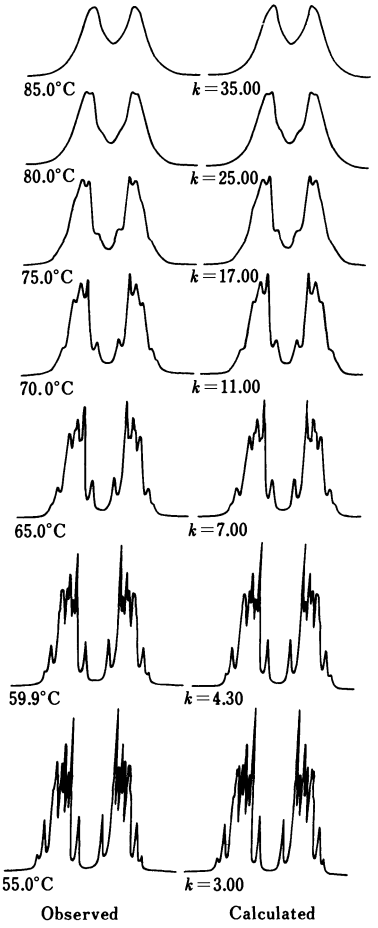

Fig. 1. Observed and calculated AA'BB' ^{1}H NMR spectra of 4-methoxy-1-(1,3-dithiolan-2-yl)pyridinium perchlorate at various temperatures.

Table 1. Equations Correlating the Chemical Shift Differences and Temperature and Coupling Constants of AA'BB' Systems in Substituted 1-(1,3-Dithiolan-2-yl)pyridinium Perchlorates

Substituent	$f(T)$[a]	J_{gem}/Hz	J_{cis}/Hz	J_{trans}/Hz
4-CH_3O	106.12—0.18T	−11.9	5.2	6.8

1a 1b (1)

Typical line shapes at various temperatures together with the simulated spectra of 4-methoxy-1-(1,3-dithiolan-2-yl)pyridinium perchlorate are given in Fig. 1. The spectral parameters of the AA'BB' patterns were obtained by simulation with the use of the LAOCN III program stored in the Computer Center of this University. The simulation was performed for the spectra at various temperatures where the rates of the exchange were negligibly small. This operation confirmed that the coupling constants were temperature-independent, while chemical shift differences for the A and B protons were temperature-dependent. The drift of the chemical shift differences could be linearly correlated with temperature. The correlation of the chemical shift differences with temperature together with coupling constants are compiled in Table 1 for the nitromethane-d_3 solutions. Thus the chemical shift differences at a given temperature could be calculated by these equations and were used for the simulation.

The rate constants of topomerization at various temperatures were obtained by simulation of the line shapes with the use of DNMR3 program.[9] The rate constant k and the transverse relaxation time T_2 were treated as variables. In spite of this practice, thanks to the complicated line shapes, the variation of k gives a different trend in modification of the line shape from that in T_2, thus enabling us to determine unique values of k and T_2. The values k and T_2 are given in Table 2. The agreement of the calculated spectra with the observed was satisfactory, as is shown in Fig. 1.

Putting the rate constants and temperatures into the Eyring equation, we obtained the kinetic parameters which are shown in Table 3. A trend is apparent: The more basic is the pyridine derivative, the higher is the enthalpy of activation. Indeed, the pK_a values of the pyridine bases and the free energy of activation for the dissociation gives a good straight line, as is shown in Fig. 2, the slope and the correlation coefficient being 4.8 and 0.995, respectively. The linearity is not necessarily held between the base strengths toward the proton and carbon acids,[11] but the increase in the hardness of the carbocation in this case due to the presence of two alpha sulfur atoms will be the key factor for this linearity between the proton and carbocation acids. The results clearly indicate that the bond dissociation is the key step in the observed topomerization processes. Thus we are able to show examples of self dissociation of ammonium salts which can be observed by the dynamic NMR technique. Further application of this technique in this area will certainly contribute to the understanding of the S_N1 type substitution reactions of the ammonium salts which have been known for some time.

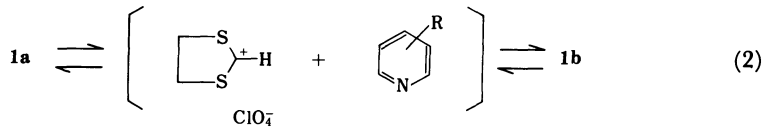
The entropies of activation are interesting: They are all close to zero. Although the reliability of entropy of activation obtained by the dynamic NMR method had been questioned, a concensus has now been established that it is reproducible and reliable, when the total line shape analyses are performed on complex line shapes.[4b,12] The observed entropies of activation make a striking contrast with the other cases we have examined so far. It has been shown that, if a covalent species dissociates to form ion pairs, the entropy of activation is large negative, whereas it is large positive, if an ion pair colapses to form a covalent species on dissociation.[5,6] Since the case studied here is the dissociation of an ion pair to covalent species, the simple application of the above generalization to the present case tells that entropy of activation should be large positive because the disorderedness of solvent molecules should increase at the transition state of the reaction.[13] Yet the observed entropy of activation is close to zero.

We should like to take this fact as indicative of the reaction mechanism and the rate determining step. In principle, the bond dissociation of the C-N can occur either in S_N1 (Eq. 2) or in S_N2 (Eq. 3) fashion.

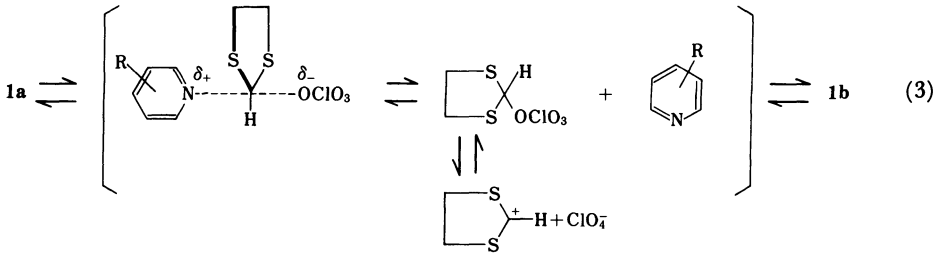
If the dissociation is of S_N1 type, 1, 3-dithiolan-2-yl cation and a pyridine molecule are partially formed at the transition state. The net electric charge is invariant, whereas a new particle is being formed. This transition state should give positive entropy of activation. The results in Table 3 are not in conformity with this expectation.

In the S_N2 type reactions, the perchlorate anion must be the nucleophile. This is unusual but not without precedence. Perchlorate esters are known[14] and perchlorate anion shows nucleophilic nature in some instances.[15] It is possible, therefore, that the reaction proceeds in the S_N2 fashion. However, in the S_N2 type reactions, the electric charges are to be extinguishing and this contributes to the increase in the entropy of activation. Thus there must be good reasons why the observed entropy of activation is close to zero, if we postulate the rate-determining step of the reaction to be of S_N2 type.[16,17]

We believe the followings are the explanations for the observation. In the ground state of the reaction, perchlorate anion will be rotating freely with having interactions through its four equivalent oxygens, bearing the negative charge, with the cationic center. In the transition state, a partial covalent bond is to be formed, thereby losing the freedom of motion of the perchlorate ion. This should contribute to the



(2)



(3)

decrease in entropy. The decrease in entropy due to the loss of freedom of motion of the anion and the increase in entropy due to the increase in the freedom of motion of the solvent molecules may compensate to make the absolute values of the entropy of activation very small. There are examples of this sort: Whereas proton transfer reactions from an ammonium ion to chloride ion exhibits a large positive entropy of activation, that between an ammonium ion and sulfonate anion proceeds with nearly zero entropy of activation.[19] Therefore, we conclude that the bond dissociation reaction in the 1-(1,3-dithiolan-2-yl)-pyridinium ions takes place with the S_N2 type mechanisms.

Table 4. ^{1}H NMR Data and Kinetic Parameters for the Dissociation of 1-(1,3-Dithiolan-2-yl)pyridinium Perchlorates in CD_3CN

$\Delta\nu$/Hz vs. Temperature/K Correlation	$\Delta\nu = 66.46 - 0.10T$
J_{gem}/Hz, J_{cis}/Hz, J_{trans}/Hz	−11.9, 5.4, 6.8
k/s^{-1} (T_2/s, Temperature/°C)	4.0 (0.30, 25.1), 6.4 (0.33, 30.3), 9.2 (0.30, 35.4), 13.3 (0.25, 40.0), 19.3 (0.18, 45.0), 28.0 (0.17, 50.0)
Correlation Coefficient	0.9997
$\Delta H^{\ddagger}$/kcal mol^{-1}	14.2±0.5
$\Delta S^{\ddagger}$/cal mol^{-1} K^{-1}	−8.1±1.6
$\Delta G^{\ddagger}_{298}$/kcal mol^{-1}	16.4

Since the perchlorate ester which is transiently formed is very unstable due to the fact that the cation is stabilized by the presence of two alpha sulfur atoms, it rapidly dissociates to an ion pair which subsequently topomerizes and then recombines to form the topomer of the starting material. This series of reactions completes the observed process.

The dissociation reaction of 1-(1,3-dithiolan-2-yl)-pyridinium perchlorate can also be detected in acetonitrile-d_3. The NMR data as well as kinetic parameters are listed in Table 4. The chemical shift differences are small in acetonitrile relative to those in nitromethane. This causes coalescence of the signals at lower temperature in acetonitrile than in nitromethane. However, the kinetic parameters for the dissociation in the two solvents are very close with each other. This may be rationalized by the fact that the polarity of the solvents is similar. Because of the similarity of the results, no further measurements were carried out for other compounds in acetonitrile.

Experimental

The compounds examined here are easily hydrolyzable with water in the air or in solvents. Special care was exercised to remove trace of water from the solvents and to avoid contact with air. Nitromethane-d_3 and acetonitrile-d_3 were dried over Molecular Sieves 3A, the method being recommended by a literature for acetonitrile.[20] Acetonitrile for the syntheses of the compounds was distilled from its mixture with phosphorus pentaoxide and dried over Molecular Sieves 3A. Ether was distilled from its mixture with lithium tetrahydridoaluminate.

Substituted 1-(1,3-Dithiolan-2-yl)pyridinium Perchlorates. The whole operations were carried out under dry argon. Triphenylmethyl perchlorate[21] (0.44 g or 1.3 mmol) was dissolved in 5 mL of acetonitrile. To this solution was added 0.15 g (1.4 mmol) of 1,3-dithiolane[22] in one portion and the mixture was stirred for 10 min at room temperature, and then 30 mL of dry ether was added to form yellow precipitates. The solvent was removed by filtration and the solid was washed with ether for several times. The solid was then dissolved in acetonitrile and mixed with 1.3 mmol of an appropriate pyridine derivative. Ether was added to the mixture until slight turbidity was observed at room temperature and the whole was cooled to −40~−50 °C. The precipitate was collected by filtration and recrystallized from acetonitrile-ether. The melting points and analytical data are given in Table 5 and the ^{1}H NMR data in Table 6.

Dynamic NMR Spectral Study. The spectral measurement was carried out with either a JEOL GX400 machine installed in Nippon Kayaku Company, Ltd., or that in Institute for Molecular Science. Samples were dissolved in nitromethane-d_3 or in acetonitrile-d_3 to make up a solution of ca. 200 mmol L^{-1}. Temperature was read by a thermocouple. For measurements of the dependence of the chemical shift differences on temperature, the spectra were obtained at 4—5 points of temperatures where the exchange of sites of magnetic spins was negligibly slow. The straight line was drawn by the least squares method. Fitting of the calculated spectra with the observed was carried out visually.

We wish to thank Dr. G. Izumi of Nippon Kayaku Co., Ltd., for measuring the ^{1}H NMR spectra at various temperatures and Institute for Molecular Science for the permission of using the NMR spectrometer. This work was supported by a Grant-in-Aid for Scientific Research of the Ministry of Education, Science and Culture, to which our thanks are due.

16) Ordinary S_N2 reactions are known to proceed with negative entropy of activation.[18] However, this is due to the fact that the reaction occurs from a free nucleophile and a substrate in solution and is different from the case discussed here, where the reaction occurs from tight ion pairs or solvent-separated ion pairs. This assumption is consistent

with the fact that ammonium chlorides and a bromide give large positive entropy of activation for their dissociation.[6,19]

17) In Eq. 3, it is not meant that the reaction to afford the topomerized product proceeds with S_N2 mechanism between the perchlorate ester and the pyridine, but that a reaction between the pyridine and the perchlorate ester and/or the ion pair takes place. The necessary information for the diagnosis of the contribution of the two possible routes cannot be obtained because this step is not rate-determining. At any rate, a simple S_N2 reaction between the formed perchlorate ester and the pyridine does not account for the topomerization: It gives back the original topomer. The ester must dissociate to the ion pair in which topomerization takes place.

The Preparation and Some Properties of 1,4,7-Trithia[7]- and 1,5,9-Trithia[9]ferrocenophanes and Their Copper(I), Silver(I), Mercury(II), and Palladium(II) Complexes

Masaru SATO,* Kaoru SUZUKI, and Sadatoshi AKABORI†

(Received May 27, 1986)

1,5,9-Trithia[9]ferrocenophane was prepared by the reaction of 1,1′-bis(3-chloropropylthio)ferrocene with sodium sulfide. The complexes of 1,5,9-trithia[9]ferrocenophane, along with 1,4,7-trithia[7]ferrocenophane, with copper(I), silver(I), mercury(II), and palladium(II) salts were prepared. Some interaction between the iron atom and the metal atoms coordinated to the thia-crown moiety was suggested from their spectral data in the solution for the complexes of 1,4,7-trithia[7]ferrocenophane with mercury(II) and palladium(II) salts and the complex of 1,5,9-trithia[9]ferrocenophane with silver(I) tetrafluoroborate.

Much attention was focused on the metal-metal interaction existing between metallocenes and metal cations from the viewpoints of biochemical and catalytic interests.[1,2] Ferrocene has been known to form an unstable complex with mercury(II) salts,[3] while [2]Ferrocenophanes, in which the two cyclopentadienyl rings are tilted by 20° because of their shorter bridging, can form more stable 1:1 complexes with mercury(II) chloride[4] and tin(IV) chloride,[5] since a direct metal-metal interaction is present as revealed by their Mössbauer spectra. Recently, dative Fe–Pd and Fe–Pt bonds have been confirmed by X-ray analyses of (1,1′-ferrocenedithiolato-S,S,Fe)(triphenylphosphine) palladium(II)[6] and platinum(II).[7] In regard to these results, we now report on the preparation and various properties of 1,4,7-trithia[7]- (**1**) and 1,5,9-trithia[9]-ferrocenophanes (**2**) and their copper(I), silver(I), mercury(II), and palladium(II) complexes.

Results and Discussion

Synthesis of 1,5,9-Trithia[9]ferrocenophane (2). It has been reported that 1,4,7-trithia[7]ferrocenophane was prepared by the reaction of 1,1′-bis(2-chloroethylthio)ferrocene with sodium sulfide.[8] In a similar manner, 1,5,9-trithia[9]ferrocenephane (**2**) was prepared in 53% yield by refluxing a mixture of 1,1′-bis(3-chloropropylthio)ferrocene and sodium sulfide in ethanol–tetrahydrofuran (THF). The structure was determined by an elemental analysis and spectral data. Thus, the molecular formula of **2** was deduced to be $C_{16}H_{20}S_3Fe$ by an elemental analysis and by the mass spectrum (M^+ m/z 364). In the ^1H NMR spectrum of **2**, the α- and β-ring protons of the cyclopentadienyl rings (Cp-rings) appeared as a singlet (8H) at δ 4.23, while the methylene protons next to the sulfur atoms resonated as two triplets at δ 3.10 and 2.82 and the other methylene protons as a quintet at δ 2.02. The ^{13}C NMR spectrum of **2** showed a bridge-head carbon as well as α- and β-carbons at 88.8, 71.8, and 68.3 ppm, respectively. Specific spectral behavior observed in the electronic and ^{13}C NMR spectra of 1,4,7-trithia[7]-ferrocenophane (**1**)[9] was not observed in the present ferrocenophane.

Copper(I) Complexes. A solution of **1** and $(CH_3CN)_4CuBF_4$ was refluxed in acetonitrile for 1 h and then diluted with diethyl ether to give the copper(I) complex **3a** in good yield. The copper(I) perchlorate complex **3b** was similarly obtained by a reaction of **1** with $(CH_3CN)_4CuClO_4$ in acetonitrile. An elemental analysis showed that **3a** was a 1:1 complex of **1** with $CuBF_4$, containing one equivalent of acetonitrile in the crystal. The IR spectrum of **3a** showed the absorption characteristic of a coordinated

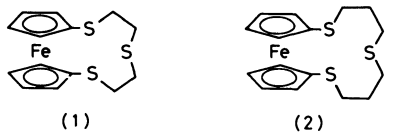

Fig. 1.

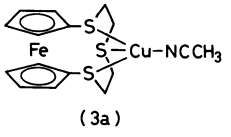

Fig. 3.

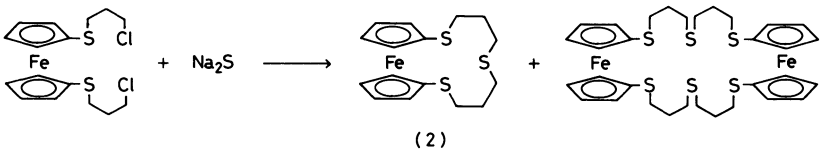

Fig. 2.

cyano group at 2256 cm^{-1}. From the IR spectrum of the perchlorate complex **3b**, it appears that an intermediate between a free and covalently bounded perchlorate anion was present owing to the appearance of three well-defined maxima in the region between 1200 and 1000 cm^{-1}.[10] Upon considering a stereo-model of **1** it was found that the size of the ferrocenothiacrown ring is too small to allow the inclusion of the Cu(I) ion (r_{ion} 0.96 Å)[11] into the center of the trithia-macrocycle. Moreover, it was confirmed by an X-ray analysis that the Cu(I) ion in the 1,4,8,11-tetrathiacyclotetradecane with $CuClO_4$ had a tetrahedral configuration.[12] From these facts and the IR spectra, it is suggested that the copper(I) ion in complex **3** is coordinated by the three sulfur atoms of ligand **1** and the nitrogen atom of acetonitrile or the oxygen atom of a perchlorate anion in the crystal of complex **3**. On the other hand, in the ^1H NMR spectrum of **3a**, the signals of the Cp-rings and the methylene protons appeared as multiplets centered at δ 4.37 and 3.13, respectively, indicating the presence of a symmetrical structure. This view was supported by the ^{13}C NMR spectrum of **3a**, which showed only three Cp-ring carbon signals at 91.1 (C_b), 69.8 (C_α), and 69.0 (C_β). The appearance of symmetrical signals for the Cp-rings in a solution of **3** seems to be due to a rapid dissociative equilibrium to afford an averaged spectra. Small changes in the IR, ^{13}C NMR ($\Delta\delta$ −1.9 and +0.2 ppm in α- and β-carbons, respectively), and electronic spectral data [hypsochromic shift ($\Delta\lambda$ 14 nm) and a decreased absorbance ($\Delta\varepsilon$ 155) in the 440 nm-band] when going from the free ligand **1** to the metal complex **3a** may suggest that the ferrocene moiety of complex **3** is little influenced by the Cu(I) ion coordinated to the sulfur atoms of the thia-crown moiety. Such a small perturbation was also observed in the tetrathia[*n*]ferrocenophane series.[13]

Table 1. Visible Spectral Data of **1**—**9** in Acetonitrile

Compd	λ_{max} (ε)
1	462 (349)

Ag(I) Complexes. A solution of **1** in acetonitrile was added to a solution of silver(I) tetrafluoroborate in acetonitrile; the solution was then diluted with anhydrous diethyl ether to give the 1:1 complex **4** in good yield. In a similar manner, the 1:1 complex **5** was obtained from **2** and $AgBF_4$. An elemental analysis confirmed that **5** contained one equivalent of acetonitrile in its crystal form. The IR spectrum showed a C≡N stretching vibration at 2260 cm^{-1}. In the ^1H NMR (Table 2) and the electronic spectra (Table 1), negligible differences were observed between ligand **1** and complex **4**. In the ^{13}C NMR spectrum of **4**, rather small up-field shifts of the α- ($\Delta\delta$ 2.1) and β-carbons ($\Delta\delta$ 0.2) of the Cp-rings were observed. These spectral data suggest two possible coordinations: (i) the silver(I) ion is coordinated to only the sulfur atom (S-4) farthest from the ferrocene nucleus of ligand **1**; (ii) complex **4** is in a rapid equilibrium with the free ligand **1** and $AgBF_4$ in acetonitrile. In any case, the interaction between the ferrocene nucleus and the Ag(I) ion in **4** was negligible. Also, complex **5** exhibited similar features regarding the electronic spectrum, but showed a specific behavior regarding the ^1H NMR spectrum. That is, the H-3 and H-7 signals appeared at δ 2.83 as multiplets and the H-4 and H-6 signals at δ 1.74 as multiplets. These chemical shifts are nearly comparable with the corresponding values of the free ligand **2**. However, the signals of the Cp-ring protons

Table 2. ^1H NMR Spectral Data of **1**—**9** in CD_3CN

a) at 70 °C, b) in DMSO-d_6, c) at 60 °C.

and H-2 and H-8 shifted down-field (δ ca. 6.3) and collapsed to become extremely broad. This phenomenon can be understood as resulting from the scanty appearance of the unpaired electrons on the Cp-ring carbons as well as the C-2 and C-8 by means of a partial electron transfer from the iron atom of the ferrocene nucleus to the coordinated Ag(I) ion in intermediate **5a**, which may lie in the rapid equilibrium (Scheme 1). In a solution of **5** in acetonitrile, at least, the silver(I) ion seemed to be incorporated into the center of the thia-crown or located near the iron atom of the ferrocene nucleus of **5**.

Hg(II) Complexes. A solution of mercury(II) chloride in anhydrous diethyl ether was added to a solution of **1** in anhydrous diethyl ether to give the 1:1 complex **6** as dark-red crystals in good yield. In the same manner, a 1:1 complex **7** was obtained from **2** and $HgCl_2$ as red-orange cubes in good yield. As can be seen in Tables 1 and 3, the electronic and IR spectra of **6** and **7** are similar to those of the free ligands **1** and **2**, respectively. The octahedral coordination of the Hg(II) ion in a 1:1 complex of 1,4,8,11-tetrathiacyclotetradecane with $HgCl_2$ was suggested from its IR spectrum;[14] an X-ray analysis has confirmed that the coordination about the Hg(II) atom is approximately tetrahedral in the 1:2 complex of 1,4,8,11-tetrathiacyclotetradecane with $HgCl_2$.[15] The Hg(II) ion (r_{ion} 1.10 Å)[10] does not seem to be incorporated into the smaller thia-macrocycle of **6** and **7** than that of 1,4,8,11-tetrathiacyclotetradecane. Therefore, a structure in which the Hg(II) atom coordinates to only the sulfur atoms attached to a ferrocene nucleus in the thia-maclocycle is suggested. In the ^1H NMR spectrum (70 °C) of **7** in acetonitrile-d_3, the Cp-ring protons appeared as a symmetrically broad singlet and shifted down-field ($\Delta\delta$ 0.09), suggesting the same reason given for the Ag(I) complexes. On the other hand, the ^1H NMR spectrum (60 °C) of **6** in CD_3CN showed features that were similar to those observed in a silver(I) complex **5**: The Cp-ring protons and H-2 and H-6 collapsed and shifted down-field (δ ca. 6.3). This suggests some type of interaction between the iron atom and the Hg(II) atom coordinated to the thia-macrocycle moiety in the solution, as described for complex **5**.

Palladium(II) Complexes. Compound **1** reacted with dichlorobis(acetonitrile)palladium(II) in hot acetonitrile to give the 1:1 complex **8** as black crystalline powder in good yield. Compound **2**, on the other hand, gave two products: black crystals **9** and black violet powder **10** in a similar manner. The former was confirmed to be a 1:1 complex by an elemental analysis. The IR spectra of **8**—**10** showed absorption at 330—315 cm^{-1}, the region for *cis*-$PdCl_2$ moieties.[16] The ^1H NMR spectrum of **8** in DMSO-d_6 showed three multiplets at δ 4.81 (2H), 4.61 (2H), and

Fig. 5.

4.43 (m, 4H) for the Cp-ring protons, indicating a strong coordination of $PdCl_2$ to the sulfur atoms at 1 and 7 positions on one side of the thiamacrocycle in **1** and no intervention of the dissociative equilibrium in the solution observed in the Cu(I), Ag(I), and Hg(II) complexes. On the other hand, in the ^1H NMR spectrum of **9** in DMSO-d_6, the Cp-ring protons appeared at δ 4.85 (m, 1H), 4.50 (m, 3H), and 4.28 (m, 4H). This pattern of the Cp-ring protons can probably be rationalized by the coordination of a $PdCl_2$ moiety to the sulfur atoms at 1 (or 9) and 5 positions in **9**. Compounds **8** and **9** were very insoluble in most organic solvents. As the complexes of 1,1′-bis(alkylthio)ferrocene with $PdCl_2$ are soluble in a polar solvent,[17] a possibility that the present $PdCl_2$ complexes have a polymeric structure cannot be ruled out. Complex **10** gave an unsatisfactory elemental analysis as a 1 : 1 complex and a rather broad IR spectrum, suggesting a polymeric product.

Mössbauer Spectra. ^{57}Fe Mössbauer spectral data can give useful information about the state of an iron atom in various complexes. The IS and *QS* values of the free ligand **2** and the metal complexes **4**—**9** are summarized in Table 4. A large change in the *QS* value was observed in complexes of [2]ferrocenophanes with mercury(II)[4] and tin(IV) chlorides,[5] in which a direct interaction between the iron atom of a ferrocene nucleus and the metal atoms was suggested on the basis of their Mössbauer spectra. The negligible change observed here is within the limits of the difference in the packing mode of the crystal, suggesting that the metal atoms coordinated to the polythia-crown moiety in the trithia[*n*]ferrocenophanes **1** and **2** exert little interaction on the iron atom of a ferrocene nucleus in the solid state. A similar change was also observed in the metal complexes of tetrathia[*n*]ferrocenophanes[13] and the complex of 1,1′-bis(diphenylphosphino)ferrocene with $HgCl_2$.[18]

Experimental

The melting points are uncorrected. The IR spectra were taken on a Hitachi 270-50 Infrared Spectrometer. The ^1H and ^{13}C NMR spectra were measured on a JEOL FX-90Q Spectrometer, TMS being chosen as the standard material. The electronic spectra were taken on a Hitachi 340 spectrometer. The Mass spectra were measured on a Hitachi M-80B spectrometer.

Materials. 1,4,7-Trithia[7]ferrocenophane (**1**) was previously reported.[8] Mercury(II) chloride, silver(I) tetrafluoroborate, and copper(II) tetrafluoroborate hydrate were commercially available. Tetrakis(acetonitrile)copper(I) perchlorate[19] and dichlorobis(acetonitrile)palladium(II)[20] were prepared according to methods described in the literature.

1,5,9-Trithia[9]ferrocenophane (2). Sodium sulfide nonahydrate (3.6 g, 15 mmol) was dissolved in ethanol (650 cm^3). To the solution was added a solution of 1,1′-bis(3-chloropropylthio)ferrocene[8] (2.0 g, 5 mmol) in tetrahydrofuran (120 cm^3). The mixture was refluxed for 24 h under a nitrogen atmosphere. After evaporation under reduced pressure, the residue was dissolved in water. The mixture was extracted with benzene and the extract was dried over anhyd sodium sulfate. After evaporation under reduced pressure, the residue was chromatographed on silica gel by the elution of hexane-toluene (1:1) and, subsequently, toluene. The following products were separated.

1,5-Dithia[5]ferrocenophane.[9] Yield 28 mg (1.9%).

1,5,9-Trithia[9]ferrocenophane (2). Red orange crystals, mp 69—70 °C (recrystallization from cyclohexane). Yield 0.96 g (53%). Found: C, 52.74; H, 5.74%. Calcd for $C_{16}H_{20}S_3Fe$: C, 52.74; H, 5.53%. MS: *m/z* 364 (M^+). ^{13}C NMR ($CDCl_3$) 87.5 (C_b), 71.2 (C_α), 67.7 (C_β), 33.9 (SCH_2), 31.1 (SCH_2), and 29.6 (CH_2).

1,5,9,21,25,29-Hexathia[9.9]ferrocenophane. Yellow orange needles, mp 102—103 °C (recrystallization from benzene). Yield 0.32 g (8.6%). Found: C, 52.77; H, 5.60%. Calcd for $C_{32}H_{40}S_6Fe_2$: C, 52.74; H, 5.53%. MS: *m/z* 728 (M^+). IR (KBr): 3080, 1418, 1190, 1022, and 810 cm^{-1}. ^1H NMR ($CDCl_3$) δ=4.34 (t, *J*=1.6 Hz, 4H), 4.28 (t, *J*=6.8 Hz, 4H), 2.74 (t, *J*=6.8 Hz, 4H), 2.63 (t, *J*=7.5 Hz, 4H), and 1.83 (p, 4H).

(1,4,7-Trithia[7]ferrocenophane)copper(I) Perchlorate (3b). To a solution of **1** (34 mg, 0.1 mmol) in hot anhyd acetonitrile (2 cm^3) was added tetrakis(acetonitrile)copper(I) perchlorate (33 mg, 0.1 mmol). After tetrakis(acetonitrile)-copper(I) perchlorate had been dissolved, the solution was filtered. The filtrate was diluted with anhyd diethyl ether (5 cm^3) to form orange crystals. After the mixture had been kept for 2 h in a refrigerator, the crystals were collected by filtration. Orange needles. Yield 36 mg (72%). This compound was very explosive on heating. ^{13}C NMR ($CDCl_3$) 69.8 (C_α), 69.2 (C_β), 37.0 (SCH_2), and 34.9 (SCH_2).

(1,4,7-Trithia[7]ferrocenophane)copper(I) Tetrafluoroborate (3a). Copper(II) tetrafluoroborate hydrate (18 mg, 0.075 mmol) and excess copper powder were refluxed in anhyd acetonitrile (5 cm^3) for 1 h under nitrogen and then the mixture was filtered. To the filtrate was added **1** (50 mg, 0.15 mmol) and the mixture was refluxed for 0.5 h. After being cooled to room temperature, the solution was diluted

with anhyd diethyl ether (20 cm^3) to form orange crystals. The mixture was kept overnight in a refrigerator, and the resulting crystals were collected by filtration. Orange needles (63 mg, 86.4%), mp ~230 °C (decomp). Found: C, 36.56; H%, 3.53%. Calcd for $C_{14}H_{16}BF_4S_3FeCu \cdot CH_3CN$: C, 36.42; H, 3.63%. ^{13}C NMR (CD_3CN) 91.1 (C_b), 69.8 (C_α), 69.0 (C_β), 36.9 (SCH_2), and 35.0 (SCH_2).

(1,4,7-Trithia[7]ferrocenophane)silver(I) Tetrafluoroborate (4). To a hot solution of **1** (34 mg, 0.1 mmol) in acetonitrile (2 cm^3) was added to a hot solution of silver(I) tetrafluoroborate (20 mg, 0.1 mmol) in acetonitrile (1 cm^3). The resulting solution was filtered and the filtrate was diluted with anhyd diethyl ether (10 cm^3). The solution was kept overnight in a refrigerator. The title compound **4** (43 mg, 81%) was obtained as yellow orange needles, mp 195 °C (decomp). Found: C, 31.61 H, 2.99%. Calcd for $C_{14}H_{16}BF_4S_3FeAg$: C, 31.67; H, 3.04%. ^{13}C NMR (CD_3CN) 91.3 (C_b), 69.6 (C_α), 68.6 (C_β), 35.3 (SCH_2), and 32.5 (SCH_2).

(1,5,9-Trithia[9]ferrocenophane)(acetonitrile)silver(I) Tetrafluoroborate (5). To a solution of **2** (100 mg, 0.27 mmol) in anhyd acetonitrile (7 cm^3) was added a solution of silver(I) tetrafluoroborate (53 mg, 0.27 mmol) in anhyd acetonitrile (3 cm^3). The resulting dark red-brown solution was filtered and then diluted with anhyd diethyl ether (35 cm^3). After the solution had been kept in a refrigerator, the resulting crystals were collected by filtration. The complex **5** (108 mg, 66%) was obtained as yellew plates, mp 115 °C (decomp). Found: C, 36.06; H, 3.97%. Calcd for $C_{16}H_{20}BF_4FeAg \cdot C_2H_3N$: C, 36.03; H, 3.86%.

Dichloro(1,4,7-Trithia[7]ferrocenophane)mercury(II) (6). To a solution of **1** (68 mg, 0.2 mmol) in anhyd diethyl ether (4 cm^3) was added a solution of mercury(II) chloride (55 mg, 0.2 mmol) in anhyd diethyl ether (4 cm^3). The solution was stirred for 15 min. The resulting crystals were collected by filtration. Light orange crystals (104 mg, 85%), mp 121 °C (decomp). Found: C, 28.02; H, 2.58%. Calcd for $C_{14}H_{16}Cl_2S_3FeHg$: C, 27.67; H, 2.65%.

Dichloro(1,5,9-trithia[9]ferrocenophane)mercury(II) (7). To a solution of **2** (200 mg, 0.55 g) in anhyd diethyl ether (25 cm^3) was added a solution of mercury(II) chloride (136 mg, 0.5 mmol) in anhyd diethyl ether (20 cm^3). The solution was refluxed for 30 min and then kept overnight in a refrigerator. The title compound **7** (257 mg, 81%) was obtained as red fine crystals, mp 115—116 °C (decomp). Found: C, 30.29; H, 3.46%. Calcd for $C_{16}H_{20}Cl_2FeHg$: C, 30.22; H, 3.17%.

Dichloro(1,4,7-trithia[7]ferrocenophane)palladium(II) (8). To a solution of **1** (36 mg, 0.1 mmol) in hot acetonitrile (5 cm^3) was added a solution of dichlorobis(acetonitrile)-palladium(II) (26 mg, 0.1 mmol) in hot acetonitrile (5 cm^3). The solution was kept for 1 h at room temperature. The resulting crystals were collected by filtration. Greenish black crystals (41 mg, 80%), mp~300 °C. Found: C, 32.95; H, 3.15%. Calcd for $C_{14}H_{16}Cl_2S_3FePd$: C, 32.74; H, 3.15%.

Dichloro(1,5,9-trithia[9]ferrocenophane)palladium(II) (9). To a solution of **2** (180 mg, 0.5 mmol) in hot acetonitrile (20 cm^3) was added a solution of dichlorobis(acetonitrile)-palladium(II) (130 mg, 0.5 mmol). The solution was kept overnight in a refrigerator. The resulting violet fine powder (**10**) was collected by filtration. Yield: 105 mg (39%). Mp ~250 °C. Found: C, 33.77; H, 3.65%. Calcd for $(C_{16}H_{20}Cl_2S_3FePd)_n$: C, 35.48; H, 3.72%.

The filtrate was kept for several days in a freezer. The resulting black-brown crystals were filtered and washed with acetonitrile. Yield 102 mg (38%). Mp 235 °C (decomp). Found: C, 35.71; H, 3.72%. Calcd for $C_{16}H_{20}Cl_2S_3FePd$: C, 35.48; H, 3.71%.

We thank Prof. Izumi Motoyama and Prof. Motomi Katada for measurement of Mössbauer spectra. The present work was supported by a Grant-in-Aid for Science Research (No. 61540362) from the Ministry of Education, Science and Culture.

(Received May 29, 1986)

Selenium tetrachloride($SeCl_4$) reacts smoothly with alcohols in various nonpolar solvents to give the corresponding alkyl chlorides in 44—97% yield. Similar reaction also proceeds with tellurium tetrachloride ($TeCl_4$), while the treatment of benzyl, 1-phenylethyl, and *t*-butyl alcohols with $TeCl_4$ in aromatic solvents results in a high yield formation of alkylated aromatics instead of alkyl chlorides. Such Friedel-Crafts aromatic alkylation hardly occurs in the $SeCl_4$ case. The chlorinating species is not chlorine which might be evolved by dissociation of $SeCl_4$ or $TeCl_4$, but the metal chloride itself. The conversion of optically active (*R*)-(+)-1-phenylethanol to 1-phenylethyl chloride proceeds with nearly complete racemization.

During a search for direct aryl migration method of 2-hydroxypropiophenones to 2-arylpropionic acids by various sulfur, selenium, and tellurium reagents[1] we came across the replacement of hydroxyl group by chlorine when the ketones were treated with selenium or tellurium tetrachloride ($SeCl_4$ or $TeCl_4$). Although $SeCl_4$ has been known as chlorinating agent of olefins,[2] acetylenes,[3] and isocyanides,[3] there is no precedent for the use of $TeCl_4$ as chlorinating agent as well as the reactions of each reagent with alcohols to our knowledge.[4] In order to know the scope and limitation of this replacement reaction the reactions of typical primary, secondary, and tertiary alcohols with $SeCl_4$ or $TeCl_4$ were carried out in various solvents. It is worthwhile to note that selenium tetrafluoride is known to react with alcohols to give the corresponding alkyl fluorides in good yields.[5] During this study we also disclosed that $TeCl_4$, but not $SeCl_4$, works as a mild Lewis acid catalyst for aromatic alkylation. We report here the details of our new findings.

Results and Discussion

Conversion of Alcohols to Alkyl Chlorides by $SeCl_4$ or $TeCl_4$. Treatment of 1- and 2-phenylethanols, diphenylmethanol, triphenylmethanol, and 1- and 2-octanols with $SeCl_4$ in toluene, dichloromethane, or 1,2-dichloroethane as solvent at 25—60 °C for 1.5—15 h afforded the corresponding alkyl chlorides respectively in 44—97% yield. The addition of amine sometimes improved the product yield. Selenium tetrafluoride-pyridine complex is known to be a good fluorinating agent of alcohols.[5] Similar treatment with $TeCl_4$ also gave alkyl chlorides in 65—86% yield, but the addition of triethylamine or pyridine resulted in lowering the product yield probably because of the

Table 1. Conversion of Alcohols to Alkyl Chlorides Using $SeCl_4$ or $TeCl_4$

R in **1** (2 mmol)	$SeCl_4$ or $TeCl_4$ (2.4 mmol)	Base (equiv)[a]	Solvent (4 ml)	Temp/°C	Time/h	Products/%[b]

$PhCHCH_3$[d]	$SeCl_4$[$TeCl_4$]	Et_3N(1.0)	CH_2Cl_2	25	1.5	96[e][39][e]	—[f][7][e]
Ph_3C	$SeCl_4$[$TeCl_4$]		CH_2Cl_2	25	15	95[77]	3[3]
Ph_3C	$SeCl_4$[$TeCl_4$]	C_5H_5N(1.2)	CH_2Cl_2	25	15	92[22]	2[64]
1-C_8H_{17}	$SeCl_4$[$TeCl_4$]		$ClCH_2CH_2Cl$	60	2	92[2]	0[98]
2-C_8H_{17}	$SeCl_4$[$TeCl_4$]		$ClCH_2CH_2Cl$	60	2	49[71]	22[0]

a) Equivalent to $SeCl_4$ or $TeCl_4$. b) GLC yield based on **1** charged unless otherwise stated. c) *N*,*N*-Dimethylformamide-toluene (2 ml-2 ml). d) **1** (30 mmol), $SeCl_4$ or $TeCl_4$ (36 mmol), and solvent (60 ml) were used. e) Isolated yield. f) Not determined.

formation of too stable adducts between $TeCl_4$ and the amine.[6] Applicability of the reaction with $TeCl_4$ for this conversion seems to be more limited than that with $SeCl_4$ from the following observations: 1) Primary alcohols such as 1-octanol and 1-butanol were almost recovered intact, 2) secondary alcohols sometimes reacted very slowly; e.g., 2-butanol gave *s*-butyl chloride in less than 20% yield even under somewhat severe conditions, and 3) in toluene as solvent aromatic alkylation often predominated (vide infra). Typical results are shown in Table 1.

$$\underset{1}{R\text{-}OH} \xrightarrow[\text{solvent}]{SeCl_4 \text{ or } TeCl_4} \underset{2}{R\text{-}Cl}$$

It is knwon that $SeCl_4$ is almost completely dissociated to lower chlorides and chlorine in the vapor, while there is little such dissociation in the case of $TeCl_4$.[7] In order to know whether a true chlorinating species is $SeCl_4$ itself or chlorine evolved by dissociation in the liquid phase, the reaction of 1-phenylethanol with $SeCl_4$ in dichloromethane was compared with that with chlorine gas. As a result it was revealed that in the chlorine case the reaction is slow and always accompanied by the formation of 1-chloroacetophenone (**3**), while only the expected 1-phenylethyl chloride, **2** (R=PhCHCH$_3$), is obtained quantitatively in the $SeCl_4$ case (Table 2). These results show $SeCl_4$ itself to be a reactive species for this conversion in accord with the observation obtained so far in the liquid-phase chlorination of various olefins with $SeCl_4$.[2]

$$\underset{\substack{\text{1(R=PhCHCH}_3\text{)}}}{\text{PhCHOH}\ (\text{CH}_3)} \xrightarrow[CH_2Cl_2]{SeCl_4 \text{ or } Cl_2} \underset{\substack{\text{2(R=PhCHCH}_3\text{)}}}{\text{PhCHCl}\ (\text{CH}_3)} + \underset{\substack{\mathbf{3}}}{\text{PhCCH}_2\text{Cl}\ (\text{O})}$$

Next, the stereochemistry of this conversion to alkyl chlorides was investigated using almost optically pure (*R*)-(+)-1-phenylethanol as follows. Treatment of the alcohol with $SeCl_4$ in toluene at 25 °C for 6 h afforded 1-phenylethyl chloride in 90% isolated yield which did not show any optical activity. The reaction of the alcohol with $TeCl_4$ in dichloromethane at −50 °C for 6 h produced the chloride in 89% isolated yield, optical rotation $[\alpha]_D^{20}$ of which being −0.5° (optical purity, 0.5%; inversion), while similar reaction at 25 °C for 48 h in the presence of pyridine gave the chloride of $[\alpha]_D^{20}$ +1.6° in 18% isolated yield (optical purity, 1.5%; retention). These results show that the replacement of hydroxyl group by chlorine with either $SeCl_4$ or $TeCl_4$ proceeds with nearly complete racemization in the case of 1-phenylethanol.

From experimental observations described above an S_Ni like reaction scheme may be conceivable for this chlorination at least in the cases of secondary and tertiary alcohols as exemplified using 1-phenylethanol as a substrate as follows.

$$\text{PhCHOH}\ (\text{CH}_3) \xrightarrow[-HCl]{MCl_4} \left[\text{PhCH}(\text{CH}_3)\text{-O}(MCl_3)\right] \xrightarrow{-MOCl_3^-} \left[\text{PhCH}^+(\text{CH}_3)\right] \xrightarrow[-MOCl_2]{MOCl_3^-} \text{PhCHCl}\ (\text{CH}_3)$$

(M=Se,Te)

Friedel-Crafts Alkylation Catalyzed by $TeCl_4$. When the reaction of 1-phenylethanol with $TeCl_4$ was carried out in toluene as solvent at 25 °C, the product was not the expected 1-phenylethyl chloride but an isomeric mixture of 1-phenyl-1-tolylethanes (**4**) in a sharp contrast to the reaction with $SeCl_4$ under similar conditions. On the other hand, the same reaction at −50 °C afforded mainly 1-phenylethyl chloride. This fact suggests that the alkyl chloride initially produced further reacts with aromatic solvent at higher temperature and $TeCl_4$ works as a Lewis acid catalyst. In fact, this was confirmed by a separate experiment using 1-phenylethyl chloride and a catalytic amount of $TeCl_4$ which revealed the formation of **4** of the same isomer ratio as that obtained directly from 1-phenylethanol. Namely, $TeCl_4$ worked as a reagent for the conversion of alcohols to alkyl chlorides and then as a catalyst for aromatic alkylation. Similar phenomenon was also observed in the reactions using *t*-butyl alcohol and *t*-butyl chloride as substrates, an equivalent and a catalytic amount of $TeCl_4$ being required in the former and the latter case respectively. The alkylation using 1-phenylethanol could be applied to other aromatic compounds such as benzene, *p*-xylene, and anisole to produce 1-phenylethylated aromatics, **7**—**10**, in moderate yields. One of the characteristic features of the reaction is the formation of only o- and p-isomers from toluene and

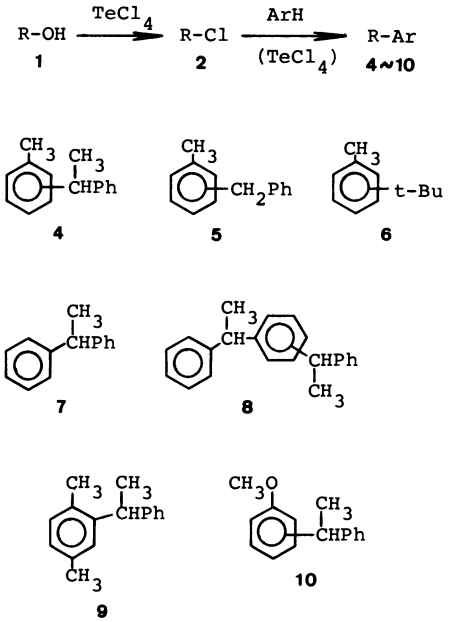
anisole, none of m-isomer being produced. In the case of benzene as solvent the initially formed product, 1,1-diphenylethane (**7**), was far more reactive than benzene itself and alkylated further to give dialkylated benzene **8** highly selectively. Typical results are summarized in Table 3. The catalytic activity of $TeCl_4$ seems to be not so strong, as alkylation proceeded only with very reactive (benzyl, 1-phenylethyl, *t*-butyl etc.) alcohol or chloride and even *s*-butyl chloride did not alkylate toluene under similar conditions. It has been known that $TeCl_4$[8] and tellurium(IV) oxide(TeO_2)[9] work as a mild catalyst for aromatic acylation and alkylation respectively. However, no data are so far available on the catalytic activity of $TeCl_4$ for Friedel-Crafts aromatic alkylation. We are sure that this is a first example of $TeCl_4$ working as Friedel-Crafts alkylation catalyst, though its activity is mild.



Experimental

General. ^1H NMR spectra were recorded with JEOL FX-90Q (90 MHz) instrument on solutions in $CDCl_3$ with Me_4Si as an internal standard. GLC analyses were carried out with a Shimadzu 4CMPF apparatus using Thermon-1000(5% or 0.5%)-Chromosorb-W(3 mm×3 m or 1.5 m), SILAR-10C(5%)-Chromosorb-W(3 mm×1 m), PEG 20 M(10%)-Chromosorb-W(3 mm×2 m), Silicone CBP 5-M-25-025(0.2 mm×25 m), and Silicone OV-101(0.24 mm×30 m) columns (N_2 as carrier gas). Optical rotations were measured on a UNION PM-201 automatic polarimeter. All organic and inorganic materials were commercial products of the purest grade and used without further purification. Authentic samples of **2** were all commercially available for GLC analyses.

Conversion of Alcohols to Alkyl Chlorides by $SeCl_4$ or $TeCl_4$ (Table 1). A typical experimental procedure is as follows. To a solution of 2-phenylethanol, [**1**(R=$PhCH_2CH_2$)], (0.244 g, 2 mmol) in toluene (4 ml) was added selenium tetrachloride (0.533 g, 2.4 mmol) and the resulting mixture was stirred at 50 °C for 4 h. After being cooled down to room temperature, the mixture was added with water (6 ml) and stirred for 0.5 h. The precipitated red-brown solids were filtered off. The organic layer was separated, washed with brine (3 ml), and dried ($MgSO_4$). GLC analysis using Thermon-1000(5%)-Chromosorb-W(3 mm×3 m) column and propiophenone as an internal standard revealed the presence of 2-phenylethyl chloride, [**2**(R=$PhCH_2CH_2$)], (0.88 mmol, 44%) and unreacted 2-phenylethanol (0.48 mmol, 24%). The reactions with $TeCl_4$ were similarly carried out. In the case of 1-phenylethanol the experiment of 15 times scale was carried out and the product 1-phenylethyl chloride was isolated by distillation.

Reaction of 1-Phenylethanol[1(R=$PhCHCH_3$)] with Chlorine (Table 2). To a solution of chlorine (3.06 g, 43.2 mmol) in dichloromethane (30 ml) was added 1-phenylethanol[**1**(R=$PhCHCH_3$)] (3.67 g, 30 mmol) at −50 °C and the mixture was stirred at the same temperature for 4.5 h. After the addition of 10% aqueous sodium thiosulfate (20 ml) the resulting solution was stirred at room temperature for 0.5 h. The organic layer was separated, washed with brine (10 ml×2), and dried ($MgSO_4$). Evaporation of the solvent left an oily residue which was subjected to column chromatography on SiO_2 [hexane-ethyl acetate (20:1) as eluent] to give 1-phenylethyl chloride [**2**(R=

$PhCHCH_3$)] (0.10 g, 0.71 mmol, 2.4% yield), 1-chloroacetophenone (**3**) (0.73 g, 4.72 mmol, 15.7% yield) and the starting **1**(R=$PhCHCH_3$) (2.74 g, 22.5 mmol, 74.9% yield), respectively.

Treatment of Optical Active Alcohol with $SeCl_4$ or $TeCl_4$. A typical example is as follows. To a solution of commercially available optical active (*R*)-(+)-1-phenylethanol($[\alpha]_D^{20}$ +42°, 1.00 g, 8.19 mmol) in dichloromethane (10 ml) was added tellurium tetrachloride (2.65 g, 9.84 mmol) at −50 °C; the reported maximum optical rotation of the alcohol is $[\alpha]_D^{25}$ +43.4°.[10] The resulting mixture was stirred at the same temperature for 6 h. The mixture was then added with water (20 ml) and stirred at room temperature for 10 min. The precipitated white solids were filtered off. The organic layer was separated, washed with brine (20 ml) and dried ($MgSO_4$). Evaporation of the solvent left an oily residue which was distilled in vacuo to give 1-phenylethyl chloride (1.02 g, 7.26 mmol, 88.6% yield) at bp 64 °C/8 mmHg (1 mmHg=133.322 Pa). It shows the optical rotation of $[\alpha]_D^{20}$ −0.5°, the value corresponding to the optical purity of 0.5% calculated from $[\alpha]_D^{20}$ +109° of optically pure (*R*)-(+)-1-phenylethyl chloride.[11]

Friedel-Crafts Aromatic Alkylation Catalyzed by $TeCl_4$ (Table 3). A typical experimental procedure starting from alcohol is as follows. To a solution of 1-phenylethanol, **1**(R=$PhCHCH_3$), (3.7 g, 30 mmol) in toluene (30 ml) was added slowly tellurium tetrachloride (9.7 g, 36 mmol) keeping the reaction temperature at 25 °C (exothermic reaction). Small amounts of white precipitates appeared immediately and then the color of the mixture turned dark-brown in a few minutes. The mixture was stirred for 3 h and then quenched with water (20 ml). The organic layer was separated, washed with brine (20 ml×2) and dried ($MgSO_4$). Evaporation of the solvent left an oily residue which was distilled in vacuo to afford a mixture of 1-phenyl-1-tolylethanes (**4**)(4.9 g, 25 mmol, 83.3% yield) at bp 117—128 °C/1 mmHg. GLC analysis of **4** using Silicone OV-101 (0.24 mm×30 m) capillary column at 100→260 °C (4 °C min^{-1}) revealed the presence of two isomers of ortho/para=12/88: ^1H NMR, para-isomer, δ=1.57 (d, J=7 Hz, 3H), 2.26 (s, 3H), 4.07 (q, J=7 Hz, 1H), 7.05 (m, 4H), 7.18 (m, 5H); ortho-isomer, 2.19 (s, 3H). Found: C, 91.92; H, 8.08%. Calcd for $C_{15}H_{16}$: C, 91.78; H, 8.22%.

Analytical data of other alkylated aromatics are as follows.

Benzyltoluenes (5): A colorless liquid of o/p=35/65 by ^1H NMR; ^1H NMR, para-isomer, δ=2.40 (s, 3H), 4.02 (s, 2H), 7.14—7.28 (m, 9H); ortho-isomer, 2.35 (s, 3H), 4.06 (s, 2H).

***t*-Butyltoluenes (6):** A colorless liquid, bp 38 °C/1 mmHg; ^1H NMR δ=1.25 (s, 9H), 2.24 (s, 3H), 6.98 (d, 2H), 7.17 (d, 2H). The isomer ratio (o/p) was determined by GLC using Silicone OV-101 capillary column as 1/99.

1,1-Diphenylethane (7): A colorless liquid isolated by column chromatography on SiO_2 (hexane as eluent); ^1H NMR δ=1.57 (d, 3H), 4.03 (q, 1H), 6.92—7.32 (m, 10H).

Bis(1-phenylethyl)benzenes (8): A colorless liquid isolated by column chromatography on SiO_2 (hexane as eluent), o/p=24/76 by ^1H NMR; ^1H NMR, para-isomer, δ=1.65 (d, 6H), 4.87 (q, 2H), 6.88—7.24 (m, 14H); ortho-isomer, 1.46 (d, 6H), 3.95 (q, 2H).

1,4-Dimethyl-2-(1-phenylethyl)benzene (9): A colorless liquid, bp 129 °C/2 mmHg; ^1H NMR, δ=1.55 (d, 3H), 2.13 (s, 3H), 2.47 (s, 3H), 4.22 (q, 1H), 6.80—7.24 (m, 8H).

(1-Phenylethyl)anisoles (10): A colorless liquid of o/p=17/83 by ^1H NMR, bp 156 °C/5 mmHg; ^1H NMR, para-isomer, δ=1.58 (d, 3H), 3.71 (s, 3H), 4.05 (q, 1H), 6.68—7.20 (m, 9H); ortho-isomer, 1.55 (d, 3H).

Enzymatic Esterolysis of Polymers Containing 2-Biphenylyl Ester Bonds in Side Chains

Tomomichi Ishikawa,* Makoto Otsuki, and Toshiaki Iwatsuki
Department of Industrial Chemistry, Fucalty of Technology, Tokyo Metropolitan University, Fukasawa, Setagaya-ku, Tokyo 158
(Received June 4, 1986)

The preparation and α-chymotrypsin-catalyzed esterolysis of polymeric substrates anchoring fungicidal biphenyl-2-ol are described. In order to obtain information regarding the influence of one type of polymeric backbone and the distance between a cleavable bond and a polymer main chain, poly(2-biphenylyl acrylate), poly(2-biphenylyl methacrylate), and poly(methacryloylamino acid 2-biphenylyl ester)s were studied. The esterolysis were evaluated by means of Michaelis constant K_m and the catalytic reaction rate constant $k_{cat.}$ Poly(2-biphenylyl methacrylate) was a more suitable substrate than poly(2-biphenylyl acrylate). Poly[6-(methacryloylamino)hexanoic acid 2-biphenylyl ester] was the most suitable substrate in a series of polymers containing amino acid side chains with 2-biphenylyl ester terminal groups. The release rate of biphenyl-2-ol could also be controlled by using copolymers with an appropriate comonomer.

The use of polymers in drug delivery systems has recently received a great deal of attention.[1-5] The mildew defacement of water-soluble paints and their coatings has been a serious problem in the paint industry and for keeping of a good life environment. In connection with this problem, Pittman and co-workers[6,7] examined the biological properties of film-forming polymers with chemically attached biocides using microbiological accelerated fungus-growth tests. In a previous paper[8] we reported on the kinetics of the chymotrypsin-catalyzed hydrolytic cleavage of free biphenyl-2-ol (fungicides, abbreviated to BPOL) from ester groups in the side chains of homopolymer and copolymers with various comonomers in order to simulate microbiological degradation. Kopecek and co-workers[9] also reported on the kinetics of the enzymatic cleavage for the copolymers of various 4-nitroanilides of methacryloylamino acids or origopeptides with *N*-(2-hydroxypropyl)methacrylamide. On the other hand, Kloss and Schröder[10] reported on the hydrolysis of 51 kinds of peptides alkyl esters by chymotrypsin and trypsin. These results suggest that one type of carboxylic acid which forms cleavable ester bonds affects the enzymatic cleavage rates. Therefore, this paper describes the influence of the structure of a polymer main chain and the distance between a cleavable bond and the main chain upon the kinetics of the enzymatic cleavage of polymers **1**, **2**, and **3a—c**.

3a m = 1
3b m = 2
3c m = 5

Experimental

Materials. Methacryloyl chloride was distilled prior to use. BPOL and dicyclohexylcarbodiimide (DCC) were purified by distillation. Solvents were dried by the usual methods and distilled. The α-chymotrypsin was the same as in a previous paper,[8] and its activity was checked at the bigining of the experiments. Other chemicals were of reagent grade.

Monomer Preparation. 2-Biphenylyl acrylate (BPA) was prepared according to a method described in a previous paper.[11]

2-Biphenylyl methacryloylaminoacetate (BPMAA-1) was prepared by the esterification of *N*-methacryloylglycine[9,10] with BPOL in the presence of DCC in a way similar to that of a known procedure.[12] Yield 12.3%; mp 131.5—132.9 °C; IR (KBr) 3310 (NH), 1765 (C=O), 1650 (C=O), 1610 (C=C), 760, 730, and 700 cm^{-1}; ^1H NMR (DMSO-d_6) δ=1.90 (3H, s, CH_3), 4.02 (2H, d, CH_2), 5.39 (H, s, CH=), 5.83 (H, s, CH=), 7.30—7.75 (9H, m, Aromatic) and 8.54 (H, broad, NH).

2-Biphenylyl 3-(methacryloylamino)propionate(BPMAA-2) was prepared by the esterification of 3-(methacryloylamino)propionic acid with BPOL in the presence of DCC.[12] Yield 16.3%; mp 88—88.5 °C; IR (KBr) 3340 (NH), 1740 (C=O), 1645 (C=O), 1610 (C=C), 770, 740, and 700 cm^{-1}; ^1H NMR (DMSO-d_6) δ=1.81 (3H, s, CH_3), 2.53 (2H, t, CH_2), 3.39 (2H, q, CH_2), 5.15 (H, s, CH=), 5.45 (H, s, CH=), 6.00 (H, broad, NH) and 7.00—7.40 (9H, s, Aromatic).

2-Biphenylyl 6-(methacryloylamino)hexanoate(BPMAA-5) was prepared by the esterification of BPOL with 6-(methacryloylamino)hexanoic acid[9] in the presence of DCC.[12] Yield 57.1%; mp 64.7—66.0 °C; IR (KBr) 3350 (NH), 1710 (C=O), 1650 (C=O), 1600 (C=C), 750 and 700 cm^{-1}; ^1H NMR (DMSO-d_6) δ=0.90—1.80 (6H, m, $3CH_2$), 1.83 (3H, s, CH_3), 2.23 (2H, t, CH_2), 3.05 (2H, q, CH_2), 5.25 (H, s, CH=), 5.61 (H, s, CH=), 7.10—7.60 (9H, m, Aromatic) and 8.13 (H, broad, NH).

General Procedure for Polymerization. All polymerization experiments were carried out in a hot oil bath at 60 °C using a solution-polymerization technique (in toluene) in the presence of 1 mol% AIBN. The mixtures were poured into methanol. The obtained polymers were dissolved in toluene and precipitated into methanol. The precipitation was repeated, and the polymer was dried in a vaccum oven at 40 °C.

Synthesis of Model Compounds. 2-Biphenylyl propionate (BPP) was obtained by a reaction of BPOL with propionyl chloride.[8]

2-Biphenylyl isobutyrate(BPIB) was obtained by the reaction of BPOL with isobutyryl chloride.[8] Yield 19.0%; bp 155—160 °C (665 Pa); ^{1}H NMR (DMSO-d_6) δ=0.99 (6H, d, 2CH$_3$), 2.41 (1H, m, CH) and 6.95—7.50 (9H, m, Aromatic).

2-Biphenylyl pivalate (BPPV) was obtained by the reaction of BPOL with pivaloyl chloride.[8] Yield 69.3%; bp 114.0 °C (133 Pa); ^{1}H NMR ($CDCl_3$) δ=1.11 (9H, s, 3CH$_3$), 7.00—7.60 (9H, m, Aromatic).

Rate of Esterolysis with α-Chymotrypsin. An esterolysis of monomeric and polymeric substrates was carried out in 50 cm^3 of a buffer solution (0.08 mol dm^{-3} 2-amino-2-hydroxymethyl-1,3-propanediol (Tris) and 0.1 mol dm^{-3} $CaCl_2$ adjusted with HCl to pH=8.0) in the presence of 2.8 mg α-chymotrypsin. For each experiment a substrate converted into 0.15—1.0 mmol dm^{-3} BPOL was used. The reactions were carried out at 25 °C with a regulated water bath. The reaction mixture was continuously shaken. After a given time, some part of this mixture was removed and then the detection of released BPOL was performed by UV at 240.0 nm. The degree of conversion was evaluated by observing the difference between the absorbance at time zero and t.

Results and Discussion

Polymeric substrates anchoring BPOL were obtained by the polymerization of vinyl monomers in proportion to the structure of their polymer units. In order to observe the influence of the structure of a polymer backbone on the rate of esterolysis of a 2-biphenylyl ester bond in a side chain, polymer **2** was obtained by the polymerization of BPA,[11] and its reactivity during esterolysis was compared with that for polymer **1**.[8] On the other hand, it is known that the hydrolysis rate for a cleavable bond at the end of a side chain is affected by the distance between the cleavable site and the polymer backbone.[9,13] Therefore, some methacryloylamino acid 2-biphenylyl esters were synthesized and polymerized; then their polymers were hydrolyzed. We chose an amino acid such as glycine, 3-aminopropionic acid, and 6-aminohexanoic acid as a spacer of side chains in polymeric substrates. Some monomeric model compounds were also synthesized for a comparison with the polymeric substrates. The abbreviation of the monomers and model compounds are shown in Fig. 1.

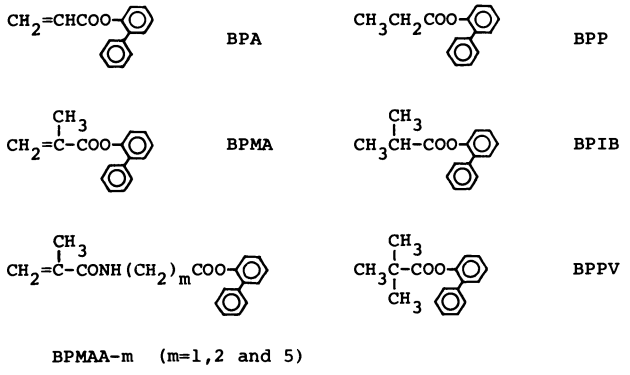

Fig. 1. Abbreviation of 2-biphenylyl esters.

The monomeric and polymeric substrates were hydrolyzed with α-chymotrypsin in a Tris-buffer solution (pH 8). The amount of released BPOL was periodically determined using UV.[8] It is well-known that a chymotrypsin-catalyzed reaction can be expressed by the equation of Michaelis-Menten[14]; thus, the Michaelis constant K_m and the maximum reaction rate V_{max} were determined by a method of Lineweaver and Burk[15] from the relation between the initial reaction rate and the initial concentration of the substrate.

The results for polymer **1** and **2** and the model compounds are summarized in Table 1. It is quite evident from Table 1 that the values of K_m and k_{cat} for the model compounds are in the order BPIB>BPP>BPPV. The order of BPIB and BPP agree with those of the Hammett-Taft's σ^* values. However, no systematic structural correlation was found between BPPV and the others. The small values of K_m and k_{cat} for the BPPV indicate that an enzyme-substrate complex formed is more stable in comparison with those for the others. This can be attributed to the significantly large hydrophobic and steric properties of the t-butyl group. The enzyme was also inactivated

Table 1. α-Chymotrypsin-Catalyzed Esterolysis of Monomeric and Polymeric Substrates

Substrate	Yield / %	K_m 10^3 / mol dm^{-3}	V_{max} 10^5 / mol dm^{-3} h^{-1}	k_{cat}[a] / h^{-1}	k_{cat}/K_m / l mol^{-1} h^{-1}
BPP	64.0	0.89	74	330	370000

3a	12.3		No change		
3b	95.3	0.93	1.0	4.5	4800
3c	57.1	0.63	7.2	32.1	51000

a) Calculated by using a value of 25000 as the molecular weight of α-chymotrypsin. b) Reported in the previous paper (Ref. 8).

owing to a so-called product inhibition[16,17] of pivalic acid which was formed while hydrolyzing BPPV. This result suggests that the reactivity of the substrates is affected by the alkyl groups adjoining to the cleavable bond. As shown in Table 1, both K_m and k_{cat} for polymer **1** is larger than those for polymer **2**, and that the reactivity of the polymeric substrates with α-chymotrypsin varies with the structure of the polymeric main chain. Both K_m and k_{cat} indicate that the formation of the enzyme-polymer **2** complex is easier than that for the polymer **1**; however, the reactivity of the polymer **2**-complex is lower than that of the polymer **1**-complex. When the kinetic parameters for the polymeric substrates is compared with those for the monomeric substrates, the former gave almost the same K_m value as with the latter; a remarkably large difference was observed in the k_{cat} values. The reactivity of chymotrypsin-catalyzed hydrolysis can be estimated by a k_{cat}/K_m value.[18] The high k_{cat}/K_m value for polymer **1** indicates that this polymeric structure is more useful than that of polymer **2**.

The results of the enzymatic hydrolysis of the polymeric substrates containing amino acid side chains with 2-biphenylyl ester terminal groups are also presented in Table 1. It can be seen from Table 1 that no BPOL is released from the glycine 2-biphenylyl ester terminals in polymer **3a**. This is in agreement with the resistance of glycine ethyl ester,[10] *N*,*N*-succinylglycine 4-nitroanilide and the polymer with glycine 4-nitroanilide terminals.[9] Although the k_{cat} values are in the order of polymer **3b**<**1**<**3c**, the values of K_m and k_{cat}/K_m indicate that the general influence of the spacer become greater with an increase in the number of methylene groups. From these results, it seems that the reactivity of the substrates depends on the stability of enzyme-substrate complexes. In the polymeric substrates, the complex of polymer **3c** with enzyme is easily formed and shows a high reactivity: Namely, that the Michaelis constant K_m is the lowest and the reaction rate constant k_{cat} is the highest value of the series. Kopecek and coworkers[9] examined the necessity of a spacer having a certain length for the cleavage of polymers with amino acid 4-nitroanilide terminals. He concluded that in the case of chymotrypsin the spacer must be at least 6-atoms long. In this study the result for polymer **3d** was in agreement with their conclusion.

Table 2. Additional Effect of 3-(Methacryloylamino)-propionic Acid (MAA-2) in Esterolysis of BPMAA-2

BPMAA-2 / mol dm^{-3}	MAA-2 / mol dm^{-3}	v_0 / mol dm^{-3} h^{-1}
9.99×10^{-4}	5.01×10^{-4}	0.370×10^{-4}
9.86×10^{-4}	—	1.79×10^{-4}
3.96×10^{-4}	11.0×10^{-4}	0.216×10^{-4}
4.09×10^{-4}	—	1.43×10^{-4}
2.78×10^{-4}	—	1.16×10^{-4}
1.36×10^{-4}	13.6×10^{-4}	0.105×10^{-4}
1.55×10^{-4}	—	0.709×10^{-4}

The substrates anchoring BPOL through the amino acid residues are competitively degraded in both the amide and the ester bonds with α-chymotrypsin. Therefore, some mixtures of the BPMAA-2 and 3-(methacryloylamino)propionic acid were hydrolyzed in order to obtain information on the influence of amides regarding the esterolysis rate. All the experiments were carried out under the conditions of the same initial concentration on the amide group. The results are shown in Table 2. It is evident from Table 2 that all the initial rates for the mixtures were slower than that for a single substrate, BPMAA-2. In the case of mixtures, values of K_m=0.52×10^{-3} mol dm^{-3} and k_{cat}=20 h^{-1} were obtained. The K_m and k_{cat} values for BPMAA-2 were 0.52×10^{-3} mol dm^{-3} and 143 h^{-1}, respectively. These results suggest that 3-(methacryloylamino)propionic acid acts as a so-called noncompetitive inhibitor, because the Michaelis constant K_m for the mixture gives the same value as that for mixture, whereas the maximum reaction rate V_{max} decrease with an increase in the content of the amide groups. If the cleavage of the ester and amide bonds proceeds competitively, the K_m value for the mixture ought to be different from that for the substrate BPMAA-2. Therefore, the same K_m value for the mixture and for the BPMAA-2 can be assumed to be caused by a very slow cleavage rate of the amide bonds with α-chymotrypsin.

Generally, water-soluble paints are prepared from vinyl acetate (VAc) and methyl methacrylate (MMA). Film-forming polymers with chemically attached BPOL can be used as a vehicle for fungicidal paints. Therefore, copolymers of BPMAA-2 with VAc or

a) Reacted in toluene at 60 °C in the presence of AIBN(1—1.4 mol%). b) Reprecipitated with hexane. c) Determined by ^{1}H NMR. d) Measured in $CHCl_3$ at 25 °C.

MMA were also prepared, and hydrolyzed with α-chymotrypsin. The results are given in Table 3. As shown in Table 3, a small difference between the homopolymer and the copolymers was observed in the K_m values, whereas the k_{cat} values were apparently in the order of polymer **3b**<VAc-BPMAA-2 copolymer< MMA-BPMAA-2 copolymer. On the other hand, we have reported in a previous paper[7] that the reaction rate of a VAc-BPMA copolymer is slower than that of a BPMA homopolymer, and that the K_m value for both the homopolymer and the copolymer was equal to 1.9 mol dm^{-3}. The contrast between the two cases could readily be explained in terms of differences in a steric conditions at the cleavable bond, which is surrounded with acetoxyl groups. In the case of a VAc-BPMAA-2 copolymer, the 2-biphenylyloxycarbonyl groups that are sensitive to chymotrypsin attack a row of acetoxyl groups and can easily form a complex with the enzyme. In contrast to this case, the 2-biphenylyloxycarbonyl groups on the VAc-BPMA copolymer are buried into the acetoxyl groups. Azori and co-workers[19] examined the chymotrypsin catalyzed hydrolysis in the range 1 to 20 mol% for side chains containing *p*-nitroaniline bound to poly(*N*-vinyl-2-pyrrolidone-co-maleic anhydride), and reported that the maximum reaction rate V_{max} varies with the mole fraction of the side chains. These results indicate that the release rate of BPOL from the polymers can be controlled by using copolymers with an appropriate comonomer. Although the hydrolysis rate constant k_{cat} for the MMA-BPMAA-2 copolymer showed a considerably large value among the polymeric substrates used in this work, only 4% of total BPOL was released during a four-hour period. However, the conversion of the same substrate in hydrolysis without chymotrypsin was 0.9% during a four-day period.

α-Fluorination of Sulfides with *N*-Fluoropyridinium Triflates

Teruo UMEMOTO* and Ginjiro TOMIZAWA
Sagami Chemical Research Center, Nishi-Ohnuma 4-4-1, Sagamihara, Kanagawa 229
(Received June 4, 1986)

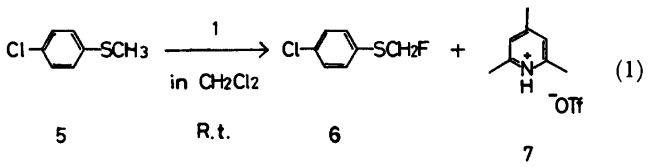
The reaction of sulfides possessing α-hydrogen with various *N*-fluoropyridinium salts was examined. While the fluorinating power increased in the order of *N*-fluoro-2,4,6-trimethylpyridinium triflate **1**<*N*-fluoropyridinium triflate **2**<*N*-fluoro-3,5-dichloropyridinium triflate **3**, the yield of an α-fluoro sulfide decreased in the order of **1**>**2**, and **3** no longer produced the α-fluoro sulfide. Triflate **1** was more reactive than the corresponding tetrafluoroborate **4**. Thus, it was shown that **1** satisfactorily fluorinated various kinds of sulfides under very mild conditions, giving α-fluoro sulfides. A two-step mechanism, oxidative fluorination of sulfur and Pummerer-type rearrangement, was proposed for the fluorination. The corresponding α-fluoro sulfoxide or sulfones were easily prepared from the sulfides by successive fluorination-oxidation procedure.

In recent years, introduction of fluorine into organic molecules is of increasing importance in the biological and pharmaceutical fields because it can alter the biological activity of the molecules or make them specific irreversible enzyme inhibitors with high possibility.[1] Therefore the methodologies for preparing the fluoro-compounds are being investigated actively.[1,2] Among them, α-fluorination of sulfides is of importance since some of sulfides are biologically active compounds such as β-lactam antibiotics[3] and amino acids[4] or since the resulting α-fluoro sulfides can serve as useful synthetic intermediates for the biologically active fluoro-compounds.[5] The reported methods for the preparation of α-fluoro sulfides are as follows; (1) direct fluorination of sulfides with xenon difluoride,[6] (2) replacement reaction of α-chloro sulfides with rigorously dried potassium fluoride and 18-crown-6,[7] and (3) conversion of sulfoxides to α-fluoro sulfides with diethylaminosulfur trifluoride (DAST).[8] However, xenon difluoride is very expensive and difficult to handle, and in order to prepare acid-labile α-fluoro sulfides, the special technique using bis (trimethylsilyl) amine is needed to remove hydrogen fluoride resulting from the reaction.[6b,c] The latter two methods required two steps from sulfides and severe reaction conditions for the fluorination because of the use of very hygroscopic potassium fluoride or thermally unstable and moisture-sensitive DAST.

We developed *N*-fluoropyridinium salts as easily handled fluorinating agents with variable fluorinating power[9] and found that the reaction of sulfides having α-hydrogen with the reagents resulted in the easy formation of α-fluoro sulfides. In this paper, α-fluorination of the sulfides with various *N*-fluoropyridinium salts was examined.

Results and Discussion

The reactivity of *N*-fluoropyridinium triflates **1**—**3** to the sulfide **5** was examined and the results are shown in Table 1. It was found that, while the fluorinating power increased in the order of **1** < **2** < **3**,[9] the yield of an α-fluoro sulfide **6** decreased in the order of **1** > **2** and **3** no longer produced **6**. It has been demonstrated that the fluorinating power is variable depending on the electron density at the positive nitrogen site.[9] The least reactive **1** mildly reacted with **5** in dichloromethane at room temperature to produce the α-fluoro sulfide **6** in a high yield (Eq. 1). On the other hand, the most reactive **3** underwent rapid and exothermic reaction with **5**, but the fluoro sulfide **6** and any other organic fluorides were not detected in



(1)

the ^{19}F-NMR spectrum of the resulting reaction solution. **2** afforded **6** in a moderate yield (48%) under

the similar conditions. As seen from Eq. 1, the reaction of **1** proceeded under almost neutral conditions because triflic acid liberated during the reaction was trapped by collidine simultaneously liberated. This is of great benefit to the preparation of acid-labile α-fluoro sulfides. Accordingly, the relatively low Yield and the unproductiveness of the fluoro sulfide **6** using **2** and **3** should be concerned with their relatively acidic conditions because of low and very low basicity of pyridine and 3,5-dichloropyridine liberated, respectively, compared to collidine. Of course, it cannot be excluded that the high oxidation power, particularly, of **3** is reponsible for it.

A tetrafluoroborate **4** which was expected to have the same fluorination power as triflate **1**[9a] exhibited the great difference in the reactivity. **4** did not react with the sulfide **5** under the same conditions as **1**, but **4** reacted at an elevated temperature to give the fluoro sulfide **6** in a 75% yield (Table 1, Run 5). The low reactivity of **4** is probably due to the low solubility compared to **1**. But another reason cannot entirely be excluded that the reactivity is somewhat dependent on the nature of the counter anions.

Furthermore, the reaction of *N*-fluoropyridinium salts was greatly dependent on the solvents. It was found from the ^{19}F NMR spectra of the resulting reaction solutions that no α-fluoro sulfides were produced in the polar solvents such as tetrahydrofuran (THF) and acetonitrile though the reagents were consumed (Table 2, Runs, 6, 11, and 12). The cause of the great solvent dependence is not clear. The *N*-fluoropyridinium salts do not fluorinate THF and acetonitrile.

Table 2 shows the results about α-fluorination of several kinds of sulfides including ones having functional groups such as alkoxycarbonyl and amido with triflate **1** or **2**. Alkyl aryl sulfides were converted to α-fluoroalkyl aryl sulfides in high yields. More acid-labile α-fluoroalkyl alkyl sulfides were also prepared by the present method though their yields were generally moderate. Since the more labile fluoro sulfides decomposed during the post-treatment, they were determined by ^{19}F NMR and their structures were confirmed by oxidizing them to stable α-fluoro sulfones which were characterized.

An unsymmetrical dialkyl sulfide, methyl dodecyl sulfide, afforded fluoromethyl dodecyl sulfide only. Ethyl methylthioacetate gave the product resulting from the fluorination at activated hydrogen site only. Benzyl methyl sulfide gave a mixture of benzyl fluoromethyl sulfide and α-fluorobenzyl methyl sulfide (3:4). Thus, the present method using **1** has been shown to be very useful and broadly applicable to the preparation of α-fluoro sulfides because of stable and nonhygroscopic crystals of **1**, mildness of the reaction conditions, and the simplicity of the procedure.

The above-mentioned selectivity of the α-fluorination with *N*-fluoropyridinium salts is very similar to that of Pummerer rearrangement which converted sulfoxides to α-acetoxy sulfides.[10] We propose the following two-step mechanism, oxidative fluorination of sulfur and Pummerer-type rearrangement, for

a) See b) in Table 1. b) Chloroform-*d* was used as a solvent for Run 1, 2, 8, and 13, and dichloromethane for Runs 5, 7, and 9. c) No α-fluoro sulfides were detected.

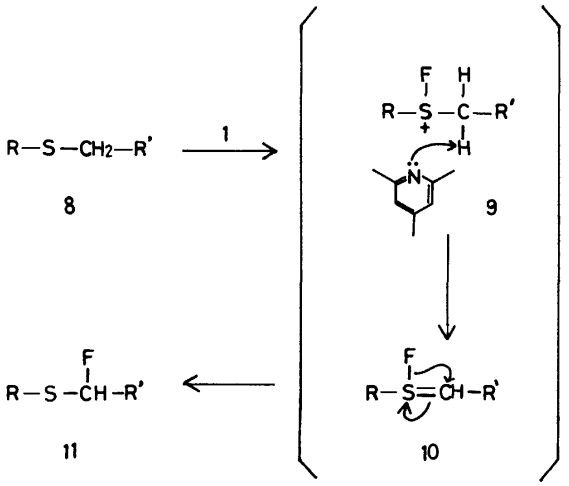
the α-fluorination (Scheme 2). Marat and Janzen suggested a similar mechanism for the α-fluorination with xenon difluoride.[5b] McCarthy et al. proposed Pummerer-type rearrangement as the mechanism for the conversion of sulfoxides to α-fluoro sulfides with DAST.[8]

Our attempt to detect intermediate S-F compounds on ^{19}F NMR spectra was unsuccessful. In the α-fluorination of methyl phenyl sulfide, the ^{19}F-peak corresponding to the α-fluoro sulfide appeared with the consumption of triflate **1**, indicating that the intermediates are very unstable. M. Zupan also failed to detect the intermediate S-F compounds by ^{19}F NMR technique in the reaction with xenon difluoride.[6a]

Furthermore, we tried to detect a ^{19}F-peak corresponding to S-F in the reaction of **1** with diphenyl sulfide without α-hydrogen in order to demonstrate the transfer of a fluorine atom from the positive nitrogen to the sulfur site. The reaction of **1** with diphenyl sulfide in dichloromethane was carried out at room temperature in a NMR-tube and followed by NMR measurement. A new singlet peak at −3.25 ppm was definitely observed after 19 h. It was found that the peak slightly shifted to downfield with time and reached to −5.25 ppm after 4 d. The reaction mixture became completely homogeneous in 5 d and addition of water into the solution resulted in immediate disappearence of the peak. The subsequent usual

$$\text{Ph-S-Ph} \xrightarrow{\mathbf{1}} \xrightarrow{H_2O} \text{Ph-SO-Ph} \qquad (2)$$

workup gave diphenyl sulfoxide in a 34% yield. Although the slight shift with time cannot be explained at the present stage, the chemical shift of the new peak is very close to the ^{19}F-chemical shift (−5.43 ppm) of diphenylsulfur difluoride[6b] which was easily hydrolyzed to diphenyl sulfoxide. The above results indicated that the new peak corresponded to a S-F compound and supported that the α-fluorination of sulfides occurred via the oxidative fluorination of sulfur followed by the rearrangement of fluorine to α-carbon. But we have no full data for determining the exact structures of the intermediate S-F compounds.



Scheme 2.

The mechanism is in agreement with that of the other α-halogenation of sulfides with chlorine, bromine, sulfuryl chloride, or *N*-chloro- or bromosuccinimide.[11] However, the present α-fluorination should be essentially different in the mechanism of the initial transfer of fluorine to sulfur site from the case of the other α-halogenation, because the N^+-F bond is very firm[9a] due to extreme difficulty in the formation of a fluorine cation in contrast to the case of the other halogen atoms.[12] Although a stepwise mechanism by a one-electron transfer for the initial fluorine transfer may be suggested, the detailed mechanism is not clear at the present stage.

α-Fluoro sulfoxide[7,8] or sulfones[8] were easily prepared by the fluorination, followed by oxidation with *N*-bromosuccinimide-water or *m*-chloroperbenzoic acid (Table 3). The successive fluorination-oxidation were conveniently carried out by one-pot

method. Since most of α-fluoro sulfides decompose partly or completely during the post-treatment, our one-pot procedure is very advantageous for praparing the α-fluoro sulfoxides or sulfones from sulfides.

Experimental

General. Melting points were uncorrected. ^{1}H NMR spectra were determined with a Varian HA-100 NMR spectrometer or a Varian EM 390 NMR spectrometer. ^{19}F NMR spectra were determined with a Varian XL-100 A NMR spectrometer or a Hitachi R-20 B NMR spectrometer. ^{19}F NMR chemical shifts are given in ppm upfield from trichlorofluoromethane as an internal standard. IR spectra were measured on a Jasco A-202 diffraction grating infrared spectrophotometer. Dichloromethane used was dried by treatment with calcium chloride followed by distillation on calcium hydride.

Materials. *N*-Fluoropyridinium salts **1**—**4** were prepared according to our methods reported previously.[9a]

α-Fluorination of Sulfides. A Typical Procedure: *p*-Chlorophenyl methyl sulfide (158 mg, 1 mmol) was added into a mixture of triflate **1** (290 mg, 1 mmol) and dry dichloromethane (3 ml) at room temperature under argon atmosphere and the reaction mixture was stirred for 8 h. The reaction was followed by checking the oxidation power with aq KI solution. After **1** completely disappeared, anhydrous sodium carbonate (0.5 g) was added and the organic layer was thin-layer chromatographed on silica gel by using a mixture of hexane and triethylamine (100:1) as an eluent to give *p*-chlorophenyl fluoromethyl sulfide as an oily product (133 mg, 76%).

Spectral date of fluoromethyl phenyl sulfide and *p*-chlorophenyl fluoromethyl sulfide are in good agreement with the reported data.[7] Although the products of Runs 5, 7, 9, 10, 13 and 14 in Table 2 were detected by ^{19}F NMR analysis, they completely decomposed during the post-treatment using chromatography on silica gel. Therefore the labile α-fluoro sulfides were converted to the easily isolated fluoro sulfones.

Methyl Phenylthio Fluoroacetate: Oil, ^{1}H NMR ($CDCl_3$) δ=3.70 (3 H, s, CH_3), 6.08 (1 H, d, J_{H-F}=52.5 Hz, CHF), 7.20—7.70 (5 H, m, Ar); ^{19}F NMR ($CDCl_3$) 158.4 (d, J_{H-F}=52.5 Hz); IR (neat, cm^{-1}) 1760 (CO); MS (*m/z*) 200 (M^+). Found: C, 53.97; H, 4.46%. Calcd for $C_9H_9FO_2S$: C, 53.99; H, 4.53%.

One-Pot Synthesis of Fluoromethyl Phenyl Sulfoxide from Methyl Phenyl Sulfide. α-Fluorination of methyl phenyl sulfide (124 mg, 1 mmol) by using **1** (290 mg, 1 mmol) and dry dichloromethane (3 ml) as a solvent was carried out in the same manner as the above. The reaction time was 4 h. After that, methanol (1 ml), water (0.1 ml) and then *N*-bromosuccinimide (270 mg, 1.5 mmol) were added into the resulting reaction mixture under cooling with ice bath and it was stirred at room temperature for 0.5 h. The reaction mixture was washed with aq sodium thiosulfate and the aq layer was extracted with ethyl acetate. The combined organic layer was washed with aq sodium hydrogen carbonate solution, 10% hydrochloric acid, and then aq sodium chloride solution. The organic layer was dried over magnesium sulfate, filtered and concentrated. The residue was column-chromatographed on silica gel by using a mixture of hexane and ethyl acetate (2:1) as an eluent to give fluoromethyl phenyl sulfoxide (105 mg, 66%). The spectral data of the sulfoxide was in good agreement with the reported.[7]

One-Pot Synthesis of α-Fluoro Sulfones from Sulfides. A Typical Procedure: α-Fluorination of dodecyl methyl sulfide (216 mg, 1 mmol) by using **1** (290 mg) and dry dichloromethane (2 ml) was carried out in the same manner as the above. The reaction time was 4 h. Then, 80—90%

m-chloroperbenzoic acid (540 mg, about 2.5 mmol) was added into the resulting reaction mixture under cooling with ice bath and then the mixture was stirred at room temperature for 4 h. The same workup as the above gave dodecyl fluoromethyl sulfone (99.4 mg, 37%). The spectral data and elemental analysis of new α-fluoro sulfones are shown in Table 4.

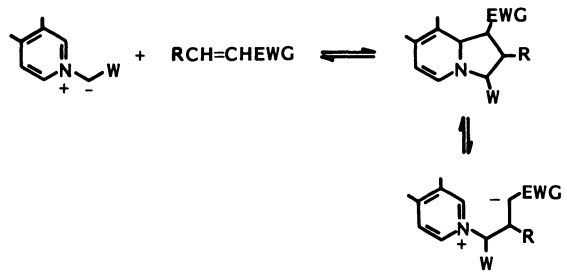
Stereoselective Cycloadditions of Pyridinium or Isoquinolinium Methylides with Olefinic Dipolarophiles and Subsequent Cycloadditions of the Cycloadducts with Nitrile Oxides

Otohiko TSUGE,* Shuji KANEMASA, and Shigeori TAKENAKA
Research Institute of Industrial Science, and Department of Molecular Science and Technology, Interdisciplinary Graduate School of Engineering Sciences, Kyushu University, Kasugakoen, Kasuga 816
(Received June 7, 1986)

Pyridinium or isoquinolinium methylides undergo highly stereo- and regioselective cycloadditions with olefinic dipolarophiles to form unstable tetrahydroindolizine derivatives. One of the two double bonds existing in the dihydro heteroaromatic ring of the cycloadducts reacts with nitrile oxides, in the same flask, in stereo-, regio-, and periselective fashions to lead to stable isoxazole-fused tetrahydroindolizines in good yields.

Although the cycloadditions of heteroaromatic *N*-ylides such as pyridinium, quinolinium, isoquinolinium, pyridazinium, thiazolium, and triazolium methylides with electron-deficient olefins take place in a highly diastereoselective manner to give fused heterocycles which bear a nitrogen atom at the point of fusion,[1-13] the cycloadducts are not always thermally stable. This instability is mainly due to the loss of aromaticity of the heteroaromatic ring of ylides in the step of cycloaddition. The cycloadducts frequently undergo retro cycloaddition[1,2] or carbon–carbon bond cleavage into betaine intermediates,[2,14-16] both of which are encouraged by the recovery of aromaticity.

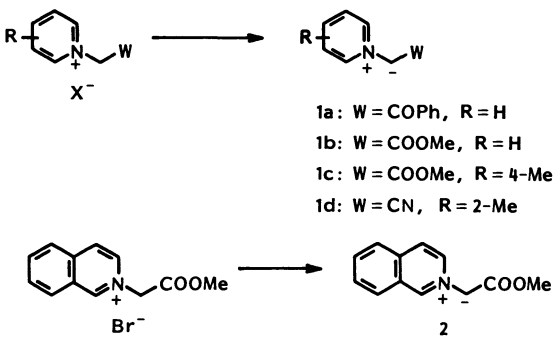


The cycloadducts derived from pyridinium methylides contain a fused dihydropyridine ring. Therefore, formal reduction of one of the two double bonds involved in the dihydropyridine skeleton should be effective for isolation of the cycloadducts as stable products. A cycloaddition and desilylation sequence of 4-silyloxypyridinium methylides is a successful example along this line.[17] In the present article, another method was applied for the formal reduction of these instability-causing double bonds: a cycloaddition method of such unstable cycloadducts with nitrile oxides.

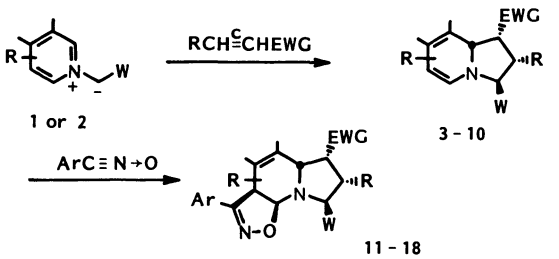
Results and Discussion

Pyridinium **1** and isoquinolinium methylides **2** were generated in situ from the corresponding pyridinium and isoquinolinium halides by treatment with triethylamine in dichloromethane and used for subsequent reactions without isolation (Scheme 1). More than two equivalent amounts of triethylamine were employed in general. One equivalent was for the ylide generation and the rest for the nitrile oxide generation which is to be carried out in the same flask as shown later.

These ylides **1** and **2** were first allowed to react with olefinic dipolarophiles to form diastereoselective cycloadducts **3**—**10**, though only **3** and **4** could be isolated and assigned as endo cycloadducts to the anti form of **1a** (Scheme 2 and Table 1).[1] The other cycloadducts **5**—**10** were too labile to be isolated, but their structures were readily deduced on the basis of the exclusive diastereoselectivity observed in the reaction of isoquinolinium phenacylide with unsymmetrical olefins such as methyl acrylate and acrylonitrile.[18] High regioselectivity (or periselec-



Scheme 1.



Scheme 2.

tivity) in favor of the 5-methyl derivative **9** is also consistent with the previously observed selectivity.[1]

The diastereoselective cycloadducts **3**—**10** formed in situ as thermally unstable products were next subjected to react with nitrile oxides (Scheme 2). Thus, *N*-(α-chloro-*p*-methoxybenzylidene)hydroxylamine was added to the reaction mixture which consisted of **3** and the remaining triethylamine. After 1 h at room temperature, nitrile oxide cycloadduct **11** was obtained as a single stereo- and regioisomer in an almost quantitative yield (based on the ylide precursor). Similar reactions of other unstable tetrahydroindolizines **4**—**7** with benzonitrile oxide or *p*-methoxybenzonitrile oxide gave also single isomers **12**—**15** of nitrile oxide cycloadducts (Scheme 2 and Table 1). Substitution on the fused dihydropyridine ring of **8**—**10** did not affect the cycloaddition with nitrile oxides, similar products **16**—**18** being produced.

It is clear that nitrile oxide cycloadducts **11**—**18** are all those formed through regioselective cycloaddition across the carbon–carbon double bond adjacent to the fused nitrogen. In every case, the newly formed methine carbon carrying an oxygen and a nitrogen substituent (10a-C in **11** and **12**, 9a-C in **13**—**17**, and 3a-C of **18**) appeared as low as 92—98 ppm, and the methine hydrogen on this carbon was observed around 5.8—6.0 ppm as a doublet.

Stereochemistry of the fused pyrrolidine ring of **11**—**18** should be the same with that of the initial cycloadducts **3**—**10**, respectively. Thus, the endo fusion of the maleimide ring and the exo configuration of 9-benzoyl of **11** were confirmed by the coupling constants J_{8a-9} and J_{5a-5b} (the same to **12**). The 6-endo (or 7-endo) and 8-exo (or 5-exo) substitution of **13**—**17** (or **18**) was assigned on the basis of the coupling patterns of **17** as well as the magnetic shielding of ester methyl at the 7-endo position of **18** (Fig. 1).

Table 1. Cycloaddition of Ylides **1** or **2** with Olefins and Then with Nitrile Oxides[a]

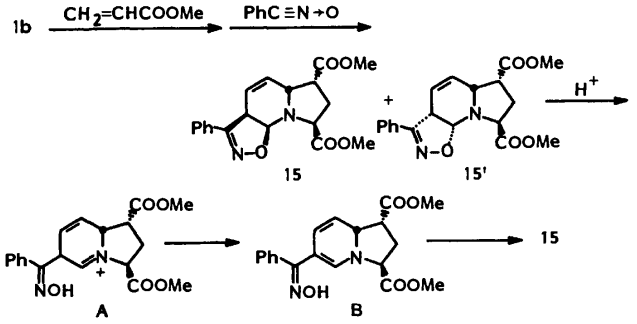
Ylide	Dipolarophile[b]	Cycloadduct		Nitrile oxide precursor[c]	Product		Yield/%[d]
1a	*N*-methylmaleimide rt, 10 min		**3**	*p*-MeOC$_6$H$_4$C(Cl)=NOH, rt, 1 h		**11**	97
1a	*N*-phenylmaleimide rt, 1 h		**4**	PhC(Cl)=NOH, −85 °C, 1h		**12**	96
1a	CH$_2$=CHCOOMe rt, 50 min		**5**	PhC(Cl)=NOH, rt, 1 h		**13**	45
1a	CH$_2$=CHCN rt, 20 min		**6**	*p*-MeOC$_6$H$_4$C(Cl)=NOH, rt, 10 min		**14**	55
1b	CH$_2$=CHCOOMe reflux, 1 h		**7**	PhC(Cl)=NOH, reflux, 4 h		**15**[e]	51
1c	CH$_2$=CHCOOMe reflux, 6 h		**8**	PhC(Cl)=NOH, reflux, 3 h		**16**	50
1d	CH$_2$=CHCOOMe reflux, 1 h		**9**	PhC(Cl)=NOH, reflux, 5 h		**17**	45
2	CH$_2$=CHCOOMe rt, 1 h		**10**	PhC(Cl)=NOH, rt, 10 h		**18**	62

a) All reactions were carried out in dichloromethane. b) One equivalent amounts of ylide precursor and dipolarophile were allowed to react in the presence of 2—4 equivalents of triethylamine. c) Nitrile oxide precursor was added at room temperature and the reactions were continued under the conditions shown in this table. d) Isolated yield based on ylide precursor. e) After treatment with a catalytic amount of trifluoroacetic acid.

Although stereochemistry of the fused isoxazoline ring of **11—18** could not be determined only by a spectroscopic analysis, these cycloadducts were tentatively assigned to have exo-fused isoxazolines on the basis of the following discussion: The reaction of stereoselective cycloadduct **7** with benzonitrile oxide provided, after chromatographic work-up over silica gel, a 1 : 1 mixture of two stereoisomers of nitrile oxide cycloadducts **15** and **15′**. When treated with a catalytic amount of trifluoroacetic acid in chloroform at room temperature, **15′** was converted into **15** in a quantitative yield. Thus, **15** and **15′** were assigned as thermodynamically controlled exo and kinetically controlled endo cycloadducts, respectively. Acid-catalyzed isomerization of **15′** into **15** was easily rationalized with a mechanism via iminium **A** and dienamine intermediate B (Scheme 3).

Experimental

General Methods. Melting points were determined on a Yanagimoto micro melting point apparatus and are uncorrected. IR spectra were taken with a JASCO A-702 spectrometer. ^{1}H NMR spectra were recorded on a Hitachi R-40 or a JEOL FX-100 instrument and ^{13}C NMR on a JEOL FX-100 spectrometer at 25.05 MHz. Chemical shifts are expressed in parts per million downfield from tetramethylsilane. Mass spectra were measured with a JEOL JMS-O1SG-2 spectrometer at 70 eV of ionization energy. Elemental analyses were performed on a Hitachi 026 CHN micro analyzer. Thin-layer chromatography (TLC) was accomplished on 0.2 mm precoated plates of silica gel 60 F-254 (Merck). Visualization was accomplished with ultraviolet light (254 and 365 nm) and iodine. Silica gel 60 (70—230 mesh or 230—400 mesh, Merck) or Wakogel C-200 (100—200 mesh) was used for preparative column chromatography. Micro vacuum distillation was performed with a Shibata GTO-250 R Kugelrohr distilling apparatus. Solvents were evaporated with a Tokyo Rikakikai rotary evaporator type V.



Scheme 3.

Ylide Precursors: The precursors for pyridinium methylides **1** and isoquinolinium methylide **2** were prepared from the reactions of substituted pyridines or isoquinoline with alkyl halides in dry acetone or dry ether at room temperature. The precursor salts precipitated were collected on a filter and washed with dry ether: 1-Phenacylpyridinium bromide:[19] Mp 204—206 °C; 96% (1 h in acetone). 1-(Methoxycarbonylmethyl) pyridinium chloride:[20] Mp 170—173 °C; 78% (24 h in acetone). 1-(Methoxycarbonylmethyl)-4-methylpyridinium bromide: Colorless prisms; mp 175—176 °C (decomp); 63% (54 h at 0 °C in ether); Found: C, 44.12; H, 4.95; N, 5.57%. Calcd for $C_9H_{12}NO_2Br$: C, 43.90; H, 4.88; N, 5.69%. 1-Cyanomethyl-2-methylpyridinium bromide: Colorless prisms; mp 194—197 °C (decomp); 49% (17 h in ether); Found: C, 44.90; H, 4.31; N, 12.96%. Calcd for $C_8H_9N_2Br$: C, 45.07; H, 4.23; N, 13.15%. 2-(Methoxycarbonylmethyl)isoquinolinium bromide:[21] Mp 158—160 °C; 62% (51 h in ether).

General One-pot Procedure for Cycloadditions of Ylides 1 or 2 with Olefins and Subsequent Cycloadditions of Cycloadducts 3—10 with Nitrile Oxides Leading to 11—18. An equimolar mixture of ylide precursor and olefin in dry dichloromethane (10—25 ml for 1 mmol of the precursor) was stirred in the presence of 2—4 equivalents of triethylamine at room temperature or under reflux (see Table 1). After the mixture was cooled to room temperature, 1 equivalent amount of an imidoyl chloride as nitrile oxide precursor was added. The mixture was allowed to react under the conditions listed in Table 1 and poured into ice water. The dichloromethane separated was dried over anhydrous magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel with hexane-ethylacetate (5-1 : 1) to give **11—18**. The yields are summarized in Table 1.

11: Colorless prisms (ethyl acetate-hexane); mp 210 °C; IR (KBr) 1770, 1700, and 1680 cm^{-1}; ^{1}H NMR (CD_3CN) δ=2.87 (3H, s, NMe), 3.42 (1 H, dd, J=7.6 and 0.8 Hz, 8a-H), 3.51 (1H, t, J=7.6 Hz, 5b-H), 3.77 (3H, s, p-MeO), 3.9—4.1 (1H, m, 3a-H), 4.2—4.3 (1H, m, 5a-H), 5.32 (1H, d,

Preparation and Characterization of a Resin-Supported Palladium Catalyst

Takayoshi UEMATSU,* Masao UMINO, Shogo SHIMAZU, Masatoshi MIURA, and Hidehisa HASHIMOTO
Department of Synthetic Chemistry, Faculty of Engineering, Chiba University, Yayoi-Cho, Chiba 260
(Received February 26, 1986)

The process of the ligand release and the reduction of $[Pd(NH_3)_4]$-form sulfonic resin has been studied by chemical analysis, X-ray photoelectron spectroscopy and adsorption techniques. The removal of ammonia ligands remarkably increased with hydrogen treatment above 353 K, and was complete at around 393 K. It is suggested that the released ammonia partly transfers to $-SO_3^-$ groups to form $-SO_3NH_4$ groups as the reduction proceeds. The dispersion of the metal particles prepared by hydrogen reduction ranged from 0.11 to 0.31 depending on the loading concentration of the palladium cation. The metal particles are considered to be entrapped in the pores of the resin. The formation of cationic palladium sites by the low temperature reduction is also suggested.

During our study on the nature of active sites of polymer anchored complex catalysts, we found that the various types of active sites can be prepared on ion-exchange resins by varying the pretreatment methods of cation-form resins. Several reports have been focussed on the differences in the catalytic nature of the active sites prepared on commercialy available ion-exchange resins.[1-4] In our trial, starting from cation-form sulfonic resins, two different types of active sites were prepared on the resin,[5] one of which is active for the isomerization and the other for the hydrogenation of butenes.

In the present study, we tried to scrutinize the process of active site formation by ligand removal from $[Pd(NH_3)_4]$-form sulfonic resin. The active sites thus prepared on the resin are characterized by means of chemical analysis, X-ray photoelectron spectroscopy (XPS), and adsorption of CO, NH_3, and acetylene. The catalytic activity was tested over these sites for the hydrogenation of ethylene. Further detailed catalytic behavior will be reported in a succeeding paper.

Experimental

Tetraamminepalladium complex cation, $[Pb(NH_3)_4]^{2+}$, was supported on Na-form sulfonic resin, denoted as AMNa (Amberlyst-15, Room & Haas; surface area: 51.3 $m^2 g^{-1}$; ion-exchange capacity for Na^+ ion: 4.02 mmol g^{-1}-Na-form dry resin) according to the following ion-exchange process, viz.,

$$\left\{\begin{matrix}-SO_3\text{-}Na\\ \\ -SO_3\text{-}Na\end{matrix}\right. + [Pd(NH_3)_4]^{2+} \longrightarrow \left\{\begin{matrix}-SO_3\\ \\ -SO_3\end{matrix}\right.\!\!\!

Table 1. Chemical Analysis of Pretreated Palladium-Form Sulfonic Resin

	Treatment	Content/mmol g^{-1}					
		S	Pd	N(anal)	N(s)	N(Pd)	N(Pd)/Pd
1	Evac Room Temp	4.06	0.080	0.625	0.305	0.320	4.00
2	Evac 373 K 2 h H_2 353 K	3.96	0.082	0.568	0.305	0.263	3.21

6	HCHO-treat. 333 K	4.02	0.082	0.400	0.305	0.095	1.16

N(anal) is the total nitrogen by chemical analysis. N(s) and N(Pd) indicate the number of NH_4 on $-SO_3^-$ and NH_3 on the palladium, respectively. See text.

the amount of the ammonium ion originally bound to sulfonic groups was calculated as N(s)=0.305 mmol g^{-1} by substraction of the stoichiometrically coordinated ammonia ligands to the palladium, N(Pd)= 0.320 mmol g^{-1}, from the total ammonia which was given by nitrogen chemical analysis as N(anal)=0.625 mmol g^{-1} for Pd-Comp/AMNa evacuated at room temperature.

Since ammonium sulfonate is stable and N(s) was considered to be constant for all samples treated by H_2 below 493 K, the values of N(Pd) for the variously treated Pd-Comp/AMNa were determined, in turn, from the differences between N(anal) and N(s). The ammonia coordination number to the palladium, N(Pd)/Pd, was also calculated. These values are listed in Table 1.

The coordination number for Pd-Comp/AMNa (Pd: 0.08 mmol g^{-1}) decreased from 4 to 2.45 when the hydrogen treatment temperature was increased up to 393 K. The reduction at a higher temperature of 473 K (No. 5) led to a marked decrease in nitrogen content, N(anal), and only 0.113 mmol g^{-1} of ammonia ligand was left on the palladium. The reduction in the formaldehyde solution (No. 6) gave rise to a similar dramatic decrease in N(Pd) to 0.095 mmol g^{-1}. However, these values still correspond to the residual coordination number of N(Pd)/Pd=1.38 and 1.16 respectively.

The weight loss due to the ammonia release during pretreatment was also studied as shown in Fig. 1. The hydrogen treatment at 353 K was only sufficient to remove 10% of the ammonia from the palladium. The treatment at higher temperatures facilitated the ligand removal and 50% of ammonia release, NH_3(des), was attained at 433 K. It is noticeable that further elevation of the reduction temperature up to 453 K had no effect on the residual ammonia on the resin.

Figure 2 shows the effect of the hydrogen treatment on the oxidation state of the palladium studied by

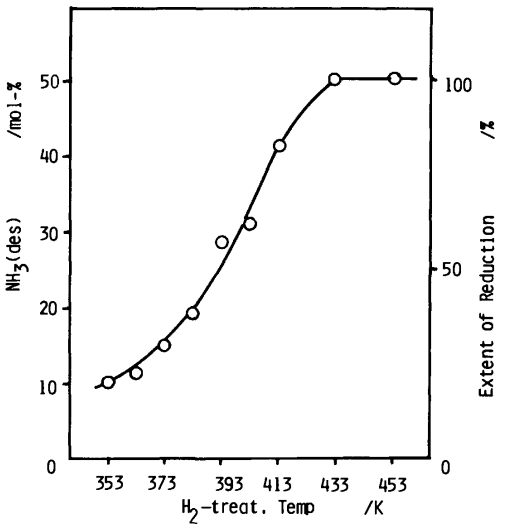

Fig. 1. Removal of ammonia ligand by H_2-treatment Pd-Comp/AMNa(Pd: 0.519 mmol g^{-1}): evacuated at 373 K for 2 h and subjected to hydrogen treatment for 1 h at $P(H_2)$=26.6 KPa.

XPS. Pd-Comp/AMNa (Pd: 0.519 mmol g^{-1}) was first evacuated in the preparation chamber over night at 1.33×10^{-6} Pa. The peak due to Pd^{2+} (3d-5/2) was detected at a binding energy B. E. of 339.2 eV, but gradually shifted to 337.2 eV on increasing the hydrogen treatment temperature up to 433 K. The latter peak was ascribed to palladium metal, Pd^0 (3d-5/2) on the sulfonic resin. The hydrogen treatment at 453 K appeared to complete the reduction of the palladium cations. Refluxing in a formaldehyde solution at 353 K seemed also to reduce them completely to the metal.

However, as shown in Table 1, the complete reduction with H_2 or formaldehyde did not necessarily result in the decrease in the total nitrogen to zero. The reason for this may well be explained in terms of "ammonia transfer" from the palladium to

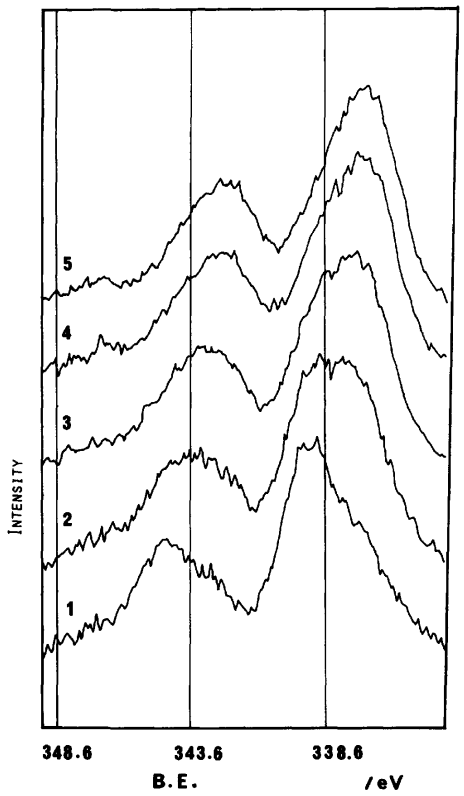

Fig. 2. XPS spectra for H_2-treated palladium-form sulfonic resin.
Sample: Pd-Comp/AMNa(Pd: 0.519 mmol g^{-1}). 1: evacuated at 353 K in the preparation chamber over night at 1.33×10^{-10} Pa, 2: H_2-treated at 358 K for 60 min after 1, 3: H_2-treated at 398 K for 20 min after 2, 4: H_2-treated 433 K for 20 min after 3, 5: H_2-treated at 453 K for 20 min after 4. The binding energy was referred to C(1s): 284.9 eV, Pd metal on Na-form sulfonic resin: 336.5 eV and Pd metal(Solid): 335.0 eV.

the sulfonic groups during the reduction; this was previously proposed in an analogous system of a palladium ammine complex cation on zeolites,[6] viz.,

$$\left\{\begin{matrix}-SO_3\\-SO_3\end{matrix}\right\}[Pd(NH_3)_4] + H_2 \longrightarrow \left\{\begin{matrix}-SO_3NH_4\\-SO_3NH_4\end{matrix}\right\} + Pd^\circ + 2NH_3 \quad (2)$$

If this is the case, the extent of reduction is directly related to the removal of ammonia ligands from the palladium. As shown in Fig. 1 the weight loss due to the ammonia release was almost complete at 433 K, where 50% removal of ammonia from Pd-Comp/AMNa was attained. This suggests that Eq. 2 is also valid for Pd-Comp/AMNa and the 100% reduction was accomplished as indicated also by the XPS study. An Arrehenius plot for the ammonia release gave an activation energy of 74 KJ mol^{-1}.

Re-adsorption of ammonia was studied over the hydrogen treated Pd-Comp/AMNa (Pd: 0.519 mmol g^{-1}) and the result is shown in Fig. 3. After the

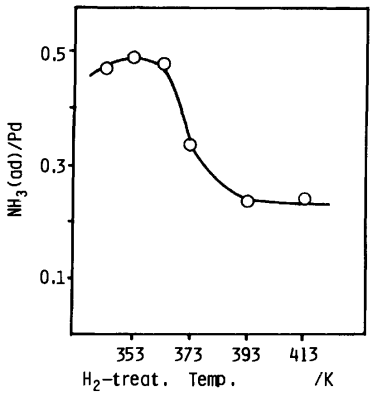

Fig. 3. Re-adsorption of NH_3 over H_2-treated palladium-form sulfonic resin
Pd-Comp/AMNa(Pd: 0.519 mmol g^{-1}) was evacuated at 373 K for 2 h and subjected to H_2-treatment for 1 h under $P(H_2)=26.6$ KPa. Adsorption: 303 K, $P(NH_3)=399$ Pa.

hydrogen treatment at 353 K, the ammonia re-adsorption amounted to about NH3(ad)/Pd=0.5. This value is close to that of ammonia previously removed, 0.4, during the hydrogen treatment. This suggests that the coordination and the release of ammonia are quite reversible over the samples treated at this low temperature region. However, after the treatment above 373 K the amount of ammonia re-adsorption decreased remarkably to give the ratio, NH3(ad)=0.25. Thus, the ammonia was removed irreversibly when the Pd-Comp/AMNa was once reduced at high temperatures.

Carbon monoxide has been widely used as a probe to characterize catalytic sites of supported metal catalysts.[7,8] The effect of hydrogen treatment on CO adsorption are shown in Figs. 4 and 5. In the case of Pd-Comp/AMNa (Pd: 0.519 mol g^{-1}), the amount of adsorbed CO was increased on raising the hydrogen treatment temperature from 353 K to 393 K and reached a constant level of CO(ad)/Pd=0.28. The further elevation of temperature did not change the value.

Figure 5 shows similar results for Pd-Comp/AMNa with different palladium concentrations and for Pd-Comp/SiO_2. The temperature where the ratio, CO(ad)/Pd, attained constant values almost coincided with each other at about 393 K, irrespective of the different supports and different loading concentrations applied. Moreover, the amount of CO adsorbed on Pd-Comp/SiO_2 decreased little on further elevation of the treatment temperature up to 673 K.

A similar trend was obtained for the adsorption of acetylene. Figure 6 shows that the amount of adsorption increased with the hydrogen treatment temperature up to 403 K and reached a constant value, which may be related to the completion of the reduction.

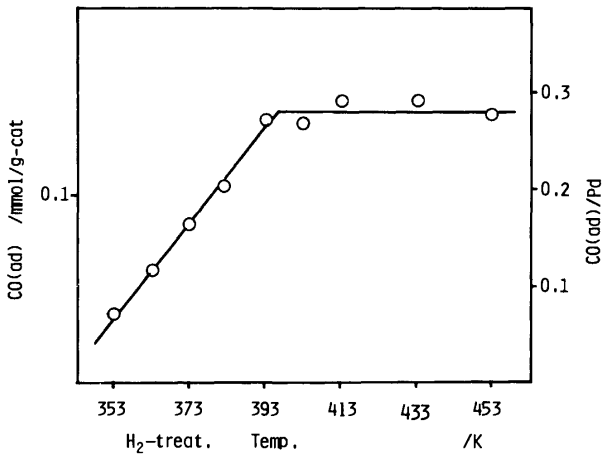

Fig. 4. Effect of H_2-treatment on CO adsorption Pd-Comp/AMNa (Pd: 0.519 mmol g^{-1}) was evacuated at 373 K for 2 h and subjected to H_2-treatment for 1 h. Adsorption of CO at 303 K, under $P(CO)=399$ Pa.

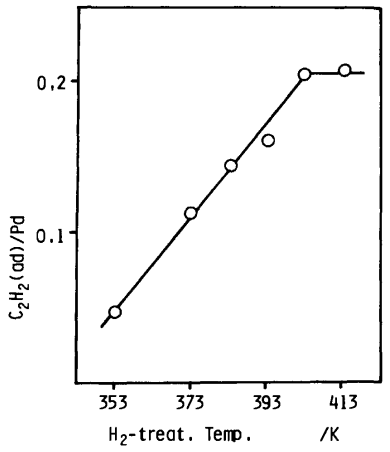

Fig. 6. Effect of H_2-treatment on C_2H_2 adsorption Pd-Comp/AMNa (Pd: 0.519 mmol g^{-1}) was evacuated at 373 K for 2 h and subjected to H_2-treatment at T K for 1 h.

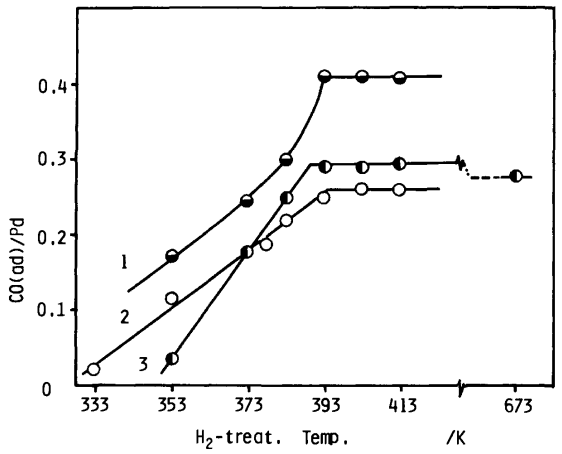

Fig. 5. Effect of CO adsorption on palladium-form sulfonic resin and silica supported palladium.
Samples were evacuated at 373 K for 2 h and subjected to H_2 hydrogen treatment at T K for 1 h. Adsorption was carried out at 273 K at $P(CO)=399$ Pa. 1: Pd-Comp/AMNa (Pd: 0.0904 mmol g^{-1}). 2: Pd-Comp/AMNa (Pd: 0.12 mmol g^{-1}). 3: Pd-Comp/SiO_2. (Pd: 1.00 mmol g^{-1}).

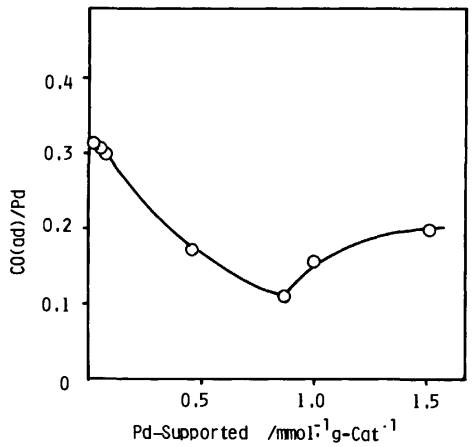

Fig. 7. Effects of palladium loading concentration on CO adsorption.
Pd-Comp/AMNa (Pd: 0.519 mmol g^{-1}) was evacuated at 373 K for 2 h and subjected to H_2 treatment at 403 K for 1 h. Adsorption at 273 K at $P(CO)=399$ KPa.

If the reduction of palladium was once completed, the number of CO adsorption sites would not increase any more by further elevation of the reduction temperature. Moreover, the values of CO(ad)/Pd would decrease if the sintering proceeded. However, the observed values were almost constant from 393 to 453 K for Pd-Comp/AMNa (Pd: 0.519 mmol g^{-1}) and to 673 K for Pd-Comp/SiO_2, and thus, it may be said that the palladium metal particles are highly stable over the widespread temperature range.

In view of the different behavior between ammonia and CO adsorption in Figs. 3, 4, and 5, the adsorption sites produced by the treatments can be ascribed respectively to palladium cations with unsaturated ligands and the metal sites. The isomerization of butenes takes place over the cation site,[5] while the adsorption of CO and acetylene (Fig. 6) can be attributed to the metal sites formed by the high temperature reduction according to Eq. 2.

The effect of the loading concentration on the dispersion of palladium is given in Fig. 7. In this case, the palladium cations were completely reduced to the metal by hydrogen treatment at 403 K. The dispersion of the metal particles is defined by D=Pd(surface)/Pd(total),[9] where Pd(surface) was determined by CO adsorption. The average particle sizes were estimated from the equation, $d=1.23/D$ nm.[10] The maximum dispersion, 0.31, and the minimum, 0.11 correspond respectively to d=3.97 and 11.2 nm. The formation of these fine particles may be facilitated by the retardation of the diffusion and the sintering of palladium by anchoring on $-SO_3^-$ groups.

Table 2. Dispersion and Particle Size of Palladium Metal Prepared by Reduction with Formaldehyde

Sample	Pd loaded /mmol g^{-1}	Dispersion D=CO/Pd	Diameter d/nm
1 Pd-Comp/AMNa(F)	0.090	0.075	16.5
2 Pd-Comp/AMNa(F)	1.11	0.020	62.0

Pd-Comp/AMNa(F): Pd-Comp/AMNa was reduced by refluxing in a formaldehyde solution at 358 K for 5 min.

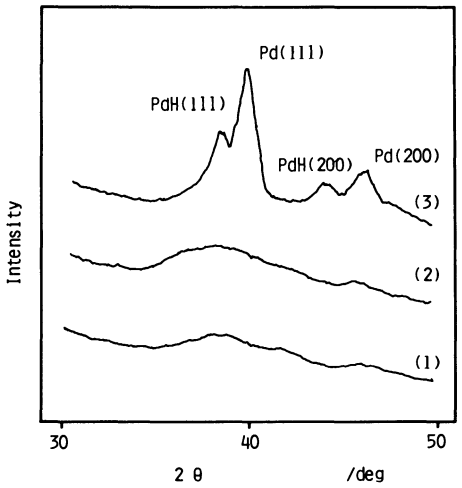

Fig. 8. XRD spectra for palladium-form sulfonic resin Pd-Comp/AMNa(Pd: 0.519 mmol g^{-1}).
1: H_2-treated at 353 K. 2: H_2-treated at 393 K. 3: formaldehyde treated at 358 K.

The mean pore diameter measured by the mercury penetration method was 24.8 nm for the support AMNa which agreed well with the reported value of 25.6 nm.[11] The total amount of palladium complex contained in a pore can be estimated from the loading concentration and the BET surface area. A pore of average diameter of 24.8 nm has a surface area of 1.93×10^3 nm^2 where the palladium cations anchored are 1.98×10^3 and 1.25×10^4, respectively for Pd-Comp/AMNa (Pd: 0.08 mmol g^{-1}) and Pd-Comp/AMNa (Pd: 0.519 mmol g^{-1}).

Based on a cubo-octahedral crystal model,[12] the expected dispersions of the metal particles in the pore was estimated to be about D=0.32 and 0.19 which are very close respectively to the observed values of 0.31 and 0.18 in Fig. 7. This fact suggests that the particle size of the metal palladium was controlled by entrapment within each pore in the resin.

While the reduction by formaldehyde resulted in a smaller dispersion as given in Table 2. A highly loaded Pd-Comp/AMNa (Pd: 1.1 mmol g^{-1}) gave larger particles than that for the mean pore size. They might grown outside of the pore due to the increase in the sintering probability and the particle sizes.

The X-ray diffraction spectra for a formaldehyde-treated Pd-Comp/AMNa(F) in Fig. 8 shows clear patterns of palladium metal. The crystallite diameter obtained by Scherre's equation was about 12 nm. The formation of palladium hydride, $PdH_{0.706}$ was also indicated in the spectra.

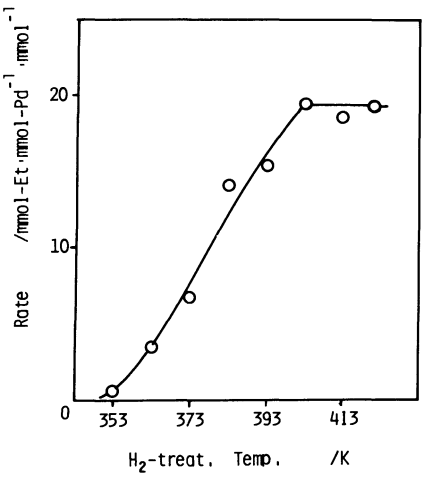

Fig. 9. Catalytic activity for the hydrogenation of ethylene over H_2-treated Pd-Comp/AMNa.
Pd-Comp/AMNa (Pd: 0.519 mmol g^{-1}): evacuated at 373 K for 2 h and subjected to H_2-treatment at T K for 1 h. The reaction was carried out at 313 K with 1 : 1 mixture of C_2H_4 and H_2.

The evidence of the formation of catalytic sites due to metallic palladium is given in Fig. 9. The catalytic activity for the hydrogenation of ethylene changed almost in parallel with the numbers of the metal sites for CO and acetylene adsorption sites (Figs. 4, 5, and 6). Thus, it may be conclusively said that the partial reduction takes place gradually from low temperature hydrogen treatment and the complete reduction is accomplished above 393 K where the catalytic activity also the reached a constant level. The results by XPS study also supports this observation.

Conclusion

Fine metal palladium can be prepared on a sulfonic resin by the reduction of $[Pd(NH_3)_4]$-form resin. The particle size can be controlled by changing the loading concentration and the reducing condition. The metal particles may be formed in the pores by the effect of the entrapment, when the loading concentration was kept low. The low temperature treatment may also produce cationic sites with vacant ligands by removing the ammonia ligands.

(Received April 24, 1986)

The catalytic effects of $MoCl_3$-LiCl-KCl and $NiCl_2$-LiCl-KCl molten salts were studied for the hydroliquefaction of Morwell brown and Taiheiyo subbituminous coals at 400 °C for 1 h in a batch reactor with an initial hydrogen pressure of 9.8 MPa. The conversion to pyridine-soluble materials and the yield of hexane-soluble materials (HS) with the $MoCl_3$ catalyst were 82 and 42% for Morwell coal, and 84 and 61% for Taiheiyo coal, respectively. The conversion and HS yield with the $NiCl_2$ catalyst were 87 and 43% for Morwell coal, and 82 and 56% for Taiheiyo coal, respectively. The HS yield of the catalytic runs was about 2.6—3.2 times higher than that of noncatalytic runs. This finding established the effectiveness of the two new catalysts for the hydroliquefaction of brown and subbituminous coals. Detailed analyses of the reaction products have revealed that these catalysts promoted a depolymerization of the coals and strongly catalyzed the hydrocracking of polynuclear aromatic structures of heavy products into hydroaromatic and aromatic structures with smaller ring sizes. Most of these smaller hydroaromatic and aromatic structures did not undergo much further ring-opening reactions. This accounts for the high HS selectivity of the catalysts.

One of the most promising approaches to the development of coal liquefaction processes is the development of new and novel catalytic systems.[1] We have previously found[2] that $MoCl_3$- and $NiCl_2$-LiCl-KCl molten salts acted as excellent hydrocracking catalysts for the hydroliquefaction of an Australian subbituminous coal (Wandoan). Since different ranks of coal generally show different reactivities toward hydroliquefaction, it is necessary to examine the effectiveness of these new catalysts for the hydroliquefaction of other coals different from Wandoan coal.

Two coals, Morwell brown coal (Australia) and Taiheiyo subbituminous coal (Japan), which have lower carbon contents and higher oxygen contents compared with Wandoan coal, were used in the present work. This paper reports on the hydroliquefaction of Morwell and Taiheiyo coals over $MoCl_3$-LiCl-KCl and $NiCl_2$-LiCl-KCl molten salt catalysts; their catalysis is characterized by a detailed analytical study of the reaction products.

Experimental

Reagents and Materials. Morwell brown and Taiheiyo subbituminous coals were used in the present work. The coals were pulverized to <74 μm and then stored under an N_2 atmosphere. Proximate and ultimate analyses of the coals are listed in Table 1. For each experiment the required quantity of coal was dried at 105 °C in vacuo for 1.5 h before use. The examined catalysts were $MoCl_3$-LiCl-KCl (molar composition, 12:51:37; eutectic temperature, 387 °C) and $NiCl_2$-LiCl-KCl (14:54:36; 360 °C) ternary molten salts. $MoCl_3$ was synthesized according to a procedure proposed by Mallock,[3] except that resulting $MoCl_3$ was further purified by washing with distilled methanol. The X-ray diffraction pattern of thus-purified $MoCl_3$ is very consistent with that of literature.[4] The $MoCl_3$ and guaranteed reagent-grade $NiCl_2$, LiCl, and KCl were used as salt constituents of the catalysts. For each experiment the required quantity of catalyst was dried at 140 °C in vacuo for 6 h before use. Guaranteed reagent-grade hexane, benzene and pyridine were used as received.

Hydroliquefaction Procedures. Hydroliquefaction reactions were carried out in a 200 ml batch autoclave (SUS 316) that was shaken horizontally. In a typical run, coal was impregnated with the same weight of catalyst by immersing the coal into a methanol solution or a suspension in methanol followed by drying at 105 °C in vacuo for more than 6 h. Thus-treated coal was placed into an autoclave. Hydroliquefaction was carried out at 400 °C for 1 h with an initial hydrogen pressure (cold) of 9.8 MPa (100 kg cm^{-2}). After the reaction, products were separated into gases consisting of C_1–C_4 hydrocarbons and COx ($CO+CO_2$), hexane-soluble fraction (HS), hexane-insoluble and benzene-soluble fraction (BS), benzene-insoluble and pyridine-soluble fraction (PyS) and pyridine-insoluble fraction (PyI). The HS, BS, and PyS fractions are denoted as oil, asphaltene and preasphaltene, respectively. Details of the procedures have been described elsewhere.[2] The yield of products,

Table 1. Representative Analyses of Coals

Coal	Morwell	Taiheiyo
Proximate (wt%)		
Volatile matter	41.4	45.5
Fixed carbon	37.4	33.9
Ash	1.6	14.5
Moisture	19.6	6.1
Ultimate (wt%, daf)

Hydrogen	5.0	6.7
Nitrogen	0.5	1.5
Sulfur	0.3	0.2
Oxygen (by difference)	26.8	15.5

conversion and amount of hydrogen consumed were calculated on a d.a.f. coal basis.

Analytical Method of Products. The HS and BS fractions obtained from the hydroliquefaction of the two coals were subjected to elemental and ^{1}H NMR analyses. The ^{1}H NMR spectra were measured in a $CDCl_3$ solution with tetramethylsilane as an internal standard using a JNM-PS-100 spectrometer operating at 100 MHz. Deuterium oxide was added to some of the solutions of HS and BS fractions in order to identify the phenolic OH resonance; contribution from overlapping signals was then subtracted. The integrated intensity from all the hydrogen was divided into several parts, which could be assigned to the hydrogen of different chemical environments. A distribution of hydrogen types was calculated as the numbers of hydrogen atoms per 100 carbon atoms from the ^{1}H NMR data and elemental analysis. The average structural parameters of the HS and BS fractions were calculated based on Brown-Ladner equations[5] from the data of ^{1}H NMR and elemental analyses.

Results

Hydroliquefaction of Coals. Table 2 gives conversion and H_2 consumption values and Fig. 1 shows the product distribution of the hydroliquefaction of Morwell brown and Taiheiyo subbituminous coals. Without a catalyst, the hydroliquefaction of Morwell and Taiheiyo coals gave relatively low conversions (66.0—67.8%) with low H_2 consumptions (0.7—0.9%). The use of both $NiCl_2$-LiCl-KCl and $MoCl_3$-LiCl-KCl catalysts considerably increased the coal conversion and H_2 consumption, indicating the great effectiveness of these catalysts for converting brown and subbituminous coals.

The increases in the conversion and H_2 consumption with the $MoCl_3$ and $NiCl_2$ catalysts (Table 2) were accompanied by pronounced changes in the product distribution (Fig. 1); the important features of the catalytic runs compared with noncatalytic runs are considerably decreased PyI and PyS yields and greatly increased HS yield. The net production of HS was, as would be expected,[6-7] lower with Morwell brown coal than with Taiheiyo subbituminous coal.

Table 2. Hydroliquefaction of Morwell and Taiheiyo Coals

Run No.	Coal	Catalyst	Conversion[a] (wt%, daf)	H_2 consumed (wt%, daf)
1	Morwell	None	66.0	0.7
2	Morwell	$NiCl_2$-LiCl-KCl	86.8	3.6
3	Morwell	$MoCl_3$-LiCl-KCl	82.4	5.5
4	Taiheiyo	None	67.8	0.9
5	Taiheiyo	$NiCl_2$-LiCl-KCl	82.3	4.0
6	Taiheiyo	$MoCl_3$-LiCl-KCl	84.0	4.7

a) Conversion = (1-PyI/coal) × 100%.

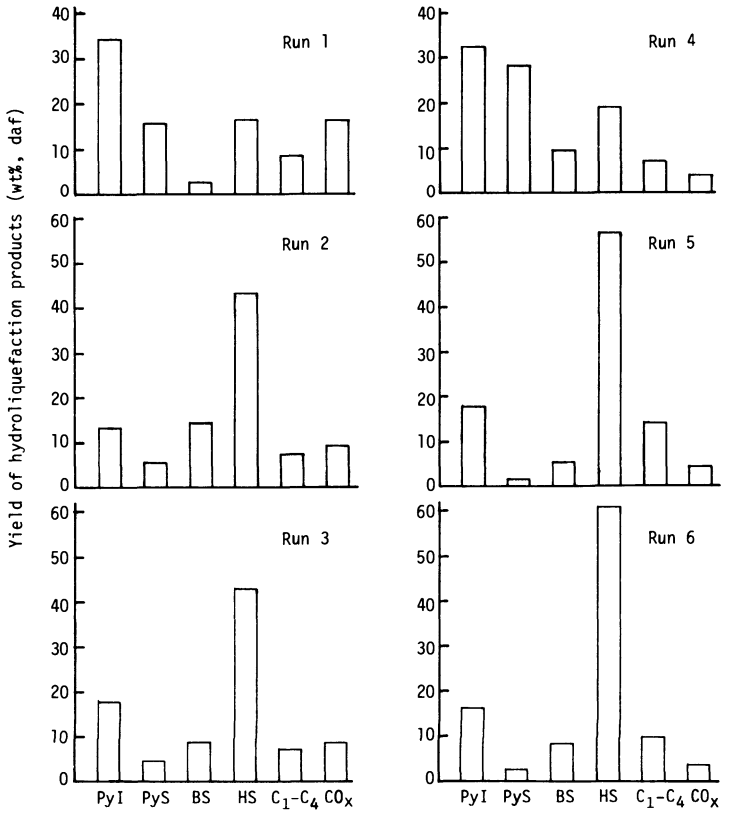

Fig. 1. Product distribution of hydroliquefaction of Morwell and Taiheiyo coals. See Table 2 for run number.

However, it should be noted that relative to noncatalytic runs of the two coals, both the $MoCl_3$ and $NiCl_2$ catalysts selectively enhanced the production of the HS yield without a significant change in the C_1-C_4 gas yield.

Elemental Analysis. Table 3 shows the results of an elemental analysis of the HS and BS fractions. The HS of the catalytic runs had a little higher carbon content, a lower hydrogen content and a lower H/C atomic ratio than that of noncatalytic runs. The content of heteroatoms (N+O+S) of the former was lower or similar to that of the latter. In runs involving Morwell coal, nitrogen was completely removed from the HS by the use of both catalysts. On the other hand, more heteroatoms were retained in the BS of catalytic runs, as compared with its corresponding HS.

^{1}H NMR Spectroscopy. Table 4 gives assignments of ^{1}H NMR spectra bands of HS and BS. The assignments are based on both the chemical shifts of the model compounds[8] containing structures that are believed to be present in coal-derived products and some other assignments found in the literature.[9-12]

Table 3. Elemental Analysis of HS and BS from Morwell and Taiheiyo Coals

Run No.	Product	C	H	N	O+S[a]	H/C
		wt%				
1	HS	85.3	9.0	0.4	5.3	1.25
	BS	85.0	6.7	0.7	7.6	0.94
2	HS	87.9	8.9	—	3.2	1.20
	BS	86.7	6.6	1.0	5.7	0.91
3	HS	87.4	8.7	—	3.9	1.19
	BS	83.4	6.4	0.9	9.3	0.92
4	HS	85.2	10.2	0.4	4.2	1.43
	BS	87.6	6.9	1.3	4.2	0.94
5	HS	86.3	8.9	0.3	4.5	1.23
	BS	83.9	6.9	1.6	7.7	0.98
6	HS	87.2	9.4	—	3.4	1.29
	BS	76.8	6.6	1.3	15.4	1.03

a) By difference.

The major separation was between the aromatic (9.20—6.00 ppm) and aliphatic (5.00—0.20 ppm) hydrogen resonances; the aliphatic region was further divided into six subgroups because the aliphatic region of the spectrum gave highly characteristic structural data regarding coal-derived products.[9] The chemical shift of the phenolic OH proton was variable and its resonance was observed at between 8.50—4.00 ppm. The contribution of phenolic OH was small and made little difference in both the trends and conclusions deduced from the analytical data reported here. However, where applicable, we have subtracted its contribution based on an examination of the D_2O addition.

Tables 5 and 6 show the hydrogen distribution per 100 carbon atoms and the average structural parameters of HS and BS from Morwell and Taiheiyo coals, respectively. For a comparison, Table 7 gives the analytical data of HS and BS derived from the hydroliquefaction of Wandoan coal,[2] among which all the data of BS and hydrogen distribution data of HS have not been previously reported. Important structural differences between the products from catalytic and noncatalytic runs (Tables 5—7) are cited as follows. The HS fractions of noncatalytic runs of Morwell and Taiheiyo as well as Wandoan coals have the highest $H_{\alpha 2}$, $H_{\beta 2}$, H_γ (except Morwell coal), and

Table 4. Assignments of Bands in ^{1}H NMR Spectra of HS and BS

Chemical shift δ (ppm from TMS)	Symbol	Assignments of hydrogen type
9.20—6.00	H_{ar}	Aromatics
5.00—3.40	H_F	CH_2 α to two aromatic rings
3.40—2.35	$H_{\alpha 1}$	CH_2 α to an aromatic ring
2.35—2.00	$H_{\alpha 2}$	CH_3 α to an aromatic ring
2.00—1.60	$H_{\beta 1}$	CH_2 β to an aromatic ring
1.60—1.05	$H_{\beta 2}$	CH_3 β to an aromatic ring CH_2 γ or further from an aromatic ring
1.05—0.20	H_γ	CH_3 γ or further from an aromatic ring

Tabe 5. Hydrogen Distribution and Structural Parameters of HS and BS from Morwell Coal

	BS	23.0	7.7	16.9	7.4	10.1	20.1	10.8	0.67	0.39	0.57

a) Catalyst: run 7, none; run 8, $NiCl_2$-LiCl-KCl; run 9, $MoCl_3$-LiCl-KCl.

H_{aru}/C_{ar} values. The values of H_F, $H_{\alpha 1}$, $H_{\beta 1}$ and f_a of HS from the catalytic runs are higher than those of HS from noncatalytic runs.

A somewhat surprising observation is that the trends of differences in hydrogen distribution between the HS of noncatalytic and catalytic runs were quite clear and were the same for the three kinds of coals, regardless of the different nature of the coals (Tables 5—7). Generally, a BS showed a higher f_a value and lower $H_{\alpha'\beta'\gamma'}$, σ and H_{aru}/C_{ar} values than its corresponding HS. The values of H_{ar} and H_{aru}/C_{ar} of BS from catalytic runs were lower than those of the BS from noncatalytic runs, the $H_{\beta 1}$ value of the former being higher than that of the latter.

Discussion

Catalytic Effects of $MoCl_3$- and $NiCl_2$-LiCl-KCl Molten Salts. In direct coal hydroliquefaction, the initial step is a thermal fragmentation (depolymerization) of coal organic materials to produce large quantities of fragments which are extremely reactive.[13-14] A thermogravimetric examination (in N_2) of the coal impregnated with catalysts indicated that the $MoCl_3$ and $NiCl_2$ catalysts effectively enhanced the initial thermal fragmentation of the coal.[2] The coal-derived reactive fragments must be stabilized by the hydrogen of the coal, itself, through an autogeneous hydrogen-transfer mechanism[14] and by the hydrogen from such external hydrogen sources as a hydrogen-donor solvent and/or gas-phase hydrogen; otherwise, they would promptly recombine or repolymerize to form insoluble organic materials.[14-16]

It has been commonly recognized that in this stabilizing step, molecular hydrogen is much less effective than a hydrogen donor solvent such as tetralin.[17] Taking our reaction conditions into consideration, the considerably decreased PyI yield of catalytic runs (Fig. 1) and our previous results[2,18-23] suggest that in the initial reaction stage the molten-salt catalysts not only promote coal depolymerization but also act to reduce repolymerization by stabilizing the reactive fragments and permitting them to be capped by gas-phase hydrogen.

After the initial fragmentation and stabilization steps, these salts function as hydrocracking catalysts[2] for the hydrocracking of stabilized heavy products such as PyS and BS. As shown in Table 2 and Fig. 1, for each run of the two coals, the increasing extent of the HS yield with the catalysts is much higher than that of conversion. Therefore, the high H_2 consumption during catalytic runs (Table 2) is probably mainly associated with the hydrocracking of PyS and BS to give a light HS product. These results reinforced our previous conclusion[2] derived from results with Wandoan subbituminous coal: the $MoCl_3$ and $NiCl_2$ catalysts have a high hydrocracking ability and also show a high catalytic activity and HS selectivity.

It should be noted that the selectivity of a coal-liquefaction catalyst is probably more important than its activity.[1] The high HS selectivity of the new catalysts is both of scientific and practical interest since HS is the most desirable oil product of coal hydroliquefaction.

Characteristics of Catalysis by $MoCl_3$- and $NiCl_2$-LiCl-KCl Molten Salts. It has been indicated[24] that

the best procedure for characterizing catalytic effects during coal liquefaction is to pay maximum attention to the liquid-oil part (HS) of the coal products. Yoshida et al.[25] have concluded that during the hydroliquefaction of coal, a cleavage of its ether bonds mainly contributes to the formation of PyS (preasphaltene); however the scission of CH_2 bridges and some naphthenic CH_2 bonds mainly contributes to the formation of HS (oil). As shown in Tables 5—7, ^1H NMR analysis indicated that among all the HS of catalytic and noncatalytic runs, HS of noncatalytic runs of the three coals had the lowest content of hydrogens α to two aromatic rings (H_F). This might be due to a cleavage of the ring-joining methylene bridges (Ar-CH_2-Ar), being consistent with highest content of methyl hydrogens in α-CH_3 (Ar-CH_3) ($H_{\alpha 2}$) of HS of noncatalytic runs. Moreover, the fact that the HS of noncatalytic runs has the highest amounts of hydrogens in β-CH_3 and γ-CH_2 ($H_{\beta 2}$) and γ-CH_3 (H_γ) together with its highest content of hydrogens in α-CH_3 ($H_{\alpha 2}$) suggests that many bridge structures like Ar-$(CH_2)_n$-Ar ($n \geq 2$) which are rich in coal[26-27] and some naphthenic CH_2 bonds which are thermally sensitive,[25-26] have been cleavaged.

Interestingly, all the HS of catalytic runs had an even higher content of hydrogens in CH_2 α to two aromatic rings (H_F) than those of noncatalytic runs (Tables 5—7). Probably this was mainly the result of an increase of CH_2 hydrogen existing in structures like 9,10-dihydroanthracene and fluorene types. This is because the formation of these type compounds is reasonable[9] and their CH_2 hydrogens also resonate in the region of H_F.[8-9] Secondly, all the HS of catalytic runs contain larger amounts of hydrogens in α-CH_2 ($H_{\alpha 1}$) and β-CH_2 ($H_{\beta 1}$) than all of the HS of noncatalytic runs, indicating an increase in CH_2 hydrogens in hydroaromatic structures such as 9,10-dihydrophenanthrene,[9] tetralin and indan types.[12] With regard to the high HS yield, these results suggest that large amounts of polynuclear aromatic structures of the heavy products from these coals were considerably hydrocracked into relatively smaller hydroaromatic and aromatic structures as well as some alkyl aromatic structures, which accounts for the high activity of the catalysts.

Furthermore, all the HS of the catalytic runs contained smaller amounts of hydrogens in β-CH_3 and γ-CH_2 ($H_{\beta 2}$) and in γ-CH_3 (H_γ)(except Morwell coal) and showed higher f_a and lower H_{aru}/C_{ar} values than those of noncatalytic runs. These results, together with the relatively low yield of C_1-C_4 hydrocarbons of the catalytic runs, suggest that most of the newly formed smaller hydroaromatic and aromatic structures did not undergo much further ring-opening reactions. Therefore, the detailed structural study of HS has rationalized the high HS selectivity and activity of the $MoCl_3$ and the $NiCl_2$ catalysts.

It can be seen from Tables 5—7 that the structural differences between the BS of catalytic and noncatalytic runs are not as clear as those observed in HS. This suggests that the structural features of HS can not be directly correlated with those of BS, presumably because HS might also be formed directly from the thermal cracking and hydrocracking of BS and PyS as well as the coal.[28] Nevertheless, all the BS from catalytic runs contained smaller amounts of H_{ar}, larger amounts of $H_{\beta 1}$ and show a lower H_{aru}/C_{ar} value than all the BS of noncatalytic runs. This suggests that the relatively larger polynuclear aromatic compounds contained in coal and PyS were converted into BS by using the catalysts.

Through the present study, we have established the effectiveness of $MoCl_3$-LiCl-KCl and $NiCl_2$-LiCl-KCl molten salt catalysts for the hydroliquefaction of subbituminous and brown coals (especially subbituminous coals). Also, the characteristics of hydroliquefaction catalysis of these new catalysts was clarified. We believe that the analytical methods presented in this paper are useful in characterizing the catalytic effects of a catalyst for the hydrocracking of coal and coal-related materials.

The authors would like to thank Mr. Hiroshi Maki for his assistance in preparation of this manuscript.

Effect of CH_2Br_2-Addition upon Direct Oxidative Dehydrogenation of Butane into 1,3-Butadiene over Fe-Sb-O Composite Catalyst

Hitoshi SAITOH, Satoshi SATOH, Toshiaki SODESAWA, and Fumio NOZAKI*
Department of Industrial Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba 260
(Received February 27, 1986)

Synopsis. Effect of CH_2Br_2-addition upon direct oxidative dehydrogenation of butane into 1,3-butadiene has been investigated in a conventional flow apparatus. The activity and selectivity of Fe-Sb-O catalyst were much improved by the addition of CH_2Br_2 to butane in the mole ratio, CH_2Br_2/n-C_4H_{10}, of 0.03 to 0.10 at temperatures near 450 °C.

The dehydrogenation of paraffinic hydrocarbons such as butane (hereafter referred to as n-C_4H_{10}) is endothermic, so that high temperature is required to facilitate the reaction. The oxidative dehydrogenation has no such difficulty; however, catalytic selectivity is often poor.

The oxidative dehydrogenation of olefin such as 1-butene (1-C_4H_8) is selectively achieved by the use of composite catalysts such as Fe-Sb-O[1] and Bi-Mo-O.[2] On the other hand, the oxidative dehydrogenation of n-C_4H_{10} using oxygen or air as the oxidant gives preferentially a large amount of CO_2 and the selectivity to form butenes (C_4H_8) or 1,3-butadiene (C_4H_6) is generally lowered. It is well known that the addition of small amounts of halogen (I_2, Br_2, etc.) or halogen compound (HBr, HCl, KBr, etc.) is effective for the dehydrogenation or oxidative dehydrogenation of paraffinic hydrocarbons or ethylbenzene.[3-5] In addition, attempts to use COS[6] or N_2O[7] as the oxidant for the dehydrogenation of C_4H_{10} or ethane have recently been made. In these studies, however, a large portion of the dehydrogenated products was C_4H_8 or olefinic hydrocarbons such as propylene and ethylene, and the extent of C_4H_6 formation was usually very small.

We have previously reported on the oxidative dehydrogenation of 1-C_4H_8 to C_4H_6 over Fe-Sb-O catalyst.[1] In this paper, we describe a promoting action of CH_2Br_2 for the direct oxidative dehydrogenation of n-C_4H_{10} to C_4H_6 over Fe-Sb-O catalyst. It should also be noted that CH_2Br_2 is chosen as a promoter because of its appropriate magnitude of vapor pressure and its low cost.

Experimental

The catalytic tests were conducted in a conventional tubular-flow reactor operating at atmospheric pressure. The reaction products were analyzed by the gas chromatography on a 4 m column of VZ-7 (Gasukuro-kogyo Co.) operated at room temperature. The conversion of n-C_4H_{10} (expressed by x), the selectivity to C_4H_6 (S_{C_4}), C_4H_8 (S_{C_4}), etc. were calculated by the usual procedure on the mole basis of n-C_4H_{10} fed.

The method of preparation of the Fe-Sb-O catalyst was similar to that previously reported[1]: $Fe(NO_3)_3$ and Sb_2O_3 were used as the starting materials for the preparation of $FeSb_2O_4$ composite catalyst. In order to compare the activity of the Fe-Sb-O catalyst with other catalysts, Cr_2O_3(7.5 wt%)/Al_2O_3 and Fe_2O_3(30 wt%)/SiO_2 were also used in the catalytic tests. These two materials were commercially supplied from Nissan-Girdler Co., Ltd.

Results and Discussion

The results of catalytic tests obtained by three kinds of catalysts, Fe-Sb-O, Cr_2O_3/Al_2O_3, and Fe_2O_3/SiO_2, are summarized in Table 1. Table 1 indicates that an addition of small amounts of CH_2Br_2 to the reactant mixture is effective for the oxidative dehydrogenation of n-C_4H_{10} to give C_4H_6. Especially in the case of the Fe-Sb-O catalyst, the high conversion and selectivity (x=67%, S_{C_4}=59%) were obtained with the addition of CH_2Br_2.

Catalyst: Fe–Sb–O, W: 3.0 g, t: 450 °C, F: 130 ml min^{-1}, Mole ratio n-C_4H_{10}/Air/CH_2Br_2: 1/12/0.12.

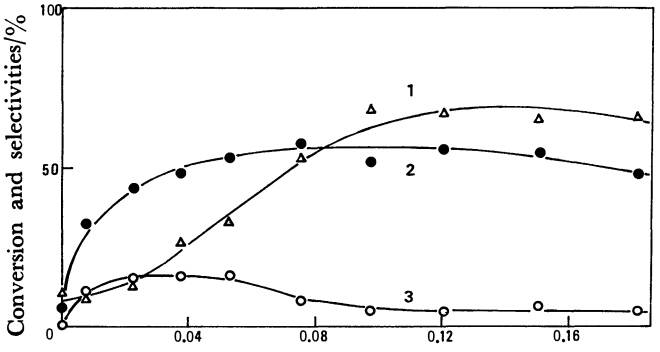

Fig. 2. Influence of CH_2Br_2/n-C_4H_{10} ratio upon the reaction. The reaction conditions and the symbols are the same as for Fig. 1.

CH_2Br_2 for the Fe–Sb–O catalyst is further illustrated in Fig. 1. Figure 1 depicts clearly that the oxidative dehydrogenation to form C_4H_6 continues to occur so long as CH_2Br_2 is fed into the reaction. When the introduction of CH_2Br_2 is stopped, the enhanced activity gradually decreases and tends to resume the original activity.

The influence of CH_2Br_2 concentration upon the catalytic reaction is shown in Fig. 2. The conversion of n-C_4H_{10} (curve 1) is increased with an increase of the CH_2Br_2 concentration and then levels off when the mole ratio of CH_2Br_2 to n-C_4H_{10} becomes approximately 1:10. The selectivity to C_4H_6 or C_4H_8 (curve 2 or 3) is much improved even at a low CH_2Br_2 concentration (CH_2Br_2/n-C_4H_{10}=0.03—0.05).

The activity and selectivity of the Fe–Sb–O catalyst enhanced by the addition of CH_2Br_2 stayed at the same level for as long as CH_2Br_2 was being supplied. The changes in the conversion and selectivity with reaction temperature and contact time were also investigated. The results indicated that the reaction temperature near 450 °C was the best for the formation of C_4H_6, and its yield decreased with a decreasing contact time.

No reaction occurred between n-C_4H_{10} and CH_2Br_2 without air over the Fe–Sb–O catalyst. This fact suggests that oxygen is essential for the dissociation of CH_2Br_2 to Br_2 and for the formation of C_4H_6 and C_4H_8. As was shown in Table 1, the dehydrogenation of n-C_4H_{10} into C_4H_8 took place to a certain extent even in the absence of the Fe–Sb–O catalyst.

In accordance with the above findings and with other information, we have tentatively speculated the reaction pathways as follows:

$$\left.\begin{aligned} &CH_2Br_2 + 3/2O_2 \longrightarrow CO_2 + H_2O + Br_2 \\ &Br_2 \rightleftarrows 2Br\cdot \end{aligned}\right\} \quad (1)$$

$$\left.\begin{aligned} &C_4H_{10} + Br\cdot \longrightarrow C_4H_9\cdot + HBr \\ &C_4H_9\cdot + Br\cdot \longrightarrow C_4H_8 + HBr \end{aligned}\right\} \quad (2)$$

$$C_4H_8 + 1/2O_2 \xrightarrow{\text{Fe-Sb-O cat.}} C_4H_6 + H_2O \quad (3)$$

$$\left.\begin{aligned} &FeSb_2O_{4-y} + 2HBr \longrightarrow FeSb_2Br_2O_{3-y} + H_2O \\ &FeSb_2Br_2O_{3-y} + 1/2O_2 \longrightarrow FeSb_2O_{4-y} + Br_2 \end{aligned}\right\} \quad (4)$$

(here, $FeSb_2O_{4-y}$ shows the partially reduced state of the Fe–Sb–O catalyst).

The bromine radical Br· generated by Eq. 1[8] probably plays an important role in the formation of C_4H_8. The resulting C_4H_8 is oxidatively dehydrogenated to C_4H_6 by the subsequent reaction step, Eq. 3, over the Fe–Sb–O catalyst.[1]

In addition, it can be speculated that the resulting HBr is converted into Br_2 by the redox mechanism of the Fe–Sb–O catalyst, as is shown by Eq. 4. This is probably responsible for the experimental fact that such a high conversion and selectivity as x=60—70%, Sc≅ 60% have been attained even at the low CH_2Br_2/n-C_4H_{10} ratio.

However, the more definitive reaction scheme must remain to be the subject for a further study.

8) $Log_{10} K_p$ for the reaction $Br_2 \rightarrow 2Br$ has been estimated to be about −7.9 at 450 °C by the use of data listed in "JANAF Thermochemical Tables," 2nd ed., p. 290 and p. 318 (National Bureau of Standards). The low value of log K_p appears to be unfavorable to the proposed mechanism; however, a small amount of Br can be formed and it can initiate the subsequent reaction steps represented by Eqs. 2—4.

Nonexistence of Hydration Number Change of Cd^{2+} Ions in Aqueous $Cd(NO_3)_2$ Solution

Hitoshi KANNO
Department of Chemistry, The National Defence Academy,
Hashirimizu, Yokosuka, Kanagawa 239
(Received May 13, 1986)

Synopsis. Raman spectra for the Cd^{2+}–OH_2 stretching vibration (ν_1 band) were measured for aqueous $Cd(NO_3)_2$ solutions of R=15 and 40 (R: moles of water/moles of salt). Contrary to the results reported by Kuznetsov et al.,[5] it is concluded that the hydration number of Cd^{2+} ions does not change with salt concentration in the $Cd(NO_3)_2$ solution.

In recent years, inner-sphere hydration numbers have been determined by X-ray diffraction method for many metal cations in aqueous electrolyte solutions.[1-4] Most divalent cations are reported to have six water molecules in their inner-coordination spheres.[1,2] However, the recent X-ray diffraction study by Kuznetsov et al.[5] asserts that the hydration number of Cd^{2+} ions changes from four in an aqueous $Cd(NO_3)_2$ solution (R=40) to six in the R=25 solution where R is the molar ratio of water to salt in the solution. If this is the case, it should be the first experimental evidence for the hydration number change with variation of salt concentration for divalent cations and has a significant implication for our understanding of aqueous electrolyte solutions. Valeev et al.[6] have very recently reported that the Cd^{2+} ions in the R=10 solution are tetrahedrally coordinated with two water molecules and two nitrate ions. When ligands other than water molecules constitute a part of the coordination sphere, geometrical factors such as size and the manner of coordination (monodentate or bidentate) of the ligands have a large effect on the coordination number so that comparison between the coordination number of an all-aquated metal ion and that of a partially-aquated metal ion should be made with care.

On the other hand, Bol et al.[7] determined the coordination number of Cd^{2+} ions in aqueous $Cd(NO_3)_2$ solution ($R\simeq55$) by X-ray diffraction method and reported that the hydration number of Cd^{2+} ions is six. The X-ray diffraction study by Ohtaki et al.[8] of aqueous $Cd(ClO_4)_2$ solution ($R\simeq19$) also reports that it is about six. With these experimental data, it is evident that Cd^{2+} ions are octahedrally coordinated in concentrated Cd-salt solutions ($R\lesssim25$). However, there is a clear discrepancy between the two reports by Kuznetsov et al.[5] and Bol et al.[7] in rather dilute $Cd(NO_3)_2$ concentration range (R=40—55). Therefore, it is important to determine whether the hydration number change really occurs with decreasing salt concentration in aqueous $Cd(NO_3)_3$ solution.

In this work, we examined the possibility of hydration number change of Cd^{2+} ions in aqueous $Cd(NO_3)_2$ solution by Raman spectroscopy. As a symmetric M–OH_2 stretching vibration (a ν_1 band) of aquated metal ions (M: metal cation) is sensitive in frequency to the constituents of the coordination spheres of the cations, it can serve as a sensitive probe for the hydration number change, if any, in aquated Cd^{2+} ions. We measured the ν_1 spectra for the aqueous $Cd(NO_3)_2$ solutions of R=15 and 40 and the ν_4 spectra of the NO_3^- ions in the solutions. Raman measurements were carried out in the same way as previously reported.[9]

Results and Discussion

The ν_1 spectra are shown in Fig. 1. We see only a small frequency change ($\Delta\nu_1=6\pm2\,cm^{-1}$) from the R=15 solution to the R=40 solution. From the ν_4 spectra shown in Fig. 2, we know that some nitrate ions are coordinated to cadmium ions in the R=15 solution because the coordinated NO_3^- ions give a higher ν_4 frequency (about 738 cm^{-1}) than 718 cm^{-1} (the ν_4 frequency for non-coordinated NO_3^- ions).[10] In the R=40 solution, the $\approx$738 cm^{-1} peak is much weaker than that in the R=15 solution, indicating that the inner-coordination sphere around a Cd^{2+} ion consists mostly of water molecules in the R=40 solu-

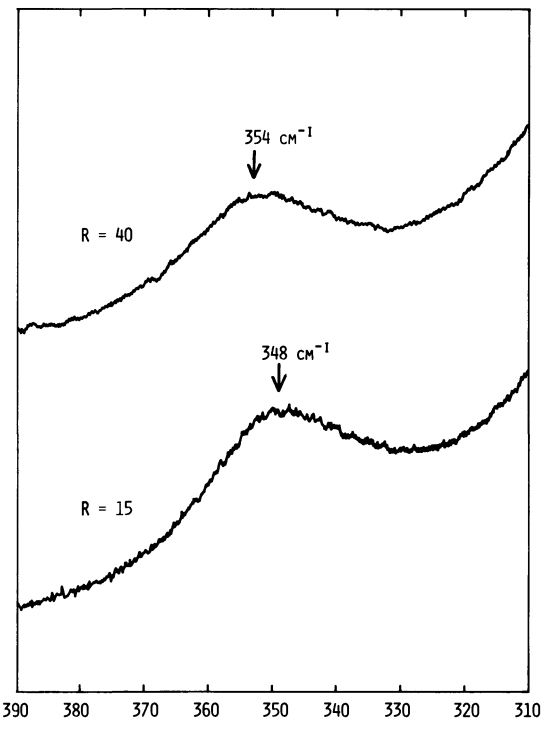

Fig. 1. Raman spectra of the Cd^{2+}–OH_2 stretching vibration for aqueous $Cd(NO_3)_2$ solutions of R=15 and 40.

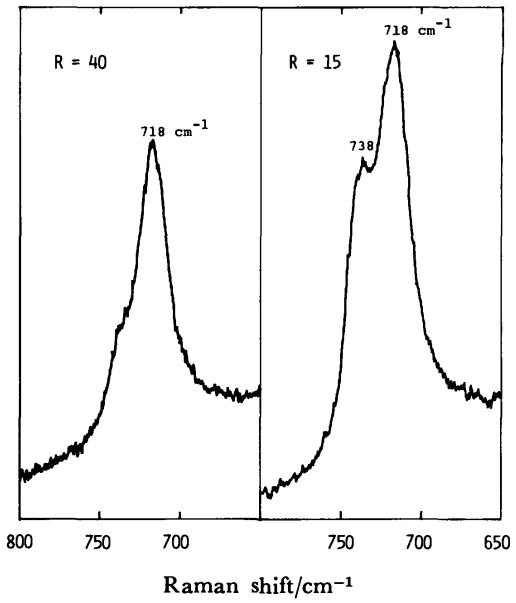

Fig. 2. Raman spectra of the ν_4 band of the NO_3^- ions in aqueous $Cd(NO_3)_2$ solutions of $R=15$ and 40.

tion. It is a well-known fact that a ligand other than water molecules enters into an inner-coordination sphere of an aquated cation, the frequency of a ν_1 band gets lower than that for all-aquated cations.[10,11] In other words, the overall effects of increasing in mole fraction of a aquated Cd^{2+} ions partially substituted with nitrate ion(s) such as $[Cd(NO_3)(OH_2)_n]^+$ ion are a steady decrease in the total ν_1 frequency. Therefore, the frequency change $\Delta\nu_1=6\pm2\ cm^{-1}$ between the $R=15$ and 40 solutions is mainly ascribable to the difference of the average constituents of the innersphere coordinations: The mole fraction of nitrate ions complexed to Cd^{2+} ions is larger in the $R=15$ solution than in the $R=40$ solution. In the Raman study by Davis and Plane,[12] it is reported that the nitrate ions coordinated to Cd^{2+} ions are acting as a monodentate ligand and that no evidence for complex species higher than $[Cd(NO_3)(OH_2)_n]^+$ was found. The smallness of the ν_1 frequency change from $R=40$ to $R=15$ indicates that the mole fraction of nitrate ions coordinatig to Cd^{2+} ions is not large. This is also confirmed by the Raman ν_4 spectrum for the $R=15$ solution.

There have been a few examples[13,14] which can be a guide for the estimation of the frequency change when the hydration number change really takes place in aqueous $Cd(NO_3)_2$ solution. The conversion from an octahedral to a tetrahedral configuration of a metal halide gives rise to an increase in the frequency of the symmetric stretching vibrations (a ν_1 band): e.g.,

$$[InCl_6]^{3-}(\nu_1:\ 275\ cm^{-1}) \longrightarrow [InCl_4]^-(\nu_1:\ 366\ cm^{-1})$$

and

$$[SnCl_6]^{2-}(\nu_1:\ 301\ cm^{-1}) \longrightarrow [SnCl_4](\nu_1:\ 360\ cm^{-1}).^{13}$$

Hydration number change of rare earth ions from 9 to 8 results in the ν_1 frequency change of about 25 cm^{-1}, e.g., $[Eu(OH_2)_9]^{3+}(\nu_1:\ 369\ cm^{-1}) \rightarrow [Eu(OH_2)_8]^{3+}(\nu_1:\ 394\ cm^{-1})$.[14] Thus, the hydration number change, if it really occurs in an aqueous $Cd(NO_3)_2$ solution between $R=15$ and 40, should give rise to a ν_1 frequency change of more than 30 cm^{-1}. However, the observed ν_1 frequency shift is much smaller than the one expected from the hydration number change. Accordingly, we conclude that the hydration number change, at least the one proposed by Kuznetsov et al.,[5] does not takes place in aqueous $Cd(NO_3)_2$ solution between $R=15$ and 40. From the ν_1 results shown in Fig. 1 and the X-ray diffraction results by Bol et al.,[7] it is considered that the coordination number of all-aquated Cd^{2+} ions in an aqueous $Cd(NO_3)_2$ solution remains six in all concentration ranges ($15 \lesssim R \lesssim 55$). This is supported by the observation[15] that the ν_1 band is at $356\pm3\ cm^{-1}$ in an aqueous $Cd(ClO_4)_2$ solution ($R=15$), in which all Cd^{2+} ion are octahedrally hydrated according to the X-ray diffraction study by Ohtaki et al.[8]

Raman measurements were carried out in National Chemical Laboratory for Industory, for which the author is thankful to Dr. K. Tanabe.

Solvent Effects on the Unimolecular Dissociation of Radical Anions Studied by Pulse Radiolysis

Norio KIMURA* and Setsuo TAKAMUKU
The Institute of Scientific and Industrial Research, Osaka University,
8-1 Mihogaoka, Ibaraki, Osaka 567
(Received May 26, 1986)

Synopsis. The rate constants of the unimolecular dissociation of radical anions formed by one-electron reduction of chloroacetophenone isomers in dipolar aprotic solvents were measured by a pulse radiolysis technique. The reactivities of these isomers were affected by the polarity of the solvent used.

Solvent effects on chemical reactivity are commonly found in a wide variety of reactions involving electron-transfer reactions which are currently attracting the interest of chemists.[1,2] However, only a few investigations have been reported about solvent effects on the further reactions of radical anions formed by one-electron reduction.[3] For example, radical anions of aromatic halides are well-known to undergo unimolecular dissociation producing an aryl radical and halide ion,[3-7] but the rate constants reported spread over a wide range, probably due to the effect of the solvent used.[4,7] Therefore, the present purpose is to clarify the solvent effects on the unimolecular dissociation of radical anions of chloroacetophenone isomers (*o*-, *m*-, and *p*-CAP) and also to elucidate the reaction mechanism by use of a pulse radiolysis technique.

Experimental

Chemicals. Chloroacetophenone isomers (Wako Pure Chemical and Aldrich) and *o*-chlorobenzaldehyde (Wako Pure Chemical) were purified by distillation. *N,N*-dimethylacetamide (DMA), *N,N*-dimethylformamide (DMF), dimethyl sulfoxide (DMSO), *N*-methyl-2-pyrrolidone (NMePy), and hexamethylphosphoric triamide (HMPA) used as solvents were distilled over calcium hydride. Solutions were prepared freshly before irradiation and were degassed under high vacuum.

Apparatus. The electron pulse from Osaka Univ. linear accelerator was used. The energy was 28-MeV and the pulse width was 8-ns. The dose was 1 kGy per pulse. A 450W xenon pulse lamp (OPG-450, Osram), a monochromator (Nikon G-250), and a photomultiplier (R-928) were used. The output of the photomultiplier was monitored by a programable transient digitizer (Tektronix 7912AD) with 7A29 plug-in and stored for display in a Melcom 70/25 computer (Mitsubishi Electric Co.).

Results and Discussion

Transient absorption spectra obtained by the pulse radiolysis of *o*-CAP in HMPA are shown in Fig. 1. The spectra with λ_{max} at 330 and 490 nm are assigned to the radical anion of *o*-CAP on the basis of the similarity to that of acetophenone which was measured in this work under the same reaction conditions (λ_{max} 330 and 490 nm).[8] The decay of the 330-nm band followed first order kinetics and the rate, 5.3×10^{6} s^{-1}, was independent of the concentration of *o*-CAP (1×10^{-2}—1×10^{-3} mol dm^{-3}). This fact is consistent with the unimolecular dissociation of the radical anion. Similar spectra were observed with *m*- and *p*-CAP. The decay rate of 330-nm bonds of *m*- and *p*-CAP were 9.6×10^{4} and 2.8×10^{5} s^{-1}, respectively. These rates are much slower than that of *o*-CAP.

The chemical reactivities of radical anions of these CAP isomers were also examined in other dipolar aprotic solvents such as DMA, DMF, DMSO, and NMePy. The spectral features of the radical anions formed in these solvents were not different from that in HMPA. However, the rate constants were dependent on the nature of solvents used. A good correlation between the rate constants (log k) and an acceptor number (AN) of the solvent[9] which is an empirical parameter reflecting the electrophilic properties of solvent was obtained as shown in Fig. 2.

In the cases of *m*- and *p*-CAP, an increase of solvent polarity resulted in an increase in the rate. In general, an acceleration of the rate is induced in such a case where the solvation is stronger in the transition state than in the initial state. In the present reactions, therefore, the negative charge of the radical anion must be localized in a molecule at the transition state which makes the solvation more tight. Indeed, the negative charge may be present initially at the delocalized π-orbital of an acetophenone moiety since the absorption spectra of the CAP radical anions are

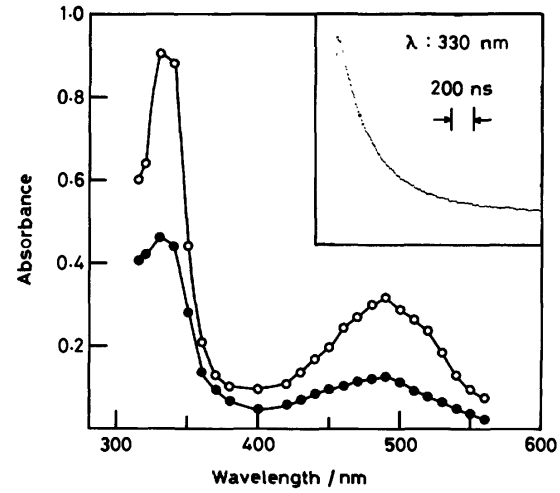

Fig. 1. Transient absorption spectra observed at immediately (○) and 200 ns (●) after an 8-ns pulse irradiation of a degassed HMPA solution of *o*-CAP (1×10^{-2} mol dm^{-3}) at room temperature. Absorption dose was 1 kGy/pulse. Insert: Decay curve of the 330-nm band.

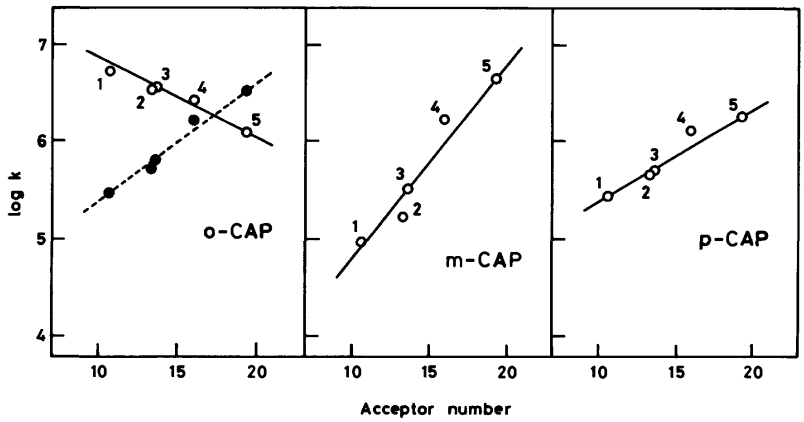

Fig. 2. Plot of log $k(s^{-1})$ vs. the acceptor number of the following solvents: 1, HMPA, 2, NMePy; 3, DMA; 4, DMF; 5, DMSO. The dotted line (--●--) indicates the result for *o*-chlorobenzaldehyde.

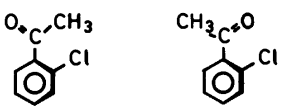
similar to that of acetophenone itself. The negative charge migrates to a C-Cl σ^* orbital at the transition state and finally localizes at a dissociated chlorine atom. Such an intramolecular electron-transfer mechanism has been proposed for the dissociation of aromatic halides by Neta and Behar[5] as shown in Eq. 1. The present observation is compatible with this mechanism.

$$\underset{\text{(I)}}{\overset{\cdots\overset{\cdot}{\cdot}\cdots}{CH_3COC_6H_4\text{-}Cl}} \rightleftharpoons \underset{\text{(II)}}{CH_3COC_6H_4\text{-}\overset{\cdot}{Cl}} \longrightarrow \underset{\text{(III)}}{CH_3COC_6H_4\cdot} + Cl^- \quad (1)$$

The slope of the straight line for the plot of log k vs. AN reflects the relative extent of solvation to the initial state and the transition state. The larger slope for *m*-CAP than for *p*-CAP as shown in Fig. 2 is explained by the fact that the negative charge at the C-Cl σ^* orbital in the transition state is more delocalized in *p*-CAP than in *m*-CAP simply due to the presence of an electron-withdrawing group at the para position. This delocalization of the negative charge at the transition state decreases the solvation and reduces the rate.

On the other hand, a negative slope was obtained in the case of *o*-CAP, that is, an increase of solvent polarity resulted in a decrease in the rate. This means that the extent of solvation decreased in the transition state. In the case of *o*-CAP, two conformers (IV and V)



(IV) (V)

exist and the C-CO-C plane is rotated from that of the phenyl ring on the basis of the strong steric interaction between the chlorine atom and oxygen atoms or methyl groups.[10] Consideration of steric and electrostatic factors indicated that an antiperiplanar-conformation, IV, is more favored than V. This argument concerning the stable conformation is also applicable to the radical anion. Therefore, the solvation of the negative-charged C-Cl bond at the transition state of the radical anion will be subject to steric hindrance by the proximately faced methyl group which leads to the abnormal solvent effect. The validity of such an explanation is supported by the findings that a normal behavior is observed for *o*-chlorobenzaldehyde in which such an intense steric effect as *o*-CAP cannot be expected as shown in Fig. 2 (dotted line).

In conclusion, we have demonstrated that the unimolecular dissociation of radical anions is subject to a remarkable solvent effect; normally an increase of solvent polarity results in an increase in the rate in consistent with the dissociation mechanism. Works along these lines are currently in progress.

Polystyrene Resin-Supported Aluminium Copper(I) Chloride as Selective Ethylene Adsorbent

Hidefumi HIRAI,* Masahiro NAKAMURA, Susumu HARA, and Makoto KOMIYAMA
Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, 7-3-1, Hongo, Bunkyo-ku, Tokyo 113
(Received June 13, 1986)

Synopsis. Solid adsorbents for ethylene are prepared by stirring copper(I) chloride, aluminium chloride, and a macroreticular type polystyrene resin in carbon disulfide, followed by removal of the liquid phase. The adsorbents effectively adsorb ethylene at 20 °C under 1 atm, and exhibit no measurable adsorptions of nitrogen, hydrogen, and methane.

Ethylene, one of the most important raw materials in chemical industry, is usually obtained as gas mixtures with nitrogen, hydrogen, methane, carbon monoxide, and others. Thus, ethylene must be separated from the gas mixtures prior to utilization.[1]

Previously, the authors have reported that toluene solutions of aluminium silver chloride[2] and the macroreticular type polystyrene resin-supported aluminium silver chloride[3] reversibly and selectively absorb ethylene under mild conditions.

This paper reports preparation of solid adsorbents for ethylene from copper(I) chloride, aluminium chloride, and a macroreticular type polystyrene resin. The ethylene adsorbing and desorbing abilities as well as selectivities of the ethylene adsorptions with respect to the adsorptions of other gases are described.

Experimental

A macroreticular type polystyrene resin, purchased from Bio-Rad Laboratories (Bio-Beads SM-2; divinylbenzene content, 20 mol%; diameter, 296—740 μm; average pore diameter, 9 nm; surface area, 300 m^2/g),[4] was successively washed with aqueous hydrochloric acid solution (6 mol dm^{-3}), with aqueous sodium hydroxide solution (4 mol dm^{-3}), with water, with methanol, and with dichloromethane, and then was dried in vacuo at 80 °C for 12 h. Aluminium chloride was purified by sublimation. Copper(I) chloride was reprecipitated using concentrated aqueous hydrochloric acid solution-water system, was washed with ethanol and diethyl ether, and was dried in vacuo at 80 °C for 12 h. Ethylene, nitrogen, hydrogen, methane, and carbon monoxide were passed through columns of molecular sieve 3A immediately before use.

The adsorbents were prepared by refluxing copper(I) chloride, aluminium chloride, and the polystyrene resin in carbon disulfide under dry nitrogen for 6 h. The charged molar ratios of copper(I) chloride and the aromatic residue of the polystyrene resin, respectively, to aluminium chloride were 1.0 and 1.2. Then the liquid phase was removed at 4 mmHg, where the temperature was gradually elevated from 20 to 60 °C. The adsorbents were obtained as orange colored beads.

Adsorptions of gases by the adsorbents were carried out at 20 °C under 1 atm, and were followed by the gas uptake using a gas burette. Gas compositions were determined by gas chromatography (Ohkura Model 701; column, Porapak Q; column temperature, 80 °C; carrier gas, helium).

Results and Discussion

The open circles in Fig. 1 depict the adsorption of ethylene at 20 °C under 1 atm by the adsorbent prepared from copper(I) chloride, aluminium chloride, and the macroreticular type polystyrene resin. The adsorption is rapid, and the equilibrium molar ratio of adsorbed ethylene to the charged copper(I) chloride is 1.40. The amount of ethylene adsorbed by 1 g of the adsorbent is 89 cm^3 (standard temperature and pressure).

Then, desorption of the adsorbed ethylene has been carried out by subjecting the adsorbent to a reduced pressure (8 mmHg) at 20 °C for 10 min. In the second adsorption, shown by the closed circles in Fig. 1, the equilibrium molar ratio of the adsorbed ethylene to the charged copper(I) chloride is 0.29. Both the time courses of the adsorptions and the equilibrium molar ratios in the third, the fourth, and the fifth adsorptions are identical with those in the second adsorption within experimental error. Reversible adsorption of ethylene is successfully achieved by use of the present adsorbent.

The difference between the molar ratio (1.40) of the adsorbed ethylene to the charged copper(I) chloride in the first adsorption and that (0.29) in the second and the later adsorptions corresponds to the amount of ethylene, which is not desorbed under the desorption conditions employed (8 mmHg, 20 °C for 10 min).

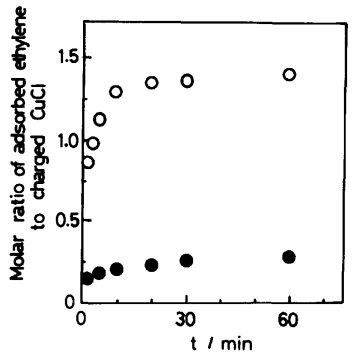

Fig. 1. Adsorption of ethylene under 1 atm at 20 °C by the polystyrene resin-supported aluminium copper (I) chloride: The first adsorption (○); the second adsorption (●) by the adsorbent which was subjected to a reduced pressure (8 mmHg) at 20 °C for 10 min after the first adsorption; the adsorbent was prepared from 2.57 g (26.0 mmol) of copper(I) chloride, 3.47 g (26.0 mmol) of aluminium chloride, and 3.24 g (31.1 milliequivalents in phenyl residue) of the macroreticular type polystyrene resin by use of 30 cm^3 of carbon disulfide.

The desorption of the ethylene adsorbed by the present adsorbent was also effectively carried out by heating the adsorbent to 90 °C under 1 atm for 10 min. The molar ratio of the desorbed ethylene to the charged copper(I) chloride was 0.47, as followed by the gas burette. In the following adsorption, the molar ratio of adsorbed ethylene to the charged copper(I) chloride was 0.47, which was exactly identical with the value for the ethylene desorbed in the foregoing desorption.

When the desorption of adsorbed ethylene was carried out under 8 mmHg at 142 °C for 10 min, the molar ratio of the desorbed ethylene to the charged copper(I) chloride was 0.87.

The present adsorbents exhibited no measurable adsorptions of nitrogen, hydrogen, and methane under 1 atm at 20 °C.

Separation of ethylene from ethylene–carbon monoxide mixture was examined by use of the adsorbent prepared from 12.0 mmol of copper(I) chloride, 12.0 mmol of aluminium chloride, and 1.50 g of the resin. Here, 1050 cm^3 of ethylene–carbon monoxide mixture having initial molar fraction 0.47 of ethylene was contacted with the adsorbent at 20 °C under 1 atm. The adsorbent rapidly adsorbed both ethylene and carbon monoxide[5] from the gas mixture, and the equilibrium amounts of adsorbed ethylene and adsorbed carbon monoxide were 9.0 mmol and 1.8 mmol, respectively. These values were evaluated by use of both the molar fraction (0.35) of ethylene in the gas phase after the contact with the adsorbent, measured by gas chromatography, and the total amount (264 cm^3) of the adsorbed gas, determined by a gas burette. Thus the amount of adsorbed ethylene was 5 times as large as that for carbon monoxide.

The efficient adsorptions of ethylene by the present adsorbents are ascribed to coordination of ethylene to the aluminium copper(I) chloride, which is formed from copper(I) chloride and aluminium chloride and is highly dispersed in the polystyrene resin.[5] The aluminium copper(I) chloride forms molecular complexes with carbon monoxide[5] and with various aromatic compounds.[6,7] The adsorbing capacity of the adsorbent, prepared from copper(I) chloride and the polystyrene resin in the absence of aluminium chloride, is minimal: the molar ratio of adsorbed ethylene to the charged copper(I) chloride is only 0.03.

Rather low price of copper(I) chloride, in comparison with the price of silver chloride used for the preparation of the polystyrene resin-supported aluminium silver chloride as selective ethylene adsorbent,[3] is an advantage of the present adsorbents from the viewpoints of practical applications.

In conclusion, solid adsorbents for ethylene are prepared from copper(I) chloride, aluminium chloride, and a macroreticular type polystyrene resin. The adsorbents are applicable to selective separation of ethylene from gas mixtures containing ethylene together with nitrogen, hydrogen, methane, and carbon monoxide.

High Stereoselectivity of Tris[4-(*l*-menthyloxy)-1-(*p*-tolyl)-1,3-butandionato]lanthanoid(III)[1)]

Hisashi Ōkawa,* Michio Nakamura, Yūko Shuin, and Sigeo Kida†

(Received May 30, 1986)

Synopsis. Tris[4-(*l*-menthyloxy)-1-(*p*-tolyl)-1,3-butanedionato]lanthanoid(III), [Ln(*l*-moba-Me)$_3$](Ln=La, Pr, Nd, Eu, Gd, Dy, Ho, Er, Tm), showed a high stereoselectivity effected by intramolecular noncovalent interactions, giving rise to the cis-Δ form.

We have shown that interligand noncovalent interactions operate within a complex molecule and cause a high stereoselectivity of metal complexes to give rise to one of the possible stereoisomers.[2)] In the case of tris[4-(*l*-menthyloxy)-1-phenyl-1,3-butanedionato]metal(III) [M(*l*-moba)$_3$] (M=Co, Cr, Mn, Ln-(lanthanoid ions)) the cis-Δ form is predominantly formed.[3,4)] Further, it was found that tris[4-(*l*-menthyloxy)-1-(*p*-tolyl)-1,3-butanedionato]metal(III) [M(*l*-moba-Me)$_3$] (M=Co, Cr, Mn) showed a higher stereoselectivity compared with [M(*l*-moba)$_3$].[5)] The configurational analysis for [Co(*l*-moba-Me)$_3$] by means of high resolution NMR spectroscopy has demonstrated that this complex is in pure cis-Δ form.[6)] For our ultimate object to develope new stereoselective reactions by use of sterically-controlled lanthanoid complexes, it is desired to prepare new complexes of higher stereoselectivity. This paper deals with the synthesis and stereoselectivity of lanthanoid complexes with H(*l*-moba-Me).

Experimental

Preparations. H(*l*-moba-Me) was prepared by the method described previously.[5)]

[Ln(*l*-moba-Me)$_3$]. H(*l*-moba-Me) (1×10^{-3} mole) and NaOH (1×10^{-3} mole) in ethanol (30 cm^3) were stirred for 30 min. To the resulted gelatinous solution was added lanthanoid(III) chloride (3.3×10^{-4} mole), and the mixture was stirred for 3 h. The reaction mixture was filtered, and the solvent was evaporated to dryness. The oily substance thus obtained was crystallized from ethanol.

Measurements. Electronic and circular dichroism spectra were recorded in benzene on a Shimadzu UV-215 Spectrophotometer and a JASCO J-500 Spectropolarimeter, respectively. Molecular weights were determined with a Hitachi Perkin-Elmer 115 Apparatus in benzene. The elemental analyses were obtained at the Elemental Analysis Service Center, Kyushu University.

Results and Discussion

The elemental analyses for the complexes (Table 1) suggest that all the complexes obtained can be described by the general formula [Ln(*l*-moba-Me)$_3$]. The molecular weight (1150) of [Eu(*l*-moba-Me)$_3$] determined at the 0.13 wt% concentration in benzene

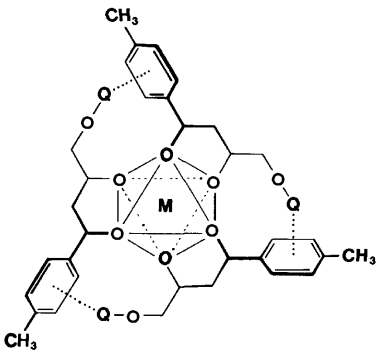

Fig. 2. Schematical representation of interligand interaction in [M(*l*-moba-Me)$_3$].

well agrees with the value (1140.4) for this composition, whereas the molecular weight (1260) at the 0.87 wt% is slightly larger. It is likely that [Ln(*l*-moba-Me)$_3$] dimerizes at a higher concentration, as demonstrated for the complexes with H(*l*-moba)[4] and other lanthanoid complexes with 1,3-diketones.[7] However, such a tendency to dimerize is much low compared with the *l*-moba complexes[4] as judged from the molecular weight measurements, and [Ln(*l*-moba-Me)$_3$] may be assumed to be practically monomeric in the concentration range ($\approx 10^{-2}$ M (1 mol dm^{-3})) for the electronic and circular dichroism spectral measurements.

In Table 2 are given spectral and circular dichroism spectral data in benzene. Electronic and circular dichroism spectra for [Pr(*l*-moba-Me)$_3$] are shown in Fig. 1 together with the circular dichroism spectrum of [Pr(*l*-moba)$_3$]. The Pr, Nd, Eu, Dy, Ho, Er, and Tm complexes show circular dichroism at the f-f transition bands. The CD intensities are significantly high and comparable to those of the L-amino acidato complexes.[8,9] This fact indicates that the optical activities observed are due to the configurational effect (disymmetry around the metal) but not the vicinal effect from the *l*-menthyl moiety. It is likely that the noncovalent interligand interaction occuring between the *l*-menthyl and *p*-tolyl groups leads to a controlled disposition of the *l*-moba-Me$^-$ molecules about the metal (Fig. 2). The preferred configuration of the complexes is assumed as cis-Δ by analogy with the case of [Co(*l*-moba-Me)$_3$] and [Cr(*l*-moba-Me)$_3$].[5]

As is seen in Fig. 1, the CD bands of f-f transitions of [Pr(*l*-moba-Me)$_3$] are more intense than those of [Pr(*l*-moba)$_3$].[4] The same trend was observed for the Nd, Dy, Eu, Ho, and Tm complexes with *l*-moba and *l*-moba-Me (the comparison can not be made for the Gd and Er complexes because Gd complexes show no f-f band (and thence no CD) below 310 nm[10] and the Er complex of *l*-moba has not been obtained). This trend is the same as that found for the transition metal homologs.[5] Thus, it is revealed that the interligand *l*-menthyl/*p*-tolyl interaction is more effective than the *l*-menthyl/phenyl interaction also for lanthanoid complexes in causing the stereoselectivity of the complexes.

This work was supported by the joint Studies Program (1980—1981) of the Institute for Molecular Science.

Molecular Structure of a Reductive Dimer of Pulegone

Mitsuko KIKUCHI* and Zenei TAIRA†
Department of Industrial Chemistry, College of Engineering, Nihon University, Koriyama, Fukushima 963-11
†Department of Pharmacology, Tokushima Bunri University, Tokushima 770
(Received March 24, 1986)

Synopsis. The molecular structure of "bishydropulegone," a reductive dimer of pulegone, was determined as (1*R*,3′a*R*,4*R*,6′*R*,7′a*S*)-7-′a-hydroxy-2′,2′,3′,3′,4,6′-hexamethylspiro[cyclohexane-1,1′-indan]-2-one by X-ray crystallographic analysis.

After "bishydropulegol" $C_{20}H_{36}O_2$ had been isolated by Pascual et al. as one of the dimeric products of the reduction of (*R*)-(+)-pulegone with sodium,[1] a systematic investigation of this reduction was carried out by the same group.[2-15] They isolated five hydroxy ketones and the diols as the reductive dimer and elucidated their structures by chemical degradation and spectral studies. Furthermore, many derivatives of these products were also synthesized for the structural elucidation of these dimers. Among their work, the most prominent results obtained were the classification of the five ketols into two groups acording to the orientation of the carbonyl group in the ring B[9] and a determination of the absolute configurations of the spiro-carbons of two hydroxy ketones ("bishydropulegone" and "isobishydropulegone") and the relative stereochemistries of the hydroxyl and carbonyl groups of these and other hydroxy ketones.[14] However, the stereochemistry at the C05 and C09 positions of these products has not yet been elucidated.

In this paper, we describe the molecular structure of bishydropulegone (Fig. 1) determined by an X-ray crystallographic analysis.

Experimental

Melting points were determined with a Mitamura melting point apparatus (No. 8209) and are uncorrected. IR spectra were recorded on a JEOL JIR 100 FT-IR spectrophotometer in CCl_4. ^1H NMR spectra were recorded on a JEOL FX-90Q (90 MHz) instrument in $CDCl_3$, unless otherwise stated. Coupling constants (*J*) are given in hertz.

(*R*)-(+)-pulegone was supplied by Takasago Perfumery Industrial Co., Ltd.: Bp 94—95 °C/10 mmHg (1 mmHg= 133.322 Pa); n_D^{20} 1.4875; d_4^{20} 0.9351; $[\alpha]_D^{20}$ +20.2° (*c* 1.01, $CHCl_3$).

Bishydropulegone was prepared through the oxidation of bishydropulegol, which was obtained by a modified Pascual procedure as follows.[1] Small pieces of Sodium (ca. 9 g) were gradually added to a solution of (*R*)-(+)-pulegone (10.4 g, 68.4 m mol) in ether (20 ml) in an ice bath. The whole mixture was stirred at room temperature for 24 h. Then, unreacted sodium pieces were removed and wet ether (50 ml) was added to the reaction mixture. Water (each 5 ml) was added three times over 3 d. The product was extracted with ether and the extract was washed with water and saturated brine and then dried (anhydrous sodium sulfate). The removal of the solvent left an oil (10.3 g), which was distilled to give a fraction (6.35 g, 61.5%) boiling at 90—144 °C (bath temperature/15—12 mmHg) and a residual oil (3.97 g, 38.5%). The residue was passed through a sillica-gel column by eluting with hexane-AcOEt (5:1) to give a soft mass (2.34 g). The mass was further purified using a sillica-gel column chromatography by eluting with hexane-AcOEt (10:1) to give bishydropulegol (1.20 g, 51.2% of the residue) as an amorphous soft mass. To a stirred solution of bishydropulegol (230 mg, 0.75 m mol) in acetic acid (1.6 ml) was added dropwise a 10% CrO_3-CH_3COOH solution (ca. 16 ml). After being stirred at room temperature for 24 h, the mixture was diluted with water (3.3 ml) and extracted with benzene. The extract was washed with water and saturated brine and dried (anhydrous sodium sulfate). The removal of the solvent afforded an oil (214 mg), which was purified by sillica-gel column chromatography using hexane-AcOEt (10:1) as the solvent to give bishydropulegone (124 mg, 54.3%) as crystals, mp 100 °C, recrystallized from petroleum ether-EtOH (10:1); $[\alpha]_D^{19}$ +72.1° (*c* 1.06, $CHCl_3$); IR (CCl_4) 3474 (intramolecularly hydrogen-bonded OH), 1678 (C=O) cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.86 (3H, d, *J*=6.4 Hz, Me), 1.01 (3H, d, *J*=6.4 Hz, Me), 0.87 (3H, s, Me), 0.98 (3H, s, Me), 1.09 (3H, s, Me), 1.25 (3H, s, Me), 4.97 (1H, d, *J*=2.1 Hz, OH). Anal. Calcd for $C_{20}H_{34}O_2$: C, 78.37; H, 11.18%. Found: C, 78.64; H, 11.57%.

X-Ray diffraction analysis of bishydropulegone. For the X-ray experiments, a single crystal (0.4×0.4×0.4 mm) was mounted on a Rigaku automatic four-circle diffractometer AFC-6B using graphite monoclomated Mo $K\alpha$ radiation (λ=0.71069 Å). Crystal data: Orthorhombic; space group $P2_12_12_1$; *a*=11.765(3), *b*=14.392(4), *c*=10.833(3) Å; *U*=1834.3 Å^3; D_x=1.110 g cm^{-3} for *Z*=4; μ(Mo $K\alpha$)=0.745 cm^{-1}.

Intensity data with a range $2°<2\theta<50°$ were collected by the ω scan method at a rate of 4° min^{-1}. The data were corrected for Lorentz, polarization factors and background effects, but not corrected for the absorption. The independent reflections (1729) were observed under the criterion $|F|>6\sigma_F$ and were used in subsequent calculations.

The crystal structure was solved by a direct method using the program MULTAN.[16] Refinements of the structure were performed by block-diagonal least-squares calculations with anisotropic thermal parameters for non-hydrogen atoms. The hydrogen atoms were located on a difference map and included only structure-factor calculations which assumed the isotropic thermal parameters of the binding non-hydrogen atoms. The final refinement yielded an *R* value of 0.089 and an R_w of 0.103 (used unit weight).

The atomic scattering factors used were those from the literature.[17]

The absolute configuration was elucidated in the relation with (*R*)-(+)-pulegone[18] used as the reactant.

All crystallographic calculations were performed on the PANAFACOM U-1400 computer in Tokushima Bunri University (RASA and X-STANP program package) and at the computer center in Tokushima University (MULTAN program package).

Results and Discussion

The molecule is depicted in Fig. 2 (drawn by ORTEP).[19] The absolute configuration of the spiro-carbon atom of bishydropulegone was unequivocally established as *R*.[14] The configuration of the 4-methyl

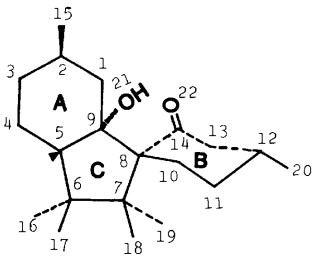

Fig. 1.

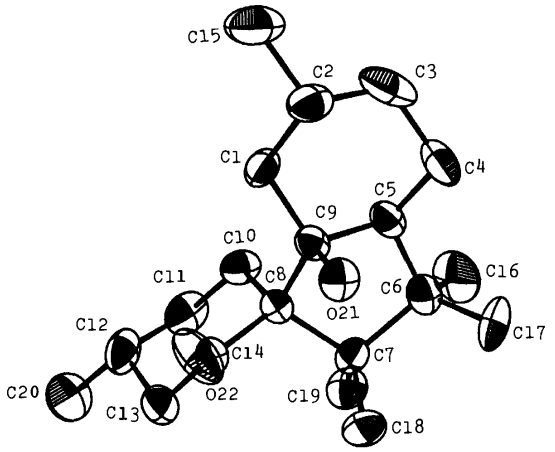

Fig. 2. ORTEP drawing of the molecular structure of bishydropulegone. Hydrogen atoms are omitted for clarity.

group relative to C06 and C07 is syn; also, the carbonyl group is syn with respect to the hydroxyl group. There is an intramolecular hydrogen bond between the hydroxyl group 021-H and the ketone 022 as shown by the short contact 2.635(8) Å[021···022]. This was also confirmed by measurements of the IR spectra with an FT-IR spectrometer in highly diluted solutions (2.5×10^{-3} mol dm^{-3}) of bishydropulegone (3474 and 1678 cm^{-1}).

The above results were completely the same as the conclusions obtained by Pascual et al.[14] As a new result, we showed that the ring fusion in perhydroindene is trans.

As a characteristic structural feature of bishydropulegone, the bond distances C06 and C07 [1.629 Å (11)] and C08 and C07 [1.615 Å (10)] were unusually extended. This may be due to four bulky tertiary methyl groups at C06 and C07.

In conclusion, the whole stereochemistry of bishydropulegone was determined to be (1*R*,3′a*R*,4*R*,-6′*R*,7′a*S*)-7′a-hydroxy-2′,2′,3′,3′,4,6′-hexamethylspiro[cyclohexane-1,1′-indan]-2-one.

We thank professor Akira Yoshikoshi of Tohoku University, and Professor Yoshinori Asakawa of Tokushima Bunri University for their helpful discussions. We also thank Dr. Shinji Onodera of Tohoku University for FT-IR measurements and Takasago Perfumery industrial Co., Ltd. for kindly supplying the (*R*)-(+)-pulegone.

The list of the structure factor, table of atomic parameters, bond distances, bond angles and torsion angles data has been deposited as Document No. 8649 at the Office of the Editor of Bull. Chem. Soc. Jpn.

Interaction of Iron(III) Chloride with D-Fructose in an Acidic Solution

Koji ARAKI* and Shinsaku SHIRAISHI*
Institute of Industrial Science, The University of Tokyo,
7-22-1 Roppongi, Minato-ku, Tokyo 106
(Received June 13, 1986)

Synopsis. Complex formation between Fe(III) and D-fructose in an acidic solution was studied by electronic and CD spectroscopy, and the role of the complex in the photochemically-induced oxidation of D-fructose by Fe(III) was discussed.

An Fe(III)–monosaccharide complex was suggested to play an essential role in the photochemically-induced oxidation of monosaccharides by $FeCl_3$.[1-3] The reaction was assumed to proceed via an Fe(III)–D-fructose complex, and irradiation of near-UV light caused oxidative cleavages of C–C bonds of monosaccharides with high specificity.[1] Though interactions between monosaccharides and a variety of metal ions have been the subject of intense studies,[4-6] only a little has been known as to the interaction of Fe(III) with monosaccharides in solutions.[6,7] Because of the physiological importance of the Fe(III)–monosaccharide systems,[3,8] we report here the interaction of Fe(III) with D-fructose in an acidic solution and clarify further the role of the Fe(III)–D-fructose complex in the photooxidation of D-fructose.

Experimental

Photoirradiation was carried out according to the method described previously.[1,3] Electronic and CD spectra (path length 10 mm) were recorded with JASCO UVIDEC-505 and J-20 spectrophotometers, respectively.

Results and Discussion

An aqua complex of Fe(III) shows a strong ligand-to-metal charge-transfer (LMCT) band in near-UV region.[9] Upon addition of D-fructose to an acidic $FeCl_3$ solution, the initial brown solution becomes reddish with concomitant decrease in pH. Difference spectra of the $FeCl_3$ solutions before and after addition of D-fructose showed appearance of the absorption band at 300—350 nm along with the band at 280 nm due to an acyclic form of D-fructose (Fig. 1).[10] The absorption at 300—350 nm in the difference spectra increased as the D-fructose concentration increased, though D-fructose alone had no absorption in this range. Therefore, this absorption band is ascribed to the Fe(III)–D-fructose complex. CD spectra of an $FeCl_3$–D-fructose solution further supported this assignment (Fig. 2). In addition to a strong positive absorption at 280 nm presumably due to the acyclic form of D-fructose, the CD spectra showed a weak negative absorption at 320 nm. The presence of the CD absorption at 320 nm indicated the contirbution of D-fructose to this absorption band, confirming the formation of the Fe(III)–D-fructose complex. Thus, the band observed at 300—350 nm in the difference spectra is ascribed to the LMCT band of the Fe(III)–D-fructose complex. Upon photoirradiation, the CD absorption at 320 nm disappeared (Fig. 2b). As the highest quantum yield for the photooxidation of D-fructose was observed at around 330 nm,[1] the result presented here confirmed that the reaction proceeded by the excitation of the LMCT band of the Fe(III)–D-fructose complex.

Apparent stability constants (K_{app}) of the Fe(III)–D-fructose complex in aqueous acidic solutions (pH 1—3) at 20 °C were determined from the electronic (380 nm) and CD (337 nm) spectra by the Benesi-Hildebrand and Rose-Drago methods.[11,12] The plots obtained by assuming a formation of the 1:1 complexes (Eq. 1) in the presence of a large excess amount of D-fructose gave satisfactory results. Typical Benesi-Hildebrand plots are shown in Fig. 3, and

$$\text{Fe(III)} + \text{D-fructose} \overset{K_{app}}{\rightleftharpoons} \text{complex};$$
$$K_{app} = \frac{[\text{complex}]}{[\text{Fe(III)}][\text{D-fructose}]} \quad (1)$$

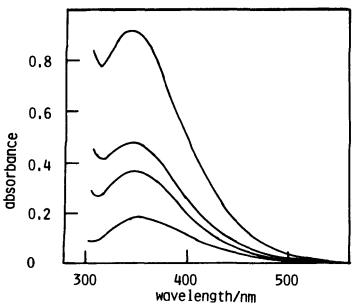

Fig. 1. Difference spectra of of $FeCl_3$(1×10^{-3} mol dm^{-3} solutions before and after addition of D-fructose; D-fructose concentrations are 0.4, 0.8, 1, and 2 mol dm^{-3}, respectively.

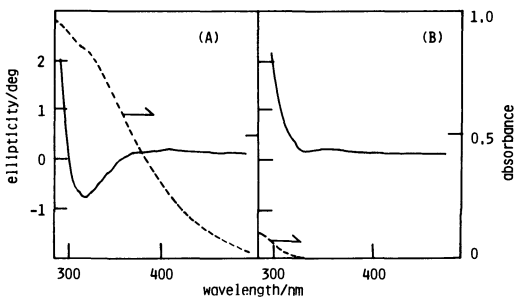

Fig. 2. CD(——) and electronic (----) sectra of $FeCl_3$ (1×10^{-3} mol dm^{-3})–D-fructose(0.4 mol dm^{-3}) solution (A) before and (B) after irradiation of Pyrex-filtered light at 20 °C.

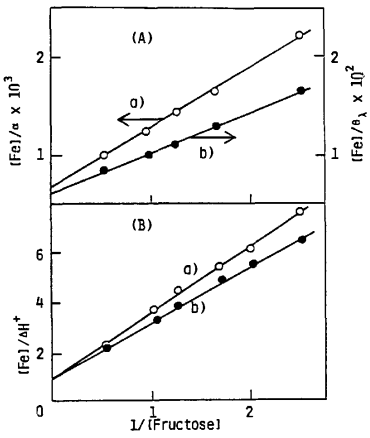

Fig. 3. Benesi-Hildebrand plots ([Fe]/absorbance vs. 1/[Fructose], where [Fructose]≫[Fe]) for the complex formation between Fe(III) and D-fructose at 20 °C. (A) Applied for the (○) electronic (380 nm) and (●) CD (337 nm) spectra of the $FeCl_3$(5×10^{-4} mol dm^{-3})-D-fructose solutions at pH 2.82; (B) Applied for the amounts of H^+ liberated upon addition of D-fructose to (○) $FeCl_3$ and (●)$Fe(NO_3)_3$ solutions (4×10^{-3} mol dm^{-3}) at pH 2.50.

the results are summarized in Table 1. When pH of a solution was below 2, the absorption bands due to the complex was too small to determine the K_{app} values, and a rough estimation was made only from the electronic spectra. The stability constants could also be estimated from the amounts of H^+ liberated ($\Delta[H^+]$) on addition of D-fructose to $FeCl_3$ solutions. The $\Delta[H^+]$ values were estimated from pH decreases of freshly-prepared $FeCl_3$ solutions on addition of a large excess amount of D-fructose. If we assume that n H^+ are liberated upon formation of the 1 : 1 complex, the concentration of the complex is expressed as $\Delta[H^+]/n$ and the Benesi-Hildebrand plot can be applied by replacing absorbance and molar extinction coefficient with $\Delta[H^+]$ and n, respectively.[11] The plot gave a linear line yielding $1/(n\,K_{app})$ as a slope and $1/n$ as an intercept (Fig. 3), and the K_{app} values obtained here were in good agreement with those obtained from the electronic and CD spectra (Table 1). Therefore, formation of the complex can be written as follows (Eq. 2), and log K_s is estimated to be −2.8.

$$\text{Fe(III)} + \text{D-fructose} \overset{K_s}{\rightleftharpoons} \text{complex} + H^+ \qquad (2)$$

$$K_s = \frac{[\text{complex}][H^+]}{[\text{Fe(III)}][\text{D-fructose}]}$$

Table 1. Apparent Stability Constants (K_{app}) at 20 °C.

pH	Fe(III) salt	K_{app}
2.82	$FeCl_3$	1.03(UV); 1.04(CD)
2.50	$FeCl_3$	0.4(UV); 0.4(CD); 0.40(pH)
	$Fe(NO_3)_3$	0.37(pH)
1.20	$Fe(NO_3)_3$	0.03(UV)

K_{app} values were estimated from (UV): the electronic spectra (380 nm), (CD): the CD spectra (337 nm), and (pH): the amounts of H^+ liberated.

We previously reported that the quantum yield of the reduction of Fe(III) in the photochemically-induced oxidation of D-fructose (0.5 mol dm^{-3}) by Fe(III) (2×10^{-3} mol dm^{-3}) was 0.061 at 338 nm.[1] Since the action spectrum of the reaction coincided well with the absorption spectrum of the complex,[1] the reaction was assumed only to proceed by the light absorption of the complex but not by that of free Fe(III). Proportion of the light absorbed by the complex was determined from the electronic and difference spectra, and concentration of the complex was estimated from the K_s value obtained here. Thus, the quantum yield for the photoreactivity of the complex was estimated to be 0.3, showing that the excitation of the LMCT band of the complex efficiently induced reduction of Fe(III) with concomitant oxidation of D-fructose.

Viscosity *B* Coefficients for *N,N'*-Polymethylenebis-(trialkylammonium) Dibromides in Aqueous Solutions

Kunio TAMAKI,* Goro HORII, Takashi CHIDA, Keiko OCHIAI, and Yoshiyuki KADOKURA
Department of Chemistry, Yokohama City University, Kanazawa-ku, Yokohama 236
(Received May 14, 1986)

Synopsis. The viscosity *B* coefficients for aqueous solutions of *N,N'*-polymethylenebis(trialkylammonium) dibromides $[(C_mH_{2m+1})_3N(CH_2)_nN(C_mH_{2m+1})_3]Br_2$ (m=2—4, n=3—6, 8, 10, and 12) and, for comparison, of $C_nH_{2n+1}N(C_mH_{2m+1})_3Br$ (m=2, n=1—6; m=3,4, n=2—6) have been determined at 25 and 35 °C. The effect of structural changes in the solvent water upon the dissolution of these homologous electrolytes is discussed.

The physicochemical properties of aqueous solutions of tetraalkylammonium salts have been studied by many investigators in terms of the structural changes in liquid water caused by these hydrophobic solutes.[1] However, the solubilities of tetrapentylammonium salts and the higher homologs of this series are too small for precise measurements. On the other hand, bis(quaternary ammonium) salts are highly soluble in water, and it seems that bis(quaternary ammonium) salts can be expected to exhibit the characteristics of large hydrophobic solutes in water. In order to elucidate the balance of the ionic hydration and the hydrophobic hydration of *N,N'*-polymethylenebis(trialkylammonium) dibromides in water, we have extended the measurements of the viscosity *B* coefficients for these electrolytes in water. In a previous paper,[2] the results of *N,N'*-polymethylenebis-(trimethylammonium)dibromides (to be abbreviated as MeC_nMe) and, for comparison, of alkyltrimethylammonium bromides (to be abbreviated as C_nMe) were reported. This paper will describe the experimental results for three homologous series of electrolytes; *N,N'*-polymethylenebis(triethylammonium) dibromides (to be abbreviated as EtC_nEt), *N,N'*-polymethylenebis(tripropylammonium) dibromides (to be abbreviated as PrC_nPr) and *N,N'*-polymethylenebis-(tributylammonium) dibromides (to be abbreviated as BuC_nBu). For comparison, the viscosity *B* coefficients of the corresponding alkyl compounds with a single terminal quaternary ammonium group, alkyltriethylammonium bromides (to be abbreviated as C_nEt), alkyltripropylammonium bromides (to be abbreviated as C_nPr) and alkyltributylammonium bromides (to be abbreviated as C_nBu), have also been studied.

Experimental

Materials. EtC_nEt, PrC_nPr, and BuC_nBu were prepared by refluxing the α,ω-dibromoalkanes with an excess of the respective trialkylamines in ethanol or acetonitrile.[3,4,5] After the solvent had been removed, the salts were purified several times by recrystallization from suitable solvents: acetone–ethanol solutions for EtC_nEt and ethyl acetate–ethanol solutions for PrC_nPr and BuC_nBu. $PrC_{12}Pr$, BuC_8Bu, $BuC_{10}Bu$, and $BuC_{12}Bu$ were found to be fairly difficult to obtain as solid samples from reaction mixtures, so they were precipitated from reaction mixtures by means of the repeated extraction of the unreacted or impure materials with dry ethyl acetate at −20 °C. C_nEt (except for C_1Et), C_nPr, and C_nBu were prepared by refluxing the alkyl bromides with an excess of the respective trialkylamines in ethanol. C_1Et was prepared by the reaction of *N,N*-diethylmethylamine with ethyl bromide in ethanol. The salts were recrystallized several times from suitable solvents: ethyl acetate–ethanol solutions for C_nEt, ethyl acetate–acetone solutions for C_nPr and C_2Bu, and ethyl acetate for C_3Bu, and C_4Bu. C_5Bu and C_6Bu were found to be fairly difficult to obtain as solid samples from reaction mixtures. C_5Bu and C_6Bu were precipitated by the repeated extraction of the unreacted or impure materials with butyl acetate and isopentyl acetate respectively. All the salts were dried in vacuo at room temperature for several days and then analyzed for bromide ion by means of argentrometric titration. The salts were found to have a purity greater than 99.5%. Water was triply distilled.

Viscosity Measurements. The viscosities were measured at 25 and 35 °C using an automatic viscometer of the Shibayama Scientific Co., Ltd. The densities were measured using a vibrating-tube densimeter, twin-type SS-D-200 of the Shibayama Scientific Co., Ltd. The detailed procedure was described in a previous paper.[6] The electric conductivities were measured with a Yokogawa audio-frequency bridge using a frequency of 1000 Hz.

Results and Discussion

The Viscosity *B* Coefficients of Electrolytes. Jones and Dole[7] showed that the viscosity of dilute electrolyte solutions, η, can be related to the following equation:

$$\eta = \eta_0(1 + Ac^{1/2} + Bc), \quad (1)$$

where η_0 is the viscosity of the solvent, c is the molar concentration, and A and B are the characteristic constants of the solute. In a previous work[2] for MeC_nMe and C_nMe, it was found that the viscosities can be represented by Eq. 1 for concentrations up to about 0.1 mol dm^{-3}. However, successive studies of organic electrolytes with large values of viscosity *B* coefficients such as are used in this work revealed that the viscosities even in fairly dilute solutions cannot be described by Eq. 1; therefore the extended Jones-Dole equation with an extra term in c^2 was applied:

$$\eta = \eta_0(1 + Ac^{1/2} + Bc + Dc^2), \quad (2)$$

where D is a constant, whose significance is not completely understood. The A coefficient was interpreted theoretically by Falkenhagen and Vernon[8]; it can be calculated using the data of the limiting equivalent conductivities of the salt, the cation, and the anion. The electric conductivities of the aqueous solutions for bis(quaternary ammonium) salts as used in this work were interpreted in terms of 2-1

electrolytes by Fuoss and Chu[9] and Evans et al.[3,10] The A coefficient is fairly small numerically, and the contribution of the $Ac^{1/2}$ term to the viscosity is relatively small, in the solutions of such organic electrolytes with large B coefficients as are used in this work. The B coefficients are related to the ion-solvent interactions and to the size and shape of the ions, and are highly specific for the electrolytes and the temperature.

Equation 2 may be converted to:

$$(\eta/\eta_0 - 1 - Ac^{1/2})/c = B + Dc. \quad (3)$$

When the left-hand side of Eq. 3 is plotted against c, the viscosity B coefficient is obtained as the intercept

of a straight line. For example, Figs. 1—3 show the results of plotting Eq. 3 for EtC_nEt, PrC_nPr, and BuC_nBu respectively. The values of A and B for the electrolytes are summarized in Table 1. The B values for C_2Et, C_3Pr, and C_4Bu are in reasonable agreement with the literature values.[11,12] The B values for six homologous series of compounds increase approximately linearly with the number of carbon atoms in the polymethylene or alkyl group, n, respectively.

The Solute-Solvent Interaction. The temperature dependence of the B values is a factor of the solute-solvent interaction; the B values increase with the temperature for a solvent-structure-breaking salt, and decrease with the temperature for a solvent-structure-making solute.[13] For all the organic electrolytes used in this work, it may be seen in Table 1 that the B values decrease as the temperature is raised from 25 to 35 °C; therefore they may be considered to behave as structure-making salts in water.

Figure 4 shows the changes in the viscosity B coefficients which occur as the temperature is raised from 25 to 35 °C, ΔB, as a function of n for all the homologous series used in this work. The results for the MeC_nMe and C_nMe series reported in a previous paper[2] are also included in Fig. 4. It is found that the ΔB values generally decrease with n for each homologous series of electrolytes, and that the ΔB values for both bis(quaternary ammonium) compounds and the corresponding terminal mono-(quaternary ammonium) compounds with the same number of n are in these orders: $BuC_nBu<PrC_nPr<EtC_nEt<MeC_nMe$ and $C_nBu<C_nPr<C_nEt<C_nMe$ respectively. If we take one-half the ΔB values for $[(C_mH_{2m+1})_3N(CH_2)_nN(C_mH_{2m+1})_3]Br_2$, the ΔB values for a series of $-(CH_2)_nN(C_mH_{2m+1})_3Br$ can be estimated. The ΔB vs. n relations thus obtained are plotted as dotted lines in Fig. 4. It may be seen that, for the same number of n, the ΔB values for $-(CH_2)_nN(CH_3)_3Br$ are larger than those of ΔB for C_nMe. This fact indicates the hydrophobic character of the polymethylene chain in MeC_nMe is considerably diminished as compared with that of the alkyl chain in C_nMe with the same number of n. Analogous results are still observed by a comparison of the ΔB values for the EtC_nEt and C_nEt series; the ΔB values for $-(CH_2)_nN(C_2H_5)_3Br$ are larger than those of C_nEt. It seems that two terminal $(C_2H_5)_3N^+$- groups situated at opposite ends of a chain may interfere with the interaction of a polymethylene group with water.

On the other hand, it may be seen from Fig. 4 that, for the same number of n, the ΔB values of $-(CH_2)_nN(C_3H_7)_3Br$ and $-(CH_2)_nN(C_4H_9)_3Br$ are nearly the same as those of C_nPr and C_nBu, respectively. In these cases, the hydrophobic hydration of propyl or butyl groups attached to the charge-bearing nitrogen atoms surpass the ionic hydration due to the ionic parts. Therefore, it seems that the hydrophobic characteristics of the polymethylene groups of the PrC_nPr and BuC_nBu series are comparable to those of the alkyl group of the corresponding mono(quaternary ammonium) salts.

A: $-(CH_2)_nN(CH_3)_3Br$, B: $-(CH_2)_nN(C_2H_5)_3Br$, C: $-(CH_2)_nN(C_3H_7)_3Br$, D: $-(CH_2)_nN(C_4H_9)_3Br$.

B coefficients of electrolytes are considered to be determined by adding the individual contribution of the solute constituent ions. The ionic B values for the Br^- ion, derived according to the convention of Gurney[14] that the ionic B values for K^+ and Cl^- ions are equal, are -0.40 and -0.26 dm³ mol⁻¹ at 25 and 35 °C respectively.[12] Therefore, the values of ΔB for all the organic ions used in this work become more negative than those of the corresponding salts, and the organic ions may also be classified as structure-making ions.

A Kinetic Study of the Thermal Conversion of 1′,3′,3′-Trimethylspiro-[2*H*-1-benzopyran-2,2′-indoline]-8-carboxylic Acid

Yoshimi Sueishi, Masanobu Ohcho, Shunzo Yamamoto, and Norio Nishimura*
Department of Chemistry, School of Science, Okayama University, Tsushima, Okayama 700
(Received May 26, 1986)

Synopsis. The rate of the thermal conversion of 1′,3′,3′-trimethylspiro[2*H*-1-benzopyran-2,2′-indoline]-8-carboxylic acid (8-COOH-SP) from its spiro form to its merocyanine form has been measured in several solvents at high pressures. Small solvent- and pressure-dependencies of the rate were observed. These results suggest that the electronic structure of the transition state of this reaction is nonpolar and that it is similar to that previously observed for the thermal conversion of so-called 6-nitrospiropyran from its merocyanine form to its spiro form.

It is a matter of interest, when an isomerization is accompanied by a π- or σ-bond fission, what kind of bond fission (homolytic or heterolytic?) is involved. Hitherto, we have investigated the cis-trans thermal isomerizations of azobenzenes,[1-3] acetylindigos,[4] and formazans[5] from such a point of view. The isomerization of the so-called spiropyrans has attracted much attention because of their reversible photochromic and thermochromic behavior. In a previous paper,[6] we have studied the solvent and pressure effects on the rate of the thermal conversion of 1′,3′,3′-trimethyl-6-nitro[2*H*-1-benzopyran-2,2′-indoline](6-NO_2-SP) and suggested that the observed results are more consistent with the mechanism involving the homolytic fission of the C_{spiro}-O bond than with that involving the heterolytic fission (Scheme 1). In contrast to 6-NO_2-SP, it was shown[7] that the spiro (SP) form of 8-COOH-SP is less stable than its merocyanine (MC) form; an intramolecular hydrogen bonding for the latter may be responsible for this. Therefore, the SP form thermally isomerizes to the MC form. In spite of this, it seems natural to consider that the thermal isomerizations of the two compounds proceed via the same reaction path or the same type of transition state. In order to confirm our previous view, we have now examined the kinetic solvent and pressure effects on the thermal conversion (SP→MC) of 8-COOH-SP.

Experimental

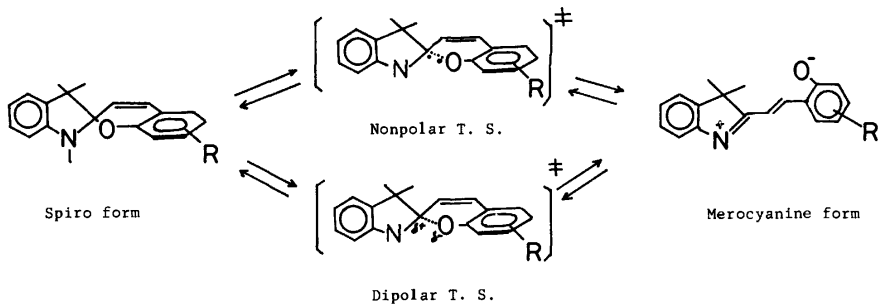
Materials. The 8-COOH-SP was generously supplied by Nippon Kanko Shikiso Kenkyusho (Japanese Research Institute for Photosensitizing Dyes, Co., Ltd.), and it was recrystallized from acetone: mp 244—245 °C (lit,[7] 245 °C). The reagent-grade solvents were purified and distilled in the usual manner.

Apparatus and Procedure. The high-pressure apparatus and procedure for the kinetic measurements were identical with those described elsewhere.[6] The solvents were deaerated by means of N_2 bubbling. The sample solution (ca. 10^{-4} mol dm^{-3}) was irradiated with a 650W projection lamp through a filter of a $CuCl_2$ solution. The absorption maximum (λ_{max} 530 nm) was monitored by means of a Hitachi 139 spectrophotometer, and the absorbance was recorded as a function of the time.

Results and Discussion

It was found that the first-order kinetics holds for this reaction. The rate constants obtained in several solvents and at various pressures are given in Table 1, together with the activation parameters. In such nonpolar solvents as hexane, the solubilities are very poor; this made the estimation of the rate constant impossible in nonpolar solvents.

Solvent Effects. For the thermal conversion of 8-COOH-SP, there are two possible routes: the conversion via the C_{spiro}-O bond stretching to produce either homopolar or dipolar transition states (Scheme 1). If the conversion proceeds via the dipolar transition state, a very large kinetic solvent effect can be expected, as has been observed in Menschutkin reactions.[7] However, as may be seen in Table 1, no systematic solvent effects are observed. In DMSO, the rate is remarkably smaller than in other solvents. In spite of this, the activation energy is roughly compensated for by the activation entropy (Fig. 1). This suggests that a simple interaction mechanism[8] is involved in this reaction, too, as in the case of 6-NO_2-



Scheme 1.

Table 1. Rate Constants and Activation Parameters for the Thermal Conversion of 8-COOH-SP at 30 °C (Probable errors in parentheses)

Solvent	10^3 k/s^{-1}				ΔV^*	E_a [b]	$\Delta S^*_{303\,K}$ [b]
P/kg cm^{-2} [a]	1	400	800	1200	cm^3 mol^{-1}	kJ mol^{-1}	J K^{-1} mol^{-1}
Chloroform	60.8(0.2)	58.8(0.3)	58.5(0.4)	55.7(0.6)	1.2	88.1(0.7)	14.1(2.2)
Ethyl acetate	38.9(0.3)	36.7(0.2)	32.6(0.9)	30.2(0.8)	4.7	75.1(12.7)	−29.8(42.4)
Dichloroethane	48.1(0.2)	46.9(0.3)	45.9(0.9)	45.7(1.8)	2.1	89.6(0.4)	17.1(1.4)
Acetone	18.3(0.3)	17.9(0.2)	16.2(0.1)	14.6(0.1)	1.4	79.6(1.3)	−24.4(4.3)

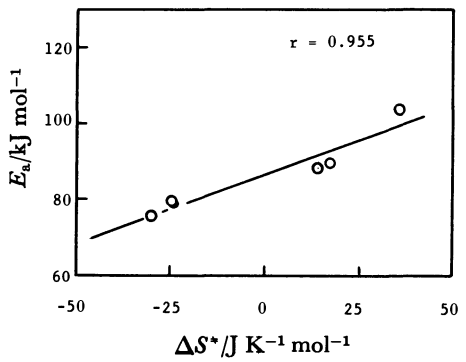

Fig. 1. $E_a-\Delta S^*$ relationship for the thermal conversion of 8-COOH-SP.

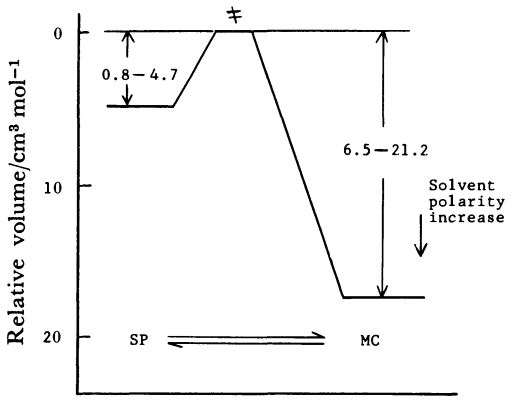

Fig. 2. Approximate volume profile for the SP⇄MC isomerization of spiropyrans.

SP. In the present case, what kind of interaction is operative has not yet been clarified. However, it would be hard to explain the kinetic solvent effect, at least, in terms of solvent-polarity parameters or a special solvent-solute interaction, since the plots do not line up in the order of changing solvent polarities. As a whole, the above findings suggest that the nonpolar transition state is more likely than the dipolar or ionic one.

Pressure Effects. In order to confirm the above view, the rate was followed under high pressures. The pressure dependence on the rate constants was appoximated by a quadratic equation (Eq. 1), while the activation volume (ΔV^*) at atmospheric pressure were estimated according to Eq. 2:

$$\ln k = a + bP + cP^2 \quad (1)$$

$$\Delta V^* = -RT(\partial \ln k/\partial P)_{T,P=1} \approx -bRT \quad (2)$$

If the reaction proceeds by the heterolytic mechanism, ΔV^* may be expected to be negative and its absolute value ($|\Delta V^*|>20$ cm^3 mol^{-1}) will decrease with an increase in the solvent polarities, as exemplified by Menschutkin reactions.[7] In the present case, however, the thermal conversion are slightly retarded by external pressures and the activation volumes take small positive values, virtually independent of the solvent polarity. This also supports the idea presented above.

The volume of activation could be explained in terms of the intrinsic volume alone. The stretching of the C_{spiro}-O bond upon activation must cause a small increase in volume. On the assumption that the stretching of the bond is 30%[9] of its original length, and that the thickness of the spiro ring is kept constant (34 nm),[10] the increment of the van der Waals volume due to the expansion of the ring is estimated to be 1.7 cm^3 mol^{-1}. Since the partial molar volume is about twice as large as its van der Waals volume,[11] ΔV^* would be about 3.4 cm^3 mol^{-1}. If this is compared with the experimental ΔV^*- values, the homolytic fission is judge to be more likely.

Approximate Energy and Volume Profiles. For the MC→SP conversion of 6-NO_2-SP, the activation energies and activation volumes are in the ranges of 71—105 kJ mol^{-1} and 6.5—21.2 cm^3 mol^{-1} respectively in solvents of different polarities. It was found that there is a trend for both E_a and ΔV^* to be greater in polar solvents than in nonpolar solvents. In the case of the SP→MC conversion of 8-COOH-SP, the E_a's are in the range 75—104 kJ mol^{-1} and the ΔV^*'s are 0.8—4.7 cm^3 mol^{-1}. In this case, no trend relating them to the solvent-polarity parameters could be observed. The above findings can be regarded as reasonable when one remembers the difference in the electronic structures between the MC and SP forms (Scheme 1).

Using the activation volume data of 6-NO_2—SP and 8-COOH-SP, we obtained the approximate volume profile shown in Fig. 2. Judging from the volume profile, the transition state is shifted to the SP form.

This implies that the bond breaking does not proceed very far at the transition state if the reaction is started from the SP form. The reverse is true if the reaction is started from the MC form.

It has been reported that some kinds of spiropyrans are in equilibrium with their MC form in solutions.[12] If we use such species and estimate ΔV and $\Delta V^{\neq}$, a more precise volume profile can be drawn. Along this line of thought, work is now under way.

A Comment on the Existence of Intermediates for the SP ⇌ MC Isomerization. From the NMR study of some kinds of spiropyrans at various temperatures, to account for their experimental facts Toppet et al.[12] suggested that an open-ring cis-isomer exists as the intermediate for the SP⇌MC thermal isomerization (Scheme 2):

$$\text{SP} \rightleftharpoons \text{X(open-ring cis-isomer)} \rightleftharpoons \text{MC trans-isomer}$$

Scheme 2.

By using the picosecond-flash photolysis method, Krysanov and Alfimov[13] observed a transient spectrum with a very short lifetime during the photoisomerization of 6-NO_2-SP. They assigned the band peaking at 440 nm to the intermediate nonplanar cis configuration with the broken C-O bond of the pyran ring. This isomer corresponds to that suggested by Toppet et al.

Meanwhile, Inoue et al.[14] reported colorless intermediates were observed in the photo-decoloration process of 8-COOH-SP derivatives. They therefore considered that an energy minimum exists along the reaction coordinate. For unsubstituted 8-COOH-SP, however, they could not detect any such intermediate. It would be natural to assume the existence of such intermediate cis-isomer just after the breaking of the C_{spiro}-O bond. The intermediates observed by Inoue et al. are fairly stable and have activation energies as large as 80 kJ mol^{-1} for the reactions producing SP and MC isomers. Therefore, these can not correspond to the cis-isomer in Scheme 2. Incidentally, Zerbetto et al.[15] reported that no minimum was found in the ground-state potential curves computed by the NMDO method for the ring-opening reactions of chromens, which can be regarded as model compounds of spiropyrans. If we take these situations into account, it may be concluded that the transition state is involved in the formation process of X, followed by the rapid conversion to the MC trans isomer (Scheme 2).

Orthogonal Approximation and Classification of Molecules for Zero-Point Energy Shifts Due to H/D Isotope Substitutions

Takao Oi* and Takanobu Ishida†
Department of Chemistry, Sophia University, 7-1 Kioicho, Chiyodaku, Tokyo 102
†Department of Chemistry, State University of New York, Stony Brook, New York 11794, U.S.A
(Received June 17, 1986)

Synopsis. Dozens of hydrogenous molecules have been classified for the approximation of the H/D isotope shifts in zero-point energies. The classification, based on their molecular structures, has yielded relative approximation errors of better than one percent with a few predictable exceptions. A further refinement of the classification has been suggested.

The zero-point energy (ZPE) of a molecule can be expressed in terms of the traces of the vibrational $\boldsymbol{H}$ ($\equiv\boldsymbol{GF}$) and $\boldsymbol{H}^2$ matrices in a second-order orthogonal approximation[1]

$$\text{ZPE} \simeq \frac{\hbar}{2}[b_0 f + b_1 \text{Tr}(\boldsymbol{H}) + b_2 \text{Tr}(\boldsymbol{H}^2)], \quad (1)$$

where f is the internal degrees of freedom, $\text{Tr}(\boldsymbol{A})$ is the trace of a square matrix $\boldsymbol{A}$ and b_0, b_1, and b_2 are approximation coefficients and are simple functions of approximation parameters involved. The precision of the approximation depends on the choice of the values of approximation parameters, which have been determined by minimizing a weighted integral of the square of the approximation error taken over the range of vibrational eigenvalue λ between zero and its largest value $\lambda_{\max}$. The weighting function $w(\lambda)$ used has the form of

$$w(\lambda) = (k+1)\lambda^k/\lambda_{\max}^{k+1}, \quad (2)$$

where k is the weighting parameter and the approximation parameters have been calculated in the range of $k \geq 0$. Parameter values thus determined are to optimize the approximation for the ZPE itself rather than the approximation for the difference between two ZPE's such as differences between the ZPE's of two isotopic molecules and those between the ZPE's of a molecule in two phases.

In a recent paper,[2] we developed another second-order approximation for the ZPE and on the basis of the approximation established a theoretical foundation for the additivity of the ZPE. In the new approximation, the zeroth-order term, which is the ZPE of an imaginary molecule consisting of completely uncoupled oscillators, i.e., consisting only of diagonal elements of $\boldsymbol{F}$ and $\boldsymbol{G}$ matrices, $\frac{\hbar}{2}\Sigma(f_{ii}g_{ii})^{1/2}$, has been singled out. The approximation parameters in the new approximation were determined by minimizing the weighted integral of the square of the derivative of the error. The weighting function used was the same as that of Eq. 2 in form and parameters were determined in the range of $k > -1/2$. The parameter values thus obtained were expected to give better approximation for ZPE differences than for the ZPE itself since they are designed to optimize the differential ZPE.

In this paper, we report on results of the approximation for the ZPE shifts due to deuterium-for-hydrogen substitutions, using the approximation form of Eq. 1 with parameters obtained in the new approximation. A scheme of classification of molecules based on their molecular structures is presented for satisfactory H/D ZPE shift approximations.

Computation

From Eq. 1, the isotopic difference in the ZPE, δ(ZPE), can be expressed as

$$\delta(\text{ZPE}) \simeq \frac{\hbar}{2}[\beta_1 \delta\text{Tr}(\boldsymbol{H}) + \beta_2 \delta\text{Tr}(\boldsymbol{H}^2)], \quad (3)$$

where $\delta\text{Tr}(\boldsymbol{A})$=Tr($\boldsymbol{A}$)(lighter isotope)−Tr($\boldsymbol{A}$)(heavier isotope), and β_1 and β_2 are the approximation coefficients which were determined in the new procedure for ZPE approximation[2] and are unique at a given k value. The values of the approximation coefficients have been tabulated for various k values.[2]

We examined dozens of hydrogenous molecules. All the isotopic pairs studied were grouped according to the molecular geometries around the site of the H/D substitutions. In a somewhat trial-and-error manner, we first determined the best k value, k_o, at which the error in the δ(ZPE) is almost zero for each pair. We then obtained a group average of k_o's, $\bar{k}_o$ for each group, and calculated percent errors of δ(ZPE) by using the same $\bar{k}_o$ value for all isotopic pairs of the molecules belonging to the same group.

Grouping of molecules is important. We have already shown in a previous paper[3] that for a very limited set of sample molecules the best k value for the approximation of H/D isotope shifts in ZPE can be well correlated with the number of H-X bonds and H-X-Y angles, where X is the site of isotopic substitutions and H is the substituted hydrogen atom (SHA), and with the number of torsional and other plane-wagging motions involving the SHA.

Results and Discussion

The molecular species studied were classified as shown in the first two columns of Table 1. In the second column of the table, (Y), (Z), and (W) represent polyatomic moieties of a species while those letters without parentheses denote single atoms ($\neq$H). Also, X-Y means a direct bonding, which may be a multiple bond, while X···(Y) indicates that there may be more than one bond between X and (Y). The values of $\bar{k}_o$'s are listed in the third column. In the fourth through seventh columns are listed the k_o values and % errors of

Table 1. Classification of Molecules for H/D Isotope Shifts in Zero-Point Energies[a)]

a) Case B approximation. See Ref. 2 for details. b) The group average of the optimum k. See text. c) The first-named isotopic species is the reference molecules from which λ_{max} was obtained. d) With no possibility of torsion involving the H atom being substituted. e) Alternate $\bar{k}_o$ value obtained by excluding fluoro compounds. f) The numbers in the parentheses are the percent errors obtained by using the alternate $\bar{k}_o$ listed in the parentheses in the third column. g) With possibility of torsions involving the H atom being substituted.

δ(ZPE) at the $\bar{k}_o$ for isotopic pairs of representative molecules of each group. Each group contains more isotopic pairs than listed, but we limit the presentation of the results to the molecules that are used in the discussion hereafter, thus avoiding a lengthy listing of numerical results. In the last column of the table, the origin of the used frequency data is shown.

With a few exceptions, the k_o values within any given group are similar and consequently, the relative errors obtained by using the group average of the k_o's are less than one percent. Any larger error suggests a further subdivision of the classification when it occurs. For instance, Group Ie should be further divided into fluoro compounds and others. Figures 1(a) and 1(b) compare the patterns of the eigenvalue shifts upon the H/D substitutions in fluoroform and chloroform. The high electronegativity of F induces relatively high stretching and bending force constants in CHF_3, which in turn causes the higher frequencies for CHF_3 than for $CHCl_3$, especially in the region below ρ ($\equiv\lambda/\lambda_{max}$)~0.2. Thus one needs different weighting parameters for CHF_3 and for other haloforms. The results of using $\bar{k}_o$=0.278 for the other haloforms are shown in the parentheses in the 7th

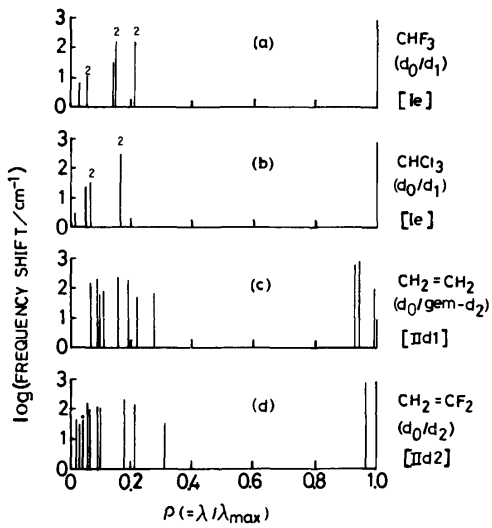

Fig. 1. Examples of differences in eigenvalue shift patterns; (a) vs. (b) for fluoro vs. other halo compounds and (c) vs. (d) for H vs. heavier atoms at β position. A vertical line is positioned at the eigenvalue of the lighter molecule, and its height shows the magnitude of the red-shift in the corresponding frequency due to the indicated H/D substitution. A number at the top of the shift line denotes the degeneracy of the shift.

column of Table 1. Group IIIb is another example of the potential advantage of decoupling fluoro compounds from other halo compounds.

The reason for the necessity for distinguishing between hydrogen atom and non-hydrogen atoms in Group Ib (Ib1 and Ib2) and IId (IId1 and IId2) is illustrated in Figs. 1(c) and 1(d). The substitution of H's by heavy atoms such as F not only reduces the number of H-Y stretching vibrations into half, thus affecting the high frequency population, but also does it decrease the frequencies of angle-bending and out-of-plane vibrations.

In general, the number of hydrogen atoms at the α and β positions relative to the site of H/D substitutions significantly affect the shift pattern. The expectation that molecular structure beyond the β positions would have been negligible effects on δ(ZPE) is in good agreement with the cut off procedure[16] and the general fact that the hydrogen isotope effects are well localized.[17]

As illustrated in acetylene (Ib1) and methane (IV), multiple H/D substitutions at the equivalent hydrogen positions do not significantly affect k_o. On the other hand, the substitutions at nonequivalent positions, such as methylene and methyl hydrogen, do require different k_o values as exemplified by CH_3CH_2Cl and $CH_3CH_2CH_3$ (cf: IIe and IIId).

The evidently satisfactory results obtained on the basis of the present scheme of classification are, in a sense, surprising especially because 1) this classification scheme has been based only on the molecular geometries and has given no consideration to the possible effects of intramolecular forces (except for the discussion on fluorine vs. other halogens), and 2) δ(ZPE) for the H/D effect has been approximated as a difference between two large numbers.

The present groups do not cover all hydrogenous molecules. However, the geometrical aspect of the classification is not far from being complete. Effects of substituents and bond orders can be incorporated in further refinements of the classification without qualitative knowledge of intramolecular forces. The prospect of such a classification is in that an appropriate parameter value may be obtained directly from a molecular structure, which in turn enables one to write δ(ZPE) as an explicit function of the elements of $\boldsymbol{F}$ and $\boldsymbol{G}$ matrices even before knowing the $\boldsymbol{F}$ matrix. Furthermore, coupled with the analytical method for δ(ZPE) presented in a previous paper,[18] the present classification scheme would provide a means for a deeper insight into correlation of the isotopic ZPE shifts with molecular structure and molecular forces.

Synopsis. Dimeric copper(II) 2,2-dimethylpropanoate complexes, $[Cu(Me_3CCOO)_2 \cdot L]_2$, where L is pyridine, acridine, quinaldine, 2-picoline, 4-picoline, and 2,6-lutidine, have been prepared. Magnetic data show that the singlet-triplet separation ($-2J$) ranges from 319 to 397 cm^{-1}. Strong antiferromagnetic interaction observed for the acridine adduct ($-2J$=397 cm^{-1}) is discussed on the basis of weak Cu-N(acridine) bond. The magnetic behavior of the non-adduct compound $[Cu(Me_3CCOO)_2]_2$ ($-2J$=403 cm^{-1}) is explained with respect to its non-polymeric structure.

A large number of dimeric copper(II) carboxylate adducts, $[Cu(RCOO)_2 \cdot L]_2$, have been studied to elucidate the factors affecting the magnetic properties of these compounds. In particular, effects of the carboxylate substituent R and of apical ligand L on the strength of antiferromagnetic interaction have been extensively investigated.[1,2] The X-ray diffraction and magnetic measurement by Kirillova et al.[3] on the dimeric copper(II) 2,2-dimethylpropanoate adduct with acridine, $[Cu(Me_3CCOO)_2(ac)]_2$, showed that the dimeric molecule has copper(II) acetate monohydrate structure. The singlet-triplet separation ($-2J$) of 340 cm^{-1}, which is considerably larger than those reported for the well-characterized dimeric copper(II) acetate adducts (284—325 cm^{-1}),[1] was attributed to electron-releasing properties of *t*-butyl substituents in the carboxylato bridges. A structural characteristic of the acridine adduct is the Cu-N distance of 2.371(5) Å, which is longer than those found for other dimeric copper(II) carboxylate adducts with pyridine analogues (2.10—2.20 Å).[1,2] The anomalies made us investigate the influence of apical ligand on magnetic interaction. We prepared purposely six copper(II) 2,2-dimethylpropanoate complexes, $Cu(Me_3CCOO)_2$ and $Cu(Me_3CCOO)_2 \cdot L$, where L denotes pyridine (py), quinaldine (qu), 2-picoline (2-pic), 4-picoline (4-pic), and 2,6-lutidine (2,6-lu), to compare their magnetic properties with that of acridine adduct.

Rakitin et al.[4] reported magnetic properties of some of these complexes. They suggested that the molar magnetic susceptibility, χ_A, depends only weakly on the apical ligand.

Experimental

Syntheses. $Cu(Me_3CCOO)_2$: A solution of 2,2-dimethylpropanoic acid (12 mmol) in 0.25 M sodium hydroxide (100 ml (1 M=1 mol dm^{-3})) was filtered and neutralized with dilute nitric acid with phenolphthalein indicator. Addition of a solution of copper(II) nitrate (6 mmol) in water (25 ml) to the above solution with stirring gave green crystals. The crystals were recrystallized from acetone with a small amount of 2,2-dimethoxypropane.

$Cu(Me_3CCOO)_2 \cdot L$ (L=py, qu, ac, 2-pic, 4-pic, and 2,6-lu): Mixtures of $Cu(Me_3CCOO)_2$ (2 mmol) and L (3 mmol) in benzene (50 ml) were stirred for about 30 min at room temperature. The resultant solution was filtered and concentrated to one-third of the volume. When petroleum ether was added to the solution, green crystals precipitated, which were washed with petroleum ether and dried in vacuo at room temperature.

The results of the elemental analyses are given in Table 1.

Physical Measurements. Magnetic susceptibility in the temperature range of 80—300 K was determined by the Faraday method. The correction for diamagnetic contribution was made by use of Pascal's constants.[5] The cryomagnetic data were applied to the modified Bleaney-Bowers equation,

$$\chi_A = \frac{Ng^2\beta^2}{3kT}\left[1+\frac{1}{3}\exp\left(\frac{-2J}{kT}\right)\right]^{-1} \times (1-P) + \frac{Ng_i^2\beta^2}{4kT}\cdot P + N\alpha, \quad (1)$$

where P is the mole fraction of the noncoupled copper(II) impurity and g_i is the average g factor for the impurity. The values of g_i of 2.2 and $N\alpha$ of 60×10^{-6} cgs emu (1 cgs emu=$4\pi\times10^{-6}$ m^3) were used throughout the present study. The best-fit parameters of $-2J$, g, and P were obtained by a nonlinear least-squares fitting procedure. The quantity of fit was estimated by means of a discrepancy index,

$$\sigma_{dis} = \left[\frac{\Sigma(\chi_{obsd}-\chi_{calcd})^2}{\Sigma\chi_{obsd}^2}\right]^{1/2}. \quad (2)$$

Table 1. Analytical Data

Complex	Found(Calcd) (%)			
	C	H	N	Cu
$Cu(Me_3CCOO)_2$	44.83	6.93		23.91

Effective magnetic moments at room temperature were calculated from the equation,

$$\mu_{eff} = 2.83\sqrt{(\chi_A - N\alpha)\cdot T}. \quad (3)$$

The values of $-2J$, g, P, σ_{dis}, and μ_{eff} are summarized in Table 2.

Polycrystalline powder EPR spectrum of $Cu(Me_3CCOO)_2$ in Fig. 1 was recorded by Jeolco JES-ME 2 spectrometer in the X-band range.

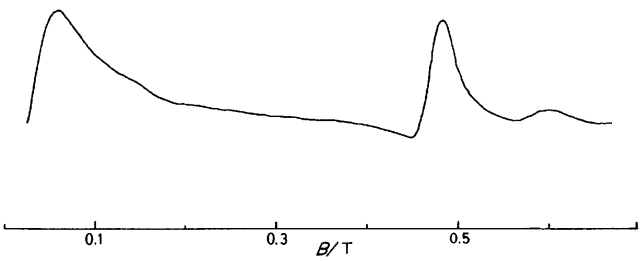

Fig. 1. Room-temperature polycrystalline powder EPR spectrum of $Cu(Me_3CCOO)_2$ at X-band frequency.

Results and Discussion

The magnetic susceptibility data of the complexes are well represented by Eq. 1, indicating that all complexes have a copper(II) acetate type dimeric structure. The $-2J$ value of 397 cm^{-1} observed for the acridine adduct prepared in the present study differs from the previously reported value of 340 cm^{-1};[3] this difference may partially be attributed to different fitting procedures of experimental χ_A values to those calculated from Eq. 1.

The $-2J$ value of acridine adduct is largest among values of adducts examined in the present study (cf. Table 2). Since the coordination bond between N of acridine and Cu seems to be weak as is indicated by long bond length (2.371 Å),[3] this result will be an evidence of the previous conclusion[6,7] that the antiferromagnetic interaction in dimeric copper(II) carboxylate adducts, $[Cu(RCOO)_2\cdot L]_2$, becomes stronger as the σ electron donation from L to copper becomes weaker. Weaker donation resulting in stronger Cu-O covalent bonds in CuO_4 basal planes enhances the spin-spin coupling between unpaired electrons of metal ions by superexchange interaction through bridging carboxylato ligands. This mechanism may be further supported by the following facts. First, the $-2J$ values of the adducts with quinaldine and 2,6-lutidine, both of which have substituents at 2- and 6-positions of pyridine ring, are larger than those of other adducts with apical ligands which have no or only one substituent at the ortho-position of pyridine ring (cf. Table 2). The apical ligation is hindered by the ortho-substituents as in the case of acridine in $[Cu(Me_3CCOO)_2(ac)]_2$[3] and, consequently, the N-Cu bonds in both the adducts must be weak. Secondly, as shown in Table 2, the $-2J$ value of 4-picoline adduct is much smaller than those of other adducts. Since 4-picoline has no substituent at ortho-position of the donor site and the basicity is higher than other pyridine bases examined in this study, except for 2,6-lutidine, the N-Cu bond in the 4-picoline adduct is considered to be much stronger than in other adducts. Thus, in contrast with the acridine adduct, the smallest $-2J$ value of 319 cm^{-1} found for 4-picoline adduct can be ascribed to strong Cu-N bond.

The $-2J$ value of 403 cm^{-1} found for the non-adduct compound, $Cu(Me_3CCOO)_2$, is larger than those of any other adducts in the present study. This fact differs from the general tendency that for many dimeric copper(II) carboxylates the $-2J$ values for non-adducts are smaller than those for the corresponding adducts.[8-10] In addition, the X-band EPR spectral pattern of $Cu(Me_3CCOO)_2$ is quite different from that of many non-adduct copper(II) carboxylates. In many cases, the EPR spectra of non-adduct copper(II) carboxylates show a single broad line in the 0.2—0.4 T region and this fact has been regarded as a sign of the existence of a polymeric chain structure consisting of dimeric molecules.[11-13] The EPR spectral feature of the present non-adduct compound shown in Fig. 1 is fundamentally the same as that usually observed for dimeric copper(II) carboxylates with axial ligands.[14] The obtained EPR parameters are: $g_\perp$ 2.139, $g_{//}$ 2.415, g_{av} 2.235, and D 0.340 cm^{-1}. The relation commonly observed for dimeric copper(II) carboxylates is held; i.e., D (0.340 cm^{-1})$>H_0$ (0.316 cm^{-1}).[14,15] These facts suggest that the strong antiferromagnetic interaction in $Cu(Me_3CCOO)_2$ is due to absence of (or very weak) coordination at the apical positions.

Stabilities of the Copper(II) Complexes with Quadridentate Derivatives of L-Prolinamide and L-Proline Methylamide

Tasuku MURAKAMI* and Koichi CHIBA
Faculty of Education, Iwate University, Ueda, Morioka 020
(Received March 29, 1986)

Synopsis. The stability constants of the copper(II) complexes with potentially quadridentate derivatives of L-prolinamide and L-proline methylamide (see text) have been determined by potentiometric titrations. The amide-proton dissociations from the complexes have also been estimated. These were then discussed in terms of the ligand structure and the complex geometry.

Chelating ligands with amide groups have been of considerable interest in connection with the biological signification that the amide group has a character essentially identical with those of peptide bonds in proteins.[1] This work is concerned with the stability of the copper(II) complexes with the potentially quadridentate ligands (shown in Chart 1) which have two L-prolinamide and L-proline methylamide moieties linked by ethylene and trimethylene. Some of the complexes with neutral or anionic amide ligands have exhibited unique absorption, circular dichroism (CD), and ESR spectra very different from those usually observed for ordinary square-planar copper(II) complexes; hence, unusual complex geometries have been postulated for such complexes.[2,3] Therefore, it seemed that it would be worthwhile to estimate the stability of these complexes, to study the ease of the proton dissociation of the amide groups, and to connect them with the ligand structure.

$n=2$	R=CH_3	H_2epma
$n=3$	R=H	H_2tpa
$n=3$	R=CH_3	H_2tpma

Chart 1. Structure and abbreviations of quadridentate derivatives of L-prolinamide and L-proline methylamide.

Experimental

Reagents. The synthesis and nomenclature of the diamides in Chart 1 have been described in previous papers.[4,5] The stock solutions of the diamides were prepared by the addition of twice equimolar amounts of HCl prior to titration. The $Cu(NO_3)_2$ solution was standardized by chelatometry with edta. The ionic strengths of the sample solutions were adjusted to 0.1 M (1 M=1 mol dm^{-3}) with KNO_3.

pH Titrations. The potentiometric titrations were carried out with a TOA HM-50AT auto pH meter, equipped with a TOA GC-125C multiple electrode and a temperture probe, and a TOA ADT-1 automatic dispenser synchronized with the pH meter. The apparent ion product of water was 0.719×10^{-14} M^2 at I=0.1 M. Solutions (1×10^{-3} M) of ligands only and of copper(II) and each ligand (molar ratio 1:1) were titrated with 0.1 M of NaOH at 25±0.1 °C under moistened N_2. Each titration was run at least three times. Some typical titration curves are shown in Fig. 1.

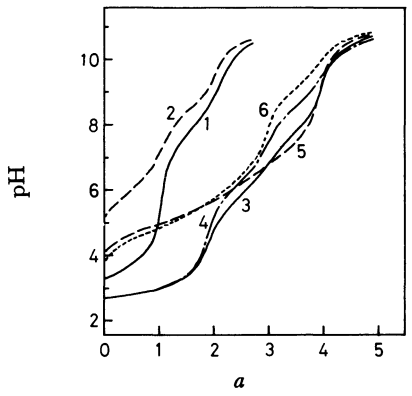

Fig. 1. Typical titration curves for proton-ligand and 1 : 1 Cu(II)-ligand systems. Curves: 1: H_4epa^{2+}, 2: H_4tpa^{2+}, 3: Cu(II)–H_4epa^{2+}, 4: Cu(II)–H_4epma^{2+}, 5: Cu(II)–H_4tpa^{2+}, 6: Cu(II)–H_4tpma^{2+}. a represents moles of NaOH added per mole of ligand.

Calculations. The proton-dissociation process of the protonated ligands occurs in two steps (the charges are omitted for the sake of clarity):

$$H_4L \rightleftarrows H_3L + H \qquad K_{a_1} = \frac{[H_3L][H]}{[H_4L]}$$

$$H_3L \rightleftarrows H_2L + H \qquad K_{a_2} = \frac{[H_2L][H]}{[H_3L]}$$

where H_2L represents neutral ligands. The copper(II) ion reacts with the neutral ligands to form Cu (H_2L):

$$Cu + H_2L \rightleftarrows Cu(H_2L) \qquad K = \frac{[Cu(H_2L)]}{[Cu][H_2L]}$$

Since these ligands possess two amide groups, two protons can be released step-by-step from Cu (H_2L):

$$Cu(H_2L) \rightleftarrows Cu(HL) + H \qquad K_{a_3'} = \frac{[Cu(HL)][H]}{[Cu(H_2L)]}$$

$$Cu(HL) \rightleftarrows Cu(L) + H \qquad K_{a_4'} = \frac{[Cu(L)][H]}{[Cu(HL)]}$$

All these constants were calculated by the method of linear least-squares by means of a micro computer.[6]

Results and Discussion

Table 1 lists the obtained data, and also those for 3,7-diazanonanedioic acid diamide (H_2DANA) and its bis-(diethylamide) (H_2 DANEA),[7] which are open-

R-NHCOCH$_2$NHCH$_2$CH$_2$CH$_2$NHCH$_2$CONH-R

R=H: H_2DANA R=C_2H_5: H_2DANEA

chain analogues of H_2tpa and H_2tpma, and for *N,N'*-dimethylethylenediamine(dmen)[8] and *N,N'*-dimethyl-1,3-propanediamine(dmtn).[7]

Table 1. Proton-Dissociation Constants and Stability Constants at 25 °C and $I=0.1$ M(KNO_3)[a]

Ligand	pK_{a_1}	pK_{a_2}	log K	$pK_{a_3'}$	$pK_{a_4'}$

Table 2. Stabilizing Effect in the Linear Relationship between Ligand Basicities and Complex Stabilities

Ligand	ΔpK[a]	Δ_R[b]
H_2epa	3.18	0.05
H_2epma	3.13	
H_2tpa	6.50	0.19
H_2tpma	6.31	
H_2DANA	4.72	0.53
H_2DANEA	4.19	
dmen	7.38	
dmtn	11.52	

a) $\Delta pK=pK_{a_1}+pK_{a_2}-\log K$. b) Δ_R represents the stabilizing effect by the inductive effect of alkyl substituents on the amide group.

Proton Dissociation of Ligand. The K_{a_1} and K_{a_2} values of H_2tpa and H_2tpma are larger than those of H_2DANA and H_2DANEA. This indicates that the steric effect of the methylene groups hindering the proton association on the tertiary amino group is superior to their electron-donating inductive effect, as is commonly observed in going from a secondary to a tertiary amine.

Formation of Cu(H_2L). The inspection of the linear relationship between the proton-dissociation and complex-formation constants of structurally similar ligands[9] often reveals the factor favoring complex formation.[7] Table 2 gives the values of $\Delta pK=pK_{a_1}+pK_{a_2}-\log K$ for the systems studied. A small ΔpK value implies that the stabilizing effect for the complex is more than would be expected from the ligand basicity. For example, the ΔpK values of Cu(H_2DANA)$^{2+}$ and Cu(H_2DANEA)$^{2+}$ are smaller than that of Cu(dmtn)$^{2+}$ by about 7 log units, which indicates a strong stabilizing effect attributable to the noticeable carbonyl coordination forming a 5,6,5-membered trifused chelate.[7] In addition, the inductive effect of the ethyl substituent which increases the electron density on the carbonyl group properly makes Cu(H_2DANEA)$^{2+}$ more stable than Cu(H_2DANA)$^{2+}$ (see Table 2).

Table 2 also shows that Cu(H_2tpa)$^{2+}$ and Cu(H_2tpma)$^{2+}$ have an instability factor of 2 log units compared with Cu(H_2DANA)$^{2+}$ and Cu(H_2DANEA)$^{2+}$. This may be a result of the steric restriction of the pyrrolidine rings, which makes the planar geometry unfavorable[10,11] and, consequently, the carbonyl coordination weaker. The small difference in ΔpK between Cu(H_2tpa)$^{2+}$ and Cu(H_2tpma)$^{2+}$ is other evidence that the carbonyl coordination is weak. The view that these ligands containing pyrrolidine rings act essentially as bidentate in aqueous solutions is supported also by the fact that the stabilizing effect in H_2epa-type complexes is larger than that in H_2tpa-type complexes, just as in the case of the dmen and dmtn complexes. In methanol, however, these neutral ligands seem to act as quadridentate rather than as bidentate[2,3] as a result of the change in the coordination ability of the solvent.

Proton Dissociation from Cu(H_2L). The $pK_{a_3'}$ value corresponding to the first amide-proton dissociation is smaller for the complexes with alkyl-substituted amide groups (Table 1). The electron-donating property of alkyl groups suppresses the proton dissociation.

The second proton dissociation from Cu(Htpa)$^+$ is easier than that from Cu(Htpma)$^+$ because of the ability of dianionic tpa to form a stable planar chelate. For dianionic tpma, the large repulsion between the *N*-methyl groups, in addition to the steric effect of the pyrrolidine rings, forces it to take a non-planar geometry, an unsymmetric cis form.[2,3] Thus, the second amide-proton dissociation takes place in a rather high pH region, corresponding to the inflection at $a=3.5$ in the titration curve. The tpma complex exhibits the spectral features typical for the tetragonal ligand-field, with a strong apical coordination.[2,3]

Although, in DANEA, the steric repulsion between the amide groups would be almost the same as in tpma, there is no reason why this linear ligand should favor any cis form containing an apical coordination of the ionic amide group.[12,13] Therefore, it is much harder for the second proton dissociation corresponding to $K_{a_4'}$ to occur, and this dissociation has been assigned to a coordinated water.[7]

The complexes with dianionic epa and epma, on the other hand, have been considered, on the basis of their visible and ESR spectra,[2,3] to have a similar

geometry, one highly distorted, probably to a tetrahedral form, from a squre-planar geometry. Whether or not the amide group is methyl-substituted seems to be insignificant for the proton release leading to such a distorted geometry.

Photolytic Formation of a Uranium(V)-DMSO Complex and the Paramagnetic Shift of DMSO by Uranium(V)

Hiroshi FUKUTOMI* and Toshie HARAZONO
Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology,
O-okayama, Meguro-ku, Tokyo 152
(Received June 2, 1986)

Synopsis. A U(V)-DMSO complex (DMSO=dimethyl sulfoxide) formed by photoreduction of $[UO_2(dmso)_5]^{2+}$ was stable in acid-free DMSO and a small quantum yield of U(V) was attributed to the difficulty in electron transfer from ligands to U(VI). The paramagnetic shift of DMSO by U(V) indicates that only the pseudo-contact shift is induced.

Uranium(V)[1] ions are known to be extremely unstable in aqueous solution owing to its rapid disproportionation.[2,3] Therefore, the absorption spectrum of U(V) was only roughly obtained as that of an intermediate in aqueous solution[2,4] and in rigid methanol matrix.[5] Gritzner and Selbin obtained the absorption spectrum of U(V) by electrolytic reduction of $UO_2(NO_3)_2$ in DMSO solution.[6] Miyake et al. observed the absorption and ESR spectra of U(V) in photo- and electrolytic reduction processes of $[UO_2(dmf)_5](ClO_4)_2$ in DMF (=*N*,*N*-dimethylformamide).[7] Recently, photoreduction of U(VI) in nonaqueous solutions was found to be a better method for U(V) preparation.[8-10] On the other hand, chemical properties of U(V) having electron configuration of $5f^1$ became a subject of great interest, but only a few of information are available about its absorption spectra in solid state,[11] in eutectic mixture,[12] and in rigid matrix,[5] and about magnetic property in solution.[9] In the present paper, we report the results of photoreduction of $[UO_2(dmso)_5](ClO_4)_2$ in DMSO and the paramagnetic shift of DMSO by the resulting U(V).

Experimental

The $[UO_2(dmso)_5](ClO_4)_2$[13] and $[U(dmso)_8](ClO_4)_4$[14] complexes were prepared by the same method as reported previously. Acetone was purified as described previously.[14] Dimethyl sulfoxide was distilled twice in vacuo and stored over 3A molecular sieves. Analytical grade benzene and acetone-d_6 (Merck 99%) were used without further purification. NMR shift reagent Pr(fod)$_3$ (Dojin, fod=6,6,7,7,8,8,8-heptafluoro-2,2-dimethyl-3,5-octanedionate) was dried over phosphorus pentaoxide under vacuum. Sample solutions for the measurements of UV-visible, luminescence, NMR and ESR spectra were degassed under vacuum. The UV-visible spectra were measured at 25±0.1 °C on a Shimadzu UV-210A spectrophotometer. Luminescence spectra were recorded by using a JASCO FP-550A fluorescence spectrophotometer at room temperature. NMR measurements were carried out on a JEOL JNM-FX 100 FT-NMR spectrometer. Acetone-d_6 was used as an internal lock for the measurement of paramagnetic shifts, and D_2O and benzene were used as an external lock and an internal standard, respectively, for the measurement of magnetic susceptibility. The DMSO solution of $[UO_2(dmso)_5](ClO_4)_2$ was irradiated with the light from a 500 W ultrahigh-pressure mercury lamp (Ushio USH-500D) through a filter (Corning 052) which cut off the wavelengths shorter than 365 nm. ESR spectra were recorded on a JEOL JES-FX3 spectrometer during the light irradiation.

Results and Discussion

The molar extinction coefficient of $[UO_2(dmso)_5](ClO_4)_2$ in DMSO was 34.8 M^{-1} cm^{-1} (M=mol dm^{-3}) at 430 nm. The luminescence of the uranyl ion was not observed in DMSO at room temperature, but observed in acetone. Figure 1a shows spectral changes of 0.04 M $[UO_2(dmso)_5]^{2+}$ in DMSO during the light irradiation, where a different absorption peak at 770 nm appeared at the beginning of the irradiation, and further irradiation induced another absorption spectrum with two peaks at 558 and 657 nm. The 770 nm peak disappeared immediately with addition of a small amount of perchloric acid under nitrogen atmosphere, and the two peaks at 558 and 657 nm became more intense. *Addition of concentrated perchloric acid to the DMSO solution should be carried out with great caution to avoid a possible explosion.* The appearance of the peak at 770 nm suggests the

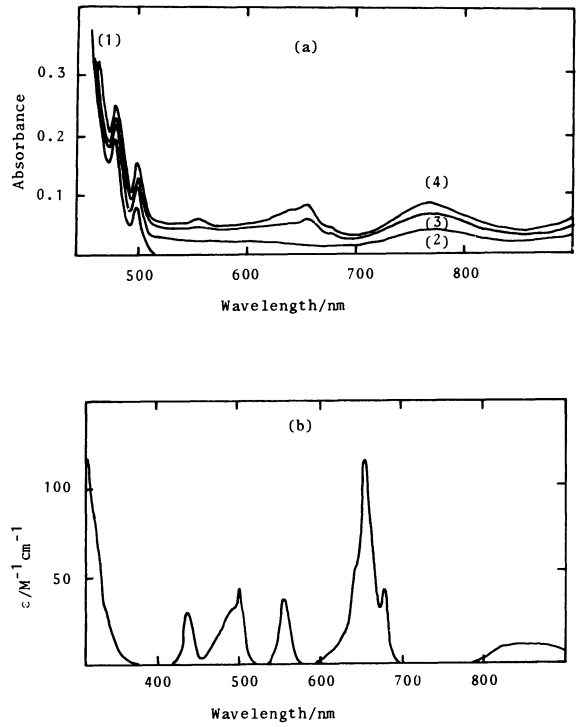

Fig. 1. (a): Spectral changes of 0.04 M $[UO_2(dmso)_5]^{2+}$ in DMSO irradiated with the light (>365 nm) at 25 °C. (1), 0 h; (2), 3 h; (3), 4.5 h; (4), 6 h. (b): Absorption spectrum of $[U(dmso)_8]^{4+}$ in DMSO.

formation of a new cmplex(I), and the absorption spectrum with the two peaks after further irradiation implies the formation of another complex(II). The latter two peaks are well consistent with those of $[U(dmso)_8](ClO_4)_4$ in DMSO (ε=115.2±2.0 M^{-1} cm^{-1} at 657 nm) as shown in Fig. 1b. Therefore, complex II was assigned to the U(IV)-DMSO complex. On the other hand, complex I was identified as the U(V)-DMSO complex which rapidly disproportionated with addition of perchloric acid as follows:

$$2UO_2^+ + 4H^+ \longrightarrow UO_2^{2+} + U^{4+} + 2H_2O$$

The concentration of U(V) was determined from the resulting U(IV) by using a relation, [U(V)]=2[U(IV)], after adding an appropriate amount of perchloric acid to the solution containing U(V). The absorption spectrum of the U(V)-DMSO complex is shown in Fig. 2, and the value of the molar extinction coefficient at 770 nm was determined to be 59.0±3.2 M^{-1} cm^{-1}. This spectrum is almost the same as that of the U(V)-DMSO complex prepared by electrolytic reduction of $UO_2(NO_3)_2$ in DMSO, which has the absorption maximum at 773 nm,[8] and very similar to those of U(V)-DMF[9] and U(V)-DMA (DMA=*N*,*N*-dimethylacetamide) complexes,[10] both of which were obtained by photoreduction of U(VI).

The quantum yield of the U(V)-DMSO complex was estimated to be 1.5×10^{-3}, which is very small compared with the values (0.3—0.4) for U(V)-DMF and U(V)-DMA complexes. This might be due to the difference in structure of ligands. The light irradiation of $[UO_2(dmf)_5]^{2+}$[14] and $[UO_2(dma)_5]^{2+}$[10] at −170 °C yielded the radicals $HCON(CH_3)CH_2\cdot$ and $CH_3CON(CH_3)CH_2\cdot$ respectively, while $[UO_2(dmso)_5]^{2+}$ gave no radical formation. As was reported in an earlier paper,[15] electron transfer from ligands to the excited uranyl ion leads to the formation of radicals and U(V) as follows:

$$UO_2L_5^{2+} \xrightarrow{h\nu} (UO_2L_5^{2+})^* \longrightarrow$$

$$(\overset{e^-}{\frown}UO_2LL_4^{2+})^* \longrightarrow UO_2L_4^+ + L\cdot + H^+,$$

where L represents a ligand. In DMF and DMA, all the atoms of $O{=}C{-}N{<}\begin{matrix}C\\C\end{matrix}$ lie on the same plane, and π orbitals of C=O and $-N<$ overlap pseudo π orbitals of two methyl groups. This favors transfer of electrons from ligands to the uranyl ion on excitation by light irradiation. On the other hand, DMSO has a trigonal pyramidal structure and no overlap of the π orbital of S=O with the pseudo π orbitals of two methyl groups. This structure of DMSO seems to be unfavorable to electron transfer from ligand dmso to the excited uranly ion, which results in no release of radicals and a rather small quantum yield of U(V).

The paramagnetic susceptibility of U(V) was determined by Evans' method[16] which was employed in a previous study.[17] It has been known that benzene, which was used as the internal standard, forms an excited complex with the uranyl ion, but does not contribute to chemical reactions except deactivation of the excited uranyl ion.[18,19] The results are shown in Table 1. The value of molar magnetic susceptibility ($10^6\chi_M$ emu mol^{-1}) of the U(V)-DMSO complex is well consistent with values of so far reported U(V)-TEP complex (2014, TEP=triethyl phosphate),[8] U(V)-DMF complex (2140)[17] and U(V)-DMA complex (2230—2330).[17]

The ^1H and ^{13}C NMR measurements for the paramagnetic shifts were carried out for bulk DMSO in the presence and absence of the U(V) complex. The

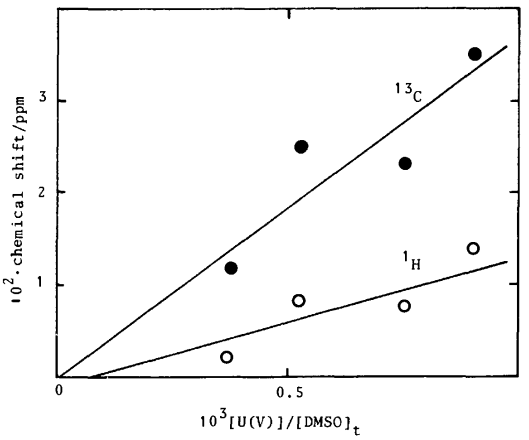

Fig. 3. Plots of ^1H and ^{13}C chemical shifts of DMSO vs. [U(V)]/[DMSO]$_t$ at 25 °C. $[UO_2(dmso)^{2+}]$= 0.40 M, $[DMSO]_t$=10.52 M.

NMR spectra of the bulk DMSO gave each single signal for ^{1}H and ^{13}C, and exhibited the paramagnetic shift to the higher field by U(V). The paramagnetic shift depends on the U(V) concentration, and the plots of the ^{1}H and ^{13}C chemical shifts of DMSO against $[U(V)]/[DMSO]_t$ at 25 °C, where t denotes total, give straight lines as seen in Fig. 3. The value of the slope is expressed as nS, where n is the number of ligands coordinated to U(V). The ratio of nS for ^{1}H and ^{13}C of DMSO was obtained as 0.42, where the complex formation shift (CFS) was neglected from the following reason. The CFS correction was estimated by using diamagnetic $[UO_2(dmso)_5]^{2+}$ in the mixture of DMSO and acetone-d_6. The value of correction was 0.84 ppm which was negligibly small compared with 14 ppm of the paramagnetic shift observed at $[U(V)]/[DMSO]_t=1$.

The value of $S(^{1}H)/S(^{13}C)$ by $Pr(fod)_3$ was 0.48. A satisfactory agreement between these two values indicates that the pseudocontact shift (PCS) is mainly responsible for the paramagnetic shifts of DMSO induced by U(V) and the contribution of contact shift is negligible, because the PCS is of major importance for Pr(III). This conclusion is compatible with the fact that the quantum yield of U(V) is very small on account of a lack of orbital overlap in the DMSO complex.

Determination of a Small Amount of a Biological Constituent by Use of Chemiluminescence. VIII. Effect of Heating on the Determination of Protein

Tadashi HARA,* Kazuhiko TSUKAGOSHI, Akihiro ARAI, and Takeshi IHARADA
Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602
(Received June 2, 1986)

Synopsis. The effect of heating on the determination of protein by chemiluminescence was examined by estimating the apparent coupling constant of a copper(II)-protein complex after treatment of a solution at 25 °C or 95 °C and by comparing the values with each other. The values obtained for two proteins were as follows: 1.3×10^{8} mol^{-1} dm^3—2.1×10^{11} (mol^{-1} dm^3)$^{1.5}$ at 25 °C and 4.3×10^{17} (mol^{-1} dm^3)$^{2.3}$—1.9×10^{18} (mol^{-1} dm^3)$^{2.2}$ at 95 °C. These values suggest that heating makes a copper(II)-protein complex more stable and improves the concentration range for the determination of protein.

New methods for the determination of protein by chemiluminescence (CL) reaction between 5-amino-2,3-dihydro-1,4-phthalazinedione(luminol) or 1,10-phenanthroline(phen) and hydrogen peroxide (H_2O_2) were reported by the authors in the previous papers.[1,2] The determination is based on the measurement of the decreasing catalytic activity of copper(II) (Cu(II)) for CL reaction in the presence of protein. Both the concentration range of determinable protein and the detection limit were improved by heating a Cu(II)-protein complex sample solution.[1] This seemed to be attributed to the formation of a more stable Cu(II)-protein complex by heating. However, no attempt to confirm this has been carried out in detail. The present study deals with the estimation of an apparent ratio of Cu(II) to protein and a coupling constant of a Cu(II)-protein complex after treatment of a sample solution at 25 °C or 95 °C. The values obtained were compared and discussed.

Experimental

A phen solution, a H_2O_2 solution, a Cu(II) catalyst solution, and a buffer solution were prepared as in the previous paper.[2] The 1.2×10^{-4} mol dm^{-3} phen solution contained 4.0×10^{-3} mol dm^{-3} ethylhexadecyldimethylammonium bromide, 2.0×10^{-7} mol dm^{-3} tetraethylenepentamine, and 1.0×10^{-1} mol dm^{-3} sodium hydroxide. A 5.0 wt% H_2O_2 solution was prepared by diluting 30 wt% H_2O_2 with water. A Cu(II) catalyst solution was prepared by diluting a 2.0×10^{-2} mol dm^{-3} Cu(II) stock solution with a buffer solution (pH 10.2) consisting of 1.0×10^{-1} mol dm^{-3} boric acid and 1.0×10^{-1} mol dm^{-3} potassium hydroxide. This solution also contained L-aspartic acid (its concentration is 1.2×10^{3} times of Cu(II)) instead of tartrate in a biuret reagent.

All reagents were of commercially available special grade. Ion-exchange water was distilled before use. Bovine serum albumin (BSA) and human serum albumin (HSA) from NAKARAI CHEMICAL, LTD were prepared by diluting them with a buffer solution. A definite volume of Cu(II) solution was added to a sample solution containing protein and the resulting solution was heated for a definite period.

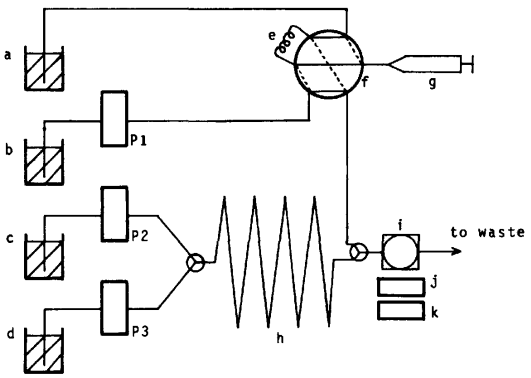

Fig. 1. Flow-injection system.
a: Sample solution, b: buffer solution, c: hydrogen peroxide solution, d: 1,10-phenanthroline solution, e: sampling loop, f: six-way cock, g: sylinge, h: mixing coil, i: flow cell, j: photon counter, k: recorder, and P1, P2, P3: pump.

After the solution was cooled to room temperature, an aliquot of the solution was injected into the flow-through system.

The schematic diagram of the apparatus which was set up for flow-injection analysis is shown in Fig. 1. All the tubes and connectors used were made of Teflon. A buffer solution(b), a H_2O_2 solution(c), and a phen solution (d) were delivered at the flow rate of 1.6 cm^3 min^{-1} with the corresponding pumps: (p_1), (p_2), (p_3)-(PERISTA MINI PUMP SJ-1211). A phen solution and a H_2O_2 solution were first mixed using a mixing coil(h) (346 cm, 0.5 mm i.d.) and the resulting mixture was combined with a buffer solution. A definite amount (50 mm^3) of the sample solution was injected into the line of a buffer solution. A poly(vinyl chloride) tube (45 cm, 0.8 mm i.d.) was spirally wound and was then used as the cell(i). The CL intensity of the solution passing through the cell was measured by a photon counter-(j) (HAMAMATSU, C1230) and recorded on a recorder(k) (National. PEN RECORDER). The net CL intensity of a sample solution was obtained by subtracting the background (the CL intensity of the solution containing no sample) from the intensity obtained.

Results and Discussion

After a Cu(II) catalyst solution was held at 25 °C or 95 °C for a definite period and then cooled at room temperature, the catalytic activity of Cu(II) for CL was measured. The calibration curve thus obtained was linear for 1×10^{-9}—1×10^{-7} mol dm^{-3} Cu(II) (Fig. 2).

The relationship between reaction time and the CL intensity in the presence of 1.0×10^{-7} mol dm^{-3} Cu(II) and BSA as a model protein was examined at 25 °C and 95 °C, respectively. The reaction between Cu(II)

Initial BSA concd $=6.1\times10^{-8}$ mol dm^{-3}. a) Estimated from Fig. 2.

Table 2. An Apparent Coupling Ratio and Coupling Constant at 25 and 95 °C

Protein	25 °C		95 °C	
	Coupling ratio (Cu(II) : Protein)	Coupling constant	Coupling ratio (Cu(II) : Protein)	Coupling constant
BSA	1 : 1	1.3×10^{8} mol^{-1} dm^{3}	2.3 : 1	1.9×10^{18} (mol^{-1} dm^{3})$^{2.3}$
HSA	1.5 : 1	2.1×10^{11} (mol^{-1} dm^{3})$^{1.5}$	2.2 : 1	4.3×10^{17} (mol^{-1} dm^{3})$^{2.2}$

Protein concd $=6.1\times10^{-8}$ mol dm^{-3}. Cu(II) concd $=7.50\times10^{-8}$—1.50×10^{-7} mol dm^{-3}. Ionic strength $\fallingdotseq 0.1$ mol dm^{-3}.

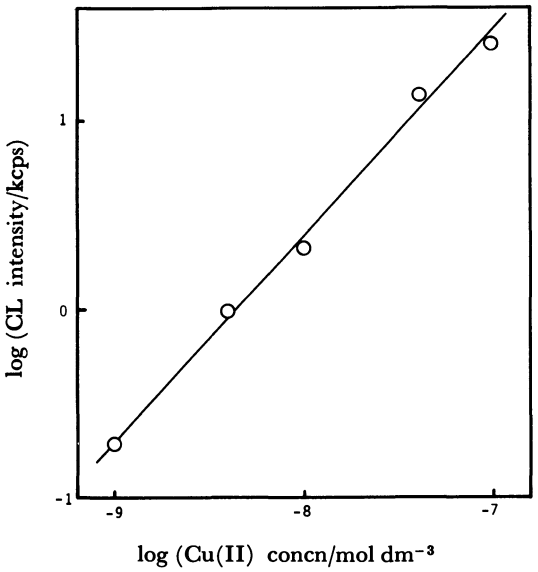

Fig. 2. Calibration curve of Cu(II) catalyst solution.

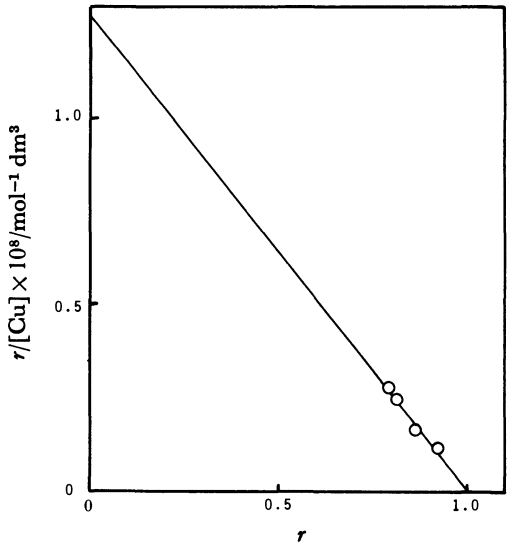

Fig. 3. Relationship between r and r/[Cu] at 25 °C for BSA.

catalyst and BSA went to completion in 30 min at 25 °C and in 45 min at 95 °C. These reaction times contain the times required for a sample solution to reach the individual temperature from room temperature. In the following experiment, the CL intensity of a protein solution was examined in 45 min at 25 °C and 60 min at 95 °C.

The reaction between Cu(II) and protein is assumed to proceed as follows (Eq. 1).

$$x[\mathrm{Cu}] + [\mathrm{Prot}] \rightleftharpoons [\mathrm{Cu}\,x\cdot\mathrm{Prot}] \quad (1)$$

where [Cu], [Prot], [Cu x·Prot], and x are the concentration of free Cu(II), free protein, and associated complex, and an apparent coupling ratio, respectively. An apparent coupling constant K is defined by Eq. 2.

$$K=\frac{[\mathrm{Cu}\,x\cdot\mathrm{Prot}]}{[\mathrm{Cu}]^{x}[\mathrm{Prot}]} \quad (2)$$

From Eq. 2, Eq. 3 is derivered.

$$r/[\mathrm{Cu}]^{x} = xK - rK \quad (3)$$

where r means the mole ratio of bound Cu(II) to total protein. The free Cu(II) concentration is estimated from the CL intensity and the bound Cu(II) concentration is obtained by subtracting the free Cu(II) concentration from the initial Cu(II) concentration. Thus r is found from the bound Cu(II) and total protein concentration.

The value of x was determined so as to satisfy Eq. 3 by the use of the experimental data, and the plot of r/[Cu]^{x} to r was obtained. The value of K was found from the slope of a straight line in the plot. Table 1

and Fig. 3 show the data and the plot for BSA at 25 °C. An apparent coupling ratio and coupling constant were Cu(II):protein=1:1 and 1.3×10^{8} mol^{-1} dm^{3} respectively under the following conditions: initial Cu(II) concentration 7.50×10^{-8}—1.25×10^{-7} mol dm^{-3} and ionic strength about 0.1 mol dm^{-3}. An apparent coupling ratio and coupling constant for two proteins (BSA and HSA) were estimated similarly as above at 25 °C and 95 °C, respectively (Table 2). A molecular weight of 66000 was assumed for these proteins for the calculation.

On the basis of these data the effect of heating on the determination of protein by the use of CL can be understood. Though heating made a Cu(II)–protein complex more stable and improved the concentration range for the determination of protein, the reaction mechanism between Cu(II) and protein still remains unknown.

The authors wish to thank Mr. Masakatsu Imaki (Horiba Ltd.) for providing the apparatus necessary for the present study.

Determination of a Small Amount of a Biological Constituent by Use of Chemiluminescence. IX. Effect of a Ligand on a Peak Shape

Tadashi HARA,* Akihiro ARAI, and Takeshi IHARADA
Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602
(Received June 6, 1986)

Synopsis. The chemiluminescence intensity of a 1,10-phenanthroline-hydrogen peroxide system was systematically examined in the presence of various types of copper(II) chelate-forming ligands. There was a good relation between the peak shape on a recorder chart and the types of ligands; they could be classified into four groups as follows: A) Both bidentate and tridentate ligands gave positive and negative peaks. B) The ligand having more than four donor atoms, as in a quadridentate ligand or protein, gave a single negative peak. C) A liberated porphine ring gave a single sharp negative peak. D) Some metal organic compounds such as vitamine B-12 and ferritin gave broader positive and negative peaks in comparison with those in A). These unique peak shapes were applicable to the estimation of the type of ligand. α-Fetoprotein as a tumor marker could be also easily detected with a detection limit of 250 pg and with a typical coefficient of variation of 3.8%.

In order to establish a new analytical method by which several proteins can be sensitively and rapidly determined without labeling, the flow-injection method using the fact that the catalytic activity of copper(II) for the chemiluminescence (CL) reaction between 1,10-phenanthroline (phen) and hydrogen peroxide (H_2O_2) decreased in the presence of protein has been reported by the authors.[1]

As pointed out in the previous paper, the peak shape of the CL intensity changed, depending upon the type of ligand. The relationship between the type of ligand (e.g. uni-, bi-, tri-, and quadri-dentate ligands) and the peak shape has been systematically investigated in the present paper.

Furthermore, such ligands as α-fetoprotein (AFP), ferritin, and polyamines which are well-known as cancer markers were also investigated.

Experimental

All chemicals used were reagent grade. A phen solution, a H_2O_2 solution, and a copper(II) catalyst solution were prepared as in the previous paper. The sample solution of AFP (human placental) from The Green Cross Co., and ferritin (TYPE IV, human liver) from Sigma Chemical Co., and polyamines (sperminetetrahydrochloride, spermidine, and putrescine), and all other samples were prepared by diluting them in a buffer solution (pH 10.2) consisting of 0.1 mol dm^{-3} boric acid and 0.1 mol dm^{-3} potassium hydroxide.

The experiment was carried out using the same apparatus as in the previous paper.

Results and Discussion

According to the previous paper, the injection of an α-amino acid solution into the copper(II)-tartrate catalyst solution flow showed a first positive peak and then a second negative peak based on the formation of a copper(II)-amino acid complex compound. Since this result appeared to have a close relation with the composition of a copper(II) complex compound, an investigation was systematically carried out for various ligands, and the results obtained are shown in Table 1.

The effect of an unidentate ligand such as ammonia and pyridine on a peak shape was small. Neither positive nor negative peaks were observed until the mole ratio of ligand to copper(II) ([ligand]/[copper(II)]=r) exceeded 10^5.

Both positive and negative peaks were observed for a bidentate or a tridentate ligand such as in Group A. This was explained on the assumption that the positive peak corresponding to the positive catalytic activity was obtained first due to the formation of a

a) L-Aspartic acid, L-glutamic acid, L-glycine, L-alanine, L-proline, L-lysine hydrochloride, L-arginine hydrochloride, and L-histisine hydrochloride. b) glycylglycine, glycyl-L-phenylalanine, glycyl-L-proline, and glycylglycylglycine. c) bovine serum albumin, bovine serum γ-globulin, human serum albumin, human serum γ-globulin, and ovalbumin. d) $r<10^6$. e) $r<10^3$. f) $r<10^6$.

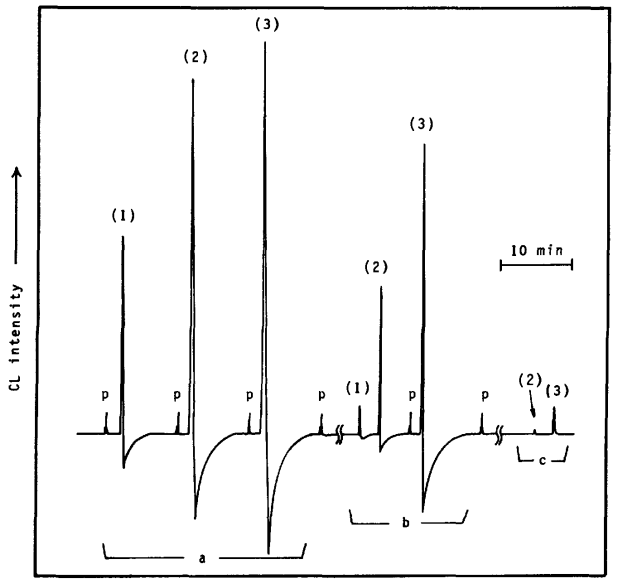

Fig. 1. Observed signals of polyamines.
a: Spermine, b: spermidine, c: putrescine, p: periodical shock peak accompanying with a reciprocation of the pump piston, (1): 1.0×10^{-6} mol dm^{-3}, (2): 1.0×10^{-5} mol dm^{-3}, and (3): 1.0×10^{-4} mol dm^{-3}.
Conditions: 5.0×10^{-5} mol dm^{-3} phen(4.0×10^{-3} mol dm^{-3} ethylhexadecyldimethylammonium bromide (EHDAB), 2.0×10^{-7} mol dm^{-3} tetraethylenepentamine (TEPA), 1.0×10^{-1} mol dm^{-3} sodium hydroxide(NaOH)), 5% H_2O_2, and 1.0×10^{-7} mol dm^{-3} copper(II) (5.0×10^{-5} mol dm^{-3} L-arginine hydrochloride(Arg)).

1:1 copper(II)-ligand complex compound, followed by the negative peak corresponding to the inactivation of the catalyst due to the complete occupation of the four coordination sites of copper(II) by the ligand. These results are consistent with the fact that the negative peak area increased with an increase of the *r* value.

A ligand which had more than four donor atoms, as in a quadridentate ligand, strongly linked with all four coordination sites in a planar square by way of a chelate effect, in which case a negative peak alone was obtained (Group B).

In addition, such liberated porphine ring as 5,10,15,20-tetrakis(4-carboxyphenyl)porphine (TCPP), 5,10,15,20-tetraphenylporphinesulfonic acid (TPPS) (Dojindo Laboratories.), and hematoporphyrin (Porphyrin Products.) (Group C) showed sharp negative peaks which were different from the peak shape of Group B and proteins. These results suggest that the center of the porphin molecule was rapidly occupied by copper(II), and that the catalytic activity of copper(II) was lowered rapidly.

The present method was further applied to other compounds which were of importance in clinical diagnostics as a tumor marker. The peaks obtained for polyamines such as sperminetetrahydrochloride, spermidine, and putrescine are shown in Fig. 1. Considerably large positive and negative peaks were obtained for both spermine and spermidine while a small positive peak alone was obtained for putrescine.

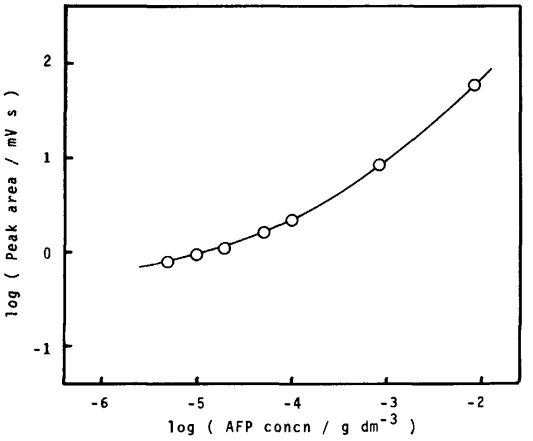

Fig. 2. Calibration curve of AFP.
Conditions: 5.0×10^{-5} mol dm^{-3} phen(4.0×10^{-3} mol dm^{-3} EHDAB, 2.0×10^{-7} mol dm^{-3} TEPA, 1.0×10^{-1} mol dm^{-3} NaOH), 5% H_2O_2, and 1.0×10^{-7} mol dm^{-3} copper(II) (5.0×10^{-5} mol dm^{-3} Arg).

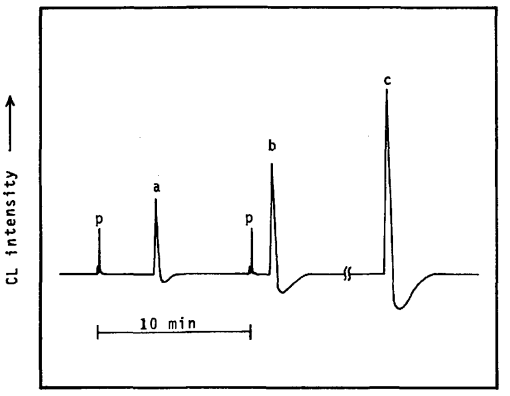

Fig. 3. Observed signals of ferritin.
a: 2×10^{-5} g dm^{-3}, b: 1×10^{-4} g dm^{-3}, c: 4×10^{-4} g dm^{-3}, and p: periodical shock peak accompanying with a reciprocation of the pump piston.
Conditions: 5.0×10^{-5} mol dm^{-3} phen(4.0×10^{-3} mol dm^{-3} EHDAB, 2.0×10^{-7} mol dm^{-3} TEPA, 1.0×10^{-1} mol dm^{-3} NaOH), 5% H_2O_2, and 1.0×10^{-7} mol dm^{-3} copper(II) (5.0×10^{-5} mol dm^{-3} Arg).

This was reasonably understood by considering the following complex formations: two six-membered chelate rings for spermine; one six-membered chelate ring for spermidine; and one single seven-membered chelate ring for putrescine.

The calibration curve of AFP which is well-known as a tumor marker is shown in Fig. 2. The AFP as a glycoprotein also formed a stable complex compound with copper(II) and showed a single negative peak. Using the present detector, the detection limit of AFP was 250 pg with the coefficient of variation of 3.8% for five measurements of 1×10^{-4} g dm^{-3} AFP. This sensitivity is satisfactory for practical use from the standpoint that the criterion of hepatoma is approximately 20 ng.

The peaks of ferritin which are also utilized as a marker for lung cancer and another malignant tumor including a blood disease are also shown in Fig. 3.

Judging from the molecular structure containing iron(III) at the central position, the positive peak was assumed to be due to the existence of iron(III) as a CL catalyst, while the negative peak to be due to the existence of protein. Vitamine B-12 containing a cobalt(II)–porphine complex structure was experimentally confirmed to act as a catalyst similarly to ferritin. The detection limit of ferritin corresponding to the negative peak was 200 pg, while the diagnostic significance of ferritin is regarded as "abnormaly large value" for more than 25 ng.

To sum up, there were good relations between the peak shape and the type of ligands that formed stable complex compounds with copper(II). The peak shapes were available for the estimation of the type of a ligand. According to the present study, several cancer markers are also sensitively determinable though their peak shapes differ from one another.

Potentiometric Study of Copper(II) Complexes with β-Diketone in Micellar Solution Using a Copper(II) Ion-Selective Electrode

Makoto AIHARA,* Kyoko SUGI, and Yumiko GOYA
Laboratory of Inorganic Chemistry, Faculty of Home Life Science, Fukuoka Women's University, Higashi-ku, Fukuoka 813
(Received June 5, 1986)

Synopsis. The distribution of copper(II) complexes with thenoyltrifluoroacetone, pivaloyltrifluoroacetone and 3-phenyl-2,4-pentanedione between micellar and bulk phases in aqueous solution containing nonionic surfactant was investigated by potentiometry with a copper(II) ion-selective electrode. The apparent equilibrium constants for the copper(II) complexes in micellar solution were determined.

The spectrophotometric method using β-diketone in aqueous solution containing nonionic surfactant is usefull for the determination of metal ions.[1-6] The method is based on solubilizing metal complexes to aqueous solution containing nonionic surfactant and it is simple and rapid method compared with solvent extraction-spectrophotometric determination of metal ions.[7-10]

On the other hand, ion-selective electrodes have been used for complex formation studies in aqueous solutions.[11-14] The solid membrane ion-selective electrode could be employed effectively for study of complex formation in micellar solution, too.

In the present paper, the distribution behavior of copper(II) complexes with thenoyltrifluoroacetone (abbreviated as TTA), pivaloyltrifluoroacetone (PTA) and 3-phenyl-2,4-pentanedione(3-phenylacetylacetone, PAA) in aqueous solutions containing trideca (oxyethylene) dodecyl ether, $CH_3(CH_2)_{11}$-O-$(CH_2$-CH_2-$O)_{13}$-H (Emulgen 120) were investigated by potentiometry with a copper(II) ion-selective electrode and the apparent equilibrium constants for the systems were obtained.

Experimental

Materials. A standard solution of copper(II) was prepared by dissolving reagent grade copper(II) chloride to dilute hydrochloric acid. The concentration of copper(II) ion was determined by EDTA titration. A 1×10^{-2} M (1 M=1 mol dm^{-3}) chelating agent (TTA, PTA, or PAA) solution was prepared by dissolving a known amount of the reagent (Dojin Co., Ltd.) in 5 W/V% Emulgen 120 (Kao-Atlas Co., Ltd.), which was purified with ion-exchange resin (Bio Rad; AG501-X8(D), analytical grade mixed bed resin). All other chemicals used were of an analytical reagent grade.

Copper membrane disks were supplied by Denki Kagaku Keiki Co., Ltd. The preparation of a copper(II) ion-selective electrode was described in previous paper.[15]

Procedure. Direct potentiometry in the solution containing copper(II) ion and 0.5% Emulgen 120 was perfomed by usual method.

Known amounts of copper(II) and a chelating agent containing 0.5% Emulgen 120 were placed in a titration vessel. Dilute hydrochloric acid solution was added to the above solution. After equilibrium was reached, the value of pH was measured and the potential of copper(II) ion-selective electrode was measured to determine the concentration of free copper(II) ion in the system. Each system was allowed to attain equilibrium (±0.1 mV). All measurements were carried out in a 0.1 M sodium perchlorate at 25±0.1 °C.

Results and Discussion

It was recognized by a spectrophotometric method that most of TTA or PTA exists outside the micelle, i.e. in the bulk phase.[4-6] PAA is also anticipated to be exist outside the micelle. On the other hand, metal-β-diketone complex could not be dissolved in an aqueous solution at the low concentration of nonionic surfactant.

The complex CuL_n (HL; TTA, PTA, and PAA) is presummed to be formed by the following equilibrium.

$$Cu^{2+}_{(b)} + nHL_{(b)} = CuL_{n(m)} + nH^{+}_{(b)} \quad (1)$$

the subscripts (b) and (m) refering to mutually equilibrated bulk and micellar phases, respectively.

The equilibrium constant, K, and distribution ratio, D, are defined by

$$K = \frac{[CuL_n]_{(m)}[H^+]^n_{(b)}}{[Cu^{2+}]_{(b)}[HL]^n_{(b)}} \quad (2)$$

$$D = \frac{[CuL_n]_{(m)}}{[Cu^{2+}]_{(b)}} \quad (3)$$

From Eqs. 2 and 3, Eq. 4 was derived

$$\log D = -n\log[H^+]_{(b)} + n\log[HL]_{(b)} + \log K \quad (4)$$

The following relationship for copper(II) concentration can be expected to hold

$$(V_{(b)}+V_{(m)})\sum Cu = V_{(b)}[Cu^{2+}]_{(b)} + V_{(m)}[CuL_n]_{(m)} \quad (5)$$

where $\sum$ Cu is total concentration of copper ion, $V_{(b)}$ and $V_{(m)}$ are volume of bulk and micellar phases, respectively. Then making use of one approximation,

$$V_{(b)} \gg V_{(m)} \quad (6)$$

Eq. 5 will be written in the form

$$V_{(b)}\sum Cu = V_{(b)}[Cu^{2+}]_{(b)} + V_{(m)}[CuL_n]_{(m)} \quad (7)$$

Combination of Eqs. 3 and 7 results in the Eq. 8

$$D = \frac{\sum Cu - [Cu^{2+}]_{(b)}}{[Cu^{2+}]_{(b)}} \cdot \frac{V_{(b)}}{V_{(m)}} \quad (8)$$

$$= D_{app} \cdot \frac{V_{(b)}}{V_{(m)}} \quad (9)$$

Apparent distribution ratio, D_{app} is determined by potentiometry with a copper(II) ion-selective electrode

for each system. Thus, log D_{app} is expressed by

$$\log D_{app} = n\mathrm{pH} + n\log [\mathrm{LH}]_{(b)} + \log K_{app} \quad (10)$$

where $K_{app}=K\times V_{(m)}/V_{(b)}$. The value of n is obtained as follows

$$\frac{d\log D_{app}}{d\mathrm{pH}} = n \quad (11)$$

The concentration of free copper(II) in the bulk, $[Cu^{2+}]_{(b)}$, were obtained from the measurement of free ion concentration with a Cu(II) ion-selective electrode and the value of D_{app} were calculated.

Figure 1 shows the calibration curves for copper(II) ions in 0.5% Emulgen 120 solutions at the different pH. The copper(II) ion selective electrode responds very well to copper(II) concentration of 10^{-6} M. Nernstian response was observed in each 0.5% Emulgen 120 solution.

The determination of free copper(II) ion concentration was made in the solution containing copper(II) and β-diketone in 0.5% Emulgen 120. The values of D_{app} at each system of TTA, PTA, and PAA were calculated from the experimental data.

Figure 2 shows the variation of log D_{app} as a function of pH at 15 and 25 °C. These plots are found to be linear and each value of log D_{app}/dpH was nearly equal to two. These show that the formation of [Cu(tta)$_2$], [Cu(pta)$_2$], and [Cu(paa)$_2$] complexes occur in micellar solution. The results are in agreement with the previous results by spectrophotometric method.[2] The facts described above indicate that the equilibrium (Eq. 1) is set up between bulk and micellar phases. But, it appears to necessary to explain also the equilibrium by dependence of log D_{app} on the concentration of the β-diketone. It will be a subject for further study.

The apparent equilibrium constants were calculated from the data for Fig. 2 by Eq. 10. The results are summarized in Table 1. The orders of apparent equilibrium constants are [Cu(tta)$_2$]>[Cu(pta)$_2$]>[Cu(paa)$_2$].

These data indicate that the formation reaction of [Cu(tta)$_2$] is endothermic and those of [Cu(pta)$_2$] and [Cu(paa)$_2$] are exothermic. But the dependence of the equilibrium constant on the temperature is small. The distribution behavior of the complexes in micellar solutions will be cleared by further study.

Catalytic and Electrocatalytic Hydrogenation of Benzylideneazlactone and Benzylidenehydantoin

Tomokazu MATSUE, Tsukasa YAMADA, Hiroko TAKAHASHI, and Tetsuo OSA*
Pharmaceutical Institute, Tohoku University, Aobayama, Sendai 980
(Received March 3, 1986)

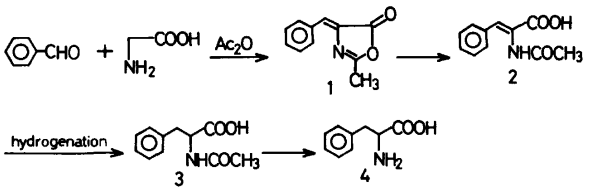
Synopsis. The electrocatalytic hydrogenatoin of benzylideneazlactone and 5-benzylidenehydantoin with Raney-nickel cathode proceeded smoothly to afford *N*-acetylphenylalanine and 5-benzylhydantoin, respectively. In addition, refluxing the electrolyte solution after the electrolysis finally yielded phenylalanine with satisfactory chemical yields and current efficiencies. This electrocatalytic process showed slightly higher reactivity than the ordinary catalytic hydrogenation.

The previous studies[1-5] have demonstrated that Raney-nickel (R-Ni) powder acts as an effective cathode for electrocatalytic hydrogenation of various reducible compounds. The electrocatalytic hydrogenation has several unique characteristics in comparison with direct, uncatalyzed electroreduction or ordinary catalytic hydrogenation, as described previously.[4,5] In this paper, we report the hydrogenation of benzylideneazlactone and 5-benzylidenehydantoin aimed at preparing finally phenylalanine by using the electrocatalytic and ordinary catalytic processes. The present results have shown that the electrocatalytic process has slightly higher reactivity than the ordinary catalytic one.

Results and Discussion

The Erlenmeyer method[6] via benzylideneazlactone (**1**) as an intermediate has been widely used for preparing α-amino acids, especially phenylalanine derivatives (Scheme 1). This method contains several reaction steps involving one for catalytic hydrogenation of 2-acetamide-3-phenyl-2-propenoic acid (**2**). The most widely adopting method for this step is the catalytic hydrogenation with platinum catalysts such as PtO_2 under a hydrogen pressure of about 3×10^5 Pa.[6] We have applied the electrocatalytic hydrogenation with R-Ni powder cathode to this step. The results are summarized in Table 1.

The electrocatalytic hydrogenation of **2** produced *N*-acetylphenylalanine (**3**) with satisfactory isolating yields and current efficiencies. The present hydrogenation proceeds smoothly under mild conditions (atmospheric pressure and room temperature). The isolating yield and the current efficiency were dependent on the electrolysis time. The long electrolysis time assures a high chemical yield but turns out a low current efficiency. The electrochemical process of the present electrolysis is the discharge of proton in the electrolyte solution to form active hydrogen at the R-Ni cathode surface. This active hydrogen is then transferred to a substrate to give a hydrogenation product. If the concentration of the substrate is not sufficiently high, two active hydrogens combine each other to form hydrogen gas. This is a main side reaction. The decrease in the current efficiency with the electrolysis time is caused by



Scheme 1.

a) Weight ratio of R-Ni to **2**. b) Charge passed. c) Current efficiency. d) Electrocatalytic hydrogenation. e) Catalytic hydrogenation. M = mol dm^{-3}

formation of hydrogen gas due to the lowering the concentration of substrate in the solution. Indeed, the bubble formation became noticeable as the electrolysis proceeded. The ordinary catalytic hydrogenation also produced **3**. However, the yields observed in the latter hydrogenation are slightly lower than those observed in the former.

The relative amount of the R-Ni to the substrate affected the hydrogenation. Table 1 also lists the W_R values (the weight ratio of the R-Ni to the substrate) used in this hydrogenation. In both types of the hydrogenation, the decrease in the W_R value reduces the reactivity as is shown by the prolonged reaction time to obtain satisfactory isolating yields. The influence of the W_R ratio is serious on the catalytic hydrogenation (Runs 10, 11, and 12). On the other hand, the electrocatalytic hydrogenation proceeded fairly smoothly even at W_R=0.08 and afforded a satisfactory chemical yield and a current efficiency (Run 8). It is ovbious from the table that the electrocatalytic process has higher reactivity than the ordinary catalytic process.

The use of a base as a supporting electrolyte showed good chemical yields and current efficiencies since basic solution enhanced the reactivity of R-Ni.[7] Perchlorate salts such as $NaClO_4$ also acted as a supporting electrolyte, but the chemical yield was relatively low. The effect of the basic atmosphere is eminent in the catalytic hydrogenation. The hydrogenation of **2** at W_R=0.08 in methanol (Run 12) proceeded very slowly and the chemical yield of **3** was only ca. 5% even after 12 h of the reaction time. However, the addition of NaOH to the methanol solution accelerated the hydrogenation more than 10 times (Run 13). In this case, the isolating yield of **3** was 69%, comparable to that observed in the electrocatalytic hydrogenation.

Since the present electrolysis was usually conducted in a basic solution, the use of **1** as a starting material burings about concurrent opening of the lactone ring during the electrolysis besides hydrogenation of the carbon–carbon double bond. Thus, the hydrogenation of **1** yielded **3** (Table 2). There is no significant difference in reactivity between **1** and **2**. The both substrates afforded **3** with almost same isolating yields and current efficiencies. The ordinary catalytic hydrogenation of **1** also gave **3**. However, the isolating yield was slightly low compared with that obtained in the electrocatalytic hydrogenation under the same conditions (Runs 14 and 21). In this case, use of water:ethanol (1:1 in volume) as a solvent showed good results. When the reaction solution was basic enough to hydrolyze the amide linkage of **3**, the reflux of the reaction solution after the hydrogenation gave phenylalanine (**4**), the final product, without isolating intermediates (Runs 20, 21, and 24).

The Wheeler method[8] via 5-benzylidenehydantoin (**5**) is also a typical method for preparing **4** (Scheme 2). This method contains a hydrogenation step. As shown in Table 3, the ordinary catalytic hydrogenation of **5** in ethanol at 5×10^6 Pa (Run 29) of hydrogen pressure gave 5-benzylhydantoin (**6**) with a high yield, whereas no hydrogenation proceeded at 2.6×10^5 Pa of hydrogen pressure (Run 28). On the other hand, the electrocatalytic hydrogenation under the equivalent conditions (Run 26) afforded **6** with a 57% chemical yield. In this case, the hydrogenation proceeded solwly and the current efficiency was quite unsatisfactory. The addition of NaOH to the solution facilitated the reaction to proceed due to the enhancement of the catalytic activity by the basic atmosphere.[7] This effect is pronounced on the ordinary catalytic hydrogenation (Runs 28 and 30). This is also true in the electrocatalytic hydrogenation.

29		EtOH, H_2 5×10^6 Pa	5	**6**	94		
30		2.0 M NaOH aq, H_2 2.6×10^5 Pa	12	**6**	80		

a) $W_R=0.5$.

The use of NaOH as a supporting electrolyte resulted in a reduction of the reaction time as well as an improvement of the chemical yield and the current efficiency (Runs 25 and 26). If the electrolyte solution was basic enough, reflux of the solution after the electrolysis gave **4** (Run 27).

In the hydrogenation of **5**, the electrocatalytic hydrogenation showed slightly higher yields than the ordinary process. Similar trend was also observed in the hydrogenation of **1** or **2** as described above. These phenomena may be accounted for by the following argument. As pointed out previously,[5)] the concentration of the active hydrogen on the R-Ni surface could be higher in the electrocatalytic hydrogenation than that in the ordinary catalytic one. The present electrocatalytic process will produce 8×10^{-8} mol of hydrogen in an apparent unit area (1 cm^2) in every second under the present conditions if a substrate is absent. If we dare to caluculate roughly by using the diffusion coefficient of hydrogen of 3.6×10^{-5} cm^2 s^{-1},[9)] the concentration of hydrogen in an aqueous system is estimated to be ca. 1×10^{-2} M (mol dm^{-3}) in the vicinal region from the cathode under the nonequilibrium state. On the other hand, the concentration is calculated to be ca. 8×10^{-4} M in the ordinary catalytic hydrogenation under the hydrogen pressure of around 3×10^5 Pa since the absorption coefficient is 0.018.[10)] Thus, the calculated concentration of hydrogen is ca. 13 times higher in the electrocatalytic process than that in the ordinary catalytic one. Although the effective concentration of dissolved hydrogen may be low due to the bubble formation in the electrocatalytic process, it is probably still higher than that in the ordinary catalytic hydrogenation. This in turn indicates high surface concentration of the active hydrogen at the cathode. Another considerable important factor is the basicity of the electrolyte solution near the R-Ni cathode. The discharge of proton makes the solution basic and thus the R-Ni is activated by the basic atmosphere, resulting in high chemical yields and short reaction time.

In conclusion, the hydrogenation of **1**, **2**, and **5** was accomplished by the electrocatalytic and ordinary catalytic hydrogenation with R-Ni powder. The addition of a base into the solution facilitated the hydrogenation to proceed and the reflux of the reaction mixture after the hydrogenation afforded **4** without isolating intermediates. In this hydrogenation, the electrocatalytic process showed slightly higher reactivity than the ordinary catalytic one.

Experimental

Electrolysis was carried out with a conventional H-type cell equipped with a R-Ni cathode and a Pt gauze anode under a constant current density (16 mA cm^{-2}). The preparation of R-Ni cathode was described previously.[4,5)] The electrolyte consisted of 2.0 g of a substrate dissolved in a solution (60 cm^3) described in Tables 1—3. After the electrolysis, the R-Ni cathode was filtered off from the solution. The solution was acidified, extracted with ethyl acetate three times, and dried over magnesium sulfate for a day. The products were obtained as crystalline forms by concentration of the solution. The products were identified by ir and mass spectroscopies. In order to evaluate the electrocatalytic hydrogenation, the ordinary catalytic hydrogenation was also carried out with a Burgess-Parr instrument under the hydrogen pressure of around 3×10^5 Pa with the basically same solution and R-Ni as used in the electrocatalytic hydrogenation.

This work was supported in part by Grant-in-Aids for Scientific Research (Nos. 59470070 and 60219003) from the Ministry of Education.

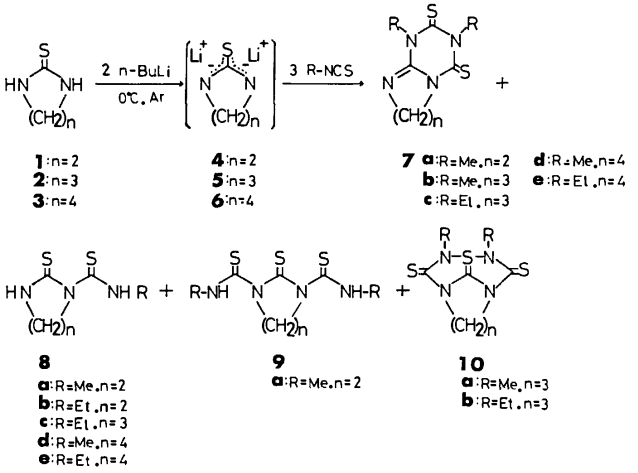
(Received March 22, 1986)

Synopsis. The reactions of methyl (or ethyl) isothiocyanate with dianions (**4**, **5**, and **6**), which are readily derived from available cyclic thioureas (**1**, **2**, and **3**) with butyllithium, gave ring fused 1,3-disubstituted 1,3,5-triazine-2,4(1*H*,3*H*)-dithiones (**7**) and/or thiocarbamoyl derivative (**8**) as major products.

Recently we have reported that the bromomagnesium thioureide acts effectively as a carbon dioxide carrier in the carboxylation of active methylene compounds under mild conditions.[1] In our continuing investigation on the properties of the dianions, which are readily derived from available cyclic thioureas with butyllithium, we have found the formation of 7,8-dihydro-1,3-dimethyl-6*H*-pyrimido[1,2-*a*][1,3,5]-triazine-2,4(1*H*,3*H*)-dithione (**7b**) and 3,4-dimethyl-1,6-propano-1*H*,6*H*-**3a**-thia(S^{IV})-1,3,4,6-tetraazapentalene-2,5(3*H*,4*H*)-dithione (**10a**) by the reaction of methyl isothiocyanate with dianion (**5**). The reaction behavior of dianions of cyclic thioureas has not been well investigated so far.[2] This paper reports the reaction of alkyl isothiocyanates with dianions (**4**, **5**, and **6**). The reactions were carried out in tetrahydrofuran (THF) at room temperature for 24 h under argon. When the RNCS:dianion molar ratio was 3:1, **7** was obtained in relatively good yield. The outline of the reaction pathway is shown in Scheme 1.

Reactions of alkyl isothiocyanates with dianions **4**, **5**, and **6** gave ring fused 1,3-disubstituted 1,3,5-triazine-2,4(1*H*,3*H*)-dithione (**7**), thiocarbamoyl de-



Scheme 1.

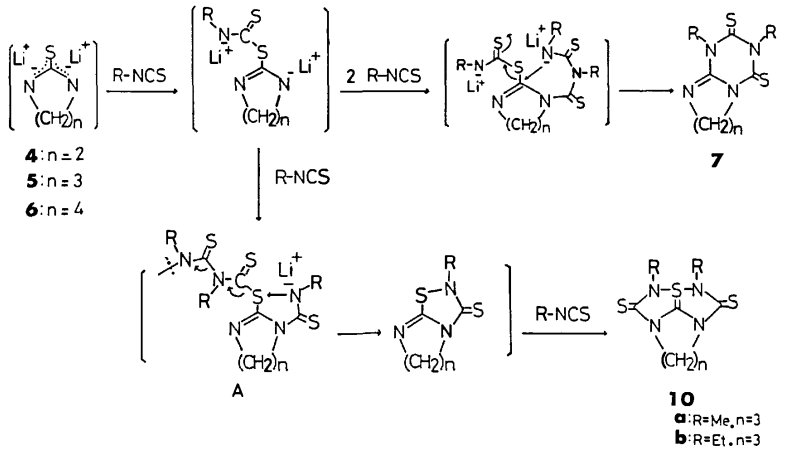
a) All reactions were carried out at room temperature for 24 h. b) Isolated yields. c) Isolated products are designated in parentheses.

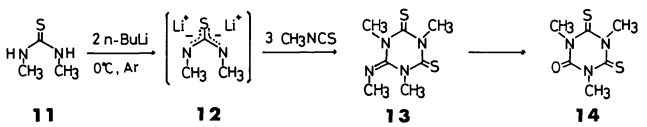


Scheme 2.

rivative (**8**), bis(thiocarbamoyl) derivative (**9**), and heteropentalene derivative (**10**). The yields are summarized in Table 1. The yields of products depended on the ring size of cyclic thiourea, the alkyl group of alkyl isothiocyanate, and reaction conditions. The dianions, **5**, and **6**, reacted with alkyl isothiocyanate to give the ring fused compound **7** in good yields, whereas the dianion **4** to give **7** in poor yields. A possible mechanism for the formation of **7** is given in Scheme 2.

The reaction of methyl (or ethyl) isothiocyanate with dianion **5** at room temperature for 24 h under argon afforded heteropentalene derivative **10** as a minor product together with ring fused compound **7**. The compound **10**, **3a**-thia(S^{IV})pentalene system containing π-hypervalent sulfur, is of interest from the structural point of view. The structure of **10** was determined by IR, Mass, ^{1}H NMR, ^{13}C NMR, and elemental analysis. Our mechanistic interpretation for the formation of **10** is outlined in Scheme 2. When the dianions **4** and **6** were used, heteropentalene derivatives were not obtained. For these results there are two possible explanations. One is that the intermediates A derived from the dianions **4** and **6** have unfavorable configurations for the attack of N atom to S atom compared with the intermediate A derived from the dianion **5**. The other is that the strain of heteropentalene derivative with five- or seven-membered ring is larger than that of **10**.

Next, we have examined the reaction of alkyl isothiocyanate with the dianion of acyclic thiourea.



11 **12** **13** **14**

When the reaction of methyl isothiocyanate with dianion (**12**), which is derived from *N,N'*-dimethylthiourea (**11**) with butyllithium, was carried out at room temperature for 24 h under argon, 5,6-dihydro-1,3,5-trimethyl-6-methylimino-1,3,5-triazine-2,4-(1*H*,3*H*)-dithione (**13**) was obtained as a crude product in 84% yield. The structure of **13** was determined by the following spectral data: IR (KBr) 1682 cm^{-1} (C=N); MS (70 eV) *m/z*, 216 (M$^+$); ^{1}H NMR ($CDCl_3$) δ=3.25 (s, 3H), 3.60 (s, 6H), and 3.90 (s, 3H). When the crude product **13** was chromatographed on preparative TLC (silica gel using dichloromethane as an eluent), it was converted into the 3,4,5,6-tetrahydro-1,3,5-trimethyl-4,6-dithioxo-1,3,5-triazin-2(1*H*)-one (**14**) in quantitative yield.

Experimental

Melting points were determined on a Yanagimoto melting point apparatus and were uncorrected. Proton magnetic resonance (^{1}H NMR) spectra were obtained using a Hitachi Perkin-Elmer R-24 spectrometer (60 MHz), JEOL FX-90Q (90 MHz), and JEOL JNM-GX270 (270 MHz). ^{13}C NMR spectra were obtained using a JEOL FX-90Q and JEOL JNM-GX270. Chemical shifts are reported in ppm form TMS as an internal standard and are given in δ units. The IR spectra were determined on a Hitachi 215 Grating infrared spectrometer. Mass spectra were obtained with a SHIMADZU-LKB 9000 instrument equipped with a solid injector; the ionizing voltage was 70 eV.

General Procedure for the Reaction of Alkyl Isothiocyanate with Dianions, (4, 5, and 6). To a cooled THF solution (0 °C) of 3,4,5,6-tetrahydro-2(1*H*)-pyrimidinethione (**2**, 2.0 mmol) was added a hexane solution of butyllithium (4.4 mmol) with stirring at 0 °C under argon, and the mixture was stirred for 1 h under same conditions. To the resulting dianion (**5**) was added dropwise a THF solution of methyl isothiocyanate (6.0 mmol). The solution immediately became orange, and the mixture was stirred for 24 h under argon. After THF was evaporated, the residue was poured into an aqueous ammonium chloride. The solution was extracted with chloroform, and the extract was washed with water, dried over Na_2SO_4, and condensed under reduced pressure. The residue was chromatographed on a silica-gel column or preparative TLC (dichloromethane as an eluent) to give products, **7b** (61%) and **10a** (15%). All compounds were recrystallized from hexane–chloroform to give colorless solid.

Synopsis. Arbusov reaction of alkyl α-phosphoranylideneamino-α-alkenoates with several halides gave the corresponding α-phosphinylamino-α-alkenoates and Δ^2-dehydrodipeptide derivatives.

In connection with the synthesis of α-dehydroamino acids (DHAs) and dehydropeptides (DHPs), we briefly reported that the an Arbusov-type reaction of alkyl 2-triethoxyphosphoranylideneamino-2-alkenoates (**2**) gave the corresponding diethoxyphosphinyl (Dep) derivatives and that a similar reaction of **2** with phthaloyl (Pht)-Leu-Cl also gave Pht-(Dep)-Δ^2-dehydrodipeptide derivatives.[2-4)]

This paper deals with the utilization of **2** and alkyl 2-triphenylphosphoranylideneamino-2-alkenoates (**3**),[2)] derived from alkyl (*Z*)-2-azido-2-alkenoates (**1**) and $P(OEt)_3$ or $P(C_6H_5)_3$ respectively, to the synthesis of DHA and DHP derivatives. In order to further extend the reaction of **2** and **3**, we chose several halides, including Pht-(L)-α-amino acid (AA) chlorides as reagents.

According to the method reported,[3)] a similar reaction of (*Z*)-**2** with chloroacetyl chloride gave alkyl 2-(*N*-chloroacetyl)-2-diethoxyphosphinylamino-2-alkenoates (**5**). From the results, it was found that after an addition of acyl chloride to the N=P bond of **2** (**4**), an Arbusov reaction of **4** immediately took place, giving **5**, as is illustrated in Scheme 1.

Furthermore, when **2** was treated with alkyl iodide or methyl iodoacetate, a similar reaction readily proceeded to give alkyl 2-[*N*-(alkyl)diethoxyphosphinylamino]-2-alkenoates (**6**). As a result, alkyl halides as well as acyl chlorides were found to be sensitive to the 2-triethoxyphosphoranylideneamino function. In addition, a reaction of **2** with Pht-Gly-Cl or Pht-(L)-Leu-Cl was attempted under similar conditions as those mentioned above to give the expected Pht-(Dep)-Δ^2-(L,Z)-dehydrodipeptide esters (**7** and **8**).

Subsequent treatments of **7** and **8**, respectively, with 25% HBr in acetic acid gave deblocked Pht-Δ^2-(L,Z)-dehydrodipeptide esters (**9** and **10**). However, it was found that the other deprotection of **7** and **8** with HCl in MeOH, HCl in benzene, and with CF_3COOH, respectively, did not take place, even under heating. On the other hand, interestingly, a treatment of **3** with Pht-Gly-Cl in benzene under reflux, and then that of the resulting solution with $NaHCO_3$ aqueous solution, directly gave **9**; however, a similar reaction of **2** did not proceed. Moreover, even a one-pot reaction of **1** with Pht-Gly-Cl and $P(C_6H_5)_3$, **9** was also obtained (see Scheme 2). The results, thus obtained, are summarized in Tables 1—4.

Table 1. Properties of Products (**5** and **6**)

Compd[a)] No.	Yield %	Bp[b)] (θ_b/°C)mmHg[c)]	^{1}H NMR (δ) -CH= (*J*, Hz)

Compd. No.	From **1**	From **3**	From **7**	Mp(θ_m/°C[a])
9a	48	51	97	177—179 (180.5—181.5[b])
9b	43	50	86	173—175 (173—173.5[b])
9c	43	48	72	174—175[c]
9d	41	45	71	164—165 (162—165[b])

a) Colorless needles. b) Lit,[5]. c) See footnote a) in Table 1.

Based on the spectral data as well as a satisfactory elemental analysis, the structures of all the new compounds could be readily determined. The NMR spectra of the products showed long-range coupling between β-olefinic, γ-methyl or γ-methylene protons and the phosphorus atom. In the case of **6**, in addition to the above long-range couplings, another coupling between *N*-alkyl protons and phosphorus also appeared.

As is summarized in the Tables, the characteristic olefin proton signals of **6** shifted at the δ 7.06—6.52 ($J_{3,4}$=7.0—11.0 Hz) region, whereas those of **5**, **7**, and **8** resonated at a slightly lower magnetic field at the δ 7.60—6.75 region with a similar coupling constant ($J_{3,4}$=7.0—11.0). On the other hand, the coupling constants between the β-olefinic proton and phosphorus in **6** were also found to be almost the same ($J_{3,P}$=1.9—2.2 Hz) as that of **5**, **7**, and **8**. In addition, the methyl and methylene protons at the nitrogen coupled with phosphorus and was observed as a doublet (J=7.5—10.0 Hz). Consequently, all the signals and the coupling constants of the new compounds obtained could be assigned.

Furthermore, in the IR spectrum of the products, the characteristic absorption bands of ester carbonyl, C=C, -P=O, and =P-O-CH_2- functions appear at 1715—1760 (strong; s), 1615—1660 (medium), 1260—1280 (s), and 1020—1040 (s) cm^{-1}, respectively.

In closing, since **9** was in accordance with the authentic samples[5] and **10** was prepared independently by a reaction of Pht-(L)-Leu-Cl with ethyl 2-amino-2-alkenoates or *N*-carboxy α-dehydroamino acid anhydrides,[6] the structures could be readily determined as alkyl 2-phthaloylglycyl-and-(L)-leucyl-amino-2-alkenoates, respectively.

10c	55	117—119	6.41 d (10.0)	−55.8°
10d	65	164—165	7.22— 7.50m (Ph+H)	−49.6°

a) See footnote a) in Table 1. b) Colorless needles from ethyl acetate and cyclohexane. c) Measured in methanol.

Experimental

All the boiling and melting points are uncorrected. The IR spectra were recorded with a Hitachi EPI-G3 spectrometer. The NMR spectra were measured with a JEOL JNM-PS-100 spectrometer in a $CDCl_3$ solution with tetramethylsilane as the internal standard.

Preparation of 5. To a solution of **2** (25 mmol) in dry benzene (30 ml) was added chloroacetyl chloride (50 ml) with stirring under cooling. The resulting solution was continuously stirred at room temperature for 2.5 h. After removing the solvent, the obtained residual syrup was purified on a silica-gel column using a mixture of benzene-ethyl acetate (4:1 v/v) as the eluent to give **5**.

Preparation of 6. A reaction of **2** (15 mmol) with an appropriate alkyl iodide or methyl iodoacetate (45 mmol) was similarly worked up under reflux for 4 h to give a residual syrup, which was distilled in vacuo or purified on a silica-gel column using a mixture of benzene-ethyl acetate (5:1 v/v) as the eluent to give **6**.

Preparation of 7 and 8. A treatment of **2** (10 mmol) with Pht-(L)-AA-Cl (11 mmol) was similarly worked up at room temperature for 12 h to give a reaction solution which was washed with saturated $NaHCO_3$ solution and water and then dried over anhydrous Na_2SO_4. The removal of the solvent under reduced pressure gave a crude syrup, which was purified on a silica-gel column using a mixture of benzene-ethyl acetate (4:1 v/v) as the eluent to give **7** and **8** as a syrup or crystals.

Preparation of 9. a) A solution of **7** (3 mmol) in 25% HBr in acetic acid (5 ml) was stirred at room temperature for 3h and then the excess solvent was removed to give crystals. Recrystallization from EtOH gave **9**.

In a similar manner, a treatment of **8** with 25% HBr in acetic acid was worked up to give **10**.

b) A solution of an equimolar **3** (10 mmol) and Pht-Gly-Cl in dry benzene (30 ml) was refluxed for 5 h. The resulting solution was washed five times with a saturated $NaHCO_3$ solution and then three times with water and finally dried over anhydrous Na_2SO_4. The removal of the solvent gave residual crystals, which were recrystallized from EtOH to give **9**.

c) Into a solution of **1** (10 mmol) in dry benzene (30 ml) $P(C_6H_5)_3$ (10 mmol) was added with stirring, portionwise, under cooling. After stirring at room temperature for 1 h, Pht-Gly-Cl (10 mmol) was added to the

resulting solution and then refluxed for 5 h. Finally, the reaction solution was similarly worked up to give **9**.

Formation of 2-Substituted 1,3-Diphenylindenes by an *N*-Bromosuccinimide Prompted Dehydrocyclization of 2-Substituted 1,3,3-Triphenyl-1-propenes

Kimiaki YAMAMURA,* Hideyoshi MIYAKE, and Akira SERA†

†Department of Chemistry, Faculty of Science, Kobe University, Rokkodai, Nada, Kobe 657
(Received April 23, 1986)

Synopsis. The reactions of a series of 2-substituted 1,3,3-triphenyl-1-propenes with *N*-bromosuccinimide (NBS) afforded the corresponding 2-substituted 1,3-diphenylindenes in moderate yields. A reaction mechanism involving a novel free-radical intramolecular ring-closure reaction is suggested.

N-Bromosuccinimide (NBS) has been extensively used both in the bromination of the allylic and benzylic positions and in the oxidation of many classes of organic compounds.[1] This article details an NBS-prompted conversion of a series of 2-substituted 1,3,3,-triphenyl-1-propene derivatives (**1**) to the 2-substituted 1,3-diphenylindenes (**2**) by means of a novel free-radical intramolecular ring-closure reaction. The starting 2-substituted 1,3,3-triphenyl-1-propenes (**1**) were readily obtainable by the phenylation of the corresponding 2-substituted 1-phenyl-1-propenes using palladium(II) salts as previously reported.[2]

The reactions of **1** with NBS in the presence of benzoyl peroxide unexpectedly gave 2-substituted 1,3-diphenylindenes(**2**); no corresponding benzylic bromination product was detected. The results are shown in Table 1. Thus, ethyl (*E*)-α-(diphenylmethyl)cinnamate ((*E*)-**1a**) reacted with NBS in refluxing benzene or carbon tetrachloride to give 2-ethoxycarbonyl-1,3-diphenylindene (**2a**) as the sole crystalline product in 66—69% yields (Runs 1 and 2). Similar reactions of (*E*)-**1a** by the use of *N*-bromocaprolactam or *N*-bromoacetamide also yielded **2a**, though the yields were somewhat unsatisfactory. In these reactions some of the starting (*E*)-**1a** was recovered together with its isomer ((*Z*)-**1a**). The (*Z*)-isomer ((*Z*)-**1a**) also underwent a similar reaction with NBS to afford **2a** in 63% yield (Run 3). In the same manner, α-(diphenylmethyl)cinnamic acid (**1b**), α-(diphenylmethyl)chalcone (**1c**), 1,2,3,3-tetraphenyl-1-propene (**1d**) and 2-(*p*-methoxyphenyl)-1,3,3-triphenyl-1-propene (**1e**) reacted with NBS to produce the corresponding 2-substituted 1,3-diphenylindene derivatives, **2b—d**, and **2e**, respectively (Run 4—10). The structures of **2a—e** were determined by spectroscopic and elemental analyses. Compound **2d** was identified by a comparison of its melting point and NMR spectrum with those reported in the literature.[3] Furthermore, the hydrogenation of **2d** on Pd–C afforded known *r*-1, *c*-2, *c*-3-triphenylindan, whose structure was identified by comparing its physical data with that from the literature.[4]

However, an attempted conversion of the nitro derivative (**1f**) into 2-nitro-1,3-diphenylindene (**2f**) was unsuccessful. The starting material was recovered unchanged (Run 11). The reaction, under forced conditions, gave an intractable product mixture.

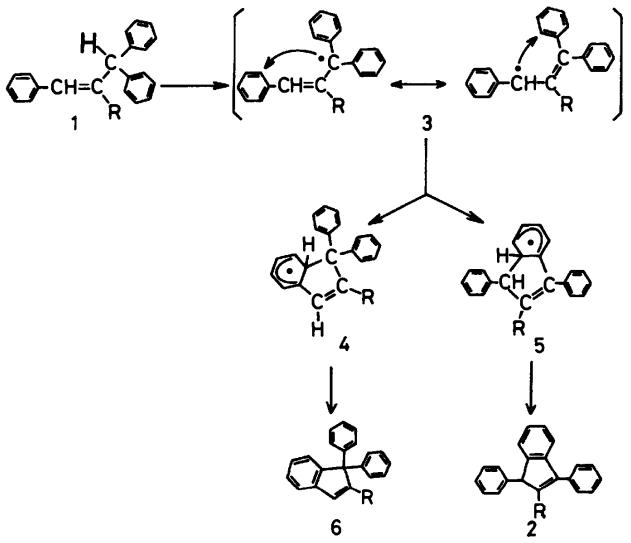
a) Isolated yields of the pure products. b) Recovered unchanged. c) The formation of **2g** was not detected.

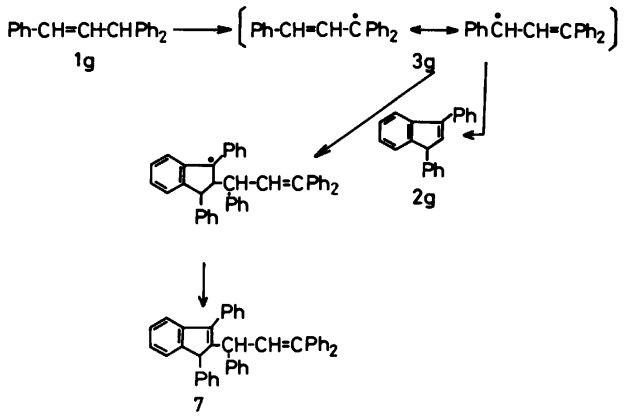


Scheme 1.

The formation of **2** can best be rationalized by the mechanism given in Scheme 1. The boldfaced hydrogen atom in **1**, being both allylic and benzylic, is readily abstracted by NBS to give a resonance-stabilized substituted cinnamyl radical (**3**). In general a cinnamyl radical generated in solutions tends to give products which result from an intramolecular attack; thus, indene was produced.[5,6] The formation of indene was observed solely during the gas-phase pyrolysis of cinnamyl ester.[7] A kinetic isotope effect suggested an intervention of a reversible process of the cinnamyl radical to a cyclic radical intermediate (Ar_2-5 mechanism) and a following rate-determining aromatization step.[7] These results are in contrast to the present observation where the indene derivatives were produced from 1,2,3-trisubstituted cinnamyl radicals. The radical could cyclize either through a cyclized radical (**4**) to give 1,1-diphenylindene derivative (**6**), or through another cyclized radical (**5**) to **2**, or could couple to give a dimer. The absence of the coupling process is best rationalized by taking account of steric hindrance near the reaction sites. The same steric factor also gives an explanation for the failure of a cyclization of the radical to the intermediate radical (**4**).

As mentioned before, the nitro derivative (**1f**) did not afford the corresponding indene (**2f**) (Run 11). The presence of the nitro group on the carbon atom next to the benzylic carbon atom is responsible for the innertness of **1f** under the present reaction conditions.[1c] By the same token, 1,1-diphenyl-2-nitroethane, which has a similar structural feature, also resisted hydrogen abstraction by NBS.

The reaction of 1,3,3-triphenyl-1-propene (**1g**)[8] with NBS did not afford the expected product, 1,3-diphenylindene (**2g**). Instead, a dimeric product, 1,3-diphenyl-2-(1,3,3-triphenyl-2-propenyl)indene (**7**),[9] was obtained (Run 12). This observation suggests that the initially formed **2g** is capable of being attacked by an intermediate 1,3,3-triphenyl-2-propenyl radical (**3g**) at the unsubstituted 2-position of **2g** (Scheme 2).



Scheme 2.

Indene itself was, in fact, supposed to be added by radicals to yield unidentified polymeric materials.[6] However, similar attacks by rather bulky 2-substituted 1,3,3-triphenyl-2-propenyl radicals were highly restricted in the reactions of **1a—e**; hence, 1,2,3-trisubstituted indenes survived under the present reaction conditions.

In summary, although NBS has been known to be an effective reagent for the dehydrogenation of allylic and benzylic positions, such an intramolecular dehydrocyclization between allyl and phenyl groups is almost unprecedented. Also, the diphenylation of the 2-substituted 1-phenyl-1-propenes and subsequent cyclization reaction may serve as a synthetic route to a series of 2-substituted 1,3-diphenylindene derivatives.

Experimental

All melting points were uncorrected. ^1H NMR spectra were determined with a Hitachi R-24A spectrometer in $CDCl_3$ using tetramethylsilane as an internal reference.

General Procedure for the Dehydrocyclization of 1,3,3-Triphenyl-1-propenes (1). A mixture of the 2-substituted 1,3,3-triphenyl-1-propene (1 mmol), *N*-bromosuccinimide (1.2 mmol) and a catalytic amount of benzoyl peroxide in 30 ml of benzene or carbon tetrachloride was refluxed with stirring for the stated period of time, cooled, and partitioned between benzene and water. The benzene extracts were dried over anhydrous magnesium sulfate, and the solvent was removed under reduced pressure. The residue was purified by column chromatography (silica gel) and recrystallization to give **2**. The physical properties of **2** are given below.

A Convenient Synthesis of Cholesta-1,5,7-trien-3β-ol

Yoji TACHIBANA
Central Research Laboratory, Nisshin Flour Milling, Co., Ltd.,
Tsurugaoka, Ooimachi, Iruma-gun, Saitama 354
(Received May 7, 1986)

Synopsis. Cholesta-4,6-dien-3β-ol (**4**) was obtained selectively by the dehydrobromination of 7-bromocholesterol with a base in the presence of a catalytic amount of tetrabutylammonium bromide. The oxidation of **4** with 2,3-dichloro-5,6-dicyano-p-benzoquinone gave cholesta-1,4,6-trien-3-one (**7**). Treatment of **7** with isopropenyl acetate under acidic conditions afforded 3-acetoxy-1,3,5,7-cholestatetraene, which was reduced with calcium borohydride to yield cholesta-1,5,7-trien-3β-ol (**2**).

The synthesis of cholesta-5,7-diene-1α,3β-diol (**1**), the photoprecursor of the physiologically active 1α-hydroxyvitamin D_3, has been reported by many research groups.[1-13] Kaneko et al.[5] reported the synthesis of cholesta-1,5,7-trien-3β-ol (**2**), a key intermediate for the preparation of **1**, by the base-catalyzed rearrangement of cholesta-1,4,6-trien-3-one (**7**)[14,15] followed by the reduction of the formed cholesta-1,5,7-trien-3-one. This method is interesting and attractive, but generally gives a poor yield of **2**. Thus, it is desirable to prepare **2** in higher yield. In the present paper, an improved method for the preparation of cholesta-4,6-dien-3-one (**6**)[16] and its conversion to **2** are described.

Lappordt et al.[17] reported the selective synthesis of cholesta-4,6-dien-3-β-ol (**4**) through the dehydrobromination of 7-bromocholesterol (**3**) derivative[18,19] in the presence of a combination of a large excess of tetrabutylammonium bromide and 2,4,6-trimethylpyridine in tetrahydrofuran. In contrast to their results, we have found that at higher temperature, the dehydrobromination of **3** by a base proceeded smoothly in the presence of a catalytic amount of tetrabutylammonium bromide (Table 1).

The 4,6-dien-3-ol (**4**) was oxidized by various oxidizing agents to give the corresponding 4,6-dien-3-one (**6**) in 50—85% yields (Table 2). Treatment of **4** with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone[20,21] afforded **7** in one stage without isolation of **6**.

It is well-known that the steroidal 1,4-dienone and 1,4,6-trienone undergo rearangement to give the phenol derivatives under acidic conditions.[22,23] However it was found that the enol acetylation of the 1,4,6-trien-3-one (**7**) with isopropenyl acetate in the presence of p-toluenesulfonic acid successfully yielded 3-acetoxy-1,3,5,7-cholestatetraene (**8**)[12] in a fairly good yield. The tetraenyl acetate (**8**) was reduced with calcium borohydride to afford the 1,5,7-trien-3-ol (**2**)

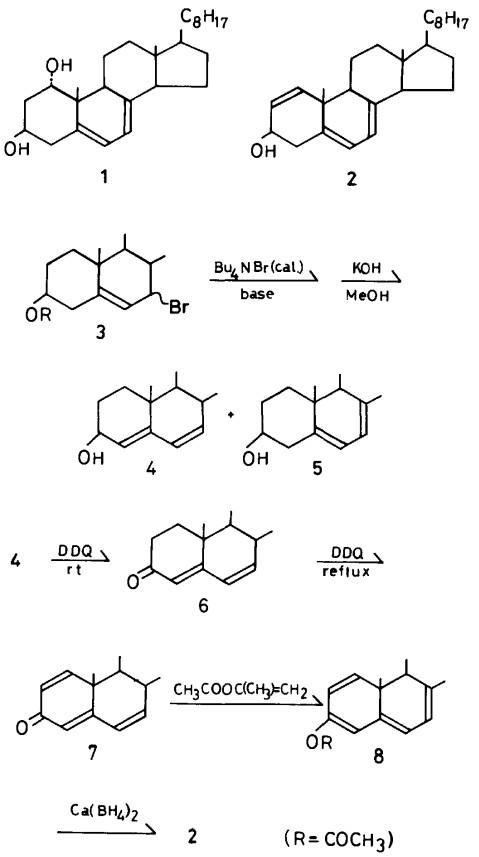

Table 1. Yields of Cholesta-4,6-dien-3β-ol (**4**) in the Dehydrobromination of 7-Bromocholesteryl Acetate (**3**)[1]

Bu_4NBr/**3**	Base	Temp °C	Time min	Yield[2] %	4/5[4]
0.1	2,4,6-Trimethylpyridine	100	20	60	7.4
0.1	2,4,6-Trimethylpyridine	125	10	62	6.8
0.1	2,4,6-Trimethylpyridine	65	70	18[3]	9.5
1.0	2,4,6-Trimethylpyridine	125	10	68	8.3
1.0	2-Methylquinoline	125	10	44	5.9

1) 7-Bromocholesteryl acetate was prepared by the reaction of cholesteryl acetate with *N*-bromosuccinimide and employed without further purification. 2) Isolated yield. 3) Tetrahydrofuran was used as a solvent. 4) The formation ratio was determined on the basis of UV spectra.

Table 2. Oxidation of Cholesta-4,6-dien-3β-ol (**4**) into Cholesta-4,6-dien-3-one (**6**) under Various Conditions

Oxidizing agent	Time h	Solvent	Temp °C	Yield[1] %
DDQ[2]	20	Dioxane	rt[3]	85

RuO_2-$NaIO_4$	48	Trichloro-ethylene/ methanol/H_2O	rt	50

1) Isolated yield. 2) 2,3-Dichloro-5,6-dicyano-*p*-benzoquinone. 3) Room temperature. 4) Pyridinium dichromate. 5) Pyridinium chlorochromate.

quantitatively. The 1,5,7-trien-3-ol (**2**) was converted to **1** by the method described in the literatures.[5,12-13]

Since cholesta-1,5,7-trien-3β-ol (**2**) is obtainable readily from cholesterol as described above, the present study provides a simple and efficient method for the preparation of 1α-hydroxyprovitamin D_3 (**1**).

Experimental

Melting points are uncorrected. UV spectra were taken on a Hitachi 320 spectrometer. Optical rotations were determined with JASCO DIP-4 polarimeter.

Cholesta-4,6-dien-3β-ol (4). A hexane solution of cholesteryl acetate (42.8 g), *N*-bromosuccinimide (21.0 g) and a catalytic amount of benzoyl peroxide was allowed to react under reflux for 40 min. The hexane solution was filtered to remove succinimide and the filtrate was evaporated to dryness under reduced pressure at below 40 °C. The residue was dissolved in butyl acetate (150 ml). Tetrabutylammonium bromide (3.2 g) and 2,4,6-trimethylpyridine (14.5 g) were added to the butyl acetate solution. The mixture was refluxed for 20 min. The solution was washed with dil. hydrochloric acid, water, dried over sodium sulfate and concentrated to a semi-crystalline residue under reduced pressure. To the residue, methanolic potassium hydroxide solution (KOH 6.2 g, methanol 200 ml) was added and the mixture was refluxed for 10 min. The methanol solution was allowed to stand overnight at room temperature. The crude cholesta-4,6-dien-3β-ol (**4**) was collected by filtration. The crude product was purified by silica-gel column chromatography (eluted with chloroform) to give **4**. 23.8 g (62%): Mp 116—117 °C (lit,[15] mp 119—120 °C); λ_{max} 239 nm (ε=25,000, EtOH).

Cholesta-4,6-dien-3-one (6). A typical procedure for the preparation of cholesta-4,6-dien-3-one (**6**) from cholesta-4,6-dien-3β-ol (**4**) is described in the following. A mixture of **4** (3.8 g) and 2,3-dichloro-5,6-dicyano-p-benzoquinone (DDQ) (2.9 g) in dioxane (20 ml) was allowed to react at room temperature for 18 h. After the formed hydroquinone was filtered off, the filtrate was condensed to dryness at reduced pressure. The residue was chromatographed on silica gel using hexane-ethyl acetate (9/1) as eluent. Crystallization from acetone gave cholesta-4,6-dien-3-one (**6**). 3.2 g (85%): Mp 81—82 °C (lit,[17] mp 80.5—81.5 °C); λ_{max} 284 nm (ε=28,700, EtOH).

Cholesta-1,4,6-trien-3-one (7). A dioxane solution containing the 4,6-dienol (**4**) (7.7 g) and DDQ (5.2 g) was treated with stirring at room temperature for 18 h. After the hydroquinone was removed by filtration, a further DDQ (4.4 g) was added to the filtrate. The dioxane solution was refluxed for 2 h. After filtration and removal of the solvent under reduced pressure, the resulting residue was chromatographed on silica gel. Elution with hexane-ethyl acetate (9/1) and crystallization from acetone gave the 1,4,6-trienone (**7**). 4.9 g (65%): Mp 89—90 °C (lit,[14] mp 82—83 °C; λ_{max} 300 nm (ε=13,400, EtOH).

Cholesta-1,5,7-trien-3β-ol (2). A mixture of the 1,4,6-trien-3-one (**7**) (38.0 g), *p*-toluenesulfonic acid (19.0 g) in butyl acetate (500 ml) and isopropenyl acetate (400 ml) was refluxed for 7 h. The butyl acetate solution was washed with water and dried over sodium sulfate. The solution was concentrated to dryness under reduced pressure. The residue was crystallized from acetone to give 3-acetoxy-1,3,5,7-cholestatetraene (**8**) as yellow needles. 27.0 g (64%): Mp 123—124 °C (lit,[12] mp 122—124 °C); $[\alpha]_D^{25}$ −507° (*c* 0.6, $CHCl_3$).

The ether solution of the tetraene (**8**) (15.0 g) was added dropwise at −10 °C to a stirred solution of calcium borohydride in ethanol-methanol (calcium chloride (30.0 g) in methanol (250 ml) and sodium borohydride (15.0 g) in ethanol (250 ml)).[5] The mixture was stirred at 0 °C for 3 h and standed overnight. After addition of 50% acetic acid to dissolve the resulted precipitate, the product was extracted with ether. The extract was washed with aq sodium hydrogencarbonate, water and dried over sodium sulfate. The ether was evaporated to dryness under reduced pressure and the residue was chromatographed on silica gel. The product, which was eluted with hexane-ethyl acetate (4/1) was crystallized from acetone to give **2**. 12.8 g (94%): Mp 126—127 °C (lit,[5] mp 128—129 °C); λ_{max} 282 nm (ε=10,900, EtOH).

Carbon Dioxide-Promoted Telomerization of 1,2- and 1,3-Dienes with Benzenesulfinate Catalyzed by Palladium(0)*

Yoshio INOUE* and Harukichi HASHIMOTO
Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aoba, Aramaki, Sendai 980
(Received May 12, 1986)

Synopsis. The telomerization of 1,2- and 1,3-dienes with benzenesulfinate dihydrate catalyzed by palladium(0) has been promoted by the presence of carbon dioxide.

Palladium complexes catalyze the dimerization of 1,3-butadiene with incorporation of nucleophiles such as alcohols, phenols, carboxylic acids, amines, enamines and active methylene compounds to form 1-substituted 2,7-octadiene and 3-substituted 1,7-octadiene.[1]

$$2CH_2{=}CHCH{=}CH_2 + YH \xrightarrow{Pd} CH_2{=}CH(CH_2)_3CH{=}CHCH_2Y + CH_2{=}CH(CH_2)_3CH(Y)CH{=}CH_2$$

Allene reacts similarly to afford 2,3-dialkyl-1,3-butadiene derivatives.[1]

$$2CH_2{=}C{=}CH_2 + YH \xrightarrow{Pd} CH_2{=}C(CH_3)C(CH_2Y){=}CH_2$$

In certain cases, introduction of carbon dioxide profoundly alters the properties of the catalyst. For example, formation of 2,7-octadien-1-ol has been accomplished from the reaction of water with two moles of 1,3-butadiene in the presence of a considerable amount of carbon dioxide.[2] In the absence of carbon dioxide, the formation of the alcohol is very sluggish. The telomerization of 1,3-dienes with arenesulfinic acids or sodium arenesulfinates in acetic acid has been carried out in the presence of palladium catalysts to afford high yields of allylic sulfones.[3]

In the course of the study on the CO_2-promoted reactions,[4] we have discovered that 1,2- and 1,3-dienes react with sodium benzenesulfinate dihydrate in the presence of a palladium(0) catalyst to give allylic sulfones under CO_2 atmosphere.

The results are shown in Table 1. The reaction of sodium benzenesulfinate dihydrate with 3.8 equiv of 1,3-butadiene (**1a**) in *N*,*N*-dimethylformamide (DMF) at 80 °C for 2 h under the pressure of CO_2 in the presence of [$Pd(PPh_3)_3$] gave the 1:1 addition product, 2-butenyl pheny sulfone (**2a**), in 20% yield (*E*:*Z*=2:1) together with the 1:2 addition product, (*E*)-2,7-octadienyl phenyl sulfone, in 78% yield. The effect of CO_2 was remarkable because the addition reaction did not take place at all in the absence of CO_2.

Isoprene (**1b**) afforded exclusively the 1:1 addition product 3-methyl-2-butenyl pheny sulfone (**2b**).

$$CH_2{=}CHC(CH_3){=}CH_2 + PhSO_2Na{\cdot}2H_2O \xrightarrow[CO_2]{Pd} PhSO_2CH_2CH{=}C(CH_3)_2$$

Table 1. Reaction of Dienes with Sodium Benzenesulfinate Dihydrate[a]

Diene	Reaction temp/time °C/h	Product	Yield %
 **1a**	80/2	**2a**	20 (*E*:*Z*=2:1)
			78 (*E*:*Z*=6:1)
1b	80/2	**2b**	94
1c	100/4	 **2c**	67
 **1d**	110/4	 **2d**	31[b] (*E*:*Z*=19:1)
 **1e**	80/2	 **2e**	48 (*E*:*Z*=3:1)
3	80/2	 **4**	44

a) $PhSO_2Na{\cdot}2H_2O$ 9.1 mmol, 1,3-diene 10—34 mmol, [$Pd(PPh_3)_3$] 0.2 mmol, DMF 10 cm³, CO_2 15 kg/cm². For the 1,2-diene **3**, see the experimental part. b) 2-Pentenyl phenyl sulfone was also formed in 11% yield.

* The term "telomerizartion" is meant here to imply formation of adducts between one or more dienes and a second substance.

These results contrasted sharply with those reported earier,[3] where the reaction of dienes with arenesulfinic acid or sodium arenesulfinate in acetic acid gave allylic sulfones containing large proportion of the more substituted isomer. 2,3-Dimethyl-1,3-butadiene (**1c**) gave predominantly 2,3-dimethyl-2-butenyl phenyl sulfone (**2c**) in a moderate yield at the reaction temperature of 100 °C. The reaction of (*E*)-1,3-pentadiene (**1d**) with the sulfinate was sluggish at the reaction temperature of 80 °C. Under forced conditions (110 °C, 4 h), the diene afforded 1-methyl-2-butenyl phenyl sulfone (**2d**) in 31% yield. Myrcene (**1e**) underwent the addition reaction at 80 °C to give mainly geranyl phenyl sulfone. 1,4-Disubstituted 1,3-dienes such as 1,3-cyclooctadiene and methyl sorbate did not take part in this reaction.

Allene (**3**) underwent smoothly the 2:1 addition reaction to afford 3-methyl-2-methylene-3-butenyl phenyl sulfone (**4**) selectively under the pressure of CO_2 in the presence of the palladium catalyst.

$$2CH_2{=}C{=}CH_2 + PhSO_2Na{\cdot}2H_2O \xrightarrow[CO_2]{Pd} PhSO_2CH_2C(=CH_2)C(=CH_2)CH_3$$

We point out here one of possible roles of CO_2 in the telomerization reaction. Benzenesulfinic acid may be formed from its sodium salt as follows.

$$PhSO_2Na{\cdot}2H_2O + CO_2 \rightleftharpoons PhSO_2H{\cdot}H_2O + NaHCO_3$$

Although the equilibrium is declined to the left due to the strong acidity of the free sulfinic acid (pK_a ca. 2), the sulfinic acid thus formed may, in turn, begin to undergo telomerization with dienes in the presence of a palladium catallyst.[3]

The intermediate has been supposed to be a π-allylpalladium species, which is attacked by benzenesulfinate to afford allylic sulfones.[3] There are several preceedings concerning the attack of sulfinate on an in situ-generated π-allyl palladium complex.[5] Usually thermodynamically-controlled products were reported to be predominated. The observations coincide well with our results.

As free sulfinic acid is unstable having a tendency to undergo disproportionation into thiosulfonic *S*-ester and sulfonic acid,[6] the employment of CO_2 and a sulfinic acid salt, that is stable, instead of free sulfinic acid may be a choice in the diene telomerization reaction.

Experimental

Materials. The dienes (1,2- and 1,3-) were used as received except myrcene. Myrcene was distilled under reduced pressure before use. [$Pd(PPh_3)_3$] was prepared according to the reported method.[7]

General Procedure for the Telomerization of Dienes with Benzenesulfinate Dihydrate. A mixture of sodium benzenesulfinate dihydrate (1.82 g, 9.1 mmol), a diene, and [$Pd(PPh_3)_3$] (179 mg, 0.2 mmol) in 10 cm^3 of DMF was stirred in an autoclave under CO_2 pressure (15 kg cm^{-2}) under the conditions described in Table 1. After the teaction was completed, the whole content was poured into water. The products were extracted with diethyl ether and the organic layer was dried on $MgSO_4$. After the solvent was evaporated, the residue was subjected to column chromatography on silica gel eluting with hexane–ethyl acetate.

Reaction of 1,3-Butadiene (1a) with Benzenesulfinate. Reaction of **1a** (1.86 g, 34.4 mmol) in the usual way as above gave an oil after column chromatography (hexane/ethyl acetate=2/1). Yield 2.13 g. GLC analysis (OV-1, 3 m, 3%, 194 °C) showed the formation of 2-butenyl phenyl sulfone (**2a**) and 2,7-octadienyl phenyl sulfone in a 1:4 ratio. The products were isolated by GLC and characterized spectroscopically (IR, ^{1}H NMR, Mass).[3] The *E*/*Z* ratios of **2a** and 2,7-octadienyl phenyl sulfone were determined by ^{1}H NMR spectroscopy to be 2:1 and 6:1, respectively.

Reaction of Isoprene (1b) with Benzenesulfinate. Reaction of **1b** (1.36 g, 20 mmol) in the usual way gave 3-methyl-2-butenyl phenyl sulfone (**2b**) as a pale yellow oil after column chromatography (hexane/ethyl acetate=2/1). Yield 1.79 g (8.52 mmol, 94%). Spectroscopic (IR, ^{1}H and ^{13}C NMR, Mass) and elemental analysis supported the structure.

Reaction of 2,3-Dimethyl-1,3-butadiene (1c) with Benzenesulfinate. Reaction of **1c** (0.8 g, 10 mmol) at 100 °C for 4 h in the usual way gave 2,3-dimethyl-2-butenyl phenyl sulfone (**2c**)[8] after column chromatography (hexane/ethyl acetate=3/1). Yield 1.36 g (6.1 mmol, 67%). Recrystallization from toluene/hexane (1/3) afforded pure material as white needles: mp 98—99 °C. IR (KBr) 1285, 1135, 750, 580 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=1.24 (s, 3H), 1.60 (s, 3H), 1.74 (s, 3H), 3.80 (s, 2H), 7.40—7.92 (m, 5H). Found: C, 64.27; H, 7.31. Calcd. for $C_{12}H_{16}O_2S$: C, 64.29; H, 7.14.

Reaction of (*E*)-1,3-Pentadiene (1d) with Benzenesulfinate. Reaction of **1d** (0.77 g, 10.3 mmol) at 110 °C for 4 h in the usual way gave an oil after kugelrohr distillation at 140 °C (4 mmHg) (1 mmHg=133.322 Pa). Yield 796 mg (42%). Found: C, 63.10; H, 7.01. Calcd. for $C_{11}H_{14}O_2S$: C, 62.83; H, 6.71. IR (neat) 1300, 1140, 965, 720, 680 cm^{-1}. GLC analysis (OV-1, 2 m, 3%, 150 °C) of the product showed two peaks in the ratio of 77:23. The major portion, which was isolated by GLC, was composed of (*E*)- and (*Z*)-1-methyl-2-butenyl phenyl sulfone (**2d**). (*E*)-Isomer: ^{1}H NMR ($CDCl_3$) δ=1.36 (d, *J*=7 Hz, 3H), 1.58 (d, *J*=5 Hz, 3H), 3.40—3.90 (m, 1H), 5.24—5.60 (m, 2H), 7.30—7.96 (m, 5H). The absorption of the (*Z*)-isomer occurred differently at δ=1.40 (d, *J*=7 Hz) instead of δ=1.36 in the (*E*)-isomer. The *E*/*Z* ratio was determined by ^{1}H NMR to be 19:1. The minor portion, which was also isolated by GLC, was composed of (*E*)- and (*Z*)-2-pentenyl phenyl sulfone. (*E*)-Isomer: ^{1}H NMR ($CDCl_3$) δ=0.84 (t, *J*=8 Hz, 3H), 1.60—2.00 (m, 2H), 3.68 (d, *J*=6 Hz, 2H), 5.24—5.65 (m, 2H), 7.35—7.90 (m, 5H). The absorption of the (*Z*)-isomer occurred at δ=3.78 (d, *J*=9 Hz) instead of δ=3.68 in the (*E*)-isomer. The *E*/*Z* ratio was determined by ^{1}H NMR to be 9:1.

Reaction of Myrcene (1e) with Benzenesulfinate. Reaction of **1e** (1.36 g, 10 mmol) in the usual way gave 3,7-dimethyl-2,6-octadienyl phenyl sulfone[5] as an oil on chromatography (hexane/ethyl acetate=2/1) followed by kugelrohr distillation at 165 °C (3 mmHg). Found: C, 69.08; H, 7.72. Calcd for $C_{16}H_{22}O_2S$: C, 69.03; H, 7.97. The *E*/*Z* ratio was determined by GLC (OV-1, 2 m, 3%, 200 °C) to be 3:1. IR (neat) 1445, 1310, 1150 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=1.28 (s, 3H), 1.56 (s, 3H), 1.64 (s, 3H), 1.80—2.24 (m, 4H), 3.78 (d, *J*=8 Hz, 2H), 4.80—5.40 (m, 2H), 7.20—8.00 (m, 5H).

Reaction of Allene (3) with Benzenesulfinate. $PhSO_2Na{\cdot}2H_2O$ (3.64 g, 20 mmol) and **3** (0.70 g, 17.5 mmol) were reacted in an autoclave at 80 °C for 2 h in the presence of [$Pd(PPh_3)_3$] (179 mg, 0.2 mmol) in DMF (20 cm^3) under CO_2 pressure (15 kg cm^{-2}). Isolation as above by column

chromatography on silica gel (hexane/ethyl acetate=3/2) gave 3-methyl-2-methylene-3-butenyl phenyl sulfone as a pale yellow oil. Yield 860 mg (3.87 mmol, 44%). An analytical sample was obtained by kugelrohr distillation at 150 °C (4 mmHg). This compound polymerized partially during the distillation. ^{1}H NMR ($CDCl_3$) δ=1.83 (s, 3H), 4.08 (s, 2H), 4.96 (s, 1H), 5.02 (s, 1H), 5.06 (s, 1H), 5.36 (s, 1H), 7.20—7.96 (m, 5H). ^{13}C NMR ($CDCl_3$) δ=140.585 (s), 138.730 (s), 136.102 (s), 133.467 (d), 128.789 (d), 128.399 (d), 120.949 (t), 115.003 (t), 60.133 (t), 20.710 (q). IR (neat) 1722, 1300, 1145, 895, 775 cm^{-1}. Mass (70 eV) *m/z* 222 (M^+), 143, 81, 79, 77, 53. Found: C, 64.71; H, 6.24. Calcd. for $C_{12}H_{14}O_2S$: C, 64.84, H, 6.35.

A Supercritical Carbon Dioxide Extraction from Mackerel (Scomber Japonicus) Powder: Experiment and Modeling

Yutaka IKUSHIMA,* Norio SAITO, Kiyotaka HATAKEDA, Shota ITO, Takashi ASANO, and Tomio GOTO
Government Industrial Research Institute, Tohoku, Nigatake 4-Chome, Sendai 983
(Received March 12, 1986)

The extraction of some organic substances from freezed-dried mackerel powder was performed using supercritical carbon dioxide (SC-CO_2) at 4.9—24.5 MPa and 313 K in a fixed-bed flow extractor. It was found that the rate of extraction was enhanced by raising the pressure. The overall yield of the SC-CO_2 extraction was comparable to that of a hot-hexane-extraction from the same material. The SC-CO_2 extraction produced glycerides of pharmacologic significance such as icosapentaenoic acid (IPA) and docosahexaenoic acid (DHA) from mackerel. In addition, a kinetic model for extraction with supercritical fluids is described, and is applied to correlate our results obtained in the SC-CO_2 extraction of mackerel. This model could express the transport within the solid in the supercritical fluid extraction process.

Recently much attention has been drawn to the separation process using a supercritical fluid (SCF). As compared with usual extraction procedure performed at relatively high temperature, the SCF extraction has several advantages. For example, it can yield thermolabile materials without denaturalization because of its low operating temperature. The feature of SCF techniques has previously been described and discussed in detail.[1-4] In some industries, the SCF has effectively separated the desired materials from natural products.[5-8]

We have been studying supercritical carbon dioxide (SC-CO_2) extraction of mackerel powder to obtain unsaturated fatty acids of pharmacologic value such as icosapentaenoic acid (IPA) and docosahexaenoic acid (DHA). These two acids have recently been reported to be efficacious against arteriosclerois.[9,10] The present study concerns the effective utilization of natural resources rich in our area where over one million tons of mackerel are caught every year for domestic use. Therefore, it should make possible the extraction of such high-valued substances as IPA and DHA from this inexpensive material.

In the present work, we carried out SC-CO_2 extraction from freezed-dried mackerel powder in a fixed bed extractor at pressures of 4.9—24.5 MPa and a temperature of 313 K. The pressure dependence of the extraction effectiveness of SC-CO_2 is discussed. The composition of the SC-CO_2-extracted oil is analyzed and compared with that of a hot hexane-extracted oil. We also present a kinetic model for the SCF extraction and attempt to use it to correlate our results of the SC-CO_2 extraction. For the practical design of SCF extraction plants, it is highly desirable to kinetically express the extraction process in order to optimize process parameters. For this not only knowledge of phase equilibria but also a kinetic analysis of the processes involved is essential. For the latter, however, little consideration has been made so far in the literature.

A Model of SCF Extraction

A mass transfer model is used to express the SCF extraction process. We regard the extraction process as a reaction such that one molecule of a solute, B, associates with j molecules of a SCF, A, with the formation of a complex, BA_j, $B+jA \rightarrow BAj$, and use a kinetic and diffusional model of solid-gas reaction. In the application of this model to the extract of mackerel, we will suppose the oils to be extracted to consist of a single component, as described later.

At first, the mass transfer for a single spherical extract is considered. Then the results are applied to a fixed bed of spheres. The model for solid-gas reactions proposed by Ishida and Wen[11] is used for a single spherical extract. Ishida et al. presented a kinetic and diffusional model for solid-gas reaction occurring in a spherical particle. We apply this model for the extraction of a solute from a solid with SCF. In applying this model to a fixed bed of spheres in the extractor, we make some modifications as mentioned later. The extraction process in a single spherical particle with SCF will be described in the following manner. Since the extraction near the surface is faster, the solute in this region is completely extracted after a certain time. That is to say, as the extraction progresses, a so-called raffinate layer is formed in the outside of the extract. Here, the stage of extraction prior to the formation of the raffinate layer is regarded as the first stage and the following stage as the second stage. Two models, 1

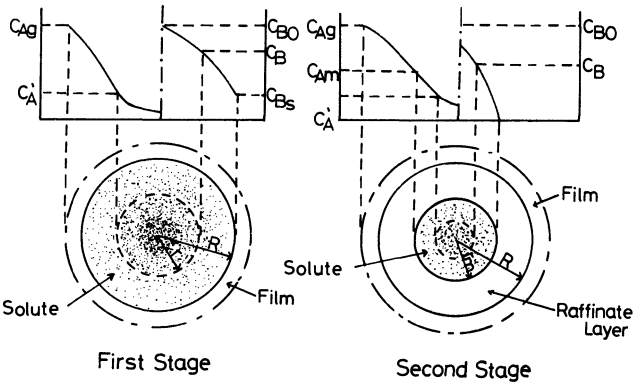

Fig. 1. Schematic diagram of the concentration profile in the first and second stage.

and 2, are presented for the first and second stages, respectively. Schematic diagram for these two stages are shown in Fig. 1. The following assumptions are employed:

—A steady state approximation for the transfer of SCF,A, holds.

—The rate of extraction is independent of the extract concentration in the solid.

—The fixed bed consists of spherical particles of uniform size which remain unchanged during the extraction.

Model 1: The mass balance and boundary conditions for gas A and solute B are given by

$$0 = D'(d^2C_A'/dr^2+2/r\, dC_A'/dr) - jk_VC_{B0}(C_A'-C_A^*), \quad (1)$$

$$dC_B/dt = - k_VC_{B0}(C_A-C_A^*), \quad (2)$$

$$D'dC_A'/dr = k_g(C_{Ag}-C_A^*) \quad \text{at } r = R, \quad (3)$$

$$dC_A'/dr = 0 \quad \text{at } r = 0, \quad (4)$$

where C_A' is the concentration of component A in solid B, C_A^* is C_A' at equilibrium, C_{Ag} is the concentration of component A in gas, C_B is the concentration of solid extract B, C_{B0} is the initial concentration of solid extract B, D' is the effective diffusivity of component A in the extraction layer, j is a stoichiometric coefficient, k_g is the mass transfer coefficient of component A, k_V is the extraction rate constant based on volume, r is a distance from the center of the sphere, R is a particle radius, t is a time.

The concentration profile of solute B can be obtained

$$C_B = C_{B0} - \int_0^t k_VC_{B0}(C_A'-C_A^*)dt \quad (5)$$

as

$$C_B/C_{B0} = 1 - (\sinh(\phi'\xi)/(\xi \sinh\phi')(\theta_V/\theta_{Vc}), \quad (6)$$

where ξ is a dimensionless radius, $\phi'$is a Thile modulus based on D', θ_v is a dimensionless time, θ_{vc} is θ_v at the end of the first stage as defined respectively by

$$\xi = r/R, \quad (7)$$

$$\phi' = R(jk_VC_{B0}/D')^{1/2}, \quad (8)$$

$$\theta_V = k_V(C_{Ag}-C_A')t, \quad (9)$$

$$\theta_{Vc} = 1 + (\phi' \coth\phi' - 1)/N_{sh}', \quad (10)$$

$$N_{sh}' = k_gR/D', \quad (11)$$

where N_{sh}' is a Sherwood number. Further, the degree of extraction X is given as follows.

$$X = 1 - \left[\int_0^R 4\pi r^2C_B dr/\int_0^R 4\pi r^2C_{B0}dr\right] \quad (12)$$

as

$$X = 3/(\phi')^2[\phi'\coth\phi' - 1]\theta_V/\theta_{Vc} \quad (13)$$

At the end of the first stage, the degree of extraction X can be obtained upon substituting $\theta_v=\theta_{vc}$ in Eq 13 as follows.

$$X = 3/(\phi')^2[\phi'\coth\phi' - 1] \quad (14)$$

The concentration profile of gas A in the solid is obtained from Eqs. 1, 3, and 4 as

$$(C_A'-C_A^*)/(C_{Ag}-C_A^*) = \sinh(\phi'\xi)/\theta_{Vc}\xi \sinh\phi', \quad (15)$$

Model 2: As the extraction progresses, the solute is completely extracted at an outer layer, the raffinate layer is gradually formed as a new diffusion resistance for the gaseous solvent, but the extraction still occurs inside the raffinate layer. The mass balance and boundary conditions for gas A and solute B are then given as follows. In the inner core (extraction region), the mass balance and boundary conditions are identical to Eqs. 1, 2, and 4. In the raffinate layer, as extraction dose not occur, the mass balance for gas A can be obtained by

$$0 = D(d^2C_A/dr^2+r/2\, dC_A/dr), \quad (16)$$

$$C_B = 0 \quad \text{at } r = R, \quad (17)$$

$$DdC_A/dr=k_g(C_{Ag}-C_A) \quad \text{at } r = R, \quad (18)$$

where D is the effective diffusivity of component A in raffinate layer. Further, at the boundary between the extraction region and the raffinate layers,

$$C_A' = C_A \quad (19)$$

$$D'dC_A'/dr = DdC_A/dr. \quad (20)$$

The concentration profile of the solid extract can be obtained from

$$C_B = C_{Bm} - \int_{tc}^t k_VC_{B0}(C_A'-C_A^*)dt \quad (21)$$

as

$$C_B/C_{B0} = 1 - \sinh(\phi'\xi)/\xi \sinh\phi' - \sinh(\phi'\xi)/\xi\left[\int_{\theta_{Vc}}^{\theta_V}[\xi_m/\sinh(\phi'\xi_m)]d\theta_V/[1+D'/D\,[1-\xi_m+\xi_m/N_{sh}][\phi'\xi_m\coth(\phi'\xi_m) - 1]]\right], \quad (22)$$

where C_{Bm} is C_B at the end of the first stage, $N_{sh}=k_gR/D$, $\xi_m=r_m/R$, r_m is r at the boundary between the extraction region and the raffinate layer. The time required for the raffinate layer to reach r_m is obtained as

$$\theta_V = \theta_{Vc} + \int_1^{\xi_m}(d\theta_V/d\xi_m)d\xi_m \quad (23)$$

θ_v can be obtained from Eqs. 22 and 23 as follows.

$$\theta_V = 1 + (1-D'/D)\ln[\xi_m\sinh\phi'/\sinh(\phi'\xi_m)]+\phi^2(1-\xi_m)^2(1+2\xi_m)/6+D'/D(1-\xi_m)[\phi'\xi_m\coth(\phi'\xi_m)-1] + \phi^2(1-\xi_m^3)/3N_{sh} + \xi_m[\phi'\xi_m\coth(\phi'\xi_m)-1]/N_{sh}'. \quad (24)$$

When we substitute Eq. 24 into Eq. 22, the concentration profile for the solid extract is obtained as

$$1 - C_B/C_{B0} = \xi_m\sinh(\phi'\xi)/\xi\sinh(\phi'\xi_m). \quad (25)$$

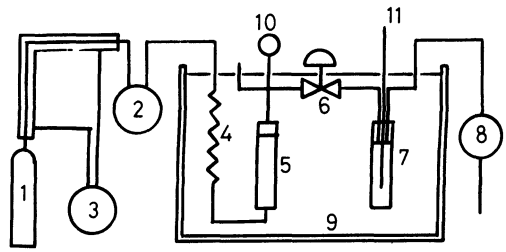

Fig. 2. Schematic diagram of supercritical CO_2 extraction apparatus. 1: CO_2 Cylinder, 2: High pressure pump, 3: Cooling circulator, 4: Preheater, 5: Extractor, 6: Back pressure regulator, 7: Receiver, 8: Flow totalizer, 9: Constant temperature bath, 10: Pressure gauge, 11: Thermocouples.

Thus, the degree of extraction X_2 can be obtained from Eq. 25 as

$$X_2 = 1 - \xi_m^3 + 3\xi_m[\phi'\xi_m \coth(\phi'\xi_m) - 1]/(\phi')^2. \quad (26)$$

Experimental

Materials. Mackerel were obtained commercially. They were freezed-dried and sieved in the range of about 32 to 64 mesh. The average diameter of the mackerel particles was 10^{-5} m. The amount of water contained was 7.3 wt%. Commercial-grade carbon dioxide was used as solvent.

Extraction Procedures. A flow diagram of the extraction apparatus used is shown in Fig. 2. Liquid carbon dioxide is charged into a Hitachi high pressure liquid pump through a 1/16 inch tube and a check valve, and compressed to the desired pressure. The pump can deliver the solvent at a constant flow rate of 1 NL min^{-1} (1 NL=1 L of gas at 293 K and 101.3 kPa). The pressure is controlled by a back pressure regulator. The extraction pressure is measured with a Bourdon-type pressure gauge. Fluctuations in pressure due to the pump are less than ± 1 Kg cm^{-2} below 300 Kg cm^{-2}. The temperature is controlled within ± 0.1 K.

A 25 g sample of mackerel particles is placed in a 0.1 L extractor and extracted at pressures of 4.9—24.5 MPa and 313 K. The extracted solution is flashed to atmospheric pressure across a heated back pressure regulator and the component is collected in a receiver. The amount collected is determined by weighing and the corresponding total volume of CO_2 used is measured with a flow totalizer.

Further, mackerel particles were extracted with hexane for 5 h in a Soxhlet for comparison.

Analytical Methods. Extracted glycerides were changed into methyl esters of fatty acids according to the usual method. The esters were identified by GC-MS and gas chromatography. Phosphorus was analyzed colorimetrically.[12]

Results and Discussion

In Fig. 3, the yield of extracted oil is plotted against the total amount of CO_2 consumed under the conditions that carbon dioxide was forced to flow at a rate of 1 NL min^{-1} at 19.6 MPa and 313 K. The linear portion of the curve indicates that steady-state extraction conditions are readily established at the beginning of the extraction. The extraction rate is maintained

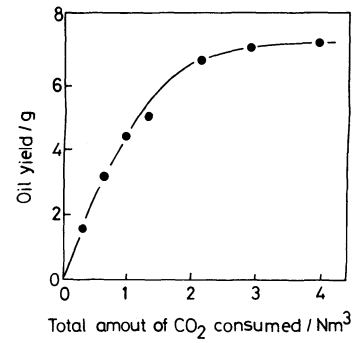

Fig. 3. Oil yield from freezed-dried mackerel powder during supercritical CO_2 extraction at 19.6 MPa and 313 K.

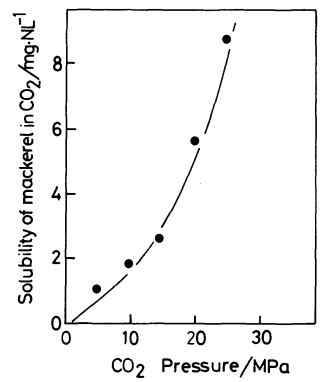

Fig. 4. Effect of pressure on the solubility of mackerel in CO_2 during the initial 6 h at 313 K.[13]

at about 0.27 g h^{-1} until an oil yield of 6.7 g is obtained. The overall yield is comparable to 85% of that obtained by the hot hexane extraction.

The solubility at 313 K between 4.9—24.5 MPa is given in Fig. 4. The initial solubility of mackerel oil in CO_2 was determined from the slope of the plot of oil yield-to-total amount of CO_2 consumed (as shown in Fig. 3, for example).[13] The solubility at 313 K increased greatly with the pressure. For example, the amount of the oil extracted at 24.5 MPa is about 4.6 times that at 9.8 MPa. This is considered to be associated with an increased solute holding power. Previously, Yamaguchi[14] reported that 14.4 g of oil per 100 g of mackerel could be extracted at 39.2 MPa, 313 K and a flow rate of 10 kg h^{-1}.

Table 1 provides an analytical characterization of SC-CO_2-extracted and hot hexane-extracted oils from the same mackerel particles. In this Table are listed the kinds of fatty acid components and the amounts of phosphorus contained in both SC-CO_2- and hexane-extracted mackerel oils. Under these conditions, the oils obtained by SC-CO_2 extraction contains both IPA and DHA and the amounts of fatty acid components compete with those obtained by the hot hexane extraction.[13] Furthermore, SC-CO_2-extracted oil has significantly less phosphorus than hexane-extracted oil. The

hexane-extracted oil is red brown and turbid whereas the SC-CO_2-extracted oil is yellow and clear. The method used to estimate the phosphatide content is to multiply the percent elemental phosphorus by 25.4.[12] The phosphatide content calculated on this basis is 1% for the hexane-extracted oil and 0.023% for the SC-CO_2-extracted oil. These values are reflected in a significant difference in the refining loss on the removal of the phosphatide content in the purification process between the SC-CO_2- and hexane-extracted oils. Therefore, the oil extracted with SC-CO_2 has the advantage of being essencially comparable to a degummed, hexane-extracted crude oil. In addition, it was reported[15] that oil extracted from soybeans with SC-CO_2 had less phosphorus than hexane-extracted oil. That is to say, with SC-CO_2, phosphatide free oil not only from plant seed but from fish is shown to be extracted.

The Application of the Kinetic Models. The results obtained for a single sphere in the models 1 and 2 using the Ishida's model[11] are transfered to a fixed bed of spheres by correcting the Sherwood number. In the model 1, we present the modification of the Sherwood number N_{sh}' as follows.

Table 1. Compositions of SC-CO_2- and Hexane-Extracted Mackerel Oils[13]

Fatty acid	Hexane	SC-CO_2
	%	%
Myristoreic	4.8	6.3
Palmitic	20.4	21.8
Palmitoleic	5.7	7.3
Stearic	2.3	1.1
Oleic	33.4	32.2
Linoleic	—	1.9
Icosenoic	5.4	2.0
Icosapentaenoic	7.8	5.8
Erucic	0.5	0.6
Docosahexaenoic	11.7	8.1
Lignoceric	0.4	—
	Hexane	SC-CO_2
	ppm	ppm
Phoshorous	405	3
	Hexane	SC-CO_2
Oil description	Yellow oil	Red brown oil

$$N_{sh}^* = N_{sh}'\psi, \tag{27}$$

where N_{sh}^* is the Sherwood number for a fixed bed of spheres. In the model 2, we regard the correction factor ψ as a function of the dimensiomless radius ξ_m of the extraction region as follows.

$$\psi = \exp(-K/\xi_m), \tag{28}$$

where K is a constant, which is treated here as an adjustable parameter.

The results calculated from the above two models employing Eqs. 27 and 28 are compared with the experimental results in Fig. 5. Table 2 summarizes the parameters used in the present calculations. The stoichiometric coefficient was estimated from the components of each fatty acids of the SC-CO_2-extracted mackerel oils shown in Table 1 and the solubility constant of triglycerides in SC-CO_2 studied by Chrastll.[16] The initial concentration of the mackerel oil was determined as follows. The weight of the mackerel oil obtained from 25 g of mackerel powder with n-hexane in a Soxhlet was 8.8 g. We assumed that it was the total yield contained in the powders and that the oil consisted of triglycerides. From the analytical results shown in Table 1, 25 g of mackerel powder contained 9.9×10^{-3} mol (=0.01 mol) of the oil. Since the bulk density of the mackerel powder was 0.25, the initial concentraion was about 100 mol m^{-3}. The effective diffusivity D' and D were estimated in the following manner. First, for D', we applied the equation of Grigull.[17]

$$m/m_c = C_q(1-\exp(-EF_o)), \tag{29}$$

where F_o is the Fourier number, C_q and E are coefficients (C_q=0.6079, E=9.8696), m is the remaining quantity of SC-CO_2-extracted oil, m_c is the initial quantity of mackerel oil. Further, F_o was defined as

$$F_o = D't/R^2, \tag{30}$$

where R is the radius of the sphere. D' was determined from Eqs. 29 and 30. Next, in the second stage, the mass transfer coefficient k_g was considered as follows.

$$1/k_g = 1/\beta_i + 1/\beta_a, \tag{31}$$

where β_i is the mass transfer coefficient in the extraction layer, β_a is the mass transfer coefficient in the raffinate layer. Since $\beta_a \gg \beta_i$,

Table 2. Parameters Used in the Model Calculations for Extraction of Mackerel Oil with SC-CO_2

Diameter of the equivalent sphere	$d=10^{-4}$/m
Initial concentration of the solute	$C_{BO}=100$/mol Nm^{-3}
Effective diffusivity of the solvent in the extraction region	$D'=4\times10^{-7}/m^2\,h^{-1}$
Effective diffusivity of the solvent in the raffinate layer	$D=9\times10^{-5}/m^2\,h^{-1}$
Pressure	P=19.6/MPa
Temperature	T=313/K
Volumetric flow of the solvent	F=60/NL h^{-1}
Stoichiometric coefficient	$j=4$
Thiele modulus	$\phi'=2.5$, $\phi'=0.17$
Correction constant	$K=3.2$

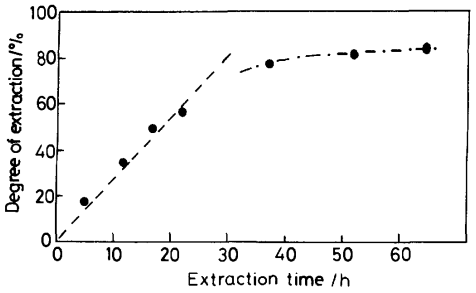

Fig. 5. Degree of extraction of mackerel oil at 19.6 MPa and 313 K.
●: Exp., ——: Model 1, —·—: Model 2.

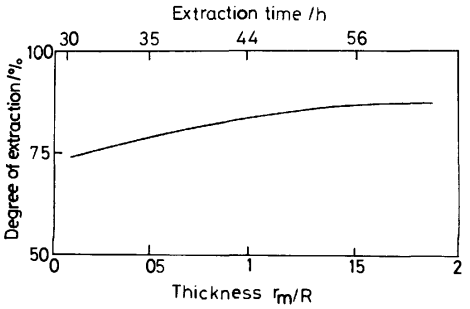

Fig. 6. Calculated relation between the degree of extraction and the thickness of raffinate layer in the second stage.

$$k_g \simeq \beta_1. \tag{32}$$

Schlunder proposed the following equation.[18]

$$\beta_1 R/D = (10.82^2 + 4/\pi F_0)^{1/2}. \tag{33}$$

In addition, Brauer[19] assumed that if F_0 was larger than 0.4,

$$\beta_1 \sim 1/t. \tag{34}$$

Therefore, D was estimated from Eqs. 32, 33, and 34. The optimal Thile modulus and the correction constant K were determined so as to minimize the difference between the experimental results in Fig. 3 and the estimates using the models.

As shown in Fig. 5, the overall extraction process can be represented by these models well, the initial stage being by model 1 while the latter stage by model 2. Furthermore, using the parameters in Table 2 and the results in Fig. 5, the overall yield in the first stage from Eq. 14 and the duration for it is shown to be about 74% and 28 h, respectively. This means that beyond this extraction region, the solvent CO_2 rapidly becomes more difficult to diffuse into the particle because under these conditions, the raffinate layer begins to form.

In model 2, the ralationship between the thickness of the raffinate layer and the degree of extraction derived from Eqs. 24 and 26 is shown in Fig. 6. The formation rate of the raffinate layer decreases with the extraction time. As the raffinate layer thickens, the degree of extraction gradually decreases and attains a steady value such that the thickness of the raffinate layer is over about 10% of the whole extraction region. That is to say, the raffinate layer acts as a diffusion resistance for the extraction and decrease the degree of extraction. Estimating from the above calculated results, the extraction occurs near the surface of the mackerel particle and large amounts of the materials contained remain unextracted. Therefore, the diffusion of the gas in the particle must progress in order to improve the degree of extraction. This may be attained by the adjustment of the extraction pressure and temperature. Finally, we would like to note that the addition of a suitable third substance to the CO_2 enhances the extraction efficiency.[20,21]

An Analysis of the Voltammetric Adsorption Waves of Methyl Viologen

Katsuyoshi KOBAYASHI,* Fumiaki FUJISAKI, Toshifumi YOSHIMINE, and Katsumi NIKI
Department of Electrochemistry, Faculty of Engineering, Yokohama National University, Tokiwadai, Hodogaya-ku, Yokohama 240
(Received March 14, 1986)

The electrochemical behavior of 1,1′-dimethyl-4,4′-bipyridinium dichloride (methyl viologen, MV) is complicated with the strong adsorption of both the oxidized (MV^{2+}) and the reduced ($MV^{+\cdot}$) forms of MV on a mercury electrode. MV^{2+} adsorbs on the electrode with a flat orientation at more positive potentials than the potential of zero charge of the mercury electrode. $MV^{+\cdot}$ adsorbs on the electrode with a vertical orientation at more negative potentials than the formal potential of the $MV^{2+/+\cdot}$ couple, $(E^{0'})_{MV}$. It is probable that the change in the orientation of the adsorbed $MV^{+\cdot}$ from flat to vertical with the increase in the $MV^{+\cdot}$ concentration in the vicinity of the $(E^{0'})_{MV}$ leads to a strongly attractive interaction between the adsorbed $MV^{+\cdot}$ molecules and a sharp voltammetric adsorption peak results at higher concentrations of MV^{2+}.

Methyl viologen has been widely used as one of the active herbicides, the "paraquat" family.[1] This herbicidal activity originates from the formation of the cation radical of methyl viologen.[2,3]

MV^{2+} is reduced in two steps. The first step is a reversible one-electron transfer with a very negative half-wave potential, −(0.68—0.69) V vs. a saturated calomel electrode (SCE).[4,5] The reduction of MV^{2+} to the methyl viologen cation radical, which is relatively stable in an oxygen-free solution,[6-8] causes a marked color change. MV acts as a good electron-transfer mediator for biological systems.[5,9] These properties lead to the applications of MV to photoelectrodes,[10-14] electrochromisms,[15-19] and electrocatalyses.[20-24]

The electrochemical behavior of MV itself is complicated by the strong adsorption of both MV^{2+} and $MV^{+\cdot}$ molecules on a mercury electrode. Pospisil et al.[3,25] and Grachev et al.[8] have reported on the analysis of the adsorption waves of MV by means of classical d.c. and a.c. polarographic techniques. Recently, resonance and surface enhanced Raman scattering spectroscopies[26,27] and UV-visible reflectance spectroscopy[28] have been used for in situ studies of the redox behavior of adsorbed methyl viologen molecules on silver and platinum electrodes. However, the conformation of both the adsorbed MV^{2+} and $MV^{+\cdot}$ molecules at the electrode surface has not yet been discussed in detail.

Wopshall and Shain[29] showed in the simulation of cyclic voltammograms that a sharp adsorption wave appears when the adsorption coefficient varies with the electrode potential. In many redox systems, similar sharp adsorption waves have been reported.[30-35] In classical d.c. polarograms of Methylene Blue, the half-wave potential ($E_{1/2}$) of the single adsorption wave depends upon its concentration, while the $E_{1/2}$ of the prewave has a constant value when a double wave is observed.[36] Laviron[37] has shown that the dependence of $E_{1/2}$ on the concentration of the reactant is due to the interaction between the adsorbed redox molecules, provided that the adsorption coefficient is large enough. Flanagan et al.[38,39] discussed the effects of reactant and product adsorption in the digital simulation of pulse polarograms.

In the present work, we have found several unusual adsorption phenomena of methyl viologen using the normal pulse (NPP), differential pulse (DPP), and a.c. polarographic techniques. That is, in NPP, 1) a single wave is observed at concentrations lower than 0.5 mM, and a sharp prewave appears at concentrations higher than 0.5 mM for the forward scan. However, a sharp postwave appears over the whole concentration range investigated for the reverse scan. 2) The half-wave potential of the single wave ($E_{1/2,s}$) is about 0.2 V more positive than the $(E^{0'})_{MV}$ and depends upon both the sampling time (t_s) and the initial potential (E_{in}) of NPP. 3) The cathodic prewave on the forward scan always appears at a more negative potential than the anodic postwave on the reverse scan. At concentrations lower than 0.5 mM, the $E_{1/2,s}$ on the forward scan is much more positive than the peak potential (E_p) of the postwave on the reverse scan. 4) On the forward scan, the $E_{1/2,s}$ in the lower concentration range of (0.01—0.5) mM shifts toward negative potentials with the increase in the MV^{2+} concentration in contrast to the positive shift of the E_p of the prewave in the higher concentration range (>0.5 mM). On the reverse scan, the E_p of the postwave always shifts toward positive potentials with an increase in the MV^{2+} concentration.

The surface concentrations of adsorbed MV^{2+} and $MV^{+\cdot}$ molecules, as determined by the present potential-step chroncoulometry, indicate that the orientation of MV^{2+} molecules adsorbed on a mercury electrode is different from that of $MV^{+\cdot}$ molecules.

The peculiar adsorption behavior of methyl viologen can be explained by considering an orientation change in the adsorbed redox species.

Experimental

Materials. The 1,1′-dimethyl-4,4′-bipyridinium dichloride (BDH Chemical, Ltd) and 4,4′-bipyridyl (Tokyo Kasei Kogyo Co.) were of a reagent grade and were used without further purification. The phosphate buffer solution (pH 7.0) was 0.1 M (M=mol dm^{-3}) and was prepared from chemicals of the pH standard grade from Wako Pure Chemical Industries, Ltd. All the solutions were prepared from triply

distilled water.

Apparatus and Procedures. The d.c. polarographic measurements (classical d.c., tast, normal pulse, and differential pulse polarographies) were carried out with a Fuso Polarograph (Fuso and Co., Model 312) and the cyclic voltammetric measurements with a Fuso Potentiostat (Model 311) and a Fuso Potential Scanning Unit (Model 321). The a.c. polarographic measurements were carried out with a Fuso Potentiostat (Model 311), a Fuso Phase-sensitive Detector (Model 332), and a RC Oscillator (Matsushita Communication Industrial Co., Ltd, Model VP 722A). The potential-step chronocoulometric measurements were carried out with a Transient Converter (Riken Denshi Co., Ltd, Model TCA 1000) and a Fuso Potentiostat (Model 311 S2). The concentration of MV in the stock solution was determined spectrophotometrically (molar absorption coefficient at 605 nm, ε_{605}=12400 $M^{-1}cm^{-1}$)[5] with a UV-visible Recording Spectrophotometer (Shimadzu Corporation, Model UV2).

A two-compartment water-jacketed electrochemical cell was used; the compartments were separated by porous Vycor glass so that the contamination of oxygen could be minimized. The working electrode used was a dropping mercury electrode (DME), and the flow rate of mercury was 1.335 mg s^{-1} at an open circuit in a 0.1 M phosphate buffer solution (pH 7.0). The working electrode in the cyclic voltammetry was a Metrohm hanging mercury drop electrode (25.6×10^{-3} cm^2). The counter electrode was a mercury pool in the working electrode compartment. The reference electrode was a saturated calomel electrode which was separated from the working electrode compartment by porous Vycor glass. The reference electrode was coupled with a platinum wire (0.3 mm diameter) electrode in the working electrode compartment through a 0.1 μF capacitor in order to improve the response at higher frequencies in the a.c. polarographic measurements. The solution was deaerated by bubbling purified argon through the solution. All the experiments were carried out at (25±0.5) °C.

Results

Cyclic Voltammetry. Figure 1 shows some cyclic voltammograms of 1 mM MV^{2+} in 0.1 M of a phosphate buffer solution at pH 7.0. The i_p of the main wave was linear with respect to $v^{1/2}$, and the plot passed through the point of the origin, where i_p was the peak current and v the rate of the potential scan. The ratio of cathodic to anodic peak currents was almost unity. The peak-to-peak separation was about 60 mV, and the midpoint potential was −0.68 V. That is, the electrode reaction of MV in the bulk is a diffusion-controlled reversible electrode process. The prepeak shifted toward positive potentials with an increase in the concentration of MV^{2+}. The anodic postpeaks were sharper and higher than the cathodic prepeaks.

Classical d.c. Polarography. A small prewave was followed by the main wave. The $E_{1/2}$ of the main wave was −0.68 V in the concentration range of (0.4—5) mM MV^{2+}. The prewave observed at −0.62 V in 5 mM of a MV^{2+} solution shifted toward negative potentials with the decrease in the MV^{2+} concentration and merged into the main wave at concentrations below 0.25 mM.

Differential Pulse Polarography. Figure 2 shows

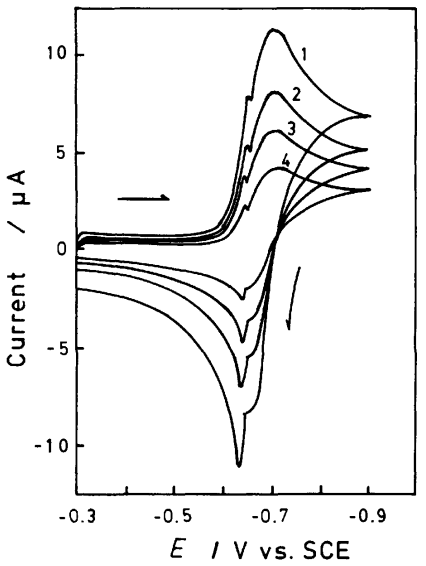

Fig. 1. Cyclic voltammograms of 1 mM MV^{2+} in a 0.1 M phosphate buffer solution (pH 7.0). Scan rates are (1): 200 mV s^{-1}, (2): 100 mV s^{-1}, (3): 50 mV s^{-1}, and (4): 20 mV s^{-1}.

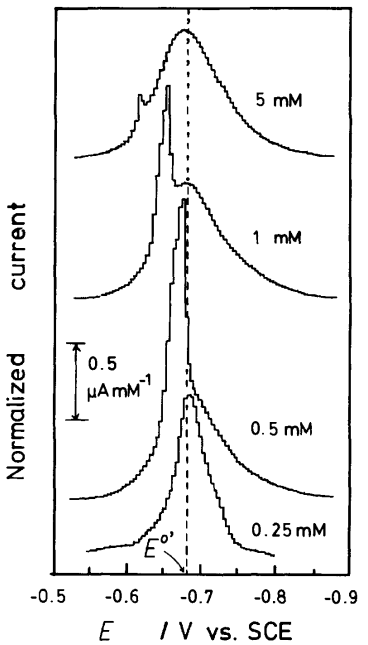

Fig. 2. Concentration dependence of differential pulse polarograms of methyl viologen in a 0.1 M phosphate buffer solution (pH 7.0). The concentrations are given on polarograms. The scan rate is 2 mV s^{-1}, the drop time 2 s, the sampling time 30 ms, and the modulation amplitude 10 mV.

the concentration dependence of the differential pulse polarograms of MV. At 0.1 mM, a single asymmetric peak was observed at −0.7 V, and the width of the peak at half height ($W_{1/2}$) was about 60 mV. At 0.25 mM, a single asymmetric peak was at −0.68 V, and $W_{1/2}$ was about 50 mV. At concentrations higher than 0.5 mM, a very sharp prepeak ($W_{1/2}$<20 mV) was separated from the main wave ($W_{1/2}$=90 mV, E_p=−0.68 V), and the

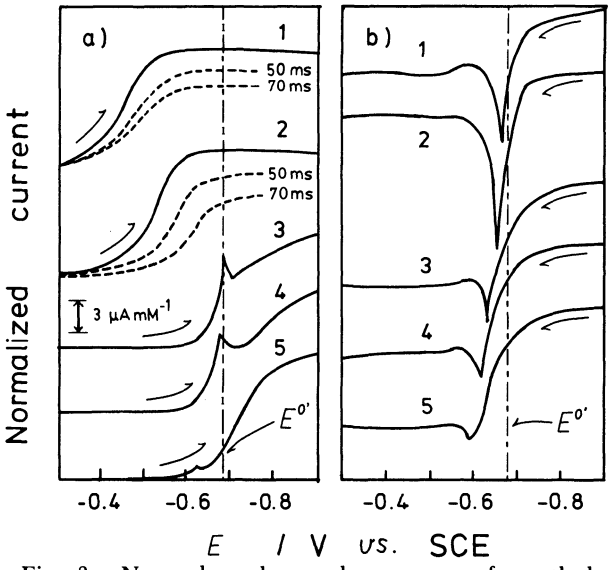

Fig. 3. Normal pulse polarograms of methyl viologen in a 0.1 M phosphate buffer solution (pH 7.0). a) On the forward scan with E_{in}=−0.3 V, and b) on the reverse scan with E_{in}=−0.9 V. The concentrations are (1): 0.1 mM, (2): 0.25 mM, (3): 0.75 mM, (4): 1 mM, and (5): 5 mM. (-----): Measured at the sampling times of 50 ms and 70 ms. t_d=2 s and t_s=30 ms.

potentials of the prepeak shifted toward positive potentials with an increase in the concentration of MV^{2+}. In the concentration range of (0.1—5) mM, the E_p of the prepeak on DPP was almost independent of the drop time (t_d) and the sampling time.

Normal Pulse Polarography. The adsorption waves of normal pulse polarograms varied with the concentration, the initial potential, the sampling time, and the direction of the potential scan. Figure 3 shows the concentration dependence of the NPP of MV.

Forward Scan: Above 0.5 mM, a sharp prewave appeared with the main wave, and the peak potential of the prewave shifted toward positive potentials with the increase in the MV^{2+} concentration. Below 0.5 mM, the prewave disappeared and a single wave was observed. The limiting current of the main wave or the single wave was proportional to $h^{1/2}$ and $t_s^{-1/2}$ throughout the concentration range of (0.01—5) mM, where h is the height of the mercury column. Below 0.25 mM, $E_{1/2,s}$ shifted by about 0.2 V toward the positive potential from $(E^{0'})_{MV}$, while at concentrations higher than 0.4 mM, the $E_{1/2,s}$ and the E_p of the prewave were not far from $(E^{0'})_{MV}$. The dependence of $E_{1/2,s}$ on E_{in} was observed only in the concentration range of (0.1—0.3) mM, in the range of E_{in} at −(0.3—0.5) V, and with a short t_s (Table 1). The drop time did not affect $E_{1/2,s}$ (Table 1).

Reverse Scan: A sharp postwave appeared throughout the measured concentration range, and the peak potential of the postwave shifted toward positive potentials with an increase in the concentration of MV^{2+}. The peak potential of the postwave on the reverse scan was always more positive than that of the

prewave on the forward scan, and the potential difference between these peaks increased with the decrease in the MV^{2+} concentration. The peak potential of the postwave was independent of t_s and t_d.

a.c. Polarography. Figure 4 shows the differential capacity (C_s) of the mercury electrode in various concentrations of MV^{2+}. Figure 5 shows the variation in C_s with respect to the a.c. frequency. The height of the C_s peak in the vicinity of $(E^{0'})_{MV}$ increased rapidly with the increase in the MV^{2+} concentration and with the decrease in the a.c. frequency. This C_s-peak potential shifted toward positive potentials with an increase in the concentration of MV^{2+}. A broad and symmetric C_s peak ($W_{1/2}$=about 120 mV) was observed at −0.49 V throughout the measured concentration range of (0.01—5) mM. The height of the C_s peak at −0.49 V

a) Concentrations of methyl viologen in 0.1 M of a phosphate buffer solution (pH 7.0). b) $\Gamma_{MV^{2+}}$ and $\Gamma_{MV^{+\cdot}}$ are the amounts of the adsorbed MV^{2+} and $MV^{+\cdot}$ molecules which were determined by means of potential-step chronocoulometry from −0.3 V to −0.8 V and from −0.8 V to −0.3 V, respectively.

varied slightly with the a.c. frequency and approached a saturation value at concentrations higher than 5 mM. The peak potential at −0.49 V was almost independent of both the concentration of MV^{2+} and the a.c. frequency. The increase in the MV^{2+} concentration led to the depression of C_s in the potential range of −(0.7—0.8) V, and C_s reached a minimum value of 8 μF cm^{-2} in the concentration range of (0.2—1) mM.

The resistive component of the alternating current (R_s) also depended markedly on the concentration of MV^{2+} and the a.c. frequency in the vicinity of $(E^{0'})_{MV}$. At −0.49 V, R_s was almost independent of the concentration of MV^{2+} and the a.c. frequency, and R_s was almost equal to R_{sol}, where R_{sol} was the solution resistance. At −0.65 V in 1 mM of the MV^{2+} solution, the phase angle of the faradaic impedance plot obtained by using the Randles-Ershler equivalent circuit exceeded 45°.

Potential-Step Chronocoulometry. The amounts of MV^{2+} and $MV^{+\cdot}$ adsorbed on the mercury electrode at −0.3 and −0.8 V were evaluated by means of potential-step chronocoulometry.[40]

The amounts of the adsorbed redox species were calculated by the use of

$$(Q_{total})_{t=0} = n_e FS\Gamma + Q_{dl}, \quad (1)$$

where $(Q_{total})_{t=0}$ was the intercept of Q_{total} vs. the $t^{1/2}$ plot; Q_{total}, the total electric charge from time $t=0$ to t; n_e, the number of electrons involved in the redox reaction; S, the area of the electrode; Γ, the surface concentration of adsorbed redox species, and Q_{dl}, the capacitive charge of the double layer. The interfacial capacitance of the electrode covered by methyl viologen, Q_{dl}, was assumed to be equal to that covered by 4,4′-bipyridyl, which is electrochemically stable in the stepped potential range ($E_{1/2}$=−1.06 V)[41] and which has a structure analogous to that of methyl viologen. Table 2 shows the amounts of MV^{2+} and $MV^{+\cdot}$ molecules adsorbed on the mercury electrode, as calculated from Eq. 1.

Discussion

Formal Potential and Diffusion Coefficient of Methyl Viologen. The formal potentials of the $MV^{2+/+\cdot}$ couple in 0.1 M of a phosphate buffer solution at pH 7.0, as obtained by cyclic voltammetry, classical d.c. polarography, and differential pulse polarography, were −(0.680±0.005) V, −(0.682±0.002) V, and −(0.683±0.007) V, respectively. These values were in agreement with the formal potentials of methyl viologen reported in the literatures.[4,5]

Both the diffusion coefficients of MV^{2+} and $MV^{+\cdot}$ which were calculated by the Cottrell equation from NPP, were 4.4×10^{-6} cm^2 s^{-1}.

Adsorption of MV^{2+} Molecules. In the analysis of C_s vs. E curves of methyl viologen obtained by a.c. polarography, Pospisil et al.[3,25] and Grachev et al.[8] have reported that the C_s peak at about −0.49 V is attributable to an adsorption-desorption process of MV^{2+}, for this peak is greatly stretched out along the potential axis, the peak potential is much more positive than $(E^{0'})_{MV}$, and no faradaic wave is observed at about −0.49 V in classical d.c. polarograms. As is shown in Table 2, however, the amount of MV^{2+} molecules adsorbed at −0.3 V is about 1×10^{-10} mol cm^{-2} in 1 mM of a MV^{2+} solution. That is, MV^{2+} has already been adsorbed on a mercury electrode at the foot of the positive side of this C_s peak. The height of the C_s peak is practically independent of the a.c. frequency, and R_s in the vicinity of −0.49 V is equal to R_{sol}. Since the faradaic impedance of a reversible surface redox reaction of the adsorbed species is inde-

pendent of the a.c. frequency,[35,42-44] it is probable that the C_s peak at −0.49 V is attributable to the reversible redox reaction of the adsorbed species and that a repulsive interaction between the adsorbed redox species gives rise to a broad peak.[45,46] In the present NPP study, on the forward scan below 0.25 mM, we have found a diffusion-controlled faradaic wave with a half-wave potential close to −0.49 V, the value at which the broad C_s peak was observed in a.c. polarograms. These results strongly suggest that the C_s peak at −0.49 V is not an adsorption-desorption peak, but the faradaic pseudo-capacitive peak due to the adsorbed MV^{2+} and the adsorbed $MV^{+\cdot}$.

It is probable that the adsorption of MV^{2+} on a positively charged mercury electrode is due to the π-electron interaction between adsorbed molecules and a mercury electrode, which has been reported by Frumkin and Damaskin,[47] and others.[48-56] Moreover, it has been reported that aromatic cations can also be adsorbed on electrodes at more positive potentials than the potential of zero charge of the mercury electrode by means of the π-electron interaction.[8,32,36,57,58]

C_s Peak in the Vicinity of $(E^{0'})_{MV}$. Grachev et al.[8] surmised that, in a.c. polarograms of MV, the C_s peak in the vicinity of $(E^{0'})_{MV}$ was observed only in the narrow concentration range of (0.1—0.2) mM because the first reduction step of MV^{2+} becomes irreversible because of the inhibition by both the adsorbed MV^{2+} molecules in the MV^{2+} concentrations lower than 0.1 mM and the adsorbed $MV^{+\cdot}$ molecules in the MV^{2+} concentrations higher than 0.2 mM. However, both the present and previous studies[2-5,11] have proved that the first reduction step of MV^{2+} is not irreversible, even at the concentrations higher than 0.2 mM. As is shown in Fig. 6, the C_s peak potential in the vicinity of $(E^{0'})_{MV}$ in a.c. polarograms is almost identical with the potential of the prewave in classical d.c. and differential pulse polarograms. It is clear in Fig. 4 that the C_s peak in the vicinity of $(E^{0'})_{MV}$ did not disappear, but shifted toward positive potentials with an increase in the concentration of MV^{2+}.

Orientation of MV^{2+} and $MV^{+\cdot}$. Pospisil et al.[3,25] reported that the marked depression of C_s over −(0.7—0.8) V is caused by a complete coverage of the mercury electrode by $MV^{+\cdot}$ and that the C_s peak at −0.9 V is due to the reorientation of the adsorbed $MV^{+\cdot}$ from flat to vertical.

As is shown in Table 2, the maximum surface concentration of adsorbed $MV^{+\cdot}$ molecules, as determined by potential-step chronocoulometry at −0.8 V, was $(4.0\pm0.1)\times10^{-10}$ mol cm^{-2}. Figure 7 shows the structure of methyl viologen. The area occupied by one molecule adsorbed on an electrode (S_{ad}) can be estimated from the van der Waals radii. If methyl viologen is oriented vertically on the electrode, and if the methyl group of MV can rotate freely around the C-N sigma-bond axis,[59] S_{ad} is estimated to be 34 Å^2 per molecule. If hexagonal array is considered in addition

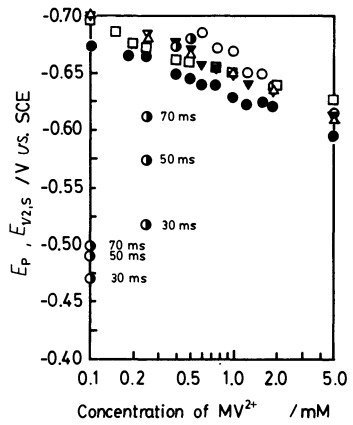

Fig. 6 Concentration dependence of E_p and $E_{1/2,s}$ of methyl viologen. The values of E_p are plotted as (○) for NPP on the forward scan, (●) for NPP on the reverse scan, (□) for a.c. polarograms, (△) for DPP, and (▼) for classical d.c. polarograms. The values of $E_{1/2,s}$ are plotted as (◑) for NPP on the forward scan and (▽) for classical d.c. polarograms. The conditions of measurements are given in Fig. 2—4.

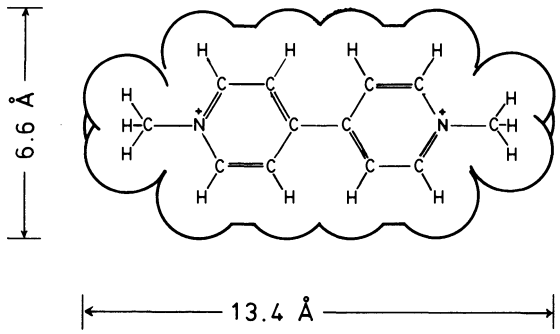

Fig. 7. Structure of methyl viologen.

to a vertical orientation, S_{ad} becomes 38 Å^2 per molecule, which corresponds to 4.4×10^{-10} mol cm^{-2} for the maximum surface concentration (Γ_m). If methyl viologen is oriented flat on an electrode, S_{ad} becomes 88 Å^2 per molecule, which corresponds to 1.9×10^{-10} mol cm^{-2} for Γ_m. If the twisting by 37.2° between two pyridyl rings is considered in addition to a flat orientation, S_{ad} becomes 84 Å^2 per molecule, which corresponds to 2.0×10^{-10} mol cm^{-2} for Γ_m. The good agreement between the measured and the calculated maximum surface concentrations suggests that adsorbed $MV^{+\cdot}$ molecules are oriented vertically, at least in the potential region of −(0.7—0.8) V (cf. Fig. 4). On the other hand, the maximum surface concentration of MV^{2+} has not yet been attained at −0.3 V, as is shown in Table 2 (probably because of a repulsive interaction between adsorbed MV^{2+} molecules) and the orientation of the MV^{2+} molecules adsorbed at a positively charged electrode by means of π-electron interaction is considered to be flat rather than vertical.[43,44,47-58]

Orientation Change of Adsorbed $MV^{+\cdot}$ Molecules. The findings that the C_s peak with the symmetric

shape[37,46] at −0.49 V is independent of the a.c. frequency and that the resistive component at −0.49 V is equal to the solution resistance[44] suggest a surface redox reaction between the adsorbed MV^{2+} molecules and the adsorbed $MV^{+\cdot}$ molecules without the reorientation of the adsorbed species in the vicinity of −0.49 V. If $MV^{+\cdot}$ molecules with a flat orientation are adsorbed on the mercury electrode much more strongly than MV^{2+} molecules (that is, if the ratio of the adsorption coefficient of $MV^{+\cdot}$ to that of MV^{2+} is higher than 10^3), it would be expected that a faradaic prewave would appear at a potential about 0.2 V more positive than $(E^{0'})_{MV}$.

The potential step from the initial potential at which only MV^{2+} molecules have been adsorbed to about −0.49 V gives rise to the formation of adsorbed $MV^{+\cdot}$ at the electrode. A faradaic current and consequently, the $E_{1/2,s}$ are determined by the interfacial concentration gradient and by the surface concentration change of the redox species at the time when the current is sampled.[39] That is, the $E_{1/2,s}$ depends on the t_s, the bulk concentration, and the adsorption states of the redox species at E_{in}. In NPP with a short sampling time at lower concentrations of MV^{2+}, an adsorption wave which is diffusion-controlled can be observed. In NPP at higher concentrations of MV^{2+} and with a long sampling time, and in the differential pulse and the tast polarographic techniques where the electrode potential is kept practically at the sampling potential during the drop time, the amount of the adsorbed $MV^{+\cdot}$ at −0.49 V approaches the value at the adsorption equilibrium or the saturation value. Consequently, the interfacial concentration would be rehomogenized[35] and the adsorption current would decay and would be apt to be overlooked when the current is sampled. On the other hand, in a.c. polarography, a faradaic pseudo-capacitive peak due to the adsorbed MV^{2+} and the adsorbed $MV^{+\cdot}$ molecules can be observed, and also, in cyclic voltammetry, an adsorption peak can be observed provided that the eletrode potential where the $MV^{+\cdot}$ molecules are not adsorbed is chosen for the initial potential.

At concentrations higher than 0.5 mM, as the electrode potential approaches $(E^{0'})_{MV}$, the surface concentration of the adsorbed $MV^{+\cdot}$ molecules increases so abruptly that a reorientation of adsorbed $MV^{+\cdot}$ molecules from flat to vertical takes place.[53,54] The vertical orientation makes possible an attractive interaction between adsorbed $MV^{+\cdot}$ molecules, which causes the further adsorption of $MV^{+\cdot}$ and leads to a sharp adsorption peak. The increase in the bulk concentration of MV^{2+} gives rise to the increase in the interfacial concentration of $MV^{+\cdot}$ after the reduction by a potential step, and the surface concentration of the adsorbed $MV^{+\cdot}$ molecules will be sufficient to change the orientation from flat to vertical at a more positive potential than the potential where the reorientation takes place at lower concentrations of MV^{2+}. It is probable that the positive shift of the peak potential with an increase in the MV^{2+} concentration shown in Fig. 6 is to be attributed to the concentration dependence of the potential at which the reorientation of adsorbed $MV^{+\cdot}$ molecules occurs.

Parry and Parsons[50] have reported that the orientation of *p*-toluenesulfonate adsorbed on a mercury electrode changes from flat at lower concentrations to vertical at higher concentrations, and that the flat orientation accelerates a repulsive interaction between adsorbed *p*-toluenesulfonate molecules, and the vertical orientation, an attractive interaction. Similar discussions of the relation between an orientation and the interaction constants of redox species have been reported by Ershler et al.[60] and others.[48,49,55,56,61,62] Laviron[32] has reported that, in cyclic voltammetry, *trans*-1,2-di(4-pyridyl)ethylene adsorbed on a mercury electrode displays a similar orientation change with the concentration and that the vertical orientation of the redox molecules at the electrode surface causes an attraction force between them which leads to a sharp adsorption peak.

The abrupt change in the orientation of the adsorbed $MV^{+\cdot}$ molecules at the electrode surface leads to the strong frequency dependence of the sharp C_s peak in the vicinity of $(E^{0'})_{MV}$ (Fig. 5). In Fig. 5, the main C_s peak is not observed because of the mergence with the larger adsorption C_s peak. At 6.4 Hz, the appearance of a shoulder corresponding to the main faradaic C_s peak on the negative potential side of a larger C_s peak has been reported.[3] At concentrations lower than 50 μM, no C_s peak appears in the vicinity of $(E^{0'})_{MV}$ because the interfacial concentration of the redox species is negligible compared to the surface concentration of these species because of the depletion of the interfacial concentration as a result of the strong adsorption of the redox species.

In the reverse scan of NPP, the surface concentration of $MV^{+\cdot}$ molecules pre-adsorbed at the initial potential is so high that the adsorbed $MV^{+\cdot}$ molecules are already oriented vertically, even at 0.1 mM (cf. Table 2). The potential step from the initial potential, where the adsorbed $MV^{+\cdot}$ molecules are oriented vertically, to the anodic potential always leads to an orientation change from vertically adsorbed $MV^{+\cdot}$ molecules to flat adsorbed MV^{2+} molecules. This orientation change leads to the situation in which a sharp postpeak always appears over the measured concentration range and the postpeak potential always shifts toward positive potentials with an increase in the concentration.

In the forward scan of NPP, the direction of the shift of the $E_{1/2,s}$ with the concentration in the lower concentration range (<0.5 mM) is opposite to the shift of the prepeak potential with the concentration in the higher concentration range (>0.5 mM). This is probably caused by the change in the orientation of the adsorbed $MV^{+\cdot}$ at the electrode surface and the change in the interaction between adsorbed $MV^{+\cdot}$ molecules. The

potential difference between the prepeak for the forward scan and the postpeak for the reverse scan which is observed at concentrations higher than 0.5 mM probably originates from both the sigmoid-type adsorption isotherm with the strongly attractive interaction between the adsorbed $MV^{+\cdot}$ molecules and the difference between the S_{ad} values of MV^{2+} and $MV^{+\cdot}$ molecules, as has been discussed by Laviron.[37] The peculiar adsorption behavior of methyl viologen is simulated by the digital simulation of the normal pulse polarograms based on the Frumkin-type Flory-Huggins isotherm, which will be published in a subsequent paper.

The present work was supported by a Grant-in-Aid for Scientific Research No. 5670031 from the Ministry of Education, Science and Culture.

Pressure and Temperature Effects on the Excess Conductance of the Hydroxide Ion in Water

Masakatsu UENO,* Yasushi SAKATA, Noriaki TSUCHIHASHI, and Kiyoshi SHIMIZU
Department of Applied Chemistry, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602
(Received March 27, 1986)

The limiting molar conductances, Λ°, of sodium hydroxide were determined at 15, 25, and 40 °C as a function of the pressure up to 1500 kgf cm^{-2} (1 kgf cm^{-2}=0.9807×10^5 Pa) from the conductances measured in a dilute concentration range (1×10^{-3}—2×10^{-2} M, 1 M=1 mol dm^{-3}). The excess conductances at an infinite dilution, λ°_E, of the hydroxide ion, as estimated by [$\lambda^\circ_E(OH^-)=\Lambda^\circ(NaOH)-\Lambda^\circ(NaCl)$], were found to increase with an increase in the pressure and temperature, as well as those of the oxonium ion, $\lambda^\circ_E(H_3O^+)$. However, there was a significant difference in the magnitude of λ°_E, itself, and a slight difference in the magnitude of the pressure and temperature dependences of λ°_E between hydroxide and oxonium ions. These results may be related to a difference between the proton-jump mechanisms of the hydroxide and oxonium ions.

In our previous papers,[1,2] the oxonium ion was used as a probe to study the variation of the solvent structure in hydrogen-bonded solvents with the pressure, temperature, and ethanol content, since protons are transferred through the hydrogen-bonded networks in addition to the hydrodynamic migration, resulting in a high mobility of the oxonium ion. The high mobility of the hydroxide ion in aqueous solutions can also be attributed to a proton-jump mechanism. There is, however, a significant difference between the proton-jump mechanisms of hydroxide and oxonium ions. According to the theory of Conway et al.,[3] the rate-determining step in the proton-jump mechanism is a rotation of hydrogen-bonded water molecules as dipoles near the ions, necessary to make possible the next proton jump. In the case of the oxonium ion, the driving force for the rotation is a repulsion between the two OH groups facing each other as a result of the proton jump in addition to an ion-dipole interaction. The force causing the rotation arises principally from an ion-dipole interaction in the case of the hydroxide ion. This difference between the ions may be reflected by the variation in their excess conductances due to a proton jump with the pressure and temperature. So far, only a few papers[4-6] have been published on the conductances of alkaline solutions at high pressures and at moderate temperatures. Here, the pressure and temperature effects on the excess conductances of the hydroxide ion are reported, and are compared with those of the oxonium ion.

Experimental

Chemicals, Solutions, and Properties of Water. Conductivity water was prepared by passing distilled water through a mono-bed ion-exchange resin; it was stored in a stainless-steel tank under a nitrogen atmosphere. Its conductivity, κ_S, was about 4.3×10^{-7} S cm^{-1} at 25 °C and at 1 atm as is shown in Table 1. Table 1 also summarizes such properties of water used in the data analysis as the density, ρ,[7,8] the static dielectric constant, ε,[10,11] and the viscosity, η.[13,14]

The aqueous solutions of sodium hydroxide were prepared by the same method as Darken and Meier.[15] All the dilute solutions of NaOH were prepared gravimetrically by diluting a stock solution (about 2×10^{-2} M) made from a saturated solution at 0 °C. The saturated solution was prepared from the analytical-grade sodium hydroxide supplied by Merck. The concentration of the stock solution was determined by titration with oxalic acid solutions, using a phenolphthalein indicator. The titrations were performed with a micro burette; the reproducibility was about one part in one thousand. The concentrations of the dilute NaOH solutions at 25 °C and at 1 atm were determined by using the densities, ρ(NaOH), of the stock solution and dilute solutions, which were measured at 25 °C and at 1 atm by means of a digital vibrating densimeter (SS-D-200 twin-type) manufactured by the Shibayama Scientific Co., Ltd. The following equation was obtained:

$$\rho(\mathrm{NaOH}) = 0.9970_6 + 0.046_0 c, \quad (1)$$

where ρ(NaOH) is in g cm^{-3} and c is the concentration of the solution in M. The above equation is in very good agreement with the one described in Ref. 15. The concentrations of the solutions at other pressures and temperatures were calculated by assuming that the ratios of densities between

a) Concentrations (10^{-3} M) at atmospheric pressure.

the solutions under various conditions were equal to those of pure water under the corresponding conditions. All the solutions were treated in a dry box under a nitrogen atmosphere.

Apparatus. Two kinds of conductivity cells with lightly platinized electrodes were employed: a glass cell (capacity, 10 cm^3)[16] at 15 and 25 °C, and a Teflon cell (capacity, 12 cm^3)[2] at 40 °C. The resistances of NaOH aqueous solutions in the glass cell did not change at 15 and 25 °C for at least 5 h required for one run. The resistances, however, increased with time at 40 °C because of a reaction involving hydroxide ions with glass. Thus, the Teflon cell was used, though it has several disadvantages compared with a glass cell: the walls are very tenacious retainers of gas-bubbles and the cell constant varies greatly with the pressure. The cell constants at 1 atm and at each temperature were determined from the conductances of a 0.01 M KCl aqueous solution.[17-20] They were assumed to be invariant with the pressure for the glass cell; for the Teflon cell, the correction factors, $f^{(P)}=K_{cell}^{(P)}/K_{cell}^{(1)}$, in which $K_{cell}^{(P)}$ and $K_{cell}^{(1)}$ are the cell constant at pressure P and 1 atm respectively, were determined by comparing the conductances of 5×10^{-3} and 1×10^{-2} M KCl aqueous solutions obtained by the glass cell with those by the Teflon cell, as have been described in a previous paper.[2] The values of $f^{(P)}$, thus determined, are also listed in Table 1.

The procedure and the apparatus used here for conductance measurements at high pressures were the same as those described in a previous paper.[16]

Results and Discussion

Table 2 shows the molar conductances, Λ, of NaOH at various concentrations at 15, 25, and 40 °C as a function of the pressure. The molar conductances, Λ, were reproducible within ±0.15%. The Fuoss-Onsager equation of conductance for unassociated electrolytes:[21,22]

$$\Lambda = \Lambda° - Sc^{1/2} + Ec\log c + Jc, \quad (2)$$

where c is the concentration (M), and S, E, and J have the usual meanings, was employed to determine the limiting molar conductance, $\Lambda°$, at each pressure and temperature. The limiting molar conductances, $\Lambda°$, thus obtained, are listed in Table 2, together with their related quantities: the ion-size parameter, $\mathring{a}$, and the standard deviation of Λ, σ_Λ. The present values of $\Lambda°$(NaOH)/S cm^2 mol^{-1} at 1 atm (207.4 at 15 °C, 250.4 at 25 °C, and 318.6 at 40 °C) are larger by about (0.3—0.8)% than the literature ones (205.65[23] at 15 °C, 249.33[23] and 248.85[15] at 25 °C, and 317.66[23] at 40 °C). However, no high-pressure data are available for a comparison. As is shown in Table 2, $\Lambda°$(NaOH) increases monotonously with an increase in the pressure up to 1500 kgf cm^{-2} at 15 °C; it then appears to have a maximum at about 1500 kgf cm^{-2} at 25 °C, but slightly decreases with pressure at 40 °C.

The limiting ionic molar conductances, $\lambda°$, of the hydroxide ion under various conditions were determined by Kohlrausch's law regarding the independent migration of ions, using the values of $\Lambda°$(NaOH), $\Lambda°$(NaCl),[24-26] $\Lambda°$(KCl),[27,28] and the limiting cation-transference number for KCl, $t°(K^+)$;[16,29-31] those of the oxonium ion, $\lambda°(H_3O^+)$, were also obtained from the data on $\Lambda°$(HCl).[2,33] The values of the $\lambda°$'s of hydroxide and other ions, thus obtained, are listed in Table 3. Table 3 shows that the values of $\lambda°(OH^-)$ are about 2.5-times larger than those of $\lambda°(Cl^-)$ at each pressure and temperature, and that compared with the $\lambda°$'s of other ions, $\lambda°(OH^-)$ increases with an increase in the pressure as well as $\lambda°(H_3O^+)$, irrespective of the pressure dependence of the solvent viscosity, although the rate of the increase in $\lambda°(OH^-)$ with the pressure

1500	65.2	92.9	100.2	252.2	440.9	152.0	348.0

is much smaller than that in $\lambda^\circ(H_3O^+)$. It is apparent that these features are closely related to the proton-jump mechanism of hydroxide and oxonium ions.

The excess conductance due to the proton-jump mechanism, λ°_E, was estimated according to:

$$\lambda^\circ_E(OH^-) = \lambda^\circ(OH^-) - \lambda^\circ(Cl^-) = \Lambda^\circ(NaOH) - \Lambda^\circ(NaCl), \quad (3)$$

where the translational mobility of the OH^- ion was approximated by that of the Cl^- ion since their sizes are similar. There is only one literature data compared with the present values. The present values of $\lambda^\circ_E(OH^-)$ at 25 °C shown in Table 3 are a little larger than those obtained by Hamann and Strauss[4] from the equation: $[\lambda^\circ_E(OH^-)=\Lambda^\circ(KOH)-\Lambda^\circ(KCl)]$; their values are 123, 124, and 125 S cm^2 mol^{-1} at 1, 1000, and 2000 atm, respectively. As is shown in Table 3, $\lambda^\circ_E(OH^-)$ increases with the pressure and temperature as well as $\lambda^\circ_E(H_3O^+)$, as estimated by $[\lambda^\circ_E(H_3O^+)=\lambda^\circ(H_3O^+)-\lambda^\circ(K^+)]$, and the rate of the increase in the relative excess conductance, $\lambda^\circ_{E(P)}/\lambda^\circ_{E(1)}$, with the pressure becomes larger with a decrease in the temperature as is shown in Fig. 1. These results qualitatively correspond to the pressure and temperature dependences of the reorientational relaxation time of water molecules studied by the NMR method,[34] and those of the dielectric relaxation time.[35] That is, the rotation of water molecules is accelerated by an increase in the pressure and/or temperature; at lower temperatures it is more accelerated by the pressure. Molecular dynamics simulations[36,37] have suggested that the hydrogen bonds between water molecules become more distorted in compressed water. The things mentioned above confirm the proton-jump mechanism of Conway et al.[3] which proposes that the rate-determining step in the proton-jump mechanism is the rotation of hydrogen-bonded water molecules near the hydroxide or the oxonium ion.

From Table 3, the contribution of the proton-jump mechanism to the conductance of hydroxide and oxonium ions, $\lambda^\circ_E/\lambda^\circ$, can be calculated; the average values of $\lambda^\circ_E/\lambda^\circ$ are about 0.63 at 15 °C, 0.62 at 25 °C, and 0.60 at 40 °C for the hydroxide ion, and 0.81 at 15 °C, 0.80 at 25 °C, and 0.78 at 40 °C for the oxonium ion. The difference in $\lambda^\circ_E/\lambda^\circ$ between the ions is about 0.18 at each pressure and temperature. Table 3 also shows that the values of $\lambda^\circ_E(OH^-)$ are about (0.40—0.47)-times those of $\lambda^\circ_E(H_3O^+)$. These results would suggest that there is a significant difference between the proton-jump mechanisms of hydroxide and oxonium ions. The driving force for rotation is a repulsion between the two OH groups facing each other as a result of the proton jump in addition to an ion-dipole interaction in the case of the oxonium ion. In the case of the hydroxide ion, the driving force arises principally from an ion-dipole interaction owing to a proton deficience of the OH^- ion. Conway et al.[3] have shown from their model that the average hydroxide ion-dipole force is approximately 1/4-times the total force causing the rotation in the oxonium ion case, and that since the time of the rotation is inversely proportional to the square root of the driving force, the excess conductance of the hydroxide ion is about 1/2-times that of the oxonium ion; this can be seen in Table 3.

When the pressure and temperature dependences of λ°_E were examined in greater detail, it was found that there is a slight difference between the hydroxide and oxonium ions regarding the rate of the increase in the relative excess conductance with the pressure and temperature (Figs. 1 and 2). The pressure dependence of the relative excess conductance of the hydroxide ion was smaller than that of the oxonium ion, while the reverse tendency was found regarding the temperature

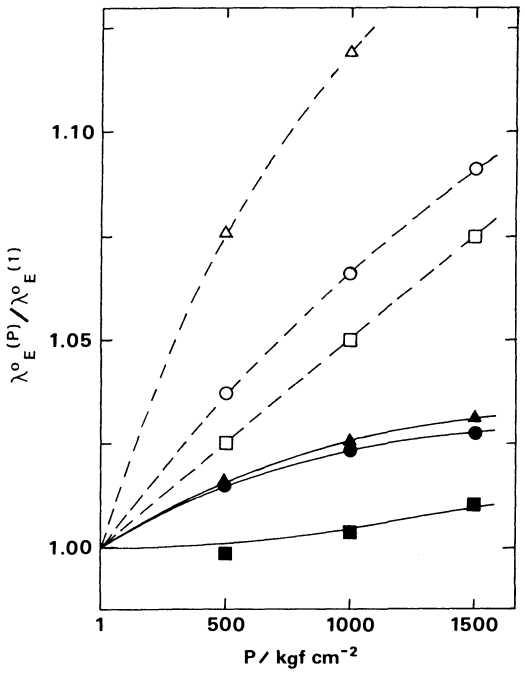

Fig. 1. Pressure dependence of the relative excess conductances of the OH^- and H_3O^+ ions at various temperatures.
▲: 15 °C, ●: 25 °C, ■: 40 °C for the OH^- ion;
△: 15 °C, ○: 25 °C, □: 40 °C for the H_3O^+ ion.

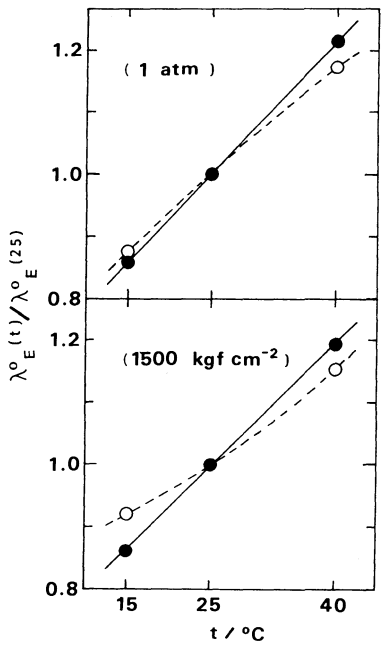

Fig. 2. Temperature dependence of the relative excess conductances of the OH^- and H_3O^+ ions at 1 atm and 1500 kgf cm^{-2}.
●: OH^-, ○: H_3O^+.

dependence. The apparent activation volume for λ°_E, $\Delta V^* = -RT(\partial \ln \lambda^\circ_E / \partial P)_T$, at 1 atm and at 25 °C is about -0.9 cm^3 mol^{-1} for the hydroxide ion and -2.0 cm^3 mol^{-1} for the oxonium ion, and the values of ΔV^* for both ions decrease with a decrease in the temperature. The apparent activation energy for λ°_E, $E^* = RT^2(\partial \ln \lambda^\circ_E / \partial T)_P$, at 1 atm and at 25 °C is about 11 kJ mol^{-1} for the hydroxide ion and 8.9 kJ mol^{-1} for the oxonium ion, and the values of E^* for both ions decrease with an increase in the pressure. The difference in ΔV^* and E^* between hydroxide and oxonium ions may be based on the difference in the proton-jump mechanism between the ions; however, a more thorough interpretation of the results shown in Figs. 1 and 2 would require more detailed microscopic information concerning the structure and the potential-energy profile of the nearest hydration shell around the ions in dilute solutions at high pressures and over a wide range of temperatures. Neutron diffraction[38] and computer simulation studies concerning these systems are, therefore, hoped to be extended to high pressures.

Adsorption of Organic Halides on Amine-Impregnated Silica Gels

Tatsuo ISHIKAWA,* Naoki YAMAGAMI, and Seiichi KONDO
School of Chemistry, Osaka University of Education, 4-88 Minamikawahori-cho, Tennoji-ku, Osaka 543
(Received April 1, 1986)

The adsorption behaviors of methyl and propyl iodides, propyl chloride and chlorobenzene were examined on silica gels impregnated with 1,4-diazabicyclo[2.2.2]octane (DABCO), pyperazine (PPZ), hexamethylene tetramine (HMTA), and modified with (3-aminopropyl)triethoxysilane (ATS) and dimethoxybis[3-(methylamino)-propyl]silane (DAS). The irreversibly adsorbed amount of these halides except chlorobenzene was proportional to the amount of impregnated amines. The molar ratios of irreversible adsorption of the halides to the impregnated amine were less than 2 and in the order of DABCO>PPZ>HMTA>ATS>DAS. The former three amine compounds are less stable than the last two materials against thermal pretreatment.

Organic halides such as trichloromethane in city water, organic chlorides from waste plastics and solvents, 2,3,7,8-tetrachlorodibenzo[*b*,*e*][1,4]dioxin (dioxin) in insecticides and methyl iodide from nuclear reactors are serious environmental pollutants. Therefore, it is very important to find effective ways of removing these pollutants. From this point of view, silver-impregnated silica gels were found to adsorb organic halides effectively.[1] Silver-impregnated molecular sieves are used to remove organic iodides in waste gases from nuclear reactors.[2] However, in order to expect a good performance, a rather careful procedure of pretreatment of these materials seems to be necessary. Also, activated carbons impregnated with 1,4-diazabicyclo[2.2.2]octane triethylene diamine (DABCO) are used as an adsorbent to analyze atmospheric alkyl iodides.[3]

In the present paper, the adsorption behaviors of methyl and propyl iodides, propyl chloride and chlorobenzene were described in detail on well-characterized mesoporous silica gels impregnated with DABCO, piperazine (PPZ), hexamethylene tetramine (HMTA) and modified with (3-aminopropyl)triethoxysilane (ATS) and dimethoxybis[3-(methylamino)propyl]silane (DAS). The mechanism of adsorption is clarified in view of thermodynamic properties and ir spectra.

Experimental

Materials. Thin and transparent plates of mesoporous silica gels suitable for spectroscopic measurement were synthesized by hydrolyzing tetraethoxysilane according to the method mentioned elsewhere.[4] The BET specific surface area, pore volume and mean pore radius of this material obtained from the N_2 adsorption isotherm are 705 $m^2 g^{-1}$, 0.60 $ml g^{-1}$ and 1.7 nm respectively. These gels were impregnated with DABCO, PPZ, and HMTA by immersing them in methanol solutions of each of these amines of various concentrations at 298 K for 10 h and then evaporating methanol in the samples in vacuo at room temperature. The impregnated amounts were determined by CN elemental analysis. Free silanol groups on silica surface were modified with ATS and DAS by immersing gels in toluene solutions of ATS and DAS of various concentrations at 323 K for 5 h and washing with acetone and then drying at room temperature. The amounts of ATS and DAS reacted were determined

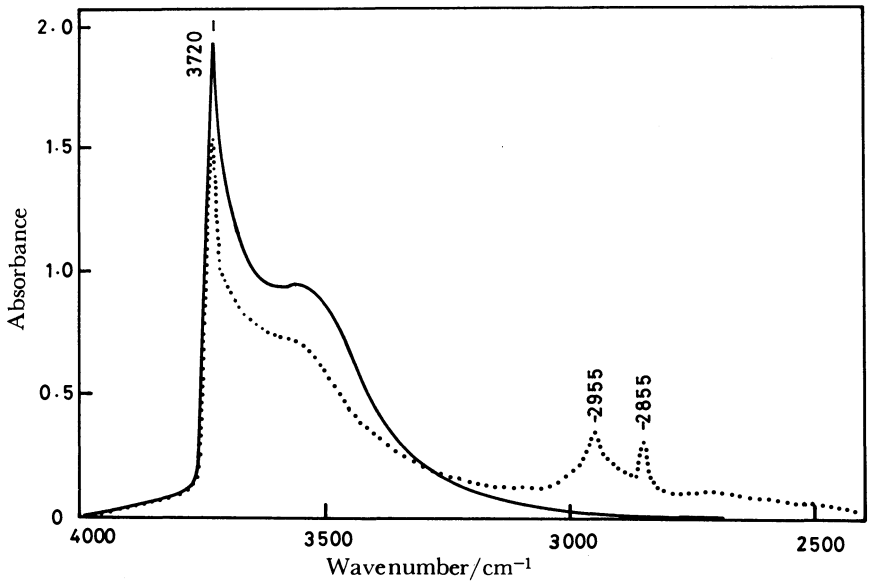

Fig. 1. IR spectra of silica gels before and after impregnating DABCO of 0.331 mmol g^{-1}. The full line, before impregnation; the dotted line, after impregnation.

by CN elemental analysis.

Methods of Measurements. The adsorption isotherms of methyl and propyl iodides, propyl chloride and chlorobenzene were measured at 298 K by means of a computer-operated quartz spring balance using a diaphragm manometer (BARATRON, 170M-6C). These samples were pretreated at desired temperatures under 10^{-3} Pa for 2 h. The adsorbates were dried with molecular sieves 3A and then distilled into a reservoir of the adsorption apparatus in the same vacuum system without exposing to air.

IR spectra were measured with a dispersion-type IR spectrophotometer (Hitachi-Perkin Elmer) and a FT-NIR spectrometer (Digilab, FTS-15E). A vacuum and high-temperature cell[5] was used to measure spectra at room temperature after pretreating the sample at 423 K unless otherwise stated.

Results and Discussion

In Fig. 1, the IR spectrum of silica gels before impregnating DABCO (a full line) has a sharp 3720 cm^{-1} and a broad 3500 cm^{-1} absorption bands which are assigned to the stretching vibration of free and hydrogen-bonded silanol groups respectively. After impregnating 0.331 DABCO mmol g^{-1} SiO_2 (about 0.3 DABCO molecules nm^{-2} of the original surface), the intensity of 3720 cm^{-1} band decreased to about 80% and two bands assigned to assymmetric and symmetric C-H vibrations of methylene groups of DABCO appeared at 2955 and 2855 cm^{-1} as is shown by a dotted line in this figure. Since there are about three free silanol groups per nm^2 on this mesoporous silica gels[6] and 0.6 free silanol groups (about 20% of total silanol groups) adsorbed DABCO, one DABCO molecule seems to be adsorbed on two free silanol groups by hydrogen bond.

The adsorption isotherms of methyl iodide on pure silica gels at 288 K (a full line) and on silica gels impregnated with 1.00 DABCO mmol g^{-1} SiO_2 and pretreated at 303 K for 2 h in vacuo (a dotted line) are shown in Fig. 2. No hysteresis was observed in the former isotherm, but the latter material shows a remarkable irreversible desorption in the low pressure range after evacuation at the temperature of adsorption, the amount of which at $P/P_0=0$ is shown by W_{ir} molecules nm^{-2} in Table 1. The same kind of hysteresis was observed on the adsorption isotherms of methyl iodide to the PPZ- and HMTA-impregnated samples pretreated at 303 K in vacuo. The monolayer adsorption capacities, W_m molecules nm^{-2} obtained by applying BET equation to the isotherms of the halides except chlorobenzene increased on impregnating these amines as is shown in Table 1. The adsorption behav-

	C_6H_5Cl	0	0	0	0	0

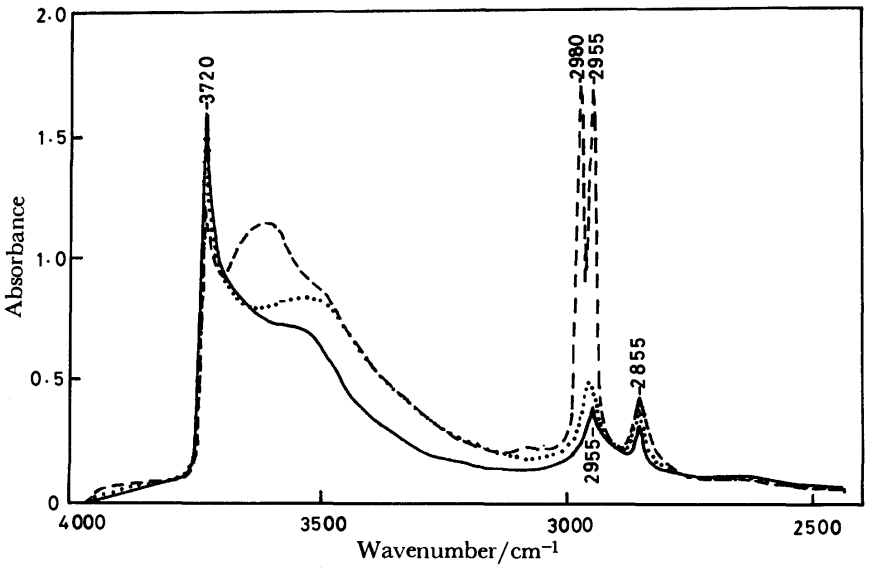

Fig. 3. The influence of adsorption and desorption of methyl iodide on the IR spectrum of DABCO-impregnated silica gels. The full line, before adsorption; the broken line, after adsorption; the dotted line, after desorption.

iors of propyl iodile and propyl chloride were similar to that of methyl iodide. On the other hand, the adsorption and desorption of chlorobenzene was reversible on pure and amine-impregnated samples. W_m in this case was larger for pure material than these with amines.

A full, a broken and a dotted lines in Fig. 3 show the IR spectrum of original DABCO-impregnated sample, that after the adsorption of methyl iodide at 1.3×10^4 Pa, and that after desorption by evacuation at room temperature respectively. After methyl iodide adsorption, the intensity of the 3720 cm^{-1} band decreased by the hydrogen-bond adsorption of methyl iodide, and the 2980 and 2955 cm^{-1} bands assigned to C-H vibrations of methyl groups of the adsorbate appeared. When evacuating this sample at 298 K, these C-H bands disappeared and the 3720 cm^{-1} band revived. These changes indicate the reversible desorption of most of methyl iodide molecules adsorbed. There is no positive evidence of irreversible adsorption in these spectra because the amount of irreversible adsorption was very small. However, there may exist an irreversible adsorption as follows. Methyl iodide is known to react easily with DABCO at room temperature by the reaction.[7]

$$N(CH_2CH_2)_3N + 2CH_3I \rightarrow I^-[H_3CN^+(CH_2CH_2)_3N^+CH_3]I^- \quad (1)$$

The IR spectrum of this resultant compound shown in Fig. 4 has two bands at 2945 and 2871 cm^{-1} which may be assigned to assymmetric and symmetric C-H vibrations of the methyl radicals of the resultants in Eq. 1. The bands mentioned above are different from those of methyl groups of methyl iodide molecules, because the molecular orbitals of these radicals would be different

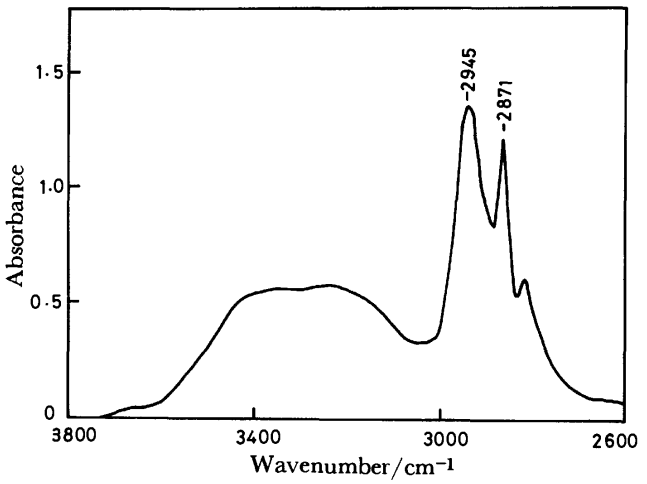

Fig. 4. The IR spectrum of the resultant of reaction of methyl iodide with DABCO in tetrachloromethane at room temperature.

from sp^3 hybrid orbitals of methyl groups by the Reaction (1). Since the irreversible amount of adsorption is rather small and the wave numbers of the bands of radicals are close to those of impregnated amines, it was not possible to identify the existence of the bands of methyl radicals in the spectrum after desorption in Fig. 3 under the present experimental error. Therefore, it may be plausible to postulated Reaction (1) for the present irreversible adsorption.

The amount of irreversible adsorption, W_{ir}, in Table 1 is in the order of methyl iodide>propyl iodide >propyl chloride>chlorobenzene for each amine impregnated. This is because the Reaction (1) can take place more easily for larger ionicity of carbon-halogen bonds which can be estimated from the nuclear quad-

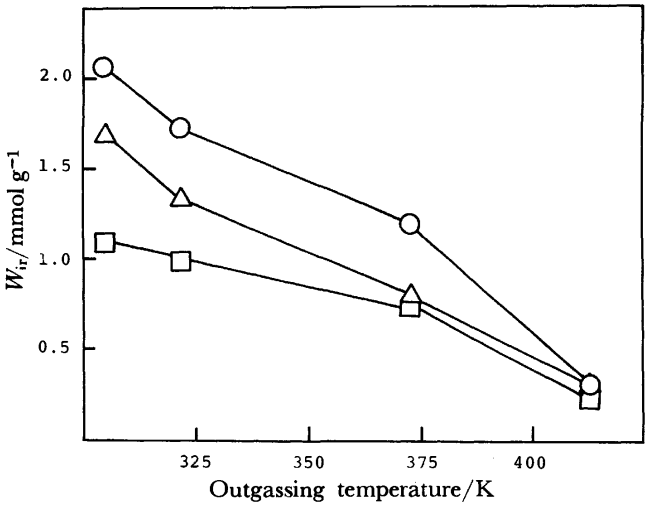

Fig. 5. The relations between the amount of irreversible adsorption of methyl iodide and pretreatment temperature. O: DABCO-impregnated sample, △: PPZ-impregnated sample, □: HMTA-impregnated sample.

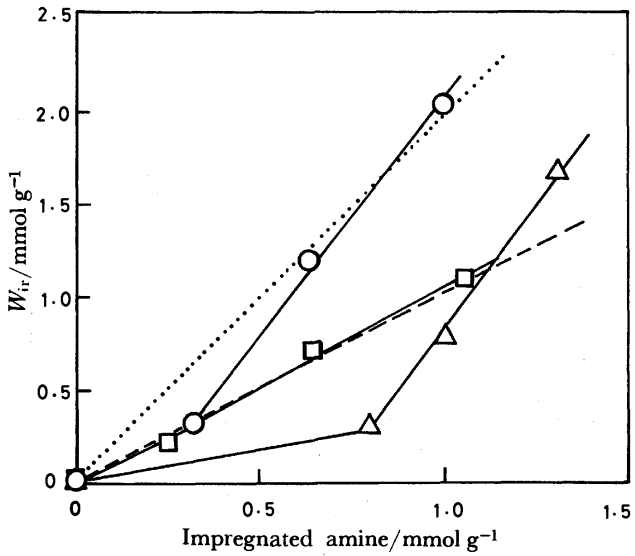

Fig. 6. The relations between the amount of irreversible adsorption of methyl iodide and the amount of amines impregnated. The dotted and broken lines show that the molal ratios of adsorbed methyl iodide to impregnated amine are 2 and 1 respectively. O: DABCO, △: PPZ, □: HMTA.

rupole moments.[8] In Fig. 5, W_{ir} of all the amine impregnated samples decreased as the pretreatment temperature was raised. This is because the impregnated amines are removed by evacuating samples above 303 K as confirmed by CN elemental analysis.

Figure 6 shows the relations between W_{ir} of methyl iodide and the amount of impregnated amines. The molar ratios of adsorbed methyl iodide to impregnated DABCO and that to HMTA are 2 and 1 respectively as is shown by the dotted and broken lines in Fig. 6 respectively, suggesting that two nitrogen atoms of a

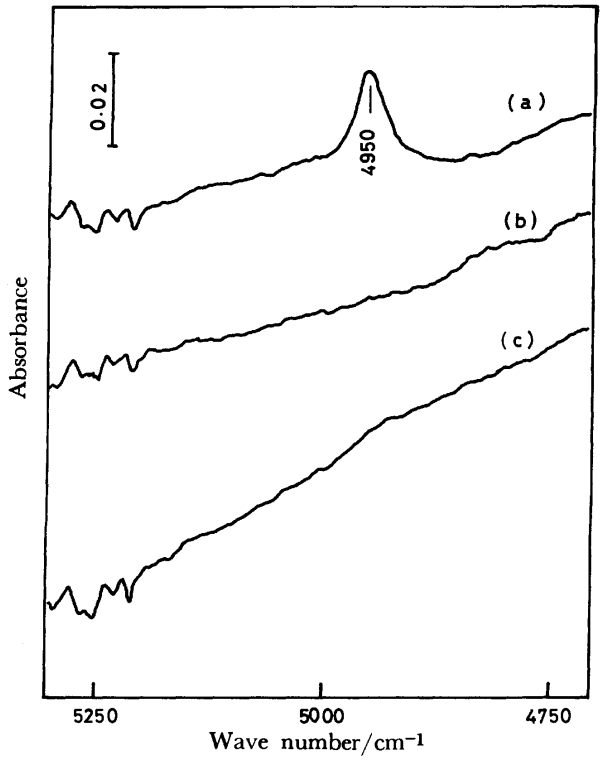

Fig. 7. The influence of adsorption and desorption of methyl iodide on NIR spectra of ATS modified sample. (a): Before adsorption, (b): after adsorption, (c): after desorption.

DABCO molecule react with two methyl iodide molecules. This result supports the postulated Reaction (1). On the other hand, only one nitrogen atom of HMTA molecule having four nitrogen atoms reacts with one methyl iodide molecule, the reason for which lies perhaps in the lower basicity of HMTA than that of DABCO. The molar ratio of PPZ-impregnated sample is 2 above 0.8 PPZ mmol g^{-1} SiO_2, and, below this amount, this molar ratio is very small as is seen in Fig. 6. The reason for this difference can be interpreted as follows. Below 0.8 PPZ mmol g^{-1}, molecules are likely to lie on the surface with their molecular plane parallel to the surface and with two nitrogen atoms in the molecule are hydrogen-bonded to the surface silanol groups. This impregnated amount corresponds to the monolayer adsorption capacity estimated with the cross sectional area of PPZ molecules as equal to that of molecular plane. Therefore, these nitrogen atoms may not react with methyl iodide. The steep increase of W_{ir} above this amount can be interpreted as that both nitrogen atoms of PPZ molecules on the second layer may be free to capture methyl iodide molecules. The molar ratios of adsorbed propyl iodide to impregnated DABCO, PPZ, and HMTA are always less than unity, probably because C-I bond of propyl iodide has less ionicity than that of methyl iodide.

Most of impregnated amines are removed by outgassing at 423 K and hence W_{ir} decreases by heating

as is seen in Fig. 5. In order to increase W_{ir}, amino groups were fixed on the surface of mesoporous silica gels by substituting free silanol groups to ethoxy and methoxy groups of ATS and DAS, and thus the surface density of substituted amino groups was about 1/nm^2. CN elemental analysis indicated more thermal stability of ATS than the above mentioned amines till 673 K. The adsorption isotherm of methyl iodide on ATS-modified sample shown by a broken line in Fig. 2 is irreversible like these of amine-impregnated samples. W_{ir} in this case did not decrease on heating, and was in the order of methyl iodide>propyl iodide> propyl chloride>chlorobenzene. One methyl iodide molecule is adsorbed to about one nitrogen atom of ATS. NIR spectra of this sample before methyl iodide adsorption in Fig. 7 has a combination vibration band of N-H bond of ATS molecule at 4950 cm^{-1}. This band diminished after methyl iodide adsorption and did not recover on heating in vacuo, suggesting the irreversible adsorption of methyl iodide by amino groups. The 4950 cm^{-1} band diminished after propyl chloride adsorption, but revived almost after desorption. W_{ir} of DAS-modified sample was very little, perhaps because dimethylamino groups interact with free silanol groups on the surface as will be reported soon.

Temperature-Programmed Desorption of Ammonia on Zeolites. Influence of the Experimental Conditions on the Acidity Measurement

Miki NIWA,* Masakazu IWAMOTO,† and Koh-ichi SEGAWA††
Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya 464
†Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852
††Department of Chemistry, Sophia University, 7-1 Kioicho, Chiyoda-ku, Tokyo 102
(Received April 17, 1986)

The Influence of the experimental conditions of the TPD (Temperature-Programmed Desorption) of ammonia on the measurement of acidity of mordenites and Y zeolites was studied. The results were applicable to the measurements of the strength and the number of acid sites of zeolites. For contact times of the carrier gas from 10^{-2} to 10^{-6} g min ml^{-1} defined as W/F (W, sample weight; F, flow rate of the carrier gas), the peak maximum temperature was related to the parameter (W/F). The relationship was explained on the basis of a theoretical equation derived by Cvetanović and Amenomiya under the conditions of readsorption. Ammonia is readsorbed on zeolites under these conditions, and one has to use the experimental conditions of the same contact time in order to evaluate the acid strength of zeolite from the peak maximum temperature. On the other hand, the ratio of intensity of low temperature peak (l-peak) to that of the high temperature peak (h-peak) increased with increasing the contact time of the carrier gas. This relation suggested that the l-peak intensity depended upon the degree of evacuation of the weakly-held ammonia. The l-peak is ascribable to very weakly or physically adsorbed ammonia on zeolites, and only the h-peak has to be accounted for to measure the number of acid sites.

Currently, much attention is focused on the activity and selectivity of catalytic reactions over acid-type zeolites. Because the acidity as well as the structure strongly affects the catalytic activity, it is of extreme importance to characterize the zeolite catalyst from the viewpoint of the acidity. Usually, the acidity of zeolite can not be measured by the titration method using Hammett indicators, because the diffusion of base molecules may be strictly retarded due to the small pores of the zeolite. Temperature-programmed desorption (TPD) of ammonia[1-3] and the microcalorimetry of differential heat of adsorption of ammonia[4] have been recommended.

One of the authors has already reported the usefulness of TPD of ammonia for the measurement of the acidity, and has compared the strength and number of acid sites of various zeolites.[1] This method is preferable to others because of the rapidness of the experiment. However, some problems remain unsolved. Firstly, the experimental conditions including sample weight, flow rate of carrier gas, rate of increasing temperature, partial pressure within the cell, etc., have to be examined in more detail to determine the acidity precisely. Although some criteria were proposed theoretically to design the conditions,[5] no experimental confirmations were attempted. Secondly, the identification of desorption peaks is still a matter of controversy: the origin of the l-peak (desorbed at ca. 323 K) is not clearly known, although the h-peak (another peak desorbed at a higher temperature) is attributed to an IR absorption band at 3600 cm^{-1}.[1,2]

We started a project on the TPD of ammonia under the organization of the Catalysis Society of Japan, committee of reference catalysts. Five kinds of acid-type mordenite and Y zeolites were distributed to research groups in universities and industrial companies. Each group measured the acidity of zeolites using TPD of ammonia by their own procedures, some of the conditions being unified. Results thus obtained were compared and discussed. As a result of the cooperative work, important conclusions were obtained about the acidity measurement using the TPD of ammonia. In this communication, we will report on the influence of experimental conditions on the measurement of acidic strength and amount of zeolites.

Experimental

Zeolites Reference Catalysts (JRC-Z) were supplied by the Catalysis Society of Japan: Some properties are shown in Table 1. All of them had been converted into the decationized form before distribution, and no pretreatment except for the evacuation was performed before the measurements.

Only the following experimental conditions were unified:

(1) pretreatment: evacuation at 773 K for 1 h.

(2) adsorption of ammonia, at 373 K.

(3) increase of bed temperature, at a rate of 10 K min^{-1} from 373 K.

Other experimental conditions were chosen individually, as shown in Table 2. Experimental methods were divided into those of vacuum and of flow. Intensity of desorbed ammonia was detected by thermal conductivity detector (tcd), mass spectroscopy (ms), gravimetry, or vacuum gauge. The carrier gas, helium, was made to flow into the zeolite bed with or without pumping, or the zeolite was pumped to evacuate the desorbed ammonia.

The strength and amount of acidic sites were measured by the peak maximum temperature and the desorbed amount.

Results and Discussion

Dependence of Desorption Temperature on Experimental Conditions. The TPD spectra obtained were characteristic of two desorption peaks (l- and h-peaks at low and high temperatures, respectively) on not only mordenite but also Y-zeolite (Fig. 1), which was in agreement with in the previous study.[1] The resolu-

a) Measured in ambient pressure. b) The pressure in the TPD cell was below the ambient pressure when the carrier gas was pumped. c) F=760 f/p. d) 1 Torr=133.3 Pa.

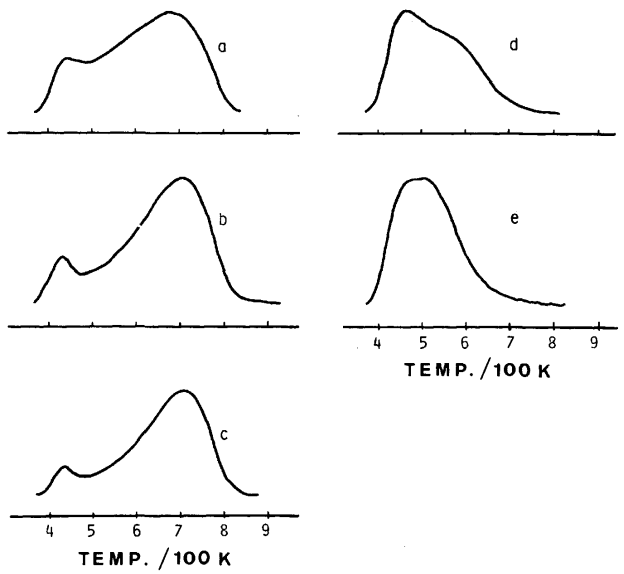

Fig. 1. Typical example of TPD spectra on Zeolites HM-10 (a), HM-15 (b), HM-20 (c), HY-4.8 (d), and HY-5.6 (e) obtained in the W/F of 7.7×10^{-5} g min ml^{-1}. Spectrum intensity was shown in an arbitrary units divided by grams of zeolite. Temperatures for the h-peak maximum were 680 (a), 703 (b), 705 (c), ca. 590 (d), and ca. 490 K (e).

tion of double peaks was good in cases of mordenites, but imperfect in those of Y-zeolites. The acid strength of these zeolites could be summarized due to the comparison between peak maximum temperatures of the h-peak. The comparison consistently afforded the following sequence for the acidity strength:

$$\text{HM-15} \geq \text{HM-20} > \text{HM-10} \gg \text{HY-4.8} > \text{HY-5.6}$$

However, the desorption temperatures did not agree at all, when comparisons were made between those obtained by various groups. For example, the peak temperature on the HM-15 was distributed from 673 to 883 K. In order to understand such a large difference, we examined experimental conditions relevant to the desorption temperature. Although various experimental methods were included in these experiments, such a large difference could not be understood only by differences in apparatus or in measuring the temperature.[7] It was thus found that the desorption temperature was correlated with the contact time of the carrier gas W/F, where W and F denoted the zeolite weight and the flow rate of carrier gas. If the carrier gas was pumped, F should be replaced by a corrected flow rate 760 f/p, where p was the pressure in the TPD cell in Torr (1 Torr=133.3 Pa), and f was the flow rate measured in atmospheric pressure, because the carrier gas was made to flow at a faster rate than under atmospheric conditions. The relationship in the case of the HM-15 is shown in Fig. 2; the peak temperature gradually increased with increasing the contact time W/F in the range of 10^{-2} to 10^{-6} g min ml^{-1}.

According to the kinetical analysis of the TPD spec-

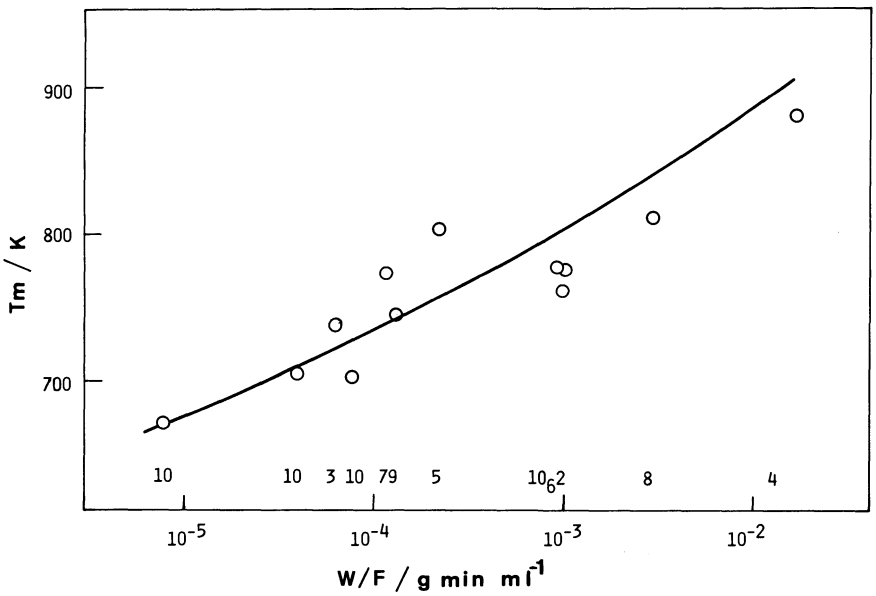

Fig. 2. Correlation between the peak maximum temperature and the W/F on HM-15. The theoretical curve was simulated for the parameters. β: 10 ($K\,min^{-1}$), ΔH: 1.5×10^5 ($J\,mol^{-1}$), θ: 0.35, ρ: 0.5, R: 8.31 ($J\,K^{-1}\,mol^{-1}$). Experimental run numbers in this Figure are referred to in Table 2.

tra by Cvetanović and Amenomiya,[8] the conditions of the TPD experiment are divided into three limiting cases: (a) When the readsorption of a desorbed molecule does not occur, (b) when the readsorption occurs freely, and (c) when the diffusion controls the desorption. The correlation found in this study indicates that the present experiments are carried out under the readsorption conditions, because, in case (b), the peak maximum temperature (Tm) is theoretically correlated with the contact time:

$$2\log T_m - \log\beta = \Delta H/2.303RT_m + \log Q$$
$$Q = (1-\theta)^2 V\Delta H/FAR$$
$$V = W/\rho$$

Here β and θ show the rate of temperature increase and the coverage at peak maximum, ΔH and R are heat of adsorption and gas constant, and V and ρ are the volume and density of solid. Parameter A is equal to $\exp(\Delta S/R)$, where ΔS is the increase of entropy upon desorption. After the values of parameters were assumed, theoretical relations could be calculated, as shown in Fig. 2. When A is assumed to be 2.86×10^5, the simulated curve follows the relation between the peak temperature and W/F. One can thus conclude that ammonia was freely readsorbed on these zeolites in the TPD experiment, and the peak temperature depends on the contact time of the carrier gas.

The conclusion is in agreement with the theoretical consideration by Gorte[5]: He showed that the desorption temperature was changed by several hundreds K due to the effect of the readsorption on the porous catalyst. Additionally, Demmin and Gorte[5] reported on the influence of the crystal size on the desorption temperature. According to their analysis, a temperature gradient exists along the catalyst bed, when the $Fr^2\rho/3WD$ is larger than 0.1, where r is the radius of the crystal and D is the diffusion constant. In such a case, the desorption temperature will be affected by the diffusion of molecules inside the pore, and the peak maximum temperature will not correspond to the strength of the acid sites. When these parameters are assumed: r=1 μm; $D=10^{-5}$ $cm^2\,s^{-1}$, their proposed conditions are satisfied only in less than 2.7×10^{-5} g min ml^{-1} of W/F, and almost all the present experiments are carried out under different conditions. Furthermore, it was found experimentally that the sequence of zeolites in order of the acid strength did not change throughout these experiments. Therefore, the influence of crystal size on the judgment of the acid strength may be disregarded, as far as the present experiments are concerned. Measurements on larger crystals seems to be required for the confirmation of the influence of crystal size.

This method has recently been used frequently by many researchers. However, these measurements are utilized only for a relative comparison of the acidities of their own zeolites, but not for comparisons with findings reported elsewhere. However, the present conclusion indicates the possibility of comparison of the strength of zeolite acidities which were obtained by TPD of ammonia, if only some parameters such as A and ΔH are given. Therefore, from now on, the experimental conditions of contact time of carrier gas must be described together with the experimental results.

Identification of Low Temperature Peak. Desorbed amounts of ammonia measured by various groups distributed significantly. For example, the desorbed amounts from HM-15 were 1.09—3.18 and 0.21—1.87

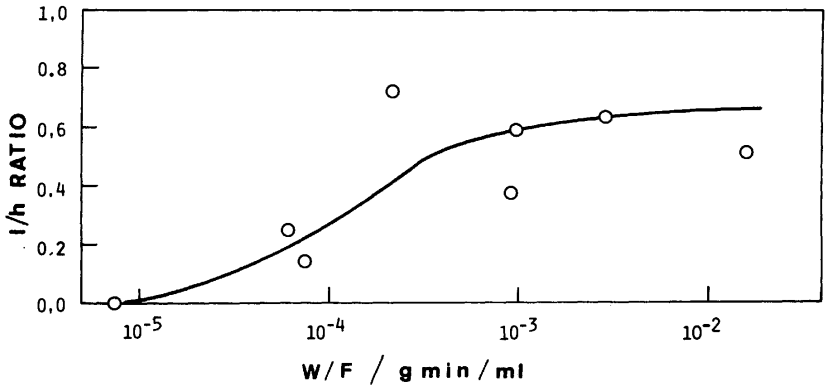

Fig. 3. Correlation between the peak intensity ratio (l-/h-peaks) and the W/F.

(mmol g^{-1}) in the h- and l-peaks, respectively. The distribution in the h-peak was not, however, related with any experimental conditions or measurement method. Experimental errors were probably included in measuring the desorbed amount. On the other hand, the intensity ratio of the l- to h-peaks which was used in order to compensate for the experimental errors in the quantitative measurements was related with the contact time W/F, as shown in Fig. 3. The intensity of l-peak was almost negligible at the small contact time, and the intensity relative to that of h-peak increased with increasing the contact time. This trend indicates that the l-peak does not depend on the catalyst property, but on the experimental conditions.

Furthermore, it was found that the Na-mordenite possessed only the l-peak, whose amount was much greater than that on the decationized one (Fig. 4). The appearance of the desorption spectrum at this temperature has been already reported on non-acidic zeolite by Kanazirev,[9] who measured the TPD for the study of diffusion processes.

These findings indicate that the l-peak of the mordenite does not originate from molecules adsorbed on the weak-acid site but from physically or very weakly chemisorbed molecules. The dependence of the l- to h-peak ratio on the contact time may be caused by the degree of the removal of the weakly-held ammonia. Under the conditions of the large contact time, i.e. slow flow rate of the carrier gas and/or large amount of zeolites, the weakly-held ammonia is difficult to remove by evacuation, and some molecules remain undesorbed. Those remaining molecules may be desorbed as the l-peak upon increase of the bed temperature. In other words, the l-peak could be regarded as the *remainder* of the desorbable ammonia. Therefore, it is concluded that only the h-peak has to be accounted for to measure the acidity of zeolites.

The method of removal of gaseous ammonia was not strictly determined. However, it is practical to require that the removal of gaseous ammonia should be done until the detector reaches the base level. In these conditions, small amounts of desorbed ammonia

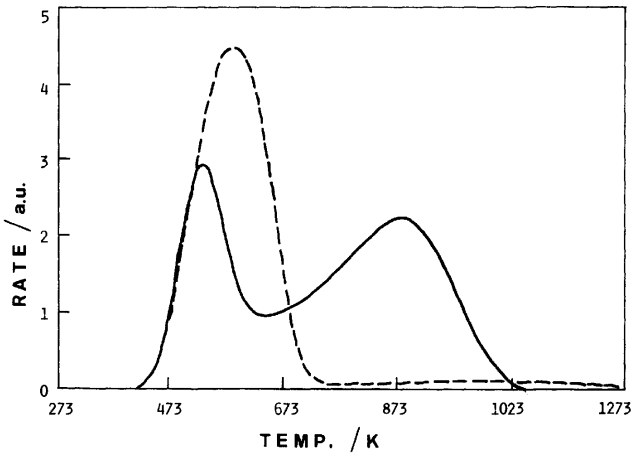

Fig. 4. Comparison between spectra on HM-15 (solid line) and on M-15 (Na-mordenite)(dotted line). These were obtained in the W/F of 1.7×10^{-2} (g min ml^{-1}).

may be undetectable, and a desorption peak will be readily found as the l-peak. The completely evacuation of ammonia is difficult and impractical, because it requires a long time, and the extent of evacuation is not properly decided.

On the other hand, the NaY-zeolite showed only a smaller intensity of the l-peak than the HY, unlike the mordenite. For example, in the experiment of run number 1 (see Table 2), the amount of ammonia desorbed from Y-4.8 (NaY type) was 0.08 (mmol g^{-1}), while that from HY-4.8 was 1.87 (mmol g^{-1}). Although it is difficult to analyze precisely the components of the TPD spectra on the HY-zeolite because of the poor resolution, the peak appearing in the low temperature seems to be easily evacuated due to the large pore size of the Y-zeolites.

The Regulation of Emulsion Polymerization of Styrene with Anionic-Nonionic Emulsifier Mixtures

Kazufumi KATO,* Harumi KONDO, Kunio ESUMI, and Kenjiro MEGURO
Department of Applied Chemistry and Institute of Colloid and Interface Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received April 24, 1986)

The emulsion polymerization of styrene was carried out in the presence of mixtures of a nonionic surfactant (poly(oxyethylene) hexadecyl ether; BC-20) and an anionic surfactant (sodium dodecyl sulfate; SDS or lithium perfluorooctanesulfonate; LiFOS). The polymerization rate changed with the hydrophile-lypophile balance (HLB) of the BC-*n* series. The polymerization rate considerably increased on the addition of SDS or LiFOS. However, the further addition of LiFOS caused a gradual depression of the polymerization rate. The polymerization rate was not dependent on the amount of styrene solubilized in the mixed emulsifier solution. The particle sizes decreased remarkably on adding SDS. The molecular weights of polystyrene in latex synthesized in mixed emulsifier solutions were larger than those in a single emulsifier solution. The molecular-weight distributions of polystyrene formed in mixed emulsifier solutions were wider than those of polystyrene formed in a single emulsifier solution. These results may be attributed to properties such as the composition and the charge density of the mixed micelles, and to the solubilized amount of styrene monomer in the mixed nonionic-anionic emulsifier solutions.

There are many reports concerning the physical properties of mixed surfactant solutions, such as, size, form, aggregation number, composition of components and surface charge of the mixed micelles.[1-3] Mixtures of emulsifiers have been also used for emulsion polymerization. There are also some reports about the effect of mixtures of emulsifiers on the emulsion polymerization process, compared with that of a single emulsifier.[4-6] The emulsifiers play important roles: for example, their micelles offer sites for polymerization and they stabilize the synthesized latex in the process of emulsion polymerization.[7-9]

In our previous paper, the emulsion polymerization of styrene in the presence of a mixture of anionic fluorocarbon-anionic hydrocarbon emulsifiers was studied.[10] And it has been confirmed that the fluorocarbon surfactant has the effect of slowing down the polymerization rate. The addition of a fluorocarbon emulsifier reduced the particle number concentration of the latex and the molecular weight of the polystyrene latex formed. It also caused an increase in the size of the latex particles.

In this work, the emulsion polymerization of styrene was carried out using a mixture of a nonionic emulsifier and an anionic emulsifier (sodium dodecyl sulfate; SDS, or lithium perfluorooctanesulfonate; LiFOS). The effect of the mixture of nonionic-anionic emulsifiers on the emulsion polymerization process was investigated by measuring the polymerization rate, the particle size, the molecular weight and their distribution.

Experimental

Materials. Poly(oxyethylene) hexadecyl ethers ($RO-(C_2H_4O)_nH$; BC-*n*) were used as nonionic emulsifiers. As anionic emulsifiers, sodium dodecyl sulfate ($C_{12}H_{25}OSO_3Na$; SDS) and lithium perfluorooctanesulfonate($C_8F_{17}SO_3Li$; LiFOS) were used. LiFOS was prepared by the same synthesis described in the previous paper.[10] SDS was marketed for biochemical use (Wako Pure Chem. Ind. Ltd.) and was purified by recrystallization twice from ethanol. The purities of the SDS and LiFOS were confirmed by elemental analysis and the absence of a minimum in the surface tension measurement. BC-*n* (Nikko Chemical Co.) were used without further purification.

The styrene monomer was distilled under a nitrogen atmosphere, and was stored in a refrigerator under nitrogen before use. For an initiator potassium peroxodisulfate ($K_2S_2O_8$) of analytical grade supplied by Wako Pure Chemical Ind. Ltd. was used. Water was purified by Milli-Q Reagent Grade Water System (Millipor Ltd.) until its specific conductivity fell below 0.1 $\mu S\,cm^{-1}$.

Procedure. Each run of emulsion polymerization was done using a batch process in a one-liter glass reactor fitted with a metal screw, thermometer and facilities for charging and sampling. A typical polymerization recipe is shown in Table 1. The main conditions of the emulsifiers using in the polymerization process were as follows.

a) HLB in BC-*n* series are varied. Each hydrophile-lypophile balance (HLB) of BC-*n* series is summarized in Table 2.

b) The amounts of BC-20 (HLB; 17) are varied.

c) Mixing ratios of anionic-nonionic emulsifiers are varied. The changes in the mixing conditions were done in two ways; one of them was made up by adding various quantities of SDS or LiFOS to a definite quantity of BC-20 (5.0 g), and the other was made up by varing the mixed ratios of each emulsifier (SDS-BC-20, LiFOS-BC-20).

At first, the water and emulsifier were added to the reactor at room temperature. The styrene monomer was then added. The reactor was immersed in a constant temperature bath adjusted to 60±1°C under a nitrogen atmosphere, and the mixture was stirred at 250 rpm. When the temperature reached 60°C, the aqueous solution of potassium peroxodisulfate (0.2 g/50 cm^3) was added to the contents in the reactor to initiate the polymerization.

The 5 cm^3 of emulsion samples for determination of the conversion ratio in the polymerization process was withdrawn with pipettes at fixed intervals. The samples were poured into 5 cm^3 of *p*-benzoquinone methanol solution (1.5

g dm^{-3}) as an inhibitor to terminate the polymerization reaction. Then, the unreacted styrene monomer, methanol and water were evaporated at 70°C. The percent conversions of styrene to polystyrene were estimated by measuring the ratios: (polymer/total monomer) on the assumption that the (monomer+polymer)/water was constant throughout the reaction.

In order to determine the particle sizes and the molecular-weight distributions of the latex particles after 90 min of reaction time, the samples were cooled rapidly in cold water (0°C). The particle sizes and the size distributions were determined by a submicron particle sizer (AUTOSIZER MODEL-700; Malvern Instruments Ltd.). This was carried out at 25.0°C by assuming that the refractive index of the latex-suspended solution was 1.33 and its viscosity $8.909*10^{-4}$ Pas.[11,12] Their polydispersity indexes (Pusey'Q factor) which gave an indication of the breadth of the size distribution were determined.

The molecular-weight distributions of polystyrene latex samples were measured by using a gel permeation chromatograph (GPC) fitted with a packed column (Showa Denko Co. A-80M). The weight-average molecular weights (M_w) and their molecular-weight distributions (M_w/M_n) were calculated with a Shimadzu Chromatopac C-R2AX.

The amounts of ethylbenzene solubilized in the mixed emulsifier solutions were determined spectrophotemetrically by measuring the absorbance of ethylbenzene at a wavelength of 262.6 nm at 25°C. It was assumed that the solubilized amount of ethylbenzene was similar to that of styrene in several emulsifier solutions.

Results and Discussion

In general, emulsifiers play important roles in the good running of emulsion polymerization. Especially, nonionic emulsifiers have a high selectivity toward the emulsification of the monomer and the stabilization of emulsion droplets and polymer particles. Greth has systematically studied the suitabilities of nonionic emulsifiers for several monomers, such as, styrene and vinyl acetate. He has also reported that the solubility of a monomer for water is correlated with the HLB of nonionic emulsifiers, which give good stability to the latex.[4]

In our report, the emulsion polymerization of styrene was carried out by using BC-*n* series as nonionic emulsifiers which have various different HLB. The time-conversion curves were first obtained and the polymerization rates (%min^{-1}) were calculated from their initial slopes. The effects of HLB of BC-*n* on the polymerization rate and on the particle size are shown in Fig. 1. It can be seen that the polymerization rate has a maximum value in the range of 17—20 of the HLB. The polymerization rate is dependent on the HLB of the BC-*n*. The particle size was also changed with the HLB. The change of particle size will be caused by the change of the number of latex particles accompanying the change of the polymerization rate with HLB.

It was confirmed in the first stage that the latex formed by using the nonionic emulsifiers (BC-*n*) of its HLB ranged at 17—20 was stable. In the next stage, the effect of the concentration of BC-20 (HLB; 17) on the polymerization rate and on the size of latex particle was examined. The changes of the polymerization rate (Rp) and the particle size of the latex formed with the change of the concentration of BC-20 are shown in Fig. 2. From this figure, it is evident that an exponential increase in polymerization rate accompanies an arith-

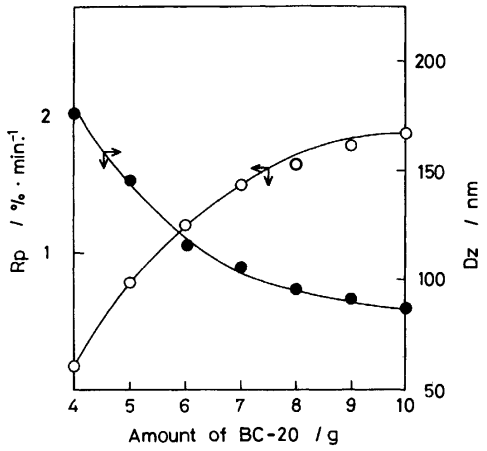

Fig. 2. The change of polymerization rate (Rp) and particle size (Dz) with amount of BC-20 (g).

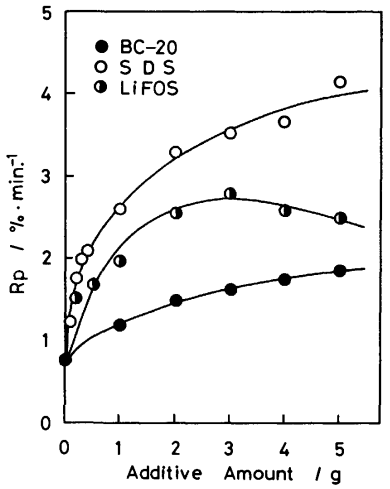

Fig. 3. Polymerization rate (Rp) as a function of additive amount of SDS(○), LiFOS(◑), BC-20(●) to BC-20 (5.0g).

metic increase in the concentration of BC-20 [BC-20]. Indeed, this relationship can be mathematically expressed as;

$$Rp \propto [BC\text{-}20]^{0.17}$$

The mechanism of particle formation in emulsion polymerization has been studied by many workers. According to the micellar nucleation theory of Smith-Ewart,[7] the number concentration (N) and the polymerization rate can be expressed as follows; when a homogeneous nucleation occurred in the emulsion polymerization of a water-insoluble monomer such as a styrene;

$$N \propto [I]^{2/5}[S]^{3/5}$$

$$Rp \propto (N/2)[M]$$

where [I] is the initiator concentration, [S] the emulsifier concentration and [M] the monomer concentration. These expressions have been proven to be valid only for the emulsion polymerization of a water-insoluble monomer in an aqueous solution of an anionic emulsifier above its cmc. However, when the nonionic emulsifiers were used in emulsion polymerization, the Smith-Ewart theory does not often coincide with the polymerization process, owing to the change of several factors; HLB, solubilized amount and their affinity for the monomer.[4,6]

In this study, the polymerization rate increased in proportion to the BC-20 concentration of 0.17 power. This power value is further changeable with temperature, mixing process, mixed ratio of water to monomer and conversion. Therefore, it was confirmed that the Smith-Ewart theory was inapplicable to this emulsion polymerization system of styrene in the presence of BC-20.

Figure 3 shows the change of the polymerization rate when various quantities of SDS or LiFOS are added to a definite quantity of BC-20, whereas the total amount of the mixed emulsifiers is different in each

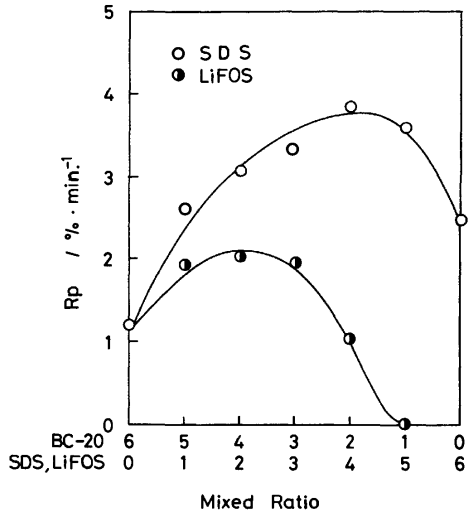

Fig. 4. The change of polymerization rate (Rp) with mixed ratio of (BC-20–SDS) or (BC-20–LiFOS) at the total concentration of 6.0g 250cm^{-3}.

reaction system. Figure 4 shows the change of the polymerization rate with various mixed ratios in the emulsifier mixtures, by keeping the total amount of emulsifiers constant. It can be seen from Fig. 3 that the polymerization rate increases with increase of the additive amount of SDS or LiFOS. Especially, only a small addition of anionic emulsifier to the system caused a steep increase of the polymerization rate. Figure 4 indicates that the polymerization rate in the mixture of (SDS-BC-20) or (LiFOS-BC-20) is much larger than that using each single emulsifier (BC-20, SDS or LiFOS).

In this work, it was assumed that the solubilized amount of ethylbenzene was equal to that of styrene in the emulsifier solutions. The solubilized amount of ethylbenzene is shown in Fig. 5 as a function of the additive amount of each emulsifier being adjusted by

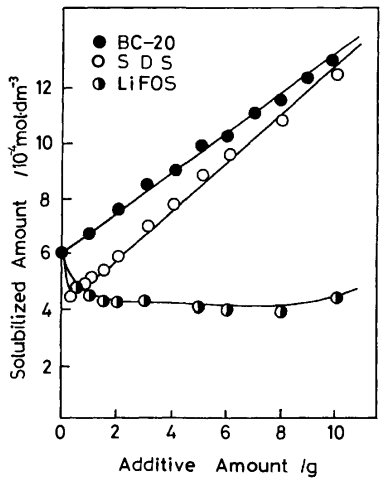

Fig. 5. Solubilized amount of ethylbenzene in mixed emulsifier aqueous solution as a function of additive amount of emulsifiers; SDS(○), LiFOS(◑), BC-20(●) to BC-20, at temperature 25°C.

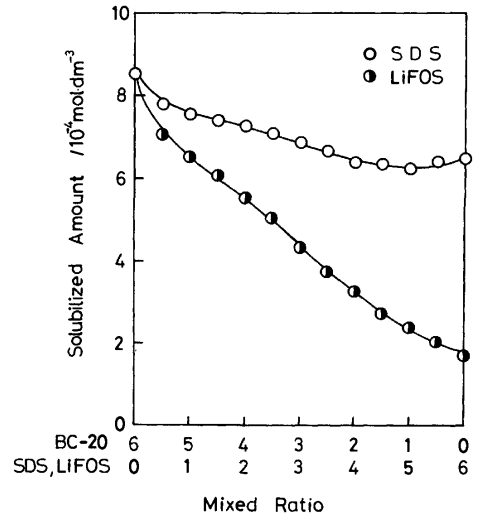

Fig. 6. Solubilized amount of ethylbenzene in mixed emulsifier aqueous solution as a function of mixed ratio of (BC-20-SDS) or (BC-20-LiFOS) at temperature 25°C.

the same amounts of emulsifiers as used in Fig. 3. The solubilized amount of ethylbenzene is also shown in Fig. 6 as a function of the mixed ratio of (SDS-BC-20) or (LiFOS-BC-20) being adjusted as indicated in Fig. 4. By the addition of the emulsifier, the solubilized amount of ethylbenzene increased in proportion to the concentration of BC-20 and this increase of the solubilized amount was higher than that in the case of a nonionic-anionic emulsifier mixture. The solubilized amount of ethylbenzene in the mixed solutions by adding a little amount of SDS to BC-20 became smaller than that in the case of single nonionic emulsifier. However, on the further addition of SDS, the solubilized amount of ethylbenzene increased. This amount was always smaller than that of the solubilized amount in the same concentration of BC-20.

It is known that the polymerization rate is proportional to the solubilizing power of various emulsifiers.[13] By a comparison between Figs. 3 and 5, while the solubilized amount of ethylbenzene in the mixed emulsifier solution, (BC-20-SDS) or (BC-20-LiFOS), was smaller than that in the single BC-20 solution, the polymerization rate in the former solution was larger than in the latter. In Fig. 4, the polymerization rate is seemed to increase with mixing the emulsifiers more than in the case of a single emulsifier, while the solubilized amount of styrene is reduced in the mixed emulsifier solutions. This would be expected from the same effect in the solubilized amount of ethylbenzene as shown in Fig. 6. These results confirmed that the polymerization rate was not much associated with the solubilized amount in nonionic-anionic emulsifier mixtures.

In general, it is difficult to predict the properties of mixed nonionic-anionic surfactant solutions theoretically,[2,3] such as the micelle size, the aggregation number and the composition in their mixed micelles. This is because of the specific difference in the interaction among hydrophilic polar groups of their molecules in the mixed micelles, compared with that in single micelles. Therefore, emulsion polymerization with nonionic-anionic emulsifier mixture cannot be directly attributed to the solubilized amount in mixed emulsifier solutions.

In the mixture of BC-20-LiFOS, the polymerization rate increased with increase of the addition of LiFOS. But the further addition of LiFOS caused the polymerization rate to decrease in spite of an increase in the total amount of the emulsifiers. In a previous paper,[10] it was confirmed that LiFOS has a repressive effect on the polymerization rate. According to Suzuki et al.[14] it was also reported that the addition of a fluorocarbon surfactant is effective to expel any materials solubilized in the micelles of a hydrocarbon surfactant by forming mixed micelles. From the above consideration, it is also supported that the deacceleration of the polymerization rate occurs due to the expulsive effect of LiFOS. The added LiFOS expels styryl radicals from the micelles in aqueous emulsifier solutions, resulting in a depression of the polymerization rate. However, this effect was slight in this nonionic-anionic emulsifier mixture.

The particle number concentration in synthesized latex per cubic meter of the aqueous phase (N) was calculated from the z-average diameter and the conversion ratio, and the diagram of the particle number concentration plotted against the addition of emulsifiers is shown in Fig. 7. The increase of the number of latex particle is seemed to be caused by the increase of the number of micelles and the increase in the number of emulsion particle with the total amount of emulsifier in the reaction solution. The increase of the particle number concentration caused by the addition of SDS or LiFOS is much larger than that with BC-20, while further addition of LiFOS causes a gradual

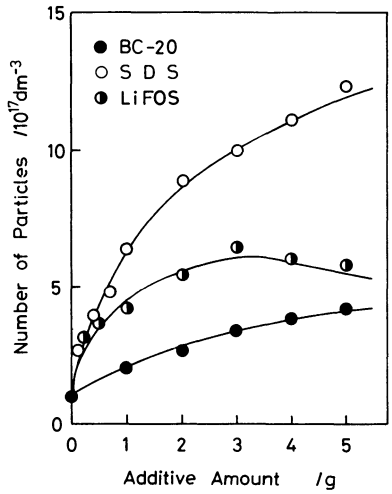

Fig. 7. Particle number concentration as a function of additive amount of SDS(○), LiFOS(◑), BC-20(●).

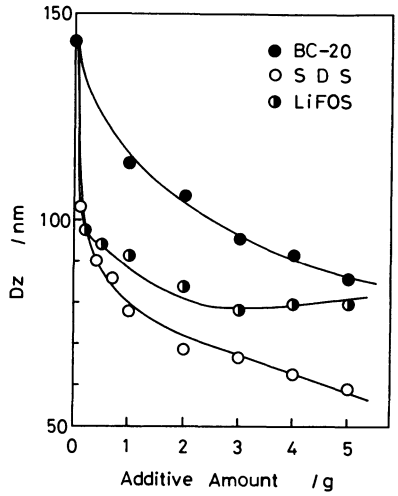

Fig. 8. Particle size (Dz) as a function of additive amount of emulsifiers; SDS(○), LiFOS(◑), BC-20(●).

decrease in the particle number concentration. These results can be explained by the same reason as mentioned about the change of the polymerization rate, for example, the variation of the composition in nonionic-anionic emulsifier micelles and the change of the solubilized amount of monomer in mixed emulsifier solutions.

The change in the latex particle size with the addition of BC-20, SDS, LiFOS to BC-20 (5.0 g) is shown in Fig. 8. Each particle size became smaller with increasing the addition of emulsifiers. The explanation for this result is based on the number of latex particles with the addition of the emulsifier, resulting in the increase of the polymerization rate. That is to say, as the particle number increases, the amount of monomer which is supplied for one latex particle decreases. In other words, since the polymerization of water-insoluble monomer proceeds in micelles containing

Table 3. Weight-Average Molecular Weight (M_w) and Molecular-Weight Distribution (M_w/M_n) of Formed Polystyrene Latex

monomer, the slower the polymerization rate is, the longer is the time in which the polymer particles and emulsion droplets coexist. As a result, the latex particle sizes are continuously increasing up to the depletion of monomer droplets. Furthermore, the particle size decreases with only a small addition of the anionic emulsifier, compared with the corresponding addition of BC-20. The remarkable decrease of particle sizes may occur because of the considerable increase in the number of latex particles. As an anionic is added to a nonionic emulsifier, the composition of the mixed micelles changes and the charge density of the anionic head group in the mixed micelles' surface increases. This increase of surface charge may bring about the increase in the repulsion between styryl oligomeric radical and the micelles. Actually, it has been established that the surface properties of a mixed micelle are remarkably changed upon a small addition of an anionic to a nonionic surfactant. This has been shown by measuring the surface potential,[1] and self-diffusion coefficients and line width at half height by NMR.[3]

The molecular-weight of the polystyrene latex formed was measured by GPC after being dissolved in tetrahydrofuran. These samples were the same ones used for the particle size measurement. The weight-average molecular weights (M_w) and their molecular weight distributions (M_w/M_n) are shown in Table 3 as a function of mixed ratio of (BC-20-SDS) or (BC-20-LiFOS). It was found that the breadth of the molecular-weight distribution of the polystyrene formed in a latex by using the mixed emulsifiers was rather broadened compared with that by using each single emulsifier. These results demonstrate that the compositions of emulsions and micelles in the mixed emulsifier solutions have a much wider distribution than that in a single emulsifier solution. The M_w of polystyrene latex formed with mixed emulsifiers increased more

than that of polystyrene latex formed with each single emulsifier. The increase of M_w on adding SDS was higher than that on adding LiFOS. These results depend on the change of the polymerization rate and the particle number concentration with the mixed ratio of emulsifiers.

(Received May 21, 1986)

A stopped-flow small-angle X-ray scattering method was applied to study the structural change of Taka-amylase A by acid-denaturation. The structural change could be described by two successive steps. The first step is described by a change in the eccentricity of a prolate ellipsoid from 2.0 to 2.4; this was estimated by a comparison between the observed scattering profile and the theoretical scattering function of the prolate ellipsoid. The second step supposes that the X-ray scatterer in a solution comprises two kinds of particles with large and small radii of gyration. The X-ray scatterer with a large radius expands with time. By contrast, the radius of gyration of the small scatterer corresponds to that of a native Taka-amylase A monomer and it remains unchanged. These facts imply that in the denaturation of Taka-amylase A the molecule is prolonged by a partial unfolding of the polypeptide chain and then aggregates with each other.

Taka-amylase A (EC 3.2.1.1,α-1,4-glucan-4-glucano hydrolase) is an α-amylase that catalyzes the hydrolysis of α-1,4-glucosidic linkages in polysaccharides. Many studies have been undertaken on Taka-amylase A since Akabori and Okahara extracted the enzyme from *Aspergillus oryzae*.[1] The enzyme is monomeric, composed of a single polypeptide chain (478 amino acid residues[2]) and has a molecular weight of 51000. The three-dimensional structure of Taka-amylase A has been determined at a 3.0-Å resolution by an X-ray crystal structure analysis,[3] and the mechanism of its enzymatic activity has been proposed.[4]

Takagi et al. have studied the renaturation of Taka-amylase A from an acid- or a urea-denaturated molecule by such means as optical rotatory dispersion, pH titration, and sedimentation velocity.[5-7] They have suggested that through acid-denaturation the hydrogen bonds between the side-chain groups are completely cleaved and most of the peptide hydrogen bonds are retained to maintain the structure of the helical region, though the urea-denaturation results in unfolded molecules devoid of secondary and tertiary structures. It has also been reported that the acid-denaturation of Taka-amylase A proceeds very slowly at pH 3.3 with a time resolution of 1 min.[5] For studies concerning the slow change in the structure, it is useful to analyze the structural change with a small-angle X-ray scattering method with a stopped-flow mixing device and a position-sensitive detector. From these points of view, the present paper concerns a study of the time-resolved structural change of Taka-amylase A by acid-denaturation at pH 3.3 by means of stopped-flow small-angle X-ray scattering.

Experimental

Sample Preparation for X-Ray Experiments. Taka-amylase A was isolated from Takadiastase Sankyo according to the method of Akabori et al.,[8] and purified with chromatography on a DEAE-cellulose column. The eluent from the column was desalted by ultrafiltration with a Diaflo YM-30 membrane followed by a repeated addition of distilled water. At the end of the desalting process, the purified protein solution was concentrated to more than 70 mg ml^{-1} by ultrafiltration. The protein concentration of the purified Taka-amylase A, which was determined spectrophotometrically by UV absorption at 279 nm by using $E^{1\%}_{1cm}$=22.1, was then adjusted to be 20.0 mg ml^{-1} by diluting the solution with distilled water. The protein solution was mixed with a 0.1-M glycine/NaCl-HCl (1 M=1 mol dm^{-3}) buffer in the stopped-flow mixing device. The pH of the buffer was determined so that the pH of the mixed solution might be 3.3 (tested at each temperature before X-ray experiments).

Stopped-Flow Mixing Device. A stopped-flow mixing device was constructed by Union Giken Co. Ltd.. Equal volumes of two solutions were mixed in a jet mixer and transferred into a 1.0-mmφ thin-walled quartz capillary using the pressure difference of nitrogen gas; this was also used for draining the mixed solution. The irradiated area was modified so that line-collimated X-rays could completely irradiate the capillary. The temperature in the device was controlled by circulating water with a constant temperature. The temperature of the mixed solution was detected by a copper-constantan thermocouple located beside the capillary and was monitored on a recorder. The dead time between the transmission of the signal and the filling of the tube with the mixed solution was about 100 ms. No meaningful difference was found between the scattering intensity distribution of the distilled water obtained from one time accumulation of 200-s measured data and that obtained from 2000 accumulations of 100-ms measured data. This shows that no mixing artifact was observed during the experiments. About 100 μl of a mixed solution was consumed per shot. The capillary was washed out with two shots of immediately mixed solution just before each measurement was started. All operations for the stopped-flow mixing device were controlled with a microcomputer connected with an X-ray detector.

X-Ray Measurements. The X-ray source was a 0.4×8 mm spot on the copper anode of a Philips fine-focus X-ray tube operated with a Rigaku Denki D9C X-ray generator run at 40 KV, 30 mA. A line focus was used to obtain sufficiently intense scattered X-rays. The spot was foreshortened to 0.04×8 mm at a glancing angle of 6°. The nickel-filtered (10 μm in thickness) X-rays were collimated with a 0.3×10

mm slit, and then reflected and focussed by a nickel-coated glass mirror[9] through two kinds of limiting slits. One was located immediately after a mirror holder to collimate reflected X-rays; the other was located just before a stopped-flow mixing device to reduce the parasitic scattering originating from the edge of the former slit. The scattered X-rays were recorded on a one-dimensional position-sensitive proportional detector (delay-line type). The flowing gas (11 mm in thickness) used was a mixture of 90% argon and 10% methane. The width of the detector window was 10 mm. The detector length was 50 mm and was divided into 256 channels on a multichannel analyzer. The sample-to-detector distance was 310.0 mm. The scattered X-rays were collected in the range of the scattering angles from 3.8×10^{-3} to 7.7×10^{-2} rad. The X-ray path from the stopped-flow mixing device to the detector was evaculated to avoid air scattering. All the X-ray camera units were located in the small chamber with the temperature controlled to be 5 °C (with a cooling unit) in order to prevent dew from appearing on and in the stopped-flow mixing device during low-temperature experiments. X-Ray experiments were performed at 0, 5, 10, and 15 °C, respectively. These temperatures were kept within ±0.1 °C by circulating water with a constant temperature within the device. For each experiment, 32 frames of scattering profiles of 256 points were sequentially stored in the process memory of the multichannel analyzer in the following time pattern: 10 frames of 60 s accumulation with a time gap of 1 s; 6 frames of 60 s accumulation with a time gap of 10 s; 5 frames of 60 s accumulation with a time gap of 60 s; 5 frames of 60 s accumulation with a time gap of 120 s; and 6 frames of 60 s accumulation with a time gap of 240 s. Ten cycles of these measurements were summed and saved on the floppy disk of a microcomputer.

Data Reduction. The scattering intensities recorded on both sides of the primary beam were averaged at equivalent points after subtracting background intensities. The center of the primary beam (zero-angle scattering) was precisely searched so as to realize the best coincidence of the scattering intensities at the equivalent points on both sides of the zero-angle. The coincidences expressed by a reliability factor R_{sym}[10] were all good. The scattering intensity $I(s)$ was then obtained by a deconvolution (desmearing) for the beam-height effects according to the method of O. Glatter.[11] The scattering parameter s is defined by $s=4\pi\sin\theta/\lambda$, where 2θ is the scattering angle and λ the wavelength (λ=1.5418 Å).

Results

Radius of Gyration and Zero-Angle Scattering Intensity. The radius of gyration R_g and zero-angle scat-

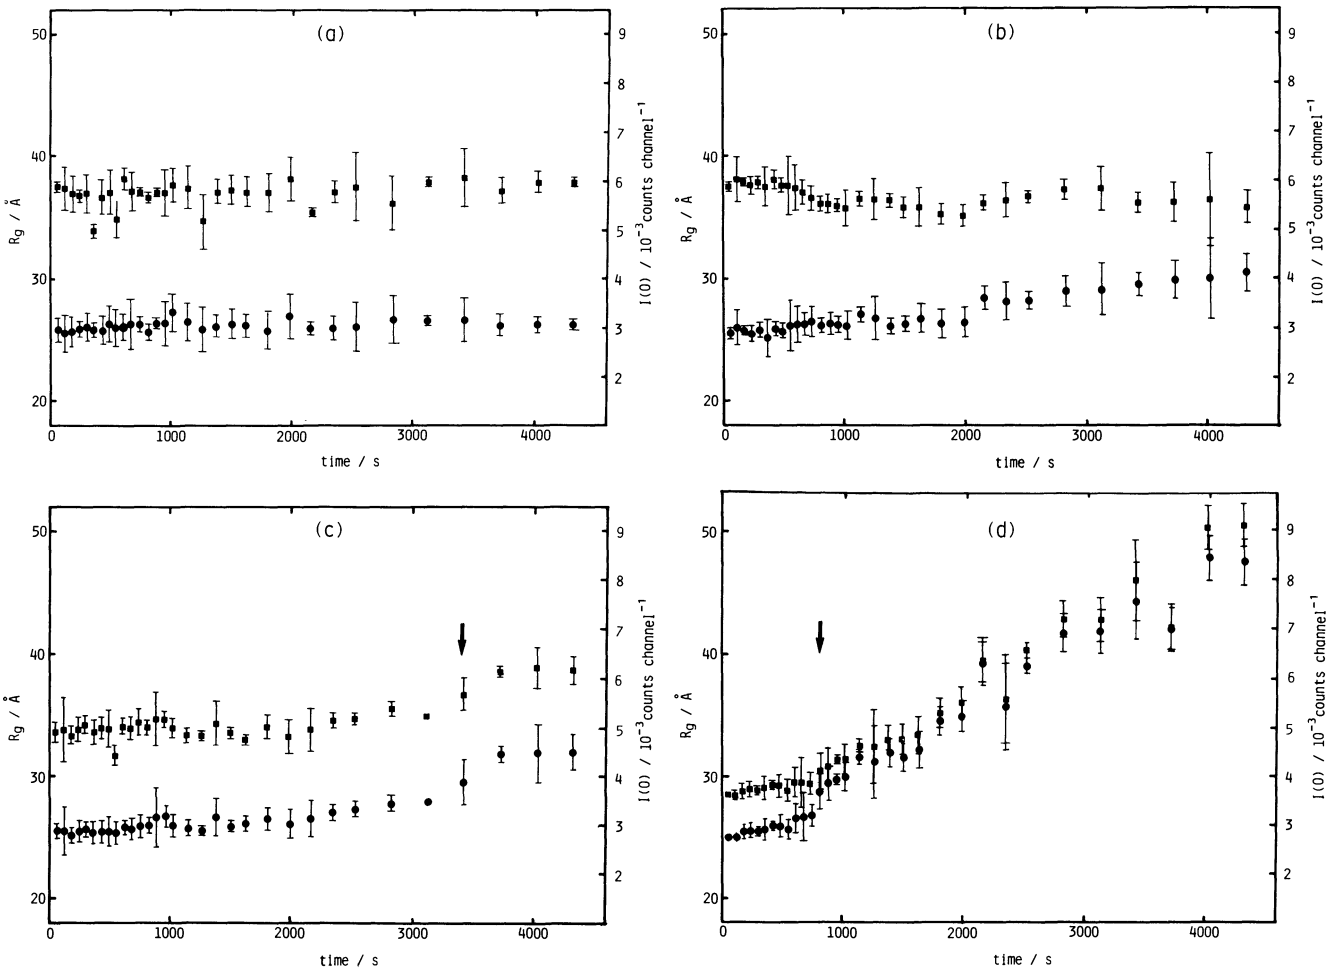

Fig. 1. Time courses of radius of gyration, R_g(●) and zero-angle scattering intensity, $I(0)$(■): (a) at 0°C, (b) at 5°C, (c) at 10°C, and (d) at 15°C. Error bar is drawn by 3σ, where σ is the standard deviation obtained from the least-squares method.

tering intensity $I(0)$ were derived from a Guinier plot[12] of the small-angle scattering profile by a least-squares method. The time courses of R_g and $I(0)$ at each temperature are plotted in Fig. 1. At 15 °C, R_g and $I(0)$ increase appreciably after about 800 s, within the time during which R_g gradually increases and $I(0)$ remains unchanged. This phenomenon was also observed at 10 °C; however the time at which the large increases of R_g and $I(0)$ were observed was retarded to about 3400 s. At 5 °C, only the phenomenon of a gradual increase of R_g and an almost constant $I(0)$ was observed over the whole range of the time course. However, neither R_g nor $I(0)$ changed at 0 °C. These results show that the acid-denaturation of Taka-amylase A can be explained by two steps of a structural change from the time courses of R_g and $I(0)$. Also, its rate is strongly dependent on the temperature. The arrow in Fig. 1 shows the time between the first and second steps. A further analysis regarding the respective steps resulted in the following two paragraphs.

The Time Courses of Structural Parameters in the First Step. The X-ray crystal structure analysis has clarified that the Taka-amylase A molecule is an ellipsoid with approximate dimensions of 35×45×80 Å.[13] Since the ellipsoid was considered to be a prolate ellipsoid of revolution with a semi-axis length of a=20 Å and an eccentricity of w=2.0, the observed scattering profile for each frame was compared with the theoretical scattering function of a prolate ellipsoid (Fig. 2). This comparison was performed in a time range in which $I(0)$ was nearly constant, because the increase of $I(0)$ corresponds to that of the molecular mass.[12] The time courses of the semi-axis lengths, a and b (b=a×w), of the ellipsoid are plotted in Fig. 3. The structural parameters of the initial and the final stages in the first step are summarized in Table 1. Taking account of the hydration in solution and/or the experimental errors, the structural parameters (a, b and R_g) of the initial stage were all in good agreement with those obtained from the X-ray crystal structure analysis[13] (a=20 Å, b=40 Å) and from the ellipsoidal model with a=20 Å and b=40 Å (R_g=22 Å), respectively. These parameters changed with time. As shown in Fig. 3, the eccentricity w of the ellipsoid increased from 2.0 to 2.4 and the semi-axis length a did not change. However, neither a nor w changed at 0 °C. These findings indicate that the native Taka-amylase A elongates with time during the first step of the acid-denaturation.

The Time Courses of Structural Parameters in the Second Step. As described above, the increase of $I(0)$ may be attributed to an aggregation of a Taka-amylase A molecule. Figure 4 depicts Guinier plots of the small-angle scattering profiles at 15 °C. Time frames of 1, 18, 24, and 29 are plotted. The single straight line just after mixing (Fig. 4(1)) can be approximated by two lines (Fig. 4(2)—(4)) with time. The slope of the Guinier plots in the smaller-angle region gradually increases, whereas that in the larger-angle region remains unchanged. This behavior (of the Guinier plot) suggests that the X-ray scatterer in solution is composed of two kinds of particles with different sizes.[14]

Jellinek and Fankuchen have proven that in a polydispersed solution, R_g of each X-ray scatterer can be estimated from the small-angle scattering profile.[15] Figure 5 shows the R_g' s of the two X-ray scatterers derived from the method of Jellinek and Fankuchen using scattering profiles at 15 °C. From the figure it was found that the R_g of the large X-ray scatterer increased with time, and that of the small one remained unchanged and corresponded to that of a Taka-amylase A monomer. This is because the R_g of the ellipsoidal model of Taka-amylase A was estimated to be 27 Å.

The distance distribution function $P(r)$[16] was also calculated by a Fourier transform of the scattering profile at 15 °C. The maximal dimension D_{max} of the particle, which was approximated at an r where $P(r)$ decreases to zero, corresponds to that of the larger particle of the two X-ray scatterers in the present system. The D_{max} becomes larger with time as the R_g of the large X-ray scatterer.

Discussion

As shown in Fig. 1, the time courses of R_g and $I(0)$ could be described by two steps: one a gradual increase in R_g and almost constant $I(0)$, and the other a large increases in both R_g and $I(0)$. Since $I(0)$ corresponds to the square of the number of excess electrons in the X-ray scatterer (for details regarding $I(0)$, see the next stage), the nearly constant $I(0)$ throughout the time means that the morphological change (such as the aggregation or dissociation of X-ray scatterer) was not brought about by acid-denaturation. Therefore, the gradual increase in R_g implies that the internal structure of the X-ray scatterer changes without aggregation or dissociation. On the other hand, the large increase in $I(0)$ indicates that X-ray scatterers aggregate with each other through acid-denaturation; this simultaneously causes a large increase in R_g. In addition, the higher the temperature, the faster they aggregate. The details of the structural changes in the two steps are discussed in the following paragraphs, respectively.

Structural Change in the First Step. The small-angle X-ray scattering method does not give as many structural parameters as does an analysis in the crystalline state. This indicates that a unique structural model could not be constructed in some cases in spite of the recent development of such analytical method as the contrast variation.[16,17] Therefore, the structural change was analyzed regarding the shape of a native Taka-amylase A molecule as a prolate ellipsoid. It was ascertained by X-ray crystal structure analysis. This analysis is supported by the fact that the values of the

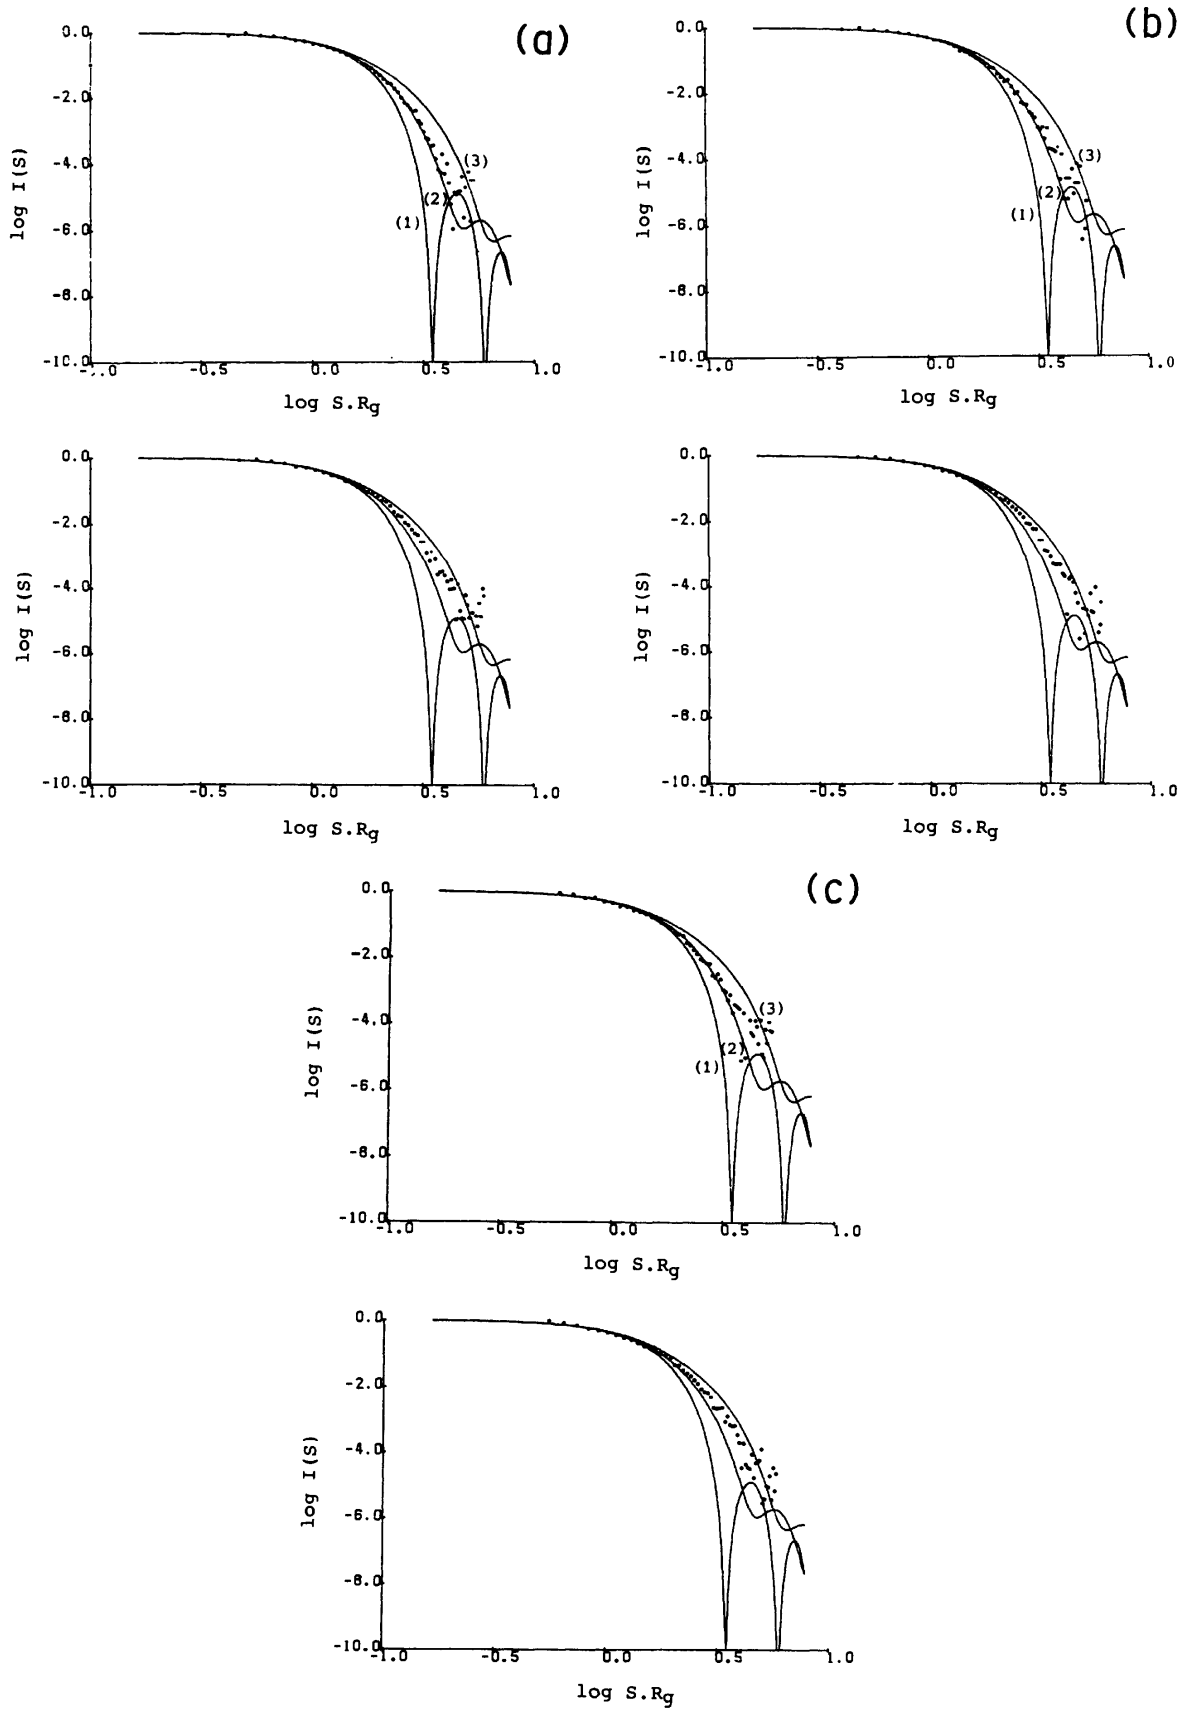

Fig. 2. Log $I(s)$-log s plot of the observed scattering intensities (●). (a), (b), and (c) are the plots at 5, 10, and 15°C, respectively. In (a), (b), and (c), top corresponds to the time frame 1 at each temperature and bottom corresponds to the time frame 32 at 5°C, 29 at 10°C and 13 at 15°C. Superimposed are the theoretical scattering functions (soild lines) of the prolate ellipsoids with the eccentricities, w of (1) w=1.0, (2) w=2.0 and (3) w=3.0.

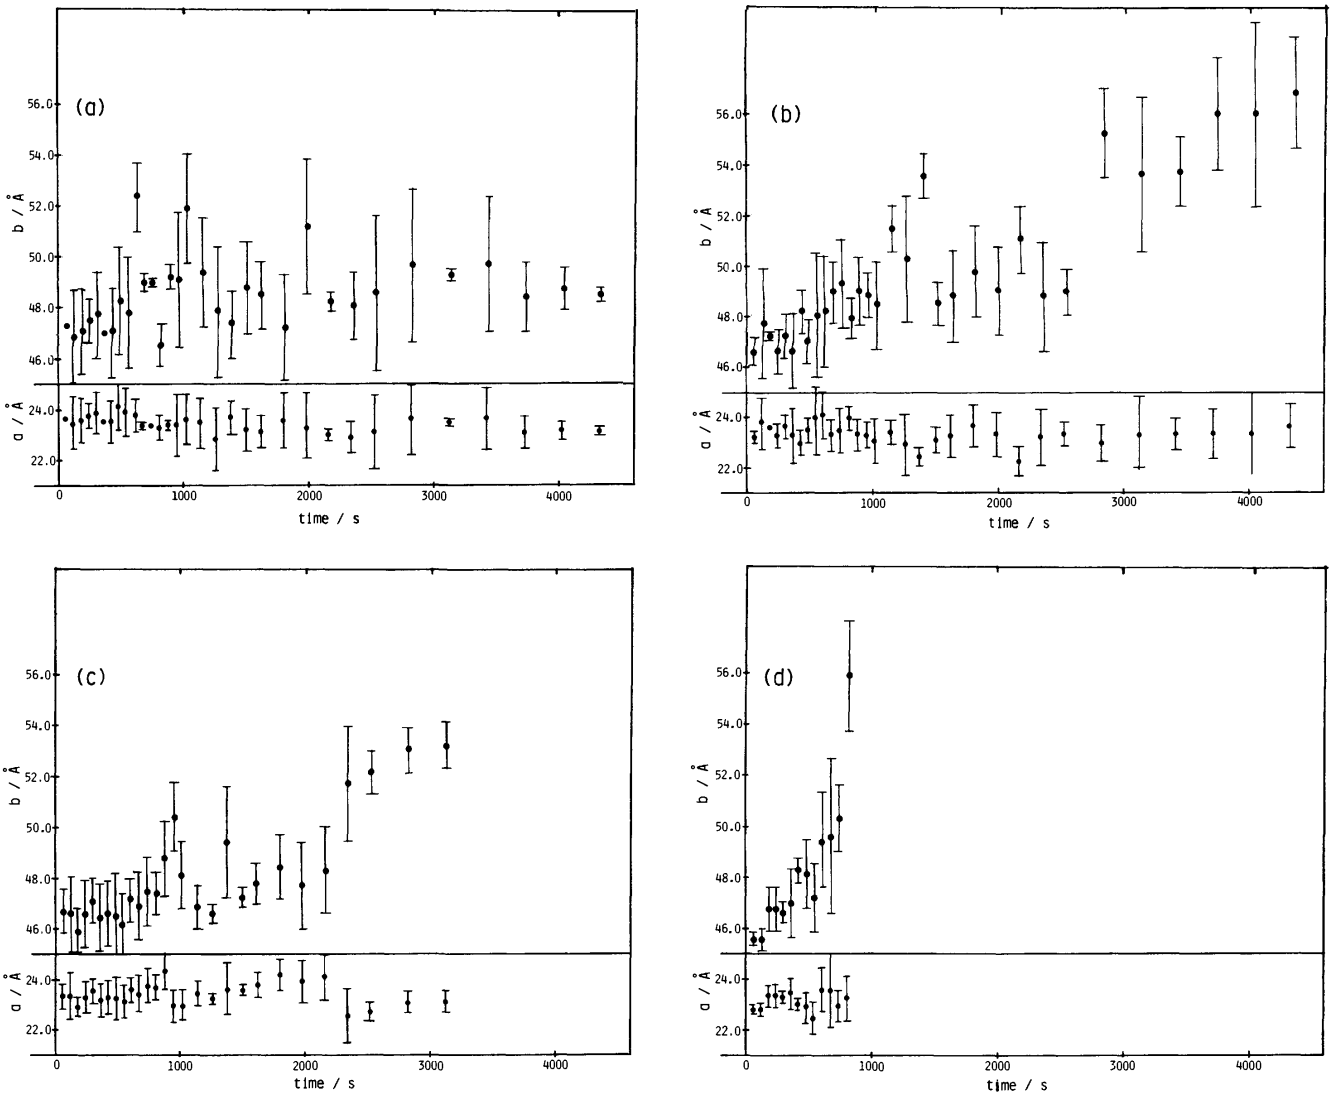

Fig. 3. Time courses of semi-axis lengths, a and b ($b=a\times w$) of a prolate ellipsoid. (a) at 0°C, (b) at 5°C, (c) at10°C, (d) at 15°C. Error bar is drawn by 3σ, where the σ is the standard deviation obtained from the least-squares method.

Table 1. The Structural Parameters of the Initial Stage (Time 1) and the Final Stage (Time 2) in the First Step

t/°C	Time 1/s			Time 2/s		
	R_g/Å	a/Å	b/Å	R_g/Å	a/Å	b/Å

	25.0	22.8	45.6	29.0	23.3	55.9

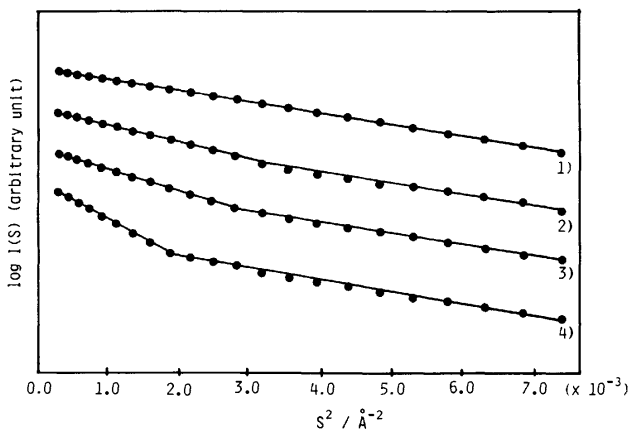

Fig. 4. Guinier plots of the small-angle scattering profiles at 15°C. Time frames 1 (1), 18 (2), 24 (3), and 29 (4) are plotted.

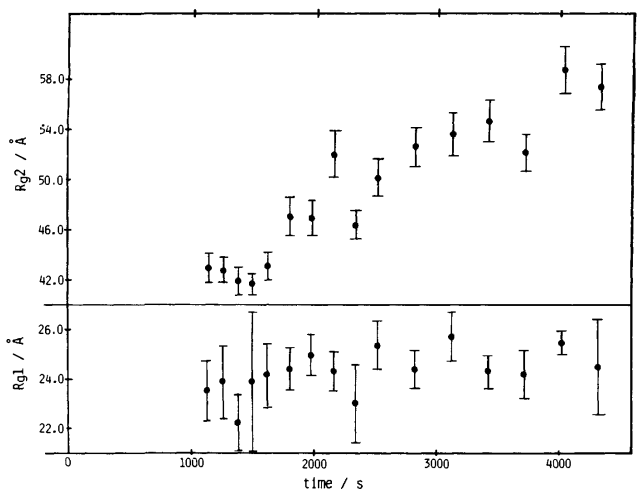

Fig. 5. Time courses of radii of gyration of a small X-ray scatterer, R_g1 and a large X-ray scatterer, R_g2 at 15°C. Error bar is drawn by 3σ, where σ is the standard deviation obtained from the least-squares method.

radius of gyration and the semi-axis lengths (a and b) of the ellipsoid just after mixing (*Time1* in Table 1.) are all in good agreement with those from the X-ray crystal structure analysis. As can be seen in Fig. 3, the eccentricity of native Taka-amylase A gradually increases to about 2.4 until 800 s at 15 °C, 3400 s at 10 °C and 4300 s or more at 5 °C. The semi-axis length a was constant throughout all time. These results show that a Taka-amylase A molecule extends along the b-axis. However, since this extension of the molecule reduces the difference between the average electron densities of the molecule and the solvent, $I(0)$ must gradually decrease, because $I(0)$ is directly proportional to the square of the number of excess electrons in the molecule (sum of the electron density difference over the molecule). The actual state in which $I(0)$ is almost constant may arise from an experimental error in $I(0)$.

Takagi and Toda[6] have indicated that by acid-denaturation the hydrogen bonds between side-chain groups were completely cleaved and most of the peptide hydrogen bonds were retained to maintain a helical region; that is, most helical structures of a Taka-amylase A molecule remain during acid-denaturation. The fact that the eccentricity of the prolate ellipsoid gradually increases and the semi-axis length a is unchanged may arise from a cleavage of the hydrogen bonds between the side-chain groups. This is because a complete destruction of secondary and tertiary structures is expected to provide more drastic changes in the structural parameters. The CD spectra of acid-denaturated Taka-amylase A also showed little difference regarding the α-helix content between native Taka-amylase A and the acid-denaturated one.

The X-ray crystal structure analysis[3] has also clarified the fact that native Taka-amylase A is composed of two large domains (main domain and C-terminal domain) with a narrow cleft between them. These domains are linked by a single polypeptide chain and stabilize each other with some hydrogen bonds. Therefore, the cleavage of the hydrogen bonds by acid-denaturation is expected to cause an increase in the molecular eccentricity; this is because a domain is supposed to be the folding unit of a protein[18] and most of the hydrogen bonds are more stable than those between the two domains. A $(\beta\alpha)_8$ super-secondary structure (β-barrel), similar to those of triose phosphate isomerase,[19] pyruvate kinase[20] or aldolase[21] is found in the main domain of the native Taka-amylase A. The β-barrel contains the active site and protects against the destruction of the large cleft located in the main domain. The destruction of the cleft by the cleavage of the hydrogen bonds is also considered to be one of the factors which cause an elogation in the native molecule.

The small-angle X-ray scattering method, however, does not give much information concerning the internal structure of a molecule. As a result, no direct experimental evidence for the cleavage of the hydrogen bonds between the domains and the destruction of the β-barrel structure has been obtained in the present analysis. It is necessary to analyze the middle- and high-angle scattering intensities which give information about the internal structure. The correlation of the middle- and high-angle scattering intensities with secondary and tertiary structures of protein is now being investigated in our laboratory.

Structural Change in the Second Step. As shown in Fig. 4, the Guinier plot of the small-angle scattering profile at 15 °C became biphasic with time. This phenomenon indicates that the X-ray scatterer in a solution comprises two kinds of particles with different sizes. Using analyses by the method of Jellinek and Fankuchen as well as the distance distribution function, it was elucidated that the large particle further expanded with time and the small one remained unchanged. The R_g of the small particle showed a good coincidence with that of Taka-amylase A monomer. These results indicate that Taka-amylase A molecules aggregate with each other and the X-ray scatterer in solution consists of a large aggregate and a small elongated molecule transformed from native Taka-amylase A by a partial unfolding of the polypeptide chain.

It was, however, shown from a sedimentation velocity study that acid-denaturated Taka-amylase A molecules became highly aggregated with each other to different degrees.[6] However, this may result from the differences in the times at which the X-ray scattering intensities and the sedimentation patterns of Taka-amylase A were measured. In the present X-ray analysis, Taka-amylase A molecules started to aggregate with each other at 800 s after the molecules began to be denaturalized at 15 °C. However, in the sedimentation

velocity study, the sedimentation patterns were measured in an acid-denaturated Taka-amylase A solution dialyzed against a 0.02-M glycine-HCl buffer (pH 2.2) for one day after the enzyme solution was acidified to pH 2.2.[6]

We thank Professor Masao Kakudo for his interest, valuable discussions, and warm encouragement throughout this study.

The Arrhenius Parameters for the Reactions of $N(2^4S_{3/2})$ with Halogen Molecules

Hironobu UMEMOTO,* Teruo UCHIDA, Seiko NAKAGAWA, Shigeru TSUNASHIMA, and Shin SATO†
Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
†Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
(Received May 23, 1986)

The temperature dependence of the rate constants for the reactions of ground-state atomic nitrogen with halogens were measured by means of a pulse radiolysis-resonance absorption technique. The rate constants for iodine and bromine were well expressed by the following Arrhenius expressions below 410 K: $k(N+I_2)=1.1\times10^6 \exp(-1170/T)$; $k(N+Br_2)=1.1\times10^5 \exp(-1490/T)$, in units of $m^3\,mol^{-1}\,s^{-1}$. The rate constant for the reaction with chlorine was found to be 1.1×10^3 $m^3\,mol^{-1}\,s^{-1}$ at 411 K. Below this temperature, the rate constants for $N+Cl_2$ were too small to be measured. The preexponential factors for the I_2 and Br_2 reactions were found to be much smaller than the semiempirically calculated ones. These small preexponential factors suggest that the reactions between $N(^4S)$ and halogens proceed via nonadiabatic routes.

Ground-state atomic nitrogen, $N(2^4S_{3/2})$, is unreactive to stable molecules which do not have unpaired electrons. For example, the rate constants for the reactions of atomic nitrogen with unsaturated hydrocarbons are too small to be measured by ordinary techniques,[1,2] although ground-state atomic hydrogen and oxygen react with unsaturated hydrocarbons once in every ten or one hundred gas kinetic collisions at room temperature.[3,4] The situation is similar in the cases of inorganic species with even-numbered electrons, such as oxygen, ozone, and phosphine.[5,6] The halogen molecules are not exceptions. In the 1960's Phillips and his co-workers measured the rate constants for the reactions of $N(^4S)$ with halogens near room temperature and found that they are several orders of magnitude smaller than that for gas kinetic collisions.[7,8] In our recent work, we also measured the rate constant for the reaction with molecular iodine at 302 K and found it to be 2.4×10^4 $m^3\,mol^{-1}\,s^{-1}$.[1] The slow reaction rates for the addition of $N(^4S)$ to unsaturated hydrocarbons have been explained by the concept of the simple spin-conservation rule.[1] However, the unreactiveness to halogens, as well as to oxygen and ozone,[5] cannot be explained by this concept, because there are spin-allowed and energetically accessible exit channels—for example, the formation of triplet-state nitrogen halide and atomic halogen. In other words, there must be large potential barriers or entropies of activation for these exit channels. Therefore, in order to ascertain why $N(^4S)$ is unreactive, it is necessary to determine the preexponential factors and the activation energies separately. In the present work, we measured the temperature dependence of the rate constants for the reactions of $N(^4S)$ with chlorine, bromine, and iodine, by employing a pulse-radiolysis resonance-absorption technique. The preexponential factors were then compared with those predicted by the semiempirical LEPS (London-Eyring-Polanyi-Sato) and BEBO (Bond Energy-Bond Order) calculations.

Experimental

The experimental apparatus and the procedure were similar to those described in previous publications.[1,9] Atomic nitrogen was produced by the irradiation of a pulsed electron beam generated by a Febetron 706 apparatus. The pseudo-first-order decay in the concentration of $N(^4S)$ atoms was measured by means of the resonance absorption around 120 nm. The temperature of the reaction vessel was controlled by winding it with a nichrome heater or by introducing cold nitrogen gas from boiling liquid nitrogen into the surrounding copper tubing. A temperature controller (Sanyo Rikagaku SR-4000) was used to reduce the fluctuation in temperature within ±2 K. The relationship between the gas temperature in the chamber and the temperature of the outside wall of the chamber was measured prior to the experiments, and the gas temperature for each run was estimated by measuring the wall temperature with a copper-constantan thermocouple. The halogen pressures were measured with a capacitance manometer (MKS Baratron). After measuring the halogen pressure, an excess amount of nitrogen gas was introduced into the vessel. In general, considerable care is required in the measurement of the gas pressure when the temperature of the reaction zone and that of the pressure gauge are different. Under the conditions of viscosity flow, normally when the pressure is over 100 Pa, the pressure at the gauge, P_0, agrees with that at the reaction zone, P. On the other hand, under the conditions of molecular flow, below 0.1 Pa, the ratio of the pressure at the reaction zone to that at the gauge, P/P_0, is equal to the square root of the ratio of the temperature of the reaction zone, T, to that of the gauge, T_0. In the present experiments, the pressures of halogens were in the intermediate region: 0.8—4.0 Pa for I_2 and 3—20 Pa for Br_2 and Cl_2. In other words, P should be between P_0 and $P_0(T/T_0)^{1/2}$. Therefore, at high temperatures and at low pressures, the error in the estimation of the pressures should be around 10 %. However, since the above error decreases with the increase in the pressure, the error in the estimation of the second-order rate constants as well as the Arrhenius parameters should be much smaller than this. Therefore, the rate constants were estimated with using P_0 without corrections.

The sources and purities of N_2, He, I_2, and Cl_2 were the same as those reported previously.[1,9] Br_2 was separated from its aqueous solution (Koso Chemical Co.) and used after repeated trap-to-trap distillation and drying with P_2O_5.

Results

Evaluation of the Arrhenius Parameters. Figure 1

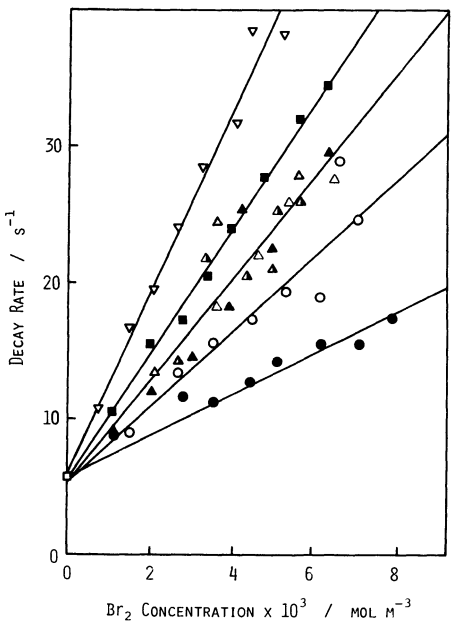

Fig. 1. The decay rate of N(⁴S) as a function of the Br_2 concentration. The temperatures and the total pressures are 410 K and 93 kPa(▽), 387 K and 93 kPa(■), 365 K and 93 kPa(▲), 365 K and 53 kPa(▲), 365 K and 133 kPa(△), 330 K and 93 kPa(○), and 293 K and 93 kPa(●). The symbol □ stands for the average of 24 runs measured in the absence of halogens.

illustrates the dependence of the pseudo-first-order decay rates of N(⁴S) on the Br_2 concentration at several temperatures. As has been observed for the N+I_2 reaction,[1] no total pressure dependence could be observed in this case, either. This suggests that termolecular processes are not important. Similar linear relationships could also be obtained for the cases of I_2 and Cl_2. The intercepts of such linear plots correspond to the decay in the absence of halogens. This value was found to be temperature-independent and to be 6.2± 1.7 s^{-1} (average of 24 runs). In a previous paper, we reported this value to be 3.2 s^{-1}.[1] This change is due to the difference in the reaction vessel. The decay of N(⁴S) in the system of pure nitrogen is considered to be the sum of the homogeneous and heterogeneous recombination of atomic nitrogen. The rate for the homogeneous loss is supposed to be independent of the size of the reaction vessel, while that for the heterogeneous loss may depend on the size. In the present work, we used a smaller vessel in order to obtain better temperature control; this may be the cause of the difference. It should be noted that the room temperature experiments with iodine showed that the slope of the plots was independent of the size of the reaction vessel.

From the slopes of the plots, such as are shown in Fig. 1, the rate constants could be obtained. In a previous paper, we proposed the following reaction scheme for the N_2+I_2 system in order to explain the nonlinear relationship between the decay rate of N(⁴S) and the I_2 pressure in the presence of ethene:[1]

Table 1. Rate Constants for the Reactions of N(⁴S) with Halogens

Reactant	T/K	$k\times10^{-4}$/m³ mol⁻¹ s⁻¹
I_2	410	6.28 ±0.45
	366	3.93 ±0.38
	325	2.95 ±0.17
	302	2.39 ±0.15[a]
	275	1.37 ±0.13
Br_2	410	0.330±0.010
	387	0.226±0.003
	365	0.182±0.010
	330	0.136±0.010

	387	<0.07

a) Ref. 1.

$$N(^4S) + I_2 \longrightarrow NI(X^3\textstyle\sum^-) + I, \quad (1)$$

$$N + NI \longrightarrow N_2(\text{or } N_2^*) + I, \quad (2)$$

$$NI + I_2 \longrightarrow NI_2 + I, \quad (3)$$

$$N + NI_2 \longrightarrow \text{Products}, \quad (4)$$

If NI and NI_2 are not reactive with N(⁴S), the apparent decay rate of N(⁴S) should agree with that for Reaction 1. However, it seems unreasonable to assume that Reactions 2 and 4 are slow. Their rate constants should be of the same order as those for the N+OH, N+CN, and N+NH_2 reactions, which have been measured to be very fast.[10] If NI and NI_2 react with N(⁴S) rapidly, the apparent decay rate should be twice that for Reaction 1. As has been mentioned in a previous paper, the addition of ethyne and 1,3-butadiene, which have been considered to be reactive with NI, to the N_2+I_2 system has halved the apparent decay rate of N(⁴S). This strongly suggests that Reaction 1 is rate-determining and that the apparent decay rate of N(⁴S) in the N_2+I_2 system can be regarded as twice that for Reaction 1. It should also be pointed out that the concentrations of NI and NI_2 are considered to be much less than that of N(⁴S) and that such processes as NI+NI may be neglected. Similar reaction mechanisms may also be assumed for the cases of Br_2 and Cl_2. As for the system of N_2+Cl_2, a reaction similar to Reaction 3, NCl+Cl_2→NCl_2+Cl, has been proposed by Combourieu et al.[11] Table 1 summarizes the rate constants for the reactions of N(⁴S) with halogens calculated by the least squares method at various temperatures. The error limits are the standard deviations. As for Cl_2, the reaction rates were too small to be measured precisely below 387 K. All the data for I_2 and Br_2 are well characterized by Arrhenius equations; the Arrhenius plots are shown in Fig. 2, together with the results of Phillips and his co-workers.[7,8] The Arrhenius parameters, as determined by the weighted least-squares method,[12] are listed in Table 2.

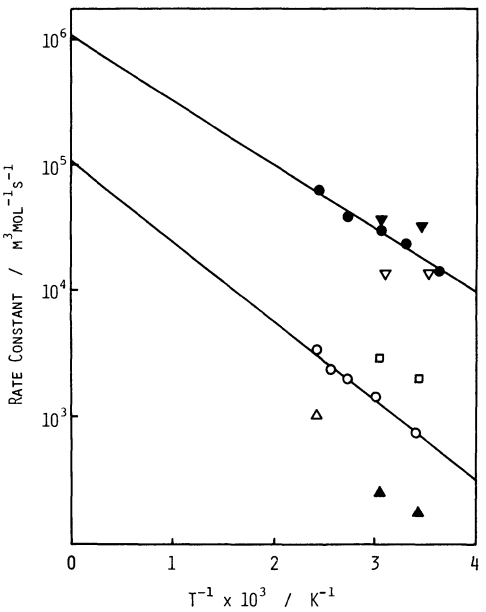

Fig. 2. Arrhenius plots for the reactions of N+I_2(●), N+Br_2(○), and N+Cl_2(△). Results reported by Phillips for N+I_2(▽), and by Grigor and Phillips for N+I_2(▼), N+Br_2(□), and N+Cl_2(▲) are also shown.[7,8]

Table 2. Arrhenius Parameters for the Reactions of N(⁴S) with I_2 and Br_2

Reactant	$A\times10^{-6}$/m³ mol⁻¹ s⁻¹	E_a/kJ mol⁻¹
I_2	1.08 ±0.26	9.7±0.6
Br_2	0.110±0.029	12.4±0.8

Semiempirical Calculations of the Preexponential Factors. The LEPS and BEBO calculations were performed. The general procedures for these calculations have been reviewed by Johnston.[13] In the LEPS calculation, Sato's empirical parameters were adjusted to give the experimental activation energies. The Morse parameters were evaluated from the molecular constants listed in the table of Huber and Herzberg, except for NI.[14] As for those of NI, since the molecular constants were not listed in that table, they were extrapolated from the NF/NCl/NBr series. For a given Sato parameter, the calculated activation energy was the lowest at the linear symmetric configuration in both cases. The force constants for the bending vibrations at the transition states were calculated to be in the order of 10^3 J mol⁻¹ rad⁻². As has been discussed by Mayer et al., the conventional transition state theory should not be used to calculate the rate constants when the bending force constant is less than 10^4 J mol⁻¹ rad⁻², because the amplitude of the vibration becomes too large.[15,16] Therefore, the rate constants were evaluated by the hard-sphere collision treatment.[15,16] From the Arrhenius plots of the calculated rate constants from 280 to 420 K, the preexponential factors were estimated to be 2.5×10^8 and 2.4×10^8 m³ mol⁻¹ s⁻¹ for the N+I_2 and N+Br_2 reactions respectively.

As for the BEBO calculation, many modifications of its original form have been presented.[16-21] Mayer et al. have demonstrated that the anti-Morse function for the repulsion potential must be modified for reactions which involve transfers of atoms other than hydrogen.[17] It has also been suggested that the anti-Morse function should be scaled in some cases.[16-18] In the present work, we not only employed the modification by Mayer et al., but also parametrized the factor of the anti-Morse function to give the experimentally obtained activation energy. The modification to change the Pauling constant, which has been proposed by Gilliom,[20] was also employed, but it was found to have little effect on the final results. The molecular constants of the noble gas clusters which originate from the recent crossed molecular beam-scattering experiments and which are recommended by Bérces and Dombi[22] were used for the calculation. The conventional transition-state theory with unit transmission coefficients was employed to evaluate the preexponential factors. The results are 6.0×10^7 m³ mol⁻¹ s⁻¹ in the cases of both N+I_2 and N+Br_2.

Both of the semiempirical calculations predict the presence of early potential barriers, loose transition states, and, consequently, fairly large preexponential factors for the reactions of N(⁴S) with halogens.

Discussion

Comparison with Literature Values. Figure 2 compares the present results with those of Phillips and his co-workers.[7,8] In Ref. 7, Phillips has mentioned that he performed the experiments on N+I_2 under conditions in which the homogeneous loss of NI is negligible and that the rate constant for Reaction 1 is 1.4×10^4 m³ mol⁻¹ s⁻¹ at room temperature. However, the rate constant cited from this paper by Grigor and Phillips (Ref. 8) is 3.3×10^4 m³ mol⁻¹ s⁻¹. We cannot judge which is more reliable. Therefore, both results are plotted in Fig. 2. At any rate, the present results are not greatly different from those of Phillips. Phillips estimated the activation energy for N+I_2 to be around 0.3 kJ mol⁻¹. This value is much smaller than the present one, and we think their temperature range, 283—323 K, is too small to estimate activation energies. As for Cl_2, the very small rate constants reported by Grigor and Phillips near room temperature are consistent with the present results if the activation energy is in the order of 10 kJ mol⁻¹. In this case, the preexponential factor for N+Cl_2 should be less than that for Br_2. The unreactiveness of N(⁴S) to Cl_2 has also been reported by Iannuzzi and Kaufman.[23] The rate constants for N+Br_2 obtained in the present work are much smaller than those reported by Grigor and Phillips. We have no idea of how to account for this discrepancy.

Comparison with the Semiempirically Calculated Values. As has been mentioned in the Results section, the agreement between the calculated and the observed

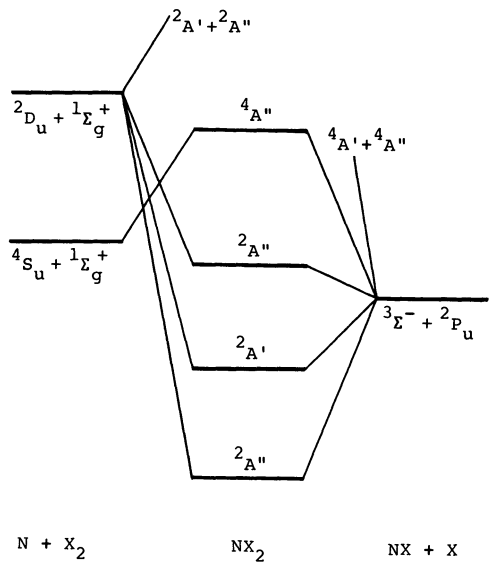

Fig. 3. Schematic correlation diagram connecting the states of N+X_2 and NX+X.

preexponential factors is very poor, especially for the N+Br_2 reaction. The experimental ones are two or three orders of magnitude smaller than the calculated ones. The LEPS method has originally been developed for the system of three hydrogen atoms.[24] Although the LEPS method has been applied to many systems, it is not necessarily accurate enough to evaluate the reaction rates, especially in the systems with p-electrons. The BEBO method has also been developed for the H-atom-transfer reactions. It is also questionable if the conventional transition-state theory is applicable.[25] However, the disagreement between the experimental and the calculated values seems beyond the uncertainty in the experiments or the calculations. In the next section, we would like to discuss the reason why.

Correlation between N+X_2 and NX+X. The reaction between N(^{4}S) and X_2 (X represents halogen atoms) presumably proceeds via a collision complex, N-X-X, in the C_s symmetry. Although the LEPS calculation suggests that the transition state is collinear, this should not be considered to be conclusive, for the LEPS calculation predicts that the geometry of the transition state for the reaction of N+O_2 is also linear, while the more reliable ab initio calculations suggest that it is bent.[26] As is shown in Table 38 of Ref. 27, the ground state and the first and the second excited states of NF_2 in C_{2v} symmetry are doublets. By analogy with the case of NH_2, the energy of the lowest quartet state should be fairly high.[28] This situation will not change in the case of C_s symmetry, or in the cases of the other nitrogen dihalides. On the other hand, the intermediate state which can be correlated with N(^{4}S)+X_2 is a quartet. Therefore, under the assumption of weak spin-orbit coupling, there must be a crossing between the quartet and the doublet surfaces. A schematic correlation diagram is shown in Fig. 3. In such a case, the activation energy for the adiabatic route is very high; the only path to the product state, NX+X, is the non-adiabatic one via a doublet surface, and the preexponential factor should be much smaller than the theoretical one. On the other hand, under the approximation of strong spin-orbit coupling, the level crossings which appear in Fig. 3 are avoided and the reaction can proceed adiabatically. In conclusion, the extremely small preexponential factors for the N+Br_2 and N+I_2 reactions can be explained by considering that the reactions are non-adiabatic, while the increase in the preexponential factor from Br_2 to I_2 may be accounted for in terms of the increase in the degree of the spin-orbit interaction. The preexponential factors for the N+Cl_2 and N+F_2 reactions should be even smaller. Now, we are trying to measure the reaction rates for the N+HI reaction, which is also expected to have a small preexponential factor.

Oxygen-17 NMR Study of the Uranyl Ion. III.[1] Factors Influencing ^{17}O Chemical Shifts of Uranyl Oxygens in Aqueous Perchlorate Media

Woo-Sik Jung, Hiroshi Tomiyasu, and Hiroshi Fukutomi*
Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152
(Received May 29, 1986)

Effects of concentrations of perchlorate ion, nitrate ion, uranyl ion, and acid, isotopic substitutions, and temperature on ^{17}O chemical shifts of oxygen in the uranyl ion (uranyl oxygens hereafter) have been studied in aqueous perchlorate media. Insensitivity of the ^{17}O chemical shifts to $[ClO_4^-]$ leads to the conclusion that the perchlorate ion is not coordinated to the uranyl ion. The stability constant (0.10 ± 0.04 m^{-1} at 25 °C and ionic strength 5.0 m; m=mol kg^{-1}) of a $UO_2NO_3^+$ complex has been obtained from the dependence of the ^{17}O chemical shifts on $[NO_3^-]$. The ^{17}O resonances shift toward the lower field with increasing concentrations of uranyl ion and acid, indicating the possibilities of the dimer formation of the uranyl ion and the protonation of uranyl oxygen atoms in concentrated solution, respectively. Isotope shifts in ^{17}O nuclear magnetic shielding in the uranyl ion are interpreted in terms of the change of mean separation between the ground and lowest excited electronic states upon oxygen and uranium isotopic substitutions. Temperature dependence of ^{17}O chemical shifts is discussed in connection with the isotope effects.

The aqueous solution chemistry of a uranyl ion (UO_2^{2+}) is fundamental and important in understanding chemical and physical properties of the uranyl ion. In spite of many studies on the aqueous solution chemistry, there remain several unsolved problems in the uranyl ion in aqueous solution, e.g. whether or not a counter ion (perchlorate or nitrate ion) is coordinated to the uranyl ion, or whether uranyl oxygen atoms are chemically inert. ^{17}O chemical shifts of uranyl oxygens were reported to be sensitive to the base strength of ligands in the equatorial plane.[1] The ^{17}O chemical shifts were correlated with the reciprocal of the lowest electronic transition energies of uranyl complexes in nonaqueous solvents. ^{17}O NMR spectroscopy plays an important role in studying the uranyl ion because of the sensitivity of ^{17}O chemical shifts to chemical surroundings and the electronic structure of the uranyl ion. In order to pursue the above-mentioned problems in aqueous solution chemistry of the uranyl ion, we have investigated effects of concentrations of perchlorate ion, nitrate ion, uranyl ion, and acid on ^{17}O chemical shifts of uranyl oxygens in aqueous perchlorate solution.

The oxygen isotope effect on ^{17}O NMR spectra of uranyl oxygens reported in previous papers[1,2] will be interpreted on the basis of spectroscopic information which is currently available for the uranyl ion. Temperature dependence of ^{17}O chemical shifts of uranyl oxygens is measured and discussed in connection with the isotope effects in ^{17}O chemical shifts.

Experimental

The uranyl complex and acid used were uranyl perchlorate pentahydrate $UO_2(ClO_4)_2\cdot5H_2O$[2] and 60% perchloric acid (Wako Pure Chemical Ind., Ltd.), respectively. Sodium perchlorate(Wako) and sodium nitrate (Wako) were recrystallized twice from aqueous solution before use. The ionic strength was adjusted by using sodium perchlorate. Procedure for preparation of ^{17}O-enriched uranyl oxygens is described in the previous paper.[2] A 5 mm o.d. NMR sample tube was immersed in a 10 mm o.d. NMR tube containing $(CD_3)_2CO$ (Merck). Measurements of ^{17}O NMR spectra were carried out at 13.46 MHz on a JEOL JNM-FX 100 FT-NMR spectrometer equipped with a JNM-VT-3B temperature controller. Typical spectral settings for the measurements of ^{17}O NMR spectra are as follows: 8 K data points, 90° pulse angle corresponding to ca. 10 μs pulse width, 10 or 20 kHz spectral width (leading to 2.44 or 4.88 Hz digital resolution), and normally 2000 scans.

Results and Discussion

Effects of Concentrations of Perchlorate Ion, Nitrate Ion, Uranyl Ion, and Acid. Addition of $NaClO_4$ (up to 1.5 m) to the solution, where $[UO_2^{2+}]=0.02$ m and $[H^+]=0.06$ m, did not change ^{17}O chemical shifts of uranyl oxygens, while ^{17}O resonance of solvent H_2O shifted toward the higher field by the addition.[3] The former result indicates that the perchlorate ion is not coordinated to the uranyl ion in solution[4,5] as in the solid state.[6] In contrast to the result on the effect of the perchlorate ion, the addition of $NaNO_3$ to the solution, where $[UO_2^{2+}]=0.11$ m and $[H^+]=0.08$ m at ionic strength 5.0 m, increased ^{17}O chemical shifts of uranyl oxygens relative to $(CD_3)_2CO$ at 25 °C, as shown in Fig. 1. This result can be explained by the formation of a $UO_2NO_3^+$ complex:

$$UO_2^{2+} + NO_3^- \overset{K_1}{\rightleftharpoons} UO_2NO_3^+ \quad (1)$$

Assuming that $[NO_3^-]\gg[UO_2^{2+}]$ and the equilibrium reaction is very fast, the observed ^{17}O chemical shifts $\delta(^{17}O)_{obsd}$ is given by

$$\delta(^{17}O)_{obsd} = \delta(^{17}O) + \frac{\Delta\delta K_1[NO_3^-]}{1+K_1[NO_3^-]} \quad (2)$$

or

$$\frac{1}{\delta(^{17}O)_{obsd}-\delta(^{17}O)} = \frac{1}{\Delta\delta}\left(1+\frac{1}{K_1[NO_3^-]}\right), \quad (3)$$

where $\delta(^{17}O)$ is the ^{17}O chemical shift of the UO_2^{2+} ion and $\Delta\delta$ is the difference in ^{17}O chemical shift between UO_2^{2+} and $UO_2NO_3^+$ ions. The positive value of $\Delta\delta$ is

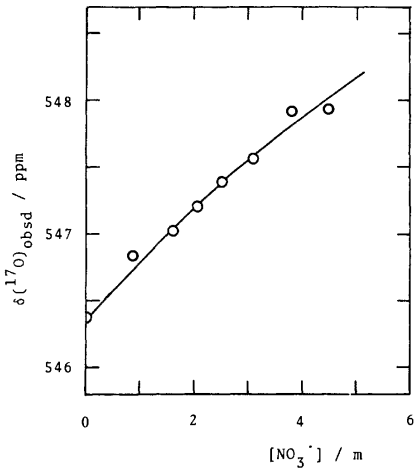

Fig. 1. Dependence of ^{17}O chemical shifts of uranyl oxygens on $[NO_3^-]$ at 25°C and ionic strength 5.0 m. $[UO_2^{2+}]$=0.11 m and $[H^+]$=0.08 m. The ^{17}O chemical shift is referred to external $(CD_3)_2CO$.

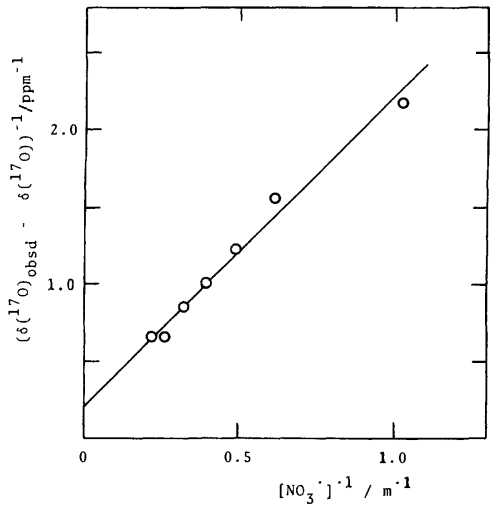

Fig. 2. A plot of $1/(\delta(^{17}O)_{obsd}-\delta(^{17}O))$ vs. $1/[NO_3^-]$ at 25°C and ionic strength 5.0 m. $[UO_2^{2+}]$=0.11 m and $[H^+]$=0.08 m.

expected from the bathochromic shift of electronic absorption bands by the complexation of NO_3^- ion.[1,7] Figure 2 shows a linear relationship between $1/(\delta(^{17}O)_{obsd}-\delta(^{17}O))$ and $[NO_3^-]^{-1}$, as expected from Eq. 3. The formation constant K_1 of (0.10±0.04) m^{-1} was calculated from the slope and intercept in Fig. 2. This value is comparable to the literature values: 0.15 M^{-1} (M=mol dm^{-3}) at ionic strength 6.25 M[4] and 0.21 M^{-1} at ionic strength 5.38 M.[8] The value of $\Delta\delta$ was determined to be (4.9±2.1) ppm at 25 °C.

The $\delta(^{17}O)$ values relative to $(CD_3)_2CO$ at 25 °C increased linearly with increasing concentration of the uranyl ion up to 1.5 m in acidic solution ($[H^+]$=0.06 m), i.e. $d\delta(^{17}O)/d[UO_2^{2+}]$=(0.57±0.11) ppm m^{-1}. This may suggest the possibility of the dimer formation of the uranyl ion

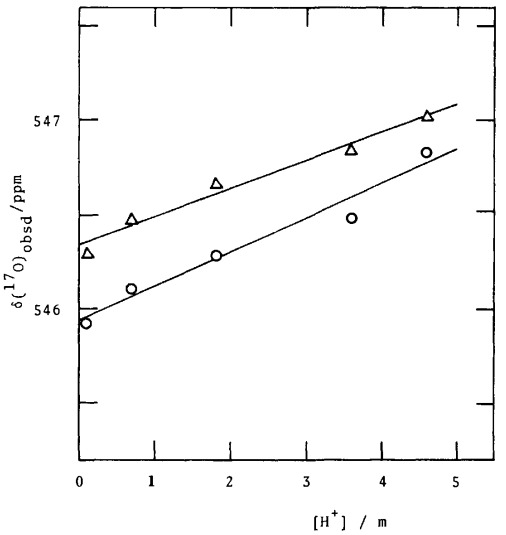

Fig. 3. Dependence of ^{17}O chemical shifts of uranyl oxygens on the acid concentration at 25(○) and 39(△)°C. $[UO_2^{2+}]$=0.1 m and ionic strength=5.0 m. The ^{17}O chemical shift is referred to external $(CD_3)_2CO$.

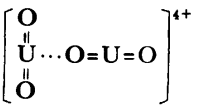

with increasing concentration of the uranyl ion. The coordination ability of uranyl oxygen atoms is well known for UO_2(β-diketonate)$_2$ complexes.[9] The fact that the hydration number of the uranyl ion decreases with lowering H_2O/UO_2^{2+} mole ratios may not be due to the inner-sphere coordination of ClO_4^- as indicated by Åberg et al.,[5] but be due to the dimer formation.

Figure 3 shows that ^{17}O chemical shifts of uranyl oxygens increase with increasing acid concentration. This can be explained by the following fast equilibrium reaction.[10,11]

$$UO_2^{2+} + H^+ \overset{K_2}{\rightleftharpoons} UO_2H^{3+} \quad (4)$$

Assuming that $K_2[H^+] \ll 1$, the observed ^{17}O chemical shift $\delta(^{17}O)_{obsd}$ is given by $\delta(^{17}O)+\{\delta'(^{17}O)-\delta(^{17}O)\}K_2[H^+]$, where $\delta'(^{17}O)$ and $\delta(^{17}O)$ are ^{17}O chemical shifts of uranyl oxygens in the protonated and unprotonated uranyl ion, respectively. Thus the slopes in Fig. 3 correspond to $\{\delta'(^{17}O)-\delta(^{17}O)\}K_2$, whose values are determined to be (0.18±0.02) and (0.15±0.02) ppm m^{-1} at 25 and 39 °C, respectively.

Isotope Shifts. We reported in the previous paper[1] that chemical shifts for the signals of $[^{17}O=U=^{17}O]^{2+}$ and $[^{18}O=U=^{17}O]^{2+}$ isotopomers were observed to be −0.059 and −0.117 ppm, respectively, relative to $[^{16}O=U=^{17}O]^{2+}$. To our knowledge, these isotope shifts are the first finding with respect to two-bond isotope shifts in ^{17}O NMR spectroscopy, and we have attempted to elucidate the origin of these shifts.

The nuclear magnetic shielding is the sum of diamagnetic (σ_d) and paramagnetic (σ_p) terms. The latter

a) In liquid phase.

term is proportional to the reciprocal of the mean transition energy (ΔE) between the ground and excited electronic states,[12] which is obtained by averaging over the vibrational levels of these states. Benedek et al.[13] investigated the dependence of ΔE upon the vibrational frequencies, ω_0 and ω_1, in the ground and excited states. In the temperature range studied ($\omega_{0j}>kT$), the vibronic dependence of the nuclear magnetic shielding for a single excited state can be expressed by

$$\sigma = \sigma_d + \sigma_p\left\{1 + \sum_{j=1}^{p}(4\Delta E_0)^{-1}\left[1-\left(\frac{\omega_{1j}}{\omega_{0j}}\right)^2\right]\omega_{0j}\right\}, \quad (5)$$

where ΔE_0 is the separation of the ground and excited electronic states at the zero vibrational levels, and the summation is carried out over the p normal vibration mode. Since the ratio ω_{1j}/ω_{0j} will not be affected by isotopic substitution, the two-bond oxygen-isotope shift ($\Delta\sigma_{x,y}$)[14] in ^{17}O nuclear shielding of uranyl oxygens ($(^2\Delta^{17}O(^{17,18/16}O))$[15] is given by

$$\Delta\sigma_{x,y} = \sigma_{x,y} - \sigma_{16,17} = \frac{B}{4(\Delta E)^2}\sum_{j=1}^{p}\left[1-\left(\frac{\omega_{1j}}{\omega_{0j}}\right)^2\right](\omega_{0j}^{x,y}-\omega_{0j}^{16,17}). \quad (6)$$

Parameter B (-2.50×10^7ppm cm) can be obtained from the slope in Fig. 4, which shows a linear relationship between the ^{17}O chemical shifts and the reciprocal of the lowest electronic transition energies for compound containing oxygen bonded to transition metals.[16] The ω_{1j}/ω_{0j} value can be taken as $(f_1/f_0)^{1/2}$, where f_0 (7.52 mdyne Å^{-1})[17] and f_1 (6.54 mdyne Å^{-1})[18] are force constants in the ground and lowest excited states, respectively. If three vibrations in the UO_2 unity are assumed to be harmonic and the force constants are unchanged by isotopic substitutions, the effect of isotopic substitutions on vibrational frequencies can be calculated theoretically.[19] The calculated vibrational frequencies in the ground states for various isotopomers are listed in Table 1. The values for a $[^{16}O=U=^{16}O]^{2+}$ isotopomer are those obtained experimentally for the uranyl ion in aqueous solution. The calculated $\Delta\sigma_{17,17}$ and $\Delta\sigma_{18,17}$ from Eq. 6 are 0.063 and 0.12 ppm, respectively, which agree surprisingly with the experimental results, when considered the assumptions involved in deriving Eq. 6 and estimating the parameters. The calculated difference (1.9 cm^{-1}) in the lowest electronic transition energies between $[^{16}O=U=^{17}O]^{2+}$ and $[^{18}O=U=^{17}O]^{2+}$ isotopomers for the hydrated uranyl ion is of the same order as that (5.0 cm^{-1}) obtained experimentally for $Cs_2UO_2Cl_4$.[20]

The one-bond uranium isotope shift in ^{17}O nuclear shielding ($(^1\Delta^{17}O(^{235/238}U))$,[15] which is defined by $\sigma([^{16}O=^{235}U=^{17}O]^{2+})-\sigma([^{16}O=^{238}U=^{17}O]^{2+})$, can be estimated in a similar way. The estimated isotope shift of -2×10^{-3} ppm is too small compared with the linewidth (ca. 1 Hz) of ^{17}O resonance of uranyl oxygens. This might make it difficult to observe the uranium isotope effect in the ^{17}O NMR spectrum. It is noted that no uranium isotope effect was observed in ^{19}F nuclear shielding for UF_6.[21] Isotope shifts in ^{17}O nuclear shieldings so far reported are summarized in Table 2, which shows that the isotope shift becomes larger with increasing fractional change in mass upon isotopic substitution.[22]

Temperature Dependence. We investigated the temperature dependence of ^{17}O chemical shift of uranyl oxygens and the results are shown in Fig. 5. The ^{17}O resonances of the uranyl oxygens shift toward the lower field with increasing temperature ((0.087 ± 0.002) ppm $°C^{-1}$), whereas the ^{17}O resonances of solvent H_2O

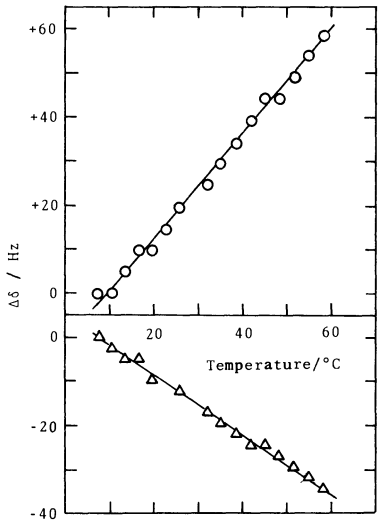

Fig. 5. Temperature dependence of ^{17}O resonances of uranyl oxygens (O) and solvent H_2O (△). The positive sign means the shift to the lower field. $[UO_2^{2+}]$=0.32 M and $[H^+]$=0.01 M.

shift toward the higher field with temperature ((−0.050±0.001) ppm °C^{-1}). The latter is due to the increasing fraction of broken hydrogen bonds with temperature.[3] The former result is in accord with that for temperature dependence of magnetic susceptibility, i.e. the uranyl ion becomes more paramagnetic as the temperature increases.[26] Bell and Biggers[27] resolved the overlapping bands in the absorption spectrum of the uranyl ion in aqueous solution and studied the temperature dependence of position of each band. They showed that the positions of all the bands shift linearly toward the red with increasing temperature. This result consists with that for the temperature dependence of ^{17}O chemical shifts in view of the fact that ^{17}O chemical shifts of uranyl oxygens for uranyl complexes in nonaqueous solvents increase as absorption bands of the complexes shift toward the red.[1]

Changes in ^{17}O nuclear shielding of uranyl oxygens with temperature can arise from the following effects: (1) variation of effective separation between the ground and excited states because of thermal statistical occupancy of the ground vibrational levels[13]; (2) thermal expansion of U=O bond length with increasing temperature, where the energy separation between the ground and excited states is calculated to increase with decreasing U=O bond length.[28]

Effects of temperature and isotopic substitutions on ^{17}O nuclear shielding of uranyl oxygens may be also explained by using Jameson's model,[29] where the nuclear shielding is considered as an electronic property which depends on the relative positions of nuclei. The heavier isotopomer has smaller amplitude of motion than a lighter one on the same potential surface, while the average amplitude of vibrational motion increases with temperature. Thus the average U=O bond length is expected to vary with isotopic substitution and temperatue, resulting in the change in ^{17}O nuclear shielding.

(Received June 4, 1986)

The conformation of molecules of normal alcohols in their pure liquids is estimated through an analysis of their self-diffusion coefficients, viscosities, and molar volumes. The conformation of molecules of shorter chained alcohols (C_1-C_3) is approximately of sphere, while that for longer chains is of rodlike shape. In pure liquids of alcohols, rigid rod molecules whose free rotating motions along their rod axes seem to be restricted, are randomly orientated and entangled with one another. The self-diffusion of long-chain alcohols involves a longitudinal translation of rodlike molecules. Large apparent hydrodynamic radii suggest that the transport unit of normal alcohol is a dimer (on an average) of alcohol molecules.

A linear macromolecule in its solution is known to have many conformations such as a rod and a flexibly coiled shape[1] owing to interaction between solute and solvent molecules. However, the conformation of a small alcohol molecule in pure liquid state has scarcely been investigated probably because of theoretical and experimental difficulties. The present study has thus been made for estimating the rigidity and conformation of molecules of normal alcohol homologs (C_1—C_8) by use of data from viscosity, self-diffusion, and density experiments at 298 K.

Experimental

Materials. Purest grade samples (>99%) of methanol, ethanol, 1-propanol, 1-butanol, 1-pentanol, 1-hexanol, 1-heptanol, and 1-octanol, from Wako Pure Chemical Industries, Ltd., were used without further purification. The water used was triply distilled one. Deuterium oxide (99.75%) from E. Merck AG was used without further purification.

Viscosity. The viscosity of alcohol was measured with two Ostwald capillary viscometers (characterized by times 1 and 3 min required for a given volume of water to flow through their capillaries) in a thermostat with an accuracy of ±0.2 K. Pure water (0.8902 mPa s at 298.15 K)[2] was used for calibrating the viscosity.

Self-Diffusion Coefficient. The self-diffusion coefficient of alcohol was obtained by the pulsed-gradient FT-NMR method.[3,4,5] All measurements were made on protons at 99.6 MHz, with internal D_2O lock, at an ambient temperature of 298±0.5 K on a JEOL FX-100 Fourier transform NMR spectrometer.** A spin echo was produced by a 90°—τ—180° pulse. The gradient was turned on before and after a 180° pulse. The magnitude of gradient, G, can be varied from 0 to about 0.5 T m^{-1}. The absolute magnitude of G was calibrated against the value of the diffusion coefficient of pure water at 298.15 K, 2.30×10^{-9} m^2 s^{-1}.[6]

The diffusional attenuation of a signal for the component i, at the time of echo, is given by[7]

$$\ln\frac{M(G)}{M(0)} = -\gamma^2G^2D_i\delta^2(\Delta-\delta/3), \quad (1)$$

where $M(G)/M(0)$ is the ratio of the echo amplitude in the presence of the gradient to that in its absence, γ the gyromagnetic ratio (2.675×10^{-8} T^{-1} s^{-1} for ^{1}H), δ the duration of each gradient pulse, and Δ the time between two gradient pulses. In our experiments, G was about 0.087 T m^{-1}. The value of Δ was kept constant at 50 ms and δ was varied from 4 to 12 ms. Each sample was placed in a 1 mm-dia. tube inserted in a 5 mm-dia. tube containing D_2O (for NMR lock) for avoiding the saturation of signal. All spectra were obtained with a high signal-to-noise ratio by one pulse sequence. Self-diffusion coefficients were obtained from gradients of ln $M(G)/M(0)$ vs. $\delta^2(\Delta-\delta/3)$ plots.

Molar Volume. Molar volumes for normal alcohols were obtained from their densities.[8] Theoretical molar volumes were calculated by use of the CPK molecular model[9] and by assuming a hexagonal close-packed structure of rods rotating along the axis or pilelike packing of rectangular solids for longer chain alcohols (C_4—C_8) and a face-centered cubic packed structure of spheres for shorter ones (C_1—C_3).

Results and Discussion

Table 1 summarizes values of molar weight, density,[8] viscosity, and self-diffusion coefficient for normal alcohol homologs.

For a moving spherical particle almost equal in size to surrounding solvent molecules under the slip boundary condition, Stokes' equation for frictional coefficient,[5,10,11] f, is given by

$$f = 4\pi\eta a, \quad (2)$$

where π is the ratio of the circular constants, η the viscosity of the solvent, and a the radius of the spherical particle.

Let us apply this equation to a flow of a pure normal alcohol. By assuming a hypothetical sphere with an equivalent radius a_0 for a linear alcohol molecule, the a_0 is expressed as

$$a_0 = \left[\frac{3M}{4\pi\rho N}\right]^{1/3}, \quad (3)$$

where M is the molar weight of the alcohol, ρ the density of the alcohol at 298.15 K, and N the Avogadro number. By substituting a_0 in Eq. 3 for a in Eq. 2, the

**PGNMR measurements were carried out at the Instrument Center of Institute for Molecular Science.

Table 1. Molar Weight (M), Density (ρ), Viscosity (η), and Self-diffusion Coefficient (D) for Normal Alcohol Homologs

	$M/10^{-3}$ kg	$\rho/10^{-9}$ kg m^{-3}	$\eta/10^{-3}$ N sm^{-2}	$D/10^{-10}$ m^2 s^{-1}
Methanol	32.04	0.78664[8]	0.5573 0.5445[8]	23.2[18]
Ethanol	46.07	0.78504[8]	1.056 1.078[8]	10.1[18]
1-Propanol	60.10	0.79975[8]	1.887	5.52[19]

1-Heptanol	116.21	0.8189[8]	5.897	1.72
1-Octanol	130.23	0.8221[8]	7.450	1.42 1.38[19]

frictional coefficient, f_0, for the hypothetical sphere is given by

$$f_0 = 4\pi\eta\left[\frac{3M}{4\pi\rho N}\right]^{1/3}. \quad (4)$$

On the other hand, from Einstein's equation for diffusion, the frictional coefficient is expressed by

$$f = kT/D, \quad (5)$$

where k is the Boltzmann constant, T the absolute temperature, and D the diffusion coefficient.

Combining Eqs. 4 and 5, we obtain

$$f/f_0 = kT/[4\pi\eta D(3M/4\pi\rho N)^{1/3}]. \quad (6)$$

The ratio f/f_0 should be unity when the actual molecule is a sphere. For most rod-shaped or prolate macromolecules including proteins in an organic solvent or in an aqueous solution, the frictional ratio is in general greater than unity.[12]

Figure 1 shows a plot of the ratio against the number of carbon atoms for normal alcohols. The ratios for the short-chained alcohols (C_1—C_3) are almost unity, while, for those with longer chains, they decrease with increasing hydrocarbon chain. This suggests that the molecule of a short-chain alcohol (C_1—C_3) can be regarded as a sphere and that a molecule with a longer chain is deformed more from a spherical shape.

Let us estimate the shape of a long-chained molecule in its pure liquid. By combining Eqs. 2 and 5, the apparent hydrodynamic radius, a, is given by

$$a = kT/(4\pi\eta D). \quad (7)$$

This is the Stokes-Einstein formula under the slip boundary condition.[5,10,11]

In Fig. 2, the Stokes-Einstein radii, a, of the normal alcohols (open circles) are plotted against the hydrocarbon chainlengths, together with the hypothetical radii (filled ones) obtained by substituting the value of the density of normal alcohol into Eq. 3. The latter radii increase monotonously with increase in the chain-length, whereas the former increase up to 1-propanol and saturate at 1-butanol giving a constant value of ca. 3.2×10^{-10} m., which suggests a sphere for the molecules of the short-chained alcohols and a rod with a

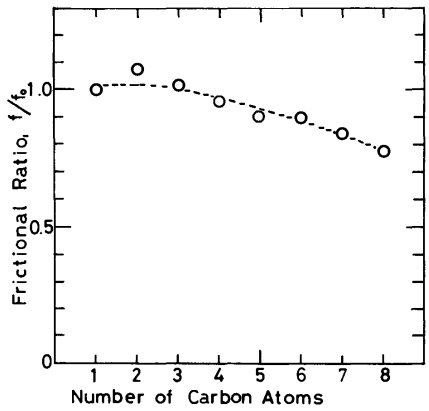

Fig. 1. Frictional ratio, f/f_0, of n-alcohol against the number of carbon atoms at 298.15 K.

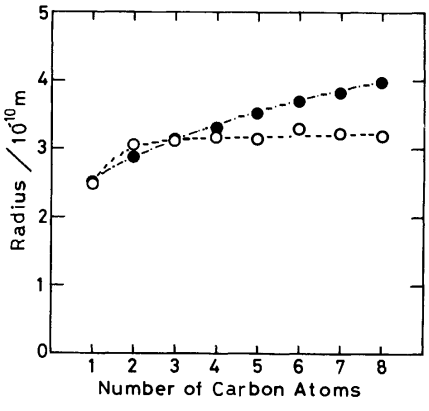

Fig. 2. Molecular radius of normal alcohol against the number of carbon atoms at 298.15 K. Open circles indicate the apparent hydrodynamic radius (the Stokes-Einstein radius), while filled ones were obtained from the density of the normal alcohol according to Eq. 3.

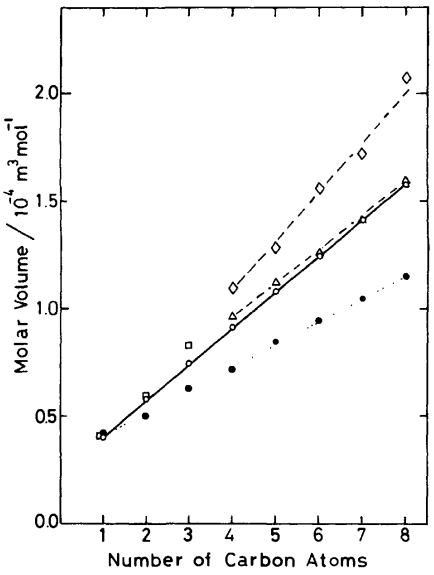

Fig. 3. Effects of the number of carbon atoms in the normal alcohol molecule upon the molar volumes based on the density data,[8] O, and on the CPK model with assumptions of the hexagonal close packing of the rotating rods with a radius of 3.2×10^{-10} m, ◇, the hexagonal close-packing of the rotating rods with a radius of 2.4×10^{-10} m, △, the face-centered cubic packing of the sphere with radii of 2.4×10^{-10} m (methanol), 2.63×10^{-10} m (ethanol) and 2.96×10^{-10} m (1-propanol), □, and the pile-like packing of rectangular rods with a corss sectional area of $3.6\times4.0\times10^{-20}$ m^2, ●.

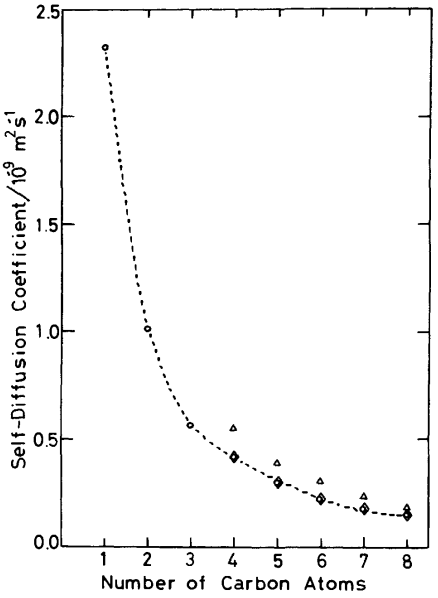

Fig. 4. Self-diffusion coefficient of normal alcohol against the number of carbon atoms at 298.15 K. O, experimental results; △ and ◇, calculated by Eq. 7 using the hydrodynamic radii of 2.4×10^{-10} m, and 3.2×10^{-10} m, respectively.

constant crosssection for the alcohol molecules having longer hydrocarbon chains than 1-butanol.

In order to confirm the validity of the value 3.2×10^{-10} m, which is larger than expected for the crosssection of a hydrocarbon chain in its solid state,[13] the experimental molar volumes based on the density data[8] for the normal alcohols were compared with those based on the CPK molecular model.[9] In Fig. 3 are shown effects of the number of carbon atoms in the normal alcohol molecules on the molar volumes based on various calculations. The sphere molecule model (open rectangles) for the short-chained alcohols, except 1-propanol, gives a molar volume almost equal to that based on the density data[8] (open circles). The molecules of methanol and ethanol can therefore be perfectly spherical in their shape, while the 1-propanol molecule deviates more or less from the spherical shape. For the alcohols having longer carbon chains than 1-propanol, the molar volume values (open circles) are always larger than those based on the pilelike packed model (filled circles) with a value of $3.6\times4.0\times10^{-20}$ m^2*** for the crosssectional area of a rectangular rod, and also too small to be compared with those based on the hexagonal close-packed model (open diamonds) with a value of 3.2×10^{-10} m for the radius of the helically coiled hydrocarbon chain. For the rotating rods whose radii are commonly 2.4×10^{-10} m (a half of the diagonal length for the above rectangular rod), the calculated values (open triangles) are almost comparable with those based on the density data.

If, however, the pure liquid of the normal alcohol consists of the above rotating rods orientated in the hexagonal close-packed structure, optical anisotropy should be observed for the pure liquid of the normal alcohol as if it were a liquid crystal. However, no optical anisotropies such as streaming birefringence have ever been observed for pure liquids of short-chained normal alcohols. The alcohol molecules would therefore be randomly orientated and the free rotating motion along the rodaxis should be restricted, which conditions are in support of the experimental molar volumes. The gradual decrease in the self-diffusion coefficients (open circles in Fig. 4) from 1-butanol to 1-octanol may support the above argument; the straight rodlike molecules entangle with one another and the rotational (end-over-end), as well as transverse,[14] motion of each rod may be severely restricted. The self-diffusion of the long-chained alcohols, therefore, must involve the longitudinal rather than transverse motion of the rodlike molecules.[14]

In Fig. 4 are compared the experimental values of self-diffusion coefficient with the theoretical ones calculated by Eq. 7 with a value of 2.4×10^{-10} m (open triangles) or 3.2×10^{-10} m (open diamonds) for the hydrodynamic radius a. The open diamonds agree exactly with the experimental values. The value of the

***The theoretical cross section of hydrocarbon chain in solid state was obtained by use of the CPK molecular model. The value is in fair agreement with the reference value by X-ray diffraction measurement.[13]

radius (3.2×10^{-10} m), however, does not satisfy the molar volume based on the density data as mentioned above. This discrepancy may be reconciled in terms of dimerization of alcohol molecules through hydrogen bonding of their hydroxyl groups.[15,16] Consequently, the self-diffusion coefficient of such a dimer becomes inversely proportional to the root of the mass for two molecules of monomeric alcohol, when one assumes a hard sphere model[12,17] for the self-diffusion of the alcoholic systems. Thus the hypothetical value of the self-diffusion coefficient for the monomer alcohol gives 2.25×10^{-10} m as the apparent hydrodynamic radius, which seems reasonable for the cross-section of hydrocarbon chain.[13] The values of the apparent hydrodynamic radii of methanol, ethanol, and 1-propanol have been similarly calculated as 1.77×10^{-10}, 2.15×10^{-10}, and 2.20×10^{-10} m, respectively. The significantly small value of methanol results from the extremely large value of its experimental self-diffusion coefficient as compared with those of the other alcohols (see Fig. 4); dimers of methanol molecules seem to be too short to entangle with one another and can translate not only longitudinally but also transversely.

The Epitaxial Growth of the Methyl Triacontanoate Crystal

Yasukiyo UEDA
Department of Industrial Chemistry, Faculty of Engineering, Kobe University, Rokko, Nada, Kobe 657
(Received June 4, 1986)

Methyl triacontanoate (MT) was deposited on the cleavage face of the KCl crystal in vacuo. The MT film was composed of V-shaped crystals growing along two directions crossing at 32°, and these crystals intersected at right angles to each other. The bisectional direction of the V-shaped crystals corresponds to the [110] direction of the substrate crystal. The electron-diffraction pattern from the film consisted of the reflection spots corresponding to the $(hkl)_s$ planes of the subcell and the series of $00l$ reflections in the small-angle region. The crystal structure of the deposited MT crystal was monoclinic in form. The (110) plane of the MT crystal was oriented parallel to the substrate (001) plane, and its c-axis was parallel to the [110] direction of the substrate crystal. The V-shaped crystal was explained by the molecular arrangement in the epitaxial growing crystals. When the substrate was kept at a higher temperature than the melting point of MT, the deposit coagulated to disk-like crystals whose c-axis was perpendicular to the substrate.

Recently organic thin films have attracted a good deal of attention for use in new systems which enable one to draw out various functions by the design of the molecular construction and various combinations. Their electronic, photoelectronic, and optical properties can be expected to improve those of metals and inorganic compounds. These properties are probably controlled by the molecular arrangement in the films. The techniques for preparing organic films can be divided into two types of processes: dry and wet. The Langmuir-Blodgett (L-B) method has been well developed as a wet process, and the properties of L-B films have been reported by many workers.[1] However, the L-B method can be applied only to amphiphilic molecules. In the case of vacuum-evaporation as a dry process, on the contrary, there have been many reports on the structures and nucleation mechanisms of metals and inorganic compounds, but few reports on those of organic compounds.[2-5]

Ashida and his co-workers have studied the epitaxial growth from the vapor phase of polycyclic aromatic[6-8] and linear molecules, such as paraffins,[9] polyethylene[10] and polypropylene.[11] Paraffin molecules took two orientations on the cleavage surface of alkali halide, depending on the evaporation conditions. The films deposited on the cleavage face of alkali halide crystals kept at room temperature were found to be composed of raft-like crystallites. The (110) plane of these crystals was oriented parallel to the substrate (001) plane, and their fiber axes were parallel to the [110] direction of the substrate crystal. When paraffins were deposited on the substrate kept at temperatures near or above their melting points, the films were composed of discrete disk-like crystals and their fiber axes were oriented perpendicular to the substrate. The linear polymers, such as polyethylene and polypropylene, were decomposed thermally to compounds of a low molecular weight during the evaporation process; these compounds also took an orientation similar to that of the paraffin crystals. The crystals composed of linear molecules probably exhibit a distinguished anisotropy of electrical and mechanical properties as a result of interaction between long-chain molecules. It is well-known that these crystals exhibit polymorphs depending on the crystallization temperature. It is interesting to investigate the effect of end group on the morphology and orientation of linear molecular crystals. In this work, the epitaxial overgrowth of methyl triacontanoate (MT) film evaporated on the potassium chloride (001) surface was studied by using an electron micrograph and electron diffraction.

Experimental

MT ($C_{29}H_{59}COOCH_3$, mp, 71.0 °C) was obtained from the Tokyo Chemical Industry Co., Ltd.. The purity of the MT was 99.5%. The single crystal of potassium chloride used as the substrate was cleaved in air and immediately placed in the evaporation chamber. After the substrate had been baked out at 200 °C for one hour in 1.33×10^{-3} Pa, the MT was evaporated vertically from a quartz crucible heated with a tungsten coil onto the substrate surface, which was kept at a temperature between 20 and 90 °C. The average thickness of the deposited film, monitored by means of a quartz crystal microbalance, was 100 nm. The specimen used for electron microscopy was prepared by the dissolution of the substrate in water after the film had been reinforced with evaporated carbon film. The orientation of the deposited crystal related to the substrate crystal was determined by shadowcasting the chromium metal along the [100] direction of the substrate crystal. Thallium(I) chloride prepared by evaporation was used as a standard calibration material for the spacing measurements.

Results and Discussion

The features and orientation of the deposited crystallites depend on the evaporation conditions. The crystalline size increases generally with an elevation of the substrate temperature, whereas the crystal shape and the molecular orientation have a close relation to the substrate treatment, mainly the bake-out procedure of the substrate. When MT was evaporated onto a cleavage surface of potassium chloride without heat treatment, the film was composed of randomly-oriented granules about 100 nm in diameter. When, on the other hand, the substrate was heated at 200 °C

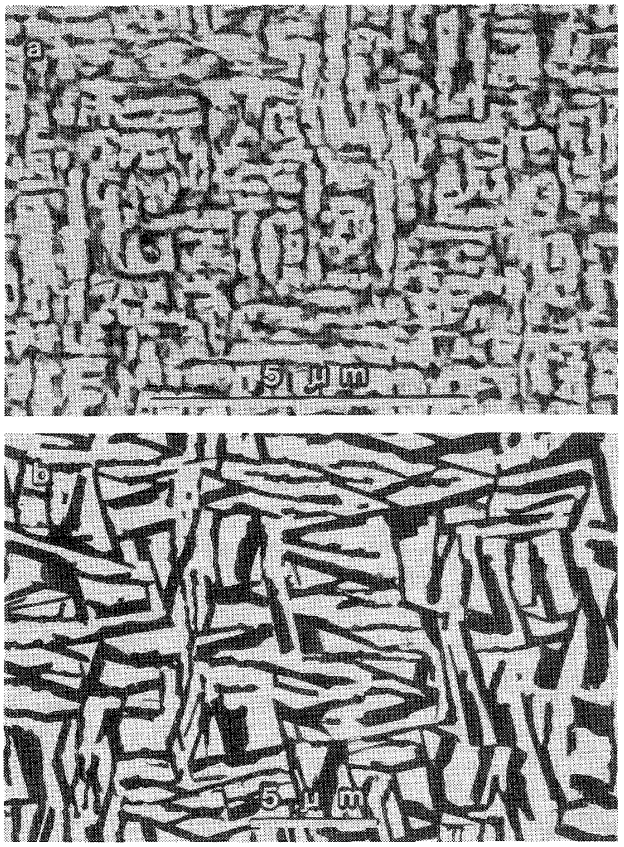

Fig. 1. Electron micrographs of MT films vacuum-deposited on the (001) plane of KCl kept at 20°C (a) and 30°C (b) after being preheated at 200°C.

for 1 h in advance and then kept at about 20 °C, the MT film vacuum-deposited on the substrate was composed of string-like crystals, as is shown in Fig. 1 (a). Although these crystals appeared to cross each other at right angles, careful observation showed that each string-like crystal was composed of many small rod-like crystals. A slight elevation of the substrate temperature to 30 °C caused a considerable growth of the crystallites, as is shown in Fig. 1 (b). The film was composed of V-shaped crystals growing along two directions crossing at 32°, and the [110] direction of the substrate crystal corresponded to the bisectional direction of the V-shaped crystals. These crystals intersected at right angles to each other. Figure 2 shows the electron-diffraction pattern from the film. This diffraction pattern as well as the intensity appeared identical to the diffraction pattern from hexatriacontane film reported in a previous paper.[9] Although the crystal structure of MT has not been reported, it seems that the evaporated films of MT and paraffin are similar in crystal structure and take the same orientation. In order to generalize the similarity detected among the crystal structures of chain molecules, Vand has introduced the concept of a subcell determined by the positions of the methylene groups.[12] The most widely encountered type of subcell is the orthorhombic paraffin cell. The crystals, composed of chain molecules, have long spacings which are defined as the distance between the basal planes of the crystal lattice passing through the end groups of the chain molecules. These distances are of the order of a chain length of one molecule. Francis and Piper have measured the long spacings of a series of methyl esters of fatty acids containing carbon atoms from 16 to 38.[13] The long spacings of these esters fall accurately on two individual straight lines corresponding to their carbon number. The line for the esters containing an odd number of carbon atoms lies about 0.5 Å above the line of the even. Malkin found that methyl esters containing an even number of carbon atoms have only one crystal form, in which the chains are tilted 63° relative to the basal plane.[14] Because the MT molecule contains 30 carbon atoms, it seems that the MT crystal belongs to the same crystal form as those crystals with even carbon atoms and that its long spacing is 150 Å. Among the homologous series of methyl esters with the even number of carbon atoms, the crystal structure of methyl stearate (C_{18}) is investigated in detail. The crystal form is monoclinic, with dimensions of $a=5.61$, $b=7.33$, $c=106.6$ Å, and $\beta=116°\ 47'$.[15] The carbon chains are arranged in an orthorhombic packing, $O\perp(101)$, and the subcell dimensions are $a_s=5.07$, $b_s=7.33$, $c_s=2.53$ Å, and $\beta_s=89°$, the suffix s indicates the subcell lattice. On the basis of these results, it is assumed that the crystal dimensions of MT are $a=5.61$, $b=7.33$, $c=150$ Å, and $\beta=116°\ 47'$, including the subcell of $a_s=5.07$, $b_s=7.33$, $c_s=2.53$ Å, and $\beta_s=89°$. The relationship between the unit cell and the subcell is represented schematically in Fig. 3. The (001) plane of the unit cell corresponds to the (101) plane of the subcell, and the (110) plane is held in common between the unit cell and the subcell. The electron-diffraction

pattern shown in Fig. 2 showed the reflection spots corresponding to hkl_s of the sublattice and a series of $00l$ reflections in the small-angle region. On the basis of the subcell dimensions, the reflection spots in Fig. 2 were indexed as is shown in Fig. 4, in which the closed circles represent the basic single-crystal pattern. The total pattern is overlapped by rotating the pattern at 90°. All the crystals are classified as A- or B-set, corresponding to the reflection spots indicated by the closed and the open circles. As a result of the finite thickness of the layers, the reflection spots are elongated in the direction perpendicular to the layer surface. They intersect at the points and/or in the elongated intensity regions of the reciprocal lattice with the Ewald sphere. From a consideration of the observed and calculated spacing as well as the intensities, the reciprocal lattice points, 250_s and 002_s, were found to lie directly on the Ewald sphere. The direction of the c_S-axis corresponds to the [110] direction of the substrate crystal. Consequently, the a_s-, b_s-, and c_s-axes of the subcell lattice are inclined to the normal of the substrate surface at angles of about 30°, 120°, and 90° respectively. On the other hand, the normal of the (110) plane is inclined to the a_s-, b_s-, and c_s-axes at angles of about 34°, 124°, and 90° respectively. When the two sets of angles are compared, it is found that the (110) plane of the MT crystal is oriented parallel to the substrate (001) plane and that its c-axis lies parallel to the [110] direction of the substrate crystal. From a consideration of the molecular arrangement, these findings indicate that the close-packed layer of molecules lies parallel to and adjacent to the substrate face and that the chain molecules are aligned along the lines of the same charge in the substrate [110] direction. The $00l$ reflection spots of hexatriacontane crystals were clearly observed on the line between the point of origin and the 001_s reflection spot; they divide the space into half the number of its carbon atoms, as has been described in a previous paper.[9] In the case of the MT crystal, the lines of the $00l$ reflection spots intersect the equator by an angle of about 74°, the spot intensities on the line through the point of origin are very weak, while those on the line through the 110_s reflection spot are relatively strong. The crossing angle between c_u*- and c_s*-axes, in which the suffix u indicates the unit lattice, is calculated to be about 16° when these axes are projected on the (110) plane. Therefore, the direction of the $00l$-reflection-spots line corresponds to the direction of the reciprocal c_u*-axis of the crystal, indicated by a dotted line in Fig. 4.

In order to determine the molecular orientation of

MT, the film was tilted against the incident beam. When the film was tilted about 23° around the [110] axis of the substrate crystal, that is, the c_u-axis of the B-set crystals, so that the incident beam became perpendicular to the reciprocal c_u*-axis of the A-set crystals, $00l$ reflection spots clearly appeared on the line through the point of origin and intersected the equator at about 74°, as is shown in Fig. 5. Because the order of $00l$ reflection spots appeared to be more than 50th, it seems that the crystallinity of the evaporated MT film is very high. The reflection spots were indexed as is shown in Fig. 6. The diffraction pattern from the A-set crystals contained hkl_s spots of the sublattice and the series of $00l$ reflection spot crossing each other at about 32°, while that from the B-set crystals shows the net pattern of 110_s and 001_s reflection spots. The reflection spots of the A-set crystals show a mirror symmetry, whose mirror plane corresponds to the (110) plane of the substrate crystal. Therefore, two MT crystals (A_1- and A_2-sets), related with mirror symmetry, and oriented so as to cross each other at about 32°. The long spacing was found to be 75.0 Å by the measurement of the distance of the $00l$ reflection spots. Because of the symmetry of the MT crystal, $00l$ reflections are absent when l is odd. The observed intensities of the $00l$ reflection spots are strong when l is $4n$, while they are very weak when l is $2n$. The calculated values of the structure factor of the $00\cdot 4n$ reflection are several times higher than those of the $00\cdot 2n$ reflection. This phenomenon was also observed in the methyl stearate crystal.[15] These facts suggest that the longer the aliphatic chain length, the less the effect of the end groups on the structure factor. Considering the rule of the absent reflection, the long spacing ($=c\sin\beta$) of the MT crystal is determined to be 150.0 Å. This value agrees well with the one calculated as has been described in a previous section. Since the $12l$ and its higher-order reflection spots from the A-set crystals appeared strongly, the reciprocal lattice points, 120_s and 001_s, were found to lie nearly on the Ewald sphere. The intersection angle between the normal of the (110) plane and the zone axis [210] of the $(001)_s$ and $(120)_s$ planes is calculated to be about 21°. This value coincides well with the tilting angle of the film against the incident beam.

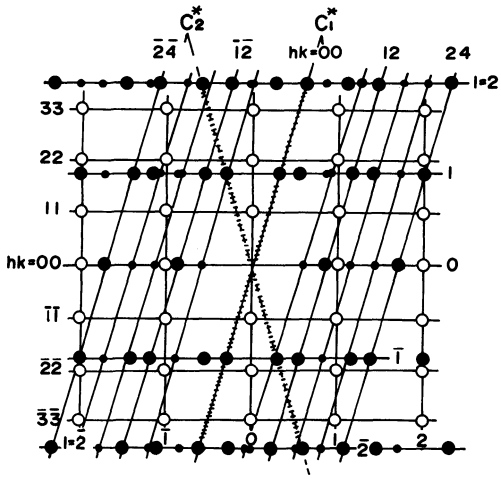

Fig. 6. The interpretation of the diffraction pattern shown in Fig. 5.

On the other hand, the diffraction pattern from the B-set crystals shows the single net pattern of the higher-order reflections of 110_s and 001_s. Each reflection spot has a very strong intensity and shows a streak to the reciprocal c_u*-axis of the crystal. Figure 7 shows schematically the relationship of the B-set reflection

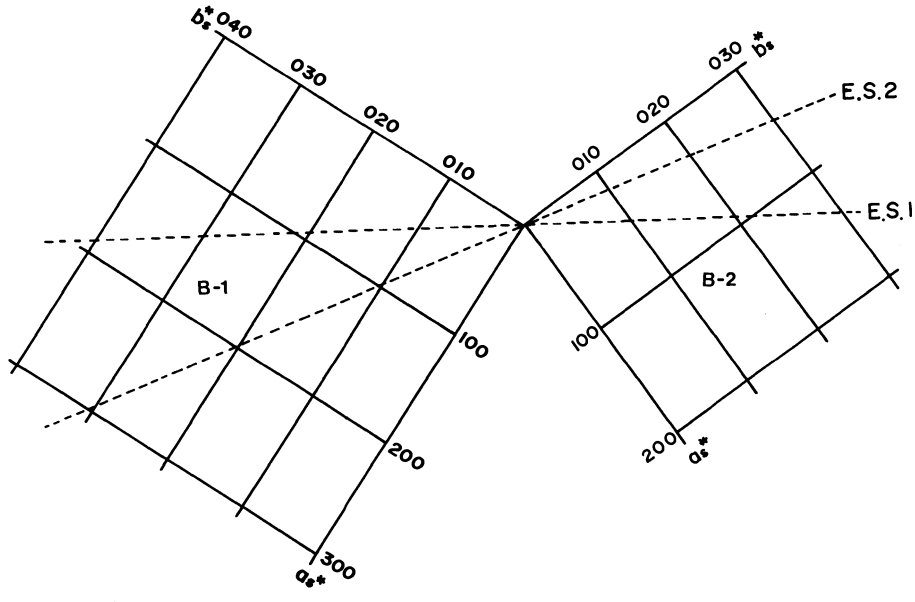

Fig. 7. Schematic diagram of the reciprocal B-set lattice points and Ewald spheres corresponding to Figs. 2 and 5. The lines of E.S.1 and E.S.2 represent the cross sections of Ewald sphere before and after tilting the film.

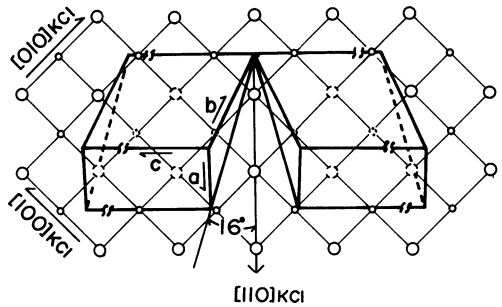

Fig. 8. Schematic diagram of the relative orientation of MT crystals and KCl (001) surface.

spots before and after tilting the film by 23°. The lines of E.S.1 and E.S.2 represent the cross-sections of the Ewald sphere before and after tilting the film. Before tilting the film, the 120_s and 130_s lattice points of the crystals related to the mirror symmetry in the B-set (B_1-and B_2-sets) and situated near the E.S.1. After tilting the film, on the other hand, 110_s and its higher-order reflection spots of the B_1-set crystal came to lie directly on the E.S.2.

The epitaxial overgrowth of MT crystals on the surface of potassium chloride is represented schematically in Fig. 8. The (110) planes of the two crystals related by mirror symmetry, whose mirror plane corresponds to the (110) plane of potassium chloride, are oriented parallel to the substrate surface. Their *c*-axes are parallel to the [110] direction of potassium chloride. Consequently, the [110] direction of the MT crystals crosses the [110] direction of the substrate crystal at 16°. The longitudinal directions of the deposited MT crystals cross at 32°, corresponding to such a molecular orientation. Therefore, the morphology of the deposited MT is V-shaped and these V-shaped crystals grow epitaxially, crossing each other orthogonally corresponding to the C_{4v} symmetry of the substrate crystal.

When the substrate was kept at a temperature between 80 and 90 °C, the MT vacuum-deposited on the substrate formed discrete, disk-like crystals, as is shown in Fig. 9 (a). The electron-diffraction pattern from these crystals shows the single net pattern of higher-order reflections of 100_s and 010_s, as is shown in Fig. 9 (b), which indicates that the *c*-axes of the crystals are perpendicular to the substrate surfaces. This diffraction pattern is similar to the pattern obtained from solution-grown crystallites of linear molecules. It is well-known that the crystals of linear molecules containing MT grow in lamellae from organic solutions. This fact suggests that this crystal habit of linear molecules is the most stable form thermodynamically.

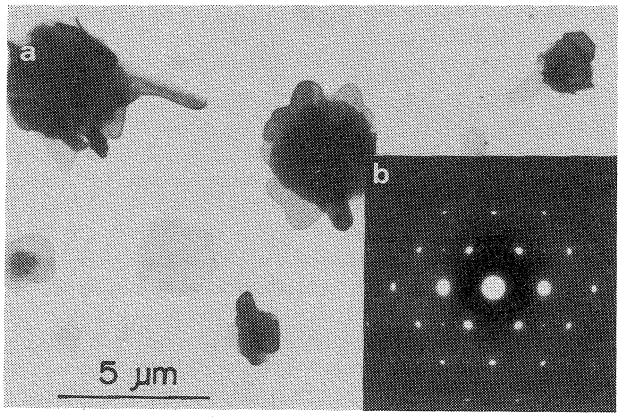

Fig. 9. Electron micrograph (a) and electron diffraction (b) of MT crystals deposited on KCl at 80°C.

When the substrate is kept at a higher temperature than the melting point of MT, the deposit melts completely on the substrate and crystallizes independently of the molecule-substrate interaction on cooling.

The author wishes to express his thanks to Professor Michio Ashida of his helpful discussions. Thanks are also due to Mr. Hisao Yanagi for his assistance.

How Do Proton Chemical Shifts Reflect Aromaticity ? Graph Theory of the Secondary Magnetic Field Due to Ring Currents

Jun-ichi AIHARA
Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka 422
(Received June 7, 1986)

A secular determinant for a polycyclic conjugated molecule, combined with a test dipole, is definable as a function of the applied magnetic field. It was found that this determinant can be expanded graph-theoretically into a characteristic polynomial. A secondary magnetic field is brought about by so-called ring currents. A new formula for evaluating the secondary field was derived by applying Newton's method to this polynomial. This formula indicates that the secondary field at any point in the molecular plane is given exactly as a sum of the contributions of all π-electron circuits. The contribution of each π-electron circuit is expressible in terms of a pure geometric factor and an aromatic stabilization energy assigned to the circuit. The secondary field and then the proton chemical shifts can thus be related to aromaticities of individual π-electron circuits. Magnetotropism of most polycyclic conjugated molecules can be rationalized in this manner. π-Electron circuits which share the conjugated atom nearest to a given proton dominate the chemical shift. In general, a peripheral π-electron circuit contributes modestly to the overall thermodynamic stability of a molecule, but contributes much to the secondary fields at attached protons.

It is well-known that ring currents are induced in an aromatic hydrocarbon on application of an external magnetic field.[1,2] Ring currents are equivalent to magnetic shells, and the field at an attached proton consequently differs from the applied field owing to the resultant secondary field.[3-6] A significant part of the deshielding of aromatic protons is presumed to be due to ring current effects.[3-7] The deshielding can be estimated from what we call proton chemical shifts, i.e., shifts in the magnetic resonance peaks of the protons.[6]

In 1958, the secondary magnetic field was formulated independently by Pople and McWeeny within the Hückel framework.[4-6,8,9] The problem of finding a secondary field differs somewhat from that of finding London susceptibility, i.e., magnetic susceptibility associated with ring currents.[2] Pople managed to expand London's field-dependent secular determinant[2] into a characteristic polynomial, and solved the problem.[4] McWeeny introduced an infinitesimal test dipole into an aromatic molecule placed in the magnetic field, and evaluated the coupling energy between the dipole and the induced current distribution in the molecule.[5,6,8,9] The secondary field experienced by the dipole was obtainable from it. McWeeny employed the perturbational technique of Coulson and Longuet-Higgins[10] to derive the secondary field.

In 1979 Sachs' graph theory[11-14] proved very useful for expanding the field-dependent secular determinant for an aromatic molecule straightforwardly into a characteristic polynomial. We succeeded in devising the graph-theoretical formulas of London susceptibility and ring currents for cyclic conjugated systems.[15-26] Our graph-theoretical formula of London susceptibility established the existence of a distinct relationship between aromatic stabilization and diamagnetic susceptibility exaltation.[15,20,21] Diamagnetic susceptibility exaltation is an experimental manifestation of London susceptibility.

Sachs' graph theory[11-14] can likewise be used to formulate the secondary magnetic field experienced by the test dipole in a polycyclic aromatic molecule. McWeeny's secular determinant for such a system[5] can be expanded graph-theoretically into the characteristic polynomial. The secondary field at any proton can then be deduced without using any complicated perturbational technique. In this paper we present the graph-theoretical formulas thus obtained for ring currents and secondary fields. They are expressed in terms of pure geometric factors and circuit currents[24,25] or circuit resonance energies.[20,21] As will be seen, this kind of formulation is very useful for answering the question as to why and how proton chemical shifts reflect aromatic stabilization of a cyclic conjugated system.

General Terminology and Notation

Some unfamiliar terms and symbols are surveyed beforehand. A given conjugated molecule is denoted by G, which is assumed to have N conjugated atoms. In this paper, we deal only with cyclic conjugated molecules. If G is cyclic in geometry, one or more cyclic paths can be chosen from it. Such cyclic paths are termed π-electron circuits,[25,27] which are identical with ring components in Sachs' graph theory.[11-14] All possible cyclic paths in G constitute an entire set of π-electron circuits. The tth π-electron circuit is denoted by r_t. For example, seven π-electron circuits can be chosen from the acenaphthylene conjugated system. They are two six-membered, one five-membered, one ten-membered, and two nine-membered circuits, together with one eleven-membered peripheral circuit. $G-r_t$ represents the subsystem of G, obtained by deleting from G the tth π-electron circuit and all π bonds incident to it.[11-14]

Some geometric factors are then defined to characterize the individual π-electron circuits. The origin of the coordinates is usually set at the point in the molecular plane where the secondary magnetic field is to be evaluated. The signed area of the triangle formed by the origin and the i-j π bond is denoted by s_{ij}. It is counted positive if i→j is right-handed about the unit vector normal to the molecular plane.[2,4-6] Then, the following two quantities, S_t and F_t, are defined for the tth π-electron circuit:

$$S_t = \sum_{(ij)}^{r_t} s_{ij} \tag{1}$$

$$F_t = \sum_{(ij)}^{r_t} s_{ij} f_{ij} \tag{2}$$

Here, (ij) stands for the i-j π bond. It runs over all π bonds forming the tth π-electron circuit. The absolute value of S_t is equal to the area of the tth π-electron circuit.[2,4-6] f_{ij} is defined for (ij) as follows:

$$f_{ij} = \frac{1}{d_i^3} + \frac{1}{d_j^3}, \tag{3}$$

where d_i and d_j are the distances of atoms i and j, respectively, from the origin.

The polynomial obtained by expanding the Hückel secular determinant for G is termed the characteristic polynomial for G. This polynomial is denoted by $P_G(X, B)$ because the coefficients in it depend upon the applied magnetic field B. $P_{G-r_t}(X, B)$ represents a characteristic polynomial for $G-r_t$. Roots of the equation $P_G(X, B)=0$ represent the energies of N π-electron molecular orbitals in G. They are given relative to α, in units of β, where α and β are the standard Coulomb and resonance integrals, respectively.

When the external magnetic field is absent, the resonance integral for the i-j π bond is expressed in the form:

$$\beta_{ij}^{\circ} = k_{ij}\beta, \tag{4}$$

where k_{ij} is the resonance integral parameter which depends upon the bond type and bond order. The wth largest root of the equation $P_G(X,0)=0$, i.e., the energy of the wth π-electron molecular orbital in the absence of the external field is denoted by X_w. The number of π-electrons present in the wth molecular orbital is denoted by g_w. $Q_{G-r_t}(X)$ is defined by[25]

$$Q_{G-r_t}(X) = \frac{P_{G-r_t}(X,0)}{P_G'(X,0)} \prod_{(ij)}^{r_t} k_{ij}, \tag{5}$$

where (ij) runs over all π bonds forming the tth π-electron circuit. $P_G'(X,0)$ is the first derivative of $P_G(X,0)$ with respect to X. Finally, e, c, $\hbar$, and μ_o are the standard constants with these symbols.

Graph-Theoretical Formulation of the Secondary Magnetic Field

The strength of the secondary magnetic field due to ring currents was formulated in the following manner. A given cyclic conjugated molecule G is placed in the magnetic field **B**, which is assumed to be perpendicular to the molecular plane, i.e., $\mathbf{B}=B\mathbf{n}$, where **n** is the unit vector normal to the molecular plane. An infinitesimal test dipole of moment $\mathbf{m}=m\mathbf{n}$ is introduced at a given point in the plane of G, this point being chosen as origin of the coordinates. The entire system now consists of the molecule G and the test dipole D. The resonance integral for the i-j π bond becomes[5,6]

$$\beta_{ij} = \beta_{ij}^{\circ} \exp\left[\frac{ie s_{ij}}{\hbar}\left(B + \frac{\mu_o m}{4\pi} f_{ij}\right)\right]. \tag{6}$$

It is to be noted that Eq. 6 represent the general form of off-diagonal elements of the secular determinant for this complex system. The diagonal elements remain the same as those of the secular determinant for the conjugated molecule alone.[2,6,15] Such a secular determinant can be expanded into a characteristic polynomial without difficulty.

As in the case of the system with no test dipole,[15,21] Sachs' graph theory[11-14] is applicable, and every coefficient in the polynomial is expressed as a combination of cyclic products of resonance integrals. Such cyclic products can be classified into two groups. The first group consists of cyclic products of two resonance integrals associated with individual π bonds. They take the general form $\beta_{ij}\beta_{ji}$, which in this case is associated with the i-j π bond. The second group consists of cyclic products of more than two resonance integrals associated with individual π-electron circuits. They take the general form $\beta_{op}\beta_{pq}\cdots\beta_{uv}\beta_{vo}$, which in this case is associated with a π-electron circuit formed by atoms o, p, q, ···, u, and v. This indicates that if one or more π-electron circuits can be chosen from the molecule, there always are cyclic products of more than two resonance integrals corresponding to them all.

The following two relationships can be deduced with regard to these cyclic poducts of resonance integrals:

$$\begin{aligned}\beta_{ij}\beta_{ji} &= \beta_{ij}^{\circ}\beta_{ji}^{\circ} \\ &= k_{ij}^2\beta^2\end{aligned} \tag{7}$$

$$\begin{aligned}&\beta_{op}\beta_{pq}\cdots\beta_{uv}\beta_{vo} + \beta_{ov}\beta_{vu}\cdots\beta_{qp}\beta_{po} \\ &= 2\beta_{op}^{\circ}\beta_{pq}^{\circ}\cdots\beta_{uv}^{\circ}\beta_{vo}^{\circ}\cos\left[\frac{e}{\hbar}\left(BS_t + \frac{\mu_o m}{4\pi}F_t\right)\right] \\ &= 2k_{op}k_{pq}\cdots k_{uv}k_{vo}\beta^{z_t}\cos\left[\frac{e}{\hbar}\left(BS_t + \frac{\mu_o m}{4\pi}F_t\right)\right].\end{aligned} \tag{8}$$

Here, z_t is the number of atoms constituting the tth π-electron circuit. Since the applied field and the test dipole can be treated as small perturbations, Eq. 8 can be approximated to:

$$\begin{aligned}&\beta_{op}\beta_{pq}\cdots\beta_{uv}\beta_{vo} + \beta_{ov}\beta_{vu}\cdots\beta_{qp}\beta_{po} \\ &= 2k_{op}k_{pq}\cdots k_{uv}k_{vo}\beta^{z_t}\left[1 - \frac{e^2}{2\hbar^2}\left(BS_t + \frac{\mu_0 m}{4\pi}F_t\right)^2\right].\end{aligned} \tag{9}$$

We have previously investigated the magnetic response of a conjugated molecule, not combined with a test dipole.[15-26] In this case, Eq. 7 remains unchanged, but the value of m in Eqs. 8 and 9 vanishes, so that

$$\beta_{op}\beta_{pq}\cdots\beta_{uv}\beta_{vo} + \beta_{ov}\beta_{vu}\cdots\beta_{qp}\beta_{po} = 2k_{op}k_{pq}\cdots k_{uv}k_{vo}\beta^{z_t}\left[1-\frac{e^2}{2\hbar^2}(BS_t)^2\right]. \quad (10)$$

A characteristic polynomial for the molecule alone is expressed in the form:[15,16,19]

$$P_G(X,B) = P_G(X,0) + \frac{e^2}{\hbar^2}\sum_t^G (BS_t)^2 P_{G-r_t}(X,0)\prod_{(ij)}^{r_t} k_{ij}. \quad (11)$$

It is noteworthy that Eq. 9 can be derived formally by replacing BS_t in Eq. 10 by $BS_t+(\mu_o m/4\pi)F_t$. This indicates that the characteristic polynomial for the present system can likewise be derived by replacing BS_t in Eq. 11 by $BS_t+(\mu_o m/4\pi)F_t$:

$$P_{G+D}(X,B) = P_G(X,0) + \frac{e^2}{\hbar^2}\sum_t^G\left(BS_t+\frac{\mu_o m}{4\pi}F_t\right)^2 P_{G-r_t}(X,0)\prod_{(ij)}^{r_t} k_{ij}, \quad (12)$$

where G+D stands for the whole system consisting of the molecule G and the test dipole D.

By solving the equation $P_{G+D}(X,B)=0$ by means of the Newton method, energies of the π-electron molecular orbitals in the whole system can be obtained, each as a function of the field strength B. When there are no degenerate orbitals in G, the energy of the wth π-electron molecular orbital is given in the form:

$$\varepsilon_w(B) = \alpha + X_w(B)\beta = \alpha + \beta\left[X_w^\circ - \frac{e^2}{\hbar^2}\sum_t^G\left(BS_t+\frac{\mu_o m}{4\pi}F_t\right)^2 Q_{G-r_t}(X_w^\circ)\right]. \quad (13)$$

Here, $X_w(B)$ is the wth largest root of the equation $P_{G+D}(X,B)=0$. If there are degenerate orbitals in G, $X_w(B)$ for them must be evaluated by the procedure described in Refs. 16 and 22.

Toal π-electron energy of the whole system becomes

$$E_{G+D}(B) = \sum_{w=1}^N g_w\varepsilon_w(B) = \sum_{w=1}^N g_w\left\{\alpha+\beta\left[X_w^\circ - \frac{e^2}{\hbar^2}\sum_t^G\left(BS_t+\frac{\mu_o m}{4\pi}F_t\right)^2 Q_{G-r_t}(X_w^\circ)\right]\right\}, \quad (14)$$

where g_w is the occupation number for the wth orbital.

It is readily seen that Eq. 14 contains the term linear in m. This term represents the coupling energy between the test dipole and the secondary magnetic field.[5,6] Therefore, it can be identified with $-mB'$, where B' is the secondary field at the position where the test dipole is placed. Then, the strength of the secondary magnetic field is given by

$$B' = -\left[\frac{\partial}{\partial m}E_{G+D}(B)\right]_{m=0} = \frac{\mu_o e^2 B}{2\pi\hbar^2}\beta\sum_t^G F_t S_t\sum_{w=1}^N g_w Q_{G-r_t}(X_w^\circ), \quad (15)$$

This graph-theoretical formula is in marked contrast to McWeeny's one expressed in terms of imaginary bond-bond polarizabilities,[5,6] and had an advantage in that the secondary field can be related to the molecular geometry straightforwardly.

We have previously shown that London susceptibility and ring currents can both be partitioned exactly among the constituent π-electron circuits.[16,19-26] Equation 15 clearly indicates that the secondary field can also be partitioned among the π-electron circuits. This is expressed explicitly as

$$B' = \sum_t^G \gamma_t, \quad (16)$$

where γ_t stands for the contribution of the tth π-electron circuit:

$$\gamma_t = \frac{\mu_o e^2 B}{2\pi\hbar^2}\beta F_t S_t\sum_{w=1}^N g_w Q_{G-r_t}(X_w^\circ). \quad (17)$$

As shown previously,[24,25] a bond current, i.e., a ring current flowing through a given π bond, is expressed as a sum of the contributions of π-electron circuits sharing the very π bond in common. The current contribution of the tth π-electron circuit is called the tth circuit current, which is given by[24,25]

$$I_t = -\frac{2e^2 B}{\hbar^2}\beta S_t\sum_{w=1}^N g_w Q_{G-r_t}(X_w^\circ) = \frac{9I_o S_t}{S_o}\sum_{w=1}^N g_w Q_{G-r_t}(X_w^\circ), \quad (18)$$

where I_o is the bond current induced in benzene under the same experimental condition, and S_o is the area of the benzene ring. Using this expression for circuit currents, Eq. 15 is rewritten as

$$B' = \frac{\mu_o}{4\pi}\sum_t^G I_t F_t. \quad (19)$$

The secondary field thus is a function of not only all circuit currents in G but also all F_t values. The quantity F_t is purely geometric in nature, depending merely upon the shape and the location of the tth π-electron circuit with respect to the origin, i.e., the position where the secondary field is evaluated.

In 1958, McWeeny derived the formula similar to, but not the same as, Eq. 19.[5,6,28-30] It is expressed analogously as

$$B' = \frac{\mu_o}{4\pi}\sum_{t'}^G \bar{I}_{t'}\bar{F}_{t'}, \quad (20)$$

where t' runs over all rings in G, but not over π-electron circuits, $\bar{I}_{t'}$ is the current contribution of the tth ring, and $\bar{F}_{t'}$ is the quantity analogous to $F_{t'}$, but defined for the t'th ring. Here, the term "ring" has the usual meaning in chemistry. It is used in such a

manner that the acenaphthylene conjugated system consists of one five-membered and two six-membered rings. It is worth noting that Eqs. 19 and 20 represent two different physical aspects of the secondary field. Both ring currents and secondary fields can thus be partitioned not only among the constituent rings but also among the π-electron circuits.

Relationship between the Secondary Field and Aromaticity

We have developed the graph theory of aromaticity, in which the resonance energy arising from cyclic π-electron conjugation is defined graph-theoretically.[13,21,31,32] This type of resonance energy, RE_G, has ben recognized as a reasonable index for determining the degree of aromatic stabilization. In 1981, we found that the resonance energy can be estimated as[20,21]

$$RE_G \approx \sum_t^G \rho_t, \tag{21}$$

where t runs over all π-electron circuits in G, and

$$\rho_t = -2\beta \sum_{w=1}^{N} g_w Q_{G-r_t}(X_w^\circ). \tag{22}$$

The quantity denoted by ρ_t can obviously be attributed to the tth π-electron circuit, and can be interpreted as a contribution of the tth π-electron circuit to the overall resonance energy, which we term the tth circuit resonance energy. The same quantity has previously been called the tth ring resonance energy.[20,21] Thus, the resonance energy can be partitioned among the π-electron circuits. In other words, the overall resonance energy is given approximately by adding up all the circuit resonance energies defined by Eq. 22. In general, circuit resonance energy is positive for $(4n+2)$-membered carbocyclic circuits, and negative for $(4n)$-membered carbocyclic circuits.[25,27]

By the use of Eq. 22, Eq. 15 can be rewritten as

$$B' = -\frac{\mu_0 e^2 B}{4\pi\hbar^2} \sum_t^G A_t \rho_t, \tag{23}$$

where A_t is the pure geometric factor defined by $F_t S_t$. This expression is nothing other than what we wanted to derive in this paper. It clearly shows that the secondary field at any position is associated with the resonance energy or the extra thermodynamic stability due to aromaticity. Exactly speaking, the secondary field reflects not only all geometric factors denoted by A_t but also all circuit resonance energies. Both quantities are mathematically independent to each other within a Hückel framework.

Unfortunately, the interrelation between the resonance energy and the secondary field is never straightforward. As shown in Eq. 23, the secondary field is a function of all A_t values and all circuit resonance energies. If all A_t values were equal, B' would be proportional to the overall resonance energy. However, such a situation never occurs. Therefore, the secondary field cannot be predicted easily from the resonance energy and the molecular geometry.

Every A_t value is strongly dependent upon the distance from the origin and the shape of the π-electron circuit. Since the value of A_t is large for nearby π-electron circuits, it is quite possible that for many condensed aromatic hydrocarbons the secondary field is dominated primarily by the π-electron circuits which share the carbon nearest to the origin, i.e., the carbon to which a given proton is attached.

In a previous paper,[25] we proved that $(4n+2)$-membered circuits are diatropic in nature while $(4n)$-membered circuits are paratropic in nature. In the case of alternant hydrocarbons, smaller $(4n+2)$- and $(4n)$-membered circuits sustain stronger diamagnetic and paramagnetic currents, respectively. Therefore, if one or more $(4n+2)$-membered circuits can be chosen from a given conjugated hydrocarbon, in such a manner that they contain the carbon nearest to the origin, a proton at the origin will exhibit a downfield shift in the NMR spectrum. However, if one or more $(4n)$-membered circuits can also be chosen in the same manner, a downfield shift will be suppressed to some extent, or a net upfield shift will sometimes occur. This constitutes the very reason why typical aromatic compounds exhibit large downfield shifts of the constituent protons. There are no $(4n)$-membered circuits in catacondensed benzenoid hydrocarbons, so all protons necessarily exhibit downfield shifts.

Benzene is monocyclic in geometry, so only one π-electron circuit can be chosen from the conjugated system. The circuit resonance energy defined by Eq. 22 is $-2/9\beta$ or -0.2222β for it. The value of A_t is -5.28731×10^{-10} m at any benzene proton. Accordingly, using the strength of the secondary field at benzene protons, B_0, Eq. 23 is rewritten as

$$B' = -0.85110 \times 10^{10} B_0 \sum_t^G A_t \rho_t, \tag{24}$$

where

$$B_0 = -9.3500 \times 10^{-12} \frac{\mu_0 e^2 B}{\hbar^2}. \tag{25}$$

We will use Eq. 24 in what follows.

Secondary Fields in Anthracene

theory. In general, calculated magnetic properties are often very sensitive to the degree of sophistication of the molecular orbital (MO) method for computing them.[33] The MO model employed here is an iterative $\beta\omega'\omega''$ method,[34,35] which is a kind of self-consistent Hückel method. This method has successfully been applied to many conjugated hydrocarbons.[33-37] Compounds **1** and **2** are both alternant hydrocarbons in the neutral state, so all Coulomb integrals remain unchanged by application of this method. Resonance integrals are all functions of the bond order. The resonance integral parameter employed is of the form:[25]

$$k_{ij} = \exp(0.6327p_{ij} - 0.4218), \quad (26)$$

where p_{ij} is the bond order for the i-j π bond. MO calculations were iterated until resonance integrals were made self-consistent with the corresponding bond orders.

Anthracene **1** is a typical catacondensed aromatic hydrocarbon. Three rings in it are assumed to be regular hexagons with all edge lengths equal to the carbon-carbon bond lengths of benzene (139.65 pm).[38] All carbon-hydrogen bond lengths are set equal to 108.5 pm.[38] There are three non-identical protons and six π-electron circuits in the conjugated system. They are numbered as shown in Table 1 and Fig. 1. Positions of all non-identical protons were succesively taken as origin of the coodinates, and the secondary fields and related quantities were calculated using Eqs. 15—25. All the numerical results are presented in Table 1 and Fig. 3.

As shown in Table 1, all π-electron circuits in anthracene contribute to the increase in the secondary field at any proton. This corresponds to the fact that they are all $(4n+2)$-membered circuits. It is clear that not all π-electron circuits contribute much to the secondary field at a given proton. In general, each

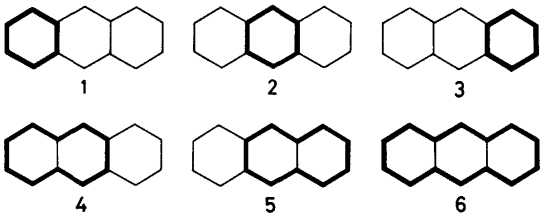

Fig. 1. π-Electron circuits in anthracene **1**.

π-electron circuit contributes much to the secondary fields at the protons located around it.

Proton 1 in anthracene is predicted to suffer the secondary field of 1.594 B_o, which is comparable to the value obtained by the simple Hückel method, 1.707 B_o.[38] This indicates that this proton must exhibit a fairly large downfield shift in the NMR spectrum as long as local anisotropic effects[7] are not very unusual. π-Electron circuits 2, 4, 5, and 6 contribute almost equally to the secondary field although the circuit resonance energy decreases in this order. The decrease in the circuit resonance energy is obviously compensated by the increase in the geometric factor. These π-electron circuits share the carbon atom to which proton 1 is attached. The contribution of the peripheral π-electron circuit is far from negligible owing to the very large geometric factor.

π-Electron circuits which do not share the carbon nearest to proton 1 have much smaller geometric factors than those of circuits 2, 4, 5, and 6. Therefore, they contribute much less to the secondary field at proton 1. It is in marked contrast to the overall resonance energy, which is determined primarily by smaller π-electron circuits. Therefore, it is obvious that the relationship between the overall resonance energy and the secondary field is considerably obscured by the geometric factors which are unrelated to the thermodynamic stability. This supports Mallion's view that

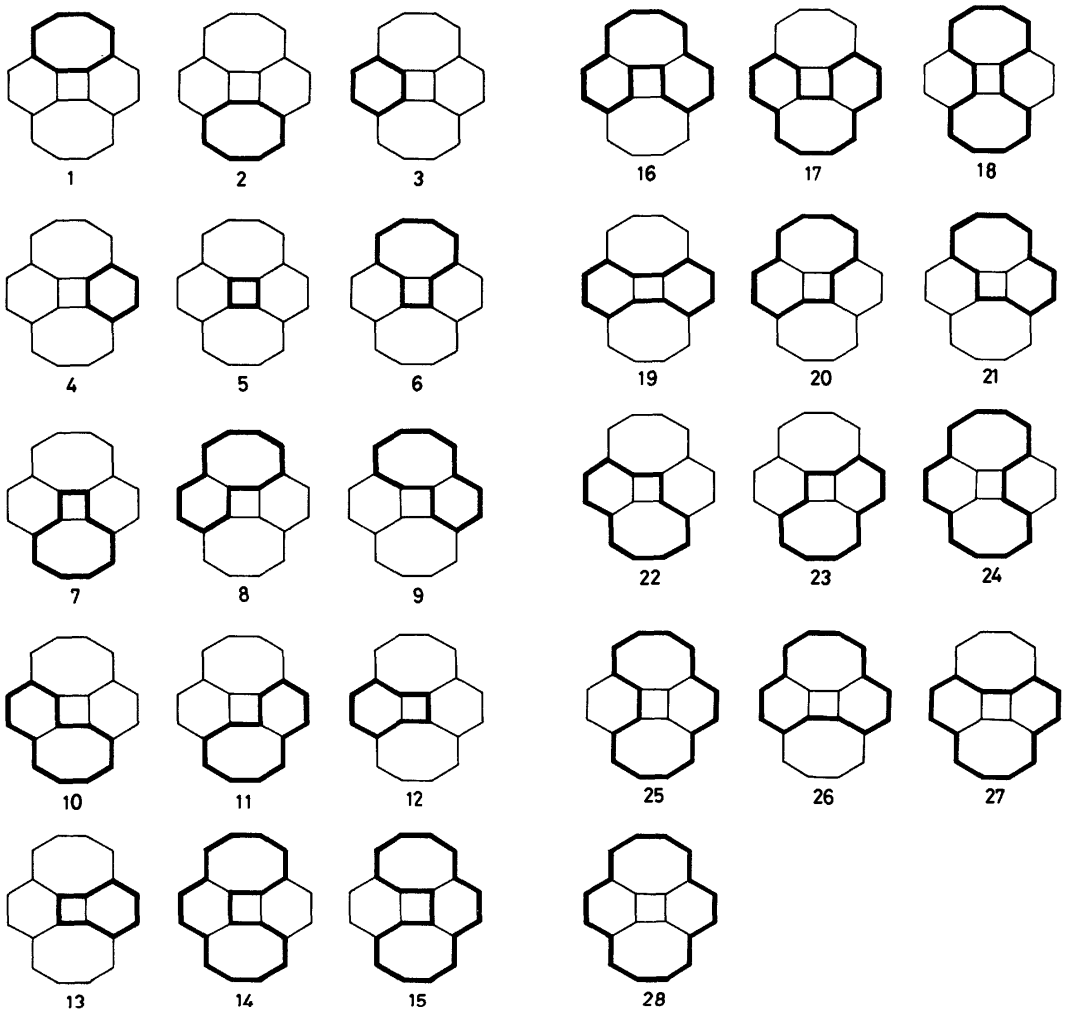

Fig. 2. π-Electron circuits in dicyclooctabiphenylene **2**.

the graph-theoretical and geometric contributions to ring-current intensities are disentangled.[9]

The situation is essentially the same for protons 2 and 3. Protons 2 and 3 are predicted to suffer the secondary fields of 1.201 B_0 and 1.021 B_0, respectively. They are also comparable to the values calculated by the simple Hückel method, 1.387 B_0 at proton **2** and 1.197 B_0 at proton 3.[38] π-Electron circuits which share the carbon atom nearest to each of these protons again contribute primarily to the secondary field.

Every circuit current is proportional to the circuit area and the circuit resonance energy defined by Eq. 22. Thus, it is not influenced by the value of A_t, and independent of the distance from the origin.

Haigh et al. obtained the following regression line between experimental proton chemical shifts and the corresponding B'/B_0 ratios for a number of condensed benzenoid hydrocarbons:[38]

$$\delta = 5.66 + 1.56\frac{B'}{B_0} \qquad (27)$$

This is based on the secondary fields calculated by the simple Hückel method. The regression line has not been obtained with the fields calculated by the iterative $\beta\omega'\omega''$ method, but Eq. 27 is not too bad to predict the proton chemical shifts from them. Protons 1, 2, and 3

a)—e) See Table 1, footnotes a)—e).

are predicted from Eq. 27 to resonate at δ 8.15, δ 7.53, and δ 7.25, respectively. They are well compared to the experimental values, δ 8.36 for proton 1, δ 7.93 for proton 2, and δ 7.39 for proton 3.[38]

Secondary Fields in Dicyclooctabiphenylene

Secondary fields in dicyclooctabiphenylene **2** can be evaluated in the same manner. One four-membered and two six-membered rings in it are assumed to be regular in shape. Two eight-membered rings are made centrosymmetric in such a manner that they are attached closely to the biphenylene structure. All carbon-carbon bond lengths are assumed to be equal to those of benzene (139.65 pm).[38] All carbon-hydrogen bond

lengths are again assumed to be 108.5 pm.[38] There are three non-identical protons and 28 π-electron circuits in all. They are numbered as shown in Table 2 and Fig. 2. All the numerical results are also presented in Table 2 and Fig. 3.

In contrast to anthracene, not all π-electron circuits contribute to the increase in the secondary field at a given proton. Since the geometric factor of any π-electron circuit has the same sign, the sign of the contribution depends upon the sign of the circuit resonance energy. As stated before, the circuit resonance energy is positive for all $(4n+2)$-membered circuits and negative for all $(4n)$-membered circuits. There are no odd-membered π-electron circuits in dicyclooctabiphenylene. Accordingly, all $(4n+2)$-membered π-electron circuits contribute to the increase in the secondary field at all protons, while all $(4n)$-membered π-electron circuits contribute to the decrease in it.

Circuits 3, 4, 6, 7, 14, 15, 26, and 27 are the $(4n+2)$-membered ones. When these π-electron circuits share the carbon atom nearest to a given proton, they contribute much to the increase in the secondary field thereat. Other π-electron circuits are the $(4n)$-membered ones. When these π-electron circuits share the carbon atom nearest to a given proton, they generally contribute much to the decrease in the secondary field. The contribution of the peripheral π-electron circuit is not negligible owing to the very large geometric factor.

Circuits 20—23 are exceptional, in that they contribute little to the secondary field. When any of these π-electron circuits is deleted from the entire conjugated system, Kekulé structures cannot be written for the residual system. In general, such π-electron circuits have very small positive or negative resonance energy,[39] so it follows that they little contribute to the secondary field.

Circuits 2 and 4 are also exceptional in another sense. For example, circuit 4 contributes much to the secondary fields at protons 1 and 2 although these protons are not attached to this π-electron circuit. This is due to the exceptionally large circuit resonance energy. These exceptions suggest that the secondary field and the proton chemical shift cannot always be inferred from the nearby bond currents.

Protons 1 and 2 are predicted to experience the secondary fields of $-1.267\ B_0$ and $-1.255\ B_0$, respectively, which indicates that these protons must exhibit fairly large upfield shifts in the NMR spectrum. Proton 3 is predicted to suffer a secondary field of $-0.455\ B_0$, which indicates that this proton must exhibit a slightly upfield shift. This is in good agreement with experiment. According to Wilcox and Farley,[36] the two benzene rings in 2 are esssentially atropic, while the two eight-membered rings are highly paratropic.

Protons 1, 2, and 3 in dicyclooctabiphenylene are predicted from Eq. 27 to resonate at δ 3.68, δ 3.70, and δ 4.95, respectively. They are again in good agreement with the experimental values, δ 3.63 for proton 1, δ 3.59 for proton 2, and δ 4.55 for proton 3.[36] It seems that Eq. 27 is still very applicable to the results obtained by use of the iterative $\beta\omega'\omega''$ method. However, this may be due to the fact that both anthracene and dicyclooctabiphenylene happen to be alternant hydrocarbons with uniform charge distribution. Local anisotropic effects[7] appear fairly uniform over all conjugated atoms and bonds.

Concluding Remarks

It was in 1961 that Elvidge and Jackman put forward the proposal that a molecule should be defined as aromatic if it will sustain an induced diamagnetic ring current.[40] They implied that the proton chemical shifts may be taken to be a quantitative measure of aromaticity. An NMR criterion has since been established according to which downfield proton chemical shifts indicate aromaticity while upfield proton chemical shifts indicate antiaromaticity. However, it has not at all been clear why the molecules which exhibit downfield proton chemical shifts have strong conjugative stabilization.[41]

In this paper, we proved that proton chemical shifts are really related to aromatic stabilization, but clarified that proton chemical shifts of a polycyclic conjugated system are never proportional to the degree of aromatic stabilization. The calculated secondary magnetic field was a function of both the circuits resonance energies and the pure geometric factors. It is now clear that marked downfield proton chemical shifts are associated with one or more π-electron circuits which contribute much to aromatic stabilization.

Gayoso[42] and Gomes and Mallion[43] have attempted to estimate magnetic properties of cyclic conjugated hydrocarbons by means of Randić's conjugated circuit theory.[44] The present approach gives a physical basis for these attempts.

The author thanks Dr. R. B. Mallion for helpful discussions. This work was supported by the Grant-in-Aid for Scientific Research (No. 60540283) from the Ministry of Education, Science and Culture.

The Microwave Spectrum and Molecular Structure of Methyl Selenocyanate

Takeshi SAKAIZUMI,* Masahiko OBATA, Katsumasa TAKAHASHI, Eiichi SAKAKI, Yaeko TAKEUCHI, Osamu OHASHI, and Ichiro YAMAGUCHI

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioi-cho, Chiyoda-ku, Tokyo 102

(Received June 13, 1986)

The microwave spectra of $CH_3{}^{80}SeCN$, $CH_3{}^{78}SeCN$, $CH_3{}^{80}Se{}^{13}CN$, $CH_3{}^{80}SeC{}^{15}N$, *sym*-$CH_2D{}^{80}SeCN$, and *asym*-$CH_2D{}^{80}SeCN$ have been observed. In order to determine the rotational constants of $^{13}CH_3{}^{80}SeCN$, we used the transition frequencies observed by Landsberg. From these spectra the complete r_s coordinates of seven atoms have been calculated using Kraitchman's equation. The structural parameters (bond lengths in Å(1Å=0.1 nm) and angles in degree) are: r(C1-H1)=1.073(4), r(C1-H2)=1.083(6), r(C1-Se)=1.954(7), r(Se-C2)=1.836(11), r(C2-N)=1.162(9), ∠H1-C1-H2=110.6(6), ∠H2-C1-H2′=111.4(3), ∠H1-C1-Se=105.4(5), ∠H2-C1-Se=109.3(6), ∠C1-Se-C2=96.0(11), and ∠Se-C2-N=179.3(15). It was found from the r_s structural parameters that the methyl group is at a staggered position with respect to the cyano group, the methyl group does not show C_{3v} symmetry, the bond length of r(Se-C2) is much shorter than that of r(Se-C1), and the chain bond of Se-C2-N is linear.

In a previous paper,[1] we reported on the microwave spectra, the rotational constants, the dipole moments, the barrier heights of the methyl internal rotation, the first excited state of the methyl torsional mode, and the r_0 structure of methyl selenocyanate (with ^{80}Se, ^{78}Se, ^{77}Se, and ^{76}Se) and methyl selenocyanate-d_3 (with ^{80}Se and ^{78}Se).

The selenocyanates are interesting molecules for several reasons. When a selenium atom is bonded to a cyano group, it is expected that the bond length of r(Se-C2) will be shorter than the normal single-bond length. The numbering of the atoms on the methyl selenocyanate is shown in Fig. 1. Another question is whether the chain bond of Se-C2-N is linear or bent.

In this research four isotopic species were newly prepared and the spectra were observed. The r_s structural parameters of methyl selenocyanate were calculated from the r_s coordinates of all atoms. The r_s structural parameters obtained are compared with those of related molecules and are discussed.

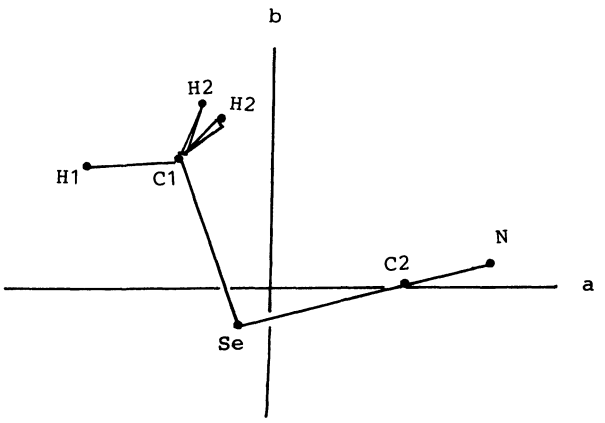

Fig. 1. The numbering of the atoms on methyl selenocyanate.

Experimental

The sample of methyl selenocyanate-*d* (CH_2DSeCN) was prepared by a reaction of methyl-*d* iodide (99% D, Merck Sharp & Dohme Canada) with potassium selenocyanate according to the method used for normal species.[1] The isotopic species of $CH_3Se{}^{13}CN$ and $CH_3SeC{}^{15}N$ were prepared by mixing potassium selenocyanate-^{13}C or potassium selenocyanate-^{15}N with methyl iodide. The potassium selenocyanate-^{13}C and potassium selenocyanate-^{15}N were synthesized by mixing potassium cyanide-^{13}C (91.6% ^{13}C, British Oxygen Co. Ltd.) or potassium cyanide-^{15}N (96.6% ^{15}N, Boxy Brown Co. Ltd.) with black selenium in ethanol.

The spectra were observed in the frequency region from 8.0 to 37 GHz with a conventional 100-kHz Stark modulation microwave spectrometer. The microwave source employed was a synthesized signal generator (HP 8672A). The absorption cell was cooled to about −20 °C with dry ice.

Results and Discussion

In order to determine as accurately as possible the rotational constants which are used to calculate the r_s coordinates of the Se atom, several a-type R-branch transitions of ^{80}Se and ^{78}Se species for which the discrepancies between the observed and the calculated frequencies were large in the previous measurement[1] were remeasured. In addition, a-type Q-branch transitions were newly assigned as listed in Table 1. The microwave spectra of $CH_3{}^{80}Se{}^{13}CN$ and $CH_3{}^{80}SeC{}^{15}N$ were newly observed and were assigned as listed in Table 2. In partially deuterated methyl selenocyanate, two conformations are possible. The symmetrical conformer (sym-species) has a plane of symmetry whereas the asymmetrical conformer (asym-species) exists in two equivalent forms. The sym-species shows the spectrum of an ordinary asymmetric rigid-rotor while the asym-species is expected to show splittings due to a tunnelling effect through the two equivalent potential wells. The observed transitions of *sym*-$CH_2D{}^{80}SeCN$ were assigned as listed in Table 3. The a-type R-branch transitions in asym-species were little affect by the tunnelling effect, but small splittings due to the tunnelling effect in a-type Q-branch transitions were observed. The center frequencies of the splittings observed in the Q-branch transitions were used to fit the rigid-rotor approximation Hamiltonian. The observed transitions of *asym*-$CH_2D{}^{80}SeCN$ were assigned as shown in Table 4. The rotational and cen-

a) $\Delta\nu = \nu_{obsd} - \nu_{calcd.}$

trifugal distortion constants obtained for normal and isotopic species are listed in Table 5 except for $^{13}CH_3{}^{80}SeCN$ species.

For the $^{13}CH_3{}^{80}SeCN$ species, Landsberg[2] has determined the rotational constants by using the frequencies of the a-type R-branch transition, but has not determined the centrifugal distortion constants. We obtained the rotational constants by using a Hamiltonian which included the centrifugal distortion effects for all of isotopic species. Therefore, in order to consider the effects for $^{13}CH_3{}^{80}SeCN$ species, we used the centrifugal distortion constants of $CH_3{}^{80}SeCN$ as those of $^{13}CH_3{}^{80}SeCN$. The rotational constants of $^{13}CH_3{}^{80}SeCN$ were calculated by using the assumed centrifugal distortion constants and the frequencies of an a-type R-branch transition observed by Landsberg.[2] The obtained rotational constants are listed in Table 5 and are in good agreement with those reported by Landsberg.[2]

The obtained values of moments of inertia and the planar moments of inertia,[3] P_c, are shown in Table 6. The values of P_c in isotopic species were close to 1.42

a) $\Delta\nu=\nu_{obsd}-\nu_{calcd}$.

uÅ² (1 uÅ²=1.66053×10⁻²⁹ kg(nm)²) except for *asym*-CH_2DSeCN. This is in conformity with the fact that the heavy atoms (C1, Se, C2, and N) and the deuterium atom in the methyl group are located in the symmetry plane. The large value (2.159 uÅ²) of P_c of *asym*-CH_2DSeCN agrees with the fact that the deuterium atom of the methyl group is located out of the plane.

The coordinates of the atoms in the principal-axis system of the normal species ($CH_3{}^{80}SeCN$), as obtained using Kraitchman's equation,[4] are listed in Table 7. The b-coordinate of C2 atom obtained from Kraitchman's equation was small (0.0898 Å) and unreliable. Therefore, the b-coordinate of C2 was calculated from the first moment equation. Although the c-coordinates(Å) of H1, C1, Se, C2, and N obtained from Kraitchman's equation were found to be either extremely small or imaginary (0.1557(121), 0.0032*i*, 0.0002*i*, 0.0272(674), and 0.0019*i*), respectively, these c-

∠H2-Cl-H2′	111.4(3)	111.3(2)
∠H1-Cl-M[c)]	105.4(5)	105.4(3)
∠H2-Cl-M[c)]	109.3(6)	109.7(1)

a) This work. b) Ref. 5. c) M=Se or S atom.

The r_s structural parameters of the methyl group for CH_3SeCN were compared with those for CH_3SCN[5)] as listed in Table 9. The structural parameters of the methyl group for CH_3SeCN are quite similar to those for CH_3SCN. The bond length of r(Cl-H1) for CH_3SCN has been found to be shorter by about 0.01 Å than that of r(Cl-H2).[5)] The numbering of the atoms of CH_3SCN is the same as that of CH_3SeCN, as shown in Fig. 1. Although a similar trend can be seen for CH_3SeCN, the bond length of r(Cl-H1) agrees with that of r(Cl-H2) within the limits of error. The two H-C-H angles are almost the same, but the angle of H1-Cl-Se is much smaller than that of H2-Cl-Se. Neither the methyl group of CH_3SeCN nor that of CH_3SCN shows a C_{3v} symmetry. The methyl group is staggered with respect to the cyano group.

The r_s structural parameters of CH_3SeCN were compared with those of related molecules as listed in Table

Table 10. Comparison of the Structural Parameters of CH_3SeCN with Those of Related Molecules. (Bond Lengths in Å and Angles in degree).

	r(Cl-Se)	∠Cl-Se-C2	r(Se-C2)	r(C2≡N)	∠Se-C2≡N
CH_3SeCH_3[a] (r_s)	1.943(1)	96.2(2)	1.943(1)		
CH_3SeCN[b] (r_s)	1.954(7)	96.0(11)	1.836(11)	1.162(9)	179.3(15)
$CH_3C(H)=Se$[c] (r_o)			1.758(10)		
CH_3CN[d] (r_s)				1.157(1)	
CH_3SCN[e] (r_s)	1.824(2)[f]	99.03(8)[g]	1.684(3)[h]	1.170(2)	179.8(13)[i]

a) Ref. 6. b) This work. c) Ref. 7. d) Ref. 8. e) Ref. 5. f) r(Cl-S). g) ∠Cl-S-C2. h) r(S-C2). i) ∠S-C2≡N.

10. The bond length of r(Cl-Se) is almost the same as that for a normal single bond of CH_3SeCH_3.[6] On the other hand, the bond length of r(Se-C2) comes between those of a single bond and a double bond and has the value which is shorter by about 0.1 Å than a normal single bond[6] and is longer by about 0.1 Å than a normal double bond of $CH_3C(H)=Se$.[7] This intermediate bond length arises from the back donation of electrons from the selenium atom to a cyano group. The same trend has also been seen in the bond length of r(Cl-S) and r(S-C2) of methyl thiocyanate,[5] as shown in Table 10. The bond length of r(C2-N) of methyl selenocyanate agrees with that of CH_3CN[8] within 0.01 Å. The bond angle of Cl-Se-C2 is similar to that of CH_3SeCH_3[6] but is smaller by about 3° than that of Cl-S-C2 of methyl thiocyanate.[5] Both the chain bonds of Se-C2-N of methyl selenocyanate and that of S-C2-N of methyl thiocyanate[5] were found to be linear.

It was concluded from the r_s structural parameters of methyl selenocyanate that (i) the methyl group is staggered with respect to the cyano group, (ii) the bond angle of H1-C1-Se is much smaller than that of H2-C1-Se and the methyl group does not have the C_{3v} symmetry, (iii) the bond length of r(Se-C(N)) is much shorter than that of r(Se-C(CH_3)) because of the back donation of electrons in bonding a selenium atom to a cyano group, and (iv) the chain bond of Se-C2-N is linear.

Relations between Diatomic Constants and the Features of the Potential Energy Surfaces

Noboru TANAKA
Hachinohe Institute of Technology, Hachinohe 031
(Received June 16, 1986)

The semiempirical method is used to calculate potential energy surfaces. The linear H_3 and rectangular H_4 systems have been chosen as standard surfaces in order to compare the surface features. Relationships between diatomic constants and topological features along a minimum energy path, and the height and location of the barrier, are demonstrated.

The knowledge of the relation between the effect of vibrational and translational energies on the reaction cross section and the topological features of potential energy surfaces have provided valuable information in understanding the fundamental nature of collision dynamics.[1-3] We are seeking additional insight into this relation. In this attempt, we investigate correlations between the features of the potential energy surfaces and the characters of the reactant molecules. With the understanding of the correlations, the effect of the two kinds of energies on the chemical reaction can be estimated directly from the characters of the reactant molecules.

Recently, more accurate ab initio potential energies have been calculated for many reaction systems, using fast computers. Even though the potential energies calculated by ab initio method are accurate, it is difficult to relate the potential energies with the character of reactant molecules because of the complicated calculation method. On the other hand, a semiempirical method can relate directly the potential energies with the character without complicated calculations. Commonly used semiempirical methods[4,8,10] employ the diatomic constants as the characteristics of reactant molecules.

This report investigates the relation between diatomic constants and features of potential energy surfaces, using our semiempirical method.[5] In this article, such simple models as linear H_3 and rectangular H_4 will be chosen. Varying the values of the diatomic constants which are used to calculate potential energies in the both systems, we observe the changes of the topological features along minimum energy path, and height and location of the barrier.

Theoretical

Our semiempirical method[5] to calculate potential energies (E) is based on a valence bond treatment[6] of an n-electron n-atom system. In this method, E can be obtained from the secular equation,

$$|\boldsymbol{H} - \boldsymbol{M}E| = 0 \tag{1}$$

where $\boldsymbol{H}$ is a Hamiltonian matrix and $\boldsymbol{M}$ is an overlap matrix. Each matrix element is defined as

$$H_{ij} = \sum \varepsilon_P \langle \Omega | H | P\Omega \rangle \langle \theta_i | P\theta_j \rangle,$$
$$M_{ij} = \sum \varepsilon_P \langle \Omega | P\Omega \rangle \langle \theta_i | P\theta_j \rangle, \tag{2}$$

where H is the Hamiltonian of the system, P is a permutation operator of electrons, ε_p is the parity, and θ_i is the spin function.

The matrix elements of $\boldsymbol{H}$ contain multiple exchange integrals given by

$$\Lambda_p = \langle \Omega | H | P\Omega \rangle. \tag{3}$$

We found that Λ_p is reduced to two basic types.[5] One of them is a transposition type, and the other is a cycle type. These integrals can be formulated in terms of diatomic components α_i, Q_i, and S_i, using the Mulliken approximation,[7] as follows;

$$\Lambda_P^1 \simeq \Pi S_i^2 [\sum (\alpha_i / S_i^2) + Q - \sum Q_i],$$
$$\Lambda_P^2 \simeq (1/2) \Pi S_i [\sum (\alpha_i / S_i^2) + 2Q - \sum Q_i], \tag{4}$$

where Q is a Coulomb integral, which is expressed by the diatomic Coulomb integrals Qi, and i shows pairs formed with electrons (atoms). Since the multiple exchange integral Λ_P consists of these Λ_P^1 and Λ_P^2 the calculation of Λ_P is to evaluate the diatomic components α_i, Q_i, and S_i. The first two diatomic components α_i and Q_i are evaluated from the Morse and anti-Morse functions which contain diatomic constants:[8,10] dissociative energy D, force constant α, and internuclear equilibrium distance R_e. These diatomic constants are combined with spectroscopic information on diatomic molecules.[9] The last diatomic component S_i is formulated empirically with adjustable parameters κ and λ.

$$S_i = (1 + R_i \zeta_i + \frac{1}{3} \zeta_i^2 R_i^2) \exp(-\zeta_i R_i), \tag{5}$$

where the screening parameter ζ_i is given by[10,11]

$$\zeta_i = 1.0 + \kappa \exp(-\lambda R_i). \tag{6}$$

Thus the potential energy E takes the following analytical form of coordinates of internuclear distance R as

$$E = f(\chi, \beta : R), \tag{7}$$

with the adjustable parameter β and diatomic constants χ which are abbreviations for κ, λ and for D, α, R_e, respectively.

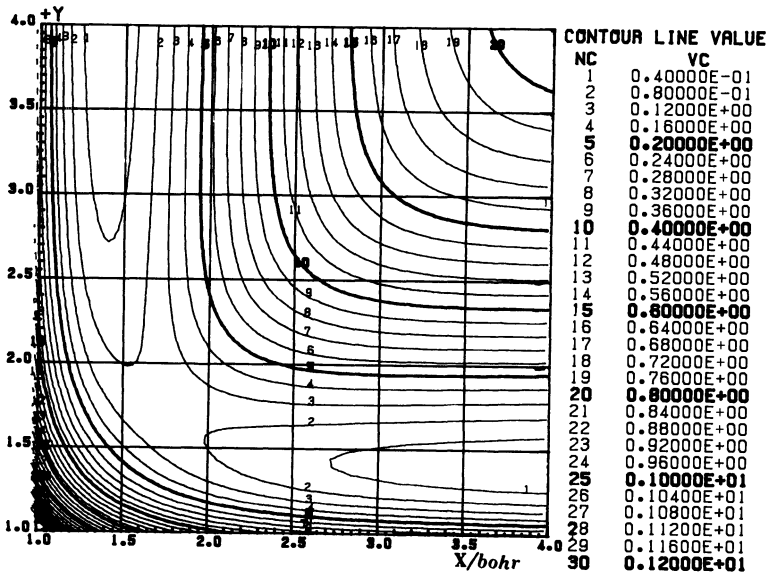

Fig. 1. Equipotential contour maps for H_3 surface corresponding to linear arrangement of the three atoms. The contour intervals are 1/25 of the H_2 dissociation energy. Number and value of the contour line are denoted by NC and VC, respectively.

In order to investigate the relationships between diatomic constants and the feature of potential energy surfaces, we define the surfaces by equipotential contour maps. The character of the surfaces are interpreted from the three following points of view;

1) Height, depth, and slope of the valley along the minimum energy path,

2) Height and location of the barrier,

3) Shape and passing positions of the minimum energy path.

Results

Equipotential contour maps for the linear H_3 and rectangular H_4 systems are presented in Figs. 1 and 4 as standard surfaces to compare the surface features. In order to assess the nature of these surfaces, we have changed the diatomic constants which are used to calculate the potential energies.[11,14] In six cases of diatomic constant change, the contour maps (a)—(f) are shown in both Figs. 3 and 5. The increase and decrease of the D, α, and R_e correspond to the cases of (a) and (b), (c) and (d), and (e) and (f), respectively. The barrier heights and the coordinates along the minimum energy path, at the starting point (entrance valley), at the saddle point (barrier), and at the ending point (exit valley), are presented in Tables 1 and 2, for each of six cases.

1) **Model of Linear H_3 System.** Figure 1 and Fig. 2 show equipotential contour maps for H_3 surfaces corresponding to a linear arrangement of the three hydrogen atoms calculated by our method[11] and the Truhlar-Horowitz method.[12,13]

The values of the diatomic constants D, α, and R_e are 0.174475 a.u., 1.05 a.u.,$^{-1}$ and 1.401 bohr, respectively. The adjustable parameters κ and λ in Eq. 6 have been so determined that the barrier height calculated by using Eq. 7 agrees with that calculated by Liu[12]; that is κ=3.20 and λ=1.202.[11] In Table 1, the values of the barrier height and coordinates of the minimum energy path are shown together with the results of Liu. Comparisons of the minimum energy path, contour

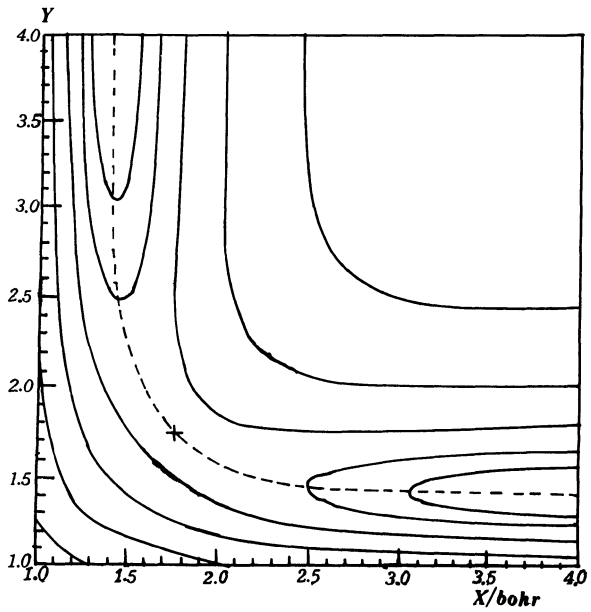

Fig. 2. Truhlar-Horowitz contour map for linear arrangement H_3 surface. The solid curves are cotours of the interaction potential corresponding to 3, 6, 12, 24, 48, 96, and 192 kcal mol^{-1}. The dashed curve is a minimum energy path and the cross is a saddle point.

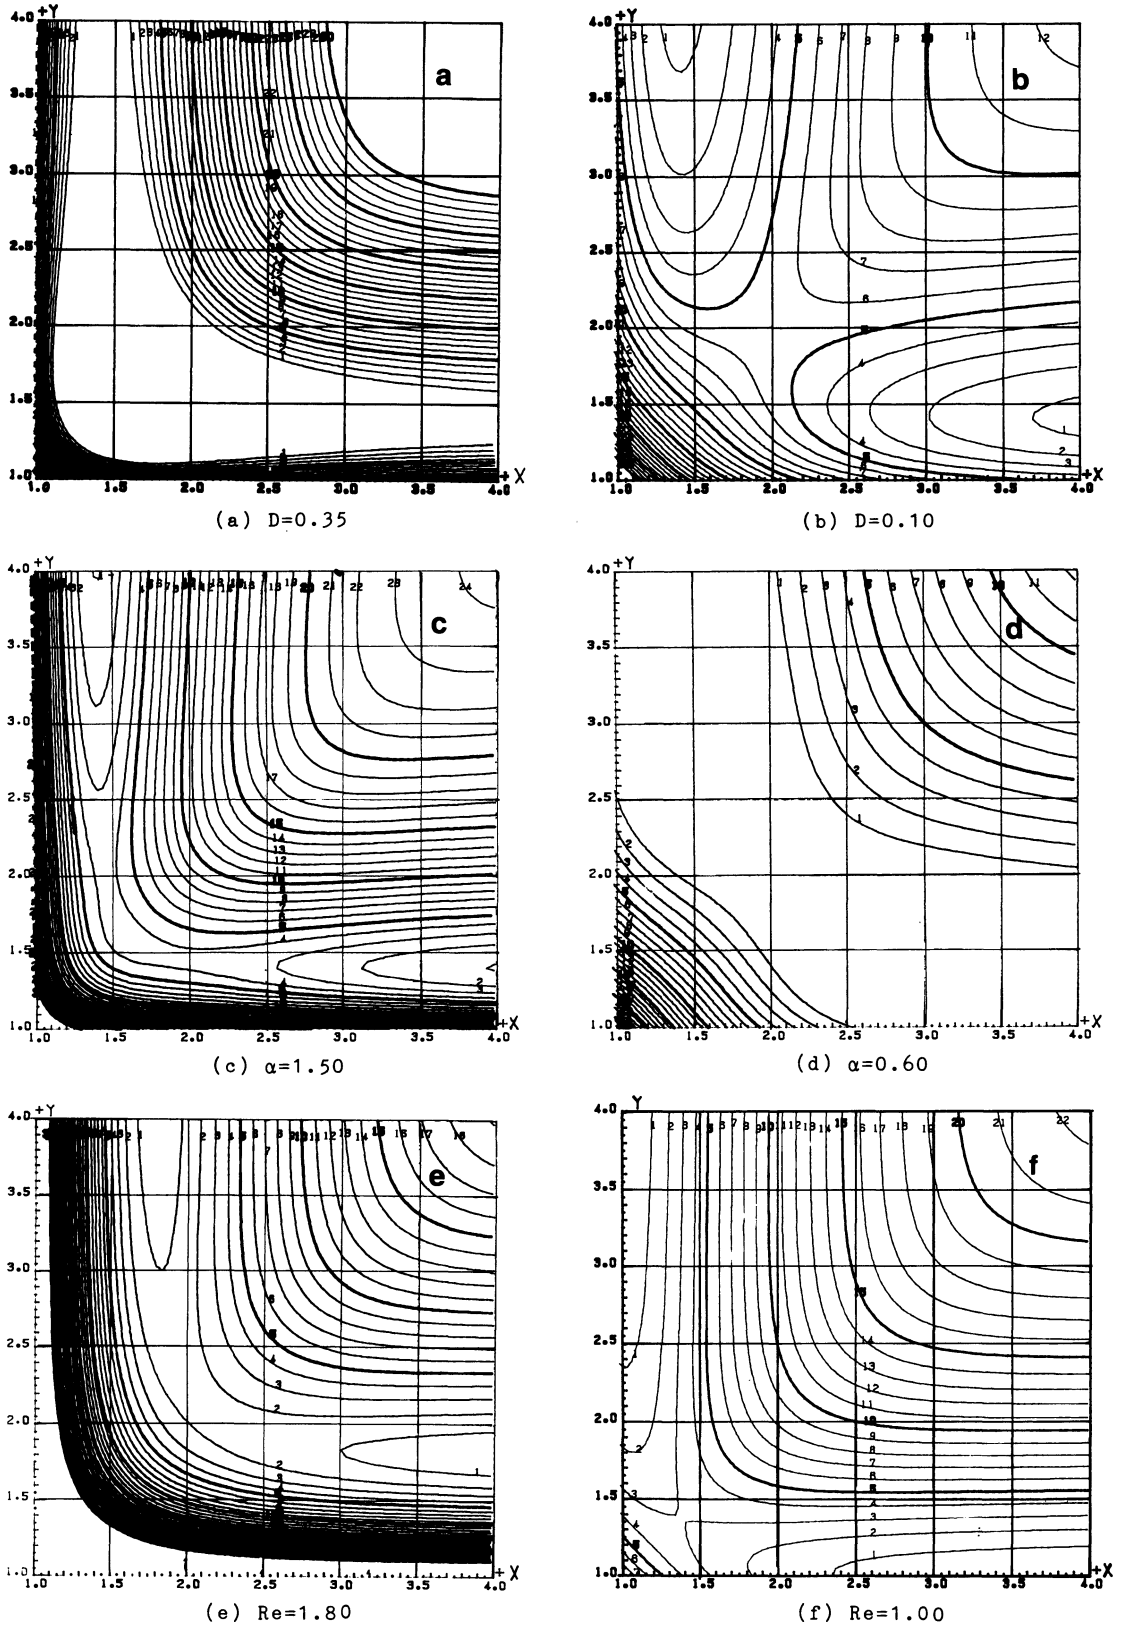

Fig. 3. Equipotential contour maps on different D, α, R_e for model of the linear H_3 system.

line, and barrier height between Figs. 1 and 2 are satisfactory.

The changes of the features of the maps can be read off from Fig. 3 and Table 1 in the case of (a)—(b) as follows;

(a) D=0.35: The valley along the minimum energy

Table 1. Barrier Height and Coordinates of the Minimum Energy Path in Six Cases[a] of the Changes of Diatomic Constants for the Model of Linear H_3 System

Case	Starting point	Saddle point	Barrier height	Ending point
	bohr	bohr	kcal/mole^{-1}	bohr
H_3[b]	(4.00, 1.40)	(1.757, 1.757)	9.802	(1.40, 4.00)
H_3[c]	(4.00, 1.40)	(1.743, 1.743)	9.802	(1.40, 4.00)
(a)	(4.00, 1.40)	(1.60, 1.60)	(−38.83)	(1.40, 4.00)
(b)	(4.00, 1.60)	(1.90, 1.90)	24.49	(1.60, 4.00)
(c)	(4.00, 1.40)	(1.60, 1.60)	15.83	(1.40, 4.00)
(d)	(4.00, 1.40)	(2.05, 2.05)	(−1.46)	(1.40, 4.00)
(e)	(4.00, 1.90)	(2.10, 2.10)	7.35	(1.90, 4.00)
(f)	(4.00, 1.275)	(1.675, 1.675)	13.12	(1.275, 4.00)

a) See the text. b) Results of this Liu; Ref. 12. c) Results of this study; Ref. 11.

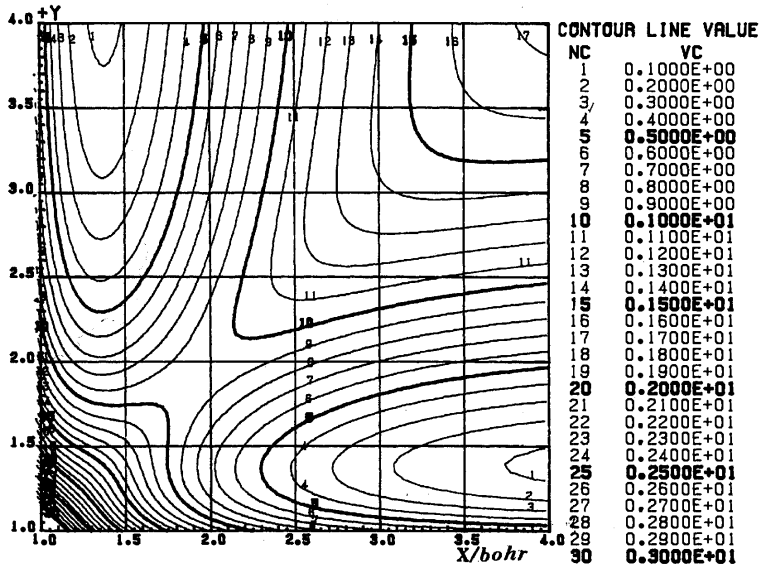

Fig. 4. Equipotential contour maps for H_4 surface corresponding to rectangular arrangement of the four atoms. The contour intervals are 1/10 of the H_2 dissociation energy. Number and value of the contour line are denoted by NC and VC, respectively.

path greatly increases in height, depth, and slope. The path moves to the inside. A deep ditch arises along the path.

(b) D=0.10: The valley along the minimum energy path decreases in height, depth, and slope, but the slope toward the barrier becomes steeper. The saddle point moves to the outside. The barrier height increases reasonably in value.

(c) α=1.50: The valley along the minimum energy path shallows but the slope becomes steep. The saddle point moves also to the inside. The basin lies between (2.0, 1.5) and (1.5, 2.0). The potential energy at the bottom in the basin is 16.87 kcal (1 cal=4.184 J) and is 15.83 kcal around the basin.

(d) α=0.60: There is no barrier but a ditch, and the slope becomes low-pitched along the minimum energy path.

(e) R_e=1.80: The depth and slopes of the valley change very little, but the minimum energy path shifts to the outside.

(f) R_e=1.00: The depth and slopes of the valley change very little, but the minimum energy path shifts to the inside.

2) **Model of rectangular H_4 System.** Figure 4 shows equipotential contour maps for H_4 surfaces corresponding to a rectangular arrangement of the four atoms calculated by our method.[14] The values of the diatomic constants D, α, and R_e are 0.174475 a.u., 1.05 a.u.$^{-1}$, and 1.401 bohr, respectively. The adjustable parameters κ and λ in Eq. 6 have been so determined that the barrier height calculated by using Eq. 7 agrees with that calculated by Bender and Schaefer III[15]; that is κ=1.00 and λ=0.40.[11] The contour maps for rectangular H_4 system were calculated from the various semiempirical methods by Silver and Brown[16]

The changes in the features of the maps can be read off from the Fig. 5 and Table 2 in the case of (a)—(b) as follows;

(a) D=0.30: The valley along the minimum energy path increases in height, depth, and slope. The saddle

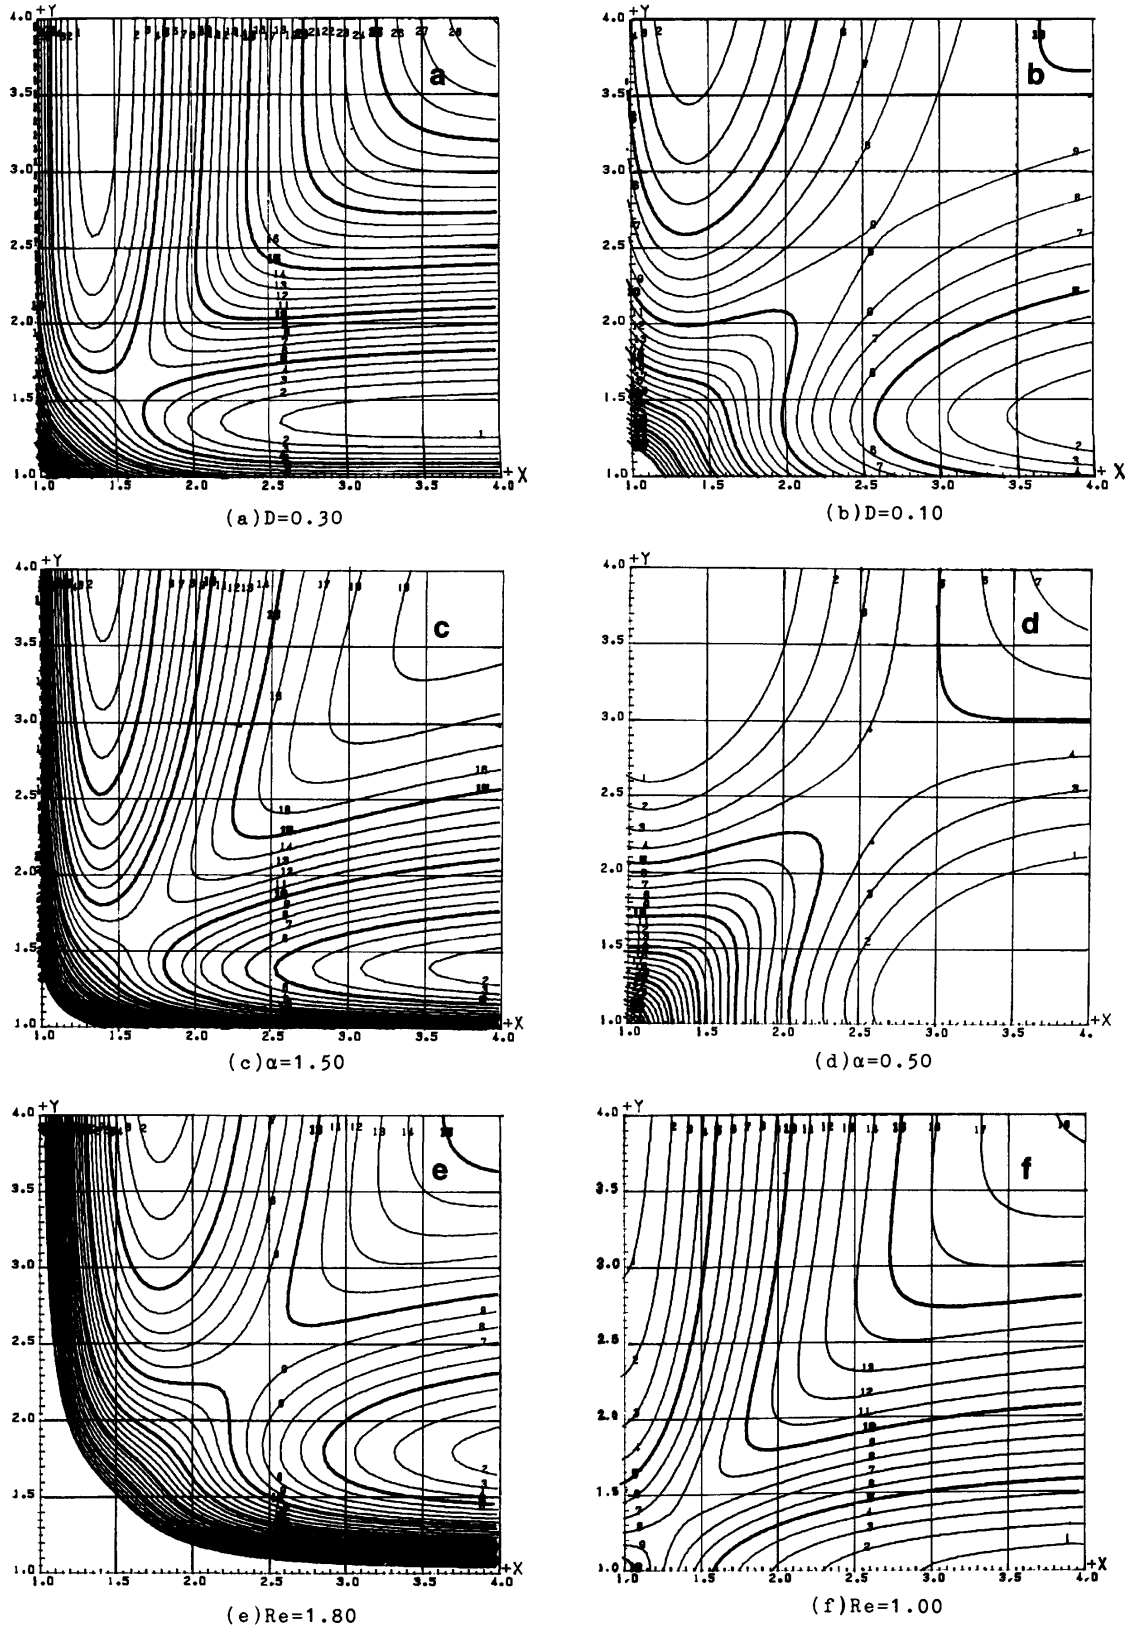

Fig. 5. Equipotential contour maps on different D, α, R_e for model of the rectangular H_4 system.

point moves to the inside. The barrier height decreases a little.

(b) D=0.10: The valley along the minimum energy path decreases in height, depth, and slope. The barrier height changes very little.

(c) α=1.50: The valley along the minimum energy

Table 2. Barrier Height and Coordinates of the Minimum Energy Path in Six Cases[a] of the Changes of Diatomic Constants for the Model of Linear H_4 System

Case	Starting point	Saddle point	Barrier height	Ending point
	bohr	bohr	kcal/mole^{-1}	bohr
H_4[b]	(4.00, 1.40)	(2.10, 2.10)	114.11	(1.40, 4.00)
(a)	(4.00, 1.40)	(1.70, 1.70)	92.58	(1.40, 4.00)
(b)	(4.00, 1.50)	(2.65, 2.65)	97.41	(1.50, 4.00)
(c)	(4.00, 1.40)	(1.80, 1.80)	145.48	(1.40, 4.00)
(d)	(4.00, 1.30)	(2.70, 2.70)	45.00	(1.30, 4.00)

path shallows and the slope becomes steep. The saddle point moves also to the inside.

(d) α=0.50: The depth and width of the valley increases and their slopes become very low-pitched along the minimum energy path.

(e) R_e=1.80: The depth and slopes of the valley changes very little, but the minimum energy path shifts to the outside. The barrier height changes a little.

(f) R_e=1.00: The depth and slopes of the valley change very little, but the minimum energy path shifts to the inside. The barrier height changes a little.

Conclusions

As is evident from the Figs. 3 and 5, the diatomic constants have sensitive effects on the features of the potential energy surfaces. Except for the case (c) in Fig. 3 where the basin is formed near the saddle point, it should be noted that there appears common outcomes on both cases of the linear H_3 and the rectangular H_4 systems as follows:

(1) The binding energy D correlates remarkably well with the depth, height and slope of the valley along the minimum energy path.

(2) The force constant α correlates especially well with the slope of the valley.

(3) The internuclear equilibrium distant R_e correlates explicitly with the position of the minimum energy path.

Finally, the next step is to investigate for a more complicated system the relationships between the diatomic constants and the curvature of the minimum energy path or position of the saddle point.

The author wishes to thank Professor Takenori Suzuki of Hachinohe Institute of Technology for many helpful discussions. The numerical calculations were performed on the NEC ACOS-1000 computer at the Tohoku University Computing Center.

Thermoanalytical and Calorimetric Studies on Polymorphic Behaviors of Crystalline Modifications in Aliphatic α-Amino Acids with Normal Alkyl Chains

Masayuki MATSUMOTO,* Hirofumi YAJIMA,† and (the late) Takashi HANDA†
M & A Laboratory, 428-12, Kami-asao, Asao-ku, Kawasaki 215
†Department of Applied Chemistry, Faculty of Science, Science University of Tokyo, 1-3, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received February 18, 1986)

The B-A transition in DL-ABA occurs in the wide range of temperature near its decomposition temperature, and the transition pattern is similar to that of γ-α transition in glycine, whereas the pattern of α-γ transition in DL-NL is different from that in glycine, and the α-γ transition of DL-NL is of the first order. The enthalpy difference between modifications A and B of DL-ABA was nearly equal to the enthalpy of transition determined by DSC.

Much attention has been directed to polymorphic transition of aliphatic α-amino acids with normal alkyl chains, including glycine. Only the following compounds, however, have been studied. According to X-Ray diffraction and IR absorption studies, many of the aliphatic α-amino acids have crystalline modifications.[1-5] For example, glycine has 3 crystal modifications called α-, β-, and γ-forms, and the γ-form (trigonal) is transformed into the α-form (monoclinic) in the temperature range between 433 and 483 K. The enthalpy of transition is of the order of 1 kJ mol^{-1}. The transition is inferred to be due to the rearrangement of molecular layers bound with hydrogen bonds between the constituent molecules.[6-8] Iitaka and others found that the B-form of DL-2-aminobutanoic acid(DL-ABA) is transformed into the A-form at 468 K, and X-Ray analysis showed that the γ-carbon atom of the A-form DL-ABA (monoclinic) distributes among anti-position, gauche I, and gauche II with respect to nitrogen atom, whereas the γ-carbon atom in the B-form (tetragonal) is restricted to the anti-position.[6] As for polymorphic transitions of the B-form of DL-ABA and the α-form of DL-norleucine(DL-NL), it is considered that the enthalpy of transition includes contributions of rearrangement of molecular layers due to intermolecular interactions between constituent molecules and conformational change due to the rotation of carbon-carbon bonds in alkyl chains.

The thermodynamic study of phase equilibrium (or transition phenomenon) between crystal modifications seems to be useful together with the structural study of polymorphism, because the combination of structural analysis with thermodynamic study provides a significant information for polymorphism. In particular, the thermal analysis on solid-solid phase transitions between crystalline amino acids brings about suggestive information on transition phenomena of biological systems, especially of biomembranes. The objective of this work is to obtain information on polymorphic modifications of DL-ABA and DL-NL in comparison with the case of glycine by means of differential scanning calorimetry(DSC) and solution calorimetry.

Experimental

Materials. DL-2-Aminobutanoic acid(DL-ABA) and DL-norleucine(DL-NL) were purchased from Tokyo Kasei Co. and glycine from Takara Kohsan Co. All the samples used were the purest reagents commercially available: the purity of the compounds was guaranteed by each manufacturer to be 98%. The DL-NL was obtained as plate-like crystals by standing at 290 K for 24 h and the fibrous DL-ABA from a water-ethanol solution at 283 K for 48 h. By X-Ray diffraction and IR absorption, the DL-NL and DL-ABA samples were identified as α-form and B-form, respectively. The A-form DL-ABA was obtained as tabular crystals from aqueous solution by keeping at 283 K for 24 h, and the α-form glycine as tabular crystals by evaporating water. The A-form DL-ABA and α-form glycine were dried over silica gel for two months, and were dried again in vacuo for 6 h before use.

Apparatus and Procedure. Differential scanning calorimeter used in this experiment is Perkin Elmer DSC-II with Thermal Analysis Data Station(TADS). A few mg of sample was sealed in an aluminum pan, and the sample and the blank pans were set in each respective holder. The measurements of temperature and enthalpy were made in the

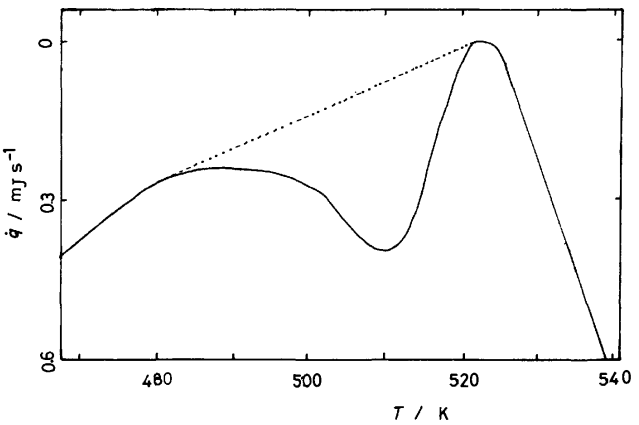

Fig. 1. DSC curve of the B-form of DL-ABA crystals heated at 5 K min^{-1} in the atmosphere of nitrogen. Sample weight: 2.64 mg.

Table 1. Thermodynamic Parameters for the Solid-Solid Transitions of Glycine and DL-2-Aminobutanoic Acid (DL-ABA)

Phase transition	Peak temperature T/K	Enthalpy change ΔH_t/kJ mol^{-1}	Entropy change ΔS_t/J mol^{-1} K^{-1}
Glycine	473(433—483)	0.92±0.08[a)]	1.95
$(\gamma\rightarrow\alpha)_{trs}$	478(459—491)	1.94±0.06	4.06

$(B\rightarrow A)_{trs}$	506(480—520)	4.91±0.29	9.70

a) Ref. 8.

range of heating rate between 0.63 and 10 K min^{-1}. The calorimeter was calibrated with indium, T_f=429.78 K and ΔH=28.5 J g^{-1}, supplied by Perkin Elmer Co. The melting point and enthalpy of fusion of indium obtained by extrapolating to null heating rate, was 429.6±0.1 K and 29.3±0.4 J g^{-1}, respectively. The apparatus for measuring enthalpy of solution was the same as described in the previous work.[9] The infrared spectra and X-Ray diffraction patterns were determined by model DR-31L of Japan Spectroscopic Co. and model JDX-8P of JEOL, respectively. Specific heat capacity measurements were carried out by model SH-3000M of Shinku-Riko Co. at heating rate of 1.5 K min^{-1}. The accuracy of the heat capacity apparatus was ±3%.[10]

Results and Discussion

DSC Measurements of DL-2-Aminobutanoic Acid(DL-ABA). The DSC result for DL-ABA is shown in Fig. 1. Phase transition from B- to A-form is observed in the temperature range between 480 and 520 K. The B-A transition of DL-ABA occurs near its decomposition temperature (577.15 K), and the transition pattern is similar to that of γ-α transition of glycine. The rate of the B-A transition of DL-ABA was slow similarly as the γ-α transition of glycine. Tsuboi et al. confirmed by means of IR spectra that the B-form was transformed into the A-form.[2] IR spetcrum of DL-ABA after transition was identical with that of A-form obtained by them. For comparison, the enthalpy of transition of glycine from γ-form to α-form was measured. The enthalpy value of transition of glycine was compared with that of DL-ABA at the same heating rate of 5 K min^{-1}. The enthalpy change of the B-A transition of DL-ABA was obtained by calculating the area between DSC curves at rise and fall (dotted line) of temperature. The results obtained are summarized in Table 1, where the enthalpy data are the average of 3 runs. Table 1 shows that the apparent entropy change of the B-A transition of DL-ABA is more than twice as that of the γ-α transition of glycine, where the entropy change was estimated by a calculation with the enthalpy change and peak temperature. Large entropy change in the B-A transition of DL-ABA seems to relate to the fact that the compound aquires the rotation around carbon-carbon bond in alkyl chain in solid state.[6] Furthermore, to confirm the value of enthalpy of transition obtained by DSC, the measurement of molar heat capacity of the B-form of DL-ABA was made. In Fig. 2, it appears that molar heat capacity, C_p, exhibits a steep peak and that enthalpy content, H, changes continuously. This feature is similar to that of specific heat capacity of $CuCl_2 \cdot 2H_2O$,[11] and seems as if C_p shows a discontinuity, that is a second-order phase transition. However, in view of the fact that the transition is accompanied by a volume change,[6] C_p and H at the transition temperature is considered to be continuous and discontinuous, respectively. Therefore, this feature makes us conclude that the transition is of the first order. As is shown in Fig. 2, the enthalpy of transition was estimated by extrapolation from both the lower and higher temperature regions to be approximately 5 kJ mol^{-1} at the transition temperature of 481 K.

Solution Calorimetry of DL-2-Aminobutanoic Acid (DL-ABA). It is known that the A-form of DL-ABA is metastable at room temperature, whereas the B-form of DL-ABA is stable below the decomposition temperature (577.15 K). Since it is expected that the difference in the enthalpy of solution at room temperature between A and B is comparable to the enthalpy of transition of B- to A-form of DL-ABA obtained above, the

enthalpy of solution of crystal modifications of DL-ABA was measured at 298.15 K. The results obtained are given in Tables 2 and 3 together with data of preceding authors. The enthalpy of solution of glycine was measured for reference. The enthalpy of solution of both the crystal modifications in water at 298.15 K was determined by an isoperibol calorimeter. As was shown in a previous work, the systematic errror of the calorimeter was 1.4%, and the accuracy was 0.34%.[9] The enthalpy was compared between the final concentrations of glycine and DL-ABA, i.e., 1×10^{-2} and 5×10^{-3} mol kg^{-1}, respectively. The average value of enthalpy of solution for 5 determinations was used. The enthalpy data obtained agree fairly well with those of Abraham et al.[12] The difference in the enthalpy of solution between α- and γ-forms of glycine is more than twice as that obtained by Sasaki.[8] This may be due to the difference of apparatus used and purity of α-glycine used for the solution calorimetry. Sasaki pointed out that the enthalpy difference in two forms of glycine can be ascribed to the difference in intermolecular hydrogen bonds caused by rearrangement of molecular layers.[8] Assuming that the contribution of the difference in intermolecular hydrogen bonds of two forms of DL-ABA is nearly equal to that of glycine polymorphs, the difference of intermolecular hydrogen bonds is about 2 kJ mol^{-1}. The data in Table 3 suggest that the contribution due to intramolecular interactions, such as rotation around carbon-carbon bonds in alkyl chain, is predominant in the case of DL-ABA. From Tables 1 and 3, the difference in enthalpy of solution between two forms of DL-ABA appears to be nearly equal to the enthalpy of transition determined by DSC. This fact may be explained as follows. The enthalpy difference between two forms, $\Delta\Delta H_s$, is expressed as

$$\Delta\Delta H_s = \Delta H_t - \int_{T_s}^{T_t} \Delta C_p \mathrm{d}T, \quad (1)$$

where ΔC_p is the difference between molar heat capacity values at transition temparature, T_t, and at temperature of solution calorimetry, T_s. Experimental results show that $\Delta\Delta H_s$ is nearly equal to ΔH_t. The ΔC_p is negligible in the case of DL-ABA, but ΔC_p in glycine is not negligible for small quantity of enthalpy.

DSC Measurements of DL-Norleucine (DL-NL). The previous work[13] reported that a solid-solid phase transformation of crystalline DL-NL was displayed by means of DSC and X-Ray diffraction. As is shown in Fig. 3, the values of peak temperature depend on the heating rate, but the enthalpy of transition is nearly constant. The transition temperature and enthalpy of transition are estimated to be 390 K and 4.4 kJ mol^{-1}, respectively, by extrapolation to null heating rate.

On the other hand, Grunenberg et al. observed the transitions for the group of crystalline neutral apliphatic α-amino acids by means of DSC, infrared absorption spectra, and Raman spectra;[14,15] the transition of DL-NL occurs at 390 K and the enthalpy of transition is 4.41 kJ mol^{-1} at a heating rate of 10 K min^{-1}. Although the form of DL-NL was not identified as α-form by Grunenberg et al., our values are in good agreement with those by them. Therefore, the

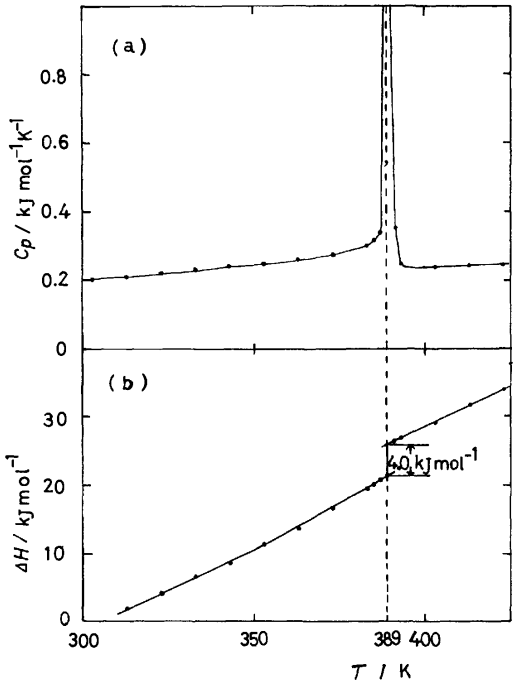

Fig. 4. Molar heat capacity (a) and enthalpy change (b) during the α-γ transition in DL-norleucine. Sample weight: 2.841 g. Heating rate: 1.5 K min^{-1}.

α-form DL-NL seems to be transformed into a new form called γ-form at 390 K.

In order to know the nature of transition of DL-NL, the specific heat capacity was measured. The sample weight was 2.841 g. As is shown in Fig. 4, the α-γ transition of DL-NL was found to be of the first order.[16] Figure 4 indicates that the transition temperature and the enthalpy of transition correspond to those by DSC measurements. The transition of DL-NL is reversible, whereas the γ-α transition of glycine and the B-A transition of DL-ABA are irreversible. Therefore, the free energy curves should intersect at the α-γ transition temperature, T_t. The entropy change in the α-γ transition of DL-NL by DSC was estimated to be 11 J mol^{-1} K^{-1}. The transition will be characterized by a large structural change similarly to the B-A transition in DL-ABA (9.70 J mol^{-1} K^{-1}, see Table 1).

Infrared Absorption Spectra and X-Ray Diffraction of DL-NL. Other physical methods such as X-Ray diffraction and IR absorption spectra were used for analysing structure change above and below the transition temperature of DL-NL.[13] The X-Ray pattern obtained was identical with that of the α-form crystals reported by Dawson and Mathieson (J.C.P.D.S. Powder Diffraction File No. 7-717).[17] Also IR spectrum of the α-form DL-NL at room temperature was identical with that of known structure.[18] The existence of polymorphism of DL-NL was suggested by Mathieson, who deduced it to be the β-form or the superlattice from the dimorphs of DL-methionine.[19-21] X-Ray diffraction result was different from the spacings either of β-form or of the superlattice. Also IR spectra of DL-NL crystals measured above and below the transition temperature are given in Fig. 5. The spectral pattern at 443 K(b) is different from that at 353 K(a). In the wavenumber range of 2000—3000 cm^{-1}, the band of the α-form (a) at 2100 and 2950 cm^{-1} were assigned to be of NH_3^+ stretching,[18] and these bands shifted to shorter wavenumbers by about 20 and 50 cm^{-1} at 443 K(b). Accordingly, it is considered that intermolecular hydrogen bond distance between NH_3^+ and COO^- groups in the γ-form is shorter than that of the α-form. Also the bands at 1470 and 925 cm^{-1} in the α-form are assigned to be of CH_3 asymmetric deformation and CH_3 rocking plus CC stretching, respectively.[18,22] The changes of the bands were observed at 443 K(b). The IR spectrum change obtained is similar to that of L-leucine reported by Bougeard.[15] The spectral change suggests that the α-γ transition in DL-NL is caused by the change of intermolecular interactions between layers accompanied by the conformational change of alkyl chains.

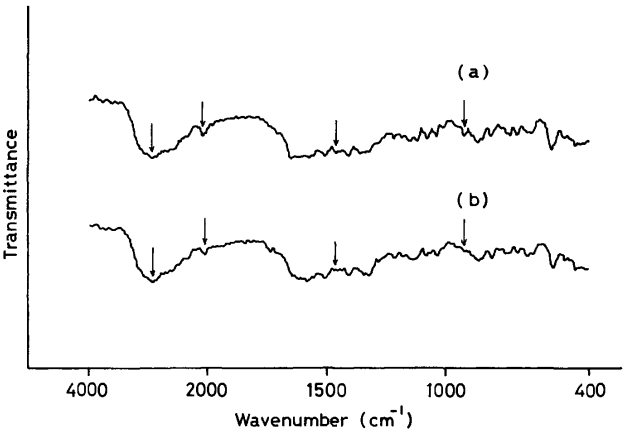

Fig. 5. Infrared absorption spectra of DL-norleucine at 353 K (a) and at 443 K (b).

Application of the Enthalpy of Solution to the Analysis of Mixtures of A- and B-Forms of DL-ABA. The enthalpy of solution of DL-ABA in water has been measured calorimetrically by some investigators, but the values obtained were different to each others.[23-25] The different solution enthalpy data can be ascribed to samples which are mixtures of A- and B-forms. Plate-like A-form crystals are easily obtained by recrystallization from water or water-ethanol mixture, but it is difficult to obtain pure B-form uncontaminated with the A-form as demonstrated by Abraham et al.[12] A sample of DL-ABA was regarded as pure B-form, because the IR spectrum of fibrous DL-ABA was identical with that given by Tsuboi et al.[2]

If the sample used is a mixture of A- and B-forms, the molar enthalpy of solution, ΔH_s^m, is expressed by

$$\Delta H_s^m = (1-x)\Delta H_s^A + x\Delta H_s^B, \quad (2)$$

where x is mole fraction of B-form in DL-ABA, and ΔH_s^A and ΔH_s^B is molar enthalpy of pure A- and B-

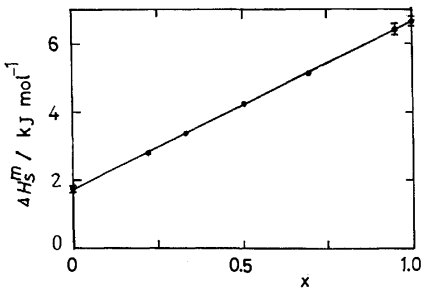

Fig. 6. Plots of the enthalpy of solution of mixture, ΔH_s^m, against mole fraction of the B-form, x, in DL-ABA at 298.15 K. It shows that Eq. 2 is found to hold as ΔH_s^m variation of arbitrary mixing ratios on mole fraction gives straight line.

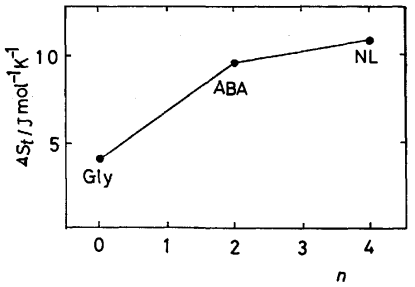

Fig. 7. Correlation between number of carbon atoms, n, in the alkyl chains of amino acids and apparent entropy of transition.

form, respectively.

To confirm whether Eq. 2 is hold, the solution calorimetry of mixing of A-form with B-form was performed at 298.15 K. Figure 6 shows linear relationship between ΔH_s^m and ΔH_s^A (or ΔH_s^B). Accordingly, we can estimate the mole fraction of a component in the mixture from the enthalpy data obtained by mixtures of known mole fractions. ΔH_s^A and ΔH_s^B values are given in Table 2.

For example, the crystallization from ethanol-water mixture at 290 K for 24 h gave ΔH_s^m of 6.43±0.14 kJ mol^{-1} at 298.15 K as the average of 3 determinations; Eq. 2 gave the result that the mixture consists of 95% B-form and 5% A-form.

Conclusion

The polymorphic transitions of DL-2-aminobutanoic acid(DL-ABA) and DL-norleucine(DL-NL) were studied by differential scanning calorimetry(DSC). The experimental results show that the B-A transition in DL-ABA occurs in the wide range of temperature near its decomposition temperature, and the transition pattern is similar to that of γ-α transition in glycine, whereas the pattern of α-γ transition in DL-NL is different from that in glycine. The DL-NL transition is of the first order. The solution calorimetry of crystalline modifications of DL-ABA was performed by an isoperibol calorimeter at 298.15 K to reveal that the enthalpy difference is nearly equal to the enthalpy of transition by DSC. The α-γ transition in DL-norleucine is accompanied with change of intermolecular interactions such as hydrogen bond and van der Waals force between layers caused by the conformational change of alkyl chains. The correlation between the number of carbon atoms in alkyl chains of amino acids and the apparent entropy of transition is shown in Fig. 7.

We are grateful to Dr. Kazuko S. Kunihisa of National Chemical Laboratory for Industry for the sample of γ-form glycine and for advice on DSC measurement. We also would like to thank Drs. Kazuo Amaya, Midori Gotoh, and Masato Mamiya of the Laboratory for advice of calorimetry, computation of X-Ray diffraction data, and IR absorption measurements, respectively.

A Model of Crystal Defects in Calcite by Sodium and Potassium Uptake

Masamichi Ishikawa† and Masami Ichikuni
Department of Environmental Chemistry and Engineering, Tokyo Institute of Technology, Midori-ku, Yokohama 227
(Received April 21, 1986)

Crystal defects in calcite containing Na and K ions were investigated by means of a model based on statistical thermodynamics and measurements of thermoelectric power. The varying amount of Na and K ions in the crystal was interpreted on an assumption of ideal solution of the ions as $Ca_{1-x-y}\square_{x+y}[Na_{2x}, K_{2y}]CO_3$, where □ and [ ] means Ca-vacancy and interstitial ion, respectively. In the model, the excess charge of Na and K ions is balanced with Ca-vacancy to form interstitial-vacancy pairs ($[Na, K]_2\square$). Measurements of thermoelectric power in calcite showed the cationic transport which resulted from Na and K interstitials and/or Ca-vacancies. From the ideal mixing of Na and K ions at interstitial sites, the K/Na molar ratio in calcite was correlated with that in aqueous solution at 20 °C and pH 8.5 by the formula,

$$\frac{K_S}{Na_S} = 0.20\frac{K_L}{Na_L},$$

where S and L refer to solid- and aqueous-phase, respectively.

The study of sodium and potassium partitioning between carbonate minerals and aqueous solution has suggested the incorporation of these monovalent ions into the carbonate lattice rather than their presence as solid non-carbonate impurities or liquid inclusions.[1,2] In the partitioning of an ion with different valence from that of host carbonate ion, electroneutrality must be maintained in the crystal. The incorporation of such ions is usually accompanied with the formation of crystal defects, such as vacancies, interstitial ions, and substitutional ions.[3] The identification of crystal defects associated with impurity ions is needed to establish the partition theory of carbonate minerals. Although defect in calcite has been considered in the partitioning process of Na and K, the identification of defects has not fully been performed.

Electrical properties, such as ionic conductivity, dielectric loss and thermoelectric power, of calcium carbonate have been studied to characterize the crystal defects in the crystals.[4-6] These transport properties depend on the concentration and mobility of defects in the crystal and give direct information concerning the defect characteristics. However, it is difficult to assign the type of defect to each impurity ion, because natural and synthetic calcium carbonates contain different amounts of impurity ions. The nature of defect induced by impurity ions needs to be better understood. For the study of electrical properties, it is necessary to use samples having controlled impurity content. Further difficulty arises from the polycrystalline nature of samples. It is pointed out that the measurement of thermoelectric power of ionic crystals is not affected by the state of aggregation of samples.[7] The method, therefore, seems to be practical when we use substances not in a single-crystal form.

Statistical thermodynamics has been applied to the theoretical investigation of crystal defects in ionic crystals.[8-11] Assuming random distribution of defects in a crystal, configurational entropy is calculated to derive the equation which satisfies the condition of minimum free energy. The equation describes the equilibrium concentration of defect with respect to impurity concentration and temperature. This method requires a defect model which makes us calculate the configurational entropy and is useful for identifying the type of crystal defects.

Ishikawa and Ichikuni[2] suggested the interstitial incorporation of sodium and potassium in calcite, and assumed that the position between the carbonate ion and CaO_6 octahedron would be a possible interstitial site. Formation of Ca-vacancy in calcite was also assumed in order to explain compensation for the excess charge due to sodium and potassium. The purpose of this paper is to verify the above model based on the statistical thermodynamic calculation of sodium and potassium doping in calcite and the measurement of thermoelectric power. The model gives the formula expressing the relationship between K/Na ratio in calcite and that in aqueous phase.

Experimental

Calcite was precipitated from $Ca(OH)_2$ solution containing different amounts of NaCl and KCl by adding CO_2-saturated water. The solution was constantly stirred at 20 °C in a closed reaction vessel until an equilibrium after about 40 h. Precipitated calcite was about 1 μm in size and rhombohedral in shape. The uniform distribution of Na and K in calcite crystals was confirmed by fractional leaching in dilute HCl solution.[2] Synthetic calcite contained Cl of about 0.001 mol kg^{-1}. The content was 10^2 times lower than Na and K contents. The effect of Cl on the Na and K uptake by calcite was, therefore, disregarded in the discussion.

The measurement of thermoelectric power was made on calcite samples containing 0.13 mol kg^{-1} of Na and 0.073 mol kg^{-1} of K. The thermoelectric cell used was made of pyrophyllite preheated at 800 °C for 3 h. The arrangement of the cell was similar to that of Parravano.[7] Calcite

sample was pressed at about 0.5 GPa to form a pellet of 5 mm in diameter and 7 mm thick, and was set between two platinum electrodes inside the cell. The electrodes were tightly pressed against the sample by two pyrophyllite supports, which contain chromel-alumel thermocouples and nichrome heaters near the sample. In order to reduce thermal convection current, the cell was mounted horizontally in the furnace. Supplementary heating was provided with nichrome heater to establish a temperature gradient between the electrodes.

Results

Coprecipitation of Na and K with calcite was carried out under controlled conditions where aqueous concentration of Ca^{2+} and HCO_3^- was fixed at 0.6 and 1.2 mM, respectively, at pH 8.5. Table 1 gives the amounts of coprecipitated Na and K with respect to various Na and K compositions of aqueous solutions. To investigate the relationship between contents of Na and K in calcite, the amount of coprecipitated K was determined as a function of that of Na as shown in Fig. 1, where aqueous K activity was fixed at a constant value ($a_K^L=0.058$). The result shows that K incorporation into calcite decreases with increasing Na content. The relationship between Na content and K content in calcite will be quantitatively examined in Discussion.

The thermoelectric voltage (ΔV) in samples was reversibly changed with increasing and decreasing temperature gradient (ΔT) between two electrodes. Figure 2 shows the thermoelectric power ($\Delta V/\Delta T$) as a function of temperature when ΔT was maintained at 10—15 °C. Bars in Fig. 2 show the range of the thermoelectric power of increasing and decreasing temperature. For all the samples the colder side of the sample was found to be positive in the temperature range between 360 and 570 °C and thermoelectric power showed a maximum and a minimum.

Discussion

Interstitial-Vacancy Type Solid Solution. A mech-

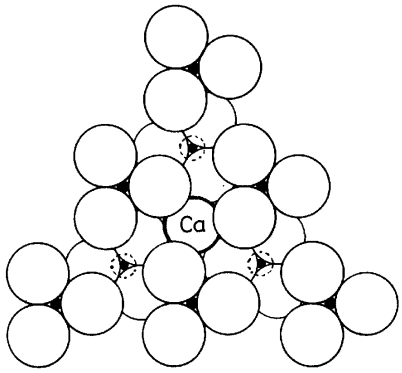

Fig. 3. Interstitial positions in the calcite lattice. The symbol ◌ represents equivalent interstitial sites around a Ca ion. Another set of three sites, found at inversion points with respect to the Ca ion, are omitted for the sake of simplicity.

anism of Na and K uptake by calcite was suggested by the present authors,[2] who assumed that Na and K are incorporated into interstitial positions in the calcite lattice. The total numbers of available interstitial sites for Na and K were 0.15 and 0.12 mol kg^{-1}, respectively, and Ca-vacancy (net charge is −2) balances with the positive charge of the ions. The interstitial sites in the calcite crystal are indicated in Fig. 3. The calculated size of the sites is about 0.89 A in radius (see Appendix), and a site is surrounded by six O^{2-} ions. Oxide ions cause a negative atmosphere around the sites.

According to the mechanism, solid solution of Na_2CO_3 and K_2CO_3 in $CaCO_3$ is formulated as,

$$(1-x-y)CaCO_3(S) + xNa_2CO_3(L) + yK_2CO_3(L) = Ca_{1-x-y}\square_{x+y}[Na_{2x}, K_{2y}]CO_3(S), \quad (1)$$

where □ and [ ] means Ca-vacancy and interstitial ion, respectively.

In order to deduce the equilibrium relationship between x and y in reaction (1), we assume as follows:

(i) Formation of interstitial-vacancy pairs ([Na, $K]_2\square$), to maintain electroneutrality in calcite.

(ii) Random distribution of the interstitial-vacancy pairs in the crystal, where dimer or trimer aggregations of the pairs are disregarded.

(iii) Ideal mixing of Na and K on the interstitial sites.

Assumptions (ii) and (iii) are introduced to simplify a calculation. As to assumption (ii), formation of dimer and trimer complexes of impurities and vacancies has been known in alkali halides at low temperature and high impurity contents.[12-14] Although this phenomenon may occur in the present case, simplicity of the model would be preferable, because any such treatments to produce an aggregation of impurity-vacancy complexes had not been done.

The dependence of K composition (y) on Na composition (x) in calcite at a constant temperature is determined by minimizing the free energy of $Ca_{1-x-y}\square_{x+y}[Na_{2x}, K_{2y}]CO_3$. To calculate the Gibbs free energy, $G=U+pV-TS$, of the solid solution, it is necessary to know the entropy term. The entropy of crystalline solids is the combination of the entropy due to thermal vibration of lattice ions (S^t) and the configurational entropy (S^c) due to mixing of ions in the crystal.

The configurational entropy among degenerate configurations is defined by the formula,

$$S^c = k \ln \Omega, \quad (2)$$

where Ω, multiplicity of thermodynamic probability of the system, is the number of distinguishable configurations that the system can adopt, and k is Boltzmann's constant. Using Eq. 2, the configurational entropy of $Ca_{1-x-y}\square_{x+y}[Na_{2x}, K_{2y}]CO_3$ is calculated as,

$$S^c = k \ln \Omega^{\text{i-v pair}} = k \ln \left[\left(\frac{N_0!}{\left(N_0 - \frac{n^T}{2}N_0\right)!\left(\frac{n^T}{2}N_0\right)!} \times \frac{\left(\frac{n^T}{2}N_0\right)!}{\left(\frac{n^T}{2}N_0 - xN_0 - yN_0\right)!(xN_0+yN_0)!} \right)_v \times \left(\frac{(2xN_0+2yN_0)!}{(2xN_0)!(2xN_0)!} \right)_i \times 3^{(xN_0+yN_0)} \right], \quad (3)$$

where i and v denotes interstitial and vacancy, respectively, and N_0 is Avogadro's number and n^T the total number of available interstitial sites in calcite. In Fig. 3, there are six equivalent interstitial sites (only three of such sites are shown) around a Ca ion just above and below the same cationic layer of the lattice. Since it results in three equivalent inversion-related [Na, $K]_2$ □ pairs with respect to one Ca-vacancy, the multiplicity increases by a factor of 3 over each interstitial-vacancy pair of a configuration. By use of Stirling's approximation, $\ln N! \simeq N \ln N - N$, Eq. 3 is transformed,

$$S^c = -kN_0 \ln \left[\left(1-\frac{n^T}{2}\right)\ln\left(1-\frac{n^T}{2}\right) + \left(\frac{n^T}{2}-x-y\right)\ln\left(\frac{n^T}{2}-x-y\right) + (x+y)\ln(x+y) + 2x\ln 2x + 2y\ln 2y - (2x+2y)\ln(2x+2y) - (x+y)\ln 3 \right]. \quad (4)$$

The difference in the free energy (ΔG) of reaction (1) is then formulated as Eq. 5, using the molar free energy of species i, $g_i=u_i+pv_i-Ts_i^t$, where u_i is the molar internal energy, v_i the molar volume, and s_i^t the molar vibrational entropy.

$$\begin{aligned}\Delta G &= [(1-x-y)g_{Ca} + (x+y)g_\square + 2xg_{Na} + 2yg_K + g_{CO_3} - TS^c] - [(1-x-y)g_{Ca} + (1-x-y)g_{CO_3} + x\mu^L_{Na_2CO_3} + y\mu^L_{K_2CO_3}] \\ &= x(2g_{Na}+g_\square+g_{CO_3}-\mu^L_{Na_2CO_3}) + y(2g_K+g_\square+g_{CO_3}-\mu^L_{K_2CO_3}) - TS^c, \end{aligned} \quad (5)$$

where μ^L is the chemical potential of Na_2CO_3 and K_2CO_3 in aqueous solution. Thus, the relationship between x and y is obtained from Eqs. 4 and 5, with the condition that at the equilibrium $\partial\Delta G/\partial y=0$ at constant x and constant temperature,

$$\left(\frac{\partial \Delta G}{\partial y}\right)_{x,T} = (2g_K + g_\square + g_{CO_3} - \mu^L_{K_2CO_3}) - T\left(\frac{\partial S^c}{\partial y}\right)_{x,T}$$
$$= (2g_K + g_\square + g_{CO_3} - \mu^L_{K_2CO_3}) + kN_0T\ln\left[\frac{(x+y)(2y)^2}{3\left(\frac{n^T}{2}-x-y\right)(2x+2y)^2}\right] = 0. \quad (6)$$

Replacing x and y by Na composition Na_S, and K composition K_S, respectively, Eq. 6 is rewritten as,

$$\ln\frac{K_S}{Na_S+K_S} = -0.5\ln\frac{Na_S+K_S}{n^T-Na_S-K_S} - 0.5\left(\frac{2g_K+g_\square+g_{CO_3}-\mu^L_{K_2CO_3}}{kN_0T} - \ln 3\right). \quad (7)$$

If aqueous activity of K_2CO_3 is fixed at a constant value, then $\mu^L_{K_2CO_3}$ becomes constant and Eq. 7 shows a linear relationship between Na_S and K_S in calcite with an inclination of -0.5.

To examine the validity of the interstitial-vacancy model described above, $\ln(K_S/[Na_S+K_S])$ is plotted against $\ln([Na_S+K_S]/[n^T-Na_S-K_S])$ in Fig. 4. As to n^T, different values of 0.15 and 0.12 mol kg^{-1} were obtained for Na and K, respectively. Since interstitial-vacancy pairs should be defined with respect to the sites available for both Na and K, 0.12 mol kg^{-1} was adopted as n^T. Other data used are given in Table 1. The empirical equation was formulated by the least-squares fit as,

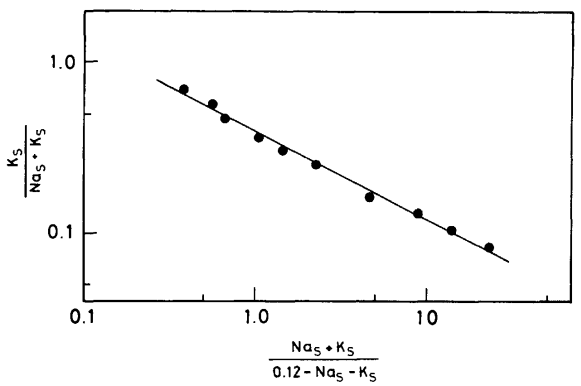

Fig. 4. Logarithmic relationship between sodium and potassium contents of calcite at 20°C and a constant activity of K_2CO_3 in aqueous solution.

$$\ln\frac{K_S}{Ka_S+K_S} = -0.51\ln\frac{Na_S+K_S}{0.12-Na_S-K_S} - 0.94. \quad (8)$$

The inclination of Eq. 8 (-0.51) is identical with the theoretical value in Eq. 7 (-0.5), showing that the interstitial-vacancy model gives an adequate explanation for Na and K mixing in calcite.

Defects associated with Na and K in calcite were investigated by measuring the thermoelectric power of the doped calcite crystal. The sign of thermoelectric power relates with the sign of dominant charge carriers in the crystal. Since charge carriers move along the temperature gradient toward the colder electrode, the positive sign indicates that the charge carrier is a cation. As shown in Fig. 2, the sign of thermoelectric power was positive in the temperature range of 360—570 °C, where defects induced by impurities dominate in calcite.[5] This result indicates the presence of charged defects which cause the transportation of cations and are attributed to interstitial cations or cation vacancies, that is, Na and K interstitials or Ca-vacancies. It has been observed in the measurements of ionic conductivity in alkali halides that the concentration of free interstitials or vacancies is increased by the dissociation of impurity-vacancy pairs in the similar temperature range.[15] The maximum and the minimum of thermoelectric power in Fig. 2 may correspond to the change in transportation mechanism induced by the dissociation of the interstitials-vacancy pairs. These results support the interstitial incorporation of Na and K, when the electroneutrality is maintained by formation of Ca-vacancies in calcite.

K/Na in Calcite as a Function of Aqueous K/Na. Natural calcites contain different amounts of Na and K depending on the origin. Table 2 summarizes the difference in K/Na molar ratio in various natural calcites. Some studies have reported a correlation of K/Na in calcites with chemical composition of natural waters from which precipitation took place.[16,17] In spite of considerable scattering of K/Na in natural calcites, however, the applicability of K/Na value as a geochemical indicator has not been established. Our study strongly suggests that K/Na in calsites can be formulated as a function of K/Na in aqueous solutions based on the mechanism of ion incorporation into the crystal.

Equilibrium partitioning of the ions between calcite

Table 2. Potassium/Sodium Molar Ratio in Marine and Freshwater Calcite

	Salinity	K_L	Ks	Nas	Ks/Nas	
	‰	Na_L	ppm	ppm	Obsd	Calcd
Marine calcite						
Shells[20]	35	0.0218	18—280	2160—6580	0.0040—0.037	0.0044
Freshwater calcite						
Travertines[17,21]	0.8—4.7	0.013—0.044	16—282	220—1410	0.034—0.40	0.0026—0.0088
Limestones[18]	0.23—0.25	0.017—0.063	3—33	19—47	0.099—0.50	0.0034—0.013

and aqueous solution is represented by Eqs. 9 and 10 for Na and K, respectively, where Na and K incorporation into the crystal is assumed to be independent of aqueous Ca and pH.[2)]

$$K_{Na} = \frac{Na_S}{\gamma_{Na} Na_L [*]_S} \quad \text{and} \tag{9}$$

$$K_K = \frac{K_S}{\gamma_K K_L [*]_S}, \tag{10}$$

in which K is the equilibrium constant of Na and K partitioning, γ is the activity coefficient of aqueous Na and K, and $[*]_S$ means the number of vacant interstitial sites in calcite. On the assumption of ideal mixing of Na and K, the activity coefficient of each ion in the crystal is unity and Eq. 11 is obtained from Eqs. 9 and 10.

$$\frac{K_S}{Na_S} = \frac{K_K \gamma_K K_L [*]_S}{K_{Na} \gamma_{Na} Na_L [*]_S} \simeq \frac{K_K}{K_{Na}} \times \frac{K_L}{Na_L}. \tag{11}$$

The proportional relationship of K/Na between calcite and aqueous solution was confirmed by the result in Fig. 5 by use of data in Table 1. The empirical equation was obtained as,

$$\frac{K_S}{Na_S} = 0.20 \frac{K_L}{Na_L}. \tag{12}$$

The K/Na ratios in marine shells, travertines, and limestones are estimated by Eq. 12 and given in Table 2. Observed values of K/Na differ by 1—2 orders of magnitude from those of marine shells to those of fresh water limestones. Calculated K/Na ratio in marine biogenic calcite (0.0044) is in the same range of observed K/Na values (0.0040—0.037). The wide range of observed values will be due to variations in physiological conditions of marine invertebrates as explained by the present authors.[2)] Travertines and freshwater limestones, however, have higher K/Na ratios (0.034—0.5) than the calculated values (0.0026—0.013). It is known that K in limestones correlates with acid-insoluble residues and is attributed to contamination from clay minerals.[18,19)] The discrepancy described above may be due to the increase in K content by the contamination.

Conclusions

The distribution of Na and K ions in calcite was formulated on an assumption of ideal mixing of the ions at interstitial sites which are associated with Ca-vacancies. The presence of the pairs composed of Na and K interstitials and Ca-vacancy was confirmed by measuring the thermoelectric power of calcites containing Na and K ions.

A model for Na and K uptake by calcite was presented to treat the partition mechanism of monovalent ions and the mechanism of formation of interstitials and vacancies. Although the theory of elemental partitioning between carbonates and natural waters has asserted the simple substitution of host ions by divalent impurities, most natural carbonates contain some mono- and trivalent ions, such as F^- an PO_4^{3-}. The partitioning of such ions has been qualitatively estimated with respect to ionic charge and radius. It should be noted that the role of crystal defects during the diagenesis of carbonate minerals is poorly understood. An extensive characterization of defects associated with various impurity ions will be fruitful in clarifying geochemical properties of sedimentary minerals.

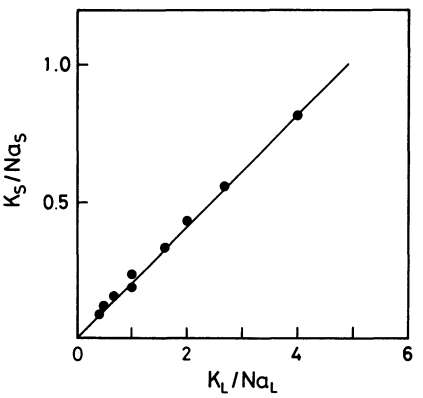

Fig. 5. Potassium/sodium molar ratio in calcite as a function of that in aqueous solution at 20°C.

The authors wish to thank Dr. Takaaki. Kobayashi for his critical comments on the study, and Dr. Kenichi Kondo for his technical assistance in the measurements of thermoelectric power.

Appendix

The calculated size of the coordination polyhedron of the presumed interstitial sites.

The interstitial site is surrounded by six oxygens. In the hexagonal system, the crystallographic coordinates of the four neighboring carbons in calcite are given by C_1 (0, 0, 1/4), C_2 (1, 1, 1/4), C_3 (0, 1, 1/4), and C_4 (1/3, 2/3, 1/12). Then those of the six oxygens will be O_1 (d, d, 1/4), O_2 (1−d, 1, 1/4), O_3 (0, 1−d, 1/4), O_4 (1/3−d, 2/3−d, 1/12), $O_{4'}$ (1/3, 2/3+d, 1/12), and $O_{4''}$ (1/3+d, 2/3, 1/12), where d corresponds to the C-O distance in CO_3^{2-} divided by the lattice parameter a, and O_4, $O_{4'}$, and $O_{4''}$ belong to the same CO_3^{2-}. The d value is calculated as 0.2568 based on the crystallographic data by Effenberger et al.[22)]

The co-ordinates of the interstitial site are given by i (1/3, 2/3, 0.1863), which is equidistant from the six oxygens. The distance r between two points (x_1, y_1, z_1) and (x_2, y_2, z_2) can be calculated by,

$$r^2 = a^2[(x_1-x_2)^2 + (y_1-y_2)^2 - (x_1-x_2)(y_1-y_2)] + c^2(z_1-z_2)^2,$$

where a and c are the lattice parameters for calcite. The distance between i and any O is then 2.1744 Å. Assuming that the O radius is equal to the C-O distance in CO_3^{2-}, we get 0.8929 Å as the radius of the interstitial site.

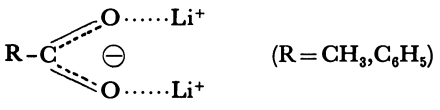
The Specific Effects of Tetraalkylammonium and Alkali Metal Ions on the Polarographic Reduction of Nitroalkanes and Nitrobenzenes in Acetonitrile

Masashi Hojo,* Kazukiyo Nishikawa, Yoshihiro Akita, and Yoshihiko Imai
Department of Chemistry, Faculty of Science, Kochi University, Kochi 780
(Received May 6, 1986)

The polarographic behavior of 2-methyl-2-nitropropane ($(CH_3)_3CNO_2$) was examined at DME in acetonitrile with various supporting electrolytes. The addition of Et_4N^+ or n-Bu_4N^+ caused the half-wave potential ($E_{1/2}$) of $(CH_3)_3CNO_2$ to shift negatively in the presence of a fixed concentration of $NaClO_4$. The negative shift was explained in terms of the interaction between tetraalkylammonium cations and the unreduced molecule of $(CH_3)_3CNO_2$. The formation of $(CH_3)_3CNO_2^{\cdot-}(Na^+)_2$ was also suggested, and the conditional formation constants of the species were obtained by the positive shift in the $E_{1/2}$ of $(CH_3)_3CNO_2$ with increasing concentration of Na^+ at certain concentrations of Et_4N^+ and n-Bu_4N^+. Other nitroalkanes and nitrobenzenes were also examined. The effect of water on the half-wave potentials of the first waves of the nitro compounds suggested the formation of $RNO_2^{\cdot-}(H_2O)_2$-type species.

The anion radicals of nitro compounds have attracted a number of electrochemists as well as organic chemists.[1,2] The ion-pair formation between the anion radicals and alkali metal ions in nonaqueous solutions has been suggested both by ESR[3,4] and polarography.[5-7] However, the shift in the half-wave potential of nitrobenzene in polarography has not been connected directly to the thermodynamic value of the ion-pairing.[8] Krygowski et al.[7] tried to evaluate the ion-pair formation constants between the nitrobenzene-anion radical and cations (alkali metal and tetraalkylammonium ions), using the effective ionic potential of the solvated cations in DMF. Kakutani et al.[9] discussed the effect of supporting electrolytes on kinetic paramaters in the polarographic reduction of *p*-nitrotoluene from the point of view of the double-layer theory.

We ourselves have studied polarographically ion-pair formation (or complex formation) reactions between alkali metal ions and carboxylate ions in nonaqueous solvents.[10,11] The formation of the $RCO_2^-(M^+)_2$ (M=Li and Na)-type species was clarified in acetonitrile, one of the protophobic solvents.[11]



(R=CH_3,C_6H_5)

Moreover, we have found that the $RCO_2^-(M^+)_2$ species plays an important role in the polarographic reduction of carboxylic acids in pyridine solutions containing alkali metal ions as the supporting electrolyte cation.[12] Itabashi has proposed the formation of the $[CH_3COOLi_2]^+$ species in the polarographic reduction of copper(II) acetate in acetonitrile containing lithium ions.[13]

Now, let us give our attention to the similarity in the apparent structure between the carboxylate ion (RCO_2^-) and the anion radical ($RNO_2^{\cdot-}$) of a nitro compound:

In the present investigation, nitroalkanes and nitrobenzenes were examined polarographically in acetonitrile containing tetraalkylammonium (R_4N^+) and alkali metal (M^+) perchlorates as the supporting electrolytes. The specific effects of the coexistence of R_4N^+ and M^+ will be discussed. The effects of proton donors, phenol and water, will also be discussed briefly.

Experimental

Commercial nitro compounds—2-methyl-2-nitropropane ($(CH_3)_3CNO_2$, Aldrich Chemical Company, Inc.), 1-nitrobutane (Aldrich), nitroethane (Wako Pure Chemicals, EP grade), nitromethane (Wako, GR grade), nitrobenzene (Wako, GR grade), and *p*-nitrotoluene (Wako, GR grade)—were used without further purification. Lithium, sodium, tetraethylammonium, and tetrabutylammonium perchlorates were prepared by the methods mentioned previously.[14] The method of purifying acetonitrile has been described elsewhere.[15] Phenol (Wako, GR grade) was used as received.

All the polarograms were recorded with a Yanagimoto polarograph, Model P-1000, and a Watanabe X-Y recorder, Model WX-4401-L0. The rate of the potential sweep was 5 mV s^{-1}. The dropping mercury electrode had the following open-circuit characteristics: m=2.34 mg and τ=2.9 s in a 0.1 M (1 M=1 mol dm^{-3}) Et_4NClO_4–MeCN solution at h=50 cm. The drop time was regulated so as to be 1.0 s by means of a Yanagimoto P-1000-ST drop-timer, except for the potential range of −2.7 V and more negative potentials. The reference electrode was a silver-silver perchlorate electrode, Ag/0.1 M $AgClO_4$–MeCN. All the measurements were carried out at (25±0.2) °C. High-purity nitrogen gas was used for the deoxygenation.

Results and Discussion

Effect of Coexistence of Tetraalkylammonium and Alkali Metal Ions on the Reduction of Nitroalkanes.

Fiure 1 shows polarograms of 2-methyl-2-nitropropane ($(CH_3)_3CNO_2$) in acetonitrile containing various supporting electrolytes. With 0.1 M Et_4NClO_4, 2-methyl-2-nitropropane gave two cathodic waves at −2.07 and −2.85 V. These results are similar to those reported by Sayo et al.[16] with the same supporting electrolyte and solvent. The first wave is attributed to the one-electron reduction of the compound to form the monoanion radical.[16,17] With 0.1 M n-Bu_4N^+ as the supporting electrolyte cation, the second wave was hardly observed. A single wave was given in a 0.1-M $NaClO_4$ solution at a more positive potential than the potential in the tetraalkylammonium perchlorates. The positive shift may suggest interaction between the anion radical and Na^+. The wave height of the cathodic wave of the compound with 0.1 M $LiClO_4$ was larger than that with 0.1 M $NaClO_4$ by the factor of 3, as is shown in Table 1. The large wave height indicates that additional reduction is induced by the presence of Li^+.

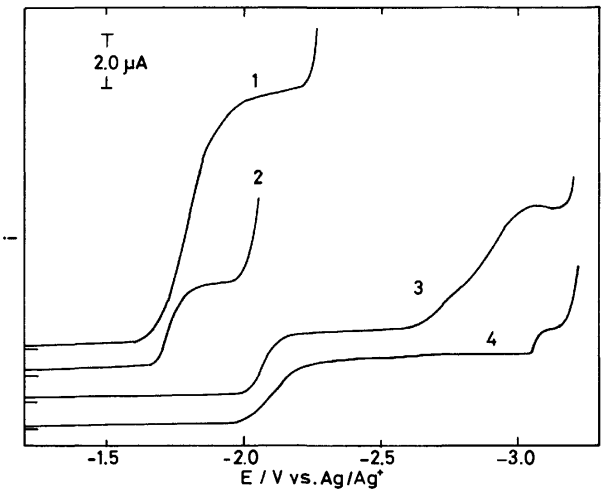


Fig. 1. Polarograms of 2-methyl-2-nitropropane in acetonitrile with various supporting electrolytes. $[(CH_3)_3CNO_2]$=0.4 mM. (1) Li^+, (2) Na^+, (3) Et_4N^+, (4) n-Bu_4N^+ of 0.1 M perchlorate.

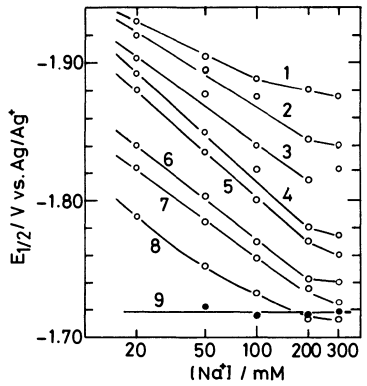

Fig. 2. Effect of Na^+ and n-Bu_4N^+ on the $E_{1/2}$ of 2-methyl-2-nitropropane. $[(CH_3)_3CNO_2]$=0.39 mM. (1) 200, (2) 100, (3) 50, (4) 20, (5) 10, (6) 5, (7) 2, (8) 1, (9) 0 mM of n-Bu_4NClO_4.

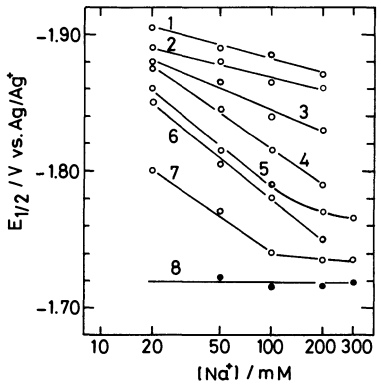

Fig. 3. Effect of Na^+ and Et_4N^+ on the $E_{1/2}$ of 2-methyl-2-nitropropane. $[(CH_3)_3CNO_2]$=0.4 mM. (1) 200, (2) 100, (3) 50, (4) 20, (5) 10, (6) 5, (7) 1, (8) 0 mM of Et_4NClO_4.

The effect of the concentration change of Na^+ on the $E_{1/2}$ of $(CH_3)_3CNO_2$ was also examined. The $E_{1/2}$ value was not significantly shifted by the increase in the concentration of $NaClO_4$ (50—300 mM) in the absence of a tetraalkylammonium salt, as is shown in Fig. 2. However, the addition of a small amount of n-Bu_4NClO_4 caused a remarkable change in $E_{1/2}$. In the presence of 10 or 20 mM n-Bu_4N^+, the $E_{1/2}$ of $(CH_3)_3CNO_2$ was shifted 110 mV to the positive by a 10-fold increase in the concentration of Na^+ ($\Delta E_{1/2}/\Delta$-log[Na^+]=110 mV). The value of $\Delta E_{1/2}/\Delta$log[Na^+] decreased to ca. 90 mV with 2 or 50 mM n-Bu_4N^+ and to smaller values with 1 or 100 mM n-Bu_4N^+. The waves were diffusion-controlled in the presence of both 10—100 mM n-Bu_4N^+ and 20—100 mM Na^+. The slope of $-E$ vs. log[$i/(i_1-i)$] was ca. 60 mV for 20—100 mM $NaClO_4$ with 5—20 mM n-Bu_4NClO_4 and for 200 mM $NaClO_4$ with more than 50 mM n-Bu_4NClO_4. The polarographic behavior with Et_4N^+ and Na^+ was quite similar to that with n-Bu_4N^+ and Na^+, except that the slope of $\Delta E_{1/2}/\Delta$log[Na^+] was, at most, 100 mV at 5 and 10 mM of Et_4N^+ (cf. Figs. 2 and 3).

The data given in Figs. 2 and 3 may be analyzed by

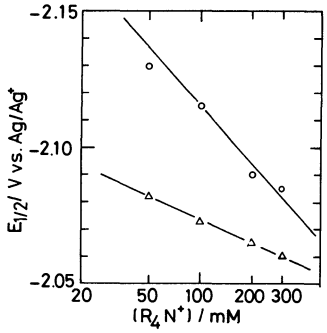

Fig. 4. Effect of the concentration of the supporting electrolyte on the $E_{1/2}$ of the first wave of 2-methyl-2-nitropropane. $[(CH_3)_3CNO_2]$=0.4 mM. (○): n-Bu_4NClO_4, (△): Et_4NClO_4.

means of the following equations, in which ion-pair formation and "complex-formation" reactions are taken into account:

$$(\Delta E_{1/2})_{R_4N^+} = \frac{0.059}{n}\log K' + \frac{0.059}{n}p\log[M^+] \quad (1)$$

$$(\Delta E_{1/2})_{M^+} = -\frac{0.059}{n}\log K'' - \frac{0.059}{n}q\log[R_4N^+] \quad (2)$$

where $(\Delta E_{1/2})_{R_4N^+}$ means the change in $E_{1/2}$ caused by the addition of M^+ at a constant concentration of R_4N^+ and where $(\Delta E_{1/2})_{M^+}$ is that caused by the addition of R_4N^+ at a constant concentration of M^+. K' and K'' are the conditional formation constants. p and q are the numbers of M^+ and R_4N^+ "coordinated" to the anion radical and the unreduced nitro compound respectively. The other conditions for Eqs. 1 and 2 are similar to those given in Ref. 11. For a fixed concentration of n-Bu_4N^+ (e.g., 10 mM), the value of p is derived as 2 from the slope of 110 mV and n=1. On the other hand, q equals ca. 1 at a constant concentration of Na^+ (e.g., 50 mM), as will be described in detail below. The fact that p=2 and q=ca. 1 for $(CH_3)_3CNO_2$ can be explained by the following scheme:

$$\begin{array}{ccc} (CH_3)_3CNO_2 & \overset{e^-}{\rightleftharpoons} & (CH_3)_3CNO_2^{\cdot-} \\ n\text{-}Bu_4N^+ \quad \Big\updownarrow K'' & & K' \Big\updownarrow \quad 2Na^+ \\ (CH_3)_3CNO_2\cdot n\text{-}Bu_4N^+ & & (CH_3)_3CNO_2^{\cdot-}(Na^+)_2 \end{array}$$

The conditional formation constant of the sodium complex was given as log (K'/M^2)=9.6 in the presence of 10 mM n-Bu_4N^+. The $E_{1/2}$ value for the case of [n-Bu_4N^+]=10 mM without Na^+ was estimated by the extrapolation from the $E_{1/2}$ values with 50—300 mM n-Bu_4N^+ (see Fig. 4). The irreversibility of the wave with n-Bu_4N^+ alone was ignored in this case. Similarly, log (K'/M^2) of 7.7 was obtained for [Et_4N^+]=10 mM from Fig. 3.

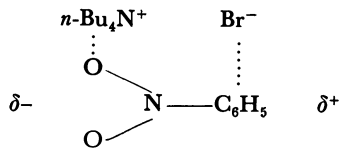
The degree of interaction between n-Bu_4N^+ and $(CH_3)_3CNO_2$ is expressed by the other conditional formation constant, K''. For a constant concentartion of Na^+ (50 mM), the $E_{1/2}$ shifted ca. 65 mV negatively

upon a 10-fold increase in the concentration of n-Bu_4N^+ (from 2 to 20 mM). In the presence of 50 mM Na^+, log (K''/M^2) was estimated to be ca. 4.4 for n-Bu_4N^+. Log (K''/M^2) was 3.8 for the interaction between Et_4N^+ and $(CH_3)_3CNO_2$ in the presence of 50 mM Na^+.

Strange to say, the half-wave potential of the first wave of $(CH_3)_3CNO_2$ shifted positively with increasing concentration of n-Bu_4N^+ or Et_4N^+ ($\Delta E_{1/2}/\Delta\log[R_4N^+]$= ca. 70 and 30 mV for n-Bu_4N^+ and Et_4N^+ respectively) without Na^+, as is shown in Fig. 4. The positive shift suggested the interaction between the R_4N^+ ion and the anion radical. The interaction between the tetraalkylammonium cations and the anion radical of nitrobenzene[7] has also been suggested by the positive shift in the $E_{1/2}$ of the reduction wave of nitrobenzene in DMF solutions. As has been shown above, the half-wave potential shifted negatively with increasing concentration of R_4N^+ in the presence of Na^+. The shifts of opposite directions between the absence and presence of Na^+ can be cleared up by the following idea: The $RNO_2^{\cdot-}$ ion as well as RNO_2 interacts with R_4N^+ in the absence of Na^+. However, the strong interaction of Na^+ with $RNO_2^{\cdot-}$ (the formation of $RNO_2^{\cdot-}(Na^+)_2$) prevents the R_4N^+ ion from interacting with $RNO_2^{\cdot-}$.

The strength of these interactions may vary with the concentration ratio between R_4N^+ and Na^+. We think that two interactions in opposite directions bring the change in the slope in Figs. 2 and 3. The minor change in the half-wave potentials with the concentration change of Na^+ in the absence of R_4N^+ can not be explained exactly at the present time, although the positive potential shift (+0.35 V) by 0.1 M $NaClO_4$, compared with 0.1 M Et_4NClO_4 (see Table 1), suggested interaction between the anion radical and Na^+. The slope of $\log[i/(i_d-i)]$ with 0.1 M $NaClO_4$ alone was rather small (35 mV). The reduction process of 2-methyl-2-nitropropane in acetonitrile seems not to be straightforward with alkali metal cations in the absence of tetraalkylammonium cations. At any rate, we have given a quantitative explanation for some typical cases in the extraordinary phenomena, without considering the other reactions or the double-layer effect.

Hyne has reported interaction between the neutral molecule of nitrobenzene and tetrabutylammonium bromide in a mixture of nitrobenzene and methanol, based on the conductivity data etc.[18] His proposal seems to support our mechanism, in which the interaction between the nitro compound and R_4N^+ is accounted.



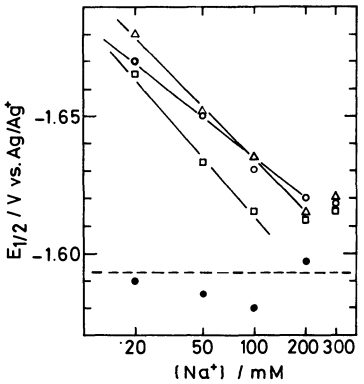


Fig. 5. Change of $E_{1/2}$ of nitroalkanes with Na^+ concentration. (○): 1-Nitrobutane, (△): nitroethane, (□): nitromethane in the presence of 10 mM n-Bu_4NClO_4, (●): 1-nitrobutane, in the absence of n-Bu_4NClO_4. The concn. of a nitroalkane is 0.4 mM.

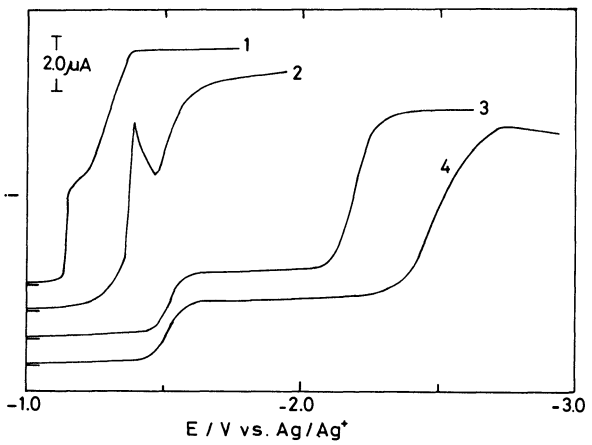

Fig. 6. Polarograms of nitrobenzene in acetonitrile with various supporting electrolytes. [Nitrobenzene]=0.4 mM. (1) Li^+, (2) Na^+, (3) Et_4N^+, (4) n-Bu_4N^+ of 0.1 M perchlorate.

Krigowsky et al. suggested the existence of two different species, $N^{\cdot-}K^+$ and $N^{\cdot-}2K^+$ ($N^{\cdot-}=C_6H_5NO_2^{\cdot-}$), in the polarographic reduction of nitrobenzene ($\Delta E_{1/2}/\Delta\log[K^+]$ of 65 and 110 mV) in DMF.[7]

As for other nitroalkanes, the values of the $\Delta E_{1/2}/\Delta\log[Na^+]$ slope were 50, 65, and 80 mV for 1-nitrobutane, nitroethane, and nitromethane respectively in the presence of 10 mM n-Bu_4N^+, as is shown in Fig. 5. These values suggest the interaction of the anion radical with a single Na^+ ion ($RNO_2^{\cdot-}Na^+$) or more in the presence of 10 mM n-Bu_4N^+. The half-wave potential of 1-nitrobutane was not so much influenced by the concentration change of $NaClO_4$ in the absence of n-Bu_4NClO_4. The increase in the concentration of n-Bu_4NClO_4 caused the half-wave potential of the first wave of 1-nitrobutane to shift positively (e.g., $E_{1/2}$=−2.02 V at 20 mM and −1.99 V at 200 mM of n-Bu_4N^+) without $NaClO_4$.

On the Reduction of Nitrobenzenes. Polarographic data of nitrobenzene and p-nitrotoluene with var-

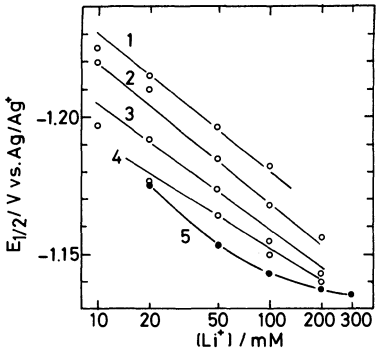

Fig. 7. Effect of Li^+ and Et_4N^+ on the $E_{1/2}$ of the first wave of nitrobenzene. [Nitrobenzene]=0.39 mM. (1) 100, (2) 50, (3) 20, (4) 5, (5) 0 mM of Et_4NClO_4.

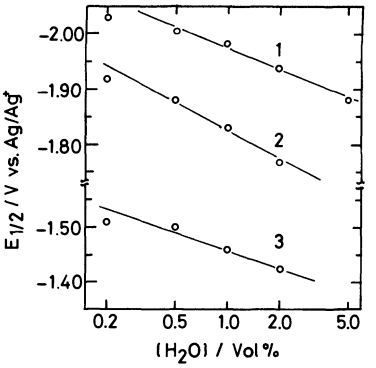

Fig. 8. Effect of H_2O on the $E_{1/2}$ of the first wave of nitroalkanes and nitrobenzene in acetonitrile solutions containing 0.1 M Et_4NClO_4. (1) 2-Methyl-2-nitropropane, (2) nitromethane, (3) nitrobenzene. The concns. of the nitro compounds are all 0.4 mM.

ious supporting electrolytes are also listed in Table 1. Nitrobenzene gave two cathodic waves with each supporting electrolyte (Fig. 6). The first wave showed a good reversibility with 0.1 M n-Bu_4N^+ or Et_4N^+. However, the slope of $-E$ vs. $\log[i/(i_d-i)]$ was extremely small (10 mV) with 0.1 M Li^+. The small slope observed with Li^+ became larger ($\approx$30 mV) upon the addition of 0.1 M n-Bu_4N^+ or Et_4N^+. The half-wave potential of nitrobenzene shifted positively ca. 50 mV ($\Delta E_{1/2}/\Delta\log[Li^+]$) with increasing concentration of $LiClO_4$ in the presence of 20—100 mM Et_4N^+, as is shown in Fig. 7. With 50 mM Et_4N^+, the highest slope (52 mV) was obtained. For p-nitrotoluene, the slope was 58 mV with a concentration change of Li^+ at 50 mM n-Bu_4N^+. From the data in Fig. 7, p=1 and q=ca. 0.5 in Eqs. 1 and 2 were derived for nitrobenzene, assuming n=1. The fact that p=1 in the presence of both Li^+ and Et_4N^+ suggests the following reaction:

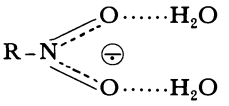
$$C_6H_5NO_2^{\cdot-} + Li^+ \overset{K'}{\rightleftharpoons} C_6H_5NO_2^{\cdot-}Li^+ \qquad (3)$$

The interaction between the nitrobenzene molecule and the Et_4N^+ cation was also suggested, even though the value of q was not unity.

The difference in the number of alkali metal ions "coordinated" to the anion radicals between 2-methyl-2-nitropropane (p=2) and nitrobenzene (p=1) seems to be caused by the difference in the electron density on the nitro group. Peover and Powell described[19] that, in the anion radical of an aliphatic compound, the charge on the nitro group is virtually unity, while in that of a nitrobenzene, the charge can be delocalized into the aromatic system.

Effect of Proton Donors on the Reduction Wave of Nitro Compounds. The effect of phenol on the polarographic reduction of 2-methyl-2-nitropropane was examined. By the addition of 10 mM of phenol to a 0.4 mM $(CH_3)_3CNO_2$ solution, the two waves of $(CH_3)_3CNO_2$ without phenol merged into a single wave of $E_{1/2}$=−1.97 V. The wave height with 10 mM phenol was 3—4 times as large as the first wave height without phenol. The further addition of phenol up to 100 mM caused the half-wave potantial to shift positively, without changing the wave height.

Figure 8 shows the effect of H_2O on the half-wave potentials of 2-methyl-2-nitropropane, nitromethane, and nitrobenzene. The half-wave potentials of $(CH_3)_3CNO_2$ and nitrobenzene both shifted ca. 120 mV positively upon a 10-fold increase in the water concentration. The wave height of $(CH_3)_3CNO_2$ or nitrobenzene (the first wave) remained constant even upon the addition of water up to 2% (2.15 μA, cf. 2.1 μA without water for $(CH_3)_3CNO_2$). The waves were reversible and seemed to be diffusion controlled. Therefore, the value of 120 mV for $\Delta E_{1/2}/\Delta\log[H_2O]$ suggested that the anion radicals of $(CH_3)_3CNO_2$ and nitrobenzene interact with two molecule of water:



We have previously reported elsewhere[11] the interaction between the benzoate ion ($C_6H_5CO_2^-$) and two molecules of water in an acetonitrile solution.

For nitromethane, the value of $\Delta E_{1/2}/\Delta\log[H_2O]$ was 145 mV, which may also suggest the interaction between the anion radical of nitromethane and two molecules of water.

Lipsztajn et al.[20] have reported the experimental results that the slope of $\Delta E_{1/2}/\Delta\log[H_2O]$ is ca. 120 mV (0.1—1 M H_2O) for the half-wave potential of the first wave of nitrobenzene in DMF containing 0.1 M Et_4NClO_4 as the supporting elctrolyte. They[20] suggested the formation of both $NB^{\cdot-}$ Na^+ and $NB^{\cdot-}$ $2Na^+$ ($NB^{\cdot-}$=nitrobenzene anion radical) in DMF containing 1.66 M of H_2O (3% by volume).

We wish to express our thanks to Professor Toyokichi Kitagawa of Osaka City University for his helpful suggestions.

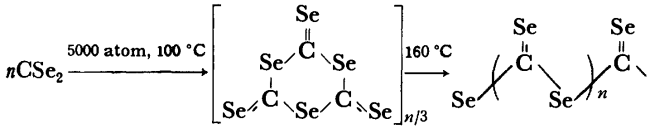
(Received May 13, 1986)

The physical properties and the structure of black solids obtained by the high-pressure reaction of CSe_2 were examined by IR, X-ray diffraction, scanning electron microscope, electron diffraction, thermal analyses and magnetic experiments. The crystalline solid, which was metallic ($\sigma(RT)\approx 50$ S cm^{-1}) at ambient pressure became superconductor above 20 GPa(T_c(onset)=6 K), while the amorphous solid was insulating. Contrary to the previously proposed one- or two-dimensional polymerization structure of $(CSe_2)_x$, it has been revealed that the metallic CSe_2 sample have a rather complex structure that is composed of the crystalline hexagonal Se, graphite and some amorphous parts. Thus, the high conductivity and the diamagnetism of the crystalline solid at ambient pressure seems to come from graphite part and the superconductivity seems to come from hexagonal Se part. The superconducting transition behavior depended on the path of the pressure-cooling steps. The superconducting state was observed only when the pressure was increased at the low temperature.

Recent discoveries of many organic superconductors based on the multi-sulfur (or selenium) π-donor or π-acceptor molecules have aroused a considerable interest in the field of synthetic metals. Contrary to the traditional organic conductors with the disadvantage of the Peierls instabilities originated from their one-dimensionalities, in these multi-sulfur compounds the two-dimensional (or three-dimensional) intermolecular close contacts of chalcogen atoms in the π-conjugated molecules play a central role for the formation of the conduction bands. Carbon diselenide is the simplest π-conjugated molecule with Se atoms.

Okamoto and Wojciechowski reported that CSe_2 was polymerized into conductive amorphous solid (10^{-3} S cm^{-1}).[1] Okamoto et al. proposed the two step reactions:



The second step appears to be analogous to the solid state polymerization of S_2N_2, into the well known inorganic polymer superconductor, $(SN)_x$.[2] Since the similar linear chain structure had been already suggested in the polymerization of CS_2 under a pressure of 30 kbar,[3] this polymerization mechanism of CSe_2 seemed to be reasonable. We tried to obtain the similar polymer. Various types of the black solids were obtained.[4,5] Most of them were amorphous but in some cases, highly conducting crystalline solids were obtained. This crystalline solid was revealed to exhibit a superconducting transition at high pressure.

Initially we proposed the two-dimensional polymerization model as to the crystalline solid,[6] because the EXAFS analysis showed that the linear chain structure model was incorrect. However, recently we have found the evidence of the existence of hexagonal Se and graphite in the conducting solid.

In this report, the electrical properties of the high pressure reaction products of CSe_2 and their characterization by X-ray diffraction, scanning electron microscope, chemical analysis, EXAFS, DSC, IR, electron microscope, electron diffraction, magnetic susceptibility and ESR experiments are described.

Experimental

Carbon diselenide, CSe_2 is a toxic, malodorus and golden-yellow liquid reagent used in the synthetic studies of the π-donor molecules with the Se atoms, which was obtained by the reaction of Se vapor with dichloromethane in the nitrogen stream and the subsequent distillation.[7] Liquid CSe_2 in the teflon cell was pressurized at about 5 kbar and heated to 80—100 °C for 2—3 h. Then the pressure was released and the cell was heated at 100—130 °C. Various types of black solids were obtained. About 0.3 ml of CSe_2 was used at a time. The degree of the crystallinity of the solid was very sensitive to the conditions of the preparation (pressure and temperature) and the reaction was hardly to controll. When the reaction temperature was too high (130—160 °C), the amorphous solid was obtained. On the contrary, when the reaction temperature was below 70 °C, nonreacted CSe_2 was remained.

The conductivity measurements were performed by the fourprobe method with silver paint within the temperature range of 1.5 K to 300 K. The high-pressure resistivity experiments were performed on the compaction sample by the two probe method using the diamond anvil high-pressure cell.

The X-ray powder patterns were measured on a Rigaku X-ray powder diffractometer. Intensities were extremely weak and those data were obtained by scanning up to 2θ=130° (Cu $K\alpha$ radiation, Ni filter, 35 kV, 15 mA) for a week running (0.72°/h).

Temperature dependence of X-band ESR spectra from 100

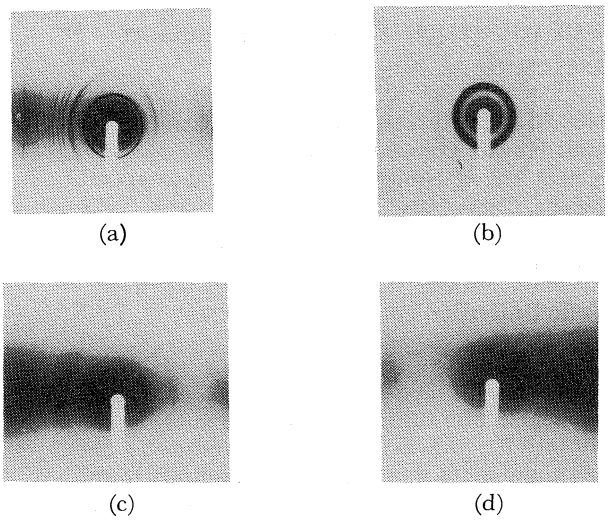


Fig. 1. X-Ray diffraction diagrams of high-pressure reaction products of CSe_2.

to 300 K was examined on a JEX-FEIX ESR spectrometer with flowing liquid nitrogen gas. Skin effect of ESR was observed as to the metallic sample and the experiment was performed on the finely-ground powder sample.

Magnetic susceptibility of metallic sample was measured by a Faraday method on a powder sample of about 0.13 g over a temperature range between 2 and 296 K. A permanent magnet and electro-balance were used. The temperature of the sample was controlled through the pure helium gas at a pressure of about 3 Torr (1 Torr=133.322 Pa). The helium gas was purified by passing through a charcoal trap held at 75 K.

The measurement of the EXAFS spectra was performed at the Photon Factory of National Laboratory for High Energy Physics (KEK-PF), using EXAFS facilities at the beam line 10-B with a Si(311) channel-cut monochromator.

The IR spectra were taken of a dispersion in KBr within the range of 400 cm^{-1} to 4000 cm^{-1}.

The thermogravimetric analyses were performed on a Rigaku differential scanning calorimeter within the temperature range between 20 to 400 °C.

Electron microscope and electron diffraction experiments were performed on H-800 Hitachi Electron Microscope.

Scanning electron microscope experiments were made by using X-650 Hitachi Scanning Electron Microanalyser.

Results and Discussion

Electrical and Magnetic Properties. As described before, black solids were prepared from CSe_2. By changing the applied pressure and the heating temperature, we obtained various solids. The X-ray diffraction diagrams of the products are shown in Fig. 1. There are various solids with different crystallinities. The conductivity of the compaction sample of the crystalline solid, which gave sharp X-ray diffraction patterns (Fig. 1a), was about 50 S cm^{-1} and the resistivity ratio at 1.7 K ($\rho_{1.7}/\rho_{300}$) was 2—3 (Fig. 2a). This small resistivity ratio and almost linear temperature

dependence of the thermoelectric power described later suggests that the highly conducting sample is essentially metallic.

Besides the highly conducting samples, there are insulating, low-conducting and semiconducting samples. The conductivity of the insulating sample, which gave amorphous X-ray halos (Fig. 1c) was less than 10^{-8} S cm^{-1} and that of the semiconducting sample was about 5 S cm^{-1} with activation energy of 0.09 eV (Fig. 3a). The semiconducting solid gave extremely broad Debye rings suggesting the heavily disordered lattices (Fig. 1b). The conductivity of the samples obtained by reheating the insulating sample up to 250 °C is ca. 10^{-3} S cm^{-1}, almost identical to the conductivity of poly(carbon diselenide) reported by Okamoto and Wojciekowski.[1] The low-conducting material was almost amorphous to X-ray diffraction (Fig. 1d). These facts indicate that the solid is metallic in an ordered crystalline state and it becomes less conductive when crystalline imperfection increases. The X-ray powder pattern of the crystalline material was measured on the X-ray diffractometer and more than twenty peaks were obtained. The lattice spacings and the X-ray powder patterns are shown in Fig. 4. The thermoelectric power of the crystalline solid was negative and as small as -12 μV/K at room temperature. The almost linear temperature dependence suggests the existence of negative free carriers (Fig. 2b).

The IR spectrum of the insulating sample showed the absorption bands at 880, 1260, and 1380 cm^{-1}. The strong band at 880 cm^{-1} was assigned to the C=Se stretching vibration. The conducting sample was opaque down to at least 400 cm^{-1} probably due to the free carrier absorption.

The Fourier transform of EXAFS spectra of the metallic sample was different from that of insulating

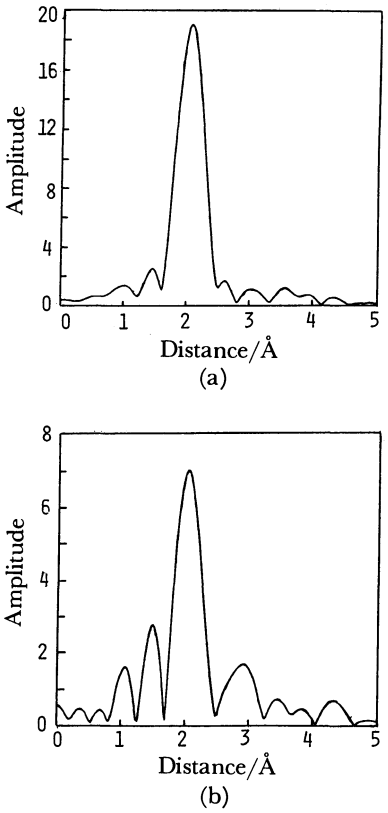

Fig. 5. Fourier transform of the EXAFS oscillation, $k^3\chi(k)$ for (a) metallic and (b) insulating solids.

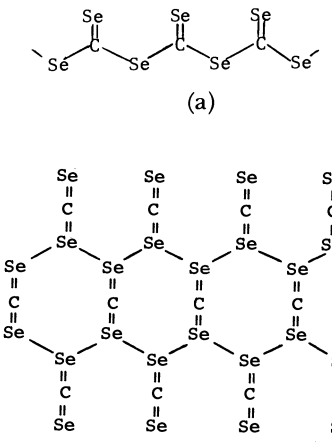

Fig. 6. Structure model of $(CSe_2)_x$ polymer.
a): Chain structure model[1] b): Two-dimensional structure model.[6]

sample but was quite similar to that of hexagonal Se powder (Fig. 5). The prominent peak in the Fourier transform of metallic sample corresponded to Se-Se bond. But no indication of Se-C or Se=C bond was found except in the insulating sample. The bond distances and coordination numbers were obtained by the curve-fitting analyses with empirical parameters. Since hexagonal Se had a helical structure of Se-Se distance of 2.37 Å, the coordination number of Se in

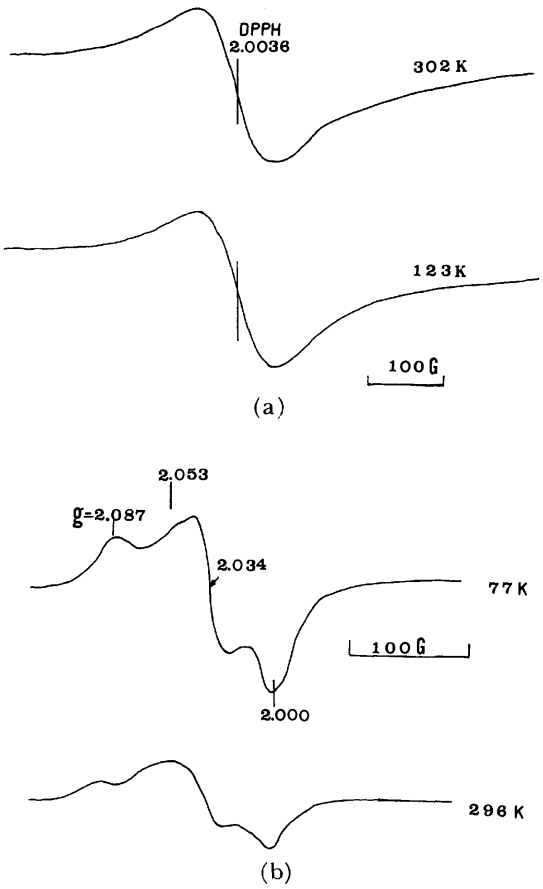

Fig. 7. ESR spectra of a) metallic and b) insulating high pressure reaction products of CSe_2.

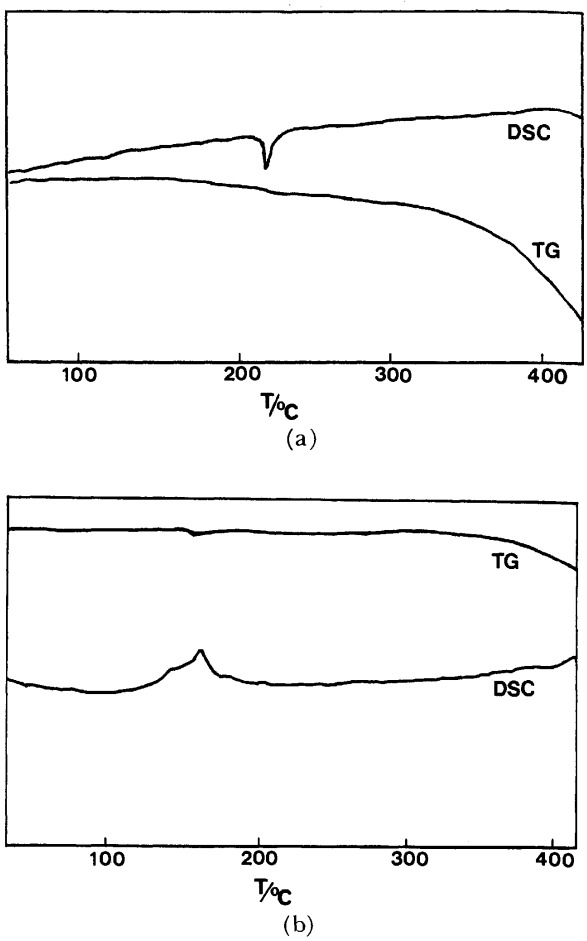

Fig. 8. DSC-TG curves of a) metallic and b) insulating solids.

hexagonal Se was fixed as 2.0. The coordination number of metallic sample was almost 2.0, which indicates that each Se atom has two neighbouring Se atom. Insulating sample had the coordination number of 0.7, but Se-Se distances were almost the same for all the samples. Since the result of EXAFS analyses indicated the existence of -Se-Se- (2.37 Å) infinite chains in the metallic sample, the chain structure model proposed by Okamoto (Fig. 6a) did not conform with the EXAFS experiments. Thus, two-dimensional structure model with -Se-Se- chains was proposed at this stage (Fig. 6b).[6] However, further characterization revealed that this structure model was not correct one, which will be mentioned later.

X-band ESR measurements of metallic and insulating powder samples of CSe_2 solid are shown in Fig. 7. The broad ESR signal (the peak-to-peak linewidth is 98 G) and the g value of 2.0038, which is very close to that of free electron (2.0023). The temperature was varied within 123—243 K at the interval of 20 K. The peak-to-peak linewidth and g-value, are almost constant within this temperature range. The lineshape was almost Lorentzian in the measured field range of four times as large as the linewidth. These results support the metallic character of the solid and the existence of the conduction electrons. For insulating sample, ESR measurements were performed at room temperature and 77 K. The g-anisotropic spectra at 77 K indicates that there are more than two radical species. The large g-shift suggests that these radical species are not C-centered radicals but Se-centered radicals. These ESR measurements indicate that in the metallic sample there exist conduction electrons and in the insulating sample there exist Se-centered radicals produced by broken Se-Se bonds.

Figure 8 shows the DSC-TG curves of the solids. For metallic sample, the endothermic reaction was observed at 220 °C. The thermogravimetric study of the insulating sample showed that three percent of the weight was lost at ca. 160 °C and the remaining was stable up to 300 °C.

In Fig. 9 the magnetic susceptibility of the crystalline sample is shown. From 5 to 296 K the magnetic susceptibility was almost constant and below 5 K the susceptibility increased gradually, which would be an effect of magnetic residuals. The effect of the oxygen molecules included in the sample was observed around 40 K. The magnetic susceptibility performed diamagnetic corrections was $\chi=-1.75\times10^{-6}$ cgsemu g^{-1}. The magnetic susceptibility of an electron gas mainly consists of the Pauli paramagnetism and the Landau-

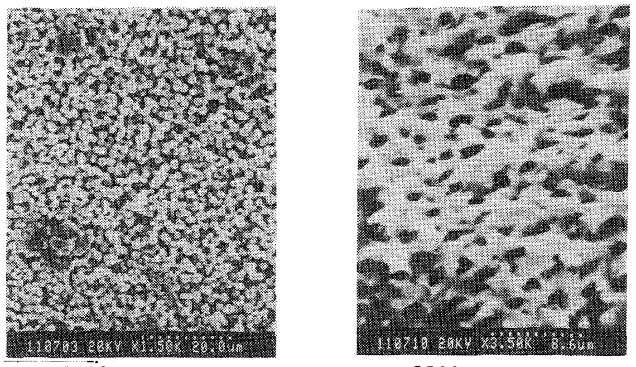
where μ_B: Bohr magneton

$\langle f^2\rangle$= effective mass correction $(2m_t+m_l)/(m_t^2 m_l)^{1/3}$

χ_{LPP} becomes large negative value, when the second term of above equation is large. The second term is dependent on the anisotropy of the mass. It is well-known that in semimetallic materials such as graphite a large negative magnetic susceptibility is observed due to the large Landau-Peierls term which is derived from the two-dimensional anisotropy. Therefore, it is plausible that metallic crystalline sample has a possibility of having an anisotropic electronic structure.

Superconductivity at High Pressure. The high pressure resistivity experiments were performed on the compaction sample by the two probe method using the diamond anvil high pressure cell. The pressure dependence of the room-temperature resistivity is shown in Fig. 10. There was an anomaly around 3 GPa, where a high-conducting state appeared within a small pressure range. Above this anomaly, the solid transformed again into the less conductive state. The resistivity of this high-conducting state was about 10 times smaller than the resistivity at ambient pressure. Above 10 GPa, the pressure dependence of the resistivity became very small. Besides the hysteresis of the 3 GPa transition, the resistivity behavior was almost reversible. The temperature and pressure dependences of the resistivity were measured along two different paths shown in Fig. 11. In the path A, the pressure was increased initially to ca. 20 GPa at room temperature, then the temperature was decreased at constant pressure of ca. 20 GPa. The resistivity at high pressure (20—22 GPa) was almost temperature-independent. Any anomaly was not observed at least down to 2.1 K (the lower temperature limit of the experiment) (Fig. 10).

On the other hand, in the path B, where the temperature was lowered initially and the pressure was increased above 20 GPa with keeping the low temperature, our crystalline sample showed a decrease of the resistivity indicating the onset of the super conducting transition. The result is shown in Fig. 12. Similar dependence of the transition temperature on the measurement process has been also found in black phosphorous.[9] The superconducting transition temperature of black phosphorus measured along the path B (after temperature was decreased, pressure was increased) was much enhanced than that obtained by the path A (after pressure was increased, temperature was lowered) (T_c(25 GPa)=10 K (path B), 6 K (path A)).



×1500 (a) ×3500 (b)

Fig. 13. Photographs of SEM. a) amorphous insulating solid (×1500) b) metallic crystalline solid (×3500).

Fig. 14. Photographs of metallic crystalline solid by the electron microscope (×1500000 magnification). Crystalline parts with lattice spacings of ≈3 Å and some amorphous or cluster regions are observed.

Black phosphorus is considered to be converted into a mixed system consisting of metallic fine threads dispersed in the semiconducting matrix. The appearance of superconductivity in the mixed system by the excitonic mechanism was suggested by Fukuyama.[10] However, the origin of the enhancement of the transition temperature remains an open questions.

In our crystalline sample, the onset of the superconducting transition was 6 K with the mid-point temperatures of 3.5 K at 22 GPa and 4.1 K at 24 GPa. The temperature range of the transition (ΔT) was fairly large, but the transition became sharp with increasing pressure (ΔT=2.7 K (22 GPa), 1.9 K (24 GPa)). This superconducting transition of the crystalline sample reminds us of those of various kinds of selenium by ordinary path A. Amorphous Se undergoes a semiconductor to metal transformation at a pressure of 13 GPa and at 7 K superconductivity was observed.[11] Monoclinic Se has a discontinuity in resistance near 15 GPa, as in amorphous Se. Superconducting transition has onsets at 7 K, but never complete.[11] Pure hexagonal Se was pressurized to about 16 GPa, no sharp semiconductor to metal transition was observed at any pressure, and at high pressure no superconductivity was found to 1.5 K.[11]

Decomposition Reaction of CSe_2. The physical properties and the structure of the black solids obtained by the high pressure reaction of CSe_2 were examined by several methods as described above. EXAFS indicated the existence of an infinite -Se-Se- chain in the metallic sample, which showed that the $(CSe_2)_x$ chain model (Fig. 6a) was not correct at least for the high conducting samples. Thus, we proposed two-dimensional structure model of $(CSe_2)_x$. However, recent examination of the metallic samples have revealed the existence of the crystals of hexagonal Se. Except for the appearance of the small peak around 26° (Cu $K\alpha$) and large intensities of the peaks around 90°, the X-ray diffraction patterns of the metallic sample (Fig. 4) are almost identical to that of hexagonal Se crystal. Since hexagonal Se is not high conductive, the metallic nature of the reaction product seems to be puzzling. However, DSC of the crystalline sample gave another evidence of the existence of hexagonal Se crystals. An endothermic peak was observed around the temperature of the m.p. (220 °C) of the hexagonal Se crystal. The photographs of SEM showed that the amorphous insulating solid was composed of the spheres with diameter of about 13000 Å, while the metallic solid appeared to be composed of the uniform black flakes (×3500) (Fig. 13). However, recent electron microscope (×1500000 magnification) and electron diffraction experiments (Fig. 14) have suggested the existence of graphite, which is consistent with the appearance of the small peak around 26° (d=3.375 $Å^{-1}$, the strongest peak of graphite crystal) in the X-ray powder diffraction. The electron microscope photographs show that the metallic solid is composed of the crystalline regions and the amorphous or cluster ones. Although the patterns of the electron diffraction and microscope photographs are not simple,[12] the conducting product could be characterized fairly satisfactorily. There are considerable amount of evidences showing the existence of hexagonal Se. Graphite powder seems to also exist. The value of magnetic susceptibility is plausible for that of graphite. If we assume magnetic susceptibility is derived from almost graphite, it will be -24.8×10^{-6} cgsemu g^{-1}. Thus we may say that the unexpected novel reaction took place. Contrary to the expected polymerization reaction, CSe_2 is decomposed into the component atoms to produce crystalline hexagonal Se with small crystal size (<500 Å), graphite and some amorphous solids or clusters. Although there exist considerably large amorphous (or cluster) regions, any conductive anomaly was not observed around the pressure where the insulating amorphous Se transform into the metallic (or superconducting) state (≈15 GPa). Therefore, it may be

unlikely that there are large amount of amorphous Se. The high conductivity and the diamagnetism seems to come from the properties of the graphite and the superconductivity from crystalline hexagonal Se. Thus our experiment seems to indicate that superconducting transition of hexagonal Se occurs at the pressure greater than 20 GPa and this may be the first observation of the superconducting transition of hexagonal Se.

However, there remain unsolved interesting features concerning the superconducting transition:

(1) Superconductivity was observed only along the path B. What is the mechenism of the enhancement of T_c? Is it plausible that the superconducting transition occurs under 2.1 K (lower limit of the experiments) along the path A and is observed at 2.5—6 K along the path B by the enhancement of the superconducting transition temperature?

(2) Why the transition occurs stepwise (Fig. 12)? The sharpning of the transition with increasing the pressure seems to indicate the increase of the onset temperature of the second step, which shows that there exist two situations of the solid which have different superconducting transition temperatures individually. Since the onset temperature of 6 K resembles that of the transition of Se, what is the origin of the transition with onset temperature of 3.5 K? Further, what is the reason of the partial occurrence of the superconducting transition of 6 K?

In this paper, we presented a novel decomposition reaction of CSe_2 and the characterization of the conducting solid product. What triggars the decomposition of CSe_2 and systematic recombination of the component atoms? What is the mechanism of the abnormal superconducting behavior? These problems are open questions.

The authors (A. K. and H. K.) are grateful to Prof. Okamoto of Polytechnic Institute of New York for helpful discussions about the possibility of the decomposition reaction of CSe_2. They are also much obliged to the members of the Application Laboratory of the Hitachi Naka Works for the assistance of the electron microscope and diffraction experiments.

12) Professor Okamoto suggested the existence of $(CSe)_x$ polymer, which is very interesting from the view-point of the molecular designing. However, direct evidence of the existence of such a polymer could not be found in our experiments. Unlike the relatively simple X-ray diffraction patterns, the electron diffraction patterns show some extra reflections other than those from hexagonal Se and graphite crystals. Probably oxidation of the surface of the powdered solid will be responsible for the appearance of the complex electron diffraction patterns.

The Solvent Extraction of Palladium(II) from Hydrochloric Acid with Triisobutylphosphine Sulfide

Yoshinari BABA,* Masanori OHSHIMA, and Katsutoshi INOUE
Department of Industrial Chemistry, Faculty of Science and Engineering, Saga University, Honjo-machi, Saga 840
(Received May 22, 1986)

The equilibrium and kinetic aspects of palladium(II) extraction from hydrochloric acid with triisobutylphosphine sulfide (TIBPS) in toluene were studied, along with the aqueous solubility and interfacial adsorption equilibrium of the extractant. From the equilibrium study, palladium(II) was found to be extracted as a 1 : 1 Pd:extractant binuclear complex. The extraction rate of palladium(II) was reasonably explained by the interfacial reaction model, assuming that the elementary reactions between the extractant adsorbed at the interface and the aquatrichloro and tetrachloro complexes of palladium(II), $[PdCl_3]^-$, and $[PdCl_4]^{2-}$ in the aqueous phase are the rate-determining steps.

The solvent-extraction techniques of metals have recently become increasingly important as energy-saving and non-polluting separation and purification processes in hydrometallurgy in view of the dangers of exhausting resources and energy. While the solvent extraction of metals has so far been extensively studied with a number of commercial extractants, the majority of these have been extractants containing oxygen or nitrogen as donor atoms, such as hydroxy oximes, carboxylic acids and organophosphorus compounds. However, relatively few works have been conducted on extractants containing sulfur as the donor atom.

It is well-known that sulfur-containing extractants are highly effective and selective for palladium(II). Among the sulfur-containing extractants, dialkyl sulfides, petroleum sulfides and their oxides, and *O,O'*-dialkyl hydrogenphosphorodithioate have been extensively investigated, especially in the USSR,[1-3] though these works have not necessarily been quantitative. Actually, dialkyl sulfides are now commercially utilized for the separation of palldium(II) from platinum(IV) at the Acton precious metal refinery of INCO in the United Kingdom[4] and for the recovery of precious metals from various kinds of scrap, such as spent catalysts in Japan. However, dialkyl sulfides have a serious drawback in their slow extraction rate of palladium(II).[5]

Recently, the American Cyanamid Co. developed a new extractant for the recovery of silver(I) and palladium (II),[6] CYANEX 471, the active component of which is triisobutylphosphine sulfide. This extractant is said to have an acceptably high extraction rate of palladium (II). Following the previous investigations of the kinetics of the solvent extraction of palladium(II) from chloride media with various sulfur-containing extractants, i.e. dihexyl sulfide,[7] 1,2-bis(*t*-hexylthio)-ethane[8] and 2-(butylthio)dodecanoic acid,[9] the present authors have now conducted a quantitative investigation of the extraction kinetics of palladium(II) from hydrochloric acid with triisobutylphosphine sulfide(TIBPS) in order to elucidate its extraction mechanism. Prior to the study of the extraction kinetics, the distribution equilibrium of palladium(II), and the aqueous solubility and interfacial adsorption equilibrium of the extractant were investigated in order to obtain the fundamental information which is necessary for the analysis of the extraction kinetic data.

Experimental

Reagents. The triisobutylphosphine sulfide, abbreviated as TIBPS hereafter, used in the present study as the extractant was purified from CYANEX 471 donated by the American Cyanamid Co. by recrystallization from a water–ethanol mixture. The purity of the reagent was confirmed by elemental analysis to be as follows: Found: C, 61.3; H, 11.5%. Calcd for $C_{12}H_{27}PS$: C, 61.5; H, 11.6%. The organic phase was prepared on a gravimetric basis by diluting TIBPS with toluene of an analytical grade. The aqueous phase was prepared by dissolving palladium(II) chloride in hydrochloric acid.

Measurement of Extraction Equilibrium. As in the previous work,[7,8] it was impossible to make a precise quantitative determination of palladium(II) in the aqueous phase in the presence of a large excess concentration of the extractant because it was almost completely extracted over the whole concentration range of hydrochloric acid. Accordingly, in order to determine the mole ratio of palladium(II) to the extractant in the extracted complex under the conditions of ultimate loading, only a loading test was carried out in the presence of a large excess of the palladium(II) concentration in order to determine the mole ratio of palladium(II) extracted into the organic phase to TIBPS, in the same manner as in previous papers.[7,8]

Equal volumes (0.015 dm^3) of the organic and aqueous phases of known concentrations were vigorously shaken for 5 h in a separatory funnel using a Iwaki, V-DV-type mechanical shaker in a thermostated air bath maintained at 303 K. It had been confirmed by a preliminary experiment that the equilibrium was attained within 5 h. After the separation of the two phases, the palladium(II) concentration in the aqueous phase was determined by means of atomic absorption spectrometry using a Nippon Jarrell-Ash model AA-782 spectrophotometer. The palladium(II) concentration in the organic phase was calculated by the use of the mass balance from the aqueous palladium(II) concentrations before and after the equilibration.

Measurement of Aqueous Solubility of the Extractant. The distribution of TIBPS between the organic and aqueous phases was measured spectrophotometrically at 303 K in a method similar to that described in a previous paper.[8] A

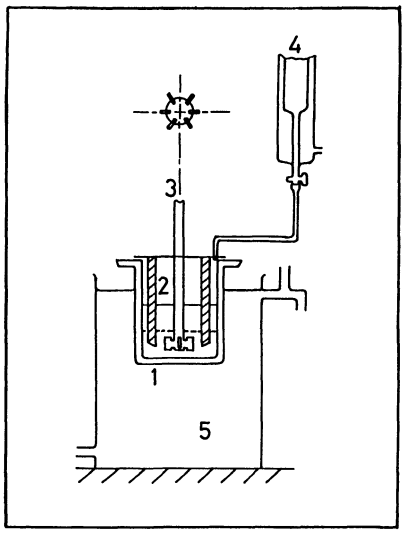

Fig. 1. Experimental apparatus.
1: Stirred glass cell, 2: baffle, 3: impeller, 4: reservoir with jacket, 5: thermostat.

toluene solution of TIBPS of a known concentration and 1 mol dm^{-3} of hydrochloric acid were shaken vigorously for 24 h with a volume ratio of the aqueous phase to the organic phase of 10 : 1 using an Iwaki mechanical shaker, V-VD-type. After phase separation, a sample of the aqueous phase (0.19 dm^3) was transferred to a separatory funnel. In order to completely convert any TIBPS dissolved in the aqueous phase to its palladium(II) complexes, 5×10^{-2} dm^3 of a 2×10^{-3} mol dm^{-3} aqueous palladium(II) chloride solution containing 0.01 mol dm^{-3} of hydrochloric acid and 1×10^{-2} dm^3 of toluene were added to the aqueous sample, and the mixture was shaken for 24 h using a mechanical shaker. The absorbance of the palladium(II) complex in toluene was measured at 329 nm against a toluene blank using a Shimadzu UV 140 spectrophotometer.

Measurement of Interfacial Adsorption Equilibrium. The interfacial tension between the organic solution and 1 mol dm^{-3} of aqueous hydrochloric acid was measured at 303 K by means of the drop-weight method in order to elucidate the interfacial adsorption equilibrium of TIBPS.

Measurement of Extraction Kinetics. The apparatus used in this study was a batch-type stirred glass cell, as is shown in Fig. 1. It is the same as that used in the previous kinetic studies of the palladium(II) extraction with 1,2-bis(*t*-hexylthio)ethane[8] or 2-(butylthio)dodecanoic acid.[9]

Equal volumes (0.3 dm^3) of hydrochloric acid containing palladium(II) and toluene solutions of TIBPS of known concentrations were carefully introduced into the cell so as not to disturb the interface. After that, stirring was initiated at a constant stirring speed and 10-cm^3 portions samples were taken out at definite time intervals. After the phase separation, the palladium(II) concentration in the aqueous phase was determined using the atomic-absorption spectrophotometer. The initial palladium(II) concentration was 1×10^{-3} mol dm^{-3} in all kinetic runs. The concentrations of the extractant and hydrochloric acid varied over the range from 8×10^{-3} to 1.6×10^{-1} mol dm^{-3} and from 1×10^{-1} to 4.7 mol dm^{-3} respectively.

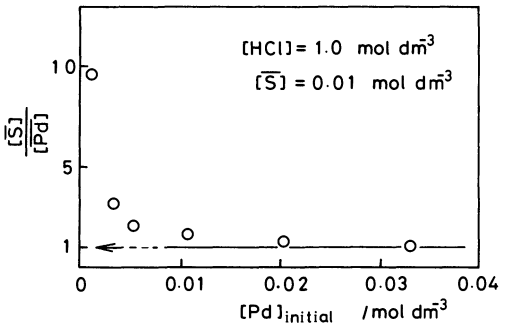

Fig. 2. Experimental results of the loading test.

Results

Distribution Equilibrium of Palladium(II). Figure 2 shows the results of the loading test. The mole ratio of TIBPS to palladium(II) in the organic phase asymptotically approaches unity with an increase in the palladium(II) concentration in the aqueous phase. This result indicates that palladium(II) is present as a metal : reagent 1 : 1 complex in the organic phase. Taking account of the coordination number of palladium(II)(=4), the stoichiometry of this extraction reaction may be expressed as follows:

$$2[PdCl_i]^{(i-2)-} + 2\overline{S} \rightleftharpoons [\overline{(PdCl_2)_2S_2}] + 2(i-2)Cl^- \quad (1)$$

where S is TIBPS and where bars denote the organic phase.

Aqueous Solubility of TIBPS. The distribution of TIBPS between the organic and aqueous solutions is expressed as follows:

$$\overline{S} \rightleftharpoons S \quad ;K_D, \quad (2)$$

where K_D is the partition coefficient of TIBPS and is expressed as follows:

$$K_D = [S]/[\overline{S}]. \quad (3)$$

The logarithm of Eq. 3 gives:

$$\log [S] = \log [\overline{S}] + \log K_D. \quad (4)$$

The partition coefficient is so small that the concentration of TIBPS in the organic phase, $[\overline{S}]$, is nearly equal to its initial concentration, C_{B0}.

The concentration of TIBPS in the aqueous phase was plotted against that in the organic phase, as is shown in Fig. 3. The points plotted in this figure appear to lie on a straight line with a slope of 1, as is to be expected from Eq. 4. From the intercept of the straight line with the ordinate, the partition coefficient, K_D, was evaluated as 5.4×10^{-6} for 1 mol dm^{-3} of hydrochloric acid.

Interfacial Tension. Figure 4 shows the plot of the interfacial tension, γ, between the organic solution containing TIBPS and 1 mol dm^{-3} of aqueous hydrochloric acid against the concentration of TIBPS. The results shown in Fig. 4 suggest that TIBPS is interfacially active and is adsorbed at the interface between

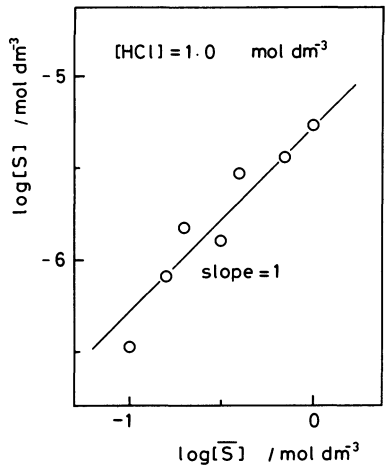

Fig. 3. Aqueous solubility of TIBPS to 1 mol dm^{-3} hydrochloric acid.

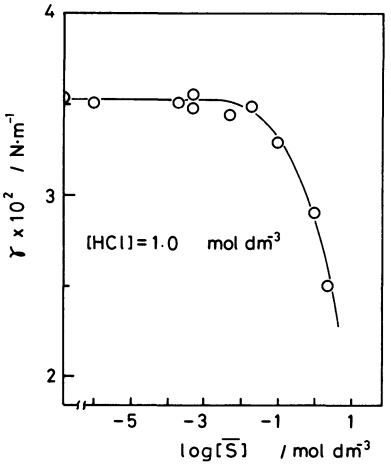

Fig. 4. Relation between interfacial tension, γ, and log [$\bar{S}$].

the two phases. The adsorption equilibrium of TIBPS is expressed as follows:

$$\bar{S} \rightleftharpoons S_{ad} \quad ;K_{ad} \tag{5}$$

where K_{ad} is the adsorption equilibrium constant defined by Eq. 6 and where the subscript "ad" denotes the adsorbed species at the interface:

$$K_{ad} = \frac{\theta_s}{[\bar{S}](1-\theta_s)} \tag{6}$$

Here, θ_s denotes the fractional coverage of the interface by TIBPS.

The combination of Gibb's adsorption isotherm and Langmuir's monolayer adsorption model gives the following relation[10] between the interfacial tension, γ, and the TIBPS concentration, [$\bar{S}$]:

$$\gamma = \gamma_0 - (RT/S_s) \ln (1+K_{ad}[\bar{S}]) \tag{7}$$

where γ_0 denotes the interfacial tension between the pure diluent and 1 mol dm^{-3} of aqueous hydrochloric acid, and where S_s denotes the interfacial area occupied

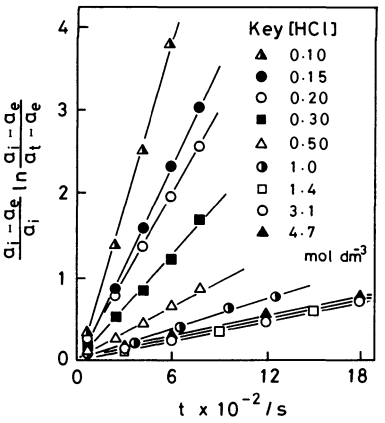

Fig. 5 A typical plot of the experimental results based on the pseudo-first-order rate expression (C_{B0} =0.01 mol dm^{-3}).

by a unit mole of TIBPS. From the experimental results shown in Fig. 4, the values of K_{ad} and S_s were evaluated by the nonlinear least-squares method based on Eq. 7 to be as follows: K_{ad}=4.4 dm^3 mol^{-1}, S_s=6.3×10^5 m^2 mol^{-1}.

The solid curve in Fig. 4 is the curve calculated from Eq. 7 using the above values. The calculated curve is in good agreement with the experimental results.

Extraction Kinetics. If it is assumed that the forward and reverse reactions are pseudo-first-order with respect to palladium(II) in the aqueous and organic phases respectively, the relation between the palladium(II) concentration(a) in the aqueous phase and the contact time(t) is expressed as follows[11]:

$$\frac{a_i-a_e}{a_i} \ln \frac{a_i-a_e}{a_t-a_e} = k_f t, \tag{8}$$

where k_f represents the observed reaction-rate constant for the forward reaction and where the quantities with the subscripts "t", "i", and "e" denote the concentrations after time t, at t=0, and at equilibrium respectively.

Figure 5 shows a typical experimental result plotted on the basis of Eq. 8. The plots in this figure give straight lines passing through the point of origin, as is to be expected from Eq. 8. This result suggests that the forward reaction rate of palladium(II) extraction is first-order with respect to palladium(II) in the aqueous phase. The apparent reaction-rate constants were obtained from the slopes of these straight lines. Since the apparent reaction-rate constant was found in the preliminary experiment to be independent of the stirring speed over the range greater than 1300 rpm, subsequent experiments were carried out at a constant stirring speed of 1500 rpm.

Figure 6 shows the effect of the chloride-ion concentration on the observed reaction rate constant. As is evident from Fig. 6, the plotted points lie on a straight line, with a slope of −1, in the low-concentration region of chloride ions and tend to approach a con-

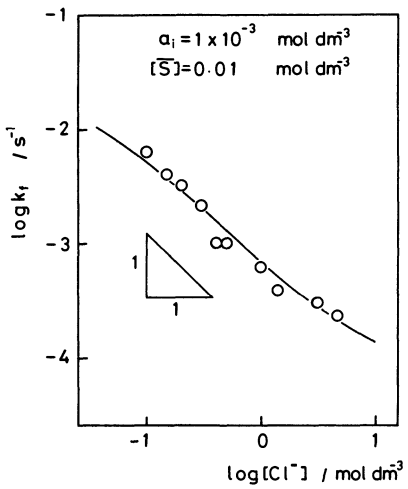

Fig. 6. Effect of chloride ion concentration on the observed extraction rate constant.

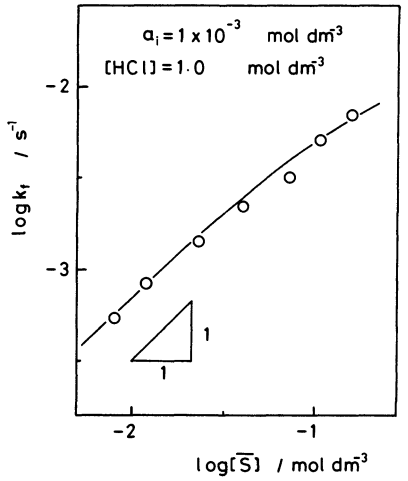

Fig. 7. Effect of TIBPS concentration on the observed extraction rate constant.

stant value in the high-concentration region. This tendency is in accordance with that observed in the extraction of palladium(II) with 1,2-bis(*t*-hexylthio)-ethane.[8] That is, it may be concluded that the extraction rate is inversely first-order with respect to the chloride ion in its low-concentration region and zeroth-order in its high-concentration region.

Similarly, the effect of the TIBPS concentration on the observed reaction rate constant is shown in Fig. 7. In this figure, the plots appear to lie on a straight line, with a slope of about 0.75. This result suggests that the extraction-reaction mechanism of this system can not be interpreted in terms of the classical homogeneous heterophase reaction mechanism.[12] Therefore, we in the following section will analyse the experimental results of the extraction kinetics based on the heterogeneous interfacial reaction model.

Discussion

The following results obtained in the present experiment suggest that a certain elementary process taking place at the interface plays an important role in the extraction mechanism: (1) The aqueous solubility of TIBPS is too low to assume that homogeneous reactions take place to any considerable extent in the aqueous phase; (2) TIBPS is adsorbed at the interface, and (3) the reaction order with respect to the extractant is less than unity. The great majority of palladium(II) exists as the tetrachloro complex, $[PdCl_4]^{2-}$, and a small amount of the aquatrichloro complex, $[PdCl_3(H_2O)]^-$, coexists in the aqueous phase over the range of chloride-ion concentrations studied. Of these, Rund,[13] in his paper on the reaction rates of palladium(II) with 1,10-phenanthroline and 2,2′-bipyridyl, reported that the latter is much more labile than the former. Taking account of these facts, the following reaction scheme was proposed to explain the extraction kinetics of palladium(II) with TIBPS:

$$[PdCl_3(H_2O)]^- + S_{ad} \xrightarrow{k_1} [PdCl_3S]^-_{ad} + H_2O \quad (9)$$

$$[PdCl_4]^{2-} + S_{ad} \xrightarrow{k_2} [PdCl_3S]^-_{ad} + Cl^- \quad (10)$$

$$[PdCl_3S]^-_{ad} + \bar{S} \rightleftharpoons \overline{[PdCl_2S_2]} + Cl^- \quad (11)$$

$$2\overline{[PdCl_2S_2]} \rightleftharpoons \overline{[(PdCl_2)_2S_2]} + 2\bar{S} \quad (12)$$

The elementary steps described by Eqs. 9 and 10 form the parallel reaction; of these steps, the former is much more rapid than the latter, as has been mentioned earlier. From the fact that the reaction order with respect to TIBPS is less than unity, the interfacial steps expressed by Eqs. 9 and 10 may be considered to be the rate-determining steps. Assuming that the parallel reactions of $[PdCl_3(H_2O)]^-$ and $[PdCl_4]^{2-}$ with TIBPS adsorbed at the interface are the rate-determining steps, the rate expression can be described as follows:

$$-\frac{da_t}{dt} = (k_1[[PdCl_3(H_2O)]^-] + k_2[[PdCl_4]^{2-}])\theta_s \quad (13)$$

where k_1 and k_2 are the forward reaction rate constants of Eqs. 9 and 10 respectively.

In case the preceding elementary step expressed by Eq. 5 is in equilibrium, θ_s is expressed by Eq. 14 from Eq. 6:

$$\theta_s = \frac{K_{ad}[\bar{S}]}{1+K_{ad}[\bar{S}]} \quad (14)$$

The substitution of Eq. 14 into Eq. 13 gives the following rate expression.

$$-\frac{da_t}{dt} = \frac{K_{ad}[\bar{S}]}{1+K_{ad}[\bar{S}]}(k_1[[PdCl_3(H_2O)]^-] + k_2[[PdCl_4]^{2-}]) \quad (15)$$

It is well known that palladium(II) gives rise to chloro complexes in hydrochloric acid as follows:

$$Pd^{2+} + iCl^- \rightleftharpoons [PdCl_i]^{(i-2)-} \quad ;\beta_i \quad (16)$$

$$\beta_i = \frac{[[PdCl_i]^{(i-2)-}]}{[Pd^{2+}][Cl^-]^i} \quad (17)$$

where β_i indicates the stability constants of the ith chloro complex of palladium(II).

The concentrations of the aquatrichloro complex, $[PdCl_3(H_2O)]^-$, and the tetrachloro complex, $[PdCl_4]^{2-}$, in Eq. 15 are expressed by Eqs. 18 and 19, using the equilibrium relations of the chloro complexes in the aqueous phase mentioned above:

$$[[PdCl_3(H_2O)]^-] = \beta_3[Cl^-]^3 a_t/\alpha \quad (18)$$

$$[[PdCl_4]^{2-}] = \beta_4[Cl^-]^4 a_t/\alpha, \quad (19)$$

where α is defined by the following equation:

$$\alpha = 1 + \sum_{i=1}^{4} \beta_i[Cl^-]^i \quad (20)$$

As has been mentioned earlier, over the chloride-ion-concentration range studied, α may be approximated as follows:

$$\alpha \simeq \beta_3[Cl^-]^3 + \beta_4[Cl^-]^4 \quad (21)$$

Consequently, Eq. 15 is ultimately expressed by Eq. 22:

$$-\frac{da_t}{dt} = \frac{K_{ad}[\bar{S}]}{1+K_{ad}[\bar{S}]}\left(\frac{k_1\beta_3 + k_2\beta_4[Cl^-]}{\beta_3+\beta_4[Cl^-]}\right)a_t \quad (22)$$

The effects on the extraction rate of varying the concentrations of each reactant species, shown in Figs. 6 and 7, can be qualitatively interpreted by means of Eq. 22, derived from the proposed interfacial reaction scheme.

The optimum values of k_1 and k_2 in Eq. 22 were evaluated by the nonlinear least-squares method from the data shown in Fig. 6, using the K_{ad} value evaluated earlier and the stability constants of the palladium(II) chloro complexes reported in the literature[14] ($\beta_3 = 2.00\times10^{10}$, $\beta_4 = 7.94\times10^{11}$) as follows: $k_1 = 6.1\times10^{-1}$ s^{-1}, $k_2 = 1.7\times10^{-3}$ s^{-1}. The solid lines shown in Figs. 6 and 7 were obtained by inserting these values into Eq. 22. The calculated lines are in fairly good agreement with the experimental results.

Conclusion

The kinetic study of the solvent extraction of palladium(II) from hydrochloric acid with triisobutylphosphine sulfide (TIBPS=S) in toluene was conducted using a stirred cell, along with studies of the aqueous solubility or the equilibrium distribution of the extractant between the organic and aqueous phases, its adsorption equilibrium at the interface, and the distribution equilibrium of palladium(II).

The experimental results on the distribution equilibrium of palladium(II) showed that palladium(II) is extracted as a Pd : extractant 2 : 2 complex, $[(PdCl_2)_2S_2]$.

From the experimental results of the equilibrium distribution and the interfacial adsorption equilibrium of the extractant, it was elucidated that TIBPS has a very low aqueous solubility and a fairly high interfacial activity, suggesting the importance of the interfacial reaction in the extraction of palladium(II) with TIBPS.

The experimental results of the extraction kinetics were quantitatively explained by the interfacial reaction model on the assumption that the ligand substitutions between the extractant adsorbed at the interface and the aquatrichloro and tetrachloro complexes of palladium(II) in the aqueous phase are the rate-determining steps. That is, the extraction rate was found to be satisfactorily expressed by the rate equation described by Eq. 22, derived from the interfacial reaction model presented above.

The authors are deeply indebted to American Cyanamid Co. for supply of the sample of CYANEX 471.

Extraction Equilibria of Mercury(II) from Hydrochloric Acid with Trialkylphosphine Sulfides

Yoshinari BABA,* Yukihiro UMEZAKI, Takashi UEDA, and Katsutoshi INOUE
Department of Industrial Chemistry, Faculty of Science and Engineering, Saga University, Honjo-machi 1, Saga 840
(Received June 5, 1986)

The extraction of mercury(II) from hydrochloric acid was compared using five kinds of sulfur-containing extractants. Mercury(II) was extracted most effectively by trialkylphosphine sulfides. Subsequently, the distribution equilibria of mercury(II) from hydrochloric acid with triisobutylphosphine sulfide (TIBPS=$\bar{S}$) and trioctylphosphine sulfide (TOPS=$\bar{S}$) in toluene have been measured at 303 K in order to clarify the concentration dependencies of the reactant species. It was found that mercury(II) is extracted according to the solvation reaction by TIBPS or TOPS as a mercury(II): extractant 1:2 complex, $HgCl_2S_2$, in the range of low loading ratio of mercury(II) to the extractants, and as a 1:1 binuclear complex, $(HgCl_2)_2S_2$, in the region of high loading ratios, as follows:

$$HgCl_2 + 2\bar{S} \rightleftharpoons \overline{HgCl_2S_2} \qquad K_e$$

$$2HgCl_2 + 2\bar{S} \rightleftharpoons \overline{(HgCl_2)_2S_2} \qquad K_e'$$

The extraction equilibrium constants, K_e and K_e', were evaluated as $K_e=4.0\times10^5$ $(dm^3\ mol^{-1})^2$ and $K_e'=2.0\times10^8$ $(dm^3\ mol^{-1})^3$ for TIBPS and as $K_e=7.2\times10^6$ $(dm^3\ mol^{-1})^2$ for TOPS.

Thus far, the solvent extraction of mercury(II) has been investigated using various kinds of extractants: trioctylphosphine oxide (TOPO),[1,2] tributyl phosphate (TBP),[2] trioctylamine,[3] and trioctylmethylammonium chloride (Aliquat 336).[4] However, these extractants, containing nitrogen or oxygen as a donor atom, have only poor selectivities to mercury(II) over other metals. On the other hand, it is well-known that the extractants containing sulfur as a donor atom, such as dialkyl sulfides[5,6] and trialkyl thiophosphate,[7] are very powerful and selective extractants for mercury(II). From this point of view, in a previous work[8] we studied the extraction equilibrium of mercury(II) with 1,2-bis(hexylthio)ethane, which contains two sulfurs as donor atoms.

Recently, the American Cyanamid Co. has developed a new commercial extractant, CYANEX 471, the active species of which is triisobutylphosphine sulfide, as a selective extractant for palladium(II) and silver(I).[9] Hitchcock et al.[10] reported that tributylphosphine sulfide (TBPS) completely extracted mercury(II) from 0.1 mol dm^{-3} hydrochloric acid; however, they did not succeed in finding an effective aqueous solution for stripping. Further, no detailed studies of the extraction of mercury(II) with trialkylphosphine sulfides have been carried out to date.

In the present investigation, the authors have conducted a detailed and quantitative investigation of the distribution equilibrium of mercury(II) in extraction from hydrochloric acid with two kinds of trialkylphosphine sulfides: triisobutylphosphine sulfide and trioctylphosphine sulfide.

Prior to the detailed study of the extraction equilibrium, preliminary experiments were carried out in order to compare qualitatively the extraction behavior of trialkylphosphine sulfides with that of other sulfur-containing compounds for mercury(II).

Experimental

Reagents. Two kinds of trialkylphosphine sulfides, possessing different alkyl chains-triisobutylphosphine sulfide and trioctylphosphine sulfide-were used as the extractants. These will be abbreviated to TIBPS and TOPS respectively and denoted by S hereafter. The TIBPS was purified from a commercial extactant, CYANEX 471, donated by the American Cyanamid Co., by recrystallization from a water-ethanol mixture. The purity of the purified reagent was confirmed by elemental analysis to be as follows: Found: C, 61.34; H, 11.48%. Calcd: C, 61.49; H, 11.61%. The TOPS, which was kindly supplied by the Nippon Chemical Industry Co., was used as delivered, without further purification. The purity of this reagent was also confirmed by elemental analysis to be as follows: Found: C, 71.95; H, 12.64%. Calcd: C, 71.64; H, 12.64%. Among the extracting reagents used in the preliminary experiment for the sake of comparison, 1,2-bis-(hexylthio)ethane and 2-(butylthio)dodecanoic acid were synthesized and purified in the manners reported in previous papers,[8,11] while dihexyl sulfide was used as delivered from the Daihachi Chemical Co., Ltd. These reagents will be abbreviated as BHTE, 2-BTDA and DHS respectively hereafter. An organic phase was prepared by diluting these extractants with toluene of an analytical grade on a gravimetric basis. An aqueous phase was prepared by dissolving mercury(II) chloride in hydrochloric acid.

Procedure. Equal volumes of the aqueous and organic phases were shaken in a 0.1 dm^3 stoppered glass flask immersed in a thermostated bath maintained at 303 K—for 3 h or 1 h for TIBPS or TOPS respectively—in order to attain equilibrium. It was confirmed from a preliminary experiment that the equilibration could be attained within these times. The initial total concentration of mercury(II) was 1×10^{-3} or 5×10^{-3} mol dm^{-3} in all experiments. The total concentration of mercury(II) in the aqueous phase was determined by titration with EDTA in the presence of an excess of Mg-EDTA, using Eriochrome Black T (BT) as an indicator, or by atomic-absorption spectrochemical analysis

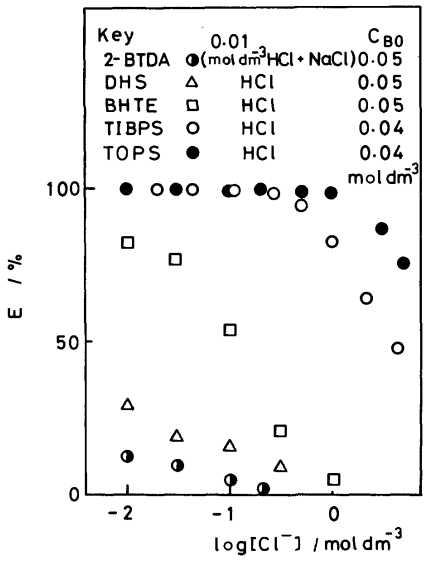

Fig. 1. Relation between % extraction of mercury(II) and log [Cl⁻] (Initial concentration of mercury(II) is 5×10^{-3} mol dm^{-3}).

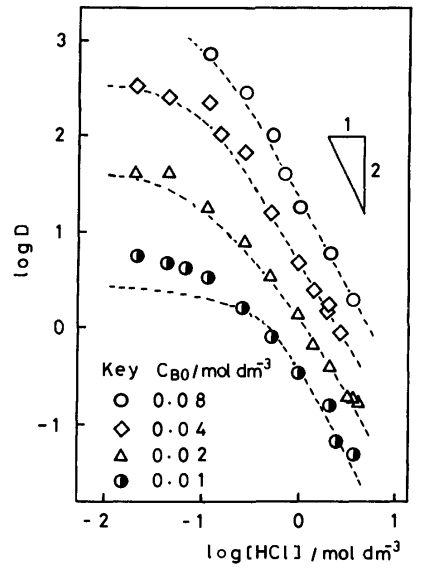

Fig. 2. Equilibrium distribution of mercury(II) from hydrochloric acid solutions with TIBPS in toluene (Initial concentration of mercury(II) is 5×10^{-3} mol dm^{-3}).

using a Nippon Jarrell-Ash model AA-782 spectrophotometer. In the range of low loading ratios, the concentration of mercury(II) in the organic phase was determined by the methods described above after stripping with a 1 and a 2 mol dm^{-3} aqueous ammonium thiocyanate solution for TIBPS and TOPS respectively. In the range of high loading ratios, it was calculated from the difference between the initial and equilibrium concentrations of mercury(II) in the aqueous phase.

Results and Discussion

Figure 1 shows the results of the preliminary experiment as the plot of the % extraction of mercury(II) by each extractant from chloride media against the chloride-ion concentration. Here, the % extraction is defined as the ratio of mercury(II) content in the organic phase after equilibration to the initial mercury(II) content in the aqueous phase. C_{B0} denotes the initial concentration of the extractants. From Fig. 1, mercury(II) is shown to be effectively extracted by TIBPS and TOPS in the range of low chloride-ion concentrations in particular; the % extractions are more than 50%, even in the high-chloride-ion-concentration region, which suggests that these extractants are very effective for the separation and recovery of mercury(II). On the other hand, DHS and 2-BTDA show only a poor extraction capacity for mercury(II) in chloride media, while BHTE shows an extraction capacity intermediate between the trialkylphosphine sulfides and DHS or 2-BTDA. Therefore, the present authors conducted a detailed and quantitative study of the extraction equilibria of mercury(II) with TIBPS and TOPS.

Figures 2 and 3 show the effects of the hydrochloric acid concentration on the distribution ratio of mercury(II) for various concentrations of the extractant in

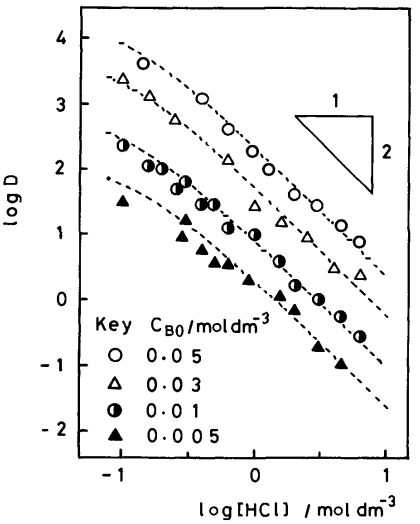

Fig. 3. Equilibrium distribution of mercury(II) from hydrochloric acid solutions with TOPS in toluene (Initial concentration of mercury(II) is 1×10^{-3} mol dm^{-3}).

the extractions with TIBPS and TOPS respectively. As is evident from these figures, the distribution ratio, D, decreases with the increase in the hydrochloric acid concentration, which is similar to the extractions of mercury(II) from hydrochloric acid with 1,2-bis-(hexylthio)ethane and 2-BTDA observed in the previous works.[8,12] Therefore, mercury(II) is considered to be extracted from hydrochloric acid according to the following solvation reaction for both the extractants:

$$HgCl_2 + n\bar{S} \rightleftharpoons \overline{HgCl_2S_n} \qquad K_e, \qquad (1)$$

where $\bar{S}$ denotes the extractant species in the organic phase. The equilibrium constant, K_e, for the above

reaction is given by Eq. 2:

$$K_e = \frac{[\overline{HgCl_2S_n}]}{[HgCl_2][\bar{S}]^n}. \quad (2)$$

It is well-known that mercury(II) gives rise to chloro complexes in the aqueous chloride solution as follows:

$$Hg^{2+} + iCl^- \rightleftharpoons HgCl_i^{(i-2)-} \quad \beta_i \ (i=1\text{–}4) \quad (3)$$

$$\beta_i = \frac{[HgCl_i^{(i-2)-}]}{[Hg^{2+}][Cl^-]^i}, \quad (4)$$

where β_i is the stability constant of the ith chloro complex of mercury(II).[13] From Eqs. 3 and 4, the concentration of the neutral complex, $[HgCl_2]$, which takes part in the extraction reaction described by Eq. 1 is expressed as follows:

$$[HgCl_2] = \alpha_2 C_{Hgw}, \quad (5)$$

where

$$\alpha_2 = \beta_2[Cl^-]^2/(1+\sum_{i=1}^{4}\beta_i[Cl^-]^i). \quad (6)$$

In the region of high chloride-ion concentrations ($[Cl^-]>1$ mol dm^{-3}), it can be approximated by Eq. 7:

$$[HgCl_2] = \alpha_2 C_{Hgw} \simeq (\beta_2/\beta_4[Cl^-]^2)C_{Hgw}. \quad (7)$$

In Eqs. 5 and 7, C_{Hgw} denotes the total concentration of mercury(II) in the aqueous phase. From Eqs. 2 and 5, the distribution ratio is expressed by Eq. 8:

$$D = \frac{[\overline{HgCl_2S_n}]}{C_{Hgw}} = K_e\alpha_2[\bar{S}]^n, \quad (8)$$

which is approximated by Eq. 9 in the regions of high concentrations of the chloride ion:

$$D \simeq K_e(\beta_2/\beta_4[Cl^-]^2)[\bar{S}]^n. \quad (9)$$

The logarithm of Eq. 9 gives:

$$\log D = -2\log[Cl^-] + a, \quad (10)$$

where

$$a = \log(\beta_2/\beta_4) + n\log[\bar{S}] + \log K_e. \quad (11)$$

In Eq. 11, the concentration of the unreacted extractant, $[\bar{S}]$, is nearly equal to its initial concentration, C_{B0}, in the region of low loading ratios.

As is evident from Figs. 2 and 3, the plotted points lie on straight lines, with a slope of −2, in the high-concentration ranges of hydrochloric acid, as is to be expected from Eq. 10. The values of a, defined by Eq. 11, were obtained from the intercepts of these straight lines with the ordinate for each C_{B0} and for each extractant. In Fig. 4, they are plotted against log C_{B0} to evaluate n and K_e. As is evident from this figure, the plotted points lie on straight lines, with a slope of 2, which suggests that n=2 in Eq. 11; that is, mercury(II) is coordinately solvated by two molecules of TIBPS or TOPS in the organic phase. Therefore, the stoichiometric relation of these extraction reactions may be expressed as follows for both the extractants:

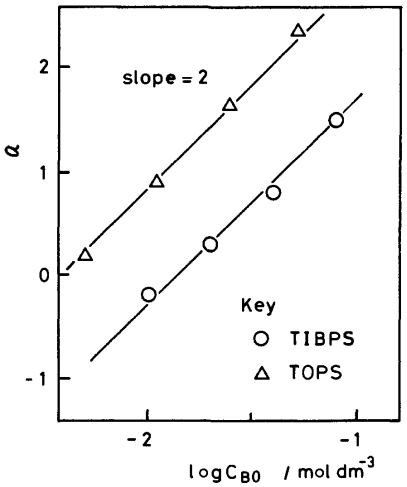

Fig. 4. Plot of a against log C_{B0} based on Eq. 11.

$$HgCl_2 + 2\bar{S} \rightleftharpoons \overline{HgCl_2S_2} \quad K_e \quad (12)$$

On the basis of Eq. 11, the extraction equilibrium constant, K_e, was evaluated as $K_e=4.0\times10^5$ (dm^3 mol^{-1})^2 for TIBPS, and as $K_e=7.2\times10^6$ (dm^3 mol^{-1})^2 for TOPS, from the intercepts of the straight lines with the ordinate in Fig. 4.

Meanwhile, in the region of high loading ratios, the mass balances with regard to the extractant and mercury(II) should be taken into consideration. The initial concentration of the extractant (C_{B0}) in the organic phase and that of mercury(II)(C_{Hg0}) in the aqueous phase are expressed as follows:

$$C_{B0} = [\bar{S}] + 2[\overline{HgCl_2S_2}] \quad (13)$$

$$C_{Hg0} = C_{Hgw} + [\overline{HgCl_2S_2}]. \quad (14)$$

Equations 8 and 14 are then combined to give Eq. 15, taking into account the fact that n=2:

$$C_{Hgw} = C_{Hg0}/(1+\gamma[[\bar{S}]^2), \quad (15)$$

where

$$\gamma = \alpha_2 K_e. \quad (16)$$

The mass balance equation of the extractant in the organic phase expressed by Eq. 13 is reduced to the cubic equation expressed by Eq. 17 with respect to the unreacted extractant concentration ($[\bar{S}]$):

$$\gamma[\bar{S}]^3 + (2\gamma C_{Hg0} - \gamma C_{B0})[\bar{S}]^2 + [\bar{S}] - C_{B0} = 0. \quad (17)$$

The distribution ratio is ultimately given by:

$$D = \frac{[\overline{HgCl_2S_2}]}{C_{Hgw}} = \frac{C_{Hg0}}{C_{Hgw}} - 1 = \gamma[\bar{S}]^2 \quad (18)$$

The dotted lines in Figs. 2 and 3 show the results calculated from Eqs. 17 and 18. The calculated curves shown in Figs. 2 and 3 are in good agreement with the experimental results except for C_{B0}=0.01 mol dm^{-3} in the extraction with TIBPS in Fig. 2.

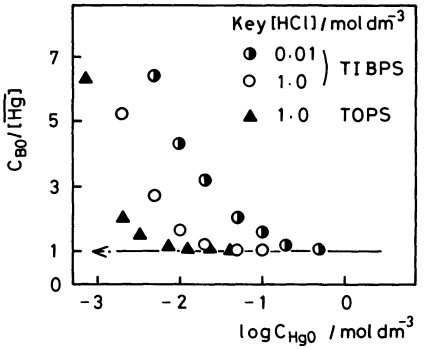

Fig. 5. Experimental results of the loading test (C_{B0}=0.01 mol dm^{-3}).

Since the calculated curve corresponding to C_{B0}=0.01 mol dm^{-3} in Fig. 2 deviates downwards from the experimental results as the mercury(II) concentration in the organic phase increases, the loading test was carried out for a constant initial concentration of the extractant in order to examine the mole ratio of mercury(II) extracted into the organic phase ($[\overline{Hg}]$) to the extractant under the conditions of excess concentrations of mercury(II), by varying the initial mercury(II) concentration (C_{Hg0}) in the aqueous phase.

In Fig. 5, the experimental results are shown as plots of the mole ratio, $C_{B0}/[\overline{Hg}]$, against C_{Hg0}, which shows that the mole ratio asymptotically approaches unity for both extractants. From these results, it is evident that mercury(II) is extracted as a 1 : 1 metal : reagent complex in the region of high loading ratios. Consequently, it may be considered to be extracted as a binuclear complex according to the extraction reaction described by Eq. 19, taking the coordination number of mercury(II)(=4) into consideration and referring to the study by Mikhailov et al.[5] on the extraction of mercury-(II) with dialkyl sulfides:

$$2HgCl_2 + 2\overline{S} \rightleftharpoons \overline{(HgCl_2)_2S_2} \qquad K_e' \qquad (19)$$

$$K_e' = \frac{[\overline{(HgCl_2)_2S_2}]}{[HgCl_2]^2[\overline{S}]^2} \qquad (20)$$

Taking account of the fact that mercury(II) is extracted according to the extraction reaction described by Eq. 19 in the region of high loading ratios, the calculated curves for the extraction with TIBPS in Fig. 2 were reconsidered. The distribution ratio, D, is described by Eq. 21 by taking account of the two reactions expressed by Eqs. 12 and 19:

$$D = \frac{[\overline{HgCl_2S_2}] + 2[\overline{(HgCl_2)_2S_2}]}{C_{Hgw}} \qquad (21)$$

The substitution of Eqs. 2, 5, and 20 into Eq. 21 gives Eq. 22, taking into account the fact that n=2:

$$D = (K_e + 2K_e'C_{Hgw}\alpha_2)\alpha_2[\overline{S}]^2 \qquad (22)$$

Further, the total concentration of the extractant in the organic phase, C_{B0}, and the initial concentration of

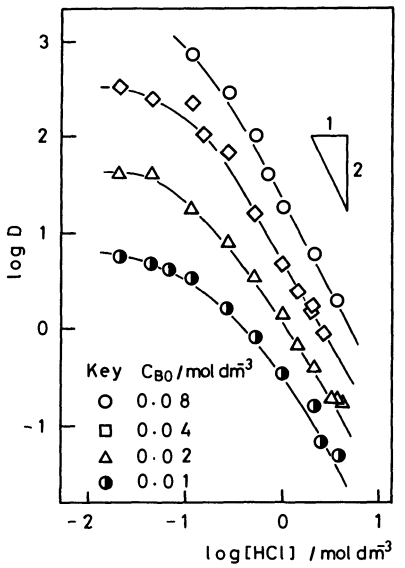

Fig. 6. Equilibrium distribution of mercury(II) from hydrochloric acid solutions with TIBPS in toluene.

mercury(II) in the aqueous phase, C_{Hg0}, are expressed as follows:

$$C_{B0} = [\overline{S}] + 2[\overline{HgCl_2S_2}] + 2[\overline{(HgCl_2)_2S_2}] \qquad (23)$$

$$C_{Hg0} = C_{Hgw} + [\overline{HgCl_2S_2}] + 2[\overline{(HgCl_2)_2S_2}] \qquad (24)$$

The subtraction of Eq. 24 from Eq. 23, followed by the substitution of Eq. 8 and taking into account the fact that n=2, yields the following quadratic equation with respect to the unreacted extractant concentration ($[\overline{S}]$):

$$K_e\alpha_2C_{Hgw}[\overline{S}]^2 + [\overline{S}] - C_{B0} + C_{Hg0} - C_{Hgw} = 0 \qquad (25)$$

The equilibrium constant for the extraction reaction described by Eq. 19, K_e', was evaluated, using the least-squares method so as to minimize the deviations between the observed and calculated results from Eqs. 22 and 25, as K_e'=2.0×10^8 (dm^3 mol^{-1})^3. The solid lines in Fig. 6 are the calculated results obtained from Eqs. 22 and 25 using the values of K_e=4.0×10^5 (dm^3 mol^{-1})^2 and K_e'=2.0×10^8 (dm^3 mol^{-1})^3. For all of the extractant concentrations, the calculated curves are in good agreement with the experimental results.

The authors are deeply indebted to American Cyanamid Co. for supply of the sample of CYANEX 471.

Solvation and Ionic Association of Bis(2,4-pentanedionato)-(diamine)cobalt(III) Perchlorates in 1-Propanol, Acetone, and Their Mixtures

Kazuaki Ito,†,* Etsuro Iwamoto, Shigehito Suehisa, Hiroyuki Isono, and Yuroku Yamamoto††
Department of Chemistry, Faculty of Science, Hiroshima University, Naka-ku, Hiroshima 730
(Received May 29, 1986)

The conductances of bis(2,4-pentanedionato)(diamine)cobalt(III) perchlorates ([Co(acac)$_2$(diamine)]ClO$_4$, diamine: en=ethylenediamine, pn=1,2-propanediamine, *N,N*-dmen=*N,N*-dimethylethylenediamine, *N,N'*-dmen=*N,N'*-dimethylethylenediamine, *N,N,N'*-trimen=*N,N,N'*-trimethylethylenediamine, *N,N,N',N'*-tmen=*N,N,N',N'*-tetramethylethylenediamine) were measured in isodielectric solvents, 1-propanol (*n*-PrOH), acetone (Me_2CO), and 60 and 80 mol% acetone in 1-propanol (*n*-PrOH–Me_2CO) at 25 °C. In spite of the increase in size of [Co(acac)$_2$(diamine)]$^+$ due to the introduction of *N*-methyl groups, the Walden products ($\lambda_0^+ \cdot \eta$) of the chelate cations were found to increase in all solvents. The contribution per *N*-methyl group was large in *n*-PrOH. The variation in the ionic association constants (K_a) with the number of NH protons in the chelate cations was small in all solvents. The K_a values for [Co(acac)$_2$(*N,N'*-dmen)]ClO$_4$ were larger than those for other chelate salts in all solvents. These results could be explained in terms of the solvation of the NH protons (diamine in [Co(acac)$_2$-(diamine)]$^+$) by oxygen atoms of *n*-PrOH and Me_2CO, and of oxygen atoms (acac) by the OH proton of *n*-PrOH owing to hydrogen bonding interactions and desolvation resulting from the introduction of the *N*-methyl groups. For [Co(acac)$_2$(en)]$^+$ in *n*-PrOH a solvation model to form a six-membered ring was proposed.

Our previous conductometric studies of [Co(acac)$_2$-(en)]X (X$^-$=ClO$_4^-$, I$^-$, and Br$^-$) and their *N*-methyl derivatives in nitrobenzene and 1,2-dichloroethane[1,2] indicated that NH protons in the chelate cations are solvated by the dipolar aprotic solvent nitrobenzene, and that the substitution of *N*-methyl groups for NH protons prevents solvation, leading to an increase in mobility in spite of the increasing size. The *N*-methylation results in an apparent increase in the acidity of the residual and the nearest-neighbor NH protons. These trends were not observed in 1,2-dichloroethane with a lower polarity. The association constants decrease with a decrease in the number of NH protons in both solvents and the change per proton is larger in 1,2-dichloroethane. These solvents are aprotic and weak in basicity but have different dielectric constants and polarities. Thus, it is suggested that ionic association processes of the chelate cations are affected by ion-solvent dipole interactions.

In this study, in an effort to obtain more information concerning the effects of the solvent dipole moment and the solvent acidity and basicity, the conductances of [Co(acac)$_2$(diamine)]ClO$_4$ were measured in the protic solvent 1-propanol, aprotic acetone, and their mixtures. 1-Propanol has acidic and basic sites that are effective for solvation; acetone interacts through its electron lone pair. Since the solvents have nearly the same dielectric constants, the electrostatic interaction energy between a cation and an anion is regarded as constant for a given electrolyte. Solvation of the ClO$_4^-$ ion is weak compared to that of halide ions. Thus, it is considered that specific cation-solvent interactions in ionic association process become much apparent.

Experimental

[Co(acac)$_2$(diamine)]ClO$_4$ was prepared and purified as described previously.[2] 1-Propanol was refluxed over calcium hydride for 2 d and fractionally distilled. Acetone was refluxed over Drierite after dehydration by molecular sieves (4A) for one week and fractionally distilled. The distillation was performed under a flow of N_2 gas since the solvents were relatively hygroscopic. Typical densities (d in g cm^{-3}), viscosities (η in mPa s), and specific conductances of pure solvents (κ in S cm^{-1}) at 25 °C and water contents (wc in wt%) are: for *n*-PrOH d=0.79963, η=1.952, $\kappa=2\times10^{-8}$, and $wc=8\times10^{-3}$; for Me_2CO d=0.78426, η=0.3052, $\kappa=2\times10^{-8}$, and $wc=5\times10^{-3}$.

The procedure for the conductance measurements and other measurements (viscosity and density) have been described previously.[2] The water content was measured coulometrically using a Hiranuma AQ-3 aqua counter. *n*-PrOH–Me_2CO mixtures were prepared by weight just before a conductance measurement. The dielectric constant (ε) and viscosity (η in mPa s) of the solvents used for an analysis were as follows: for *n*-PrOH ε=20.45,[3] η=1.952; for Me_2CO ε=20.45,[4] η=0.3052; for *n*-PrOH–Me_2CO (60 mol% Me_2CO) ε=18.64,[4] η=0.463; for 80 mol% Me_2CO ε=19.37,[4] η=0.361.

Results and Discussion

The measured molar conductances, Λ (S cm^2 mol^{-1}) and the corresponding electrolyte concentrations, C (mol dm^{-3}) for [Co(acac)$_2$(diamine)]ClO$_4$ in 1-propanol and acetone are given in Table 1 and those in 1-propanol–acetone mixtures (60 and 80 mol% acetone) in Table 2. The data were analyzed by the Fuoss-Hsia equation with $E=E_1\Lambda_0-2E_2$ in the form[5]

$$\Lambda = \Lambda_0 - S(C\gamma)^{1/2} + EC\gamma \log C\gamma + J_1C\gamma - J_2(C\gamma)^{3/2} - K_aC\gamma f_\pm^2\Lambda \quad (1)$$

Walden products of $[Co(acac)_2(diamine)]^+$ with the introduction of methyl groups in 1-propanol and acetone, compared with that of tetraalkylammonium cations[3,4] for which n refers to the number of carbons in the alkyl group. For tetraalkylammonium ions which have approximately the same size as the chelate cations used here and no specific site for solvation, the Walden product decreases with increasing ionic size, as is hydrodynamically expected. It should be noted that, in contrast, the Walden product of the che-

late cations in both 1-propanol and acetone roughly increases with the *N*-methylation of NH protons in spite of the increase in the size of the cations. Similar results were also obtained in nitrobenzene which has a poor basicity and can be explained in terms of the solvation of the NH proton site by nitrobenzene through an ion-solvent dipole interaction and desolvation by *N*-methylation.[1,2]

However, this *N*-methylation effect in 1-propanol is more marked than in nitrobenzene. The difference in the Walden products between *N,N,N',N'*-tmen and en complexes in acetone, 0.020 S cm² mol⁻¹ 10⁻¹ Pa s is comparable with that in nitrobenzene; however, a large difference of 0.054 S cm² mol⁻¹ 10⁻¹ Pa s was observed in 1-propanol. A small difference of 0.003 S cm² mol⁻¹ 10⁻¹ Pa s was obtained in 1,2-dichloroethane.[2] The large variation of the Walden product with the substituted groups in diamine for the 1-propanol system is suggestive of a specific solvation of the chelate cations.

The dipole moment of acetone, 1-propanol, nitrobenzene, and 1,2-dichloroethane is 2.88, 1.68, 4.22, and 1.40 in Debye, respectively,[6] and the large variation in the Walden products in 1-propanol can not be explained by only the dipole moment.

The following two specific interactions for the solvation of chelate cations are considered: A hydrogen-bonding interaction between the NH protons in $[Co(acac)_2(diamine)]^+$ and the oxygen atom of 1-propanol and acetone which act as hydrogen bonding acceptor. The second is the hydrogen-bonding of the oxygen atom of the coordinated acac ligand with the

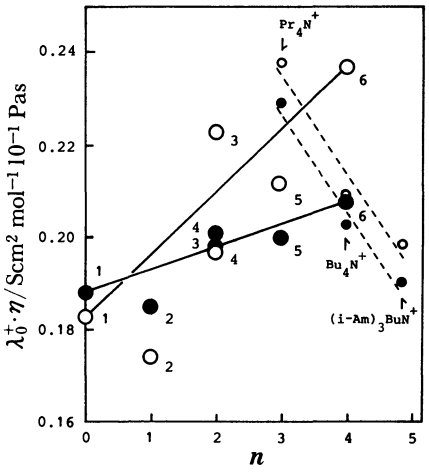

Fig. 1. Walden products of $[Co(acac)_2(diamine)]^+$ as a function of the increased carbon number, *n* compared to $[Co(acac)_2(en)]^+$. ○: in *n*-PrOH, ●: in Me_2CO. Diamine, 1: en, 2: pn, 3: *N,N*-dmen, 4: *N,N'*-dmen, 5: *N,N,N'*-trimen, 6: *N,N,N',N'*-tmen. For onium salts, *n* refers to the number of carbon in the alkyl group and the data are from Refs. 3 and 4.

OH proton of 1-propanol which acts as a hydrogen-bonding donor.

The hydrogen-bonding acceptor ability or donicity is evaluated by the Gutmann donor number. The donor numbers (DN) of acetone, nitrobenzene, and 1,2-dichloroethane are 17, 4.4, and 0.0, respectively.[7] The DN value of 1-propanol, although not available in the literature, was reasonably estimated to be around 20, since that of methanol and ethanol is 19 and 20, respectively. The ^{59}Co NMR for $[Co(en)_3]^{3+}$ was measured in several organic solvents and the signal was shifted to a higher field upon increasing the donicity of the solvents.[8] This was interpreted as the result of a donor solvent attack on the NH protons. Although an ion-dipole interaction for acetone is weaker than that for nitrobenzene, the solvation of NH protons by acetone is strengthened by its stronger donicity, resulting in a comparable difference in the Walden product between acetone and nitrobenzene.

A relatively large increase in the mobility by the *N*-methylation in 1-propanol indicates the strong solvation power of 1-propanol. The IR spectra of methanol in the carbon tetrachloride solutions of bis- and tris (2,4-pentanedionato) complexes such as $Be(acac)_2$ and $Cr(acac)_3$ showed that for $Cr(acac)_3$ hydrogen bonding occurrs between the oxygen atom of acac and the OH proton of methanol but does not occur for $Be(acac)_2$ because of a steric hindrance.[9] The ^1H NMR study of paramagnetic $Cr(acac)_3$ indicated that the OH group of methanol is closer to the central metal Cr(III) than the CH_3 group of methanol.[10] Furthermore, the X-ray study of $[Cr(acac)_2(tn)]I$ (tn=1,3-propanediamine)[11] showed that the intramolecular distance between the NH protons and oxygen atoms of the acac is 2.5 and 2.6 Å. A molecular model of $[Co(acac)_2(en)]^+$ indicates that it possesses spaces enough to accomodate the OH group of 1-propanol. Thus, it is possible that $[Co(acac)_2(en)]^+$ is solvated by 1-propanol through hydrogen bonding to form a six-membered ring.

In 1-propanol-acetone mixtures (Table 4) the mobility of the complex ions increases with the *N*-methylation in a similar manner. The differences in the Walden product between *N,N,N',N'*-tmen and en complexes are 0.031 and 0.019 S cm^2 mol^{-1} 10^{-1} Pa s in 60 and 80 mol% acetone in 1-propanol, respectively. These values are closer to the value for acetone (0.020) than that for 1-propanol (0.054), thereby suggesting that the selective solvation of $[Co(acac)_2(en)]^+$ by 1-propanol is not seen in the mixed solvents.

The methylation effect on the mobility depends on the substituted position. As can be seen for $[Co(acac)_2(pn)]^+$, the *C*-methylation leads to a decrease in the mobility. A similar result was obtained in nitrobenzene and 1,2-dichloroethane.[2] This shows that the methyl group does not prevent the solvation of NH protons, but contributes only to a decrease in mobility by increasing the size. It is interesting to compare the Walden product between $[Co(acac)_2(N,N\text{-dmen})]^+$ and $[Co(acac)_2(N,N'\text{-dmen})]^+$ in 1-propanol: the *N,N*-dmen ligand increases more the mobility than the *N,N'*-dmen ligand, compared with the ligand en. Therefore, it is likely that the mono-methylation of the two NH protons does not have a large desolvation effect; however, the doble-methylation completely prevents solvation by 1-propanol with a six-membered ring and compensates for the effect of an increasing size on mobility. This can be also seen in the decrease in the mobility from *N,N*-dmen to *N,N,N'*-trimen and an increase in the mobility from *N,N'*-dmen to *N,N,N'*-trimen and *N,N,N',N'*-tmen.

Ionic Association. The association constants of the chelate electrolytes show three features: (a) the K_a value in 1-propanol is much larger than that in acetone. (b) The variation of K_a with the number of NH protons in $[Co(acac)_2(diamine)]^+$ is small in all solvents. (c) The K_a value of $[Co(acac)_2(N,N'\text{-dmen})]^+$ is larger than that of $[Co(acac)_2(en)]^+$ in all the systems.

Observation (a) held for Bu_4NClO_4[4]: Although the dipole moment of 1-propanol (1.68 Debye) is small compared to that of acetone (2.88 Debye), the magnitude of the bulk dielectric constant of 1-propanol which is similar to that of acetone is due to the structure arising from hydrogen bonding. However, in the vicinity of the ion pairs, the structure is destroyed by the solvation of the chelate cations, leading to a diminution of the local dielectric constant. Thus, ionic association constants in 1-propanol are larger than those in acetone.

(b) The ratio of K_a for $[Co(acac)_2(en)]ClO_4$ to $[Co(acac)_2(N,N,N',N'\text{-tmen})]ClO_4$ is 0.9 and 1.3 for 1-propanol and acetone, respectively. These values are smaller than those for 1,2-dichloroethane (7.9) and

nitrobenzene (2.4).[2] The NH protons in $[Co(acac)_2(en)]^+$ associates with ClO_4^- by hydrogen bonding in 1,2-dichloroethane, leading to the larger K_a value for $[Co(acac)_2(en)]ClO_4$. In nitrobenzene, the protons are solvated due to the high polarity of the nitrobenzene molecule. However, the ion pair, $[Co(acac)_2(en)]ClO_4$ is a contact ion pair, formed by the partial exclusion of nitrobenzene molecules. On the other hand, in 1-propanol and acetone the protons are solvated owing to an acid-base interaction. Especially, the solvation is large in 1-propanol because $[Co(acac)_2(en)]^+$ is specifically solvated by the 1-propanol molecule as discussed in the preceding section. This leads to the formation of solvent-separated ion pairs and observation (b).

Previous studies showed that the trend of observation (c) was also seen in nitrobenzene and nitrobenzene-carbon tetrachloride mixtures but chloroalkane solvents such as 1,2-dichloroethane and dichloromethane, and that the results could be ascribed to a difference in polarity of the solvent.[12] For the $[Co(acac)_2(N,N'\text{-dmen})]^+$ ion in solvents which provide observation (c), the methyl substitution (CH_3-NH-) interferes with the solvation of the residual NH protons due to a steric hindrance. This leads to an increase in the acidity of the NH protons and to a larger association of $[Co(acac)_2(N,N'\text{-dmen})]ClO_4$ compared with $[Co(acac)_2(en)]ClO_4$. The K_a value of $[Co(acac)_2(N,N,N'\text{-trimen})]ClO_4$ is larger than that of $[Co(acac)_2(N,N\text{-dmen})]ClO_4$ in a similar manner. It can be said that the existence of a relatively strong specific solvation of NH protons such as solvations due to ion-dipole and hydrogen-bonding interactions gives the pattern shown in (c).

The equilibria were studied in the extraction of divalent transition metal ions (M^{2+}: Co^{2+}, Ni^{2+}, Zn^{2+}, Cd^{2+}) with 8-quinolinol (Hq) from aqueous solutions containing various anions (X^-) into some organic solvents. The effects of $-\log[H^+]$ and total concentrations of 8-quinolinol and metal ions on the distribution were examined in detail. Three species, $M_2q_3(Hq)_3X$, $Mq_2(Hq)$, and $M_2q_4(Hq)_2$ are responsible for the extraction. The extraction of $M_2q_3(Hq)_3X$ is favorable when hydrophobic anions and polar solvents are used. On the other hand, the extraction constants of $Mq_2(Hq)$ are almost the same for each metal ion irrespective of anions and solvents. With increasing the metal ion concentration in the organic phase, $Mq_2(Hq)$ dimerizes to form $M_2q_4(Hq)_2$. The decrease in the distribution ratio by prolonged shaking under certain conditions is reasonably ascribed to the slow precipitation of $Mq_2 \cdot 2H_2O$ which has been made supersaturated by the rapid establishment of all the equilibria except the precipitation reaction. An X-ray crystallographic study for $Ni_2q_4(Hq)_2$ showed that two nickel atoms are surrounded by three bidentate ligands with facial and meridional configurations about their oxygen atoms and these two isomers form a binuclear structure jointed by two strong hydrogen bonds.

8-Quinolinol (Hq) is one of the most familiar extracting reagents, and its behavior in the extraction of various metal ions has been repeatedly studied.[1] Among the divalent transition metal ions copper is simply extracted as Cuq_2. In contrast, the extraction equilibria of other metal ions, such as cobalt, nickel, zinc and cadmium, are rather complicated and conflicting results have been reported as shown in Table 1.[2-18] As for nickel ion, Oki and Terada have found the presence of two extracted species $Ni_2q_3(Hq)_3X$ (X^-: anion) and $Ni_2q_4(Hq)_2$,[10,11] whereas Bhatki et al. have stated the unique presence of $Niq_2(Hq)$.[12] Moreover, Sekido et al. found that the species once extracted into chloroform gradually precipitate during the prolonged shaking.[19,20] About the extracted species of the other metal ions there has also been similar confusion. Thus we made extensive equilibrium study to understand these findings altogether.

Among these proposed species, $Ni_2q_3(Hq)_3X$(X^-: I_3^- or ClO_4^-) has recently been identified by X-ray crystallographic studies.[21] We determined the crystal structure of one of the neutral extracted species $Ni_2q_4(Hq)_2$.

a) SP: spectrophotometry; R: radiometry; AAS: atomic absorption spectrometry. b) Converted from the constants in literature. c) Into toluene, whereas others into chloroform.

Experimental

Reagents and Equipments. Metal(II) solutions were prepared from the sulfates and standardized against a Na_2H_2 edta solution. Organic solvents were shaken successively three times with conc. sulfuric acid, 4 mol dm^{-3} potassium hydroxide solution and distilled water. Other reagents were used as received.

All experiments were carried out in a room at 25±2 °C. Absorption spectra and $-\log[H^+]$ were measured with a thermoelectric circulating bath at 25±0.5 °C. The ionic strength was maintained at 0.10 mol dm^{-3} except for sulfate medium at 0.30 mol dm^{-3}.

Hydrogen ion concentration was measured with a Radiometer pH METER 26. The solution containing 1.00×10^{-2} mol dm^{-3} perchloric acid and 9.00×10^{-2} mol dm^{-3} sodium perchlorate was used as a $-\log[H^+]$ standard. Visible absorption spectra were recorded on a Union spectrometer SM-401 and atomic absorption spectrometry was carried out with a Daini Seikosha SAS-727.

Procedure. The details of the measurement were the same as described previously.[22] A 4×10^{-5} to 4×10^{-3} mol dm^{-3} metal solution was shaken with an equal volume of an organic solvent containing 1.6×10^{-3} to 2.4×10^{-1} mol dm^{-3} 8-quinolinol. Shaking 15—30 min for nickel and 1—5 min for other metal ions at 250 strokes min^{-1} was found sufficient for equilibration. In the cases of nickel, zinc and cadmium the absorbance of the organic phase was decreased by prolonged shaking under certain conditions (see below).

After centrifugation, $-\log[H^+]$ and metal concentration were measured for the aqueous phases. The visible spectra of the organic phases were recorded with a quartz cell of 1 or 10 mm. Absorbances at 410 nm for cobalt complexes and at 400 nm for others were used for the determination of the extraction constants.

With less 8-quinolinol and at high $-\log[H^+]$ cobalt(II) is oxidized to form extractable Coq_3. In this study extraction was examined without any reducing reagents, and the data were discarded when absorption spectra indicated the formation of Coq_3.

Perchlorate ion in the organic phase was stripped into an aqueous phase buffered at $-\log[H^+]$ 7 and was determined by modifying the method in literature.[23]

Preparation of the Nickel 8-Quinolinolate Complex. The complex was prepared by two methods: One is the addition of less polar solvents to chloroform extracts of the nickel complex from sulfate solution.[10,24] The other is the reaction of Niq_2 with an excess of 8-quinolinol in refluxing benzene. These complexes were recrystallized from benzene to give greenish crystals suitable for X-ray structural determination.

The infrared spectra of these compounds were the same to each other and were also identical to those reported elsewhere.[25] Although it was assigned as $Niq_2(Hq)$,[24,25] the elemental analysis suggested the presence of water and benzene molecules. Found: C, 68.1; H, 4.1; N, 7.7%. Calcd for $Ni_2q_4(Hq)_2\cdot H_2O\cdot C_6H_6$: C, 66.7; H, 4.3; N, 7.8%.

X-Ray Analysis. Crystal data: $Ni_2q_4(Hq)_2\cdot H_2O\cdot C_6H_6$, $F.W.$=1080.5, triclinic, $P\bar{1}$, a=13.900(6), b=15.797(7), c=13.353(6) Å, α=110.82(3), β=94.84(3), γ=78.73(3)°, V=2687(2) Å^3, D_m=1.34, D_x=1.335 g cm^{-3}, Z=2, μ(Mo $K\alpha$)=0.76 mm^{-1}, $F(000)$=1120.

Approximately spherical crystal of 0.15 mm diameter was used. Three-dimensional intensity data were collected on a Rigaku AFC-5R diffractometer using graphite-monochromatized Mo $K\alpha$ radiation (λ=0.71069 Å). 6346 reflections of 9456 unique ones measured in the range of $\theta\leq25.0°$ were observed with $|F_o|>2\sigma(F_o)$. No correction was applied for absorption.

The structure was solved by conventional heavy atom method and refined by block-diagonal least-squares technique. H atoms were not located. Positional and thermal parameters, anisotropic for the non-H atoms except for benzene and isotropic for the benzene atoms, were refined to R=0.091, R_w=0.125, and S=1.04 for 6213 reflections.[26] Weights for observed reflections were estimated as $w=[\sigma^2(F_o)+0.00712|F_o|^2]^{-1}$. Very intense reflections (8) and unreliable ones with $w^{1/2}|\Delta F|\geq4.0$ (125) were rejected for the final refinement. Computations using the program of MULTAN84, PLUTO and XPACK86 SHIONOGI[27] were performed by a FACOM M-340R computer at Shionogi Research Laboratories.

Results and Discussion

Distribution data were collected under various conditions in each system. In many systems more than one species coexist in the organic phase, so the change in the distribution ratio with $-\log[H^+]$ is not straightforward. There are the conditions where only the ion-pair species is extracted in M^{2+}-ClO_4^--chloroform systems, whereas only the neutral species is extracted in M^{2+}-SO_4^{2-}-chloroform systems. The compositions of the species were determined by the slope methods with the data in these systems. The results are shown for nickel systems.

Species Extracted as an Ion-Pair. The concentration of perchlorate was determined to be half that of nickel in chloroform as reported earlier.[10] Taking into account the electroneutrality, the extraction equilibrium for a general ion-pair species, $Ni_2q_3(Hq)_m$-ClO_4, is expressed by

$$2Ni^{2+} + (3+m)(Hq)_o + ClO_4^- \rightleftharpoons (Ni_2q_3(Hq)_mClO_4)_o + 3H^+ \quad :K_{ex,1}, \tag{1}$$

where the subscript o refers to the organic phase. When D' is defined by $[Ni_2q_3(Hq)_mClO_4]_o/[Ni]^2$, we have the following relations:

$$\log D' - (3+m)\log[Hq]_o = -3\log[H^+] + \log K_{ex,1} + \log[ClO_4] \tag{2}$$

$$[Hq]_o = K_DC_{Hq}/(1/K_1[H^+] + 1 + K_2[H^+] + K_D), \tag{3}$$

where K_D is the partition constant of 8-quinolinol and K_1 and K_2 are the stepwise protonation constants of 8-quinolinolate.[28] The best linearity of the plot was obtained for m=3 as shown in Fig. 1, when various values were applied to m. Thus the extraction of the ion-pair species is expressed by[10]

$$2Ni^{2+} + 6(Hq)_o + ClO_4^- \rightleftharpoons (Ni_2q_3(Hq)_3ClO_4)_o + 3H^+. \tag{4}$$

Neutral Extracted Species. Extraction equilibrium

of a neutral j-meric complex of the composition $Ni_jq_{2j}(Hq)_m$ is represented by[22,29]

$$j\,Ni^{2+} + (2j+m)(Hq)_o \rightleftharpoons (Ni_jq_{2j}(Hq)_m)_o + 2jH^+ \quad : K_{ex,n}. \tag{5}$$

The total concentration of nickel(II) in the organic phase, $C_{Ni,o}$ is given by

$$C_{Ni,o} = j[Ni_jq_{2j}(Hq)_m]_o = jK_{ex,n}[Ni]^j[Hq]_o^{(2j+m)}[H]^{-2j},$$

which is rewritten as a logarithmic form:

$$\log C_{Ni,o} = j(\log C_{Ni,w} - 2\log[H^+]) + (2j+m)\log[Hq]_o + \log jK_{ex,n} \tag{6}$$

If the j-meric species is responsible for the extraction,

the plot of log$C_{Ni,o}$ vs. (log$C_{Ni,w}$—2log[H^+]) would yield a straight line of slope j.

The results are shown in Fig. 2. Only monomeric species is extracted when the total concentration of nickel in the organic phase is less than 10^{-4} mol dm^{-3}, whereas at higher region some polymerized species also participate (closed circles in Fig. 2).

The number of neutral 8-quinolinol molecules in the monomeric extracted species was determined from the slope of the plot of (log $C_{Ni,o}$—log $C_{Ni,w}$+2log[H^+]) vs. log[Hq]$_o$. The actual plot falls on the straight line with a slope of 3, so m is equal to unity (Fig. 3). Thus the extraction equilibrium for the monomeric species is expressed by

$$Ni^{2+} + 3(Hq)_o \rightleftharpoons (Niq_2(Hq))_o + 2H^+ \quad : K_{ex,2}. \tag{7}$$

When the total concentration of nickel is increased, higher total concentration of 8-quinolinol is required to avoid the precipitation of $Niq_2 \cdot H_2O$ (see below).

Then nickel is extracted at lower $-\log[H^+]$ region, where $[Hq]_o$ in Eq. 6 is no longer constant to give an systematic error in such plot shown in Fig. 2. Taking account of the composition of the solid complex prepared under the same conditions, m is assumed to be equal to j. Then Eq. 6 becomes as follows:

$$\log C_{Ni,o} = j(\log C_{Ni,w} - 2\log[H^+] + 3\log[Hq]_o) + \log jK_{ex,n}. \quad (8)$$

The plot according to Eq. 8 is given in Fig. 4. At higher $\log C_{Ni,o}$ the slope of the plot tends to approach to two, which suggests the extraction of $Ni_2q_4(Hq)_2$.

$$2Ni^{2+} + 6(Hq)_o \rightleftharpoons (Ni_2q_4(Hq)_2)_o + 4H^+ : K_{ex,3} \quad (9)$$

Fitting the obtained curves with the normalized curve, $X=\log V$, $Y=\log V(1+V)$,[30] two extraction constants were obtained.

Against the previous works,[2-18] both monomeric and dimeric species prove to be responsible for the extraction. Narrow range of the total concentration of metal ion studied and unreasonable assumption of the degree of polymerization may have led to incorrect conclusion. All the reported extraction constants are too high because it was assumed that only one species was extracted instead of two (Table 1).

These two species are related by the following equation:

$$2(Niq_2(Hq))_o \rightleftharpoons (Ni_2q_4(Hq)_2)_o : K_{dim} = K_{ex,3}/(K_{ex,2})^2, \quad (10)$$

where K_{dim} is the dimerization constant. The constant is around 10^4 $mol^{-1}dm^3$ for all the metal ions except nickel. The reason for the smaller constant of nickel complexes is not clear.

Effects of Anions, Solvents and Central Metal Ions. When the total concentration of a metal ion is less than 10^{-4} mol dm^{-3}, only $M_2q_3(Hq)_3X$ and $Mq_2(Hq)$ are responsible for the extraction and the formation of $M_2q_4(Hq)_2$ is negligible. Using the absorbance vs. $-\log[H^+]$ data under these conditions (Fig. 5(a)—(i)), $K_{ex,1}$ and $K_{ex,2}$ in each system were refined to give a minimum error square sum about absorbance, $U=\sum(A_{obsd}-A_{calcd})^2$ (Table 2). The effects of anions on the distribution were examined in nickel-chloroform systems, whereas those of organic solvents in cobalt-perchlorate systems. As there formed a precipitate in hexane, carbon tetrachloride and toluene, comprehensive data were obtained in benzene, chlorobenzene and chloroform.

The extraction constant for the neutral species, $K_{ex,2}$ is almost the same for each metal ion irrespective of anions and organic solvents. Although the constants from the sulfate solution are slightly smaller than those from others, the difference is reasonably ascribed to a side reaction of metal ions with 0.1 mol dm^{-3} sulfate ion. The solvent effect on the extraction constants appears in the change of the distribution constants of the reagent and the chelate, but these influences sometimes cancel out to each other to make the effect small.[31,32] It holds also in this system.

When hydrophobic anions and polar solvents are used, the extraction is actually enhanced because of the contribution of the ion-pair species (Fig. 6). This is why polar solvents have been favorably used in the extraction with 8-quinolinol in relation to the precipitation of $Mq_2 \cdot H_2O$ (see below).

As to metal ion, all the three constants follow the well-known order, Co<Ni>Zn>Cd. Use of perchlorate medium is advantageous for the separation of cadmium ion.

Slow Reaction-Precipitation of $Mq_2 \cdot 2H_2O$. When nickel, zinc or cadmium is extracted with smaller concentration of 8-quinolinol at higher $-\log[H^+]$, decrease in absorbance of the organic phase is observed during the prolonged shaking. It has been ascribed to the precipitation of $Mq_2 \cdot 2H_2O$ by chemical analyses and infrared spectra of the precipitates,[19,20] but has not been given a sound explanation.

Figure 7 shows absorbance in Zn^{2+}-ClO_4^--chloroform system after prolonged shaking at $C_{Zn}=10^{-4}$ and $C_{Hq}=0.06$ mol dm^{-3}. If only the three extraction equi-

libria identified above were considered, the absorbance should be as the solid line. At $-\log[H^+]$ below 4.7 the absorbance simply increased with time and the final one agreed with that given by this line. At higher $-\log[H^+]$, however, it once reached a maximum value and then slowly decreased to that shown by a circle. Table 3 tells that under these conditions the product $[Zn^{2+}][q^-]^2$ exceeds the solubility product of $Znq_2\cdot H_2O$.[33] Thus when the extraction is performed with usual procedure, all the equilibria except the precipi-

tation reaction are attained rapidly and Znq_2 becomes supersaturated in aqueous phase. Then $Znq_2 \cdot 2H_2O$ starts precipitating slowly with shifting other equilibria until the precipitation equilibrium holds.

When the precipitation equilibrium of $Znq_2 \cdot 2H_2O$ as well as extraction equilibria is included in the consideration, the calculated value given by a broken line well explains the experimental points. More pronounced decrease in Zn^{2+}-SO_4^{2-}-chloroform system shown by a dotted line is explained by the absence of species extracted as an ion-pair.

Crystal Structure of $Ni_2q_4(Hq)_2 \cdot H_2O \cdot C_6H_6$. The atomic coordinates and isotropic thermal parameters are listed in Table 4, and the atomic-numbering system is presented in Fig. 8. The atoms of water and benzene are represented by O(600) and C(701)—C(706), respectively.

Two crystallographically independent nickel atoms are surrounded by three bidentate ligands with facial and meridional configurations about their oxygen atoms. These two octahedra are joined by the two strong hydrogen bonds, O(11)···O(411) [2.44(1) Å] and O(111)···O(311) [2.41(1) Å], to form the binuclear unit as shown in Fig. 8. The direction of the hydrogen bonds on the oxygen atoms is reasonable: 125 for Ni(1)-O(11)-O(411), 121 for Ni(1)-O(111)-O(311), 128 for Ni(2)-O(311)-O(111) and 124° for Ni(2)-O(411)-O(11). The two equivalent units related by a center of symmetry are linked by the hydrogen bonds between the respective O(211) atoms and the water molecules, 2.93(1) and 2.81(1) Å. Only O(511) does not form any

a) Equivalent isotropic temperature factors for Ni(1)—O(600) were estimated as $B_{eq} = 4/3 \sum_i \sum_j \beta_{ij} \mathbf{a}_i \cdot \mathbf{a}_j$. For C(701)—C(706), isotropic ones, B, were used.

hydrogen bond.

The interatomic distances between Ni and O are 2.095(6), 2.064(5), 2.030(5), 2.063(5), 2.110(6), and 2.034(6) Å for O(11)—O(511). Oxygen atoms participating in the strong hydrogen bonds lie more distant from a nickel atom than those completely deprotonated. The Ni-N distances range from 2.057(7) to 2.098(7) Å, their average value being 2.074 Å. The bond lengths and angles in the ligand part are all comparable for the six ligands and reasonable compared with those of metal complexes with 8-quinolinol already reported.

The benzene molecules lie more than 3.35 Å apart from the metal complex and water molecules, the atoms of which undergo large thermal motion (B=10.3—11.7 Å^2). The average bond lengths and angles are 1.34 Å [1.26(3)—1.42(2) Å] and 120° [117(2)—125(2)°], respectively.

The structure of the conjugate acid complex, $Ni_2q_3(Hq)_3X$ ($X=I_3^-$ or ClO_4^-), is different in that there are three hydrogen bonds and only facial configuration about their oxygen atoms. But there is essential similarity that hydrogen atoms of free 8-quinolinol are located deep in the large hydrophobic structure.

The dimeric species can have the same structure also in the organic solvents.

Solvent Extraction of Copper(II) with Lipoic Acid in Benzene. Evidence for the Preferential Coordination of Carboxylate

Hiromichi YAMADA,* Toshiyuki OKUDA, Yukio FUJII,
Masateru MIZUTA, and Motoharu TANAKA†
Faculty of Engineering, Gifu University, 1-1 Yanagido, Gifu 501-11
†Laboratory of Analytical Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received June 11, 1986)

The extraction of copper(II) was carried out with lipoic acid in benzene at 25 °C and at a constant ionic strength in the aqueous phase: 0.1 mol dm^{-3} ($NaNO_3$). The partition constant, $K_{D,HA}$ of lipoic acid between benzene and water, and the dimerization constant, $K_{2,HA}$ of lipoic acid in benzene were determined: log $K_{D,HA}$=1.17 and log $K_{2,HA}$=2.51. The dimeric copper(II) lipoate is responsible for the extraction:

$$2Cu^{2+} + 3(HA)_{2,o} \overset{K_{ex(22)}}{\rightleftharpoons} (Cu_2A_4(HA)_2)_o + 4H^+$$

with the extraction constant, log $K_{ex(22)}$=−11.00. It was proved that lipoate ion coordinates to copper(II) with the carboxylate group without a remarkable participation of the disulfide moiety in the coordination.

1,2-Dithiolane-3-pentanoic acid (lipoic acid) is widely distributed in nature in a protein-bound form, and it is an essential component of "multienzyme" units which catalyze the oxidative decarboxylation of α-keto acids. Lipoic acid has two different binding sites, that is, the carboxyl group and the disulfide linkage. The carboxylate group is known to coordinate dominantly to the biologically important metal ions, while the disulfide group is also anticipated to participate in coordination. These coordination tendencies of two groups in solution were summarized and discussed in relation to their biochemical significance by Sigel.[1,2]

Recently, some synthetic applications of lipoic acid derivatives to organic reactions utilizing their redox function were reported.[3]

It is well-known that the copper(II) carboxylates have a dimeric structure not only in the crystalline state but also in various nonsolvating solvents. It has been previously reported that only the dimeric copper(II) decanoate involving free decanoic acids, $Cu_2A_4(HA)_2$ is responsible for the extraction of copper(II) with decanoic acid in some nonsolvating solvents such as benzene and carbon tetrachloride.[4]

The present paper describes the results of the extraction of copper(II) with lipoic acid in benzene. Comparing the present results with those obtained in the extraction of copper(II) decanoate in benzene, it was found that the carboxylate group preferentially coordinates to copper(II) ions in the dimeric copper(II) lipoate, that is, the disulfide group does not participate in complex formation.

Experimental

Reagents. Lipoic Acid: Reagent grade DL-α-lipoic acid (purity: over 98%) was dissolved in benzene just before its use.

Benzene: Reagent grade benzene was washed successively with concentrated sulfuric acid, with dilute potassium hydroxide solution, with dilute perchloric acid solution, and then with distilled water. All other reagents were reagent grade and used without further purification.

Procedure. Partition was carried out in a bath thermostated at 25.0±0.2 °C. 15 cm^3 each of the aqueous and organic phases were contacted in a brown centrifuge tube. Ionic strength of the aqueous phase was adjusted to 0.1 mol dm^{-3} with sodium nitrate. Shaking for about 1 h was found sufficient for complete equilibration. After centrifugation, the aqueous phase was immediately separated from the organic phase. And then, hydrogen-ion concentration of the aqueous phase was measured with 1.00×10^{-2} mol dm^{-3} nitric acid solution (ionic strength 0.1 mol dm^{-3}) as a standard. The measured pH values were corrected for the apparent liquid junction potential. The concentration of copper in the aqueous phase was determined complexiметrically, with 4-(2-thiazolylazo)resorcinol (TAR) as an indicator.[5] In the partition of lipoic acid between water and benzene, the concentration of lipoic acid in the aqueous phase was determined by potentiometric titration. An absorption maximum at 330 nm of DL-lipoic acid was used for the determination of the lower concentration of lipoic acid in the aqueous phase.

Apparatus. For mechanical shaking in a thermostat, Taiyo Incubator M-100^N (Taiyokagaku-Kogyo Co., Tokyo) was used. The pH measurements and potentiometric titrations were carried out with a Horiba pH Analyzer F-80 (Horiba Seisakusho Ltd., Kyoto). Spectrophotometric determination was performed on a UVIDEC-430A Double Beam Spectrophotometer (Japan Spectroscopic Co. Ltd., Tokyo). KNAUER Vapor Pressure Osmometer (KNAUER Ltd., Berlin, West Germany) was used for the determination of dimerization constant of lipoic acid in benzene. A Swing Type Centrifuge Model CD-50SR (Tomy Seiko Co. Ltd., Tokyo) was used for centrifugation.

Results and Discussion

Distribution of Lipoic Acid. In studying the extraction of a metal ion with a carboxylic acid, it is indispensable to have information about the partition of the carboxylic acid between the aqueous and organic phases. Then in the present extraction system the following equilibria should be considered.

(a) The dissociation of lipoic acid HA in the aque-

ous phase:

$$HA + H_2O \rightleftharpoons H_3O^+ + A^-$$

with the dissociation constant,

$$K_a = [H_3O^+][A^-][HA]^{-1}. \quad (1)$$

(b) The partition of lipoic acid between benzene and the aqueous phase:

$$(HA)_w \rightleftharpoons (HA)_o$$

where the subscripts w and o refer to the aqueous and benzene phases, respectively. The partition constant is defined as

$$K_{D,HA} = [HA]_o[HA]_w^{-1}. \quad (2)$$

(c) The dimerization of lipoic acid in the organic phase:

$$2(HA)_o \rightleftharpoons (HA)_{2,o}$$

with $(HA)_{2,o}$ denoting the dimeric lipoic acid in the organic phase, and the dimerization constant defined as

$$K_{2,HA} = [(HA)_2]_o[HA]_o^{-2}. \quad (3)$$

Then, the distribution ratio of lipoic acid between benzene and water is written as follows:

$$D = C_{HA,o}C_{HA,w}^{-1}$$
$$= K_{D,HA}(1+2K_{2,HA}K_{D,HA}[HA]_w)(1+K_a[H^+]^{-1})^{-1}. \quad (4)$$

In the lower pH region where the dissociation of lipoic acid in the aqueous phase is negligible, that is, $1 \gg K_a/[H^+]$, Eq. 4 can be rewritten as follows:

$$D = K_{D,HA} + 2K_{2,HA}K_{D,HA}^2[HA]_w \quad (5)$$

As shown in Eq. 5, a linear relationship between the distribution ratio D of lipoic acid and the concentration of unionized lipoic acid in the aqueous phase is expected to hold. Benzene solutions of lipoic acid ranging from 0.025 to 0.7 mol dm^{-3} were equilibrated at 25 °C with 0.01 mol dm^{-3} nitric acid (I=0.1 mol dm^{-3} H, $NaNO_3$). From the results obtained, the dimerization and partition constants of lipoic acid were determined by the least-squares method according to Eq. 5: $\log K_{2,HA}$=2.51 and $\log K_{D,HA}$=1.17, respectively.

On the other hand, the dimerization constant of lipoic acid in benzene is obtained by the vapor pressure osmometry: $\log K_{2,HA}$=2.52. This value is in good agreement with that determined by the partition experiment. Thus the dimeric lipoic acid prevails in benzene.

Extraction of Copper(II) with Lipoic Acid. If a j-merized copper(II) lipoate $Cu_jA_{2j}(HA)_a$ (HA: lipoic acid) is responsible for the extraction, the extraction equilibrium can be expressed as follows:[4]

$$jCu^{2+} + 0.5(2j+a)(HA)_{2,o} \rightleftharpoons (Cu_jA_{2j}(HA)_a)_o + 2jH^+$$

with the extraction constant defined as

$$K_{ex(ja)} = [Cu_jA_{2j}(HA)_a]_o[H^+]^{2j}[Cu^{2+}]^{-j}[(HA)_2]_o^{-0.5(2j+a)}. \quad (6)$$

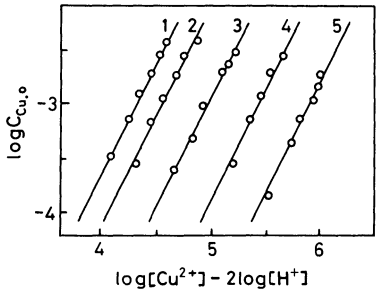

Fig. 1. Determination of the degree of polymerization of copper(II) lipoate. C_{HA}; No. 1: 1.0, No. 2: 0.7, No. 3: 0.4, No. 4: 0.2, No. 5: 0.1 mol dm^{-3}. Solid lines are the straight lines with a slope of 2.

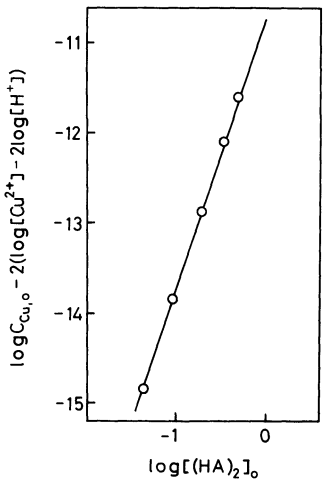

Fig. 2. Determination of the number of lipoic acid molecules involved in the dimeric copper(II) lipoate. Solid line is the straight line with a slope of 3.

When only $Cu_jA_{2j}(HA)_a$ is extracted into benzene, the total concentration of copper(II) in benzene is written as follows:

$$C_{Cu,o} = j[Cu_jA_{2j}(HA)_a]_o$$
$$= jK_{ex(ja)}[Cu^{2+}]^j[H^+]^{-2j}[(HA)_2]_o^{0.5(2j+a)} \quad (7)$$

which is rewritten as a logarithmic form:

$$\log C_{Cu,o} = j(\log[Cu^{2+}] - 2\log[H^+])$$
$$+ 0.5(2j+a)\log[(HA)_2]_o + \log j + \log K_{ex(ja)}. \quad (8)$$

According to Eq. 8, the degree of polymerization of copper(II) lipoate can be obtained from the slope of a plot of $\log C_{Cu,o}$ vs. $(\log[Cu^{2+}]-2\log[H^+])$ at a constant $[(HA)_2]_o$. The plot shown in Fig. 1, falls along the straight line with a slope of 2: only the dimeric copper(II) lipoate is responsible for the extraction under the present experimental conditions.

The number of lipoic acid molecules involved in the dimeric copper(II) lipoate is given by the slope of a plot of $\{\log C_{Cu,o}-2(\log[Cu^{2+}]-2\log[H^+])\}$ vs. $\log[(HA)_2]_o$. As shown in Fig. 2, the plot falls on the straight line with a slope of 3.0, that is, $(4+a)/2=3$ or $a=2$. Consequently, only $Cu_2A_4(HA)_2$ is extracted in

the present extraction system as in the extraction of copper(II) with decanoic acid in benzene. The extraction constant of the dimeric copper(II) lipoate, $K_{ex(22)}$ can be calculated from the intercept of the plot in Fig. 2. Then the extraction equilibrium for copper(II) lipoate can be expressed as follows:

$$2Cu^{2+} + 3(HA)_{2,o} \overset{K_{ex(22)}}{\rightleftharpoons} (Cu_2A_4(HA)_2)_o + 4H^+$$

with

$$\log K_{ex(22)} = -11.00.$$

Comparison of Lipoic with Decanoic Acids. Both the dissociation constant in the aqueous phase and the dimerization constant in benzene of lipoic acid are similar to those of decanoic acid. This would be attributed to the shielding of the electron-withdrawing effect of the disulfide group by four methylene groups.

The smaller partition constant of lipoic acid than that of decanoic acid suggests that the 1,2-dithiolane ring is more hydrophilic than the pentyl group. The extraction constant stated above is formulated as

$$K_{ex(22)} = K_{D,Cu_2A_4(HA)_2} K_{D,HA}^{-6} K_{2,HA}^{-3} \beta_{Cu_2A_4(HA)_2} K_a^4 \quad (9)$$

where $K_{D,Cu_2A_4(HA)_2}$ and $\beta_{Cu_2A_4(HA)_2}$ denote the partition constant of $Cu_2A_4(HA)_2$ between benzene and water and the overall formation constant of this complex in the aqueous phase defined, respectively as follows:

$$(Cu_2A_4(HA)_2)_w \rightleftharpoons (Cu_2A_4(HA)_2)_o$$

with

$$K_{D,Cu_2A_4(HA)_2} = [Cu_2A_4(HA)_2]_o [Cu_2A_4(HA)_2]_w^{-1}$$

and

$$2Cu^{2+} + 4A^- + 2(HA)_w \rightleftharpoons (Cu_2A_4(HA)_2)_w$$

with

$$\beta_{Cu_2A_4(HA)_2} = [Cu_2A_4(HA)_2]_w [Cu^{2+}]^{-2} [A^-]^{-4} [HA]_w^{-2}.$$

From the additive nature of the molar cohesive energy and molar volume of ligand in a complex, the partition constant of a complex MA_n can be approximately correlated to that of the ligand HA as follows[6]: $K_{D,MA_n} \simeq K_{D,HA}^n$. Since a similar relation, namely, $K_{D,Cu_2A_4(HA)_2} \simeq K_{D,HA}^6$ can be presumed to hold also for the present extraction system, the overall formation constant can be approximated as follows:

$$\beta_{Cu_2A_4(HA)_2} \simeq K_{ex(22)} K_{2,HA}^3 K_a^{-4}. \quad (10)$$

On the other hand, taking into account the electrostriction of ligands in the complex, that is, $V_{Cu_2A_4(HA)_2} = 6 \times 0.95 V_{HA}$, the partition constant of $Cu_2A_4(HA)_2$ can be approximated as follows: $\log K_{D,Cu_2A_4(HA)_2} \simeq 5.7 \log K_{D,HA}$. Then, the overall formation constant, $\beta_{Cu_2A_4(HA)_2}$ can be calculated by the following relation:

$$\beta_{Cu_2A_4(HA)_2} \simeq K_{ex(22)} K_{D,HA}^{0.3} K_{2,HA}^3 K_a^{-4}. \quad (11)$$

The results for lipoic and decanoic acids obtained from these relations are listed in Table 1 together with other constants. As can be seen from Table 1, the value of the overall formation constant of the dimeric copper(II) lipoate in the aqueous phase is close to that of the dimeric copper(II) decanoate. This suggests strongly that in the dimeric copper(II) lipoate the copper(II) ions coordinate not to the disulfide group, but to the carboxyl group of lipoic acid in the same manner as in the dimeric copper(II) decanoate.

Table 1. Comparison of Various Constants of Lipoic with Decanoic Acids

Constants	Lipoic Acid	Decanoic Acid
pK_a	4.85[a]	4.92[c,d]
$\log K_{D,HA}$	1.17[b]	2.80[c,d]
$\log K_{2,HA}$	2.51	2.41[d]
$\log K_{ex(22)}$	−11.00[b]	−11.36[c,e]
$\log \beta_{Cu_2A_4(HA)_2}$	15.93[b,f]	15.55[c,f]
	(16.28)[g]	(16.39)[g]

a) The value is estimated from the data in 50% (v/v) dioxane-water mixture.[2] b) Ionic strength 0.1 mol dm^{-3} (NO_3^-). c) Ionic strength 0.1 mol dm^{-3} (ClO_4^-). d) Ref. 7. e) Ref. 4. f) Calculated by Eq. 10. g) The values in the parentheses are evaluated by taking into account the electro-striction of ligands in the complex (Eq. 11).

In the visible region, the spectrum of copper(II) lipoate in benzene grossly resembles that of copper(II) decanoate in the presence of an excess of the respective acid, that is, copper(II) lipoate shows an absorption peak at 680 nm assigned to a so-called metal-ligand interaction. In the UV region, the spectra for copper(II) lipoate and decanoate in benzene differ from each other, because of the difference in the spectra between lipoic and decanoic acids. This result will also support that copper(II) ions coordinate to the carboxylate group in the dimeric copper(II) lipoate.

In general, soft metal ions like silver(I) ion have a tendency to coordinate to the disulfide moiety. Then we have attempted to study the extraction of silver(I) ion with lipoic acid in carbon tetrachloride. Disappointingly, silver(I) ion could not be extracted, and a white precipitate formed which would be a decomposition product of lipoate. It can be presumed that coordination of silver(I) ion to the disulfide moiety causes cleavage of the disulfide link.

To conclude, lipoate ion coordinates to copper(II) with the carboxylate group without a remarkable participation of the disulfide moiety in the coordination.

S-Bridged Polynuclear Complexes. I. Selective Formation and Crystal Structure of (+)$^{CD}_{600}$-Bis[tris(L-cysteinato-*N,S*)cobaltate(III)-*μ*-*S*,*μ*-*S'*,*μ*-*S''*]cobalt(III) Nitrate Pentahydrate

Ken-ichi Okamoto,* Sen-ichi Aizawa, Takumi Konno, Hisahiko Einaga,[1] and Jinsai Hidaka
Department of Chemistry, University of Tsukuba, Sakura, Ibaraki 305
(Received June 18, 1986)

The crystal structure and the absolute configuration of the selectively formed title isomer, (+)$^{CD}_{600}$-[Co{Co(L-cys-*N,S*)$_3$}$_2$](NO$_3$)$_2$·5H$_2$O,[2] have been determined by X-ray diffraction. In the (+)$^{CD}_{600}$ isomer, the six L-cysteinates coordinate through the nitrogen and sulfur atoms to give two terminal [Co(L-cys-*N,S*)$_3$] moieties. The central cobalt atom spans the six sulfur atoms in these terminals to form a trinuclear structure. The (+)$^{CD}_{600}$ isomer takes selectively a $\Lambda_{LLL}\Lambda_{LLL}$ configuration, in which both of the two terminals have a Λ_{LLL}-*fac*(S) configuration, and the six sulfur donor atoms take an *R* one. The L-cysteinate chelate rings take a lel conformation along the C_3 axis and the carboxyl or carboxylato groups take the axial orientations forming the intramolecular hydrogen bonds. The (−)$^{CD}_{600}$ isomer is assigned to the $\Delta_{LLL}\Delta_{LLL}$ configuration on the basis of the electronic absorption, CD, and ^{13}C NMR spectral behaviors. The selective formation for each of the (+)$^{CD}_{600}$ and (−)$^{CD}_{600}$ isomers is discussed in relation to their reaction conditions.

2-Aminoethanetholate, aet, has a propensity to form the S-bridged polynuclear metal complexes, which have been investigated by the stereochemical and spectrochemical interests,[3-9] or by the relevance to the catalytic and biological systems.[7,8] The trinuclear cobalt(III) complexes with 2-aminoethanethiolate, [Co{Co(aet)$_3$}$_2$]$^{3+}$, have been prepared by the reaction of *fac*(S)-[Co(aet)$_3$] with Co(II) or Co(III),[4] and resolved into the optically active isomers, ΛΛ and ΔΔ.[5] In this work, the reaction of Δ_{LLL}-*fac*(S)-tris(L-cysteinato-*N,S*)cobaltate(III), Δ_{LLL}-*fac*(S)-[Co(L-cys-*N,S*)$_3$]$^{3-}$,[10-12] which has a similar framework to *fac*(S)-[Co(aet)$_3$], with Co(II) or Co(III) was investigated. This starting Δ_{LLL}-*fac*(S) complex has been selectively formed because of the preferred lel conformation of the L-cysteinate chelate rings with the equatorial carboxylato groups.[11,12] This paper deals with the stereochemistry of the (+)$^{CD}_{600}$ and (−)$^{CD}_{600}$ isomers formed selectively by the reaction mentioned above, and with the X-ray crystal analysis of the (+)$^{CD}_{600}$ isomer. Namely, each of the (+)$^{CD}_{600}$- and (−)$^{CD}_{600}$-bis[tris(L-cysteinato-*N,S*)cobaltate(III)-*μ*-*S*,*μ*-*S'*,*μ*-*S''*]cobaltate(III) isomers, (+)$^{CD}_{600}$- and (−)$^{CD}_{600}$-[Co{Co(L-cys-*N,S*)$_3$}$_2$]$^{3-}$,[2] was selectively prepared. The crystal structure of (+)$^{CD}_{600}$-[Co{Co(L-cys-*N,S*)$_3$}$_2$](NO$_3$)$_2$·5H$_2$O,[2] which is crystallized from a 4 mol dm^{-3} nitric acid, is established by the X-ray diffraction study. The absolute configurations of the two terminal [Co(L-cys-*N,S*)$_3$] moieties and the six sulfur donor atoms were also determined. The electronic absorption, CD, and ^{13}C NMR spectral behaviors of the (+)$^{CD}_{600}$ and (−)$^{CD}_{600}$ isomers are discussed in relation to their geometrical and absolute configurations.

Experimental

1) Preparation of Complexes. a) **Δ_{LLL}-*fac*(S)-Potassium Tris(L-cysteinato-*N,S*)cobaltate(III): Δ_{LLL}-*fac*(S)-K$_3$[Co(L-cys-*N,S*)$_3$]·9H$_2$O·0.5KCl.** This complex was prepared by the method of Schubert,[10] and the Δ_{LLL}-*fac*(S) isomer formed selectively.[11,12] Found: C, 14.77; H, 4.50; N, 5.74%. Calcd for $C_9H_{33}N_3O_{15}Cl_{0.5}S_3K_{3.5}Co$: C, 14.75; H, 4.54; N, 5.73%.

b) (+)$^{CD}_{600}$-Potassium Bis[tris(L-cysteinato-*N,S*)cobaltate(III)-*μ*-S,*μ*-S',*μ*-S'']cobaltate(III): (+)$^{CD}_{600}$-K$_3$[Co{Co(L-cys-*N,S*)$_3$}$_2$]·9H$_2$O.[2] To a solution containing an excess amount (0.9g, 3.78 mmol) of CoCl$_2$·6H$_2$O in 25 cm^3 of water was added a solution containing 1.0 g (1.36 mmol) of Δ_{LLL}-*fac*(S)-K$_3$[Co(L-cys-*N,S*)$_3$]·9H$_2$O·0.5KCl in 10 cm^3 of water. The color of the solution turned immediately from deep green to deep brownish green. The solution (ca. pH 9) was stirred at room temperature for 10 min. To this was added a large amount of ethanol in an ice bath. The resultant complex was recrystallized twice from water by adding ethanol in an ice bath, and washed with ethanol and ether. It was found, from the QAE-Sephadex A-25 column chromatographic technique and the absorption and CD spectral measurements, that the reaction solution contained only (+)$^{CD}_{600}$-[Co{Co(L-cys-*N,S*)$_3$}$_2$]$^{3-}$. Found: C, 18.25; H, 4.04; N, 7.29%. Calcd for $C_{18}H_{48}N_6O_{21}S_6K_3Co_3$: C, 18.46; H, 4.13; N, 7.17%.

This isomer was also prepared by the following procedure. To a solution containing 0.01 g of (−)$^{CD}_{600}$-K$_3$[Co{Co(L-cys-*N,S*)$_3$}$_2$]·6.5H$_2$O described in **1c**) (vide infra) in 10 cm^3 of water was added 1.0 g of zinc powder. After the solution was allowed to stand at room temperature for a week, the reaction solution was filtered to remove the zinc powder. The filtrate showed the identical absorption and CD spectra to (+)$^{CD}_{600}$-[Co{Co(L-cys-*N,S*)$_3$}$_2$]$^{3-}$.

The single crystal of the (+)$^{CD}_{600}$ isomer, which was used for the X-ray crystal structure analysis, was obtained as follows. (+)$^{CD}_{600}$-K$_3$[Co{Co(L-cys-*N,S*)$_3$}$_2$]·9H$_2$O was recrystallized from an 1 mol dm^{-3} warm nitric acid (ca. 40 °C). Then the crystals obtained were dissolved in a 4 mol dm^{-3} warm nitric acid (ca. 40 °C) again, and stood at room temperature for 3 d. The crystals which appeared as nitrate salt, (+)$^{CD}_{600}$-[Co{Co(L-cys-*N,S*)$_3$}$_2$](NO$_3$)$_2$·5H$_2$O,[2] were collected by filtration.

c) (−)$^{CD}_{600}$-Potassium Bis[tris(L-cysteinato-*N,S*)cobaltate(III)-*μ*-S,*μ*-S',*μ*-S'']cobaltate(III): (−)$^{CD}_{600}$-K$_3$[Co{Co(L-cys-*N,S*)$_3$}$_2$]·6.5H$_2$O. This complex was prepared selectively by a procedure similar to that used for the (+)$^{CD}_{600}$ isomer described in **1b**), using [CoCl(NH$_3$)$_5$]Cl$_2$ (0.2 g, 0.80 mmol) instead of an excess amount of CoCl$_2$·6H$_2$O. It was found, from the same manner as in **1b**), that the reaction solution contained only (−)$^{CD}_{600}$-[Co{Co(L-cys-*N,S*)$_3$}$_2$]$^{3-}$. Found: C, 19.12; H, 3.91; N, 7.49%. Calcd for $C_{18}H_{43}N_6O_{18.5}S_6K_3Co_3$: C, 19.20; H, 3.85; N,

a) B_{eq} is the equivalent isotropic temperature factors defined by Hamilton.[20]

7.49%.

2) General Data. The electronic absorption spectra were recorded with JASCO UVIDEC-1 and UVIDEC-610 spectrophotometers, and the CD spectra with a JASCO J-20 spectropolarimeter. The infrared spectra were recorded with a JASCO IRA-2 infrared spectrophotometer using the KBr disk method. The ^{13}C NMR spectra were recorded on a JEOL JNM-FX-100 or -FX-90Q NMR spectrometer at the probe temperature in D_2O. Sodium 2,2-dimethyl-2-silapentane-5-sulfonate was used as an internal reference. The pH of the aqueous solution was measured with a Hitachi-Horiba pH meter, model F7-SS, equipped with a glass and saturated calomel electrodes. The X-ray analysis calculations were carried out on a FACOM M-380 computer at the University of Tsukuba.

3) X-Ray Characterization. Unit cell parameters and intensity data for the single crystal (ca. 0.10×0.15×0.40 mm^3) were measured on a Rigaku-denki four-circle diffractometer (AFC-5) with graphite-monochromatized Mo $K\alpha$ radiation. The unit cell parameters were determined by least-squares refinement based on 19 reflections. Crystal data: $[Co\{Co(L\text{-}cys)_3\}_2](NO_3)_2\cdot 5H_2O=Co_3S_6O_{23}N_8C_{18}H_{45}$, triclinic, space group $P\bar{1}$, M.W.=1110.76, a=12.087(8), b=9.541(4), c=9.214(4) Å, α=99.09(5), β=109.32(4), γ=87.86(5)°, V=990(1) Å^3, D_m=1.86 g cm^{-3} (by the flotation), D_x=1.863 g cm^{-3}, Z=1, and μ(Mo $K\alpha$)=1.692 mm^{-1}.

Intensity data were collected by a ω–2θ scan technique up to 2θ=50° with a scan rate of 3° min^{-1}. The intensity data were converted to F_o data in the usual manner. Absorption corrections were not applied. A total of 3677 independent reflections with $|F_o|>3\sigma(|F_o|)$ of the measured 3741 reflections were considered as 'observed' and used for the structure analysis.

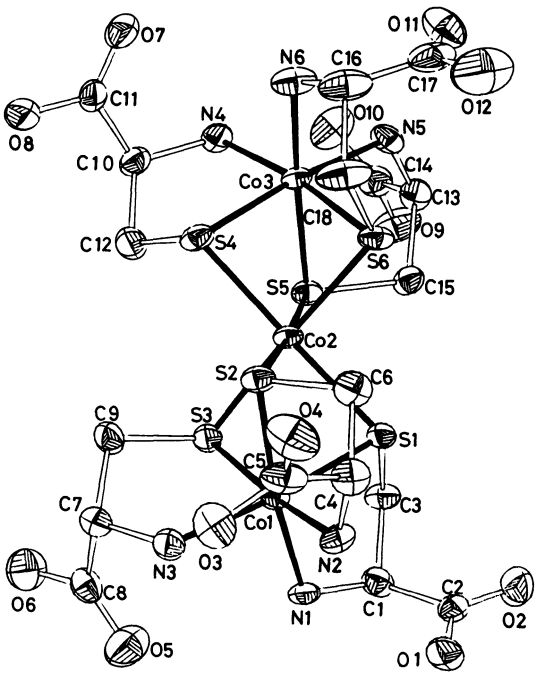

Fig. 1. Perspective view of $(+)^{CD}_{600}$-$[Co\{Co(L\text{-}cys\text{-}N,S)_3\}_2]^{2+}$ ion,[2] with the numbering scheme.

4) Determination of the Crystal Structure. The positions of three cobalt atoms were obtained from a three-

dimensional Patterson function. Difference Fourier maps, based on the three cobalt positions, revealed all the non-hydrogen atoms. The structure was refined by a full-matrix least-squares refinement of the positional and anisotropic thermal parameters of all the non-hydrogen atoms (program RFINE by L. W. Finger was used). The neutral atomic scattering factors for all the non-hydrogen atoms were taken from the literature.[13] The final R and R_w values were 0.044 and 0.057, respectively. The absolute configuration was determined on the basis of the known configuration of L-cysteinates.[14]

The final atomic parameters are given in Table 1. A list of structure factors (Table A) and anisotropic thermal parameters of non-hydrogen atoms (Table B) are kept at the Chemical Society of Japan as Document No. 8704.

Results and Discussion

Description of the Structure. A perspective drawing of the complex cation, $(+)^{CD}_{600}$-[Co{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{2+}$,[2] is given in Fig. 1, together with a numbering scheme. The bond lengths and angles (with their standard deviations) in the complex cation and the nitrate anions are summarized in Table 2. Three cobalt atoms are aligned at short intervals (Co1-Co2=2.863(3) and Co2-Co3=2.849(3) Å, Co1-Co2-Co3=177.66(9)°); thus the complex cation takes a trinuclear structure. The coordination geometries around each cobalt atom are approximately octahedral. All the six L-cysteinates coordinate to two cobalt atoms (Co1 and Co3) through the nitrogen and sulfur atoms, and they form two ter-

minal [Co(L-cys-N,S)$_3$] moieties. The Col and Co2 atoms or the Co2 and Co3 ones are bridged by the sulfur atoms in the L-cysteinates, namely, the central cobalt atom, Co2, is surrounded by the six sulfur atoms.

The absolute configuration of the $(+)^{CD}_{600}$ isomer in the crystal could be confirmed on the basis of the known configuration, R, of the asymmetric carbon atom in the coordinated L-cysteinate.[14] Both of the two terminal [Co(L-cys-N,S)$_3$] moieties in the $(+)^{CD}_{600}$ isomer have Λ configuration and all the six sulfur donor atoms, which become chiral by coordination, have R one. This indicates that the reaction with $CoCl_2 \cdot 6H_2O$ causes an inversion of the absolute configuration of the starting complex, Δ_{LLL}-*fac*(S)-[Co(L-cys-N,S)$_3$]$^{3-}$, to give selectively two terminal Λ_{LLL}-*fac*(S)-[Co(L-cys-N,S)$_3$] moieties.

The average bond lengths of [Co{Co(L-cys-N,S)$_3$}$_2$]$^{2+}$ are quite similar to those of [Co{Co(aet)$_3$}$_2$]$^{3+}$;[9] Col-S and Co3-S (2.226(3) Å), Co2-S (2.258(4) Å), Co-N (2.006(9) Å), S-C (1.831(10) Å), N-C (1.484(13) Å), and C-C (1.534(14) Å). A similar trend was also observed for the bond angles; Col-S-Co2 and Co3-S-Co2 (79.0 (1)°), S-Col-S and S-Co3-S (84.5(1)°), S-Co2-S (83.2 (1)°), N-Col-N and N-Co3-N (94.1(4)°), S-Col-N and S-Co3-N (87.8(3)°), Col-S-C and Co3-S-C (95.9 (3)°), Co2-S-C (112.9(4)°), S-C-C (106.1(7)°), and C-C-N (110.2(8)°).[9] The acute S-Co2-S angle and the Co2-S distance indicate that the central cobalt atom, Co2, is trigonally distorted from regular octahedron and its distortion has the effect of lengthening the molecule along the C_3 axis through the Col, Co2, and Co3 atoms. In the terminal [Co(L-cys-N,S)$_3$] moieties, the average bond lengths and angles (given above) indicate the compressions of the S1-S2-S3 and S4-S5-S6 faces and the concomitant expansions of the N1-N2-N3 and N4-N5-N6 ones. The average bond lengths of Col-N and Co3-N in the present complex seem to be longer than those of the cobalt(III) complexes with the amino carboxylate ligands.[15-17]

The crystal structure consists of the complex cation, two nitrate anions, and five water molecules, as shown in Fig. 2. In the crystal, the hydrogen bonds are recognized between the carboxyl or carboxylato groups and water molecules: e.g., OW1-O3 (2.644(13) Å), OW1-O5 (2.825(15) Å), OW2-O1 (2.905(12) Å), OW2-O9 (2.649(9) Å), OW3-O8 (3.079(13) Å), OW4-O2 (2.627(10) Å), OW4-O8 (2.475(16) Å), and OW5-O12 (2.488(22) Å). Similar O-O bond distances to the short hydrogen bonds in this work (2.475—2.649 Å) have also been observed for the hydrogen bis(*p*-methylbenzoate) anions.[18] Taking account of the facts that only two nitrate anions exist in the unit cell and the five carboxyl groups are connected strongly to the water molecules (2.475—2.649 Å), it may be considered that the five carboxyl groups in the L-cysteinates are protonated and the one carboxylato group is not. This is supported from the result that the IR spectrum of the present $(+)^{CD}_{600}$-$\Lambda_{LLL}\Lambda_{LLL}$ isomer exhibits a strong band

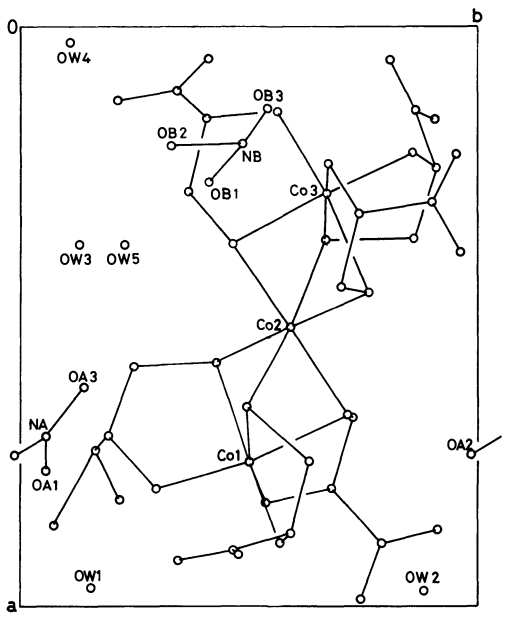

Fig. 2. The crystal packing diagram of the complex.

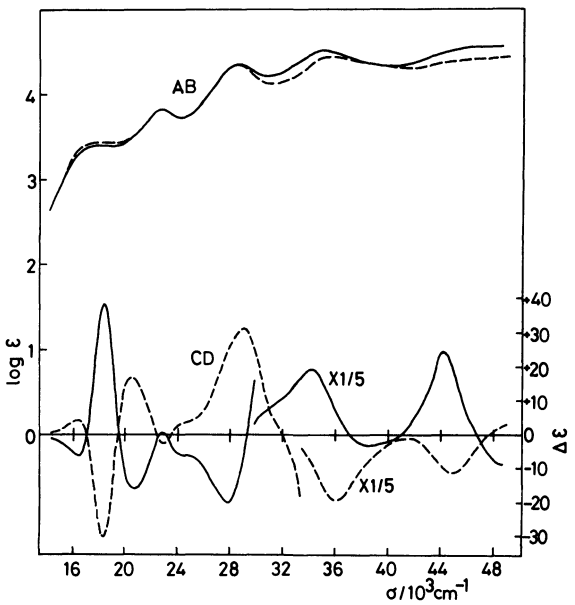

Fig. 3. Absorption and CD spectra of [Co{Co(L-cys-N,S)$_3$}$_2$]$^{3-}$;[2] the $(-)^{CD}_{600}$ isomer (——) and the $(+)^{CD}_{600}$ one (---).

at ca. 1720 cm^{-1} due to the COOH group and a week band at ca. 1625 cm^{-1} due to the COO$^-$ group.[19]

In [Co{Co(L-cys-N,S)$_3$}$_2$]$^{2+}$,[2] all of the bond distances between the oxygen atoms in the carboxyl or carboxylato groups and the nitrogen atoms in the adjacent amine groups range from 2.919 to 3.260 Å (average 3.080 Å). This indicates that they are also hydrogen bonds and incidentally, all the six L-cysteinate chelate rings take the lel conformations along the C_3 axis, which is accompanied by the axial orientations of the carboxyl or carboxylato groups.

Formation of Isomers. Three isomers, $\Lambda_{LLL}\Lambda_{LLL}$, $\Lambda_{LLL}\Delta_{LLL}$, and $\Delta_{LLL}\Delta_{LLL}$, are possible for the trinuclear

complex, [Co{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{3-}$,[2] with respect to the absolute configuration of two terminal [Co(L-cys-*N*,*S*)$_3$] moieties. The $(-)^{CD}_{600}$ isomer exhibits a quite similar absorption spectral behavior over the whole region to the $(+)^{CD}_{600}$-$\Lambda_{LLL}\Lambda_{LLL}$ isomer as shown in Fig. 3 and Table 3. Furthermore, each of the present two isomers exhibits three ^{13}C NMR resonance lines (39.0, 64.1, and 179.3 ppm for the $(+)^{CD}_{600}$-$\Lambda_{LLL}\Lambda_{LLL}$ isomer and 38.6, 67.1, and 178.3 ppm for the $(-)^{CD}_{600}$ isomer) due to the methylene, methine, and carboxylato carbon atoms in each of the six L-cysteinate ligands (Fig. 4). The ^{13}C NMR spectral behaviors point out that the present $(-)^{CD}_{600}$ isomer takes $\Delta_{l.l.l}\Delta_{l.l.l.}$ configuration having D_3 symmetry, because the $(+)^{CD}_{600}$-$\Lambda_{LLL}\Lambda_{LLL}$ isomer has approximately D_3 symmetry in the crystal (Fig. 1) but the $\Lambda_{LLL}\Delta_{LLL}$ isomer has lower than or equal to a C_3 symmetry. This assignment is supported by the fact that the $(-)^{CD}_{600}$ isomer exhibits almost enantiomeric CD spectrum over the whole region to that of $(+)^{CD}_{600}$-$\Delta_{LLL}\Delta_{LLL}$-[Co{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{3-}$ (Fig. 3 and Table 3). Accordingly, the $(-)^{CD}_{600}$ isomer can be assigned to $\Delta_{LLL}\Delta_{LLL}$-[Co{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{3-}$. The absorption and CD spectra of the $(-)^{CD}_{600}$-$\Delta_{LLL}\Delta_{LLL}$ isomer are also in good agreement with those of $\Delta\Delta$-[Co{Co(aet)$_3$}$_2$]$^{3+}$ whose absolute configuration was assigned on the basis of the CD spectral behavior by Brubaker and Douglas.[5] The similarity between these CD spectra suggests that the CD contribution due to the chiral carbon atom, *R*(*C*), of the coordinated L-cysteinate is minor.

The reaction of Δ_{LLL}-*fac*(*S*)-[Co(L-cys-*N*,*S*)$_3$]$^{3-}$ with [CoCl(NH$_3$)$_5$]Cl$_2$ gave only $(-)^{CD}_{600}$-$\Delta_{LLL}\Delta_{LLL}$-[Co{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{3-}$. Namely, the reaction with Co(III) proceeds with retention of the absolute configuration of the starting $\Delta_{l.l.l.}$-*fac*(*S*) complex to give two terminal Δ_{LLL}-*fac*(*S*)-[Co(L-cys-*N*,*S*)$_3$] moieties. In contrast with

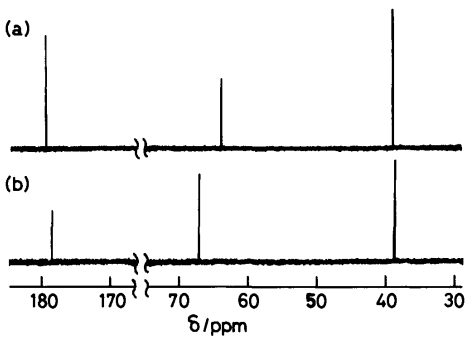

Fig. 4. ^{13}C NMR spectra of [Co{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{3-}$;[2] (a) the $(+)^{CD}_{600}$ isomer and (b) the $(-)^{CD}_{600}$ one.

this reaction, the reaction (pH≈9) with an excess amount of CoCl$_2$ was accompanied by the inversion of the starting complex to give $(+)^{CD}_{600}$-$\Lambda_{l.l.l}\Lambda_{l.l.l.}$-[Co{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{3-}$. Moreover, the inversion of the two terminals in the $(-)^{CD}_{600}$-$\Delta_{LLL}\Delta_{LLL}$ isomer was also observed for its reaction solution with zinc powder. These facts suggest that the Co(II) ion relates catalytically to the inversion of the starting $\Delta_{l.l.l.}$-*fac*(*S*) complex and accelerates the formation of the $(+)^{CD}_{600}$-$\Lambda_{LLL}\Lambda_{LLL}$ isomer, i.e., bridging the sulfur donor atoms of the starting complex to Co(II) ion is favorable to the labilization and inversion of the terminals. Here, an intramolecular hydrogen bonding is accompanied by the inversion. Considering from the result of the X-ray analysis of the $(+)^{CD}_{600}$-$\Lambda_{LLL}\Lambda_{LLL}$ isomer (Fig. 1), it is probable for the $\Lambda_{LLL}\Lambda_{LLL}$ isomer that in the above reaction conditions (pH≈9), the hydrogen bonds are formed between the axial carboxylato groups regulated by the lel conformation of the N-S chelate rings and the adjacent amine protons. While, the model construction of the $\Delta_{LLL}\Delta_{LLL}$ isomer reveals that this isomer prefers to the lel conformation with the equa-

torial carboxylato groups (unfavorable orientation for the hydrogen bond formation) because of the repulsion between the carboxylato groups and the lone pairs of the adjacent sulfur donor atoms. The difference in the hydrogen bond formation is probably related to the selective formation of the $(+)^{CD}_{600}$-$\Lambda_{l.l.l.}\Lambda_{l.l.l.}$ isomer.

Structural Effects in the Reactions of Diazoalkanes with 2,3-Dichloro-5,6-dicyanobenzoquinone

Takumi OSHIMA* and Toshikazu NAGAI
Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560
(Received May 6, 1986)

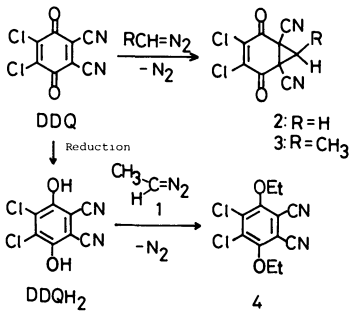
2,3-Dichloro-5,6-dicyanobenzoquinone (DDQ) reacted with diazoethane to give stereoisomeric bicyclic diones (**3**, isomer ratio=3.4) arising from dipolar addition to the C=C bond of DDQ. DDQ reacted with phenyldiazomethane to afford also stereoisomeric bicyclic diones (**7**) in the ratio of 5 : 1, together with stilbenes (**8**). On the other hand, DDQ gave the (ethenyloxy)benzene derivative (**14**) with 1-phenyldiazoethane. The formation of **8** and **14** was interpreted by considering the participation of 1 : 1 betaines resulting from addition to the C=O bond. The added methanol captures the betaines, thus giving rise to dimethyl acetals of benzaldehyde and acetophenone, along with 2,3-dichloro-5,6-dicyanohydroquinone. These reactivities of DDQ were discussed in comparison with those of chloranil.

As one area of the addition chemistry of quinones, comprehensive studies have been made of reactions with diazoalkanes from the synthetic and mechanistic points of view.[1] Quinones behave as dipolarophiles[2] as a result of their conjugated C=C and C=O bonds, while diazoalkanes behave as 1,3-dipoles.[3] A number of reports have been concerned with the reaction of diazomethane because of its commonness and high reactivity. Diazomethane tends to add to the conjugated C=C bonds of 1,4-benzoquinone[4] and its mono-,[5] di-,[5] and trichlorinated analogues[6] to yield pyrazolines. On the other hand, the C=O bonds become active when the C=C bonds are blocked with the bulky halogens, as is exemplified in the formation of the oxirane derivative in the reaction with chloranil.[7] Recently, we extended the reaction of chloranil to phenyldiazomethane,[8] diphenyldiazomethane,[9] and 1-phenyldiazoethane,[10] and found that these diazoalkanes similarly add to the C=O bond, but variously provide stilbenes and spirooxetane, and poly(tetrachlorohydroquinone benzhydrylether), and 1-alkoxy-4-ethenyloxy-2,3,5,6-tetrachlorobenzene, respectively.

On the other hand, the reaction of diazomethane with 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ) has been reported to afford bicyclic dione (**2**),[11] in contrast to the reaction with chloranil. However, we found in a previous investigation[12] that DDQ reacts with diphenyldiazomethane in a manner similar to that of chloranil. In view of the general interest in the reactions of diazoalkanes with quinones, it is desirable to extend the DDQ reaction to other diazoalkanes of structural types not previously investigated. In this paper, reactions of DDQ with diazoethane, phenyldiazomethane, 1-phenyldiazoethane, were investigated in order to gain a better understanding of the structural effects on the reactivity of diazoalkanes and to compare the results with those obtained for the corresponding chloranil reactions.

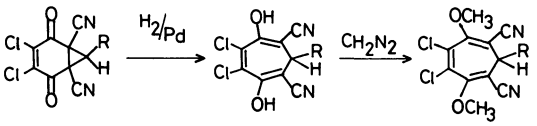
Results and Discussion

Reaction with Diazoethane. Diazoethane (**1**) reacted with 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ) to provide the bicyclic dione (**3**, isomer ratio=3.4), in analogy with diazomethane,[11,13] together with a small amount of 2,3-dichloro-5,6-dicyanohydroquinone diethyl ether (**4**) (Scheme 1). In conformity with the



Scheme 1.

bicyclic dione structure, each isomer of **3** could be converted into the identical dimethoxycycloheptatriene derivative (**5b**) upon catalytic hydrogenation and the subsequent methylation (Scheme 2).



Scheme 2.

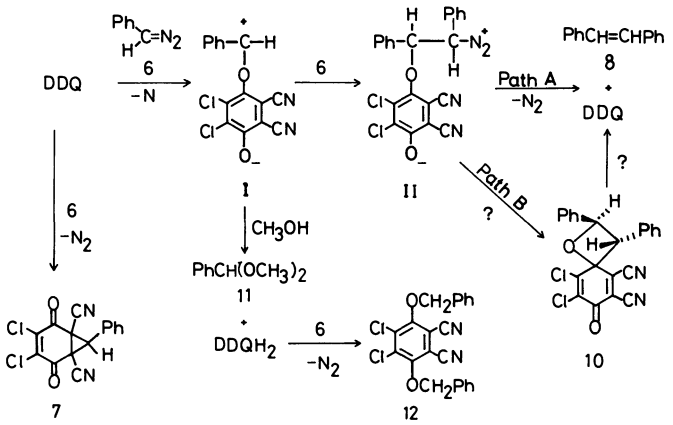
Though the ^{1}H NMR spectrum of the major isomer of **3** showed the methyl and cyclopropyl protons at a slightly higher field (0.1—0.2 ppm) than those of the minor one, it is not clear which of the two isomers corresponds to the exo or endo adduct, since both the carbonyl and cyano groups may be expected to exert magnetic anisotropy effects on the ethylidene moiety.[14] However, it may be suggested that the major **3** has an exo configuration on the basis of the estimated dihedral angles (θ) of the H-C-C-CN (134°) and H-C-C-CO (19°) fragments.[15] In fact, the fairly high isomer ratio appears to reflect the steric repulsion between the methyl group and the bulky quinone moiety.

A bicyclic dione **3** may be given by the dipolar addi-

tion of **1** to the cyano-substituted C=C bond and the subsequent release of nitrogen. Compound **4** is a usual product of the reaction of **1** and 2,3-dichloro-5,6-dicyanohydroquinone ($DDQH_2$), which indicates the reduction of DDQ during the reaction. Such a hydroquinone diether as **4** has already been obtained in a high yield by Eistert et al. in the reaction of **1** with chloranil.[16]

Unlike chloranil,[16] DDQ was found to react with **1** at the cyano-substituted C=C bond because of the reduced steric hindrance as well as the favorable LUMO energy for the dipolar addition.[17]

Reaction with Phenyldiazomethane. The reaction of DDQ with 1.6 equiv of phenyldiazomethane (**6**) mainly produced bicyclic diones (**7**, isomer ratio=5 : 1), together with stilbenes (**8**, cis/trans=0.8) (Scheme 3).

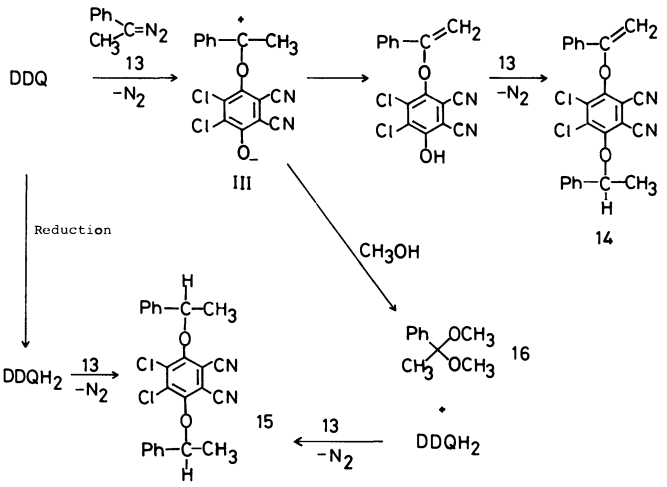


Scheme 3.

The structure of **7** was also established by the chemical conversion into the substituted cycloheptatriene (**9b**) (Scheme 2). The stereochemistry of **7** is unknown, but it is also likely that the major isomer is an exo adduct and that the much higher isomer ratio (=5) than in **3** is to be ascribed to the more enhanced steric repulsion between the phenyl group and the quinone moiety, by analogy with the case of **3**.

The formation of **8** can be explained by considering the participation of a 1 : 1 betaine intermediate, by analogy with our preceding reaction of **6** with chloranil.[8] According to the previous mechanism, the betaine I leads to the diazonium betaine(II) by the attack of another **6**, and subsequent El- and E2-type elimination (Path A) can afford **8**. On the other hand, intramolecular cyclization (Path B) is expected to build up spirooxetane (**10**). However, the DDQ reaction is somewhat different from the chloranil one in that the former gave no spirooxetane and provided more trans isomer for **8**, while the latter provided more *cis*-**8**. These phenomena may be ascribed mainly to the electronic effects of these two quinones.[18] The more electronegative DDQ moiety tends to destabilize II, thereby increasing the proportion of El elimination, mostly leading to *trans*-**8**. On the other hand, the predominant occurrence of E2-type elimination would result in the high cis to trans ratio of **8**, this is because of the steric reason mentioned previously for the chloranil reaction.[8] Moreover, the lack of spirooxetane in the present reaction must be due to its own instability, affected by the electronic factor, in the light of the relative bulkiness of these two quinones; the CN substituent of DDQ exerts less steric hindrance than the Cl substituent of chloranil.[19] Indeed, the spirooxetane of DDQ could not be obtained by the 3-h irradiation of a benzene solution (50 ml) of an equiv amount of DDQ (0.63 g, 2.8 mmol) and *trans*-**8** (0.50 g, 2.8 mmol) by using a high-pressure mercury lamp at 0 °C, though this photochemical method succeeded in providing a good yield of the *trans*-spirooxetane of chloranil.[8] Supporting the mechanistic explanation presented above, I reacted with added methanol to yield benzaldehyde dimethyl acetal (**11**) and $DDQH_2$. However, the dipolar addition to the C=C bond was not essentially affected, as is indicated by the 65% yield of **7**.

Reaction with 1-Phenyldiazoethane. The reaction of DDQ with 1-phenyldiazoethane (**13**) gave the (ethenyloxy)ethoxybenzene derivative (**14**, 92%) by a reaction sequence involving 1 : 1 betaine(III) formation, proton migration, and etherification with excess diazoalkane (Scheme 4). This reaction was accompanied



Scheme 4.

by a small amount of a product from **13** and $DDQH_2$, 2,3-dichloro-5,6-dicyanohydroquinone bis(α-methylbenzyl) ether (**15**), as in the case of diazoethane.

In contrast to phenyldiazomethane, neither bicyclic diones nor dimeric olefins were yielded in this case. The marked change in the reaction fashion must be caused by the additional methyl substituent on the diazo-carbon, which will serve to increase the steric repulsion both on the dipolar addition to the C=C bond and on the nucleophilic attack upon the cation center of III responsible for the formation of the bicyclic dione and dimeric olefin respectively. These situations resulted in the exclusive addition to the C=O bond and the following proton migration, just as in the chloranil reaction.[10] Expectedly, added methanol

Table 1. Reactivities of Diazoalkanes in the Reactions with DDQ and Chloranil[a)]

completely inhibited the proton migration and produced acetophenone dimethyl acetal (**16**) and $DDQH_2$.

In order to demonstrate that the reactions of diazoalkanes with DDQ are substantially controlled by the structural natures, we present again in the table the representative reaction features for a series of diazoalkanes in comparison with those of the comparable chloranil reactions.

Experimental

All the melting points were taken with a Laboratoty Devices Mel-Temp instrument and are uncorrected. The infrared spectra were recorded on a Hitachi 260-10 apparatus and on a Perkin Elmer 983 G spectrometer. The ^1H and ^{13}C NMR spectra were taken on a Varian EM 390 spectrometer and on a JEOL FX 90-Q spectrometer respectively. The mass spectral data were obtained with a Hitachi RMU 6E mass spectrometer.

Materials. The 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ) was of commercial origin and was recrystallized from dichloromethane or chloroform. The diazoethane (**1**),[20] phenyldiazomethane (**6**),[21] and 1-phenyldiazoethane (**13**),[22] were prepared according to the procedure described in the literature. The oily **6** and **13** contained the corresponding azines formed by the spontaneous thermal decomposition in ca. 10 and 30% respectively, as detected in the ^1H NMR spectra. However, these azines remained unchanged when allowed to stand for 1 h with DDQ in benzene-d_6, as was confirmed by the NMR measurements. The benzene was refluxed over lithium aluminum hydride and was fractionated.

3,4-Dichloro-2,5-dioxo-7-methylbicyclo[4.1.0]hept-3-ene-1,6-dicarbonitrile (3) and 2,3-Dichloro-5,6-dicyanohydroquinone diethyl Ether (4). An ether solution of diazoethane was added, drop by drop, to a stirred solution of DDQ (800 mg, 3.52 mmol) in benzene (20 ml) at 25 °C until the deep orange-red color due to the CT band of DDQ and benzene disappeared. At that point, a crystalline precipitate was formed. After a further 1 h stirring, the precipitate was filtered off and washed with benzene (10 ml×3) to leave the major isomer **3** (403 mg, 45%): Mp 245—246 °C (from acetone); IR (KBr) 2269 (C≡N), 1702 (C=O), 1558 (C=C), 1260, 1178, 987, 792 cm^{-1}; ^1H NMR (acetone-d_6) δ=1.75 (d, J=6.2 Hz, 3H, CH_3), 3.77 (q, J=6.2 Hz, 1H, cyclopropyl H); ^{13}C NMR (acetone-d_6) δ=13.2 (CH_3), 39.3 (C-CH_3), 40.1 (C-CN), 111.8 (CN), 141.7 (C=C), 176.7 (C=O); MS, m/z 254 (M^+). Found: C, 47.22; H, 1.64; N, 10.94%. Calcd for $C_{10}H_4Cl_2N_2O_2$: C, 47.09; H, 1.58; N, 10.98%.

The filtrate and the washing were then combined and evaporated to dryness. The residue was column chromatographed on silica gel. Elution with petroleum ether-benzene (1 : 1) gave **4** (87 mg, 9%): Mp 101—102 °C (from petroleum ether); IR (KBr) 2237 (C≡N), 1431, 1383, 1357, 1022, 926 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.50 (t, J=7.0 Hz, 6H, 2×CH_3), 4.27 (q, J=7.0 Hz, 4H, 2×methylene); MS, m/z 284 (M^+). Found: C, 50.64; H, 3.57; N, 9.77%. Calcd for $C_{12}H_{10}Cl_2N_2O_2$: C, 50.55; H, 3.54; N, 9.83%.

Further elution with benzene subsequently yielded a second crop of the major isomer **3** (90 mg, 10%) and the minor **3** (142 mg, 16%): Mp 236—238 °C (from acetone); IR (KBr) 2260 (C≡N), 1688 (C=O), 1556 (C=C), 1253, 1168, 802 cm^{-1}; ^1H NMR (acetone-d_6) δ=1.63 (d, J=6.8 Hz, 3H, CH_3), 3.53 (q, J=6.8 Hz, cyclopropyl H); MS, m/z 254 (M^+). Found: C, 47.08; H, 1.63; N, 10.75%. Calcd for $C_{10}H_4Cl_2N_2O_2$: C, 47.09; H, 1.58; N, 10.98%. Finally, an unidentified black powder (110 mg, mp>300 °C, IR (KBr) 3440, 1625, 1524 cm^{-1}) was eluted, with benzene-acetone (1 : 1) as the eluent.

Hydrogenation of 3. 3,4-Dichloro-2,5-dimethoxy-7-methyl-1,3,5-cycloheptatriene-1,6-dicarbonitrile (5b). The major isomer **3** (150 mg, 0.59 mmol) was hydrogenated with palladium carbon (100 mg, ca. 10%) at 25 °C in 1,4-dioxane (10 ml) under a hydrogen atmosphere. After 6 h stirring, the filtration of the catalyst and the evaporation of the solvent in vacuo gave a colorless solid (140 mg) showing a strong OH band at 3220 cm^{-1}. The treatment of the crude product with excess ethereal diazomethane and the subsequent column chromatography on silica gel, with benzene-ether (10 : 1) as an eluent, provided **5b** (108 mg, 64%): Mp 136—137 °C (from petroleum ether-benzene); IR (KBr) 2220 (C≡N), 1593 (C=C), 1309, 1280, 1058, 782 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.56 (d, J=7.0 Hz, 3H, CH_3), 2.63 (q, J=7.0 Hz, 1H, methine), 3.93 (s, 6H, 2×OCH_3); MS, m/z 284 (M^+). Found: C, 50.51; H, 3.53; N, 9.74%. Calcd for $C_{12}H_{10}Cl_2N_2O_2$: C, 50.55; H, 3.54; N, 9.83%.

The same workup converted the minor isomer **3** (80 mg) into **5b** (53 mg, 59%).

3,4-Dichloro-2,5-dioxo-7-phenylbicyclo[4.1.0]hept-3-ene-1,6-dicarbonitrile (7) and Stilbene (8). To a stirred solution of DDQ (480 mg, 2.1 mmol) in benzene (10 ml), we added, drop by drop at 25 °C over a 10-min period, a solution of phenyldiazomethane (400 mg, 3.4 mmol) in benzene (5 ml). After 1 h stirring, the precipitate was filtered off and washed with benzene (10 ml×3) and ether (5 ml×2) to leave the major **7** (280 mg, 42%): Mp 215—216 °C (from methanol); IR (KBr) 2253 (C≡N), 1707 (C=O), 1559 (C=C), 1172, 834 cm^{-1}; ^1H NMR (acetone-d_6) δ=5.16 (s, 1H, cyclopropyl H), 7.1—7.6 (m, 5H, Ph); MS, m/z 316 (M^+). Found: C, 56.91; H, 1.97; N, 9.01%. Calcd for $C_{15}H_6Cl_2N_2O_2$: C, 56.81; H, 1.91; N, 8.83%.

The filtrate and the washing were then combined, and the solvent was evaporated. A slight amount of the residue was submitted to HPLC analysis in order to determine the cis to trans ratio of **8** according to the previous procedure.[23] The rest of the residue was chromatographed on silica gel. Elution with petroleum ether-benzene (5 : 1) gave a mixture of *cis* and *trans*-**8** (78 mg, 25%, based on the **6** used). The increasing benzene content provided, successively, benzaldehyde azine, a second crop of the major isomer **7** (110 mg, 17%), and the minor isomer **7** (80 mg, 12%): Mp 208—209 °C

(from methanol); IR (KBr) 2256 (C≡N), 1699 (C=O), 1548 (C=C), 1182, 836 cm^{-1}; ^1H NMR (acetone-d_6) δ=5.03 (s, 1H, cyclopropyl H), 7.4—7.7 (m, 5H, Ph); MS, m/z 316 (M^+). Found: C, 57.12; H, 1.91; N, 8.75%. Calcd for $C_{15}H_6Cl_2N_2O_2$: C, 56.81; H, 1.91; N, 8.83%.

Hydrogenation of 7. 3,4-Dichloro-2,5-dimethoxy-7-phenyl-1,3,5-cycloheptatriene-1,6-dicarbonitrile (9b). The major isomer **7** (230 mg, 0.73 mmol) was hydrogenated with palladium carbon (100 mg) at 25 °C in 1,4-dioxane (20 ml) under a hydrogen atmosphere. After 6 h stirring, the catalyst was filtered off and the solvent was evaporated. We were unsuccessful in our attempt to crystallize **9a**, so the hydrogenated product was methylated with diazomethane and column chromatographed on silica gel, with benzene–ether (10 : 1) as the eluent, to give **9b** (175 mg, 69%): Mp 158—160 °C (petroleum ether); IR (KBr) 2190 (C≡N), 1591 (C=C), 1291, 946 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.93 (s, 6H, 2×OCH_3), 4.40 (s, 1H, methine), 7.27 (s, 5H, Ph); MS, m/z 346 (M^+). Found: C, 58.76; H, 3.47; N, 8.03%. Calcd for $C_{17}H_{12}Cl_2N_2O_2$: C, 58.80; H, 3.48; N, 8.07%.

Benzaldehyde Dimethyl Acetal (11) and 2,3-Dichloro-5,6-dicyanohydroquinone Dibenzyl Ether (12). To a stirred solution of DDQ (480 mg, 2.1 mmol) in benzene (10 ml) containing methanol (0.50g, 16 mmol), we added, drop by drop at 25 °C over a 10-min period, a solution of phenyldiazomethane (**6**) (400 mg, 3.4 mmol) in benzene (5 ml). After 1 h stirring, a precipitate was filtered off and washed with benzene (10 ml×3) and ether (5 ml×2). The crystalline product was assigned to the major isomer **7** (280 mg, 42%) on the basis of the IR analysis. The evaporation of the combined filtrate and washing in vacuo gave an pasty residue, the ^1H NMR spectrum of which showed the presence of benzaldehyde dimethyl acetal (**11**) (10%, as determined by the integral ratios, with 1,1,1,2-tetrachloroethane as the internal standard). This acetal was easily degradated to benzaldehyde and methanol on 1 d standing in the NMR tube, as confirmed by the disappearance of the acetal signal: ($CDCl_3$) δ=3.30 (s, 6H, 2×OCH_3) and 5.37 (s, 1H, methine). The column chromatographic treatment of the residue, with petroleum ether–benzene (20 to 100%) as eluents, gave, successively, benzaldehyde (16 mg, 7%), benzaldehyde azine, **12** (110 mg, 13%), the second crop of the major isomer **7** (80 mg, 12%), and the minor isomer **7** (70 mg, 11%). Compound **12** had a mp of 192—194 °C (from benzene): IR (KBr) 2228 (C≡N), 1421, 1355, 993 cm^{-1}; ^1H NMR ($CDCl_3$) δ=5.28 (s, 4H, methylene), 7.2—7.6 (m, 10H, 2×Ph); MS, m/z 408 (M^+). Found: C, 64.51; H, 3.44; N, 7.09%. Calcd for $C_{22}H_{14}Cl_2N_2O_2$: C, 64.56; H, 3.45; N, 6.85%.

2,3-Dichloro-5,6-dicyano-1-(1-phenylethenyloxy)-4-(1-phenylethoxy)benzene (14) and 2,3-Dichloro-5,6-dicyanohydroquinone bis(α-methylbenzyl) Ether (15). To a stirred solution of DDQ (0.50 g, 2.2 mmol) in benzene (10 ml), we added, drop by drop at 25 °C and over a 10-min period, a solution of 1-phenyldiazoethane (0.80 g, 6.1 mmol) in benzene (10 ml). After 6 h stirring, the evaporation of the solvent gave a brown solid. The ^1H NMR spectrum of this residue showed the formation of **14** and **15** in yields of 92 and 4% respectively, as determined by using 1,1,1,2-tetrachloroethane as the internal standard. Column chromatography on silica gel gave, successively, **15** and **14** by using petroleum ether–benzene (1 : 2). Compound **14** had a mp of 126—127 °C (from petroleum ether–benzene); IR (KBr) 2238 (C≡N), 1637 (C=C), 1420, 1268, 699 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.82 (d, J=6.3Hz, 3H, CH_3), 3.77 (d, J=4.3Hz, 1H, olefinic H), 4.90 (d, J=4.3Hz, 1H, olefinic H), 5.80 (q, J=6.3Hz, 1H, methine), 7.2—7.8 (m, 10H, 2×Ph); MS, m/z 434 (M^+). Found: C, 65.99; H, 3.91; N, 6.47%. Calcd for $C_{24}H_{16}Cl_2N_2O_2$: C, 66.22; H, 3.71; N, 6.44%.

Compound **15** was identified by a comparison of its IR spectrum with that of an authentic specimen prepared by the treatment of 1-phenyldiazoethane with $DDQH_2$, having a mp of 119—120 °C (from benzene); IR (KBr) 2236 (C≡N), 1420, 1242, 1057, 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.73 (d, J=6.3 Hz, 6H, 2×CH_3), 5.65 (q, J=6.3 Hz, 2H, 2×methine), 7.37 (s, 10H, 2×Ph); MS, m/z 332 (M^+−$PhCH{=}CH_2$). Found: C, 65.95; H, 4.09; N, 6.37%. Calcd for $C_{24}H_{28}Cl_2N_2O_2$: C, 65.91; H, 4.15; N, 6.41%.

Acetophenone Dimethyl Acetal (16). To a stirred solution of DDQ (1.0 g, 4.4 mmol) in benzene (20 ml), we added, drop by drop, at 25 °C and over a 10-min period, a solution of 1-phenyldiazoethane (0.70 g, 5.3 mmol) and methanol (1.0 g, 31 mmol) in benzene (10 ml). After 1 h stirring, the solvent was evaporated to dryness and the yield of **16** (69%) was determined by the integration of the methoxyl signals at δ 3.13 by using 1,1,1,2-tetrachloroethane as a standard in the ^1H NMR spectrum. Though the signals assignable to **15** were also observed, the two characteristic olefinic doublets (δ=3.77 and 4.90) attributable to **14** were not found, which is consistent with the complete inhibition of the proton migration process (see Scheme 4). The crude reaction mixture was extracted with pentane (20 ml×3) and the combined pentane solution was washed with 5% aqueous sodium carbonate (5 ml×3) and with NaCl saturated water (5 ml×2), dried over sodium sulfate, and concentrated in vacuo to give a pale yellow oil. Column chromatography on alumina, using pentane–benzene (9 : 1) as the eluent, gave **16** (260 mg, 36%): colorless oil; IR (film) 1277, 1148, 1044, 701 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.50 (s, 3H, CH_3), 3.13 (s, 6H, 2×OCH_3), 7.2—7.6 (m, 5H, Ph). Found: C, 72.47; H, 8.57%. Calcd for $C_{10}H_{14}O_2$: C, 72.26; H, 8.49%.

We wish to thank Dr. S. Itoh (Osaka University) for the ^{13}C NMR measurements.

14) Dreiding et al. have reported that unsubstituted bicyclic dione, bicyclo[4.1.0]hept-3-ene-2,5-dione, shows only a small difference ($\Delta\delta$(exo-endo)=+0.06 ppm) in the chemical shifts of H(exo) and H(endo). However, they have also estimated the corresponding difference to be large and negative ($\Delta\delta$=−0.69 ppm) for the tetramethyl substituted system; *Helv. Chim. Acta.*, **57**, 1259 (1974).

15) The dihedral angles (θ) were calculated from the coupling constants $J(^{13}C, H)$ obtained between the cyclopropyl proton and the cyano carbon (4.87 Hz) or the carbonyl carbon (6.11 Hz) in DMSO-d_6, according to the Wasylishen and Schaefer equation; *Can. J. Chem.*, **50**, 2710 (1972). Though their equation gave two θ values for each fragment, H-C-C-CN (33 and 134°) and H-C-C-CO (19 and 143°), we have chosen the pair of 134 and 19° as estimated values because the other value (θ=33°) is too large for the *cis* arrangement of the cyclopropane-ring substituents.

Reaction of β-Nitro Enamines with Isocyanates, Isothiocyanates and Dimethyl Acetylenedicarboxylate

Takao TOKUMITSU
Department of Chemistry, Faculty of Science, Yamaguchi University, Yoshida, Yamaguchi 753
(Received May 10, 1986)

β-Nitro enamines (**1**) reacted with isocyanates and isothiocyanates to give β-(substituted carbamoyl) and β-(substituted thiocarbamoyl) β-nitro enamines, respectively. The reaction of **1** with benzoyl isothiocyanate gave β-(benzoylthiocarbamoyl) β-nitro enamines (**8**) and/or a mixture of **8** and 4(1*H*)-pyrimidinethione derivatives (**9**) which were cyclization products of **8**. The isolated **8** afforded the corresponding **9** in high yields upon heating in DMF. The reaction of **1** with dimethyl acetylenedicarboxylate gave [2+2] cycloadducts (**12**) and/or a mixture of **12** and δ-nitro dienamino diesters (**13**) which were ring cleavage products of **12**. Compounds **12** afforded **13** upon heating in toluene or xylene.

β-Nitro enamines are useful synthetic intermediates, and their reactivities are of interest in connection with that of β-amino enones. In a previous paper, the author reported that the primary and secondary β-nitro enamines (**1**) reacted with electrophiles, *N*-halosuccinimides, *o*-nitrobenzenesulfenyl chloride and thiocyanogen, to give exclusively the β-substituted β-nitro enamines.[1] The reaction of electrophiles such as isocyanates and isothiocyanates with **1** also is of interest because it may occur either at the nitrogen of the amino group or at the β-carbon. However, these reactions have been little studied: it has been reported only that 2-(nitromethylene)perhydroazepine reacts with benzoyl isothiocyanate to give a pyrimidine derivative.[2] On the other hand, it is known that tertiary β-nitro enamines react at the double bond with dipolar reagents such as nitrilimines, nitrile oxides and aryl azides to give azoles, [2+3] dipolar cycloaddition products.[3,4] However, there has been no report concerning the reaction of **1** with electrophilic alkynes.

In this paper, I wish to report the results of the reaction of **1** with isocyanates, isothiocyanates and dimethyl acetylenedicarboxylate.

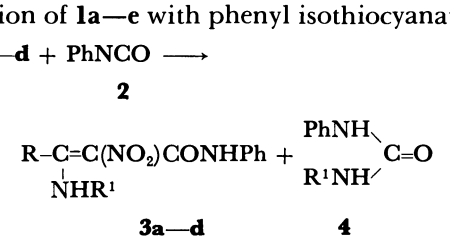
Results and Discussion

Reaction of β-Nitro Enamines (1) with Isocyanates and Isothiocyanates. The reaction of **1a—d** with phenyl isocyanate (**2**) in acetonitrile afforded β-(phenylcarbamoyl) β-nitro enamines (**3a—d**) in 29—81% yields and a small amount of the corresponding *N*-substituted ureas (**4**), which were considered to be decomposition products of an *N*-acylated product of **1**, respectively. In these reactions, tertiary β-nitro enamine, **1e**, decomposed. With methyl isocyanate, only **1b** at 90 °C in a sealed tube gave *N*-methyl-3-methylamino-2-nitro-2-butanamide (**5b**) in a 35% yield. In the reaction of **1a—e** with phenyl isothiocyanate, only



1a—d + PhNCO ⟶ **2**

R–C(NHR¹)=C(NO_2)CONHPh + $PhNH(R^1NH)C{=}O$

3a—d **4**

1b and **1e** gave β-(phenylthiocarbamoyl) β-nitro enamines (**6b**) and (**6e**), in 25 and 5% yields, respectively. These results have revealed that the electrophilic addition of isocyanates and isothiocyanate to **1** takes place predominantly on the β-carbon of **1**; this reactivity is attributable to the enamine character of **1**.[1,5] New compounds **3a—d**, **5b** and **6b,e** were identified by spectral data and elemental analyses. In the IR spectra, **3a** and **3b—d**, **5b** showed three and two weak absorptions, respectively, which were assigned to νNH. The absorptions in the carbonyl region were complex: **3a—d** and **5b** showed strong absorptions in the region 1602—1588 cm^{-1}, which may be assigned to νC=O overlapped with a ring stretching that is shifted to a lower frequency by the enamino ketone conjugation and an intramolecular hydrogen bonding strengthened by the electron-withdrawing resonance effect of α-nitro group (as described below). A strong νC=S absorption of **6b** and **6e** was found at 1168 and 1160 cm^{-1},[6] respectively. The NMR spectra of **3a—d**, **5b**, and **6b,e** showed new peaks of $NHCH_3$ or NHC_6H_5 protons with a disappearance of a =CH- proton signal near 6.5 ppm of the corresponding **1a—e**, respectively.

a) C: Silica-gel column chromatography.

In the reaction of **1** with benzoyl isothiocyanate (**7**), **1a,b,d,h** gave a mixture of corresponding β-(benzoylthiocarbamoyl) β-nitro enamines (**8a,b,d,h**) (17—81%), 4(1*H*)-pyrimidinethione derivatives (**9a,b,d,h**) (0.5—17%) and *N*-benzoyl *N'*-R^1-thioureas (**10**) (1—26%), and **1c,i** gave a mixture of corresponding **9c, i** (9 and 16%) and **10** (26 and 6%); **1e,g,j** and **1f** gave only corresponding **8e,g,j** (50—87%) and a small amount of *N*-benzoylthiourea, respectively. deStevens et al.[5] have reported that ethyl 3-amino-2-(benzoylthiocarbamoyl)-crotonate can be converted to the corresponding 4(1*H*)-pyrimidinethione derivative upon refluxing in THF. Therefore, compounds **9** appear to be produced by a thermal *Z-E* isomerization of the initially formed β-adducts, **8**, during the reaction, followed by a ring closure and dehydration. These results are also supported by the reaction of **1h** with **7**. Namely, plots of the yields of **8h** vs. the reaction times showed a maximum (about 60%) in about 18 h, while **9h** increased with increasing time. These results are shown in Fig. 1. On the other hand, the isolated primary and secondary **8a,b,d,g,h** afforded the corresponding **9a,b,d,g,h** in 90—96% yields upon heating in DMF for 5 min at 110 °C. Compounds **10** are the decomposition products of *N*-adducts of **7**. New compounds **8a,b,d,e,g,h,j** and **9a—d, g—i** were identified by the spectral data and elemental analyses. The IR spectra for **8** showed one, two and three absorptions assigned to νNH in the region of 3500—3100 cm^{-1}, and νC=O and νC=S absorptions were observed at 1708—1706 and 1180—1162 cm^{-1}, respectively. In cyclic compounds **9b—d, g—i**, the νC=O and νNH absorptions disappeared, and **9a** showed a weak absorption of the νNH at 3400 cm^{-1}. The absorptions of νC=C+νC=N and νC=S of **9a—d, g—i** were observed at 1677—1605 and 1172—1149 cm^{-1} respectively. The NMR spectra also supported the structure of **8** and **9**, respectively.

As previously described, **3b—d** and **5b** showed two weak νNH absorptions in the regions at 3350—3270 and 3180—3150 cm^{-1}; also, a strong absorption of νC=O that overlapped with νC=C of the aromatic ring was found in the lower-frequency region of 1602—1588 cm^{-1}, respectively. 4-(Monosubstituted amino)-3-nitro-3-penten-2-one (substituent: Me, $PhCH_2$, and

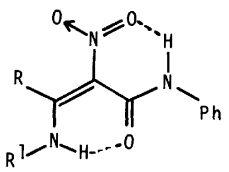
Ph) show a strong νC=O in the lower-frequency region of 1605—1568 cm^{-1}. Such a low-frequency shift of the νC=O absorption can be attributed to a delocalization of π-electrons of the chelate ring through an intramolecular hydrogen bonding, owing to the electron-withdrawing resonance effect of the α-nitro group.[7]



[**I**]

The peaks of two NH protons for NMR were found for a lower magnetic field at δ 13.8—12.2 and 10.5—10.4 respectively. Compound **3a** was also similar to **3b—d**. Further, the peaks of NCH_3 and NCH_2- protons for **3b,c** and **5b** split into a doublet through a spin-spin coupling with the NH proton at δ 3.16—2.87 (J=5—6 Hz) and 4.6 (J=6 Hz), respectively. From these results, **3a—d** and **5b** appear to exist in a double intramolecular hydrogen-bonded structure [**I**].

In conclusion, it has been found that **1** reacts with

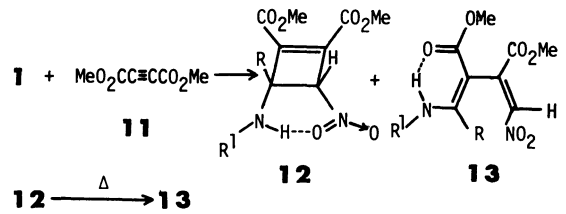
isocyanates and isothiocyanates at β-carbon predominantly to give the β-adducts. With benzoyl isothiocyanate it gives 4(1*H*)-pyrimidinethiones by β-addition followed by cyclization.



Reaction of 1 with Dimethyl Acetylenedicarboxylate (11). In a reaction of **1** with **11** in refluxing THF, **1d, h, i** gave a mixture of corresponding [2+2] cycloadducts (**12d,h,i**) and β,γ-bis(methoxycarbonyl) δ-nitro dienamines (**13d,h,i**), and **1b,f,g** gave only **12b,f,g**; **1a,j** and **1c, e** gave only the corresponding **13a, j** and decomposition products, respectively. These results are shown in Table 2. It is known that enamino ketones and esters also react similarly with **11** to give dienamino keto diesters and dienamino triesters, respectively, which are presumed to be produced via a rearrangement of unstable cyclobutene intermediates.[8] In a similar manner, **13** appears to be produced by a ring-cleavage of the initially formed cycloadducts **12**. This is also illustrated by the fact that plots of the yields of **12h** vs. the reaction times showed a maximum (58%) after about 12 h, while that of **13h** increased up to 81% with time (Fig. 2). The isolated **12** isomerized upon being heated in toluene or xylene to give the corresponding **13** in 49—99% yields. These results are summarized in Table 3. Compounds **12b,d,h,i** were

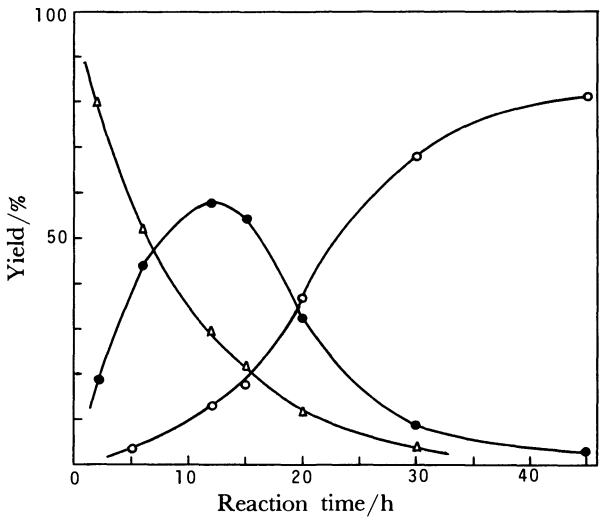


Fig. 2. Yields of **12h** and **13h** vs. reaction time in boiling THF. ●: **12h**, ○: **13h**, △: recovered 1h.

easily cleaved by refluxing in toluene to give **13b,d,h,i**, respectively. **12f,g** were stable upon prolonged heating in toluene and required a long heating period at 130 °C in xylene. Such a difference in the thermal stability of **12** is consistent with the yield of **13** for the reaction described above.

The new compounds (**12** and **13**) were identified by spectral data and elemental analyses. The IR spectra of **12b,d, f—i** all showed a weak broad νNH absorption at 3190—3120 cm^{-1}, and a strong νC=O absorption was observed in the region of 1728—1720 cm^{-1}. A weak absorption at 1639—1625 cm^{-1} region was assigned to νC=C absorption, and a strong absorption at 1603—

1561 cm^{-1} region was assigned to depend primarily on $\nu_{as}NO_2$ absorption. The NMR spectra for **12b,d,f—i** were also in agreement with the [2+2] cycloadducts, respectively, and a broad NH peak was observed at δ 12.37—9.9, respectively. These results suggested that **12b, d, f—i** have an intramolecular hydrogen-bonded structure of NH ··· O=N type. In the IR spectra of **13a,b,d,f—j** a weak broad absorption of νNH was observed in the region of 3200—3150 cm^{-1} except for **13j**, and a strong absorption of νC=O and a medium absorption of νC=C was observed at 1725—1718 and 1640—1618 cm^{-1} region, respectively. Strong absorptions of $\nu_{as}NO_2$ and ν_sNO_2 were also observed at 1614—1544 and 1376—1351 cm^{-1}, respectively. The NMR spectra were also consistent with the ring-cleavage products, respectively, and a broad NH peak was observed at δ 12.49—9.95 as observed **12**. These results suggested that **13** were δ-nitro dienamino diester and that **13a,b,d,f—j** had an intramolecular hydrogen-bonded structure of the enamino ester type. Consequently, it is considered that the compounds **13** are produced via the conrotatory ring cleavage upon heating the corresponding cyclobutenes **12**.

In conclusion, it has been found that **1** reacts with the electrophilic dimethyl acetylenedicarboxylate at the double bond, in spite of the delocalization of π-electrons as a push-pull alkene,[9] to give the [2+2] cycloadducts, and that their adducts afford the corresponding δ-nitro dienamino diesters by the ring opening reaction.

Experimental

Melting points were uncorrected. IR and UV spectra were recorded with a JASCO IRG and a Hitachi 124 spectrophotometers, respectively. NMR spectra were recorded with a Hitachi R24B (60 MHz) instrument using TMS as an internal standard. Isocyanates, isothiocyanates and dimethyl acetylenedicarboxylate were of commercial grade and used without further purification. The preparation of *N*-substituted β-nitro enamines, **1a—j**, was described in a previous paper.[7]

General Procedure for the Reaction of 1 with Isocyanates and Phenyl Isothiocyanate. A solution containing **1** (5 mmol) and phenyl isocyanate or phenyl isothiocyanate (5.5 mmol) in acetonitrile 15 ml was refluxed for 9—90 h; then, the solvent was removed by a rotary evaporator. The residue was purified by recrystallization and/or column chromatography (silica-gel, benzene/acetone 5/1) to give **3a—d** and **6b,e**. The reaction of **1** with methyl isocyanate was performed in a sealed tube at 90 °C for 48 h, and purified in a similar manner as above. The results are as follows.

***N*-Phenyl-3-amino-2-nitro-2-butenamide (3a):** Reaction time 48 h; yield 29%; mp 177—178 °C (column chromatography); IR ($CHCl_3$) 3470m, 3300w, 3130w, 1658w, 1631m, 1591s, 1530s, 1444s, and 1322s cm^{-1}; UV (EtOH) λ_{nm} ($10^{-3}\varepsilon$) 252 (14.0) and 338 (21.1); ^1H NMR (DMSO-d_6) δ=10.35 (br, 1H), 9.5 (br, 1H), 9.05 (br, 1H), 7.4 (m, 5H), and 2.11 (s, 3H). Found: C, 68.08; H, 3.80; N, 10.65; S, 8.05%. Calcd for $C_{22}H_{15}N_3O_2S$: C, 68.55; H, 3.92; N, 10.90; S, 8.32%.

General Preparation of 4(1*H*)-Pyrimidinethione Derivatives (9) by the Cyclization of 8. A solution containing **8** in DMF (10 times) was heated at 110 °C for 5 min. The solvent was evaporated under reduced pressure. The residue was purified by column chromatography (silica-gel, CH_2Cl_2) to give corresponding **9**. The results are as follows.

6-Methyl-5-nitro-2-phenyl-4(1*H*)-pyrimidinethione (9a): Yield 90%; mp 238 °C; IR ($CHCl_3$) 3400w, 1675w, 1549s, 1328s, and 1155m cm^{-1}; UV (EtOH) λ_{nm} (10^{-3} ε) ≈270 (≈10.0) and 305 (12.0); ^1H NMR (DMSO-d_6) δ=7.7 (m, 5H), 6.5 (br, 1H), and 1.29 (s, 3H). Found: C, 53.32; H, 3.54; N, 16.91; S, 12.82%. Calcd for $C_{11}H_9N_3O_2S$: C, 53.41; H, 3.67; N, 17.00; S, 12.91%.

1,6-Dimethyl-5-nitro-2-phenyl-4(1*H*)-pyrimidinethione (9b): Yield 93%; mp 219—220 °C; IR ($CHCl_3$) 1619s, 1517s, 1294s, and 1153s cm^{-1}; UV (EtOH) λ_{nm} (10^{-3} ε) 251 (8.0) and 335 (18.0); ^1H NMR (DMSO-d_6) δ=7.6 (m, 5H), 3.45 (s, 3H), and 2.36 (s, 3H). Found: C, 55.15; H, 4.25; N, 15.95; S, 12.31%. Calcd for $C_{12}H_{11}N_3O_2S$: C, 55.16; H, 4.24; N, 16.08; S, 12.27%.

6-Methyl-5-nitro-1,2-diphenyl-4(1*H*)-pyrimidinethione (9d): Yield 92%; mp 252—253 °C; IR ($CHCl_3$) 1620s, 1592s, 1535s, 1320m, and 1172s cm^{-1}; UV (EtOH) λ_{nm} (10^{-3} ε) 243 (14.0), 308 (16.8), and 386 (13.2); ^1H NMR (DMSO-d_6) δ=7.6 (m, 10H) and 1.92 (s, 3H). Found: C, 63.01; H, 3.99; N, 12.78; S, 9.86%. Calcd for $C_{17}H_{13}N_3O_2S$: C, 63.14; H, 4.02; N, 12.99; S, 9.91%.

1-Methyl-5-nitro-2,6-diphenyl-4(1*H*)-pyrimidinethione (9g): Yield 96%; mp 235—236 °C; IR ($CHCl_3$) 1613s, 1589m, 1540s, 1330s, and 1153s cm^{-1}; UV (EtOH) λ_{nm} (10^{-3} ε) 245 (11.0) and 338 (19.0); ^1H NMR ($CDCl_3$) δ=7.6 (m, 10H) and 3.50 (s, 3H). Found: C, 63.00; H, 3.98; N, 13.00; S, 9.66%. Calcd for $C_{17}H_{13}N_3O_2S$: C, 63.14; H, 4.05; N, 12.99; S, 9.91%.

1-Benzyl-5-nitro-2,6-diphenyl-4(1*H*)-pyrimidinethione (9h): Yield 91%; mp 237—238 °C; IR ($CHCl_3$) 1605s, 1589s, 1552s, 1328s, and 1168s cm^{-1}; UV (EtOH) λ_{nm} (10^{-3} ε) 248 (11.0) and 340 (16.0); ^1H NMR ($CDCl_3$) δ=7.6 (m, 15H) and 4.98 (s, 2H). Found: C, 69.02; H, 4.11; N, 10.38; S, 7.95%. Calcd for $C_{23}H_{17}N_3O_2S$: C, 69.15; H, 4.29; N, 10.52; S, 8.02%.

General Procedure for the Reaction of 1 with Dimethyl Acetylenedicarboxylate (11). A solution containing **1** (5 mmol) and **11** (5.5 mmol) in THF (15 ml) was refluxed until **1** was consumed as checked by TLC. The solvent was evaporated under reduced pressure. The residue was separated by fractional crystallization and/or column chromatography on silica-gel (CH_2Cl_2) to give [2+2] cycloadducts (**12**) and their ring opening products (**13**), respectively. The results are listed in Table 2.

Dimethyl 3-Methyl-3-methylamino-4-nitro-1-cyclobutene-1,2-dicarboxylate (12b): Mp 120—121 °C; IR ($CHCl_3$) 3150w, 1720s, 1630m, 1604m, 1578s, and 1364s cm^{-1}; UV (EtOH) λ_{nm} (10^{-3} ε) ≈238 (≈5.9) and 354 (6.7); ^1H NMR ($CDCl_3$) δ=11.0 (br, 1H), 6.01 (s, 1H), 3.73 (s, 6H), 3.12 (d, *J*=6Hz, 3H), and 2.19 (s, 3H). Found: C, 46.57; H, 5.43; N, 10.80%. Calcd for $C_{10}H_{14}N_2O_6$: C, 46.51; H, 5.46; N, 10.84%.

Dimethyl 3-Anilino-3-mehtyl-4-nitro-1-cyclobutene-1,2-dicarboxylate (12d): Mp 149—150 °C; IR ($CHCl_3$) 3120w, 1723s, 1639m, 1603s, and 1361s cm^{-1}; UV (EtOH) λ_{nm} (10^{-3} ε) 230 (11.4) and 362 (12.4); ^1H NMR ($CDCl_3$) δ=12.37 (br, 1H), 7.3 (m, 5H), 6.20 (s, 1H), 3.78 (s, 6H), and 2.16 (s, 3H). Found: C, 56.02; H, 4.98; N, 8.73%. Calcd for $C_{15}H_{16}N_2O_6$: C, 56.25; H, 5.03; N, 8.74%.

Dimethyl 3-Amino-4-nitro-3-phenyl-1-cyclobutene-1,2-dicarboxylate (12f): Mp 154—155 °C; IR ($CHCl_3$) 3470w, 3290w, 3190w, 1728s, 1638m, 1599s, 1574s, and 1350s cm^{-1}; UV (EtOH) λ_{nm} (10^{-3} ε) ≈240 (≈8.6), ≈310 (≈5.2), and 355 (11.7); ^1H NMR (DMSO-d_6) δ=9.8 (br, 1H), 9.46 (br, 1H), 7.4 (s, 5H), 5.61 (s, 1H), 3.60 (s, 3H), and 3.42 (s, 3H). Found: C, 54.83; H, 4.53; N, 9.07%. Calcd for $C_{14}H_{14}N_2O_6$: C, 54.90; H,

4.60; N, 9.14%.

Dimethyl 3-Methylamino-4-nitro-3-phenyl-1-cyclobutene-1,2-dicarboxylate (12g): Mp 164—165 °C; IR ($CHCl_3$) 3180w, 1725s, 1630s, 1593s, 1572s, and 1366m cm^{-1}; UV (EtOH) λ_{nm} (10^{-3} ε) ≈240 (≈7.3) and 362 (12.0); ^1H NMR ($CDCl_3$) δ=10.92 (br, 1H), 7.40 (s, 5H), 5.50 (s, 1H), 3.75 (s, 3H), 3.55 (s, 3H), and 2.90 (d, J=6Hz, 3H). Found: C, 56.44; H, 4.87; N, 8.64%. Calcd for $C_{15}H_{16}N_2O_6$: C, 56.25; H, 5.03; N, 8.74%.

Dimethyl 3-Benzylamino-4-nitro-3-phenyl-1-cyclobutene-1,2-dicarboxylate (12h): Mp 114—115 °C; IR ($CHCl_3$) 3190w, 1724s, 1624m, 1590s, 1569s, and 1371s cm^{-1}; UV (EtOH) λ_{nm} (10^{-3} ε) ≈240 (≈7.8) and 362 (13.3); ^1H NMR ($CDCl_3$) δ=11.3 (br, 1H), 7.3 (m, 10H), 5.50 (s, 1H), 4.35 (d, J=6Hz, 2H), 3.75 (s, 3H), and 3.53 (s, 3H). Found: C, 63.39; H, 5.01; N, 7.07%. Calcd for $C_{21}H_{26}N_2O_6$: C, 63.62; H, 5.10; N, 7.07%.

Dimethyl 3-Anilino-4-nitro-3-phenyl-1-cyclobutene-1,2-dicarboxylate (12i): Mp 127—128 °C; IR ($CHCl_3$) 3190w, 1724s, 1625s, 1590s, 1569s, and 1371s cm^{-1}; UV (EtOH) λ_{nm} (10^{-3} ε) ≈231 (≈13.5), ≈310 (≈7.5), and 378 (16.0); ^1H NMR ($CDCl_3$) δ=12.25 (br, 1H), 7.3 (m, 10H), 5.50 (s, 1H), 3.80 (s, 3H), and 3.60 (s, 3H). Found: C, 62.72; H, 4.70; N, 7.12%. Calcd for $C_{20}H_{18}N_2O_6$: C, 62.81; H, 4.76; N, 7.33%.

Dimethyl 2-(1-Aminoethylidene)-3-(nitromethylene)-butanedioate (13a): Liquid; IR ($CHCl_3$) 3360w, 3272w, 3200w, 1720s, 1640m, 1614s, and 1355s cm^{-1}; UV (EtOH) λ_{nm} (10^{-3} ε) 340 (6.4); ^1H NMR ($CDCl_3$) δ=9.95 (br, 1H), 7.58 (br, 1H), 6.95 (s, 1H), 3.81 (s, 3H), 3.73 (s, 3H), and 2.22 (s, 3H). Found: C, 43.99; H, 4.87; N, 11.25%. Calcd for $C_9H_{12}N_2O_6$: C, 44.26; H, 4.95; N, 11.47%.

Dimethyl 3-Nitromethylene-2-(α-piperidinobenzylidene)-butanedioate (13j): Mp 167—168 °C; IR ($CHCl_3$) 1718s, 1618m, 1544s, and 1351s cm^{-1}; UV (EtOH) λ_{nm} (10^{-3} ε) ≈287 (≈8.2) and 404 (12.6); ^1H NMR ($CDCl_3$) δ=7.5 (m, 5H), 6.15 (s, 1H), 3.81 (s, 3H), 3.65 (s, 3H), 3.40 (m, 4H), and 2.88 (m, 6H). Found: C, 60.91; H, 5.93; N, 7.37%. Calcd for $C_{19}H_{22}N_2O_6$: C, 60.96; H, 5.92; N, 7.48%.

General Preparation of δ-Nitro Dienamino Diesters (13) by the Ring Opening Reaction of 12. A solution of **12** in toluene or xylene (10 times of **12**) was refluxed or stirred at 130 °C until **12** was consumed as revealed by TLC. The solvent was evaporated in vacuo, and the residue was recrystallized from CCl_4 or column chromatographed (silica-gel, CH_2Cl_2) to give **13** in 49—99% yields. The results are summarized in Table 3.

Dimethyl 2-[1-(Methylamino)ethylidene]-3-(nitromethylene)butanedioate (13b): IR ($CHCl_3$) 3150w, 1719m, 1608m, and 1363s cm^{-1}; UV (EtOH) λ_{nm} (10^{-3} ε) 322 (6.4); ^1H NMR ($CDCl_3$) δ=11.26 (br, 1H), 6.84 (s, 1H), 3.75 (s, 3H), 3.70 (s, 3H), 3.16 (d, J=6Hz, 3H), and 2.12 (s, 3H). Found: C, 46.23; H, 5.28; N, 10.85%. Calcd for $C_{10}H_{14}N_2O_6$: C, 46.51; H, 5.46; N, 10.84%.

Dimethyl 2-(1-Anilinoethylidene)-3-(nitromethylene)-butanedioate (13d): IR ($CHCl_3$) 3150w, 1721s, 1638m, 1605m, 1583s, and 1364s cm^{-1}; UV (EtOH) λ_{nm} (10^{-3} ε) 356 (6.6); ^1H NMR ($CDCl_3$) δ=12.49 (br, 1H), 7.4 (m, 5H), 6.98 (s, 1H), 3.80 (s, 3H), 3.75 (s, 3H), and 2.00 (s, 3H). Found: C, 56.24; H, 5.00; N, 8.80%. Calcd for $C_{15}H_{16}N_2O_6$: C, 56.25; H, 5.03; N, 8.84%.

Dimethyl 2-(α-Aminobenzylidene)-3-(nitromethylene)-butanedioate (13f): IR ($CHCl_3$) 3470w, 3280w, 3180w, 1725s, 1639m, 1601s, 1572m, and 1370s cm^{-1}; UV (EtOH) λ_{nm} (10^{-3} ε) ≈240 (≈8.6) and 350 (10.0); ^1H NMR ($CDCl_3$) δ=9.88 (br, 1H), 7.39 (m, 5H), 6.53 (s, 1H), 6.38 (br, 1H), 3.79 (s, 3H), and 3.58 (s, 3H). Found: C, 55.00; H, 4.61; N, 8.96%. Calcd for $C_{14}H_{14}N_2O_6$: C, 54.90; H, 4.60; N, 9.14%.

Dimethyl 2-[α-(Methylamino)benzylidene]-3-(nitromethylene)butanedioate (13g): IR ($CHCl_3$) 3150w, 1724s, 1639m, 1600s, and 1375s cm^{-1}; UV (EtOH) λ_{nm} (10^{-3} ε) 323 (6.6); ^1H NMR ($CDCl_3$) δ=10.95 (br, 1H), 7.30 (m, 5H), 6.50 (s, 1H), 3.78 (s, 3H), 3.68 (s, 3H), and 2.90 (d, J=5Hz, 3H). Found: C, 56.18; H, 5.05; N, 8.76%. Calcd for $C_{15}H_{16}N_2O_6$: C, 56.25; H, 5.03; N, 8.74%.

Dimethyl 2-[α-(Benzylamino)benzylidene]-3-(nitromethylene)butanedioate (13h): IR ($CHCl_3$) 3180w, 1725s, 1638m, 1592s, 1571m, and 1376s cm^{-1}; UV (EtOH) λ_{nm} (10^{-3} ε) 327 (6.1); ^1H NMR ($CDCl_3$) δ=11.19 (br, 1H), 7.3 (m, 10H), 6.50 (s, 1H), 4.33 (d, J=6Hz, 2H), 3.73 (s, 3H), and 3.63 (s, 3H). Found: C, 63.53; H, 5.01; N, 7.07%. Calcd for $C_{21}H_{20}N_2O_6$: C, 63.62; H, 5.10; N, 7.07%.

Dimethyl 2-(α-Anilinobenzylidene)-3-(nitromethylene)-butanedioate (13i): IR ($CHCl_3$) 3160w, 1725s, 1639m, 1595m, 1568s, and 1380s cm^{-1}; UV (EtOH) λ_{nm} (10^{-3} ε) ≈233 (≈12.8) and 378 (11.0); ^1H NMR ($CDCl_3$) δ=12.30 (br, 1H), 7.2 (m, 10H), 6.53 (s, 1H), 3.75 (s, 3H), and 3.55 (s, 3H). Found: C, 62.72; H, 4.73; N, 7.27%. Calcd for $C_{20}H_{18}N_2O_6$: C, 62.81; H, 4.76; N, 7.33%.

Liquid Crystal Materials with Sulfur Atoms Incorporated in the Principal Structure. VI. Optically Active New Smectic Liquid Crystal Compounds with 1,3-Oxathiane or 1,3-Dithiane Ring

Yuichiro HARAMOTO,* Yoko TOMITA, and Hiroyoshi KAMOGAWA
Department of Applied Chemistry, Yamanashi University, Takeda 4, Kofu 400
(Received May 16, 1986)

(+)-2-Methylbutyl *p*-(5-alkyl-1,3-oxathian-2-yl)benzoate and -cinnamate (**7**) were synthesized. The mesomorphic behavior of these compounds were measured. Though (+)-2-methylbutyl *p*-(5-alkyl-1,3-oxathian-2-yl)-benzoate did not exhibit any liquid-crystal phase, the corresponding 1,3-dithiane compounds (**8-1**, **8-2**, and **8-3**) and compound (**7-4**) having R' of a normal alkyl chain exhibited a smectic phase. This must originate in the wider molecular widths of compounds **7-1**, **7-2**, and **7-3**. Though cinnamate of compounds **7** and **8** exhibited an enantiotropic behavior, the corresponding benzoate did not. This must originate from an increase in the length of the conjugated system and the molecular length.

In recent years, 2,5-disubstituted 1,3-dithianes and 1,3-oxathianes have been reported as new types of liquid-crystal materials.[1-9]

In proportion to the increase in attention given to new types of liquid-crystal displays using ferroelectric liquid crystals, various optically active smectic liquid-crystal compounds have been synthesized. Thus, the basic structure of optically active new smectic liquid-crystal compounds with a 1,3-oxathiane (**7**) or a 1,3-dithiane ring (**8**) was synthesized.

This paper is related to this synthesis and the mesomorphic behavior of these compounds.

Results and Discussion

(+)-2-Methylbutyl *p*-(5-alkyl-1,3-oxathian-2-yl)benzoate and -cinnamate **7** and the corresponding 1,3-dithiane compounds **8** were synthesized via the following route.

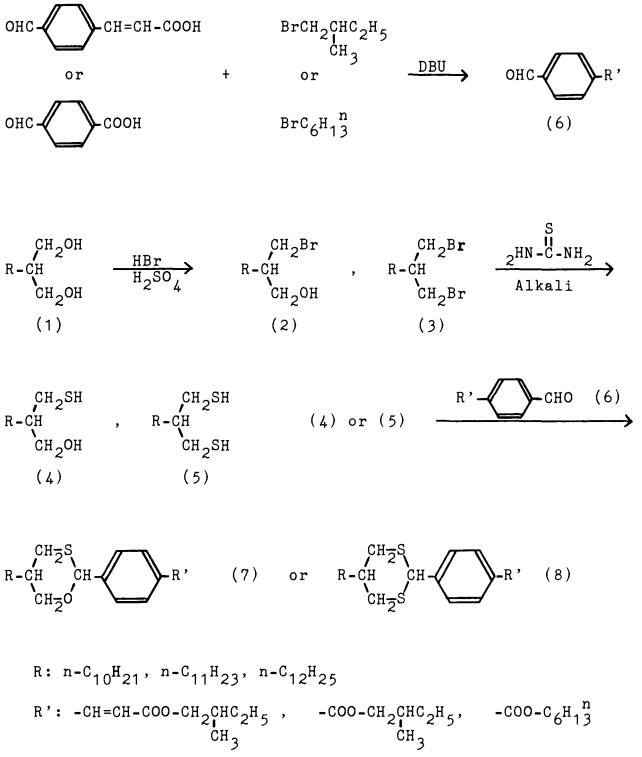

Fig. 1.

In step **1**→**2**, **3**, the reaction temperature was kept at between 80 and 85 °C so as to produce compounds **2** and **3** at nearly equal rates. A separation between **2** and **3** was not carried out. In step **2**, **3**→**4**, **5**, compounds **4** and **5** could be successfully separated by column chromatography. That is, compound **5** effused in a hexane fraction and **4** in an ether fraction. In steps **4**→**7** and **5**→**8**, cis and trans isomers were produced which differed at the C-5 position of the 1,3-oxathiane and 1,3-dithiane ring, respectively. Repeated recrystallizations (about five to seven times) were required to obtain purified trans isomers. Though for several compounds of **7** and **8**, trans isomers could not be separated by recrystallization, they were gained by using a separative TLC (hexane : ether=5 : 2). In the ^{1}H NMR data of 1,3-dithiane and 1,3-oxathiane compounds, C-2 proton signals of the 1,3-dithiane or 1,3-oxathiane ring for the trans isomer exhibited about 0.05 ppm with a different magnetic field than those for a cis isomer. For example, in compounds **8-1** and **7-4**, the trans isomer absorbs δ=5.2 (**8-1**) and 5.75 (**7-4**) but the cis isomer absorbs at δ=5.15 (**8-1**) and 5.80 (**7-4**), respectively. Therefore, the contamination of the cis isomers can be detected.

The angle of optical rotation was measured for compound **8-1** using a polarimeter; a value of +9.5° was obtained. This must mean that racemization did not occur in this reaction course.

A measurement of the mesomorphic ranges and assignment of the mesophases were carried out by means of a micro melting-point apparatus equipped with polarizers and a differential scanning calorimeter (DSC).

To determine the type of smectic phase, these smectic phases were compared with the color photographs found in the literature.[10]

A focal-conic fan texture of smectic A was observed.

Mesomorphic ranges of the synthesized 1,3-dithianes and 1,3-oxathianes are given in Table 1.

Compounds **7-1**, **7-2**, and **7-3** did not exhibit any

a) C: crystal; S: smectic; I: isotropic.

liquid-crystal phases. However, the corresponding 1,3-dithiane compounds (**8-1**, **8-2**, and **8-3**) exhibited a smectic phase. Also, compound **7-4** having a normal alkyl chain in substituent R′ exhibited a smectic phase. From these results, the main factor for the formation of the mesophase must be the molecular width; thus, compounds **7-1**, **7-2**, and **7-3**, having wider molecular widths, can not exhibit any mesophases. That is, the bend at the 1,3-oxathiane ring due to a difference in the atomic size between sulfur and oxygen and the side chain included in R′ increase the molecular width of compounds **7-1**, **7-2**, and **7-3**; this must weaken interactions among the molecules.

Though compounds **7-5**, **7-6**, **8-5**, and **8-6** exhibited an enantiotropic-type behavior, corresponding benzoate compounds (**7-1**, **7-2**, **8-1**, **8-2**) did not. The existence of the CH=CH part implies an increase in molecular length and the length of the conjugated system. These two factors must contribute to the appearance on the enantiotropic behavior.

The transition temperatures of isotropic to smectic for 1,3-oxathiane compounds (**7-5**, **7-6**) were lower than those for the corresponding 1,3-dithianes (**8-5**, **8-6**). Generally, in a smectic liquid crystal, the temperature of isotropic to smectic is affected by two factors: the molecular width and interactions of side substituents.[11] In this case, a wider molecular width caused by a bend at the oxathiane ring seems to be the cause.

All of compounds **7** and **8** exhibited supercooling states, especially **7-5** and **7-6** have a wide range.

$\Delta H_{C\text{-}I}$ of compounds **7-1**, **7-5**, **8-1**, and **8-5** are 24.64, 21.25, 23.78, and 26.07 kJ mol^{-1} and $\Delta S_{C\text{-}I}$ of them are 79.9, 68.99, 79.96, and 75.77 $JK^{-1}mol^{-1}$, respectively. These values are somewhat smaller than those of other common liquid-crystal materials.[12]

Experimental

IR, ^{1}H NMR, and mass spectra were obtained with a Hitachi 215 spectrophotometer, a JNM-PMX 60 spectrometer, and a Hitachi M-80B spectrometer, respectively. Elemental analyses were carried out with a Perkin-Elmer 250 instrument. Transition temperatures and mesomorphic phases were determined by means of both a Mitamura Riken micro melting-point aparatus equipped with polarizers and a Rigaku Denki DSC CN8059L1, CN8208A2. The rate of cooling was fixed to 1 °C min^{-1}.

Mixture of 2-Alkyl-3-bromo-1-propanol (2) and 2-Alkyl-1,3-dibromopropane (2). To a solution of 48% HBr (50 g) and concd H_2SO_4 (15 g) cooled in an ice bath were added, successively, compound **1** (0.1 mol) and concd H_2SO_4 (25 g). The solution was kept at 80—85 °C for 15 h. The reaction mixture was then poured into ice water (200 g), stirred and extracted twice with ether (each 400 ml). The extract was washed with cold 10% aq $NaHCO_3$ (100 ml), dried over anhyd Na_2SO_4, and concentrated on an evaporator at 30 °C. The residue was distilled in vacuo to afford a transparent liquid in a 50—60% yield.

2-Alkyl-3-mercapto-1-propanol (4) and 2-Alkyl-1,3-propanedithiol (5). To a solution of thiourea (0.2 mol) in triethylene glycol (15 ml) kept at 75 °C was added a mixture of compounds **2** and **3** in a nitrogen atmosphere, followed by stirring at 75 °C for 18 h. Tetraethylenepentamine (0.05 mol) was then added, and the mixture was stirred at 75 °C for 2 h under a nitrogen atmosphere. The reaction mixture was distilled in vacuo to afford a transparent liquid. The separation of compounds **4** and **5** was carried out by column chromatography (Wakogel C-300). Compounds **5** effused in a hexane fraction and **4** in an ether fraction. Compound **4** was a colorless transparent liquid and **5** was a yellow transparent liquid.

IR ($CHCl_3$) Compounds **4**: 3600 (OH), 2800—3000 (alkyl) cm^{-1}. Compounds **5**: 2800—3000 (alkyl).

^{1}H NMR ($CDCl_3$) Compounds **4**: δ=0.6—2.0 (m, R-CH, SH), 2.5—2.8 (m, 2H, CH_2S), 3.3—3.9 (m, 3H, CH_2OH). Compounds **5**: δ=0.6—2.0 (m, R-CH, SH), 2.5—2.9 (m, 4H, $-CH_2S$).

(+)-2-Methylbutyl *p*-Formylcinnamate (6-1). A solution of *p*-formylcinnamic acid (0.03 mol) and 1,8-diazabicyclo-[5.4.0] undec-7-ene (0.03 mol) and (+)-2-methylbutyl bromide (0.03 mol) in anhyd DMF (60 ml) was stirred at 80—90 °C for 18 h under a nitrogen atmosphere. The solution was poured into ice water and extracted twice with ether (each 200 ml). The extract was washed with cold 2% aq HCl, dried over anhyd Na_2SO_4, and evaporated in vacuo at 30 °C. The residue was dissolved in hexane (30 ml) and filtered. The filtrate was evaporated in vacuo at 40 °C. A transparent liquid was obtained in 70—80% yields.

IR ($CHCl_3$) 2800—3000 (alkyl), 2730 (CHO), 1680—1720 (C=O) cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=0.5—2.0 (m, 9H, OCH_2R''), 4.1 (d, 2H, OCH_2), 6.6 (d, 1H, =CH), 7.5—8.1 (q, 5H, CH=, ArH), 10.1 (s, 1H, CHO).

(+)-2-Methylbutyl *p*-Formylbenzoate (6-2). IR ($CHCl_3$) 2800—3000 (alkyl), 2730 (CHO), 1680—1720 (C=O) cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=0.6—2.1 (m, 9H, $OCH_2\underline{R}''$), 4.25 (d, 2H, OCH_2), 8.2 (q, 4H, ArH), 10.2 (s, 1H, CHO).

Hexyl *p*-Formylbenzoate (6-3). IR ($CHCl_3$) 2800—3000 (alkyl), 2730 (CHO), 1680—1720 (C=O) cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=0.7—2.1 (m, 11H, $OCH_2C_5\underline{H}_{11}$), 4.4 (t, 2H, OCH_2), 8.1 (q, 4H, ArH), 10.2 (s, 1H, CHO).

Alkyl *p*-(5-Alkyl-1,3-oxathian-2-yl)benzoate or -cinnamate (7). To a solution of compound **4** (0.04 mol) and *p*-substituted benzaldehyde **6** (0.04 mol) in anhyd $CHCl_3$ (200 ml) cooled in an ice bath were added $BF_3\cdot(C_2H_5)_2O$ (0.5 g) and molecular sieves (3A, 1/15; 3g). The mixture was stirred at 0—5 °C for 8h and then at 20 °C for 15h. The solution was first washed with 10% aq $NaHCO_3$ (400 ml), then with water (400 ml), dried over anhyd Na_2SO_4, and evaporated in vacuo at 40 °C. The crude product was purified by column chromatography and recrystallizations from hexane; then, several compounds which could not be isolated as trans isomers were subjected to separative TLC (hexane:ether= 5 : 2) to isolate trans isomers.

IR ($CHCl_3$) 2800—3000 (alkyl), 1710 (C=O), 1605 (Ar) cm^{-1}. ^{1}H NMR ($CDCl_3$).

(+)-2-Methylbutyl *p*-(5-Alkyl-1,3-oxathian-2-yl)benzoate. δ=0.7—2.1 (m, R-CH, OCH_2R''), 2.8 (d, 2H, CH_2S), 3.3, 4.3 (m, 2H, CH_2O), 4.2 (d, 2H, OCH_2R''), 5.75 (s, 1H, $\overset{S}{O}\!>\!CH$), 7.8 (q, 4H, ArH).

Hexyl *p*-(5-Undecyl-1,3-oxathian-2-yl)benzoate: δ=0.5—2.1 (m, 35H, R-CH, $OCH_2C_5H_{11}$), 2.8 (d, 2H, CH_2S), 3.3, 4.3 (m, 2H, CH_2O), 4.3 (t, 2H, $OC\underline{H}_2C_5H_{11}$), 5.75 (s, 1H, $\overset{S}{O}\!>\!CH$), 7.8 (q, 4H, ArH).

(+) 2-Methylbutyl *p*-(5-Alkyl-1,3-oxathian-2-yl)cinnamate: δ=0.5—2.2 (m, R-CH, OCH_2R''), 2.8 (d, 2H, CH_2S), 3.3, 4.2 (m, 4H, CH_2O), 5.7 (s, 1H, $\overset{S}{O}\!>\!CH$), 6.4 (d, 1H, =CH), 7.5 (s, 4H, ArH), 8.0 (d, 1H, CH=).

Alkyl *p*-(5-Alkyl-1,3-dithian-2-yl)benzoate or -cinnamate (8). Compounds **8** were synthesized according to the same ptocedure as that for compounds **7**.

IR ($CHCl_3$) 2800—3000 (alkyl), 1705 (C=O), 1600 (Ar) cm^{-1}. ^{1}H NMR ($CDCl_3$).

(+)-2-Methylbutyl *p*-(5-Alkyl-1,3-dithian-2-yl)benzoate: δ=0.5—2.1 (m, R-CH, $OCH_2\underline{R}''$), 2.6—2.9 (m, 4H, CH_2S), 4.2 (d, 2H, CH_2O), 5.2 (s, 1H, $\overset{S}{S}\!>\!CH$), 7.8 (q, 4H, ArH).

Hexyl *p*-(5-Dodecyl-1,3-dithian-2-yl)benzoate: δ=0.6—2.1 (m, 37H, R-CH, $OCH_2C_5\underline{H}_{11}$), 2.6—2.9 (d, 4H, CH_2S), 4.3 (t, 2H, CH_2O), 5.2 (s, 1H, $\overset{S}{S}\!>\!CH$), 7.8 (q, 4H, ArH).

(+)-2-Methylbutyl *p*-(5-Alkyl-1,3-dithian-2-yl)cinnamate: δ=0.5—2.2 (m, R-CH, OCH_2R''), 2.6—2.9 (m, 4H, CH_2S), 4.05 (d, 2H, OCH_2), 5.15 (s, 1H, $\overset{S}{S}\!>\!CH$), 6.4 (d, 1H, =CH), 7.5 (s, 4H, ArH), 8.05 (d, 1H, CH=).

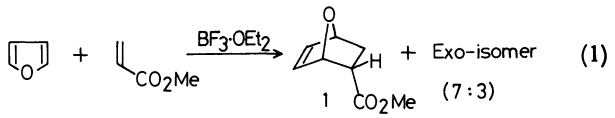
Synthetic Studies of Diels-Alder Adduct of Furan. Formal Total Synthesis of (±)-Avenaciolide

Hiyoshizo KOTSUKI,* Hiroyuki OHNISHI, Yasuhiro AKITOMO, Masamitsu OCHI
Department of Chemistry, Faculty of Science, Kochi University, Akebono-cho, Kochi 780
(Received May 30, 1986)

The *endo*-Diels-Alder adduct of furan with methyl acrylate was transformed into a bis-γ-lactone derivative which is a well-known precursor for the synthesis of (±)-avenaciolide. The route involves 13 steps and the overall yield was 17.9%.

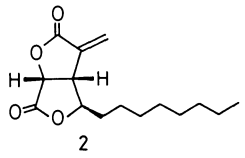
The 7-oxabicyclo[2.2.1]heptene derivatives, which can be prepared by Diels-Alder reaction of furan with appropriate dienophiles, are versatile precursors for the synthesis of various important natural products.[1] However, mainly due to the sluggish reactivity of furan itself, such derivatives have remained difficult to access.

Recently, we demonstrated a practical method for the preparation of the Diels-Alder adduct (**1**) between furan and methyl acrylate under $BF_3 \cdot OEt_2$-catalyzed conditions (Eq. 1).[2] Herein, we wish to report on the



(1)

stereoselective synthesis of the antifungal metabolite (±)-avenaciolide (**2**).[3] The strategy of the synthesis



2

relies on the advantageous structure of adduct (**1**) which has two of three stereocenters in the target system and the stereoselective iodolactonization for the preparation of the remaining one (Scheme 1).

The *endo*-ester (**1**) was transformed into the alcohol (**5**) via the triol (**4**) in 77.8% overall yield. Swern oxidation[4] of this alcohol under carefully controlled conditions gave cleanly aldehyde (**6**) without epimerization,[5] this was treated with Wittig reagent to give **7** as the sole product. The structure of the olefin was determined as having a cis-configuration by ^1H NMR measurement (J=11 Hz). Deprotection of acetonide, $NaIO_4$ cleavage, and Jones oxidation provided dicarboxylic acid (**9**). Since this product was rather unstable, presumably due to its sterically congested structure, the crude sample was used directly for the further experiment.

For the construction of the remained stereocenter we applied the well-known chemistry of iodolactonization.[6] Thus, by treatment with KI-I_2 **9** was smoothly converted into the iodo lactone carboxylic acid (**10**). The relative stereochemistry of this product could not be determined at this stage, but we expected the reaction to yield predominantly compound (**10**) with the

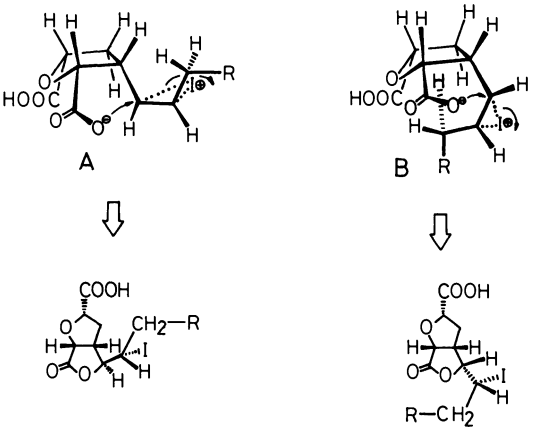

Fig. 1.

desired stereochemistry based on the consideration of molecular models. As illustrated in Fig. 1, there are two stereoselections for this cyclization process in which the ring closure should take a favored *5-Exo-Trig* path[7] and the nucleophile should cleave the iod-

onium ring by rear-side attack. When the reaction takes place through an intermediate **A**, the desired product will be obtained. While the intermediate **B** will give the undesired one which possesses an isoavenaciolide skeleton. The obvious relative steric comfort will favor the intermediate **A** over **B**. We recognized that this expectation is correct after completion of our work (vide infra).

In analogy with Masamune's earlier work,[8] bis-γ-lactone formation was performed by a 4-step process; decarboxylative acetylation with lead tetraacetate, deiodination with tributyltin hydride, hydrolysis of acetate, and Jones oxidation. Purification by silica-gel column chromatography gave the desired bis-γ-lactone (**13**) as a single product in 32.3% overall yield from **8** and the structure was confirmed by the comparison with an authentic sample.[9] This result means that as expected the iodolactonization proceeded in a desired fashion.[10] Introduction of the α-methylene group on **13** was reported previously,[3] so this work constitutes a formal total synthesis of (±)-avenaciolide.

By using optically pure starting material[11] it will be possible to synthesize avenaciolide in the natural form.

Experimental

General. All boiling and melting points are uncorrected. ^{1}H NMR spectra were obtained on a JEOL-MH-100 spectrometer using TMS as the internal standard. ^{13}C NMR spectra were obtained at 25.05 MHz on a JEOL-FX-100 spectrometer. The IR spectra were measured with a JASCO infrared spectrophotometer Model IRA-1 or A-302 and the high resolution mass spectra on a JEOL-HX-100 spectrometer.

TLC was conducted using Merck's precoated Kieselgel 60 F-254 plates (0.25 mm) and for column chromatography, Wakogel C-200 was employed.

Ether and THF were distilled from sodium benzophenone ketyl. Benzene was distilled from sodium metal. Dichloromethane, triethylamine and DMSO were distilled over CaH_2. Acetone was distilled once from CrO_3 and stored over molecular sieves 3A.

Reduction of 1: To a stirred suspension of 360 mg (9.5 mmol) of $LiAlH_4$ in 36 ml of dry Et_2O at 0 °C was added a solution of **1** (1.68 g, 11 mmol) in 12 ml of dry Et_2O. After being stirred at room temperature for 5 h, the reaction mixture was diluted with Et_2O (20 ml) and quenched at 0 °C by addition of a minimum amount of water. After drying with anhydrous $MgSO_4$ the mixture was filtered through Celite and the solid washed well with AcOEt. Evaporation of the solvent gave 1.38 g (100%) of almost pure alcohol (**3**).

3: TLC R_f=0.34 (Et_2O); Bp 110 °C/5 mmHg (1 mmHg =133.322 Pa; bath temperature); IR (neat) 3400 and 1035 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.64 (1H, dd, J=12, 4 Hz), 1.96 (1H, ddd, J=12, 9, 4.5 Hz), 2.2—2.6 (1H, m), 3.10 (1H, t, J=10 Hz), 3.4—3.7 (2H, m), 4.90, 4.98 (each 1H, dd, J=4.5, 1.5 Hz), 6.26, 6.37 (each 1H, dd, J=6, 1.5 Hz). Found: C, 66.47; H, 8.03%. Calcd for $C_7H_{10}O_2$: C, 66.64; H, 7.99%.

Formation of Triol (4) with OsO_4: To a solution of **3** (1.19 g, 9.4 mmol) in 35 ml of acetone and 9 ml of Et_2O were successively added 11.5 ml aqueous solution of OsO_4 (0.055 mmol) and 3.8 ml of 30% H_2O_2 at 0 °C and the resulting brownish solution was stirred at room temperature overnight. At the end of the reaction the solution color disappeared. After evaporation of the solvent, finally azeotropically with toluene, the residue was purified by silica-gel column chromatography, elution with AcOEt–MeOH (9 : 1), and recrystallized from AcOEt–MeOH to give 1.22 g (80.7%) of triol (**4**) as colorless needles.

4: TLC R_f=0.34 (AcOEt–MeOH, 9:1); Mp 101.0—101.5 °C; IR (nujol) 3400 and 1075 cm^{-1}; ^{1}H NMR (DMSO-d^6–$CDCl_3$) δ=0.93 (1H, dd, J=12.5, 5 Hz), 1.82 (1H, ddd, J=12.5, 12, 6 Hz), 2.0—2.4 (1H, br m), 2.7 (1H, br), 3.3—4.0 (4H, m), 4.0—4.4 (4H, m). Found: C, 52.47; H, 7.59%. Calcd for $C_7H_{12}O_4$: C, 52.49; H, 7.55%.

Formation of Acetonide (5): A mixture of **4** (1.22 g, 7.63 mmol) and 2,2-dimethoxypropane (5.6 ml) in 2.4 ml of dry MeOH containing a catalytic amount of pyridinium *p*-toluenesulfonate was stirred at room temperature overnight. After evaporation of most of the organic solvent the residue was poured into CH_2Cl_2 and washed successively with water, satd $NaHCO_3$, and satd NaCl, dried with $MgSO_4$, and evaporated. Recrystallization from hexane–Et_2O gave 1.47 g (96.4 %) of the acetonide (**5**).

5: TLC R_f=0.63 (AcOEt–MeOH, 9 : 1); Mp 104.5—107 °C; IR (nujol) 3460 and 1055 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.89 (1H, dd, J=12.5, 5.5 Hz), 1.29, 1.48 (each 3H, s), 1.89 (1H, ddd, J=12.5, 12, 6 Hz), 2.1—2.5 (1H, m), 2.6 (1H, br), 3.51 (1H, dd, J=11, 8.5 Hz), 3.72 (1H, dd, J=11, 7 Hz), 4.15 (1H, d, J=6 Hz), 4.33 (1H, d, J=2 Hz), 4.39 (1H, br s), 4.55 (1H, d, J=6 Hz). Found: C, 59.76; H, 7.97%. Calcd for $C_{10}H_{16}O_4$: C, 59.98; H, 8.05%.

Swern Oxidation of the Alcohol (5): To a stirred suspension of 0.39 ml (4.5 mmol) of oxalyl dichloride in 7 ml of dry CH_2Cl_2 at −78 °C was added 0.64 ml (9.0 mmol) of dry DMSO. After being stirred at −78 °C for 10 min, to the suspension was added a solution of **5** (500 mg, 2.5 mmol) in 3 ml of dry CH_2Cl_2 at the same temperature. After being stirred at −78 °C for 1 h,[12] to the reaction mixture was added 2.44 ml (17.5 mmol) of dry Et_3N. The reaction mixture was diluted with 120 ml of AcOEt and quickly washed with cold satd $NaHCO_3$ and satd NaCl, dried with $MgSO_4$, and evaporated. The crude product was purified by silica-gel column chromatography and elution with hexane–AcOEt (1 : 2), to give 395 mg (80%) of pure aldehyde (**6**) as colorless crystals.

6: TLC R_f=0.25 (Et_2O); Mp 93—94.5 °C (from hexane–acetone); IR (nujol) 1710, 1210, and 1065 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.26, 1.46 (each 3H, s), 1.71—1.88 (2H, m), 3.08 (1H, m), 4.19 (2H, s), 4.45 (1H, dd, J=4, 2 Hz), 4.69 (1H, dd, J=6, 1.5 Hz), 9.17 (1H, d, J=1.5 Hz); MS (30 eV) m/z (rel intensity) 183 (M^+-CH_3, 100), 111 (8), 95 (3), 83 (31), 66 (20), 59 (22), 55 (7), 43 (27). Found: m/z 198.0871. Calcd for $C_{10}H_{14}O_4$: M, m/z 198.0892.

Wittig Reaction of the Aldehyde (6): To 22 ml of dry THF solution of Ph_3P^+n-$C_8H_{17}Br^-$ (4.1 g, 9.0 mmol)[13] was added 4.9 ml (8.0 mmol) of butyllithium at 0 °C under N_2 and the resultant reddish solution was stirred at room temperature for 1 h. To this solution 395 mg (2.0 mmol) of **6** in 4.4 ml of dry THF was introduced at −20 °C by using cannula and the mixture was stirred at room temperature overnight under N_2. After quenching by careful addition of satd NaCl at 0 °C, the insoluble substance which formed was filtered through Celite and washed with AcOEt. After evaporation of most of the organic solvent, the residue was

extracted with AcOEt. The combined extracts were washed with satd NaCl, dried with $MgSO_4$, and evaporated. The crude product was purified by silica-gel column chromatography, elution with hexane-AcOEt (9:1), to give 586 mg (100%) of **7** as a colorless oil.

7: TLC R_f=0.18 (hexane-AcOEt, 9:1); IR (neat) 1455, 1370, 1210, and 1070 cm^{-1}; ^1H NMR (CCl_4) δ=0.90 (3H, t, J=6 Hz), 1.18, 1.37 (each 3H, s), 1.31 (10H, br s), 2.2—1.6 (4H, m), 2.83 (1H, m), 4.04, 4.08 (each 1H, d, J=3 Hz), 4.21, 4.33 (each 1H, d, J=6 Hz), 5.09 (1H, dd, J=11, 9.5 Hz), 5.43 (1H, dt, J=11, 7.5 Hz).

Formation of Diol (8): A mixture of **7** (610 mg, 2.07 mmol) and 8.7 ml of 2M HCl (1M=1 mol dm^{-3}) in 8.7 ml of MeOH was refluxed overnight under N_2. After evaporation of MeOH, the aqueous layer was extracted with AcOEt. The combined extracts were washed with satd $NaHCO_3$ and satd NaCl, dried with $MgSO_4$, and evaporated. Recrystallization from hexane-AcOEt gave 470 mg (89.2%) of diol (**8**).

8: TLC R_f=0.63 (AcOEt); Mp 77.5—78.5 °C; IR (nujol) 3400, 1460, 1205, 1080, 990, and 910 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.88 (3H, t, J=6 Hz), 1.27 (10H, br s), 1.6—2.2 (4H, m), 2.93 (1H, m), 3.2—3.6 (2H, m), 3.7—3.9 (1H, m), 4.0—4.2 (1H, m), 4.18, 4.33 (each 1H, d, J=6 Hz), 5.08 (1H, dd, J=10, 8 Hz), 5.50 (1H, dt, J=10, 8 Hz). Found: C, 70.90; H, 10.31%. Calcd for $C_{15}H_{26}O_3$: C, 70.83; H, 10.30%.

Formation of Dicarboxylic Acid (9): To a stirred solution of 660 mg (2.6 mmol) of **8** in 12 ml of THF was added at 0 °C 830 mg (3.88 mmol) of $NaIO_4$ in 3.5 ml of water. The resulting white creamy mixture was stirred at room temperature overnight. After evaporation of THF, the aqueous layer was saturated with NaCl and extracted with AcOEt. The combined extracts were washed with satd NaCl, dried with $MgSO_4$, and evaporated to give 700 mg of product: TLC R_f=0.33 ($CHCl_3$-AcOEt, 1:1).[14]

The product so obtained was dissolved in 15 ml of acetone and to this solution was added at −20 °C 5.2 ml of Jones reagent (1.25 M) and the mixture stirred at 0 °C for 20 min. After quenching by addition of MeOH, the mixture was diluted with 6M H_2SO_4. After evaporation of most of the organic solvent, the aqueous layer was extracted with AcOEt. The combined extracts were washed with satd NaCl, dried with $MgSO_4$, and evaporated to give 700 mg (94.9% crude overall yield from **8**) of dicarboxylic acid (**9**) as an oil: IR (neat) 3400—2800, 1730, 1365, and 1230 cm^{-1}. This sample was sufficiently pure judging from its TLC and ^1H NMR result and was used immediately for the next reaction.[15]

Formation of Iodo Lactone Acetate (11): To a stirred solution of 700 mg (2.47 mmol) of **9** in 30 ml of THF were successively added 2 ml aqueous solution of $NaHCO_3$ (2.07 g) and 4 ml aqueous solution of KI (2.05 g) and I_2 (1.81 g). Then the resulting black solution was stirred at room temperature overnight. After quenching the excess of I_2 by addition of aq $Na_2S_2O_3$ solution and evaporation of THF, the aqueous phase was saturated with NaCl and extracted thoroughly with AcOEt. The combined extracts were washed with satd NaCl, dried with $MgSO_4$, and evaporated to give 948 mg of iodo lactone carboxylic acid (**10**): IR (neat) 1785 and 1740 cm^{-1}.

The product (175 mg, 0.43 mmol) so obtained was dried azeotropically with toluene, and then dissolved in 4 ml of dry C_6H_6 and treated with 210 mg (0.47 mmol) of freshly recrystallized $Pb(OAc)_4$ under reflux for 2 h. After cooling the mixture was filtered through Celite and washed well with Et_2O. Evaporation of the solvent gave another crop of precipitate. From the Et_2O soluble fraction 190 mg of iodo lactone acetate (**11**) was obtained as almost 1:1 mixture of acetate.

11: R_f=0.60 (Et_2O); IR (neat) 1790, 1750, and 1230 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.90 (3H, t, J=6 Hz), 1.31 (12H, br s), 1.95, 2.01 (total 3H, each s), 1.8—2.6 (3H, m), 2.8—3.2 (1H, m), 4.15 (1H, m), 4.75, 4.87 (total 1H, each d, J=8 Hz), 6.34 (1H, d, J=8 Hz). Found: m/z 424.0733. Calcd for $C_{16}H_{25}O_5I$: M, m/z 424.0747.

Fomation of Bis-γ-Lactone (13): A mixture of 190 mg of **11**, 0.15 ml of n-Bu_3SnH, and a catalytic amount of α,α′-azobisisobutyronitrile in 4 ml of dry C_6H_6 was refluxed under N_2 for 20 h. Evaporation of the solvent gave 230 mg of crude product (**12**). This sample was used for the next reaction without further purification. In a separate experiment **12** was prepared in 43.3% overall yield from **8** as crystalline solid after purification by silica-gel column chromatography (elution with Et_2O).

12: R_f=0.48 and 0.44 (Et_2O); Mp 131—134 °C (from hexane-Et_2O); IR ($CHCl_3$) 1785, 1240, and 1185 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.90 (3H, t, J=6 Hz), 1.31 (12H, br s), 1.98, 2.04 (total 3H, each s), 1.8—2.6 (3H, m), 2.8—3.3 (1H, m), 4.2 (1H, m), 4.85, 4.97 (total 1H, each d, J=8 Hz), 5.75 (0.4H, m), 6.48 (0.6H, d, J=5 Hz). Found: m/z 255.1617. Calcd for $C_{16}H_{26}O_5$-$COCH_3$: M, m/z 255.1596.

The crude product so obtained was dissolved in 3 ml of MeOH and then treated with 0.8 ml aqueous solution of K_2CO_3 (270 mg). After stirring for 4 h, the mixture was acidified with 2M HCl and extracted with Et_2O. After evaporation of the solvent, the residue was dissolved in 3 ml of acetone and to this solution at 0 °C Jones reagent was added until the solution showed an orange color. After being stirred for 20 min at 0 °C, the excess reagent was decomposed with MeOH and the mixture extracted with AcOEt. The combined extracts were washed with water and satd NaCl, dried with $MgSO_4$, and evaporated to give the crude product. Purification by silica-gel column chromatography, elution with hexane-Et_2O (1:1), afforded 40 mg (32.3% overall yield from **8**) of **13** as a colorless oil.

13: R_f=0.43 (Et_2O); IR (neat) 1790, 1460, 1240, 1210, 1140, 1070, and 970 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.89 (3H, t, J=6 Hz), 1.29 (12H, br s), 1.71 (2H, m), 2.4—3.2 (3H, m), 4.25—4.45 (1H, m), 5.00 (1H, d, J=7.5 Hz); ^{13}C NMR ($CDCl_3$) δ=14.0, 22.7, 25.0, 29.1 (×2), 29.3, 31.8, 32.8, 35.5, 40.2, 77.1, 85.0, 170.0, 173.8. Found: m/z 254.1493. Calcd for $C_{14}H_{22}O_4$: M, m/z 254.1518.

All these spectral data were in good agreement with those reported in the literature.[3,9]

The authors are grateful to Professor Takashi Tokoroyama of Osaka City University for his helpful suggestions. We are indebted to Dr. Takashi Sakai of Okayama University for spectral data of (±)-avenaciolide and bis-γ-lactone (**13**), and we also thank Dr. Ayumi Ohsaki of Kinki University for performing the high-resolution mass spectra measurements.

10) Although we could not detect an isomer in the reaction mixture of **13**, the possibility of the formation of this one, which would be derived from the intermediate **B** as shown in Fig. 1, can not be excluded completely. Unfortunately, however, at no stage we could clarify this problem because of the complexity of the ^{1}H NMR spectra. So the conclusion relies on the result of the last stage composition.

11) Optical resolution of the corresponding carboxylic acid is reported: see Ref. 1c.

12) When Et_3N was introduced after 30 min stirring, exclusive formation of the *exo*-aldehyde was observed. Data for *exo*-isomer: Mp 61—63 °C (from hexane-acetone); IR (nujol) 1725, 1215, 1165, 1095, 1075, and 1055 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.28, 1.47 (each 3H, s), 1.39—1.62 (1H, m), 2.05 (1H, ddd, J=13.5, 6, 4.5 Hz), 2.31 (1H, ddd, δ=9, 4.5, 2 Hz), 4.19 (2H, s), 4.49 (1H, d, J=6 Hz), 4.62 (1H, s), 9.57 (1H, d, J=2 Hz). Found: m/z 198.0896.

13) This reagent was prepared by refluxing 1-bromooctane with triphenylphosphine in dry C_6H_6 and washed well with C_6H_6. The product was a highly viscous oil. It was hard to purify, so was used as obtained.

14) This compound would exist in the hydrated form from ^{1}H NMR measurement.

15) The use of stored or chromatographed samples gave poor results.

Syntheses of (−)-8-*epi*-Swainsonine and (−)-1,8-Di-*epi*-swainsonine, Stereoisomers of Physiologically Interesting Indolizidine Alkaloid, Swainsonine

Kin-ichi TADANO,* Youichi IIMURA, Yukinori HOTTA, Chiyoko FUKABORI, and Tetsuo SUAMI*
Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223
(Received June 10, 1986)

Two stereoisomers of the indolizidine alkaloid swainsonine, (−)-8-*epi*-swainsonine (**2**) and (−)-1,8-di-*epi*-swainsonine (**3**), have been synthesized from the known methyl 3-acetamido-2-*O*-acetyl-4,6-*O*-benzylidene-3-deoxy-α-D-glucopyranoside and methyl 3-acetamido-2-*O*-acetyl-3-deoxy-4,6-di-*O*-mesyl-α-D-glucopyranoside (**14**), respectively. The key pyrrolidine ring formation was achieved by intramolecular cyclization of a 6-*O*-tosyl derivative or a di-*O*-mesyl derivative **14** efficiently. The α-mannosidase inhibitory activity of the synthetic **2** and **3** was also evaluated.

(−)-Swainsonine (**1**), (1*S*, 2*R*, 8*R*, 8a*R*)-octahydro-1,2,8-indolizinetriol, is one of the indolizidine alkaloids isolated from *Swainsona canescens*,[1] *Astragalus lentiginosus*,[2] *Rhizoctonia leguminicola*,[3] and *Metarhizium anisopline*[4] (Fig. 1). The structure of **1** was established by chemical and spectral means,[1,3] and the rarely known trihydroxylated octahydroindolizine structure of **1** prompted us to achieve the total synthesis. We have completed the total synthesis of **1** in the natural form from 3-amino-3-deoxy-D-mannose derivative.[5] The total synthesis of **1** has also been achieved by Richardson et al.,[6] Fleet et al.,[7] Takaya et al.,[8] Sharpless et al.,[9] and Hashimoto et al.[10] Meanwhile, the alkaloid **1** was found to exhibit a remarkable physiological effects such as an α-mannosidase inhibitory activity[3] and an immunoregulating activity.[4,11] In order to elucidate a relationship between structure and physiological activity, the synthesis of stereoisomers of **1** is another interesting problem.[12] Recently, we have finished the syntheses of 8-*epi*-swainsonine **2** and 1,8-di-*epi*-swainsonine **3** from readily available 3-amino-3-deoxy-D-glucose derivatives.[13] Herein, we wish to describe details of these syntheses, and the α-mannosidase inhibitory activity of **2** and **3** is also reported.

Fig. 1.

Results and Discussion

The synthesis of **2** was commenced with the known methyl 3-acetamido-2-*O*-acetyl-4,6-*O*-benzylidene-3-deoxy-α-D-glucopyranoside (**4**)[14] (Fig. 2). The compound **4** possesses all the chiral centers in **2** with correct configurations (the configurations at C-2, 3, 4, and 5 in **4** are corresponding to C-8, 8a, 1, and 2 in **2**, respectively). Hydrolysis of **4** in 50% aqueous acetic acid under reflux, and successive preferential *O*-tosylation of the primary hydroxyl group provided a compound **5** in 83% yield. Intramolecular *N*-alkylation at *N*-3 in **5** (a pyrrolidine ring formation) was achieved smoothly by treatment of **5** with sodium hydride in DMF at 100 °C, and the product was acetylated in the usual manner to afford a bicyclic compound, methyl 2,4-di-*O*-acetyl-3,6-acetylimino-3,6-dideoxy-α-D-glucopyranoside (**6**) in 68% yield. *O*-Deacetylation of **6** with sodium methoxide in methanol, dithioacetal formation with ethanethiol in concd HCl, and successive *O*-benzylation of the diethyl dithioacetal with benzyl bromide in the presence of sodium hydride, furnished a trisubstituted pyrrolidine (**7**) in 59% yield. A two-carbon elongation of **7** for construction of the octahydroindolizine skeleton was accomplished as follows. Dethioacetalization of **7** with mercury(II) chloride in aqueous acetonitrile followed by the Horner-Emmons olefination of the resulting aldehyde with diethyl ethoxycarbonylmethylphosphonate in the presence of sodium hydride provided an (*E*)-α,β-unsaturated ester (**8**) in 82% yield. The (*E*) geometry of the double bond in **8** was established by the ^{1}H NMR spectrum, in which the α-vinyl proton of the α,β-unsaturated ester appeared at δ 6.10 as a double-doublet with J=2 and 15 Hz. No (*Z*)-isomer was detected in the reaction mixture. In the ^{1}H NMR spectrum of **8**, two singlets with totally three protons appeared at δ 1.95 and 2.10 (approximately 3 to 1 ratio) and these signals are attributable to methyl protons of the *N*-acetyl group. This spectral phenomenon is explained by the exsistence of both endo and exo stereoisomers on the trisubstituted nitrogen atom. Some of other trisubstituted pyrrolidine derivatives exhibited the same property in the ^{1}H NMR spectra (see the spectral data of each compound in the Experimental). Catalytic hydrogenation of **8** in the presence of Raney nickel T-4 in ethanol gave a saturated ester (**9**) in 86% yield. Intramolecular cyclization (δ-lactam formation) of the compound **9** to an octahydro-5-indolizinone (**10**) was best accomplished by heating **9** in a mixture of 15 mol dm^{-3} aqueous KOH and ethanol at 120 °C (sealed tube) for 14 d. Under these conditions, the compound **10** was obtained in 40% yield along with an uncyclized carboxylic acid (**11**) in 51% yield. Although a pro-

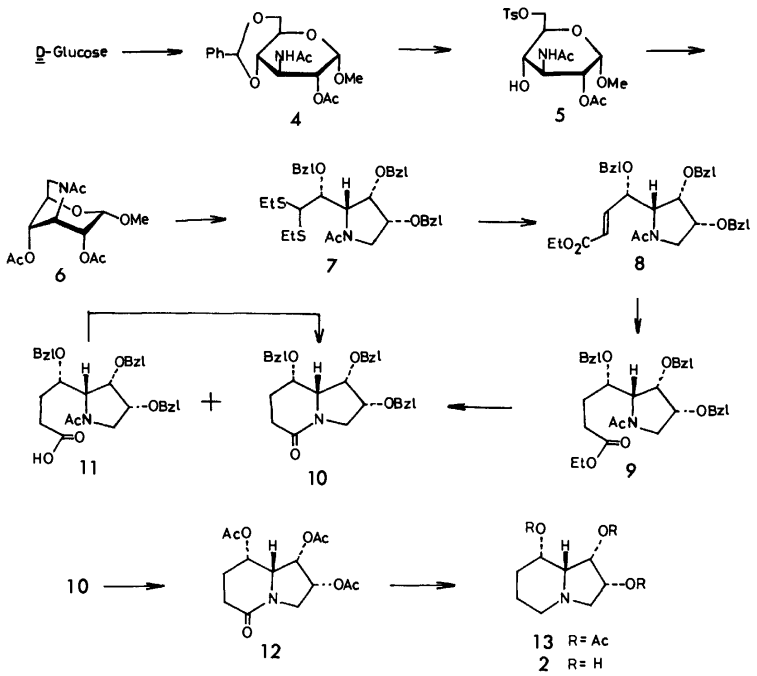

Fig. 2.

longed heating of **9** in the basic solution decreased the yield **10**, the isolated carboxylic acid **11** was converted to **10** in 43% yield by the same conditions. Reduction of the compound **10** to the corresponding octahydroindolizine was a troublesome step. In the case of swainsonine synthesis,[5] the corresponding octahydro-5-indolizinone derivative was smoothly converted to tribenzyloxyswainsonine by lithium aluminium hydride reduction in a high yield. On the contrary, lithium aluminium hydride reduction of **10** in THF gave a complex mixture. The other conditions (BH_3-THF and $NaBH_4$-pyridine-reflux) gave the same disappointing results. We have no rational explanation for this complex reaction. Next, reduction of the *O*-acetyl derivative (**12**) was examined. The compound **12** was prepared by *O*-debenzylation of **10** with cyclohexene in refluxing ethanol in the presence of 20% $Pd(OH)_2$ on charcoal[15] followed by acetylation in 84% yield. Reduction of **12** with borane-dimethyl sulfide complex in THF followed by aqueous $NaHCO_3$ treatment provided 8-*epi*-swainsonine triacetate (**13**) in 64% yield. To convert an intermediate amine-borane complex to **13**, the work-up with $NaHCO_3$ solution was necessary. Deprotection of **13** with K_2CO_3 in methanol, the same conditions employed for *O*-deacetylation of swainsonine triacetate,[5] gave an uncharacterized complex mixture. On the contrary, hydrolysis of **13** in refluxing 1 mol dm^{-3} aqueous HCl followed by deionization with Amberlite IRA-400 (OH^-) afforded 8-*epi*-swainsonine **2** as crystals in 86% yield. The synthetic **2** was fully characterized by the correlation of the ^1H and ^{13}C NMR spectra with those of swainsonine **1**. The optical rotation value of **2** ($[\alpha]_D^{21}=-24.8°$) was somewhat different from the reported value ($[\alpha]_D^{21}=-3.4°$).[12] The $[\alpha]_D^{21}$ of our synthetic compound was determined with a pure crystalline sample, while the reported value[12] was taken with a syrupy compound. Therefore, we believe that our measurement gave the correct $[\alpha]_D^{21}$ value of the compound **2**.

The synthesis of the other stereoisomer **3** was started from the known methyl 3-acetamido-2-*O*-acetyl-3-deoxy-4,6-di-*O*-mesyl-α-D-glucopyranoside (**14**)[16] (Fig. 3). Solvolysis of the compound **14** in refluxing 90% aqueous 2-methoxyethanol in the presence of sodium acetate followed by acetylation, according to the literature,[16] furnished methyl 2,4-di-*O*-acetyl-3,6-acetylimino-3,6-dideoxy-α-D-galactopyranoside (**15**, 68%) accompanied by methyl 3-acetamido-2,4,6-tri-*O*-acetyl-3-deoxy-α-D-galactopyranoside (**16**, 27%), which was readily separated by silica-gel chromatography. In contrast to our result, Guthrie and Mutter[16] did not show the isolation of the 3,6-imino compound **15** in their literature. After acetolysis of the solvolytic product, *O*-deacetylation and successive acid hydrolysis, they isolated 3-amino-3-deoxy-D-galactose hydrochloride as a sole product (no yield was given). In our opinions, they would miss accidentally the presence of the compound **15** in the reaction mixture. The D-galacto configuration of **16** was confirmed in the following way. Hydrolysis of **16** in refluxing 2 mol dm^{-3} HCl followed by acetylation gave an anomeric mixture of 3-acetamido-1,2,4,6-tetra-*O*-acetyl-3-deoxy-α-D-galactopyranose (**17**-α) and (**17**-β), which were readily separated by silica-gel chromatography (**17**-α, 41%; **17**-β, 43%). The α-anomer **17**-α was the known compound,[17] and the melting point and $[\alpha]_D$ value of **17**-α were in accordance with the reported ones. The 3,6-imino structure of the bicyclic compound **15** pos-

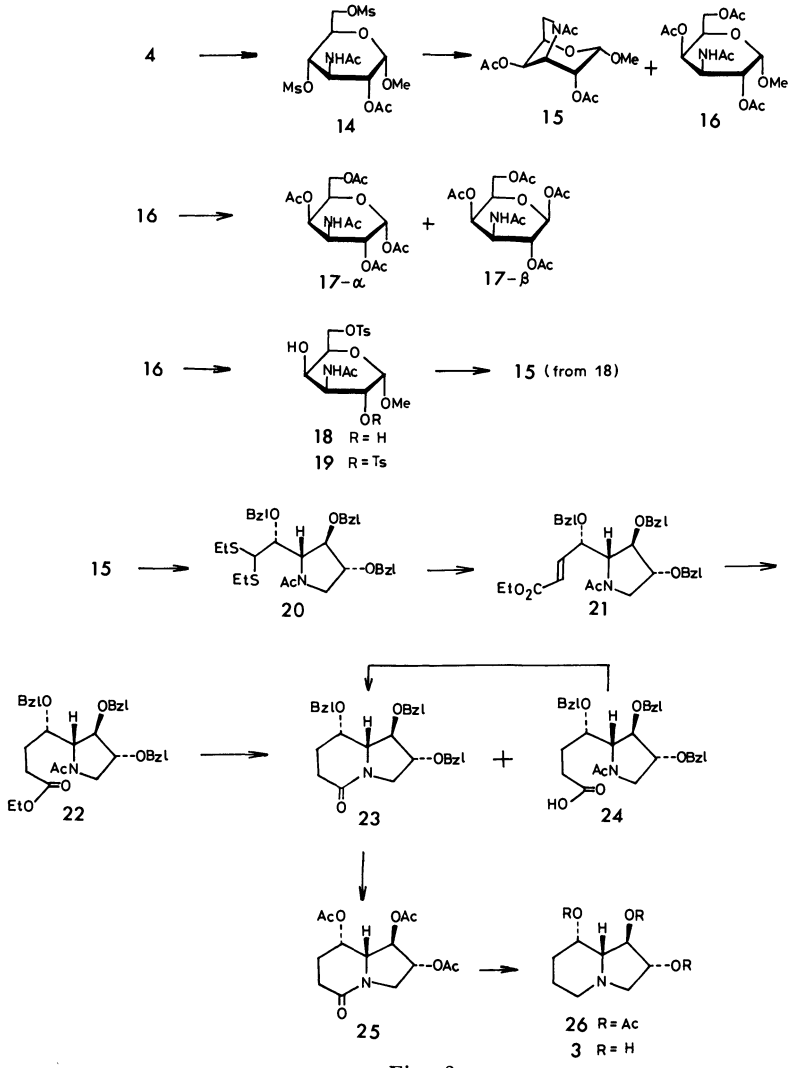

Fig. 3.

sessing D-galacto configuration was established as follows. *O*-Deacetylation of **16** with sodium methoxide in methanol and preferential *O*-tosylation of the primary hydroxyl group in the 2,4,6-triol afforded a 6-*O*-tosyl derivative (**18**) in 32% yield [a 2,6-di-*O*-tosyl derivative (**19**, 12% yield) was accompanied, and 28% of the 2,4,6-triol was recovered]. Treatment of the compound **18** with sodium hydride in DMF at 100 °C for 3,6-imino formation and successive acetylation provided the compound **15** in 56% yield as a sole product. The compound **15** is equipped with the correct configuration of all chiral centers in **3**, and the route from **15** to **3** was virtually the same as in the synthesis of **2** from **6**. *O*-Deacetylation of the compound **15** with sodium methoxide in methanol, diethyl dithioacetal formation with ethanethiol in concd HCl and successive *O*-benzylation afforded a trisubstituted pyrrolidine (**20**) in 56% yield. Dethioacetalization of **20** with mercury(II) chloride in aqueous acetonitrile followed by Horner-Emmons reaction of the aldehyde with diethyl ethoxycarbonylmethylphosphonate gave an (*E*)-α,β-unsaturated ester (**21**) as a sole product in 52% yield. Hydrogenation of **21** in the presence of Raney nickel T-4 provided a saturated ester (**22**) in 86% yield. Intramolecular cyclization of **22** by the treatment with a mixture of 15 mol dm^{-3} aqueous KOH and ethanol in a sealed tube at 120 °C for 10 d furnished a compound (**23**, 34%) and an uncyclized carboxylic acid (**24**, 62%). The compound **24** was converted to **23** in 75% yield by the same base treatment. *O*-Debenzylation of **23** by the Hanessian's condition[15] and successive acetylation afforded compound (**25**) in 83% yield. Reduction of **25** with borane-dimethyl sulfide complex, aqueous $NaHCO_3$ treatment and successive acetylation gave 1,8-di-*epi*-swainsonine triacetate (**26**) in 67% yield. Finally, deprotection of **26** with potassium carbonate in methanol afforded 1,8-di-*epi*-swainsonine **3** in 98% yield. In this case, methanolysis of the *O*-acetyl groups proceeded cleanly under the basic conditions. This newly synthesized compound **3** was fully characterized by the spectral methods (^{13}C and ^{1}H NMR spectra).

The α-mannosidase inhibitory effect of the compounds **2** and **3** was examined at pH 4. Under the conditions, in which swainsonine **1** exhibits a 92%

inhibition, the compounds **2** and **3** exhibit 15 and 20% inhibition, respectively. So the inhibitory effect of **2** and **3** against the enzyme is approximately one-fifth of that of swainsonine.

Experimental

General. Evaporations were performed under diminished pressure at below 40 °C (bath). Melting points were determined with a Mitamura Riken micro apparatus and are uncorrected. Specific rotations were measured in a 1-dm tube with a Jasco DIP-4 polarimeter. Column chromatography was performed on Kieselgel 60 (Merck), and TLC was performed on Kieselgel 60 GF_{254} (Merck) with detection by UV light and charring with sulfuric acid. Preparative TLC was performed on Kieselgel 60 PF_{254} (Merck). IR spectra were recorded with Hitachi Model 225 (KBr) and Jasco A-202 ($CHCl_3$) spectrometers. ^1H NMR spectra were recorded with a Varian EM-390 spectrometer for solutions in $CDCl_3$ (internal standard Me_4Si). ^{13}C NMR spectra were recorded with a JEOL FX-200 spectrometer for solutions in CD_3OD (internal standard Me_4Si). High resolution mass spectra were obtained using a Hitachi M-80 mass spectrometer. Elemental analyses were performed by Mr. Saburo Nakada to whom our thanks are due.

Methyl 3-Acetamido-2-*O*-acetyl-3-deoxy-6-*O*-tosyl-α-D-glucopyranoside (5). A suspension of methyl 3-acetamido-2-*O*-acetyl-4,6-*O*-benzylidene-3-deoxy-α-D-glucopyranoside (**4**)[14] (10.20 g, 27.9 mmol) in 50% aqueous acetic acid (250 ml) was heated under reflux for 30 min and evaporated. The residue was dissolved in water (400 ml) and the aqueous solution was washed with ethyl acetate (300 ml). After evaporation of the aqueous layer, the residual white solid was dissolved in pyridine (70 ml). To the solution was added *p*-toluenesulfonyl chloride (10.66 g, 55.9 mmol), and the mixture was stirred at 0 °C for 18 h. After evaporation of the mixture, the residue was partitioned between chloroform (200 ml) and water (200 ml). The aqueous layer was extracted with chloroform (200 ml×2), and the combined extracts were dried (Na_2SO_4). After evaporation of the extracts, the residue was chromatographed on SiO_2 (300 g, ethanol: toluene=1 : 20). Fractions corresponding to R_f 0.58 (ethanol: toluene=1 : 3) were evaporated to afford **5** (9.93 g, 83%) as a colorless foam, $[\alpha]_D^{24}$+88.7° (*c* 1.10, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 3010, 1740, 1660, 1520, 1370 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.97 (3H, s, $NCOCH_3$), 2.10 (3H, s, $OCOCH_3$), 2.47 (3H, s, $OSO_2C_6H_4C\underline{H}_3$), 3.36 (3H, s, OCH_3), 3.40—5.00 (8H, m, H-1, 2, 3, 4, 5, 6, 6′, OH), 6.60 (1H, d, *J*=8 Hz, NH), 7.59 (4H, ABq, *J*=10 Hz, $SO_2C_6\underline{H}_4CH_3$). Found: C, 50.14; H, 5.82; N, 3.09; S, 7.31%. Calcd for $C_{18}H_{25}NO_9S_2$: C, 50.11; H, 5.84; N, 3.25; S, 7.43%.

Methyl 2,4-Di-*O*-acetyl-3,6-acetylimino-3,6-dideoxy-α-D-glucopyranoside (6). To a stirred suspension of sodium hydride (60% emulsion in mineral oil, 1.88 g, 47.0 mmol, washed with hexane; 10 ml×3) in DMF (25 ml) was added a DMF (60 ml) solution of **5** (5.80 g, 13.4 mmol). The mixture was heated at 100 °C for 30 min with stirring, and ethanol (10 ml) was added. After evaporation of the resulting solution, the residue was triturated with methanol (50 ml). The resulting insoluble materials were removed by filtration, and the filtrate was evaporated. The residue was acetylated with acetic anhydride (50 ml) in pyridine (60 ml) for 12 h and the solution was evaporated. The residue was partitioned between chloroform (250 ml) and water (400 ml), and the aqueous layer was extracted with chloroform (250 ml×1, 100 ml×1). The combined extracts were washed with saturated aqueous NaCl (300 ml), dried (Na_2SO_4) and evaporated. The residue was chromatographed on SiO_2 (100 g, ethyl acetate: toluene=1 : 1), and fractions corresponding to R_f 0.50 (ethanol: toluene=1 : 3) were evaporated to afford **6** (2.75 g, 68%), mp 166—168 °C; $[\alpha]_D^{22}$+89.0° (*c* 1.00, $CHCl_3$); IR ν_{max}^{KBr} 2940, 1750, 1650, 1410, 1390, 1300 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.10 (3H, s, $NCOCH_3$), 2.20, 2.21 (3H×2, each s, 2×$OCOCH_3$), 3.56 (3H, s, OCH_3), 3.40—3.91 (2H, m, H-6, 6′), 4.42—5.32 (5H, m, H-1, 2, 3, 4, 5). Found: C, 52.10; H, 6.25; N, 4.38%. Calcd for $C_{13}H_{19}NO_7$: C, 51.82; H, 6.36; N, 4.65%.

(2*S*,3*S*,4*R*)-1-Acetyl-3,4-bis(benzyloxy)-2-[(1*R*)-1-benzyloxy-2,2-bis(ethylthio)ethyl]pyrrolidine (7). To a stirred solution of **6** (4.30 g, 14.3 mmol) in dichloromethane (15 ml) was added sodium methoxide in methanol (1 mol dm^{-3}, 34.3 ml, 34.3 mmol). After stirring for 30 min, the solution was neutralized with Amberlite IR-120 B (H^+). The resin was removed by filtration and the filtrate was evaporated. The residue was dissolved in concd HCl (10.0 ml) and ethanethiol (10.0 ml) was added at 0 °C. After stirring for 18 h at the temperature, the mixture was diluted with water (50 ml) and neutralized with lead(II) carbonate hydroxide. The resulting insoluble materials were removed through Celite-pad, and the filtrate was evaporated. The residue was triturated with methanol (70 ml) and insoluble materials were removed. After evaporation of the filtrate, the residue was benzylated without purification. To a suspension of sodium hydride (60%, 2.05 g, 51.4 mmol, washed with hexane; 10 ml×3) in DMF (15 ml) was added a DMF (40 ml) solution of the above residue. After stirring for 20 min at ambient temperature, benzyl bromide (6.1 ml, 51.4 mmol) was added to the mixture. The mixture was stirred for 1.5 h and ethanol (15 ml) was added. The solution was evaporated and the residue was partitioned between dichloromethane (300 ml) and water (400 ml). After extraction of the aqueous layer with dichloromethane (300 ml×2), the combined extracts were dried (Na_2SO_4) and evaporated. The residue was chromatographed on SiO_2 (200 g, ethyl acetate: hexane=1 : 1), and fractions corresponding to R_f 0.52 (ethanol: toluene=1 : 6) were evaporated to afford **7** (4.88 g, 59%) as a colorless syrup, $[\alpha]_D^{22}$+8.5° (*c* 1.10, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 3000, 2920, 1630, 1450, 1360 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.98, 1.18 (3H×2, each t, *J*=8 Hz, 2×$SCH_2C\underline{H}_3$), 2.10 (3H, s, $NCOCH_3$), 2.38, 2.70 (2H×2, each q, *J*=8 Hz, 2×$SC\underline{H}_2CH_3$), 3.40—4.75 (13H, m, H-2,3,4,5,5′, H-1,2 of the side chain, 3×$OC\underline{H}_2C_6H_5$), 7.26, 7.33, 7.34 (total 15H, each s, 3×$OCH_2C_6\underline{H}_5$). High resolution mass spectrum, calcd for $C_{33}H_{42}NO_4S_2$: *m/z* 580.2553, found: M+H, 580.2563.

(2*R*,3*S*,4*R*)-1-Acetyl-3,4-bis(benzyloxy)-2-[(1*S*,2*E*)-1-benzyloxy-3-ethoxycarbonyl-2-propenyl]pyrrolidine (8). To a stirred solution of **7** (1.00 g, 1.72 mmol) in a mixture of acetonitrile (8 ml) and water (2 ml) were added mercury(II) chloride (2.34 g, 8.62 mmol) and calcium carbonate (0.95 g, 9.49 mmol). After stirring for 4 h, an insoluble material was removed through Celite-pad. The filtrate was diluted with dichloromethane (200 ml), washed with 1 mol dm^{-3} aqueous KI (100 ml×3), dried (Na_2SO_2), and evaporated. The residue was subjected to the Horner–Emmons reaction directly. To a suspension of sodium hydride (60%, 0.24 g, 6.04 mmol, washed with hexane; 2 ml×3) in THF (5 ml) was added diethyl ethoxycarbonylmethylphosphonate (1.20 ml, 6.04

mmol) at 0 °C. After stirring for 20 min, a solution of the above residue in THF (10 ml) was added. The mixture was stirred for 3 h at ambient temperature and diluted with water (100 ml). The aqueous solution was extracted with dichloromethane (150 ml×2, 100 ml×1), and the combined extracts were dried (Na_2SO_4) and evaporated. The residue was chromatographed on SiO_2 (60 g, ethyl acetate : hexane=2 : 5), and fractions corresponding to R_f 0.28 (ethyl acetate : hexane=1 : 2) were evaporated to afford **8** (0.77 g, 82%) as a colorless syrup, $[\alpha]_D^{23}$+71.5° (*c* 1.10, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 2990, 2930, 2860, 1730, 1630, 1450, 1420, 1360, 1260, 1150 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.24 (3H, t, *J*=7 Hz, $COOCH_2C\underline{H}_3$), 1.95, 2.10 (total 3H, each s, $NCOCH_3$), 3.36 (1H, d, *J*=13 Hz, H-5), 3.72 (1H, d, *J*=7 Hz, H-5′), 3.76—5.00 (12H, m, H-2, 3, 4, H-1 of the side chain, $COOC\underline{H}_2CH_3$, 3×$OC\underline{H}_2C_6H_5$), 6.10 (1H, dd, *J*=2 and 15 Hz, H-3 of the side chain), 7.00—7.05 (16H, m, H-2 of the side chain, 3×$OCH_2C_6\underline{H}_5$). High resolution mass spectrum, calcd for $C_{33}H_{38}NO_6$: *m/z* 544.2696, found: M+H, 544.2677.

(2*R*,3*S*,4*R*)-1-Acetyl-3,4-bis(benzyloxy)-2-[(1*S*)-1-benzyloxy-3-(ethoxycarbonyl)propyl]pyrrolidine (9). A solution of **8** (2.45 g, 4.51 mmol) in ethanol (20 ml) was hydrogenated in the presence of Raney nickel T-4 under atmospheric hydrogen pressure for 5 h. After removal of the catalyst through Celite-pad, the filtrate was evaporated. The residue was chromatographed on SiO_2 (200 g, ethyl acetate : hexane =1 : 1), and fractions corresponding to R_f 0.19 (ethyl acetate : hexane=2 : 1) were evaporated to afford **9** (2.11 g, 86%) as a colorless syrup, $[\alpha]_D^{22}$+0.9° (*c* 1.10, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 2990, 2930, 2860, 1730, 1630, 1450, 1420, 1360, 1260, 1150, 1090 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.13, 1.16 (total 3H, each t, *J*=7 Hz, $COOCH_2C\underline{H}_3$), 1.50—2.50 (7H, m, $C\underline{H}_2C\underline{H}_2COOEt$, $NCOCH_3$), 3.45—4.80 (14H, m, H-2, 3, 4, 5, 5′, H-1 of the side chain, $COOC\underline{H}_2CH_3$, 3×$OC\underline{H}_2C_6H_5$), 7.23, 7.33 (total 15H, each s, 3×$OCH_2C_6\underline{H}_5$). High resolution mass spectrum, calcd for $C_{33}H_{40}NO_6$: *m/z* 546.2853, found: M+H, 546.2853.

(1*S*,2*R*,8*S*,8*aR*)-1,2,8-Tris(benzyloxy)-octahydro-5-indolizinone (10) and (2*R*,3*S*,4*R*)-1-Acetyl-3,4-bis(benzyloxy)-2-[(1*S*)-1-benzyloxy-3-carboxypropyl]pyrrolidine (11). A solution of **9** (240 mg, 0.44 mmol) in a mixture of ethanol (8 ml) and 15 mol dm^{-3} aqueous KOH (2 ml) was heated at 120 °C (Pyrex-glass sealed tube) for 14 d. After neutralization with 1 mol dm^{-3} aqueous HCl, the resulting solution was evaporated. The residue was diluted with water (25 ml) and extracted with dichloromethane (20 ml×3). The extracts were dried (Na_2SO_4) and evaporated. The residual brown syrup was chromatographed on SiO_2 (20 g, ethanol : toluene =1 : 30). Fractions corresponding to R_f 0.46 (ethanol : toluene =1 : 5) were evaporated to afford **10** (80 mg, 40%), and fractions corresponding to R_f 0.43 were evaporated to afford **11** (115 mg, 51%) as a colorless syrup. **10**: Mp 98—99 °C; $[\alpha]_D^{22}$—28.2 (*c* 1.00, $CHCl_3$); IR ν_{max}^{KBr} 3420, 2920, 2860, 1640, 1450, 1410, 1370, 1200, 1140 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.56—2.68 (4H, m, H-6,6′,7,7′), 3.30—4.84 (12H, m, H-1, 2, 3, 3′, 8, 8a, 3×$OC\underline{H}_2C_6H_5$), 7.27, 7.29 (total 15H, each s, 3×$OCH_2C_6\underline{H}_5$). Found: C, 76.27; H, 6.85; N, 3.08%. Calcd for $C_{29}H_{31}NO_4$: C, 76.12; H, 6.83; N, 3.06%. **11**: $[\alpha]_D^{23}$—4.0° (*c* 1.05, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 3670, 3500, 3020, 2400, 1710, 1630, 1450, 1420, 1360, 1260, 1210, 1170 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.57—2.60 (7H, m, H-2, 2′, 3, 3′ of the side chain, $NCOCH_3$), 3.43—4.76 (12H, m, H-2, 3, 4, 5, 5′, H-1 of the side chain, 3×$OC\underline{H}_2C_6H_5$), 7.00—7.50 (15H, m, 3×$OCH_2C_6\underline{H}_5$).

Conversion of 11 to 10. A solution of **11** (219 mg, 0.42 mmol) in a mixture of ethanol (4 ml) and 15 mol dm^{-3} aqueous KOH (1 ml) was heated at 120 °C for 14 d. After the analogous work-up described above, the crude mixture was chromatographed on SiO_2 to afford **10** (80 mg, 43%) [95 mg (46%) of **11** was recovered].

(1*S*,2*R*,8*S*,8*aR*)-1,2,8-Triacetoxyoctahydro-5-indolizinone (12). To a solution of **10** (80 mg, 0.175 mmol) in ethanol (1.5 ml) were added cyclohexene (1.5 ml) and 20% $Pd(OH)_2$ on charcoal (40 mg). The mixture was heated under reflux for 4 h, and the catalyst was removed through Celite-pad. The filtrate was evaporated, and the residue was acetylated with acetic anhydride (1 ml) in pyridine (1 ml) for 4 h. After evaporation of the mixture, the residue was chromatographed on SiO_2 (5 g, ethanol : toluene=1 : 20). Fractions corresponding to R_f 0.51 (ethanol : toluene=1 : 3) were evaporated to afford **12** (46 mg, 84%), mp 126—127 °C; $[\alpha]_D^{21}$ −21.8° (*c* 0.90, $CHCl_3$); IR ν_{max}^{KBr} 3450, 2960, 1730, 1640, 1470, 1420, 1380, 1270, 1230, 1110 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.47—2.83 (13H, m, H-6, 6′, 7, 7′, 3×$OCOCH_3$), 3.50—4.30 (3H, m, H-3, 3′, 8a), 5.20—5.77 (3H, m, H-1, 2, 8). Found: C, 53.52; H, 6.05; N, 4.47%. Calcd for $C_{14}H_{19}NO_7$: C, 53.67; H, 6.11; N, 4.47%.

(1*S*,2*R*,8*S*,8*aR*)-1,2,8-Triacetoxyoctahydroindolizine, 8-*epi*-Swainsonine Triacetate (13). To a stirred solution of **12** (26 mg, 0.08 mmol) in THF (1 ml) was added borane-dimethyl sulfide complex (Aldrich, 10.0 mol dm^{-3} in BH_3, 0.04 ml, 0.42 mmol) at 0 °C under argon atmosphere. After stirring at ambient temperature for 2 h, the mixture was diluted with water (10 ml) and stirred for 15 min. The aqueous solution was extracted with dichloromethane (10 ml×3). The extracts were dried (Na_2SO_4) and evaporated. The residue was dissolved in dioxane (1.5 ml) and saturated aqueous $NaHCO_3$ solution (0.5 ml) was added. After stirring for 5 h at ambient temperature, the solution was diluted with water (10 ml), extracted with dichloromethane (10 ml×3). The extracts were dried (Na_2SO_4) and evaporated. The residue was purified by PTLC (ethanol : toluene=1 : 15) to afford **13** (R_f= 0.44; ethanol : toluene=1 : 5) (16 mg, 64%), mp 79—80 °C; $[\alpha]_D^{19}$—17.1° (*c* 0.35, $CHCl_3$); IR ν_{max}^{KBr} 3450, 2940, 1730, 1380, 1270, 1250, 1160, 1130 cm^{-1}; ^1H NMR ($CDCl_3$) δ= 1.14—2.30 (6H, m, H-5, 6, 6′, 7, 7′, 8a), 2.00, 2.03, 2.11 (3H×3, each s, 3×$OCOCH_3$), 2.42 (1H, dd, *J*=7 and 12 Hz, H-3), 3.10—3.35 (2H, m, H-3′, 5′), 5.13—5.50 (3H, m, H-1, 2, 8). High resolution mass spectrum, calcd for $C_{14}H_{22}NO_6$: *m/z* 300.1446, found: M+H, 300.1447.

(1*S*,2*R*,8*S*,8*aR*)-Octahydro-1,2,8-indolizinetriol, 8-*epi*-Swainsonine (2). A solution of **13** (27.0 mg, 0.09 mmol) in 1 mol dm^{-3} aqueous HCl (1 ml) was heated under reflux for 3 h and evaporated. The residue was dissolved in a minimum volume of water and charged on a column of Amberlite IRA-400 (OH^-) (2 ml). The column was eluted with water, and the ninhydrin-positive fractions (R_f 0.35, aqueous ammonia : 1-butanol : chloroform : ethanol=1 : 4 : 4 : 4) were evaporated to afford **2** (13.4 mg, 86%), mp 93—95 °C; $[\alpha]_D^{21}$—24.8° (*c* 0.67, MeOH); IR ν_{max}^{KBr} 3600—3000 (br), 2940, 2850, 2820, 1440, 1150, 1100 cm^{-1}; ^1H NMR (D_2O) δ=1.40—2.30 (6H, m, H-5, 6, 6′, 7, 7′, 8a), 2.50 (1H, dd, *J*=7 and 11 Hz, H-3), 2.86—3.20 (2H, m, H-3′, 5′), 4.20—4.46 (3H, m, H-1,2,8); ^{13}C NMR (CD_3OD) δ=20.63, 32.09, 54.27, 62.98, 67.53, 69.40, 69.96, 74.29. High resolution mass spectrum, calcd for $C_8H_{15}NO_3$: *m/z* 173.1051, found: M, 173.1056.

Methyl 2,4-Di-*O*-acetyl-3,6-acetylimino-3,6-dideoxy-α-D-

galactopyranoside (15) and Methyl 3-Acetamido-2,4,6-tri-*O*-acetyl-3-deoxy-α-D-galactopyranoside (16). A solution of methyl 3-acetamido-2-*O*-acetyl-3-deoxy-4,6-di-*O*-mesyl-α-D-glucopyranoside (**14**)[16] (7.80 g, 18.0 mmol) in a mixture of 2-methoxyethanol (180 ml) and water (20 ml) containing sodium acetate (7.82 g, 95.0 mmol) was heated under reflux for 6 h, and evaporated. The residue was triturated with boiling acetone (400 ml) and insoluble materials were removed by filtration. After evaporation of the filtrate, the residue was acetylated with acetic anhydride (65 ml) in pyridine (65 ml) for 14 h. The mixture was evaporated with toluene and the residue was chromatographed on SiO_2 (300 g, ethanol : toluene=1 : 30). Fractions corresponding to R_f 0.32 (ethanol : toluene=1 : 5) were evaporated to afford **15** (3.67 g, 68%) as a foam, and fractions corresponding to R_f 0.27 were evaporated to afford **16** (1.72 g, 27%) as crystals. **15**: $[\alpha]_D^{26}$+25.3° (*c* 1.36, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 3660, 3020, 2400, 1750, 1650, 1410, 1370, 1260, 1220, 1170 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.03 (3H, s, $NCOCH_3$), 2.09, 2.12, 2.15, 2.19 (total 6H, each s, 2×$OCOCH_3$), 3.45, 3.49 (total 3H, each s, OCH_3), 3.60—3.76 (2H, m, H-6, 6′), 4.23—4.68 (2H, m, H-3, 5), 4.71, 4.73 (total 1H, each d, *J*=2 Hz, H-1), 5.02—5.49 (2H, m, H-2, 4). High resolution mass spectrum, calcd for $C_{13}H_{19}NO_7$: *m/z* 301.1160, found: M, 301.1133. **16**: Mp 107—108 °C; $[\alpha]_D^{21}$+117.8° (*c* 1.48, $CHCl_3$); IR ν_{max}^{KBr} 3340, 3240, 2930, 1735, 1655, 1540, 1440, 1370, 1230 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.90 (3H, s, $NCOCH_3$), 2.06, 2.10, 2.17 (3H×3, each s, 3×$OCOCH_3$), 3.45 (3H, s, OCH_3), 3.95—4.32 (3H, m, H-5, 6, 6′), 4.66 (1H, ddd, *J*=3, 8, and 12 Hz, H-3), 4.84 (1H, d, *J*=4 Hz, H-1), 5.10 (1H, dd, *J*=4 and 12 Hz, H-2), 5.40 (1H, dd, *J*=1 and 3 Hz, H-4), 5.72 (1H, d, *J*=8 Hz, NH). Found: C, 50.14; H, 6.50; N, 3.93%. Calcd for $C_{15}H_{23}NO_9$: C, 49.86; H, 6.41; N, 3.88%.

3-Acetamido-1,2,4,6-tetra-*O*-acetyl-3-deoxy-α- and -β-D-galactopyranose (17-α and 17-β). A solution of **16** (45 mg, 0.12 mmol) in 2 mol dm^{-3} aqueous HCl (2 ml) was heated under reflux for 13 h and evaporated. The residue was acetylated with acetic anhydride (0.5 ml) in pyridine (0.5 ml) for 4 h. After evaporation of the mixture, the residue was chromatographed on SiO_2 (5 g, ethanol : toluene=1 : 20). Fractions corresponding to R_f 0.49 (ethanol : toluene=1 : 5) were evaporated to afford **17-β** (21 mg, 43%), and fractions corresponding to R_f 0.45 were evaporated to afford **17-α** (20 mg, 41%). **17-α**: Mp 178—179 °C, lit,[17] mp 181—182 °C; $[\alpha]_D^{26}$+123.8° (*c* 1.00, $CHCl_3$), lit,[17] $[\alpha]_D^{23}$+119° (*c* 1.00, $CHCl_3$); IR ν_{max}^{KBr} 3440, 1760, 1740, 1680, 1530, 1435, 1375 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.93 (3H, s, $NCOCH_3$), 2.03, 2.19 (6H×2, each s, 4×$OCOCH_3$), 3.85—4.25 (2H, m, H-6, 6′), 4.38 (1H, dt, *J*=1 and 7 Hz, H-5), 4.68 (1H, ddd, *J*=3, 9, and 11 Hz, H-3), 5.25 (1H, dd, *J*=4 and 11 Hz, H-2), 5.48 (1H, dd, *J*=1 and 3 Hz, H-4), 6.01 (1H, d, *J*=9 Hz, NH), 6.31 (1H, d, *J*=4 Hz, H-1). **17-β**: Mp 117—118 °C; $[\alpha]_D^{24}$+36.0° (*c*, 1.06, $CHCl_3$); IR ν_{max}^{KBr} 3370, 1740, 1650, 1520, 1370, 1220 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.89 (3H, s, $NCOCH_3$), 2.02, 2.04, 2.10, 2.15 (3H×4, each s, 4×$OCOCH_3$), 3.97—4.23 (3H, m, H-5, 6, 6′), 4.44 (1H, ddd, *J*=4, 8, and 9 Hz, H-3), 5.06 (1H, dd, *J*=9 and 12 Hz, H-2), *5.40 (1H, d, J=4Hz, H-4), 5.80 (1H, d, J=9 Hz, H-1), 6.04* (1H, d, *J*=8 Hz, NH). Found: C, 49.09; H, 5.91; N, 3.66%. Calcd for $C_{16}H_{23}NO_{10}$: C, 49.36; H, 5.95; N, 3.60%.

Methyl 3-Acetamido-3-deoxy-6-*O*-tosyl-α-D-galactopyranoside (18) and Methyl 3-Acetamido-3-deoxy-2,6-di-*O*-tosyl-α-D-galactopyranoside (19). To a stirred solution of **16** (350 mg, 0.97 mmol) in methanol (3 ml) was added sodium methoxide in methanol (1 mol dm^{-3} solution, 3.8 ml, 3.8 mmol) at 0 °C. After stirring at the temperature for 30 min, the solution was neutralized with Amberlite 120B (H^+). The resin was removed by filtration and the filtrate was evaporated to afford a colorless syrup. To a solution of the syrup in pyridine (4 ml) was added *p*-toluenesulfonyl chloride (184 mg, 0.97 mmol). The mixture was stirred for 10 h at −17 to −10 °C and evaporated. The residue was chromatographed on SiO_2 (60 g, chloroform : methanol=40 : 1). Fractions corresponding to R_f 0.58 (ethanol : toluene=1 : 3) were evaporated to afford **19** (64 mg, 12%), fractions corresponding to R_f 0.31 were evaporated to afford **18** (120 mg, 32%), and fractions corresponding to R_f 0.10 were evaporated to recover the 2,4,6-triol (64 mg, 28%). **18**: Mp 146—147 °C; $[\alpha]_D^{23}$+136.1° (*c* 1.09, MeOH); IR ν_{max}^{KBr} 3340, 2920, 1630, 1600, 1570, 1445, 1370, 1190 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.04 (3H, s, $NCOCH_3$), 2.45 (3H, s, $OSO_2C_6H_4C\underline{H}_3$), 2.56—2.98 (2H, m, 2×OH), 3.36 (3H, s, OCH_3), 3.62—4.33 (6H, m, H-2, 3, 4, 5, 6, 6′), 4.71 (1H, d, *J*=4 Hz, H-1), 6.54 (1H, d, *J*=8 Hz, NH), 7.58 (4H, ABq, $OSO_2C_6\underline{H}_4CH_3$). High resolution mass spectrum, calcd for $C_{16}H_{24}NO_8S$: *m/z* 390.1220, found: M+H, 390.1214. **19**: Mp 194—195 °C; $[\alpha]_D^{24}$+75.2° (*c* 1.00, DMF); IR ν_{max}^{KBr} 3330, 3200, 1640, 1590, 1540, 1360, 1190, 1175 cm^{-1}; ^1H NMR (DMSO-d_6) δ=1.69 (3H, s, $NCOCH_3$), 2.42 (6H, s, 2×$OSO_2C_6H_4C\underline{H}_3$), 3.12 (3H, s, OCH_3), 3.53—4.62 (7H, m, H-1, 2, 3, 4, 5, 6, 6′), 5.34 (1H, d, *J*=6 Hz, NH), 7.61, 7.63 (total 8H, 2×$OSO_2C_6\underline{H}_4CH_3$). Found: C, 51.08; H, 5.43; N, 2.77; S, 11.50%. Calcd for $C_{23}H_{29}NO_{10}S_2$: C, 50.82; H, 5.38; N, 2.58; S, 11.80%.

Compound 15 from Compound 18. To a suspension of sodium hydride (60%, 31 mg, 1.28 mmol, washed with hexane; 1 ml×3) in DMF (0.5 ml) was added a solution of **18** (86 mg, 0.22 mmol) in DMF (1 ml). The mixture was heated at 100 °C for 3 h and ethanol (0.5 ml) was added. After evaporation of the mixture, the residue was acetylated with acetic anhydride (2 ml) in pyridine (2 ml) for 16 h. The mixture was evaporated and the residue was partitioned between chloroform (30 ml) and water (30 ml). The aqueous layer was extracted with chloroform (30 ml). The combined extracts were dried (Na_2SO_4) and evaporated. The residue was chromatographed on SiO_2 (5 g, ethanol : toluene=1 : 10), and fractions corresponding to R_f 0.32 (ethanol : toluene= 1 : 5) were evaporated to afford **15** (37 mg, 56%) which was identical in all respects with that prepared by the solvolysis of **14**.

(2*S*,3*R*,4*R*)-1-Acetyl-3,4-bis(benzyloxy)-2-[(1*R*)-1-benzyloxy-2,2-bis(ethylthio)ethyl]pyrrolidine (20). Compound **15** (1.43 g, 4.75 mmol) was *O*-deacetylated with 1 mol dm^{-3} sodium methoxide in methanol (14.2 ml) at 0 °C for 30 min. After neutralization of the mixture with Amberlite IR-120B (H^+), the crude product was treated with ethanethiol (5 ml) in concd HCl (3 ml) at 0 °C for 1 h. Work-up as described in preparation of **7** gave the dithioacetal derivative (R_f=0.51, ethanol : toluene=1 : 2) which was directly benzylated with benzyl bromide (1.72 ml) in DMF (25 ml) in the presence of sodium hydride (580 mg) for 12 h. Extractive work-up *($CHCl_3$)* and *chromatography of the product on SiO_2 (100* g, ethyl acetate : toluene=1 : 10) afforded **20** (R_f=0.36, ethyl acetate : hexane=1 : 1) (1.55 g, 56%) as a colorless syrup; $[\alpha]_D^{27}$+9.6° (*c* 1.17, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 3000, 1620, 1450, 1420, 1360, 1260, 1210, 1170 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.13, 1.20 (3H×2, each t, *J*=8 Hz, 2×$SCH_2C\underline{H}_3$), 2.09 (3H, s, $NCOCH_3$), 2.50, 2.66 (2H×2, each q, *J*=8 Hz, 2×$SC\underline{H}_2CH_3$),

3.20—4.70 (13H, m, H-2, 3, 4, 5, 5′, H-1, 2 of the side chain, 3×OC$\underline{H}_2$C$_6$H$_5$), 7.25, 7.30, 7.35 (total 15H, each s, 3×OCH$_2$C$_6\underline{H}_5$). High resolution mass spectrum, calcd for $C_{33}H_{41}NO_4S_2$: *m/z* 579.2475, found: M, 579.2503.

(2*R*,3*R*,4*R*)-1-Acetyl-3,4-bis(benzyloxy)-2-[(1*S*,2*E*)-1-benzyloxy-3-ethoxycarbonyl-2-propenyl]pyrrolidine (21). Compound **20** (2.66 g, 4.6 mmol) in a mixture of acetonitrile (40 ml) and water (10 ml) was treated with mercury(II) chloride (3.99 g) and calcium carbonate (1.61 g). Work-up as described in preparation of **8** gave the dethioacetal derivative (R_f 0.54, ethyl acetate : hexane=1 : 2), which was subjected to Horner-Emmons reaction with diethyl ethoxycarbonylmethylphosphonate (3.19 ml) in THF in the presence of sodium hydride (0.64 g) for 90 min at ambient temperature. Extractive work-up (CH_2Cl_2) and repeated chromatography on SiO_2 (2-butanone : toluene=1 : 14, then ethyl acetate : toluene=1 : 2) of the reaction mixture afforded **21** (R_f 0.47, ethyl acetate : toluene=1 : 2) (1.29 g, 52%) as a colorless syrup, $[\alpha]_D^{27}$+9.9° (*c* 0.91, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 2990, 2960, 2930, 1710, 1630, 1450, 1410, 1370, 1300, 1270, 1175, 1095 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.22, 1.31 (total 3H, each t, *J*=7 Hz, COOCH$_2$C$\underline{H}_3$), 2.00, 2.05 (total 3H, each s, NCOCH$_3$), 3.06—4.90 (14H, m, H-2, 3, 4, 5, 5′, H-1 of the side chain, COOC$\underline{H}_2$CH$_3$, 3×OC$\underline{H}_2$C$_6$H$_5$), 5.91, 6.01 (total 1H, d and dd, *J*=15 Hz and *J*=2 and 15 Hz, CH=C$\underline{H}$COOEt), 6.60—7.02 (1H, m, C$\underline{H}$=CHCOOEt), 7.30, 7.34 (total 15H, each s, 3×OCH$_2$C$_6\underline{H}_5$). High resolution mass spectrum, calcd for $C_{33}H_{37}NO_6$: *m/z* 543.2618, found: *m/z* 543.2589.

(2*R*,3*R*,4*R*)-1-Acetyl-3,4-bis(benzyloxy)-2-[(1*S*)-1-benzyloxy-3-(ethoxycarbonyl)propyl]pyrrolidine (22). Compound **21** (668 mg, 1.23 mmol) in ethanol (9 ml) was hydrogenated in the presence of Raney nickel T-4 for 3 h. Work-up as described in preparation of **9** and chromatography of the product on SiO_2 (2-butanone : toluene=1 : 10) afforded **22** (R_f=0.46, ethyl acetate : toluene1=1 : 1) (577 mg, 86%) as a colorless syrup, $[\alpha]_D^{20}$−28.1° (*c* 1.34, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 3660, 3570, 3480, 3010, 1725, 1630, 1420, 1270, 1170 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.18, 1.20 (total 3H, each t, *J*=7 Hz, COOCH$_2$C$\underline{H}_3$), 1.57—1.93 (2H, m, H-2, 2′ of the side chain), 2.00, 2.04 (total 3H, each s, NCOCH$_3$), 2.30, 2.32 (total 2H, each t, *J*=7 Hz, H-3, 3′ of the side chain), 3.27—4.73 (13H, m, H-2, 3, 4, 5, 5′, COOC$\underline{H}_2$CH$_3$, 3×OC$\underline{H}_2$C$_6$H$_5$), 7.27, 7.30 (total 15H, each s, 3×OCH$_2$C$_6\underline{H}_5$). High resolution mass spectrum, calcd for $C_{33}H_{39}NO_6$: *m/z* 545.2775, found: M, 545.2786.

(1*R*,2*R*,8*S*,8*aR*)-1,2,8-Tris(benzyloxy)-octahydro-5-indolizinone (23) and (2*R*,3*R*,4*R*)-1-Acetyl-3,4-bis(benzyloxy)-2-[(1*S*)-1-benzyloxy-3-carboxypropyl]pyrrolidine (24). A solution of **22** (577 mg, 1.1 mmol) in a mixture of ethanol (20 ml) and 15 mol dm^{-3} aqueous KOH (20 ml) in sealed tubes (100—120 mg of **22**/tube) was heated at 120 °C for 10 d. The soluble part was collected, and the unsoluble material was washed with ethanol several times. The ethanolic soluble part and washing were combined, diluted with water (20 ml), neutralized with acetic acid and evaporated. The residue was partitioned between chloroform (50 ml) and water (50 ml), and the aqueous layer was extracted with chloroform (50 ml×2). The extracts were dried (Na_2SO_4) and evaporated. The residue was chromatographed on SiO_2 (50 g, ethanol : toluene=1 : 35). Fractions corresponding to R_f 0.38 (ethanol : toluene=1 : 10, acidified with acetic acid) were evaporated to afford **23** (166 mg, 34%) as a colorless syrup which crystallized gradually from ether and petroleum ether. Fractions corresponding to R_f 0.35 were evaporated to afford **24** (340 mg, 62%) as a colorless syrup. **23**: Mp 52—54 °C; $[\alpha]_D^{20}$+15.1° (*c* 1.18, $CHCl_3$); IR ν_{max}^{KBr} 3420, 3020, 2880, 1640, 1490, 1410 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.43—2.54 (4H, m, H-6, 6′, 7, 7′), 3.40—4.85 (12H, m, H-1, 2, 3, 3′, 8, 8a, 3×OC$\underline{H}_2$C$_6$H$_5$), 7.27, 7.29, 7.33 (total 15H, each s, 3×OCH$_2$C$_6\underline{H}_5$). High resolution mass spectrum, calcd for $C_{29}H_{31}NO_4$: *m/z* 457.2251, found: M, 457.2226. **24**: $[\alpha]_D^{20}$−21.5° (*c* 0.93, $CHCl_3$); IR ν_{max}^{KBr} 3660, 3020, 2880, 1720, 1650, 1450, 1420, 1360, 1260, 1170 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.42—1.92 (2H, m, H-2, 2′ of the side chain), 1.98, 2.03 (total 3H, each s, NCOCH$_3$), 2.13—2.58 (2H, m, H-3, 3′ of the side chain), 3.23—4.70 (12H, m, H-2, 3, 4, 5, 5′, H-1 of the side chain, 3×OC$\underline{H}_2$C$_6$H$_5$), 7.27, 7.29, 7.32 (total 15H, each s, 3×OCH$_2$C$_6\underline{H}_5$).

Compound 23 from 24. Compound **24** (66 mg) was cyclized under the same conditions employed above. After SiO_2 chromatography, 44 mg (75%) of **23** was obtained and 13 mg (20%) of **24** was recovered.

(1*R*,2*R*,8*S*,8*aR*)-1,2,8-Triacetoxy-octahydro-5-indolizinone (25). *O*-Debenzylation of **23** (103 mg, 0.23 mmol) and successive acetylation under the same conditions and work-up described in preparation of **12** provided **25** (59 mg, 83%) after SiO_2 chromatography (ethanol : toluene=1 : 20, **25**: R_f=0.39, ethanol : toluene=1 : 8). **25**: Mp 118—119 °C; $[\alpha]_D^{24}$−20.9° (*c* 1.04, $CHCl_3$); IR ν_{max}^{KBr} 3440, 1740, 1635, 1460, 1380, 1260, 1230 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.58—2.75 (4H, m, H-6, 6′, 7, 7′), 2.09, 2.10, 2.13 (3H×3, each s, 3×OCOCH$_3$), 3.60—4.04 (3H, m, H-3, 3′, 8a), 5.10—5.53 (3H, m, H-1, 2, 8). Found: C, 53.38; H, 5.90; N, 4.43%. Calcd for $C_{14}H_{19}NO_7$: C, 53.67; H, 6.11; N, 4.47%.

(1*R*,2*R*,8*S*,8*aR*)-1,2,8-Triacetoxyoctahydroindolizine (26). Reduction of compound **25** (33 mg, 0.11 mmol) with borane-dimethyl sulfide (0.03 ml) at 0 °C, extractive work-up, saturated aqueous $NaHCO_3$ treatment, and successive acetylation as described in preparation of **13** afforded **26** (21 mg, 67%) after PTLC purification (ethanol : toluene=1 : 10). **26** (R_f=0.38, ethanol : toluene=1 : 10): Mp 124—125 °C; $[\alpha]_D^{20}$ −20.8° (*c* 1.00, $CHCl_3$), IR ν_{max}^{KBr} 3440, 2950, 2800, 1730, 1240, 1170 cm^{-1}; ^{1}H NMR δ=1.20—2.32 (6H, m, H-5, 6, 6′, 7, 7′, 8a), 2.07, 2.10, 2.17 (3H×3, each s, 3×OCOCH$_3$), 2.64 (1H, dd, *J*=8 and 11 Hz, H-3), 2.99—3.23 (2H, m, H-3′, 5′), 4.96—5.25 (3H, m, H-1, 2, 8). High resolution mass spectrum, calcd for $C_{14}H_{21}NO_6$: *m/z* 299.1367, found: M, 299.1344.

(1*R*,2*R*,8*S*,8*aR*)-Octahydro-1,2,8-indolizinetriol, 1,8-Di-*epi*-swainsonine (3). To a stirred solution of **26** (21 mg, 0.07 mmol) in methanol (1.5 ml) was added potassium carbonate (29 mg, 0.21 mmol). After stirring for 3 h at ambient temperature, the mixture was evaporated. The residue was purified by PTLC (aqueous ammonia : acetone : chloroform : water=1 : 30 : 5 : 4, the edge of the plate was colorized with ninhydrin and iodine) to afford a crystalline **3** (12 mg, 98%, R_f=0.28), which was recrystallized from chloroform, mp 138—140 °C (decomp); $[\alpha]_D^{21}$−35.6° (*c* 0.59, MeOH); IR ν_{max}^{KBr} 3600—3000 (br), 2920, 2810, 1330, 1240, 1210, 1150, 1135, 1100 cm^{-1}; ^{1}H NMR (D_2O) δ=1.22—2.27 (6H, m, H-5, 6, 6′, 7, 7′, 8a), 2.60 (1H, dd, *J*=6 and 11 Hz, H-3), 2.75—3.10 (2H, m, H-3′, 5′), 3.83—4.30 (3H, m, H-1, 2, 8); ^{13}C NMR (CD_3OD) δ=20.39, 32.19, 54.08, 62.74, 64.66, 75.05, 77.89, 80.23. High resolution mass spectrum, calcd for $C_8H_{15}NO_3$: *m/z* 173.1051, found: M, 173.1052.

The authors wish to express their thanks to Professor Anthony C. Richardson and Dr. Brian Winchester of the University of London for the mannosidase

inhibitory assay of the compound **2** and **3**. ^{13}C NMR spectral measurements were kindly performed by Dr. Yoshimasa Fukuda (Meiji Seika Co. Ltd) to whom our thanks are due. The financial support by the Kawakami Memorial Foundation is also acknowledged.

Pyrolyse und Massenspektren von 5-(Hydroxyphenoxymethyl)-2-oxazolidinon und *p*- oder *m*-Bis(2-oxooxazolidin-5-ylmethoxy)benzol[1)]

Choichiro SHIMASAKI,* Mariko WAKABAYASHI, und Shizuo YOSHIDA
Fakultät für Ingenieurwissenschaften, Universität Toyama, Gofuku, Toyama 930
(Eingangsdatum: 12. Juni, 1986)

5-(Hydroxyphenoxymethyl)-2-oxazolidinone (**1**) and *p*- or *m*-bis(2-oxooxazolidin-5-ylmethoxy)benzene (**2** or **3**) were prepared by the reaction of tris(2,3-epoxypropyl)-1,3,5-triazin-2,4,6(1*H*,3*H*,5*H*)-trione with hydroquinone and resorcinol. These compounds were found by the thermal analysis to be thermally stable. The activation energies of the pyrolysis for **1**, **2**, and **3** were calculated from the DTA curves to be 142.7, 158.8, and 130.0 kJ mol^{-1}, respectively. The mechanism of the main fragmentation of the linkages between the benzene and oxazolidinone rings by electron impact was found to consist of two processes; a simple cleavage and a rearrangement reaction. Further, each process had the three cleavage modes. In mass spectra of **2** and **3**, the fragment ion which corresponded to the molecular ion peak for **1** was detected. High resolution mass spectrometry established the composition of many peaks in the low resolution spectra of the compounds studied.

5-(Hydroxyphenoxymethyl)-2-oxazolidinon (**1**) und *p*- oder *m*-Bis(2-oxooxazolidin-5-ylmethoxy)benzol (**2** oder **3**) wurden aus Tris(2,3-epoxypropyl)-1,3,5-triazin-2,4,6(1*H*,3*H*,5*H*)-trion und Hydrochinon oder Resorcin hergestellt. Durch die thermischen Analysen wurden es gefunden daß diese Verbindungen der Hitze gegenüber relativ stabil waren. Beide, **1** und **2**, haben die dimorphischen Kristalle gegeben. Eine kinetische Berechnung der thermischen Zersetzungsreaktion auf Grund von DTA Kurven hat gezeigt, daß die Aktivierungsenergien der Zersetzungsreaktionen von **1**, **2**, und **3** jeweils 142.7, 158.8, und 130.0 kJ mol^{-1} sind. Der Hauptspaltungsmechanismus der Bindung zwischen Benzolring und Oxazolidinonring bei dem Elektronenschlag besteht aus den zwei Prozesse; die einfache Spaltungsreaktion und die Wasserstoff-Umlagerungsreaktion. Außerdem besteht jeder Prozeß aus der drei Spaltungsstilen. Bei der Spaltung von **2** und **3** wurden Spitze M^+ von **1** gemessen. Die hochauflösende Massen-spektrometrie bestätigte die Zusammensetzung einer grossen Anzahl von Spitzen in niederauflösenden Massenstrahlenspektren.

Einige Forschungen[2)] wurde über die Synthese von Poly(2-oxazolidinon) ausgeführt, aber die thermischen Eigenschaften von Poly(2-oxazolidinon) im Festzustand sind noch nicht vollständig erforscht. In der vorliegenden Abhandlung wurden die thermische Zersetzungsreaktion mit Differenz-Thermo-Analyse (DTA), Differential-Scanning-Kalorimetrie (DSC), und Thermogravimetrische Analyse (TG) und Zersetzung mit dem Elektronenschlag zusammengefaßt. Außerdem wurde die dimorphischen Kristalle von Poly(2-oxazolidinon) diskutiert.

Durchführung der Experimente

Materialien. 5-(Hydroxyphenoxymethyl)-2-oxazolidinon (**1**) und *p*- oder *m*-Bis(2-oxooxazolidin-5-ylmethoxy)benzol (**2** oder **3**) wurden nach Ishikawa et al.[3] hergestellt. Die Trennung von **1** und **2** wurde nach der Method in Schema 1 ausgeführt. **3** wurde aus Tris(2,3-epoxypropyl)-1,3,5-triazin-2,4,6(1*H*, 3*H*, 5*H*)-trion und Resorcin mit Natriumhydroxid als Katalysator synthetisiert. Die Ergebnisse der physikochemischen Eigenschaften von **1**, **2**, und **3** sind in Tabelle 1 zusammengestellt.

Messapparatur und Verfahren. Die DTA, DSC, und TG Kurven wurden in der Luft mit einer Aufheizgeschwindigkeit von 5 °C min^{-1} mit einem Rigaku TG-DTA, TG-DSC Thermoflex aufgenommen. Für DTA und DSC α-Al_2O_3 als Bezugsmittel gebraucht. Die IR Spektren wurden mittels Präparat von KBr-Presslingen mit einem Beugungsgitter IR Spektrometer der JASCO aufgenommen. ^1H und ^{13}C NMR-Spektren wurden mit einem JEOL JNM-FX 90 QET Spektrometer aufgenommen. Tetramethylsilan wurde als innere Standardsubstanz verwendet. Die Massenspektren wurden durch einen JMS-D300 Massenspektrometer mit direkten Probeinjektionen registriert.

Die Schmelzpunkte wurden durch einen Mitamura-Mikroschmelzpunkt-Apparat bestimmt und nicht korrigiert. Für Dünnschicht-Chromatographie wurden Platten mit Kiselgel G nach Stahl (typ 60) von Merck gebraucht. Die Elementaranalysen wurden bei der Analysen-Zentrale in der Medizinischen-Pharmazeutischen Universität Toyama durchgeführt.

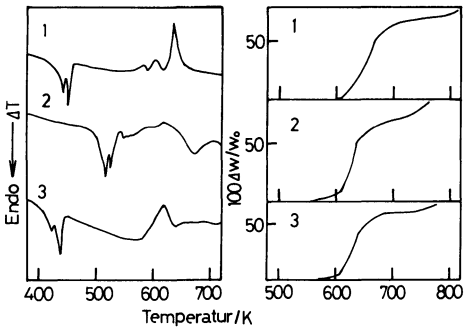

Abb. 1. DSC-TG Kurven von **1**, **2**, und **3**.

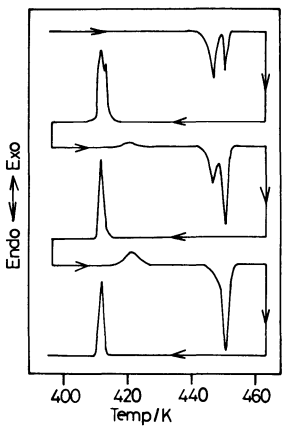

Abb. 2. Effekt des Heiz-Abkühlungsprozesses auf DTA von **1**.

Ergebnisse und Diskussionen

Thermische Analyse. Die DSC und TG Kurven der Probe (**1**, **2**, und **3**) sind in Abb. 1 dargestellt. Die DSC Kurven ergeben in allen drei Proben durch den Schmelzprozeß eine endotherme Spitze, die in zwei Teile geteilt ist. Die TG Kurven zeigen, daß der Prozeß der Zersetzung zwischen 10—50% vom Gewichtverlust bei allen drei Proben in einer Stufe geschieht. Es gibt keine deutliche Hochebene an der TG Kurven bei allen Fällen. Beim Heiz-Abkühlungskreisprozeß der DTA Kurven von **1** und **2** war das thermische Benehmen[3] gleich wie von 5-Phenoxymethyl-2-oxazoldinon. Abbildung 2 zeigt den Effekt des Heiz-Abkühlungskreisprozesses auf DTA von **1**. Bei erstem Kreisprozeß wird jeweils eine endotherme oder eine exotherme Spitze angezeigt, die in zwei Teile geteilt ist. Wenn der Kreisprozeß über dreimal wiederholt wurde, erschien deutlich eine schwache exotherme Spitze vor der Spitze des Schmelzpunktes. Diese Spitze hat ihren Ursprung in der Kristallisationswärme. Durch das Mikroskop wurde der Zustand der Veränderung von Amorphe zu Kristalle erkannt. Bei der Untersuchung der Kristalle durch das Mikroskop wurde beim Kreisprozeß einmal die Zweiform des Gemisches von Blätter- und Nadelkristalle festgestellt, aber danach nur Nadelkristalle.

IR Spektren. Abbildung 3 zeigt den Heizeffekt auf IR Spektren unter vermindertem Druck (10^{-3} mmHg)[4] bei 3 Proben. Die Kurven von **1** und **2** sind nach Erwärmung gleich. Die $\nu_{C=O}$ Bänder von **2** und **3**, die in zwei Teile geteilt sind, zeigen nach der Erwärmung eine Spitze. Die Benzolkern Bänder (1505 cm^{-1}) von **1**, **2**, und **3**, die in schmalen großen Spitze erscheinen, zeigen am Anfang und am Ende der Erwärmung auf

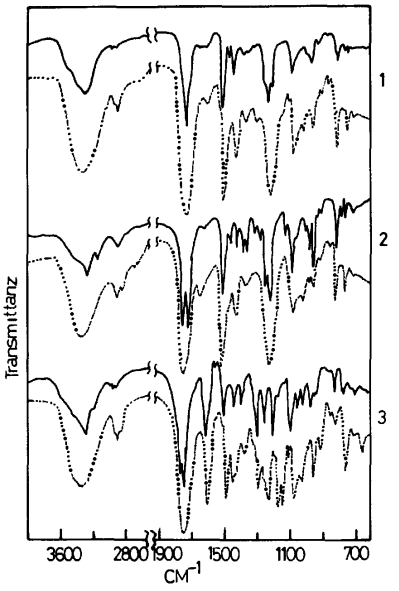

Abb. 3. Heizeffekt auf IR Spektren unter vermindertem Druck (10^{-3} mmHg) bei **1**, **2**, und **3**. Eine durchgehende Linie: vor Erwärmung. Eine punktierte Linie: nach Erwärmung bei 250°C.

alle Fälle eine gleiche Spitze. Aus den Veränderungen der IR Spektren von **1**, **2**, und **3** mit zunehmender Laufzeit der Erwärmung läßt sich schließen, daß gemäß der Erwärmung einige CH_2O-Bindung zwischen Benzolring und Oxazolidinonring zerreißt wird. Durch die Erwärmung wurde alle 3 Proben in 2-Imidazolidinon und Hydrochinon oder Resorcin zersetzt.

Massenspektren. Der Zersetzungsverlauf kann mittels der entsprechenden Massenspektroskopie direkt verfolgt werden. Die Veränderung der Massenspektren von den 3 Proben wurde im Bereich der Ionisierungsspannung 10—75 eV untersucht. Die niederauflösenden Massenspektren von **1**, **2**, und **3** sind in Abb. 4 dargestellt. Wie in Abb. 4 ersichtlich ist, ergibt sich in allen drei Proben eine Molekulionspitze. Die Basisionenspitze von **1**, **2**, und **3** ist m/z 110 ($C_6H_6O_2^+$, Unsättigungsgrad=4.0). Diese Spitze entspricht einer Spaltungstücksion von Hydrochinon und Resorcin. Aus den Resultate der niederauflösenden Massenspektren wurde vorausberechnet, daß der durch Elektronenschläge erregte Hauptspaltungsmechanismus von allen 3 Proben über der Spaltung der Bindung zwischen Benzolring und oxazolidinonring in sechs Spaltungsstilen besteht. Die hierbei auftretenden Spaltungsstile lassen sich in zwei Gruppen gliedern:

— Einfache Spaltungsreaktionen (3 Stile)

— Wasserstoff-Umlagerungsreaktionen (3 Stile)

In Abb. 5 sind sechs Spaltungsstile dargestellt. Die Spaltstücksionen, $RC_6H_4^+$, $RC_6H_5^+$, die durch den Prozeß(I) in Abb. 5 bei niederauflösenden Massenspektren festgestellt wurden, konnten - vom Gesichtspunkt der hochauflösenden Massenspektren aus - nicht

Abb. 5. Hauptspaltungsmechanismus des Elektronenschlages von **1**, **2**, und **3**.

erfaßt werden. Das war dasselbe Result wie bei der früheren Untersuchung über Phenol.[5] Die Spaltstücksionen bei den Hauptspaltungsmechanismen des Elektronschlages zwischen Benzolring und Oxazolidinonring von **1**, **2**, und **3** zeigten, daß die Benzolring enthaltende Spaltstückionen in überwiegender Mehrheit existierten. Die hochauflösende Massenspektroskopie wurde ausgeführt, um den Spaltungsmechanismus bis in Details zu untersuchen. Die Ergebnisse der Messung von **2** sind in Tabelle 2 zusammengestellt.

Kinetik vom thermischen Zersetzungsvorgang. Die Kinetik der thermischen Zersetzung wurde an der DTA Kurves untersucht. Am Anfang wurde die Abhängigkeit der Temperatur des DTA-Maximums von der Aufheizgeschwindigkeit bei der thermischen Zersetzung von **1**, **2**, und **3** untersucht. Kissinger[6] leitete die einer thermischen Zersetzungsreaktion entsprechende Gleichung ab

$$\frac{d\ln(\phi/T_m^2)}{d(1/T_m)} = E/R \qquad (1)$$

wo ϕ für Aufheizgeschwindigkeit steht, T_m für Temperatur des DTA-Maximums, und E für Aktivierungsenergie, und R für Gaskonstant. Aus Gl. 1 ersieht man, daß bei kleinen Aktivierungsenergien eine starke Verschiebung des Temperaturmaximums der DTA-Kurve zu erwarten ist. In Abb. 6 ist das $\ln(\phi/T_m^2)-1/T_m$

Verbindungen	Schmelzwärme	Aktivierungsenergie	Kristallisationswärme[a]
	kJ mol^{-1}	kJ mol^{-1}	kJ mol^{-1}
1	30.5	142.7	—
2	42.7	158.8	3.8
3	48.1	130.0	—

a) Berechnete Wert von einer exothermen Spitze, die nach dreimaliger Wiederholung des Kreisprozess in Abb. 2 erschien.

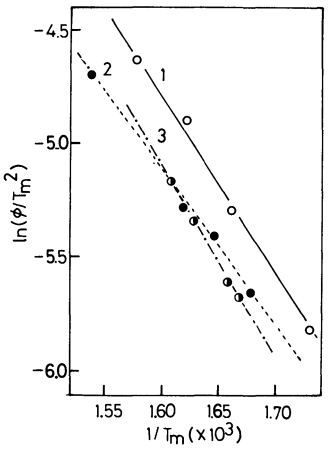

Abb. 6. $\ln(\phi/T_m^2)-1/T_m$ Diagram zur Berechnung der Aktivierungsenergie nach der Kissingerschen-Gleichung.

Diagram zur Berechnug der Aktivierungsenergie dargestellt. In Tabelle 3 sind die, aus dem Flächengröße der DSC Kurve berechneten, Schmelzwärme, Kristallisationswärme, und die aus DTA Kurven nach der Kissingerschen Gleichung berechneten Aktivierungsenergien der Zersetzungsreaktionen bei den 3 Proben zusammengestellt. Aus Tabelle 3 ist ersichtlich, daß der Wert der Schmelzwärmen nach der Reihe **3>2>1** zunahm und der Wert der Aktivierungsenergien nach der Reihe **2>1>3**. Aus diese Resultate wurde bestätigt, daß die thermischen Zersetzung von **2** oder **3** über den Prozeß der Bildung von **1** oder 4-(Hydroxyphenoxymethyl)-2-oxazolidinon verlaufe. Die Aktivierungsenergie nimmt mit der Zahl der Bindungen zwischen Benzolring und Oxazolidinonring ab.

Die Materialien in der vorliegenden Arbeit wurden von Nissankagaku A.G. angeboten. Für die Bedienung der Apparatur zur Anfertigung der Mass und NMR Spektren haben sich in dankenwerterweise Fräulein M. Shinoda und Herr K. Yoneyama zur Verfügung gestellt. Herrn Prof. S. Takeuchi danken wir bestens für wertvolle Hinweise.

The Lithium Diisopropylamide-Induced Fragmentation of 2,2-Diphenyl-1,3-dithiolane *S*-Oxide and Several 2,2-Diaryl-1,3-dithiolane *S,S'*-Dioxides

Yoshihiko INOUE, Shigeo TANIMOTO,* and Tatsuo OIDA
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received June 12, 1986)

The reaction of 2,2-diphenyl-1,3-dithiolane *S*-oxide with lithium diisopropylamide results in fragmentation to thiobenzophenone followed by further conversion leading to alkyl diphenylmethyl sulfide on trapping with alkyl halide. The reaction of 2,2-diaryl-1,3-dithiolane *S,S'*-dioxides with lithium diisopropylamide proceeded smoothly to afford 1,1-diaryl-*N,N*-diisopropylmethanesulfinamides in moderate yields via the intermediate diaryl thioketone *S*-oxides.

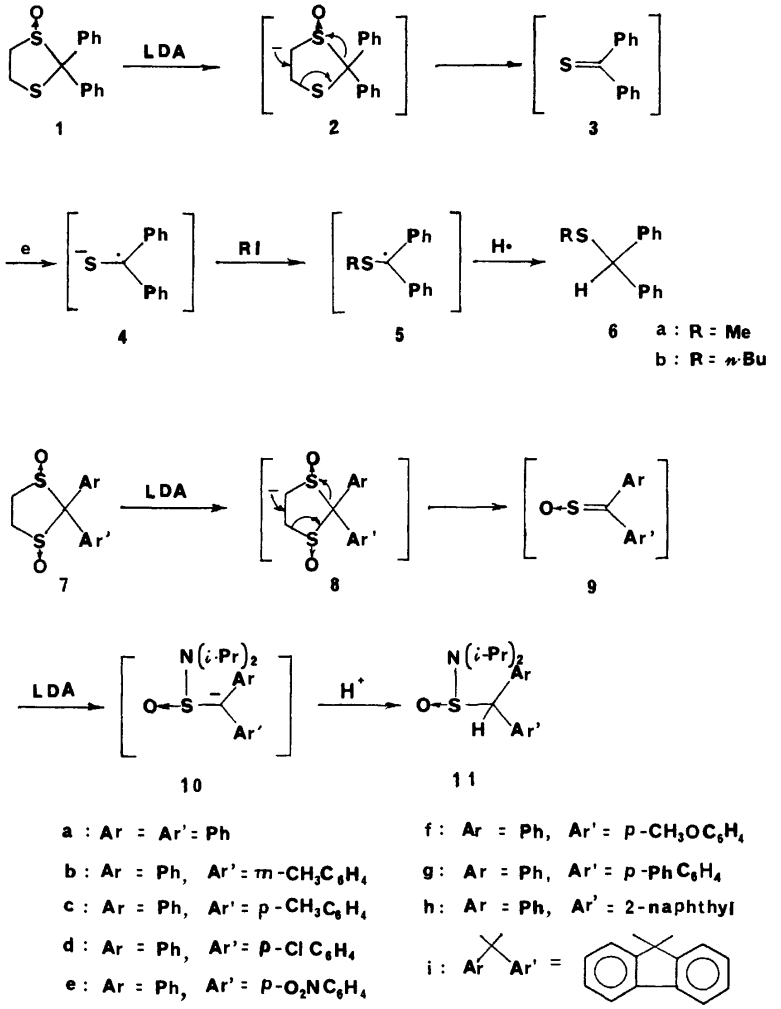
It is well-known that 2-lithio-1,3-dithiolanes undergo facile elimination to form ethylene and dithiocarbonates.[1,2] On the other hand, 4-lithio-1,3-dithiolanes, as unstable intermediates occurring in the reaction of 1,3-dithiolanes with butyllithium, undergo facile fragmentation to the corresponding thiocarbonyl compounds followed by further reaction such as reduction, *S*-addition, *C*-addition, or double addition with butyllithium.[3,4] 4-Lithio-1,3-dithiolanes bearing two aromatic substituents at *C*-2 are also formed by the reaction of 2,2-diaryl-1,3-dithiolanes with less nucleophilic lithium diisopropylamide (LDA), and diaryl thioketones arising from these 4-lithio-1,3-dithiolanes afforded alkyl diarylmethyl sulfides or their α-alkyl derivatives by quenching the reaction mixture with alkyl halides.[2] The same fragmentation-alkylation sequence using LDA has also been applied to several 2-alkyl-2-aryl-1,3-dithiolanes.[5] Moreover, it has been reported[6] that 1,3-dithiolane *S,S*-dioxides derived from benzophenone and camphor undergo facile metalation with LDA or potassium *t*-butoxide followed by fragmentation to the corresponding thiobenzophenone and thiocamphor, respectively. These thioketones have been isolated[6] without any conversion by the bases used in the reaction systems. With these considerations in mind, we have studied the reaction of 2,2-diphenyl-1,3-dithiolane *S*-oxide (**1**) and several 2,2-diaryl-1,3-dithiolane *S,S'*-dioxides (**7**) with LDA in tetrahydrofuran.

Results and Discussion

A noteworthy observation[7] on the stereoselectivity in oxidation of 2-substituted 1,3-dithiolanes with *m*-chloroperbenzoic acid is recorded in the literature. Also, the oxidation of a few 2,2-disubstituted 1,3-dithiolanes such as 2,2-diphenyl-1,3-dithiolane with H_2O_2 providing the corresponding *S*-oxides or *S,S'*-dioxides has been reported.[8] However, no report thus far appears in which the oxidation of 2,2-diaryl-1,3-dithiolanes with *m*-chloroperbenzoic acid is described. Although not proved, almost all of **1** and **7** used in this research will probably be a mixture of two or more stereoisomers. Compound **1** is a racemic mixture, and both 2,2-diphenyl-1,3-dithiolane *S,S'*-dioxide (**7a**) and spiro[1,3-dithiolane-2,9'-[9*H*]fluorene] *S,S'*-dioxide (**7i**) are mixtures of cis and trans-forms.[9] Other 2,2-diaryl-1,3-dithiolane *S,S'*-dioxides (**7b—h**) are constituted of four stereoisomers. This may be evidenced by the fact that most of **7** melt over a relatively broad range of temperature, especially 2-(2-naphthyl)-2-phenyl-1,3-dithiolane *S,S'*-dioxide (**7h**) melts abnormally.[10] Alo, according to Henbest and his coworker,[11] the competitive formation of 2,2-diaryl-1,3-dithiolane *S,S*-dioxides in the oxidative process of 2,2-diaryl-1,3-dithiolanes with *m*-chloroperbenzoic acid giving **7** seems to be negligible. Thus, **1** and **7** have been prepared using *m*-chloroperbenzoic acid and submitted to the action of LDA in tetrahydrofuran.

The reaction of **1** with an excess of LDA proceeded smoothly via proton abstraction at *C*-5 followed by cyclo-elimination affording thiobenzophenone (**3**) and an ethylenesulfinate anion. The resulting **3** is labile in this reaction system, and hence **3** is converted to alkyl diphenylmethyl sulfides (**6**) via a process involving a one-electron transfer from LDA, the charge neutralization by the added alkyl iodide (methyl iodide or butyl iodide), and the abstraction of a hydrogen radical from tetrahydrofuran. Thus, we have obtained excellent yields of diphenylmethyl methyl sulfide (**6a**) and butyl diphenylmethyl sulfide (**6b**), which are identical with those obtained[2] by the reaction of 2,2-diphenyl-1,3-dithiolane itself and LDA followed by trapping with methyl iodide and butyl iodide, respectively.

Next, 2,2-diaryl-1,3-dithiolane *S,S'*-dioxides (**7a—i**) were submitted to fragmentation with an excess of LDA in tetrahydrofuran at low temperature. These, without any trapping with alkyl halide, led to the corresponding 1,1-diaryl-*N,N*-diisopropylmethanesulfinamides (**11a—i**) via a successive attack of 2 molar equivalents of LDA to **7a—i**. Though the exact mechanism is still in doubt, it is certain that the deprotonation at *C*-4 of the ring affording **8** is the first step. Probably, the intermediate **8** undergoes cyclo-elimination leading to diaryl thioketone *S*-oxides (**9**) and an ethylenesulfinate anion. The former is converted to an anionic species (**10**) by the nucleophilic attack of a second LDA molecule. In another experiment with **7a**,



in which only a 1.2-fold excess of LDA was used, *N,N*-diisopropyl-1,1-diphenylmethanesulfinamide (**11a**) was obtained in 28% yield. This result indicates that the nucleophilic attack of a second LDA molecule to thiobenzophenone *S*-oxide (**9a**) takes place very rapidly. When D_2O was used in the quenching step of the experiment, which was conducted with **7a** and a 2.5-fold excess of LDA, 1-deuterio-*N,N*-diisopropyl-1,1-diphenylmethanesulfinamide was obtained in almost the same yield as **11a**. These experimental facts substantiate the proposed mechanical assignment of the present reaction. The results with **1** and **7a—i** are summarized in Table 1. The physical and analytical data of the products obtained are listed in Table 2.

Except **11a** and *N,N*-diisopropyl-9*H*-fluorene-9-sulfinamide (**11i**), the 1,1-diaryl-*N,N*-diisopropylmethanesulfinamides (**11b—h**) obtained possess two dissimilar asymmetric centers, and hence four stereoisomers are possible. Each of the two products, 1-(4-chlorophenyl)-*N,N*-diisopropyl-1-phenylmethanesulfinamide (**11d**) and *N,N*-diisopropyl-1-(4-nitrophenyl)-1-phenylmethanesulfinamide (**11e**), was chromatographically separated into two kinds of racemates distinguishable from each other by a difference in melting point. Each of **11a** and **11i** is a racemic mixture; the former was isolated as crystals with relatively sharp melting point and the latter was an oily substance.

Experimental

Preparation of 2,2-Diphenyl-1,3-dithiolane *S*-Oxide (1). To a stirred, cooled (0 °C) solution of 2,2-diphenyl-1,3-dithiolane (5.2 g, 20 mmol) in dichloromethane (50 ml) a solution of *m*-chloroperbenzoic acid (3.4 g, 20 mmol) in dichloromethane (40 ml) was added during 2 h, followed by stirring at reflux temperature for 3 h. The reaction mixture was cooled overnight in an ice bath. The precipitated benzoic acid was filtered off and the filtrate was washed with 10% aqueous $NaHCO_3$ (3×50 ml). The washings were extracted with dichloromethane (3×50 ml) and the dichloromethane extract obtained was combined with the above filtrate. It was dried over $MgSO_4$ and the solvent was removed in vacuo to give a residue which was recrystallized from ethanol, yield 3.7 g (65%), mp 127—129 °C (lit,[8] mp of 2,2-diphenyl-1,3-dithiolane *S*-oxide prepared from 2,2-diphenyl-1,3-dithiolane and H_2O_2 is 131—132 °C). Found: C, 65.67; H, 5.22%. Calcd for $C_{15}H_{14}OS_2$: C, 65.66; H, 5.14%. ^{1}H-NMR ($CDCl_3$) δ=2.9—4.0 (m, 4H), 7.0—8.1 (m, 10H).

Preparation of 2,2-Diaryl-1,3-dithiolane *S,S'*-Dioxides (7a—i). 2,2-Diphenyl-1,3-dithiolane *S,S'*-Dioxide (7a): To a stirred, cooled (0 °C) solution of 2,2-diphenyl-1,3-dithiolane

Table 1. The Reaction of 2,2-Diphenyl-1,3-dithiolane S-Oxide (**1**) and 2,2-Diaryl-1,3-dithiolane S,S'-Dioxides (**7a—i**) with Lithium Diisopropylamide (LDA)

a) Racemic mixture. b) Mixture composed of four stereoisomers unseparable from each other by column chromatography. 1 Torr = 133.322 Pa.

(5.2 g, 20 mmol) in dichloromethane (50 ml) a solution of *m*-chloroperbenzoic acid (6.9 g, 40 mmol) in dichloromethane (50 ml) was added during 3 h, followed by stirring at reflux temperature for 3 h. The reaction mixture was conducted as above. The crude product obtained was recrystallized from ethanol. If necessary, the crude product was purified by column chromatography on silica gel, using ethyl acetate as eluent, prior to the recrystallization, yield 6.51 g (56%), mp 186—189 °C. Found: C, 61.98; H, 4.95%. Calcd for $C_{15}H_{14}O_2S_2$: C, 62.04; H, 4.86%. ^{1}H-NMR ($CDCl_3$)

δ=3.42 (ddd, 2H), 3.93 (ddd, 2H), 6.9—7.6 (m, 10H).

In a similar manner, other 2,2-diaryl-1,3-dithiolane *S,S'*-dioxides (**7b—i**) were prepared from the corresponding 2,2-diaryl-1,3-dithiolanes.

2-(3-Methylphenyl)-2-phenyl-1,3-dithiolane *S,S'*-Dioxide (7b): 97%, mp 167—171 °C (from ethanol). Found: C, 63.01; H, 5.14%. Calcd for $C_{16}H_{16}O_2S_2$: C, 63.13; H, 5.30%. ^{1}H-NMR ($CDCl_3$) δ=3.44 (d, 2H), 3.80 (d, 2H), 6.9—7.6 (m, 9H).

2-(4-Methylphenyl)-2-phenyl-1,3-dithiolane *S,S'*-Dioxide (7c): 80%, mp 177—180 °C (from ethanol). Found: C, 62.88; H, 5.09%. Calcd for $C_{16}H_{16}O_2S_2$: C, 63.13; H, 5.30%. ^{1}H-NMR ($CDCl_3$) δ=3.31 (s, 3H), 3.3—4.1 (m, 4H), 6.9—7.5 (m, 9H).

2-(4-Chlorophenyl)-2-phenyl-1,3-dithiolane *S,S'*-Dioxide (7d): 61%, mp was not measured. Found: C, 55.24; H, 4.06%. Calcd for $C_{15}H_{13}ClO_2S_2$: C, 55.46; H. 4.03%. ^{1}H-NMR ($CDCl_3$) δ=3.2—4.1 (m, 4H), 6.8—7.6 (m, 9H).

2-(4-Nitrophenyl)-2-phenyl-1,3-dithiolane *S,S'*-Dioxide (7e): 83%, mp was not measured. Found: C, 53.65; H, 4.05; N, 4.11%. Calcd for $C_{15}H_{13}NO_4S_2$: C, 53.72; H, 3.91; N, 4.18%. ^{1}H-NMR ($CDCl_3$) δ=3.5—4.3 (m, 4H), 7.0—7.5 (m, 7H), 8.11 (s, 1H), 8.26 (s, 1H).

2-(4-Methoxyphenyl)-2-phenyl-1,3-dithiolane *S,S'*-Dioxide (7f): 84%, mp 180—183 °C (from ethanol). Found: C, 59.95; H, 5.07%. Calcd for $C_{16}H_{16}O_3S_2$: C, 59.97; H, 5.03%. ^{1}H-NMR ($CDCl_3$) δ=3.71 (s, 3H), 3.3—4.0 (m, 4H), 6.70 and 6.86 (s and s, 2H), 7.1—7.6 (m, 7H).

2-(1,1'-Biphenyl-4-yl)-2-phenyl-1,3-dithiolane *S,S'*-Dioxide (7g): 48%, mp 186—189 °C (from ethanol). Found: C, 68.70; H, 4.68%. Calcd for $C_{21}H_{18}O_2S_2$: C, 68.82; H, 4.95%. ^{1}H-NMR ($CDCl_3$) δ=3.2—4.1 (m, 4H), 7.0—7.8 (m, 14H).

2-(2-Naphthyl)-2-phenyl-1,3-dithiolane *S,S'*-Dioxide (7h): 59%, mp 163— °C (from ethanol). Found: C, 67.68; H, 5.05%. Calcd for $C_{19}H_{16}O_2S_2$: C, 67.03; H, 4.74%. ^{1}H-NMR ($CDCl_3$) δ=3.2—4.5 (m, 4H), 7.0—8.0 (m, 12H).

Spiro[1,3-dithiolane-2,9'-[9*H*]fluorene] *S,S'*-Dioxide (7i): 74%, mp 176—181 °C (from ethanol). Found: C, 62.22; H, 4.06%. Calcd for $C_{15}H_{12}O_2S_2$: C, 62.47; H, 4.19%. ^{1}H-NMR ($CDCl_3$) δ=3.69 (dd, 2H), 4.27 (dd, 2H), 7.1—7.9 (m, 8H).

The Reaction of 2,2-Diphenyl-1,3-dithiolane *S*-Oxide (1) with Lithium Diisopropylamide (LDA) (Entries 1 and 2 of Table 1). To a stirred, cooled (−78 °C) solution of diisopropylamine (0.35 g, 3.5 mmol) in tetrahydrofuran (7 ml) was added a 1.56 molar solution (2.1 ml, 3.3 mmol) of butyllithium in hexane under nitrogen, followed by stirring at the same temperature for 30 min and further stirring at −15 °C for 10 min. The solution of LDA thus prepared was maintained at −15 °C. It was slowly added to a stirred, cooled (−78 °C) solution of **1** (0.35 g, 1.3 mmol) in tetrahydrofuran (4 ml) under nitrogen. The reaction mixture was warmed to room temperature and the stirring was continued for 1 h. The mixture was cooled again to −78 °C, and 3.3 mmol of an alkyl halide (0.47 g of methyl iodide or 0.61 g of butyl iodide) was added with stirring. The mixture was stirred for 1 h at 0 °C, warmed to room temperature, stirred an additional 24 h, quenched with 20 ml of a saturated aqueous solution of NH_4Cl, and extracted with ether (3×60 ml). The ethereal extract was dried over $MgSO_4$ and concentrated in vacuo to give a residue, which was subjected to purification by column chromatography on silica gel.

The Reaction of 2,2-Diaryl-1,3-dithiolane *S,S'*-Dioxides (7a—i) with Lithium Diisopropylamide (LDA) (Entries 3—12 of Table 1). The LDA solution prepared in the same way as above was slowly added with stirring to a cooled (−78 °C) solution of the appropriate **7a—i** (1.3 mmol) in tetrahydrofuran (4 ml) under nitrogen. Stirring was continued for 2 h at −78 °C, and the reaction mixture was quenched with 100 ml of H_2O and 20 ml of a saturated aqueous solution of NH_4Cl. It was extracted with ether (3×60 ml). The ethereal extract was dried over $MgSO_4$, filtered, and concentrated in vacuo to give a residue, which was purified by column chromatography on silica gel. Only in the case of Entry 4 in Table 1, an excess of butyl iodide was added to the reaction mixture prior to the quenching with H_2O. However, the yield of the objective **11a** was not altered by the addition, suggesting that the anionic species **10** is unreactive to butyl iodide and hence the true trapping agent is H_2O.

Exo/Endo Stereoselectivity in 1,3-Dipolar Cycloaddition of Trifluoroacetonitrile Oxide and -nitrilimine with Bicyclic Olefins[1)]

Kiyoshi TANAKA,* Hideyuki MASUDA, and Keiryo MITSUHASHI
Department of Industrial Chemistry, College of Technology, Seikei University, Musashino, Tokyo 180
(Received June 13, 1986)

Trifluoroacetonitrile oxide and *N*-phenyl-*C*-(trifluoromethyl)nitrilimine cycloadded with norbornenes, resulting in the exclusive formation of the exo-adducts, while the concomitant formation of the endo-adducts was observed in their cycloadditions with norbornadienes. The nitrile oxide was subjected to the cycloaddition with 2,3-disubstituted norbornadienes to evaluate the effect of the substituents on the exo/endo stereoselectivity. The electron-withdrawing substituents tend to favor the formation of the exo-adducts.

Remarkable stereoselectivity has been observed in 1,3-dipolar cycloadditions with bicyclic systems,[2)] and indeed, that with norbornenes proceeds exclusively on the exo face.[3)] In norbornadiene system, however, the stereospecificity is released. Cycloadditions of benzonitrile oxide and *C,N*-diphenylnitrilimine with norbornadiene itself, for example, afford a small amount of the endo-adducts together with the exo-adducts as the major products.[4,5)] Imoto and his coworkers have reported that the substituents attached to the unsaturated carbon in norbornadiene system affect the exo/endo product ratios. The amount of the endo-adduct, in the cycloadditions of phenylglyoxylonitrile oxide, increases with the electron-withdrawing substituents.[5)] These interesting results prompted us to investigate the exo/endo stereoselectivity in 1,3-dipolar cycloadditions of trifluoroacetonitrile oxide (**2**), which could be comparable to phenylglyoxylonitrile oxide in point of its electronic effect, with norbornenes and norbornadienes. The stereoselectivity of *N*-phenyl-*C*-(trifluoromethyl)nitrilimine (**10**) is also described.

The nitrile oxide **2**, generated in situ from trifluoroacetohydroximoyl bromide etherate (**1**) with triethylamine, cycloadded with norbornene in toluene, resulting in the exclusive formation of the exo-adduct, 5-trifluoromethyl-3-oxa-4-azatricyclo[5.2.1.$0^{2,6exo}$]dec-4-ene (**3a**), in a good yield (Table 1). Its configuration was determined on the basis of the absence of the coupling between the 2-proton and the vicinal bridgehead

proton and that between the 6- and 7-protons in ^{1}H NMR spectrum.[6] In the cycloaddition with 2,3-dicyanonorbornene, the product was isolated as the sole exo-adduct **3b** and, however, its absolute configuration around the carbon atom bearing the cyano group was ambiguous. The similar high stereospecificity was observed in the cases with endo-bicyclo-[2.2.1]hept-5-ene-2,3-dicarboxylic anhydride and dicyclopentadiene to afford the exo-adducts **4** and **5**, respectively. The adduct **5** was a mixture consisting of two isomers, having the carbon-carbon double bond at different position. And their double bonds were selectively saturated by hydrogen using palladium-carbon catalyst to give the same product **6**.

In the cases with norbornadienes, the high stereospecificity was relaxed. The nitrile oxide **2** was first subjected to the reaction with norbornadiene in toluene at room temperature to afford a mixture of the exo-adduct, 5-trifluoromethyl-3-oxa-4-azatricyclo-[5.2.1.$0^{2,6\text{exo}}$]deca-4,8-diene (**7a**), and its endo-isomer **7'a** in the ratio of 79/21 (Scheme 2). In ^{1}H NMR spectrum of the latter, both 2- and 6-protons couple with their adjacent bridgehead protons in 4 Hz (Table 2).[5] Although being stable at room temperature, both isomers were found to undergo the retro Diels-Alder reaction into 3-trifluoromethylisoxazole (**8**) under more drastic conditions.[7] ^{1}H NMR analysis of their breakdown with lapse of time reveals that the exo-adduct **7a** is much more stable than the endo-adduct **7'a**. After heating at 130 °C for 1 h, **7'a** was completely disappeared to form **8** in a 93% yield, whereas 33% of **7a** was found to survive even after 4 h, accompanied by the formation of 65% of **8**. These results support that **7'a** does not isomerize to the stable isomer **7a** on heating, indicating **7a** and **7'a** to be both primary products of the cycloaddition. The effect of the substituents, attached to the unsaturated carbon atom in the norbornadiene system, on the exo/endo stereoselectivity was next investigated. The reactions were carried out in toluene at room temperature and the results are summarized in Table 3. The electron-withdrawing substituents such as methoxycarbonyl and cyano groups

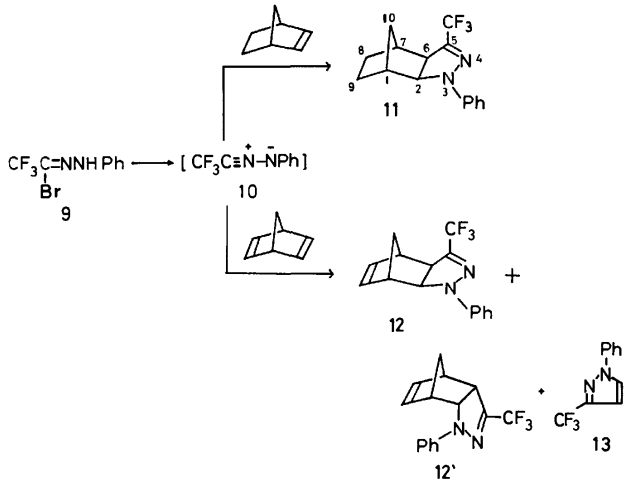

Scheme 3.

were found to favor slightly the formation of the exo-adducts, compared with that in unsubstituted norbornadiene itself. And, in the case of trifluoromethyl group as the substituent, the exo-adduct was exclusively formed, accompanying no endo-adduct any longer. The temperature dependence of the exo/endo stereoselectivity is not apparently observed whereas the appreciable solvent effect between toluene and tetrahydrofuran is detected in the cases of norbornadiene and 2,3-dicyanonorbornadiene, as shown in Table 3.[8] However, in any case, the tendency of the electron-withdrawing substituents in favor of the exo-adducts is always consistent. This tendency is in sharp contrast to that of phenylglyoxylonitrile oxide, where the electron-withdrawing substituents increase the formation of the endo-adducts reversely (Table 3).[5] Although the reason why the tendency of **2** in the exo/endo stereoselectivity is different from that of phenylglyoxylonitrile oxide is not definite, it is suggested that the selectivity could be controlled by not only the electronic status of the substituted norbornadienes but also the interactions between the norbornadienes and the 1,3-dipolar compounds.

The stereoselectivity was next investigated with regard to the nitrilimine **10**, derived in situ from *N*-phenyltrifluoroacetohydrazonoyl bromide (**9**) in the presence of triethylamine. It was allowed to cycloadd with norbornene in toluene, giving rise to only the exo-adduct, 3-phenyl-5-trifluoromethyl-3,4-diazatricyclo-[5.2.1.$0^{2,6exo}$]dec-4-ene (**11**), in a moderate yield. With norbornadiene, the concomitant formation of the endo-adduct was again observed. 3-Phenyl-5-trifluoromethyl-3,4-diazatricyclo[5.2.1.$0^{2,6exo}$]deca-4,8-diene (**12**) and its endo-isomer **12'** as well as 1-phenyl-3-trifluoromethylpyrazole (**13**) were obtained in 45, 18, and 7% yields, respectively. The endo-adduct **12'** was found to undergo the breakdown rather easily even at room temperature into the pyrazole **13**.[9]

Experimental

All melting and boiling points are uncorrected. The IR spectra were recorded on a JASCO A-100 spectrometer. Samples were run as potassium bromide pellets for crystals or as film for oil. The ^{1}H NMR spectra were measured with a JEOL JNM-PMX 60 spectrometer using tetramethylsilane as an internal standard, the chemical shifts being given in δ ppm downfield. The MS spectra were obtained on a Finnigan 4023 GC-MS DS spectrometer. The bromides **1** and **9** were prepared by the methods reported in our previous papers.[10]

Cycloaddition of 2 with Norbornenes. General Procedures. A solution of triethylamine (20.0 mmol) in 10 cm^3 of toluene was added dropwise to a solution of **1** (10.0 mmol) and the corresponding norbornene derivative (30.0 mmol) in

20 cm^3 of toluene. After stirring at room temperature for 3 h, excess of hexane was added to the reaction mixture. The formed solid was filtered off and the filtrate was washed with water and brine, dried over magnesium sulfate, and evaporated to leave a residue. The resulting residue was (a) distilled under reduced pressure to give **3a** and **5**, respectively, (b) recrystallized from ethanol to give **3b**. On the other hand, **4** was isolated from the formed solid as follows. The solid consisting of **4** and triethylammonium bromide was extracted with acetone. Removal of the solvent left a solid which was recrystallized from chloroform–methanol to give **4**.

Hydrogenation of 5. A mixture of **5** (0.70 g, 2.88 mmol) and 5% palladium-carbon (40 mg) in 20 cm^3 of methanol was stirred at room temperature under an atmosphere of hydrogen. When an equivalent of hydrogen was consumed, the reaction was stopped. The catalyst was filtered off and, after the solvent was removed, the resulting oil was distilled to give 0.55 g (78%) of **6**.

Cycloaddition of 2 with Norbornadienes. General Procedures. To a solution of **1** (13.0 mmol) and the corresponding norbornadiene derivative (39.0 mmol for norbornadiene itself or 13.0 mmol for other substituted norbornadienes) in 20 cm^3 of toluene or tetrahydrofuran was added dropwise a solution of triethylamine (16.9 mmol) in 10 cm^3 of toluene or tetrahydrofuran at the temperature shown in Table 3. After the reaction mixture was stirred at the same temperature for 2 h, excess diethyl ether was added to the mixture and the resulting triethylammonium bromide was removed by filtration. The filtrate was washed with water and brine, dried over magnesium sulfate, and evaporated to leave a residue. Thus obtained residue was chromatographed on silica gel to separate the corresponding exo- and endo-adducts, respectively. Each adduct was further purified by distillation or recrystallization.

Retro Diels–Alder Reaction of 7'a. The endo-adduct **7'a** (100 mg) was heated at 130 °C in a sealed tube. After 1 h of heating, the mixture was cooled. ^1H NMR analysis of the mixture showed **8** in a 93% yield and dicyclopentadiene. The isoxazole **8** was purified by preparative GLC, ^1H NMR ($CDCl_3$) δ=6.64 (d, J=2.3 Hz, 1H), 8.59 (br.s, 1H), IR 3160, 3140 (CH), 1190, 1150 cm^{-1} (CF_3).

Found: C, 34.83; H, 1.21; N, 10.18%. Calcd for $C_4H_2F_3NO$: C, 35.05; H; 1.47; N, 10.22%.

Cycloaddition of 10 with Norbornadiene. Triethylamine (4 ml) was added dropwise to a solution of **9** (2.00 g, 7.5 mmol) and norbornadiene (2.07 g, 22.5 mmol) in 20 cm^3 of toluene. After 20 h of stirring at room temperature, 100 cm^3 of diethyl ether was added. The mixture was washed with water and brine, dried over magnesium sulfate, and evaporated under reduced pressure to leave a residue which was placed on a column (silica gel) and eluted with hexane–chloroform (10:1) to give 0.94 g (45%) of **12**, 0.37 g (18%) of **12'**, and 0.11 g (7%) of **13**, respectively. The exo-adduct **12** was further purified by recrystallization from hexane, mp 75—77 °C, ^1H NMR (CCl_4) δ=1.61 (br.s, 2H), 3.2—3.8 (m, 3H), 4.47 (d, J=10 Hz, 1H), 6.14 (dd, 1H), 6.32 (dd, 1H), 6.5—7.5 (m, 5H), IR 1604 (C=N), 1180, 1165 cm^{-1} (CF_3).

Found: C, 64.87; H, 4.54; N, 10.33%. Calcd for $C_{15}H_{13}F_3N_2$: C, 64.74; H, 4.71; N, 10.07%.

12': Pale yellow oil, ^1H NMR (CCl_4) δ=1.2—1.7 (m, 2H), 3.2—3.7 (m, 2H), 3.85 (ddq, J=11, 4, and 2 Hz, 1H), 4.83 (dd, J=11 and 4 Hz, 1H), 5.83 (dd, 1H), 6.06 (dd, 1H), 6.5—7.5 (m, 5H). IR 1602 (C=N), 1180, 1150 cm^{-1} (CF_3). The reliable elemental analysis could not be performed because of its easy breakdown.

Spectral data of thus obtained pyrazole **13** are consistent with those of our authentic sample.[11]

The exo-adduct **11** was similarly obtained in a 67% yield from the reaction of **9** with norbornene, mp 78.5—79.5 °C (lit,[12] 78.5—79.5 °C).

Radiation-Induced Alkylation of Quinoline Derivatives with Alcohol

Akira SUGIMORI,* Tetsuo YAMADA, Hiroaki ISHIDA, Masayuki NOSE, Keiko TERASHIMA, and Noriko OOHATA
Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioi-cho 7-1, Chiyoda-ku, Tokyo 102
(Received June 16, 1986)

Gamma-irradiation of quinoline and its derivatives in alcohols brings about alkylation at the 2- or 4-position of pyridine ring. Hydroxyalkyl radicals play important roles in the radiation-induced alkylation with alcohol. The radiation-induced substitution of CF_3CH_2- and $CF_3CH(OH)$- for H in pyridine and pyrimidine rings occurs in low yields.

The introduction of substituents in aromatic rings can be effectively done by the use of electrophilic reagents. However, electophilic substitution is not effective for the electron-deficient heteroaromatic rings such as pyridine nucleus.

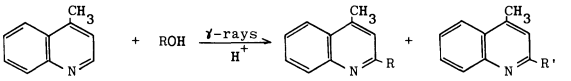
The method utilizing anionic species such as Grignard reagents and organolithium compounds have been developed for the introduction of alkyl groups in the pyridine ring.[1] Free radical species have also been used for the substitution in the pyridine ring. Alkylation and hydroxyalkylation initiated by peroxodisulfate have been studied extensively by Minisci et al.[2,3] Ultraviolet irradiation causes the alkylation of pyridine ring with alcohols[4] or alkanoic acids.[5]

The irradiation of ionizing radiation can generate free radical species but it has not been used effectively for the introduction of substituents in the electron-deficient heteroaromatic ring. We have reported the radiation-induced alkylation and hydroxyalkylation of pyridinecarboxylic esters,[6] pyridinecarboxamides,[7] and pyridinecarbonitriles[8] in alcohols.

In this paper, we describe the radiation-induced alkylation and hydroxyalkylation by alcohols using quinoline derivatives as fundamental pyridine derivatives. The method of γ-irradiation is compared with other methods generating free radical species.

Results and Discussion

Radiation-Induced Alkylation with Alcohol. The γ-irradiation of the alcoholic solutions of 4-methylquinoline (**1a**) in the presence of sulfuric acid brings about the alkylation at the 4-position in good radiation chemical yields (*G*-values) (Table 1). The alkyl groups introduced have mainly the same skeletal structures as those of the alcohols. However, with higher alcohols, especially with secondary alcohol (2-propanol), the alkyl groups of the smaller carbon numbers than those of the original alcohols are introduced.



R': Alkyl group with smaller carbon number than R.

The radiation-induced alkylation in the pyridine ring occurs efficiently in the γ-irradiation of the quinolinium salt in alcohol in the presence and absence of sulfuric acid (Table 1).

The main reactive species formed in the radiolysis of alcohols are solvated electron, hydrogen atom, and 1-hydroxyalkyl radical. The *G*-values of e_{solv}^-, $\cdot H$, $\cdot OH$, $\cdot CH_2OH$, and $\cdot CH_3$ in the radiolysis of methanol have been reported to be 2.0, 1.1, 0.2, 2.7, and 0.2, respectively.[9]

Methyl radical can bring about methylation of the pyridine ring.[10,11] However, the methyl radical formed in the radiolysis of methanol can explain only a part of the radiation-induced methylation of **1a** with methanol, because the *G*(methylation) is larger than $G(\cdot CH_3)$. Thus, hydroxymethyl radical should play more important roles than methyl radical.

Hydroxymethyl radical can be produced by the hydrogen abstraction from methanol by free radicals pro-

	Thermal decomposition of *t*-BuCOOO-*t*-Bu at 65 °C[b)]	10.1					
	UV-irradiation in the presence of acetone[c)]	1.8					

Yield=Amount of product/Amount of substrate reacted. a) [Substrate]=0.06 mol dm^{-3}; [H_2SO_4]=0.10 mol dm^{-3}; Dose, 1.0×10^7 rad. b) [Substrate]=0.06 mol dm^{-3}; [H_2SO_4]=0.10 mol dm^{-3}; [*t*-BuCOOO-*t*-Bu]=0.06 mol dm^{-3}; Heated at 64 or 65 °C for 4 h under Ar. c) [Substrate]=0.01 mol dm^{-3}; [H_2SO_4]=0.02 mol dm^{-3}; [Acetone]=2.0 mol dm^{-3}; Irradiated in a Pyrex vessel with a high-pressure mercury lamp for 16 h under Ar.

duced in the thermal decomposition of peroxides such as *t*-butyl peroxypivalate. The UV-irradiation of acetone in methanol can also produce hydroxymethyl radical via hydrogen abstraction of excited acetone from methanol.

$$CH_3COCH_3 \xrightarrow{h\nu} {}^1(CH_3COCH_3)^* \longrightarrow {}^3(CH_3COCH_3)^*$$

$${}^3(CH_3COCH_3)^* + CH_3OH \longrightarrow CH_3\dot{C}(OH)CH_3 + \cdot CH_2OH$$

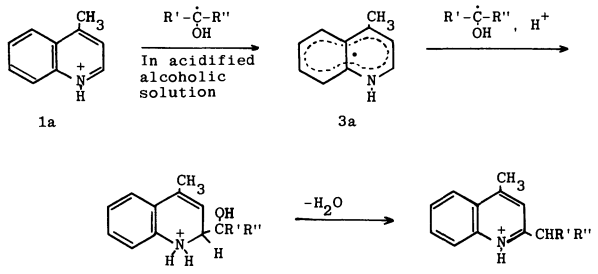
As is shown in Table 2, quinoline and isoquinoline are methylated similarily in radiation-induced reaction and in the reaction initiated by the thermolysis of *t*-butyl peroxypivalate. When the solution of quinoline or isoquinoline was irradiated in methanol in the presence of acetone with a high-pressure mercury lamp, the light from which is absorbed selectively by acetone, methylation of the pyridine rings occurs actually.

In the radiolysis of alcohol in the presence of sulfuric acid, solvated electron is converted to hydrogen atom.

$$e^-_{solv} + H^+ \longrightarrow \cdot H$$

Hydrogen atom can react either with methanol to give $\cdot CH_2OH$ radical or with quinolinium. The rate constants of $\cdot H$ with methanol (in acidified aqueous solutions) and with pyridinium ion are reported to be 2.4×10^6 [12] and 2.2×10^8 dm^{3}mol^{-1} s^{-1},[13] respectively. Considering that the concentrations of methanol and quinolinium under our reaction conditions are 25 and 0.06 mol dm^{-3}, respectively, we can postulate that hydrogen abstraction from methanol is the more favorable process for hydrogen atom than the reaction with pyridinium.

As a mechanism for alkylation by hydroxyalkyl radical, the reaction path in Scheme 1 can be postulated.



Scheme 1.

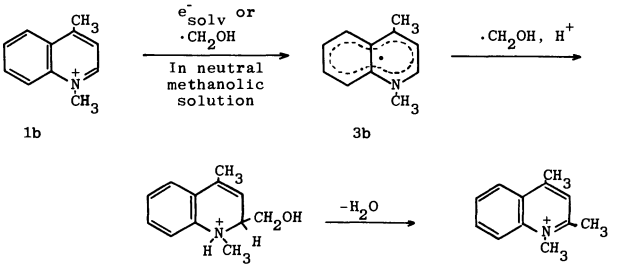
In the radiation-induced reaction of 1,4-dimethylquinolinium (**1b**) in neutral methanol, solvated electron would contribute to the methylation.

The radiation-induced methylation of **1b** is slightly affected by N_2O which converts solvated electron to hydroxymethyl radical via hydroxyl radical.

$$e^-_{solv} + N_2O \xrightarrow{H^+} \cdot OH + N_2$$

$$\cdot OH + CH_3OH \longrightarrow \cdot CH_2OH + H_2O$$

If the solvated electron does not contribute to the methylation, the *G*-value for methylation under Ar should be lower (about a half) than that under N_2O. The experimental results indicate that solvated electron and hydroxymethyl radical participate equivalently in the methylation. The lower chemical yield of methylation under N_2O than under Ar can not be explained at present.



Scheme 2.

Table 3. Radiation-Induced Reactions of Quinoline Derivatives and 4-Methylpyrimidine in CF_3CH_2OH. Dose rate, 1.0×10^6 rad h^{-1}; Dose, 5.0×10^7 rad

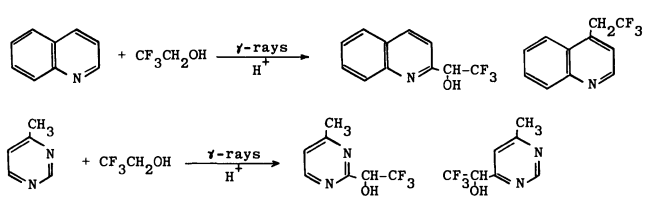
Substrate	[Substrate] / mol dm^{-3}	[H_2SO_4] / mol dm^{-3}	Substituent introduced	G-value	Yield / %
4-Methylquinoline	0.15	0.25	2-CF_3CH_2-	0.08	6.7
			2-CF_3CH(OH)-	0.07	5.6
2-Methylquinoline	0.15	0.25	4-CF_3CH_2-	0.13	8.3
Quinoline	0.30	0.50	2-CF_3CH(OH)-	0.02	1.1
			4-CF_3CH_2-	0.09	5.5
4-Methylpyrimidine	0.50	1.00	2-CF_3CH(OH)-	0.09	0.3
			6-CF_3CH(OH)-	0.48	1.3

Yield=Amount of product/Amount of substrate reacted.

As a mechanism in which solvated electron and hydroxymethyl radical participate equivalently, the reaction paths in Scheme 2 can be postulated.

According to the mechanism in Schemes 1 and 2, the efficiency for alkylation should depend both on the efficiency for the formation of the radical **3** via the attack of electron or the electron transfer from hydroxyalkyl radical to the substrate and on the efficiency for the coupling of **3** with hydroxyalkyl radical. If the two efficiencies of the hydroxyalkyl radicals are in good balance, the alkylation should proceed efficiently. 1-Hydroxy-1-methylethyl radical which is formed in the radiolysis of 2-propanol is a good electron donor but is not a reactive free radical. The inefficiency of the second step would result in the low *G*-value for isopropylation by 2-propanol. Instead, in the radiation-induced reaction in 2-propanol ethylation occurs in greater *G*-value than isopropylation. Ethylation in 2-propanol is brought about probably by 1-hydroxyethyl radical which is formed by the cleavage of a C-C bond of 2-propanol.

Radiation-Induced Reaction in 2,2,2-Trifluoroethanol. As an extension of the radiation-induced alkylation with alcohols, we examined the radiation-induced reaction of 4-methylquinoline, 2-methylquinoline, quinoline, and 4-methylpyrimidine in 2,2,2-trifluoroethanol in the presence of sulfuric acid, aiming at the introduction of fluorinated alkyl groups in the pyridine and pyrimidine rings (Table 3). Although the trifluoroethylated quinolines are formed, their chemical yields (and their *G*-values) are low. Another difference between the reactions in CH_3CH_2OH and in CF_3CH_2OH is the substitution of the 2,2,2-trifluoro-1-hydroxyethyl group in the reaction in CF_3CH_2OH.



One of the reasons for the low *G*-values of trifluoroethylation is due to the low efficiency of the electron transfer from $CF_3\dot{C}HOH$ to the electron-deficient hetroaromatic molecules, because of the high electronegativity of fluorine in the radical. In the radiation-induced reaction of **1a** in a mixed solvent of CF_3CH_2OH, CH_3OH, and H_2O (6:3:1 by volume), 4-methyl-2-(2,2,2-trifluoroethyl)quinoline (**4**) and 4-methyl-2-(2,2,2-trifluoro-1-hydroxyethyl)quinoline (**5**) are formed in equal or greater *G*-values (G(**4**)=0.07 and G(**5**)=0.09) than in the reaction in a mixed solvent of CF_3CH_2OH and H_2O (9:1 by volume)(G(**4**)=0.07 and G(**5**)=0.07) in spite of the lower formation of $CF_3\dot{C}HOH$ because of the lower concentration of CF_3CH_2OH. The fact can be explained by the contribution of $\cdot CH_2OH$ radical from methanol to the formation of **4** and **5** by the electron transfer to the protonated **1** to give the radical **3**.

The fact that the radical reaction initiated by *t*-butyl hydroperoxide and iron(II) sulfate in CF_3CH_2OH brings about neither trifluoroethylation nor trifluorohydroxyethylation, suggests that the formation of $CF_3\dot{C}HOH$ radical is not a favorable process. (In this case quinoline is methylated by the methyl radical formed by the decomposition of *t*-BuO· radical). The unfavorable formation of $CF_3\dot{C}HOH$ radical is supported by the observation that the UV-irradiation of 4-methylquinoline in CF_3CH_2OH in the presence of sulfuric acid gives no trifluoroethylation nor trifluorohydroxyethylation products. The low efficiency of the formation of $CF_3\dot{C}HOH$ is another reason for the low yields of the introduction of CF_3CH_2- and CF_3CH(OH)- groups. Only the high energy radiation enables the reaction which is not realized by free radical or photochemical processes, although the efficiencies are not high.

The formation of a trifluorohydroxyethylated products can partly be explained by the low basicity of O atom to which H^+ attack to cause dehydration.

Experimental

Materials. Commercial quinoline (GR grade reagent of Wako Junyaku Co.), isoquinoline (EP grade reagent of

Wako Junyaku Co.), 4-methylquinoline(GR grade reagent of Tokyo Kasei Co.), 2-methylquinoline (EP grade reagent of Tokyo Kasei Co.), and 4-methylpyrimidine (made by Aldrich Co.; purity, 99.7%) were purified by vacuum distillation.

1,4-Dimethylquinolinium methyl sulfate was synthesized in the reaction of 4-methylquinoline with dimethyl sulfate.

Commercial methanol (GR grade reagent of Wako Junyaku Co.), ethanol (Nippon Alcohol Co.), 1-propanol (GR grade reagent of Wako Junyaku Co.), 2-propanol (EP grade reagent of Wako Junyaku Co.) were purified by distillation.

A solution of *t*-butyl hydroperoxide (70% of purity, supplied by Aldrich Co.) was used.

2,2,2-Trifluoroethanol and *t*-butyl peroxypivalate were kindly given by Japan Halon Co. and Nippon Oil and Fats Co., respectively.

Gamma-Irradiation. Solutions containing the substrate and sulfuric acid if necessary in alcohol were deaerated by bubbling Ar (in some cases by N_2O) for 45 min before irradiation.

The solution was irradiated by Co-60 γ-rays at the irradiation facility of Japan Atomic Energy Research Institute in Takasaki at the dose of 1.0×10^7 rad (at the dose rate of 5.0×10^5 rad h^{-1} for 20 h) or at the dose of 5.0×10^7 rad (at the dose rate of 1.0×10^6 rad h^{-1} for 50 h).

Reaction Initiated by Peroxides. A methanolic solution (100 cm^3) of quinoline or isoquinoline ([Substrate]=0.06 mol dm^{-3}), sulfuric acid (0.1 mol dm^{-3}), and *t*-butyl peroxypivalate (0.06 mol dm^{-3}) was deaerated by bubbling Ar and then heated at 64 or 65 °C for 4 h.

The free radical-initiated reaction in CF_3CH_2OH was carried out in the following procedure. To a solution of the substrate (0.01 mol), *t*-butyl hydroperoxide (0.02 mol), and sulfuric acid (0.5 cm^3) in trifluoroethanol (8.3 cm^3) kept below 10 °C, was added dropwise an aqueous solution of iron(II) sulfate (0.02 mol) and sulfuric acid under Ar. After the addition of the peroxide, the solution was kept at 10—20 °C for 80 min. The reaction mixture was treated in a similar manner to that for the radiation-induced reaction.

Photoreaction in the Presence of Acetone. Solutions of the substrate (0.01 mol dm^{-3}) in methanol or trifluoroethanol in the presence of acetone (2.0 mol dm^{-3}) and sulfuric acid (0.02 mol dm^{-3}) were irradiated with a high-pressure mercury lamp for 16 h. The work up of the reaction mixture was similar to that for the radiation-induced reaction.

Separation of Products. The products in the radiation-induced reactions in alcohol in the presence of sulfuric acid were separated by means of TLC (plate, GF_{254} Type 60 supplied by E. Merck Co.), after the removal of the most part of the solvent under reduced pressure, neutralization with sodium carbonate, and the extraction with dichloromethane.

The reaction mixture from the radiation-induced reactions in 2,2,2-trifluoroethanol in the presence of sulfuric acid was treated as follows. Most part of the solvent were removed under reduced pressure and the solution was neutralized with aqueous sodium carbonate solution. The products were extracted with dichloromethane and separated by TLC (plate, GF_{254} Type 60 of E. Merck Co.). The developing solvents for the separation of the products from quinoline, 2-methylquinoline, 4-methylquinoline, and 4-methylpyrimidine are dichloromethane, dichloromethane(90%)-ethyl acetate(10%), and dichlomethane(75%)-ethyl acetate(25%), respectively.

The products were further purified by preparative gas-chromatography (column, 2 m column of PEG 20M (5%)). The column temperatures for the separation of the products from quinoline, 2-methylquinoline, 4-methylquinoline, and 4-methylpyrimidine are 190, 180, 190, and 140 °C, respectively.

Identification of Products. The formation of 2,4-dimethyl-, 2-ethyl-4-methyl-, 4-methyl-2-propyl-, and 2-isopropyl-4-methylquinolines were identified by the agreement of the spectra and gas-chromatographic behavior with the authentic samples. Authentic 2,4-dimethylquinoline is commercially available. 2-Ethyl-4-methyl-, 4-methyl-2-propyl-, and 2-isopropyl-4-methylquinolines were prepared by the reaction of 4-methylquinoline with the alkanoic acids having the alkyl moiety to be introduced under the catalysis of ammonium peroxodisulfate and silver nitrate according to Minisci et al.[11]

2-Ethyl-4-methylquinoline: ^1H NMR ($CDCl_3$) δ=1.38 (3H, t, J=7.6 Hz, 2-$CH_2C\underline{H}_3$), 2.67 (3H, s, 4-CH_3), 2.95 (2H, q, J=7.6 Hz, 2-$C\underline{H}_2CH_3$), 7.15 (1H, s, ring H at the 3-position), and 7.45—8.07 (4H, m, H of benzene ring).

4-Methyl-2-propylquinoline: ^1H NMR δ=1.02 (3H, t, J=7.5 Hz, 2-$CH_2CH_2C\underline{H}_3$), 1.83 (2H, sextet, J=7.5 Hz, 2-$CH_2C\underline{H}_2CH_3$), 2.65 (3H, s, 4-CH_3), 2.89 (2H, t, J=7.5 Hz, 2-$C\underline{H}_2CH_2CH_3$), 7.12 (1H, s, ring H at the 3-position), and 7.44—8.07 (4H, m, H of benzene ring).

2-Isopropyl-4-methylquinoline: ^1H NMR δ=1.38 (6H, d, J=6.8 Hz, 2-$CH(C\underline{H}_3)_2$), 2.66 (3H, s, 4-CH_3), 3.21 (1H, septet, J=6.8 Hz, 2-$C\underline{H}(CH_3)_2$), 7.15 (1H, s, ring H at the 3-position), and 7.43—8.08 (4H, m, H of benzene ring).

The products from the radiation-induced reactions in 2,2,2-trifluoroethanol were identified on the basis of their spectral data.

4-Methyl-6-(1-hydroxy-2,2,2-trifluoroethyl)pyrimidine: White crystals; mp 75—76 °C (sublime); IR (KBr disk) 3120, 2870, 2730, 1600, 1540, 1470, 1380, 1360, 1340, 1320, 1280, 1260, 1170, 1140, 1130, 1110, 1045, 1000, 945, 900, 850, 810, 770, 740, 710, and 660 cm^{-1}; ^1H NMR δ=2.55 (3H, s, 4-CH_3), 5.10 (1H, q, J=6.8 Hz, 6-$C\underline{H}(OH)CF_3$), 7.60 (1H, s, ring H at the 5-position), and 8.98 (1H, s, ring H at the 2-position); MS (70 eV) m/z (rel intensity) 192 (M^+; 19), 124 (8), 123 (100), 95 (10), 94 (6), 93 (13), 68 (9), 67 (7), 66 (22), and 52 (6). Found: m/z 192.0507. Calcd for $C_7H_7F_3N_2O$: M, 192.0510.

2-(1-Hydroxy-2,2,2-trifluoroethyl)-4-methylpyrimidine: White crystals; mp 37—38 °C; IR (KBr disk) 3420, 3100, 1600, 1560, 1460, 1370, 1350, 1260, 1180, 1170, 1140, 1130, 1110, 1000, 930, 860, 840, 820, 790, 700, and 680 cm^{-1}; ^1H NMR (CD_3OD) δ=2.50 (3H, s, 4-CH_3), 5.10 (1H, q, J=6.7 Hz, 2-$C\underline{H}(OH)CF_3$), 7.33 (1H, d, J=7.2 Hz, ring H at the 5-position), and 8.61 (1H, d, J=7.2 Hz, ring H at the 6-position); MS (70 eV) m/z (rel intensity) 192 (M^+, 15), 125 (5), 124 (18), 123 (100), 95 (42), 94 (6), 93 (10), 68 (9), 66 (9), 53 (6), and 52 (6). Found: m/z 192.0508. Calcd for $C_7H_7F_3N_2O$: M, 192.0510.

4-(2,2,2-Trifluoroethyl)quinoline: IR (neat) 3450, 3080, 3050, 2970, 1600, 1580, 1520, 1430, 1400, 1360, 1320, 1280, 1260, 1240, 1170, 1140, 1100, 1040, 910, 830, 770, and 670 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.83 (2H, q, J=10 Hz, 4-CH_2CF_3), 7.26—8.19 (5H, m, ring H), and 8.85 (1H, d, J=4 Hz, ring H at the 2-position); MS (70 eV) m/z (rel intensity) 212 (13), 211 (M^+, 100), 143 (80), 142 (59), 116 (55), 115 (25). Found: m/z 211.0611. Calcd for $C_{11}H_8F_3N$: M, 211.0608.

2-(1-Hydroxy-2,2,2-trifluoroethyl)quinoline: White crys-

tals; mp 97—98 °C; IR (KBr disk) 3360, 3090, 2900, 2760, 1620, 1600, 1580, 1520, 1470, 1440, 1380, 1340, 1270, 1190, 1160, 1130, 1100, 1030, 980, 940, 860, 830, 805, 795, 770, 760, 710, and 630 cm^{-1}; ^1H NMR (CD_3OD) δ=5.22 (1H, q, J=7.8 Hz, 2-C<u>H</u>(OH)CF_3) and 7.50—8.40 (6H, m, ring H); MS (70 eV) m/z (rel intensity) 227 (M^+, 25), 207 (10), 159 (14), 158 (100), 156 (6), 130 (17), 129 (20), 128 (77), 103 (7), 102 (11), 101 (18), 77 (15), 76 (6), 75 (10), and 51 (8). Found: m/z 227.0558. Calcd for $C_{11}H_8F_3NO$: M, 227.0557.

2-Methyl-4-(2,2,2-trifluoroethyl)quinoline: White crystals; mp 47—48 °C; IR (KBr disk) 3450, 3370, 2990, 1600, 1560, 1520, 1380, 1370, 1330, 1280, 1260, 1230, 1200, 1150, 1140, 1100, 1050, 920, 910, 830, 770, 750, and 610 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.75 (3H, s, CH_3), 3.81 (2H, q, J=10.4 Hz, -CH_2CF_3), 7.27 (1H, s, ring H at the 3-position), and 7.50—8.10 (4H, m, H of benzene ring); MS (70 eV) m/z (rel intensity) 226 (14), 225 (M^+, 100), 205 (9), 156 (18), 129 (8), and 115 (5). Found: m/z 225.0763. Calcd for $C_{12}H_{10}F_3N$: M, 225.0765.

4-Methyl-2-(2,2,2-trifluoroethyl)quinoline: White crystals; mp 62—63 °C; IR (KBr disk) 3450, 3100, 3000, 2980, 2930, 1600, 1560, 1510, 1450, 1430, 1420, 1380, 1370, 1340, 1270, 1260, 1140, 1130, 1080, 1070, 970, 920, 860, 830, 770, and 760 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.66 (3H, s, CH_3), 3.70 (2H, q, J=10.8 Hz, -CH_2CF_3), 7.25 (1H, s, ring H at the 3-position), and 7.42—8.10 (4H, m, H of benzene ring); MS (70 eV) m/z (rel intensity) 226 (14), 225 (M^+, 100), 206 (13), 205 (57), 156 (16), 142 (6), 141 (5), 140 (6), 129 (6), 116 (9), and 115 (13). Found: m/z 225.0750. Calcd for $C_{12}H_{10}F_3N$: M, 225.0765.

4-Methyl-2-(2,2,2-trifluoro-1-hydroxyethyl)quinoline: White crystals; mp 117—118 °C; IR (KBr disk) 3100, 2870, 2700, 1600, 1570, 1510, 1450, 1420, 1370, 1270, 1260, 1190, 1180, 1140, 1130, 1120, 970, 900, 880, 860, 780, and 760 cm^{-1}; ^1H NMR (CD_3OD) δ=2.72 (3H, s, CH_3), 5.20 (1H, q, J=7.7 Hz, -C<u>H</u>(OH)CF_3), and 7.52—8.22 (5H, m, ring H); MS (70 eV) m/z (rel intensity) 241 (M^+, 24), 173 (13), 172 (100), 144 (10), 143 (14), 142 (28), 140 (5), 116 (9), and 115 (18). Found: m/z 241.0715. Calcd for $C_{12}H_{10}F_3NO$: M, 241.0714.

The products from the reaction of 1,4-dimethylquinolinium methyl sulfate (**1b**) in methanol could not be separated from the starting material by means of gel filtration (column, Sephadex G-10; eluent H_2O)

Quantitative Analyses. The irradiated alcoholic solutions were concentrated by distillation under reduced pressure and were neutralized with aqueous sodium hydrogencarbonate. The products were extracted several times with dichloromethane and were submitted to the GLC analyses (column, 2 or 3 m column of 5 or 10% PEG 20M; column temperature, 140 or 160 °C; internal standard, 3-pyridinecarbonitrile). The products from the peroxide-initiated and photochemical reactions were analyzed under similar conditions.

The work has been partially supported by a Grant-in-Aid for Scientific Research No. 60470028 from the Ministry of Education, Science and Culture and by the Inter-University Program for the Common Use of JAERI Facilities. The authors thank Japan Halon Co. and Nippon Oil and Fats Co. for kindly supplying 2,2,2-trifluoroethanol and *t*-butyl peroxypivalate, respectively.

Visible Light- and Radiation-Induced Alkylation of Pyridine Ring with Alkanoic Acid. Effective Alkylation in the Presence of Iron(III) Sulfate

Akira SUGIMORI* and Tetsuo YAMADA
Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioi-cho 7-1, Chiyoda-ku, Tokyo 102
(Received June 16, 1986)

Quinoline and 4-methylquinoline are efficiently alkylated with alkanoic acid in the presence of iron(III) sulfate upon visible light-irradiation. Iron(III) sulfate not only accelerates the photoreaction but also increases the yield of alkylation. Gamma-irradiation also brings about the alkylation. In the photo- and radiation-induced alkylation with alkanoic acid, alkyl radicals play important roles.

The utilization of solar light for organic syntheses is one of the challenging problems in photochemistry. The catalyses by transition metal ions and transition metal complexes which absorb solar light effectively are one of the promising fields for the chemical utilization of the solar light.

Many types of photoreactions catalyzed by metal salts or metal complexes have been studied,[1] including $TiCl_4$-catalyzed photochemical addition of alcohol to ketone[2] and $FeCl_3$-catalyzed photooxidation of olefins.[3] Sato et al. proposed a long range electron-transfer mechanism for the transition metal ion-catalyzed photooxidation.[4]

However, there have been a few attempts to use solar light for the metal salt- (or metal complex-) catalyzed photoreactions. The examples of the recent studies which have been done in aiming the effective uses of solar light are photochemical carbon dioxide fixation catalyzed by metal porphyrins[5] and photo-reduction of methyl viologen under the catalysis by ferrocene derivatives.[6,7]

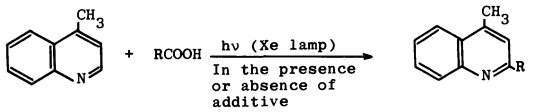
The generation of free radicals by solar light under the catalysis by transition metal salts and complexes is a useful reaction. Free radical species can play important roles in the chemistry of heteroaromatic compounds, because free radical species can attack electron-deficient heteroaromatic rings to give substitution products, while electrophiles which attack the normal aromatic rings to undergo substitution are not effective for the introduction of substituents in the electron-deficient heteroaromatic rings. One of the successful reactions of the category is the alkylation of the pyridine derivatives with alkanoic acids initiated by the thermal decomposition of peroxodisulfate under the catalysis by silver salt.[8]

The free radical species generated by gamma-irradiation, such as hydroxyalkyl radicals from alcohols, can be used for the alkylation of the pyridine ring.[9]

This paper describes the alkylation of the pyridine ring by alkyl radicals formed from alkanoic acids by the visible (or solar) light-irradiation under the catalysis by iron(III) sulfate or by γ-irradiation.[10] The iron(III)-catalyzed photoreaction is compared with the photoreactions catalyzed by TiO_2 and $EuCl_3$.

Results and Discussion

Visible Light-Induced Alkylation with Alkanoic Acid. The irradiation of 4-methylquinoline (**1**) in aqueous alkanoic acid solutions with a Xe lamp in the presence or absence of additives (sulfuric acid, metal salts, and titanium(IV) oxide) brings about alkylation at the 2-position of **1** (Table 1).



1 **2**

Although the photoalkylation with alkanoic acid occurs without any additives (the reaction in this case should be caused by the UV-light contained in the light emitted by a Xe lamp),[11] the reaction is the most effective in the acidic media in the presence of iron(III) sulfate. Iron(III) sulfate not only accelerates the photoreaction but also increases the yield of alkylation (yield=amount of product formed/amount of substrate reacted) either in the presence or absence of sulfuric acid. In particular, the effect of iron(III) sulfate is more remarkable in the presence of sulfuric acid than in its absence. In the reaction in the absence of iron(III), the addition of sulfuric acid inhibits the photoalkylation. The inhibition of photoreaction can be ascribed to the destruction of a hydrogen bond between quinoline and carboxylic acid. The addition of iron(III) sulfate in the acidic system results in the formation of the greater amount of the product than in the reaction in the absence of sulfuric acid and iron(III).

Europium chloride which has been reported to catalyze the photochemical hydroxymethylation of 1,3-dimethyluracil with methanol[12] inhibits the photoalkylation of 4-methylquinoline with alkanoic acid. Platinized titamium(IV) oxide promotes the photoalky-

lation much less efficiently than iron(III) sulfate.

The irradiation of quinoline (**3**) with propionic acid with the light from a Xe lamp causes the ethylation at the 2- and 4-position (Table 2).

The effects of iron(III) on the photoreaction of the quinoline-propionic acid system are similar to those of the 4-methylquinoline-propionic acid system. In iron(III) sulfate-catalyzed photochemical alkylation, alkyl radicals should play important roles. The reaction is inhibited by oxygen. Alkyl radicals would be produced by the excitation of a sort of complex between iron(III) and alkanoic acid (or alkanoate) which has an absorption band spreading over near ultraviolet-visible region. Brownish yellow color appears, when iron(III) sulfate and propionic acid are mixed in an aqueous sulfuric acid solution. The appearance of color is ascribed to the formation of a complex between iron(III) and propionic acid. No color develops, when iron(III) sulfate and 4-methylquinoline are mixed in an aqueous sulfuric acid solution. The alkyl radicals thus formed attack the electron-deficient protonated quinoline derivative.

Another role of iron(III) would be as an oxidant of the intermediate (**7**) and the reduction products of alkylquinoline, which are formed by the disproportionation of **7**. This contributes to the improvement of

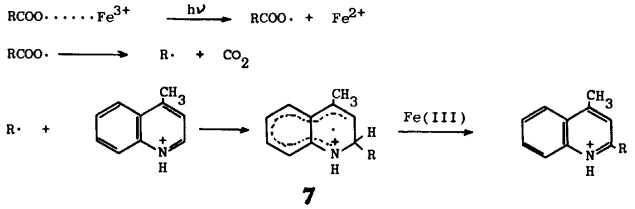
the yield of the alkylation.

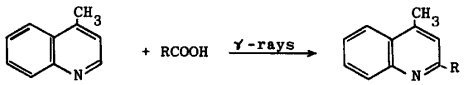


7

The excitation of the semiconducting titanium(IV) oxide generates electrons in the conduction band and holes. The holes undergo the oxidative decarboxylation of carboxylate to give an alkyl radical. The holes can also oxidize the intermediary formed radical **7** and/or the reduction products of quinoline and alkylquinolines. Therefore, the mechanism for the titanium(IV) oxide-catalyzed photoalkylation of the pyridine ring with alkanoic acid is similar to that for the iron(III)-catalyzed photoalkylation.

However, the TiO_2-catalyzed alkylation under the irradiation with a Xe lamp is inferior to the iron(III) sulfate-catalyzed reaction both with respect to the reaction rates and with respect to the yield of the alkylation. The low reaction rate is due to the low light absorption of titanium(IV) oxide in the visible region. The low yield for alkylation can be ascribed to the reduction of the substrate and the intermediate by the electron in the conduction band. The addition of Ag^+ which removes the electron in the conduction band of TiO_2 and/or oxidize the intermediate **7** improves the yield for alkylation (Table 1). In the semiconductor-catalyzed photo-cycloreversion and -valence isomerization, the promotion by oxygen has been reported.[13] The promoting effect of oxygen is ascribed to the acceleration of the charge separation of a hole-electron pair and the increase in the lifetime of a hole due to the removal of electron from depletion layer. However, in the titanium(IV) oxide-catalyzed photoalkylation of pyridine ring with alkanoic acid, oxygen inhibits the reaction. In this case, oxygen would inhibit the reaction by trapping the alkyl radicals.

Radiation-Induced Alkylation with Alkanoic Acid. Gamma-irradiation of **1** and **3** in alkanoic acid also brings about the substitution of alkyl group derived from the decarboxylation of alkanoic acid for the hydrogen of the pyridine ring (Tables 3 and 4).



Methyl, ethyl, propyl, and isopropyl groups are introduced at the 2- and 4-positions of the pyridine ring in fairly good radiation-chemical yields (G-value=Number of molecules of product/100 eV of absorbed radiation energy).

Added sulfuric acid has only a small effect on the radiation-induced alkylation (Fig. 1). Oxygen retards the conversion of the substrate but increases the yield of the alkylation (Tables 3 and 4).

As it has been established that the main radiolysis product of alkanoic acid is carbon dioxide,[14] the formation of alkyl radicals by the radiolysis of the alkanoic acid can be safely postulated. The key step of radiolytic alkylation with alkanoic acid should be the attack of the alkyl radicals to the pyridine ring. The isopropylation with isobutyric acid (2-methylpropanoic acid) which has a large G-value for decarboxylation ($G(CO_2)$=14.4[15]) occurs in higher G-value than propyla-

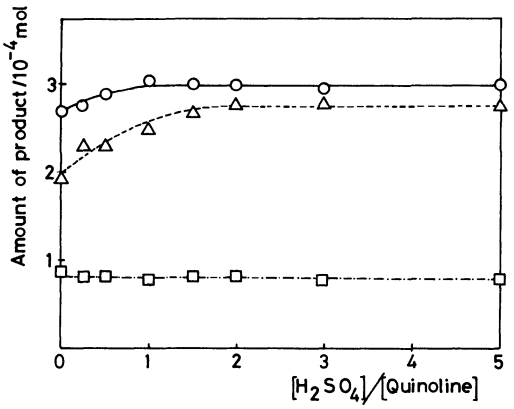


Fig. 1. Relation between yields of products and concentration of added sulfuric acid in radiation-induced alkylation of quinoline with propionic acid. tion with butyric acid.

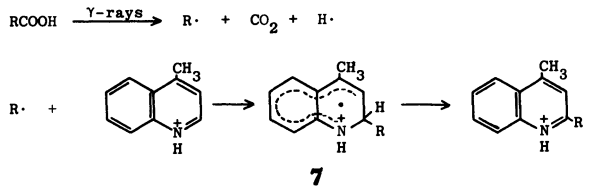
The radical species **7** would be converted to the alkylation product presumably via disproportionation. The fact that we observed the peak at m/z=161 in GC-MS of the mixture of the products in radiation-induced reaction of quinoline in propionic acid indicates the formation of the tetrahydro compound of **4** and/or **5**. The increase in the selectivity for **4** and **5** by oxygen can be explained by the oxidation of the intermediate **7** and/or reduction products.



7

Experimental

Materials. Commercial quinoline (GR grade reagent of Tokyo Kasei Co.) and 4-methylquinoline (GR reagent of Wako Junyaku Co.) were used after the purification by distillation. Commercial GR grade reagents of acetic, propionic, butyric, and isobutyric acids (Wako Junyaku Co.) were used without further purification. Commercial europium(III) chloride 6 hydrate (made by Wako Junyaku Co.; 99.9% of purity), silver nitrate (EP grade reagent of Nisshin Kasei Co.), and iron(III) sulfate x hydrate (GR grade reagent of Wako Junyaku Co.) were used without further purification. The content of iron which was determined by the colorimetry with 1,10-phenanthroline was 72%.

Platinized titanium(IV) oxide was prepared by grinding 0.025 g of platinum black (Nippon Engelhard Co.) and 0.475 g of titanium(IV) oxide (P-25 made by Nippon Aerosil Co., a mixture of anatase and rutile) in a mortar according to Kawai and Sakata.[16]

Irradiation with a Xenon Lamp. Solutions (50 cm^3) of the substrate (0.02 mol dm^{-3}) and the additives in a mixed solvent of water and alkanoic acid (H_2O : RCOOH=4 : 1 v/v) were deaerated by bubbling Ar for 45 min before irradiation. The solutions were irradiated with a 500 W Xe lamp for 20 h under magnetical stirring.

For the irradiation under O_2 was bubbled oxygen gas through the solution for 45 min before irradiation.

Irradiation with γ-Rays. A solution containing the substrate (0.3 mol dm^{-3}) in alkanoic acid was deaerated by bubbling Ar (in some cases by oxygen) for 45 min before irradiation.

The solution was irradiated by Co-60 γ-rays at the irradiation facility of Japan Atomic Energy Research Institute in Takasaki at the dose of 5.0×10^7 rad (Dose rate, 1.0×10^6 rad h^{-1}).

For the dependence of the reaction on added sulfuric acid, solutions containing **3** (0.18 mol dm^{-3}) and sulfuric acid in a mixed solvent of H_2O (40%) and propionic acid (60%) were used.

Identification of Products. The identification of the alkylquinolines was described in our another paper.[9]

Quantitative Analysis of Photoproducts. The solution which was irradiated in the presence of sulfuric acid was neutralized with sodium carbonate. In the case of the irradiation in the presence of iron(III) sulfate, the formed precipitate of iron hydroxide was filtered off. The aqueous filtrate and the precipitate were extracted repeatedly with dichloromethane. After the removal of dichloromethane, the solvent was replaced by ethyl acetate and the solution was submitted to the gas-chromatographic analysis (column, 3 m column of PEG 20 M (10%); column temperature, 190 °C), using 3-pyridinecarbonitrile as an internal standard.

The work has been supported in part by a Grant-in-Aid for Scientific Research No. 60470028 from the Ministry of Education, Science and Culture. The γ-irradiation was done under the Inter-University Program for the Common Use of JAERI Facilities.

Convenient Synthesis of 3-Aminocoumarin Derivatives by the Condensation of 1,4-Diacetyl- or 3-Substituent-2,5-piperazinediones with Various Salicylaldehyde Derivatives

Chung-gi SHIN,* Yoshiharu NAKAJIMA, Toshiya HAGA, and Yoshiaki SATO
Laboratory of Organic Chemistry, Faculty of Technology, Kanagawa University, Rokkakubashi, Kanagawa-ku, Yokohama 221
(Received June 17, 1986)

The condensation of 1,4-diacetyl- or 3-substituted 2,5-piperazinediones (PDO) with various salicylaldehyde derivatives in the presence of a base, such as potassium *t*-butoxide or triethylamine, was found to give two extremely different kinds of products: 1-acetyl-3-arylmethylene-PDO and 3-(acylamino)coumarin derivatives. The former, which has a (*Z*)-geometric structure, was readily converted to the latter by irradiation. Furthermore, the conversion mechanism and the structural confirmation are discussed.

In a previous paper,[1] we briefly reported on the synthesis of a (*Z*)-3-salicylidene-2,5-piperazinedione derivative (**2a**; 2,5-piperazinedione=PDO), which was supposed to be the most promising precursor for the synthesis of spiro[benzofuran-2(3*H*), 2′-piperazine]-3′,6′-dione as the main skeleton of aspirochlorin.[2,3] In addition, interestingly enough, a similar reaction of 1,4-diacetyl-PDO (**1**) with salicylaldehyde gave an unexpected 3-aminocoumarin derivative **3a** along with **2a**, which was found to be further converted to **3a** upon irradiation. However, in regard to the synthesis of 3-(acylamino)coumarin from α-amino acid derivatives, at present only a few synthetic methods have been reported.[4-6]

In the present paper we wish to report on details regarding the facile and convenient syntheses of several kinds of 3-(acylamino)coumarin derivatives by the condensation of **1**, (3*S*)-1,4-diacetyl-3-alkyl-PDO (**4**) or 4-substituted (*Z*)-1-acetyl-3-alkylidene-PDO (**7**) with various salicylaldehyde derivatives, followed by the irradiation. Furthermore, the mechanism of the photochemical conversion and the structural confirmation of all the new compounds are also discussed.

Results and Discussion

Condensation of 1,4-Diacetyl-PDO with Salicylaldehydes. According to the Gallina and Liberatori method,[7] the condensation of equimolar **1** with salicylaldehyde in the presence of potassium *t*-butoxide was performed to give 1-acetyl-3-(2-hydroxybenzylidene)-PDO (**2a**) and 3-(*N*-acetylglycylamino)coumarin (**3a**) derivatives in a 53 and a 40% yields, respectively. As was previously reported,[1] the structure of **3a** could be readily determined by the conversion of **3a** with 1 M† HCl to the authentic 3-hydroxycoumarin; this was completely consistent with the product derived by the hydrolysis of known 3-(acetylamino)coumarin with 1 M HCl.

Furthermore, in order to generallize the synthesis of 3-(acylamino)coumarin (**3**) derivatives, first a similar condensation of **1** with several mono- and disubstituted 2-hydroxybenzaldehydes (**b**; X_1=5-Cl, **c**; X_1=5-Br, **d**; X_2=3,5-Cl_2, **e**; X_2=3,5-Br_2, **f**; X_1=3-OCH_3, **g**; X_1=4-$OCOCH_3$, **h**; X_1=4-OCH_2OCH_3) in *N*,*N*-dimethylformamide (DMF) at 10 °C was carried out, as shown in Scheme 1. As a result, both 1-acetyl-3-(2-hydroxyarylidene)-PDO (**2b—h**) as main products and 3-(*N*-acetylglycylamino)coumarin derivatives **3b—h** were also obtained in good yields. However, in the case of the reaction of **1** with 2-hydroxy-3-methoxybenzaldehyde (**f**), it was found that a similar condensation ultimately took place in the presence of two molar potassium *t*-butoxide to give only 3-(2-hydroxy-3-methoxybenzylidene)-PDO (**2f**) in a 30% yield not accompanied by the corresponding 3-aminocoumarin derivative **3f**. On the other hand, a similar reaction in the presence of equimolar triethylamine instead of potassium *t*-butoxide was found to give **2f** and **3f** in a 80 and a 16% yields, respectively. In addition, the analogous condensation of **1** with 2-hydroxy-4-(methoxymethoxy)benzaldehyde (**h**) was also carried out to give the corresponding 3-benzylidene-PDO (**2h**) and 3-aminocoumarin derivatives **3h** in a 43 and a 21% yields, respectively.

The reaction conditions of the above several condensations and the ratio of the yield of products **2** and **3** are summarized in Table 1.

Subsequently, compounds **2b—h** were irradiated in methanol with a high-pressure mercury lamp (500 W) under a stream of N_2 gas at room temperature to give **3b—h** in almost quantitative yields. In addition, it was found that the condensation products obtained as a mixture of **2** and **3** were in situ also irradiated to give only **3**. In both cases, the photochemical conversion of **2** to **3** was completed in less than 1 h.

Furthermore, in order to develop the above consecutive reaction and to investigate the asymmetric addition to the aminocoumarin derivatives containing a chiral α-amino acid residue, the other 1,4-diacetyl-PDO derivatives **4** and **7** as substrates were chosen and subjected to a similar condensation, followed by the irradiation. The optically active PDO (**4**: **a**; R=CH_3, **b**; R=*i*-C_3H_7, **c**; R=$C_6H_5CH_2$, **d**; R=CH_3-$COOCH_2$) were similarly condensed with salicylalde-

hyde to give the desired 1-acetyl-6-alkyl-3-salicylidene-PDO (**5a—d**) and 3-[α-(acetylamino)acylamino]-coumarin derivatives **6a—d** in 49—64 and 16—25% yields, respectively. In an analogous manner as in the case of **2**, the subsequent irradiation of **5a—d** were also converted to **6a—d** within 1 h, as illustrated in Schemel.

On the other hand, in the case of 3-alkylidene-PDO derivatives **7**, for example, 1-acetyl-3-isobutylidene-(**7a**), 1,4-diacetyl-3-benzylidene-(**7b**), and 1-acetyl-3-benzylidene-4-methyl-PDO (**7c**) were found to not react at all when the Gallina and Liberatori method[7] was used. However, according to the Sasaki method,[8] compounds **7a—c** reacted with 2.5 mole of salicylaldehyde in the presence of 4 mole of anhydrous sodium acetate in acetic anhydride under reflux for 8 h to give the corresponding 3-alkylidene-6-salicylidene-PDO derivatives **8a—c** in 60—74% yields as the main products along with a very small amount of 3-(α-acetylamino-α-alkylideneacetylamino)coumarins **9a, c** in low yields. As shown in Scheme 2, in the case of **7b**, the by-product **9b** could not be obtained at all. Unfortunately, it was found that not only increasing the yield of **9** by even the modified Sasaki method but also the photochemical conversion of **8** to **9** was unsuccessful.

The yields, physical constants, and the spectral (IR and ^1H NMR) data of **2, 3, 5, 6, 8,** and **9** are summarized in Tables 2—5, and 6.

In order to further extend the above sequential reactions, another type of aromatic aldehyde was explored as an alternative to the salicylaldehyde derivatives. For example, the condensation of **1** with 2-hydroxy-1-naphthaldehyde in the presence of potassium *t*-butoxide was carried out in order to give the expected (*Z*)-1-acetyl-3-(2-hydroxy-1-naphthylmethylene)-2,5-piperazinedione (**10**) and 2-(*N*-acetylglycylamino)-3*H*-naphtho[2,1-*b*]pyran-3-one (**11**) in a 50 and a 20% yields, respectively. Subsequently, the former **10** was also converted in quantitative yield to **11** by irradiation. As a result, it could be concluded that the aromatic aldehyde having a vicinal hydroxyl group was applicable to the above successive condensation with PDO derivatives and irradiation.

Conversion Mechanism. For the purpose of the investigating the photochemical conversion mechanism of **2** to 3-aminocoumarin derivatives, in particular, (*Z*)-**2a** was subjected to geometric isomerization; this is because it was assumed that **2a** isomerized to (*E*)-isomer, followed immediately by a conversion to

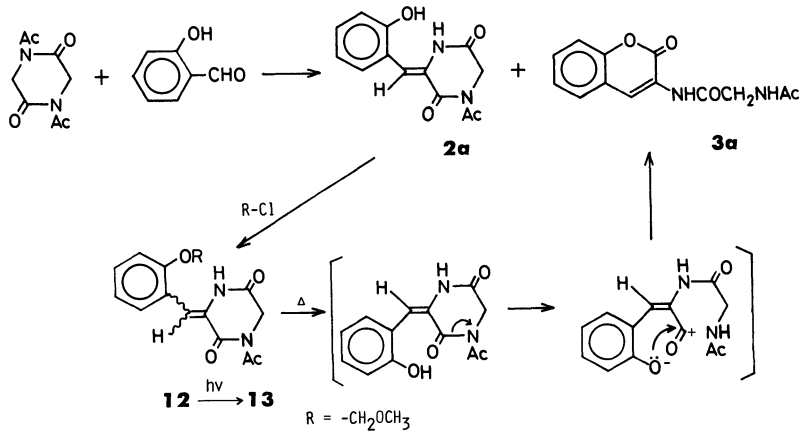
the coumarin derivative **3a**. Accordingly, firstly, in order to confirm the resulting isomerization and to prevent the transformation, *o*-hydroxyl group of 3-salicylidene in **2a** was protected with methoxymethyl (MOM) chloride by the usual method to give (*Z*)-1-acetyl-3-[(*O*-MOM)salicylidene]-PDO (**12**) in good yield. Subsequently, the photochemical conversion of **12** with a high-pressure Hg lamp (500 W) gave the expected (*E*)-1-acetyl-3-[(*O*-MOM)salicylidene]-PDO (**13**) in ca. a 40% yield. The configurational structure of **13**, thus obtained, was readily confirmed by a comparison with both chemical shifts of the olefin protons between the two geometric isomers. Generally, it is well-known that the olefin proton of α,β-unsaturated α-amino acid and its cyclic dipeptide of (*E*)-isomer shift at a higher magnetic field than that of (*Z*)-isomer.[9-11] In fact, it was found that the olefin proton of (*E*)-isomer **13** shifted at a higher magnetic field (δ 6.62) than that of (*Z*)-isomer **12** (δ 7.10) by ca. $\Delta\delta$ 0.48. The subsequent deprotection of **13** with a saturated HCl methanol solution at room temperature gave the desired **3a**, as illustrated in Scheme 3. From this result, it could by readily determined that, after the photochemical isomerization of **12** to **13** and subsequent deprotection of **13**, the PDO ring of the unstable intermediate (*E*)-1-acetyl-3-salicylidene-PDO [(*E*)-**2**], thus obtained, easily cleaved and a simultaneous nucleophilic addition of the resulting *o*-hydroxyl group to the neighboring carbonyl group took place to form **3**.

In conclusion, the conversion mechanism could be confirmed unambigously that the condensation of **1**, **4**, or **7** with salicylaldehyde derivatives yielded a mixture of (*Z*)- and (*E*)-isomers during the first step, the latter of which was immediately transformed by a successive ring cleavage and then recyclized to give **3**, **6**, **9**, and **11**.

Experimental

General. Melting points were determined with a Yamato micro melting-point apparatus model MP-21 and were uncorrected. The IR spectra were recorded with a Hitachi EPI-G2 grating spectrometer. The ^{1}H NMR spectra were measured with a JEOL JMN PS-100 spectrometer in a CDCl$_3$ solution with tetramethylsilane as the internal standard. The specific rotations were measured in a 0.5-dm tube using a JASCO DIP-4 polarimeter (Japan Spectroscopic Co. Ltd.).



Scheme 3.

Condensation of 1 with Salicylaldehyde Derivatives. General Procedure. To a solution of **1** (19.8 g, 100 mmol) and an appropriate salicyladehyde (110 mmol) in DMF (260 ml) was added 1.1 mole of 0.5 M potassium *t*-butoxide, with stirring, drop-by-drop at 0 °C for 1 h. After the addition, the solution was continuously stirred at room temperature for 12 h and neutralized with acetic acid. It was then poured into ice-water (100 ml). A colorless crystalline deposited substance was collected and recrystallized from methanol to give two kinds of colorless needles. Repeated recrystallization from methanol gave pure **2** as colorless needles. On the other hand, after concentrating the mother liquor, the residual crystalline mixture was then chromatographed on a silica-gel column using a mixture of benzene and acetone (40 : 1 v/v) as the eluent to give two fractions. The main fraction was evaporated under reduced pressure to give residual crystals, which were also recrystallized from methanol to give **3** as colorless needles.

In the case of reactions with 3-methoxy- and 4-(*O*-MOM)-salicylaldehyde, a similar condensation was worked up in the presence of triethylamine, instead of potassium *t*-butoxide (See Table 1).

Irradiation of 2. A solution of **2** (0.1 mmol) in methanol (50 ml) was irradiated with a 500-W high-pressure mercury lamp under a N_2 gas stream at room temperature. The photochemical conversion of **2** was terminated within 1 h. The solution was concentrated under reduced pressure to give residual crystals which were subsequently recrystallized from methanol to give **3**.

Condensation of 4 with Salicylaldehyde. In a similar manner as in the case of **1**, the treatment of **4** (9.35 mmol) with 1.1 equivalent of salicylaldehyde (10.30 mmol) in the presence of 0.5 M potassium *t*-butoxide was worked up for 30 min to give **5** and **6** as colorless needles.

Irradiation of 5. A solution of **5** (0.1 mmol) in methanol (50 ml) was similarly irradiated to give **6**.

Condensation of 7 with Salicylaldehyde. A solution of **7** (20 mmol) and salicylaldehyde (6.1 g, 50 mmol) in acetic anhydride (29 ml) in the presence of anhydrous sodium acetate (6.5 g, 79 mmol) was refluxed for 8 h. After removing excess acetic anhydride under reduced pressure, the residue was dissolved in ethyl acetate (200 ml) and the solution was washed once with 1 M hydrochloric acid and once with a saturated sodium chloride aqueous solution and then dried over anhydrous magnesium sulfate. The removal of the solvent under reduced pressure gave colorless crystals which comprised two chemical species. Subsequent separation by chromatography on a silica-gel column using a mixture of chloroform and acetone (30 : 1 v/v) as the eluent afforded two fractions. The first fraction was concentrated under reduced pressure to give **8** and the second gave **9** as colorless needles (See Table 6).

Condensation of 1 with 2-Hydroxy-1-naphthaldehyde. To a mixture of **1** (5.0 g, 28.1 mmol) in DMF (80 ml) was slowly added triethylamine (3.4 g, 33.6 mmol), with stirring, at −10 °C. After stirring at room temperature for 16 h, the reaction solution was neutralized to pH 7 with 3 M HCl under cooling and then diluted with water (300 ml). The solution was extracted three times with ethyl acetate (300 ml) and the combined extracts were dried over anhydrous sodium sulfate. After removing the solvent under reduced pressure, the obtained residual syrup was gradually solidified to give crude crystals; these were collected after adding diisopropyl ether. Recrystallization from acetone gave yellowish fibrous solid as a mixture of **10** and **11**, which were did not separated. However, based on the ^{1}H NMR spectrum, the ratio of yield was found to be 4 : 1 (**10** : **11**).

Preparation of 11. The above mixture (300 mg) in methanol (70 ml) was irradiated with a 500-W high-pressure Hg lamp under a N_2 gas stream at room temperature for 3 h. The mixture gradually dissolved to give a homogeneous solution. The removal of methanol gave a crude crystalline substance, which was recrystallized from acetone to give **11** as a pale-yellow fibrous solid. Mp 250 °C (decomp). ν_{max}^{KBr} (cm^{-1}) 3200 (NH), 1685, 1530 (NHCO), 1650 (C=C); ^{1}H NMR (DMSO-d_6) δ=9.79 (bs, 1H, NH), 9.27 (s, 1H, -CH=), 8.35 (t, 1H, J=6.0 Hz, NH), 4.10 (d, 2H, J=6.0 Hz, -CH_2-). Found: C, 65.93; H, 4.41; N, 8.97%. Calcd for $C_{17}H_{14}N_2O_4$: C, 65.80; H, 4.55; N, 9.03%.

Preparation of 12. To a solution of **2a** (3 g, 11.5 mmol) in tetrahydrofuran (45 ml) in the presence of triethylamine (1.28 g, 12.6 mmol) was slowly added chloromethyl methyl ether (1.21 g, 15.0 mmol) with stirring at 0 °C for 1 h. The deposited salt was filtered off and the filtrate was concentrated under reduced pressure. The residual crystals, thus obtained, were collected and then recrystallized from ethyl acetate to give **12** as colorless needles. Yield 82%, mp 137—138 °C. ν_{max}^{KBr} (cm^{-1}) 1725, 1700 (C=O), 1620 (C=C); ^{1}H NMR δ=10.1 (bs, 1H, NH), 7.10 (s, 1H, -CH=), 4.35 (s, 2H, -CH_2-). Found: C, 59.15; H, 5.28; N, 9.16%. Calcd for $C_{15}H_{16}N_2O_5$: C,

59.20; H, 5.30; N, 9.21%.

Preparation of 13. A solution of **12** (1.49 g, 4.9 mmol) in methanol (70 ml) was irradiated with a 500-W high-pressure Hg lamp under a N_2 gas stream at room temperature for 8 h. Insoluble materials separeted out were filtered off and then the filtrate was concentrated under reduced pressure to give a crystalline residue. The crystals, thus obtained, were purified on a silica-gel column using a mixture of chloroform and acetone (20 : 1 v/v) as the eluent. After concentration of the fraction, the obtained crystals were recrystallized from carbon tetrachloride to give **13** as colorless needles. Yield 33%, mp 85—86 °C. ν_{max}^{KBr} (cm^{-1}) 3040 (NH), 1630 (C=C); ^1H NMR δ=10.62 (bs, 1H, NH), 4.30 (s, 2H, $-CH_2-$). Found: C, 58.99; H, 5.27; N, 9.17%. Calcd for $C_{15}H_{16}N_2O_5$: C, 59.20; H, 5.30; N, 9.21%.

Conversion of 13 to 3a. A solution of **13** (110 mg, 0.38 mmol) in methanol (10 ml) was stirred below 0 °C. To the solution was added a methanol solution (10 ml) saturated with hydrogen chloride gas. After stirring for 2 h and then removing the solvent, the obtained residue was purified on a silica-gel column using a mixture of chloroform and methanol (10 : 1 v/v) as the eluent to give **3a** in a 70% yield.

Chemical Reactivities of Coordinatively Unsaturated Hydridotris(phosphonite)-cobalt(I) Species Photogenerated towards Allylic and Related Compounds

Masayoshi Onishi,* Shigero Oishi,†,†† Mitoshi Sakaguchi, Isato Takaki, and Katsuma Hiraki
Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Bunkyo-machi, Nagasaki 852

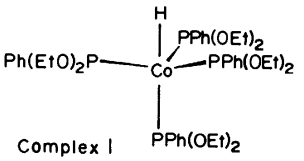
(Received June 18, 1986)

Pyrex-filtered photoirradiation with a high-pressure Hg lamp was performed for a thermally inert hydridocobalt(I) $CoH[PPh(OEt)_2]_4$ in the presence of some allylic compounds. Allyl benzoate and allyl phenyl ether showed the cleavage of allylic-O bonds to give propene in a stoichiometric quantity to the complex charged. Photoassisted catalytic double-bond migration occurred for *N*-allylacetamide, *N*,*N*-diethylallylamine, and allylbenzene to afford the respective (*E*)- and (*Z*)-1-propenyl derivatives with kinetically controlled *E*, *Z* compositions, and the fractions of *Z* isomers at the initial stage of the reaction proceeding were near 79, 30, and 20%, respectively. Laser flash photolysis study revealed that the double-bond migration was initiated by the coordination of the substrates through C=C double bond rather than nitrogen or oxygen donor-atom to the coordinatively unsaturated species "$CoH[PPh(OEt)_2]_3$" photogenerated.

Pyrex-filtered photoirradiation of a thermally inert hydridocobalt(I) complex $CoH[PPh(OR)_2]_4$ caused dissociation of a $PPh(OR)_2$ ligand from cobalt efficiently without cleavage of the hydrido-cobalt bond, and produced a coordinatively unsaturated hydrido species "$CoH[PPh(OR)_2]_3$."[1,2] Nitrogen-laser pulse excitation was also found to generate the hydrido species with a quantum yield of almost 1.0, and absolute rate constants were determined for coordination of free $PPh(OR)_2$ and some olefins to the species.[3] Furthermore, high catalytic activities of the hydrido species were realized in hydrogen transfer from secondary alcohols to ketones and isomerization of olefins.[1,4,5]

In the present paper, chemical reactivities of the hydrido species "$CoH[PPh(OEt)_2]_3$" ($CoHP_3$) photogenerated from $CoH[PPh(OEt)_2]_4$ (**1**) were studied towards some allylic compounds linked to heteroatoms or aromatic rings, which included *N*-allylacetamide, *N*,*N*-diethylallylamine, allylbenzene, allyl benzoate, and allyl phenyl ether. Incentive for studies on these reactions was derived from the following; (i) competitive coordination through two coexisting ligating sites i.e. the olefinic moiety and the heteroatoms with lone pairs of electrons to $CoHP_3$, (ii) chemical reactivities of $CoHP_3$ with the allylic compounds to cleave bonds between the allylic carbon and the heteroatoms,[6] and (iii) potential synthetic utility of catalytic olefin isomerization.[7] One of the authors (S.O.)[8] communicated that photoreaction of **1** with allyl phenyl ether gave almost equimolar quantity of propene to **1** charged and a small amount of 1-propenyl phenyl ether, and excluded initial coordination to $CoHP_3$ via the ether oxygen. As for nitrogen donor-ligands with higher coordination ability than ether oxygen, there were a few papers on formation of their cobalt(I) complexes.[9] It seems worthwhile to compare two ligating sites of the olefinic nitrogen compounds on coordination towards the transient $CoHP_3$ species, by means of laser flash photolysis.



Complex I

Experimental

Materials. *N*,*N*-Diethyl-1-propenylamine,[10] *N*-(1-propenyl)acetamide,[11] and *N*-allylacetamide[12] were prepared by the literature methods, and other allylic compounds and their isomerized 1-propenyl derivatives were commercially available. The complex $CoH[PPh(OEt)_2]_4$ **1** was prepared according to the Gray's method.[13] Benzene was treated with concentrated sulfuric acid until thiophen-free. After water washing, it was dried over anhydrous magnesium sulfate, and distilled from sodium under nitrogen. Toluene was purified similarly.

General Procedures. ^1H NMR spectra were recorded on a JEOL FX-90Q and a BRUKER AM-400 spectrometers. The gas chromatographic (GLC) analyses were performed on a SHIMADZU GC-8AIT (TCD) and a GC-8APF (FID) instruments. For irradiation, a high-pressure mercury lamp (400 W) was used with a Pyrex filter, and reactant solutions were placed at about 45 mm from the lamp.

Olefin Isomerization and GLC Analyses of the Products. Benzene solutions (5 cm^3) of **1** (0.04 mmol) and allylic compounds (0.8 mmol) were degassed by freeze-pump-thaw cycles in a Pyrex Schlenk tube (18 mm^{ϕ}). After standing the solutions at 30 °C in the dark or under irradiation to proceed double-bond migration of the olefins, GLC analyses of gaseous products were performed using a Porapak Q or a molecular-sieve 5A column (3 m×3 mm^{ϕ}) with a TCD detector, and other organic compounds were determined with a similar PEG-20M column and a FID detector.

Cis-trans isomerization of 1-propenyl derivatives was carried out analogously.

In the case of *N*,*N*-diethylallylamine, toluene was used as solvent for better resolution of GLC signals to evaluate conversion of the double-bond migration. However, determination of the *E*, *Z* composition in *N*,*N*-diethyl-1-propenylamine made it necessary to adopt ^1H NMR product analyses,

††Present address: Radiation Laboratory, University of Notre Dame, Notre Dame, Indiana 46556, U.S.A.

as follows.

Reaction of *N,N*-Diethylallylamine or *N,N*-Diethyl-1-propenylamine and ^{1}H NMR Product Analyses. *N,N*-Diethylallylamine (0.8 mmol) was added to a C_6D_6 solution (0.6 cm^3) of **1** (0.04 mmol) and the mixture was degassed in a Schlenk tube (5 mm$^\phi$). After reaction at 10 °C, a small amount of tetramethylsilane was added to the mixture. Some quantity of the volatile components was separated from the nonvolatiles by trap-to-trap vacuum distillation without heating, and was sealed in NMR tubes under vacuum. The ^{1}H NMR spectrum of the distillate showed resonances for *E* and *Z* isomers of *N,N*-diethyl-1-propenylamine together with some unreacted *N,N*-diethylallylamine, and olefinic proton signals in the 1-propenylamines were useful for determination of the *E*/*Z* ratio.

Cis-trans isomerization of *N,N*-diethyl-1-propenylamine was performed similarly.

Laser Flash Photolysis. The apparatus of laser flash photolysis consists of a nitrogen laser (National Research Group, pulse width 5 ns, 4 mJ/pulse) for excitation at 337 nm, a 150 W xenon lamp (Ushio) for monitoring, a grating monochromator (Union Giken), a photomultiplier (Hamamatsu Photonics R446 or R212), a storage oscilloscope (Iwatsu TS-B123), and a personal computer (Sharp MZ-2000) for controlling the system, averaging the signal, and analyzing the data. A right-angle optical system was employed for the excitation-analysis set-up. An average of at least 9 shots, at each particular wavelength, was used for the determination of transient spectra or the investigation of reaction kinetics. The rate constants were determined according to the procedure of Ref. 16 and can be regarded as accurate to within ca. 10%. Solutions (5 cm^3) of **1** (≈0.6 mM†††) and *N,N*-diethylpropylamine (1.0—6.4 M), *N,N*-diethylallylamine (13—47 mM), *N*-propylacetamide (0.108—0.51 M), or *N*-allylacetamide (1.9—11.7 mM) were purged of oxygen by bubbling with argon and subjected to laser flash photolysis at 23 °C. Toluene and benzene were used as solvents for the amines and the amides, respectively.

Results and Discussion

Photoassisted Double-Bond Migration of Olefins with the Hydridocobalt(I) Complex. The complex $CoH[PPh(OEt)_2]_4$ (**1**) was mixed with 20-fold moles of allylic compounds in deaerated benzene or toluene solutions. In the cases of *N*-allylacetamide, *N,N*-diethylallylamine, and allylbenzene, photoirradiation of the solutions led to their catalytic double-bond migration, yielding the corresponding (*E*)- and (*Z*)-1-propenyl derivatives, which are thermodynamically stabilized through π-conjugation with a lone electron pair on nitrogen or a delocalized π-system. Figure 1

$$RCH_2CH{=}CH_2 \xrightarrow{Cat} RCH{=}CH{\sim}CH_3$$

$$R = -NHCOCH_3,\ -NEt_2,\ -C_6H_5$$

shows plots of the conversions versus time for the double-bond migration of these compounds at 30 °C. The double-bond migration of *N*-allylacetamide proceeded well and was completed within 20 min. On the other hand, photoreactions of allyl benzoate and allyl phenyl ether for 6 h gave 1-propenyl derivatives with the conversions of only ca. 1 and 5%, respectively, and large quantities of unreacted substrates were recovered. However, propene was formed in the yields of 71 and 76% based on **1**, respectively. In the photocatalytic reaction with *N,N*-diethylallylamine, we detected only small amount of propene (1.6% based on **1**) together with traces of ethylene and ethane, whereas the reaction with *N*-allylacetamide did not yield propene at all.

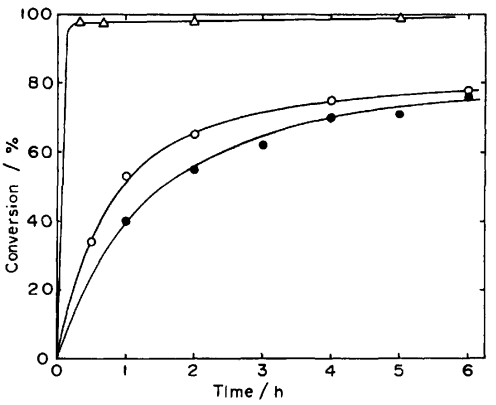


Fig. 1. Double-bond migration of allylic compounds to (*E*)- and (*Z*)-1-propenyl derivatives under irradiation with **1**.
At 30°C; Monitored by GLC; △: *N*-Allylacetamide, ○: *N,N*-Diethylallylamine, ●: Allylbenzene.

Allylic compounds did not afford propene or 1-propenyl derivatives under irradiation in the absence of **1**, and addition of free $PPh(OEt)_2$ did not change the situation either. Furthermore, neither double-bond migration nor propene formation occurred for the allylic compounds in the presence of **1** in the dark at 30 °C. These two types of reactions proceeded only in the presence of **1** under irradiation, and were attributed to operations of the photogenerated $CoHP_3$.

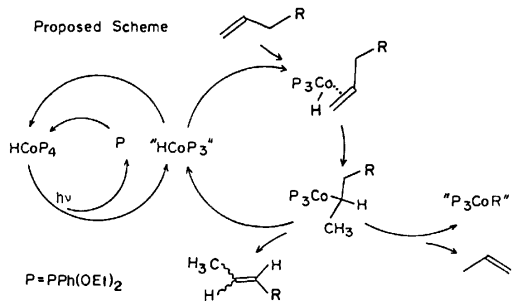
When irradiation of *N*-allylacetamide, *N,N*-diethylallylamine, and allylbenzene with **1** was stopped in the middle of the reaction proceeding, the double-bond migration ceased immediately. On restarting irradiation, the migration proceeded again. The double-bond migration of the present system was determined to be virtually "photoassisted" rather than "true photocatalytic."[14] The immediate cessation of the reaction proceeding upon interruption of irradiation was due to easy recombination of $CoHP_3$ with the photodissociated $PPh(OEt)_2$.[1,3] After incorporation of these allylic compounds with the photogenerated $CoHP_3$, insertion of their olefinic moieties into the hydridocobalt bond formed alkyl intermediates, which released (*E*)- and (*Z*)-1-propenyl derivatives through β-hydrogen abstraction by cobalt, and $CoHP_3$ was regenerated, as shown in Scheme.

Kurosawa[15] performed reactions of allylamines with some cationic platinum(II) hydrides, affording π-allyl

†††1 M=1 mol dm^{-3}.

complexes and amine products through replacement of the allylic group in the parent amines with hydrogen, and suggested that allylamines ligated to platinum via the nitrogen atoms rather than via the C=C double-bond at the first stage. On the other hand, laser flash photolysis (vide infra) of the present system with **1** revealed the initial π-coordination of the C=C bonds to cobalt, leading to the catalytic double-bond migration under continuous irradiation. Furthermore, photoassisted double-bond migration of *N*-allylacetamide with **1** showed a sharp contrast to the case with the platinum(II) hydrides, which formed a catalytically inactive [1-(acetylamino)propyl-C^1,O]platinum(II) complex.[15]

Photoirradiation of allyl benzoate and allyl phenyl ether in the presence of **1** would form alkyl intermediates similarly, but then alternative abstraction of β-benzoyloxy and β-phenoxy entities[8] by cobalt was presumed to occur as the major pathway, affording benzoato- and phenoxocobalt species with release of propene (Scheme). These cobalt species were not catalytically active, and the formation of propene was stoichiometric to **1** charged. Similar cleavage of allylic-O bonds in allylic carbonates and esters was observed by Yamamoto and his co-workers,[6h,6i] in reactions with some transition-metal hydrides without photoirradiation.



Coordination Process of Substrates to the CoHP$_3$ Species. Time-resolved absorption spectra were observed after laser flash photolysis of **1** in the presence of amides or amines, and second-order rate constants k' were determined for coordination of substrates to the transient CoHP$_3$ species photoproduced. Photoisomerization of *N*-allylacetamide and *N*,*N*-diethylallylamine observed in the present study was presumed to involve their coordination of CoHP$_3$ as one of key processes in catalytic cycles, similarly to that communicated for allylbenzene.[1]

Amides and amines may coordinate to CoHP$_3$ through a lone electron pair of an oxygen or nitrogen donor-atom. In the case of a nonolefinic amide or amine, the transient absorption spectra showed both peak-decay of the band at 580 nm and peak-growth of the band in the region of about 450 to 420 nm, with formation of an isosbestic point (Figs. 2 and 3). The peak of the latter band grew almost on the same rate as the peak at 580 nm decayed (Table 1). On the other hand, in the case of an olefinic amide or amine, we observed only the peak-decay at 580 nm (Figs. 4 and 5). The band at 580 nm is attributed to the living CoHP$_3$ species, and its peak-decay was caused by the coordination of the substrates and by the recombination of CoHP$_3$ with the photodissociated PPh(OEt)$_2$.[3,8,16]

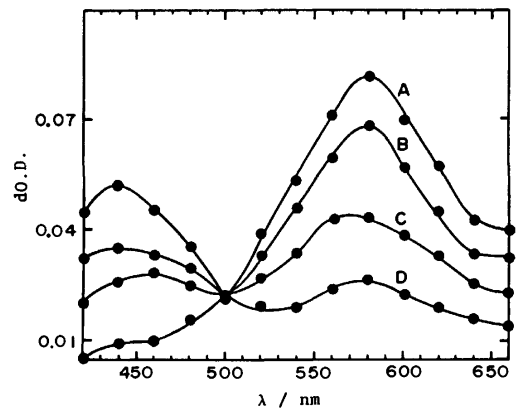


Fig. 2. Time-resolved absorption spectra for *N*-propylacetamide after pulsed laser photolysis. Substrate, 0.108 M (benzene); Complex **1**, 0.656 mM. A: 0.20 μs, B: 0.98 μs, C: 2.49 μs, D: 4.99 μs.

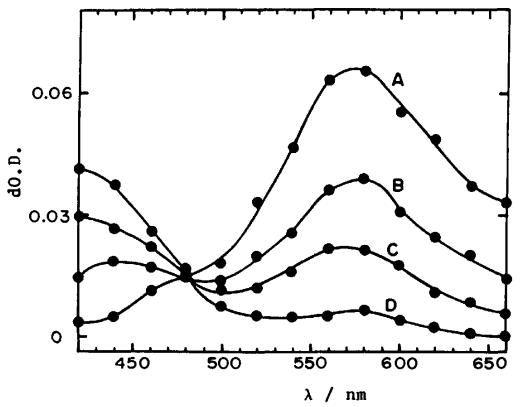

Fig. 3. Time-resolved absorption spectra for *N*,*N*-diethylpropylamine after pulsed laser photolysis. Substrate, 6.44 M (neat); Complex **1**, 0.656 mM. A: 0.82 μs, B: 4.49 μs, C: 8.79 μs, D: 20.0 μs.

Table 1. Second-Order Rate Constants k' for Coordination ($M^{-1}s^{-1}$)[a]

$(C_2H_5)_2N$	1.9×10^4 (1.9×10^4)	H_3C N H O	1.8×10^6 (2.1×10^6)
$(C_2H_5)_2N$	4.7×10^7	H_3C N H O	1.9×10^8

a) Values were determined from the peak-decay at 580 nm, and those in the parentheses were obtained from the peak-growth in the region of about 450 to 420 nm; The rate constants k' were evaluated from the following equation.[16]

$$-\frac{d[CoHP_3]}{dt} = k[CoHP_3][P] + k'[CoHP_3][Substrate]$$

The olefinic compounds, *N*-allylacetamide and *N,N*-diethylallylamine gave similar spectral change to that observed for 1-hexene or allylbenzene,[3,16] indicating the ligation to $CoHP_3$ via the double bond in a π-fashion, rather than via the oxygen or nitrogen donor-atom.

The peak-growth in the region of about 450 to 420 nm for the nonolefinic amide or amine was associated with formation of the new adducts of $CoHP_3$ with the substrates attached via the oxygen or nitrogen donor-atom. These donor-atoms have not empty low-lying orbitals appropriate for back donation bonding with metal, in contrast to $PPh(OEt)_2$ and the C=C double bond. Accordingly, absorption spectra of the hydridocobalt adducts with oxygen or nitrogen donor-ligands are expected to show red shifts of bands significantly from those of **1**.[17] On the other hand, absorption spectral change would be small on transformation from **1** to the adducts of $CoHP_3$ with olefins, and it is no wonder that we observed only the peak-decay of the band at 580 nm, attributable to $CoHP_3$, in the laser photolysis of **1** in the presence of the olefinic compounds.

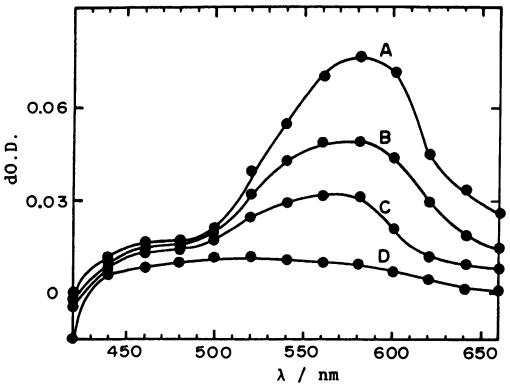

Fig. 4. Time-resolved absorption spectra for *N*-allylacetamide after pulsed laser photolysis. Substrate, 3.90 mM (benzene); Complex **1**, 0.656 mM. A: 0.29 μs, B: 0.98 μs, C: 1.76 μs, D: 4.39 μs.

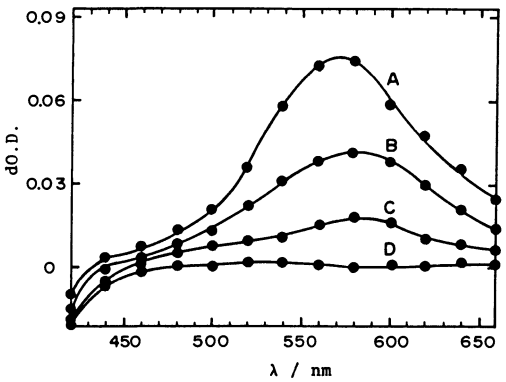

Fig. 5. Time-resolved absorption spectra for *N,N*-diethylallylamine after pulsed laser photolysis. Substrate, 20.1 mM (toluene); Complex **1**, 0.656 mM. A: 0.27 μs, B: 0.98 μs, C: 1.95 μs, D: 20.0 μs.

The rate constants k' of *N*-allylacetamide and *N,N*-diethylallylamine were comparable to those of 1-hexene and allylbenzene ($\approx 1.2\times10^8$ M^{-1} s^{-1}),[16] and were far larger than those of *N*-propylacetamide and *N,N*-diethylpropylamine, confirming the π-coordination of the allylic compounds via the C=C double bond.

***E,Z* Selectivity in 1-Propenyl Derivative Formation from Allylic Compounds.** 1-Propenyl compounds with several *E/Z* isomeric ratios were added in 20-fold molar quantities to deaerated solutions of the complex **1**, and their cis-trans isomerization was attempted. Table 2 summarizes the results of *N*-(1-propenyl)-acetamide, *N,N*-diethyl-1-propenylamine, and 1-propenylbenzene. Photoirradiation with **1** promoted the isomerization, and the fraction of *Z* isomer in each of the 1-propenyl compounds approached one equilibrium value at the photostationary state after prolonged irradiation. The *Z* fractions were 51±2, 2±2, and 2±1% for *N*-(1-propenyl)acetamide, *N,N*-diethyl-1-propenylamine, and 1-propenylbenzene, respectively. In several runs performed with the constant quantity of **1**, change of the amount of 1-propenyl compounds charged did not show any significant effect on the *Z* fractions at the photoassisted equilibrium.

Table 2. Cis-trans Isomerization of 1-Propenyl Derivatives[a]

R	Analysis	Reaction Time / h	Reaction Temp / °C	*Z* Fraction/% Before Reaction	*Z* Fraction/% After Reaction
$-NHCOCH_3$	GLC	6	30	72±2	51±2
		6	30	22±1	52±2
$-N(C_2H_5)_2$	^1H NMR	5	10	27±2	12±2
		24	10	26±2	2±2
		24	10	2±2	2±2
$-C_6H_5$	GLC	5	30	61±2	23±1
		5	30	15±1	2±1
		14	30	35±2	2±1
		5	30	2±1	3±1

a) The cobalt(I) complex **1** (0.04 mmol) was mixed with the 1-propenyl derivatives (0.8 mmol) in benzene, and the mixture was irradiated. See the experimental section.

Table 3. *Z* Fraction of 1-Propenyl Derivatives Formed during the Early Stage from Allylic Compounds[a)]

R	Analysis	Temp	*Z* Fraction/% (Conversion/%)	
		°C	Experimental Values	Extrapolated Value[b)]
-NHCOCH$_3$	GLC	30	75±2 (5.4), 68±2 (14)	~79 (0)
-N(C$_2$H$_5$)$_2$	^{1}H NMR	10	26±2 (20), 24±2 (30)	~30 (0)
-C$_6$H$_5$	GLC	30	20±4 (1.3), 26±2 (17), 24±2 (27)	~20 (0)

a) The cobalt(I) complex **1** (0.04 mmol) was mixed with the allylic compounds (0.8 mmol) in benzene, and the mixture was irradiated. See the experimental section. b) These values were obtained by extrapolating plots of the experimental value vs. conversion to the intercept at zero conversion.

In consideration of absorption spectra of **1** and the 1-propenyl compounds and of the radiation spectrum from the Hg lamp equipped with the Pyrex filter, the line at 366 nm and its trailing part were mainly responsible for the photoreactions with **1**, and incident photons in this wavelength region were absorbed almost completely by **1**. Thus, direct cis-trans photoisomerization of the 1-propenyl compounds without intervention of the CoHP$_3$ species, was presumed to make relatively small contribution to the photoassisted equilibrium states. Main contribution to the states was believed to be thermodynamically equilibrated interconversion between two isomers of the respective 1-propenyl compounds. For *N*-(1-propenyl)-acetamide and 1-propenylbenzene, the cis-trans isomerization was not observed in the presence of **1** in the dark at 30 °C, and hence the thermodynamic interconversion was assumed to occur actually only under assistance of CoHP$_3$ photogenerated. On the other hand, the *Z* isomer of *N*,*N*-diethyl-1-propenylamine is thermally labile, and prolonged standing at 10 °C converted it slowly to *E* isomer. Photoirradiation of the *Z* isomer in the presence of **1** enhanced the isomerization rate considerably.

As for the double-bond migration of allylic compounds, Table 3 shows the *Z* fractions in 1-propenyl derivatives formed during the early stage of the reaction proceeding. The *Z* fractions extrapolated back near zero conversions were approximately 79, 30, and 20% for the reactions of *N*-allylacetamide, *N*,*N*-diethylallylamine, and allylbenzene, respectively. These numerical values were considerably different from those of the above-described photoassisted equilibrium for the cis-trans isomerization of the 1-propenyl compounds. Accordingly, the present double-bond migration was determined to yield kinetically controlled products of the 1-propenyl derivatives.

In the course of the double-bond migration, allylic compounds were allowed to coordinate to CoHP$_3$ photoproduced, and insertion of the olefins into the hydrido-cobalt bond probably followed to form alkyl intermediates (Scheme). At the stage immediately before conversion of the intermediates to CoHP$_3$ and product olefins through β-hydogen elimination, steric interactions within the alkylmetal groups would favor an eclipsed transient conformation A (Fig. 6), which is

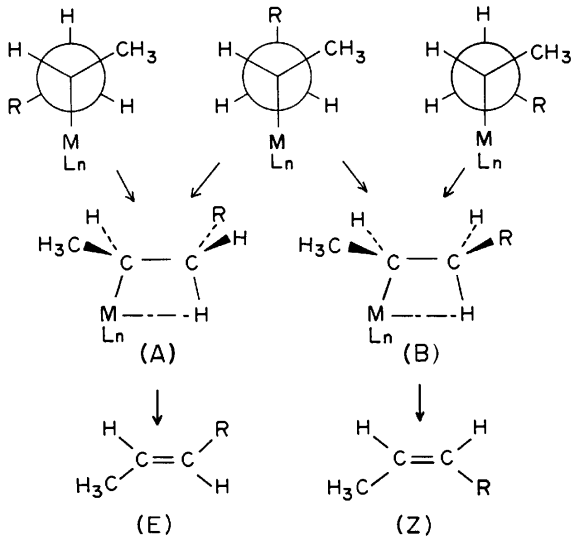

Fig. 6. β-Hydrogen elimination from the alkyl intermediates.

expected to yield *E* isomer of product olefins predominantly. This was probably the case for *N*,*N*-diethylallylamine and allylbenzene. However, in case of *N*-allylacetamide, we believed that probable additional weak interaction[18)] of the amide oxygen with cobalt in the alkyl intermediate enhanced steric interactions between the alkyl group and other coexisting ligands on cobalt significantly, causing preferential formation of the transient conformation B to release the *Z* isomer mainly.

Concluding Remarks

The CoHP$_3$ species, photogenerated from the thermally inert hydridocobalt(I) **1**, cleaved the allylic-O bonds in allyl benzoate and allyl phenyl ether with release of propene, whereas the species catalyzed the double-bond migration of *N*-allylacetamide, *N*,*N*-diethylallylamine, and allylbenzene to the respective 1-propenyl derivatives with kinetically controlled *E*, *Z* isomeric compositions. For the double-bond migration of the latter group of allylic compounds, π-coordination of the C=C double bond to CoHP$_3$ was found to occur at the first stage rather than via the nitrogen or oxygen donor-atom. The present study confirmed the utility of pulsed-laser photolysis in

observation of time-resolved absorption spectra of transient metal species and in determination of absolute rate constants for coordination, suggesting further application to other organometallic systems.

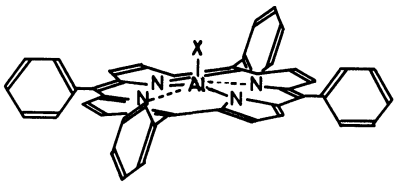
Reactivity of (Porphinato)aluminum Phenoxide and Alkoxide as Active Initiators for Polymerization of Epoxide and Lactone

Tomokazu YASUDA, Takuzo AIDA, and Shohei INOUE*
Department of Synthetic Chemistry, Faculty of Engineering, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received June 18, 1986)

Reactivity of the axial aluminum-phenoxyl and -alkoxyl bond (Al-X) of aluminum porphyrin (**1**, (TPP)AlX, (TPP): (5,10,15,20-tetraphenylporphinato)) toward epoxide, β-lactone, and ε-lactone was examined in relation to the ring-opening polymerization of these cyclic compounds catalyzed by **1**. The reactivity of



(TPP)AlX (1)

aluminum phenoxide was in the order, epoxide>β-lactone>ε-lactone, while that of the alkoxide, ε-lactone >β-lactone.

Control of molecular weight of polymer is a subject of primary importance for elaborate design of polymeric materials with desired function.[1] Recently, we found aluminum porphyrin such as (5,10,15,20-tetraphenylporphinato)aluminum chloride (**1**, X=Cl: (TPP)AlCl) to be an excellent initiator or catalyst for the ring-opening polymerization of epoxide[2] and β-lactone[3] to give polyether and polyester, respectively, of very narrow molecular-weight distribution.[4] This remarkable characteristics is due to unusually high reactivity of the aluminum-axial ligand bond (Al-X) of the aluminum porphyrin.[2-4] Typically, the reactivity of aluminum-chlorine bond in (TPP)AlCl is much higher than that expected for usual aluminum-chlorine bond, and (TPP)AlCl reacts readily with epoxide to initiate the polymerization which proceeds with a (porphinato)aluminum alkoxide as the growing species.[5]

(1)

1 (X = Cl) **2**

The reactivity of (porphinato)aluminum chloride toward epoxide is considered higher than, or at least the same as, that of (porphinato)aluminum alkoxide, taking into account the narrow molecular-weight distribution of the polymer formed. If the reactivity of (porphinato)aluminum chloride were lower than that of the alkoxide, slower initiation followed by faster propagation should result in the broad molecular-weight distribution of polymer. The reactivity of (porphinato)aluminum carboxylate (**1**, X=O_2CR) toward epoxide is also considered not lower than that of the alkoxide, on the basis of the fact that the polymerization of epoxide initiated by (porphinato)aluminum carboxylate affords the polymer with narrow molecular-weight distribution.[6]

Polymerization of β-lactone initiated by (TPP)AlCl proceeds by the ring cleavage at alkyl-oxygen linkage, with a (porphinato)aluminum carboxylate as the growing species.[7]

(2)

1 (X = Cl)

The narrow molecular-weight distribution of the polymer indicates that the reactivity of (porphinato)-aluminum chloride toward β-lactone is higher than, or the same as, that of the carboxylate, on the basis of the same consideration as described above.

Corresponding to the above findings, (porphinato)-aluminum alkoxide (**1**, (X=OR): **2**) and carboxylate (**1**, X=O_2CR) initiate the polymerization of epoxide[2,5] and β-lactone,[7] respectively. The latter can initiate also the polymerization of epoxide as mentioned above.[6] (Porphinato)aluminum phenoxide (**1**, X=OAr) was found to initiate the polymerization of epoxide and β-lactone to give the polymers with narrow molecular-weight distribution.[6]

These interesting findings prompted us to examine the reactivity of aluminum porphyrin in more detail by NMR analysis of the reaction system, which proved very useful to follow the reaction by virtue of the remarkable effect of the porphyrin ring current.[4-7] The present paper places emphasis on the reactivity of (porphinato)aluminum phenoxide, which is expected to exhibit an intermediate reactivity between the alkoxide and the carboxylate, toward epoxide, β-lactone, and ε-lactone.

Results and Discussion

Reaction of (Porphinato)aluminum Phenoxide. In the reaction of (tetraphenylporphinato)aluminum phenoxide (**1**, X=OPh: (TPP)AlOPh) with eight molar equivalents of β-propiolactone (PL) in $CDCl_3$ at

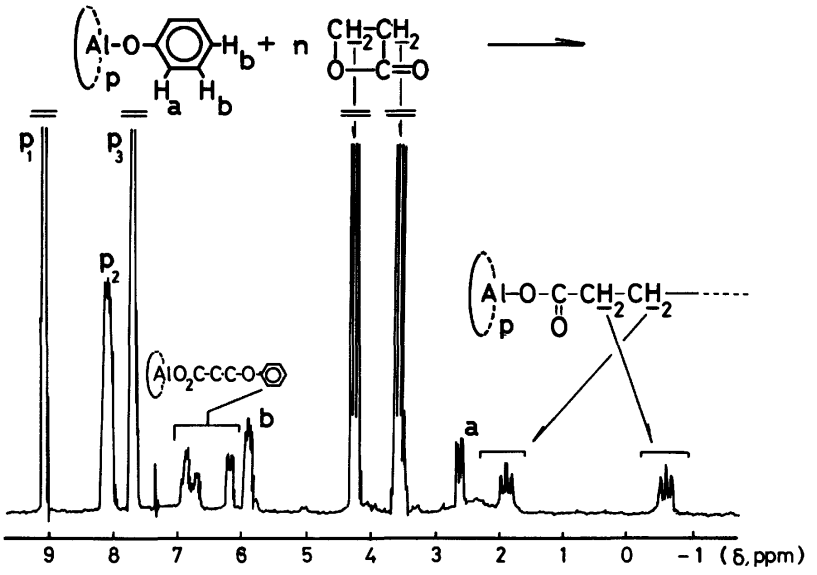


Fig. 1. ^{1}H NMR spectrum of the reaction mixture between (TPP)AlOPh (**1**, X=OPh) and β-propiolactone (PL) in $CDCl_3$. $[PL]_o/[(TPP)AlOPh]_o$=8.1; $[(TPP)AlOPh]_o$=130 mmol dm^{-3}; r.t.; 6 h.

room temperature (≈20 °C), the ^{1}H NMR spectrum of the reaction mixture (Fig. 1) showed that the signals at δ 2.6 (a, *o*-H) and δ 5.9 (b, *m*- and *p*-H) due to the phenoxyl group of (TPP)AlOPh[6] decreased in intensity. On the other hand, a new signal appeared at δ −0.66, which is assigned to a carboxylate (TPP)AlO_2C-$C\underline{H}_2$-CH_2-[7,8] formed by the ring opening of the β-lactone at alkyl-oxygen bond. Similarly, the formation of a (porphinato)aluminum alkoxide by the reaction of (TPP)AlOPh with an excess of 1,2-epoxypropane (PO) was confirmed by the ^{1}H NMR spectrum of the reaction mixture; (TPP)AlOCH($C\underline{H}_3$)-CH_2-, δ −1.86.[5]

The reaction of (TPP)AlOPh with an excess (7—8 times) of β-lactone or epoxide at room temperature in $CDCl_3$ was followed by the change in the intensity of the signal for the phenoxyl group (δ 5.9 (b, 3H), *m*-, *p*-H) with respect to that due to the pyrrole β-proton of aluminum porphyrin (δ 9.1 (p_1, 8H)) as standard. In each case, the signal due to the corresponding polymeric unit[9] was hardly observed under the conditions examined, indicating that the observation made here can be related to the initiation step to give $\mathbf{3}_1$ and $\mathbf{4}_1$, respectively. As shown in Fig. 2, the reaction of (TPP)AlOPh with epoxide proceeded rapidly and was completed in about 4 h, while the reaction with β-lactone was rather slow to attain the complete consumption of (TPP)AlOPh after about 24 h. On the other hand, in the attempted reaction of (TPP)AlOPh with ε-caprolactone (6-hexanolide) under similar conditions, no change was observed in the ^{1}H NMR spectrum of the reaction mixture.

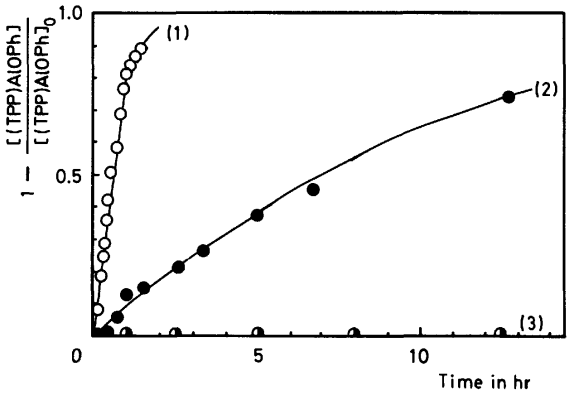

Fig. 2. Reaction of (TPP)AlOPh (**1**, X=OPh) with (1) 1,2-epoxypropane (PO), (2) β-propiolactone (PL), and (3) ε-caprolactone (CL). $[PO]_o/[(TPP)AlOPh]_o$=8.0, $[PL]_o/[(TPP)AlOPh]_o$=8.1, $[CL]_o/[(TPP)AlOPh]_o$=7.2; $[(TPP)AlOPh]_o$=130 mmol dm^{-3}; in $CDCl_3$; at r.t.

Reaction of (Porphinato)aluminum Alkoxide. The reaction of (tetraphenylporphinato)aluminum alkoxide (**1**, X=OR: (TPP)AlOR) with lactone was exam-

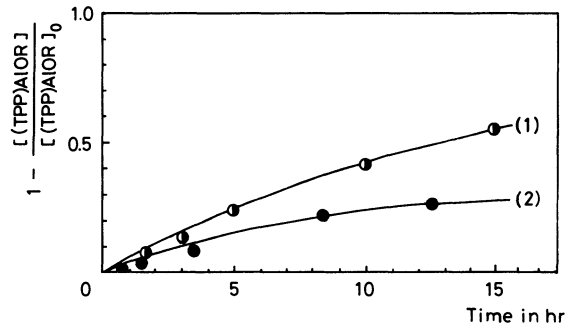

Fig. 3. Reaction of (TPP)AlOR (**2**) with (1) ε-caprolactone (CL), and (2) β-propiolactone (PL). $[CL]_0/[(TPP)AlOR]_0=8.2$, $[PL]_0/[(TPP)AlOR]_0=7.8$; $[(TPP)AlOR]_0=227$ mmol dm^{-3}; in $CDCl_3$; r.t.

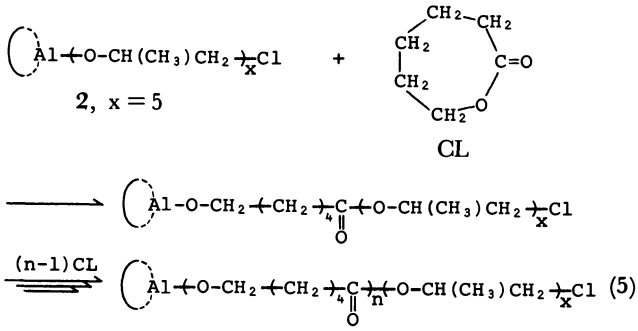
ined by using an oligomeric alkoxide **2** prepared from 1,2-epoxypropane with (TPP)AlCl as initiator.[5,10] In contrast to (TPP)AlOPh, (TPP)AlOR exhibited a moderate reactivity toward ε-caprolactone (CL) (Fig. 3). In the ^{1}H NMR spectrum of the reaction mixture of (TPP)AlOR (**2**) with a large excess of the lactone, a new signal appeared at δ −1.09, at the expense of the signal at δ −1.86 due to (TPP)Al-OCH-($C\underline{H}_3$)-CH_2- of **2**. The former signal is assigned to an alkoxide (TPP)Al-O-$C\underline{H}_2(CH_2)_4$-CO-,[11] the product of ring opening at acyl-oxygen bond of ε-caprolactone.



On the other hand, the reaction of (TPP)AlOR with β-propiolactone proceeded much slower. The main product as detected by the ^{1}H NMR spectrum was a (porphinato)aluminum carboxylate resulting from the ring cleavage at alkyl-oxygen bond, similarly to the reaction of (TPP)AlOPh.

Thus, the reactivity of (porphinato)aluminum phenoxide is much different from that of the alkoxide, but is rather similar to the reactivity of the carboxylate, which does not react with ε-caprolactone. Much lower reactivity with ε-lactone than with β-lactone is of particular interest, since in many cases the reactivity of the former has been reported to be higher than the latter.[12]

Experimental

Materials. 5,10,15,20-Tetraphenylporphine ($TPPH_2$) was synthesized by the reaction of pyrrole with benzaldehyde.[13] (Tetraphenylporphinato)aluminum phenoxide (**1**, X=OPh: (TPP)AlOPh) and 3-phenoxypropionate[8] (**1**, X=O_2C-CH_2CH_2-OPh: (TPP)$AlO_2CCH_2CH_2OPh$) were synthesized, respectively, by the reaction of phenol[6] and 3-phenoxypropionic acid with ethyl(tetraphenylporphinato)-aluminum (**1**, X=Et: (TPP)AlEt) which was obtained by the reaction of $TPPH_2$ and triethylaluminum.[14] Oligomeric (tetraphenylporphinato)aluminum alkoxide (**2**) was prepared by the reaction of (tetraphenylporphinato)aluminum chloride (**1**, X=Cl: (TPP)AlCl) with five molar equivalents of 1,2-epoxypropane.[5,10] 1,2-Epoxypropane was purified by refluxing over a mixture of potassium hydroxide and calcium hydride and then distilled twice under a nitrogen atmosphere. β-Propiolactone, dried by stirring with calcium hydride overnight at room temperature, was purified by fractional distillation under reduced pressure under a nitrogen atmosphere over calcium hydride. ε-Caprolactone was distilled over calcium hydride under reduced pressure. Deuterated chloroform ($CDCl_3$) was distilled after refluxing over calcium hydride under a nitrogen atmosphere.

Reaction. To a 50 cm^3 flask equipped with a three-way stop cock containing a $CDCl_3$ solution of an aluminum porphyrin, epoxide or lactone was added by syringe at room temperature under a nitrogen atmosphere with constant stirring. After an appropriate time, a portion of the reaction mixture was subjected to ^{1}H NMR spectroscopy with a JEOL JNM PS-100 spectrometer to follow the reaction. Chemical shift was separately determined with an improved accuracy by using a JEOL JNM GX-400 FT spectrometer operating at 399.7 MHz with $CHCl_3$ (δ 7.28) as standard.

The Hydrogenation of 1,3-Butadiene over a Palladium Membrane

Hidetoshi NAGAMOTO* and Hakuai INOUE
Department of Chemical Engineering, The University of Tokyo, Hongo 7-3-1, Bunkyo-ku, Tokyo 113
(Received February 20, 1986)

The hydrogenation of 1,3-butadiene was carried out over a palladium membrane at 100 °C in two ways: (1) by hydrogen permeating the membrane, and (2) by hydrogen premixed in the gas phase. In the reactions using permeate hydrogen, hydrogenation at the higher pressures of butadiene was limited by the hydrogen permeation; namely, the rate was determined by the pressure of hydrogen upstream. The product composition was, at the same time, unchanged by the reaction rate. At the lower pressures of butadiene, the selectivity for butene formation was decreased with the decrease in the butadiene pressure, and the reaction rate was approximately equal to that when the premixed hydrogen was used over the β-phase membrane. The mechanism of the reaction using premixed hydrogen over the α-phase membrane was analyzed quantitatively by obtaining the dissolved hydrogen concentration from the measurement of the hydrogen-permeation rate from the reaction surface. It was elucidated that the reaction was limited by the hydrogen adsorption, the rate of which was affected by the presence of 1,3-butadiene, and that the reaction rate was much smaller than that when permeate hydrogen was used.

The catalytic hydrogenation of olefins is one of the reactions investigated most frequently. Palladium, among the metallic catalysts employed for hydrogenation, has the peculiar property of dissolving a large amount of hydrogen at room temperature and of making the hydrogen diffuse through it. It has been reported that the reaction of propylene by the hydrogen dissolved in palladium proceeds much faster than that by gaseous hydrogen.[1] The present authors have also observed that the hydrogen permeating the palladium membrane enhanced the hydrogenation of 1,3-butadiene.[2] For the hydrogenation of ethylene, however, no such enhancement could be observed.

The measurement of the hydrogen-permeation rate through the α-phase palladium membrane showed that the hydrogen permeation from the reaction surface was decreased by the reaction of 1,3-butadiene, not by the reaction of ethylene. It was considered, therefore, that the enhancement of olefin hydrogenation was related to the decrease in the hydrogen-permeation rate.[2]

In a previous study,[3] the present authors analyzed the kinetic mechanism of ethylene hydrogenation by means of permeate hydrogen. The hydrogen transport was considered to consist of three processes: (I) hydrogen adsorption or desorption on the membrane surface, (II) transfer into or out of the membrane through the interface, and (III) diffusion through the membrane. As for the hydrogenation of ethylene by means of permeate hydrogen, the reaction rate was found to be expressed by the mechanism assuming that the equilibrium was established for Processes (I) and (II) at the reaction surface of the membrane.[3] In the case of 1,3-butadiene hydrogenation, the results of the hydrogen-permeation-rate measurement suggested that the equilibrium was not established.

In the present paper, the concentration of dissolved hydrogen in the vicinity of the reaction surface of the membrane was calculated from the permeation rate and the hydrogen sorption equilibrium data. Using the concentration thus calculated, the kinetic mechanism of 1,3-butadiene hydrogenation was investigated quantitatively based on the mechanism of hydrogen transport memtioned above.

Experimental

Materials. The palladium membranes purchased from the Tanaka Kikinzoku Kogyo Co. were 99.95% pure and 50 μm thick. The membrane was pretreated before the reaction as follows: Primarily, the membrane degreased with acetone was polished electrolytically in 0.5 M† H_2SO_4 aqueous solution, and palladium black was electrodeposited on both the surfaces of the membrane in 0.05 M of a $PdCl_2$ aqueous solution. Secondly, the membrane was oxidized in air at 600 to 700 °C.[4] Then, the oxidized membrane which was set into the reactor was reduced by hydrogen at room temperature and heated in nitrogen stream to the reaction temperature in order to remove the hydrogen dissolved in the membrane.

The hydrogen contained in a cylinder was 99.99999% pure, and the other gases and reagents employed in the experiments were commercial-grade and were used without further purification.

Reactor and Procedure. The reactor, made of stainless steel, was separated into two compartments of equal volumes by the use of a palladium membrane pinched by reduced copper gaskets. Reactant gases were introduced into one compartment, called the reaction compartment, and hydrogen into the other, called the hydrogen compartment, for hydrogenation by means of permeate hydrogen. The effective area for hydrogen permeation was 4.9 cm^2. The details about the reactor was described elsewhere.[3]

The hydrogenation of 1,3-butadiene was carried out by two different methods: (I) by the use of hydrogen permeating the palladium membrane from the hydrogen compartment, and (II) by the use of premixed hydrogen. The reaction system by Method (I) was named the permeation system; here, a mixture of 1,3-butadiene and a diluent gas such as nitrogen passed through the reaction compartment. The system by Method (II) was named the mixture system; here, a mixture of hydrogen, 1,3-butadiene, and nitrogen was passed through the reaction compartment, with nitrogen filling the hydrogen compartment.

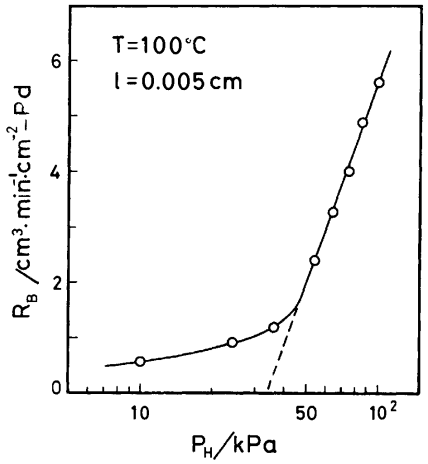

Fig. 2. Hydrogenation rate of 1,3-butadiene by permeate hydrogen through a 0.005 cm Pd membrane at the butadiene pressure of 40 kPa and at 100°C as a function of the upstream hydrogen pressure.

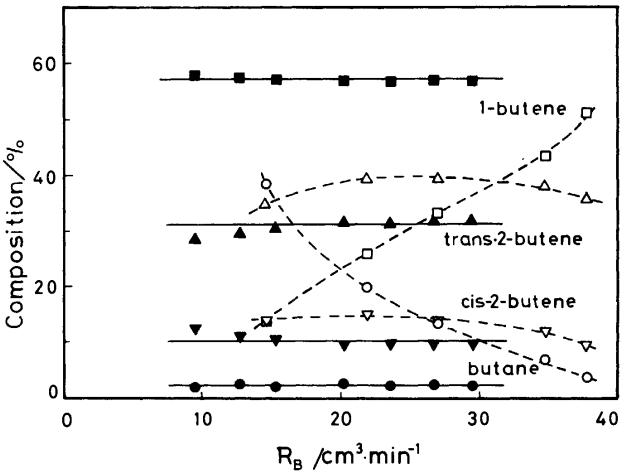

Fig. 3. Product distribution in the hydrogenation of 1,3-butadiene by permeate hydrogen at 100°C. Filled symbols represent the compositions under the hydrogen permeation limitation and open symbols otherwise.

The molar fractions of the component gases were determined with a gas chromatograph equipped with a TC detector. The column packings were VZ-7 for the analysis of hydrocarbons and Molecular Sieve 13X for hydrogen.

The reaction was carried out at 100 °C for both systems. The partial pressures of 1,3-butadiene ranged from 1 to 41 kPa. The hydrogen partial pressures ranged from 10 to 100 kPa for the permeation system and from 1 to 47 kPa for the mixture system. The flow rate in the reaction compartment was kept at 500—600 cm^3 min^{-1} in order to avoid limiting the reaction rate by mass transfer in the gas-boundary film.[5]

Results

Hydrogenation by Permeate Hydrogen. Figure 1 shows the hydrogenation rate and the hydrogen permeation rate as a function of the 1,3-butadiene pressure at the upstream hydrogen pressure of 100 kPa. The behavior of the reaction rate was different from that for ethylene hydrogenation, which showed that the dependence of the reaction rate on the ethylene pressure could be expressed approximately by two straight lines.[5]

At the butadiene pressures higher than 20 kPa, the hydrogenation rate was approximately constant and almost identical with the hydrogen-permeation rate. The hydrogenation rate at the butadiene pressure of 40 kPa is shown in Fig. 2 as a function of the upstream hydrogen pressure. The rate was varied linearly with ln P_H when the hydrogen pressure was higher than 35 kPa, which approximately corresponds to the minimum pressure for forming the β-phase at the reaction temperature.[6] While the reaction rate was changed by the upstream hydrogen pressure, the composition of the products was substantially unchanged, and the selectivity for butene formation was more than 0.98 (Fig. 3).

At the butadiene pressures lower than 20 kPa, the hydrogenation rate was dependent on the butadiene pressure. At a pressure as low as 1 kPa, the rate was very close to that obtained for the mixture system at the hydrogen pressure of 47 kPa, where the membrane formed the β-phase. However, the pressure of the unreacted hydrogen in the reaction compartment was much lower than the minimum pressure for forming the β-phase. Since the hydrogen-permeation rate under a reaction was approximately independent of the reaction rate or the butadiene pressure, the pressure of the unreacted hydrogen increased as the reaction rate decreased. With the increase in the unreacted hy-

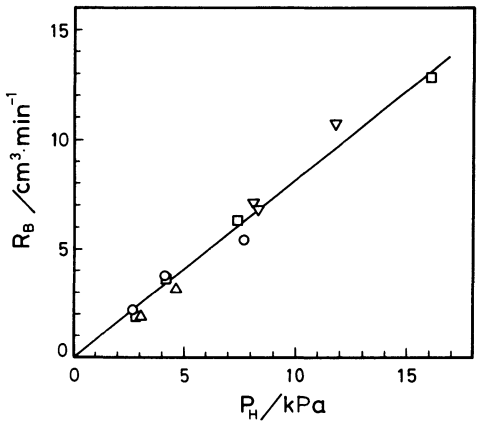

Fig. 4. Hydrogenation rate of 1,3-butadiene by premixed hydrogen over an α-phase Pd membrane of 0.005 cm at 100°C. 1,3-Butadiene pressure (kPa)----- ○: 1.0, □: 2.5, △: 5.0, ▽: 7.0.

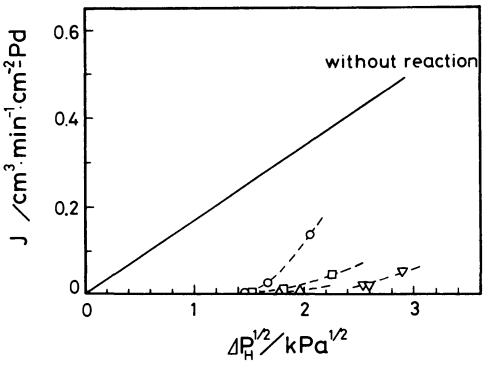

Fig. 5. Hydrogen permeation rate from the reaction surface of a 0.005 cm Pd membrane at 100°C. Keys are the same as in Fig. 4.

drogen pressure, the product composition was remarkably changed, as is shown in Fig. 3.

Hydrogenation by Premixed Hydrogen. The hydrogenation was performed over the palladium membrane of two different phases. When the membrane consisted of the β-phase, i.e., when the hydrogen pressure was over 30 kPa, the hydrogenation rate was proportional to the butadiene pressure, as is shown in Fig. 1. In the case of the α-phase membrane, the rate was proportional to the hydrogen pressure and independent of the butadiene pressure, as is shown in Fig. 4.

As for the latter case, the hydrogen-permeation rate from the reaction side to the other side of the membrane was also measured; it is shown in Fig. 5. The permeation rate was strongly dependent on the butadiene pressure. The hydrogen-permeation rate after the butadiene feed to the reactor had been stopped was well recovered to the initial permeation rate. The concentration of the dissolved hydrogen in the vicinity of the reaction surface, n, was calculated from the permeation rate by the use of Eq. 1:

$$n = \frac{P_H}{K_H} + \frac{J}{\kappa D_\alpha / l} \quad (1)$$

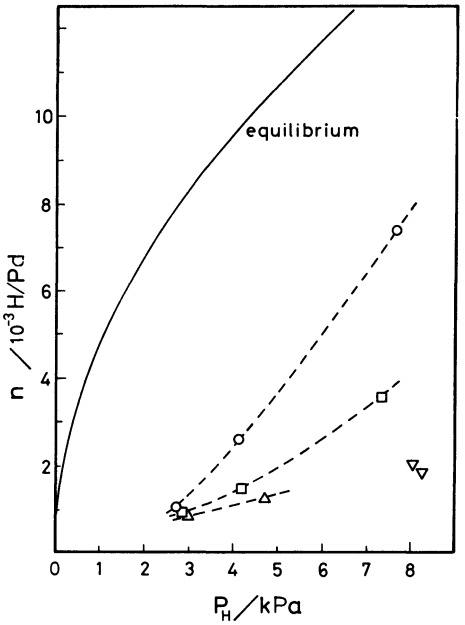

Fig. 6. Dissolved hydrogen concentration in the vicinity of the reaction surface under reaction at 100°C as a function of hydrogen pressure. Keys are the same as in Fig. 4.

P_H is the hydrogen pressure in the compartment to which hydrogen diffuses, and J is the hydrogen permeation rate. K_H is Sieverts' constant; l, the membrane thickness; κ, the hydrogen concentration at n=1, and D_α, the hydrogen-diffusion coefficient through the α-phase palladium. The calculated values of the hydrogen concentration under the reaction, shown in Fig. 6, were lower than those in equilibrium with the gaseous hydrogen and decreased as the butadiene pressure increased.

Discussion

Hydrogenation by Permeate Hydrogen. The previous kinetic analysis of reaction by permeate hydrogen[3] obtained the following results. When the adsorption constant of hydrogen is much larger than the value determined by the operational condition, the reaction rate increases in proportion to the olefin-surface coverage until the rate becomes equal to the hydrogen-diffusion rate, and thereafter the rate is limited by the diffusion rate. This case was observed in the hydrogenation of ethylene. When the hydrogen-adsorption constant is as large as the value determined by the operational condition, the reaction rate increases, but not in proportion to the olefin surface coverage.

Based on the analysis presented above, the behavior of the hydrogenation of 1,3-butadiene shown in Fig. 1 can be explained either by the small adsorption constant of hydrogen affected by butadiene, or by the nonlinear adsorption isotherm of butadiene and the large hydrogen-adsorption constant. The hydrogenation

rate by permeate hydrogen at a butadiene pressure of less than 3 kPa was found to be smaller than that by premixed hydrogen over the β-phase membrane, where the hydrogen surface coverage was considered to be unity. The adsorption constant of hydrogen under the reaction of 1,3-butadiene, therefore, was not so large as that under the reaction of ethylene. It was concluded that the presence of 1,3-butadiene affected the hydrogen adsorption. This conclusion was supported by the change in the butene selectivity caused by the butadiene pressure, as is shown in Fig. 3.

At a butadiene pressure as high as 40 kPa, it was observed that the hydrogenation rate for the permeation system was over ten times larger than that for the mixture system at the same hydrogen pressure as low as 0.2 kPa.[2] This suggested that the rate-determining step was different between the two systems. For the permeation system, the reaction rate was limited by the hydrogen permeation through the membrane, since the rate was varied linearly with ln P_H and since its slope was in good agreement with that predicted for the hydrogen permeation limitation.[6] Thus, it is reasonable to consider that the permeate hydrogen is ready to react with the adsorbed butadiene after reaching the reaction surface when butadiene is adsorbed in a sufficient amount.

Rate Process over α-Phase Membrane for the Mixture System. The hydrogenation rate equation over the α-phase membrane was expressed as:

$$R = kP_H^{1.0}P_B^{0}. \tag{2}$$

This equation for the α-phase is different from that for the α-phase, but is often met with in the hydrogenation of olefins. Sato et al.[7] analyzed the kinetic mechanism of ethylene hydrogenation over various metallic catalysts, including palladium, and reached the conclusion that the rate-determining step lies on the hydrogen adsorption. Since it was found that 1,3-butadiene affects the hydrogen adsorption, as has been discussed above, it is reasonable to assume that the hydrogenation of butadiene proceeds under the hydrogen-adsorption limitation.

It is generally difficult to determine the rate equation of the surface reaction under the adsorption limitation. In the 1,3-butadiene hydrogenation, however, there have been many studies which provide some knowledge about the reaction mechanism. The mechanism neglecting the conformations of the adsorbed butadiene and butenes can be described as follows[8]:

$$C_4H_6(\text{gas}) \rightleftharpoons C_4H_6(\text{ads}) \underset{2}{\overset{1}{\rightleftharpoons}} C_4H_7 \xrightarrow{3} C_4H_8(\text{ads}).$$

The half-hydrogenated species, C_4H_7 may change back to diene and to butene. Since it has been reported that the ratio of hydrogen to deuterium atoms on the palladium surface is low,[9] the reverse reaction of the half-hydrogenation (Step 2) can be considered to be a slow step. When the reaction of half-hydrogenated species with hydrogen (Step 3) proceeds faster than the reverse reaction, the rate equation is expressed as:

$$R = k_B\theta_H\theta_B. \tag{3}$$

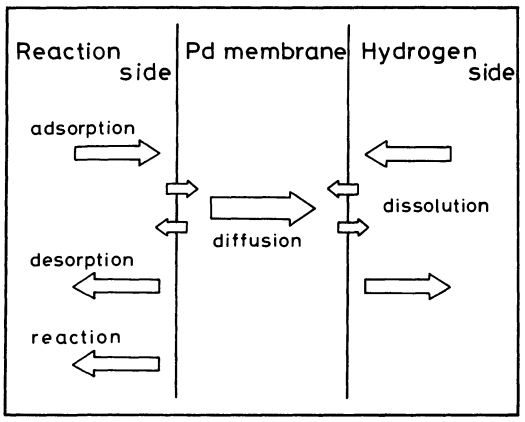

Fig. 7. Illustration of mass transfer process of hydrogen.

When the hydrogenation occurs on the palladium membrane, hydrogen is, at the same time, dissolved into the membrane and diffuses through the membrane. These processes are shown schematically in Fig. 7. The rate equations of these processes may be presented as:

$$\text{dissolution: } r_s = k_i\theta_H - k_o n \tag{4}$$

$$\text{diffusion : } r_d = k_d(n-n_o) \fallingdotseq k_d n \tag{5}$$

The hydrogen adsorption rate is:

$$\text{adsorption: } r_a = k_a P_H \tag{6}$$

Where k_i and k_o are the rate constants for hydrogen transfer into a membrane and out of a membrane respectively. k_d is equal to $\kappa D_\alpha/l$, as has been noted previously. k_a is the rate constant of hydrogen adsorption.

From Eqs. 4 and 5, the concentration of the dissolved hydrogen atom, n, in the steady-state is expressed as:

$$n = \frac{k_i}{k_o+k_d}\theta_H \tag{7}$$

and:

$$r_s = r_d = \frac{k_d k_i}{k_o+k_d}\theta_H. \tag{8}$$

Since the hydrogen-adsorption rate is equal to the sum of the reaction rate and the diffusion rate, then:

$$r_a = \left(k_B\theta_B + \frac{k_d k_i}{k_o+k_d}\right)\theta_H. \tag{9}$$

From Eqs. 6, 7, and 9, the following expression is obtained:

$$n = \frac{k_a P_H}{(k_o+k_d)k_B\theta_B/k_i + k_d}. \tag{10}$$

The reaction rate was much larger than the hydrogen-permeation rate, as is shown in Fig. 5, and the next expression can be derived:

$$k_B\theta_B \gg k_1k_d/(k_o+k_d). \quad (11)$$

Finally, n is expressed as:

$$n = \frac{k_1k_a}{k_B(k_o+k_d)}\frac{P_H}{\theta_B}. \quad (12)$$

Equation 12 shows that the concentration of the dissolved hydrogen is dependent on the butadiene surface coverage as well as the hydrogen pressure. It was found that the behavior of the hydrogen concentration shown in Fig. 6 can be qualitatively explained by Eq. 12.

From Eq. 12, the butadiene coverage is expressed by the following equation:

$$\theta_B = \frac{k_1k_a}{k_B(k_o+k_d)}\frac{P_H}{n} \quad (13)$$

Since the Langmuir-type adsorption isotherm has a wide applicability, it was assumed that the adsorption of butadiene obeys the Langmuir-type isotherm under the present experimental conditions; namely:

$$\frac{P_B}{\theta_B} = \frac{1}{K_B} + P_B \quad (14)$$

Therefore, a quantitative examination of Eq. 12 can be made by a cross plotting of nP_B/P_H against P_B, as is shown in Fig. 8. Since the relationship between nP_B/P_H and P_B was described fairly well by a straight line, Eq. 12 was considered to be reasonable. In addition, the result that the calculated value of the butadiene adsorption constant, 0.23 kPa^{-1}, was larger than that of 1-butene[3] at 100 °C was consistent with the result obtained by other investigators.[9] It was concluded that, for the present mixture system, the reaction was limited by the hydrogen adsorption and that the hydrogen adsorption was affected by the adsorption and/or the reaction of 1,3-butadiene.

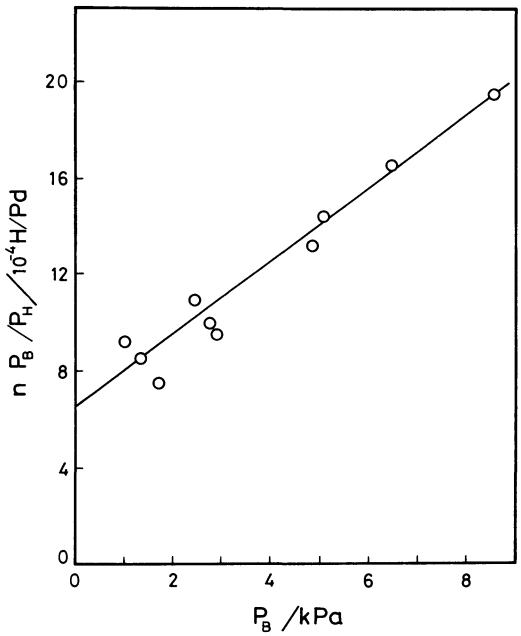

Fig. 8. Plot of nP_B/P_H against P_B for the hydrogenation of 1,3-butadiene at 100°C.

Comparison of Reaction Rates for the Mixture and Permeation Systems. Based on the above considerations, the reason for the difference in the reaction rates for the permeation and mixture systems at the same composition of reactant gases may be explained as follows.

For the mixture system, the concentration of hydrogen atoms on the catalyst surface is very small because the hydrogen adsorption is strongly affected by the butadiene adsorption and/or the reaction. For the permeation system, on the other hand, hydrogen atoms are supplied from the dissolved phase in palladium, and the hydrogen-transfer process through the interface is scarcely affected at all since the reaction was not limited by this process, but by the diffusion process in bulk. Therefore, the surface coverage of hydrogen for the permeation system can considerably exceed that for the mixture system, even at the same hydrogen pressure. Thus, the reaction proceeded much faster for the permeation system than for the mixture system.

Epoxidation of Fatty Acid Esters with Aqueous Hydrogen Peroxide in the Presence of Molybdenum Oxide-Tributyltin Chloride on Charcoal Catalyst

Yasushi Itoi, Masami Inoue,* and Saburo Enomoto
Faculty of Pharmaceutical Sciences, Toyama Medical and Pharmaceutical University, 2630 Sugitani, Toyama 930-01
(Received May 31, 1986)

The epoxidation of fatty acid esters was carried out with a 30% aqueous hydrogen peroxide in the presence of a molybdenum oxide-tributyltin chloride on a charcoal catalyst in 2-propanol at 50 °C. Such inner olefins as ethyl erucate and ethyl oleate gave good yields of 77 and 76%, respectively. Ethyl elaidate, a trans-form of ethyl oleate, was less reactive (40% yield). Several vegetable oils such as rapeseed oil, olive oil, soybean oil, cottonseed oil, corn oil, and linseed oil were oxidized with the oxirane oxygen contents of 5.3 to 3.5%.

Epoxy fatty acid esters have been used for the plasticizer of a poly(vinyl chloride) resin since it was found by Greenspan et al.[1] Among various oxidation processes, an in situ method using acetic acid and a highly-concentrated hydrogen peroxide is practical.[2] However, epoxidation with peracetic acid or performic acid tends to open the oxirane rings. Also, it has some difficulties to separate acid catalysts from the reaction products. Furthermore, hydrogen peroxide of a high concentration is dangerous to handle. Therefore, the use of 30% aqueous hydrogen peroxide in place of organic peroxy acids is favorable.

Hitherto, we have studied the epoxidation of C_5-C_8 alkenes using 30% aqueous hydrogen peroxide as an oxidizing agent. We used molybdenum oxide on charcoal under the presence of organotin compounds as cocatalysts.[3] The catalyst system was applied on several unsaturated fatty acid esters to give epoxides in good yields. The epoxidation was selectively carried out and the separation of the catalyst was easily performed by filtration.

Results and Discussion

Epoxidation of Various Unsaturated Fatty Acid Esters. Previously, we found that certain alkenes such as cyclopentene, cyclohexene, cyclooctene, 1-octene, and 2-octene were epoxidized selectively in high yields in the presence of molybdenum blue (MB), a type of mixed acids of Mo(V) and Mo(VI),[4] and tributyltin chloride on charcoal.[3] In this paper we applied the catalyst for the epoxidation of various unsaturated fatty acid esters. Then, the epoxidation of ethyl erucate, ethyl oleate, ethyl elaidate, ethyl linoleate, ethyl 2-hexenoate, and ethyl 3-hexenoate was carried out with 30% aqueous hydrogen peroxide in 2-propanol solvent for 15 h at 50 °C. Results are shown in Table 1. In all the substrates examined, products were the epoxidized fatty acid esters and recovered materials as was confirmed by the analyses of HPLC and flash chromatography. The epoxidation of unsaturated fatty acid esters of cis-form such as ethyl erucate, ethyl oleate, and ethyl linoleate afforded higher yields than those of the trans-form; it was considered that the activity to the cis-form was higher than that of the trans-form owing to a steric effect.

Table 1. Epoxidation of Various Unsaturated Fatty Acid Esters with 30% H_2O_2 in the Presence of Molybdenum Oxide-Bu_3SnCl-Charcoal (DMFBA) Catalyst[a]

Material	Epoxide yield/%
Ethyl erucate	77
Ethyl oleate	76
Ethyl elaidate	40
Ethyl 10-undecenoate	29
Ethyl linoleate	56
Ethyl 2-hexenoate	0
Ethyl 3-hexenoate	0

a) Substrate (3.0 mmol), 30% H_2O_2 (1.8 ml, 17.6 mmol), 1.25% MB-charcoal (0.4 g), Bu_3SnCl (50 mg, 0.15 mmol), and 2-propanol (12 ml) were used. The reaction was carried out at 50°C for 15 h. DMFBA; *N,N*-dimethylformamide dibutyl acetal.

Ethyl 10-undecenoate, an ester including a terminal double bond, gave a lower yield than those of inner ones. On the other hand, unsaturated fatty acids which included a double bond near the carbonyl group, such as ethyl 2-hexenoate or ethyl 3-hexenoate, did not epoxidized at all.

Recently, it has been reported that a pair of isomers, methyl oleate and methyl elaidate, were epoxidized using excess molar ratios of aqueous hydrogen peroxide in the presence of iron(III) acetylacetonate.[5] The epoxidation has took place to give trans-isomer in high yields either from methyl oleate or methyl elaidate. In our reaction system, a double bond was epoxidized by keeping its configuration. This tendency has also been reported in the epoxidation using *m*-chloroperbenzoic acid.[5]

In the epoxidation of ethyl linoleate, the oxidation rate of one double bond was faster than that of others. The monoepoxides were selectively separated from ethyl linoleate and the oxirane ring was confirmed by elemental analyses; NMR spectra though the epoxidized site could not be determined. The epoxidation of α,β-unsaturated acids has been carried out using hydrogen peroxide in the presence of tungstic acid in an alkaline media.[6] The active species for the reaction systems were suggested to be HOO^- which reacted at the electron-poor double bond of α,β-unsaturated

Table 2. Epoxidation of Various Vegatable Oils Using 30% H_2O_2 in the Presence of Molybdenum Oxide-Bu_3SnCl-Charcoal (BSA) Catalyst[a]

Oil (Iodine number)	Iodine number	Oxirane oxygen/%	Constitution[b] Erc[c]	Ole[d]	Li_2[e]	Li_3[f]

a) Oil (3 g), 30% H_2O_2 (6 ml, 58.7 mmol), 1.25% MB-charcoal (0.8 g), Bu_3SnCl (100 mg, 0.3 mmol), and 2-propanol (24 ml) were used. The reaction was carried out at 50°C for 15 h. b) These constitutions were quoted from JP IX and Yushi Kagaku Binran (ed by Chemical Society of Oil and Fats, 1971). c) Erucic acid. d) Oleic acid. e) Linoleic acid. f) Linolenic acid. BSA; *N,O*-bis(trimethylsilyl)acetamide.

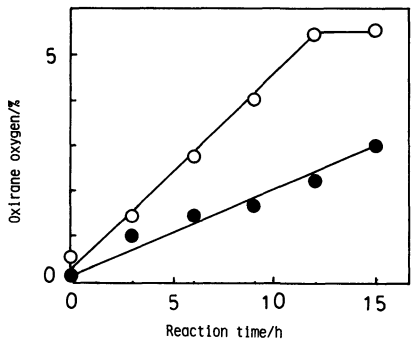

Fig. 1. Oxirane oxygen (%) vs. reaction time in the epoxidation of ethyl erucate and soybean oil with 30% H_2O_2 in the presence of molybdenum oxide-Bu_3SnCl-charcoal (DMFBA) catalyst.
○: Soybean oil, ●: ethyl erucate.
Substrate (2 g), 30% H_2O_2 (3 ml), 1.25% molybdenum oxide-charcoal (0.8 g), Bu_3SnCl (100 mg), and 2-propanol (19 ml) were used. DMFBA; *N, N*-dimethylformamide dibutyl acetal.

acids.

Epoxidation of Various Vegetable Oils. In the plastic industries, soybean oil and oleic acid derivatives are used as a plasticizer. Therefore, we epoxidized various vegetable oils such as rapeseed oil, olive oil, soybean oil, corn oil, cottonseed oil, and linseed oil with 30% aqueous hydrogen peroxide in the presence of molybdenum oxide-tributyltin chloride-charcoal catalyst.

In the oxidation of soybean oil and ethyl erucate, a linear increase of oxirane oxygen according to the reaction time to give the values of 5.6 and 3.0%, respectively (Fig. 1). Also, various vegetable oils were oxidized. Results are shown in Table 2. According to Japanese Pharmacopoeia IX, rapeseed oil contains an erucic acid ester as the main component, and was expected to give a high yield of epoxides since ethyl erucate gave the epoxide in good yield (Table 1). However, the oil gave a poor yield. For this result, it was supposed that the rapeseed oil used in our experiment did not contain erucic acid ester according to the history of the recent process.[7] On the other hand, olive oil which contains an oleic acid ester as a main component was epoxidized in high yield.

Vegetable oils which have linoleic or linolenic acid as a main component gave rather low yields. In our experiments, the epoxidized soybean oil contained 5.3% oxirane oxygen. Other epoxidized vegetable oils, such as olive oil or linseed oil, could also be used as a plasticizer.

Experimantal

Materials. Aqueous hydrogen peroxide (30%) (Hayashi Pure Chemicals), ethyl oleate, ethyl erucate, ethyl linoleate, 2-hexenoic acid, 3-hexenoic acid, tributyltin chloride (Tokyo Chemical Industry), elaidic acid, *N,N*-dimethylformamide dibutyl acetal (DMFBA), and *N,O*-bis(trimethylsilyl)acetamide (BSA)(Wako Pure Chemicals) were purchased. Charcoal (DC-5200w) was kindly provided by Dia Catalysts & Chemicals.

Esterification. 2-Hexenoic acid, 3-hexenoic acid, and elaidic acid (1 g) were respectively esterified with ethanol (10 ml) in the presence of two drops of concd H_2SO_4 at room temperature for 6 h. After the ethanol was evaporated off under reduced pressure, the reaction solution was diluted with water (20 ml). The product was extracted with ether and dried with anhydrous Na_2SO_4. The evaporation of ether gave an oily product.

Pretreatment of Charcoal. Charcoal powder (1 g) was treated with DMFBA or BSA (50 mg) in cyclohexane (20 ml) by stirring at 50 °C. After 2 h, the charcoal was filtered off, washed with hexane, and dried.

Preparation of Catalyst. The molybdenum oxide-charcoal catalyst was prepared by fixing MB which was prepared from molybdenum powder and H_2O_2[4,8] on pretreated charcoal (65 mesh) by stirring overnight at room temperature. The catalyst was separated by filtration and dried.

Epoxidation Procedure. Into the dispersed 2-propanol solution of the molybdenum oxide-charcoal catalyst (0.4 g), Bu_3SnCl (50 mg) was added. After 30 min, additional 2-propanol (10 ml), substrate (1 g), and 30% aqueous hydrogen peroxide (2 ml) were added. The reaction was carried out at 50±1 °C in an oil bath under magnetic stirring.

Analyses of Products. After the reaction, the catalyst was filtered off and 2-propanol was evaporated from the reaction solution. Then, the reaction mixture was extracted with ether and dried. After the removal of ether, the residue was subjected to flash chromatography by passing it through a

Kieselgel 60 column. Elution with benzene-hexane (9:1, v/v) and evaporation of the solvents gave epoxides.

The melting point was uncorrected. NMR spectra were recorded on a Varian XL-200 spectrometer with tetramethylsilane (TMS) as an internal standard. The chemical shifts and coupling constants (J) are given in δ and Hz, respectively.

Solvation of Carboxylic Acids in Nonaqueous Binaries. Solvation Models for Butyric and Trichloroacetic Acids in Nitrobenzene-Toluene Mixtures

Mohamed M. Fahmi Hegazi†
Kuwait Institute of Technology, Shuwaikh, Kuwait
(Received June 20, 1985)

The partitions of trichloroacetic and butyric acids between aqueous solutions and various nitrobenzene-toluene mixtures have been carried out at 25.0 and 30.0 °C, respectively. The observed nonlinearities for both acids of the monomer partition constants and the dimerization constants with the nitrobenzene mole fraction are interpreted in terms of the fractionation factors of effective exchangeable solvation sites of the involved species. Butyric acid monomer is concluded to have three sites for the solvation of the carboxylic hydrogen, carboxylate region, and alkyl chain. Desolvation of the former two sites is necessary for the formation of the dimer for which only two sites corresponding to its two alkyl chain are identified. The solvation sites of trichloroacetic acid monomer and dimer are identical and a singly hydrogen-bonded structure for the dimer is deduced. Dimerization of this acid in the organic phase proceeds by desolvation of what is equivalent to the sites of only one monomer.

Considerable attention has been devoted to solute-solvent interactions in binary solvent mixtures. The larger solute stabilization derived from one of the solvent components compared to that from the other is known to lead to the phenomenon of preferential solvation. This phenomenon is of paramount importance in interpretation of many kinetic data measured in these binaries.[1] Although several studies pertaining to this phenomenon have been reported,[1-3] a refined picture of various solute-solvent interactions has not as yet emerged.

Recently, partition data of acetic acid between aqueous solutions and various nitrobenzene-toluene mixtures have been interpreted in terms of Gross-Butler formalism to deduce various exchangeable sites involved in solvation of the monomer and the dimer in such binaries.[4] Although developed, long time ago, for studying reactions in H_2O-D_2O mixtures,[5-7] this formalism seems to provide a quantitative approach for elucidation of various interactions involved in solute solvation in these extracting binaries. Two assumptions are considered (i) the solvation number of a solute is the same in pure binary components and (ii) solvent exchange processes at various sites take place independently and on the basis of one by one replacement of solvent molecules.

In the present work, the applicability of the above aproach in studying the solvation of butyric and trichloroacetic acids in these binaries are confirmed. The results are compared with those reported for acetic acid in order to examine the effect of solute structural change on the observed solvation behavior.

Experimental

Materials. Nitrobenzene, toluene (Riedel De Haen AG), butyric and trichloroacetic acids (BDH) were used without additional purification.

Procedure. Extracting mixtures of nitrobenzene and toluene as well as aqueous solutions of butyric and trichloroacetic acids were prepared by weight. Appropriate amounts of sodium chloride and hydrochloric acid were added to butyric acid aqueous solution so that their final concentrations were 0.09 and 0.01 mol dm^{-3}, respectively. No sodium chloride was added to trichloroacetic acid solution and the concentration of hydrochloric acid was 0.8 mol dm^{-3}. Partition experiment was made by stirring equal volumes of aqueous and organic phases (20 cm^3 each) in a stoppered conical flask for 1 h with a magnetic stirrer. The contents were transferred into a test tube sealed tightly with a high quality rubber stopper and thermostated at the desired temperature where it is shaked several times before it is allowed to settle overnight for complete phase separation. Carboxylic acid content in the organic phase was determined by titrating a known volume of that phase with NaOH using phenolphthalein indicator. The corresponding concentration in the aqueous phase was determined by difference from initial aqueous phase acid concentration. Blank partition experiments using various extracting mixtures were carried out similarly in the absence of carboxylic acids and no acid (due to HCl) in organic phases was detected. For the determination of association constants of these acids with toluene and nitrobenzene similar partition experiments were carried out using organic phases composed of cyclohexane containing various concentrations of either toluene or nitrobenzene.

Results

The partition coefficient, $D^{(n)}$, of a carboxylic acid between an aqueous solution and a binary mixture of toluene and nitrobenzene (mole fraction n) is related to the partition constant of monomer, $K_d^{(n)}$, and the dimerization constant in the organic phase, $K_{dim}^{(n)}$, by Eq. 1[8]

$$D^{(n)} = (K_d^{(n)} + 2(K_d^{(n)})^2 K_{dim}^{(n)}[HA]_{aq})/(1+K_a/[H^+]), \quad (1)$$

where $[HA]_{aq}$ is the concentration of undissociated acid in the aqueous phase. The partition data of butyric acid were obtained under conditions where its ionization in the aqueous phase was negligible i.e. $[H^+] \gg K_a$. On the other hand, ionization of tri-

chloroacetic acid (pK_a=0.62)[8] was significant at 0.8 mol dm^{-3} HCl used for partition experiments and $[HA]_{aq}$ was accordingly calculated. Salting out effect by such concentration of electrolyte is reported to be insignificantly small.[9] The partition coefficients for butyric and trichloroacetic acids by various binary mixtures as a function of the concentration of undissociated acid in the aqueous phase are presented in Tables 1 and 2, respectively. The values of $K_d^{(n)}$ and $K_{dim}^{(n)}$ at

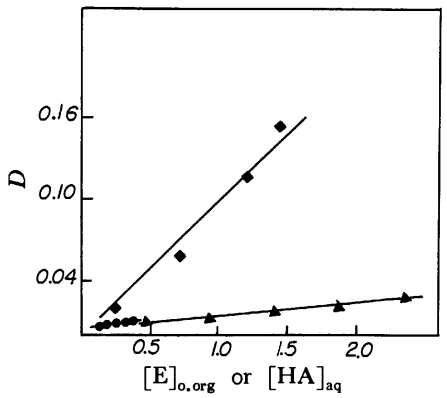

Fig. 2. Partition coefficient of trichloroacetic acid at 25°C between cyclohexane and 1.0 mol dm^{-3} HCl aqeous solution as a function of the concentration of undissociated acid in the aqueous phase; ● and as a function of the concentration of free toluene; ▲ or free nitrobenzene; ■ in the cyclohexane phase at a constant trichloroacetic acid concentration of 0.24 mol dm^{-3}.

various n were deduced from the intercepts and the slopes of linear least squares D-$[HA]_{aq}$ plots (not shown). These are listed in Tables 3 and 4.

The n dependencies of $K_d^{(n)}$ and $K_{dim}^{(n)}$ for butyric acid are portrayed in Figs. 3 and 4 while those of trichloroacetic acid are presented in Figs. 5 and 6, respectively.

Since nitrobenzene and toluene are hydrogen-bonding acceptors,[10] it is necessary in the present study to determine the association constants of each of these compounds with each of the individual acids used. These constants, determined in cyclohexane, as an inert solvent, were calculated from Figs. 1 and 2 using

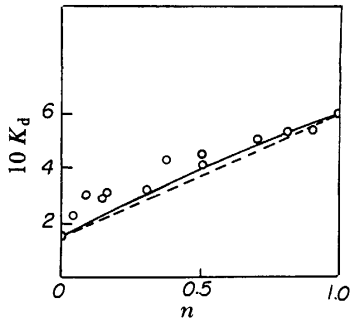

Fig. 3. Dependence of the partition constants of butyric acid monomer on the nitrobenzene mole fraction in the nitrobenzene-toluene mixture at 30°C. The solid curve is calculated based upon the three sites model represented by Eq. 7.†)

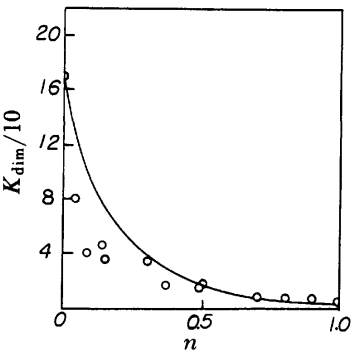

Fig. 4. Plot of the dimerization constant of butyric acid against the nitrobenzene mole fraction in the binary mixture at 30°C. The solid curve is generated from Eq. 11.

Eq. 2[11]

$$D = D_o + K_{ass}K_d[E]_{o,org}/(1+K_a/[H^+]), \quad (2)$$

where D_o is the partition coefficient in the absence of toluene or nitrobenzene and $[E]_{o,org}$ represents the concentration of free toluene or nitrobenzene in cyclohexane phase. The K_d values for both acids in cyclohexane were deduced from the intercepts of the corresponding D-$[HA]_{aq}$ plots shown in Figs. 1 and 2. The association constants for butyric acid with toluene and nitrobenzene are 3.3±0.4 and 9.4±0.1 mol^{-1} dm^3 at 30.0°C while those of trichloroacetic

†) The systematic deviation of the observed K_d values from the fitted ones obtained from Eq. 7 can be attributed to the fact that the fitted values are calculated on the basis of a solvation model for the unhydrated monomer only while the observed value at a given solvent composition represents infact the sum of contributions generated from the solvation of both monomer and its dihydrate. The smaller the extent of hydration the smaller the difference between the observed value and the predicted value will be. The extent of hydration would be expected to decrease as the nitrobenzene mole fraction in the binary increases (I. Kojima, M. Kako, and M. Tanaka, *J. Inorg. Nucl. Chem.*, **32**, 1651 (1970)). Accordingly, the predicted K_d values approach the observed ones at higher nitrobenzene mole fractions, as shown in Fig. 3.

acid are 1.96±0.09 and 25.1±1.9 $mol^{-1}dm^3$, at 25.0°C respectively.

Discussion

Consider a single molecular solute partitioned between an aqueous solution and a binary mixture of nitrobenzene (mole fraction n) and toluene (mole fraction $1-n$). The solute partition constant, $K^{(n)}$, according to its additive constituent nature,[12] equals to the product of contributions $A_1^{(n)}$, $A_2^{(n)}$, $A_3^{(n)}$, ··· $A_m^{(n)}$ generated from stabilization or destabilization of various structural units a_1, a_2, a_3, ··· a_m of that solute in the organic phase. The contribution from mutual interactions among various structural units is assumed to be negligible,

$$K^{(n)} = A_1^{(n)} \cdot A_2^{(n)} \cdot A_3^{(n)} \cdots A_m^{(n)}, \quad (3)$$

where (n) is just a superscript refering to the binary solvent composition. If each of the solute structural units is assumed to have only one effective exchangeable solvation site, any single contribution $A_i^{(n)}$ will equal to the mole fraction weighted average of contributions of a_i in pure nitrobenzene, A_i^{NB} and in pure toluene, A_i^{TL}:

$$\begin{aligned} A_i^{(n)} &= (1-n)A_i^{TL} + n A_i^{NB} \\ &= A_i^{TL}(1-n+\Phi_i n), \end{aligned} \quad (4)$$

where $\Phi_i = A_i^{NB}/A_i^{TL}$ reflects the preference of structural unit a_i for solvation by nitrobenzene relative to that preference for solvation by toluene. It might be considered as a solvation fractionation factor for structural unit a_i. $K^{(n)}$ can thus be expressed in terms of all possible solvation sites as follows:

$$K^{(n)} = K^{TL} \prod_i^v (1-n+\Phi_i n), \quad (5)$$

where K^{TL} is the solute partition constant when pure toluene is used and v is the number of solvation sites, each contributing a $(1-n+\Phi_i n)$ term to the observed $K^{(n)}$. The magnitude of Φ_i is determined by the electronic and geometric factors involved in both the site under consideration and the exchangeable solvents as well.

In the present study, when Φ_i is greater than unity, the i-th site will be stabilized to a greater extent by nitrobenzene than by toluene and vice versa. As Φ_i approaches one, the site will be equally stable in both solvents and no contribution to $K^{(n)}$ will be seen.

It may be noted that Eq. 5 is a special form of the general Gross-Butler equation originally derived for studying chemical reactions in H_2O–D_2O mixtures and is currently used in the well known proton inventory technique.[5-7] Equation 5 predicts that $K^{(n)}$ will vary linearly with n if the partitioning solute has only one solvation site and nonlinearly if the solute have multisolvation sites.

When a solute dimerizes in such binary mixture, the extent of dimerization is governed by the contributions generated from solvation of various structural units composing the monomer and the dimer. It can be shown, in analogy with the above derivation that the dimerization constant, $K_{dim}^{(n)}$, in a given nitrobenzene-toluene mixture is related to the dimerization constant in pure toluene, K_{dim}^{TL}, by a series of correction factors,

$$K_{dim}^{(n)} = K_{dim}^{(n)} \prod_i^v (1-n+\Phi_j^D n) / \prod_i^v (1-n+\Phi_i^M n), \quad (6)$$

where each correction factor $(1-n+\Phi_i^D n)/(1-n+\Phi_i^M n)$ represents the contribution of i-th site in the dimer relative to that contribution in the monomer. The total number of sites v in mumerator and denominator is not necessary to be the same since any $(1-n+\Phi_i n)$ term may be either contributing if $\Phi_i \neq 1$ or not contributing if $\Phi_i = 1$.

Solvation of Butyric Acid. The nonlinear n dependence of partition constant of butyric acid monomer, $K_d^{(n)}$, portrayed in Fig. 3 suggests the involvement of two or more sites for monomer solvation. It is therefore, necessary to formulate a chemically reason-

Table 5. Comparison of Sum of Squared Residuals after Regressions Representing Various Mathematical Monomer Solvation Models

Proposed model	Values	Sum of squared residual
	Butyric acid[a]	
Two sites	Φ_2=1.30	6.5×10^{-2}
Three sites A	Φ_2=4.32; Φ_3=0.30	7.5×10^{-2}
Three sites B	Φ_2=2.16; Φ_3=0.60	3.9×10^{-2}
Three sites C	Φ_2=1.62; Φ_3=0.80	5.7×10^{-2}
	Trichloroacetic acid	
One site	Φ=13.48	2.2×10^{-2}
Two sites D	Φ_1=14.00; Φ_2=0.96	3.1×10^{-2}
Two sites E	Φ_1=12.85; Φ_2=1.05	1.2×10^{-2}
Two sites F	Φ_1=11.00; Φ_2=1.23	1.2×10^{-3}
Two sites G	Φ_1= 9.00; Φ_2=1.50	1.1×10^{-2}

a) A value of 2.90 is used for Φ_1 in all butyric acid models.

able solvation model capable of reproducing the experimental data. Possible models may include a site for the carboxylic hydrogen and one or two sites for the remainder of the molecule. A reasonable estimate for the fractionation factor of carboxylic hydrogen site, Φ_1, is obtained from the ratio of the association constants of butyric acid with nitrobenzene and toluene in the inert solvent cyclohexane. This ratio (2.9) is used for this site in all proposed models, listed in Table 5. The other fractionation factors Φ_2 and Φ_3 corresponding to the other sites are derived so that the product of all fractionation factors for any single model is equal to K_d^{NB}/K_d^{TL} ratio. In order to arrive at the most probable solvation model, the sums of squared residuals after various regressions were computed and compared. The minimum sum of squared residuals is exhibited by model B. Substitution of various values of n in Eq. 7 duplicates reasonably the experimental data, as illustrated in Fig. 3.

$$K_d^{(n)} = K_d^{TL}(1-n+2.90n)(1-n+2.16n)(1-n+0.6n) \quad (7)$$

It is of interest to compare this equation with that reported earlier for solvation of acetic acid monomer in the same binaries,[4] Eq. 8.

$$K_d^{(n)} = K_d^{TL}(1-n+2.85n)(1-n+1.91n) \quad (8)$$

The additional term in Eq. 7 with a fractionation factor of 0.6 must reflect the contribution generated from the solvation site of alkyl chain in butyric acid. A reasonable estimate for the fractionation factor of this site can be independently produced from the ratio of contributions of this alkyl chain to K_d's in nitrobenzene and toluene. These contributions can be obtained from the K_d's of acetic and butyric acids in both solvents using Hansch equation;[12]

$$\Phi_3^{calcd} = \frac{\text{Antilog}(\log K_{d.But}^{NB} - \log K_{d.Acet}^{NB})}{\text{Antilog}(\log K_{d.But}^{TL} - \log K_{d.Acet}^{TL})}. \quad (9)$$

The excellent agreement between the calculated value of 0.7±0.1 and the one obtained from model B, 0.6±0.1, offers a support for the proposed solvation model of butyric acid monomer in these binaries.

The similarity in the second terms of Eqs. 7 and 8 implies their contributing sites are nearly identical. These terms are more likely to arise from interactions of carboxylate region of the monomer with the exchangeable solvent molecules.

In order to deduce a suitable solvation model for butyric acid dimer, it is necessary to determine the various fractionation factors involved. The product of these factors obtained from Eq. 6 (n=1) equals 0.45±0.13. Because of the known cyclic and the nearly symmetrical nature of this dimer,[13] an even number of solvation sites might be anticipated. The value of 0.45 is more likely, therefore, to represent the product of at least two similar fractionation factors (0.67±0.14 each) corresponding to two identical sites. This predicted value for each site is very close to the fractionation factor for alkyl chain solvation site in the monomer obtained from both Eq. 9 and the above $K_d^{(n)}$–n analysis. It is not unreasonable, therefore, to assign this obtained fractionation factor product to solvation sites of the two alkyl groups present in the dimer. According to this picture, no contribution is seen from the other two sites involved in monomer solvation. This seems to be consistent with the conclusion drawn earlier for the dimerization of acetic acid in such binaries that desolvation of its two monomer sites is necessary for the formation of the dimer.[4] The n dependence of $K_{dim}^{(n)}$ may thus be represented by:

$$K_{dim}^{(n)} = K_{dim}^{TL}(1-n+0.67n)^2/ ((1-n+2.90n)(1-n+2.16n)(1-n+0.6n))^2, \quad (10)$$

where the denominator represents the contribution from solvation of two butyric acid monomers. Since the contribution of alkyl chain in both the dimer and monomer is nearly the same, the alkyl chain terms in Eq. 10 could be cancelled out and the n dependence of $K_d^{(n)}$ can be expressed by Eq. 11

$$K_{dim}^{(n)} = K_{dim}^{TL}/((1-n+2.90n)(1-n+2.16n))^2, \quad (11)$$

which duplicates reasonably the experimentally determined $K_{dim}^{(n)}$ data by substitution of various values of n, as shown in Fig. 4. The excellent agreement between $K_{dim}^{(n)}(K_d^{(n)})^2$ values, calculated from Eq. 12,

$$K_{dim}^{(n)}(K_d^{(n)})_{calcd}^2 = K_{dim}^{TL}(K_d^{TL})^2(1-n+0.67n)^2, \quad (12)$$

and the corresponding experimental ones, displayed in Table 3 lend another support to the proposed solva-

tion model of butyric acid dimer in these binaries.

Solvation of Trichloroacetic Acid. The curved $K_d^{(n)}$–n relationship, depicted in Fig. 5 implies the presence of more than one solvation sites for the monomer. It is therefore necessary to formulate a solvation model that is both statistically and chemically acceptable. The fractionation factors of carboxylic hydrogen solvation site for various two sites models, listed in Table 5, are derived either from the ratio of association constants of this acid with nitrobenzene and toluene or from other assumed value in the neighborhood of that ratio. It transpires form Table 5 that regression F represents the most probable model. The experimentally determined $K_d^{(n)}$ values fit nicely the curve generated from

$$K_d^{(n)} = K_d^{TL}(1-n+11.0n)(1-n+1.23n). \quad (13)$$

The product of fractionation factors for the dimer sites is predicted from Eq. 6 (n=1) to be ca. 12, a value very close to that obtained for the monomer sites. This speaks for the similarity in the solvation sites of both species and is consistent with a singly hydrogen-bonded structure for the dimer in nitrobenzene–toluene binaries. Formation of the two hydrogen bonds linking the two monomers is known to be favorable when the dimer has an eight membered cyclic structure.[14] The presence of nitrobenzene in such solvent binaries would tend, however, to form with the acid monomer a stronger hydrogen bond than those formed between the two monomeric entities. This occurs because of the higher hydrogen bonding acceptor basicity of nitrobenzene compared to that of trichloroacetic acid monomer itself.[10] Two effects are thus generated i) a dramatic decrease in the extent of dimerization as the nitrobenzene mole fraction increases in the binary and ii) formation of an open singly hydrogen-bonded dimer. According to this view dimerization proceeds by desolvation of what is equivalent to the sites of one monomer. The n dependence of $K_{dim}^{(n)}$ could thus be represented by:

$$K_{dim}^{(n)} = K_{dim}^{TL}/((1-n+11.0n)(1-n+1.23n)). \quad (14)$$

Substitution of n values in Eq. 14 duplicates reasonably the experimentally determined $K_{dim}^{(n)}$ values, as shown in Fig. 6. Equation 14 predicts that:

$$(K_{dim}^{(n)} K_d^{(n)})_{calcd} = K_{dim}^{TL} K_d^{TL} = \text{constant}.$$

This is born out to be true as illustrated in Table 4.

In summary, the present work offers an approach towards elucidation of various solute–solvent interactions involved in binary nonaqueous mixtures. The nonlinear n dependence of both $K_d^{(n)}$ and $K_{dim}^{(n)}$ for butyric and trichloroacetic acids has been quantitatively rationalized in terms of fractionation factors of various solvation sites of involved species using Gross-Butler formalism. The interactions of the studied species with nitrobenzene are certainly different from those with toluene and require reorientation of solvent molecules upon exchanges. This factor does not seem to materially affect the results reported here.

Titanium Determination under High-Sensitivity Conditions with 2-(5-Chloro-2-pyridylazo)-5-dimethylaminophenol. I

Héctor Jose MARINI, Rosa Isabel ANTÓN, Maria Susana BOERIS,† and Roberto Antonio OLSINA*
Departamento de Quimica Analitica "Dr. Carlos B. Marone," Universidad Nacional de San Luis, Argentina
†Universidad Nacional de La Pampa, Argentina
(Received August 16, 1985)

The optimum working conditions for the complexing reactions between Ti(IV) and 2-(5-chloro-2-pyridylazo)-5-dimethylaminophenol (5.ClDMPAP) in aqueous alcoholic solutions were studied. When an ethanol solution of 5.ClDMPAP is added to a Ti(IV) aqueous solution, complex species, whose spectral and stoichiometric characteristics depend on pH, develop rapidly. The complex selected for the analytical work forms between pH 4.7 and 5.8 and has a 3:1 ligand-metal molar ratio. The complex fulfils Beer's law up to a Ti(IV) concentration of 0.7 ppm, working at λ_{max}=580 nm. The optimum concentration range (Ringbom) was between 0.05 and 0.7 ppm of Ti(IV). The molar absorptivity at λ_{max}=580 nm and Sandell index are 4.39×10^4 dm^3 mol^{-1}cm^{-1} and 0.0011 μg cm^{-2}, respectively. An absorptiometric method to determine Ti(IV) was developed and the proper ways to reduce interferences produced by some anions and cations are described. The method developed was applied to Ti(IV) determination in optical glass and ceramic materials.

The determination of small quantities of titanium is a very important fact when analyzing diverse materials such as glass, frits, ceramics, paints, sands, and natural water from nearby vanadium mines.

The atomic absorption technique, using flame as an atomization means, has not the sensitivity necessary for many cases. So, the searching of chromogenic reagents and the perfecting of techniques having analytical procedures with the proper sensitivity and selectivity for Ti(IV), is interesting. Reagents derived from phenylfluorone[1] and the azo group (pyridylazo)[2] and thiazolylazo[3] yielded significant results. As to those reagents of the pyridylazo type, Shibata et al.[4] proved that the presence of a dialkylamino group in a *p*-position with respect to the azo group and the existence of one halogen atom in the pyridine nucleus are highly important to attain a larger sensitivity in chromatic reactions. The reagent selected, 2-(5-chloro-2-pyridylazo)-5-dimethylaminophenol, fulfils both requirements. The general characteristics of this reagent and its use in zinc and vanadium determination have already been studied.[5,6]

Experimental

Reagents. A 5.ClDMPAP solution was prepared by coupling *m*-dimethylaminophenol with sodium 5-chloro-2-pyridyldiazotate, according to the method described by Shibata et al.[7] Purification was carried out by means of repeated cycles of dissolution-reprecipitation starting from ethanol-water mixtures. A 0.25% (w/v) solution from the pure material was prepared. Lower concentration solutions from the above one by dilution with ethanol, were prepared. All solutions were kept away from light. A 5×10^{-4} mol dm^{-3} solution can be kept unaltered for at least 25 d. The Ti(IV) solution was prepared according to that described by Roseman and Thornton.[8] Its titer was determined by complexometric titration.[9] To obtain reproducible results, the solution must be prepared daily. All the other chemicals were also of an analytical-reagent grade.

Apparatus. A Varian 634 UV-vis. spectrophotometer with 10 mm optical path cell to obtain the absorption spectra and absorbance measures was used. An Orion 701-A pH meter for pH measurements was used. Volumes in Ti(IV) complexometric titrations were obtained by means of an automatic Metrohm Dosimat E412P buret.

Results and Discussion

Influence of pH, Stoichiometry, and Conditions for Ti(IV) Absorptiometric Determination. The reaction between aqueous solutions of Ti(IV) and 5.ClDMPAP dissolved in ethanol produces, almost instantaneously and at different pH values, diverse complex species (Fig. 1). Table 1 shows the most important characteristics of the complexes. For the analytical work, the complex selected is the one formed quantitatively between pH 4.7 and 5.8 as it shows larger values of absorptivity and bathochromatic shift. Its formation starts at pH 4.3 and its maximum development is at the above pH range. As shown by the application of the method of continuous variations (Fig. 2) stoichiometry of the complex was 3:1 (5.ClDMPAP:Ti(IV)). The order in which the reagents are added is very important. First, the reaction between Ti(IV) and 5.ClDMPAP is promoted at low pH values (<2), and then a 5.0 pH buffer is added, so it is possible to work with the selected complex. According to the

electrophoretic migration studies and the extraction with different solvents (benzene, chloroform, 3-methyl-1-butanol, and nitromethane) which have demonstrated the ionic nature of the chelates formed, and also assuming that $(Ti(OH)_2)^{2+}$ is the predominant species of Ti(IV),[10] the following reactions can be written:

$$(Ti(OH_2))^{2+} + 2RH \rightleftharpoons (Ti(OH)R_2)^+ + H_2O + H^+$$

$$(Ti(OH)R_2)^+ + RH \rightleftharpoons (TiR_3)^+OH^- + H^+.$$

The results obtained by applying the equilibrium shift method[11] (Figs. 3 and 4) have shown a release of one hydrogen-ion for each complexed Ti(IV)-ion in every chelation reaction. The above results sustain the proposed reactions. The equilibrium constant of the chelation reaction was studied by means of absorptiometric measurements;[12] the value obtained was 4.41×10^{15} at 25 °C. Table 2 shows experimental variables of Ti(IV) absorptiometric determination.

Influence of the Nature and Concentration of the Organic Solvent. Considering the poor solubility in water of 5.ClDMPAP and its Ti(IV) complexes, the

Table 2. Experimental Variables of Ti(IV) Absorptiometric Determination

pH Range	4.7—5.8
Solvent	Ethanol-water 55% (v/v)

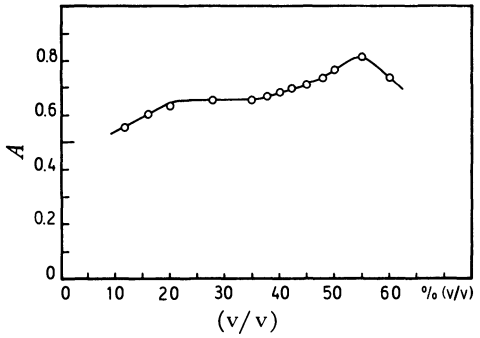

Fig. 5. Influence of the concentration of ethanol on the absorbance of Ti(IV)-5.ClDMPAP complex. pH=5.0; Wavelength 580 nm. Ethanol-Water % (v/v): variable.

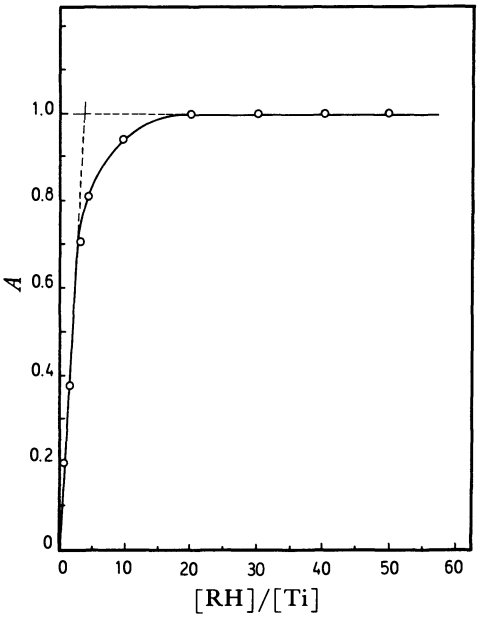

Fig. 6. Saturation curve. pH=5.0; Ethanol-Water 55% (v/v); C_{Ti}=constant=2.4×10^{-5} M. Wavelength 580 nm.

addition of an organic solvent miscible in water is necessary. The influence of different solvents (methanol, ethanol, dioxane, acetone, and pyridine) was studied. Experimental results show that there are no changes in λ_{max} of the complex whichever the solvent used, but a maximum absorptivity is obtained when methanol or ethanol are used. The latter was selected for the work. The minimum ethanol concentration necessary to produce a maximum absorbance was 55% (v/v). It is also possible to work with a lower sensitivity by reducing ethanol percentage up to 30% (v/v) (Fig. 5) and no variations in the spectral characteristics or in the stoichiometric of the complex are observed.

Reagent Concentration. To evaluate this variable, a saturation curve was plotted (Fig. 6) at pH 5.0. The Ti(IV) concentration was kept constant 2.4×10^{-5} mol dm^{-3} and the one belonging to 5.ClDMPAP was modified between 2.0×10^{-6} and 1.2×10^{-3} mol dm^{-3}. Absorbance was read at λ_{max}=580 nm and ethanol concentration remained in 55% (v/v). The absorbance of the complex's solutions reached a maximum value for a 15:1 ligand-metal ratio and they remained unaltered for proportions of up to 50:1. On the other hand, the graph shows that the complex formed has a relatively high stability and that, at the same time, proves stoichiometry already established. The complex's solutions at pH 5.0, keeping a 20:1 ligand: metal molar ratio, show no changes in their spectral curves and absorptivity at λ_{max}=580 nm for, at least, 5 minutes.

Effect of Foreign Ions. Under the experimental conditions required for the 5.ClDMPAP complexation with Ti(IV), the reagent also reacts with other metal ions. This is the case for other reagents of this type and thus there occur more or less severe spectral interferences that cannot be controlled by masking. Interferers are Fe(III), Cu(II), Ni(II), Co(II), W(VI), Nb(V), Ta(V), and V(V). The Zn(II), Mn(II), Mo(VI), and Cr(VI) ions are tolerated in a 10:1 molar ratio (foreign ion:Ti(IV)). For Al(III) and Mg(II), the ratio tolerated is 50:1; for Na(I) and K(I), it is 1000:1. Besides, the tolerances for different anions, especially those from strong acids used to dissolve samples and other anions and compounds added as possible masking agents, were delimited. If a maximum 2% error is admitted, the hydrogen phtalate, bromide, perchlorate, sulfate, thiosulfate, and iodide ions may be present in a 2000:1 ratio in front of Ti(IV), whereas thiourea and sulfamic

Table 3. Tolerances for Some Common Cations

Ion	Ion-Ti(IV) tolerated molar ratio	Ion-Ti(IV) tolerated mass ratio	Notes[a)]
Cd(II)	10	26	b)
Co(II)	10	13	b)
Ni(II)	10	13	b)
Mn(II)	20	25	b)
Pb(II)	25	119	b)
Zn(II)	50	75	b)
Mo(VI)	100	220	b)
Cr(VI)	100	119	b)

acid may exist in a 5000:1 molar ratio. The acetate ion may be present in a 10000:1 molar ratio. The tolerance for oxalate and fluoride were 10:1; for ascorbic acid, 50:1. Tartrate, phosphate, citrate, EDTA, and CDTA also interfere. In order to attain a larger selectivity, the behavior of several reagents (cupferron,[13)] 8-quinolinol,[14)] diethyldithiocarbamate[15)]) that allow Ti(IV) separation by means of liquid-liquid extraction was studied. The extraction procedure using 8-quinolinol and chloroform as solvent, together with pH regulation and the presence of complexing agents, proved to be the most efficient method to separate several interferes.

Method Using 8-Quinolinol and Chloroform. Into a decanting flask, pour 5 cm^3 of solution having between 0.25 and 3.5 ppm of Ti(IV) and the foreign ion under analysis. Then add 5 cm^3 of 8-quinolinol 0.1 mol dm^{-3} in chloroform and stir it vigorously during 5 min; separate the organic phase, put it dry into a porcelain crucible on sand bath and melt it with 0.4 g of potassium hydrogensulfate. Cool it, take it with water and pour it into a 25 cm^3 flask; then add 2 cm^3 of reagent, 6 cm^3 of ethanol, 1 cm^3 of sodium hydroxide 1 mol dm^{-3}, 4 cm^3 of buffer (acetic/acetate) of pH 5.0 and bring it to gauging. Read the solution absorbance at λ_{max}=580 nm against a reference prepared as usual. By the above method, tolerances shown in Table 3 are attained (the maximum admissible error was set in 2%).

The characteristics of interferences by Nb(V), Ta(V), V(V), and Cu(II) made it necessary a new methodology, still under development, which yielded significant results.

Applications. The methodology developed was applied to two kinds of samples:

1. Optical glass: samples: Athermal 50 and Soda-Lime Flat (NBS N° 620). The method applied is as follows: In a platinum crucible, weigh one amount of crushed glass sample having no more than 1 mg of TiO_2. Then add 10 cm^3 of sulfuric acid 1:1 and 15 cm^3 of hydrofluoric acid. Evaporate on sand bath until sulfuric acid white fumes appear. Let it get cold and take with 15—20 cm^3 of distilled water. Pour it into a 150 cm^3 flask and heat it until salt dissolution. Pour it into a 100 cm^3 flask (filter in case barium sulfate is present) and bring it up to gauging. Take 2 cm^3 of the filtrate; add 1 cm^3 of solution 0.2 mol dm^{-3} of sodium oxalate and adjust pH at 3.9 in 5 cm^3 as final volume; proceed with the method as above described. Results obtained for Athermal 50 optical glass contrasted against the hydrogen peroxide method[16,17] (Table 4).

2. Ceramic material:sample: Soda Feldspar (BCS N° 375). The method was the same as the one described for glass samples. Results are shown in Table 5.

(Received December 17, 1984)

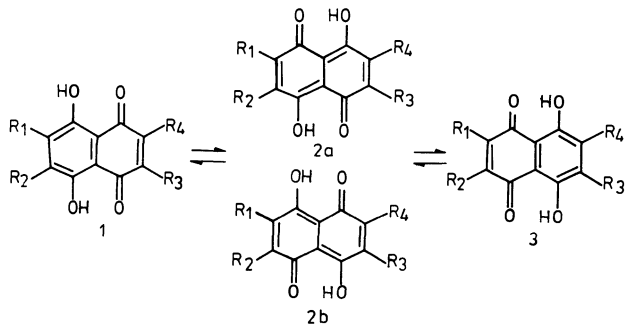
The synthesis and analysis by ^{1}H NMR of the methyl substituted naphthazarins were attempted. The chemical shifts of the substituents and of the ring protons were compared with those in their diacetates and were then correlated with the quinonoid or benzenoid nature of the rings. X-Ray diffraction analysis of tetramethylnaphthazarin, 2,3,6,7-tetramethyl-5,8-dihydroxy-1,4-naphthoquinone, has shown that this exists, in solid state, as a centrosymmetric charge-transfer complex with itself. The compound crystallizes in the *Ibam* space group, with an orthorhombic cell of dimensions a=17.479(1), b=9.983(1), c=6.752(1) Å, and four molecules in the unit cell. The crystal is built from molecules stacked up the c-axis and the interplanar distance between two overlapping molecules is 3.38 Å.

The naphthazarin nucleus 5,8-dihydroxy-1,4-naphthoquinone exists in nature in the spinochromes of the echinoderms,[1] and some derivatives can be used as the starting products in the synthesis of the tetracyclic antibiotics.[2]

Various investigations in the solid state of each of the three naphthazarin crystalline forms,[3] designated A, B, and C, have led to the conclusion that the molecule is centrosymmetric.

"Magic angle" spinning techniques, in ^{13}C NMR analysis, have provided evidence for dynamic disordered structures of naphthazarin (B form) in the solid state at −160 °C.[4]

On the other hand, NMR studies in solutions[5] indicates that a fast tautomeric equilibrium among **1⇄2a⇄2b⇄3** (Scheme 1) is present until −75 °C. From IR analysis,[6] it is observed that naphthazarin exists as 5,8-dihydroxy-1,4-naphthoquinone.

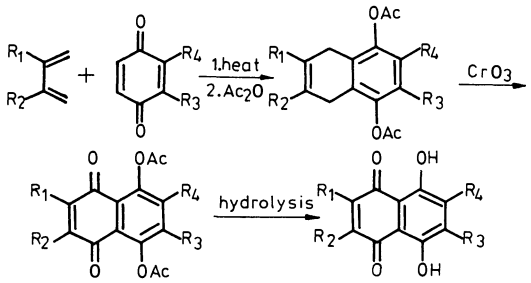


Scheme 1.

In a previous paper[7] we reported a structural study of dimethylnaphthazarin as a charge-transfer complex. This compound is present in the solid state as 2,3-dimethyl-1,5-dihydroxynaphthoquinone whilst a tautomeric equilibrium is observed in chloroform solution. The molecular structure of the tetramethylnaphthazarin in solid state has now been investigated and compared with that in chloroform solution. In a continuing study of the tautomerism of the naphthazarin system, the structural behavior in solution of the methylnaphthazarins with the substitution has now been analyzed. This structural elucidation can be applicable to the polyhydroxyanthraquinones and other related systems.

Synthesis

According to the known procedures,[8] methyl substituted naphthazarins were obtained by Diels–Alder cycloaddition of appropriate 1,3-butadiene and *p*-benzoquinone, followed by acetylation and chromium trioxide oxidation of the adducts and hydrolysis of the corresponding diacetate of naphthazarin (Scheme 2).



Scheme 2.

Experimental

For the preparation of unknown compounds, the synthesis of the methyl substituted naphthazarins which were not reported in the previous paper,[8] are now described in this section.

All melting points were taken in a hot plate microscope and are uncorrected. ^{1}H NMR spectra were obtained in $CDCl_3$, with TMS as an internal reference, at 60 MHz with a Hitachi Perkin Elmer R 24 A or at 100 MHz with a Varian XL 100 spectrometers. The elemental analysis were made in a Perkin Elmer Model 240 Elemental Analyzer. X-Ray analysis were carried out with an automatic Philips 1100 diffractometer. IR spectra were obtained with a Pye Unicam SP-1100 spectrophotometer.

Dimethylnaphthazarin (General Procedure). 2,3-Dimethyl-*p*-benzoquinone. 2,3-Dimethyl-*p*-benzoquinone was obtained by oxidation of 2,3-dimethylphenol (6 g) with Fremy's salt (1440 ml aqueous solution composed by 30 g of Fremy's salt and 3 g of sodium acetate); ethereal extraction was washed with aqueous sodium hydroxide, dried with sodium

sulfate and finally recrystallized from heptane, yielding 75% of pure quinone, mp 54—55 °C. Found: C, 70.51; H, 5.82%. Calcd for $C_8H_8O_2$: C, 70.57; H, 5.92%.

2,3-Dimethyl-4a,5,8,8a-tetrahydro-1,4-naphthoquinone. A benzene solution of 2,3-dimethyl-*p*-benzoquinone (5 g) and 1,3-butadiene (3.5 g) was heated at 100 °C in a glass sealed tube for 4 h. The adduct was recrystallized from heptane, yielding 81% of the title compound, mp 74—75 °C. IR 1685 cm^{-1} (C=O). ^1H NMR (60 MHz) δ=5.6 (s, 2H), 3.2 (m, 2H), 2.3 (m, 4H), 2.0 (s, 6H). Found: C, 75.58; H, 7.36%. Calcd for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42%.

Diacetate of the 2,3-Dimethyl-5,8-dihydro-1,4-naphthalenediol. A solution of 2,3-dimethyl-4a,5,8,8a-tetrahydro-1,4-naphthoquinone (3 g) in 20 ml of acetic anhydride and 2 ml of acetic acid were refluxed for 3 h. The mixture was added over 500 ml of ice-water. Precipitate was filtered off and the white crystalline product recrystallized from ethanol, yielding 80% of the diol, mp 186 °C. IR 1750 cm^{-1} (C=O). ^1H NMR (60 MHz) δ=5.7 (s, 2H), 3.1 (s, 4H), 2.3 (s, 6H), 2.1 (s, 6H). Found: C, 70.12; H, 6.56%. Calcd for $C_{16}H_{18}O_4$: C, 70.06; H, 6.61%.

Diacetate of the 2,3-Dimethylnaphthazarin. To a saturated solution of chromium trioxide (4.5 g) in acetic acid (80%), was added a solution of the diacetate of the adduct (3 g) in glacial acetic acid, while the reaction temperature was kept at 0—5 °C. The mixture was stirred at room temperature overnight and finally added on 500 ml of ice-water with continuous stirring. By filtration was obtained a yellow solid which was recrystallized from ethanol, yielding 35% of the diacetate, mp 184—186 °C. ^1H NMR at 100 MHz of this solid indicates that it was a mixture of the diacetates of 2,3- and 6,7-dimethylnaphthazarin. Integration of the ^1H NMR signals shows that the ratio of 2,3- to 6,7-dimethyl compounds is 97:3. Found: C, 63.39; H, 4.58%. Calcd for $C_{16}H_{14}O_6$: C, 63.57; H, 4.67%.

Dimethylnaphthazarin. An aqueous solution of sodium hydroxide (10%) was stirred with the diacetate of 2,3-dimethylnaphthazarin for 2 h until a dark blue homogeneous solution was formed. Neutralization was carried out with aqueous hydrochloric acid (10%) and a red precipitate was formed. Then, it was extracted with chloroform and purified by silica-gel column chromatography eluting with chloroform, to give the dimethylnaphthazarin, in nearly quantitative yield, as the sole product, mp 165 °C (subl.). Found: C, 66.20; H, 4.53%. Calcd for $C_{12}H_{10}O_4$: C, 66.05; H, 4.62%.

Trimethylnaphthazarin. 2,3,6-Trimethyl-4a,5,8,8a-tetrahydro-1,4-naphthoquinone. This compound was obtained according to the method described above for 2,3-dimethylnaphthazarin.

2,3-Dimethyl-*p*-benzoquinone (5 g) and isoprene (3 g) in benzene, were refluxed for 4 h. The adduct was recrystallized from heptane, yielding 83% of the title compound, mp 71—72 °C. IR 1680 cm^{-1} (C=O). ^1H NMR (60 MHz) δ=5.3 (s, 1H), 3.2 (m, 2H), 2.3 (m, 4H), 2.0 (two s, 6H), 1.7 (s, 3H). Found: C, 76.47; H, 7.72%. Calcd for $C_{13}H_{16}O_2$: C, 76.44; H, 7.90%.

Diacetate of 2,3,6-Trimethyl-5,8-dihydro-1,4-naphthalenediol. 2,3,6-Trimethyl-4a,5,8,8a-tetrahydro-1,4-naphthoquinone was acetylated in a similar manner as described above, yielding 82% of the title compound, mp 137—138 °C. IR 1750 cm^{-1} (C=O). ^1H NMR (60 MHz) δ=5.5 (m, 1H), 3.0 (s, 4H), 2.3 (two s, 6H), 2.1 (s, 6H), 1.8 (s, 3H). Found: C, 70.91; H, 6.84%. Calcd for $C_{17}H_{20}O_4$: C, 70.81; H, 6.99%.

Diacetate of 2,3,6-Trimethylnaphthazarin. Oxidation of the diacetate of the adduct with chromium trioxide provides a yellow solid, in 35% yield, mp 164—167 °C. ^1H NMR at 100 MHz of this solid, indicates that it was a mixture of the diacetates of 2,3,6- and 2,6,7-trimethylnaphthazarins. Integration of the ^1H NMR signals indicates the ratio of 2,3,6- to 2,6,7-trimethyl compounds is 88:12. Found: C, 64.47; H, 5.29%. Calcd for $C_{17}H_{16}O_6$: C, 64.55; H, 5.10%.

Trimethylnaphthazarin. Hydrolysis of the diacetates of 2,3,6- and 2,6,7-trimethylnaphthazarin gave the trimethylnaphthazarin in quantitative yield, as the sole product, mp 165 °C (subl.). Found: C, 67.20; H, 5.27%. Calcd for $C_{13}H_{12}O_4$: C, 67.23; H, 5.21%.

Tetramethylnaphthazarin. 2,3,6,7-Tetramethyl-4a,5,8,8a-tetrahydro-1,4-naphthoquinone. 2,3-Dimethyl-*p*-benzoquinone (12 g) and 2,3-dimethyl-1,3-butadiene (7.2 g), in benzene, were refluxed for 4 h. The adduct was recrystallized from heptane, yielding 80% of the title compound, 100—101 °C. IR 1680 cm^{-1} (C=O). ^1H NMR (60 MHz) δ=3.2 (m, 2H), 2.2 (m, 4H), 2.0 (s, 6H), 1.6 (s, 6H). Found: C, 76.87,; H, 8.26%. Calcd for $C_{14}H_{18}O_2$: C, 77.03; H, 8.31%.

Diacetate of the 2,3,6,7-Tetramethyl-5,8-dihydro-1,4-naphthalenediol. 2,3,6,7-Tetramethyl-4a,5,8,8a-tetrahydro-1,4-naphthoquinone was acetylated in a similar manner as described above, yielding 75% of the title compound, mp 205—207 °C. IR 1760 cm^{-1} (C=O). ^1H MNR (60 MHz) δ=3.0 (s, 4H), 2.3 (s, 6H), 2.0 (s, 6H), 1.7 (s, 6H). Found: C, 71.36; H, 7.19%. Calcd for $C_{18}H_{22}O_4$: C, 71.50; H, 7.33%.

Diacetate of 2,3,6,7-Tetramethylnaphthazarin. Oxidation of the diacetate of the adduct with chromium trioxide provided 50% of a yellow solid, mp 219—220 °C. Found: C, 65.46,; H, 5.38%. Calcd for $C_{18}H_{18}O_6$: C, 65.45; H, 5.49%.

2,3,6,7-Tetramethylnaphthazarin. Hydrolysis of the diacetate of 2,3,6,7-tetramethylnaphthazarin gave 2,3,6,7-tetramethylnaphthazarin in nearly quantitative yield, mp 186—187 °C (subl.). Found: C, 68.19; H, 5.79%. Calcd for $C_{14}H_{14}O_4$: C, 68.28; H, 5.73%.

X-Ray Structure Determination

Good crystals of 2,3,6,7-tetramethylnaphthazarin for X-ray study were formed by evaporation from an ethyl acetate solution at low temperature.

Space group and preliminary cell dimensions were determined from oscillation and Weissenberg photographs. Accurate lattice constants and intensities were measured on an automatic Philips 1100 diffractometer with Mo $K\alpha$ radiation (0.71069 Å) monochromatized by a graphite crystal. Refined cell parameters were calculated by a least-squares fit of the θ angles of 25 reflections.

The crystal data are: $C_{14}H_{14}O_4$, M=246.3, space group *Ibam* with a=17.479(1), b=9.983(1), c=6.752(1) Å, V=1178.2 Å^3, Z=4, density (calcd)=1.388 g cm^{-3}, absorption coefficient μ=0.9507 cm^{-1}.

The intensities were collected within the range $2<2\theta<60°$ by the $\omega/2\theta$ scan technique. Of the 1386 reflections measured, 1023 were considered observed, $I>2\sigma(I)$. Two standard reflections monitored every 61, remained essentially constants, showing no X-ray damage. Lorentz and polarization factors but no

Results and Discussion

^{1}H NMR analysis of the methyl substituted naphthazarins (see Tables 1 and 2).

Naphthazarin. The 100 MHz ^{1}H NMR spectrum of the naphthazarin in solution of $CDCl_3$ shows only one signal for both, the benzenoid and the quinonoid protons, at δ 7.15. This averaged chemical shift of the signals for the benzenoid and the quinonoid protons of the naphthazarin, can be observed as a fast prototropic tautomerism among **1**⇄**2**⇄**3** forms (Scheme 1). This equilibrium is blocked by acetylation of the hydroxyl groups of the naphthazarin and thus, their diacetate shows two different signals for the benzenoid and the quinonoid protons at δ 7.31 and 6.86 respectively (7.09 as averaged value for both protons).

Methylnaphthazarin. ^{1}H NMR spectrum of the methylnaphthazarin shows a quartet signal centered at δ 6.99 (J= 1.38 Hz) for a quinonoid proton, a doublet signal at δ 2.34 (J=1.38 Hz) for a quinonoid methyl and two benzenoid protons at δ 7.30 vs. 6.66 q (J=1.6 Hz), 2.09 d (J=1.6 Hz), and δ=7.35 for their diacetate.

From those spectral data it can be deduced that methylnaphthazarin in $CDCl_3$ solution is mainly as 2-methyl-5,8-dihydroxy-1,4-naphthoquinone (Scheme 1).

Dimethylnaphthazarin. ^{1}H NMR spectrum of the dimethylnaphthazarin shows two protons at δ 7.18 and two methyl groups at 2.18 as singlet signals (vs. 7.30 and 2.07 for their diacetate). Those averaged chemical shift of the signals for annular and methyl protons can be rationalized by the above referred prototropic tautomerism (Scheme 1). In solid state this molecule is mainly present as the tautomer 2,3-dimethyl-5,8-dihydroxy-1,4-naphthoquinone.[7]

Trimethylnaphthazarin. ^{1}H NMR spectrum of the trimethylnaphthazarin shows a quartet signal centered at δ 6.89 (J=1.02 Hz) for a quinonoid type proton, a doublet signal at 2.23 (J=1.02 Hz) for a quinonoid methyl and a singlet signal at δ 2.12 for two methyl

groups (vs. 6.56 q (J=1.4 Hz), 2.07 d (J=1.4 Hz), and 2.22 for the diacetate of 2,6,7-trimethylnaphthazarin). The quadruplet signal indicates that this proton have an appreciable quinonoid character and the averaged chemical shift of the signals can be rationalized by the above referred prototropic tautomerism (Scheme 1) for this compound.

Tetramethylnaphthazarin. ^{1}H NMR spectrum of the tetramethylnaphthazarin shows a singlet at δ=2.23 for all the methyl groups, while their diacetate shows two different signals at δ 2.39 and 2.20 for the methyl groups attached to the benzenoid or to the quinonoid ring respectively (δ 2.30 as averaged value for both methyl groups type). This spectral data indicates that a tautomeric equilibrium among **1**⇄**2**⇄**3** is present, in solution, at room temperature.

Hydroxyl Groups. Hydroxyl groups in these methyl substituted naphthazarins show an important intramolecular chelation of the hydroxyl group in ^{1}H NMR as a bridge hydrogen bonding between phenolic and quinonoid oxygens. The effect of the methyl substituents on the chemical shift of the peri-hydroxyl protons is summarized in Table 1. The signal of the hydroxyl protons in the ^{1}H NMR spectrum is shifted further to downfield when the methyl substituent is nearer to this hydroxyl group. Of the steric and electrical substituent effect, the former is predominant.

X-Ray Analysis of the Tetramethylnaphthazarin

Structure Solution and Refinement. Assuming the centrosymmetric space group *Ibam* (vs. *Iba*2) as it was evidenced by refinement techniques and suggested by the normalized structure factor statistics, the molecule must occupy a special position at the intersection of a twofold axis with a mirror plane or at the intersection of three twofold axes. The first position is the only possible accordingly to the symmetry of the molecule. From an analysis of the Patterson function, it was deduced the position of the molecule. The atomic positions were refined by full-matrix least-square methods, first isotropically and finally anisotropically. The minimized function was $\sum\omega(|F_o|-|F_c|)^2$ with ω= 1.00.

A difference synthesis showed all the hydrogen atoms. These were included in the refinement with an isotropic B value equal to that of the carried carbon atoms and they were allowed to vary. Refinement was stopped when the parameter shifts were $<0.1\sigma$. The adequacy of the weight was checked by inspection of the mean of $\omega|F_o^2|$ as a function of the F_o and sin δ/λ ranges. In both cases the function was nearly constant. The final R and R_ω are 0.087 and 0.068 respectively for all observed reflections. Scattering factors were taken from International Tables for X-Ray Crystallography.[9] Positional and thermal parameters are in Table 3.

The X-ray diffraction study in the solid state of the tetramethylnaphthazarin showed that the molecule is completely planar and centrosymmetric since it is situated in the intersection of a symmetry mirror plane and a twofold axis. Both, the bond distances C(2)–O(1)=1.293(3) and C(4)–O(2)=1.304(4) Å (Fig. 1) and the important intramolecular chelation of the hydroxyl group observed in solution, indicates that the H(O2) should occupy a mid-way position between the two oxygen atoms. A peak was experimentally observed in this position by difference synthesis (Fig. 2); bond distances O(2)–H(O2)=1.24(5) and O(1)···H(O2)= 1.37(5) Å. When the H(O2) was refined, however, its position moved closer to the O(2) atom which may indicate a double-minimum potential energy surface. What should be taken into account is that the temperature factor value of the H(O2) atom was perceptibly decreased. The refined bond length resulted to be O(2)–H(O2)=1.01(5) and the nonbonded intramolecular distance was O(1)···H(O2)=1.63(5) Å.

In addition, the bond lengths C(1)–C(2)=1.444(4) and C(4)–C(5)=1.451(5) indicates a considerable single bond character.

Moreover, C(1)–C(5′)=C(5)–C(1′) has a value of 1.357(4) slightly larger than the corresponding double bond of diacetate of naphthazarin,[10] whilst the corresponding double bond of 2,3-dimethylnaphthazarin[7] and diacetate of tetramethylnaphthazarin[11] reach a similar value. Then, it is assumed that this lengthening is due to the steric hindrance between the two methyl groups bearing in those carbon atoms (see also bond angles in Fig. 1).

Final position and thermal parameters for the tetramethylnaphthazarin are listed in Table 3.

The structural molecular disorder can be considered as a frequent fact in the crystalline solid state of the compounds forming CT complexes. Molecular disorder was analyzed around C_6–C_7, which are more affected by thermal vibrations, in tetramethylnaphthazarin but all the attempts in this way does result unsuccessful and thus molecular disorder was not detected.

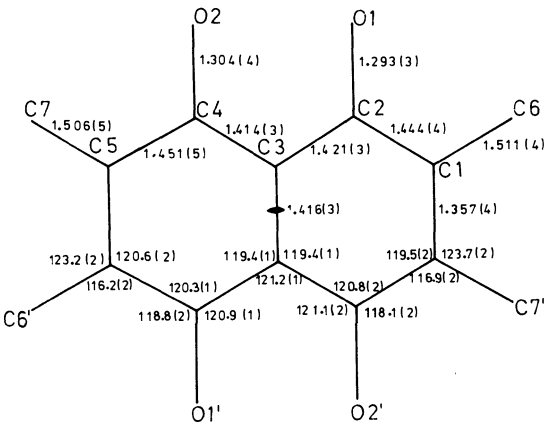

Fig. 1. Bond distances and angles of tetramethylnaphthazarin.

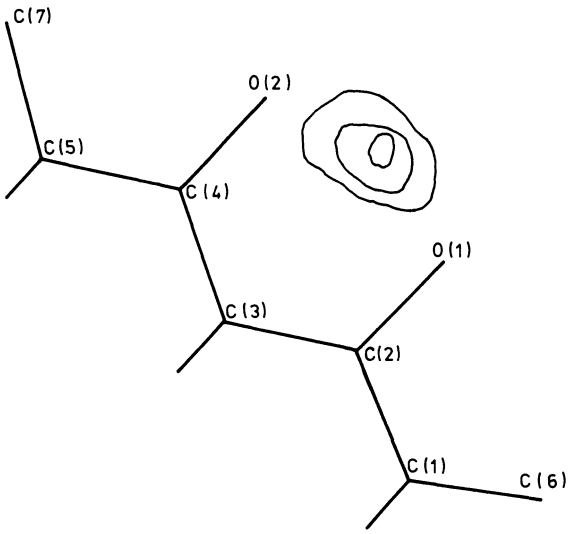

Fig. 2. Density map showing the hydroxyl hydrogen position before refinement.

There could be distortion in the bond distances of the naphthazarin nucleus (Fig. 1) arising from the fact that a molecular charge-transfer complex is formed between two molecules of the tetramethylnaphthazarin. The molecular overlap is shown in Fig. 3 and the interplanar distance, C/2, is 3.38 Å.

Finally, according to bond distances in tetramethylnaphthazarin, the molecular structure of this compound, in solid state, could be represented as a resonance hybrid between molecular forms of the type **2a**. **2b** and **1** and **3** contributing in minor extent, Scheme 1, better than a tautomerism because of the absence of molecular disorder.

Ring substitution seems to affect the tautomerism of the naphthazarin system in chloroform solution. Thus, while methylnaphthazarin is present as the tautomer

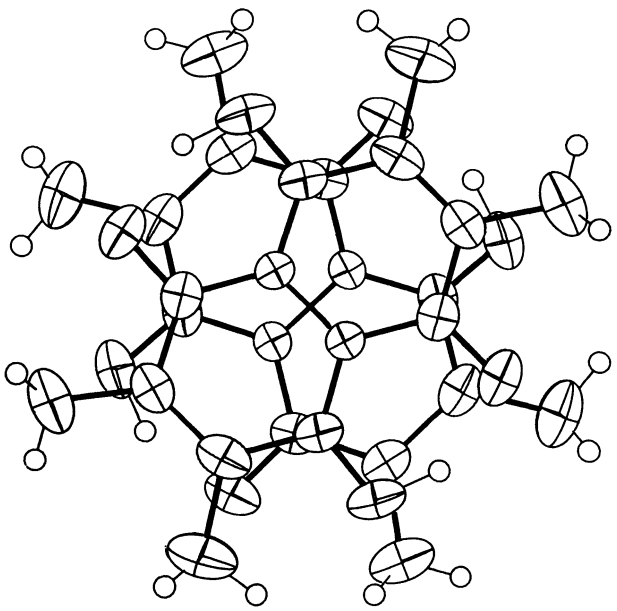

Fig. 3. Molecular overlapping of tetramethylnaphthazarin being 3.38 Å the interplanar distance.

with the substituent on the quinonoid ring, dimethyl-, trimethyl-, and tetramethylnaphthazarins, which have two methyl groups attached on the same ring show averaged structures according to the prototropic equilibrium pointed out in Scheme 1. This effect agrees with the observed increase of the C_2–C_3 bond length in solid state.

Balance in Forces Acting on Electrons in Molecules

Makoto ISIHARA
Department of General Education, Shotoku-Gakuen Women's Junior College, Nakauzura 1-38, Gifu 500
(Received April 2, 1986)

Synopsis. The force theorem is generalized by using the spin-specified momentum operator in the hypervirial theorem. A theorem consequent on this concerns a balance in forces acting on up- and down- spin electrons. The theorem is expected to be useful for examining accuracy of approximate wave functions for open-shell molecules.

In the previous paper[1] the author has shown the spin virial theorem as a consequence of a generalization of the virial theorem, suggesting a natural way of deriving various spin-related theorems from the hypervirial theorem.[2] Amongst such theorems, fundamental and significant in molecular electronic structure theory is a theorem obtained through a generalization of the force theorem.[3,4] The theorem has lucid physical meaning, describing a balance in forces acting on up- and down-spin electrons.[5] Although the derivation is rather straightforward, the explicit expression will be worth communicating with some remarks.

Let $\phi_{i\sigma}(\boldsymbol{r})$ be the σ-spin component of the electron field operator. The spin index σ is allowed to take $\uparrow$ (up) or $\downarrow$ (down), $\boldsymbol{r}$ stading for spatial coordinates. We use the notation $\overline{\sigma}$ for the spin state opposite to σ in what follows. Suppose the electronic Hamiltonian consisting of the kinetic energy of electrons, the nuclear attraction potential, and the electronic repulsion potential. It is suitable for our purpose to retain the spin index; we put

$$H = \sum_{\sigma} (T_{\sigma} + V_{\sigma} + W_{\sigma\sigma} + W_{\sigma\overline{\sigma}}) \tag{1}$$

with

$$T_{\sigma} = \int \phi_{\sigma}^{\dagger}(\boldsymbol{r})(-\nabla^2/2)\phi_{\sigma}(\boldsymbol{r})\mathrm{d}\boldsymbol{r}, \tag{2}$$

$$V_{\sigma} = \int \phi_{\sigma}^{\dagger}(\boldsymbol{r}) \sum_{\alpha} (-Z_{\alpha}|\boldsymbol{r}-\boldsymbol{R}_{\alpha}|^{-1})\phi_{\sigma}(\boldsymbol{r})\mathrm{d}\boldsymbol{r}, \tag{3}$$

and

$$W_{\sigma\tau} = \frac{1}{2}\iint \phi_{\sigma}^{\dagger}(\boldsymbol{r})\phi_{\tau}^{\dagger}(\boldsymbol{q})|\boldsymbol{r}-\boldsymbol{q}|^{-1}\phi_{\tau}(\boldsymbol{q})\phi_{\sigma}(\boldsymbol{r})\mathrm{d}\boldsymbol{q}\mathrm{d}\boldsymbol{r}, \tag{4}$$

where Z_{α} and $\boldsymbol{R}_{\alpha}$ are the atomic number and the position of the α-th nucleus, respectively. Of course, we have

$$W_{\uparrow\downarrow} = W_{\downarrow\uparrow}. \tag{5}$$

On the other hand, we define the momentum operator as

$$\boldsymbol{P}_{\sigma} = \int \phi_{\sigma}^{\dagger}(\boldsymbol{r})(-\mathrm{i}\nabla)\phi_{\sigma}(\boldsymbol{r})\mathrm{d}\boldsymbol{r} \quad (\sigma=\uparrow,\downarrow), \tag{6}$$

specifying the spin state. What is to be done is to work out the commutator between $\boldsymbol{P}_{\sigma}$ and H.

Among the commutators of $\boldsymbol{P}_{\sigma}$ with the constituents of H, only the two kinds are nonvanishing:

$$[V_{\sigma}, \boldsymbol{P}_{\sigma}] = -\mathrm{i}\boldsymbol{F}_{\sigma} \tag{7}$$

and

$$[W_{\sigma\overline{\sigma}}, \boldsymbol{P}_{\sigma}] = -\mathrm{i}\boldsymbol{B}_{\sigma\overline{\sigma}}/2, \tag{8}$$

where

$$\boldsymbol{F}_{\sigma} = \int \phi_{\sigma}^{\dagger}(\boldsymbol{r}) \sum_{\alpha} (-Z_{\alpha}(\boldsymbol{r}-\boldsymbol{R}_{\alpha})|\boldsymbol{r}-\boldsymbol{R}_{\alpha}|^{-3})\phi_{\sigma}(\boldsymbol{r})\mathrm{d}\boldsymbol{r} \tag{9}$$

and

$$\boldsymbol{B}_{\sigma\overline{\sigma}} = \iint \phi_{\sigma}^{\dagger}(\boldsymbol{r})\phi_{\overline{\sigma}}^{\dagger}(\boldsymbol{q})(\boldsymbol{r}-\boldsymbol{q})|\boldsymbol{r}-\boldsymbol{q}|^{-3}\phi_{\overline{\sigma}}(\boldsymbol{q})\phi_{\sigma}(\boldsymbol{r})\mathrm{d}\boldsymbol{q}\mathrm{d}\boldsymbol{r}. \tag{10}$$

We can regard $\boldsymbol{F}_{\sigma}$ and $\boldsymbol{B}_{\sigma\overline{\sigma}}$ as representing the forces exerted on σ-spin electrons by nuclei and by $\overline{\sigma}$-spin electrons, respectively. After all, since H contains $W_{\sigma\overline{\sigma}}$ twice, we obtain

$$[H, \boldsymbol{P}_{\sigma}] = -\mathrm{i}(\boldsymbol{F}_{\sigma} + \boldsymbol{B}_{\sigma\overline{\sigma}}). \tag{11}$$

It should be noted that

$$\boldsymbol{B}_{\uparrow\downarrow} = -\boldsymbol{B}_{\downarrow\uparrow}. \tag{12}$$

We often abbreviate $\boldsymbol{B}_{\uparrow\downarrow}$ to $\boldsymbol{B}$ below, $\boldsymbol{B}_{\downarrow\uparrow}$ being identically equal to $-\boldsymbol{B}$.

The hypervirial theorem asserts that an arbitrary stationary state of a system of the Hamiltonian H fulfils

$$\langle [H, A] \rangle = 0 \tag{13}$$

for any operator A of the system, the bracket standing for the stationary state expectation value. Now we adopt $\boldsymbol{P}_{\uparrow} \pm \boldsymbol{P}_{\downarrow}$ as A. A new result, to which we will refer tentatively as the spin force theorem, immediately follows besides the force theorem;

$$\begin{cases} \langle \boldsymbol{F} \rangle = 0 & (14) \\ \langle \Delta\boldsymbol{F} \rangle + \langle \Delta\boldsymbol{B} \rangle = 0 & (15) \end{cases}$$

with

$$\boldsymbol{F} = \boldsymbol{F}_{\uparrow} + \boldsymbol{F}_{\downarrow}, \tag{16}$$

$$\Delta\boldsymbol{F} = \boldsymbol{F}_{\uparrow} - \boldsymbol{F}_{\downarrow} \tag{17}$$

and

$$\Delta\boldsymbol{B} = \boldsymbol{B}_{\uparrow\downarrow} - \boldsymbol{B}_{\downarrow\uparrow} = 2\boldsymbol{B}. \tag{18}$$

From now on, we abbreviate the force theorem to FT and the spin force theorem to SFT. Whereas FT is derivable also from the electrostatic theorem,[6] SFT is not. The latter has no classical counterpart in a strict sense, being inherently quantum-mechanical. If $\boldsymbol{P}_{\uparrow}$ and $\boldsymbol{P}_{\downarrow}$ are taken as A, we have the set of equations tantamount to the set of FT and SFT;

$$\begin{cases} \langle \boldsymbol{F}_{\uparrow} \rangle + \langle \boldsymbol{B} \rangle = 0 & (19) \\ \langle \boldsymbol{F}_{\downarrow} \rangle - \langle \boldsymbol{B} \rangle = 0, & (20) \end{cases}$$

where FT is implicit. Here note that each of the above two equations is equivalent to SFT under FT because of

$$\langle \Delta F \rangle = 2\langle F_{\uparrow} \rangle = -2\langle F_{\downarrow} \rangle. \quad (21)$$

An important point is that SFT directly concerns the interelectronic interaction in sharp contrast to FT.

The molecular symmetry sometimes makes FT trivial.[4] The same is true for SFT, the simplest example being atoms and homonuclear diatomic molecules. In particular, the symmetry in distributions of up- and down-spin electrons is enough for SFT (aside from FT). For most of molecular open-shell systems SFT is obviously meaningful. One can thus utilize SFT together with FT for examining accuracy of approximate wave functions for such systems. The fulfillment of these theorems is a necessary condition for sound approximate wave functions.[7] Surely it is interesting to see how far the theorems hold for elaborate approximate wave functions obtained with various advanced methods; this will be entrusted to computational chemists. Finally we add that SFT lets the spin virial theorem be origin-independent as FT does the virial theorem.[4]

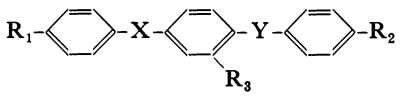
The Preparation and Thermal Properties of Terminal Disubstituted *N*-(4-Benzoyloxybenzylidene)anilines

Shunsuke TAKENAKA,* Tetsuya IKEMOTO, and Shigekazu KUSABAYASHI
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565
(Received May 6, 1986)

Synopsis. The homologous series of *N*-[4-(4-*n*-alkoxybenzoyloxy)benzylidene]-4-(2-methylbutoxy)aniline (**1**), and *N*-[4-[4-(2-methylbutoxy)benzoyloxy]benzylidene]-4-*n*-alkoxyaniline (**2**), and *N*-[4-(4-*n*-alkoxybenzoyloxy)-3-hydroxybenzylidene]-4-(2-methylbutoxy)aniline (**3**) where the 2-methylbutoxyl group has an S-configuration, have been prepared. Series **1** and **2** form a chiral smectic C (S_C^*) phase in addition to a cholesteric (Ch) and a chiral smetic G (S_G^*) phases, and series **3** form (S_C^*) and Ch phases.

It has been known that three-ring compounds incorporating ester **4** or azomethine **5** linkages display highly stable liquid crystalline phases.[1,2]



1 X = -COO-, Y = -CH=N-, R_1=*n*-$C_nH_{2n+1}O$-, R_2 = 2MBO-, R_3 = H-

2 X = -COO-, Y = -CH=N-, R^1 = 2MBO-, R_2 = *n*-$C_nH_{2n+1}O$-, R_3 = H-

3 X = -COO-, Y = -CH=N-, R_1 = *n*-$C_nH_{2n+1}O$-, R_2 = 2MBO-, R_3 = HO-

4 X = -COO-, Y = -OOC-, R_1, R_2 = *n*-$C_nH_{2n+1}O$-, R_3 = H-

5 X = -N=CH-, Y = -CH=N-, R_1, R_2 = *n*-$C_nH_{2n+1}O$-, R_3 = H-

(2MBO- = (*S*)-2-methylbutoxy)

Series **4** in which the linkages are relatively polar, and flexible, display stable nematic (N), smectic A and C phases (S_A and S_C, respectively). Series **5** in which the linkages are less polar and more rigid than those of series **4**, display some tilt smectic phases in addition to an N phase, and undergo complicating smectic-smectic transitions.[2] On the other hand, the series of **1—3**, which incorporate both ester and azomethine linkages, are expected to display mesomorphic properties between those two series.

In this paper, we have examined the thermal properties of series **1—3**, where a chiral group is introduced at one of the terminal positions, in order to examine the applicability to ferroelectric liquid crystals.

Experimental

Materials. 4-[(*S*)-2-Methylbutoxy]aniline was obtained by the reaction of *p*-nitrophenol and (*S*)-2-methyl-1-bromobutane, followed by catalytic hydrogenation with palladium-carbon. 4-[(*S*)-2-Methylbutoxy]benzoic acid was obtained by the reaction of methyl 4-hydroxybenzoate and (*S*)-2-methyl-1-bromobutane, followed by hydrolysis. 4-(4-*n*-Alkoxybenzoyloxy) and 4-[4-(2-methylbutoxy)benzoyloxy]-benzaldehydes and 4-(4-*n*-alkoxybenzoyloxy)-3-hydroxybenzaldehydes were obtained by the reaction of corresponding acid chlorides and 4-hydroxybenzaldehyde or 2,4-dihydroxybenzaldehyde in dry pyridine. Series **1—3** were obtained by the condensation of the corresponding benzaldehydes with the substituted anilines in absolute ethanol. Purification was carried out by recrystallization from absolute ethanol. The purity of the products was confirmed by elementary analysis.

Method: The transition temperatures were determined by using a Nikon POH polarizing microscope fitted with a Mettler FP-5 heating stage, and also a Daini-seikosha SSC-560 differential scanning calorimeter.

Results and Discussion

The transition temperatures and latent heats for series **1—3**, are summarized in Tables 1—3.

The S_G^* phase was identified by an examination of the miscibility diagram with *p*-bis(4-*n*-hexylphenyliminomethyl)benzene.[3]

The series **1** and **2** fundamentally have a similar mesomorphic sequence, i.e., S_G^*-S_C^*-Ch-I, while the

thermal stabilities of the mesophases are slightly different. The phase sequence is simpler than those of *p*-bis(4-*n*-alkoxyphenyliminomethyl)benzenes (**5**),[2] and the thermal stability of the S_C^* phase is higher than those of *p*-bis(4-*n*-alkoxyphenoxycarbonyl)benzenes (**4**).[1] The difference in the smectic properties must be concerned with the difference in the geometrical and electrostatic structure, i.e., the cores of **1** and **2** are more rigid but less polar than those of **4**, and more polar but less rigid than **5**.

A noteworthy fact in the two series is that series **1** display a more stable S_C^* phase than **2**. A similar trend has been observed in the thermal properties of some liquid crystals. For example, 4-*n*-alkoxyphenyl 4-[(*S*)-2-methylbutoxy]benzoates do not display an S_C^* phase, while 4-[(*S*)-2-methylbutoxy]phenyl 4-*n*-alkoxybenzoates display it.[4] From these facts, we can assume that a relative orientation of the 2-methylbutoxyl group, a relatively bulky substituent, with respect to the carboxyl group, a polar linkage, is important in determining the thermal stability of the S_C^* phase.

In series **3**, a lateral hydroxy group was introduced in order to increase the chemical stability of the azomethine linkage. Although the mesophase stabilities of **3** are lower than those of series **1** and **2**, probably due to the increased molecular breadth, these appear to have similar mesomorphic properties, while no S_G^* phase could be observed in series **3**.

It is concluded that series **1**—**3** having one ester and one azomethine linkages have simpler smectic polymesomorphism than the corresponding azomethine compounds **5**, and display a higher stable S_C^* phase than the corresponding ester compounds **4**, so that the present series are more useful for dopant liquid crystals for devices employing a ferroelectric mode.

Photoinduced Hydrogen Evolution with Viologen Linked Porphyrin in a Micellar System

Ichiro OKURA,* Naruhiko KAJI, Shigetoshi AONO, and Tsuyoshi NISHISAKA†
Department of Chemical Engineering, Tokyo Institute of Technology, Meguro-ku, Tokyo 152
†Health Science Center, Tokyo Noh-Koh University, Nakamachi, Koganei, Tokyo 184
(Received May 28, 1986)

Synopsis. Viologen linked porphyrins, $ZnP(C_nV)_4$, with various methylene chain lengths (n=2—5) between the porphyrin and the viologen have been synthesized. These compounds were applied to photoinduced hydrogen evolution in a system containing NADPH-$ZnP(C_nV)_4$-hydrogenase under steady state irradiation. On the addition of surfactant to the system, a remarkable rate increase of hydrogen evolution was observed in the case of $ZnP(C_5V)_4$.

Photoinduced hydrogen evolution systems containing an electron donor, a photosensitizer, an electron carrier, and a catalyst have been studied extensively. As photosensitizers metallo-porphyrins have been widely used and methyl viologen has been a popular electron carrier. Recently we synthesized viologen linked water-soluble zinc porphyrins and found that they took part as both a photosensitizer and an electron carrier in the same molecule for photoinduced hydrogen evolution.[1,2] To improve the rate of photoinduced hydrogen evolution, effective charge separation between the photoexcited sensitizer and the quencher is needed. As electrostatic field, such as a micellar surface, has been widely applied to separate the charges effectively.[3] Only in a few of the micellar systems, however, has the hydrogen evolution been studied. In this paper we describe the effect of micelles on the photoinduced hydrogen evolution in a system containing NADPH, $ZnP(C_nV)_4$ and hydrogenase.

Experimental

The structure of the viologen linked water soluble zinc porphyrins, $ZnP(C_nV)_4$, is illustrated in Fig. 1. These compounds were synthesized as described elsewhere.[1,2] Hydrogenase was obtained from Desulfovibrio vulgaris (Miyazaki type, IAM 12604) and purified by Yagi's method.[4] The concentration of hydrogenase is not known, but 1.48×10^{-6} mol of hydrogen was generated by the following reaction system: hydrogenase (0.5 cm^3)-$Na_2S_2O_4$ (5.7×10^{-3} mol dm^{-3})-methylviologen (4.1×10^{-5} mol dm^{-3}) in 5.0 cm^3 of 0.02 mol dm^{-3} Tris-HCl buffer (pH 7.0) at 30 °C for 10 min.

Laser flash photolysis was carried out by using a Nd-YAG laser, model DCR-2A-10 from Quanta-Ray Inc., generating the second harmonic (532 nm). Pulses of 10 ns duration, energy of 200 mJ per pulse, and a repetion rate 10 Hz were used for excitation of the sample solution throughout this study. The light beam, after passage through a sample cell, was collimated into the entrance slit of a monochromator (model BM 50/50 from B & M Spectronik Co.). The output signal from the photomultiplier (Hamamatsu Photonics, R 446) attached to the slit of the monochromator was displayed

10% Triton X-100 τ_T/s	150	400	890	2000

on a Hitachi oscilloscope, model V-1050F.

For steady state irradiation a 200 W tungsten lamp was used as a light source. The light of wavelength less than 390 nm was removed by a Toshiba L-39 filter.

Photoinduced hydrogen evolution was carried out with $ZnP(C_nV)_4$ with n=2—5 under steady state irradiation at 30 °C. A sample solution containing nicotineamide-adenine dinucleotide phosphate (reduced form, NADPH), $ZnP(C_nV)_4$, hydrogenase and Triton X-100 was deaerated by repeated freeze-pump-thaw cycles.

Results and Discussion

When an aqueous solution containing $ZnP(C_nV)_4$, NADPH and hydrogenase was irradiated, hydrogen evolution was observed as added in Figs. 2 and 3. When surfactant, Triton X-100, was added to the above three component system, remarkable increase of hydrogen evolution rate was observed in the case of $ZnP(C_nV)_4$. On the contrary, the hydrogen evolution rates decreased in the cases of $ZnP(C_2V)_4$ and $ZnP(C_3V)_4$.

The photoexcited lifetimes of these compounds in the presence and in the absence of Triton X-100 were investigated by using laser flash photolysis technique (Table 1). The triplet lifetime of viologen linked porphyrin, $ZnP(C_5V)_4$, increased in the case of the system showing a rise of hydrogen evolution rate by the addition of Triton X-100. On the contrary the triplet lifetimes of $ZnP(C_2V)_4$ and $ZnP(C_3V)_4$ slightly decreased in the case of the systems showing a decrease of hydrogen evolution rate with Triton X-100.

The fact that hydrogen evolution rate increases in the case of $ZnP(C_5V)_4$ in spite of the increase of the triplet state lifetime indicates that the intramolecular quenching between the photoexcited porphyrin and viologen occurs only with difficulty. Accordingly, the reductive quenching of the photoexcited triplet state of porphyrin by NADPH will be predominant, and the following reaction mechanism is proposed.

$$^3P^*\text{-}V + D \longrightarrow P^-\text{-}V + D^+$$

$$P^-\text{-}V \longrightarrow P\text{-}V^-$$

At the first stage of the reaction the photoexcited triplet state ($^3P^*$-V) is reductively quenched by NADPH (D) and the reduced form of porphyrin (P^--V) is formed after which the electron transfers from the porphyrin to the viologen.

The cause of the remarkable increase of hydrogen evolution rate in micelles in the case of $ZnP(C_5V)_4$ has not been clarified completely. As the absorption spectrum of $ZnP(C_5V)_4$ in water is broad, there are some intra- or inter-molecular interactions. When the surfactant, Triton X-100, was added to the system, a sharp absorption spectrum of $ZnP(C_5V)_4$ was obtained. The result indicates that the intra- or inter-molecular interactions disappear and that the suppression of the interaction extends the lifetime of the excited $ZnP(C_5V)_4$ in the micelles.

Temperature Dependences of ^{69}Ga and ^{81}Br NQR Frequencies in $[R_4N]_2Ga_2Br_6$ ($R=CH_3$ and C_2H_5)

Hideta ISHIHARA,* Koji YAMADA,† and Tsutomu OKUDA†

(Received June 7, 1986)

Synopsis. Temperature dependences of ^{69}Ga and ^{81}Br NQR frequencies showed that phase transitions take place at 98 and 137 K in $[(CH_3)_4N]_2Ga_2Br_6$ and that the C_3 reorientation of the $GaBr_3$ group occurs in $[(C_2H_5)_4N]_2Ga_2Br_6$ around room temperature.

Unusual temperature dependences of ^{69}Ga and ^{81}Br nuclear quadrupole resonance (NQR) frequencies were observed for $[R_4N]_2Ga_2Br_6$ ($R=CH_3$ and C_2H_5) in a study of bond character in Ga(II) compounds.[1] Although no crystal structure analysis of these two compounds has been reported as yet, we expect that the ethane-like $Ga_2Br_6^{2-}$ ions exist in both crystals, and that the cations are situated on the extension of the Ga-Ga bond of the $Ga_2Br_6^{2-}$ ion in a similar manner to the crystal of $[(CH_3)_4N]_2Ga_2Cl_6$.[2] On the basis of these expected crystal structures, we examined a possibility that unusual temperature dependences of ^{69}Ga and ^{81}Br NQR frequencies can be attributed to reorientations of the cation and/or anion.

Experimental

The compounds were prepared according to Ref. 3. NQR spectra of ^{81}Br and ^{69}Ga were recorded on a pen-recorder using a superregenerative oscillator with Zeeman modulation. The temperature dependence of the NQR frequencies was measured in the temperature range between 77 and ca. 300 K by immersing the sample into a bath of cooled petroleum-ether or heated silicone oil. The sample-temperature was measured using a copper-constantan thermocouple whose e.m.f. was displayed on a digital multimeter. Broad-line ^1H NMR spectra were observed at 60 MHz using a JEOL JNM-FW 60 spectrometer in a temperature range between 300 and 110 K and at 77 K.

Results and Discussion

Figure 1 shows the temperature dependence of ^{69}Ga NQR frequencies in $[(CH_3)_4N]_2Ga_2Br_6$. Three weak ^{69}Ga NQR lines were observed at 77 K and intensities of these lines increased on raising the temperature to 83 K. Another resonance line appeared at 83 K. The discontinuous change of the temperature dependence took place at 98 K and four NQR lines reduced to three. On further increasing the temperature, three lines reduced to two at 137 K. Accordingly we infer that phase transitions take place at 98 and 137 K. Figure 2 shows the temperature dependence of ^{81}Br NQR frequencies. The ^{81}Br NQR lines observed between 77 and 137 K were too weak to measure accurately the frequency variation especially above 98 K. Five NQR lines were observed above 137 K. A differential thermal analysis (DTA) experiment was carried out above 100 K using a homemade apparatus. On heating, an endothermic peak with a small shoulder at

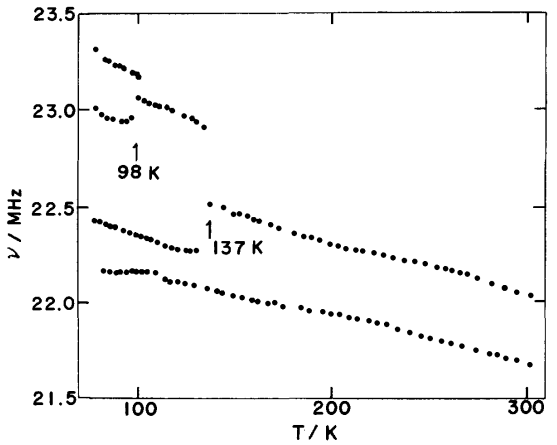

Fig. 1. Temperature dependence of ^{69}Ga NQR frequencies in $[(CH_3)_4N]_2Ga_2Br_6$.

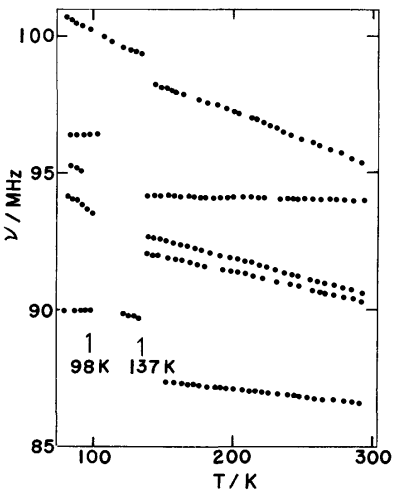

Fig. 2. Temperature dependence of ^{81}Br NQR frequencies in $[(CH_3)_4N]_2Ga_2Br_6$.

ca. 135 K appeared at 137 K. Unsymmetrical DTA peaks with a long tail on the low-temperature side were reported for $(CH_3NH_3)_2PtX_6$ (X=Cl, Br, and I) and attributed to the structural phase transitions related to the rearrangement of the octahedral anions PtX_6^{2-}.[5] In $[(CH_3)_4N]_2Ga_2Br_6$, it can be considered that the phase transitions at 98 and 137 K are related to motions of the $(CH_3)_4N^+$ ion.

The temperature dependence of the second moment M_2 of ^1H NMR spectra is shown in Fig. 3. On cooling, M_2 showed a constant value of ca. 0.5×10^{-8} T^2 down to ca. 140 K, while it increased rapidly below ca. 140 K and reached 20.1×10^{-8} T^2 at 77 K. According to the M_2

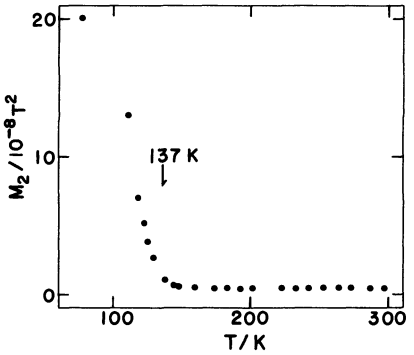

Fig. 3. Temperature dependence of the ^{1}H NMR second moment in $[(CH_3)_4N]_2Ga_2Br_6$.

calculation for $(CH_3)_4NX$(X=Cl, Br, and I),[4] the theoretical M_2 values in these halides are as follows: ca. 30×10^{-8} T^2 for the rigid lattice; ca. 11×10^{-8} T^2 for the rotaion of all methyl groups about C_3 axes; ca. 1×10^{-8} T^2 for the isotropic reorientation of $(CH_3)_4N^+$ ion. Accordingly, motions of the cation in $[(CH_3)_4N]_2Ga_2Br_6$ freeze for the most part at 77 K and the isotropic reorientation takes place above 140 K. On the other hand, a single ^{69}Ga NQR line was observed in $[(CH_3)_4N]_2Ga_2Cl_6$ and its frequency decreased monotonously from 23.37 MHz at 77 K to 22.68 MHz at 293 K with increasing temperature. The M_2 values of ^{1}H NMR spectra were 0.5×10^{-8} T^2 above 110 K and 11.3×10^{-8} T^2 at 77 K. Accordingly the rotation of the methyl group takes place even at 77 K for the chloro-complex. We predict that the phase transitions in $[(CH_3)_4N]_2Ga_2Br_6$ at 98 and 137 K can be ascribed to the onset of the isotropic reorientation of the $(CH_3)_4N^+$ ion and/or the rotation of the methyl groups. The occurence of these motions leads to the highly symmetric structure of the crystal being consistent with the fact that the number of the ^{69}Ga NQR lines decreased above these transition temperatures.

Figure 4 shows the temperature dependence of the ^{81}Br and ^{69}Ga NQR frequencies in $[(C_2H_5)_4N]_2Ga_2Br_6$. The single ^{69}Ga NQR line observed was so weak and broad between 77 and 118 K that we could not determine the resonance frequency accurately. A similar phenomenon was also observed for the above-mentioned $[(CH_3)_4N]_2Ga_2Br_6$, although the reason of the broadening is unknown. On heating, the resonance line became sharp and could be observed from 118 K up to 308 K, above which the resonance line disappeared. Three ^{81}Br lines which could be seen at low temperatures disappeared at ca. 275 K when the temperature was increased. The disappearance of the NQR lines can be attributed to the onset of the C_3 reorientation of the $GaBr_3$ group about the Ga-Ga bond for the following reasons. If the $Ga_2Br_6^{2-}$ ion has

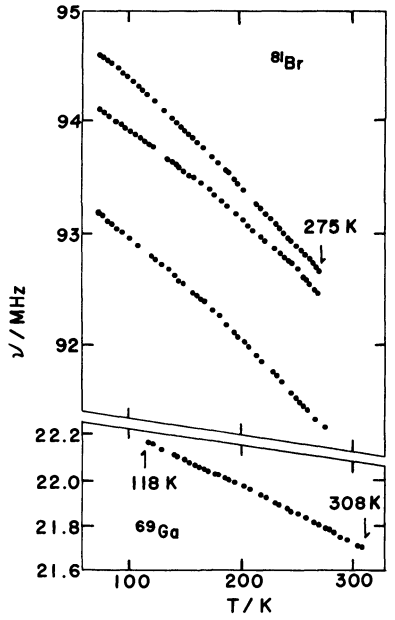

Fig. 4. Temperature dependences ^{81}Br and ^{69}Ga NQR frequencies in $[(C_2H_5)_4N]_2Ga_2Br_6$.

a structure of D_{3d} symmetry, the C_3 reorientation of the $GaBr_3$ group about the C_3 axis must not affect the ^{69}Ga NQR line.[6,7] The $Ga_2Br_6^{2-}$ ion in $[(C_2H_5)_4N]_2Ga_2Br_6$, however, has no D_{3d} symmetry because three ^{81}Br NQR lines were observed. Therefore, we can expect that the asymmetry parameter of the ^{69}Ga EFG is not zero and the principal z-axis of the EFG tensor is not parallel to the Ga-Ga bond. In addition, two bulky $GaBr_3$ groups should have a high barrier for rotation about the C_3 axis. Accordingly, the onset of the C_3 reorientation gives so drastic change of the EFG's at both ^{81}Br and ^{69}Ga nuclei that it is probable that this motion causes the disappearance of the NQR lines.

Comparison of Reactivities of Dibromide Anion Radical and Dichloride Anion Radical in Neutral Aqueous Solution

Yuusuke KATSURAGI, Osamu NEDA, Kotaro YAMAUCHI, and Takahiro MASUDA*
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukasawa, Setagaya-ku, Tokyo 158
(Received June 11, 1986)

Synopsis. Rate constants of reactions of dibromide anion radical with some aliphatic dipeptides or unsaturated compounds including pyrimidine bases have been determined by flash photolysis. Difference in activation energy between dibromide and dichloride anion radicals has been estimated by comparing rate constants obtained for common substrates.

Dibromide anion radical ($Br_2^{\cdot-}$ as well as dichloride anion radical ($Cl_2^{\cdot-}$) has often been used as a probe for the oxidation of biomolecules.[1-6] The reactivities of both the anion radicals appear to be somewhat different from each other, in particular, with respect to specificity. No detailed investigation, however, has been found in literatures on the difference of their reactivities, because radiation-chemical determination of rate constants for $Cl_2^{\cdot-}$ is restricted to acid solution. Recently, we found a convenient system to be used to determine rate constants for $Cl_2^{\cdot-}$ in neutral aqueous solutions.[7-10] Thus, a quantitative comparison of reactivity between $Br_2^{\cdot-}$ and $Cl_2^{\cdot-}$ was attempted by determining rate constants for $Br_2^{\cdot-}$ with some common substrates, with which rate constants had already been obtained for $Cl_2^{\cdot-}$ in neutral aqueous solutions. Since at least two kinds of reactions, hydrogen atom abstraction and one-electron oxidation, are expected to take place with these anion radicals, a series of aliphatic dipeptides and some unsaturated compounds including several pyrimidine bases were adopted as common substrates. From the results obtained, some difference in activation energy could roughly be evaluated between $Br_2^{\cdot-}$ and $Cl_2^{\cdot-}$.

Experimental

Dipeptides were obtained from Nutritional Biochemical Corp. and pyrimidine bases from Sigma Chemical Corp. The other chemicals were of reagent grade.

Solutions for irradiation were prepared by dissolving 10^{-2} mol dm^{-3} KBr, 10^{-4} mol dm^{-3} $K_2S_2O_8$, and a desired amount of substrate in triply distilled water and adjusting pH to 7. The solutions were bubbled with N_2 for 20 min immediately before flash photolysis. Experimental conditions, the apparatus used for flash photolysis, and the procedure of kinetic analysis were described in detail elsewhere.[10,11]

Results and Discussion

During flash photolysis of N_2-saturated solutions containing 10^{-2} mol dm^{-3} KBr and 10^{-4} mol dm^{-3} $K_2S_2O_8$, the following reactions are expected to take place:

$$Br^- + h\nu \longrightarrow Br\cdot + e_{aq}^-, \quad (1)$$

$$S_2O_8^{2-} + h\nu' \longrightarrow 2SO_4^{\cdot-}, \quad (2)$$

$$e_{aq}^- + S_2O_8^{2-} \longrightarrow SO_4^{\cdot-} + SO_4^{2-}, \quad (3)$$

$$Br^- + SO_4^{\cdot-} \longrightarrow Br\cdot + SO_4^{2-}, \quad (4)$$

$$Br\cdot + Br^- \longrightarrow Br_2^{\cdot-}. \quad (5)$$

Since the rate constant of Reaction 3 was reported to be 1.1×10^{10} dm^3 mol^{-1} s^{-1} and the concentration of $S_2O_8^{2-}$ is 10^{-4} mol dm^{-3}, the lifetime of hydrated electrons is calculated as 9.1×10^{-7} s. If it is assumed that the rate constant k_4 is equal to that of the reaction of $SO_4^{\cdot-}$ with Cl^-, the lifetime $SO_4^{\cdot-}$ with respect to Reaction 4 is 3.2×10^{-7} s. Therefore, the decay rate of $SO_4^{\cdot-}$ due to Reaction 4 is faster than its formation by Reaction 3. Hence the lifetime of $SO_4^{\cdot-}$ can be estimated to be of the order of 10^{-6} s. The lifetime with respect to Reaction 5 may be taken to be of the order of nanosecond because the rate constant of the analogous reaction, $Cl\cdot + Cl^- \rightarrow Cl_2^{\cdot-}$, is known to be 2.1×10^{10} dm^3 mol^{-1} s^{-1}.[12] Since the rate constant of the reaction of $Br_2^{\cdot-}$ with e_{aq}^- is 1.3×10^{10} dm^3 mol^{-1} s^{-1} [13] and $Br_2^{\cdot-}$ of approximately 10^{-5} mol dm^{-3} has been observed to exist at the initial stage, a few percent portions of e_{aq}^- will be consumed by Reaction 6 in competition with Reaction 3:

$$e_{aq}^- + Br_2^{\cdot-} \longrightarrow 2Br^-. \quad (6)$$

The above discussion leads to a conclusion that the majority of reactive species found in the system 50 μs after start of flash are $Br_2^{\cdot-}$. Since the kinetic analysis is based on the data obtained during the period 50—100 μs, the following reactions are conceivable to take place in the presence of substrate, S:

$$Br_2^{\cdot-} + Br_2^{\cdot-} \longrightarrow Br_2 + 2Br^-, \quad (7)$$

$$Br_2^{\cdot-} + S \longrightarrow 2Br^- + \text{product(s)}. \quad (8)$$

From these reactions a rate equation is derived as follows:

$$\ln\frac{[Br_2^{\cdot-}]_0(2k[Br_2^{\cdot-}]+k_{ob})}{[Br_2^{\cdot-}](2k[Br_2^{\cdot-}]_0+k_{ob})} - k_{ob}t = 0, \quad (9)$$

where k_{ob} is equal to k_8 [S], $[Br_2^{\cdot-}]_0$ and $[Br_2^{\cdot-}]$ are the concentrations of $Br_2^{\cdot-}$ at times zero and t, respectively, and $2k$ is the rate constant of Reaction 7. Equation 9 can be solved numerically for k_{ob} with the aid of microcomputer. The second order rate constant, k_8, is obtained by plotting k_{ob} vs. [S]. In Fig. 1, rate constants for $Cl_2^{\cdot-}$ are plotted against those for $Br_2^{\cdot-}$ for several aliphatic dipeptides, which are known to undergo hydrogen atom abstraction reaction with these anion radicals.[14] A linear relation can be seen between the reactivities of both the anion radicals, although there is left a small intercept, -6.4×10^6 dm^3 mol^{-1} s^{-1}. The slope is obtained as 9.9 with a correlation coefficient of 0.944. Similarly, a linear relation was found for some unsaturated compounds including pyrimidine bases, as shown in Fig. 2. A slope of 2.64 and an intercept of 2.9×10^7 dm^3 mol^{-1} s^{-1} are obtained with a correlation coefficient of 0.938. An addition

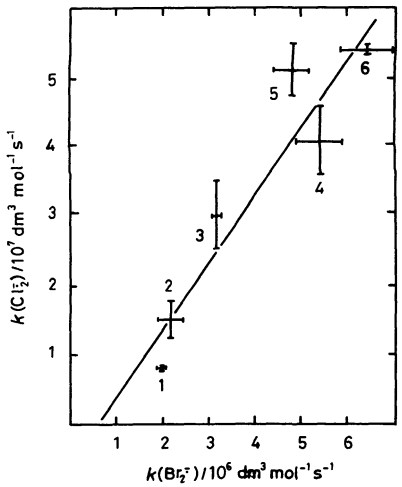

Fig. 1. $k(Cl_2^-)$ vs. $k(Br_2^-)$ for dipeptides.
1: Glycylglycine, 2: glycylalanine, 3: *N*-glycyl-2-aminobutyric acid, 4: glycylvaline, 5: glycylnorvaline, 6: glycylleucine. $k(Cl_2^-)$, see Ref. 7.

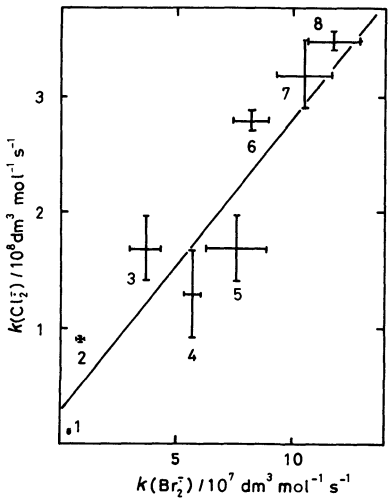

Fig. 2. $k(Cl_2^-)$ vs. $k(Br_2^-)$ for unsaturated compounds.
1: Pyrimidine, 2: acrylate, 3: maleate, 4: orotic acid, 5: isoorotic acid, 6: uracil, 7: thymine, 8: cytosine. $k(Cl_2^-)$, see Refs. 8 and 9.

reaction of Cl_2^- was reported for some unsaturated compounds.[14,15] If maleate and acrylate are excluded from the calculation, a slope of 3.1 and an intercept of -2.1×10^7 dm^3 mol^{-1} s^{-1} are obtained with a correlation coefficient of 0.968. Since ESR studies have shown that with pyrimidine bases one-electron oxidation takes place to yield their cation radicals,[16] the slope obtained above must correspond to the difference in reactivity of one-electron oxidation between Br_2^- and Cl_2^-.

If the Arrhenius equation is applied, the apparent difference in activation energy between Br_2^- snd Cl_2^- for hydrogen atom abstraction or one-electron oxidation may be estimated from the slopes of the straight lines shown in Figs. 1 and 2, because each slope corresponds to a ratio of rate constants. For the estimation, the ratio of frequency factors is required. If the ratio is taken as unity, the differences in activation energy are 5.7 kJ mol^{-1} for hydrogen atom abstraction reaction and 2.4 kJ mol^{-1} for one-electron oxidation reaction. If the value 1.4, which is estimated from $2k$, is adopted as the ratio, they are 4.8 and 1.6 kJ mol^{-1} respectively. These values are smaller than the differences in heat of reaction obtainable from thermodynamic data, which satisfies the Horiuchi-Polanyi rule. Furthermore, these differences in activation energy indicate that Br_2^- is more appropriate to unsaturated compounds as a one-electron oxidation probe than Cl_2^-.

Size Effects of Small Platinum Particles on the Electrocatalytic Oxidation of Methanol

Yoshio TAKASU,* Yuichi FUJII, and Yoshiharu MATSUDA
Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, 2557 Tokiwadai, Ube 755
(Received March 22, 1986)

Synopsis. A cyclic voltammetry study of a platinum-glassy carbon model catalyst-electrode (Pt/GC) in an aqueous solution of H_2SO_4 revealed that the peak potentials for the anodic oxidation of methanol shifted a little to the negative potential and that the current densities decreased greatly with the decrease in the size of the platinum particles.

A model catalyst, consisting of metal particles embedded on a flat and electric conducting substrate by means of vacuum evaporation, enables us to examine precisely the effects of metal-particle size on the catalytic properties of supported metal catalyst-electrodes.[1] Since the substrate is flat, not only is the observation of the shape of the particles by transmission electron microscopy (TEM) easy, but also any effect of the pore structure of the substrate on the catalytic properties can be neglected. This study will discuss the effect of the particle size of Pt/GC catalyst-electrode on the electrocatalytic oxidation of methanol in an aqueous solution of H_2SO_4.

Experimental

The support for the electrode was a glassy carbon rod (Tokai Carbon, GC-10, 0.53 cm in diam.). The base of the rod was polished with a cloth and alumina powder (ca. 0.3μm in diam.). The amount of platinum evaporated onto the base of the glassy carbon rod was determined with a quartz thickness monitor (Anelva, EVM-32B); i.e.,the amount of incident platinum was determined as the mass. The platinum particles were observed by means of a TEM (JEOL, JEM-200 CX). The electrochemical measurements were carried out by using a glass beaker cell filled with 0.2 dm^3 of a 1.0 mol dm^{-3} H_2SO_4 solution at 25 °C containing 1.0 mol dm^{-3} CH_3OH. The counter and reference electrodes were a platinum plate (3×3 cm^2) and a saturated calomel electrode (SCE) respectively.

Results and Discussion

Figure 1 shows same typical cyclic voltammograms for a platinum-wire, a galssy-carbon, and three Pt/GC model catalyst-electrodes under a steady state. Prior to the measurements of these voltammograms, the electrodes were treated by means of electrochemical aging; i.e., the electrode potential was swept repeatedly between −0.190 V and +0.920 V (vs. SCE) at a sweep rate of 300 mV s^{-1} for 10 min. By this treatment, the numerical mean diameter of the platinum particles, $\bar{d}$, increased a little; e.g., the $\bar{d}$ of a specimen evaporated with 3.8×10^{15} Pt atoms cm^{-2} increased 20% after the treatment. The anodic peak which appeared around 0.65 V (vs. SCE) during the anodic sweep and that around 0.5 V during the cathodic sweep are termed P_{a1}, and P_{a2} respectively. The first noticeable feature in Fig. 1 is that the anodic peak potential, $E_{P_{a1}}$, for the platinum-wire electrode (0.665 V) was higher than that

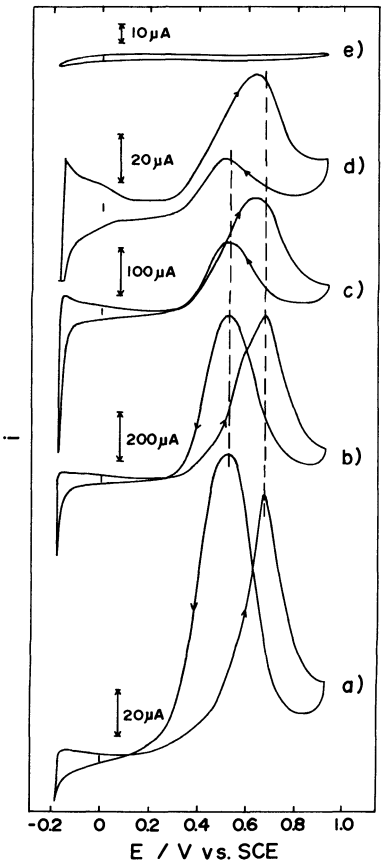

Fig. 1. Steady-state cyclic voltammograms for platinum wire, glassy carbon, and Pt/GC model catalyst electrodes in an aqueous solution of H_2SO_4 containing CH_3OH. Electrolyte: 1.0 mol dm^{-3} H_2SO_4, 1.0 mol dm^{-3} CH_3OH, 25°C. Sweep rate: 100 mV s^{-1}. Working electrode: a) platinum wire (geometric surface area; S_g=0.019 cm^2, real surface area determined by a cyclic voltammetry in 1.0 mol dm^{-3} H_2SO_4; S_r=0.093 cm^2), b) Pt/GC (S_r= 0.393 cm^2, the amount of the incident platinum atoms on the substrate; $M=7.6\times10^{15}$ Pt atoms cm^{-2}, mean diameter of platinum particles determined by TEM; $\bar{d}$=2.3 nm), c) Pt/GC (S_r=0.190 cm^2, $M=2.3\times10^{15}$ Pt atoms cm^{-2}, $\bar{d}$=1.9 nm), d) Pt/GC (S_r=0.067 cm^2, $M=7.6\times10^{14}$ Pt atoms cm^{-2}, $\bar{d}$= 1.5 nm), e) glassy carbon (S_g=0.22 cm^2).

for the Pt/GC electrodes which consisted of smaller platinum particles (0.622 V). A shoulder peak was found for the Pt/GC electrode with larger platinum particles (voltammogram b)), as had also been observed by Sobokowsky and his co-workers.[2] Similar shifts of the peak potential can also be observed for $E_{P_{a2}}$, although the potential shift is only about 0.02 V. The second noticeable feature is that the ratio of the

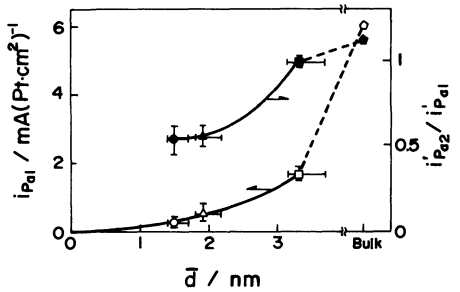

Fig. 2. The ratio of the peak current for P_{a1} and P_{a2} and the peak current density of P_{a1} for the oxidation of CH_3OH, as a function of mean diameter of platimum particles. The experimental conditions: see in Fig. 1. Amount of platinum evaporated. ○, ●: (M=7.6×10¹⁴ Pt atoms cm⁻²), △, ▲: (M=2.3×10¹⁵ Pt atoms cm⁻²), □, ■: (M=7.6×10¹⁵ Pt atoms cm⁻²), ◇, ◆: (Platinum wire).

peak currents for P_{a1} and P_{a2}, $i'_{P_{a2}}/i'_{P_{a1}}$, decreased with a decrease in the platinum particle size, $\bar{d}$, as is illustrated in Fig. 2. In order to determine the current density per surface area of the platinum particles, the real surface area of the platinum particles, S_r, was estimated from the total amount of electricity used for the anodic desorption of adsorbed hydrogen on the platinum particles in a 1.0 mol dm^{-3} H_2SO_4 solution after the electrochemical aging of the electrodes.[3,4] The current density for P_{a1} is shown in Fig. 2. It is worth noting that the peak current density, $i_{P_{a1}}$, abruptly decreased with a decrease in the size of the platinum particles.

As regards the size effects on the catalytic properties of supported platinum particles, the following aspects must be considered: a) the geometry of surface atoms,[5] b) the electronic state of the surface,[6] and c) the interaction with the substrate. The anodic oxidation of methanol on platinum is a typical structure-sensitive reaction;[7-9] i.e., Clavilier et al. found that the (110) plane of a single crystal was the most active in the initial stage, but that it became less active during continuous cycling, while the Pt(100) plane was the most electroactive plane under steady state conditions.[7] Contrary to their results, we observed that the ratio of the peak current due to the desorption of hydrogen from Pt(110) to that from Pt(100), $i'_{Pt(110)}/i'_{Pt(100)}$, decreased with a decrease in the size of the platinum particles [Ref. 1 Fig. 2, 2-a, b)].[1] However, the peak potential for the Pt(100) plane decreased with a decrease in the particle size, while that for the Pt(110) increased a little.[1] In order to explain the size effects, therefore, we must consider the contribution of each of the crystal planes of the small metal particles, which have rather different properties from those of the single crystals, to the electrocatalytic properties. Moreover, it has been suggested that methanol requires three adjacent sites for the adsorption, viz;[9,10]

$$CH_3OH + 3Pt = \underset{\displaystyle Pt \diagup \underset{Pt}{\diagup\!\diagdown} Pt}{\overset{COH}{\overset{|}{C}}} + 3H^+ + 3e^-.$$

It may not be easy for small platinum particles to provide such suitable sites with respect to the adsorption of methanol. The shifts of the anodic-peak potentials [Fig. 1] and the change in the peak-current ratio [Fig. 2], $i'_{P_{a2}}/i'_{P_{a1}}$, with the particle size must be caused by the ease of the formation of either the oxide layer of platinum or the oxidized adsorbed species of methanol, which interfere with the methanol oxidation, on the smaller rather than on the larger platinum particles. This speculation can be supported by the fact that the peak potentials for the reduction of the surface-oxide layer of platinum particles, as measured by a cyclic voltammetry in an aqueous solution of H_2SO_4, shifted to the negative potential with a decrease in the platinum-particle size.[1,11]

The authors are grateful to Dr. Akiko Aramata, of the Research Institute for Catalysis of Hokkaido University, for sending us useful literature.

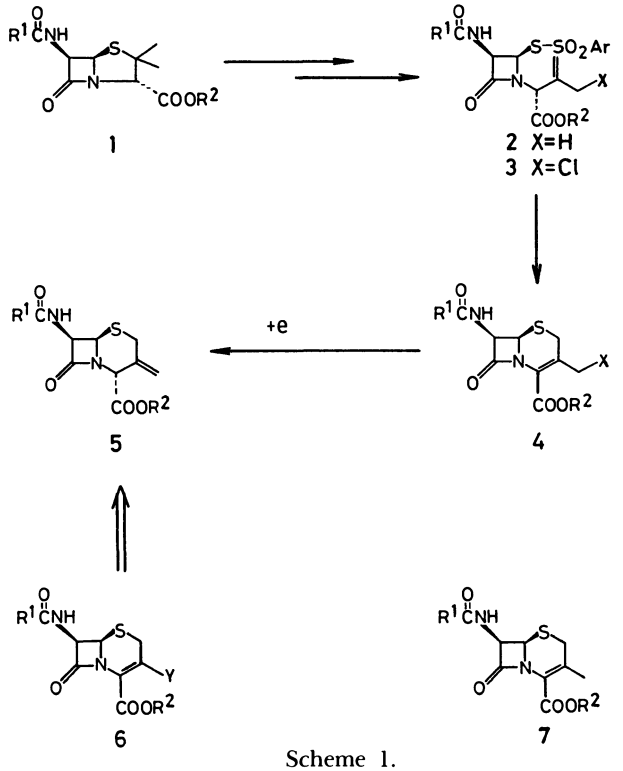
Penicillin-Cephalosporin Conversion. XII.[1] Electroreductive Dechlorination of 3′-Chlorocephalosporins into 3-Methylenecephams

Sigeru TORII,* Hideo TANAKA, Toshiyuki OHSHIMA, and Michio SASAOKA
Department of Industrial Chemistry, School of Engineering, Okayama University, Tsushima Naka 3-1, Okayama 700
(Received May 29, 1986)

Synopsis. An efficient electroreductive conversion of 3′-chlorocephalosporins and their analogues into the corresponding 3-methylenecephams has been performed in an aqueous THF-$LiClO_4$-(Pb cathode) and/or aqueous MeCN-EtOH-$LiClO_4$-NH_4ClO_4 (Pb cathode) system.

3-Methylenecephams (**5**) are useful precursors of 3-norcephalosporins (**6**), unnatural β-lactam antibiotics, where the C(3)-position directly combines with a heteroatom (Y), e.g., chlorine and methoxy groups.[2] Recently, we have succeeded in exploring a simple and efficient synthetic scheme of 3′-chlorocephalosporins (**4**), which comprises the ene-type chlorination of azetidinone (**2**) derived from natural penicillins and subsequent cyclization of **3** with ammonia (Scheme 1).[3] Consequently, our next efforts were focused on reductive elimination of the chlorine atom at C(3′)- position of **4** as a straightforward access to the 3-methylenecephams. We investigated this possibility by use of electroreductive procedure.



Scheme 1.

Electroreductive elimination of C(3′)-substituents of cephalosporins **4** (X=OAc, SAc, $^+NC_5H_5$, etc.) has been extensively investigated in buffer solution with Hg cathode under controled potential electrolysis conditions.[4] To our knowledge, however, electroreductive conversion of 3′-chlorocephalosporins (**4**) (X=Cl) into the corresponding 3-methylenecephams (**5**) has not been realized. In this paper, we wish to describe an efficient electroreductive elimination of C(3′)-substituents of 3′-chlorocephalosporins (**4**) (X=Cl) and their analogues **4** (X=I and SBT) in a slightly modified electroreductive system, wherein Hg cathode was replaced with Pb cathode and electrolysis was conducted under regulated current density without strict control of the electrode potential.

Electrolysis was carried out in a divided cell fitted with Pt anode and Pb cathode (3 cm^2 each). A mixture of tetrahydrofuran (THF) and H_2O (4/1) containing $LiClO_4$ and NH_4ClO_4 was charged into both compartments of the cell. The cephalosporins **4** (X=Cl, I, SBT, and OAc) were added into the cathode compartment and regulated d.c. power at 3.3 mA cm^{-2} was supplied at room temperature, until most of the starting materials **4** were consumed.

Typical results of electroreductive removal of the C(3′)-substituents of **4** are summarized in Table 1. Electroreduction of 3′-chlorocephalosporins (**4**) (X=Cl) proceeded smoothly and, after passage of 3.5 F mol^{-1} of electricity, afforded the corresponding 3-methylenecephams (**5**), which contained less than 2% of their endo isomers **7** (Entries 1 and 2). Electroreduction of **4a** (R^1, R^2=$PhCH_2$; X=Cl) into **5** was also performed in MeCN-H_2O-EtOH (4/1/0.07) with the same supporting electrolytes (Entry 3), while the electrolysis of **4a** in the absence of ethanol (Entry 4) provided no reduction product. Proper choice of the cathode material is significant. Thus, Pb cathode was indispensable for the successful conversion of **4** into **5**, since the yields of **5** varied depending on the choice of cathode materials in the order: Pb (87%)>C(58%)>Cu (51%)>Pt(19%).

Next, the electroreductive procedure was applied to 3′-iodo-, 3′-(2-benzothiazolylthio)- and 3′-acetoxycephalosporins (**4**) (X=I, SBT, and OAc). Iodide **4c** (X=I) was less effective than chloride **4a** (X=Cl), affording only 64% yield of **5** (Entry 5). It is likely that considerable portion of **4c** would suffer from decomposition in the aqueous electrolysis media prior to the electroreduction. 3′-(2-Benzothiazolylthio)cephalosporin (**4d**) (X=SBT)[5] was smoothly converted to the corresponding 3-methylenecepham (**5**) in 78—90% yields (Entries 6 and 7). On the other hand, 3′-acetoxycephalosporin **4e** (X=OAc) could not be reduced in the present electroreductive media (Entry 8). The almost complete recovery of **4e** was somewhat surprising in comparison with the successful conversion of **4** (X=OAc) to **5** in a buffer solution-(Hg cathode) system, reported by Ochiai, et al.[4a,b] Although scope and limitation of the present electroreductive procedure are still unclear, it is evident that a combination of the electroreductive dechlorination of 3′-chlorocephalosporins **4** (X=Cl)

and previous "Penicillin-Cephalosporin Conversion"[3)] (Scheme 1) provides a new convenient route for synthesis of **5**.

Experimental

IR spectra were obtained on a JASCO IRA-1 grating infrared spectrophotometer. ^1H NMR spectra were recorded with a Hitachi R-24 spectrometer and chemical shifts are reported in part per million (δ) relative to tetramethylsilane (δ=0.0 ppm) as an internal standard in a $CDCl_3$ solution. C(3′)-Substituted cephalosporins **4a**, **4b** (X=Cl),[3)] **4d** (X=SBT)[5)] and **4e** (X=OAc)[5)] were prepared by the reported procedure. Iodide **4c** (X=I) was prepared by treatment of **4a** with KI (1.2 equiv) and $NaHCO_3$ in refluxing acetone for 1 h.

General Procedure for Electrochemical Reductions. The electroreduction was carried out at room temperature in a H-shaped cell separated by fritted glass, which was fitted with lead cathode (3 cm^2) and platinum anode (3 cm^2). Regulated d.c. power was supplied by Metronix Galvanostat Model 543B. When the starting materials were almost consumed (3.5—7.0 F mol^{-1}), the electrolysis was terminated and the catholytes were worked up in the usual manner. The structual assignment of the products **5** and **6** were performed by comparison of the IR and ^1H NMR spectra with those of authentic samples.[2d)] The conditions and results are summarized in Table 1. A typical electrolysis procedure is as follows.

Electroreduction of 4a (R^1=$PhCH_2$; R^2=*p*-CH_3O-$C_6H_4CH_2$; X=Cl) (Entry 1). A mixture of THF (12 ml) and H_2O (3 ml) containing $LiClO_4$ (330 mg) and NH_4ClO_4 (460 mg) was added into both the cathode and anode compartments (7.5 ml each) and **4a** (101 mg, 0.21 mmol) was added into the catholytes. The mixture was electrolyzed under stirring at 3.3 mA cm^{-2} for 1.4 h. The catholytes were concentrated in vacuo to ca. 2 ml and the residue was extracted with AcOEt. The extracts were combined, washed with brine, and dried (Na_2SO_4). Evaporation of the solvents followed by column chromatography on SiO_2 with hexane/AcOEt (5 : 1) afforded 2-methylenecepham **5a** (=**5c**) (R^1=$PhCH_2$; R^2=*p*-CH_3O-$C_5H_4CH_2$, 82 mg, 87%)[2d)]: IR ($CDCl_3$) 3398, 3010, 1779, 1745, 1689, 1620, 1597, 1519, 1251 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.01, 3.43 (2H, AB q, *J*=14 Hz, CH_2S), 3.57 (3H, s, OCH_3), 3.76 (2H, s, CH_2), 5.04 (2H, s, CH_2), 5.12 (2H, s, H_2C=C), 5.21 (1H, d, *J*=4 Hz, CH (6)), 5.57 (1H, dd, *J*=4 Hz and 10 Hz, CH (7)), 6.80 (1H, d, *J*=10 Hz, NH), 7.10—7.41 (9H, m).

2-Methylenecepham **5b** (R^1=$PhCH_2$; R^2=$PhCH_2$)[2d)]: IR ($CDCl_3$) 3398, 3000, 1768, 1742, 1680, 1510, 1220 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.07, 3.56 (2H, AB q, *J*=14 Hz, CH_2S), 3.48 (2H, s, CH_2), 5.03 (2H, s, CH_2), 5.12 (2H, s, H_2C=C), 5.20 (1H, d, *J*=4 Hz, CH (6)), 5.12 (1H, dd, *J*=4 Hz and 8 Hz, CH (7)), 6.78 (1H, d, *J*=8 Hz, NH), 7.10—7.41 (10H, m).

2-Methylenecepham **5d** (R^1=$PhOCH_2$; R^2=$PhCH_2$): IR ($CDCl_3$) 3390, 3010, 1775, 1744, 1681, 1610, 1590, 1220 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.06, 3.51 (2H, AB q, *J*=14 Hz, CH_2S), 4.50 (2H, s, CH_2), 5.14 (2H, s, CH_2O), 5.22 (2H, s, H_2C=C), 5.36 (1H, d, *J*=4 Hz, CH (6)), 5.66 (1H, dd, *J*=4 Hz and 10 Hz, CH (7)), 6.85 (1H, d, *J*=10 Hz, NH), 7.00—8.75 (10H, m).

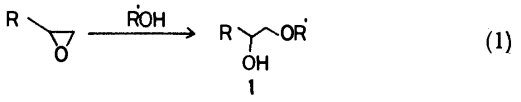
Novel Synthesis of Enol Ethers from β-Alkoxy Alcohols through *t*-BuOK-Promoted Elimination Reaction

Junzo OTERA* and Yoshihisa NIIBO
Department of Applied Chemistry, Okayama University of Science, Ridai-cho, Okayama 700
(Received June 3, 1986)

Synopsis. A new synthesis of enol ethers from β-alkoxy alcohols was achieved through a *t*-BuOK-promoted elimination reaction.

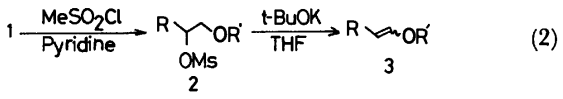
It was not until recently that enol ethers proved to be synthetically useful intermediates and accordingly so much attention has not been paid for their efficient synthetic methods.[1] Previously, we have demonstrated a new route via *t*-BuOK-promoted elimination of a phenylsulfinyl or phenylsulfonyl group from α-methoxy sulfoxides or sulfones.[2] Here we wish to describe another route starting from β-substituted alcohols.

We have already disclosed the practical ring opening of epoxides by alcohols with the aid of organotin phosphate condensate catalysts (Eq. 1).[3] The reaction



1 (1)

proceeds under neutral conditions with an excellent regioselectivity so that a wide variety of the β-alkoxy alcohols **1** are now accessible. In the development of synthetic applications of these compounds, we have achieved an effective route to enol ethers which has recourse to a *t*-BuOK-promoted elimination reaction of the corresponding mesylates **2** (Eq. 2).



2 3 (2)

Treatment of **1**[4] with methanesulfonyl chloride in pyridine at room temperature delivered **2** in quantitative yields. β-Alkoxy mesylates thus obtained were exposed to five equiv of *t*-BuOK in THF at room temperature or under reflux. The reaction proceeded smoothly to give various types of enol ethers **3** in good yields. The results are summarized in Table 1. It should be noted that the allyloxy derivative suffered from substantial contamination of 1-propenyl ether **4** under analogous reaction conditions due to the base-catalyzed isomerization of the allyl ether. The difficulty, however, was overcome by decreasing the amount of employed *t*-BuOK (1 equiv) along with employment of one equiv of 18-crown-6. As a whole, the present procedure has established a new method for transformation of epoxides to enol ethers.

4

Experimental

Preparation of β-Alkoxy Mesylates 2 (Typical Procedure). A pyridine solution (10 cm³) of 2-hydroxypropyl octyl ether[3] (1.24 g, 6.60 mmol) and methanesulfonyl chloride (903 mg, 7.90 mmol) was stirred at room temperature for 12 h. The reaction mixture was extracted with ether-water and the ethereal layer was washed with water repeatedly. Drying ($MgSO_4$), evaporation, and column chromatography (silica gel, 50:1 hexane-ethyl acetate) gave 2-(methylsulfonyloxy)-propyl octyl ether (1.58 g, 90%): ^{1}H NMR (CCl_4) δ=0.87 (br t, 3H), 1.07—1.77 (m, 15H), 2.88 (s, 3H), 3.20—3.53 (m, 4H), and 4.47—4.97 (m, 1H).

Synthesis of Enol Ethers 3 (Typical Procedure). A THF solution (10 cm³) of 2-(methylsulfonyloxy)propyl octyl ether (266 mg, 1 mmol) and *t*-BuOK (561 mg, 5 mmol) was heated at reflux for 2 h. The reaction mixture was extracted with ether-water. The organic layer was dried ($MgSO_4$) and evaporated. The residual oil was distilled (120 °C/4660 Pa, Kugelrohr bath temperature) to give 1-octyloxy-1-propene (128 mg, 75%, *E*/*Z*= 62:38): ^{1}H NMR ($CDCl_3$) δ=0.89 (t, 3H, *J*=7.1 Hz), 1.14—1.44 (m, 12H), 1.54 (dd, 1.86H, *J*=6.7 and 1.7 Hz), 1.57 (dd, 1.14H, *J*=6.7 and 1.7 Hz), 3.47—3.77 (m, 2H), 4.34 (dq, 0.38H, *J*=6.4 and 6.7 Hz), 4.73 (dq, 0.62H, *J*=12.6 and 6.7 Hz), 5.89 (dq, 0.38H, *J*=6.4 and 1.7 Hz), and 6.18 (dq, 0.62H, *J*=12.6 and 1.7 Hz); MS *m*/*z* 170 (M^+) and

Synthesis of Substituted Crown Ether Acetals

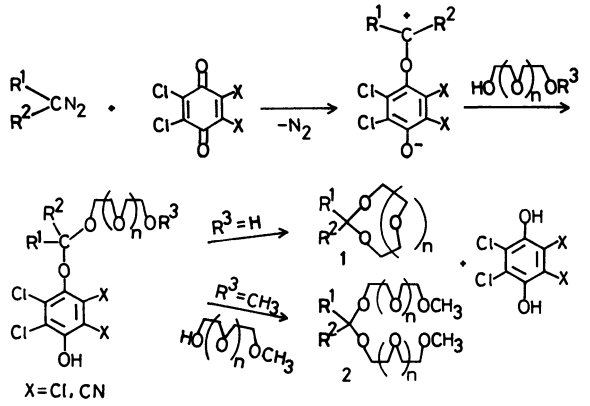
Takumi OSHIMA* and Toshikazu NAGAI
Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560
(Received July 11, 1986)

Synopsis. Reactions of phenyldiazomethane with chloranil and of 1-phenyldiazoethane and 9-diazofluorene with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone in the presence of oligoethylene glycols and its monomethyl ethers gave the corresponding substituted crown ether acetals and open-chain analogues.

Crown ether acetals (**1**) which involve one (or more) $-OCR^1R^2O-$ function in the crown rings, are interesting compounds as they exhibit cation-binding properties[1] and also undergo polymerization[2] and hydrolysis.[1b,3] A few varieties in which R^1 and/or R^2 are hydrogen were hitherto available by conventional methods using acid catalysts[2a,4] ion-exchange resins[5] from aldehydes and oligoethylene glycols. However, the formation of disubstituted acetals is noticeably difficult by the traditional methods.[6] Therefore, a new type of method is required to synthesize various disubstituted acetals.

We have recently reported a new method for the synthesis of diphenyl-substituted crown ether acetals ($Ph_2\overline{C(OCH_2CH_2)_nO}$, n=1—6) by way of the redoxical acetalization caused by three reactants, i.e., diphenyldiazomethane (DDM), 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ), and oligoethylene glycols.[7]

We have found that this technique is conveniently applicable for the preparation of several new substituted crown ether acetals (**1a—c**, **e**, and **f**) and open-chain analogues (**2a**, **b**) when adapted to other diazoalkanes like phenyldiazomethane (**3**), 1-phenyldiazoethane (**4**), and 9-diazofluorene (**5**). In a reaction with **3**, DDQ provided significant amounts of bicyclic dione derivatives[8] formed from the dipolar addition to the C=C bond, so that chloranil was utilized for this diazoalkane as an alternative quinone. As previously described,[7] this promising acetalization proceeds via a reaction sequence involving the formation of 1:1 betaines from diazoalkanes and quinones, subsequent nucleophilic attack of glycols, and final splitting into acetals and hydroquinones (Scheme).



The present diazoalkanes provided only about half yields of acetals compared to DDM as tested for the fourteen-membered crown acetals (Table). The drop in the yields may be due to two reasons. First, diazoalkanes, **3** and **4**, tended to thermally decompose to azines and further reacted with the generated hydroquinones giving hydroquinone diethers. However, stable **5** provided 9,9′-bifluorenylidene and oxirane[9] as

Table 1. Crown Ether Acetals (**1a—f**) or Open Acetals (**2a**, **b**) from Reactions of Diazoalkanes, Quinones, and Oligoethylene Glycols or Its Monomethyl Ethers

by-products. Second, newly prepared crown acetals are appreciably sensitive to water as is evidenced by their complete degradation into carbonyl components and alcohols even after standing one week in a stoppered NMR tube(in $CDCl_3$). This observation, combined with the presence of fairly amounts of benzaldehyde, acetophenone, and 9-fluorenone in the crude reaction mixtures, implies that some parts of acetals were lost during such work-up treatments as washing with aqueous alkaline solution and separation by column chromatography.

However, our technique is expected to play a role in the preparation of many-membered disubstituted crown ether acetals for which no other efficient method has been found in a literature search.

Experimental

Infrared spectra were recorded on a Hitachi 260-10 and on a Perkin Elmer 983G spectrometer. ^1H NMR spectra were taken at 90 MHz on a Varian EM 390 spectrometer. Mass spectral data were obtained with a Hitachi RMU 6E mass spectrometer.

Materials. DDQ was of commercial origin (98%, Aldrich Chemical Co. Inc.) and was used without further purification. Chloranil was recrystallized from benzene. Phenyldiazomethane (**3**),[10] 1-phenyldiazoethane (**4**),[11] and 9-diazofluorene (**5**)[12] were prepared according to the procedure described in the literatures. Oily **3** and **4** were contaminated with 10—30% azines, but were used without purification because of their thermal instability. The **5** was recrystallized from ether; mp 94—95 °C. Benzene was refluxed over lithium aluminum hydride and was fractionated.

General Procedure. To a stirred solution of DDQ (1.2 g, 5.0 mmol) in benzene (20 ml) was added dropwise over 10 min at 20—25 °C a benzene solution (10 ml) of an 1 equiv mixture of diazoalkane and oligoethylene glycol (3 equiv for oligoethylene glycol monomethyl ether). After the mixture was stirred for the requisite times, the precipitated hydroquinone was filtered off and was washed with benzene (10 ml×3). The filtrate and washing parts were combined and were treated according to the previous manner.[7] The crude acetals containing such by-products as azines, hydrolyzed carbonyl compounds, hydroquinone diethers, and 9,9′-bifluorenylidene were column chromatographed on alumina. After a complete elution of these by-products, the acetals were eluted with benzene (**1b**), ether (**1a, c**), ether–ethanol (50:1) (**2a, b**), and ether–methanol (4:1) (**1e, f**). The structures of these acetals were established by following analytical data.

2-Phenyl-1,3,6,9,12-pentaoxacyclotetradecane (1a): Colorless viscous oil; IR (film) 2867, 1116 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.6—3.9 (16H, m), 5.72 (1H, s), 7.2—7.6 (5H, m); MS m/z 282 (M^+). Found: C, 63.66; H, 7.76%. Calcd for $C_{15}H_{22}O_5$: C, 63.81; H, 7.85%.

The Structure of Isoaplysin, a Brominated Rearranged Cuparane-Type Sesquiterpenoid from the Red Alga *Laurencia okamurai* Yamada[1]

Minoru SUZUKI,* Kazuya KURATA,† and Etsuro KUROSAWA
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
†Department of Industrial Chemistry, Hakodate Technical College, Hakodate 042
(Received June 21, 1986)

Synopsis. The structure of isoaplysin isolated from the red alga *Laurencia okamurai* Yamada has been established by the spectral and chemical methods.

A number of halogenated and nonhalogenated sesquiterpenes with the cuparane or the rearranged cuparane skeleton have been isolated from the red alga *Laurencia* species and also from the sea hare *Aplysia* species.[2] In the course of our continuing studies on the constituents of the red alga *Laurencia okamurai* Yamada ("Mitsude-sozo"), we have reported, in the preliminary communication,[3] that the structure of isoaplysin has been shown by formula **1**. However, the possibility of an alternative formula **2** for isoaplysin could not be completely eliminated. In this note, we describe the structural determination of isoaplysin (**1**) in detail.

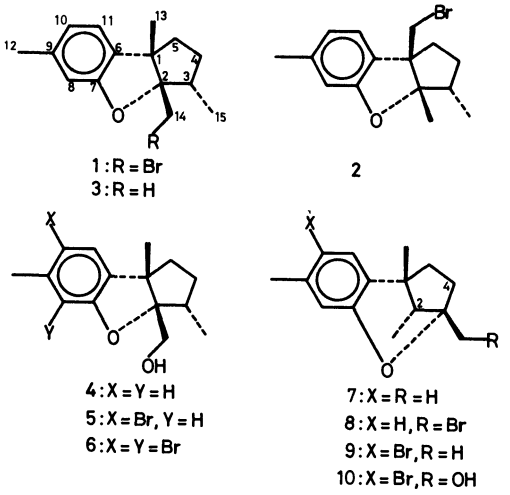
Isoaplysin (**1**) was isolated as a minor metabolite from the methanol extract of *L. okamurai* collected at various locations in Japan by a combination of column and thin-layer chromatography.[3,4]

Isoaplysin (**1**), colorless oil, $C_{15}H_{19}OBr$ (*m/z* 296 and 294; M^+), $[\alpha]_D^{24}$ −33° ($CHCl_3$), revealed in its ^1H NMR spectrum the presence of a secondary methyl group at δ=1.09 (3H, d, *J*=6 Hz), a tertiary methyl group at δ=1.50 (3H, s), an aromatic methyl group at δ=2.26 (3H, s), a methylene group with a heteroatom at δ=3.55 (2H, s), and a 1,2,4-trisubstituted phenyl moiety at δ=6.50 (1H, br s), 6.58 (1H, br d, *J*=8 Hz), and 6.82 (1H, d, *J*=8 Hz). The IR spectrum of **1** showed no hydroxyl and carbonyl absorptions, indicating that the oxygen atom in **1** was involved in a ether linkage. Since the ^{13}C NMR spectrum of **1** exhibits no signal due to a $-CH_2-O-$ grouping at near 70 ppm, the heteroatom above mentioned, which is adjacent to the methylene group at δ=3.55, must be bromine atom. The ^1H and ^{13}C NMR spectra of **1** were very similar to those of debromoaplysin (**3**), which has been obtained from this species[5] and also from the sea hare *Aplysia kurodai*.[6] However, in the ^1H NMR spectra, the distinct difference was observed in the higher magnetic field region as follows. As described above, the ^1H NMR spectrum of **1** indicates the presence of three methyl groups and one bromomethyl group, while the four methyl groups, including one secondary methyl and three tertiary methyls, are present in the spectrum of **3**. This fact suggested that one of the tertiary methyl groups in **3** is replaced by the bromomethyl group. Treatment of **1** with lithium aluminum hydride in tetrahydrofuran gave the debromo ether, $C_{15}H_{20}O$, $[\alpha]_D^{25}$ −53°, which was identical with debromoaplysin (**3**) in all respects. In view of the above-mentioned data, two possible formulae **1** and **2** could be proposed for isoaplysin.

Table 1. Selected ^{13}C NMR Chemical Shifts[a]

Carbon No	1	3	4	7	8	9[b]	10[b]
1	55.5	54.0	55.0	44.6	45.1	44.9	44.9
2	97.1	98.8	99.8	46.6	44.3	46.4	43.1
3	43.7	46.1	43.5	85.0	85.7	85.3	87.4
4	31.5	31.2	31.0	37.3	34.5	37.3	33.0
5	42.6	42.6	43.5	42.1	41.8	42.2	41.8

a) Measured at 25.0 MHz in $CDCl_3$ (TMS=0). b) Quoted from Ref. 9.



In the ^{13}C NMR spectra (Table 1), the signal for C-3 in **1** was shifted upfield by 2.4 ppm compared with that in **3**. The close upfield shift was seen in the spectrum of debromoaplysinol (**4**).[4] Furthermore, the comparative upfield shifts were also observed for the signals for C-2 and C-4 in the spectra of compounds **7**[7] and **8**[8] and also in those of filiformin (**9**)[9] and filiforminol (**10**).[9] The upfield shift of the signal for C-3 in isoaplysin is due to the γ-gauche interaction of this carbon with the bromomethyl carbon, whose situation is explicable well only by formula **1**. Confirmation of the structure **1** was obtained by the following chemical correlation.

In the previous paper,[4] the structure of debromoaplysinol (**4**) was deduced from the spectral properties. Debromoaplysinol (**4**), on treatment with bromine in acetic acid, yielded aplysinol (**5**)[5,6,10] in poor yield along with dibromo ether (**6**). On the other hand, treatment of **4** with carbon tetrabromide and triphenylphosphine in benzene gave a bromo ether, $C_{15}H_{19}OBr$, $[\alpha]_D^{18}$ −42°, which was identified as isoaplysin (**1**) by comparison of the spectral data. Accord-

ingly, the structure of isoaplysin is represented by formula **1**, including the absolute configuration.

Experimental

The melting points were uncorrected. The IR spectra were recorded on a JASCO A-102 or a JASCO IR-S spectrophotometer. The ^1H and ^{13}C NMR spectra were measured on a JEOL JNM-PS-100 or a JEOL JNM-FX 100 spectrometer, using tetramethylsilane as an internal standard. The low and high resolution mass spectra were taken with a JEOL JMS-D300 spectrometer. Specific rotations were measured on a JASCO DIP-140 or a Hitachi PO-B polarimeter, using $CHCl_3$ as solvent. Silica gel (Merck, Kieselgel 60, 70—230 mesh) was used for column chromatography. Silica gel (Merck, Kieselgel 60 GF_{254}) was used for preparative TLC. High-performance liquid chromatography was performed on a JASCO TRI ROTAR-III with a Finepak SIL-C_{18}column.

Isoaplysin (1): Colorless oil; $[\alpha]_D^{24}$ −33° (*c* 0.69); IR (film), ν_{max} 1620, 1597, 1501, 1275, 1265, 1255, 1135, 1001, 987, 960, 950, 855, and 802 cm^{-1}; ^1H NMR (CCl_4), in the text; ^{13}C NMR (25.0 MHz, $CDCl_3$), δ=158.7 (s; C-7), 138.2 (s; C-9), 132.9 (s; C-6), 122.1 (d; C-11), 121.4 (d; C-10), 109.3 (d; C-8), 97.1 (s; C-2), 55.5 (s; C-1), 43.7 (d; C-3), 42.6 (t; C-5), 34.5 (t; C-14), 31.5 (t; C-4), 22.9 (q; C-13), 21.5 (q; C-12), and 13.8 (q; C-15); MS (70 eV), *m/z* (rel intensity) 296, 294 (47 : 47; M^+) 281, 279 (7 : 7), 239, 237 (7 : 7), 215 (35), 201 (20), 199 (12), 173 (16), 159 (100), 145 (15), 135 (75), 121 (31), 115 (11), 107 (11), and 91 (12). Found: *m/z* 294.0607. Calcd for $C_{15}H_{19}O^{79}Br$: M, 294.0618.

Conversion of Isoaplysin (1) to Debromoaplysin (3). To a solution of **1** (13 mg) in dry tetrahydrofuran (7 ml) was added lithium aluminum hydride (50 mg), and the mixture was refluxed for 5 h, cooled, and mixed with water. After filtration and evaporation of the filtrate, the residue was extracted with ether. The ethereal solution was washed with saturated brine, dried over Na_2SO_4, and evaporated to leave an oily substance which was chromatographed on a silica-gel plate to give **3** (4 mg); oil; $[\alpha]_D^{25}$ −53° (*c* 0.15); The IR, ^1H NMR, and MS spectra were consistent with those of authentic debromoaplysin.

Conversion of Debromoaplysinol (4) to Aplysinol (5). To a solution of **4** (7 mg) in acetic acid (1 ml) was added a small excess of bromine in acetic acid, and the mixture was allowed to stand at room temperature for 30 min and then extracted with ether. The ethereal solution was successively washed with water, 5% aqueous $NaHCO_3$, and saturated brine. After drying over Na_2SO_4, the solvent was evaporated to give an oily residue which was subjected to high-performance liquid chromatography eluted with methanol/water (85 : 15) to afford **5** (2 mg) and **6** (6 mg): **5**: Mp 156—157 °C; $[\alpha]_D^{21}$ −53° (*c* 0.23); The IR and ^1H NMR spectra were identical with those of authentic aplysinol; **6**: Mp 91—93 °C; $[\alpha]_D^{19}$ −34° (*c*0.96); ^1H NMR ($CDCl_3$) δ=1.12 (3H, d, *J*=6 Hz), 1.50 (3H, s), 2.50 (3H, s), 3.86 (2H, m), and 7.14 (1H, s); MS (70 eV), *m/z* 392, 390, 388 (51 : 100 : 52; M^+).

Conversion of Debromoaplysinol (4) to Isoaplysin (1). A solution of **4** (8 mg) in dry benzene (1 ml) was refluxed with triphenylphosphine (35 mg) and carbon tetrabromide (40 mg) for 1 h in N_2 atmosphere. After removal of the solvent, the residual oil was chromatographed on silica-gel column to yield **1** (8 mg); oil; $[\alpha]_D^{18}$ −42° (*c* 0.77); The spectral properties were compatible with those of natural isoaplysin.

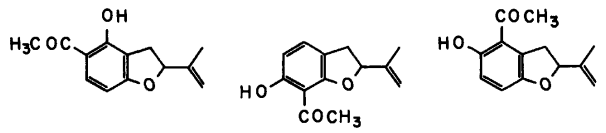
The Revised Structure of a Dihydrobenzofuran Derivative Isolated from *Lasiolaena morii*

Seiji YAMAGUCHI, Akihito SAITOH, and Yoshiyuki KAWASE*
Department of Chemistry, Faculty of Science, Toyama University, Gofuku 3190, Toyama 930
(Received March 24, 1986)

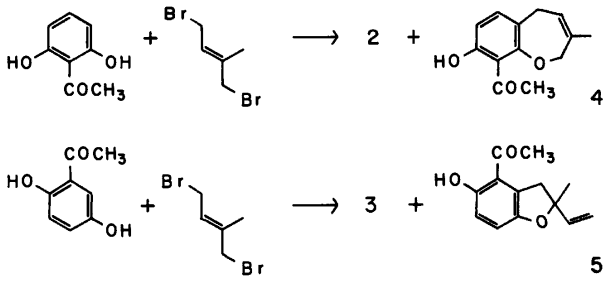
Synopsis. Two isopropenyldihydrobenzofuran derivatives are synthesized. By the comparison of ^{1}H NMR spectra, the proposed structure of a natural dihydrobenzofuran is revised to 4-acetyl-2-isopropenyl-2,3-dihydrobenzofuran-5-ol.

In 1982, F. Bohlmann et al. isolated a new dihydrobenzofuran from *Lasiolaena morii* and proposed a structure of 5-acetyl-2-isopropenyl-2,3-dihydrobenzofuran-4-ol (**1**).[1] We have already synthesized this compound by a demethylation of 5-acetyl-2-isopropenyl-4-methoxy-2,3-dihydrobenzofuran.[2] However, our synthetic compound showed a different ^{1}H NMR spectrum from that of the natural one. In the ^{1}H NMR spectra, the synthetic sample showed aromatic proton signals at δ=6.4 and 7.6 ppm, while the natural sample showed the corresponding signals at δ=6.81 and 6.99 ppm (Table 1). This fact indicates that the natural compound has another structure. Since the spectrum of the natural compound showed an intramolecular hydrogen-bonding (δ_{OH}=12.16 ppm) and no aromatic proton deshielded by an acetyl group in its ortho position, two structures, 7-acetyl-2-isopropenyl-2,3-dihydrobenzofuran-6-ol (**2**) and 4-acetyl-2-isopropenyl-2,3-dihydrobenzofuran-5-ol (**3**), are possible. In this paper, we describe the synthesis of these two dihydrobenzofurans and the structural reversion of the natural compound isolated from *Lasiolaena morii*.



1 2 3

The compound **2** and **3** were synthesized by the procedure reported by F. Bigi et al.[3] After the similar treatment of 2′,6′-dihydroxyacetophenone with 1,4-dibromo-2-methyl-2-butene, **2** and 9-acetyl-3-methyl-2,5-dihydro-1-benzoxepin-8-ol (**4**)[4] were obtained as cyclized products. In this reaction, 1,4-bis(2-acetyl-3-hydroxyphenoxy)-2-methyl-2-butene was also isolated as non-cyclized product. Similarly, the treatment of 2′,5′-dihydroxyacetophenone with 1,4-dibromo-2-methyl-2-butene gave two dihydrobenzofurans, **3** and 4-acetyl-2-methyl-2-vinyl-2,3-dihydrobenzofuran-5-ol (**5**).



4

5

In the ^{1}H NMR spectra, two isopropenyldihydrobenzofuran derivatives **2** and **3** showed an ABX coupling pattern due to protons in the dihydrofuranring, and **5** showed signals due to a quarternary methyl and a vinyl proton. On the other hand, **4** gave another spectral mode of the oxepin ring part [a broad methyl singlet, a broad two-proton doublet (H-5), a broad two-proton singlet (H-2), and a broad one-proton triplet (H-4)], similar to those of some natural 3-methyl-2,5-dihydro-1-benzoxepin derivatives.[5]

In the cyclization of 2′,4′-dihydroxyacetophenone,[3] two 2-isopropenyl-2,3-dihydrobenzofurans, 5-acetyl-2-isopropenyl-2,3-dihydrobenzofuran-4-ol (major) and 5-acetyl-2-isopropenyl-2,3-dihydrobenzofuran-6-ol (minor), were obtained. However, in a similar cyclization of 2′,5′-dihydroxyacetophenone, all isolated products were formed via the alkylation at C-6, and no products derived from the C-4 alkylation were isolated.

a) The data of natural compound from *Lasiolaena morii* provided by Bohlmann et al.[1] b) The data of our synthetic sample prepared by demethylation of 5-acetyl-2-isopropenyl-4-methoxy-2,3-dihydrobenzofuran.[2]

The ^{1}H NMR data of the three 2-isopropenyl-2,3-dihydrobenzofuran derivatives are summarized in Table 1. As shown in the table, the natural compound isolated from *Lasiolaena morii* was identical with 4-acetyl-2-isopropenyl-2,3-dihydrobenzofuran-5-ol (**3**).

Experimental

The melting points were uncorrected. The IR spectra were measured on a Hitachi EPI-S2 spectrophotometer in KBr disks, and the UV spectra were taken on a Hitachi 220A spectrophotometer in ethanol. The ^{1}H NMR spectra were recorded on a JEOL JNM-MH-60 NMR spectrometer or Varian XL-200 FT NMR spectrometer in CCl_4 or $CDCl_3$ and the mass spectra were determined on a JEOL JMS-OISG-2 mass spectrometer.

Cyclization of 2′,6′-Dihydroxyacetophenone with 1,4-Dibromo-2-methyl-2-butene. A suspension of the sodium salts was prepared by mixing 2′,6′-dihydroxyacetophenone (2.04 g, 13.4 mmol) and sodium hydride (52% mineral oil dispersion, 1.26 g, 27.8 mmol) in refluxing dry toluene (80 mL), and cooled to room temperature. To the suspension, 1,4-dibromo-2-methyl-2-butene (3.20 g, 14.0 mmol) was added and the mixture was refluxed for 24 h with stirring. After cooling, the mixture was treated with 10% hydrochloric acid and the toluene layer was collected. The toluene layer was washed with a 10% sodium carbonate solution and then extracted with a 5% sodium hydroxide solution. The sodium hydroxide solution was acidified with 10% hydrochloric acid and extracted with ether. The ethereal solution was dried over anhydrous sodium sulfate. After removing the ether, the oily residue was chromatographed on a silica-gel column to give two fractions as benzene eluents. One of the fractions (185 mg) showed three peaks (ratio **A**:**2**:**4**=1.4:4.1:1) in GLC. Pure samples of **2** and **4** were obtained after re-chromatography and recrystallization, but the component **A** could not be isolated as pure state.[6] From the other fraction (45 mg), 1,4-bis(2-acetyl-3-hydroxyphenoxy)-2-methyl-2-butene was isolated in pure crystals. The three compounds isolated showed the following data. **2**: mp 59—60 °C (from hexane); IR 1640 cm^{-1}; ^{1}H NMR cited in table 1; UV 230 (log ε 4.10), 268 (4.13), 356 nm (3.66); MS *m*/*z* 218 (M^+), 203, 185. Found: C, 71.78, H, 6.64%. Calcd for $C_{13}H_{14}O_3$: C, 71.54, H, 6.47%. **4**: mp 81—82 °C (from hexane); IR 1640 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.6 (3H, broad s), 2.8 (3H, s), 3.3 (2H, broad d, *J*=6 Hz), 4.5 (2H, broad s), 5.7 (1H, broad t, *J*=6 Hz), 6.7 (1H, d, *J*=8 Hz), 7.2 (1H, d, *J*=8 Hz), 12.8 ppm (1H, s); UV 221 (log ε 4.10), 260 (3.93), 341 nm (3.40); MS *m*/*z* 218 (M^+), 203, 185. Found: C, 71.49, H, 6.45%. Calcd for $C_{13}H_{14}O_3$: C, 71.54, H, 6.47%. 1,4-Bis(2-acetyl-3-hydroxyphenoxy)-2-methyl-2-butene; mp 133—135 °C (from benzene); IR 1630 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.9 (3H, s), 2.6 (3H, s), 2.7 (3H, s), 4.6 (2H, s), 4.7 (2H, d, *J*=7 Hz), 5.9 (1H, t, *J*=7 Hz), 6.4 (2H, d, *J*=8 Hz), 6.6 (2H, d, *J*=8 Hz), 7.4 (2H, t, *J*=8 Hz), 13.2 ppm (2H, s); MS *m*/*z* 370 (M^+), 259, 218. Found: C, 67.79, H, 6.04%. Calcd for $C_{21}H_{22}O_6$: C, 68.09, H, 5.99%. From the fraction soluble in a 10% sodium carbonate solution, ca. 20% of 2′,6′-dihydroxyacetophenone was recovered.

Similarly, cyclization of 2′,6′-dihydroxyacetophenone (20.0 mmol) with sodium hydride (23.3 mmol) and 1,4-dibromo-2-methyl-2-butene (21.6 mmol) gave **2** (1.85%), **4** (0.84%), and 1,4-bis(2-acetyl-3-hydroxyphenoxy)-2-methyl-2-butene (1.00%) and 40% of the starting material was recovered.

Cyclization of 2′,5′-Dihydroxyacetophenone with 1,4-Dibromo-2-methyl-2-butene. A similar treatment of 2′,5′-dihydroxyacetophenone (2.70 g, 17.8 mmol) with 1,4-dibromo-2-methyl-2-butene (4.30 g, 18.9 mmol) and sodium hydride (52% mineral oil dispersion, 0.84 g, 18.5 mmol) in dry toluene (90 mL) gave an oily product. This was purified on a silica-gel column and the fraction (total 282 mg) eluted by benzene showed two peaks (ratio **3**:**5**=2.2:1) in GLC. Some pure samples were obtained after re-chromatography and recrystallization. These two compounds showed the following data. **3**: mp 75—76 °C (from hexane); IR 1640 cm^{-1}; ^{1}H NMR cited in table 1; UV 233 (log ε 4.21), 261sh (3.90), 368 nm (3.65); MS *m*/*z* 218 (M^+), 203, 185, 177, 175. Found: C, 71.40, H, 6.67%. Calcd for $C_{13}H_{14}O_3$: C, 71.54, H, 6.47%. **5**: mp 96—98 °C (from hexane); IR 1640 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.6 (3H, s), 2.6 (3H, s), 3.4 (1H, d, *J*=18 Hz), 3.5 (1H, d, *J*=18 Hz), 5.2 (1H, dd, *J*=1 and 11 Hz), 5.4 (1H, dd, *J*=1 and 17 Hz), 6.1 (1H, dd, *J*=11 and 17 Hz), 6.8 (1H, d, *J*=9 Hz), 7.0 (1H, d, *J*=9 Hz), 12.2 ppm (1H, s); UV 232 (log ε 4.31), 261sh (4.08), 366 nm (3.80); MS *m*/*z* 218 (M^+), 205, 175. Found: C, 71.78, H, 6.59%. Calcd for $C_{13}H_{14}O_3$: C, 71.54, H, 6.47%. From the fraction soluble in 10% sodium carbonate solution, ca. 50% of 2′,5′-dihydroxyacetophenone was recovered.

Similarly, in a cyclization of 2′,5′-dihydroxyacetophenone (7.83 mmol) with sodium hydride (17.4 mmol) and 1,4-dibromo-2-methyl-2-butene (7.89 mmol), a mixture (105 mg) of **3** and **5** (ratio **3**:**5**=2.4:1 in GLC) was obtained.

We wish to thank Professor Dr. Ferdinand Bohlmann for providing a copy of the ^{1}H NMR spectrum of the natural compound.

An Improved Method for Stereoselective Synthesis of (*E*)-Alkenes via Alkenyldialkylboranes

Masayuki HOSHI, Yuzuru MASUDA, and Akira ARASE*
Department of Industrial Chemistry, Kitami Institute of Technology, Kitami 090
(Received April 2, 1986)

Synopsis. Successive treatments of alkenyldialkylboranes, formed by the reaction of alkynes and sterically hindered dialkylboranes, with alkyllithium and benzenesulfenyl chloride afforded highly pure (*E*)-alkenes in good or excellent yields.

(*Z*)-[1] and (*E*)-[2] alkene syntheses reported by Zweifel and co-workers are some of the interesting reactions using alkenylboranes; it has a limitation that the available alkyl group is restricted to those derived from sterically hindered alkenes.[3] From a different point of view, the reactions provide a convenient method for the regio- and stereoselective synthesis of alkenes by the combination of the alkenyl group to the alkyl group on the boron moiety.

For a practical use of above (*E*)-alkene synthesis (Scheme 1), the reaction had two disadvantages: The use of very poisonous cyanogen bromide and contamination by the *Z* isomer. We wish to report here a modified method for the (*E*)-alkene synthesis using alkyllithium and benzenesulfenyl chloride instead of cyanogen bromide.

In the Zweifel's reactions, the combined yields of the (*E*)- and (*Z*)-alkenes seemed to be affected by the degree of the coordination of the anion (CN^-) to the boron atom; also, the ratio of the two isomers seemed to be affected by the ease of the elimination of the electrophile (Br^+), which once attacked the alkenyl double bond, from the carbon atom. Accordingly, we examined both nucleophilic reagents for the boron atom and electrophilic reagents for the double bond, using (*E*)-1-hexenyldicyclohexylborane. Thus, successive treatments of the 1-hexenylborane with alkyllithium and benzenesulfenyl chloride gave excellent results.

In preliminary examinations, where alkyllithium was absent, (*E*)-1-hexenyldicyclohexylborane was treated with an equimolar amount of benzenesulfenyl chloride in THF. The reaction mixture was then treated with hexane for an analysis. However, only a small amount of a mixture of (*E*)- and (*Z*)-1-cyclohexyl-1-hexene was obtained. In similar treatments of an ate-complex formed by the addition of an equimolar amount of methyllithium or butyllithium to the 1-hexenylborane, gave the mixture of the alkenes quantitatively. Essentially, the pure *E*-isomer was obtained at −78 °C. These results are shown in Table 1.

In a similar reaction, [(*E*)-1-hexenyl]bis(1,2-dimethylpropyl)borane also gave almost pure (*E*)-2,3-dimethyl-4-nonene in 92% yield. [(*E*)-1-Hexenyl]bis(*trans*-2-methylcyclohexyl)borane gave a mixture of (*E*)- and (*Z*)-(*trans*-2-methylcyclohexyl)-1-hexene (*E*/*Z*=90/10), while the *trans*-2-methylcyclohexyl group migrated with a retention of the configuration. A stereochemical consideration for the above facts suggested that the large steric hindrance between the 2-methylcyclohexyl group R, remaining on the boron atom, and the phenylthio group interfered somewhat with the favorable arrangement regarding to the cis-elimination; thus, it increased the chance for the trans-elimination which gave the *Z* isomer (Scheme 2). In a reaction of [(*E*)-3,3-dimethyl-1-butenyl]bis(*trans*-2-methylcyclohexyl)-borane or [(*E*)-2-phenylethenyl]bis(*trans*-2-methylcyclohexyl)borane, having such a bulkier group as *t*-butyl or phenyl group instead of *n*-butyl group on the β-carbon atom, exclusively gave the *E* isomer. In this case, a steric hindrance between the *trans*-2-methylcyclohexyl group R, migrated to the α-carbon, and the *t*-butyl or the phenyl group R' interfered with the arrangement favored with the trans-elimination and

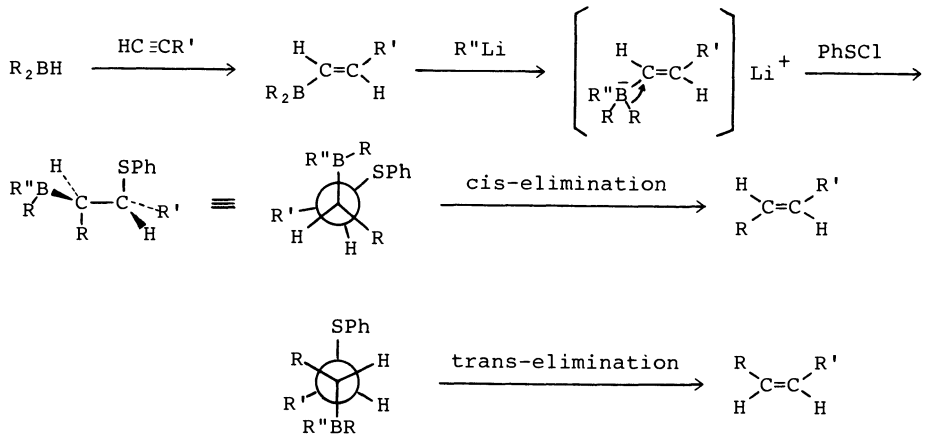
a) The alkenyldialkylborane was treated with equimolar amounts of alkyllithium (at 0°C, for 0.5 h) and benzenesulfenyl chloride (at −78°C, for 0.5 h) to the alkenyldialkylborane. b) Determined by GLC. c) The value in the parenthesis is isolated yield.



Scheme 2.

gave no chance for the formation of the *Z* isomer (Scheme 2). Similar alkenylboranes, having a *t*-butyl or a phenyl group on the β-carbon atom, gave almost pure (*E*)-alkenes. In all the cases examined, (*E*)-alkenes were isolated from the reaction mixtures by column chromatography.[4)] These results are shown in Table 2.

The high stereoselectivity and the ease of the reaction procedure, shown above, seem to make the present reaction of practically applicable to the synthesis of (*E*)-alkenes, especially having two bulky alkyl groups on the alkenyl carbon atoms.

Experimental

Instruments. IR spectra were recorded using a Hitachi 285 spectrometer. ^1H NMR and ^{13}C NMR (200 MHz) spectra ($CDCl_3$, TMS) were run on a JEOL FX-200 spectrometer. Mass spectra were recorded by a Hitachi M-52 mass spectrometer.

Reagents. Cyclohexene, 2-methyl-2-butene, 1-methyl-1-cyclohexene and THF were dried over lithium aluminium hydride and distilled under an argon stream. Commercial 1-hexyne and phenylacetylene were dried over Molecular Sieves-4A. 3,3-Dimethyl-1-butyne was prepared by a method described in the literature,[5)] and dried over Molecular Sieves-4A. Commercial alkyllithiums were used without any purification. Benzenesulfenyl chloride was prepared by the method described in the literature.[6)]

Reaction Procedure. A 50-ml round-bottomed flask, equipped with a gas inlet for argon, a sample inlet with a serum cap and a magnetic stirring bar, was flushed with argon. In the flask, alkenyldialkylborane was prepared by the addition of alkyne (10 mmol) to dialkylborane (10 mmol) in THF under appropriate conditions. Then, butyllithium (10 mmol) in hexane or methyllithium (10 mmol) in diethyl ether was added at 0 °C and the solution was stirred for 0.5 h, and then cooled to −78 °C. To this solution, benzenesulfenyl chloride (10 mmol) was slowly added and the reaction mixture was stirred for 0.5 h and then extracted three times with diethyl ether. The combined extracts were washed twice with NaCl-saturated water and dried over anhydrous magnesium sulfate. After evaporation of the solvent, the residue was put on a column packed with silica gel (Wako-gel Q-50) and eluted by pentane.

Spectral Data of the Products are as Follows. (*E*)-1-Cyclohexyl-1-hexene: ^1H NMR δ=0.88 (t, *J*=6.8Hz, 3H), 0.89—2.10 (m, 17H) and 5.30—5.40 (m, 2H); ^{13}C NMR δ=13.98, 22.18, 26.14 (-CH_2-, 2C), 26.27, 31.88, 32.55, 33.30 (-CH_2-, 2C), 40.69 (>CH-), 127.68 (-CH=) and 136.38 (-CH=); IR 970 cm^{-1} (⁀C=C⁀); MS *m/z* 166 (M^+).

(*E*)-1-Cyclohexyl-3,3-dimethyl-1-butene: ^1H NMR δ=0.97 (s, 9H), 0.97—1.97 (m, 11H), 5.22 (dd, *J*=15.6 and 6.3 Hz, 1H) and 5.39 (d, *J*=15.6 Hz, 1H); ^{13}C NMR δ=26.19 (-CH_2-, 2C), 26.27, 29.87 (-CH_3, 3C), 32.54 (-C-). 33.44 (-CH_2-, 2C), 40.69 (>CH-), 130.72 (-CH=) and 138.82 (-CH=); IR 1360 and 970 (⁀C=C⁀) cm^{-1}; MS *m/z* 166 (M^+).

(*E*)-1-Cyclohexyl-2-phenylethene: ^1H NMR δ=1.06—2.23 (m, 11H), 6.16 (dd, *J*=16.1 and 6.8 Hz, 1H), 6.34 (d, *J*=16.1 Hz, 1H) and 7.13—7.40 (m, 5H); ^{13}C NMR δ=26.02 (-CH_2-,

2C), 26.17, 32.93 (-CH_2-, 2C), 41.55 (>CH-), 125.90 (-CH=, 2C), 126.68 (-CH=), 127.19 (-CH=), 128.41(-CH=, 2C), 136.80 (-CH=) and 138.01 (>C=); IR 965 ($\diagdown$C=C$\diagup$), 745 and 690 cm^{-1}; MS m/z 186 (M^+).

(*E*)-2,3-Dimethyl-4-nonene: ^{1}H NMR δ=0.82 (d, J=6.8 Hz, 3H), 0.84 (d, J=6.8 Hz, 3H), 0.89 (t, J=6.8 Hz, 3H), 0.92 (d, J=6.8 Hz, 3H), 1.22—1.60 (m, 5H), 1.78—2.10 (m, 3H) and 5.26—5.36 (m, 2H); ^{13}C NMR δ=13.96, 17.68, 19.63, 19.89, 22.18, 31.93, 32.37, 33.05, 42.98, 129.35 (-CH=) and 134.49 (-CH=); IR 970 ($\diagdown$C=C$\diagup$) cm^{-1}; MS m/z 154 (M^+).

(*E*)-1-Phenyl-3,4-dimethyl-1-pentene: ^{1}H NMR δ=0.87 (d, J=7.3 Hz, 3H), 0.89 (d, J=6.8 Hz, 3H), 1.05 (d, J=6.3 Hz, 3H), 1.48—1.74 (m, 1H), 1.98—2.24 (m, 1H), 6.12 (dd, J=16.1 and 8.3 Hz, 1H), 6.23 (d, J=16.1 Hz, 1H) and 7.12—7.39 (m, 5H); ^{13}C NMR δ=17.44, 19.80, 19.97, 33.27, 43.54, 125.95 (-CH=, 2C), 126.70 (-CH=), 128.43 (-CH=, 2C), 128.82 (-CH=), 135.34 (-CH=) and 138.04 (>C=); IR 965 ($\diagdown$C=C$\diagup$), 745 and 690 cm^{-1}; MS m/z 172 (M^+).

(*E*)-1-(*trans*-2-Methylcyclohexyl)-3,3-dimethyl-1-butene: ^{1}H NMR δ=0.80 (d, J=5.8 Hz, 3H), 0.85—1.80 (m, 10H), 0.98 (s, 9H), 5.07 (dd, J=15.6 and 8.3 Hz, 1H) and 5.38 (d, J=15.6 Hz, 1H); ^{13}C NMR δ=20.82, 26.29, 26.63, 29.89 (-CH_3, 3C), 32.66 (-$\underset{|}{\overset{|}{C}}$-), 34.03, 35.31, 37.14 (>CH-), 48.91 (>CH-), 129.72 (-CH=) and 140.69 (-CH=); IR 1355 and 970 ($\diagdown$C=C$\diagup$) cm^{-1}; MS m/z 180 (M^+).

(*E*)-1-(*trans*-2-Methylcyclohexyl)-2-phenylethene: ^{1}H NMR δ=0.87 (d, J=6.3 Hz, 3H), 0.90—1.90 (m, 10H), 6.03 (dd, J=15.6 and 8.3 Hz, 1H) 6.34 (d, J=15.6 Hz, 1H) and 7.07—7.43 (m, 5H); ^{13}C NMR δ=21.01, 26.10 26.46, 33.59, 35.17, 37.11 (>CH-), 49.37 (>CH-), 125.90 (-CH=, 2C), 126.65 (-CH=), 128.41 (-CH=, 2C), 128.87 (-CH=), 136.04 (-CH=) and 138.04 (>C=); IR 960 ($\diagdown$C=C$\diagup$), 740 and 690 cm^{-1}; MS m/z 200 (M^+).

Stereoselectivity of Diels-Alder Reactions of 6,7-Dioxabicyclo[3.2.2]-nona-3,8-dien-2-one and 6,7-Diethoxycarbonyl-6,7-diazabicyclo[3.2.2]nona-3,8-dien-2-one

(Received May 22, 1986)

Synopsis. A Diels-Alder reaction of 6,7-dioxabicyclo[3.2.2]-nona-3,8-dien-2-one (**2**) with cyclopentadiene gave the *cis-endo*-[4+2] adduct and the *trans-endo*-[4+2] adduct. Their yields were improved when the reaction was carried out under high-pressure conditions. The reaction of 6,7-diethoxycarbonyl-6,7-diazabicyclo[3.2.2]nona-3,8-dien-2-one (**3**) gave the *cis-endo*-[4+2] adduct. Reactions of **2** and **3** with isobenzofuran and its 1,3-diphenyl derivative gave the thermodynamically-controlled *exo*-[4+2] adducts.

Several years ago, we investigated the Diels-Alder reaction[1] of bicyclo[3.2.2]nona-3,6-dien-2-one (**1**),[2] to give stereospecific *cis-endo*-adducts[3] from several dienes. The bicyclic enone, **1**, is an interesting dienophile, whose structure possesses an ideal arrangement of a vinylene group having an intramolecular homoconjugation with the enone,[4] to evaluate the secondary stereoelectronic effect in the Diels-Alder reaction. An HMO calculation supported the results.[1] In this connection, it will be worthwhile to check the Diels-Alder reaction of the heterocyclic analogs of **1** as dienophiles. Herein, we wish to describe the reaction of 6,7-dioxabicyclo[3.2.2]nona-3,8-dien-2-one (**2**)[5] and 6,7-diethoxycarbonyl-6,7-diazabicyclo[3.2.2]nona-3,8-dien-2-one (**3**),[6] dioxa and diaza analogs of **1**, with dienes.

Heating of **2** in benzene with cyclopentadiene (**4**) and a catalytic amount of *p*-toluenesulfonic acid (TsOH) formed two products (**5** and **6**). Silica-gel column chromatography led to an isolation, from the less polar eluent, of colorless needles (**5**) in 2% yield. Its ^1H NMR spectrum revealed a broad vinylic proton signal at a somewhat higher field than expected, δ=5.93 (2H, m), ascribable for the norbornene part. In addition, mutually coupled two-proton signals appeared at 6.50 (dd, J=9, 7 Hz, Hc) and 5.77 (dd, J=9, 7 Hz, Hb). The coupling constant of the methine protons, J_{ej}=3 Hz, showed that the stereochemistry was an *endo*-attack to the enone part. These findings indicated that the stereochemistry of **5** is same to that of the Diels-Alder adducts of **1** with **4** and some cyclic dienes.[1] Subsequent elution afforded colorless needles (**6**) in 3% yield. Its NMR signals of vinylic protons revealed different stereochemistry with **5**; the characteristic signals ascribable to the norbornene part were at 6.06 and 6.35 as each dd; the other signals at 6.29 and 6.83 were those of the dioxacyclohexene moiety. Yet, the coupling constants of the methine protons, J_{ej}=3 Hz and J_{fg}=4 Hz, had the same magnitude as **5** and confirmed the *endo*-orientation. Thus, **6** is *trans-endo*-adduct.

Similarly, **2** with isobenzofuran (**7**),[7] afforded two products (**8**, 41% yield, and **9**, 18% yield) which were deduced to be both *exo*-adducts from a different magnitude of the spin-spin couplings; J_{ch}=J_{fg}=0 Hz for both **8** and **9**. A comparison of the chemical shifts ascribable to H_e and H_f determined the rest of the stereochemistry as depicted; **5** and **9** showed signals at a lower field than **6** and **8**. Moreover, the reaction of **2** with 1,3-diphenylisobenzofuran (**10**) also only yielded a *trans-exo*-adduct (**11**) in 31% yield.

These observations indicated: i) in the reaction of **2** with **4**, the secondary effect of the orbital interaction was still operative for an exclusive *endo*-adducts formation, ii) the secondary effect of the lone-pair electrons of dioxy oxygens is capable of determining the stereochemistry of the adducts to the same extent as the π-orbital of the vinylene group,[8] and iii) an exclusive formation of the thermodynamically stable *exo*-adducts from **7** is attributable to a facile cycloreversion of the kinetically controlled *proto*-adducts under the reaction conditions. The Diels-Alder adducts of furans fall into a category.[9]

When a reaction of **2** with **4** was carried out under high-pressure conditions, the yields were improved to a great extent; the best result was 45% for **5** and 38% for **6** (Table 1).

It is evident that the improved formation of **5** and **6** under high-pressure conditions showed them to be the kinetically controlled products; an inhibition of the *retro*-Diels-Alder process should favor a retention of the *proto*-adducts. It should be noted that a reaction of **2** and **4** under atmospheric pressure produced **5** and **6** only in the presence of TsOH at 80 °C. However, due to the instability of **2** under acidic conditions, an accel-

Table 1. The Reaction of **2** and **4** under Various Conditions

Runs	Solv.	Conditions Press./bar	Temp/°C	Consumption/% Additive	2	Yield/% 5	6
1	Benzene	1	80	TsOH	79	2	3
2	Cumene	2500	40	TsOH	66	36	28
3	Cumene	2500	40		64	45	38
4	Acetone	2000	40		49	27	8

eration of the product formation was compensated by the decomposition of **2**. This may be attributable to the lower yields for **5** and **6** with TsOH than without TsOH at 2500 bar.

In cases of reactions of **3**, the nitrogen analogs of **2**, a similar secondary orbital effect should also play a role in the stereochemistry of the adducts; however, at the same time, the inversion of unshared electron pairs of nitrogen and a steric hindrance due to bulky ethoxycarbonyl groups on the hydrazo linkage should minimize the effect of the secondary interaction. The reaction of **3** with **4** yielded a *cis-endo*-adduct (**12**, 96% yield) as the product only identified. The improved yield was due to the stability of the bicyclic dienophile under the conditions. The reaction of **3** with **7** gave two products, *cis-exo*-adduct (**13**, 54% yield) and *trans-exo*-adduct (**14**, 31% yield), while that of **3** with **10** gave the sole product, *cis-exo*-adduct (**15**, 46% yield).

In conclusion, the reactions of **2** and **3** with **4** verified the operation of an attractive secondary interaction between the dioxy group or the hydrazo group as well as the vinylene group and the diene chromophore of **4**, and the absence of a *trans-endo*-adduct from **3**, should be interpreted as a steric effect rather than a lack of the secondary orbital interaction. However, this could not be extended to the reactions with **7** and **10**, since the furans are known to preferably give the thermodynamically controlled cycloadducts.[9]

Experimental

Elemental analyses were performed at the Research Institute of Industrial Science, Kyushu University. The NMR spectra were measured by a JEOL FX 100 Spectrometer in a $CDCl_3$ solution, unless otherwise specified, and the chemical shifts were expressed in δ units (internal Me_4Si). The mass spectra were measured by a JEOL 01SG-2 Spectrometer. The IR spectra were taken either as KBr disks or as liquid films inserted between NaCl plates using a Jasco IR-A 102 Spectrometer.

Reaction of 2 and 4. **a)** A benzene solution (10 cm^3) of **2** (1.01 g) and **4** (5 cm^3) containing TsOH (200 mg) was refluxed for 1.5 h. The mixture was chromatographed on a silica-gel column to give colorless needles, mp 119—121 °C, 29 mg (2%), **5** [Found: M.W., 204.0786. Calcd for $C_{12}H_{12}O_3$: 204.0784. ^1H NMR δ=1.36 (d, J=8.5 Hz, Hm), 1.55 (dt, J=8.5, 2 Hz, Hk), 2.85 (m, Hj), 3.08 (dtd, J=11, 3, 1.5 Hz, He), 3.4 (m, Hf and Hg), 4.67 (dt, J=7, 3 Hz, Hd), 4.93 (dd, J=7, 2 Hz, Ha), 5.77 (dd, J=9, 7 Hz, Hb), 5.93 (m, Hh and Hi), and 6.50 (dd, J=9, 7 Hz, Hc). ^{13}C NMR δ=43.8, 44.8, 45.8, 49.0, 54.6, 80.4, 84.2, 118.4, 132.7, 134.8, 136.6, and 200.3. IR ν: 1700 cm^{-1}], and colorless needles, mp 104—105.5 °C, 37.2 mg (3%), **6** [Found: M.W., 204.0786. ^1H NMR δ=1.34 (dtt, J=8.5, 1.5, 0.5 Hz, Hm), 1.52 (dt, J=8.5, 2 Hz, Hk), 2.55 (dt, J=9.5, 3 Hz, He), 2.98 (m, Hj), 3.12 (dd, J=9.5, 4 Hz, Hf), 3.34 (m, Hg), 4.57 (ddd, J=7, 2, 1 Hz, Ha), 4.73 (dddt, J=7, 3, 2, 1 Hz, Hd), 6.06 (dd, J=5.5, 2.5 Hz, Hh), 6.29 (ddd, J=9, 7, 1 Hz, Hb), 6.35 (dd, J=5.5, 3 Hz, Hi), and 6.83 (ddd, J=9, 7, 1 Hz, Hc). ^{13}C NMR δ=45.2, 46.5, 48.4, 49.4, 51.1, 78.5, 83.4, 123.0, 132.9, 136.0, 136.5, and 204.3. IR ν: 1700 cm^{-1}], together with the recovered **2**, 207.3 mg (21%).

b) A cumene solution (3 cm^3) of **2** (ca. 0.5 mmol) and **4** (ca. 10 mmol), with or without TsOH (21 mg), was heated at 40 °C by means of the pressure vessel under the pressure as indicated in Table 1, for ca. 10 h. The mixture was chromatographed to obtain the products **5** and **6**, and the recovered **2**.

c) An acetone solution (3 cm^3) of **2** (102.6 mg) and **4** (551 mg) was similarly heated by use of the pressure vessel under 2000 bar at 40 °C for 10 h. The results are compiled in Table 1.

Reaction of 2 and 7. A CH_2Cl_2 solution (2 cm^3) of **2** (112.5 mg) was added at −70 °C to **7**, generated in situ by the pyrolysis of dihydro derivative of benzyne-furan adduct.[10] The mixture was kept at 4 °C for 2 d, and chromatographed on a silica-gel column to give colorless needles, mp 144—147 °C, 75.5 mg (41%), **8** [Found: C, 70.27; H, 4.65%. Calcd for $C_{15}H_{12}O_4$: C, 70.30; H, 4.73%. ^1H NMR δ=2.22 (dd, J=9, 4 Hz, He), 2.80 (d, J=9 Hz, Hf), 4.90 (ddd, J=7, 2, 1 Hz, Ha), 5.07 (ddd, J=7, 4, 2.5 Hz, Hd), 5.46 (s, Hh), 5.54 (s, Hg), 6.35 (ddd, J=9, 7, 1 Hz, Hb), 6.82 (ddd, J=9, 7, 1 Hz, Hc), and 7.1—7.4 (4H, m). ^{13}C NMR δ=46.2, 52.8, 78.4, 81.8, 83.6, 84.3, 119.0, 119.8, 123.0, 127.2, 127.4, 135.4, 144.8, 146.0, and 200.9. IR ν: 1695 cm^{-1}], and colorless needles, mp 137—140 °C, 34.1 mg (18%), **9** [Found: C, 70.45; H, 4.65%. ^1H NMR δ=2.69 (dd, J=8, 3 Hz, He), 2.92 (d, J=8 Hz, Hf), 5.0—5.15 (m, Ha and Hd), 5.16 (s, Hh), 5.70 (s, Hg), 6.23 (dd, J=9.5, 8 Hz, Hb), 6.87 (dd, J=9.5, 8 Hz, Hc), and 7.1—7.4 (4H, m). ^{13}C NMR δ=44.7, 54.7, 79.8, 80.9 (2C), 83.8, 119.0, 120.0, 121.4, 127.4, 127.5, 135.2, 143.9, 145.3, and 199.2. IR ν: 1710 cm^{-1}], together with the recovered **2**, 12.6 mg (11%).

Reaction of 2 and 10. A CH_2Cl_2 solution (2 cm^3) of **2** (102.2 mg) and **10**[11] (298.5 mg) was refluxed for 14 h. The mixture was then chromatographed on a silica-gel column to give colorless crystals, mp 139—141 °C, 94 mg (31%), **11** [Found: M.W., 408.1362. Calcd for $C_{27}H_{20}O_4$: 408.1360. ^1H NMR δ=3.30 (dd, J=8, 3 Hz, He), 3.48 (dd, J=8, 1 Hz, Hf), 4.55 (ddt, J=7, 2, 1 Hz, Ha), 4.76 (dddd, J=7, 3, 2, 1 Hz, Hd), 5.99 (ddd, J=9, 7, 1 Hz, Hb), 6.39 (ddd, J=9, 7, 1 Hz, Hc), and 7.1—7.8 (14H, m). ^{13}C NMR δ=48.9, 59.7, 79.2, 83.7, 88.9, 90.3, 118.7, 119.3, 119.7, 125.6 (2C), 126.8 (2C), 127.3, 127.7 (2C), 127.8 (2C), 128.6, 129.3 (2C), 135.1, 135.3, 136.5, 145.5, 148.7, and 195.0. IR ν: 1700 cm^{-1}].

Reaction of 3 and 4. A toluene solution (5 cm^3) of **3** (367.5 mg), and **4** (5.5 cm^3), TsOH (59 mg) was refluxed for 10 h. Silica-gel column chromatography of the mixture yielded colorless needles, mp 146.5—149.5 °C, 344.6 mg (96%), **12** [Found: C, 62.61; H, 6.41; N, 8.06%. Calcd for $C_{18}H_{22}O_5N_2$: C, 62.40; H, 6.41; N, 8.09%. ^1H NMR δ=1.25 (3H, t, J=7 Hz), 1.30 (3H, t, J=7 Hz), 1.15—1.4 (m, Hm, underneath the t), 1.48 (dt, J=8.5, 2 Hz, Hk), 2.75 (dt, J=9, 2.5 Hz, He), 2.8—2.9 (m, Hj, underneath the dd), 2.96 (dd, J=9, 3 Hz, Hf), 3.38 (m, Hg), 4.18 (2H, q, J=7 Hz), 4.25 (2H, q, J=7 Hz), 4.83 (2H, dm, J=7 Hz, Ha and Hd), 5.50 (ddd, J=9, 7, 3 Hz, Hb), 5.94 (2H, t, J=2 Hz, Hh and Hi), and 6.40 (ddd, J=9, 7, 1.5 Hz,

Hc). IR ν: 1700 cm^{-1}] together with the recovered **3**, 76.5 mg (21%).

Reaction of 3 and 7. A CH_2Cl_2 solution (2 cm^3) of **3** (293.6 mg) was added to similarly generated **7**. The mixture was then chromatographed on silica-gel column to give a colorless oil, 173 mg (54%), **13** [Found: M.W., 398.1477. Calcd for $C_{22}H_{22}O_2N_2$: 398.1476. ^1H NMR δ=1.18 (3H, t, J=7 Hz), 1.26 (3H, t, J=7 Hz), 2.49 (m, He and Hf), 4.17 (2H, q, J=7 Hz), 4.20 (2H, q, J=7 Hz), 4.98 (d, J=7 Hz, Ha), 5.26 (s, Hh), 5.29 (dm, J=6 Hz, Hd), 5.74 (s, Hg), 5.97 (dd, J=9, 7 Hz, Hb), 6.78 (dd, J=9, 6 Hz, Hc), and 7.1—7.4 (4H, m). IR ν: 1705 cm^{-1}], and a colorless oil, 100.2 mg (31%), **14** [Found: M. W., 398.1479. ^1H NMR δ=1.1—1.4 (6H, m), 2.30 (dd, J=8.5, 5.5 Hz, He), 2.75 (dd, J=8.5, 1.5 Hz, Hf), 4.0—4.4 (4H, m), 4.94 (dd, J=7, 2 Hz, Ha), 5.2—5.4 (m, Hd), 5.32 (s, Hh), 5.39 (s, Hg), 6.12 (ddd, J=9, 7, 1.5 Hz, Hb), 6.69 (dd, J=9, 6.5 Hz, Hc) and 7.1—7.4 (4H, m). IR ν: 1710 cm^{-1}] together with the recovered **3**, 66.5 mg (23%).

Reaction of 3 and 10. Similarly, a toluene solution (4 cm^3) of **3** (101.8 mg) and **10** (100.2 mg) was refluxed for 4 h. The mixture was then chromatographed on a silica-gel column to give colorless crystals, mp 182—184 °C, 63.6 mg (46%), **15** [Found: C, 71.74; H, 5.56; N, 5.57%. $C_{33}H_{30}O_6N_2$: C, 71.97; H, 5.50; N, 5.09%. ^1H NMR δ=1.14 (3H, t, J=7 Hz), 1.20 (3H, t, J=7 Hz), 3.09 (dd, J=8, 2 Hz, He), 3.20 (dd, J=8, 0.5 Hz, Hf), 3.9—4.2 (4H, m), 4.66 (d, J=7 Hz, Ha), 5.03 (ddd, J=6, 2, 1 Hz, Hd), 5.72 (ddd, J=9, 7, 1 Hz, Hb), 6.27 (ddd, J=9, 6, 1 Hz, Hc), and 7.1—7.8 (14H, m). ^{13}C NMR δ=14.2, 14.5, 48.4, 57.2, 62.8, 63.1, 63.5, 78.4, 89.4, 90.1, 119.2, 119.5, 120.0, 125.7, 126.8 (2C), 127.2, 127.6 (3C), 128.5 (3C), 129.2 (2C), 135.9, 136.7, 137.1, 145.9, 148.3, 155.4, 157.4, and 191.4. (Received June 14, 1986)

Synopsis. The association constants (K) of β-cyclodextrin with 13 amphiphilic ions were determined. For a homologous series 1-alkanesulfonate ions, the saturation phenomenon of K occurred at the number of carbon atoms of 10. The values of K for amphiphilic ions with dodecyl chain were similar to one another.

It is well-known that the hydrophobic interaction between hydrophobic moieties of host and guest molecules plays an important role in the complexation of cyclodextrins.[1] In this connection, studies have been made for the associations of cyclodextrins with fatty acids[2] and amphiphilic ions[3-6] which have a long hydrocarbon chain of varying hydrophobicity. With a homologous series 1-alkanesulfonate ions, we found that the association constant of α-cyclodextrin (αCD) increases monotonously with increasing carbon atom (n) and become abruptly constant at n=10.[4] A similar saturation phenomenon of the association constant has also been observed for the complexation of fatty acid salts with α- and β-cyclodextrins.[7] We also found that the association constants of αCD for ionic surfactants with the same alkyl chain length are similar to one another regardless of the sign of ionic head group.[4]

In order to elucidate the effect of cavity size on the cyclodextrin-amphiphilic ion interactions, the conductometric investigation was made in this paper for the association constants (K) of β-cyclodextrin (βCD) with ionic surfactants and their homologs.

Experimental

Materials. Sodium 1-alkanesulfonates with n from 8 to 12 were synthesized from the corresponding alkyl bromides purified by vacuum distillation.[8] Dodecylammonium chloride (DAC) was prepared from dodecylamine (purity>99%, Nakarai Chemicals Ltd.).[9] Sodium dodecyl sulfate (SDS, Nakarai Chemicals Ltd.) and 1-dodecylpyridinium chloride (DPC, Tokyo Kasei Kogyo Co. Ltd.) were purified further by the procedures described elsewhere.[4] Sodium 1-alkanesulfonates with n from 5 to 7 (Tokyo Kasei Kogyo Co. Ltd., guaranteed grade), sodium p-dodecylbenzenesulfonate (SDBS, purity>99%, Wako Pure Chemical Industry Co. Ltd.), dodecyltrimethylammonium bromide (DTAB, purity>99%, Tokyo Kasei Kogyo Co. Ltd.), and β-cyclodextrin ($[\alpha]_D^{25}$=+162°, Seikagaku Kogyo Co. Ltd.) were used without further purifications. Deionized water was obtained by passing twice distilled water through the mixed ion bed (Bio-Rad AG501-X8).

Measurements. The conductivity was measured to a precision of 0.1 μS by using a TOA Electronics Ltd. Conductivity Meter model CM-50AT and the conductivity cell with cell constant of 1.000 cm^{-1} at 25 °C. The concentration of βCD was determined by drying aliquots of the stock solution over phosphorus pentaoxide in vacuo at 110 °C. The conductivity was followed as a function of βCD concentration, C_h, under the conditions of a constant amphiphile concentration, C.

The solution viscosities of α- and βCD were measured by a Ubbelohde's viscometer at 25 °C.

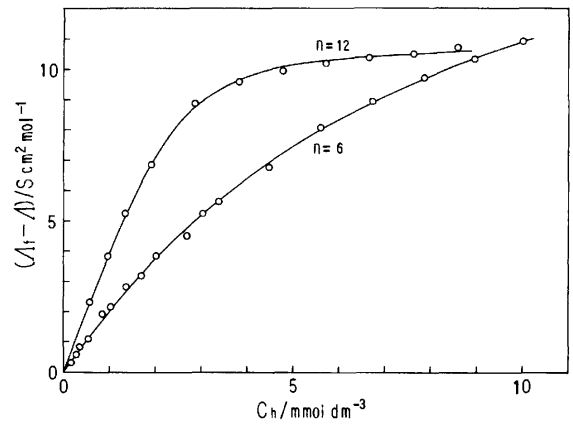

Fig. 1. Plots of $\Lambda_f-\Lambda$ vs. βCD concentration (C_h) for sodium 1-alkanesulfonates with n=6 and 12 at 25°C. C=2.584 mmol dm^{-3} (n=6), 2.434 mmol dm^{-3} (n=12) O, observed; solid line: calculated curve from Eq. 1 with parameters shown in Table 1.

Results and Discussion

On the basis of the assumption of a 1 : 1 reaction scheme, the change in the equivalent conductivity, Λ, with βCD concentration can be described as follows.[4]

$$\Lambda_f - \Lambda = \frac{\lambda_f-\lambda_a}{2KC}[K(C+C_h) + 1 - \sqrt{\{K(C+C_h) + 1\}^2 - 4K^2CC_h}] \quad (1)$$

Here, Λ_f refers to the equivalent conductivity in the absence of βCD, and λ_f and λ_a to the ionic equivalent conductivities of unassociated and associated amphiphilic ion, respectively. Thus the nonlinear least squares treatment of Λ_f—Λ vs. C_h plots permits the simultaneous determinations of K and λ_f—λ_a.[4]

In Flg. 1 is shown the typical plots of Λ_f—Λ vs. C_h for sodium 1-hexane- and 1-dodecanesulfonates at 25 °C, together with the calculated curves which give the best fit of the experimental data. An excellent agreement between observed and calculated conductivity curves supports the foregoing assumption of a 1 : 1 reaction scheme for βCD- amphiphilic ion interaction. This is also the case for whole systems studied. The association constants and the conductometric parameters thus determined are summarized in Table

Table 1. The Conductometric and Thermodynamic Parameters of βCD-Amphiphile Systems

Amphiphile	C	Temp	Λ_f	$\lambda_f-\lambda_a$	K	$-\Delta G^\circ$

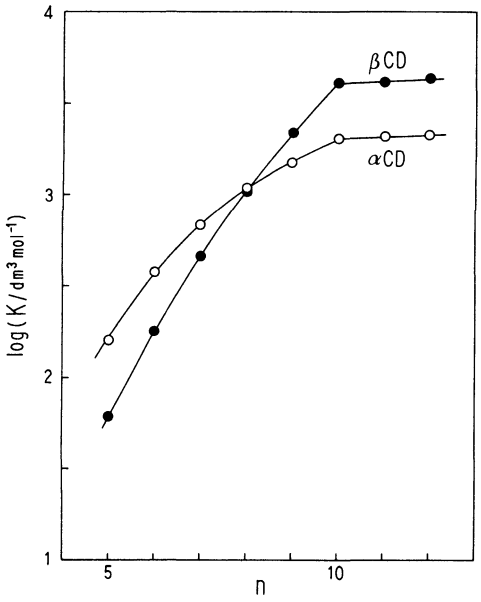

Fig. 2. The chain length dependence of K for sodium 1-alkanesulfonate at 25°C. ●, βCD; ○, αCD.[4]

1. In this table is also given the standard free energy change of complex formation, ΔG° ($=-RT$ ln $K_X=-RT$ ln $55.5K$). Figure 2 shows the chain length dependence of K for 1-alkanesulfonate ion. For the sake of comparison, the previous data for αCD[4] are also shown in this figure.

It can immediately be seen that the association constant of βCD increases more rapidly than that of αCD with increasing chain length but become also constant at n=10. In the complexation of homologous series amphiphilic ions, therefore, the hydrophobic cavity of βCD is supposed to accomodate the hydrocarbon tail in a similar manner to αCD, even though the degree of interaction is different from each other. However, it seems difficult to interpret the observed saturation phenomena at n=10 in terms of the hydrophobic interaction alone, since the hydrophobic cavities of α- and βCD molecules are of the order of 0.67—0.7 nm[1a] in depth and can accomodate at most 6 methylene groups of a fully extended chain. A tentative application of Einstein equation to the viscosity data for cyclodextrin solutions leads immediately to the hydrodynamic volumes of α- and βCD molecules of 1.40 and 1.90 nm^3, which correspond to the diameters of 1.40 and 1.54 nm respectively. On the other hand, the head-to-tail distance of 1-decanesulfonate ion with a fully extended chain can be estimated to be 1.55 nm on the basis of an assumption that the radius of hydrated sulfonate group is comparable to that of HSO_3^- ion (0.23 nm[10]). In connection with the saturation phenomena of K at n=10, it is interesting to note that the estimated size of 1-decanesulfonate ion is slightly larger than the diameter of hydrated αCD but almost identical with that of hydrated βCD. Moreover, the methylene group adjacent to head group has been recognized to make little or no contribution to the hydrophobic interaction.[11] With these observations in mind, α- and βCD molecules seem to include the successive 10 methylene groups of 1-alkanesulfonate ion with n larger than 10 in such a manner as the head group and first methylene group in hydration shell on one side of the cavity, succeeding 6 methylene groups in the hydrophobic cavity, and the residual 3 methylene groups in hydration shell on another side of the cavity. If this is really the case, the thermodynamic parameters such as the enthalpy and entropy of complexing will probably reflect the difference in the microscopic environment around hydrocarbon chain.

Table 2. The Thermodynamic Parameters of Complexing for Sodium 1-Alkanesulfonates with $n=5$, 6, 8, and 9 at 25 °C

n	ΔH°	ΔS°	$\Delta(\Delta H^\circ)$	$\Delta(\Delta S^\circ)$
	kJ mol^{-1}	J K^{-1} mol^{-1}	kJ mol^{-1}	J K^{-1} mol^{-1}
5	−5.87	47.7	≈0	9.1
6	−5.86	56.8		
8	−4.39	76.5	3.7	18.3
9	−0.74	94.8		

Table 2 shows the standard enthalpy and entropy changes estimated for 1-alkanesulfonate ions with $n=5$, 6, 8, and 9 from temperature dependence of K_X. In last two columns are given the increments of ΔH° and ΔS° per methylene group which correspond to the enthalpy and entropy changes for transferring one methylene group from an aqueous medium to the complex state respectively. It should be noted that the observed increment of ΔH° accompanying the increase in n from 5 to 6 is comparable to the enthalpy changes per methylene group characteristic of hydrophobic interaction. For example with heptane-βCD system, Wishnia and Lappi[12] obtained ΔH° of 0.84 kJ mol^{-1} at 20 °C, which corresponds roughly to 0.12 kJ mol^{-1} per methylene group. In the case of micellization process, the enthalpy change per methylene group has been found to be of the order of 0.2 kJ mol^{-1}.[13] On the contrary, the increments of ΔH° and ΔS° accompanying the change in n from 8 to 9 are quite different from those from 5 to 6. In a previous paper,[4] we assumed the partial breakdown of the hydration shell around lateral hydrophilic surface through which hydrocarbon tail penetrates. Apart from the plausible explanation of the effect of hydrocarbon tail on hydration shell, the thermodynamic data seem to support the foregoing geometric consideration on the inclusion mechanism of long-chain 1-alkanesulfonate ions. In their study of the complexation of homologous series fatty acid salts, Ono et al.[7] found that the saturation phenomenon of K occurs at $n=8$ for αCD and $n=12$ for βCD respectively. They assumed a trans to gauche conformational change of hydrocarbon chain in cavity of βCD.

The qualitative features of the association constants of βCD for surfactant ions with dodecyl chain are identical with those of αCD.[4] As was pointed out previously,[4] a marked resembrance in the values of K for sodium 1-dodecanesulfonate, DAC, DTAB, and DPC suggests that the interaction between βCD and surfactant ion does not depend appreciably on the chemical and electrical properties of ionic head group. A striking increase in K for SDBS can also be attributed to the presence of the aromatic ring which interacts strongly with βCD.[1]

The Crystal and Molecular Structure of Inner Triple-Layered Paracyclophanequinone

Toshihiro TOYODA, Hitoshi TATEMITSU, Yoshiteru SAKATA, Nobutami KASAI,*,† and Soichi MISUMI*
The Institute of Scientific and Industrial Research, Osaka University, Ibaraki, Osaka 567
†Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565
(Received April 25, 1986)

Synopsis. The molecular structure of inner quinone isomer of two triple-layered paracyclophanequinones has been determined by means of X-ray diffraction. $C_{26}H_{24}O_2$, M 368.5, orthorhombic, space group $Pbcn$, a=12.923(1), b=11.507(1), c=12.550(1) Å, V=1866.2(3) Å^3, Z=4. The structure was solved by the direct method. Anisotropic refinement by the block-diagonal least-squares procedure gave R=0.042 for non-zero reflections. The molecule has a two-fold symmetry. The benzoquinone moiety is sandwiched by two donor benzene rings, and the two-fold axis passes through the O=C···C=O bonds of the twisted benzoquinone moiety. The outer benzene rings take a boat-form and the central benzoquinone ring is twisted.

Three isomeric triple-layered and two isomeric quadruple-layered charge-transfer cyclophanes containing benzoquinone and dimethoxybenzene moieties have been synthesized together with two quadruple-layered paracyclophanes and interesting charge-transfer spectra related to their structures, e.g. number of layers and relative donor-acceptor orientation, have been reported.[1] Two isomeric triple-layered paracyclophanequinones also showed a structural relationship corresponding to the position of quinone group in their CT spectra.[2]

Experimental

Yellow prismatic crystals were recrystallized from a solution of benzene-hexane mixed solvent. The crystal used had dimensions of ca. 0.15×0.23×0.20 mm. A Rigaku automated, four-circle diffractometer combined with rotating-anode X-ray generator was used at the Institute for Protein Research, Osaka University. Ni-filtered Cu$K\alpha$ radiation (λ=1.54178 Å) was used.

Intensity data were collected by the θ—2θ scan technique: the 2θ scan rate was 16° min^{-1} and the scan width from $\{2\theta(\alpha_1)-1.0\}$ to $\{2\theta(\alpha_2)+1.0\}$°. Backgrounds were measured ca. 1 s at both ends of a scan. Three standard reflections were measured after every 57 reflections, which showed no intensity decrease during the data collection. In total, 1307 reflections out of 1567(2θ<118°), were observed ($|F_o|>3\sigma(F_o)$). Usual Lorentz and polarization corrections were applied but absorption correction was ignored[μ(Cu)=6.3 cm^{-1}].

Structure Solution and Refinement

The structure was solved by the direct method (*MULTAN*),[4] and refined anisotropically by the block-diagonal least-squares procedure (*HBLS* V).[5] The function minimized was $\sum w(\Delta F)^2$. All the hydrogen atoms were located on a difference Fourier map, which were included in the refinement with isotropic temperature factors. The R value converged to 0.042. The weighting schemes used at the final stage were $w=\{\sigma^2(F_o)-0.096|F_o|+0.005|F_o|^2\}^{-1}$ for $|F_o|>0$ and w=0.667 for $|F_o|=0$, where σ is the standard deviation obtained by the counting statistics. The final atomic parameters are given in Table 1.††

Table 1. Final Atomic Coordinates of Non-Hydrogen Atoms with Equivalent Isotropic Temperature Factors[6]

Atom	x	y	z	B_{eq}/Å^2

C(12)	0.43766(11)	0.27001(14)	0.16987(12)	2.7
C(13)	0.50000	0.33463(19)	0.25000	2.7
C(14)	0.50000	0.09285(19)	0.25000	2.9

Atomic scattering factors were taken from International Tables for X-Ray Crystallography.[7] Computations were done mainly on an NEAC 2200—500 computer at the Computation Center, Osaka University, and at the final stage an ACOS 850 computer was used at the Crystallographic Research Center, Institute for Protein Research, Osaka University.

Results and Discussion

Figure 1 shows a perspective view[8] of the molecule. Selected bond distances and bond angles are given in Fig. 2.

The feature of the molecular structure is that the O(1), C(13), C(14), and O(2) atoms lie on a crystallographic two-fold axis, and the molecule has a two-fold symmetry. Three benzene rings are not in the exact eclipsed position. They are mutually rotated slightly in a helical way (Fig. 3): the C(5)-C(4) and C(12)-C(13) bonds projected onto the least-squares plane of the central benzoquinone ring make an angle of 5.5°, and similarly the C(12)-C(13) and C(3′)-C(4′) bonds form 4.3°. The corresponding angles in XD(Br)X[3] are 4.1 and 6.4°, respectively.

The outer benzene rings deformed to a boat form as in [2.2]paracyclophanes.[9-12] The bending angle P_1, i.e. the dihedral angle between the plane defined by the

††Tables of anisotropic thermal parameters, coordinates of hydrogen atoms, and observed and calculated structure factors are kept at the Chemical Society of Japan, Document No. 8703.

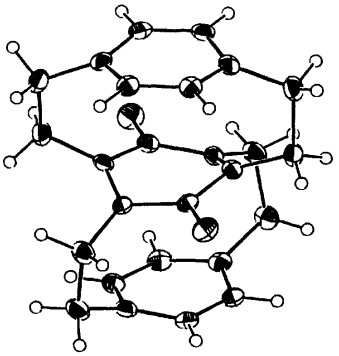

Fig. 1. A perspective view[8] of the molecule. Non-hydrogen atoms are represented as thermal ellipsoids with 30% probability level, and hydrogen atoms as spheres with B=1.0 Å^2.

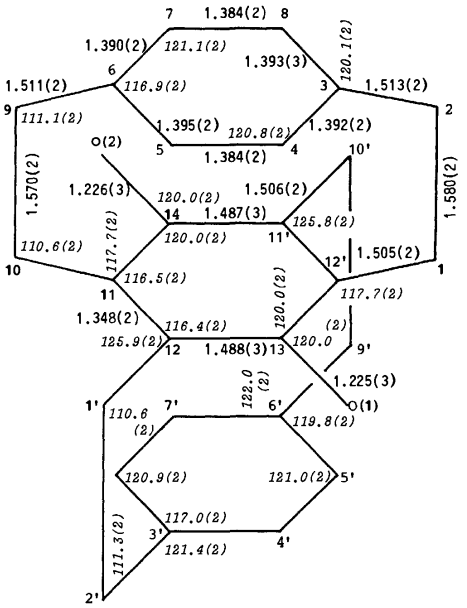

Fig. 2. Selected bond lengths [l/Å] and bond angles [ϕ/°] with estimated standard deviations in parentheses.

(b_2)

Fig. 3. Projections of the molecules.[8]
(a): Projected along the normal to the mean plane defined by the C(11), C(12), C(13), C(14), C(11'), and C(12') atoms.
(b_1): Projected along the normal to the plane defined by the C(6), C(11), and C(12') atoms.
(b_2): Schematic drawing of the (b_1) with nonbonded atomic distances between the outer benzene and central benzoquinone rings [l/Å]. p, q,[3] and other angles [ϕ/°] are also given.

C(4), C(5), C(7), and C(8) atoms (Plane 1) and that by the C(3), C(4), and C(8) (Plane 2) is 10.5°, and P_2, the dihedral angle between the Plane 1 and the Plane 3 (formed by the C(5), C(6), and C(7) atoms) is 9.9°. These are smaller than the corresponding angles in XD(Br)X [12.0 and 12.1°, respectively],[3] [2.2]paracyclophane [12.6°],[9] and other multi-layered paracyclophanes.[10-12] The C(2)-C(3) bond forms an angle q_1 of 11.9° with the Plane 2, and the C(6)-C(9) an angle q_2 of 11.5° with the Plane 3. These values are almost the same as those of the XD(Br)X and other [2.2]paracyclophanes.

Six C-C bond distances in the outer benzene rings are equal within a range of error [av. 1.390 Å]. The C(4)-C(3)-C(8) and C(5)-C(6)-C(7) angles [117.0(2) and 116.9(2)°], which are the bow and stern of the boat form, are smaller than the other four inner angles which have normal values [from 120.8(2) to 121.1(2)°].

The C_{sp^3}-C_{sp^3} bonds of ethylene bridges, C(1)-C(2) and C(9)-C(10), are 1.580(3) and 1.570(2) Å, which seem slightly shorter than that in [2.2]paracyclophane [1.593 Å].[8] Torsional angles around the C(1)-C(2) [15.5°] and C(9)-C(10) [18.8°] bonds can be compared with those in XD(Br)X [12.5 and 17.6°, respectively].

In the central benzoquinone moiety, the C(11)=C(12)

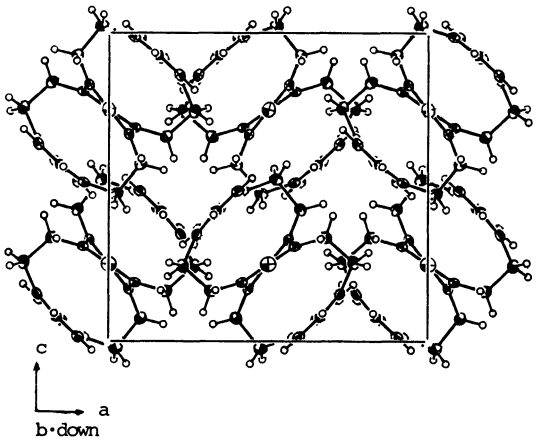

Fig. 4. Crystal structure projected along the b axis.[8]

double bond distance [1.348(2) Å] is slightly longer and the C(12)-C(13)-C(12′) bond angles[120.0(2)°] is smaller than the corresponding bond distances and bond angles in the free benzoquinone molecule,[13] and the rest has normal values. In the benzoquinone moiety, three bond angles around the C(13) and C(14) atoms are all equal [120.0(2)°]. The benzoquinone moiety consists of two planes, one defined by the O(1), C(12), C(13), and C(12′) atoms and the other formed by the rest of atoms. The dihedral angle made by these planes, i.e. the twisting angle δ (Fig. 3(b_1)) is 16.7°, which is much larger than the corresponding angles in triple- and quadruple-layered paracyclophanes [13.6 and 13.4°].[12] Closest nonbonded distances between the benzoquinone moiety and outer layer benzene ring are those observed between the C(6) and C(11) atoms [2.683(2) Å] and between the C(3) and C(12′) [2.685(2) Å], which are shorter than the corresponding distances in XD(Br)X [2.744(7) and 2.754(7) Å] (Fig. 3(b_2)). The C(1)-C(12′) bond bends by 1.4° away from the plane defined by the C(11′), C(12′), and C(13) atoms and the C(10)-C(11) bond by only 0.2° away from the plane made by the C(11), C(12), and C(14). These two angles are much smaller than the corresponding angles in XD(Br)X [6.6 and 4.7°, respectively]. Among the intramolecular nonbonded O···H distances, the O(1)···H(1B) [2.40(2) Å] and O(2)···H(10B) [2.38(2) Å] are closest. Next to these are O(1)···H(4) [2.97(2) Å] and O(2)···H(7) [3.09(2) Å].

The packing of molecules in the crystal is drawn in Fig. 4.[8] The structure of the present crystal is isomorphous with that of XD(Br)X. All of the intermolecular atomic contacts are longer than the van der Waals distances. The closest distance [3.637(2) Å] is observed between the O(1)(x, y, z) and C(9)(0.5−x, 0.5+y, z) atoms.

The authors wish to express their deep thanks to Miss Nobuko Kanehisa who helped them at the final stage of the refinement and *ORTEP* drawings.

(Received April 21, 1986)

Synopsis. As a solution of 3,4,5,6-tetrachlorogallein (T.Cl.gall) in a weakly acidic medium was easily decomposed by vanadium(V), a simple and sensitive spectrophotometric determination of vanadium by using the difference in absorbance at 385 nm between T.Cl.gall and T.Cl.gall-vanadium(V) solutions in the presence of hexadecylpyridinium chloride (HPC) and poly (*N*-vinylpyrrolidone) (PVP) was established. Under optimum conditions, vanadium could be determined in the range of 0—0.8 μg/10 cm^3. The apparent molar absorptivity was calculated to be 7.0×10^5 $dm^3 mol^{-1} cm^{-1}$, with a Sandell sensitivity of 0.00006 μg cm^{-2}, by the use of a decomposed T. Cl. gall solution in the presence of vanadium(V) at 385 nm. The recovery tests of vanadium added to prepared artificial water were examined; the results were a good agreement with the certified values (98.6—102.8%).

We have already reported[1] the spectrophotometric determination of vanadium by using the color reaction system between vanadium and Gallein (gall) in the presence of sodium sulfite and sodium dodecyl sulfate.

On the other hand, Cabeza et al.[2,3] have reported the methods of the determination of vanadium utilizing the oxidation reaction of pyrogallolsulfophthalein= Pyrogallol Red (PR) by vanadium(V) or bromate ions. Also, we ourselves have recognized that 3,4,5,6-tetrachlorogallein (T.Cl.gall),[4] in the presence of hexadecylpyridinium chloride (HPC) and poly (*N*-vinylpyrrolidone) (PVP) as surfactants in a weakly acidic medium, was readily decomposed by the coexistence of vanadium(V) (=oxidation of T.Cl.gall), and that the difference in absorbance between the T.Cl.gall solution (Solution A) and the T.Cl.gall-vanadium(V) solution (Solution B) was proportional to the concentration of vanadium.

This paper describes a simple and sensitive spectrophotometric determination of micro amounts of vanadium using the oxidation and decomposition of a T. Cl. gall solution by the catalytic reaction of trace amounts of vanadium(V) in the presence of HPC and PVP.

Experimental

Apparatus and Reagents. The absorption spectra and absorbance were measured by the use of Shimadzu model UV-200 and Hitachi model 150-20 recording spectrophotometers, with 1.0-cm silica cells. Hitachi-Horiba model M-5 and F-7AD glass electrode pH meters were employed for the pH measurements.

A 1.0×10^{-3} mol dm^{-3} T. Cl. gall solution was prepared by dissolving T.Cl.gall[4] in methanol according to the method of a previous report.[5] 1.0×10^{-2} mol dm^{-3} HPC and 1.0% PVP (K-90) solutions were prepared by dissolving HPC and PVP respectively in water. A 5.0×10^{-4} mol dm^{-3} vanadium(V) solution was prepared according to the method of a previous report.[1] A 2.0×10^{-1} mol dm^{-3} sodium acetate-acetic acid buffer solution (Walpole buffer, pH 4.5) was used for the pH adjustments. The other reagents were of an analytical reagent grade, and twice-distilled or deionized water was used.

Standard Procedure. A solution containing up to 0.8 μg of vanadium(V) was placed in a 10-cm^3 volumetric flask. To this solution, 2.0 cm^3 of the buffer solution (pH 4.5), 1.5 cm^3 of a 1.0×10^{-2} mol dm^{-3} HPC solution, 1.0 cm^3 of a 1.0% PVP solution, and 1.4 cm^3 of a 1.0×10^{-3} mol dm^{-3} T.Cl.gall solution were added. This mixture was diluted to the mark with water and then heated at 60 °C for 30 min (Solution B). After the solution had then been cooled in water for 10 min, the absorbance of Solution B at 385 nm was measured against Solution A. The concentration of vanadium was determined by using a calibration curve.

Results and Discussion

Absorption Spectra and Analytical Wavelength. The T.Cl.gall solution, including vanadium as vanadium(V) in a weakly acidic medium (pH 4.5) (Solution B), was unstable and was gradually decomposed in proportion to the concentration of vanadium(V). Moreover, the use of T.Cl.gall was superior to the use of gall in terms of sensitivity and reproducibility. As is shown in Fig. 1, a large differences in absorbance between Solutions A and B were found at around 555 nm and 385 nm. The absorbance at 555 nm was unsa-

tisfactory in terms of reproducibility and the effect of foreign ions. On the other hand, the use of the difference in absorbance at 385 nm between Solutions A and B was satisfactory in reproducibility and the influence of foreign ions.

Consequently, the later measurements were carried out by measuring the absorbance of Solution B at 385 nm against Solution A.

Effect of pH. The maximum and constant absorbance was obtained in the pH range from 3.7 to 4.8 by using 2.0 cm^3 of a 2.0×10^{-1} mol dm^{-3} sodium acetate-acetic acid buffer solution (Walpole buffer) for the pH adjustments. Subsequent measurements were carried out at pH 4.5 for the determination of vanadium.

Effects of Surfactants. Among the various surfactants tested (HPC, hexadecyltrimethylammonium chloride (HTAC), and Zephiramine (Zp) as cationic surfactants, and PVP and poly (vinyl alcohol) (PVA) as nonionic surfactants), the combination of HPC and PVP had the effect of remarkably increasing the stabilization, reproducibility, and sensitivity. The effects of the concentrations of HPC and PVP were also studied. A maximum and almost constant absorbance was observed upon the addition of 0.5—2.0 cm^3 of a 1.0×10^{-2} mol dm^{-3} HPC solution, together with 1.0 cm^3 of a 1.0% PVP solution, to the final volume of 10 cm^3. Thus, all further measurements were made with 1.5×10^{-3} mol dm^{-3} HPC and 0.1% PVP as the final concentrations.

Effect of T.Cl.gall Concentration. The effect of the T.Cl.gall concentration on the standard procedure was examined by measuring the absorbance at 385 nm for 5.0×10^{-6} mol dm^{-3} vanadium(V). The absorbance at 385 nm was constant when the volume of the 1.0×10^{-3} mol dm^{-3} T.Cl.gall solution was varied between 1.25—1.5 cm^3 in the final 10 cm^3. Hence, 1.4 cm^3 of the 1.0×10^{-3} mol dm^{-3} T.Cl.gall solution was chosen for the determination of vanadium.

Effects of Temperature and Time. The absorbance at 385 nm of Solution B against Solution A was instantaneously unconstant at room temperature (15—25 °C) and was gradually decomposed. The effect of the temperature was examined by heating Solutions A and B at various temperatures (10, 20, 40, 60, and 80 °C). The most favorable results were obtained by heating Solutions A and B at 60 °C for 20—30 min and by then cooling these solutions to room temperature (15—25 °C) in water for 10 min. The solution B decomposed by the standard procedure was relatively stable, but further standing (for more than 60 min) caused a gradual and slight decrease in the absorbance.

Calibration Curve, Sensitivity, and Reproducibility. A good linear relationship was observed over the range of 0—0.8 μg of vanadium in the final volume of 10 cm^3 at 385 nm against a reagent blank (Solution A). The sensitivity on Sandell's scale and the apparent molar absorptivity were calculated for vanadium to be 0.00006 μg cm^{-2}, and 7.0×10^5 dm^3 mol^{-1} cm^{-1} at 385 nm, using a T.Cl.gall solution decompsed by the presence of vanadium(V) in the presence of HPC and PVP. Although a further investigation of the mechanism and the produced species of this reaction is necessary, this reason for the high sensitivity was assumed to be that the oxidation and decomposition of the T.Cl.gall solution in the presence of HPC and PVP was catalyzed by trace amounts of vanadium(V). The relative standard deviation was 1.7% at the concentration of 0.5 μg/10 cm^3 vanadium (n=5).

Vanadium(V) taken: 0.3 μg/10 cm^3; T.Cl.gall: 1.4×10^{-4} mol dm^{-3}; HPC: 1.5×10^{-3} mol dm^{-3}; PVP: 1.0 cm^3 of 1.0% PVP solution/10 cm^3; pH: 4.5; Reference: Reagent blank. a): Fe(II)+Co(II)+Al(III)+Zn(II)+Co(II), b): Mean of 5 determinations, c): NaF, 6.0×10^{-4} mol dm^{-3}; KCN, 6.0×10^{-4} mol dm^{-3}; notice that a potassium cyanide solution is used in an acidic medium.

Effect of Foreign Ions. The interfering effects of various foreign ions on the determination of vanadium were examined. As is shown in Table 1, the presence of copper(II), aluminum(III), and iron(III) interfered with the determination of vanadium in forming a colored complex in a weakly acidic media. The interference from aluminum(III), copper(II), or iron(III) could, however, be overcome by the addition of sodium fluoride or a nitrilotriacetic acid (NTA) or potassium cyanide (KCN) solution as masking agents respectively. (Needless to say, it must be kept in mind that a slight amount of HCN gas is produced by the addition of the KCN solution in a weakly acidic medium as a masking agent.)

Moreover, the presence of molybdate, tungstate, thiosulfate, citrate, and such oxidizing agents as perman-

ganate, bromate and chlorate, seriously interfered. These interfering ions must be removed by a suitable procedure.

Application. The proposed methods were applicable for the recoveries of vanadium in prepared artificial water (involving various metal ions-iron(III), cobalt(II), aluminum(III), zinc(II), copper(II), etc.). The sample solution (as vanadium(V)) was treated with sodium carbonate solutions, and then filtered or centrifuged. The filtrated or centrifuged solution was adjusted to about pH 5 with hydrochloric acid and sodium hydroxide solutions. Also, sodium fluoride, potassium cyanide and NTA solutions were added to this sample solution as masking agents, and then the concentration of vanadium in the artificial water(molar ratio of total metal ions to vanadium=25 : 1) was determined by using the standard procedure, as is shown in Table 2. The experimental results were in a good agreement with the certified values (recovery test, 98.6—102.8%).

In conclusion, a rapid and sensitive spectrophotometric determination of trace amounts of vanadium (0—0.8 μg/10 cm^3 vanadium) was established by using the oxidation and decomposition of the T.Cl.gall solution by the catalytic reaction of vanadium(V) in the presence of HPC and PVP. The sensitivity of this proposed method was about 16 times greater than that of the method[6] using *N*-benzoyl-*N*-phenylhydroxylamine, and about 20—40 times greater than, that of the PR-oxidation method,[3] the 4-(2-pyridylazo) resorcinol (PAR) method,[7] or the gall-sodium sulfite method.[1] This proposed method should be useful for the determination of trace amounts of vanadium in air pollution, petroleum, steel, the sea, river and lake water, etc.

Control of Product in the Reaction of Tributyltin ω-Haloalkoxide (n-$Bu_3SnO(CH_2)_nX$) with Diphenylketene

Ikuya SHIBATA,* Akio BABA, and Haruo MATSUDA
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka 2-1, Suita, Osaka 565
(Received June 20, 1986)

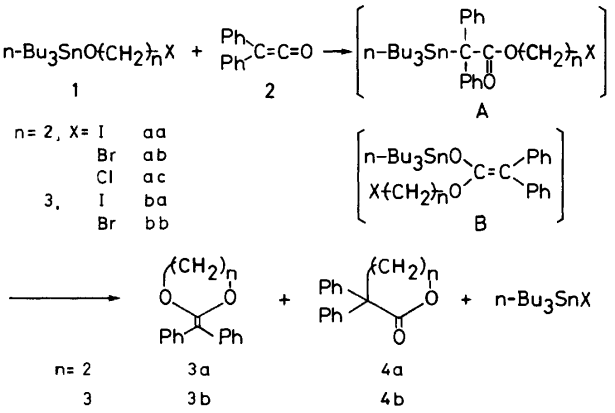
Synopsis. The reaction of tributyltin ω-haloalkoxide with diphenylketene gave cyclic ketene acetals and/or lactones, and the ratio of these products were controled by the number of methylene groups and by the addition of Lewis base in the reaction system. Moreover, the direct cycloaddition of diphenylketene with cyclic ethers proceeded in high yields, catalyzed by organotin halide-Lewis base complexes.

We have recently reported the novel use of tributyltin ω-haloalkoxides (**1**) (n-$Bu_3SnO(CH_2)_nX$, X=Cl, Br, I, n=2, 3),[1,2] yielding a variety of five- and six-membered heterocycles in the reactions with heterocumulenes such as isocyanates, isothiocyanates and carbodiimides.[1,2] In particular, it has been pointed out that the addition of Lewis bases significantly stimulated the formation of heterocyclic compounds. Moreover, new effective catalysts, the complexes of organotin halides with bases, have been developed on the basis of investigations on this reaction mechanism, conducting the direct cycloaddition of oxiranes with heterocumulenes under very mild conditions.[3] In the course of the study on this type of reaction in terms of diphenylketene (**2**) with **1**, we recognized some different features from the reactions of other heterocumulenes which have been already reported.[1,2] Thus, the types of the products were drastically changed by the number of methylene (n) of **1**, and moreover the addition of bases completely changed the product in the reaction with n-$Bu_3SnO(CH_2)_3X$ (**1b**). In addition, the direct cycloadditions of oxiranes or oxetane with **2** were performed.

The results of the reactions between tributyltin β-haloethoxides (n-$Bu_3SnO(CH_2)_2X$) (**1a**) with **2** are summarized in Table 1 (Entries 1—8). The types of products and the reactivity varied with temperature, additives and the kind of halogen. γ-Butyrolactone (**4a**) was obtained in only the reactions with iodide derivative (**1aa**) (Entries 1—3), and the 1,3-dioxolane **3a** was exclusively produced from the bromide (**1ab**) (Entry 4). Moreover, the ratio of **4a** to **3a** was increased with lowering the reaction temperature, however the reaction proceeded very slowly below 60 °C. The presence of Lewis bases allowed the reaction to proceed in high yields under significantly milder conditions, in addition, giving **3a** exclusively (Entries 6—8).

The effect of the number of methylene groups was very definitive as shown in the reaction with tributyltin γ-halopropoxides (n-$Bu_3SnO(CH_2)_3X$) (**1b**). In sharp contrast to the 1,3-dioxolane formation from the reaction of **1a**, δ-valerolactone (**4b**) was selectively obtained with **1b** (Entries 9 and 10). Moreover, the effect of base was more remarkable than in the reaction of **1a**, and the product was completely changed from the lactone **4b** to the 1,3-dioxane **3b** (Entry 11). This drastic change is very characteristic of the reaction of diphenylketene. Thus, no change of products by the addition of bases was observed in the reaction of **1b** with isocyanates or isothiocyanates.[1,2]

As Bloodworth et al. have reported,[4] these reactions are thought to proceed via stannyl ester type of adduct (**A**) as shown in Scheme 1. Products, **3** and **4**, may be



Scheme 1.

formed by intramolecular *O*- and *C*-alkylations, respectively. As to the formation of **3**, stannyl enolate type of adduct (**B**) can be considered. However, IR spectrum showed the absorption at 1730 cm^{-1} (C=O) in the addition of **2** with **1a** or **1b**, where no cyclization occurred. And this absorption was also observed in the case using HMPA as a solvent. From these facts, we propose **A** as an intermediate rather than **B**.[5] While it is unclear exactly why the remarkable alternation of products occurred, the significant effect of the number of methylene group seems to suggest an important role of the intramolecular coordination of the terminal halide to the tin atom. The characteristic reaction mode of diphenylketene may be rationalized by the lower ability of an intermolecular coordination of **A** in comparison with the adducts of **1** with an isocyanate. Namely, the nitrogen atom in the adduct of isocyanates, *n*-$Bu_3SnN(R)COO(CH_2)_nX$, can bring an intermolecular coordination toward another tin atom,[4] whereas the carbon atom adjacent to Sn atom in **A** has no coordinative ability.

In the next stage, we tried to use *n*-Bu_3SnI-HMPA complex (**5**) as a catalyst for the cycloaddition of oxiranes with **2**. As shown in Table 2, cycloaddition proceeded under very mild conditions, and a variety of 1,3-dioxolanes, **3c—h**, were obtained in good to excellent yields. In this reaction system, the complex **5**, formally forms in situ, undergoes ring opening to give organotin β-iodoalkoxides.[6] The activated halogen by the coordination of base to a tin atom of *n*-Bu_3SnI is effective for ring opening. Next, these tin alkoxides react with diphenylketene, and the 1,3-dioxolanes are formed, accompanied by the regeneration of the Sn-I bond. While, oxetane showed a lower reactivity than oxiranes, and heterocycles were scarcely obtained by using **5**. However, $MeSnI_3$-HMPA complex showed higher catalytic activity in direct cycloaddition reaction using oxetane and **2**, and heterocycles **3b** and **4b** were obtained in 18 and 40% yields, respectively. Although the yields are not so good as the case of oxiranes, this result is interesting because cycloaddition of heterocumulenes with oxetanes has been scarcely reported.[7]

Experimental

Reaction of Tributyltin ω-Haloalkoxide (*n*-$Bu_3SnO(CH_2)_nX$) (1) with Diphenylketene (2). All reactions were carried out under dry nitrogen. A typical procedure is described for the reaction of **1aa** with **2**. **1aa** (2.30 g, 5 mmol) and **2** (0.78 g, 4 mmol) were stirred in a 50 ml round-bottomed flask, then heat was evolved about 40 °C. The infrared spectrum showed disappearance of the characteristic absorption band of ν_{CCO} at 2100 cm^{-1}, and the presence of the new band at 1730 cm^{-1}. After 1 h at 80 °C, addition of excess amounts of hexane on cooling induced 0.57 g (60%) of white precipitates immediately, which were collected by filtration, washed with hexane and dried in vacuo. The precipitates were turned out to 2-diphenylmethylene-1,3-dioxolane (**3a**) (24% yield) and α,α-diphenyl-γ-butyrolactone (**4a**) (36% yield). The **3a**/**4a** ratio was determined by ^1H NMR spectra. When the reaction was carried out in a solvent, **1**, **2**, and a solvent were charged in this turn.

2-Diphenylmethylene-1,3-dioxolane (3a): Mp 148—149 °C (lit,[8] mp 149—151 °C); IR (KBr) 1660 cm^{-1} (C=C); MS *m*/*z* 238 (M^+); ^1H NMR ($CDCl_3$) δ=4.20 (s, 4H, CH_2), 7.00—7.40 (m, 10H, Ph).

2-Diphenylmethylene-1,3-dioxane (3b): Mp 80—81 °C; IR (KBr) 1640 cm^{-1} (C=C); MS *m*/*z* 252 (M^+); ^1H NMR ($CDCl_3$) δ=1.95—2.25 (m, 2H, CH_2), 4.15 (t, 4H, OCH_2), 7.10—7.40 (s, 10H, Ph).

α,α-Diphenyl-γ-butyrolactone (4a): Pure sample was isolated by column chromatography (Silica-gel, $CHCl_3$); Mp 80—81 °C (lit,[9] mp 77—79 °C); IR (KBr) 1780 cm^{-1}; MS *m*/*z* 238 (M^+); ^1H NMR ($CDCl_3$) δ=2.98 (t, 2H, CH_2), 4.22 (t, 2H, CH_2O), 7.32 (s, 10H, Ph).

α,α-Diphenyl-δ-valerolatone (4b): Mp 116 °C (lit,[10] mp 112 °C); IR (KBr) 1730 cm^{-1}; MS *m*/*z* 252 (M^+); ^1H NMR ($CDCl_3$) δ=1.88 (m, 2H, CH_2), 2.62 (t, 2H, Ph_2CCH_2), 4.22 (t, 2H, CH_2O), 7.22 (s, 10H, Ph).

Cycloaddition of Diphenylketene (2) with Oxiranes or Oxetane: A typical procedure is described for the reaction of diphenylketene with 2-methyloxirane, catalyzed by *n*-Bu_3SnI-HMPA. To a solution of *n*-Bu_3SnI (0.42 g, 1 mmol) and HMPA (0.18 g, 1 mmol) in 2-methyloxirane (1.45 g, 25 mmol) was added **2** (0.97 g, 5 mmol) with stirring under dry nitrogen. The resulting mixture was stirred at 40 °C for 2 h and the yield was monitored by GLC. Diphenylketene was no longer detected, which was confirmed by the disappearance of IR absorption band of ketene (2100 cm^{-1}). Excess amounts of hexane was added on cooling to the reaction mixture, then 1.12 g (89%) of white precipitates were obtained immediately. This was collected by filtration, washed with hexane and dried in vacuo. The precipitates was 2-diphenylmethylene-4-methyl-1,3-dioxolane (**3c**). Compounds **3b**, **4b**, **3d**, and **3e** were isolated by a similar method. **3f**, **3g**, and **3h** were isolated by distillation from the reaction mixture.

2-Diphenylmethylene-4-methyl-1,3-dioxolane (3c): Mp 88—89 °C; IR (KBr) 1660 cm^{-1}; MS *m*/*z* 252 (M^+); ^1H NMR ($CDCl_3$) δ=1.42 (d, 1H, CH_3), 3.82 (t, 1H, one of CH_2O), 4.38 (dd, 1H, one of CH_2O), 4.70 (m, 1H, OCH), 7.00—7.40 (m, 10H, Ph).

2-Diphenylmethylene-4-ethyl-1,3-dioxolane (3d): Mp 57—58 °C; IR (KBr) 1660 cm^{-1} (C=C); MS *m*/*z* 266 (M^+); ^1H NMR ($CDCl_3$) δ=1.00 (t, 3H, CH_3), 1.50—1.90 (m, 2H, $MeCH_2$), 3.90 (t, 1H, one of OCH_2), 4.30 (t, 1H, one of OCH_2), 4.30—4.60 (m, 1H, OCH), 7.00—7.40 (m, 10H, Ph).

2-Diphenylmethylene-4,4-dimethyl-1,3-dioxolane (3e): Mp 98—100 °C; IR (KBr) 1660 cm^{-1} (C=C); MS *m*/*z* 266 (M^+); ^1H NMR ($CDCl_3$) δ=1.15 (s, 3H, CH_3), 1.45 (s, 3H, CH_3), 4.00 (d, 2H, CH_2O), 7.00—7.40 (m, 10H, Ph).

2-Diphenylmethylene-4-chloromethyl-1,3-dioxolane (3f): Bp 142 °C/10^{-3} mmHg (1 mmHg=133.322 Pa); IR (KBr) 1660 cm^{-1} (C=C); MS *m/z* 286.5 (M^+); ^1H NMR ($CDCl_3$) δ=3.60 (d, 2H, $ClCH_2$), 4.30 (t, 2H, CH_2O), 4.60—4.80 (m, 1H, OCH), 7.00—7.60 (m, 10H, Ph).

2-Diphenylmethylene-4-phenoxymethyl-1,3-dioxolane (3g): Bp 140 °C/10^{-3} mmHg (lit,[8] 220—260 °C/0.8 mmHg); IR (neat) 1660 cm^{-1} (C=C); MS *m/z* 344 (M^+); ^1H NMR ($CDCl_3$) δ=4.10 (d, 2H, $PhOCH_2$), 4.30 (dd, 2H, CH_2O), 4.70—5.00 (m, 1H, OCH), 6.70—7.40 (m, 15H, Ph).

2-Diphenylmethylene-4-phenyl-1,3-dioxolane (3h): Bp 132 °C/10^{-3} mmHg (lit,[8] bp 225—230 °C/0.8 mmHg); IR (neat) 1660 cm^{-1} (C=C); MS *m/z* 314 (M^+); ^1H NMR ($CDCl_3$) δ=4.10 (t, 1H, one of CH_2O), 4.60 (t, 1H, one of CH_2O), 5.50 (t, 1H, OCH), 7.00—7.40 (m, 15H, Ph).

Synopsis. Six substance P (SP) analogs, in which the glutaminyl residue(s) at the position(s) 5 or/and 6 were replaced by homoglutamine (Hgn), were prepared using a novel N^{α},N^{ca}-$(Boc)_2$-Hgn-OH by the solid phase method. The activity of the analogs was assayed on isolated guinea pig organs. Results indicate that the elongation of the methylene on glutaminyl residue(s) in SP enhances the activity on isolated guinea pig ileum.

Chang and Leeman[1] isolated in 1970 substance P (SP) from bovine hypothalami and the amino acid sequence was elucidated by Chang, et al.,[2] to be H-Arg-Pro-Lys-Pro-Gln-Gln-Phe-Phe-Gly-Leu-Met-NH_2.[3] Studies on the relationship between peptide chain length and activity[4] of SP revealed that the contractile activity of certain C-terminal fragments was as high as or even higher than that of SP itself on the smooth muscle of isolated guinea pig ileum. Although the C-terminal pentapeptide had much lower activity, addition of Gln residue(s) at the N-terminal of the pentapeptide leads to an enhancement of biological activity. The conformation analyses suggest a U shape for the C-terminal part of the molecule, providing an explanation for the observation that full biological activity is retained in SP hexapeptide, and that bioactive structures are stabilized by the formation of intramolecular hydrogen bond between the amide proton (or amino proton) of the glutamine residue at position 6 and the carbonyl group of the C-terminal amide.[5] These imply that the Gln residue(s) of SP is very important for inducing the activity.

This paper describes the first synthetic example of bioactive peptide analogs substituted with homoglutamine (Hgn; α-aminoadipamic acid). In order to examine the biological effect of the elongation of methylene group in the Gln residue(s) at positions of 5 or/and 6 by the displacement with Hgn, we synthesized six analogs and submitted them for biological assay to compare with our synthetic SP.

The SP analogs were synthesized by the solid phase technique[6] using an automated peptide synthesizer. Deprotection and dicyclohexylcarbodiimide (DCC) coupling were programed as given in Table 1. *t*-Butoxycarbonyl (Boc) protection was used for α-amino function and the amide nitrogen (N^{ca}) of Hgn. The Hgn residue was incorporated into peptide chains as usual manner using N^{α},N^{ca}-$(Boc)_2$-Hgn-OH,[7,8] which was derived from an ester of $(Boc)_2$-Lys-OH by ruthenium tetraoxide oxidation. This oxidative transformation[9,10] made it possible to produce quite conveniently the novel Hgn derivative which is applicable to synthetic studies (on the structure-activity relationships of peptides). The protecting group on the amide can be deblocked by the same reagents as those for the groups on α-amino function to yield Hgn residue.[8] Other side-chain protecting groups were Z for Lys and tosyl (Tos) for Arg. After the completion of the chain elongations, the peptide resin was treated with liquid hydrogen fluoride (HF)[11] in the presence of anisole to cleave the peptide from the resin with simultaneous removal of the protecting groups and formation of the carboxyl terminal amide. The crude product was purified by preparative reverse-phase high-performance liquid chromatography (HPLC) using 0.1% TFA in acetonitrile (CH_3CN) as eluent. Highly purified peptides were obtained after gel filtration on Sephadex G-10 column. The yield was sacrificed for the purity. Homogeneity of the peptides was demonstrated by analytical HPLC and thin-layer chromatography (TLC). When single peaks and single spots were observed for a peptide in all chromatographic systems, the sample

Table 4. Relative Potencies of SP Analogs on Guinea Pig Organs

Analog	Relative contractile activity to SP=1	
	Ileum	Trachea
1	1.81	2.09
2	1.25	1.20
3	3.41	2.09
4	3.41	4.36
5	1.97	1.00
6	1.50	2.75

was considered appropriately pure for bioassay. These chromatographic data were reinforced by the amino acid analytical data.

Biological properties of the synthetic SP analogs in this study were examined on isolated guinea pig organs and the contractile activities of the analogs were compared with that of synthetic SP. The results are shown in Table 4.

The elongation of the methylene group of Gln residue(s) at position 5 or/and 6 of SP enhanced the biological activity on isolated guinea pig ileum, and [$Hgn^{5,6}$]-SP **3** possessed the highest potency among the three analogs (**1**—**3**). Octapeptide analogs **4** and **5** showed about 340 and 200% of the activity of SP respectively and their potencies were higher than those of **1** and **2** replaced at the same position, while [$Hgn^{5,6}$]-SP (**4**—**11**) **6** had significant activity, but its potency was less than those of analogs **4** and **5**, and about a half of the undecapeptide **3**.

The analogs **1**, **3**, **4**, and **6** were also found to be highly active on the trachea assay, while **2** and **5** were as high as that of SP. Octapeptide analog **4** had the highest activity on the both bioassays. Thus the potencies of Hgn^5 analogs **1** and **4** were higher than the activities of Hgn^6 analogs **2** and **5** respectively. The potencies of all analogs prepared in the present investigation were as high as or higher than the activity of SP itself. This indicates probably that resistibility of the peptides to metabolic breakdown is increased by the introduction of Hgn residue(s) and the Hgn analogs may possess a U-shape conformation and hydrogen bond very similar to natural SP.

Experimental

Amino acid derivatives were purchased from Peptide Institute, Inc., Osaka, Japan and benzhydrylamine (BHA) resin (available amine of the resin: 0.6 mmol g^{-1} of support) from Beckman Inc., Palo Alto, Calif. Optical rotations were measured in a Nipponbunkoh DIP-4 Polarimeter. Amino acid analyses on samples previously hydrolyzed with 6M HCl (1 M=1 mol dm^{-3}) (110 °C, 24 h) were performed on a Hitachi KLA-5 Amino Acid Analyzer. TLC was carried out on silica-gel plates (Merck). The following solvent systems were used and allowed to ascend for 10 cm: R_f^I, *n*-BuOH : AcOH : H_2O (4 : 1 : 5, upper phase); R_f^{II}, *n*-BuOH: pyridine : AcOH : H_2O (30 : 20 : 6 : 24). Analytical HPLC was effected on the following systems: column, NOVA-PAK C_{18} (3.9×150 mm); flow rate, 1 ml min^{-1}, detection, 210 nm; eluent system, linear gradient of CH_3CN in 20 mM phosphate buffer (pH 3.0).

General Procedure for the Preparation of Analogs. The solid phase synthesis was carried out using a Beckman System 990C Peptide Synthesizer. Half gram of BHA-resin hydrochloride for each analog served as the solid support. For the incorporation of each N^{α}-Boc-protected amino acid, a program given in Table 1 was used. The amino acid derivatives were dissolved in dichloromethane, except Boc-Arg(Tos)-OH and Boc-Gln-OH which were dissolved in DMF, and employed for the coupling reaction. A 2.5 fold excess of the amino acid derivative was used for all couplings. One equivalent of HOBt was added as an additive to facilitate the repetitive coupling reaction, using the program

without step 1—4. In the case of Boc-Gln-OH, 2.5 equiv of HOBt was used for all couplings. The completion of the coupling reaction was assessed by a negative ninhydrin test. When the ninhydrin test was positive, even after repetition of the coupling two or three times, the unreacted amino groups were blocked completely by acetylation using an excess of Ac_2O (5 equiv of resin used) in the presence of pyridine (1 equiv) in dichloromethane for 20 min. The protected peptide resin was treated with anhydrous liquid HF containing 10% anisole. Approximately 5 ml of liquid HF was used for 0.25 g resin, and the reaction time was 1 h at 0 °C. After evaporation of HF in vacuo under ice-cooling, the peptide-resin mixture was washed with AcOEt. The peptide was extracted with three portions of 10% AcOH and the combined extracts were lyophilized.

Purification of the Peptides. The crude peptide was subjected to HPLC. The apparatus was composed of a model 590 pump and a U6K injector (Waters) connecting with a column (20×300 mm) of Chemcosorb ODS (Chemco). The eluates were monitored with a UV detector S-310A model-II (Soma) at 210 nm wavelength. CH_3CN–0.1% TFA solvent system was used as eluent at flow rate 10 ml min^{-1}. Each peptide was emerged at 40—60 min by isocratical elution with 21—23% CH_3CN contents of the solvent system. The desired fraction was passed through a Sephadex G-10 column (16×930 mm) eluted with 2M AcOH and the product was lyophilized. Homogeneity of the peptides was analyzed by analytical HPLC and TLC. The peptides on silica-gel plate were detected with ninhydrin and chlorine-*o*-tolidine reagents. When single peaks and single spots were observed for a peptide in all chromatographic systems and the amino acid compositions after hydrolysis of the peptides were consistent with the calculated values, the sample was submitted for bioassay.

Bioassay. Male guinea pig (weighing 200—250 g) was stunned by a blow to the back and exsanguinated. Ileum and trachea were rapidly isolated and kept for dissection in Tyrode's solution (137 mM NaCl, 2.7 mM KCl, 1.8 mM $CaCl_2$, 1.1 mM $MgCl_2$, 0.4 mM NaH_2PO_4, 12 mM $NaHCO_3$, 5.6 mM glucose) at room temperature. Both organs were suspended in a 30 ml organ bath containing Tyrode's solution thermostated at 30 °C and bubbled with 95% O_2 and 5% CO_2 gas for 1 h. The contraction was recorded by means of isotonic transducer (Nippon Kohden, TD-111T) with load of 1 or 2 g (for trachea and ileum respectively) on a Servocorder (Watanabe Instruments, SR6204). Trachea was transversely cut into pieces and six pieces were connected to make a trachea preparation. Concentration-response curves were obtained using a cumulative dose-assay, the time between two consecutive dose-response curves being longer than 10 min.

Neurokinin B Analogs Substituted with Glycine

Tadashi HASHIMOTO,* Tadashi MORO, and Yoshiki UCHIDA
School of Pharmacy, Hokuriku University, Ho-3, Kanagawa-machi, Kanazawa 920-11
(Received July 2, 1986)

Synopsis. Four Neurokinin B analogs substituted with glycine at position 4, 5, 6, or 7 were synthesized by Merrifield's solid phase method. Pharmacological property of the analogs is described. The results suggest that Phe[6] and Val[7] residues may be essential for intrinsic activity on smooth muscle.

Neurokinin B (NKB, also called neuromedin K) is a novel neuropeptide isolated from porcine spinal cord. Structure elucidation[1] revealed that NKB has close structural homologies with tachykinin such as substance P (SP), kassinin and physalaemin (Fig. 1). NKB, decapeptide amide, is very similar to the undecapeptide SP, particularly in the sequence between Phe[6] and Met[10] residues of NKB, and between Phe[7] and Met[11], and has the same C-terminal pentapeptide sequence of dodecapeptide kassinin.

The structural determination of NKB led us to undertake systematic studies on structure-activity relationship by means of highly purified synthetic peptides related to the neuropeptide. This paper describes synthesis and biological property of four kinds of NKB analogs.

In study[3] of the relationships between chain length and activity, it is revealed that the removal of the N-terminal two amino acids from NKB increases the contractile activity on rat vas deferens as the peptide chain is shortened and NKB (5—10) shows unequivocal loss of activity. In the present investigation, in order to examine the biological effect of the substitution of Gly moiety for Asp[4], Phe[5], Phe[6], and Val[7] residues, we synthesized [Gly[4]]-, [Gly[5]]-, [Gly[6]]-, and [Gly[7]]-NKB (3-10) (Fig. 2), and submitted them for biological assay to compare with our synthetic NKB.

Synthesis of NKB and the related peptides used in this study was performed on a Beckman System 990C Peptide Synthesizer by standard solid phase method[4] starting from *t*-butoxycarbonyl (Boc)-Met benzhydrylamine-resin. Boc protection was used for α-amino function. The side-chain protective groups used were cyclohexyl for Asp and *p*-toluenesulfonyl for His. Deprotection and dicyclohexylcarbodiimide (DCC) coupling were programed as given in Table 1. For second coupling, a program without steps 1—4 was used. A 2.5 fold excess of amino acid derivatives was used for all couplings. The second coupling was repeated with additive of one equivalent of 1-hydroxybenzotriazole (HOBt). The coupling reaction was monitored by the ninhydrin color test procedure of Kaiser et al.[5] A trace of unreacted amino group was acetylated. After the completion of the chain elongations, the peptide resin was treated with liquid hydrogen fluoride (HF)[6] in the presence of anisole for 1 h at 0 °C to cleave the peptide from the resin with simultaneous removal of the protecting groups and formation of the carboxyl terminal amide. The excess HF was removed in vacuo, and the resulting material was washed with ethyl acetate prior to extraction of the peptide with aq acetic acid (50%). The crude product was purified by preparative reverse-phase high-performance liquid chromatography (HPLC) using dil trifluoroacetic acid (0.1%) in acetonitrile as eluent. The desired fractions were collected and desalted on a column of Sephadex LH-20 eluted with aq *N,N*-dimethylformamide (90%), giving pure peptide. The yield was sacrificed for the purity of the fractions selected. Homogeneity of the peptides was demonstrated by analytical HPLC and thin-layer chromatography (TLC) (Table 2). When single peaks and single spots were observed for a peptide in all chromatographic systems, the sample was considered

Table 1. Program for Solid Phase Synthesis

Step	Reagent	Operation	Mix time/min
1	CH_2Cl_2	3×Wash	1.5
2	TFA (25% in CH_2Cl_2)	Prewash	1.5
3	TFA (25% in CH_2Cl_2)	Deprotection	30
4	CH_2Cl_2	3×Wash	1.5
5	CH_2Cl_2	3×Wash	1.5
6	TEA (10% in CH_2Cl_2)	3×Neutralization	1.5
7	CH_2Cl_2	6×Wash	1.5
8	Boc-Amino Acid (in CH_2Cl_2)	Mix	5
9	DCC	Mix	120
10	CH_2Cl_2	6×Wash	1.5

Table 2. Physical Properties and Yield of the Peptides

Analog	$[\alpha]_D^{22}$/° (*c* 0.1, DMF)	Retention time[a)]/min	R_f^I	R_f^{II}	Yield/%
1	−36.0	17.5	0.15	0.75	39.2
2	−33.0	15.1	0.10	0.68	6.3
3	−83.0	14.8	0.10	0.68	10.5
4	−47.0	16.9	0.10	0.68	38.0

a) Condition of analytical HPLC: column, NOVA-PAK C_{18}; flow rate, 1 ml min^{-1}; Detection, 210 nm; eluent system, linear gradient from 7% to 42% CH_3CN (15 min) in 20 mM phosphate buffer (pH 3.0).

Table 3. Amino Acid Analyses of the Peptides

Analog	Found (Calcd)							
	His	Asp	Gly	Val	Met	Leu	Phe	NH_3
1	0.93 (1)	—	2.04 (2)	1.16 (1)	0.98 (1)	0.94 (1)	1.90 (2)	1.79 (1)
2	1.04 (1)	1.19 (1)	1.87 (2)	1.03 (1)	0.89 (1)	1.09 (1)	0.84 (1)	1.27 (1)
3	1.33 (1)	1.21 (1)	1.80 (2)	0.94 (1)	0.84 (1)	0.90 (1)	1.03 (1)	1.67 (1)
4	1.08 (1)	1.23 (1)	1.95 (2)	—	0.93 (1)	1.00 (1)	1.82 (2)	1.57 (1)

Table 4. Relative Potencies of Synthetic NKB Analogs

Analog	GPI[a)]	RVD[a)]
1	0.28	0.63
2	2.0	1.58
3	0	0
4	0	0

a) Relative activity accepted NKB as 1.

appropriately pure for bioassay. These chromatographic data were reinforced by the amino acid analytical data (Table 3).

Biological properties of the synthetic NKB analogs in this study were examined on the isolated rat vas deferens (RVD) and the guinea pig ileum (GPI). The contractile activities of the analogs were compared with those of synthetic NKB. The results are shown in Table 4.

The potencies of analog **2** were higher than the activities of NKB itself on both assays. Analog **1** showed reduced potency, while the peptides **3** and **4** possessed no activity. Thus, these results suggest that Phe^6 and Val^7 residues of NKB may be essential for the intrinsic activity.

Experimental

Amino acid derivatives were purchased from Peptide Institute, Inc., Osaka, Japan and benzhydrylamine (BHA) resin (available amine of the resin: 0.6 mmol g^{-1} of support) from Beckman Inc., Palo Alto, Calif. Optical rotations were measured in a Nipponbunkoh DIP-4 Polarimeter. Amino acid analyses on samples previously hydrolyzed with 6 M HCl (1 M=1 mol dm^{-3}) (110 °C, 24 h) were performed on a Hitachi KLA-5 Amino Acid Analyzer. TLC was carried out on silica-gel plates (Merck). The following solvent systems were used and allowed to ascend for 10 cm: R_f^I, *n*-BuOH : AcOH : H_2O (4 : 1 : 5, upper phase); R_f^{II}, *n*-BuOH : pyridine : AcOH : H_2O (30 : 20 : 6 : 24). Analytical HPLC was effected on the following systems: column, NOVA-PAK C_{18} (3.9×150 mm); flow rate, 1 ml min^{-1}, detection, 210 nm; eluent system, linear gradient of CH_3CN in 20 mM phosphate buffer (pH 3.0).

General Procedure of Analog. The first Boc-amino acid was coupled as follows to the BHA-resin (0.60 mequiv N g^{-1}). The BHA-resin hydrochloride was treated with a solution of 10% (by volume) triethylamine (TEA) in dichloromethane (10 ml g^{-1} of resin) for 4.5 min. Then the resin was washed with 10 ml of dichloromethane per gram. For half gram of the resin, 2.5 equiv of Boc-Met-OH and DCC were used. The quantitation of coupling reaction was revealed by a negative ninhydrin color test. When the ninhydrin test was positive, even after second coupling, the unreacted amino

groups were blocked by acetylation using Ac_2O (5 equiv) and pyridine (1 equiv) in dichloromethane for 20 min. For the coupling reactions, using 2.5 equiv of DCC in dichloromethane, the amino acid derivatives were dissolved in dichloromethane. Deprotection and DCC coupling were programed as given in Table 1. For second coupling, a program without steps 1—4 was used. A 2.5 fold excess of the amino acid derivative was used for all couplings. One equivalent of HOBt was used only for the second DCC-coupling. The protected peptide resin was simultaneously cleaved and deblocked with anhydrous liquid HF containing 10% anisole. Approximately 5 ml of liquid HF was used for 0.25 g resin, and the reaction time was 1 h at 0 °C. After evaporation of HF, the peptide-resin mixture was washed with AcOEt. The peptide was extracted with three portions of 50% AcOH and the extracts combined were lyophilized.

Purification of the Peptides. The crude peptide was subjected to HPLC which is composed of a model 590 pump and a U6K injector (Waters) connecting with a column (20×300 mm) of Chemcosorb ODS (Chemco). The eluates were monitored with a UV detector S-310A model-II (Soma) at 210 nm wavelength. CH_3CN-0.1% TFA solvent system was used as eluent at flow rate 10 ml min^{-1}. Each peptide was emerged at 40—60 min by isocratical elution with 22—28% CH_3CN contents of the solvent system. The desired fraction was desalted on a Sephadex LH-20 column (15×500 mm) eluted with DMF-H_2O (9:1) and the product was lyophilized. Homogeneity of the peptides was analyzed by analytical HPLC on a column of NOVA-PAK C_{18} (3.9×150 mm) with gradient elution using 20 mM phosphate buffer (pH 3.0)/CH_3CN and by TLC on silica-gel plate. The peptides on silica- gel plate were detected with ninhydrin and chlorine-*o*-tolidine reagents. When single peaks and single spots were observed for a peptide in all chromatographic systems and amino acid composition after hydrolysis of the peptides were consistent with the calculated values, the sample was submitted for bioassay.

Bioassay. The bioactivities of NKB analogs were measured on the isolated rat vas deferens and guinea pig ileum. Male rat (weighing 250—300 g) and male guinea pig (weighing 200—250 g) were stunned by a blow to the neck and exsanguinated. Vas deferens and ileum were rapidly isolated and kept for dissection in Tyrode's solution (137 mM NaCl, 2.7 mM KCl, 1.8 mM $CaCl_2$, 1.1 mM $MgCl_2$, 0.4 mM NaH_2PO_4, 12 mM $NaHCO_3$, 5.6 mM glucose) at room temperature. Both organs were suspended in a 30 ml organ bath containing Tyrode's solution thermostated at 30 °C and bubbled with 95% O_2 and 5% CO_2 gas for 1 h. The contraction was recorded by means of an isotonic transducer (Nippon Kohden, TD-111T) with load of 1 or 2 g (for vas deferens and ileum respectively) on a Servocorder (Watanabe Instruments, SR6204). Concentration-response curves were obtained using a cumulative dose-assay, the time between two consecutive dose-response curves longer than 10 min.
